Relativistic many-body perturbation theory using discrete basis expansion method: accurate representation of second-order energy of Xe atom with contracted well-tempered Gaussian basis set

YASUYUKI ISHIKAWA

Department of Chemistry and The Chemical Physics Program, University of Puerto Rico, Rio Piedras, PR 00931 U.S.A.

Received June 26, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

YASUYUKI ISHIKAWA. Can. J. Chem. **70**, 399 (1992).

Relativistic many-body perturbation theory calculations on Xe have been performed with basis sets of well-tempered Gaussian-type functions of Huzinaga and Klobukowski. The well-tempered Gaussian-type functions were used in both contracted and uncontracted form. The contracted Gaussian basis sets used in the relativistic many-body study are designed to retain flexibility for correlated calculations both in the core and the valence region. They reproduce second-order energy corrections computed with uncontracted Gaussian basis sets to an accuracy of greater than 99%. A compact representation of the relativistic wave functions in terms of contracted well-tempered Gaussian functions used in the present study provides a useful means of curtailing integral storage requirements and the time needed for correlated calculations, while still retaining high accuracy in relativistic electron correlation effects.

Key words: Dirac–Fock, relativistic many-body perturbation theory, well-tempered Gaussian basis, xenon.

YASUYUKI ISHIKAWA. Can. J. Chem. **70**, 399 (1992).

Utilisant des ensembles de base de fonctions gaussiennes de Huzinaga et Klobukowski bien aplanies, on a effectué des calculs relativistes de la théorie perturbationnelle à plusieurs centres sur le Xe. On a utilisé les formes tant contractée que non-contractée de ces fonctions de type gaussien. Les ensembles gaussiens de type contracté sont utilisés dans l'étude relativiste à plusieurs centres afin de conserver une certaine flexibilité dans les calculs comportant une corrélation dans les régions tant du coeur que de valence. Ils permettent de reproduire, avec une précision de plus de 99%, les corrections d'énergie du deuxième ordre calculées avec des ensembles de base gaussiens non-contractés. Une représentation compacte des fonctions d'onde relativistes en termes de fonctions gaussiennes bien aplanies contractées utilisées dans la présente étude fournit un moyen utile de réduire les besoins d'emmagasinage intégral et le temps nécessaire pour effectuer des calculs corrélés, tout en maintenant une grande précision dans les effets relativistes de corrélation électronique.

Mots clés : Dirac–Fock, théorie perturbationnelle relativiste à plusieurs centres, ensemble de base gaussien bien aplani, xénon.

[Traduit par la rédaction]

Introduction

Many-body perturbation theory (MBPT) has been recognized as a powerful approach to the non-relativistic correlation problem for atoms and molecules (1). In the last few years, a relativistic version of the many-body theory, which accounts for both relativistic and electron correlation effects, was developed by a number of groups by using analytic basis functions (2–11). The relativistic MBPT algorithm, based on an expansion in analytic basis functions (2–11), has the advantage that it provides the compact representation of the complete Dirac spectrum, and greatly facilitates the evaluation of the many-body diagrams using finite summations (2, 6).

The technique of basis set contraction has not been widely employed in atomic calculations. In view of the computational difficulties in many-body calculations on heavy-atom systems, a basis set contraction that does not affect the accuracy in electron correlation energy would be especially useful in applications to heavier atoms. The approach to contraction in molecular calculations has been articulated by Dunning (12), Huzinaga (13), Pople and co-workers (14), and Wilson (15). In this approach, Gaussian-type functions (GTF) that represent the core region are extensively contracted, while valence functions are left uncontracted to provide flexibility in describing bond formation. The contracted basis sets reproduce the relativistic corrections well at the Dirac–Fock (DF) SCF level (16). However, they give relatively poor values for second- and third-order MBPT energy corrections (16). These basis sets have been derived to reproduce valence, but not core or core–valence interactions.

Atomic calculations, which aim at much higher accuracy, must employ the largest practical basis sets. Provided that the error introduced by basis set contraction is a fraction of the absolute error in an atomic calculation, contracted basis sets should provide a useful means of curtailing computation time as well as integral storage in relativistic MBPT calculations on heavier atoms. In a previous study (17), we explored a way to reduce the computational burden in relativistic MBPT calculations on Kr by using contracted and uncontracted GTF basis sets. In the present study, the feasibility of a practical relativistic MBPT on heavy atoms is examined by electronic structure calculations of the ground state Xe atom by using contracted well-tempered GTF. The Xe atom possesses 54 electrons, and is one of the heaviest atoms to which non-relativistic and relativistic MBPT employing analytic basis functions have ever been applied.

Methods

In c-number theory, the approximate N-electron Hamiltonian for our development of relativistic MBPT calculations is the so-called relativistic "no-pair" Dirac–Coulomb (DC) Hamiltonian (18, 19),

$$[1] \qquad H_+ = \sum_i h_D(i) + \mathcal{L}_+\left(\frac{1}{2}\sum_{i,j} 1/r_{ij}\right)\mathcal{L}_+$$

where $\mathcal{L}_+ = L_+(1) \cdot L_+(2) \cdots L_+(N)$, and $L_+(i)$ is the projection operator onto the space spanned by the positive-energy eigenfunctions, $\{\phi^+_{n\kappa}\}$ of the radial Dirac–Fock operator, F_κ (19, 20).

$$[2] \quad F_\kappa \phi^+_{n\kappa}(r) = \epsilon_{n\kappa} \phi^+_{n\kappa}(r)$$

where

$$[3] \quad F_\kappa = \begin{bmatrix} V^{LL} & c\Pi_\kappa + V^{LS} \\ c\Pi_\kappa + V^{SL} & V^{SS} - 2c^2 \end{bmatrix}$$

and

$$[4] \quad \phi^+_{n\kappa}(r) = \begin{bmatrix} P_{n\kappa}(r) \\ Q_{n\kappa}(r) \end{bmatrix}$$

The radial functions $P_{n\kappa}(r)$ and $Q_{n\kappa}(r)$ are referred to as the large and small components, respectively. $P_{n\kappa}(r)$ and $Q_{n\kappa}(r)$ may be expanded in sets of basis functions.

In the second-quantized, particle-hole formalism, the "no-pair" DC Hamiltonian may be expressed in terms of normally ordered products of the spinor operators, $[r^+s]$ and $[r^+s^+ut]$,

$$[5] \quad H_N = \sum_{r,s} f_{rs}[r^+s] + \frac{1}{4} \sum_{r,s,t,u} \langle rs \| tu \rangle [r^+s^+ut]$$

Here f_{rs} and $\langle rs \| tu \rangle$ are, respectively, one-electron DF and antisymmetrized two-electron Coulomb interaction matrices over the DF four-component spinors, r, s, t, and u. Normal ordering implies that, in the vacuum state, annihilation operators are moved to the right of creation operators as if all anticommutators vanish. The Fermi level is shifted to the highest occupied positive energy state. The creation operator then appears to the right of a normally ordered set when it refers to an occupied positive energy state, while the annihilation operator remains on the right for a positive energy virtual state. In this form, the no-pair Hamiltonian is restricted to contributions from the positive energy branch of the spectrum.

In a series of studies (9, 21), we have performed DF Gaussian basis expansion calculations on one- and many-electron systems with a finite nucleus model. In these studies, we have emphasized alteration of the boundary conditions such that GTF become the best form for basis functions. Representing the nucleus as a finite body of uniform proton charge accomplishes that feat. With this representation of the potential, for example, the exact $s_{1/2}$ solutions of the Dirac equation near the origin are

$$[6] \quad P(r)/r = 1 + g_2 r^2 + g_4 r^4 + \ldots$$

$$[7] \quad Q(r)/r = f_1 r + f_3 r^3 + \ldots$$

so that, for α arbitrary parameters

$$[8] \quad P(r) = r + g_2 r^3 + \ldots \approx r \exp(-\alpha r^2)$$

$$[9] \quad Q(r) = f_1 r^2 + f_3 r^4 + \ldots \approx r^2 \exp(-\alpha r^2)$$

Thus, in the finite nuclear model, the GTF of an integer power of r are appropriate basis functions because imposition of the finite nuclear boundary results in a solution that is Gaussian at the origin. In a previous study, we have shown that the failure to satisfy the proper boundary conditions near the origin may lead to a spurious solution (21).

The GTF basis functions that satisfy the boundary conditions associated with the finite nucleus automatically satisfy the condition of the so-called "kinetic balance" for a finite value of c. The kinetically balanced GTF basis functions are precisely the form given in eqs. [8] and [9]. This is a consequence of the fact that the exponent of r in the GTF basis functions does not depend on the speed of light. In this sense, the GTF are chosen to satisfy the condition of kinetic balance and relativistic boundary conditions associated with a finite nucleus.

The expansion scheme is applied to basis sets of contracted functions in a direct extension of its application to uncontracted functions. Large-component radial functions, $P_{n\kappa}(r)$, are expanded in a basis of contracted functions, $\{X_{\kappa i}{}^L(r)\}$ with expansion coefficients $\{C_{n\kappa i}{}^L\}$ as (16)

$$[10] \quad P_{n\kappa}(r) = \sum_i C_{n\kappa i}{}^L X_{\kappa i}{}^L(r)$$

where

$$[11] \quad X_{\kappa i}{}^L(r) = \sum_p d_{\kappa ip} f_{\kappa p}{}^L(r)$$

Here the $\{d_{\kappa ip}\}$ are the contraction coefficients. The $\{f_{\kappa p}{}^L(r)\}$ are the primitive GTFs. The small-component radial function, $Q_{n\kappa}(r)$ are expanded in a basis of $\{X_{\kappa i}{}^S(r)\}$,

$$[12] \quad Q_{n\kappa}(r) = \sum_i C_{n\kappa i}{}^S X_{\kappa i}{}^S(r)$$

To insure proper balance, $X_{\kappa i}{}^S(r)$ is related to $X_{\kappa i}{}^L(r)$ as

$$[13] \quad X_{\kappa i}{}^S(r) = (d/dr + \kappa/r) X_{\kappa i}{}^L(r)$$

We performed DF and MBPT calculations on ground state xenon with the well-tempered GTF basis sets of Huzinaga and Klobukowski (22) in a contracted and an uncontracted form. The well-tempered GTF basis sets have proven very useful in accurate DF SCF (23) and relativistic MBPT calculations (9). The Xe nucleus was represented as a sphere of uniform proton charge distribution. The atomic mass used in the calculations was 131.30 amu. The speed of light used was 137.0370 au. To simulate the non-relativistic limit, a value of c of 10^4 was used.

The virtual orbitals used in the study were calculated in the field of the nucleus and of all the electrons (V_N potential). Goldstone diagrams have been summed to compute Dirac–Coulomb correlation corrections to second order. Diagrammatic summation was done within the subspace of the positive energy branch, i.e., in the no-pair approximation (18, 19).

The DC Hamiltonian used in the present study is approximate. In the DC Hamiltonian, one-electron interactions are treated relativistically as a sum of Dirac one-electron Hamiltonians, whereas the two-electron interaction is treated non-relativistically as the instantaneous Coulomb repulsion. However, the energy shift induced by the low-frequency Breit interaction in the SCF and correlated calculations is known to be significant for inner-shell orbitals of heavy systems (24). In the present study, we have neglected the Breit interaction along with the radiative corrections, mass polarization, and reduced mass effects.

Results and discussion

We performed DF and MBPT calculations on the Xe atom by systematically enlarging the order of partial wave expansion, i.e., L_{max}. Throughout this work, the non-relativistically optimized well-tempered basis set of Huzinaga and Klobukowski (22) was used in a contracted and an uncontracted form. Table 1 contains the uncontracted well-tempered GTF exponents for Xe. Exponents of higher angular momentum functions used to generate the virtual orbitals are also tabulated in the table for the $21s17p12d7f6g5h$ primitive GTF basis set. Basis functions in the $21s$, $17p$, and $12d$ primitive sets in Table 1 were contracted to generate the $[14s13p10d]$ contracted set. The contracted basis set was derived by grouping the functions of highest exponents. Table 2 displays the contraction coefficients for the contracted $[14s13p10d]$ set. The contraction coefficients were taken from the results of the Hartree–Fock calculations obtained by Huzinaga and Klobukowski (22).

Table 3 displays the total DF energies, E_{DF} computed by using contracted and uncontracted GTF basis sets. In the table, the $21s17p12d$ primitive functions are those of non-relativistically optimized well-tempered Gaussians. The $21s19p13d$ primitive set was constructed by augmenting the $21s17p12d$ basis with two $2p$ and one $3d$ Gaussian functions whose exponents are the next highest in Table 1. The results reveal that contracting basis functions of high exponents raises the total DF energy markedly. The DF energy is sensitive to the type of contraction used in the present study. This is understandable because relativistic dynamics near the origin are described by the GTF of high exponents, and contracting these functions affects the accuracy of the relativistic energies.

Table 4 displays the second-order (E_2) correlation energy corrections computed with a partial-wave expansion up to $L_{max} = 5$. The reductions in the second-order energies, ΔE_2, caused by basis set contraction, are given in the third column of the table. The results show that such a contraction scarcely affects the computed correlation energy corrections. Comparison of the second-order energy obtained by using an uncontracted $21s17p12d$ basis with that obtained by using a contracted $14s13p10d$ basis set shows that the reduction of the second-order correlation energy due to the basis set contraction is only 0.0168 au. The overall reduction amounts to 1.7% of the second-order energies obtained by using a $21s17p12d$ primitive GTF basis set. This is in contrast to the DF SCF calculations in which contracting basis functions of high exponents noticeably affects the total DF SCF energy. The error in E_2 is primarily due to the reduction of the virtual space in size caused by the basis set contraction in $s_{1/2}$ and $p_{1/2,3/2}$ symmetries. Consequently, this error in the second-order energy remains constant even when the virtual space is enlarged by including the partial wave expansion up to $L_{max} = 3$: Use of a $14s13p10d7f$ contracted basis gives the error of 0.01695 au, which accounts for 0.76% of the second-order energy, −2.2297 au, obtained by using the $14s14p10d7f$ contracted basis set.

The basis set with the highest L_{max} used in the present study is the contracted $14s13p10d7f6g5h$ set. The second-order many-body energy obtained by using this basis is −2.74029 au. The experimental estimate of the correlation energy in Xe is not known. Using a density functional approximation for the correlation energy of the inhomogeneous electron gas, Perdew estimated theoretically the non-relativistic correlation energy of Xe to be −3.31 au (25).

For neutral atoms, the error in the computed correlation correction, caused by the truncation of the partial wave expansion for $L_{max} \geq 6$, varies between 1 and 3% depending

Basis set	E_2	ΔE_2
21s17p12d	−1.03044	
14s13p10d	−1.01356	0.01688
21s17p12d7f	−2.24665	
14s13p10d7f	−2.22970	0.01695
14s13p10d7f6g	−2.59315	
14s13p10d7f6g5h	−2.74029	

on the system (9). Thus, the error caused by the basis set contraction is less than the error in the correlation correction caused by the truncation of the partial wave expansion.

We have computed the non-relativistic limit of E_2 by taking $c = 10^4$ in our relativistic DF and MBPT calculations. This gave −2.7077 au. The results give an estimate of the nonadditive contribution due to the interference between relativity and Coulomb correlation to be 0.0326 au, which is twice as large as that of the Kr atom (17).

Conclusion

The present study reveals that the DF energy is sensitive to the contraction of GTF of high exponents because of the importance of the relativistic dynamics near the origin, while electron correlation is insensitive to such a contraction. This fact makes it possible to contract the GTF of high exponents without sacrificing the accuracy in correlated calculations. Relativistic atomic structure calculations, which aim at high accuracy, must employ uncontracted Gaussian basis sets at the SCF level, while contraction can be employed at the correlated level.

The contraction scheme discussed in the present study works well for heavy systems because there are a number of primitive GTF of high exponents used to represent the core region of high Z nucleus, and they may be contracted without significantly affecting the accuracy of the computed correlation energy. The contracted basis sets are kept flexible both in the core and the valence region to enable us to recover accurate correlation energies both in the core and the valence region. The results obtained in the present study indicate that it is possible to contract the Xe primitive basis to a size comparable to those used in MBPT calculations on the neon atom (9), while maintaining the accuracy in the correlation energy. Contracting the 21s17p12d primitive set into 14s13p10d reduces both the storage of integrals and the computation time by more than 30%. We believe that this type of contraction would be very useful for accurate relativistic many-body calculations on heavy systems because the contraction considerably curtails integral storage requirements and the time needed for correlated calculations.

Dipped adcluster model study for the end-on chemisorption of O_2 on an Ag surface

HIROSHI NAKATSUJI[1] AND HIROMI NAKAI

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606, Japan

Received June 10, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

HIROSHI NAKATSUJI and HIROMI NAKAI. Can. J. Chem. **70**, 404 (1992).

Theoretical study for the end-on adsorption of an O_2 molecule on an Ag surface is carried out with the use of the dipped adcluster model (DAM). The adcluster of AgO_2 is taken and the highest spin coupling model is employed. Electron transfer from the bulk metal to the adcluster considered by DAM is important for the occurrence of the chemisorption, and this cannot be described by the small-size cluster model. Electron correlations are also quite important and are described by the SD-CI method based on the corresponding parent configurations. In the end-on geometry, the superoxide species is the ground state, and there are no peroxide species in the lower energy region. The calculated adsorption energy compares reasonably with the experimental value. The O—O axis of the superoxide is inclined by 70°–80° from the surface normal. The outside oxygen atom of the adsorbed species seems to be more reactive than the inside one, while the net charge on the former is smaller than that on the latter.

Key words: DAM (dipped adcluster model), silver, superoxide, chemisorption.

HIROSHI NAKATSUJI et HIROMI NAKAI. Can. J. Chem. **70**, 404 (1992).

Utilisant le modèle de l'«adagrégat» plongé (DAM), on a effectué une étude théorique de l'adsorption par le bout de la molécule d'oxygène sur une surface. On a pris l'«adagrégat» du AgO_2 et on a utilisé le modèle du couplage des spin les plus élevés. Sur la base du DAM, le transfert d'électron de l'ensemble du métal vers l'«adagrégat» semble une condition importante pour que la chemisorption puisse se produire; cette importance ne peut pas être décrite par le modèle des petits agrégats. Les corrélations d'électrons sont aussi très importantes et elles peuvent être décrites par la méthode SD-CI basée sur les configurations des parents correspondants. Dans le géométrie d'addition par le bout, l'espèce superoxyde est dans l'état fondamental et il n'y a pas d'espèce peroxyde dans la région d'énergies plus faibles. L'énergie d'adsorption calculée se compare raisonnablement bien avec la valeur expérimentale. L'axe O—O du superoxyde est incliné de 70° à 80° par rapport à la surface normale. L'atome d'oxygène qui se trouve à l'extérieur de l'espèce adsorbée semble plus réactif que celui qui se trouve à l'intérieur alors que la charge nette du premier est plus faible que celle du dernier.

Mots clés : DAM (modèle de l'«adagrégat» plongé), argent, superoxyde, chemisorption.

[Traduit par la rédaction]

Introduction

An oxygen molecule adsorbed on a silver surface can undergo several important catalytic reactions. In particular, the partial oxidation of ethylene (1) is a very useful reaction in chemical industry. Several studies for clarifying the nature of the adsorbed oxygen have been performed in order to understand the mechanism of this reaction (2–4). However, there still remain many questions about the structure and electronic states of the adsorbed oxygen species involved in the epoxidation.

Two different observations have been made about the structure of the adsorbed oxygen. The NEXAFS study of O_2/Ag(110) shows that the O—O axis is parallel to the surface along the [1$\bar{1}$0] azimuthal axis with the O—O distance of 1.47 ± 0.05 Å (5). The ESDIAD experiment of O_2/Ag(110) indicates that O_2 is bonded end-on to a single Ag atom, slightly inclined away from the surface normal along the [001] azimuth (6).

In our previous study (7), we examined a side-on adsorption of O_2 onto an Ag surface by using the dipped adcluster model (DAM) (8, 9) combined with the SAC (symmetry adapted cluster)/SAC-CI method (10, 11). It has been shown that two superoxide (O_2^-) and one peroxide (O_2^{2-}) species exist in that geometry, while the latter is 13 kcal/mol more stable than the former. The peroxide species leads to dissociative adsorption with further stabilization. It was concluded that electron correlations in low-lying surface states and electron transfer from bulk metal to the adcluster are important for the oxygen chemisorption. The heats of molecular and dissociative chemisorptions and the O—O vibrational frequencies agreed well with the experimental values. In addition to other theoretical studies (12–16) on the side-on adsorptions of O_2 onto the silver surface, which use the cluster model, the structures and electronic states of the side-on oxygen species are considerably clarified.

In this study, we investigate the end-on adsorption of an O_2 molecule on an Ag surface with the use of DAM. Electron correlation is described by the SD-CI method based on the respective parent configurations. On the other hand, cluster-model SCF calculations for AgO_2 were carried out by Broomfield and Lambert (17). They showed the existence of two superoxide species in the end-on geometry with inclined O—O axis, but no stabilization energies were presented.

Dipped adcluster model

The dipped adcluster model was proposed as a theoretical model for studying chemisorptions and surface reactions involving electron transfers between admolecules and surfaces (8, 9). The "adcluster," a combined system of an admolecule and a cluster, is dipped onto the electron "bath" of a solid metal and an equilibrium is established for electron and (or) spin transfers between them. The equilibrium condition is described by using the chemical potentials of the

adcluster and the solid surface. Namely, at equilibrium, the adcluster is at the min[$E(n)$] in the range,

$$[1] \quad -\frac{\partial E(n)}{\partial n} \geq \mu$$

where $E(n)$ is the energy of the adcluster, with n being the number of electrons transferred from the bulk metal to the adcluster and μ the chemical potential of the electrons of the metal surface. While all the electrons transferred into the admolecule must be supplied by the cluster alone in the conventional cluster model, some of the electrons are supplied from the electron bath of the bulk metal in DAM. The admolecule charged by this electron transfer induces an electrostatic polarization on the metal surface and receives an electrostatic attractive force. In DAM, the energy of the adcluster is given by

$$[2] \quad E = E^{(0)} + E^{(1)}$$

where $E^{(0)}$ is the electronic energy of the adcluster alone and $E^{(1)}$ the energy of the electrostatic interaction between the adcluster and the bulk metal. For $E^{(0)}$, the molecular orbital model of the dipped adcluster was proposed (8) and, for $E^{(1)}$, estimation by the method of image force was suggested (9). The energy E of the system is calculated as a function of n.

In the present study, a linear Ag—O_a—O_b system is taken as an adcluster. At infinite separation, the O_2 molecule is in the $^3\Sigma_g^-$ state and the Ag atom in the ^2S ($d^{10}s^1$) state. The highest (or parallel) spin coupling model is adopted, since it gives a continuous picture leading to the correct separation limit. In the linear AgO_2 system, the frontier MOs are mainly composed of the degenerate π^* MOs of O_2. Since the π^* orbitals of O_2 are already singly occupied by two α-spin electrons, an $n/2$ β-spin electron is added to each of the degenerate π^* orbitals.

The DAM calculations have been performed with the *ab initio* RHF SCF MO program. The Gaussian basis set for the silver atom is (3*s*3*p*4*d*)/[3*s*2*p*2*d*] and the Kr core is replaced by the relativistic effective core potential (18). For oxygen, we use the (9*s*5*p*)/[4*s*2*p*] set of Huzinaga–Dunning (19) augmented by the diffuse *s*,*p* functions of $\alpha = 0.059$ as anion bases (20) and the polarization *d* function of $\alpha = 0.30$.

Figure 1 is a display of the $E(n)$ curves, energy as a function of n. This figure is for the Ag—O_a distance at 2.20 Å, which is almost the most stable distance. The O—O distance is changed from 1.20741 Å, which is an equilibrium length of O_2 (21), to 1.35 Å, which is an equilibrium length for O_2^- (22). The curves are upper convex and the curvature is discontinuous at $n = 0.0$ and $n = 1.0$. At $n = 0.0$, $R_{O—O} = 1.20741$ Å is more stable, but at $n = 1.0$, $R_{O—O} = 1.35$ Å is more stable. The tangents of the curves coincide with the experimental chemical potential $-\mu$ of the solid silver metal (4.52 eV) (23) at $n = 0.7$. Therefore, as judged from the equilibrium condition of eq. [1], one electron flows from the bulk metal into the adcluster after a certain barrier.

O_2 approaching process

We next investigate the end-on approach of the O_2 molecule to the silver surface. Electron correlations in the low-lying states of the adcluster are calculated by including all the single and double (SD) excitation configurations relative to the corresponding parent configurations. Zero- and

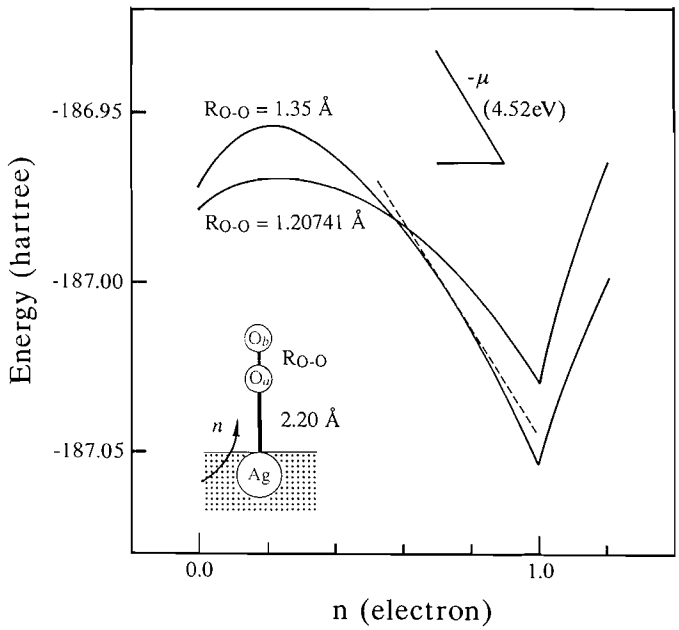

FIG. 1. $E(n)$ curve for the Ag—O_a—O_b system in the highest spin coupling model with the O_a—O_b distance of 1.20741 and 1.35 Å, and the Ag—O_a distance of 2.20 Å.

one-electron transferred states are calculated in relation to the results of Fig. 1. The active space in the SD-CI calculations consists of 11 higher occupied orbitals and 16 lower unoccupied orbitals calculated by the HF method. The 11 occupied orbitals are mainly made up from the 4*d* and 5*s* atomic orbitals of Ag and the 2*p* atomic orbitals of O. The CI calculations are carried out with the use of the program GAMESS (24).

Figure 2 shows the potential energy curves for the approaching process. The ground state of the separated system, Ag plus O_2, corresponds to the $^4\Sigma^+$ state. The energy of the separated system is estimated to be −187.089988 hartree by SD-CI calculation of the supermolecule. On the other hand, it is estimated to be −187.108991 hartree by SD-CI calculation of the free Ag plus O_2 system, of which the active spaces are [6 × 7] and [5 × 9], respectively. The energy scale on the right-hand side in Fig. 2 is in kcal/mol relative to the free system. The energy difference between the two estimations is due to the truncated nature of the CI method, which causes an unsatisfactory size consistency, as is well known. Therefore, the adsorption energy calculated from the CI of the separated free system is always smaller than that obtained from the CI for the supermolecule.

The $^4\Sigma^+$ state does not involve electron transfer between the bulk metal and the adcluster. The potential energy curve of the $^4\Sigma^+$ state rises monotonously as O_2 approaches and shows that O_2 is not adsorbed on the silver surface along this state. While the curve of the $^4\Sigma^+$ state is calculated for $R_{O—O}$ fixed at 1.20741 Å, a similar repulsive curve is also obtained for $R_{O—O}$ fixed at 1.35 Å and lies at higher energy than the curve shown in Fig. 2.

On the other hand, the ground state of the adsorbed system is the $^3\Pi$ state and involves one-electron transfer from the bulk metal. The potential energy curve of the $^3\Pi$ state is attractive and has a minimum at the Ag—O distance of

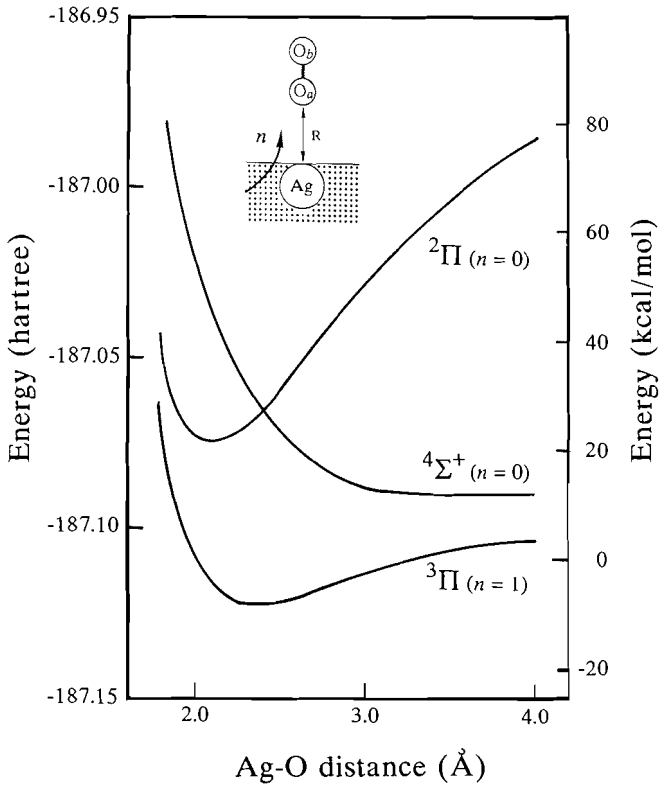

FIG. 2. Potential energy curves for the end-on approach of the O_2 molecule onto silver, calculated by the SD-CI method. The O—O length is fixed at 1.20741 Å for the $^4\Sigma^+$ state and at 1.35 Å for the $^2\Pi$ and $^3\Pi$ states. n denotes the number of electrons transferred into the adcluster from the bulk metal. The energy scale on the right-hand side is in kcal/mol relative to the free Ag plus O_2 system.

2.2 Å. The $^3\Pi$ state corresponds to the superoxide species O_2^-, since the degenerate π^* orbitals of O_2 are formally occupied by three electrons. The adsorption energy of the superoxide is calculated to be 19.4 kcal/mol relative to the energy of the supermolecule, and to be 7.5 kcal/mol relative to the energy of the free system. These calculated adsorption energies are positive in both cases and comparable with the experimental value of 9.2 kcal/mol (25).

The $^2\Pi$ state is an electron-transferred state from Ag to O_2, but no electron is supplied from the bulk metal. The potential energy curve of the $^2\Pi$ state has a minimum at the Ag—O distance of 2.0 Å, but the energy is always higher than that of the separated system (negative adsorption energy). This state corresponds to the superoxide species obtained by the conventional cluster model, though the present potential energy contains the electrostatic energy correction $E^{(1)}$. This result shows that the electron transfer from the bulk metal to the adcluster considered by DAM is important, though this cannot be dealt with by the conventional cluster model.

Table 1 shows Mulliken's atomic charges of the AgO_2 adcluster with R_{Ag-O} = 2.20 Å and R_{O-O} = 1.35 Å. In the $^4\Sigma^+$ state, which does not involve electron transfer from the bulk metal, as mentioned above, the charge of O_2 is small. The large negative charge −0.75 of O_2 in the $^2\Pi$ state is transferred from the Ag atom alone, since no electron is supplied from the bulk metal. This electron transfer is unfavorable in energy as seen in Fig. 2. On the other hand, in the $^3\Pi$ state all the electrons transferred to O_2 are supplied from the bulk metal. Note that the charge distribution of O_2 in the $^3\Pi$ state, the superoxide described by the DAM, is similar to that in the $^2\Pi$ state, the superoxide in the cluster model. The negative charge on the Ag atom seems to reflect the smallness of the size of the adcluster. It also seems to be due to the use of the highest spin coupling model, which is an extreme model. Actually, in the calculation of the PdO_2 adcluster based on the paired spin coupling model, the Pd atom has positive charge (9).

TABLE 1. Mulliken's atomic charges for the Ag—O_a—O_b adcluster[a]

State	n	Mulliken's atomic charge			
		Ag	O_a	O_b	O_a + O_b
$^4\Sigma^{+b}$	0.0	−0.103	−0.017	+0.120	+0.103
$2\Pi^b$	0.0	+0.751	−0.637	−0.114	−0.751
$^3\Pi^b$	1.0	−0.328	−0.507	−0.165	−0.672
$^3A''^c$	1.0	−0.184	−0.501	−0.315	−0.816

[a]Ag—O and O—O lengths are at 2.20 and 1.35 Å, respectively.
[b]Linear Ag—O—O adcluster.
[c]Declining angle θ of 70°.

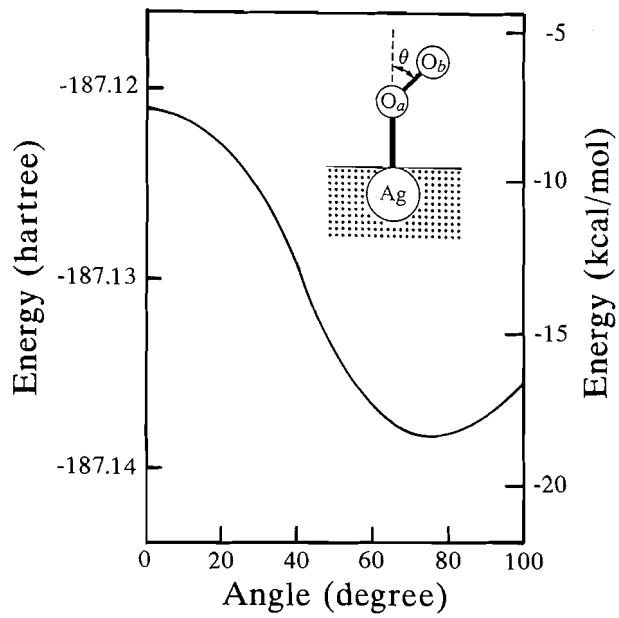

FIG. 3. Potential energy curve for the ground state of the AgO_2 adcluster calculated by the SD-CI method for the O_2 declining process. The declining angle θ is defined in the figure. The Ag—O_a and O_a—O_b lengths are fixed at 2.20 and 1.35 Å, respectively. The energy scale on the right-hand side is in kcal/mol relative to the free Ag plus O_2 system.

O_2 declining process

We examine the O—O axis declining on the silver surface. While the π^* MOs of O_2, which have three electrons for the superoxide species, are degenerate in the linear system, they are separated into a' MO (in-plane) and a'' MO (out-of-plane) in the declining process. The $^3A''$ state, in

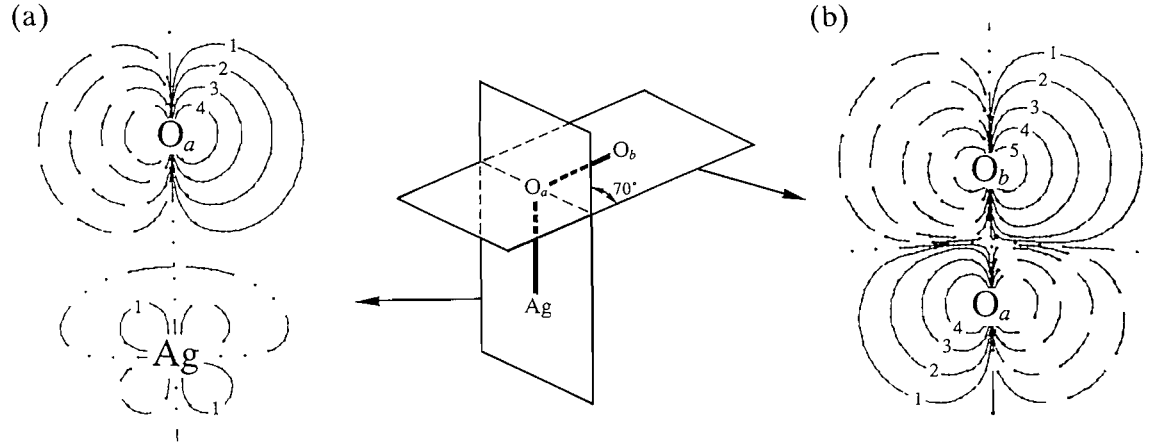

FIG. 4. Contour maps of the frontier orbital of the superoxide on silver calculated from the AgO_2 adcluster with Ag—O_a and O_a—O_b distances of 2.20 and 1.35 Å, respectively, and the declining angle θ of 70°; (*a*) and (*b*) are the maps on the planes including the Ag—O_a and O_a—O_b bonds, respectively. Solid and broken lines correspond to plus and minus signs in the MO. Double dotted line shows the node of the MO. The numbers 1–5 on the contours correspond to the values 0.01, 0.03, 0.10, 0.30, 1.00, respectively.

For personal use only.

which the π* MOs are splitting into doubly occupied *a'* and singly occupied *a"* MOs, is more stable than the $^3A'$ state, in which the occupations in the π* MOs are reversed. Figure 3 shows the potential energy curve of the $^3A''$ state for the declining angle from the linear system. It is calculated by the SD-CI method with the Ag—O and O—O distances fixed at 2.20 and 1.35 Å, respectively. We find a minimum at the declining angle of 70–80°, which is similar to the result of Broomfield and Lambert (17). The energy at the minimum is more stable by 10.4 kcal/mol than that of the linear system. The adsorption energy is calculated to be 18.0 and 29.8 kcal/mol, relative to the energies of the separated system calculated for free molecules and supermolecule, respectively. The experimental value is 9.2 kcal/mol (25). The calculated state corresponds to the superoxide species, and no peroxide species is found in the lower energy region.

At the potential minimum, the net charges on O_a and O_b are calculated to be −0.50 and −0.32, respectively, as shown in Table 1. Namely, the negative charge on the inside O_a atom is larger than that on the outside O_b atom, which seems to be opposite to the charge distribution expected from the covalent Ag—O—O^- system.

Reactivity of superoxide

The frontier orbital of the superoxide species is the out-of-plane π* MO, which is the singly occupied (SO) MO, while the in-plane π* MO is doubly occupied as mentioned above. Figure 4 illustrates the frontier orbital map, which is related to the reactivity of the adsorbed oxygen species. Figures 4(*a*) and (*b*) correspond to the maps on the planes including the Ag—O_a and O_a—O_b bonds, respectively. These figures show much contribution of the π* orbital of O_2, but little of the $4d_{yz}$ orbital of Ag. Furthermore, in contrast to the charge distribution, the frontier orbital is larger at O_b than at O_a, which indicates that the former is more reactive than the latter.

Finally, we summarize the properties of the superoxide in the end-on form in contrast to the side-on dioxygen species studied in the previous work (7).

1. The O—O bond of the superoxide is moderately relaxed: Since the π* orbitals of the species are formally occupied by three electrons, the O—O bond is weaker than the neutral species, but stronger than the peroxide species. As shown in the previous paper (7), the peroxide species leads to the dissociative oxygen on an Ag surface.

2. In the end-on geometry, the superoxide is not liable to become the peroxide: The present study shows that in the end-on geometry the superoxide is the ground state and no peroxide state exists in the lower energy region. On the contrary, the superoxide in the side-on form seems to be easily transformed into the peroxide, since the peroxide is more stable than the superoxide (7).

3. The outside oxygen of the superoxide is more reactive than the inside oxygen: The amplitude of the frontier orbital is larger at the outside oxygen than at the inside one, in contrast to the charge distribution. Furthermore, since the frontier orbital, which is SOMO, is mainly composed of the π* MO of O_2, one-electron flow into this orbital causes a breaking of the O—O bond.

4. The charge distribution of the end-on superoxide is favorable for the approach of electron-rich molecules: By the above reasoning, the electron-rich molecule may attack the outside oxygen of the end-on superoxide. The electrostatic repulsion in this attacking process is reduced, since the negative charge on the outside oxygen atom is smaller than that on the inside one. On the other hand, in the side-on form there is no charge polarization between the two oxygen atoms.

The *ab initio* model potential method. Cowan–Griffin relativistic core potentials and valence basis sets from Li ($Z = 3$) to La ($Z = 57$)

ZOILA BARANDIARÁN AND LUIS SEIJO

Departamento de Química Física Aplicada, C-14, Universidad Autónoma de Madrid, 28049 Madrid, Spain

Received June 25, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

ZOILA BARANDIARÁN and LUIS SEIJO. Can. J. Chem. **70**, 409 (1992).

A comprehensive tabulation of Cowan–Griffin relativistic *ab initio* core model potentials and valence basis sets corresponding to the Cowan–Griffin *ab initio* model potential method is presented. It includes those for the elements from Li ($Z = 3$) to La ($Z = 57$), the alkaline M^+ and alkaline earth M^{2+} cations, and for the halogen X^- anions. Molecular results are presented in order to test the potentials and basis sets and to estimate the extent of the mass–velocity and Darwin relativistic effects considered within the method, which lie within the expected margins.

Key words: relativistic, model potential, effective core potential, basis sets, *ab initio*.

ZOILA BARANDIARÁN et LUIS SEIJO. Can. J. Chem. **70**, 409 (1992).

On présente un tableau exhaustif des bases de valence et des potentiels de polarisation interne du modéle relativiste *ab initio* interne de Cowan–Griffin correspondant à la méthode CG-AIMP. Il comporte les données relatives aux éléments allant du Li ($Z = 3$) au La ($Z = 57$), aux cations alcalins M^+, aux cations des métaux alcalino-terreux M^{2+} et aux anions des halogènes X^-. Afin de vérifier les potentiels et les bases ainsi que pour évaluer l'importance des effets de masse–vélocité et les effets relativistes de Darwin considérés dans cette méthode, on présente des résultats moléculaires qui tombent à l'intérieur des marges attendues.

Mots clés : relativiste, potentiel modèle, potentiel interne, bases, *ab initio*.

[Traduit par la rédaction]

1. Introduction

The *ab initio* model potential method (AIMP) for valence-electron molecular calculations has been presented in previous papers (1–3). It shows the following characteristics.

(*i*) It makes use of valence orbitals with the correct nodal structure.

(*ii*) The atomic core model potentials are obtained directly from the operators they represent, without resorting to any parametrization procedure making use of valence reference orbitals. This characteristic is peculiar to the method. As a consequence of it, the AIMP can also be used to obtain complete-ion potentials (both cations and *anions*), becoming a useful tool to represent crystal lattices in solid state calculations (4).

(*iii*) The model potentials result from the addition of *explicit* representations of the core Coulomb exchange and projection operators, as well as the mass–velocity and Darwin operators that appear if the relativistic effects are handled within the Cowan–Griffin (CG) approximation (3, 5, 6). This gives the opportunity to analyze the physical effects associated with each operator.

(*iv*) The atomic valence basis sets are optimized according to the variational principle; their design and optimization is a replica of the procedure followed for all-electron basis sets.

Systematic studies on atomic and molecular calculations have been conducted, with the objective of reproducing, within an acceptable margin of error, the corresponding all-electron results if the same kind of wave function and valence basis set is used. As a consequence of them, nonrelativistic core model potentials and valence basis sets from Li to Xe have already been proposed (1–3), as well as Cowan–Griffin relativistic ones for the second series transition metal elements (3).

Numerical experimentation at the Hartree–Fock level has shown that nonrelativistic all-electron (AE) results are acceptably reproduced at a fraction of the cost. Furthermore, the effects of changes in the valence part of molecular basis sets run parallel in the AE and AIMP calculations. This is particularly important, since it means that the experience already gathered in the design of AE molecular basis sets from atomic basis sets (splitting of outermost contracted GTF's, addition of polarization functions, . . .) can safely be used for model potential calculations. Also, the high quality of the core operators used and, hence, the close reproduction of the AE basis set dependencies point out subtle effects on the molecular results, leading to the conclusion that, if there are symmetry blocks having core orbitals but lacking inner components in the molecular basis set, they must be supplied with *orthogonalization* functions in order to provide the ability to reach sufficient orthogonality between the core orbitals and the *molecular* valence orbitals. Finally, the Cowan–Griffin relativistic version of the AIMP method reproduces fairly well not only the absolute value of the equilibrium distance of AgH calculated by Lee and McLean (7) at the AE Dirac–Fock level, but also its relativistic contraction (3). The result of this test may be taken only as an additional support for the use and expected quality of the CG-AIMP method in molecules where relativistic effects other than mass–velocity and Darwin (such as spin-orbit) are not very significant, since a systematic comparison of results with AE Dirac–Fock (DF) calculations is not possible for molecules containing atoms up to La: All-electron DF calculations are available for molecules containing heavier atoms (8), where the inclusion of spin-orbit effects is compulsory.

In addition to the Cowan–Griffin relativistic core model potentials and valence basis sets already published for the second series transition metal elements, those for Sr, Ba, Br, and I have been obtained prior to conducting theoretical

[a]From ref. 3.

studies of the equilibrium geometry of alkaline earth dihalides (9). The latter are presented in this paper together with those of their respective periods, in order to facilitate the systematic performance of CG-AIMP molecular calculations. We have also obtained relativistic potentials and basis sets for the lighter elements, for completeness, even though the relativistic effects are known to be almost negligible for them (10). Finally, we include here the relativistic model potentials and basis sets for La($6s^25d^1$—^2D) as well as for the alkaline and alkaline earth cations and halogen anions. The results of molecular calculations performed in order to test the potentials and basis sets and to assess the extent of the mass–velocity and Darwin relativistic effects are presented.

2. Method

The nonrelativistic and Cowan–Griffin relativistic versions of the AIMP method, as applied to the valence electrons of a molecule, have already been described in refs. 1–3 and are simply summarized here. The one-electron contribution to the AIMP Hamiltonian for the valence electrons of a molecule is

$$[1]\quad h(i) = -\frac{1}{2}\Delta_i - \sum_I \frac{Z^I - Z^I_{\text{core}}}{r_{Ii}} + \sum_I \{V^{I,\text{MP}}_{\text{Coul}}(i) + V^{I,\text{MP}}_{\text{exch}}(i) + V^{I,\text{MP}}_{\text{MV}}(i) + V^{I,\text{MP}}_{\text{DW}} + P^I(i)\}$$

where I runs over the nuclei. The atomic core model potential components are as follows.

(*i*) The Coulomb core model potential,

$$[2]\quad V^{I,\text{MP}}_{\text{Coul}}(r_{Ii}) = \sum_k \frac{A^I_k \exp(-\alpha^I_k r^2_{Ii})}{r_{Ii}}$$

where the parameters $\{A^I_k, \alpha^I_k\}$ are determined through least-squares fitting to the genuine core Coulomb operator (including $-Z^I_{\text{core}}/r_{Ii}$).

(*ii*) The core exchange potential plus the relativistic mass–velocity and Darwin model potentials, which are the spectral representations of the genuine operators on the subset of the molecular primitive basis set that is centered on each nuclei:

$$[3]\quad V^{I,\text{MP}}_{\text{exch}}(i) + V^{I,\text{MP}}_{\text{MV}}(i) + V^{I,\text{MP}}_{\text{DW}}(i) = \sum_I \sum_{m=-l}^{+l} \sum_{a,b} |alm;I\rangle\, A^{I,\text{MP}}_{l;ab}\, \langle blm;I|$$

the $\{|alm;I\rangle\}$ are the spherical primitive Gaussian-type functions in the molecular basis set centered on I, and the coefficients $A^{I,\text{MP}}_{l;ab}$ are the elements of the matrix

$$[4]\quad A^{I,\text{MP}} = (S^I)^{-1} V^I_{\text{EMD}} (S^I)^{-1}$$

where S^I and V^I_{EMD} are, respectively, the overlap matrix and

the matrix of the genuine core exchange, mass–velocity, and Darwin operators on the basis set $\{|alm;I\rangle\}$.

(*iii*) The core projection operator,

$$[5]\quad P^l(i) = -\sum_{c}^{\text{core}-l} 2\varepsilon_c^l |\phi_c^l\rangle\langle\phi_c^l|$$

where ε_c^l and ϕ_c^l are the core orbital energies and functions of atom I.

The necessary atomic core orbitals, as well as the genuine (numerical) mass–velocity and Darwin relativistic operators, are obtained in an atomic AE numerical Cowan–Griffin–Hartree–Fock calculation. The numerical core orbitals are represented by linear combinations of primitive GTF's (using a maximum overlap criterium (11)) to facilitate integral calculations. Once the atomic core operators are well defined, none of them needs to be parametrized in an atomic valence-electron calculation. The atomic valence basis set is obtained by minimization of the valence energy following standard all-electron methods (12).

The Cowan–Griffin relativistic AIMP method, as it has been summarized, does not take into account spin-orbit interactions. A procedure to also include these effects in molecular calculations has already been proposed (5, 13).

3. Model potentials, basis sets, and atomic results

We present in this section Cowan–Griffin relativistic core model potentials and valence basis sets for the elements from Li (Z = 3) to La (Z = 57), except those for the second series transition metal elements, which have already been presented in ref. 3. We also include model potentials and basis sets for alkaline cations M^+, alkaline earth cations M^{2+}, and halogen anions X^-.

We use the experience already gathered with the nonrelativistic atoms in order to establish the size of the model potentials and the basis set patterns as those which led to optimum results for the nonrelativistic elements. They are described in Table 1, where, together with the size of the expansions of the core orbitals in terms of primitive GTF's and of the Coulomb model potentials, eq. [2], the pattern and structure of the valence basis sets are also shown. The notation of ref. 12 is followed for the basis set pattern, which is accompanied by the *structure* of the basis set, that is, the number of primitive GTF's used to represent the inner parts of the valence orbitals and, thus, to provide a high degree of core-valence orthogonality. Let us take In–Xe as an example: The actual minimal basis set is (11/10), meaning that an 11-GTF expansion is used for the 5*s* orbital and a 10-GTF expansion for the 5*p* orbital; its structure is (32222/3223),

that is, the three innermost GTF s provide the ability to reach $1s$–$5s$ orthogonality, the following two GTF s are used for $2s$–$5s$ orthogonality, etc.

The core orbitals, Coulomb model potentials, and valence basis sets are all tabulated and deposited as supplementary material.[1] A list of libraries containing these tables as well as the numerical mass–velocity and Darwin potentials are available from the authors upon request. These are all the data necessary to perform molecular CG-AIMP calculations. The fact that the coefficients of the nonlocal spectral representation, eq. [3], depend on the actual molecular basis set (they vary with the addition of diffuse functions, etc.) makes a tabulation of them impractical: alternatively, they can be actually computed, eq. [4], along the input processing part of the molecular calculation, since their evaluation is not time consuming.

The molecular basis set for an AIMP calculation can be built up from the atomic valence basis sets in the very same manner as the AE molecular basis sets are obtained from the atomic AE minimal segmented basis sets of ref. 12: the *splitting* of the contracted functions (note that here we only have one per symmetry) is used to increase the flexibility of the basis set, and the *addition* of extra functions available in the literature provides specific abilities to the molecular basis set. For instance, *polarization functions* are available in ref. 12. *Diffuse functions* for Rydberg states and for anions can be taken from ref. 14, and, for those not available, the same obtention procedure can be followed, i.e., p-type GTF with exponents 0.043 and 0.039 for Br and I provide an excellent agreement with the numerical HF atomic electron affinities and they can be used as diffuse functions for anions (9). *Diffuse* d-*functions* able to provide a balanced description of s^2d^n, s^1d^{n+1}, and s^0d^{n+2} configurations of first-row and second-row transition metal elements are available in refs. 15 and 16, respectively. *Extra d-functions* for alkaline earth elements that allow for the participation on the bonding of the unoccupied (in the atom) $(n-1)d$ orbitals, are available in ref. 17 for Ca. We tabulated[1] these d functions for Sr and Ba, which correspond to the valence $(n-1)d$ orbital optimized along atomic calculations on $Sr^+(4d^1-{}^2D)$ and $Ba^+(5d^1-{}^2D)$, and used them in molecular calculations in ref. 9. We include the functions for Rb and Cs optimized in the corresponding $Rb(4d^1-{}^2D)$ and $Cs(5d^1-{}^2D)$ atomic calculations. As we comment in the Introduction, in cases where atomic symmetry blocks having core orbitals lack inner components in the basis set, *orthogonalization functions* have

been found necessary in molecular model potenial calculations, to provide sufficient core-valence orthogonality (1–3). The following cases appear in the set of atoms covered here.

(*i*) Alkaline and alkaline earth elements. In *ns*-valence calculations, a *p* orthogonalization function is needed, starting on Na, to provide orthogonality between the atomic core *p* orbitals and the *molecular* valence orbitals: a contracted function corresponding to the outermost lobe of the $(n-1)p$ orbital in the tabulated $(n-1)p$,*ns*-valence basis set may be used as orthogonalization function. In addition, starting on Rb, a *d* orthogonalization function is needed as well to provide high orthogonality with the *d* core orbitals. In these cases, if the *extra* $(n-1)d$ functions are used, their inner lobes provide the desired ability and no additional function is needed. If, on the contrary, they are not used, their inner lobes may be taken as orthogonality functions.

(*ii*) IIIA to VIIA main group elements from Ga to Kr and In to Xe. Analogously, these elements demand a *d* orthogonalization function. We have tabulated (see footnote 2) 3-GTF contracted *d* functions for Ga–Kr, which maximize the overlap with the Cowan–Griffin relativistic numerical orbitals; for In–Xe, the 3-GTF contracted functions corresponding to the three outermost components of the tabulated GTF expansion of the relativistic 4*d* core orbitals are valid orthogonalization functions.

In Tables 2–5 the orbital energies and radial expectation values of the CG-AIMP atomic valence orbitals can be compared with those corresponding to the numerical Cowan–Griffin calculation. The discrepancies are comparable with the ones obtained for nonrelativistic AIMP versus numerical HF calculations. It should be noted that, for the nonrelativistic atomic tests, the deviations of the AIMP results from the AE numerical HF results are very similar to those of the AE calculations with limited basis sets having a valence part of the same size, the AIMP results being slightly better (1–3).

4. Molecular calculations

The ability of the method to reproduce the results of AE molecular calculations if the same kind of wave function and valence basis set is used has already been shown (1–3), as well as its ability to represent genuine mass–velocity and Darwin relativistic effects in molecules containing second-row transition metal elements (3), where the spin-orbit effects are not expected to be very significant. The size of the relativistic effects on equilibrium distances and angles, vibrational frequencies, and bending barriers of alkaline earth dihalides, as calculated by means of the potentials and basis sets for Sr, Ba, Br, and I presented here, have been analyzed in ref. 9. We present here results of CG-AIMP restricted HF calculations on molecules of main group elements and first series transition metal elements. The results are

$ScS(\sigma^1-{}^2\Sigma)$	2.136	2.136	622	621
$MnO(\delta^2\pi^2\sigma^1-{}^6\Sigma)$	1.789	1.787	649	641
$CuO(\sigma^2\delta^4\pi^3-{}^2\Pi)$	1.873	1.854	589	530

summarized in Table 6. The relativistic effects on the equilibrium distance and vibrational frequency of N_2, P_2, and As_2 are negligible, becoming significant only on Sb_2, where a bond-length contraction of 0.03 Å is found, the vibrational frequency being unaffected. The effects on the first-row transition metal molecules increase towards the end of the series: they are insignificant for ScO, ScS, and MnO, whereas for CuO a contraction of 0.02 Å in r_e is found (in agreement with the results of previous calculations (10)) as well as a reduction of 10% in $\bar{\nu}_e$. This tendency along the series has also been observed in the second-row transition metal elements (3), where the effects are, however, larger.

5. Conclusions

In this paper we complete the tabulation of Cowan–Griffin relativistic *ab initio* core model potentials and valence basis sets for the elements from Li ($Z = 3$) to La ($Z = 57$); we also include those for alkaline and alkaline earth cations, as well as for halogen anions. Even though the relativistic effects are only expected to be important starting from the fifth period of the periodic table, the tabulation for the lighter elements is also presented for the sake of completeness and in order to facilitate systematic studies on mass–velocity and Darwin relativistic effects. Tests of the potentials and basis sets on restricted Hartree–Fock molecular calculations are presented, which complete those previously performed with second-row transition metal elements (3), and alkaline earth dihalides (9). The relativistic effects along the periodic table, as estimated by the CG-AIMP method, lie within the expected margins (10).

Acknowledgements

In 1984 we had the fortune to meet Professor Sigeru Huzinaga at the University of Alberta, where he received us as post-doctoral fellows. Since then, we have enjoyed working with him. As a consequence of his sharing with us both his scientific knowledge and experience, and his friendship, we have learned from him many important things of both scientific and human nature. As a scientist, he is the person who has most influenced our present scientific attitudes. As a person, his behaviour has left an indelible impression on us. We have developed deep and intimate feelings of gratitude and respect towards Professor Huzinaga. This work was partly supported by a grant from MEC (DGICYT PS89-0021), Spain.

The use of special coordinate axes in direct and semi-direct implementations of second-order perturbation theory, including the derivation of a horizontal recurrence relation

TRACY P. HAMILTON AND HENRY F. SCHAEFER III[1]

Center for Computational Quantum Chemistry, University of Georgia, Athens, GA 30602, U.S.A.

Received June 25, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

TRACY P. HAMILTON and HENRY F. SCHAEFER III. Can. J. Chem. **70**, 416 (1992).

A horizontal recurrence relation (HRR) is derived which may be used in the generation of two-electron repulsion integrals (ERIs). Also, special Cartesian coordinate axes may be used to reduce the number of intermediate terms. Heretofore, the use of local axis systems entailed rotations every time a shell quadruple of ERIs was computed. Recently, we pointed out the possibility of postponing the transformation using choices of Cartesian reference frames based on nuclear positions. In our pilot implementation of direct and semi-direct Møller–Plesset second-order perturbation theory (MP2) we construct the integrals in local coordinate systems and perform the back-transformation in the middle of the AO to MO integral transformation, rather than rotating the ERIs after the computation of each shell quadruple. The efficacy of this approach depends on whether the gains in ERI computation are greater than the losses incurred in transformation. Preliminary CPU profiles indicate that the increased time spent in rotating axes is quite small.

Key words: horizontal recurrence relation, second-order perturbation theory.

TRACY P. HAMILTON et HENRY F. SCHAEFER III. Can. J. Chem. **70**, 416 (1992).

On a développé une relation de récurrence horizontale (RRH) qui peut être utilisée dans la génération d'intégrales de répulsion de deux électrons (IRE). On peut aussi utiliser des axes de coordonnées cartésiennes pour réduire le nombre des termes intermédiaires. Jusqu'à maintenant, l'utilisation de systèmes d'axes locaux impliquait des rotations chaque fois que l'on calculait une couche quadruple d'IRE. Récemment, on a démontré la possibilitié de retarder la transformation en utilisant des ensembles de références cartésiens basés sur les positions nucléaires. Dans nos essais pilotes de la théorie de perturbation du deuxième ordre de Møller–Plesset directe ou semi-directe (MP2), on a construit des orbitales dans des systèmes de coordonnées locales et, au lieu de faire subir une rotation aux IRE après la calcul de chaque couche quadruple, on a effectué la rétro-transformation au milieu de la transformation de l'intégrale d'OA à OM. L'efficacité de cette approche suppose que le gains dans le calcul de l'IRE sont plus grands que les pertes encourues dans la transformation. Des profils préliminaires de CPU indiquent que le temps supplémentaire nécessaire pour la rotation des axes est très petit.

Mots clés : relation de récurrence horizontale, théorie de perturbation du deuxième ordre.

Introduction

With the development of direct SCF (1) and direct Møller–Plesset second-order perturbation theory (MP2) (2, 3), in which ERIs are recomputed many times rather than stored because of disk access limitations, interest in efficient ERI evaluation has increased. The 1986 paper of Obara and Saika (4) (OS) derived a recursion relation that has prompted recent, intense activity in this field. This relation was implicit in earlier work on integral derivatives by Schlegel (5). A 1988 Head-Gordon and Pople paper (6) (HGP) presented another recursion relation, which they used in conjunction with that of OS to compute ERIs. Again, the recurrence formula given by HGP was previously used as the "transfer" equations in the Rys polynomial procedure (7). Recently, another recurrence relation was derived for ERIs over Cartesian Gaussians that moved powers of coordinates from electron one to electron two (8, 9). An alternative derivation to the one given in ref. 8 is reported in this paper. Considering the intertwined relationships between the use of these recurrence equations in ERI and ERI derivatives, new formulas using the rotational invariance conditions may be possible. Using recursion relations involving Hermite Gaussians as well, Gill, Head-Gordon, and Pople (10–12) (GHP) are investigating various integral and integral derivative algorithms.

Many of the intermediate terms involved in ERI computation become zero in special Cartesian coordinate systems; this is a main feature of the original Pople–Hehre (13) (PH) algorithm. We recently pointed out the possibility of moving the back-transformation (rotation) from the level of the ERIs to the level where the quantities to be transformed are smaller in number, enabling the rotation of axes to be done less frequently. To achieve this, the special axis systems cannot depend on orbital exponents. In the present paper, we use this idea in a preliminary implementation of direct and semi-direct second-order perturbation theory (MP2) to gauge the CPU requirements for the transformations needed.

Recurrence relations among Cartesian Gaussian ERIs

We shall only consider Cartesian Gaussian functions in this paper, and will use the notation of HGP (6):

$$[1] \qquad \phi_{ak}(\boldsymbol{r}) = (x - A_x)^{a_x}(y - A_y)^{a_y} \times (z - A_z)^{a_z} \exp(-\alpha_k(\boldsymbol{r} - \boldsymbol{A})^2)$$

The centers of the basis functions are denoted by $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, $\boldsymbol{D}$ where $\boldsymbol{A} = (A_x, A_y, A_z)$, etc. The angular momentum of the Gaussian on center $\boldsymbol{A}$ is $\boldsymbol{a} = (a_x, a_y, a_z)$ where $a_x + a_y + a_z$ is the total angular momentum. The exponents are given by the Greek letters α, β, γ, and δ. The product of the Gaussian centered on $\boldsymbol{A}$ and the Gaussian on $\boldsymbol{B}$ is a charge

distribution on point $\boldsymbol{P}$ with exponent $\zeta = \alpha + \beta$ where $\boldsymbol{P}$ is given by

$$[2] \qquad \boldsymbol{P} = \frac{\alpha\boldsymbol{A} + \beta\boldsymbol{B}}{\alpha + \beta}$$

Similarly, a function with exponent $\eta = \gamma + \delta$ centered at $\boldsymbol{Q}$ results from the product of the functions centered at $\boldsymbol{C}$ and $\boldsymbol{D}$. Repeating this process for the product of the charge distributions centered at $\boldsymbol{P}$ and $\boldsymbol{Q}$, we obtain a Gaussian of exponent $\zeta + \eta$ with a center

$$[3] \qquad \boldsymbol{W} = \frac{\zeta\boldsymbol{P} + \eta\boldsymbol{Q}}{\zeta + \eta}$$

The OS approach (4) for ERI calculation was based on their recurrence relation for incrementing angular momentum, which HGP (6) call the vertical recurrence relation (VRR):

$$[4] \qquad [(a + \boldsymbol{l}_i)\boldsymbol{b}|\boldsymbol{cd}]^{(m)} = (P_i - A_i)[\boldsymbol{ab}|\boldsymbol{cd}]^{(m)} + (W_i - P_i)[\boldsymbol{ab}|\boldsymbol{cd}]^{(m+1)} + \frac{a_i}{2\zeta}\left\{[(\boldsymbol{a} - \boldsymbol{l}_i)\boldsymbol{b}|\boldsymbol{cd}]^{(m)} - \frac{\eta}{\zeta + \eta}[(\boldsymbol{a} - \boldsymbol{l}_i)\boldsymbol{b}|\boldsymbol{cd}]^{(m+1)}\right\}$$
$$+ \frac{b_i}{2\zeta}\left\{[\boldsymbol{a}(\boldsymbol{b} - \boldsymbol{l}_i)|\boldsymbol{cd}]^{(m)} - \frac{\eta}{\zeta + \eta}[\boldsymbol{a}(\boldsymbol{b} - \boldsymbol{l}_i)|\boldsymbol{cd}]^{(m+1)}\right\} + \frac{c_i}{2(\zeta + \eta)}[\boldsymbol{ab}|(\boldsymbol{c} - \boldsymbol{l}_i)\boldsymbol{d}]^{(m+1)}$$
$$+ \frac{d_i}{2(\zeta + \eta)}[\boldsymbol{ab}|\boldsymbol{c}(\boldsymbol{d} - \boldsymbol{l}_i)]^{(m+1)}$$

where $\boldsymbol{l}_i = (\delta_{ix}, \delta_{iy}, \delta_{iz})$. Square brackets represent primitive integrals, whereas rounded ones (parentheses) denote ERIs over contracted Gaussians. They recursively generate ERIs using eq. [4], starting from the $[\boldsymbol{00}|\boldsymbol{00}]^{(0)}$ to $[\boldsymbol{00}|\boldsymbol{00}]^{(m)}$ auxiliary integrals generated by a $F_m(T)$ subroutine, where

$$[5] \qquad m = \sum_{i=1}^{3}(a_i + b_i + c_i + d_i)$$

For integrals of low total angular momentum, $F_m(T)$ can be one of the more computation-intensive steps. The superscript m denotes whether the integral is a true ERI ($m = 0$) or an intermediate ($m \neq 0$) that can be used in the assembly of true ERIs. Similar equations may be written to increment the angular momenta of $\boldsymbol{b}$, $\boldsymbol{c}$, and $\boldsymbol{d}$.

HGP noted that subtracting the VRR for $[\boldsymbol{a}(\boldsymbol{b} + \boldsymbol{l}_i)|\boldsymbol{cd}]^{(m)}$ from $[(\boldsymbol{a} + \boldsymbol{l}_i)\boldsymbol{b}|\boldsymbol{cd}]^{(m)}$ yields

$$[6] \qquad [\boldsymbol{a}(\boldsymbol{b} + \boldsymbol{l}_i|\boldsymbol{cd}]^{(m)} = [(\boldsymbol{a} + \boldsymbol{l}_i)\boldsymbol{b}|\boldsymbol{cd}]^{(m)} + (A_i - B_i)[\boldsymbol{ab}|\boldsymbol{cd}]^{(m)}$$

Since eq. [6] does not involve exponents or different values of m, it may be applied to true *contracted* ERIs:

$$[7] \qquad (\boldsymbol{a}(\boldsymbol{b} + \boldsymbol{l}_i)|\boldsymbol{cd}) = ((\boldsymbol{a} + \boldsymbol{l}_i)\boldsymbol{b}|\boldsymbol{cd}) + (A_i - B_i)(\boldsymbol{ab}|\boldsymbol{cd})$$

HGP (6) construct integrals of the form $(\boldsymbol{e}\,\mathbf{0}|\boldsymbol{f}\,\mathbf{0})$ using the VRR, with $\boldsymbol{e}$ ranging from $\boldsymbol{a}$ to $\boldsymbol{a} + \boldsymbol{b}$ and $\boldsymbol{f}$ ranging from $\boldsymbol{c}$ to $\boldsymbol{c} + \boldsymbol{d}$. They then use eq. [7], which they called the horizontal recurrence relation (HRR). The advantages are threefold: there are fewer $(\boldsymbol{e}\mathbf{0}|\boldsymbol{f}\mathbf{0})$ integrals to construct inside loops over contractions, there are a maximum of five non-zero terms in the VRR instead of eight, and eq. [9] is used after all contractions have been done.

Recently, a new horizontal recurrence relation was derived (8) by considering ERI derivatives. However, an alternative is to consider the OS relation for $[\boldsymbol{ab}|(\boldsymbol{c} + \boldsymbol{l}_i)\boldsymbol{d}]^{(m)}$:

$$[8]\quad [\boldsymbol{ab}|(\boldsymbol{c}+\boldsymbol{l}_i)\boldsymbol{d}]^{(m)} = (Q_i - C_i)[\boldsymbol{ab}|\boldsymbol{cd}]^{(m)} + (W_i - Q_i)[\boldsymbol{ab}|\boldsymbol{cd}]^{(m+1)} + \frac{c_i}{2\eta}\left\{[\boldsymbol{ab}|(\boldsymbol{c}-\boldsymbol{l}_i)\boldsymbol{d}]^{(m)} - \frac{\zeta}{\zeta+\eta}[\boldsymbol{ab}|(\boldsymbol{c}-\boldsymbol{l}_i)\boldsymbol{d}]^{(m+1)}\right\}$$
$$+ \frac{d_i}{2\eta}\left\{[\boldsymbol{ab}|\boldsymbol{c}(\boldsymbol{d}-\boldsymbol{l}_i)]^{(m)} - \frac{\zeta}{\zeta+\eta}[\boldsymbol{ab}|\boldsymbol{c}(\boldsymbol{d}-\boldsymbol{l}_i)]^{(m+1)}\right\} + \frac{a_i}{2(\zeta+\eta)}[(\boldsymbol{a}-\boldsymbol{l}_i)\boldsymbol{b}|\boldsymbol{cd}]^{(m+1)}$$
$$+ \frac{b_i}{2(\zeta+\eta)}[\boldsymbol{a}(\boldsymbol{b}-\boldsymbol{l}_i)|\boldsymbol{cd}]^{(m+1)}$$

The $(m + 1)$ terms can be eliminated by adding $\zeta/\eta\,[(\boldsymbol{a} + \boldsymbol{l}_i)\boldsymbol{b}|\boldsymbol{cd}]^{(m)}$ to $[\boldsymbol{ab}|(\boldsymbol{c} + \boldsymbol{l}_i)\boldsymbol{d}]^{(m)}$ to get

$$[9]\quad \frac{\zeta}{\eta}[(\boldsymbol{a}+\boldsymbol{l}_i)\boldsymbol{b}|\boldsymbol{cd}]^{(m)} + [\boldsymbol{ab}|(\boldsymbol{c}+\boldsymbol{l}_i)\boldsymbol{d}]^{(m)} = \left\{\frac{\zeta}{\eta}(P_i - A_i) + (Q_i - C_i)\right\}[\boldsymbol{ab}|\boldsymbol{cd}]^{(m)} + \left\{\frac{\zeta}{\eta}(W_i - P_i) + (W_i - Q_i)\right\}[\boldsymbol{ab}|\boldsymbol{cd}]^{(m+1)}$$
$$+ \frac{a_i}{2\eta}[(\boldsymbol{a}-\boldsymbol{l}_i)\boldsymbol{b}|\boldsymbol{cd}]^{(m)} + \frac{b_i}{2\eta}[\boldsymbol{a}(\boldsymbol{b}-\boldsymbol{l}_i)|\boldsymbol{cd}]^{(m)} + \frac{c_i}{2\eta}[\boldsymbol{ab}|(\boldsymbol{c}-\boldsymbol{l}_i)\boldsymbol{d}]^{(m)} + \frac{d_i}{2\eta}[\boldsymbol{ab}|\boldsymbol{c}(\boldsymbol{d}-\boldsymbol{l}_i)]^{(m)}$$

The prefactor of the remaining $(m + 1)$ term is identically zero. Solving for $[\boldsymbol{ab}|(\boldsymbol{c} + \boldsymbol{l}_i)\boldsymbol{d}]^{(m)}$ and dropping the superscript (m) gives

$$[10]\quad [\boldsymbol{ab}|(\boldsymbol{c}+\boldsymbol{l}_i)\boldsymbol{d}] = \frac{1}{(2\gamma+2\delta)}\{-2(\alpha+\beta)[\boldsymbol{a}+\boldsymbol{l}_i)\boldsymbol{b}|\boldsymbol{cd}] - [2\beta(A_i - B_i) + 2\delta(C_i - D_i)][\boldsymbol{ab}|\boldsymbol{cd}]$$
$$+ a_i[(\boldsymbol{a}-\boldsymbol{l}_i)\boldsymbol{b}|\boldsymbol{cd}] + b_i[\boldsymbol{a}(\boldsymbol{b}-\boldsymbol{l}_i)|\boldsymbol{cd}] + c_i[\boldsymbol{ab}|(\boldsymbol{c}-\boldsymbol{l}_i)\boldsymbol{d}] + d_i[\boldsymbol{ab}|\boldsymbol{c}(\boldsymbol{d}-\boldsymbol{l}_i)]\}$$

Inspection of eq. [10] shows that it can be used to move powers of coordinates from center $\boldsymbol{A}$ to center $\boldsymbol{C}$, and so can be used as a second type of HRR in ERI algorithms. Equation [10] can be used to modify the HGP method (6) in a straightforward way. Instead of creating $[\boldsymbol{e}\mathbf{0}|\boldsymbol{f}\mathbf{0}]$ using the VRR, we can make $[(\boldsymbol{e} + \boldsymbol{f})\mathbf{0}|\mathbf{00}]$ using the VRR, and then use eq. [10] to shift coordinate dependence from $\boldsymbol{A}$ to $\boldsymbol{C}$ to form $[\boldsymbol{e}\mathbf{0}|\boldsymbol{f}\mathbf{0}]$. The remaining part of the HGP scheme is unaltered. Equation [10] has an exponent dependence that includes α, β, γ, and δ, so that in this form it must be applied inside all of the loops over contractions. Included in our implementation of this algorithm will be the computation of the ERIs in coordinate axes specified by prescriptions based on atom positions. In local coordinate axes, some of the terms in the recurrence equations discussed above become zero. Research on the optimal computational implementation of this algorithm is in progress in our group. Therefore, the MP2 programs discussed in the next section used integrals computed by our Rys polynomial code to gauge the extra effort induced by the transformations to and from local Cartesian reference frames. Other improvements to the HGP method may be possible using different techniques to generate the $[\boldsymbol{e}\mathbf{0}|\boldsymbol{f}\mathbf{0}]$ integrals that are required (9, 10).

Direct and semi-direct MP2 energy evaluation

Figure 1 shows a scheme for the direct MP2 energy method that uses local Cartesian coordinate axes. The axes are chosen such that $\boldsymbol{A}$ is at the origin, $\boldsymbol{B}$ is on the z-axis, and the other two axes are arbitrary. This is essentially a modification of the program structure outlined in ref. 2. A check is made at the level of loops over atoms using

$$[11]\quad Q_{AB} = \max_{\substack{\mu\in A\\ \nu\in B}} Q_{\mu\nu}$$

with

$$[12]\quad Q_{\mu\nu} = (\mu\nu|\mu\nu)^{1/2}$$

and the upper bound of (14, 15):

$$[13]\quad (\mu\nu|\rho\sigma) \le (\mu\nu|\mu\nu)^{1/2}(\rho\sigma|\rho\sigma)^{1/2}$$

If Q_{AB}*Q_{CD} is lower than a certain threshold, then all of the integrals on the center combinations $ABCD$ are neglected.

The local axis transformation steps scale as 2*a*n_i*(NAT)^2*N^2/4 and a*OVN^2, where n_i is the number of passes through the integral list, NAT is the number of atoms, N is

FIG. 2. Loop structure for semi-direct MP2 energy evaluation. The maximum number of basis functions in a shell is m.

the number of basis functions, O is the number of occupied orbitals, V is the number of virtual orbitals, and a is the average number of FLOPs needed to rotate a basis function ($2l - 1$ FLOPs for a basis function with angular momentum l). P and Q cannot be precomputed any longer, so they need to be reconstructed at an ultimate cost of $n_i*(\mathrm{NPRIM})^2(\mathrm{NAT})^2*11/4$. NPRIM is the number of primitive exponents, not the number of primitive basis functions. Table 1 contains some of these quantities for C_6H_6 with DZP and TZ2P basis sets (six frozen cores and virtuals, no symmetry). The number of FLOPs for ERI evaluation is $kN^4/8$, where k is usually a large number ($\sim$100). The Δk needed for breakeven with respect to an algorithm that does not use special Cartesian axes is obtained by dividing the number of integrals ($N^4/8$) by the sum of the last three terms. Δk is 2.6 for the DZP basis set and 1.5 for the TZ2P basis set in this example. For larger values of n_i, Δk is even smaller, with limiting values of 0.57 and 0.15.

In a somewhat more formal manner, we may consider the number of FLOPs required for the computation of important blocks of integrals. For the 81 electron repulsion integrals in a $(pp|pp)$ block the FLOP count is

$$836K^4 + 30K^2 + 324$$

for the HS algorithm (8), where K is the contraction length, i.e., the number of primitive Gaussians in the contracted function. In the present local axes scheme ($C_y - D_y \neq 0$) the FLOP count is

$$738K^4 + 30K^2 + 216$$

For the case $K = 4$ (found in the standard double zeta $9s5p/4s2p$ basis sets for C, N, and O), the number of FLOPs is 215 000 for the earlier scheme (8) and 190 000 for the present local axes algorithm.

For the 1296 integrals in the larger $(dd|dd)$ block, the FLOP count expressions are

$$13\,900K^4 + 30K^2 + 11\,300$$

for our earlier method (8) and

$$13\,200K^4 + 30K^2 + 6\,300$$

with the present scheme. For the common, uncontracted $K = 1$ case the FLOP counts are 25 200 and 19 500 for the two methods. One concludes from this analysis that there should be an advantage to the new algorithm.

Profiling of our pilot direct MP2 program for DZ, C_{10} showed that the time spent in axis transformation was only 0.29%. Given that the transformation time is less than 0.5%, a well-designed integral algorithm should recover the miniscule effort involved. Figure 2 shows a modification of Fig. 1 in ref. 16 that gives our current algorithm for semi-direct MP2 energy computation using local axes. The largest MP2 energy evaluation done with the semi-direct program to date is C_8H_6 with a DZ + d basis set (C_{2v} symmetry with 132 basis functions). The integrals evaluation for SCF took 2048 s on the IBM 3090-400E computer, and the semi-direct MP2 energy required 2201 s. The program that computes the ERIs only in symmetry orbitals has a more stringent threshold for computation, thus accounting for some of the "speedup" in the MP2 program.

Concluding remarks

We have introduced a new recursion relation that may be useful in reducing the CPU time required to evaluate ERIs. Because eq. [10] is exponent dependent, the reduction in work is inside the loops over primitives. Direct MP2 may benefit from calculating ERIs in a special Cartesian axis system that depends only on nuclear positions, because the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

extra work introduced appears to be insignificant. The semi-direct algorithm modifications are the same as in the direct MP2 program, since the $(\mu\nu|ia)$ integrals are already rotated to the original coordinate system specified by the user. The IBM Almaden group (9) has derived eq. [10] independently and has written a computer program using an algorithm like the one outlined here, without the use of local axis systems, however.

Ab initio relativistic molecular orbital self-consistent field calculations for the thorium–platinum diatomic

G. L. MALLI

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received September 12, 1991

This paper is dedicated to Professor S. Huzinaga on the occasion of his 65th birthday

G. L. MALLI. Can. J. Chem. **70**, 421 (1992).

Ab initio relativistic as well as the corresponding non-relativistic limit (NRL) MO calculations are reported for the ground state ($\Omega = 0$) of the closed-shell diatomic ThPt. It is found that relativistic effects lead to a very *pronounced* bond shortening of ca 1.68 bohr. The predicted bond length of 2.7398 Å with the relativistic molecular orbital (RMO) wavefunction (WF) for the diatomic ThPt is ca. 0.25 Å *shorter* than the Th—Pt distance reported in a recently synthesized complex with a thorium–platinum bond as well as the shortest Th—Pt bond distance reported for the Th–Pt alloy. The calculated relativistic total molecular energy and the force constant at the predicted bond distance of 5.1774 bohr are −44 963.5050 hartree and 0.34650 hartree/(Å)^2, whereas the corresponding predicted non-relativistic values are 6.824 bohr, −41 690.6970 hartree, and 0.08388 hartree/(Å)^2, respectively. The vibrational frequencies predicted by the RMO and the non-relativistic limit MO SCF wavefunctions are 155.4 cm^{-1} and 76.46 cm^{-1}, respectively. The relativistic effects are very pronounced for ThPt and lead to a very *significant* bond contraction, an almost *fourfold* increase in the force constant, and *doubling* of the vibrational frequency.

Key words: relativistic effects, ThPt, RMO, bond contraction, DF SCF.

G. L. MALLI. Can. J. Chem. **70**, 421 (1992).

On a effectué des calculs d'OM *ab initio* relativistes ainsi que les calculs correspondants de limites non-relativistes (LNR) pour l'état fondamental ($\Omega = 0$) de la couche fermée diatomique ThPt. On a observé que les effets relativistes conduisent à un raccourcissement important de la liaison d'environ 1,68 bohr. La longueur de 2,7398 Å prédite pour la liaison ThPt diatomique à l'aide d'une fonction d'onde (FO) de l'orbitale moléculaire relativiste (OMR) est environ 0,25 Å plus courte que la distance rapportée pour une liaison thorium–platine d'un complexe synthétisé récemment ainsi que la plus courte liaison Th—Pt observée dans un alliage de Th—Pt. L'énergie moléculaire totale et la constante de force calculées d'une façon relativiste à le longueur de liaison prédite de 5,1774 bohr sont respectivement −44963,5050 hartree et 0,34650 hartree/(Å)^2 alors que les valeurs correspondantes calculées par des méthodes non-relativistes sont respectivement 6,8624 bohr, −41690,6970 hartree et 0,08388 hartree/(Å)^2. Les fréquences de vibration prédites par les orbitales moléculaires relativistes et les fonctions d'onde d'orbitales moéculaires auto-cohérentes limites non-relativistes sont respectivement 155,4 cm^{-1} et 76,46 cm^{-1}. Les effets relativistes sont très prononcés pour le ThPt et ils conduisent à un important raccourcissement de liaison alors que la constante de force est pratiquement quadruplée et que la fréquence vibrationnelle est doublée.

Mots clés : effets relativistes, ThPt, OMR, raccourcissement de liaison, DF SCF.

[Traduit par la rédaction]

Introduction

The theoretical aspects of the chemistry of heavy elements with 5*d*, 5*f*, 6*d*, and 7*s* valence electrons present a formidable challenge to computational quantum chemists because both the relativistic and the electron correlation effects are expected to be very significant for systems involving atoms of these heavy elements.

We recently discussed in detail the methodology for performing *ab initio* all-electron Dirac–Fock (DF) self-consistent-field (SCF) and relativistic configuration interaction (RCI) calculations with all single and pair-type double excitations (RCISPD) taking the DF SCF wavefunction as the reference (1, 2).

We have reported *ab initio* DF SCF and the RCISPD calculations for AuH and have discussed in detail the effects of relativity and electron correlation in bonding, spectroscopic properties, dipole moment, etc., for diatomics of heavy elements (1, 3, 4). In addition, we have reported *ab initio* fully relativistic RMO SCF calculations for the diatomics UO and ThO and have shown that the relativistic (and the correlation) effects are very pronounced for the systems involving atoms of heavy third-row transition elements and actinides (1–5). Recently Dyall *et al.* (6) reported Dirac–Hartree–Fock calculations for the tetrahydrides of the group IV elements and discussed the relativistic effects for the ground states of these systems.

In this paper, we report the RMO SCF calculations for the closed-shell ground state of the diatomic ThPt, a hetero bimetallic species involving atoms of an actinide and a third-row transition element. Our objective in this study is twofold, viz., firstly to assess the relativistic effects in this species and secondly to understand the nature of the metal–metal bond involving an actinide and a third-row transition element; we will ignore the electron correlation effects at present, however. It is well established (7) that all metallic elements participate in metal–metal bonding and that bonds between elements with *d* orbitals (valence) are especially strong. Examples of the metal–metal bonds are also well known for the lightest metal Li in $[LiCH_3]_4$ and the heaviest metal U in $U_6O_4(OH)_4(SO_4)_6$.

Gingerich (8) used an empirical valence bond approach for calculating bond energies of diatomic intermetallic compounds of platinum and compared these with the experimental bond energies obtained using Knudsen-cell mass spectroscopy. Recently, Hay *et al.* (9) used their effective-core-potential (ECP) scheme for calculations on $C_{12}Th(\mu\text{-}PH_2)_2Pt(PH_3)$, using the Th—Pt distance reported in the recently synthesized $Cp^*_2Th(\mu\text{-}PPh_2)_2(Pt(PMe_3)$ complex.

For personal use only.

However, *ab initio* all-electron RMO SCF calculations for the diatomic ThPt have not been reported and we present such calculations and discuss the relativistic effects in this species, since such a hetero bimetallic system is of great interest to both experimental and theoretical chemists.

Methodology

Our DF SCF methodology has been delineated in detail elsewhere (1–5) and only a brief summary of the salient features relevant to relativistic diatomic calculations is presented here.

The basic idea behind the Relativistic Integral Program (RIP) (10, 11) used in our calculations is to express the wavefunction for the diatomic molecule in terms of the Dirac–Fock atomic orbitals (DFAO) of the constituent atoms. The DFAOs for the atoms can be easily calculated using the Dirac–Fock programmes (12). In addition, since the innermost electrons of the heavy atoms (with $Z \geq 75$) are hardly expected to be affected by the formation of the molecule, a frozen core approximation is used in which the wavefunction $\Psi(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_N)$ for the closed-shell N-electron diatomic molecule system is written as:

$$[1] \quad |\Psi(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_N)\rangle = S\hat{A}'[|\Phi_{ca}(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n_{ca}})\rangle \times |\Phi_{cb}(\boldsymbol{r}_{n_{ca}+1}, \ldots, \boldsymbol{r}_{n_{ca}+n_{cb}})\rangle \times |\Phi_V(\boldsymbol{r}_{n_{ca}+n_{cb}+1}, \ldots, \boldsymbol{r}_N)\rangle]$$

where in eq. [1] S is a normalization constant. The $|\Phi_{ca}\rangle$ and $|\Phi_{cb}\rangle$ in eq. [1] are wavefunctions for the cores containing n_{ca} and n_{cb} electrons of the atoms "a" and "b" of the diatomic and these core wavefunctions are taken to be single determinants (SD) of the DFAOs of the isolated atoms, viz.,

$$[2] \quad |\Phi_{ca}(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_{n_{ca}})\rangle = \hat{A}\left(\prod_{i=1}^{n_{ca}} |\boldsymbol{u}_{a,i}(\boldsymbol{r}_{a,i})\rangle\right)$$

$$[3] \quad |\Phi_{cb}(\boldsymbol{r}_{n_{ca}+1}, \ldots, \boldsymbol{r}_{n_{ca}+n_{cb}})\rangle = \hat{A}\left(\prod_{i=1}^{n_{cb}} |\boldsymbol{u}_{b,i}(\boldsymbol{r}_{b,i} + \boldsymbol{n}_{ca})\rangle\right)$$

In eqs. [2] and [3] $|u_{b,i}\rangle$ is the ith core orbital for atom b, $r_{b,i}$ is the position vector of the ith electron with respect to the nucleus b, and $\hat{A}$ is the antisymmetrizer, while in eq. [1] $\hat{A}'$ is the partial antisymmetrizer, which contains, besides the identity, only permutations interchanging coordinates belonging to one of the set $(r_1, \ldots, r_{n_{ca}})$, $(r_{n_{ca}+1}, \ldots, r_{n_{ca}+n_{cb}})$, and $(r_{n_{ca}+n_{cb}+1}, \ldots, r_N)$ with those belonging to a different set. The $|\Phi_V\ (r_{n_{ca}+n_{cb}+1}, \ldots, r_N)\rangle$ appearing in eq. [1] is an antisymmetric wavefunction for the $(N - n_{ca} - n_{cb})$ valence electrons, which is built from those DFAOs of the isolated atoms not appearing in the core wavefunctions Φ_{ca} and Φ_{cb} defined in eqs. [2] and [3].

Each of the DFAO in eqs. [2] and [3] is taken to be of the standard central field form with respect to the nucleus on which it is centred and therefore carries the additional labels κ and m (13), so that

$$[4] \quad |\boldsymbol{u}_{\mu,b}\kappa\boldsymbol{m}\rangle = \boldsymbol{r}_\mu^{-1}\begin{pmatrix} \boldsymbol{P}_B(\boldsymbol{r}_\mu) & \boldsymbol{\chi}_{\kappa,m}(\boldsymbol{\theta}_\mu, \boldsymbol{\phi}_\mu) \\ i\boldsymbol{Q}_B(\boldsymbol{r}_\mu) & \boldsymbol{\chi}_{-\kappa,m}(\boldsymbol{\theta}_\mu, \boldsymbol{\phi}_\mu) \end{pmatrix}$$

where $P_B(r_\mu)$ and $Q_B(r_\mu)$ are the large and small radial functions, respectively centered on nucleus μ. The $(2j + 1)$ orbitals differing only in the m_j quantum number are said to constitute a subshell (14) denoted by B, and are taken to have the same radial functions. The label b in eq. [4] defines the orbital uniquely after specification of the centre μ, thus defining the κ and m quantum numbers, which may both carry the additional subscript b. The $\boldsymbol{\chi}_{\kappa,m}$ is a vector-coupled two-component spinor eigenfunction of the operators j^2 and j_z corresponding to the total and z-component of the angular momentum ($\boldsymbol{j} = \boldsymbol{l} + \boldsymbol{s}$) of an electron with eigenvalues $j(j + 1)$ and m respectively, so that m is the m_j quantum number. These functions can be written as

$$[5] \quad \boldsymbol{\chi}_{\kappa,m}(\boldsymbol{\theta}_\mu, \boldsymbol{\phi}_\mu) = \sum_{m_s=-1/2}^{1/2} \left\langle \ell\, \frac{1}{2}\, (m - m_s)\, \frac{1}{2}\, m_s \middle| jm \right\rangle \times Y_{\ell,m-m_s}(\theta_\mu, \phi_\mu) \left| \frac{1}{2}\, m_s \right\rangle$$

where in eq. [5] the $Y_{\ell,m-m_s}$ are the normalised spherical harmonics and $|\frac{1}{2}\, m_s\rangle$ is a two-component spin function:

$$|1/2\ 1/2\rangle = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \equiv |\alpha\rangle, \quad |1/2\ -1/2\rangle = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \equiv |\beta\rangle$$

The quantum number κ defines both the total angular momentum (j) and the orbital angular momentum (ℓ) as follows:

$$[6] \quad \kappa = -\left(j + \frac{1}{2}\right) a, \qquad \begin{aligned} a &= +1 \text{ for } j = \ell + \frac{1}{2} \\ a &= -1 \text{ for } j = \ell - \frac{1}{2} \end{aligned}$$

It should be borne in mind that only completely filled subshells (B), namely those in which each of the $(2j_B + 1)$ orbitals contains one electron, can be included in the core wavefunction in order to ensure both that the core has no net angular momentum, and that it is symmetric under the symmetry operators of the (double) symmetry group of the diatomic molecule (15, 16).

The valence wavefunction $|\Phi_V(r_{n_{ca}+n_{cb}+1,\ldots}\, r_N)\rangle$ is constructed from a set of relativistic orbitals, each member of which is orthogonal to all the orbitals entering the core functions of the two atoms given by eqs. [2] and [3]. The number of electrons to be included in the valence wavefunction depends upon the accuracy required; however, the electrons in the open shells of the isolated atoms of the diatomic *must* be included in Φ_V, which can be enlarged to include those outermost orbitals of the isolated atoms that are expected to be significantly affected by the formation of the molecule, e.g., 5*d** and 5*d* DFAO in the gold atom in AuH.

The valence wavefunction $|\Phi_V\rangle$ for most diatomic calculations is taken to be a single Slater determinant (SD) or antisymmetrized product (AP) of valence relativistic molecular orbitals (RMO), which are taken as eigenfunctions of the operator $\hat{j}_z$ with eigenvalue m. In this case the N-electron wavefunction becomes a molecular relativistic self-consistent-field (SCF) wavefunction and the SCF valence wavefunction Φ_V^{SCF} can be written as:

$$[7] \quad |\Phi_V^{SCF}\rangle = \hat{A}\left(\prod_{m>0}\prod_{a=1}^{N_{V_m}} |\psi_a m\rangle|\psi_a - m\rangle\right)$$

where N_{V_m} is the number of valence RMO's occurring in eq. [7] that have $m_j = m$.

The wavefunction $|\Phi_V^{SCF}\rangle$ is an eigenfunction of the z-component of the total angular momentum J_{zT} with zero eigenvalue and furthermore it is symmetric under both the N-electron relativistic operators $\boldsymbol{H}_{XT}$ and $\boldsymbol{H}_{YT}$, i.e., for reflections in the YZ and XZ planes (15, 16). Moreover, it can be shown either by double group arguments (15) or by using the properties of the $\boldsymbol{H}_{YT}$ operator (16) that the pair of orbitals $|\Psi_a \pm m\rangle$ occurring in Φ_V^{SCF} of eq. [7] is degenerate and constitutes a closed shell.

The Dirac–Fock atomic orbitals used to construct the core wavefunctions given in eqs. [2] and [3] describe automatically the behaviour of *electrons* and not positrons. Furthermore, all the orbitals used in the construction of the valence wavefunction $|\Phi_V\rangle$ have the form given in eq. [4] and are constructed to maintain the appropriate relation between the large and small components (17), and therefore lie within the subspace of the electron-like solutions of some single particle Dirac–Fock hamiltonian. The energy $E(R)$ of the wavefunction given in eq. [1], which depends on the internuclear separation (R), can therefore be calculated as

$$[8] \quad \boldsymbol{E(R)} = \langle \boldsymbol{\Psi}(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_N)|\boldsymbol{H}|\boldsymbol{\Psi}(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_N)\rangle$$

i.e., as the expectation value of the N-electron relativistic hamiltonian $\boldsymbol{H}$, *without* the need to introduce any projection operators (18) where

$$[9] \quad \boldsymbol{H} = \sum_{\mu=1}^{N} H_D(\mu) + \sum_{\mu<\nu} \boldsymbol{r}_{\mu\nu}^{-1}$$

$$[10] \quad H_D(\mu) = \boldsymbol{c}\boldsymbol{\alpha}_\mu \cdot \boldsymbol{p}_\mu + \boldsymbol{c}^2(\boldsymbol{\beta}_\mu - \boldsymbol{I}_4) - \sum_{a=1}^{n} \frac{\boldsymbol{Z}_a}{\boldsymbol{r}_{a\mu}}$$

In eq. [9] $r_{\mu\nu}^{-1}$ is the Coulomb repulsion between electrons μ and ν and $H_D(\mu)$ is the Dirac Hamiltonian for the μth electron in the potential of all the nuclei of the molecular system. In eq. [10], c is the velocity of light (c = 137.037 in a.u.), Z_a is the nuclear charge on the ath nucleus, $r_{a\mu}$ is the distance between the ath nucleus and the μth electron, and the sum over "a" runs over all the "n" nuclei. The α and β are well-known 4 × 4 matrices defined below, and I_4 is the 4 × 4 unit matrix:

$$\alpha = \begin{pmatrix} 0 & \sigma \\ \sigma & 0 \end{pmatrix}, \qquad \beta = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix}$$

In eq. [10], the rest mass energy of an electron has been subtracted in order to obtain its binding energy, and H of eq. [9] is the so-called Dirac–Coulomb Hamiltonian for molecules. The I in the definition of β is the 2 × 2 unit matrix.

Moreover, the strong orthogonality between the core and valence wavefunctions ensured by the orthogonality between the core and valence orbitals enables eq. [8] to be decomposed into core and valence contributions (19) as follows,

$$[11] \quad E(R) = E_{ca}^{(M)} + E_{cb}^{(M)} + \Delta E_{core}^{int}(R) + E_V(R)$$

where in eqs. [11] $E_{ca}^{(M)}$ and $E_{cb}^{(M)}$ are the energies of the core functions given in eqs. [2] and [3], respectively, and $\Delta E_{core}^{int}(R)$, which includes the nuclear–nuclear repulsion, is the difference between the energy of this core in the molecule and that of the same core in the isolated atoms. The $E_V(R)$ is the energy of the valence electrons and it contains both the direct and exchange interactions between the core and the valence electrons.

The dissociation energy (D_e) defined as positive (1) for a bound molecule, equals the negative of the interaction energy $\Delta E_{int}(R)$ at the predicted equilibrium internuclear separation (R_e) and $\Delta E_{int}(R)$ is given by the expression:

$$[12] \quad \Delta E_{int}(R) = E(R) - E_a - E_b$$

where E_μ, the total energy of the isolated atom μ, is given by

$$[13] \quad E_\mu = E_{\mu c} + E_{\mu v}$$

where in eq. [13] $E_{\mu c}$ and $E_{\mu v}$ are energies of the core and valence electrons, respectively, in the isolated atom μ. It should be borne in mind that the $E_{\mu c}$ only equals the energy $E_{\mu c}^{(M)}$ in the molecule if the same set of core orbitals is used both in the free μth atom wavefunction and in the molecular core function given in eqs. [1] and [2], and in this case $\Delta E_{int}(R)$ simplifies to

$$[14] \quad \Delta E_{int}(R) = \Delta E_{core}^{int}(R) + E_V(R) - E_{aV} - E_{bV}$$

Calculations and results

Ab initio RMO SCF calculations were performed for the ground state (Ω = 0) of the closed-shell ThPt molecule, assuming point nucleii at four internuclear distances, viz., 4.50, 5.50, 6.00, and 6.50 bohr.

The Oxford MCDF program of Grant *et al.* (12) was used to generate a nine-configuration state function (CSF) WF and the corresponding NRL WF for the neutral Th atom with the ground state electronic configuration [Rn] $6d^27s^2$, where [Rn] stands for the ground state electronic configuration of the radon atom (Z = 86). Similarly, wavefunctions were generated for the ground J = 3 state of the Pt atom with the configuration $1s^2 \ldots 5d^{*4}\ 5d^5\ 6s$, where the $5d^*$ stands for the ($5d$) AO with j = 3/2. In these calculations, the inner 86 electrons of the Th atom and the 68 electrons of the Pt atom were treated as "core" and the $6d$, $7s$ Dirac–Fock atomic orbitals (DFAO) of Th and the $5d$, $6s$ DFAOs of Pt were included in the valence RMO SCF WF of ThPt. It should be pointed out that although the core orbitals are taken to be unchanged from the isolated atoms, the following three important effects of the core on the valence wavefunctions are *exactly* calculated and therefore taken explicitly into account (1): (*i*) A direct Coulombic potential is generated by the core and is easily calculated by the Relativistic Integral Program (RIP) (10, 11). (*ii*) Core-valence exchange, whose exact computation by RIP or any other program requires explicitly the presence of the core orbitals in the total wavefunction, which is written as an antisymmetrized product of the core and valence wavefunctions (see ref. 1 for details). (*iii*) The strong orthogonality between the core and valence wavefunctions, which is ensured in the RIP program by construction of the valence wavefunction from the orbital set, which is orthogonal to the core orbitals.

Our approach, therefore, is to be clearly distinguished from the effective-core-potential (ECP) and the so-called relativistic pseudo-potential schemes, which *do not* explicitly incorporate the core orbitals and thus introduce approximations to the effects (*ii*) and (*iii*) of the core.

Moreover, the inclusion of inner-shell orbitals in the core wavefunction is for the sake of computational cost considerations, since it is not mandatory to do so, and we have re-

TABLE 1. Calculated total molecular relativistic MO (RMO) SCF energies (E_{Rel}) for ThPt in hartree (1 hartree = 27.211 eV) at various internuclear distances R in bohr (1 bohr = 0.529177 Å)

R (bohr)	$-E_{Rel}$ (hartree)	$R_{min,Rel}$(bohr)[a]	k_{Rel}[a]	$\bar{\nu}_{Rel}$(cm^{-1})[a]
4.50	44 963.475 51	5.1774	0.346 50	155.4
5.50	44 963.500 63			
6.00	44 963.484 85			
6.50	44 963.473 12			

[a]The values of $R_{min,Rel}$, the force constant k_{Rel}, and $\bar{\nu}_{Rel}$ (cm^{-1}), the vibrational frequency, are obtained by fitting the results of RMO SCF calculations for ThPt at four points to a cubic polynomial.

TABLE 2. Calculated total molecular non-relativistic limit MO SCF energies (E_{NR}) for ThPt in hartree (1 hartree = 27.211 eV) at various internuclear distances R in bohr (1 bohr = 0.529177 Å)

cently performed all-electron calculations for CdH^+, in which all the 24 RMOs were expressed as linear combination of DFAOs of Cd^+ and H; however, such calculations even for this 48-electron system are prohibitively expensive at present, even using supercomputers.[1] Moreover, it was found[1] that the first 23 RMOs consist of pure atomic DFAOs for this species. In the near future, we plan to perform similar calculations for non-hydride diatomics but, until then, we will content ourselves with calculations on ThPt with the core and valence wavefunctions described above, since even such calculations are very expensive for ThPt at our IBM 3081G mainframe computer.

We are aware of the limitations of our calculations; however, even such calculations are nonexistent for the diatomic ThPt, with 168 electrons. A full DF SCF calculation using about 100 DFAOs as valence basis set would require hundreds of CPU hours for RMO SCF calculations even with the CRAY XMP28 supercomputer. We believe that we can obtain fairly reliable understanding of the effects of relativity in bonding of the diatomics involving atoms of actinide and third-row transition elements even using the type of WF's we are reporting here for ThPt.

The seven doubly occupied valence relativistic molecular orbitals or molecular spinors (MS) were constructed as linear combinations of the (numerical) relativistic atomic orbitals or atomic spinors (AS), whereas the core wavefunction for ThPt was taken as the appropriate antisymmetrized products (AP) of the "cores" of the Th and Pt atoms as detailed elsewhere (1–5).

A cubic polynomial fit of the calculated total RMO SCF molecular energies at various internuclear separations was employed to predict R_{min}, total molecular energy energy at R_{min}, force constant k_{Rel}, and vibrational frequency ($\bar{\nu}_{Rel}$) and the results are collected in Table 1.

It should be pointed out, however, that the RMO SCF calculations predict the ThPt diatomic to be unbound only by 0.05075 hartree (1.38 eV) at R_{min}. Therefore, an RCI treatment taking the DF SCF WF with a very extended basis as the reference will be mandatory to obtain the dissociation energy of 109 kcal mol^{-1}, predicted (8) from the empirical valence-bond approach, and the experimental dissociation energy of 130.7 kcal mol^{-1} for ThPt reported by Gingerich (20) from a mass spectrometric study. However, such calculations will entail very enormous computational costs and can only be performed using dedicated state-of-the-art supercomputer technology, and are not feasible at present.

An RMO SCF calculation was also performed at the predicted R_{min} for ThPt and the calculated seven RMO energy eigenvalues are −0.3459, −0.3297, −0.2872, −0.2829, −0.2713, −0.2121, and −0.1817 hartree.

The non-relativistic limit (NRL) MO SCF calculations were performed for ThPt at four internuclear separations of 4.5, 5.5, 6.5, and 7.5 bohr. The NRL wavefunctions for the atoms Th and Pt were also generated using the Oxford MCDF program (12), and the calculations were performed in a similar manner to those of the RMO SCF calculations as discussed above. A cubic polynomial fit of the calculated total molecular energies using the NRL MO SCF wavefunctions for ThPt at various internuclear separations was performed to predict R_{min}, total molecular energy (at R_{min}), force constant (k_{NR}), and vibrational frequency ($\bar{\nu}_{NR}$) and the results are given in Table 2.

It should be pointed out that the NRL MO SCF wavefunction predicts the ThPt molecule to be almost bound at R_{min} (predicted binding energy of 0.000453 hartree, i.e., 0.0123 eV). However, this should not be construed to conclude that the NRL MO SCF WF is better for ThPt than the RMO SCF WF, since the calculated relativistic total molecular energy at the relativistically predicted R_{min} (5.1774 bohr) is *lower* by about 3273 hartree, i.e., 89 062 eV, than the NRL total molecular energy at the NRL predicted R_{min} (6.8624 bohr).

An NRL MO SCF calculation was also performed at the internuclear separation of 6.8624 bohr and the calculated seven orbital eigenvalues are found to be −0.2401, −0.2389, −0.2339, −0.2338, −0.2332, −0.2006, and −0.1534 hartree.

The RMO and the NRL MO SCF wavefunctions (at the respective predicted R_{min}) using Koopman's theorem predict ionization potentials (IP) of 4.944 and 4.174 eV, respectively; however, both predicted values of IP differ significantly from the value reported by Gingerich (20) for the appearance potential of 8 ± 2 eV for ThPt. It should also be mentioned that Gingerich (20) estimated molecular parameters for ThPt by means of standard statistical thermodynamic relations, and his estimates for bond distance and vibrational frequency are 2.54 Å and 221 cm^{-1}, respectively, which are in better agreement with the R_{min} and vibrational frequency ($\bar{\nu}$) predicted with our RMO SCF wavefunctions, viz., 2.7398 Å and 155.4 cm^{-1}, than the values predicted by the NRL MO SCF wavefunctions, viz., 3.6314 Å and 74.46 cm^{-1}, respectively.

To discuss bonding in ThPt, it is instructive to use the four-component functions defined through equations (3.5a)–(3.5d) of Malli and Pyper (1), to express the calculated valence

RMOs in terms of the large components of the $|\ell_m m_s\rangle$ functions, where $|s_m m_s\rangle$, $|p_m m_s\rangle$, $|d_m m_s\rangle$ functions have s, p, d-like angular functions with m_ℓ quantum number m and $m_s = \pm 1/2$ (the z-component of the spin angular momentum corresponds to the two-component spin functions $|\alpha\rangle$ and $|\beta\rangle$). Therefore, the valence RMOs (and the NRL MOs) can be expressed in terms of $|p\sigma\alpha\rangle$, $|p\pi\beta\rangle$, $|d\sigma\alpha\rangle$, $|d\pi\beta\rangle$, $|f\sigma\alpha\rangle$, $|f\sigma\beta\rangle$ functions, etc., which can give insight into the bonding characteristics of the valence RMOs and the NRL MOs of the molecular species under study. The valence relativistic HOMO (RHOMO) of ThPt designated as $|7e3/2\rangle$ using the double group theoretical notation for the extra or additional irreducible representations of heteronuclear diatomics (at R = 5.1744 bohr) has the following form:

$$|7e3/2\rangle = -0.971|6d\delta\beta\rangle_{Th} + 0.171|6d\pi\alpha\rangle_{Th} - 0.159|5d\delta\beta\rangle_{Pt} - 0.156|5d\pi\alpha\rangle_{Pt}$$

It consists of almost pure $|6d\delta\beta\rangle$ on the Th atom (plus a small contribution of $|6d\pi\alpha\rangle$ on Th) with very small contributions from the $|5d\delta\beta\rangle$ and $|5d\pi\alpha\rangle$ orbitals on Pt.

The valence RMO $|6e1/2\rangle$, lying just below the RHOMO, however, is found to consist of a bonding combination of a $7s\sigma$–$6d\sigma$ hybrid on Th with a $6s\sigma$–$5d\sigma$ hybrid on Pt, but the dominating contributions are from the bonding arising from the interaction of the $7s$ DFAO on Th with the $6s$ DFAO of Pt:

$$|6e1/2\rangle = 0.661|7s\sigma\alpha\rangle_{Th} - 0.426|6s\sigma\alpha\rangle_{Pt} - 0.271|5d\sigma\rangle_{Pt} - 0.137|6d\sigma\alpha\rangle_{Th}$$

The next five calculated valence RMOs (lying below the $|6e1/2\rangle$ RMO) are of the following form:

$$|5e5/2\rangle = 0.995|5d\delta\alpha\rangle_{Pt}$$

$$|4e3/2\rangle = 0.792|5d\pi\alpha\rangle_{Pt} + 0.498|5d\delta\beta\rangle_{Pt} + 0.220|6d\pi\alpha\rangle_{Th} - 0.131|6d\delta\beta\rangle_{Th}$$

$$|3e1/2\rangle = 0.670|5d\pi\beta\rangle_{Pt} + 0.584|5d\sigma\alpha\rangle_{Pt} - 0.240|6d\sigma\alpha\rangle_{Th} + 0.196|6d\pi\beta\rangle_{Th} - 0.166|7s\sigma\alpha\rangle_{Th}$$

$$|2e3/2\rangle = -0.853|5d\delta\beta\rangle_{Pt} + 0.497|5d\pi\alpha\rangle_{Pt} + 0.0853|6d\pi\alpha\rangle_{Th}$$

$$|1e1/2\rangle = -0.698|5d\sigma\alpha\rangle_{Pt} + 0.653|5d\pi\beta\rangle_{Pt} + 0.164|6d\sigma\alpha\rangle_{Th} + 0.105|6d\pi\beta\rangle_{Th} - 0.0971|7s\sigma\alpha\rangle_{Th}$$

It can be seen that except for the $|5e5/2\rangle$ valence RMO (VRMO), the VRMOs lying below the RHOMO involve bonding mostly due to the interaction of the $5d$ DFAOs of Pt with the $6d$ DFAOs of Th or a hybrid of the $6d$ DFAO with small amounts of the $7s$ DFAO on Th. This is easily understood, since whereas the $7s$ DFAO is *stabilized* (i.e., lowered in energy) due to the *direct* relativistic effect, the $6d$ DFAOs of Th are *destabilized* due to the *indirect* relativistic effect, i.e., pushed up in energy, and thus the $7s$ DFAO of Th is involved in bonding (as can be seen from the VRMO $|6e1/2\rangle$) due to its interaction with the $6s$ DFAO of Pt, which is also lowered in energy due to the direct relativistic effect. The contribution of the $6d$ DFAOs of Th in lower lying VRMOs is fairly small; however, the destabilized $6d$ DFAOs of Th contribute significantly to the RHOMO.

The calculated NRL valence HOMO (at $R_{min,NR}$ = 6.8624 bohr) of ThPt has the following form:

$$7|e1/2\rangle_{NR} = 0.66|7s\sigma\alpha\rangle_{Th} - 0.510|6d\pi\beta\rangle_{Th} - 0.400|6d\sigma\alpha\rangle_{Th} - 0.221|5d\sigma\alpha\rangle_{Pt} - 0.146|6s\sigma\alpha\rangle_{Pt}$$

It consists of a $7s$–$6d$ hybrid on Th in a bonding interaction with a $5d$–$6s$ hybrid containing very small amounts of the $5d$ and $6s$ DFAOs of Pt. This is in contrast to the calculated RHOMO for ThPt, which, as discussed above, contains very substantial contributions from the $6d$ DFAOs of the Th atom, but very small contributions from the $5d$ DFAO of Pt, again due to the indirect relativistic effect on the $6d$ DFAO of Th. However, the next six lower lying valence nonrelativistic limit (NRL) MOs, with the exception of the $6|e3/2\rangle$ NRL MO, are calculated to consist almost of the pure $5d$ NRL AOs of Pt with very small contributions from the $6d$ NRL AOs of Th and almost negligible amounts of the $7s$ NRL AO of Th. The calculated NRL MO, $|6e3/2\rangle_{NR}$, has the following form:

$$|6e3/2\rangle_{NR} = -0.896|6d\delta\beta\rangle_{Th} - 0.394|6d\pi\alpha\rangle_{Th} + 0.208|5d\pi\alpha\rangle_{Pt} - 0.0860|5d\delta\beta\rangle_{Pt}$$

Thus the RHOMO is $|7e3/2\rangle$ and the VRMO lying below it is $|6e1/2\rangle$; however, the NRL calculations predict reversal of the symmetries, since the NR HOMO is $|7e1/2\rangle$ and the NR VMO lying below is $|6e3/2\rangle$.

We conclude, therefore, that the main features of bonding characteristics, the calculated valence RMOs and the NRL MOs of ThPt, can be understood due to the interplay of both the direct and indirect effects of relativity, as discussed here, and that the relativistic effects are very pronounced in bonding, bond length contraction, force constant, and vibrational frequency for ThPt.

Acknowledgements

I sincerely thank Professor Russell J. Boyd and Dr. Mariusz Klobukowski for inviting me to contribute to this issue on the occasion of the 65th birthday of Professor Sigeru Huzinaga, a pioneering theoretical chemist, whom I have known as an esteemed colleague and a very valuable personal friend for over 30 years. This work was supported in part by Grant No. A3598 from the Natural Sciences and Engineering Research Council (NSERC) of Canada, which is gratefully acknowledged. I wish to express my sincerest thanks to Ms. Vanessa Mah who has word-processed the manuscript very diligently and carefully.

Received June 27, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

AKITOMO TACHIBANA, SHIGERU ISHIKAWA, WATARU SAHARA, and TOKIO YAMABE. Can. J. Chem. **70**, 427 (1992).

The extended local vibronic constant (ELVC) is introduced for the study of the strength of local electron pairing for superconductivity based on vibronic interaction using a model of an oxygen-containing organic polymer. The ELVC consists of the electrostatic part and the two-electron part, which originates in the response of the electron density to the nuclear vibration. It is found that the two-electron part has opposite sign to, and almost the same magnitude as, that of the electrostatic part. The difference between the ELVC and the Fock matrix derivative, which is related to the derivative of the Hückel parameters used as the electron–phonon coupling constant, is discussed. The vibronic interaction in the in-plane orbitals, which is characteristic of the interaction in a two-dimensional conductor, is also discussed.

Key words: vibronic interaction, superconductivity, local electron pairing, extended local vibronic constant, *ab initio* calculation.

AKITOMO TACHIBANA, SHIGERU ISHIKAWA, WATARU SAHARA et TOKIO YAMABE. Can. J. Chem. **70**, 427 (1992).

Utilisant comme modèle un polymère organique contenant de l'oxygène, on fait appel à la constante vibronique locale étendue (CVLE) pour étudier la force du couplage électronique local dans la supraconductivité causée par l'interaction vibronique. La CVLE est formée de la partie électrostatique et de la partie à deux électrons qui trouve son origine dans la réponse à la densité électronique par rapport à la vibration nucléaire. On a trouvé que la partie à deux électrons est d'une amplitude égale, mais de signe opposé, à la partie électrostatique. On discute de la différence entre la CVLE et la dérivée de la matrice de Fock qui est reliée à la dérivée des paramètres de Hückel utilisés comme constante de couplage électron–phonon. On discute aussi de l'interaction vibronique dans les orbitales dans le plan qui est caractéristique de l'interaction dans un conducteur bidimensionnel.

Mots clés : interaction vibronique, supraconductivité, couplage électronique local, constante vibronique locale étendue, calculs *ab initio*.

[Traduit par la rédaction]

Introduction

The discovery of high-T_c copper-oxide superconductors (1) has renewed interest in the search for the origin of the attractive interaction between a Cooper pair of superconducting electrons. In this connection, various mechanisms of superconductivity, such as bipolaron (2, 3), exciton (4), plasmon (5), spin-polaron (6), and resonating valence bond (RVB) (7), have been proposed in addition to the conventional electron–phonon coupling mechanism (8–10). We have proposed a vibronic electron pairing mechanism (11), which is based on a specific vibronic interaction in molecules.

Vibronic interaction in molecules has been one of the primary subjects in molecular spectroscopy. Various theories for determining the vibronic coupling constants have been proposed (12–14). However, these theories are not specific to the attractive interaction for superconductivity.

Our vibronic attractive interaction originates from nonadiabatic coupling, and is obtained in closed form using normal coordinates Q_n of molecular vibration as parameters, in contrast with the use of the diabatic perturbation series for the attractive interaction in the conventional electron–phonon coupling mechanism (8–10). The vibronic attractive interaction is instantaneous with respect to the electronic interaction because it is caused by nuclear vibrational momentum $-i\partial/\partial Q_n$ acting on the electronic wavefunction, while the conventional electron–phonon coupling is delayed because it is caused by small but finite displacement of Q_n. The vibronic attractive interaction is negative definite, while conventional electron–phonon coupling contains repulsive interaction. Calculation of the attractive interaction of arbitrary chemical species can be done using *ab initio* molecular orbital methods, which enables us to design novel vibronic processes for superconductivity. Orbital and vibrational mode-specific characterization of the vibronic attractive interaction can be done using the extended orbital vibronic constant (EOVC) (15), which is related to the orbital vibronic constant (OVC) in Bersuker's study of the Jahn–Teller effect (14).

The EOVC is a measure of the vibronic interaction for the electronic stationary state. We may now ask the following

question: how does the molecular vibration give rise to the local polarization of the electrostatic field and of the electron density? This will be represented by the extended local vibronic constant (ELVC) defined by eq. [3] in this paper. The ELVC gives a measure of the favorable atomic site and the interaction range for vibronic electron pairing.

We have calculated the vibronic interaction for superconductivity in heteroatom-substituted polyacetylene such as $(CHO)_n$, and found that the polar bond between oxygen and carbon is interesting for local electron pairing (16–19). Hence we shall examine in this paper the ELVC of $(CHO)_n$ using a structural model molecule $(CH_2)_2O$. The difference between the ELVC and the Fock matrix derivative, which is often used as the electron–phonon coupling constant, will be discussed. Another interesting aspect of this molecule is the vibronic interaction for the in-plane orbitals, which is characteristic of the interaction in a two-dimensional conductor. We have found that large vibronic attractive interaction is obtained in the in-plane orbitals centered at the oxygen atom (17). Hence, we shall examine the ELVC for the in-plane atomic orbitals.

Theory

The vibronic interaction for superconductivity

The effective interaction energy V^{ij}_{eff} of a Cooper pair or a time-reversal pair of electrons associated with the vibronic scattering process in between the ith molecular orbital ψ_i and the jth one ψ_j is given as (11, 15–19)

$$[1a] \quad V^{ij}_{\text{eff}} = V^{ij}_{\text{Coul}} - \Delta_{ij}$$

$$[1b] \quad V^{ij}_{\text{Coul}} = \langle\psi_j(1)\psi_j(2)|1/r_{12}|\psi_i(1)\psi_i(2)\rangle$$

$$[1c] \quad \Delta_{ij} = \sum_n |\langle\psi_i|\partial\psi_j/\partial Q_n\rangle|^2$$

where V^{ij}_{Coul}, Δ_{ij}, and Q_n denote the Coulombic repulsion energy, the vibronic attraction energy, and the nth normal vibrational coordinate, respectively. Δ_{ij} represents the nonadiabatic coupling between a pair of different electronic states ψ_i and ψ_j. V^{ij}_{Coul} is positive and is normally larger than Δ_{ij}. Δ_{ij} is positive definite and reduces the magnitude of V^{ij}_{Coul}, acting as the *attractive force*. The alternative form of Δ_{ij} is written as

$$[2a] \quad \Delta_{ij} = \sum_n |f^{ij}_n|^2/(\varepsilon_i - \varepsilon_j)^2$$

$$[2b] \quad f^{ij}_n = \langle\psi_i|\partial f/\partial Q_n|\psi_j\rangle$$

where f^{ij}_n, ε_i, and f denote the extended orbital vibronic constant (EOVC), the ith orbital energy, and the dynamic Fock operator that determines $\{\psi_i\}$ and $\{\varepsilon_i\}$ incorporating the vibronic interaction. The EOVC characterizes the selection rule and the strength of the vibronic interaction (15). If the EOVC is nonzero, a small orbital energy difference brings about a large vibronic attraction energy.

As the size of the system becomes large, V^{ij}_{Coul} decreases to zero in proportion to the volume of the system, whereas Δ_{ij} grows to infinity for a one-dimensional system, converges to a finite value for a two-dimensional system, and decreases to zero for a three-dimensional system if only the longitudinal vibrational modes are used for simple Hückel molecular orbitals (19). Even for a three-dimensional system, Δ_{ij} decreases much more slowly than does V^{ij}_{Coul} (19). This shows that a net attractive interaction responsible for superconductivity emerges if the system becomes large enough.

Definition of the ELVC

To elucidate the attractive interaction for local electron pairing, atomic orbital-wise characterization of the EOVC is required. Adopting the linear combination of the atomic orbital (LCAO) approximation for ψ_i, we get the expression for the EOVC in the atomic orbital basis $\{\chi_r\}$

$$[3a] \quad f^{rs}_n = \langle\chi_r|\partial f/\partial Q_n|\chi_s\rangle$$

Moreover, since Q_n is given by a linear combination of atomic cartesian coordinates, we have more basic representation of the EOVC as follows:

$$[3b] \quad f^{rs}_{\xi_a} = \langle\chi_r|\partial f/\partial\xi_a|\chi_s\rangle$$

where ξ_a denotes the Cartesian coordinates x_a, y_a, or z_a of atom a. We call f^{rs}_n and $f^{rs}_{\xi_a}$ the extended local vibronic constant (ELVC) with respect to Q_n and ξ_a, respectively. Differentiating f with respect to ξ_a, we get

$$[4] \quad \partial f/\partial\xi_a = \partial V_{eN}/\partial\xi_a + \partial G/\partial\xi_a + \partial\hat{\Delta}/\partial\xi_a$$

where V_{eN}, G, and $\hat{\Delta}$ denote the nuclear attraction potential, the two-electron operator, which consists of the Coulombic repulsion and the exchange interaction operators, and the vibronic interaction operator, respectively. The first and second terms in eq. [4], respectively, represent the instantaneous polarization of the electrostatic field and of the electron density brought about by the nuclear momentum. In Hartree–Fock theory, we may write $\partial G/\partial\xi_a$ in the functional form

$$[5] \quad \partial G(\rho)/\partial\xi_a = \int\delta G(\rho)/\delta\rho(r)\cdot\partial\rho(r)/\partial\xi_a\cdot d^3r$$

where r and ρ denote the electron coordinate and the electron density, respectively. The third term in eq. [4] is neglected in this paper, because the $\hat{\Delta}$ itself is negligible for small molecules like the one treated here.

The ELVC is different from the Fock matrix derivative simply because the ELVC does not have the atomic orbital derivative. The Fock matrix derivative is related to the derivative of the atomic α and resonance β integrals in the Hückel treatment, which are often used to study the electron–phonon coupling in the frame of a tight-binding approximation such as the Su–Schrieffer–Heeger (SSH) model (20).

Method of calculation

Ab initio calculations were performed with a 3-21G basis set by the GAUSSIAN80 and GAUSSIAN82 programs (21), incorporating new subroutines to calculate the vibronic interaction. Because we neglected the vibronic coupling term in eq. [4], the adiabatic Fock operator was used for the dynamic Fock operator. The EOVC was obtained using the relation

$$[6] \quad \langle\psi_i|\partial f/\partial Q_n|\psi_j\rangle = (\varepsilon_i - \varepsilon_j)\langle\partial\psi_i/\partial Q_n|\psi_j\rangle + \partial\varepsilon_j/\partial Q_n\delta_{ij}$$

The ELVC was calculated by transforming the EOVC from the molecular orbital basis to the atomic orbital basis:

$$[7] \quad \langle\psi_i|\partial f/\partial Q_n|\psi_j\rangle \rightarrow \langle\chi_r|\partial f/\partial Q_n|\chi_s\rangle$$

Results and discussion

The out-of-plane ELVC

A possible structure of the model polymer is shown in Fig. 1(*a*). The polymer is formally metallic; however, it may be

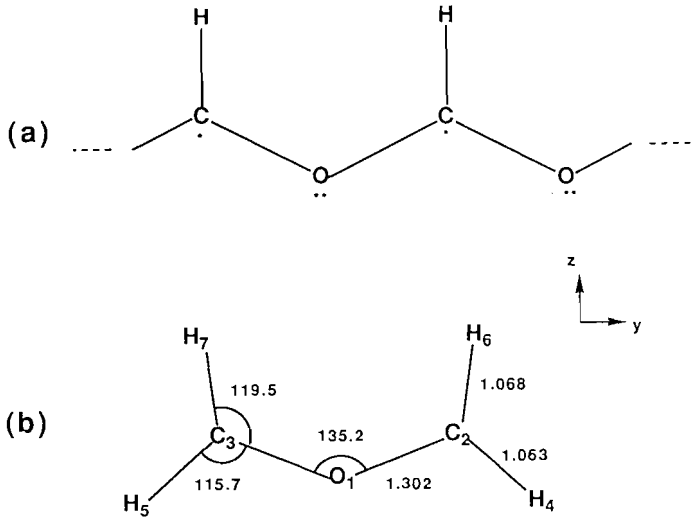

FIG. 1. (*a*) A possible structure of the oxygen-containing model organic polymer $(CHO)_n$. (*b*) Optimized C_{2v} geometry of the structural unit molecule $(CH_2)_2O$. The molecule is lying in the y–z plane. Units of bond lengths and angles are Å and degrees, respectively. The Cartesian coordinate of atom α is denoted as $(x_\alpha, y_\alpha, z_\alpha)$.

unstable with respect to generation of the spin density wave (SDW) or the charge density wave (CDW), which are characteristic of low-dimensional conductors. To suppress the generation of the insulating phase, two- or three-dimensional contact between polymer chains and doping of conducting carriers should be necessary as in the case of known organic superconductors. In Fig. 1(*b*), the optimized geometry of the structural unit molecule $(CH_2)_2O$ is shown. The molecule has C_{2v} symmetry, and is lying in the y–z plane. The diradical character of this molecule has been reported (22).

In Table 1, the Fock matrix elements for the out-of-plane p orbitals are shown. Since we are interested in the attractive interaction for the Cooper pair, we consider only outer atomic orbitals of the split-valence basis set because the outer atomic orbitals are thought to play a major role in electron conduction. The diagonal elements correspond to the Hückel α parameters and the nearest-neighbor elements to the Hückel β parameters. In Table 2, the Fock matrix derivatives with respect to the in-plane vibration of the oxygen and carbon atoms are shown. The nearest-neighbor vibrations, such as $\xi_a = y_1$ for the O_1—$C_{2,3}$ elements and $\xi_a = y_2$ and z_2 for the O_1—C_2 element, have large values. The sign is positive (negative) if the bond length increases (decreases). As distinct from the derivative of the Hückel parameters, the Fock

	C_3	p_x(o)	0.1410	0.0	0.0529
$\xi_a = z_1$	O_1	p_x(o)	−0.1023		
	C_2	p_x(o)	−0.0392	−0.0256	
	C_3	p_x(o)	−0.0392	−0.0236	−0.0256
$\xi_a = y_2$	O_1	p_x(o)	0.1493		
	C_2	p_x(o)	0.1348	0.0529	
	C_3	p_x(o)	−0.0067	0.0481	0.0081
$\xi_a = z_2$	O_1	p_x(o)	0.0563		
	C_2	p_x(o)	0.0487	0.0224	
	C_3	p_x(o)	−0.0098	0.0107	0.0005

matrix derivative originates not only from the nearest-neighbor vibration, but also the non-nearest-neighbor one. Moreover, the diagonal Fock matrix element derivative exists, which is conventionally set equal to zero in the Hückel framework. A large diagonal element is found in the O_1 site for $\xi_a = z_1$, y_2, and z_2. The diagonal elements of O_1 for $\xi_a = y_2$ and z_2 are larger than the O_1—C_2 element. The nearest-neighbor elements with respect to remote atom vibration, such as the O_1—C_3 elements for $\xi_a = y_2$ and z_2, are found to be small. The non-nearest-neighbor elements, such as the C_2—C_3 element for $\xi_a = z_1$, y_2, and z_2, are not negligible.

Various modes of the Fock matrix element derivatives appear according to the motion of the nuclei. The magnitude of the Fock matrix element derivative does not necessarily reflect that of the corresponding Fock matrix element shown in Table 1.

In Table 3, the ELVC's for the out-of-plane p orbitals are shown (bold-face type) with separation into the electrostatic contribution (upper parentheses) and the two-electron contribution (lower parentheses). The ELVC can be classified into three types: the on-site type, the nearest-neighbor type, and the non-nearest-neighbor or long-range type. This is the same as the Fock matrix element derivative. Indeed, *the ELVC originating from remote atom vibration coincides with the corresponding Fock matrix element derivative.* On the other hand, *the ELVC originating from the local atom vibration shows different sign and magnitude from the Fock matrix element derivative.* This is simply because the Fock matrix element derivative includes the derivative of the atomic orbital that is attached to the local atom vibration. For instance, the diagonal element of O_1 for $\xi_a = z_1$ is positive although the corresponding Fock matrix element is negative. As the interaction energy for the Cooper pair is related to the product of the ELVC, the sign and magnitiude of the ELVC are important in determining favourable site and interaction range for the electron pairing.

As shown in Table 3, *the two-electron contribution has opposite sign to, and almost the same magnitude as, that of the electrostatic contribution.* Therefore, *the two-electron contribution cancels the electrostatic contribution and makes the ELVC small.*

For $\xi_a = y_1$, the diagonal element of O_1 and the non-nearest-neighbor elements of C_2—C_3 vanish because of the symmetry. The nearest-neighbor elements of O_1—$C_{2,3}$ are the largest in magnitude. The electrostatic contribution to the O_1—C_2 element is negative, −0.2759, because the bond length between O_1 and C_2 decreases as O_1 moves in the $+y_1$ direction. On the contrary, the two-electron contribution is positive, 0.1719, so that it cancels the electrostatic contribution. The magnitude of the electrostatic contribution is 1.6 times that of the two-electron contribution. The magnitude of the diagonal element of C_2 is smaller than that of the O_1—C_2 element although the magnitude of the electrostatic and two-electron contributions to it are larger than those of the O_1—C_2 element. Since the magnitude of the electrostatic contribution is 1.1 times that of the two-electron contribution, they cancel each other and make the ELVC small.

For $\xi_a = z_1$, the diagonal element of O_1 is the largest in magnitude. This element may bring about the on-site pairing of electrons on the oxygen site. As the electrostatic contribution vanishes because of the symmetry, only the two-electron contribution remains. This element is positive although the corresponding element of the Fock matrix derivative is negative. The magnitude of the non-nearest-neighbor element for C_2—C_3 is comparable to the other elements.

For $\xi_a = y_2$, the O_1—C_2 element is the largest in magnitude. The magnitude of the electrostatic contribution to it is 2.9 times that of the two-electron contribution. The diagonal element of O_1 is smaller than the O_1—C_2 element due to the cancellation between electrostatic and two-electron contributions, although their magnitude is large. On the contrary, for the Fock matrix element derivative, the O_1 element is larger than the O_1—C_2 element. The non-nearest-neighbor C_2—C_3 element is comparable to the on-site C_2 element.

For $\xi_a = z_2$, the O_1—C_2 element is the largest in magnitude. The magnitude of the electrostatic contribution to it is 3.5 times that of the two-electron contribution. The diagonal element of O_1 is smaller than the O_1—C_2 element due to the cancellation between two contributions.

The ELVC's originating from the vibration of hydrogen atoms are smaller than those for heavy atoms. However, if we substitute a polarizable side chain for a hydrogen atom, a large ELVC is brought about by the vibration of the side chain. The vibronic interaction produced by a polarizable side chain is interesting in connection with Little's model of an organic superconductor (23).

The out-of-plane ELVC with respect to the normal vibrational coordinate

We have shown that the ELVC with respect to the Cartesian coordinate can be characterized by three types: the on-site type, the nearest-neighbor type, and the non-nearest-neighbor type. We shall examine now the ELVC with respect to the normal vibrational coordinate. The normal coordinates adopted in this paper are depicted in Fig. 2. In Table 4, the ELVC with respect to these normal coordinates are shown.

For $n = 1$, the magnitude of the diagonal element of O_1 is the largest. The magnitude of the nearest-neighbor elements and the diagonal element of C_2 are about 0.3 times that of the O_1 element. Hence this mode, $n = 1$, is characterized by the on-site type of the ELVC.

For $n = 9$, the elements largest in magnitude are the nearest-neighbor elements of O_1—$C_{2,3}$. The diagonal element of C_2 is smaller by about one order of magnitude than the nearest-neighbor element. Hence this mode, $n = 9$, is characterized by the nearest-neighbor type of the ELVC.

For $n = 9$, the diagonal element of O_1 and the non-nearest-neighbor element of C_2—C_3 vanish because of the symmetry. In an actual organic polymer, these elements do not necessarily vanish because the dispersion of the lattice vibration gives different motions to C_2 and C_3.

For comparison, we also calculated the Fock matrix derivatives. The Fock matrix derivative with respect to the normal coordinate $n = 1$ was not the on-site type, while the other was the nearest-neighbor type.

The in-plane ELVC

The vibronic interactions among the in-plane orbitals are thought to be characteristic of two-dimensional conductors. In our previous study, a large vibronic attractive interaction is found in the in-plane orbitals in $(CH_2)_2O$ with respect to the transverse vibration of the spine (17). In this connection, we calculated the ELVC for the in-plane atomic orbit-

als as shown in Table 5. In some elements, the magnitude of the electrostatic and two-electron contributions is larger than that for the out-of-plane atomic orbitals. However, as is similar to the ELVC for the out-of-plane p orbitals, the two-electron contribution is of opposite sign to the electrostatic contribution, and they cancel each other.

As O_1 moves in the z direction, the change of hybridization between s and p_z orbitals of O_1 gives a large on-site ELVC between them. The magnitude of this ELVC is larger by about one order of magnitude than that ELVC for the out-of-plane atomic orbitals. The sign of the electrostatic contribution is opposite that of the two-electron contribution. The magnitude of the electrostatic contribution is 2.5 times that of the two-electron contribution.

A large element is also found in between the p_z orbital of O_1 and the p_y orbital of C_2. This coupling is interesting from the point of view of two-dimensional coupling (17, 18). The sign of the electrostatic contribution is opposite to that of the two-electron contribution. The magnitude of the electrostatic contribution is 2.2 times that of the two-electron contribution.

There is no extremely large value for the on-site elements in C_2 and for the non-nearest-neighbor elements in C_2—C_3.

To see the two-dimensional character of the vibronic interaction in the in-plane atomic orbitals, we calculated the ELVC for the D_{2h} form of $(CH_2)_2O$. The optimized structure of the D_{2h} form is shown in Fig. 3, where the molecular axis is set to the y axis. The ELVC for the D_{2h} form is shown in Table 6. As O_1 moves in the z direction, a large element also appears in between the s and p_z orbital of O_1 due to the instantaneous hybridization between them. The sign of the electrostatic contribution is opposite that of the two-electron contribution. The magnitude of the electrostatic contribution is 2.5 times that of the two-electron contribution.

The ELVC between the p_z orbital of O_1 and the p_y orbital of C_2 is also large. This coupling has two-dimensional character since these orbitals have no overlaps between them. The sign of the electrostatic contribution is opposite to that of the two-electron contribution. The magnitude of the electrostatic contribution is 2.3 times that of the two-electron contribution. This large ELVC represents the instantaneous electronic polarization due to the sudden overlap of the nonoverlapping atomic orbitals.

We also calculated the Fock matrix element derivatives for the in-plane atomic orbitals. It is found that the Fock matrix element derivatives between the s and p_z orbitals of O_1, and between the p_z orbital of O_1 and the p_y orbital of C_2 are not the largest for both C_{2v} and D_{2h} forms. For the D_{2h} form, the values of the Fock matrix element derivatives between the s and p_z orbitals of O_1, and between the p_z orbital of O_1 and the p_y orbital of C_2, are 0.2290 and −0.1926, respectively. These values are smaller in magnitude than those of the corresponding ELVC's.

Conclusion

We have applied the ELVC using a model molecule to evaluate the strength of the vibronic attractive interaction for the local electron pairing of superconducting electrons. The ELVC is brought about by the Fock operator derivative, which represents the instantaneous electronic polarization due to the presence of the nuclear momentum as well as the polarization of the electrostatic field. However, the Fock matrix derivative cannot represent the instantaneous electronic polarization correctly because it is concomitant with the atomic orbital derivative, which represents the motion of the atomic orbital following local nuclear motion. The ELVC consists of electrostatic and two-electron contributions. The two-electron contribution originates in the response of the electron density to the nuclear vibration. This has an opposite sign to that of the electrostatic contribution and often cancels the electrostatic contribution. The vibronic interaction can be characterized by three types of the ELVC: the on-site type, the nearest-neighbor type, and the long-range type. This sheds new light on the electron–phonon coupling constant of the tight-binding approximation, where the on-site and the long-range interactions are neglected and only the nearest-neighbor interaction remains. Indeed, we have found that a large ELVC out-of-plane element with respect to a certain normal coordinate appears locally on the oxygen site. The long-range type may play an important role if the nuclear vibrational mode has a large dispersion as the system becomes large.

The ELVC's with respect to the vibration of the hydrogen atoms are found to be small. However, if we substitute a polarizable side chain for a hydrogen atom, a large ELVC is expected with respect to the vibration of the side chain.

A large in-plane ELVC appears locally on the oxygen site because of the change of hybridization between s and p_z orbitals as O_1 moves transversally. A large ELVC also appears in between the p_z orbital of O_1 and the p_y of C_2, which represents the two-dimensional vibronic coupling. The magnitude of these in-plane ELVC's is larger than that of the largest out-of-plane ELVC.

The vibronic interactions that we calculated may be too small to create a Cooper pair in the model molecule; however, if the system becomes large enough, a large vibronic attraction would be expected, because the energy gap between a pair of the electronic states becomes small and then the vibronic attraction becomes large. To generate a superconducting phase in the $(CHO)_n$ polymer, the instability characteristic of low-dimensional conductors such as SDW or CDW should be suppressed. This would be done by two- or three-dimensional contact between polymer chains,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

which would also serve to generate long-range order in the superconducting phase. Vibronic coupling between in-plane orbitals is considered to be important in designing two-dimensional superconductors.

Analytic derivative theory based on the Hellmann–Feynman theorem

K. HIRAO

Department of Chemistry, College of General Education, Nagoya University, Nagoya, Japan

Received August 2, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

K. HIRAO. Can. J. Chem. **70**, 434 (1992).

General formulae for the second, third, and fourth derivatives of the energy with respect to the nuclear coordinates of a molecule are derived from the Hellmann–Feynman theorem. Hurley's condition is used to obtain approximations to the first-order wavefunction, from which the second, third, and fourth energies can be obtained, leading to quadratic, cubic, and quartic force constants. The procedure is equivalent to minimizing the derivative energy by perturbed variation techniques. The expressions for these higher energy derivatives are much simpler than those of the direct analytic derivative method. The electrostatic calculation involves only one-electron integrals. The coupled Hartree–Fock equations to obtain the wavefunction derivatives become much simpler. The present theory provides a great conceptual simplification. However, the theory is correct only if the basis set is complete or basis functions are independent of the perturbation.

Key words: analytic derivative theory, Hellmann–Feynman theorem, force constants, the curvature theorem.

K. HIRAO. Can. J. Chem. **70**, 434 (1992).

En utilisant le théorème de Hellmann–Feynman, on a dérivé des formules générales pour les deuxième, troisième et quatrième dérivées de l'énergie par rapport aux coordonnées nucléaires d'une molécule. On a utilisé la condition de Hurley pour obtenir des approximations de la fonction d'onde du premier ordre, à partir de laquelle on a obtenu les deuxième, troisième et quatrième énergies, qui ont conduit aux constantes de force quadratique, cubique et quartique. La procédure équivaut à minimiser l'énergie dérivée à l'aide des techniques de la variation perturbée. Les expressions de ces dérivées élevées de l'énergie sont beaucoup plus simples que celles obtenues grâce à la méthode de la dérivée analytique directe. Le calcul électrostatique n'implique que les intégrales d'un seul électron. Les équations couplées de Hartree–Fock nécessaires pour obtenir les dérivées de la fonction d'onde deviennent beaucoup plus simples. La présente théorie présente une grande simplification conceptuelle. Toutefois, la théorie n'est correcte que si la base est complète ou si les fonctions de base sont indépendantes de la perturbation.

Mots clés : théorie de la dérivée analytique, théorème de Hellmann–Feynman, constantes de force, théorème de courbure.

[Traduit par la rédaction]

1. Introduction

Many important molecular properties are directly defined as the derivatives of an electronic energy. Electric moments and polarizabilities are property defined as the derivatives of the energy with respect to the applied electric fields. Magnetic properties such as diamagnetic susceptibilities and nuclear magnetic resonance chemical shifts are related to energy derivatives with respect to external and nuclear magnetic fields. Differentiation of the energy with respect to nuclear coordinates corresponds to the calculation of forces and force constants. These nuclear displacement energy derivatives are very important in the exploration of potential surfaces.

The first derivatives of the energy with respect to nuclear coordinates give the force acting on the nucleus and are used to find the stationary points such as equilibrium structures and transition structures. The second derivatives are related to the harmonic force constants as well as to the nature of the stationary point. The third and fourth derivatives are related to the cubic and quartic force constants, respectively. The knowledge of these derivatives yields anharmonic spectroscopic constants.

There are two general approaches to the calculation of analytic energy derivatives. The first method is the direct analytic differentiation of the expectation value of the Hamiltonian. The procedure has been the most commonly used and has been the focus of many investigations in recent years. The idea underlying the direct analytical derivative method is to rigorously differentiate the true quantum mechanical energy. Generally this involves solving a type of eigenfunction equation or a simultaneous system of linear equations. Consequently n differentiations are necessary to reach nth energy derivatives.

Direct analytic first derivatives of the SCF energy were first derived by Pulay (1). It is now relatively straightforward to calculate the first derivatives with respect to nuclear coordinates for any method. Pople *et al.* (2) presented the analytical method for the evaluation of SCF second derivatives. To obtain second derivatives it is necessary to solve the coupled perturbed Hartree–Fock equations of Gerratt and Mills (3). The most severe bottleneck in this approach is the drastic increase in the number of basis molecular integrals to be computed. In spite of this, such a second derivative approach is used rather routinely for SCF and some MC-SCF schemes. The formulations of SCF third derivatives were first given by Gaw, Yamaguchi, and Schaefer (4). Some simplifications in the formula were given by Gaw and Handy (5). The fourth derivatives have been presented by Handy and coworkers.[1] This requires the solution of the second-order coupled perturbed Hartree–Fock equations. However, the scheme becomes more time consuming and complicated as the order of the energy derivatives increases. This is mainly due to the error terms, which vanish when the wavefunctions obeying the Hellmann–Feynman theorem are used. Nothing will be gained if we evaluate the unphysical error terms.

An alternative method is possible, based on the use of the

Hellmann–Feynman theorem (6, 7). The Hellmann–Feynman theorem gives the first derivatives of the energy with respect to the nuclear coordinates as a simple expectation value. Consequently, $n - 1$ differentiations are required to reach the nth derivatives of the energy. In addition we have the so-called Hurley's condition (8) for the optimal variational wavefunction, which serves as an auxiliary condition. Thus, the Hellmann–Feynman approach seems to be much superior to the direct differentiation method. However, although there have been isolated successes of the Hellmann–Feynman approach (9),[2] thus far there is no general theoretical understanding of the situation. This is mainly due to the unreliability of the Hellmann–Feynman method for evaluating forces on nuclei. Although the Hellmann–Feynman theorem is valid for true Hartree–Fock wavefunctions, it is found to be of little value for the finite basis sets typically used in molecular calculations. Thus, the error in the Hellmann–Feynman theorem arises essentially from basis set inadequacies in the underlying calculations.

The Hellmann–Feynman theorem provides a great conceptual simplification and may lead to practical advantages. We will develop here the analytic derivative theory based on the Hellmann–Feynman theorem. In Sect. 2, the second, third, and fourth energy derivatives for a diatomic molecule will be derived from the Hellmann–Feynman theorem. In Sect. 3, general analytic expressions for these higher energy derivatives will be given. Results will be discussed in the final section.

2. Analytic derivative theory for diatomic molecules

Let Ψ be a normalized optimal variational wavefunction and E the corresponding energy

$$[1] \qquad \langle\Psi|H - E|\Psi\rangle = 0$$

By differentiating eq. [1] with respect to a nuclear coordinate λ we obtain

$$[2] \qquad E^1 = \langle\Psi|H^1|\Psi\rangle + \langle\Psi^1|H - E|\Psi\rangle + \langle\Psi|H - E|\Psi^1\rangle$$

Here we used the notation

$$H^n = \frac{\partial^n H}{\partial\lambda^n}$$

and analogous notation for Ψ^n and E^n. The variational condition ensures that

$$[3] \qquad \langle\Psi^1|H - E|\Psi\rangle + \langle\Psi|H - E|\Psi^1\rangle = 0$$

whence we have the Hellmann–Feynman theorem

$$[4] \qquad E^1 = \langle\Psi|H^1|\Psi\rangle$$

The negative energy gradient is called the Hellmann–Feynman force. Such a condition as eq. [3] was first given by Hurley (8) and is known as Hurley's condition. True Hartree–Fock approximations (as distinct from the SCF approximations), be they restricted, unrestricted, open-shell, closed-shell, multi-configurational, or whatever, satisfy the Hellmann–Feynman theorem.

For simplicity, in this paper we will consider $2n$ electron closed-shell systems. The wavefunction is expressed as a Slater determinant

$$[5] \qquad \Psi = \|\varphi_1\alpha\varphi_1\beta \ldots \varphi_i\alpha\varphi_i\beta \ldots\|$$

The Hartree–Fock orbitals $\varphi_1 \ldots \varphi_n$ are eigenfunctions of the Fock operator, the corresponding eigenvalues being $\varepsilon_1 \ldots \varepsilon_n$

$$[6] \qquad F\varphi_i = \varepsilon_i\varphi_i$$

Orbital labels $i, j, k \ldots$ denote occupied orbitals, $a, b, c \ldots$ denote virtual orbitals, and $p, q, r \ldots$ denote general orbitals. The Hellmann–Feynman theorem is satisfied if Hurley's condition, eq. [3], is fulfilled. The wavefunction derivative is given by

$$[7] \qquad \Psi^1 = \sum_i^{\text{occ}} \|\varphi_1\alpha\varphi_1\beta \ldots \varphi_i^1\varphi_i\,(\alpha\beta - \beta\alpha) \ldots\|$$

Taking account of the one-electron property of H^1, we assume that the derivative of the orbital is expressed as a linear combination of the other orbitals

$$[8] \qquad \varphi_i^1 = \varphi_p U_{pi}/\sqrt{2}$$

where $p = i$ is excluded from the orthogonality condition of orbitals. We used Einstein summation notation for repeated indices. Substituting eq. [8] into eq. [7], we have

$$[9] \qquad \Psi^1 = U_{ai}\Psi_{ai}$$

with

$$\Psi_{ai} = \|\varphi_1\alpha\varphi_1\beta \ldots \varphi_a\varphi_i(\alpha\beta - \beta\alpha)/\sqrt{2} \ldots\|$$

The Ψ_{ai} are singly excited configurations. Thus Hurley's condition of eq. [3] is equivalent to the Brillouin theorem

$$[10] \qquad \langle\Psi_{ai}|H - E|\Psi\rangle + \langle\Psi|H - E|\Psi_{ai}\rangle = 0$$

As well known, the Hellmann–Feynman theorem is satisfied for the optimal wavefunction as a consequence of the variational principle.

The differentiation of the Fock equations $\langle\varphi_j|F - \varepsilon_i|\varphi_i\rangle = 0$ leads to

$$[11] \qquad \langle\varphi_j|F^1 - \varepsilon_i^1|\varphi_i\rangle + (\varepsilon_j - \varepsilon_i)\langle\varphi_j|\varphi_i^1\rangle = 0$$

In the case of $i = j$ we have the Hellmann–Feynman theorem with respect to the orbital energy

$$[12] \qquad \varepsilon_i^1 = \langle\varphi_i|F^1|\varphi_i\rangle$$

Now let us derive the second, third, and fourth energy derivatives based on the Hellmann–Feynman theorem. For the sake of formal simplicity, we will consider the $2n$-electron closed-shell SCF wavefunction for a diatomic molecule. The electron energy is given by eq. [1]. The nuclear coordinates are understood to have been written in terms of the internuclear distance R. Thus only R appears as a parameter. Differentiation of eq. [1] results in the Hellmann–Feynman theorem if Hurley's condition is fulfilled. We observe that R is real so that the derivative wavefunctions are

[2]Other formulations are possible based on the use of the virial theorem to define $\partial E/\partial\lambda$, see for example, ref. 10.

For personal use only.

assumed to be real. This is not a serious restriction. The normalization condition of the wavefunction requires

$$[13] \quad \langle\Psi^1|\Psi\rangle = 0$$

(i) Second derivative

Differentiation of the Hellmann–Feynman theorem with respect to R yields

$$[14] \quad E^2 = \langle\Psi|H^2|\Psi\rangle + 2\langle\Psi^1|H^1|\Psi\rangle$$

The second derivative of the energy requires knowledge of the first derivative of the wavefunction. The essential difficulty in calculating higher energy derivatives lies in finding a good approximation to the first derivative of the wavefunction. By differentiating Hurley's condition we have the first-order Hurley's condition

$$[15] \quad \langle\Psi^1|H^1|\Psi\rangle + \langle\Psi^1|H - E|\Psi^1\rangle + \langle\Psi^2|H - E|\Psi\rangle = 0$$

Equation [15] is the equation to determine the first derivative of the wavefunction. As shown later, finding Ψ^1 based on the use of eq. [15] is equivalent to finding the optimal Ψ^1 by the perturbation variation method (11). We assume that Ψ^1 can be expanded in terms of the singly excited configurations

$$[16] \quad \Psi^1 = U^{(1)}_{ai} S^+_{ai}\Psi$$

Here $U^{(1)}_{ai}$ are expansion coefficients, namely the first-order variational parameters, and S^+_{ai} are the single excitation operators defined by

$$[17] \quad S^+_{pq} = (a^+_{p\alpha}a_{q\alpha} + a^+_{p\beta}a_{q\beta})/\sqrt{2}$$

The a^+_p and a_q are the creation and destruction operators that satisfy the Fermion anticommutation relation. From the orthogonality relations of orbitals, we have

$$[18] \quad U^{(1)}_{pq} + U^{(1)}_{qp} = 0$$

The S^+_{ai} generates a singlet, singly excited, configuration when operating on Ψ

$$[19] \quad S^+_{ai}\Psi \equiv S^+_{ai}|\rangle = \| \ldots \varphi_a\varphi_i(\alpha\beta - \beta\alpha)\sqrt{2} \ldots \|$$

Equation [15] involves the second derivative of the wavefunction Ψ^2. So we must eliminate Ψ^2. Ψ^2 can be written in general in terms of the excitation operators as

$$[20] \quad \Psi^2 = U^{(1)}_{pq}U^{(1)}_{rs}S^+_{pq}S^+_{rs}|\rangle$$

The orbital pairs pq, rs run over all orbitals. Thus Ψ^2 consists of the ground, singly, and doubly excited configurations

$$[21] \quad \Psi^2 = [U^{(2)} + U^{(2)}_{ai}S^+_{ai} + U^{(2)}_{ai,bj}S^+_{ai}S^+_{bj}]|\rangle$$

The ground state component comes from the excitations $S^+_{ia}S^+_{ai}|\rangle$ and singly excited configurations arise from $S^+_{ab}S^+_{bi}|\rangle$ and $S^+_{ji}S^+_{aj}|\rangle$. Ψ^2 can be expressed in terms of the first-order parameters as

$$[22] \quad \Psi^2 = [U^{(1)}_{ia}U^{(1)}_{ai}S^+_{ia}S^+_{ai} + U^{(1)}_{ab}U^{(1)}_{bi}S^+_{ab}S^+_{bj} + U^{(1)}_{ji}U^{(1)}_{aj}S^+_{ji}S^+_{aj} + U^{(1)}_{ai}U^{(1)}_{bj}S^+_{ai}S^+_{bj}]|\rangle$$

Comparing eqs. [21] and [22] we have

$$[23a] \quad U^{(2)} = -|U^{(1)}_{ai}|^2$$

$$[23b] \quad U^{(2)}_{ai} = U^{(1)}_{ab}U^{(1)}_{bi} + U^{(1)}_{ji}U^{(1)}_{aj}$$

$$[23c] \quad U^{(2)}_{ai,bj} = U^{(1)}_{ai}U^{(1)}_{bj}$$

The $U^{(2)}$ can also be obtained from the second-order normalization condition

$$[24] \quad \langle\Psi^2|\Psi\rangle + \langle\Psi^1|\Psi^1\rangle = 0$$

Returning to eq. [15], we observe that the last term requires only the knowledge of the doubly excited configurations of Ψ^2. Using the relation given by eq. [23*c*], we can rewrite eq. [15] as

$$[25] \quad \langle|S_{ai}H^1|\rangle + [\langle|S_{ai}(H - E)S^+_{bj}|\rangle + \langle|S_{ai}S_{bj}H|\rangle]U^{(1)}_{bj} = 0$$

These are a set of linear equations, which are sufficient for finding $U^{(1)}_{ai}$. We only need solutions of eq. [25] to obtain Ψ^1. There is no iteration involved. From a practical point of view, the iterative scheme is preferred simply because it is less expensive. Equations [25] are known as the coupled perturbed Hartree–Fock equations, as discussed by Stevens *et al.* (12). Note here that once the first-order wavefunction has been determined, the second-order wavefunction Ψ^2 can be obtained, except for $U^{(2)}_{ai}$. $U^{(2)}_{ai}$ requires knowledge of $U^{(1)}_{ab}$ and $U^{(1)}_{ji}$, which cannot be fixed from the first-order wavefunction.

Finally, the second energy derivative can be written in terms of the excitation operators as

$$[26] \quad E^2 = \langle|H^2|\rangle + 2U^{(1)}_{ai}\langle|S_{ai}H^1|\rangle$$

Equation [26] can be formulated in another way. Let us consider the general expression of E^2 obtained by double differentiation of eq. [1]

$$[27] \quad E^2 = \langle\Psi|H^2|\Psi\rangle + 4\langle\Psi^1|H^1|\Psi\rangle + 2\langle\Psi^1|H - E|\Psi^1\rangle + 2\langle\Psi^2|H - E|\Psi\rangle$$

It can be shown (13) for any approximate Ψ^1, say $\tilde{\Psi}^1$, that

$$[28] \quad \langle\Psi|H^2|\Psi\rangle + 4\langle\tilde{\Psi}^1|H^1|\Psi\rangle + 2\langle\tilde{\Psi}^1|H - E|\tilde{\Psi}^1\rangle + 2\langle\tilde{\Psi}^2|H - E|\Psi\rangle \equiv \tilde{E}^2 \geq E^2$$

Thus we may choose an arbitrary trial function with variable parameters and optimize it by minimizing $\tilde{E}^2$. If $\tilde{\Psi}^1$ contains only linear parameters and $\tilde{\Psi}^2$ can be written as in eq. [21], it is easy to show that the optimized trial function Ψ^1_{opt} satisfies

$$[29] \quad \langle\Psi^1_{opt}|H|\Psi\rangle + \langle\Psi^1_{opt}|H - E|\Psi^1_{opt}\rangle + \langle\Psi^2_{opt}|H - E|\Psi\rangle = 0$$

This implies that Ψ^1_{opt} satisfies eq. [15] derived from Hurley's condition. Also we have the expression of E^2 for the optimal Ψ^1_{opt}

$$[30] \quad E^2 = \langle\Psi|H^2|\Psi\rangle + 2\langle\Psi^1_{opt}|H^1|\Psi\rangle$$

which takes the same form as given in eq. [14]. Thus, finding approximate Ψ^1 from the Hurley's condition of eq. [15] is equivalent to optimizing Ψ^1 using the perturbation variation technique (11).

That is, the analytic energy derivative derived from the Hellmann–Feynman theorem is the optimal function determined by the variation perturbation method. It must be emphasized that the variational perturbation method will lead to successful results only for the wavefunction obeying the Hellmann–Feynman theorem.

Equation [25] can be expressed in a simple matrix form

$$[31] \quad \mathbf{b} + (\boldsymbol{A} + \boldsymbol{B})\mathbf{U} = 0$$

The **b** and **U** are column vectors of $\langle|S_{ai}H^1|\rangle$ and first-order variational parameters $U^{(1)}_{ai}$, respectively. The $\boldsymbol{A}$ and $\boldsymbol{B}$ matrices are defined by

$$[32a] \quad (\boldsymbol{A})_{ai,bj} = \langle|S_{ai}(H - E)S^+_{bj}|\rangle$$

$$[32b] \quad (\boldsymbol{B})_{ai,bj} = \langle|S_{ai}S_{bj}H|\rangle$$

Since we are dealing with closed-shell systems, all the integrals can be chosen as real. So the $\boldsymbol{A}$ and $\boldsymbol{B}$ matrices are symmetric. Now let us consider the unitary transformation among singly excited configurations, which diagonalizes the $(\boldsymbol{A} + \boldsymbol{B})$ matrix

$$[33] \quad \boldsymbol{O}^\dagger(\boldsymbol{A} + \boldsymbol{B})\boldsymbol{O} = \boldsymbol{d}$$

Here $\boldsymbol{O}$ is the unitary matrix and $\boldsymbol{d}$ is a diagonal matrix. If we further define the unitary transformed excitation operators by

$$[34a] \quad R^+_{ai} = S^+_{bj}O_{bj,ai}$$

together with

$$[34b] \quad T^{(1)}_{ai} = U^{(1)}_{bj}O_{bj,ai}$$

then we have

$$[35] \quad \Psi^1 = T^{(1)}_{ai}R^+_{ai}|\rangle$$

and

$$[36] \quad T^{(1)}_{ai} = -\langle|R_{ai}H^1|\rangle/\Delta E_{ai}$$

with

$$[37] \quad \Delta E_{ai} = \langle|R_{ai}(H - E)R^+_{ai}|\rangle + \langle|R_{ai}R_{ai}H|\rangle$$

Finally, the second energy derivative can be written as

$$[38] \quad E^2 = \langle|H^2|\rangle - 2|\langle|R_{ai}H^1|\rangle|^2/\Delta E_{ai}$$

Equation [38] is derived without any approximation in spite of its simplicity. Namely, by choosing $\boldsymbol{O}$ as diagonalizing the matrix $(\boldsymbol{A} + \boldsymbol{B})$, the second energy derivative can be expressed in a form similar to a simple sum-over-state perturbation method (14). A similar procedure has been used to analyze the second-order perturbation energy of the coupled Hartree–Fock theory and the unlinked terms of the SCF effect of orbitals (15). Note here that ΔE_{ai} is not really the excitation energy; it includes the additional term originated from the $\boldsymbol{B}$ matrix. It is called the generalized exchange integral (15) since $\langle|S_{ai}S_{ai}H|\rangle$ equals the usual exchange integral $(\varphi_a\varphi_i|\varphi_a\varphi_i)$. The generalized exchange integral represents the higher order effect of the change in the orbitals due to the displacement of the internuclear distance.

The first term of the right-hand side of eq. [38] is the classical formula for the force constant and corresponds to moving the nuclei while holding the electrons fixed. It is positive. The second terms are often referred to as relaxation terms since they represent the effect of the changes in charge distribution due to the movement of the nuclei. From eq. [38], we have

$$[39] \quad E^2 - \langle|H^2|\rangle = -2|\langle|R_{ai}H^1|\rangle|^2/\Delta E_{ai} < 0$$

if

$$[40] \quad \Delta E_{ai} = \langle|R_{ai}(H - E)R^+_{ai}|\rangle + \langle|R_{ai}R_{ai}H|\rangle > 0$$

This is an alternative proof of the upper bound relation of second derivatives of the energy (the curvature theorem) (16). Equation [40] is the stability condition for the optimized variational wavefunction (17). The stability condition ensures that the wavefunction represents a true minimum of the energy. Thus, the upper bound condition is equivalent to the stability condition and provides an additional criterion to that of the variational principle for judging the quality and stability of an approximate wavefunction.

(ii) Third derivative

The third energy derivative is obtained by further differentiating eq. [14] with respect to R:

$$[41] \quad E^3 = \langle\Psi|H^3|\Psi\rangle + 4\langle\Psi^1|H^2 - E^2|\Psi\rangle + 2\langle\Psi^1|H^1 - E^1|\Psi^1\rangle + 2\langle\Psi^2|H^1 - E^1|\Psi\rangle$$

This expression of the third energy derivative contains the second derivative of the wavefunction Ψ^2. The unknown quantities of Ψ^2 are the parameters $U^{(2)}_{ai}$ for the singly excited configurations. So it is necessary to look at the second-order Hurley's condition obtained by differentiating eq. [15]

$$[42] \quad \langle\Psi^3|H - E|\Psi\rangle + 2\langle\Psi^2|H^1 - E^1|\Psi\rangle + 3\langle\Psi^2|H - E|\Psi^1\rangle + \langle\Psi^1|H^2|\Psi\rangle + 2\langle\Psi^1|H^1 - E^1|\Psi^1\rangle = 0$$

However, eq. [42] includes the third derivative of the wavefunction, Ψ^3. Therefore, we shall try to eliminate the third-order wavefunction. This is possible. The general form of Ψ^3 is

$$[43] \quad \Psi^3 = [U^{(3)} + U^{(3)}_{ai}S^+_{ai} + U^{(3)}_{ai,bj}S^+_{ai}S^+_{bj} + U^{(3)}_{ai,bj,ck}S^+_{ai}S^+_{bj}S^+_{ck}]|\rangle$$

However, we can express $U^{(3)}_{ai}$, $U^{(3)}_{ai,bj}$, and $U^{(3)}_{ai,bj,ck}$ in terms of the lower order parameters by analyzing the excitations,

$$[44a] \quad U^{(3)} = -3U^{(2)}_{ai}U^{(1)}_{ai}$$

$$[44b] \quad U^{(3)}_{ai,bj} = 3U^{(2)}_{ai}U^{(1)}_{bj}$$

$$[44c] \quad U^{(3)}_{ai,bj,ck} = U^{(1)}_{ai}U^{(1)}_{bj}U^{(1)}_{ck}$$

The relation of eq. [44*a*] can be derived directly from the third-order normalization condition of the wavefunction

$$[45] \quad \langle\Psi^3|\Psi\rangle + 3\langle\Psi^2|\Psi^1\rangle = 0$$

Note here that only the doubly excited configurations of Ψ^3 can contribute to the first term of eq. [42]. Thus, eq. [42] contains only unknown parameters $U^{(2)}_{ai}$ if $U^{(1)}_{ai}$ are known. Expressing eq. [42] in terms of $U^{(2)}_{ai}$ and $U^{(1)}_{ai}$, we have the following relations

$$[46] \quad U^{(2)}_{ai}\langle|S_{ai}H^1|\rangle = U^{(1)}_{ai}[\langle|S_{ai}H^2|\rangle + 2\langle|S_{ai}(H^1 - E^1)S^+_{bj}|\rangle U^{(1)}_{bj} + \{2\langle|S_{ai}S_{bj}HS^+_{ck}|\rangle + \langle|S_{bj}S_{ck}HS^+_{ai}|\rangle\}U^{(1)}_{bj}U^{(1)}_{ck}]$$

Thus, the $U^{(2)}_{ai}$ can be expressed explicitly in terms of the first-order parameters. The third energy derivative is now rewritten as

$$[47] \quad E^3 = \langle|H^3|\rangle + 6U^{(1)}_{ai}\langle|S_{ai}H^2|\rangle + 6U^{(1)}_{ai}U^{(1)}_{bj}\langle|S_{ai}(H^1 - E^1)S^+_{bj}|\rangle + 6U^{(1)}_{ai}U^{(1)}_{bj}U^{(1)}_{ck}\langle|S_{ai}S_{bj}HS^+_{ck}|\rangle$$

The formula is much simpler than that of the direct analytic derivative method. Note here that the final expression of E^3

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

contains only the first-order variational parameters. Explicit knowledge of Ψ^2 is not necessary. This point will be discussed later.

If we use the unitary transformed excitation operators, the above expression can be expressed in the form of the sum-over-state perturbation method

$$[48]\quad E^3 = \langle|H^3|\rangle - 6\langle|H^1R_{ai}^+|\rangle\langle|R_{ai}H^2|\rangle/\Delta E_{ai} + 6\langle|H^1R_{ai}^+|\rangle\langle|R_{ai}(H^1 - E^1)R_{bj}^+|\rangle\langle|R_{bj}H^1|\rangle/(\Delta E_{ai}\Delta E_{bj}) - 6\langle|H^1R_{ai}^+|\rangle\langle|H^1R_{bj}^+|\rangle\langle|R_{ai}R_{bj}HR_{ck}^+|\rangle\langle|R_{ck}H^1|\rangle/(\Delta E_{ai}\Delta E_{bj}\Delta E_{ck})$$

This equation is also exact. There is no approximation employed.

Now let us consider the general analytic expression of E^3 derived by successive differentiation of eq. [1]

$$[49]\quad E^3 = \langle\Psi|H^3|\Psi\rangle + 6\langle\Psi^1|H^2 - E^2|\Psi\rangle + 6\langle\Psi^1|H^1 - E^1|\Psi^1\rangle + 6\langle\Psi^2|H^1 - E^1|\Psi\rangle + 6\langle\Psi^2|H - E|\Psi^1\rangle + 2\langle\Psi^3|H - E|\Psi\rangle$$

Expanding the wavefunction derivatives in terms of the excitation operators as before and minimizing E^3 with respect to the unknown parameter $U_{ai}^{(2)}$, we have

$$[50]\quad \frac{\partial E^3}{\partial U_{ai}^{(2)}} = \langle|S_{ai}H^1|\rangle + [\langle|S_{ai}(H - E)S_{bj}^+|\rangle + \langle|S_{ai}S_{bj}H|\rangle]U_{bj}^{(1)} = 0$$

Equation [50] holds automatically if Ψ^1 is chosen optimal, that is, if $U_{ai}^{(1)}$ satisfies eq. [25]. The E^3 expression for the optimal Ψ^2 takes the same form as given by eq. [41]. Thus, the first-order wavefunction suffices to determine the third energy derivatives. This property is also utilized to derive the third energy derivatives of the direct analytic method (4).

(iii) Fourth derivative

The fourth derivative is obtained by differentiating eq. [41] again with respect to R:

$$[51]\quad E^4 = \langle\Psi|H^4|\Psi\rangle + 6\langle\Psi^1|H^3|\Psi\rangle + 6\langle\Psi^2|H^2 - E^2|\Psi\rangle + 6\langle\Psi^1|H^2 - E^2|\Psi^1\rangle + 6\langle\Psi^2|H^1 - E^1|\Psi^1\rangle + 2\langle\Psi^3|H^1 - E^1|\Psi\rangle$$

The last term on the right-hand side of eq. [51] involves the third derivative of the wavefunction. We need the singly excited components of Ψ^3 to evaluate this term due to the one-electron property of H^1. To determine the unknown quantities, we start with the third-order Hurley's condition

$$[52]\quad \langle\Psi^4|H - E|\Psi\rangle + 3\langle\Psi^3|H^1 - E^1|\Psi\rangle + 4\langle\Psi^3|H - E|\Psi^1\rangle + 3\langle\Psi^2|H^2 - E^2|\Psi\rangle + 9\langle\Psi^2|H^1 - E^1|\Psi^1\rangle + 3\langle\Psi^2|H - E|\Psi^2\rangle + \langle\Psi^1|H^3|\Psi\rangle + 3\langle\Psi^1|H^2 - E^2|\Psi^1\rangle = 0$$

Again, the above condition contains the fourth derivative of the wavefunction. However, the quantities required to evaluate the first term of eq. [52] are the doubly excited configurations of Ψ^4. From analysis of the excitation operators, we observe that

$$[53]\quad U_{ai,bj}^{(4)}S_{ai}^+S_{bj}^+ = (4U_{ai}^{(3)}U_{bj}^{(1)} + 3U_{ai}^{(2)}U_{bj}^{(2)})S_{ai}^+S_{bj}^+$$

Thus we can find the unknown parameters $U_{ai}^{(3)}$ from eq. [52]. The final expression of $U_{ai}^{(3)}$ becomes

$$[54]\quad U_{ai}^{(3)}\langle|S_{ai}H^1|\rangle = U_{ai}^{(1)}[\langle|S_{ai}H^3|\rangle + 3\langle|S_{ai}(H^2 - E^2)S_{bj}^+|\rangle U_{bj}^{(1)} + 9\langle|S_{ai}S_{bj}H^1S_{kc}^+|\rangle U_{bj}^{(1)}U_{kc}^{(1)} + \{3\langle|S_{ai}S_{bj}(H - E)S_{ck}^+S_{dl}^+|\rangle + 4\langle|S_{ai}S_{bj}S_{ck}HS_{dl}^+|\rangle\}U_{bj}^{(1)}U_{ck}^{(1)}U_{dl}^{(1)}] + 3U^{(2)}U_{ai}^{(1)}\langle|S_{ai}H^1|\rangle + 3U_{ai}^{(2)}[\langle|S_{ai}H^2|\rangle + 3\langle|S_{ai}(H^1 - E^1)S_{bj}^+|\rangle U_{bj}^{(1)} + \{\langle|S_{ai}(H - E)S_{bj}^+|\rangle + \langle|S_{ai}S_{bj}H|\rangle\}U_{bj}^{(2)} + 2\{2\langle|S_{ai}S_{bj}HS_{ck}^+|\rangle + \langle|S_{bj}S_{ck}HS_{ai}^+|\rangle\}U_{bj}^{(1)}U_{ck}^{(1)}]$$

Note here that it is not necessary to solve the second-order coupled perturbed Hartree–Fock equations for the calculation of the third-order parameters. It is also possible to represent $U_{ai}^{(3)}$ in terms of the first-order parameters $U_{ai}^{(1)}$ if we utilize the relations given by eq. [46].

The fourth energy derivative can be expressed in terms of the excitation operators:

$$[55]\quad E^4 = \langle|H^4|\rangle + 6U_{ai}^{(1)}\langle|S_{ai}H^3|\rangle + 6U_{ai}^{(2)}\langle|S_{ai}H^2|\rangle + 6U^{(2)}\langle|H^2 - E^2|\rangle + 6U_{ai}^{(1)}U_{bj}^{(1)}\langle|S_{ai}(H^2 - E^2)S_{bj}^+|\rangle + 6U^{(2)}U_{ai}^{(1)}\langle|S_{ai}^+H^1|\rangle + 6U_{ai}^{(2)}U_{bj}^{(1)}\langle|S_{ai}(H^1 - E^1)S_{bj}^+|\rangle + 6U_{ai}^{(1)}U_{bj}^{(1)}U_{ck}^{(1)}\langle|S_{ai}S_{bj}H^1S_{ck}^+|\rangle + 2U_{ai}^{(3)}\langle|S_{ai}H^1|\rangle$$

Utilizing the relations given in eq. [54] we can eliminate $U_{ai}^{(3)}$ and have

$$[56]\quad E^4 = \langle|H^4|\rangle + 8U_{ai}^{(1)}\langle|S_{ai}H^3|\rangle + 12U_{ai}^{(1)}U_{bj}^{(1)}\langle|S_{ai}(H^2 - E^2)S_{bj}^+|\rangle + 24U_{ai}^{(1)}U_{bj}^{(1)}U_{ck}^{(1)}\langle|S_{ai}S_{bj}H^1S_{ck}^+|\rangle + 6U_{ai}^{(1)}U_{bj}^{(1)}U_{ck}^{(1)}U_{dl}^{(1)}\langle|S_{ai}S_{bj}(H - E)S_{ck}^+S_{dl}^+|\rangle + 8U_{ai}^{(1)}U_{bj}^{(1)}U_{ck}^{(1)}U_{dl}^{(1)}\langle|S_{ai}S_{bj}S_{ck}HS_{dl}^+|\rangle + 6U_{ai}^{(2)}U_{bj}^{(2)}\{\langle|S_{ai}(H - E)S_{bj}^+|\rangle + \langle|S_{ai}S_{bj}H|\rangle\}12U_{ai}^{(2)}[\langle|S_{ai}H^2|\rangle + 2U_{bj}^{(1)}\langle|S_{ai}(H^1 - E^1)S_{bj}^+|\rangle + \{2\langle|S_{ai}S_{bj}HS_{ck}^+|\rangle + \langle|S_{ai}HS_{bj}^+S_{ck}^+|\rangle\}U_{bj}^{(1)}U_{ck}^{(1)}]$$

since, according to the relations of eq. [46], the last four terms on the right-hand side of the above equation are

$$[57]\quad 12U_{ai}^{(2)}[\langle|S_{ai}H^2|\rangle + 2U_{bj}^{(1)}\langle|S_{ai}(H^1 - E^1)S_{bj}^+|\rangle + \{2\langle|S_{ai}S_{bj}HS_{ck}^+|\rangle + \langle|S_{ai}HS_{bj}^+S_{ck}^+|\rangle\}U_{bj}^{(1)}U_{ck}^{(1)}] = 12|U_{ai}^{(2)}|^2\langle|S_{ai}H^1|\rangle/U_{ai}^{(1)}$$

provided that $U_{ai}^{(1)} \neq 0$. If we further use the relations given by eq. [46] we can express E^4 only in terms of the first-order parameters $U_{ai}^{(1)}$. Although the formula looks complicated, it consists only of straightforward combinations of known quantities. There are no algebraic problems.

The fourth energy derivatives can be expressed in terms of the unitary transformed excitation operators as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

[58] $$E^4 = \langle|H^4|\rangle - 8\langle|H^1R_{ai}^+|\rangle\langle R_{ai}H^3|\rangle/\Delta E_{ai} + 12\langle|H^1R_{ai}^+|\rangle\langle|R_{ai}(H^2 - E^2)R_{bj}^+|\rangle\langle|R_{bj}H^1|\rangle/(\Delta E_{ai}\Delta E_{bj})$$
$$- 24\langle|H^1R_{ai}^+|\rangle\langle|H^1R_{bj}^+|\rangle\langle|R_{ai}R_{bj}H^1R_{ck}^+|\rangle\langle|R_{ck}H^1|\rangle/(\Delta E_{ai}\Delta E_{bj}\Delta E_{ck})$$
$$+ 6\langle|H^1R_{ai}^+|\rangle\langle|H^1R_{bj}^+|\rangle\langle|R_{ai}R_{bj}(H - E)R_{ck}^+R_{dl}^+|\rangle\langle|R_{ck}H^1|\rangle\langle|R_{dl}H^1|\rangle/(\Delta E_{ai}\Delta E_{bj}\Delta E_{ck}\Delta E_{dl})$$
$$+ 8\langle|H^1R_{ai}^+|\rangle\langle|H^1R_{bj}^+|\rangle\langle|H^1R_{ck}|\rangle\langle|R_{ai}R_{bj}R_{ck}HR_{dl}^+|\rangle\langle|R_{dl}H^1|\rangle/(\Delta E_{ai}\Delta E_{bj}\Delta E_{ck}\Delta E_{dl}) - 6|T_{ai}^{(2)}|\Delta E_{ai}$$

Here, $T_{ai}^{(2)}$ are the transformed second-order parameters

[59] $$T_{ai}^{(2)} = (\Delta E_{ai})^{-1}[\langle|R_{ai}H^2|\rangle - 2\langle|R_{ai}(H^1 - E^1)R_{bj}^+|\rangle\langle|R_{bj}H^1|\rangle/\Delta E_{bj}$$
$$+ \{2\langle|R_{ai}R_{bj}HR_{ck}^+|\rangle + \langle|R_{ai}HR_{bj}^+R_{ck}^+|\rangle\}\langle|R_{bj}H^1|\rangle\langle|R_{ck}H^1|\rangle/(\Delta E_{bj}\Delta E_{ck})]$$

Equation [59] is also an exact equation.

Let us again consider the general formula for E^4 obtained by successive differentiations of eq. [1]:

[60] $$E^4 = \langle\Psi|H^4|\Psi\rangle + 8\langle\Psi^1|H^3|\Psi\rangle + 12\langle\Psi^2|H^2 - E^2|\Psi\rangle + 12\langle\Psi^1|H^2 - E^2|\Psi^1\rangle + 24\langle\Psi^2|H^1 - E^1|\Psi^1\rangle$$
$$+ 8\langle\Psi^3|H^1 - E^1|\Psi\rangle + 6\langle\Psi^2|H - E|\Psi^2\rangle + 8\langle\Psi^3|H - E|\Psi^1\rangle + 2\langle\Psi^4|H - E|\Psi\rangle$$

Taking account of eq. [53], we minimize E^4 with respect to $U_{ai}^{(3)}$. This yields

[61] $$\frac{\partial E^3}{\partial U_{ai}^{(3)}} = \langle|S_{ai}H^1|\rangle + [\langle|S_{ai}(H - E)S_{bj}^+|\rangle + \langle|S_{ai}S_{bj}H|\rangle]U_{bj}^{(1)} = 0$$

This is also satisfied if Ψ^1 is chosen optimal and the E^4 for the optimal Ψ^3 becomes identical to that in eq. [51]. Thus, the optimal Ψ^1 is sufficient to evaluate the derivatives of the energy up to fourth order. Analogous results for E^5, E^6, ... may be derived. The only difficulty is that these lower-order wavefunctions must be known exactly.

3. General formulae for the second, third, and fourth energy derivatives

In this section we shall give the general formulae for the second, third, and fourth energy derivatives based on the Hellmann–Feynman theorem. We will start with the energy expression given by eq. [1]. By differentiating eq. [1] with respect to a nuclear coordinate λ, we obtain the Hellmann–Feynman theorem

[62] $$E^\lambda = \langle\Psi|H^\lambda|\Psi\rangle$$

and the Hurley's condition

[63] $$\langle\Psi^\lambda|H - E|\Psi\rangle + \langle\Psi|H - E|\Psi^\lambda\rangle = 0$$

We assume the wavefunction is normalized to unity and have

[64] $$\langle\Psi^\lambda|\Psi\rangle + \langle\Psi|\Psi^\lambda\rangle = 0$$

Second energy derivatives can be obtained by differentiating eq. [62] with respect to μ

[65] $$E^{\lambda\mu} = \langle\Psi|H^{\lambda\mu}|\Psi\rangle + 2\langle\Psi^\lambda|H^\mu|\Psi\rangle$$

Here, assuming that all the functions are real, we used the relations

[66] $$\langle\Psi^\lambda|H^\mu|\Psi\rangle = \langle\Psi^\mu|H^\lambda|\Psi\rangle$$

The second derivatives require the first derivative wavefunctions Ψ^λ. By differentiating eq. [63] with respect to μ we have the first-order Hurley's condition

[67] $$\langle\Psi^\lambda|H^\mu|\Psi\rangle + \langle\Psi^\lambda|H - E|\Psi^\mu\rangle + \langle\Psi^{\lambda\mu}|H - E|\Psi\rangle = 0$$

As shown in the previous section, Ψ^λ may be expanded in terms of the singly excited configurations

[68] $$\Psi^\lambda = U_{ai}^\lambda S_{ai}^+|\rangle$$

Then $\Psi^{\lambda\mu}$ can be expressed as

[69] $$\Psi^{\lambda\mu} = [-|U_{ai}^\lambda|^2 + U_{ai}^{\lambda\mu}S_{ai}^+ + U_{ai}^\lambda U_{bj}^\mu S_{ai}^+S_{bj}^+]|\rangle$$

Equation [67] with $\lambda = \mu$ gives

[70] $$\langle|S_{ai}H^\lambda|\rangle + [\langle|S_{ai}(H - E)S_{bj}^+|\rangle + \langle|S_{ai}S_{bj}H|\rangle]U_{bj}^\lambda = 0$$

By solving a set of linear equations we can obtain Ψ^λ and then $E^{\lambda\mu}$,

[71] $$E^{\lambda\mu} = \langle|H^{\lambda\mu}|\rangle + 2U_{ai}^\lambda\langle|S_{ai}H^\mu|\rangle$$

The third energy derivatives are derived by further differentiating eq. [65] with respect to ν. It is not symmetrized with respect to λ, μ, ν. It can be recast in a symmetrical form. The third energy derivatives are given by

[72] $$E^{\lambda\mu\nu} = \langle\Psi|H^{\lambda\mu\nu}|\Psi\rangle + \frac{4}{3}P_1^{(3)}\langle\Psi^\lambda|H^{\mu\nu} - E^{\mu\nu}|\Psi\rangle$$
$$+ \frac{2}{3}P_2^{(3)}\langle\Psi^{\lambda\mu}|H^\nu - E^\nu|\Psi\rangle$$
$$+ \frac{2}{3}P_3^{(3)}\langle\Psi^\lambda|H^\mu - E^\mu|\Psi^\nu\rangle$$

The notation $P_1^{(3)}$, $P_2^{(3)}$, $P_3^{(3)}$ means the permutation of the superscripts

$$P_1^{(3)} = (\lambda)(\mu\nu) + (\mu)(\nu\lambda) + (\nu)(\lambda\mu)$$
$$P_2^{(3)} = (\lambda\mu)(\nu) + (\mu\nu)(\lambda) + (\nu\lambda)(\mu)$$
$$P_3^{(3)} = (\lambda)(\mu)(\nu) + (\mu)(\nu)(\lambda) + (\nu)(\lambda)(\mu)$$

This implies there are three forms from each $P^{(3)}$. The third energy derivatives require the second-order parameters, $U_{ai}^{\lambda\mu}$. The second-order Hurley's condition is given by

[73] $$\langle\Psi^{\lambda\mu\nu}|H - E|\Psi\rangle + \frac{2}{3}P_2^{(3)}\langle\Psi^{\lambda\mu}|H^\nu - E^\nu|\Psi\rangle$$
$$+ P_2^{(3)}\langle\Psi^{\lambda\mu}|H - E|\Psi^\nu\rangle + \frac{1}{3}P_1^{(3)}\langle\Psi^\lambda|H^{\mu\nu} - E^{\mu\nu}|\Psi\rangle$$
$$+ \frac{2}{3}P_3^{(3)}\langle\Psi^\lambda|H^\mu - E^\mu|\Psi^\nu\rangle = 0$$

For personal use only.

Using the relations

[74] $$U^{\lambda\mu\nu}_{ai,bj} = P^{(3)}_2 U^{\lambda\mu}_{ai} U^{\nu}_{bj}$$

we can express $U^{\lambda\mu}_{ai}$ in terms of U^{λ}_{ai} from eq. [73] as

[75] $$\frac{1}{3} P^{(3)}_2 U^{\lambda\mu}_{ai} \langle|S_{ai}H^{\nu}|\rangle = \frac{1}{3} P^{(3)}_1 U^{\lambda}_{ai}\langle|S_{ai}H^{\mu\nu}|\rangle + \frac{2}{3} P^{(3)}_3 U^{\lambda}_{ai}\langle|S_{ai}(H^{\mu} - E^{\mu})S^{+}_{bj}|\rangle U^{\nu}_{bj} + P^{(3)}_2 U^{\lambda}_{ai}\langle|S_{ai}S_{bj}HS^{+}_{ck}|\rangle U^{\mu}_{bj}U^{\nu}_{ck}$$

In the case of $\lambda = \mu = \nu$, eqs. [75] are reduced to

[76] $$U^{\lambda\lambda}_{ai}\langle|S^{+}_{ai}H^{\lambda}|\rangle = U^{\lambda}_{ai}[\langle|S_{ai}H^{\lambda\lambda}|\rangle + 2\langle|S_{ai}(H^{\lambda} - E^{\lambda})S^{+}_{bj}|\rangle U^{\lambda}_{bj} + \{2\langle|S_{ai}S_{bj}HS^{+}_{ck}|\rangle + \langle|S_{ai}HS^{+}_{bj}S^{+}_{ck}|\rangle\}U^{\lambda}_{bj}U^{\lambda}_{ck}]$$

Also we have the following relations by putting $\lambda = \nu$ in eq. [75]

[77] $$2U^{\lambda\mu}_{ai}\langle|S_{ai}H^{\lambda}|\rangle + U^{\lambda\lambda}_{ai}\langle|S_{ai}H^{\mu}|\rangle = 2U^{\lambda}_{ai}\langle|S_{ai}H^{\lambda\mu}|\rangle + U^{\mu}_{ai}\langle|S_{ai}H^{\lambda\lambda}|\rangle + 4U^{\lambda}_{ai}\langle|S_{ai}(H^{\lambda} - E^{\lambda})S^{+}_{bj}|\rangle U^{\mu}_{bj}$$
$$+ 2U^{\lambda}_{ai}\langle|S_{ai}(H^{\mu} - E^{\mu})S^{+}_{bj}|\rangle U^{\lambda}_{bj} + 3U^{\lambda}_{ai}\langle|S_{ai}S_{bj}HS^{+}_{ck}|\rangle U^{\lambda}_{bj}U^{\mu}_{ck} + 6U^{\lambda}_{ai}\langle|S_{ai}S_{bj}HS^{+}_{ck}|\rangle U^{\mu}_{bj}U^{\lambda}_{ck}$$

So once $U^{\lambda\lambda}_{ai}$ have been determined from eq. [75], the remaining $U^{\lambda\mu}_{ai}$ can be obtained from eq. [77]. Now the third energy derivatives given in eq. [72] can be rewritten in terms of the excitation operators as

[78] $$E^{\lambda\mu\nu} = \langle|H^{\lambda\mu\nu}|\rangle + 2P^{(3)}_1 U^{\lambda}_{ai}\langle|S_{ai}H^{\mu\nu}|\rangle + 2P^{(3)}_3 U^{\lambda}_{ai}U^{\mu}_{bj}\langle|S_{ai}(H^{\nu} - E^{\nu})S^{+}_{bj}|\rangle + 2P^{(3)}_2 U^{\lambda}_{ai}U^{\mu}_{bj}U^{\nu}_{ck}\langle|S_{ai}S_{bj}HS^{+}_{ck}|\rangle$$

Thus, we only need solutions of linear equations of eq. [70] to evaluate the third energy derivatives.

The fourth energy derivatives are given in a symmetrical expression by

[79] $$E^{\lambda\mu\nu\kappa} = \langle\Psi|H^{\lambda\mu\nu\kappa}|\Psi\rangle + \frac{3}{2} P^{(4)}_1\langle\Psi^{\lambda}|H^{\mu\nu\kappa}|\Psi\rangle + P^{(4)}_2[\langle\Psi^{\lambda\mu}|H^{\nu\kappa} - E^{\nu\kappa}|\Psi\rangle + \langle\Psi^{\lambda}|H^{\mu\nu} - E^{\mu\nu}|\Psi^{\kappa}\rangle$$
$$+ \frac{1}{2}\{\langle\Psi^{\lambda\mu}|H^{\nu} - E^{\nu}|\Psi^{\kappa}\rangle + \langle\Psi^{\lambda\mu}|H^{\kappa} - E^{\kappa}|\Psi^{\nu}\rangle\}] + \frac{1}{2} P^{(4)}_1\langle\Psi^{\lambda\mu\nu}|H^{\kappa} - E^{\kappa}|\Psi\rangle$$

with

$$P^{(4)}_1 = (\lambda)(\mu\nu\kappa) + (\mu)(\nu\kappa\lambda) + (\nu)(\kappa\lambda\mu) + (\kappa)(\lambda\mu\nu)$$
$$P^{(4)}_2 = (\lambda\mu)(\nu\kappa) + (\mu\nu)(\kappa\lambda) + (\nu\kappa)(\lambda\mu) + (\kappa\lambda)(\mu\nu) + (\mu\kappa)(\lambda\nu) + (\lambda\nu)(\mu\kappa)$$

The above expression includes third derivatives of the wavefunction, which requires knowledge of the singly excited configurations of $\Psi^{\lambda\mu\nu}$. The variational parameters $U^{\lambda\mu\nu}_{ai}$ of $\Psi^{\lambda\mu\nu}$ can be determined by the third-order Hurley's conditions obtained by differentiating eq. [73] and the relations

[80] $$U^{\lambda\mu\nu\kappa}_{ai,bj} S^{+}_{ai}S^{+}_{bj} = \left(P^{(4)}_3 U^{\lambda\mu\nu}_{ai}U^{\kappa}_{bj} + \frac{1}{2} P^{(4)}_2 U^{\lambda\mu}_{ai}U^{\nu\kappa}_{bj}\right)S^{+}_{ai}S^{+}_{bj}$$

with

$$P^{(4)}_3 = (\lambda\mu\nu)(\kappa) + (\mu\nu\kappa)(\lambda) + (\nu\kappa\lambda)(\mu) + (\kappa\lambda\mu)(\nu)$$

Then we have the following relations

[81] $$\frac{1}{4} P^{(4)}_3 U^{\lambda\mu\nu}_{ai}\langle|S_{ai}H^{\kappa}|\rangle = \frac{1}{4} P^{(4)}_1 U^{\lambda}_{ai}\langle|S_{ai}H^{\mu\nu\kappa}|\rangle + \frac{1}{4} P^{(4)}_2 U^{\lambda}_{ai}U^{\mu}_{bj}\langle|S_{ai}(H^{\nu\kappa} - E^{\nu\kappa})S^{+}_{bj}|\rangle + P^{(4)}_3 U^{\lambda}_{ai}U^{\mu}_{bj}U^{\nu}_{ck}U^{\kappa}_{dl}$$
$$\times\left[\frac{9}{4}\langle|S_{ai}S_{bj}(H - E)S^{+}_{ck}S^{+}_{dl}|\rangle + 2\langle|S_{ai}S_{bj}S_{ck}HS^{+}_{dl}|\rangle\right] + \frac{1}{4} P^{(4)}_2[U^{\lambda}_{ai}\langle|S_{ai}H^{\mu}|\rangle U^{\nu\kappa} + U^{\mu}_{ai}\langle|S_{ai}H^{\lambda}|\rangle U^{\nu\kappa}]$$
$$+ \frac{1}{2} P^{(4)}_2 U^{\lambda\mu}_{ai}\Bigg[\langle|S_{ai}H^{\nu\kappa}|\rangle + \frac{3}{2}\{\langle|S_{ai}(H^{\nu} - E^{\nu})S^{+}_{bj}|\rangle U^{\kappa}_{bj} + \langle|S_{ai}(H^{\kappa} - E^{\kappa})S^{+}_{bj}|\rangle U^{\nu}_{bj}\} + \{\langle|S_{ai}(H - E)S^{+}_{bj}|\rangle$$
$$+ \langle|S_{ai}S_{bj}H|\rangle\}U^{\nu\kappa}_{bj} + 2\{2\langle|S_{ai}S_{bj}HS^{+}_{ck}|\rangle + \langle|S_{ai}HS^{+}_{bj}S^{+}_{ck}|\rangle\}U^{\nu}_{bj}U^{\kappa}_{ck}\Bigg]$$

In the case of $\lambda = \mu = \nu = \kappa$, the above equations are reduced to eq. [54]. Once $U^{\lambda\lambda\lambda}_{ai}$ have been determined, $U^{\lambda\lambda\mu}_{ai}$ can be obtained by putting $\lambda = \nu = \kappa$ in eq. [81]. Finally we can determine the remaining $U^{\lambda\mu\nu}_{ai}$ using the known $U^{\lambda\lambda\lambda}_{ai}$ and $U^{\lambda\lambda\mu}_{ai}$. Now the fourth derivatives can be evaluated in terms of known quantities. Although the equations are rather complicated, there are no algebraic problems. Finally, the fourth energy derivatives can be written as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

$$[82]\quad E^{\lambda\mu\nu\kappa} = \langle|H^{\lambda\mu\nu\kappa}|\rangle + 2P_1^{(4)}U_{ai}^{\lambda}\langle|S_{ai}H^{\mu\nu\kappa}|\rangle + 2P_2^{(4)}U_{ai}^{\lambda}U_{bj}^{\mu}\langle|S_{ai}(H^{\nu\kappa} - E^{\nu\kappa})S_{bj}^{+}|\rangle + 6\,P_3^{(4)}U_{ai}^{\lambda}U_{bj}^{\mu}U_{ck}^{\nu}\langle|S_{ai}S_{bj}H^{\kappa}S_{ck}^{+}|\rangle$$
$$+ 8\,U_{ai}^{\lambda}U_{bj}^{\mu}U_{ck}^{\nu}U_{dl}^{\kappa}\langle|S_{ai}S_{bj}S_{ck}HS_{dl}^{+}|\rangle + 6\,U_{ai}^{\lambda}U_{bj}^{\mu}U_{ck}^{\nu}U_{dl}^{\kappa}\langle|S_{ai}S_{bj}(H - E)S_{ck}^{+}S_{dl}^{+}|\rangle$$
$$+ P_2^{(4)}U_{ai}^{\lambda\mu}U_{bj}^{\nu\kappa}\{\langle|S_{ai}(H - E)S_{bj}^{+}|\rangle + \langle|S_{ai}S_{bj}H|\rangle\} + 2\,P_2^{(4)}U_{ai}^{\lambda\mu}[\{\langle|S_{ai}H|\rangle + \langle|S_{ai}(H^{\nu} - E^{\nu})S_{bj}^{+}|\rangle U_{bj}^{\kappa}$$
$$+ \langle|S_{ai}(H^{\kappa} - E^{\kappa})S_{bj}^{+}|\rangle U_{bj}^{\nu} + \{2\langle|S_{ai}S_{bj}HS_{ck}^{+}|\rangle + \langle|S_{ai}HS_{bj}^{+}S_{ck}^{+}|\rangle\}U_{bj}^{\nu}U_{ck}^{\kappa}]$$

Of course we can express $E^{\lambda\mu\nu\kappa}$ in terms of the first-order parameters by eliminating $U_{ai}^{\lambda\mu}$ with the help of eq. [77].

4. Discussion

We have derived equations that provide the second, third, and fourth derivatives of the energy of a molecule based on the Hellmann–Feynman theorem. Hurley's condition can be used to obtain approximations to the first-order wavefunction, from which the second, third, and fourth energies can be obtained.

The present theory is correct if the basis set is complete or basis functions are independent of the perturbation. Thus the derived formulae can be applicable to any real one-electron perturbation such as electric properties if the basis functions are independent of the perturbation. It is easy to modify the formulae for the purely imaginary perturbed wavefunctions in the case of magnetic properties. If the spin-dependent perturbations are considered, the singlet excitation operators defined in eq. [16] should be replaced by the triplet excitation operators

$$[83]\quad S_{pq}^{+} = (a_{p\alpha}^{+}a_{q\alpha} - a_{p\beta}^{+}a_{q\beta})/\sqrt{2}$$

We have also derived these higher derivatives in a form similar to the sum-over-state perturbation method. These expressions will help us to understand the physical meaning associated with each energy derivative.

Let us now consider the derivatives of the energy with respect to nuclear coordinates in the SCF approximation. The molecular orbitals are defined in terms of the finite basis functions $\chi_1 \cdots \chi_m$

$$[84]\quad \varphi_i = \chi_\alpha C_{\alpha i} = \mathbf{X}\mathbf{C}_i$$

The $\mathbf{X}$ and $\mathbf{C}_i$ are the row and column vectors of χ_α and $C_{\alpha i}$, respectively. The derivative of φ_i with respect to λ is given by

$$[85]\quad \varphi_i^1 = \mathbf{X}^1\mathbf{C}_i + \mathbf{X}\mathbf{C}_i^1$$

in a matrix representation. The first term on the right-hand side of eq. [85] arises from the fact that the basis functions will generally be defined in such a way that they move with the nucleus. The second term arises from the fact that the coefficients may also depend on λ. Hurley's condition is satisfied if

$$[86a]\quad \mathbf{F}\mathbf{C}_i = \varepsilon_i\mathbf{S}\mathbf{C}_i$$

and

$$[86b]\quad \sum_i \mathbf{C}_i^{\ddagger}(\mathbf{F}_i^{(1)} - \varepsilon_i\mathbf{S}^{(1)})\mathbf{C}_i = \sum_i \Delta_i = 0$$

where

$$(\mathbf{F}^{(1)})_{\alpha\beta} = \langle\chi_\alpha^1|F|\chi_\beta\rangle, \qquad (\mathbf{S}^{(1)})_{\alpha\beta} = \langle\chi_\alpha^1|\chi_\beta\rangle$$

Equations [86*a*] are the Fock equations and hold for any SCF orbitals. However, eqs. [86*b*] are not fulfilled in general. Thus the Hellmann–Feynman theorem is not necessarily satisfied for SCF wavefunctions with finite basis set.

There are two approaches to obtaining the wavefunction obeying the Hellmann–Feynman theorem. One way is to employ floating functions (8). In floating functions the individual orbitals are not fixed a priori on the nuclei. Rather, the centers are allowed to float, the variational method then determining the optimal centering. Floating functions obey the Hellmann–Feynman theorem and therefore both eqs. [86*a*] and [86*b*] are satisfied. However, it does not mean that the basis functions are independent of the perturbation in the first order. The fact that a wavefunction constructed from floating functions satisfies the Hellmann–Feynman theorem is only due to the fact that the energy is stationary with respect to variation of the centers of the floating functions. If each Δ_i in eq. [86*b*] is forced to be zero, then the enlarged basis functions composed of $\boldsymbol{X}$ and $\boldsymbol{X}^1$ become independent of the nuclear coordinates.

Alternatively, one may leave the basis set fixed at the nuclei but basis sets $\boldsymbol{X} = \{\chi, \chi^1, \chi^2, \ldots\}$ are employed, where χ^n denotes the nth derivative of χ. It is necessary to include the derivative basis functions for every basis function. Then eq. [86*b*] is fulfilled and the SCF wavefunction obeys the Hellmann–Feynman theorem (18). If these basis sets are used, the space spanned by derivatives of the basis functions is included in the original basis function space. Thus we can expand the derivatives of the basis functions $\boldsymbol{X}^1$ in terms of the original basis functions. However, from a practical point of view, we must truncate χ^n at some low order.

In both cases we should introduce the approximation to apply the present theory. Practical applications are now being investigated in order to check a theoretical and numerical justification.

Universality among topological properties of electron density associated with the hydrogen–hydrogen nonbonding interactions

JERZY CIOSLOWSKI[1] AND STACEY T. MIXON

Department of Chemistry and Supercomputer Computations Research Institute, Florida State University, Tallahassee, FL 32306-3006, U.S.A.

Received July 29, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

JERZY CIOSLOWSKI and STACEY T. MIXON. Can. J. Chem. **70**, 443 (1992).

Nonbonding repulsive interactions between hydrogen atoms, separated by less than ca. 2.18 Å and connected to two carbon atoms in the 1,4-positions, are associated with additional pairs of bond and ring critical points in the electron density, $\rho(\boldsymbol{r})$, and the corresponding attractor interaction lines. Such topological features of $\rho(\boldsymbol{r})$ are present in some planar benzenoid hydrocarbons, including chrysene, benzanthracene, and phenanthrene. They also appear in conformations of the biphenyl molecule with the torsional angles between the benzene rings lying within the range of 0°–27°. Properties such as the bond point – ring point distance, the difference in $\rho(\boldsymbol{r})$ at the bond point and the ring point, and the bond ellipticity are found to follow *universal* functional dependencies with the hydrogen–hydrogen distance as the controlling variable. The same is true about the corresponding difference in the second derivatives of $\rho(\boldsymbol{r})$ in the direction of the vector connecting the bond and ring points.

Key words: atoms in molecules, electron density, attractor interaction lines, steric repulsions.

JERZY CIOSLOWSKI et STACEY T. MIXON. Can. J. Chem. **70**, 443 (1992).

Les interactions répulsives non-liées entre des atomes d'hydrogène séparés par moins de 2.18 Å et liés à deux atomes de carbone situés dans les positions 1 et 4 sont associées aux paires de liaisons additionnelles, aux points critiques de cycles dans la densité électronique, $\rho(\boldsymbol{r})$, et aux lignes d'interactions attractives correspondantes. Des telles caractéristiques topologiques du $\rho(\boldsymbol{r})$ sont aussi présentes dans les hydrocarbures benzénoïdes plans, y compris dans le chrysène, le benzanthracène et le phénanthrène. Elles apparaissent aussi dans les conformations de la molécule du biphényle alors que les angles de torsion entre les noyaux benzéniques se situent entre 0° et 27°. On a trouvé que les propriétés telles que la distance entre le point de la liaison et le point du cycle, la différence dans les $\rho(\boldsymbol{r})$ au point de liaison et au point du cycle et l'ellipticité suivent des relations fonctionnelles *universelles* dans lesquelles la distance hydrogène–hydrogène est la variable qui agit comme contrôle. Ceci est aussi vrai pour la différence correspondante dans les deuxièmes dérivées de $\rho(\boldsymbol{r})$ dans la direction du vecteur qui relie les points de la liaison et du cycle.

Mots clés : atomes dans les molécules, densité électronique, lignes d'interactions attractives, répulsions stériques.

Introduction

It is well known that analysis of the topological properties of the electron density, $\rho(\boldsymbol{r})$, provides a comprehensive description of electronic structures of chemical systems (1). Identification of the critical (extremal or stationary) points in Cartesian space, at which the gradient of electron density disappears

$$[1] \qquad \nabla\rho(\boldsymbol{r}_{crit}) = 0$$

constitutes the first step in such an analysis. Depending on the number of negative eigenvalues of the corresponding Hessian matrix,

$$[2] \qquad h_{pq} = \frac{\partial}{\partial p}\frac{\partial}{\partial q}\rho(\boldsymbol{r})\bigg|_{\boldsymbol{r}=\boldsymbol{r}_{crit}}, \quad p, q = x, y, z$$

the critical points are classified as belonging to one of the four categories: attractors, bond points, ring points, or cage points. The unions of two gradient paths (the lines of steepest ascent in $\rho(\boldsymbol{r})$) originating at the bond points and terminating at the corresponding attractors are known as the attractor interaction lines.

The second step of the topological analysis is based upon the *empirical* observation that, in most chemical systems, the only attractors are nuclei. The existence of a bond point between a pair of attractors was originally thought to be the necessary and sufficient condition for the existence of a chemical bond between the nuclei [2], justifying the name bond paths for the attractor interaction lines in chemical systems at equilibrium geometries. Indeed, in his comprehensive monograph on the topological theory of atoms in molecules [1], Bader states that "the presence of a bond path linking a pair of nuclei implies that the corresponding atoms are bonded to one another" (ref. 1, p. 33). Although such an identification is supported by the "strong" bonds, which are characterized by large values of the corresponding $\rho(\boldsymbol{r}_{crit})$, the recent findings about "weak" bonds (3) cast doubts about its validity.

