It is well established that the position of the hydrido proton resonance in ^1H NMR spectra of iridium(III) hydride complexes is a function of the nature of the *trans* ligand (33, 34). Ligands which have high *trans* influence in square planar platinum(II) complexes induce downfield shifts in the resonance of *trans* hydrido nuclei in iridium(III) complexes. In addition, Olgemoller and Beck (35) found that a linear relationship exists between the $\nu_{Ir\text{-}H}$ stretching frequency and the $\delta_{H(hydride)}$ value in ^1H NMR spectra of [IrHCl(CO)L-$(PPh_3)_2$]$^{(0\text{ or }1+)}$, where L is a neutral or anionic ligand (r = 0.98). We found only a moderately good correlation of this plot in our system [r = 0.75 (r = 0.91 if the data for **6***b* are excluded)].[9] Part of the deviation from linearity of this plot may be due to vibrational interaction between the iridium hydride stretch and the *trans* moiety (36).

The chemical shift of the hydrido protons correlated with the *syn*/*anti* stereochemistry of complexes **6**–**8**. In all eight *syn*/*anti* pairs of diastereomers (**6***c*,*f*–*i*; **7***b*; **8***b*,*b*′) prepared in this study, the hydrido protons in the *anti* diastereomer always resonated at lower field than the protons in the corresponding *syn* diastereomer. The same behavior was also noted for the two *apical*-hydrido protons in *mer*-[IrH_3(Cyttp)] (**6***b*) in that the apical proton *syn*-to-phenyl resonated at a

[9]The hydride chemical shifts of mixtures **6***c*, **6***f*, **6***g*, **6***h*, **6***i*, **7***b*, **8***b*, and **8***c* were estimated by calculating a weighted average of the hydride shifts based on relative abundancies.

[bb] *Anti*-to-Ph *apical* methyl-C nucleus 5: δ_5 −33.61, $^2J_{15}$ 8 Hz, $^2J_{25}$ 5 Hz; methyl-H nuclei 6: δ_6 0.06, $^3J_{16}$ 6 Hz, $^3J_{26}$ 4 Hz, $^3J_{36}$ <1 Hz; ν(CO) 2010 cm^{-1}.

[cc] *Mer* carbonyl-C nucleus.

[dd] 2240 cm^{-1} (shoulder).

[ee] Not assigned, chemical shifts of the four signals are all within a range of 20.5 ± 1.0 ppm.

lower field as compared with the apical proton which is *anti*-to-phenyl. Moreover, this correlation is also found in ^{1}H NMR spectra of diastereomeric ruthenium hydride compounds containing polyphosphine ligands that were reported earlier (7, 10*c*).

It is tempting to rationalize the upfield chemical shifts of the *apical* hydrides of the *syn* isomers as compared with the *anti* as being due to the *apical* hydrido being located in the deshielding region of the arene ring in the *anti* isomers (37). It is seen, however, that the *mer* hydrides, which have the same arrangement vis-a-vis the phenyl ring in both isomers, show a parallel trend (Table 2).

The relatively upfield chemical shifts of the *syn* isomer hydrides may be due, in part, to differences in metal–li-

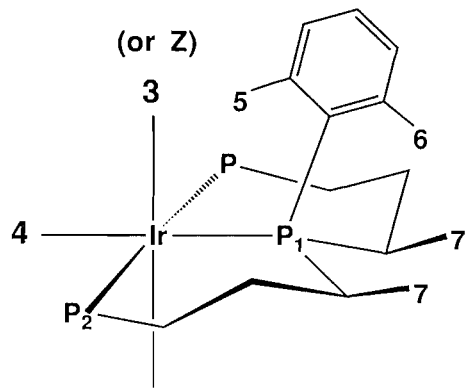
gand bond lengths and shielding by metal *d*-electrons. The high-field shifts in the ^{1}H NMR of metal hydrides have been partially rationalized in terms of shielding by incomplete metal *d*-shells (38). This effect is dependent on the inverse cube of the distance from the hydride to the *d*-electrons and will thus be a function of the metal–hydride bond length (38). It would seem reasonable that metal – *apical* ligand *Z* distances would be shorter in *anti*-isomers **4** as opposed to *syn*-isomers **3** due to the less steric interactions involving the phenyl group attached to the Cyttp central phosphorus and the *syn*-to-phenyl *apical* ligand. A shorter metal–ligand bond will most likely increase the effective *cis* and *trans* influence of the ligand, lengthen the metal–hydride bonds, and thus mitigate the shielding effect of the metal *d*-orbitals. The observation that the difference in the chemical shift of H(3) in *syn* vs. *anti* isomers increases with increasing steric size of the *trans* ligand supports this explanation. For example, the difference in chemical shifts of the two mutually-*trans* hydrides in **6***b* is 0.22 ppm, as compared with 0.82 ppm and 0.83 ppm in **6***c* and **6***f* (where the *trans* ligands are the relatively small CH_3CN and CN), and 1.44, 1.46, 2.25 ppm in **6***g*, **6***h*, and **6***i*, respectively (where the *trans* ligands are larger). An analysis of the H(4) resonances yields the same result.



14

Of all the complexes **6**–**8** studied by ^{1}H NMR in this investigation, only one of them, *anti*-[$IrH_2(CH_3CN)$(Cyttp)]-[BF_4] (**6***c*) exhibited a long-range homonuclear coupling constant, $^4J_{47}$ 2.2 Hz, between the *mer*-hydrido proton and two chemical shift equivalent spin-1/2 nuclei. Selective homonuclear decoupling experiments showed the two nuclei to be the aliphatic protons H(7) giving rise to a signal at δ 2.48, see diagram **14**. Irradiation of the *ortho* aromatic protons resulted in a ca. 5% NOE enhancement for the δ 2.48 protons. The most likely candidates for H(7) are the pair of enantiotopic methylene protons adjacent (on both sides) to the central phosphorus nucleus. Using the X-ray diffraction structure of crystalline *anti*-[IrH_2Cl(Cyttp)] (**6***a*) as a model, these protons (which are not symmetry related in the solid state) are 2.30 and 2.52 Å away from one of the two *ortho* protons, and thus their positions are consistent with the observed NOE phenomenon. These chelating ring protons are favored candidates since long-range coupling constants of such a magnitude (2.2 Hz) are usually associated with relatively rigid arrangements in which the nuclei involved are disposed in a planar zig-zag path (39). It is presently unclear why only the *anti*-**6***c* diastereomer showed this long-range phenomenon.

In five of the six diastereomeric pairs reported herein (**6***c,f,g,h,i* and **7***b*) the P(1) nuclei in the *syn* diastereomer were found at higher field than in those of the corresponding *anti* diastereomers, whereas the P(2) nuclei in the *syn* diastereomers were found at relatively lower field. This relationship was also seen in the previously reported diastereomeric pairs of ruthenium hydride complexes which contain chelating triphosphines (7, 10*c*). The diastereomeric pairs of **6***i* do not follow this trend in that whereas the P(1) nucleus of the *syn* isomer was found upfield of the *anti* diastereomer, the P(2) nuclei of the *syn* diastereomer was also found at higher field than that of the corresponding *anti* isomer.

Conclusions

NMR spectroscopic techniques have been used to characterize the configuration of six-coordinate [IrH_2L(Cyttp)] diastereomeric pairs and to follow the stereochemical course of their reactions. Most of the reactions noted in this investigation proceed with a loss of the stereochemical integrity of the starting complex, which is suggestive of dissociative mechanisms. The relatively upfield chemical shifts of the hydride ligands in *syn* vs. *anti* isomers is rationalized in terms of expected shorter metal–hydride bond distances and, hence, greater shielding by metal *d*-orbitals.

Acknowledgements

The authors would like to thank Dr. Charles Cottrell for performing the NOE experiments and Mr. Carl Engleman for his assistance in producing some of the ^{1}H NMR spectra. Gratitude is also expressed to Prof. Robert Crabtree, Mr. Daniel Perreault, Ms. Heather Heywood, Dr. Michael DiPierro, and Dr. William C. Stevens for their assistance in the preparation of the manuscript. FT-NMR spectra at 11.75 T (500 MHz) were obtained at the Ohio State University Chemical Instrument Center using equipment funded in part by NIH grant no. 1 S10 RR01458-01A1. This study was partially supported by Proctor and Gamble Company's University Exploratory Research Program and by a grant from SOHIO.

Received February 17, 1992

TING-HUA TANG, DENNIS M. WHITFIELD, STEPHEN P. DOUGLAS, JIRI J. KREPINSKY, and IMRE G. CSIZMADIA. Can. J. Chem. **70**, 2434 (1992).

It is a well-recognized conjecture that the unusual reactivity of certain carbohydrate hydroxyls in glycosylation reactions is due to non-covalent intramolecular bonding interactions involving that hydroxyl. A model compound 1-[β-D-2′,3′-dideoxyribofuranosyl]-2-(1*H*)-pyrimidinone, which is related to the poor glycosyl acceptor 2′-deoxy-3′-*O*,4-*N*-diacetylcytidine (**1**), has been studied in order to assess the effects of hydrogen bonding involving O5′—H and the heteroaromatic system present in the molecule. The conformational potential energy surfaces of the model compound (lacking only the acetoxy at C3′ and the acetamido at C4) were calculated, using semiempirical (PM3) and *ab initio* (STO-3G) methods. The O5′—H···O2 intramolecular hydrogen-bonded *syn* conformation of the model compound is the global minimum at the *ab initio* level of theory. The existence of this intramolecular hydrogen bonding was confirmed, theoretically, by Bader-type topological analysis of charge distribution at the 3-21G**//STO-3G level of theory. Such a conformation of the model compound strongly resembles that found for **1** by NMR in CD_2Cl_2 solution. The complex formation between this model compound and BF_3 was also studied at the STO-3G, 3-21G**//STO-3G, and 6-31G**//STO-3G levels of theory. The results explain why glycosylation of hydrogen-bonded substrates succeeds when promoted by Lewis acids.

TING-HUA TANG, DENNIS M. WHITFIELD, STEPHEN P. DOUGLAS, JIRI J. KREPINSKY et IMRE G. CSIZMADIA. Can. J. Chem. **70**, 2434 (1992).