The unexpected bond points, found in several chemical systems, fall into two categories (3). In charge-transfer complexes, ionic pairs, and other systems with weak interactions, the Hopf–Poincaré theorem (4) dictates the presence of at least one bond point corresponding to the bond path linking the interacting moieties. The resulting paths can usually be interpreted as those describing delocalized bonding interactions, although the coordination numbers of some atoms involved in such bonding turn out to be unexpectedly high (such as 30 for the Ne atom in the $C_{60} \cdot Ne$ complex (3, 5). The additional bond atoms are characterized by low values of the electron density and large ellipticities with the major axes pointing in a direction (almost) *parallel* to the respective ring surfaces, if any ring points are present. One should note that these bond points are persistent in the sense

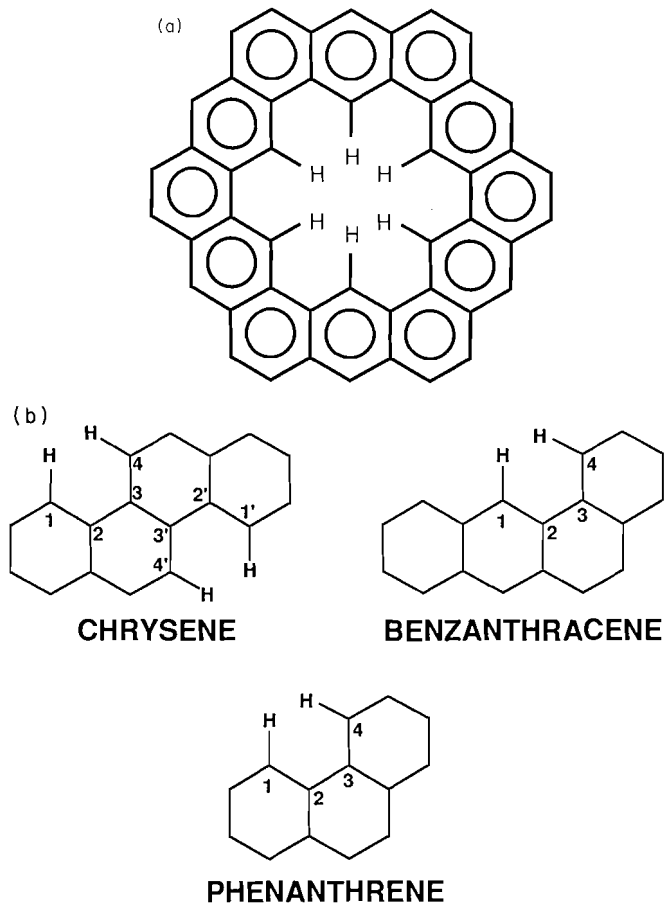

FIG. 1. (*a*) Molecular skeleton of the kekulene molecule. The sterically interacting hydrogen atoms are displayed. (*b*) Molecular skeletons of the chrysene, benzanthracene, and phenanthrene molecules. The sterically interacting hydrogen atoms, as well as the corresponding tetrads of carbon atoms are displayed.

that they do not vanish even at very large separations between the moieties. Typical examples of systems exhibiting such topological features of $\rho(\boldsymbol{r})$ are (3), to name a few, the benzene–tetracyanoethylene complex, the $C(NH_2)_3^+$ $C(CN)_3^-$ ionic pair, and the $C_{60} \cdot Ne$ endohedral complex (5).

The second category encompasses molecules and ions in which the presence of additional bond points indicates significant *nonbonding repulsive* interactions. The case of the kekulene molecule (Fig. 1*a*) is a typical example of such a situation (6). In this molecule, the six inner hydrogen atoms, which are separated by ca. 1.85 Å, are linked by highly curved interaction lines forming an inner hexagonal ring. Another example is provided by the $C(NO_2)_3^-$ ion, in which the steric interactions between the oxygen atoms give rise to three unexpected pairs of bond and ring points (7). These bond points again correspond to low electron densities; however, their ellipticities are much smaller than those of the bond points belonging to the aforementioned first category. More importantly, the major axes of their ellipticities lie in the directions *perpendicular* to the ring surfaces (3).

The existence of the second class of weak bonds hints that one should abandon the current interpretation of interaction lines in favor of a new one stating that interaction lines delineate major (not necessarily bonding!) interactions present within a given chemical system. Such a change would make it consistent with the notion that the molecular graph "isolates the pairwise interactions present in an assembly of atoms which dominate and characterize the properties of the system" (ref. 1, p. 33). The term bond path should be reserved for the interaction lines describing ordinary strong bonds.

Thus far, the major emphasis of research on the properties of $\rho(\boldsymbol{r})$ reported in the chemical literature has been directed toward bond paths (1, 2, 8). Therefore, in this paper we attempt to elaborate on the properties of interaction lines describing steric repulsive interactions. The particular example of the interaction lines linking the hydrogens connected to 1,4-carbon atoms is used for this purpose.

Topological features of electron density associated with interactions between hydrogens connected to 1,4-carbon atoms

In the following discussion, the characteristics of electron densities obtained from the HF/6-31G** calculations, pertinent to molecular geometries optimized at the same level, are used. Taking into account the results of numerical experiments with different theoretical levels, we do not expect the described topological properties of $\rho(\boldsymbol{r})$ to change qualitatively upon replacing the present wave functions by more accurate ones. We also believe that the corresponding quantitative changes should be rather small.

As mentioned in the introduction, in the kekulene molecule, the unique arrangement of six hydrogen atoms inside the inner molecular cavity leads to a quite unusual pattern of six highly curved H–H interaction lines forming a hexagonal ring. However, isolated H–H interaction lines indicating significant steric repulsions between pairs of hydrogen atoms occur in many other systems. In particular, spatial arrangements of two hydrogen atoms that result in short H–H distances are present in molecules in which the two hydrogens in question are bonded to a pair of 1,4-carbon atoms in the *Z*(*cis*) configuration. Such a bonding situation exists, for example, in all benzenoid hydrocarbons possessing the phenanthrene fragment.

Analysis of the topological properties of $\rho(\boldsymbol{r})$ in three such hydrocarbons with planar geometries, namely chrysene, benzanthracene, and phenanthrene (Fig. 1*b*), confirms these expectations. In benzanthracene and phenanthrene, one finds, in addition to "ordinary" critical points, a single bond point – ring point pair originating from the H–H repulsive interactions. In chrysene, two such pairs exist owing to molecular symmetry. In all three cases, the respective electron densities at the bond and ring points (ρ_B and ρ_R, respectively, Table 1) assume low values. The same is true about the corresponding Laplacians, $\nabla^2\rho_B$ and $\nabla^2\rho_R$. In accordance with our previous observations (3), the bond ellipticities (ε) are quite small, with the major axes directed perpendicularly to the vector connecting the corresponding bond and ring points. The H–H interaction lines are highly curved, as reflected in the large differences (Δl) between their lengths and the H–H internuclear separations (R_{HH}). The curvatures generally increase with increasing R_{HH}, whereas the bond point – ring point distances (z_{BR}) follow the opposite trend.

To gain a deeper insight into the properties of these critical points and the corresponding interaction lines, one needs a simple molecular system in which the H–H distance can be continuously varied and the accompanying variations in

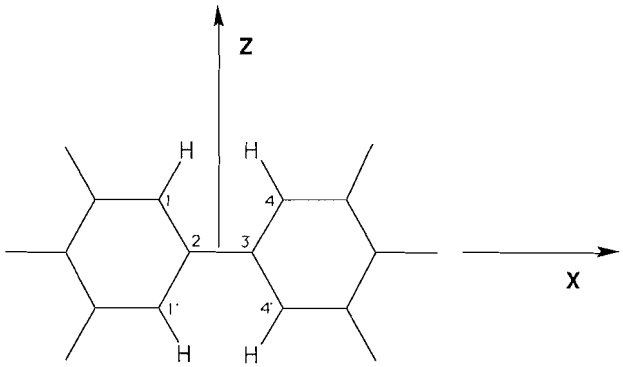

FIG. 2. The molecular skeleton of the biphenyl molecule with the sterically interacting hydrogen atoms displayed. The torsional angle (φ) is defined as the dihedral angle between the atoms 1–2–3–4 (or equivalently 1–2–3–4'). Note the coordinate axes.

the topological properties of the electron density can be monitored and, even more importantly, analyzed. The biphenyl molecule, with a variable torsional angle between the benzene rings and all other geometrical parameters fully optimized, affords such a system.

The fold catastrophe in the electron density of the biphenyl molecule

Optimization of the molecular geometry of biphenyl (Fig. 2) at the HF/6-31G** level yields the value of 45.5° for the torsional angle (φ). This is in excellent agreement with both the experimental data (φ = 44.4° ± 1.2°) (9) and previous *ab initio* calculations (HF/6-31G: φ = 44.7°) (10). Although the biphenyl molecule possesses two pairs of hydrogen atoms linked to (*Z*)-1,4-carbon atoms, at the equilibrium geometry the H–H distances are large enough to prevent the appearance of the H–H interaction lines. On the other hand, in the planar structure (φ = 0°), which is a transition state separating two identical minima, two H–H interaction lines with the corresponding four (two bond and two ring) critical points located along the *z* axis (Fig. 2) are present. These interaction lines persist up to the critical torsional angle φ_0 = 27.2°. At that geometry, in which the H–H distance equals R_0 = 2.178 Å (4.118 au, Fig. 3), the bond and ring critical points merge, annihilating each other through a fold catastrophe (4, 11).

The above observations are nicely illustrated by Figs. 4–6, in which the dependencies of the positions of the critical points, the corresponding electron densities, and the Laplacians on the torsional angle displayed. As φ_0 is approached, the properties of the bond and ring points become indistinguishable. The data displayed in these and other figures are based upon the HF/6-31G** calculations car-

ried out for the following values of φ: 0.0°, 5.0°, 10.0°, 15.0°, 20.0°, 21.0°, 22.0°, 23.0°, 24.0°, 25.0°, 26.0°, 26.8°, 26.9°, 27.0°, 27.1°, and 27.2°.

The calculated properties of $\rho(r)$ can be accounted for with the help of catastrophe theory (1, 4, 11, 12). In the particular case of the biphenyl molecule, the one-dimensional control and behavior spaces (11, 12) consist of the H–H distance (R_{HH}) and the distance along the z axis (z, Fig. 2), respectively. In the vicinity of the catastrophe point, the electron density is described by the unfolding (11)

$$[3] \quad \rho(R_{HH},z) = A\,(z - z_0)^3 + B(R_{HH})\,(z - z_0) + C$$

where $A < 0$, and $B(R_{HH})$ is positive for R_{HH} smaller than the critical H–H distance (R_0), while $B(R_{HH}) < 0$ for $R_{HH} > R_0$. For $R_{HH} < R_0$, the first derivative

$$[4] \quad \frac{\partial}{\partial z}\rho(R_{HH},z) = 3A\,(z - z_0)^2 + B(R_{HH})$$

has two zeros corresponding to one bond and one ring point, yielding

$$[5] \quad z_{BR}(R_{HH}) = z_B(R_{HH}) - z_R(R_{HH}) = 2\left[\frac{-B(R_{HH})}{3A}\right]^{1/2}$$

for the bond point – ring point distance. The corresponding difference in the electron densities equals

$$[6] \quad \begin{aligned}\Delta\rho(R_{HH}) &= \rho_B(R_{HH}) - \rho_R(R_{HH}) \\ &= \rho(R_{HH},z_B) - \rho(R_{HH},z_R) \\ &= \left(\frac{4}{3}\right) B(R_{HH}) \left[\frac{-B(R_{HH})}{3A}\right]^{1/2}\end{aligned}$$

Finally, for the difference between the second derivatives of $\rho(r)$ *along the direction of the vector connecting the corresponding bond and ring points*, one obtains

$$[7] \quad \begin{aligned}\Delta h(R_{HH}) &= h_B(R_{HH}) - h_R(R_{HH}) \\ &= \frac{\partial^2}{\partial z^2}\rho(R_{HH},z_B) - \frac{\partial^2}{\partial z^2}\rho(R_{HH},z_R) \\ &= 6A\left[\frac{-B(R_{HH})}{3A}\right]^{1/2}\end{aligned}$$

Since, in the vicinity of R_0, $B(R_{HH})$ changes linearly with R_{HH}, one expects the following critical behavior:

$$[8a] \quad z_{BR}(R_{HH}) = k_z\,(R_0 - R_{HH})^{1/2}$$

$$[8b] \quad \Delta\rho(R_{HH}) = k_\rho\,(R_0 - R_{HH})^{3/2}$$

$$[8c] \quad \Delta h(R_{HH}) = k_h\,(R_0 - R_{HH})^{1/2}$$

as R_{HH} approaches R_0 from below. An asymptotic analogous to [8*c*] is also expected for the difference between the electron density Laplacians,

$$[8d] \quad \Delta(\nabla^2\rho) = \nabla^2\rho_B - \nabla^2\rho_R$$

Plots of the appropriate powers of z_{BR}, $\Delta\rho$, Δh, and $\bar{\Delta}(\nabla^2\rho)$ vs. R_{HH} (Fig. 7–10) indeed reveal such behavior. However, the domains of validity of eqs. [8*a*] and [8*b*] are much broader than expected. Thus, the plot of z_{BR}^2 vs. R_{HH} (Fig. 7) shows a very small deviation from linearity throughout the entire range of R_{HH}. The same is true, although to a lesser extent, about the plot of $\Delta\rho^{2/3}$ vs. R_{HH} (Fig. 8). On the other hand, the relationships between Δh^2 and R_{HH} (Fig. 9) and between $\Delta(\nabla^2\rho)$ and R_{HH} (Fig. 10) are markedly nonlinear for larger differences between R_0 and R_{HH}.

An equation relating the values of z_{BR}, $\Delta\rho$, and Δh can be derived by combining eqs. [8*a*]–[8*c*]. The characteristic ratio is given by

$$[9] \quad \kappa = -\Delta h\,\frac{z_{BR}^2}{\Delta\rho} = 12.$$

This relationship is satisfied to a high degree of accuracy for the entire range of R_{HH}, as the plot of $-\Delta h\ z_{BR}^2$ vs. $\Delta\rho$

(Fig. 11) is indistinguishable from a straight line with a slope of 12. The singularity of the bond ellipticity (ϵ) (1, 2, 8) at $R_{HH} = R_0$ (Fig. 12) is also easily understood from eq. [8*c*]: As the critical value of R_{HH} is approached, one of the eigenvalues of the Hessian matrix becomes vanishingly small resulting in the singularity of ϵ. On the other hand, we are unable to explain the observed dependence of Δl on R_{HH} (Fig. 13).

Universality among the topological properties of electron density associated with the hydrogen–hydrogen nonbonding interactions

Inspection of Figs. 7–13 reveals that some of the aforementioned properties follow *universal* functional dependencies on the distance between the hydrogen atoms involved in the repulsive interactions. Such universality, which is exhibited by the values of z_{BR} (Fig. 7), $\Delta\rho$ (Fig. 8), Δh (Fig. 9), κ (Fig. 11), and ϵ (Fig. 12) is quite unexpected. One should note that, in planar benezoid hydrocarbons, the four carbon atoms and the two hydrogen atoms linked by a six-membered ring of interaction lines are coplanar. On the other hand, in the twisted biphenyl molecule, this coplanarity is nonexistent. This difference in the arrangement of the relevant nuclei is the probable cause of deviations present in the plots of $\Delta(\nabla^2\rho)$ vs. R_{HH} (Fig. 10) and Δl vs. R_{HH} (Fig. 13). Indeed, inspection of the eigenvalues of the Hessian matrix

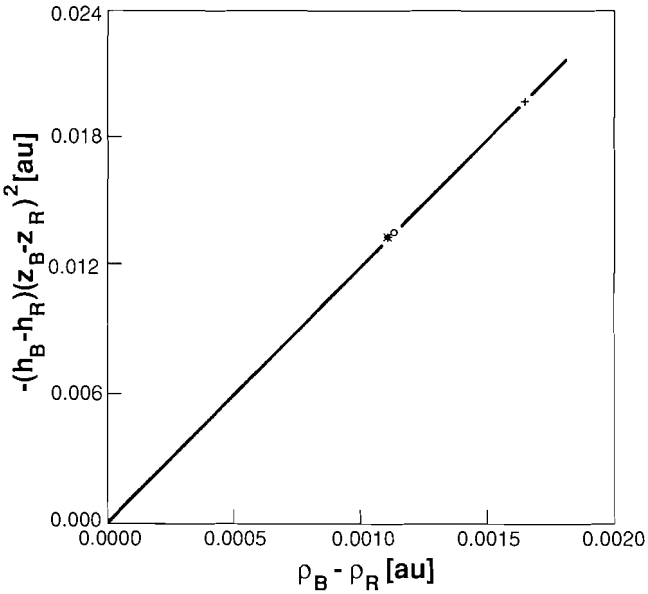

FIG. 11. Constancy of the characteristic ratio. +, chrysene; *, benzanthracene; o, phenanthrene.

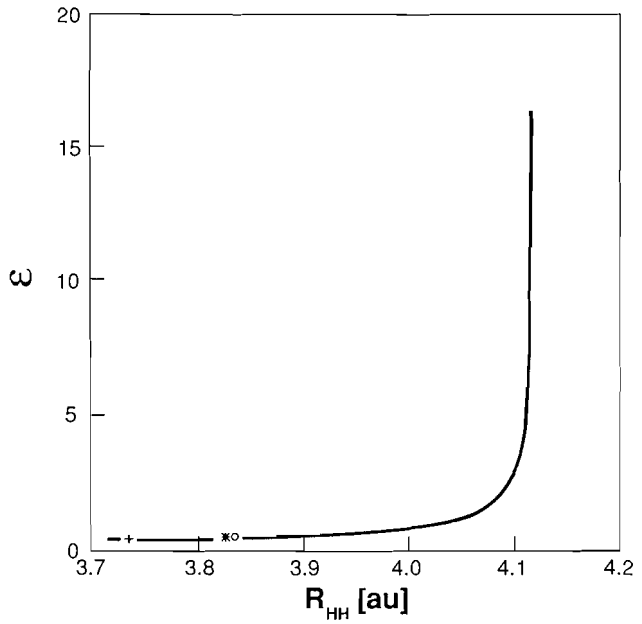

FIG. 12. The bond ellipticity vs. the torsional angle. +, chrysene; *, benzanthracene; o, phenanthrene.

makes it possible to conclude that most of the observed deviations in $\Delta(\nabla^2\rho)$ come from the component of $\nabla^2\rho_B$ perpendicular to the interaction line.

The remarkable accuracy to which the universal relationships are satisfied is particularly apparent from the values of the characteristic ratio (κ), eq. [9], computed for the benzenoid hydrocarbons. The values listed in Table 2 deviate from 12 by less than 0.5%! The projected Hessians, used in eq. [9] and in Fig. 9, are calculated by contracting the Hessian matrices, eq. [2], with the components of the vector (r_{BR}) connecting the respective bond and ring points and applying the appropriate normalization; z_{BR} is the length of r_{BR}.

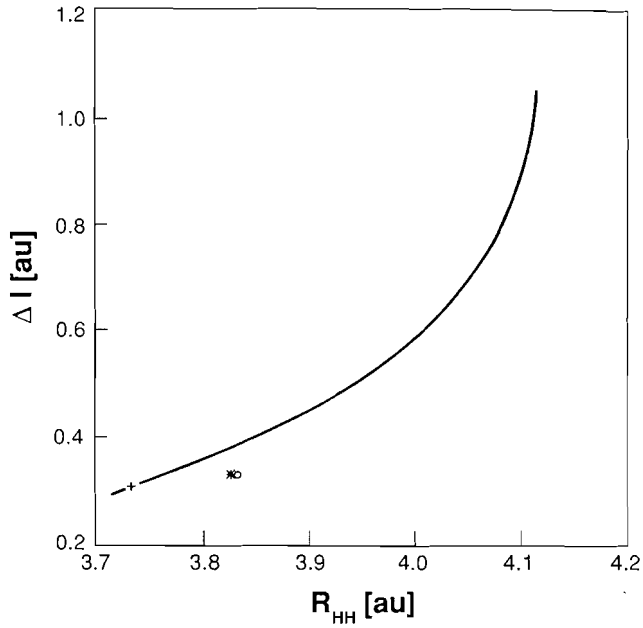

FIG. 13. The difference between the interaction line length and the H—H distance vs. the torsional angle. +, chrysene, *, benzanthracene; o, phenanthrene.

TABLE 2. Differences in the electron densities and the corresponding projected Hessians at the H—H bond and ring points in benzenoid hydrocarbons

Molecule	$\Delta\rho$ (au)	Δh (au)	κ (au)
Chrysene	0.001 654	−0.023 63	11.94
Benzanthracene	0.001 111	−0.020 02	12.00
Phenanthrene	0.001 127	−0.019 79	11.98

Finally, one should note that the low values of bond ellipticities found in the aforementioned benzenoid hydrocarbons (including kekulene, see Table 1 and ref. 6) are a consequence of the universality of ϵ, as displayed in Fig. 12, and the fact that the relevant H–H distances are quite small in these molecules.

Conclusions

The calculated properties of $\rho(r)$ in some benzenoid systems lead us to the following conclusions:

1. The existence of an attractor interaction line between a pair of nuclei does not necessarily imply the presence of bonding between those nuclei. Instead, the attractor interaction lines should be interpreted as those delineating major (either bonding or nonbonding, attractive or repulsive) interactions in a given molecular system.

2. In organic molecules in which two hydrogen atoms attached to carbon atoms separated by three carbon—carbon bonds (1,4-carbon atoms) are present, there is a possibility of the existence of H–H interaction lines. If present, such interaction lines result in an additional pair of bond and ring critical points.

3. The hydrogen–hydrogen distance (R_{HH}) appears to be the controlling variable that not only determines whether the

H–H interaction lines are present, but also controls the values of several properties of $\rho(r)$ pertinent to the critical points associated with such interaction lines.

4. One should expect the H–H interaction lines to be present if R_{HH} is less than ca. 2.18 Å. Therefore, the H–H interaction lines are present in the kekulene, chrysene, benzanthracene, and phenanthrene molecules, but are absent in the biphenyl molecule at its equilibrium geometry. For the same reason, the molecular graph of the planar transition state of (*Z*)-butadiene is devoid of the H–H interaction lines, because the relevant H–H distance equals 2.335 Å (at the HF/6-31G** level). The value of 2.18 Å can be therefore regarded as the contact interatomic separation (CIS) (13) for the H–H pair. This should be compared with double the van der Waals radius of the hydrogen atom, which equals ca. 2.4 Å (14). The values of CIS for other pairs of atoms or functional groups can be defined in a similar fashion (13).

5. The CIS values are expected to depend not only on the pair of atoms involved, but also on the manner in which they are bonded. For this reason, the H–H interaction lines are absent in $C_{60}H_{60}$, although the H–H separation (2.0 Å at the HF/6-31G** level (15) in this molecule is less than CIS for the pair of hydrogens bonded to 1,4-carbon atoms. However, in the $C_{60}H_{60}$ molecule, the two hydrogen atoms in question are bonded in a highly unusual manner to two adjacent carbon atoms through two almost parallel bonds.

We believe that the present work will contribute to a better understanding of the attractor interaction lines. The interaction lines associated with nonbonding steric repulsions certainly deserve no less attention than the more common bond paths.

The relationship between the rate–equilibrium coefficient α and transition state properties: a second-order Møller–Plesset perturbation study of S_N2 reactions

ZHENG SHI AND RUSSELL J. BOYD
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received January 25, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

ZHENG SHI and RUSSELL J. BOYD. Can. J. Chem. **70**, 450 (1992).

Ab initio calculations including electron correlation are used to study rate–equilibrium relationships in gas-phase S_N2 reactions. The difference between the "intrinsic" α and "group" α is emphasized. In general, the "group" α cannot be used as a measure of the transition state structure. The relationships between the "intrinsic" α and other properties, such as reaction endothermicity, geometry change, and the charge transfer, are discussed. A geometry change parameter R_α, defined by analogy with the definition of the "intrinsic" α, is shown to be linearly related to the "intrinsic" α. The charge transfer at the transition state is related not only to energy changes but also to the electronegativities of the entering nucleophile and leaving group in the product and reactant, respectively, and to the electronic structures at the transition state. Thus, the charge transfer parameter Q_α, unlike the "intrinsic" α and R_α, is affected by the electronegativities of the groups involved in the reaction. The systems studied are S_N2 reactions of the type $N^- + CH_3X \rightarrow CH_3N + X^-$, where X = H, NH_2, OH, OOH, F, CCH, *C*N, *N*C, PH_2, SH, and Cl when N = H, and where X = H, NH_2, OH, F, *C*N, *N*C, PH_2, SH, and Cl when N = F.

Key words: S_N2 reactions, rate–equilibrium relationships, transition state properties.

ZHENG SHI et RUSSELL J. BOYD. Can. J. Chem. **70**, 450 (1992).

On a utilisé les calculs *ab initio* incluant la corrélation d'électrons pour étudier la relation existant entre la vitesse et l'équilibre des réactions S_N2. On a mis l'accent sur la relation entre le α «intrinsèque» et le groupe α. En général on ne peut pas utiliser le groupe α comme mesure de la structure de l'état de transition. On discute de la relation entre le α «intrinsèque» et les autres propriétés tels le caractère endothermique de la réaction, le changement de géométrie et le transfert de charge. On démontre que le paramètre de changement de géométrie R_α, défini par analogie avec la définition de α «intrinsèque», est relié de façon linéaire au α «intrinsèque». Le transfert de charge au niveau de l'état de transition est relié non seulement aux changements d'énergie mais également à l'électronégativité du nucléophile attaquant et du groupe labile dans le produit et dans le réactif respectivement et à la structure électronique de l'état de transition. Ainsi, le paramètre de transfert de charge Q_α, contrairement au α «intrinsèque» et au R_α, est affecté par l'électronégativité des groupes impliqués dans la réaction. Les systèmes étudiés sont des réactions S_N2 du type $N^- + CH_3X \rightarrow CH_3N + X^-$ où X = H, NH_2, OH, OOH, F, CCH, *C*N, *N*C, PH_2. SH et Cl lorsque N = H, et où X = H, NH_2, OH, F, *C*N, *N*C, PH_2, SH et Cl lorsque N = F.

Mots clés : réactions S_N2, relations vitesse–équilibre, propriétés de l'état de transition.

[Traduit par la rédaction]

Introduction

Rate–equilibrium relationships have enjoyed widespread usage and success for many years. They have been used not only to predict reaction rates and equilibrium constants but also to discover under what conditions a change in mechanism occurs (1). Furthermore, the α coefficient of rate–equilibrium relationships is used to measure the position of the transition state (TS) along the reaction coordinate. This is based on the Leffler–Hammond postulate (2), according to which the transition state properties are intermediate between reactant and product. A more exothermic reaction has a small α and the TS resembles the reactant more than the product. Moreover, α should have a value between zero and one. However, anomalous values ($\alpha < 0$ and $\alpha > 1$) have been observed (3) and questions about the validity of using α as an indicator of TS structure have been raised (4). Thus, further studies on the subject are needed, especially with respect to geometry changes and charge transfer at the transition state. Such properties cannot be obtained directly from experiments and much remains to be done (5).

In this paper, we present an *ab initio* study of gas-phase S_N2 reactions at the second-order Møller–Plesset perturbation level. The study is done within the framework of the Marcus equation. The intention is to provide a better understanding of rate–equilibrium relationships and to see whether or not there is a relationship between α and transition state properties, especially the geometry change and charge transfer.

The Marcus equation (6) has been applied to a wide range of reactions including electron transfer, proton transfer, and methyl transfer reactions (5*b*, 7). According to the Marcus equation, the free energy of activation ($\Delta G^{\ddagger}$) is related (eq. [1]) not only to the free energy of a reaction (ΔG^0) but also to the intrinsic barrier ($\Delta G_0^{\ddagger}$)

$$[1] \qquad \Delta G^{\ddagger} = \Delta G_0^{\ddagger} + 0.5\Delta G^0 + \frac{(\Delta G^0)^2}{16\Delta G_0^{\ddagger}}$$

or in the potential energy form (6*b*)

$$[2] \qquad \Delta E^{\ddagger} = \Delta E_0^{\ddagger} + 0.5\Delta E^0 + \frac{(\Delta E^0)^2}{16\Delta E_0^{\ddagger}}$$

Thus, when $\Delta E_0^{\ddagger}$ is a constant,

$$[3] \qquad \alpha = \frac{\partial \Delta E^{\ddagger}}{\partial \Delta E^0} = 0.5\,(1 + x)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

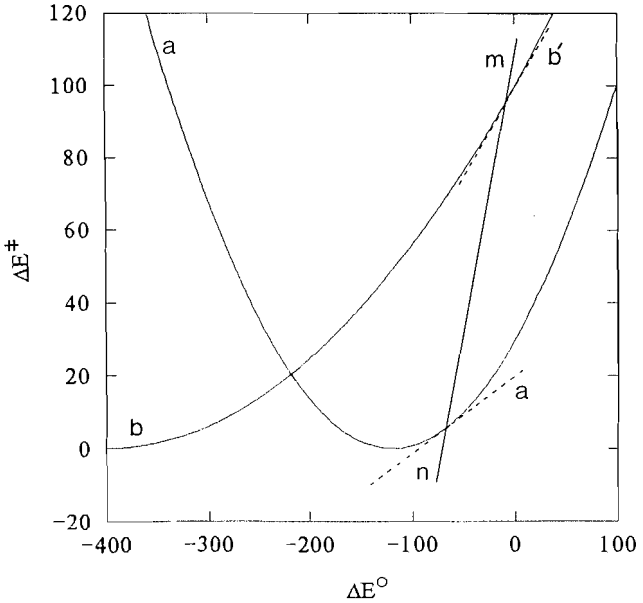

FIG. 1. Illustration of $\Delta E^{\ddagger}$ versus ΔE^0 (eq. [2]). In curve *a*, $\Delta E_0^{\ddagger} = 30$ kJ/mol and in curve *b*, $\Delta E_0^{\ddagger} = 100$ kJ/mol.

whereas if $\Delta E_0^{\ddagger}$ is not a constant

$$[4] \qquad \alpha = \frac{\partial \Delta E^{\ddagger}}{\partial \Delta E^0} = 0.5\,(1 + x) + (1 - x^2)\,\frac{\partial \Delta E_0^{\ddagger}}{\partial \Delta E^0}$$

where $x = \Delta E^0/4\Delta E_0^{\ddagger}$. Equations [3] and [4] were originally given by Marcus (6*c*).

For any reaction, α can be calculated from eq. [3] provided the ΔE^0 and $\Delta E_0^{\ddagger}$ values are known, and also α can be calculated according to eq. [4] if $\partial \Delta E_0^{\ddagger}/\partial \Delta E^0$ is known. Thus, at least two possible α values can be calculated for each reaction (by putting different reactions into one group, i.e., by changing $\partial \Delta E_0^{\ddagger}/\partial \Delta E^0$, different α values can be obtained from eq. [4]). The mathematical and physical differences between α's obtained from eqs. [3] and [4] should be understood and stressed as they often cause misinterpretations and confusion. The α obtained from eq. [3] is the derivative of the energy barrier with respect to the reaction energy in the absence of any variation in the intrinsic barrier. This α, which we call the "intrinsic" α, is characteristic of each reaction. On the other hand, the α obtained from eq. [4] includes the variation of intrinsic barriers; it involves information about other reactions ($\partial \Delta E_0^{\ddagger}/\partial \Delta E^0$). Thus, the α obtained from eq. [4] is characteristic of each group and is referred to as the "group" α. Figure 1 illustrates the difference between the "intrinsic" α and the "group" α. In this simplified example, we have two reactions; one (reaction [I]) has an intrinsic barrier $\Delta E_0^{\ddagger} = 30$ kJ/mol and $\Delta E^0 = -70$ kJ/mol and the other reaction (reaction [II]) has an intrinsic barrier $\Delta E_0^{\ddagger} = 100$ kJ/mol and $\Delta E^0 = -10$ kJ/mol. Using the Marcus equation (eq. [2]), when $\Delta E_0^{\ddagger} = 30$ kJ/mol, we obtain curve *a* and when $\Delta E_0^{\ddagger} = 100$ kJ/mol, we obtain curve *b* (see Fig. 1). The tangent of curve *a* at $\Delta E^0 = -70$ kJ/mol (*a'*) corresponds to the intrinsic α for reaction [I]. Similarly, the tangent of curve *b* at $\Delta E^0 = -10$ kJ/mol (*b'*) corresponds to the intrinsic barrier for reaction [II], whereas the slope of line mn corresponds to the group α of the two reactions.

Marcus indicated that only the intrinsic α, which has a normal range between zero and one (6*c*), can be used as a TS index. Lewis noted that the group α does not reflect product-like character as it is related to $\partial \Delta E_0^{\ddagger}/\partial \Delta E^0$ (5*d*). Other people (4*d*, *e*) also pointed out that the group α is not a reliable measure of the TS structure. At best, if the last term in eq. [4] is small, the group α is close to the average of the intrinsic α's.

In this paper, we present studies of the gas-phase S_N2 reactions $N^- + CH_3X \rightarrow CH_3N + X^-$, where X = H, NH_2, OH, OOH, F, CCH, *C*N, *N*C, PH_2, SH, and Cl when N = H, and where X = H, NH_2, OH, F, *C*N, *N*C, PH_2, SH, and Cl when N = F. The emphasis is on energy changes, geometry changes, and charge transfer at the TS and their relationship with α.

Computational methods

In earlier papers of our series on gas-phase S_N2 reactions (8*a–d*) we described the computational methods and results obtained at three levels of sophistication (8*b*, *c*). In this paper, the method denoted by MP2′ in previous papers is used (8*a–d*), unless stated otherwise. That is, the geometries were optimized at the Hartree–Fock level using the analytic gradient method and energies were calculated by use of second-order Møller–Plesset perturbation theory. Details about optimized geometries and energies can be found elsewhere (8*b*, *c*). The 6-31G basis set supplemented with diffuse and polarization functions (standard notation 6-31++G**) was used for all atoms except the three methyl hydrogens for which the 6-31G basis set was used. The justification for using single point Møller–Plesset calculations carried out at the geometries optimized at the Hartree–Fock level has been discussed in previous papers (8*b–d*). It has been shown that for those properties which involve at least two states, for example, energy differences and configuration contribution analysis of the TS, the MP2′ method gives results which are consistent with the full MP2 treatment (second-order Møller–Plesset perturbation calculations carried out at the geometries optimized at the same level).

The calculations were done by using the GAUSSIAN 80 and GAUSSIAN 86 programs (9) and the topological properties were calculated using the PROAIM and modified PROAIM packages (10).

Results and discussion

To repeat our earlier discussion, the intrinsic α is characteristic of each reaction, whereas the group α is a group property. In the following discussion, the intrinsic α's are used and the elementary step of converting the reactant ion–molecule complex ($N^- \cdots RX$) to the product ion–molecule complex ($NR \cdots X^-$) is considered unless stated otherwise.

Values of the α coefficients calculated from eqs. [3] and [4] and from linear plots of $\Delta E^{\ddagger}$ versus ΔE^0 (8*b*, *e*) are listed in Table 1. For exothermic reactions, the intrinsic α's are <0.5 (the second column), whereas the group α's (the third column) are usually >0.5. This is a direct result of the large gradient $\partial \Delta E_0^{\ddagger}/\partial \Delta E^0$ for these groups of reactions (8*b*, *e*). For the group of reactions in which X = CCH, *C*N, and *N*C the gradients ($\partial \Delta E_0^{\ddagger}/\partial \Delta E^0$) are 0.27 and 0.18 when N = H and F, respectively; for the group of reactions in which X = PH_2, SH, and Cl the gradients are 0.30 and 0.23 when N =

[d]From the ΔE^+ versus ΔE^0 linear plot of ref. 8*e*.

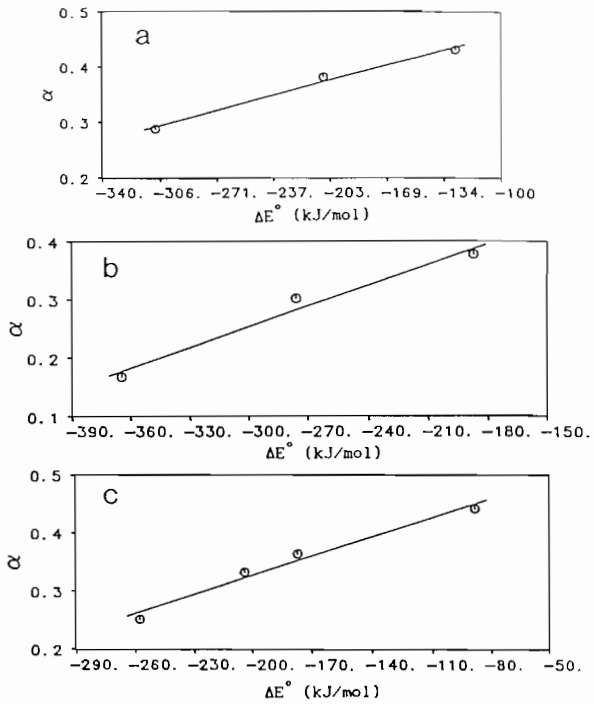

FIG. 2. Plot of α values versus ΔE^0 for the reactions $H^- + CH_3X \rightarrow CH_4 + X^-$. (*a*) X = CCH, *C*N, and *N*C; (*b*) X = PH_2, SH, and Cl; (*c*) X = NH_2, OH, OOH, and F.

H and F, respectively; for the group of reactions X = NH_2, OH, OOH, and F the gradients are 0.36 and 0.25 when N = H and F, respectively (8*b*, *e*). The α values obtained from ΔE^+ versus ΔE^0 linear plots (the fourth column) are averages of the values obtained from eq. [4] for each group and therefore they are larger than 0.5 as well.

Plots of intrinsic α versus ΔE^0 are shown in Fig. 2. Linear plots between α and ΔE^0 are observed within groups X = CCH, *C*N, *N*C, or X = PH_2, SH, Cl or X = NH_2, OH, OOH, and F. The observed linear relationship is due to the linear relationship between $\Delta E_0^{\ddagger}$ and ΔE^0 within these groups (8*b*, *e*). Detailed rationalization of the establishment of the reaction groups is provided elsewhere (8*b*, *e*). A brief explanation about the relationship between the intrinsic barrier and the reaction energy is provided by the following.

There are six important valence bond configurations in S_N2 reactions (11)

$N^{\cdot}\,R\cdot\cdot X$ $\quad$ $N\cdot\cdot R:X^-$ $\quad$ $N^{\cdot}R^+:X^-$ $\quad$ $N\cdot\,R^{\cdot}\cdot X$

1 $\quad$ **2** $\quad$ **3** $\quad$ **4**

$N^{\cdot}\,R^{\cdot}X^+$ $\quad$ $N^+:R^-:X^-$

5 $\quad$ **6**

The reactant and product wavefunction can be approximated as (12)

[5] $\quad \Psi_R = a_1\psi_1 + a_2\psi_3 + a_3\psi_5$

[6] $\quad \Psi_P = b_1\psi_2 + b_2\psi_3 + b_3\psi_6$

and the TS wavefunction can be approximated as (8*ab*, *d*)

[7] $\quad \Psi_{TS} = a\Psi_R + b\Psi_P + c\psi_3 + d\psi_4$

It has been shown that the intrinsic barrier is affected by the TS electronic structure, the hybridization factor of X and the electronegativity of X (8*b*, *e*). A considerable contribution of $N^{\cdot}R^+:X^-$ to the transition state (in addition to its contribution to the reactant and product) indicates a large difference in progress of the two reaction events (the main reaction and disparity reaction (8*e*, 13)) and a low intrinsic barrier. An *sp*-hybridized leaving group leads to a rapid ascent of the energy barrier and it increases the intrinsic barrier. Thus variation of TS electronic structures and the hybridization of the leaving group results in different relationships between $\Delta E_0^{\ddagger}$ and ΔE^0. For those reactions which have similar TS structures (similar values of *c* or *d* in eq. [7]) and the same hybridization of the leaving group, a linear relationship between $\Delta E_0^{\ddagger}$ and ΔE^0 is observed.

α *and geometry changes*

From the definition of α, it is clear that α is related to energy. In fact, it can be shown that α is related to the forward ($\Delta E_f^{\ddagger}$) and reverse energy barriers ($\Delta E_r^{\ddagger}$). By using eq. [2], and since $\Delta E_r^0 = -\Delta E_f^0$ ($\Delta E_f^0 = \Delta E^0$), we obtain

$$[8] \quad \frac{\Delta E_f^{\ddagger}}{\Delta E_f^{\ddagger} + \Delta E_r^{\ddagger}} = 0.5 + 0.25\,\frac{\Delta E^0}{\Delta E_0^{\ddagger} + \dfrac{(\Delta E^0)^2}{16\Delta E_0^{\ddagger}}}$$

and by omitting the quadratic term, we obtain

$$[9] \quad \frac{\Delta E_f^{\ddagger}}{\Delta E_f^{\ddagger} + \Delta E_r^{\ddagger}} \approx 0.5 + 0.25\,\frac{\Delta E^0}{\Delta E_0^{\ddagger}}$$

Thus, combining eq. [3] with eq. [9] yields

$$[10] \quad \alpha \approx 0.5\,\frac{\Delta E_f^{\ddagger}}{\Delta E_f^{\ddagger} + \Delta E_r^{\ddagger}} + 0.25$$

However, it is not obvious that a relationship between α and

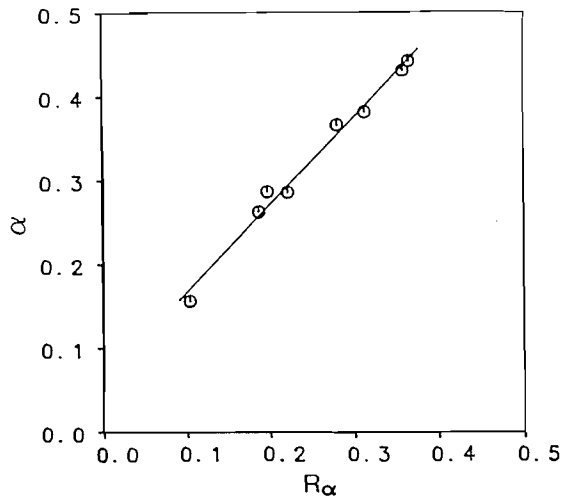

FIG. 3. A plot of α versus R_α for the reactions $H^- + CH_3X \rightarrow CH_4 + X^-$ at the MP2 level, where X = CCH, *C*N, *N*C, SH, Cl, NH_2, OH, and F.

transition state structure changes exists, although it is often assumed to exist. Furthermore, there is a lack of an unambiguous definition of geometry changes. For the latter problem, we may follow the example of the intrinsic α. According to eq. [10] the index for the energy change is related to the ratio of the forward and the sum of the forward and reverse activation energies. Similarly, an index for the geometry change (R_α) can be defined as the ratio of the forward and the sum of the forward and reverse geometry changes at the TS. Thus, we define

$$[11] \quad R_\alpha = \frac{f_f}{f_f + f_r}$$

In principle, f_f and f_r should be defined such that they measure the major geometry change of the reaction (for example, the breaking and forming of bonds). For the S_N2 reactions we have studied, f_f and f_r are defined as

$$[12] \quad f_f = \frac{R_{C-X}(TS) - R_{C-X}(R)}{R_{C-X}(R)}$$

and

$$[13] \quad f_r = \frac{R_{C-N}(TS) - R_{C-N}(P)}{R_{C-N}(P)}$$

where $R_{C-A}(TS)$ is the bond length between C and A in the transition state and $R_{C-A}(R)$ and $R_{C-A}(P)$ are the bond lengths between C and A in the reactant and product, respectively. Hence, if the TS resembles the reactant more than the product, $f_f < f_r$ and $R_\alpha < 0.5$. Otherwise, $R_\alpha > 0.5$. A plot of R_α versus intrinsic α is shown in Fig. 3 in which the ground state is taken to be the ion–molecule complex and the reactions have the same nucleophile, N = H. The results are obtained at the MP2 level (i.e., the geometries are optimized at the MP2 level).

It is interesting to note that even though a simple relationship between intrinsic α and ΔE^0 (see Fig. 2) only exits within each group, a simple relationship between intrinsic α and R_α can exist between members of more than one group. The rationalization is that the intrinsic α is related to the forward and reverse activation energies (eq. [10]) while the geometry change measured by f_f is related to the forward activation energy and that of f_r is related to the reverse activation energy. Therefore, R_α (eq. [11]) which is related to f_f and f_r is related to the forward and reverse activation energies as well. Thus, the relationship between α and R_α is not surprising. Furthermore, we can expect to observe a similar relationship between R_α and ΔE^0 as between α and ΔE^0, that is the linear relationship between R_α and ΔE^0 only exists within each reaction group.

TABLE 2. Calculated Q_α and ΔE^0 (kJ/mol) at the MP2 level[a]

	N = H		N = F	
X	Q_α	ΔE^0	Q_α	ΔE^0
CCH	0.38	−145.90		
*C*N	0.34	−251.55	0.74	33.31
*N*C	0.07	−361.34		
SH	0.41	−296.02	0.80	−11.20
Cl	0.27	−399.08	0.65	−114.22
NH_2	0.29	−91.44	0.80	193.42

F	0.09	−284.86	0.50	0.00

[a] $N^- + CH_3X$ and $CH_3N + X^-$ are taken as the reactant and product, respectively, for convenience. $\Delta E^0 = E(CH_3N + X^-) - E(N^- + CH_3X)$.

α and charge transfer at the transition state

The extent of charge transfer at the transition state is difficult to measure. Thus, in experiments, substituent or solvent effects are used as a means to measure the relative charge transfer at the TS (5). The study of charge transfer at the TS is also not trivial for theoretical calculations. It involves a proper definition of atoms in molecules and a proper partition of the charge distribution among atoms.

In this work, we used the charge partition scheme due to Bader and co-workers, according to which an atom in a molecule is defined as a real space surrounded by a zero-flux surface (a closed surface which is not traversed by any trajectories of ∇ρ) (14). The charge on an atom is obtained by subtracting the total number of electrons over the atomic basin from its nuclear charge.

By analogy with α and R_α, we can define a charge transfer index Q_α by

$$[14] \quad Q_\alpha = \frac{q_f}{q_f + q_r}$$

where

$$[15] \quad q_f = |Q_X(TS) - Q_X(R)|$$

and

$$[16] \quad q_r = |Q_N(TS) - Q_N(P)|$$

$Q_A(B)$ is the integrated charge on A in wavefunction B. For example, $Q_X(TS)$ is the integrated charge on X in the TS. Calculated Q_α values for reactions with N = H and N = F are listed in Table 2. Unlike intrinsic α and R_α, which have values <0.5 when $\Delta E^0 < 0$ and > 0.5 when $\Delta E^0 > 0$, Q_α can be >0.5 even when $\Delta E^0 < 0$ (for example, see Table 2 when N = F and X = Cl). The special behaviour of Q_α can be rationalized in terms of the factors discussed elsewhere

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

(8*b*, *d*). In previous papers, we have shown that the charge on atom A at the TS can be approximated as (8*b*, *d*)

$$[17] \quad Q_A(TS) = a^2Q_A(\Psi_R) + b^2Q_A(\Psi_P) + c^2Q_A(\psi_3) + d^2Q_A(\psi_4)$$

where a^2, b^2, c^2, and d^2 are the contributions of the reactant, product, and valence bond configurations ψ_3 and ψ_4 to the TS, respectively (see eq. [7]). $Q_A(\Psi_R)$, $Q_A(\Psi_P)$, $Q_A(\psi_3)$, and $Q_A(\psi_4)$ are the charges on A in the reactant, product, and valence bond configurations ψ_3 and ψ_4, respectively.

From eq. [17], the charge at the TS is related to the charges of A in various states ($Q_A(\Psi_R)$, $Q_A(\Psi_P)$, etc.). The charge on A in the reactant ($Q_A(\Psi_R)$ is A = X) and the charge on A in the product ($Q_A(\Psi_P)$ if A = N) are related to the electronegativity of A in the reactant and product, respectively. For example, a more electronegative A will attract more electrons, and hence a large negative value of $Q_A(\Psi_R)$ (when A = X). Therefore, the charge development at the TS is related to the electronegativity of A in the reactant and product. Furthermore, it is related to the contribution of various configurations to the TS (i.e., a^2, b^2, c^2, and d^2). All other things being equal, a large c^2 (i.e., large contribution of configuration $N^-{:}R^+{:}X^-$, in addition to its contribution to reactant and product, to the TS) tends to make the charge on A (A = N or X) at the transition state more negative. Moreover, as shown in previous papers (8*b*, *d*), if the reactions have similar electronic structures at the TS (i.e., similar values of *c* or *d* in eq. [7]), the ratio b^2/a^2 (product to reactant contribution to the TS) is related to the reaction energies. The smaller b^2/a^2 is, the more exothermic the reaction (8*a*, *b*, *d*). To sum up, the factors which affect charge transfer on A at the TS are the electronegativity of A, the electronic structure at the TS (i.e., whether there is a significant contribution of $N^-{:}R^+{:}X^-$, in addition to its contribution to the reactant and product, to the TS) and the reaction energy.

As we discussed above, only when the other two factors (electronic structure at the TS and electronegativities of N and X) are similar or at least change linearly with ΔE^0 will the simple relationship between q_f (and q_r) and ΔE^0 exist (see Figs. 1 to 4 in ref. 8*d*). Similarly, for a series of reactions, the simple relationship between Q_α and ΔE^0 will exist only when the reactions have similar TS electronic structures and the electronegativities of the X's are similar (or change linearly with ΔE^0).

It should be noted that the requirement for a simple relationship between Q_α and ΔE^0 discussed above is not sufficient to guarantee that $Q_\alpha < 0.5$ when $\Delta E^0 < 0$ or $Q_\alpha > 0.5$ when $\Delta E^0 > 0$. For that to be true, the electronegativity of the entering nucleophile N must be similar to that of the leaving group X. The relative charge transfer q_f and q_r is related to the relative electronegativities of N and X (8*b*, *d*). If N has a smaller electronegativity than X (for example N = H), $q_f < q_r$ and Q_α will tend to be smaller than when the electronegativities of N and X are similar. On the other hand, if N has a larger electronegativity than X (for example, N = F), q_f will be larger than q_r and Q_α would tend to be larger than when the electronegativities of N and X are similar.

The relationship between Q_α and ΔE^0 is illustrated in Fig. 4. For those X's which have similar electronic structures at the TS and electronegativities (for example, X = H and SH; X = CCH, CN, and Cl; X = OH, F, and NC; see refs. 8*b*, *d*), a simple relationship between Q_α and ΔE^0 is observed.

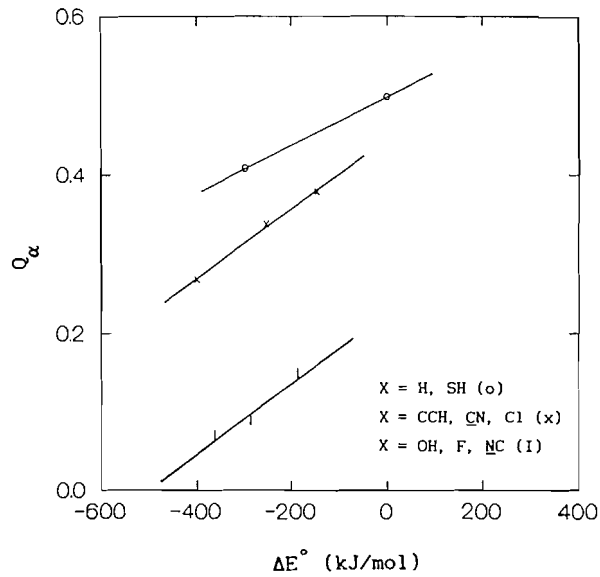

FIG. 4. Plot of Q_α versus ΔE^0 for the reactions $H^- + CH_3X \rightarrow CH_4 + X^-$ at the MP2 level.

Summary

The group α and the intrinsic α are different concepts. The α obtained experimentally is usually the group α. As noted by other workers (4*d*, *e*, 5*d*, 6*c*) and confirmed herein, the group α cannot be used as a measure of the TS structure in general. The intrinsic α is characteristic of each reaction. In this paper, we have discussed the relationships between the intrinsic α and other properties.

For gas-phase S_N2 reactions, the rate–equilibrium relationship is governed by the TS electronic structure and hybridization of the leaving group. Those reactions which have the same TS electronic structure and hybridization of the leaving group have a linear relationship between the intrinsic α and ΔE^0. In this case, a smaller intrinsic α indicates a more exothermic reaction.

An appropriate definition of the geometry change parameter is required in order to relate changes in geometry to the intrinsic α. R_α is proposed as the normalized TS geometry change. It measures the major geometry change of the forward reaction at the TS as compared to that of the sum of the forward and reverse reactions. A linear relationship between α and R_α is observed and explained by the fact that both α and R_α measure the forward activation energy as compared to the sum of the forward and reverse activation energies. Based on the relationships between R_α and α, and between α and ΔE^0, a linear relationship between R_α and ΔE^0 within each reaction group is expected.

The extent of charge transfer at the TS is related not only to energy changes but also to the electronegativities of the reactant and product and to the electronic structures at the TS. The explicit dependence of Q_α on electronegativity makes Q_α different from α and R_α. In order to observe a linear relationship between Q_α and ΔE^0, the electronegativities of X within the group must be similar.

The calculation of atomic oscillator strengths: the lithium atom revisited

A. W. WEISS

National Institute of Standards and Technology, Gaithersburg, MD 20899, U.S.A.

Received May 30, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

A. W. WEISS. Can. J. Chem. **70**, 456 (1992).

Extensive configuration interaction calculations have been done for the ground and first excited states of neutral lithium and singly ionized beryllium. While the calculations reproduce the ionization and excitation energies to within 3 cm^{-1} for Li and 10 cm^{-1} for Be^+, the main purpose of this work is the accurate evaluation of the $2s$–$2p$ resonance line oscillator strength. The calculated value of 0.7478 agrees to within less than 1% with the very accurate laser excitation lifetime measurement of 0.7416 ± 0.0012. However, internal consistency checks of the accuracy of these calculations suggest that more precise calculations are unlikely to reduce this discrepancy significantly. Furthermore, when placed together with other independent calculations that should be of comparable, if not better, accuracy, all theoretical predictions strongly indicate an f-value of 0.7475 ± 0.0010, which differs from the experiment by 4 experimental standard deviations.

Key words: configuration interaction, correlation, oscillator strength.

A. W. WEISS. Can. J. Chem. **70**, 456 (1992).

On a effectué des calculs étendus d'interactions de configuration de l'état fondamental et du premier état excité du lithium neutre et du béryllium mono-ionisé. Alors que les calculs permettent de reproduire les énergies d'ionisation et d'excitation à moins de 3 cm^{-1} pour le Li et à moins de 10 cm^{-1} pour le Be^+, le but principal de ce travail est d'évaluer d'une façon précise la force de l'oscillateur de la raie de résonance $2s$–$2p$. La valeur calculée, 0,7478, est à moins de 1% de la valeur très précise, 0,7416 ± 0,0012, obtenue par des mesures de temps de vie d'excitation au laser. Toutefois, des évaluations d'auto-cohérence de la précision de ces calculs laissent croire que des calculs plus précis ne réduiraient pas cette différence d'une façon significative. De plus, lorsqu'on utilise cette valeur avec celles obtenues par d'autres calculs indépendants d'une précision au moins semblable, si non meilleure, on en déduit que toutes les prédictions théoriques indiquent fortement que la valeur de f est égale à 0,7475 ± 0,0010 qui diffère de la valeur expérimentale par 4 écarts types expérimentaux.

Mots clés : interaction de configuration, corrélation, force de l'oscillateur.

Introduction

The accurate calculation of atomic structures over the past 30 years has been driven primarily by the steady development of greater and greater computing power. The most accurate calculations have been, and continue to be, those on the bound states of the helium atom and its isoelectronic ions (1–4). For the two-electron atom, it is possible to carry out exhaustive variational calculations using trial functions that explicitly incorporate the interelectronic coordinate, r_{12}.

The next atom in complexity after helium is lithium, which, with a single electron outside a closed shell $1s$ core, remains a very simple system. Nevertheless, calculations of the energy of the atom comparable in precision to those on helium have not generally been possible, and the best calculations that have been done, although quite precise for a greater-than-two electron atom, have been of substantially lower accuracy (5). It is only recently that variational r_{ij} calculations have been reported which approach the precision of the two-electron calculations (6). Lithium has therefore been the beginning proving ground of truly many-electron methodologies, such as many-body perturbation theory (7) (MBPT) and the various versions of configuration interaction (8, 9).

For the most part these calculations, as well as many of those on more complex atoms and molecules, have concentrated on accurate determinations of the total energy of the system. This paper too reports variational configuration interaction (CI) or superposition of configurations (SOC) calculations of total energies and wave functions for lithium and singly ionized beryllium. However, the main emphasis here is on the *ab initio* determination of the spectroscopic properties of the atom, in particular energy differences, i.e., ionization and transition energies, and especially the transition oscillator strength, or f-value. Special attention will therefore be given to the contribution to the f-value and transition energies of the various classes of correlation configurations, as well as the convergence of these properties with respect to the CI partial wave expansion. All calculations begin with the Hartree–Fock approximation and are based on expansions in a basis set of Slater type orbital functions (STO). As it happens, the initial round of these wave function calculations had already been done in connection with a model study of transition moment bounding theorems (10).

Lithium is also of special interest in that the $2s$–$2p$ resonance line f-value is among the most accurately yet measured experimentally. Laser excitation lifetime measurements on Li and other alkali atoms have been reported (11) with an uncertainty of ±0.15%, a truly remarkable achievement, considering the longstanding extreme difficulty of measuring this property with a precision better than ≈5%. Unfortunately, the present calculations are unable to predict an f-value within these error limits, irrespective of the expansion lengths, the class of pair correlations, and the extent of the partial wave expansion included in the CI wave function. A comparison with all the other theoretical calculations that account for correlation at a comparable level of sophistication supports a predicted value that differs from the experimental one by more than 3 times the experimental uncertainty.

The next section will describe the details of the wave

function calculations, the systematics of incorporating the various aspects of correlation into the trial functions, and the method of choosing the basis sets. This section will also include a summary of the results on correlation energies and an analysis of the various correlation contributions to the ionization and excitation energies, as well as the total energy. The following section will present the results for the resonance transition oscillator strengths, with a parallel analysis of the various correlation components of the calculations. Comparisons with other comparable calculations and with the experimental results will also be given and discussed.

Description of calculations and energy results

For an atom of this simplicity, one should expect pair correlation corrections to the Hartree–Fock to provide the overwhelmingly dominant correlation effect. The trial wave function, therefore, was initially taken to be a single/double (SD) substitution CI function. For the ground state this has the form

$$[1]\quad \Psi = a_0 1s^2 2s + \sum_i a^i_{2s} 1s^2 n_i s + \sum_i a^i_{1s}[1s2s\ ^{1,3}S]n_i s + \sum_{i,j,l} a^{ijl}_{1s2s} 1s[n_i l n_j l\ ^{1,3}S] + \sum_{i,j,l} a^{ijl}_{1s^2} 2s[n_i l n_j l\ ^1S]$$

and for the $2p$ excited state,

$$[2]\quad \Psi = b_0 1s^2 2p + \sum_i b^i_{2p} 1s^2 n_i p + \sum_i b^i_{1s}[1s2p\ ^{1,3}P]n_i s + \sum_{i,j,l} b^{ijl}_{1s2p} 1s[n_i l n_j (l+1)\ ^{1,3}P] + \sum_{i,j,l} b^{ijl}_{1s^2} 2p[n_i l n_j l\ ^1S]$$

where all summations are assumed to run over some set of correlation orbitals, which will be described later on.

The first double sum in both cases represents the *KL* intershell correlation, since one valence and one core orbital are replaced by a correlation orbital. The single sum terms belong naturally to this class of correlation, since one of the $1s$ functions is left undisturbed. These single replacement terms also include the semi-internal (12) configurations such as

$$1s2s^2,\ 1s2sns\ ^2S \quad \text{and} \quad 1s2s2p,\ 1s2pns\ ^2P$$

The second double sum, of course, represents the *K*-shell core correlation corrections, and it too includes semi-internal, or configuration interference (8), terms that contribute differently to the correlation energies of the two states, as well as the ion limit. These are terms like

$$2s^2ns,\ 2p^22s, \quad \text{and} \quad (2pnp\ ^1S)\ 2s$$

for the ground state, and

$$2s^22p,\ (2sns\ ^1S)\ 2p,\ 2p^3, \quad \text{and} \quad 2p^2(^3P,^1D,^1S)\ np$$

for the $2p$ state. As will be discussed shortly, the CI wave function expansions [1] and [2] were also augmented beyond the SD scheme in a very selective way so as to include the largest of the triple substitution configurations, i.e., configurations where all three H–F orbitals have been replaced by correlation functions.

The starting point for these calculations, for each state, was the expansion method Hartree–Fock approximation, based on the usual normalized Slater type orbitals (STO),

$$[3]\quad \chi^\zeta_{plm} = \sqrt{\frac{(2\zeta)^{2p+1}}{(2p+1)!}}\, r^p e^{-\zeta r} Y_{lm}(\vartheta,\varphi)$$

The Hartree–Fock basis was augmented by a set of functions designed to represent the intershell correlation and an additional set to represent the *K*-shell core correlation. The set of correlation orbitals of eqs. [1] and [2] was then generated by sequential Schmidt orthogonalization of this full STO basis.

Since the core correlation is expected to be very similar for the atom and the helium-like ion limit, the additional *K*-shell correlation basis set was determined by independent configuration interaction calculations on the ground states of the helium-like ions, Li^+ and Be^{2+}. The partial wave expansion here was carried through *i*-orbitals, i.e., $l = 6$, and all exponential parameters were determined by minimizing the ground state energy for these ions. After some numerical experimentation, a double ζ set was decided on for each symmetry, with principal quantum numbers for each ζ running up to some maximum, much like the bases recently used for helium r_{12} calculations (2, 3) and those used in some of the earliest of the CI calculations (13). These calculations recover better than 99% of the correlation energy of the ground state of the helium-like ions, which should be adequate to represent core correlation contributions to the three-electron atom ionization and excitation energies. This Slater basis is included in the basis set tabulation given in the appendix.

Even tempered basis sets, defined as a set of STO's all with the same principal quantum number, but with the zetas defined by the geometric sequence (14)

$$[4]\quad \zeta_k = \alpha_0\beta^k, \qquad k = 0, 1, 2, \ldots,$$

were also examined and, upon optimizing α_0 and β, were found to give approximately the same improvement in energy as the double ζ set of the same number of basis functions. The double ζ set was chosen here, however, since the comparable, variationally optimized even-tempered set appeared to show a somewhat greater degree of linear dependence, as measured by the magnitude of the expansion coefficients in a Schmidt orthogonalized set of functions.

With the *K*-shell STO correlation basis established, a natural orbital transformation (15) was carried out for the helium-like ion wave functions in order to provide an orthonormal basis in which the correlation information was condensed, as much as possible, in the first few orbitals. This made it possible to slough off, without degrading the correlation calculations, the last natural orbital of some of the lower *l*-value symmetries where there was a suggestion of linear dependency. The total number of correlation orbitals was therefore smaller than the number of basis functions. This set of *K*-shell correlation functions was added to the Hartree–Fock function for each state, and then augmented further by a set of functions designed specifically to account for the intershell correlation.

The approach followed for the intershell correlation set was more direct, adding to the core correlation set a sequentially Schmidt orthogonalized group of STO's variationally opti-

[a]Johansson, ref. 16.

mized on the intershell correlation only. That is, for purposes of variationally determining the STO exponential parameters, the core correlation configurations, i.e., the last double summations of eqs. [1] and [2], were omitted from the calculations. The *K*-shell basis set was included in these intershell calculations, but *K*-shell correlation configurations were not. The point of this exercise was to circumvent the distortion imposed on the variational problem by the much larger core correlation energy, which would otherwise dominate the ζ optimization procedure.

Here too, orbitals with angular symmetry through $l = 6$ were included in the calculations, with basis functions added within each symmetry until the energy appeared stable to $\approx 10^{-5}$ au. These basis sets for both the $2s$ and $2p$ states are included in the tabulation in the Appendix. It soon became clear that, except for *s*-functions, the same basis set could be used for both the ground and excited state. Repeated attempts to optimize parameters independently led to so small an energy improvement as to make it not worthwhile to pursue this approach.

The calculations included all possible configurations in [1] and [2] that could be constructed from this set of correlation orbitals. The total energies (in atomic units) calculated with this basis set, and labeled set A, are given in Table 1 for neutral lithium and in Table 2 for Be^+ and compared with experiment (16, 17). The number of basis functions for each symmetry is also shown in each case. The tables display the sequence of total energies (in au) obtained with the addition of successively higher angular momentum configurations representing the intershell correlation, followed by a similar sequence for core correlation. The corresponding computed energy differences, ionization and excitation energies (in cm^{-1}), are also given. In every case, the binding energies are computed relative to the energy of the helium-like ion at exactly the same level of approximation. All the KL intershell correlation calculations are, of course, referred to the $1s^2$ Hartree–Fock approximation of the ion limit.

An additional set of calculations including selected triple excitation configurations was also performed, based on the dominant double replacement core configurations,

$$s_1^2 2s + p_1^2 2s\ ^2S \quad \text{and} \quad s_1^2 2p + p_1^2 2p\ ^2P$$

Here s_1 and p_1 are the first natural correlation orbitals of *s*- and *p*-symmetry for the He-like core. For these calculations all possible single and double and substitution configurations referred to these configurations, but distinct from those already used, were added to the SD configuration interaction wave function. The improvements so obtained are indicated by the entries labeled "triples." This procedure generated a total of 1044 symmetry-adapted configuration state functions (CSF) for the ground state and 1773 for the $2p$ excited state. Relativistic energy shifts were estimated from Hartree–Fock calculations of the lowest order, single-particle Pauli approximation, and these corrections were added to the final calculated total energies.

Finally, for the case of neutral lithium, the entire set of calculations was repeated utilizing a larger set of STO's for the core and intershell correlation, here labeled basis set B. An enhanced basis set was optimized for the Li^+ ground state, the helium-like natural orbitals were obtained, and this set was added to the neutral atom H–F and an augmented intershell basis, generating 1695 CSF's for the ground state and 2895 for the $2p$ state. This basis is also given in the Appendix, and the energy results so obtained are shown in Table 3 in exactly the same way as Table 1.

Several conclusions stand out from these numerical results. Firstly, convergence of the total intershell correlation energy with respect to the partial wave expansion has been achieved to within $\approx 10^{-5}$ au. Results obtained with the larger basis, set B, are similar. The additional SD calculations of the core correlation also show that, for purposes of computing total energies, convergence with respect to this *l*-series has reached the regime of maddeningly slow convergence so common for helium and its isoelectronic ions. Furthermore, the absolute total energy corrections are quite large. No attempt has been made here to extrapolate the *l*-series; all

numbers are exactly as calculated. Comparison of results for basis sets A and B also indicate slow convergence with respect to radial basis functions.

However, it is also clear that, for purposes of predicting energy differences for valence shell spectroscopy, all correlations of the core involving *d*-orbitals or higher are very nearly irrelevant, at least to within 1–2 cm^{-1}. The total energies, of course, show much larger changes with these core correlations. However, the shifts are all virtually the same for both the ground and $2p$ states as well as the $1s^2$ of the helium-like ion. This is not so for the correlations $1s^2 \rightarrow s^2$ and $1s^2 \rightarrow p^2$, where differential correlation shifts are produced because of the occupancy status of *s*- and *p*-symmetries in the reference state wave functions. Higher symmetry triple substitution terms are likewise of little consequence, once the occupied symmetries have been included. Even the intershell contributions to ionization and excitation energies stabilize with respect to the *l*-series after the addition of *f*- or *g*-type orbitals. It is now of interest to pursue the effects of these various correlation contributions on the transition oscillator strengths.

Oscillator strength results

The oscillator strength, or *f*-value, for an electric dipole transition is given, in the length gauge, by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

$$[5] \quad f_{\text{len}} = \frac{2\Delta E}{3g_i} |\langle \Psi_i | \mathbf{r} | \Psi_f \rangle|^2$$

where ΔE is the transition energy in au, g_i is the statistical weight of the initial state, and the squared transition moment, the multiplet strength, is presumed summed over all degeneracies in both initial and final states, i and f. One can also compute f-values using the formally equivalent velocity form of the transition moment,

$$[6] \quad f_{\text{vel}} = \frac{2}{3g_i} \frac{1}{\Delta E} |\langle \Psi_i | \nabla | \Psi_f \rangle|^2$$

If the exact bound state wave functions are used to calculate the f-value, the length and velocity forms must agree exactly. With approximate wave functions, they need not, and frequently do not, agree, and it is common practice to compute both forms, taking the agreement as some measure of the accuracy of the calculation. Unfortunately, it is not at all clear how well this agreement or disagreement measures the accuracy. Length–velocity agreement is a necessary, not sufficient, condition of the correctness of the prediction. It can easily happen that both values agree quite well and both are wrong. Nevertheless, it is frequently a useful extra handle on one's calculations, albeit a potentially embarassing one. While the question of which form is to be preferred has been discussed at some length throughout the literature (18, 19), there is no hard and fast rule. It has been the author's experience that the length form seems to be preferable more often than not, but this is little better than a rough rule of thumb.

All CI contributions to the lithium transition moment were computed exactly, with no numerical approximations such as assuming orbital orthogonality for the two states. In principle, there is no reason for the orbitals used in the ground state to be orthogonal to those used in the $2p$ state calculations, and all requisite determinants of overlap integrals were dutifully computed here. In this case, because of the choice of a uniform correlation basis for $l > 0$, this is a minor point. Furthermore, since the K-shell electrons are so tightly bound, moving a single outer electron around among different valence orbitals, or removing it entirely, should cause negligible core relaxation. It is important to note, however, that this unimportance of the non-orthogonality problem is almost certainly peculiar to this particular application. In larger atoms, with larger and more polarizable cores, relaxation effects may well be substantially more important. Also, in atoms with more than one valence electron, term-dependent orbital relaxation can be, and often is, very significant. In such cases, orbital non-orthogonality must be incorporated into the calculations, either by direct calculation or indirectly, simulating this orbital relaxation by the appropriate configuration interaction. In the latter case, of course, care must be taken to include all the pertinent simulation configurations in the calculation.

The results of the oscillator strength calculations, using the sequences of wave functions indicated in Tables 1–3, are summarized in Table 4 and compared with the relevant experimental measurements (11, 20). In each case, the wave functions of both states of the transition have been truncated in exactly the same way. Thus, for example, $KL(i)$ means the CI wave function using all intershell correlation configurations through i-orbitals, and was used for both the $2s$ and $2p$ states. Several selected intermediate calculations in the sequences shown in Tables 1–3 have been omitted, since it is clear that they would add little to any conclusions one might derive from the results. In every case, the experimental transition energies were used to compute the oscillator strengths, since this throws the burden of any discrepancies or trends unambiguously onto the transition moment calculation itself.

Within each class of correlation configurations — intershell, core, and triple substitutions — we see that the higher angular momentum terms, as with the transition energy calculations, have virtually no effect on the oscillator strength. Adding intershell correlations through d-orbitals makes a significant change in the f-value compared with the Hartree–Fock and brings the length and velocity forms into much better agreement. However, adding f- and g-orbitals to the intershell correlation terms has only a marginal effect on the results, and adding h- and i-orbitals has none at all. Similar comments apply for the core correlation and triple substitution configurations, even though the former have a large effect on the total energy. The net effect for lithium of adding core and triple replacement terms to the wave function is to change the length and velocity f-values by 0.8% and 0.3% respectively from the intershell calculation.

It should be noted, of course, that these effects are all quite small. The Hartree–Fock values differ by only 3–4% from the final calculated numbers, a result that is already as good as, or better than, most current experimental measurements, and which is probably as accurate as needed for most applications. This, of course, is the point of the strategy followed in most current correlated calculations of f-values. By correlating only the valence electrons sufficiently, one hopes to bring the f-value calculations to the level of accuracy of the Hartree–Fock approximation for the corresponding alkali atom. For example, for carbon the procedure is to correlate the outer electrons only, which would then be expected to produce f-values of the precision of the Li Hartree–Fock. To go beyond this requires the inclusion of intershell and selected core correlation corrections, as has been done here.

The lithium results are somewhat disappointing in not being any more stable with respect to expansion lengths or categories of correlation configurations. It would also be nice to have seen better agreement of the length and velocity forms. The trends in the calculated values, however, strongly suggest that the f-value is unlikely to come down much closer to the experimental value than it already has. It is conceivable that a still more exhaustive correlation basis set would do the trick, but the very near equality of the two sets of calculated values produced by basis sets A and B suggests otherwise. It is possible that the addition of still more triple substitution configurations will depress the f-value still further. However, the set of triples that have been included already brings the ionization energy to within 3 cm^{-1} of the experiment, and it is difficult to see how the omitted remainder could make a change in the f-value three times larger than that due to the triple replacement terms already present. The calculations for Be^+ appear to be in much better shape than lithium, which is not surprising since isoelectronic ions generally tend to become rapidly less sensitive to correlation than the neutral atom. Also, the Be^+ experimental data are not claimed to be nearly as accurate as for lith-

ium, although here too there appears to be reason to question the precision of the measurement.

One caveat would seem to be in order with regard to truncating a sequence of calculated f-values as given for lithium in Table 4. Had the calculations been stopped at only the level of intershell correlation, the length form would have been in virtually exact agreement with the cited experimental value. While this would have given the appearance of an extremely accurate calculation, it would clearly have been quite misleading. On the other hand if one had stopped the calculations at the intershell correlation but used the theoretical transition energy, which is 100 cm^{-1} too large, the length and velocity values would have been 0.7465 and 0.7469 respectively. As it happens, this beautiful, but fortuitous, agreement is not even far from the length value finally obtained with the fully correlated wave functions.

The bothersome situation for neutral lithium becomes yet more puzzling when placed in the context of all the other published calculations designed to fully account for correlation (7, 21–23). This is illustrated in Table 5, which compares all these values with the experiment and with each other. The table also includes the ionization energies predicted for both states by each calculation. Except for the MBPT calculation, which is relativistic, these ionization energies have been adjusted by adding the Hartree–Fock relativistic shifts computed here.

The opacity calculation (22) is part of a recent large-scale project to generate atomic data needed for modelling stellar opacities. The wave function calculations are all done within a uniform framework for treating both radiative and collisional processes in both the discrete and continuous spectrum. For bound state calculations this methodology is equivalent to a configuration interaction calculation. The MC + CI calculation (23) is a calculation using numerical multiconfiguration Hartree–Fock orbitals in a follow-on full-scale CI. Both of these calculations are therefore similar to the present ones. The calculation labeled r_{12} is a variational calculation that selectively includes the interelectronic coordinate in the wave function, by allowing only one r_{ij} factor per term (21). Although this represents a real restriction, for this kind of system it can be argued that it should not be a severe one. The MBPT result (7) has been obtained by a relativistic many-body perturbation calculation applied directly to the ionization energy. The calculation therefore assumes no orbital relaxation in going from Li to Li^+, simulating this effect by higher order perturbative corrections, which as discussed above should be easily done for this system. For neutral lithium, the fact that the calculations are relativistic is of little importance.

The consistently close agreement of the f-values, particularly for the dipole length form, is striking. An oscillator strength of 0.7474 ± 0.0007 encompasses all of the length

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

values, and 0.7482 ± 0.0016 would include all the calculated f-values, both length and velocity. The fact that these are all entirely independent calculations, each one designed to fully account for correlation, makes this consistency still more persuasive. Since the smallest of these theoretical predictions differs from the experimental value by more than 4 standard deviations, it would appear that either a new measurement or a careful reevaluation of the old one would be called for.

Conclusions

This paper has reported extensive configuration interaction calculations of correlated wave functions at the level of single and double substitution configurations plus selected triples for the ground and first excited states of lithium and singly ionized beryllium. The calculations were based entirely on a Slater function basis, with the K-shell correlation basis determined by variational calculations on the helium-like ions, followed by a natural orbital transformation to compress the correlation information into a rapidly converging set of core correlation orbitals. These calculations generated a sequence of CI wave functions, which were then used to calculate a sequence of putatively more accurate oscillator strengths for the resonance transition.

The results clearly show that core correlation configurations are necessary in addition to intershell ones. While core correlation energies are large, only the s- and p-wave contributions make a significant contribution to the ionization and excitation energies. Similarly, only the lowest orbital angular momentum triple replacement terms are needed for the final 10 cm^{-1} accuracy for energy differences. Similar conclusions hold for the oscillator strength calculations. Here, however, only the lowest angular terms (through d-orbitals) in the intershell correlation as well are important.

Although the computed f-value for lithium agrees to within 1% with the most accurate measurement, which in turn carries a stated uncertainty of ±0.15%, analysis of the calculations suggests that the agreement should be better. When juxtaposed with a broad variety of other independent *ab initio* calculations, all of which agree closely with one another, there is a strong indication that this discrepancy is real, and that the experiment should be reevaluated. Another more recent laser excitation experiment, using delayed coincidence, has produced (24) an f-value of 0.7435, but with an uncertainty of ±0.0055. While this would tend to support the measurement of Gaupp *et al.* (11), the error bars are large enough to encompass all the values quoted here.

On the other hand, very accurate variational wave function calculations on lithium, involving extensive use of the interelectronic coordinates, are currently being reported in the literature (6,25). It would be of considerable interest therefore to apply them to the calculation of the resonance line oscillator strength to attempt to resolve this discrepancy.

Appendix

Tables A1 and A2 display the STO parameters for the two Slater basis sets labeled A and B respectively. The parameters are the principal quantum number, p, and the value of ζ, defined by eq. [3] in the main text. The basis sets are divided into two groups, the first referring to the Hartree–Fock and intershell bases, and the second the pure K-shell basis. In the latter case, e.g., the notation such as $2p$–$6p$ denotes a set of five p-type STOs all with the same value of ζ, but with principal quantum numbers, p, ranging from 2 through 6.

The infrared spectrum of 2-methylaziridine from scaled *ab initio* force fields

ARVI RAUK,[1] T. EGGIMANN, H. WIESER, AND DANYA YANG
Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received July 29, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

ARVI RAUK, T. EGGIMANN, H. WIESER, and DANYA YANG. Can. J. Chem. **70**, 464 (1992).

The structures of the *cis* and *trans* invertomers of 2-methylazirdine were optimized at the RHF/6-31G*$^{(0.3)}$ level of theory and the composition of the equilibrium mixture was determined to be *trans*/*cis* = 0.71:0.29, in good agreement with the experimental value, 0.66:0.35. The *ab initio* force field was scaled and a complete assignment of the vibrational spectra of the two conformers is presented. The IR spectrum of 2-methylazirdine was recorded in the vapor phase and in solution (cyclohexane and CCl_4). The predicted IR spectrum of the equilibrium mixture agrees very well with the experimental spectrum. The 6-31G*$^{(0.3)}$ basis set is found to provide better geometries and more uniformly scalable force fields than the conventional 6-31G* basis set.

Key words: *ab initio* force fields, 2-methylaziridine.

ARVI RAUK, T. EGGIMANN, H. WIESER et DANYA YANG. Can. J. Chem. **70**, 464 (1992).

On a optimisé les structures des invertomères *cis* et *trans* de la 2-méthylaziridine au niveau RHF/6-31G*$^{(0.3)}$ de la théorie et on a évalué que l'équilibre de mélange devrait se situer à *trans*/*cis* = 0,71 : 0,29, en bon accord avec la valeur expérimentale de 0,66 : 0.34. On a attribué une échelle au champ de force *ab initio* et on présente une attribution complète du spectre de vibration des deux conformères. On a enregistré le spectre IR de la 2-méthylaziridine tant en phase vapeur qu'en solution (cyclohexane et CCl_4). Le spectre IR prédit pour le mélange à l'équilibre est en bon accord avec le spectre expérimental. On a trouvé que, comparé à l'ensemble de base conventionnel 6-31G*, l'ensemble de base 6-31G*$^{(0.3)}$ fournit de meilleures géométries et des champs de force que l'on peut fixer d'une façon plus uniforme sur une échelle.

Mots clés : champs de force *ab initio*, 2-méthylaziridine.

[Traduit par la rédaction]

Introduction

The explicit connection between the infrared (IR) spectrum of a substance and its molecular structure began to be elucidated in the last decade with the increasing availability of reliable *ab initio* force fields and atomic polar tensors (APT) for intensity calculations. The coincident introduction of chiroptical techniques in the form of vibrational circular dichroism (VCD) spectroscopy and the Raman equivalent has promised further insights. Extraction of the inherent information from the latter techniques (and to some extent the former) has been hampered by theoretical difficulties that have largely been overcome with the introduction of practical nonempirical formalisms by Nafie and Freedman (1), Stephens (2), and Buckingham, Fowler, and Galwas (3) and their computer implementations by Stephens and co-workers (4), Morokuma and Sugeta (5), and Dutler and Rauk (6). The structural rigidity and relatively small size of three-membered ring compounds makes them ideal platforms for the assessment of both experimental and theoretical procedures. The parent achiral compounds can be rendered optically active by isotopic substitution. Investigations have been reported on 1,2-dideuterio- (4) and 1,2-dicyanocyclopropane (7), the deuterated oxiranes (6, 8, 9) and their methyl (10–12) and dimethyl (12) derivatives, and on methyl- (13, 14) and dimethylthiirane (14). The analogous nitrogen heterocycle has escaped attention, perhaps since it lacks the conformational rigidity of the carbon, oxygen and sulfur analogues. 2-Methylaziridine exists as an equilibrium mixture of *trans* and *cis* diastereoisomeric forms whose composition has been determined by nuclear magnetic resonance (15) and IR (16) measurements. The present compound as well as numerous other amines have been the subject of exhaustive IR and Raman spectroscopic studies by Lattes and co-workers (16, 17). A partial assignment of the observed IR and Raman frequencies in the frequency range 100–4000 cm^{-1} was carried out by Durig *et al.* (18) and repeated in the region above 400 cm^{-1} by Razumova and Kostyanovsky (19). Both groups concentrated on the dominant *trans* isomer. The two sets of assignments were in agreement except in the position of the lower frequency N—H bending mode. A number of absorptions due to the *cis* invertomer could clearly be assigned (for a discussion, see ref. 20). In the present work, the gas phase and solution IR spectra are remea-

sured in the range 400–4000 cm^{-1} and the relative frequencies and intensities are determined. On the basis of the present study, many of the previous assignments must be revised.

Use of scaled *ab initio* force fields is fraught with several difficulties, not the least of which is the unfortunate fact that the conventional 6-31G* basis set does not yield as satisfactory a geometry for a heteroatom containing three-membered rings as for less strained systems. Typically, the C—X bond is too short by about 0.04 Å. While it is possible to transfer the *ab initio* field from the equilibrium geometry to the experimental geometry, there remains the

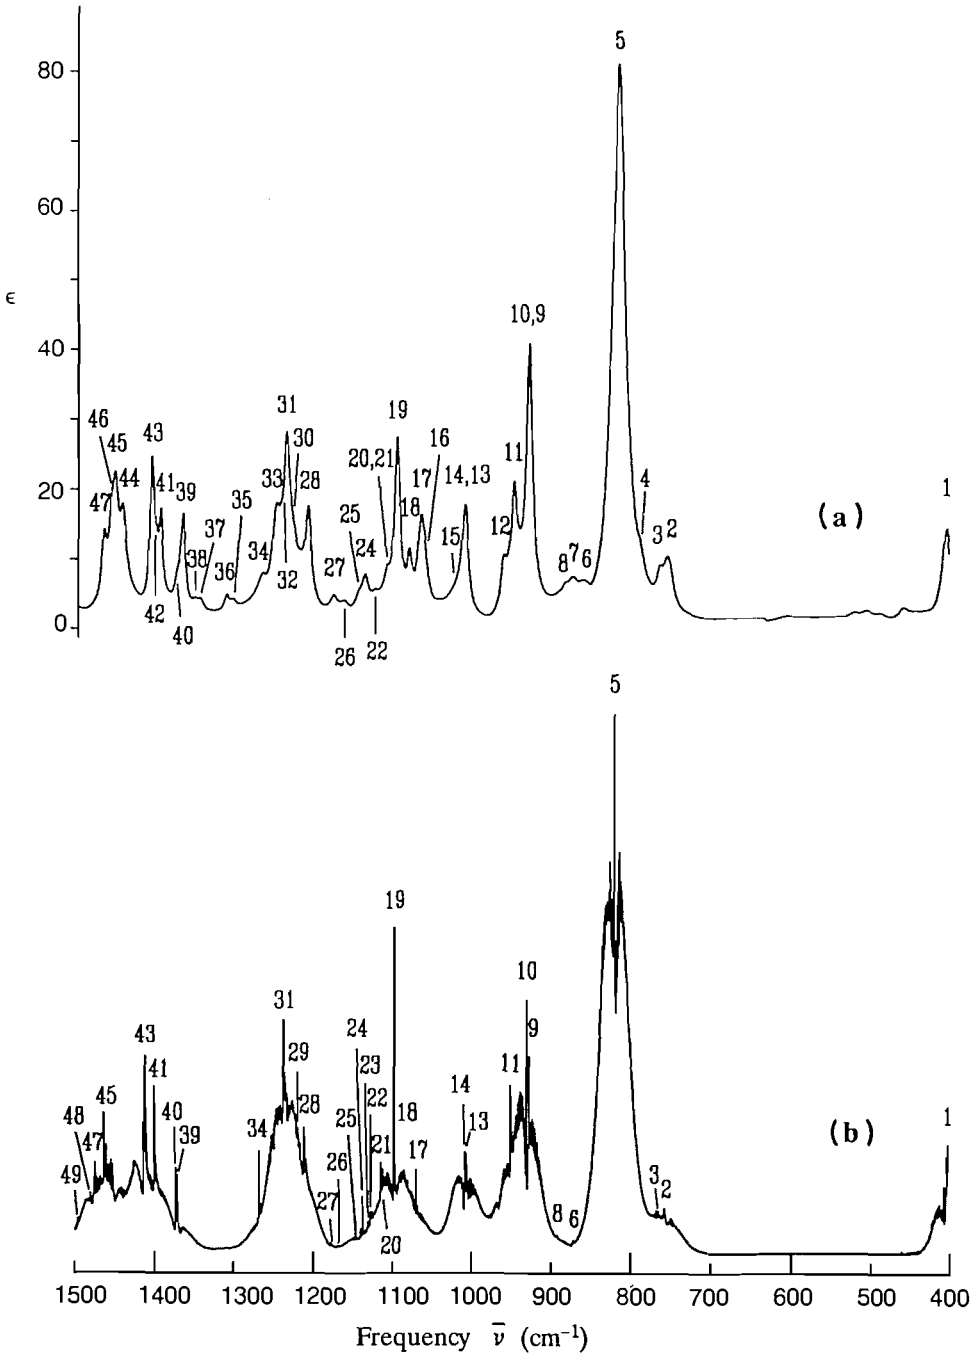

FIG. 2. Experimental IR spectrum of 2-methylaziridine (for experimental conditions, see text), 400–1500 cm^{-1}: (*a*) CCl_4 solution; (*b*) gas phase, 50 Torr.

suspicion that deficiencies in the structure are due to underlying deficiencies in the force field itself. It is well known that Hartree–Fock force fields are subject to a systematic, nearly constant, error (21), a theoretical rationalization of which has recently been presented (22). They are also subject to structure-related nonsystematic errors, which arise in part from deficiencies in the theoretical model (e.g., lack of electron correlation) but primarily from deficiencies in the basis set. Scaling of the force field attempts to correct for these deficiencies. *Uniform* scaling by a factor of 0.8 (21) largely compensates for systematic overestimation of force constants at the HF level and does not modify the normal mode descriptions from which intensity data may be derived. *Non*uniform scaling to match specific assigned frequencies is necessary to correct for basis set deficiencies. The success of nonuniform scaling procedures is contingent upon correct assignments being made in the first instance. Use of multiple scale factors also alters the normal mode descriptions and therefore the derived intensities. Ideally, the scaling should be as uniform as possible to avoid the latter difficulties. The recently introduced 6-31G*$^{(0.3)}$ basis set (12) yields geometries and "raw" *ab initio* force fields that appear to be superior to those derived using the standard 6-31G* (hereafter re-

ferred to as 6-31G*$^{(0.8)}$) basis set for first row atoms. We report herein scaled *ab initio* 6-31G*$^{(0.3)}$ force fields for the two invertomers of 2-methylaziridine, and compare the calculated IR spectra with the spectrum simulated for the equilibrium mixture. In a following paper we report on a theoretical investigation of the vibrational circular dichroism spectra of the individual invertomers and of the equilibrium mixture (23).

Computational details

The geometries of *trans*- and *cis*-2-methylaziridine were determined by complete optimization at the restricted Hartree–Fock level of theory using the analytical procedures of the GAUSSIAN 82 (24) or GAUSSIAN 86 (25) systems of programs and the internal 6-31G*$^{(0.8)}$ (12, 26) basis set and the modified 6-31G*$^{(0.3)}$ (12) basis set. We distinguish the original and modified 6-31G* basis sets by indicating explicitly the value of the *d* exponent. Thus 6-31G*$^{(0.8)}$ is equivalent to the original 6-31G* basis set for C, N, and O (26). Since bond lengths are calculated to be a little longer by the 6-31G*$^{(0.3)}$ basis set, an effect also observed with optimization at the MP2 level of theory, an improved estimate of the relative energies of the two isomers was obtained by single point recalculation of the energies at the MP2 level of

theory using the internal 6-31G** basis set at the 6-31G*$^{(0.3)}$ geometry, i.e., MP2/6-31G**//6-31G*$^{(0.3)}$ in the accepted notation. Normal coordinate analysis at the 6-31G*$^{(0.3)}$ equilibrium geometry was carried out by analytical second differentiation of the Born–Oppenheimer RHF energy (27). IR intensities were accomplished by the program system Freq85 (6), which implements the vibronic coupling theory (VCT) of Nafie and Freedman (1) at the *ab initio* level, and permits recalculation for arbitrary isotopic substitutions. For IR intensities, VCT is identical to the atomic polar tensor (APT) theory that is implemented in GAUSSIAN 86 and subsequent versions of the GAUSSIAN system of quantum chemistry codes. For improved agreement with experiment, frequencies were either uniformly scaled (28), or selectively scaled according to the procedure of Pulay *et al.* (29, 30). The VCT intensity evaluations were computed using the 6-31G*$^{(0.3)}$ basis set (VCT/6-31G*$^{(0.3)}$). Simulated IR spectra were obtained assuming a Lorentzian lineshape of width at half height 10 cm^{-1}.

Geometries

Neither complete experimental nor theoretical structures of the 2-methylaziridines have previously been reported. The RHF/6-31G*$^{(0.3)}$//6-31G*$^{(0.3)}$ geometries of *trans*- and *cis*-2-methylaziridine are shown in Fig. 1. Complete details of the structures in terms of parameters defined in Fig. 1 are shown in Table 1. The RHF/6-31G*$^{(0.8)}$//6-31G*$^{(0.8)}$ structural parameters are also listed in Table 1. Partial experimental data deduced from MW studies (31) are compared to the calculated values. With the 6-31G*$^{(0.3)}$ basis set, the C—C and C—N bonds of the ring are very similar in length, the C—N bonds being calculated to be about 0.025 Å longer than with the 6-31G*$^{(0.8)}$ basis set. Examination of the structures of Fig. 1 reveals a tipping of the external H—C*—Me plane (the plane of the bonds d and f) away from the N—H bond (or toward the N lone pair) in each isomer. Although not apparent from the figure, examination of the data of Table 1 reveals a similar effect of the N configuration on the tilt of the CH_2 plane. The influence of the N lone pair, n_N, is

probably electronic rather than simply steric, and may be rationalized in terms of perturbative MO theory as causing a distortion so as to improve the energetically favorable n_N–σ* interaction, where σ* is the out-of-phase combination of the antibonding orbitals of the d, f, and (or) g, h bonds.

Relative energies

2-Methylaziridine exists as an equilibrium mixture of the *trans*- and *cis*- isomeric forms. Both ^{1}H NMR (15) and IR (16) data indicate that the *trans* form is favored by about (ΔG^0 =) 1.6–1.7 kJ/mol in dilute solution, corresponding to a *trans*/*cis* ratio of 0.66:0.35 at ambient temperature. Total energies and relative energies of the two isomers computed by several methods are shown in Table 2. As discussed in the Computational Details section, the most accurate practical estimate of the relative energies of the Born–Oppenheimer minima should be obtained by single point MP2 calculation using the 6-31G** basis set at the 6-31G*$^{(0.3)}$ geometry (MP2/6-31G**//6-31G*$^{(0.3)}$ in Table 2). The zero point vibrational energy (ZPVE) is found to be slightly higher for the *cis* form. Correction for the change in ZPVE yields

an estimate of $\Delta H^0 = 2.17$ kJ/mol for the gas phase difference. Assuming that $\Delta S \approx 0$, a *trans/cis* mixture of 0.706:0.294 at 298 K is predicted. Since it is quite close to the experimental estimates and the effects of differential solvation are unknown, the theoretical ratio is used in the simulation of the IR spectra shown in Figs. 4 and 5, and discussed below.

Experimental methods

The racemic 2-methylaziridine was purchased from Aldrich (90%) and purified by distillation in a vacuum line before use. The solution absorption spectra (Figs. 2 and 3) were recorded at various concentrations in the solvents cyclohexane (700–850 cm^{-1}) and CCl_4 (rest of the spectral range) using a Nicolet 8000 FT-IR interferometer running at 1 cm^{-1} resolution (1000 scans). For the vapor phase absorption spectra (400–4000 cm^{-1}, see Figs. 2 and 3), 300 scans were collected with a resolution of 0.12 cm^{-1} in a 10 cm cell with KBr windows, at pressures of 50 and 70 Torr (1 Torr = 133.3 Pa).

In spite of the initial daunting appearance, the IR spectrum of the 2-methylaziridine yielded to modern techniques. Fourier self-deconvolution (32) provided exact frequency measurements for many of the overlapping bands that dominate the condensed phase spectrum. These band positions were then used for the determination of the intensities, some of which could not be measured precisely due to severe overlapping. A list of the observed frequencies and intensities may be found in Table 3. The intensities of bands 66 and 35–38 are concentration dependent, likely caused by hydrogen bonding. The intensities were measured with a sample concentration of 0.8 mol/L.

A number of vapor phase bands exhibit two distinct *Q*-branches clearly arising from the two conformers (e.g., nos. 9/10, 13/14, and 39/40). Some regions of the spectrum are so complex as to prevent firm identification of the fundamental transitions on the basis of the vapor phase spectrum alone.

Force field refinements and assignments

The *ab initio* Cartesian force constants for both conformers were transferred to a nonredundant set of local symmetry coordinates (Table 4), chosen in accordance to the recommendations of Pulay *et al.* (29). The scaling of the local symmetry force constants, K_{ij}, was achieved by the method, $F_{ij} = (c_i c_j)^{1/2} K_{ij}$, where F_{ij} are the scaled force constants and c_i and c_j are the scale factors associated with the local modes i and j, respectively (30). Our scaling and refining proce-

dures have been described in more detail in earlier publications (33).

Great caution was mandatory for the refinements of the 6-31G*$^{(0.3)}$ force fields since no scale factors have been developed to date for this basis set. The favorable reference point for the refinement of the 2-methylaziridine force fields appears to be the 6-31G*$^{(0.8)}$ scale factors for azetidine (34). However, a direct transfer of the parameters is not advisable because the differences between the force fields of the two basis sets are not known. Therefore, the force fields were initially scaled uniformly with a factor ($f = 0.813$) that is the average of the six optimized azetidine 6-31G*$^{(0.8)}$ parameters. With the resulting frequency predictions, 25 of the 54 fundamental transitions for both conformers including the N—H stretches (ν_1) and C—H stretches (ν_2) were assigned unambiguously. The uniform scale factor was then divided up into three separate factors, one each for N—H stretching, C—H stretching, and the remaining modes, respectively. The optimized values after the first refinement run are given in Table 5 (column 3sf). Most frequencies below 1500 cm^{-1} were calculated high while the vibration, ν_{25}, which is an almost pure methyl out-of-plane bend, was predicted 22 cm^{-1} low for both conformers. This coordinate has been shown to require an unusually high scale factor for the 3-21G force field of methyloxetane (33*c*). It seemed justified and appropriate therefore to allow a separate scale factor just for this mode. With this modification, the previous refinement was repeated with a much improved frequency fit (column 4sf, Table 5).

It was now possible to assign with confidence another five fundamentals and to define two separate scale factors for the C—C stretch and C—N stretch. Starting with the preoptimized factors, all six parameters were allowed to vary independently in another refinement (6sf-1, Table 5). Column 6sf-2 in Table 5 contains the results from the final optimization including a total of 33 firmly assigned transitions, showing that all parameters remain constant and are well defined within this refinement. The average deviation experiment of the calculated frequencies is 4.2 cm^{-1} (0.37%). The absolute numbers of these new 6-31G*$^{(0.3)}$ force field scale factors are similar to previously optimized factors for other basis sets. The parameter for the CH_3 out-of-plane deformation is again found to be much larger than the others. All the factors except for the C—C stretch are higher than

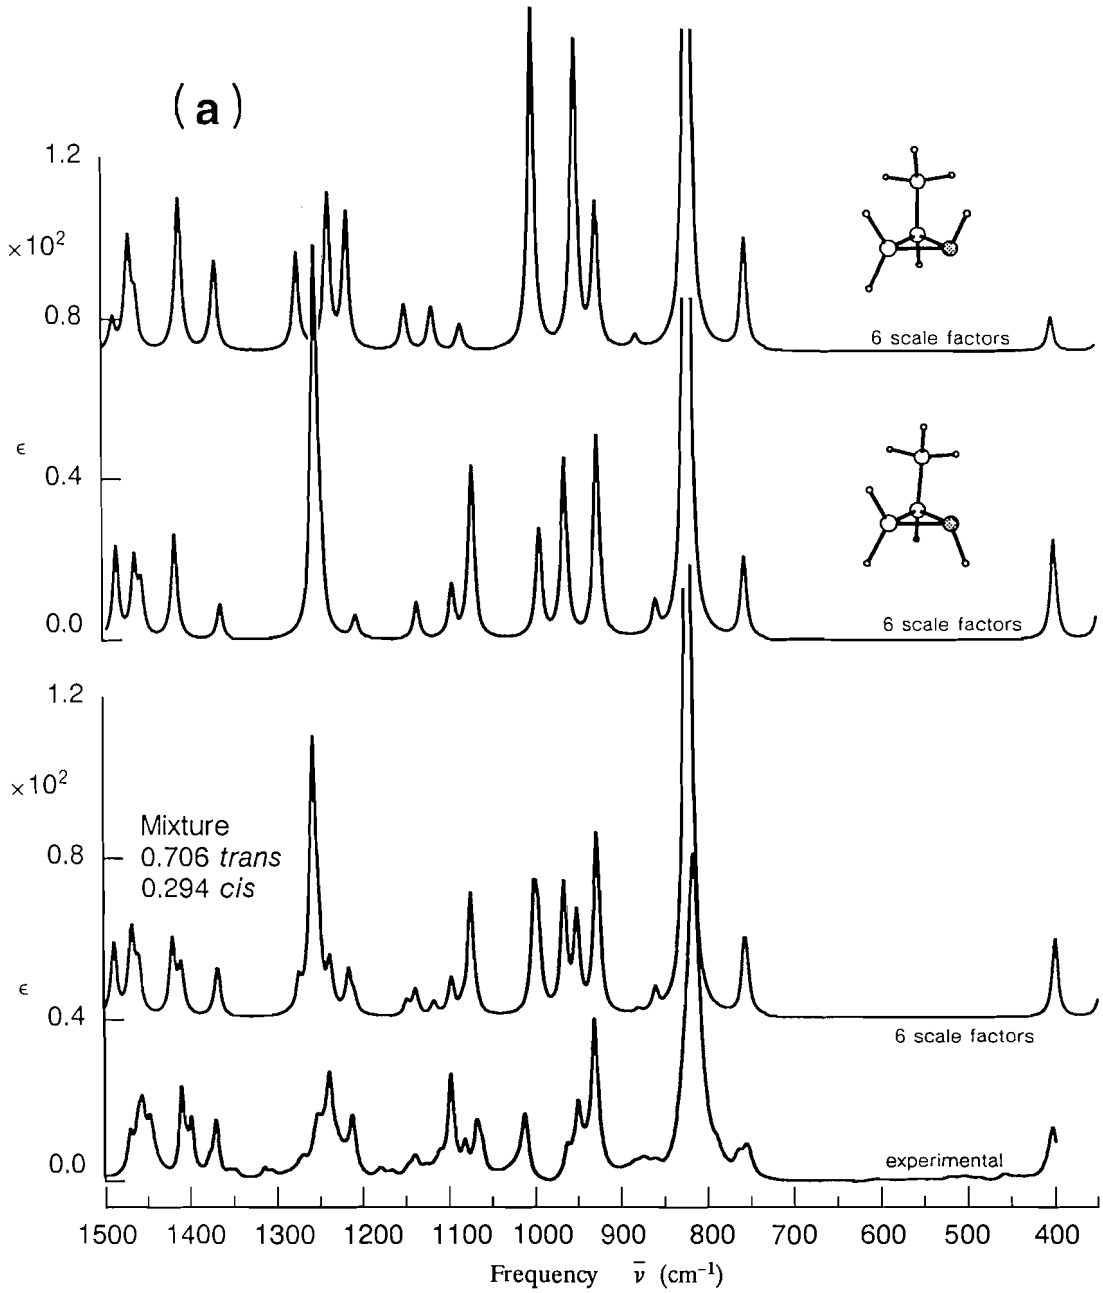

FIG. 4. Simulated IR spectra by VCT/6-31G*$^{(0.3)}$ theory in the region 350–1500 cm^{-1} for the individual invertomers of 2-methylaziridine, and of the theoretical equilibrium mixture at 298 K compared with the experimental spectrum in CCl_4 (bottom spectrum); the linewidth for simulations is 8 cm^{-1}: (*a*) scaled with six scale factors; (*b*) uniformly scaled.

the corresponding 6-31G*$^{(0.8)}$ values for azetidine. The parameters for C—C and C—H stretching remarkably resemble the corresponding 6-31G** scale factors of oxirane (9). Finally, the 6-31G*$^{(0.3)}$ factors are considerably more uniform than for the 6-31G*$^{(0.8)}$ or any smaller basis sets, indicating a more balanced treatment of the various intramolecular motions by the original *ab initio* 6-31G*$^{(0.3)}$ force field.

The refinements were also carried out with the 6-31G*$^{(0.8)}$ force constants for 2-methylaziridine. Although it was possible here to transfer directly the scale factors from azetidine, the spectral assignments were more tedious because of inferior frequency predictions compared to the 6-31G*$^{(0.3)}$ basis set. The final spectral assignment was essentially the same as above, included 33 bands as well, but required eight scale factors to reproduce the frequencies with an average error of 6.2 cm^{-1} (0.56%). The additional parameters had to be employed for the C—CH_3 stretch and for the methyl C—H stretches in order to achieve a reasonable fit. The optimized values are similar to the azetidine factors but generally lower.

Thus the present experience indicates that the errors of the 6-31G*$^{(0.3)}$ force constants for 2-methylaziridine are smaller and more uniform than for the conventional 6-31G*$^{(0.8)}$ basis set. The 6-31G*$^{(0.3)}$ force constants therefore lie closer to the Hartree–Fock limit values. It would be

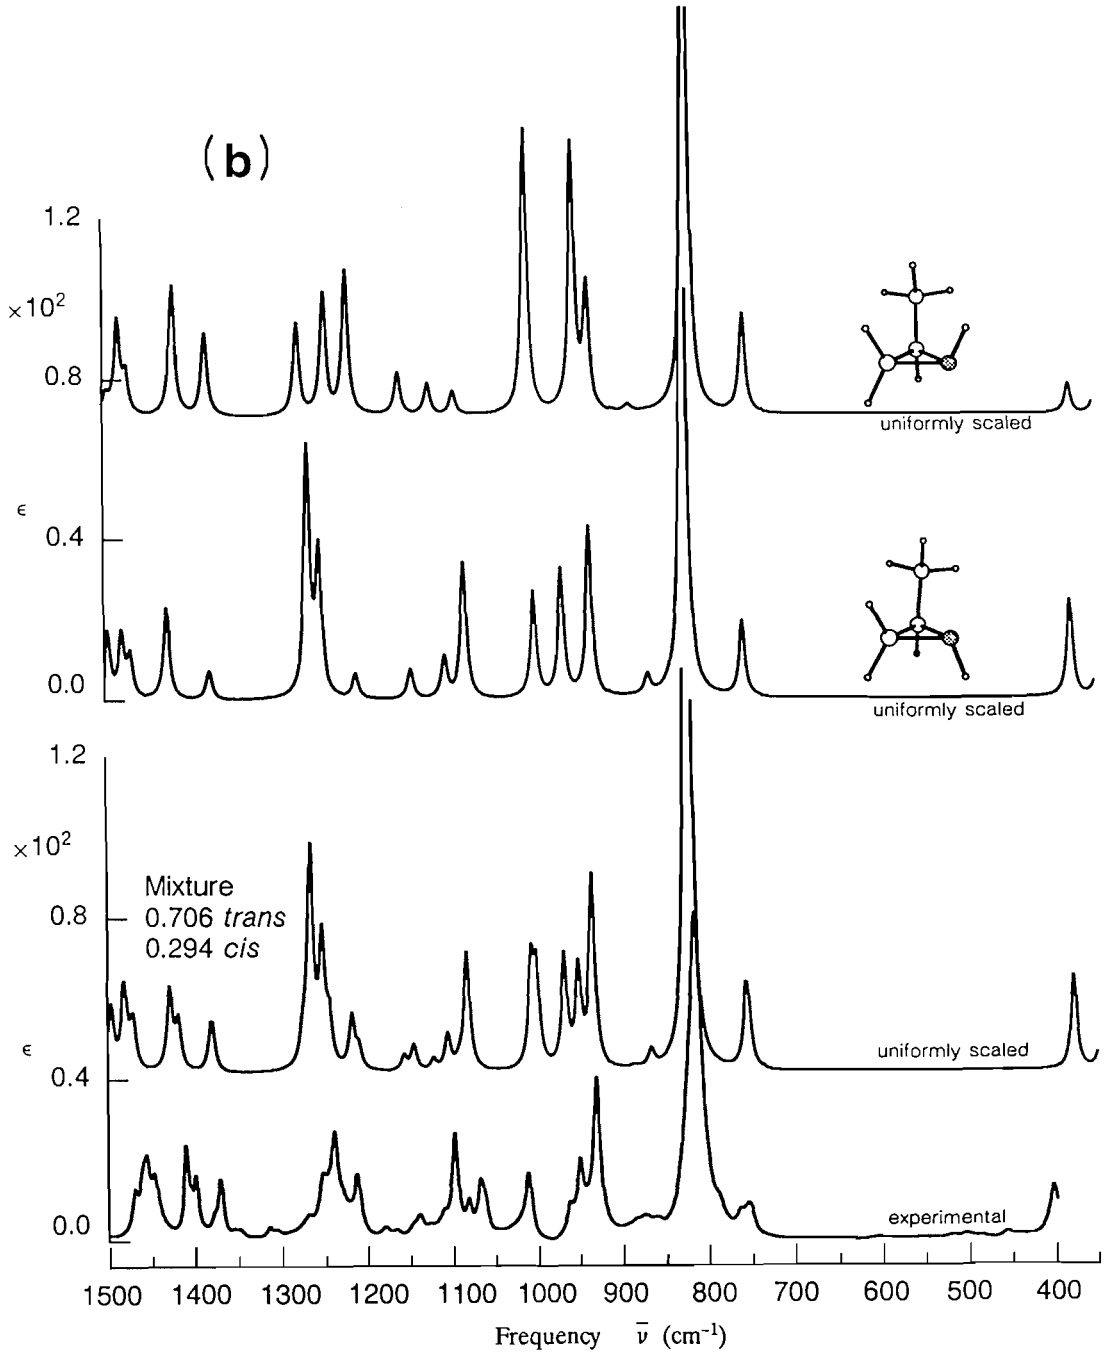

FIG. 4 (*concluded*)

necessary now to test the performance of this basis set with other molecules.

Results and discussion

The experimental solution and vapor phase spectra of 2-methylaziridine are shown in Fig. 2 (400–1500 cm^{-1}) and Fig. 3 (2800–3500 cm^{-1}). The numbering on the bands corresponds to the listing of observed bands in Table 3. A number of the bands cannot be assigned to fundamental transitions. Most of them are probably overtone or combination bands. However, there are relatively strong bands in the solution spectra (in both CCl_4 and cyclohexane) that are not observed in the gas phase. Examples are the signals between 420 and 520 cm^{-1} and the four bands, nos. 35–38, that we believe arise from N—H bending modes (ν_{13}, ν_{14}) of hydrogen-bonded molecules. The corresponding modes for ν_{19} and ν_{21}, which also involve the N—H deformations, should then be shifted up into the region 980–1050 cm^{-1}. Indeed, two unassigned bands are observed in or nearby this region (nos. 15, 16). The broad feature in the solution spectrum around 3260 cm^{-1} (no. 66) clearly corresponds to the N—H stretch involved in hydrogen bonding. One of the two vapor phase bands near 3180 cm^{-1}, no. 65 (3172.6 cm^{-1}), has been observed by Durig *et al.* (18) and assigned to a combination band due to the methyl torsion and an asymmetric stretch of the methyl group of the *trans* isomer, $\nu_5 + \nu_{27} = 3161$ cm^{-1}

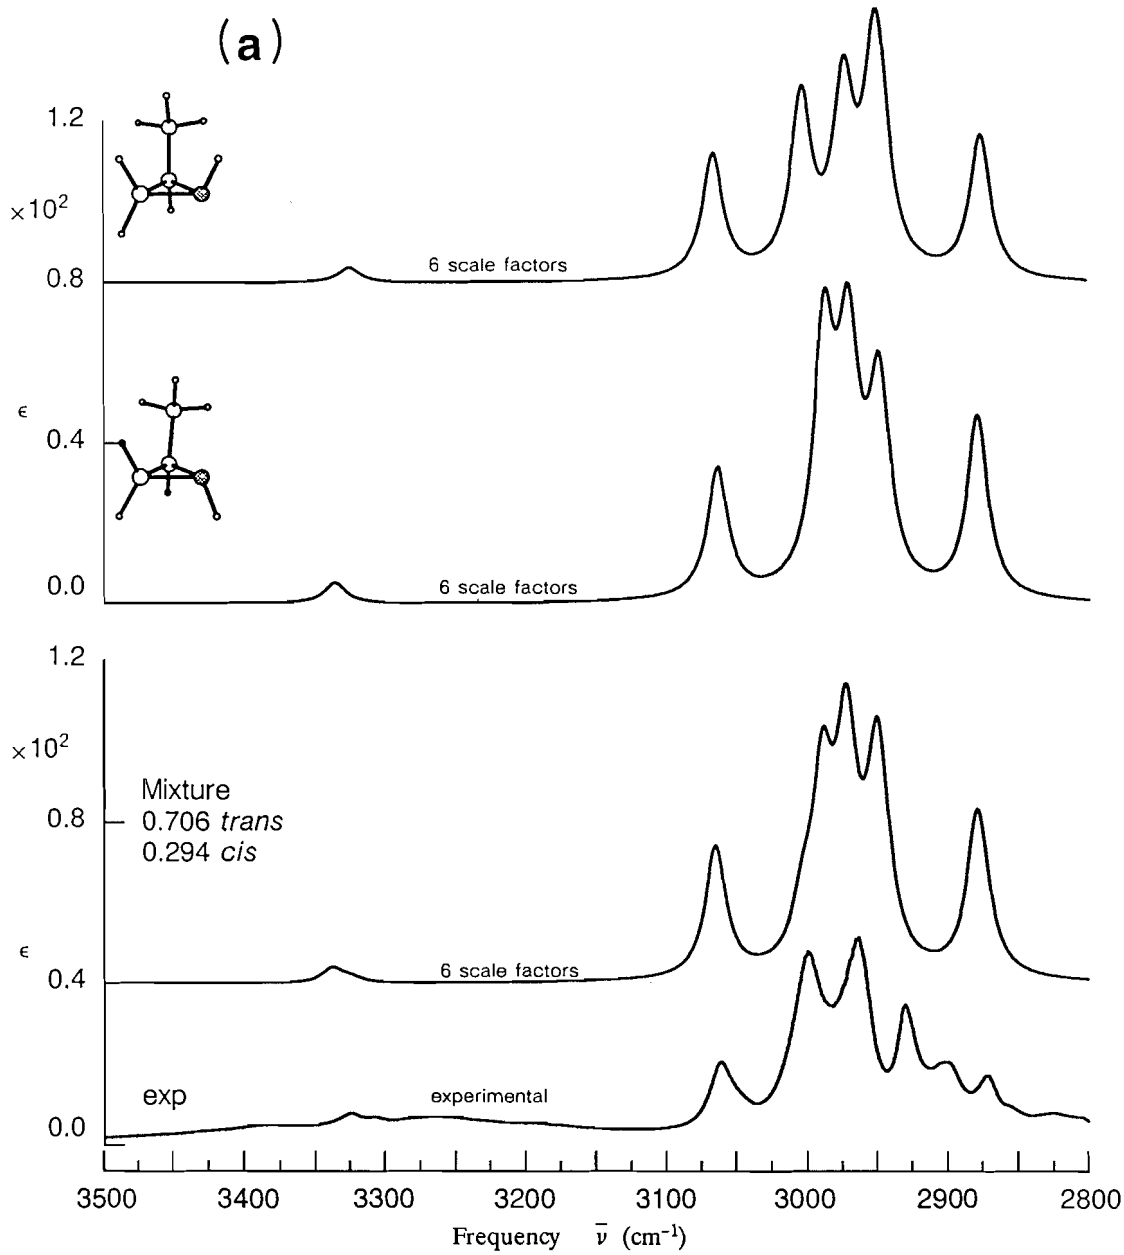

FIG. 5. Simulated IR spectra by VCT/6-31G*$^{(0.3)}$ theory in the region 2800–3500 cm^{-1} for the individual invertomers of 2-methylaziridine, and of the theoretical equilibrium mixture at 298 K compared with the experimental spectrum in CCl_4 (bottom spectrum); the linewidth for simulations is 18 cm^{-1}: (*a*) scaled with six scale factors; (*b*) uniformly scaled.

(calcd.). Band 65 (3155.1 cm^{-1}) may originate from a second combination of the same kind, namely $\nu_6 + \nu_{27} = 3147$ cm^{-1} (calcd.) since the calculated separation of the two asymmetric stretches (assumed to be degenerate by Durig *et al.*) is similar to the observed separation of bands 64 and 65.

Frequencies calculated by RHF/6-31G*$^{(0.3)}$//6-31G*$^{(0.3)}$ for the *trans* and *cis* isomer of 2-methylaziridine are listed in Tables 6 and 7, respectively. Also listed are the uniformly scaled frequencies, the optimally scaled values (six scale factors), and the corresponding observed bands. Dipole strengths were calculated from the uniformly and optimally scaled force fields by VCT/6-31G*$^{(0.3)}$ (= APT), and descriptions of the normal modes. The descriptions of the bands are assigned on the basis of visualizations of the animated normal modes and inspection of the normal modes in displacement vector representation (see Fig. 6, discussed below). The subsequent discussion is based on the optimally scaled results, which are very similar to the uniformly scaled values.

Vibrational frequencies and assignments

Some substantial differences are predicted in the frequencies of equivalent vibrational modes of the two isomers. Normal modes, ν_{22} and ν_{17}, primarily rocking and wagging motions of the CH_2 group, are predicted to occur 20 and 19 cm^{-1} to lower frequency in *trans*-2-methylaziridine than in the *cis* diastereomer. On the other hand, ν_{20}, a mixed mode consisting of C—CH_3 stretch and ring distortion, is predicted to be at higher frequency by 15 cm^{-1}. Lesser pertur-

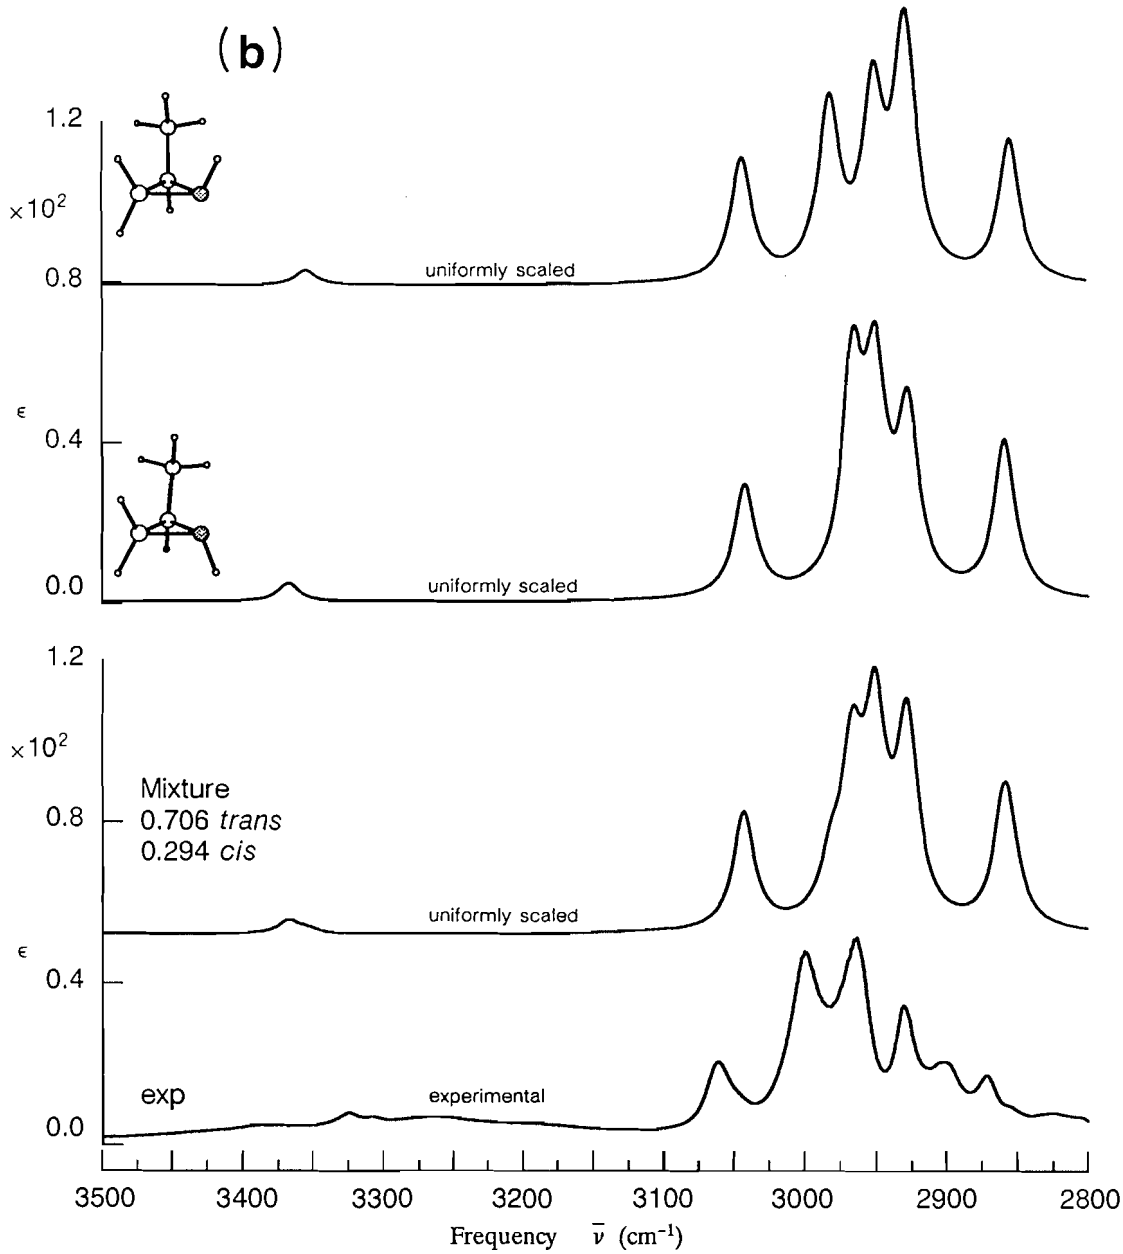

FIG. 5 (*concluded*)

bations to lower (ν_{27}, ν_{18}, ν_{16}, ν_{15}, ν_{13}, and ν_3) and higher (ν_{14}, ν_{11}, ν_5, and ν_1) frequencies in the *trans* compared to the *cis* conformer are easily resolved experimentally and therefore are significant for the scaling of the force fields and the interpretation of the IR spectra of the equilibrium mixture. The nature of the vibrations is particularly complex in the range 800–1400 cm^{-1}. In the assignments listed in Tables 6 and 7, only the major group motions are identified, in decreasing order of their apparent involvement. The modes are discussed further in their connection to the predicted IR intensities.

Comparison of the uniformly scaled and optimally scaled frequencies (columns 3 and 4 in Tables 6 and 7) reveals that the two sets are very similar, the greatest deviations occurring in the N—H and C—H stretching regions where the uniformly scaled values differ by +31 cm^{-1} (N—H) and −21 cm^{-1} (C—H) from the optimally scaled values. In the mid-IR region, most of the uniformly scaled values are too high, the maximum difference being 13 cm^{-1}.

The IR spectrum of 2-methylaziridine

The calculated electric dipole strengths are listed in Tables 6 and 7. Very little difference is found between the values obtained from the nonuniformly scaled force field and the uniformly scaled values.

On the basis of previous studies with the 6-31G*$^{(0.3)}$ basis set (12, 14), most of the calculated dipole strengths are expected to be within a factor of two of the most accurate results achievable with the present level of theory and with experiment. The most prominent feature, near 820 cm^{-1} in both isomers, is due to ν_{23} (a deformation of the three-membered ring). The observed intensity of this mode (268×10^{-40} esu^2 cm^2) is very close to the calculated values. For the majority of the modes, it is difficult to compare observed intensities with the predicted values. The simulated IR spectra

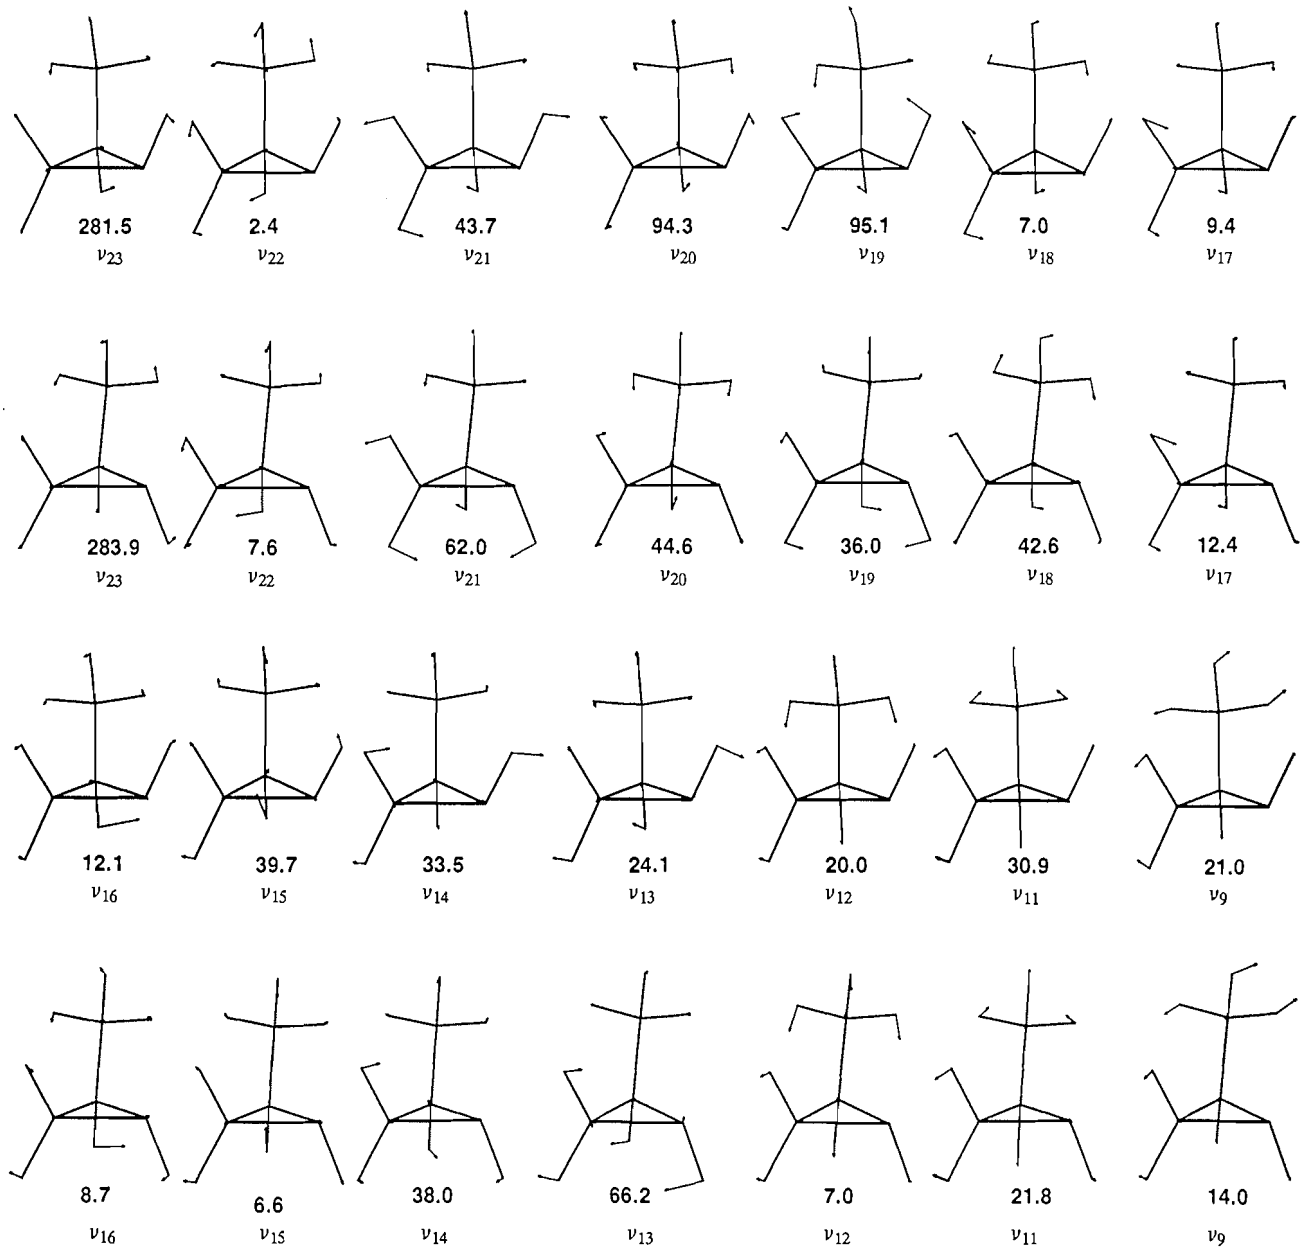

FIG. 6. Cartesian displacement vector representation of some of the normal modes between 800 and 1100 cm^{-1} of *cis*- and *trans*-2-methylaziridine. The bold-face numbers are the calculated dipole strengths in units of $esu^2\ cm^2$ ($\times 10^{40}$). The numbering is consistent with Tables 6 and 7.

of *trans*- and *cis*-2-methylaziridine, and of the calculated equilibrium mixture at room temperature (298 K), are compared to the experimental spectra in Figs. 4 and 5. In the region 400–1500 cm^{-1}, the majority of the line widths are in the range 5–12 cm^{-1}. The single major exception is the strong band at 820 cm^{-1}, which has a measured width of 19 cm^{-1}. In the simulations (Fig. 4), a constant linewidth of 8 cm^{-1} has been employed. As a consequence, the appearance of the 820 cm^{-1} feature is misleading. The remaining bands have about the correct overall intensity. The most obvious error occurs for the band at 1250 cm^{-1} in the spectrum of the *trans* isomer. This band is predicted to be much too intense, a situation exacerbated somewhat by the nonuniform scaling procedure. The associated normal mode, ν_{13}, involves motion of the N—H bond along the coordinate for pyramidal inversion (Fig. 6). Two other bands of the *trans* isomer are calculated to be anomalously intense, namely ν_{20} and ν_{18}, and one, ν_{17}, appears to be too weak, although the predicted intensity is only about a factor of two too low. The first of these, ν_{20} (and also ν_{19}) is predicted to be even more intense in the *cis* invertomer, while the second, ν_{18}, is a factor of six weaker.

Initial experience with the 6-31G*$^{(0.3)}$ basis set, based on comparison with calculations employing a much larger basis set, has suggested that the performance of this basis set with respect to the prediction of intensities in the C—H stretching region would be inferior to its performance in the mid-IR (12). The simulated spectra of the two isomers, the predicted equilibrium spectrum, and the experimental solution spectrum in the C—H and N—H stretching region are com-

pared in Fig. 5. The observed lines in this region are substantially broader than in the mid-IR. A width of 18 cm^{-1} (approximately the average of the observed values) has been used in the simulation. It is apparent that the predicted intensities are in the correct range and the simulated spectrum is, in fact, in reasonable agreement with the observed spectrum. It appears that with a few notable exceptions, the 6-31G*$^{(0.3)}$ basis set, originally developed to facilitate calculation of vibrational circular dichroism intensities, provides an economical means to obtain reasonable predictions of molecular geometries, force fields, and IR intensities.

Received August 13, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

GARY G. HOFFMAN, ROBERT A. HARRIS, and LAWRENCE R. PRATT. Can. J. Chem. **70**, 478 (1992).

This paper derives the finite temperature *optimized* Thomas–Fermi theory applicable to the electronic structure of atoms, molecules, and ions under conditions where both the bulk electron density and the electron temperature are substantial. The derivation provides a simple rule for transcribing the finite temperature case from the previous ground-state statistical electron-density functional theories.

Key words: plasma simulation, plasma chemistry, statistical theory of electron densities, Thomas–Fermi theory, optimized Thomas–Fermi theory.

GARY G. HOFFMAN, ROBERT A. HARRIS et LAWRENCE R. PRATT. Can. J. Chem. **70**, 478 (1992).

Dans ce travail, on a dérivé la théorie de Thomas–Fermi *optimisée* pour une température finie qui pourrait s'appliquer à la structure atomique d'atomes, de molécules et d'ions dans des conditions sous lesquelles la densité électronique globale ainsi que la température électronique sont importantes. Cette dérivation fournit une règle simple pour transcrire le cas de la température finie à partir des théories fonctionnelles de densité électronique statistique de l'état fondamental.

Mots clés : simulation de plasmas, chimie des plasmas, théorie statistique des densités électroniques, théorie de Thomas–Fermi, théorie optimisée de Thomas–Fermi.

Introduction

Interesting current research has focused on the ability to carry out numerical simulations of plasmas while explicitly treating electronic degrees of freedom (1). Such an ability is expected to further the understanding of a wide spectrum of problems (2, 3) including advanced methods for synthesis, processing, and characterization of exotic materials. The chemistry that takes place in laboratory plasmas is clearly important in plasma polymerization or plasma-assisted chemical vapor deposition (4–7), and in many analytical chemical methods (8), including methods involving laser ablation of surfaces.

Theoretical descriptions of plasmas of chemical interest typically focus first on identification of chemical species and of elementary chemical processes. These data are then often used as building blocks in modelling the dynamics of the plasma. The identification of chemical species usually begins with the Saha equation and the description of the ionic composition under equilibrium conditions at a temperature T (9). The primitive Saha treatment is physically sound for plasmas in the limit of low densities. But it will incur errors for higher densities because the electronic structures of the chemical constituents are not treated self-consistently with the electronic milieu. Going beyond the conditions of the primitive Saha treatment (10), there is special interest in circumstances where the electronic degrees of freedom equilibrate at a temperature $T = T_{\text{electron}}$ on a time scale that is short compared with the time required for equilibration of the nuclear translations. If the nuclear translations separately achieve thermal equilibrium, at least approximately, at a different temperature, the system would be regarded as a "two-temperature plasma." But if the nuclei are considered motionless on the electronic time scale this is just the familiar Born–Oppenheimer approximation (11).

The determination of the electron density as a function of nuclear coordinates is a first step towards a broader theory. In addition, it is just the information required by recent simulation calculations (1). The electron-density theory derived below starts from the assumption of the Born–Oppenheimer approximation and determines the electron densities self-consistently. No assumption of the equilibrium of the nuclear degrees of freedom is required. It will be clear that the present treatment is most natural when the electron density in the plasma is not too low. The present treatment is, therefore, complementary to the more traditional theoretical approaches that are correct at low density (9).

These developments build from recent work on statistical theories of electron densities in extended systems (12–17). The principal objective here is to work out the finite temperature version of the *optimized* Thomas–Fermi theory (14–17). The new result is indeed presented below. However, the finite temperature results can be *directly* transcribed from the previous ground state electron-density theory. This can be established by a simple, general, and physically transparent argument that is also given below. Some formal aspects of the finite temperature extension of our ground state approach have been derived previously (18). However, the present general derivation is important because of its simplicity in comparison with the previous derivation.

The corresponding spin density functional theory is formally a straightforward extension of these statistical meth-

ods (18, 19). Such an extension should be important in practical applications. However, since the consideration of spin densities is entirely independent of the issue of finite temperature, we ignore that extension here.

Statistical formulation of finite temperature electron density theory

Our previous developments studied the *ground state* electron density given by filling all levels below the Fermi energy μ:

$$[1] \quad \rho(\boldsymbol{r};\mu) = 2\sum_{\zeta} |\phi_\zeta(\boldsymbol{r})|^2 \eta(\mu - \varepsilon_\zeta)$$

where $\eta(z)$ is the Heaviside function and $\phi_\zeta(\boldsymbol{r})$ and ε_ζ are, respectively, eigenfunctions and eigenvalues of the density-dependent, single-particle Hamiltonian

$$[2a] \quad \boldsymbol{H} = -\frac{\hbar^2}{2m}\nabla^2 + v(\boldsymbol{r};\rho)$$

It is known as a matter of principle that a $v(\boldsymbol{r};\rho)$ exists, which produces the exact density (20–22). Furthermore, approximate $v(\boldsymbol{r};\rho)$ are available, which produce reasonable densities (23). Double occupancy has been assumed in [1] and this accounts for the factor of 2.

The density theories we will construct here are based upon the fact that, at a nonzero temperature $T \equiv \beta^{-1}$, the density can be obtained from thermal population of the self-consistent eigenstates of a thermal $\boldsymbol{H}(\beta)$:

$$[3] \quad \rho(\boldsymbol{r};\mu,\beta) = 2\sum_{\zeta} \frac{|\psi_\zeta(\boldsymbol{r},\beta)|^2}{1 + \exp\{\beta(\varepsilon_\zeta(\beta) - \mu)\}}$$

Here $\psi_\zeta(\boldsymbol{r},\beta)$ and $\varepsilon_\zeta(\beta)$ are eigenfunctions and eigenvalues of the Hamiltonian $\boldsymbol{H}(\beta)$:

$$[2b] \quad \boldsymbol{H}(\beta) = -\frac{\hbar^2}{2m}\nabla^2 + v(\boldsymbol{r};\beta,\rho)$$

The structure of this theory is analogous to the thermal Hartree or Hartree–Fock theories (24). However, it is clear that a functional $v(\boldsymbol{r};\beta,\rho)$ exists that would produce the exact thermal density (25). The dependence of the $v(\boldsymbol{r};\beta,\rho)$ on β has been made explicit in [2*b*]. Although the β dependence, beyond the functional dependence on the density, should be assumed throughout, we subsequently drop this explicit notation.

The density matrix associated with this theory is just

$$[4] \quad \rho(\boldsymbol{r},\boldsymbol{r}') = 2\sum_{\zeta} \frac{\psi_\zeta(\boldsymbol{r})\psi_\zeta^*(\boldsymbol{r}')}{1 + \exp\{\beta(\varepsilon_\zeta - \mu)\}}$$

We next focus on expressing [4] so that it provides a natural description of the electron densities in disordered, extended materials where the manipulation of the orbitals $\psi_\zeta(\boldsymbol{r})$ is likely to be awkward. To this end, the density matrix [4] is written as

$$[5] \quad \rho(\boldsymbol{r},\boldsymbol{r}') = 2\int_{-\infty}^{\infty} \sum_{\zeta} \frac{\psi_\zeta(\boldsymbol{r})\psi_\zeta^*(\boldsymbol{r}')\delta(\varepsilon - \varepsilon_\zeta)}{1 + \exp\{\beta(\varepsilon - \mu)\}} d\varepsilon$$

An integration-by-parts yields

$$[6] \quad \rho(\boldsymbol{r},\boldsymbol{r}') = 2\int_{-\infty}^{\infty} \left\{\sum_{\zeta} \psi_\zeta(\boldsymbol{r})\psi_\zeta^*(\boldsymbol{r}')\eta\left(\mu + \frac{4\alpha}{\beta} - \varepsilon_\zeta\right)\right\} \times \operatorname{sech}^2(2\alpha)\, d\alpha$$

This extremely simple formula allows us to transcribe corresponding finite-β theories from all the previous ground state results. Note that $\operatorname{sech}^2(2\alpha)$ is a simple probability density on the interval $(-\infty,\infty)$. Therefore, [6] shows that the finite β result corresponds to an averaging of ground state densities according to a distribution of Fermi energies. Because of this, the Monte-Carlo methods devised elsewhere (13, 15, 16) to implement the ground state theory are directly applicable to the finite temperature theory as well. In particular, the thermal result can be implemented by considering cyclic paths $\{\boldsymbol{r},\boldsymbol{r}_1,\ldots,\boldsymbol{r}_{p-1},\boldsymbol{r}\}$ and evaluating the integrals

$$[7a] \quad \rho(\boldsymbol{r}) = \frac{4}{2^{3p/2}\,\Gamma\left[\frac{3(p-1)}{2}\right]\pi^{3/2}} \lim_{z^*\to\infty} \int_0^{\infty} \langle (k_p z)^{3p/2} J_{3p/2}(k_p z)\eta(k_p^2)\rangle_{z,\beta} \frac{e^{-z/z^*}\,dz}{z^4}$$

with the definitions:

$$[7b] \quad \langle f(k_p^2)\rangle_{z,\beta} = \frac{\int d^3a_1 \ldots \int d^3a_{p-1}\,\delta\left(z^2 - \sum_{m=1}^{p-1} a_m^2\right)\int_{-\infty}^{\infty} d\alpha\, f(k_p^2)\operatorname{sech}^2(2\alpha)}{\int d^3a_1 \ldots \int d^3a_{p-1}\,\delta\left(z^2 - \sum_{m=1}^{p-1} a_m^2\right)}$$

$$[7c] \quad \frac{\mathbf{a}_m}{\sqrt{2p\left\{1 - \cos\left(\frac{m\pi}{p}\right)\right\}}} = \sqrt{\frac{2}{p}}\sum_{j=1}^{p-1} (\boldsymbol{r}_j - \boldsymbol{r})\sin\left(\frac{mj\pi}{p}\right)$$

$$[7d] \quad \frac{\hbar^2 k_p^2}{2m} = \mu + \frac{4\alpha}{\beta} - \frac{1}{p}v(\boldsymbol{r};\rho) - \frac{1}{p}\sum_{j=1}^{p-1} v(\boldsymbol{r}_j;\rho)$$

The $p \to \infty$ limit identifies the exact density. Reference 15 can be consulted for further discussion of these formulae.

Finite temperature optimized Thomas–Fermi theory

If the potential was weakly varying over lengths compa-

rable with the Fermi wavelength $(8\pi/3\rho)^{1/3}$ then the Thomas–Fermi approximation for the ground state density,

$$[8] \quad \rho(\boldsymbol{r};\mu,\beta=\infty) = \frac{1}{3\pi^2}\left\{\frac{2m}{\hbar^2}[\mu - v(\boldsymbol{r};\rho)]\right\}^{3/2} \times \eta[\mu - v(\boldsymbol{r};\rho)]$$

would be appropriate (14–17, 26). When β is finite the familiar thermal Thomas–Fermi approximation obtains

$$[9] \quad \rho(\boldsymbol{r};\mu,\beta) = \left(\frac{1}{\pi}\right)^2 \int_0^\infty \frac{k^2\,dk}{1 + \exp\left\{\beta\left[\frac{\hbar^2k^2}{2m} + v(\boldsymbol{r};\rho) - \mu\right]\right\}}$$

The functional relation between the density and the potential depends on β.

The *optimized* Thomas–Fermi approximation is motivated by the view that it is rather draconian to evaluate the potential $v(\boldsymbol{r};\rho)$ only at the point where the density is sought. More physically, the density depends on the potential in the neighborhood of the point in question. In the interest of simplicity, we can agree to retain the simple form, [9], but we can make it more accurate by replacing $v(\boldsymbol{r};\rho)$ with a parameter v_r chosen so as to make the first-order corrections to [9] vanish (14–17). Using [6] together with the results of ref. 14 or 17, we can express the finite temperature *optimized* Thomas–Fermi theory as the two equations:

$$[10] \quad \rho(\boldsymbol{r};\mu,\beta) = \left(\frac{1}{\pi}\right)^2 \int_0^\infty \frac{k^2\,dk}{1 + \exp\left\{\beta\left(\frac{\hbar^2k^2}{2m} + v_r - \mu\right)\right\}}$$

and

$$[11] \quad 0 = \int d^3r'\left[\frac{v(\boldsymbol{r}';\rho) - v_r}{|\boldsymbol{r} - \boldsymbol{r}'|^2}\right]\int_0^\infty dk\, k^3 j_1(2k|\boldsymbol{r} - \boldsymbol{r}'|) \times \operatorname{sech}^2\left[\frac{\beta}{2}\left(\frac{\hbar^2k^2}{2m} + v_r - \mu\right)\right]$$

$j_1(z)$ is the spherical Bessel function of order $\nu = 1$. Equation [11], although implicit and nonlinear, operationally determines the v_r that is required in [10]. The functional relation between density and v_r depends on β in just the same way as the thermal Thomas–Fermi theory. But the effective potential v_r acquires additional temperature dependence.

Discussion

Several aspects of this theory deserve further discussion. Firstly, the electron density provided by the Thomas–Fermi theory becomes infinitely large near an atomic nucleus. There is a long history of concern with just this behavior. The *optimized* Thomas–Fermi theory removes this divergence and this advantage is inherited by the finite temperature *optimized* Thomas–Fermi theory. Alternatively, the use of effective core potentials can lead to improvements in the theory. This procedure accurately reflects the finite temperature quantum behavior of electrons near an atomic nucleus (1, 27). Incorporation of such an effective potential in the present theory could lead to a concomitant, self-consistent improvement of the theoretical description.

Secondly, these methods can be further extended to establish the equilibrium concentrations of ions of various types, as the Saha equation does in its regime of validity. The spectroscopy of the plasma (3) can also be treated by similar methods. The connection is that all these quantities intrinsically depend, as does the electronic correlation energy (28), upon the density of states defined by

$$[12] \quad g(\boldsymbol{r},\boldsymbol{r}';\varepsilon) = \sum_\zeta \psi_\zeta(\boldsymbol{r})\psi_\zeta^*(\boldsymbol{r}')\delta(\varepsilon - \varepsilon_\zeta)$$

Since this density of states can be expressed by the statistical methods utilized here, the physical quantities mentioned above also can be worked-out within the present approach.

Finally, it deserves to be emphasized that statistical methods are especially natural for extended systems without explicit simplifying symmetries associated with nuclear positions. The computational study of irregular many atom systems is no more difficult than that of a single atom. Therefore, we expect that these results should help in understanding chemistry that can occur in laboratory plasmas. We hope to return to those problems with more applied results in the future.

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

W. G. LAIDLAW, W. G. WILSON, and DENNIS A. COOMBE. Can. J. Chem. **70**, 482 (1992).

We introduce two simple foam blockage rules and examine their effect on sweep efficiency through a porous medium. Applying a random walk simulation method, it is found that an efficient sweep can be performed by a blockage mechanism where every invaded throat is blocked upon invasion. The blocking foam lamella must also have a large, but not necessarily infinite, decay time. This result is interpreted as a reduction in the interface speed.

Key words: porous media, viscous fingering, foam flow.

W. G. LAIDLAW, W. G. WILSON et DENNIS A. COOMBE. Can. J. Chem. **70**, 482 (1992).

On présente plusieurs régles relatives au blocage de mousses simples et on examine leur effet sur l'efficacité de déplacement à travers un milieu poreux. Lorsqu'on applique une méthode de simulation aléatoire, on trouve qu'un déplacement efficace nécessite un mécanisme de blocage par lequel chaque gorge doit être bloquée lorsqu'elle est envahie. Le temps de dégradation de la lamelle de mousse qui assure le blocage doit être assez grand, sans être nécessairement égal à l'infini. On interprète ce résultat en fonction d'une suppression des longueurs d'onde instables d'un point de vue de la diffusion; normalement cette suppression conduirait à la croissance de doigts du liquide qui envahit et un encerclement du fluide qui assure la défense.

Mots clés : milieux poreux, doigts du liquide visqueux, écoulement de mousses.

[Traduit par la rédaction]

Introduction

Foam has been introduced into the invading phase of a flood of an oil-saturated porous medium in an attempt to reduce the residual oil saturation (1). The expectation is that local regions of high permeability (invader-saturated regions) will become blocked, forcing the invader fluid into regions of lower permeability (oil-saturated regions). Network simulations of the effect of foam on the mobility of two-phase displacements in porous media have been suggested by a number of authors (2). Of particular interest is the pore-scale percolation-like treatment of Rossen, who suggested that the presence of blocking "foam lamella" could be accommodated by a rescaling of percolation results (2*a*). We have extended this idea to a number of foam-blockage scenarios (3). Unfortunately percolation treatments do not provide any dynamic information and so preclude an investigation of the effect of foam on phenomena such as viscous fingering. Methods of generating structures dynamically using systems of "random walkers" have been developed and applied to a variety of problems from simple invasion (4*a*) to local representations of rate processes (4*b*). In previous work we applied these concepts to pore-scale simulation of an immiscible displacement process in porous media and discussed in some detail a computer simulation based on the use of two armies of random walkers, the invaders and the defenders (5). Since a random walker method is essentially a diffusion process we were able to assess dynamic effects such as viscous fingering in two-phase flow.

In this report we apply our random walk pore-scale simulations in an attempt to understand foam effects on flow through porous media. The "foam rules" that we have implemented in the following work have sufficient complexity to produce the qualitative features expected with blockage by foam lamella under a variety of viscosity ratio values.

Incorporating the effects of foam at the microscopic scale involves knowledge of the precise mechanisms operating at that scale. However, most of the known results come from either the core scale or the field scale (1). In our simulations we would ideally utilize qualitative results, if not quantitative results, from pore-scale micromodels as the input to our simulations. The input would be framed as a rule or set of rules governing lamella creation, motion, and destruction while in the network. Although there is some information available to stipulate microscopic rules (6) we will consider a variety of plausible mechanisms. Simple rules can be incorporated within the two-species simulation, implicitly assuming that the foam has some statistical behavior that can be "integrated" out of the problem. More complex rules may require the introduction of a third "species" of random walker in the simulation.

Simple foam rules

Although we have examined only two of the potential simple rules, let us discuss several. The first, and trivial, case is to consider simple entrainment of lamella. As long as no other properties of foam are added, such as hanging up in small throats, this amounts to a simple change in the viscosity of the invading phase. The effects of viscosity on the invaded network are known (7) and range from the viscous fingering situation (low viscosity invader phase) to the stable displacement situation (highly viscous invader). In the

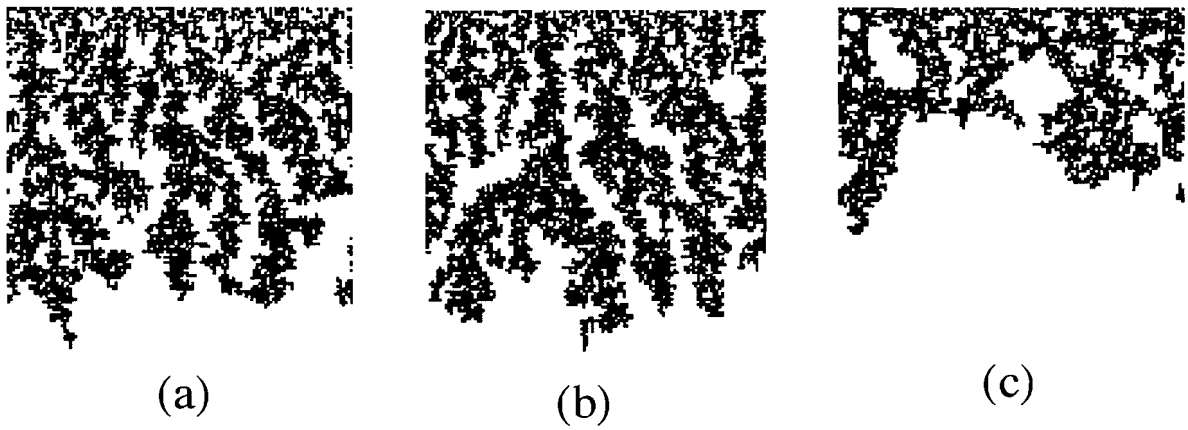

FIG. 1. The effect of static foam blockage on a viscous fingering displacement process with a viscosity ratio $\mu_r = 0.1$ and blockage probabilities (*a*) $\rho_b = 0.05$, (*b*) $\rho_b = 0.25$, and (*c*) $\rho_b = 0.5$. Very little effect on the invader saturation is observed.

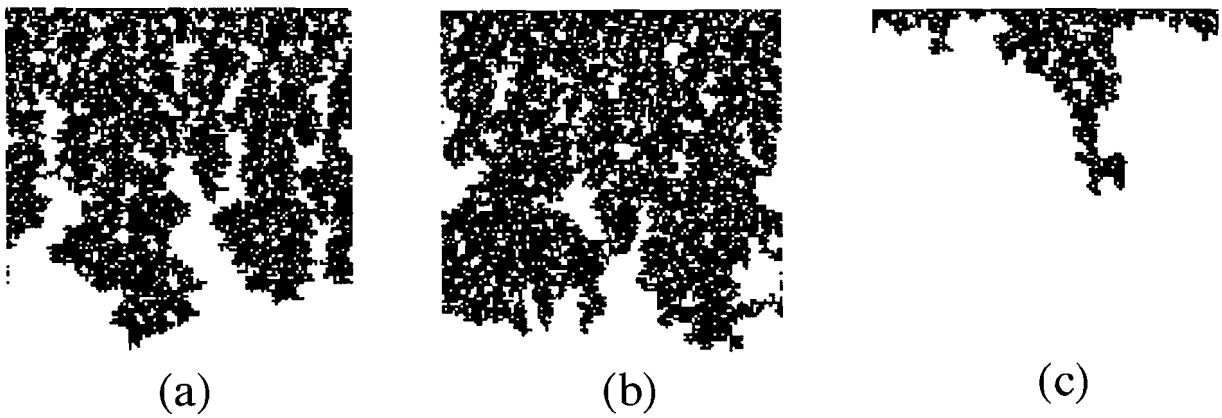

FIG. 2. The effect of static foam blockage on a displacement process with a viscosity ratio $\mu_r = 1.0$ and blockage probabilities (*a*) $\rho_b = 0.05$, (*b*) $\rho_b = 0.25$, and (*c*) $\rho_b = 0.5$. As in Fig. 1, very little effect on the invader saturation is observed. In (*c*), the invasion process has been halted by complete front blockage.

"entrained lamella interpretation," the viscous fingering would give way to stable displacement, to some extent, when lamella are included. In this case, the question becomes how lamella density changes the invader viscosity (1*a*, 8). But this viscosity change also depends on how easily the lamella are pushed through the network, which must depend on local conditions such as throat size. However, this is more of a hydrodynamic problem than a network problem and will not be treated in our simulations at this time.[2]

Static foam blockage

A nontrivial incorporation of lamella (at the macroscopic scale) is to allow lamella to block throats through the network. Two levels of complexity can be included. The most difficult scenario is to follow the lamella's movement throughout the network; then, via some microscopic rules, let it stop and permanently block a throat. These rules could be arbitrarily complex, depending on such things as throat size, local pressure gradients, and so on. However, this complexity adds to the simulation time. We instead make an appeal to statistical arguments.

As shown in our earlier work (9), no significant qualitative change is observed in the invaded structure when details such as individual throat sizes are included in the simulation. The exact configuration of randomly positioned throats is of no consequence to the global displacement process. Hence, to increase speed, we have chosen to perform simulations on networks with throats of a single size. Given this consideration, we can assume that a single simulation represents a possible outcome from an ensemble of different specific configurations of throat sizes. From some presumed understanding of lamella blocking behavior with respect to throat size, we could calculate the probability that a randomly chosen throat is blocked. It is this probability that we incorporate in our algorithm. Consider blocking at the invader front: all that is needed is to block a newly invaded throat with the chosen probability. Once blocked, no more of the invader phase is allowed to pass through that particular throat. This process is simple to add to the algorithm. A set of bits (one per throat) is distributed with one's and zero's according to the blockage probability. A second set of bits representing throat states (0 = flowing, 1 = blocked)

[2]The effect of throat and pore size on the conductivity of a network was investigated extensively in earlier work; see ref. 9, especially sections 4B and 4C using the method of Kirkpatrick to calculate the conductivity of small networks.

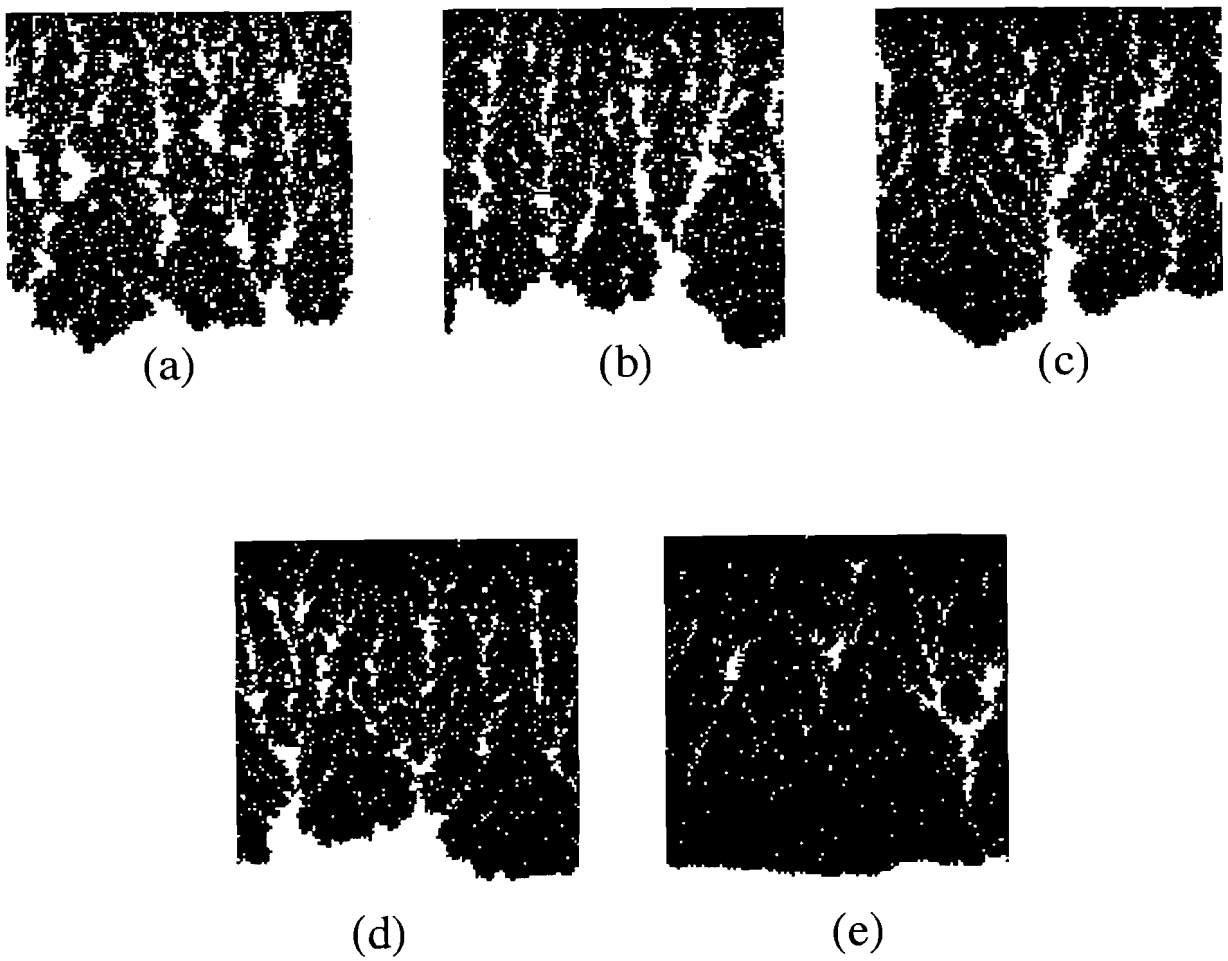

FIG. 3. The effect of dynamic foam blockage on a displacement process with a viscosity ratio $\mu_r = 1.0$, blockage probability $\rho_b = 1.0$, and unblockage probabilities (*a*) $\rho_u = 0.1$, (*b*) $\rho_u = 0.01$, (*c*) $\rho_u = 0.005$, (*d*) $\rho_u = 0.0025$, and (*e*) $\rho_u = 0.001$. A large effect on the invader saturation is observed.

is also included. At every simulation step the probability bits are randomly shuffled, and if the invasion of a throat takes place when its "blockage probability bit " is one, the throat is not invaded, but rather blocked by setting its state to one.

Figures 1 and 2 show results for such a blocking mechanism under a variety of conditions. In each pattern the dark regions represent invader fluid and the light parts the defender fluid. These simulations have been performed on a square lattice with a width of 128 and length of 200 sites. The runs in Fig. 1 represent a viscous fingering situation with an invader-to-defender viscosity ratio, denoted by $\mu_r = 0.1$, and with throat blockage probabilities, denoted by ρ_b, of (*a*) 0.05, (*b*) 0.25, and (*c*) 0.5. Figure 1(*a*) is essentially identical to a no-blockage scenario. It is obvious that this specific form of the foam mechanism is of no help in enhancing the removal of the defender phase. In fact, for any blockage probabilities greater than one-half, the two-dimensional bond-percolation threshold fraction, the invasion process must stop due to blockage of all throats along the invader front. The runs in Fig. 2 have identical blockage probabilities, but represent the case when the two phases have identical viscosities. It may appear that a blockage probability of 0.25 increased the invader saturation, but this is a statistically unsound conclusion from comparing just this one run. However, at 0.5, the front has completely stopped due to complete blockage at the front. Clearly, more structure must be included in the foam model.

The runs in Figs. 1 and 2 represent only one of three possible blocking mechanisms, blockage that occurs in throats as the invading phase sweeps through the throat for the first time. Another scenario would permit blockage to occur at any time and at any place within the invader-saturated region. This latter mechanism is called "behind-the-front" blockage, while what we have treated is "at-the-front" blockage. Behind-the-front blockage likewise suffers from the percolation threshold problem. A final scenario is the "leave-behind" blockage, which is the blockage of throats whose attached pores have been invaded, but the throat itself has not been invaded. This mechanism may result in an anisotropic percolation problem, meaning the percolation threshold problem may not have a significant effect.

Dynamic foam blockage

The treatment discussed in the previous section assumed that the lifetime of a blocking lamella is infinite. Thus, once a throat is blocked, it is forever blocked, leading to the front stoppage shown in Fig. 2(*c*). It is well known that lamella are not infinitely long-lived; thin film drainage is a major

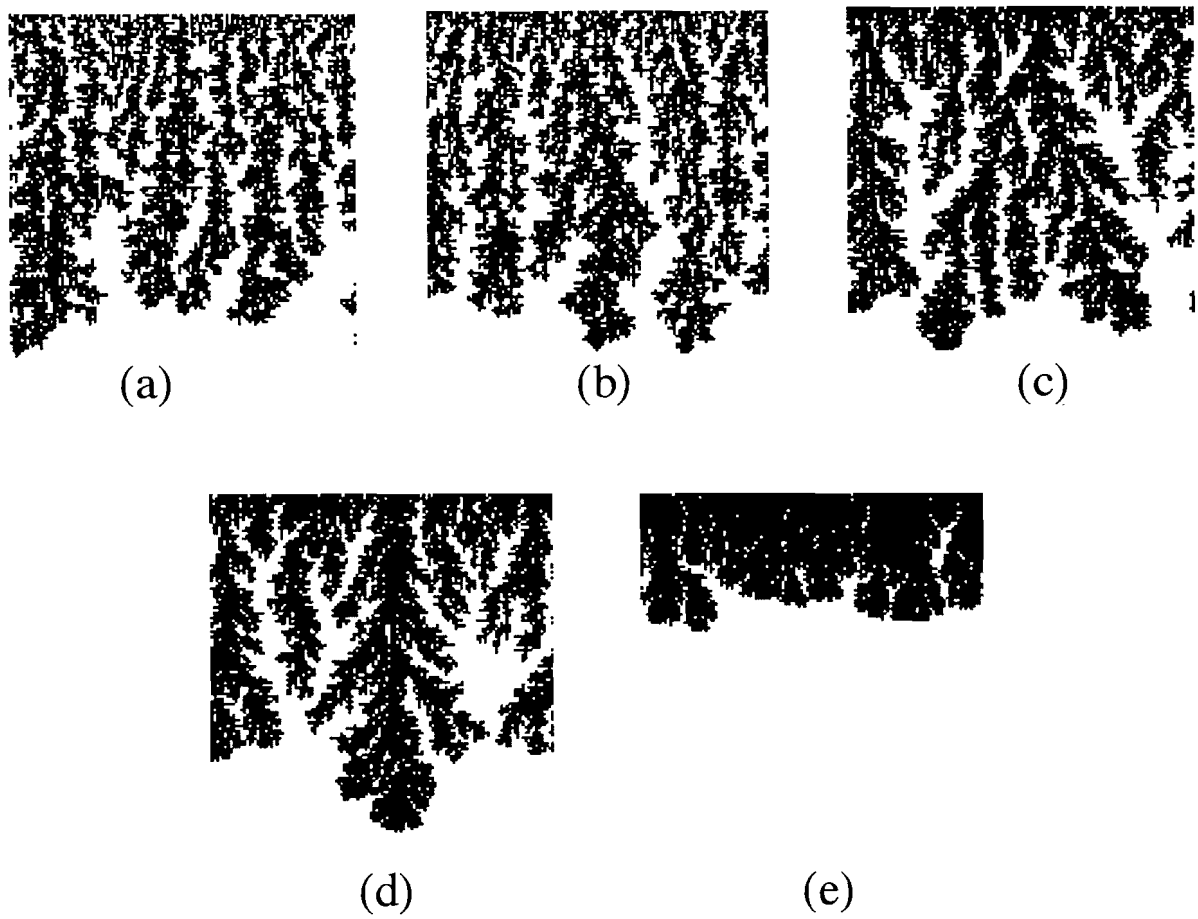

FIG. 4. The effect of dynamic foam blockage on a displacement process with a viscosity ratio $\mu_r = 0.1$, blockage probability $\rho_b = 1.0$, and unblockage probabilities (*a*) $\rho_u = 0.1$, (*b*) $\rho_u = 0.01$, (*c*) $\rho_u = 0.001$, (*d*) $\rho_u = 0.0005$, and (*e*) $\rho_u = 0.0001$. As in Fig. 3, a large effect on the invader saturation is observed, but at smaller unblockage probabilities.

problem in stability of foams (6, 8, 10). We have made an attempt to incorporate this feature by adding a half-life to the lamella. This is accomplished by giving each "living" lamella blockage some probability to "die" every simulation step and subsequently unblock the throat. Again, this is included within simple foam constructs since no additional walker species are needed in order to perform the simulation. What is required, however, is an additional set of bits distributed according to the "unblockage probability per simulation step."

Figure 3 displays the results for a viscosity ratio of $\mu_r = 1.0$ for the two phases, with various lamella half-lives $\tau_{1/2}$. In all of the following simulations, blockage occurs in every invaded throat, i.e., $\rho_b = 1.0$. This could not be allowed in the static blockage scenario, as discussed above, since a blockage probability greater than one half results in a fully plugged network. We anticipate that lower blockage probabilities would show the same relative shifts with sweeps of lower efficiency. Figures 3(*a*)–(*e*) show the final configurations for the unblocking probabilities, denoted ρ_u, of 0.1, 0.01, 0.005, 0.0025, and 0.0010, respectively. These probabilities correspond to lamella half-lives of roughly 7, 69, 140, 280, and 690 timesteps, respectively. As can be seen, the effect is to increase the invader saturation to nearly 100% for the large half-life case. This is the same effect as is seen by changing the viscosity ratio to ever increasing values: the invader phase becomes effectively more viscous, resulting in a much more stable displacement.

Figure 4 presents the corresponding pictures for a viscosity ratio of 0.1, where the defender phase is an order of magnitude more viscous than the invader phase. Given in Figs. 4(*a*)–(*e*) are the final configurations for lamella unblockage probabilities of 0.1, 0.01, 0.001, 0.0005, and 0.0001, respectively. The smallest unblockage probability corresponds to a lamella half-life of approximately 6 900 simulation steps. Again, one can see the increasing invader saturation for increasing lamella half-life.

The effect of keeping the lamella half-life constant at $\rho_u = 0.001$ while changing the viscosity ratio is shown in Figs. 5(*a*)–(*d*) for the viscosity ratios 1.0, 0.5, 0.25, and 0.1. It is apparent that the stability of the foam need not be as great for the higher viscosity ratios in order to obtain a complete sweep of the network, but the same foam has little effect on viscous fingering situations.

These pictorial representations of dynamic foam blockage are given a more quantitative representation in Fig. 6. Each simulation for a given viscosity ratio and chosen decay rate was repeated five times to obtain an average value of the invader saturation in a central portion of the lattice. For an adverse viscosity ratio ($\mu_r = 0.125$) and a very unstable foam ($\rho_u = 0.01$) the invader saturation is quite low, typical of a viscous fingering displacement process. However, for this

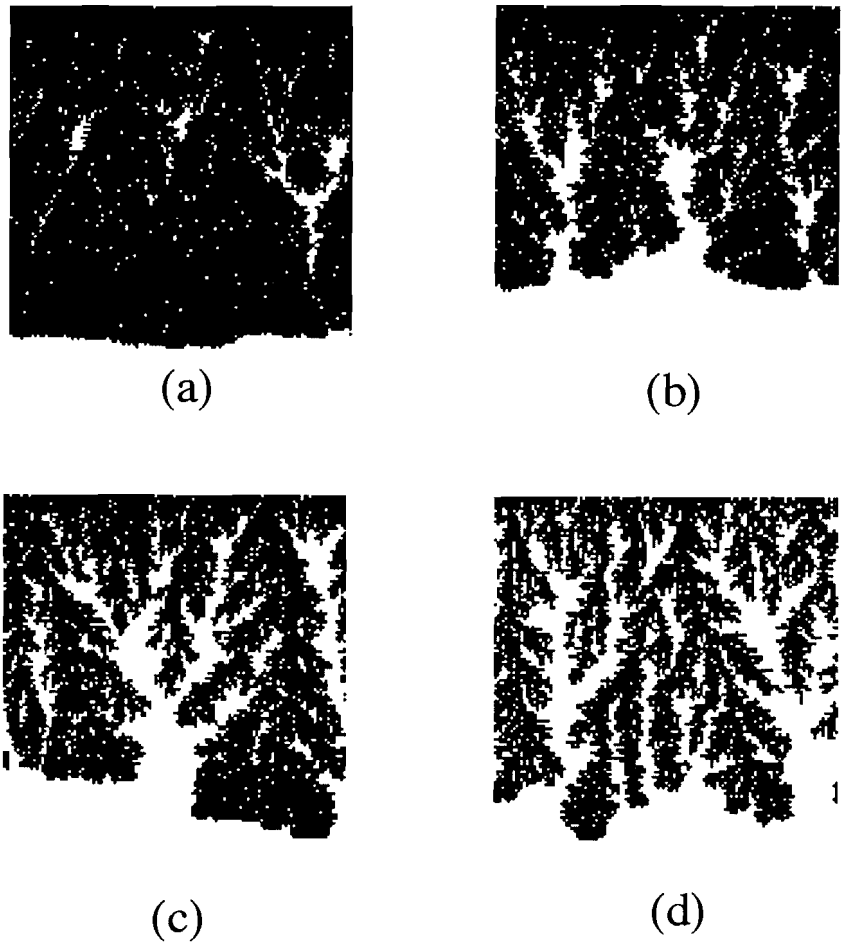

FIG. 5. The effect of dynamic foam blockage on a displacement process with a blockage probability $\rho_b = 1.0$, unblockage probability $\rho_u = 0.001$, and viscosity ratios (*a*) $\mu_r = 1.0$, (*b*) $\mu_r = 0.5$, (*c*) $\mu_r = 0.25$, and (*d*) $\mu_r = 0.125$.

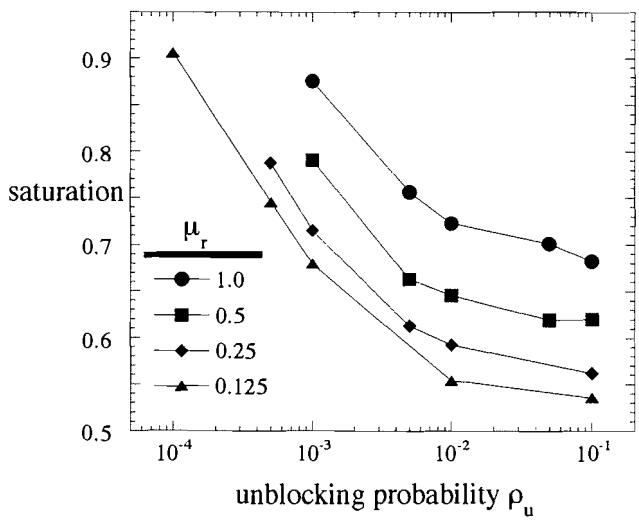

FIG. 6. The effect of dynamic foam blockage on the invader phase saturation as a function of the unblockage probability for various viscosity ratios. The lower right region represents viscous fingering while the upper left region represents stable displacements.

same viscosity ratio but a more stable foam ($\rho_u = 0.0001$) the invader saturation rises dramatically to about 90%.

Discussion

Inefficient sweeps occur, in part, because of an instability present in the coupled equations governing fluid flow through porous media, as discussed by Saffman and Taylor (*7a*). For a viscosity ratio $\mu_r < 1$, the growth of these instabilities is proportional to the speed of the interface between the two fluids. Without the dynamic foam blockage presented here, advance occurs randomly in throats all along the surface of the front, the front velocity is high, and viscous fingering erupts. There are two approaches to remove the instability, one involving a bulk mechanism, and the other involving a surface mechanism. For the bulk mechanism the approach would be to reduce the viscosity of the invader fluid phase. We have not considered this mechanism in this paper. The other approach is to reduce the velocity of the interface. This is exactly what is accomplished by the foam blockage we have presented. While a throat is blocked, advance of the front at that location cannot occur and, for a long lamella half-life, this is the case for most of the throats. Thus advance is occurring, on average, only in widely separated throats, and the interface speed is very low. As shown in our

results, this lowered interface speed is sufficient to supress the fingering instabilities.

In summary, we have examined two foam blockage scenarios for their effect on enhanced sweeps of porous media. Limited foam blockage by infinitely stable lamella does not result in greater sweep efficiency. Very high blockage is required, and even then one must have lamella that decay with a half-life appropriate for the invasion-to-defender viscosity ratio.

Clearly, there are practical difficulties with such a blocking process. The lamella that are introduced to the medium at the source must be completely stable against decay while moving to the front. Once a lamella has reached the front, it must then decay with the appropriate half-life.

Classical phase space is not homogeneous, but contains barriers (such as KAM tori) that, whether intact or broken, affect the temporal evolution of dynamical systems. In this article, we study the quantal manifestations of these classical-mechanical structures. Here, the particular system is the kicked top, which consists of an angular momentum vector precessing about one direction and experiencing periodic sudden kicks around another direction. We find that a suitably defined probability distribution function (constructed from the time-dependent state vector) shows transitions from classically allowed regions to inaccessible regions at the locations where the classical dynamics places the KAM tori.

Key words: bottlenecks, phase space, transport, spin systems, Correspondence Principle.

J. L. BOORSTEIN et T. UZER. Can. J. Chem. **70**, 488 (1992).

L'espace d'une phase classique n'est pas homogène, mais comporte des barrières (telles que des tores de KAM) qui, intactes ou brisées, affectent l'évolution temporale des systèmes dynamiques. Dans cet article, on étudie les manifestations en termes quantiques de ces structures de la mécanique classique. Ici, le système particulier est le «kicked top» qui consiste en un vecteur de moment angulaire effectuant une précession dans une direction et éprouvant d'une façon périodique des sauts soudains dans une autre direction. On a observé qu'une fonction de distribution de probabilités définie adéquatement (construite à partir d'un vecteur d'état dépendant du temps) montre que les transitions entre les régions permises d'une façon classique et les régions inaccessibles sont situées là où la dynamique classique place les tores de KAM.

Mots clés : goulots, espace d'une phase, transport, systèmes de spin, principe de correspondance.

Introduction

The two key assumptions of the Rice–Ramsperger–Kassel–Marcus (RRKM) theory of unimolecular reactions are that intramolecular energy redistribution is complete and fast compared with the time scale for unimolecular dissociation (1, 2). Notwithstanding the widespread success of this theory, even early on it was recognized that its hypotheses did not seem to apply to some chemical reactions (such as chemical activation experiments (1)). Another particularly severe breakdown was seen in the predissociation of excited van der Waals molecules like HeI_2, where the molecule has more than enough energy to dissociate, but lives for a very long time because the dissociation energy has great difficulty reaching the reactive mode (3).

With the application of classical mechanics to molecular systems through classical trajectories (4) it became possible to gain insight into the microscopic dynamical processes that are subsumed by statistical theories. These and related applications of nonlinear dynamics (5) have demonstrated that phase space is not homogeneous, but contains barriers that can steer the dynamics away from some energetically allowed regions. For example, when the mode energies of the molecule OCS were explored by classical trajectories (6), it was found that they did not decay or increase monotonically to their statistical limits. Instead, trajectories were sometimes trapped behind intramolecular bottlenecks for many vibrational periods, resulting in nonstatistical relaxation (7). Clearly, the dissociation behavior of such molecular systems can also be expected to be nonstatistical and nonrandom.

These chemical observations are among the many manifestations of how dynamical phase-space barriers affect transport phenomena. Their identification in widely differing physical systems attests to their universality (for a review, see ref. 8). According to the Kolmogorov–Arnol'd–Moser (KAM) theorem (9), these barriers must exist in generic nearly integrable systems, and are therefore referred to as KAM tori. As some nonlinearity parameter is varied, however, these impenetrable barriers gradually break up, giving rise to partially penetrable barriers called "cantori" (10). The latter structures may still act as obstacles to phase-space flow, and determine the transport properties of mechanical systems.

Based on earlier work on the transition to global stochasticity (5), MacKay *et al.* (11) and Bensimon and Kadanoff (12) developed a quantitative approach to transport that predicts relaxation rates even when nonstatistical correlations persist (13). Davis (7) undertook the application of these ideas to intramolecular energy transfer (for a recent review, see ref. 14), and coined the term "intramolecular bottleneck" to describe cantori. This terminology emphasizes the connection of this recent work with earlier statistical theories.

Since molecular systems are subject to the laws of quantum rather than classical mechanics, it is necessary to question whether or not these phase-space barriers are relevant for the quantum mechanical regime. The answer turns out to be affirmative and, perhaps surprisingly, these barriers assert their existence and significance even away from the Correspondence Principle limit (8, 15). Furthermore, while one usually associates confinement (of particles) with clas-

sical mechanics and spreading (of wavepackets) with quantum mechanics, many times these barriers are found (8, 15) to be more confining in quantum mechanics than in classical mechanics!

A thorough investigation of these barriers in realistic quantum mechanical systems is a difficult task. The difficulties are both technical (a large parameter space, complicated classical behavior, corresponding quantum mechanics being further complicated by the very large number of states involved) as well as conceptual (the need to use subtle forms of the quantum–classical correspondence to mimic classical phase space). These barriers have now been seen in the quantal multiphoton dissociation calculations of HF (16), in the comparison of quantal and classical dynamics for OCS (17, 18), and in the microwave ionization of hydrogen atoms (for reviews, see ref. 19).

While such efforts are continuing, most salient features of the quantum–classical correspondence at these barriers can be readily researched on relatively simple systems. Since these structures are generic and universal, understanding them in a particular model can (and does) provide understanding for a very broad class of related problems. This approach is very much in keeping with the great success and decisive impact that simple, generic models such as the Standard Map (5) and kicked rotator (5, 20, 21) have had in chaos research. The Standard Map has been the proving ground for chaos in classical mechanics (thus the name), while much of our understanding of the quantal manifestations of chaos is derived from research on the kicked rotor (or pendulum). In fact, a most illuminating study on the effects of KAM barriers on quantum dynamics was recently performed on the kicked rotor (8, 15).

Because of our interest in the classical–quantal correspondence for rotating systems (22), we investigated the effect of KAM barriers on quantum–mechanical probability flow when rotations (rather than only translations, as in the kicked rotor) are involved. As our model, we have chosen the paradigm for chaotic rotations, namely the kicked top (23–26). The kicked top is a spin system in which an angular momentum vector $\boldsymbol{J}$ (of fixed magnitude $j(j + 1)$) undergoes a linear precessional motion about one direction, and receives impulsive nonlinear kicks about an orthogonal direction. The classical dynamics of this system shows both regular and chaotic motion. Quantum mechanically, the system can be described in terms of a finite dimensional Hilbert space of dimension $2j + 1$, and therefore no artificial truncation in the number of states needs to be imposed. This, in addition to the generic nature, is one of the most desirable aspects of the model. In this article, we show that the KAM barriers and cantori can hinder probability flow in rotational systems, and that tunneling allows probability to penetrate into classically forbidden regions, as was observed in the kicked rotor.

The model

Consider a compass needle in a oscillating magnetic field (27). The quantum-mechanical generalization of that classical system is governed by the Hamiltonian

$$[1] \qquad H = AS_z^2 - \mu \boldsymbol{B}(t) \cdot \boldsymbol{S}$$

where μ is the magnetic moment of the quantum-mechanical particle with spin $\boldsymbol{S}$, A is the anisotropy in an easy plane of magnetization (28), and $\boldsymbol{B}(t)$ is the external time-varying magnetic field. When $\boldsymbol{B}$ has the form $\boldsymbol{B} = B_0 \cos \omega t \, \hat{x}$, chaotic trajectories are observed (27) for any B_0, and the system becomes completely stochastic at a critical field strength. The semiclassical dynamics of Hamiltonian [1] was studied by Frahm and Mikeska (29).

The kicked top is obtained from eq. [1] by replacing the continuous action of the magnetic field by a periodic train of impulsive kicks, i.e.,

$$[2] \qquad H = \frac{\hbar k}{2j\tau} J_z^2 + \hbar p J_y \sum_{n=-\infty}^{\infty} \delta(t - n\tau)$$

where j is the angular momentum quantum number, τ is the duration between kicks, and k and p are related respectively to A and μB in eq. [1]. Here, the system is characterized by an angular momentum vector $\hbar \boldsymbol{J} = \hbar(J_x, J_y, J_z)$, where the components of the angular momentum satisfy the usual commutation relation $[J_k, J_l] = i\hbar\epsilon_{\mathrm{klm}}\mathrm{J_m}$.

One of the technical advantages of this system is the resulting "stroboscopic" view of the dynamics, which then can be easily converted to a map. Quantum mechanically this is achieved by constructing a relatively simple time evolution operator U which takes the system from kick to kick. This way, Nakamura *et al.* (23) studied the changes in the wave function structure of the system as a function of external parameters. They showed how KAM tori, dominant in the weak-field regime, gradually collapse with increasing field. A number of experimental realizations of kicked systems have been suggested (30). Haake *et al.* (24, 31) have proposed two such scenarios for the kicked top. For example, in magnetized solids, crystal anisotropies allowing for an easy plane of magnetization can be represented as in the first term in the Hamiltonian, and a temporally periodic sequence of very short pulses could be imposed to generate the dynamics of the kicked top (24). They have also shown (31) how the dynamics of two laser modes in a medium with quartic nonlinearities corresponds to the kicked top.

Our Hamiltonian H, defined by

$$[3] \qquad H = \frac{\hbar p}{\tau} J_y + \frac{\hbar k}{2j} J_z^2 \sum_{n=-\infty}^{\infty} \delta(t - n\tau)$$

has been shown (25) to be equivalent to the Hamiltonian in eq. [2], and was originally used by Haake *et al.* (24). This Hamiltonian represents the dynamics of the system as a function of time with the first term representing the precession around the y axis with the angular frequency p/τ and the second term accounting for the train of periodic nonlinear kicks experienced by the system. These kicks can be thought of as an impulsive rotation around the z axis by an angle proportional to J_z.

In a classical-mechanical treatment, symmetries (such as invariance of the classical map under rotation around the precession axis by π and invariance of the composition of the classical map with itself around the x axis by π) may be introduced into this model by the appropriate selection of the strength of the magnetic field (which is related to p) and the kick strength. These special cases aid greatly in the study of critical points and periodic orbits. Under these symmetries Haake *et al.* (24) have studied the expectation value of the y component of the angular momentum of an initial state

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

chosen to be localized in the vicinity of a fixed point. They showed that the expectation value of this state initially exhibits damped oscillations and that for short time the quantum and classical distributions are indistinguishable. However, for long times the quantal expectation value exhibits periodic recurrences of the initial value while the classical mean has died off. Initial states in the chaotic region exhibit recurrence in the expectation value of the y component of the angular momentum; however, these recurrences occur irregularly.

Our aim is to study the quantum mechanical effects of KAM barriers (which characterize the dynamics for the kicked rotator) in the kicked top model. Since the introduction of symmetries used by other authors constrains the dynamics of the kicked top, it is found to be expedient to move away from these symmetries in order to find dynamics that is more suitable for comparison to the kicked rotator.

The Standard Map (5, 21)

$$[4]\qquad P_{n+1} = P_n + K \sin \theta_{n+1}$$
$$\theta_{n+1} = [\theta_n + P_n] \text{ modulo } 2\pi$$

describes how a kicked rotor with the Hamiltonian

$$[5]\qquad H = \frac{1}{2}p^2 + \epsilon_0 \cos\theta \sum_{n=-\infty}^{\infty} \delta(t - nT)$$

evolves from the nth to the $(n + 1)$st kick. Here, $K = \epsilon_0 T$.

In the Standard Map there exist barriers (KAM-tori) (20) that wrap around the map parallel to the angle coordinate and that act to separate the dynamics into bounded regions. As the strength of the nonlinearity, K, is varied, these barriers begin to break down, with the last one being a torus that is formed when the ratio of the relevant local frequencies, α, is related to the Golden Mean γ (5), viz.

$$[6]\qquad \alpha = 1 + \gamma, \qquad \gamma = (\sqrt{5} - 1)/2$$

The break-up of the "Golden Torus" has attracted the attention of researchers searching for a transition to global stochasticity (5). Simply put, the Golden Mean is the irrational number that is the hardest to approximate by rationals (5). Intuitively, the Golden Torus as the last obstacle to unrestricted transport in phase space is appealing, because it is found in phase-space regions where the coupled oscillators have the greatest difficulty driving each other resonantly (7). When propagated, the quantum-mechanical system exhibits only limited expansion into classically prohibited areas in the form of an exponential drop-off at these barriers.

The symmetric cases studied earlier (e.g., ref. 24) do not readily exhibit this bounding of the probability distribution for initial states that are eigenstates of the z component of the angular momentum. To produce barriers that limit the spreading of such an initial state it is convenient to break these symmetries. Allowing p to vary as well as k gives a doubly rich system of dynamics from which to study the correspondence between the classical and quantum models of the kicked top. For appropriate levels of precession rate and kick strength we encounter dynamics that qualitatively resembles the Standard Map. These regimes are shown to be more suitable for the investigation of structures in the phase space and the correspondence between the classical chaos and its quantal manifestations.

For the kicked top, both Hamiltonians (eqs. [2], [3]) can be studied with the help of a unitary operator that acts to propagate the state vector from kick to kick in time steps of length τ. This time evolution operator can be written in the form[3]

$$[7]\qquad U = \exp\left[-i\left(\frac{k}{2j}\right)J_z^2\right]\exp(-ipJ_y)$$

We will choose to interpret U in terms of the second Hamiltonian (eq. [3]) with the precession around the y axis and the nonlinear kick around the z axis. The unitary operator develops the initial state $|t = 0\rangle$ with n applications of U over a period of time $n\tau$ into the state $|t = n\tau\rangle = U^n|t = 0\rangle$.

Since the commutation relations

$$[8]\qquad [J^2,H] = 0; \qquad [J^2,U] = 0$$

hold for the kicked top, it is apparent that the magnitude of the angular momentum is a conserved quantity. We will therefore define our system on a $(2j + 1)$-dimensional Hilbert space spanned by the usual eigenvectors of J_z and J^2 with

$$[9]\qquad J_z|jm\rangle = m|jm\rangle$$
$$J^2|jm\rangle = j(j + 1)|jm\rangle \qquad (\hbar = 1)$$

We will see later that this is also an appropriate selection of eigenfunctions because the horizontal barriers that characterize the system limit the spreading of state vectors formed by composition of these eigenvectors. Furthermore, whereas the kicked rotator calls for a truncation scheme because the dynamics takes place in an infinite dimensional space, we are able to represent the dynamics from kick to kick in an exact matrix representation of the unitary operator expanded in this finite basis. Actual computational problems occur only for very large j. For our dynamical studies, we have chosen j's that do not exceed 60.

In the classical limit, the dynamics can also be represented by a recursive map (24). From the Heisenberg picture one can generate the discrete time evolution sequence of operators

$$[10]\qquad J_{in} = U^{+n}J_iU^n$$

The corresponding Heisenberg equations take the form of nonlinear recursion relations, which in the classical limit as $j \to \infty$ reduce to the following map:

$$[11]\qquad \begin{aligned} X' &= \text{Re} \\ Y' &= \text{Im} \\ Z' &= -X \sin p + Z \cos p \end{aligned} \Big\{(X \cos p + Z \sin p + iY)e^{ik(Z\cos p - X\sin p)}\Big\}$$

where the rescaled quantities $\boldsymbol{X} = \boldsymbol{J}/j$ have been introduced. As one immediately notices, this map reduces considerably with the selection of $p = \pi/2$ to

$$[12]\qquad \boldsymbol{X}' = F(\boldsymbol{X}) = \begin{bmatrix} Z \cos kX + Y \sin kX \\ -Z \sin kX + Y \cos kX \\ -X \end{bmatrix}$$

This map possesses various symmetries (24) that allow for

[3]This particularly simple form of the time evolution operator results from the presence of a δ-function, which simplifies the time-ordered expression. The derivation follows the argument outlined in eqs. [7.1]–[7.3]. of ref. 32.

a systematic study of the fixed points and periodic orbits of the system. In particular Haake *et al.* (24) have shown that

$$[13] \quad FR_x = R_x F R_y; \qquad FR_y = R_y F$$

where R_x and R_y define rotations of π radians around the x and y axes, respectively. Similarly the unitary operator U with $p = \pi/2$ exhibits these symmetries with R_x and R_y replaced by unitary operators defining rotations of π around the x and y axes.

To better understand the map [11] we define a coordinate system on the unit sphere given by

$$[14] \quad \begin{aligned} x &= \sin\theta\cos\phi \\ y &= \sin\theta\sin\phi \\ z &= \cos\theta \end{aligned}$$

which are the natural coordinates for the model because the magnitude of the angular momentum is conserved. This coordinate system is in turn projected onto the x–z plane with both hemispheres visible. Other useful coordinate systems are the flat local coordinates of Zhang *et al.* (33), which were used to study the effect of quantum fluctuations in the system.

In Fig. 1 we show a series of classical maps with p ranging from $\pi/2$ to 0.1, which exhibit a wide range of dynamics as k is varied. Though Figs. 1*a*–*d* exhibit periodic orbits and regions of bound motion, we notice that the dynamics on the sphere are not localized vertically, i.e., orbits are allowed to range widely in the z component as they are propagated in time. Immediately noticeable, however, is the breakdown of symmetry between the hemispheres as p is varied away from $\pi/2$. Figure 1*d* shows a mostly chaotic scenario. As p is decreased further away from $\pi/2$, trajectories begin to align themselves with the equator as expected; however, eventually all chaotic motion is suppressed with p close to zero. In Fig. 1*e* we notice the dynamics has resolved into periodic orbits parallel to the x–y plane, which suggests that in the limit, as p becomes small compared to k, the dynamics should separate into periodic orbits perpendicular to the z axis. These orbits correspond to barriers that limit the spreading in the z component of the angular momentum in the classical as well as the quantum regime.

Selection of parameters

For the kicked rotator, where only the kick strength may be varied, there is a critical value $K = K_c$ which corresponds to the destruction of the last invariant nonresonant curve. This critical value has been found (34) to be $K_c \approx 0.9716$. Similarly for the kicked top there exists a family of critical k's each corresponding to a specific set value of p. For $p = 0.1$ we find $k_c \approx 9.716$ (see Fig. 1*f*), and for $p = 0.2$ we obtain $k_c \approx 4.858$. We also note that there exists a critical value for k only in the range that p is small, hence confirming the idea that the kicked top system can be studied as a kicked rotator for p far from $\pi/2$. Indeed, the kicked rotor is a limiting case of the kicked top (35). This connection can be readily explained by taking a closer look at the classical dynamics of the Hamiltonian [3] when the initial z component of the angular momentum is approximately zero. In terms of the conjugate variables (36, 37)

$$[15] \quad \begin{aligned} J_y &= (J^2 - J_z^2)^{1/2}\cos\psi \\ J_x &= (J^2 - J_z^2)^{1/2}\sin\psi \end{aligned}$$

where ψ is the angle conjugate to J_z. If p is small, the second term in the Hamiltonian of eq. [3] will not change J_z much, so that J_z is approximately constant. The Hamiltonian can then be approximated by

$$[16] \quad H = \frac{\hbar k}{2j\tau} J_z^2 + \hbar p j \cos\psi \sum_{n=-\infty}^{\infty} \delta(t - n\tau)$$

This classical dynamics obeys the following Hamilton's equations:

$$[17] \quad \begin{aligned} \dot{\psi} &= \frac{\partial H}{\partial J_z} = \frac{\hbar k}{j\tau} J_z \\ \dot{J}_z &= -\frac{\partial H}{\partial \psi} = \hbar p j \sin\psi \sum_{n=-\infty}^{\infty} \delta(t - n\tau) \end{aligned}$$

Integrating these equations over one kick gives the recursion relations:

$$[18] \quad \begin{aligned} \psi_{n+1} &= \psi_n + \frac{\hbar k}{j}(J_z)_n \\ (J_n)_{n+1} &= (J_z)_n + \hbar p j \sin\psi_{n+1} \end{aligned}$$

which may be normalized by setting $(\hbar k/j)\, J_z \rightarrow J_z$. The result is the map

$$[19] \quad \begin{aligned} \psi_{n+1} &= \psi_n + (J_z)_n \\ (J_z)_{n+1} &= (J_z)_n + \hbar^2 p k \sin\psi_{n+1} \end{aligned}$$

which is equivalent to the Standard Map for the kicked rotator where the kick strength of the kicked rotator is $K = \hbar^2 p k$.

Measurements on the quantum system

Having determined appropriate combinations of the rate of precession and the nonlinear kick strength that give rise to vertical separation of the dynamics on the spherical projection of the classical map, we expect to be able to determine similar structures in the quantum phase space that also act to isolate the dynamics. If the state vector is described as an ensemble of eigenvectors of the z component of the angular momentum, then the propagation from kick to kick can readily be determined in the matrix representation of the unitary operator U. Furthermore, in the quantum regime, the dynamics is represented in the development of the coefficients of the expansion of the state vector.

For this reason we choose to study the asymptotic average of the projection of the angular momentum, which has been studied by Geisel *et al.* (15) for the kicked rotator. This value $P(m|m_0)$ is simply the time-averaged probability of finding the system in the state $|jm\rangle$ if the system is initially prepared in the state $|jm_0\rangle$. For the most readily evaluated distribution we choose the initial state to consist of a single eigenvector of J_z, namely $|jm_0\rangle = |j0\rangle$. The choice of /this state as the initial state also makes sense in light of the fact that for m approximately zero the system behaves locally as the kicked rotator. This quantity is defined for each eigenvector of the z component of the angular momentum as

$$[20] \quad P(m|m_0) = \lim_{N\to\infty} \frac{1}{N} \sum_{n=1}^{N} |\langle jm|U^n|jm_0\rangle|^2$$

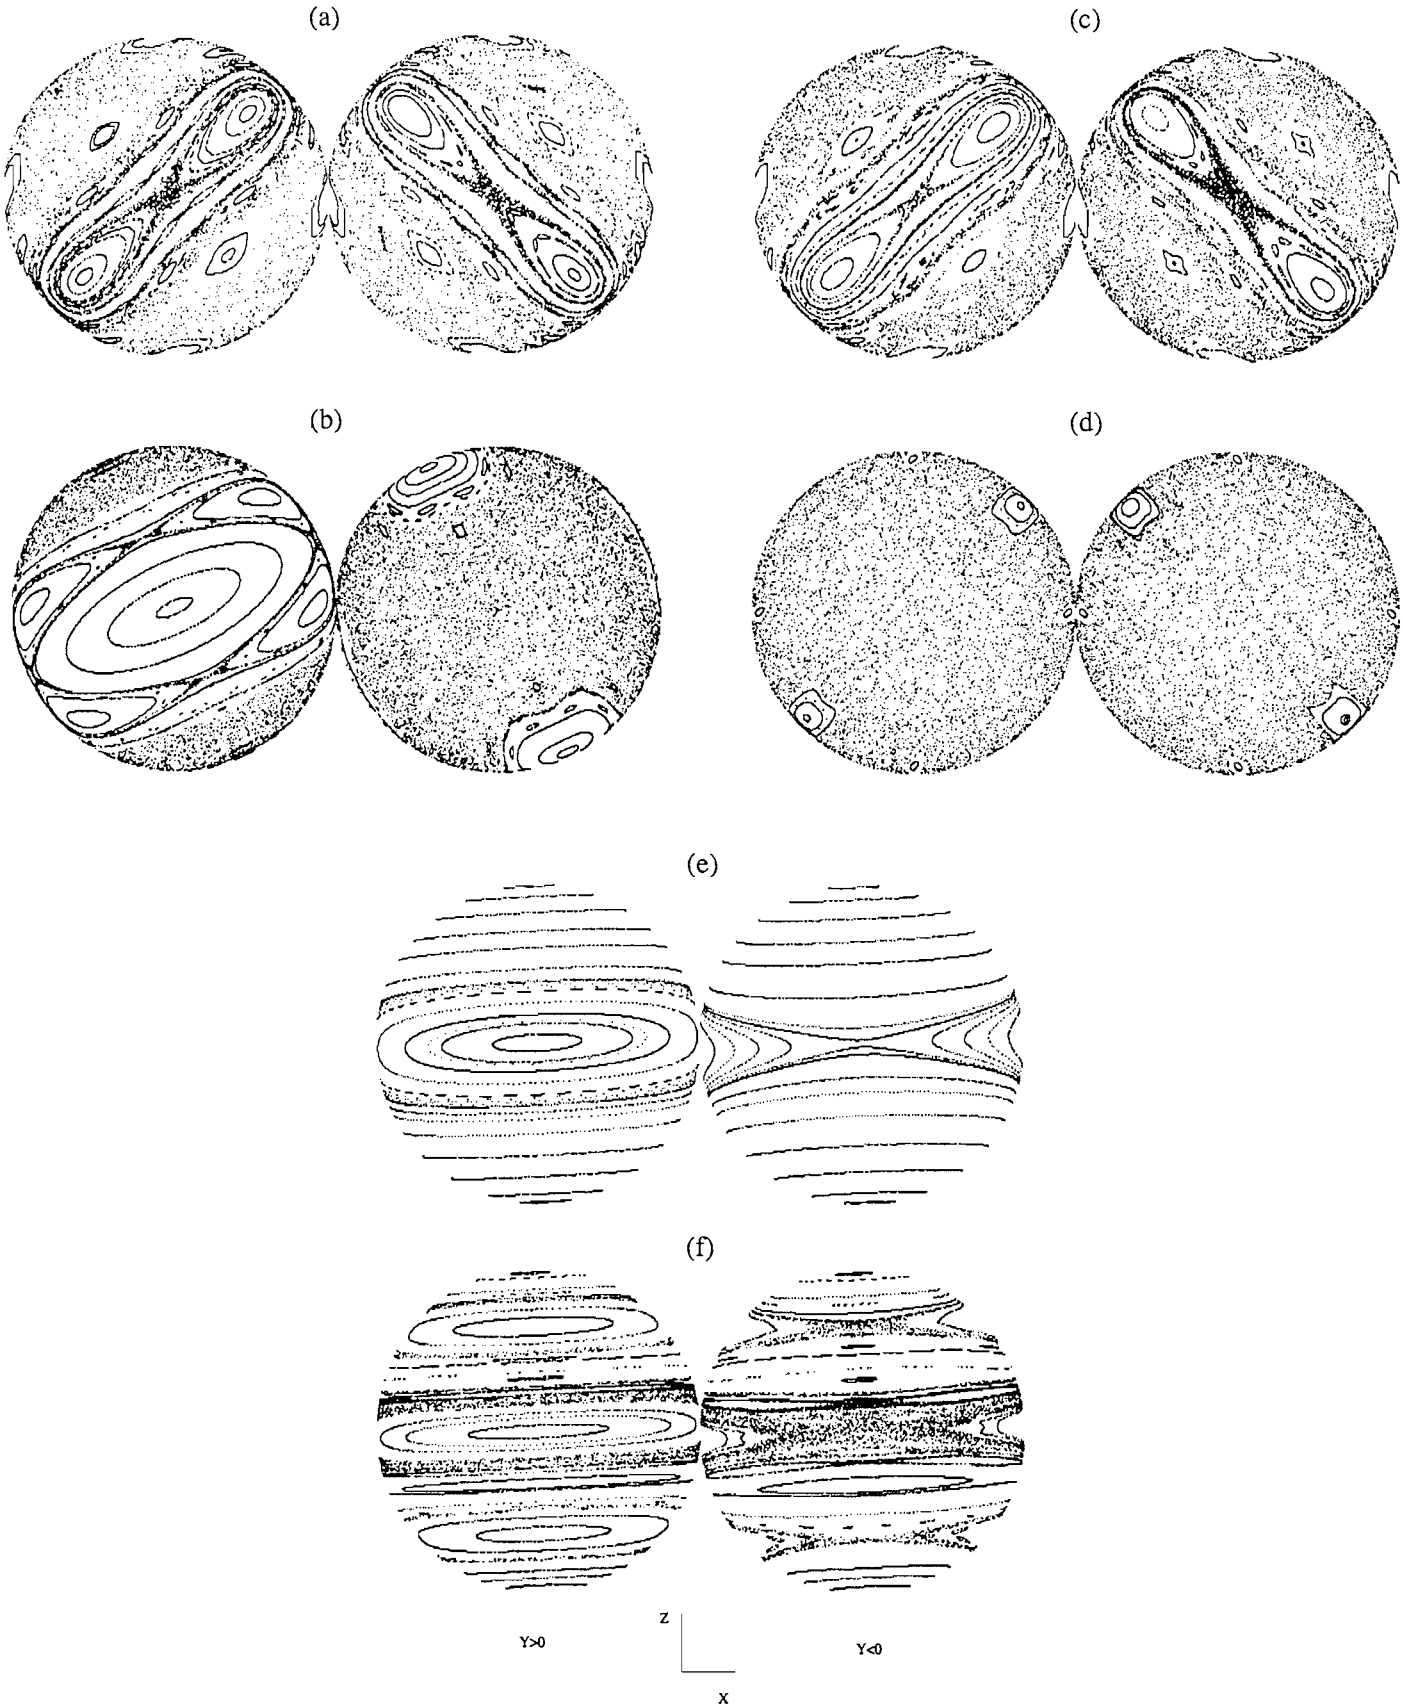

FIG. 1. (*a*)–(*f*) Classical maps on the unit sphere showing trajectories of selected points for up to 5000 iterations. (*a*) $p = \pi/2$, $k = 2.5$; (*b*) $p = 0.9$, $k = 2.5$; (*c*) $p = 1.54$, $k = 2.5$; (*d*) $p = \pi/2$, $k = 3.3$; (*e*) $p = 0.1$, $k = 2.5$; (*f*) $p = 0.1$, $k = 9.716$.

which can be expressed analytically for the kicked top in terms of the Wigner function (38) for rotation around the y axis as

$$[21] \quad \langle jm|U|jm'\rangle = \exp\left[-i\left(\frac{k}{2j}\right)m^2\right] d^{(j)}_{mm'}(p)$$

A linear plot of this distribution reveals that the system remains within the region bounded by the KAM torus (mostly within the band on the equator of Fig. 1*f*). However, there exist slight populations in the states outside the barriers, which in classical mechanics would prevent any diffusion. To see the effects of barriers in the quantum regime the natural logarithm of the asymptotic distribution among the eigenvectors of J_z is displayed. Figure 2 shows the convergence of this distribution as a function of the number of iterations. In this case we exhibit the critical case for $p = 0.1$, which shows a large amount of variation even over J_z even for $j = 20$. In principle an infinite number of iterations would be necessary to define this distribution; however, in practice after 50 iterations the distribution is approximately stable. Hence we are able to derive information of a particular system without lengthy computations (on the order of an hour) even on an Apple MacIntosh using the symbolic manipulation software Mathematica.