Il est bien connu que la réactivité de groupes hydroxyles de certains hydrates de carbone dans les réactions de glycosylation est due aux liaisons intermoléculaires non covalentes impliquant ces groupes hydroxyles. Afin de déterminer les effets des liaisons hydrogènes O5′—H et le système hétéroaromatique présent dans la molécule, on a étudié la 1-[β-D-2′,3′-didéoxyribofuranosyl]-2(1*H*)-pyrimidinone, un modèle moléculaire apparenté à la 2′-déoxy-3′-*O*,4,*N*-diacétylcytidine (**1**), un faible accepteur de glycosyle. Faisant appel aux méthodes semi-empiriques (PM3) et *ab initio* (STO-3G), on a calculé l'énergie potentielle des surfaces d'énergie du composé modèle (dans lequel il ne manque que le groupe acétoxy en C3′ et le groupe acétamido en C4). Au niveau théorique *ab initio*, l'énergie de la conformation *syn* de la liaison hydrogène intramoléculaire O5′—H···O2 du composé modèle correspond à un minimum global. On a théoriquement confirmé l'existence de cette liaison hydrogène par une analyse topologique, du type Bader, de la distribution de charges au niveau théorique 3-21G**//STO-3G. Une telle conformation du modèle ressemble fortement à celle trouvée pour **1** par RMN en solution dans le CD_2Cl_2. On a également étudié la formation du complexe entre le composé modèle et le BF, aux niveaux théoriques STO-3G, 3-21G**//STO-3G et 6-31G**//STO-3G. Les résultats expliquent pourquoi les réactions de glycosylation des substrats ayant des liaisons hydrogènes se font avec succès lorsqu'on utilise des acides de Lewis comme catalyseurs.

[Traduit par la rédaction]

Introduction

It is a known phenomenon in carbohydrate chemistry that certain hydroxyl groups do not undergo glycosylation under standard conditions for the formation of glycosidic bonds (1). This is particularly surprising in the case of primary hydroxyl groups of aldohexopyranosides (C6) and aldopentofuranosides (C5) (2). In some cases the glycosylating agent glycosylates exclusively at the secondary hydroxyl[4] instead of the usually more reactive primary one (3). This happens in spite of the fact that in most cases one would expect that the primary hydroxyls should experience lesser steric hindrance. This puzzling situation negatively affects the planning and execution of multistep oligosaccharide syntheses. Since the efficient synthesis of oligosaccharides is of increasing importance for the application of biologically active glycopeptides and glycolipids in biomedical sciences and biotechnology industries (4), understanding and overcoming this unusual reactivity is essential for the rational development of oligosaccharide syntheses.

Closer examination of molecular models of substances with such unreactive hydroxyls does not suggest unusual steric problems. However, all observed cases contain a π-electron system, either aromatic or heteraromatic, or just double bonds. The π-electron systems are mostly in such

protecting groups as benzyl or allyl (2), or in the heterocyclic base in the case of nucleosides.[5] In certain conformations these π-electron systems can be oriented to interact with the unreactive hydroxyl groups. A simplified case involving water and benzene molecules was investigated, and quantum chemical calculations showed that H_2O can interact with benzene in two different ways. In one, the O—H bond of water is perpendicular to the benzene ring and a hydrogen-bond-like interaction is present between the proton of water and the π-electron of benzene (approximately 2 kcal/mol). In the other, an electron lone pair of the oxygen is hydrogen-bonded to one of the aromatic C—H protons in an edge-on geometry (5, 6). Such interactions have been shown to be important for the structure of globular proteins (7). The question arises whether analogous intramolecular interactions could be responsible for the low reactivity (or unreactivity) in glycosylation reactions.

Such an interaction essentially involves a hydrogen bond (5, 8), and intramolecular hydrogen bonding in molecules containing hydroxyls as the proton donor (in systems such as O—H···O) has been used as an explanation of unusual reactivities on numerous occasions (3, 9–11). Since it appears that the oxygen of the hydroxyl experiences an increase in electron density (by the partial "removal" of the counterbalancing proton), the rates of reactions in which this oxygen acts as a nucleophile should be enhanced. This has indeed been observed in a large number of examples (3, 9–11). A decreased reactivity, or unreactivity, of hydrogen-bonded hydroxyls in certain apparently nucleophilic reactions is not satisfactorily explained. The reaction of diazomethane with hydroxyls resembles glycosylations in that proton dissociation is a necessary step. Certain hydrogen-bonded phenolic hydroxyls are unreactive with diazomethane and its derivatives (11). It may be postulated that proton loss is rate limiting in these cases.

Recently, during the syntheses of a series of 5′-*O*-galactosylated nucleosides in this laboratory, a low-reactivity problem involving the primary O5′—H was encountered.[5] This is surprising since the 5′-hydroxyl in nucleosides is the most reactive hydroxyl in the sugar portion of the molecule (3) and this fact has been utilized for differential protection in many synthetic strategies. Glycosylation reactions are normally described as nucleophilic attack of a hydroxyl of an aglycon at the anomeric carbon of a glycosylating agent. Considering 3′-*O*-,4-*N*-diacetyl-2′-deoxyribocytosine (**1**, cf. Fig. 1) (12) as an example, it seems obvious that access to the 5′-hydroxyl should not be hindered in any possible conformation. NMR studies have shown that in dichloromethane, a solvent typically used for glycosylation, the molecule adopted one predominant conformation that was suitable for formation of a hydrogen bond. This compound is small enough so that quantum chemical calculations might feasibly be carried out to confirm the presence or the absence of hydrogen bonding. Moreover, if no hydrogen bond exists, then such calculations could conceivably indicate whether any unusual electronic properties exist that could explain the low reactivity. Such rationalization by theoretical means is very desirable since it has recently become possible in our laboratory to overcome the unreactivity of such nucleosides

using Lewis acid-catalyzed glycosylation conditions. It is, of course, a possibility that a stereoelectronic preference for glycosylation exists in a transition state that would not be available for hydrogen-bonded systems (13, 14).

The existence of intramolecular hydrogen bonding in nucleosides, including **1**, is well documented (15). For example, crystallographic data have shown that an intramolecular O5′—H···O2 bond associated with the sugar ring puckering can be observed in the *syn* conformation for pyrimidine nucleosides (16). Such a type of intramolecular hydrogen bonding was also observed (17) for uridine derivatives in $CHCl_3$ solution by combined used of NMR, CD, and IR spectroscopy. The conformations of nucleoside antibiotics such as formycin and showdomycin were studied (18*a*) theoretically using a semiempirical method of calculations (PCILO). It was reported that the *syn* conformation is stabilized by intramolecular hydrogen bonding between O5′—H of the sugar and N3 of the base for formycin and there is also an intramolecular hydrogen bond between O5′—H of the sugar and O2 of the base for showdomycin. Only a few *ab initio* studies have been published about nucleosides and these dealt with adenosine (18*b*, *c*) at the STO-3G level of theory. However, even in these MO studies no attention was paid to intramolecular hydrogen bonding that may exist between the 5′-hydroxyl group of the sugar and the heteroaromatic base. On the other hand, intramolecular hydrogen bonds involving the hydroxymethyl group and the tetrahydrofuran ring oxygen and thymine's C2 carbonyl oxygen in 3′-azido-3′-deoxythymidine (AZT) have been suggested recently, using molecular mechanics and NMR techniques (19). For this reason, it seemed that a theoretical study of the conformational analysis of a 2′-deoxycytidine derivative was needed in order to gain some understanding of the conformational dependence of the various attractive and repulsive interactions that may exist between such hydroxyl groups and the heteroaromatic system in the nucleoside. Obviously the understanding of the detailed nature of such intramolecular interactions at the level of electron density redistribution was also desirable.

Since, as mentioned above, Lewis acids have been shown to help overcome the unreactivity of such nucleosides during glycosylation reactions, the Lewis complex formation between BF_3 and the selected cytidine model compound was also studied.

Although the NMR study was performed on 2′-deoxy-3′-

O,4-*N*-diacetylcytidine (**1**), to simplify the calculations they were done on a model substance 1-[β-D-2′,3′-dideoxyribofuranosyl]-2-(1*H*)-pyrimidinone (**2**).

Experimental and computational methods

NMR spectrometry

2′-Deoxy-3′-*O*,4-*N*-diacetylcytidine (compound **1**) was prepared as described (12). ^{1}H NMR spectra of **1** were obtained with a Bruker AM 500 spectrometer in the NMR Laboratory, Carbohydrate Research Centre, University of Toronto, at 19 ± 2°C in CD_2Cl_2 (Merk, Sharpe and Dohme) using the residual $CHDCl_2$ resonance (5.32 ppm) as reference signal. A small amount of activated powdered 4Å molecular sieves was added directly to the NMR tube to remove any residual H_2O. For D_2O exchange one drop of D_2O was added to the sample and then mixed vigorously. The spectrum was recorded after equilibration and removal of residual D_2O (HDO) by the molecular sieves. Steady-state ^{1}H–^{1}H NOE data were obtained in the difference mode using stationary samples, a 90° monitor pulse, and a frequency cycling method for low-power preirradiations. Individual irradiation periods at a given frequency value were set equal to the 90° decoupler pulse at the chosen decoupler power level; the total preirradiation period was determined experimentally by monitoring enhancements of resonances due to spatially distant protons with low NOE buildup rates.

Computational methods

Parametric Method 3 (PM3) type molecular orbital calculations (20) were carried out using the MOPAC program (21) on an Apollo DN 10000 minicomputer at the Department of Chemistry, University of Toronto. The PM3 method is a new semiempirical method that has been developed to improve the modified neglect of diatomic overlap (MNDO) method (22, 23).

All *ab initio* computations were conducted on the Cray X-MP/24 supercomputer at the Ontario Centre for Large Scale Computation (OCLSC) using the GAUSSIAN 90 program (24). The *ab initio* geometrical optimizations were performed at the STO-3G basis set level (25) for each of the conformers obtained previously by semiempirical PM3 SCF computations. Thus the starting or input geometries for the *ab initio* computation were the final geometries obtained previously by the PM3 calculations. *Ab initio* energies reported in this paper are, therefore, for the fully optimized geometries obtained by energy gradient optimization. Each conformation at the present basis set level took more than 3 h CPU time on the Cray supercomputer; therefore it seemed impractical to carry out calculations at a higher basis set level of theory.

On going from a lower level to a higher level of theory, local minima on the potential energy surface (PES) very often (26, 27) disappear. However, to ensure that it is indeed the case here, a careful search was carried out in those cases where a conformation obtained by the PM3 method was annihilated on going to the *ab initio* level of theory.

For Bader-type topological analysis of charge density (28), the 3-21G** and 6-31G** polarized basis set (29) was used on the STO-3G optimized geometries. The topological properties of the electronic density were determined by the atoms in molecules theory (28) using the AIMPAC program.[6]

Results and discussion

Conformational analysis

Conformational potential energy surfaces of a simplified model compound were generated to establish the nature of possible interactions between the 5′-hydroxyl and the heteroaromatic base. The model compound **2** and its atomic labels of interest are specified in Fig. 2. Compound **2** lacks the 4-acetamido and 3′-*O*-acetate of the parent compound **1**.

[6]Available from Professor R. F. W. Bader's laboratory, McMaster University, Hamilton, Ont., Canada L85 4M1.

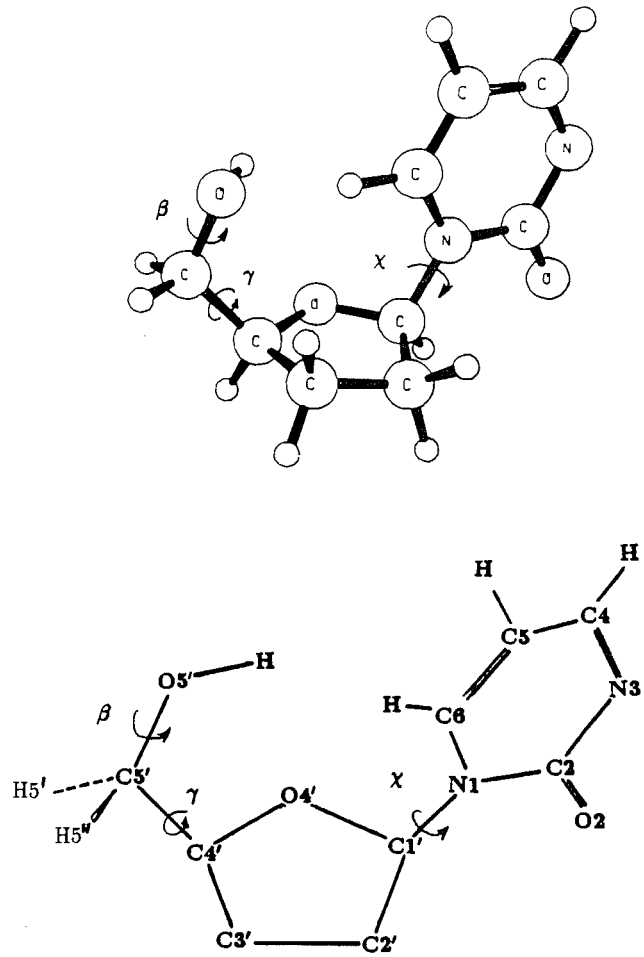

FIG. 2. Model compound (**2**) mimicking 2′-deoxycytidine derivative and the atomic labels of interest.

Neither of these groups should significantly affect the conformational degrees of freedom studied here. The conformation about the aromatic base – carbohydrate linkage N1—C1′ is described by the torsional angle χ. The orientations of the hydroxymethyl group and hydroxyl group are described by the torsion angles γ and β, respectively.

[1] $\chi = \theta(O4'—C1'—N1—C2)$

[2] $\gamma = \theta(O5'—C5'—C4'—C3')$

[3] $\beta = \theta(H—O5'—C5'—C4')$

The sign of the torsion angles is defined and labelled[7] in agreement with the recommendations of the IUPAC–IUB commission of Biochemical Nomenclature (30). For each optimal γ, corresponding to the nominal 60°, 180°, and 300° values, representing the $-sc$, ap, and $+sc$ conformations, respectively, potential energy surfaces $E = E(\beta, \chi)$ were

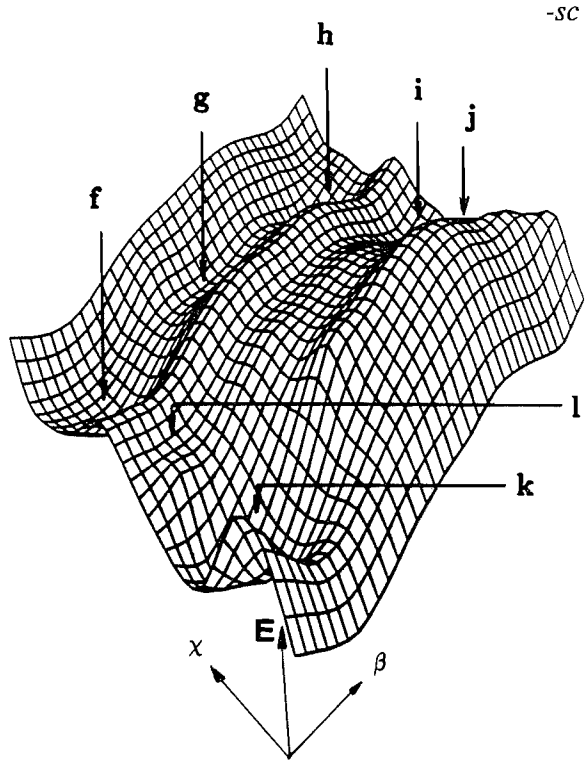

FIG. 4. The PM3 potential energy surface related to the $-sc$ conformation about the C5′—C4′ bond.

generated at 30° increments along the β and χ torsional angles.

In the first phase of this study, the SCF energy values of the model compound were calculated by the PM3 method. Three potential energy surfaces (PES), shown in Figs. 3, 4, and 5 were found to relate to *ap*, $-sc$, and $+sc$ conformations respectively. On the first PES (Fig. 3) associated with *ap*, five minima were found corresponding to conformers **a**, **b**, **c**, **d**, and **e**. Seven conformers (**f**–**l**) were located on the second PES (Fig. 4) associated with $-sc(\gamma \approx 60°)$ and again five conformers (**m**–**q**) were identified on the third PES (Fig. 5) associated with $+sc$ ($\gamma \approx 300°$). The geometries of these 17 conformers (**a**–**q**) are illustrated in Fig. 6. For conformer **k**, the O5′—H and O2 atom of the carbonyl group of the heteroaromatic base are almost colinear and the distance between the H of the hydroxyl group and O2 is 1.82 Å (with the O5′···O2 distance being 2.76 Å). This corresponds to a computed bond order of 2.9% of a single bond. The PM3 bond order using the MOPAC program was computed as the sum of squares of the density matrix elements connecting any two atoms. In spite of the above, as may be judged from the PM3 SCF energy value, conformation **k** is not the global minimum. The global minimum on the three PM3 PES is an *anti* conformation **c**.

In the second phase of this study, the geometries of the 17 conformers (**a**–**q**) related to the 17 local energy minima on the three PM3 PES (Figs. 3–5) were reoptimized by the *ab initio* method using a standard STO-3G basis set. The SCF energies, both PM3 and *ab initio* results, as functions of the β, γ, and χ torsional angles are summarized in Table 1. Instead of 17, only 14 minima were found on the *ab initio* PES. The *ab initio* geometries (**a′**–**q′**), as illustrated in Fig. 7, are related to the semiempirical conformers (**a**–**q**) with **i′**, **j′**, and

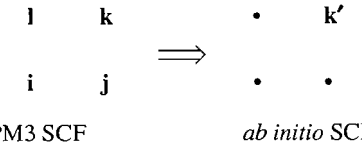
l′ being annihilated. The geometry of each of the *ab initio* conformers seems to show no substantial change when compared with the PM3 geometries (see Table 1).

Recognizing that β, just like all torsional angles, are periodic, the minima labelled as **i**, **j**, **k**, **l** are next to one another and similarly **i′**, **j′**, **k′**, **l′** would also represent nearest neighbours. On going from PM3 to *ab initio* these four PM3 minima collapsed to a single minimum, annihilating three minima (**i′**, **j′**, and **l′**) retaining only one minimum that corresponded to **k′**.



PM3 SCF *ab initio* SCF

It should be noted that during the collapse of these four minima into a single minimum not only β and χ were altered but γ as well: **k** (γ = 36.49°) → **k′** (γ = 27.83°). Nevertheless, the hydrogen-bonded *syn* conformation is **k′** at the *ab initio* level of theory. This **k′** conformer (χ = 62.69°, β = 58.91°, and γ = 27.83°) is in fact the global (i.e., the lowest energy) minimum among these 14 minima on the *ab initio* potential energy hypersurfaces. The next conformer is an *anti* conformer **g′**. For conformer **k′**, the O5′—H and O2 atom are also close to being colinear. The distance between the hydroxyl group H and O2 is 1.77 Å (O5′···O2 distance being 2.74 Å). For this intramolecular hydrogen-bonded system, the optimized geometrical parameters, obtained at the STO-3G basis set level of theory, are summarized in Table 2.

Multidimensional conformational analysis (MDCA) (31) predicts $3^3 = 27$ minima for a triple rotor with threefold topological multiplicity. In the case of saturated hydrocarbons this is indeed the case and all 27 legitimate minima may be obtained by gradient optimization (32, 33). These represent ideal conformational systems. However, heteroatom-containing molecules have extensive interactions that result in the annihilation of some of the legitimate minima, leading to nonideal conformational PES (34). Simple peptides, for example, have been shown to exhibit such behaviour (27). The present model compound **2** therefore corresponds to a nonideal system both in terms of PM3 and *ab initio* SCF calculations, since out of the 27 legitimate minima only 17 and 14 minima, respectively, were found on these PES. There is reason to believe that all minima on both the PM3 and *ab initio* PES have been located.

The topological representation of three conformational PES obtained at the PM3 and *ab initio* level of theory is shown in Fig. 8. The topology for the *ab initio* surfaces at γ ≈ 180° and γ ≈ 300° are analogous, as shown in Fig. 8. However, the two γ ≈ 60° surfaces show a marked difference with respect to each other and with respect to the surfaces generated at γ ≈ 180° and 300°. This dramatic difference is due to the fact that the O5′—H···O2 hydrogen bonding occurs at the γ ≈ 60° (i.e., −*sc*) surfaces.

NMR determinations

Figure 9 shows the 500 MHz ^{1}H NMR anomeric proton (H1′) irradiated NOE spectrum of deoxycytidine derivative **1** in CD_2Cl_2 solution. Surprisingly, a large NOE to the base proton H6 is observed. This result indicates that this derivative is predominantly in the *syn* conformation, χ ≈ 60° (cf. $\chi_{calc.}$ = 62.69° for **k′** and H1′···H6 is 2.116 Å). Most deoxycytidine derivatives investigated to date are found in the *anti* conformation (35).