In Fig. 3 we take $j = 20$ and $k = 2.5$ while p is varied from $\pi/2$ to 0.25. Initially with $p = \pi/2$ the distribution shows approximately equal population of the even states while there is virtually no population in the odd states. This can be explained by the high level of symmetry in this case along with the absence of horizontal barriers, which allows the state to spread freely in the z direction. As p is varied we see the immediate breakdown of the even-odd state populations corresponding to the break in symmetry. As p moves into a system showing horizontal barriers in the classical map the distribution conforms in such a way as to follow these barriers as they narrow. In other words, as p moves away from $\pi/2$ the nonlinear kick around the z axis begins to dominate the dynamics, causing flattened trajectories on the sphere. This corresponds to confining the wave packet in phase space and a localization of the probability flow. In Fig. 3 as p approaches 0.5 the confinement is more precisely defined and

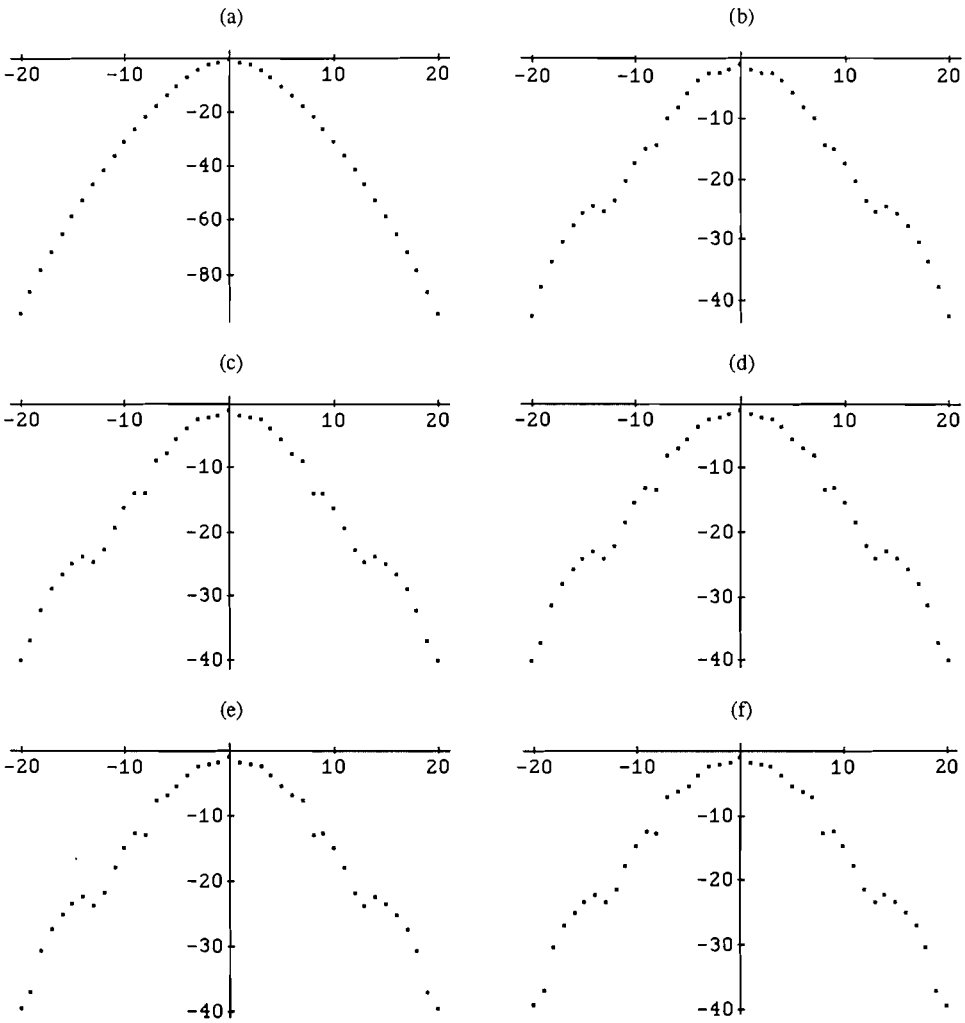

FIG. 2. The asymptotic distributions for the kicked top with $k = 9.716$ and $p = 0.1$ is shown to reach an approximately stable value after only 50 iterations. Each figure is shown at 10 iterations after the preceding figure with (*a*) shown after only one iteration of the initial state. The vertical axis denotes ln P (see eq. [20]), the horizontal axis is m.

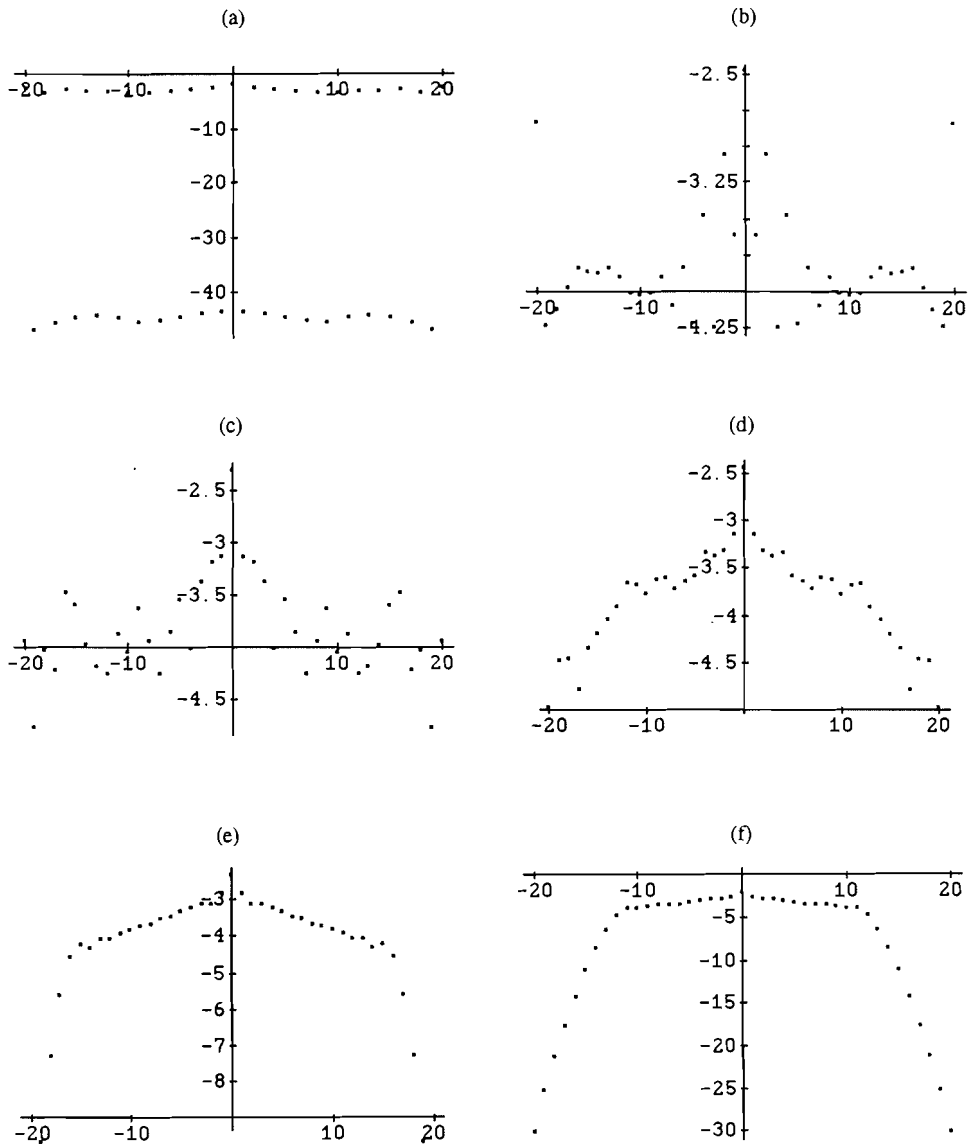

FIG. 3. Asymptotic distributions plotted on a logarithmic scale for a fixed $k = 2.5$. The precession angle p is varied from $\pi/2$ to 0.25 showing the effect of the cantori on confinement of the distribution. (*a*) $p = \pi/2$; (*b*) $p = 1.5$; (*c*) $p = 1.0$; (*d*) $p = 0.75$; (*e*) $p = 0.5$; (*f*) $p = 0.25$. The axes are the same as in Fig. 2.

the distribution outside the barriers decays exponentially away from the classically allowed regions.

In the kicked rotator model the critical value of the kick strength corresponds to a boundary between regular and chaotic motion in the dynamics. Hence any $K > K_c$ will allow trajectories to move more readily into classically forbidden regions. Similarly, for $K < K_c$ trajectories will be more strongly bound, providing less information to the structure of the phase space outside the barriers. The dynamics of the kicked top also exhibits this loss of information for kick strengths above and below k_c. In Fig. 4 we set $p = 0.1$ and $j = 20$, allowing k to vary around the critical nonlinear value $k_c = 9.716$ (for which we obtain KAM-tori in the classical map, see Fig. 1*f*). As expected, the distribution has difficulty sampling structures outside the barriers as k is decreased below k_c, whereas when k is increased above k_c the distribution reveals the breaking down of the tori, which allows the probability to flow more easily into classically inaccessible regions. However, as with the kicked rotator, the quantum phase-space structures work to greatly inhibit this probability flow as the asymptotic distributions still show exponential decay.

We also investigated the effect of increasing the size of j in order to study the distribution with more resolution. Figure 5 shows a series of distributions with $p = 0.1$ and $k = k_c = 9.716$. The actual shape of the distribution appears to be suppressed for very low values of j. However, the distribution takes on a distinctive shape with increasing j by revealing plateaus that mark other barriers on the sphere outside the initial bounded region.

Concluding remarks

In this article, we studied the quantum mechanics of the kicked top by constructing its time-dependent state and interrogating it for manifestations of KAM tori. The effect of these tori was revealed through the examination of a suita-

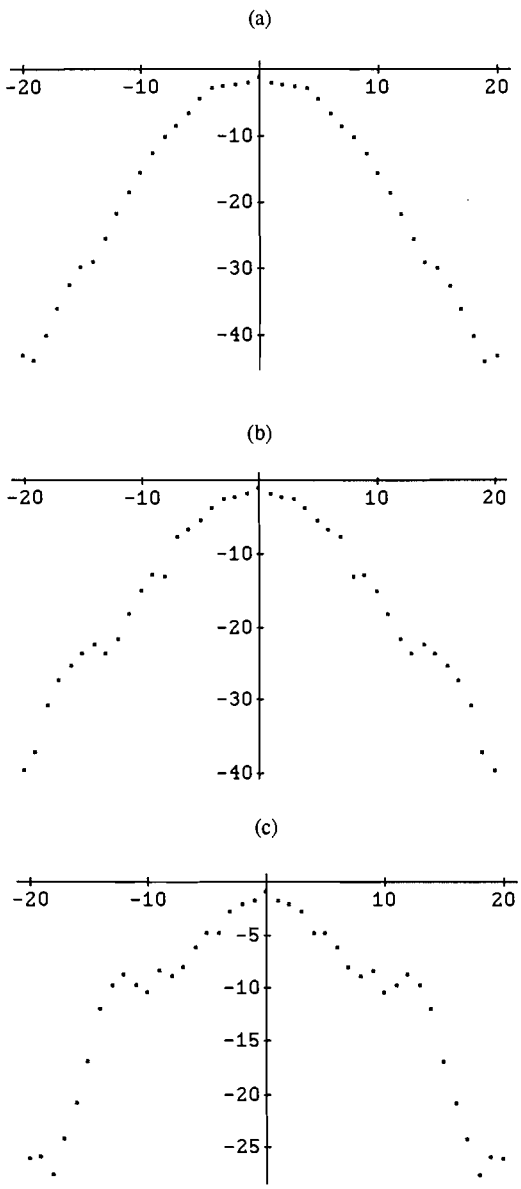

FIG. 4. The asymptotic distribution for $p = 0.1$ and (*a*) $k = 8.216$; (*b*) $k = 9.716$; and (*c*) $k = 11.216$. Below the critical value of k the cantori overly constrain the system, while above the critical value the distribution spreads more freely into classically inaccessible regions. The axes are the same as in Fig. 2.

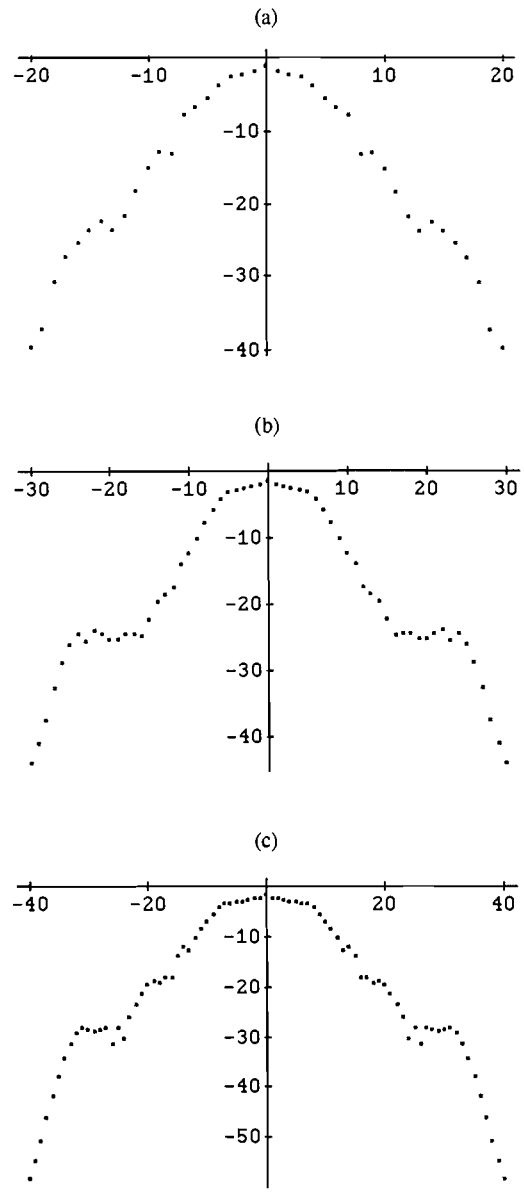

FIG. 5. The asymptotic distributions for the critical case $k = 9.716$ and $p = 0.1$. Here the magnitude of J is increased showing greater detail in the distribution outside the KAM-tori. All figures were obtained after 50 iterations, and j increases according to the sequence $j = 20$, 30, and 40. The axes are the same as in Fig. 2.

bly defined distribution function, and by moving away from special sets of parameters used by previous researchers. The connection between the kicked rotator and the kicked top was very useful to our investigation. We found a close correspondence between the locations of KAM tori as revealed by classical maps and by shoulders or kinks in the distribution functions, showing that for appropriate combinations of system parameters, probability flow in rotational systems is strongly affected by these phase-space structures.

In some recent research, the kicked rotator has been used as a testing ground for a number of interrelated speculations concerning the effect of measurements (39, 40), the dynamics of pure-state density matrices (39), localization (34), coherent quantum tunneling (25), as well as the effect of small variations in the parameters on the quantum dynamics (26). However, all these studies were restricted to the highly symmetric case $p = \pi/2$, which, as we have shown in this article, eliminates some very interesting dynamics. An analogous series of investigations, but performed in parameter ranges where the KAM barriers restrict probability flow, are expected to contribute to our understanding of the phenomenon of quantum state localization in rotational systems. Such work is currently in progress.

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

J. D. DOLL, STEVEN W. RICK, and DAVID L. FREEMAN. Can. J. Chem. **70**, 497 (1992).

As summarized by Hamming's motto, "the purpose of computing is insight, not numbers." In the spirit of this dictum, we describe here recent algorithmic developments in the theory of quantum dynamics. Through the use of the somewhat unlikely combination of modern numerical simulations and a visualization device borrowed from 19th century optics, the present efforts suggest the existence of an important, underlying structure in the general problem. This structure, verified for a relatively simple class of model problems, provides broad guidelines for the formulation and treatment of the general quantum dynamical problem.

Key words: Monte Carlo, stationary phase, quantum dynamics.

J. D. DOLL, STEVEN W. RICK et DAVID L. FREEMAN. Can. J. Chem. **70**, 497 (1992).

Comme l'a résumé la devise de Hamming, «le but des calculs par ordinateur n'est pas les valeurs numériques obtenues, mais l'aperçu général qu'on peut en dégager». Dans l'esprit de ce dicton, on décrit des développements récents d'algorithmes dans la théorie de la dynamique quantique. Par le biais de l'usage d'une combinaison saugrenue de simulations numériques modernes et d'un appareil de visualisation emprunté à l'optique du 19^{e} siècle, nos efforts suggèrent l'existence d'une structure sous-jacente importante dans le problème général. Cette structure, vérifiée par une classe relativement simple de problèmes modèles, fournit des lignes directrices importantes pour la formulation et le traitement du problème général de la dynamique quantique.

Mots clés : Monte Carlo, phase stationnaire, dynamique quantique.

[Traduit par la rédaction]

1. Introduction

In his autobiography Stan Ulam (1), one of the pioneers of modern computational science, made a series of surprisingly accurate observations concerning the likely future impact of numerical simulation methods in science. He correctly anticipated that the greatest significance of such methods was their ability to liberate one's thinking concerning the proper formulation and treatment of physical phenomena from the limitations imposed by purely analytic methods of analysis. These general numerical methods allow one to examine broad problem areas, to identify particular topics whose phenomenology warrants further investigation, and, most importantly, to produce the insight necessary to produce a unified, conceptual theory from the particular results so obtained. In this process, computational machines become significantly more than merely devices for producing answers to particular problems of the moment. Rather, they become the central enabling technology, the very engines that drive the analysis of complex physical phenomena.

The extent to which Ulam's program can be implemented is, of course, governed by the power of the computational machines that are available. Starting with postwar machines of relatively limited capabilities, these devices have undergone a dramatic evolution. In this relatively brief period, they have reached the stage where it is now possible to probe important classes of physically significant questions concerning the behavior of systems of realistic complexity. It is likely, moreover, that this rapid expansion of computational capability will accelerate, thus significantly extending the class and scale of problems that can be considered.

Broadly speaking, computational problems in finite temperature condensed matter theory can be broken into categories depending on whether they are essentially classical (e.g., Newtonian) or quantum mechanical in character and depending on whether they involve the study of equilibrium or time-dependent properties. This division is summarized by the simple "computational matrix," depicted in Fig. 1. This matrix serves to highlight the comments made by Ulam discussed above and to set the stage for the present discussion.

The computational machines available in the two decades following WWII, although primitive by current standards, were adequate to begin the study of equilibrium and dynamical properties of classical systems. A number of particular results from these calculations, such as the hard sphere freezing transition (2, 3) and the discovery of the long-time tails for the velocity autocorrelation functions for dense fluids (4), were of special interest. The lasting importance of these studies, however, did not reside in the particulars of these problems. Rather, the greater significance of these investigations was that they led to the development of general purpose tools for the analysis of many-body classical systems. As envisioned by Ulam, the resulting Monte Carlo (see, for example, ref. 5) and molecular dynamics methods (ref. 6 for a general review) freed investigators from the limitations imposed by uncontrolled numerical approximations typical of prior work and ultimately provided them with insight necessary to develop intelligent, physically well-founded theories of classical many-body systems.

Over the past decade, the statistically based, Monte Carlo methods designed for the classical equilibrium studies described above have been extended to treat corresponding quantum mechanical problems (7). The basic conceptual development involved was the realization that the quantum mechanical problem could be recast as a related classical problem in a higher-dimensional space. Since Monte Carlo methods are relatively insensitive to dimensionality, this formulation of the equilibrium problem proves a practical one. Current applications of the resulting "Quantum Monte Carlo" methods encompass a diverse range of problems in physics, chemistry, and biology and represent many of the largest computational problems yet undertaken (see ref. 8 for a cross section of recent activity.)

Anticipating the continued rapid expansion in computational capabilities, attention has now turned to the remaining entry in the computational matrix of Fig. 1, the study of general, time-dependent quantum mechanical methods. While lying at the outer edges of current algorithmic and computational capabilities, such problems are at the center of broad areas of chemistry and physics. Our particular interest in such developments will be their application to the areas of spectroscopy (the response of physical systems to time-dependent perturbations) and kinetics (the rates of chemical and physical processes). The time-dependent problem is formally similar in nature to its equilibrium counterpart. However, the time-dependent problem is substantially more "complex," both technically and in practical terms, than the equilibrium situation. Mathematically, these technical difficulties are related to the appearance of highly oscillatory quantities in the result. The treatment of these difficulties has prompted the search for new classes of more suitable Monte Carlo methods (9, 10) and the present efforts are a part of that search.

We describe here an observation concerning the composition of the general quantum dynamics problem. Exploiting a combination of numerical and graphical methods, we find indications that the principal quantum mechanical object of interest has an appreciably simpler theoretical structure than has heretofore been appreciated. This insight, gained through a series of particular model investigations, offers a number of general, and hopefully significant, suggestions for the formulation of the quantum dynamical problem.

Much of the present work is directed at extracting information concerning general theoretical structure that underlies objects obtained from numerical procedures. Section 2 describes and illustrates a visual device that we have found to be particularly useful in this regard. Section 3 presents a brief summary of the physical context of the present discussion and identifies the primary computational objects under consideration. The central result required for subsequent discussion is contained in eq. [12] and the associated discussion. The physical applications and associated conclusions are contained in Sects. 4 and 5, respectively.

2. Cornu analysis

In the theory of optics, a convenient visual device was developed for the analysis of certain classes of problems relating to diffraction (11). This device utilizes an elegant geometrical representation introduced by Cornu (12). Besides being rather pleasing aesthetically, we have found this instrument to be quite useful in the present work. This technique proves particularly valuable for revealing structure otherwise hidden within purely numerical procedures.

To appreciate the character of the Cornu analysis, consider a complex integral of the form

$$[1] \qquad I(t) = \int_{-\infty}^{\infty} dx\, \rho(x) e^{itf(x)}$$

As indicated above, integrals of this type arise naturally in the theory of optics. We will see in the following section that similar integrals also arise in the treatment of the dynamics of quantum mechanical systems. In the present illustrations, the functions $\rho(x)$ and $f(x)$ are specified. This generic integral is an example of what is typically termed the "stationary phase" problem (13). That is, if the parameter t is large, then the integral $I(t)$ will generally be dominated by those regions of x for which the phase of the complex exponential is "stationary" (i.e., locally constant). Within nonstationary phase regions, the complex exponential will oscillate rapidly for a small variation in the position x, thus effectively cancelling the region's contribution to the final integral. If $f(x)$ is known, then such stationary phase behavior can be readily anticipated. If, however, the integrand of eq. [1] is produced numerically, then such behavior is typically far from obvious.

In numerical applications, integrals of the type in eq. [1] are often approximated by quadrature. If these are written as an ordinary Reimann sum, the result becomes

$$[2] \qquad I(t) \approx \sum_{n=1}^{N} \Delta x_n \rho(x_n) e^{itf(x_n)}$$

where the summation is over the numerical grid points, $\{x_n\}$,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

$n = 1, 2, \ldots N$, that cover the integration interval and Δx_n is the spacing between successive quadrature points.

We now consider the sequence of partial sums that make up eq. [2],

$$[3] \qquad I_M(t) = \sum_{n=1}^{M} \Delta x_n \rho(x_n) e^{itf(x_n)}$$

The partial sums defined by eq. [3] are the accumulation of M successive vectors, whose individual lengths and orientations are governed by the magnitudes and phases of the corresponding complex numbers in the original sum. The Cornu construction consists of following the real and imaginary parts of the sequence of partial sums defined in eq. [3] parametrically as a function of the index M. For $M = 1$, the partial sum consists of a single vector pointing from the origin to the first complex number in the summation of eq. [2]. With increasing values of M, successive complex vectors corresponding to the terms in eq. [2] are added sequentially to the preceding partial sum. The sequence of partial sums so produced thus begins at the origin in the complex plane and traces out a contour that provides a graphical representation of the original integral. So written, the integral is analogous to a many jointed, folding "carpenter's rule." In this representation, the integral's numerical value is given by the single, complex vector that corresponds to the ruler's end-to-end distance. What makes this construction convenient is that it provides a ready visual indication of those integration regions that contribute strongly to the overall result. Specifically, in regions where the phase function varies rapidly, the contributions from successive terms in the summation are tightly "knotted" and thus contribute little to the integral. Conversely, regions where the phase function is relatively constant tend to add coherently and thus to dominate. The geometry of the resulting construction is thus a convenient way of revealing the underlying structure of the original integral.

To illustrate these ideas, we examine the integral

$$[4] \qquad I(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \exp(-x^2/2 + itx^2)\, dx$$

Easily evaluated by analytic means, this integral is equal to $1/\sqrt{(1 - 2it)}$. The corresponding Cornu analysis is shown in Fig. 2 for the particular case of $t = 10$. In this case the integral was approximated by a simple trapezoidal quadrature with a numerical mesh of a sufficiently fine scale that the resulting Cornu plot in Fig. 2 appears continuous. This analysis vividly reveals the stationary phase character that underlies this integral, a character not immediately apparent if one considers merely the integral's exact numerical value. As anticipated, the bulk of the integration region from minus infinity up to zero forms a tightly knotted spiral centered at the origin of the complex plane (the lower left hand corner) in Fig. 2. As the integration variable nears the stationary phase point at zero, however, the Cornu spiral begins to open. Once past this region, the phase oscillations again become severe and the spiral collapses to a new accumulation point. The numerical value of the integral is given by the complex vector connecting the ends of the Cornu spiral. Changing the value of the parameter t in eq. [4] changes the orientation and absolute scale of the associated spiral, but the characteristic sigmoidal structure is a reflection of the stationary phase structure of the original integral and remains qualitatively undisturbed.

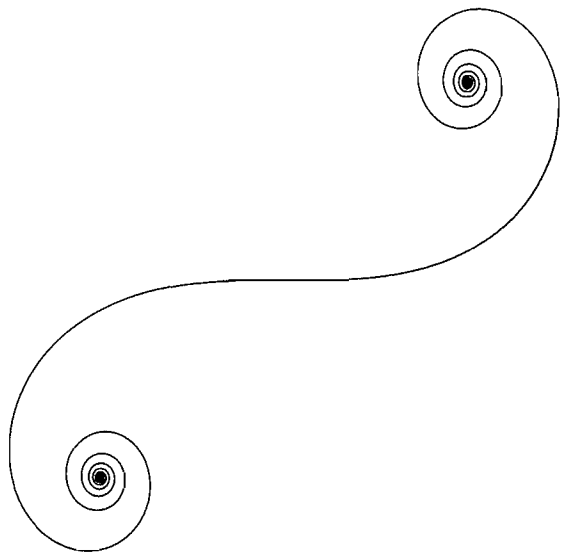

FIG. 2. Cornu analysis of the integral

$$I(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} dx\, e^{-x^2/2}\, e^{itf(x)}$$

where $f(x) = x^2$ and $t = 10$. The plot displays the real and imaginary parts of the integral from $-\infty$ up to a point y parametrically as a function of the variable y over the range $-\infty < y < \infty$. The plot begins at the origin (the lower left-hand spiral) and proceeds to the upper right. The value of the integral is thus the vector connecting the ends of the curve. In this case the integral has the value $1/\sqrt{(1 - 20i)}$. Note the characteristic spiral corresponding to the single stationary phase point (the region near $y = 0$).

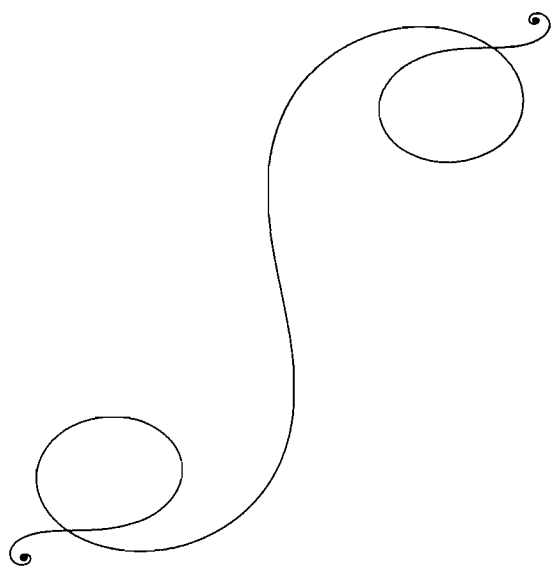

FIG. 3. As in Fig. 2, except that $f(x) = (x^2 - 2)^2$ and $t = 2$. Here the Cornu spiral reflects three stationary phase regions (corresponding to $y = 0$ and $y = \pm\sqrt{2}$). The value of the integral is 0.231 + 0.300 i.

Shown in Figs. 3–5 are examples of the Cornu analysis of more elaborate integrals. In Fig. 3 and 4 we display the results for the integral

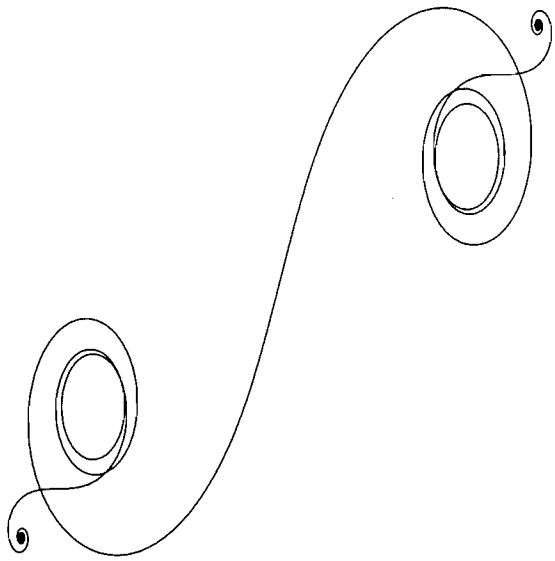

FIG. 4. As in Fig. 3 with $t = 5$. With the larger t value, the stationary phase structure in the Cornu spirals is more highly developed. The value of the integral for this value of t is 0.203 + 0.117 i.

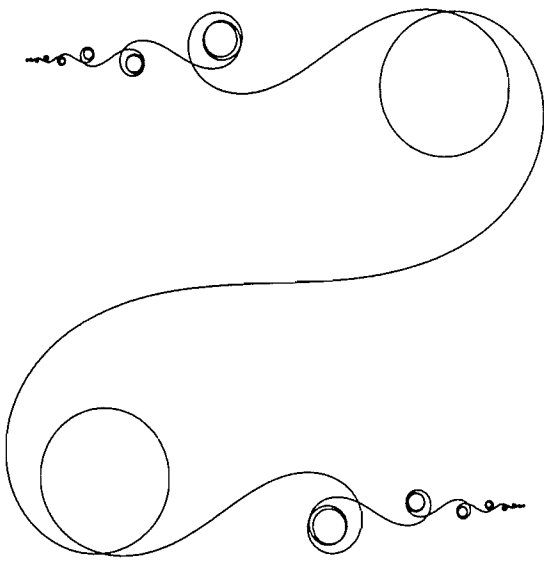

FIG. 5. Cornu analysis of the integral

$$I(t) = \frac{1}{\sqrt{8\pi}} \int_{-\infty}^{\infty} dx\, e^{-x^2/8}\, e^{itf(x)}$$

where $f(x) = \sin(x^2)$ and $t = 10$. The intricate structure arises from the multiple stationary phase regions ($f'(x) = 0$). The value of the integral is $-0.1085 + 0.0969$ i. This corresponds to the complex vector that connects the lower right to upper left ends of the figure.

$$[5] \qquad I(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \exp(-x^2/2 + it(x^2 - 2)^2)\, dx$$

We see that the Cornu spirals in this case are effectively a composite of three separate spirals of the type shown in Fig. 2. This composite nature reflects the contributions from the three stationary phase points of the original integrand, located at $x = 0$ and $x = \pm\sqrt{2}$, respectively. The existence and relative magnitudes of these stationary phase regions are easily visible in Figs. 3 and 4. Examination of the sequence of partial sums in the Cornu analysis reveals that the central portion of the figures corresponds to the contributions from the stationary phase region near $x = 0$. As the parameter t increases, the various portions of the Cornu construction pivot about in the complex plane, a "dynamics" that introduces additional "windings" into its spiral structure. Consequently, the central portion of Fig. 4 where $t = 5$ is more strongly developed than that of Fig. 3 where $t = 2$. We note in passing that the asymmetry in the outer spirals in Figs. 3 and 4 reflects the symmetry of the Gaussian term about the outer ($\pm\sqrt{2}$) stationary phase regions.

Shown in Fig. 5 is our final example. We hope that the reader will agree that Fig. 5 is one of the more lovely ways to write the integral

$$[6] \qquad I(t) = \frac{1}{\sqrt{8\pi}} \int_{-\infty}^{\infty} \exp(-x^2/8 + it \sin(x^2))\, dx$$

This majestic beast, resplendent in its myriad of stationary phase accoutrements, has a "dynamics" that is equally flamboyant!

The Cornu analysis described above represents an algorithm for the construction of an analog device that corresponds to our original mathematical problem. This device, is, in effect, a "clock" whose ornate hands pinwheel about in the complex plane chronicling not the passage of time but rather the "temporal" evolution of the particular object under study. The significance of this result for the present discussion is that it is possible to design such "timepieces" so that they follow the quantum dynamics of physical systems. The following section briefly summarizes the tools necessary for such developments.

3. Time-dependent quantum mechanics

Classically, physical systems and their time evolution are characterized by the positions and momenta of their constituents and their associated equations of motion. Once the interactions between the various constituents are specified, these well-known classical (Newtonian) equations of motion provide a complete description of the time development of the physical systems.

Quantum mechanically, this simple picture is valid only as an asymptotic, limiting case of a more general theory. Rather than simple, sharply defined classical variables, the objects of interest become various complex valued amplitudes whose functional form and time dependence are governed by the equations of wave mechanics.

To be concrete, let us consider a simple one-dimensional system characterized by a position variable, x, a mass m, a momentum p, and a potential energy function, $V(x)$. Classically, we proceed by constructing the Hamiltonian of the system, $H(p,x)$, given by

$$[7] \qquad H(p,x) = \frac{p^2}{2m} + V(x)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

The time dependence of the system is governed by the classical equations of motion,

$$[8] \quad \frac{\partial x}{\partial t} = \frac{\partial H(p,x)}{\partial p} \qquad \frac{\partial p}{\partial t} = -\frac{\partial H(p,x)}{\partial x}$$

where t is the physical time. Once the initial positions and momenta are specified, eq. [8] permits us to determine the classical trajectory (the subsequent positions and momenta as functions of time) for all time.

Quantum mechanically, the problem is formulated rather differently. For example, the quantum mechanical generalization of the classical Hamiltonian turns out to be an "operator," $\hat{H}$. The explicit forms for such operators, the rules for their manipulation, and their mathematical properties are well known (14) and need not concern us further. We simply summarize here the basic results necessary for the present discussion. In terms of the quantum mechanical Hamiltonian, the time dependence of the physical system is governed by the related "time development operator," $\exp(-it\hat{H}/\hbar)$, where $\hbar$ is Planck's constant, a fundamental constant of nature. Here the exponential operator is understood in terms of the actions of its formal power series expansion. The second basic result that we will require is that the motion of a system from a position x at $t = 0$ to a position x' at a subsequent time t is governed by the quantum mechanical "matrix element," $\langle x'|\exp(-it\hat{H}/\hbar)|x\rangle$, a quantity that depends on the time development operator and on the coordinate labels, x and x'. Finally, we utilize the fact that the thermodynamic properties of a quantum mechanical system maintained at a finite temperature, T, are determined by matrix elements of the type $\langle x'|\exp(-\beta\hat{H})|x\rangle$, where $\beta = 1/(k_B T)$ and where k_B is another fundamental natural constant, Boltzmann's constant.

We note in passing that Newtonian physics is recovered from the above results in the limit that Planck's constant tends to zero. As will be discussed below, we can anticipate that this limit will be rather subtle since it is the *reciprocal* of Planck's constant that appears in the exponential of the time development operator. A large body of previous work (15) indicates that this "semiclassical" regime is an important and interesting one for chemistry and physics.

The above discussion reveals that the temperature and time dependence of a quantum mechanical system are intimately related. The reader will thus perhaps not be too surprised when we state the basic result we require for the present developments, that the complete *time dependence* of a *finite temperature* quantum mechanical system can be deduced from the knowledge of matrix elements of the type $\langle x'|\exp(-\beta_c\hat{H})|x\rangle$. Here the complex temperature has a real (imaginary) part related to the physical temperature (time) in the problem. For completeness, the parameter β_c is defined by

$$[9] \quad \beta_c = \beta/2 + it/\hbar$$

where the factor of two is included in the definition as a matter of convention.

Except for a relatively restricted set of model systems, the requisite quantum mechanical objects described above are not available analytically. Consequently, general equilibrium and dynamical quantum mechanical studies must ultimately make use of numerical methods of some type to produce the required results. The numerical approach adopted depends intimately on the scale of the problem under study. For problems where there are relatively few quantum mechanical variables (e.g., three or less), a number of efficient numerical methods are available. These include direct numerical solutions of the basic partial differential equations of wave mechanics, fast Fourier transform based methods, and approaches based on the exact diagonalization of a suitable matrix representation of the quantum mechanical Hamiltonian. Unfortunately, these more direct methods are of intrinsically limited utility in the treatment of larger scale quantum mechanical problems.

For larger scale applications, we must adopt methods whose inherent difficulty is only weakly related to the dimensionality of the problem. Much recent progress in the formulation of such methods (7, 9, 10) for larger systems is based on the use of Feynman's path integral formulation of quantum mechanics (14). In this approach the necessary quantum mechanical density matrix elements are written in the form of a formal sum over alternative ways for the quantum mechanical system to travel from one point to another. Numerical applications proceed by introducing a labeling procedure to enumerate the various alternatives in this sum, thereby recasting the formal path integral results in a form amenable to practical numerical calculation.

For the case of quantum dynamics, the path integral representation of the relevant matrix element is given symbolically as

$$[10] \quad \langle x'|\exp(-it\hat{H}/\hbar)|x\rangle = \sum_{\text{paths}} \exp\left(\frac{i}{\hbar} S([\text{path}])\right)$$

where the sum is over all possible paths, $x(t)$, that connect the position x at time zero with position x' at the time t. The amplitude for the contribution of each path depends on that particular path through a known function, S. As exploited by Feynman and Hibbs (14), eq. [10] constitutes the gateway between the classical and quantum mechanical worlds. The particular result that makes this connection possible is that the function S that appears in eq. [10] is a *classical mechanical* object. In particular, $S([x(t)])$ turns out to be the classical "action," the time integral along the path $x(t)$ of a known and relatively simple classical mechanical function. In the limit that Planck's constant tends to zero, only those paths in eq. [10] for which the variation in this action vanishes will contribute to the final result. That is, unless the variation in the action vanishes, the contributions of a particular path will be obliterated by neighboring paths, a cancellation induced by the rapid phase oscillations of the complex exponential in eq. [10]. As is well known from classical physics, the requirement that the variation of the action vanish is precisely the condition that the path be a classical trajectory, that is, a solution of eq. [8]. Thus, in the limit that Planck's constant tends to zero, the "stationary phase" character of eq. [10] reduces the summation over *all* paths to a summation over *classical* paths. Moreover, past experience indicates (15) that the contributions from these classical path regions frequently prove dominant in the actual quantum mechanical

problem. In general, for fixed values of x and x', the number of such paths is an increasing function of time.

The path integral formulation of the equilibrium problem is constructed similarly. For this problem, the corresponding matrix element is

$$[11] \quad \langle x'|\exp(-\beta\hat{H})|x\rangle = \sum_{\text{paths}} \exp\left(-\frac{1}{\hbar}\bar{S}([\text{path}])\right)$$

where $\bar{S}$ is also a related and known function of the path. The positive, exponential weight associated with each path from x to x' makes it a relatively simple matter to accumulate the various contributions. As Planck's constant tends to zero, the paths that minimize $\bar{S}$ tend to dominate the result.

Statistical methods have proved of use in equilibrium problems and numerous examples of the application of such formulations have appeared in the literature. The essential result behind such applications is that the importance of a particular path in the equilibrium problem can be considered in isolation, independently from the contribution of its neighbors. The significance of a particular path can be judged by an examination of the exponential weight associated with the path in question. By contrast, however, in the dynamics problem the significance of a particular path tends to be judged only retroactively, through an analysis of its interaction and possible phase cancellation with neighboring paths. This difference prevents the trivial extension of equilibrium statistical methods to the dynamical problem.

With the above discussion as background, we now consider the principal quantum mechanical objects in the present study, the matrix elements $\langle x'|\exp(-\beta_c\hat{H}|x\rangle$. Using a primary result of matrix mechanics (the matrix element of a product of operators is the matrix product of the corresponding elements of the individual operators), we can write an integral representation of our matrix elements as

$$[12] \quad \langle x'|\exp(-\beta_c\hat{H})|x\rangle = \int_{-\infty}^{\infty} dy\, \langle x'|\exp(-it\hat{H}/\hbar)|y\rangle\, \langle y|\exp(-\beta\hat{H}/2)|x\rangle$$

The familiar matrix multiplication formula appears here with a continuous integration rather than the usual discrete summation since the relevant coordinate labels are themselves continuous. This integral is generically similar in form to those considered in Sect. 2 (cf. eq. [1]) and proves useful in the discussion of the properties of the quantum mechanical matrix elements.

Equation [12] is not for the faint of heart! Taken superficially, it suggests that the matrix elements we desire are a continuous superposition of what are individually quite complicated objects. Even in the classical limit, where the matrix elements on the right-hand side are in some sense relatively simple, the outlook is not promising. In particular, it would appear at minimum that the calculation of a particular complex temperature density matrix element for specified value of x' in the classical limit will require us to include the contributions from *all* classical paths of temporal duration t that connect a continuously varying position, y, and our desired position, x'. Since the number of such paths grows with time in a generally unlimited fashion, finding and including the contributions arising from this multiply infinite set of trajectories would appear to be a rather hopeless endeavor.

The principal result of the present work is the suggestion that this rather bleak conclusion may be premature. To see how this may be the case, let us consider the case where the dynamical term in eq. [12] is given by its classical limiting expression (eq. [10] with only classical paths contributing). In this limit, the same stationary phase argument that was used to suggest the classical limit of eq. [10] implies that not all integration regions will contribute to the final result. In particular, the only regions that will contribute strongly to eq. [12] will be those for which the variation in the classical object S with respect to y vanishes. However, from classical physics, the y-variation of S corresponds to the initial momentum of the classical trajectory that begins at the point y and travels to the point x' in a time t. The requirement that the variation of S vanish implies that a particular region will contribute to the final result only if there exists a classical trajectory that begins with zero momentum at that point and travels to the point x' in a time t. The number of such classical trajectories for given values of y, x', and t is typically zero and *rigorously* never more than one. We thus obtain the rather startling suggestion that the matrix elements we require are not hopelessly complicated, but instead have a rather simple structure.

To investigate this suggestion further, we analyze the integral in eq. [12] for suitable model systems by means of a Cornu analysis. The objective will be to see if such an analysis confirms the existence of the underlying structure suggested above. If the presence of such a structure is demonstrated, it may provide a valuable focal point for the organization of the general quantum dynamical problem.

4. Results

As a model system, we consider a specific one-dimensional problem, that of a simple harmonic oscillator perturbed by an interaction term that varies as the fourth power of the oscillator displacement. The quantum mechanical Hamiltonian for the perturbed system can be written as

$$[13] \quad \hat{H} = \frac{p^2}{2} + \frac{x^2}{2} + \lambda x^4$$

where λ is a dimensionless constant. The conventional harmonic oscillator is recovered in the limit that λ is set to zero. We are using units in which the natural unit of energy is the spacing between successive energy levels of the conventional oscillator and the natural unit of distance is the square root of the ratio of Planck's constant to the product of the oscillator mass and unperturbed frequency.

We solve this quantum mechanical problem numerically by means of established matrix techniques. Specifically, we construct a matrix representation of the Hamiltonian operator in eq. [13] using information contained in the problem's unperturbed ($\lambda = 0$) solutions. As the number of such unperturbed solutions included in the treatment tends to infinity, the resulting matrix eigenvalues and vectors yield the exact energy levels and quantum mechanical wavefunctions of the problem. After they were so obtained, the energy levels and wavefunctions for the problem were utilized to construct the various matrix elements appearing in eq. [12] and to perform the associated Cornu decomposition of the final results.

We begin with a simple problem, the case of the simple harmonic oscillator (i.e., $\lambda = 0$). For this situation, all the

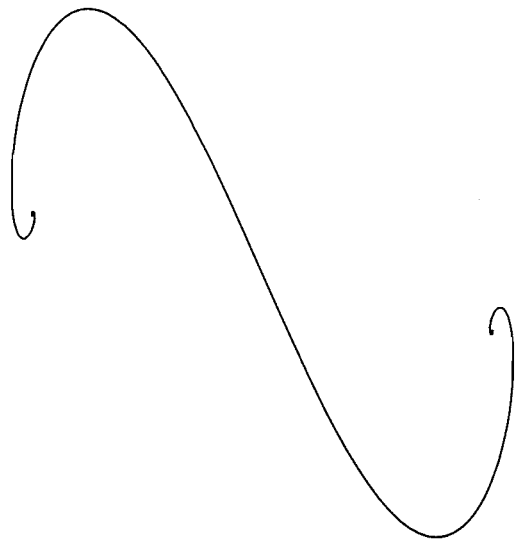

FIG. 6. Cornu analysis (eq. [12]) of the quantum mechanical amplitude $\langle x'|\exp(-\beta_e H)|x\rangle$ for the harmonic oscillator. The result shown corresponds to $x' = x = 0$ and reduced values of β and t of 1 and 0.1, respectively. As expected, the analysis reveals that a single stationary phase point is present. For scale, the numerical value of the matrix element (the complex vector from the left to right-hand ends of the figure) is equal to $0.545 - 0.058$ i.

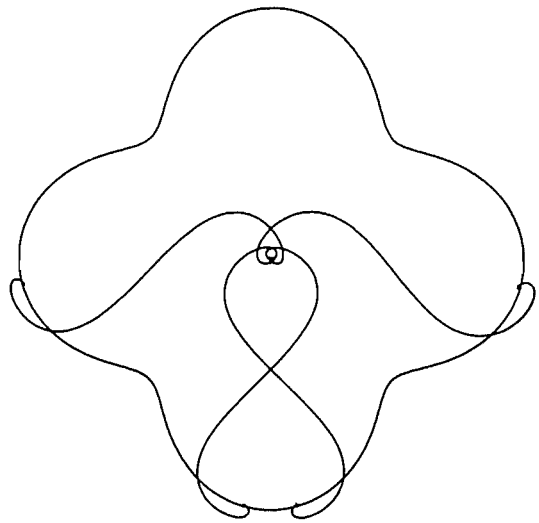

FIG. 7. The quantum mechanical oscillator matrix element of Fig. 6 is plotted in the complex plane parametrically as a function of time over the range $0 < t < 4\pi$. The resulting clover-leaf pattern represents the time-dependent locus of points that is swept out by the moving tip of the Cornu spiral in Fig. 6 as t advances over this interval. Superimposed on the figure are the Cornu spirals (cf. Fig. 6 and eq. [12]) for $t = .01$, $\pi - 0.1$, $\pi + 0.1$, and $2\pi - 0.1$. These results proceed from the $t = 0.1$ result (roughly in the three o'clock position) around the figure in a clockwise order. As expected, behavior corresponding to a single stationary phase point is seen for all times.

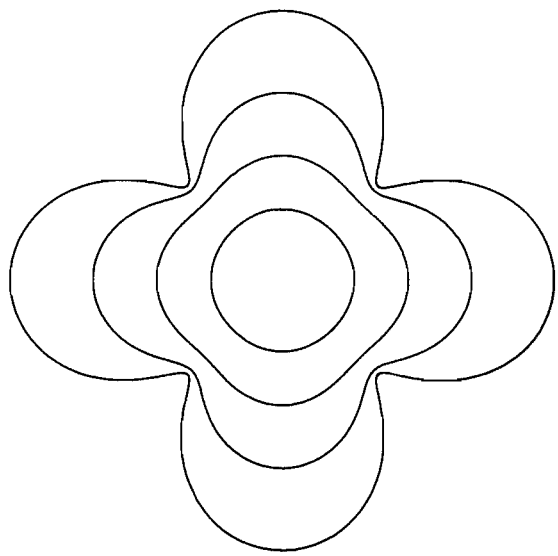

FIG. 8. Parametric time (cf. Fig. 7) plots of the complex temperature matrix elements for the harmonic oscillator described in Fig. 7 for temperatures corresponding to $\beta = 4.0$, 2.0, 1.0, and 0.5. The temperature dependence is monotonic with the outer (inner) curve corresponding to $\beta = 0.5$ (4.0).

necessary quantities are known exactly, and the various numerical pieces can thus be checked against their analytic counterparts. Furthermore, the various matrix elements involved for the oscillator contain a very simple coordinate dependence that leads to a simple, single stationary phase point behavior. Displayed in Fig. 6 is the Cornu analysis of a particular complex temperature density matrix element for the oscillator. As anticipated, the results indicate the presence of a single stationary phase point (cf. Fig. 2). Moreover, the particular results displayed in Fig. 6 agree with the corresponding analytic values.

As the parameter t advances, the spiral in Fig. 6 pivots about, coiling and uncoiling as illustrated in Fig. 7. For the oscillator, the locus of points traced out by the tip of the spiral forms a closed figure (Fig. 7), a figure whose overall physical extension varies with temperature (Fig. 8). The quantum dynamics of the physical system are thus monitored by the dynamics of its associated Cornu clock, which, perhaps cognizant of its role, even runs in a "clockwise" fashion! Although not explicitly of concern here, the precession of this clock reflects the details of the energy levels of the quantum mechanical system.

For a nonzero perturbation, the simple results of Figs. 6–8 are modified. As illustrated in Fig. 9, small perturbations introduce a slight dephasing into the dynamics and the locus of points traced out by the Cornu spiral no longer forms a simple closed curve. Although significant remnants of the original harmonic structure are evident for this case of $\lambda = 0.001$, we also see evidence of a modest precession in the dynamics.

The modifications of the harmonic results become more pronounced as the strength of the perturbation is increased. Relatively little of the original harmonic structure remains as λ is increased to a value of 0.05 (Fig. 10). In addition to the time development of the overall locus of points for the Cornu decompositions of the system, we also display in Fig. 10 specific constructions for various intermediate times. At the relatively short time of 0.1, the result is virtually identical to that of the corresponding harmonic system displayed in Fig. 7, indicating that the results are dominated by single stationary point phase behavior (cf. Figs. 2 and 6). This is consistent with the fact that with a zero initial momen-

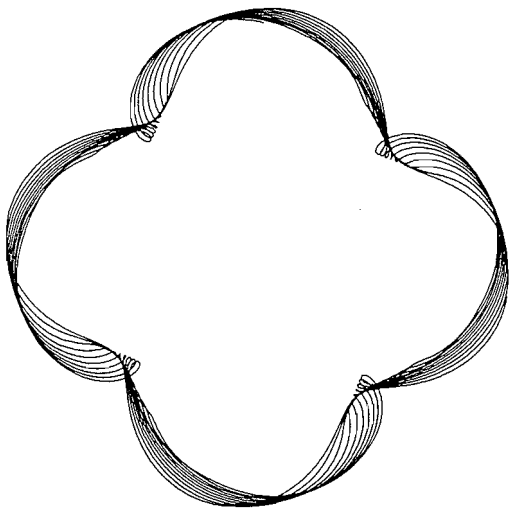

FIG. 9. The efect of a small anharmonic perturbation on the time dependence of the complex temperature density matrix element displayed in Fig. 7. The perturbation ($0.001\ x^4$) introduces a modest dephasing into the problem, as is evidenced by the slight precession evident in the figure. The time here ranges up to $t = 40\pi$.

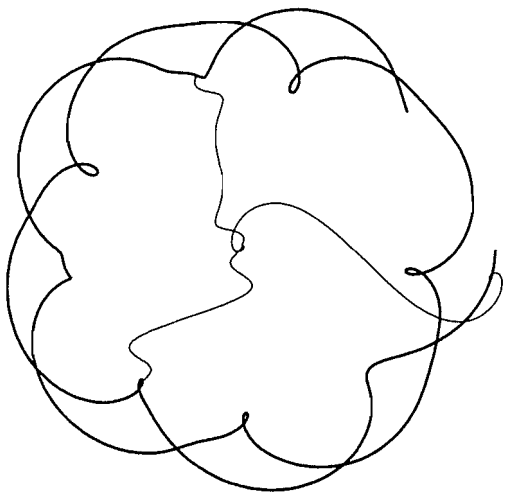

FIG. 10. The effect of a large anharmonic perturbation on the time dependence of the complex temperature density matrix element described in Fig. 7. The outer spiral follows the time dependence of the anharmonic ($\lambda = 0.05$) density matrix element parametrically in the complex plane as a function of t over the range $0 < t < 22$. The outer spiral begins at the three o'clock position at $t = 0$ at the value of $0.544 - 0.059$ i, a value only slightly different from the analogous harmonic result shown in Fig. 6. Superimposed on this figure clockwise from the three o'clock position are three Cornu constructions (eq. [12]) of the matrix element for three values of t (0.1, 4.0, and 20.0). At short times, the Cornu analysis reveals single stationary phase point behavior. At longer times, however, multiple stationary phase points are indicated. As confirmed in Figs. 11 and 12, the location and nature of these stationary phase points are correctly predicted by the analysis of Sect. 4.

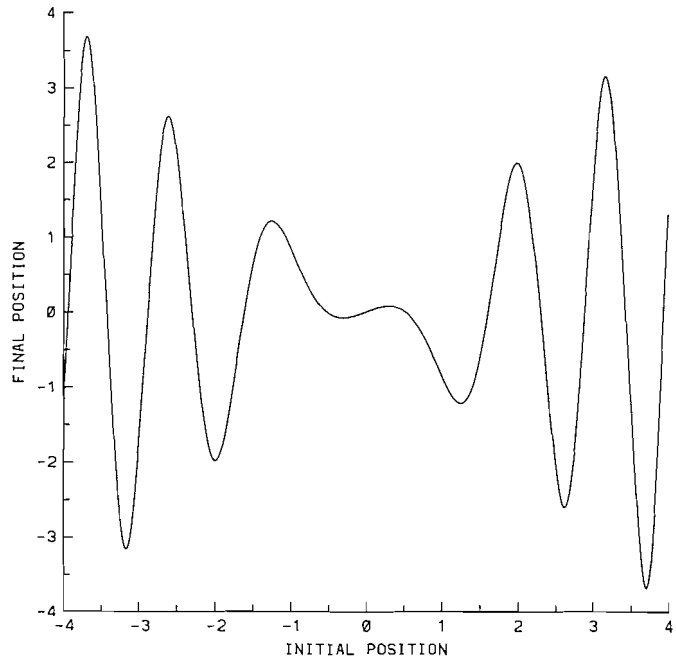

FIG. 11. Shown are the final positions of a classical particle that begins at various initial positions and proceeds forward 20 units of time on the anharmonic potential, $V(x) = x^2/2 + \lambda x^4$, where $\lambda = 0.05$. The initial positions that would lead to a final position of $x' = 0$ are thus the intersections of the curve plotted with a horizontal line at $x' = 0$. For example, the region $-0.3 < x < 0.3$ contains one such solution, the region $-1.2 < x < 1.2$ contains three and so on.

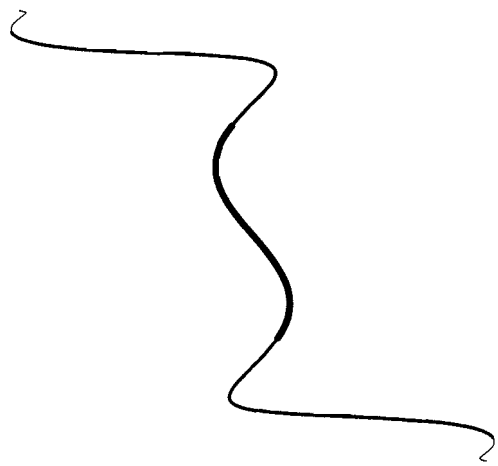

FIG. 12. A decomposition of the Cornu construction of the $t = 20$ result of Fig. 10 (cf. eq. [12]). The darkest portion corresponds to contributions that arise from the region $(-0.3,0.3)$, the next darkest portion from the region $(-1.2,1.2)$, and so on. This result combined with Fig. 11 confirms that the matrix element in question is dominated by the zero momentum stationary phase regions described in Sect. 4.

tum, the only particles that can reach the desired final position ($x' = 0$) in such a brief period are those that start at the origin. At longer times zero momentum trajectories can reach the origin from a variety of other positions, as illustrated in Fig. 11. However, from eq. [12] we see that each of the contributions from the various starting positions will be weighted by its associated equilibrium factor. Thus positions that are thermally inaccessible will effectively be eliminated from the problem. This important fact means that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

the number of stationary phase regions contributing to the final result will ultimately saturate with time. The Cornu decomposition at $t = 20$ displayed in Fig. 12 exhibits multiple stationary phase character. As indicated in the figure, a careful analysis of the various contributions to the result reveals that the stationary phase regions involved are precisely the ones that would be predicted by the zero momentum classical analysis shown in Fig. 11. Although not explicitly shown here, a similar conclusion also holds for the $t = 4.0$ result shown in Fig. 10. Figure 12 is this a visual confirmation of the underlying structure in the quantum mechanical objects of interest.

5. Summary/Conclusions

The present work has considered a variety of topics of relevance in the development of quantum dynamical algorithms. Using a combination of numerical and graphical techniques, we have examined the principal computational objects of interest for a series of model problems. This analysis has revealed the presence of a significant underlying structure in the dynamical problem, a structure that we feel is rather general and that likely extends well beyond the particular model problems considered here. The significance of this structure is twofold. First, it demonstrates that the general quantum dynamical problem may be appreciably simpler than has previously been feared. Second, it provides a specific identification of the dominant contributions in the dynamical problem. In the spirit of Hamming's maximum (16) cited at the outset, we are hopeful that the insight gained in the present study will prove valuable in the ongoing efforts directed at the development of general, statistically based dynamical algorithms.

An investigation of atomic structure in position and momentum space by means of "ideal shells"

HARTMUT SCHMIDER, ROBIN P. SAGAR, AND VEDENE H. SMITH, JR.[1]
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received September 3, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

HARTMUT SCHMIDER, ROBIN P. SAGAR, and VEDENE H. SMITH, JR. Can. J. Chem. **70**, 506 (1992).

For atomic systems, the boundaries in position and momentum space that enclose the exact electron number given by the aufbau principle have been numerically calculated. Their relatively irregular behavior as a function of the atomic number Z is demonstrated and explained in terms of corresponding irregularities of the aufbau principle. Direct comparisons of these radii with those derived from density functionals that are known to exhibit atomic shell structure are shown to be useful in judging the ability of the latter to define "physical" shells compatible with the aufbau principle.

Key words: atomic radii, shell structure, aufbau principle, charge density, momentum density.

HARTMUT SCHMIDER, ROBIN P. SAGAR et VEDENE H. SMITH, JR. Can. J. Chem. **70**, 506 (1992).

Pour des systèmes atomiques, on a calculé les limites de la position et du moment spatial qui délimitent le nombre électronique exact données par le principe d'aufbau. On démontre que leur comportement en fonction du nombre atomique Z est relativement irrégulier et on l'explique en fonction des irrégularités correspondantes du principe d'aufbau. On montre qu'une comparaison directe de ces rayons avec ceux que l'on peut obtenir à partir de densités fonctionnelles connues pour présenter une structure de la couche atomique est utile pour juger de l'habilité de cette dernière à définir les couches «physiques» compatibles avec le principe d'aufbau.

Mots clés : rayons atomiques, structure de la couche, principe d'aufbau, densité de charge, densité de vitesse acquise.

Introduction

In recent years, there have been several investigations into the ability of various functionals of the position density (1–9) $\rho(r)$ and the momentum (10–12) density $\Pi(p)$ of atomic systems to represent the atomic shell structure as suggested by the aufbau principle of the periodic table. That this structural feature could be exhibited by the charge or momentum densities themselves is excluded by the finding that the former is a monotonically decaying function (2, 13–15) of r, whereas the latter shows a maximum at $p > 0$ (10, 16–18) for some atomic systems. It has been shown that some of the above-mentioned functionals show a relatively large number of critical radii (roots and extrema) that can be meaningfully assigned to particular shell contributions.

On the other hand, the ability of these radii to define physical regions corresponding to an atomic shell with the "correct" number of electrons is much less pronounced. Partitioning schemes analogous to the so-called Politzer–Parr partitioning (19) show somewhat limited success for some (19, 20) and practically none for other (21) functionals.

Though most of these critical-point analyses fail to exhibit all shells for all atoms, the behavior of the resulting radii as a function of the atomic number Z shows remarkable regularities in many cases. For $D(r) = 4\pi r^2\rho(r)$ and $\nabla^2\rho(r)$ as quantities defined in position space, the inverse of the critical radii is proportional to Z (2, 4, 5) according to Bohr theory, whereas the corresponding radii p (or k) in the momentum (or reciprocal) space quantities $I(p) = 4\pi p^2\Pi(p)$, $\nabla^2\Pi(p)$, and $\nabla^2F(k)$ show direct linear behavior as a function of the atomic number (9, 11, 12).

One of the goals of this paper is to investigate if this kind of simple regular behavior is compatible with the notion of a given number of electrons in fixed shells as suggested by the aufbau principle of the periodic table. For this, "ideal-shell" radii have to be calculated.

[1]Author to whom correspondence may be addressed.

"Ideal-shell" radii for the neutral atoms

To judge if a given partitioning scheme, based for example on the critical radii of a density functional, is suitable for the definition of shell boundaries that comply with the aufbau principle, one has to check if the integral

$$[1a] \quad N_n = 4\pi \int_{r_{n-1}}^{r_n} \rho(r) r^2 dr$$

yields approximately the number of electrons, N_n^{HF}, that occupy orbitals with the corresponding principal quantum number n in the Hartree–Fock description of the atom. In eq. [1*a*] r_n denotes the radius that has been assigned to the boundary between the nth and the $(n + 1)$st shell, with $r_0 = 0$ by definition. The analogous expression in a momentum space description of the system is

$$[1b] \quad N_n = 4\pi \int_{p_n}^{p_{n-1}} \Pi(p) p^2 dp$$

Note that in position space $r_n > r_{n-1}$, whereas in momentum space $p_n < p_{n-1}$, since the K shell (i.e., $n = 1$) is the innermost shell in position, but the most diffuse one in momentum space. Analogously, high principal quantum numbers correspond to electrons that are far from the nucleus but relatively slow. Note that $p_0 = \infty$ by definition.

The extent to which these "shell occupations" agree with the expected values gives a measure of how strongly the corresponding region of space is dominated by a particular shell. To construct radii that fulfill the above condition *perfectly*, one has to solve the integral equations

$$[2] \quad N_n^{HF} = N_n$$

in position and momentum space for r_n and p_{n-1}, respectively. Note that in this labeling scheme $r_{n_{max}}$ and p_0 lie at infinity in the corresponding space, n_{max} denoting the maximum principal quantum number of the atom. The equations have to be solved recursively by starting at $r_0 = 0$ in position and at $p_{n_{max}} = 0$ in momentum space, respectively.

This can be done with small computational expense by a Newton algorithm, noting that the first derivatives of the integrals on the right-hand side of eq. [2] with respect to r and p are just the integrands, i.e., the radial position and momentum densities $D(r)$ and $I(p)$. The resulting iterative equations are

$$[3a] \quad r_n^{(i+1)} = r_n^{(i)} - \frac{\int_{r_{n-1}}^{r_n^{(i)}} D(r)\mathrm{d}r - N_n^{HF}}{D(r_n^{(i)})}$$

and

$$[3b] \quad p_{n-1}^{(i+1)} = p_{n-1}^{(i)} - \frac{\int_{p_n}^{p_{n-1}^{(i)}} I(p)\mathrm{d}r - N_n^{HF}}{I(p_{n-1}^{(i)})}$$

Here the superscript (i) denotes the result of the ith iteration. With a reasonable initial guess (e.g., from a binary search), these equations show quadratic convergence.

It is interesting to note that constraints similar to the ones in eq. [2] have been employed in density functional schemes where the density was represented by piecewise-exponentially decaying functions (22). The resulting values of r_n naturally deviate from the ones obtained here, since the underlying functions are of entirely different origin. As we will see later, the differences are not extreme.

Values of ideal-shell radii obtained from eqs. [3*a*] and [3*b*] can be used as a reference to judge how closely a given set of radii produces shells corresponding to the aufbau principle, from which they were derived. They have, however, no direct counterpart in any of the above-mentioned density functionals, but are a quite arbitrary partitioning scheme based on the (uncorrelated) orbital description in the framework of the independent-particle model. The assumption is made that the electrons of an atomic shell are confined exclusively to a well-defined region of space, whereas in reality each shell extends over all space. Note that it is only in the independent-particle model that the notion of atomic shells has any clear-cut meaning. As we will see in the following, it is also the aufbau principle that is responsible for the relatively spiky behavior of the "ideal" shells of the ground state atoms in the Hartree–Fock picture.

Results and discussion

Since most of the calculations on atomic shell structure and its expression in topographical features of density functionals have been based on the nonrelativistic Hartree–Fock calculations of Clementi and Roetti (23) and McLean and McLean (24), we have computed the ideal-shell radii for the neutral atoms ($3 \leq Z \leq 92$) in their ground states from the corresponding densities. Note that the Hartree–Fock ground state configurations were used, which do not in all cases coincide with the experimental ones. The necessary numerical integrations have been performed using a 50-point Fejér-quadrature and were checked with a 100-point quadrature of the same kind. The above algorithm was employed until a given accuracy of the resulting electron numbers was reached (10^{-10}). The starting values were chosen by a binary search with a small step size (0.02). Since the wave functions are given with an accuracy of five significant figures, and the algorithm works from the origin outwards, the number of electrons in the outermost shell (in the respective space) deviates somewhat from the expected integer value, i.e., the limited accuracy of normalization is entirely concentrated on these shells.

Tables 1 and 2 give the radii for the atoms with $3 \leq Z \leq 92$ in position and momentum space, respectively. The general trend of an inverse behavior in position space and a linear behavior in momentum space with respect to the atomic number Z is already visible from these values.

This trend can also be seen in Figs. 1 and 2, where the inverse radii r_n^{-1} (position space) and the radii p_n (momentum space) are plotted against the atomic number. The points have been connected to avoid confusion. As can be seen from Figs. 1*b* and 2*b* this general trend is frequently interrupted by spikes and jumps. For the boundaries between higher shells (M/N upwards), this becomes so prevalent that it is difficult to speak of a linear behavior at all. The linearity holds obviously only "piecewise." Note also that the figures for position and momentum space bear an amazing similarity.

This kind of behavior is rooted in the nature of the aufbau principle itself. As an example, consider the sudden jump in the radius r_5 corresponding to the O/P boundary after $Z = 79$ (gold). Up to $Z = 78$ (platinum), the 5*d* subshell has been gradually filled, whereas the P shell consists of a doubly occupied 6*s*. For Pt, however, the configuration $(Xe)5d^{10}6s^0$ becomes energetically favorable, and the corresponding ideal-shell boundary vanishes altogether. This phenomena occurs also for element 46 (palladium). With the following elements the P shell ($n = 6$) gets gradually filled and the shell boundary returns, but moves inward much faster. The reason for this is clear: the contractive effect of the growing nuclear charge is no longer counterbalanced by the increasing electron numbers in the O shell, since all "new" electrons are now filled into the outer, the P shell. The stronger movement of the radii inward results in a larger slope of the corresponding r^{-1}–Z plot.

As for the spikes, they may be explained on a similar basis of the filling of subshells. We take the example of $Z = 43$ (technetium). The (smaller) slope before this element corresponds to the filling of the 4*d* subshell. With Mo, this is half filled and the 43rd electron goes rather into the 5*s* orbital, which was only half occupied in the few preceding elements. Ru, however, shows again a singly occupied 5*s* and goes on with the population of 4*d* orbitals. The filling of the higher, rather than the lower, shell of a given boundary always has the effect of moving the shell boundary inward faster, which leads to higher slopes in the graphs or, in case only one element is affected, to spikes. The opposite scheme of filling inner shells may counterbalance the contractive increase in Z so strongly that the shell boundary moves outward, rather than inward. This leads to negative slopes in the graphs. Analogous, although less pictorial, arguments can be made in momentum space.

With the exception of the K/L and the L/M boundaries, which are naturally not much affected by irregularities in the

aufbau principle, these effects lead to a relatively poor description of the r_n^{-1}/Z (p_i/Z) relation by a linear least-squares fit. Resulting slopes and y intercepts, together with R^2 coefficients, are collected in Tables 3 and 4 to underline this point. The comparison of the correlation coefficients with those in the corresponding fits for radii derived from density functionals (2, 4, 6, 9) makes it quite clear that one side effect of the general deviation of the latter from the "correct" shell-occupation numbers is a much smoother behavior as a function of Z. The ideal (inverse) linearity of the radii in Z would not be compatible with the aufbau principle.

It is finally interesting to compare our results with the ones obtained for the r_n by Wang (22) in his density functional calculations that employ eq. [2] as a constraint for the first-row atoms. Table 5 contains a compilation of his results and ours. Taking into account the entirely different premises, the

values are surprisingly similar. Calculations analogous to Wang's with radii fixed to the HF values would perhaps yield reasonable results. How far the values of r enclosing fixed electron numbers coincide with areas of approximately piecewise-exponential decay would have to be investigated by studying the logarithm of ρ or connected density functionals.

Conclusions

Since any atomic partitioning scheme based on functionals of the position or momentum density has to be judged on its ability to reproduce the aufbau principle in terms of the number of electrons enclosed by its shell regions, we have in this study computed the radii, for which this criterion is met exactly. We have done this for the neutral atoms in their ground states with $3 \leq Z \leq 92$, employing HF–SCF wavefunctions (23, 24).

These values should serve as a quick reference as to the extent with which a certain partitioning scheme is compatible with the underlying aufbau principle. They may as well be used to define radii of "inner parts" of atoms, e.g., core regions, if one wishes to represent these by "hard spheres" based solely on the density normalization. Their "spiky" behavior as a function of the atomic number Z shows their sensitivity towards irregularities in the filling of shells in the periodic table. They provide a quite pictorial map of these "ups and downs." This is not surprising, since the radii have been calculated with the *ad hoc* knowledge of the electron configuration.

From these relatively strong deviations from an (inverse) linear behavior of the resulting radii in Z, it can be inferred

that such a behavior is of quite limited compatibility with the aufbau principle, which is inherently somewhat irregular. The fact that this behavior is nevertheless followed by many partitioning radii based on density functionals, can be assigned to a tendency of these functionals to "wash out details" of the latter.

Earlier results of Wang (22), employing fixed-electron number constraints in a piecewise exponential description of the atomic charge density, seem not too different from the ones in the paper, given the different nature of the underlying densities.

By using the K-matrix technique for the continuum states that was previously employed with particularly diffuse L^2 basis sets, it is shown that GTO bases are also capable of yielding accurate values for the properties belonging to the electronic continuum. The method has been tested for helium and proved of satisfactory accuracy also for the analysis of the autoionizing states. The results include the phase shifts of the continuum states of the $^1S^e$ and $^1P^o$ manifolds, the properties of the lowest resonances of these symmetries, the ground state photoionization cross section, and the S contribution to the $1s2p\ ^1P^o$ photoionization cross section. The results obtained suggest that the proposed technique should be useful for computing molecular differential photoionization cross sections by exploiting the widely used codes that employ GTO bases.

Key words: photoionization, Gaussian basis sets, helium, autoionizing states.

ROBERTO MOCCIA et PIETRO SPIZZO. *Can. J. Chem.* **70**, 513 (1992).

Utilisant la technique de la matrice K pour le continuum des états qui a été employée antérieurement avec des ensembles de base L^2 particulièrement diffus, on a montré que les bases GTO peuvent aussi fournir des valeurs précises pour les propriétés appartenant au continuum électronique. On a vérifié la méthode avec l'hélium et on a prouvé que sa précision est aussi satisfaisante pour l'analyse d'états auto-ionisants. Les résultats incluent les déplacements de phase du continuum des états de multiplicités $^1S^e$ et $^1P^o$, les propriétés des résonances les plus basses de ces symétries, la section efficace de la photo-ionisation de l'état fondamental et la contribution S à la section efficace de la photo-ionisation de l'état $^1P^o$ $1s2p$. Les résultats obtenus suggèrent que, en exploitant des codes fréquemment utilisés qui utilisent des bases GTO, la technique proposée pourrait étre utile pour calculer les sections efficaces de la photo-ionisation différentielle moléculaire.

Mots clés : photo-ionisation, ensembles de base gaussiens, hélium, états auto-ionisants.

[Traduit par la rédaction]

Introduction

Electron emission is one of the most efficient decay mechanisms for atoms and molecules excited above the first ionization threshold. This makes a knowledge of reliable photoionization cross sections very valuable in a variety of fields. Their importance has also grown due to the development of laser sources and of synchrotron radiation, which have greatly extended both the range of photon energies and the number of photons involved in the experiments. In the numerical evaluation of photoionization cross sections, a pivotal role is played by the transition matrix elements involving states of the electronic continuum. It should be stressed that the differential cross section, in contrast to the integral, requires a more detailed knowledge of the states lying in the continuum, such as the individual phase shifts of their degenerate partial wave components.

The calculation of the matrix elements involving the continuum may be accomplished by several techniques characterized either by the use of purely L^2 basis sets or by the utilization of truly continuum orbitals. These latter techniques, derived from the calculations of scattering cross sections and known as scattering methods, should afford, in principle, a more accurate evaluation of the properties pertaining to the continuum; on the other hand, the former methods appear to have some decisive computational advantages. In fact, the L^2 algorithms may be reduced to a sequence of matrix operations that can be efficiently implemented on modern computers. In addition, the L^2 methods may exploit the well-established computer codes available to compute the electronic bound states of molecules employing L^2 bases, generally of the GTO type.

The lack of spherical symmetry in molecules curtails the possibility of directly applying the methods developed and extensively used to study the photoionization of atoms, such as the Close-Coupling (1) or many-body methods (2, 3). Specific approaches were thus developed for the molecular cases. Among those which truly determine continuum orbitals by solving differential or integral equations, the most extensively used are the Iterative Schwinger Variational method (4), the Multiple Scattering Xα method (5), and the Linear Algebraic method (6). The most widely applied L^2 methods are the Complex Basis method (7), the Reaction K-matrix method (8, 9), and the Stieltjes Moment Theory method (10). This last one may be employed usefully only to calculate integral cross sections.

To use L^2 methods for computing the differential cross sections, particular basis functions and numerical techniques were employed to obtain the partial wave phase shifts (11). These techniques rely upon a correct behavior of the more extended part of the wavefunction in order to interpolate it by an adequately phase-shifted Coulomb wave. These methods cannot be applied with the GTO bases since,

at large distance from their origin, the GTO cannot give a reliable description of a Coulomb wave.

In this paper it is shown how, exploiting the reaction K-matrix technique, this shortcoming may be overcome. Thus the possibility of obtaining useful knowledge about the electronic continuum may be added to the many services already supplied by the GTO. Section 2 describes the method, while Sect. 3 reports some preliminary calculations, which, although made for the simple atomic system He, represent a stringent test of the methods due to the accuracy required by the quantities evaluated.

2. Method of calculation

The theory of the K-matrix technique and its implementation upon L^2 bases to represent the properties belonging to the continuum have been thoroughly described elsewhere. Here only a brief outline is given and the reader is referred to a previous paper (9) for details. This work will therefore focus on the differences needed to employ short-range basis orbitals like the Gaussian instead of the more suitable STOCOS functions (11) employed in our previous K-matrix calculations (8, 9, 12).

The present approach is an extension of the K-matrix method, in which all orthogonality constraints have been removed to achieve the fastest convergence of the variational expansion with the basis size. The method, as pioneered by Fano (13), is essentially a configuration interaction (CI) in the continuum, carried out for a fixed energy, and allows us (at a formal level) to expand the variational solution upon continuous basis sets. It turns the Schrödinger equation into a system of integral equations for the K-matrix elements, which is then transformed into a linear system by a quadrature upon a finite L^2 basis set. The formal basis employed to expand the continuum states includes a discrete subset of localized functions, which more efficiently represent the autoionizing states and the correlation effects, in addition to the relevant partial wave channel (pwc) subspaces. In the atomic case, these are defined by the ion level I and the l value of the electron partial wave. In the following the subspaces will be indexed with greek letters; a subspace index α will designate explicitly an open pwc subspace, while an index β designates an arbitrary subspace; $\hat{Q}_\beta$ will denote the projector inside the subspace.

In the present calculation, the formal basis functions $|\Phi_{\beta E}\rangle = |\Phi_I^+ \chi_{\epsilon l}\rangle$ of the pwc subsets are the eigenfunctions of the channel Hamiltonian $\hat{H}_\beta = \hat{Q}_\beta \hat{H} \hat{Q}_\beta$. They are therefore (antisymmetrized spin- and symmetry-adapted) products of the ion states $|\Phi^+_{IM_LM_S}\rangle$ and of the partial l-waves $|\chi_{\epsilon lmm_s}\rangle$ that diagonalize the effective channel Hamiltonian for the outer electron. These waves behave asymptotically as standing shifted Coulomb waves and the pwc basis functions may be indexed by the corresponding energy $E = E_I^+ + \epsilon$. To allow a safe representation upon a discrete basis, it is required that these states possess properties (phase shifts, off-diagonal overlap, and Hamiltonian matrix elements) weakly dependent upon the energy indexes.

In the case of helium, the effective channel Hamiltonians $\hat{H}_\beta$ do not support shape resonances, so these conditions are satisfied. If narrow shape resonances occur, as is often the case in molecular systems, $\hat{H}_\beta$ may be properly redefined to avoid this occurrence, while localized representations of these states must be included in the localized correlating subspace.

The calculation of the differential cross sections requires the phase shifts of the pwc basis functions $|\Phi_{\beta E}\rangle$, which in the present approach are obtained via K-matrix calculations performed inside the separate channels. In fact, according to the formula given in the next subsection, these phase shifts are immediately obtained when the K-matrix technique is employed to diagonalize the channel Hamiltonians in bases of zero phase shift; i.e., those obtained by coupling hydrogenic eigenfunctions $|\chi^{(0)}_{\epsilon l}\rangle$ to the ion levels. In the present L^2 approach, the $|\chi^{(0)}_{\epsilon l}\rangle$ are conveniently represented by diagonalizing the Coulomb Hamiltonian upon the same bases employed for the $|\chi_{\epsilon l}\rangle$; we stress that this procedure yields the phase shifts of the pwc basis functions even if the L^2 representations actually employed do not have a correct long-range behavior. It is also worth noting that the basis functions $|\Phi^{(0)}_{\beta E}\rangle = |\Phi_I^+ \chi^{(0)}_{\epsilon l}\rangle$ are not necessarily orthonormal nor do they diagonalize any model Hamiltonian. This preliminary step, hereafter referred to as the SC-KM (Separate Channel K-Matrix) step, yields the phase shifts of the basis functions $|\Phi_{\alpha E}\rangle$ employed to calculate the correlated eigenfunctions in the subsequent step, referred to as the IC-KM (Interacting Channel KM) step.

The present approach may be considered equivalent to a Close-Coupling calculation with the same open and closed channels plus a large number of pseudostates for the correlation effects. It should be clear, however, that the K-matrix method is much more suitable for a molecular calculation: it may be directly linked to the L^2 methods employed in molecular structure and may more easily handle the large number of channels that are needed in a molecular calculation.

The K-matrix method

The method will be outlined employing the notation proper of the IC-KM step, but the equations for the SC-KM step may be immediately derived from them. In this last case, of course, $\hat{H}$ stands for the channel Hamiltonian. For ease of writing, the same notation $|\Phi_{\beta E}\rangle$ will be employed for discrete and continuous eigenfunctions, normalized to unity and $\delta(E - E')$ respectively.

Corresponding to the n channels that are open at energy E (at the energies investigated in the present work the only open channel is that corresponding to the ion ground level), one may define n linearly independent trial functions $|\Psi_E\rangle = (|\Psi_{1E}\rangle \ldots |\Psi_{nE}\rangle)$ of the form

$$[1] \quad |\Psi_{\alpha E}\rangle = |\Phi_{\alpha E}\rangle + \sum_{\beta'} \oint\!\!\!\!\!\!\int dE' |\Phi_{\beta' E'}\rangle P \frac{1}{E - E'} K_{\beta' E', \alpha E}$$

where P denotes the principal part of the integral and for each subset β' denotes the summation over its discrete part and the integration over the continuous one. The expansion coefficients are determined by imposing $\langle \Phi_{\beta' E'} | \hat{H} - E | \Psi_{\alpha E}\rangle = 0$ and this leads to the system of coupled integral equations

$$[2] \quad K_{\beta' E', \alpha E} - \sum_{\beta''} \oint\!\!\!\!\!\!\int dE'' V_{\beta' E', \beta'' E''}(E) P \frac{1}{E - E''} K_{\beta'' E'', \alpha E} = V_{\beta' E', \alpha E}(E)$$

$$V_{\beta' E', \beta'' E''}(E) = \langle \Phi_{\beta' E'} | \hat{H} - E | \Phi_{\beta'' E''}\rangle - (E' - E)\delta_{\beta' \beta''}\delta(E' - E'')$$

In the present calculations, in the IC-KM step the matrix

[d]Computed from the data in Tables III and V of A.

elements $V_{\beta E',\beta E''}(E)$ inside a channel are identically zero, since the pwc bases are the eigenfunctions of the projected Hamiltonian $\hat{Q}_\beta \hat{H} \hat{Q}_\beta$.

For real energies the K-matrix on the energy shell $\mathbf{K}(E)$, defined by $K_{\alpha'\alpha}(E) = K_{\alpha' E,\alpha_E}$, is a real symmetric matrix. As discussed in ref. 9, it is related to the scattering matrix and contains the quantities needed to analyze the resonances. Moreover, when only one open channel is present (e.g., in the SC-KM step), the solution $|\Psi_{\alpha E}\rangle$ is a standing wave with phase shift

$$\delta_\alpha(E) = \delta_{\alpha 0}(E) - \tan^{-1}[\pi K_{\alpha\alpha}(E)]$$

where $\delta_{\alpha 0}(E)$ is the phase shift of the pwc basis function. In the SC-KM step, this basis satisfies $\delta_{\alpha 0}(E) = 0$ and this makes

it possible to obtain the phase shifts of the pwc basis for the IC-KM step.

The variational wavefunctions so obtained satisfy

$$\langle \Psi_{E'} | \hat{H} - E'' | \Psi_E \rangle = (E - E'')[1 + \pi^2 \mathbf{K}(E)^2]\delta(E - E')$$

and two sets of complex orthonormal eigenfunctions may be obtained by:

$$|\Psi_E^{(\pm)}\rangle = (|\Psi_{1E}^{(\pm)}\rangle \ldots |\Psi_{nE}^{(\pm)}\rangle)$$
$$= (|\Psi_{1E}\rangle \ldots |\Psi_{nE}\rangle)[1 \pm i\pi \mathbf{K}(E)]^{-1} \mathbf{\Delta}^{(\pm)}(\mathrm{E})$$

where $\Delta_{\alpha'\alpha}^{(\pm)}(E) = \delta_{\alpha\alpha'} e^{\pm i\xi_{\alpha E}}$ and $\xi_{\alpha E}$ is the total phase shift of $|\Phi_{\alpha E}\rangle$, inclusive of $-\pi l_\alpha/2$ (i.e., the i^l factor). The states $|\Psi_{\alpha E}^{(-)}\rangle$ contain an outgoing Coulomb wave (with zero phase shift) only in the channel α and are therefore suitable for photoionization calculations.

The L^2 *representation of the partial wave channels*

The present work is concerned with the $^1S^e$ and $^1P^o$ continua from the ionization threshold at -2 au up to about -0.59 au; beyond this energy the GTO bases employed in the present work are unable to represent the higher resonances. All the calculations performed upon Gaussian bases have been checked, employing also extended bases that include, beside Slater and Hydrogenic orbitals, a large number of STOCOS functions

$$\chi_{\xi lm}(\mathbf{r}) = N_{\xi kl}\, r^l e^{-\xi r} \cos(kr) Y_{lm}(\theta,\phi)$$

These are probably the most efficient L^2 bases for calculations in the electronic continua; previous work has discussed in great detail their capabilities (11) and applications (9, 12, 14, 15).

The L^2 sets employed to represent the pwc subspaces in the IC-KM step were obtained by diagonalizing the Hamiltonian upon (spin- and symmetry-adapted) configurations of the form $1s\ nl$, where $1s$ is the exact (extended basis case) or an approximate (GTO case) ground state of He^+, while nl are diffuse orbitals for representing the electron wave. With both bases, the variational states $|\phi_{\beta j}\rangle$ obtained in this way include accurate representations for the lowest bound states of the channel Hamiltonian, a few wavepackets in the higher Rydberg region, a number of narrow wavepackets in the lowest continuum, and broad wavepackets at higher energy. The narrow wavepackets are those variational states whose waves resemble closely (apart from an energy-normalization constant $C_{\beta j}$) the true waves of the same energy inside a sufficiently large portion of space. The advantage of the present method is that this portion must include only the rather limited region where the potential deviates from $-1/r$, i.e., the "molecular region." The L^2 basis for the discretized K-matrix calculations is formed by the states $|\varphi_{\beta j}\rangle$, defined by $|\varphi_{\beta j}\rangle = C_{\beta j}|\phi_{\beta j}\rangle$ for the narrow wavepackets and by $|\varphi_{\beta j}\rangle = |\phi_{\beta j}\rangle$ for all the other states.

The K-matrix calculations may obviously be performed only at energies inside the range covered by the narrow wavepackets, which should allow interpolation of the matrix elements and the phase shifts of the channel basis functions. The contributions to the integrals in eqs. [1] and [2] from the high-energy regions, which should be small and

weakly energy dependent, are instead approximated by summing the contributions of the broad wavepackets.

The GTO are poorly suited to represent the short-period oscillatory behavior of the high-energy continuum states; instead it appears that they are able to describe the long oscillations of the higher Rydberg and of the lower continuum. In this energy region, GTO and extended bases yield about the same number of states, while at higher energies the GTO variational states are much more spaced. With the GTO bases described in the next subsection, the variational waves propagate up to about 70 au, but they are reasonably close to the true waves of the same energy only in a more limited region, whose radius is about 20 au for the lowest states and shrinks for the higher ones. In the present case, the ion is very compact and the potential may be considered Coulombic already at 5 au from the nucleus, so the analysis of the waves in the range 5–20 au yields the normalization and the phase shift of the lowest variational states with good accuracy. However, this procedure is clearly inapplicable to larger atoms or molecular systems, and therefore a method independent of the wave analysis in a Coulombic region, like that proposed here, is in general required. The energy-normalization constants may be fairly well approximated from the energy spacings, $C^2_{\beta j} \approx 2/(E_{\beta,j+1} - E_{\beta,j-1})$, while the phase shifts may be obtained by the SC-KM step described above.

The discretized (on the first energy index) representation $K^{\text{disc}}_{\beta j,\alpha E}$ of the K-matrix on the variational basis is solution of

$$\sum_{\beta' j'} [1 - V(E)\mathbf{P}(E)]_{\beta j,\beta' j'} K^{\text{disc}}_{\beta' j',\alpha E} = V^{\text{int}}_{\beta j,\alpha E}$$

$$V_{\beta j,\beta' j'}(E) = \langle \varphi_{\beta j}|\hat{H} - E|\varphi_{\beta' j'}\rangle - (E_{\beta j} - E)\delta_{\beta,\beta'}\delta_{j,j'}$$

$$V^{\text{int}}_{\beta j,\alpha E} = \langle \varphi_{\beta j}|\hat{H} - E|\Phi_{\alpha E}\rangle^{\text{int}}$$

where the superscript "int" denotes interpolated matrix elements and $\mathbf{P}(E)$ is an almost diagonal matrix that represents the principal part of the integration and whose structure has been discussed elsewhere (9).

The GTO basis set

The $1s$ orbital of He^+ has been approximated by a linear combination of 6 GTO with $n = 1$ and orbital exponents 205, 31.5, 7.41, 2.241, 0.799, 0.306, and 0.1933. The ground state He^+ energy with this orbital is -1.999701 au.

The GTO basis for the localized $^1S^e$ configurations included all the configurations arising from the following orbitals: 14 s (with $n = 1$ and orbital exponents Z ranging from 87.36 to 0.01), 11 p (with $n = 2$ and Z from 8 to 0.005), 11 d (with $n = 3$ and Z from 8 to 0.01), and 8 f (with $n = 4$ and Z from 8 to 0.08).

The s-wave basis set includes the $1s$ ion orbital plus 63 GTO with $n = 3$ and orbital exponents in geometric progression of ratio 0.81 and first term 250. This basis yields 13 narrow wavepackets with energies between -2 and 0 au.

The GTO bases for the localized $^1P^o$ configurations included all the configurations arising from the following orbitals: 13 s (with $n = 1$ and orbital exponents Z ranging from

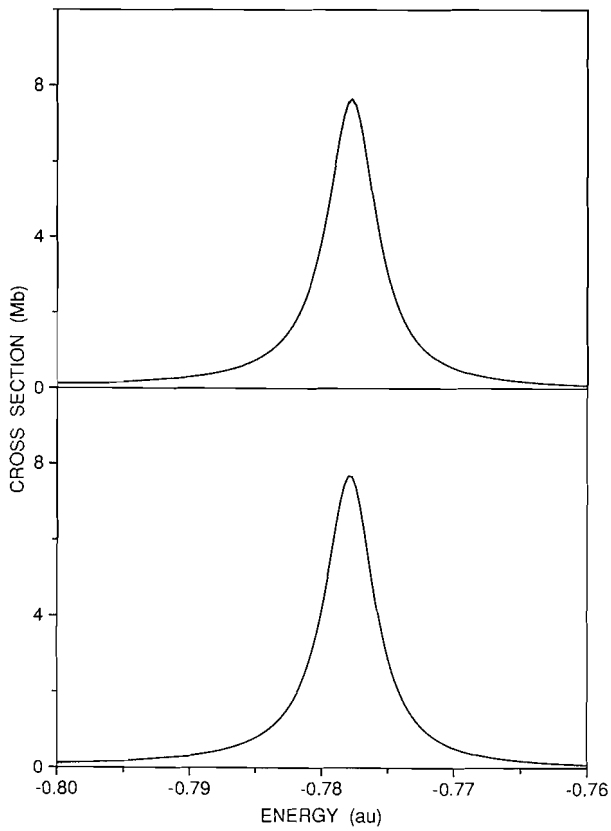

FIG. 7. $1s2p\ ^1P^o$ photoionization cross section across the $2s^2 + 2p^2\ ^1S^e$ resonance. Upper figure: GTO basis; lower figure: extended basis. LG and VG results are indistinguishable on this scale. $'S^e$ contribution.

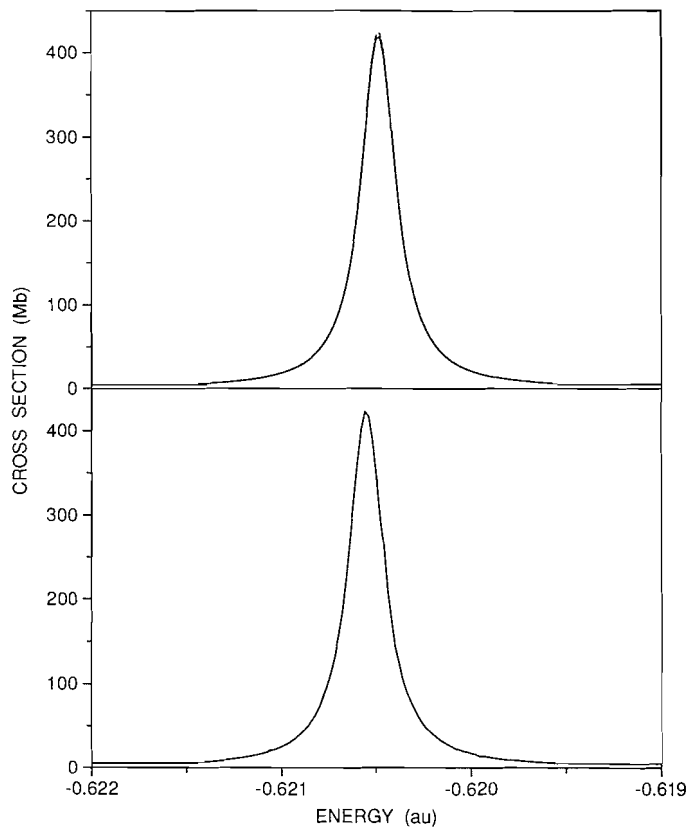

FIG. 8. $1s2p\ ^1P^o$ photoionization cross section across the $2s^2-2p^2\ ^1S^e$ resonance. Upper figure: GTO basis; lower figure: extended basis. Full line: LG results; broken line: VG results. $'S^e$ contribution.

87.36 to 0.01), 10 p (with $n = 2$ and Z from 8 to 0.01), 10 d (with $n = 3$ and Z from 8 to 0.02), and 9 f (with $n = 4$ and Z from 8 to 0.08). The p-wave basis set includes 44 GTO with $n = 2$; the first three of them have orbital exponents 8, 4, and 2; the other 41 of them have exponents in geometrical progression of ratio 0.77 and first term 1. This basis yields 12 narrow wavepackets with energies between -2 and 0 au.

3. Results

The calculated helium ground state energy was -2.903592 au in the STO basis and -2.900315 au in the GTO basis. For the $1s2p\ ^1P^o$ state, the calculated energies were respectively -2.123812 and -1.121688 au.

The $^1S^e$ and $^1P^o$ phase shifts calculated with the GTO and the extended bases are plotted in Figs. 1 and 2. Since in this case there is only one open channel, a variational representation of the continuum may also be obtained by diagonalizing the whole variational space (i.e., the localized correlating and the pwc subsets $1swl$). The phase shifts and the normalization constants may then be extracted by interpolating their long-range behavior with shifted Coulomb waves. With the extended basis, this calculation yields results practically coincident with the K-matrix ones. On the contrary, this procedure proved quite unreliable with the GTO basis, since these waves do not extend sufficiently outside the region where the correlation effects are important, i.e., where the localized states of the correlating subset have significant amplitudes. For the GTO basis, a few phase shifts computed in this way in various ranges of r are also shown in these figures.

The lowest resonances of the two mainfolds were analyzed by the methods described in ref. 9 and the S-matrix results are listed in Table 1 together with a few data reported in the literature (3, 16, 17). Many classification schemes are currently in use for these resonances. Here they are labelled in the Fano notation (18), which employs the dominant configurations. The correspondence between the various notations may be found in ref. 16. Our present extended-basis results update those reported in our previous work (14). The analysis of Table 1 shows that the GTO bases reproduce quite well the widths of the autoionizing states, while the positions are slightly too high.

The ground state photoionization cross section is reported in Fig. 3 and its details around the two lowest $^1P^o$ resonances are expanded in Figs. 4 and 5. The $^1S^e$ contribution to the cross section of the $1s2p\ ^1P^o$ level is plotted in Fig. 6 and its details around the two lowest resonances are expanded in Figs. 7 and 8. In all cases the calculations were performed in both the Length Gauge (LG) and in the Velocity Gauge (VG); the gauge agreement is very satisfactory with the extended basis and only slightly inferior with the GTO basis. The greatest differences are found for the second $^1P^o$ resonance, which projects mainly on the $2s3p$ and $2p3s$ configurations, since the GTO localized basis set does not reproduce the $3s$ and $3p$ orbitals very accurately.

The cross sections at these resonances were fitted to a Fano profile; the positions and the widths so obtained were practically coincident with the S-matrix results. The q values for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

shapes like those of the $^1S^e$ resonances have hardly a definite meaning; indeed our values differ greatly from those which may be computed from the data of Cordes and Altick (17), although our absorption maxima are in good agreement with theirs.

4. Conclusions

The present results strongly suggest that, if properly handled, the GTO basis sets may yield accurate values for several properties of the states lying in the continuum. This increases still more the importance of the GTO's, whose usefulness was recognized long ago by Huzinaga, who in several papers has shown how to use them effectively. In our opinion, several of the rather sophisticated codes available to compute the lower-lying electronic states of molecular systems should be amenable for adaptation to the method proposed here. This should extend their capabilities to the calculation of accurate differential photoionization cross sections.

To test this contention, work is in progress here to calculate the differential ionization cross section of some simple polyatomic molecules using GTO bases and different levels of approximation.

Infrared intensities of liquids. IX. The Kramers–Kronig transform, and its approximation by the finite Hilbert transform via fast Fourier transforms

JOHN E. BERTIE AND SHULIANG L. ZHANG
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 16, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

JOHN E. BERTIE and SHULIANG L. ZHANG. Can. J. Chem. **70**, 520 (1992).

It is well known that the infinite Kramers–Kronig transform is equivalent to the infinite Hilbert transform, which is equivalent to the allied Fourier integrals. The Hilbert transform can thus be implemented using fast Fourier transform routines. Such implementation is usually some 60 times faster than the Kramers–Kronig transform for a data file containing about 7 points. This paper reports that, for transformations between the real and imaginary refractive indices, $n(\tilde{\nu})$ and $k(\tilde{\nu})$ in $\hat{n} = n(\tilde{\nu}) + ik(\tilde{\nu})$, the FFT-based Hilbert transform can be much less accurate than, or as accurate as, the Kramers–Kronig transform, depending on the algorithm used. The Kramers–Kronig transform, incorporating Mclaurin's formula for finding the principal value of the integral, transforms $k(\tilde{\nu})$ spectra into $n(\tilde{\nu})$ spectra that are accurate to about 0.05%. Some Hilbert transform algorithms in the literature yield only about 4% accuracy. The BZ algorithm for the Hilbert transform is presented, for use on a laboratory computer running under DOS, that yields $n(\tilde{\nu})$ spectra accurate to 0.05%. For the transform from $n(\tilde{\nu})$ to $k(\tilde{\nu})$, the BZ algorithm gives $k(\tilde{\nu})$ accurate to about −0.2% of the largest k value in the spectrum. This compares with an accuracy of 0.5% for the Kramers–Kronig transform. In cases where the $k(\tilde{\nu})$ spectrum is truncated at low wavenumbers, a simple method is presented that improves by a factor of ~10 the accuracy at low wavenumber of the $n(\tilde{\nu})$ spectrum obtained by Hilbert or Kramers–Kronig transforms of the k($\tilde{\nu}$) spectrum.

Key words: infrared intensities, complex refractive indices, Kramers–Kronig transform, Hilbert transform, optical constants.

JOHN E. BERTIE et SHULIANG L. ZHANG. Can. J. Chem. **70**, (1992).

Il est bien connu que la transformation infinie de Kramers–Kronig est l'équivalent d'une transformation infinie de Hilbert qui est elle-même l'équivalent des intégrales allied Fourier. On peut donc réaliser une transformation de Hilbert en utilisant des routines rapides de transformation de Fourier. Pour une base de données contenant 7000 points, une telle réalisation est généralement 60 fois plus rapide qu'une transformation de Kramers–Kronig. Dans ce travail, on montre que, pour des transformations entre des indices de réfraction réels et imaginaires, $n(\tilde{\nu})$ et $k(\tilde{\nu})$ dans $\hat{n} = n(\tilde{\nu}) + ik(\tilde{\nu})$, la transformation de Hilbert basée sur FFT est beaucoup moins ou aussi précise que la transformation de Kramers–Kronig suivant l'algorithme utilisé. La transformation de Kramers–Kronig, incorporant les formules de McLaurin pour trouver la valeur principale de l'intégrale, transforme des spectres $k(\tilde{\nu})$ en spectres $n(\tilde{\nu})$ qui sont précis à environ 0,05%. Quelques algorithmes rapportés dans la littérature pour la transformation de Hilbert ne conduisent qu'à une précision de 4%. On présente l'algorithme BZ qui peut être utilisé sur un ordinateur de laboratoire, opérant sous DOS, qui permet d'effectuer la transformation de Hilbert et qui donne des spectres $n(\tilde{\nu})$ précis à 0,05%. Pour la transformation $n(\tilde{\nu})$ en $k(\tilde{\nu})$, l'algorithme BZ conduit à une précision d'environ −0,2% pour la valeur la plus importante du spectre. Cette valeur se compare à une précision de 0,5% pour la transformation de Kramers–Kronig. Pour les cas où le spectre $k(\tilde{\nu})$ est tronqué aux faibles valeurs des nombres d'onde, on présente une méthode simple qui améliore la précision par un facteur d'environ 10 aux faibles valeurs des nombres d'onde de spectres $n(\tilde{\nu})$ obtenus par des transformations de Hilbert ou Kramers–Kronig de spectres $k(\tilde{\nu})$.

For personal use only.

Introduction

Equations [1*a*] and [1*b*] give the Kramers–Kronig transform (1, 2) between the optical constants (3–5), which are the real and imaginary components of the complex refractive index, $\hat{n}(\tilde{\nu}) = n(\tilde{\nu}) + ik(\tilde{\nu})$.

$$[1a] \quad n(\tilde{\nu}_i) - n(\infty) = \frac{2}{\pi} P \int_0^\infty \frac{\tilde{\nu}\, k(\tilde{\nu})}{\tilde{\nu}^2 - \tilde{\nu}_i^2} \, d\tilde{\nu}$$

$$[1b] \quad k(\tilde{\nu}_i) = -\frac{2\tilde{\nu}_i}{\pi} P \int_0^\infty \frac{n(\tilde{\nu}) - n(\infty)}{\tilde{\nu}^2 - \tilde{\nu}_i^2} \, d\tilde{\nu}$$

The real and imaginary components of the complex dielectric constant (6), $\hat{\epsilon}(\tilde{\nu}) = \epsilon'(\tilde{\nu}) + i\epsilon''(\tilde{\nu})$, are usually called the dielectric constant and the dielectric loss, respectively. The Kramers–Kronig transform between them (6) is obtained by replacing n and k by ϵ' and ϵ'' in eqs. [1]. Similarly, the Kramers–Kronig transform between the reflectance, $R(\tilde{\nu})$, and the phase, $\phi(\tilde{\nu})$, of reflection (4, 7, 8) can be written by substitution. The complex reflection is $\hat{r}(\tilde{\nu}) = r(\tilde{\nu}) \times e^{i\phi(\tilde{\nu})}$, and the reflectance, $R(\tilde{\nu})$, is $\hat{r}(\tilde{\nu}) \times \hat{r}^*(\tilde{\nu}) = |\hat{r}(\tilde{\nu})|^2$. Since $\ln \hat{r}(\tilde{\nu}) = \ln r(\tilde{\nu}) + i\phi(\tilde{\nu})$ and $\ln r(\tilde{\nu}) = 1/2 \ln R(\tilde{\nu})$, the Kramers–Kronig transform is obtained by substituting $(1/2 \ln R)$ for n and ϕ for k in eqs. [1].

The Kramers–Kronig transform has been used by several authors in recent years to aid the determination of the optical constants or dielectric constants from infrared transmission (9, 10), reflection (7, 11), or multiple attenuated total reflection (12, 13) spectra.

It is well known (6, 14–18) that the infinite Kramers–Kronig transform is equivalent to two successive Fourier

transforms, usually called the allied Fourier integrals. Stated more fully, the Kramers–Kronig transform is equivalent to the infinite Hilbert transform, provided that the real variable is an even function of wavenumber and the imaginary variable is an odd function of wavenumber, i.e., $n(\tilde{\nu}) = +n(-\tilde{\nu})$ and $k(\tilde{\nu}) = -k(-\tilde{\nu})$. Further, the Hilbert transform is equivalent to the allied Fourier integrals (6, 14–18). The Hilbert transform between the optical constants is shown in eqs. [2*a*] and [2*b*], and in eqs. [3*a*] and [3*b*] in its Fourier transform representation.

$$[2a] \quad n(\tilde{\nu}_i) - n(\infty) = \frac{1}{\pi} P \int_{-\infty}^{\infty} \frac{k(\tilde{\nu})}{\tilde{\nu} - \tilde{\nu}_i} \, d\tilde{\nu}$$

$$[2b] \quad k(\tilde{\nu}_i) = -\frac{1}{\pi} P \int_{-\infty}^{\infty} \frac{n(\tilde{\nu}) - n(\infty)}{\tilde{\nu} - \tilde{\nu}_i} \, d\tilde{\nu}$$

$$[3a] \quad n(\tilde{\nu}) - n(\infty) = -2 \int_0^{\infty} dt \cos(2\pi c\tilde{\nu}t) \int_{-\infty}^{\infty} k(\tilde{\nu}) \sin(2\pi c\tilde{\nu}t) \, d\tilde{\nu}$$

$$[3b] \quad k(\tilde{\nu}) = -2 \int_0^{\infty} dt \sin(2\pi c\tilde{\nu}t) \int_{-\infty}^{\infty} [n(\tilde{\nu}_i) - n(\infty)] \cos(2\pi c\tilde{\nu}t) \, d\tilde{\nu}$$

For the remainder of this paper we will use the term Hilbert transform to mean the use of eqs. [3] to perform a Hilbert transform via fast Fourier transform routines. We have not used eqs. [2] at all.

The Kramers–Kronig transform is slow on most laboratory computers. For example, a fairly efficient program written in Microsoft Fortran version 5.0 and running under Microsoft DOS on a 16 MHz laboratory computer with an Intel 28386 cpu chip requires 13 min for the Kramers–Kronig transform of a spectrum containing 8192 data points. In contrast, fast Fourier transform (FFT) routines are available, which transform a data file of this length in seconds. The routines used by most FT-IR spectrometer systems to transform the interferogram into the spectrum are fast and can sometimes be used in application programs written by the user. Thus authors have described the use of FFT routines supplied by the instrument manufacturers to accomplish the Hilbert transform (19, 20). Other authors have described the use of FFT routines to Hilbert transform largely specular reflection data (16–18).

We have recently developed computer programs that run under Microsoft DOS to permit more efficient computation of our spectral data than on the Aspect 2000 computer of our (1982) Bruker IFS 113V FT-IR spectrometer. To check our programs, we have used the classical damped harmonic oscillator model (21–23) to synthesize real and imaginary refractive index spectra. This model calculates, for dielectric loss bands that are essentially Lorentzian in shape, the correct real refractive index spectrum to accompany the calculated imaginary refractive index spectrum.

This work began when we compared these correct real refractive index spectra with those obtained by Hilbert transformation of the imaginary refractive index spectra using our original algorithm (20). Unless all of the bands are very sharp, which is frequently not the case for liquids, the Hilbert $n(\tilde{\nu})$, i.e., the $n(\tilde{\nu})$ spectrum obtained by Hilbert transform, deviates by several percent from the correct result.

We have also obtained the $n(\tilde{\nu})$ spectra by Kramers–Kronig (KK) transformation of the imaginary refractive index spectra. The KK $n(\tilde{\nu})$ spectra differ significantly from the Hilbert $n(\tilde{\nu})$ spectra, but are, however, in excellent agreement with the correct ones. Exceptions occur if the imaginary refractive index is not near zero at the low-wavenumber limit of the spectrum.

At about the time that we discovered the discrepancies between the Hilbert and KK transforms empirically, Bracewell (24) reported that discrepancies are to be expected, but he gave no details of their magnitude. Thus, the appealing very fast method of Hilbert transform gave results that are in considerable error, while the slow Kramers–Kronig transform gave correct answers. It was clearly worthwhile to explore whether the accuracy of the fast Hilbert transform method could be improved. Most previous authors considered the accuracy of the transform qualitatively. Only Ohta and Ishida (25) have addressed the accuracy of the Hilbert transform at this level.

In this paper we present the results of our exploration of the magnitude of the discrepancies between the correct $n(\tilde{\nu})$ spectra, the KK $n(\tilde{\nu})$ spectra, and the Hilbert $n(\tilde{\nu})$ spectra. We explore different literature algorithms for the Hilbert transform to determine the important parameters for accuracy. We present an algorithm that yields 0.05% agreement with the correct $n(\tilde{\nu})$ spectrum. In 1988 Ohta and Ishida (25) reported in less detail a similar study, which we have found very helpful. The algorithm we recommend from this work is similar to theirs, but uses symmetry to reduce the size of the transforms by a factor of two, and real variables rather than complex ones to speed computation.

The Hilbert transform also converts $n(\tilde{\nu})$ spectra to $k(\tilde{\nu})$ spectra, although we use this less frequently. For this Hilbert transform, we give an algorithm that yields very good agreement with the correct $k(\tilde{\nu})$ spectrum.

We also discuss procedures to follow when the experimental data are available over most of the fingerprint region, but do not extend to the very low wavenumbers where the imaginary refractive index often returns to near zero. This situation is common due to experimental limitations and difficulties. When the $k(\tilde{\nu})$ spectrum terminates at low wavenumber on a peak, rather than at $k(\tilde{\nu})$ values near zero, the real refractive index spectrum calculated by either the Kramers–Kronig transform or the Hilbert transform is seriously in error over the last several hundred wavenumbers. A method is presented that allows very good results to be obtained in those cases in which the entire $k(\tilde{\nu})$ spectrum is known. In such cases the $n(\tilde{\nu})$ spectrum can be calculated from the full $k(\tilde{\nu})$ as well as from the truncated version of it, so the accuracy of our method of treating the truncated spectrum can be evaluated. We believe this method also gives the best result available when the full $k(\tilde{\nu})$ spectrum is not known. But we cannot be sure of its accuracy in such cases until the influence of the missing part of the $k(\tilde{\nu})$ spectrum is known.

General methods

The Classical Damped Harmonic Oscillator model (21–23) gives eqs. [4*a*] and [4*b*] for the real and imaginary parts of the dielectric constant in terms of the wavenumbers, $\tilde{\nu}_j$, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

intensities, S_j, and the damping constants γ_j, of the oscillators.

$$[4a] \quad \epsilon'(\tilde{\nu}) = \epsilon'(\infty) + \sum_j \frac{S_j(\tilde{\nu}_j^2 - \tilde{\nu}^2)}{(\tilde{\nu}_j^2 - \tilde{\nu}^2)^2 + \gamma_j^2\tilde{\nu}^2}$$

$$[4b] \quad \epsilon''(\tilde{\nu}) = \sum_j \frac{S_j\gamma_j\tilde{\nu}}{(\tilde{\nu}_j^2 - \tilde{\nu}^2)^2 + \gamma_j^2\tilde{\nu}^2}$$

The optical constants $n(\tilde{\nu})$ and $k(\tilde{\nu})$ are calculated from these dielectric constants by eqs. [5]

$$[5a] \quad n(\tilde{\nu}) = \sqrt{(\sqrt{(\epsilon'(\tilde{\nu}))^2 + (\epsilon''(\tilde{\nu}))^2} + \epsilon'(\tilde{\nu}))/2}$$

$$[5b] \quad k(\tilde{\nu}) = \sqrt{(\sqrt{(\epsilon'(\tilde{\nu}))^2 + (\epsilon''(\tilde{\nu}))^2} - \epsilon'(\tilde{\nu}))/2}$$

In these equations, the intensity parameter S_j is related to the molecular dipole moment derivative, $\partial\mu/\partial Q_j$, in the approximation of mechanical and electrical harmonicity by $S_j = \{N/3\pi c^2\}(\partial\mu/\partial Q_j)^2 F_j^2$. Here N is the number of molecules in unit volume, c is the velocity of light in vacuum, and F_j^2 is the local field correction for a molecule in a liquid. In general theory, S_j is related to the sum of the squares of the molecular transition moments that contribute to the band, $|R_{v_j''v_j'}|^2$ by

$$S_j = \frac{8\pi^3}{3\,h\,c} \sum [\tilde{\nu}_j |R_{v_j''v_j'}|^2 (N_{v_j''} - N_{v_j'})]$$

where one must sum over all v_j'' states that are significantly populated.

Equations [4] and [5] were used to calculate corresponding pairs of $k(\tilde{\nu})$ and $n(\tilde{\nu})$ spectra through the Fortran program FHARM. The program reads ASCII input and produces spectral files in the **.SPC** format of Galactic Industries Spectracalc program.

In the first half of this work, the $k(\tilde{\nu})$ spectrum so calculated was entered into the Hilbert transform program under consideration, with the appropriate value for $n(\infty)$, and the $n_H(\tilde{\nu})$ spectrum was calculated. The $k(\tilde{\nu})$ spectrum was also entered into the Kramers–Kronig transform program, and the $n_K(\tilde{\nu})$ spectrum was calculated.

We are interested in obtaining values of $n(\tilde{\nu})$ to suitable accuracy, approximately 0.1% being all that our experimental absorption data can justify. Accordingly, we have chosen to show in most of our figures the percentage deviation of the Hilbert $n(\tilde{\nu})$ spectrum from the correct $n(\tilde{\nu})$ spectrum at each wavenumber, $100\{n_H(\tilde{\nu}) - n(\tilde{\nu})\}/n(\tilde{\nu})$. For the $n(\tilde{\nu})$ spectrum calculated via the Kramers–Kronig transform, we show $100\{n_K(\tilde{\nu}) - n(\tilde{\nu})\}/n(\tilde{\nu})$ to illustrate the accuracy.

For the purpose of demonstrating the actual error in the Hilbert transform routines it would be better to subtract the value of $n(\infty)$, and to compare $\Delta n_H(\tilde{\nu}) = n_H(\tilde{\nu}) - n(\infty)$ or $\Delta n_K(\tilde{\nu}) = n_K(\tilde{\nu}) - n(\infty)$ with $\Delta n = n(\tilde{\nu}) - n(\infty)$, because the transforms calculate these differences, which are converted to the $n_H(\tilde{\nu})$ and $n_K(\tilde{\nu})$ spectra simply by adding $n(\infty)$. We give this comparison for our initial and final Hilbert transform algorithms.

In the second half of this work, the $n(\tilde{\nu})$ spectra are entered into the Kramers–Kronig or Hilbert transform after subtracting $n(\infty)$ from each value, and the $k_K(\tilde{\nu})$ or $k_H(\tilde{\nu})$ spectra are calculated. In these cases the deviation of the calculated k from the correct one is calculated as a percentage of the largest k value in the spectrum to illustrate the accuracy of the transform.

TABLE 1. Parameters used for spectra[a] calculated from the classical damped harmonic oscillator model

j	$\tilde{\nu}_j$ (cm^{-1})	γ_j (cm^{-1})	S_j (cm^{-2})

[a]The spectra were calculated between 7800 and 50 cm^{-1}, data points are 0.964 cm^{-1} apart, and $n(\infty) = 1.325$.

[b]$\gamma_j = 50$ cm^{-1} was also used with $S_j = 180\,000$ and $\tilde{\nu}_j = 1600$ cm^{-1}.

The correct spectra

Three different types of spectra have been calculated via the classical damped harmonic oscillator model for this work. The first consists of a single band at 1600 cm^{-1} with a full width at half height (FWHH) ranging from 4 cm^{-1} up to 50 cm^{-1}. The second is a complex spectrum based on that of pure liquid methanol, and the third is a complex spectrum based on liquid acetic acid. The classical damped harmonic oscillator parameters used for these spectra are tabulated in Table 1. The $k(\tilde{\nu})$ and $n(\tilde{\nu})$ spectra are shown in Figs. 1–3. It should be noted that each $k(\tilde{\nu})$ spectrum is complete, i.e., contains completed bands. Thus, the k values at the highest and lowest wavenum-

ber points were about 10^{-5} of the peak value for the single band spectra and about one thousandth of the maximum peak height for the methanol and acetic acid simulations.

The Kramers–Kronig transform

A Fortran program, KKTRANS, for this transform was based on that included in program 46 of the National Research Council of Canada's Bulletins of Computer Programs for Infrared Spectroscopy (26). Several changes were made to improve the speed of the program on the laboratory computer by a factor of about eight, and a further factor of two was obtained by incorporating Ohta and Ishida's (25) Maclaurin formula method of calculating the principal value of the integral. This latter feature also considerably improved the accuracy of the transform near the intense peaks. Program KKTRANS takes 13 min to transform a file containing 8192 REAL (4 byte) data points on our 16 MHz 386SX computer with a 387 math coprocessor. It reads and writes files in the **.SPC** format of Spectracalc.

Hilbert transforms

The Hilbert transform via two successive fast Fourier transforms (FFTs), following eqs. [3], consists of the following five steps.

Step 1. Arranging the input spectral data into the appropriate form

Step 2. The first FFT

Step 3. Arranging the output of the first FFT into the appropriate form

Step 4. The second FFT

Step 5. Obtaining the desired spectrum from the output of the second FFT.

The details of the first, third, and fifth step depend on the algorithm used for the Hilbert transform, and depend on whether the transform is from $k(\tilde{\nu})$ to $n(\tilde{\nu})$ or vice versa. These features will be discussed in the Results sections.

The FFT is common to all algorithms, but may be used to transform real data or complex data. The output is complex in both cases, but is written into two arrays of real variables. To improve execution speed, complex variables are not used.

We tested four FFT subroutines by ensuring that they give the transform of a Gaussian peak of unit height correct (15, 27) to six decimal places. All subroutines gave correct transforms, and we chose to use the fastest subroutine, the Fortran subroutine described by Ng and Horlick (28). This subroutine is based on the algorithm first suggested by Gentleman and Sande (in ref. 29), and its listing is in the Ph.D. thesis of Ng (30). It is also given in the appendix to this paper, because there is a version of it in circulation that contains incorrect signs.

The subroutine is written with real variables to find the

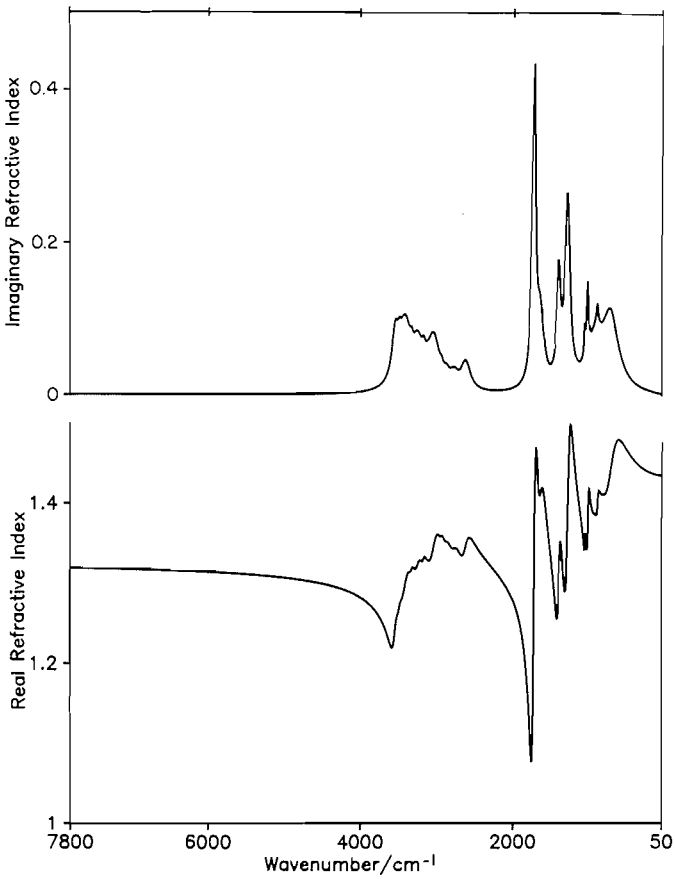

FIG. 3. Refractive index spectra calculated with the classical damped harmonic oscillator model. Simulated spectra of liquid acetic acid (Table 1).

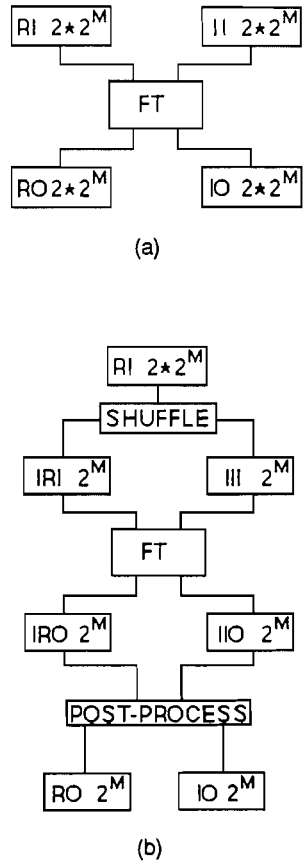

FIG. 4. Schematic representation of the fast Fourier transform subroutine used in this work. (a) The COMPLEX data mode; (b) The REAL data mode.

complex Fourier transform of a real function. It consists of three phases. (*a*) The "shuffle" of the real input array into half-sized real and imaginary input arrays to a complex FFT. (*b*) The complex FFT of real and imaginary input arrays to real and imaginary output arrays. (*c*) The "post-processing" phase to reconstruct the complex FFT of the original real input array. The shuffle consists of placing the odd- and even-indexed points of the real input array into the real and imaginary, respectively, arrays input to the complex FFT. The post-processing phase is that described by Zachor in an advertisement (31).

As noted above, this subroutine can be used in its REAL mode to obtain the complex transform of real data, or in its COMPLEX mode to obtain the transform of complex data. The REAL mode uses all three phases of the subroutine, while the COMPLEX mode uses only the middle phase. We have found the diagrams shown in Fig. 4 to be helpful illustrations of these two modes. In Fig. 4, RI, IO, etc. stand for Real Input, Imaginary Output, etc., and IRI, IIO, etc. stand for Intermediate Real Input, Intermediate Imaginary Output, etc. Figure 4 also notes that a Real Input array of size 2×2^M in REAL mode yields all other arrays of size 2^M. In COMPLEX mode all arrays have the same size.

The details of the use of this subroutine in the different Hilbert transform algorithms is given in the Results sections. All of our programs that use this subroutine read and write spectral files in the **.SPC** format of Spectracalc.

Results: transforms from $k(\tilde{\nu})$ to $n(\tilde{\nu})$ for complete $k(\tilde{\nu})$ spectra

We present first the results for those cases in which the $k(\tilde{\nu})$ spectrum is complete. Results for cases in which the $k(\tilde{\nu})$ spectrum contains incompleted bands at the lowest wavenumbers will be discussed later. It should be noted that all of our spectral files start at high wavenumber and run to low wavenumber.

Kramers–Kronig transforms

Figure 5 shows the percent deviation of the $n_K(\tilde{\nu})$ values calculated via KKTRANS from the $k(\tilde{\nu})$ spectra of Figs. 1–3. The greatest deviation of the n_K values from the correct ones is 0.07% for the single band of 4 cm^{-1} FWHH, 0.004% for the single band of 50 cm^{-1} FWHH, and 0.05% for the complex spectra. Thus, to the accuracy of our experimental data, program KKTRANS gives the correct $n(\tilde{\nu})$ spectrum, provided the $k(\tilde{\nu})$ spectrum is complete.

Hilbert transforms

Our original Hilbert transform algorithm

This has been described only in general terms (20). It uses the FFT subroutine in REAL mode (Fig. 4).

Consider a $k(\tilde{\nu})$ spectrum that contains NP data points. Step 1 of the Hilbert transform consists of three actions. First, adding zeros to the (low-wavenumber) end of the spectral data to make the number of points a power of 2, 2^M, as required by the FFT subroutine. Second, adding a zero point. Third, folding the file about that zero point to create a symmetrical

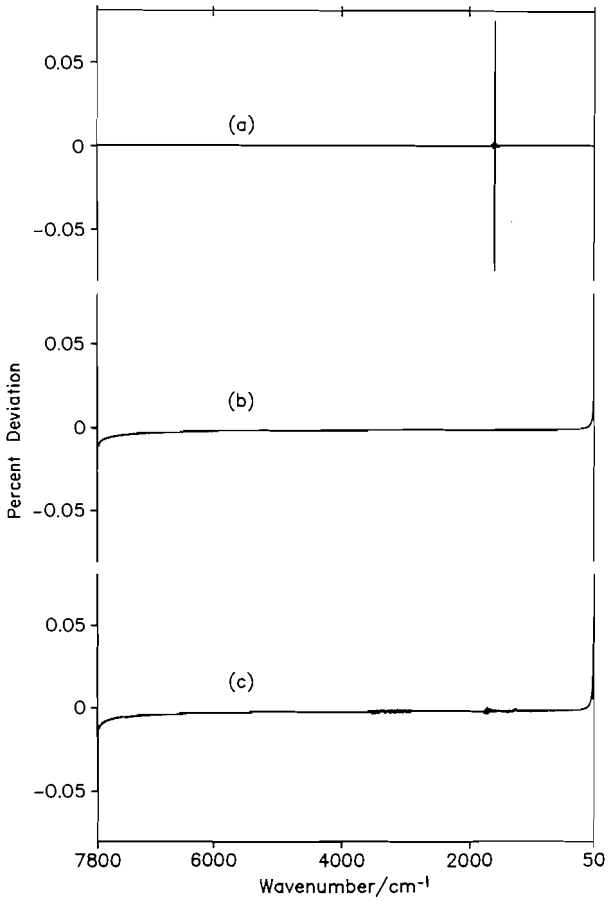

FIG. 5. Percent deviations from the correct spectra of $n(\tilde{\nu})$ spectra calculated by Kramers–Kronig transformation of $k(\tilde{\nu})$. Curve (a), Single band $k(\tilde{\nu})$, FWHH = 4 cm^{-1}; curve (b), simulated methanol spectrum; curve (c), simulated acetic acid spectrum.

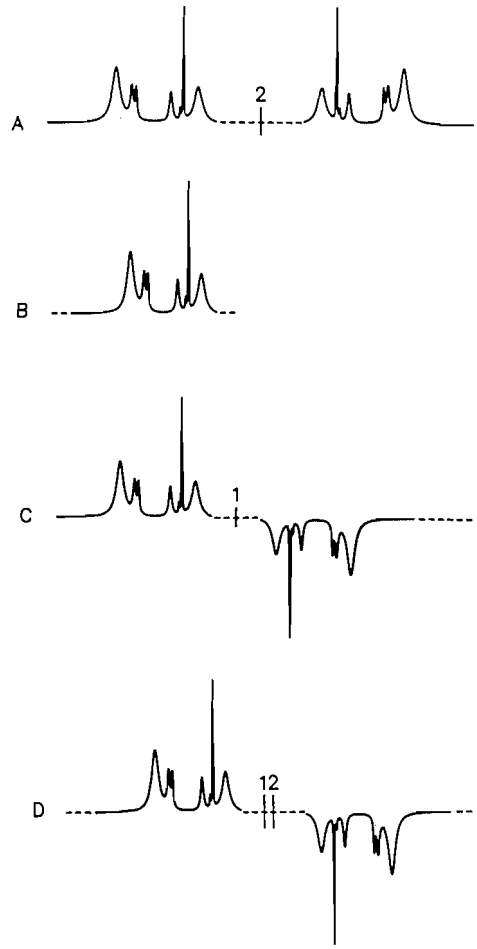

FIG. 6. Schematic representation of the input arrays to step 2 of the Hilbert transform algorithms. Curve A, Our original algorithm; curve B, Marshall's algorithm; curve C, Ohta and Ishida's algorithm; curve D, the BZ algorithm, our preferred algorithm. 1 indicates a zero value at 0 cm^{-1}; 2 indicates an additional zero value added as a folding or inverting centre.

array centered on the added zero. In fact the array is not quite symmetrical, because the first data point in the file must be omitted from its folded position at the end of the file to keep the number of points equal to a power of 2 (2×2^M). Figure 6, curve A, shows the resulting real input array schematically. This array is then input to step 2, the FFT in REAL mode.

The FFT of this real array consists of a zero imaginary transform array and a nonzero real transform array, both of size 2^M. Step 3 of this algorithm consists of 2 actions, replacing the second half of the real transform array by zeros and adding an additional 2^M zeros to restore the file to the full length of the real input to step 2. The resulting file is put into step 4, the FFT in REAL mode.

Step 5 of this algorithm is to obtain the NP values of $-\Delta n_H(\tilde{\nu}) = n(\infty) - n(\tilde{\nu})$ from the first NP points in the imaginary transform array, with wavenumber decreasing with increasing point index, and to subtract them from $n(\infty)$ to obtain the desired $n(\tilde{\nu})$ in the same wavenumber sequence as in the original $k(\tilde{\nu})$ array with NP points.

This algorithm programmed in Fortran takes 14 s to Hilbert transform an 8192-point $k(\tilde{\nu})$ spectrum.

This Hilbert transform program was checked in 1983 before it was used. However, the check was made using the single-band $k(\tilde{\nu})$ spectrum shown in Fig. 1, with a 4 cm^{-1} FWHH, by comparing the correct and Hilbert $n(\tilde{\nu})$ spectra (curves (a) and (b) of Fig. 7, lower box). The agreement appears very good. If the percent deviation is compared (curve (B) of Fig. 7, upper box) the agreement appears less good. As the FWHH of the single band is increased, problems become evident, as curve (C) of Fig. 7 upper shows for a single band of FWHH 50 cm^{-1}. If a more complex spectrum is used, the magnitude of the problem that initiated this work is seen. Curves (a) and (b) of Fig. 8 lower show the correct $n(\tilde{\nu})$ spectrum for the simulated methanol $k(\tilde{\nu})$ spectrum of Fig. 2 and that calculated from this Hilbert transform program. Curve (B) of Fig. 8 upper shows the percent deviation. Recall that the KK transform gave exact results for this spectrum (Curve (C) of Fig. 8). Clearly this Hilbert transform program yields an error in $n(\tilde{\nu})$ that increases in magnitude with decreasing wavenumber, from +0.3% to −4%. The error in the quantity actually calculated by the Hilbert transform, $\Delta n_H(\tilde{\nu}) = n(\tilde{\nu}) - n(\infty)$, reaches 80% at the lowest wavenumber.

Marshall's Hilbert transform algorithm

We turned next to an algorithm presented by Marshall and co-workers (32, 33). This was presented for the transformation of electron spin resonance absorption spectra to dis-

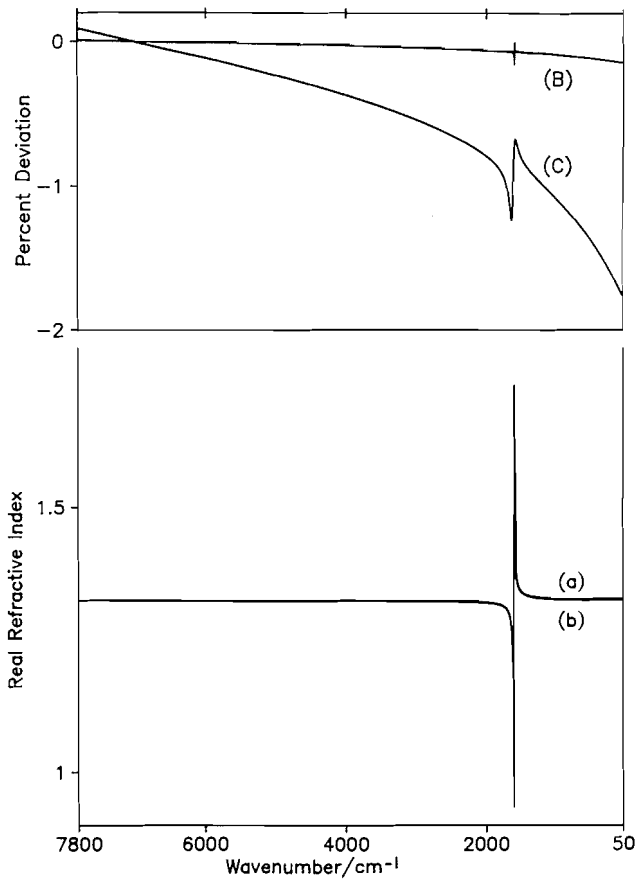

FIG. 7. Results for our original Hilbert transform algorithm. Lower box: curve (a), correct $n(\tilde{\nu})$ spectrum, single band, FWHH = 4 cm^{-1} (Fig. 1, Table 1); curve (b), $n_H(\tilde{\nu})$ calculated by Hilbert transformation of the corresponding $k(\tilde{\nu})$ spectrum. Curves (a) and (b) are indistinguishable on this scale. Upper box: percent deviation of the Hilbert transformed $n_H(\tilde{\nu})$ from the correct $n(\tilde{\nu})$ for: curve (B), single band spectrum, FWHH = 4 cm^{-1}; curve (C), single band spectrum, FWHH = 50 cm^{-1}.

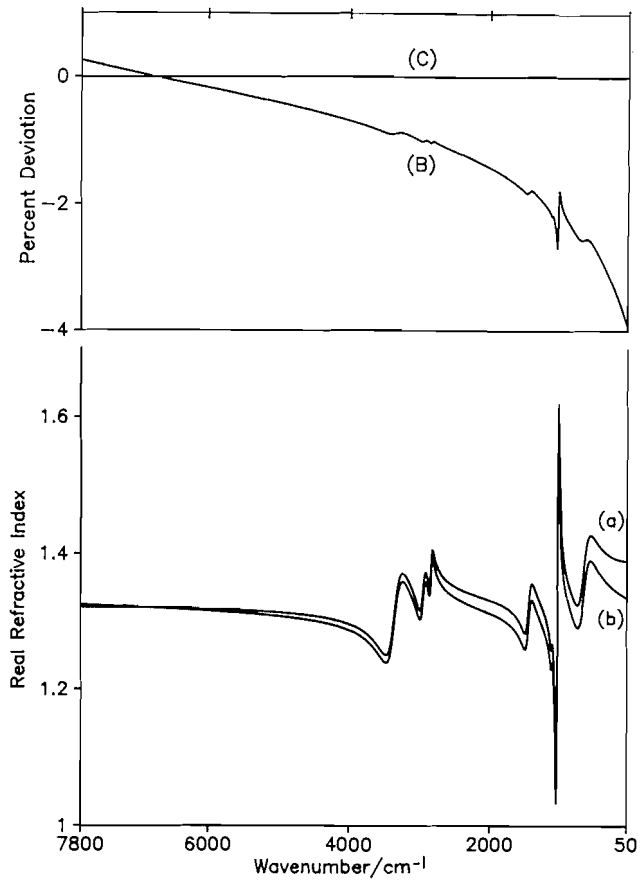

FIG. 8. Results for the simulated methanol spectrum (Fig. 2). Lower box: (a) correct $n(\tilde{\nu})$ and (b) our original Hilbert transformed $n_H(\tilde{\nu})$ spectra. persion spectra, but the theoretical considerations are identical (33) to those for optical absorption and dispersion.

This algorithm uses the FFT in its COMPLEX mode. Step 1 is to add zeros to increase the number of data points to 2^M from the NP $k(\tilde{\nu})$ values. These zeros are added symmetrically, i.e., half at the beginning of the array and half at the end. The resulting array is shown schematically in Fig. 6 curve B. This array is input as the real array to step 2, the FFT in COMPLEX mode, and an array of zeros is input as the imaginary array. The FFT of this complex input is complex, with nonzero real and imaginary transform arrays. Step 3 of this algorithm is to negate the second half of the real and imaginary transform arrays. These arrays are then input to the complex FFT in step 4. The $\Delta n(\tilde{\nu})$ values are found in the imaginary transform array output from step 4. The $\Delta n(\tilde{\nu})$ value for the highest wavenumber is at point index $\{2^{M+Z} - 0.5\,(2^{M+Z} - 2^M) + 1\}$, where Z is the level of zero-filling used (see below), and they run to lower point indices with decreasing wavenumber.

This algorithm takes about the same time as the previous one. The result for the simulated methanol spectrum (Fig. 2) is shown as curve (a) in Fig. 9. The percent deviations cover a 4% range, as for the previous algorithm, but range

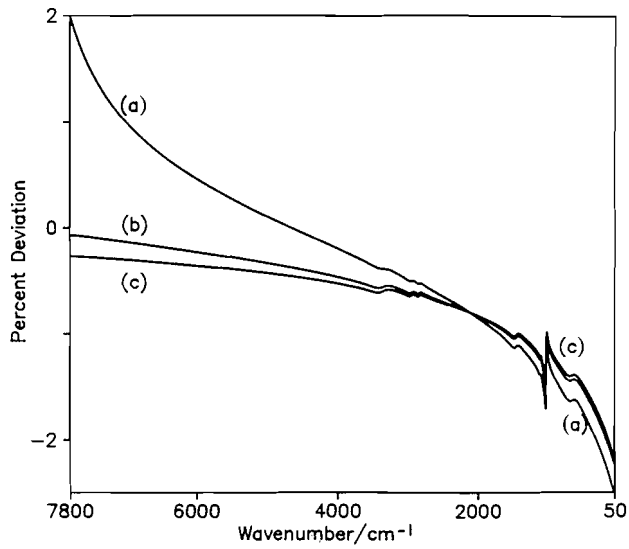

FIG. 9. Results for Marshall's Hilbert transform algorithm applied to the simulated methanol spectrum (Fig. 2). Percent deviations from the correct $n(\tilde{\nu})$ spectrum of the Hilbert $n_H(\tilde{\nu})$ spectrum transformed with no zero-filling (curve (a)), one level of zero-filling (curve (b)), and two levels of zero-filling (curve (c)).

from +2% to −2%. The agreement can be improved to some extent by additional zero-filling. To use one level of zero-filling you add, in step 1 of the algorithm, 2^M zero points to the 2^M points described above. These points are added symmetrically, half at the beginning and half at the end of the array, leaving the rest of the algorithm as described. The result for one level of zero-filling is shown as curve (b) of Fig. 9. One level of zero-filling considerably improves the accuracy at the high-wavenumber end of the spectrum, reducing the percent deviation to about −0.1%, but does little to improve the low-wavenumber end of the $n(\tilde{\nu})$ spectrum. A second level of zero-filling[1] (curve (c) of Fig. 9) makes little improvement. The errors involved in both of these algorithms are too large to allow them to be used with current experimental data.

Ohta and Ishida's Hilbert transform algorithm

At this stage of our study we became aware of the recent paper by Ohta and Ishida (25) who carried out a similar study. We programmed the algorithm they concluded was the most accurate. They emphasized the importance of continuing the data set to 0 cm^{-1}, and of folding the data to simulate $k(-\tilde{\nu}) = -k(\tilde{\nu})$. The latter is in keeping with the condition under which the Hilbert transform is equivalent to the Kramers–Kronig transform, while the former ensures that the correct phase relationship is maintained between the data for $\tilde{\nu}$ and that for $-\tilde{\nu}$.

Ohta and Ishida's algorithm uses the FFT in its COMPLEX mode. In step 1 of the algorithm, the $k(\tilde{\nu})$ spectrum, which consists of NP data points extending from XSP to XEP cm^{-1}, is extended to 0 cm^{-1} by adding N_1 zeros, and is then inverted in the zero wavenumber point to yield an array of 2(NP + N_1) −1 points, which is antisymmetric about the 0 cm^{-1} point. $2N_2 + 1$ zero points are then added to the end of the array to make the array contain 2×2^M points. The resulting array is shown schematically as curve C in Fig. 6. This array forms the real input array to the FFT of step 2, with an array of zeros as the imaginary input array.

The FFT of this complex input consists of nonzero real and imaginary transform arrays, each containing 2×2^M points. In step 3 of this algorithm, the second half of each transform array is replaced with zeros. The resulting real and imaginary arrays form the real and imaginary, respectively, inputs to step 4. In step 5, the values of $\Delta n_H(\tilde{\nu}) = n_H(\tilde{\nu}) - n(\infty)$ are obtained from the imaginary array. However, we found that they are not in the first 2^M points of the imaginary output as stated in Ohta and Ishida's paper, but they start at point $2N_2 + 3$ for the highest wavenumber and proceed to increasing index for decreasing wavenumber.

This algorithm uses arrays that are twice as long as those of previous algorithms, so it takes twice as long to execute. The result for the simulated methanol spectrum is shown in Fig. 10, curve (a). The percent deviations are now −0.4% at the high-wavenumber end and reduce to −0.2% at the low-wavenumber end of the spectrum. If one level of zero-filling is used, by simply adding a further 2×2^M zero points to the end of the array in step 1, the agreement is improved to about 0.07% (curve (b) of Fig. 10), but the program then takes twice as long to execute, about 70 s for a spectrum containing between 4096 and 8192 data points. The same result was found for the simulated acetic acid spectrum (Fig. 3).

[1]The second level of zero-filling consists of adding 2^M zero points to each end of the data set used for one level of zero-filling.

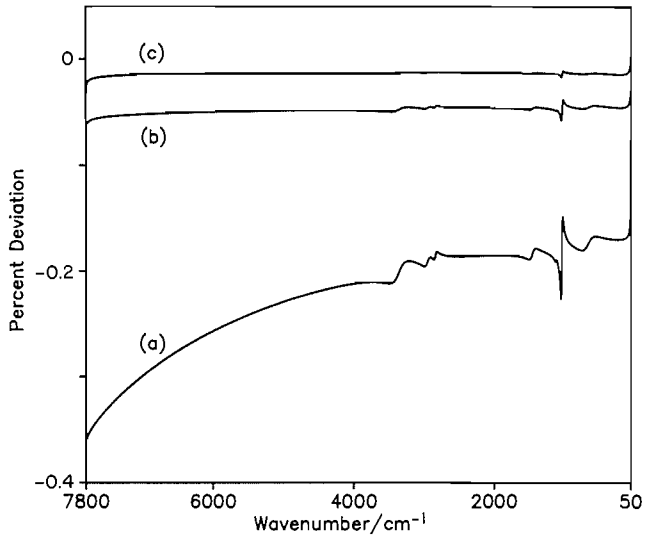

FIG. 10. Results for the simulated methanol spectrum (Fig. 2). Curves (a) and (b): percent deviations from the correct $n(\tilde{\nu})$ of Ohta and Ishida's Hilbert transformed $n_H(\tilde{\nu})$, calculated with no zero-filling (curve (a)) and one level of zero-filling (curve (b)). Identical results were obtained from the BZ algorithm, our preferred algorithm. Curve (c), percent deviation from the correct $n(\tilde{\nu})$ of $n_H(\tilde{\nu})$ calculated by the BZ algorithm with two levels of zero-filling.

The BZ algorithm: our preferred algorithm

We have built on the indication from Ohta and Ishida's work that it is important to extend the data to 0 cm^{-1}, thus maintaining the correct phase difference between $k(-\tilde{\nu})$ and $k(\tilde{\nu})$, and to ensure that $k(-\tilde{\nu}) = -k(\tilde{\nu})$. In fact eqs. [2] and [3] suggest that the equivalence of the Hilbert and Kramers–Kronig transforms hinges on these two points, in spite of their omission from some current algorithms.

Accordingly, step 1 of this algorithm consists of extending the $k(\tilde{\nu})$ spectrum, which contains NP points between XSP and XEP cm^{-1}, to 0 cm^{-1} by adding zeros, adding an extra zero, inverting the array in this added zero point to generate an antisymmetric array, then adding N_2 zero points to the beginning of the file and $N_2 - 1$ zero points to the end of the file, to generate an antisymmetric array of length 2×2^M. This array is shown schematically in Fig. 6 as curve D.

This algorithm uses the FFT in its REAL mode, and the array is input as the real input to the FFT in step 2. The transform consists of a zero real transform array and a nonzero imaginary transform array, each of length 2^M. In step 3 of the algorithm, the second half of the imaginary transform array is zeroed, and a further 2^M zeros are added to the end of the array. The resulting array is the real input to the FFT in step 4. Step 5 of the algorithm is to obtain the $\Delta n_H(\tilde{\nu}) = n_H(\tilde{\nu}) - n(\infty)$ values from the real transform array from step 4, starting at the $N_2 + 1$ point for the highest wavenumber and running to increasing index for decreasing wavenumber. This algorithm uses arrays half as large as those of Ohta and Ishida's method, but gives identical results to those shown in Fig. 10. We show as curve (c) of Fig. 10 the result with this, our preferred, algorithm, which was obtained with two levels of zero-filling. This level of zero-filling is not possible with Ohta and Ishida's algorithm under the memory limitations of Microsoft DOS, because of their

For personal use only.

double length arrays. The percent deviation with two levels of zero-filing is up to 0.05%, which is the same as the percent deviation from the Kramers–Kronig transform. The same result was found for the simulated acetic acid spectrum. For single band spectra, the maximum percent deviation using two levels of zero-filling was 0.15% for 4 cm^{-1} FWHH and 0.007% for 50 cm^{-1} FWHH.

It is not immediately obvious why the BZ algorithm and that of Ohta and Ishida give identical results. In fact the identity stems from the FFT routines. To the FFT, Ohta's input array is identical to ours except that it is phase-shifted by a constant amount for each point. Thus neither the real nor the imaginary transform arrays from step 2 of Ohta and Ishida's algorithm is zero while the real one is zero in our algorithm. Provided both of the transform arrays are used in step 4, Ohta and Ishida's method allows correctly for their asymmetrical input, but at the expense of using larger arrays.

Summary

The FFT-based Hilbert transform of $k(\tilde{\nu})$ to $n(\tilde{\nu})$ can be as accurate as the Kramers–Kronig transform, provided the $k(\tilde{\nu})$ spectrum is extended with zeros to 0 cm^{-1}, and provided it is then inverted to yield an antisymmetric array to input to the FFT. The percent deviation of the calculated $n(\tilde{\nu})$ from the correct values is up to 0.05% for complex spectra.

It has been noted that this percent deviation is $100\{n_H(\tilde{\nu}) - n(\tilde{\nu})\}/n(\tilde{\nu})$, which overestimates the accuracy of the computation of the Hilbert transform that actually calculates $\Delta n_H(\tilde{\nu}) = n_H(\tilde{\nu}) - n(\infty)$. A percent deviation of 0.05% in n_H corresponds to a percent deviation of about 1% in $\Delta n_H(\tilde{\nu})$. The accuracy appears to be limited by the resolution with which the first Fourier transforms are defined. Zero-filling increases this resolution, and leads to a more accurate result for $\Delta n_H(\tilde{\nu})$ from the second transform.

In passing it should be noted that the addition of an extra zero point after the 0 cm^{-1} point in some of the algorithms is not essential. For the BZ algorithm, omission of this extra zero causes the $\Delta n_H(\tilde{\nu})$ output to start at point $N_2 + 2$ instead of at $N_2 + 1$, and for Ohta's algorithm its inclusion causes the $\Delta n_H(\tilde{\nu})$ output to start at point $2N_2 + 1$ instead of $2N_2 + 3$.

We have tested the effect of relaxing the requirements of extending the data to zero and making the $k(\tilde{\nu})$ spectrum antisymmetric. We have used the BZ algorithm, but (*a*) without extending the $k(\tilde{\nu})$ spectrum to 0 cm^{-1}, and (*b*) extending it to 0 cm^{-1} but folding the array to make a symmetrical array instead of inverting it to make an antisymmetrical array. In case (*b*) the accuracy of the results was as poor as that in our original method and Marshall's method. In case (*a*), the accuracy at high wavenumber was essentially the same as for the BZ algorithm, but deteriorated at low wavenumbers. The deterioration was to 0.4% and 1% when the lowest wavenumbers in the $k(\tilde{\nu})$ spectrum were 50 and 250 cm^{-1}, respectively. Thus both requirements are necessary for results accurate to 0.05 to 0.1%.

Results: transform from $n(\tilde{\nu})$ to $k(\tilde{\nu})$

We have based an algorithm for Hilbert transformation from $n(\tilde{\nu})$ to $k(\tilde{\nu})$ on the BZ algorithm for $k(\tilde{\nu})$ to $n(\tilde{\nu})$, with the necessary logical changes. First $n(\tilde{\nu}_{MAX})$ is subtracted from the $n(\tilde{\nu})$ to give $\Delta n(\tilde{\nu})$. The $\Delta n(\tilde{\nu})$ spectrum is then extended to 0 cm^{-1} by adding the value of $\Delta n(\tilde{\nu})$ at the lowest wavenumber instead of by adding zeros. The extra point below 0 cm^{-1} is added, not as a zero but as the value of $\Delta n(\tilde{\nu})$ at the lowest wavenumber, and the array is then folded about this point to create an array that is symmetrical. N_2 zero points are then added to the beginning of the array and $N_2 - 1$ are added to the end, to create a symmetric array of length 2×2^M.

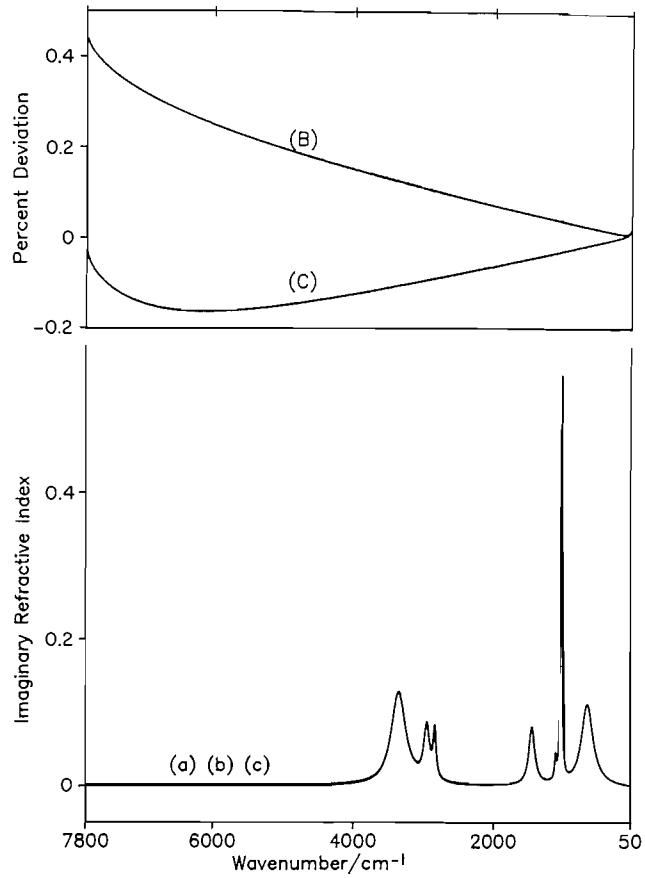

FIG. 11. Results of Kramers–Kronig and Hilbert transforms from $n(\tilde{\nu})$ to $k(\tilde{\nu})$. Lower box, the correct $k(\tilde{\nu})$ (curve (a)) and those calculated by KK (curve (b)) and Hilbert (curve (c)) transformation of the simulated $n(\tilde{\nu})$ spectrum of methanol. The three are indistinguishable on this scale. Upper box, deviations of the transformed $k(\tilde{\nu})$ from the correct $k(\tilde{\nu})$ as a percentage of the largest k value in the spectrum (Fig. 2) for the KK transform (curve (b)) and the BZ Hilbert transform (curve (c)).

If the $\Delta n(\tilde{\nu})$ spectrum is extended to 0 cm^{-1} with zeros, the calculated $k(\tilde{\nu})$ decreases steadily with decreasing wavenumber to a value −10% of the highest peak. If the extra point is zero instead of the constant value, the discontinuity on the input to the FFT causes ripples on the transform.

This array is the real input to the FFT in REAL mode in step 2 of the Hilbert transform algorithm. The Fourier transform consists of a zero imaginary array and a nonzero real array, both of size 2^M. In step 3 of the algorithm, the second half of the real transform is zeroed, and a further 2^M zero points are added to the end of the array. The resulting array is input to the FFT in step 4 and in step 5 the $k(\tilde{\nu})$ spectrum is obtained from the imaginary transform array from step 4, starting at the $N_2 + 1$ point for the highest wavenumber and running to increasing index with decreasing wavenumber.

Figure 11 shows the results obtained for the simulated methanol spectrum of Fig. 2. The lower box contains the correct $k(\tilde{\nu})$ spectrum (curve (a)), that calculated by Kramers–

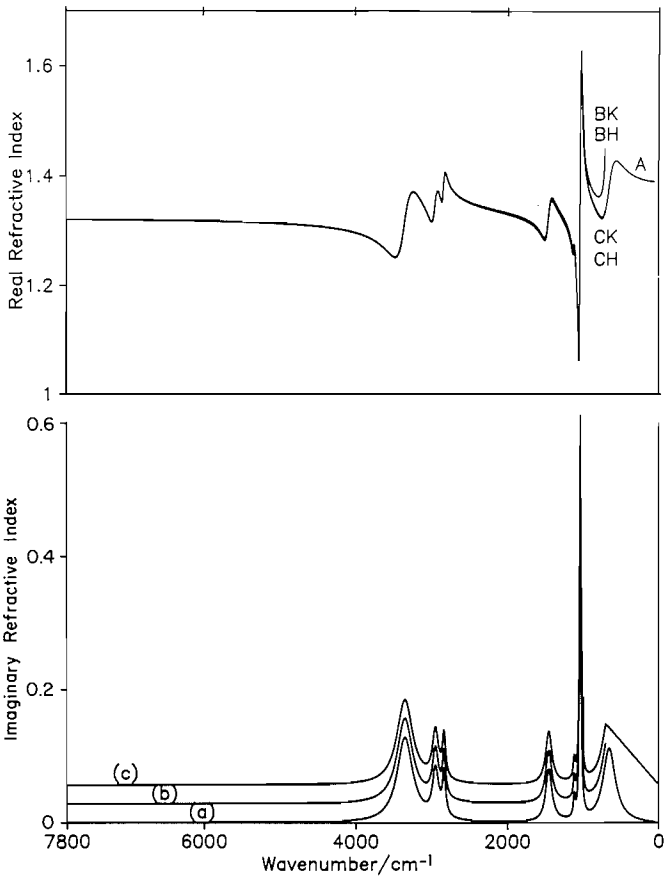

FIG. 12. $k(\tilde{\nu})$ to $n(\tilde{\nu})$ transform of truncated $k(\tilde{\nu})$ files. Lower box: curve (a), the complete $k(\tilde{\nu})$ spectrum; curve (b), the $k(\tilde{\nu})$ spectrum truncated at 700 cm^{-1}; curve (c), curve (b) extended linearly to 0 at 0 cm^{-1}; curves (b) and (c) are offset for clarity. Upper box: curve A, the correct $n(\tilde{\nu})$ spectrum; curves BK and CK, $n_K(\tilde{\nu})$ obtained by KK transformation of curves (b) and (c) of the lower box; curves BH and CH, $n_H(\tilde{\nu})$ obtained by BZ Hilbert transformation of curves (b) and (c) of the lower box.

Kronig transform (curve (b)), and that calculated by this BZ Hilbert transform (curve (c)). The KK transform is slightly higher than the other two at high wavenumbers. The upper box shows the deviation of the calculated and correct k values as a percentage of the largest k value in the spectrum for the Kramers–Kronig transform (curve B) and for the BZ Hilbert transform (curve C). The maximum deviation is about -0.2% of the largest k value for the Hilbert transform and about $+0.5\%$ for the Kramers–Kronig transform. The same result was obtained for acetic acid. For single band spectra (Fig. 1) deviations were smaller; the greatest deviation for the BZ Hilbert transform was 0.06% for FWHH = 4 cm^{-1} and -0.04% for FWHH = 50 cm^{-1}, and for the KK transform 0.07% for 4 cm^{-1} FWHH and +0.1% for 50 cm^{-1}. For 4 cm^{-1} FWHH the deviations were on the sides of the peak while for 50 cm^{-1} FWHH and the complex spectra they were as shown in Fig. 11, upper. Zero-filling does not improve the accuracy of our $n(\tilde{\nu})$ to $k(\tilde{\nu})$ Hilbert transforms.

Results: transforms from $k(\tilde{\nu})$ to $n(\tilde{\nu})$ for truncated $k(\tilde{\nu})$ spectra

It frequently happens that experimental $k(\tilde{\nu})$ spectra are incomplete and end halfway up an absorption band rather than in the baseline. In such cases neither Kramers–Kronig nor Hilbert transforms can be expected to give correct results, indeed the correct results are unknown. Sometimes, however, the complete spectrum is known, but it is necessary to refine a partial spectrum on its own before merging it with previously recorded spectra to cover a broader wavenumber range. Thus it is of interest to explore whether modifications can be made to a $k(\tilde{\nu})$ spectrum that terminates above the baseline, in order to improve the $n(\tilde{\nu})$ spectrum calculated from it.

We have found that a simple procedure similar to triangular apodisation usually improves the transformed result. Figure 12 shows in the lower box the full $k(\tilde{\nu})$ spectrum simulated for methanol (curve (a)), offset from the $k(\tilde{\nu})$ spectrum truncated at 700 cm^{-1} (curve (b)), which in turn is offset from the $k(\tilde{\nu})$ spectrum truncated at 700 cm^{-1} and linearly extended from the last point to $k = 0$ at 0 cm^{-1} (curve (c)). The upper box shows the correct $n(\tilde{\nu})$ spectrum (curve A) and those obtained by KK transformation (curves BK and CK) and by BZ Hilbert transformation (curves BH and CH). The $n(\tilde{\nu})$ spectra obtained by KK transformation are indistinguishable from those obtained by BZ Hilbert transformation in the figure. Comparison of curves BK and CK (or BH and CH) shows that the linear extension to low wavenumber improves the transform of the truncated file. Quantitatively, the percent deviations from the correct $n(\tilde{\nu})$ are reduced from about 10% to about 1%.

This method of extending the $k(\tilde{\nu})$ spectrum to zero at 0 cm^{-1} has been applied to acetic acid, and to many other test systems with and without peaks below the truncation point. It leads to an improvement in the deviations at low wavenumbers by a factor of about 10 in all cases.

Received June 10, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

YUICHI YAMAMOTO, TAKESHI NORO, and KIMIO OHNO. Can. J. Chem. **70**, 532 (1992).

Approximate natural orbitals (NO's) of a larger system can be constructed from the NO's of smaller fragment systems. These orbitals, called composite NO's (CNO's) are expected to be useful in configuration interaction (CI) calculations. The effectiveness of these NO's is shown for the benzene molecule. This molecule is considered a combination of three ethylenes. The CI calculations were carried out for the $S_1 - S_3$ and $T_1 - T_3$ states. We take into account single and double excitations from σ and π electrons in the CI calculations. The calculated excitation energies are in good agreement with the experimental values.

Key words: benzene, π–π^* excited state, composite natural orbital, ionic and covalent, SDCI.

YUICHI YAMAMOTO, TAKESHI NORO et KIMIO OHNO. Can. J. Chem. **70**, 532 (1992).

On peut construire des orbitales naturelles (ON) approximatives de systèmes plus grands à partir d'ON de systèmes formés de fragments plus petits. On s'attend à ce que ces orbitales, que l'on appelle orbitales naturelles composites (ONC), soient utiles dans les calculs d'interactions de configuration (IC). On a démontré l'efficacité de ces ON avec la molécule de benzène. On considère la molécule comme une combinaison de trois molécules d'éthylène. On a effectué des calculs d'IC sur les états $S_1 - S_3$ et $T_1 - T_3$. Dans les calculs d'IC, on tient compte des excitations simples et doubles à partir des électrons σ et π. Les énergies d'excitation calculées sont en bon accord avec les valeurs expérimentales.

Mots clés : benzène, état excité π–π^*, orbitale naturelle composite, ionique et covalent, ICSD.

1. Introduction

In quantum-chemical calculations beyond the Hartree–Fock level, CI is widely used for obtaining electronic states of molecules because of its simple concept and highly developed codes available for many types of computers. But CI has a serious defect in that the number of configuration state functions (CSF's) increases rapidly as the used orbital basis set becomes larger. For most molecules, therefore, a full CI calculation is almost impossible to carry out without the truncation of its expansion. It is well known that the convergence of CI expansion depends on the choice of the orbital set. Self-consistent field molecular orbitals (SCFMO's) commonly used in CI are not adequate for describing electron correlation. The canonical SCF virtual MO's are determined under the influence of $N + 1$ electron potential, so that they have only small amplitudes in the region of space covered by the occupied orbitals and thus are not suitable in describing electronic correlation. It was proved that NO's give the fastest convergence in two-electron systems. It is generally believed that NO's give the fastest convergence in CI expansion. A drawback about NO's is that they cannot be obtained before a CI calculation.

There are several attempts (1–4) to obtain approximate NO's without actually carrying out the CI calculation of a target system. These approximate NO's show definitely better convergence than the ordinary canonical SCFMO's. We have proposed another way of preparing approximate NO's. A molecule can usually be regarded as consisting of fragments. Composite natural orbitals (CNO's) are constructed from NO's of fragments. These orbitals gave excellent convergence in the calculation of excitation energies of C_4H_6 (5) and bipyrrole (6). Its effectiveness has also been shown in a CI calculation of free base porphine (7). The aim of this work is to investigate convergence of the CNO that is constructed from C_2H_4 as a fragment of benzene.

The benzene molecule is a typical aromatic molecule. The π-electron theory of Hückel (8) and the resonance theory of Pauling and Wheland (9) were formulated using benzene as an example. The first *ab-initio* SCF calculation was carried out by Schulman and Moskowitz (10). A large SCF calculation for the ground state by Almlöf and Faegri yielded SCF energy within 0.03 hartree of the estimated Hartree–Fock limit (11). The first CI calculation was carried out by Buenker, Whitten, and Petke (12). An extensive CI study of the excited states was carried out by Hay and Shavitt using a double zeta basis set and included single, double, and triple excitations of π electrons (13). The excitation energies of S_1, T_1, and T_2 were in agreement with experiment. However, for S_2, S_3, and T_3 the excitation energies were still higher than the experimental result by 1.0 eV. Matos, Roos, and Malmqvist performed CASSCF (14–18) contracted CI (CCI) (17) calculations using a double zeta basis set augmented with a $3d$-type polarization function and diffuse p-type functions on carbon (18). They included correlation effects of σ electrons that reduced the errors in the S_2, S_3, and T_3 states to less than 0.6 eV. Kitao and Nakatsuji carried out the SAC-CI (19, 20) calculation on valence and Rydberg excited states and ionized states of benzene using a double zeta basis set plus a $3d_\pi$-type polarization function and diffuse functions on carbon (21). They also considered the σ correlation effects and some higher excitations. The calculated excitation energies agreed with the experimental values to within 0.5 eV except T_1.

The second purpose of this work is to find out how close the present calculations using CNO's compare with the previous CI calculations of benzene (18, 21).

The method of calculation is described in Sect. 2, results and discussion in Sect. 3, followed by concluding remarks.

2. Method

2.1 Basis set and molecular structure

Split-valence basis sets of Tatewaki and Huzinaga (22) were employed. Two diffuse p functions were added on the carbon atoms. The exponents are 0.03477 and 0.01074 as recommended by Hay and Shavitt (13). The total number of contracted Gaussian-type orbitals (CGTO's) is 102. However, the set has near linear dependence. To remove numerical difficulty, the basis set was reduced by projecting out the lowest two eigenvectors of the overlap matrix. The eliminated orbitals were both σ type.

For benzene, we took the bond lengths of C—C and C—H to be 1.397 and 1.084 Å as determined by Raman spectroscopy (23).

2.2 Computational procedures

The procedure of the calculation was as follows: (*1*) A SCF calculation was carried out on the ground state. (*2*) Preliminary CI calculations were performed to identify the main configurations of $S_1 - S_3$, $T_1 - T_3$ states by using the canonical ground state SCF orbital. These CI's included all single excitations from the ground state configuration except the 1*s* orbitals of carbon. A few main configurations were selected as a reference function (cf. Table 3). (*3*) SCF or single excitation CI(SCI) calculation from the reference functions mentioned above was performed for each state to prepare the occupied MO's. (*4*) A SDCI calculation was carried out on the ground state of ethylene to obtain the natural orbitals (NO's). (*5*) By merging the occupied MO's with the approximate NO's constructed from the fragment systems, a CNO set was prepared for each state (5). (*6*) The following three different levels of CI calculations were carried out using the CNO sets. (*a*) In the first level of CI, referred to πCI, single and double excitations of π electrons from the reference configurations were taken into account. (*b*) In the second level of CI, referred to σπCI1, we included single and double excitations of σ and π electrons from the reference configurations except simultaneous double excitations of σ electrons. By this CI, electronic correlations between σ and π electrons are considered but those among σ electrons are not. (*c*) In the third and most extensive CI in our treatment, referred to σπCI2, all single and double excitations of σ and π electrons from the reference configurations were taken into account.

Since the number of configuration state functions (CSF's) was too large, we used the second order perturbation theory to select the more important CSF's from the set of produced CSF's. The selection threshold of −50 μHartree was used. The effect of the rejected configurations on the energy, ΔE, was estimated by

$$[1] \quad \Delta E = \sum_{i}^{c\text{-space}} \left| \sum_{k}^{a\text{-space}} H_{ik} C_k \right|^2 \Big/ (E_{CI} - H_{ii})$$

where a and c spaces were spanned by the reference functions and the rejected CSF's, respectively, and C_k and E_{CI} are the eigenvector and eigenvalue of the Hamiltonian within the selected space (24). When all virtual orbitals are used as correlating orbitals, the eigenvalue should not depend on the orbital set by which excitations are represented. However, when we select more important CSF's, the resultant energy $E_{CI} + \Delta E$ depends on the choice of orbital set. The CNO set is expected to give a more accurate estimated energy than the SCFMO set.

3. Results and discussion

3.1 Total energies resulting from SCF and CI calculations

The SCF orbital energy is shown in Table 1. Table 2 gives the total energies and the correlation energies of the ground state obtained by the SCF and CI calculations compared with the previous calculations.

The correlation energy of σπCI2 is −13.30 eV, which is more than twice that of σπSACCI (21). Kitao and Nakatsuji truncated 35% of σ orbitals and selected the important operators by a perturbation selection technique to decrease the size of calculations. The SCFMO's of the ground state were used to represent the reference configurations and the excitation operator. As shown in the following section, truncation of orbitals causes serious loss of correlation energies when the SCFMO's are employed. This is probably the reason they obtained only 40% of the correlation energy in the present calculation in spite of the inclusion of a polarization function and higher excitations. Thus, their good agreement on excitation energies might be a result of fortuitous cancellation of errors. Although Matos *et al.* obtained the lowest total energy published so far, their correlation energy of 10.47 eV is still smaller than ours. They employed a larger

basis set than ours and they also took into account the double excitations of σ electrons with the CCI approach. In the CCI, doubly excited configurations are contracted into pair functions whose coefficients are obtained through second order perturbation theory. This contraction might explain some of the loss of the correlation energy.

Table 3 gives the reference configurations and the weight of reference functions $\Sigma_{i=1}^{\text{ref}}|C_i|^2$, which is expected to be a good index to measure the accuracy of a CI wavefunction (25). Since the weight of the each level was the same for all states of interest, our CI calculations seem to be impartial for all states.

3.2 Excited states

In Table 4 and Fig. 1, we show the calculated excitation energies of CI calculations with the experimental results for $S_1 - S_3$, $T_1 - T_3$. The πCI calculation yielded good results for S_1, T_1, and T_2. But the excitation energies for S_2, S_3, and T_3 are 1 eV higher than experiments.

Inclusion of correlation effects of π and σ electrons (σπCI1) caused the lowering of 0.7 eV for S_2, S_3 and T_3; however, it raised the excitation energies thus increasing discrepancies with experiment for S_1, T_2, and T_3. Inclusion of σ–σ correlation effects (σπCI2) gave considerable lowering in all excitation energies. For S_1 and triplet states, we obtained excellent agreement with experiment. For S_2 and S_3, we still had a small discrepancy of 0.25–0.30 eV that would be reduced by using the larger basis sets.

From the valence bond theory, these valence excited states can be classified in ionic and covalent states. The covalent states include S_2, T_1, and T_2. The ionic states are S_2, S_3, and T_3. The importance of σ–π and σ–σ correlation effects has been stressed for the ionic states (28–32). The results of

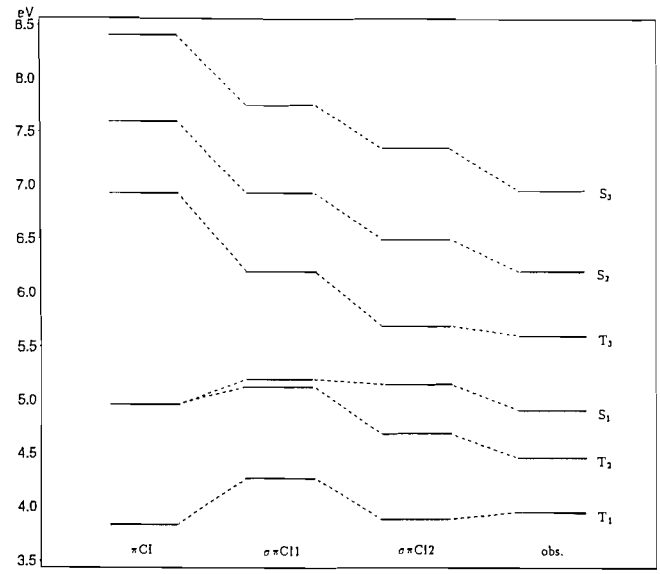

FIG. 1. Comparison of the theoretical and observed excitation energy of $S_1 - S_3$, $T_1 - T_3$ states.

σπCI1 and σπCI2 show that they also exert a significant effect to the covalent states.

Matos *et al.* (18) included σ–σ correlation effects; however, they could not obtain good excitation energies. They selected the reference configurations having the largest weight in the CASSCF wavefunction. The weight of reference space varied from 80% to 95% for different excited states. They mentioned that this imbalance might explain some of the remaining errors even if this part of the error is rather small. However, the present result shows that a well-balanced treatment for all states is extremely important to obtain more reliable results.

3.3 Convergence of CNO

To demonstrate the effectiveness of CNO, a series of truncated CI calculations were performed for σπCI2. First, we tested the convergence for the truncation of σ correlating orbitals. The number of σ correlating orbitals was reduced from 58 to 52, 44, 36, 32, 28, 24, 20, 16, and 12 and all π correlating orbitals was kept. To show the kind of calculations, we used (N_σ/N_π) as symbols, where N_σ and N_π mean the number of correlating orbitals used for σs and π orbitals, respectively. The calculation (58/21) corresponds to the untruncated CI.

The result is shown in Fig. 2. The CI calculations using CNO's give a rapid convergence in comparison with SCFMO's. In (24/21), the correlation energy of about 90% is obtained with CNO but only about 20% with SCFMO. In the calculation of Kitao and Nakatsuji, 35% of the σ SCFMO's (15 MO'S) were truncated to reduce the size of calculation. From Fig. 2, the truncation of 35% of σ SCFMO's would cause a loss of 55% of the total correlation energy.

Second, we tested the convergence for the truncation of π correlating orbitals. The number of π correlating orbitals was reduced from 21 to 17, 13 and 9 while keeping the number of σ correlating orbitals to be 36.

The results are shown in Figs. 3 and 4. For the ground state, S states and T states, the total energies for (36/9) went up only about 0.5 eV in comparison with (58/21). In

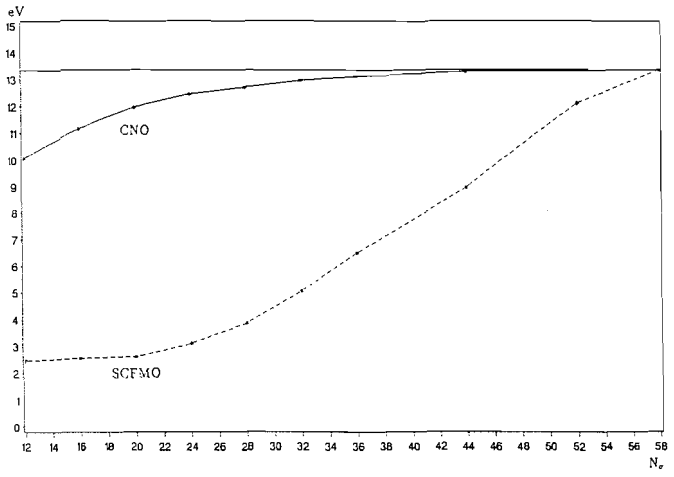

FIG. 2. Convergence of total energies of the ^1A_g state for the truncation of σ correlating orbitals. The lines show the correlation energies.

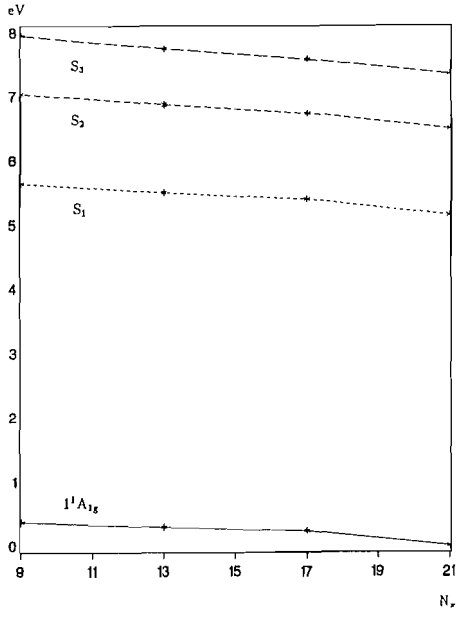

FIG. 3. Convergence of total energies of $S_1 - S_3$ states for the truncation of π correlating orbitals. N_σ is kept at 36. The lines show the energy differences, $(36/N_\pi) - (36/21)$ (^1A_g).

Table 5, we show the calculated excitation energies of truncated CI calculations for $S_1 - S_3$, $T_1 - T_3$. The excitation energies have changed only about 0.2 eV between (58/21) and (36/9). This means that the truncated CI for the ground state and excited states using CNO produces the results close to the untruncated CI values.

4. Concluding remarks

The present CI calculations used CNO, which yields excellent convergence of the CI expansion for the ground state and excited states. For the ground state, the correlation energy of 90% can be obtained when we truncate the σ correlation orbitals from 50 to 24. The error in excitation energies caused by the truncation of π orbitals from 21 to 9 is only 0.2 eV. Thus, the CNO's are expected to be quite useful for

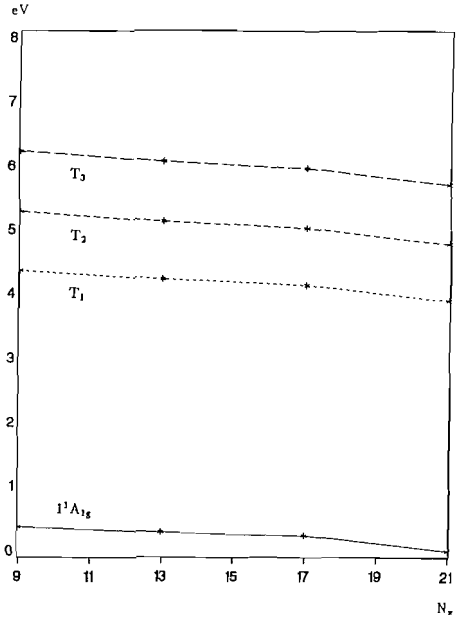

FIG. 4. Convergence of total energies of $T_1 - T_3$ states for the truncation of π correlating orbitals. N_σ is kept at 36. The lines show the energy differences, $(36/N_\pi) - (36/21)$ (^1A_g).

CI calculations of a larger system including a cyclic system, where orbital truncation is necessary.

The CI calculation gave better results for excitation energies compared with the previous calculations. For S_1 and triple states, we obtained excellent agreement with experiment. For S_2 and S_3, we still have a small discrepancy of 0.25–0.30 eV that will be reduced by using a much larger basis set. Inclusion of correlation effect of σ electrons is important in both the so-called covalent and ionic states.

Acknowledgements

The authors thank Professors F. Sasaki and K. Tanaka for many helpful discussions. We are also grateful to Mr. A. Murakami for his helpful suggestions. All calculations were performed on the computers at the Hokkaido University Center for Information Processing Education and the Institute of Molecular Science using JAMOL3 (SCF) (33) and MICA3 (SDCI) (34) programs.

It is our great pleasure to dedicate this paper to Professor Sigeru Huzinaga. Having known Professor Sigeru Huzinaga for almost 40 years, one of the authors (K.O.) would like to offer his tribute of admiration to a man of conscience and

The subdivision of an atom into an inner core and an outer valence region reveals an interesting statistical aspect about the Hartree–Fock (HF) eigenvalues, ε_i, and the electron populations in the valence region, N_i^v, namely $\Sigma_i N_i^v \varepsilon_i = T^v + V_{ne}^v + V_{ee}^{cv} + 2V_{ee}^{vv}$, where T^v and V_{ne}^v are, respectively, the kinetic energy and the nuclear-electronic potential energy of the $\Sigma_i N_i^v$ valence electrons, V_{ee}^{vv} the interelectronic repulsion confined within the valence region, while V_{ee}^{cv} is the repulsion between the core electrons and those of the valence region. This relationship (and a similar one for the core region) holds for any number of electrons arbitrarily assigned to the core, but is accurate only for HF (or near-HF) wave functions. This leads to a definition of the valence region energy, $\Sigma_i N_i^v \varepsilon_i - V_{ee}^{vv} = T^v + V_{ne}^v + V_{ee}^{cv} + V_{ee}^{vv}$, which, however, cannot be compared to the energy actually required for the removal of the outer electrons, because relaxation is not accounted for. An accurate energy expression has also been derived, $E^v = \frac{1}{3}(V_{ne}^v + V_{ee}^{cv} + \Sigma_i N_i^v \varepsilon_i)$, which measures the actual withdrawal of the valence electrons. The latter expression requires the use of discrete values of N^c, the number of electrons assigned to the core, namely $N^c = 2$ for the first-row and $N^c = 10$ e for the second-row elements.

Key words: atoms, core–valence separation.

S. FLISZÁR, N. DESMARAIS et G. DANCAUSSE. Can. J. Chem. **70**, 537 (1992).

Le découpage d'un atome en une région interne et une région de valence externe conduit à une relation exacte impliquant les populations électroniques de valence, N_i^v, et les valeurs propres de Hartree–Fock, ε_i, soit $\Sigma_i N_i^v \varepsilon_i = T^v + V_{ne}^v + V_{ee}^{cv} + 2V_{ee}^{vv}$, où T^v and V_{ne}^v sont, respectivement, l'énergie cinétique et l'énergie potentielle noyau-électron des électrons de valence, V_{ee}^{vv} est la répulsion interélectronique dans cette région et V_{ee}^{cv} est la répulsion entre les électrons internes et ceux de valence. Cette relation (ainsi qu'une expression similaire pour la région interne) s'applique quelque soit le nombre d'électrons, N^c, associés à la région interne. Elle conduit à une énergie de la couche de valence, $\Sigma_i N_i^v \varepsilon_i - V_{ee}^{vv} = T^v + V_{ne}^v + V_{ee}^{cv} + V_{ee}^{vv}$, qui traduit un état de fait mais ne correspond pas à une ionisation physique. Cette dernière est bien décrite par l'énergie de valence $E^v = \frac{1}{3}(V_{ne}^v + V_{ee}^{cv} + \Sigma_i N_i^v \varepsilon_i)$, qui n'est valable que pour des valeurs discrètes de N^c, soit $N^c = 2$ pour les éléments de la première rangée et $N^c = 10$ e pour ceux de la deuxième.

Mots clés : atomes, énergie de valence.

1. Introduction

The idea of subdividing an atom into an inner core and an outer valence region is not a new one. Though intuitively appealing — "much of the chemistry resides in the valence region" — such a core–valence separation is by no means obvious. Indeed, no electron can be assigned to any region in particular, because each individual electron occupies the entire atom. In turn, we can construct arguments rooted in the notion of electron density, $\rho(\boldsymbol{r})$, building on the fact that the exact nonrelativistic ground-state energy of an atom, E, can be expressed in terms of the electrostatic potential at its nucleus (1) or, more generally (2), because E is a functional of $\rho(\boldsymbol{r})$.

Along these lines, Politzer and Parr (3) offered an approximation for the valence region energy, E^v,

$$[1] \qquad E^v = -\frac{3}{7}(Z - N^c)\int_{r_b}^{\infty} 4\pi r\rho(r)\mathrm{d}r$$

in which N^c is the number of electrons in the core region of an atom with nuclear charge Z and r_b defines the boundary separating the core from the valence region. The factor 3/7 is brought in by the Thomas–Fermi theory (4) involved in the derivation of eq. [1]. A number of studies (5) have exploited this Thomas–Fermi-like approach and have ultimately led to an approximate but accurate description of molecules (6).

The Politzer–Parr partitioning defines the boundary surface separating the core and valence regions at the minimum of the radial distribution function, $R(r) = R(r) = 4\pi r^2\rho(r)$. It is certainly reassuring to find a recognizable feature suggesting a justification for the selection of a boundary surface. But it remains that, in the last resort, any selection is largely arbitrary. Here we reformulate the question by asking about the energy of the outer electrons, which could be measured by the energy required to remove them. This implies the notion of integral numbers of electrons in the core and valence regions. Specifically, we consider here first-row elements with two core electrons, and second-row elements with 10 core electrons. Inroads will also be discussed, however, taking r_b at the minimum of the radial distribution function, as well as other possible definitions of the core region.

Sharply contrasting with approaches rooted in the Thomas–Fermi model, we tackle the problem within the framework of Hartree–Fock theory. The familiar Hartree–Fock orbital energies are part of our description and we take full advantage of these eigenvalues. A core–valence separation is described, new energy formulas are given, but, at the end, all this will bring us back to an expression resembling eq. [1], assessing its true merits.

2. Methodology

Consider a sphere of radius r, centered at the nucleus. The electron populations N_{1s}, N_{2s}, . . ., contained in this sphere are

$$[2] \qquad N_i(r) = \nu_i \int_0^r 4\pi r^2 |\phi_i(r)|^2 \mathrm{d}r$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

where the ϕ_i's are normalized Hartree–Fock orbitals occupied by ν_i electrons. The total core population, N^c, is then

$$N^c = \sum_i N_i(r_b)$$

where $r = r_b$ defines the boundary surface separating the core and valence regions. Similarly, the valence populations are

$$[3] \qquad N_i^v = \nu_i \int_{r_b}^{\infty} 4\pi r^2 |\phi_i(r)|^2 dr$$

The $1s$, $2s$, ..., electrons are well entangled in the inner region and, of course, also in the outer valence region. Briefly, in examining the energy associated with the "valence electrons" we must deal with a mix-up of electrons assigned to different Hartree–Fock orbitals ϕ_i, each one with its own eigenvalue ε_i.

These Hartree–Fock energies are reasonably good approximations to the orbital energies of an atom, as determined by X-ray and optical spectroscopy term values. We take them at their face value, in their integrality, as the energies of the individual electrons, knowing, of course, that each of these orbital energies is computed over the entire atom and that no localization of the individual electrons in certain regions of space should be attempted. Under these circumstances, all we can do is to evaluate the amount of energy statistically accumulated in a given region, using the densities of the electrons assigned to the various orbitals ϕ_{1s}, ϕ_{2s}, ..., with orbital energies ε_{1s}, ε_{2s}, ..., respectively. Hence we associate the electronic energies

$$[4] \qquad \sum_i N_i^c \varepsilon_i = \sum_i \varepsilon_i \nu_i \int_0^{r_b} 4\pi r^2 |\phi_i(r)|^2 dr$$

and

$$[5] \qquad \sum_i N_i^v \varepsilon_i = \sum_i \varepsilon_i \nu_i \int_{r_b}^{\infty} 4\pi r^2 |\phi_i(r)|^2 dr$$

with the core and valence regions, respectively. Our objective is to find the relationship between $\Sigma_i N_i^v \varepsilon_i$ and the energy of the valence region. The precise definition of the latter is momentarily postponed.

Now we switch to something else and pay attention to the individual kinetic and potential energy components of interest, namely

$V_{nc}^c = -Z \int_0^{r_b} \frac{\rho(r)}{r} dr$ = nuclear-electronic potential energy involving only the core electrons (inside the boundary r_b),

$V_{nc}^v = -Z \int_{r_b}^{\infty} \frac{\rho(r)}{r} dr$ = nuclear-electronic potential energy of the valence electrons (outside the boundary r_b),

T^c = kinetic energy of the core electrons,

T^v = kinetic energy of the valence electrons,

V_{ee}^{cv} = repulsion between the $(Z - N^c)$ valence and the N^c core electrons,

V_{cc}^{vv} = electron–electron repulsion involving only the electrons of the valence region,

V_{cc}^{cc} = electron–electron repulsion between core electrons.

The nuclear-electronic potential energies are readily obtained from

$$-Z \sum_i \nu_i \int 4\pi r |\phi_i(r)|^2 dr$$

and the use of the appropriate limits of integration. Similarly, it is easy to separate the kinetic energy, $T = \Sigma_i \nu_i \int \phi_i^* \hat{T} \phi_i d\boldsymbol{r}$, into a core contribution and a part associated with the valence region by using the appropriate limits of integration.

The separation of the V_{ee}^{cv}, V_{cc}^{vv}, and V_{cc}^{cc} parts of the total interelectronic repulsion V_{ee} also follows from appropriate selections of the integration limits. The Coulomb integrals

$$J_{ij} = \int^{\tau_1} \int^{\tau_2} \phi_i(1)\phi_j(2) \frac{1}{r_{12}} \phi_i(1)\phi_j(2) d\tau_1 d\tau_2$$

and the exchange integrals

$$K_{ij} = \int^{\tau_1} \int^{\tau_2} \phi_i(1)\phi_j(2) \frac{1}{r_{12}} \phi_j(1)\phi_i(2) d\tau_1 d\tau_2$$

were deduced with the help of the standard expansion of $1/r_{12}$ in terms of spherical harmonics (7). The integration goes over the spatial coordinates of electrons 1 and 2, with $d\tau_1 = r_1^2 \sin\theta_1 d\theta_1 d\varphi_1 dr_1$ and a similar expression for $d\tau_2$. Let us write these integrals in shorthand notation:

$$I = \int^{\tau_1} \int^{\tau_2} \ldots d\tau_1 d\tau_2 = \int_0^{2\pi} \int_0^{2\pi} \int_0^{\pi} \int_0^{\pi} \int_0^{\infty} \int_0^{\infty} \ldots dr_1 dr_2 d\theta_1 d\theta_2 d\varphi_1 d\varphi_2$$

Representing the angular part by A,

$$A = \int_0^{2\pi} \int_0^{2\pi} \int_0^{\pi} \int_0^{\pi} \ldots d\theta_1 d\theta_2 d\varphi_1 d\varphi_2$$

we rewrite I as follows:

$$I = A\int_0^\infty\int_0^\infty \ldots \mathrm{d}r_1\mathrm{d}r_2 = A\int_0^{r_b}\int_0^{r_b} \ldots \mathrm{d}r_1\mathrm{d}r_2 + A\int_0^\infty\int_{r_b}^\infty \ldots \mathrm{d}r_1\mathrm{d}r_2$$

$$= A\int_0^{r_b}\int_0^{r_b} \ldots + A\int_{r_b}^\infty\int_0^{r_b} \ldots + A\int_0^{r_b}\int_{r_b}^\infty \ldots + A\int_{r_b}^\infty\int_{r_b}^\infty \ldots$$

i.e.,

$$I = \int^{\tau_1^c}\int^{\tau_2^c} \ldots \mathrm{d}\tau_1\mathrm{d}\tau_2 + \int^{\tau_1^v}\int^{\tau_2^c} \ldots \mathrm{d}\tau_1\mathrm{d}\tau_2 + \int^{\tau_1^c}\int^{\tau_2^v} \ldots \mathrm{d}\tau_1\mathrm{d}\tau_2 + \int^{\tau_1^v}\int^{\tau_2^v} \ldots \mathrm{d}\tau_1\mathrm{d}\tau_2$$

The Coulomb and exchange integrals are thus conveniently separated into three contributions, namely

$$I^{cc} = \int^{\tau_1^c}\int^{\tau_2^c} \ldots \mathrm{d}\tau_1\mathrm{d}\tau_2$$

$$I^{vv} = \int^{\tau_1^v}\int^{\tau_2^v} \ldots \mathrm{d}\tau_1\mathrm{d}\tau_2$$

$$I^{cv} = \int^{\tau_1^v}\int^{\tau_2^c} \ldots \mathrm{d}\tau_1\mathrm{d}\tau_2 + \int^{\tau_1^c}\int^{\tau_2^v} \ldots \mathrm{d}\tau_1\mathrm{d}\tau_2$$

for the calculation of the V_{ee}^{cc}, V_{ee}^{vv}, and V_{ee}^{cv} repulsion energies, respectively.

This completes the breakdown of the kinetic and potential energies into core and valence contributions, for future use. We now proceed with the theory.

3. Theory. The "unperturbed" atom

Let us begin with a simple energy balance involving orbital energies. The potential energy part of ε_i includes, in an average way, the repulsion energy between electron i and all the other electrons of the atom. The sum of orbital energies, $\Sigma_i \nu_i\varepsilon_i = \Sigma_i N_i^v\varepsilon_i + \Sigma_i N_i^c\varepsilon_i$, thus counts each interelectronic repulsion twice. And the Hartree–Fock energy of an atom is

$$[6] \qquad E = \sum_i \nu_i\varepsilon_i - V_{ee}$$

where V_{ee} is the interelectronic repulsion energy including exchange. This means that $\Sigma_i N_i^v\varepsilon_i$ includes some double-counting of interelectronic repulsions, say V_{ee}(valence). So does $\Sigma_i N_i^c\varepsilon_i$, with V_{ee}(core). On these grounds we define

$$[7] \qquad E(\text{valence}) = \sum_i N_i^v\varepsilon_i - V_{ee}(\text{valence})$$

$$[8] \qquad E(\text{core}) = \sum_i N_i^c\varepsilon_i - V_{ee}(\text{core})$$

So far, we are deliberately vague as regards the energies, but this is just a temporary situation. Let us proceed with our energy balance. $\Sigma_i N_i^v\varepsilon_i$ also includes V_{ee}^{cv}, the repulsion between the valence and the core electrons. So does $\Sigma_i N_i^c\varepsilon_i$. But the double-counting of V_{ee}^{cv} only occurs when we form the sum $\Sigma_i N_i^v\varepsilon_i + \Sigma N_i^c\varepsilon_i$, which includes twice

$$[9] \qquad V_{ee} = V_{ee}^{cv} + V_{ee}(\text{valence}) + V_{ee}(\text{core})$$

Finally, we obtain from eqs. [6]–[9] that

$$[10] \qquad E(\text{valence}) + E(\text{core}) = E + V_{ee}^{cv}$$

We now use eq. [7] for the description of $E_{\text{unp.}}^v$, the valence energy of an unperturbed ground-state atom, meaning that there is no intent on our side of stripping it of its electrons. We observe this atom "as it is," after our mental subdivision into a core and a valence region. The interelectronic repulsion energy involving only the electrons associated with the valence region is V_{ee}^{vv}, which is unambiguously given by applications of standard formulas for Coulomb and exchange integrals. This V_{ee}^{vv} is used in eq. [7], which becomes

$$[11] \qquad E_{\text{unp.}}^v = \sum_i N_i^v\varepsilon_i - V_{ee}^{vv}$$

The validity of this equation rests entirely with the validity of our description, $\Sigma_i N_i^v\varepsilon_i$, of the electronic energy statistically accumulated in the valence region.

On the other hand, we can also express the total energy found in the valence region in a more conventional way, namely as the sum of the kinetic and potential energies associated with the valence electrons, i.e.,

$$[12] \qquad E_{\text{unp.}}^v = T^v + V_{ne}^v + V_{ee}^{cv} + V_{ee}^{vv}$$

Thus we obtain that

$$[13] \qquad \sum_i N_i^v\varepsilon_i = T^v + V_{ne}^v + V_{ee}^{cv} + 2V_{ee}^{vv}$$

and its companion

$$[14] \qquad \sum_i N_i^c\varepsilon_i = T^c + V_{ne}^c + V_{ee}^{cv} + 2V_{ee}^{cc}$$

(The latter follows immediately because the individual core and valence terms add up correctly to give the corresponding totals for the entire atom, e.g., $T^{\text{total}} = T^v + T^c$.) This result is exact and holds for any arbitrarily selected value of N^c, as illustrated by the numerical examples presented and discussed in Sect. 5. The statistical concept embodied in $\Sigma_i N_i^v\varepsilon_i$ is now clearly identified, eq. [13], in terms of the familiar kinetic and potential energies that can be associated with the valence region. It follows from the definition of these energy components and integration of the Hartree–Fock equations, $\hat{F}\phi_i = \varepsilon_i\phi_i$, i.e., after multiplication by ϕ_i^*, integration from r_b to ∞, and sum over i.

Up to this point we have described an atom left alone. Its valence energy corresponds to a hypothetical ionization in which the valence electrons would be simply skimmed off as they are in the unperturbed atom, with no relaxation of the core. This does not occur, of course. But this atom offers a convenient term of reference.

4. Theory. Valence energy including relaxation

Now we look for a valence-region energy, E^v, which is not any longer subject to the constraints having led to $E^v_{unp.}$. We hope to achieve this by examining the general properties of an atom in which the core and valence electrons are interdependent. This amounts to considering implicitly a relaxation energy term from which one region would benefit at the expense of the other in the event of an actual ionization. But this E^v and its core counterpart E^c are still tied by the general energy balance given in eq. [10]. Thus we write

$$[15] \quad E = E^v + E^c - V^{cv}_{ee}$$

Consider first the electronic energy of a ground-state atom with nuclear charge Z, $E = \langle\psi|\hat{H}|\psi\rangle$, and apply the Hellmann–Feynman theorem taking Z as parameter. This gives, in conventional notation,

$$\left(\frac{\partial E}{\partial Z}\right)_\rho = \left\langle\psi\left|\frac{\partial \hat{H}}{\partial Z}\right|\psi\right\rangle = \left\langle\psi\left|-\sum_i r_i^{-1}\right|\psi\right\rangle$$

where the sum over i runs over all electrons. The well-known result is

$$[16] \quad \left(\frac{\partial E}{\partial Z}\right)_\rho = \frac{V_{ne}}{Z}$$

On the other hand, the virial theorem, $2E = V_{ne} + V_{ee}$, and the Hartree–Fock formula, eq. [6], combine to give

$$[17] \quad 3E = V_{ne} + \sum_i \nu_i\varepsilon_i$$

This result and eq. [16] lead to

$$[18] \quad 3E - Z\left(\frac{\partial E}{\partial Z}\right)_\rho = \sum_i \nu_i\varepsilon_i$$

Now we define

$$[19] \quad \gamma = \frac{Z}{E}\left(\frac{\partial E}{\partial Z}\right)_\rho$$

and rewrite eq. [18] as follows

$$[20] \quad (3 - \gamma)E = \sum_i \nu_i\varepsilon_i$$

Moreover, it follows from eqs. [16] and [19] that

$$[21] \quad E = \frac{1}{\gamma}V_{ne}$$

Equations [20] and [21] represent an identity in Hartree–Fock theory. The particular interest offered by eq. [21] lies in the fact that $\gamma = 7/3$ appears to be the characteristic homogeneity of both Thomas–Fermi (8) and local density functional theory (9), in which case eq. [20] gives the Ruedenberg approximation (10), $E = (3/2)\,\Sigma_i\nu_i\varepsilon_i$, while eq. [21] gives the Politzer formula (11), $E = (3/7)\,V_{ne}$, contained in eq. [1]. Equations [15], [20], and [21] are our working formulas.

We pick up things where we left them with eq. [15] and write

$$[22] \quad \gamma E = \gamma^v E^v + \gamma^c(E^c - V^{cv}_{ee})$$

This expression is more general than what would follow from a simple multiplication by γ. It is noncommittal as to whether the atomic γ suits the individual core and valence parts: in writing eq. [22], γ is taken as the average of γ^v (with a weight of E^v) and γ^c (weighted by $E^c - V^{cv}_{ee}$), i.e.,

$$\gamma = \frac{\gamma^v E^v + \gamma^c(E^c - V^{cv}_{ee})}{E^v + E^c - V^{cv}_{ee}}$$

Next we consider $V_{ne} = V^v_{ne} + V^c_{ne}$, which we write

$$V_{ne} = (V^v_{ne} + V^{cv}_{ee}) + (V^c_{ne} - V^{cv}_{ee})$$

The reason for this association of terms is physical: in a central force problem, V^v_{ne} and V^{cv}_{ee} play roles that are similar in nature. V^v_{ne} measures the attraction of the valence electrons by the nucleus and V^{cv}_{ee} the accompanying repulsion by the core electrons. With eq. [21] in mind we now write

$$[23] \quad \frac{1}{\gamma}V_{ne} = \frac{1}{\gamma^v}(V^v_{ne} + V^{cv}_{ee}) + \frac{1}{\gamma^c}(V^c_{ne} - V^{cv}_{ee})$$

In this case $1/\gamma$ is the weighted average of $1/\gamma^v$ (with a weight of $V^v_{ne} + V^{cv}_{ee}$) and of $1/\gamma^c$ (with a weight of $V^c_{ne} - V^{cv}_{ee}$).

At this point we use eqs. [22] and [23] and solve for γ^v. After some algebra one obtains $(\gamma^v)^2 + b\gamma^v + c = 0$ with $b = -[(V^v_{ne} + V^{cv}_{ee})/E^v + \gamma]$ and $b^2 - 4c = [(V^v_{ne} + V^{cv}_{ee})/E^v - \gamma]^2$. The trivial root is $\gamma^v = \gamma$. The other root gives

$$[24] \quad E^v = \frac{1}{\gamma^v}(V^v_{ne} + V^{cv}_{ee})$$

So far we have exploited eq. [21]. We have one more step to go. Using eqs. [15] and [22] we write

$$(3 - \gamma)E = (3 - \gamma^v)E^v + (3 - \gamma^c)(E^c - V^{cv}_{ee})$$

and compare this expression with $\Sigma_i\nu_i\varepsilon_i = \Sigma_i N^v_i\varepsilon_i + \Sigma_i N^c_i\varepsilon_i$. Equation [20] tells us that

$$\left[(3 - \gamma^v)E^v - \sum_i N^v_i\varepsilon_i\right] + \left[(3 - \gamma^c)(E^c - V^{cv}_{ee}) - \sum_i N^c_i\varepsilon_i\right] = 0$$

This equation achieves a core–valence separation. The terms in brackets are certainly individually zero at the limits $N^c = 0$ and $N^v = 0$, but this does not warrant that these terms are individually zero for any value of N^c, i.e., that any N^c satisfies a meaningful core–valence separation. We shall tentatively proceed with

$$[25] \quad (3 - \gamma^v)E^v = \sum_i N^v_i\varepsilon_i$$

and examine which, if any, N^c values are acceptable. Equation [25] defines E^v. It is the "valence counterpart" of eq.

[20]. Comparison with eq. [24] yields the new energy formula

$$[26] \quad E^v = \frac{1}{3}\left(V^v_{ne} + V^{cv}_{ee} + \sum_i N^v_i \varepsilon_i\right)$$

which is visibly the "valence counterpart" of eq. [17]. Extensive numerical verifications are presented in Sect. 5 in order to assess the range of validity of eq. [25]. E^v expresses a valence region energy that takes the relaxation of the core into proper account. It corresponds to the appropriate sum of ionization potentials.

In closing, let us compare this physically observable E^v with $E^v_{unp.}$, which reflects the description of the electrons as they are found in the valence region of an unperturbed atom. We eliminate V^{vv}_{ee} from eq. [12] with the help of eq. [11] and compare the result with eq. [26]. This gives

$$[27] \quad E^v_{unp.} = \frac{1}{2}(3E^v + T^v)$$

Surely, $E^v \neq E^v_{unp.}$. Equation [27] indicates that the virial theorem, $-T^v = E^v$, and thus $-T^v = E^v_{unp.}$, is not obeyed in the valence region.

5. Numerical verifications

All our calculations are based on normalized wave functions

$$\phi_i = \sum_k c_k \chi^{lm}_k \qquad (e.g., \phi_{1s}, \phi_{2s}, \ldots)$$

constructed from normalized Slater basis functions

$$\chi^{lm}_k = A_k r^{n_k - 1} e^{-\varsigma_k r} Y^m_l(\theta,\varphi)$$

$$A_k = (2\varsigma_k)^{n_k + 1/2}/[(2n_k)!]^{1/2}$$

Unless stated otherwise, we have used the near-Hartree–Fock wave functions of Clementi and Roetti (12) as well as the corresponding orbital energies ε_{1s}, ε_{2s}, ... Correlation and relativistic effects are not included in these calculations. The core and valence electron populations were calculated from eqs. [2] and [3], respectively. The boundary surfaces (i.e., r_b) are those that collect exactly $N^c = 2$ or $N^c = 10$ e in the core regions of the first- and second-row atoms and ions, respectively. The core results are given in Tables 1 and 2. The corresponding valence populations are readily deduced by difference. These populations are instrumental in the evaluation of $\Sigma_i N^v_i \varepsilon_i$. Table 3 reports the breakdown of V_{ee} and T for the atoms Li–Ar. This concludes the presentation of the input data required for our intended verifications of the new energy formulas.

Let us begin with eq. [26], using the data collected in Tables 1 and 2. The orbital energies were taken from the literature (12) and the ionization potentials used for comparisons are those given by Moore (13). The results presented in Table 4 for the first-row atoms and ions are self-explanatory. Those given for the second-row elements (Table 5) reveal discrepancies between calculated and observed quantities, particularly for the larger atoms. Now, the present results were entirely obtained from Hartree–Fock wave functions, which, of course, do not reproduce the experimental energies of the atoms. So it is only natural that non-inclusion of correlation and relativistic effects will show up in our comparisons. Taking these limitations into account, it seems fair to conclude that our verification of eq. [26] is acceptable both for the neutral atoms and their ions.

The following verification is instructive. When we subtract the calculated E^v's from the total Hartree–Fock energies of the corresponding atoms or ions, we obtain, eq. [15],

$$E - E^v = E^c - V^{cv}_{ee} = E^{ion}$$

This is what we did in Table 6, using the Hartree–Fock energies of ref. 12. Our results for $E^c - V^{cv}_{ee}$ are compared with independent calculations (12) of the helium isoelectronic series (for the first-row elements) and with the neon

For boron we used the electron affinity (0.3 eV) calculated by Clementi and McLean (14).

isoelectronic series (for the second row). Moreover, a comparison is offered with the corresponding sums of ionization potentials. The overall agreement is generally satisfactory. Finally, we show the deviations between our results and their experimental counterparts. The sum of these "core" and "valence" deviations equals, of course, the true error introduced by the neglect of correlation and relativistic effects. This analysis permits an estimate regarding the distribution of errors in the core and valence regions.