Figure 10*a* shows the 500 MHz ^{1}H NMR spectrum of the H4′, H5′, H5″, H2′, H2″, and O5′-H protons of the same deoxycytidine derivative (**1**). The coupling patterns of the H2′ and H2″ are indicative of an approximately 50:50 mixture of the two common 2-*endo* and 3-*endo* conformations of the furanoside ring. Figure 10*b* shows the spectrum of the same sample after exchange with D_2O. The O5′-H disappears and one coupling is removed from each of the H5′ and H5″ res-

onances as expected. The residual H4′–H5′ and H4′–H5″ couplings are both small and are nearly identical to those before D_2O exchange (2.7 and 2.9, Hz respectively, cf. Figs. 10*a* and 10*b*). Such couplings are only consistent with O5′ being *anti*-periplanar to H4′, i.e., $\gamma \approx 60°$ (36) (cf. $\gamma_{calc.} = 27.83°$ for **k**′).

If the C5′—C4′ bond is constrained to one minimum as suggested by the coupling constants, then it is possible to stereospecifically assign the prochiral protons by NOE spectroscopy. Indeed, irradiation of the most upfield H5″ proton produces NOE's to H3′ and H4′ whereas irradiation of H5′ produces only NOE's to H4′. Thus H5″ can be assigned as the pro*R* and H5′ as the pro*S* proton. This assignment agrees with previous assignments based on stereospecific deuteration of other deoxynucleosides (38). If conformation **k**′ is populated in solution, then O5′—H should be *anti*-periplanar to H5″ (calcd. 178.43°) and therefore the corresponding coupling constant should be about 12.1 Hz and $J_{O5'—H,H5'}$ about 1.5 Hz (O5′—H-O5′—C5′—H5′ = −64.11° in **k**′) (37). These calculated values compare to experimental values of 5.9 and 3.0 Hz, suggesting preferential but not exclusive population of conformers like **k**′. If the hydroxyl were freely equilibrating in solution, then the two couplings to H5′ and H5″ would be equivalent and the signal for O5′—H would be a broad triplet and not the observed doublet of doublets (see Fig. 10*a*). The NMR spectral parameters of compound **1** were sensitive to concentration, solvent, and the amounts of residual water in the sample. All these factors should affect any intramolecular hydrogen bonding. It can be concluded that conformers like **k**′ are the predominant conformers in dry CH_2Cl_2 solutions in which glycosylations are typically performed.

Lewis acid (BF_3) complexes with the model compound

Lewis acids, such as BF_3 supplied in the form of $BF_3 \cdot Et_2O$, are frequently used as promoters in glycosylation reactions. In fact such promoters have been shown to overcome the unreactivity of compound **1** in glycosylation reaction. In the present paper, we only examine the possible complex formation between the model compound **2** (that mimics the 2-deoxycytidine derivative) and a Lewis acid. In the simplified model compound **2**, three heteroatoms could be attacked by the Lewis acid; these are O5′, O2, and N3. Due to the lack of parameters for the element boron (21) in the PM3 program, the CH_3^+ cation was used instead of BF_3 in the initial part of the present study. Because the PM3 method was used systematically in the present work, it did not seem prudent to switch to another semiempirical method since CH_3^+ is as suitable a Lewis acid as BF_3. The five PM3 geometries of CH_3^+ complexes labelled from **K**(O5′)1 to **K**(O2)2 are shown in Fig. 11. Since each oxygen atom (O5′ and O2) has two lone electron pairs, it is possible to have two sites where CH_3^+ might be attached leading to four geometries **K**(O5′)1, **K**(O5′)2, **K**(O2)1, and **K**(O2)2. Of course, BF_3 could attach in one mode only to N3, forming one geometry labelled **K**(N3). The distances between the H atom of the 5′-hydroxyl group and O2 of the carbonyl group ($d_{H\cdots O2}$), for the **K**(N3), **K**(O2)1, and **K**(O2)2 conformers, are 2.7054, 3.3011, and 4.4471 Å respectively. These values are too large to be intramolecular hydrogen-bonded systems. However, the values of $d_{H\cdots O2}$ are 1.6540 and 1.6310 Å for the first two CH_3^+ complexes (**K**(O5′)1 and **K**(O5′)2), still indicating hydrogen bonding. Complex

energies (in kcal/mol) are all exothermic at all possible attachment sites: **K**(N3), −104.08; **K**(O2)1, −93.68; **K**(O2)2, −84.65; **K**(O5′)1, −74.80; and **K**(O5′)2, −73.90. The two last complexes involved in hydrogen bonding are of higher energy content than the remaining ones. The lower energy complexes, including the lowest one **K**(N3), thus can be the possible reactive intermediates in the glycosylation reaction. This observation would explain why some glycosylations do not proceed unless Lewis acids are present.

The complex formation between BF_3 and model compound (**2**) was studied by *ab initio* MO. The BF_3 was attached to one site of the O5′ atom of **k**′, forming a BF_3 complex labeled **K**′(O5′)1. This geometry is analogous to that of **K**(O5′)1. The conformer **K**′(O5′)1 was of course optimized using a standard STO-3G basis set in the *ab initio* calculation. Its geometry is shown in Fig. 12 and its geometrical parameters are summarized in Table 3. The energetics of such Lewis complex formation, as computed with different basis sets, are shown in Fig. 13. The reaction is computed to be strongly exothermic at all three basis set levels.

Charge density distribution analysis

In addition to the energetic considerations mentioned above, there is an alternative method to analyze hydrogen bonding. This involves the topological analysis of the electronic density distribution, which can be used to analyze intramolecular hydrogen bonding between the hydroxyl group with the oxygen atom of the carbonyl group of model compound **2** to gain some insight into the reactivity of 5′-OH. Although the topic of intramolecular hydrogen bonding has been widely studied (5) experimentally and theoretically, it has only recently been analyzed by using Bader-type topological analysis of charge density distribution (28, 40). The topological properties of the electronic density distribution are based on the gradient vector field of the electronic density $\nabla\rho(\boldsymbol{r})$, and on the Laplacian of the electronic density $\nabla^2\rho(\boldsymbol{r})$. Several excellent reviews have been published (28) on this subject, therefore only a brief description of selected topological parameters, pertinent to the present work, is discussed here. The electronic charge distribution of a molecule is described by $\rho(\boldsymbol{r}, \boldsymbol{X})$ where $\boldsymbol{r}$ is a variable position vector in ordinary three-dimensional space with r_1, r_2, and r_3 components and $\boldsymbol{X}$ represents a particular set of nuclear coordinates in the space corresponding to the nuclear configurations of the molecule in question. An atom in a molecule is defined (28) as a region of real three-dimensional space bounded by a zero-flux surface of the gradient vector field of $\rho(\boldsymbol{r})$, that is, a surface for which all points on this surface satisfy the equation

$$[4] \quad \nabla\rho(\boldsymbol{r}) \cdot \mathrm{n}(\boldsymbol{r}) = 0$$

where $n(\boldsymbol{r})$ is the unit vector normal to the surface at $\boldsymbol{r}$. Two

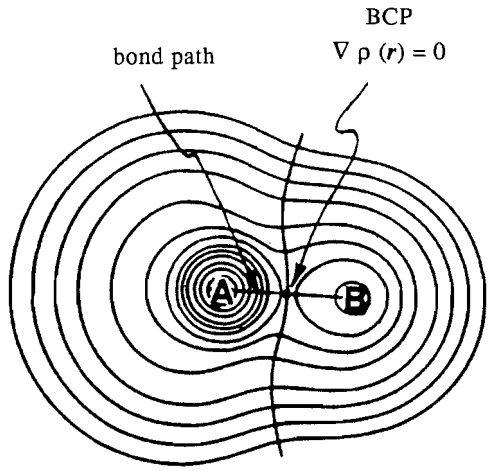
interacting atoms in a molecule form a critical point in the electronic density called a bond critical point (BCP), where

[5] $\nabla\rho(\boldsymbol{r}) = 0$

The pairs of gradient paths, which originate at a BCP and terminate at neighbouring nuclei ("attractor" in the gradient field of $\rho(\boldsymbol{r})$) define a line through electronic charge distribution along which $\rho(\boldsymbol{r})$ is a maximum with respect to any lateral displacement called an atomic interaction line. The presence of such a line linking two nuclei in a molecule that exists in a minimum energy geometry implies that the two atoms are bonded to one another, and in this instance this line is called a bond path. The necessary and sufficient condition for two atoms to be bonded to one another is that their nuclei be linked by a bond path. The network of bond paths for a molecule in a given nuclear configuration $\boldsymbol{X}$ defines the molecular graph, which essentially is the union of the closures of the bond paths. As a topological structure the molecular graph usually corresponds to the commonly drawn chemical bond network. For a molecule AB, the bond path, the BCP, and the zero-flux surface between these two atoms can be portrayed as follows:



$\nabla\rho(\boldsymbol{r}) \cdot n(\boldsymbol{r}) = 0$
zero-flux surface

The Laplacian of electronic charge density, the quantity

[6] $\nabla^2\rho(\boldsymbol{r}) = \Sigma_{j=1,3}\partial^2\rho(\boldsymbol{r})/\partial x_j^2$

determines the regions of space wherein electronic charge is locally concentrated or depleted. From the definition of a second derivative, one finds that $\rho(\boldsymbol{r})$ is greater than the average of its values over an infinitesimal sphere centered on $\boldsymbol{r}$ when $\nabla^2\rho(\boldsymbol{r}) < 0$, and $\rho(\boldsymbol{r})$ is less than this average when $\nabla^2\rho(\boldsymbol{r}) > 0$. Thus a local maximum (or minimum) in $-\nabla^2\rho(\boldsymbol{r})$ signifies a local concentration (or depletion) of electronic charge. The numbers, location, and relative sizes of the bonded and nonbonded concentration of charge in the valence shell of a bonded atom as determined by the Laplacian of $\rho(\boldsymbol{r})$ are found to be in generally good agreement with the corresponding properties that are ascribed to bonded and nonbonded pairs in Gillespie's VSEPR model of molecular geometry (39).

The theory of atoms in molecules has been widely applied to many chemical problems including the description of hydrogen-bonded systems (see for example refs. 28*a* and 41).

For conformer **k′**, there is a bond path linking the H of the 5′-hydroxyl group and O2 of the carbonyl group for the intramolecular hydrogen-bonded system of model compound (**2**) (Fig. 14). Thus, at this point, one can say unambiguously that hydrogen bonding does exist in this system. The electronic density $\rho(\boldsymbol{r})$ at the bond critical point is called $\rho_b(\boldsymbol{r})$,

the magnitude of which is a measure of bond strength (28*b*). From the 3–21G**//STO-3G calculation, for O5′—H the $\rho_b(\mathbf{r})$ is 0.3456 au and for H···O2 the $\rho_b(\mathbf{r})$ is 0.0322 au, respectively. Moreover, the value of $\nabla^2\rho(r_c)$ at the bond critical point for O5′—H is −2.4521 au and for H···O2 is +0.1229 au. Thus, this is a typical intramolecular hydrogen bond in which a hydrogen atom is bound to the heteroatom contained in the acid fragment (O5′) by a shared interaction and to the heteroatom of the base (O2) by a closed-shell interaction (28*b*).

The Laplacian "relief plot" generated according to Bader's method (28*b*) for the fragment plane of the O5′—H···O2 system is displayed in Fig. 15. Two nonbonded regions of charge concentration are seen in the oxygen of the carbonyl group of the heterocyclic base and this is in agreement with the VSEPR model. The region of charge depletion in the valence shell of O5′—H, which is located away from the position of the proton on the O5′—H bond axis, is directed at one of the nonbonded charge concentrations of O2, thereby yielding a stable hydrogen-bonded structure (see arrows in Fig. 15).

The Bader-type topological analysis of charge density was also performed on the BF_3 complex, labeled as **K**′(O5′)1, at the 3–21G**//STO-3G level of theory. Contrary to expectation, it is found that only one bond critical point (BCP) exists between the H of the 5′-hydroxyl group and O2 (Fig. 16) at this level of theory. Using the more flexible basis set (6–31G**) two BCP were found, as expected, along the nearly colinear bond paths (O5′—H···O2).[8] Again, this confirms intramolecular hydrogen bonding. Moreover, based on the value of $\rho_b(\mathbf{r})$, which equals 0.0574 au (3–21G**), it seems that the hydrogen bonding in the BF_3–**2** complex, labeled as **K**′(O5′)1, is strengthened compared with conformer **k**′ of the uncomplexed model compound **2**. The topological properties of the charge density of **k**′ and **K**′(O5′)1 are summarized in Table 4.

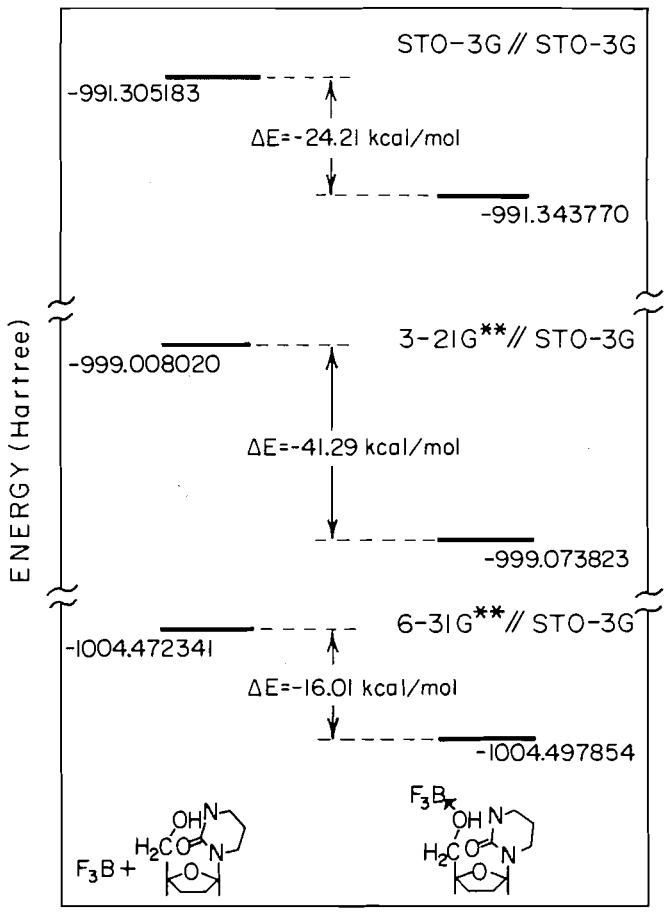

FIG. 13. Energetics of Lewis complex formation involving BF_3 and model compound **2**.

Conclusion

It has been shown at both semiempirical and *ab initio* levels of calculation that hydrogen bonding between O5′—H and O2 is a stabilizing factor for the predominant conformation **k**′ of model compound **2**. This result has been confirmed by solution NMR measurements on the parent compound **1**. The *ab initio* calculations gave the best fit to the NMR data, re-

[8]The use of Bader-type topological analysis of electron density to detect hydrogen bonding is rigorously correct for the exact density. Moreover, it is usually valid for electron density computed from sophisticated wave functions. However, at a lower level of theory the analysis might be unable to detect the existence of hydrogen bonding and in that case one must use a larger basis set to determine if a hydrogen bond does or does not exist.

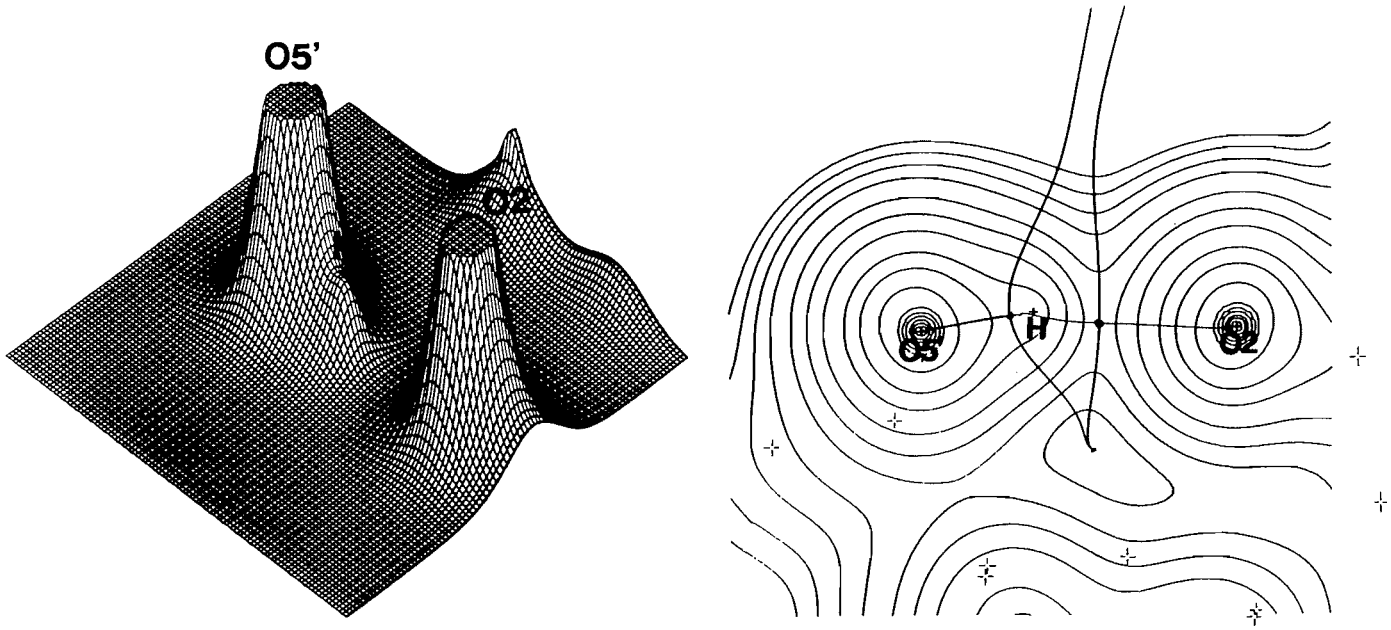

FIG. 14. (*a*) Three-dimensional plot of $\rho(\mathbf{r})$ for a plane containing O5′—H···O2 nuclei in conformer **k**′. The plot was made using a 3-21G**//STO-3G basis set. (*b*) Contour map of the charge density for a plane containing O5—H···O2 nuclei in conformer **k**′. The bond critical points are denoted by black dots. The bond paths, a line linking the nuclei along which the charge density is a maximum with respect to any neighboring line, and the intersection of the interatomic surface, which are defined by the lines of steepest descent through the three-dimensional charge distribution starting from the bond critical point, are also shown. The projected positions of out-of-plane nuclei are indicated by open crosses. The plot was made using a 3-21G**//STO-3G basis set.

k′	3-21G**//STO-3G	0.3456	−2.4521	0.0322	+0.1229
K′ (O5′)1	3-21G**//STO-3G	—	—	0.0572	+0.1875
	6-31G**//STO-3G	0.3127	−2.1390	0.0582	+0.2096

affirming the utility of this level of calculation to investigate organic reactions. These calculations permitted the use of Bader's charge density topological approach to model the hydrogen bond. Furthermore, it has been found that Lewis acids can form strongly exothermic complexes with O5′ of **2** that enhance the hydrogen bridge between O5′—H and O2. Other Lewis acid complexes are of lower energy and, more importantly, are not involved in hydrogen bonding. These results explain why glycosylation reactions involving hydrogen-bonded substances occur in the presence of Lewis acids, although they do not advance under other conditions. Clearly, several examples containing a variety of OH groups reacting differently need to be examined at this level of calculation, so that the importance of non-covalent interactions in the mechanism of the glycosylation reaction can be assessed. The utility of such approaches, in this direction, is currently being investigated.

The development and synthesis of anticonvulsant new chemical entities that are distinct from the cyclic ureides in current clinical use is a continuing neuropharmacologic priority. The design of neuronal specific dihydropyridines active at the L-type calcium channel protein represents a rational approach to this design problem. To provide the structural data required for the design of anticonvulsant dihydropyridines, an AM1 semi-empirical molecular orbital study has been undertaken. Forty-six dihydropyridine calcium channel antagonists have been fully optimized at the AM1 level. Each of the 46 analogues was considered in six conformations to provide a systematic evaluation of changes in ester and phenyl ring orientation. The calculational validity of the AM1 Hamiltonian when applied to dihydropyridines was demonstrated by comparing AM1-optimized structures to experimental (X-ray crystallographic) and *ab initio* molecular orbital (STO 3G basis set) geometries. For each dihydropyridine, 79 AM1-derived geometric and electronic descriptors were obtained. The resulting descriptor matrix comparing structural descriptors with biological activity was statistically reduced to provide regression and discriminant structure–activity models for dihydropyridine calcium channel antagonism.

JACK ANDREW BIKKER et DONALD FREDRIC WEAVER. Can. J. Chem. **70**, 2449 (1992).