Additional tests were performed in order to learn about the selection of N^c. Calculations made for the series Na–Ar, assuming now a core N^c = 2, gave valence region energies that, on the whole, are of the same quality as those deduced for N^c = 10. Interestingly, this also holds true for the results obtained with N^c = 12. It should not be inferred, however, that the appropriate selection of N^c is not important. Calculations made for the series B–Ne with N^c = 4, for example, reveal major discrepancies, up to ~3.4 au for Ne. This N^c is definitely a bad choice. Core populations between 1.8 and 2.2 e were also examined for the first-row atoms, using experimental estimates along the lines given in ref. 3 for comparisons with eq. [26]. For carbon, the deviations are 1.607 (N^c = 1.8), 0.928 (N^c = 1.9), 0.148 (N^c = 2), 0.450 (N^c = 2.1), and 0.639 au (N^c = 2.2 e). N^c = 2 is the obvious choice for the first-row elements. Our results concur with the general idea (3) that the minima of the radial distribution function represent physically meaningful

[a]For Na, Al, Si, and P we used the electron affinities computed by Clementi, McLean, Raimondi, and Yoshimine (15), using correlation plus relativistic corrections obtained from ionization processes.

core–valence boundary surfaces, but also suggest that this should not be taken too literally with Hartree–Fock wave functions. The latter reproduce quite accurately the electronic shell structure, as revealed by electron diffraction data (16), but small differences evidently persist. A final assessment on this matter is left to future studies, at a post Hartree–Fock level.

We now examine eq. [13], using the data collected in Tables 1–3 and the ε_i's of Clementi and Roetti (12). The example presented for argon (Table 7) illustrates that eq. [13] holds for any arbitrarily selected N^c. This result is not automatic, however: it reflects a property of Hartree–Fock (or near Hartree–Fock) spin orbitals. This point is revealed by an analysis of the numerical differences between $\Sigma_i N^v_i \varepsilon_i$ and $(T^v + V^v_{ne} + V^{cv}_{ee} + 2V^{vv}_{ee})$. They were calculated using $N^c = 1, 2, \ldots, N - 1$ for each individual atom, from Li through Ar, by means of the single-ζ, double-ζ, and near-HF basis sets of ref. 12. The selection of results offered in Table 8 vividly illustrates that $\Sigma_i N^v_i \varepsilon_i$ and $(T^v + V^v_{ne} + V^{cv}_{ee} + 2V^{vv}_{ee})$ converge as we approach the Hartree–Fock limit.

Finally, we examine the valence energy $E^v_{unp.}$ using eqs. [11] and [12] (Table 9) and consider, in an approximate way, the correlation and relativistic corrections suggested by the deviations reported in Table 6. We also indicate the results deduced from eq. [27], using "experimental" E^v's (as given by the appropriate sums of ionization potentials) and the calculated values of T^v (Table 3). The latter are only a minor part of the corresponding total kinetic energies. Hence, we can reasonably anticipate that no serious bias is introduced by their use. As a consequence, the results thus obtained for $E^v_{unp.}$ should represent the closest possible approximation to their "true" values. Surely, these valence energies are for valence regions containing fractional electron populations, those given by eq. [3]. For comparison, we offer the sum of ionization potentials accounting for the fractional populations by linear interpolation. This, of course, represents only a rough estimate, to be taken with a grain of salt, but gives a physical feeling for the energy accumulated in the valence region of an unperturbed atom. The last three entries of Table 9 reveal the general agreement between these different estimates of $E^v_{unp.}$ and support the basic tenets underlying their derivation.

Turning now to the Thomas–Fermi-like description of valence energy, eq. [1], we inquire whether it resembles E^v or $E^v_{unp.}$.

6. Alternate energy formulas. Approximations

Consider first eq. [24] and examine the physical nature of its V^{cv}_{ee} part. This potential energy describes the repulsion between an outer electron cloud (the valence electrons) and the N^c core electrons. Gauss' theorem tells us that the V^{cv}_{ee}

potential is just as though all the core electron charge were lumped at the nuclear position. Hence, the $\int_{r_b}^{\infty} [\rho(r)/r]dr$ integrals being the same in the evaluation of V_{ee}^{cv} and V_{ne}^v, and taking into account that the nuclear charge Z has been replaced by N^c, it follows that $V_{ee}^{cv} = -(N^c/Z)V_{ne}^v$. It is readily seen that, in this approximation,

$$[28] \quad V_{ne}^v + V_{ee}^{cv} = -(Z - N^c)\int_{r_b}^{\infty} \frac{\rho(r)}{r}\,dr$$

is the nuclear-electronic potential energy of the outer electrons in the field of an expanded "effective nucleus" $(Z - N^c)$.

This is an approximation, of course, because it does not consider the spin of the core electrons. We evaluated V_{ee}^{cv} energies by means of Gauss' theorem (using the V_{ne}^v results of Tables 1 and 2) and subtracted the appropriate exchange integrals, ΣK_{ij}^{cv}, involving the core and valence electrons. In this approximation we considered that for $N^c = 2$ the core consisted only of 1*s* electrons and computed all the 1*s*2*s* and 1*s*2*p* exchange integrals occurring in first-row atoms. For the second row we proceeded similarly, assuming a $N^c = 10$ core consisting only of 1*s*, 2*s*, and 2*p* electrons, and calculated all the relevant integrals with 3*s* and 3*p* electrons. The results obtained in this approximation are compared in Table 10 with their genuine counterparts, i.e., those that correspond to SCF calculations. The spin part is relatively small (e.g., ~0.499 au for Ne and ~0.765 au for Ar) but not negligible. These results are in general agreement with those of Politzer and Daiker (17). In short, eq. [28] is not bad, but is approximate.

On the other hand, this approximation is valuable for the physical picture it conveys, that of a valence electron cloud in the field of a nucleus partially screened by its core electrons. Using it in eq. [24] we get

$$[29] \quad E^v \simeq -\frac{1}{\gamma^v}(Z - N^c)\int_{r_b}^{\infty} \frac{\rho(r)}{r}\,dr$$

which is visibly the counterpart of eq. [1]. The $V_{ne}^v + V_{ee}^{cv}$ and E^v results (Tables 4 and 5) and eq. [24] reveal that, except for Li, Be, Na, and Mg, γ^v is of the order of 7/3. For the neutral atoms Be–Ne it appears that, in this approximation, $\gamma^v = 7/3$ works best under the conditions explored by Politzer and Parr (3). The point is that the straightforward use of Gauss' theorem for the evaluation of V_{ee}^{cv}, i.e., the simple approximation $V_{ne}^v + V_{ee}^{cv} = (Z - N^c)V_{ne}^v/Z$, introduces no major bias in applications of eq. [26]: the root-mean-square deviation between the calculated and experimental results has risen to 0.31 au for the first-row atoms and ions, from 0.16 au in calculations not involving this approximation.

Finally, there is one additional relevant point deserving attention. **Equation [29] represents a valence energy in which relaxation effects are included.** It was derived from eq. [24]. It cannot be mistaken for $E_{unp.}^v$. This particular aspect was not recognizable in earlier derivations (3, 18) of energy formulas like eq. [29]. It holds true for eq. [1].

In the light of these results we can now substantiate two important aspects regarding the appropriateness of the Politzer–Parr-like core–valence separation that was described earlier (6, 18) for molecules. This separation postulated, in a generalization including internuclear repulsions, the approximate validity of eq. [29]. This generalization and the energy formulas that were thus derived for the molecules involved the systematic use of Gauss' theorem: this approximation is now clearly justified. More importantly, it also appears that this generalization, which was entirely derived from a consideration of the valence electrons on the basis of eq. [29], does, indeed, include core relaxation effects as well, although originally the latter had not been contemplated in an explicit manner in the description of molecular systems. We thus retrace a posteriori at least part of the possible reasons explaining the accuracy of molecular energy formulas rooted in the core–valence separation approximated by eq. [29], as revealed by extensive numerical applications (6, 18) pertaining to the calculation of atomization energies and bond dissociation energies.

7. Conclusions

The mental subdivision of a Hartree–Fock atom into an inner core and an outer valence region leads to an amazingly simple statistics involving the eigenvalues, ε_i, of the spin orbitals. The electronic energies statistically accumulated in the core and valence regions are adequately described by $\Sigma_i N_i^c \varepsilon_i$ and $\Sigma_i N_i^v \varepsilon_i$, respectively, where N_i^c and N_i^v are the corresponding electron populations. The result $\Sigma_i N_i^v \varepsilon_i = T^v + V_{ne}^v + V_{ee}^{cv} + 2V_{ee}^{vv}$ for the valence region (with a similar equation for the core) does not depend on the number of electrons assigned to the core. This result is exact.

TABLE 9. Valence region energies of "unperturbed" atoms, with $N^c = 2$ for Li–Ne, and $N^c = 10$ for Na–Ar (au)

[a]Results deduced from $-(N^c/Z)V^v_{ne}$, using the results of Tables 1 and 2, and corrected for the core-valence exchange terms, ΣK^{cv}_{ij}.

It reflects a property of Hartree–Fock (or near Hartree–Fock) atomic orbitals. As a corollary of this property of $\Sigma_i N_i^v \varepsilon_i$, we can define the energy of the valence region as $E^v_{unp.} = \Sigma_i N_i^v \varepsilon_i - V^{vv}_{ee}$, where this valence region consists of an entangled mix-up of electrons belonging to different spin orbitals, with fractional populations defined by their densities. This description is in harmony with the fact that each electron occupies the entire atom, that its energy is represented by that of its spin orbital in its integrality, and, finally, with the usual concepts embodied in that of electron density.

This novel assignation of orbital energies to the core and valence regions of an atom and the notion of repulsion between these regions, V^{cv}_{ee}, are instrumental in the derivation of E^v, the energy that mirrors the actual removal of electrons from the valence shell. The key is in the use of Hartree–Fock identities describing the relationships between the total energy of the atom and the sum of occupied orbital energies, on one hand, and the nuclear-electronic potential energy, on the other. A combination of these relationships leads to a simple formula for E^v and establishes a clear relationship between E^v and $E^v_{unp.}$. But, unlike the latter energy, which is meaningful for any arbitrary choice of N^c, E^v is meaningful only for discrete values of N^c, namely integer core populations confined within boundaries lying in the vicinity of the minima of the radial distribution function. This result casts light on the physical involvement of the electronic shell structure in a meaningful separation of an atom into core and valence regions.

KENRO HASHIMOTO and YOSHIHIRO OSAMURA. Can. J. Chem. **70**, 547 (1992).

We have applied the analytical energy gradient method with respect to the orbital exponents for molecular self-consistent-field wave functions including the polarization functions. The gradients for Gaussian-type functions in Huzinaga–Dunning's double zeta basis set with and without polarization functions were compared for some hydrides of the first-row elements. The changes in the gradients caused by the polarization functions were observed. It was found that the polarization functions on hydrogen play a role in reducing the gradients produced in the absence of these functions. Although optimization of the exponents gives results depending on the molecules, the total energies as well as the dipole moments are insensitive to the exponent values. We could confirm that the exponents for Gaussian functions in the standard double zeta plus polarization basis set work adequately by coupling with the variational parameters for the simple hydrides even if they have gradients in the molecules.

Key words: orbital exponent, Gaussian-type functions, analytical energy gradient, molecular SCF wave function, polarization function.

KENRO HASHIMOTO et YOSHIHIRO OSAMURA. Can. J. Chem. **70**, 547 (1992).

On a appliqué la méthode du gradient de l'énergie analytique aux exposants orbitalaires des fonctions d'onde moléculaires en champ auto-cohérent, y compris aux fonctions de polarisation. Pour quelques hydrures des éléments de la première rangée, on a comparé les gradients des fonctions de type gaussien de bases double zêta de Huzinaga–Dunning avec et sans fonctions de polarisation. On a observé les changements dans les gradients, causés par les fonctions de polarisation. On a trouvé que les fonctions de polarisation affectent l'hydrogène en réduisant les gradients produits en l'absence de ces fonctions. Même l'optimisation des exposants donne des résultats qui dépendant des molécules; les énergies totales ainsi que les moments dipolaires ne sont pas sensibles aux valeurs des exposants. On a pu confirmer que les exposants des fonctions gaussiennes, dans la base standard de polarisation double zêta plus, donne des résultats adéquats en se couplant à des paramètres variationnels pour les hydrures simples, même s'ils possèdent des gradients dans les molécules.

Mots clés : exposant orbitalaire, fonctions de type gaussian, gradient de l'énergie analytique, fonction d'onde moléculaire en SCF, fonction de polarisation.

Introduction

Since Gaussian-type functions (GTF's) were introduced as basis sets for *ab initio* molecular orbital (MO) methods, many were made to obtain adequate GTF exponents in the basis functions for the precise description of the electronic wave function. The energy gradient method as well as variational and numerical optimization has often been utilized in determining the orbital exponent of the GTF's. Kari *et al.* first introduced the gradient method to develop a basis set that has uniform quality for various atoms (1). Partridge reported many basis functions using this gradient method (2). He carefully assessed the quality of the basis set by varying the number of GTF's. Faegri and Almlof continued the research by examining the efficiency of the analytical Hessian in optimization (3).

Orbital exponents for GTF's in currently available basis sets were determined to be optimum for atoms (4–6), based on the concept and methodology of the Linear Combination of Atomic Orbitals (LCAO–MO) scheme. Thus, the computation for molecules could sometimes be biased, depending on the molecules and on how the basis set was constructed (7).

It would be desirable to optimize all parameters to describe the electronic wave function in each particular system. Some attempts have been made for variational parameters, e.g., orbital exponents, not only in atoms but also in molecules (8, 9). Such an approach to obtaining the molecular basis set would be feasible if an analytical gradient were available. However, the difficulty in evaluating multicenter integrals for the products of GTF's with high angular quantum numbers has obstructed the extension of the gradient method from atoms to molecules.

The recent development of the energy gradient technique for molecular wave functions enables us to examine the extent to which gradients for atomic exponents emerge in molecular wave functions. Tonachini and Schlegel (10) first overcame the difficulty in computing the integrals by using Rys polynomials (11). In this pioneering work (10), the au-

[e]Square root of {(optimized exponent for molecule)/(standard exponent)}.

thors showed the variation in energy gradients with respect to the orbital exponents of GTF's on sulfur by comparing the S atom and HS^-, H_2S, and H_3S^+ molecules. They also demonstrated that the exponents of *d* functions vary, depending on the molecular geometries during the course of the reaction pathway (12). In their approach, however, they limit the optimization to polarization exponents only.

In our own approach (13), we use the McMurchie–Davidson formulas (14) for derivative integral evaluation. By optimizing all of the orbital exponents using this technique, we can investigate whether or not the atomic exponents work adequately in the molecular calculations. We can also study the deviation of the orbital exponents for molecules from those for atoms, caused by chemical bond formation. In the present study, we focus on the effect of the polarization function, whose exponent can only be determined by molecular calculations. We also discuss the effect of optimization of the exponents upon the value of the dipole moment, which is one of the important one-electron properties of a molecule.

Method

The analytical energy gradient method with respect to the orbital exponent is applied to GTF sets including a single polarization function for each atom. Details of the method for calculating the gradients were described in our previous paper (15).

The molecules investigated are BH_3, CH_4, NH_3, H_2O, and HF. The molecular structures of BH_3 were optimized with the double zeta (DZ) basis set (16) and those for the other molecules were taken from the literature (16–19). For comparison, these structures are the same as those used in the case without polarization functions (15).

The size of the GTF sets is (9*s*5*p*1*d*) for the first-row elements and (4*s*1*p*) for hydrogen. We did not contract the GTF's but employed the primitive functions. The initial exponents of (9*s*5*p*) functions for the first-row elements are taken from Huzinaga (20). Huzinaga's exponents of (4*s*) functions for the hydrogen atom (20) with a molecular scale factor (1.2) are also used as initial exponents. The initial exponent of the *d*-type polarization function on heavy at-

oms and that of the *p*-type polarization function on hydrogen are values reported by Dunning and Hay (21). Six *d* functions (d_{xx}, d_{yy}, d_{zz}, d_{xy}, d_{yz}, and d_{zx}) are included in a set of *d*-type polarization functions. This initial set of GTF's is one of the most frequently used basis-function sets in the double zeta plus polarization basis (DZ+P) with a contraction.

Energy gradients are calculated with respect to the natural logarithm of the orbital exponents, instead of the genuine exponents, as shown in our previous papers (13, 15). The modified quasi Newton–Raphson method proposed by Schlegel (22) is employed in optimization of the exponents.

Numerical computations were carried out with a Fujitsu FACOM M-780 computer at the computation center in the Institute of Physical and Chemical Research (RIKEN).

Results and discussion

Tables 1–5 summarize the results of the exponent optimization for BH_3, CH_4, NH_3, H_2O, and HF molecules, respectively. Each of the tables contains the gradients for atoms and molecule, optimized exponents, and their molecular scale factors relative to the standard exponents. We tabulated the results for each molecule because the correspondence between the standard exponents and the molecular exponents is important. However, we had better look at the items in the tables comparing the molecules to make the discussion clear and to understand the molecular characteristics. We will first pay attention to the gradients in the atoms.

Atomic gradients for GTF's on heavy atoms

The gradients for the standard exponents in the atoms are given in the second left column of the tables. Since we used six *d* functions as a set of polarization functions on heavy atoms, the gradients in the atom are affected by the additional *s*-type function due to the contribution from the sum of d_{xx}, d_{yy}, and d_{zz} functions. As pointed out in the previous paper (15), the standard exponents without the *d*-type polarization function are shown to be well optimized for B and C atoms, while not so much for N, O, and F atoms. Addition of the *d*-type function generally allows the gradients for the *s*-type functions to increase in all of the first-row atoms we examined. This increment in the gradients for *s*-type functions in atoms can be seen not only in the exponents of

diffuse *s*-type functions but also in those of some *s*-type functions with a middle range of exponent values for C, N, O, and F atoms. On the other hand, the gradients for *p*-type functions in the atom do not change much in the presence of the *d*-type polarization function, irrespective of the kind of atom. The atomic gradient of the *d*-type function itself is generally small in all these atoms.

Gradients in hydride molecules

Gradients for the standard exponent in the hydride molecules are shown in the third column of Tables 1–5. The gradients in the molecule depend not only on the molecule itself but also on each exponent value of the GTF's. It is convenient for our discussion to divide the *s*-type GTF's into three groups according to their exponent values. One is the *inner* group of three GTF's with large exponents, another is the *middle* group of three GTF's with middle values of exponents, and the rest belong to the *outer* group of three GTF's whose exponents are small. Almost all of the gradients for the outer group functions are found to be reduced or kept small by adding the *d*-type polarization function in all molecules. Because adding the *d*-type polarization function does not reduce the gradients for the middle group functions so much as for the outer group functions, we observe a large gradient for the middle group GTF's instead of for the outer ones, in the presence of the polarization function. The molecular gradients for the inner group functions with large exponents are small with and without the *d*-type function.

The gradient values of *p*-type functions are calculated to be fairly large in a molecule without a polarization function. We found that the large gradients of the *p*-type functions decreased by adding the *d*-type function in BH_3 and CH_4 molecules. In NH_3, the molecular gradients for only two diffuse *p*-type functions become small with the *d*-type function. In H_2O and HF molecules, the absolute value of the gradients for *p*-type functions becomes greater with the *d*-type function than for those without the polarization function. The gradients for the *d*-type function increase from atomic gradients in CH_4, H_2O, and HF molecules. They are, however, still small compared to other large gradients in *s* and *p* functions.

The gradients for four *s*-type functions on hydrogen are larger in NH_3, H_2O, and HF molecules than in BH_3 and CH_4 when the *p*-type polarization function is not included on the H atom. The *p*-type polarization function plays a role in conspicuously reducing the gradients for *s*-type functions on

hydrogen in all of the molecules we studied, although the gradient for the *p*-type polarization function itself is small throughout these hydrides.

Optimized exponents in molecules and their scale factors

The optimized exponents in hydrides and their scale factors relative to the standard exponents are presented in the two right columns of Tables 1–5. The scale factor is defined as the square root of the ratio of the molecular exponent over the standard exponent. It is convenient for us to use scale factors rather than the molecular exponents themselves in order to see the change in the exponent values from atom to molecule. A scale factor greater than 1.0 means that the GTF shrinks compared to the standard function, while the GTF with a scale factor less than 1.0 diffuses as a result of the optimization in the molecule.

Throughout Tables 1–5, we note a general trend for the scale factors of *s*-type functions on heavy atoms. The scale factor of *s*-type functions whose exponents are smaller than that of the added *d*-type function becomes less than 1.0. When the exponent values of the *s*-type functions are larger than that of the *d*-type function, the scale factors for *s*-type functions turn out to be greater than 1.0 by the optimization. This result clearly indicates that the interaction between the normal *s*-type function and the extra *s*-type function involved in the six *d*-function sets is important in determining optimum values of the orbital exponents.

The scale factors of the *p*-type functions depend on the molecules much more than those of the *s*-type functions on heavy atoms. All *p*-type functions on the B atom tend to shrink in the BH_3 molecule. The deviation of orbital exponents of the *p*-type functions from the standard values is not so large after optimization in the BH_3 molecule.

The *p*-type functions on C, N, O, and F tend to diffuse in the order CH_4, NH_3, H_2O, and HF molecules. The largest change in orbital exponents of the *p*-type function is observed in the case of NH_3. The most diffuse function tends to diffuse more than the other four *p*-type functions except in the BH_3 molecule.

The optimized values of the orbital exponents of the *d*-type polarization functions on heavy atoms are 0.5799, 0.8435, 0.7992, 1.0477, and 1.1710 for BH_3, CH_4, NH_3, H_2O, and HF, respectively.

The scale factors obtained for the *s*-type functions on hydrogen are greater than 1.0 by optimization in all the hydrides. The shrinkage is larger in NH_3, H_2O, and HF

molecules than in BH_3 and CH_4 molecules. The optimized exponents of *p*-type polarization functions on hydrogen atoms are 1.0193, 1.2224, 1.0916, 0.6673, and 0.7661 for BH_3, CH_4, NH_3, H_2O, and HF, respectively. These results clearly indicate that the orbital shape of the hydrogen atom strongly depends on each molecular environment.

General discussion on exponent optimization

Here, we will discuss some other features commonly seen in the molecules examined.

Firstly, the total energy is not very sensitive to the exponent optimization. Energy lowering by exponent optimization without the polarization function is calculated to be 1.00, 1.28, 1.78, 1.38, and 1.25 kcal/mol for the BH_3, CH_4, NH_3, H_2O, and HF molecules, respectively (15). When the polarization function is included in the optimization, the largest improvement in energy (3.05 kcal/mol) is obtained in the case of the HF molecule. The small improvement in the energy might be because the GTF's used are uncontracted.

Secondly, the shrinking and diffusing of the GTF's by molecular optimization cannot be predicted by the sign of their initial gradients, as is also true for the case without polarization function (15). Moreover, the largest deviation from 1.0 in the scale factors shown in Tables 1–5 is not always found for the exponent whose initial gradient is largest. This means that the exponents are strongly coupled in the optimization procedure.

Effect of exponent optimization on dipole moment

To see how much the electron distribution or density is improved by exponent optimization, we calculated the dipole moments for NH_3, H_2O, and HF molecules with standard and molecular optimized basis functions. The dipole moments are evaluated both with the optimized geometries and with the experimental structures. The results are summarized in Tables 6–8. The values obtained with the DZ and DZ+P contracted basis functions are also presented.

The dipole moments at the experimental geometries calculated without polarization functions deviate greatly from

the experimental values (23–25) for all three molecules. They moved closer to the experimental values, by about 0.31–0.45 debye, by adding the polarization functions. It is very interesting that the change in dipole moments by exponent optimization is one order smaller than that obtained by adding the polarization functions without optimizing the exponents. We can also see that the polarization function is indispensable for geometry optimization, while the structures are rather insensitive to the exponent optimization when a high enough number of atomic optimized GTF's are uti-

lized. This result indicates that the wave function is greatly improved by the augmentation of polarization functions rather than the electron redistribution being optimized by the orbital exponents. Furthermore, it is important that our results show the standard exponents in the DZ+P basis set work adequately, without exponent optimization in molecules, to obtain the property as well as the electronic energy within this size of the basis functions.

Concluding remarks

We have applied the analytic energy gradient method with respect to the orbital exponent of GTF's for molecular SCF wavefunctions. In the present study, we have focused on the effect of polarization functions in order to see how the energy gradients change from those without polarization functions. We have observed that the gradients vary not only for small exponents but also for medium and large exponents when the polarization functions are included. The change in gradient values by adding the polarization function depends on the molecules. The coupling between the six *d*-type functions and the *s*-type functions plays a role in changing the gradients for both *s*-type and *p*-type functions. On the other hand, the *p*-type polarization function on the hydrogen atom tends to reduce the gradients for the original *s*-type GTF's.

The interaction between the six *d*-type functions and the *s*-type functions is found to be important in determining the optimum orbital exponents for molecules. Scale factors indicate how the exponents change from the atomic exponents. The scale factors for *s*-type functions on hydrogen indicate that the optimum orbital exponents depend on the molecular environment of the hydrogen atom. However, it is very interesting that the molecular energies as well as the dipole moments are confirmed to be quite insensitive to exponent optimization. The effect of the polarization functions is very important in describing the optimum electron distribution in the molecule so that the expectation values of the wave functions are much improved. Consequently, our present results support the suitability of the exponents in the Huzinaga–Dunning double zeta plus polarization basis set for simple hydride molecules with stable structures.

It is also important to know whether the basis functions work properly for any molecular structure. Sola *et al.* demonstrated recently, by optimizing only the exponents of the polarization functions (12), how the exponents of the polarization functions change at the transition state of the isomerization reaction of H_2SO and CH_3SH. Although it may be costly to optimize all the exponents, it is effective to use the gradient method to investigate how they couple with each other depending on structural changes in the molecules and whether their deficiency is acceptable even for unusual structures.

The effect of multiple-polarization functions for various molecules is more interesting and its importance will grow, since multiple polarization functions have been increasingly utilized for simple molecules in recent *ab initio* MO calculations. A study designed to give the optimum exponents of double polarization functions is now in progress and the results will be presented in a separate paper.

ANDRÉ D. BANDRAUK and HAI SHEN. Can J. Chem. **70**, 555 (1992).

A new method of splitting exponential operators is proposed for the exponential form of the operator solution to the time-dependent Schrödinger equation. The method is shown to hold for any desired accuracy in the time increment. A comparison of different algorithms is made as a function of accuracy and computation time.

Key words: splitting operator, Fast Fourier Transform (FFT), Schrödinger equations.

ANDRÉ D. BANDRAUK et HAI SHEN. Can. J. Chem. **70**, 555 (1992).

On propose une nouvelle méthode pour diviser les opérateurs exponentiels de la forme exponentielle de la solution basée sur l'opérateur de l'équation de Schrödinger. On démontre que la méthode possède la précision désirée lors de l'augmentation du temps. On présente une comparaison des divers algorithmes en fonction de leur précision et de leur temps de calcul.

Mots clés : méthode pour diviser les opérateurs, FFT, équations de Schrödinger.

1. Introduction

Recent developments in laser physics and laser chemistry have pointed out the need for efficient algorithms to solve the time-dependent Schrödinger equation (1–4). In general, in describing molecular multiphoton transition, we have recourse to a linear parabolic partial differential equation, which can be written as

$$[1]\quad i\hbar\frac{\partial\varphi_n(\boldsymbol{R},t)}{\partial t} = -\frac{\hbar^2}{2m}\frac{\partial^2\varphi_n(\boldsymbol{R},t)}{\partial\boldsymbol{R}^2} + V_{nn}(\boldsymbol{R})\varphi_n(\boldsymbol{R},t) + \sum_{n'} V_{nn'}(\boldsymbol{R},t)\varphi_{n'}(\boldsymbol{R},t)$$

In the above, $V_{nn}(\boldsymbol{R})$ is the time-independent field free molecular (electronic) potential and $V_{nn'}(\boldsymbol{R},t)$ is the time-dependent electromagnetic–molecule interaction,

$$[2]\quad V_{nn'}(\boldsymbol{R},t) = \boldsymbol{\mu}_{nn'}(\boldsymbol{R})\boldsymbol{E}(\boldsymbol{r},t)$$

$\boldsymbol{R}$ is a molecular coordinate whereas $\boldsymbol{r}$ is the electromagnetic pulse coordinate, and $\mu_{nn'}(\boldsymbol{R})$ is a transition moment representing transitions between different electronic states of quantum number n.

In refs. 5 and 6, we developed a fourth order accurate formula for splitting the exponential operator $\exp[\lambda(A + B)]$ and used it to solve the time-dependent Schrödinger equation. The comparison of this new method and the standard second order accurate method (7–9) showed the new method to be more accurate and more efficient.

In the present note we wish to present an improved scheme for solving numerically the linear parabolic equation [1] to high order by the splitting exponential operator method. We extend here our previous work in refs. 5 and 6. The new improved method can give any desired order of accuracy. A comparison will be made of the order of the accuracy versus computation time (CPU).

[1]Author to whom correspondence may be addressed.

2. Symmetric formulas for splitting exponential operators $\exp[\lambda(A + B)]$

The most general method of splitting exponential operators is based on the Trotter product form for the operator $\exp[\lambda(A + B)]$ (10–15),

$$[3]\quad e^{\lambda(A+B)} = \lim_{m\to\infty}(e^{\lambda A/m}\, e^{\lambda B/m})^m$$

From this follows the most currently used standard *second order* accurate formula (7–9),

$$[4]\quad e^{\lambda(A+B)} = S_2(\lambda) + C_3\lambda^3 + O(\lambda^4)$$

where

$$[5]\quad S_2(\lambda) = e^{\lambda A/2}\, e^{\lambda B}\, e^{\lambda A/2}$$

and C_3 is some remnant combination of commutators of A and B (5, 6).

We showed previously that eq. [4] can be expressed as

$$[6]\quad e^{\lambda(A+B)} = e^{\lambda s(A+B)}\, e^{\lambda(1-2s)(A+B)}\, e^{\lambda s(A+B)}$$

so that higher order accuracy is obtained, i.e., by substituting eq. [5] in eq. [6],

$$[7]\quad e^{\lambda(A+B)} = S_2(s\lambda)S_2((1-2s)\lambda)S_2(s\lambda) + C_3\lambda^3(2s^3 + (1-2s)^3) + O(\lambda^4)$$

To get third order accuracy, the leading error term $O(\lambda^3)$ must vanish, i.e.,

[8] $2s^3 + (1 - 2s)^3 = 0$

Thus, if s is a root of eq. [8], we can obtain

[9] $e^{\lambda(A+B)} = S_3(\lambda) + C_4\lambda^4 + O(\lambda^5)$

where we have now defined

[10] $S_3(\lambda) = S_2(s\lambda)S_2((1 - 2s)\lambda)S_2(s\lambda)$

Equation [10] gives therefore a third order accurate formula for the exponential operator [3]. By iterating [7] further, we can obtain the general iteration:

[11] $e^{\lambda(A+B)} = S_{n-1}(s\lambda) + C_n\lambda^n + O(\lambda^{n+1})$

from which follows, by one more iteration, that

[12] $e^{\lambda(A+B)} = S_n(s\lambda) + O(\lambda^{n+2})$

where now

[13] $S_n(\lambda) = S_{n-1}(s\lambda)S_{n-1}((1 - 2s)\lambda)S_{n-1}(s\lambda)$

and s is a root of the more general equation

[14] $2s^n + (1 - 2s)^n = 0$

In ref. 5, we pointed out that if eq. [14] does not have real roots, the formula $S_n(\lambda)$ will not preserve unity since $\lambda = i\Delta t$, a complex number. This will create divergent exponentials in any iteration with concomitant loss of accuracy. One can shown that eq. [14] always has a real root when n is *odd*, i.e., for such cases, the symmetric expansion [13] for S_n is always unitary.

In summary, we have developed the iterations,

[15] $e^{\lambda(A+B)} = S_{2n-1}(\lambda) + O(\lambda^{2n+1}), \qquad n = 2,3, \ldots$

where

$$S_2(\lambda) = e^{\lambda A/2}\, e^{\lambda B}\, e^{\lambda A/2}$$

$$S_n(\lambda) = S_{n-1}(s\lambda)S_{n-1}((1 - 2s)\lambda)S_{n-1}(s\lambda)$$

and s is the real root of equation

$$2s^{2n-1} + (1 - 2s)^{2n-1} = 0$$

The symmetric decomposition of the general exponential operator [13] by the above algorithm furnishes, by construct, unitary approximations to propagator $e^{-iH\Delta t}$ to any order of accuracy, $O(\lambda^{2n+1})$, in the time increment Δt when we choose $\lambda = i\Delta t$, as shown in the next section.

3. Formal solution of TDSE and higher order propagation

We consider the Schrödinger equation

[16] $i\hbar \dfrac{\partial\varphi(x,t)}{\partial t} = H\varphi(x,t)$

If we choose a *time-independent* Hamiltonian,

[17] $H = -\dfrac{\hbar^2}{2m}\dfrac{\partial^2}{\partial x^2} + V(x)$

then the formal solution of eq. [16] is

[18] $\varphi(x,t + \Delta t) = e^{-i\Delta tH/\hbar}\varphi(x,t)$

We can therefore apply eq. [15] to solve [16] with [17] numerically with any desired accuracy in the time increment Δt.

On the other hand if one is dealing with a *time-dependent problem*,

[19] $H = -\dfrac{\hbar^2}{2m}\dfrac{\partial^2}{\partial x^2} + V(x,t)$

the formal solution of eq. [16] become more complicated. The general time-dependent solution can now be written (16),

[20] $\varphi(x,t + \Delta t) = U(t + \Delta t,t)\varphi(x,t)$

where

[21] $U(t + \Delta t,t) = T\exp\left[-\dfrac{i}{\hbar}\int_t^{t+\Delta t} H\, dt\right]$

and T is the time ordering operator. One can truncate eq. [20] and obtain

[22] $U(t + \Delta t,t) = \exp\left[-\dfrac{i}{\hbar}\int_t^{t+\Delta t} H\, dt\right] + D_3(t)(i\Delta t)^3 + D_4(t)(i\Delta t)^4 + \ldots$

Since $U(t + \Delta t,t)$ is unitary, we have at all time

[23] $U(t + \Delta t,t)U^\dagger(t + \Delta t,t) = 1$

Since the operator $\exp[-i/\hbar \int_t^{t+\Delta t} H\, dt]$ is also unitary, then by comparing the two unitarity conditions, one finds that any approximation to $U(t + \Delta t,t)$ has always odd order in the leading error, i.e.,

[24] $U(t + \Delta t,t) = \exp\left[-\dfrac{i}{\hbar}\int_t^{t+\Delta t} H\, dt\right] + D_3(t)(i\Delta t)^3 + D_5(t)(i\Delta t)^5 + \ldots$

Clearly, by using S_2, eq. [4], to approximate $U(t + \Delta t,t)$, we will obtain only a second order accurate propagation scheme.

We will now develop a propagation technique based on the group property of the operator $U(t + \Delta t,t)$ and eq. [15] to solve the Schrödinger equation for time-dependent potentials, in order to obtain high order accurate algorithms.

We divide $[t,t + \Delta t]$ into three subintervals $[t,t + s\Delta t]$, $[t + s\Delta t, t + (1 - s)\Delta t]$, and $[t + (1 - s)\Delta t, t + \Delta t]$. On each subinterval, we use eqs. [22] and [4]. Thus for the first interval we obtain

---

[25] $U(t + s\Delta t,t) = \exp\left[-\dfrac{i}{\hbar}\int_t^{t+s\Delta t} H\, dt\right] + D_3(t)(s\Delta t)^3 + O(\Delta t)^5$

$$= S_2(s\Delta t,t) + (C_3(t) + D_3(t))(s\Delta Dt)^3 + O(\lambda^5)$$

where

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

$$[26]\quad S_2(s\Delta t,t) = e^{-is\Delta tA/2\hbar}\, e^{-iB(t)/\hbar}\, e^{-is\Delta tA/2\hbar}, \qquad A = -\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2}, \qquad B(t) = \int_t^{t+s\Delta t} V(x,t)\, dt$$

For the second interval, one has

$$[27]\quad U(t + (1-s)\Delta t, t + s\Delta t) = \exp\left[-\frac{i}{\hbar}\int_{t+s\Delta t}^{t+(1-s)\Delta t} H\, dt\right] + D_3(t)((1-2s)\Delta t)^3 + O(\Delta t)^5$$
$$= S_2((1-2s)\Delta t, t + s\Delta t) + (C_3(t) + D_3(t))((1-2s)s\Delta t)^3 + O(\Delta t)^5$$

where

$$S_2((1-2s)\Delta t, t + s\Delta t) = e^{-i\Delta t(1-2s)A/2\hbar}\, e^{-iB(t+s\Delta t)}\, e^{-i(1-2s)\Delta tA/2\hbar}$$

Finally for the last interval one obtains the equation,

$$[28]\quad U(t + (1-s)\Delta t, t + \Delta t) = \exp\left[-\frac{i}{\hbar}\int_{t+(1-s)\Delta t}^{t+\Delta t} H\, dt\right] + D_3(t)(s\Delta t)^3 + O(\Delta t)^5$$
$$= S_2(s\Delta t, t + (1-s)\Delta t) + (C_3(t) + D_3(t))(s\Delta Dt)^3 + O(\Delta t^5)$$

where

$$S_2(s\Delta t, t + (1-s)\Delta t) = e^{-is\Delta tA/2\hbar}\, e^{-iB(t+(1-s)\Delta t)/\hbar}\, e^{-is\Delta tA/2\hbar}$$

By the group property of $U(t + \Delta t,t)$ we have

$$[29]\quad U(t + \Delta t,t) = U(t + s\Delta t,t)U(t + (1-s)\Delta t, t + s\Delta t)U(t + \Delta t, t + (1-s)\Delta t)$$

and substituting eqs. [25], [27], and [28] into eq. [29], we obtain

$$[30]\quad U_3(t + \Delta t,t) = S_2(s\Delta t,t)S_2((1-2s)\Delta t, t + s\Delta t)S_2(s\Delta t, t + (1-s)\Delta t) + O(\Delta t^5)$$

where s is the real root of eq. [8].

The above procedure gives a fourth order accurate algorithm to calculate the evolution operator U for the time-dependent Schrödinger equation, using products of these second order accurate propagators. The results holds for both time-dependent and time-independent Hamiltonians. Iterating eq. [30] according to the scheme explicited in eq. [15] will generate schemes of any desired accuracy in the time increment Δt.

4. Numerical comparison

We previously compared the second and fourth order accurate splitting operators [26] and [30]. The latter is always more accurate (5, 6). In the preceding two sections we obtained higher order accurate formulas. Now we try to find the optimum algorithm with respect to maximum accuracy and minimum computation time (CPU). First, we note that the second order formula, S_2 in eq. [5], has three exponential operators; the fourth order one, S_3 in eq. [10], has seven exponential operators; the sixth order one, S_5, has 19 exponential operators, and the eighth order one, S_7, has 55 exponential operators. Thus from the eighth order formula, one does not seem to have practical algorithms due to the growing number of exponential operators.

We consider eq. [18] (we set $m = \hbar = 1$) with $V(x) = x^2$ as a test. This *time-independent* harmonic oscillator model has an exact ground state solution,

$$[31]\quad \varphi(x,t) = \left[\frac{\sqrt{2}}{\pi}\right]^{1/4} \exp\left[\frac{-(x^2 + it)}{\sqrt{2}}\right]$$

We solved this problem numerically using the various exponential splitting schemes presented in Sect. 2, using Fast Fourier Transform techniques (FFT) for the exponential of the Laplacian. All reported calculations were performed in an IBM RISC 6000/530 workstation (10 megaflop performance). In Fig. 1 a detailed comparison is presented of the L^2 errors (defined as: L^2 error = $(\Delta x \Sigma e_i^2)^{1/2}$, $e_i = |s^n - s^r|$ where s^n is a numerical solution and s^r is an exact solution) of the amplitudes of wavefunctions as a function of CPU computation time (seconds).

We see directly that the second order accurate formula S_2 (3rd order error) takes much CPU time for high accuracy. The eighth order accurate expansion S_7 is also not efficient because of too many exponential operators. So we focus on the fourth (S_3) and sixth (S_5) order accurate formulas. In the high accurate range (about 10^{-3}), the sixth order formula S_5 is better than the fourth one S_3. In view of the numerical results of Fig. 1, in general, the sixth order formula S_5 seems to be the optimum method, i.e., with minimum CPU seconds one obtains the highest accuracy. In practice, if a problem does not require high accuracy, the fourth order accuracy formula S_3 seems to be preferred to the sixth order one (seventh order error), S_5.

We next solve eq. [20] ($m = \hbar = 1$) with $V(x,t) = x^2 + x * \sin(t)$, i.e., the forced harmonic oscillator, using 2nd, 4th, 6th order accurate formulas S_2, S_3, S_5. We compare with these numerical results, the exact solution to eqs. [16] and [19] for an initial vibrational ground state (17),

$$[32]\quad \varphi(x,t) = \left[\frac{\sqrt{2}}{\pi}\right]^{1/4} \exp\left[-\frac{(x - \xi(t))^2}{\sqrt{2}}\right] * \exp\left[\frac{i\dot{\xi}(t)}{\sqrt{2}} + \dot{\xi}(x - \xi) + \int_0^t L\, dt\right]$$

where

$$\xi(t) = \sqrt{2}\,[\sin(\sqrt{2}t) - \sqrt{2}\sin(t)]/2$$

and

$$L = \frac{1}{2}\dot{\xi}^2 - \xi^2 + \xi \sin(t)$$

L is the Lagrangian of the classical forced harmonic oscillator. This time-dependent problem was solved numerically in Sect. 3 using the exponential splitting scheme for the propagator U.

In Tables 1–3 we present, for various orders of accuracy in the time increments, the L^2 errors for the amplitude and the phase of the numerical time-dependent wavefunctions as a function of the computation time in CPU seconds. These tables show that the sixth order accurate formula S_5 requires fewer CPU seconds and gives the best results. For instance, when the errors of the amplitude and phase are about 10^{-3} and 10^{-2} respectively, the second order formula S_2 requires 739 CPU seconds (Table 1), the fourth order one S_3 re-

quires 322 s (Table 2), and the sixth, S_5, gives $0.85*10^{-4}$ in amplitude and $0.5*10^{-3}$ in phase using only 235 s (Table 3).

When we double the time interval from [0,600] to [0,1200], the results for 2nd, 4th, and 6th order accurate formulas in Tables 4–6 show that accumulations of the error in the sixth order formula are fewer than those of the other two lower order schemes. Therefore in long time propagation the sixth order formula offers the best possible algorithm in terms of maximum accuracy in amplitude and phase for the least CPU time.

In conclusion, we have shown that the sixth order accurate formula S_5 as given by eq. [14] allows explicit exponential numerical integration of parabolic partial differential equations, such as the time-dependent Schrödinger equation, with sixth order accuracy, i.e., errors depend on $(\Delta t)^7$. This method is shown to be superior in accuracy over the second and fourth order accurate methods. The second order scheme is the most frequently used method in current time-dependent problems (7–9). For high order accuracy ($\simeq 10^{-3}$), the sixth order operator, S_5, is optimum. For low order accuracy ($\simeq 10^{-2}$), the fourth order accurate operator S_3, previously proposed by us (5, 6), seems to be a more useful algorithm (see Fig. 1). Both methods are always superior to the standard second order accurate methods based on S_2 (7–9). We are currently examining the efficiency of these algorithms for coupled equations, as occur in multiphoton electronic transitions (1). Of note is that the present algorithms are always unitary as compared to other efficient propagation schemes that are not unitary, such as Chebyshev polynomial expansions (18).

Received September 19, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

NATHALIE GODBOUT, DENNIS R. SALAHUB, JAN ANDZELM, and ERICH WIMMER. Can J. Chem. **70**, 560 (1992).

Gaussian-type orbital and auxiliary basis sets have been optimized for local spin density functional calculations. This first paper deals with the atoms boron through neon. Subsequent papers will provide a list through xenon. The basis sets have been tested for their ability to give equilibrium geometries, bond dissociation energies, hydrogenation energies, and dipole moments. These results indicate that the present optimization technique yields reliable basis sets for molecular calculations.

Key words: Gaussian basis sets, density functional theory, boron–neon, geometries, energies of reactions.

NATHALIE GODBOUT, DENNIS R. SALAHUB, JAN ANDZELM et ERICH WIMMER. Can. J. Chem. **70**, 560 (1992).

Des bases orbitalaires et auxiliaires de type gaussienne ont été optimisées pour des calculs de la fonctionelle de la densité de spin locale. Ce premier article étudie les atomes de bore jusqu'au néon. Des articles subséquents fourniront des bases pour tous les atomes jusqu'au xénon. Les bases ont été vérifiées pour leurs capacités à reproduire des géométries d'équilibre, énergies de dissociation de liaison, énergies d'hydrogénation et moments dipolaires. Ces résultats indiquent que la présente technique d'optimisation produit des bases fiables pour les calculs moléculaires.

Mots clés : Bases orbitalaires gaussienne, théorie de la fonctionnelle de la densité, bore–néon, géométries, énergies de réactions.

1. Introduction

1.1 General considerations

Ever since their introduction, orbital basis sets have been the subject of extensive efforts and discussions. Because of their critical role in determining the accuracy and because of computational cost, the subject of basis sets in molecular calculations continues to be of great interest. All computational approaches that solve the Schrodinger equation with the expansion method express the molecular wave functions in terms of a basis set that contains a finite number of basis functions. As mentioned in a review by Huzinaga (1), "it is this finiteness that is the cause of all the frustrations and fascinations about the basis set."

A number of reviews about basis sets have been published (2–7). The fact that there has been many a review article about the subject serves to show that the field is important and very much alive. There exists no one finite basis set for each element that is small enough to be used in molecular calculations with today's computers, yet is flexible enough to universally describe all properties. In fact, results of various degrees of accuracy are obtained depending on the choice of the basis set. The choice of the basis set is critical.

1.2 Basis set functions

Several types of functions have been proposed. The two more commonly used are the Slater-type functions (STF), introduced by Slater (8) in 1930, and the Gaussian-type functions (GTF) proposed by Boys (9) in 1950. The STO's are functions that represent the main features of the radial part of an atomic orbital. The problem in using these functions comes from the difficulty in calculating the integrals.

Boys showed that by taking GTF, complete systems of functions can be constructed appropriate to any molecule, and that the necessary integrals can be evaluated explicitly. Although they do not describe the atom as well as does the STF (a linear combination has to be used in order to represent an STO), they retain the advantage that the molecular integral formulas are straightforward to derive and to code.

The usefulness of GTF as basis functions for large-scale molecular calculations was put forward by Huzinaga (10) in 1965. He concluded that even if the number of GTF needed in the analytical Hartree–Fock expansion calculation would be larger than if STF were used, the number of GTF would not be prohibitively large. Currently, most molecular calculations are done using CGTF (Contracted Gaussian-Type Functions).

1.3 Basis sets of GTF

Various methods to obtain expansions of STO in terms of GTO have already been proposed. A variational method (11) was developed but it suffered from the difficulty of achieving true minimization because of the multiple minima problem which grew rapidly with the number of variational parameters. A least-squares method had also been proposed, Boys and Shavitt (12), but it also had the problem of multiple minima. Huzinaga (10, 13) proposed a method based on a least-squares-fit procedure that could avoid such a problem. In parallel, Pople and co-workers proposed the STO-nG method (14–18).

A method based on least-squares fitting and atomic optimisation was proposed by Tavouktsoglou and Huzinaga (19). The emphasis was put on bonding valence orbitals in order to achieve accurate molecular results. In this method,

the orbital exponents are optimized together with the contraction coefficients. While they remain at the 3G level (3 Gaussians to represent 1 STF), this was a new approach to their formation. This technique yielded very good molecular results for main group elements and succeeded with third row elements where the STO-3G basis sets had failed. This was mainly due to the fact that no least-squares fit to the STO was done and therefore the basis set did not inherit the defects of the STO. A similar contraction scheme had been proposed by Clementi and co-workers (20) but was limited to the contraction coefficients.

This method was further improved by Tatewaki and Huzinaga (21) and applied to third row transition metals. The main problem with the Tavouktsoglou and Huzinaga method (19) was that, with the limited number of Gaussian functions used, primitive Gaussians were overspent in the inner core region of the atom. Pople's method was a success in that sense since it considered the electronic distribution throughout the atom. Huzinaga's new scheme was able to achieve a proper electron distribution. Valence shell orbital energies that were quite close to those of double-zeta quality were obtained using a minimal basis set with a modest representation of the core orbitals. The authors concluded that basis sets constructed in that manner should provide good molecular results.

These minimal basis sets could be improved further for molecular calculations by splitting the valence shell orbitals into two parts in order to better describe a molecular environment, as suggested by the work of Pople and co-workers (22) and Hehre and Latham (23) with the 4-31G basis sets. The success of the method intitiated a series of articles by Huzinaga and co-workers in which basis sets were systematically prepared for the atoms helium through cadmium (24–29). A monograph by Huzinaga *et al.* (30) contains various basis sets developed in this method for all atoms of the periodic table.

1.4 Basis sets in density functional theory

The major drawback of the Hartree–Fock theory (HFT) is that it neglects electron correlation, which is known to be important for many systems including transition metal complexes, organometallic compounds, and even relatively small highly correlated molecules like FOOF (31, 32), C_2F_2 (34), and CH_3NO_2 and CH_3NH_2 (33). The HFT formally scales as N^4, N being the number of primitive basis functions, although some programs can perform as N^3 or N^2 due to the Gaussian-type decay of the localized basis sets and (or) the use of pseudospectral techniques (35, 36). When electron correlation is included, the scaling factor grows rapidly, making calculations on large molecular systems impossible unless some approximations are made to the integrals. There is growing evidence (33, 37–40) that density functional theory (DFT) (41–44) is a promising alternative to the Hartree–Fock approach (33). The DFT includes electron correlation and it scales formally as N^3. With increasing system size, the computational effort scales between N_2 and N_3, while correlated Hartree–Fock based methods giving results of similar quality scale at least with the fifth power of N. It is believed (33) that these features of molecular DTF open opportunities for the study of large and complex molecular systems that are out of reach for other *ab initio* molecular orbital methods.

Various techniques are used to solve the Kohn–Sham equations. Those techniques can use various types of functions. There have been implementations using Slater-type functions (45, 46), numerical functions (47–49), numerical functions generated from a muffin-tin potential (50, 51) plane-waves (52, 53), augmented plane-waves (54, 56), and Gaussian-type functions (57, 58). Basis set free solutions have also been introduced (59). The reason for using GTF in DFT, apart from the straight-forwardness of the integral evaluations, is that one can benefit from extensive Hartree–Fock experience.

The Gaussian-based implementation of the DFT equations relies on a variational, analytical approximation to the density. To achieve a variational fit to the density, the Coulomb energy term arising from the difference between the exact and the fitted density is minimized. This procedure was proposed by Dunlap *et al.* (58). It leads to an analytical expression for the fitting coefficients involving Coulomb-type three-index two-electron integrals. It may be noted that, with Gaussians, the Coulomb terms may be evaluated exactly, if desired, by the usual methods involving N^4 integrals.

The first implementation of DFT that used Gaussian functions (LCGTO–LSD, Linear Combination of Gaussian-Type Orbitals–Local Spin Density) employed extended uncontracted Hartree–Fock Gaussian basis sets, which inevitably limited the size of the systems that could be studied. Contracted basis sets were optimized in the LSD approximation for a series of transition metal atoms by Andzelm, Radzio, and Salahub (60) using Huzinaga's method (19, 21). It was actually found (60) that using contracted HF optimized basis sets in LSD calculations might not be appropriate since there are quite pronounced differences in the valence region between LSD and HF atoms that could influence the molecular results. Furthermore, it was shown that Hartree–Fock optimized basis sets used in DFT calculations would likely create basis set superposition errors (BSSE). Hartree–Fock optimized basis sets such as 6-31G* (61, 62) can be used in DFT calculations to give good geometries, but accurate, and economical, predictions of reaction energies require the use of DFT optimized Gaussian-type basis sets (33).

1.5 Overview of the present paper

In this first paper of a series, LSD optimized Cartesian Gaussian basis sets for boron to neon are reported and their performance in molecular calculations is discussed. For that purpose, we have used a recent implementation of the density functional Gaussian-type orbital approach, DGauss (for Density-Gaussian) (33, 34). Subsequent papers will include basis sets for atoms through xenon. Equilibrium geometries, bond dissociation and hydrogenation energies, and electric dipole moment results obtained with the proposed basis sets will be presented and compared with experimental and *ab initio* results. It seems that the present technique of optimizing LSD basis sets yields high quality double-zeta-split-valence + polarization (DZVP) basis sets.

2. Theory

2.1 Atomic numerical calculation

The optimization scheme of the contracted LSD-VWN (Vosko, Wilk, and Nusair (63)) basis sets, based on the Huzinaga method (21) as implemented by Andzelm, has been described elsewhere (60). Only an abbreviated version will be given here. The atomic numerical calculations were done as a first iteration because they provide an exact solution to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

the LSD equations and therefore a reference for the atomic calculation with an orbital basis set. The radial Schrödinger equation can be written in the following way:

$$[1] \quad (-1/2\nabla_i^2 + V_i(r))R_{nl}(r) = \epsilon_i R_{nl}(r)$$

where ϵ_i is the orbital energy, $R_{nl}(r)$ is the radial function, and $V_i(r)$ is the total potential. There is one radial function attributed for each sub-shell. For example, for carbon, there are three radial functions: $R_{1s}(r)$, $R_{2s}(r)$, and $R_{2p}(r)$ and they are obtained by solving [1].

2.2 Atomic calculation with an orbital basis set

In the analytical SCF (Self-Consistent Field) method, the radial functions are approximated by a linear combination of basis functions denoted by $s_1(r),s_2(r),\ldots,s_{Ms}(r);p_1(r),p_2(r),\ldots,p_{Mp}(r);d_1(r),d_2(r),\ldots,d_{Md}(r)$ for s, p, and d symmetry respectively.

The radial functions can then be written in the following way:

$$[2] \quad R_{ns}(r) \simeq \sum_{i=1}^{M_s} c_{ns,i}s_i(r)$$

$$[3] \quad R_{np}(r) \simeq \sum_{i=1}^{M_p} c_{np,i}p_i(r)$$

$$[4] \quad R_{nd}(r) \simeq \sum_{i=1}^{M_d} c_{nd,i}d_i(r)$$

These radial functions can approach those obtained numerically if the basis functions and the length of the expansions M_s, M_p, and M_d are well chosen. Theoretically there is an optimal form for these basis functions. It can be obtained by expressing it as a linear combination of simple functions, the primitives. The primitives chosen for this work, as mentioned in the introduction, are GTF,

$$[5] \quad g_s(\alpha;r) \sim e^{-\alpha r^2}$$

$$[6] \quad g_p(\alpha;r) \sim re^{-\alpha r^2}$$

$$[7] \quad g_d(\alpha;r) \sim r^2e^{-\alpha r^2}$$

The CGTF are then defined as

$$[8] \quad s_i(r) = \sum_{k=1}^{K_{si}} d_{si,k}g_s(\alpha_{si,k};r)$$

$$[9] \quad p_i(r) = \sum_{k=1}^{K_{pi}} d_{pi,k}g_p(\alpha_{pi,k};r)$$

$$[10] \quad d_i(r) = \sum_{k=1}^{K_{di}} d_{di,k}g_d(\alpha_{di,k};r)$$

where K_{si}, $d_{si,k}$, and $\alpha_{si,k}$ are the parameters to be varied. For example, substituting the s basis function in eq. [8], the radial s function in eq. [2] becomes

$$[11] \quad R_{ns}(r) \simeq \sum_{l=1} a_{ns,l}g_s(\alpha_l;r)$$

where $R_{ns}(r)$ are the approximate functions. Once the size of the K_{si} expansions has been chosen, the optimization of the atomic orbital basis set is done by optimization of the exponents and linear coefficients so as to minimize the total atomic energy.

For example, the procedure to optimize an orbital basis set for carbon can be described as follows. If the $K2s(2)2p(2)$ electronic configuration is approximated using a (63/3) basis set, there are 6, 3, and 3 GTO used to represent the s_1, s_2, and p_1 CGTO (Contracted Gaussian-Type Orbital) of carbon respectively. First, the $s_1(r)$ basis function is varied so as to minimize the energy while keeping the $s_2(r)$ and $p_1(r)$ frozen, that is, the exponents and coefficients are not varied. The $s_2(r)$ function is then varied while the others are kept frozen. This process is repeated until consecutive calculations do not produce any improvement in the total energy within 10^{-5} a.u. Most of the computing time was spent on the core orbitals as this is where most of the energy resides. The Hartree–Fock optimized basis sets (30) were used as the starting basis sets.

In ref. 60, a (4333/43/41+) expansion pattern was chosen for all the first row transition metal atoms. This choice was based on the orbital energies and molecular calculations as it fulfilled reasonable requirements of accuracy and economy. In the present work, three expansion patterns, which differ in the number of primitives used for the core orbitals, were optimized: (63/5) for boron through neon, (73/6) for boron through fluorine, and (83/7) for carbon and fluorine. The augmented number of primitive functions for the core orbitals is expected to reduce the BSSE. The orbital basis for hydrogen (Table 1) was derived from a least-squares fit to numerical LSD results followed by scaling by the usual factor (1.44, which corresponds to 1.2 for a hydrogenic orbital (64)).

The basis sets are optimized as minimal basis sets but they are decontracted for molecular calculations. For example, the (63/5) set was split to a (621/41) set. To further improve the molecular results, a d polarization function was added and the basis set would become a (621/41/1*) set. The polarization functions were chosen from the previous experience in LCGTO-LSD calculations and from Pople's 6-31G* basis sets. This brings the basis sets to the quality of DZVP for the valence electrons.

3. Results and discussion

3.1 Basis sets and orbital energies

The LSD-VWN optimized orbital basis sets are shown in Tables 1–4. The basis sets found in these tables are as they were optimized, except for the d polarization functions, which was not optimized, and the hydrogen basis set that was decontracted as it was used. The electronic configurations of the atoms are $K2s^22p^n$ where n takes the value 1–6 when going from boron to neon.

The orbital energies as a function of the expansion pattern are shown in Table 5. The orbital energies calculated with the (63/5) basis sets are in very good agreement with

the ones calculated numerically and the ones with the (73/6) are in even better agreement. They are all calculated higher in energy than the numerical ones. This is also the case for the (73/6) set with the exception of the $1s\downarrow$ orbitals for boron, carbon, nitrogen, and fluorine, which are lower in energy. The average difference between the orbital energies calculated with an expansion and numerically ($\bar{x}$) along with the standard deviations are shown in Table 5. The errors in the orbital energies for the (63/5) set are in the tenth of an eV range for both valence and core levels. We would therefore expect a good valence representation for most purposes, and also a small BSSE. The errors are even smaller for the (73/6) set. The (83/7) set, for fluorine, leads to some further improvement but probably not enough to justify the additional expense. Finally, the total energy of the system decreases with the size of the expansion as a better description of the atoms is provided. With these results in mind, we expect that these basis sets will perform well in molecular calculations.

3.2 *Auxiliary sets*

Besides the orbital basis sets, fitting basis sets have to be introduced to approximate the electron density and the exchange-correlation potential and energy. Sambe and Felton (57) first proposed fitting the electron density and the exchange-correlation potential, thereby obtaining a method that scaled as N^3 rather than N^4. The fit to the electron density was later made variational by the work of Dunlap *et al.* (58). The electron density and exchange-correlation potential are expanded in auxiliary sets of Gaussian-type basis functions. The expansion of the *s*-, *p*-, and *d*-type uncontracted Gaussians provides a flexible enough representation of the atomic density provided the variational method of fitting is chosen. As for the exchange-correlation terms, the determination of the expansion coefficients has to be carried out numerically using a grid. The fit to the electron density is done analytically.

These auxiliary sets are derived from the orbital basis sets, according to a procedure similar to that developed by Dunlap. The smallest exponent of the orbital set is used to start the expansion for the electron density set. Since the charge density is the sum of the squares of the molecular orbitals, this small exponent is multiplied by two. It was found that an economical expansion could be built, to represent the density well, by using an even-tempered expansion for the lowest $n - 1$ exponents, and then breaking the even-tempered sequence for the tightest exponent. The auxiliary set is built using *s*-type functions and blocks of *s*-type, *p*-type, and *d*-type functions with shared exponents. This facilitates the calculation of molecular integrals. For carbon-like atoms,

the use of three *s*-type and three *p*-type functions having the same exponents in addition to four *s*-type functions was found to work well. In our notation, this corresponds to a (4,3;4,3) auxiliary set where the semi-colon separates the charge density from the exchange correlation. The resulting set is shown in Table 6. The same pattern is used for the exchange-correlation set. It is built from the electron density set by dividing the exponents by 3 since the exchange correlation goes essentially as $\rho^{1/3}$ (58).

The auxiliary sets shown in Tables 6 and 7 were made to be used with the (63/5) and the (73/6) orbital sets respectively. Each of the sets in Table 7 have one more *p*- and *d*-type function. Typically, the calculations were performed with triple-zeta *p*- and *d*-type fitting sets, i.e., (4,3;4,3). It was found (Dixon in ref. 33) that quadruple-zeta sets do not change molecular results significantly.

3.3 *Equilibrium geometries*

The LSD optimized basis sets presented in this paper have already been successfully used in LSD (and NLSD, Non-LSD) calculations by several authors to study fluorinated methanes (Dixon *et al.* in ref. 33), a methylamine complex (Hill *et al.* in ref. 33), nitro compounds (Redington and Andzelm in ref. 33), organic molecules (Andzelm in ref. 33), and many small organic compounds (34) as a part of the validation of the DGauss code to study various properties such as equilibrium geometries, vibrational frequencies, energetics of different types of reactions, and electric dipole moments. For completeness, some of these results will also be shown in the present paper.

The (63/5) basis set pattern was chosen for the present calculations as we initially hoped it would become the default pattern for DGauss. From other studies, this basis set seemed, at least on paper, to be a good compromise between economy and quality. In ref. 33, Dixon *et al.* tested these LSD basis sets as a function of the number of primitive functions for the core orbitals and the expansion pattern (DG-1 to DG-9 in their notation) for the study of isodesmic reactions for fluoromethanes. Hartree–Fock optimized 6-31G** and 6-311G** basis sets were also included in the study. Their finding was that all the levels predict about the same bond distances but that the LSD bonds calculated with the Hartree–Fock basis sets come out shorter, but still they are respectable. This is in agreement with the statement by Andzelm (in ref. 33) that Hartree–Fock basis sets used in DFT calculations lead to accurate molecular geometries for this class of molecules (see Redington in ref. 33).

Andzelm and Wimmer (34) used the CH_3NH_2 molecule to study the sensitivity of calculated geometric, vibrational, and energetic properties on the computational level. They found that the calculated bond lengths differ by 0.004 Å or less when the different levels are compared. The largest variation in bond angles is 1.4° (for HCN). Overall they concluded that there is relatively little sensitivity of the geometric variables on the choice of the computational levels. For small molecules and fragments containing C, N, O, and F atoms with the (621/41/1*) orbital basis sets and (41/1*) set for hydrogen, they found that the C—C single bond lengths are typically 0.01–0.02 Å too short whereas the C—C double bond and C—C aromatic bond are within a few thousandths of an Å of experiment. As for the C—H bond length, it is usually too long by about 0.01–0.02 Å and this trend is even more pronounced for the O—H, N—H, and

[a]Num. refers to the numerical calculation.

H—F distances. For C—O, C—N, C—F, N—O, and N—F bonds, they find agreement within 0.02 Å or less. The bond angles deviate from experiment by less than 1°. The homonuclear diatomics are fairly well described.

The orbital basis set effect, i.e., the effect of the number of primitive basis functions and decontraction pattern, on the geometrical parameters can be seen in Tables 8 and 11. The basis set notation is given at the end of Table 8. The orbital basis sets are given on the left side of the semi-colon and the auxiliary sets on the right side. The notation used in ref. 34 is also indicated. From Table 8, we conclude that the C—H bond distance in CH_4 and in the CH_3 radical does not vary significantly with the basis sets. The standard deviation is 0.002 Å for both systems. In the case of the C—C, C—N, and C—O bonds, the addition of a *d* polarization function affects the bond lengths more than in the case of the C—H bond. The average bond lengths and the standard deviations when considering the results from the five basis sets studied for the C—C, C—N, and C—O bond lengths respectively are 1.518 ± 0.005, 1.450 ± 0.003, and 1.418 ± 0.016 Å.

0.040	0.060	0.083	0.100	0.130	0.170

If we exclude the results obtained with the basis set without the polarization function, on the ground that polarization functions are necessary, these results become 1.517 ± 0.005, 1.451 ± 0.002, and 1.411 ± 0.002 Å and all the standard deviations are in the thousandths of an Å. These results reinforce the previous conclusion that the geometrical parameters are not significantly affected by the orbital and auxiliary basis sets chosen for this study.

The equilibrium geometries for a series of compounds containing first-row atoms are shown in Tables 9 and 10. These geometries were obtained using the LSD (621/41/1*) orbital basis sets for carbon-like atoms and (41) orbital basis set for hydrogen. The triple-zeta auxiliary sets were built as previously described. The equilibrium geometries for ethane, ethene, and ethyne are shown in Table 9. The results show that this bond is very well described using our basis sets. The differences with the experimental values are of 0.014, 0.003, and 0.014 Å for the triple, double, and single bonds respectively. The carbon–hydrogen bond is well reproduced, being too long by 0.01–0.02 Å.

Table 10 shows the calculated equilibrium geometries for first-row heteroatom compounds. Again, we find our results to be in excellent agreement with the experimental data. With the somewhat limited number of compounds studied, we have derived some statistics using the average difference between the calculated and experimental bond lengths and angles ($\overline{\Delta r}$). For the C—F(1), C—N(2), C—O(3), C—H(8), N—H(2), and O—H(1) bond types we find the values of ($\overline{\Delta r}$) of 0.005, 0.010, 0.009, 0.011, 0.013, and 0.011 Å respectively, the numbers in parentheses being the number of values from which the values of ($\overline{\Delta r}$) were tabulated. On average, all the bond lengths are calculated within 0.02 Å and in many cases within 0.01 Å of experiment, which is respectable. The highest deviation for the bond angles is 2.3° but most (six out of ten) are predicted within 1° of experiment. The average deviation regardless of the types of angles is 1°. These values are in agreement with the previous statement that LSD can predict bond angles within 2.0° of experiment and bond lengths within 0.02 Å. Out of the 11 angles calculated, four are calculated higher than the ex-

perimental value, six are smaller, and one is exact. As for the calculated bond distances, most overestimate the corresponding experimental value. In conclusion, the equilibrium geometries that we showed, calculated using the proposed LSD basis sets, provide structures that compare favorably with MP2 results, obtained with 6-31G* basis sets, and experiment.

3.4 Bond dissociation energies

The bond dissociation energies, and the hydrogenation energies, are calculated by subtracting the sum of the energies of the reactants from those of the products. Fully optimized geometries were used. The non-local corrections to the energy are calculated as a perturbation at the end of the LSD calculation using the functional forms proposed by Becke for exchange (65) and Perdew for correlation (66) and using the LSD equilibrium geometries.

The results from the study of the $CH_4 \rightarrow CH_3^{\cdot} + H^{\cdot}$ reaction are in Table 11. At the MP4(6-31G**//6-31G*) level, a 6-31G** MP4 single-point calculation using a Hartree–Fock 6-31G* equilibrium geometry, a 3 kcal/mol difference with experiment still remains. Increasing the size of the basis set (6-311G**) at the same level of theory does not change the accuracy. The LSD(VWN) results overestimated the dissociation energy by an average of 11.9 kcal/mol. This result is not suprising since it is known that the binding energy is overestimated in the LSD approximation. The use of non-local corrections, Becke–Perdew potential, greatly improves the D_e, which is then only overestimated by 0.9 kcal/mol. This conclusion has been drawn by other authors (33). The D_e is basis set independent as is the geometry and the zero point energy. For the D_e, this can be seen by the small value of 0.2 kcal/mol of the standard devia-

tion at the LSD and NLSD level. Since the decontraction pattern and the number of core primitive functions does not affect the D_e significantly, it is not certain that larger or more decontracted basis sets may improve the results.

Andzelm and Wimmer (34) computed the bond energies for the successive removal of H atoms from methane with a (621/21/1*) orbital basis set for carbon and (41/1*) set for hydrogen. They found that the CH—H bond is overestimated at the LSD level by as much as 15 kcal/mol. The NLSD calculations bring results to within 2 kcal/mol of experiment. The C—C bond dissociation energies were also studied and the same conclusions as for the C—H bond were obtained in terms of the need to include non-local corrections to the energy. None of the correlated Hartree–Fock based methods came as close to experiment as the NLSD approach.

The bond dissociation energies involving the atoms C, N, O, and F in a reaction of the type A—B → A + B represent a difficult problem for the *ab initio* approach. The Hartree–Fock approach gives poor agreement with experiment whereas MP2 often brings agreement within a few kilocalories per mole. Table 12 shows the dissociation energies for the C—C, C—N, and C—O bonds for the CH_3-CH_3, CH_3-NH_2, and CH_3-OH molecules as a function of the basis sets at the LSD and NLSD levels. The average D_e and the standard deviations for these bonds in the order given above are 115.8 ± 0.8, 114.2 ± 1.1, and 121.3 ± 3.7 kcal/mol. At the NLSD level, these values are 94.8 ± 0.9, 90.4 ± 0.6, and 96.5 ± 3.4 kcal/mol. The deviations are larger than in the case of the C—H bonds, the highest being for the dissociation of the C—O bond. The NLSD level is necessary to bring agreement to within 3 kcal/mol of experiment.

These results are preliminary and it would be dangerous to draw too general conclusions from them, but they are very encouraging since reasonable D_e, within 1–2 kcal/mol of the experimental results, could be obtained and this at a lesser cost than that of perturbation theory. Certainly, more results are needed to complement the present ones but one conclusion that seems unavoidable is that non-local corrections are needed if a close agreement with experiment is to be expected.

3.5 *Hydrogenation reactions*

The LSD and NLSD hydrogenation energies for a series of reactions are found in Table 13 along with the Hartree–Fock and Moller–Plesset results as compiled by Hehre *et al.* (61). In ref. 61 it is said that, at the Hartree–Fock level, the 6-31G* and 6-31G** sets are needed to bring the agreement to within 3–5 kcal/mol of experiment.

The calculation of energies of hydrogenation is quite new in DFT. When looking at the LSD and NLSD results in Table 13, what is first surprising is that the inclusion of a *d* polarization function to the DZV (double-zeta-split-valence) basis set slightly deteriorates the agreement with experiment. In general, a polarization function improves the results. The average energies of hydrogenation and the standard deviations for the CH_3-CH_3, CH_3-NH_2, and CH_3-OH molecules at the LSD level are respectively 17.8 ± 0.7, 24.7 ± 1.4, and 27.5 ± 1.7. At the NLSD level, these values are 18.9 ± 0.6, 25.7 ± 1.2, and 27.7 ± 1.8. The standard deviations indicate a basis set sensitivity of 1–2 kcal/mol. Even if the basis sets cause fluctuations in the energies, the extent of this behavior is restrained to within 2 kcal/mol, which is reasonable. Further, no large discrepancies with experiment are found. At the LSD level, the agreement with experiments is on average within 1–3 kcal/mol. The non-local corrections to the density bring the agreement to within 2 kcal/mol or less. The correction is not as large as was the case with dissociation energies. With a few exceptions, the energies are underestimated.

Again, the present LSD optimized basis sets provide quality results. In their study Andzelm and Wimmer (34) found that there were some serious deficiencies for reactions involving triple bonds while the hydrogenation of the single bonds is fairly well described at the LSD level. The NLSD level performs as well as the MP2 with 6-31G**//6-31G* orbital basis sets and is closer to the MP4 approach with the same basis sets. They also found that the agreement between NLSD and the experimental values corrected for zero-point energies is quite reasonable for many of the reactions but significant discrepancies of up to about 10% do exist.

3.6 *Electric dipole moments*

The calculation of the electric dipole moments provides an insight into the overall distribution of charge, which may be important to know when structures and reactivities of molecules are to be evaluated. This one-electron property can be measured experimentally so that comparisons with theory can be made. Generally, this comparison is limited to the

magnitude of the vector as a lot of uncertainties often exist in the experimental directions. The dipole moments were calculated by computing the expectation value of the dipole moment operator, μ.

Again we turn to the Hartree–Fock experience to give us an idea of the basis set effect (61) on the electric dipole moments. For diatomic and small polyatomic molecules, the 6-31G* model is the most successful of the theoretical models as it provides a reasonable description of the magnitude of the dipoles for a variety of different compounds. In going from STO-3G to 6-31G*, the mean absolute deviation difference is 0.35 D and from 3-21G* to 6-31G* it is 0.04 D. From this we may conclude that once a somewhat high quality of basis set is reached, the calculated dipole moment is not affected as much by the choice of the basis set. This conclusion can also be applied to compounds containing heteroatoms. Still, significant errors remain if we consider that the typical range of values for dipole moments is 0 to about 5 D. Near the Hartree–Fock limit, the magnitudes of the electric dipole moments are frequently in error by a few tenths of a debye. From this comparative study, we expect that our basis sets will provide at least as good dipole moments as does the 6-31G* level.

The LSD dipole moments of two compounds as a function of the basis sets are shown in Table 14 along with the Hartree–Fock values. They were calculated with the equilibrium geometry as calculated by each of the basis sets. We do not feel that this will prevent us from having a discussion in terms of the basis set pattern as no major differences are found between the geometries. Looking at the LSD results as a function of the basis set, it is apparent that it is necessary to include a *d* polarization function to get agreement with experiment within 0.2 D or less. Disregarding the results without the *d* function, the highest deviation from experiment is of 0.193 D (CH_3NH_2) and the lowest one is of 0.046 D (CH_3OH). The best agreement is found with the basis set C. In all cases the dipole moments are overestimated. On average, the dipole moments for CH_3NH_2 and CH_3OH, when considering all the basis sets studied, are 1.34 ± 0.26 and 1.89 ± 0.2 D respectively. If we neglect the results obtained with basis set A from our statistics, these values become 1.46 ± 0.04 and 1.80 ± 0.04 D. The important conclusion is that the deviations become smaller.

Expt.		1.31	1.70

The effect of electron correlation can be tentatively accounted for as our basis sets are of similar size as the 6-31G* Hartree–Fock set. If that comparison can be made, the correlation has lowered the dipole moment by 0.2 D. The NLSD dipole moments are not shown here but other preliminary results tend to show that the correction should not be large (0.1–0.2 D) (67). In conclusion, for the two systems studied, the basis sets provide reasonable results but a more lengthy study is needed to determine trends and account for the 0.2 D (or less) difference with experiment that remains.

3.7 Final conclusions

We have proposed all-electron LSD optimized Gaussian basis sets for the atoms boron through neon. The optimization procedure used, based on the Tatewaki and Huzinaga method, provides high quality valence orbitals as judged by comparison with the energies and orbitals obtained by the numerical solution of the Kohn–Sham equations. We be-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

lieve that these sets will cause only small BSSE since they have a good representation of the core orbitals.

The equilibrium geometries, bond dissociation and hydrogenation energies, and electric dipole moments have been calculated with the newly optimized basis sets. The results that we have shown make us believe that we have basis sets that can provide information with a reliable accuracy. The equilibrium geometry parameters are predicted at least within 0.02 Å and 1° of experiment.

The bond dissociation energies for one homolytic dissociation process could be predicted within 1 kcal/mol of experiment and other results obtained using the proposed basis sets are quite encouraging. They are as good as the MP2 and MP4 results, with the 6-31G**//6-31G* orbital basis sets, in reproducing the experimental values. Such an agreement is obtained, though, only if non-local corrections to the energies are included. The hydrogenation energies can be calculated within 1–3 kcal/mol and 2 kcal/mol of experiment at the LSD and NLSD levels respectively using the proposed basis sets. The electric dipole moments were calculated within 0.2 D of the experimental values. These conclusions are based on very preliminary studies. At first glance, the basis sets that we have proposed give results that are as good as those of calculations with other correlated methods and this can be an indication that they are adequate.

These basis sets were also used in other studies to calculate harmonic vibrational frequencies and energies of isodesmic reactions. Dixon (in ref. 33) found a much better agreement with experiment when using LSD optimized basis sets in LSD calculations than when using Hartree–Fock optimized basis sets for isodesmic reactions. He studied several patterns and sizes and concluded that the results are sensitive to the number of contracted functions in the core orbitals. The basis set with six primitives for the 1*s* orbital gives an error of about 4 kcal/mol whereas an improved treatment of the core by just one additional function decreases this error by more than 1 kcal/mol.

The vibrational frequencies in DFT are currently calculated with the second derivatives being obtained by numerical differentiation of the gradient at the equilibrium geometries, since the analytical second derivatives are not available yet. Andzelm (in ref. 33) calculated the vibrational frequencies, using the basis sets proposed in this paper, for a series of simple organic molecules containing C, N, O, H, and F using the basis sets found in this paper. He found a good agreement between the LSD and experimental data. Typically, the high energy frequencies are overestimated while the low frequencies are smaller than the corresponding experimental frequencies. The average percentage deviations in the calculated frequencies from the measured harmonic values are 4.5% at the DZVPP/LSD level. Andzelm and Wimmer (34), again using the present basis sets, calculated vibrational frequencies consistently closer to experiment than those obtained with the Hartree–Fock theory. The LSD results were at least as close to experiment as those obtained from the MP2 theory with similar size and quality of orbital basis sets.

Acknowledgments

We would like to thank Cray Research Inc. for their summer intern program which has rendered this work possible. We also acknowledge the contribution of D. Dixon for helpful discussions. Financial support from the Natural Sciences and Engineering Research Council of Canada and la Fondation pour la Formation des Chercheurs et l'Aide à la Recherche is also acknowledged.

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

ROBERTA P. SAXON and MEGUMU YOSHIMINE. Can. J. Chem. **70**, 572 (1992).

Calculations designed to characterize the transition state and determine the barrier height for rearrangement of nitromethane to methyl nitrite are reported. Structures of CH_3NO_2, CH_3ONO, dissociation products, CH_3 + NO_2 and CH_3O + NO, and the transition state for nitro–nitrite rearrangement have been optimized at the MCSCF/4-31G level. The geometry of the transition state may be approximately described as separated CH_3 and NO_2 species with extremely long C—N and C—O bond lengths, 3.396 and 3.654 Å, respectively. Energies have been obtained by large-scale multireference single- and double-excitation CI calculations (6-31G* basis). The transition state is calculated to lie 56.7 kcal/mol above nitromethane (with zero-point energy). A C—N bond dissociation energy of 51.7 kcal/mol is obtained. Results are compared with the infrared multiphoton dissociation experiment of Wodtke, Hintsa, and Lee.

Key words: nitromethane, *ab initio* calculations, transition state, rearrangement, dissociation.

ROBERTA P. SAXON et MEGUMU YOSHIMINE. Can. J. Chem. **70**, 572 (1992).

On rapporte les résultats de calculs effectués dans le but de caractériser l'état de transition et de déterminer la hauteur de la barrière au réarrangement du nitrométhane en nitrite de méthyle. Opérant au niveau MCSCF/4-31G, on a optimisé les structures du CH_3NO_2, du CH_3ONO, des produits de dissociation, CH_3 + NO_2 et CH_3O + NO, et de l'état de transition du réarrangement nitro–nitrite. La géométrie de l'état de transition ressemble approximativement aux espèces CH_3 et NO_2 séparées dans lesquelles les liaisons C—N et C—O sont extrémement allongées, à des distances respectives de 3,396 et 3,654 Å. On a obtenu les énergies à l'aide de calculs d'IC (base 6-31G*) avec multi-références simplement ou doublement excitées. On a calculé que l'état de transition se trouve à 56,7 kcal/mol au-dessus du nitrométhane (avec énergie du point zéro). On obtient une énergie de dissociation de la liaison C—N de 57,1 kcal/mol. On a comparé les résultats avec ceux d'expériences de dissociation par infrarouge multiphotonique de Wodtke, Hintsa et Lee.

Mots clés : nitrométhane, calculs *ab initio*, état de transition, réarrangement, dissociation.

[Traduit par la rédaction]

Introduction

The decomposition kinetics of nitro compounds is complicated by the competition between different mechanisms, e.g., simple bond cleavage, concerted molecular dissociation, and rearrangement or elimination through cyclic transition states. The high energy content of such molecules both provides alternative decomposition pathways and makes them attractive as prototype energetic materials.

Experimental evidence for unimolecular nitro–nitrite rearrangement, R—NO_2 → R—ONO, as an initial step in thermal decomposition has been reported in several systems. Wodtke, Hintsa, and Lee (1), using a molecular beam, infrared multiphoton dissociation technique, and an analysis based on RRKM theory to relate their results to pyrolysis experiments, observed isomerization of nitromethane, CH_3NO_2, to methyl nitrite, CH_3ONO, by detecting the CH_3O and NO products from dissociation of the nitrite.

In a study (2) of the kinetics of thermal decomposition of dimethylnitramine, $(CH_3)_2NNO_2$, numerical modeling satisfactorily reproduces the observed temperature and product formation only when rearrangement to the nitrite is included as a competitive process. Another experiment (3) on the same compound, which mass spectrometrically sampled the initial products, reported observation of NO and fragment ions of the nitroxyl radical $(CH_3)_2NO$, presumably formed from the nitrite. However, a recent IRMPD study (4) of dimethylnitramine reported no evidence of the isomerization channel. Finally, evidence of the rearrangement in nitrobenzene, detection of C_6H_5OH in the presence of radical scavenger, has also been reported (5).

Because of the great interest in the chemistry of nitro compounds, theoretical studies have been carried out over many years (6–8), although the multiconfigurational methods needed to describe open shell transition states and even the ground states of the stable isomers have only recently been applied to mechanistic studies (9–11).

In an effort to understand the mechanism of nitro–nitrite rearrangement in N—NO_2 compounds, we recently reported (9) MCSCF/CI calculations of stable isomers and the rearrangement transition state of NH_2NO_2, the unsubstituted analog of dimethylnitramine. Optimized at the MCSCF/4-31G level, the geometry of the transition state may be approximately described as separated NH_2 and NO_2 species with an N—N bond length of 2.8 Å. The wavefunction of the transition state is characterized by two singly occupied orbitals. At the CI level, the energy of the transition state is within 1 kcal/mol of the NH_2 + NO_2 asymptote. From these results, isomerization is expected to be competitive with N—NO_2 bond scission, as observed experimentally.

A similar computational approach was used in a careful study (10) by Mowrey *et al.* to determine the 5-membered ring transition state for elimination of HONO from CH_2NNO_2, which was predicted to have an activation energy below the N—NO_2 bond dissociation energy, consistent with indirect evidence from molecular beam experiments.

The nitromethane system has been studied theoretically by various techniques. However, a consistent mechanism for nitro–nitrite rearrangement in CH_3NO_2 has yet to emerge. The possibility of decomposition of nitro compounds by isomerization to nitrites was suggested by Dewar *et al.* (6). Rice and Thompson (12) recently reported a classical trajectory study of the rearrangement process, using three different model potential energy surfaces. They found best agreement with the reported branching ratio of isomerization vs. C—NO_2 dissociation for the model surface with a barrier 7.5 kcal/mol below the dissociation energy. This surface goes through what may be termed a tight transition state, C—N and C—O bond lengths on the order of 2 Å. A tight transition state with similar bond lengths, optimized at the SCF level, with an energy significantly above the C—N bond energy was reported by McKee (8). He indicated, however, that the result was likely to be an artifact of the SCF computational model. In a subsequent paper (11), McKee found a loose transition state, bond lengths > 3.6 Å, in a small active space MCSCF optimization. However, at the highest level CI calculation reported, the energy remained 10 kcal/mol above the C—N bond energy. The N—O bond lengths at the transition state geometry were quite uneven, indicative of an NO_2 radical in an energetically unfavorable conformation, in contrast to the situation found (9) for NH_2NO_2.

In this paper, we apply the MCSCF/CI computational model used to determine the nitro–nitrite rearrangement transition state in NH_2NO_2 to isomerization of nitromethane. Structures of the stable isomers as well as that of the transition state have been optimized as the MCSCF level by the gradient technique. Large-scale configuration interaction (CI) calculations were performed at the optimized geometries for determinations of energy differences. In the next section, the design of appropriate MCSCF and subsequent CI calculation is described. Results and discussion, including comparison with previous determinations and with the nitramine transition state, are presented in the following section.

Calculations

Geometries of the stable isomers, the rearrangement transition state, and the dissociation products were optimized at the MCSCF level with a standard 4-31G Gaussian basis set using analytic second derivatives at each step to facilitate the optimization. Calculations for the asymptotes were carried out on the supermolecule. The choice of the active space of the MCSCF calculation is crucial. Following the procedure described for NH_2NO_2, the active space should consist of seven orbitals: a complete valence space of 19 orbitals less the two O 2*s* orbitals, two N—O bonds, two N—O antibonds, three C—H bonds, and three C—H antibonds. This would provide, in principle, one orbital of C character and six orbitals of N—O character. In practice, at the equilibrium geometry, all seven orbitals in the active space describe the NO_2 (using σ and π to describe the NO_2 plane): two N—O σ bonds, one O σ lone pair, one O π lone pair, one N—O π bond, and N—O π^* and σ^* correlating orbitals. At the transition state, one N—O σ bonding orbital and the N—O σ^* orbital become the singly occupied orbitals on carbon and nitrogen.

Energies were determined by multireference single- and double-excitation CI calculations with the standard 6-31G* basis set using MCSCF molecular orbitals. In constructing the CI expansions, the orbitals were divided into four spaces: frozen; inactive, composed of 10 orbitals; active, composed of four orbitals; and external, composed of the remaining 48 orbitals. The four lowest occupied orbitals, corresponding to the C, N, and O 1*s* were kept doubly occupied. The configuration list included all single and double excitations from the inactive and active spaces with at most one electron in the external space and all double excitations from the inactive and active spaces to the external space, which differed by no more than two electrons from a set of reference configurations. Interacting space restrictions on the coupling were imposed for double excitations from the inactive space.

A four-orbital active space was used to construct the CI expansions, in contrast to the seven-orbital active space used in the MCSCF optimization calculations, in order to provide a more compact CI expansion. MCSCF orbitals determined with the four-orbital active space were used in these CI calculations. CI calculations were also performed for the isomers and the CH_3O + NO asymptote with the seven-orbital active space. The weight of the reference configurations in the CI wavefunctions was approximately 0.87 for all calculations. This resulted in CI expansions of up to 400 000 configurations with the four-orbital active space in C_s symmetry (900 000 with the seven-orbital active space) and 700 000 (four-orbital active space) in C_1 symmetry. Preliminary geometry optimizations were carried out with the GAMESS program (13); final geometry determinations (14) and all other calculations used the ALCHEMY II program system (15).

Results and discussion

Structures of stable isomers

Geometrical parameters for CH_3NO_2, CH_3ONO, and the dissociation products optimized at the MCSCF level are given in Tables 1–3. Experimentally obtained geometries and results of previous calculations, with which reasonable agreement is noted, are also given. The numbering of the atoms is illustrated in Fig. 1. In nitromethane, the four heavy atoms are predicted to be nearly coplanar. The angle between the CN bond and the NO_2 plane is 1.8°. Results are presented for the *cis* staggered isomer of methyl nitrite, which has been shown by experiment (16) and calculations (8) to be the lowest energy form. In this form, the four heavy atoms and the hydrogen labeled H1 are strictly coplanar. The *cis* eclipsed form with the in-plane H on the opposite side of the C—O bond was found to be a transition state for methyl group rotation.

Comparison with structural parameters obtained from microwave spectra shows excellent agreement for most bond lengths and all bond angles. For methyl nitrite, the analysis has been done with and without a small tilt of the methyl group off the C—O axis. Other parameters are insensitive to this assumption. The greatest discrepancy between the calculated and experimental geometries is found for the N—O bond length in CH_3NO_2 and the terminal N—O2 bond length in CH_3ONO, which are calculated to be longer by 0.02 and 0.06 Å, respectively, than the experimental determinations. In both cases, the dominant correlation in the MCSCF wavefunction is excitation to N—O antibonding orbitals. As discussed previously for NH_2NO_2, it is possible that the length of these bonds is overestimated by the 4-31G basis set as well as by the present MCSCF model, which does not correlate

all bonds to the same extent. These bond lengths appear to be underestimated, however, by the RHF model. The correlation included in the two electron in two orbital MCSCF calculations reported previously (11) had a modest effect on optimized geometries.

Vibrational frequencies for CH_3NO_2, CH_3ONO, and the dissociation products are reported in Table 4. Those modes that were identified as corresponding to pure motions of portions of the molecules in the experimental analysis are indicated in the table. They also correspond to pure motions in the calculated normal modes except for the *a"* NO_2 stretch in CH_3NO_2 for which some mixing was found. For the methyl stretches and bends noted, the calculated frequencies are larger than the observed values by an average of 12%. The calculated NO_2 or NO frequencies are smaller than experimental values by 2–19% (26–260 cm^{-1}). Similar comparisons are noted for the CH_3 modes of the dissociation products except for the low-frequency mode of the methyl radical, which is calculated to be anomalously low. The calculated NO and NO_2 frequencies in the isolated molecules are in excellent agreement with experiment. Summing the frequencies, the calculated zero point energies are in good agreement with experimental values. For CH_3NO_2 a value of 32.2 kcal/mol is predicted vs. 30.2 kcal/mol from the experimental frequencies. For CH_3ONO, the calculated zero point energy is 32.0 kcal/mol, vs. 29.0 from experiment.

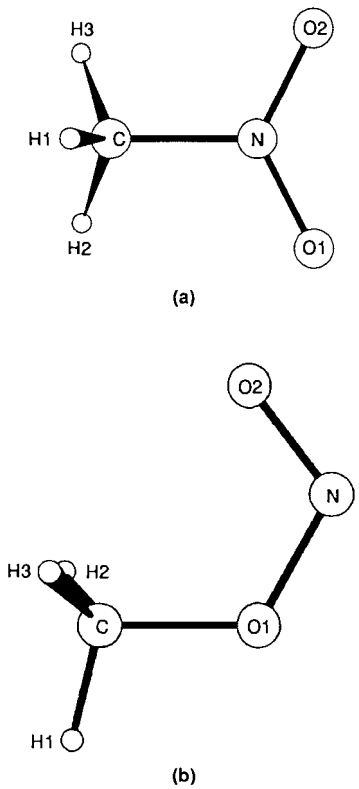

FIG. 1. MCSCF/4-31G optimized equilibrium geometry of (*a*) CH_3NO_2 and (*b*) CH_3ONO, *cis* staggered isomer. In (*b*), H1 and the heavy atoms are strictly coplanar and H2 and H3 are equivalent.

Transition state

The geometry of the transition state for rearrangement of CH_3NO_2 to CH_3ONO is illustrated in Fig. 2. Optimized geometrical parameters and calculated harmonic frequencies are given in Table 5. The transition state has one small imaginary frequency. The geometry may be approximately described as separated CH_3 and NO_2 species. The C—N bond is extremely long, 3.396 Å. The distance between C and O1, the atom with which the carbon will become bonded in CH_2ONO, is, however, slightly shorter at the transition state, 3.654 Å, than the C—O2 distance, 3.668 Å. All of the C—H and N—O parameters have very nearly the same values given for the isolated species at the same level of calculation in Table 3. The C—N bond makes an angle of 83° with the plane of the NO_2. The average plane of the nearly planar methyl radical fragment is virtually parallel to the NO_2 plane. Looking along the N—C bond, the oxygens and hydrogens are staggered, as shown in Fig. 2*b*. The MCSCF wavefunction at the transition state is characterized by two singly occupied orbitals, singlet coupled, as expected for this loose combination of radical species.

All of the significant frequencies for the transition state in Table 5 readily can be identified with frequencies of the fragments. They differ by less than 10 cm^{-1} from the frequencies of the separated species, calculated at the same level, except for the low methyl bend. The frequencies below 100 cm^{-1} correspond to motions connecting the two fragments.

The energy profile along an approximate reaction path shown in Fig. 3 demonstrates that the transition state that has been located does in fact smoothly connect nitromethane and methyl nitrite, as claimed. In constructing this plot, the C—N bond distance was taken as the reaction coordinate for the path between CH_3NO_2 and the transition state. Fixing the C—N distance at the plotted values, the remaining coordinates were optimized at the MCSCF/4-31G level. Relative energies obtained by MCSCF calculations with the 6-31G* basis are plotted in Fig. 3. The C—O1 bond distance was used as the reaction coordinate for the path between the transition state and CH_2ONO. For the first two points to the right of the transition state, C—O1 = 3.0 and 2.5 Å, it was necessary to fix the C—O1—N internal angle at interpolated values of 95 and 105.9°, respectively. The reaction path shown leads to the *cis*, staggered methyl nitrite, the lowest isomer.

Energies

Total energies for all calculations carried out in this study, as well as relative energies with respect to CH_3NO_2 and calculated zero point energies, are given in Table 6. As mentioned above, CI calculations based on the same seven-orbital active space used for the MCSCF optimizations were performed for CH_3NO_2, CH_3ONO, and the CH_3O + NO asymptote, taking advantage of C_s symmetry, in order to test the four active orbital CI model. Relative energies for the nitrite and the asymptote from the two CI calculations are in good agreement, within 1.0 kcal/mol. Including the multireference Davidson correction for quadruple excitations, i.e., comparing the calculations labeled CI7D and CI4D in Table 6, the relative energies agree to within 0.1 kcal/mol. Note that the energy predictions with the small active space MCSCF calculations are not reliable. However, the structure of the MCSCF wavefunction and the molecular orbitals from the two MCSCF calculations are very similar.

Final results of this study are given by the quadruple corrected CI calculations, CI4D, with calculated zero point

energies. These numbers correspond to energies at temperatures of 0°C. Nitromethane and methyl nitrite are calculated to be essentially isoenergetic. The transition state is predicted to lie 56.7 kcal/mol above nitromethane and 0.4 kcal/mol below the $CH_3 + NO_2$ asymptote. The energy to break the CH_3O—NO bond from these calculations is 34.5 kcal/mol.

Experimental energies given for comparison in Table 6 have been obtained from room temperature heats of formation extrapolated to 0°C assuming a rigid rotator, harmonic oscillator approximation.[1] The nitromethane, methyl nitrite energy difference, and C—NO_2 bond dissociation energy are in excellent agreement with experimental energies. The calculated energy of the $CH_3O + NO$ asymptote lies almost 6 kcal/mol below the value from experimental heats of formation.

Discussion

The goal of this work was to theoretically determine the mechanism for the rearrangement of nitromethane to methyl nitrite. These calculations predict an energy barrier to rearrangement of 56.7 kcal/mol, via a loose transition state. This barrier is very close in magnitude to the calculated energy to break the C—NO_2 bond, 57.1 kcal/mol. Furthermore, the preexponential Arrhenius A factors calculated from the vibrational frequencies in an RRKM treatment should be similar for isomerization and bond dissociation, leading to the prediction of comparable rates for isomerization and dissociation. This prediction should be compared with the results of the IRMPD experiment of Wodtke, Hinsta, and Lee (1) (WHL). Comparable reaction rates are consistent with the

[1]Heats of formation at 298 K of −17.76 kcal/mol for CH_3NO_2 and of −15.85 kcal/mol for CH_3ONO were taken from ref. 25*a*. For CH_3O, the value 3.99 kcal/mol from ref. 25*b* was used. Reference 25*c* was used for NO_2 and NO. Experimental structures and frequencies were used in the rigid rotator, harmonic oscillator extrapolation to 0°C except for CH_3O for which the calculated structure was adopted.

branching ratio of isomerization to dissociation (0.6) inferred from the experimental observations.

The calculated barrier height is compared in Table 6 with the barrier height reported by WHL. This value is not observed directly in these experiments but emerges from an RRKM analysis with stated assumptions. The most critical of these, as discussed previously by McKee (11), may be the assumed A factor for the isomerization channel. WHL adopted the value reported by Dewar *et al.* (6) from the tight transition state indicated by semiempirical MINDO/3 calculations. This A factor is two orders of magnitude smaller than that taken for bond dissociation, which should be similar to the A factor from the loose transition state reported here. WHL estimated the uncertainty in the barrier height from a factor of three variation in the assumed A factor.

We may also note that while none of the model potential surfaces used by Rice and Thompson (12) in their classical trajectory study corresponds to a loose transition state, their results raise the possibility that trajectories that sample the rearrangement transition state may dissociate to $CH_3 + NO_2$, presumably via another transition state, rather than rearrange to the methyl nitrite. This introduces a subtlety that needs to be considered in rigorous calculations of reaction rates.

The structure of the transition state is compared in Table 5 with previously reported determinations. The C—N and C—O bond distances from the four electron in four orbital MCSCF optimization of McKee (11) are similar to the present results. The main differences in geometry are that the transition state has equal N—O bond lengths in the present work, while the previous MCSCF study reported one long and one short N—O bond, i.e., the present results correspond to the NO_2 radical portion of the loose transition state at its ground state equilibrium geometry while the previous work (11) describes the NO_2 fragment at the transition state as promoted to the O-N=O electronic configuration. In an attempt to explain these results, we investigated whether there are metastable states of the NO_2 radical at asymmetric geometries similar to that reported at the transition state. Using a nine electron in six orbital MCSCF with a 6-31G* basis, a minimum of $^2A''$ symmetry with bond lengths of 1.318 and 1.212 Å and an ONO bond angle of 109° was obtained. We may speculate that the transition state reported in ref. 11 corresponds to reaction on an excited electronic surface.

The transition state geometry obtained from SCF optimi-

zation (8) is also listed in Table 5. The determination of much longer C—N and C—O bond distances by MCSCF optimization than those predicted by the closed shell SCF model is expected. The SCF transition state is reported (8) to be significantly higher in energy than the C—N bond dissociation energy. While the energetics from semiempirical calculations should be interpreted with caution, the tight transition state, C—N = 1.516 Å, C—O1 = 1.584 Å, and N—O1 = 1.299 Å, from the MINDO/3 study of nitro–nitrite rearrangement (6) have been widely quoted (1, 12). We therefore investigated both of the tight transition states reported previously (6, 8) using the current MCSCF model to make sure that they do not correspond to another stationary point on the potential energy surface. In both cases, the structure of the MCSCF wavefunction is indeed closed shell. The gradients of the energy were far from zero; in particular, the gradients with respect to the C—N bond distance were quite large. At the MCSCF level, the energies were very high, >40 kcal/mol above the $CH_3 + NO_2$ asymptote. While it is not possible to prove that a tight transition state does not exist, our results suggest the tight transition states reported previously (6, 8) are artifacts of the approximate computational methods employed and do not represent stationary points on the potential energy surface of nitromethane.

In summary, the results reported here for nitro–nitrite rearrangement of nitromethane are very similar to those obtained previously (9) for rearrangement of NH_2NO_2 with a comparable MCSCF/CI computational model. The transition state in both cases can be characterized as a loose combination of radical species, CH_3 and NO_2 for nitromethane, and the energy of the transition state is within 1 kcal/mol of that of the separated fragments. The rate of unimolecular dissociation of CH_3NO_2 to $CH_3 + NO_2$ can be estimated using the hindered rotational Gorin model (26) while RRKM theory can be used to estimate the rate of the unimolecular isomerization reaction to CH_3ONO. The predicted loose transition state configuration will give an entropy contribution in the RRKM calculation very similar to the entropy contribution of the Gorin transition state and the activation energies are also calculated to be quite similar, leading to the prediction that the rate of isomerization to the nitrite is comparable to the rate of bond dissociation, consistent with experiment. The MCSCF approach is essential to determining the open shell transition state for nitro–nitrite rearrangement. Application of this model to other reactions should lead to improved understanding of detailed reaction mechanisms.

R. CUSTODIO, J. D. GODDARD, M. GIORDAN, and N. H. MORGON. Can. J. Chem. **70**, 580 (1992).

The Simplex method was used to define atomic and universal meshes using the integral discretization technique for the Griffin–Hill–Wheeler–Hartree–Fock equations. This technique represents a basis set as an exponential set of the form:

$$\alpha_i(k) = \exp[\Delta\Omega_o(k) + (i-1)\Delta\Omega(k)], \qquad i = 1, \ldots, N$$

For atoms, the minimum total energy criterion was employed. For the universal basis, three different procedures were tested: (*a*) defining the universal basis using information on the isolated atoms, (*b*) determining the universal $\Omega_0(k)$ through atomic calculations and reoptimizing the $\Delta\Omega(k)$ for different symmetries employing simultaneously a single atomic calculation as a reference point, and (*c*) optimizing the universal mesh using a statistical criterion such as the squares of the deviations of the total energy. The meshes obtained by the minimum total energy criterion or the squares of deviations of the total energy for the universal basis are accurate for the total energy but the weight functions are deficient in the valence region. Shifting the optimized $\Omega_0(k)$ to $\Omega_0'(k) = \Omega_0(k) - \Delta\Omega(k)$, fixing $\Omega_0'(k)$, and reoptimizing $\Delta\Omega(k)$ for each symmetry species produces a better description of weight functions at the expense of a less accurate total energy. In general, no significant statistical difference was observed for the various universal bases generated by procedures (*a*) and (*b*) or by (*c*) provided the shift correction was made to the latter. Application of these bases to diatomic molecules (N_2, CO, P_2, CS) showed that the universal bases are as accurate as those optimized for atomic systems. If the bases are transferred from atoms to molecules, the shift corrections to the weight functions of the atoms are not useful in molecular calculations. The almost equivalent molecular properties and the good total energies show that the best basis for molecular calculations is that optimized by procedure (*c*).

Key words: universal basis sets, integral discretization technique.

R. CUSTODIO, J. D. GODDARD, M. GIORDAN et N. H. MORGON. Can. J. Chem. **70**, 580 (1992).

On a fait appel à la méthode Simplex utilisant la technique de la discrétisation intégrale des équations de Griffin–Hill–Wheeler–Hartree–Fock pour définir des mailles atomiques et universelles. Cette technique représente un ensemble de base sous la forme d'un ensemble exponentiel de la forme :

$$\alpha_i(k) = \exp[\Delta\Omega(k) + (i-1)\Delta\Omega(k)], \qquad i = 1, \ldots, N$$

Pour les atomes, on a employé le critère de l'énergie totale minimale. Pour les bases universelles, on a vérifié trois méthodes différentes : (*a*) en définissant la base universelle à l'aide d'information sur des atomes isolés; (*b*) en déterminant un $\Omega_0(k)$ universel à l'aide de calculs atomiques et en réoptimisant le $\Delta\Omega(k)$ pour diverses symétries en employant simultanément un calcul atomique unique comme point de référence et (*c*) en optimisant la maille universelle à l'aide d'un critère statistique comme les carrés des déviations de l'énergie totale. Les mailles obtenues par le critère de l'énergie totale minimale ou par les carrés des déviations de l'énergie totale pour les bases universelles sont précises pour l'énergie totale; les fonctions pondérales présentent toutefois des déficiences dans la région de valence. En remplaçant $\Omega_0(k)$ par $\Omega_0'(k) = \Omega_0(k) - \Delta\Omega(k)$, puis en fixant $\Omega_0'(k)$ et en réoptimisant $\Delta\Omega(k)$ pour chaque espèce de symétrie, on obtient une meilleure description des fonctions pondérales au dépens d'une énergie totale moins précise. En général, on n'a observé aucune différence statistique importante pour les diverses bases universelles générées par les méthodes (*a*) et (*b*); c'est aussi le cas avec la méthode (*c*) à condition de faire une correction pour le déplacement. L'application de ces bases à des molécules diatomiques (N_2, CO, P_2 et CS) a permis de montrer que les bases universelles sont aussi précises que celles qui sont optimisées pour des systèmes atomiques. Lorsqu'on transfère des bases d'atomes à des molécules, les corrections de déplacement aux fonctions pondérales des atomes ne sont pas utiles dans les calculs moléculaires. Les propriétés moléculaires pratiquement équivalentes et les bonnes énergies totales montrent que le meilleur ensemble pour des calculs moléculaires est optimisé par la méthode (*c*).

Mots clés : bases universelles, technique de la discrétisation intégrale.

1. Introduction

The possibility of creating universal bases for atomic systems (1–3) is an interesting development in basis set design. In addition, the universal basis for different atoms has

some practical advantages with respect to conventional basis sets (4). The most important advantage is the transferability with little loss of accuracy of one- and two-electron integrals among different molecules with the same internuclear distances.

Two methods have been employed to create the universal basis: the even-tempered (ET) technique (1–5), and integral discretization (ID) of the Griffin–Hill–Wheeler–Hartree–Fock (GHWHF) equations (6, 7). These methods employ three parameters to define the universal basis for each symmetry function. The general form is

$$[1] \quad \alpha_i = x.y^{(i-1).z}, \qquad i = 1, \ldots, N$$

where N is the number of primitives in the mesh. For the ET method $z = 1$. For the ID technique $x = \exp(\Omega_0.A)$ and $y^{(i-1).z} = e^{[(i-1).\Delta\Omega.A]}$. N, Ω_0, $\Delta\Omega$, and A are referred to as the discretization parameters. The parameter "x" defines the first element of the mesh and "y" or "z" the distances among exponents. Both methods require that the parameter "x" must be small to ensure a wide range of exponents, while the parameter "y" (ET bases) or "z" (ID technique) must be sufficiently large to avoid linear dependencies. N must represent an almost complete set. The choice of these parameters in the ET method has been somewhat arbitrary (1–3). The ID technique employs an additional criterion through the GHWHF equations. These are a set of integral equations of the form:

$$[2] \quad \int[F(\alpha,\beta) - \varepsilon_i.S(\alpha,\beta)]f_i(\beta)d\beta = 0, \qquad i = 1, \ldots, n$$

where $F(\alpha,\beta)$ and $S(\alpha,\beta)$ are the Fock and overlap kernels, respectively. They are obtained by use of the one-electron functions as an integral transform:

$$[3] \quad \psi_i(1) = \int\phi_i(1,\alpha)f_i(\alpha)d\alpha$$

where ϕ_i and f_i are the generator and weight functions, respectively, and α the generator coordinate. The ID technique solves eq. [2] numerically employing the mesh defined by eq. [1]. This procedure searches for universal parameters through analysis of the weight functions by probe calculations (8–11). With N constant, the Hartree–Fock method is applied to different atoms to find the extreme cut-off points of the basis set. N and the value of $\Delta\Omega$ are then varied with these extreme exponents held constant to obtain a desired precision in the energy. $\Delta\Omega$ and N are considered interdependent.

In a recent paper (12), we adjusted the ID parameters for an s generator function for atomic systems containing two or four electrons and the H_2 molecule employing an optimization technique. The application of an optimization procedure systematizes the search for the discretization parameters. Our earlier application of the optimization procedure led us to test this technique for obtaining universal bases (12). The objective of this work is to test the applicability of an optimization technique to define the meshes with s and p generator functions for neutral, ground state atoms from He to Ar using the ID method. Analysis of the optimized meshes should establish systematic ways to search for atomic universal bases for the elements of the first and second period. An analysis of the transferability of the optimized meshes as well as the universal ones from atomic to diatomic calculations also is evaluated.

2. Computational methods

Optimization of the meshes was performed both for single atoms and for the universal basis for the neutral, ground state atoms He to Ar. s and p Gaussian generator functions were employed in these calculations. The ID definition of the mesh (eq. [1]) was applied in this work (6, 7). As discussed above, the original ID technique relabels the generator coordinate space α according to:

$$[4] \quad \Omega_i = \frac{\ln \alpha_i}{A}, \qquad A \geq 1$$

A previously was set to 6 (8–11). This parameter contracts the relabelled space and facilitates the detection of the cut-off points of the weight functions. Optimization eliminates the necessity of defining the A parameter. In this work, $A = 1$ was employed.

The individual bases or the universal ones were evaluated maintaining the number of s and p type functions constant at $(16s10p)$. The choice of $(16s10p)$ is based on the existence of a universal basis with this same number of Gaussians (9). The values of $\Omega_0(s)$, $\Delta\Omega(s)$, $\Omega_0(p)$, and $\Delta\Omega(p)$ were optimized simultaneously. For individual atoms, the minimum total energy criterion was adopted to define the best meshes. The optimum universal parameters were chosen to minimize the squares of the deviations of the calculated total energies with respect to the optimized $(16s10p)$ basis sets of this work.

The SIMPLEX method of Nelder and Mead (13) was chosen as the optimization procedure. The algorithm in ref. 14 was used to optimize $\Omega_0(k)$ and $\Delta\Omega(k)$. As in our previous work (12), different values of the starting simplex were tested. The initial values of $\Omega_0(k)$ and $\Delta\Omega(k)$ multiplied by 0.05 were adequate simplex parameters. Truncation of the overlap matrix ($\boldsymbol{S}$) was employed to eliminate problems with linear dependence (15, 16). A cut-off value of the eigenvalues of $\boldsymbol{S}$ was kept at 10^{-6}.

The SIMPLEX program requires that the decrease in the function value being minimized in the terminating step be fractionally smaller than a certain tolerance. Optimizing the basis sets for the individual atoms, the tolerance was set at 10^{-8}–10^{-9} to achieve accurate results. The definition of this parameter for the universal bases is more difficult to establish since the mimimum in the squares of the deviations of the total energies depends on the limiting energy values. One way to define the tolerance is to set it at a relatively high value (10^{-3}–10^{-4}), and then restart the calculation with the optimized simplex employing a smaller tolerance (0.1 or 0.01 of the previous parameter). The Hartree–Fock convergence criterion was maintained at 10^{-8} au.

3. Optimization for the atoms

The development of universal bases depends on the regularity of basis sets and presupposes a good knowledge of the meshes employed for the atoms. To obtain additional information on the individual atoms, this work initially analyses the applicability of the SIMPLEX method to define meshes using the ID technique. The characteristics of the optimized $(16s10p)$ basis set and their influence on atomic properties also are examined.

Table 1 shows the optimized data for the $(16s10p)$ meshes. The use of the optimized integral discretization technique (OID) provides very good energies when compared with the

accurate results of Clementi and Roetti (17). The fifth column in Table 1 shows that the error in the total energy for the first row elements is between 4×10^{-7} and 1.8×10^{-4} au and for the second row between 1.14×10^{-3} and 6.34×10^{-3} au. This is the greatest accuracy that can be obtained with a (16s10p) universal basis using the OID method. Obviously, to increase the precision of this universal basis a larger number of primitives as well as polarization functions are required. The possibility of the optimized bases being trapped in local minima has been examined. Independent of reasonable initial values of the discretization parameters, trapping in local minima can occur and some care is required to find the absolute minima.

The optimized discretization parameters depend strongly on the atomic species (see the third and fourth columns in Table 1). The plots of $\Omega_0(s)$ and $\Delta\Omega(s)$ vs. atomic number in Figs. 1(a) and 1(b) show that the discretization parameters depend on the occupation of the s and p sub-shells. In Fig. 1(a) the presence of one electron in the 2s orbital of Li drastically changes the value of $\Omega_0(s)$ with respect to the He parameter. The necessity of more diffuse primitives to describe adequately the 2s orbitals shifts the $\Omega_0(s)$ of Li to more negative values relative to He. On the other hand, Fig 1(b) shows $\Delta\Omega(s)$ increasing in magnitude to maintain a reasonable description of the inner shell of Li. Further changes in the nuclear charge and in the occupation of the p orbitals provide constant increments to $\Omega_0(s)$ up to Ne (Fig. 1(a)). The almost constant values of $\Delta\Omega(s)$ for these elements (Fig. 1(b)) show that the meshes are being shifted in the direction of the nucleus. Adding one electron to the 3s orbital diminishes $\Omega_0(s)$ (Fig. 1(a)) and the magnitude of $\Delta\Omega(s)$ increases (Fig. 1(b)). These two effects maintain an "equilibrium" between an adequate description of the 3s orbital and the inner shells.

Nevertheless, Fig. 1(a) shows nearly equivalent values of $\Omega_0(s)$ for different elements with the same valence electronic combination. Thus the same $\Omega_0(s)$ may be used for elements with the same electronic configuration. However, the $\Delta\Omega$ for the second row elements are very different from those for the first period. This difference in the $\Delta\Omega$ parameter governs the spacing between the exponents. Due to the number of inner orbitals and the greater nuclear charge for the second row elements, the meshes are more widely spaced than for the first row elements (Fig. 1(a)). Thus reasonable descriptions of the inner shells of the second row elements are retained. The differences between the calculated energies and Clementi and Roetti's values (17) in the fifth column of Table 1 indicate the need for larger bases for the

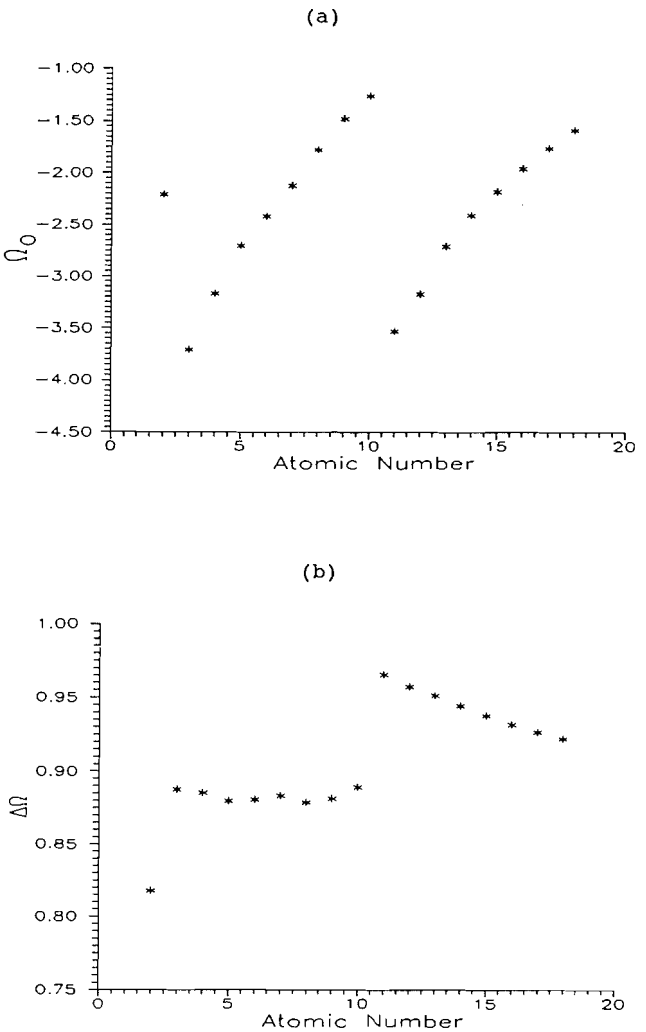

FIG. 1. Dependence of (*a*) $\Omega_0(s)$ and (*b*) $\Delta\Omega(s)$ with atomic number for the optimized (16*s*10*p*) basis sets.

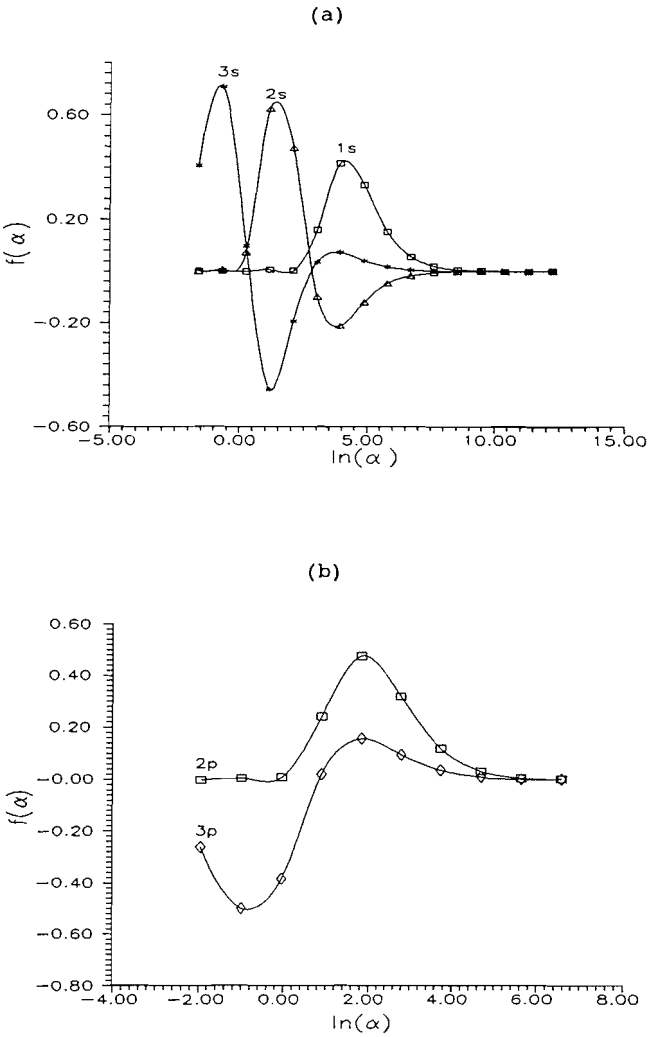

FIG. 2. The (*a*) *s* and (*b*) *p* weight functions for Ar obtained with the optimized (16*s*10*p*) basis set.

second row elements to reach a better precision in the total energy using OID. All these observations also hold for the *p* type functions.

The necessity of a good description of the weight function was stressed previously (6–11). Figures 2(*a*) and 2(*b*) show examples of the weight functions for the *s* and *p* atomic orbitals of Ar. The minimum energy criterion emphasizes the innermost region (more positive ln(α)). The primitives with small weight functions are more important in the minimization of the total energy than the outer Gaussians. All the inner orbitals in Ar have well-described weight functions in the sense that their coefficients are almost zero in that region. The outer functions require improvement for the 3*s* and 2*p* functions (Figs. 2(*a*) and 2(*b*)) since these outer orbitals do not have weight functions close to zero for the most negative value of ln(α). All the optimized meshes for the other atoms present the same behaviour. Figures 2(*a*) and 2(*b*) show that the description of the outer region can be improved after optimization if $\Omega_0(k)$ is changed by $\Omega_0'(k) = \Omega_0(k) - \Delta\Omega(k)$. Thus a better representation of the outer *s* and *p* type functions is obtained. However, the total energies increase, as shown in the sixth column in Table 1. The ΔE are a factor of 3.91 to 2.5 times larger. An improvement is possible if, after shifting $\Omega_0'(k)$, this parameter is maintained constant and $\Delta\Omega(k)$ is reoptimized. In this way, a more reasonable balance between the cutoff of the weight functions and the minimum energy criterion is obtained. Table 2 shows the improvement in the total energies after shifting the mesh and the reoptimized $\Delta\Omega(k)$. The ratios of the ΔE values of Table 2 to those of Table 1 on an atom by atom basis are now between 2.54 and 1.76.

Are the meshes adjusted by the last procedure improving other atomic properties? For Table 3, the orbital energies ε_i, $\langle p^n \rangle$, and $\langle r^n \rangle$, where $n = -2, -1, 1, 2, 3$, and 4, for the Ar atom were calculated. In the second column (SLT) are the results obtained with Clementi's accurate Slater basis functions (17), in the third column (AT1) the optimized (16*s*10*p*) Gaussian mesh data, and in the last column the results fixing $\Omega_0'(k)$ and reoptimizing $\Delta\Omega(k)$(AT2). The orbital energies and the $\langle r^n \rangle$ properties of the last column show a better correlation with Clementi's results (17) than those obtained with the optimized meshes. The opposite is concluded for $\langle p^n \rangle$. The sensitivity of $\langle p^n \rangle$ to small changes near the nuclei and the fixing of $\Omega_0'(k)$ far from the nucleus explains this trend. More detailed analysis shows that even the $\langle p^n \rangle$ properties calculated by the translated meshes and reoptimiza-

[a]$\Omega_0'(k) = \Omega_0(k) - \Delta\Omega(k)$, where $\Omega_0(k)$ and $\Delta\Omega(k)$ are the optimized parameters of Table 1.

[b]The calculated total energies minus the total energies from ref. 17.

tion of $\Delta\Omega(k)$ are in general closer to Clementi's results than those obtained with the optimized meshes.

Since atomic properties have significant differences in magnitude, some preprocessing of the data is needed before any general analysis. The atomic properties are renormalized with respect to Clementi's results (17). The sum of the squares of the deviations of the renormalized properties with respect to Clementi's data are taken as measures of the correlation between the models. Table 4 shows a generally better description of the electronic structure when the meshes are shifted to $\Omega_0'(k)$ and the $\Delta\Omega(k)$ are reoptimized. The $\langle p'' \rangle$ also show an improvement employing this method. The loss in accuracy in the total energy due to the shift of $\Omega_0'(k)$ and reoptimization of $\Delta\Omega(k)$ is compensated for by this improvement in other properties.

4. The universal bases

Three procedures were studied to obtain the universal bases (UBn): (*i*) the use of the optimized atomic meshes, (*ii*) the choice of selected parameters from these meshes (1) with reoptimization of the universal mesh employing a single atom as reference, or (*iii*) determining a mesh for a set of atoms simultaneously. With procedures (*i*) and (*ii*), the discussion above shows that there are two adequate meshes. The first is optimized based on the minimum energy criterion (Table 1) and the second involves substitution of the previously optimized $\Omega_0(k)$ for the s and p symmetry functions by $\Omega_0'(k) = \Omega_0(k) - \Delta\Omega(k)$, then fixing $\Omega_0'(k)$ and reoptimizing the $\Delta\Omega(k)$ parameter for each symmetry species simultaneously (Table 2).

The universal $\Omega_0(k)$ and $\Delta\Omega(k)$ must adequately cover the space of the generator functions for all atoms. In this sense, $\Omega_0(k)$ can easily be chosen as the most negative parameter in either Table 1 or Table 2. For the atoms studied the best choices for $\Omega_0(s)$ and $\Omega_0(p)$ are the values for Li and B that possess the most diffuse basis functions. The choice of $\Delta\Omega(k)$ for the s and p meshes requires knowledge of the magnitude of the largest exponent among all the atoms. Employing the equation, $\Omega_f(k) = \Omega_0(k) + (N_k - 1) \cdot \Delta\Omega(k)$, the largest s and p exponents of the atoms can be evaluated. In either Table 1 or Table 2 the Ar atom can be used for the s and p type functions. The most negative $\Omega_0(k)$ and the greatest $\Omega_f(k)$ provide an adequate representation of the weight functions for the atoms covered by this universal basis. The universal $\Delta\Omega$ for each symmetry species can be obtained through: $\Delta\Omega(k) = (\Omega_f^{\max.}(k) - \Omega_0^{\min.}(k))/(N_k - 1)$.

The second (UB1) and third (UB2) columns of Table 5 show the universal parameters using the data from Tables 1

and 2, respectively, and the statistical data for the atomic properties. The universal basis obtained using the data from Table 2 (UB2) produces a reasonable improvement in $\langle r^n \rangle$ at the expense of all other properties. The mesh that represents correctly the initial and final cutoffs of the weight functions for all the atoms is basis UB2. Table 5 shows that the UB1 mesh with a smaller $\Delta\Omega(k)$ produces a more reasonable description of the orbital energies ε_i, $\langle p^n \rangle$, and total energies. However, the inadequate representation of the weight functions for some atoms causes the inferior statistics for $\langle r^n \rangle$ with UB1.

[b]$n = -2, -1, 1, 2, 3, 4$.
[c]Total energy.

Further attempts to improve these universal meshes through optimization were made. The simplest possibility is to fix the $\Omega_0(k)$ parameters of UB1 and UB2 and to reoptimize $\Delta\Omega(k)$ to look for the most contracted Gaussians. For these most contracted primitives it is possible to use one atom that provides a good description of these Gaussians. Thus, it is possible to define the universal basis applying the optimization procedure to a single atom. That possibility was tested using the $\Omega_0(k)$ from UB1 and UB2 with Ar as the reference. The fourth (UB3) and fifth (UB4) columns in Table 5 present the meshes obtained and the statistical results for the properties for all the atoms with these meshes. The use of the minimum energy criterion has improved the total energy as well as the $\langle r^n \rangle$ properties for UB3 and UB4 by decreasing the range of the meshes (Table 5) when compared with UB1 and UB2, respectively. Because this decrease in the range of the meshes was at the expense of the large exponents, the quality of the $\langle p^n \rangle$ properties diminished. Thus, the optimization procedure with reference to only one atom can yield bases similar in quality to those determined using all atoms as UB1 and UB2 universal basis set.

A more general procedure to optimize universal bases involves minimization of a statistical property for a set of the atoms as suggested by Mezey (5). This possibility was verified by minimizing the sum of the squares of the deviations of the total energy. The optimized energies for the atoms from

this work (Table 1) were taken as references. The second column in Table 6 represents the (16s10p) optimized universal basis (UB5) as well as the statistical information. There is a considerable difference in these discretization parameters from those presented in Table 5. The statistical information for UB5 in Table 6 shows a considerable improvement in the total energy. The total energy of Ar is the poorest and is 0.00721 au higher than the optimized value in Table 1. However, using the minimum of the squares of the deviations of the total energy as a criterion, the range for the meshes decreases, thus producing a poorer description of other atomic properties. The discretization parameters of this UB5 are very similar to those of the (16s10p) universal basis of da Costa, Trsic, and Mohallem (9) (CTMUB). Results with this basis are given in the third column of Table 6. Although the discretization parameters are almost identical for both methods, the optimized universal parameters of this work produce slightly better statistical results. The differences between the normalized total energies employing UB5 from this work and CTMUB of da Costa *et al.* are on the order of 10^{-5} hartree.

UB5 in Table 6 was obtained looking for the best total energies by minimizing the squares of the deviations of the total energy with respect to the optimized energy (Table 1). The small values of $\Omega_0(k)$ when compared with those of Table 5 suggest that this mesh can be improved for other properties using the technique discussed previously: change $\Omega_0(k)$ by $\Omega_0'(k) = \Omega_0(k) - \Delta\Omega(k)$, then fix $\Omega_0'(k)$ and reoptimize $\Delta\Omega(k)$. This universal basis (UB6) and the statistical results are given in the fourth column of Table 6. Comparing with the results of UB5, a significant improvement in the atomic properties was obtained without a great loss in total energy. UB6 in Table 6 provides the smallest sum of the squares of the deviations of the orbital energies and $\langle r^n \rangle$ of all the bases studied. The magnitude of the $\Omega_0(k)$ parameters for UB6 is close to reasonable cutoffs of the weight functions, as can be seen by comparing Table 6 with Tables 2 or 5. The accuracy of the total energies for this universal basis is poorer only in comparison with UB3 (Table 5) and UB5 and CTMUB (Table 6).

Although all atoms were used to define the sum of the squares of the deviations, a smaller set could be employed. A reasonable choice uses the atoms that have the most diffuse Gaussians as well as the most contracted ones for each period. For the set of atoms studied, the family {Li,B,Ne,Na,Al,Ar} yields the following mesh:

$$\Omega_0(s) = -3.2995 \qquad \Omega_0(p) = -2.4991$$

$$\Delta\Omega(s) = 0.9736 \qquad \Delta\Omega(p) = 0.9943$$

which is close to the values of the optimized universal basis (UB5 in Table 6). This mesh does not provide good atomic properties overall, and, thus, the $\Omega_0(k)$ were shifted by $\Omega_0'(k) = \Omega_0(k) - \Delta\Omega(k)$, $\Omega_0'(k)$ fixed, and the $\Delta\Omega(k)$ reoptimized. The fifth column (UB7) in Table 6 shows that this mesh is almost equivalent to that obtained including all atoms.

Three different procedures were applied to generate universal bases in atomic systems. Eight universal bases were generated for the atoms He to Ar. The choice of the best method can be done statistically, for example, using the Manhattan (city block) distance (18, 19) with respect to the Clementi–Roetti results (17). Taking all the properties calculated for all the atoms with all the bases in Tables 5 and 6, employing an autoscaling to remove the weighting that arises due to different units, and measuring the Manhattan distance from the Clementi–Roetti results indicates that the best bases are UB3, UB1, and UB6. However, the information in Tables 5 and 6 shows that there are no large statistical differences, except for UB5 and CTMUB, which were optimized considering exclusively the minimum energy criterion. The UB5 energy-optimized set could be modified by the inclusion of other atomic properties in the least-squares procedure, thus increasing the similarity of this basis to the others.

5. Applications to molecular systems

The bases discussed above attempt to improve the wavefunction such that good total energies and other atomic properties can be obtained simultaneously. A natural extension of this work is to evaluate the effect of these corrections in molecular systems. Calculations for N_2, CO, P_2, and CS were performed with two atom-optimized bases (AT1 and

AT2 of Tables 1 and 2) and with two universal ones (UB5 and UB6 of Table 6). The choice of these two universal bases was made considering that UB5 presents the worst results for atomic properties and good total energies, while UB6 was corrected to improve the atomic properties and to provide reasonable total energies. No contraction of the bases was employed to preserve the character of the numerical integration of eq. [2]. Table 7 presents the results of some molecular properties.

There is great similarity among the results obtained with the four bases. The universal bases provide results that are as accurate as the optimized ones independent of the property being analyzed. The correction of the weight functions for atomic systems does not produce significant changes in the molecular systems using either the optimized bases or the universal ones. Figure 3 shows that, in a molecule, bases optimized with respect to the total energy are deficient in their description of the weight function in the diffuse region. However, the nearly equivalent molecular properties calculated with different bases show that the best set for molecular calculations is UB5, which also gives the best energy.

The relatively large size of the bases may be responsible for the nearly equivalent results in Table 7. The incorrect magnitudes of the electric fields at the nuclei suggest that the deficiencies in the bases probably are due to the absence of polarization functions.

6. Conclusions

The SIMPLEX method defined the meshes of the s and p generator functions for the discretized version of the Griffin–Hill–Wheeler–Hartree–Fock equations. Analysis of the optimized basis sets showed that the meshes obtained through the minimum total energy criterion are accurate with respect to the total energy but deficient in the valence region. This deficiency leads to a poor description of other atomic properties such as orbital energies, $\langle r^n \rangle$ and $\langle p^n \rangle$. Changing

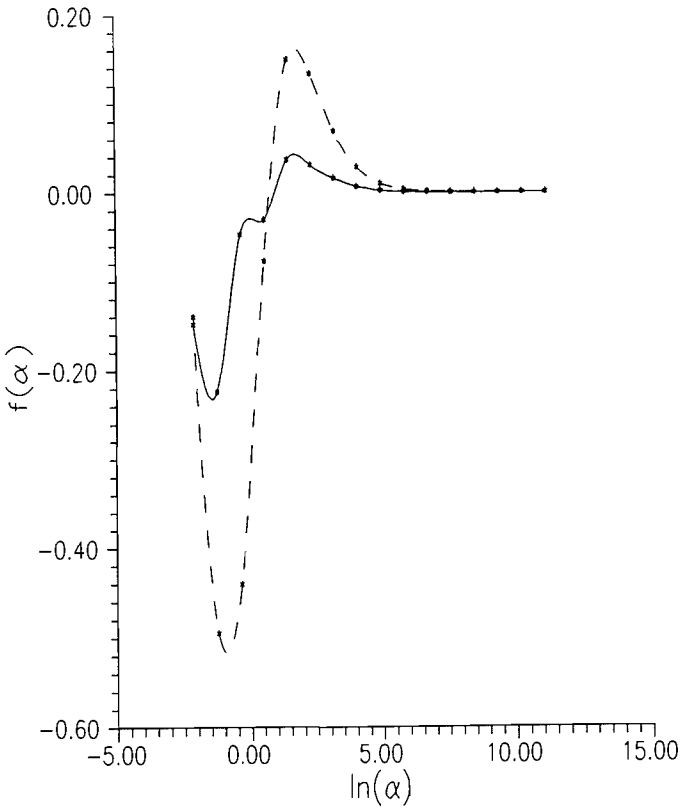

FIG. 3. The *s* weight function (dashed line) and the *p* weight function of the $3\sigma_g$ orbital for one nitrogen atom in the N_2 molecule obtained with the AT1 basis at the theoretical equilibrium bond length (continuous line).

the parameters $\Omega_0(k)$ to $\Omega_0'(k) = \Omega_0(k) - \Delta\Omega(k)$, fixing $\Omega_0'(k)$, and reoptimizing $\Delta\Omega(k)$ for each symmetry species simultaneously produces a better general description of the atomic properties at the expense of a somewhat poorer energy. Methods that maintain a good description of the weight function in both the outer and inner regions are needed.

Three different procedures were explored to obtain universal bases: (*a*) defining the universal basis using information from the isolated atoms, (*b*) defining the universal $\Omega_0(k)$ through atomic calculations and reoptimizing the $\Delta\Omega(k)$ for the different symmetries simultaneously with a single atom calculation as a reference, and (*c*) optimizing the universal mesh using statistical criteria such as the sum of the squares of the deviations of the total energy.

The universal bases generated by these procedures are almost equivalent statistically except for the basis obtained employing method (*c*). If the universal mesh is optimized with respect to the minimum deviation in the total energies, the mesh will yield a poor description of the weight function for a set of atoms. Changing $\Omega_0(k)$ to $\Omega_0'(k) = \Omega_0(k) - \Delta\Omega(k)$ and further reoptimization of $\Delta\Omega(k)$ improves the mesh and produces results statistically close to the other bases.

Applications of the atom-optimized and universal bases to diatomic molecules (N_2, CO, P_2, CS) show that the universal bases are as accurate as the atom-optimized ones. Bases AT1 and UB5 are deficient in the descriptions of the weight functions in the valence region. However, the shift corrections in the weight functions that improve the atomic properties are not useful in the molecular calculations when the bases are transferred from the atoms to a molecule. The bases yield nearly equivalent molecular properties. The important requirement of good total energies shows that the best basis for molecular calculations is that optimized by procedure (*c*), that is UB5.

Computational studies on hydrates of alkaline-earth dications

MARIUSZ KLOBUKOWSKI
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 9, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

MARIUSZ KLOBUKOWSKI. Can. J. Chem. **70**, 589 (1992).

SCF and Møller–Plesset calculations were done for the hydrated alkaline-earth ions in the gas phase. The systems studied were $M^{2+}(H_2O)_n$, where M = Mg, Ca, and Sr, and n = 1, 2, 3, 4, and 6. The successive ion–water bond energies were in the range anticipated on the basis of extrapolation of results from experimental studies on larger hydrates.

Key words: hydrates, alkaline-earth cations, quantum-chemical calculations.

MARIUSZ KLOBUKOWSKI. Can. J. Chem. **70**, 589 (1992).

On a effectué des calculs SCF et des calculs de Møller–Plesset sur les ions hydratés de métaux alcalino-terreux en phase gazeuse. On a étudié les systèmes $M^{2+}(H_2O)_n$, dans lesquels M = Mg, Ca et Sr et n = 1, 2, 3, 4 et 6. Les valeurs des énergies de liaison ion–eau successives sont dans l'ordre des valeurs attendues sur la base de l'extrapolation de résultats obtenus avec des hydrates plus importants.

Mots clés : hydrates, cations de métaux alcaline-terreux, calculs de la chimie quantique.

Introduction

Recently, an experimental breakthrough achieved by Kebarle and co-workers (1) allowed for experimental studies *in the gas phase* of the equilibria involving water molecules and bivalent ions of the alkaline-earth elements:

$$M^{2+}(H_2O)_{n-1} + H_2O \rightleftharpoons M^{2+}(H_2O)_n$$

The electrospray technique used in the experiments provides accurate data on the ion–ligand bond energies for larger coordination numbers; in the case of divalent alkaline-earth ions the smallest clusters for which reliable data were reported contained as many as seven to eight water molecules. However, the interactions in the inner hydration shell involving a doubly charged metal ion and one to six water molecules and leading to binding energies in the 40–80 kcal/mol range, while interesting from a chemical viewpoint, are beyond the range of the present experimental apparatus (1).

Fortunately, the small-cluster range is amenable to computational studies, especially when the interacting systems possess high charges and closed electronic shells. The present work was conceived as a preliminary study in the computational continuation of the experimental investigation of the metal-ion–water clusters. To gain insight into the importance of basis set composition and the role played by the electron correlation, various large basis sets were used in SCF and post-SCF calculations. Furthermore, the accuracy of valence-electron representation in such studies, important for studies involving heavier atoms, was also investigated. Full geometry optimization of all species involved was done, thus furnishing not only the required energy data (which could be easily obtained from a refined experiment) but also the structural information (which is more difficult to acquire by experimental techniques).

In experiment, the successive ligands adapt the geometric arrangement corresponding to the lowest total energy. In computations, the imposed symmetry of the ligand arrangement can be utilized to reduce the computational effort. To establish the ligand conformation that is most favorable energetically, in the present work various possible symmetries were considered.

Calculations, results, and discussion

Basis sets

Basis sets of triple-zeta quality in the valence region were used in the present study. For hydrogen, Huzinaga's (5*s*) basis (2) was contracted to (3*s*). For oxygen, Huzinaga's (10*s*6*p*) basis (2) was used, contracted to (5*s*3*p*) following Dunning (3) and augmented with a diffuse *p*-type function (ζ_p = 0.059) (4). For magnesium, the McLean–Chandler (12*s*9*p*) basis, contracted to (6*s*5*p*), was used (5). Calcium was represented in the all-electron calculations by the (8*s*4*p*) basis obtained from the uncontracted (14*s*9*p*) set of Wachters (6). In the valence-electron calculations, the (5*s*5*p*) basis set, corresponding to the effective core potential including outer core electrons as developed by Hay and Wadt (7), was used in the contraction (5*s*4*p*) (with the two innermost *p*-type primitives contracted). In the valence-electron calculations on $Sr^{2+}(H_2O)_n$, the strontium (5*s*5*p*) basis of Hay and Wadt (7) was contracted as for calcium.

The exponents of the polarization functions were developed for all systems by optimization in the Møller–Plesset calculations (8) on the monohydrates (at geometries close to the optimum, with both the core orbitals and their counterparts among the virtual space removed from the active space). The polarization functions for hydrogen and oxygen were determined in the calculations on $Mg^{2+}(H_2O)$ and used for all the complexes.

The values of the exponents in the basis sets with single polarization functions (denoted here TZ1P) were: ζ_d^O = 1.2976, ζ_p^H = 0.9399, ζ_d^{Mg} = 0.2218, ζ_d^{Ca} = 1.1419, and ζ_d^{Sr} = 0.699. The exponents of the polarization functions in the TZ2P basis were: ζ_d^O = {2.3803,0.6844}, ζ_p^H = {1.4647,0.4261}, ζ_d^{Mg} = {0.4131,0.1580}, and ζ_d^{Ca} = {1.7336,0.5576}.

The optimization of exponents was done with the HONDO 7.0 program (9); the code was modified in this laboratory to allow for the geometry optimization in the Møller–Plesset

calculations via the conjugate gradient method of Powell (10). For all systems studied, the complete optimization of geometry using gradient techniques was done using the GAMESS program (11). For the evaluation of electric moments and polarizabilities HONDO 8.1 code was used (12).

All calculations were done on a SUN SPARCstation 4/370.

Monohydrates

The data on energy and structure of the isolated water are collected in Table 1. The calculated geometries, both on the SCF and MP level, are almost independent of the polarization space. The valence-electron results are satisfactorily close to the corresponding all-electron values. On the SCF level, the geometric parameters of water are quite close to the near Hartree–Fock results (13) (especially when two polarization exponents are employed). Corrections for the electron correlation bring the computed geometry close to the experimental structure with OH = 0.957 Å and HOH = 104.5° (14).

To gain insight into the quality of the various basis sets used, dipole and quadrupole moments are tabulated in Table 2 together with the values of static dipole polarizabilities. The results are compared with recent accurate values of Szczęsniak and Scheiner (15), who used very large basis sets (for oxygen, (15*s*10*p*3*d*) was contracted to (7*s*6*p*3*d*); for hydrogen, (10*s*3*p*) basis was contracted to (5*s*3*p*); the exponents of the polarization functions were optimized in molecular Møller–Plesset and polarizability calculations). Expansion of the polarization space brings about reduced dipole and quadrupole moments and increased polarizabilities. The best SCF values differ by 3, 15, 29, and 21% for μ_z, α_{xx}, α_{yy}, and α_{zz}, respectively (the corresponding errors in the MP2 values are 11, 15, 33, and 21%).

The results for the complexes of Mg^{2+}, Ca^{2+}, and Sr^{2+} are presented in Table 3. Coordination of water by metal ions results in the lengthening of the OH bond (by 0.02 Å for the magnesium complex and 0.01 Å for calcium and strontium); the bond angle in the coordinated water becomes smaller, by 1°–2°, than that in free water (the only exception is found in the magnesium complex treated at the MP level). The metal–oxygen bond length increases with the size of the metal ion while the total hydration energy ΔE decreases. For the magnesium and calcium hydrates, the MOH bond angle changes only slightly with the change in the composition of the polarization space; small changes (less than 1°) are induced by the use of the MP method. The length of the metal–oxygen bond responds in expected fashion when the polarization set is expanded or correction for the electron correlation is added.

The total hydration energies are relatively stable with respect to both the size of the polarization space and the treatment of electron correlation. The largest absolute changes are seen in the magnesium complex, where they are about 1–2 kcal/mol. The valence-electron results (for the calcium hydrate) are very close to the corresponding all-electron values; it may be expected that the results for the strontium hydrate are equally accurate.

Ågren and co-workers (16) studied the $Mg^{2+}(H_2O)$ complex using fairly large basis sets in SCF and CASSCF calculations aiming at the evaluation of infrared intensities. However, only the geometry of water was optimized, while the Mg—O distance was kept fixed at 2.05 and 2.10 Å (these distances bracket the interval of ion–water distances found in various Mg^{2+} crystalline compounds (17)). Their computed OH bond lengths were 0.959 and 0.979 Å at the SCF and CASSCF levels, respectively; these values are very close to the ones obtained in the present work.

Calcium dication hydrates were recently studied by Castro and co-workers (18), who used a variety of basis sets for the monohydrate. However, only one basis set used in that work gives the total energy comparable to the ones shown in Table 3; the remaining six lead to total energies differing by 1–3 E_h from the present values. Davy and Hall (19) also used a rather small basis set (of about STO-3G quality for the core orbitals and DZ1P for the valence ones) in SCF calcula-

tions, obtaining the geometry of the monohydrate similar to the ones reported in the present work, despite a rather large difference in the total energy (about 6 E_h).

All three monohydrates were the subject of a computational study by Zahradník and co-workers (20) who used very small MINI-1 basis sets of Huzinaga and co-workers (21) without polarization functions (to minimize the basis set superposition errors). The metal–oxygen distances, affected by BSSE, were significantly shorter than the present ones; the interaction energies computed with the MINI-1 basis sets and corrected for BSSE were fairly close to the present values for the three systems studied. However, the (BSSE corrected) energies obtained with the more flexible MIDI basis sets were about 10 kcal/mol larger than the ones obtained with the large basis sets in the present work.

Dihydrates

Table 4 shows the results of calculations for the ions coordinated by two water molecules. The calculations were done for two symmetries of the complex, D_{2h} and D_{2d}.

As seen in the previous section, coordination lengthens the OH bond and decreases the bond angle in water (again, the exception is found in the magnesium complex treated on the MP level). Extension of the polarization space reduces the total hydration energies by about 2–3 kcal/mol; the changes brought about by the electron correlation effects are smaller. Again, the valence-electron description of the calcium dihydrate is adequately close to the all-electron picture, reinforcing confidence in the quality of the results for the strontium complex.

The two structures, D_{2h} and D_{2d}, lead to almost equal hy-

[d]$\Delta E = E[M^{2+}(H_2O)_3] - \{E[M^{2+}] + 3E[H_2O]\}$.

dration energies, with the D_{2d} structure being infinitesimally more stable.

Castro and co-workers (18) in the studies on Ca^{2+} dihydrate with small basis sets obtained poorer energies (by about 2 E_h) and shorter metal–oxygen distance.

Trihydrates

In view of the great similarity in the interaction energies obtained with and without the corrections due to the electron correlation, only the SCF calculations were performed for trihydrates (and all larger complexes). The results, for the three geometric configurations of the complex, are shown in Table 5.

The water molecules respond to coordination in the manner seen in the smaller complexes, by increasing the bond length and reducing the bond angle. The angle between metal, oxygen, and hydrogen is quite similar to those found in the mono- and dihydrates (about 127°). The larger size of the central ion correlates with the longer metal–oxygen bond distance and smaller interaction energies. The larger polarization set reduces the hydration energies by 2–5 kcal/mol.

The interaction energies increase slightly in the series $D_{3h}^{\perp}$, $D_{3h}^{\parallel}$, and C_3 corresponding to a decreased repulsive contact between the lone electron pairs in water molecules. This change is accompanied by a diminutive lengthening of the metal–oxygen bond.

The total energies by Castro and co-workers (18) are again more than 2 E_h above the present values and their Ca—O bond lengths shorter.

Tetrahydrates

The larger size of these complexes, and the correspondingly larger basis sets, allowed for the use of the extended polarization space only for the tetrahydrates of magnesium in the highest symmetry D_{2h}.

The complexes with the "tetrahedral" S_2 symmetry have the largest binding energies (see Table 6). It is interesting to note, though, that as the size of the central ion increases, the difference between the hydration energies in C_4 and S_2 conformations becomes smaller. This is consistent with the recent experimental study on the structure of the Sr^{2+} ion in aqueous solution, which demonstrated lack of orientational order in the hydration shell (22). The reaction of water to coordination is similar to that seen in the smaller hydrates. The distances between the oxygen atoms in S_2 symmetry are fairly large, hence the metal–oxygen bond length is only slightly larger than in trihydrates.

The Ca—O bond lengths from the study by Castro and co-workers (18) are smaller (by about 0.7 Å for their best basis used).

Hexahydrates

For reasons of computational economy only the smallest, TZ1P, basis sets were used in T_h symmetry (see Table 7). The deviation of the geometric structure of the coordinated water from that of the free water is smaller in hexahydrates than in all other hydrates. The water molecules are found at relatively large distances from the metal ion. For the alkaline earth ions studied here, six water molecules are usually found in the first hydration shell. The Sr—O distance was found to be about 2.65 Å in solution (22), 2.61 Å in crystal (23).

In a recent theoretical study of hydrated Be^{2+} ions (24) it was found that two of the water molecules in the hexacoordinated ion form the second hydration shell, connecting with the first hydration shell via hydrogen bonds. The ions studied here are much larger than Be^{2+} and the first hydration shell could easily accommodate six water molecules. To check the relative stabilities of the two possible distributions of the six water molecules around the central ion, full geometry optimization was done for the magnesium ion hexahydrate in T_h and C_1 symmetries (the latter structure could be best written as $[Mg^{2+}(H_2O)_4](H_2O)_2$); following Iwata and co-workers (24), the 3–21G* basis set was used. The Mg—O distance in the T_h structure was found to be 2.075 Å, shorter than the value obtained with the TZ1P basis set, and the total hydration energy was 408 kcal/mol. The geometry of the C_1 structure is defined in Fig. 1 and in Table 8, and the corresponding interaction energy is only 385 kcal/mol, more than 20 kcal/mol smaller than in the T_h

complex. Even though both the geometries and the interaction energies are affected by the basis set superposition errors, unavoidable with the small 3–21G* basis set, the energy difference is probably large enough to allow for concluding that the first hydration shell of the divalent alkaline earth atoms consists of six molecules. For the Sr^{2+} hexahydrate, Castro and co-workers (18) used only the MINI-3 basis of Huzinaga and co-workers (21). The resulting geometry in T_h symmetry, with the Sr—O bond length 0.3 Å shorter than the present value, indicates considerable effects of the BSSE.

Conclusions

The energy changes obtained in the present study can be recast in the format that gives more information about the hydration process. The total energy change, $\Delta E(n)$, for the reaction:

$$M^{2+} + n\,H_2O \rightleftharpoons M^{2+}(H_2O)_n$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

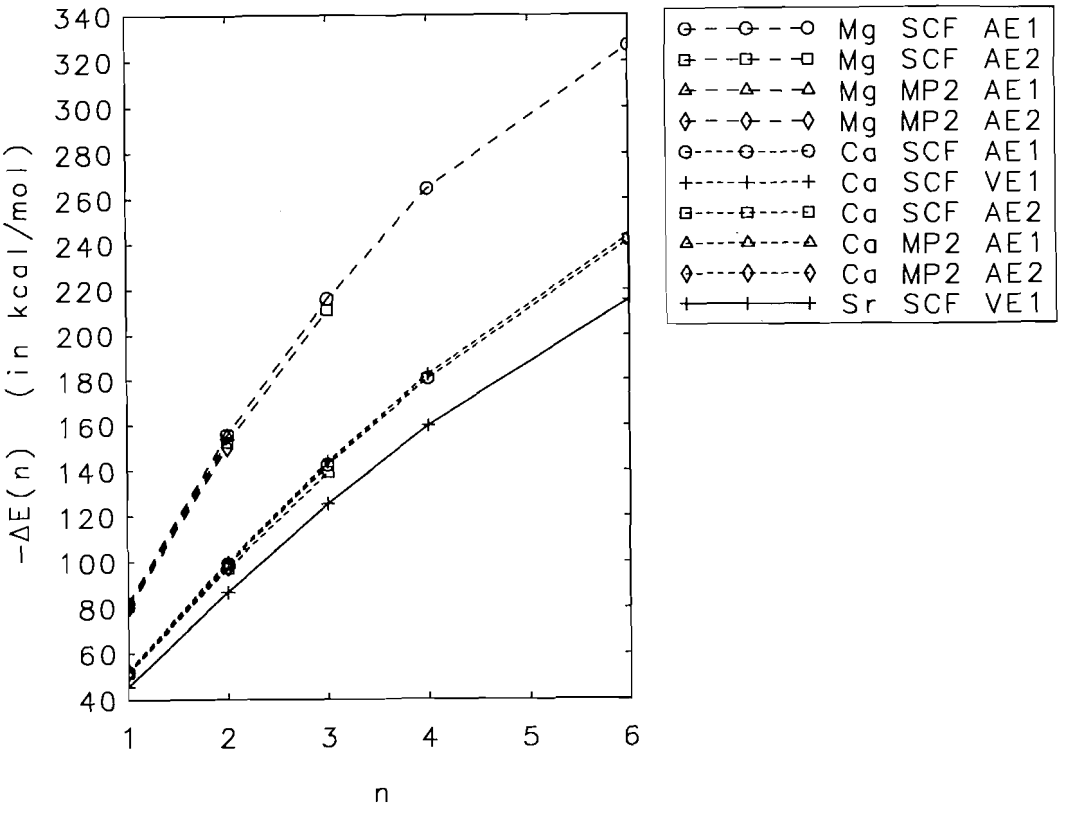

FIG 2. The total hydration energy.

is shown in Fig. 2. The average metal–water bond energies,

$$\Delta E(n)_{av} = \Delta E(n)/n$$

are depicted in Fig. 3. Finally, the successive metal–water bond energies that are closest to the quantities measured experimentally (1) in the reaction

$$M^{2+}(H_2O)_{n-1} + H_2O \rightleftharpoons M^{2+}(H_2O)_n$$

and which are defined as

$$\Delta E_{n-1,n} = E[M^{2+}(H_2O)_n] - \{E[M^{2+}(H_2O)_{n-1}] + E[H_2O]\}, \quad \text{for } n = 1, \ldots, 4$$

and

$$\Delta E_{n-1,n} = (E[M^{2+}(H_2O)_n] - \{E[M^{2+}(H_2O)_{n-2}] + 2E[H_2O]\})/2, \quad \text{for } n = 6$$

are presented in Fig. 4. Only the data for the symmetries with the lowest total energies are shown in the figures.)

It is interesting to note the behavior of $\Delta E_{n-1,n}$ for the magnesium hydrates: considering that the $\Delta H^0_{8,9}$ values for the three ions are in the 14.9–15.1 kcal/mol range (1), the rapid decrease of the calculated values may indicate that the structure of the hydration shell for $n > 6$ (and possibly even for $n = 6$) in the magnesium complex differs from the structure of the corresponding complexes with calcium and strontium ions. Clearly, the extension of the computational studies to the higher hydrates is needed.

The binding energies of all the hydrates studied decrease

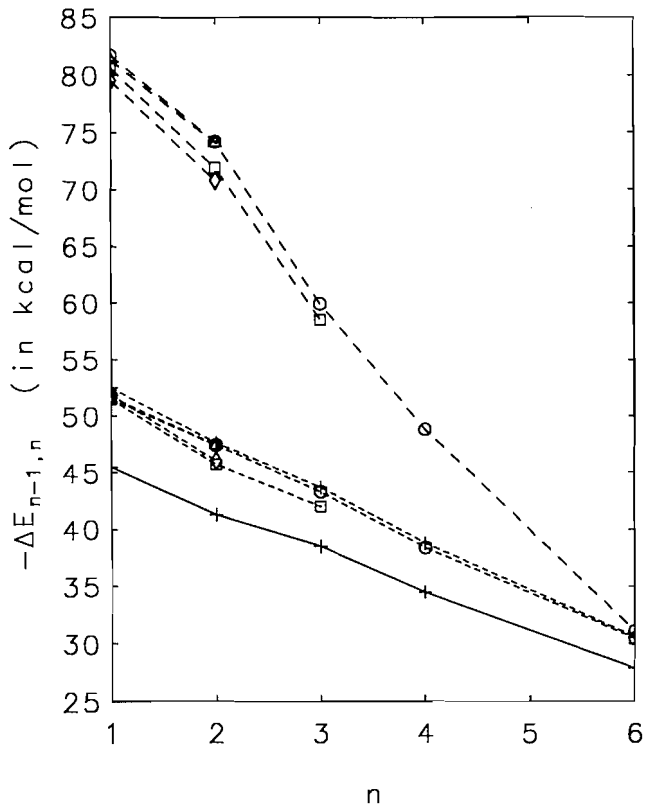

FIG. 4. The successive metal–water bond energy (see the legend in Fig. 2 for explanation of symbols).

when the basis set is increased. Considering that the bonding in the complexes is mainly electrostatic, the possible cause of the decreased interaction energies is the decrease of the dipole and quadrupole moments and increase of the dipole polarizability of the water molecule (cf. Table 2) upon extension of the basis set.

The present results indicate that neither extended (and expensive) polarization space nor electron correlation effects have to be necessarily considered in the studies on the hydrates involving the divalent alkaline earth atoms. Furthermore, the effective core potential method used with the basis set equipped with a small polarization space was found to be an adequate, and economical, computational approach to such calculations. The computational savings will be substantial especially in the studies on the harmonic vibrational frequencies.

The successive metal–water bond energies fall within the range of values predicted by Kebarle in the experimental studies (40–80 kcal/mol) (1). The agreement may be even better if the zero-point-energy corrections are added to the present values.

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

ANDRÉ G. MICHEL, CHAKIB AMEZIANE-HASSANI, and NATHALIE BREDIN. Can. J. Chem. **70,** 596 (1992).

In the framework of molecular mechanics conformational energy calculations, a random-search and minimization procedure is presented to characterize low-energy domains of polypeptidic structures. Rather than striving for global minima, populations of conformers are randomly generated, and their energy is minimized in order to study their intrinsic properties. The application to the opioid peptide Met-Enkephalin allowed the identification of low-energy domains that are compared with previous results of conformational studies on this molecule. Our method gives a complete overview of the conformational behaviour of the polypeptide under study, including previously reported structures as determined from experimental and theoretical studies. To illustrate the usefulness of this method to determine bioactive peptidic structures and their active conformers, the application to geometrically constrained chemotactic tripeptides is presented.

Key words: peptides, conformation, theoretical prediction.

ANDRÉ G. MICHEL, CHAKIB AMEZIANE-HASSANI et NATHALIE BREDIN. Can. J. Chem. **70,** 596 (1992).

Une méthode théorique de caractérisation des domaines conformationnels des molécules polypeptidiques est présentée. Les calculs d'énergie conformationnelle sont effectués dans le cadre empirique de la mécanique moléculaire. Plutôt que chercher à localiser le minimum global d'une hypersurface énergétique, des populations de conformères sont générées en vue d'en étudier les propriétés intrinsèques. L'application au peptide opiacé Met-Enképhaline a permis d'identifier des domaines dans la population générée et de comparer ces résultats à des études conformationnelles antérieures. On démontre que cette approche fournit une vue complète du comportement conformationnel du polypeptide, incluant les structures proposées par des travaux théoriques ou expérimentaux. Afin d'illustrer l'applicabilité de la méthode pour l'identification de conformation d'intérêt biologique, une étude a été menée sur des tripeptides chimiotactiques à géométrie restreinte.

Mots clés : peptides, conformation, prédictions théoriques.

Introduction

In the past decade, much effort has been made to identify absolute minimum energy structures for peptidic molecules. In such investigations, thousands of energy-minimized molecular conformations have been thrown away, retaining only a few lowest energy structures. Nevertheless, such generated structures constitute an ensemble wherein classes or groups of organisations are expected. In fact, experimental evidence suggests that polypeptides as short as four or five residues can adopt nonrandom conformations in aqueous solutions (1). Strategies based on energy minimization, dynamics, and Monte-Carlo simulations have been used in various studies (2, 3) to simulate the conformational space. The determination of minimum energy conformations of polypeptides by dynamic programming was also recently presented (4). A comparative study of the different methods has been published recently (5).

Here we describe an approach based on energy minimization after random generation of initial conformations. Our purpose is to generate the population of conformations characterizing a particular peptidic sequence. Subsequent analysis of this ensemble of conformers is expected to reveal the intrinsic organization in conformational space. The largest part of the conformational space is sampled by generating a large number of initial random conformations. Subsequently, the conformational energies of the resulting structures are minimized, using the conjugate gradient technique, to the nearest local minimum into the torsional space.

Such a procedure allows us to generate a sample of conformers representative of the conformational behaviour of the peptide of interest. The empirical conformational energy program for peptides (ECEPP) force field (6–8) appeared to be very well suited for such applications, as the use of a rigid geometry reduces the number of variables to only torsional angles. Actually, this force field has proven to be well adapted for applications of molecular mechanics to peptidic structure. Particularly, the procedure of Scheraga, called the "Build-Up" method, allowed reasonable predictions of global minima for small and medium peptides to be made (9). The same energy function was recently applied by Wüthrich and co-workers (10). A population of conformers for Enkephalin was generated, using a systematic search procedure.

During the past decade, the conformation of the endogenous opioid pentapeptide Tyr-Gly-Gly-Phe-Leu-Met **M-Enk**[2] has been extensively investigated. Studies to identify local minima, using theoretical simulations, have proposed conformations that can be classified in four main categories. The first class of structures adopts a β-turn involving residues Gly^3 and Phe^4. Such structures are generated by the existence of a (5 → 2) intramolecular hydrogen bond involving $CO(Gly^2)$ and $NH(Met^5)$. Both theoretical results (10–20) and NMR

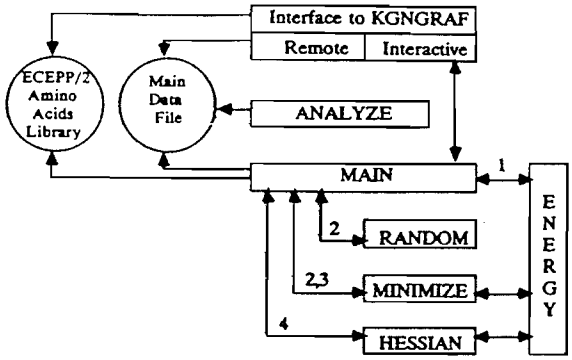

FIG. 1. Flowchart of the PEPSEA program.

studies (21–24) have supported this conformation. The application of recent multi-spin methods has confirmed these results (25, 26). Another group of structures involves β-turns including residues Gly^2 and Gly^3, generated by the existence of a (4 → 1) intramolecular hydrogen bond between $CO(Tyr^1)$ and the terminal $OH(Phe^4)$. Pioneering investigations of DeCoen *et al.* first mentioned this possibility (19), which was also suggested by C.P.K. model studies (27) and confirmed by a systematic conformational search (10). Exclusively extended structures were determined by X-ray diffraction studies (28–30). However, a folded β-turn structure was observed by X-ray diffraction studies of Leu-Enkephalin (31). Finally, a γ-turn involving the three residues Gly^2-Gly^3-Phe^4 was predicted by Scheraga, from simulations based on a statistical mechanical algorithm (32). Our purpose in this study has been to generate a population of conformers for **M-Enk,** and to evaluate its representation of the full conformational space by comparison with previous results.

The investigation of chemotactic peptides has also proven to be very challenging, the most potent agent being the tripeptide formyl-Met-Leu-Phe-OH: **fMLP.**[2] Structure–activity relationships were established, trying to identify the *active* conformer. In a recent publication, we formulated a hypothesis about the structural requirements for chemotactic activity (33). Although more rigid than **fMLP,** the peptide **fMAP,**[2] where the Leu residue has been substituted by the residue **Aib** (α-aminoisobutyric acid), retains the chemotactic activity (34–36). Structural studies by ^1H and ^{13}C NMR (34,37) and infrared spectroscopy (37) inferred that the presence of intramolecular hydrogen bonds suggests a structure involving a β- or γ-turn, with CO(Met) and NH(Phe). To corroborate our model of the *active* conformer for a chemotactic tripeptide, we have investigated the conformational properties of **fMAP.**

Method

Our method of population generation of conformations, based on random search and energy minimization, has been implemented as an interactive molecular modeling package.

Description of the PEPSEA[3] program

The scheme of the program is shown in Fig. 1. The MAIN module assumes the control and data file management, routing the execution following the options chosen by the user. PEPSEA can be used in two different modes. The interactive mode is suitable for data preparation and for single conformation calculations. The remote mode is used for multiple conformation applications and to submit applications to local or remote computers. In its present version, the interactive mode is interfaced with the KGNGRAF molecular modeling package (38). Interactive tools have been implemented to build up specific sequences, using the ECEPP amino-acid library (6–8).

As indicated by the numbers in Fig. 1, the program offers four different options. Option 1 allows us to perform a single ECEPP energy calculation. Route 2 allows us to generate a population of conformers. Random values are assigned to torsional angles and the corresponding energy minimized. This process is repeated a number of times corresponding to the number of conformers one wishes to study. Route 3 allows the minimization of predefined conformers, while option 4 computes the Hessian matrices in order to estimate free energies.

The ENERGY module is similar to the energy function of the ECEPP/2 program (39). It reproduces, exactly, ECEPP calculations for the residues included in the amino-acid library (6–8). The RANDOM module returns a random number between 0 and 1 based on a subtractive method (40). These numbers are converted to values between −180 and 180°, to be assigned to the variable torsional angles as specified by the user. The MINIMIZE module is used to find the minima of the energy function. It uses the conjugate gradient algorithm (41). A subroutine has been implemented to estimate the first derivatives by finite differences. Based on comparative studies described by Fletcher (42), the method of the central derivative was used, and proved to be well adapted for the polynomial function of the energy. The convergence criterion was set to 10^{-4}, terminating the calculation when the module of the vector constituted by the first derivatives becomes less than that value. Step sizes of 0.001 degree are used. The module does not impose any restrictions on the number of iterations. The HESSIAN module calculates the determinant of the Hessian matrix, constituted by the second derivatives of the energy function at the minimum under investigation. This is done for a predefined set of low energy conformers.

The subroutine used to compute second derivatives is similar to the one used for first derivatives. Nevertheless, optimal values for the step size have to be determined by the user. In its present version, the ANALYZE module estimates partition functions and free energy values following well-established methods (43). This program can also sort and manipulate the main data file.

Experimental procedure

In practice, the user needs to decide about the sequence of residues, making sure that the residues are included in the library. Secondly, variable angles must be specified before submitting the process.

For **M-Enk,** the peptidic sequence has been built using the standard residue library of ECEPP (6–8) with the end groups uncharged, $-NH_2$ and -COOH. A dielectric constant of 2 was used in the energy calculations. A total number of 3000 conformers was randomly generated and energy-minimized to the closest minimum, using all 13 possible ϕ, Ψ, $\chi 1$ angles as variables. The resulting population of conformers was sorted by increasing values of the conformational energies. Subsequently, the first 100 conformers of lower energies have

been submitted to energy minimization, allowing all rotatable bonds to be modified.

For **fMAP,** the peptidic sequences were built from the standard library of ECEPP (6–8) updated for the α-aminoisobutyric acid residue **Aib.** Atomic partial charges for this particular residue were computed by CNDO/2 calculations (44). Fifteen hundred starting conformers were randomly generated and energy-minimized to the closest minima. Again, a dielectric constant of 2 was used in the energy calculations. For this generating process, all torsional angles ϕ, Ψ and $\chi 1$'s were allowed to vary. The first 100 conformers of lower energies were submitted to a further energy minimization, allowing all rotatable bonds to be modified. The resulting population of conformers was sorted by increasing values of the conformational energies.

The calculations were performed on IBM RISC/6000 model 520 workstations (Laboratoire de modélisation moléculaire, Université de Sherbrooke), and on an IBM 4381, VM/CMS operating system (Centre de l'informatique, Université de Sherbrooke). The SYBYL molecular modeling system was used for displaying, plotting, and fitting of the molecular structures (45). Dihedral angles are labelled according to the IUPAC–IUB Commission on Biochemical Nomenclature (46).

Results and discussion

Conformational domains of Met-Enkephalin

The corresponding conformations have been identified in accordance with the conventional letter-coded partition of the [ϕ,Ψ] maps (43). The most stable conformers appeared to be distributed into three major classes presented in Fig. 2. For each structure, one finds an identification number (no.), the ranking order by increasing energy, the conformational code, the type of turn, (N) the frequency of occurrence, (ΔE) the relative conformational energy, (ΔG) the relative conformational free energy computed at 300 K, and finally the

presence and nature of possible hydrogen bonds. The different possible hydrogen bonds are also indicated, the thick line indicating the main hydrogen bond, which characterizes the type of structure for a particular class of structures.

The first class is the most populated (14 structures over 30). It is characterized by a β-turn involving residues Gly^3 and Phe^4, with the existence of an (5 → 2) intramolecular hydrogen bond involving $CO(Gly^2)$ and $NH(Met^5)$. The global minima no. 1, coded GA*C*AE (E = −14.20 kcal/mol), and no. 3, coded FDC*AC (ΔG = −0.98 kcal/mol), identical to the global minimum proposed by Wüthrich (10) and similar to the second minimum of Scheraga (9), belong to this group. Interestingly, a frequency of occurrence of 4 was obtained for this most probable structure no. 3. It is important to mention the contribution of the Tyr^1 OH^{η} in the stabilisation of folded structures. Most theoretical (10–20) and experimental (21–26) studies have proposed such conformations. Figure 3*a* gives the superposition of the structures belonging to this group. Another kind of Gly^3-Phe^4 type II′ β-turn was reported by Moskowitz and co-workers (13, 47). In this particular structure, the ω angle of Met^5 differed by 180°; nevertheless, after minimization by PEPSEA, this structure converged exactly to our conformer no. 3 coded and FDC*AC.

Class 2 involves similar structures but with a γ-turn including residue Gly^3 generated by the existence of a (4 → 2) intramolecular hydrogen bond between $CO(Gly^2)$ and the $NH(Phe^4)$. Figure 3*b* gives the superposition of the structures belonging to this group. More flexibility is allowed by this class of conformers, especially for the Tyr and Phe side chains. Recent theoretical studies have also mentioned the probable existence of these structures (32). Again in this group the Tyr^1 OH^{η} contributes to hydrogen bonding in seven cases.

The third class is characterized by the presence of a β-turn with the central residues Gly^2-Gly^3 generated by a (4 → 1) intramolecular hydrogen bond between $CO(Tyr^1)$ and the terminal $OH(Phe^4)$. Interestingly, the similarities between this type of structure and potent rigid opioid compounds led Momany (48) and other groups (49, 50) to suggest a Gly^2-Gly^3 type II′ β-turn as the bioactive conformation for recognition at the opioid receptor. Figure 3*c* shows that the structures differ only by the orientation of the methionine residue, the rest of the molecule adopting a globular shape of structure similar to rigid opioids.

These three groups of structures obtained for **M-Enk** include most of the structures previously reported. Some particular structures are interesting to examine. Structures similar to the extended X-ray structures were found with ΔE higher than 20 kcal/mol. Also the folded structure observed for **Leu-Enk** (31) converged, after energy minimization, to a minimum with a ΔE = 17 kcal/mol.

*The chemotactic peptide f-Met-Aib-Phe **fMAP***

Figure 4 presents the first 100 most stable conformers resulting from the minimization of all torsional angles. Conformational energies are relative to the global minimum no.

1 (E −2.66 kcal/mol). The table gives the code corresponding to the conformations. The frequency of occurrence is the number of times the conformer was obtained after minimization. Among the 100 conformers, 80 are distributed into three classes. The first two classes are composed of folded structures and the third one includes extended structures. Folded structures can be stabilized by two main hydrogen bonds, one between formyl(CO) and Phe(NH), giving rise to a C_{10} β-turn, and the other, between formyl(CO) and Aib(NH), to form a γ-turn structure.

The first class is characterized by the presence of a type III or III′ β-turn. It includes 20 conformers of relatively low energies (less than 2 kcal/mol) and includes the global minimum (no. 1). Figure 5*a* shows a superposition of these structures and demonstrates the similarity of the members of the class. The variability is due to the possible rotations of the Phe side chain. Previous NMR studies have concluded that the presence of an Aib residue favored the formation of 3_{10} helices characterized by type III or III′ β-turns (51). More specifically, by empirical energy calculations Semus reached the conclusion that **fMAP** adapted a β-turn structure (52).

The second class includes 21 conformers characterized by the presence of the γ-turn. Superpositions of Fig. 5*b* show

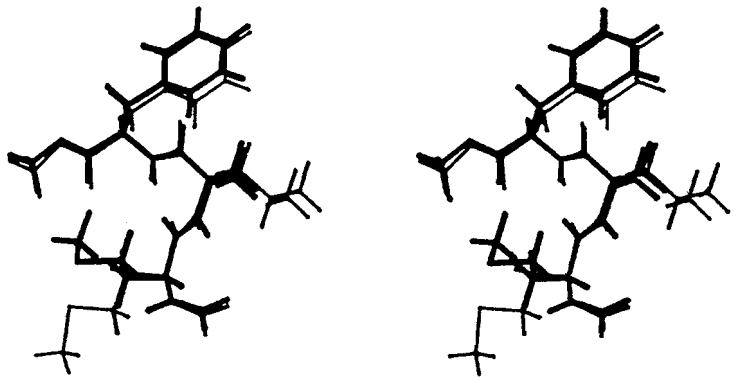

FIG. 6 Superposition of the proposed active conformer of **fMLP** (33) with **fMAP** from class 3 (thick lines).

For personal use only.

that the Met is mainly oriented in two different ways, while the Phe residue can rotate more freely than in class 1.

The third class is composed of 39 conformers of energies lower than 3 kcal/mol. The main structural feature is the extended structure, without hydrogen bond. By examining the superposition of Fig. 5*c*, one observes the proximity between the Met side chain and the backbone. This interaction constitutes the main factor of electrostatic stabilization for this class of compounds. Only 15 among the first 100 structures do not belong to our classes. The structures are extended, and the only conformer no. 43 forms a C_7 hydrogen bond between Met(CO) and Aib(NH) giving rise to a γ-turn structure, also proposed by Antony Raj and Balaram (37) from infrared and ^{1}H NMR studies.

To verify our hypothesis of active structure for this family of compounds (33), we present in Fig. 6 the superposition of our previously proposed active conformer of **fMLP** and **fMAP** (thick lines) as it appears in the third class of structures. It is seen that the only modifications are observed for the Met side chain, while the backbones are similar. Although not stabilized by hydrogen bonds, this third class of peptides appears to be compatible with our hypothesis of active conformer and includes 50% of the population generated. This also indicates that an active chemotactic peptide must have the formyl group free of intramolecular interaction in order to be available for the formation of the complex with the receptor.[4]

In conclusion, the strategy based on random generation of peptidic structures, followed by energy minimization, has been shown to generate relevant populations of conformers. The method appears to be an excellent alternative when a systematic conformational search of conformations is prohibitive. The analysis of such populations led to the conclusion that the structures are organized into domains. Further investigations have already been undertaken in our group to develop methods of analysis based on statistical mechanics, in order to predict physico-chemical properties of ensembles of conformations. Such an approach is expected to give a better understanding of the conformational behaviour of flexible molecules and particularly of polypeptides.

Received May 30, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

F. GREIN and P. DESLONGCHAMPS. Can. J. Chem. **70**, 604 (1992).

Using geometry optimizations at the 6-31G** level, energies, bond distances, and charges were obtained for systems XH_n—CH_2—OH with X = F, O, N, C, for various rotational conformers of the OH group. Conformational analysis shows that systems with X = F and O receive anomeric stabilization due to a partial π-bond forming in the CH_2—OH fragment of the molecule, amplified or diminished by lone pair repulsion (or dipole) energies. For the systems with N and C, no π-bond stabilization is found. However, the e-NH_2—CH_2—OH system is still stabilized due to favourable lone pair repulsion circumstances.

Key words: anomeric effect, *ab initio* studies, π-bonding model.

F. GREIN et P. DESLONGCHAMPS. Can. J. Chem. **70**, 604 (1992).

Utilisant des optimisations de géométrie au niveau 6-31G**, on a déterminé les énergies, les longueurs de liaison et les charges de divers conformères rotationnels du groupe OH des systèmes XH_n—CH_2—OH (X = F, O, N et C). L'analyse conformationnelle montre que les systèmes dans lesquels X = F et O reçoivent de la stabilisation anomérique qui résulte de la formation d'une liaison π partielle dans le fragment CH_2—OH de la molécule, amplifiée ou diminuée par les énergies de répulsion (ou dipolaire) de la paire d'électrons libre. Pour les systèmes avec N et C, on n'a pas observé de stabilisation par liaison-π. Toutefois, le système e-NH_2—CH_2—OH est encore stabilisé à cause des circonstances favorables créées par la répulsion de la paire libre.

Mots clés : effet anomérique, études *ab initio*, modèle de liaison-π.

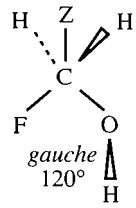
Introduction

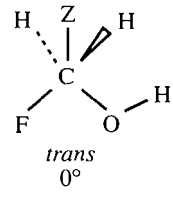
Considerable experimental evidence has been found in recent years for "stereoelectronic" effects, which relate the conformation and reactivity of molecules to the orientation of electron pairs in space. Such evidence is summarized in books by Deslongchamps (1) and Kirby (2). The term "anomeric" effect was introduced in 1958 by Lemieux and Chu (3) in connection with the orientation of an alkoxy group in the pyranose ring. As a general rule, a lone pair of electrons (lp) on O oriented antiperiplanar (app) to a polar bond stabilizes the molecule, leading to a shortening of the C—O bond and a lengthening of the polar bond. A simple explanation is given by the partial donation of a lone pair electron into the polar bond resulting in the formation of a partial C—O double bond combined with a lengthening of the polar bond C—Y due to the negative charge on Y. In molecular orbital terms, this electronic stabilization is understood by delocalization of an n_p lone pair of O into the σ* orbital of the adjacent C—Y bond (4, 5). In an earlier interpretation (6), the anomeric effect was considered to be destabilizing due to the electrostatic repulsion of dipoles (or electron pairs) (7).

Molecular orbital studies have been found to reproduce this effect quite well. A large number of theoretical papers have appeared in the literature, considering many different systems and various aspects of the anomeric effect, starting in 1971 with the ground-breaking work by Wolfe *et al.* (8). For recent work see, for example, Reed and Schleyer (9, 10), as well as articles to be cited later on.

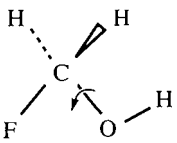
As a simple example, which was discussed in detail by



1*a*

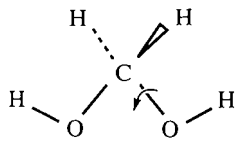


1*b*



F–CH_2–OH

1*c*



a-OH–CH_2–OH

2

Wolfe *et al.* (8), the lowest energy of fluoromethanol occurs for OH being *gauche* to CF, **1***a*, which is about 5 kcal/mol more stable than the *trans* conformer **1***b*. For the *gauche* conformer, the CO distance is about 0.01 Å shorter, and the CF distance about 0.015 Å longer than for *trans*. Also the OCF angle undergoes change.

While theoretical results obtained for energy and geometry changes are in good agreement with experimental findings, it is considerably more difficult to explain the nature of the anomeric effect, and in particular to decompose the

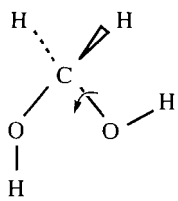
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

calculated energy differences into components corresponding to familiar concepts like steric effects, "electronic" effects, lone pair repulsions, etc.

In the following work, systems of type XH_n—CH_2—OH will be investigated, where in each case the OH hydrogen is being rotated about the CO bond. X will be F, O, and N. For reference purposes, C will also be included. While each of the above systems individually, or in combination with others, has been studied before (see, for example, Wolfe *et al.* (11), Smits *et al.* (12)), in this work a new analysis of energetic and bond distance changes will be presented, allowing us to classify the systems into various categories according to interactions that take place in the course of the OH rotation.

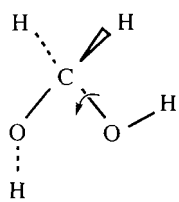
Method

For each of the systems XH_n—CH_2—OH, with X = F, O, N, C, geometry optimizations were performed at the 6-31G** level, using the GAUSSIAN 86 program (13). The Z—C—O—H dihedral angle (denoted briefly as the OH dihedral angle ϕ) was varied from 0° (*anti*), to 60°, to 90°, to 120° (*gauche*), to 180° (*syn*), where Z is defined in **1***a*, and the notations *anti*, *syn*, and *gauche* refer to the orientation of OH relative to the CX bond. Examples are shown in **1***a* and **1***b*. Besides the 60° intervals, ϕ = 90° was included due to its significance in the Fourier analysis to be discussed later. For each choice of OH dihedral angle, a complete geometry optimization of all other parameters, bond distances, bond angles, and remaining dihedral angles, was carried out.



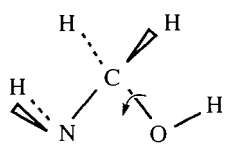
s-OH–CH_2–OH

3



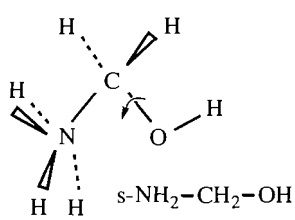
g-OH–CH_2–OH

4



e-NH_2–CH_2–OH

5



s-NH_2–CH_2–OH

6

For a given series of OH rotations, the dihedral angles of the XH_n hydrogens were fixed. For example, in the *a*-OH—CH_2—OH series, the dihedral angle of the (left) *a*-OH was kept at 0°, *anti*, whereas for *s*-OH—CH_2—OH, *s*-OH was kept at 180°, *syn*. Table 1 and structures **1***c*, **2**–**8** give the XH_n dihedral angles of all systems. For XH_n = OH, the prefixes *a*, *s*, *g* refer to *anti*, *syn*, and *gauche*, respectively, with respect to CX, whereas for XH_n = NH_2 and CH_3, the prefixes e and s refer to eclipsed and staggered, respectively, with respect to CH_2X.

Results and Fourier analysis

In Table 2, the calculated energy differences ΔE relative to ϕ = 0 (OH *trans*) are given for all geometry-optimized structures. It is seen that the first four systems, with X = F and O, all have the energy minimum at 120°, *gauche*, as one would expect, or at 90° for *s*-OH—CH_2—OH. (Actually, if ϕ is optimized, the minimum occurs at 127.77° for *a*-OH—CH_2—OH, being 0.06 kcal/mol lower than at 120°, and at 95.44° for *s*-OH—CH_2—OH, being 0.04 kcal/mol lower than at 90°; and so on for the other systems. For the purposes of this work, angles of 90°, 120° will be required.) While e-NH_2—CH_2—OH has its minimum at 180°, the remaining three systems of Table 2 are most stable at 0°. They are examples of the "*gauche* effect," as formulated by Wolfe *et al.* (8, 14, 15), whereby conformations with a maximum number of *gauche* interactions between adjacent electron pairs or polar bonds are most stable. Wolfe *et al.* (8) found that in the case of the anomeric effect conformations with a polar bond between two electron pairs will be destabilized.

[a]$V'_1 = -1.47$, $V'_2 = 1.10$ kcal/mol.
[b]Some signs changed due to opposite convention for 0°.

In summary, judging by the $\phi = 120°$ conformer being more stable than the 0° conformer, the anomeric effect applies to all systems with X = F and O. While the above criterion also applies to e-NH_2—CH_2—OH, it is noted that for this system the 180° conformer is even more stable than the 120° one.

In the following, a Fourier analysis of ΔE will be performed, according to the method given by Radom and coworkers (16, 17). The formula used is

$$[1] \quad \Delta E(\phi) = (V_1/2)(1 - \cos\phi) + (V_2/2)(1 - \cos 2\phi) + (V_3/2)(1 - \cos 3\phi)$$

Additional terms $V'_1\sin\phi + V'_2\sin 2\phi$ will be needed for *g*-OH—CH_2—OH, which is not symmetric about 180°. According to the formula, $V(\phi)$ is zero at 0° and 360°, and therefore $\Delta E(0)$ was chosen as reference energy in Table 2.

From ΔE at 60, 120, and 180°, the V_i values of Table 3 were obtained. Taking $\Delta E(90)$ instead of ΔE at 60 or 120° leads to nearly identical V_i's. An interpretation of the V_i is given by Radom *et al.* (16). However, it is important to restate the important aspects. The V_3 portion of eq. [1] has maxima at 60 and 180°, and is zero at 0° and 120°. V_3 describes the threefold repulsion the rotating OH receives when it is eclipsing the two CH bonds at 60° and 300°, and the CX bond at 180°. V_3 is a strictly steric term, and is always positive. For the rotation of OH in CH_3OH, the energy difference between the staggered and eclipsed positions is 1.29 kcal/mol (6-31G**), and therefore V_3 is expected to be about 1.3 kcal/mol. Table 3 confirms this.

The V_2 part of eq. [1] has a maximum at 90°, and is zero at 0° and 180°. For the X = F, O systems, V_2 is negative, implying that the system is more stable at $\phi = 90$ than at $\phi = 0$, which checks with Table 2. Small negative values of V_2, as seen for the s-NH_2 and the CH_3 systems, are not considered to be significant, as will be explained later.

The V_1 portion of eq. [1] has a maximum at 180°, and a minimum at 0°. Since $\Delta E(180) = V_1 + V_3$, we can estimate $V_1 \cong \Delta E(180) - 1.3$ kcal/mol, or in other words, V_1 is the energy difference between 0 and 180°, corrected for the threefold steric repulsion. Essentially V_1 is negative if the conformation with OH at 180° (*syn*) is more stable than at 0° (*anti*), and positive if less stable. Negative and positive V_1 parameters occur in Table 3. The nature of V_1 and V_2 will be explained in detail later on.

Optimized C—O distances are given in Table 4. C—X distances will not be shown, since they depend on the nature of *X* and the orientation of the XH_n hydrogens, and are therefore not so useful for the comparative studies that follow. For the X = F and O systems, R_{CO} decreases starting with the 0° conformer, going through a minimum at 120°. For the remaining systems, R_{CO} increases between $\phi = 0$ and $\phi = 60°$, decreasing thereafter with a minimum again at 120°. It is known that SCF wavefunctions with polarization functions, such as 6-31G**, give bond distances significantly shorter than experimental values, and that correlated wavefunctions are required to correct this error. However, for our purposes only changes in *R* values are required, which are essentially independent of basis set.

In Table 5, the Mulliken charges on OH and XH_n are given. The charge on CH_2 can be derived as $Q_{CH2} = -Q_{OH} - Q_{XHn}$. A cursory look at Table 5 shows that for the systems with X = F and O, the negative charge on OH decreases as one goes from 0° to 90°, increasing thereafter. The OH charges on the remaining systems change little over the range 0–120°, but become more negative at 180°. The negative XH_n charges increase for all systems as one goes from 0 to 180° (or the positive charges for X = C decrease).

Discussion

For a simple definition of the anomeric stabilization, one may use the energy difference between the *anti* and *gauche* conformers, or $\Delta E(120)$ of Table 2. Accordingly, systems with *X* = *F* and *O*, as well as e-NH_2, have $\Delta E(120)$ negative, and therefore receive anomeric stabilization when OH is rotated from $\phi = 0$ to $\phi = 120°$. The remaining systems are not stabilized. The changes of R_{CO} and of charges mentioned earlier suggest that e-NH_2—CH_2—OH does not fit the same pattern as systems **1**–**4**. This will be discussed in detail later on. Since $\Delta E(120) = 0.75\,V_1 + 0.75\,V_2$, anomeric stabilization in terms of the V_i parameters means that $V_1 + V_2$ has to be negative. If both V_1 and V_2 are negative, such is assured (systems with *F*, *a*-OH, and *g*-OH). If V_1 is positive and V_2 negative, V_2 has to be more negative than $-V_1$. This is the case for *s*-OH—CH_2—OH. At the dihedral angles $\phi = 0°$ and 120°, OH is staggered relative to CH_2X, and the V_3 term is zero. Therefore, the anomeric stabilization depends only on V_1 and V_2, their signs and relative magnitudes.

Let us consider V_2 in more detail. In all cases of anomeric stabilization (omitting the special case of e-NH_2), V_2

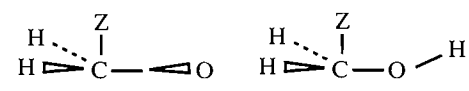
is negative. (Small negative V_2, as obtained for s-NH_2 and the CH_3 systems, should be ignored. They are artifacts of the fitting formula.) A negative V_2 means that the system is more stable at $\phi = 90°$ than at 0°.

Such a negative V_2 can be explained by considering the "π-bonding model." If X in XH_n—CH_2—OH is sufficiently electronegative, then partial charges $XH_n^{(-)}$, CH_2—$OH^{(+)}$ are to be expected. CH_2—$OH^{(+)}$ carries a partial double bond, depending on the amount of positive charge. For the extreme case of a full positive charge, we have the cation CH_2=OH^+.

In the following, energies, C—O bond distances and Mulliken charges of CH_2=OH^+ will be compared with the corresponding quantities of the eight systems studied here. If the systems under investigation have ΔE, R_{CO}, and Q_{OH} values following the pattern of CH_2=OH^+ values as OH is being rotated, we invoke the π-bonding model to be valid for the system under consideration.

First, *ab initio* geometry optimizations with the 6-31G** basis set were performed on CH_2=OH^+. At equilibrium, this cation is planar, **9***a*, due to the π-bond. If OH is tilted 90° out of this plane, with a dihedral angle between CH and OH of 90°, **9***b*, an energy of 22.95 kcal/mol has to be expended. Since for planar CH_2=OH^+ V_1 and V_3 are zero, and $\Delta E(90) = 0.5\ V_1 + V_2 + 0.5\ V_3$ according to eq. [1], one finds $V_2 = -22.95$ kcal/mol, where 90° corresponds to the planar conformation. To mimic the CH_2—OH group in XH_n—CH_2—OH, the CH_2 group was pyramidalized, with dihedral angles fixed at ±60° with respect to the plane Z—C—O, **10***a*. OH was rotated about C—O, with $\phi = 0$ when OH is in the Z—C—O plane, **10***b*. This is equivalent to the definition of $\phi = 0$ for the other systems. The ΔE values (relative to $\phi = 0$), C—O distances, and Mulliken charges for OH are given in Table 6. The energy differences are very large, which is not surprising since rotations occur about a double bond.



$\phi = 90°$ $\phi = 0°$

10*a* **10***b*

The important point is that for CH_2=OH^+ ΔE is negative

Table 6. 6-31G** results for $CH_2{=}OH^+$ with OH rotating about C—O, and CH_2 held in pyramidal position. For definition of the OH dihedral angle see **10***a* and **10***b*[a]

	0°[b]	60°	90°[c]	120°	180°
ΔE (kcal/mol)	0.00	−24.28	−32.62	−29.89	−13.48
R_{C-O} (Å)	1.2508	1.2370	1.2350	1.2394	1.2425
Q(OH)	0.048	0.126	0.140	0.127	0.085

[a]For $CH_2{=}OH^+$, $V_1 = -12.7$, $V_2 = -27.1$, $V_3 = -0.8$ kcal/mol.
[b]For 0°, the COH angle was fixed at 120°. Without setting this angle, OH would move from *cis* (0°) to *trans* (180°).
[c]The energy minimum occurs at 97.95° with ΔE 0.38 kcal/mol lower than at 90°.

at 60°, the energy reaching a minimum at 90° (or actually 97.95°, see Table 6), and is still close to this value at 120°, rising significantly at 180°, where, however, $\Delta E(180)$ is still negative.

In a similar manner, systems $XH_n{-}CH_2{-}NH_2$ can be compared with $CH_2{=}NH_2^+$, which is also planar at equilibrium. For $F{-}CH_2{-}NH_2$, Irwin *et al.* (18) obtained the global minimum for the N lone pair being antiperiplanar to C—F, 180°, and a local minimum at 0° (lp synperiplanar to CF). The potential curve has a maximum at 101.5°.

For $CH_2{=}OH^+$, the CO distance drops by 0.015 Å when going from 0 to 90°, and is still about 0.01 Å lower at 180° than at 0°. This is understandable since the π-bond is strongest at $\phi = 90°$, and nonexistent at 0 and 180°. Also, the *trans* configuration 180° is more stable than *cis*, 0°. The OH charges, as given in Table 6, also reflect the π-stabilization. Whereas they are close to 0 at 0°, and quite small at 180°, they reach a maximum of +0.140 at 90°, implying that the electrons are maximally involved in bonding and therefore not available as atomic charges. For $CH_2{=}OH^+$, the ΔE values of Table 6 lead to the Fourier parameters $V_1 = -12.7$, $V_2 = -27.1$ (V_2 was −22.9 for the planar cation), and $V_3 = -0.8$ kcal/mol. Due to the lack of threefold symmetry, V_3 is not meaningful. V_1 and V_2 are both negative, V_1 reflecting the fact that 180° is more stable than 0°, and V_2 the fact that 90° is more stable than 0°, as outlined above.

The V_i, ΔE, R_{CO}, and Q_{OH} values of $CH_2{=}OH^+$ will be used for comparison with the corresponding values of the systems under investigation.

The systems $F{-}CH_2{-}OH$ and *a*-OH—CH_2—OH resemble $CH_2{=}OH^+$ in all detail, as far as ΔE, V_i, R_{CO}, and Q_{OH} values are concerned. For example, ΔE is negative at 60°, and still negative at 180°. The shift of the minimum from 90° (actually 98°) to 120° (or thereabouts) is explained by the 90° conformer having a contribution from the destabilizing V_3, and a smaller contribution from V_1 (but a larger one from V_2). This is seen by comparing $\Delta E(90) = 0.5\,V_1 + V_2 + 0.5\,V_3$ with $\Delta E(120) = 0.75\,V_1 + 0.75\,V_2 + 0\,V_3$ (from eq. [1]). For both systems, not only is CH_2 + OH positive, but F is more negative than OH, Table 5, a fact one can readily accept. For *a*-OH—CH_2—OH, there are oxygens on each side of *C*, having the same electronegativity, but Table 5 shows that for the various conformers *a*-OH is more negative than the rotating OH, except at 0° where they are the same by symmetry.

For *s*-OH—CH_2—OH the charge on the rotating OH is more or less negative than on *s*-OH, depending on ϕ. For *g*-OH—CH_2—OH, the rotating OH is always more negative than *g*-OH, except at 120° where they are the same by symmetry. This might imply that for these systems C—X is less polar than CO and that therefore the π-bonding model may not apply. However, as ΔE and R_{CO} values show, the π-bonding model is still working well. Slight differences to the first two systems are that $\Delta E(180)$ is positive, and $R_{CO}(180)$ is larger than $R_{CO}(0)$. The charges Q_{OH} for both systems are least negative at 90°, corresponding to being most positive at 90° for $CH_2{=}OH^+$. Also, the CH_2—OH fragment overall still has a positive charge. This implies that the *s*-OH and *g*-OH systems can also be classified as receiving their stabilization according to the π-bonding model.

All systems in the π-bonding category have a sizeable negative V_2, ranging from −1.29 to −4.26 kcal/mol. It results, as outlined before, from the energy of the system at 90° being more stable than at 0°. A negative V_2 is essential for the π-bonding model to hold.

The remaining systems, with X = N and C, all have $\Delta E(60)$ positive. The ΔE values remain positive except for e-NH_2, for which system they turn increasingly negative, having an energy minimum at 180°. Looking at ΔE values only, the e-NH_2 system might still be considered to follow the π-bonding model. However, a glance at R_{CO} and Q_{OH} values tells otherwise. For this, as well as for the other N and C systems, R_{CO} increases when going from 0 to 60°, decreases to 120°, and increases again to 180°. This pattern is opposite to that calculated for $CH_2{=}OH^+$ (except 120° → 180°) and corresponds closely to the CO distance changes in CH_3—OH, where R_{CO} is about 0.004 Å larger at the eclipsed ($\phi = 60$, 180°) positions than at the staggered ones ($\phi = 0$, 120°).

For both X = N and X = C systems, the OH charges are essentially constant, except that they turn considerably more negative at 180°. For s-NH_2 and the two CH_3 systems, this is due to the stronger H–H repulsion at 180° than at 60°, resulting from the proximity of the rotating hydrogen to the NH_2 or CH_3 hydrogens at 180°, as is also reflected in the higher energies at 180° (and positive V_1). For e-NH_2, the reason is not obvious. For comparison, in CH_3—OH the OH charges at the eclipsed positions (60°, 180°) are 0.004 units more negative than at the staggered positions (0°, 120°), closely resembling the pattern observed for the X = N and C systems.

For both NH_2 systems, the CH_2—OH portion of the molecule is still positive, allowing the π-bonding model to hold in principle. However, contrary to the *s*-OH and *g*-OH systems discussed before, the higher electronegativity of O vs. N is now so dominant that the CH_2—OH fragment of the molecule behaves nearly like CH_3—OH, and no similarities to $CH_2{=}OH^+$ can be found.

For the CH_3 systems, the combined charge on CH_2—OH is negative, as is expected. They were included as reference

systems for which the anomeric effect is known not to hold. They follow closely the pattern of CH_3—OH. The system with s-NH_2 will be classified as belonging to the same group.

The reverse anomeric effect is cited as holding for s-NH_2—CH_2—OH by Krol *et al.* (19). Using a 4-21G basis set, they found s-NH_2—CH_2—OCH_3 to be 0.78 kcal/mol more stable at 0° than at 120°, in qualitative agreement with our result for s-NH_2—CH_2—OH (0.06 kcal/mol). On the other hand, Senderowitz *et al.* (20) found for s-NH_2—CH_2—OH the 120° conformation to be more stable than 0° by 1.40 (3-21G), 0.14 (6-31G*), and 0.31 kcal/mol (MP3//6-31G* with partial geometry optimization). While such small energy differences depend on the details of the optimization procedure, the main point made in the present study is that C—O distance changes and charge changes in s-NH_2—CH_2—OH are in contradiction to those pattern established for CH_2=OH^+. Therefore, it is considered better to classify s-NH_2—CH_2—OH as having no anomeric effect rather than invoking the reverse anomeric effect. If the NH_2 and OH dihedral angles of s-NH_2—CH_2—OH are relaxed, not fixed at ±120° as in the present study for reasons of Fourier analysis, then the 6-31G** basis set predicts the most stable conformer of s-NH_2—CH_2—OH to have ϕ = 110.7° and to be 0.17 kcal/mol more stable than the 0° conformer, close to 0.14 as obtained in ref. 20. However, the V_i parameters, calculated using ϕ(120), stay the same.

Obviously, despite some similarities, e-NH_2—CH_2—OH is quite different from its s-NH_2 counterpart. In particular the ΔE values, although positive at 60°, become negative, and are most negative at 180°.

This leads us to a detailed consideration of the remaining Fourier parameter V_1. Radom *et al.* (16) explain V_1 as resulting from dipole interactions. Using e-NH_2—CH_2—OH as example, for ϕ = 0 the dipole moments N → lp and O → lp point in the same direction, **11***a*, and repel each other, whereas for ϕ = 180°, they point in opposite directions and attract each other, **11***b*. An equivalent, but simpler, concept is to talk about lone pair (lp) repulsions. (A form of intramolecular hydrogen bonding may also be included, see below.) At 0°, the lone pairs of N and O repel each other, but at 180° there is no such repulsion (**11***a*, **11***b*). For the systems with e-NH_2, as well as for F and *a*-OH, there is lone pair repulsion at 0°, but none at 180°. Therefore, these systems have negative V_1, with values of −3.91 for F, −4.69 for *a*-OH and −4.91 kcal/mol for e-NH_2. (For *g*-OH—CH_2—OH, a V_1 of −0.48 kcal/mol can be explained on the same basis.) Due to the large negative V_1, and the small (even positive) V_2, the energy pattern of e-NH_2—CH_2—OH is governed by the V_1 term, leading to a large negative energy at 180°. (Since $V_1 + V_2 < 0$, there is still anomeric stabilization at 120°.) As was outlined before, the π-bonding model does not apply.

V_1 can also arise from the repulsion of the OH hydrogen with one of the XH_n hydrogens, in which case it is positive under the conventions adopted in this paper. For *s*-OH—CH_2—OH, at 0° there is no lp–lp repulsion (**12***a*), but at 180° (**12***b*) H–H repulsion is present. For this system, V_1 = 3.82 kcal/mol. The same situation applies also to s-NH_2 and the CH_3 systems. All have positive, if small, V_1 parameters.

In summary, V_1 can have two contributions, one from lone pair repulsions, and one from OH—XH_n H–H repulsion. The former may be considered to be electrostatic, the latter is steric. With our conventions, V_1 is always negative for lp repulsions (since they occur for ϕ = 0), and always positive for H–H repulsions (since they occur for ϕ = 180°).

Classification of systems

The systems with X = F and O all have sizeable negative V_2 parameters, and follow in all respects the π-bonding model. The main mechanism for anomeric stabilization is the desire of the CH_2—OH portion of the molecule to achieve maximal π-bonding character, which is accomplished between ϕ = 90 and ϕ = 120°. Within this class of π-bonding molecules, two subclasses can be distinguished, according to whether V_1 is negative or positive. If V_1 is negative, then the systems (F, *a*-OH, and *g*-OH) receive additional anomeric stabilization due to the decreasing lone pair repulsions as the OH group is rotated away from the *anti* position. If V_1 is positive (*s*-OH), the relation $V_1 < -V_2$ must be sat-

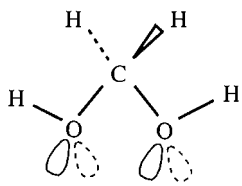
For personal use only.

isfied; otherwise there is no more anomeric stabilization. For positive V_1, there is increasing H–H repulsion as the OH group moves towards 180°. This energy term opposes the π-bonding stabilization.

The second class consists of molecules for which there is no π-electron stabilization (e-NH_2, s-NH_2, both CH_3 systems). In these cases, V_2 is zero or small. Again, there are two subclasses. For e-NH_2—CH_2—OH, V_1 is negative and large. Since at 120° ΔE (= 0.75 V_1 + 0.75 V_2) is negative, there is formally anomeric stabilization, despite the absence of π-bonding (or very small amount only). For the remaining systems, V_1 is positive and small, and there is no way to achieve anomeric stabilization. The CH_3—CH_2—OH systems, as was mentioned earlier, have been included in this study as reference systems in order to illustrate just this point.

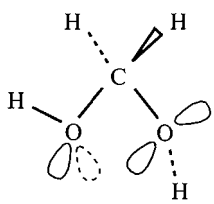
Comparison with other energy decomposition schemes

Earlier, Grein and Deslongchamps (21) proposed a simple model for predicting anomeric stabilization energies for systems XH_m—CH_2—YH_n, where X, Y = N and O. This energy is decomposed into contributions from an electronic effect, operating when a lone pair on X is in antiperiplanar position to CY, represented by the energy parameter a, lp–lp repulsions with energy parameter r_{lp}, 1,3-diaxial H–H repulsions r_{HH}, and intramolecular hydrogen bonding due to the proximity of a lone pair on X and a hydrogen on Y, with parameter h. For example, for a-OH—CH_2—OH, at 0° (**13***a*), $E_{rel}(0) = 2r_{lp}$, and at 120° (**13***b*) $E_{rel}(120) = r_{lp} + h + a$. So the anomeric stabilization energy is $E_{rel}(120) - E_{rel}(0) = h + a - r_{lp}$. Arguments were given for $h \cong -r_{lp} \cong -r_{HH} \cong -1$ kcal/mol, and $a \cong -2$ kcal/mol for O. Therefore, for a-OH—CH_2—OH, $\Delta E(120)$ is predicted to be −4 kcal/mol, compared with the calculated −4.49 kcal/mol, Table 2. With $a_O = -2$ and $a_N = -2.5$ kcal/mol, all anomeric stabilization energies of the systems XH_m—CH_2—YH_n were predicted within 0.5 kcal/mol. The methoxy systems OH—CH_2—OCH_3 and OCH_3—CH_2—OCH_3 were also included.



a-OH, 0°

13*a*



a-OH, 120°

13*b*

Smits *et al.* (12) considered *anti* and *gauche* conformers of the same systems as were studied here. A single determinant of non-orthogonal localized molecular orbitals was used. The energy (4-31G) was decomposed into quasiclassical, interference, and charge transfer terms. Interference terms were found to be most important for stabilizing the *anti* conformer. A direct comparison with the present scheme of energy decomposition is not possible.