Le développement et la synthèse de nouvelles entités chimiques anticonvulsives distinctes des uréides cycliques actuellement en usage clinique sont des priorités neuropharmacologiques permanentes. La conception de dihydropyridines de spécificité neuronale, actives au niveau de la protéine de type L du canal du calcium, représente une approche rationnelle à ce problème. Afin d'obtenir les données structurales nécessaires pour la conception de dihydropyridines anticonvulsives, on a entrepris une étude d'orbitales moléculaires semi-empiriques AM1. Opérant au niveau AM1, on a optimisé 46 dihydropyridines antagonistes du canal du calcium. Afin d'obtenir une évaluation systématique des changements dans l'orientation de l'ester et du noyau phényle, on a considéré chacun de ces 46 analogues dans six conformations. On a démontré que l'hamiltonien AM1 appliqué aux dihydropyridines est valide pour les calculs en procédant à une comparaison des structures optimisées par AM1 avec celles obtenues expérimentalement (diffraction des rayons X) et avec les géométries obtenues par des calculs d'orbitales moléculaires *ab initio* (base STO 3G). Pour chaque dihydropyridine, on a obtenu 79 descripteurs géométriques et électroniques dérivés du AM1. On a réduit statistiquement la matrice résultante de descripteurs comparant les descripteurs structuraux avec l'activité biologique afin d'obtenir des modèles de régression et d'activité–structure discriminatoires pour la dihydropyridine antagoniste du canal du calcium.
[Traduit par la rédaction]

1. Introduction

Of the more than 50 million people worldwide suffering from epilepsy, approximately 35% are either unable to tolerate conventional drugs or simply do not respond to these medications (1). Therefore, there is a need to devise new approaches in the rational design of antiepileptic drugs, thus developing novel compounds distinct from the cyclic ureides in current clinical use. Modulation of the neuronal calcium currents involved in the propagation of seizure-related aberrant electrical activity within the brain represents such an approach. Dihydropyridine (DHP) calcium channel antagonists are an important class of pharmacotherapeutic compounds (2, 3). Although initially used for cardiovascular indications, recent studies have investigated DHPs as a potential treatment for neurologic disorders such as epilepsy (4–9). These studies suggest that, while the DHPs possess significant anticonvulsant activity, they are not as potent as currently available anticonvulsants, such as 5,5-diphenylhydantoin (9). The reason for these limitations is that the currently available DHPs were designed primarily for cardiovascular indications, not neurologic indications.

Recently, the need to design neuronal-specific DHPs for the treatment of seizures has been suggested (10). The design problem may be conceptualized as twofold: (*i*) the DHP must bind strongly with its receptor site on the transmembrane voltage-activated calcium channel protein and (*ii*) the DHP must have the capacity to cross the blood–brain barrier and be delivered to the microenvironment of the receptor site. The first is a pharmacodynamic consideration; the latter is a pharmacokinetic consideration. If the molecular fragment of the DHP that interacts with the receptor can be identified, the rest of the molecule can be engineered to improve site-specific delivery to the brain.

To provide the structural data necessary for the design of anticonvulsant dihydropyridines, a semi-empirical quantum mechanical study has been undertaken. The goals of this study are threefold: (*i*) to evaluate the utility of the AM1 Hamiltonian in the optimization of DHP geometries and conformation, (*ii*) to perform a rigorous search of the con-

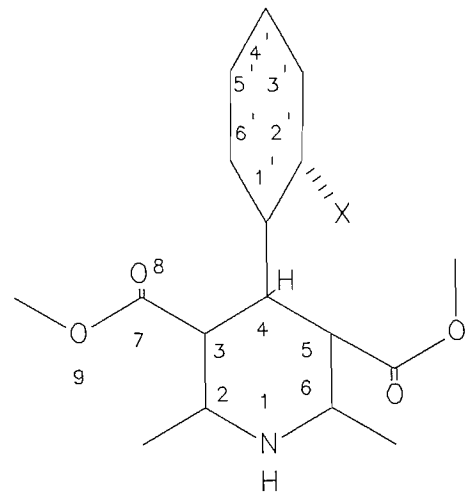

FIG. 2. Basic dihydropyridine calcium antagonist structure with numbering scheme.

formations available to the DHPs, and (*iii*) to preliminarily evaluate the correlation of AM1-derived properties with biological activities in an attempt to deduce the bioactive structural and electronic congeners. To achieve these goals, 46 DHPs have been fully optimized using AM1. Six conformers of each of the DHPs were fully optimized, providing the heats of formation of the various conformations and assisting in the prediction of the putative bioactive conformation. AM1 geometries were then compared to their corresponding crystal structures and *ab initio* conformations to assess the usefulness of the semi-empirical calculational approach. To permit this comparison, seven DHPs were fully optimized at the STO-3G *ab initio* level. Finally, AM1-derived geometric and electronic properties were statistically correlated with pharmacologic data for 34 mono-substituted DHPs for which comparable biological data was available.

2. Calculations

2.1. AM1 conformational optimization calculations

The first phase of this study ascertained the utility of AM1 calculations in representing DHP geometries. Conformational calculations were performed on an IBM RS/6000 550 RISC computer operating under AIX. For semi-empirical molecular orbital calculations, the AM1 (11) Hamiltonian implemented in MOPAC 5.01 was used (12). For *ab initio* molecular orbital calculations, STO-3G basis set calculations were performed using the HONDO (13) program within the MOTECC-90 family of programs (14).

The conformations of the DHPs are labelled according to the convention shown in Fig. 1; the numbering system about the rings and side chains of the DHP is shown in Fig. 2. An ester is considered to be *synperiplanar* (*sp*) if its carbonyl group eclipses the adjacent double bond of the dihydropyridine ring and *ap* if the carbonyl group is oriented *anti* to the adjacent double bond. The *synperiplanar* conformation can also be considered to be *cis* or *Z*, and the *antiperiplanar* (*ap*) to be *trans* or *E*. The conformation of the phenyl ring is classified according to the orientation of the phenyl substituent with the C(4)—H bond of the dihydropyridine ring. Thus, a conformation in which the phenyl substituent lies above the dihydropyridine ring is *ap*; that in which it is oriented away from the ring and eclipses the C(4)—H bond is *sp*. The esters are distinguished as "left" and "right" with respect to the dihydropyridine ring viewed with the phenyl group oriented forward and up above the C(2)—C(3)—C(5)—C(6) plane. (In all cases, the acronym DHP represents the entire dihydropyridine calcium channel blocker; where only the six-membered dihydropyridine ring is indicated, the entire word is used.)

Initial geometries of the dihydropyridine calcium channel blockers were taken from crystal structures of the 2-nitro (15) and 3-nitro (16) substituted DHPs obtained from the Cambridge Crystallographic Database (17). Templates were constructed based upon the AM1-optimized conformations of these structures. Using these templates, the KGNMOL molecular graphics package (18) was used to generate starting conformations for the balance of the compounds. For each of the 46 DHPs, six starting conformations were examined (*phenyl:left ester/right ester*): *sp:sp/sp*; *sp:sp/ap*; *sp:ap/ap*; *ap:sp/sp*; *ap:sp/ap*; and *ap:ap/ap* (see Fig. 3). These conformations were chosen to evaluate the six most probable conformers available to the DHPs; they represent systematic rotations about the three bonds that significantly affect DHP conformation. The side chains were set so that the torsional angle between the carbonyl of the ester and the adjacent double bond of the ring deviated by less than 5° from either 0 or 180 degrees. Similarly, the phenyl ring was rotated so that it eclipsed the C(4)—H bond. In the subsequent optimizations, the ester groups and the phenyl ring were free to rotate.

Root-mean-square comparisons of geometries were performed using the Comp routine in the KGNGRAF program (14). To compare AM1 with experimental conformations, crystal structures were obtained from the Cambridge Crystallographic Database (17).

To compare AM1 with *ab initio* conformations, seven DHPs were fully optimized using *ab initio* calculations at the STO-3G basis set level. Starting conformations were obtained from the AM1-optimized conformations. The convergence threshold on the maximum gradient component was set at 10^{-6}. Convergence was achieved in all cases.

2.2. Statistical structure–activity relationship calculations

In the second phase of this study, AM1-derived structural and electronic properties were statistically correlated with biological activity. Statistical calculations were per-

formed on an IBM ES/9129 mainframe computer operating under VM/CMS. Regression and discriminant analyses were performed using the SAS package of programs (19), version 6.06.

To describe DHP molecular properties, a series of geometric and electronic descriptors were obtained from the AM1 optimizations for each DHP analogue. All descriptors were obtained from the optimized geometry having the phenyl substituent oriented *sp* and the ester side chains oriented *sp*/*sp*. Each analogue was described by 79 descriptors. These descriptors may be classified into the following 11 groups. (*i*) bond lengths about the dihydropyridine and phenyl rings, (*ii*) bond angles about the dihydropyridine rings, (*iii*) torsional angles about the dihydropyridine ring, (*iv*) torsional angles about the C(3)—C(7) and C(4)—C(1′) bonds, (*v*) interatomic distance between the distal atomic centre of the phenyl substituent and its point of attachment to the phenyl ring, (*vi*) atomic charges about the dihydropyridine and phenyl rings, as well as the sum of atomic charges of the substituent, (*vii*) bond orders about the dihydropyridine and phenyl rings, (*viii*) energies of the HOMO and LUMO, (*ix*) magnitude of the molecular dipole, (*x*) molecular weight, and (*xi*) ring puckering parameters.

Biological data for calcium channel blocking activity were obtained from Coburn *et al.* (20). These data were acquired using a standard protocol that measured the inhibition of smooth muscle contraction by calcium channel blockade. As calcium channel antagonism is believed to be the mechanism of the DHP's anticonvulsant action, these data serve as an indirect, rather than a direct, measure of anticonvulsant activity. Complementary data for a number of compounds were obtained from Rovnyak *et al.* (21, 22).

A total of 34 compounds of differing biological activity were used in the analysis. Each compound was described by its biological activity and 79 geometric and electronic descriptors, giving rise to a 34 × 79 descriptor matrix. A principal goal of the study was to identify a restricted number of descriptors that correlated well with the biological activity and could therefore be used to predict compound activity. Stepwise regression analysis and stepwise discriminant analysis were used to identify subgroups of descriptors that were correlated with the biological data. These subsets of descriptors were then incorporated into regression and discriminant models, which provided complementary methods of estimating compound activity.

The regression models were constructed using the following procedure. A subset of descriptors that correlated well with activity was selected from the full descriptor matrix using stepwise and forward selective regression procedures at the 95% confidence level. These descriptors were then fit to pharmacologic activity (obtained from ref. 20 as -log EC_{50}) using linear regression. This procedure was applied to subgroups of compounds substituted at the 2′, the 3′, and the 4′ positions of the phenyl ring, to those substituted at either the 2′ or 3′ positions on the phenyl ring, and to the entire data set of 34 compounds.

For the discriminant analysis, DHPs were classified as more active (MA) if their biological activity was greater than 7.00 or less active (LA) if less than 7.00. Stepwise discriminant analysis at the 95% confidence level was used on the entire data set to identify a subset of descriptors with discriminatory ability. Discriminant analysis using this smaller group of descriptors was then performed on the entire data set.

To critically evaluate this discriminatory model, a balanced subset of DHPs consisting of the 14 most active and 14 least active DHPs was created. The remaining compounds were those at the border between classes (and thus somewhat ambiguously classified) and the 3′-N_3 and 4′-Me for which no comparable biological data was available. Thirty trials of the discriminant model were performed using the smaller test set. In each trial, 10 randomly chosen compounds (5 more active, 5 less active) were used as a test set and the remaining 18 (9 active, 9 less active) were used as the training set. The performance of the discriminant model could be evaluated for each trial by its ability to correctly classify the molecules in the training set itself, the randomly determined test set, and the molecules at the class border. The error for each trial was estimated by the misclassified compounds as a fraction of all classified compounds in both the training and test data sets. The error in the discriminant function was then estimated by calculating the percentage misclassified for all trials.

NOTE: Torsional angles reported are for AM1 compounds in the *sp*/*ap* ester conformation. $\Sigma|\tau|$ is the sum of the absolute values of the torsional angles and Q is the total puckering amplitude of the ring as determined the method of Cremer and Pople (25).

3. Results

3.1. Comparison between AM1 conformations and crystal structures

AM1-optimized structures were compared with experimental crystallographic data for 10 DHPs (Table 1). Root-mean-square values ranged from 0.200 to 0.568. Distances and angles about the DHP ring are better conserved among AM1-optimized geometries than among their corresponding crystal structures (15, 16, 21, 23, 24). As shown in Table 2, AM1-optimized geometries have longer bonds between the ring nitrogen and the adjacent C_{sp^2} carbon, but shorter carbon double bonds within the dihydropyridine ring. In addition, the intra-annular angles at N(1) and C(4) of the AM1-optimized geometries are smaller than those in the crystal structures. In the case of the ester group, AM1 predicts carbon–oxygen bonds that are longer than those experimentally observed. However, AM1 also predicts that the C3—C7 bond is shorter than that in the crystal structures. This is also true of the C4—C1′ single bond.

The pucker of the dihydropyridine ring of AM1-optimized geometries and crystal geometries was also compared. Two measures of ring pucker were employed: a simple sum of the absolute values of the torsional angles about the dihydropyridine ring and the total puckering amplitude as defined by Cremer and Pople (25). The latter is a measure of deviation from a mean plane fit to the coordinates of the

ring atoms. Results are reported in Table 1. No correlation between crystal and calculated pucker was found.

3.2. Comparison of AM1 and STO-3G conformations

The AM1 results were compared to seven DHPs fully optimized using the *ab initio* molecular orbital at the STO-3G basis set level. All were optimized in the *sp:sp/sp* conformation. The results reported in Tables 3 and 4 show that AM1 calculations closely match those obtained using the *ab initio* approach.

The AM1-optimized bond lengths match those of the corresponding STO-3G optimized bond lengths to within 0.06 Å. Within the dihydropyridine ring, AM1-optimized geometries have double bond lengths 0.06 Å longer than their corresponding STO-3G geometries and N—C_{sp^2} and C_{sp^2}—C_{sp^3} bond lengths, which are respectively 0.04 and 0.03 Å shorter. The dihydropyridine–phenyl bond is also shorter, by approximately 0.04 Å. In the case of the ester substituents, both the single bond from the carbonyl carbon to the C_{sp^2} carbon of the dihydropyridine ring and the single bond to the methoxy oxygen are calculated to be shorter in AM1 geometries than in STO-3G optimized structures. Conversely, the carbonyl double bond is calculated to be longer by AM1. Overall, the root-mean-square fit of non-hydrogen atoms ranged from 0.088 to 0.277.

Using both calculational methods, bond lengths and angles determined for different DHPs were conserved. Where there were changes, AM1 appears to reproduce the trends in bond lengths observed in STO-3G geometries.

Bond angles about the dihydropyridine ring calculated by AM1 and STO-3G are in close agreement, differing by less than 3°. The torsional angles differ somewhat more; the dihedral angles of the nitrogen–C_{sp^2} bond are calculated to be approximately 8° less than those calculated by STO-3G. However, the torsional angles of the ring double bonds are about 4° larger. Generally, the ester side chains as calculated by AM1 deviate from a conformation coplanar with the dihydropyridine ring more than those calculated by STO-3G. Similarly, the phenyl ring is less constrained to lie in the N(1)—C(4)—C(1′) plane. Overall, there is good correspondence between STO-3G and AM1 geometries.[2]

3.3. Energies of conformers

The heats of formation of the six optimized conformers of each compound are given in Table 5. Overall, the energy differences among conformers were not large; differences less than 5 kcal/mol between the highest and lowest energy conformer for each compound were typical. In all cases, a

[2]Tables of AM1 geometries: bond lengths, and bond angles and torsional angles about the DHP ring have been deposited as supplementary material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

These tables have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

these cases, the *sp* phenyl conformation was often preferred. Those conformations with ester carbonyl groups in opposite orientations (i.e., *sp/ap*) generally had associated energies close to that of the *sp/sp* orientations. The 2′-NH2 and 3′-OAc substituted DHP both showed a notable preference for the *sp:sp/ap* conformation.

3.4. Correlation of AM1 properties with biological activity

The geometric and electronic information obtained from the AM1-optimized conformations was analyzed for structure–activity relationships. A set of 34 monosubstituted compounds for which comparable biological testing exists was used for this investigation. All data was obtained from the *sp:sp/sp* conformation. For each compound, 79 electronic, geometric, and *ad hoc* descriptors were generated. The dimensionality of this data set was reduced using statistical routines contained in the SAS (19) family of programs.

The forward and stepwise regression procedures within SAS that selected descriptors correlated with activity were employed. The confidence level for entry and removal from the model was set at 95%. These models were then tested using standard linear regression procedures. The statistical

models obtained are given below for the DHPs substituted at the *ortho* position (eq. [1]), for the data without *para*-substituted compounds (eq. [2]), and for the entire data set of mono-substituted DHPs (eq. [3]). The order of the descriptors in a model is the same order in which they were entered into the model by the stepwise regression procedure.

$$[1]\quad \text{Act} = -61.4 - 4.01\,(E_{\text{HOMO}}) + 24.84\,(\text{bo}_{2'3'})$$
$$R^2 = 0.84, \qquad F = 24.8, \qquad n = 13$$

where E_{HOMO} = energy of HOMO in kcal/mol; $\text{bo}_{2'3'}$ = bond order of the C(2′)—C(3′) bond of the phenyl ring; Act = pharmacologic activity (-log(EC_{50})).

$$[2]\quad \text{Act} = 79.4 - 0.54\,(\text{L}_{3'}) - 1.44\,(E_{\text{HOMO}}) - 105\,(\text{bo}_{34}) - 1.38\,(A_{345}) + 142\,(\text{bo}_{56}) + 0.92\,(A_{165})$$
$$R^2 = 0.89, \qquad F = 26.9, \qquad n = 27$$

where $\text{L}_{3'}$ = distance from point of attachment to distant atom on substituent at *meta* (3′) position of phenyl ring; E_{HOMO} = energy of HOMO in kcal/mol; bo_{34} = bond order of the C(3)—C(4) bond of the dihydropyridine ring; bo_{56} = bond order of the C(5)—C(6) bond of the dihydropyridine ring; A_{345} = C(3)—C(4)—C(5) bond angle; A_{165} = N(1)—C(6)—C(5) bond angle; Act = pharmacologic activity (-log(EC_{50})).

$$[3]\quad \text{Act} = -3.17 - 2.05\,(l_{4'}) - 0.47\,(\text{L}_{3'}) - 2.88\,(E_{\text{HOMO}}) + 567\,(\text{Q}_5)$$
$$R^2 = 0.73, \qquad F = 20.5, \qquad n = 35$$

where $l_{4'}$ = axial length of *para* substituent on phenyl ring; $L_{3'}$ = distance from point of attachment to distant atom on substituent at *meta* (3′) position of phenyl ring; E_{HOMO} = energy of HOMO in kcal/mol; Q_5 = charge at C(5) of dihydropyridine ring; Act = pharmacologic activity (-log(EC_{50})).

No significant correlations with R^2 greater than 0.70 were obtained from the series of *para*- and *meta*-substituted compounds.

A discriminant model was also developed to distinguish active from less active compounds. The DHPs in the full data set were divided into two categories, more active and less active. The somewhat arbitrary criterion used for this assignment was that all compounds with activity (-log EC_{50}) of 7.00 or greater were assigned as more active; the rest as less active. Stepwise discriminant analysis at the 95% confidence level yielded four descriptors which could be used to assign the class of a molecule. These descriptors were

$\text{bo}_{3'4'}$ = bond order of C(3′)—C(4′) bond of phenyl ring

$\text{bo}_{4'5'}$ = bond order of C(4′)—C(5′) bond of phenyl ring

E_{HOMO} = energy of HOMO

$l_{3'4'}$ = length of C(3′)—C(4′) bond

The discriminant model using these descriptors was evaluated using smaller subsets of data as training and test sets. Overall, the four-descriptor model using subsets of 18 compounds (9 active, 9 less active) as training sets and 10 randomly chosen compounds (5 more active, 5 less active) as a test set correctly classified both the training and test sets in 97% of all cases. The misclassified compounds were 4′-I, 3′-NMe_2, and 2′-NH_2. Of the remaining data, the 3′-Me and 2′-OEt DHPs were consistently classified as more active by all models, and the 3′-N_3 DHP was classified as more active in 10 of 30 cases.

Table 6 provides a summary of experimental activities and predicted activities of the DHPs determined using the regression model for the full data set, the classes assigned initially and predicted by the discriminant model, and the values of descriptors used in generating the discriminant model.