For dimethoxymethane (DMM), Wiberg and Murcko (22) calculated and analyzed a conformational energy map. Interesting for our purposes is the energy decomposition for a-OCH_3—CH_2—OCH_3 (our notation). The energy difference between $\phi = 0$ and 120° is 3.3 kcal/mol. To estimate the lp–lp repulsion in the $\phi = 0$ conformer, they found the energy difference between the two corresponding conformers of methyl propyl ether to be 1.4 kcal/mol, with $\phi = 0$ being more stable. From this they obtained the anomeric stabilization of DMM, corrected for lp–lp repulsion, to be 3.3 + 1.4 = 4.7 kcal/mol. According to the present analysis, the reduction in the lone pair repulsion at 120° is already contained in $\Delta E(120)$, and therefore the portion remaining for the electronic effect is the difference between the 120° stabilization and the lp repulsions, rather than the sum.

Summary and conclusion

The anomeric effect predicts the *gauche* conformer to be more stable than the *anti* conformer for the systems XH_n—CH_2—OH studied here, provided the electronegativity of X is sufficiently high. *Ab initio* calculations on conformers with OH dihedral angles from 0° (*anti*) to 180° (*syn*) showed that anomeric stabilization is obtained for XH_n = F, a-OH, g-OH, and s-OH. For these systems, energies, C—O distances and charges on OH follow closely the corresponding values of $CH_2{=}OH^+$, for which OH is rotated in a similar fashion. Anomeric stabilization derives from the tendency to form a π-bond in the CH_2—OH fragment of the molecule. For XH_n = F, a-OH, and g-OH, lone pair repulsions are diminished when rotating the OH group from *anti* to *gauche*, thereby increasing the anomeric stabilization energy. For s-OH—CH_2—OH, however, the OH hydrogens experience increasing repulsion as OH is rotated towards the *syn* position. Therefore, the π-bonding stabilization is diminished by H–H repulsion.

For the X = N systems, the electronegativity of N is insufficient to cause π-bonding stabilization. However, the e-NH_2 system is still stabilized by decreasing lp repulsions as the dihedral angle of OH moves towards 180°. On the other hand, for s-NH_2 there is no such stabilization, and this system behaves in all respects like the reference systems CH_3—CH_2—OH.

The π-bonding model requires the OH hydrogen of XH_n—CH_2—OH to be rotated 90 to 120° out of the X—C—O plane (starting at H *trans* to C—X) for maximal π-bonding and energy lowering. The orientation of lone pairs on oxygen is of no immediate concern and is incidental only. For an angle of 120° (*gauche*), idealized sp^3-type lone pairs happen to be antiperiplanar (app) to the C—X bond. The π-bonding model puts emphasis on the conformation of the OH hydrogen rather than the oxygen lone pairs. The two pictures are intimately connected. For example, consider the n–σ* model. Using $sp^2 + p$ hybridization on O, instead of sp^3, the p-type lone pair on O is parallel to, and overlaps best with, the σ* orbital of the C—X bond when OH has a dihedral angle of 90°. Partial π-bonding character in the SN

bond of *syn*-F—S—NH_2 (the most stable conformer) has been demonstrated by Reed and Schleyer (9).

In forthcoming papers, conformational analysis will be applied to other neutral and to corresponding protonated systems. Also, a more detailed quantitative treatment of the various energetic contributions will be given.

Acknowledgements

A number of undergraduate students from the Chemistry Department at UNB have performed computations on the anomeric effect. For the present paper, the help of Robin Martin and Garn Pomeroy is gratefully acknowledged. Relativistic compact effective potentials (RCEP), which replace the atomic core electrons in molecular calculations, have been derived from numerical Dirac–Fock atomic wavefunctions using shape-consistent valence pseudo-orbitals and an optimizing procedure based on an energy-overlap functional. Potentials are presented for the third-, fourth-, and fifth-row atoms of the Periodic Table (excluding the lanthanide series). The efficiency of molecular calculations is enhanced by using compact Gaussian expansions (no more than three terms) to represent the radial components of the potentials, and energy-optimized, shared-exponent, contracted-Gaussian atomic orbital basis sets. Transferability of the potentials has been tested by comparing calculated atomic excitation energies and ionization potentials with values obtained from numerical relativistic Hartree–Fock calculations. For the alkali and alkaline earth atoms, core polarization potentials (CPP) have been derived which may be added to the RCEP to make possible accurate molecular calculations without explicitly including core-valence correlating configurations in the wavefunction.

Key words: model potentials, effective core potentials, transition metals, relativistic calculations.

WALTER J. STEVENS, MORRIS KRAUSS, HAROLD BASCH et PAUL G. JASIEN. Can. J. Chem. **70**, 612 (1992).

Faisant appel à des fonctions d'onde atomiques Dirac–Fock numériques et utilisant des pseudo-orbitales de valence cohérentes avec la forme et une procédure d'optimisation basée sur un recouvrement fonctionnel d'énergie, on a déterminé des potentiels efficaces compacts relativistes (RCEP) qui remplacent les électrons atomiques internes dans les calculs moléculaires. On présente les potentiels d'atomes des troisième, quatrième et cinquième lignes du tableau périodique (excluant la série des lanthanides). L'efficacité des calculs moléculaires est rehaussée par l'utilisation d'expansions gaussiennes compactes (pas plus de trois termes) pour représenter les composantes radiales des potentiels ainsi que par l'utilisation d'ensembles de base d'orbitales atomiques gaussiennes contractées, optimisés pour l'énergie et à exposant partagé. On a vérifié la transférabilité de ces potentiels en comparant les énergies d'excitation atomique et les potentiels d'ionisation calculés avec les valeurs obtenues par des calculs numériques relativistes de Hartree–Fock. Pour les atomes des métaux alcalins et alcalino-terreux, on a pu déduire des potentiels de polarisation interne (CPP) qui peuvent être ajoutés au RCEP pour éventuellement obtenir des calculs moléculaires précis sans inclure d'une façon explicite dans la fonction d'onde les corrélations entre les électrons internes et ceux de valence.

Mots clés : potentiels modèles, potentiels internes efficaces, métaux de transition, calculs relativistes.
[Traduit par la rédaction]

Introduction

The use of atomic effective core potentials (ECP) and model potentials (MP) to eliminate chemically inactive atomic core electrons from quantum mechanical calculations has become routine in the past decade. The development of such potentials in the early 1970's and applications through the mid-1980's have been reviewed previously (1). The use of such potentials in molecular calculations has gained widespread acceptance, and sets of effective potentials are included in widely distributed quantum chemistry programs such as HONDO (2), GAMESS (3), and GAUSSIAN (4). We previously published accurate compact effective potentials (CEP) and matching basis sets for the atoms of the first two rows (Li–Ar) of the Periodic Table (5). We designated the potentials "compact" because they are represented analytically by small Gaussian expansions and, therefore, offer significant economy in molecular calculations where the computer time required to construct the electronic integrals is proportional to the complexity of the potentials. In this report, we present effective potentials and basis sets of similar quality for the third, fourth, and fifth rows of the Periodic Table derived from numerical, relativistic, Dirac–Fock atomic wavefunctions. The analytic expansions of these potentials are also limited to a few Gaussian terms (three or less), so we have designated them as "relativistic compact effective potentials" (RCEP).

Recently, several compilations of model potentials and effective core potentials for use in molecular calculations have appeared in the literature. For the heavier atoms, relativistic effects have been incorporated by deriving the potentials from relativistic Hartree–Fock (6) or Dirac–Fock (7) atomic

wavefunctions. There are generally two types of potentials that have attained widespread use: the model potentials of Huzinaga and co-workers (8), which retain the nodal characteristics of the valence orbitals in the core region, and effective core potentials, which result in nodeless valence "pseudo-orbitals" (9). The Huzinaga model potentials offer the advantage of valence wavefunctions that resemble those from all-electron calculations and are therefore optimum for calculating valence contributions to molecular properties, but they do not offer the economic advantage of reduced basis set size that can be achieved with the ECP method and corresponding nodeless pseudo-orbitals.

ECPs for most of the atoms in the Periodic Table have been published by several authors. Bachelet *et al.* (10) published potentials based on the method of Hamann *et al.* (11) for use in density functional calculations. Hay and Wadt (12) published a set of *ab initio* ECPs derived from numerical, relativistic Hartree–Fock (6) calculations. Christiansen and co-workers (13) published relativistic potentials derived from numerical Dirac–Fock calculations (7). In the latter two cases the potentials are generated on a numerical grid by inverting Fock equations for pseudo-orbitals derived from numerical atomic wavefunctions. The numerically tabulated potentials are then least-squares fit with analytic Gaussian expansions. Due to the complex shape, accurate fits for each numerical potential can require as many as six or more Gaussian functions. The ECP generation method described in detail below is similar to the Dirac–Fock approach of Christiansen and co-workers (13), but offers an alternative to least-squares fitting that leads to very compact analytic potentials with no loss of accuracy.

Among other sets of potentials being used extensively in molecular calculations, the pseudopotentials reported by Preuss and co-workers (14), and by Durand, Barthelat, and co-workers (15) are most noteworthy. The Preuss potentials have the same form as the ECP, but the parameters in the Gaussian expansions are optimized by minimizing the differences between ECP-computed valence energies of several neutral and ionic atomic states and those obtained from all-electron Hartree–Fock or quasi-relativistic Hartree–Fock calculations. This method makes no explicit use of the all-electron atomic orbitals in the pseudo-potential derivation, and relies on the spectral fit to produce a pseudo-Hamiltonian with the correct properties. The analytic Gaussian expansions used for these pseudopotentials generally contain a small number of terms, due to the limited amount of data being fit. The Durand/Barthelat potentials were also optimized by comparing ECP and all-electron calculations, but a unique functional based on orbital overlap and eigenvalue differences was used (16). The optimized RCEP parameters reported in this paper were determined by the same method.

Before the RCEPs can be used in molecular calculations, atomic orbital basis sets must be specified. In the generation of the Gaussian basis sets reported here, we considered several things. First, the number of primitive Gaussians required to accurately represent the atomic pseudo-orbitals was determined for each type of atom. For efficiency in molecular calculations, the exponents of the s and p primitive Gaussians were required to be the same. Also for efficiency in molecular calculations, a contraction scheme was developed that kept the number of basis functions as small as possible while still predicting accurately the low-lying neutral and ionic states of the atoms.

Method

Background

We briefly review the derivation of relativistic effective potentials, following the formalism first introduced by Lee *et al.* (17). The effective potentials are constructed to reproduce the valence electron orbital energies and densities obtained from numerical solutions of the Dirac–Fock equations for an appropriate atomic configuration (7). It is assumed that the valence electron density is dominated by the large components of the Dirac–Fock spinors and that the small components may be neglected. The Dirac–Fock Hamiltonian for the large components has the general form (18)

$$[1]\qquad \{\boldsymbol{H}_0(r) + \boldsymbol{H}_{\mathrm{m}}(r) + \boldsymbol{H}_{\mathrm{d}}(r) + \boldsymbol{H}_{\mathrm{so}}(r) + \boldsymbol{H}(O[\boldsymbol{\alpha}^4])\}P_{l,j}(r) = \boldsymbol{\varepsilon}_{l,j}P_{l,j}(r)$$

where H_0 is the nonrelativistic Hamiltonian, H_{m} the mass–velocity correction to the kinetic energy, H_{d} the Darwin term, and H_{so} the spin-orbit coupling. $P_{l,j}(r)$ is a spinor depending on the orbital and total angular momentum eigenvalues l,j. In the effective potential derivation, the Dirac–Fock equation for each angular momentum is replaced by

$$[2]\qquad \{\boldsymbol{H}_0^{\mathrm{val}} + \boldsymbol{V}_{l,j}^{\mathrm{REP}}(r)\}\boldsymbol{\chi}_{l,j}(r) = \boldsymbol{\varepsilon}_{l,j}\boldsymbol{\chi}_{l,j}(r)$$

where H_0^{val} is the nonrelativistic part of the valence Fock Hamiltonian, $\chi_{l,j}$ is a nodeless pseudo-spinor constructed from the large component Dirac–Fock spinor, and $V_{l,j}^{\mathrm{REP}}$ is a relativistic effective potential (to be determined) that replaces the relativistic terms in the valence Hamiltonian as well as the core-valence interaction terms. The nonrelativistic part of the valence Fock Hamiltonian for angular momentum, l, is given by

$$[3]\qquad \boldsymbol{H}_0^{\mathrm{val}} = -\frac{1}{2}\nabla^2 - \frac{Z_{\mathrm{eff}}}{r} + \frac{l(l+1)}{2r^2} + \boldsymbol{W}_{\mathrm{val}}^*$$

Z_{eff} is the nuclear charge minus the number of core electrons. $V_{l,j}^{\mathrm{REP}}$ absorbs the remaining nuclear attraction terms, which are canceled by the core-electron coulomb potential at long range. The valence coulomb and exchange term, W_{val}^*, is constructed from valence pseudo-spinors. This means that $V_{l,j}^{\mathrm{REP}}$ also contains the difference between the exact valence coulomb/exchange term, W_{val}, and the effective term, W_{val}^*. This difference is minimized in the valence region through the use of "shape-consistent" pseudo-spinors (19) as discussed in a subsection below.

Once the pseudo-spinors and eigenvalues are available, the REP may be derived by inverting the atomic valence Fock equation:

$$[4]\qquad \boldsymbol{V}_{l,j}^{\mathrm{REP}} = \boldsymbol{\varepsilon}_{l,j} + \frac{Z_{\mathrm{eff}}}{r} - \frac{l(l+1)}{2r^2} + \frac{\left(\frac{1}{2}\nabla^2 - \boldsymbol{W}_{\mathrm{val}}^*\right)\boldsymbol{\chi}_{l,j}}{\boldsymbol{\chi}_{l,j}}$$

Each valence spinor with a given angular momentum generates a unique REP. These j-dependent potentials may be used directly in molecular calculations (17, 20), but it is more common to use averaged relativistic potentials (AREP), as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

defined by Lee *et al.* (17), which eliminate the j-dependence due to spin-orbit coupling

$$[5] \qquad V_l^{\mathrm{AREP}}(r) = \frac{1}{(2l+1)} \times [l V_{l,l-1/2}^{\mathrm{REP}}(r) + (l+1) V_{l,l+1/2}^{\mathrm{REP}}(r)]$$

The total, semi-local, AREP for use at each atomic center in molecular calculations is given by

$$[6] \qquad V^{\mathrm{AREP}}(r) = \sum_l \sum_{m=-l}^{l} V_l^{\mathrm{AREP}}(r) \, |lm\rangle\langle lm|$$

where the projectors ensure that the potentials operate on the proper angular momentum components of the molecular wavefunction.

The sum over angular momentum, l, in eq. [6] formally runs to infinity. For those orbitals that are orthogonal to core orbitals of the same angular momentum, the potentials are repulsive and have shapes that are unique for each angular momentum value. However, for orbitals with angular momentum greater than the maximum orbital angular momentum occurring in the core, there is no orthogonality constraint, and the potentials are attractive and represent the unshielding of the nuclear charge as the core electron density is penetrated. All such attractive potentials are found to have similar shapes, so it is a good approximation to use a finite expansion for the AREP of the form (17)

$$[7] \qquad V^{\mathrm{AREP}} = V_{\mathrm{LMAX}}^{\mathrm{AREP}} + \sum_{l=0}^{\mathrm{LMAX}-1} \sum_{m=-l}^{l} [V_l^{\mathrm{AREP}} - V_{\mathrm{LMAX}}^{\mathrm{AREP}}] \, |lm\rangle\langle lm|$$

where LMAX is one more than the maximum orbital angular momentum in the core. It is common to designate the AREP for a given angular momentum as a difference potential with the notation $V_{l-\mathrm{LMAX}}$.

While the AREP potentials defined by eq. [5] do not contain spin-orbit coupling effects, one can define an effective spin-orbit coupling operator in terms of the difference between the $j = l + \frac{1}{2}$ and $j = l - \frac{1}{2}$ potentials. This was first proposed by Ermler *et al.* (21), and used by Stevens and Krauss (22) to calculate spin-orbit splittings for several diatomic molecules. The form of the spin-orbit coupling operator is

$$[8] \qquad H^{\mathrm{so}} = \sum_{l=1}^{\infty} \Delta V_l^{\mathrm{REP}} \left[\frac{l}{2l+1} \left| l, l+\frac{1}{2} \right\rangle\left\langle l, l+\frac{1}{2} \right| + \frac{l+1}{2l+1} \left| l, l-\frac{1}{2} \right\rangle\left\langle l, l-\frac{1}{2} \right| \right]$$

where the difference potential is defined by

$$[9] \qquad \Delta V_l^{\mathrm{REP}}(r) = V_{l,l+1/2}^{\mathrm{REP}}(r) - V_{l,l-1/2}^{\mathrm{REP}}(r)$$

The exact form of the REP, and thus of the effective spin-orbit operators, depends on the pseudo-spinors that are used to generate the REP. Pacios, Christiansen, and co-workers (13) have recently published analytic fits of effective spin-orbit operators for the atoms Li–Rn. The operators were generated from pseudo-spinors similar to the ones reported below, so they should be compatible with the potentials presented in this work. Wadt (23) has suggested an alternative method for obtaining molecular spin-orbit coupling constants from pseudo-wavefunctions without using effective operators. The spin-orbit integrals are calculated in the usual way, but a scaling parameter is used which is defined by matching calculated atomic spin-orbit coupling constants to *ab initio*, all-electron values. This procedure also could be used in conjunction with the effective potentials presented here.

Shape-consistent pseudo-spinors

The starting point for the REP generation is an atomic Dirac–Hartree–Fock (DHF) wavefunction obtained with the computer program of Desclaux (7). The atomic spinors from such calculations are in numerical form, tabulated on a logarithmic radial grid. The exact DHF atomic configuration and the partitioning of the numerical orbitals into core and valence subgroups are choices that depend on the type of atom being considered, as discussed below.

For all atoms, the large components of the valence j-dependent DHF spinors were used to construct nodeless pseudo-spinors by the shape-consistent procedure of Christiansen *et al.* (19). Shape-consistent construction is not necessary for DHF spinors with orbital angular momenta LMAX or greater, since they are already nodeless. The idea behind the shape-consistent approach is to make the pseudo-spinor match the Dirac–Fock atomic spinor as closely as possible, thereby minimizing the difference between the all-electron and ECP valence interaction terms and maintaining the correct overlap behavior in molecular bond formation. The shape-consistent pseudo-spinors, $\chi_{l,j}$, are defined by

$$[10a] \qquad \chi_{l,j}(r) = \sum_{i=0}^{4} c_i r^{i+N}, \qquad r \le r_{\mathrm{m}}$$

$$[10b] \qquad \chi_{l,j}(r) = P_{l,j}(r), \qquad r \ge r_{\mathrm{m}}$$

$$[10c] \qquad \langle \chi_{l,j} | \chi_{l,j} \rangle = 1$$

where r_{m} is a match point at which a four-term polynomial with leading power N is joined smoothly to the DHF spinor to produce a normalized pseudo-spinor with no nodes, one radial maximum, and two inflection points. The advantage of this procedure is that the pseudo-spinor is identical to the DHF spinor in the chemically important valence region outside the match point. We have modified the Christiansen procedure slightly to simplify the pseudo-spinor generation. In the Christiansen procedure, r_{m} is set as small as possible while still maintaining the nodeless character and a maximum of two inflection points in the pseudo-spinor. In our procedure, r_{m} is chosen as close as possible to the outermost radial density maximum of the DHF spinor. We found that the pseudo-spinors constructed in this way consistently had the desired properties for this choice of r_{m}. Christiansen *et al.* also recommend a leading power of $l + 2$ for the polynomial segment (where l is the orbital angular momentum), to satisfy cusp conditions at $r = 0$. We have used instead a cubic leading term for s, p, and d spinors, and a quartic leading term for f spinors. This causes no problems for atomic and molecular calculations using basis sets, but it could lead to difficulties if the potentials were used in numerical calculations where proper boundary conditions are crucial for numerical integration. Our modified procedure was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

used previously in the successful generation of nonrelativistic effective potentials for lighter atoms (5).

Relativistic compact effective potentials

Once the nodeless pseudo-spinors are defined on the same numerical grid as the DHF spinors, numerical REPs are generated according to eq. [4]. For orbital angular momenta greater than zero, AREPs are then obtained by averaging the two REPs for each l to eliminate the j-dependence, as shown in eq. [5]. At this point one may obtain an analytic representation of the AREP by a least-squares fit to an expansion of suitable functions such as Gaussians. This procedure has been adopted by Hay and Wadt (12) and by Christiansen *et al.* (13). However, the shape of the REPs is often complicated, and a large number of Gaussians (>6) is usually required to obtain a reliable fit. An alternative to direct least-squares fitting is the generation of compact analytic expansions by a method similar to the one used by us previously (5). These compact expansions improve the efficiency of molecular calculations, since the computer time required to calculate electronic integrals over the potentials is proportional to the length of the analytic expansions.

In our method, the numerically tabulated AREPs from eq. [5] are considered to be "exact." They are then used in atomic valence-only Hartree–Fock calculations to generate a set of *j-independent*, "exact" pseudo-orbitals and eigenvalues. This may be accomplished either on a numerical grid or with a basis set expansion for the orbitals. We chose to use large, even-tempered basis sets of Gaussian functions for this purpose. The resulting analytic pseudo-orbitals and eigenvalues are very similar to those derived by Hay and Wadt (12) from j-independent, numerical, relativistic Hartree–Fock orbitals (6). Following our previous compact effective potential procedure [5], analytic, relativistic compact effective potentials (RCEP) are generated that reproduce the "exact" pseudo-orbitals and eigenvalues as closely as possible. The analytic RCEP expansions are written

$$[11] \quad r^2 V_l^{\mathrm{AREP}}(r) = \sum_k A_{l,k} r^{n_{l,k}} \mathrm{e}^{-B_{l,k} r^2}$$

where the number of terms in the expansion is no more than three. For fixed values of $n_{l,k}$, the parameters $A_{l,k}$ and $B_{l,k}$ are directly varied in atomic Hartree–Fock calculations until the variationally determined "trial" pseudo-orbitals and eigenvalues match the "exact" pseudo-orbitals and eigenvalues to within a certain tolerance. Barthelat *et al.* (16) have proposed a useful criterion for optimization. The parameters are varied until the functional $\|\boldsymbol{O}\|$ is minimized, where

$$[12a] \quad \|\boldsymbol{O}\| = [\langle \chi_l | \boldsymbol{O}^2 | \chi_l \rangle]^{1/2}$$

$$[12b] \quad \boldsymbol{O} = \tilde{\varepsilon}_l |\tilde{\chi}_l\rangle\langle\tilde{\chi}_l| - \varepsilon_l |\chi_l\rangle\langle\chi_l|$$

χ_l and ε_l are the "exact" pseudo-orbital and eigenvalue, and $\tilde{\chi}_l$ and $\tilde{\varepsilon}_l$ are calculated by solving the Hartree–Fock equations with the trial analytic potential, $\tilde{V}_l^{\mathrm{AREP}}$, in

$$[13] \quad \left[-\frac{1}{2}\nabla^2 - \frac{Z_{\mathrm{eff}}}{r} + \frac{l(l+1)}{2r^2} + \tilde{V}_l^{\mathrm{AREP}} + W_{\mathrm{val}}^* \right] \tilde{\chi}_l = \tilde{\varepsilon}_l \tilde{\chi}_l$$

with the valence Coulomb and exchange operators, W_{val}^*, constructed from the "exact" pseudo-orbitals, and the trial pseudo-orbital, $\tilde{\chi}_l$, expanded in the same large, even-tempered basis set of Gaussians as the "exact" pseudo-orbital. This procedure converges quite rapidly, and has the advantage that optimized parameters for one atom can be used as initial guesses for the next atom as one moves across rows or down columns of the Periodic Table. The parameters, $n_{l,k}$, were not varied exhaustively, but several sets were tried until values were found that gave sufficiently accurate potentials for each type of atom. For all potentials reported in Tables 1–3 the overlap of the "exact" and calculated pseudo-orbitals is greater than 0.99999, and the difference between the "exact" and calculated eigenvalues is less than 0.001 hartree.

Results and discussion

The relativistic compact effective potentials are presented in Tables 1–3. Energy-optimized basis sets with shared exponents for the s and p primitives are given in Tables 4–6. Enforcing shared exponents in the basis sets could increase the number of primitive Gaussians required for a given level of accuracy, but the speed with which molecular integrals are calculated is significantly enhanced due to the common exponential terms.

The exact procedure used for the RCEP and basis set generation depends on the type of atom being considered. Each unique atom type is discussed separately below.

Alkali and alkaline earth atoms

For the alkali and alkaline earth atoms, the core was taken as all orbitals up to and including the $(n-1)$ shell, where n is the principal quantum number of the outermost s-electron in the ground state. For simplicity, monovalent cations were used for the alkaline earth potential generation. s-Orbitals were obtained from DHF calculations on the ground states, while p-, d-, and f-orbitals were taken from configuration-averaged wavefunctions for the lowest excited states of each angular momentum with fixed, degeneracy-weighted coefficients.

We found that the valence pseudo-orbitals of the alkali and alkaline earths could be represented very accurately by four-term Gaussian sp expansions. The exponents and s-function coefficients were energy-optimized for the ns^1 (^2S) states of the alkalis and the ns^2 (^1S) states of the alkaline earths. The p-function exponents were set equal to the s values and the p coefficients were optimized for the np^1 (^2P) states of the alkalis and the ns^1np^1 (^3P) states of the alkaline earths. Test calculations showed that these basis sets accurately described the lowest S and P states of the neutral atoms and the alkaline earth cations. Double-zeta, 3,1 contractions of these basis sets are given in the tables. Accurate representation of alkali anionic states will require the addition of diffuse s Gaussians to the basis sets.

There are large core-valence correlation effects for these atoms that cannot be included explicitly in molecular calculations if the penultimate shell is absorbed into an effective core potential. The importance of such effects on molecular structure has been noted by several authors (24–26). Core–core correlation can also indirectly affect the valence electrons (27) and lead to errors in atomic excitation energies and ionization potentials. Müller *et al.* (28, 29) have shown that core–valence and core–core correlation energy may be calculated to a high level of accuracy without introducing explicit core–valence correlating configurations into

the wavefunction. This is accomplished through the use of a "core polarization" potential (CPP) that interacts with the valence electrons. The CPP recommended by Müller is centered on the atomic nucleus and has the form

$$[14] \qquad \mathbf{V}_{pol} = \sum_i \sum_j \frac{(1 - e^{-\beta r_i^2})\mathbf{r}_i}{r_i^3} \alpha \frac{(1 - e^{-\beta r_j^2})\mathbf{r}_j}{r_j^3}$$

where the indices i and j run over all valence electrons, α is the measured or calculated polarizability of the core electrons, and the electric field is multiplied by a Gaussian cutoff that accounts for the penetration of the polarizable core by the valence electrons. The cutoff exponent, β, is adjusted empirically by matching the calculated ionization potential of the single-valence-electron atom to the experimentally measured value.

Müller *et al.* developed CPP for all-electron alkali and alkaline earth atoms (28) and demonstrated their accuracy in a series of molecular calculations (29). Christiansen (30), Jeung *et al.* (31), Preuss and co-workers (32), and Spiegelman *et al.* (33) have also made use of CPP in effec-

ported in Table 7. The alkaline earth CPP were derived for singly charged cations, but were found to work quite well for the two-electron ground states as shown in Table 7. Krauss and Stevens have used the alkali RCEP and CPP in studies of alkali cluster polarizabilities (34) and calculations of accurate alkali diatomic potential energy curves (35). In test calculations we have found that the CPP perform well for the P and D excited states of the alkali atoms, but less accurately for the excited states of the neutral alkaline earths. Improved results could be obtained by introducing a unique CPP cutoff exponent for each angular momentum, but this seriously complicates the use of the CPP in molecular calculations and was not done in the work reported here.

One must use the RCEP for the alkali and alkaline earth atoms with caution, especially in strong ionic bonding situations or in calculations of ligands bonding to the monovalent alkali cations or the divalent alkaline earth cations. We have found that the exchange repulsion interaction between the cation core electrons and the ligand electrons is underestimated by the RCEP for small ligand–metal separations.

TABLE 7. Core polarizabilities ((bohr)^3), Gaussian cutoff exponents, and valence energies (hartree) for the Group IA and Group IIA atoms. The energies were calculated with the uncontracted 4GTO basis sets given in Tables 4–6 and ref. 5. The Group IIB energies are taken from full two-electron configuration interaction calculations. The form of the core polarizability operator is

$$\sum_i \sum_j \frac{(1 - e^{-\beta r_i^2})\,\bar{r}_i}{r_i^3}\,\alpha\,\frac{(1 - e^{-\beta r_j^2})\,\bar{r}_j}{r_j^3}$$

This underestimation will occur for all potentials that do not include the penultimate shell in the valence space. Alkali and alkaline earth effective potentials with the penultimate shell in the valence space have been reported by other authors (12, 13).

Transition metal atoms

Before proceeding with RCEP generation for the transition metal atoms, one must decide which orbitals are to be considered part of the core. This choice has been discussed and tested by a number of authors (1, 12, 13, 36). Certainly, the outermost $(n + 1)s$ orbital (where n is the principal quantum number) and the partially occupied nd orbitals are in the valence space. However, the nd orbitals have large spatial overlap with the ns and np orbitals. Also, the radial shape of the nd orbitals is sensitive to different d occupation numbers in the low-lying excited states and cationic configurations (37). These occupancy-related shape changes can result in significant changes in the ns/nd and np/nd Coulomb and exchange interactions. We have found that placing the ns and np orbitals in the core does not give the correct energy behavior for atomic states of different d occupancy. Other authors have come to similar conclusions (12, 13). Hence, to maximize the transferability of the potentials to various atomic configurations, the transition metal ns and np orbitals are considered to be part of the valence space.

Another question arises concerning the boundary between the transition metals and the main-group elements to the right side of the Periodic Table. For the third-row atoms (first transition series) trial calculations were made for both Zn and Ga with the $3s$, $3p$, and $3d$ orbitals in the core. For Zn, relatively poor results were obtained, particularly for the energies and geometries of ligands interacting with the dication, Zn^{2+}. For Ga, the differences between molecular SCF calculations (e.g., GaH_3 and GaF_3) with three valence electrons versus 21 valence electrons on Ga were about the same size as the differences between RCEP and all-electron results, e.g., ~0.02 Å in bond lengths and 0.005–0.008 hartree in atomization energies (~2%). Consequently, we decided to define Ge, Sn, and Pb as the first group of the main-group elements. For completeness, however, we have included the tested Zn and Ga potentials with the $3s$,$3p$, and $3d$ electrons in the core in Table 3. They should be used only with caution.

For the transition metal V_{LMAX} potentials, the Dirac–Fock atomic spinors and eigenvalues were obtained from atomic ion configurations with the outer nd and $(n + 1)s$ electrons removed to give a ns^2np^6 configuration plus one electron in an orbital with l = LMAX (f for 3rd and 4th row atoms, g for the 5th row atoms). For the 5th row atoms, this procedure was also used to generate the V_{f-g} potentials. For all transition metals, the V_{l-LMAX} potentials for l = 0, 1, and 2 were generated from $ns^2np^6nd^m$ 2+ cation states using multiplet-averaged relativistic atomic wavefunctions.

Energy-optimized, double-zeta quality sp basis sets and triple-zeta quality d basis sets for the transition metal atoms are given in Tables 4–6. The triple-zeta d basis set was found to be necessary to describe the orbital shape changes that accompany changes in the d occupancy. For the third-row atoms, Sc–Cu, Gaussian d basis sets with six primitives were already available from the all-electron energy-optimized sets reported by Rappe *et al.* (37). For consistency we also generated six primitive d sets for Zn and Ga. For all other transition metals, the d basis sets were energy-optimized along with the s and p basis sets according to the following scheme.

Basis sets consisting of five primitives each for s, p, and d were optimized without the outer s-electrons for the $ns^2np^6nd^m$ atomic states with the highest possible spin and angular momentum coupling. The s and p functions were required to have common sets of exponents. The d occupation number, m, was chosen so that neutral atom states were used whenever possible. Since it is not possible to have $m > 10$, cationic configurations were necessarily used for the rightmost atoms in the three series. The five d primitives were contracted triple-zeta, 3,1,1 (4,1,1 in the case of the third row). This triple-zeta contraction was found to adequately handle the change in d-orbital shape that accompanies changing occupation number. The tight s and p primitives were contracted double-zeta, 4,1 using the variationally determined atomic orbital coefficients from the above config-

[a]There is a large overlap between the spherical component of the *d* basis functions and the *s* basis functions in some cases. Thus, different computer programs may produce slightly different energies depending on the threshold for linear dependence and the removal of neary linearly dependent functions.

uration. Attempts to use minimal basis (single-zeta) contractions for these functions resulted in unacceptable energetic errors for states with different *d* occupancies.

For optimization of the outer shell basis sets, different procedures were used depending on the atomic *d* occupancy. For atoms with less than full *d* shells, three *s* primitives were added to the basis set and optimized for the $ns^2np^6nd^{m-1}(n+1)s^1$ state with the highest possible spin and angular momentum coupling. Three *p* primitives were then added with exponents set equal to the corresponding *s* primitives. For the final basis set, these outer *s* and *p* primitives were contracted 2,1 with the *s* contraction coefficients taken from the above state, and the *p* contraction coefficients taken from the $ns^2np^6nd^{m-1}(n+1)p^1$ state. For Zn, Cd, and Hg, with full *d* shells, the three outermost *s* and *p* primitives were optimized and contracted for the $ns^2np^6nd^{10}(n+1)s^1(n+1)p^1$ triplet configuration. For Ga, In, and Tl they were optimized and contracted for the $ns^2np^6nd^{10}(n+1)s^2(n+1)p^1$ doublet configuration. The final transition metal basis sets consist of 34 basis functions (if all six Cartesian *d* components are retained). Reference energies[3] for spin- and space-restricted atomic calculations using the transition metal RCEP and matching basis sets are given in Tables 8–10.

The transferability of the transition metal RCEPs and the adequacy of the optimized basis sets were tested by calculating the relative energies of various atomic and ionic states and comparing the results with all-electron numerical, relativistic Hartree–Fock values (38). The comparisons are presented in Table 11. The RCEP results generally agree with the corresponding all-electron numerical results to well within 0.01 hartree.

Main group atoms

The valence space of the main group atoms to the right of Ga, In, and Tl in the periodic table was taken as the outermost occupied *s* and *p* orbitals. The V_{LMAX} potentials were generated from atomic ion configurations with three electrons outside the core, two in the outermost *s* orbital, and one in an orbital with LMAX angular momentum. The V_{l-LMAX}

potentials for $l > 1$ were also generated from three-valence-electron atomic ion configurations. The $V_{s-\mathrm{LMAX}}$ and $V_{p-\mathrm{LMAX}}$ potentials were generated from multiplet-averaged ns^2np^m neutral atom states. The RCEP for the main group atoms are given in Tables 1–3.

The pseudo-orbitals of the main group elements are accurately represented by shared-exponent, Gaussian *sp* basis sets of five primitives. In the tables, these basis sets are contracted to double-zeta, 4,1. The exponents and contraction coefficients were energy-optimized using the multiplet-averaged ns^2np^m atomic configurations. Reference energies[3] from spin- and space-restricted SCF calculations using the RCEP and matching basis sets are presented in Tables 8–10.

Molecular calculations

The RCEPs and basis sets reported here have been used in a number of quantum mechanical investigations of molecular structures and energetics. The selenium and tellurium potentials were used by Jasien and Stevens (39) in a study of proton affinities of molecules containing Group VIA atoms. Basch *et al.* (40) used the tellurium potential and multiconfiguration self-consistent-field (MCSCF) methods to study the geometry and properties of the low-lying electronic states of TeO_2. The chromium potential and an energy-optimized Slater-type basis set were used by Jasien and Stevens (44) to study the potential energy curves and properties of low-lying states of CrO and CrO^+ using MCSCF and multireference configuration interaction (MRCI) methods. Basch *et al.* used the zinc RCEP along with CEP and basis sets previously published for the lighter elements (5) to study the effect of cations on imidazole hydrogen bonding (42) and on imidazole tautomerism (43). The calcium potential and basis set were used by Krauss and Stevens (44) to study metal binding selectivity by proteins. Krauss and Stevens have used the cesium potential and basis set, along with the core polarization potential, to study the polarizabilities of alkali clusters (34). They also have published very accurate low-lying potential energy curves for several alkali diatomic molecules using the RCEP, CPP, and corresponding basis

sets (35). The Cs potential was also used to characterize the binding of Cs clusters to GaAs surfaces (45). More recently, Garmer and Krauss used the zinc RCEP in a study of the effect of active site ionicity on the transition states for CO_2 hydrolysis by carbonic anhydrase (46), and the cobalt RCEP and basis set in a study of the spectroscopy of cobalt-substituted carbonic anhydrase (47). Gordon and co-workers used the RCEP to study Group IV propellanes (48), Group IV sulfur and oxygen propellane derivatives (49), and high valent transition metal alkylidenes (50) and alkylidene complexes (51). They have also used the RCEP in recent studies of hetroatom analogues of benzene (52), olefin metathesis catalysts (53), and transition metal – silicon double bonds (54).

Concluding remarks

The relativistic compact effective potentials and matching basis sets reported here will improve the efficiency of quantum mechanical calculations on molecules containing heavy atoms. The small number of terms in the analytic expansions of the potentials and the shared-exponent constraint on the basis sets reduce the computer time required to calculate molecular electronic integrals. Since the potentials are generated from Dirac–Fock atomic orbitals and eigenvalues, they account for the effects of relativity on valence electron spatial distribution and energetics. While spin-orbit dependencies have been averaged out during the generation of the potentials, these effects may be reintroduced via effective spin-orbit operators (17) or by scaling the usual spin-orbit integrals over valence orbitals (21).

Acknowledgment

The authors wish to thank Dr. Michael W. Schmidt for carefully reviewing the RCEPs and basis sets, and for providing the tables of spin- and space-restricted reference energies. We also thank him and others in the quantum chemistry group at North Dakota State University for installing the potentials and basis sets in the GAMESS program.

Chemical interpretation: basis set use and the Periodic Table

LELAND C. ALLEN
Department of Chemistry, Princeton University, Princeton, NJ 08544, U.S.A.

Received September 5, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

LELAND C. ALLEN. Can. J. Chem. **70**, 631 (1992).

Examination of contemporary quantum chemistry literature and texts strongly indicates the need for new interpretative measures and indices that have heuristic chemical appeal, but are rigorously defined by physics. A closer look at the Periodic Table in search of such measures leads to *configuration energy* (CE), the average energy of a valence electron, which adds a third intrinsic dimension to the Table itself, and is also strongly correlated with atomic energy level spacings. CE can be translated into a quantum mechanical operator whose expectation value in molecules and solids is the Energy Index, EI_A. Many chemical effects: rotation and inversion barriers, the anomeric and α-effects, hyperconjugation, etc., appear capable of being quantified, unified, and simplified by EI_A, but because it is a one-electron entity, it does not correlate with binding energies or heats of formation. EI_A is *in situ* electronegativity, and systematic release of basis set contraction constraints permits a controlled analysis of bond polarity in terms of radial and angular hybridization changes.

Key words: *ab initio* calculations, basis sets, electronegativity, Periodic Table, bond polarity index.

LELAND C. ALLEN. Can. J. Chem. **70**, 631 (1992).

Un examen de la littérature et des manuels de chimie quantique contemporaine montre la nécessité de nouvelles mesures et d'indices interprétatifs qui auraient un caractère chimique heuristique, mais qui seraient rigoureusement définis par la physique. Un examen plus approfondi du tableau périodique pour trouver de telles measures conduit à l'*énergie de configuration* (EC), l'énergie moyenne d'un électron de valence, qui ajoute une troisième dimension intrinsèque au tableau lui-même et qui est intimement relié aux espacements des niveaux d'énergie. L'EC peut être transformée en un opérateur de la mécanique quantique dont la valeur d'expectative dans les molécules et dans les solides est égale à l'indice d'énergie, IE_A. Il semble l'IE_A puisse aussi permettre de quantifier, d'unifier et de simplifier plusieurs effets chimiques, comme les barrières à la rotation et à l'inversion, les effets α et anomériques, l'hyperconjugaison, etc; toutefois, comme il s'agit d'une entité à un électron, elle ne permet pas d'établir de corrélation avec les énergies de liaison ou les chaleurs de formation. Le fait que l'IE_A donne lieu à une libération *in situ* systématique de l'électronégativité des contraintes des bases de contraction permet de faire une analyse contrôlée de la polarité des liaisons en fonction des changements radiaux et des angles d'hybridation.

Mots clés : calculs *ab initio*, ensembles de base, électronégativité, tableau periodique, index de la polarité des liaisons.

[Traduit par la rédaction]

Levels of chemical interpretation

It is generally acknowledged that present day quantum chemistry calculations are broadly divided into two categories: (1) *ab initio*, all-electron, exact Hamiltonian. These are identified with small molecule chemical physics, the development of new mathematically sophisticated computational techniques, and with detailed electronic structure investigations of medium sized molecules that illustrate the basic physics of a novel or controversial bonding problem. (2) One- and two-electron semiempirical models, e.g., extended Hückel theory, ZINDO, PM3. These are generally applied to large molecules of immediate interest to synthetic organic and inorganic chemists and focus on chemical trends. Although the choice of *ab initio* or semiempirical model is generally attributed to the size of the molecule addressed, more fundamentally it is a question of the style and nature of the interpretation desired. Two contemporary textbooks illustrate these contrasting approaches: *Ab initio molecular orbital theory*, (1)[1] and *Orbital interactions in chemistry* (2*a*).[2] Although both texts are based on molecular orbital concepts, the explanations and interpretative framework of the two are notably different. The application sections of the former are filled with diagrams giving detailed geometries, tables of binding and interaction energies, proton affinities, and dipole moments. There are numerous three-dimensional molecular orbital plots and the applications treated are mostly molecules made from first-row elements with occasional systems involving higher rows and a few with first-row transition elements. In contrast, *Orbital interactions* is based on qualitative/semiquantitative perturbation theory and the text is dominated by valence orbital MO energy level diagrams accompanied by qualitative AO-based MO schematics and HOMO—LUMO interaction arguments. Fragment orbitals and isolobal analogies are employed to derive trends in larger and more complex molecules. Representative element compounds and transition metal complexes from all rows, along with an energy band and density of states diagram treatment of solid state chemistry, puts nearly the whole domain of the Periodic Table on an equal footing. The simplest possible MO concepts are evoked and the patterns characteristic of chemistry are emphasized over the details of the physics, thus making this approach by far the most useful to the vast majority of practicing chemists. However, this approach sometimes leads to oversimplification and explanations are generally more qualitative.

[1]This text is primarily concerned with chemical bonding in medium sized molecules that are of interest to physical organic chemists and to the present article, rather than the high precision solutions for many different expectation values in 1–4 atom systems that are generally of interest to molecular physicists.

[2]The chapter on solids is nicely augmented by ref. 2*b*.

Even if *ab initio* calculations were easily possible for the largest molecules, the physical variables available: total energies, binding energies, ionization potentials, molecular dipole moments, inner moments such as quadrupole coupling constants, or even (undecomposed) molecular orbital plots, are not often quantities in terms of which chemical trends can be easily discerned or rationalized.

Are there other *ab initio* defined properties that can bridge the gap between these two modes of chemical interpretation? We have found one, atomic *configuration energy* and its associated molecular property, the Energy Index, EI_A, for atom A in a molecule.

A closer look at the Periodic Table[3]

It is obvious that the simplest key to chemical interpretation is the Periodic Table, but it is not clear how to make a quantitative connection between it and atoms in molecules and solids. None of the parameters describing it are continuous variables whose values might be able to reflect changes undergone by an atom when it forms a molecule or solid. A closer look at the Periodic Table also reveals it to be somewhat misleading and incomplete. These shortcomings can be resolved by defining a new variable, configuration energy, which we believe to be the Table's intrinsic third dimension. Configuration energy, in turn, can be translated into a quantum mechanical operator whose expectation value over a molecular wavefunction provides chemically significant information.

In spite of — or because of — its everyday familiarity, the Periodic Table possesses a number of puzzling and infrequently addressed features. (a) What is the origin of its diagonal line separating metals from nonmetals? (b) It is far from periodic: as one descends a group in the *p*-block the increasing metallic character of the elements has long been recognized. The chemistry of carbon is quite different than the chemistry of lead. (c) Why, among all representative atoms (excluding the noble gas atoms) are only N, O, F, Cl, and Br unable to utilize all their valence electrons in bonding? (d) It is our principal guide in anticipating which of the three types of bonding: covalent, metallic, or ionic, will form between atoms. But it provides no definition of these bond types nor a way to differentiate between them. (e) It is the most powerful instrument for organizing chemical phenomena but it does not contain any information about the energy of atoms, even though everyone knows that energy is the central parameter for describing the structure of matter.

It is clear that something is missing, and this appears to be a historical accident dating from the time when Bohr provided the physical underpinning of the Periodic Table by defining electronic configurations (4). In chemical terms, the Periodic Table is a sequence of groups whose atoms have common properties and behavior. Physicists, however, see it as a collection of valence electron configurations that depict the properties of atomic shell structure. The quantum numbers n and l are more than labels for blocks of elements, and more than indicators of atomic size and orbital shape: their primary role is to specify an *energy*, and the obviously relevant quantity is the average energy of a valence electron configuration. Thus, CE, configuration energy, is defined as the average one-electron valence shell energy of a ground state free atom:

$$[1] \quad CE = (a\epsilon_s + b\epsilon_p)/(a + b)$$

where a, b are occupancies and ϵ_s, ϵ_p the s and p ionization potentials for spherical atoms of the representative elements; for the *d*-block transition elements, $\epsilon_p \rightarrow \epsilon_d$ of the $n - 1$ shell and b is its valence region occupancy.[4] CE possesses another energy level related property that is of almost equal importance to that expressed in eq. [1]: it is strongly correlated with the spacings of the one-electron energy levels of the atom in question (3). Large CE goes with large energy level separations, thus making a close connection between the magnitude of CE and the density of states in solids and molecules. This correlation follows immediately from the fact that the effective potential seen by an electron in an atom is funnel shaped: deeper funnels have more widely spaced energy levels (this characteristic is familiar from the textbook example of the hydrogen atom).

CE answers the questions posed earlier. (a) Values generated by eq. [1][4] precisely define the metalloid band (B, Si, Ge, As, Sb, and Te) associated with the metal/nonmetal diagonal line: all elements to the right of the metalloids have higher CEs and are nonmetals, all those to the left have lower CEs and are metals. The band itself is a region of nearly constant CE. (b) Metallization down a group occurs because the size of the atoms is increasing, therefore both the magnitude of the average valence energy level and the spacings of the levels are decreasing. Bonding directionality is being lost because the *s*, *p*, and *d* levels are becoming nearly degenerate, allowing mixing in many combinations. These changes are quantified (3) by CE. (c) The oxidation state limitations of N, O, F, Cl and Br are explained by their CEs: aside from the noble gas atoms He, Ne, Ar, and Kr, these atoms have the highest CEs in the Periodic Table and some of their valence electrons are held too tightly to engage directly in bonding. Because of their high CEs they have a correspondingly large energy gap to the first available unoccupied level, likewise discouraging bonding. (d) The interrelationship between metallic (M), covalent (C), and ionic (I) bonding may be visualized as an equilateral triangle with vertices labeled M, C, and I. The M–C line is a row of the Periodic Table and along it CE quantitatively measures the relative metallic versus covalent nature of an atom in question. The legs M–I and I–C require binary combinations of atoms (e.g., Na_2S, SCl_2) and along these legs the appropriate measure is ΔCE.

Historically, the need for configuration energy has been partially met by the concept of electronegativity, originally defined by Pauling (5) 10 years after Bohr's contribution. This concept has been the subject of much debate over many years, but a survey of textbooks and the research literature since 1932 shows that only two scales, those of Pauling (5, 6) and of Allred and Rochow (7), have been extensively used by experimental scientists. We previously showed (8) that eq. [1] closely matches these two, thus assuring that the information content of electronegativity is subsumed in CE.

[3]This section summarizes a much fuller account, including graphs and data supporting statements, given in ref. 3.

[4]ϵ_s and ϵ_p are obtained from the high resolution atomic energy level data compiled at the National Bureau of Standards. A list of CEs, along with graphs of these numbers as a function of the groups of the Periodic Table, are given in ref. 3.

TABLE 1. Rotational barriers (kcal/mol)

Molecule	ΔE_T	$3/4\Delta(EI_A + EI_B)$
$HOC\text{-}NH_2$	15.7	16.66
$H_3C\text{-}CH_3$	2.98	2.99
$H_3C\text{-}NH_2$	2.39	2.34
$N_3C\text{-}OH$	1.36	1.29

In the 1989 article (8) electronegativity was emphasized and defined by eq. [1]. The new viewpoint presented here is an extension and generalization of that article.

In summary, a closer look at the Periodic Table leads to the definition of a new quantity, configuration energy, that adds a new third dimension to the Table, embodies and goes beyond the usual concept of electronegativity, and can be rigorously defined in atomic physics terms. We now need to transform this characteristic *atomic* quantity into a *molecular* environment. We previously showed how this can be done by projecting an atomic orbital on the vector representation of an LCAO MO and weighting it by the one-electron energy of the MO, thereby obtaining a new one-electron energy for an atom, A, in a molecule (the Energy Index, EI_A) (9):

$$EI_A = \sum_i^N n_i \epsilon_i \sum_j^{M(A)} \sum_k^M C_{ij}^* C_{ik} S_{jk} \Big/ \sum_i^N n_i \sum_j^{M(A)} \sum_k^M C_{ij}^* C_{ik} S_{jk}$$

Applications of the Energy Index, EI_A, and Bond Polarity Index, BPI_{AB}

Range of applications

The Energy Index, EI_A, and the closely related Bond Polarity Index, BPI_{AB}, defined below, are one-electron measures and our experience to date indicates that they may be able to quantify and unify the following chemical phenomena: (a) rotational barriers; (b) inversion barriers; (c) hyperconjugation; (d) Bent's rules; (e) substitution effect on primary, secondary, and tertiary carbon centers; (f) the α-effect; (g) the anomeric effect; (h) hydrogen bond dimerization energies; and (i) group electronegatives.

Barriers

In Table 1 we list results for the rotational barriers in four classic molecules that have long been employed as tests of rotational barrier theories: the large formamide barrier that models rotation around the peptide bond, and the famous ethane, methylamine, and methanol set that approximately obey a 3:2:1 rule (10). A chief virtue of the Energy Index is that it yields a *local* energy measure and these barriers may be simply described by the change in $\Sigma_i EI_i$ summed over those atoms that define the bond around which rotation is taking place. In formamide a partial π bond is being broken and in CH_3CH_3, CH_3NH_2, and CH_3OH a partial π anti-bond is being broken. The 3/4 in front of $\Delta(EI_A + EI_B)$ in Table 1 is the scale factor required to connect the many-electron E_T with our one-electron EI_A. We also have results for the two barriers in fluoromethanol (10), $FH_2C\text{—}OH$, and again the scale factor is 3/4. This latter molecule is especially important because rationalization of its two barriers is tantamount to an explanation of the anomeric effect. The inversion barrier in NH_3 is similarly found to have a 3/4 scale factor.

The Bond Polarity Index, BPI_{AB} (9)

As one would expect, this entity is associated with the *difference*, $EI_A - EI_B$, across a bond, but because any atom exists in a molecular environment the concept of polarity must be precisely defined and, as originally introduced by Pauling (5), this means *ionic character*, therefore requiring that the covalent component be subtracted out:

$$BPI_{AB} = (EI_A - EI_A^{ref}) - (EI_B - EI_B^{ref})$$

For example, for the C—N bond in $H_3C\text{—}NH_2$ we compute (at 6 − 31G*) $EI_C = -0.689$ au and $EI_N = -0.695$ au in $H_3C\text{—}NH_2$, $EI_C^{ref} = 0.665$ au in $H_3C\text{—}CH_3$, $EI_N^{ref} = -0.710$ au in $H_2N\text{—}NH_2$, and then $BPI_{CN} = (-0.689 + 0.665) - (-0.695 + 0.710) = -0.039$ au. Other examples and properties of BPI_{AB} are given in ref. 9. A particularly promising application is to the important, but long discounted, concept of group electronegativity. In this application (11) one chooses a reference system for A (A = CH_3 is the most satisfactory and relevant from a physical organic chemistry standpoint) and then B represents the functional group of interest (e.g., CH_2CH_3, CH_2OH, CCH, CHO, NH_2, PH_2, OH, CF_3, CN, SiH_3, etc.). We have studied 25 groups, compared them with the six other most cited definitions, and also with the three most relevant experimentally determined measurements (Swain F and Taft σ_F, field/inductive effects, and Siegbahn E_B, C 1*s* core electron binding energies). Our BPI_{AB} derived group electronegativities have considerably higher correlation coefficients with the experimental values than any of the others, thus providing encouragement for this scheme.

Hydrogen bond dimerization energies

These have been notoriously difficult to determine, both experimentally and computationally, and we recently carried out an exhaustive *ab initio* study (12) to ascertain what level will reproduce the four dimerization energies that are accurately known experimentally (as well as their geometries and vibrational frequencies). It turns out that calculations at the MO SCF level with the 6 − 31 + G* basis are quite accurate and significantly better than the many other correlated and non-correlated solutions explored. Since this computational level is within the Hartree–Fock approximation, we are investigating whether BPI_{AH} and $EI_B - EI_N$ applied to the atoms A—H ··· B in the hydrogen bonds studied will parallel our *ab initio* results (EI_N is EI for the noble gas atom at the end of the row containing B).

Solid state

There is a solid state chemistry application that we find especially appealing. This is the use of BPI_{AB} as a complement to Roald Hoffmann's ingenious invention, the overlap population weighted density of states (COOP, Crystal Orbital Overlap Population) (2*b*). Hoffmann's concept adds greatly to chemical interpretability by identifying, as far as possible, localizable chemical bonds in solids. In the same manner we propose that the polarity of these bonds be obtained by BPI_{AB}. One can immediately see application to contemporary semiconductor research where many current efforts are centered on extending the traditional Group IV compounds to the III-V and II-VI series.

Advantages of the indices

Given the results discussed here, it is not entirely unreasonable to believe that all nine of the characteristically chemical phenomena listed above may be quantified by EI_A

and BPI_{AB} (and maybe even most one-electron representable chemical bonding features might be so encompassed). If so, what advantages would this type of interpretation offer? First, it would accomplish a large measure of unification presently missing from chemistry. The possibility of unification derives ultimately from the fact that configuration energies, EI_A, and BPI_{AB}, are obtained directly from *ab initio* wavefunctions, thus providing the broadest and deepest foundation available for defining such entities. (This connection with *ab initio* theory does not, of course, preclude obtaining actual EI_A and BPI_{AB} values from semiempirical wavefunctions.) Second, if it turns out that EI_A and BPI_{AB} can represent a significant fraction of the one-electron representable chemical bonding rules and concepts, the resulting simplification in interpretation will be substantial. When properly referenced (as in the definition of BPI_{AB}), EI_A is *in situ* electronegativity, and the various chemical bonding phenomena listed and discussed above are a manifestation of electronegativity change due to angular and radial hybridization changes occurring around the bonds in question. For chemical phenomena that have a local origin, interpretation via EI_A can be simpler and less ambiguous than use of orbitals because of its atomic focus and because it avoids selection of orbitals and choice of dominant interactions. It may be noted in passing that EI_A is the first attempt to devise a true *in situ* electronegativity: the frequently discussed "equalization of electronegativity" would not lead to $\Delta(EI_A + EI_B)$ for a rotation barrier such as we obtain, unless some entirely new conformation-dependent feature were added to current discussions of this hypothesis.

Limitations of the indices

The fact that configuration energy, EI_A, and BPI_{AB} are one-electron entities immediately points out their limitation and this is most obvious and severe in their inability to correlate binding energies and heats of formation. However, it will be recalled that Pauling's original definition of electronegativity was expressed as a function of the difference between a heteronuclear bond energy and an average of its homonuclear values (5). Rationalization of the accuracy of Pauling's electronegativity values in the light of his bond energy definition was achieved in a recent study (13).

There have been numerous articles in the J. Phys. Chem. and the J. Am. Chem. Soc. during the last two years in which Y.-R. Luo *et al.* (14) claimed good linear correlations between a simple definition of electronegativity, $V_x = n_x/r_x$, where n_x = number of valence electrons, r_x = a covalent radius obtained from several different sources, and differences in heats of formation. We have made extensive plots of CE, EI_A, and BPI_{AB} against the same experimental data used by Luo and have been unable to find useful or scientifically convincing correlations. We have also found some inconsistencies in tables of data given by Luo. Recent articles by Drago *et al.* (15) support our belief that Luo's electronegativity (or anyone else's definition) does not correlate with binding energy or heats of formation (or differences in heats of formation). Drago has found that at least three parameters are required to correlate bond energy data.[5] (It is also important to note here that the hydrogen bond dimerization energy problem discussed above is a special case arising because this bond is a small perturbation between two closed shell monomers).

Finally, of course, there are subtle chemical effects, both within and outside the Hartree–Fock approximation, which cannot be catalogued by EI_A or BPI_{AB}. These include effects dependent upon multipole moments and polarizabilities of higher order than dipole.

Further developments

The expression for EI_A is readily recognized as an energy-weighted Mulliken population analysis divided by the population analysis itself, and L. H. Reed (to be published) has proposed a generalization that replaces $\bar{P}\bar{S}$ in the Mulliken formulation with $\bar{S}^{\alpha}\bar{P}\bar{S}^{1-\alpha}$. Exploration of α may provide a further reduction in basis set dependence over that already achieved by energy weighting. Another possibility for generalizing the Mulliken overlap assumption is to employ Doggett's formulation (16) of Löwdin's 1953 suggestion (17) for preserving the dipole moment of the overlap charge. Since bond polarity closely parallels bond dipole, this procedure will considerably enlarge the range of BPI_{AB} values and tend to reduce basis set sensitivity.

Basis set contractions as an aid to chemical interpretation

In the sections above we have defined a new *ab initio* index, EI_A, that we believe will help unify and simplify the one-electron concepts used by chemists to categorize chemical observations. EI_A derives its interpretative capability from *in situ* manifestation of the Periodic Table and it is our hypothesis that optimum understanding of the structure of matter and prediction of new materials can be achieved by detailed analysis of how free atoms distort when they form molecules and solids. To carry out this program we need to view basis set choice and contraction in a new light.

The development of basis sets has been governed by the trade-off between size and energy lowering ability. During the last 40 years this topic has become a sophisticated and complex research field often accompanied by good summary reviews, and three excellent recent ones are those of Feller and Davidson (18), Davidson and Feller (19), and Huzinaga (20). Our purpose here is to suggest a new way to use this large body of existing research knowledge.

For a representative element, we start with an established basis that provides a reasonable representation of the atomic Hartree–Fock solution. All linear expansion coefficients used to represent this approximate free atom Hartree–Fock wavefunction are then frozen and this basis is used to calculate a molecular wavefunction. The difference between the free atom CE and the rigid basis EI_A is the "molecular field" effect and it can be either stabilizing or destabilizing. In the next stage of calculation, a splitting of *s* valence functions only is permitted. Then splitting of the p_x, p_y, and p_z's is separately investigated (with the *s* functions returned to their initial frozen set). Splitting of *s* and *p* valence bases is then allowed simultaneously. Returning to the frozen atom basis, we now add a *d* polarization function (the *s* orbitals are also polarized by *p* orbitals and the *ps* by *s* orbitals, but these distortions largely cancel). With *d* orbitals present, the *s* and *p* splittings are successively added in, and at each step the change in EI_A values is recorded. In this process we are cataloguing the electronegativity changes due to changes in ra-

[5]Drago also has a paper in press (J. Phys. Chem.) that specifically illustrates the inadequacies of V_x.

dial and angular hybridization and correlating them with molecular geometry. This will provide rules for assigning true *in situ* electronegativities and bond polarities as a function of atom type and molecular coordinates — a goal that a very great number of papers employing Mulliken valence state orbital electronegativity have unsuccessfully attempted for over 40 years. The problem has been that valence state orbital electronegativities are given for specified *free atom* hybridizations but no method has been devised to accurately determine the needed true *molecular* hybridizations. The method given here does so because it defines a *molecular* expectation value. The price to be paid is availability of a molecular wavefunction.

Finally, a major objective of our chemical interpretation scheme is to unify the analysis of molecular and solid state electronic structure throughout the Periodic Table, and therefore it is to be expected that effective core potential (pseudopotential) methods will be employed. Recent research by Huzinaga on his *ab initio* model potential (21) and effective Hamiltonian (22) methods are important developments related to this usage.

Acknowledgements

Sigeru Huzinaga is justifiably famous for his sustained efforts in developing basis sets for *ab initio* molecular calculations. His extension of the even-tempered concept to well-tempered Gaussians has significantly advanced the pool of knowledge on this important problem and his MIMI-i, MIDI-i, and MAXi sets generate uniform quality bases for most of the representative and transition metal elements of greatest interest. Huzinaga's more than 20 years of continuous and thoroughly systematic effort in this field provides one of the cornerstones upon which *ab initio* electronic structure theory rests. He has conscientiously recorded his contributions in review articles and in a 1984 book and it continues in the Chicago tradition of Robert Mulliken and Clemens Roothaan which Sigeru experienced as a research associate starting in the late 1950's and where I first met him. He then took his knowledge back to Japan as a professor at Kyushu University where he had been an undergraduate.

In the late 1960's and early 1970's after he had returned to North America, he turned his attention to formal aspects of many-electron theory and wrote major papers on general SCF formalism, separability of many-electron systems, UHF theory, and eigenspace manipulation.

The early 1970's saw the start of his seminal work on his model potential method with its emphasis on correct representation of the Coulomb and Exchange core operators (as opposed to matching AO energies and shapes). Sigeru has also contributed to the development of semiempirical methods (e.g., CNDO) and written programs for the Xα scattered wave scheme.

We hope that he and his collaborators will continue their various useful efforts and that they will enjoy good health.

Computational determination of the relative stabilities of some nitro carbocations

PAUL C. REDFERN, JANE S. MURRAY, AND PETER POLITZER[1]

Department of Chemistry, University of New Orleans, New Orleans, LA 70148, U.S.A.

Received September 19, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

PAUL C. REDFERN, JANE S. MURRAY, and PETER POLITZER. Can J. Chem. **70**, 636 (1992).

The relative stabilities of a group of nitro carbocations (derivatives of the methyl, cyclopropyl, and cyclopropenyl cations) are determined by means of *ab initio* SCF/3-21G calculations, and compared to the corresponding results for other substituent groups, both electron donating and withdrawing. The α-nitro carbocations are generally destabilized relative to the parent cation, but often to a lesser extent than anticipated from the strongly electron-withdrawing nature of NO_2. The optimized structures indicate that this is due to the stabilizing formation of an intramolecular ring involving the nitro group; however, this requires the proximity of a sufficiently positive carbon.

Key words: carbocations, *ab initio* SCF calculations, relative stabilities, nitro derivatives.

PAUL C. REDFERN, JANE S. MURRAY et PETER POLITZER. Can. J. Chem. **70**, 636 (1992).

Utilisant des méthodes *ab initio* SCF/3-21G, on a calculé les stabilités relatives d'un certain nombre de carbocations de dérivés nitrés (dérivés des cations méthyle, cyclopropyle et cyclopropényle) et on les a comparées aux résultats correspondants obtenus avec d'autres substituants, tant électro-attracteurs que électro-donneurs. Les carbocations en α d'un nitro sont généralement déstabilisés par rapport au cation parent; toutefois, ils le sont souvent moins que ce qui avait été anticipé sur la base de la nature très électro-attractive du NO_2. Les structures optimisées indiquent que ce résultat est dû à la formation stabilisante d'un cycle intramoléculaire impliquant le groupe nitro; toutefois, ce cycle nécessite la proximité d'un carbone suffisamment positif.

Mots clés : carbocations, calculs *ab initio* en champ auto-cohérent, stabilités relatives, dérivés nitrés.

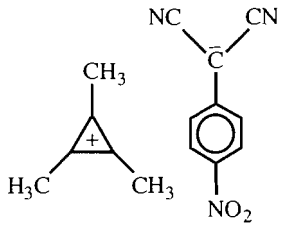
Introduction

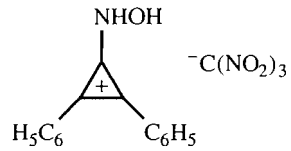
In recent years, a number of compounds containing ionic or highly polar C^+C^- linkages have been synthesized (1–6); some examples are **1**(1), **2**(4), and **3**(6):



1

$(H_2N)_3C^+ {}^-C(NO_2)_3$

2



3

The carbocations or positive portions of such systems are stabilized by electron-donating α-substituents, which allow the positive charge to be delocalized (eq. [1]), while electron-withdrawing groups correspondingly stabilize the carbanions or negative portions. These are well-established substituent effects (7–9), fully in agreement with calculations of relative stabilities (10, 11).

[1] 
4

The same reasoning suggests that electron-withdrawing groups (e.g., CF_3, CHO, CN, NO_2, etc.) will destabilize carbocations, and indeed this is generally the case. However, numerous studies, both experimental (12–22) and theoretical (23–28), have shown that this destabilizing effect is often much weaker than anticipated, and a variety of carbocations bearing electron-withdrawing α-substituents have been prepared or observed (e.g., **5** (12, 21), **6** (14), **7** (18), and **8** (19)).

In some instances, such as α-cyano and α-keto carbocations, this unexpected level of stability can be attributed to conjugative donation of electronic charge, as shown in eqs.

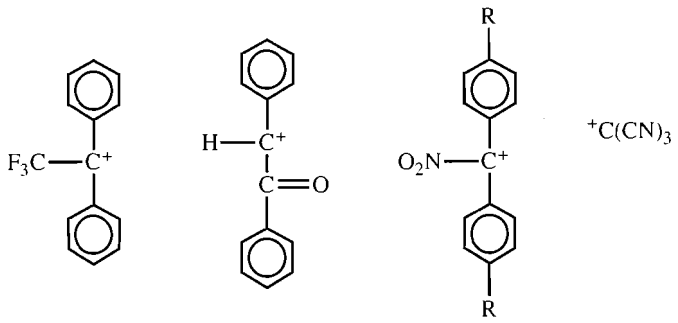
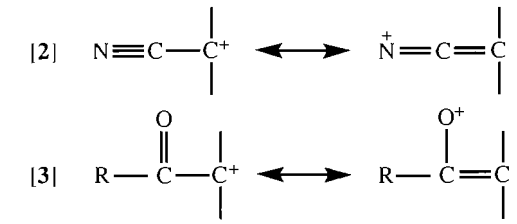
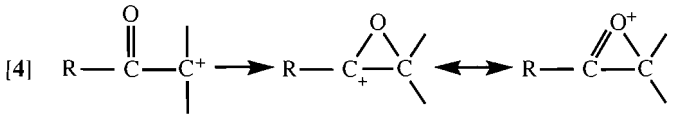
[2] and [3] (10, 16, 23, 24, 26); this can presumably be stimulated by the positive center even in groups that are not normally resonance donors (29).



5 6 7*a*: R = H *b*: R = CH_3 8

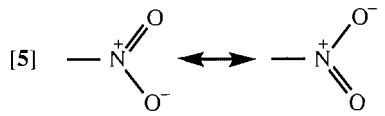


It has been pointed out that α-keto carbocations could also be stabilized through the formation of oxiranyl ions (16, 21, 27):

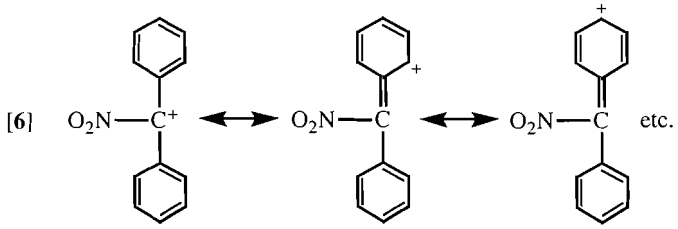


However, this is deemed unlikely on the basis of stereochemical evidence (16, 21).

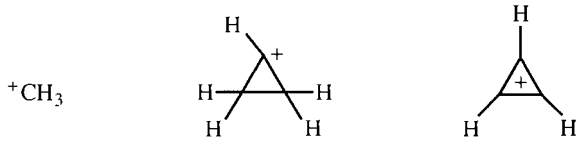
Despite the considerable activity in the area of carbocations bearing electron-withdrawing α-substituents, we have found relatively little mention of α-nitro carbocations. The NO_2 group is strongly electron withdrawing, through both induction and resonance (29), and the nitrogen bears a formal positive charge:



It would therefore be particularly interesting to determine the effect of α-NO_2 upon carbocation stability. Olah *et al.* have reported the preparation of the α-nitrodiphenylmethyl and α-nitro-*p*-tolylmethyl cations (**7***a* and **7***b*) (18); these can of course be expected to benefit from some stabilization through electron donation by the phenyl groups:



Our objective in this work has accordingly been to determine computationally the relative stabilities of a group of nitro carbocations. The hydrocarbon parents of these are the methyl (**9**), cyclopropyl (**10**), and cyclopropenyl (**11**) cations:



9 **10** **11**

To provide perspective, we shall compare the results for the NO_2 derivatives to those for several other substituents, both electron donating and electron accepting.

Methods

An approach that has been used in the past for determining the relative stabilities of carbocations is to compare their tendencies to interact with the hydride ion, H^-, to form a neutral molecule (9, 10). This can be done by means of the isodesmic reaction shown as eq. [7].

[7] $^+CXYZ + CH_4 \rightarrow H—CXYZ + {}^+CH_3$

ΔE for this reaction can be regarded as a measure of the stability of the carbocation ^+CXYZ relative to that of $^+CH_3$; the more negative is ΔE, the less stable is ^+CXYZ.

We have accordingly used the GAUSSIAN 88 system of programs (30) to compute optimized structures and energies at the *ab initio* SCF/3-21G level for the carbocations and for the corresponding neutral molecules formed by interacting with H^-. (In a few instances, including $^+CH_3/CH_4$, the data required were taken from the Carnegie-Mellon Quantum Chemistry Archive (31).) For each carbocation, the existence of a local energy minimum was confirmed by computing the vibration frequencies and verifying that there are no imaginary values.

Results

Our calculated total energies and the resulting ΔE values for eq. [7] are given in Table 1, and some of the optimized structural properties of the carbocations are in Table 2. The data taken from the Archive (31) are indicated. Most of the cations are found to be planar, either completely or at least in their frameworks (Table 2). The exceptions to this are all among the nitro derivatives.

In Table 1, the carbocations are listed in order of decreasing stability; those with $\Delta E > 0$ are viewed as being more stable than $^+CH_3$, and $\Delta E < 0$ is taken to mean less stable than $^+CH_3$. Since the reactants and products in eq. [7] differ only by the location of a C—H bond, the ΔE values can be expected to benefit from some cancellation of error. For example, Table 1 shows ΔE for the carbocations $^+C_3H_5$ and $^+C_3H_3$ to be 21 and 85 kcal/mol, respectively; at the SCF/6-31G*//6-31G* level, using energies taken from the Archive (31) these are 24 and 93 kcal/mol. Thus, the ΔE values in Table 1 should satisfactorily represent the trend in relative stabilities.

Discussion

Table 1 shows the well-established stabilization of carbocations by α-NH_2 and α-OH (9–11), and Table 2 supports its interpretation in terms of charge delocalization, as

CH_3OH	−114.39802[b]	$^+CH_2OH$	−113.51414[b]	53
$C_3H_3NO_2$	−317.45956	$^+C_3H_2NO_2$ (**14**)	−316.55349	39
$C_3H_5NO_2$	−318.69491	$^+C_3H_4NO_2$ (**12**)	−317.78613	37
C_3H_6	−116.40121[b]	$^+C_3H_5$	−115.46705[b]	21
CH_4	−39.97688[b]	$^+CH_3$	−39.00913[b]	0
$C_3H_5NO_2$	−318.69491	$^+C_3H_4NO_2$ (**13**)	−317.72713	0
CH_3NO_2	−242.25586	$^+CH_2NO_2$	−241.28449	−2
CH_3CH	−131.19180[b]	$^+CH_2CN$	−130.21045	−9
$CH_2(CN)_2$	−222.39335	$^+CH(CN)_2$	−221.39984	−16
$CH(CN)_3$	−313.58447	$^+C(CN)_3$	−312.58114	−22
$CH_2(NO_2)_2$	−444.51355	$^+CH(NO_2)_2$	−443.50322	−27
$CH(NO_2)_3$	−646.75587	$^+C(NO_2)_3$	−645.71105	−48

[a]This energy difference is for the reaction given in eq. [7].
[b]These 3-21G energies were taken from ref. 31.

in eq. [1]. Thus the calculated C—N and C—O bond lengths in $^+CH_2NH_2$ are, respectively, 0.205 and 0.188 Å shorter than in CH_3NH_2 and CH_3OH. In $^+C(NH_2)_3$, the decrease is 0.139 Å for each C—N bond; presumably the carbon cannot accept as much electronic charge from each of three NH_2 groups as it can from one alone.

In the case of $^+C(CH_3)_3$, hyperconjugation can be invoked (9):

[8] 
The C—C distances are shortened by 0.066 Å in going from $HC(CH_3)_3$ to $^+C(CH_3)_3$, and the computed average charges on the methyl hydrogens increase from +0.20 to +0.32.

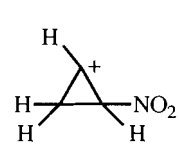
The rather large stabilization observed for the cyclopropenyl cation, **11**, can be attributed, at least in part, to delocalization of its π electrons (9):

[9] 
11

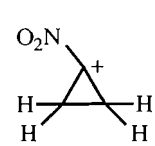
The calculated C—C bond length in **11** is 1.361 Å, compared to 1.282 and 1.523 (twice) in cyclopropene. Dewar has suggested that σ conjugation also plays a significant role in **11** (32).

Earlier studies of mono-α-cyano carbocations showed that the CN group is indeed destabilizing, but that some of the delocalization described by eq. [2] does occur, thereby presumably lessening the extent of destabilization (10, 23, 24, 26). Tables 1 and 2 extend these conclusions to di- and tri-α-cyano cations. The shortening of the C—C bond in going from the neutral molecule to the cation is 0.103, 0.089, and 0.079 Å for the mono-, di-, and tricyano systems, respectively; the corresponding lengthening of the C—N bond is 0.017, 0.012, and 0.010 Å.

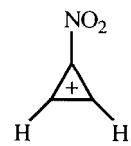
Proceeding now to the nitro carbocations, and looking first at the simplest member of this group, $^+CH_2NO_2$, it is striking that this cation is nearly as stable as $^+CH_3$ despite the presence of the strongly electron-withdrawing nitro group. (Appearance potential measurements have also indicated a surprising degree of stability for $^+CH_2NO_2$ (7, 33).) Several of the nitro carbocations are considerably *more* stable than $^+CH_3$, and the β-nitrocyclopropyl ion **12** is even stabilized relative to its parent, $^+C_3H_5$ (**10**).



12



13



14

The apparent reason for the unexpected stabilities of the NO_2 carbocations can be seen in the structures given in Table 2. Starting again with $^+CH_2NO_2$, it is seen that the NO_2 group forms a three-membered ring involving the "positive" carbon. Formally, the +1 charge thereby shifts to the nitrogen. It should be noted that the bond lengths in the ring are fairly close to their typical values; for example, the 3-21G optimized C—O distance in ethylene oxide is 1.470 Å (17), compared to 1.535 Å calculated for $^+CH_2NO_2$. Since this ring formation is a significant structural rearrangement, which may account for the surprising stability found for this carbocation, we repeated the geometry optimization at the SCF/6-31G* and MP2/6-31G* levels; the latter includes electronic correlation effects. The three-membered ring was formed in both instances. (The MP2/6-31G* geometry is given in Table 2 in parentheses.) It is interesting to note that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

an analogous cyclic structure was proposed as an intermediate in a rearrangement undergone by **7***a* (18).

Table 2 shows that the ring also occurs in the dinitro and trinitro derivatives, $^{+}CH(NO_2)_2$ and $^{+}C(NO_2)_3$. The situation becomes particularly interesting in the case of the nitrocyclopropyl cation because of the two possible isomers,

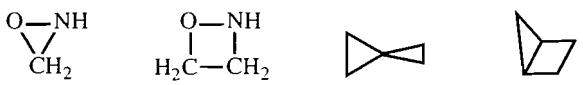
12 and **13**, in which the NO_2 can be β or α to the positive center. Cyclic rearrangement takes place in both cations, but in **12** the inclusion of the positive carbon requires that a four-membered ring be formed. **12** turns out to be considerably more stable than **13**, and (as mentioned earlier) even more stable than the parent cyclopropyl cation. The latter point is especially striking; **12** is the only nitro carbocation in Table 1 for which this is true, that it shows greater stability than its parent hydrocarbon cation.

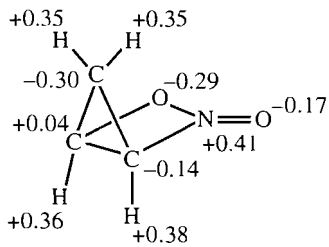
One factor that may favor **12** or **13** is a lesser degree of strain in the four-membered C—C—N—O ring compared to the three-membered C—N—O. We verified this by computing the strain energies in **15** and **16** using the isodesmic reaction procedure (11, 34); at the 3-21G level, they are 31.0 and 21.5 kcal/mol, respectively. Furthermore, the strain energy in **17** is given as 65 kcal/mol, vs. 57.3 in **18** (35). Thus it seems reasonable to infer that roughly 25% of the



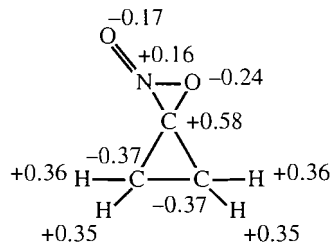
15 **16** **17** **18**

energy difference between **12** and **13** is due to the greater degree of strain in the latter. It also appears that there may be a greater delocalization of charge in **12** than in **13**. This is suggested by the distributions of calculated atomic charges in the two cases, as given by the GAUSSIAN 88 procedure and shown below.

Since the proximity of a sufficiently positive carbon is clearly a key factor in the rearrangement to a ring, the fact that this does *not* occur in the nitrocyclopropenyl cation, **14** (see Table 2), presumably reflects the fact that the positive charge is delocalized through the mechanism shown in eq. [9]. To test this interpretation, we examined the cation $^+CHNH_2NO_2$; the presence of the strong electron donor NH_2 should also significantly delocalize the positive charge and produce a more negative carbon. Indeed, the NO_2 again does *not* form a ring (Table 2). Table 1 shows that the NH_2, NO_2 combination gives an overall cation stability very similar to that of $^+CH_2OH$.



12



13

Summary

We have found that α-nitro groups do in general destabilize carbocations relative to the parent cations. However, the effect is often much weaker than would be anticipated from the strongly electron-withdrawing nature of NO_2, due to the stabilizing formation of an intramolecular ring involving the NO_2 group. This can occur when the ipso or a neighboring carbon is sufficiently positive.

The electronic structure of small transition metal clusters

HIROSHI TATEWAKI
Computer Center, Nagoya City University, Mizuhoku, Nagoya, Japan

AND

MUTSUMI TOMONARI
Fundamental Research Laborotory, NEC Corporation, Miyagaoka, Tsukuba, Japan

Received July 19, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

HIROSHI TATEWAKI and MUTSUMI TOMONARI. Can. J. Chem. **70**, 642 (1992).

In this paper we report the energy level distributions for transition metal clusters obtained by symmetry-broken and symmetry-constrained SCF methods. Investigated clusters were Fe_4, Ni_4, Cu_4, Zn_4, Fe_6, Ni_6, Cu_6, and Zn_6. Contracted Gaussian-type basis sets of the same size generated by the method of Tatewaki and Huzinaga were used throughout the paper. It will be shown that the *d*-hole localization model as well as the model with a two-electron-like ionization process is essential to discuss the electronic structure of the positive ion states, and the models bring the energy level distribution of the clusters rather close to the density of the state of the corresponding metals. The calculated first ionization potentials agree quite well with those of experiment. For example, the experimental ionization potential for Fe_4 is between 6.3 and 6.5 eV, while calculated values are 5.9 and 6.3 eV for the $3d$ electron ionization (d^{-1}) and $4s$ electron ionization (s^{-1}), respectively. If we define the Fermi level of the clusters as the first ionization potential, the Fermi level for Fe_4 is composed of the d^{-1} or $d^{-1} + s^{-1}$ state. The Fermi level for Ni_4 is found to be s^{-1} or $s^{-1} + d^{-1}$. Those of Cu_4 and Zn_4 are definitely of the s^{-1} state. Further discussion is also presented for larger clusters of M_6 (M = Fe, Ni, Cu, and Zn).

Key words: transition metal clusters, ionization potential, *ab initio* SCF calculations, energy level distributions.

HIROSHI TATEWAKI et MATSUMI TOMONARI. Can. J. Chem. **70**, 642 (1992).

Dans ce travail, on rapporte les distributions des niveaux d'énergie d'agrégats de métaux de transition qui ont été obtenues par des méthodes de champ auto-cohérent avec symétrie brisée et symétrie contrainte. On a étudié les agrégats de Fe_4, Ni_4, Cu_4, Fe_6, Ni_6 et Zn_6. Dans tout ce travail, on a utilisé une base restreinte de type gaussien de la même dimension que celle générée par la méthode de Tatewaki et Huzinaga. On va démontrer que le modèle de localisation du trou-*d* de même que le modèle avec un processus d'ionisation ressemblant à deux électrons sont essentiels pour discuter de la structure électronique des états des ions positifs et que les modèles amènent la distribution du niveau d'énergie des agrégats relativement près de la densité de l'état des métaux correspondants. Les premiers potentiels d'ionisation calculés sont en bon accord avec les valeurs expérimentales. Par exemple, le potentiel d'ionisation expérimental du Fe_4, se situe entre 6,3 et 6,5 eV alors que les valeurs calculées sont de 5,9 et 6,3 eV respectivement pour l'ionisation de l'électron $3d$ (d^{-1}) et l'ionisation de l'électron $4s$ (s^{-1}). Si l'on fait l'hypothèse que le niveau de Fermi des agrégats est égal au potentiel de la première ionisation, le niveau de Fermi du Fe_4 est donc composé de l'état d^{-1} ou de l'état $d^{-1} + s^{-1}$, le niveau de Fermi du Ni_4 est égal à s^{-1} ou $s^{-1} + d^{-1}$. Ceux du Cu_4 et du Zn_4 sont définitivement égaux à s^{-1}. On présente aussi d'autres discussions concernant les agrégats plus importants M_6 (M = Fe, Ni, Cu et Zn).

Mots clés : agrégats de métaux de transition, potentiel d'ionisation, calculs SCF *ab initio*, distributions des niveaux d'énergie.

[Traduit par la rédaction]

Introduction

The properties of transition metal clusters and the chemisorption of gases on them have been experimentally studied extensively with the aid of gas matrix techniques (1–7) as well as supersonic expansion techniques with laser or oven vaporization (8–14). The experimentalist now seems able to produce naked clusters of controlled size.

In this paper we will discuss the electronic structure of Fe_4, Ni_4, Cu_4, Zn_4, Fe_6, Ni_6, Cu_6, and Zn_6. For clusters including Fe, Ni, and Cu, experimental ionization thresholds have been reported (8–10); the uncertainty in the threshold values was smaller than 1.5 eV. The positions of the *d*-band relative to the Fermi level were given for Cu and Zn clusters (6, 7) although precise sizes of the clusters were unknown.

For years we have continuously investigated small transition metal clusters with *ab initio* SCF and CI methods (15–21). For these, the energy level distributions, namely the band structure of the clusters, were investigated. Before we studied transition metal clusters, it was commonly accepted that the energy level distributions predicted by *ab initio* SCF calculations were fairly different from the density of the state of the corresponding metals. The *d*-levels for Ni clusters (22) predicted by *ab initio* SCF calculations began around 5 eV below the Fermi level but for the solid the top of the *d*-band is at the Fermi level. The results were more exaggerated in Cu clusters (23) where the *d*-levels began around 10 eV below the Fermi level and the corresponding value of the solid Cu was only 2 eV. Two studies (22, 23) utilized orbital energies, and discussions developed there were based on the fact that reorganization energies (difference between the absolute value of the orbital energy and the ionization potential calculated by the ΔSCF method) became smaller as the cluster size became greater. Because the positive hole was shared equally by the atoms that constituted the clusters, reorganization energies should be smaller for larger clusters. They (22, 23) actually were able to demonstrate that reorganization energies decreased as the cluster size increased. Schmeisser *et al.* (6), however, using the matrix isolation

technique, showed that the *d*-band of small Cu clusters began 3 eV below the Fermi level and had its peak 4 eV below the level, which was the same as the solid if we move the peak of the cluster contributed from the *d* electrons 1 eV shallower to the Fermi level. A similar relation between the energy level distribution of the cluster and that of the solid was found for Zn clusters by Schroeder *et al.* (7).

Introducing the *d*-hole localization model that will be described in the present paper, Tatewaki *et al.* (15) showed that the *d*-level energy distribution of small Cu clusters began ca. 2 eV below the Fermi level, which was very close to the value of the solid, as well as to that of Schmeisser *et al.* Many X_α calculations (24–28) have been performed. In many cases they gave parallel results to those of the *d*-hole localization method, but some ambiguity arose, since by this method the *d*-hole localization and *d*-hole delocalization models gave almost the same energy level distributions (28). The X_α methods should be carefully applied to a system in which some types of electrons are strongly localized, when determining the physical or chemical characteristics of the system.

We feel that our interpretation of the energy level distributions of the transition metal clusters has been verified experimentally; the progression of experiments, however, provided many excellent data such as those of Powers *et al.* (8) and Rohlfing *et al.* (9, 10). It is therefore desirable to investigate the mechanism of the ionization more thoroughly. In this paper it will be shown that two-electron-process-like ionization of the *d* electron gives the Fermi level for Fe clusters. Together with a *d*-hole localization model, it will be shown that the calculated first ionization potentials always agree with experiment within an error of 0.5 eV.

Basis sets

To clarify the electronic structure of a sequence of similar molecules, it is desirable to use basis sets of the same quality for the respective molecules, which probably reveals the characteristics of the electronic structure of the sequence and even clarifies the defects or limitations of the calculations or the methods themselves. We used contracted Gaussian type functions (CGTFs) developed by the method of Tatewaki and Huzinaga (29–31) and summarized by Huzinaga *et al.* in ref. 32. The basis sets modified in the present paper are (4333/43/5) (32). Three sets of numbers separated by slashes indicate the number of primitive GTFs in the respective CGTFs of the *s*, *p*, and *d* symmetries. Dividing the outermost *s*- and *d*-type CGTFs into two parts, we generated the sets of (43321/43/41) + p.f. which were used throughout this work. The p.f. in this expression implies a polarization function spanned by two *p*-type GTFs. The exponents and expansion coefficients for the polarization functions were determined in the following way. As an example, Fe $(3d^7 4s^1)\ ^5F$ was chosen as a parent state. By using the CGTFs of (4333/43/5) and adding two primitive *p*-type GTFs, we calculated $(3d^7 4p^1)\ ^5F^o$ where (43345/43/5) was fixed to that of the parent and only the expansion coefficients and the exponents of the augmented *p*-type functions were energetically optimized. The basis set, (4333/43/5), p.f. thus determined, total energies, and orbital energies for the parent state are collected in Table 1. For Ni the parent state was $(3d^9 4s^1)\ ^3D$ and the optimized state was $(3d^9 4p^1)\ ^3P^o$, and for Cu and Zn the parents were $(3d^{10} 4s^1)\ ^2S$ and $(3d^{10} 4s^2)\ ^1S$ and the optimized states were $(3d^{10} 4p^1)\ ^2P^o$ and $(3d^{10} 4s^1 4p^1)\ ^3P^o$, respectively. Results for Ni, Cu, and Zn are also collected in Table 1. It is noted that the differences in the total and orbital energies between the fully contracted basis set of (4333/43/5) and those newly generated are, at most, 0.0024 au, indicating that the optimization of the original CGTFs is almost perfect.

Electronic structure of Fe_4, Ni_4, Cu_4 and Zn_4

(a) Geometry optimization and ground state for Fe_4

The geometry adopted for the M_4 clusters was D_{4h}. We chose Fe_4 and geometry optimization was performed for this cluster, possessing D_{4h} symmetry.

The electronic configurations considered were generated in the following way:

1. We found that the *d* electrons avoided the concentrating intermolecular region for Fe_2 and Fe_3 (21). We determined that Fe_4 has 8 vacancies in the eight molecular orbitals generated from the atomic $d_{x^2-y^2}$ and d_{zx} orbitals, which point toward the intermolecular region (the molecular axis was *z* and four Fe atoms were placed on the *x* and *y* axes); the $d_{x^2-y^2}$'s yielded a_{1g}, b_{1g}, e_{ux}, and e_{uy}, and the d_{zx}'s generated a_{2u}, b_{2u}, e_{gx}, and e_{gy}. Furthermore, we generated another four *d*-holes. They were distributed among α: a_{1g}, b_{1g}, e_{ux}, and e_{uy}, which were generated from $3d_{z^2}$; or among β: a_{1u}, b_{1u}, e_{gx}, and e_{gy}, which were generated from $3d_{yz}$; or among χ: a_{2g}, b_{2g}, e_{ux}, and e_{uy}, which were generated from $3d_{xy}$. The number of holes generated was 12 and it corresponds to three 3*d*-holes per atom. The states generated from α, β, and χ had the same spatial symmetry, B_{1g}.

2. We further assumed high spin states. It was found that the lowest configuration was always β. The electronic states arising from α, β, and χ are expressed as

$$(\alpha)\ \Phi(\alpha;{}^{15}B_{1g}) = \Phi(\beta;\ 7a_{1g},\ 7b_{1g},\ 9e_{ux},\ 9e_{uy} \rightarrow 1a_{1u},\ 1b_{1u},\ 3e_{gx},\ 3e_{gy})$$

$$(\beta)\ \Phi(\beta;{}^{15}B_{1g}) = 6a_{1g}^{\ 1}\ 3a_{2u}^{\ 1}\ 1b_{1u}^{\ 1}\ 3e_{g}^{\ 2}\ 8e_{u}^{\ 2}\ 4e_{g}^{\ 2}\ 3b_{2u}^{\ 1}\ 1a_{1u}^{\ 1}\ 6b_{1g}^{\ 1}\ 3b_{2g}^{\ 2}\ 7a_{1g}^{\ 2}\ 9e_{u}^{\ 4}\ 7b_{1g}^{\ 2}\ 10e_{u}^{\ 4}\ 3a_{2g}^{\ 2}\ 8a_{1g}^{\ 2}\ 11e_{u}^{\ 2}\ {}^{15}B_{1g}$$

$$(\chi)\ \Phi(\chi;{}^{15}B_{1g}) = \Phi(\beta;\ 3a_{2g},\ 3b_{2g},\ 9e_{ux},\ 9e_{uy} \rightarrow 1a_{1u},\ 1b_{1u},\ 3e_{gx},\ 3e_{gy})$$

3. To test the adequacy of the high spin states we calculated the lower spin state of the $^{13}A_{1g}$ and $^{13}B_{1u}$ states where the electron in the highest two half-filled orbitals was deexcited into the lowest half-filled orbital.

$$(\delta)\ \Phi(\alpha;{}^{13}A_{1g}) = \Phi(\beta;\ 6b_{1g} \rightarrow 6a_{1g})$$

$$(\varepsilon)\ \Phi(\alpha;{}^{13}B_{1u}) = \Phi(\beta;\ 1a_{1u} \rightarrow 6a_{1g})$$

Total energies for $\Phi(\alpha;{}^{15}B_{1g})$, $\Phi(\beta;{}^{15}B_{1g})$, and $\Phi(\chi;{}^{15}B_{1g})$ vs. the internuclear bond distance are shown in Fig. 1(*a*). Lower spin states were so high in energy (around 10 eV) that they are shown separately in Fig. 1(*b*). We were able to conclude that the high spin state is plausible. The lowest state takes the minimum at $R = 5.43$ au. We feel the calculated bond distance is too long.

Transition metal dimers give a considerably shorter bond distance than the distance for the bulk metal in almost all cases. Walch and Baushlicher (33, 34), Walch *et al.* (35), and Langhoff (36) showed by theoretical calculations that the difference in bond length between the dimer and the nearest neighbor of the metal is considerable and that the difference

becomes much smaller for the trimer. For example R_e of Sc_2 was 5.27 au whereas R_e of the equilateral triangle Sc_3 was 5.74 au. The bond distance for the nearest neighbor in the solid is 6.25 au. We see an abrupt increase of the distance between Sc_2 and Sc_3. Similar results are found for Cu and Ag clusters (36). From the values for Sc and other results (33–36), a plausible bond length for Fe_4 is expected to approximate the value for the nearest neighbor in the solid. Without confirming the conjecture with configuration interaction calculations, we adopted the nearest neighbor value for the solid as the bond distance for calculating the ionization potentials of Fe_4.

We have no doubt that SCF calculations would give a longer bond distance for other clusters. Geometry optimizations were, therefore, not performed for the others and the assumed bond distances for Ni_4, Cu_4, and Zn_4 were set equal to those for the nearest neighbor in the corresponding metal.

(b) Band structure by Koopmans' theorem

The ground state of Fe_4 is $^{15}B_{1g}$ with configuration β, as was discussed, and hereafter we simply denote the state as $^{15}B_{1g}$. The total energy, gross atomic orbital populations (GAOPs) (37), excitation energies, and ionization potentials are shown in Table 2. Except for Fe_4, excited states were not calculated since the ground states are well established. The results for Ni_4 are collected in Table 3. The ground state for Ni_4 was $^7B_{1g}$ as given in refs. 19 and 22 and the orbitals for the open shell, $6a_{1g}{}^18e_u{}^26b_{1g}{}^1$, were mainly composed of $3d_{x^2-y^2}$. The corresponding data for Cu_4, and Zn_4 are listed in Tables 4 and 5, respectively.

The ionization potentials calculated by Koopmans' theorem are shown in the third column of Table 2(*b*) or in the third column of Tables 3, 4, and 5. Results by this theorem are also schematically shown in Figs. 2(*a*) and 2(*b*) together with those of M_6 clusters.

We define the Fermi level of the clusters as the first ionized state. We refer to the *s*-ionized and *d*-ionized state as *s*-level and *d*-level, as in solid state physics.

Koopmans' theorem showed that the Fermi level of Fe_4 is the 4*s* ionized state (hereafter we denote the state by s^{-1}), and the 3*d* ionized state (d^{-1}) lies 3.4 eV below the Fermi level.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

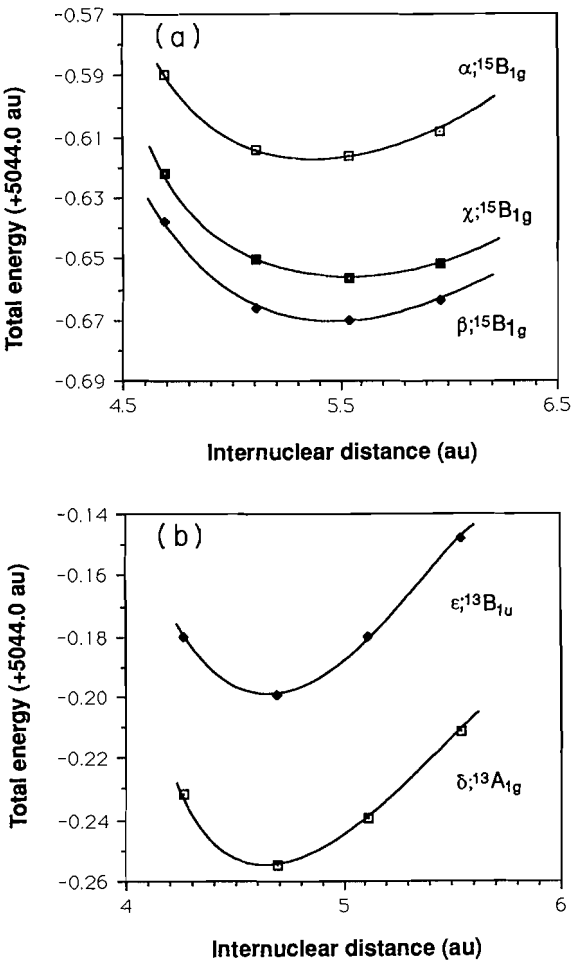

FIG. 1. (*a*) Total energies[a] versus internuclear distance for the lower three $^{15}B_{1g}$ states of Fe_4. (*b*) Total energies versus internuclear distance for the upper two states $^{13}A_{1g}$ and $^{13}B_{1u}$ of Fe_4.

[a]Total energies are in au and +5044.0 au is added to the total energies of the respective states.

In the solid Fe, however, the Fermi level consists of the top of the *s*- and *d*-bands. From Tables 3, 4, and 5 and the figures we see that the Fermi level of the other M_4 clusters also consists of the s^{-1} state so far as Koopmans' theorem is concerned. Except for Zn_4, the Fermi level takes almost the same position relative to the vacuum level. If we proceed from Fe_4 to Zn_4, the top of the *d*-band relative to the Fermi level becomes deeper; it is situated at 5.1 eV below the Fermi level for Ni_4, and at 7.0 and 16.4 eV below the Fermi level for Cu_4 and Zn_4. Corresponding values for solid Ni, Cu, and Zn are 0.0, 2.1, and 9.2 eV, respectively. Koopmans' theorem indicates how the electronic structure of small clusters differs from that of the solid.

(c) Band structure by symmetry-constrained ΔSCF

In this subsection, results given by symmetry-constrained SCF calculations for the ground and ionized states will be discussed. They are displayed in the fourth column of Tables 2(*b*), 3, 4, and 5 for the respective clusters. For Fe_4 we found that the two-electron-process-like *d* ionized state occupied the first ionized state, which lay 4.0 eV below the vacuum level; on the other hand, the first s^{-1}-like state lay 5.1 eV below the vacuum level. For symmetry-constrained ΔSCF, the Fermi level was spanned by the two-electron-process-like *d* ionized state.

[1] $3d^{2.4}\,4p^{0.1} \rightarrow 4s^{1.5}\,\infty^1$

A similar state was found for Ni_4, and was the lowest among the *d* electron ionized states. Contrary to Fe_4, the first d^{-1} for Ni_4 lay 1.5 eV below the Fermi level, namely, the first s^{-1}.

[2] $3d^{2.5} \rightarrow (4s4p)^{1.5}\,\infty^1$

No such state was found for Cu_4 and Zn_4 and the first d^{-1}-like state lay considerably below the Fermi level. An analysis of the two-electron-process-like state will be given in subsection (*d*).

The band structure predicted by the symmetry-constrained ΔSCF method gave a different form from that of Koopmans' theorem for Ni_4 and especially for Fe_4, and similar results for Cu_4 and Zn_4. In the fifth column of Tables 2(*b*), 3, 4, and 5, reorganization energies (RE) are given, where it is shown that reorganization energies (4.8–3.9 eV) of the top of the *d*-band for Fe_4 and Ni_4 are twice as large as those (2.1–1.8 eV) for Cu_4 and Zn_4. The experimental ionization potentials are given in the last column of each table and we see the ionization potential calculated for Fe_4 (4.0 eV) is very small compared with the observed threshold (6.3–6.5 eV) given by Rohlfing *et al.* (9). This disagreement requires further investigation.

(d) Band structure by symmetry-broken ΔSCF

Since the assumed bond distances for the clusters are four to five times greater than the mean values of r for the $3d$ electron, $\langle 3d|r|3d\rangle$, it might be reasonable to assume that when the *d* electron is ionized, the hole created is located at one of the atoms that constitute the clusters. (For example the bond distance is 4.69 au for the solid Fe and $\langle 3d|r|3d\rangle$ is 1.17 au for the Fe atom.) Introducing C_{2v} symmetry, we calculated the *d*-hole states. In actual calculations, orbital populations with an unequal number of *d* electrons with respect to the constituent atoms were prepared for the initial data. If the SCF procedure converges and the resulting solution has a localized *d*-hole at one of the constituents, we succeed in obtaining a localized *d*-hole state. Results are given at the bottom of Tables 2–5.

Hereafter we discuss the case of Fe_4. As expected, the state with the localized *d*-hole appeared to give lower ionization potentials. The calculated ionization potential was as small as 3.53 eV (see the second row from the bottom of Table 2). It will be shown that this state includes the Fermi level. The calculated ionization potential is too small compared with the experimental threshold of 6.3–6.5 eV. The localization of the *d*-hole implies that the atomic ionization process is important in the Fe cluster. If we assume that the relativistic energies for the neutral atom and the ion are the same, the ionization potential of the system is given by

$$\begin{aligned}[3]\quad \mathrm{IP(exptl)} &= \mathrm{TE(SCF,ion)} + \mathrm{CE(ion)} \\ &\quad - \{\mathrm{TE(SCF,neutral)} + \mathrm{CE(neutral)}\} \\ &= \{\mathrm{TE(SCF,ion)} - \mathrm{TE(SCF,neutral)}\} \\ &\quad + \{\mathrm{CE(ion)} - \mathrm{CE(neutral)}\} \\ &= \mathrm{IP(\Delta SCF)} + \Delta\mathrm{CE}\end{aligned}$$

where IP(exptl.) is the atomic ionization potential given by experiment. The TE (SCF) and CE are the atomic (ionic) SCF total and atomic (ionic) correlation energies. IP(ΔSCF) is the

ionization potential given by the total energy difference between the ion and the neutral atom. The atomic correlation correction is calculated from the experimental ionization potential and that of ΔSCF.

$$[4] \quad \Delta CE = IP(exptl) - IP(\Delta SCF)$$

ΔCEs are collected in Table 6. For Fe, the atomic correlation correction for the *d* ionization is 2.4 eV, leading to an ionization potential of 5.9 eV, which is close to the experimental ionization threshold of 6.3–6.5 eV given by Rohlfing *et al.* (9).

For the case of 4*s* electron ionization we analogously add the atomic correlation correction of 1.2 eV, leading to an ionization potential of 6.3 eV, which is slightly greater than the ionization potential of the *d*-hole state. One may doubt the validity of the use of the atomic correlation correction for 4*s* electron ionization. In atomic 4*s* ionization of Fe, Ni, and Cu, ΔCE arises mainly from the 4*s*–3*d* electronic correlations, which are included in the neutral systems but are not in the ions. If one 4*s*-like electron is shared with *n* atoms that constitute the clusters, then it might be not unreasonable to assume that the *s*–*d* correlation energy per atom is around $1/n$ of the atomic case. If we deprive the cluster of one 4*s*-like electron we may obtain a more appropriate ionization potential by adding the atomic correlation correction to IP(ΔSCF). Since we disregarded the difference in the correlation energies among the 4*s*-like valence electrons between the ion and the neutral system, the estimated ionization potential (6.3 eV for Fe_4) might be lower bound. The difference in the ionization potentials between the 3*d* and 4*s* ionizations is fairly small (0.4 eV). Taking account of the ambiguity of the correlation correction, we assign the Fermi level of the Fe_4 clusters as d^{-1} or as a mixture of the s^{-1} and d^{-1} states.

Results of the symmetry-broken calculations with the atomic correlation correction and the experimental ionization threshold are schematically shown in Fig. 3(*a*) together

with the results for Ni_4, Fe_6, and Ni_6. We immediately recognize the accuracy of the calculations.

When we calculated the Ni_4 cluster with C_{2v} symmetry, the following ionized state was found.

$$[5]\quad (3d,Ni_3)^{0.9}(3d,Ni_4)^{0.9} \rightarrow (4s4p,Ni_1)^{-0.4}(4s4p,Ni_2)^{-0.4}(4s,Ni_3)^{0.8}(4s,Ni_4)^{0.8}\ \infty^{1.0}$$

where Ni_3 and Ni_4 are on the diagonal line and the same stands for Ni_1 and Ni_2. $(4s4p, Ni_1)^{-0.4}$ means that the $4s$- and $4p$-like electrons of Ni_1 decrease by 0.4 and $(4s,Ni_3)^{0.8}$ means that the $4s$-like electrons of Ni_3 increase by 0.8. This relation implies that one of the 1.8 d-like electrons at Ni_3 and Ni_4 is ionized and the remaining 0.8 electrons are excited into $4s$ orbitals of Ni_3 and Ni_4 and, furthermore, the valence electrons distributed around Ni_1 and Ni_2 move in order to

screen the d-holes. The calculated ionization potential was very small and the electronic configuration was D_{2h}-like; we performed a D_{2h} calculation for Ni_4 to gain confidence and got the same solution as for C_{2v}. We, therefore, performed only D_{2h} calculations for Fe_4 and obtained ionization potentials of 2.80 ($^{6}A_g$) and 3.31 eV ($^{6}B_{1g}$), which are also shown in the bottom part of Table 2. The ionization process for the two states was two-electron-like as for Ni_4.

$$[6]\quad (3d,Fe_3)^{0.9}(3d,Fe_4)^{0.9} \rightarrow (4s4p,Fe_1)^{-0.4}(4s4p,Fe_2)^{-0.4}(4s,Fe_3)^{0.8}(4s,Fe_4)^{0.8}\,\infty^{1.0} \qquad \text{for } {}^{6}A_g$$

and

$$[7]\quad (3d,Fe_3)^{0.9}(3d,Fe_4)^{0.9} \rightarrow (4s4p,Fe_1)^{-0.2}(4s4p,Fe_2)^{-0.2}(3d,Fe_1)^{-0.1}(3d,Fe_2)^{-0.1}(4s4p,Fe_3)^{0.7}(4s4p,Fe_4)^{0.7}\,\infty^{1.0} \qquad \text{for } {}^{6}B_{1g}$$

We divide the process into two parts. First, atomic ionization of $(3d^74s^1) \rightarrow (3d^64s^1)$ arises at one of the Fe_3 and Fe_4, and atomic de-excitation $(3d^74s^1) \rightarrow (3d^64s^2)$ simultaneously arises at the remaining Fe_3 or Fe_4. Second, to screen the positive d-holes, the outer shells are reorganized; the $4s$ and $4p$ electrons from other atomic sites move in. As atomic correlation corrections for the ionization and the de-excitation are 2.4 and 0.9 eV, as shown in Table 6, total ΔCE is 3.3 eV,[1] leading to ionization potentials of 6.1 and 6.6 eV for $^{6}A_g$ and $^{6}B_{1g}$, which are slightly higher than that (5.9 eV) of the Fermi level (see Table 7). If we recall the uncertainty in estimating the correlation correction and the smallness of the difference in the ionization energy, we cannot say which of the two, the d-hole localized state or the two-electron-process-like ionized state, includes the Fermi level.

Information on ionization potentials for the other atoms is also collected in Table 6, together with the atomic correlation correction ΔCE. Ionization potentials for the other clusters of Ni_4, Cu_4, and Zn_4 calculated with symmetry-broken SCF and those with the correlation correction are compared with experimental values in Table 7. The latter are also shown in Figs. 3(*a*) and (*b*).

Let us discuss Ni_4, using the results given in the figure and the tables. The experimental ionization threshold given by Rohlfing *et al.* (10) was 5.6–6.4 eV while the s^{-1} level calculated with the correlation correction gave an ionization potential of 6.5 eV. Agreement is quite good. By the same level of approximation, we found that the state with the localized d-hole lay only 1 eV below the Fermi level of s^{-1}. As the separation of the two levels is fairly small, we assign the Fermi level as s^{-1} or a mixture of s^{-1} and d^{-1} states for the cluster. As before, two-electron-like ionization processes were first found for Ni_4 in both the C_{2v} and D_{2h} symmetries and the lowest two states obtained with the two symmetries were found to be identical (see the bottom part of Table 3). The magnitude of the correlation correction for the state was 4.2 eV and the state corrected lay 1.6 eV below the Fermi level. It is noted that, in Ni_4 and Fe_4, two-electron-like ionization processes bring the two d-hole states near or very near to the Fermi level. Such a state appears only if the atomic $(4s^23d^n)$ state lies near or below the $(4s^13d^{n+1})$ state.

Since the atomic de-excitation energy of $(3d^{n+1}4s^1) \rightarrow (3d^n4s^2)$ is exaggerated in the SCF-level approximation, it makes the ionized states of two-electron-like-processes, which are expressed by relations [1] and [2], stable even in the symmetry-constrained SCF.

We next discuss the case of Cu_4. The calculated ionization potential for Cu_4 is 6.7 eV while the experimental value obtained by Powers *et al.* (8) lies between 6.4 and 7.9 eV. The calculated ionization potential is in the region of the experimental threshold. For Cu clusters Schmeisser *et al.* (6) found that the top of the d-band began 3 eV below the Fermi level. As discussed in the previous subsection, symmetry-constrained ΔSCF results in the position of the top of the d-band relative to the Fermi level having a larger value of 5.2 eV, predicting a different electronic structure between the solid and the clusters. The symmetry-broken ΔSCF with correlation correction gave the top of the d-band 2.4 eV below the Fermi level, which was close to the experimental value of 3 eV. It will be shown that the top of the d-band becomes 2.7 eV below the Fermi level for Cu_6.

For Zn clusters it was found experimentally (7) that the top of the d-band began 10 eV below the Fermi level and that of the solid was 9.2 eV below. The symmetry-constrained ΔSCF gave 14.8 eV (see Table 5) while symmetry-broken ΔSCF with and without correlation correction gave 9.7 and 9.6 eV respectively. In the case of Zn_4 the effects of the correlation correction were small because the corrections for the s^{-1} and d^{-1} states were almost the same.

The positions of the Fermi level relative to the vacuum level and the top of the d-band relative to the Fermi level are

[1]One could take another route to obtain ΔCE for the ionization given by relations [6] and [7]. The ionization processes could be divided into three processes instead of two. Firstly, at Fe_3 and Fe_4 the atomic de-excitation $(3d^74s^1) \rightarrow (3d^64s^2)$ arises; secondly, one-electron ionization for the $4s$-like electrons proceeds at one of the two atoms; and thirdly, reorganization take places with a large movement of the $4s$ and $4p$ electrons, including the other atomic sties. The correlation correction for the first stage might be twice that for the de-excitation (1.8 eV). For the second stage we could use the correlation correction of 1.5 eV for $(3d^64s^2) \rightarrow (3d^64s^1)$ instead of the ΔCE of $(3d^74s^1) \rightarrow (3d^74s^0)$. Total ΔCE is 3.3 eV, which is just the same as mentioned in the main text.

thus systematically explained for M_4 clusters by symmetry-broken ΔSCF.

Band structure of Fe_6, Ni_6, Cu_6, and Zn_6

In this section the band structure of Fe_6, Ni_6, Cu_6, and Zn_6 will be discussed. We adopted O_h symmetry and the internuclear distances were fixed equal to those of nearest neighbors of the corresponding metals as in the case of the M_4 clusters. We calculated only the candidates for the ground state of the respective clusters. To discuss the band structure of the M_6 clusters we decided to modify the orbital energies of the candidate states by the following equation.

$$[8] \quad IP(M_6) = -\varepsilon_i - RE + \Delta CE$$

where RE is reorganization energy and ΔCE is the atomic correlation correction defined in Eq. [4].

In the previous section we saw that the localized *d*-hole state always consists of the top of the *d*-band, and the state resulting from the two-electron-process-like (tepl) ionization keeps the position very near to the Fermi level for Fe_4. We use the two reorganization energies of M_4 for the modification; we feel that the use of these energies may give smaller reorganization energies of ca. 1 eV or less for both s^{-1} and d^{-1} (19, 21). In Tables 8–11, the total energies, orbital energies, reorganization energies, and ionization potentials with correlation correction are shown for Fe_6, Ni_6, Cu_6, and Zn_6, respectively. The information on ionization potentials is summarized in Table 12 as well as in Figs. 3(*a*) and (*b*) where band widths are those of the orbital energy level distributions (discussed in the next paragraph). The experimental ionization thresholds are 5.8–6.0, 6.4–7.9, and 6.4–7.9 eV for Fe_6, Ni_6, and Cu_6, while the calculated first ionization potentials are 5.7, 6.8, and 6.9 eV for the respective clusters. We can say that the calculated ionization potentials agree well with the experimental values. The top of the *d*-band for Fe_6, which arises from the tepl ionization, consists only of the Fermi level among the M_6 clusters and that for Ni_6 lies 1.7 eV below the Fermi level. The value of 1.7 eV is still small and we leave the assignment of $s^{-1} + d^{-1}$ as the Fermi level with some hesitation. The top of the *d*-band was experimentally found ca. 3 and 10 eV below the Fermi level for Cu and Zn clusters. The corresponding calculated values agree with the experimental values with good accuracy (see Table 12).

We define the *s*(*d*)-band width as the difference between the orbital energy of the highest occupied *s*(*d*)-like orbital and that of the lowest occupied *s*(*d*)-like orbital. We would like to point out the uncertainty in the use of orbital energies to discuss the band width. Using the ΔSCF ionization potentials given in ref. 19, one finds that *s*-band widths provided by the orbital energies are 2.72 and 4.76 eV for Ni_4 and Ni_6, respectively, and those by ΔSCF for Ni_4 and Ni_6 are 1.15 and 4.21 eV; we can, therefore, say that the band width estimated with the orbital energies reflects the same trends as the band width calculated using ΔSCF. As shown in Figs. 2(*a*) and (*b*), the *s*-band width is one-half of the *d*-band width for Fe_4 and Ni_4, which is as wide as that for the corresponding metals (19, 21). The *s*-band width increases twice and becomes as wide as the *d*-band width for Fe_6 and Ni_6. For Cu_6 and Zn_6 the *d*-band width is close to that of the solid. The *s*-band width of Cu_6 is nearly half that of the solid and that of Zn_6 is almost the same as that of solid Zn. The data presented indicate rather rapid convergence of the *s*-band width of the clusters to that of the solid. We recall that the top of the *d*-band relative to the Fermi level is close to that of the corresponding metals for all the clusters under consider-

ation. We can, therefore, expect that the shape of the energy distributions of the clusters will resemble that of the metals even at smaller cluster size. Making a strong contrast, reasonable agreement between the first ionization potential of the clusters and the work function of the solid seems to require larger cluster size (8–10); for example, see the

ionization potentials of Fe_4 and Fe_6 in Tables 7 and 12 and compare them with the work function of 4.5 eV for the solid Fe (39).

Effect of different splitting of basis sets

We will consider what happens if we further divide the *d*-type CGTFs, taking Fe and Fe_4 as examples.

In the atomic case (43321/43/41) + p.f. gave a total energy of −1260.1602 and 1260.9893 au for the ground state ^5F and the *d*-electron ionized state ^6D, yielding an ionization potential of 4.65 eV, while (4332/43/311) + p.f. gave −1261.1602 and −1260.9900 au for ^5F and ^6D, yielding an ionization potential of 4.63 eV, which is very close to the result for the smaller splitting set. Since in the localized *d*-hole model the atomic ionization process is dominant, the results given above suggest that splitting causes only negligibly small effects.

For the tepl ionization, the effect of splitting might be larger. With smaller splitting we obtained total energies of −5044.63809 and −5044.53528 au for the ground state of $^{15}B_{1g}$ and the $14a_g{}^{-1}$ tepl ionized state, yielding an ionization potential of 2.80 eV, while larger splitting gave total energies of −5044.63832 and −5044.53776 au for the ground and ionized states respectively, yielding an ionization potential of 2.74 eV. The effects of the splitting are rather small for the total energies as well as for the ionization potentials. Results given in this paper are probably free from the problems that could arise from different ways of splitting the basis sets.

Discussion

We have discussed the electronic structure of Fe_4, Ni_4, Cu_4, Zn_4, Fe_6, Ni_6, Cu_6, and Zn_6. It was found that the experimental ionization thresholds were well explained by the symmetry-broken ΔSCF method with correlation correction. The Fermi level of the clusters consists of d^{-1} or $d^{-1} + s^{-1}$ for Fe clusters, and of s^{-1} or $s^{-1} + d^{-1}$ for Ni clusters, although for Ni_6 we have hesitated to take the assignment of $s^{-1} + d^{-1}$. The Fermi level of the Cu and Zn clusters was definitely the s^{-1} state.

For all the clusters except for Fe_6 the top of the *d*-band holds the localized *d*-hole at one of the constituent atoms. The total wave function for the ion (d^{-1}) has, in essence, the following form:

$$[9]\quad \phi = C_A|\phi_d(A^{-1}BCD\ldots)\phi_k(A^{-1}BCD\ldots)| + C_B|\phi_d(AB^{-1}CD\ldots)\phi_k(AB^{-1}CD\ldots)| + C_C|\phi_d(ABC^{-1}D\ldots)\phi_k(ABC^{-1}D\ldots)| + \ldots$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

where ϕ_d and ϕ_k symbolically represent all the d and conduction electrons, respectively. The first line implies that the d electron at atom A is ionized and the conduction electrons move to screen the positive hole at A. The other lines have a similar meaning (in the ΔSCF method only one term in eq. [9] was employed). This holds true for the atom, clusters, and the bulk metal and explains why the top of the d-band relative to the Fermi level was not very different from that of the atom. Auger spectra (40, 41) observed for bulk Cu and Zn were found to be atomic-like and are consistent with the present arguments.

In Fe_6 and (Fe_4) we found the tepl ionized state consists of the Fermi level and this type of the ionized state lies near the top of the d-band in Ni_4 and Ni_6. The wave function of the states may be written as

$$[10]\quad \phi = C_A|\phi_d(A^{-1}B^{d\to\kappa}CD\ldots)\phi_k(A^{-1}B^{d\to\kappa}CD\ldots)| + C_B|\phi_d(AB^{-1}C^{d\to\kappa}D\ldots)\phi_k(AB^{-1}C^{d\to\kappa}D\ldots)| + C_C|\phi_d(ABC^{-1}D^{d\to\kappa}\ldots)\phi_k(ABC^{-1}D^{d\to\kappa}\ldots)|$$

As in eq. [9] ϕ_d and ϕ_k represent all the s and d electrons. The first line indicates that the d electron at atomic site A is ionized and the d electron at atomic site B is simultaneously excited into the valence orbitals and that the conduction electrons move to screen the resulting positive holes; very high reorganization energy is released with a shifting of the valence electrons. This type of ionization is especially important when the atomic ground state has an electronic configuration of (s^2d^n) and the average atomic configuration for the solid or the clusters is (s^1d^{n+1}).

Acknowledgements

One of the present authors (H.T.) expresses his sincere thanks to Dr. S. Huzinaga who suggested investigation of the basis sets. Without the studies on the characteristics of the basis sets and without compact basis sets with high accuracy, the present authors could have not performed the investigations presented in this paper.

Computations were carried out on an ACOS 930-10 of the Computer Center of Nagoya City University and on HITAC M680's of the Computer Center of Hokkaido University.

Properties of atoms in molecules: structures and reactivities of boranes and carboranes

R. F. W. BADER AND D. A. LEGARE
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 1, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

R. F. W. BADER and D. A. LEGARE. Can. J. Chem. **70**, 657 (1992).

The energies, geometries, and charge distributions of the *closo*-, *nido*-, and *arachno*-boranes and *closo*-carboranes are determined in SCF calculations using a contracted (9*s*,5*p*) basis set of Huzinaga, supplemented with polarization functions. Good agreement is obtained between the experimental and calculated geometries. Molecular structures are assigned on the basis of the bond paths defined by the topology of the charge density using the theory of atoms in molecules. This theory is used to characterize the atomic interactions and to account for the stabilities of these electron-deficient systems. It is shown that their stability is a consequence of the delocalization of charge over the surfaces of the three- and four-membered rings of atoms that result from the formation of bonds of reduced order, a delocalization that is itself essential to the formation of the ring bonds. The Laplacian of the charge density is used to predict the sites of nucleophilic and electrophilic attack in these molecules, predictions that are in agreement with known experimental findings.

Key words: boranes, carboranes, charge density, Laplacian of ρ.

R. F. W. BADER et D. A. LEGARE. Can J. Chem. **70**, 657 (1992).

Faisant appel à des calculs en champ auto-cohérent utilisant l'ensemble de base contracté (9*s*,5*p*) de Huzinaga supplémenté de fonctions de polarisation, on a calculé les énergies, les géométries et les distributions de charge des *closo*-, *nido*- et *arachno*-boranes et des *closo*-carboranes. On a obtenu un bon accord entre les géométries calculées et expérimentales. On a attribué les structures moléculaires en se basant sur les voies de liaisons définies par la topologie de la densité de charge, en utilisant la théorie des atomes dans les molécules. Cette technique est utilisée pour caractériser les interactions atomiques et pour rendre compte des stabilités de ces systèmes électro-déficients. On montre que leur stabilité est une conséquence de la délocalisation de la charge sur les surfaces des atomes des cycles à trois et à quatre chaînons qui est elle-même essentielle à la formation de liaisons dans les cycles. On utilise le laplacien de la densité de charge pour prédire les sites des attaques nucléophiles et électrophiles dans ces molécules; ces prédictions sont en bon accord avec les données expérimentales connues.

Mots clés : boranes, carboranes, densité de charge, laplacien de ρ.

Introduction

This paper reports the theoretical determination of the geometries and molecular graphs for a series of boranes and carboranes. In addition to determining their molecular structures, the stabilities and reactivities of these structures are related to their atomic properties and to the atomic graphs of the boron and carbon atoms. The molecular graphs determine the atomic connectivities in terms of the topology of the charge density, whereas the atomic graphs determine the reactivity of a molecule towards nucleophilic and electrophilic attack in terms of the topology of the Laplacian of the charge density. All of these properties are defined by quantum mechanics using the theory of atoms in molecules, a theory that extends quantum mechanics to an atom in a molecule (1, 2). In addition to BH and BH_3, the molecules considered here are the *closo* structures (closed structures of *n* atoms in an *n*-atom polyhedral framework) $B_6H_6^{2-}$, $B_7H_7^{2-}$, $B_{12}H_{12}^{2-}$, $C_2B_3H_5$, and $C_2B_4H_6$; the *nido* structures (open structures of *n* atoms in an $n + 1$ atom polyhedral framework) B_2H_6, B_5H_9, and B_6H_{10}; and the single *arachno* structure (open structures of *n* atoms in an $n + 2$ atom polyhedral framework) B_4H_{10}. The reader is referred to the text by Greenwood and Earnshaw (3) for a full discussion of the nomenclature and properties of the boranes and carboranes.

The boranes are of particular interest from the point of view of theories of bonding because of their electron-deficient nature, as judged on the basis of the Lewis electron pair model of the chemical bond. The theory of atoms in molecules leads to an unequivocal assignment of a molecular structure and provides a classification of the bonds so defined (1, 4). This information adds a physical complement to the electron counting models of structure as embodied in Lipscomb's styx rules (5) and in the molecular orbital based rules of Wade (6).

Computations and comparison of calculated and experimental geometries

The results are obtained from single determinant SCF calculations using the program Gaussian 88 (7). The [6,1,1,1/4,1] Dunning contraction (8) of the (9*s*,5*p*) Huzinaga basis (9) was used for boron and carbon, augmented with a single *d* basis function. Exploratory calculations demonstrated the importance of providing an adequate description of the hydrogen atoms, particularly the inclusion of a diffuse function to describe their hydridic nature. The Duijneveldt (10) set of 6*s* functions contracted to [4,1,1] was used, together with a single *p* function with an optimized exponent of 1.0725. The energies and optimized geometries obtained in these calculations are summarized in the Appendix. The numbering of the atoms in each molecule as used throughout the paper is also indicated.

Baudet (11) has compiled the geometries of the neutral boranes based upon experimental data obtained from microwave, electron diffraction, and X-ray diffraction techniques. X-ray data are available for salts of the hexa- (12*a*)

and dodecahydroborates (12*b*). The experimentally determined geometrical parameters are compared with the theoretical values in Table 1. The agreement is good, being best when the single molecule calculations are compared with gas phase microwave data. Both experiment and theory support the general observations that B—C distances are shorter than B—B distances in the same molecule and that the angle subtended at a carbon in a three- or four-membered ring in a carborane is larger than 60° or 90° respectively, while the corresponding angles subtended at a boron are less than these values.

The orbital energy of triply degenerate HOMO in $B_6H_6^{2-}$ is found to be positive, and equal to +0.0520 au. Fowler (13) found an even more positive value (by 0.030 au) for this orbital energy, using the 6-31G* basis set, which yields a molecular energy higher by 0.08 au than that obtained here. These results suggest that the free anion may be unstable towards autoionization and is stable only when its negative charge is counterbalanced in a crystalline environment. The doubly degenerate HOMO and HOMO-1 in $B_7H_7^{2-}$ also exhibit positive eigenvalues, 0.017 and 0.013 au, respectively. The eigenvalues of all of the occupied levels in the dodecahydroborate are negative. The fact that the HOMO energy in the hexahydroborate decreased significantly with an increase in the size of the basis set shows that its value is not stable towards an expansion of the basis set, as Fowler suggests might be the case. A calculation approaching the Hartree–Fock limit or one that includes electron correlation could predict the anions to be stable entities in the gas phase.

Structure and bonding in the boranes and carboranes

Molecular structure and molecular graphs

A (3,−1) critical point in the electronic charge density ρ is formed between every pair of interacting atoms. Two gradient vectors of ρ originate there and trace out a line, the atomic interaction line, linking the two nuclei along which the electronic charge density is a maximum with respect to any neighbouring line. In an equilibrium geometry such a line is called a bond path and the associated critical point the bond critical point. The creation of the bond critical point and its associated accumulation of electronic charge in the internuclear region meet the necessary and sufficient conditions for the atoms to be bonded to one another (1, 14). The global behaviour of the gradient vector field of the electronic charge density is illustrated in Fig. 1 for $C_2B_3H_5$. It illustrates the definition of an atom as the union of an attractor and its basin — a region of space bounded by surfaces of zero flux in the gradient vector field of the charge density — together with the definition of a bond path and an interatomic surface.

The collection of bond paths defines the molecular graph for a given nuclear geometry and all geometries possessing equivalent molecular graphs possess the same molecular structure (1, 4). The molecular structures defined by the theory of atoms in molecules have been shown to recover known chemical structures. In addition, the theory predicts changes in structure by giving operational meaning to the concepts of the making and breaking of chemical bonds (1, 4).

The Lewis electron pair model of the chemical bond between pairs of atoms does not apply to the skeletal frameworks of the boranes and carboranes and one is forced to extend the electron pair concept to include three-centre two-electron bonds (15), which in the base of the boranes consist of B—H—B bridges and three-membered boron rings. The ability of theory to define the network of bonds independent of any model, by determining which nuclei are linked by lines of maximum charge density, is of particular importance for these systems. Diborane and pentaborane were used in an early application of the theory to demonstrate its ability to assign structures in systems with unusual bonding situations (16).

The molecular structures determined by theory are shown in Fig. 2. The model of the three-centre B—H—B bridging bond is recovered in the form of a hydrogen linked by bond paths to two borons in the *nido* and *arachno* compounds; however, these same structures do not exhibit linked three-membered boron rings. Only in B_4H_{10} is there a B—B bond path linking two borons that are each linked to two hydrogen bridges. In B_5H_9 and B_6H_{10} such borons are not linked to one another, but are instead linked to the apical boron atom. There is, in the latter compound, an additional bond path linking borons 9 and 10, those which are linked to only a single hydrogen bridge. The styx model (5) represents the structure of pentaborane in terms of four equivalent resonance forms, each of which possesses four hydrogen bridges, one three-membered boron ring, and two single B—B bonds to the apical boron. This corresponds to assigning two-thirds of an electron pair bond to each link with the apical boron and one-twelfth of an electron pair to each link between the borons involved in hydrogen bridging. In B_6H_{10} there are two three-membered boron rings in the styx model, one between the apical boron B2 and boron atoms B4 and B9, the other between B2, B5, and B10. Thus these B—B bonds to the apical boron atom are predicted to be weaker than the two full B—B bonds in this molecule. The *closo* anions, which do not possess any hydrogen bridges, exhibit linked three-membered rings of boron atoms so that a B—B bond path lies along each edge of the corresponding *n*-vertex polyhedron. The structure for the carborane $C_2B_3H_5$ does not exhibit any B—B bond paths and an electron pair may be associated with each bond path in this structure; it is electron precise. There are however, bond paths linking the boron atoms in the electron-deficient $C_2B_4H_6$.

At the midpoint between the basal atoms B9 and B10 in B_6H_{10} and between the adjacent basal boron atoms in $B_7H_7^{2-}$ there are (3,−3) critical points, i.e., local maxima in ρ of very small magnitude, rather than the anticipated (3,−1) bond critical points. These maxima are bounded on either side by (3,−1) critical points that are close to the maxima in position and in value, those in B_6H_{10}, for example, possessing values of ρ only 0.0004 au smaller than that at the maximum and separated from it by 0.38 au. While non-nuclear maxima are possible (1), the use of a larger, more flexible basis set in the present systems would likely cause them to disappear, with each maximum and its adjacent bond critical points being replaced by a single bond critical point, as shown in the molecular graphs of Fig. 2. What is important is that the charge density along these bond paths is very flat in the central region of the bond.

With the exception of BH_3, all of the molecules in Fig. 2 exhibit bonded rings of atoms. The electronic charge density exhibits a critical point in the interior of each ring, a (3,+1) critical point, which possesses two positive curvatures whose axes define the ring surface and a single negative curvature lying along a perpendicular axis, Fig. 1. The charge density attains its minimum value in a ring surface at

the ring critical point. The interiors of the *closo* molecules are enclosed by ring surfaces and they are cage structures. There is a critical point in the interior of each cage structure for which all three curvatures are positive, a (3,+3) or cage critical point, Fig. 1. The charge density is a local minimum at such a critical point. The set of critical points associated with a molecular charge distribution completely determines its chemical topology; N, the number of (pseudo) (3,−3)'s equals the number of nuclei; b, the number of (3,−1)'s, the number of bond paths; r, the number of (3,+1)'s, the number of rings; and c, the number of (3,+3)'s, the number of cages. The set of numbers $\{N,b,r,c\}$, the characteristic set (16), must satisfy the Poincare–Hopf relationship (17)

$$[1] \quad N - b + r - c = 1$$

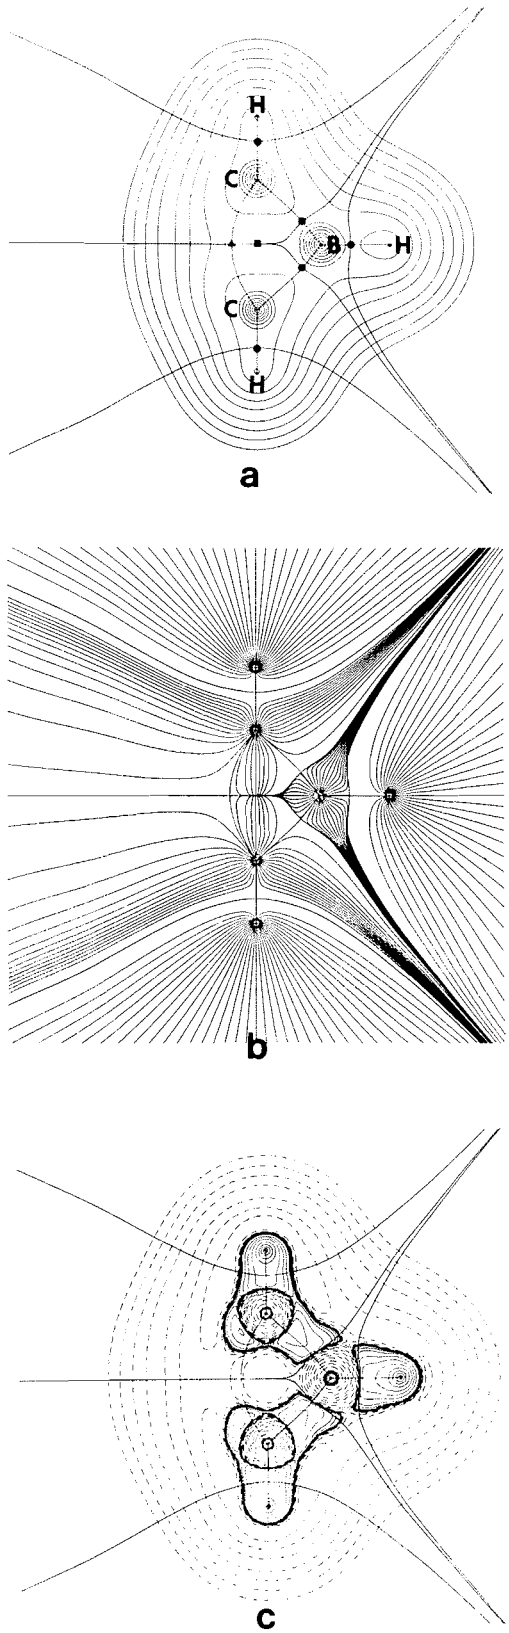

FIG. 1. Contour maps of (*a*) the electronic charge density ρ and (*c*) its Laplacian, and (*b*) a display of the gradient vector field of ρ, all for a symmetry plane of $C_2B_3H_5$ containing the nuclei H—C—B(—H)—C—H. The contour plots are overlaid with bond paths and the atomic boundaries. Bond or (3,−1) critical points are denoted by dots. All of the trajectories of $\nabla\rho$ in the vicinity of a given nucleus terminate at that nucleus, in all three dimensions, thereby defining the basin of the atom. The (3,−1) critical points whose trajectories link the nuclei in this plane appear as (2,0) critical points. The two trajectories defining the bond path originate at each such point and the two trajectories indicating the intersection of the interatomic surface with the plane terminate there. A (3,+1) or ring critical point appears as a (2,0) denoted by a triangle, and a central cage or (3,+3) critical point, which appears as a (2,+2), is denoted by a star. Solid contours denote negative values of the Laplacian, dashed contours positive values. The outer contour value for ρ is 0.001 au and remaining contours increase in the order 2×10^n, 4×10^n, and 8×10^n with n beginning at −3 and increasing in steps of unity. Plus and minus values of the same contour set apply to $\nabla^2\rho$. See Tables 2 and 6 for values of $\nabla^2\rho$ at specific points in this and succeeding diagrams.

The characteristic set for $C_2B_3H_5$ for example is {10,11,3,1}. Equation [1] is brought into correspondence with Euler's expression for a closed polyhedron by associating N with the number of vertices V, b with the number of edges E, r with the number of faces F, and transposing $c = 1$ to the RHS to yield

$$[2] \quad V - E + F = 2$$

Classification of atomic interactions

Bond order, path, ellipticity, and character

The theory, in addition to assigning a structure in terms of a set of bond paths, affords a description and characterization of how the electronic charge density is distributed in each of the atomic interactions so defined. This information is summarized in terms of the properties of the charge density at the bond critical points.

The value of the charge density at the bond critical point, the quantity ρ_b, provides a measure of bond order. For the interaction between a given pair of atoms, its value increases as the bond length decreases and the strength of the interaction increases (18, 19). Unlike C—C and N—N bonds for example, where one can define a bond order–ρ_b relationship for orders one to three, the bonds in the molecules considered here are all of formal order one or less. To allow for a facile comparison of the relative strengths of each type of bond, the values of ρ_b listed in Table 2 are referenced to the value for one such bond to give a bond order n. The B—H_t (H_t is a terminal hydrogen) and B—H_b (H_b is a bridging hydrogen) bonds in diborane are assigned orders of unity in Table 2, as is the B—B bond in B_4H_{10} and the B—C and C—H bonds in $C_2B_3H_5$. Also listed in Table 2 are the values of ρ at the ring (ρ_r) and cage (ρ_c) critical points.

The distances of the bond critical point from the two nuclei define the associated bonded radii of the atoms, r_A and r_B of Table 2. Their relative values reflect the direction of interatomic charge transfer (20). The bond paths associated with the bridging bonds are noticeably bent and, in such cases, the value of the bond path length R_b is greater than the equilibrium or geometrical path length R_e, Table 2.

The curvature of ρ at a given point determines whether electronic charge is locally depleted (curvature positive) or locally concentrated (curvature negative) at that point, in the sense that for a positive curvature the value of ρ at the point is less than its value averaged over neighbouring points, with the reverse being true for a negative curvature. The sum of the three curvatures defines the Laplacian of the electron density, the quantity $\nabla^2\rho$. The curvature of ρ at a bond critical point along the bond path is positive. Thus the charge density attains its minimum value at the critical point along

this path and electronic charge is locally depleted at the critical point with respect to neighbouring points along the bond path. The two curvatures of ρ perpendicular to the bond path at the bond critical point are negative. Thus ρ is a local maximum in the interatomic surface at the bond critical point and electronic charge is locally concentrated there. The formation of an interatomic surface and a chemical bond is, therefore, the result of a competition between the perpendicular contractions of ρ, which lead to a concentration or contraction of electronic charge towards the bond path, and the parallel expansion of ρ away from the interatomic surface, which leads to its separate concentration in one or both of the atomic basins (1, 14). The sign of $\nabla^2\rho_b$, Table 2, determines which of the two competing effects dominates a given interaction.

As a consequence of the appearance of $\nabla^2\rho$ in the local expression for the virial theorem, it can be shown that the potential energy dominates the local energy and is stabilizing in those regions of space where the Laplacian is negative and electronic charge is concentrated (1). When ρ_b is relatively large in value and $\nabla^2\rho_b$ is negative, electronic charge is accumulated and concentrated in the binding region and the atoms are bound by the charge that is shared between the nuclei. When ρ_b is relatively low in value and $\nabla^2\rho_b$ is positive, electronic charge is separately concentrated in the atomic basins and the interaction is typical of that found between closed-shell systems, such as found in ionic bonds and hydrogen bonds.

In a bond with cylindrical symmetry such as the C—C bond in ethane, the two perpendicular curvatures of ρ at the bond critical point, λ_1 and λ_2, are of equal magnitude. However, if these curvatures are of differing magnitudes, then the density falls off less rapidly along the axis of the curvature with the smaller of the two magnitudes. The resulting elliptical nature of the charge density associated with this preferred accumulation of electronic charge in a given plane containing the bond path, the plane of the π density in ethene for example, is quantitatively measured by the bond ellipticity $\varepsilon = ((\lambda_1/\lambda_2) - 1)$, where λ_2 is the curvature of smallest magnitude.

Charge density along the bond paths

The values of ρ_b and $\nabla^2\rho_b$ for the C—H bonds in the carboranes, Table 2, are typical of a shared or covalent interaction, one that is dominated by a contraction of ρ towards the bond path leading to its accumulation in the internuclear region. Thus $\nabla^2\rho_b < 0$ and ρ_b is relatively large in value for these interactions. The concentration of charge density that links the valence shell charge concentrations (VSCC's) of the carbon and hydrogen atoms and leads to their binding is shown in Fig. 1. The atomic charges are given in Table 3 and the small net charge on a hydrogen bonded to carbon in the carboranes, ±0.02, is indicative of the nearly equal sharing of electronic charge between the carbon and hydrogen atoms.

There is a considerable transfer of electronic charge from boron to a terminal or bridging hydrogen atom, $q(H) = -0.7$ e, Table 3, and the values of ρ_b and $\nabla^2\rho_b$ for the B—H bonds are intermediate in value between those for a shared interaction as found in C–H and a closed-shell or ionic interaction, for which ρ_b is less than 0.1 au and $\nabla^2\rho_b > 0$. The values of ρ_b for the B—H bonds lie within the range 0.1–0.2 and the values of $\nabla^2\rho_b$ lie on either side of zero, the point of change between the two extremes of bonding. The plots of the Laplacian distribution for $C_2B_3H_5$ in Fig. 1 show that, unlike the sharing of the charge concentration between the two atoms as found in C—H, the regions of charge concentration for B–H interactions are largely localized within the basins of the hydrogen atoms.

One anticipates that the bonding between B and a terminal hydrogen will exhibit the least variation throughout the series and the data in Table 2 bear this out. The bond lengths of the terminal B—H bonds in the *nido*- and *arachno*-boranes and carboranes vary by 0.02 au from the value 2.23 au. They have bond orders that vary by only 0.02 from the standard bond of order one in B_2H_6, with the sole exception of the bond to the apical boron in B_5H_9 for which $n = 0.96$. The values of $\nabla^2\rho_b$ are of similar magnitude and are less than zero in each case. The terminal hydrogens in the negatively charged *closo* compounds bear slightly larger negative charges than those in the neutral molecules, an effect that is most pronounced in the hexaborane. Because of

this shift towards more ionic binding, the bond lengths are somewhat longer, the bond orders smaller, and the values of $\nabla^2\rho_b$ closer to zero for the B—H_t bonds in the *closo* molecules.

The bonds to the bridging hydrogens are, in general, longer than those to the terminal hydrogens, with an average length of 2.55 au. The associated bond paths are strongly curved towards the interiors of the rings formed by the bridging hydrogens (see Fig. 2 and the bridging plane of diborane, Fig. 3). As a consequence, the bond path lengths, R_b, for the bridging hydrogens exceed their geometric lengths, R_e (Table 2). The B—H_b bonding in the *nido*- and *arachno*-boranes is characterized by lower values of ρ_b than are found for their B—H_t bonds, 0.11 compared to 0.18 au, and also by near-zero values of $\nabla^2\rho_b$, which in these cases are mostly positive. The *arachno* molecule B_4H_{10} provides an example of a case in which the two bonds to a bridging hydrogen atom are inequivalent. The values of ρ_b differ from the reference value in diborane by ±0.02 au, with the critical point linked to the boron forming the B—B bond having a large ρ_b value, and the other, linked to a boron in a BH_2 group, having the smaller value. Both have positive values of $\nabla^2\rho_b$, with the first mentioned interaction being slightly more ionic.

The reference B–B interaction is the central B—B bond in B_4H_{10}. Its ρ_b value is intermediate between those for the terminal and bridging B–H interactions. A display of the Laplacian distribution for the B—B bond, Fig. 3, shows that the valence shell charge concentrations of both atoms are joined together to give a contiguous concentration of electronic charge that is shared between them, as evidenced by a $\nabla^2\rho_b$ value of −0.31 au. These borons possess 0.6–0.7 more electrons than borons B5 and B6, which are each linked to four hydrogens. The C—C bond in ethane has a ρ_b value of 0.25 au and a $\nabla^2\rho_b$ value of −0.66 au. Thus the B—B bond in these molecules is a relatively weak shared interaction. The B–B interactions in B_5H_9 are similar to the standard, but with a reduced extent of charge accumulation and charge concentration.

The B–B interactions between the apical and basal borons in B_6H_{10} all have reduced bond orders compared to the standard, and exhibit a smaller degree of charge concentration in the internuclear region. In agreement with the styx

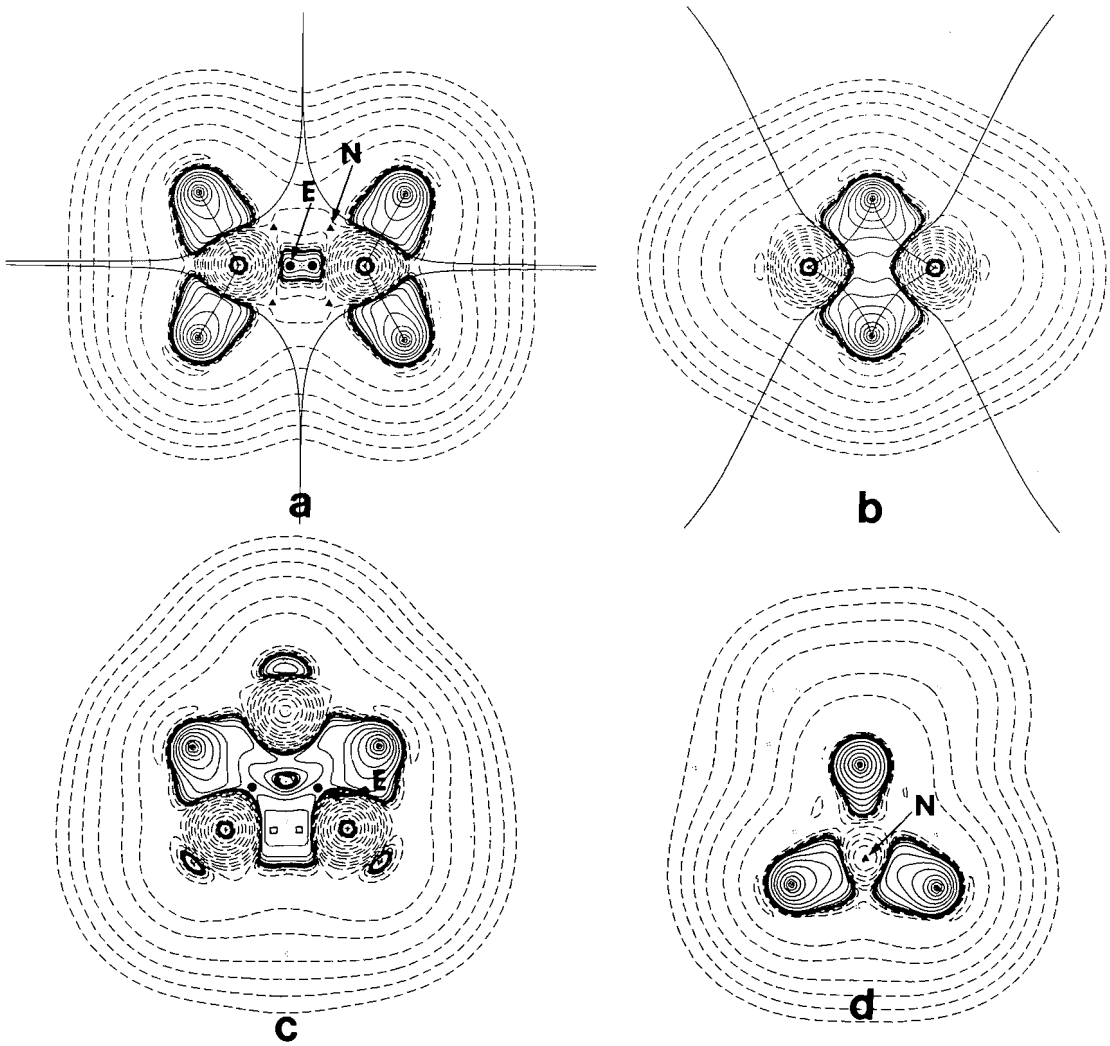

FIG. 3. Contour maps of the Laplacian distributions for *nido*-diborane and *arachno*-tetraborane, the former in the plane of the terminal hydrogens (*a*), and the bridging plane (*b*), the latter in the plane of the bonded borons and two bridging hydrogens (*c*) and in the plane of one bridging and two neighbouring terminal hydrogens (*d*). E and N denote predicted sites of electrophilic and nucleophilic attack, respectively. Note the presence of two bonded maxima in $-\nabla^2\rho$ along the bond path linking the borons in tetraborane that are absent in diborane, which does not possess a B—B bond.

model of this molecule outlined above, the weakest of these interactions are found between those atoms that, in the model, are involved in three-centre boron ring bonds, those linking the apical atom to borons 4 and 5 and to borons 9 and 10. The interaction between the two basal borons, B9 and B10, which are not linked by a bridging hydrogen, has an order equal to 1.23 and the largest degree of charge concentration in the internuclear region. The B–B interactions in the carborane $C_2B_4H_6$, which again are predicted by the styx model to be involved in three-centre bonding, have bond orders of 0.94 and a reduced extent of charge concentration compared to the standard.

The bond orders of the B–B interactions in the *closo*-boranes become progressively smaller as the size of the cage increases, from 0.91 in $B_6H_6^{2-}$ to 0.86 in $B_{12}H_{12}^{2-}$. In the heptahydroborate, the bonds to the apical boron have orders less than the standard value while those between the five equivalent borons have orders in excess of unity, to yield an average value of ρ_b that is intermediate between those for the other two *closo* compounds.

There is considerable transfer of electronic charge from boron to carbon in the carboranes, and the C—B bonds, like the B—H bonds, are very polar. The ρ_b values for the C—B bonds in $C_2B_3H_5$ are similar to those observed for the B—H_t bonds, but their values of $\nabla^2\rho_b$ lie on the ionic side of the zero value. The molecule $C_2B_4H_6$ is electron deficient with respect to the number of skeletal bond paths it exhibits and, correspondingly, the value of ρ_b for the C—B bond decreases from that found in $C_2B_3H_5$, which is electron precise.

Charge density in the ring surfaces

Because of their electron-deficient nature, the boranes form ring and cage structures to gain maximum stability from a minimum amount of electronic glue. They do this through a very pronounced delocalization of the charge density over the ring surfaces, an effect that is quantitatively characterized by the values of ρ_r and the ellipticities of the ring bonds. The three-centre model of the two-electron bond is mirrored in the molecular graphs of theory by the presence of four- and five-membered hydrogen-bridged rings and the three-membered rings of boron atoms or of a carbon and two boron atoms in a carborane. In all of these rings the value of ρ_r, the minimum value attained by the charge density in the ring surface, is only slightly less than the value of ρ_b, the minimum value attained by the charge density in the lines of maximum charge density forming the ring's perimeter, Table 2. Correspondingly, the ring bonds exhibit large ellipticities with their major axes oriented in a direction tangent to the surface of the molecule, indicating a delocalization of electronic charge over the surface of the ring. The same charge delocalization is reflected in the Laplacian of the charge density. This distribution is negative over each of the ring surfaces beyond the boron core distributions, and electronic charge is concentrated almost evenly over the entire surface, see Figs. 3–5. The contraction of ρ along the axis perpendicular to the ring surface at the ring critical point is so large it dominates the two positive curvatures of ρ in the ring surface and the Laplacian is negative even at the ring critical points in these systems. That these effects are unique to the electron-deficient systems is illustrated by a comparison of the properties of the two carboranes. The molecule $C_2B_3H_5$ is electron precise. Thus the value of ρ_r for its four-membered rings is considerably less than the values of ρ_b for the peripheral bonds, and their ellipticities are less than 0.01. The molecule $C_2B_4H_6$ is electron deficient. In this case, the value of ρ_r for the three-membered rings is the same as the value of ρ_b for the peripheral B—B bonds to four significant figures and they exhibit extreme ellipticities of 58. The B—B bond paths are inwardly curved away from the perimeter of the ring, another characteristic of the three-centre systems.

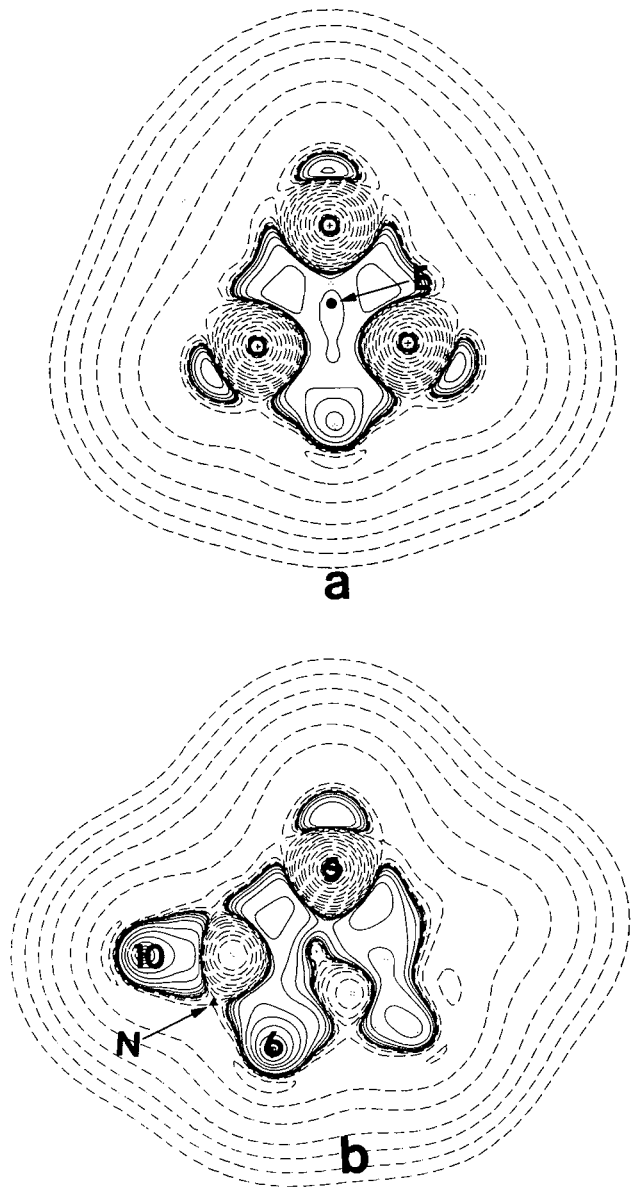

FIG. 4. Contour maps of the Laplacian distributions for *nido*-pentaborane, in a plane containing two basal and the apical boron atoms (*a*) and in a plane containing the apical boron, one bridging, and one neighbouring terminal hydrogen (*b*). The same diagrams apply to *nido*-hexaborane.

These characteristics of the charge density provide a quantitative measure of the extent to which electronic charge is delocalized over and concentrated in the ring surface of electron-deficient molecules where it serves to bind all of the nuclei of the ring. The description of such molecules as globally delocalized by King and Rouvray (21) is particularly apt. The surface delocalization of electronic charge

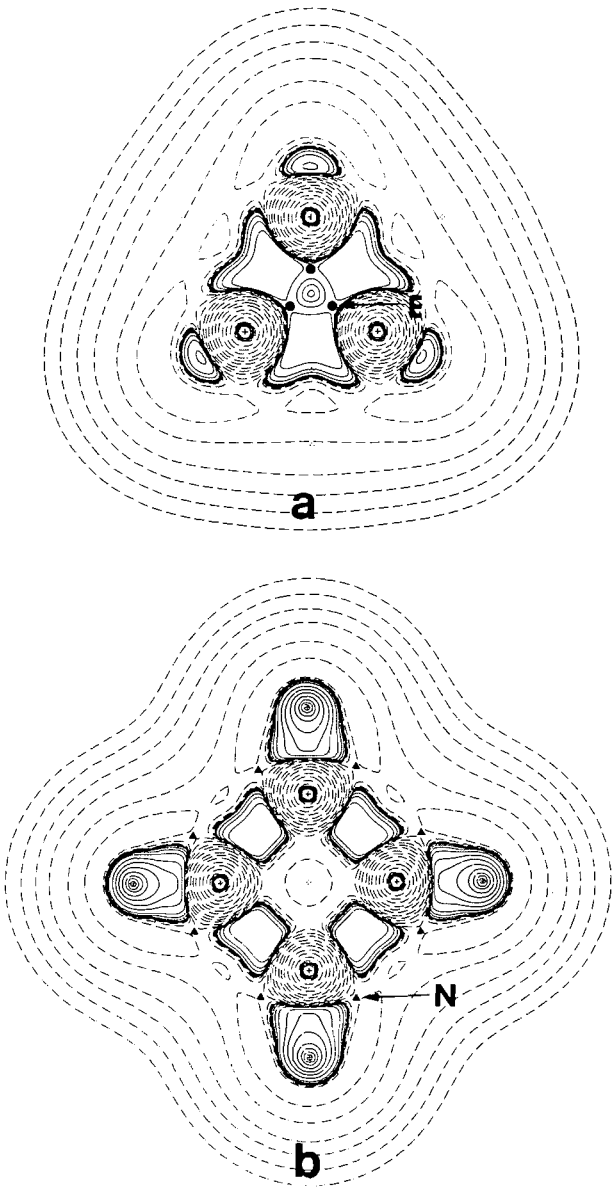

FIG. 5. Contour map of the Laplacian distribution for *closo*-hexahydrohexaborate, for a plane containing a B—B—B face (*a*) and for a plane containing a plane of four boron atoms (*b*). The same diagrams apply to the hepta- and dodecahydroborates.

demonstrated to be present in the *closo* molecules is also consistent with Stone's (22) description of the bonding in polyhedral atomic clusters as a perturbed spherical shell of atoms for which the electronic wave functions are the surface harmonics characterized by the quantum numbers l and m. The effect of this surface delocalization of charge on the energy is discussed below.

Atomic properties

Table 3 lists the atomic populations, charges, and energies, while Table 4 lists the same properties relative to their values in diborane. These atomic properties are obtained using the programs PROAIM (23) and OMEGA (24). The atomic population of atom Ω, $N(\Omega)$, is obtained by an integration of ρ over the basin of the atom. Its net charge $q(\Omega) = Z_\Omega - N(\Omega)$. An atomic energy $E(\Omega)$ is, by the atomic statement of the virial theorem, equal to the negative of the atomic electronic kinetic energy $T(\Omega)$, as obtained through an integration of the kinetic energy density (1, 4). Because of the extremely flat nature of the charge density in certain of the three-membered ring structures commented on above, the program has difficulty following certain of the paths traced out by the gradient vectors of ρ that define the interatomic surfaces for the boron atoms, and it was not possible, in these cases, to integrate the property densities over the atomic basins. There is an internal check on the accuracy of an atomic integration provided by the evaluation of the integral of the Laplacian of the charge density. The atomic value of this integral should vanish, because of the zero flux surface condition defining the atomic boundaries. When the value of this integral is less than 1×10^{-3} au the error in the energy of the atom is less than 0.2 kcal mol^{-1}. Table 5 gives the sums of the atomic populations and energies for four molecules where all the atoms could be integrated within this limit and the integration errors are seen to be 0.006 e or less in the total population and 1 kcal mol^{-1} or less in energy. In $B_6H_6^{2-}$, $B_{12}H_{12}^{2-}$, and $C_2B_4H_6$, all atoms other than the equivalent boron atoms could be integrated within the limit set on the value of the atomic Laplacian, and the boron results were obtained by difference in these cases. In B_5H_9, B_6H_{10}, and $B_7H_7^{2-}$ the average values of the populations and energies of the two borons, which could not be separately integrated, are given in Tables 3 and 4.

The bridging hydrogen atoms possess a negative charge equal to -0.71 ± 0.01 e except for pentaborane where the charge drops to -0.67 e. The bridging hydrogen atom is most stable in diborane, being least stable in pentaborane where its population is significantly less. The relative stabilities, in general, correlate with the bond orders.

Excluding the negatively charged *closo* compounds but including the carboranes, the negative charge on a terminal hydrogen is, in general, somewhat smaller than that on a bridging hydrogen and it is less stable, as reflected in the values for diborane itself. The terminal atoms most similar to the standard are those in the BH_2 groups in B_4H_{10}, the other terminal hydrogens possessing smaller populations and less negative energies. A hydrogen bonded to a boron of a single B—B bond such as H3 in B_4H_{10} and B_6H_{10} possesses the net charge of smallest magnitude. A hydrogen bonded to an apical boron has a net charge of smaller magnitude than one bonded to a basal boron. The bridging hydrogens are more stable than the terminal hydrogens in the same molecule to an extent greater than that anticipated on the basis of a slightly greater electron population. One reason for the increased stability of the bridging hydrogens is their more contracted nature. The volume of a bridging hydrogen atom, measured out to its 0.001 au density envelope, is 59.2 a_0^3 compared to 82.8 a_0^3 for a terminal hydrogen in diborane. This more contracted nature of the charge density results in a potential energy of interaction of the proton of a bridging hydrogen with its own atomic charge distribution that is more negative than that for the more diffuse terminal atom by 16 kcal mol^{-1}. Another factor contributing to the increase in stability is, as discussed in more detail below, the presence of the delocalized charge over the surface of the hydrogen-bridged rings.

The terminal hydrogens in the *closo*-boranes possess the largest electron populations of all the hydrogens. These populations decrease as the size of the cluster increases. In

$B_7H_7^{2-}$ a hydrogen bonded to an apical boron has a larger population than one bonded to a basal boron. While the terminal hydrogens in the *closo*-boranes possess larger electron populations, they are less stable than the terminal hydrogens in diborane. The charge distributions of the terminal hydrogens of the *closo*-boranes are the most diffuse of the atoms in the boranes with atomic volumes equal to 104.3 a_0^3 to give an average density of 0.017 e a_0^{-3}.

Since hydrogen withdraws charge from boron, the stability of a boron atom increases with a decrease in the number of bound hydrogen atoms. Thus the least stable boron atoms are those in diborane and the corresponding borons of the BH_2 groups in B_4H_{10}. Boron atoms linked to one other boron by a bond path possess 0.6–0.9 more electrons than does the standard atom in diborane. Boron atoms in the two *nido*-boranes are involved in ring systems over which there is significant charge delocalization and they, like the bridging hydrogens that link them, are stabilized relative to the standard atoms. For the boron atoms, the stabilization is in excess of 200 kcal mol^{-1}.

The borons in $C_2B_3H_5$, which are linked by bond paths to two carbons and a terminal hydrogen, have populations and energies that are nearly identical to those for the standard boron in diborane. In addition, the terminal hydrogen attached to boron has the same population as the standard H_t atom in diborane to within 0.001 e. Thus the boron linked to two carbons appears to a terminal hydrogen to be nearly identical to the standard boron atom in diborane. Each carbon in the dicarbapentaborane has a net charge of −2.103 e. This charge decreases slightly to −2.003 e in dicarbahexaborane and the terminal hydrogens bonded to the borons are again almost unchanged from the standard. Thus the two skeletal electrons of the added BH_t group are donated almost entirely to the borons in $C_2B_4H_6$, and each has 0.43 more electrons than do those in $C_2B_3H_5$. As a result, there is sufficient electronic charge to form bond paths between the borons in dicarbahexaborane, the bond path equivalent of three-centre two-electron bonds for a B_2C ring of atoms. Thus the two skeletal electrons of the added BH_t group initiate the formation of bond paths between the borons that serve to catalyse the delocalization of charge over the surfaces of the resulting three-membered rings. The boron atoms are significantly stabilized, by ≈280 kcal mol^{-1} relative to the standard or to the borons in dicarbapentaborane. The dicarbahexaborane molecule is, therefore, considerably stabilized by the surface delocalization of charge associated with the model of the two-electron three-centre ring of atoms.

The boron atoms in the negatively charged *closo*-boranes have considerably greater electron populations than do the

For personal use only.

boron atoms in diborane, with $\Delta N(B) \cong 1.6$ e, Table 4. While the terminal hydrogens in the *closo* molecules are somewhat less stable than the standard H_t in diborane, each boron atom is stabilized relative to the standard boron atom by an amount in excess of 420 kcal mol^{-1}. The delocalization of charge over the surfaces of the three-membered rings in the *closo* compounds leads to a considerable stabilization of these molecules, as it does in the case of $C_2B_4H_6$.

Reactivity in terms of the Laplacian of the charge density

The Laplacian of the charge density, through its ability to define and locate centres of local charge concentrations and local charge depletions, provides the physical basis for the Lewis concept of the localized electron pair and its associated models of molecular geometry and reactivity (1, 25). Since electronic charge is concentrated in regions where the Laplacian is negative, it is most useful to discuss the topology of the negative of the Laplacian distribution, a maximum in $-\nabla^2\rho$ corresponding to a local concentration of electronic charge.

The Laplacian distribution recovers the electronic shell model of an atom by exhibiting a corresponding number of pairs of shells of charge concentration and charge depletion (25–28). For a spherical atom, the outer shell or valence shell of charge concentration, the VSCC, contains a sphere over whose surface electronic charge is maximally and uniformly concentrated. Upon entering into chemical combination, the VSCC is distorted and local maxima, minima, and saddles appear on the sphere of maximum charge concentration. It has been demonstrated in many systems (25, 29, 30, 31) that the local maxima correspond in number, location, and size to the localized pairs of electrons assumed in the Lewis model. All of the properties postulated in the VSEPR model of molecular geometry (32) for bonded and nonbonded pairs of electrons are recovered by the maxima in the VSCC of the central atom (29, 30).

The Lewis model also encompasses chemical reactivity through the concept of a generalized acid–base reaction. Complementary to the local maxima in the VSCC for the discussion of reactivity are its local minima. A local charge concentration is a Lewis base or a nucleophile, while a local charge depletion is a Lewis acid or an electrophile. A chemical reaction corresponds to the combination of a "lump" in the VSCC of the base with the "hole" in the VSCC of the acid (25). It has been demonstrated in many examples that this matching of extrema in the Laplacian distributions correctly identifies the sites of electrophilic and neucleophilic attack, as well as predicting the relative orientation of approach of the two reactants (25, 33, 34). In an early study of the boranes, using the approximation of partial retention of diatomic differential overlap for the calculation of the wave function, Dixon *et al.* (35) predicted the sites of electrophilic and nucleophilic attack in terms of Mulliken atomic and group charges and the inner shell energy eigenvalues. These same papers compared localized molecular orbitals obtained in these calculations with topologically allowed structures defined by Epstein and Lipscomb (36).

The topology of the Laplacian in the VSCC determines an atom's reactivity and it is summarized in the atomic graph (1, 37). The maxima in $-\nabla^2\rho$ are $(3,-3)$ critical points and they are connected by pairs of lines originating at intervening $(3,-1)$ critical points. These lines are the analogues of the bond paths that link the maxima in ρ and their network produces the atomic graph. For example, in a tetrahedrally bonded carbon atom there are four bonded maxima in the VSCC that are linked by pairs of lines originating at six intervening $(3,-1)$ critical points to generate a tetrahedron with curved faces. In the interior of each face or ring is a $(3,+1)$ or ring critical point. The Laplacian in the VSCC attains its most positive values at these ring critical points and they are the centres of nucleophilic attack. For example, the minimum in the face opposite the bonded maximum with F in the VSCC of carbon in methylfluoride locates the point of nucleophilic attack at a saturated carbon leading to inversion. The nitrogen in ammonia has a similar atomic graph with one bonded maximum being replaced by a nonbonded concentration of charge. Nonbonded charge concentrations generally serve as the nucleophiles. In systems where there are no nonbonded charge concentrations, that is, no unshared pairs of electrons, the $(3,-1)$ critical points serve as the centres of electrophilic attack. They denote the highest concentrations of electronic charge not involved in bonding in the VSCC's of such atoms. This is the situation for a carbon atom in benzene and substituted benzenes (34), for example, and is the situation for the boron and carbon atoms in the boranes and carboranes.

The atomic graphs for boron are unique among those so far encountered because of the extreme degree of charge transfer to both hydrogen and carbon. Bonding to either of these atoms is accompanied by a nearly complete transfer of boron's valence shell of charge concentration and the local maxima in $-\nabla^2\rho$ are found within the boundaries of the hydrogen and carbon atoms. In the case of hydrogen, this corresponds to the presence of the single maximum in $-\nabla^2\rho$, which occurs at the position of the proton. For this reason the $(3,\pm1)$ critical points can occur at distances from the boron nucleus greater than the normal shell radius. The boron atom in diborane will serve to illustrate these features, Fig. 3. The atomic graph of boron is a distorted tetrahedron whose vertices correspond to the maxima in $-\nabla^2\rho$ found at the positions of the protons. The vertices are linked by six intervening $(3,-1)$ critical points and there is one $(3,+1)$ critical point in each of the four faces. The coordinates of the $(3,\pm1)$ critical points, their distances R from the nucleus, and the values of the Laplacian are listed in Table 6. The Laplacian is most negative at the $(3,-1)$ critical point linking the two bridging hydrogens and this is the predicted position of electrophilic attack, Fig. 3. Nucleophilic attack is predicted to occur at either of the two $(3,+1)$ critical points lying on either side of the bonded ring of atoms, that is, in the face of the tetrahedron formed by linking a terminal proton with the two bridging protons.

The atomic graph for boron in BH_3 is particularly simple. The VSCC is reduced to a belt-like distribution lying in the plane of the nuclei, with the maxima at the protons linked by intervening $(3,-1)$ critical points. The sphere of charge concentration is totally absent on either side of this plane and a nucleophile has direct access to the core of the boron atom, as previously illustrated (1). This molecule is a very strong Lewis acid.

In B_4H_{10}, Fig. 3, boron B1 has a bonded charge concentration in its VSCC along the bond path linking it to the other bridgehead boron atom, B2. In a shared interaction, each atom in general exhibits an associated bonded charge concentration, separated one from the other by an intervening

(3,−1) critical point. (One notes that in diborane, where there is no B—B bond path, each boron exhibits a (3,−1) critical point at the corresponding position along the internuclear axis and they are separated by a (3,+1) critical point.) Atom B1 is also linked to one terminal and two bridging hydrogen atoms and their associated maxima, together with the bonded maximum to B2, again yield a tetrahedral atomic graph for B1 and its complement B2. Reference to Table 6 shows that the most negative set of (3,−1) critical points in these graphs and in those for the other two boron atoms are those that link the bonded maximum on boron with the maximum on a bridging hydrogen on either B1 or B2. They are, therefore, the predicted sites of electrophilic attack, Fig. 3. They are accessible from the back of the molecule, that is, away from the open face, access to which is hindered by the two *endo* hydrogens, H11 and H12.

The (3,+1) critical points with the most positive values of the Laplacian are found within the atomic graphs of B1 and B2, in a face formed by the atoms 2, 7, and 10 for B1, for example. There are four such equivalent positions, each lying within the inner or open face of the molecule, and the approach of a nucleophile is hindered by the proximity of the *endo* hydrogens H11 and H12. These two borons also have (3,+1) critical points with $\nabla^2\rho$ values of 0.081 au on the opposite side of the molecule, in the faces formed by the bonded maximum to the other boron, a terminal hydrogen, and a bridging hydrogen: the face formed by the atoms 2, 3, and 7 for atom B1, for example. The (3,+1) critical points on borons B5 and B6 of the BH_2 groups are smaller by only 0.007 au, Table 6. Each lies in one of the four faces formed by one bridging and two terminal hydrogens. These sites are more accessible than those on B1 and B2 and, in addition, the positive charges on B5 and B6 are 0.6 e greater than those on B1 and B2. Thus nucleophilic attack is predicted to occur at these peripheral borons, Fig. 3. This prediction is in agreement with the statement of Muetterties (38) that cleavage of BH by a nucleophile occurs at these atoms.

There is a single bonded maximum situated between the apical boron atom B5 and each of the basal atoms in *nido*-pentaborane; it is 1.2 au from the basal atom and 2.0 au from B5. Each of these maxima is linked by a (3,−1) critical point to the hydrogen bonded to B5. The bonded maxima are themselves linked by another set of (3,−1) critical points, each of which lies in an exterior face formed by the apical and two basal boron atoms, see Fig. 4. Thus the atomic graph for the apical boron is a four-sided pyramid topped by a terminal hydrogen with a (3,+1) critical point in the bottom face formed by the four bonded maxima. There is a (3,+3) cage critical point along the symmetry axis in the interior of the molecule. The (3,−1) critical points that link the bonded maxima, each of which is 1.28 au from the apical boron atom, represent the largest nonbonded concentrations of electronic charge in this molecule and they are the predicted sites of electrophilic attack. The (3,+1) critical points with the most positive values for the Laplacian lie within the interior of the molecule and are inaccessible to nucleophiles. The most positive (3,+1) holes on the exterior of the molecule lie in a face of the tetrahedral atomic graph for a basal boron atom formed by the bonded maximum shared with the apical boron and the maxima associated with a bridging and a terminal hydrogen, Fig. 4. These predictions are in agreement with the statement (3) that electrophilic attack occurs at borons furthest removed from an open face, and nucleophilic attack occurs at borons involved in bridging.

The other *nido* compound studied here, B_6H_{10}, has a corresponding reaction profile in terms of its atomic graphs. In analogy with the atomic graph for the apical boron in B_5H_9, the largest concentrations of nonbonded charge on the exterior of B_6H_{10} are found at the (3,−1) critical points linking the bonded maxima shared by the apical boron with basal borons 1, 4, and 5. They are found 1.27 au from the apical boron where $\nabla^2\rho = -0.13$ au, compared to corresponding values of 1.28 and −0.14 au for pentaborane. Similarly, nucleophilic attack occurs, as in B_5H_9, at a basal boron, B4 or B5, in the face critical point formed by the links to the apical boron and a terminal and bridging hydrogen. The values of R and $\nabla^2\rho$ are 1.54 and +0.073 au compared to corresponding values of 1.61 and +0.076 au for pentaborane. The distributions are so similar for the two *nido* molecules that Fig. 4 serves equally well for either system.

The atomic graphs for the borons in the *closo*-boranes are similar to those found for the apical boron in the *nido*-boranes. In these molecules there are two bonded charge concentrations along each bond path linking the equivalent borons, as found for the B—B bond path in B_4H_{10}. These maxima are linked by (3,−1) critical points, as illustrated for a triangular face of the hexaborate in Fig. 5. The bonded maxima for a given boron are linked to the maximum charge concentration of its terminal hydrogen to yield a four-sided pyramid in the case of the hexaborate and a five-sided one in the dodecahydrate. There is a (3,+1) critical point in each of the corresponding faces and a (3,+3) or cage critical point at the origin in the interior of the cage, a point shared by the bases of all the boron atomic graphs. The forms of the atomic graphs and the values of the Laplacian at corresponding critical points are similar for all three *closo* compounds, and data are given in Table 6 only for the hexahyroborate.

Electrophilic attack, as in the *nido*-boranes, is predicted to occur at a concentration of nonbonded charge at a (3,−1) critical point linking the bonded maxima located on two different, neighbouring paths in the atomic graph for a given boron, Fig. 5. While the value of the Laplacian is more negative at the intervening (3,−1) critical points linking the bonded maxima along a given bond path, these are tightly bound as they are involved with the distribution of charge between the bonded borons. The values of R and $\nabla^2\rho$ for the reactive critical points are very similar for all three of the *closo* molecules. Their values in au for the hexa-, hepta-, and dodecaborate are, respectively, 1.25 and −0.14; 1.25 and −0.13; 1.26 and −0.15.

Nucleophilic attack occurs at one of the (3,+1) critical points, each of which lies in one of the pyramidal faces of the atomic graph for a boron atom, Fig. 5. The values (in au) of R and $\nabla^2\rho$ at these critical points for the six-, seven-, and 12-membered systems are, respectively, 1.42, +0.037; 1.71, +0.052; 1.40, +0.046. The (3,+1) critical point with a more positive value for the Laplacian, given in Table 6 for $B_6H_6^{2-}$, lies within the interior of the cage and is not accessible to a nucleophile.

In the carboranes there is a single bonded maximum along each B—C bond path within the basin of the carbon atom and another associated with its bond to hydrogen. Thus the atomic graph of a carbon in $C_2B_3H_5$ is tetrahedral in form and, in $C_2B_4H_6$, a pentagonal pyramid. The (3,−1) critical points

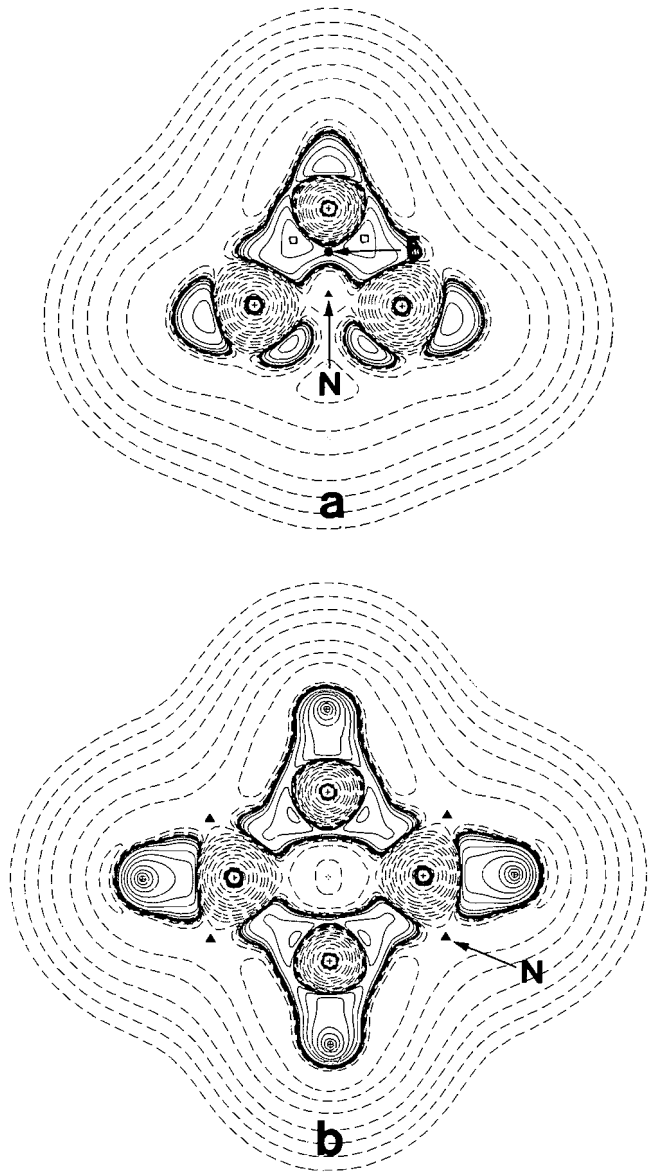

FIG. 6. Contour plots of the Laplacian distributions in a B—C—B face in $C_2B_3H_5$ (*a*) and in a plane containing the two apical carbons and two of the borons in $C_2B_4H_6$ (*b*).

linking the bonded maxima on two neighbouring C—B bond paths represent by far the largest concentrations of charge not involved in bonding and they are the predicted sites of electrophilic attack in both molecules, as illustrated in Fig. 6 for $C_2B_3H_5$. The values of R and $\nabla^2\rho$ for $C_2B_4H_6$ are quite similar, being 0.99 and −0.37 au, respectively, as is its position relative to the nuclei, illustrated in Fig. 6. Nucleophilic attack in $C_2B_3H_5$ is predicted to occur at a (3,+1) critical point close to the centre in a triangular BCB face, 1.92 au from a boron and 2.03 au from carbon, where the Laplacian equals +0.052 au. In $C_2B_4H_6$ there are bond paths between the boron atoms, and their atomic graphs differ from those in the triborane molecule. The (3,+1) critical point with the most positive value of the Laplacian in this system is located in a symmetry plane containing two carbon and two boron nuclei, 1.78 au from a boron where $\nabla^2\rho = +0.061$ au, Fig. 6. This is in agreement with the statement by Onak (39) that conversion of *closo*-dicarbahexaborane to its *nido* form by addition of trimethylamine occurs by nucleophilic attack at boron.

Since the boranes are electron deficient, nucleophilic attack should be more prevalent than electrophilic attack in these molecules. The largest value of $\nabla^2\rho$ for a site of nucleophilic attack in the boranes studied here is +0.09 au for B_2H_6. Ranking these molecules by their $\nabla^2\rho$ values, one finds for susceptibility to nucleophilic attack:

$$B_2H_6 > B_5H_9 > B_4H_{10} > B_6H_{10} > C_2B_4H_6 > B_7H_7^{2-} > C_2B_3H_5 > B_{12}H_{12}^{2-} > B_6H_6^{2-}$$

Similarly, for susceptibility to electrophilic attack:

$$C_2B_3H_5 > C_2B_4H_6 > B_{12}H_{12}^{2-} > B_6H_6^{2-} > B_5H_9 > B_6H_{10} > B_7H_7^{2-} > B_4H_{10} > B_2H_6$$

In summary, the properties of the Laplacian of the charge distributions for the boranes and carboranes lead to the following points regarding their relative reactivities: (1) $B_7H_7^{2-}$ is more susceptible to nucleophilic attack than either of the other two *closo*-boranes. (2) Among the *nido*-boranes, larger species are less reactive with respect to nucleophilic attack, in agreement with observation (3). (3) Electrophilic attack does occur preferentially at apical boron atoms, those furthest removed from an open face, and nucleophilic attack does occur most likely at basal boron atoms that are involved with hydrogen bridging, again in agreement with observation (3). (4) In carboranes, electrophilic attack occurs at carbon, while nucleophilic attack occurs at boron. (5) The *closo* compounds, whether they be boranes or carboranes, are as a group less susceptible to nucleophilic attack than any of the open clusters, and the cage species are the most stable.

Conclusions

The theory of atoms in molecules yields a precise definition of the molecular structures of the boranes and carboranes and a description of the bonded interactions that give rise to these structures in terms of characteristic features of the charge density and the properties of the atoms. The structures demonstrate that the formal electron counting scheme, which associates a bond with a pair of electrons, is not a necessary requirement for the formation of a bond path between a pair of atoms. The lines of maximum charge density, which link the atoms in the electron-deficient three-membered faces and hydrogen-bridged rings, have reduced bond orders compared to the formal electron pair standards. The reduction in bond order is, however, considerably less than that anticipated by taking the ratio of the number of electron pairs to the number of bond paths, a ratio labelled by the letter s. Thus the values of the bond orders n listed in Table 2 are greater than the corresponding s values, as illustrated by the following examples; $s = 0.75$ and $n = 0.98$ for B_5H_9, $s = 0.58$ and $n = 0.91$ for $B_6H_6^{2-}$, $s = 0.43$ and $n = 0.86$ for $B_{12}H_{12}^{2-}$, and $s = 0.58$ and $n = 0.90$ for $C_2B_4H_6$, the latter being the average of the C—B and B—B bond orders. Assigning one pair of electrons to each pair of bridged hydrogen bond paths yields a value of 0.5 for s for the hydrogen-bridged two-electron three-centre bond. Taking the B—H_t value of ρ_b as the unit bond order for a B–H interaction, one obtains n values ranging from 0.62 to 0.65 for the

orders of the bridging hydrogen bond paths. Thus electronic charge is accumulated along the bond paths in the electron-deficient systems to yield bond orders in excess of the fractional orders anticipated on the basis of the model that assigns one electron pair to each chemical bond.

The analysis of the charge density in terms of its critical points and Laplacian distribution has shown that the stabilization of these electron-deficient systems is achieved not only by the accumulation of an excess of electronic charge along the bond paths, but by a concomitant concentration of electronic charge within, and its delocalization over the rings of bonded atoms that result from the formation of the extra interatomic linkages. Thus the atoms linked by bond paths with reduced bond orders are more stable than corresponding atoms in the standard linkages, an example of this being the dramatic increase in the stability of the boron atoms in the electron-deficient $C_2B_4H_6$ compared to those in the electron-precise $C_2B_3H_5$. The stabilization of a ring system through a surface delocalization of charge has been previously discussed and illustrated for three-membered ring systems (14, 40, 41) and in the boranes (14, 42).

Diagrammatic analysis of nonlinear response properties in time-dependent Hartree–Fock theory

HIDEO SEKINO

Quantum Theory Project, University of Florida, Gainesville, FL 32611, U.S.A.

Received August 23, 1991

This paper is dedicated to Professor Sigeru Huzinaga on the occasion of his 65th birthday

HIDEO SEKINO. Can. J. Chem. **70**, 677 (1992).

Nonlinear response properties in Time-Dependent Hartree–Fock (TDHF) theory are analyzed by diagrammatic techniques and compared with the expression in propagator theory. The term that ensures that the quadratic response function is correct through first order in electron correlation emerges in the coupling term between lower order TDHF amplitudes and causes a violation of particle–hole pair conservation. It is shown diagrammatically that the dynamic hyperpolarizabilities can be expressed by lower order solutions in accordance with the $2n + 1$ rule.

Key words: nonlinear response property, TDHF, diagrammatic.

HIDEO SEKINO. Can. J. Chem. **70**, 677 (1992).

Utilisant une technique faisant appel à des diagrammes, on a analysé les propriétés de réponse non-linéaires de la théorie de Hartree–Fock dépendante du temps (TDHF) et on l'a comparé avec l'expression de la théorie du propagateur. Le terme qui assure que la fonction de réponse quadratique est correcte pour le premier ordre de corrélation électronique émerge dans le terme de couplage entre les amplitudes TDHF d'ordre les plus bas et il provoque une violation de la conservation de la paire trou–particule. On montre par un diagramme que les hyperpolarisabilités dynamiques peuvent être exprimées par des solutions de plus bas ordre, en accord avec la règle $2n + 1$.

Mots clés : propriété de réponse non-linéaire, TDHF, diagrammatique.

Introduction

The theoretical investigation of nonlinear optical properties of molecules is one of the most challenging subjects in quantum chemistry. However, because the properties are highly sensitive to the frequency of the applied optical field, theories within a framework of stationary states may not be able to provide meaningful prediction for the experimental situation. High-order Time-Dependent Hartree–Fock (TDHF) theory is one of the methods that provide nonlinear dynamic response properties such as frequency-dependent hyperpolarizabilities. We have formulated the high-order TDHF and implemented it to calculate frequency-dependent hyperpolarizabilities of general molecules in different nonlinear optical processes (1). Recently the method was reformulated using a molecular orbital (MO) based algorithm (2). Performance of the computation employing the new algorithm was dramatically improved and is promising for applications to larger systems. The theories for nonlinear properties have also been formulated by propagator techniques (3, 4) and some applications have been made at the Hartree–Fock level (5, 6). But care must be taken to ensure that the nonlinear response function is correct through first order in electron correlation (3, 5). We present here the nonlinear response properties in a TDHF framework using diagrammatic techniques and make comparison with the expression in propagator theory.

Diagrammatic representation of nonlinear response property

The Time-Dependent Hartree–Fock (TDHF) equation is obtained by projecting Hartree–Fock (HF) differential equations onto a single determinantal wavefunction $|\phi\rangle$ composed of perturbed orbitals.

$$[1] \qquad \left(\hat{f} - \mathrm{i}\frac{\partial}{\partial t}\right)|\phi\rangle = |\phi\rangle\epsilon$$

The space is then spanned by singly excited determinants $|\phi_i\rangle$ with respect to the original determinant composed of original nonperturbed orbitals.

$$[2] \qquad |\phi\rangle = (|\phi_1\rangle, |\phi_2\rangle, \ldots, |\phi_n\rangle)U$$

Here, U is an unitary transformation that back-transforms the perturbed orbitals to the original orbitals and is called the TDHF amplitude. The Lagrangian multiplier ϵ represents the Hartree–Fock manifold of the perturbed system and thus the dimension of the corresponding matrix is equal to the number of the occupied orbitals for all orders. The Fock operator includes the time-dependent perturbation, $\Sigma_j \boldsymbol{E}_j \cdot \boldsymbol{O}_j e^{\pm i\omega t}$, caused by an oscillating external electric field of field strength $|\boldsymbol{E}_j|$ and property under consideration $\boldsymbol{O}_j$. For simplicity, the perturbations considered from now on are assumed to be all of the same kind and the applied electric field is monochromatic with frequency ω. The Fock matrix is expanded in the power series of E.

$$[3] \qquad \mathbf{f}(E) = \mathbf{f}^{(0)} + E\mathbf{f}(\pm\omega)e^{\pm i\omega t} + \frac{E^2}{2}\mathbf{f}(\pm\omega, \pm\omega)e^{\pm i(\omega\pm\omega)t} + \frac{E^3}{6}\mathbf{f}(\pm\omega \pm \omega \pm \omega)e^{\pm i(\omega\pm\omega\pm\omega)t} + \ldots$$

and further decomposed to a pure one-body term $\boldsymbol{O}$ and the Hartree–Fock effective potential

$$[4a] \qquad \mathbf{f}(\pm\omega, \pm\omega, \ldots) = \mathbf{O}\delta_{(n),1} + \mathbf{g}(\pm\omega, \pm\omega, \ldots)$$

where the external perturbation $\mathbf{O}$ appears only in the first order and the effective potential consists of the two-electron integral $\mathbf{v}$ and the density matrix $\mathbf{d}$.

$$[4b] \qquad \mathbf{g}(\pm\omega, \pm\omega, \pm\omega, \ldots) = \mathbf{v}.\mathbf{d}(\pm\omega, \pm\omega, \pm\omega, \ldots)$$

Here, "." means a two-index contraction between the anti-

symmetrized two-electron integral supermatrix $\mathbf{v} = \langle pq\|rs\rangle$ and the density matrix $\mathbf{d}(\pm\omega,\pm\omega,\pm\omega,\ldots)$. The $\boldsymbol{\epsilon}$ matrix,

$$[5]\qquad \boldsymbol{\epsilon}(E) = \boldsymbol{\epsilon}^{(0)} + E\boldsymbol{\epsilon}(\omega)e^{\pm i\omega t} + \frac{E^2}{2}\boldsymbol{\epsilon}(\pm\omega,\pm\omega)e^{\pm i(\omega\pm\omega)t} + \frac{E^3}{6}\boldsymbol{\epsilon}(\omega\pm\omega\pm\omega)e^{\pm i(\omega\pm\omega\pm\omega)t} + \ldots$$

and the amplitudes,

$$[6]\qquad \mathbf{U}(E) = \mathbf{U}^{(0)} + E\mathbf{U}(\pm\omega)e^{\pm i\omega t} + \frac{E^2}{2}\mathbf{U}(\pm\omega,\pm\omega)e^{\pm i(\omega\pm\omega)t} + \frac{E^3}{6}\mathbf{U}(\pm\omega,\pm\omega,\pm\omega)e^{\pm i(\omega\pm\omega\pm\omega)t} + \ldots$$

are also expanded with respect to the field E. In eq. [5], $\boldsymbol{\epsilon}^{(0)}$ is the diagonal canonical zeroth order Hartree–Fock solution and $\mathbf{U}^{(0)} = \mathbf{1}$.

Backprojecting eq. [1] onto the zeroth order Hartree–Fock space, we have

$$[7a]\qquad \mathbf{f}^{(0)}\mathbf{U}^{(0)} = \mathbf{U}^{(0)}\boldsymbol{\epsilon}^{(0)}$$

$$[7b]\qquad \{\pm\omega + \mathbf{f}^{(0)}\}\mathbf{U}(\pm\omega) + \mathbf{f}(\pm\omega)\mathbf{U}^{(0)} = \mathbf{U}(\pm\omega)\boldsymbol{\epsilon}^{(0)} + \mathbf{U}^{(0)}\boldsymbol{\epsilon}(\pm\omega)$$

$$[7c]\qquad \{\pm(\omega\pm\omega) + \mathbf{f}^{(0)}\}\mathbf{U}(\pm\omega,\pm\omega) + \mathbf{f}(\pm\omega,\pm\omega)\mathbf{U}^{(0)} + 2\mathbf{f}(\pm\omega)\mathbf{U}(\pm\omega) = \mathbf{U}(\pm\omega,\pm\omega)\boldsymbol{\epsilon}^{(0)} + 2\mathbf{U}(\pm\omega)\boldsymbol{\epsilon}(\pm\omega) + \mathbf{U}^{(0)}\boldsymbol{\epsilon}(\pm\omega,\pm\omega)$$

$$[7d]\qquad \{\pm(\omega\pm\omega\pm\omega) + \mathbf{f}^{(0)}\}\mathbf{U}(\pm\omega,\pm\omega\pm\omega) + \mathbf{f}(\pm\omega,\pm\omega,\pm\omega)\mathbf{U}^{(0)} + 3\mathbf{f}(\pm\omega,\pm\omega)\mathbf{U}(\pm\omega) + 3\mathbf{f}(\pm\omega)\mathbf{U}(\pm\omega,\pm\omega) = \mathbf{U}(\pm\omega,\pm\omega,\pm\omega)\boldsymbol{\epsilon}^{(0)} + 3\mathbf{U}(\pm\omega,\pm\omega)\boldsymbol{\epsilon}(\pm\omega) + 3\mathbf{U}(\pm\omega)\boldsymbol{\epsilon}(\pm\omega,\pm\omega) + \mathbf{U}^{(0)}\boldsymbol{\epsilon}(\pm\omega,\pm\omega,\pm\omega)$$

All matrices can be divided into several blocks such as occupied-occupied, virtual-occupied, occupied-virtual, and virtual-virtual blocks. The Hartree–Fock condition is thus

$$[8]\qquad \epsilon_{ai}(\pm\omega,\pm\omega,\ldots) = 0$$

for all occupied orbitals, $i,j,\ldots$ and virtual orbitals, $a,b,\ldots$.

From the condition [8] and eq. [7], the TDHF amplitude $\mathbf{U}(\pm\omega,\pm\omega,\pm\omega\ldots)$ is obtained. For example, from $\boldsymbol{\epsilon}_{v-o}(\pm\omega,\pm\omega) = 0$ in eq. [7c], we have the TDHF equation for the virtual-occupied amplitude $\mathbf{U}_{v-o}(\pm\omega,\pm\omega)$,

$$[7c']\qquad \{\pm(\omega\pm\omega) + \mathbf{f}^{(0)}\}\mathbf{U}_{v-o}(\pm\omega,\pm\omega) + \mathbf{f}_{v-o}(\pm\omega,\pm\omega) + 2\mathbf{f}(\pm\omega)\mathbf{U}(\pm\omega) = \mathbf{U}_{v-o}(\pm\omega,\pm\omega)\boldsymbol{\epsilon}^{(0)} + 2\mathbf{U}(\pm\omega)\boldsymbol{\epsilon}(\pm\omega)$$

Here, $\mathbf{f}^{(0)} = \boldsymbol{\epsilon}^{(0)}$ is diagonal. As we will see, a part of $\mathbf{f}_{v-o}(\pm\omega,\pm\omega)$ can be expressed by a two-index contraction of $\mathbf{U}_{v-o}(\pm\omega,\pm\omega)$ and typical RPA-type two-electron integrals. The other terms are simply products of lower order solutions and contribute as constants. Therefore eq. [7c'] is linear in $\mathbf{U}_{v-o}(\pm\omega,\pm\omega)$. The density matrix $\mathbf{d}(\pm\omega,\pm\omega,\pm\omega,\ldots)$

$$[9]\qquad \mathbf{d}(E) = \mathbf{d}^{(0)} + E\mathbf{d}(\pm\omega)e^{\pm i\omega t} + \frac{E^2}{2}\mathbf{d}(\pm\omega,\pm\omega)e^{\pm i(\omega\pm\omega)t} + \frac{E^3}{6}\mathbf{d}(\pm\omega,\pm\omega,\pm\omega)e^{\pm i(\omega\pm\omega\pm\omega)t} + \ldots$$

is then calculated through $\mathbf{d}(E) = \mathbf{U}(E)\mathbf{U}^{\dagger}(E)$. As we have seen in eq. [4], the density matrix is in turn used to create the Fock matrix. Thus the TDHF equation can be solved iteratively. The dynamic nonlinear response properties are given as a contraction of the perturbation property $\boldsymbol{\sigma}$ with the density matrix which comprises the nonlinear perturbation process under consideration. For the Hartree–Fock case, it is given as a contraction between the property corresponding to the perturbation and the one-body density matrix corresponding to the process such as $\mathbf{d}(\pm\omega,\pm\omega)$, $\mathbf{d}(o,\pm\omega)$, $\mathbf{d}(\pm\omega,\pm\omega,\pm\omega)\ldots$ for Second Harmonic Generation (SHG), ElectroOptic Pockels Effect (EOPE), Third Harmonic Generation (THG) ... etc. We now present the TDHF equation and the nonlinear response property diagrammatically. Here, we define the TDHF amplitudes

[D-1] 
which represent $\mathbf{U}_{v-o}(+\omega)$, $\mathbf{U}_{o-o}(+\omega,+\omega)$, $\mathbf{U}_{o-o}(+\omega,+\omega)\ldots$ and the amplitudes

[D-2] 
which represent $\mathbf{U}_{v-o}(-\omega)$, $\mathbf{U}_{o-o}(-\omega,-\omega)$, $\mathbf{U}_{v-o}(-\omega,-\omega)\ldots$. The direction of the arrow with respect to the time progression corresponds to the associated time factors such as $e^{+i(\omega_1+\omega_2+\ldots)t}$ or $e^{-i(\omega_1+\omega_2+\ldots)t}$.

The density matrix of Second Harmonic Generation (SHG) $\mathbf{d}(-2\omega;\,\omega,\omega) = \mathbf{U}(+\omega,+\omega) + \mathbf{U}(+\omega)\mathbf{U}^{\dagger}(-\omega) + \mathbf{U}^{\dagger}(-\omega,-\omega)$, for example, is represented as

[D-3a] 
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

and

[D-3*b*] 
Here we have chosen the occupied-occupied block of $\boldsymbol{U}(\pm\omega,\pm\omega,\ldots)$ to have a symmetric relation $\mathbf{U}_{o-o}(+\omega, +\omega,\ldots) = \mathbf{U}_{o-o}(-\omega,-\omega,\ldots)$. This, together with the orthogonality condition, ensures

[D-4] 
for the first-order amplitude. The occupied-occupied block of the second-order amplitude is determined through the second-order orthogonality condition $\mathbf{U}^{\dagger}_{o-o}(-\omega,-\omega) + \mathbf{U}^{\dagger}(-\omega)\mathbf{U}(+\omega) + \mathbf{U}_{o-o}(+\omega,+\omega) = \mathbf{0}$

[D-5] 
Now we define the Fock matrices diagrammatically. For zeroth order $\mathbf{f}^{(0)} = \mathbf{h}^{(0)} + \mathbf{g}^{(0)}$

[D-6] 
where ---× represents the one-electron part $\mathbf{h}^{(0)}$ and ---○ represents the effective HF potential caused by the two-electron part $\mathbf{g}^{(0)}$. For the first order $\mathbf{f}(\pm\omega) = \mathbf{O} + \mathbf{g}(\pm\omega)$

[D-7*a*]

and

[D-7*b*]

where

[D-8*a*] 
and

[D-8*b*]

The Fock matrices have a one-electron part ---△ and the effective HF potentials ---⊕ and ---⊖ are perturbed once before and once after the interaction ---- by the TDHF amplitudes → and ←. For the second order, the bare one-electron part **O** does not contribute to the Fock matrix and $\mathbf{f}(\pm\omega,\pm\omega) = \mathbf{g}(\pm\omega,\pm\omega)$ for the SHG case. The effective potential $\mathbf{g}(\pm\omega,\pm\omega)$ is now represented as

[D-9*a*] 
and

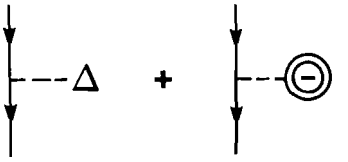
[D-9*b*] 
Similarly the occupied-occupied blocks of $\boldsymbol{\epsilon}$ are represented as follows. For $\boldsymbol{\epsilon}^{(0)}$, we have the diagrammatic representation

[D-10] 
and the incoming and outgoing lines have same indices because the matrix is diagonal for the canonical zeroth order HF orbitals. Since $\boldsymbol{\epsilon}(\pm\omega) = \mathbf{f}(\pm\omega)$ for the same block, $\boldsymbol{\epsilon}(\pm\omega)$ is represented as

[D-11*a*] 
and

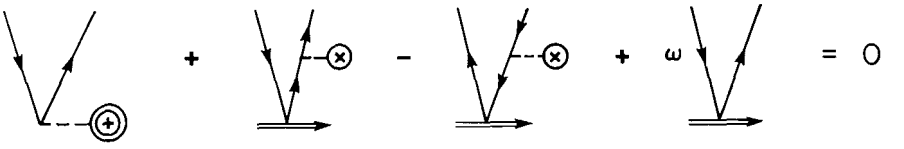
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

[D-11*b*]



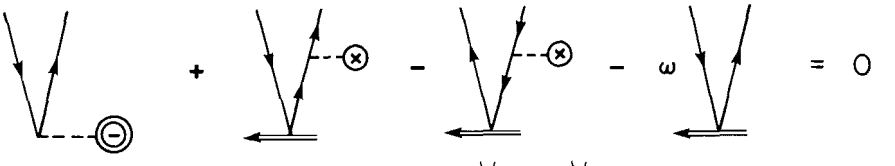
From the condition that the virtual-occupied block of $\epsilon(\pm\omega)$ in eq. [7*b*] must be zero, we obtain the linearized (first-order) TDHF equations for $U(\pm\omega) = \mathbf{U}_{v-o}(\pm\omega)$. This is represented diagrammatically as

[D-12*a*]



and

[D-12*b*]

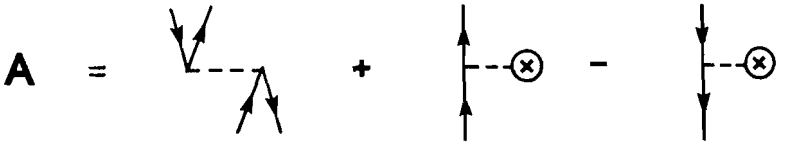


Using eqs. [D-8*a*] and [D-8*b*], we can replace the Fock matrices and by the TDHF amplitudes and and we arrive at the coupled equations for $U(\pm\omega)$.

$$[10] \quad \begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B} & \mathbf{A} \end{bmatrix} \begin{bmatrix} U(+\omega) \\ U(-\omega) \end{bmatrix} \pm \omega \begin{bmatrix} U(+\omega) \\ U(-\omega) \end{bmatrix} + \begin{bmatrix} O \\ O \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix}$$

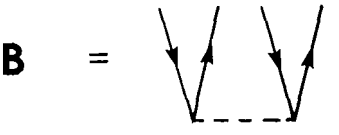
Here, **A** and **B** are ordinary Random Phase Approximation (RPA) matrices.

[D-13*a*]



and

[D-13*b*]



We can formally solve the equations

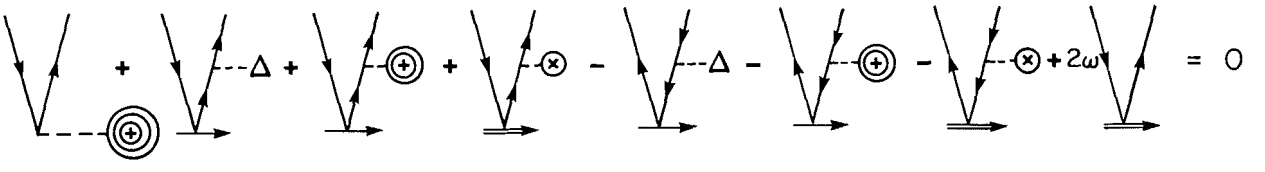
$$[11] \quad \begin{bmatrix} U(+\omega) \\ U(-\omega) \end{bmatrix} = -\mathbf{P}^{-1}(\omega) \begin{bmatrix} O \\ O \end{bmatrix}$$

where

$$[12] \quad \mathbf{P}(\omega) = \begin{bmatrix} \omega\mathbf{I} + \mathbf{A} & \mathbf{B} \\ \mathbf{B} & -\omega\mathbf{I} + \mathbf{A} \end{bmatrix}$$

From the condition that the virtual-occupied block of $\epsilon(\pm\omega \pm \omega)$ is zero in eq. [7*c*], the second-order TDHF equations are obtained.

[D-14*a*]



and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

[D-14*b*] 
Using eqs. [D-9*a*] and [D-9*b*], we again replace the Fock matrices by the TDHF amplitudes and arrive at the final equations for the amplitudes $U(\pm\omega,\pm\omega) = \mathbf{U}_{v-o}(\pm\omega,\pm\omega)$

$$[13] \quad \begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{B} & \mathbf{A} \end{bmatrix} \begin{bmatrix} U(+\omega, +\omega) \\ U(-\omega, -\omega) \end{bmatrix} \pm 2\omega \begin{bmatrix} U(+\omega, +\omega) \\ U(-\omega, -\omega) \end{bmatrix} + \begin{bmatrix} h(+\omega, +\omega) \\ h(-\omega, -\omega) \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix}$$

where $\mathbf{h}(\pm\omega,\pm\omega)$ are constant terms composed of lower order terms and represented diagrammatically as:

[D-15*a*] 
and

[D-15*b*] 
Therefore we can solve the TDHF equations for the second-order amplitudes $\mathbf{U}(\pm\omega,\pm\omega)$ in the same way as in the first-order solutions.

$$[14] \quad \begin{bmatrix} U(+\omega, +\omega) \\ U(-\omega, -\omega) \end{bmatrix} = -\mathbf{P}^{-1}(2\omega) \begin{bmatrix} h(+\omega, +\omega) \\ h(-\omega, -\omega) \end{bmatrix}$$

The **P** matrix has exactly the same form as in eq. [12] except that the frequency is now replaced by 2ω. The form of the **P** matrix is always the same for any order of TDHF equation. Therefore only a single diagonalization of the RPA matrix is sufficient to obtain all order solutions. The third-order response property of SHG is provided by contraction between the perturbation **O** and the density matrix $\mathbf{d}(+\omega,+\omega)$.

[D-16] 
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

Inserting the solutions $U(+\omega,+\omega)$ and $U(-\omega,-\omega)$ from eq. [14] for and , and introducing new amplitudes $U(+2\omega)$ = and $U(-2\omega)$ = that satisfy

[15] $$\mathbf{P}(2\omega)\begin{bmatrix} U(2\omega) \\ U(-2\omega) \end{bmatrix} + \begin{bmatrix} O \\ O \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

and diagrammatically

[D-17] 
it becomes

[D-18] 
Therefore, the property is expressed by only first-order solutions. Using eqs. [D-15*a*] and [D-15*b*], we finally have

[D-19] 
As we have seen above, the nonlinear property $\beta(-2\omega;\omega,\omega)$ can be calculated either from the first- and the second-order amplitudes $U(\pm\omega)$ and $U(\pm\omega,\pm\omega)$ or only from the first-order amplitudes $U(\pm\omega)$ and $U(\pm2\omega)$. The higher order properties such as γ can be expressed by the lower order amplitudes in a similar manner. This is of course a consequence of the $2n + 1$ or $2n$ rule (7).

Comparison with the expression in the propagator method

We now introduce a set of excitation and deexcitation operators $\{Q_J^\dagger, Q_J\}$ defined by

$$[16] \quad Q_J^\dagger = \sum_{a,i} (a^\dagger i Z_{ai}^J + i^\dagger a Y_{ai}^J), \qquad J = \pm 1, 2, \ldots, N(M-N)$$

Here M is the size of the basis set and N is the number of the occupied orbitals and $\{Z_{ai}^J, Y_{ai}^J\}$ is an RPA solution.

$$[17] \quad \begin{bmatrix} \mathbf{A} & \mathbf{B} \\ -\mathbf{B} & -\mathbf{A} \end{bmatrix} \begin{bmatrix} \mathbf{Z}^J \\ \mathbf{Y}^J \end{bmatrix} = -\mathrm{sgn}(J)\omega_J \begin{bmatrix} \mathbf{Z}^J \\ \mathbf{Y}^J \end{bmatrix}$$

The amplitudes $U(\pm\omega,\pm\omega,\pm\omega) = \mathbf{U}_{v-o}(\pm\omega,\pm\omega,\ldots)$ and the constant terms $h(\pm\omega,\pm\omega,\pm\omega\ldots) = \mathbf{h}_{v-o}(\pm\omega,\pm\omega,\ldots)$ may be transformed onto the new basis $\{Q_J^\dagger, Q_J\}$,

$$[18a] \quad \Lambda(\omega, \omega, \ldots) \equiv \begin{bmatrix} \tilde{U}(+\omega, +\omega,\ldots) \\ \tilde{U}(-\omega, -\omega,\ldots) \end{bmatrix} = [\mathbf{Z}^\dagger \; \mathbf{Y}^\dagger] \begin{bmatrix} -U(+\omega, +\omega,\ldots) \\ U(-\omega, -\omega,\ldots) \end{bmatrix}$$

and

$$[18b] \quad \begin{bmatrix} \tilde{h}(+\omega, +\omega, \ldots) \\ \tilde{h}(-\omega, -\omega, \ldots) \end{bmatrix} = [\mathbf{Z}^\dagger \; \mathbf{Y}^\dagger] \begin{bmatrix} h(+\omega, +\omega, \ldots) \\ h(-\omega, -\omega, \ldots) \end{bmatrix}$$

The first-order equations, eq. [10], become

$$[19] \quad (\mathbf{D} - \omega\mathbf{I}) \begin{bmatrix} \tilde{U}(+\omega) \\ \tilde{U}(-\omega) \end{bmatrix} + \begin{bmatrix} \tilde{h}(+\omega) \\ \tilde{h}(-\omega) \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix}$$

Here the **J**th element of the vector $h(\pm\omega)$ is

$$[20] \quad \tilde{h}(\pm\omega) = -\mathrm{sgn}(J)\langle[\kappa_{-J}, O]\rangle$$

and

$$[21a] \quad \kappa_J = Q_J^\dagger$$

for $J > 0$

$$[21b] \quad \kappa_J = Q_{|J|}$$

for $J < 0$. **D** is a diagonal matrix that contains RPA energies $\{\omega_J\}$ as its diagonal elements. Thus the first-order amplitudes are easily solved as

$$[22] \quad \tilde{U}^J(\pm\omega) = -\frac{\tilde{h}^J(\pm\omega)}{\omega - \mathrm{sgn}(J)\omega_J}$$

The second-order equations, eq. [13], become

$$[23] \quad (\mathbf{D} - 2\omega\mathbf{I}) \begin{bmatrix} \tilde{U}(+\omega, +\omega) \\ \tilde{U}(-\omega, -\omega) \end{bmatrix} + \begin{bmatrix} \tilde{h}(+\omega, +\omega) \\ \tilde{h}(-\omega, -\omega) \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix}$$

Here,

$$[24] \quad \tilde{h}(\pm\omega, \pm\omega) = -\mathrm{sgn}(J)\langle[[\kappa_{-J}, O], \Lambda(\omega)]\rangle - \frac{1}{2}\mathrm{sgn}(J)\langle[[[\kappa_{-J}, H^{(0)}], \Lambda(\omega)], \Lambda(\omega)]\rangle$$

and $H^{(0)}$ is a non-perturbed Hamiltonian. The second-order amplitudes are thus

$$[25] \quad \tilde{U}^J(\pm\omega,\pm\omega) = -\frac{\tilde{h}^J(\pm\omega,\pm\omega)}{2\omega - \mathrm{sgn(J)}\omega_J}$$

It is easy to see that the new first-order amplitudes $U(\pm 2\omega)$ introduced in eq. [15] are also expressed on the new basis as

$$[26] \quad \tilde{U}^J(\pm 2\omega) = -\frac{\tilde{h}^J(\pm\omega)}{2\omega - \mathrm{sgn(J)}\omega_J}$$

The terms 3, 6, 11, and 14 in eq. [D-19] are obtained by a contraction of the first-order solutions $U(\pm\omega)$ and $U(\pm 2\omega)$ with the property O, which is represented on the new basis $\{Q^{\dagger}_J, Q_J\}$ as

$$[27] \quad \tilde{O} = \langle [[\kappa_{-J}, O], \kappa_N] \rangle$$

and correspond to

$$[28] \quad \sum_{J,N} \frac{\mathrm{sgn}(JN)\langle O, \kappa_J]\rangle\langle [[\kappa_{-J}, O], \kappa_N]\rangle\langle [\kappa_{-N}, O]\rangle}{(2\omega - \mathrm{sgn}(J)\omega_J)(\omega - \mathrm{sgn}(N)\omega_N)}$$

The terms 17 and 18 correspond to

$$[29] \quad -\sum_{JJ'} \frac{\mathrm{sgn}(JJ')\langle (\kappa_J, O, \kappa_{J'})\rangle\langle [\kappa_{-J}, O]\rangle\langle [\kappa_{-J'}, O]\rangle}{(\omega - \mathrm{sgn}(J)\omega_J)(\omega - \mathrm{sgn}(J')\omega_{J'})}$$

and all the rest of the terms arise from a contraction among two first-order amplitudes $U(\pm\omega)$ and another first-order amplitude $U(\pm 2\omega)$ with unperturbed Hamiltonian $H^{(0)}$, which is represented on the new basis as

$$[30] \quad \tilde{H}^{(0)} = \langle (\kappa_N, [\kappa_{-J}, H^{(0)}], \kappa_M) \rangle$$

and correspond to

$$[31] \quad -\sum_{J,N,M} \frac{\mathrm{sgn}(JNM)\langle [O, \kappa_J]\rangle\langle (\kappa_N, [\kappa_{-J}, H^{(0)}], \kappa_M)\rangle\langle [\kappa_{-N}, O]\rangle\langle [\kappa_{-M}, O]\rangle}{(2\omega - \mathrm{sgn}(J)\omega_J)(\omega - \mathrm{sgn}(N)\omega_N)(\omega - \mathrm{sgn}(M)\omega_M)}$$

Since three amplitudes, two $U(\pm\omega)$ and one $U(\pm 2\omega)$, must contract to $H^{(0)}$, $H^{(0)}$ has a super matrix form such as in eq. [30].

Discussion

Higher order TDHF equations and nonlinear response properties are presented by diagrammatic techniques. As seen above, the third-order property that was originally derived using second-order TDHF amplitudes can be expressed with only first-order terms. This is a consequence of the $2n + 1$ rule (7) for dynamic properties. Klingbeil *et al.* proved this for fourth-order properties (8). Karna and Dupuis have shown it for both third- and fourth-order properties (9). Sekino and Bartlett (2) and Karma *et al.* (10) used the algorithm for calculating dynamic first and second hyperpolarizabilities β and γ. Rice *et al.* (11) and Parkinson and Oddershede (6) employed an equivalent principle for computing the first hyperpolarizability.

To express the Hartree–Fock density matrix in the space spanned by M basis functions, we need an operator manifold of dimension M^2, but only $N(M - N)$ complex variables are necessary to determine the Hartree–Fock energy of each order. Thus we need to solve $2N(M - N)$ real TDHF equations for $U(\pm\omega, \pm\omega, \ldots)$. Using the transformed basis $\{Q^{\dagger}_J, Q_J\}$, we can conveniently decouple the TDHF equations to $\tilde{U}(\pm\omega, \pm\omega, \ldots)$ and we arrive at the sum-over state representation of the nonlinear response function. This formulation is conceptually more appealing and the same formalism provides other related properties such as two-photon transition moments and transition probabilities between excited states (5, 6). However, it has computational disadvantages for calculating hyperpolarizabilities. An expression in supermatrix form, such as $\langle (\kappa_N, [\kappa_J, H^{(0)}], \kappa_M) \rangle$, is not useful in real computation where the size of operator space is not small. In our formalism, which involves Fock matrix formation, all contributions are expressed essentially by one-body terms and no supermatrix appears explicitly. The space required for mapping (ordered two-electron integrals) from density matrix to Fock matrix is $2M^2$. The typical integral lists of this kind are the P and K lists (15), which are commonly used for F matrix formation in AO basis. In contrast with the AO based methods (1, 9), the MO based algorithm presented here can divide the problem into subblocks: the occupied-occupied, virtual-occupied, etc. Only the mapping corresponding to the virtual-occupied block of the density matrix to the virtual-occupied block of the Fock matrix is required to obtain the TDHF amplitude through eqs. [10] and [13]. The mapping involving the virtual-virtual block of the density matrix to the virtual-occupied block of the Fock matrix is required for computation of third-order properties, while mapping that involves the virtual-virtual block of the density matrix to the virtual-virtual block of the Fock matrix is necessary for properties of more than fourth order. However, these mappings are required only for formation of the constant terms $h(\pm\omega, \pm\omega)$ etc., that is, required only once. The size of the space for mapping to solve eq. [10] or eq. [13] is only $2N(M - N)$ and can still be handled in the core memory of computers, even in cases with over 100 basis sets. Although those equations can be solved in a noniterative manner, we chose an iterative solution for the problem since the latter is much more efficient for nontrivial systems (2). Further, we implemented a reduced linear equation scheme (12–14) to accelerate the convergency for solving the equations. Performance of the vectorized program for dynamic hyperpolarizabilities β and γ was dramatic (2), and is promising for applications to larger systems.

It is known that the term shown in eq. [31] is necessary for the response function to be correct through first order in electron correlation (3, 5). In the first-order TDHF equation, the constant contribution is nothing but the external perturbation **O**. The second-order energy expression in Coupled Perturbed Hartree Fock (CPHF) is characterized by particle–hole bubbles. All the particle–hole pairs created at one time disappear together at another time (16). This so-called particle–hole pair conservation is no longer true in the higher order energy diagram as in eq. [D-19]. From the diagrammatic expression [D-14, 15], it is evident that the terms that violate the particle–hole pair conservation come from the coupling between two first-order terms $U(\pm\omega)$ in the second-order constant contribution $h(\pm\omega, \pm\omega)$ and those are

For personal use only.

the terms that correspond to eq. [31]. Since it is a constant contribution, the violation happens only once for third-order properties. In general, nth order nonlinear response properties have terms that violate the particle–hole pair conservation $n - 2$ times. It should be noted, however, that TDHF theory is still one-body theory. There is no possibility to create real double excitation clusters that have no constraint in connecting among each other through two-electron interactions.

The time-dependent Lippmann–Schwinger equation describing atom–diatom collisions is expressed in terms of a general reference Hamiltonian, H_r, whose dynamics are easily solved in one representation, and a corresponding disturbance Hamiltonian, H_d, whose dynamics are easily solved in a different representation. The wavefunction at time $t + \tau$ is then expressed in terms of its value at a previous time t by means of a simple quadrature approximation. The resulting expression for $\psi(t + \tau)$ has a form similar to that occurring in earlier numerical unitary solutions to the time-dependent Schrodinger equation via a Cayley transformation. The structure of the new equations is made explicit for (a) the choice where H_r is taken to be the kinetic energy and H_d is the potential energy and (b) the choice where H_r is taken to be the potential energy and H_d is the kinetic energy. In addition, we also deal with several alternatives for treating the binding potential of the diatom. Several alternatives for choosing representations are then explored for reducing the equations to a form amenable to computation. The short time structure of the equations is discussed in terms of a multiple time-scales analysis.

Key words: molecular collisions, multiple time scales, quantum dynamics.

OMAR A. SHARAFEDDIN, DONALD J. KOURI et DAVID K. HOFFMAN. Can. J. Chem. **70**, 686 (1992).

L'équation de Lippmann–Schwinger qui est reliée au temps et qui décrit les collisions atome–diatome peut être exprimée en termes d'un Hamiltonien de référence générale, H_r, dont les dynamiques peuvent facilement être résolues par une représentation et un Hamiltonien correspondant de perturbation, H_d, dont les dynamiques peuvent facilement être résolues par une autre représentation. On peut alors exprimer la fonction d'onde au temps $t + \tau$ en termes de sa valeur à un temps antérieur t par le biais d'une approximation quadratique simple. L'expression qui en résulte pour $\psi(t + \tau)$ a une forme semblable à celle que l'on retrouve dans des solutions numériques unitaires antérieures de l'équation de Schroedinger reliée au temps qui sont obtenues par le biais d'une transformation de Cayley. On rend la structure des nouvelles équations explicite en faisant le choix que (a) H_r est l'énergie cinétique et H_d est l'énergie potentiel et (b) H_r est l'énergie potentiel et H_d est l'énergie cinétique. De plus, on tient compte des divers cas possibles pour le traitement du potentiel de liaison du diatome. On explore alors plusieurs options pour le choix des représentations permettant de réduire les équations à une forme que l'on peut traiter par un ordinateur. On discute de la structure de faible temps en fonction d'une analyse d'échelles multiples du temps.

Mots clés : collisions moléculaire, échelles multiples du temps, dynamiques quantique.

[Traduit par la rédaction]

1. Introduction

Recently, time-dependent wavepacket methods have proved to be very useful in treating molecular collisions (1–57).[4] In a series of papers (47 (paper 1), 49, 50), we initiated a systematic study of the time-dependent version of the Lippmann–Schwinger equation for scattering. Our objective is to develop an assortment of efficient methods for treating molecular collisions. The philosophy pursued is to split the Hamiltonian in an exact fashion into a reference piece, H_r, whose dynamics is simple in a certain representation, and a concomitant disturbance, H_d, whose dynamics is also simple in some *different* representation. Then the formal solution to the time-dependent Schrodinger equation is expressed in terms of the wavepacket at an earlier time evolved forward to the current time by an easily calculated evolution operator for the reference dynamics, plus an integral (over time) term that combines the H_r and H_d dynamics in a sequential fashion. The reference dynamics enters in terms of the (infinite order) evolution operator for the reference dynamics, while H_d enters in a linear fashion. There are numerous options available for dealing with the integral term in order to obtain suitable equations for computations. In our earlier work, we explored methods based on the wavefunction and the time-dependent amplitude density (47, 49), and on two different choices for H_r and H_d: the standard one where H_r is the kinetic energy and H_d the potential (49, 50), and a new one where H_r is the potential and H_d is the kinetic energy (49). In ref. 50, we also derived a new computational approach using the standard splitting of the Hamiltonian H into H_r and H_d, and expressing the current

time wavepacket in terms of a modified Cayley transform acting on the earlier time wavepacket. This procedure was applied successfully to a potential modelling elastic electron–atom scattering.

In this paper, we extend the modified Cayley transform equations to the case of atom–diatom scattering, including both rotational and vibrational degrees of freedom. We present the basic equations for an arbitrary choice of H_r and H_d, and then apply them to four specialized cases: (1) H_r is the complete relative kinetic energy and H_d is the complete potential energy; (2) H_r is the complete relative kinetic energy *plus* the diatom binding potential energy, and H_d is the remaining potential energy; (3) H_r is the complete potential energy and H_d is the complete relative kinetic energy; and (4) H_r is the potential energy minus the diatom binding potential energy, and H_d is the complete relative kinetic energy plus the diatom binding potential energy. We explore several possible ways to implement these equations, and study particularly the roles of representations used and the particle masses and range of interactions in the choice of computational method. Of special interest is the possibility of time-scale separations as a means of simplifying the equations. It is also noted that our techniques apply equally well to the symmetric split operator approach (11*a*).[5]

The paper is organized as follows. In Sect. 2 we present the derivation of the modified Cayley method for an atom–diatom system and a general choice of H_r and H_d. Then in Sects. 3 and 4, we apply the choices of H_r and H_d to specialized cases (1) and (2), and cases (3) and (4), respectively, and discuss the choice of representations and the role of time scales for various motions. Finally, in Sect. 5, we indicate some directions for future work.

2. General referenced modified Cayley method

We desire to solve the time-dependent Schrodinger equation

$$[1] \qquad i\hbar \frac{\partial|\psi(t)\rangle}{\partial t} = H|\psi(t)\rangle$$

where the Hamiltonian H may be expressed as

$$[2] \qquad H = H_r + H_d$$

Here, H_r denotes the so-called reference Hamiltonian, and H_d is a disturbance Hamiltonian. In general, H_r and H_d do not commute, so that no representation exists in which both are diagonal. However, in general, some representation will exist in which H_r is diagonal, and some *different* representation will exist in which H_d is diagonal. The solution to eq. [1] may be expressed as

$$[3] \qquad |\psi(t)\rangle = \frac{-i}{\hbar}\int_{t-\tau}^{t} dt' e^{-iH_r(t-t')/\hbar} H_d|\psi(t')\rangle + e^{-iH_r\tau/\hbar}|\psi(t-\tau)\rangle$$

We note that eq. [3] is *exact,* and represents a means of splitting H into H_r and H_d so that each can be evaluated in its eigen-representation. (This is reminiscent of the split operator approach to time-dependent quantum dynamics. *However, in eq. [3] the splitting enters without approximation.* Of course, eventually, some approximations will be introduced in order to carry out calculations to a desired level of accuracy. There are *many* ways to approximate eq. [3] so that considerable flexibility is gained, and the approximate computational expressions will be chosen such that as $\tau \to 0$, the result becomes arbitrarily accurate.)

To obtain the modified Cayley form, we approximate the integral over t' in eq. [3] by the simple trapezoidal rule. This yields

$$[4] \qquad |\psi(t)\rangle = \frac{-i\tau}{2\hbar}\left[H_d|\psi(t)\rangle + e^{-iH_r\tau/\hbar}H_d|\psi(t-\tau)\rangle\right] + e^{-iH_r\tau/\hbar}|\psi(t-\tau)\rangle$$

Rearranging and solving for $|\psi(t)\rangle$ then leads to

$$[5] \qquad |\psi(t)\rangle = \left[1 + \frac{i\tau}{2\hbar}H_d\right]^{-1} e^{-iH_r\tau/\hbar}\left[1 - \frac{i\tau}{2\hbar}H_d\right] \times |\psi(t-\tau)\rangle$$

This is the modified Cayley form referenced to H_r. By way of reminder, the usual Cayley transform (or Crank–Nicholson (58) method leads to the expression (8)

$$[6] \qquad |\psi(t)\rangle = \left[1 + \frac{i\tau}{2\hbar}H\right]^{-1}\left[1 - \frac{i\tau}{2\hbar}H\right]|\psi(t-\tau)\rangle$$

Thus, it requires inverting an operator containing the full Hamiltonian, or more efficiently, solving the set of equations (8, 58)

$$[7] \qquad \left[1 + \frac{i\tau}{2\hbar}H\right]|\psi(t)\rangle = \left[1 - \frac{i\tau}{2\hbar}H\right]|\psi(t-\tau)\rangle$$

We have previously pointed out (50) that the form eq. [5] can be viewed also as being related to the symmetric split operator (11) approach, since for small enough τ,

$$[8] \qquad \left[1 + \frac{i\tau}{2\hbar}H_d\right]^{-1} \cong 1/\exp(i\tau H_d/2\hbar)$$

$$[9] \qquad = \exp(-i\tau H_d/2\hbar)$$

and

$$[10] \qquad \left[1 - \frac{i\tau}{2\hbar}H_d\right] \cong \exp(-i\tau H_d/2\hbar)$$

which leads to

$$[11] \qquad |\psi(t)\rangle = e^{-iH_d\tau/2\hbar}\, e^{-iH_r\tau/\hbar}\, e^{-iH_d\tau/2\hbar}|\psi(t-\tau)\rangle$$

However, even though the symmetric split operator expression contains $(H_d\tau/2\hbar)$ to infinite order, it is *not* necessarily more accurate than eq. [5]. In fact, as τ becomes larger, having $(H_d\tau/2\hbar)$ to infinite order, but not with the correct coefficients of the various commutators, may lead to worse results. The accuracy of eq. [5] is controlled by the degree to which the trapezoidal rule accurately yields the time integral in eq. [3] above, while the accuracy of eq. [11] depends on the size of the commutator, $[H_r,H_d]$. In fact, calculations comparing the two show that for the systems studied, the kinetic referenced modified Cayley is more robust. We shall focus on the modified Cayley version, eq. [5], in this paper, but the same analyses can be made using the symmetric split operator equations. In eq. [5], one may carry

[5]See also the symmetric split operator approach of DeVries (11*b*).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

out the usual procedure of evaluating $[1 + i\tau/2\hbar H_d]^{-1}$, $e^{-iH_r\tau/\hbar}$, and $[1 - i\tau/2\hbar H_d]$ in their respective diagonalizing representations, followed by appropriate transformations between these two representations. There are, however, other interesting options that we shall explore in this paper.

Finally, we note from the structure of eq. [5] that, in some sense, a "natural" representation in which to calculate $|\psi(t)\rangle$ is determined by H_d, since the left-most operator in eq. [5] is diagonal in this representation, and the first operator acting on $|\psi(t-\tau)\rangle$ is $[1 - i\tau/2\hbar H_d]$. The basic procedure then would require transforming $[1 - i\tau/2\hbar H_d]|\psi(t-\tau)\rangle$ from the H_d to the H_r representation, followed by application of $e^{-iH_r\tau/\hbar}$ in the H_r representation. Then one would transform back to the H_d representation for application of $[1 + i\tau/2\hbar H_d]^{-1}$, yielding $|\psi(t)\rangle$ in the H_d representation. Alternatively, one can evaluate $\exp(-iH_r\tau/k)$ in the H_d representation, or $[1 - i\rho/2\hbar H_d]$ and $[1 + i\tau/2\hbar H_d]^{-1}$ in the H_r representation, so that the entire calculation could be done without changing representations (62–64). Since these operators depend only on the time step size (65), rather than on the time itself, they may be evaluated once and stored, thereby saving computational effort if a number of wave-packet propagations are to be done.

3. Kinetic energy referenced modified Cayley method

In this case, we choose H_r to be the total relative kinetic energy operator for the atom–diatom collision system, and H_d is then the full potential energy for the system. The basic equation (eq. [5]) then becomes

$$[12]\quad |\psi^{JM}(n_0 j_0 l_0|t)\rangle = \left[1 + \frac{i\tau}{2\hbar}V\right]^{-1} e^{-i(K_R+K_r)\tau/\hbar} \times \left[1 - \frac{i\tau}{2\hbar}V\right]|\psi^{JM}(n_0 j_0 l_0|t-\tau)\rangle$$

where we choose to work initially in the coupled angular momentum (65) or Arthurs–Dalgarno representation (developed in ref. 59). Then J is the total angular momentum quantum number, $M\hbar$ is the space fixed z-component of total angular momentum, n_0, j_0, and l_0 are the initial vibrational, diatom rotational angular momentum, and orbital angular momentum quantum numbers, $\boldsymbol{R}$ is the vector from the diatom center of mass to the atom, $\boldsymbol{r}$ is the diatom internuclear vector, the symbol K represents a kinetic energy operator for motion in the coordinate occurring as a subscript, and V denotes the complete potential energy operator. It is clear from eq. [12] that a convenient representation for $|\psi^{JM}(n_0 j_0 l_0)|t)\rangle$ will be the coordinate representation, since the potential energy V is diagonal in this representation. It is also, however, convenient to employ the conservation of total angular momentum. We project eq. [12] from the left with $\langle \boldsymbol{R}\boldsymbol{r}|$, and insert resolutions of the identity

$$[13]\quad 1 = \int d\boldsymbol{R}' \int d\boldsymbol{r}' |\boldsymbol{R}'\boldsymbol{r}'\rangle\langle \boldsymbol{R}'\boldsymbol{r}'|$$

and

$$[14]\quad 1 = \frac{4}{\pi^2}\sum_{jlJ'M'}\int_0^\infty dK K^2 \int_0^\infty dk k^2 |Kl\rangle|kj\rangle|\mathcal{Y}_{jl}^{J'M'}\rangle \times \langle \mathcal{Y}_{jl}^{J'M'}|\langle kj|\langle Kl|$$

where

$$[15]\quad \langle \boldsymbol{R}'\boldsymbol{r}'|\boldsymbol{R}\boldsymbol{r}\rangle = \delta(\boldsymbol{R}-\boldsymbol{R}')\delta(\boldsymbol{r}-\boldsymbol{r}')$$

$$[16]\quad \langle R|Kl\rangle = j_l(KR)$$

$$[17]\quad \langle r|kj\rangle = j_j(kr)$$

$$[18]\quad \langle \theta\varphi\chi\xi|\mathcal{Y}_{jl}^{J'M'}\rangle = \sum_{m_j}\langle lM' - m_j jm_j|J'M'\rangle \times Y_{lM'-m_j}(\theta\psi)Y_{jm_j}(\chi\psi)$$

χ, ξ and θ, φ are the polar and azimuthal angles of $\boldsymbol{r}$ and $\boldsymbol{R}$, $j_j(kr)$ and $j_l(KR)$ are the usual spherical Bessel functions, and $\langle lM' - m_j jm_j|J'M'\rangle$ is a Clebsch–Gordan coefficient (60). This yields

$$[19]\quad \psi^{JM}(\boldsymbol{R}\boldsymbol{r}|n_0 j_0 l_0|t) = \left[1 + \frac{i\tau}{2\hbar}V(r R\hat{r}\cdot\hat{R})\right]^{-1} \times \frac{4}{\pi^2}\sum_{jlJ'M'}\int_0^\infty dK K^2 \int_0^\infty dk k^2\, e^{-i(K^2/\mu + k^2/m)\hbar\tau/2} j_l(KR) j_j(kr) \times \mathcal{Y}_{jl}^{J'M'}(\hat{R}\hat{r}) \int d\boldsymbol{R}' \int d\boldsymbol{r}' j_l(KR') j_j(kr') \mathcal{Y}_{jl}^{J'M'*}(\hat{R}'\hat{r}') \times \left[1 - \frac{i\tau}{2\hbar}V(r'R'\hat{r}'\cdot\hat{R}')\right]\psi^{JM}(\boldsymbol{R}'\boldsymbol{r}'|n_0 j_0 l_0|t-\tau)$$

To further simplify, we take advantage of conservation of total angular momentum, and write (for any time t),

$$[20]\quad \psi^{JM}(\boldsymbol{R}\boldsymbol{r}|n_0 j_0 l_0|t) = \sum_\Omega D^J_{\Omega M}(\xi\theta\varphi)\psi^{J\Omega}(Rr\alpha|n_0 j_0 l_0|t)$$

where $D^J_{\Omega M}$ is a Wigner rotation matrix (60), (ξ,θ,φ) are the Eulerian angles of a body frame whose z-axis is along $\hat{R}$, and oriented so that the diatom is in the (x,z) plane. Then α, the angle between $\boldsymbol{r}$ and $\boldsymbol{R}$, is the polar angle of the diatomic axis in the rotating frame. Noting that (61)

$$[21]\quad \mathcal{Y}_{jl}^{JM}(\hat{R}\hat{r}) = \sqrt{\frac{2l+1}{8\pi^2}}\sum_\Omega D^J_{\Omega M}(\phi\theta\varphi)\,\langle l0j\Omega|J\Omega\rangle\, P_{j\Omega}(\cos\alpha)$$

where $P_{j\Omega}(\cos\alpha)$ is a normalized associated Legendre polynomial, we can project eq. [19] with $D^{J*}_{\Omega M}(\xi\theta\varphi)$ to obtain

$$[22]\quad \psi^{J\Omega}(Rr\alpha|n_0j_0l_0|t) = \left[1 + \frac{i\tau}{2\hbar}V(Rr\alpha)\right]^{-1}\frac{4}{\pi^2}\sum_{\substack{jl\\ \Omega'}}\int_0^\infty dKK^2\int_0^\infty dkk^2\, e^{-i(K^2/\mu + k^2/m)\hbar\tau/2}j_l(KR)j_j(kr)\frac{(2l+1)}{(2J+1)}$$
$$\times \langle l0j\Omega|J\Omega\rangle\langle l0j\Omega'|J\Omega'\rangle\, P_{j\Omega}(\cos\alpha)\int_0^\infty dR'R'^2\int_0^\infty dr'r'^2\int_{-1}^1 d(\cos\alpha')j_j(kr')P_{j\Omega'}(\cos\alpha')$$
$$\times\left(1 - \frac{i\tau}{2\hbar}V(R'r'\alpha')\right)\psi^{J\Omega'}(R'r'\alpha'|n_0j_0l_0|t-\tau)$$

We note that the fact that the potential energy depends only on $\hat{r}\cdot\hat{R}$ rather than on $\hat{r}$ and $\hat{R}$ separately has been used in obtaining eq. [22]. This equation can be used to calculate $\psi^{J\Omega}(Rr\alpha|n_0j_0l_0|t)$ at time t from its previous values at time $t-\tau$.

If we include the diatomic binding potential in H_r, so that

$$[23]\quad H_r = K_R + K_r + v(r)$$

the result is easily shown to be

$$[24]\quad \psi^{J\Omega}(Rr\alpha|n_0j_0l_0|t) = \left[1 + \frac{i\tau}{2\hbar}v(Rr\alpha)\right]^{-1}\frac{2}{\pi}\sum_{\substack{jl\\ n\Omega'}}\int_0^\infty dKK^2\, e^{-i(\hbar K^2/2\mu + \epsilon_{nj}/\hbar)\tau}j_l(KR)f_{nj}(r)\left(\frac{2l+1}{2J+1}\right)\langle l0j\Omega|J\Omega\rangle\langle l0j\Omega'|J\Omega'\rangle$$
$$\times P_{j\Omega}(\cos\alpha)\int_0^\infty dR'R'^2\int_0^\infty dr'r'^2\int_{-1}^1 d(\cos\alpha')j_l(KR')f_{nj}(r')P_{j\Omega'}(\cos\alpha')\left[1 - \frac{i\tau}{2\hbar}v(R'r'\alpha')\right]$$
$$\times\psi^{J\Omega'}(R'r'\alpha'|n_0j_0l_0|t-\tau)$$

where $f_{nj}(r)$ is the vibrational eigenstate of the vibrating–rotating diatom, having energy ϵ_{nj}, and

$$[25]\quad v(R'r'\alpha') = V(R'r'\alpha') - v(r')$$

In this case, the summation over the index n replaces the integration over k.

We note that if the symmetric split operator (11) were used, then $\exp(-i\tau V(Rr\alpha)/2\hbar)$ would replace

$$\left[1 + \frac{i\tau}{2\hbar}V(Rr\alpha)\right]^{-1}\quad\text{and}\quad\left[1 - \frac{i\tau}{2\hbar}V(Rr\alpha)\right]$$

in eq. [22], and $\exp(-i\tau v(Rr\alpha)/2\hbar)$ would replace

$$\left[1 + \frac{i\tau}{2\hbar}v(Rr\alpha)\right]^{-1}\quad\text{and}\quad\left[1 - \frac{i\tau}{2\hbar}v(Rr\alpha)\right]$$

in eq. [24].

Equations [22] and [24] are the result of using a total angular momentum (30, 59, 66), rotating body frame (38, 40, 67), coordinate representation, combined with the KRMC equation. We shall use them now to examine the consequences of time-scale separations for the various motions in the atom–diatom system. The natural time scales for each degree of freedom can be determined by examination of the manner in which the time (65) enters the factors $\exp[-i(K^2\tau/\mu + k^2\tau/m)\hbar/2]$ and $[1 \pm (i\tau/2\hbar)V(Rr\alpha)]^{\mp1}$ in eq. [22], and $\exp[-i(\hbar K^2\tau/2\mu + \epsilon_{nj}\tau/\hbar)]$ and $[1 \pm (i\tau/2\hbar)V(Rr\alpha)]^{\mp1}$ in eq. [24]. The terms representing kinetic energy are easy to analyze, and for eq. [22] the ratios τ/μ and τ/m naturally occur (65). There are also natural length scales r_0 associated with the binding potential $v(r)$, and R_0 associated with the scattering potential $v(Rr\alpha)$ (65) (defined by eq. [25]). These are essentially range parameters associated with the distance over which a potential is significant. Thus it is important to understand that the length scales R_0 and r_0 essentially contain the qualitative information about (a) whether the bound motion in r permits large or small excursions (so if r_0 is small, this corresponds to a tightly bound system, and if r_0 is large, denoting large excursions, one has a loosely bound system, such as van der Waals bond); (b) whether the scattering interaction is long ranged (with R_0 large) or short ranged (with R_0 small). We define effective times τ_1' and τ_2' by (65)

$$[26]\quad \tau_1' = \tau/\mu R_0^2$$

and

$$[27]\quad \tau_2' = \tau/mr_0^2$$

It is straightforward then to introduce the natural energy units $\hbar^2/2\mu R_0^2$ and $\hbar^2/2mr_0^2$ associated with the R and r degrees of freedom respectively. If K and k are measured in units $1/R_0$ and $1/r_0$ respectively, then for eq. [22] we will have factors

$$[28]\quad \exp[-i(\hbar\tilde{K}^2\tau_1'/2 + \hbar\tilde{k}^2\tau_2'/2)]$$

and

$$[29]\quad \left[1 \pm i\hbar\left(\frac{\tau_1'}{2}\tilde{v}(Rr\alpha) + \frac{\tau_2'}{2}\tilde{v}(r)\right)\right]^{\mp1}$$

and for eq. [24], the factors are

$$[30]\quad \exp\left[-i\left(\hbar\tilde{K}^2\tau_1'/2 + \frac{\hbar\tau_2'}{2}\tilde{\epsilon}_{nj}\right)\right]$$

and

$$[31] \quad \left[1 \pm \frac{i\hbar}{2}\tau_1'\tilde{v}(Rr\alpha)\right]^{\mp 1}$$

Here, all quantities with tildes are dimensionless.

To consider time-scale separations, it is clear that one must consider the relative sizes of the masses μ and m and the lengths R_0 and r_0. The basic condition that must be satisfied by the *physical time step*, τ, is that it be short enough to ensure that an accurate description is obtained in the trapezoidal quadrature evaluation of the time integral in eq. [3]. Typically, one expects this to be governed by the rate at which the wavepacket is moving *and* being distorted by the potential, and this is strongly influenced by the energies included in the construction of the original packet for relative motion, and the initial internal state of the bounded notion. For many systems, the rate of motion will be dominated by the masses μ and m, so that τ must be chosen small enough to follow the motion of the light particle. If, for example, this is taken to be particle 1, with mass μ, then τ must be chosen small enough that τ_1' does not result in so large a change in the average position of particle 1 that the integrand changes too rapidly. We note futher that by construction,

$$[32] \quad \mu R_0^2/mr_0^2 << 1$$

and by eqs. [26] and [27],

$$[33] \quad \tau = \frac{\mu}{R_0^2}\tau_1'$$

and

$$[34] \quad \tau_2' = (\tau_1'\mu R_0^2/mr_0^2)$$

or

$$[35] \quad \tau_2' << \tau_1'$$

Thus, the effective time for the r-motion of the more massive particle is much shorter than that for the lighter particle associated with R-motion. As a result, we expect that for eq. [22], the factor $\exp[-i\hbar\tilde{k}^2\tau_2'/2]$ should be close to one and $\tau_2'\tilde{v}(r)/2$ should be small compared to $\tau_1'\tilde{v}(Rr\alpha)/2$. To see the consequence of this, we can consider the extreme case of $mr_0^2 \rightarrow \infty$, or $\tau_2' \equiv 0$. Then one has that

$$[36] \quad \int_0^\infty dk k^2 \exp(-i\hbar\tilde{k}^2\tau_2'/2) j_l(kr) j_l(kr') = \int_0^\infty dk k^2 j_l(kr) j_l(kr')$$

$$[37] \quad = \frac{\pi}{2}\frac{\delta(r - r')}{r^2}$$

Next we note that the basic parameter τ (or τ_1') is under our control. It can be chosen small enough so that the change in R is also not too great. In a recent paper (62), we showed that for τ_1' not too large, a quadrature evaluation of the integral over K,

$$[38] \quad G_l(R,R'|\tilde{K}_{max},\tau_1') = \frac{2}{\pi}\sum_{p=1}^{N_R} w_p \Delta K j_l(\tilde{K}_p R)\exp(-i\tilde{K}_p^2\hbar\tau_1'/2)\, j_l(\tilde{K}_p R')$$

leads to a strongly peaked function of R and R'. Here, ΔK is the (fixed) step size in wavenumber, Kmax equals $N_R\Delta K$, and trapezoidal weights w_p (with $w_1 = w_N = \frac{1}{2}$) are used. In fact, $G_l(R,R'|K_{max},\tau_1')$ is very weakly dependent on l. It is then possible to do the sum over l in eq. [22]:

$$[39] \quad \sum_l \frac{2l+1}{2J+1}\langle l0j\Omega|J\Omega\rangle\langle l0j\Omega'|J\Omega'\rangle = \delta_{\Omega\Omega'}$$

At this point, the sum over j can then be done:

$$[40] \quad \sum_j P_{j\Omega}(\cos\alpha)\, P_{j\Omega}(\cos\alpha') = \delta(\cos\alpha - \cos\alpha')$$

leading thereby to an equation that is only parametrically dependent on r and α. (It is important to note that eq. [40] follows because the $P_{j\Omega}$ are normalized associated Legendre polynomials.) This is reminiscent of an IOS (69) type reduction to dynamical equations in which the scattering is parametrically a function of the orientation of the target diatom.

Of course, our principal interest is *not* in such an extreme limit. Instead, one expects that for τ such that τ_1' leads to a highly peaked $G_l(R,R'|K_{max},\tau_1')$, the corresponding value of τ_2' will lead to an even more strongly peaked $G_j(r,r'|k_{max},\tau_2')$, given by

$$[41] \quad G_j(r,r'|k_{max},\tau_2') = \frac{2}{\pi}\Delta k\sum_{q=1}^{N_r} w_q j_j(k_q r)\exp(-ik_q^2\hbar\tau_2'/2) j_j(k_q r')$$

with $k_{max} = N_r\Delta k$. This can result in substantial reduction of the computational effort in solving eq. [22], since the peaking property of both G_l and G_j corresponds to their being sparse or banded matrices when R, R' and r, r' are replaced by discrete grids. This should result in a dynamical approach that goes beyond the IOS, in that the slow degrees of freedom *are* permitted to change during the collision. This is because one makes use of the banded structure of the propagator without going to the extreme Dirac delta function limit.

4. Potential referenced modified Cayley method

In this instance, we reverse the roles of the relative kinetic energy and potential energy operators (49). Then eq. [5] reads

$$[42] \quad |\psi^{JM}(n_0 j_0 l_0|t)\rangle = \left[1 + \frac{i\tau}{2\hbar}(K_R + K_r)\right]^{-1} e^{-iV\tau/\hbar} \times \left[1 - \frac{i\tau}{2\hbar}(K_R + K_r)\right]|\psi^{JM}(n_0 j_0 l_0|t - \tau)\rangle$$

Clearly, it is desirable to utilize the momentum representation in this equation due to the appearance of $[1 + (i\tau/2\hbar)(K_R$

$+ K_r)]^{-1}$ as the left-most operator on the RHS. We project eq. [22] with $\langle kj| < Kl| < Y_{jl}^{JM}|$, again insert appropriate resolutions of the identity, and carry through straightforward but tedious manipulations to obtain

$$[43]\quad \psi^J(Kkjl|n_0j_0l_0|t) = \frac{4}{\pi^2}\left[1 + \frac{i\tau\hbar}{4}\left(\frac{K^2}{\mu} + \frac{k^2}{m}\right)\right]^{-1}\int_0^\infty dRR^2\int_0^\infty drr^2\int_{-1}^{1} d(\cos\alpha) j_l(KR)j_l(kr)\sum_{\substack{j'l'\\ \Omega}}\frac{\sqrt{(2l+1)(2l'+1)}}{(2J+1)}$$
$$\times \langle l0j\Omega|J\Omega\rangle\langle l'0j'\Omega|J\Omega\rangle P_{j\Omega}(\cos\alpha)e^{-iV(R\tau\alpha)\tau/\hbar}P_{j'\Omega}(\cos\alpha)\int_0^\infty dK'K'^2\int_0^\infty dk'k'^2$$
$$\times j_l(K'R)j_j(k'r)\left[1 - \frac{i\tau\hbar}{4}\left(\frac{K'^2}{\mu} + \frac{k'^2}{m}\right)\right]\psi^J(K'k'j'l'|n_0j_0l_0|t-\tau)$$

As in the preceding analysis, body frame Euler angles (ξ,θ,φ) were introduced to simplify the equations (taking advantage of the Wigner–Eckart theorem (59)).

Finally, it is straightforward to obtain the resulting equations when the diatomic binding potential $v(r)$ is included in H_d. By use of eq. [21], we obtain

$$[44]\quad \psi^J(Knjl|n_0j_0l_0|t) = \frac{2}{\pi}\left[1 + \frac{i\tau}{2\hbar}\left(\frac{\hbar^2K^2}{2\mu} + \epsilon_{nj}\right)\right]^{-1}\int_0^\infty dRR^2\int_0^\infty drr^2\int_{-1}^{1} d(\cos\alpha)$$
$$\times j_l(KR)f_{nj}(r)\sum_{\substack{n'j'l'\\ \Omega}}\frac{\sqrt{(2l+1)(2l'+1)}}{(2J+1)}\langle l0j\Omega|J\Omega\rangle\langle l'0j'\Omega|J\Omega\rangle P_{j\Omega}(\cos\alpha)e^{-iv(R\tau\alpha)\tau/\hbar}P_{j'\Omega}(\cos\alpha)$$
$$\times \int_0^\infty dK'K'^2 j_{l'}(K'R)f_{n'j'}(r)\left[1 - \frac{i\tau}{2\hbar}\left(\frac{\hbar^2K'^2}{2\mu} + \epsilon_{n'j'}\right)\right]\psi^J(K'n'j'l'|n_0j_0l_0|t-\tau)$$

This completes the choices for H_r and H_d that we wish to consider in the present paper. We remark that one might anticipate that eq. [18] or eq. [20] will be most useful when the kinetic energy or internal energy is much larger than the potential energy. This is reflected in the fact that both eqs. [18] and [20] include the kinetic energy to infinite order. By contrast, eq. [23] and [24] should be most useful when the potential energy is much larger. Of course, we anticipate that hybrid algorithms can be devised that utilize the form most appropriate (depending on which of the energies is larger).

5. Conclusions

We note that the forms eq. [18] and eq. [23] are suitable also for treating the possibility of reactive processes since a bound state approximation to the motion in r has not been made. One possible way to treat reactions is by the use of negative imaginary arrangement decoupling potentials (39, 40, 52). Other ways are also under study. It is also possible to formulate the equations using a body frame (38, 67) description throughout, or to use hyperspherical coordinates (68). One also can use other choices of the reference Hamiltonian, H_r, thereby leading to different disturbances, H_d. Finally, the present methods are ideally suited to parallelization, and we anticipate that extremely efficient algorithms can be devised for solving these equations on parallel architecture computers. All these options are currently under study.

Selenium sulfur dihalides, Ch_nX_2 (n = 1, 2, 3; Ch = Se, S; X = Br, Cl). Raman and ^{77}Se NMR spectroscopic characterization

JOHN B. MILNE

Department of Chemistry, University of Ottawa, Ottawa, Ont. Canada, K1N 6N5

Received July 4, 1991

This paper is dedicated to the memory of Professor Thomas Birchall

JOHN B. MILNE. Can. J. Chem. **70**, 693 (1992).

Solutions of Se_2Cl_2 in S_2Cl_2, Se_2Br_2 in S_2Cl_2, Se in S_2Cl_2, and S in Se_2Cl_2 have been studied by Raman and ^{77}Se NMR spectroscopy. Selenium sulfur dihalides, $SeSCl_2$, $SeSBr_2$, and SeSBrCl, formed in these solutions, have been shown by Raman and ^{77}Se NMR spectroscopy to have chain structures. Solutions of Se_2Cl_2 in S_2Cl_2, S in Se_2Cl_2, and Se in S_2Cl_2 have been shown to contain, in addition to Se_2Cl_2, S_2Cl_2, $SeSCl_2$, Se_3Cl_2, and S_8, trichalcogen dichlorides Se_2SCl_2 and SeS_2Cl_2. Selenium-77 signals corresponding to all seven chain isomers of the expected Se-containing dichalcogen dihalides, Se_2Br_2, Se_2Cl_2, Se_2BrCl, $SeSCl_2$, $SeSBr_2$, BrSeSCl, and ClSeSBr, have been observed in the spectrum of a 1 : 1 molar mixture of S_2Cl_2 and Se_2Br_2. The disulfur dichloride and dibromide, as well as the bromide chloride, are also present. Selenium–bromine and sulfur–chlorine linkages are observed to be preferred over selenium–chlorine and sulfur–bromine bonding in these mixtures. The ^{77}Se chemical shifts correlate well with the electronegativity of the directly bonded neighbour but inversely with that of the next-nearest neighbour.

Key words: selenium halides, sulfur halides, low valent chalcogen halides, ^{77}Se NMR, Raman spectroscopy.

JOHN B. MILNE. Can. J. Chem. **70**, 693 (1992).

Faisant appel à la spectroscopie Raman et à la RMN du ^{77}Se, on a étudié des solutions de Se_2Cl_2 dans le S_2Cl_2, de Se_2Br_2 dans le S_2Cl_2, de Se dans le S_2Cl_2 et de S dans le Se_2Cl_2. En se basant sur la spectroscopie Raman et la RMN du ^{77}Se, on a montré que les dihalogénures de soufre et de sélénium qui se forment dans ces solutions ($SeSCl_2$, $SeSBr_2$ et SeSBrCl) possèdent des structures en chaîne. On a montré que les solutions de Se_2Cl_2 dans le S_2Cl_2, de S dans le Se_2Cl_2 et de Se dans le S_2Cl_2 contiennent des dichlorures de chalcogènes (Se_2SCl_2 et SeS_2Cl_2) en plus du Se_2Cl_2, du S_2Cl_2, du $SeSCl_2$, du Se_3Cl_2 et du S_8. Dans le spectre d'un mélange 1 : 1 molaire du S_2Cl_2 et de Se_2Br_2, on a observé des signaux du ^{77}Se correspondant à tous les sept isomères en chaîne attendus pour les dihalogénures de dichalcogènes contenant du Se (Se_2Br_2, Se_2Cl_2, Se_2BrCl, $SeSCl_2$, $SeSBr_2$, BrSeSCl et ClSeSBr). Le dichlorure et le dibromure de disoufre ainsi que le bromure et le chlorure de disoufre y sont aussi présents. On a observé que, dans ces mélanges, les liaisons sélénium–brome et soufre–chlore sont préférées aux liaisons sélénium–chlore et soufre–brome. Il existe une corrélation entre les déplacements chimiques du ^{77}Se et les électronégativités des atomes qui y sont directement attaché; cette corrélation est toutefois inversée avec les atomes qui se trouvent dans la position suivante.

Mots clés : halogénures de sélénium, halogénures de soufre, halogénures de chalcogènes de basse valence, RMN du ^{77}Se, spectroscopie Raman.

[Traduit par la rédaction]

Introduction

Chloro- and bromosulfanes, S_nX_2, have been extensively studied (1) and shown to consist of sulfur chains like their organic analogues. Recently Se_2Cl_2 and Se_2Br_2 were shown to contain equilibrium amounts of SeX_2, Se_3X_2, and Se_4X_2 (2). The mixed halogen compounds, Se_nBrCl (n = 1,2) have also been reported (2) but mixed chalcogen dihalides have received little attention although sulfur selenium chains in general are currently of great interest (3). Early work, using chemical methods, suggested that $SeSCl_2$ has a trigonal pyramidal structure (4). The two possible isomers, with either selenium or sulfur terminal, were prepared from mixtures of Se in S_2Cl_2 and S in Se_2Cl_2 respectively. However, other work (5) has shown that S_2Cl_2 and Se react quantitatively according to

$$[1] \quad S_2Cl_2 + 2Se = Se_2Cl_2 + 2S$$

with no evidence for $SeSCl_2$ formation.

To clarify the nature of these reactions and characterize some of the mixed chalcogen dihalides, a Raman and ^{77}Se NMR study of mixtures of S_2Cl_2 with Se_2Cl_2, Se_2Br_2, and Se, and Se_2Cl_2 with S was undertaken as part of an ongoing study of low-valent Se halide chemistry (2, 6).

Experimental section

Disulfur dichloride (BDH), sulfur (MCB), and selenium (Baker analyzed) were used directly. Diselenium dichloride was prepared from stoichiometric amounts of Se and $SeCl_4$ (2) and Se_2Br_2 was prepared from HBr (Fisher, 48%), SeO_2 (Aldrich), and Se (Baker analyzed) by the method of Lenher and Kao (5). Moisture sensitive mixtures were made up by weighing in a dry box at ambient temperature. Often 1–3 h of mixing were required to produce homogeneous mixtures and, in the case of the S in the Se_2Cl_2 mixture, heating at 75°C over several minutes was used to achieve solution. Mixing of S_2Cl_2 with Se_2X_2 (X = Br, Cl) was accompanied by marked cooling.

Raman spectra were measured using a Jobin–Yvon monochromator with a PAR photon counting system. The spectra were excited with the 647.1 nm line of a Spectra Physics Kr ion laser.

Selenium-77 NMR spectra were measured with a Varian XL300 spectrometer operating at 57.28 MHz. The probe temperature was 21°C. The spectra were run with an external D_2O lock and referenced to aqueous saturated H_2SeO_3 ($\delta(Me_2Se) = \delta(H_2SeO_3$, satd.) + 1303.7 ppm).[2] A pulse angle of 50° and 2 s recycle time were usually used and 512–1024 transients were collected with a sweep width of 30 000 Hz or less. All samples were degassed by six

freeze–thaw cycles under vacuum before sealing. The signals were all relatively broad (>21 Hz) and, for this reason and low isotopomer concentrations, no Se–Se couplings (11–65 Hz (7)) were observed.

Results and discussion

Raman spectroscopy

The Raman spectrum of a 1:1 molar mixture of S_2Cl_2 and Se_2Cl_2 is shown in Fig. 1, trace A. The spectrum exhibits peaks corresponding to S_2Cl_2 (540, 449, 243, 209, and 105 cm^{-1} (8)) and Se_2Cl_2 (359, 289, 148, 131, and 85 cm^{-1} (8)). In addition, peaks are observed at 414, 190, and 170 cm^{-1}. The contributions of S_2Cl_2 and Se_2Cl_2 to this spectrum were subtracted by using intensity scaling factors for the non-overlapped peaks of S_2Cl_2 (540, 243, and 209 cm^{-1}) and Se_2Cl_2 (290 cm^{-1}) taken from spectra of the pure compounds run under identical conditions. The resultant spectrum is given as trace B in Fig. 1 and consists of peaks at 441, 414, 369, 190, and 170 cm^{-1}. The peak at 414 cm^{-1} is coincident with ν(SeCl) of $SeCl_2$ but is 4 times stronger than that expected for the equilibrium concentration of $SeCl_2$ present (2). The observation of both SCl (441 cm^{-1}) and SeCl (369 cm^{-1}) stretching bands as well as the SeS (414 cm^{-1}) stretching band is consistent with the formation of the chain isomer of $SeSCl_2$. In addition, the SeSCl deformation modes at 190 and 170 cm^{-1} are nicely bracketed by the comparable modes for Se_2Cl_2 and S_2Cl_2, 148/131 and 243/209 cm^{-1} and show comparable intensity ratios. It should also be noted that no peak corresponding to an SeS double bond stretching mode, expected for the pyramidal isomers and estimated to lie near 560 cm^{-1} (mean of the Se_2 and S_2 diatomic stretching frequencies (9)), is observed. Apparently mixtures of Se_2Cl_2 and S_2Cl_2 are in equilibrium with the mixed chalcogen dichloride,

$$[2] \quad S_2Cl_2 + Se_2Cl_2 \overset{K(SeSCl_2)}{=} 2SeSCl_2$$

where, on the basis of peak intensities, the equilibrium lies to the reactant side. A complete assignment of the Raman spectrum of the $SeSCl_2$ molecule is given in Table 1.

The early claims (4) of the synthesis of the pyramidal isomers of $SeSCl_2$ called for long periods of reflux of Se and S_2Cl_2 for the isomer with Se terminal and of S and Se_2Cl_2 for that with S terminal. The Raman spectra of these two mixtures (initial dissolution of S in Se_2Cl_2 required a brief period of warming) remained unchanged, regardless of the time of heating at 80°C for up to 20 h. The spectrum of a 1:1 molar mixture of Se in S_2Cl_2 is shown in Fig. 1, trace C. The spectrum is similar to that of the Se_2Cl_2/S_2Cl_2 mixture, showing the presence of the reactants and a small amount of the chain isomer of $SeSCl_2$. In addition, however, three peaks at 477, 221, and 152 cm^{-1} are observed, which correspond to the three strongest bands of elemental sulfur, S_8, dissolved in S_2Cl_2, (10), and as discussed below, in Se_2Cl_2. Thus, Se dissolves readily in S_2Cl_2 according to

$$[3] \quad 8Se + 8S_2Cl_2 = 4S_2Cl_2 + 4Se_2Cl_2 + S_8$$

and some $SeSCl_2$ is formed by equilibrium [2]). The spectrum of a 1:1 molar mixture of S in Se_2Cl_2, shown in Fig. 1, trace D, shows the characteristic strong bands of Se_2Cl_2 (2), the three sharp bands due to S_8, and weak peaks due to a trace of S_2Cl_2. Because of the very low concentration of S_2Cl_2 and the fact that equilibrium [2] lies on the reactant side,

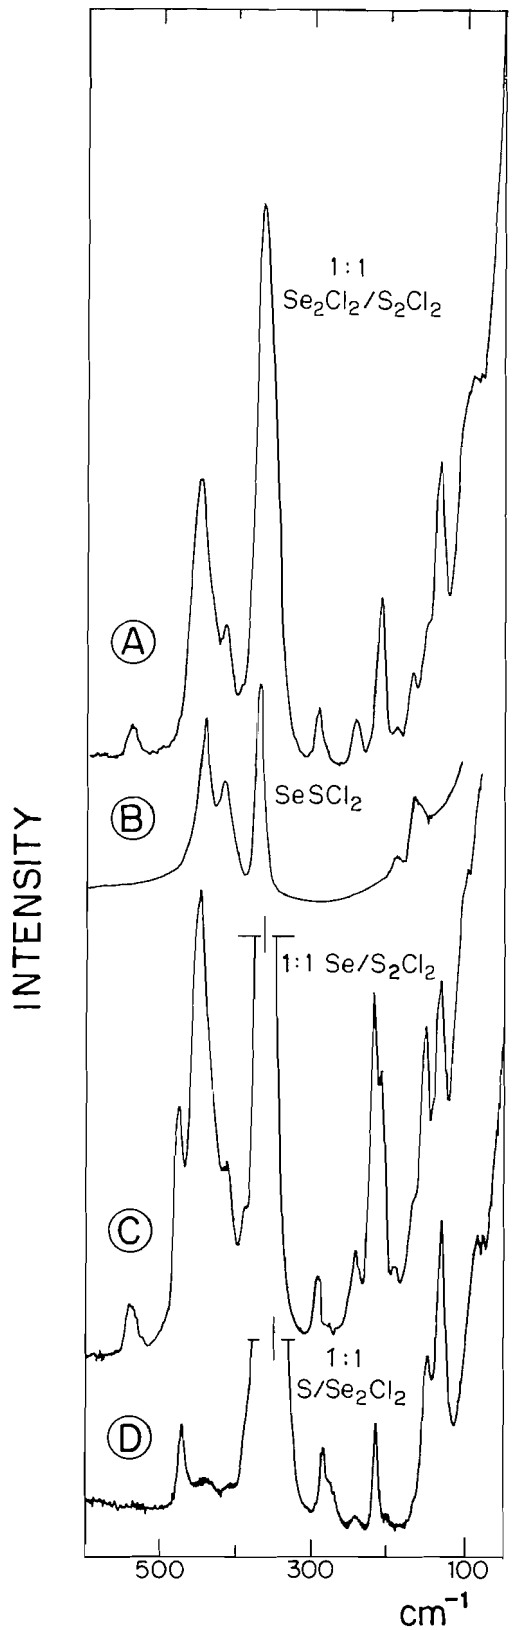

FIG. 1. Raman spectra of selenium sulfur chloride mixtures. Trace A: 1:1 molar ratio Se_2Cl_2/S_2Cl_2; trace B: Spectrum of $SeSCl_2$ determined from trace A by subtraction of Se_2Cl_2 and S_2Cl_2 bands; trace C: 1:1 molar ratio Se/S_2Cl_2; trace D: 1:1 molar ratio S/Se_2Cl_2.

TABLE 1. Vibrational assignment of the Raman spectrum of ClSeSCl

Frequency (cm^{-1})			Mode no.	Description of mode
S_2Cl_2[a]	Se_2Cl_2[a]	$SeSCl_2$		
102	87	—	4	τ
209	131	170	3	δ(ClChX)
243	148	190	6	δ′(ClChX)
449	367	369	2	ν(ChX)
540	289	414	1	ν(ChCh)
436	367	441	5	ν′(ChX)

[a]Reference 18.

the $SeSCl_2$ formed goes undetected in this spectrum. Apparently elemental sulfur dissolves in Se_2Cl_2 as S_8 rings, in the same manner as sulfur does in S_2Cl_2 (10), and only a small amount of oxidation of sulfur occurs to give S_2Cl_2.

The Raman spectrum of a 1:1 molar mixture of Se_2Br_2 and S_2Cl_2 was not very informative. Because of the strong light absorption by the sample, the spectrum was of poor quality and all of the observed peaks were coincident with those of the reactants and Se_2Cl_2 and S_2Br_2. The dominant peaks were those corresponding to Se—Cl and Se—Br stretching modes at 309 and 265 cm^{-1} respectively.

Selenium-77 NMR spectroscopy

The ^{77}Se NMR spectrum of the 1:1 molar mixture of Se_2Cl_2 and S_2Cl_2 is shown in Fig. 2, trace A. The observed chemical shifts and integrated intensities are given in Table 2. The signal due to Se_2Cl_2 is readily identified at 1285.6 ppm as well as those of $SeCl_2$ at 1741.7 ppm and one of the two signals of the Se_3Cl_2 molecule at 1280.1 ppm (2). The half-height linewidth of this latter signal is 21 Hz, compared to that for Se_2Cl_2 itself (35 Hz), which suggests that this peak is due to the central Se (β-Se) of the three-Se chain. The second strongest signal in the spectrum at 1298.4 ppm arises from $SeSCl_2$. On the basis of the integrated peak intensities listed in Table 2, the value of the equilibrium constant for reaction [2] is calculated to be 0.08, assuming that $[Se_2Cl_2] = [S_2Cl_2]$.

The ^{77}Se NMR spectrum of a 1:1 molar mixture of Se and S_2Cl_2 is shown in trace B of Fig. 2 and chemical shifts and integrated intensities are given in Table 2. The same strong signals as for the Se_2Cl_2/S_2Cl_2 mixture are observed, with minor changes in intensities, confirming the conclusion of the Raman experiment that this mixture results in, effectively, an equimolar mixture of Se_2Cl_2 and S_2Cl_2 (containing some S_8), which take part in subsequent equilibria. Evaluation of the equilibrium constant for equilibrium [2] from the signal intensities gives $K(SeSCl_2) = 0.07$, in good agreement with the constant determined from the spectrum of the Se_2Cl_2/S_2Cl_2 mixture.

The ^{77}Se NMR spectrum of a 1:1 molar mixture of S and Se_2Cl_2 is shown in trace C of Fig. 2 and the shifts and intensities are given in Table 2. The signals for the major peaks, $SeCl_2$, Se_2Cl_2, Se_3Cl_2, and $SeSCl_2$, are all observed but two changes are noteworthy; (*a*) the chemical shifts are all 5–11 ppm more shielded than those of the Se_2Cl_2/S_2Cl_2 and Se/S_2Cl_2 mixtures and (*b*) the integrated intensities of the $SeCl_2$, Se_3Cl_2, and $SeSCl_2$ peaks are much lower compared to those in the other solutions. The chemical shifts are close to those reported for pure liquid Se_2Cl_2 (2). Apparently, the presence of a small amount of S_8 as solute has little effect on the chemical shifts in Se_2Cl_2, and the 5–11 ppm negative chemical shift of the same species in Se_2Cl_2/S_2Cl_2 and Se/S_2Cl_2 mixtures results from the presence of S_2Cl_2. Using the equilibrium constant determined for reaction [2] above, $K(SeSCl_2) = 0.08$, and the intensity for Se_2Cl_2 and $SeSCl_2$ for the S/Se_2Cl_2 solution in Table 2, $[S_2Cl_2]$ (in units of relative concentration), is found to be 0.25, which is to be compared to 50 (assuming $[S_2Cl_2] = [Se_2Cl_2]$) for the other mixtures. This low concentration accounts for the failure to observe peaks for S_2Cl_2 in the Raman spectrum and indicates why the chemical shifts for this mixture are different from those of the Se_2Cl_2/S_2Cl_2 and Se/S_2Cl_2 mixtures.

A number of weak signals, which lie slightly to the less shielded side of the $SeSCl_2$ signal, appear in the spectra of all three mixtures. These must arise from the trichalcogen dichlorides, ClSeSSCl, ClSSeSCl, ClSeSSeCl, and ClSeSeSCl, for which five signals are expected. These signals are very weak and poorly defined but a reasonable assignment can be made. If a comparison of the relative intensities of these peaks in the Se/S_2Cl_2 and Se_2Cl_2/S mixtures is made, the most shielded signal (1309.2/1314.8 ppm; peak no. 4, Table 2) and the middle two peaks of the four signals that are slightly less shielded (1329.4/1334.8 ppm, peak no. 6, and 1335.3/1340.4 ppm, peak no. 7, Table 2) are of greater intensity than the remaining weak peaks in the mixtures where the selenium content is highest, indicating that these signals belong to the Se-rich species, ClSeSSeCl and ClSeSeSCl. The broader of the three peaks (1329.4/1334.8 ppm; peak no. 6) is assigned to the α-Se in ClSeSeSCl by comparison with the assignment of the two signals of differing breadths for Se_3Cl_2 (2). Of the remaining two strong signals, peak no. 7 (1335.3/1340.4 ppm, which lies closest to the α-Se signal of ClSeSeSCl) is assigned to the β-Se in this molecule by analogy with the close proximity of the α- and β-Se signals of Se_3Cl_2 (2), and peak no. 4 (1309.2/1314.8 ppm) is assigned to ClSeSSeCl. The remaining weak signals, peak nos. 5 (1327.3/1334.8 ppm) and 8 (1345.2/1350.5 ppm) are then due to the SeS_2Cl_2 species. On the basis of the ^{77}Se chemical shifts in SeS rings (3*a*,*d*), where isolated Se (SSeS) is deshielded relative to Se bound to Se (SeSeS), peak no. 8 may be assigned to ClSSeSCl relative to the shift of the β-Se for ClSeSeSCl (peak no. 7). Only one signal, lying close to the shift observed for Se_4Cl_2 (2) and probably due to a four-chalcogen species, $Se_xS_{4-x}Cl_2$ ($x = 1,2,3$), was observed in the spectra of the Se/S_2Cl_2 and S/Se_2Cl_2 mixtures.

The five chemical shifts arising from trichalcogen species are also observed in the spectrum of the Se_2Cl_2/S_2Cl_2 mixture, Fig. 2, trace A. The relative positions of these peaks remain the same as for the other mixtures.

The ^{77}Se NMR spectrum of a 1:1 molar mixture of Se_2Br_2 and S_2Cl_2 consists of eight strong signals (11), as shown in Fig. 3 and listed in Table 3, along with integrated intensities and linewidths at half-height. Weak peaks, due to Se_3X_2 and other minor species, accounted for <1% of the total area intensity of the spectrum. The eight signals are divided into two groups of four, one group in the region 1223.0–1180.6 ppm, consisting of resonances of ^{77}Se bonded to Br, and another group in the region 1285.6–1313.0 ppm for ^{77}Se bonded to Cl. Complete mixing of chalcogens and halogens to give chain-type dichalcogen dihalides will yield 10 different species, seven of which will carry at least one Se atom. Eight different ^{77}Se chemical shifts are expected, since the

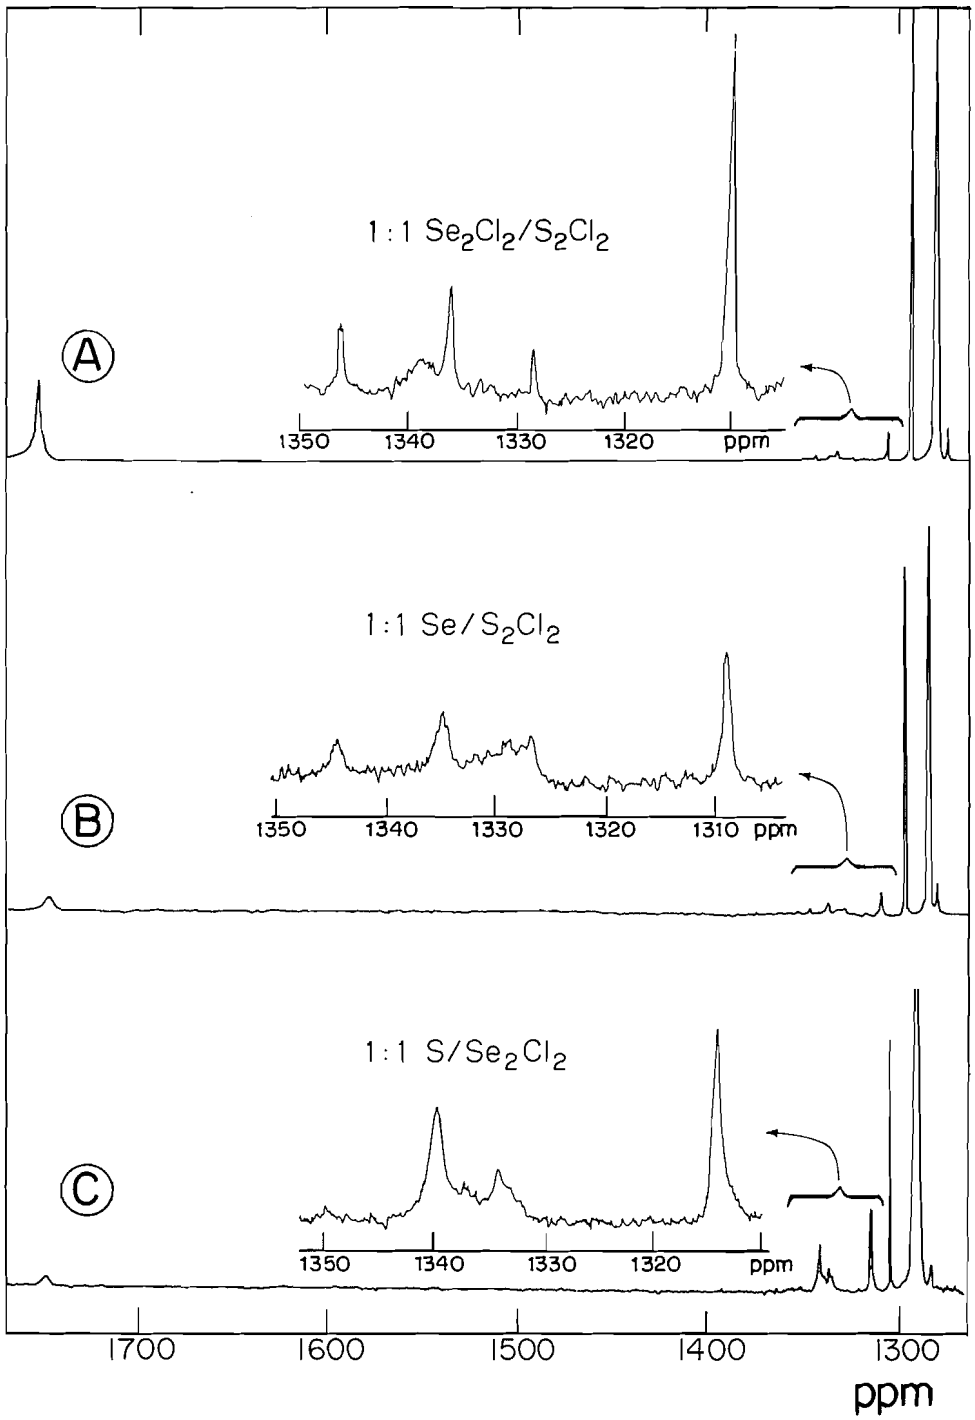

FIG. 2. Selenium-77 NMR spectra of selenium sulfur chloride mixtures. Trace A: 1 : 1 molar mixture Se_2Cl_2/S_2Cl_2; trace B: 1 : 1 molar mixture Se/S_2Cl_2; trace C: 1 : 1 molar mixture S/Se_2Cl_2.

species ClSeSeBr will give two different signals. These species are all listed in Table 3. The chemical shifts are assigned as follows. The two signals expected for ClSeSeBr are easily assigned to the peaks of nearly equivalent integrated intensity in the diselenium dibromide and diselenium dichloride parts of the spectrum (2), 1291.1 ppm (Se on Cl) and 1180.6 ppm (Se on Br). The other strong signals neighbouring these ClSeSeBr peaks are due to the parent dichloride (1285.6 ppm) and dibromide (1186.9 ppm), which lie slightly more shielded than in the pure liquids. The assignment of these four diselenium dihalide signals parallels that observed for mixtures of Se_2Cl_2/Se_2Br_2 in CH_2Cl_2 (6) and suggests that the assignment of the signals for Se attached to Cl for ClSeSeCl and ClSeSeBr in the Se_2Cl_2/Se_2Br_2 mixture (2) may be reversed. From the relative chemical shifts of Se_2Cl_2 and $SeSCl_2$ in the Se_2Cl_2/S_2Cl_2 mixture, the signal at 1298.3 ppm is assigned to $SeSCl_2$ and the remaining peak in the Se bound to Cl part of the spectrum (1313.0 ppm)

TABLE 2. ^{77}Se NMR chemical shifts for selenium sulfur chlorides[a]

Peak no.	1:1 Se_2Cl_2/S_2Cl_2	1:1 Se/S_2Cl_2	1:1 S/Se_2Cl_2	Assignment
0	[b]	700.7	704.7	$Se_{4-x}S_xCl_2$
1	1280.1	1278.9	1284.5	Se_3Cl_2
2	1285.6(100)	1283.6(100)	1291.3(100)	Se_2Cl_2
3	1298.4(14)	1296.7(13.5)	1304.7(2.0)	$SeSCl_2$
4	1310.3(0.9)	1309.2(1.6)	1314.8(1.7)	ClSeSSeCl
5	1328.2(0.3)	1327.3(0.9)	—	ClSeSSCl
6	1336.2(0.5)	1329.4(1.5)	1334.8(1.3)	ClSe*SeSCl
7	1339.1(0.5)	1335.3(1.6)	1340.4(1.8)	ClSeSe*SCl
8	1346.3(0.3)	1345.2(1.2)	1350.5(0.1)	ClSSeSCl
9	1741.7(12.6)	1741.7(9.1)	1730.2(1.4)	$SeCl_2$

[a]The chemical shifts are reported relative to $\delta = 0$ ppm for neat Me_2Se at 21° C. Their precision is estimated to be ±1.5 ppm; Signal intensities are in parentheses and are normalized to $I(Se_2Cl_2) = 100.0$.
[b]Not measured.

must be due to BrSSeCl. Thus, for the six signals assigned up to now, the ^{77}Se signal for the dichalcogen dihalide with Br attached to the remote chalcogen is deshielded relative to the case where Cl is attached to the remote chalcogen (δ(BrSSe*Cl) > δ(ClSSe*Cl); δ(BrSeSe*Cl) > δ(ClSeSe*-Cl); δ(BrSeSe*Br) > δ(ClSeSe*Br)) and in a parallel fashion the remaining peaks are assigned δ(BrSSeBr) (= 1223.0 ppm) > δ(ClSSeBr) (= 1206.1 ppm).

From a comparison of the relative intensities of the signal of Se attached to Br to those of the Se attached to Cl, it is apparent that most of the Se is bound to Br and the S to Cl. On the basis of the known ChX bond dissociation energies (12) the opposite combinations would have been expected. However, the SeX bond dissociation energies are derived from studies of SeX_2 and SeX_4 and not Se_2X_2, and the work on S_2Br_2 is of doubtful accuracy. Moreover, in view of the endothermicity of mixing of S_2Cl_2 and Se_2Br_2, entropy is obviously playing an important role in these reactions.

From the integrated intensities of the various species, their relative concentrations, c_{rel}, may be calculated and these are listed in Table 4. From the $SeSCl_2$ formation constant, calculated above for equilibrium [2], the relative concentration of S_2Cl_2, c_{rel} (S_2Cl_2), may be calculated, assuming that $K(SeSCl_2)$ is little changed by the presence of dichalcogen bromides. Calculation shows that c_{rel} (S_2Cl_2) = 110 (relative to c_{rel} (Se_2Cl_2) = 50). From the bromine and chlorine mass balances for the 1:1 Se_2Br_2/S_2Cl_2 stoichiometry, the relative concentrations of S_2Br_2 and S_2BrCl may also be calculated. The relative concentrations of all species are listed in Table 4.

From these relative concentrations, the constant governing the halogen mixing disproportionation,

$$[4] \quad Se_2Cl_2 + Se_2Br_2 \overset{K(Se_2BrCl)}{=} 2\,Se_2BrCl$$

is found to be 2.8, which is slightly less than that calculated for CH_2Cl_2 solutions, 3.0 (6). The diselenium compounds are less susceptible to the disproportionation than the disulfur species for which the comparable equilibrium constant, $K(S_2BrCl)$, is 4.5.

The linewidths at half-height, $W_{1/2}$, listed in Table 3, are three to four times larger for the diselenium dihalides than for the selenium sulfur species. In addition, while both types of lines broaden with temperature, those of the Se_2X_2 species broaden faster than those of SeX_2 species. Increasing linewidth at half-height with temperature indicates exchange broadening and this has been confirmed by two-dimensional exchange NMR spectroscopy experiments, which indicate a mechanism involving halide exchange (13) that is at least 10 times more rapid for diselenium than for selenium sulfur species. Previously the NMR signals of α- and β-Se in Se_2X_2 and Se_4X_2 were assigned on the basis of dif-

fering signal breadth, which was attributed to the differing proximity of the quadrupole relaxed Cl and Br to the Se nucleus of interest (2). It is now apparent that the greater width at half-height of the signal of α-Se, which is directly bound to Cl or Br, compared to that of the β-Se, with only Se near neighbours, is due to halide exchange.

The ^{77}Se chemical shift, δ(^{77}Se), correlates in general terms with Se oxidation state and electronegativity of the directly bonded near-neighbour atoms (14). The decreased shielding resulting from decreased electron density at the Se nucleus is usually assumed to be dominated by the paramagnetic contribution (14). The chemical shifts of the Se_2X_2 and SeX_2 (X = Br, Cl) follow this rule in general (2, 6). For the same halogens, the signal of the Se(II) species is several hundred ppm deshielded compared to the Se(I) species ($SeCl_2$: 1730.7 ppm; Se_2Cl_2: 1291.3 ppm; $SeBr_2$: 1467.7 ppm; Se_2Br_2: 1192.7 ppm; SeBrCl: 1600.7 ppm; mean of Se_2BrCl: 1248.7 ppm). For the SeX_2 compounds, the more electronegative the halogen, the more deshielded the Se. This applies to the Se_2X_2 (mean signal for Se_2BrCl) chemical shifts as well. For the same halogen or combination of halogens, the $SeSX_2$ is always deshielded relative to the analogous Se_2X_2 species, reflecting the greater Pauling electronegativity, χ_P, of sulfur (χ_P = 2.58), compared to selenium (χ_P = 2.55). However, the influence of the electronegativity of the next-nearest neighbour atom on Se shielding is opposite to that for nearest neighbours. Thus, in all cases, when Cl (χ_P = 3.16), as next-nearest neighbour, is replaced by Br (χ_P = 2.96), the remote Se is deshielded. This trend has been observed for perfluorochloromethyl selenides, diselenides, and thioselenides (7) and alkyl selenides and diselenides (15). Gombler (7) has accounted for the effect using hyperconjugation arguments, which require F—C multiple bonding and greater ionic character in C—Cl bonds, compared to C—F bonds. This present work shows that this anomalous trend occurs even with simple remote atoms (Br and Cl) and not just with $CF_{3-x}Cl_x$ groups. The trend appears to be related to the polarizability of the remote group as was suggested by Luthra *et al.* for the alkyl compounds (15).

Conclusion

Both S_2F_2 and Se_2F_2 exist in trigonal pyramidal and chain stereoforms (16). Early dipole moment studies of benzene solutions suggested that Se_2Cl_2 may also have a pyramidal form (17) but these observations are probably accounted for by the presence of equilibrium amounts of $SeCl_2$, Se_3Cl_2, and Se_4Cl_2 in these solutions (6) and all the evidence supports a chain structure for this molecule (8, 18). Seleninyl chloride, $SeOCl_2$, has a pyramidal form (19) but this work has shown that $SeSCl_2$, prepared by equilibration of S_2Cl_2 and Se_2Cl_2 mixtures, has a chain structure. No evidence for the pyramidal isomers was found even after long periods of heating. While oxygen is often found in terminal positions in compounds and ions, sulfur commonly gives catenated structures and, due to the similar electronegativity of S and Se, $SeSCl_2$ adopts the chain structure, ClSeSCl.

The observation of eight strong signals in the Se(I) part of the ^{77}Se NMR spectrum of a 1:1 molar mixture of Se_2Br_2 and S_2Cl_2 is consistent with the chain structure for all dichalcogen dihalides, Ch_2X_2 (Ch = Se, S; X = Cl, Br). The greater width at half-height of the diselenium dihalide signals indicates more rapid halide exchange for these compounds than for the selenium sulfur dihalides (13) and, by extension of this trend, than for the disulfur dihalides. This is expected, as a result of the weaker halogen bonding to Se (D(SeCl) = 243 kJ mol^{-1}) than to S (D(SCl) = 272 kJ mol^{-1}) (20). The integrated peak intensities show that the combination of Se—Br and S—Cl bonding is favoured over that of Se—Cl and S—Br bonding, indicating that for chalcogen–halogen bonds, overlap of atomic orbitals of like principal quantum number leads to stronger bonding than with unlike principal quantum number.

The ^{77}Se chemical shifts of catenated selenium alkyls (15) and perhaloalkyl derivatives (7) have been interpreted in terms of changes in shielding due to electronegativity changes in the group of atoms bonded to Se (7) and β- and γ-effects (15). Both electronegativity and β-effects are observed for the simple selenium and selenium sulfur dihalides. The greater electronegativity of the directly attached atoms leads to greater ^{77}Se deshielding while increased polarizability of the next nearest neighbour causes increased deshielding of Se.

NOTE ADDED IN PROOF: Since the acceptance of this manuscript, a paper dealing with the characterization of $SeSCl_2$ has come to my attention (Raman, mass and ^{77}Se NMR spectra of $SeSCl_2$ and its reactions with potassium iodide and titanocene pentasulfide to produce cyclic selenium

sulfides. R. Steudel, B. Plinke, D. Jensen, and F. Baumgart, Polyhedron, **10**, 1037 (1991)). There is good agreement between the two reports with respect to the interpretation and the actual measured chemical shifts and frequencies. Some discrepancies arise, however, in the assignment of the signals that appear to the higher chemical shift side of the Se_2Cl_2 signal (1305–1350 ppm).

Long-range shielding and NMR chemical shifts in silicon carbide polytypes

DEQI GUO, J. STEPHEN HARTMAN,[1] AND MARY FRANCES RICHARDSON[1]
Department of Chemistry, Brock University, St. Catharines, Ont. Canada L2S 3A1

Received July 30, 1991

This paper is dedicated to the memory of Professor Thomas Birchall

DEQI GUO, J. STEPHEN HARTMAN, and MARY FRANCES RICHARDSON. Can. J. Chem. **70**, 700 (1992).

Despite an apparently successful empirical correlation, it is incorrect to ascribe variations in ^{29}Si and ^{13}C chemical shifts in silicon carbide polytypes to diamagnetic anisotropy effects.

Key words: silicon carbide, long-range shielding, polytypism, MAS NMR.

DEQI GUO, J. STEPHEN HARTMAN et MARY FRANCES RICHARDSON. Can. J. Chem. **70**, 700 (1992).

L'attribution des variations des déplacements chimiques du ^{29}Si et du ^{13}C dans les polytypes de carbure de silicium à l'effet anisotropique diamagnétique est inexacte en dépit du succès apparent de la corrélation empirique.

Mots clés : carbure de silicium, blindage à longue distance, polytypisme, MAS RMN.

Silicon carbide, an important industrial material (1), is known for its remarkable display of polytypism. There are more than 200 known polytypes, which are characterized by having identical Si—C double layers arranged in different stacking sequences (2, 3). Since our initial work on the distinctive ^{29}Si and ^{13}C Magic Angle Spinning (MAS) NMR spectra of the 6H, 3C, and 15R polytypes (4, 5), NMR has become an important characterization tool for silicon carbide (6). All polytypes so far studied other than 3C and 2H, which have only a single silicon (and carbon) site, show several peaks in their MAS NMR spectra (4, 5, 7–9) despite the fact that the immediate-neighbour tetrahedron in SiC is essentially identical for all sites (10). We (4, 5) and others (7, 11) showed that the number of peaks could be correlated with the number and geometrical arrangement of higher neighbours. However, peaks could not be readily assigned to particular atoms in the structures. We undertook the present work as a possible approach to SiC peak assignments.

Calculations

McConnell (12) expressed the relationship between the chemical shielding increment $\Delta\sigma$ and the molar diamagnetic anisotropy $\Delta\chi$ of distant (cylindrically symmetrical) bonds as:

$$[1] \quad \Delta\sigma = \Delta\chi[(1 - 3\cos^2\theta)/3R^3]$$

where $\Delta\chi$ is the difference between the susceptibility parallel to the bond and the susceptibility perpendicular to it, R is the distance between the nucleus of interest and the electrical center of gravity of the distant bond, and θ is the angle between the vector R and the bond vector (Fig. 1).

Expansion of eq. [1] to include all contributions within a certain distance from a central atom gives the shielding increment for that atom:

$$[2] \quad \Delta\sigma = \Delta\chi(G_j)$$

$$[3] \quad G_j = \sum_n [(1 - 3\cos^2\theta_n)/3R_n^3]$$

The chemical shift, in ppm to low field of a reference compound, is related to the shielding by $\delta_{sample} = \sigma_{reference} - \sigma_{sample}$, and can be divided into local and long-range parts, so that

$$[4] \quad \delta_{X(j)} = \delta_i^X - \Delta\chi(G_j)$$

where $\delta_{X(j)}$ is the overall chemical shift of atom $X(j)$ in the structure, δ_i^X is the "intrinsic" chemical shift, i.e., the shift that atom X would have if it were bonded only to its four neighbours, and $(\Delta\chi)(G_j)$ represents the chemical shift due to long-range shielding because of the diamagnetic susceptibility of chemical bonds. G_j, the geometric factor, is a term dependent only upon the crystal structure and the location of the electrical centre of gravity for the bonds, initially taken at the midpoint. The sum is over all bonds n out to a certain radius. Equation [4] allows a value of $\Delta\chi$ to be calculated explicitly and compared to experimental values.

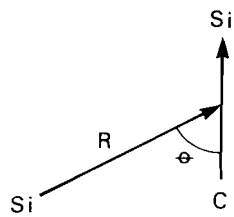

FIG. 1. Definition of parameters used in the McConnell equation for calculating the shielding increment induced by a distant bond.

Bonds to nearest neighbours were eliminated from the sum, both because the point dipole approximation is not valid at such short ranges (12) and because the nearest-neighbour effects are assumed to be accounted for in the intrinsic shift terms. Each crystallographically independent atom in the structure produces an equation. Once the chemical shifts are assigned to particular atoms in the structure, it is straightforward to carry out a least-squares fit to a series of equations and determine $\Delta\chi$ and the intrinsic chemical shifts for carbon and silicon in these structures (13).

Results and discussion

Figure 2 shows typical convergence behaviour for eq. [3] as a function of distance from the central atom. Convergence is barely achieved at a distance of 50 Å: the slowness of convergence is due to the fact that although there is an R^{-3}

[1]Authors to whom correspondence may be addressed.

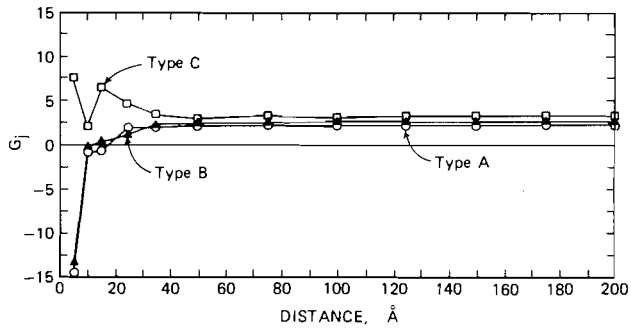

FIG. 2. Convergence behavior of the geometric factor G_j as a function of distance from the central atom for the Types A, B, and C atoms in 6H SiC. The types (5) correspond to the independent atoms.

dependence for the shielding due to one bond, the number of bonds increases as R^3. Others (14) have also noted the necessity of extending calculations out to at least 50 Å in McConnell-type calculations.

The geometric factors for the three independent silicons and carbons in 6H SiC have distinct values (Fig. 2). If these are assigned to the three peaks in the ^{29}Si and ^{13}C NMR spectra of 6H SiC in such a way that the chemical shift is to low field as G_j increases, least-squares solution of eq. [4] yields values of 97.8×10^{-33} m^3/bond (7.78×10^3 ppm A^3/bond) for $\Delta\chi$, and 0.79 and 40.13 ppm for the intrinsic chemical shifts of silicon and carbon, respectively. The intrinsic shifts are in reasonable agreement with the ^{29}Si shift in tetramethylsilane (0 ppm) and the ^{13}C shift of the central carbon in $(Me_3Si)_4C$ (77 ppm relative to TMS) (15). However, the value of $\Delta\chi$ for an Si—C bond is nearly three orders of magnitude larger than the usual values for single bonds (16). In other words, if $\Delta\chi$ for an Si—C bond has a magnitude similar to those for C—H or C—C bonds, the long-range shielding effect should amount to no more than a few tenths of a part per million, an amount similar to that observed, for example, in aryl ethers (17). Variations in the formulation of the long-range shielding (13), e.g., changing the peak assignments, moving the electrical centre of gravity, and shifting the layers (which changes the bond distances), do not alleviate the problem.

The unreasonable $\Delta\chi$ value (7.78×10^3 ppm/A^3) for the Si—C bond shows that long-range diamagnetic shielding cannot be the origin of the variation in ^{29}Si and ^{13}C chemical shifts in SiC polytypes. Furthermore, our recent work on chemical shift tensors for the 6H polytype (18) yielded firm peak assignments that are inconsistent with those based on long-range diamagnetic shielding. The results of the present calculations are consistent with the usual predominance of paramagnetic contributions to the shielding, arising from nonspherical electron density about an atom and calculated from orbital overlaps between a central atom and its successive neighbors (16). Diamagnetic shielding effects normally are a major factor only in ^{1}H NMR (e.g., ref. 19).

Sherriff has carried out diamagnetic shielding calculations based on the McConnell equation, which have successfully correlated ^{29}Si chemical shifts of a wide range of silicate minerals (20). The practical utility of this approach to calculating silicate chemical shifts is undeniable, and it can be applied to Al,Si order/disorder problems (20) and extended from the usual four-coordinate silicon to the relatively rare six-coordinate silicon in silicates (21). However, neighbour anisotropy effects on diamagnetic shielding, which are inherently long range in network solids, cannot be the true basis of the success of these calculations, which deal with atoms only out to the second-neighbour positions. The success may be attributable to an accidental modelling of a paramagnetic contribution to chemical shift, with similar geometric form but falling off much more rapidly with distance. The $\Delta\chi$ for the Si—O bond (20) (-701.6 ppm/A^3, orders of magnitude larger than expected for diamagnetic shielding) seems consistent with inadvertent modelling of a large paramagnetic shielding term.

NMR is potentially more sensitive than X-ray diffraction to local environment (22, 23), and is the analytical tool of choice for amorphous or disordered solids. Thus correlations of the chemical shift with easily calculated structure-dependent functions are becoming increasingly important. However, the diamagnetic shielding term is not the major factor in network solids such as silicon carbide and silicates. Further work is needed to elucidate the factors affecting chemical shift in systems such as these.

NEIL BURFORD, TRENTON M. PARKS, BRUCE W. ROYAN, JOHN F. RICHARDSON, and PETER S. WHITE. Can. J. Chem. **70**, 703 (1992).

Tetrachloroaluminate salts of the benzothiazarsolium and toluodithiarsolium heteronaphthalenic cations have been prepared from the corresponding chloroarsoles by a routine halide ion abstraction procedure. Characterization data are presented, including the X-ray crystal structure of the thiaza derivative. (Crystal data for $C_6H_5AlAsCl_4NS$: monoclinic, space group $P2_1/c$, a = 6.4259(5) Å, b = 23.654(3) Å, c = 8.5859(7) Å, β = 98.203(6)°, V = 1291.7(2) Å^3, Z = 4, R = 0.054.) A planar bicyclic cationic unit is observed, typical of other heteronaphthalenic systems. The crystal structure of 2-chlorobenzo-1,3,2-thiazarsole has been obtained for direct comparison, and also has a close to planar heterobicyclic moiety. (Crystal data for $C_6H_5AsClNS$: monoclinic, space group $P2_1/c$, a = 8.370(3) Å, b = 10.829(3) Å, c = 8.756(2) Å, β = 95.99(2)°, V = 789.2(3) Å^3, Z = 4, R = 0.025.) The planarity and short heterocyclic bond lengths observed in the two compounds imply a significant degree of $p\pi$ bonding, which is unique between sulfur and arsenic. In addition, the cation is a rare example of a structurally characterized cationic dicoordinate arsenic, or arsenium, system.

Key words: arsenic, arsolium, arsenium, $p\pi$-bonding, sulfur, heteronaphthalenic.

NEIL BURFORD, TRENTON M. PARKS, BRUCE W. ROYAN, JOHN F. RICHARDSON et PETER S. WHITE. Can. J. Chem. **70**, 703 (1992).

On a préparé les tétrachloroaluminates des cations hétéronaphtaléniques benzothiazarsolium et toluodithiarsolium en faisant appel à une méthode de routine pour enlever un ion halogénure des chloroarsoles correspondants. On présente les données ayant servi à leur caractérisation, y compris la structure cristalline du dérivé thiaza. (Données cristallographiques du $C_6H_5AlAsCl_4NS$: monoclinique, groupe d'espace $P2_1/c$, a = 6,4259(5), b = 23,654(3) et c = 8,5859(5) Å, β = 98,203(6)°, V = 1291,7(2) Å^3, Z = 4 et R = 0,054.) On a observé la présence d'une unité cationique bicyclique plane, typique d'autres systèmes hétéronaphtaléniques. On a obtenu la structure cristalline du 2-chlorobenzo-1,3,2-thiazarsole par une comparaison directe; elle comporte aussi une portion hétérobicyclique pratiquement plane. (Données cristallographiques du $C_6H_5AsClNS$: monoclinique, groupe d'espace $P2_1/c$, a = 8,370(3), b = 10,829(3) et c = 8,756(2) Å, β = 95,99(2)°, V = 789,2(3) Å^3, Z = 4 et R = 0,025.) Le fait que, dans les deux molécules, la structure est plane et les longueurs des liaisons hétérocycliques sont courtes implique l'existence d'une liaison $p\pi$ importante, mais unique, entre le soufre et l'arsenic. De plus, le cation est un rare exemple d'un système cationique dicoordonné de l'arsenic, ou arsénium, à être caractérisé d'un point de vue structurel.

Mots clés : arsenic, arsolium, arsénium, liaison $p\pi$, soufre, hétéronaphtalénique.

Introduction

Compounds containing multiple bonds between heavier non-metal elements are now commonplace. While they represent experimentally confirmed contradictions of the "Double Bond Rule",[3] a variety of synthetic innovations are responsible for this significant fundamental development, the most common being steric shielding (2). Nevertheless, $p\pi$ bonding is by no means general throughout the p-block, with the restricted valency and coordination of the more electron-rich elements requiring alternative structural or electronic features to support incorporation into a $p\pi$-bonded system (see, for example, ref. 3).

We recently introduced the cationic heteronaphthalenic framework **1** as a versatile template for the construction of new $p\pi$ bonded units involving pnicogens and chalcogens, including systems containing the first examples of stable $p\pi$ bonding between phosphorus and sulfur (4–6). Compounds of this type apparently benefit from the stabilization associated with accommodation of a Hückel number of π-electrons as well as the molecular positive charge. Here we present the 1,3,2-benzothiazarsolium (**2**) (for a preliminary communication of this work, see ref. 7) and 5-methyl-1,3,2-benzodithiarsolium (**3**) (preliminary communication, ref. 8) cations as the first examples of stable systems containing arsenic–sulfur $p\pi$ bonding. This is illustrated in the crystal structure of **2**$AlCl_4$ and by an inter-

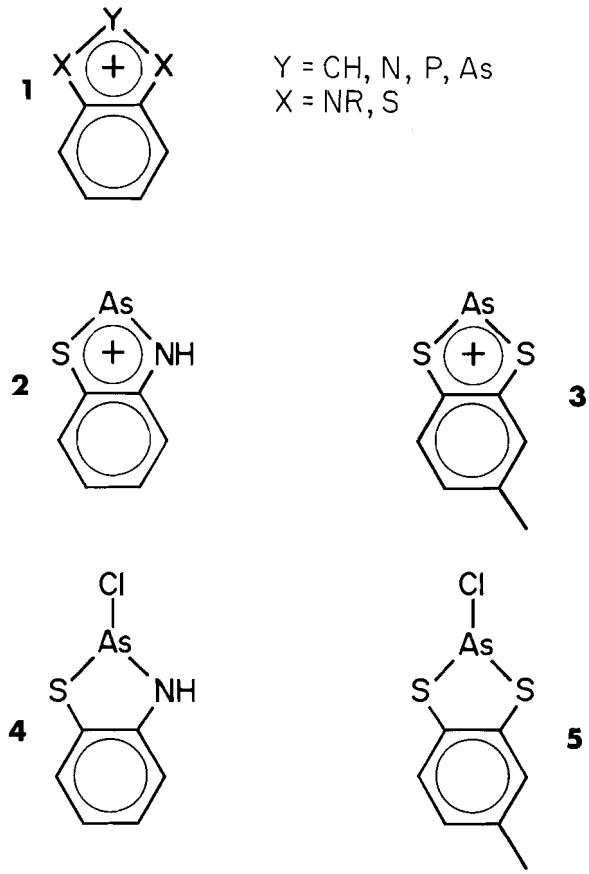
esting comparison with the structure of the corresponding 2-chloroarsole **4**.



Experimental

General procedures

All compounds reported here are extremely moisture sensitive and are handled under rigorously anaerobic and anhydrous conditions. $AsCl_3$ (AESAR) and Et_3N (BDH) were distilled under N_2 before use. $AlCl_3$ (Aldrich) was sublimed under vacuum before use. 3,4-Toluenedithiol (Aldrich) and *o*-aminothiophenol (Aldrich) were used as received. 2-Chloro-5-methyl-1,3,2-benzodithiarsole **5** was prepared by the literature procedure (9), with minor modifications. CH_2Cl_2 and hexane were dried over P_2O_5 and CaH_2 and stored in evacuated bulbs. $CDCl_3$ was dried over P_2O_5. Solids were manipulated in a Vacuum/Atmospheres nitrogen-filled glove box. Glass equipment was flame dried before use. Reactions were performed in an evacuated (10^{-3} Torr; 1 Torr = 133.3 Pa) dual compartment vessel,[4] unless otherwise indicated. Melting points were recorded on a Fisher–Johns apparatus and are uncorrected. Elemental analyses were performed by Beller Laboratories, Gottingen, Germany. IR spectra were recorded as Nujol mulls on CsI plates using a Perkin–Elmer 283B spectrophotometer. NMR spectra were recorded on a Nicolet NT-360 spectrometer in 5 or 10 mm flame-sealed Pyrex tubes. Chemical shifts are reported in ppm relative to external standards ($[Al(H_2O)_6]^{3+}$ for ^{27}Al) and relative to the internal solvent signal for ^1H and ^{13}C. Mass spectra were obtained by using a CEC model 21-104 mass spectrometer. Crystals suitable for crystallography were obtained as described in text for each compound, and were selected and mounted in Pyrex capillaries in the dry box.

[4]A modification of the H-tube reaction vessel described in ref. 10.

Preparation and characterization data

*$C_6H_4SN(H)AsCl$ **4***

A solution of $AsCl_3$ (1.08 g, 6.0 mmol) in Et_2O (15 mL) was added to a stirred mixture of *o*-aminothiophenol (0.75 g, 6.0 mmol) and Et_3N (1.21 g, 12.0 mmol) in Et_2O (20 mL), and the mixture was stirred at room temperature for 3 h. A yellow solution was decanted from the white precipitate and the solvent was removed *in vacuo* to leave a bright yellow solid, which was recrystallized from CH_2Cl_2 to give yellow/orange crystals of 2-chlorobenzo-1,3,2-thiazarsole (0.92 g, 3.9 mmol, 65%), mp 135–137°C. IR: 3290m, 1450s, 1355m, 1300m, 1250m, 1020m, 850m, 740vs, 580m, 555m, 460m, 420s, 290m, 230vs cm^{-1}. NMR, ^1H: 753–6.99 ppm (ABCD), 6.6 ppm (NH); ^{13}C: 147, 126, 126, 124, 121, 115 ppm. Anal. calcd.: C 30.85, H 2.16, N 6.00%; found: C 30.63, H 2.19, N 5.91%.

*$[C_6H_4SN(H)As]$ **2** $[AlCl_4]$*

A solution of 2-chlorobenzo-1,3,2-thiazarsole (0.332 g, 1.42 mmol) in CH_2Cl_2 (40 g) was added dropwise to a stirred suspension of $AlCl_3$ (0.193 g, 1.45 mmol) in CH_2Cl_2 (40 g) over a period of 25 min. A deep yellow solution initially formed and later produced a bright yellow microcrystalline precipitate. The solution was decanted and the solid was washed by two cold-spot back distillations, and characterized as benzo-1,3,2-thiazarsolium tetrachloroaluminate (0.391 g, 1.07 mmol, 75%), mp 135–137°C. Recrystallization from a dilute CH_2Cl_2 solution by slow removal of solvent produced small pale yellow crystals suitable for crystallography. Larger, higher quality crystals were obtained from a concentrated reaction mixture by slow removal of solvent. IR: 3230m, 1555m, 1545m, 1245m, 1220m, 760vs, 720s, 710s, 540m, 530s, 505vs, 475vs, 450s, 290m cm^{-1}. NMR, ^1H: 8.40–7.60 ppm (ABCD), 8.4 ppm (NH); ^{13}C: 130, 128, 127, 119 ppm (quarternary carbons not observed). Anal. calcd.: C 19.64, H 1.38, N 3.82, S 8.74%; found: C 19.78, H 1.24, N 3.80, S 8.87%.

*$[CH_3C_6H_4S_2As]$ **3** $[AlCl_4]$*

5-Methylbenzo-1,3,2-dithiarsole (0.497 g, 1.88 mmol) in CH_2Cl_2 (25 mL) was added dropwise over 3 h to a vigorously stirred suspension of $AlCl_3$ (0.250 g, 1.88 mmol) in CH_2Cl_2 (25 mL). The red/orange reaction mixture was stirred for 14 h and the solvent was slowly removed until crystallization began. At this point the solid was redissolved and the reaction vessel cooled in an ice water/NaCl bath. A bright orange crystalline solid was isolated and characterized as 5-methylbenzo-1,3,2-dithiarsolium tetrachloroaluminate (0.262 g, 0.66 mmol, 35%), mp 121–123°C. IR: 820s, 540m, 510m, 485vs, 435m cm^{-1}. NMR, ^1H: 8.33 (d), 8.26 (s), 7.75 (d), 2.66 (s) ppm ($^3J_{HH}$ = 8.6 Hz); ^{13}C: 153, 150, 142, 131, 129, 128, 21 ppm. Anal. calcd.: C 21.13, H 1.52, S 16.11, As 18.83%; found: C 20.97, H 1.78, S 15.82, As 18.50%.

X-ray data collection, solution, and refinement

All pertinent crystallographic data are summarized in Table 1. Data were collected at room temperature on an Enraf–Nonius CAD-4 diffractometer (MoK_α, λ = 0.70930 Å, graphite monochromator) using the ω–2θ scan technique. No significant decay of three standard reflections was observed during data collection. Unit cell parameters were obtained from the setting angles of 25 accurately centred reflections. The choice of space groups was based on systematically absent reflections. Data were corrected for Lorentz and polarization effects. Scattering factors were taken from Cromer and Waber (11) and anomalous dispersion effects were included in F_c (12). An empirical absorption correction was applied for $C_6H_4SN(H)AsCl$ **4** based on a series of psi scans. The structures were solved using direct methods (13, 14) to find the heavier elements, and the remaining non-hydrogen atoms were located from a series of difference Fourier maps. Hydrogen atom positional parameters were refined in **4** and included in ideal positions as fixed contributions to the structure. In **2**$AlCl_4$ the thermal parameters for hydrogen atoms were not refined (B_{iso} = 1.2 × B of the bonded atom). The models were refined using full-matrix least-squares techniques based on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$,

$B(iso)$ is the mean of the principal axes of the thermal ellipsoid.

where $w = [\sigma(F)^2 + (0.005F)^2 + 0.4]^{-1}$ for compound **4** (15), and was derived from counter statistics for **2**$AlCl_4$. Positional and isotropic thermal parameters are given in Tables 2 and 3 and selected bond lengths and angles are given in Table 4. Supplementary material (anisotropic thermal parameters and structure factors, 27 pages) is available.[5]

Results and discussion

Preparation and characterization of benzothiarsolium cations

The halide ion abstraction reaction is widely used in inorganic synthesis and has been exploited in the development of non-metal cations. Convenient reagents and high yields (essentially quantitative) are the principal advantages, although the non-metal salts are generally extremely reactive. The new arsolium cations are typical examples. The haloarsoles **4** and **5** react rapidly with $AlCl_3$[6] to give the corresponding tetrachloroaluminate salts of **2** and **3**. As for the phosphorus analogs, good yields and ease of isolation of the salts are only possible if the haloarsole is kept at a low concentration with respect to the acid during the reaction to

[5]These tables may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

[6]A number of halide ion abstracting agents have been employed and found to react; however, the products have proven difficult to isolate and characterize.

prevent aromatic substitution of the benzo moiety by the solvent (5).

The new arsolium salts have been characterized by the usual techniques and exhibit familiar spectroscopic features. A strong absorption around 485 cm^{-1} is observed in the IR spectra and is characteristic of the ν_3 vibration of $AlCl_4^-$ (16). The ^1H and ^{13}C NMR data show a dramatic deshielding of the nuclei in the benzo unit in the cations **2** and **3** with respect to those of the precursor arsoles **4** and **5**. This is consistent with the values obtained for other derivatives of **1** (4–6), as well as those reported for benzo-1,3-dithiolium (17), benzo-1,3-thiazolium (18), and benzo-1,3,2-dithiazolium (19) cations, and can be attributed to effective delocalization of the positive charge throughout the bicyclic framework. A similar feature is observed for the chemical shift of the amine proton of **2** with respect to **4**. For the toluo derivatives **3** and **5**, a larger $^3J_{HH}$ (*ortho*) value is observed for the cation **3**, typical of a naphthalenic system (see, for example, ref. 20).

Structural features of the benzothiazarsolium unit (4 and 2AlCl₄)

2-Chloro-1,3,2-benzothiazarsole **4** exists as dimeric units in the solid state, and is isostructural with the phosphorus analog (6). An As_2Cl_2 parallelogram (As—Cl, 2.293(1) Å; As—Cl′, 3.3842(9) Å) links the two molecules, which are related by a crystallographic centre of inversion (Fig. 1). The heterobicyclic unit is almost planar with the arsenic centre only 0.1439(3) Å from the C_6SN plane, and is essentially perpendicular to the As_2Cl_2 unit. Similar halogen-bridged dimeric arrangements have been reported for a number of non-metal halide systems (e.g., PBr_4^- (21), $As_2I_8^{2-}$ (22), $ArSnCl^+$ (23), Ar_2SnCl^+ (24)), including the chloroarsines (^{t}BuN)(Me_2Si)(^{t}BuN)AsCl (25), and $C_4H_8N_2S \cdot AsCl_3$ (26). The dimer units of **4** are associated by hydrogen bonding between the amino protons and chlorine centres (Fig. 2).

Interestingly, 5-methyl-2-chloro-1,3,2-benzodithiarsole **5** (9), which is closely related to **4**, adopts a very different structure. The molecules are arranged in sheets (Fig. 3) and the contact distances between the molecular units (As—Cl′, 3.81 Å; S—Cl′, 3.69 Å) are substantially longer than those in the dimer of **4** [As—Cl′, 3.3842(9) Å, S—Cl′, 3.436(1) Å). Furthermore, the As—Cl bond (2.236(3) Å) is considerably shorter than the shortest of those in **4** (As—Cl, 2.293(1) Å), and the bicyclic unit is far from planar with the arsenic centre displaced from the C_6S_3 plane by 0.58 Å (cf. 0.1439(3) Å in **4**). As such, the molecular structure of **5** resembles that of the severely folded 5-methyl-2-phenyl-1,3,2-benzodithiaphosphole (4, 5).

1,3,2-Benzothiazarsolium **2** tetrachloroaluminate is isostructural with other structurally characterized derivatives of **1**$AlCl_4$ salts (4, 7). While discrete cationic and anionic units are evident, there are significant (Table 4) cation–anion interactions (distances within the sums of the respective van der Waals radii: As, 2.0; S, 1.8; N, 1.5; Cl, 1.8 Å (values from ref. 27)), consistent with the contact array observed for

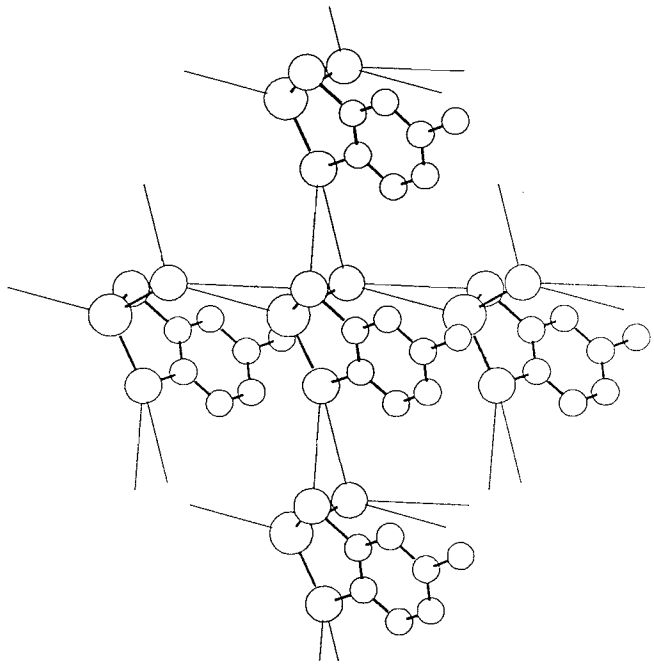

FIG. 3. PLUTO view of the molcular packing in compound **5**, generated from the data provided in ref. 9.

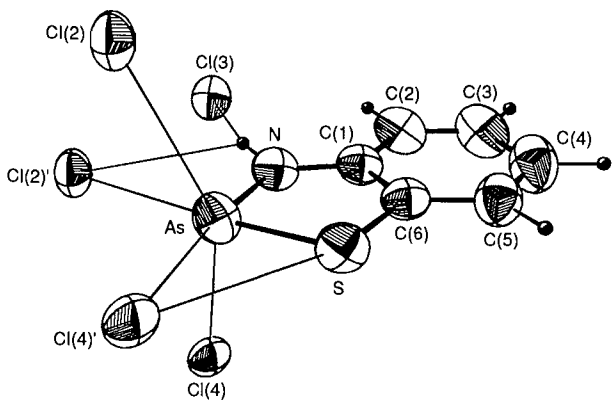

FIG. 4. ORTEP view of the cation **2** showing the cation–anion interactions involving the chlorine atoms of the $AlCl_4^-$ units.

the isostructural series, as illustrated for **2**$AlCl_4$ in Fig. 4. The contacts are similar in length and array to those reported for many Main Group cations (e.g., Ch_4^{2+}, Ch = S, Se, Te (28), which have been investigated theoretically and are envisaged as nucleophilic charge transfer interactions (29)). We believe that the magnitude of these interactions is small and their effect on the electronic structure of the cation is negligible. Identical structural features are observed within the cationic units of the tetrachloroaluminate salts of 1,3,2-benzodithiaphospholium (5) and 5-methyl-1,3,2-benzodithiaphospholium (30) despite their very different packing arrangements. This is corroborated by the regular tetrahedral geometry of the anion, which can be severely distorted in the presence of transition metal/arene cationic complexes (see, for example, refs. 24 and 31) and small polarizing cations, such as Li^+ (32).

The intermolecular interactions between the monomers in compound **4** (and those in the phosphorus analog (6)) can also be considered as contacts. Both Pn–Hal bonds are dramatically longer than standard covalent σ-bonds, and the longer bond (As—Cl′, 3.3842(9) Å) is comparable with the cation–anion interactions mentioned above. Moreover, each chlorine atom of **4** makes a secondary contact with the sulfur centre of the other molecule (3.436(1) Å), reminiscent of the same contact present in the isostructural series of **1**$AlCl_4$ (6) (S—Cl(4) in Fig. 4). On this basis, compound **4** may be regarded as partially ionic (6).

Cation **2** is planar, with a mean deviation of 0.020 Å and a maximum deviation from the best plane of 0.050(8) Å at C(4). The bonds within the heterocyclic moiety of the cation **2** (As—S, 2.1536(15) Å; As—N, 1.776(4) Å; C—S, 1.736(5) Å) are significantly shorter than those of compound **4** (As—S, 2.1991(8) Å; As—N, 1.795(3) Å; C—S, 1.755(3) Å) except for the C—N bonds, which are crystallographically identical. All of the bonds within the bicyclic units are shorter than the corresponding single bonds (As—S (for compilations of As—S bond lengths see refs. 33, 34): $(PhS)_3As$, 2.243(1) Å (35); *cyclo*-$(MeAsS)_{3or4}$: 2.19(2)–2.34(2) Å (36); As—N: (^{t}BuN)(Me_2Si)(^{t}BuN)AsCl, 1.832(3) Å (25); C—S: 1.80 Å (37); C—N: 1.47 Å (38)).

pπ *Bonding between arsenic and sulfur*

Structural studies on arsenic-sulfur compounds show a consistent As—S bond length (2.19–2.34 Å (33–36)), which is viewed as a single bond. A significantly shorter bond (2.173(3) Å) was observed in the $As_3S_4^+$ cation, and rationalized by means of a valence bond model involving a π-bonded resonance contributor (34). Cation **2** exhibits an even shorter As—S bond (2.1536(15) Å), and a dramatic shortening with respect to that of the arsine analog **4**. This bond length comparison is related to the relative planarity of the bicyclic unit in each compound (**2** and **4**), and indicates an enhancement of the heterocyclic π-structure in the cation, a rationale that is supported by ^{1}H and ^{13}C solution NMR (5, 6), MCD (39), and solid state NMR (40) spectroscopic results. This unique As–S π-interaction effects a similar bond shortening to that of the As—N π-interaction and the system shows no indication of As–N π-localization, consistent with the phosphorus analogs (6). Therefore, we conclude that within the heteronaphthalenic environment $4p$–$2p\pi$ bonding can coexist with $4p$–$3p\pi$ bonding.

The formation of the isolated cation **2** is made possible by the low basicity of the anion ($AlCl_4^-$). Nevertheless, the near planarity of the heterobicyclic unit of the neutral chlorothiazarsole **4**, the intermediacy of the bond lengths between those of the cation and typical single bonds, and the long As—Cl "covalent" (partially ionic) bond can also be interpreted in terms of a degree of heterocyclic π-bonding. Such features are completely consistent with the phosphorus analog (6) and are likely imposed by the inherent stability associated with the heteronaphthalenic (10π) framework, which is apparently competitive with the basicity of the chloride anion toward the cation **2** (consider the **2**Cl as the ionic alternative, and **4** as the covalent alternative). The dimeric arrangement is enforced by As–Cl and S–Cl contacts that resemble the anion–cation contacts in the salt and further validate the partial ionic model for the formally covalent chlorothiazarsole. With this in mind, the longer As—S bonds and more severely folded heterocycle observed in the di-

thiarsole **5** (9) can be interpeted in terms of a less effective S—As—S π-network, in comparison to the N—As—S π-network.

Coordinatively unsaturated arsenic centres

The development of π-chemistry for the heavier non-metal elements requires the consequential discovery of stable coordinatively unsaturated environments. Di- and mono-coordination have become common for phosphorus in recent years, and represent one of the most active areas of synthetic phosphorus chemistry. In contrast, systems containing monocoordinate arsenic are extremely rare (41) and dicoordinate arsenic environments are comparatively rare. Imitation of well-established dicoordinate phosphorus systems has provided examples of arsenes (2, 42), arsabenzenes (43), polyarsenides (44), and planar polyarsa homocyclic ligands (45). However, aside from the novel complexes $(C_5Me_5)_2As^+$ (46) and $[C_5Me_5(CO)_2Mn{=}As{=}Mn(CO)_2C_5Me_5]^+$ (47), the new cation **2** represents the first structural characterization of a system containing a dicoordinate cationic arsenium environment, a formal analog of the carbene unit. Phosphenium cations are well known and have an extensive chemistry (see, for example, ref. 48); however, structural studies on the corresponding arsenium systems (few examples have been reported, ref. 49) are limited, and examples have been shown to adopt dimeric structures, which allow for tri-coordination at arsenic (50). Identification of the novel cationic dicoordinate environment in **2** has been made possible by the stabilizing factors associated with the heteronaphthalenic framework (5).

Sulphur–nitrogen anions: ^{14}N and ^{15}N NMR investigations of the deprotonation of cyclic sulphur imides and sulphur–ammonia solutions

T. CHIVERS[1] AND K. J. SCHMIDT

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received June 11, 1991

This paper is dedicated to the memory of Professor Thomas Birchall

T. CHIVERS and K. J. SCHMIDT. Can. J. Chem. **70**, 710 (1992)

The following systems have been investigated by ^{14}N and (or)^{15}N NMR spectroscopy: (*a*) the deprotonation of S_7NH by *n*-BuLi, (*b*) solutions of S_8, S_7NH, 1,3- and 1,4-$S_6(NH)_2$, and K_2SN_2 in liquid ammonia, (*c*) the reaction of sodium azide with sulphur in hexamethylphosphoramide (HMPA), (*d*) the reactions of S_7NH and $S_4(NH)_4$ with potassium amide in liquid ammonia in various molar ratios, and (*e*) the reaction of $(NSCl)_3$ with potassium amide (1:6 molar ratio) in liquid ammonia. These investigations have provided an NMR characterization of the thermally unstable S_7N^- ($\delta^{15}N$ ca. −324 ppm) and $S_2N_2H^-$ ions ($\delta^{14}N$ +7 and −149 ppm, $^1J(^{14}N-^1H)$ 36 Hz, $^1J(^{15}N-H)$ 55 Hz, $^2J(^{15}N-^{15}N)$ 2.2 Hz) in liquid ammonia, demonstrated the existence of S_7N^-, in addition to $SSNSS^-$, as the major nitrogen-containing ingredient of sulphur–ammonia solutions (SAS), and confirmed the formation of the $SSNSS^-$, but not S_7N^-, from the reaction of sodium azide and sulphur in HMPA. Consistent with previous chemical investigations, the NMR data show that the S_7N^- and $S_2N_2H^-$ ions are thermally unstable with respect to the formation of $SSNSS^-$ and $S_3N_3^-$, respectively, in solution. Solutions of $S_4(NH)_4/4KNH_2$ or $(NSCl)_3/6KNH_2$ show the same two ^{14}N or ^{15}N NMR resonances at ca. +97 and −108 ppm as a solution of NSN^{2-} in liquid ammonia.

Key words: sulphur–nitrogen anions, nitrogen NMR, liquid ammonia.

T. CHIVERS et K. J. SCHMIDT. Can. J. Chem. **70**, 710 (1992)

Faisant appel à la RMN du ^{14}N et (ou) ^{15}N, on a étudié les systèmes suivants : (*a*) la déprotonation du S_7NH par le *n*-BuLi, (*b*) des solutions de S_8, de S_7NH, des 1,3- et 1,4-$(NH)_2S_6$ et du K_2SN_2 dans l'ammoniac liquide, (*c*) la réaction de l'azoture de sodium avec le soufre dans l'hexaméthylphosphoramide (HMPA), (*d*) les réactions du S_7NH et du $S_4(NH)_4$ avec l'amidure de sodium, dans l'ammoniac liquide, à divers rapports molaires et (*e*) la réaction du $(NSCl)_3$ avec l'amidure de potassium (rapport molaire 1 : 6) dans l'ammoniac liquide. Ces études ont permis (*a*) de caractériser par RMN les anions thermiquement instables S_7N^- (δ^{15} environ −324 ppm) et $S_2N_2H^-$ ($\delta^{14}N$ +7 et −149 ppm, $^1J(^{14}N-^1H)$ 36 Hz, $^1J(^{15}N-H)$ 55 Hz, $^2J(^{15}N-^{15}N)$ 2,2 Hz) dans l'ammoniac liquide; (*b*) de démontrer l'existence de l'ion S_7N^-, en plus de l'ion $SSNSS^-$, comme ingrédient majeur contenant de l'azote dans des solutions ammoniacales de soufre (SAS) et (*c*) de confirmer la formation de l'ion $SSNSS^-$, mais pas de l'ion S_7N^-, lors de la réaction de l'azoture de sodium et du soufre dans le HMPA. En accord avec les études chimiques antérieures, les données de la RMN montrent que les ions S_7N^- et $S_2H_2H^-$ sont thermiquement instables par rapport à la formation respectivement des ions $SSNSS^-$ et $S_3N_3^-$ en solution. En RMN du ^{14}N ou du ^{15}N, les solutions de $S_4(NH)_4/4KNH_2$ ou de $(NSCl)_3/6KNH_2$ présentent les mêmes résonances, à environ +97 et −108 ppm, qu'une solution de NSN^{2-} dans l'ammoniac liquide.

Mots clés : anions soufre–azote, RMN de l'azote, ammoniac liquide.

[Traduit par la rédaction]

Introduction

Investigations of binary sulphur–nitrogen (S-N) anions have contributed significantly to the development of S–N chemistry (1). The well-characterized examples include cyclic anions, $S_3N_3^-$ and $S_4N_5^-$ (2, 3), acyclic catenated anions, $SSNSS^-$ and $SSNS^-$ (4, 5), and the dianion NSN^{2-} (6). In addition, there are several S–N anions, e.g., $SNSNH^-$ and $SNSN^{2-}$, which are known only as (chelating) ligands in metal complexes (7, 8). The formation of these anions in solution has been inferred from the preparation of such metal complexes by the deprotonation of $S_4(NH)_4$ in the presence of a metal halide (9, 10). The thermally unstable anion S_7N^-, generated by the deprotonation of S_7NH (11), has also been characterized in metal complexes (12, 13) and its existence as a free anion in solution has been established by the isolation of alkyl (14) and trimethylsilyl (15) derivatives. The formation of the S_7N^- ion in sulphur–ammonia solutions (SAS) has also been the controversial subject of several recent investigations (16–18). Finally, the possible production of the S_2N^- ion from the electrochemical reduction (19) of $SNSS^-$ or the reaction of $SNSS^-$ with amide ion (20) has been suggested on the basis of UV–visible (19,20) and Raman spectroscopic evidence (20).

Several recent publications have demonstrated the value of ^{14}N NMR spectroscopy for monitoring the behavior of small S–N molecules or ions in solution (21–25). The large chemical shift differences (see Table 1) and relatively sharp resonances observed for S–N anions (24) provide a method of analysis for complex mixtures of these anions that is superior to alternatives such as UV–visible or Raman spectroscopy. The latter techniques suffer from the disadvantages of broad, overlapping absorption bands or photoinduced (laser light) decomposition of samples, respectively. As well, the ^{15}N NMR spectra of ^{15}N-enriched samples can provide useful structural information (through the observation of $^{15}N-^{15}N$ coupling) that is not available from the use of other spectroscopic methods (26).

In this investigation we have, therefore, applied the techniques of ^{14}N and ^{15}N NMR spectroscopy to monitor the deprotonation of the cyclic sulphur imides S_7NH, 1,3- and 1,4-$S_6(NH)_2$, and $S_4(NH)_4$, and the formation of S–N anions in SAS. The specific objectives were to (*a*) provide an NMR spectroscopic identification of the S_7N^-, $SNSNH^-$, $SNSN^{2-}$, and S_2N^- ions, (*b*) identify the major nitrogen-

TABLE 1. Nitrogen NMR parameters for S–N anions[a]

Anion	Solvent	Nucleus[b]	δ (ppm)[c]	$\nu_{1/2}$ (Hz)[d]
S_7N^-	NH_3(l)	14	−324	280
S_7N^-	THF[e]	15	−319	
$S_4N_5^-$	NH_3(l)	14	−326 (1 N)	160
		14	−240 (4 N)	130
$S_3N_3^-$	NH_3(l)	14	−230	110
$S_3N_3^-$	CH_3CN	14	−230	180
$S_2N_2H^-$	NH_3(l)	14	−149 (1 N)[f]	80
			+7 (1 N)	110
$S_2N_2H^-$	NH_3(l)	15	−148 (1 N)[g]	4
			+9 (1 N)[h]	4
SN_2H^-	NH_3(l)	14	−107[i]	400
SN_2^{2-}	NH_3(l)	14	+98[i]	200
S_4N^-	THF	14	+106	280
S_4N^-	HMPA	15	+107	
S_4N^-	CH_3CN	14	+107	148
S_4N^-	NH_3(l)	14	+107	110
S_3N^-	NH_3(l)	14	+230	110
S_3N^-	CH_3CN	14	+235	180

[c]Relative to $MeNO_2$(l); positive shifts are to high frequency.
[d]Linewidth at half-height.
[e]At −80°C.
[f]Doublet, $^1J(^{14}N-^1H)$ = 36 Hz.
[g]Doublet, $^1J(^{15}N-^1H)$ = 55 Hz.
[h]Doublet, $^2J(^{15}N-^{15}N)$ = 2.2 Hz.
[i]The assignment of this resonance is tentative, see text for discussion.

containing species in SAS, and (*c*) seek evidence for the existence of novel binary S–N anions that might subsequently be the target of a synthetic investigation (for preliminary communications, see ref. 27). As a prelude to our studies of the deprotonation of cyclic sulphur imides, the ^1H, ^{14}N, and ^{15}N NMR chemical shifts and coupling constants ($^1J(^{15}N-^1H)$) of these ring systems were determined (28).

Experimental

Reagents

The following reagents were prepared by the literature procedures: S_7NH (29), $S_5(NH)_3$ isomers, $S_6(NH)_2$ isomers (30), $S_4(NH)_4$ (31), $PNP^+S_4N^-$(PNP = $(Ph_3P)_2N$) (32), $(NSCl)_3$ (33), $K_2(N_2S)$ (6), 50% ^{15}N-enriched S_7NH (34), and 99% ^{15}N-enriched S_4N_4 (35) (which was converted to $S_4(^{15}NH)_4$ by reduction with $SnCl_2 \cdot 2H_2O$ in 1,2-dichloroethane/methanol) (31).

The following commercial reagents were used as received: *n*-butyllithium in hexanes (2.1 M, Aldrich), potassium amide (ROC/RIC), sodium azide (95% ^{15}N-enriched in one terminal position) and NH_4Cl (99% ^{15}N-enriched) (Stohler Isotopes), PPh_3 (Fisher), and S_8 (sublimed, Fisher). Liquid ammonia and hexamethylphosphoric triamide (HMPA) were distilled from sodium before use. Acetonitrile and DMF were purified as described previously (24).

Instrumentation

NMR spectra were obtained on Bruker AM-400 and AMX-500 standard-bore spectrometers and on a Bruker AM-400 wide-bore instrument. The ^{14}N NMR experiments on the 400 MHz spectrometers were carried out at 28.915 MHz using 12-bit digitizers. Samples in organic solvents were investigated by using a broadband probe and 10 mm NMR tubes.

Samples using NH_3(l) as a solvent required the use of NMR tubes made from thick-walled (1.5 mm) 10 mm o.d. glass tubing, narrowing to $\frac{1}{4}$-in. standard wall tubing at the open end. The solvents were transferred onto samples already in the tubes by using a vacuum line equipped with Teflon J. Young valves. Connections between the tubes and the vacuum line (which was also fitted with $\frac{1}{4}$-in. tubing) were made with valves that used Swagelok connectors containing $\frac{1}{4}$-in. Teflon ferrules. When the appropriate amount of solvent had been transferred into the tube, the solvents were cooled to −196°C, and the tubes were then flame-sealed (in the upper $\frac{1}{4}$-in. section) under vacuum.

Typical acquisition parameters were an acquisition time (AQ) of 0.07 s, a pulse length (PW) of 20 μs (ca. 90° pulse), a relaxation delay (RD) of zero, a sweep width (SW) of 30 000 Hz, and a data collection size (TD) of 4 K (zero-filled to 16 K before transformation). In all cases at least 3000 scans were collected, and most samples were run unlocked. The signal from dissolved N_2 gas ($\delta^{14}N$ −71.5 ppm relative to $MeNO_2$(l) at 0 ppm) (35) was used as an internal standard for all ^{14}N spectra, except for the NH_3(l) samples for which the ammonia signal was used as an internal reference. Care must be taken when using NH_3(l) as a reference if large amounts of NH_4^+ cations are present, since the rapid H^+ exchange between NH_3 and NH_4^+ can significantly alter the ^{14}N chemical shift of NH_3. In this case, external referencing is preferred.

The SAS samples were prepared in 10 mm thick-walled tubes, as described above, and their ^{14}N NMR spectra were obtained at 36.14 MHz on a Bruker AMX-500 spectrometer equipped with a 16-bit digitizer and a 10 mm broadband probe. The acquisition parameters were AQ = 0.13 s, PW = 40 μs (ca. 90° pulse), RD = zero, SW = 30 000 Hz, and TD = 8 K (zero-filled to 64 K before transforming).

The ^{15}N NMR spectra were acquired at 40.557 MHz on the 400 MHz spectrometers. Natural abundance spectra were run on an AM-400 wide-bore spectrometer using a 20 mm broadband probe (total sample volume ca. 12 mL) and acetone-d_6 inserts to obtain a lock. ^{15}N-enriched samples in NH_3(l) were made up as described above and were sealed in thick-walled 16 mm tubes, which were then mounted coaxially within 20 mm tubes containing D_2O to provide a lock signal. The AM-400 wide bore spectrometer and the 20 mm broadband probe were used to obtain these spectra. The acquisition parameters for this spectrometer were PW = 40 μs (ca. 45° pulse), RD = 2.5 s for natural abundance ^{15}N, or RD = 30 s for enriched ^{15}N in NH_3(l), SW = 25 000 Hz, TD = 16 K (zero-filled to 64 K).

The ^{15}N enriched samples in solvents other than NH_3(l) were run on the AM-400 standard-bore spectrometer in 10 mm tubes (D_2O inserts for lock) using a broadband probe and a PW = 16 μs (ca. 45° pulse), RD = 30 s, SW = 35 000 Hz, TD = 16 K (zero-filled to 32 K).

All ^{14}N and ^{15}N NMR chemical shifts are reported with reference to $MeNO_2$(l) at 0 ppm using the downfield positive convention. The ^{14}N and (or) ^{15}N NMR parameters for the S-N anions studied in this investigation are summarized in Table 1.

Results and discussion

NMR characterization of the S_7N^- ion

A variety of bases, including Ph_3CNa (36), Na (14*a*), NaH (14*a*), LiOH (14*a*), KOH (15), *n*-Bu_4NOH (11), EtLi (14*a*), *n*-BuLi (37), $Ph_3P{=}CH_2$ (10), $NaNH_2$ (14*a*), and liquid ammonia (17, 20) have been used for the deprotonation of S_7NH. The available evidence indicates that the yellow S_7N^- ion is thermally stable below −50°C in THF (11, 15), but it decomposes to give the blue $SSNSS^-$ ion above this temperature (11). Consequently, the combination of a base and solvent that remains mobile below −60°C was deemed to be necessary for the NMR characterization of S_7N^-. The use of *n*-BuLi in THF proved to be suitable for this purpose. The initial experiments employed ^{15}N NMR spectroscopy in order to obtain narrow resonances. As indicated in Fig. 1*a*, the natural abundance ^{15}N NMR spectrum of a 1 M solution of S_7NH in THF at −80°C shows a doublet ($^1J(^{15}N-^1H)$ 94 Hz)

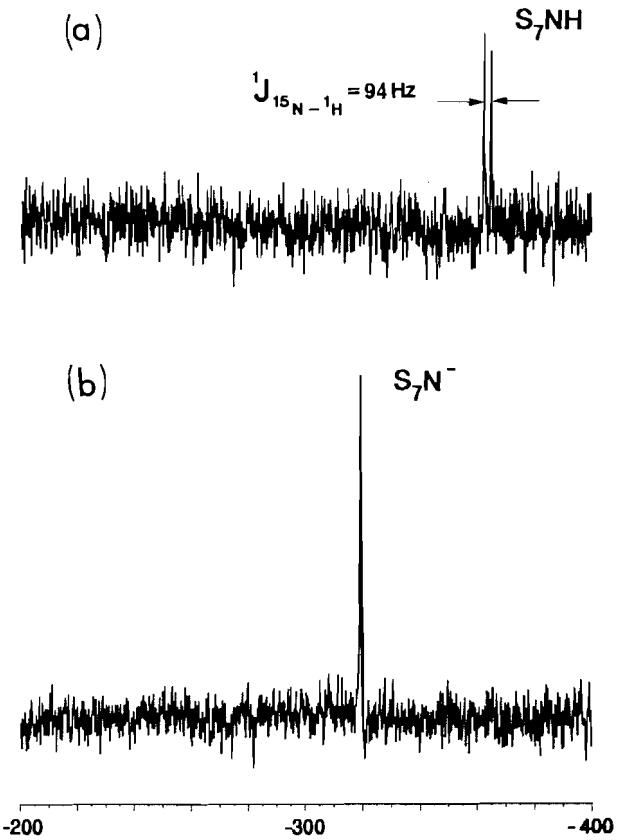

FIG. 1. The ^{15}N NMR spectra (natural abundance) of (*a*) a 1 M solution of S_7NH in THF at −80°C (2.5 h acquisition); (*b*) the same solution at −80°C after the addition of an equimolar amount of Bu^{n}Li in hexane (2 h acquisition).

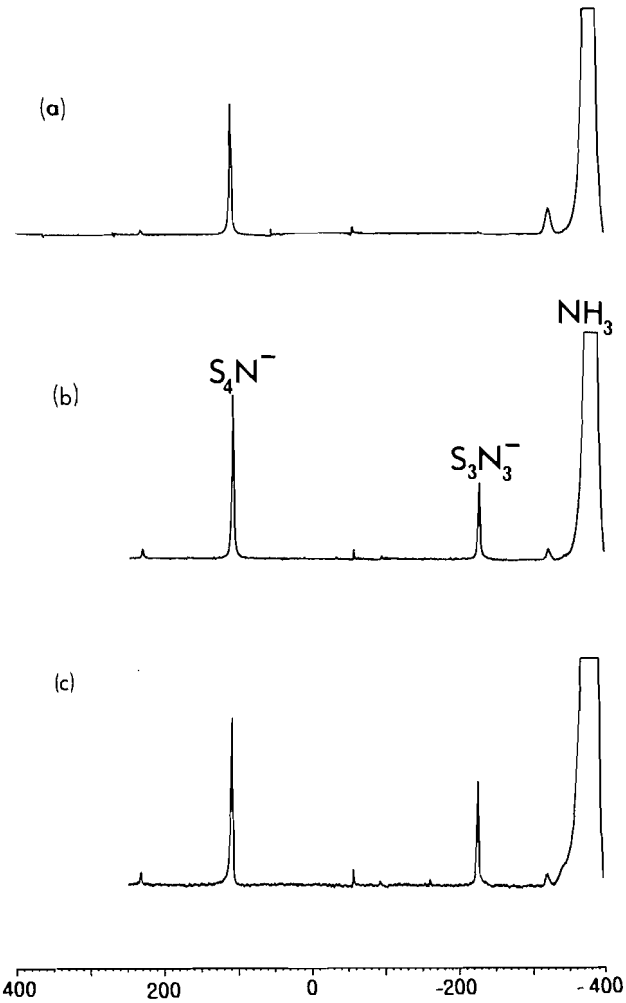

FIG. 2. The ^{14}N NMR spectra of (*a*) a ca. 0.2 M solution of S_7NH in NH_3(l) after 4 h; (*b*) a ca. 0.2 M solution of 1,4-$S_6(NH)_2$ in NH_3(l) after 4 h, (*c*) a 0.2 M solution of 1,3-$S_6(NH)_2$ in NH_3(l) after 3 h.

at −364 ppm. Upon addition of an equimolar amount of Bu^{n}Li in hexane to this solution at −80°C, this doublet disappears completely and instead a singlet at −318.8 ppm is observed (Fig. 1*b*). At this temperature the solution is yellow and there is no evidence for the formation of $SSNSS^-$ ($\delta^{15}N$ +106 ppm) (24). No other resonances are observed with the exception of that of dissolved N_2 at −71.5 ppm (35). Consequently, we assign the resonance at −318.8 ppm to the S_7N^- anion.

We also investigated the deprotonation of S_7NH with *n*-BuLi by ^{14}N NMR spectroscopy. At −80°C the ^{14}N NMR resonance for S_7N^- (generated from S_7NH and Bu^{n}Li) was very broad. However, at 25°C a resonance at ca. −327 ppm ($\nu_{1/2} \sim 1000$ Hz) was observed in addition to the signal for $SSNSS^-$ at +106 ppm. The S_7N^- ion is unexpectedly stable at room temperature in this system. The intensities of the NMR signals for S_7N^- and $SSNSS^-$ are approximately equal after 1 day and an appreciable amount of S_7N^- remains after 1 week. A third weak resonance at −134 ppm, which does not correspond to any known S–N anion (24), was also observed at 25°C.

^{14}N NMR spectra of solutions of S_7NH in liquid ammonia

A solution of S_7NH in liquid ammonia exhibits an UV absorption band at 256 nm (attributed to S_7N^-) with a wide tail extending to 600 nm (17, 20). After 2 h at −35°C this absorption decreases in intensity and bands in the visible region attributed to the formation of $SSNSS^-$(λ_{max} 578 nm) and $SSNS^-$ (λ_{max} 462 nm) are observed (17, 20). The formation of $SSNSS^-$ was confirmed by Raman spectroscopy (20). On the basis of the UV–visible and Raman spectroscopic data, Lelieur and co-workers proposed that the disproportionation of S_7N^- generated in this way is complete and produces $SSNSS^-$ and a neutral sulphur species formulated as S_{am} (am = NH_3) (20).

During the course of this work Woollins and co-workers reported that a solution of S_7NH in NH_3(l) gives rise to ^{14}N NMR signals at 104 ($\nu_{1/2}$ 120 Hz), −232 ($\nu_{1/2}$ 100 Hz), −331 ($\nu_{1/2}$ 440 Hz), and −401 ppm ($\nu_{1/2}$ 500 Hz) in the approximate percentages (sic) 50:20:20:20, which they attribute to $SSNSS^-$, $S_3N_3^-$, S_7NH, and an unidentified species, respectively (25, 38). In the light of our NMR characterization of the S_7N^- ion, we have investigated the S_7NH–NH_3(l) system by ^{14}N NMR spectroscopy in order to monitor the formation of S–N anions and identify them. The ^{14}N NMR spectrum of a deep blue solution of S_7NH in liquid ammonia after 4 h at 25°C (Fig. 2*a*) shows a major resonance attributed to $SSNSS^-$ at +107 Hz ($\nu_{1/2}$ 110 Hz), a weaker resonance at −324 ppm ($\nu_{1/2}$ 270 Hz), which we assign to the S_7N^- ion rather than S_7NH (*vide supra*), and *very weak* signals at −230 ($\nu_{1/2}$ 100 Hz), −34 ($\nu_{1/2}$ 60 Hz), and

For personal use only.

+228 ppm ($\nu_{1/2}$ 110 Hz) attributed to $S_3N_3^-$, an unidentified species, and $SNSS^-$, respectively. The ^{14}N NMR spectrum of this solution showed the same major features after 30 days and again after 1 year. The narrowness of the unassigned resonance at −34 ppm rules out a species containing an N–H group, since one-bond ^{14}N–^1H coupling constants for S–NH species are ≥35 Hz (*vide infra*). Thus it seems likely that this signal belongs to a new binary S–N anion. These NMR results are consistent with previous studies of the deprotonation of S_7NH in which the yellow S_7N^- has been shown to disproportionate to $SSNSS^-$ (and sulphur) (11, 15).

^{14}N NMR spectra of solutions of 1,3- and 1,4-$S_6(NH)_2$ in liquid ammonia

Tingle and Olson have shown that the deprotonation of 1,4- and 1,5-$S_6(NH)_2$ with ethyllithium in THF at 0°C followed by alkylation with methyl iodide produces the corresponding *N*-methyl and *N,N'*-dimethyl derivatives, indicating the formation of the $S_6N_2H^-$ and $S_6N_2^{2-}$ ions, respectively (14*b*). By contrast, the isomer 1,3-$S_6(NH)_2$ produced S_7NMe under similar conditions (14*b*). The solutions of the $S_6(NH)_2$ isomers in THF are intense blue-green after treatment with ethyllithium (14*b*) and, in an earlier study, we showed by UV–visible spectroscopy that a solution of 1,4-$S_6(NH)_2$ in hexamethylphosphoric triamide (containing dimethylamine) produces the blue $SSNSS^-$ anion (11).

In this investigation the ^{14}N NMR spectra of liquid ammonia solutions of 1,3- and 1,4-$S_6(NH)_2$ were determined. As indicated in Figs. 2*b* and 2*c*, the major component of these solutions is the $SSNSS^-$ ion ($\delta^{14}N$ +109 ppm) but, in contrast to solutions of S_7NH in liquid ammonia, significant amounts of $S_3N_3^-$($\delta^{14}N$ −228 ppm) are also present. There are also weak resonances at +232 ($SSNS^-$) and −322 ppm. The latter signal could be attributed to S_7N^-, but the possibility that it is caused by the $S_6N_2^{2-}$ ion or the deprotonated nitrogen atom of $S_6N_2H^-$ cannot be ruled out. Indeed, in the case of 1,3-$S_6(NH)_2$, another signal at −343 ppm can be detected as a weak shoulder on the NH_3(l) resonance. This signal is in the appropriate region of the NH group of the $S_6N_2H^-$ anion. These NMR results are consistent with the previously proposed equilibria between cyclic and $SSNSS^-$ that were invoked to explain the predominant formation of S_7NH in the synthesis of cyclic sulphur imides (eq. [1]) (39).

$$[1] \quad S_7N^- \rightleftharpoons SSNSS^- + \tfrac{3}{8}\,S_8 \rightleftharpoons \tfrac{1}{2}\,S_6N_2^{2-} + \tfrac{1}{2}\,S_8$$

The formation of S_7NMe upon alkylation of deprotonated 1,3-$S_6(NH)_2$ in THF (14*b*) is presumably due to the rapid transformation of 1,3-$S_6N_2^{2-}$ into S_7N^- in THF solution.

^{15}N NMR spectra of the reaction of sodium azide with elemental sulphur

The formation of the S_7N^- and $S_6N_2^{2-}$ ions has also been proposed to account for the synthesis of S_7NH and $S_6(NH)_2$ isomers from sodium azide and sulphur in HMPA (39). In this investigation the formation of S–N anions in the reaction of azide ion (90% ^{15}N-enriched on one terminal nitrogen atom) with sulphur in $(Me_2N)_3PO$ ($\delta^{15}N$ −357.8 ppm, $^1J(^{31}P-^{15}N)$ 32 Hz) was monitored by ^{15}N NMR spectroscopy. As indicated in Fig. 3*a*, the ^{15}N NMR spectrum of the dark blue reaction mixture after 2 days revealed the formation of $SSNSS^-$ and the presence of some unreacted azide ion ($\delta^{15}N$ −284.9 ppm). Consequently, an additional quantity of sulphur was added to the reaction mixture until the total amount was three times that usually used in the synthesis of

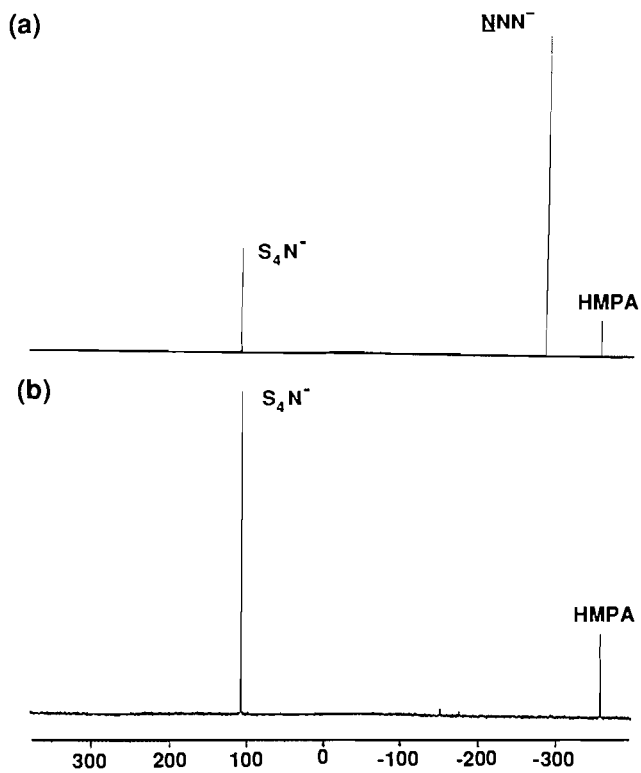

FIG. 3. The ^{15}N NMR spectra of the reaction of $^*NNN^-$ ($^*N$ = 90% ^{15}N) with S_8 in HMPA (*a*) after 2 days; (*b*) after 2 weeks and the addition of more S_8.

S_7NH (29). After 2 weeks the ^{15}N NMR spectrum showed that all the azide ion had been consumed (Fig. 3*b*). There is only one resonance ($\delta^{15}N$ +107 ppm), apart from that of the solvent, and this can be attributed to the $SSNSS^-$ ion. Surprisingly, the S_7N^- ion could not be detected in this solution even though the signal/noise ratio was sufficiently low to reveal its presence in concentrations smaller by a factor of 10^{-2} than that of $SSNSS^-$. We conclude, therefore, that the equilibria represented by eq. [1] strongly favour $SSNSS^-$ in HMPA and only shift to form S_7N^- (and $S_6N_2^{2-}$) upon hydrolysis with aqueous hydrochloric acid (29).

^{14}N NMR spectra of sulphur–ammonia solutions (SAS)

The nature of the species present in dark blue SAS has been studied extensively by UV–visible and Raman spectroscopy (16–18, 20, 40–45). In 1982 we identified the major *nitrogen-containing* species in these solutions as $SSNSS^-$ and suggested that it was formed from S_7N^- (16). Subsequently, two other groups showed that SAS are photosensitive and contain $SSNS^-$ in addition to $SSNSS^-$ (40–42), but there is disagreement about the presence of S_7N^- and the identity of the precursor of $SSNSS^-$ in such solutions. On the basis of an initial investigation by UV–visible spectroscopy, Prestel and Schindewolf claimed that 36 ± 4% of the dissolved sulphur in liquid ammonia is present as S_7N^- (17). However, in a subsequent study by the same group using anion exchange HPLC a species tentatively identified as $S_4NH_2^-$ was observed in addition to $SSNSS^-$ and $SSNS^-$ (45, 47). Lelieur and co-workers maintain that S_7N^- is not present in SAS on the basis of UV–visible and Raman spectroscopic data; they propose the formation of a neutral sulphur

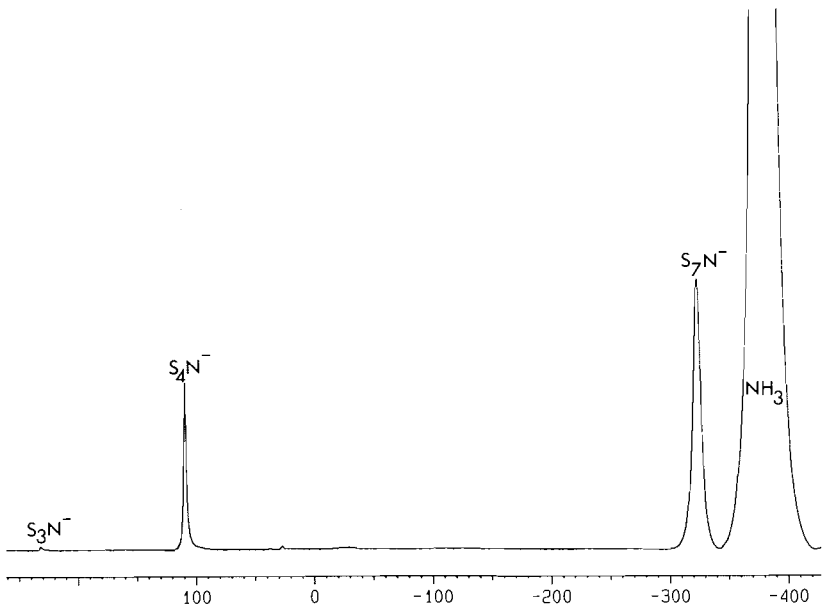

FIG. 4. The ^{14}N NMR spectrum of a 1 M (S atom) solution of S_8 in liquid ammonia after 2 h at 25°C (2 h acquisition).

species tentatively formulated as S_{2am} (am = NH_3) (18). These authors also speculate that the asymmetrical anion SSN^-, which is unknown, is the precursor of $SSNS^-$, and hence $SSNSS^-$, in SAS (18).

In the light of our ^{14}N NMR characterization of S_7N^-, SAS were investigated by ^{14}N NMR spectroscopy in an attempt to reconcile these observations and conclusions. During the course of this work Woollins and co-workers reported resonances at −329 ($\nu_{1/2}$ 350), −38 ($\nu_{1/2}$ 100), +105 ($\nu_{1/2}$ 100), and 192 ($\nu_{1/2}$ 100) (ppm (Hz)) in the approximate percentages 80:5:10:5, which they attributed to S_7NH, an unidentified species, $SSNSS^-$, and NS^+. respectively (25).[2,3] In our work, ^{14}N NMR spectra were recorded at regular intervals over the course of 9 days. A major resonance at −323 and a weaker resonance at +109 ppm attributable to S_7N^- (rather than S_7NH) and $SSNSS^-$, respectively, and a *very weak* resonance at +239 ppm assigned to $SSNS^-$ were observed (Fig. 4) (24). Surprisingly, and in agreement with the results of Woollins and co-workers (25), the resonance at −323 ppm, which we attribute to S_7N^-, accounts for ca. 80% of the nitrogen-containing species in SAS and this increases to 88% after 5 days. During the first 3 days of the experiment a weak, very narrow ($\nu_{1/2}$ 30 Hz) resonance is observed at −34 ppm. It is possible that this unidentified species is the precursor of $SSNSS^-$ in SAS, but the narrow line width rules out a species containing an N–H group. There is no evidence for the presence of any other nitrogen-containing species, e.g., $S_4NH_2^-$ or $S_2(NH_3)$, in SAS, but the resonances for such species could be obscured by the broad signal for the solvent ammonia.

In summary, our ^{14}N NMR spectra of SAS (0.2 M) recorded over a period of 9 days show the same major features as those reported by Woollins and co-workers (25) with the exception of the weak resonance at 192 ppm, which we did not observe. Our interpretation differs from that of Woollins (25), in that the strong resonance at ca. −325 ppm is assigned to the S_7N^- ion rather than S_7NH. This conclusion is consistent with the observation that S_7NH is readily deprotonated by liquid ammonia (*vide supra*). The lack of evidence for the presence of S_7N^- in SAS on the basis of UV–visible and Raman spectra (18) may be due to the lower concentrations of SAS used for these measurements and (or) the thermal and photochemical instability of S_7N^-.

The ^{14}N NMR investigation does not, however, shed any light on the *mechanism* of the formation of S_7N^- in SAS.

Attempted characterization of the S_2N^- ion

Lelieur and co-workers have shown by UV–visible and Raman spectroscopy that the progressive addition of an alkali-metal amide to SAS results in the conversion of $SSNSS^-$ to $SSNS^-$ and, subsequently, a new S–N anion tentatively formulated as the unsymmetrical anion SSN^- (20). The symmetrical SNS^- anion has been proposed to result from the thermal decomposition of $S_3N_3^-$ (4) and the electrochemical reduction of $SSNS^-$ (19). A symmetrical (C_{2v}) arrangement has been shown by Hartree–Fock–Slater self-consistent field calculations to be the most stable form of S_2N^- (47).

The cleavage of an S—S bond in $SSNSS^-$ by triphenylphosphine produces $SSNS^-$ (5) and the conversion of $SSNS^-$ into SNS^- in a similar manner is a reasonable possibility. In an attempt to identify the NS_2^- ion, the reactions of $SSNSS^-$ and $SSNS^-$($(Ph_3P)_2N^+$ salts) with Ph_3P were monitored by ^{14}N NMR spectroscopy. The reactions were carried out in both dimethylformamide and acetonitrile, since these solvents obscure different regions of the ^{14}N NMR window. In both cases, it was found that the addition of one molar equivalent of Ph_3P to a solution of $SSNSS^-$ ($\delta^{14}N$

[2]Nitrogen NMR chemical shifts (in ppm) are quoted here with reference to external $MeNO_2$(l). ^{14}N NMR chemical shifts in ref. 25 were given relative to NH_3(l) ($\delta(NH_3)$(l) = −380 ppm vs. $MeNO_2$(l)).

[3]The existence of the extremely electrophilic NS^+ cation in liquid ammonia solutions is highly unlikely. For example, NS^+ salts react vigorously with alkanes at 0°C (46).

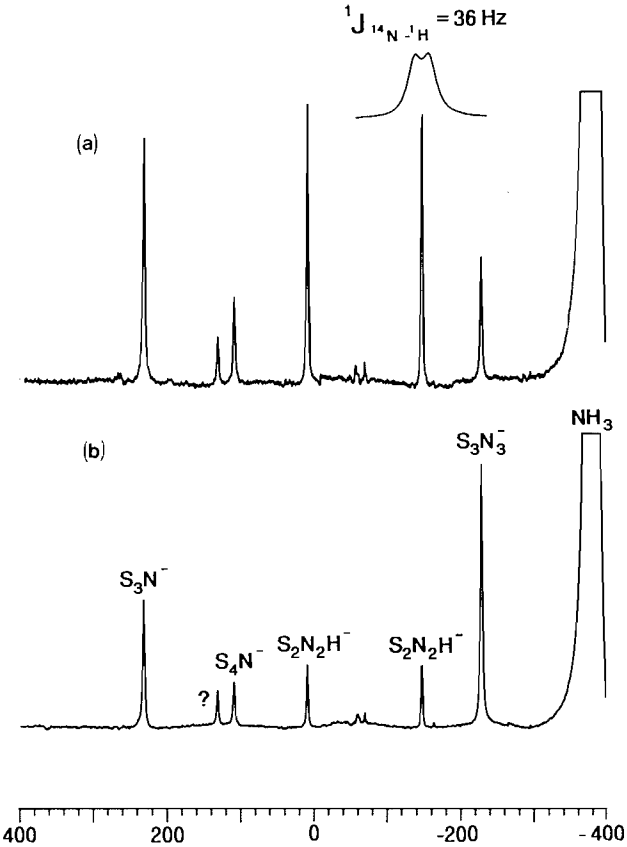

FIG. 5. The ^{14}N NMR spectra of the reaction of S_7NH with KNH_2 in a 1:3 molar ratio after (*a*) 2 h; (*b*) 10 days in NH_3(l) at 25°C.

+107 ppm) produces a new resonance at +235 ppm attributable to $SSNS^-$ (24). However, the complete conversion of $SSNSS^-$ into $SSNS^-$ required more than one molar equivalent of Ph_3P and the addition of greater than two molar equivalents of Ph_3P did not produce any new NMR resonances. Thus there is no evidence for the formation of a stable NS_2^- ion under these conditions.

Characterization of the $S_2N_2H^-$ ion

As an alternative source of the NS_2^- ion the reaction of $SSNSS^-$ (produced by the deprotonation of S_7NH) with potassium amide in liquid ammonia was also investigated. The combination of the low viscosity of liquid ammonia, which contributes to the relatively narrow resonances, the good solubility and stability of S–N anions in this solvent, and the fact that the ^{14}N NMR resonance of liquid ammonia does not obscure the region of interest make this an ideal system for monitoring the formation of S–N anions.

The addition of one molar equivalent of KNH_2 to a solution of S_7NH in liquid ammonia causes very little change in the ^{14}N NMR spectrum compared with that of S_7NH alone. However, the addition of two molar equivalents of potassium amide produces significant changes. Specifically, the relative concentration of S_7N^- is reduced and the $SSNS^-$ ($\delta^{14}N$ +230 ppm) and $S_3N_3^-$ ions ($\delta^{14}N$ −230 ppm) are readily detected as components of the reaction mixture. The addition of a third molar equivalent of potassium amide results in a more dramatic change in composition as indicated in Fig. 5*a*. A comparison of this spectrum with the ^{14}N NMR spectrum of the same solution obtained after 10 days (Fig. 5*b*) indicates that these changes result from the transformation of $SSNSS^-$ into $SSNS^-$, which in turn is converted to a previously unidentified S–N anion with equally intense resonances at +7 and −149 ppm. These resonances are associated with the same species since they grow and decay together (Fig. 5). The signal at −149 ppm is a doublet ($^1J(^{14}N-^1H)$ 36 Hz) indicating that one of the nitrogen atoms is attached to a hydrogen atom. A reasonable candidate for this species is the $S_2N_2H^-$ ion, **1**, which has previously been identified only as a ligand in metal complexes (7, 8). The coordinated $S_2N_2H^-$ ligand exhibits ^{14}N NMR signals at ca. −20 and −150 ppm (25).[3]

1

Chemical investigations of the deprotonation of $S_4(NH)_4$ indicate that this process also produces the $S_2N_2H^-$ ion (10). Consequently, the reaction of $S_4(NH)_4$ with two molar equivalents of potassium amide in liquid ammonia was also investigated. The ^{14}N NMR spectrum of the red-brown solution so obtained after 1 h at 23°C showed two major resonances at +7 and −148 ppm attributed to the $S_2N_2H^-$ ion (*vide supra*). However, after 24 h this species was partially converted to $S_3N_3^-$ ($\delta^{14}N$ −230 ppm).

To obtain $^{15}N-^{15}N$ (and $^{15}N-^1H$) spin coupling information in support of the proposed structure of **1**, the same experiment was conducted with 99% ^{15}N-enriched $S_4(NH)_4$. The ^{15}N NMR spectrum is displayed in Fig. 6*a*. Two resonances were observed at +9 and −148 ppm ($^1J(^{15}N-^1H)$ 55 Hz) in addition to a weak resonance at −230 ppm for $S_3N_3^-$. The ratio $^1J(^{15}N-^1H)/^1J(^{14}N-^1H)$ is 1.53, cf. $\gamma(^{15}N)/\gamma(^{14}N) = 1.40$ (where γ = magnetogyric ratio). The coupling between the inequivalent nitrogen atoms was determined for the resonance at +9 ppm to be ca. 2.2 Hz by the application of a convolution-difference algorithm. The corresponding coupling constant in neutral S–N rings is 2–3 Hz, while the value for the cation $S_4N_3^+$ is 8.5 Hz (48). These NMR data for the product of the deprotonation of $S_4(^{15}NH)_4$ with two molar equivalents of potassium amide are uniquely consistent with a species containing the -NSNH group and, in view of previous chemical evidence (10), we formulate this product as $SNSNH^-$, **1**.

The NMR experiments also demonstrate that the $S_2N_2H^-$ ion is partially converted into the $S_3N_3^-$ ion in liquid ammonia (Figs. 5*a* and *b*). This finding explains the previously reported observation that the deprotonation of $S_4(NH)_4$ by potassium hydride in THF produces $K^+S_3N_3^-$ as the final product (49). It is also noted that the explosive product of the reaction of $S_4(NH)_4$ with Ph_3CNa (1:2 molar ratio) was tentatively identified as $Na_2N_4S_4H_2$ on the basis of analytical data (36). It seems likely that this product is $Na[S_2N_2H]$, but the use of large cations, e.g., Ph_4As^+ or $(Ph_3P)_2N^+$, will likely be necessary to isolate stable crystalline salts (1).

Attempted characterization of the $S_2N_2^{2-}$ ion

A solution of $S_4(NH)_4$ in the presence of a base, e.g., diazabicycloundecane, has been used to prepare metal complexes of the $S_2N_2^{2-}$ ion (50). Numerous coordination compounds of this S–N ligand are known (7, 8), but it has not been characterized as the free anion. Consequently, the reaction of 99% ^{15}N-enriched $S_4(NH)_4$ with KNH_2 in liquid ammonia in a 1:4 molar ratio was investigated. As indi-

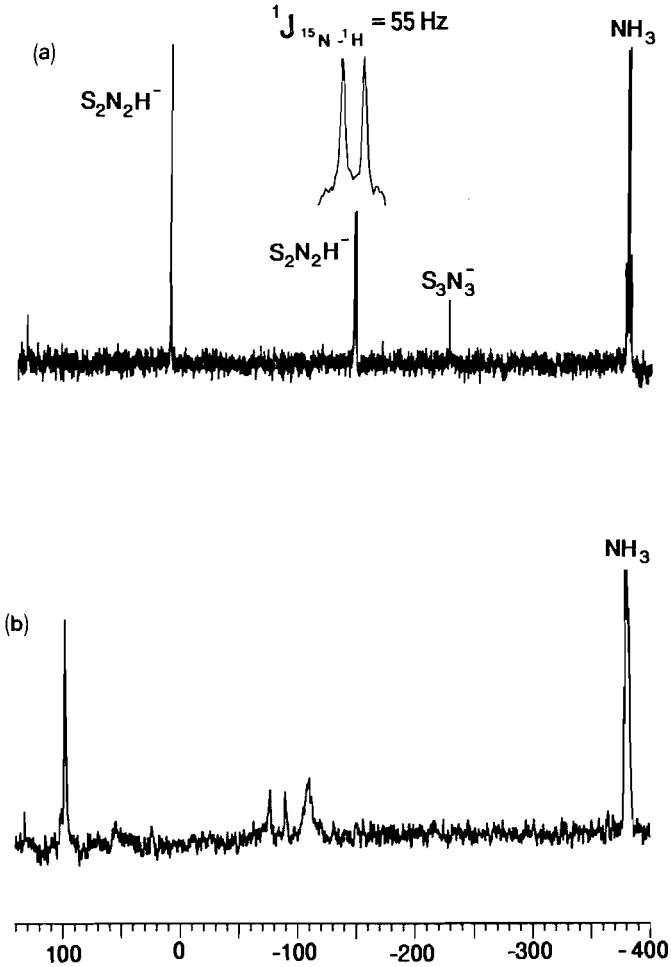

FIG. 6. The ^{15}N NMR spectra of the reaction of 99% ^{15}N-enriched $S_4(NH)_4$ (0.08 M) with KNH_2 in (*a*) a 1:2 molar ratio; (*b*) a 1:4 molar ratio in NH_3(l) at 25°C.

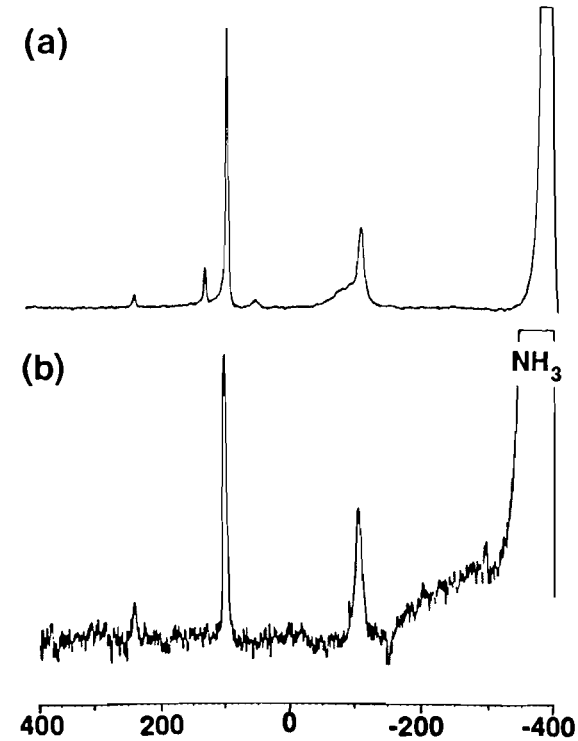

FIG. 7. The ^{14}N NMR spectra of (*a*) a solution of $(NSCl)_3$ and KNH_2 (1:6 molar ratio) after 7 days; (*b*) K_2[NSN] in NH_3(l) at 25°C.

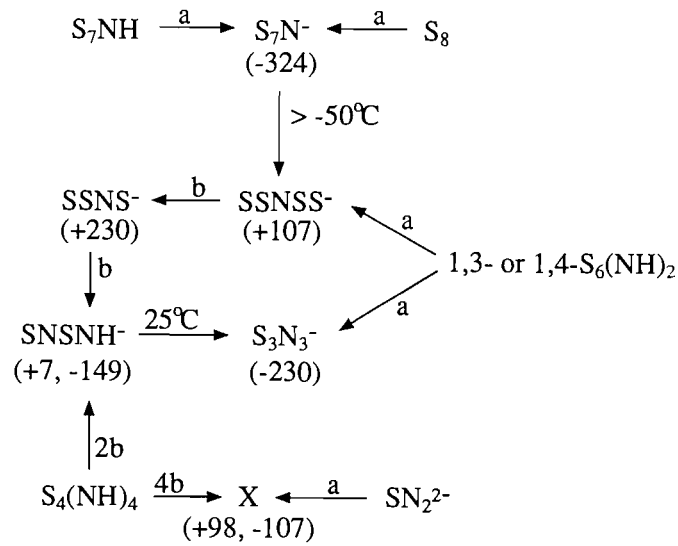

SCHEME 1. Sulphur–nitrogen anions formed in the deprotonation of cyclic sulphur imides by potassium amide in liquid ammonia; a = NH_3(l); b = KNH_2. Nitrogen NMR chemical shifts (ppm) are given in parentheses (ref. $MeNO_2$(l)). See text for a discussion of the identity of X.

cated in Fig. 6*b* the signals at +9 and −148 ppm are replaced completely by two much broader resonances at +98 ($\nu_{1/2}$ 80 Hz) and −110 ppm ($\nu_{1/2}$ 300 Hz). The broadness of the resonances prevents the detection of ^{15}N–^{15}N coupling. Consequently, it is not possible to ascertain whether these two signals belong to a single anion with inequivalent nitrogen, e.g., $S_2N_2^{2-}$ ions, or indicate the formation of two different S–N anions. The latter alternative seems more likely since it is reasonable to expect that the linewidths of the resonances for $S_2N_2^{2-}$ would be comparable to those of $S_2N_2H^-$.

The symmetrical NSN^{2-} ion is a possible product of this deprotonation reaction, but it has not been characterized by NMR spectroscopy (6). Consequently, an ^{14}N NMR spectrum of K_2[NSN] in liquid ammonia was obtained (Fig. 7*b*). This solution exhibits the same two resonances at +98 ($\nu_{1/2}$ 200 Hz) and −107 ppm ($\nu_{1/2}$ 400 Hz) that are observed for the $4KNH_2/S_4(NH)_4$ reaction in liquid ammonia.

The reaction of $(NSCl)_3$ with potassium amide (1:6 molar ratio) in liquid ammonia was also monitored by ^{14}N NMR spectroscopy, since this system provided the first synthesis of K_2[NSN] (51). After 30 min the anions $S_3N_3^-$ ($\delta^{14}N$ −230 ppm) and $S_4N_5^-$ ($\delta^{14}N$ −240 and −326 ppm) are readily identified, but the major product is an unidentified species ($\delta^{14}N$ −4 ppm). During the course of several days these signals disappear and are replaced by resonances at +96 ($\nu_{1/2}$ 110 Hz) and −109 ppm ($\nu_{1/2}$ 330 Hz) (Fig. 7*a*). Thus the same species are produced in liquid ammonia solutions

of either (*a*) $S_4(NH)_4/4KNH_2$, (*b*) $K_2[NSN]$, or (*c*) $(NSCl)_3/6KNH_2$.

An equilibrium between SN_2^{2-} and the $NSNH^-$ ion, formed by deprotonation of ammonia by the highly basic dianion, provides a possible explanation for these observations (eq. [2]).

[2] $SN_2^{2-} + NH_3 \rightleftarrows NSNH^- + NH_2^-$

The relatively sharp resonance at ca. +97 ppm can be attributed to the SN_2^{2-} ion[4] and the much broader resonance at ca. −108 ppm may be due to $NSNH^-$, which is undergoing a rapid 1,3 proton shift between equivalent nitrogen atoms.[5]

Conclusions

The thermally unstable S_7N^- ion has been characterized by ^{14}N and ^{15}N NMR spectroscopy. The NMR investigations support the conclusion, based upon previous chemical and UV–visible spectroscopic evidence, that S_7N^- decomposes to give $SSNSS^-$ and reveal that S_7N^- is the major nitrogen-containing species in solutions of sulphur in liquid ammonia (1 M in S atom). The reaction of $SSNSS^-$ with an excess of amide ion in liquid ammonia produces $SNSS^-$ and, subsequently, the novel anion $S_2N_2H^-$, which decomposes to give $S_3N_3^-$ at room temperature. No evidence was obtained for the formation of S_2N^- in this system. The deprotonation of $S_4(NH)_4$ by two molar equivalents of potassium amide in liquid ammonia also produces $S_2N_2H^-$. Liquid ammonia solutions of $S_4(NH)_4/4KNH_2$ show the same two ^{14}N or ^{15}N NMR resonances as are found for $K_2[NSN]$ or $(NSCl)_3/6KNH_2$ in liquid ammonia. These resonances are *tentatively* attributed to an equilibrium mixture of the NSN^{2-} and $NSNH^-$ ions rather than the $SNSN^{2-}$ ion. The results of these NMR studies are summarized in Scheme 1.

Acknowledgements

We thank the Natural Sciences and Engineering Research Council of Canada for financial support, Mark Edwards for the synthesis of cyclic sulphur imides, and Professor H. Vogel and Dr. D. D. McIntyre (Department of Biological Sciences, The University of Calgary) for assistance with some of the NMR experiments. Ian Drummond, a former student of Professor Tom Birchall, was instrumental in initiating our work on sulphur–nitrogen anions.

[4]The ^{14}N NMR chemical shift of NSO^- occurs ca. 125 ppm to high frequency from that of Me_3SiNSO ($\delta^{14}N$ −50 ppm) (24). By analogy, a similar shift to high frequency might be expected for NSN^{2-} compared to $Me_3SiNSNSiMe_3$ ($\delta^{14}N$ −59 ppm).

[5]Although the diprotonated species HNSNH has been characterized by ^1H NMR spectroscopy, no ^{14}N NMR data are available (52).

^{77}Se NMR spectroscopic study of the molecular composition of sulfur–selenium melts

TRISTRAM CHIVERS,[1] RISTO S. LAITINEN,[1,2] AND KENNETH J. SCHMIDT
Department of Chemistry, The University of Calgary, 2500 University Drive N.W., Calgary, Alta., Canada T2N 1N4

Received July 12, 1991

This paper is dedicated to the memory of Professor Thomas Birchall

TRISTRAM CHIVERS, RISTO S. LAITINEN, and KENNETH J. SCHMIDT. Can. J. Chem. **70**, 719 (1992).

A series of six sulfur–selenium mixtures containing 0.4, 5, 15, 25, 35, and 45 mol% of selenium were heated in evacuated ampoules at 430°C for 4 h and, keeping the material molten at 135°C, their natural-abundance ^{77}Se NMR spectra were recorded. The equilibrium melt in each case was found to contain both heterocyclic Se_nS_{8-n} species and polymeric material. The most abundant eight-membered selenium sulfide rings were SeS_7, which was the main cyclic component in all melts studied in this work, and 1,2-Se_2S_6, the quantity of which increased with increasing selenium content of the melt. In addition the melts contained smaller amounts of 1,3, 1,4, and 1,5 isomers of Se_2S_6, 1,2,3, 1,2,4, and 1,2,5 isomers of Se_3S_5, 1,2,3,4, 1,2,3,5, and 1,2,5,6 isomers of Se_4S_4, 1,2,3,4,5-Se_5S_3, 1,2,3,4,5,6-Se_6S_2, and Se_8. The relative distribution of the cyclic products as a function of the selenium content in the melt was virtually identical with that obtained earlier in the CS_2 solutions of the quenched melts, implying that the extracted quenched melts actually represent the original melt composition as far as the Se_nS_{8-n} species are concerned. The resonances due to the polymeric material in the melts could best be interpreted by the statistical random distribution of selenium and sulfur in the polymeric chains, the probability of occurrence of the different fragments being governed by the overall composition of the melt. As the selenium content increases, the relative amount of selenium bound in the polymer seems to increase at the expense of heterocyclic selenium sulfides.

Key words: selenium sulfides, sulfur–selenium melt, ^{77}Se NMR spectroscopy.

TRISTRAM CHIVERS, RISTO S. LAITINEN et KENNETH J. SCHMIDT. Can. J. Chem. **70**, 719 (1992).

Une série de six mélanges de soufre–sélénium contenant 0,4, 5, 15, 25, 35 et 45 mol% de sélénium placés dans des ampoules sous vide a été chauffé à 430°C pendant 4 h et on a alors déterminé leurs spectres RMN du ^{77}Se en abondance naturelle, tout en maintenant les produits à l'état fondu à 135°C. Dans chacun des cas, on a trouvé que les produits fondus contiennent des espèces hétérocycliques Se_nS_{8-n} ainsi que des produits polymériques. Les composés cycliques les plus abondants sont le cycle sulfuré du sélénium comportant huit chainons, SeS_7, qui est le composant cyclique principal dans tous les mélanges fondus étudiés, et le 1,2-Se_2S_6 dont la quantité augmente avec une majoration de la quantité de sélénium dans le produit fondu. On retrouve de plus des quantitiés plus faibles des isomères 1,3-, 1,4- et 1,5-Se_2S_6, des isomères 1,2,3-, 1,2,4- et 1,2,5-Se_3S_5, des isomères 1,2,3,4-, 1,2,3,5- et 1,2,5,6-Se_4S_4, du 1,2,3,4,5-Se_5S_3, du 1,2,3,4,5,6-Se_6S_2 et du Se_8. La distribution relative des produits cycliques en fonction de la quantité de sélénium contenue dans le produit fondu est pratiquement identique avec celle qui a été observée antérieurement avec des solutions de CS_2 de produits fondus préalablement soumis à une trempe; ce résultat suggère que, en ce qui a trait aux espèces Se_nS_{8-n}, les extraits des produits fondus soumis à la trempe représentent en fait la composition originale du produit fondu. On peut interpréter les résonances dues à des matériaux polymériques présents dans les produits fondus par une distribution statistique du sélénium et du soufre dans les chaines polymériques, la probabilité de rencontrer divers fragments étant définie par la composition globale du produit fondu. Lorsque la composition en sélénium augmente, les quantités relatives de sélénium présentes dans le polymère semblent augmenter au dépens des sulfures de sélénium hétérocycliques.

Mots clés : sulfures de sélénium, mélange fondu de soufre–sélénium, spectroscopie RMN du ^{77}Se.

[Traduit par la rédaction]

Introduction

In the molten state sulfur and selenium have long been known to mix in all proportions (1). Ringer (2) recorded the phase diagram of the sulfur–selenium binary system as early as 1902 and reported a eutectic point at ca. 105°C for the selenium content of 40 mol% (2). Boctor and Kullerud (3) reinvestigated the phase relations in the Se–S system by using modern thermoanalytical methods and, while they found a temperature minimum of 102°C at a composition of 35 mol% selenium, they questioned the existence of this eutectoid. On the basis of the phase diagram they explained the complete liquid miscibility in the Se–S system in terms of the equilibrium copolymerization theory.

While Ringer's phase diagram gives indications of the formation of binary compounds, it was only with the advent of modern analytical techniques that the existence of selenium sulfides could unequivocally be shown. The first reliable evidence that there are binary compounds in molten mixtures of sulfur and selenium as well as in the vapour over the melt came from vapour pressure measurements (4), even though the authors did not discuss the nature and the structures of these compounds at the time. Fergusson *et al.* (5*a*) and Ward (5*b*) were the first to deduce the existence of heterocyclic Se_nS_{8-n} molecules in crystalline phases that had been formed by quenching molten mixtures of the elements in varying molar ratios. The former based their conclusions on X-ray powder diffraction and absorption spectroscopy, and the latter on Raman spectroscopy. These conclusions were supported by mass and Raman spectroscopic studies as well as by crystal structure determinations (for recent reviews on the efforts on identification and characterization of selenium sulfides, which were prepared from melts or through a variety of other synthetic routes, see ref. 6).

It was soon apparent that the crystalline phases that had

been obtained by quenching and recrystallizing sulfur–selenium melts contained complicated mixtures of several molecular species. In fact, only the reactions of titanocene compounds of the type $[Ti(C_5H_5)_2E_5]$ and $[Ti(C_5H_5)_2(\mu\text{-}E_2)_2Ti(C_5H_5)_2]$ (E = S or Se) with dichlorosulfanes or dichlorodiselane are known to result in the formation of pure stoichiometric compounds (7). All crystal structures were disordered (6) and therefore only the overall conformation of the ring molecules could be deduced. Low-temperature Raman spectra indicated the presence of S—S, Se—S, and Se—Se bonds in all samples (8), but did not allow the identification of actual molecular species. It was only with ^{77}Se NMR spectroscopy that individual heterocyclic selenium sulfides could be identified (9). The NMR spectroscopic characterization was based on the comparison of spectra of natural-abundance samples with those of the samples with corresponding chemical composition, but with selenium enriched in the ^{77}Se- isotope (92% enrichment).

It is questionable, however, that the CS_2 solutions and crystalline phases prepared from the quenched sulfur–selenium melt represent the actual melt. The solubility of selenium sulfides rapidly decreases as the selenium content increases. In fact most of the material is insoluble in CS_2 and apparently contains polymeric species. It has indeed been estimated by DSC that the polymerization threshold is lowered with the introduction of selenium in the liquid (3). The present study was initiated in order to establish directly the equilibrium composition of the sulfur–selenium melt and its dependence on the elemental composition.

Experimental section

The preparation of the samples

A series of six samples were prepared by mixing elemental sulfur (Fisher) and selenium (Anachemia) together in various molar ratios. The mass of the resulting mixtures was adjusted to 3.0 g each and they contained 0.4, 5, 15, 25, 35, and 45 mol% selenium. Each sample was sealed in an evacuated ampoule with an external diameter of 8 mm and heated at ca. 430°C for 4 h. The ampoules were allowed to cool to 135°C and were subsequently inserted in 10 mm NMR tubes containing d_5-nitrobenzene (Aldrich) as an external ^2H lock for the NMR measurements. They were immediately lowered into the NMR probe, which was kept at 135°C throughout the acquisition.

NMR spectroscopy

The ^{77}Se NMR spectra were recorded with a Bruker AM-400 spectrometer operating at 76.31 MHz. The spectral width was 71.43 kHz and the resolution 4.36 Hz/data point. The pulse width was 6.0 μs, corresponding to the nuclide tip angle of 45°. The pulse delay was 2.8 s. The accumulations generally contained 15 000–20 000 transients. In the case of the sample containing 25 mol% of selenium 94 000 transients were acquired in order to maximize the signal-to-noise ratio. All spectra were referenced externally to a saturated solution of SeO_2 at room temperature. The chemical shifts (ppm) are reported relative to neat Me_2Se at room temperature ($\delta(Me_2Se) = \delta(SeO_2) + 1302.6$).

Results and discussion

The natural-abundance ^{77}Se NMR spectra of the six sulfur–selenium melts studied in this work are shown in Fig. 1. There are two distinct regions in all spectra: the region at 750–550 ppm is typical for the eight-membered Se_nS_{8-n} ring molecules (9), and that at 1050–850 ppm is inferred to contain resonances from the polymeric material. A more detailed assignment is presented below, after which the composition of the molten mixtures as a function of the selenium content is discussed.

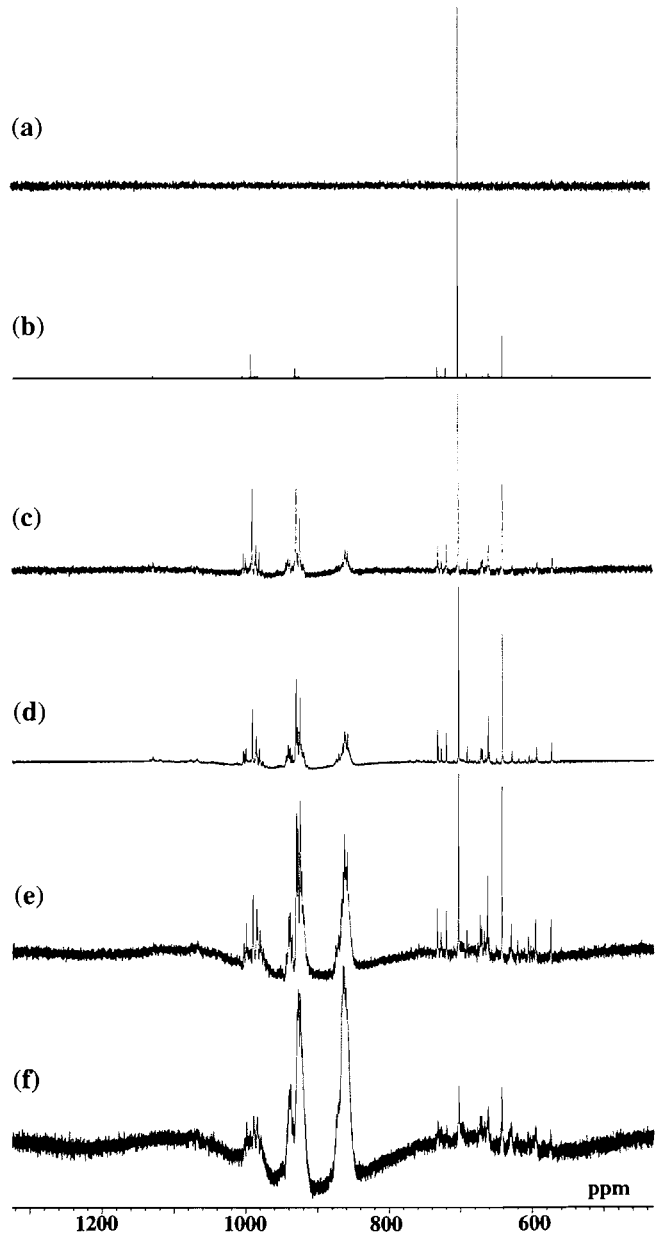

FIG. 1. The natural abundance ^{77}Se NMR spectra of six molten mixtures of sulfur and selenium recorded at 135°C. (*a*) 0.4 mol% Se; (*b*) 5 mol% Se; (*c*) 15 mol% Se; (*d*) 25 mol% Se; (*e*) 35 mol% Se; (*f*) 45 mol% Se.

Se_nS_{8-n} ring molecules

All possible Se_nS_{8-n} ring molecules formed in the melt are shown in Table 1 together with an abbreviated notation used in their designation. The main species observed in the CS_2 solutions of the quenched sulfur–selenium melts are listed in Table 2 together with their chemical shifts (9*b*). This in-

[a]For the abbreviated notation, see Table 1.
[b]See ref. 9*b*.
[c]The chemical shifts of the different molecular species are taken from the spectrum of the melt with 25 mol% of Se. The values of the chemical shifts in other samples were virtually identical.

formation can be used to assign the resonances observed in the actual melts at 750–550 ppm (see Fig. 1). The assignments are indicated in the NMR spectrum of the melt containing 25 mol% selenium, the pertinent region of which is shown in Fig. 2.

The most intense resonance in the region of eight-membered selenium sulfide rings is found at 705 ppm in all spectra (see Figs. 1 and 2). It almost coincides with the room temperature solution resonance of SeS_7 (**A_1**), the reported chemical shift of which is 699.7 ppm (9*b*). It is reasonable to assign the signal at 705 ppm to SeS_7 since, as the most sulfur-rich Se_nS_{8-n} molecule, it can be expected to be the main component in the sulfur-rich melts. Further support is found from the NMR spectrum of the melt containing 0.4 mol% of selenium (see Fig. 1), which shows only this signal.

The second most intense resonance in the spectrum of Fig. 2 is that at 644 ppm. It is assigned to 1,2-Se_2S_6 (**A_2**). This chemical shift is also close to the value of the corresponding species in CS_2 at 633.9 ppm (9*b*). This signal first appears when the melt contains 5 mol% of selenium. Its relative intensity with respect to that of SeS_7 increases with increasing selenium content, in agreement with the solution spectra (9*b*).

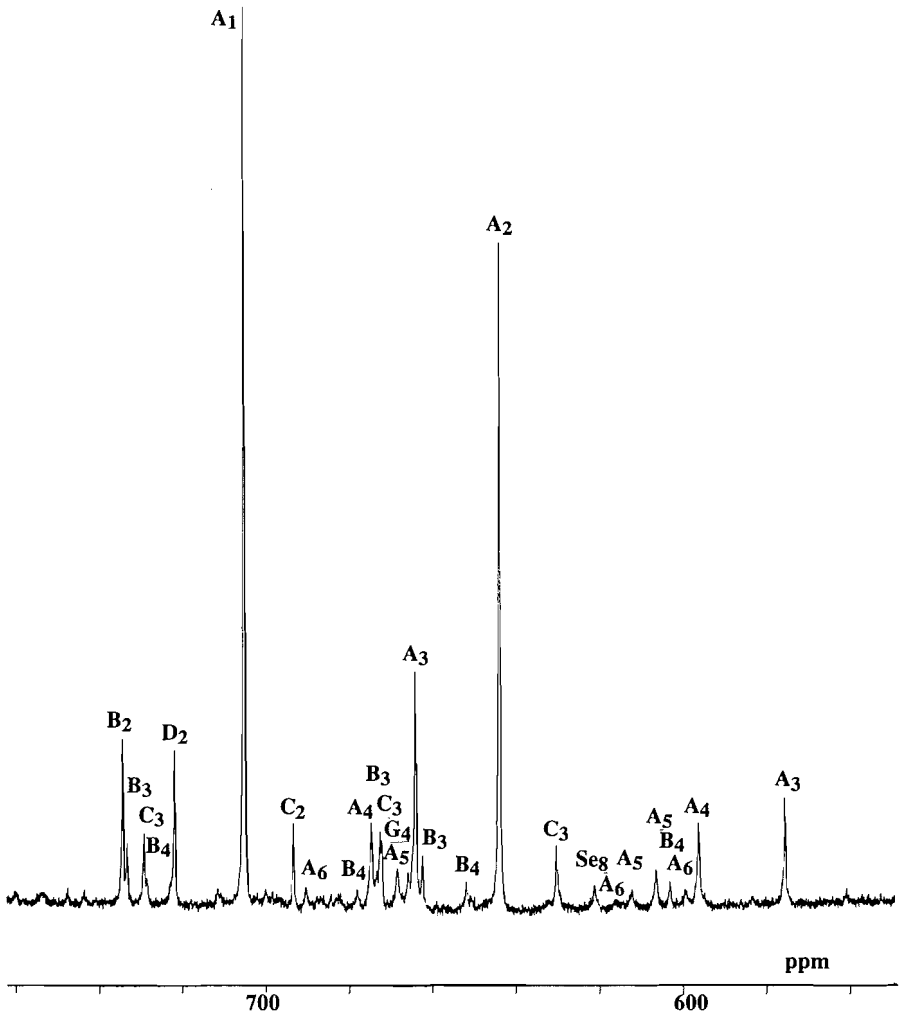

FIG. 2. An expansion of the 750–500 ppm region of the natural abundance ^{77}Se NMR spectrum of the molten mixture of sulfur and selenium containing 25 mol% Se. The assignment of the resonances is indicated in the spectrum. For the notation used in the figure, see Table 1.

Other resonances in the Se_nS_{8-n} region could be assigned by taking into consideration the earlier deductions on the trends in the chemical shifts (9*b*) as well as the relative intensities of the different signals (see Fig. 2).

In addition to the signals assigned in Fig. 2 there are some very weak resonances that remain unassigned. Those at 780–740 ppm probably indicate small concentrations of six-membered selenium sulfide ring molecules and those above 1050 ppm are due to seven-membered Se_nS_{7-n} heterocycles (10).

The comparison between the chemical shifts observed in the melts and the corresponding shifts in the solution spectra at room temperature is shown in Table 2. It is seen that all signals in the melts have been shifted downfield from their solution counterparts. In the case of isolated selenium atoms (structural type -S-Se-S-) the shift is ca. 5 ppm, with one sulfur and one selenium neighbour (-Se-Se-S-) it is ca. 10 ppm, and with two selenium neighbours (-Se-Se-Se-) the shift is 15–20 ppm. The temperature and solvent dependence of the chemical shift seem to correlate inversely with the electronegativity difference between adjacent neighbours.

Polymeric material

The three groups of resonances at 1050–850 ppm are assigned to the polymeric material in the melt (see Fig. 1). Analogously with the trend of the chemical shifts observed for the Se_nS_{8-n} rings (9*b*) it is reasonable to expect that isolated selenium atoms (i.e., selenium atoms with two sulfur neighbours) appear at the lowest field, with one selenium and one sulfur neighbour they resonate at higher field, and with two selenium neighbours at the highest field. Thus the group of signals at 1050–980 ppm implies isolated selenium atoms in the polymer, that at 970–920 ppm implies the structural unit -Se-Se-S-, and the group at 890–850 ppm the structural unit -Se-Se-Se-, i.e., three or more adjacent selenium atoms. This assignment finds support from the relative intensities of these groups as a function of selenium content in the melt (see Fig. 1). With 5 mol% Se in the melt only structural units -S-Se-S- and -Se-Se-S- are found in the melt, with the former more prominent than the latter. As the selenium content of the mixtures increases, the relative abundance of longer selenium fragments increases, as seen in the strengthening of the signals both at 970–920 and 890–850 ppm. Simultaneously the

[a]The middle selenium atom of the seven-atom chain is considered to be observed in the NMR spectrum. This atom and its immediate neighbours are indicated in bold. The computations were based on the probabilities of occurrence of the different fragments in the polymeric selenium sulfide as a function of the selenium content in the melt. The numerical values were scaled by assigning the most sulfur-rich fragment in each group (A)–(C) a reference value 100. The relative intensities <1 are denoted by a dash.

intensities of the resonances implying isolated selenium atoms diminish.

Because sulfur and selenium are distributed statistically in the polymer chains and the chemical shifts are also influenced by longer range effects than just by nearest neighbours, there is only a limited possibility of discussing the origin of the discrete resonances observed in the polymer signals. However, if the statistical distribution is assumed to be governed by the overall composition of the melt and the long-range effects on the chemical shift are arbitrarily limited only to the third adjacent atom from the observed selenium, the following qualitative inferences can be made. The computational details based on the probability of occurrence of different seven-atom fragments are shown in Table 3. In these fragments the selenium nucleus to be observed by NMR is in the middle of the chain with the intensity of its resonance directly proportional to the probability of occurrence of the fragment in question. The fragments have been divided into three groups according to the nearest neighbours to the "observed" selenium atom as indicated in Table 3. The expected relative intensities of the resonances due to different fragments (i.e., the probabilities of occurrence of these fragments) in each group have been scaled by assigning the most sulfur-rich fragment the reference value 100.

[a]For the abbreviated notation; see Table 1.

[b]The data for the melt with the selenium content of 45 mol% are missing, because the signal-to-noise ratio was not sufficient to warrant even a semi-quantitative determination of the relative distribution of the Se_nS_{8-n} rings.

[c]See ref. 9*b*.

[d]The melt composition in this case refers to the composition of the original melt, which was then quenched, extracted with CS_2, crystallized, and redissolved in CS_2.

[e]Total amount of selenium bound in Se_nS_{8-n} rings.

It is seen from Fig. 1 that in the case of the melt with 5 mol% selenium there is only one major signal in the region of isolated selenium atoms (1050–980 ppm) at 1008 ppm with a few minor resonances. Comparison of the observed intensities with those expected from the computations given in Table 3 indicates that this major resonance should be due to a selenium nucleus far separated from other selenium atoms. This of course is reasonable, since in the sulfur-rich melt the frequency of occurrence of selenium in the polymeric chain is not expected to be high. The few minor signals can be assigned to fragments where the second selenium atom is separated by one, two, or at most three sulfur atoms. The relative intensities observed in Fig. 1 are in good agreement with the computations of Table 3. As the selenium content of the melt increases these minor resonances gain in intensity. Simultaneously new signals due to fragments containing more than two selenium atoms in close proximity appear in the spectrum. As a consequence, this group of resonances becomes more complicated with more even distribution of intensities. However, the signal at 1008 ppm due to the most totally isolated selenium is a major resonance in all spectra of Fig. 1. It has the highest intensity up to the melt composition of 25 mol% Se and it is only with higher selenium contents that resonances due to other fragments become more significant. These observations are also in qualitative agreement with the computations of Table 3.

Similar conclusions can be made for the group of resonances in the region implying one selenium and one sulfur neighbour to the observed nucleus (970–920 ppm). In the sulfur-rich melt only one major signal at 943 ppm is observed. According to Table 3 this indicates Se_2 fragments far removed from each other by chains of sulfur atoms. It is only with increasing selenium content in the melt that resonances from other fragments become more prominent, and thus the group of signals is more complicated.

The region for selenium with two selenium neighbours (890–850 pm) is not so well resolved into discrete components. Therefore it is not meaningful to discuss the possible distribution of the selenium-containing fragments even at the approximate level carried out above. The computed intensities of Table 3 can be used, however, to explain why no resonances at 890–850 ppm are observed in the melt containing 5 mol% Se. The only possibility in this region would be Se_3 fragments far removed from each other by long chains of sulfur. At the sulfur-rich end the probability of occurrence of this fragment is very low.

Composition of the melts

Since all sulfur–selenium mixtures were heated well above the polymerization threshold, they contain significant amounts of polymeric material. Steudel *et al.* (11) estimated that the quantity of polymeric sulfur in the equilibrium sulfur melt is ca. 50%. The amount of polymer in sulfur–selenium melts is of similar order of magnitude. With increasing selenium content the relative amount of polymer seems to grow, and more selenium is involved in the polymer. Since only selenium is observable with ^{77}Se NMR spectroscopy, the increasing selenium content in the polymer causes a dramatic change in the spectra of Fig. 1, as discussed above.

The relative distribution of the selenium-containing Se_nS_{8-n} rings as a function of the selenium content in the melt is shown in Table 4. The melts also contain homocyclic sulfur

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

molecules, mainly cyclooctasulfur, but it is unobservable in the ^{77}Se NMR spectrum. SeS_7 (A_1) is the main eight-membered heterocyclic component in all melts studied in this work. As seen in Fig. 1, it is the sole component in the melt with 0.4 mol% Se. As expected, its content is lowered as the selenium content of the melt increases. 1,2-Se_2S_6 is another main component in melts with selenium content above 5 mol%. Its abundance steadily increases as the selenium content in the melt increases. In addition to these two main components there are several minor components in the melt. Generally it can be said that the ring molecules with higher selenium content become more abundant as the selenium content of the melt increases.

It is interesting to compare the distribution of Se_nS_{8-n} species in the melt to that observed earlier in CS_2 solutions of the quenched melts (9*b*). The product distributions in both cases are practically identical and behave similarly as a function of total selenium content (see Table 4). The composition of the quenched melts evidently represents that of the melt itself. Upon extracting the quenched amorphous material with CS_2 the Se_nS_{8-n} species dissolve totally, leaving the polymeric material behind as the undissolved residue.

Conclusions

The molecular composition of molten mixtures of sulfur and selenium at different molar ratios has been studied with ^{77}Se NMR spectroscopy at 135°C. The melts have been shown to consist of eight-membered heterocyclic selenium sulfide rings as well as of polymeric material. SeS_7 and 1,2-Se_2S_6 are the main Se_nS_{8-n} species over the whole composition range studied in this work (up to 45 mol% Se in the melt), with a variety of other molecules as minor components. The product distribution is practically identical with that observed in CS_2 solutions of the quenched melts and behaves similarly as a function of the composition of the melt.

The composition of the polymeric material in the equilibrium melt is best explained by the statistical random distribution of sulfur and selenium in the polymeric chains. The polymer resonances in the ^{77}Se NMR spectrum can be interpreted in terms of the probability of occurrence of different fragments based on the total selenium content of the melts.

Preparation and characterization of $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$: a metal complex of a least coordinating solvent and a least coordinating anion

PAUL K. HURLBURT, OREN P. ANDERSON, AND STEVEN H. STRAUSS[1]

Department of Chemistry, Colorado State University, Fort Collins, CO 80523, U.S.A.

Received July 4, 1991

This paper is dedicated to the memory of Professor Thomas Birchall

PAUL K. HURLBURT, OREN P. ANDERSON, and STEVEN H. STRAUSS. Can. J. Chem. **70**, 726 (1992).

Addition of $B(OTeF_5)_3$ to $TlOTeF_5$ in the weakly coordinating solvents dichloromethane, 1,2-dichloroethane, and 1,1,2-trichlorotrifluoroethane produces solutions of $M(solv)_x^+B(OTeF_5)_4^-$. When the solvent was 1,2-dichloroethane, the crystalline compound $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$ was isolated and studied by X-ray crystallography: triclinic, space group $P\bar{1}$, a = 9.221 (4), b = 11.396 (5), c = 12.538 (4) Å, α = 110.75 (3)°, β = 101.72 (3)°, γ = 99.74 (3)°, Z = 2, T = −116°C. The $Tl(1,2\text{-}C_2H_4Cl_2)^+$ cation contains a five-membered chelate ring with Tl—Cl distances of 3.138 (4) and 3.179 (3) Å. The metal ion is weakly bonded to four $B(OTeF_5)_4^-$ counterions, with nine Tl—F interactions that range from 2.950 (5) to 3.981 (8) Å. When the solvent is dichloromethane or 1,1,2-trichlorotrifluoroethane, only the unsolvated solid salt $TlB(OTeF_5)_4$ can be isolated by crystallization. This salt is thermally unstable, slowly forming $TlOTeF_5$ and volatile $B(OTeF_5)_3$.

Key words: noncoordinating anion, noncoordinating solvent, metal ion solvation.

PAUL K. HURLBURT, OREN P. ANDERSON et STEVEN H. STRAUSS. Can. J. Chem. **70**, 726 (1992).

Lorsqu'on ajoute du $B(OTeF_5)_3$ a du $TlOTeF_5$, dans des solvants faiblement coordinants comme le dichlorométhane, le 1,2-dichloroéthane et le 1,1,2-trichlorotrifluoroéthane, on obtient des solutions de $M(solv)_x^+B(OTeF_5)_4^-$. Avec du 1,2,-dichloroéthane comme solvant, on a isolé le composé cristallin $Tl(1,2\text{-}Cl_2C_2H_4)B(OTeF_5)_4$ et on l'a étudié par diffraction des rayons-X : triclinique, groupe d'espace $P\bar{1}$, a = 9,221(4), b = 11,396(5) et c = 12,538(4) Å, α = 110,75(3)°, β = 101,72(3)° et γ = 99,74°, Z = 2, T = 116°C. Le cation $Tl(1,2\text{-}Cl_2C_2H_4)^+$ comporte un chélate cyclique à cinq chaînons dans lequel les distances Tl—Cl sont égales à 3,138(4) et 3,179(3) Å. L'ion métallique est faiblement lié à quatre contre-ions $B(OTeF_5)_4^-$ dans lesquels neuf interactions Tl—F se trouvent entre 2,950(5) à 3,981(8) Å. Avec le dichlorométhane ou le 1,1,2-trichlorotrifluoroéthane, la cristallisation ne fournit que le sel solide $TlB(OTeF_5)_4$ non solvaté. Ce sel est thermiquement instable; il forme lentement du $TlOTeF_5$ et du $B(OTeF_5)_3$ qui est volatil.

Mots clés : anion non-coordinant, solvant non-coordinant, solvatation des ions métaux.

[Traduit par la rédaction]

Introduction

There has been increasing interest in recent years to find new anions that are more weakly coordinating than the classical "noncoordinating" anions ClO_4^-, $CF_3SO_3^-$, BF_4^-, SbF_6^-, etc. One term that has been used for such new anions is "least coordinating" anions (1). Examples include $B(OTeF_5)_4^-$ (2), $B_{11}CH_{12}^-$ (1, 3), and BAr_4^- (Ar = C_6H_5 (4) or 3,5-$C_6H_3(CF_3)_2$ (5)). The interest in such species derives in part from a desire to study coordinatively unsaturated cations such as R_3Si^+ (6) and Fe(porphyrin)$^+$ (3*b*), both of which have yet to be prepared and isolated in a condensed phase, and in part from the desire to prepare more active transition metal catalysts (4). Another goal that could be achieved if metal ions (M^{n+}) could be electrostatically decoupled from their counterions (X^-) is that compounds such as $M(L)X_n$, where L is an extremely weak Lewis base such as a chlorocarbon,[2] a chlorofluorocarbon, or a hydrocarbon, could be isolated and characterized in the solid state by X-ray crystallography. With respect to chlorocarbons, this goal has been realized in a limited number of cases.

In this paper we describe the synthesis and characterization of $TlB(OTeF_5)_4$ and $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$. The former compound is soluble in the "least coordinating" solvents dichloromethane, 1,2-dichloroethane, and 1,1,2-trichlorotrifluoroethane. The latter compound contains a Tl—Cl—C—C—Cl chelate ring. Thallium is only the third metal that has been shown by X-ray crystallography to coordinate to a simple chlorocarbon. Chlorocarbon complexes of Ag (7) and Ru (8) have also been structurally characterized.

Experimental

Dichloromethane, dichloromethane-d_2, 1,2-dichloroethane, 1,2-dichloroethane-d_4, and 1,1,2-trichlorotrifluoroethane were distilled from P_2O_5. The compounds $B(OTeF_5)_3$ (9) and $TlOTeF_5$ (2*b*) were prepared by literature procedures. These two compounds, as well as $TlB(OTeF_5)_4$ and $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$ (*vide infra*), are very sensitive to traces of moisture. Therefore, all manipulations involving them were performed under a purified dinitrogen atmosphere using standard techniques (10).

Spectroscopic measurements

Samples for IR spectroscopy were Nujol mulls between AgCl windows. Spectra were recorded at room temperature on a Perkin–Elmer 983 spectrometer. Peak positions are ±1 cm^{-1}. Samples of $TlB(OTeF_5)_4$ for ^{19}F NMR spectroscopy were dichloromethane solutions in 5-mm glass tubes. Spectra were recorded at room temperature on a Bruker WP-300 spectrometer operating at 282.4 MHz, after tuning with a separate sample of dichloromethane-d_2. Chemical shifts (δ scale) are relative to $CFCl_3$. The ^{19}F NMR spectrum of $TlB(OTeF_5)_4$ was an AB_4X pattern shielded relative to $CFCl_3$ (X = ^{125}Te, I = 1/2, 7% natural abundance). Chemical shifts and J_{AB} were determined by comparing the experimental spectrum to a simulated spectrum that was calculated using LAOCOON PC (11). The value of J_{BX} was measured directly from the experimental spectrum.

$TlB(OTeF_5)_4$ and $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$

$TlOTeF_5$ (0.40 g, 0.91 mmol) and $B(OTeF_5)_3$ (0.81 g, 1.1 mmol) were mixed in 1,2-dichloroethane (2 mL). The resulting colorless solution was kept in the freezer (−20°C) for 24 h, at which time the crystalline solid $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$ was present (stoichiometry established by X-ray diffraction (*vide infra*)). This compound slowly loses the coordinated 1,2-dichloroethane molecule under a dinitrogen atmosphere, making a per cent yield determination and elemental analysis problematic. The unsolvated compound $TlB(OTeF_5)_4$ was prepared by mixing $TlOTeF_5$ (0.26 g, 0.60 mmol) and $B(OTeF_5)_3$ (0.43 g, 0.59 mmol) in dichloromethane (3 mL). The mixture (off-white solid in a colorless solution) was stirred for 25 min, at which point all volatiles were removed under vacuum ($\sim 10^{-5}$ Torr (1 Torr = 133.3 Pa); 2 h). An infrared spectrum (*vide infra*) revealed that none of the starting materials remained. The off-white solid compound is thermally unstable, eventually (days) forming $TlOTeF_5$ and $B(OTeF_5)_3$. ^{19}F NMR of $TlB(OTeF_5)_4$ (CH_2Cl_2): δ_A −38.5, δ_B −45.5, J_{AB} = 190 Hz, J_{BX} = 3588 Hz.

X-ray crystallographic study of $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$

A Nicolet *R3m* diffractometer equipped with a LT-1 variable-temperature accessory was used. Crystals of $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$ were examined under an argon atmosphere at <−150°C. A suitable crystal was attached with Dow–Corning silicone grease to the end of a glass fiber and quickly placed into the cold nitrogen stream (−116°C) of the LT-1 unit.

Centering on 25 reflections allowed least-squares calculation of the cell constants, which are listed, along with other experimental parameters, in Table 1. The intensities of control reflections ($\bar{2}00$, $0\bar{1}0$, and 005), monitored every 97 reflections, showed no significant trend during the course of the data collection. An empirical absorption correction, based on intensity profiles for 16 reflections over a range of setting angles (ψ) for the diffraction vector, were applied to the observed data. The transmission factors ranged from 0.205 to 0.436. Although the absolute values of the transmission factors are high, the improvement in R_{merge} after the absorption correction (0.185 before and 0.053 after) indicates that these values are satisfactory. Lorentz and polarization corrections were applied to the data.

The structure was solved using an interpretation of the Patterson map.[3] The refinement involved anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were included in calculated positions (C—H = 0.96 Å, $U(H) = 1.2U_{iso}(C)$). Neutral atom scattering factors (including anomalous scattering) were taken from ref. 12. The weighted least-squares refinements converged (weights calculated as $(\sigma^2(F) + |g|F_o^2)^{-1})$, with the average shift/esd <0.005 over the last three refinement cycles. In the final difference Fourier maps, the maximum and minimum electron densities were 1.43 and −1.94 e Å^{-3}. Analysis of variance as a function of Bragg angle, magnitude of F_o, reflection indices, etc., showed no significant trends.

Table 2 contains a list of atomic positional and isotropic thermal parameters for all unique non-hydrogen atoms of $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$. Table 3 contains a list of selected bond distances and angles. Complete lists of bond distances (Table S-1), bond angles (Table S-2), anisotropic thermal parameters (Table S-3), hydrogen atom parameters (Table S-4), and observed and calculated structure factors (Table S-5) are available as supplementary material.[4]

Results and discussion

The formation of $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$ and $TlB(OTeF_5)_4$ are summarized in the reaction scheme below:

$$TlOTeF_5 + B(OTeF_5)_3 \xrightarrow{\text{solvent}} Tl(\text{solvent})_xB(OTeF_5)_4$$
solvent = CH_2Cl_2, 1,2-$C_2H_4Cl_2$, or 1,1,2-$C_2Cl_3F_3$

$$Tl(\text{solvent})_xB(OTeF_5)_4 \xrightarrow{\text{crystallize}} Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$$
solvent = 1,2-$C_2H_4Cl_2$

$$Tl(\text{solvent})_xB(OTeF_5)_4 \xrightarrow{\text{crystallize}} TlB(OTeF_5)_4$$
solvent = CH_2Cl_2 or 1,1,2-$C_2Cl_3F_3$

$$TlB(OTeF_5)_4 \xrightarrow{\text{vacuum (days)}} TlOTeF_5 + B(OTeF_5)_3$$

The difference in the stoichiometry of the compound isolated upon crystallization is almost certainly due to the ligand strength of the three different solvents. That is, the Tl—Cl(C) bonds in the presumed $Tl(CH_2Cl_2)_x^+$ and $Tl(1,1,2\text{-}C_2Cl_3F_3)_x^+$ cations are sufficiently weak that the coordinated solvent molecules are "squeezed out" of the lattice as it forms. Structural, conductimetric, and ^{13}C NMR spectroscopic data have left little doubt that 1,2-dichloroethane is a stronger ligand for Ag(I) than dichloromethane (7). It is sensible that this order would be preserved for Tl(I). It is also sensible that 1,1,2-trichlorotrifluoroethane would be the weakest donor of all three. In harmony with these expectations, we found that the solubility of $TlOTeF_5$ in 1,2-dichloroethane, 30.2 mM, is considerably greater than in dichloromethane, 1.1 mM. We conclude that this must be due to a difference in the coordinating ability of the two solvents, since the difference in their dielectric constants is small

[3]Calculations for diffractometer operations were performed by using software supplied with the Nicolet *R3m* diffractometer. All structural calculations were performed on the Data General Eclipse S/140 computer in the X-ray laboratory at Colorado State University with the SHELXTL program library written by Professor G. M. Sheldrick and supplied by Nicolet XRD Corporation.

[a]Equivalent isotropic U defined as one third of the trace of the orthogonalised U_{ij} tensor.

(the dielectric constants for dichloromethane and 1,2-dichloroethane are 9.08 and 10.65, respectively (13)). Furthermore, we found that $TlOTeF_5$ is not soluble to any detectable extent in 1,1,2-trichlorotrifluoroethane.

The overall structure of $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$ is shown in Fig. 1. The thallium coordination sphere and the conformation of the Tl—Cl—C—C—Cl chelate ring are shown in Figs. 2 and 3, respectively. A stereoview of the unit cell packing is shown in Fig. S-1, which is available as supplementary material.[4] Selected bond distances and angles are listed in Table 3.

Thallium is only the third metal that has been shown conclusively (i.e., by X-ray crystallography) to coordinate to extremely weakly basic (14) chlorocarbons.[2] Thallium is also the first such metal from Period 6 and the first such metal with a $d^{10}s^2$ electron configuration. Previous structurally characterized examples are dichloromethane complexes of Ag (7) and Ru (8), 1,2-dichloroethane complexes of Ag (7), and a 1,2,3-trichloropropane complex of Ag.[5] Based on IR and NMR spectroscopic data, others have concluded that dichloromethane can coordinate to Mo and W (15) or to Re (16), respectively. Many examples of M—Cl(C) linkages have been reported in compounds in which the chlorine atom is a substituent on a much stronger ligand such as an amine or a phenoxide (17).

The thallium–organochlorine bonds and the Tl—Cl—C—C—Cl chelate ring are the most interesting and significant aspects of the structure. The Tl—Cl distances of 3.138 (4) and 3.179 (3) Å are well within the sum of van der Waals radii for these atoms, which is probably between 3.75 Å (18) and 3.80 Å (19). For comparison, the Tl—Cl distances in the Rock Salt and CsCl modifications of TlCl are 3.15 (2) and 3.32 (2) Å, respectively (20).[6] Despite the fact that 1,2-dichloroethane is extremely weakly coordinated to Tl(I) in this structure, the five-membered Tl—Cl—C—C—Cl chelate ring (see Fig. 3) exhibits the same puckered conformation seen with more traditional and much stronger bidentate ligands such as ethylenediamine (21).

The Tl(I) ion in $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$ is weakly coordinated via secondary bonds (22) to up to nine fluorine atoms from four different $B(OTeF_5)_4^-$ counterions (see Fig. 2). The nine Tl—F(Te) distances range from 2.950 (5) Å for Tl—F11″ to 3.981 (8) Å for Tl—F3′. The next most distant fluorine atom is F13‴, which is 4.057 (9) Å from Tl. While the sum of van der Waals radii for thallium and fluorine has been reported to be either 3.35 or 3.50 Å (18, 19), we have

[5]D. M. Van Seggen, O. P. Anderson, and S. H. Strauss. Submitted for publication.

[6]The stable form of TlCl at 25°C and 1 atm (101.3 kPa) has the CsCl structure, while TlCl grown by vapor deposition onto a KCl, KBr, or KI substrate has the Rock Salt structure.

O—Te—F_{eq}	89.2 (3) – 96.1 (3)		

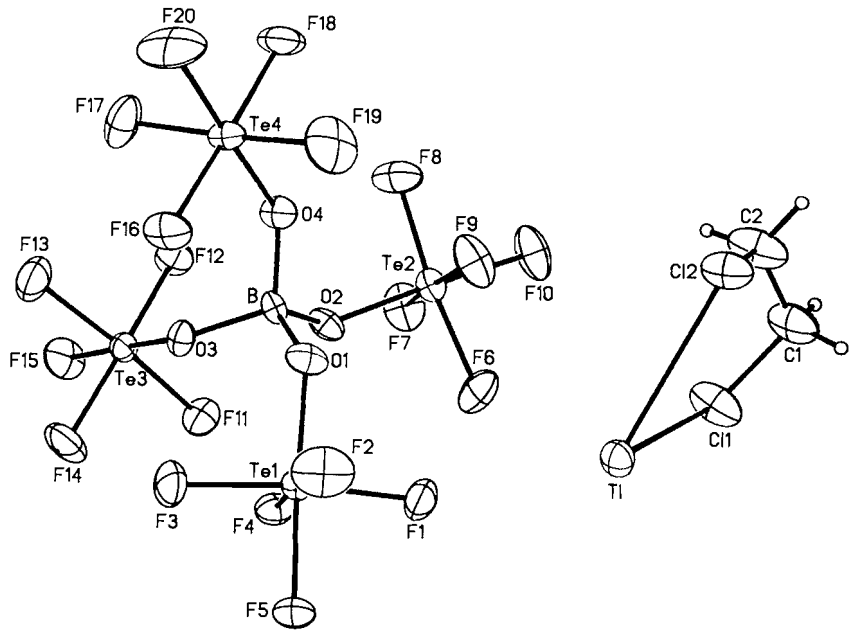

FIG. 1. Drawing of the $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$ asymmetric unit (50% probability ellipsoids). The separation of the $Tl(1,2\text{-}C_2H_4Cl_2)^+$ cation and the $B(OTeF_5)_4^-$ anion is to scale.

included two fluorine atoms whose Tl—F distances are >3.50 Å in the Tl coordination sphere shown in Fig. 2. This is because Tl—F distances in TlF, which possesses a very distorted Rock Salt structure, range all the way from 2.25 (2) to 3.90 (2) Å (23). Another relevant comparison can be made with $Tl(C_9H_{21}N_3)PF_6$,[7] in which the Tl(I) ion has a N_3F_3 donor set. In this compound, the Tl—F(P) distances are 3.23 (1), 3.27 (1), and 3.54 (2) Å (24).

The structure of the bound 1,2-dichloroethane ligand in $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$ is not significantly perturbed from the structure of the free molecule. In solid 1,2-dichloroethane at −140°C, which exists as the *anti* conformer, the C—Cl and C—C bond distances and the Cl—C—C bond angle are 1.80 (2) Å, 1.49 (4) Å, and 105.5 (5)°, respectively (25). Only the Cl—C—C bond angle is distinguishable from the values found in $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$, 113 (1)° and 114 (1)° (see Table 3). A better comparison for our complex would be a 1,2-dichloroethane solvate with a *gauche* conformation; one such example (data obtained at −160°C) has an average C—Cl bond distance, a C—C bond distance, and an average Cl—C—C bond angle of 1.798 (5) Å, 1.467 (5) Å, and 112.6 (4)°, respectively (26). This solvate has a Cl—C—C—Cl torsional angle of 61.6°, while in our complex this angle is 68.9°. In 1,2-dichloroethane complexes of Ag(I), the Cl—C—C—Cl torsional angles range from 65.0° to 70.0° (7*a*). The increase in the Cl—C—C—Cl torsional angle in the complexes relative to the solvate is minor: the change of 4°–8° may allow the ligand to achieve a more optimal Cl—M—Cl bite angle.

The structure of the $B(OTeF_5)_4^-$ counterion (idealized S_4 symmetry, with the S_4 axis bisecting the O1—B—O2 and O3—B—O4 angles) is virtually identical with those found in $Tl(mesitylene)_2B(OTeF_5)_4$ (2*b*), $AgB(OTeF_5)_4$ (2*c*), and $Ag(CO)B(OTeF_5)_4$ (2*a*). As was found in these three other structures, the bonds between Te atoms and F atoms coordinated to Tl in $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$ are not signifi-

[7] $C_9H_{21}N_3$ = *N*,*N*′,*N*″-trimethyl-1,4,7-triazacyclononane.

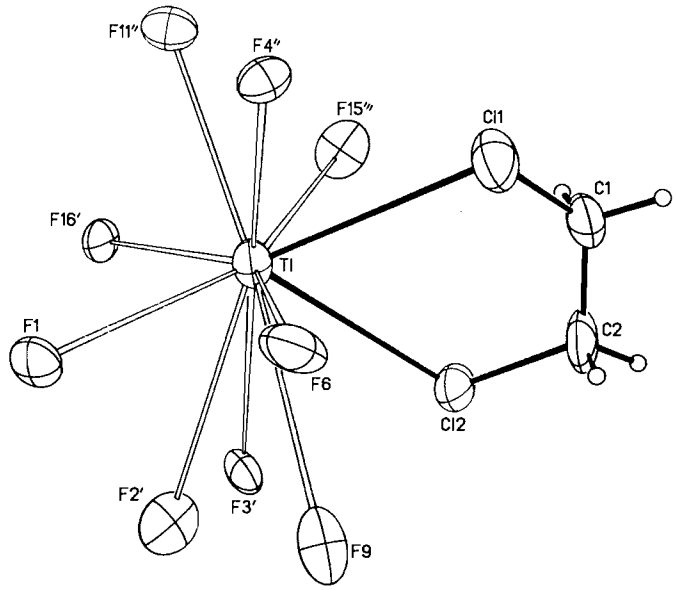

FIG. 2. Drawing of the Tl coordination sphere in $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$, emphasizing the bidentate coordination of the 1,2-dichloroethane ligand (50% probability ellipsoids).

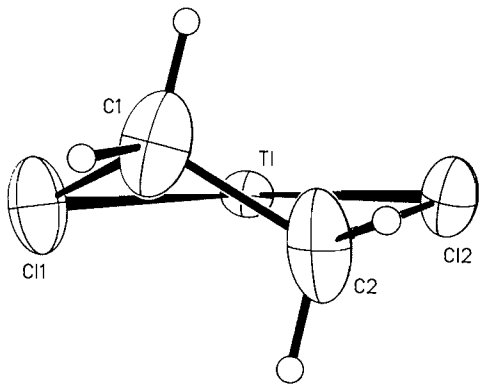

FIG. 3. Drawing of the $Tl(1,2\text{-}C_2H_4Cl_2)^+$ cation in $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$, showing the conformation of the five-membered chelate ring (50% probability ellipsoids). This asymmetric cation is inversion related to its enantiomer in the unit cell, which contains two asymmetric units.

cantly longer than the other Te—F distances in this compound. Generally, coordination of an anion such as SbF_6^- produces a longer Sb—F bond distance to the bridging F atom (27), but this is not always the case (28).

A solid-state (Nujol mull) IR spectrum of $TlB(OTeF_5)_4$ exhibits bands that are typical of the $B(OTeF_5)_4^-$ anion (2*b*):[8] 980 cm^{-1} (s, bd; ν(BO)), 799 cm^{-1} (w, sp), 723 cm^{-1} (s, sp), and 706 cm^{-1} (s, sp; ν(TeO)), and 664 cm^{-1} (s, sp), 639 cm^{-1} (m, sp), and 621 cm^{-1} (m, sp; ν(TeF)). These are matched by the following bands for $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$: 983 cm^{-1} (s, bd; ν(BO)), 798 cm^{-1} (w, sp), 721 cm^{-1} (s, sp), and 705 cm^{-1} (s, sp; ν(TeO)), and 664 cm^{-1} (s, sp), 641 cm^{-1} (m, sp), and 625 cm^{-1} (m, sp; ν(TeF)).

In addition, the IR spectrum of $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$ exhibited bands attributable to the coordinated 1,2-dichloroethane molecule at 1314 and 1282 cm^{-1} (CH_2 wag) and at 878 cm^{-1} (CH_2 rock) (29). Bands attributable to CCl stretching were not observed, presumably because they were buried under the intense Te—O and Te—F stretching bands.[9] However, the spectrum of the deuterated derivative $Tl(1,2\text{-}C_2D_4Cl_2)B(OTeF_5)_4$ exhibited a band at 610 cm^{-1}, which we assign as ν(CCl) for the coordinated chlorocarbon ligand since the *gauche* conformer of 1,2-dichloroethane-d_4 has a CCl stretching band at 616 cm^{-1} (7*a*). Coordination of 1,2-dichloroethane to Tl(I) has lowered ν(CCl) by 6 cm^{-1}, a smaller change than was seen for two 1,2-dichloroethane complexes of Ag(I) (7*a*). For these complexes, $\Delta\nu$(CCl) was 16 cm^{-1}. The larger effect on ν(CCl) is in harmony with the observation that the Ag—Cl bonds in $Ag(1,2\text{-}C_2H_4Cl_2)OTeF_5$ and $Ag_2(1,2\text{-}C_2H_4Cl_2)_4Pd(OTeF_5)_4$, which fall in the range 2.640 (3)–3.000 (3) Å (7*a*), are shorter and presumably stronger than the Tl—Cl bonds in $Tl(1,2\text{-}C_2H_4Cl_2)B(OTeF_5)_4$.

Future reports from this laboratory will detail the further use of $B(OTeF_5)_4^-$ and related highly fluorinated least coordinating anions.

Crystals of $Mn(CH_3CONH_2)_2(HPhPO_2)_2$ are monoclinic, a = 5.668(2), b = 7.500(2), c = 23.104(2) Å, β = 95.52(2)°, Z = 2, space group $P2_1/c$, and those of $Mn(HPhPO_2H)_2(HPhPO_2)_2$ are monoclinic, a = 23.281(1), b = 5.508(2), c = 20.5489(6) Å, β = 90.424(4)°, Z = 4, space group $C2/c$. The structures were solved by heavy-atom methods and were refined by full-matrix least-squares procedures to R = 0.028 and 0.035 for 2081 and 2117 reflections with $I \geq 3\sigma(I)$, respectively. Both compounds have structures consisting of polymeric chains propagating along the crystallographic b axis; two phosphinate ligands bridge adjacent manganese atoms forming square planar MO_4 units, and six coordination about the metal is achieved by axially O-bonded neutral ligands. Indirect evidence supports similar structures for the other complexes studied here. The complexes are antiferromagnetic and the magnetic susceptibilities have been analyzed according to two Heisenberg models for linear chains. The exchange coupling constants range from -0.30 cm^{-1} for the acetamide complex to -0.06 cm^{-1} for the pyridine complex. Magnetostructural correlations involving these complexes and the previously studied $Mn(HCONH_2)_2(HPhPO_2)_2$, reveal that the magnitude of the magnetic coupling is enhanced by symmetrically bridging O—P—O units and short Mn–O–P–O–Mn pathways for exchange.

Key words: polymeric manganese monophenylphosphinates, crystal structures, magnetic properties.

JING-LONG DU, STEVEN J. RETTIG, ROBERT C. THOMPSON, JAMES TROTTER, PETER BETZ et AVI BINO. Can. J. Chem. **70**, 732 (1992).

Les cristaux de $Mn(CH_3CONH_2)_2(HPhPO_2)_2$ sont monocliniques, groupe d'espace $P2_1/c$, avec a = 5,668(2); b = 7,500(2) et c = 23,104(2) Å, β = 95,52(2)° et Z = 4 alors que ceux de $Mn(HPhPO_2H)_2(HPhPO_2)_2$ sont monocliniques, groupe d'espace $C2/c$, avec a = 23,281(1); b = 5,508(2) et c = 20,5489(6) Å, β = 90,424(2)° et Z = 4. On a résolu les structures par les méthodes des atomes lourds et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de R = 0,028 et 0,035, respectivement pour 2081 et 2117 réflexions avec $I \geq 3\sigma(I)$. Les deux composés possèdent des structures formées de chaînes de polymères se propageant le long de l'axe cristallographique b; deux coordinats phosphinates établissent des ponts avec les atomes de manganèse adjacents et forment des unités MO_4 plan carré; l'hexacoordination autour du métal est obtenue par des coordinats neutres liés d'une façon axiale par le biais d'oxygènes. Des données indirectes suggèrent des structures semblables pour les autres complexes étudiés ici. Les complexes sont antiferromagnétiques et on a analysé les susceptibilités magnétiques selon deux modèles de Heisenberg pour des chaînes linéaires. Les constantes de couplage d'échange varient de $-0,30$ cm^{-1} pour le complexe de l'acétamide à $-0,06$ cm^{-1} pour le complexe de la pyridine. Des corrélations magnétostructurales impliquant ces complexes et le $Mn(HCONH_2)_2(HPhPO_2)_2$ étudié antérieurement révèlent que l'amplitude du couplage magnétique est rehaussé par la présence d'unités O—P—O formant des ponts symétriques et par de courts chemins Mn–O–P–O–Mn pour les échanges.

Mots clés : monophénylphosphinates de manganèse polymériques; structures cristallines; propriétés magnétiques.
[Traduit par la rédaction]

Introduction

Several single crystal X-ray structure determinations have revealed that the structures adopted by binary metal phosphinates, $M(R_2PO_2)_2$, involve metal ions linked in chains by double phosphinate bridges with MO_4 chromophores ranging from square planar (1) through distorted tetrahedral (2–5) to close to regular tetrahedral (6, 7) geometries, the particular structure adopted depending on both the metal and the composition of the phosphinate ligand. Compounds of composition $ML_2(R_2PO_2)_2$ in which metal ions are linked in chains by double phosphinate bridges forming square planar MO_4 chromophores with axially coordinated L groups are also known (8, 9). The three atom O–P–O bridges in these polymeric materials have been shown to be capable of transmitting magnetic exchange effects and our interest in these compounds has been in investigating how both the sign (antiferromagnetic or ferromagnetic) and magnitude of the exchange is affected by structural changes (10, 11).

We reported, earlier, studies on the formamide complex of manganese(II) monophenylphosphinate, $Mn(HCONH_2)_2(HPhPO_2)_2$, **1** (9). The compound has the double phosphinate bridged chain structure with axially coordinated formamide ligands and exhibits antiferromagnetic coupling between metal centres. With a view to examining how the nature of L, in complexes of the type $ML_2(HPhPO_2)_2$, affects the magnetic coupling we have, in the present work, synthesized and characterized five related complexes where L = CH_3CONH_2 (**2**), $HPhPO_2H$ (**3**), $HCONH(CH_3)$ (**4**), H_2O (**5**), and C_5H_5N (**6**). Compounds **2** and **3** were obtained in crystalline forms suitable for single crystal X-ray diffrac-

tion studies and the results of these are reported here. Magnetic susceptibility, infrared spectroscopic, and differential thermal analysis studies are reported on all five compounds.

Experimental

Syntheses

Poly-bis(acetamide)bis(μ-monophenylphosphinato)manganese(II), $Mn(CH_3CONH_2)_2[H(C_6H_5)PO_2]_2$, 2

Manganese(II) chloride tetrahydrate (0.501 g) was dissolved in 40 mL of acetone and the solution was added to a solution prepared by dissolving acetamide (1.82 g) and monophenylphosphinic acid (0.712 g) in 50 mL of acetone. Colorless crystals were collected by filtration, washed with acetone, and air-dried. Anal. calcd. for $MnC_{16}H_{22}O_6N_2P_2$: C 42.21, H 4.87, N 6.15; found: C 42.30, H 4.89, N 6.10.

Poly-bis(monophenylphosphinic acid)bis(μ-monophenylphosphinato)manganese(II), $Mn[H(C_6H_5)PO_2H]_2[H(C_6H_5)PO_2]_2$, 3

Monophenylphosphinic acid (3.13 g) was partially neutralized with sodium hydroxide (0.179 g) in 70 mL of distilled water. The resulting solution was added dropwise to a manganese salt solution prepared by dissolving manganese(II) perchlorate hexahydrate (1.62 g) in 10 mL of distilled water. The resulting solution became cloudy after stirring for about 40 min. The stirring of the solution was continued for ~18 h. The product was collected by filtration, washed with distilled water, and air-dried. Anal. calcd. for $MnC_{24}H_{26}O_8P_4$: C 46.40, H 4.22; found: C 46.48, H 4.25. Single crystals suitable for X-ray diffraction studies were obtained from the above reaction by slow evaporation of a solution in which reagent concentrations were about half those specified above.

Bis(N-methylformamide)bis(monophenylphosphinato)manganese(II), $Mn(HCONHCH_3)_2[H(C_6H_5)PO_2]_2$, 4

Manganese(II) monophenylphosphinate (~1.0 g) prepared as described previously (12), was dissolved in 20 mL of *N*-methylformamide. A white powder was obtained after the solvent was removed under vacuum. The powder was washed with acetone, then left to air-dry. Anal. calcd. for $MnC_{16}H_{22}O_6N_2P_2$: C 42.21, H 4.87, N 6.15; found: C 41.95, H 4.90, N 6.05.

Diaquobis(monophenylphosphinato)manganese(II), $Mn(H_2O)_2[H(C_6H_5)PO_2]_2$, 5

Monophenylphosphinic acid (2.84 g) was neutralized with potassium carbonate (1.39 g) in 50 mL of aqueous methanol solution (50:50 by volume). Manganese(II) sulfate monohydrate (1.69 g) was dissolved in 50 mL distilled water, then added dropwise to the stirring monophenylphosphinate solution. The white precipitate that formed was isolated by filtration, washed with aqueous methanol, and then air-dried. Anal. calcd. for $MnC_{12}H_{16}O_6P_2$: C 38.63, H 4.32; found: C 38.55, H 4.30.

Bis(pyridine)bis(monophenylphospinato)manganese(II), $Mn(C_5H_5N)_2[H(C_6H_5)PO_2]_2$, 6

Manganese(II) monophenylphosphinate (~1.0 g) was mixed with 40 mL of pyridine and 10 mL of 2,2-dimethoxypropane. The mixture was refluxed for 8 h, then a white powder was isolated by filtration, washed with a small portion of diethyl ether, and then dried under vacuum at room temperature for about 2 h. Anal. calcd. for $MnC_{22}H_{22}O_4N_2P_2$: C 53.34, H 4.48, N 5.66; found: C 52.54, H 4.42, N 5.31. This compound appears to contain a small amount of lattice water (approximately 0.5 mol) as evidenced by the microanalysis and the presence of a weak band centered around 3300 cm^{-1} in the infrared spectrum. Repeated syntheses always gave lattice water and attempts to remove it by heating led to the simultaneous dissociation of pyridine.

Experimental techniques

Infrared spectra (4000–250 cm^{-1}) were obtained on samples mulled in Nujol and pressed between KRS-5 plates (Harshaw Chemical Co.) using a Perkin–Elmer model 598 spectrophotometer. Frequencies are considered accurate to within ±3 cm^{-1}. Differential scanning calorimetry (DSC), measurements were made with a Mettler DSC 20 cell and a Mettler TC 10 TA processor operating over the temperature range 35–400°C. Some thermogravimetric analysis information was obtained by weighing the aluminum crucible containing the sample prior to and following a thermal event (accuracy ~±5%). Magnetic susceptibilities from ~80 to ~2 K were measured using a PAR model 155 vibrating sample magnetometer as described previously (5). Measurements were made at a field of 7501 G. The diamagnetic corrections used were (in 10^{-6} cm^3 mol^{-1}): Mn^{2+}, −14; $(C_6H_5)(H)PO_2^-$, −78; $HCONHCH_3$, −26; CH_3CONH_2, −26; H_2O, −12; C_5H_5N, −49; $H(C_6H_5)PO_2H$, −78.

X-ray crystallographic analyses of $Mn(CH_3CONH_2)_2[H(C_6H_5)PO_2]_2$, 2, and $Mn[H(C_6H_5)PO_2H]_2[H(C_6H_5)PO_2]_2$, 3

Crystallographic data for $Mn(CH_3CONH_2)_2[H(C_6H_5)PO_2]_2$ and $Mn[H(C_6H_5)PO_2H]_2[H(C_6H_5)PO_2]_2$ appear in Table 1. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with $2\theta = 29.6°–39.9°$ and 99.6°–118.8°, respectively. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, showed only small random variations. The data were processed[2] and corrected for Lorentz and polarization effects, decay, and absorption (empirical, based on azimuthal scans for four reflections).

The structure analysis of $Mn[H(C_6H_5)PO_2H]_2[H(C_6H_5)PO_2]_2$ was initiated in the centrosymmetric space group $C2/c$ on the basis of the *E*-statistics and the appearance of the Patterson function, this choice being confirmed by the subsequent successful solution and refinement of the structure. Both structures were solved by heavy-atom methods, the coordinates of the Mn and P atoms being determined from the Patterson functions and those of the remaining non-hydrogen atoms from subsequent difference Fourier syntheses. All non-hydrogen atoms of both complexes were refined with anisotropic thermal parameters. All hydrogen atoms of $Mn(CH_3CONH_2)_2[H(C_6H_5)PO_2]_2$ were refined with isotropic thermal parameters and for $Mn[H(C_6H_5)PO_2H]_2[H(C_6H_5)PO_2]_2$ the phosphorus- and oxygen-bound hydrogen atoms were refined with isotropic thermal parameters and the remaining hydrogen atoms were fixed in idealized positions (C—H = 0.98 Å, $B_H = 1.2\ B_{\text{bonded atom}}$). A correction for secondary extinction was applied for $Mn[H(C_6H_5)PO_2H]_2[H(C_6H_5)PO_2]_2$, the final value of the extinction coefficient being 1.10×10^{-6}. Neutral atom scattering factors and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* (13). Final atomic coordinates and equivalent isotropic thermal parameters, selected bond lengths, and selected bond angles appear in Tables 2–4, respectively. Hydrogen atom parameters, anisotropic thermal parameters, complete tables of bond lengths and bond angles, torsion angles, intermolecular contacts, least-squares planes, and measured and calculated structure factor amplitudes are included as supplementary material.[3]

Values given for R, R_w, and *gof* are based on those reflections with $I \geq 3\sigma(I)$.

Results and discussion

Structural studies

Crystals of the acetamide complex **2** are isomorphous with those of the previously studied (9) formamide derivative **1**, both belonging to the monoclinic crystal system and space group $P2_1/c$. Crystals of the monophenylphosphinic acid complex **3** are also monoclinic, space group $C2/c$. All three compounds have structures consisting of polymeric chains propagating along the crystallographic b axis; two phosphinate ligands bridge adjacent manganese atoms forming square planar MO_4 units. Six-coordination about the metal is achieved by axially *O*-bonded neutral ligands. Figures 1 and 2 show the structures of **2** and **3**, respectively and give the atom numbering schemes. Stereoscopic views of sections of the polymeric chains of **2** and **3** are shown in Figs. 3 and 4.

Both amide hydrogens in **2** are involved in hydrogen bonding. The interchain N—H(2)···O(1)($1 - x$, $-y$, $1 - z$) interaction gives H(2)···O(1) and N···O(1) distances of 2.11(3) and 3.074(2) Å, respectively, with an N—H(2)···O(1) bond angle of 173(2)°. The intrachain N—H(3)···O(2)($1 + x$, y, z) hydrogen bond gives H(3)···O(2) and N···O(2) distances of 2.23(2) and 2.982(2) Å, respectively, and an N—H(3)···O(2) bond angle of 152(2)°. Inter- and intrachain hydrogen bonding like that described here was reported previously for **1** where both N···O(1) and N···O(2) distances are given as ~2.9 Å (9). There is no interchain hydrogen bonding in **3**; however, this compound has strong intrachain hydrogen bonding involving O(4)—H(3)···O(2) resulting in H(3)···O(2) and O(4)···O(2) distances of 1.62(5) and 2.555(3) Å, respectively, and an O(4)—H(3)···O(2) bond angle of 175(5)°.

The coordination around manganese in **2** and **3** is approximately octahedral with O—Mn—O bond angles ranging from 87.89(5)° to 92.11(5)° in **2** and from 85.67(7)° to 94.32(7)° in **3**. The Mn—O(3) distances involving the terminal ligands are approximately the same in **2** and **3** (2.182(1) and 2.175(2) Å) and are significantly shorter than the corresponding distance in **1** (2.241(3) Å) (9). As in the case of **1** (9), there are two Mn—O distances involving the bridging phosphinate groups in **2** and **3**. The average Mn—O(bridging) distance is the same in **2** and **3** (2.203(1) and 2.204(2) Å) and is significantly greater than the corresponding average distance in **1** (2.175(3) Å) (9). It would

NOTE: The prime refers to the symmetry operation $1 + x, y, z$ for **2** and $x, 1 + y, z$ for **3**.

appear that the weaker manganese-terminal ligand interaction in **1** compared with that in **2** and **3** has resulted in stronger manganese-bridging phosphinate interactions. This has a significant effect on the magnetic properties of these compounds as will be described later.

Consideration of the internal bond parameters of the bridging phosphinate groups in **2** and **3** reveals relatively little difference in bond angles but significant differences in P—O bond distances. While the average P—O bond distance is the same in **2** and **3** (1.511(1) and 1.512(2) Å, respectively) and comparable with that reported for **1** (1.515(4) Å)[4] (9), the O—P—O group is symmetrical in **2** (as is the case for **1**) but asymmetrical in **3** (Δ P–O = 0.024(4) Å). This asymmetry in the bridging O—P—O unit is undoubtedly a consequence of hydrogen-bonding interactions. In **3**, only one of the oxygens (O(2)) is involved in hydrogen-bonding interactions (intrachain). As a result the P—O(2) bond is significantly longer than the P—O(1) bond in this compound. In both **1** and **2** the two phosphinate oxygens are both involved in hydrogen-bonding interactions (O(1) in interchain interactions and O(2) in intrachain interactions) resulting in symmetrical O—P—O groups. This, we believe, also has a significant effect on the magnetic properties of these compounds (see below).

Attempts to obtain **4**, **5** and **6** in crystalline form suitable for single crystal X-ray diffraction studies were unsuccessful and hence our conclusions concerning the structures of these compounds are based on indirect evidence only. These compounds are stoichiometrically equivalent to **1**, **2** and **3** and their properties, to be described here, are at least consistent with their having similar structures in which manganese ions are linked in chains by double phosphinate bridges and different neutral ligands occupy the axial positions. All six of the compounds under consideration here dissolve in water (where dipolar and hydrogen bonding interactions with the solvent likely break up the phosphinate bridged chains) but are insoluble in a wide range of organic solvents including ethanol, chloroform, benzene, carbon tetrachloride, and dichloromethane. Their thermal properties are also very similar. Differential scanning calorimetry studies show that while **1** exhibits loss of formamide in two steps at ~140 and 190°C, the other compounds show loss of both neutral ligands in a single step at 130°C for **2**, **4**, and **5**, at 140°C for **3** and at 123°C for **6**. Compound **6** contains a small amount of lattice water (see experimental section), which appears to be removed along with the pyridine ligands at 123°C. No other thermal events are seen for any of the compounds up to the onset of exothermic decomposition which occurs in the 220–240°C range.

Selected bands in the infrared spectra are given in Table 5. Of the six complexes, five show two bands assigned to the antisymmetric and symmetric PO_2 stretching vibrations of a bridging phosphinate group. The presence of both neutral monophenylphosphinic acid and anionic monophenylphosphinate ligands in **3** accounts for the multiplicity of bands in

[4]Bond lengths and angles for **1** not reported in ref. 9 are calculated using the positional parameters reported earlier (9).

[a]NOTE: ′, ″, *, and # refer to the symmetry operations: $1 + x, y, z$; $-x, 1 - y, 1 - z$; $1 - x, 1 - y, 1 - z$; and $x - 1, y, z$; respectively, for **2** and $x, 1 + y, z$; $1/2 - x, 3/2 - y, 1 - z$; $1/2 - x, 1/2 - y, 1 - z$; and $x, y - 1, z$ for **3**.

the PO_2 stretching region for this compound. The similarity in the PO_2 stretching frequencies observed for **1** and **2** is consistent with the nearly identical PO_2 bond parameters for these two compounds; the corresponding bands are shifted to higher frequencies in **4**, **5**, and **6**. It has been suggested that the frequency separation between the two PO_2 stretching vibrations in metal phosphinates provides a measure of the equivalence of the two P—O bonds (10). In **1** and **2** the structure determinations show the P—O bonds to be virtually equivalent and for these compounds the frequency separations are 84 and 89 cm^{-1}, respectively. The much higher separations of 114 and 122 cm^{-1} observed for **4** and **6** may reflect the presence of unsymmetrical O—P—O bridging units in these compounds. In the case of **4** this might be expected since the $HCONHCH_3$ ligand, like the $H(C_6H_5)PO_2H$ ligand in **3**, should be involved in intrachain hydrogen bonding only, resulting in nonequivalent P—O bonds as discussed above for **3**. Employing this criterion, the frequency separation of 84 cm^{-1} in **5** suggests equivalent P—O bonds in this compound.

All compounds except **3** and **6** exhibit one band over the frequency range 2360–2400 cm^{-1} assigned to the P—H stretching vibration. The pyridine complex, **6**, is somewhat unique in this regard in that the P—H band is split and shifted to lower frequencies (2310, 2280 cm^{-1}). The band splitting may reflect the presence of two structurally inequivalent phosphinate groups in this compound while the shift to lower frequency may reflect more weakly coordinated phosphinate ligands. Consistent with the latter suggestion is the fact that **6** exhibits the highest frequency antisymmetric and symmetric PO_2 stretching frequencies of the six compounds under consideration here (Table 5). That pyridine is in fact coordinated in **6** is evidenced by the fact that the 6a and 16b bands (in the notation of Kline and Turkevich (14)), which occur at 601 and 403 cm^{-1}, respectively, in the free base, are seen to exhibit their characteristic shift to higher frequencies upon coordination (15). The observation of two bands in the ν(PH) region for **3** is not unexpected owing to the presence of both neutral monophenylphosphinic acid and bridging phosphinate groups. Bands in the 3100–3400 cm^{-1} region corresponding to ν(NH) vibrations for **1**, **2**, and **4** and ν(OH) for **3** and **5** are very broad, consistent with the presence of strong hydrogen-bonding interactions. The ν(CO) vibrations are at lower

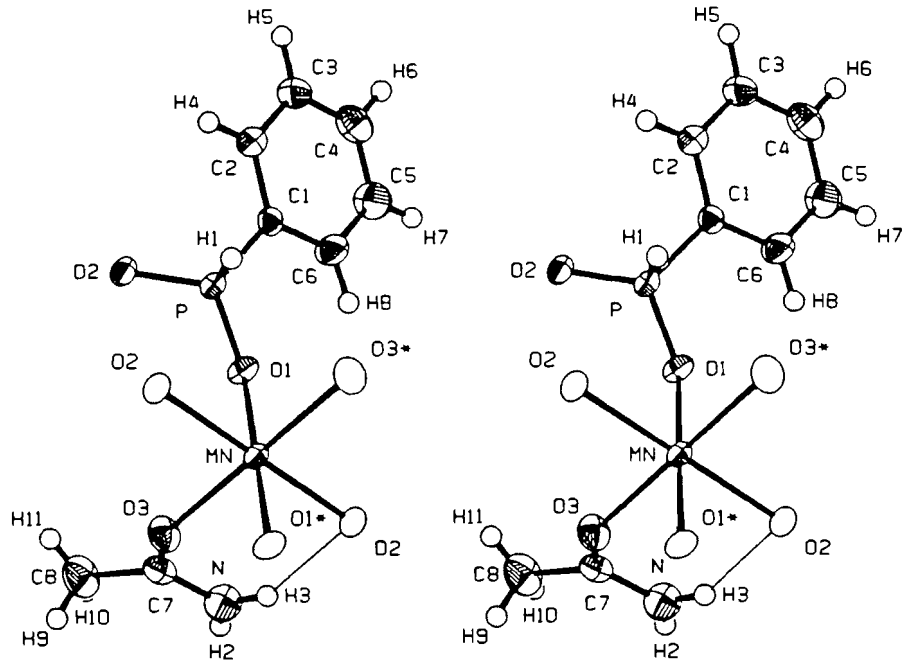

FIG. 1. Stereoscopic view of $Mn(CH_3CONH_2)_2[H(C_6H_5)PO_2]_2$, **2**, showing atom labelling and the coordination about Mn; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

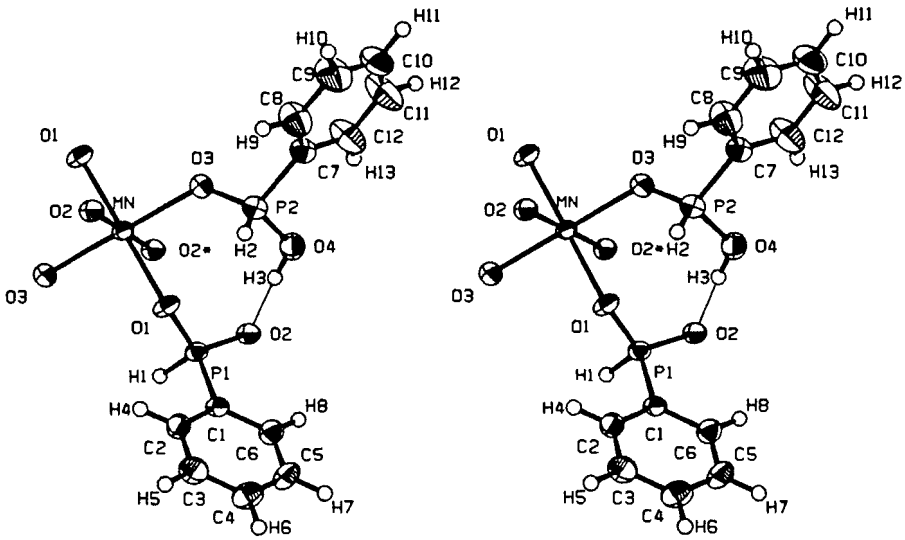

FIG. 2. Stereoscopic view of $Mn[H(C_6H_5)PO_2H]_2[H(C_6H_5)PO_2]_2$, **3** showing atom labelling and the coordination about Mn; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

frequencies in **2** and **4** compared with ν(CO) in **1** and this may reflect stronger binding to manganese in **2** and **4**. This is confirmed by the X-ray diffraction results in the case of **1** and **2**.

Magnetic studies

Magnetic susceptibility and magnetic moment data for complexes **2** through **6** are deposited. (see footnote 3) Data for **1** were given previously (9). Plots of magnetic moment versus temperature are given in Fig. 5. The $^6A_{1g}$ ground state for octahedral manganese(II) renders a relatively straightforward interpretation of magnetic properties. In the absence of magnetic exchange effects the magnetic moment should be spin-only (5.92 μ_B) and temperature independent except possibly at very low temperatures where zero-field splitting may impart some temperature dependence. All six complexes under consideration here exhibit decreasing magnetic moments with decreasing temperature (Fig. 5), indicative of antiferromagnetic exchange. Exchange is confirmed for complexes **1**, **2**, and **4** for which maxima in magnetic susceptibility versus temperature plots have been observed at 5.8 K for **1** (9) and at ~3.5 K for **2** and **4**.

As described previously for **1** (9), we have analyzed the magnetic susceptibility data for **2** through **6** according to two isotropic Heisenberg models for linear chains, the scaling model of Wagner and Friedberg with $S = 5/2$ (16) and the Weng model (17) with coefficients generated by Hiller *et al.*

For personal use only.

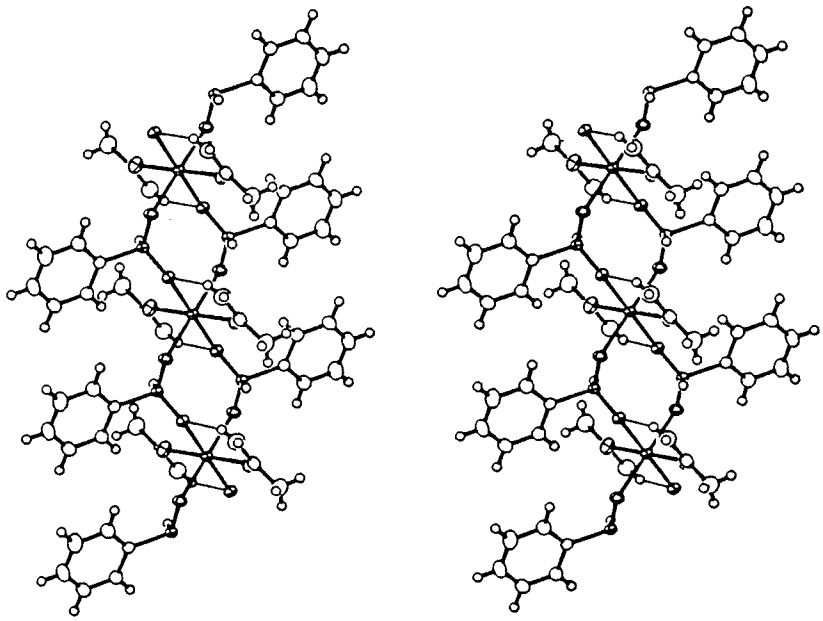

FIG. 3. Stereoscopic view of a portion of the chain structure of $Mn(CH_3CONH_2)_2[H(C_6H_5)PO_2]_2$, **2**, showing hydrogen bonding (fine bonds).

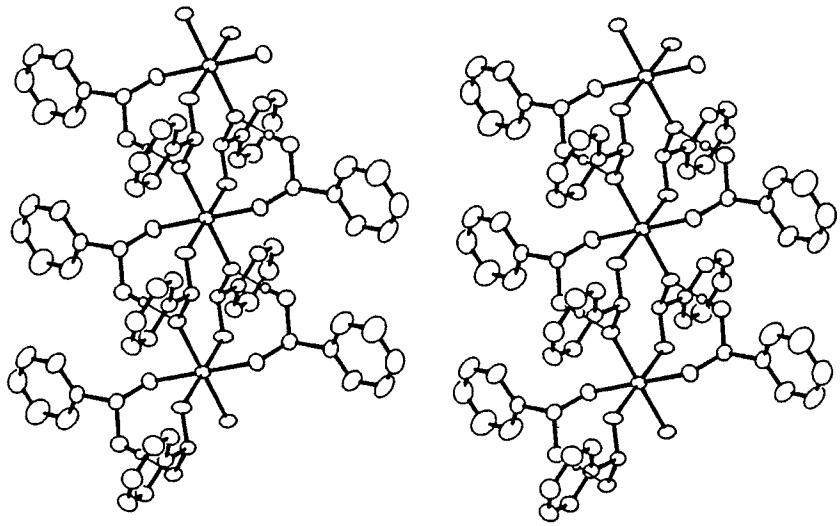

FIG. 4. Stereoscopic view of the chain structure of $Mn[H(C_6H_5)PO_2H]_2[H(C_6H_5)PO_2]_2$, **3**, fine bonds represent hydrogen bonds.

(18) for $S = 5/2$. Within these models the Hamiltonian is $\mathcal{H} = -2J\Sigma\hat{s}_i \cdot \hat{s}_j$. According to the Wagner and Friedberg model,

$$\chi_M = \left[\frac{Ng^2\beta^2S(S+1)}{3kT} \cdot \frac{(1+U)}{(1-U)}\right]$$

where

$$U = \coth K - \frac{1}{K} \qquad \text{and} \qquad K = \frac{2JS(S+1)}{kT}$$

According to the second model,

$$\chi_M = \left[\frac{Ng^2\beta^2}{kT}\right]\left[\frac{(A+BX^2)}{(1+CX+DX^3)}\right]$$

where

$$A = 2.9167, \qquad B = 208.04,$$

$$C = 15.543, \qquad D = 2707.2, \qquad X = \frac{|J|}{kT}$$

Experimental magnetic susceptibility data were analyzed using both models with the exchange coupling constant J as the only fitting parameter. The absence of orbital angular momentum in the ground state of manganese(II) permits g to be fixed at 2.00. Best fits were obtained by minimizing the function

$$F = \left[\left(\frac{1}{n}\right)\Sigma\left(\frac{(\chi_i^{calc} - \chi_i^{obs})}{\chi_i^{obs}}\right)^2\right]^{1/2}$$

where n is the number of data points. The value of F, then, provides a measure of agreement between the experimental data and the model.

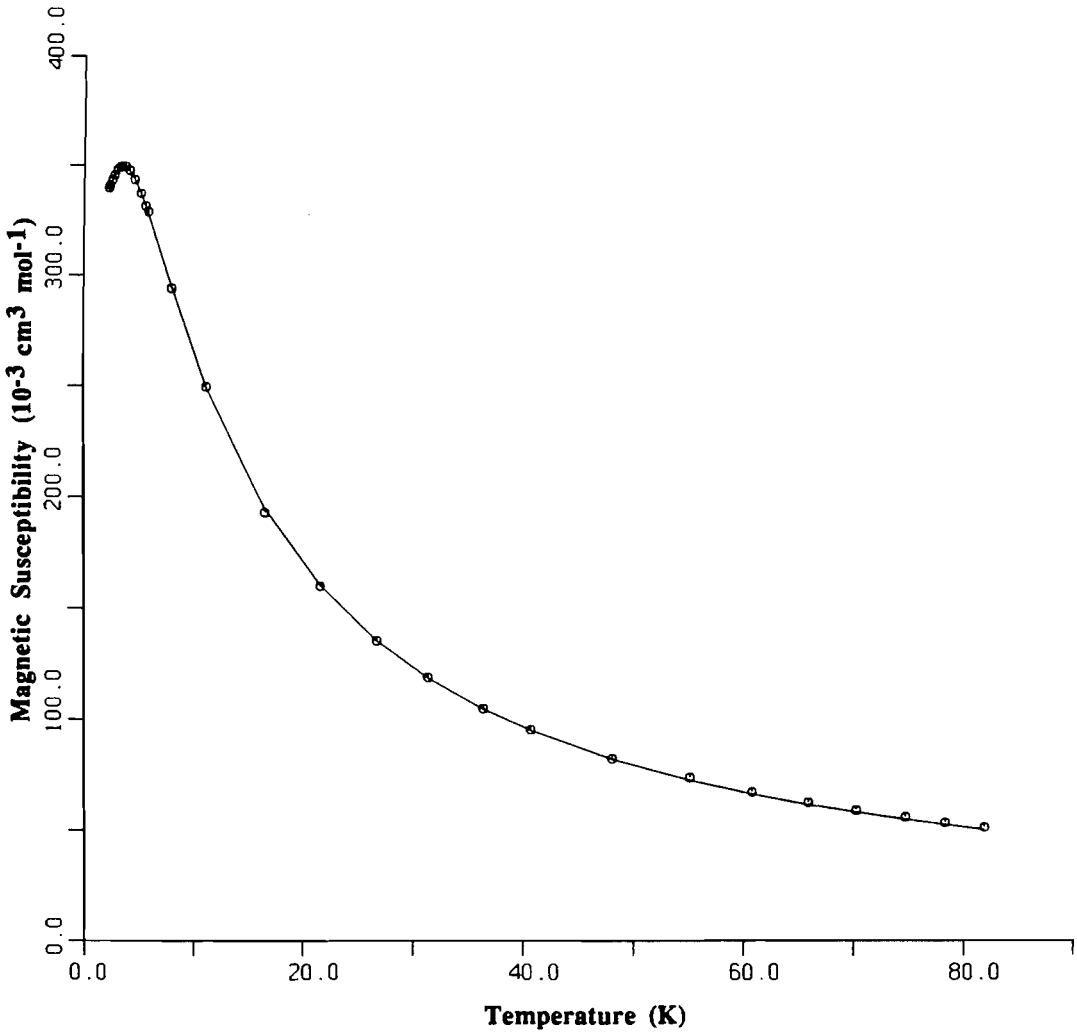

FIG. 6. Plot of magnetic susceptibility versus temperature for compound **2**. The circles are experimental data and the line is calculated using the Wagner–Friedberg model as described in the text.

Figure 6 shows the agreement between experiment and theory for the acetamide complex, **2**, and the magnetic parameters generated for the best fits between experiment and theory are given in Table 6. There is good agreement between experiment and theory using either model as judged by the value of the fitting function F, although the Wagner–Friedberg model seems generally to give better agreement and it reproduces the temperature of the susceptibility maximum in **1**, **2**, and **4** better.

The availability of single crystal X-ray diffraction determined bond parameters for **1**, **2**, and **3** permits a detailed examination of magnetostructural correlations in these complexes. For these complexes the exchange coupling clearly decreases in the order **1** > **2** > **3** (Table 6). This order can be understood if it is assumed that the magnetic exchange increases with decreasing length of the Mn–O–P–O–Mn pathway for exchange and, moreover, is favored by symmetrical O—P—O units. The latter would imply good π delocalization over the phosphinate bridge and should result in an effective π-pathway for exchange. It has been suggested for some time that the π-pathway for exchange is important in antiferromagnetic coupling between metal centres in phosphinate bridged compounds (10). The lengths of the Mn–O–P–O–Mn pathways for **1**, **2**, and **3** are 7.38(1),

7.43(1), and 7.43(1) Å, respectively. The shorter pathway in **1** is due largely to shorter Mn—O distances in this complex as discussed above. Hence the formamide complex, **1**, combines the shorter exchange pathway with symmetrical O—P—O bridges to give the largest $|J|$ of the three complexes. On the other hand, the monophenylphosphinic acid complex, **3**, combines the longer exchange pathway with unsymmetrical O—P—O bridges to give the smallest $|J|$. The intermediate $|J|$ observed for the acetamide complex, **2**, is consistent with the combination of an unfavorable path length with favorable symmetrically bridging O—P—O units.

An examination of bond angles at the bridging atoms reveals the total variation in O—P—O angles over the compounds is 1° with **1** having the intermediate angle (116.0(2)°). The Mn—O—P angles in **1** (Mn—O(1)—P = 129.1(2) and Mn—O(2)—P = 129.0(2)°) are smaller than those in **3** (132.2(1) and 133.0(1)°) while **2** exhibits both the smallest (121.9(1)°) and largest (135.6(1)°) angle of this type amongst the three compounds. The average of the Mn—O—P angles in **2** is the same as that in **1**. There appears to be no simple correlation between the magnitude of the exchange in these compounds and the angles at the bridging atoms.

Detailed magnetostructural correlation studies on **4**, **5**, and **6** are not possible owing to the absence of X-ray determined structures. The *N*-methylformamide complex, **4**, should exhibit only intrachain hydrogen bonding that would result in unsymmetrical O—P—O bridges and this may account for the fact that $|J|$ for this compound is less than that in the formamide complex, **1**. The value of $|J|$ for the pyridine complex, **6**, is quite small. Indeed, the value given in Table 6 for this compound should be considered an upper limit since in cases such as this, where the exchange is clearly very weak, the effect of the zero-field splitting may be contributing significantly to the observed magnetic properties. Since there is no possibility of hydrogen bonding in **6** we conclude the relatively high basicity of the neutral ligand in this case may lead to relatively strong pyridine–manganese interactions and correspondingly weaker manganese–phosphinate interactions and therefore weaker exchange. As discussed above, there is infrared evidence for unsymmetrical O—P—O units in this compound and this too may contribute to weakening the exchange. The aquo complex, **5**, should exhibit both intrachain and interchain hydrogen bonding as has, in fact, been observed previously for the dimethylphosphinate analogue (8). This would be expected to give symmetrical O—P—O bridges in **5**, a result supported by the infrared spectral studies described above. The fact that $|J|$ for **5** is approximately the same as the value obtained for **2** (which has symmetrical O—P—O bridges) suggests the M–O–P–O–M pathway is about the same length in these two complexes.

Electron densities and the VSEPR model of molecular geometry

R. J. GILLESPIE
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received August 25, 1991

This paper is dedicated to the memory of Professor Thomas Birchall

R. J. GILLESPIE. Can. J. Chem. **70**, 742 (1992).

This paper reviews the present status of the VSEPR model of molecular geometry in relation to electron densities. The discussion is based on the electron pair domain version of this model. The fundamental postulates of the model are summarized and illustrated by a discussion of the structures of some molecules with five and seven electron pair domains in the valence shell, including the recently discovered ions XeF_5^- and $XeOF_6^-$. The total electron density does not provide any obvious support for the model and although electron density deformation maps do provide some support they are not always reliable. The Laplacian of the electron density, however, shows the presence of valence shell charge concentrations that correspond closely in number and properties to the electron pair domains of the VSEPR model. This correspondence between electron pair domains and valence shell charge concentrations provides a physical basis for a better understanding of the VSEPR model.

Key words: VSEPR model, electron densities, molecular geometry, Laplacian of the electron density, electron pair domain.

R. J. GILLESPIE. Can. J. Chem. **70**, 742 (1992).

Dans ce travail, on examine la situation actuelle du modèle VSEPR de la géométrie moléculaire en regard des densités électroniques. La discussion est basée sur la version de ce modèle liée au domaine de la paire d'électrons. On résume les postulats fondamentaux du modèle et on les illustre par une discussion des structures de quelques molécules comportant des domaines de cinq et sept paires d'électrons dans la couche de valence, y compris les ions XeF_5^- et $XeOF_6^-$ découverts récemment. La densité électronique totale ne fournit pas un support évident pour le modèle; par ailleurs, les cartes de déformation de la densité électronique leur fournissent un léger support, même si elles ne sont pas fiables. Toutefois, le laplacien de la densité électronique montre la présence de concentrations de charges de la couche de valence qui correspondent bien, en nombre et en propriétés, avec les domaines des paires d'électrons du modèle VSEPR. Cette correspondance entre les domaines des paires d'électrons et les concentrations de charges de la couche de valence fournit une base physique pour une meilleure compréhension du modèle VSEPR.

Mots clés : modèle VSEPR, densités d'électrons, géométrie moléculaire, laplacien de la densité électronique, domaine de la paire d'électrons.

It is now over 30 years since the Valence Shell Electron Pair Repulsion (VSEPR) model of molecular geometry was first proposed and it continues to be an extremely useful model for the prediction and understanding of the geometry of covalent molecules. Despite its success it is sometimes criticised on the grounds that it is an empirical model that does not have a sound theoretical basis. The purpose of this paper is to review the present status of the model, particularly in relation to the detailed information on the electron densities of molecules that has become available since the VSEPR model was first formulated. We first describe an electron pair domain version of the model and illustrate its application by some recently determined structures of molecules with five or seven valence shell electron pairs. Then we discuss the physical basis of the model. In particular, we consider to what extent the model can be justified by an examination of the electron density and the Laplacian of the electron density. Finally we note that the theoretical basis for the model provided by the Laplacian of the electron density should lead to a better understanding of those molecules that appear to be exceptions to the VSEPR model.

The VSEPR model is a direct development from Lewis's idea that the covalent bond can be represented as a shared pair of electrons. This brilliant idea, which cleared up enormous confusion concerning valence and bonding, and which is still used by every chemist today, had no theoretical basis for many years. We now understand that the fundamental basis of the concept of the electron pair is the Pauli exclusion principle. The VSEPR model, which is a natural extension of the Lewis model, is similarly based on the Pauli exclusion principle, which plays a major role in determining the electron distribution in molecules (1, 2).

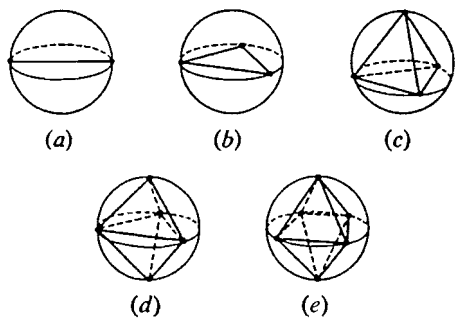

FIG. 1. Arrangements of points on the surface of a sphere that maximize their distance apart.

The electron pair domain version of the VSEPR model

The primary postulate of the VSEPR model is that the electron pairs in the Lewis structure of a molecule are arranged as far apart as possible. These electron pair arrangements are often illustrated by the arrangements of points on the surface of a sphere that maximize the least distance between any pair of points (Fig. 1). However, electron pairs are not very realistically represented by points, so it is pref-

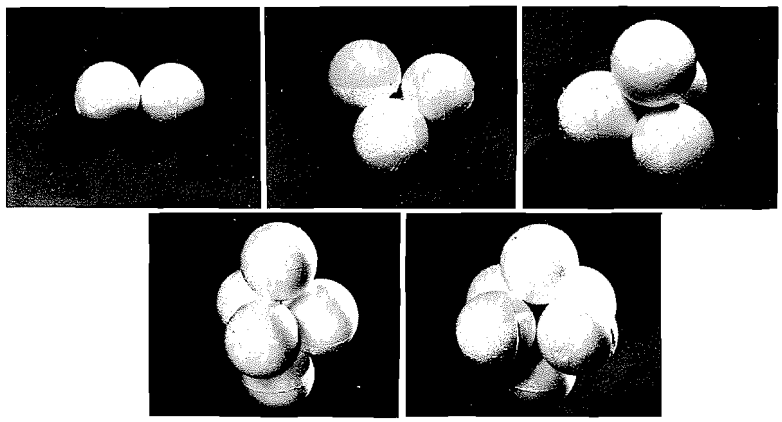

FIG. 2. Arrangements of spherical electron pair domains that minimize their distance from the nucleus.

erable to think of a valence shell electron pair as a charge cloud composed of two electrons of opposite spin and which occupies as much space as possible while excluding other electrons from this space in accordance with the Pauli exclusion principle. Thus we could consider, as an alternative model, the arrangements adopted by different numbers of circles of equal radii occupying as large a fraction as possible of the surface of a sphere without overlapping. This model leads to exactly the same arrangements as the points-on-a-sphere model. Another variation of the same basic idea that was first proposed by Kimball[1] and which has been extensively developed by Bent (3) is to consider each electron pair charge cloud as having a spherical shape of the same size. Bent called it the tangent-sphere model. I prefer to call it the domain model. The spherical electron pair domains are packed as closely as possible around the core of the atom and again we arrive at the same arrangements (Fig. 2). These basic arrangements of two to six electron pairs were first proposed by Sidgwick and Powell in 1940 (4). They are fundamental to the VSEPR model and they form the basis for the prediction of the molecular shapes.

In our paper in 1957 (5) Nyholm and I went beyond these basic electron pair arrangements by pointing out that not all the electron pairs in a valence shell should be regarded as equivalent. The differences between electron pairs were expressed in the form that lone-pair–lone-pair repulsions are stronger than lone-pair–bond-pair repulsions, which are stronger than bond-pair–bond-pair repulsions. On this basis one can account in a qualitative manner for the many small deviations of real structures from the "ideal" structures predicted on the basis of equivalent electron pairs. However, it is simpler, more realistic, and less liable to the misinterpretation that it is a classical electrostatic model to express the VSEPR model in terms of the sizes and shapes of localized electron pair domains rather than in terms of electron pair repulsions. Indeed there would be some advantage in changing the name to the VSEPD model: the Valence Shell Electron Pair Domain model. In these terms the three basic postulates or rules of the VSEPR (VSEPD) model are as follows.

1. Nonbonding domains are larger than single bond domains; they are more spread out and occupy more space in the valence shell than single bond domains. This is understandable because lone pairs are under the influence of only one positive core rather than two.

2. The size of a single bond domain in the valence shell of a central atom decreases with increasing electronegativity of the ligand.

3. Although it is often convenient to think of double and triple bonds as composed of a σ and one or two π bonds or two or three bent single bonds, respectively, it is simpler in the electron pair domain model to consider a double bond as a two electron pair domain and a triple bond as a three electron pair domain in which the individual electron pairs are not distinguished. These bond domains increase in size from a single to a double to a triple bond.

Application of the VSEPR model to molecules with five or seven valence shell electron pairs

Trigonal bipyramidal AX_5 molecules and the related AX_4E, AX_3E_2, and AX_2E_3 molecules provide particularly interesting applications of the VSEPR model because the five vertices of a trigonal bipyramid are not all equivalent. The axial positions of a trigonal bipyramid are more crowded than the equatorial positions; they have three neighbors at 90° whereas an equatorial position has two neighbors at 90° and two more at 120°. So large domains will prefer the equatorial positions, forcing smaller domains into the axial positions. Thus lone pair domains, double bond domains, and the domains of less electronegative ligands are preferentially found in the equatorial positions (Fig. 3). Moreover, because the axial domains are in a more crowded position, axial bonds are always longer than equivalent equatorial bonds (Fig. 3). No other simple model enables one to make these predictions about the geometry of molecules with a central atom with five valence shell electron pairs.

The recently prepared XeF_5^- ion (6) has a unique planar pentagonal AX_5E_2 structure based on a pentagonal bipyramidal arrangement of seven electron pairs with the two lone pairs in the axial positions (Fig. 4). In contrast to the trigonal bipyramid the lone pairs prefer the axial positions, which are the least crowded positions with all neighbors at 90° whereas each equatorial position has two neighbors at 72°. The prediction of the geometry of molecules in which there are seven electron pairs in the valence shell of the central

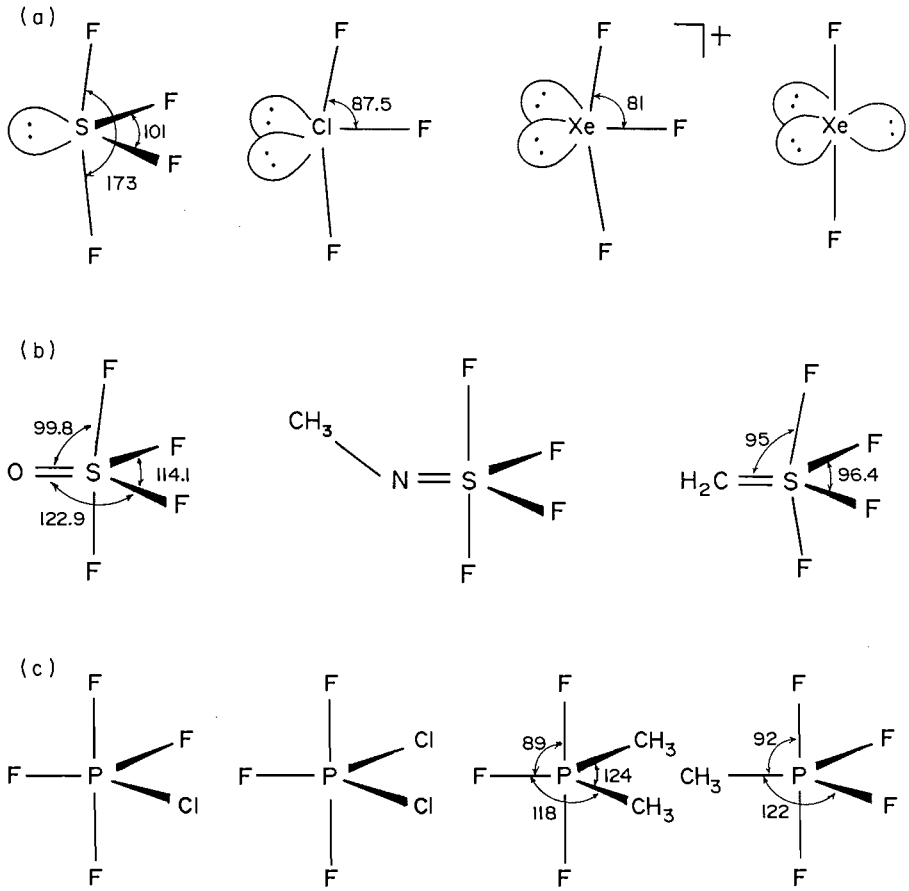

FIG. 3. Molecules with a trigonal bipyramidal arrangement of five electron pair domains in the valence shell of the central atom. (*a*) Lone pair domains always occupy the equatorial positions. (*b*) Double bond domains always occupy the equatorial positions. (*c*) Less electronegative ligands preferentially occupy the equatorial positions.

atom A cannot be made with as much certainty as for molecules in which there are six or fewer electron pairs in the valence shell because there are three electron pair arrangements with very similar interpair distances (Fig. 5). However, it is reasonable to assume that the structure will be based on the pentagonal bipyramidal arrangement of seven electron pair domains that we find in the closely related molecule IF_7. Moreover, we expect a structure based on an arrangement in which two lone pairs can occupy two equivalent less crowded positions and this is the pentagonal bipyramid with the lone pair domains in the two axial positions.

The IOF_6^- ion has recently been shown to have a penta-

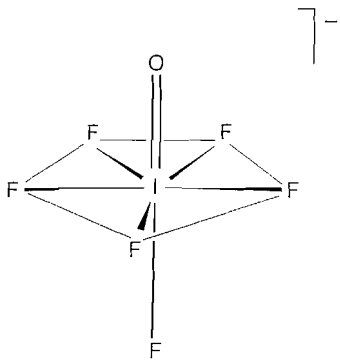

FIG. 6. The structure of the pentagonal bipyramidal ion IOF_6^-.

gonal bipyramid structure in which the doubly bonded oxygen occupies an axial position (7,8) as expected (Fig. 6). Moreover, the I—F bond in the less crowded axial position is, as expected, shorter (182.4 pm) than the equatorial bonds (187.4 pm). In contrast, in trigonal bipyramidal molecules the axial bonds are always longer than the equatorial bonds because the axial positions are the most crowded.

Although we cannot make an absolutely unambiguous prediction of the basic geometry of these seven coordinated molecules they do have one of the three possible predicted geometries. Moreover, the details of their structures are fully consistent with the postulates of the VSEPR model. No other model gives us a better understanding of the geometry of these molecules.

Electron densities

Can we legitimately think of electron pairs as essentially localized nonoverlapping charge clouds representing bonding pairs and lone pairs as the VSEPR model assumes? Many accurate calculations of electron densities in simple molecules have been made and in no case are there any features in the total electron density that represent localized bonding or nonbonding electron pairs. The water molecule provides us with a simple example (9). As we see in Fig. 7 there is no obvious localization of charge corresponding to lone pairs or bonding pairs. A bond is only apparent as a ridge of maximum density between the high concentrations of charge that surround each nucleus. This ridge has been called a bond path (10).

Total electron densities can also be obtained from accurate X-ray crystallographic studies. Again they give no evidence for localized electron pairs, either bonding or nonbonding. Nevertheless the usefulness of the Lewis and VSEPR models has inspired efforts to examine the total electron density in more detail. The total electron density is dominated strongly by the high concentration of electron density surrounding each nucleus and the changes in the

electron density that accompany molecule formation are relatively very small. Various attempts have been made to make these small changes in electron density more apparent. One method is by the calculation of electron density difference (deformation) maps, which are obtained by subtracting from the observed total electron density the densities of the isolated spherical atoms. Electron density difference maps for the water molecule in oxalic acid dihydrate are shown in Fig. 8 (11). There is a significant electron density in this difference map corresponding to the bond pairs and the lone pairs of the water molecule although the two lone pairs are not resolved. However, the problems that are sometimes associated with the interpretation of such maps are illustrated by the electron density difference map for tetrafluoroterephthalonitrile in Fig. 9, which shows no density at all in the C—F bond regions (12). These problems arise because the subtraction of the spherical densities of isolated atoms, although apparently reasonable, is an arbitrary procedure that cannot be theoretically justified.

The Laplacian of the electron density

It is only the total electron density that is an unambiguous experimentally determinable property of a molecule and so we must examine the total density and not some arbitrary difference or deformation density if we hope to obtain reliable evidence for bond pairs and lone pairs and to better understand the VSEPR model. Bader *et al.* showed that the Laplacian of the electron density, that is, the second differential of the electron density in three dimensions, provides us with a means of looking at the total electron density in some detail in a useful and informative way (9). For simplicity we first consider the one-dimensional function $f(x)$ shown in Fig. 10. This function decreases rapidly with increasing x and has two weak shoulders but no maxima or minima. The electron density in a free atom along any radius from the nucleus decreases in a somewhat similar manner although much more rapidly. The first differential of this function is everywhere negative because the slope is continually decreasing although not in a uniform manner. The second differential $f''(x)$ exhibits a minimum and $-f''(x)$ a maximum where the function has a larger value than the average of its value at the two neighboring points, in other words where $f(x), > \frac{1}{2}[f(x - dx) + f(x + dx)]$. We see that the weak shoulder in the $f(x)$ function is a much more apparent maximum in $-f''(x)$.

In an atom we have to consider the variation of ρ in three dimensions. Thus we are concerned with the Laplacian of the electron density

$$\nabla^2\rho = \frac{\partial^2\rho}{\partial x^2} + \frac{\partial^2\rho}{\partial y^2} + \frac{\partial^2\rho}{\partial z^2}$$

Wherever $-\nabla^2\rho$ is positive there is a local concentration of charge, that is, the electron density is greater than the average density in the immediate neighborhood. Wherever $-\nabla^2\rho$ is negative there is an analogous local depletion of charge. A plot of $-\nabla^2\rho$ for any plane through a spherical free atom shows maxima and minima corresponding to the electron shells (Fig. 11). For the argon atom there is an inner spike and two concentric shells in which the electron density is locally concentrated, separated by regions of electron density depletion. We can think of these as regions of locally increased and decreased electron density although they are not maxima and minima in the electron density. The outer shell corresponds to the valence shell. In the valence shell there is a spherical surface on which the electronic charge is maximally concentrated. This is called the valence shell charge concentration (VSCC). In general this surface persists when an atom forms part of a molecule but the sphere is distorted and is no longer one of uniform charge concentration.

The Laplacian of the electron density of the water molecule (9) shows two local charge concentrations in the valence shell of oxygen corresponding to the two bonds and two charge concentrations corresponding to the lone pairs (Fig. 12). These four charge concentrations have an ap-

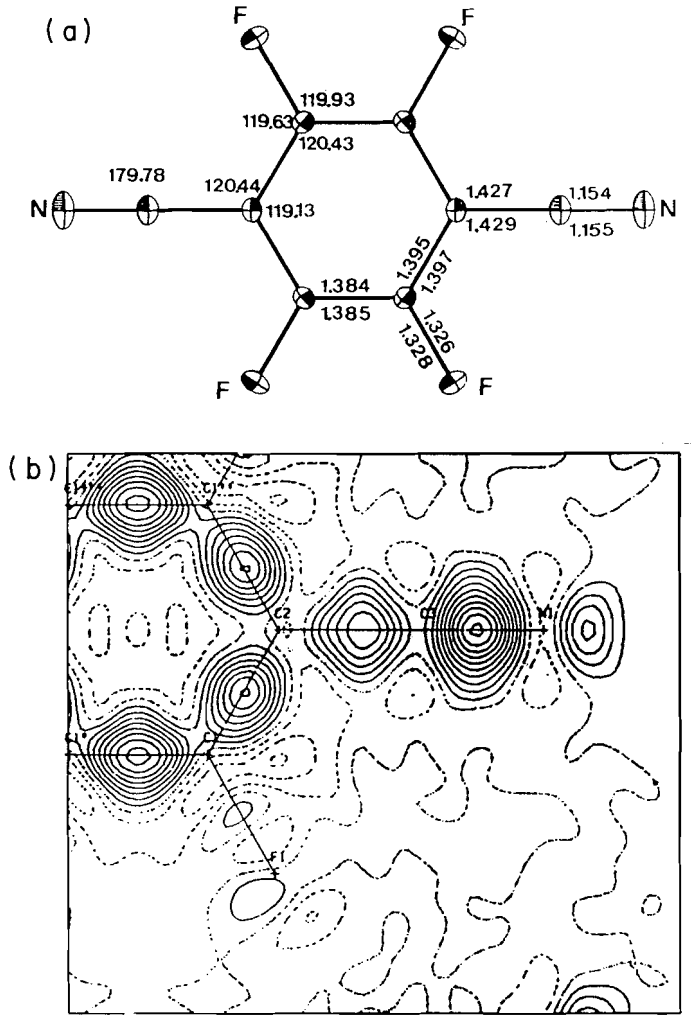

FIG. 9. Tetrafluoroterephthalonitrile. (*a*) Structure and geometrical parameters. (*b*) Electron density difference (deformation) map. This shows bonding density in the CC and CN bonds and lone pair density on nitrogen but almost no bonding density in the CF bond. Reproduced by permission from Dunitz *et al.* (12).

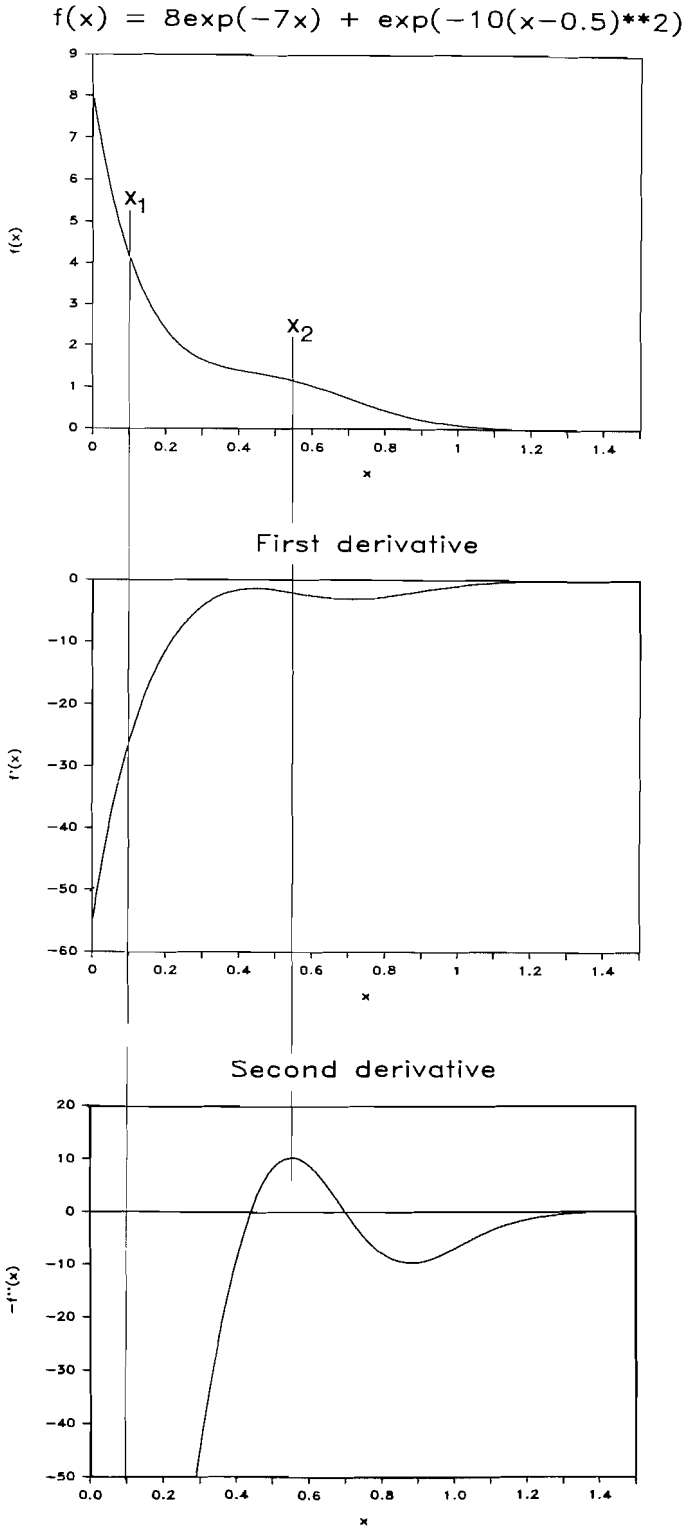

FIG. 10. Plot of a monotonically decreasing function $f(x)$ and its first and second derivatives. The negative of the second derivative is shown here. This has a maximum at x_2 where $f(x)$ has a shoulder, that is, where $f(x) > \frac{1}{2}[f(x - dx) + (x + dx)]$ or where $f(x)$ is locally concentrated.

proximately tetrahedral arrangement and their properties (Table 1) mimic exactly the properties postulated for localized electron pairs in the VSEPR model. For example, the nonbonded charge concentrations are larger and occupy a larger area on the valence shell sphere of charge concentration than the bonding charge concentrations. The nonbonding charge concentrations are closer to the nucleus than the bonding charge concentrations and the angle between the nonbonding charge concentrations is greater than the angle between the bonding charge concentrations.

The Laplacian of the electron density of the ammonia molecule shows three bonding charge concentrations and one nonbonding charge concentration, which also have relative sizes and positions that correspond closely to those postulated for localized electron pairs in the VSEPR model (Table 1).

In the five electron pair molecule ClF_3 the Laplacian of the electron density has five regions of charge concentration with a trigonal bypyramidal arrangement and exactly those properties of size and position predicted for the localized electron pair domains of the VSEPR model (Table 2 and Fig. 13). For example, the nonbonding charge concentrations are in the equatorial positions and the axial charge

concentrations are smaller and further from the nucleus than the equatorial charge concentrations.

Similar results have been obtained (13, 14) for SF_4, SOF_4, and ClF_5 (Table 2 and Fig. 14).

The important and interesting result of the study of the Laplacian of the electron density is that although the electrons are not highly localized into pairs as postulated by the VSEPR model there are an equal number of local concentrations of charge (VSCC's) that exhibit all the properties ascribed to the electron pair domains of the VSEPR model. Although the VSEPR model gives a highly exaggerated picture of the extent of localization of electron pairs in a molecule, there is nevertheless a very partial localization of electrons into pairs that gives rise to the small local concentrations of charge that have exactly the properties postulated for the localized electron pairs of the VSEPR model.

Valence shell charge concentrations and the Pauli exclusion principle

The valence shell charge concentrations result from the operation of the Pauli exclusion principle or spin correlation but because spin correlation is opposed by the electrostatic repulsion between the electrons (charge correlation) it is less effective in producing localized pairs than is assumed in the VSEPR model.

Linnett previously discussed the distribution of electrons in a molecule, a consequence of spin and charge correlation in the context of his double-quartet theory (15). According to Linnett we can consider the eight electrons of a neon atom or an oxide ion as consisting of one set of four electrons of α spin and another set of four of β spin. The most probable arrangement in each set as a consequence of both spin and charge correlation is at the corners of a tetrahedron. As a consequence of spin correlation the two sets tend to come into coincidence but this tendency is opposed by charge correlation. Linnett assumes that to a first approximation there is, as a consequence, little or no correlation between the two tetrahedral sets (Fig. 15). The overall electron density of the neon atom or the oxide ion is then spherical. We can think of forming the water molecule by the addition of two protons to an oxide ion. Each proton provides an additional attractive force tending to pull the two tetrahedral sets of electrons more towards coincidence, thus giving a partial localization of the electrons into two bonding pairs and two nonbonding pairs and the formation therefore of four corresponding local charge concentrations with an approximately tetrahedral arrangement (Fig. 15). The lone pair electrons are not as localized as the bonding pair electrons because they are not subject to the attraction of the protons and their localization depends only on spin correlation.

Summary and future developments

Although no complete theoretical justification of the VSEPR model has yet been given we now have a better understanding of its physical basis. Electrons in molecules are not as localized into electron pair domains as the VSEPR model assumes; nevertheless, there is a partial localization of electrons into pairs as a consequence of spin and charge correlation that gives rise to small local charge concentrations that have all the properties ascribed to the localized pairs of the VSEPR model. It seems reasonable to assume that an examination of the Laplacian of the electron density in those molecules that appear to be exceptions to the VSEPR model (2) will improve our understanding of the geometry of these molecules and also of the VSEPR model and its limitations. One such limitation is the assumption that the core of the atom underlying the valence shell is spherical. In the case of the transition metals and atoms with polarizable cores this may not always be the case and a nonspherical shell may have an important influence on the geometry of a molecule (2). Studies of the Laplacian of the electron density in such mol-

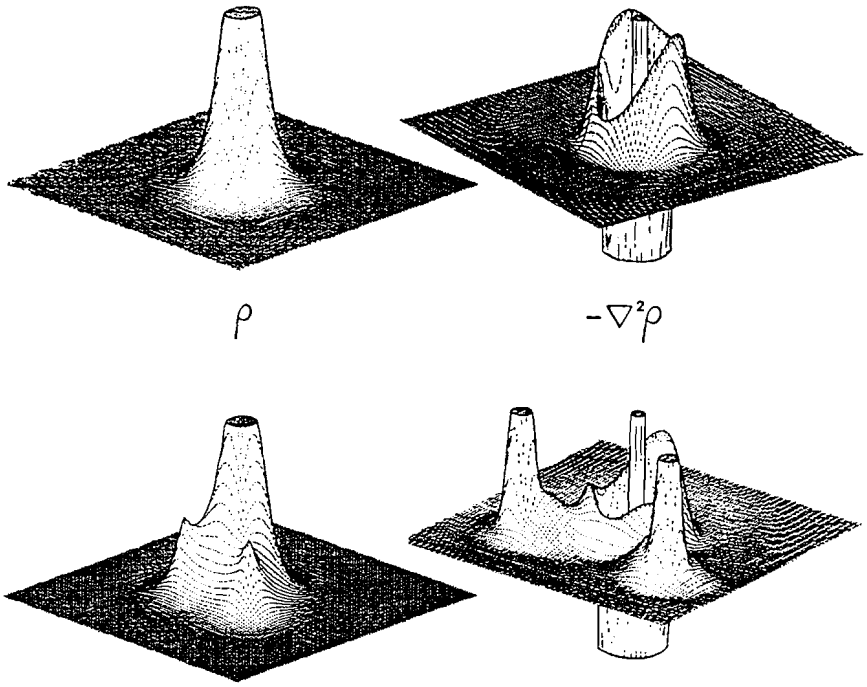

FIG. 12. Relief maps of the charge density and the negative of the Laplacian for the two symmetry planes of the water molecule. Lower maps are for the molecular plane and the upper maps are for the perpendicular plane. There is a spike-like concentration of charge surrounding the oxygen nucleus (which is terminated at an arbitrary value) that corresponds to the inner core. The valence shell charge concentration (VSCC) is not uniform but exhibits maxima and saddles in these two-dimensional relief maps. In the perpendicular (nonbonding) plane the VSCC of oxygen exhibits two maxima and two saddle points in $-\nabla^2\rho$. In the plane of the molecule $-\nabla^2\rho$ exhibits two maxima, one along each bond path to a proton. What appears to be a third maximum is another view of the two nonbonded maxima appearing in the upper diagram.

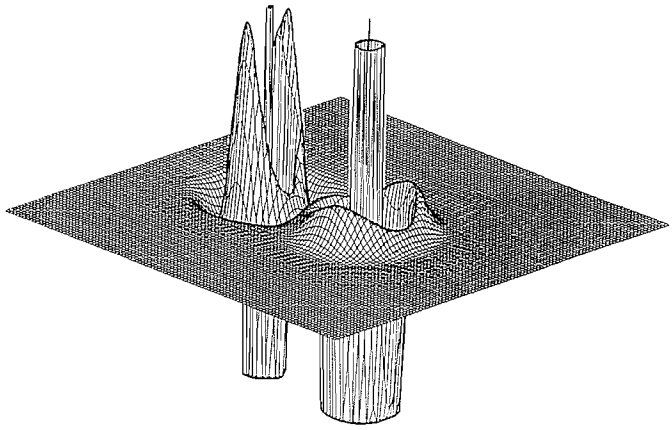
Bond pair(ax)	0.653	0.866	0.78		180.0	
Bond pair(ba)	0.662	0.619	0.64		97.2	

[a] r, distance of maximum of charge concentration from nucleus; $-\nabla^2\rho$, value at maximum of charge concentration; area, approximate area of charge concentration; l, lone pair; b, bond pair.



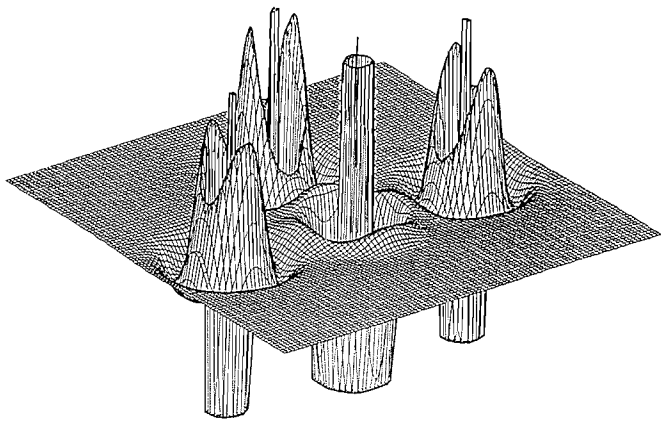


FIG. 13. Relief maps of $-\nabla^2\rho$ for the equatorial (upper) and axial (lower) planes of ClF_3. The chlorine atom exhibits three shells of charge concentration. In the equatorial plane there are two nonbonded and one bonded charge concentration in the valence shell. In the axial plane there are three bonded charge concentrations in the valence shell and a fourth apparent maximum that is another view of the saddle between the two nonbonded maxima in the equatorial plane. Thus the VSCC of the chlorine atom possesses two nonbonded and three bonded concentrations of charge.

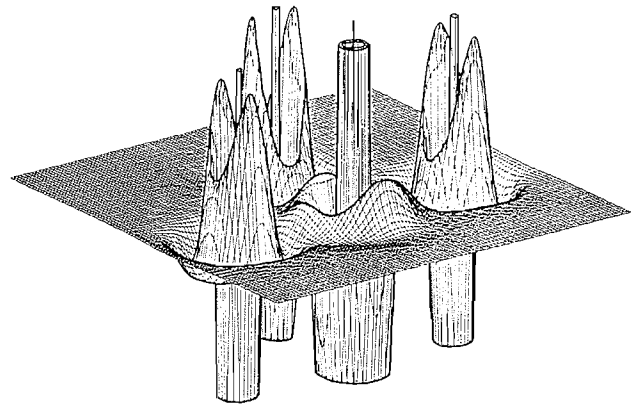

FIG. 14. A relief map of $-\nabla^2\rho$ in a symmetry plane of ClF_5 containing the chlorine, the axial fluorine, and two of the fluorine nuclei in the basal plane of the square pyramid. The figure illustrates the relative sizes of the charge concentrations; nonbonded > axial bonded > basal bonded.

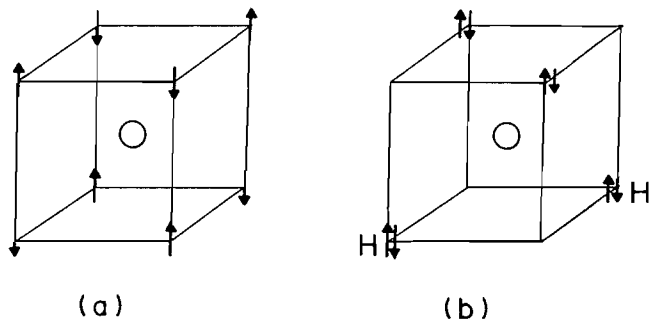

FIG. 15. (*a*) In the oxide ion there are two sets of four electrons with the same spin. In each set the most probable arrangement is tetrahedral as a consequence of spin and charge correlation. There is little correlation between the two sets as a consequence of the opposing effects of spin and charge correlation. The overall charge density in the ion is spherical. (*b*) The effect of adding two protons to the oxide ion to form the water molecule is to attract the two tetrahedra into partial coincidence, thus giving rise to four local charge concentrations, two bonding and two nonbonding.

ecules should help us to understand the effect of a nonspherical core on the geometry of a molecule and enable us to extend the VSEPR model to include such molecules.

This paper is dedicated to the memory of Professor Thomas Birchall

YUN XIE, CHUNG-LI LEE, YEPING YANG, STEVEN J. RETTIG, and BRIAN R. JAMES. Can. J. Chem. **70**, 751 (1992).

Dibromo- and diiodo[(2-pyridyl)phosphine]palladium(II) complexes are prepared by metathesis of *cis*-$PdCl_2(PPh_{3-n}py_n)_2$ species (n = 1–3) using the appropriate sodium halide; py = 2-pyridyl. NMR spectroscopy, particularly $^{13}C\{^1H\}$, is used to distinguish *cis* and *trans* isomers. The dinuclear complexes $Pd_2X_2(\mu\text{-}PPh_{3-n}py_n)_2$, X = halide, are synthesized via a conproportionation reaction using $PdX_2(PPh_{3-n}py_n)_2$ and $Pd_2(dba)_3$; dba = dibenzylideneacetone. Both $Pd_2I_2(\mu\text{-}PPh_2py)_2$ and a dimethylacetylenedicarboxylate A-frame complex $Pd_2Cl_2(\mu\text{-}Ppy_3)_2(\mu\text{-}MeO_2C \cdot C{=}C \cdot CO_2Me)$ are characterized crystallographically as head-to-tail isomers. The former crystallizes in the monoclinic space group $C2/c$ with a = 30.992(3), b = 18.764(1), c = 13.100(1) Å, β = 100.676(5)°, and Z = 8; the data were refined to R = 0.035 for 5874 reflections with $I \geq 3\sigma(I)$. The A-frame compound is triclinic of space group $P\bar{1}$ with a = 13.545(2), b = 15.064(2), c = 11.991(2) Å, α = 111.56(1), β = 95.36(1), γ = 97.63(1)°, and Z = 2; R = 0.033 from 7128 reflections with $I \geq 3\sigma(I)$. The $Pd_2X_2(\mu\text{-}PPhpy_2)_2$ complexes exist as a mixture of diastereomers because of chirality induced at the phosphorus atoms. The $Pd_2X_2(\mu\text{-}Ppy_3)_2$ complexes in water generate the $[Pd_2(H_2O)_2(\mu\text{-}Ppy_3)_2]^{2+}$ dication, which is isolated as various salts. The mononuclear complexes in water generate aquo and hydroxo species.

Key words: dimethylacetylenedicarboxylate adducts, palladium complexes (dinuclear), pyridylphosphines.

YUN XIE, CHUNG-LI LEE, YEPING YANG, STEVEN J. RETTIG et BRIAN R. JAMES. Can. J. Chem. **70**, 751 (1992).

On a préparé les complexes dibromo- et diiodo[(2-pyridyl)phosphine]palladium(II) par métathèse d'espèces *cis*-$PdCl_2(PPh_{3-n}py_n)_2$ (n = 1–3) en utilisant l'halogénure de sodium approprié; py = 2-pyridyl. On a utilisé la RMN, particulièrement celle du $^{13}C\{^1H\}$, pour distinguer entre les isomères *cis* et *trans*. On a synthétisé les complexes dinucléaires $Pd_2X_2(\mu\text{-}PPh_{3-n}py_n)_2$, X = halogénure, par le biais d'une réaction de conproportionation impliquant le $PdX_2(PPh_{3-n}py_n)_2$ et le $Pd(dba)_3$; dba = dibenzylidène acétone. Faisant appel à la cristallographie, on a pu établir que le $Pd_2I_2(\mu\text{-}PPh_2py)_2$ ainsi qu'un complexe en forme de A de l'acétylènedicarboxylate de diméthyle, $Pd_2Cl_2(\mu\text{-}Ppy_3)_2(\mu\text{-}MeO_2C \cdot C{=}C \cdot CO_2Me)$, sont des isomères tête à queue. Le premier cristallise dans le groupe d'espace monoclinique $C2/c$, avec a = 30,992(3), b = 18,764(1) et c = 13,100(1) Å, β = 100,676(5)° et Z = 8; on a affiné les données jusqu'à une valeur de R = 0,035 pour 5874 réflexions avec $I \geq 3\sigma(I)$. Le composé en forme de A est triclinique, groupe d'espace $P\bar{1}$, avec a = 13,545(2), b = 15,064(2) et c = 11,991(2) Å, α = 111,56(1), β = 95,36(1) et γ = 97,63(1)°, Z = 2 et R = 0,033 pour 7128 réflexions avec $I \geq 3\sigma(I)$. Les complexes $Pd_2X_2(\mu\text{-}PPhpy_2)_2$ existent sous la forme d'un mélange de diastéréo-isomères provoqués par la chiralité des atomes de phosphore. Dans l'eau, les complexes $Pd_2X_2(\mu\text{-}Ppy_3)_2$ conduisent à la formation du dication $[Pd(H_2O)_2(\mu\text{-}Ppy_3)_2]^{2+}$ que l'on a isolé sous la forme du plusieurs sels. Dans l'eau, les complexes mononucléaires fournissent des espèces aquo et hydroxo.

Mots clés : adduits de l'acétylènedicarboxylate de diméthyle, complexes dinucléaires du palladium, pyridylphosphines.

[Traduit par la rédaction]

Introduction

Our original interest in the well-known complexes of the type $Pd_2X_2(dpm)_2$ (X = anionic ligand)[3] arose because of their potential use in separation of gaseous components, particularly CO and H_2, in coal-gas streams (1). This then led to the discovery that such complexes readily abstract sulfur from H_2S to generate H_2 and the bridged-sulfide coproduct $Pd_2X_2(\mu\text{-}S)(dpm)_2$ (2). To extend such chemistry into aqueous media, we turned our attention to the 2-pyridyl substituted phosphines $PPh_{3-n}py_n$, whose solubility in water increases as n increases from 0 (insoluble) to 3 (3). The use of such phosphines has also rekindled a long-standing interest of this group in metal-complex catalyzed hydration of olefins (4), a topic that is of current interest and one in which both platinum and palladium–phosphine complexes show promise (5–7). To these ends, we are developing further the chemistry of, and catalysis by, complexes containing 2-pyridyl(phosphine) ligands, a subject that in itself is accruing considerable recent literature (8–13), following its instigation in the early 1970s within a PPh_2py system (14); this mono-pyridyl ligand was used extensively by Balch and coworkers (15–17), the studies including a communication on $PdCl_2(PPh_2py)_2$ and $Pd_2Cl_2(PPh_2py)_2$ (17). Newkome *et al.* (18) reported on *cis* and *trans*-$PdCl_2(PPhpy_2)_2$. These Pd complexes are, to our knowledge, the only ones reported within the complete series of $PdX_2(PPh_{3-n}py_n)_2$ and $Pd_2X_2(PPh_{3-n}py_n)_2$ complexes (X = halide).

This present paper reports on all nine mononuclear and all

[a] In CH_2Cl_2 at ~20°C.

[b] All singlets. Data measured at ~20°C unless otherwise stated: in CD_2Cl_2 at −70°C for **1***a*–**1***c*, **2***b*, **2***c*, **3***b*, **3***c*; in CD_2Cl_2 for **2***a*, **3***a*, **4***a*–**4***c*, **6***c*; in $CDCl_3$ for **5***a*–**5***c*, **6***a*, **7**–**9**; in CD_3CN for **10***a*, **10***b*; in acetone-d_6 for **10***c*.

[c] Characterized by Newkome *et al.* (18), including an X-ray structure of the *cis* isomer.

[d] Reported by Maisonnat *et al.* (17), but with no detail.

[e] % Cl 16.00; calcd. 15.80.

[f] All singlets; in $CDCl_3$ at ~20°C.

[g] IR (Nujol), $\nu(H_2O)$ 1627 cm^{-1}. Λ(MeCN, ohm^{-1} mol^{-1} cm^2): 270 (**10***a*), 255 (**10***b*), 190 (**10***c*). UV/vis: in H_2O 409 nm ($\varepsilon = 9.3 \times 10^3$ M^{-1} cm^{-1}); in MeCN 420 nm ($\varepsilon = 6.1 \times 10^3$ M^{-1} cm^{-1}).

[h] In H_2O at ~20°C.

nine dinuclear complexes; *cis* and *trans* formulations within the mononuclear species are assigned, and a head-to-tail (HT) geometry (implying the two phosphorus atoms are bound to different metals) demonstrated crystallographically for $Pd_2I_2(PPh_2py)_2$, and for the A-frame complex $Pd_2Cl_2(Ppy_3)_2(\mu$-DMAD). The anticipated chirality at the coordinated phosphorus of a bridging $PPhpy_2$ ligand is observed; and finally the solvolysis of two Ppy_3 complexes in water is studied.

Experimental section

The compounds $PdCl_2(PhCN)_2$ (19), $Pd_2(dba)_3 \cdot CHCl_3$ (20), PPh_2py (21), and Ppy_3 (22) were prepared by the literature procedures. $^{31}P\{^1H\}$ (121.4 MHz) and $^{13}C\{^1H\}$ (75.4 MHz) NMR spectra were recorded on a Varian XL-300 instrument. $^{31}P\{^1H\}$ NMR shifts are given relative to the external 85% H_3PO_4, downfield being positive; $^{13}C\{^1H\}$ NMR shifts are relative to external TMS. Infrared spectra were recorded as Nujol mulls on a Nicolet 5DX FT spectrophotometer. Visible absorption spectra were recorded on a Perkin–Elmer 552A spectrophotometer. Conductivity measurements were recorded in aqueous or MeCN solution at 10^{-3} M complex concentration in a cell (Fisher Sci. Co.) connected to a Beckman Serfass conductance bridge. pH titrations were carried out at 25°C in aqueous media under N_2 using a Corning 12 pH-meter and a combination electrode.

The $PPhpy_2$ ligand was prepared by a procedure similar to that reported for Ppy_3 (22). ^{n}BuLi (50 mL, 1.6 M in hexane) was transferred to 50 mL of Et_2O at −100°C, under N_2. 2-Bromopyridine (80 mmol) was added and the mixture stirred vigorously at −100°C until the colour turned to deep red (~4 h). Liquid $PPhCl_2$ (40 mmol in 10 mL Et_2O) was then added dropwise via a syringe with stirring of the reaction solution; this generates a light brown slurry, which is then stirred at −90°C for 2 h. The mixture was then extracted at room temperature with degassed H_2SO_4 (2 M, 2 × 100 mL), and the aqueous layer collected and made alkaline by adding (with stirring) saturated NaOH solution. The deposited yellow crystals were washed with H_2O, and with acetone/H_2O (1:1), recrystallized from acetone/petroleum ether (1:1), and dried *in vacuo*. Yield 60%; mp 96.7–98.3°C. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 20°C) δ: −1.98. Anal. calcd. for $C_{16}H_{13}N_2P$: C 72.71, H 4.96, N 10.60; found: C 72.90, H 4.99, N 10.43. (Despite reported use of $PPhpy_2$, we were unable to find details of its synthesis and characterization; see, for example, ref. 13.)

The various Pd complexes (see Table 1) were synthesized routinely under an N_2 atmosphere, but this is probably not essential. Elemental analyses of the complexes (Table 1) were satisfactory except for the C analyses of **2***b*, **2***c*, and **5***c*, which were low by 1.0–1.5% and could not be improved. The samples were "pure" as judged by $^{31}P\{^1H\}$ NMR data; impurities could be the respective sodium halides or occluded solvent; both structures determined reveal solvate molecules (*vide infra*).

*$PdX_2(PPh_{3-n}py_n)_2$ complexes (***1**a–**1**c; **2**a–**2**c; **3**a–**3**c*)*

The chloro species **1***a*, **2***a*, and **3***a* were prepared by dissolving $PdCl_2(PhCN)_2$ (300 mg, 0.78 mmol) in CH_2Cl_2 (20 mL), and adding to this reddish-brown solution 2 equivalents of the pyridylphosphine dissolved in a minimum amount of CH_2Cl_2 (~7 mL). After the solution was stirred at room temperature for 30 min, a yellow solid slowly precipitated; addition of Et_2O (40 mL) completed the precipitation. The complexes were purified by dissolution/reprecipitation twice from CH_2Cl_2/Et_2O, and dried *in vacuo*; yields ~95%. The syntheses follow that given for **3***a* in the literature, but with no details (17). The bromo (**1***b*, **2***b*, **3***b*) and iodo analogues (**1***c*, **2***c*, **3***c*) were prepared from **1***a*, **2***a* and **3***a*, respectively, by addition of 10 equivalents of the appropriate sodium halide dissolved in a minimum amount of water to the chloro complex (~0.3 mmol) dissolved in CH_2Cl_2 (150 mL); MeOH (5 mL) was introduced to homogenize the mixture, which was stirred for 2 h at room temperature. The solution colour changed from yellow to orange (bromo species) or brown (iodo species), and crystals of the product formed on reducing the solution volume to ~20 mL; the complexes were collected, washed with H_2O (100 mL) and then MeOH (100 mL), and dried *in vacuo*; yields 85–95%.

*$Pd_2X_2(PPh_{3-n}py_n)_2$ complexes (***4**a–**4**c; **5**a–**5**c; **6**a–**6**c*)*

To a suspension of $PdX_2(PPh_{3-n}py_n)_2$ complex (0.42 mmol) in CH_2Cl_2 (20 mL) was added slowly $Pd_2(dba)_3 \cdot CHCl_3$ (0.22 g, 0.21 mmol) dissolved in CH_2Cl_2 (20 mL), and the mixture stirred at room temperature for ~1 h until a clear solution resulted. The volume was then reduced to 10 mL and Et_2O (10 mL) added to yield the desired product; the collected solid was precipitated twice from CH_2Cl_2 (15 mL) using Et_2O (10 mL), and vacuum-dried; yields ≥ 80%.

*$Pd_2Cl_2(PPh_{3-n}py_n)_2(\mu\text{-}MeO_2C \cdot C{\equiv}C \cdot CO_2Me)$; n = 3(***7**), 2 (**8**), and 1(**9**)*

Excess DMAD (0.41 g, 2.8 mmol) was added to a CH_2Cl_2 solution (50 mL) containing **4***a* (0.20 g, 0.25 mmol), and the mixture stirred for 1 h at room temperature. The resulting solution was reduced to 30 mL by Rotavap, and Et_2O added (50 mL) to precipitate complex **7** in quantitative yield. **8** and **9** were made similarly from **5***a* and **6***a*, respectively.

*$[Pd_2(H_2O)_2(Ppy_3)_2]^{2+}$ $2A^-$; A = BF_4 (***10**a*), PF_6 (***10**b*), BPh_4 (***10**c*)*

Complex **4***a* (15 mg, 19 μmol) was dissolved in H_2O (100 mL) to form a green solution (~1 h), and 5 equivalents of the appropriate salt solution (5 mL) added with stirring ($NaBF_4$ or KPF_6 in H_2O; $NaBPh_4$ in MeOH). The green solid that precipitated overnight was collected, redissolved in MeCN and reprecipitated by addition of Et_2O, and dried *in vacuo*; yields 80–90%.

Crystallographic characterization of **6**c *as $Pd_2I_2(PPh_2py)_2 \cdot 1/2$(acetone), and* **7** *as $Pd_2Cl_2(Ppy_3)_2(\mu\text{-}DMAD) \cdot 2CH_2Cl_2$*

Crystals were prepared by placing test tubes containing 10 mL of a saturated solution of the complex (**6***c* in acetone, **7** in CH_2Cl_2) in a closed vessel (300 mL) containing 100 mL Et_2O; purple crystals of **6***c* · 0.5 C_3H_6O and yellow crystals of **7** · $2CH_2Cl_2$ were formed over 2 days.

Crystallographic data for both compounds are given in Table 2. Final unit-cell parameters were obtained by least squares on 2 sin θ/λ values for 25 reflections (with 2θ = 40–60° for **6***c* and 34–46° for **7**). The intensities of three check reflections, measured each hour of X-ray exposure time throughout the data collections, showed small random fluctuations. The data were processed, with absorption corrections being applied using the Gaussian integration method (23, 24)[4].

In each structural determination there was a choice between centrosymmetric and noncentrosymmetric space groups, the former being suggested by both the *E*-statistics and the Patterson functions. Both structures were solved by conventional heavy-atom methods, the coordinates of Pd, P, and metal-coordinated halogen atoms being determined from the Patterson functions and those of the remaining non-hydrogen atoms from subsequent difference maps.

In both structures there is disordering of solvent molecules. In **6***c*, an acetone solvate (O(1), C(35–37)) is disordered 1:1 about the twofold axis (1/2, *y*, 1/4). One methyl carbon, C(35), was constrained to be on the twofold axis even though it is obvious from the resulting geometry that this atom must be displaced from the twofold axis by about 0.4 Å. Unfortunately, attempts to refine C(35) in a more realistic position resulted in a singular matrix. The incorrect model employed does account for the electron density in the region and, in view of the relatively minor importance of the solvent molecule, no attempts at more sophisticated treatment were made. In **7**, one of the two independent CH_2Cl_2 molecules (Cl(5–7), C(38)) was disordered in a way such that the two Cl atoms were unequally distributed over three sites. The site occupancies were initially estimated from the relative peak heights on a Fourier map and were subsequently adjusted to result in nearly equal thermal parameters for the three positions. The thermal parameters and occupancy factors could not be simultaneously refined due to high correlations. The thermal parameters of the carbon atom C(38) are indicative of at least twofold disorder of this atom as well, but again no attempt was made to resolve this disorder.

In the final stages of full-matrix least-squares refinement all non-hydrogen atoms were refined with anisotropic thermal parameters, and hydrogen atoms (except those associated with the disordered solvent molecules) were included as fixed atoms in calculated positions (methyl H positions based on observed positions, $C(sp^3)$—H = 0.98 Å, $C(sp^2)$—H = 0.97 Å, $U_H \propto U_{parent}$). Neutral atom scattering factors and anomalous scattering corrections (Pd, I, Cl, P) were taken from ref. 24. Final positional and equivalent isotropic thermal parameters (U_{eq} = 1/3 trace diagonalized U) are given in Table 3. Selected bond lengths, bond angles, and intra-annular torsion angles appear in Table 4. Anisotropic thermal parameters, calculated hydrogen parameters, complete listings of bond lengths, bond angles, torsion angles, and measured and calculated structure factor amplitudes have been deposited (Tables S1–S6).[5]

Results and discussion

The $PdX_2(PPh_{3-n}py_n)_2$ complexes

The four-coordinate, mononuclear complexes all contain monodentate pyridylphosphine ligands bound via the phosphorus and were synthesized from $PdCl_2(PhCN)_2$ using a method published in outline only for **3***a*, $PdCl_2(PPh_2py)_2$ (17).

[4]The computer programs used include locally written programs for data processing and locally modified versions of the following: ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

[b]Reduced cell, Donnay convention.

The *cis* and *trans* forms of the $PdCl_2(PPhpy_2)_2$ complex (**2a**) were synthesized previously from $PdCl_4^{2-}$, and an X-ray structure given for the *cis* isomer (18); the $^{31}P\{^1H\}$ NMR signal is a singlet for either the *cis* or *trans* isomer, and using the structural data Newkome *et al.* (18) were able to assign the lower field signal to the *cis* isomer (Table 1). We have used $^{13}C\{^1H\}$ to distinguish the geometric isomers; in the *trans* complex, $^2J_{PP}$ is usually large (~400 Hz) compared to a value of <50 Hz in the *cis* complex, and hence the C atoms adjacent to a phosphorus appear as a virtual 1:2:1 triplet (as opposed to a doublet in a *cis* isomer) (25, 26). Table 5 lists the $^{13}C\{^1H\}$ data for selected complexes, which show that **1a** is *cis*, while the iodo species **2c** and **3c** are *trans*. The $^{31}P\{^1H\}$ data for **1a** (Table 1) fit well a tentatively suggested correlation (18) of a gradual downfield shift with sequential replacement of Ph by py in the complexes *cis*-$PdCl_2(PPh_{3-n}py_n)_2$ as n varies from 0 to 3. The same trend holds for the series of *cis*-dibromo complexes **3b**–**2b**–**1b**; the opposite trend holds for the diiodo species **3c**–**2c**–**1c**, which, however, have *trans* geometry; the data given for *trans*-**2a** and *trans*-**3a** follow the same trend as for the *trans*-diiodo complexes (Table 1).

The $^{31}P\{^1H\}$ NMR data (Table 1) refer to the dissolved, isolated complexes, but the syntheses of the *trans*-diiodo species by metathesis reactions from the predominantly *cis*-dichloro precursors probably involve an isomerization process. The *trans* geometry is normally preferred in nonpolar solvents, while a π-interaction between pyridyl groups on adjacent phosphine ligands (noted in the structure of *cis*-$PdCl_2(PPhpy_2)_2$) has been suggested as a possible reason for preferred *cis* geometry (18).

It is worth noting also that, for any given pyridyl phosphine ligand within a *cis* or *trans* triad, the $^{31}P\{^1H\}$ singlet shifts to higher field as Cl is replaced successively by Br and then I, consistent with increasing basicity of the halogeno ligand. The UV/vis absorption maximum of the complexes occurs as a charge transfer band at 337–340 nm for the three dichloro species, at 362–363 nm for the dibromo species, and

at 421–428 nm for the diiodo species, without consideration of the presence of *cis* and (or) *trans* forms (Table 1); the trend is indicative of a halogen → metal charge transfer, being of lowest energy for the diiodo complexes.

Attempts to find ν(Pd—X) and ν(Pd—P) stretches in the IR, widely used to distinguish *cis* and *trans* isomers within $PdX_2(PR_3)_2$ complexes (26, 27), were unsuccessful because of strong absorption by the pyridyl phosphine ligands.

The $Pd_2X_2(PPh_{3-n}py_n)_2$ complexes

The phosphorus atoms within the dinuclear Pd(I) complexes are equivalent whether a head-to-tail (HT) geometry exists or an HH arrangement (with the two phosporus atoms

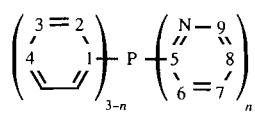
[a]In $CDCl_3$ at ~20°C for the ligands; in CD_2Cl_2 at −20°C for the complexes; s = singlet, d = doublet, t = triplet, br = broad; coupling constant given in parentheses is the $|^xJ_{PC} + {}^{x+2}J_{PC}|$ value in Hz, where x = 1–3; labelling of C atoms is depicted below.



[b]Signal is not detected due to the lack of proton NOE effect.
[c]Very low intensity.

on the same metal). The crystal structure of $Pd_2I_2(PPh_2py)_2$, **6***c*, reveals the HT arrangement (Fig. 1), and thus the singlet in the $^{31}P\{^1H\}$ NMR spectrum (Table 1) is assigned to this isomer. Balch and co-workers had assumed that the corresponding dichloro complex **6***a* had the HT configuration (17), based on this geometry being found for other structurally characterized homo- or hetero-dinuclear analogues, although HH arrangements were later shown to exist (15, 16, 28). The $^{31}P\{^1H\}$ data listed in Table 1 suggest strongly that all the $Pd_2X_2(PPh_{3-n}py_n)_2$ isolated have the HT configuration; there are regular trends in the small chemical shift changes on (*a*) changing halogen within any one pyridylphosphine triad, and (*b*) changing the pyridylphosphine within a fixed halogen triad. The trends are in the same directions observed within the mononuclear complexes. For the platinum analogue $Pt_2I_2(PPh_2py)_2$, which has been isolated in both HT and HH forms, the former (thermodynamically stable) isomer gives a $^{31}P\{^1H\}$ signal at δ −5.7, some 15 ppm to higher field than the HH isomer (15). The more labile nature of the Pd—P bond probably allows the thermodynamically more stable HT form to predominate.

Within the nine dinuclear complexes, the $^{31}P\{^1H\}$ signals at room temperature are broader for the bis(pyridyl)phosphine species **5***a*–**5***c*, and this is attributed to the presence of a mixture of diastereomers because of chirality induced at the P atoms via bridging coordination of one of the two pyridyl groups (see structures, following page).

The P nuclei in **5***a* (*R*, *R*) and **5***a* (*S*, *S*) are all equivalent and should give a singlet in the $^{31}P\{^1H\}$ NMR spectrum; the P nuclei within **5***a* (*S*, *R*), related by an inversion centre located at the centre of the Pd—Pd bond, are enantiotopic and should also give rise to a singlet. At −20 to −85°C, two sharp singlets are observed at δ 2.0 and 6.0 in about a 2:1 intensity ratio; the room temperature singlet is an averaged sig-

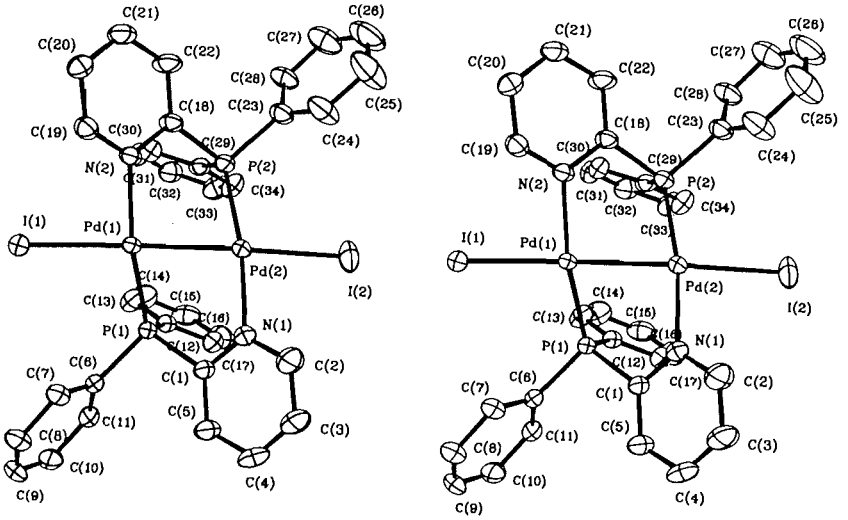

FIG. 1. Stereoview of $Pd_2I_2(PPh_2py)_2$, **6***c*, showing 33% probability thermal ellipsoids.

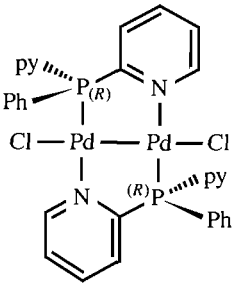
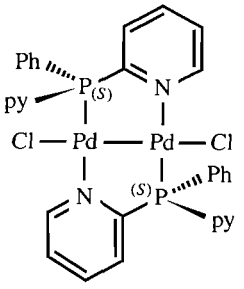
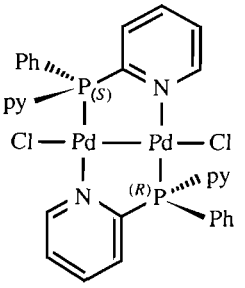
nal, the inversion at P presumably taking place via dissociation of a pyridyl moiety at a Pd centre, rotation about the Pd—P bond at the other Pd, and recoordination of the second pyridyl moiety. Direct inversion at a P centre is not feasible (29). The $^{31}P\{^1H\}$ room temperature singlet for **5***c*, the iodo analogue, separates into two broad singlets at −20°C (δ + 0.9, −0.2), but the downfield signal then coalesces at −40°C before reappearing at −60°C as an AB quartet centred at the original 0.9 ppm position (these reversible NMR spectral changes are unaffected by addition of NaI in acetone solution, showing that ionic equilibria via loss of iodide are not involved); the inequivalence of the two, now diastereotopic, P atoms of one of the diastereomers (probably the *S*, *R* isomer, judging by signal intensities) could result from a nonplanar structure evident at the lower temperatures (*vide infra*, structure of **6***c*); the J_{PP} coupling (~20 Hz) is characteristic of diagonally positioned P atoms in an HT arrangement (15).



5*a* (*R*, *R*)



5*a* (*S*, *S*)



5*a* (*S*, *R*)

Although there are several structures reported with connecting PPh_2py ligands between two metals in an HT arrangement (11, 15, 21, 30),[6] to our knowledge there are none (including the metal–metal bond) containing two four-coordinate metal centres, as in $Pd_2I_2(PPh_2py)_2$, **6***c* (Fig. 1). The structure of **6***c*, which crystallizes with one disordered acetone solvate molecule per two molecules of complex, reveals many distortions, however, from square-planar geometry at the Pd(I) atoms, while there are no unusual intermolecular contacts. The I—Pd—Pd angles at the metal centres are 8–11° from linearity, with the iodine atoms *cisoid* with respect to the Pd—Pd bond. The angles between the Pd–ligand bonds vary from 77.5 to 98.5°, but the coordination at the Pd centres is nonplanar (Table 6), and the dihedral angle between the normals to the two mean planes is 41.3°. The phenyl rings are planar within experimental error, but the pyridyl rings are significantly nonplanar with maximum deviations from the mean planes being 0.015(5) and 0.023(7) Å, respectively, for the N(1) and N(2) rings. The torsion angles (Table 4) show that the five-membered rings are very nonplanar, but the relative orientation of the two bridging ligands still leaves a *trans* arrangement of P and N at each metal. This is found also in $PdCl(PPh_2py)_2$-$RhCl(CO)$, which is four-coordinate at the Pd and six-coordinate at the Rh (15), but in $PdCl(PPh_2py)_2RuCl(CO)_2$, also a four- and six-coordinate system (21), and in $PdCl(PPh_2py)_2(\mu\text{-}CO)MoCl(CO)_2$ (11) the bridging HT pyridylphosphines are *trans* at the Pd and *cis* at the other metal. Within **6***c* and the Pd—Rh complex, the metal–metal bond lengths are 2.597 Å (a single bond) and 2.594 Å, respectively, while those of the Pd—Ru (2.660 Å) and Pd—Mo (2.817 Å) are longer; the accommodation of longer metal–metal bonds by connecting PPh_2py ligands has been dis-

[6]The $Re_2Cl_2(PPh_2py)_4^{2+}$ species has at each Re a *trans*-N and *trans*-P arrangement for the four bridged PPh_2py ligands (12).

cussed by Balch's group, the key factor being freedom of rotation about the P—C(py) bond (30). The Pd—Pd bond length in **6***c* is sufficiently short so that the two PPh_2py ligands can remain *trans* to each other. The Pd—P (av. 2.212 Å) and Pd—N (2.112 Å) distances are close to those reported for the Pd—Rh, Pd—Ru, and Pd—Mo complexes. The Pd—P distances are significantly shorter than those of 2.29 Å found in the P—P connecting ligand systems $Pd_2Br_2(dpm)_2$ (31) and $Pd_2Cl_2(dpmMe)_2$ (32); a similar shortening of the Rh—P bond in the A-frame, HT complex $Rh_2Cl_2(PPh_2py)_2(\mu$-CO) compared to dpm-bridged rhodium A-frame complexes has been rationalized in terms of the relative *trans* effects, P > N (30). The Pd—I bond lengths in **6***c* (2.696 and 2.695 Å) are unusually long for terminal Pd—I bonds, but are essentially the same as found in the unbridged complex $[PdI(MeNC)_2]_2$, which contains a linear I—Pd—Pd—I unit with a metal–metal bond length of 2.533 Å (33), and again the elongation is attributed to the *trans* effect of the Pd—Pd bond.

*The insertion products from dimethylacetylenedicarboxylate (DMAD), $Pd_2Cl_2(PPh_{3-n}py_n)_2(\mu$-$MeO_2CC{=}CCO_2Me)$; n = 3(**7**), 2(**8**), and 1(**9**)*

Studies from Balch's group have established that the molecules CO, SO_2, or MeNC do not insert into the Pd—Pd bond of $Pd_2Cl_2(PPh_2py)_2$, **6***a*, although CO or MeNC reacted to give unbridged Pd—Pd products containing these reagents as terminal ligands (17). This behaviour contrasts with that of $Pd_2Cl_2(dpm)_2$, which gives the familiar A-frame products (17, 34), and was attributed to the limited flexibility of the PPh_2py ligand and the relative lability of the pyridyl nitrogen (17).

We find that **6***a* (and **4***a* and **5***a*) does react readily with DMAD to give the "expected" insertion product (Table 1), a dimetallated olefin, exactly analogous to the $Pd_2Cl_2(dpm)_2$ system (35), and we have determined the structure of the product **7** from $Pd_2Cl_2(Ppy_3)_2$, **4***a*. The coordination at each Pd (Fig. 2) approximates to square planar with the *trans* P and N geometry, a terminal chloride, and a carbon of the bridging olefin; the geometry of the inserted ligand approximates that of a dimetallated olefin, originally determined crystallographically for a hexafluoro-2-butyne adduct, however, and not an isolated DMAD adduct from the dpm system (35). Other closely related, crystallographically characterized, bridging DMAD adducts include complexes such as $Rh_2Cl_2(\mu$-CO)(μ-DMAD)$(dpm)_2$ (36) and $Ir_2Cl_2(CO)_2(\mu$-DMAD)$(dpm)_2$ (37).

A molecule of **7** crystallizes with two solvate molecules of CH_2Cl_2, one of which is disordered. There are some possible interactions between nonbonded atoms (Table 7), but these are weak and not significant in determining the basic molecular geometry just outlined. A projection of the nearly planar $Pd_2C_4Cl_2$ portion of the molecule is shown in Fig. 3. Comparison with a corresponding figure for the structure of $Pd_2Cl_2(dpm)_2(\mu$-$F_3CC{=}CCF_3)$ (35) reveals similarities for the coordinated olefinic moieties except for a remarkable difference in the Pd. . .Pd separation (2.910 Å for **7** and 3.492 Å for the 2-butyne adduct), while the Cl—Pd—C angles are also ~10° smaller in the dpm system; the differences are "compensated for" by a closing up of each of the Pd—C—C bond angles by ~10°, and an increase to 45.2° of the dihedral angle between normals to mean planes comprising Cl(1), P(2), N(1), C(1), Pd(1) (essentially planar), and Cl(2), P(1), N(2), C(2), Pd(2) (somewhat nonplanar) (Table 6).

As mentioned above, the PPh_2py ligand is considered of insufficient bite to accommodate the longer metal–metal bonds while maintaining *trans* disposed PPh_2py ligands at the two metal sites. Nevertheless in **7**, a 2.910 Å metal separation is maintained without recourse to a change to *cis* orientation of the Ppy_3 ligands at one metal site. It is unlikely that Ppy_3 is more flexible than PPh_2py, and thus examples of dinuclear HT species, in which the latter ligand accommodates longer metal–metal bonds while remaining *trans* disposed at both metals, will probably be found. Figure 4 shows how the larger bite of Ppy_3 is accomplished by an opening up of each of the angles of the chelate ring, particularly at the nitrogen atom (Pd—N—C is 116.6° in **6***c* and 125.9° in **7**). As in **6***c*, the pyridyl rings containing the coordinating nitrogen atoms in **7** are nonplanar, but somewhat less so, the maximum deviations from the mean planes being 0.011(4) and 0.009(4) Å, respectively, for the N(1) and N(2) rings; of the other four pyridyl rings, three are planar but, surprisingly, that with N(4) shows the greatest deviation from planarity (0.017(5) Å). The (O(3), O(4), C(2), C(4)) fragment at Pd(2) is planar while the corresponding fragment at Pd(1) is distinctly nonplanar (Table 6), reflecting further the completely unsymmetrical nature of **7**; the dihedral angle (between normals to the mean planes) is 59.0° and the twisting most likely occurs in order to minimize unfavourable nonbonded contacts with the pyridyl groups (e.g., Table 7, C(6)—H(6b). . .N(3)). The geometry of the dimetallated olefin moiety resembles closely that found in $Ir_2Cl_2(CO)_2(\mu$-DMAD)$(dpm)_2$, where again the ester groups are twisted with respect to each other (37). In this Ir_2 complex, however, there is a shorter metal–metal distance of 2.779 Å (corresponding to a single bond), somewhat longer metal–carbon bonds (2.052, 2.133 Å), and a decrease in one of the two Ir—C—C bond angles (107.0, 112.3°), cf. Fig. 3. In **7**, the Ir_2 species, and related Rh_2 species (36, 38),

[a]All the interactions are intermolecular, except the entry beginning C(13); Cl(5), C(37), and H(37a) refer to the CH_2Cl_2 molecules. Superscripts refer to symmetry operations: [1] $-x$, $-y$, $1-z$; [2] $-x$, $-y$, $-z$; [3] x, y, z; [4] $-x$, $1-y$, $2-z$; [5] $1-x$, $1-y$, $1-z$.

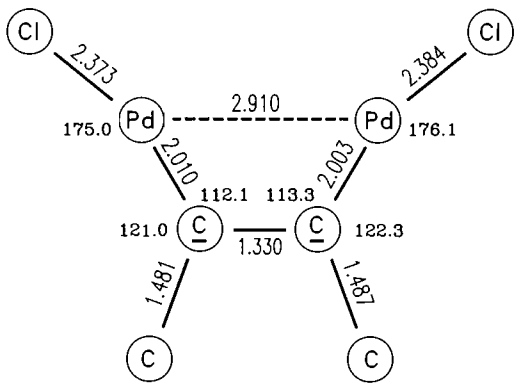

FIG. 3. Projection of the nearly planar $Pd_2C_4Cl_2$ portion of **7** (not drawn to scale).

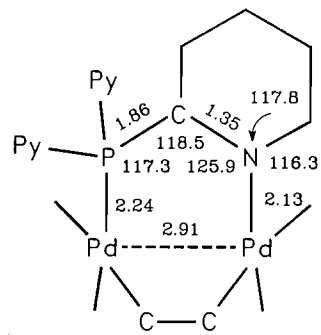

FIG. 4. Diagram showing geometry within one of the 7-membered chelate rings of **7** (not drawn to scale).

containing a bridging DMAD there is a slight twisting of the "parallel" acetylene group with respect to the metal–metal axis, which probably minimizes contacts with the pyridyl/phenyl rings.

Finally, the Pd—N bond lengths in **7** are within ~0.02 Å of those in **6***c* and the other PPh_2py systems mentioned above, Pd—Mo (11), Pd—Rh (15), and Pd—Ru (21), but the Pd—P bond in **7** is the longest observed (by up to 0.05 Å), perhaps reflecting a somewhat more electronegative effect for the pyridyl (*vs.* phenyl) substituent.

There is clearly sufficient flexibility of **7** in solution to result in a structure with equivalent P atoms, the $^{31}P\{^1H\}$ signal at ~20°C appearing as a singlet. Complex **9**, the PPh_2py analogue, similarly gives a singlet $^{31}P\{^1H\}$ signal, while the chiral $PPhpy_2$ system **8** gives rise to four singlets (cf. **5***a*); more detailed studies are required to unravel the NMR behaviour.

Whether the Ppy_3 ligand is sufficiently flexible to stabilize an A-frame, single atom, bridged complex remains to be established. Complex **4***a*, $Pd_2Cl_2(Ppy_3)_2$, in CH_2Cl_2 does react readily with CO at 1 atm (101.3 kPa) even at sub-zero temperatures but attempts to work up the product simply resulted in isolation of only **4***a*; similar behaviour has been reported for $Pd_2Cl_2(PPh_2py)_2$, where the solution product was tentatively suggested to be $[PdCl(CO)(PPh_2py)]_2$, contain-

ing monodentate PPh_2py bound via phosphorus and no bridging ligands (17).

Other structurally characterized Ppy_3 species are *trans*-$RhCl(CO)(Ppy_3)_2$, which contains monodentate P-bound Ppy_3 (9), and $Ru(Ppy_3)_2^{2+}$ in which octahedral geometry is realized via the six pyridyl N-donors (10).

Aqueous solution chemistry of $PdCl_2(Ppy_3)_2$, **1**a, *and* $Pd_2Cl_2(Ppy_3)_2$, **4**a

The interests in the aqueous solution chemistry of pyridylphosphine complexes were outlined in the Introduction; it should be mentioned also that the dpm analogue of the μ-DMAD species (7–9) is a catalyst for the cyclotrimerization of the acetylene to hexamethyl mellitate (35), and the pyridylphosphine ligand systems have the potential for such catalysis in aqueous media. Qualitatively, the most water-soluble of the complexes listed in Table 1 are $PdCl_2(Ppy_3)_2$, **1***a*, and $Pd_2Cl_2(Ppy_3)_2$, **4***a*, dissolution being accompanied by formation of aquo complexes, eq. [1].

[1] $Pd_2Cl_2(Ppy_3)_2 + 2H_2O \rightleftharpoons Pd_2(H_2O)_2(Ppy_3)_2^{2+} + 2Cl^-$

4*a* (orange) **10** (green)

Complex **4***a* dissolves with replacement of the two terminal chlorides by water, and the bis(aquo) dication has been isolated as salts with BF_4^-, PF_6^-, and BPh_4^- as anions, **10***a*–**10***c* (Table 1). A 1627 cm^{-1} IR band (obscured in **10***c*) of coordinated water is seen, and ν(OH) bands are absent. Reaction [1] is readily reversed by adding LiCl, and an HT configuration is assumed for the ionic green species; the $^{31}P\{^1H\}$ singlet is some 25–30 ppm upfield from that of the dichloro precursor. The complexes **10***a*–**10***c* dissolve in MeCN (or acetone) to give perhaps the respective bis(solvent) cations, and conductivity data in MeCN support a 1:2 electrolyte formulation.

To our knowledge, the only other reported case of a neutral, dinuclear, bridged phosphine being soluble in water is $Pd_2Cl_2(dmpm)_2$, which contains bis(dimethylphosphino)-methane; however, this species dissolves as the neutral $Pd_2(OH)_2(dmpm)_2$ species with liberation of 2 equivalents of HCl (39), implying that the pK_a of each coordinated water ligand is $<<7.0$. Aqueous solutions of **4***a* (present as the dication **10**) surprisingly show no dissociation of protons even at pH 11.0; this non-acidic character of the coordinated water (vs. that of the dmpm system) implies that bridged Ppy_3 is a far more basic ligand to the Pd_2^I unit than is dmpm, and this presumably reflects the much stronger basicity generally of a pyridine versus phosphine ligand.

Complex **1***a*, *cis*-$PdCl_2(Ppy_3)_2$, dissolves in water with immediate loss of both chloride ligands (as estimated by titration with $AgNO_3$); the resulting solution is acidic, however, and the immediate molar conductivity (265 ohm^{-1} mol^{-1} cm^2) may include a contribution from the proton(s) of coordinated water. Indeed, pH-titration data reveal loss of one proton per Pd up to pH 11.00, with 50% titration at pH ~4.8, but the titration does not give the standard S-shape curve; the behaviour is typical of *cis*-bis(aquo)palladium(II) species (40) and is summarized in eq. [2] (L = monodentate, phosphorus-bonded Ppy_3):

$$[2]\quad Pd(H_2O)_2L_2^{2+} \overset{-H^+}{\rightleftharpoons} [Pd(OH)(H_2O)L_2]^+ \overset{-H_2O}{\rightleftharpoons} 1/2[Pd_2(\mu\text{-}OH)_2L_4]^{2+}$$

The titration curve results from a combination of the equilibrium constants for proton dissociation, and dimerization.

Acidification of the aqueous solution of **1***a* to pH 1.5 (using dilute HNO_3) and addition of a methanol solution of $NaBPh_4$ precipitated a yellow powder that is probably mainly $[Pd(H_2O)_2(PPy_3)_2][BPh_4]_2$.(Λ (MeCN): 220 ohm^{-1} mol^{-1} cm^2.) Anal. calcd. for $C_{78}H_{72}N_6B_2O_2P_2Pd$: C 71.43, H 5.23, N 6.41; found: C 70.12, H 5.10, N 6.60. The presence of some hydroxy species would account for the low C analysis. Similar precipitation of a species at pH 5.6 using $NaBPh_4$ gave a more orange product that analyzed well for $[Pd(OH)(H_2O)(PPy_3)_2][BPh_4]$. (Λ (MeCN) 180 ohm^{-1} mol^{-1} cm^2. IR (for the less pure PF_6 salt, Nujol): ν(OH) 3651, 3595; ν(H_2O) 1628 cm^{-1}.) Anal. calcd. for $C_{54}H_{44}N_6BO_2P_2Pd$: C 65.42, H 4.78, N 8.48; found: C 65.39, H 4.60, N 7.72. Salts precipitated out by addition of BPh_4^- or BF_4^- to aqueous solutions of $PdCl_2(Ppy_3)_2$ (e.g., at 3.7 mM, pH = 2.9) analyze well for a 66:34 mixture of the bis(aquo)/aquo(hydroxo) species. The $^{31}P\{^1H\}$ NMR signal in MeCN at 20°C for all the above isolated samples is observed as a singlet around 33.4 ppm, which could be an averaged signal for bis(aquo)/aquo(hydroxo) species, or more likely results from a single species containing coordinated MeCN; the shift is consistent with monodentate, phosphorus-bonded Ppy_3 (cf. Table 1).

At pH 11.00 (following titration of the single proton), addition of $NaBPh_4$ results in precipitation of a purple solid, which can be recrystallized from MeCN/EtOH (1:1) at −15°C to give a complex best formulated as $[Pd_2(\mu\text{-}OH)_2(Ppy_3)_2(MeCN)_2](BPh_4)_2$ (cf. eq. [2], in which one Ppy_3 ligand at each Pd(II) centre has been replaced by MeCN). IR (CH_2Cl_2): ν(OH) 3680 cm^{-1}. NMR (CD_3CN, 20°C): $^{31}P\{^1H\}$ δ 29.1, singlet; ^1H δ 2.35, singlet (MeCN). Anal. calcd. for $C_{82}H_{76}N_8B_2O_2P_2Pd_2$: C 65.77, H 4.85, N 7.48, O 2.14; found: C 65.50, H 4.64, N 7.34, O 2.24.

The $^{31}P\{^1H\}$ NMR spectrum of *cis*-$PdCl_2(Ppy_3)_2$ in D_2O gives two singlets at 27.3 and 21.6 ppm with intensity ratio of ~2:1: the former is attributed to the equilibrium mixture of the bis(aquo)/aquo(hydroxo) species, and the latter to the dinuclear, hydroxo-bridged species; see eq. [2].

Concluding remarks

The paper has described synthesis and characterization of nine mononuclear Pd(II)–, and nine dinuclear Pd_2(I)–pyridylphosphine complexes containing also halide ligands. Some comparisons are made to analogous dpm systems and associated A-frame chemistry, but the major raison d'etre for the work is to develop the aqueous solution chemistry of palladium–phosphine complexes with a view to study their homogeneous catalytic properties in this medium. Preliminary work on some aqueous systems is presented, and a good database generally has been established for Pd–pyridylphosphine chemistry.

Although Tom Birchall worked on phenylamines and phenylphosphines, he had not to our knowledge probed the mysteries of aminophosphines. Thus, the topic of this paper is somewhat remote from his major interests as a main-group chemist, but nevertheless the dedication is of the utmost sincerity toward a most genial friend and colleague within the Canadian inorganic chemistry community.

Physical and structural studies of *N*-carboxymethyl- and *N*-(*p*-methoxyphenyl)-3-hydroxy-2-methyl-4-pyridinone

ZAIHUI ZHANG, STEVEN J. RETTIG, AND CHRIS ORVIG[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Z1

Received May 14, 1991

This paper is dedicated to the memory of Professor Thomas Birchall

ZAIHUI ZHANG, STEVEN J. RETTIG, and CHRIS ORVIG. Can. J. Chem. **70**, 763 (1992).

3-Hydroxy-1-carboxymethyl-2-methyl-4-pyridinone (Hcmp) and 3-hydroxy-1-(*p*-methoxyphenyl)-2-methyl-4-pyridine (Hpap) have been prepared and studied by single crystal X-ray diffraction. Crystals of Hcmp are monoclinic, a = 6.340 (2), b = 7.705 (1), c = 16.226 (1) Å, β = 94.74 (1), Z = 4, space group $P2_1/n$ and those for Hpap are monoclinic, a = 10.8435 (9), b = 16.680 (2), c = 13.5665 (6) Å, β = 109.450 (4), Z = 8, space group $C2/c$. Both structures were solved by direct methods and were refined by full-matrix least-squares procedures to R = 0.030 and 0.041 (R_w = 0.039 and 0.058) for 1642 and 1819 reflections with $I \geq 3\sigma(I)$, respectively. Bond lengths and bond angles in the two compounds are normal; however, Hcmp forms as a zwitterion in the solid state. The two compounds were also studied by mass spectrometry, UV, infrared, proton NMR spectroscopies, and potentiometric equilibrium measurements. The protonation constants for Hcmp are log K_1 = 9.76 (1), log K_2 = 3.43 (1), and log K_3 = 2.78 (3) and for Hpap are log K_1' = 9.42 (4) and log K_2' = 3.16 (8).

Key words: 3-hydroxy-4-pyridinone, zwitterion, hydrogen bonding, protonation constant, crystallography, solid state.

ZAIHUI ZHANG, STEVEN J. RETTIG et CHRIS ORVIG. Can. J. Chem. **70**, 763 (1992).

On a préparé la 3-hydroxy-1-carboxyméthyl-2-méthylpyridin-4-one (HCMP) et la 3-hydroxy-1-(*p*-méthoxyphényl)-2-méthylpyridin-4-one (HPAP) et on les a examinés par diffraction des rayons X par un cristal unique. Les cristaux du HCMP sont monocliniques, avec a = 6,340(2), b = 7,705(1) et c = 16,226(1) Å, β = 94,74(1), Z = 4 et groupe d'espace $P2_1/n$ et ceux du HPAP sont monocliniques, avec a = 10.8435(9), b = 16,680(2) et c = 13,5665(6) Å, β = 109,450(4), Z = 8 et groupe d'espace $C2/c$. On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,030 et 0,041 (R_w = 0,039 et 0,058), respectivement, pour 1642 et 1819 réflexions avec $I \geq 3\sigma(I)$. Les longueurs et les angles de liaisons des deux composés sont normaux; toutefois, le HCMP forme un zwitterion en phase solide. On a étudié les deux composés par spectrométrie de masse, par spectroscopies UV, infrarouge et RMN et par des mesures d'équilibres potentiométriques. Les constantes de protonation du HCMP sont log K_1 = 9,76(1), log K_2 = 3,43(1) et log K_3 = 2,78(3) alors que pour la HPAP log K_1' = 9,42(4) et log K_2' = 3,16(8).

Mots clés : 3-hydroxypyridin-4-one, zwitterion, liaison hydrogène, constantes de protonation, cristallographie, état solide.

[Traduit par la rédaction]

Introduction

As part of our project to examine the coordination chemistry and biochemical properties of aluminum, gallium, and indium complexes, we have been studying tris(ligand) complexes of these metal ions with 3-hydroxy-4-pyrones (1–3) and 3-hydroxy-4-pyridinones (4–7) as bidentate ligands. The preparation and characterization of a series of *N*-alkyl (**1**) and *N*-aryl (**2**) substituted-3-hydroxy-2-methyl-4-pyridinones and their metal complexes have been reported (7, 8). The studies have shown that these complexes have unique properties: reasonable water solubility, variable lipophilicity, high thermodynamic stability, and interesting biological activity (7, 9–11).

As these ligands have very high affinity for trivalent metal ions, there is significant interest in using them as chelators for various metal ions. We have studied the solution chemistry and the biochemical properties of tris(ligand) complexes of aluminum(III), gallium(III), and indium(III) with these ligands (4–7, 9–11). Kontoghiorghes and co-workers

have used 3-hydroxy-1,2-dimethyl-4-pyridinone (Hdpp) for iron overload treatment in preliminary clinical trials (12–15). Taylor and Kontoghiorghes also investigated the mobilization of plutonium(IV) and iron(III) from transferrin and ferritin by hydroxypyridinone chelators (16). The *N*-aryl substituted 3-hydroxy-4-pyridinones were also used as selective extractants for various metal ions, e.g., gallium(III) (17, 18), iron(III) (19–21), vanadium(V) (22–24), uranium(VI) (25), thorium(IV) (26), protactinium(V) (26), zirconium(IV) (27), niobium(V) (27), and tantalum(V) (27).

Tautomerism is one of the important features of heterocyclic compounds. For 4-pyridinones, there are two possible tautomers, 4-hydroxypyridine and 4-pyridinone (28). In the equilibrium between these two tautomers, the predominant form in polar solvents is the pyridinone; however, the hydroxypyridine tautomer appears to be more stable in the gas phase (29–31). In the crystal structures of 1-alkyl-3-hydroxy-4-pyridinones (**1***a*, **1***b*) reported in the literature (8), these compounds exist as the pyridinone forms and the ring system of the pyridinones shows some delocalization of the formal double bonds. The effect of the ring nitrogen substituent on the delocalization has also been discussed (32). Herein we report our studies of the 3-hydroxy-4-pyridinones, **1***d* and **2***c*, using various physical techniques including single crystal X-ray crystallography, potentiometric equilibrium measurements, and UV spectrophotometry. The effect on the delocalization of the formal ring double bonds is compared among the three groups of substituents: alkyl, aryl, and carboxyl groups.

Experimental

Materials and methods

All chemicals were reagent grade and were used as received unless specified: maltol (3-hydroxy-2-methyl-4-pyrone, Sigma), *p*-anisidine (Eastman Organic Chemicals), and glycine (Sigma). Water was deionized (Barnstead D8902 and D8904 cartridges) and distilled (Corning MP-1 Megapure still).

Proton NMR spectra of compounds were recorded in $CDCl_3$ or D_2O with a Varian XL-300 or a Bruker AC-200E spectrometer. Mass spectra were obtained with a Kratos MS50 (electron impact ionization, EI) instrument. Infrared spectra were recorded as KBr pellets in the range 4000–200 cm^{-1} with a Perkin–Elmer PE 783 spectrophotometer and were referenced to polystyrene film. Melting points were measured with a Mel-Temp apparatus and are uncorrected. Ultraviolet spectra were recorded in the range 350–200 nm with a Shimadzu UV-2100 spectrophotometer. Analyses for C, H, and N were performed by P. Borda of this department. Potentiometric equilibrium measurements were done as previously described (9, 10).

N-*Carboxymethyl-3-hydroxy-2-methyl-4-pyridinone, Hcmp*

Maltol (4.95 g, 39.2 mmol) and glycine (5.92 g, 78.8 mmol) were dissolved in 100 mL hot distilled water and the pH of the solution was adjusted to about 9 with 8 N NaOH. The mixture was refluxed for 20 h and then decolorized with activated charcoal. The volume of the solution was reduced to 50 mL and 6 N HCl solution was added to this solution to lower the pH to around 3; a yellowish solid precipitated. Recrystallization (twice) of this solid from hot water yielded an off-white crystalline product (3.09 g, 43%); mp 258–260°C. Infrared spectrum (cm^{-1}, KBr disk): 3300–2500 (b, hydrogen bonded), 1650–1600 (b, s), 1545, 1520, 1450, 1380–1350 (b, s), 1270 (b, s), 1210 (w), 1075, 830, and 810. ^1H NMR spectrum (D_2O, 25°C): δ 2.44 (s, 3H, $NC(CH_3)$), 4.87 (s, 2H, NCH_2COOH), 7.02 (d, 1H, 8.0 Hz, $CHC(O)$), 7.93 (d, 1H, 8.0 Hz, $CHCHN$). Mass spectrum (EI): *m/e* 183 (M^+), 165 ($M^+ - H_2O$). Anal. calcd. for $C_8H_9NO_4$: C 52.46, H 4.95, and N 7.65; found: C 52.57, H 4.98, and N 7.63. Single crystals suitable for X-ray diffraction were obtained from a saturated solution by slow evaporation.

1-(p-Methoxyphenyl)-3-hydroxy-2-methyl-4-pyridinone, Hpap

Maltol (4.02 g, 31.9 mmol) and *p*-anisidine (7.93 g, 64.4 mmol) were suspended in 100 mL dilute HCl solution (3 mL concentrated HCl in 100 mL water). This mixture was refluxed for 72 h and then cooled to room temperature. A light grey solid was collected by filtration. It was recrystallized from hot ethanol (after being decolorized with activated charcoal for 30 min) yielding a white crystalline solid (4.27 g, 58% yield), mp 249°C. Infrared spectrum (cm^{-1}, KBr disk): 3180 (b), 1630 (s), 1578 (s), 1530 (w), 1510 (s), 1465, 1400 (w), 1380 (w), 1320 (w), 1300 (s), 1250, 1205, 1170 (s), 1105 (w), 1040 (s), 845, 825. ^1H NMR spectrum ($CDCl_3$, 25°C): δ 2.11 (s, 3H, $NC(CH_3)$), 3.90 (s, 3H, OCH_3), 5.66 (s, 1H, b, *OH*), 6.45 (d, 1H, 7.8 Hz, *CH*C(O)), 6.9–7.3 (m, 5H, C_6H_4 and CHC*H*N). Mass spectrum (EI): *m/e* 231 (M^+), 215 ($M^+ - CH_4$), 199 ($M^+ - OCH_3$). Anal. calcd for $C_{13}H_{13}NO_3$: C 67.52, H 5.67, and N 6.06; found: C 67.51, H 5.71, and N 6.13. Single crystals obtained from an ethanol solution were used for X-ray crystallographic analysis.

X-ray crystallographic analyses

Crystallographic data for Hcmp and Hpap appear in Table 1. The final unit-cell parameters were obtained by least-squares refinements on the setting angles for 25 reflections with 2θ = 42.28°–54.80° for Hcmp and 2θ = 92.53°–108.29° for Hpap. The data were collected at 21 ± 1°C with a Rigaku AFC6S diffractometer. The take-off angle was 6.0° and the detector aperture was 6.0 mm in both horizontal and vertical directions at a distance of 285 mm from the crystal. Reflections with *I* between 1 σ(*I*) and 40 σ(*I*) were rescanned (maximum of 8 scans) and the counts were accumulated to ensure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. The intensities of three standard reflections, measured every 200 reflections for Hcmp and 150 reflections for Hpap throughout the data collections, remained essentially constant in each case. The data were processed and corrected for Lorentz and polarization effects. An empirical absorption correction, based on azimuthal scans of several reflections for Hpap and using the program DIFABS (applied after isotropic refinement with hydrogen atoms included in the model) for Hcmp, was applied. A correction for secondary extinction was also applied (coefficient = 1.98 (3) × 10^{-5}) for Hpap.

Both structures were solved by direct methods (33). The nonhydrogen atoms were refined anisotropically and hydrogen atoms were refined with isotropic thermal parameters. Neutral atom scattering factors were taken from ref. 34. Anomalous dispersion effects were included in F_{calc} (35); the values for $\Delta f'$ and $\Delta f''$ were chosen from Cromer (36). All calculations were performed using the TEXSAN crystallographic software package of Molecular Structure Corporation (37). Final atomic coordinates and equivalent isotropic thermal parameters B_{eq} appear in Table 2 for Hcmp and Table 3 for Hpap, respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2] Bond lengths and bond angles are listed in Table 4 and Table 5, respectively.

Results and discussion

1-Carboxymethyl-3-hydroxy-2-methyl-4-pyridinone and 1-(*p*-methoxyphenyl)-3-hydroxy-2-methyl-4-pyridinone have

[2]Tables of structure factors, anisotropic thermal parameters, and other material mentioned in the text may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen atom coordinates and intra- and intermolecular bond distances and angles relating to hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

been prepared in fair yields under differing conditions: Hcmp was obtained by maintaining the pH of the solution around 9 while Hpap was synthesized in acidic medium. This is necessitated by the different basicity of the amines.

The structures of Hcmp and Hpap were established by single crystal X-ray diffraction. ORTEP views of the two molecules are shown in Fig. 1. Stereodiagrams of the unit cell packing are shown for Hcmp in Fig. 2 and for Hpap in Fig. 3. In Hcmp, the carboxyl group is deprotonated and the ketone oxygen atom on the pyridinone ring is protonated thus forming a zwitterion. There is an extraordinarily strong O—H···O hydrogen bond (O(2)—H(2)···O(4) ($\frac{1}{2} + x$, $\frac{1}{2} - y$, $\frac{1}{2} + z$), H···O = 1.43 (2) Å, O···O = 2.475 (1) Å, O—H···O = 175 (2)°) between two molecules. Three-dimensional networks of Hcmp molecules are formed by C—H···O hydrogen bonds (C(6)—H(7)···O(4) ($\frac{3}{2} - x$, $\frac{1}{2} + y$, $\frac{1}{2} - z$), H···O = 2.46 (1) Å, C···O = 3.333 (2) Å, C—H···O = 156 (1)° and C(7)—H(8)···O(3) ($\frac{3}{2} - x$, $\frac{1}{2} + y$, $\frac{1}{2} - z$), H···O = 2.41 (2) Å, C···O = 3.322 (2) Å, C—H···O = 162(1)°) plus an additional O—H···O hydrogen bond (O(1)—H(1)···O(3) ($1 - x$, $-y$, $1 - z$),

H···O = 1.94 (2) Å, O···O = 2.719 (1) Å, O—H···O = 152 (2)°. The bridging carboxyl groups link Hcmp molecules together (Fig. 2). The Hpap structure contains centrosymmetric C—H···O hydrogen bonded dimeric units (C(8)—H(7)···O(2) ($\frac{1}{2} - x, \frac{1}{2} - y, -z$), H···O = 2.34 (2) Å, C···O = 3.279 (2) Å, C—H···O = 160 (1)°). Each dimer is linked to two others by O—H···O hydrogen bonds (O(1)—H(1)···O(2) $-x, y, -\frac{1}{2} - z$), H···O = 1.82 (2) Å, O···O = 2.662 (2) Å, O—H···O = 152 (2)°) to form the three-dimensional network (Fig. 3).

Both structures contain legitimate intermolecular (see above) and intramolecular C—H···O hydrogen bonds (C(1)—H(5)···O(1), H···O = 2.35 (2) Å, C···O = 2.803 (2) Å, C—H···O = 110 (1)° in Hcmp and C(1)—H(4)···O(1), H···O = 2.37 (3) Å, C···O = 2.798 (2) Å, C—H···O = 107 (2)° in Hpap). The formation of legitimate C—H···O bonds has not been observed in the structures of reported 1-alkyl-3-hydroxy-2-methyl-4-pyridinones, **1***a* and **1***b* (8). In addition, there is an intramolecular O—H···O bond observed both in Hcmp (O(1)—H(1)···O(2), H···O = 2.29 (2) Å, O···O = 2.719 (2) Å, O—H···O = 112 (1)°) and in Hpap (O(1)—H(1)···O(2), H···O = 2.36 (2) Å, O···O = 2.749 (2) Å, O—H···O = 106 (2)°) molecules.

The six-membered pyridinone ring systems in both Hpap and Hcmp are slightly, but significantly, nonplanar (maximum deviations from the mean planes being 0.0203 (19) Å in the former and 0.0099 (13) Å in the latter), as noted earlier for 3-hydroxy-2-methyl-4-pyridinone (Hmpp) and 3-hydroxy-1,2-dimethyl-4-pyridinone (Hdpp) (8). The deviation from planarity is towards a N(1), C(4) boat in both molecules. In the Hpap molecule, the phenyl ring is planar to within 0.0063 (15) Å and is oriented roughly at right angles to the pyridinone ring (the dihedral angle between the two planes is 73.7°) to minimize steric interaction with the adjacent C(1) methyl group. In Hcmp, the plane formed by the carboxymethyl substituent on N(1) is also perpendicular to the pyridinone ring (the dihedral angle is 91.0°) and it is planar to within 0.0148 (11) Å.

The pattern of bond lengths within the pyridinone ring in

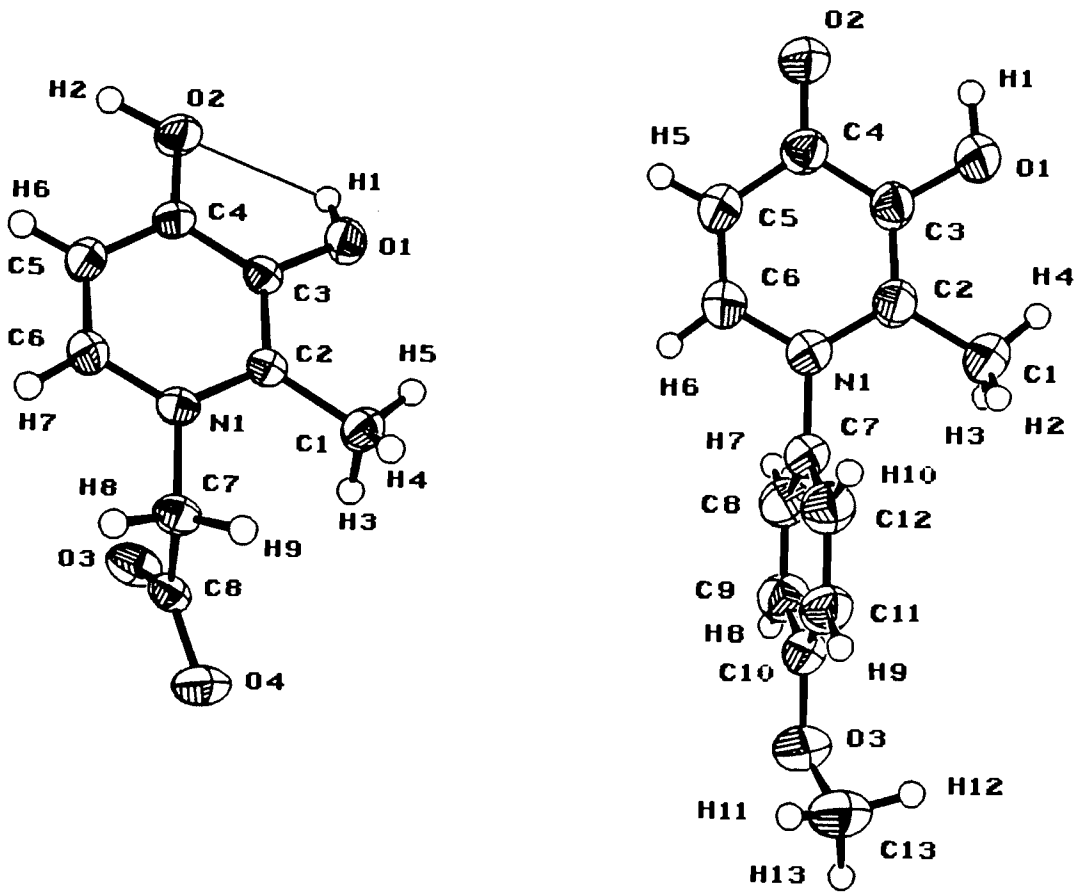

FIG. 1. ORTEP views of the Hcmp (left) and Hpap (right) molecules; 50% probability thermal ellipsoids are shown. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

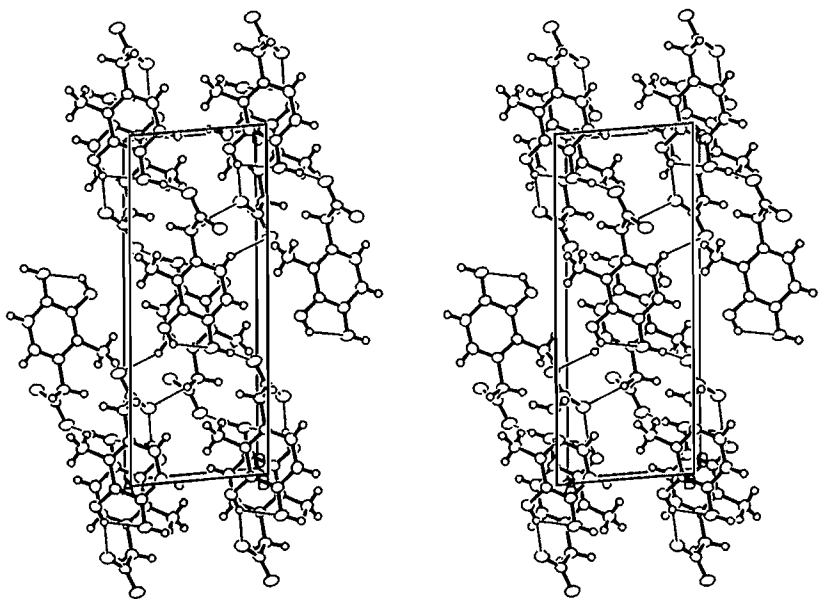

FIG. 2. ORTEP stereoscopic view of the packing arrangement in Hcmp.

Hpap is different from that observed in Hmpp and Hdpp. The most noticeable feature is the more pronounced localization of the formal double bonds in Hpap vs. that in Hmpp and Hdpp. Shorter C(2)—C(3), C(5)—C(6) and ketone C(4)—O(2) bonds, and loner N(1)—C(2) and C(4)—C(5) bonds are observed in Hpap. Also, the C(3)—C(4)—C(5) bond angle in Hpap is about 1° smaller than that in Hmpp and Hdpp and 4° smaller than in Hcmp. In Hcmp, a different

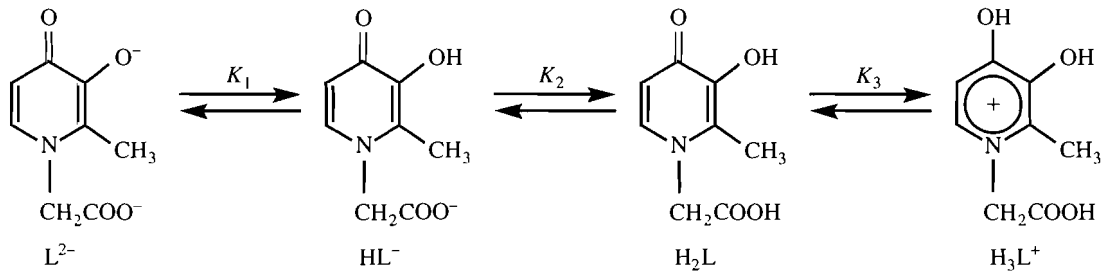
pattern of bond lengths and bond angles in the pyridinone ring is observed. The bond lengths are more averaged than in the other pyridinone systems and the intra-annular bond angles are all within 1° of 120°. A significantly longer ketone O(2)—C(4) bond (1.320 Å) is also observed than in Hpap (1.254 Å), Hmpp (1.280 Å), of Hdpp (1.272 Å). These bond lengths and angles taken together indicate that a delocalized pyridinone ring is obtained in Hcmp and that the positive charge of the zwitterion is distributed throughout the ring rather than concentrated at the nitrogen. In the pyridinone systems, which we have studied crystallographically, the extent of the delocalization of the formal double bonds in the pyridinone ring follows the order: Hcmp >> Hmpp ≈ Hdpp > Hpap. We had previously sought to isolate crystals with the ring-based cation by acidifying Hdpp (and other noncarboxyl substituted 3-hydroxy-4-pyridinones) to make H_2dpp^+ or analogues without success.

The protonation constants of Hcmp and Hpap were determined by potentiometric equilibrium measurements. The results are listed in Table 6. The protonation equilibria for the amphoteric ligands are described by eqs. [1]–[3] for Hcmp (H_2L) and eqs. [4] and [5] for Hpap (HL):

$$[1]\quad H^+ + L^{2-} \rightleftharpoons HL^- \qquad K_1 = \frac{[HL^-]}{[H^+]\,[L^{2-}]}$$

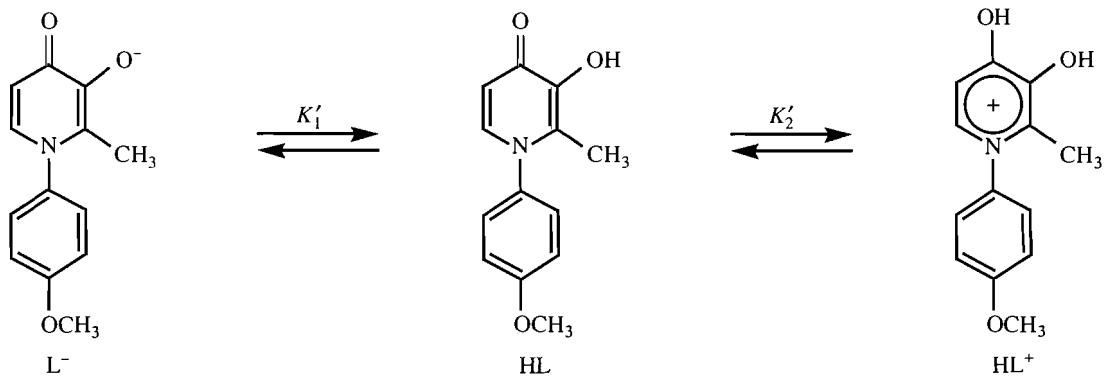
$$[2]\quad H^+ + HL^- \rightleftharpoons H_2L \qquad K_2 = \frac{[H_2L]}{[H^+]\,[HL^-]}$$

$$[3]\quad H^+ + H_2L \rightleftharpoons H_3L^+ \qquad K_3 = \frac{[H_3L^+]}{[H^+]\,[H_2L]}$$



$$[4]\quad H^+ + L^- \rightleftharpoons HL \qquad K_1' = \frac{[HL]}{[H^+]\,[L^-]}$$

$$[5]\quad H^+ + HL \rightleftharpoons H_2L^+ \qquad K_2' = \frac{[H_2L^+]}{[H^+]\,[HL]}$$



Log K_1 for Hcmp is close to that for other *N*-alkyl-3-hydroxy-2-methyl-4-pyridinones (log K_1 = 9.76 vs. ~9.8) (10). This suggests that the deprotonated carboxyl group at the ring nitrogen in solution does not affect the electron density of the pyridinone ring to any significant extent vs. the *N*-alkyl substituted pyridinones. It is possible for Hcmp to form a zwitterion in solution; therefore, an equilibrium would be established between the neutral ligand, H_2L and the zwitterion species. The protonation processes of the neutral ligand, H_2L, and the zwitterion would then contribute to both of the determined protonation constants K_2 and K_3 for equilibria [2] and [3].

The constants for Hpap are similar to those reported for 3-hydroxy-2-methyl-1-phenyl-4-pyridinone (Hppp) (log K_1 = 9.42 vs. 9.40, log K_2 = 3.16 vs. 3.03) (7) and lower than those for the *N*-alkyl-3-hydroxy-2-methyl-4-pyridinones (log K_1 = 9.42 vs. ~9.8 and log K_2 = 3.16 vs. ~3.7). This suggests that the *p*-methoxyphenyl group and unsubstituted phenyl group have similar electron-withdrawing effects on the pyridinone ring.

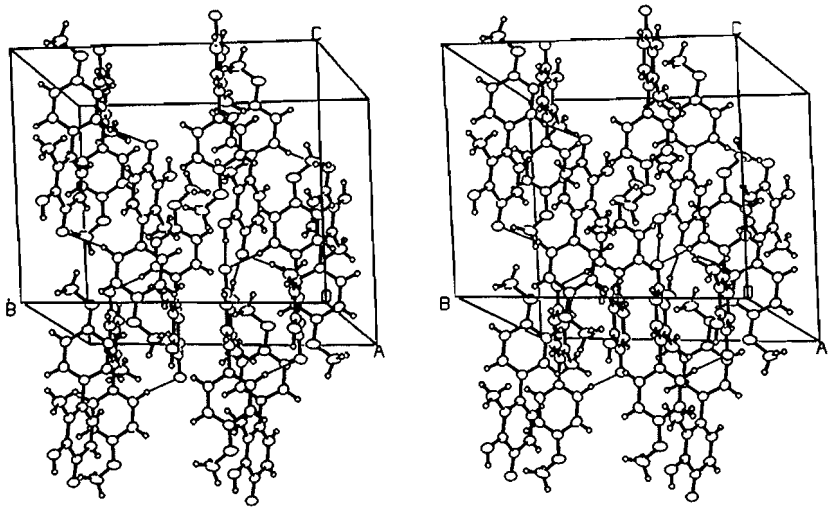

FIG. 3. ORTEP stereoscopic view of the packing arrangement in Hpap.

TABLE 6. Protonation constants (K_1, K_2) for Hcmp and Hpap at 25°C in 0.15 M NaCl[a]

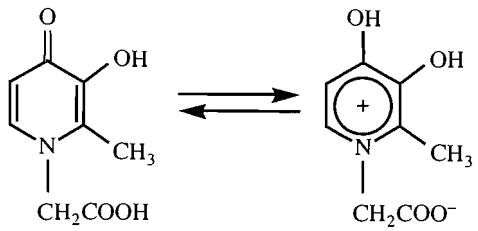
	Hcmp	Hpap
log K_1	9.76 (1)	9.42 (4)
log K_2	3.43 (1)	3.16 (8)
log K_3	2.78 (3)	

[a]Numbers in parentheses represent standard deviations between successive runs.

TABLE 7. Ultraviolet spectral data[a,b] for Hcmp and Hpap

	λ (nm)	ε (M^{-1} cm^{-1})
Hcmp	281	12 900
	218	15 100
	207	10 400
Hpap	283	19 700
	225	38 400 (sh)
	207	62 500

[a]In H_2O, pH = 7.4, 25°C.
[b]sh = shoulder.



The infrared spectrum of Hpap shows the characteristic four-band pattern in the range 1650–1500 cm^{-1}. This is assigned collectively to $\nu_{C=O}$ and ν_{ring} vibrations, since resolving these two highly mixed modes is extremely difficult (8, 38, 39). The IR spectrum of Hcmp shows a very broad band in the range 3300–2500 cm^{-1}, a result of the strong intermolecular hydrogen bonding of the carboxyl groups (40). The characteristic four-band pattern between 1650–1500 cm^{-1} for pyridinone ring stretching is not obvious in Hcmp because of the formation of zwitterions and the delocalization of the formal ring double bonds. There is a wide strong band from 1650 to 1600 cm^{-1} that is assigned to a mixture of stretchings of the carboxylate anion and the pyridinone ring.

The UV spectral data are shown in Table 7. The bands observed are from $\pi \rightarrow \pi^*$ transitions. E (ethylinic) and B (benzenoid) bands were recorded at 218 and 281 nm for Hcmp and 225 and 283 nm for Hpap, respectively. There was, in addition, a third absorption in each case. The extinction coefficients are much higher for Hpap than for Hcmp, an effect of the *p*-methoxyphenyl substituent. Proton NMR spectrum of Hcmp shows the characteristic doublet of ring proton doublets with a coupling constant of 8 Hz. In the Hpap spectrum, only one ring proton doublet with a coupling constant of 7.8 Hz was resolved; the other one appeared in the envelope of phenyl protons.

In conclusion, the structural studies of Hcmp and Hpap reveal that there is an extensive hydrogen bond network in both structures; hydroxyl and ketone functionalities contribute a number of hydrogen-bonding sites to each of the molecules. The protonated and delocalized pyridinone ring system was finally obtained in the solid state in Hcmp by formation of a zwitterion, and it does indeed show highly averaged bond distances.

Tris-triphenylsiloxy compounds of aluminium[1]

ALLEN W. APBLETT, ALISON C. WARREN, AND ANDREW R. BARRON[2]

Department of Chemistry and Materials Research Laboratory, Harvard University, Cambridge, MA 02138, U.S.A.

Received July 4, 1991

ALLEN W. APBLETT, ALISON C. WARREN, and ANDREW R. BARRON. Can. J. Chem. **70**, 771 (1992).

The reaction of $AlMe_3$ with three equivalents of $HOSiPh_3$ in THF results in the formation of the solvent complex $Al(OSiPh_3)_3(THF)$ (**1**). Hydrolysis of **1** yields the stable water complex $Al(OSiPh_3)_3(H_2O)(THF)_2$ (**2**) in which the THF molecules are hydrogen bonded to the coordinated water ligand. Compounds **1** and **2** have been fully characterized by ^1H, ^{13}C, ^{17}O, ^{27}Al, and ^{29}Si NMR and IR spectroscopy. In addition, variable temperature ^1H NMR of **2** has been employed to investigate the steric interactions between the phenyl rings of adjacent siloxide ligands. The molecular structures of the solvates **1**·(THF) and **2**·$(THF)_{1.25}$ have been determined by X-ray crystallography. **1**·(THF): monoclinic $P2_1/c$, a = 10.03 (1), b = 23.758 (6), c = 23.294 (7) Å, β = 101.13 (6)°, Z = 4, R = 0.084, R_w = 0.094. **2**·$(THF)_{1.25}$: cubic $Pa\bar{3}$, a = 23.034 (3) Å, Z = 4, R = 0.093, R_w = 0.099.

Key words: aluminium, siloxide, hydrolysis, complex, NMR spectroscopy.

ALLEN W. APBLETT, ALISON C. WARREN et ANDREW R. BARRON. Can. J. Chem. **70**, 771 (1992).

La réaction du $AlMe_3$ avec trois équivalents de $HOSiPh_3$ dans du THF conduit à la formation d'un complexe incorporant le solvant, $Al(OSiPh_3)_3(THF)$ (**1**). L'hydrolyse du composé **1** fournit le complexe aqueux stable, $Al(OSiPh_3)_3(H_2O)(THF)_2$ (**2**) dans lequel les molécules de THF sont coordonnées à l'eau par des liaisons hydrogènes. On a caractérisé complètement les molécules **1** et **2** par la RMN du ^1H, du ^{13}C, du ^{17}O, du ^{27}Al et du ^{29}Si ainsi que par spectroscopie infrarouge. De plus, on a utilisé la RMN du ^1H à température variable pour étudier les interactions stériques entre les noyaux aromatiques des coordinats siloxydes adjacents. Les structures moléculaires des produits solvatés **1**·(THF) et **2**·$(THF)_{1.25}$ ont été déterminées par diffraction des rayons-X. **1**·(THF) : monoclinique, $P2_1/c$, a = 10,03(1), b = 23,758(6) et c = 23,294(7) Å, β = 101,13(6)°, Z = 4, R = 0,084, R_w = 0,094. **2**·$(THF)_{1.25}$: cubique, $Pa\bar{3}$, a = 23,034(3) Å, Z = 4, R = 0,093, R_w = 0,099.

Mots clés : aluminium, siloxyde, hydrolyse, complexe, RMN.

[Traduit par la rédaction]

Introduction

Recent work in our laboratory has been concerned with the synthesis and structural characterization of siloxy-substituted alumoxanes (1–3). While alumoxanes is a term applied to organically substituted aluminium oxygen macromolecules in general, we have determined that siloxy-substituted derivatives all have the empirical formula $[Al(O)_x(OH)_y(OSiR_3)_z]_n$ where $2x + y + z = 3$ (3). These materials were first synthesized in 1958 by Andrianov and Zhadanov via the hydrolysis of trisiloxy compounds of aluminium (eq. [1]) (4).

$$[1]\quad Al(OSiR_3)_3 \xrightarrow[-HOSiR_3]{+H_2O} [Al(O)_x(OH)_y(OSiR_3)_y]_n$$

Since there are only a limited number of stable trialkylsilanols commercially available for use as precursors to these aluminium trisiloxides, we have developed an alternative route to siloxy-alumoxanes based on the hydrolysis of dimeric dimethylaluminium monosiloxides (2), (eq. [2]), which are readily prepared from polydiorganosiloxides (eq. [3]) (5).

$$[2]\quad n[AlMe_2(OSiR_3)]_2 \xrightarrow[-MeH\ -HOSiR_3]{+H_2O} \frac{n}{2}[Al(O)_x(OH)_y(OSiR_3)_z]_n$$

$$[3]\quad n\,AlMe_3 + (R_2SiO)_n \xrightarrow{\Delta} \frac{n}{2}[AlMe_2(OSiR_2Me)]_2$$

While both of the routes outlined in eqs. [1] and [2] lead to high molecular weight siloxy-alumoxanes, we have been unable to isolate any of the proposed intermediates in the hydrolysis reactions, for example, low molecularity species containing either coordinated water or terminal hydroxide groups (eq. [4]).

$$[4]\quad Al(OSiR_3)_3 \xrightarrow{+H_2O} Al(OSiR_3)_3(H_2O) \xrightarrow[-HOSiR_3]{\Delta} [Al(OH)(OSiR_3)_2]_x$$

In an effort to isolate such species we have investigated the hydrolysis of the aluminium siloxide compound derived from the sterically bulky triphenyl silanol, $HOSiPh_3$. The rationale for the choice of this ligand is based on the concept that sterically demanding ligands preclude oligomerization, and thus in the present case the condensation reaction that leads to alumoxane formation is prevented.

Experimental

General

Elemental analyses were performed by Oneida Research Services, Whitesboro, N.Y. Melting points and thermogravimetric analyses were obtained on a Seiko 200 TG/DTA instrument. IR spectra (4000–400 cm^{-1}) were recorded on a Nicolet 5ZDX FTIR as Nujol or Fluorolube mulls on KBr plates. ^1H and ^{13}C NMR spectra were obtained on a Bruker AM-500 spectrometer, and chemical shifts are reported relative to $SiMe_4$ in C_6D_6 unless otherwise stated. ^1H–^1H COSY NMR spectra were collected by use of a standard pulse sequence (6, 7) with 45° mixing pulse, a 1–2 s relaxation delay, and a resolution of ca. 4 Hz per point. The FID's were not weighted before Fourier transformation, and the spectral matrix was symmetrized about the diagonal. ^1H–^{13}C correlated 2D NMR spectra were obtained using a standard pulse sequence (8),

TABLE 1. Heteroatom NMR chemical shifts[a]

Compound	^{27}Al	^{29}Si	^{17}O
$Al(OSiPh_3)_3(THF)$	57.5 (3400)	−24.6	12.9 (780), THF 7.2 (730), $OSiPh_3$[b]
$Al(OSiPh_3)_3(H_2O)(THF)_2$	58.8 (4380)	−25.7	17.2 (660), THF 14.5 (585), H_2O[c] 8.8 (860), $OSiPh_3$[b]
$[AlMe_2(\mu\text{-}OSiPh_3)]_2$	57.4 (6440)	−10.8	47.8 (780)
$Al(acac)(OSiPh_3)_2$	53.0 (2300)[d]	−24.2[e]	375.0 (2200), acac 12.9 (1400), $OSiPh_3$
$HOSiPh_3$		−12.6	8.9 (414)

[a]$W_{1/2}$ values in Hz are given in parentheses. Unless otherwise stated all spectra were obtained at ambient temperatures, in CH_2Cl_2:$CDCl_3$ (1:1).
[b]22.3% ^{17}O enriched $OSiPh_3$.
[c]22.3% ^{17}O enriched H_2O.
[d]Reference 17, $C_2D_2Cl_4$, 120°C.
[e]Reference 17, $CDCl_3$.

spectral widths of 250 and 300 Hz, and 1000 and 256 data points in the F2 (^{13}C) and F1 (^1H) domains, respectively. The latter domain was zero filled to 512 K and Lorentzian line-broadening functions equal to the digital resolution (ca. 4 Hz) were applied to each axis. ^{17}O, ^{27}Al, and ^{29}Si NMR spectra (see Table 1) were recorded in a Bruker WM-300 spectrometer and chemical shifts were reported versus H_2O, $[Al(H_2O)_6]^{3+}$, and $SiMe_4(CDCl_3)$, respectively. X-ray data were collected on a Nicolet R3m/V four-circle diffractometer equipped with a LT-1 low-temperature device.

$AlMe_3$ as a 2 M solution in hexane (Aldrich), $HOSiPh_3$ (Huls), and $ClSiPh_3$ (Aldrich) were commercial samples and were used without further purification. Unless otherwise stated all manipulations were performed under an atmosphere of dry nitrogen. Solvents were dried, distilled, and degassed before use. Water was doubly distilled and deionized.

*$Al(OSiPh_3)_3(THF)$ (**1**)*

A solution of $AlMe_3$ (10.6 mL, 2 M solution in hexane, 21.2 mmol) in THF (50 mL) was added dropwise to a stirred solution of $HOSiPh_3$ (17.53 g, 63.4 mmol) in THF (50 mL) at 0°C. After 12 h all gas evolution had ceased and the volatiles were removed *in vacuo*, 50°C, to afford a powdery white solid in quantitative yield (21.06 g, 99.9%). Crystals of **1**·(THF) suitable for X-ray structural analysis were obtained by cooling a solution of 40 g of the crude material in 30 mL THF to −25°C; mp 353°C (dec. without melting). IR (Fluorolube and Nujol, cm^{-1}): 3182 (w), 3083 (w), 3064 (m), 3047 (m), 3020 (w), 3010 (w), 2975 (s), 2876 (s), 1588 (w), 1566 (vw), 1428 (s), 1304 (w), 1261 (m), 1187 (w), 1114 (vs), 1070 (vs), 1025 (w), 999 (m), 918 (w), 871 (m), 787 (s), 765 (w), 743 (s), 709 (vs), 701 (vs), 501 (vs), 484 (w), 475 (w), 433 (m). NMR ($CDCl_3$) ^1H: 7.55 (18H, d, J(H–H) = 6.7 Hz, *o*-CH), 7.32 (9H, t, J(H–H) = 7.5 *p*-CH), 7.17 (18H, dd, J(H–H) = 6.7 Hz, J(H–H) = 7.5 Hz, *m*-CH), 3.76 (4H, t, J(H–H) = 6.7 Hz, OCH_2), 1.52 (4H, t, J(H–H) = 6.7 Hz, OCH_2CH_2). ^{13}C: 138.4 (Si-C), 135.0 (*o*-CH), 128.9 (*p*-CH), 127.5 (*m*-CH), 70.5 (OCH_2), 25.1 (OCH_2CH_2). Anal. calcd. for $C_{62}H_{61}AlO_5Si_3$: C 74.66, H 6.16; found: C 74.60, H 5.99.

*$Al(OSiPh_3)_3(H_2O)(THF)_2$ (**2**)*

Degassed water (100 mg, 0.56 mmol) was added to a solution of **1** (5.0 g, 5.01 mmol) in THF (30 mL). The solution was swirled momentarily to mix the reagents. Upon sitting, the solution gradually deposited large, colorless cube-shaped crystals. After 12 h the solution was decanted and the crystals were dried *in vacuo*. A further crop of crystals of **2**·$(THF)_{1.25}$ was obtained upon cooling the mother liquor to −30°C. Drying the crystals (50°C) resulted in the removal of excess solvated THF and the formation of pure **2**. Yield: 5.02 g, 98%; mp 182°C (dec.). IR (Fluorolube and Nujol, cm^{-1}): 3659 (br s, ν O-H), 3071 (m), 3046 (m), 2948 (m), 2926 (s), 2858 (s), 1582 (w), 1478 (m), 1451 (m), 1412 (vs), 1304 (m), 1262 (m), 1186 (m), 1113 (vs), 1071 (vs), 1026 (s), 997 (s), 916 (w), 882 (m), 743 (s), 708 (vs), 644 (m), 606 (m), 517 (vs). NMR ($CDCl_3$) ^1H: 7.72 (6H, d, J(H–H) = 6.7 Hz, *o*-CH), 7.65*(12H, d, J(H–H) = 6.8 Hz, *o*-CH), 7.48 (3H, t, J(H–H) = 7.3 Hz, *p*-CH), 7.43(6H, t, J(H–H) = 7.4 Hz, *p*-CH), 7.36* (6H, dd, J(H–H) = 7.5 Hz, *m*-CH), 7.19* (12H, dd, J(H–H) = 7.6 Hz, *m*-CH), 3.86 (2H, s, OH_2), 3.74 [8H, t, J(H–H) = 6.5 Hz, OCH_2) 1.80 (8H, t, J(H–H) = 6.5 Hz, OCH_2CH_2). ^{13}C: 138.6*, 135.5 (Si-C), 135.0*, 134.9 (*o*-CH), 129.9, 128.8* (*p*-CH), 127.8, 127.4* (*m*-CH), 68.3 (OCH_2), 25.4 (OCH_2CH_2). Anal. calcd. for $C_{62}H_{63}AlO_6Si_3$: C 73.34, H 6.25; found: C 73.42, H 6.28.

Preparation of $H^{17}OSiPh_3$

Water (0.54 g, 40 mmol) enriched in ^{17}O (22.3%) was added dropwise via syringe to a stirred solution of $ClSiPh_3$ (11.79 g, 40 mmol) in THF (20 mL). After 8 h, the volatiles were stripped off, *in vacuo*, to yield a pale-yellow solid. Crystallization from 50 mL of 50:50 ether: pentane, at −25°C, yielded colorless crystals. Isolated yield: 10.17 g, 92%.

Crystallography

A crystal data summary is given in Table 2, and fractional atomic coordinates for **1** and **2** are listed in Tables 3 and 4 respectively.[3] Crystals of **1** and **3** were mounted directly onto the goniometer with silicon grease. Unit-cell parameters and intensity data were obtained by following previously detailed procedures, using a Nicolet R3m/V diffractometer operating in the θ–2θ scan mode. Data collection was controlled by using the Nicolet P3 program (9).

The structure of **1**·(THF) was solved using the direct methods program XS (10), which revealed the position of most of the heavy atoms. Standard difference map techniques were used to find the remaining non-hydrogen atoms. The crystallographic identification of the oxygen atom in the uncoordinated THF molecule was assigned on the basis of the atom thermal parameters. After all the non-hydrogen atoms were located and refined anisotropically, a

[3]Tables of all bond lengths and angles, anisotropic displacement coefficients, hydrogen atom coordinates, and observed and calculated structure factor amplitudes may be puchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A OS2.

Tables of bond lengths and angles, and hydrogen atom coordinates, for **1** and **2** have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

difference map revealed some but not all of the hydrogen atoms. Hydrogens were, therefore, included as fixed atom contributors in the final cycle, d(C—H) = 0.96 Å, U_{eq} = 0.08 Å^3. Refinement was performed to convergence (Δ/δ(max) < 0.001) with this model. The weighting scheme was $w = [\sigma^2(|F_o|) + 0.0274(|F|)^2]^{-1}$.

The structure of **2**·$(THF)_{1.25}$ was solved by direct methods (XS), which revealed the position of the Al, O, and Si atoms. The atoms Al(1) and O(2) lie on a threefold rotation axis at x, y, z, where $x = y = z$; thus their site occupancy factors were fixed at $\frac{1}{3}$, and their positions were allowed to freely refine along the threefold rotation axis. Standard difference map techniques were used to find the remaining non-hydrogen atoms, including the presence of a THF molecule, the site occupancy of which was freely refined to a value of 0.99 and was, therefore, fixed at 1.0 in the final refinement. Attempts to refine the structure with a $\frac{2}{3}$ site occupancy of the THF molecules resulted in a significant increase in the R and R_w. After all the non-hydrogen atoms were located and refined anisotropically, a difference map revealed some but not all of the hydrogen atoms. Hydrogens were therefore included as fixed atom contributors in the final cycle, d(C—H) = 0.96 Å, U_{eq} = 0.08 Å^3. Since the bound H_2O ligand can only be hydrogen bonded to two of the three symmetry-related THF molecules, it is therefore probably disordered, and the site occupancy factor for H(2B) was therefore set at $\frac{2}{3}$. After the $Al(OSiPh_3)_3(H_2O)(THF)_3$ unit was refined a peak of significant electron density remained, which generated a highly distorted six-membered ring by symmetry. Based on NMR and TGA data this is likely a disordered THF molecule. Refinement of this peak as oxygen (site occupancy $\frac{1}{6}$) and carbon (site occupancy $\frac{4}{6}$ with no hydrogens) led to convergence of the entire structure (Δ/δ (max) < 0.001) and a significant lowering of the R factor. The weighting scheme was $w = [\sigma^2(|F_o|) + 0.0124\,(|F|)^2]$.

Although both structures refined to a satisfactory level, the weighted R factor in each case remained high. However, since the bond length and angle esd's are acceptable and atom connectivity is entirely consistent with analytical and NMR spectral characterization the solutions are adequate and undoubtedly correct.

Results and discussion

The interaction of 3 equivalents of triphenylsilanol with trimethylaluminium in THF results in the formation of the solvated trisiloxide complex, Al(OSiPh$_3$)(THF), **1**, with the concomitant liberation of methane (eq. [5]).

$$[5]\quad AlMe_3(THF) + 3\ HOSiPh_3 \xrightarrow[THF]{} \underset{(\mathbf{1})}{Al(OSiPh_3)_3\,(THF)} + 3\ MeH$$

Hydrolysis of a THF solution of **1** does not result in the hydrolytic cleavage of the aluminium–siloxide bonds and the formation of an alumoxane, as is observed for the triethylsiloxide analogue (3), but instead allows for the isolation of the water complex, $Al(OSiPh_3)_3(H_2O)(THF)_2$, **2**, (eq. [6]).

$$[6]\quad Al(OSiPh_3)_3(THF) \xrightarrow[THF]{+H_2O} Al(OSiPh_3)_3(H_2O)(THF)_2$$

The molecular structure of the THF solvates **1**·(THF) and **2**·$(THF)_{1.25}$ have been determined by X-ray crystallography and are shown in Figs. 1 and 2 respectively. Selected bond lengths and angles are given in Tables 5 and 6.

The structure of **1**·(THF) consists of a discrete monomeric $Al(OSiPh_3)_3(THF)$ unit with a second THF present in the crystal lattice as a molecule of solvation; this uncomplexed THF is, however, only removed from the crystal lattice at elevated temperatures, >50°C. The structure of **2**·$(THF)_{1.25}$ consists of an $Al(OSiPh_3)_3(H_2O)$ unit situated on a threefold rotation axis. There are three symmetry-related THF molecules suitably positioned for hydrogen bonding to the coordinated water molecule. Since the site occupancy of these THF molecules is unity but only two can be hydrogen bonded to the H_2O at the same time, the H_2O hydrogens must be disordered over the three symmetry-related sites, and the presence of three, rather than two, THF molecules is a function of the crystal packing. Thus the structure is best considered as consisting of **2** with a molecule of THF present in the crystal lattice. There is no doubt that hydrogen bonding is present between the water and THF molecules, since the O···O distances (2.62 Å) are within the expected

range (11). In addition to the three THF's situated around the water, the electron density map and crystal cell packing indicate the presence of a severely disordered THF molecule in the center of the unit cell. Thus, $3\frac{1}{4}$ THF's are required per aluminium. The thermogravimetric analysis of a freshly crystallized sample of **2** indicates the loss of slightly more than 3 equivalents of THF per aluminium consistent with the presence of a further molecule of solvation. Therefore, a highly disordered THF molecule was included in the final refinement (see Experimental). The excess THF molecules are removed on prolonged drying *in vacuo*, leaving the two

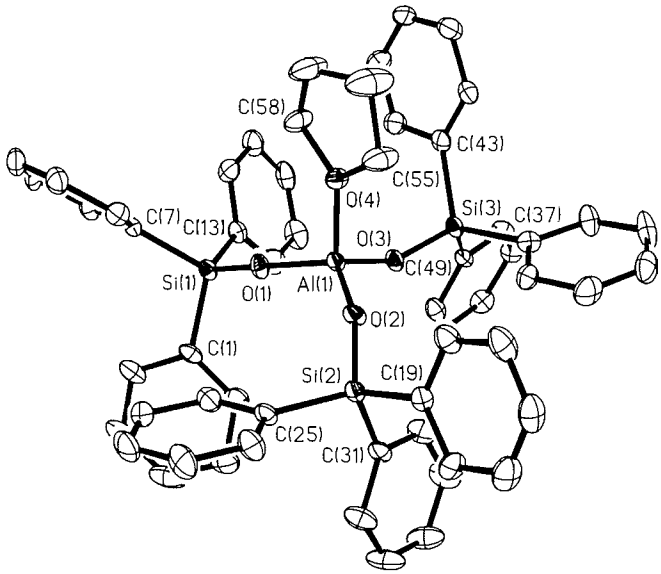

FIG. 1. Structure of $Al(OSiPh_3)_3(THF)$ (**1**) with thermal ellipsoids drawn at the 40% level. The THF of solvation and hydrogen atoms are omitted for clarity.

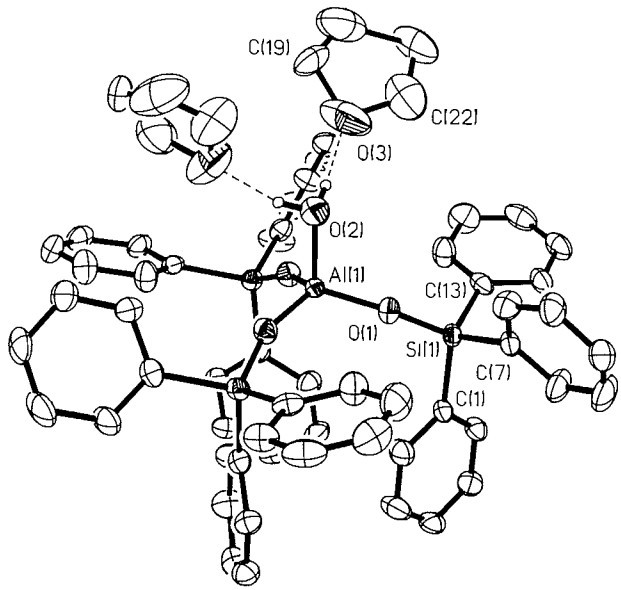

FIG. 2. Structure of $Al(OSiPh_3)_3(H_2O)(THF)_2$ (**2**) with thermal ellipsoids drawn at the 40% level. The THF's of solvation and hydrogen atoms not associated with the water ligand are omitted for clarity.

molecules hydrogen bonded to the coordinated water molecule. Although these hydrogen-bonded THF molecules are, in turn, removed upon high temperature thermolysis of **2**, the water ligand remains complexed.

As is commonly observed for four-coordinate Lewis acid base complexes of aluminium (12, 13) the geometry around each aluminium is distorted from tetrahedral, with the angles associated with the THF (**1**) and H_2O (**2**) ligands being the most acute. The similarity in aluminium coordination geometries in these compounds is illustrated by comparing the sums of interligand angles associated with the siloxide ligands (342.5(2)° (**1**), 343.2(2)° (**2**)). This similarity is perhaps unsurprising since we previously observed that the geometry around aluminum is primarily dependent on the steric bulk of substituent ligands (12, 14), and in the case of compounds **1** and **2** the coordination geometry is dominated by the sterically bulky siloxide ligands.

Whereas the THF (**1**) and H_2O (**2**) Al—O bond distances are within the range usually observed (15–18), the siloxide Al—O distances (1.696 (4)–1.709 (4) Å) are significantly shorter. The latter are, however, close to the values found in $Al(OSiPh_3)_2(acac)$ (19). This shortening was previously ascribed to a possible π-type interaction between the oxygen lone pairs and the σ^* orbitals on aluminum (17, 20). The Si—O bonds in **1** and **2** are also within the range observed for some π-type interaction (21). There appears to be no correlation, however, between the Al—O—Si bond angle and either the Al—O or Si—O bond lengths. A similar lack of correlation was observed previously for both main group and transition metal alkoxide and aryloxide complexes (17, 22).

The IR spectrum of **2** contains a broad resonance at 3659 cm^{-1} consistent with a hydrogen-bonded O-H group. This assignment is confirmed by the observation of an isotope shift for the deuterated analogue of **2**, $Al(OSiPh_3)_3(D_2O)(THF)_2$ (ν(O-D) = 2447 cm^{-1}).

In Table 1, the ^{29}Si, ^{27}Al, and ^{17}O NMR chemical shifts of compounds **1** and **2** are compared with each other, those of the parent silanol, the dimeric monosiloxide $[AlMe_2(\mu\text{-}OSiPh_3)]_2$ (23), and the literature values for $Al(acac)(OSiPh_3)_2$ (acac = acetylacetonate) (19). The ^{27}Al NMR resonances for **1** and **2** are consistent with four-coordinate aluminium complexes with three alkoxide ligands (9). The ^{29}Si and ^{17}O NMR spectra for **1** and **2** (see Table 1) are consistent with terminal siloxides (19) and are distinct from those observed for the bridging siloxides in the dimeric compound $[AlMe_2(\mu\text{-}OSiPh_3)]_2$ (23). It is also interesting to note that the ^{17}O NMR spectral shifts of the terminal siloxides are close to that of the free silanol.

The ^1H NMR signals for both **1** and **2** were sufficiently resolved at 500 MHz that fully interpretable first-order spectra could be obtained. Since the spectra of **2** displayed two sets of phenyl groups in a 1:2 ratio, due to restricted rotation (*vide infra*), it was necessary in this instance to establish ^1H–^1H connectivity using the standard COSY 2D NMR technique (Fig. 3) (6, 7). The assignment of the *ortho*, *meta*, and *para* carbons of the phenyl rings was accomplished with the assistance of a standard heteronuclear-correlated (^1H–^{13}C) experiment (e.g., Fig. 4) using delay times optimized for direct ^1H–^{13}C coupling (8).

Although the four-coordinate geometry about the aluminium center in **1**·(THF) observed in the solid state is retained in solution, as indicated by ^{27}Al NMR, there exists only a single set of resonances for the THF's, indicating the presence of a rapid degenerate exchange between free and coordinated THF (eq. [7]), which does not cease on cooling (−70°C).

[7] $Al(OSiEt_3)_3(THF) + THF^* \rightleftharpoons Al(OSiEt_3)_3(THF^*) + THF$

We previously observed that the dissociative ligand exchange for the sterically hindered aryloxide complexes $AlMe(BHT)_2$ (eq. [8]) (2,6-di-*tert*-butyl-4-methylphenol, BHT-H from the trivial name butylated hydroxytoluene) readily ceases below 0°C, whereas the associative exchange for $AlMe_2(BHT)L$ (eq. [9]) continues down to −80°C (24).

The continued exchange at low temperatures between free and coordinated THF in **1**·(THF) suggests an associative ligand exchange is in effect. The solid state structure lends partial credence to this proposal, since the uncomplexed THF is positioned for incipient complexation to the metal. The exchange of excess THF with those hydrogen bonded to the water ligand in a freshly crystallized sample of **2** does not cease at low temperatures. This facile exchange is, however, consistent with the weak hydrogen bonding as opposed to an associative exchange.

As can be seen from ^1H and ^{13}C NMR data (see Experimental) there are two distinct environments for the phenyl groups in **2**, which may be related to the solid state structure (Fig. 2) as those positioned equatorial (six phenyl groups, marked with an asterisk in the Experimental) and axial (three phenyl groups) to the Al(1)—O(2) vector. Thus the presence of a distinct phenyl environment indicates that at room temperature there is no rotation about the Al—O—Si bonds. However, the phenyl groups do exhibit free rotation, since only a single set of resonances is observed for each of the *ortho* and *meta* ring protons.

Heating an NMR sample of **2** results in coalescence of the signals for the phenyl rings (T_c = 60°C). It is possible that this is due to the onset of dissociation of the coordinated water molecule, which in turn results in a planar three-coordinated aluminum, and releases the steric restraint imposed on the siloxide groups. However, the activation energy ($\Delta G^{\ddagger}$) for this exchange is calculated (25) from the NMR data to be 16.5(±0.3) kJ mol^{-1}, which is inconsistent with ligand bond dissociation energies (BDE) previously observed for aluminium complexes, 63–115 kJ mol^{-1} (24, 26). A consideration of the space-filling representation of **2** in Fig. 5 shows that the THF molecules are sufficiently distant from the triphenylsiloxide groups to have no significant steric effects, as can be implied from their fluxional nature in solution while the siloxides remain rigid. However, the $OSiPh_3$ groups are locked together, precluding the rotation around the Al—O—Si bonds. We propose, therefore, that the measured activation barrier is the energy required to overcome this sterically induced rigidity.

If a sample of **2** is cooled below −70°C the ^1H NMR

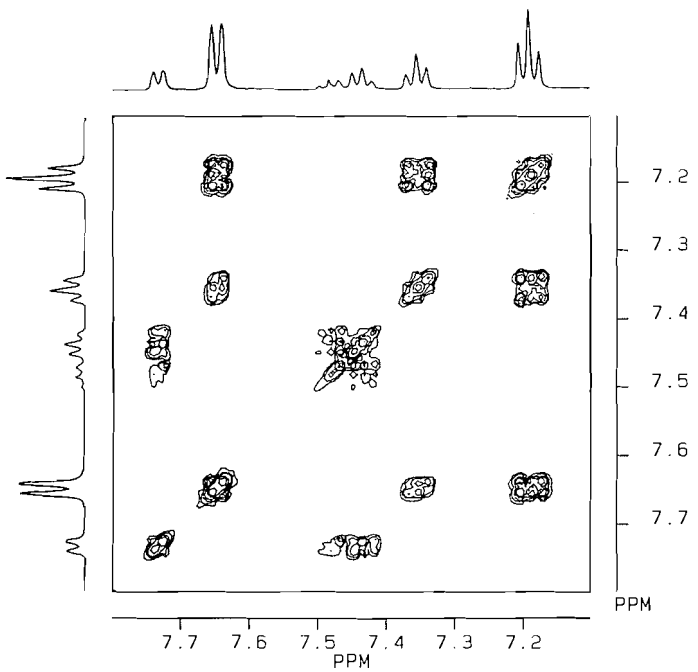

FIG. 3. ^{1}H-^{1}H COSY spectrum of $Al(OSiPh_3)_3(H_2O)(THF)_2$ (**2**).

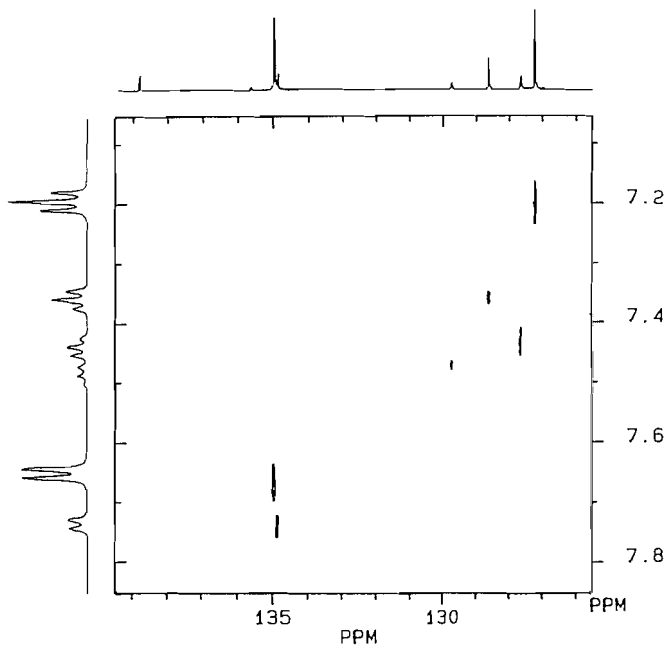

FIG. 4. ^{1}H-^{13}C correlated 2D NMR spectrum of $Al(OSiPh_3)_3(H_2O)(THF)_2$ (**2**).

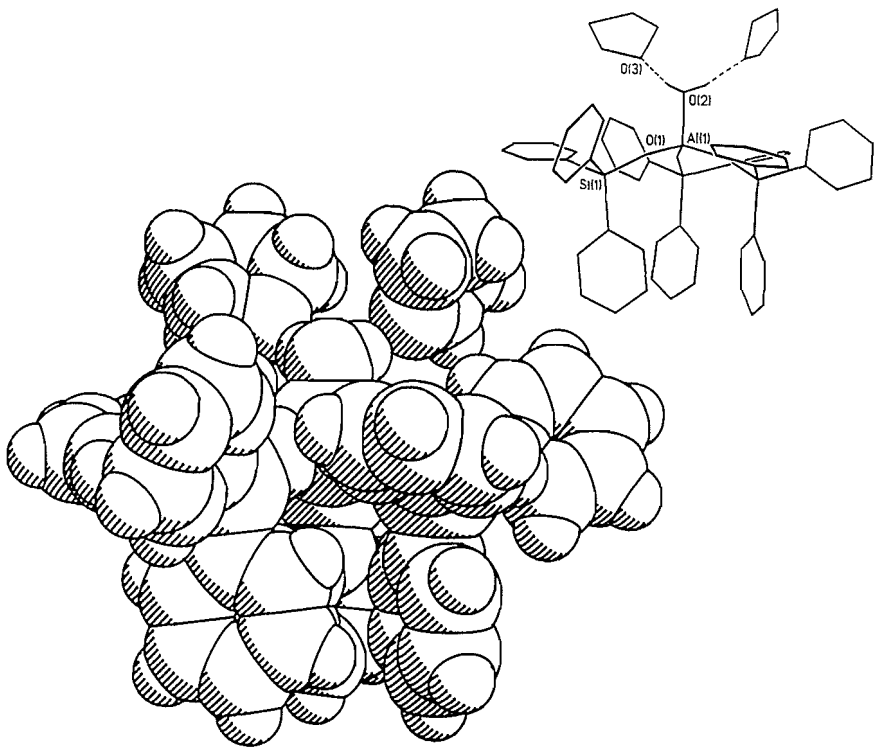

FIG. 5. Space-filling representation of $Al(OSiPh_3)_3(H_2O)(THF)_2$ (**2**), and its equivalent line drawing (inset), viewed perpendicular to the Al(1)—O(2) vector, showing the steric hindrance imposed on the triphenylsiloxide groups.

spectrum indicates that not only are the siloxide groups rigid but the axially disposed phenyl rings have ceased to rotate ($\Delta G^{\ddagger} = 9.7(\pm 0.2)$ kJmol^{-1}), providing two environments for the *ortho* and *meta* ring protons.

We note that both of these processes are rare measures of the steric constraints imposed on an organic substituent within a sterically hindered molecule.

Received July 4, 1991

This paper is dedicated to the memory of Professor Thomas Birchall

PHILIP A. W. DEAN, JAGADESE J. VITTAL, and YUYANG WU. Can. J. Chem. **70**, 779 (1992).

The self-assembly method has been used to prepare a wide range of new adamantane-like anions of the type $[(\mu\text{-}SR)_6(MX)_4]^{2-}$ (M = Zn or Cd; R = alkyl or benzyl; X = Cl, Br, or I) as their Et_4N^+ salts. Metal ($^{111\text{ or }113}Cd$) NMR data have been measured for the cadmium complexes, and also for many of the possible mixed-metal complexes $[(\mu\text{-}SR)_6(CdX)_n(ZnX)_{4-n}]^{2-}$. In the complexes with mixed metals, the effects of Zn substitution on the metal chemical shifts are generally larger for the alkyl- and benzyl-thiolate complexes than for related benzenethiolate complexes. However, for $[(\mu\text{-}SPr^i)_6(CdX)_n(CdX')_{4-n}]^{2-}$ (X/X' = Cl/Br, Cl/I, or Br/I), substituent effects are no larger than found in some PhS^--bridged complexes. The reaction of $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$ (X = Cl, Br, or I) with E'_8 (E' = S or Se) in CH_2Cl_2 gives $[Cd_4(\mu_4\text{-}E')(\mu\text{-}SPr^i)_{12}(CdX)_4]^{2-}$ as the major species detectable by metal, ^{13}C, and, where applicable, ^{77}Se NMR. However, the reaction does not occur stoichiometrically. The compound $(Et_4N)_2[(\mu\text{-}SPr^i)_6(CdBr)_4]$ crystallizes in the monoclinic space group $P2_1/c$ with cell dimensions a = 24.079(3) Å, b = 11.365(2) Å, c = 22.561(3) Å, β = 113.89(1), and Z = 4. The structure was refined to $R(R_w)$ = 0.0663(0.0703) with the use of 2669 unique data with $I > 2.5\sigma(I)$. The anion contains an adamantane-type $(\mu_2\text{-}S)_6Cd_4$ cage composed of a nearly regular Cd_4 tetrahedron and a distorted S_6 octahedron, the irregularity of which is caused by 1,3-interactions of the substituent groups on the sulfur atoms. The axial or equatorial dispositions of the six alkyl groups in the four fused M_3S_3 rings are [aae, aae, aee, aee]. For the zinc-group elements, this is the first example of an adamantane-like $(\mu\text{-}Salkyl)_6M_4$ cage that has been characterized crystallographically.

Key words: cadmium complex, cadmium-111/113 NMR, thiolate complex, X-ray analysis, zinc complex.

PHILIP A. W. DEAN, JAGADESE J. VITTAL et YUYANG WU. Can. J. Chem. **70**, 779 (1992).

On a utilisé la méthode d'auto-assemblage pour préparer une grande variété de nouveaux anions ressemblant à l'adamantane, du type $[(\mu\text{-}SR)_6(MX)_4]^{2-}$ (M = Zn ou Cd; R = alkyle ou benzyle; X = Cl, Br ou I), sous forme de sels du Et_4N^+. On a mesuré les spectres RMN des $^{111\text{ ou }113}Cd$ des complexes du cadmium ainsi que ceux de tous les composés métalliques mixtes possibles $[(\mu\text{-}SR)_6(CdX)_nZnX_{4-n}]^{2-}$. Dans les complexes métalliques mixtes, l'effet de la substitution du Zn sur les déplacements chimiques du métal sont généralement plus grands avec les complexes alkyl- et benzylthiolates qu'avec les complexes benzènethiolates apparentés. Toutefois, avec $[(\mu\text{-}SPr^i)^6(CdX)_n(CdX')_{4-n}]^{2-}$ (X/X' = Cl/Br, Cl/I ou Br/I), les effets de substituants ne sont pas plus importants que ceux observés dans quelques complexes comportant un pont PhS^-. La réaction du $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$ (X = Cl, Br ou I) avec E'_8 (E' = S ou Se), dans le CH_2Cl_2, fournit du $[Cd_4(\mu_4\text{-}E')(\mu\text{-}SPr^i)_{12}(CdX)_4]^{2-}$ comme principale espèce détectable par RMN des métaux, du ^{13}C et, lorsque c'est applicable, du ^{77}Se. Toutefois, la réaction n'est pas stoechiométrique. Les cristaux du composé $(Et_4N)_2[(\mu\text{-}SPr^i)_6(CdBr)_4]$ sont monocliniques, groupe d'espace $P2_1/c$, avec a = 24,079(3), b = 11,365(2) et c = 22,561(3) Å, β = 113,89(1) et Z = 4. On a affiné la structure jusqu'à des valeurs de $R(R_w)$ = 0,0663(0,0703) à l'aide de 2669 réflexions indépendantes avec $I > 2{,}5\sigma(I)$. L'anion contient une cage $(\mu_2\text{-}S)_6Cd_4$ du type adamantane composée d'un Cd_4 tétraédrique pratiquement régulier et d'un S_6 octaédrique déformé dont l'irrégularité est causée par des interactions-1,3 des substituants portés par les atomes de soufre. Les arrangements axiaux et équatoriaux des six groupes alkyles dans les quatre cycles M_3S_3 condensés sont [aae, aae, aee, aee]. Pour les éléments du groupe du zinc, il s'agit du premier exemple d'une cage $(\mu\text{-}Salkyl)_6M_4$ du type adamantane à être caractérisé par cristallographie.

Mots clés : complexe du cadmium, RMN des $^{111/113}Cd$, complexe thiolate, diffraction des rayons X, complexe du zinc.

[Traduit par la rédaction]

Introduction

Adamantane-like anions of the general type $[(\mu\text{-}EPh)_6(MX)_4]^{2-}$ are well established for a variety of divalent metal centres, especially for E = S and X = SPh^- or halide (1–5). Of particular relevance to the present paper, some anions of this general type are known for each of the zinc-group elements (1–5). The $(\mu\text{-}SPh)_6M_4$ cages, where they exist for Zn(II)–Hg(II),[4] provide possible models for the cysteinate-bridged tetrametallic cages occurring when some forms of the cysteine-rich metal-binding protein metallothionein are loaded with the divalent d^{10} metal ions.

It seems reasonable to suggest that cages involving alkyl thiolates might provide a better model for the cysteinyl binding sites of metallothionein than cages involving benzenethiolates. However, remarkably little attention has been paid to adamantanoid clusters containing cages of the type $(\mu\text{-}SAlk)_6M^{II}_4$.[5,6] Thus, Hagen and Holm (9) synthesized and

[3]Authors to whom correspondence may be addressed.

[4]For mercury, the $[(\mu\text{-}EPh)_6(HgX)_4]^{2-}$ anions appear to exist for E = Se or Te, but not for E = S (4).

[5]$SAlk^-$ represents alkyl- or benzyl-thiolate.

[6]Several examples of $(\mu\text{-}SAlk)_6M^I_4$ (M = Cu or Ag) have been described (6–8), but these are not directly analogous to the complexes of the divalent metal centres in that they have distorted-planar coordination at the metal centres with no terminal ligands X.

fully characterized the $[(\mu\text{-SEt})_6(FeSEt)_4]^{2-}$ anion, while in very recent work from our own laboratory we synthesized $(Et_4N)_2[(\mu\text{-SPr}^n)_6(CdI)_4]$ and characterized this and the Zn(II) and Hg(II) analogues in solution using multinuclear magnetic resonance methods (4). The Zn(II) and Cd(II) complexes are stable at ambient probe temperature, but the Hg(II) complex appears to be stable only at reduced temperature. The ^{113}Cd NMR spectra of the series $[(\mu\text{-SPr}^n)_6(CdI)_n(ZnI)_{4-n}]^{2-}$ were sufficiently different from those reported (10, 11) for $[(\mu\text{-SPh})_6(CdSPh)_n(ZnSPh)_{4-n}]^{2-}$ to warrant further study of alkylthiolate-bridged Cd_nZn_{4-n} cages by metal NMR.

In this paper we describe the synthesis of a much wider series of complexes of the type $[(\mu\text{-SAlk})_6(MX)_4]^{2-}$ (M = Zn or Cd; X = Cl, Br, or I). The multinuclear magnetic resonance spectra of these and related complexes with mixed metals or mixed terminal halides are given. A single crystal X-ray structural analysis of $(Et_4N)_2[(\mu\text{-SPr}^i)_6(CdBr)_4]$ has been carried out to characterize a representative $(\mu\text{-SAlk})_6Cd_4$ cage and to allow comparison with structures containing the $(\mu\text{-SPh})_6Cd_4$ core (3, 9). As well, the reaction of $[(\mu\text{-SPr}^i)_6(CdX)_4]^{2-}$ with elemental sulfur and selenium is reported.

Experimental

Materials and general procedure

All starting materials were from commercial sources and were used as received. The compounds $M(SR)_2$ (M = Zn or Cd; R = Me, Et, 1-Pr, 2-Pr, 1-Bu, 2-Bu, or benzyl) were prepared by an adaptation of the literature synthesis (12) of $Zn(SR)_2$, in which $Me_2CO{:}H_2O$ (1:5) was used instead of water and the metal nitrates instead of the sulphates. The salt $(Et_4N)_2[(\mu\text{-SPr}^n)_6(CdI)_4]$ was prepared as reported earlier (4), and a sample of $(Pr^iS)_2Se$ was also synthesized by the literature method (13). Red selenium was obtained by the reduction of Na_2SeO_3 with $Na_2S_2O_4$ in strongly acidic aqueous solution. The Se_8 was separated by filtration, washed with water, then alcohol, dried *in vacuo*, and stored in the dark in a refrigerator.

All solvents used in synthesis or in the preparation of NMR samples were dried over 3 Å Molecular Sieves and thoroughly deoxygenated by sparging with Ar(g). All syntheses and preparations of NMR samples were carried out under an atmosphere of Ar or N_2.

Synthesis

The tetranuclear anions were all prepared by the self-assembly method and isolated as their Et_4N^+ salts. Within this general procedure there was some variation, as exemplified by the syntheses of the salts of $[(\mu\text{-SPr}^i)_6(CdCl)_4]^{2-}$ and $[(\mu\text{-SEt})_6(CdBr)_4]^{2-}$.

$(Et_4N)_2[(\mu\text{-SPr}^i)_6(CdCl)_4$

The synthesis was generally similar to that reported for $(Et_4N)_2[(\mu\text{-SPr}^n)_6(CdI)_4]$ (4). A mixture of $CdCl_2$ (0.18 g, 0.98 mmol), $Et_4NCl.H_2O$ (0.37 g, 2.0 mmol), and $Cd(SPr^i)_2$ (0.87 g, 3.3 mmol) was stirred in CH_2Cl_2 (20 mL) for 1 h. The small amount of insoluble material was removed by filtration. The volume of the filtrate was reduced to ca. 4 mL by gentle heating under a flow of N_2(g), and then Et_2O (2 mL) was layered on. The mixture was allowed to stand in the refrigerator overnight. The white solid so formed was separated by filtration, washed with Et_2O, and dried *in vacuo* at room temperature. The yield was 1.1 g (84%).

In the same manner were prepared $(Et_4N)_2[(\mu\text{-SR})_6(MX)_4]$ for the following R/M/X combinations: Pr^i/Zn/Cl (81% yield), Br (62%), I (74%); Pr^i/Cd/Br (74%), I (78%); Me/Zn/Br (71%), I (61%); Pr^n/Zn/I (68%); Bu^n/Zn/I (45%); Bu^n/Cd/I (57%). For $(Et_4N)_2[(\mu\text{-SEt})_6(ZnX)_4]$ (X = Cl, Br), the salts prepared in this way gave unsatisfactory elemental analyses, though they appeared pure by ^1H and ^{13}C NMR.[7] For the following R/M/X combinations, the initial three-component mixture remained milky, but the procedure was otherwise the same: Et/Cd/Cl (41%), Br (29%), I (48%); Et/Zn/I (36%). Alternative, higher yield syntheses for R/M/X = Et/Cd/Br, I are given below.

The ether was replaced by pentane to produce the salts with R/M/X = benzyl/Zn/Cl (92%), Br (94%), I (84%). When this adapted procedure was used for salts of $[(\mu\text{-Sbenzyl})_6(CdX)_4]^{2-}$ (X = Cl, Br, I), oily white solids were obtained after the mixtures were refrigerated. These solids were separated by decantation and washed several times with pentane, then dried *in vacuo* to give white foamy solids. Yields for X = Cl, Br, I were 54, 84, 75%, respectively.

$(Et_4N)_2[(\mu\text{-SEt})_6(CdBr)_4]$ (Method 2)

Into a solution of $CdBr_2$ (1.1 g, 4.0 mmol) and Et_4NBr (0.42 g, 2.0 mmol) in EtOH (50 mL) at 40°C was stirred EtSH (0.50 g, 8.1 mmol) followed by Et_3N (0.81 g, 8.0 mmol). A white precipitate formed. This dissolved when MeCN (5 mL) was added to the mixture at room temperature. Cooling the resulting solution to 5°C overnight gave the product as white crystals. The yield was 1.0 g (72%). The analogous iodide can be prepared similarly, in 58% yield.

The salt $(Et_4N)_2[(\mu\text{-SEt})_6(ZnBr)_4]$, pure by ^1H and ^{13}C NMR, was obtained in a similar manner, but with the addition of Et_2O before cooling overnight. However, this salt did not give satisfactory elemental analyses.

Elemental microanalyses

Analyses for C, H, and N were carried out by Guelph Chemical Laboratories Ltd. Analytical data for the new compounds are given in Table 1.

Nuclear magnetic resonance spectra

Proton and ^{13}C NMR spectra of $(Et_4N)_2[(\mu\text{-SR})_6(MX)_4]$ were obtained at ambient probe temperature using a Varian Gemini-200 spectrometer system, with solutions in standard 5 mm o.d. NMR tubes. These spectra have been deposited. Carbon-13 NMR spectra of the reaction mixtures of $[(\mu\text{-SPr}^i)_6(CdX)_4]^{2-}$ with sulfur or selenium were measured at ambient probe temperature in 10 mm o.d. NMR tubes on a Varian XL-200 spectrometer system operating without a ^2D field/frequency lock. The CH_2Cl_2 signal (δ_C = 54.2) was used as an internal reference.

Natural-abundance $^{111/113}Cd$ and ^{77}Se NMR spectra were measured with a Varian XL-200 or -300 spectrometer system again running without a ^2D field-frequency lock; the field drift was <1 Hz/day. On both machines interference obscured part of the ^{113}Cd region, so many spectra were measured using ^{111}Cd, which is almost as sensitive as ^{113}Cd at natural abundance.[8] No primary isotope effect is expected, i.e., chemical shifts should be the same for both ^{111}Cd and ^{113}Cd. External referencing was by sample interchange, using 0.1 M $Cd(ClO_4)_2$(aq) for $^{111/113}Cd$ and pure Me_2Se for ^{77}Se. On the lower and higher field instruments, the reference frequencies were, for ^{113}Cd, 44.37 and 66.53 MHz, respectively; for ^{111}Cd, 42.41 and 63.59 MHz, respectively; for ^{77}Se, 38.15 and 57.20 MHz, respectively. The negative Overhauser effect is significant for $^{111/113}Cd$ in the Cd–Salkyl complexes, therefore inverse gated proton decoupling was used, with the decoupler off for at least 80% of each duty cycle. Most of the $^{111/113}Cd$ NMR spectra were measured using an acquisition time of 1 s, cycle time of

[7]Copies of these data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Table S5, additional bond distances and angles, has also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

[8]The natural abundances of ^{111}Cd, ^{113}Cd, and ^{77}Se are 12.75, 12.26, and 7.58%, respectively; their relative receptivities, D^C, relative to ^{13}C = 1, are 6.97, 7.67, and 3.01, respectively (14).

[a]Parameters marked with an asterisk were assigned anisotropic thermal parameters given as the isotropic equivalent displacement parameter defined as $U_{eq} = 1/3\Sigma_i\Sigma_j U_{ij} \cdot a^*_i \cdot a^*_j \cdot a_i \cdot a_j$.

5 s, spectral window of 10 kHz, and tip angles of ca. 88° (for spectra at 213 K) and ca. 83° (for spectra at ambient probe temperature). For mixtures of $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$ and sulfur or selenium, the conditions were as follows: acquisition time, 0.6 s; cycle time, 4.6 s; spectral window, 25 kHz; tip angle, 83° (at ambient probe temperature). Selenium-77 NMR spectra were measured using continuous proton decoupling. For $[Cd_4(\mu_4\text{-}Se)(\mu\text{-}SPr^i)_{12}(CdX)_4]^{2-}$, $T_1(^{77}Se)$ appears to be ca. 20 s. In final spectra, measured using the

[a]Relative to external 0.1 M $Cd(ClO_4)_2$ (aq) at 293 ± 1 K, for solutions containing 0.05 mol/L of solvent at ambient temperature, except as noted. Reproducibility ±1 ppm.
[b]Except where noted otherwise.
[c]In MeCN.
[d]Concentration 0.025 mol/L of solvent.
[e]Average position of several closely spaced resonances (see text).
[f]Data from ref. 4, for solutions having 0.06 mol/L of solvent.
[g]Broad unresolved signals occur in Cd_4:Zn_4 mixtures.
[h]Separate signals not resolved.

XL-300 spectrometer, the following conditions were used to obtain the ^{77}Se NMR spectra of these species at ambient probe temperature: acquisition time and cycle time, 1 s; spectral window, 10 kHz; tip angle, 18°. Temperature calibration was made using a calibrated thermocouple probe in a stationary dummy sample. Cadmium-111/113 chemical shifts were found to be reproducible to ±1 ppm and ^{77}Se chemical shifts to 0.1 ppm. In a single spectrum, signal separations could usually be measured more precisely.

NMR spectra were simulated as described earlier (15).

X-ray structure determination

Single crystals of $(Et_4N)_2[\mu\text{-}SPr^i)_6(CdBr)_4]$ were grown by diffusing diethyl ether into an acetone solution of the compound at 5°C. A colorless crystal of suitable quality was mounted in air on a glass fibre with epoxy cement. The crystal density was determined to be 1.75(5) g cm^{-3} by the neutral buoyancy method using a mixture of carbon tetrachloride and hexane.

The data collection was carried out on an Enraf–Nonius CAD4F diffractometer using Cu Kα radiation (16) with nickel filter. Photo and automatic indexing routines, followed by least-squares fits of 20 accurately centered reflections ($35.5 < \theta < 41.5$), gave cell constants and an orientation matrix. Intensity data were recorded in ω–2θ mode, at variable scan speeds (1.27–2.75 deg min^{-1}) and scan width of 0.8 + 0.14 tan θ, with a maximum time per datum of 60 s. Background estimates were made by extending the scan by 25% on each side. Standard reflections 200, 002, and 202 were monitored every 180 min of X-ray exposure time and showed 8.2% decay over the total period of 110.3 h. In all, 6375 reflections and 123 standards were recorded. Corrections were made for Lorentz, monochromator, and crystal polarization, background radiation effects, and decay, using the Structure Determination Package (17) running on a PDP11/23+ computer. Numerical absorption correction was applied using the program AGNOST (18). The cell parameters and the systematic absences (19*a*) indicated that the space group was $P2_1/c$ and the correctness of the choice of the space group was confirmed by successful solution and refinement of the structure.

The structure was readily solved by a combination of MULTAN (20) and difference Fourier techniques. Refinement was by full-matrix least-squares techniques on F, using the SHELX-76 software (21) running on a SUN 3/50 workstation. Scattering factors for neutral, non-hydrogen atoms were taken from ref. 19*b*. Anisotropic thermal parameters were assigned for all the Cd, Br, and S atoms and were refined, while the thermal parameters of all the remaining non-hydrogen atoms were refined isotropically. At this stage, high thermal motions were found for most of the isopropyl methyl carbon atoms, indicating possible disorder. The disorder could be successfully resolved for C133, C142, C143, C242, and C243 while for C232, C233, C342, and C343 the disorder could not be resolved due to smearing of electron density as indicated by the electron density maps. The C—C bond distances were, therefore, constrained to 1.542 Å. For the above reasons the hydrogen atoms were not included in the structure factor calculations. The tetraethylammonium cations also showed the expected high thermal activity, an artifact of unresolvable disorder. A common temperature factor was assigned for all the carbon atoms and refined in the least-squares refinements.

With the use of 2669 observations with $I > 2.5\sigma(I)$, and utilizing weights of the form $w = k/\sigma^2(F_o) + gF^2$, where $k = 1.8849$ and $g = 0.001029$, refinement of 277 variables converged at agreement factors $R = 0.0663$, $R_w = 0.0703$. The top five peaks in the final difference Fourier synthesis had electron density in the range 0.613–0.535 e A^{-3}.

The experimental details and crystal data, and positional and U(equiv) thermal parameters, are given in Tables 2 and 3, respectively. Tables of anisotropic thermal parameters, root-mean-square amplitudes of vibration, and structure amplitudes have been included in the depository materials.

Results and discussion

Synthesis

The self-assembly reaction shown in eq. [1*a*] is a straightforward route to a wide range of new adamantane-like

$$[1a] \quad 3M(SR)_2 + MX_2 + 2X^- \rightarrow [(\mu\text{-}SR)_6(MX)_4]^{2-}$$

complexes of zinc and cadmium containing bridging alkyl- or benzyl-thiolate anions. An alternative route to $[(\mu\text{-}SEt)_6(CdX)_4]^{2-}$ (X = Br or I) is shown in eq. [1*b*]. Twenty-

$$[1b] \quad 4CdX_2 + 6EtSH + 6Et_3N \rightarrow [(\mu\text{-}SEt)_6(CdX)_4]^{2-} + 6Et_3NH^+ + 4X^-$$

eight analytically pure Et_4N^+ salts have been isolated, including all members of the series where R = 2-Pr, 2-Bu, or benzyl, M = Zn or Cd, and X = Cl, Br, or I, and, in addition, salts with the following R/M/X combinations: Me/Zn/Br, I; Et/Zn/I; Et/Cd/Cl, Br, I; 1-Pr/Zn/I; 1-Bu/Zn, Cd/I. Also, spectroscopically but not analytically pure materials were obtained for R/M/X = Et/Zn/Cl, Br.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

All attempts to isolate complexes where R = Me, M = Cd, and X = Cl, Br, or I failed. Neither could we obtain any evidence for these complexes in *in situ* NMR experiments. Nevertheless, it is evident that the $[(\mu\text{-SPr}^n)_6(\text{MI})_4]^{2-}$ (M = Zn, Cd) ions, reported earlier (4), are just two members of a much wider series of zinc and cadmium complexes of the general type $[(\mu\text{-SAlk})_6(\text{MX})_4]^{2-}$.

Previously, the self-assembly method was used to synthesize $[(\mu\text{-SPh})_6(\text{FeX})_4]^{2-}$ (X = Cl or Br) (22) and $[(\mu\text{-EPh})_6(\text{HgX})_4]^{2-}$ (4) as well as $[(\mu\text{-SPr}^n)_6(\text{MI})_4]^{2-}$ (M = Zn, Cd, or Hg) (4). An alternative synthetic method, halogen oxidation of the homoleptic parent anions $[(\mu\text{-EPh})_6(\text{MEPh})_4]^{2-}$, was used for $[(\mu\text{-EPh})_6(\text{MX})_4]^{2-}$ (E = S or Se; M = Zn or Cd; X = Cl, Br, or I) (3). This latter preparative route cannot be applied in the present case because parent ions of the type $[(\mu\text{-SAlk})_6(\text{MAlk})_4]^{2-}$ have not yet been described.

Cadmium-111/113 NMR spectra of complexes with a tetranuclear cage

(i) $[(\mu\text{-SR})_6(\text{CdX})_4]^{2-}$

Cadmium-111/113 NMR chemical shift data for the new complexes, $[(\mu\text{-SAlk})_6(\text{CdX})_4]^{2-}$, are included in Table 4 (n = 4). For a given alkyl group, $^{111/113}$Cd (hereinafter indicated by just Cd) nuclear shielding varies with X in the order I > Br > Cl. This order, that of Normal Halogen Dependence (23), has been observed for $[\text{CdX}_4]^{2-}$ (24) and $[(\mu\text{-EPh})_6(\text{CdX})_4]^{2-}$ (E = S or Se) (3). For a constant halogen, the variation of Cd chemical shift with the substituent on sulfur is primary alkyl ≥ benzyl > secondary alkyl > phenyl.[9] The same order was found previously for $[\text{Cd(SR)}_4]^{2-}$ in water (25).

The complexes $[(\mu\text{-SPr}^i)_6(\text{CdX})_4]^{2-}$ (X = Cl, Br) give particularly narrow lines in their Cd NMR spectra at ambient probe temperature and, for these, two-bond ^{113}Cd–S–^{111}Cd coupling gives rise to clear satellites at this temperature. The corresponding iodide and the series $[(\mu\text{-SCH}_2\text{Ph})_6(\text{CdX})_4]^{2-}$ (X = Cl, Br, I) give satellites at reduced temperature. Values for ^2J are included in Table 5. For comparison, ^2J is 44 – ca. 56 Hz in species with the $(\mu\text{-SPh})_6\text{Cd}_4$ cage (3, 26–28). Only for the iodides does ^2J for the alkyl- and benzyl-thiolate complexes overlap the range of values found for the benzenethiolate complexes. The coupling depends on terminal halogen in the order Cl < Br < I. Thus the halogen dependence of ^2J found previously for $[(\mu\text{-SePh})_6(\text{CdX})_4]^{2-}$ (3, 28) is shown to be general.

In some cases (R = 2-Pr, 2-Bu, or PhCH_2; X = Cl, Br, or I) closely spaced multiple lines are found in the reduced temperature Cd NMR spectrum of $[(\mu\text{-SR})_6(\text{CdX})_4]^{2-}$. For example, the spectrum of $[(\mu\text{-SCH}_2\text{Ph})_6(\text{CdI})_4]^{2-}$ in CH_2Cl_2 at 213 K consists of a major signal at $\delta_{\text{Cd}} = 575._7$, with a strong shoulder at $\delta_{\text{Cd}} = 575._9$. These two lines have identical ^{111}Cd–^{113}Cd satellite splittings. We feel that in these cases the multiple signals are observed at too high a temperature to be due to slowing of inversion at sulfur, and so are more likely to result from restricted S—C bond rotation. We note that the molecular structure of $[(\mu\text{-SPr}^i)_6(\text{CdBr})_4]^{2-}$ (see below) shows evidence of disorder from rotation about most of the S—C bonds.

As can be seen from $\delta_{\text{Cd}}([(\mu\text{-SR})_6(\text{CdX})_4]^{2-})$ in Table 4, these metal chemical shifts show large temperature dependences. The changes of −0.14 to −0.25 ppm/K are of comparable size to the −0.2 ppm/K found (26, 29) for $[(\mu\text{-SPh})_6(\text{CdSPh})_4]^{2-}$.

[9]Solutions of $[(\mu\text{-SPh})_6(\text{MX})_4]^{2-}$ in acetone at 295 K give δ_{Cd} = 551, 535, and 501 for X = Cl, Br, and I, respectively (3).

[c]^2J = 20 ± 1 Hz at 292 K.
[d]^2J = 26 ± 1 Hz at 293 K.

(ii) $[(\mu\text{-SR})_6(\text{CdX})_n(\text{ZnX})_{4-n}]^{2-}$

When $[(\mu\text{-SAlk})_6(\text{CdX})_4]^{2-}$ and the analogous $[(\mu\text{-SAlk})_6(\text{ZnX})_4]^{2-}$ are mixed in various ratios, the Cd NMR spectra of newly prepared mixtures at, or below, ambient probe temperature show a total of four resonances. An example is shown in Fig. 1. These results show that redistribution of metals (eq. [2]) is rapid on the prepar-

$$[2]\quad [(\mu\text{-SAlk})_6(\text{CdX})_4]^{2-} + [(\mu\text{-SAlk})_6(\text{ZnX})_4]^{2-} \rightleftharpoons [(\mu\text{-SAlk})_6(\text{CdX})_n(\text{ZnX})_{4-n}]^{2-}$$

(equilibrium mixture)

ative time scale but not on the NMR time scale. The observation of four signals confirms the integrity of both the Cd_4 and Zn_4 cages in solution. In addition, it is evident from the spectra of the mixtures (e.g., Fig. 1) that the redistribution occurs close to statistically, unlike the case of $[(\mu\text{-SPh})_6(\text{CdSPh})_4]^{2-}$:$[(\mu\text{-SPh})_6(\text{ZnSPh})_4]^{2-}$ mixtures where $[(\mu\text{-SPh})_6(\text{CdSPh})_n(\text{ZnSPh})_{4-n}]^{2-}$ occurs, but only for n = 3 and 4 in DMF (10) and only for n = 2–4 in acetone (11).

Although separate signals are observed at ambient probe temperature, sharper lines are observed at reduced temperature. There is evidently residual exchange at ambient temperature. Cadmium NMR chemical shifts for $[(\mu\text{-SAlk})_6(\text{CdX})_n(\text{ZnX})_{4-n}]^{2-}$ at ambient and reduced temperature are given in Table 4.

As can be seen from the data in Table 4 for the two complete series $[(\mu\text{-SR})_6(\text{CdX})_n(\text{ZnX})_{4-n}]^{2-}$ (R = Pr^i or PhCH_2), the range $\Delta\delta_{\text{Cd}}(4,1)$ ($= \delta_{\text{Cd}}(n=4) - \delta_{\text{Cd}}(n=1)$) varies with X in the order I > Br > Cl, and increases with decreasing temperature. The pattern of chemical shifts for individual members of a series shows a nonlinear, second-order dependence on the number of Zn atoms in the cage. In general, the values of $\Delta\delta_{\text{Cd}}(4,1)$ for $[(\mu\text{-SAlk})_6(\text{CdX})_n(\text{ZnX})_{4-n}]^{2-}$ have the same sign as, but are significantly larger than, the 1.5 ppm that can be extrapolated from data for $[(\mu\text{-SPh})_6(\text{CdSPh})_n(\text{ZnSPh})_{4-n}]^{2-}$ (10, 11). For mixtures of $[(\mu\text{-SPh})_6(\text{CdI})_4]^{2-}$ and $[(\mu\text{-SPh})_6(\text{ZnI})_4]^{2-}$, separate signals are not observed for different members of the series $[(\mu\text{-SPh})_6(\text{CdI})_n(\text{ZnI})_{4-n}]^{2-}$ (Table 4). This result makes it clear that it is the difference in bridging rather than terminal groups that leads to differences in $\Delta\delta_{\text{Cd}}(4,1)$ between the alkyl- or benzyl-thiolate complexes and the benzenethiolate com-

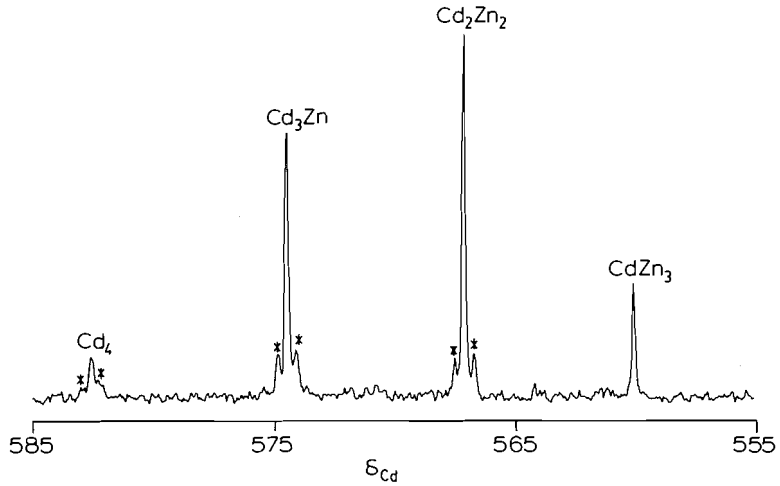

FIG. 1. 44.37 MHz 113-Cd NMR spectrum of a mixture with $[(\mu\text{-}SPr^i)_6(CdBr)_4]^{2-}$:$[(\mu\text{-}SPr^i)_6(ZnBr)_4]^{2-}$ = 1:1 in CH_2Cl_2 at 215 K. *indicates Cd satellite.

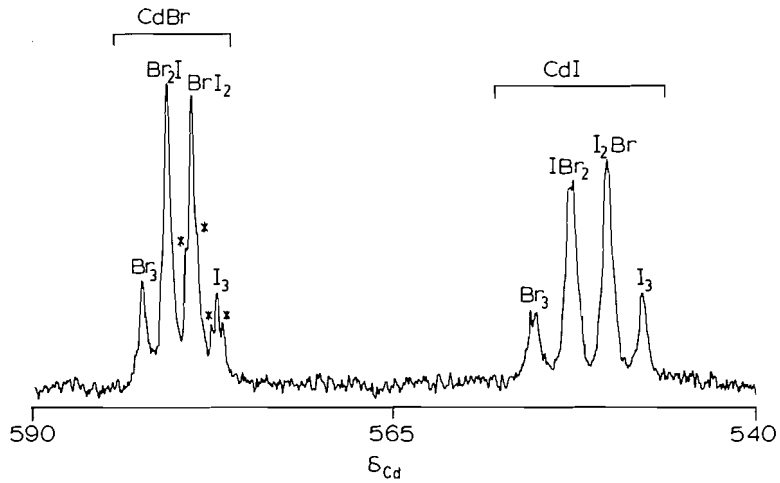

FIG. 2. 42.41 MHz 111-Cd NMR spectrum of a mixture with $[(\mu\text{-}SPr^i)_6(CdBr)_4]^{2-}$:$[(\mu\text{-}SPr^i)_6(CdI)_4]^{2-}$ = 1:1 in CH_2Cl_2 at 215 K. *indicates Cd satellite.

plexes. For Cd NMR spectroscopic purposes, at least, it is clearly dangerous to assume that benzenethiolate typifies all thiolates.

For RS/X = Pr^iS/Br and $PhCH_2S$/Cl, the reduced temperature spectra of $[(\mu\text{-}SR)_6(CdX)_n(ZnX)_{4-n}]^{2-}$ are sufficiently sharp to allow observation of the satellites due to $^2J(^{113}Cd\text{–}S\text{–}^{111}Cd)$ that are expected for n = 2–4 (e.g., Fig. 1). These couplings are given in Table 5. For both series it is found that the magnitude of ^2J varies with n in the order $2 > 3 > 4$.

(iii) $[(\mu\text{-}SPr^i)_6(CdX)_n(CdX')_{4-n}]^{2-}$

In view of the sensitivity of δ_{Cd} to zinc substitution in $[(\mu\text{-}SAlk)_6(CdX)_{4-n}(ZnX)_n]^{2-}$, we thought it of interest to study the sensitivity of the chemical shifts to the more distant changes that occur in series of the type $[(\mu\text{-}SAlk)_6(CdX)_n(CdX')_{4-n}]^{2-}$. Accordingly, we examined the Cd NMR spectra of $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$:$[(\mu\text{-}SPr^i)_6(CdX')_4]^{2-}$ mixtures (X/X' = Cl/Br, Cl/I, Br/I). No such complete series has been studied previously.

At ambient probe temperature, the mixtures show just two broad lines, one in the region expected for Cd attached directly to X, the other in the region expected for Cd attached directly to X'. At reduced temperature, however, additional fine structure becomes evident. As an example, Fig. 2 shows the ^{111}Cd NMR spectrum of a 1:1 mixture of $[(\mu\text{-}SPr^i)_6(CdBr)_4]^{2-}$ and $[(\mu\text{-}SPr^i)_6(CdI)_4]^{2-}$ in CH_2Cl_2 at 215 K. The spectrum clearly does not consist of the superimposed spectra of the two starting complexes, showing that redistribution of the halides has occurred. The region due to ^{111}Cd–Br and that due to ^{111}Cd–I both show four signals. Evidently δ_{Cd} is also sensitive to the nature of the more distant halogens. The individual lines can be assigned using the chemical shifts of the starting complexes and the variation of the intensities of the signals as the ratio of the two starting complexes is changed. Chemical shift assignments for the bromoiodo complexes, as well as the bromochloro and chloroiodo complexes, which were assigned similarly, are given in Table 6. It is noteworthy that in the spectrum of Fig. 2, the Cd NMR signal intensity distribution is close to 1:3:3:1 in both regions of absorption, showing that halide redistribution is a close-to-statistical process. This is true for the other binary mixtures also.

From the data in Table 6, it can be seen that if X'^- is a heavier halide than X^-, then substitution of X'^- for X^- in $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$ causes shielding of Cd attached to X. Con-

[c]Average values; at ambient probe temperature, additional fine structure is not well resolved.

[d]See text.

[e]^2J(Cd–Cd) ≈ 25 Hz.

[f]^2J(Cl–*Cd*–S–*Cd*–I) = 25 ± 1 Hz.

[g]^2J(Cl–*Cd*–S–*Cd*–I) ≈ 33 Hz.

[h]^2J(Br–*Cd*–S–*Cd*–I) = 34 ± 1 Hz.

versely, X'^- substitution of $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$ causes deshielding if X'^- is lighter than X. The magnitude of the effect observed depends on both X and X'. Not unexpectedly, the largest changes per substitution are found in the series $[(\mu\text{-}SPr^i)_6(CdCl)_n(CdI)_{4-n}]^{2-}$, where introduction of I^- causes an average change in δ_{Cd}(Cd–Cl) of −2.2 ppm/I^- and introduction of Cl^- causes an average change in δ_{Cd}(Cd–I) of 4 ppm/Cl^-.

In contrast to the results found for $[(\mu\text{-}SPr^i)_6(CdBr)_n(CdI)_{4-n}]^{2-}$, only two broad signals were observed for the series $[(\mu\text{-}SePh)_6(CdBr)_n(CdI)_{4-n}]^{2-}$ (3), but the spectra of the less soluble $PhSe^-$ complexes were measured at 260 K, where residual exchange might be a problem. Separate signals were observed at 213 K for several complexes of the type $[(\mu\text{-}EPh)_6(CdEPh)_n(CdNCE')_{4-n}]^{2-}$ (E = S or Se, E' = O or S) (28). In the latter case, the effects of substitution at a distant terminal site range up to 5 ppm in magnitude, comparable to the largest changes observed for the 2-propylthiolate complexes.

Reaction of $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$ with sulfur and selenium

Reaction of $[(\mu\text{-}SPh)_6(MSPh)_4]^{2-}$ (M = Cd or Zn) with E'_8 (E' = S or Se) has been shown to give the decametallic complex $[M_6(\mu_3\text{-}E')_4(\mu_2\text{-}SPh)_{12}(MSPh)_4]^{4-}$ according to eq. [3] (30). It is not at all obvious from this what the course of

[3] $5[(\mu\text{-}SPh)_6(MSPh)_4]^{2-} + E'_8$

$\rightarrow 2[M_6(\mu_3\text{-}E')_4(\mu_2\text{-}SPh)_{12}(MSPh)_4]^{4-} + 16Ph_2S_2 + 2SPh^-$

the reaction with sulfur or selenium might be if the terminal positions of the starting tetranuclear cluster are occupied by halides instead of chalcogenates. The complexes $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$, which give sharp Cd NMR spectra at ambient probe temperature (see above), are ideal starting complexes to investigate this problem.

At room temperature, sulfur or *red* selenium dissolve readily in solutions of $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$ in CH_2Cl_2. The Cd NMR spectral changes that accompany this dissolution are qualitatively similar in each case. As an example, Fig. 3(*a*) shows the ^{111}Cd NMR spectrum of a mixture where $[(\mu\text{-}SPr^i)_6(CdI)_4]^{2-}$:red Se = 1:0.5. The major Cd NMR spectral change caused by addition of selenium is the appearance of two equally intense new resonances. The one significantly less shielded than the line of the starting complex is arbitrarily assigned to a cadmium Cd_A, and the one slightly more shielded is assigned to Cd_B. By comparison with, for example, the data in Table 4, it is evident that both new signals are due to four-coordinate cadmium. The chemical shift of Cd_A shows little sensitivity to change of the terminal halide, but changes significantly if selenium is replaced by sulfur in the mixture. Conversely, $\delta_{Cd}(Cd_B)$ is sensitive to change of the terminal halide but relatively insensitive to change of the chalcogen. Both resonances show satellites. The magnitude of the satellite separation is 40 Hz. By comparison with the data in Table 5, this is clearly a two-bond ^{113}Cd–E–^{111}Cd coupling. Therefore Cd_A and Cd_B must be linked by one or more bridging groups. On the basis of these findings, the high-frequency signal in Fig. 3(*a*) is assigned to the kernel $(\mu\text{-}Se)Cd_A(\mu\text{-}SPr^i)_3$ while the low-frequency signal is assigned to $ICd_B(\mu\text{-}SPr^i)_3$, with corresponding assignments in the other mixtures.

When the mixtures contain red selenium, a ^{77}Se resonance is also found for the new cadmium-containing species. A partial ^{77}Se NMR spectrum of the $[(\mu\text{-}SPr^n)_6(CdI)_4]^{2-}$:red Se mixture is shown in Fig. 3(*b*). (There is an additional signal from $(Pr^iS)_2Se$; see below.) The position of the signal in the region of the ^{77}Se NMR spectrum shown in Fig. 3(*b*) is not very sensitive to the nature of the terminal halide: δ_{Se} = −613.6, −610.6, and −607.4 for X = Cl, Br, and I, respectively. This signal is in the region expected for Se^{2-} in various forms, e.g., δ_{Se} = −511 for 0.5 M $(NH_4)_2Se$ in D_2O (31), δ_{Se} = −490[10] in hexagonal CdSe(s) (32), δ_{Se} = −731 for $[Cd_6(\mu_3\text{-}Se)_4(\mu\text{-}SPh)_{12}(CdI)_4]^{4-}$ in DMF.[11] As exemplified by Fig. 3(*b*), the ^{77}Se signals of the new complexes have $^{111/113}$Cd satellites. The satellite splittings are insensitive to the nature of the halide X: J(ave) = 73 ± 1, 74 ± 1, and 73 ± 1 Hz for X = Cl, Br, and I, respectively. The magnitudes of the satellite splittings puts them in the range observed for $^1J(^{111/113}Cd–^{77}Se)$ in Cd(II)–$PhSe^-$ complexes (3, 30, 34). The ^{77}Se NMR spectra point to a single selenium environment in which the selenium (as selenide) is directly attached to cadmium.

The Cd and ^{77}Se NMR results are consistent with the skeleton **I**.[12] A skeleton like **I** occurs in $[Zn_4(\mu_4\text{-}Cl)(SPh)_{12}$-

[10]The chemical shift reported in ref. 32 has been converted to Me_2Se as reference using δ_{Se} (relative to Me_2Se) = δ_{Se} (relative to Na_2SeO_3(aq)) + 1253 (33).

through two bonds. Both ^{113}Cd and ^{111}Cd in site A or B will couple to ^{111}Cd in site B or A, but given the linewidths and the magnitude of ^2J, the separate couplings to $^{111/113}$Cd will not be resolved. Also, we can expect that magnetically different types of Cd in site A will couple with each other. Finally, ^{77}Se is expected to couple to magnetically active Cd in site A, but not to that in the more distant site B. Taking into account appropriate statistics, the ^{111}Cd and ^{77}Se NMR spectra of Fig. 3 can be simulated using structure **I** with $^1J(^{111}Cd\text{–}^{77}Se)$ = 73 Hz, $^2J(^{111}Cd_{A\,or\,B}\text{–}S\text{–}^{111/113}Cd_{B\,or\,A})$ = $^2J(^{111}Cd_A\text{–}S\text{–}^{113}Cd_A)$ = 40 Hz, and the empirical matching of linewidths. The good match between the observed and simulated spectra is shown in Fig. 4. On this basis, we conclude that reaction of $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$] with sulfur or selenium does indeed generate $[Cd_4(\mu_4\text{-}E')(\mu\text{-}SPr^i)_{12}(CdX)_4]^{2-}$ of structure **I**. Cadmium-111 and ^{77}Se NMR data for the various $[Cd_4(\mu_4\text{-}E')(SPr^i)_{12}(CdX)_4]^{2-}$ are given in Table 7.

The complex $[Cd_4(\mu_4\text{-}E')(SPr^i)_{12}(CdX)_4]^{2-}$ was the major product of these reactions that was detected by Cd NMR. However, for E′ = S, X = Cl, Br, I, colourless, crystalline material formed in the mixtures over several hours at ambient probe temperature. When dissolved in CD_3CN, these materials showed only Et_4N^+ by ^{1}H NMR. For the case of E′ = S, X = Br, X-ray analysis[14] showed the product to be $(Et_4N)_2[CdBr_4]$. When E′ = Se, no crystalline material formed, but at high Se/Cd_4 ratios a yellow oil separated that again showed only the ^{1}H NMR spectrum of Et_4N^+.

Carbon-13 NMR confirms that the Cd_4 complexes are converted into one major Cd-containing product. The ^{13}C NMR data of the cadmium complexes are given in Table 8. The ^{13}C NMR spectra also show that when sulfur is used as the oxidant, the oxidized isopropylthiolate is converted not to Pr^iSSPr^i alone, but to an equilibrium mixture of the disulfide (δ_C: 22.3 (CH_3), 41.4 (CH)), Pr^iSSSPr^i (δ_C = 22.2, 41.8), and $Pr^iSSSSPr^i$ (δ_C = 22.4, 42.1), even though $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$ is still present.

The ^{13}C NMR data for the new cadmium complexes formed on oxidation by selenium are included in Table 8. In this case, the thiolate that is released from $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$ appears as $(Pr^iS)_2Se$ (δ_C = 23.5 (CH_3), 41.2 (CH);

δ_{Se} = 602), which was identified by comparison of its ^{13}C and ^{77}Se NMR spectra with those of an authentic sample of the Se(II) dithiolate. The Se(II) compound reacts only very slowly with excess $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$ (days to weeks at the concentrations used for ^{13}C NMR (see Table 8)).

On the basis of the preceding information, the reaction stoichiometry is apparently that given in eq. [4].

$$[4]\quad 7[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-} + (\{3 + 3x\}/8)\,E'_8 \rightarrow 3[Cd_4(\mu_4\text{-}E')(\mu\text{-}SPr^i)_{12}(CdX)_4]^{2-} + 3Pr^iSE'_xSPr^i + 4CdX_4^{2-}$$

(X = Cl, Br, I; E′ = S, $x \approx 1$ (ave); E′ = Se, $x = 1$)

A curious feature of these reactions is that they do not, in fact, occur stoichiometrically. The $[Cd_4(\mu_4\text{-}E')(\mu\text{-}SPr^i)_{12}(CdX)_4]^{2-}$ that is initially formed appears to react with additional sulfur or selenium in preference to $[(\mu\text{-}SPr^i)_6(CdX)_4]^{2-}$, so that the octanuclear complex dies away while the starting material still exists. Our attempts to identify the new complexes formed from the octanuclear complex have so far been unsuccessful.

Crystal structure of $(Et_4N)_2[(\mu\text{-}SPr^i)_6(CdBr)_4]$, $(Et_4N)_2$ ***1***

The crystal structure of the salt contains well-separated anions and cations. The structure of the $Cd_4Br_4(S—C_1)_6$ skeleton of the anion **1** is presented in Fig. 5. This is the first example of a $(\mu\text{-}SAlk)_6M_4$ cage that has been characterized

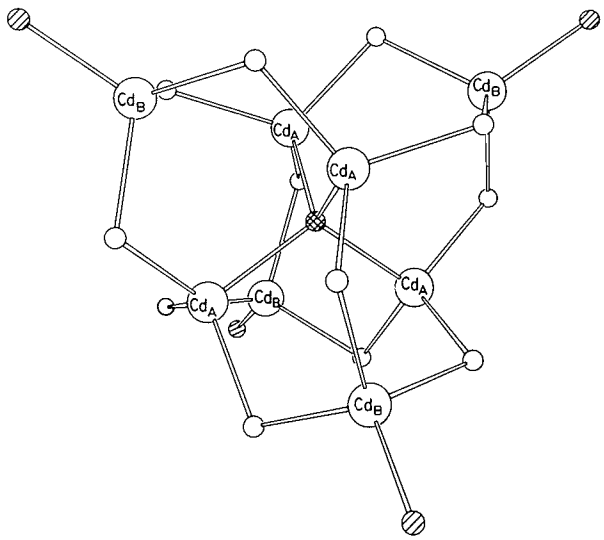
for Zn(II)–Hg(II). Selected interatomic distances and angles are compiled in Table 9.



I

(○ = sulfur (of thiolate); ⊘ = halide; ⊗ = chalcogenide)

There is no crystallographically imposed symmetry in **1**. The four cadmium atoms of the $Cd_4Br_4S_6$ core are arranged at the vertices of a nearly regular inner tetrahedron. The range of nonbonded Cd. . .Cd distances is 4.054–4.138 Å, with mean 4.074(32) Å, and the range of Cd—Cd—Cd angles is 59.21°–60.05°, with mean 59.7(4)°. The mean Cd. . .Cd distance is slightly smaller than 4.30(10) Å found for $[(\mu\text{-}SPh)_6(CdSPh)_4]^{2-}$, **2**, as the (Et_4N^+) $(Et_3N)^+$ salt (9), or 4.164(4) Å, reported for $[(\mu\text{-}SPh)_6(CdBr)_4]^{2-}$, **3**, as the Me_4N^+ salt (3). Each edge of the Cd_4 tetrahedron is bridged by one of the six isopropylthiolate ligands. The six bridging sulfur atoms occupy the corners of an octahedron that is highly distorted, as indicated by the large range of S. . .S distances (3.711–4.416 Å). Similar distortions have been observed in all other adamantane-like thiolate-bridged structures (1), and are a consequence of intramolecular interaction between the substituents on the bridging sulfur atoms as discussed further below. Tetrahedral coordination about each Cd is completed by a terminal bromide ligand. The four bromines are arranged at the apices of an irregular outer tetrahedron. The range of Br. . .Br is 8.128–8.486 Å.

The mean value of the Cd—S bond lengths in **1**, 2.53(1) Å, is comparable to the values determined for **2** and **3**, 2.56(2) and 2.545(6) Å, respectively. However, the mean Cd—Br bond length at 2.596(8) Å is larger than 2.564(3) Å observed for **3**. This may be explained in terms of electronic perturbation associated with substitution effects on the sulfur atoms. The Cd—S—Cd angles in **1** range from 106.1° to 109.4°, with a mean of 107.3(12)°. This mean value is less than the means of 113.8(34)° and 109.8(5)° in **2** and **3**, respectively, as expected for a smaller Cd_4 tetrahedron when the Cd—S distances are very similar. A large variation in S—Cd—S angles is observed (93.8°–123.1° with a mean of 109.6(88)°), as has been found for **2** (91.5°–118.8° (mean 106.2°)) and **3** (104.5°–117.1° (mean 109.1°)).

Adamantane-like $[(\mu\text{-}SR)_6M_4]$ can exist as four configurational isomers, depending on the relative orientations of the R substituents at the pyramidal sulfur atoms in the four $M_3(SR)_3$ rings (1, 3). Of the four isomers, two have C_3 symmetry and two have C_1 symmetry. Figure 5 shows that the six isopropyl groups in **1** adopt the configuration of Isomer III (C_1 symmetry). The anion **2** has the same form. In contrast, the benzenethiolate analogue, **3**, occurs as Isomer IV (C_3 symmetry).

In Isomer III, the orientations of the R substituents (axial or equatorial) in the four six-membered M_3S_3 rings are [aae, aae, aee, aee]. (This configuration has two axial–axial interactions, which is the minimum possible number.) Thus, a–a, a–e, and e–e substituent–substituent interactions occur, and accordingly both the S. . .S distances and the S—Cd—S angles should reflect the nature of the interaction involved (1). The S. . .S distances and the S—Cd—S angles for **1**, **2**, and **3** are grouped in Table 10 in terms of 1,3-substituent

For personal use only.

interactions. Both parameters follow the order a–a > a–e > e–e, as expected. It can be seen that the S_{axial}. . .S_{axial} distances and S_{axial}—Cd—S_{axial} angles for **1** are slightly larger than those found in **2** and **3**. This could be attributed to the bulkiness of the substituent in **1**.

Metal-selenolate chemistry: stereochemistry of adamantane-type clusters of formula $[(\mu\text{-SePh})_6(MSePh)_4]^{2-}$ (M = Zn and Cd)

JAGADESE J. VITTAL, PHILIP A. W. DEAN, AND NICHOLAS C. PAYNE[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 4, 1991

This paper is dedicated to the memory of Professor Thomas Birchall

JAGADESE J. VITTAL, PHILIP A. W. DEAN, and NICHOLAS C. PAYNE. Can. J. Chem. **70**, 792 (1992).

The structures of three tetramethylammonium salts containing anions of formula $[(\mu\text{-SePh})_6(MSePh)_4]^{2-}$ (M = Zn and Cd) were determined by single crystal X-ray diffraction techniques. The Zn salt crystallizes in different space groups depending upon the solvent combination used in the synthesis. Thus crystals of $(Me_4N)_2[Zn_4(SePh)_{10}]$, **1**, grown from a mixture of methanol, acetonitrile, and acetone are triclinic, space group $P\bar{1}$, with cell dimensions a = 13.214(2), b = 23.859(2), c = 13.072(1) Å, α = 91.134(8), β = 113.350(8), γ = 79.865(9)°, and Z = 2. In the absence of acetone, a solvated crystal $(Me_4N)_2[Zn_4(SePh)_{10}] \cdot CH_3CN$, **2**, is formed, which belongs to the monoclinic space group $P2_1/n$ with a = 14.248(1), b = 39.722(2), c = 13.408(1) Å, β = 97.132(5)°, and Z = 4. The Cd salt $(Me_4N)_2[Cd_4(SePh)_{10}]$, **3**, crystallizes in the monoclinic space group $P2_1/c$, with a = 20.830(2), b = 14.282(1), c = 25.872(1) Å, β = 99.626(6)°, and Z = 4. These three salts are the first examples of homoleptic, tetranuclear selenolatometal(II) anions with $(\mu\text{-Se})_6M_4$ cages of adamantane-type stereochemistry. In each case the phenyl substituents of the bridging ligands adopt the configuration [aae, aae, aee, aee], which has the minimum number of two 1,3-axial–axial non-bonding substituent interactions.

Key words: selenolate complexes, synthesis, X-ray crystallography, isomerism, adamantane stereochemistry.

JAGADESE J. VITTAL, PHILIP A. W. DEAN et NICHOLAS C. PAYNE. Can. J. Chem. **70**, 792 (1992).

Utilisant la diffraction des rayons X par un cristal unique, on a déterminé les structures de trois sels tétraméthylammonium contenant des anions $[(\mu\text{-SePh})_6(MSePh)_4]^{2-}$ (M = Zn et Cd). Le sel de zinc cristallise dans divers groupes d'espace suivant la nature de la combinaison de solvants utilisés au cours de la synthèse. Ainsi, les cristaux de $(Me_4N)_2[Zn_4(SePh)_{10}]$, **1**, obtenus par cristallisation dans un mélange de méthanol, acétonitrile et acétone sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 13,214(2), b = 23,859(2) et c = 13,072(1) Å, α = 91,134(8), β = 113,350(8) et γ = 79,865(9)° et Z = 2. En l'absence d'acétone, il se forme un cristal solvaté de $(Me_4)_2[Zn_4(SePh)_{10}] \cdot CH_3CN$, **2**, qui est monoclinique, groupe d'espace $P2_1/n$, avec a = 14,248(1), b = 39,722(2) et c = 13,408(1) Å, β = 97,132(5)° et Z = 4. Le sel de Cd, $(Me_4N)_4[Cd_4(SePh)_{10}]$, **3**, cristallise dans le groupe d'espace monoclinique, groupe d'espace $P2_1/c$, avec a = 20,830(2), b = 14,282(1) et c = 25,872(1) Å, β = 99,626(6) et Z = 4. Ces trois sels représentent les premiers exemples d'anions sélénométalliques(II) tétranucléaires et homoleptiques comportant des cages $(\mu\text{-Se})_6M_4$ avec une stéréochimie de type adamantane. Dans chacun des cas, les substituants phényles des ligands créant un pont adoptent la configuration [aae, aae, aee, aee] qui comporte le nombre minimal de deux interactions 1,3-axiales–axiales non-liantes entre de substituants.

Mots clés : complexes de sélénolate, synthèse, diffraction des rayons X, isomérie, stéréochimie de l'adamantane.

[Traduit par la rédaction]

Introduction

In the chemistry of metal-thiolates, a frequently encountered structural unit is the adamantane-type tetranuclear cluster with a $(\mu\text{-SR})_6M_4$ core (1, 2). To date more than 20 such compounds have been characterized by X-ray structure analyses (3–20). By contrast, the structural chemistry of analogous metal-selenolates is essentially undeveloped. The only well-characterized compound, to our knowledge, is the Cd complex $(Me_4N)_2[(\mu\text{-SePh})_6(CdBr)_4]$ (3). We previously reported (3, 21–27) some chemistry of $[(\mu\text{-SePh})_6(MSePh)_4]^{2-}$ (M = Zn and Cd). To obtain structural data on the selenolate anions $[(\mu\text{-SePh})_6(MSePh)_4]^{2-}$ (M = Zn and Cd), and to examine their relationships with other adamantane-type cages, we determined the crystal structures of $(Me_4N)_2[(\mu\text{-SePh})_6(CdSePh)_4]$ and $(Me_4N)_2[(\mu\text{-SePh})_6(ZnSePh)_4]$ (unsolvated and as an acetonitrile solvate). We present herein our results, which represent the first reported examples of the homoleptic tetranuclear M(II) selenolates of formula $M_4(SePh)_{10}]^{2-}$.

Experimental

Materials and general manipulative procedures

Starting materials were from commercial sources and were used as received. All manipulations were carried out under an atmosphere of Ar(g). Before use, solvents were dried over 3 Å Molecular Sieves and sparged with Ar(g). The salt $(Me_4N)_2[Cd_4(SePh)_{10}]$, **3**, was synthesized as reported earlier (22).

Syntheses of $(Me_4N)_2[Zn_4(SePh)_{10}]$

A synthesis of **1** in analytically pure form was described earlier (3). It now appears that the formation of **1** by the procedure described must have been serendipitous. We report here that the presence of acetone is necessary to obtain the unsolvated zinc complex. A reproducible synthesis of this material and of the analogous acetonitrile solvate is now given.

$(Me_4N)_2[Zn_4(SePh)_{10}]$, **1**

A solution of sodium benzeneselenolate was prepared by adding benzeneselenol (2.90 g, 18.48 mmol) to a solution of sodium (0.426 g, 18.5 mmol) in methanol (10 mL). Into the solution of NaSePh was stirred $Zn(NO_3)_2 \cdot 6H_2O$ (1.839 g, 6.18 mmol), then, after a wait of 10 min, a solution of $Me_4NC\ell$ (0.365 g, 3.33 mmol) in MeOH (10 mL), which produced a white precipitate. After addition of acetone (20 mL) and acetonitrile (10 mL), the mixture was warmed to 333 K to give a clear, pale yellow so-

lution. The warm solution was filtered hot and the filtrate was set aside for 1 day at 278 K for crystallization to occur. The colourless transparent crystals were separated by decantation, washed with a 1:1 (v:v) MeOH:H_2O mixture, then with MeOH, and finally with Et_2O before being dried *in vacuo*. In this way 2.15 g of product were obtained. A second crop of 0.50 g resulted from concentration of the mother liquor, to give a total yield of 88%. The solubility and ^{13}C and ^{77}Se NMR spectra of this product were identical to those of the analytically pure material produced previously (3).

$(Me_4N)_2[Zn_4(SePh)_{10}] \cdot CH_3CN$, **2**

Omission of the acetone in the procedure described above for **1** gave a comparable yield of this acetonitrile solvate as light yellow plate-like crystals. The solvate is significantly less soluble in MeCN or $(CH_3)_2CO$ than is **1**, e.g., the solubility of **1** in acetonitrile at 295 K exceeds 0.05 mol L^{-1}, whereas that of **2** is about 0.025 mol L^{-1}. Proton NMR ($(CD_3)_2CO$, 294 K): 2.86 (s, CH_3CN), 3.76 ($(CH_3)_4N^+$), 6.6–7.8 (aromatic H's). ^{13}C NMR ($(CD_3)_2CO$, 294 K): 6.6 (CH_3CN), 56.0 ($(CH_3)_4N^+$), 112.2 (CH_3CN), 125.5 (C_4), 128.5 ($C_{3,5}$), 130.2 (C_1, bridging), 131.9 (C_1, terminal), 135.6 ($C_{2,6}$). (Except for the resonances due to MeCN, the ^{13}C NMR spectrum is virtually identical to that reported (3) for **1**.) Anal. calcd. for $C_{70}H_{77}N_3Se_{10}Zn_4$: C 41.79, H 3.86, N 2.09; found: C 42.09 and 42.12, H 4.06 and 3.95, N 1.88 and 1.64.

NMR spectroscopy

NMR spectra were obtained as reported previously (3, 25). The reference for ^{77}Se NMR was external pure Me_2Se at 295 K.

X-ray crystallography

Compounds **1**, **2**, and **3** were examined by experimental procedures standard in our laboratory (3). An overview is given below, and crystal data are summarized in Table 1.

Crystals suitable for X-ray diffraction studies were obtained directly from the reaction mixtures. They were colorless, transparent, and fairly stable in air, though on prolonged exposure to air and (or) X-radiation the crystals tended to decompose, changing color to light yellow and becoming opaque. Precession and Weissenberg photographs were taken to establish the space groups and to get preliminary cell dimensions. Crystal densities were determined by the neutral buoyancy method in mixtures of carbon tetrachloride and 1,2-dibromoethane. The data collections were carried out on an Enraf–Nonius CAD4F diffractometer (28) at 296 K. Intensity data were recorded in ω–2θ scan mode at variable scan speeds, so chosen as to optimize counting statistics within a maximum time per datum of 60 s. Background estimates were made by extending the scan by 25% on each side. Standard reflections were monitored every 180 min of X-ray exposure time. For the Zn salts **1** and **2** crystal decay was significant, necessitating data collection from two crystals in each case. Lorentz, polarization, and decay (where applicable) corrections were applied using the Structure Determination Package running on a PDP11/23+ computer (29). A Gaussian absorption correction (30) was made to the data for compounds **1** and **2**, whereas for **3** an analytical correction was applied (31). The data were then merged using scale factors calculated from reflections in the region common to both data

[a] Anisotropic thermal parameters are given in the form of isotropic equivalent parameter defined as $U_{eq} = 1/3\ \Sigma_i\Sigma_j U_{ij} \cdot a_i^* \cdot a_j^* \cdot a_i \cdot a_j$.

sets, and averaged to produce three sets of unique data for structure solution and refinement.

All three structures were solved by a combination of MULTAN (32) and difference Fourier syntheses, and refined by full-matrix least-squares techniques on F using the SHELX76 software (33) running on a SUN 3/50 work-station. Scattering factors for Zn and Cd atoms were taken from the International Tables (34). In the refinements, all metal and selenium atoms were assigned anisotropic thermal parameters. The phenyl ring carbon atoms were constrained to regular hexagonal geometry with C—C = 1.392 Å and were allotted isotropic thermal parameters. All phenyl hydrogen atoms were located successfully by difference Fourier methods, placed in calculated positions (C—H = 0.95 Å), and included in the structure factor calculations.

Disorder of the tetramethylammonium cations was present in every structure; it was modelled by refining rigid groups of T_d symmetry, N—C = 1.485 Å, of varying multiplicities deduced from difference Fourier syntheses. The cation hydrogen atoms could not be located reliably owing to the disorder, and all were omitted from structure factor calculations. In compound **1**, both cations have disordered carbon atoms; two groups were included in the model for each ion, with major components of multiplicities 0.90 and 0.60. Individual isotropic thermal parameters were refined for the atoms of the major components, whereas overall group thermal parameters were applied to the minor components. For compound **2**, the carbon atoms of only one cation were disordered; overall group thermal parameters were refined for the two rigid groups of multiplicities 0.60 and 0.40. And in crystals of compound **3**, both cations have disordered carbon atoms; two groups were included in

[a] Anisotropic thermal parameters are given in the form of the isotropic equivalent parameter defined as $U_{eq} = 1/3\ \Sigma_i\Sigma_j U_{ij} \cdot a_i^* \cdot a_j^* \cdot a_i \cdot a_j$.

the model for each, with major component multiplicities of 0.70 and 0.60.

The final cycles of refinement were based on those unique data with $I > 3\sigma(I)$. Selected experimental details of the analyses are given in Table 1, while the remaining data are listed in Table S1. Secondary extinction corrections were applied to the data for **2** and **3**. The analyses of variance suggested that the weighting schemes were appropriate. Final positional parameters for **1** are given in Table 2, for **2** in Table 3, and for **3** in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, and root-mean-square amplitudes of vibration have been deposited as Tables S2, S3, and S4.[2]

Results and discussion

The synthesis of the Cd salt $(Me_4N)_2[Cd_4(SePh)_{10}]$, **3**, was described previously (22). The preparations of the Zn salts **1** and **2** involve the use of $Zn(NO_3)_2 \cdot 6H_2O$, $NaSeC_6H_5$, and

[2] Copies of supplementary experimental details, hydrogen atom parameters, anisotropic thermal parameters, root-mean-square amplitudes of vibration, supplementary dimensions, selected least-squares planes, selected torsion angles, and structure amplitudes for **1**, **2**, and **3** may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

The tables of supplementary experimental details, hydrogen atom parameters, and supplementary dimensions have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

[a]Anisotropic thermal parameters are given in the form of the isotropic equivalent parameter defined as $U_{eq} = 1/3\ \Sigma_i\Sigma_j U_{ij} \cdot a_i^* \cdot a_j^* \cdot a_i \cdot a_j$.

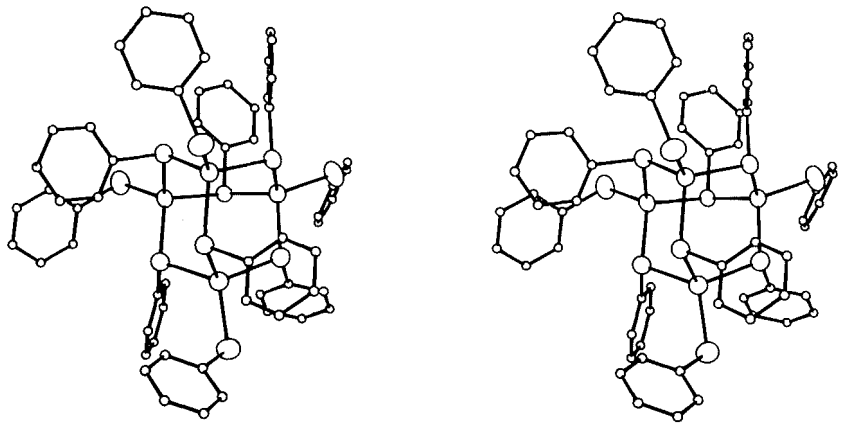

FIG. 2. A stereoview of the anion in **2**.

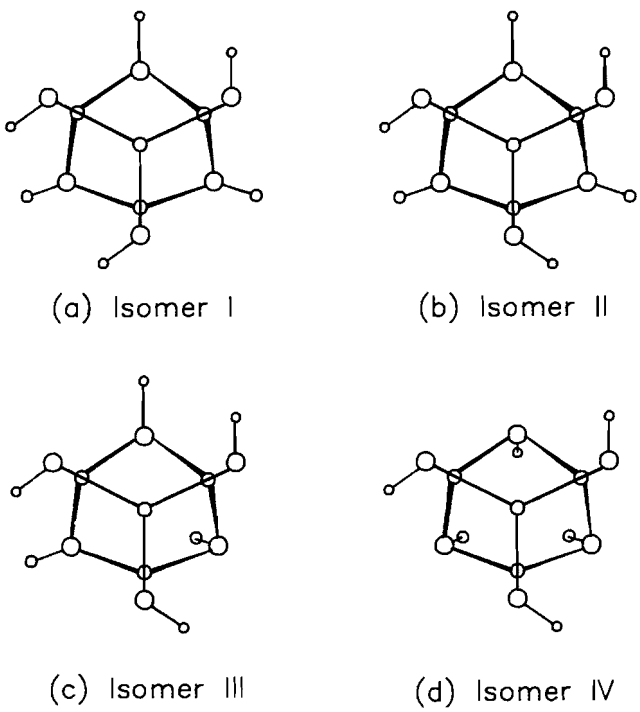

FIG. 3. The four possible configurational isomers for a $[(\mu\text{-SePh})_6(\text{MSePh})_4]^{2-}$ anion.

$(CH_3)_4NC\ell$ in the ratios 2:3–3.5:1 under anaerobic conditions. When the reaction mixture contains only acetonitrile, methanol, and water, the solvated crystals **2** are formed. If acetone is added to the above mixture, the product crystallized from solution is **1**. The syntheses of **1** and **2** are quite reproducible. It is noteworthy that the two products differ significantly in solubility in acetone and acetonitrile, **2** being less soluble than **1**. Also interesting is the finding that **2** gives sharper ^{77}Se NMR signals than **1**. At 295 K a solution having 0.025 mol of **2** per litre of MeCN has the expected two ^{77}Se resonances, at $\delta_{Se} = 37.2$ for terminal ligands ($PhSe_t$) and -10.3 for bridging ligands ($PhSe_{br}$), with line widths of ca. 33 and 24 Hz, respectively. For 0.05 mol of **1** per litre of MeCN, the corresponding values are $\delta_{Se} = 38.0$ ($PhSe_t$), and -8.8 ($PhSe_{br}$), with line widths of 75 and 55 Hz, respectively (23). The most likely explanation for the difference is a higher purity of the less soluble compound.

The crystal structures of the three compounds consist of well-separated cations and anions. The closest cation–anion and anion–anion distances of approach are given in Table S5. Cation and solvate molecule structures are unexceptional and will not be discussed further. The cage skeletons of the anions **1**, **2**, and **3** are depicted in Fig. 1, while a stereoview of the anion in **2** is shown in Fig. 2. The same numbering scheme was used consistently for all three anions, and the ligand atoms are numbered according to their connectivity; thus Se(1) and C(11) through C(16) form the terminal phenylselenolato ligand on Zn(1), Se(12) and C(121) through C(126) form the ligand bridging Zn(1) and Zn(2), and so forth.

The common structural features in these $[(\mu\text{-SePh})_6(\text{MSePh})_4]^{2-}$ anions are now briefly summarized. The metal atoms are located at the vertices of a tetrahedron, with selenolate ligands bridging the six edges. The Se atoms thus occupy the corners of a highly distorted octahedron, and each metal atom is bonded to one terminal and three bridging SePh groups. Each face of the tetrahedron is composed of a six-membered $M_3(\mu\text{-Se})_3$ ring in chair conformation, to give an adamantane-like overall stereochemistry. Unlike adamantane, isomerism occurs in these cluster anions due to the difference between the lone pair and phenyl substituents upon the selenium atoms. The phenyl groups are positioned either axially (a) or equatorially (e) in each ring (1). However, where two rings share a common edge formed by a bridging selenolate ligand, the adoption of an axial disposition with respect to one ring *ipso facto* defines this group as equatorially disposed with respect to the other; there are thus always six axial and six equatorial substituents.

In all, four geometric isomers of $M_4(\mu\text{-Se})_6$ are possible, I–IV, Fig. 3, which differ in the number of energetically disfavored 1,3-axial,axial phenyl group nonbonded interactions (3). For example, isomer I has a (3-2-1-0) axial pattern corresponding to aaa,aae,aee,eee substituent dispositions, and point symmetry C_1. Similarly isomer II has (2-2-2-0), with higher point symmetry C_3. Isomer III has (2-2-1-1), again point symmetry C_1, while (3-1-1-1), point symmetry C_3, may be assigned to Isomer IV. Isomers I and III are asymmetric, II and IV are dissymmetric, and all four can exist

in enantiomeric forms. Indeed, a spontaneous resolution of one hand has been reported (3) for $(Me_4N)_2[(\mu\text{-}EPh)_6(CdBr)_4]$ (E = S or Se), the only known example of isomer IV. All the other reported examples, with the exception of $[(\mu\text{-}TeR)_6Ag_4]^{2-}$ (20), have crystallized in centrosymmetric space groups as racemic modifications. Interestingly, in the two cases where there is crystallographically imposed symmetry (3) or geometric constraints imposed by the backbones of the bridging ligands (18, 19), the configurations of isomers II or IV (with C_3 symmetry and three 1,3-axial–axial pairs) are observed. The stereochemistry of isomer I (which has the maximum possible of four axial pairs of interactions) is found most often in Fe-thiolate cages; why this is so is not clear. Although crystallizing in different lattices, the anions in **1**, **2**, and **3** all adopt the stereochemistry of isomer III. This isomer has only two axial–axial pairs of interactions, and occurs in 12 of the 21 reported $(\mu\text{-}SR)_6M_4$ cages (3–20). For the anions of **1**, **2**, and **3** both enantiomers are present in the crystal lattice, since all crystallized in centrosymmetric space groups.

Selected interatomic distances and angles for **1**, **2**, and **3** are given in Table 5. Compound **1** is isomorphous and isostructural with $(Me_4N)_2[M_4(SPh)_{10}]$, where M = Mn (4), Co (9), or Zn (14). A comparison of interatomic distances and angles with those in the corresponding isomorphous compounds and their sulfur analogs reveals the trend expected for the change in size of metal atoms and E atoms. The ranges of nonbonded M. . .M distances of 4.098(3)–4.172(3) in **1**, 4.094(2)–4.173(2) in **2**, and 4.347(2)–4.477(2) Å for **3** imply slightly distorted T_d geometries for the metal atoms. Compound **3** contains the same $(\mu\text{-}Se)_6M_4$ cage as the only example of isomer IV, though $PhSe_t$ ligands have replaced the Br atoms, and the Cd. . .Cd distances for **3** are significantly larger than the mean value of 4.251(6) Å found in the $[\mu\text{-}(SePh)_6(CdBr)_4]^{2-}$ anion (3).

There is no significant variation in the Zn—Se_t distances in **1** and **2**, though the Cd—Se_t distances range from 2.573(2) to 2.605(2) Å. The M—Se_{br} distances vary more, from 2.440(3) to 2.511(3) in **1**, from 2.449(2) to 2.519(2) in **2**, and from 2.636(2) to 2.693(2) Å in **3**. A similar degree of variation is seen in the M—Se—M angles. It is noteworthy that the M—Se_{br} distances are all significantly longer than the M—Se_t values in each of the three anions. A mean Zn—Se_t distance of 2.471(13) Å was found in the anion $[Zn(Se_4)_2]^{2-}$ (35), and a mean Cd—Se_t value of 2.643(9) Å in the $[Cd(Se_4)_2]^{2-}$ anion (36).

There are, however, large differences in Se_{br}—M—Se_{br} angles and Se_{br}. . .Se_{br} distances. We attribute these variations to intramolecular interactions between the axial phenyl substituents on the $(\mu\text{-}SePh)_3M_3$ rings. These are also reflected in the Se_{br}—M—Se_{br} angles. A correlation between pairwise substituent orientation for Se_{br}—M—Se_{br} angles and Se_{br}. . .Se_{br} distances listed in Table 5 can be derived, and it is clearly apparent that the skeleton distorts to minimize the unfavourable repulsive interactions between axially disposed substituents.

	Se_{br}. . .Se_{br} range/values (Å)	Se_{br}—M—Se_{br} range/values (deg)
M = Zn (compounds **1** and **2**)		
aa	4.235(3)–4.320(2)	117.3(1)–121.3(1)
ae	3.863(3)–4.095(3)	101.5(1)–110.8(1)
ee	3.558(3)–3.690(3)	91.5(1)–95.9(1)
M = Cd (compound **3**)		
aa	4.522(2), 4.536(2)	116.8(1), 117.1(1)
ae	4.113(2)–4.430(2)	101.9(1), 112.3(1)
ee	4.003(2), 4.136(2)	96.4(1), 102.5(1)
M = Cd (ref. 3, isomer IV)[3]		
aa	4.582(3)	121.2(1)
ae	4.226(3), 4.351(3)	106.3(1), 111.0(1)
ee	4.108(3)	102.0(1)

Although all three anions adopt the configuration of isomer III, there are differences in the arrangements of the phenyl rings on the selenolato ligands. These arise from rotations about the metal—Se_t and the Se_{br}—C bonds. Thus the dihedral angles between the planes of the phenyl rings with 1,3-axial–axial interactions are different:

[3]The nonbonded Se_{br}. . .Se_{br} distances in the anion $[(\mu\text{-}SePh)_6(CdBr)_4]^{2-}$, compound **2** in ref. 3, were interchanged in Table III; they should read E(1) . . . E(2) 4.226(3) Å and E(1) . . . E(2)′ 4.108(3) Å.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12

Compound	Phenyl rings:	Dihedral angles (deg) 12 and 14	13 and 23
1		63.8(6)	70.3(4)
2		63.7(3)	79.1(2)
3		54.5(5)	83.9(4)

However, it can be seen from Fig. 1 that the major differences are in the relative orientations of the phenyl rings attached to the terminal Se atoms. Torsion angles describing these variations have been collected in Table S7. Since there is no obvious systematic reason for these differences, we suppose that they may be due to packing effects in the crystal lattice.

La synthèse de deux dérivés du 1,2-dihydro-6,7-diméthoxyisoquinoléine-3-carboxylate d'éthyle est décrite. Ces énamines cycliques portant un groupe ester sur le carbone énaminique réagissent de façon régio- et stéréospécifique avec une diarylnitrilimine. La régiochimie est spécifiée par voies chimique et spectroscopique. Le détermination radiocristallographique de la structure d'un cycloadduit permet de préciser la stéréochimie de la réaction et de la comparer avec celle qui avait été décrite lorsque le dipolarophile initial ne comporte pas de groupe ester sur le carbone énaminique.

Mots clés : cycloaddition dipolaire-1,3, diarylnitrilimine, énamine cyclique, régiochimie, stéréochimie.

KHADIJA MOUSTAID, NGUYEN DINH AN, BERNARD LAUDE, MARIE-FRANCE MERCIER, and AHMED SEDQUI. Can. J. Chem. **70**, 802 (1992).

Two ethyl-1,2-dihydro-6,7-dimethoxyisoquinoline-3a-carboxylate derivatives were synthesized. These cyclic enamines in which the enaminic carbon atom was bonded with an ester group react regio- and stereospecifically with a diarylnitrilimine. The regiochemistry was specified by chemical and spectroscopic methods. The radiocrystallographic structure of one cycloadduct allows us to determine the stereochemistry of the reaction and to compare it with that of the reaction of a diarylnitrilimine with a 1,2-dihydro-1,2-dialkylisoquinoline without an ester group at the enaminic carbon atom.

Key words: 1,3-dipolar cycloaddition, diarylnitrilimine, cyclic enamine, regiochemistry, stereochemistry.

Introduction

Dans un article récent (1) nous avons décrit la synthèse et l'utilisation comme précurseurs d'ylures d'azométhine des dérivés de type **4** (figure 1) de la 3,4-dihydro-6,7-diméthoxyisoquinoléine portant un groupement ester en position -3. Ayant noté que leur aromatisation en dérivés de l'isoquinoléine **5** s'effectue par simple chauffage dans l'éthanol, nous avons envisagé de transformer ces composés **5** en dérivés **7** de la 1,2-dihydro-6,7-diméthoxy-3-éthoxycarbonyl isoquinoléine. Ces derniers composés sont des dipolarophiles et il nous a semblé intéressant d'étudier le rôle joué par le groupe ester en -3 dans leur comportement vis-à-vis d'une diarylnitrilimine **8** et de la comparer du double point de vue régio- et stéréochimique, avec celui déjà décrit dans le cas des 1,2-dihydro-1,2-dialkylisoquinoléines non substituées en position -3 (2).

Synthèse des dérivés de la 1,2-dihydro-6,7-diméthoxy-2-méthyl-3-éthoxycarbonylisoquinoléine 7

Les différentes étapes de cette synthèse sont rassemblées sur la figure 1. La méthode d'accès aux composés **4** depuis le bromure de 3,4-diméthoxybenzyle a été décrite dans notre mémoire précédent (1). Ici nous avons préféré préparer l'ester éthylique pour limiter le nombre de signaux correspondant à un groupe méthoxy en rmn ^{1}H. L'oxydation des composés **4** en isoquinoléines **5** s'effectue par simple chauffage dans l'éthanol dans le cas de **5***a*. Par contre, il faut catalyser cette oxydation par une trace d'éthylate de sodium dans le cas de **5***b* (cf. partie expérimentale). Traités par l'iodure de méthyle, les composés **5** donnent les sels d'isoquinolinium **6**, mais le mode opératoire diffère selon que R = H ou CH_3 (cf. partie expérimentale).

La réduction de ces sels **6** par $NaBH_4$ selon une adaptation du mode opératoire décrit par Dyke *et al.* (3) conduit aux dipolarophiles **7***a*,*b*.

Réactions de cycloaddition et transformation d'un cycloadduit

Les composés **7** réagissent aisément avec la *C*-*para*anisyl-*N*-phénylnitrilimine formée *in situ* selon la méthode de Huisgen *et al.* (4). Les rendements sont convenables et la réaction est régio- et stéréospécifique puisqu'elle ne conduit qu'à un seul cycloadduit **9** dérivé du 1-*para*-anisyl-7,8-diméthoxy-4-méthyl-3-phényl-3a,4,5,9b-tetrahydropyrazolo[3,4-*c*]isoquinoleine-3a-carboxylate d'éthyle (figure 1).

La régiochimie est précisée à l'aide des paramètres de rmn ^{13}C des cycloadduits puisque le carbone quaternaire C−3a a un déplacement chimique de l'ordre de 90 ppm, ce qui permet d'affirmer qu'il est lié à deux atomes d'azote. Ce résultat est en accord avec plusieurs travaux antérieurs (5, 6) concernant l'orientation de la cycloaddition des diarylnitrilimines sur des sites dipolarophiliques portant un groupement ester. Ces travaux montrent que d'une manière générale,

E = CO_2Et, *a* : R = H, *b* : R = CH_3

FIG. 1

l'extrémité azotée du dipôle se fixe sur le carbone portant la fonction ester.

Cependant, une inversion de cette régiochimie a été récemment décrite par Daou et Soufiaoui (7) dans le cas du 2-éthoxycarbonyl-*N*-méthylindole. Aussi, nous a-t-il semblé nécessaire de vérifier par voie chimique la régiochimie de la cycloaddition du dipôle **8** sur les composés **7**.

Dans ce but, nous avons transformé le cycloadduit **9***a* selon les réactions représentées sur la figure 2.

Une première tentative de saponification du cycloadduit **9***a* ne permet pas d'isoler l'acide correspondant mais conduit à l'azépinone **10***a*. La saponification s'accompagne de l'ouverture de l'hétérocycle hexagonal qui se referme ensuite par réaction intramoléculaire entre les fonctions acide et amine secondaire. Cette transformation avait également été décrite par Daou et Soufiaoui (7) dans le cas d'un cycloadduit issu de l'action d'une diarylnitrilimine sur le 2-éthoxycarbonyl-*N*-méthylindole homologue inférieur de nos dipolarophiles.

Le traitement du cycloadduit **9***a* par l'acide acétique conduit après protonation et ouverture au pyrazole **11***a*.

L'analyse quantitative élémentaire du composé **11***a* est en accord avec sa structure qui est celle d'un isomère de **9***a*. Le spectre d'absorption ir présente une bande ν(N—H) = 3400 cm^{-1} et un abaissement de la fréquence ν(C=O) du groupe ester qui passe de 1730 cm^{-1} dans **9***a* à 1710 cm^{-1} dans **11***a* par suite de la conjugaison de ce groupe ester avec le cycle pyrazolique. Les paramètres de rmn ^1H et ^{13}C sont également en accord avec la structure proposée.

Mais ces propriétés spectroscopiques ne seraient pas en opposition avec une structure résultant de la transformation du régioisomère inverse du cycloadduit **9***a*. Nous avons donc cherché à transformer le groupement ester du produit **11***a* en hydrogène afin de déterminer avec certitude la structure du cycloadduit. La saponification directe du pyrazole **11***a* conduit à la même azépinone **10***a* obtenue par saponification du cycloadduit. Il convenait donc d'éviter toute réaction entre le groupe NH avec le reste ester et dans ce but nous avons acétylé le groupe NH du pyrazole **11***a* par action du chlorure d'acétyle en milieu pyridinique. Le produit acétylé **12***a* est ensuite saponifié et l'acide **13***a* obtenu est décarboxylé par chauffage. Il est alors facile de confirmer la structure du pyrazole **14***a* en examinant le spectre de rmn ^1H qui présente un singulet à 7,9 ppm caractéristique d'un proton H-5 pyrazolique alors qu'un proton H-4 pyrazolique résonne vers 6,7–6,8 ppm (8, 9).

Ces transformations confirment la régiochimie proposée pour les cycloadduits **9** sur la base du déplacement chi-

Ar = *p*-anisyle, i: KOH méthanolique 2 N, ii : HCl

FIG. 2

mique du carbone C-3a et elles invalident la régiochimie proposée initialement pour les cycloadduits issus de l'action des diarylnitrilimines sur le 2-éthoxycarbonyl-*N*-méthylindole (7) et rectifiée par la suite (10).

Stéréochimie de la cycloaddition

Les paramètres de rmn ^1H et ^{13}C des cycloadduits ne permettant pas d'accéder à leur stéréochimie, nous avons fait appel à une détermination radiocristallographique de la structure du 1-*para*-anisyl-7,8-diméthoxy-4,5-diméthyl-3-phényl-3a,4,5,9b-tétrahydropyrazolo[3,4-*c*]isoquinoléine-3a-carboxylate d'éthyle **9***b* (11).

Cette structure permet de relever les caractéristiques suivantes : (*i*) les deux groupes méthyles en N-4 et C-5 se situent de même côté du cycle diméthoxybenzo dans une disposition *cis* avec une position pseudo-axiale pour le groupe *N*-méthyle et pseudo-équatoriale pour le groupe méthyle en -5; (*ii*) le groupe *N*-méthyle en -4 et le groupe ester en -3a sont dans une disposition pseudo-*trans* diaxiale avec un angle de torsion entre les deux groupes méthyle et ester : CH_3–N–4–C–3a–CO_2Et = 156,8°.

Cette structure appelle quelques commentaires notamment par comparaison avec les résultats décrits par Kitane *et al.* (2) et Mercier *et al.* (12) dans le cas de la cycloaddition des diarylnitrilimines sur diverses 1-alkyl-*N*-méthyl-1,2-dihydroisoquinoléines **15** (figure 3).

Dans cette étude, Kitane *et al.* (2) ont montré que la stéréochimie des dipolarophiles **15** était telle que le groupe *N*-méthyle et le groupe alkyle en -1 étaient dans une disposition pseudo-*trans*-diaxiale. Ceci impose alors une approche du dipôle en *anti* du groupement le plus encombrant à savoir le groupe *N*-méthyle plus proche du site dipolarophilique. C'est effectivement ce qui est observé sur le diagramme PLUTO (figure 3) obtenue par détermination radiocristallographique de la structure de **16** (R = isopropyle). On y voit nettement que le cycloadduit s'est développé en *trans* du reste *N*-méthyle et en *cis* du groupement isopropyle, ces deux groupes étant en disposition pseudo-*trans*-diaxiale sur l'hétérocycle hexagonal azoté.

Dans le cas de notre dipolarophile **7***b*, on peut penser que sa conformation est analogue à celle proposée par Kitane *et al.* (2) pour le composé **15**. C'est d'ailleurs celle qui éloigne le plus les deux groupes *N*-méthyle en -2 et ester en -3. Dans ces conditions, on peut donc attendre la même stéréochimie pour l'approche du dipôle, à savoir en *anti* du groupe *N*-méthyle et en *syn* du groupe méthyle en -1.

Le diagramme PLUTO (figure 3) de la structure du cycloadduit **9***b* montre bien que le dipôle s'est approché en *syn* du méthyle en -1 mais il apparaît que le reste *N*-méthyle se

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

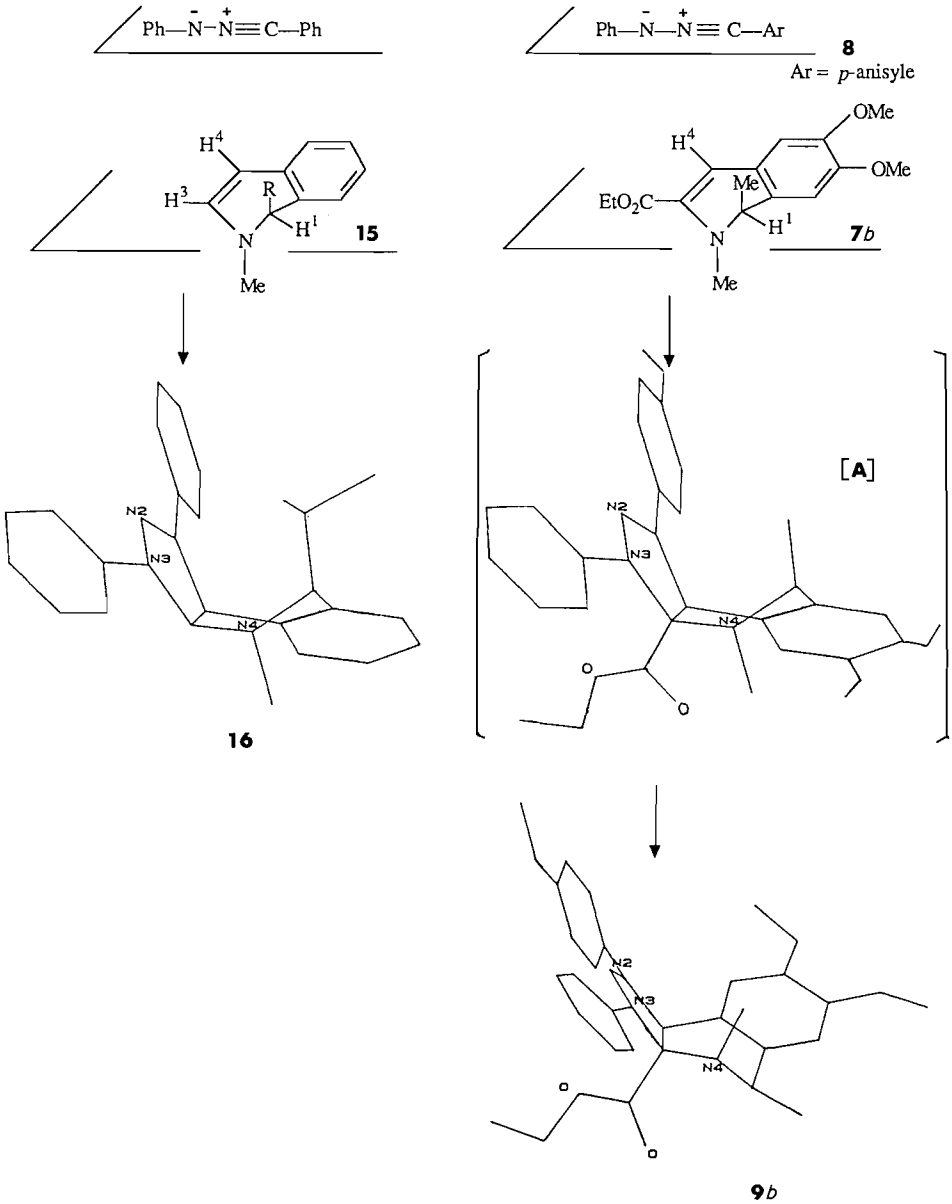

FIG. 3

retrouve dans une disposition *cis* du cycle pyrazolinique et du groupe méthyle en -5.

Nous pensons pouvoir lever cette contradiction apparente en faisant appel à une épimérisation de l'atome d'azote N-4 lors de la cycloaddition. Cette épimérisation assure alors la décompression stérique qui interviendrait si le groupe ester en -3a et le reste *N*-méthyle en -4 se retrouvaient dans une disposition *cis* comme indiqué sur l'intermédiaire **[A]** (figure 3).

Conclusion

Nous avons pu préparer des énamines cycliques dérivées du 1,2-dihydro-6,7-diméthoxy-*N*-méthylisoquinoléine-3-carboxylate d'éthyle. Ces dipolarophiles réagissent de façon régio- et stéréospécifique avec une diarylnitrilimine. La régiochimie de la réaction déterminée par voies spectroscopique et chimique correspond à l'union de l'atome de carbone du dipolarophile portant le groupe ester avec l'extrémité azotée du dipôle. Le résultat semble général.

Si la stéréochimie de la cycloaddition s'effectue de façon que le dipôle approche le dipolarophile en *syn* du substituant fixé en β du site dipolarphilique et en *anti* du groupe *N*-méthyle situé en α du site dipolarophilique, il apparaît que la présence du groupe ester fixé sur l'atome de carbone voisin du reste *N*-méthyle exerce un encombrement stérique tel que la cycloaddition s'accompagne d'une épimérisation de l'atome d'azote qui renvoie le groupe *N*-méthyle en disposition *trans* par rapport au groupe ester dans le cycloadduit.

Partie expérimentale

Les points de fusion déterminés sur banc Kofler ne sont pas corrigés. Les spectres d'absorption ir ont été obtenus avec un spectrophotomètre Beckman IR 33, les produits étant pastillés dans KBr. Les spectres de rmn ont été obtenus avec un spectomètre

Bruker–Spectrospin AC 200 (200 MHz pour le proton et 50 MHz pour le ^{13}C), les échantillons étant dissous dans $CDCl_3$ (sauf indication contraire) avec le tétraméthylsilane comme référence interne. Les microanalyses ont été assurées par le Service d'Analyses du CNRS à Vernaison.

Le précurseur de la *C-para*-anisyl-*N*-phénylnitrilimine est préparé selon la méthode de Huisgen *et al.* (4).

Dérivés du 3,4-dihydro-6,7-diméthoxyisoquinoléine-3-carboxylate d'éthyle ***4***

Le mode opératoire est calqué sur celui décrit par Lakhlifi *et al.* (1) pour l'obtention des esters méthyliques. La seule différence intervient lors de la dernière étape où le méthanol est remplacé par de l'éthanol absolu. On opère à partir de 0,01 mol de diester **3**. En fin de réaction, le résidu est repris sans chauffer par un mélange d'hexane et de propan-1-ol (4 : 1). Les produits **4** cristallisés sont essorés et chacun d'eux est décrit ci-après.

*3,4-Dihydro-6,7-diméthoxyisoquinoléine-3-carboxylate d'éthyle (****4****a)*

On obtient 1,76 g de produit (Rdt. 67%), *F* 138–140°C; ir, ν_{max} : 1725 (ester); rmn ^1H, δ : 1,32 (t, 3H, $^3J_{CH_3-CH_2}$ = 7,10 Hz, CH_3 de éthyle), 2,96 (d, 2H, $^3J_{CH_2-4-H-3}$ = 10,20 Hz, CH_2-4), 3,91 (s, 3H, OCH_3), 3,94 (s, 3H, OCH_3), 4,25 (dt, 1H, ^3J = 10,20 Hz, $^4J_{H-3-H-1}$ = 2,90 Hz, H-3), 4,32 (q, 2H, ^3J = 7,10 Hz, CH_2 de éthyle), 6,80 (s, 1H, H-5), 6,95 (s, 1H, H-8), 8,35 (d, 1H, $^4J_{H-1-H-3}$ = 2,90 Hz, H-1). Anal. calc. pour $C_{14}H_{17}NO_4$: C 63,84, H 6,51, N 5,32; tr. : C 63,92, H, 6,43, N 5,46.

*3,4-Dihydro-,6,7-diméthoxy-1-méthyl-isoquinoléine-3-carboxylate d'éthyle (****4****b)*

On obtient 2,14 g de produit (Rdt. 77%), *F* 100°C; ir, ν_{max} : 1730 (ester); rmn ^1H, δ : 1,30 (t, 3H, $^3J_{CH_3-CH_2}$ = 7,10 Hz, CH_3 de éthyle), 2,40 (d, 3H, $^5J_{CH_3-H-3}$ = 1,90 Hz, CH_3-1), 2,90 (d, 2H, $^3J_{CH_2-4-H-3}$ = 10,60 Hz, CH_2-4), 3,90 (s, 6H, OCH_3), 4,20 (tq, 1H, $^3J_{H-3-CH_2-4}$ = 10,60 Hz, $^5J_{H-3-CH_3-1}$ = 1,90 Hz, H-3), 4,30 (q, 2H, ^3J = 7,10 Hz, CH_2 de éthyle), 6,80 (s, 1H, H-5), 7,0 (s, 1H, H-8). Anal. calc. pour $C_{15}H_{19}NO_4$: C 64,96, H 6,91, N 5,05; tr. : C 65,07, H 6,83, N 5,17.

Dérivés du 6,7-diméthoxyisoquinoléine-3-carboxylate d'éthyle ***5***

*6,7-Diméthoxyisoquinoléine-3-carboxylate d'éthyle (****5****a)*

On dissout 0,01 mol de composé ***4****a* dans 40 mL d'éthanol contenus dans un bécher de forme haute de 250 mL. Cette solution est maintenue un quart d'heure à très légère ébullition sur une plaque chauffante installée sous la hotte. La solution est ensuite concentrée jusqu'à 10 mL et par refroidissement le composé ***5****a* cristallise (Rdt. quantitatif), *F* 181°C; ir, ν_{max} : 1710 (ester); rmn ^1H, δ : 1,46 (t, 3H, $J_{CH_3-CH_2}$ = 7,10 Hz, CH_3 de éthyle), 4,05 (s, 6H, OCH_3), 4,53 (q, 2H, *J* = 7,10 Hz, CH_2 de éthyle), 7,20 (s, 1H, H-5 ou H-8), 7,30 (s, 1H, H-8 ou H-5), 8,45 (s, 1H, H-4), 9,15 (s, 1H, H-1). Anal. calc. pour $C_{14}H_{15}NO_4$: C 64,35, H, 5,79, N, 5,36; tr. : C, 64,24, H 5,87, N 5,47.

*6,7-Diméthoxy-1-méthyl-isoquinoléine-3-carboxylate d'éthyle (****5****b)*

On dissout 0,01 mol de composé ***4****b* dans 40 mL d'éthanol absolu et ajoute une pointe de spatule d'éthylate de sodium et opère comme précédemment. Après départ de tout le solvant par évaporation sous vide de la trompe à eau, le résidu solide est repris par 20 mL d'acétone. Seul le composé ***4****b* y est soluble. Le produit ***5****b* insoluble est essoré et séché. Le rendement de la réaction est limité à 50%, mais le composé de départ ***4****b* non oxydé est récupéré et réengagé dans une nouvelle expérience. On peut ainsi par opérations successives obtenir un rendement global d'environ 80% en produit ***5****b*, *F* 170°C, ir, ν_{max} : 1710 (ester); rmn ^1H, δ : 1,48 (t, 3H, $J_{CH_3-CH_2}$ = 7,10 Hz, CH_3 de éthyle), 2,98 (s, 3H, CH_3-1), 4,02 (s, 3H, OCH_3), 4,05 (s, 3H, OCH_3), 4,51 (q, 2H, $J_{CH_2-CH_3}$ = 7,10 Hz, CH_2 de éthyle), 7,20 (s, 1H, H-5 ou H-8 , 7,35 (s, 1H, H-8 ou H-5), 8,32 (s, 1H, H-4). Anal. calc. pour $C_{15}H_{17}NO_4$: C65,44, H 6,22, N 5,09; tr. : C 65,35, H 6,36, N 5,12.

Sels d'isoquinoliniums ***6***

*Iodure de 6,7-diméthoxy-3-éthoxycarbonyl-*N*-méthylisoquinolinium (****6****a)*

Un mélange de 1,3 g (5 mmol) de composé ***5****a*, 15 mL d'acétone et 5 mL d'iodure de méthyle est agité à température ambiante pendant 12 h. Le précipité obtenu est filtré, lavé plusieurs fois à l'acétone et essoré. On obtient 1,1 g de produit (Rdt. 76%), *F* > 250°C; ir, ν_{max} : 1725 (ester); rmn ^1H (DMSO-d_6), δ : 1,42 (t, 3H, $J_{CH_3-CH_2}$ = 7,10 Hz, CH_3 de éthyle), 4,05 (s, 3H, OCH_3), 4,09 (s, 3H, OCH_3), 4,48 (q, 2H, $J_{CH_2-CH_3}$ = 7,10 Hz, CH_2 de éthyle), 4,58 (s, 3H, N-CH_3), 7,90 (s, 1H, H-5 ou H-8), 8,05 (s, 1H, H-8 ou H-5), 9,00 (s, 1H, H-4), 9,80 (s, 1H, H-1). Produit non analysé.

*Iodure de 6,7-diméthoxy-1-méthyl-3-éthoxycarbonyl-*N*-méthylisoquinolinium (****6****b)*

Dans un tube en verre épais de 100 mL, on introduit 2,75 g (0,01 mol) de composé ***5****b* et 20 mL d'iodure de méthyle. Le tube est scellé et chauffé à 140°C dans un bain d'huile pendant 12 h. Après refroidissement, on ouvre le tube, filtre, lave le solide plusieurs fois à l'acétone et essore. On obtient 3,67 g de produit (Rdt. 88%), *F* > 250°C; ir, ν_{max} : 1720 (ester); rmn ^1H, δ : 1,45 (t, 3H, $J_{CH_3-CH_2}$ = 7,10 Hz, CH_3 de éthyle), 3,30 (s, 3H, CH_3-1), 4,10 (s, 3H, OCH_3), 4,15 (s, 3H, OCH_3), 4,40 (s, 3H, N-CH_3), 4,50 (q, 2H, $J_{CH_2-CH_3}$ = 7,10 Hz), 7,90 (s, 1H, H-5 ou H-8), 7,95 (s, 1H, H-8 ou H-5), 8,70 (s, 1H, H-4). Produit non analysé.

*Réduction des sels d'isoquinolinium (****6****). Obtention des dérivés du 1,2-dihydro-6,7-diméthoxy-*N*-méthylisoquinoléine-3-carboxylate d'éthyle* **7**

Mode opératoire : On dissout 0,01 mol de composé **6** dans 100 mL d'une solution aqueuse d'éthanol à 50%. Sous agitation magnétique, on ajoute par petites portions 0,04 mol de $NaBH_4$. L'agitation est ensuite prolongée durant 4 h, puis l'éthanol est chassé par évaporation sous vide. Le résidu est repris par 100 mL d'une solution aqueuse à 10% d'acide acétique puis neutralisé par du carbonate de sodium et extrait trois fois avec 50 mL de chloroforme. Les extraits chloroformiques sont réunis, lavés à l'eau salée, séchés sur sulfate de sodium et évaporés sous vide. Le résidu huileux est repris par de l'éthanol dans lequel le produit **7** cristallise.

*1,2-Dihydro-6,7-diméthoxy-*N*-méthylisoquinoleine-3-carboxylate d'éthyle (****7****a)*

On obtient 2,54 g de produit (Rdt. 92%), *F* 152–153°C; ir, ν_{max} : 1725 (ester); rmn ^1H, δ : 1,45 (t, 3H, $J_{CH_3-CH_2}$ = 7,10 Hz, CH_3 de éthyle), 3,70 (s, 3H, N-CH_3), 4,00 (s, 3H, OCH_3), 4,05 (s, 3H, OCH_3), 4,10 (centre d'un syst. AB, 2H, J_{AB} = 15,9 Hz, CH_2-1), 4,40 (q, 2H, *J* = 7,10 Hz, CH_2 de éthyle), 6,70 (s, 1H, H-8), 6,90 (s, 1H, H-5), 7,80 (s, 1H, H-4). Anal. calc. pour $C_{15}H_{19}NO_4$: C 64,96, H 6,91, N 5,05; tr. : C 64,83, H 5,05, N 5,12.

*1,2-Dihydro-6,7-diméthoxy-1,2-diméthylisoquinoleine-3-carboxylate d'éthyle (****7****b)*

On obtient 2,76 g de produit (Rdt. 96%), *F* 80–82°C; ir, ν_{max} : 1720 (ester); rmn ^1H, δ : 1,40 (t, 3H, $J_{CH_3-CH_2}$ = 7,20 Hz, CH_3 de éthyle), 1,20 (d, 3H, J_{CH_3-H-1} = 6,80 Hz, CH_3-1), 2,80 (s, 3H, N-CH_3), 3,90 (s, 3H, OCH_3), 3,93 (s, 3H, OCH_3), 4,20 (q, 1H, *J* = 6,80 Hz, H-1), 4,30 (partie AB d'un système ABX_3 avec J_{AB} = 3,60 Hz et ^3J = 7,20 Hz, 2H, CH_2 de éthyle), 6,60 (s, 1H, H-8), 6,75 (s, 1H, H-5), 6,95 (s, 1H, H-4). Anal. calc. pour $C_{16}H_{21}NO_4$: C 65,96, H 7,27, N 4,81; tr. : C 65,83, H 7,32, N 4,91.

Réactions de cycloadditions

Dans un erlenmeyer bicol de 100 mL, on introduit 5 mmol de dipolarophile **7**, 5 mmol d'α-chloro-*para*-anisylidène-phénylhydrazone (précurseur de la nitrilimine **8**) et 30 mL de benzène anhydre. On chauffe ce mélange à reflux sous agitation magnétique en additionnant, en 15 min, 5 mL de triéthylamine. Le reflux est maintenu 24 h. Après retour à la température ambiante, on ajoute 20 mL de benzène, filtre le chlorhydrate de triéthylamine et chasse

For personal use only.

le solvant à l'évaporateur rotatif. Le résidu est repris par de l'éthanol et le cycloadduit cristallise.

1-para-*Anisyl-7,8-diméthoxy-4-méthyl-3-phényl-3a,4,5,9b-tétrahydropyrazolo[3,4-c]isoquinoléine-3a-carboxylate d'éthyle (**9**a)*

On obtient 1,33 g de cycloadduit (Rdt. 53%), *F* 100°C; ir, ν_{max} : 1730 (ester); rmn ^{1}H, δ : 0,98 (t, 3H, $J_{CH_3-CH_2}$ = 7,10 Hz, CH_3 de éthyle), 2,42 (s, 3H, N-CH_3), 3,52 (s, 3H, OCH_3), 3,61 (d, 1H, ^2J = 16 Hz, H-5), 3,81 (s, 3H, OCH_3), 3,84 (s, 1H, OCH_3), 4,02 (q, 2H, *J* = 7,10 Hz, CH_2 de éthyle), 4,59 (d, 1H, ^2J = 16 Hz, H'-5), 5,12 (s, 1H, H-9b), 6,50–7,80 (m, 11H arom.); rmn ^{13}C, δ : 13,55 (q, *J* = 127 Hz, CH_3 de éthyle), 37,85 (q, *J* = 135,1 Hz, N-CH_3), 45,55 (d, *J* = 140,1 Hz, C-9b), 51,55 (t, *J* = 137,5 Hz, C-5), 52,25 (q, *J* = 144 Hz, OCH_3), 55,45 (q, *J* = 144,1 Hz, OCH_3), 55,65 (q, *J* = 144,5 Hz, OCH_3), 61,40 (t, *J* = 149,5 Hz, CH_2 de éthyle), 91,95 (s, C-3a), 110–160,15 (15 signaux de carbones aromatiques), 168 (s, C=O ester). Anal. calc. pour $C_{29}H_{31}N_3O_5$: C69,44, H 6,23, N 8,38; tr. : C 69,36, H 6,32, N 8,29.

1-para-*Anisyl-7,8-diméthoxy-4,5-diméthyl-3-phényl-3a,4,5,9b-tétrahydropyrazolo[3,4-c]isoquinoléine-3a-carboxylate d'éthyle (**9**b)*

On obtient 1,88 g de cycloadduit (Rdt. 73%), *F* 137°C; ir, ν_{max} : 1740 (ester); rmn ^{1}H, δ : 0,94 (t, 3H, $J_{CH_3-CH_2}$ = 7,10 Hz, CH_3 de éthyle), 1,62 (d, 3H, $J_{CH_3-H\text{-}5}$) = 6,95 Hz, CH_3-5), 2,05 (s, 3H, N-CH_3), 3,51 (s, 3H, OCH_3), 3,87 (s, 3H, OCH_3), 3,90 (s, 3H, OCH_3), 4,04 (partie AB d'un système ABX_3, 2H, J_{AB} = 2,9 Hz, ^3J = 7,10 Hz, CH_2 de éthyle), 4,12 (q, 1H, *J* = 6.95 Hz, H-5), 4,85 (s, 1H, H-9b), 6,70–7,80 (m, 11H arom.); rmn ^{13}C, δ : 13,60 (q, *J* = 127 Hz, CH_3 de éthyle), 18,30 (q, *J* = 127,1 Hz, CH_3-5), 33,15 (q, *J* = 135,2 Hz, N-CH_3), 50,75 (d, *J* = 136,2 Hz, C-9b), 55,75 (d, *J* = 135,8 Hz, C-5), 55,20 (q, *J* = 144 Hz, OCH_3), 55,30 (q, *J* = 144,2 Hz, OCH_3), 55,70 (q, *J* = 143,9 Hz, OCH_3), 61,40 (t, *J* = 145 Hz, CH_2 de éthyle), 90,25 (s, C-3a), 108,9–160 (15 signaux de carbones aromatiques), 169,9 (s, C=O ester). Anal. calc. pour $C_{30}H_{33}N_3O_5$: C 69,88, H 6,45, N 8,15; tr. : C 71,02, H 6,37, N 8,22.

*Saponification du cycloadduit **9**. Obtention de la 1*-para-*anisyl-8,9-diméthoxy-5-méthyl-3-phényl-5,6-dihydro-4H-pyrazolo[3,4-c]benzo(e)azepin-4-one (**10**a)*

On dissout 0,5 g (1 mmol) de cycloadduit **9***a* dans 30 mL d'une solution méthanolique de potasse 2 N. Le mélange est porté à reflux pendant 1 h. On laisse refroidir et verse dans 200 mL d'eau. Le précipité est filtré, lavé à l'eau, essoré et recristallisé dans l'éthanol. On obtient 0,26 g de produit (Rdt. 58%), *F* 234°C; ir, ν_{max} : 1635 (lactame); rmn ^{1}H, δ : 3,15 (s, 3H, N-CH_3), 3,49 (s, 3H, OCH_3), 3,83 (s, 3H, OCH_3), 3,94 (s, 3H, OCH_3), 4,05 (d, 1H, ^2J = 14,20 Hz, H-6), 4,75 (d, 1H, ^2J = 14,20 Hz, H'-6), 6,90–7,70 (m, 11H arom.). Anal. calc. pour $C_{27}H_{25}N_3O_4$: C 71,19, H 5,53, N 9,23; tr. : C 71,27, H 5,47, N 9,05.

*Hydrolyse acide du cycloadduit **9**a. Obtention du 4-(4,5-diméthoxy-2-*N*-méthylaminométhylphényl)-3-*para*-anisyl-1-phényl-pyrazole-5-carboxylate d'éthyle (**11**a)*

Une solution de 1 g (2 mmol) de cycloadduit **9***a* dans 20 mL d'acide acétique est portée à léger reflux durant 1 h. Après refroidissement, la solution est versée dans 250 mL d'eau, neutralisée par du bicarbonate de sodium solide puis extraite trois fois avec 50 mL de chloroforme. Les phases organiques sont réunies, laveés à l'eau et séchées sur Na_2SO_4. Après évaporation le résidu est cristallisé dans l'éthanol. On obtient 0,55 g de produit (Rdt. 55%), *F* 200°C; ir, ν_{max} : 3400 (NH), 1710 (ester); rmn ^{1}H, δ : 0,90 (t, 3H, $J_{CH_3-CH_2}$ = 7,10 Hz, CH_3 de éthyle), 2,25 (s, 3H, N-CH_3), 3,90–4,10 (m, 4H, CH_2 de éthyle et N-CH_2), 3,76 (s, 3H, OCH_3), 3,87 (s, 3H, OCH_3), 4,05 (s, 3H, OCH_3), 6,70–7,70 (m, 11 H arom.). Anal. calc. pour $C_{29}H_{31}N_3O_5$: C 69,44, H 6,23, N 8,38; tr. : C 69,52, H 6,37, N 8,26.

La saponification de ce composé **11***a* dans les mêmes conditions que celles décrites pour le cycloadduit **9***a* conduit à l'azépinone **10***a* avec un rendement de 65%.

*Acétylation du composé **11**a. Obtention du 4-(2-*N*-acétyl-N-méthylaminométhyl-4,5-diméthoxyphényl)-3-*para*-anisyl-1-phényl-pyrazole-5-carboxylate d'éthyle (**12**a)*

À un mélange de 1 mmol (0,5 g) de composé **11***a* et 1 mmol de pyridine, on ajoute lentement et sous agitation 1 mmol de chlorure d'acétyle. L'agitation est ensuite prolongée pendant 12 h à température ambiante et on ajoute de la glace sur le mélange réactionnel. On additionne ensuite du bicarbonate de sodium pour atteindre pH 10 et laisse reposer 24 h. Le solide formé est filtré, lavé à l'eau, essoré et purifié par cristallisation dans l'éthanol. On obtient 0,43 g de produit (Rdt. 79%), *F* 90°C; ir, ν_{max} : 1720 (ester), 1640 (amide); rmn ^{1}H (certains signaux sont dédoublés par suite de l'existence de deux rotamères), δ : 0,90 (t, 3H, $J_{CH_3-CH_2}$ = 7,00 Hz, CH_3 de éthyle), 1,83 et 1,98 (2s pour 3H, $COCH_3$), 2,54 et 2,73 (2s pour 3H, N-CH_3), 3,77, 3,86 et 3,92 (3s pour 9H, 3 groupes OCH_3), 4,05 (partie AB d'un système ABX_3, 2H, J_{AB} = 16 Hz et ^3J = 7 Hz, CH_2 de éthyle), 4,30 (centre d'un système AB, 2H, J_{AB} = 16,70 Hz, N-CH_2), 6,60–7,60 (m, 11H arom.). Anal. calc. pour $C_{31}H_{33}N_3O_6$: C 68,49, H 6,12, N 7,73; tr. : C 68,58, H 5,96, N 7,67.

*Saponification du composé **12**a. Obtention de l'acide 4-(2-*N*-acétyle-N-méthylaminométhyl-4,5-diméthoxyphényl)-3-*para*-anisyl-1-phénylpyrazole-5-carboxylique (**13**a)*

À une solution de 1 mmol de composé **12***a* (0,545 g) dans 20 mL de méthanol, on ajoute 10 mL d'une solution méthanolique de potasse 2 N. Le mélange est porté à reflux pendant 1 h. Après élimination du solvant à l'évaporateur rotatif, on reprend à l'eau et acidifie par HCl à 10%. Le précipité est filtré, lavé et séché. On obtient 0,51 g de produit (Rdt. quantitatif), *F* >250°C; ir, ν_{max} : 1710 (acide), 1640 (amide); rmn ^{1}H (certains signaux sont dédoublés par suite de l'existence de deux rotamères), δ : 1,75 et 1,90 (2s pour 3H, $COCH_3$), 2,50 et 2,70 (2s pour 3H, N-CH_3), 3,80, 3,86 et 3,90 (3s pour 9H, 3 groupes OCH_3), 3,95–4,45 (m pour 2 syst. AB imbriqués, N-CH_2), 6,50–7,60 (m, 11H arom.), 8,80 (sl, OH de CO_2H). Anal. calc. pour $C_{29}H_{29}N_3O_6$: C 67,55, H 5,65, N 8,15; tr. : C 67,73, H 5,88, N 8,23.

*Décarboxylation de l'acide **13**a. Obtention du 4-(2-*N*-acétyl-N-méthylaminométhyl-4,5-diméthoxyphényl)-3-*para*-anisyl-1-phénylpyrazole (**14**a)*

Dans un ballon à fond rond de 20 mL, on place 0,51 g d'acide **13***a* (1 mmol) et à l'aide de la flamme d'un bec Bunsen, on le porte à fusion et chauffe (avec attention pour éviter tout charbonnement) jusqu'à cessation du dégagement de dioxyde de carbone. Le produit restant est repris par de l'éthanol après refroidissement et cristallise. On obtient 0,335 g de produit (Rdt. 71%); ir, ν_{max} : 1635 (amide); rmn ^{1}H (certains signaux sont dédoublés par suite de l'existence de deux rotamères), δ : 1,80 et 2,05 (2s pour 3H, $COCH_3$), 2,60 et 2,75 (2s pour 3H, N-CH_3), 3,80, 3,85 et 3,95 (3s pour 9H, 3 groupes OCH_3), 4,15 et 4,40 (2s pour 2H, N-CH_2), 6,60–7,80 (m, 11H arom.), 7,90 (s, 1H, H-5). Anal. calc. pour $C_{28}H_{29}N_3O_4$: C 71,32, H 6,20, N 8,91; tr. : C 71,47, H 6,02, N 8,78.

BRIGITTE DUTHU, KARIM EL ABED, DOURAID HOUALLA, ROBERT WOLF et JOËL JAUD. Can. J. Chem. **70**, 809 (1992).

La sulfuration de l'organophosphoré tricyclique dimère **2** conduit facilement au dérivé tricyclique disoufré **3**. Ce dernier a été caractérisé par RMN ^{31}P, ^{1}H et ^{13}C, analyse élémentaire et spectrométrie de masse. Sa structure cristalline et moléculaire a été établie par diffraction des rayons X et comparée à celle de **2** qui avait été déterminée précédemment. L'utilisation conjointe des données de RMN et de diffraction des rayons X a permis de bien préciser la structure moléculaire des deux composés. Une estimation chiffrée de l'ouverture du cône d'anisotropie de la double liaison P═S est proposée.

Mots clés : phosphécine, RMN, rayons X, tricycle.

BRIGITTE DUTHU, KARIM EL ABED, DOURAID HOUALLA, ROBERT WOLF, and JOËL JAUD. Can. J. Chem. **70**, 809 (1992).

The sulfuration of the tricyclic organophosphorus dimer **2** leads easily to the dithiotricyclic derivative **3**, which has been characterized by ^{31}P, ^{1}H, and ^{13}C NMR, elemental analysis, and mass spectroscopy. Its crystal and molecular structure has been established by X-ray diffraction and compared to that of **2**, which was previously determined. The comparative analysis of X-ray diffraction and NMR parameters gives accurate information about the molecular structure of both compounds. A numerical value of the anistropy cone of the P═S double bond is proposed.

Key words: phosphecine, NMR, X-ray, tricycle.

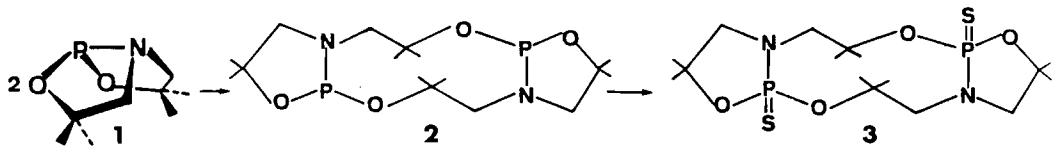
Introduction

Dans un article précédent, nous avons décrit la structure cristalline et moléculaire de l'octahydro-2,2,6,6,10,10,14,14-octaméthyl bis-1,2,3-oxazaphospholo[2,3-*b* : 2′,3′-*g*]-1,6,3,8,2,7-dioxadiazadiphosphécine **2** (1) qui résulte de la dimérisation, par rupture–fermeture d'une liaison P—O, du bicyclophosphane[3] **1**.



La formation spontanée, à la température ambiante, de ce dimère traduit, à notre sens, le relâchement de la contrainte inhérente à la géométrie en forme de toit à double pente adoptée par le bicyclophosphane **1** ainsi que par tous les composés de cette famille (2, 3).

Parmi les différentes réactions (alcoolyse, acidolyse . . .) conduites avec le composé **2** la sulfuration donne très facilement le dérivé soufré **3** dont nous avons établi la structure cristalline et moléculaire par diffraction des rayons X.

Dans cet article nous décrivons cette structure et la comparons à celle de **2**. Nous présentons également une étude comparative des données de diffraction des rayons X et des paramètres de RMN (^{1}H et ^{13}C) des deux composés qui nous permet de compléter notre connaissance de leurs structures moléculaires.

Résultats et discussion

L'action du soufre élémentaire, en quantité équimoléculaire, sur le dimère **2** a lieu en solution dans le toluène. Dès la dissolution totale du soufre, le spectre de RMN ^{31}P de cette solution montre la disparition du signal à $\delta\ ^{31}P = 140$ ppm dû au dimère **2** et son remplacement par un pic unique à $\delta = 71{,}5$ ppm. Une légère concentration de la solution laisse déposer un solide incolore dont le spectre de masse (ionisation chimique par NH_3) montre la présence du pic parent à $m/e^+ = 443$ MH^+ qui est également le pic de base (100%). Ce solide a été, en outre, entièrement caractérisé par analyse élémentaire et RMN (^{1}H et ^{13}C). Une recristallisation soignée dans le toluène sec nous a fourni des cristaux convenables pour l'étude cristallographique par diffraction des rayons X.

Structure

La maille cristalline de **3** contient deux types de molécules cristallographiquement indépendantes dans le rapport de 2 : 1. L'entité majoritaire **3***a* ne possède aucun élément de symétrie; les paramètres structuraux comme les longueurs et

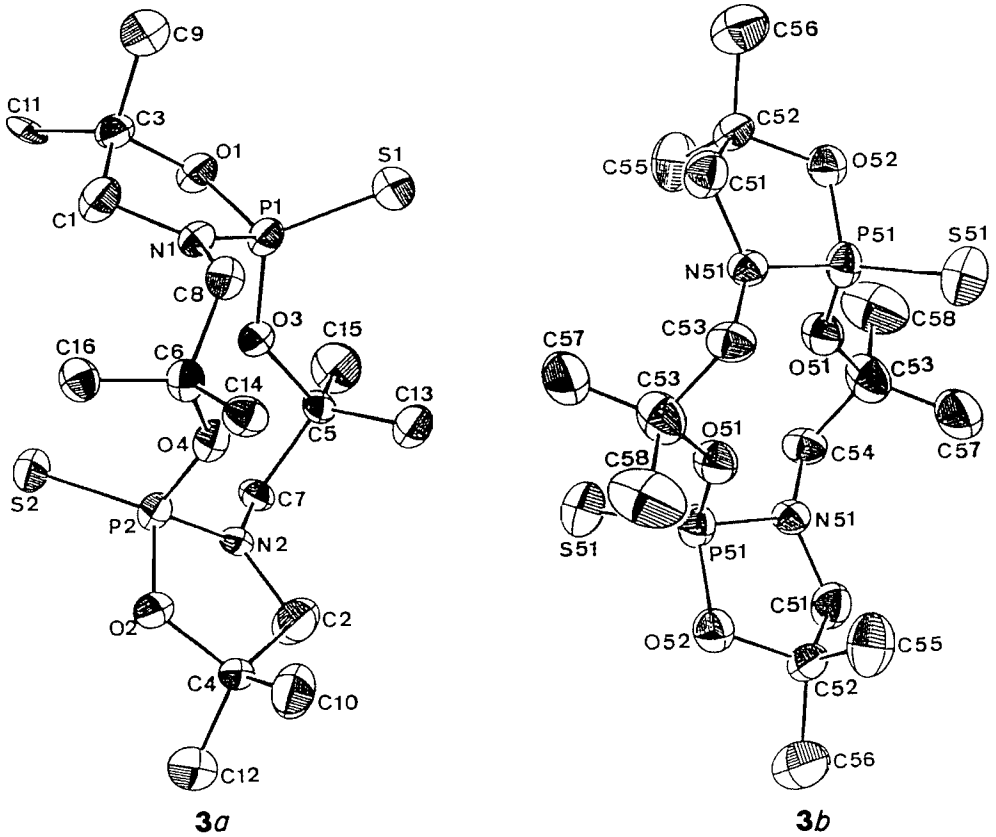

FIG. 1. Représentation ORTEP des 2 molécules présentes dans la maille cristalline de **3**. **3***a* : molécule sans aucune symétrie. **3***b* : molécule centrosymétrique. Pour des raisons de clarté les atomes d'hydrogène ont été omis.

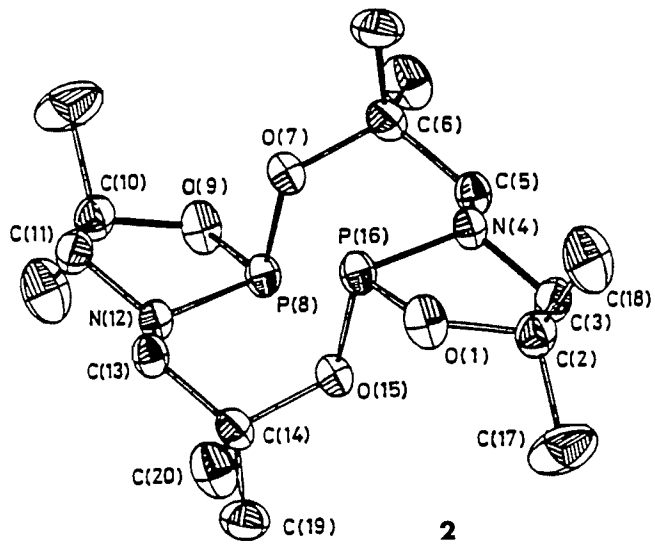

FIG. 2. Représentation ORTEP du dimère **2** extraite de la référence 1.

les angles des liaisons sont tous singuliers. En revanche, l'entité minoritaire **3***b* est, comme le dimère **2** (1), centrosymétrique et s'organise autour d'un centre de symétrie cristallographique. La figure 1 montre une vue perspective de ces deux molécules, les atomes d'hydrogène ayant été omis pour des raisons de clarté. Dans la figure 2, nous avons reproduit une vue perspective du dimère **2**; elle nous permettra de suivre les transformations intervenues suite à la sulfuration.

Les cycles à cinq chaînons P(1)O(1)C(3)C(1)N(1) et P(2)O(2)C(4)C(2)N(2) de **3***a* et les deux cycles analogues P(51)O(52)C(52)C(51)N(51) de **3***b* adoptent tous une forme enveloppe. Dans le premier et les troisièmes, les atomes de carbone en α de l'atome d'oxygène, à savoir C(3) et C(52), sont à la pointe des rabats alors que dans le second, c'est l'atome de carbone C(2) en α de l'atome d'azote qui occupe cette position. Rappelons que dans le composé **2**, les cycles à cinq chaînons homologues adoptent eux aussi une forme enveloppe avec l'atome de carbone C(3) en α de l'atome d'azote à la pointe de rabat (1). Le cycle à dix chaînons N(1)P(1)O(3)C(5)C(7)N(2)P(2)O(4)C(6)C(8) de **3***a* ne peut être décrit par aucune forme géométrique simple alors que celui de **3***b* formé par les atomes N(51)P(51)O(51)C(53)C(54) et leurs homologues cristallographiques adopte, comme dans le dimère **2**, une forme bateau–chaise–bateau.

La sulfuration de **2** se traduit par une augmentation sensible de la somme des trois angles intracycliques des liaisons autour du phosphore en pont : cette valeur passe de 293,7° dans **2** (1) à 315,3° autour de P(1), 314,5° autour de P(2) et 311,4° autour de P(51). Cette modification est tout à fait conforme à ce qui est attendu quand la coordination de l'atome de phosphore passe de 3 à 4. Dans le même temps, la somme des angles des liaisons autour de l'atome d'azote, qui était de 344,7° dans **2** (1) atteint 359,9° autour de N(1), 360° autour de N(2) et 353,9° autour de N(51). Par comparaison avec la valeur de 322,4° trouvée dans le double ad-

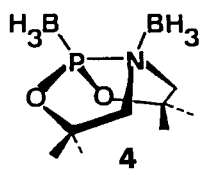
H'(5)[a]	3,25	$^3J_{H'(5)P}$ = 10,6 $^4J_{H'(5)P}$ = 1,5	H(254)	3,81 (dd)	$^2J_{H(254)H(154)}$ = 14,7 $^3J_{H(254)P}$ = 10,6

[a]H(5) et H'(5) constituent la partie AB d'un système ABX (X = P).

duit **4** (4) on voit bien que le relâchement de la contrainte due à la double cyclisation a permis à l'atome d'azote de retrouver la conformation plane qu'il a généralement quand il est directement lié à l'atome de phosphore.



4

Étude RMN

RMN ^1H

Les spectres de RMN ^1H de **2**[4] et de **3** correspondent à des molécules symétriques : dans les deux composés les huit substituants CH_3 et les quatre groupements N-CH_2 donnent respectivement naissance à quatre et deux signaux seulement. Dans le cas de **2**, ceci veut dire qu'à la température d'enregistrement des spectres (24°C) la conformation moyenne, vue en RMN, est compatible avec la structure moléculaire déterminée par diffraction des rayons X. Il en est de même pour **3**. En effet, la conformation asymétrique **3***a*, présente dans la maille cristalline, diffère très peu de la conformation centrosymétrique **3***b*. Sa distorsion est très probablement due à l'asymétrie de l'empilement, laquelle va disparaître lors du passage en solution.

L'analyse complète des ces spectres fournit les paramètres rassemblés dans le tableau 1. Un examen comparatif de ces données permet les remarques et commentaires suivants :

(*i*) Parmi les quatre groupes CH_3 du dimère **2**, il en existe un (δ = 1,62 ppm) qui présente un couplage $^4J_{H\text{-}C\text{-}C\text{-}O\text{-}P}$ de 1,8 Hz avec le phosphore. L'examen d'un modèle moléculaire montre que la conformation enveloppe du cycle à cinq chaînons avec l'atome de carbone C(3) à la pointe du rabat (1) ne permet à aucun substituant CH_3 de ce cycle de se trouver dans la position spatiale communément requise (planéité des quatre liaisons concernées, règle de M), pour qu'un tel couplage existe. En revanche un des substituants CH_3 du cycle à dix chaînons peut très bien occuper cette position spatiale compte tenu de la forme bateau–chaise–bateau de ce cycle. Cette analyse est confirmée par l'exploitation des données de diffraction des rayons X qui montre que les quatre atomes P(16), O(15), C(14) et C(19) se trouvent dans un plan qui contient un des protons portés par C(19). Il nous paraît raisonnable d'attribuer le signal à δ = 1,61 ppm au second substituant CH_3 du carbone C(14). Il en résulte que les pics à δ = 1,36 ppm et δ = 1,44 ppm sont attribuables aux deux groupes CH_3 portés par l'atome de carbone C(2).

Dans le dimère **3**, les 4 groupes CH_3 donnent naissance à 4 signaux dont aucun n'est dédoublé par couplage lointain avec le phosphore. Par comparaison avec **2**, nous attribuons les pics les plus déblindés à δ = 1,47 ppm et δ = 1,83 ppm aux substituants CH_3 du cycle à 10 chaînons et, par conséquent, les pics à δ = 1,40 ppm et δ = 1,35 ppm aux substituants CH_3 du cycle à 5 chaînons.

(*ii*) Il existe dans chacun des composés **2** et **3**, un seul groupe de protons NCH_2 dans lequel un des deux protons présente un couplage supplémentaire, à travers quatre liaisons, avec le phosphore : H'(5) pour **2**, $^4J_{H\text{-}C\text{-}C\text{-}O\text{-}P}$ = 1,5 Hz; H(154) pour **3**, $^4J_{H\text{-}C\text{-}C\text{-}O\text{-}P}$ = 7,1 Hz. Il est évident que ce groupe appartient obligatoirement au cycle à dix chaînons. En effet, les protons NCH_2 du cycle à cinq chaînons ne peu-

[4]L'étude détaillée des spectres de RMN (^1H et ^{13}C) de **2** n'avait pas été effectuée lors de la description de sa structure cristalline et moléculaire (1).

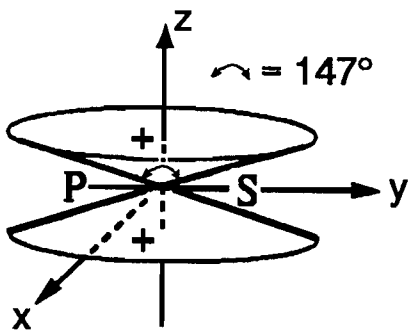
3

2			**3**		
Carbone	δ (ppm)	*J* (Hz)	Carbone	δ (ppm)	*J* (Hz)
C(19)	28,0 (d)	$^3J_{C\text{-}C\text{-}O\text{-}P}$ = 22,3	C(57)	25,6(d)	$^3J_{C\text{-}C\text{-}O\text{-}P}$ = 2,3
C(20)	28,9 (d)	$^3J_{C\text{-}C\text{-}O\text{-}P}$ = 4,3	C(55) ou(58)	27,7 (s)	
C(17) ou(18)	30,0 (s)		C(58) ou(55)	28,1 (s)	
C(18) ou(17)	30,2 (s)		C(56)	28,3 (d)	$^3J_{C\text{-}C\text{-}O\text{-}P}$ = 7,6
C(5)C(13)	59,5 (dd)	$^2J_{C\text{-}N\text{-}P}$ = 7,5 $^3J_{C\text{-}C\text{-}O\text{-}P}$ = 9,8	C(54)	58,2 (dd)	$^2J_{C\text{-}N\text{-}P}$ = 7,5 $^3J_{C\text{-}C\text{-}O\text{-}P}$ = 8,2
C(3)C(11)	62,9 (d)	$^2J_{C\text{-}N\text{-}P}$ = 4,5[a]	C(51)	62,2 (d)	$^2J_{C\text{-}N\text{-}P}$ = 14,3[a]
C(6)C(14)	76,7 (d)	$^2J_{C\text{-}O\text{-}P}$ = 6,1	C(53)	82,1 (d)	$^2J_{C\text{-}O\text{-}P}$ = 4
C(2)C(10)	83,4 (d)	$^2J_{C\text{-}O\text{-}P}$ = 9,4[b]	C(52)	84,8 (d)	$^2J_{C\text{-}O\text{-}P}$ = 10,2[b]

[a]Ces valeurs sont, en fait, la moyenne des constantes de couplage $^2J_{C\text{-}N\text{-}P}$ et $^3J_{C\text{-}C\text{-}O\text{-}P}$.
[b]De même ces valeurs sont la moyenne de $^2J_{C\text{-}O\text{-}P}$ et de $^3J_{C\text{-}C\text{-}N\text{-}P}$.

vent pas avoir d'autre couplage que $^3J_{H\text{-}C\text{-}N\text{-}P}$ car le nombre de liaisons qui les séparent du second noyau de phosphore est égal à six. En fait les données de rayons X montrent que les quatre atomes P(51), O(51), C(53) et C(54) se trouvent bien dans un plan qui contient un des protons liés à C(54) alors que les atomes analogues de **2**, à savoir P(16), O(15), C(14) et C(13), ne sont pas coplanaires. Toutefois il faut signaler que la détermination de la structure de **2** par diffraction des rayons X a été effectuée à −50°C alors que celle de **3** l'a été à la température ambiante. Il est vraisemblable qu'à la température d'enregistrement des spectres de RMN (24°C) la flexibilité du cycle à dix chaînons de **2** soit telle que les quatre atomes P(16), O(15), C(15) et C(13) puissent se trouver en moyenne dans un plan qui contienne un des protons liés à C(13), ce qui expliquerait le couplage $^4J_{H\text{-}C\text{-}C\text{-}O\text{-}P}$ observé.



Le passage du dimère **2** à son dérivé soufré **3** se traduit par des variations importantes des déplacements chimiques des substituants CH_3 et des protons NCH_2 du cycle à dix chaînons. Pour les deux groupements CH_3 nous assistons à un blindage de 0,14 ppm de l'un (δ passe de 1,61 ppm à 1,47 ppm) et à un déblindage de 0,21 ppm de l'autre (δ passe de 1,62 ppm à 1,83 ppm). Le même phénomène s'observe avec les protons NCH_2 : celui qui est couplé à travers quatre liaisons avec le phosphore, H(154), subit un blindage de 1,13 ppm (δ passe de 3,25 ppm à 2,12 ppm) alors que l'autre proton NCH_2 est déblindé de 0,81 ppm (δ passe de 3,00 ppm à 3,81 ppm). Il est clair que ces variations sont attribuables aux effets d'anisotropie résultant du remplacement du doublet libre du phosphore dans **2** par la double liaison P═S. Connaissant les positions spatiales des protons H(154) et H(254) qui subissent ces effets, nous pouvons estimer à 147° ± 12[5] la valeur de l'ouverture de la zone de blindage du cône P═S.

RMN ^{13}C

L'analyse des spectres de RMN ^{13}C de **2** et de **3** apporte quelques précisions complémentaires.

Dans chaque composé les signaux correspondant aux quatre groupes CH_3 se présentent comme deux doublets et deux singulets (voir tableau 2). Pour l'attribution de ces signaux, nous nous sommes appuyés sur les données structurales fournies par la diffraction des rayons X. En effet, il est connu que la constante de couplage $^3J_{C\text{-}C\text{-}O\text{-}P}$ obéit à une loi comparable à la loi de Karplus relative à la constante de couplage $^3J_{H\text{-}C\text{-}C\text{-}H}$ (5). Dans le dimère **2**, les quatre angles dièdres concernés sont : P(16)—O(1)—C(2)—C(17) = 124,6°(8), P(16)—O(1)—C(2)—C(18) = 115,4°(8), P(16)—O(15)—C(14)—C(19) = −177,9°(8) et P(16)—O(15)—C(14)—C(20) = −59.6°(8). L'attribution de la grande constante de couplage 22,3 Hz au carbone C(19) (δ = 28,0 ppm) paraît cohérente. Le fait qu'en RMN ^1H les

[5]Les valeurs extrêmes de cet angle ont été obtenues en calculant l'angle entre la perpendiculaire à la liaison P—S menée en son milieu I et la droite IH(154) d'une part, et la droite IH(254) d'autre part.[6]

[6]À notre connaissance, il n'existe, dans la littérature, aucune valeur chiffrée de l'ouverture du cône d'anisotropie de la double liaison P═S.

m = nombre de réflexions
n = nombre de paramètres affinés
w = schéma de pondération avec poids unitaire

déplacements chimiques des substituants CH_3 portés par le même cycle soient voisins (voir tableau 2) nous incite à considérer qu'il en est de même en RMN ^{13}C. Il en résulte que le signal à δ = 28,9 ppm avec $^3J_{C\text{-}C\text{-}O\text{-}P}$ = 4,3 Hz peut être attribué au noyau de carbone C(20). Dans le composé **3**, les angles dièdres homologues sont : P(51)—O(52)—C(52)—C(55) = −91,1°(8), P(51)—O(52)—C(52)—C(56) = −147,6°(8), P(51)—O(51)—C(53)—C(57) = 43,7°(8) et P(51)—O(51)—C(53)—C(58) = 78,7°(8). Nous attribuons la constante de couplage de 7,6 Hz au carbone C(56) et celle de 2,3 Hz au carbone C(57). On peut remarquer que dans le dimère **2**, les deux noyaux de carbone méthyliques couplés avec le phosphore appartiennent tous les deux au cycle à cinq chaînons, alors que dans son dérivé soufré **3**, l'un appartient au cycle à cinq chaînons, l'autre au cycle à dix chaînons. Il est probable que cette différence est liée à la modification de la position du rabat du cycle à cinq chaînons en passant de **2** à **3** : dans **2** le rabat de l'enveloppe est situé sur l'atome de carbone en α de l'atome d'azote alors que dans **3** il est situé sur l'atome de carbone tertiaire en α de l'atome d'oxygène.

La forme doublet de doublet des signaux à δ = 59,5 ppm dans le spectre de **2** et δ = 58,2 ppm dans celui de **3**, permet d'attributer ces pics aux noyaux de carbone en α de l'atome d'azote des cycles à dix chaînons. Il en résulte que les doublets à δ = 62,9 et 62,2 ppm sont respectivement attribuables aux noyaux de carbone C(3) C(11) de **2** et C(51) de **3**. Le blindage observé en passant du cycle à cinq chaînons au cycle à dix chaînons permet de parachever cette analyse. Les doublets à δ = 76,7 ppm et δ = 83,4 ppm dans le spectre de **2** sont respectivement attribuables aux noyaux C(6) C(14) et C(2) C(10). De même, les doublets à δ = 82,1 ppm et δ = 84,8 ppm dans celui de **3** sont respectivement attribuables aux noyaux de carbone C(53) et C(52). Les déplacements chimiques des noyaux de carbone des cycles à cinq chaînons sont en accord avec les valeurs relevées pour les mêmes noyaux de carbone dans le monomère **1** (6).

Conclusion

Au cours de ce travail nous avons effectué une étude comparative du dimère **2** et de son dérivé soufré **3** à l'aide de la diffraction des rayons X et de la RMN (^{31}P, ^1H et ^{13}C). Le rapprochement des données fournies par ces deux méthodes nous a permis d'avoir une connaissance très précise des structures moléculaires de ces deux composés. Nous avons pu, en particulier, fournir une appréciation chiffrée de l'ouverture du cône d'anisotropie lié à la liaison double P═S.

Partie expérimentale

Méthodes spectroscopiques

Les spectres de RMN ^{31}P, ^1H et ^{13}C ont été enregistrés avec différents spectromètres Bruker : AC 80, WM 250 et AM 300 WB. Les déplacements chimiques, exprimés en parties par million du champ inducteur (ppm), sont mesurés avec une précision de ±0,02

[a]Les atomes affinés anisotropiquement sont donnés sous la forme d'équivalents isotropiques définis ainsi au moyen des paramètres de la maille : $B_{eq} = 4/3[a^2B(1,1) + b^2B(2,2) + c^2B(3,3) + ab(\cos\gamma)B(1,2) + ac(\cos\beta)B(1,3) + bc(\cos\alpha)B(2,3)]$.

ppm pour ^{1}H et ±0,03 ppm pour ^{31}P et ^{13}C (références : tétraméthylsilane, TMS, ^{1}H et ^{13}C; H_3PO_4 à 85% pour ^{31}P). Les constantes de couplage, exprimées en Hz, sont mesurées avec une précision de ±0,2 Hz pour ^{1}H et ±0,5 Hz pour ^{13}C. La résolution complète des spectres a été parachevée par des expériences de découplage homonucléaire proton–proton et hétéronucléaire proton–phosphore, carbone–proton et carbone–phosphore. Le spectre de masse a été obtenu avec un spectromètre Nermag R10 utilisant l'ionisation chimique par NH_3.

Données cristallographiques

Les paramètres et le groupe spatial du composé **3** ont été déterminés à l'aide d'un diffractomètre automatique quatre cercles Enraf–Nonius du type CAD 4, également utilisé pour la collection des données (25 réflexions situées dans une couronne de 12° à 14° en angle de Bragg ont servi à déterminer la maille du cristal mesuré).

Les données cristallographiques et les conditions de mesure et d'affinement sont regroupées dans le tableau 3.

Aucune correction de décroissance d'intensité n'a été nécessaire, les taches choisies comme étalons étant restées stables au cours du temps (variation moyenne inférieure à 3%). Les données ont été corrigées des facteurs de Lorentz et de la polarisation. L'examen des taches azimuthales n'ayant pas montré de variation significative lors de la rotation autour du vecteur de diffusion, la correction d'absorption a été négligée.

La structure a été déterminée par utilisation des méthodes directes (7) (MULTAN 1982). L'ensemble des calculs cristallographiques a été effectué sur VAX 730 de Digital en utilisant la chaîne SDP de Frenz (8). Cette détermination montre la présence dans la maille de six molécules; deux d'entre elles s'organisent autour d'un centre de symétrie (la notation appliquée commence par l'atome P(51)) tandis que les quatre autres molécules sont situées en position générale dans la maille (la numérotation débute par l'atome P(1)).

L'affinement des paramètres d'agitation thermique et des positions de l'ensemble des atomes a été effectué, avant de localiser les atomes d'hydrogène, par séries de Fourier différence. Après avoir été recalculée afin de fixer les distances C—H à 0,97 Å, l'agitation thermique des atomes d'hydrogène a été prise telle que $B_{iH} = 1{,}2\ B_{iC}$. Les positions et l'agitation thermique de ces atomes ont alors été fixées, leurs contributions étant seulement introduites dans le calcul. Dans ces conditions la valeur du facteur d'accord est de 0,057.

Pour tous les atomes, les facteurs de diffusion sont ceux mentionnés par Cromer et Waber (9). La diffusion anomale des atomes de phosphore, soufre, oxygène et azote utilise les valeurs des tables internationales (Cromer et Liberman (10)). À l'issue du dernier affinement la série différence finale n'a montré aucun résidu significatif, les valeurs extrêmes des densités électroniques étant de −0,4 et de +0,3 électron.

Au dernier tour d'affinement la valeur maximum du rapport Δ/σ est de 0,075 et la moyenne est d'environ 0,03.

Les coordonnées atomiques et les facteurs d'agitation thermique équivalents des atomes semi-lourds sont regroupés dans le tableau 4,[7] tandis que la numérotation de ces mêmes atomes est indiquée sur les représentations perspectives des molécules (ORTEP) (11). Les distances et angles interatomiques sont regroupés dans les tableaux 5 et 6.

Préparation de **3**

L'octahydro-2,2,6,6,10,10,14,14-octaméthyl bis-1,2,3 thiooxazaphospho[2,3-*b* : 2′,3′-*g*]-1,6,3,8,2,7 dioxadiazadiphosphécine **3** a été obtenu de la façon suivante.

À une solution de 95 mg ($2{,}5 \times 10^{-4}$ mol) du dimère **2** dans 2 mL de toluène, on ajoute 16 mg (5×10^{-4} mol) de fleur de soufre. La dissolution totale de ce dernier nécessite 30 min de chauffage à 40°C. Le spectre de RMN ^{31}P du mélange réactionnel montre alors la présence d'un signal unique à $\delta\ ^{31}P = 71{,}5$ ppm correspondant au dérivé soufré **3**. Une légère concentration de la solution laisse déposer un solide blanc qui a été lavé à l'hexane et séché sous vide. PF = 180°C. La pureté du produit a été vérifiée par RMN (voir les tableaux 1 et 2), spectrométrie de masse (ionisation chimique NH_3) et analyse élémentaire. SM (intensité relative) : 445 (10,9), 444 (24,4), 443 (100) MH^+. Anal. calcd. pour $C_{16}H_{32}N_2O_4P_2S_2$: C 43,4; H 7,29; N 6,33; trouvé : C 43,42; H 7,34; N 6,26. Une recristallisation dans le toluène a fourni les cristaux qui ont servi à la diffraction des rayons X.

[7]Les tableaux des amplitudes des facteurs de structure, des facteurs d'agitation thermique et des équations des principaux plans moyens sont disponibles. On peut les acheter de : Dépôt de données non publiées, Service de fourniture de documents, ICIST, Conseil national de recherches Canada, Ottawa, Canada K1A OS2.

Les coordonnées atomiques, distances et angles de liaisons sont également disponibles au Cambridge Crystallographic Data Centre. On peut les obtenir en s'adressant au directeur, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, Royaume-Uni.

Remerciements

Les différentes analyses spectroscopiques ainsi que l'analyse élémentaire ont été effectuées dans les services spécialisés du Groupe Régional de Mesures Physiques de Toulouse. Les responsables et le personnel de ces services : Mme Bon, MM. Commenges, Dall'ava, Pelletier, Servin et Tran Le Trang (RMN), Mme Richelme (SM), M. Mila et Mme Bourdil (analyses élementaires) sont chaleureusement remerciés.

Synthesis of torrentin, dihydrosantamarine, and saussurea lactone from santonin

GONZALO BLAY, LUZ CARDONA, BEGOÑA GARCÍA, AND JOSÉ R. PEDRO[1]

Department of Organic Chemistry, Faculty of Chemistry, University of Valencia, E-46100 Burjassot, Valencia, Spain

Received July 22, 1991

GONZALO BLAY, LUZ CARDONA, BEGOÑA GARCÍA, and JOSÉ R. PEDRO. Can. J. Chem. **70**, 817 (1992).

The synthesis of the eudesmanolide torrentin (**1**) by sensitized photooxygenation of synthetic dihydrosantamarine (**3**) is reported. Both dihydrosantamarine and dihydroreynosin (**11**) were obtained from the 1,2-epoxide **9**, which, in turn, was prepared from the diselenide **7**. An improved procedure for the synthesis of the elemanolide saussurea lactone (**4**) is also reported.

Key words: eudesmanolide, elemanolide, santonin, torrentin, saussurea lactone.

GONZALO BLAY, LUZ CARDONA, BEGOÑA GARCÍA et JOSÉ R. PEDRO. Can. J. Chem. **70**, 817 (1992).

On rapporte la synthèse de l'eudesmolide de torrentine (**1**) par une photo-oxygénation de la dihydrosantamarine de synthèse (**3**). On a obtenu à la fois la dihydrosantamarine et la dihydroreynosine (**11**) à partir de l'époxyde **9** qui a par ailleurs été préparé à partir du disélénure **7**. On rapporte aussi une méthode améliorée de synthèse de l'élémanolide lactone de saussurea (**4**).

Mots clés : eudesmanolide, élémanolide, santonine, torrentine, lactone saussurea.

[Traduit par la rédaction]

Torrentin is an eudesmanolide isolated a few years ago (1) from *Artemisia herba-alba* subsp. *valentina*, and whose structure has been revised recently (2). This paper reports on the synthesis of torrentin (**1**) from santonin (**2**) via a multistep reaction sequence involving dihydrosantamarine (**3**) as an intermediate product. It also contributes an improved procedure for the synthesis of saussurea lactone (**4**) from santonin (**2**). The sesquiterpene lactones, which constitute an important group of natural compounds widely distributed in the family Compositae, have received much attention because of their biological activities (3).

Dihydrosantamarine (**3**) was synthesized previously (4) from the dihydrocostunolide (**5**) and, more recently, by an 11-step refunctionalization (5) of the A ring of santonin (**2**). We synthesized dihydrosantamarine (**3**) via a shorter synthetic pathway by applying a new selective transformation of diselenide **7** to the 1,2-epoxide **9**. The conversion of dihydrosantamarine (**3**) into torrentin (**1**) involved the sensitized photooxygenation of the 3,4-double bond of the former as a key step (6).

We used the diol-lactone **6** as starting product, which was prepared from santonin (**2**) according to Grieco (7), i.e., by hydrogenation and epimerization (8) at C4, formation of the corresponding tosylhydrazone and a Shapiro reaction (9), and, finally, the ozonolysis of the 2,3-double bond followed by reduction with sodium borohydride.

Our strategy was based on the synthesis of the 1,2-epoxide **9** from the diol **6** by oxidation–elimination of the diselenide **7** and the simultaneous epoxidation of the resulting double bond. Inasmuch as the elimination of the C2 selenoxide should be faster (10) than that of the C3 selenoxide, the yield of epoxide **9** must be more favourable than that of **10** in relation to those obtained by epoxidation (3) of saussurea lactone (**4**).

With the above ideas in mind, we addressed the synthesis

Reagents: (a) 4.8 eq. ArSeCN, *n*-Bu_3P; (b) 30% H_2O_2; (c) *m*-CPBA; Ar = *o*-$NO_2C_6H_4$-

SCHEME 1

of the diselenide **7** from the diol **6** by reaction with *o*-nitrophenylselenocyanate-tri-*n*-butylphosphine. Despite Grieco's explicit claim that **7** cannot be synthesized (7), our past experience with similar substrates (11, 12) told us that the synthesis in question should pose no problem. In fact, the diselenide **7** was obtained with a yield of 72% by reaction of the diol **6** with 4.8 equivalents of *o*-nitrophenylselenocyanate–tri-*n*-butylphosphine in THF–pyridine. Diselenide **7** was subjected to various simultaneous oxidation–elimination and epoxidation procedures with epoxidizing reagents such as sodium perborate/acetic anhydride (13), *p*-nitroperoxybenzoic acid (14), trifluoroacetic anhydride/H_2O_2 (15), and trichloroacetonitrile/H_2O_2 (16) at temperatures between 0 and 4°C and for long reaction times (7 days), which yielded mainly the divinyl compound **4**. However, the use of hexafluoroacetone/H_2O_2 (17) under identical reaction conditions provided the 1,2-epoxide **9** with a yield of 25%, together with the 3,4-epoxide **10** (19%) and the divinyl compound **4** (34%), while shorter reaction times and room temperature conditions yielded preferentially the 3,4-epoxide **10**. Finally, the best yields of the 1,2-epoxide **9** were secured with *m*-chloroperoxybenzoic acid. After 8 days at 0–4°C, the said epoxide was obtained with a yield of 44%, together with 11% of the 3,4-epoxide **10** and 10% of the divinyl compound **4**. Even though the yield of the 1,2-epoxide **9** obtained by oxidation of the diselenide **7** was somewhat low, it is interesting to note the selectivity of the reaction, since the epoxides **9** and **10** were obtained in a 4:1 ratio, while direct epoxidation of divinyl compound **4** yielded the same epoxides in a 1:4 ratio (4) (Scheme 1).

On the other hand, by oxidation of the diselenide **7** with H_2O_2/THF (18) saussurea lactone (**4**) was obtained with a yield of 90%. This synthesis of saussurea lactone (**4**) from santonin (**2**), through the diselenide **7**, improves remarkably those previously reported (7).

On treatment with boron trifluoride etherate, the compound **9** underwent an intramolecular Prins reaction, through the nucleophilic attack of the olefin on the coordinate form of the epoxide, and yielded a mixture of two eudesmanolides that were resolved by column chromatography (Scheme 2). The less polar compound was obtained with a yield of 59% and was identified as dihydrosantamarine (**3**) consistent with its ^1H NMR spectrum (δ_H 5.30 (brs, 3-H), 3.93 (dd, J = 9.8 and 11.1 Hz, 6-H), 3.62 (dd, J = 6.7 and 9.8 Hz, 1α-H), 1.79 (brs, 15-H)). The more polar component, which was obtained with a yield of 25%, was identified as dihydroreynosin **11**. Its ^1H NMR spectrum included two broad singlets (δ_H 4.95 and 4.80) corresponding to the protons of the exocyclic methylene group, in addition to the signals corresponding to 6-H (δ_H 4.03, t, J = 10.5 Hz) and 1α-H (δ_H 3.48, dd, J = 4.6 and 11.4 Hz).

Once dihydrosantamarine (**3**) had been synthesized it was transformed into torrentin (**1**). The introduction of an oxygenated function at C3 was thought to be feasible by sensitized photooxygenation of the 3,4-double bond (6). However, as such an oxygenated function of torrentin was an acetate

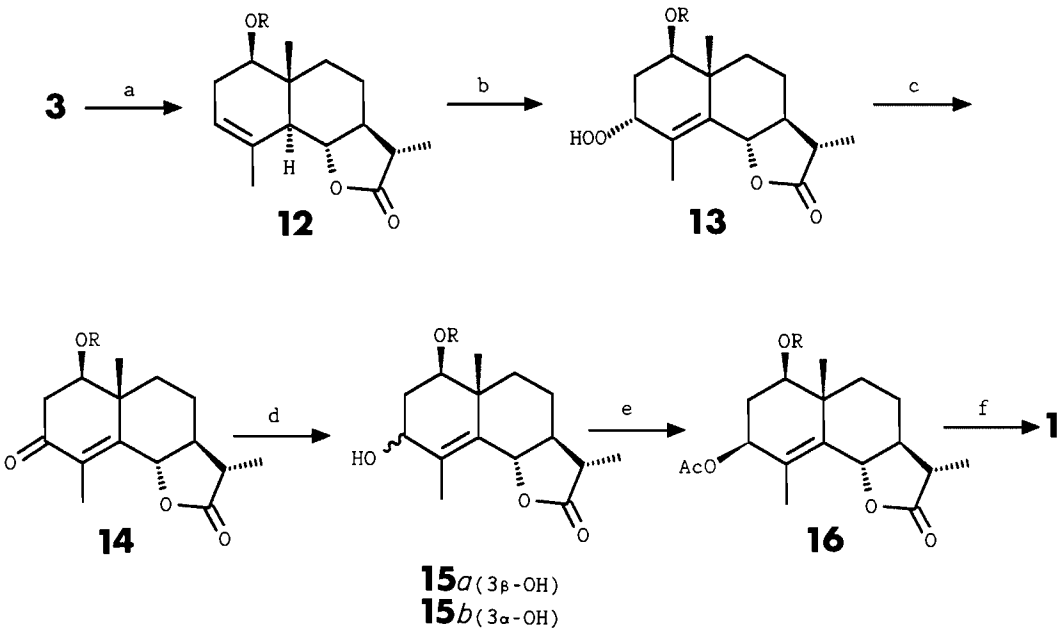

SCHEME 3

group, it required the hydroxyl group at C1 to be protected. Therefore, the first reaction involved was the treatment of dihydrosantamarine (**3**) with *tert*-butyldimethylsilyl chloride in DMF/imidazole (19) in order to protect the hydroxyl function as a silyl ether. Protected dihydrosantamarine, **12**, was converted into the corresponding 3α-hydroperoxide **13**, by bubbling oxygen through an ethanol solution sensitized by means of methylene blue and irradiated with two 400-W lamps. On treatment with acetic anhydride in pyridine (20), the hydroperoxide **13** yielded the α,β-unsaturated ketone **14**, which, by reduction with $LiAlH(O\text{-}t\text{-}Bu)_3$ in THF at 0°C, provided a mixture of the desired 3β-alcohol **15***a* (65%) and its 3α-epimer **15***b* (26%). Finally, on acetylation of **15***a* and cleavage of the silyl ether with $n\text{-}Bu_4NF$, torrentin (**1**) was obtained and was found to be identical with its natural counterpart (2) (Scheme 3).

Experimental

Melting points were determined in capillary tubes with a Büchi melting point apparatus and were used uncorrected. IR spectra were recorded on a Perkin–Elmer 281 spectrometer. ^1H and ^{13}C NMR were run on a Bruker AC-200 instrument (200.1 MHz for ^1H NMR and 50.3 MHz for ^{13}C) by using $CDCl_3$ solutions (Tables 1 and 2). Mass spectra were recorded at 70 eV on a Hewlett–Packard GC/MS system 5988A, with an ULTRA-2 GC column (25 m, cross-linked diphenyl 5% phenylmethyl silicone gum phase). Optical

rotations were taken on a Perkin–Elmer 241 polarimeter. Reaction solvents were purified and dried by standard methods (20). THF was distilled from Na–benzophenone prior to use. *o*-Nitrophenylselenocyanate was prepared by Bauer's procedure as described by Hori and Sharples (21) and had a melting point of 140–142°C.

*2,3-Di-*o*-nitrophenylseleno-5,7*α*H,4,6,11*β*H-eleman-6,12-olide* **7**

To a solution of diol **6** (35 mg, 0.127 mmol) and *o*-nitrophenylselenocyanate (141 mg, 0.62 mmol) in THF–pyridine 1:1 (1.4 mL) at room temperature under argon, was added, via syringe, tri-*n*-butylphosphine (195 μL, 0.778 mmol) and the mixture stirred for 5 h. To this reaction mixture was added, also via syringe, the resulting solution from *o*-nitrophenylselenocyanate (35 mg, 0.15 mmol), pyridine (0.5 mL), and tri-*n*-butylphosphine (48 μL, 0.19 mmol). Then the reaction mixture was stirred for 20 h. After solvent removal, the residue was chromatographed on silica gel (dichloromethane–methanol 100:1). The first eluted product was diselenide **7** (60 mg, 72%) and the second one was the monoselenide **8** (13 mg, 23%). Compound **7** was a yellow solid, mp 157–158°C (hexane–acetone); ν_{max} (KBr)/cm^{-1}: 3080, 3060, 1770, 1590, 1560, 1505, 1330, 1000, and 735; δ_H: 8.26(1H, dd, *J* 1.4 and 8.3, Ar-H), 8.14(1H, d, *J* 8.0, Ar-H), 7.50–7.20(6H, m, Ar-H), 4.04(1H, t, *J* 10.7, 6-H), 3.10–3.00(2H, m, 3-H), 2.94 (1H, td, *J* 5.5 and 12.0, 2-H), 2.75(1H, td, *J* 4.7 and 12.0, 2′-H), 2.26(1H, 2q, *J* 6.9 and 12.2, 11-H), 1.26 and 1.23 (6H, two d, *J* 6.9, 13-H and 15-H), and 1.00(3H, s, 14-H) Anal. calcd. for $C_{27}H_{32}N_2O_6Se_2$: C 50.79, H 5.05; found: C 50.8, H 5.0. Compound **8** was a yellow oil; ν_{max}/cm^{-1} (NaCl): 3540–3300, 1760, 1580, 1555, 1500, 1330, 1000, and 725; δ_H: 8.24(1H, dd, *J* 1.5 and 8.0, Ar-H), 7.56 (1H, dd, *J* 1.5 and 8.0, Ar-H), 7.49(1H, td, *J* 1.5 and 8.0, Ar-H), 7.27(1H, td, *J* 1.5 and 8.0, Ar-H), 3.99(1H, t, *J* 10.7, 6-H), 3.60–3.50(2H, m, 3-H), 3.16 (1H, td, *J* 4.5 and 12.0, 2-H), 2.82(1H, td, *J* 4.3 and 12.0, 2′-H), 2.25(1H, dq, *J* 6.9 and 12.1, 11-H), 1.20(3H, d, *J* 6.9, 13-H), 1.00(3H, s, 14-H), and 0.99(3H, d, *J* 7.0, 15-H).

*1,2β-Epoxy-5,7*α*H,6,11*β*H-elem-3-en-6,12-olide* **9** *from* **7**

To a solution containing diselenide **7** (184 mg, 0.288 mmol) in CH_2Cl_2 (7 mL), 85% *m*-chloroperbenzoic acid (439 mg, 2.16 mmol) was added at 0°C and the resulting mixture stirred at 0–4°C for 9 days. The product was treated by the usual procedure and chromatographed on silica gel (increasing polarity of hexane–ether) to afford compound **4** (7 mg, 10%), compound **9** (32 mg, 44%), and compound **10** (9 mg, 11%). Their physical and spectral features were as follows: compound **9**, mp 145–147°C (hexane–dichloromethane); ν_{max} (KBr)/cm^{-1}: 3060, 1765, 1630, 1010, 890, 860, and 800; δ_H: 5.07(1H, brs, 3-H), 4.83(1H, brs, 3′-H), 4.04(1H, dd, *J* 10.2 and 11.6, 6-H), 2.86(1H, t, *J* 3.5, 1-H), 2.64 (2H, m, 2-H), 2.42(1H, d, *J* 11.6, 5-H), 2.31(1H, dq, *J* 6.9 and 12.1, 11-H), 1.82(3H, s, 15-H), 1.20(3H, d, *J* 6.9, 13-H), and 0.86(3H, s, 14-H); *m/z* (EI): 250 (M^+, 1%), 235 ($M^+ - CH_3$, 5), 219 (2), 151 (10), 149 (21), 147 (11), 137 (15), 121 (30), 107 (38), 93 (43), 83 (58), and 55 (100). Compound **10**, mp 109–110°C (hexane–dichloromethane); ν_{max}(KBr)/cm^{-1}: 3100, 1770, 1015, 995, and 810; δ_H: 5.81(1H, dd, *J* 10.8 and 17.5, 1-H), 5.04(1H, d, *J* 17.5, 2-H), 5.02(1H, d, *J* 10.8, 2′-H), 4.01(1H, t, *J* 10.9, 6-H), 2.73(1H, d, *J* 4.4, 3-H), 2.50(1H, d, *J* 4.4, 3′-H), 2.31(1H, dq, *J* 7.0 and 12.0, 11-H), 1.37(3H, s, 15-H), 1.21(3H, d, *J* 7.0, 13-H), and 1.19(3H, s, 14-H); *m/z* (EI): 250 (M^+, 1%), 235 ($M^+ - CH_3$, 15), 221 (3), 207 (3), 193 (7), 181 (12), 167 (16), 149 (27), 137 (20), 123 (33), 109 (54), 93 (57), and 55 (100).

*5,7*α*H,6,11*β*H-Elema-1,3-dien-6,12-olide* **4** *from* **7**

A solution of diselenide **7** (26 mg, 0.041 mmol) in THF (0.3 mL) was treated with 30% aqueous hydrogen peroxide (45 μL, 0.04 mmol) at 0°C for 20 h. The reaction mixture was extracted with ethyl acetate and filtered through a short plug of silica gel to afford compound **4** (8.8 mg, 90%) with the following features: mp 149–152°C (hexane–dichloromethane); ν_{max}(KBr)/cm^{-1}: 3090, 1765, 1640, 1005, 1000, 910, and 890, δ_H: 5.78(1H, dd, *J* 10.9 and 17.3, 1-H), 5.01(1H, m, 3-H), 4.96(1H, dd, *J* 0.8 and 10.9, 2-H), 4.92(1H, dd, *J* 0.8 and 17.3, 2′-H), 4.67(1H, brs, 3′-H), 4.10(1H, dd, *J* 10.2 and 11.5, 6-H), 2.31(1H, dq, *J* 7.0 and 12.0 11-H), 2.21(1H, d, *J* 11.5, 5-H), 1.76(3H, s, 15-H), 1.21(3H, d, *J* 7.0, 13-H), and 1.06(3H, s, 14-H); *m/z* (EI): 234 (M^+, 4%), 220 (2), 219 ($M^+ - CH_3$, 11), 206 (1), 199 (1), 177 (11), 167 (16), 156 (74), 149 (48), 141 (33), and 139 (100).

*1β-Hydroxy-5,7*α*H,6,11*β*H-eudesm-3-en-6,12-olide* **3** *and 1β-hydroxy-5,7*α*H,6,11*β*H-eudesm-4(15)-en-6,12-olide* **11** *from* **9**

To a solution of epoxide **9** (71 mg, 0.287 mmol) in benzene (4 mL), $BF_3 \cdot OEt_2$ (81 μL, 0.287 mmol) was added. The mixture was stirred at room temperature for 30 min, after which it was worked up in the usual manner. By flash chromatography (increasing polarity of hexane – ethyl acetate), compounds **3** (43 mg, 59%) and **11** (18 mg, 25%) were separated. Compound **3** was a

solid melting at 130–132°C (hexane–dichloromethane); ν_{max}(KBr)/cm^{-1}: 3500, 3020, 1745, 1180, 1125, 1040, and 850; δ_H: 5.30 (1H, brs, 3-H), 3.93 (1H, dd, *J* 9.8 and 11.1, 6-H), 3.62 (1H, dd, *J* 6.7 and 9.8, 1-H), 2.50–2.30 (1H, m, 2-H), 2.27 (1H, dq, *J* 6.8 and 12.2, 11-H), 2.19(1H, brd, *J* 11.1, 5-H), 1.79(3H, brs, 15-H), 1.20(3H, d, *J* 6.8, 13-H), and 0.86(3H, s, 14-H); *m/z* (EI): 250 (M^+, 14%), 235 ($M^+ - CH_3$, 1), 232 ($M^+ - H_2O$, 1), 222 (1), 217 (1), 167 (35), and 149 (100). Compound **11** was a solid melting at 138–139°C; ν_{max}(KBr)/cm^{-1}: 3490, 3090, 1750, 1650, 1150, 1135, 1045, 995, and 890; δ_H: 4.95(1H, brs, 15-H), 4.80(1H, brs, 15′-H), 4.03(1H, t, *J* 10.5, 6-H), 3.48(1H, dd, *J* 4.6 and 11.4, 1-H), 2.40–2.25(2H, m, 3-H and 11-H, overlapped signals), 2.02(1H, brd, *J* 10.5, 5-H), 1.20(3H, d, *J* 6.9, 13-H), and 0.80(3H, s, 14-H); *m/z* (EI): 250 (M^+, 1.4%), 233 (M^+ − OH, 3), 232 ($M^+ - H_2O$, 19) 217 (2), 206 (2), 191 (3), 177 (5), 165 (23), 147 (14), 121 (33), 107 (32), and 55 (100).

*1*β-tert-*Butyldimethylsilyloxy-5,7*α*H,6,11*β*H-eudesm-3-en-6,12-olide* ***12*** *from* ***3***

To a solution of dihydrosantamarine **3** (70 mg, 0.28 mmol) in DMF (2.4 mL), *tert*-butyldimethylsilyl chloride (182 mg, 1.17 mmol) and imidazol (229 mg, 3.37 mmol) were added. The temperature of the reaction was raised to 35–40°C, with stirring for 24 h. The reaction product, extracted with ethyl acetate, was chromatographed on silica gel, from which hexane – ethyl acetate (9:1) eluted compound **12** (90 mg, 88%), mp 123–126°C from hexane–ether; ν_{max}(KBr)/cm^{-1}; 3025, 1775, 1250, 1175, 1090, 860, 830, and 770; δ_H: 5.28(1H, brs, 3-H), 3.91(1H, dd, *J* 9.8 and 11.0, 6-H), 3.55(1H, dd, *J* 6.7 and 9.4, 1-H), 2.25(1H, dq, *J* 6.7 and 12.1, 11-H), 2.15(1H, brd, *J* 11.0, 5-H), 2.35–2.10(1H, m, 2-H, overlapped with 11-H and 5-H), 2.1–1.8(3H, m, 2′-H, 8-H, and 9-H), 1.77(3H, brs, 15-H), 1.65–1.40(2H, m, 7-H and 8′-H), 1.20(3H, d, *J* 6.7, 13-H), 1.12(td, 1H, *J* 3.7, 13.0, 9′-H), and 0.85 (12H, s, 14-H and Me-C-Si); *m/z* (CI, methane): 365 [$(M + H)^+$, 19%)], 307 [$(M + H)^+ - C_4H_{10}$, 39], 233 (100), 187 (27), 158 (12), and 157 (74). Anal. calcd. for $C_{21}H_{36}O_3Si$: C 69.18, H 9.95; found: C 69.2, H 9.9.

*1*β-tert-*Butyldimethylsilyloxy-3*α*-hydroperoxy-7*α*H,6,11*β*H-eudesm-4-en-6,12-olide* ***13*** *from* ***12***

Compound **12** (102 mg, 0.281 mmol) was dissolved in absolute ethanol (23 mL) and methylene blue (2.3 mg) was added. Oxygen was gently bubbled through the solution. The reaction tube was submerged in a water bath (17°C) thermostated by an external flow of cold methanol and irradiated by two lamps (HOSRAM HQL, 400 W each) for 7 h. The product was isolated by evaporating the solution to dryness, then dissolving the residue in dichloromethane and passing it through a short column of silica gel using ethyl acetate as solvent. After solvent removal, the residue was chromatographed on silica gel (increasing polarity of hexane – ethyl acetate) to afford unreacted starting material (6 mg, 6%), compound **14** (5 mg, 5%), and compound **13** (65 mg, 58%); ν_{max}(KBr)/cm^{-1}: 3500–3120, 1790, 1745, 1100, 1030, 985, 830, and 775; δ_H: 8.24(1H, s, OOH), 4.54 (1H, brd, *J* 10.5, 6-H), 4.20(1H, brs, 3-H), 3.72(1H, dd, *J* 3.6 and 12.5 Hz, 1-H), 2.3–2.2(2H, m, 2-H and 11-H), 1.95(3H, s, 15-H), 1.18(3H, d, *J* 6.8, 13-H), 1.03(3H, s, 14-H), 0.87(9H, s, Me-C-Si), 0.10(3H, s, Me-Si), and 0.03(3H, s, Me-Si).

*1*β-tert-*Butyldimethylsilyloxy-3-oxo-7*α*H,6,11*β*H-eudesm-4-en-6,12-olide* ***14*** *from* ***13***

A solution of hydroperoxide **13** (58 mg, 0.147 mmol) in pyridine (0.6 mL) was treated with acetic anhydride (3 drops) for 1 h. The reaction mixture was dissolved in ethyl acetate (100 mL), washed with diluted aqueous HCl and brine, and dried. Evaporation of the solvent yielded pure ketone **14** (55 mg, 99%), mp 146–148°C from hexane–ether; ν_{max}(KBr)/cm^{-1}: 1775, 1660, 1610, 1090, 1020, 980, 830, and 770; δ_H: 4.72(1H, dd, *J* 1.5 and 11.6, 6-H), 3.77(1H, t, *J* 8.8, 1-H), 2.53(2H, d, *J* 8.8, 2-H), 2.32(1H, dq, *J* 7.0 and 11.6, 11-H), 2.12(1H, dt, *J* 3.0 and 13.5, 9-H), 2.1–1.9(1H, m, 8-H), 1.96(3H, d, *J* 1.5, 15-H), 1.85(1H, qd, *J* 3.0 and 12.3, 8′-H), 1.29(1H, td, *J* 4.4 and 13.3, 9′-H), 1.23(3H, d, *J* 7.0, 13-H), 1.22(3H, s, 14-H), 0.86(9H, s, Me-C-Si), 0.05(3H, s, Me-Si), and 0.02(3H, s, Me-Si); *m/z* (CI, methane): 379 [$(M + H)^+$, 39%], 321 [$(M + H)^+ - C_4H_{10}$, 60], and 247 (100). Anal. calcd. for $C_{21}H_{34}O_4Si$: C 66.62, H 9.05; found: C 66.6, H 9.0.

*1*β-tert-*Butyldimethylsilyloxy-3*β*-hydroxy-7*α*H,6,11*β*H-eudesm-4-en-6,12-olide* ***15****a from* ***14***

A solution of compound **14** (38 mg, 0.101 mmol) in THF (1.3 mL) was treated at 0°C with LiAlH(O-*t*-Bu)$_3$ (142 mg, 0.50 mmol) in THF (1.3 mL) for 2 h. The reaction mixture was worked up in the usual way. Two products were separated by flash chromatography: the 3α-alcohol ***15****b* (9.9 mg, 26%) and the 3β-alcohol ***15****a* (24.9 mg, 65%). Compound ***15****b*, an oil; ν_{max} (NaCl)/cm^{-1}: 3520–3300, 1760, 1250, 1100, 1025, 980, 830, and 770; δ_H: 4.55(1H, brd, *J* 11.3, 6-H), 3.94(1H, brs, 3-H), 3.76(1H, dd, *J* 4.8 and 11.4, 1-H), 2.25(1H, dq, *J* 6.8 and 11.8, 11-H), 1.97(3H, s, 15-H), 1.03(3H, s, 14-H), 1.46(1H, qd, *J* 3.4 and 12.2, 8-H), 1.20(1H, d, *J* 6.8, 13-H), 1.03(3H, s, 14-H), 0.87(9H, s, Me-C-Si), 0.08(3H, s, Me-Si), and 0.04(3H, s, Me-Si); *m/z* (CI, methane): 363 [$(M + H)^+ - H_2O$, 16], 277 (9), 249, (100), 231 (35), 175 (15). Prototropic equilibria of 2-pyridylbenzimidazoles in aqueous solution

MERCEDES NOVO, MANUEL MOSQUERA,[1] AND FLOR RODRÍGUEZ PRIETO[1]

Universidad de Santiago, Dpto. Química Física, Facultad de Química, E-15706 Santiago de Compostela, Spain

Received August 15, 1991

MERCEDES NOVO, MANUEL MOSQUERA, and FLOR RODRÍGUEZ PRIETO. Can. J. Chem. **70**, 823 (1992).

In this paper we report the acid–base behaviour of 2-(*n'*-pyridyl)benzimidazoles (*n'* = 2,3,4) and some methyl derivatives in aqueous solution over a wide range of acidity, involving interesting features with respect to competition in protonation between the benzimidazole N3 and the pyridyl N, with the existence of the corresponding two monocations in equilibrium in the case of *n'* = 4. The influence of pH on the electronic absorption spectra of all compounds has been studied in order to identify the ground-state species present as a function of acidity and to obtain the acidity constants of the various prototropic equilibria occurring in the wide range of acidity studied.

Key words: 2-pyridylbenzimidazoles, prototropic equilibria, protonation, acidity constants.

MERCEDES NOVO, MANUEL MOSQUERA et FLOR RODRÍGUEZ PRIETO. Can. J. Chem. **70**, 823 (1992).

Dans ce travail, on a examiné le comportement acide–base de 2-(*n'*-pyridyl)benzimidazoles (*n'* = 2, 3, 4) et des quelques-uns de leurs dérivés méthylés en solutions aqueuses, sur une grande plage d'aciditiés; les comportements considérés comprennent des caractéristiques intéressantes concernant la compétition lors de la protonation entre les positions N3 du benzimidazole et le N du pyridyle et l'existence de deux monocations correspondants en équilibre dans le cas où *n'* = 4. Dans le but d'identifier les espèces présentes dans l'état fondamental en fonction de l'acidité et pour obtenir les constantes d'acidité des divers équilibres prototropiques se produisant aux acidités très variées qui ont été examinées, on a étudié l'influence du pH sur les spectres d'absorption électronique de tous les composés.

Mots clés : 2-pyridylbenzimidazoles, équilibre prototropique, protonation, constantes d'acidité.

Introduction

The pH dependence of the photophysical behaviour of benzimidazole has been studied by a number of authors in relation to the effect of substitution on the ground- and excited-state acidity constants of this compound (1–3). The introduction of aromatic 2-substituents with heteroatoms brings additional protonation possibilities (4–7) and in some cases, e.g., those of 2-(2′-hydroxyphenyl)benzimidazole (8) and 2-(2′-aminophenyl)benzimidazole (9), the formation of intramolecular hydrogen bonds.

2-Pyridylbenzimidazoles are particularly interesting because the separate parent compounds have nitrogen atoms of very similar basicity: the pK_a values of the pyridinium ion and the N3-protonated benzimidazole cation are 5.25 and 5.532 respectively (10), which suggests that these atoms may compete for protons in pyridylbenzimidazoles. In the work described here we investigated the acid–base behaviour of 2-pyridylbenzimidazoles in order (*a*) to clarify the situation as regards such competition, and (*b*) to determine the ground-state species present at various acidities as a necessary preliminary step towards subsequent research on photoemission by these compounds (11).

Experimental

2-(2′-Pyridyl)benzimidazole (2PBI) was purchased from Aldrich Chemical Co. and purified by recrystallization from ethanol/water. 2-(3′-Pyridyl)benzimidazole (3PBI) and 2-(4′-pyridyl)benzimidazole (4PBI) were prepared by high-temperature condensation of *o*-phenylenediamine with nicotinic and isonicotinic acids respectively (12) and were purified by repeated recrystallization in ethanol/water. 1-Methyl-2-(2′-pyridyl)benzimidazole (M2PBI) was prepared by a published procedure (13), as was the quaternary salt 2-[4′-(*N*-methylpyridinylium)]benzimidazole iodide (4PBIQS) (14). The identity and purity of the prepared products was supported by measurements of their melting points and ^{1}H NMR spectra.

Acidity was varied using perchloric acid and sodium hydroxide, and sodium perchlorate was used to control ionic strength, 0.1 M in most of the series of experiments, except in those performed with $[HClO_4] > 0.1$ M, in which the ionic strength was the concentration of acid. In experiments with 4PBIQS, acidity was controlled over the range pH 6–9 by 0.01 M sodium dihydrogenphosphate buffer. All these chemicals were Merck p.a. products.

UV absorption spectra were recorded in a Kontron Uvikon 820 spectrophotometer at 25°C. Except for experiments at $[HClO_4] > 0.1$ M, for which the acidity function H_+ was calculated (15), pH was measured using a Radiometer PHM82 pH-meter with a Type B combined electrode.

Theoretical equations were fitted to the experimental data using a weighted least-squares nonlinear optimization program based on Marquardt's algorithm (16).

Results and discussion

Prototropic forms

The influence of pH on the absorption spectrum of 2PBI has been reported previously (11). The behaviour of 3PBI observed in the work described here was very similar (Fig. 1), and is interpreted identically, as follows.

The shift of the low-energy band to smaller wavenumbers upon increasing pH from neutral to pH 13 is attributed to the formation of the monoanion A by deprotonation of the neutral species N. Since a similar shift in the spectrum of 2-phenylbenzimidazole (PhBI) is due to loss of the benzimidazole N1 proton (17), we assume that it is likewise this proton that is lost by 2PBI and 3PBI. This hypothesis is supported by the behaviour of the absorption spectrum of the methyl derivative M2PBI, in which the low-energy band is independent of pH at pH > 7.

Upon increasing acidity from pH 7 to pH 3, the low-energy band of 3PBI hardly changes but isosbestic points appear in the high-energy band, reflecting acid–base equilibrium between the neutral species and a monoprotonated cation C. The change in the spectrum is nevertheless very slight, and the fact that it is a similarly slight spectral change

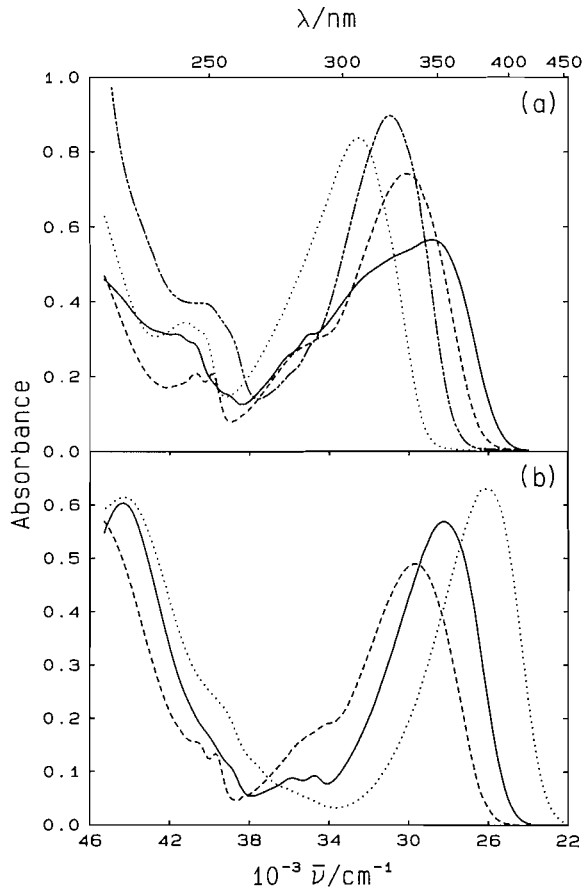

FIG. 2. (*a*) Absorption spectra of 4PBI in aqueous solutions of pH 12.94 (——), pH 6.85 (· · ·), pH 3.02 (——), and $H_+ = -0.11$ (– – –). [4PBI] = 3.7×10^{-5} mol dm^{-3}. (*b*) Absorption spectra of 4PBIQS in aqueous solutions of pH 11.90 (· · ·), pH 5.92 (——), and $H_+ = -0.27$ (– – –). [4PBIQS] = 2.1×10^{-5} mol dm^{-3}.

that is observed upon protonation of PhBI (17), whose only basic nitrogen atom is the benzimidazole N3, suggests that it is N3 that is protonated in C as well.

At higher acidities ([$HClO_4$] > 1 M for 2PBI and pH < 2 for 3PBI), the low-energy band undergoes a shift back to smaller wavenumbers, which is due to the formation of the dication D. This process involves protonation of the pyridyl nitrogen, which causes a greater modification of the spectrum than protonation at N3. As expected, in acid media M2PBI behaved like the unmethylated species,[2] the monocation being protonated at N3 and the dication being formed in the presence of proton concentrations greater than 1 M.

Scheme 1 shows the four prototropic forms of 3PBI that exist at the different pH values; the pattern for 2PBI is the same.

The influence of pH on the absorption spectrum of 4PBI (Fig. 2*a*) resembles that observed on the absorption spectra of its isomers as regards neutral-to-basic media and highly acid media. Thus, the spectrum of 4PBI at neutral pH is similar to those of 2PBI and 3PBI, being attributed to the neutral species N, and shifts to smaller wavenumbers upon increasing pH from neutral to basic due to the formation of the anion A (Scheme 2). At high acidities ([$HClO_4$] ≃ 1 M), the low-energy band of the 4PBI absorption spectrum is again shifted towards smaller wavenumbers as observed in 2PBI and 3PBI, being likewise explicable in terms of the formation of a dication D, protonated at the benzimidazole N3 and at the pyridyl N.

However, the spectrum of 4PBI at pH 3 is very different from those of its isomers, with an extremely broad, irregular low-energy band shifted considerably towards smaller wavenumbers (Fig. 2*a*). The morphology of this band suggests that it is contributed to by two different species obtained by protonation of the neutral species N. Taking into account the above-mentioned possibility that the benzimidazole N3 and the pyridyl N may compete for protons in pyridylbenzimidazoles, a feasible interpretation of the observed spectrum would be the presence of both the N3-protonated cation, C_b, and the cation protonated at the pyridyl N, C_p, in equilibrium at pH 3 (Scheme 2).

[2]Low-energy absorption maxima for M2PBI at pH 7.21, pH 2.42, and $H_+ = -3.24$ are at 34 000, 34 000, and 32 200 cm^{-1}, respectively.

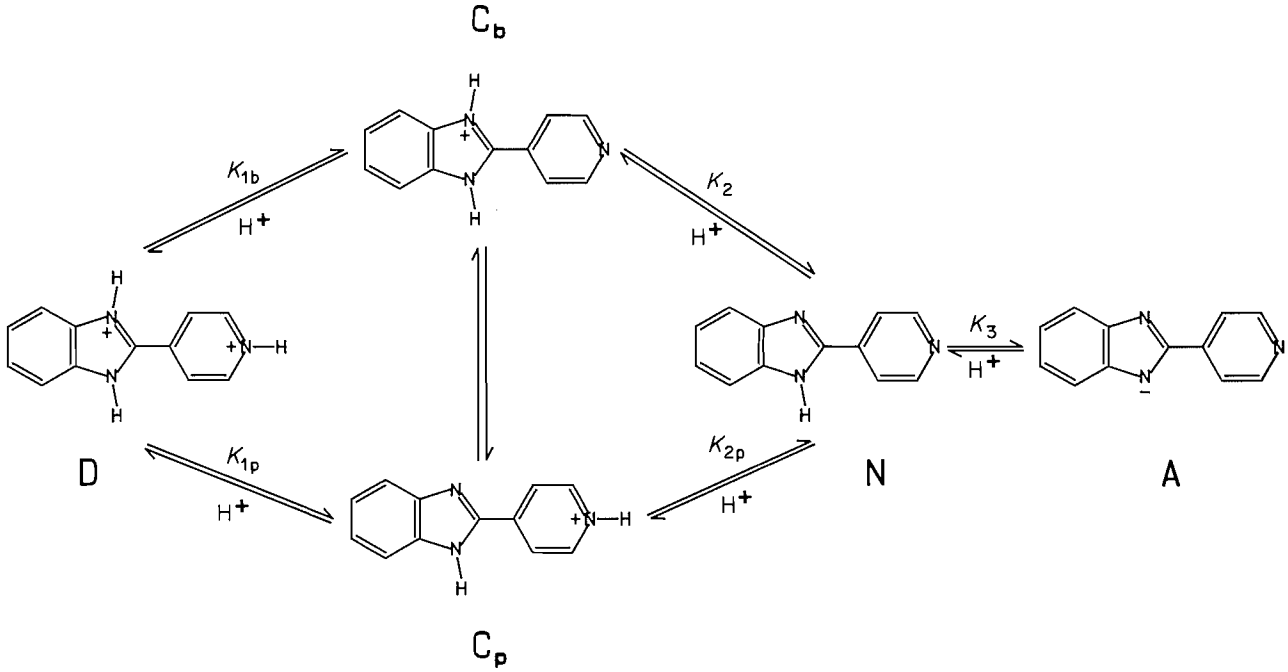

SCHEME 2. Acid–base equilibria for 4PBI.

To verify the above hypothesis, the absorption spectrum of the quaternary salt 4PBIQS was studied. Since 4PBIQS differs from the 4PBI C_p cation only in having a methyl group where C_p has its additional hydrogen, it is thought to be a most suitable molecule for our purpose.

The absorption spectrum of 4PBIQS at pH 4–7 (Fig. 2*b*) has an apparently non-composite low-energy band whose peak lies at 28 300 cm^{-1} and must be attributed to the monocation M (Scheme 3). The position of that band with respect to those of the neutral species N of 2-pyridylbenzimidazoles confirms that the presence of a positive charge on the pyridyl N results in a large shift towards smaller wavenumbers, as observed for the dications of all the compounds studied. At higher acidities, the protonation of M at the benzimidazole N3 yields the dication D, whose low-energy absorption is slightly shifted to greater wavenumbers, being almost identical to that of the 4PBI dication.

Nevertheless, the behaviour of 4PBIQS in neutral-to-basic media is quite different from that of the unmethylated pyridylbenzimidazoles: the low-energy band of the spectrum undergoes a very large shift towards smaller wavenumbers, that shift beginning to be apparent in the neighbourhood of pH 8. This behaviour can be explained by the formation of a new species, the zwitterion Z, by loss of the proton from the benzimidazole N1 in 4PBIQS (Scheme 3). The structural differences of this neutral species Z with respect to the neutral species N of the related compounds account for the great differences in the spectra. Note that an uncharged resonant form can be written for Z but, according to the results of a structural study of species Z by Alcalde *et al.* (18), the dipolar form makes the main contribution to its structure.

On the basis of the simpler behaviour of 4PBIQS, we now return to 4PBI in order to verify the hypothesis that the irregular low-energy band of the 4PBI spectrum at pH 3 was contributed to by both cations C_b and C_p, species that must be in equilibrium at that acidity (Scheme 2). Since the C_p spectrum must be very similar to that of species M of 4PBIQS and the C_b spectrum may be assumed to differ very little from that of the neutral species N of 4PBI, as observed in 2PBI and 3PBI, the sum of contributions of both spectra of M and N should account for the observed spectrum of 4PBI at pH 3. A spectrum very similar to the experimental one is indeed obtained when one assumes a 50% contribution of each species. That leads to the conclusion that the benzimidazole N3 and the pyridyl N must have very similar basicities in 4PBI. Results concerning acidity constants in the next section will give further support to this conclusion.

On the other hand, it is interesting to note that a zwitterionic species like that of 4PBIQS might exist for 4PBI, being obtainable from C_p from loss of the proton from the benz-

Curves are the result of fitting the corresponding theoretical equations (see text) to the experimental data. [4PBI] = 3.7×10^{-5} mol dm^{-3}.

imidazole N1. Nevertheless, no absorption is observed at the corresponding small wavenumbers for 4PBI in neutral media, so that the existence of such a species must be ruled out.

Acidity constants

Quantitative analysis of the dependence of absorbance on pH or H_+ at a fixed wavelength allows calculation of the acidity constants[3] of the various acid–base processes occurring in the acidity range studied. The most complex case is that of 4PBI: not only do four different species of 4PBI occur in the range pH 0–7 (see Scheme 2), but the proximity of the acidity constants for the first and second protonation processes means that both processes must be analyzed together (see Fig. 3).

The equilibria of Scheme 2 imply the following theoretical equation for the acidity range pH 0–7:

$$[1] \quad A^{\lambda} = \frac{A^{\lambda}_{N}K_1K_2 + A^{\lambda}_{C}K_2H + A^{\lambda}_{D}H^2}{K_1K_2 + K_2H + H^2}$$

where A^{λ} is the absorbance at wavelength λ (with subscripts N, C, and D indicating absorbance by the neutral species, the monocations, and the dication respectively), H is defined either as 10^{-pH} for pH > 1 or as 10^{-H_+} for greater acidities, and K_1 and K_2 are the macroscopic acidity constants for the equilibria between dication and monocation and between monocation and neutral species respectively.

The relationships between the macroscopic constants and the microscopic constants defined in Scheme 2 (K_{1b}, K_{1p}, K_{2b}, and K_{2p}) are given by

$$[2] \quad K_1 = K_{1b} + K_{1p}$$

[3]Note that pH, measured at ionic strength no greater than 0.1 M, gives hydrogen ion activity while the acidity function H_+ also includes the activity coefficients of both base and acid of the indicator used to determine H_+ (15). Therefore, our acidity constants, calculated from pH values and the spectrophotometrically measured concentrations of acid and base without activity corrections, are those usually called "mixed" or "practical" acidity constants for a certain ionic strength (19), and those in which H_+ was used are thermodynamic acidity constants on the assumption that the activity coefficients of base and acid are the same for both the species under study and the indicator.

TABLE 1. pK_a values obtained by spectrophotometric titration for the various acid–base equilibria of the species studied

Compound	pK_1	pK_2	pK_3
2PBI	−1.59 ± 0.05[a]	4.41 ± 0.03[b]	12.05 ± 0.05[c]
M2PBI	−1.27 ± 0.04[a]	4.47 ± 0.03[b]	—
3PBI	1.56 ± 0.03[c]	4.53 ± 0.03[c]	11.21 ± 0.03[c]
4PBI	1.96 ± 0.02[c]	4.47 ± 0.01[c]	10.78 ± 0.02[c]
4PBIQS	2.26 ± 0.02[d]	8.89 ± 0.01[e]	—
PhBI[f]	—	5.23	11.91
MPhBI[g]	—	5.2	—

$$[3] \quad \frac{1}{K_2} = \frac{1}{K_{2b}} + \frac{1}{K_{2p}}$$

and

$$[4] \quad K_1K_2 = K_{1b}K_{2b} = K_{1p}K_{2p}$$

The absorbances corresponding to each species are given by

$$[5] \quad A^{\lambda}_{N} = c_0\, l\, \epsilon^{\lambda}_{N}$$

$$[6] \quad A^{\lambda}_{C} = \frac{c_0\, l\, (\epsilon^{\lambda}_{Cb}K_{1b} + \epsilon^{\lambda}_{Cp}K_{1p})}{K_{1p} + K_{1b}}$$

$$[7] \quad A^{\lambda}_{D} = c_0\, l\, \epsilon^{\lambda}_{D}$$

where c_0 is the total concentration of pyridylbenzimidazole, l is the cell length, and ϵ^{λ}_{i} is the molar absorption coefficient of species i at wavelength λ.

Equation [1] is also valid for the compounds with only one form of monocation, K_1 and K_2 then being identical to the microscopic constants. When a given acidity constant is sufficiently different from the neighbouring constants that it is possible to consider the corresponding equilibrium in isolation over an appreciable acidity range, eq. [1] can be simplified to

$$[8] \quad A^{\lambda} = \frac{A^{\lambda}_{ac}H + A^{\lambda}_{bas}K_a}{K_a + H}$$

where K_a is the acidity constant in question and A^{λ}_{ac} and A^{λ}_{bas} are the absorbances of the corresponding acid and base at wavelength λ.

Figure 3 shows the experimental absorbance–pH/H_+ data for 4PBI over the acidity range studied, together with the curves fitted in accordance with eq. [1] for pH < 7 and eq. [8] for pH > 7. Table 1 lists the corresponding acidity constants together with those obtained for the other compounds studied by the same procedure. In all cases both acidity constants and absorbances by the various species were fitted, a good agreement of the latter values with the experimental ones being obtained. On the other hand, the values listed for the acidity constants are the means of those obtained from several series of data at different wavelengths.

Table 1 likewise shows the published acidity constants for PhBI (17) and 1-methyl-2-phenylbenzimidazole (MPhBI) (2).

The value of pK_3 for PhBI agrees well with that of 2PBI, but is about one unit greater than those of 3PBI and 4PBI. This suggests that the benzimidazole NH group is more acid with a pyridyl ring present than with a phenyl ring, the discrepancy for 2PBI being explicable in terms of a greater lone pair – lone pair repulsion in its corresponding anion with respect to the anions of 3PBI and 4PBI, in which benzimidazole N1 and pyridyl N are farther away.

The value of pK_2, for those cases in which it refers to the monocation ↔ neutral species N equilibrium, is practically the same for all the compounds studied; in particular, the basicity of the benzimidazole N3 is virtually the same for all the PBI isomers, and in the case of 4PBI that of the pyridyl N must be very similar. As deduced from Table 1, the benzimidazole N3 is rather less basic in the 2-pyridylbenzimidazoles than in PhBI. For 4PBIQS, pK_2 refers to the monocation ↔ zwitterion equilibrium, which is a process of different nature than those of the related compounds as it involves protonation at the benzimidazole N1. Note that a similar value may be assumed to hold for the hypothetical equilibrium C_p ↔ zwitterion of 4PBI. Since the value of that pK_a is about four units higher than the value of pK_2 for 4PBI, this result confirms our earlier conclusion that no zwitterionic species is formed for 4PBI.

K_1 varies quite widely from one compound to another. In particular, it is about 1000 times greater for 2PBI than for 3PBI and 4PBI; if in these compounds the two aromatic rings are coplanar, as in PhBI (17), this can be attributed to steric hindrance of diprotonation in 2PBI. This interpretation does not necessarily contradict M2PBI (which might be expected to suffer greater steric hindrance, having a value of K_1 about two times less than that of 2PBI), for comparison (2) of data for PhBI and MPhBI suggests that methylation results in loss of ring coplanarity and hence less steric hindrance; reduction of conjugation is apparent, for example, in the fact that methylation shifts the low-energy bands of 2PBI and PhBI to rather greater wavenumbers.

Analysis of the change in absorbance with acidity only allows calculation of the macroscopic acidity constants, which in the case of 4PBI are not identical to the microscopic constants (see eqs. [2], [3], and [4]). The microscopic constants cannot be obtained spectrophotometrically, because the absorption spectra of C_p and C_b cannot be recorded separately. It is nevertheless possible to estimate these constants on the not unreasonable assumption that the value of K_{1p} for 4PBI is very similar to the value of K_1 for 4PBIQS. This hypothesis implies the values of 2.26 for pK_{1p} and pK_{1b}, and 4.17 for pK_{2p} and pK_{2b}. These estimates confirm that the pyridyl N and the benzimidazole N3 are almost equally basic in 4PBI, and that C_p and C_b should therefore be present in roughly equal proportions, in accordance with the interpretation given above to the spectrum of 4PBI at pH 3. The fact that the benzimidazole N3 and the pyridyl N have equal basicities in 4PBI, not observed in 2PBI and 3PBI, is a curious feature since the presence of two atoms of identical basicities in the same molecule is rare.