4. Discussion

4.1. Comparison of AM1 and crystal geometries

The AM1 Hamiltonian (11) has emerged as a dominant molecular orbital method for the structural optimization of biomolecules. Previously, DHPs were not extensively analysed using this technique. Rovnyak *et al.* (21, 22) used AM1 calculations in conjunction with NMR experiments in the analysis of 13 DHPs. The current study, optimizing 237 conformations, provides a thorough examination of the viability of AM1 for the calculational study of DHPs. Moreover, since some authors (26) have identified weaknesses in the AM1 treatment of biomolecules, the AM1 geometries have been critically evaluated by comparison to crystallographic data.

The AM1-optimized geometries closely match those of the crystal structures. Both the low root-mean-square fitting values and the close agreement of bond lengths and angles indicate that the calculations closely reproduce the experimentally observed structures. The AM1 Hamiltonian therefore appears to be a reasonable method for calculating the structure of DHPs.

The variations in geometry that are observed are noteworthy. Bond lengths, angles, and torsional angles are better conserved among AM1 optimizations than among their corresponding crystal structures. This conservation of geometry with differing substitution is also seen in the series of compounds optimized at the *ab initio* level. Thus, some of the deviation in DHP conformation observed in crystal structures may be an artefact of the crystal packing forces, and not an intrinsic property of the molecule. This is emphasized by the ring pucker of AM1-optimized geometries. No correlation could be generated between the pucker of the calculated structures and those of the crystal structures.

The AM1-optimized conformations of the ester groups and the phenyl ring were less well conserved. Although in both the crystal structure and the STO-3G geometries the ester carbonyls eclipsed the dihydropyridine ring double bond, this was less the case with the AM1 results. AM1 optimizations produced ester conformations deviating by up to 50° from planarity. Similarly, the phenyl ring, constrained to lie in the N(1)—C(4)—C(1′) plane in both crystal and *ab initio* geometries, also deviated by as much as 30°. AM1 seemingly overpredicts the conformational flexibility about these bonds.

4.2. Comparison of AM1 and STO-3G geometries

In addition to reproducing experimental (X-ray) conformational data, an effective semi-empirical molecular orbital method must also reproduce *ab initio* geometries. Prior to this study, no *ab initio* studies were reported on full DHPs. Limited *ab initio* geometries obtained at the STO-3G level

[a]Data from ref. 20, values reported as -log(EC_{50}). The 3′-NMe_3 substituted DHP was not included as it represents a departure from the uncharged nature of the balance of the DHPs examined.
[b]Predicted using model based on entire data set.
[c]Data from refs. 21 and 22, values given as -log(IC_{50}).
[d]Class assigned as follows: MA (more active) if activity > 7.00, LA (less active) if activity < 7.00.

for smaller model compounds related to the DHPs have been reported (27, 28). However, in this study, *ab initio* geometries of full DHPs were judged to provide a better comparison to the AM1 geometries. The seven DHPs were calculated in the *sp:sp/sp* conformation; this conformation was selected as it was considered to be of potential biological interest (29) and because it conformed to previous calculations (28).

The STO-3G optimized geometries reported above produce consistent bond lengths and angles for the DHPs. They suggest a strong preference for a conformation in which the ester groups lie coplanar with the dihydropyridine ring and in which the phenyl ring is constrained to a plane perpendicular to the dihydropyridine ring and passing through N(1) and C(4). The dihydropyridine ring has a flattened boat conformation and is significantly puckered. The boat conformation is due to the bond angles at N(1) and C(4), which cause these atoms to lie above the plane generated by the two double bonds. Each double bond, however, constrains its attached atoms to be coplanar, with little deviation observed. The conformation of the dihydropyridine ring is conserved among different DHPs. The conformations reported by Hofmann and Cimiraglia for model DHPs are also in agreement with these results. The methyl groups at the C(2) and C(6) positions of the dihydropyridine ring produce longer C(2)—C(3) and C(5)—C(6) double bonds than those reported for the model compounds.

The AM1-optimized geometries closely reproduce STO-3G geometries, as is evidenced by the low deviations calculated by the root-mean-square fitting procedure. Generally, AM1 geometries have slightly shorter single bonds and somewhat longer double bonds than STO-3G geometries. The AM1 geometries also have conformations in which the ester carbonyls are less likely to be coplanar with the dihydropyridine ring, and in which the phenyl ring is allowed greater axial rotation. Minor variations in bond lengths, angles, and

torsional angles in the STO-3G geometries are also reproduced in the AM1 geometries and follow similar trends among compounds. AM1 results therefore appear to provide a representation of DHP conformation that closely follows the *ab initio* results.

4.3. Energies of conformers

Differences in the AM1-calculated heats of formation of the various conformers of a DHP were shown to be generally less than 5 kcal/mol. Although the differences were not substantial, most compounds had clearly identifiable preferred conformations. In all cases, the conformations with both esters oriented *ap* were energetically disfavoured. Most also had a minimum energy conformer in which both esters were oriented *sp*; if not, such a conformation was not appreciably disfavoured. The *sp/ap* ester conformations were also generally accessible, which is expected as almost all known crystal structures have geometries with the esters in either the *sp/sp* or *sp/ap* orientation (29). *ortho*-Substituted compounds generally favour an *sp* phenyl orientation, with *meta*- and *para*-substituted compounds showing less preference for a particular phenyl orientation.

These conclusions are supported by NMR analyses of isoxazolidine DHPs (30) and by studies from Rovnyak *et al.* on solution-phase DHP conformation (21, 22). These studies examined the populations of *sp* and *ap* phenyl rotamers in solution; the significance of the *ap* rotamer to solution conformation was noted.

These data may also support the recent binding model by Langs *et al.* (29, 31), which postulates that the active conformer of a DHP has *sp/sp* ester orientation. Provided binding transition state energies are not large, the populations of various conformers may influence their binding and thus pharmacologic activity. In such a case, *a priori* preference for *sp/sp* ester orientation may predispose the DHPs to bind at their receptor. Notably, the 2′-amino and 3′-acetyl substituted DHPs had *sp/ap* ester orientation in their energetically favoured conformation; they are both weakly active DHPs (20).

Other modelling studies have also been employed to explain compound activity. These have sought to identify differences between DHPs that are calcium channel blockers and DHPs of similar structure that have been shown to be calcium channel activators (32). Mahmoudian and Richards (33) proposed a model that postulates that patterns of hydrogen bonding are responsible for either activator or antagonist activity. Using pseudo-receptor modelling, Höltje and coworkers (34–36) developed a model that employed differing regions of molecular electrostatic potential. In both cases, ester conformation has been explicitly or implicitly related to the molecule's active conformation. Identification of the most probable conformer and its relative contribution is therefore of some importance to the eventual usefulness of these models.

This information is also of practical utility in the rational design of a neurologically active DHP. To be effective, such a compound must be able to cross the blood–brain barrier and enter the receptor microenvironment; considerable functional group engineering may be necessary to produce a DHP with these desired pharmacokinetic properties. The criterion developed above suggests that modifications that result in a DHP that has significantly disfavoured *sp/sp* ester orientation will probably lead to a pharmacodynamically less active compound. This is therefore a potentially useful structural consideration in the design process.

4.4. Correlation of AM1 properties with biological activity

DHPs probably exert anticonvulsant effects by the blockade of post-synaptic L-type calcium channels in the neuron (7, 9). This blockade would reduce neuronal excitability and hence suppress seizures. An understanding of the DHP properties that contribute to the blockade of L-type calcium channels is therefore of considerable interest to rational antiepileptic drug design. The recent identification of the putative DHP binding site in a region of conserved sequence homology within the calcium channel protein suggests that the features of the DHP that interact with its receptor are similar in skeletal, cardiac, and neurologic calcium channels (37). Earlier structure–activity studies using empirical descriptors (20, 38–40) have attempted to define these features; typically these have used successively larger numbers of DHPs to improve the statistical treatment. The following attributes have been correlated to DHP bioactivity: (*i*) a hydrogen available for hydrogen bonding on the ring nitrogen (38); (*ii*) decreasing activity with increasing bulk (sterimol B1) on *para*-substituted compounds and with increasing length (sterimol L) on *meta*-substituted compounds (20); (*iii*) lipophilicity effect of substituents on the phenyl ring (20, 39, 40); (*iv*) a related inductive effect of phenyl ring substituents (20); and (*v*) decreasing activity with increasing ester side-chain bulk (39).

Furthermore, in studies relating crystallographic structure to activity, it was suggested that increasing pucker of the dihydropyridine ring increases activity (16, 41). However, this observation is not general to all dihydropyridines for which a crystal structure has been determined (42). It is also not supported by the calculations reported both here and by Rovnyak *et al.* (21, 22).

The optimized geometries produced by AM1 yielded a large number of descriptors for use in quantitative structure–activity relationship (QSAR) analysis. Conceptually, AM1 results provide descriptors for electronic and geometric properties; lipophilicity and steric bulk descriptors, which are also useful in describing activity, are not obtained using AM1. Hence, the principal goals of the AM1-derived QSAR study were to refine the electronic and geometric facets of the bioactive portion ("pharmacophore") of the DHP molecule.

For the *ortho*-substituted series of compounds, the activity is well correlated with a model containing the energy of the HOMO and a bond order within the phenyl ring. For these compounds, the energy of the HOMO was most important to the model, indicating that frontier molecular orbital considerations may be important to DHP activity. The effect of the substituent on adjacent bond strength was also important, and was entered into the model as the bond order adjacent to the point of attachment of the substituent. However, the size of the substituent was not correlated with activity.

The model that was developed to describe both *ortho*- and *meta*-substituted DHPs includes the length of the *meta* substituent, the energy of the HOMO, and bond angles and bond orders within the dihydropyridine ring. The length of the *meta* substituent is the distance from the point of attachment of the phenyl ring to the most distant atom; it is therefore a direct

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

measurement that corresponds to the sterimol L descriptor used in previous studies (20, 40). The energy of the HOMO also appears in the model developed for *ortho* substituents. Angles and bond orders in the dihydropyridine ring are likewise shown to be important. This suggests that either subtle changes in the bonding and conformation of the dihydropyridine ring affect activity or, more likely, that the electronic effects of the substitution on the phenyl ring cause subtle changes in the dihydropyridine ring.

The model for the entire data merits examination. The introduction of a substituent at the 4′ position of the phenyl ring reduces the activity of the DHP. This appears in the model as the projected axial length of the 4′ substituent and is expected from previous QSAR studies (20, 38–40). The length of the *meta* substituent and the energy of the HOMO are also included in the model. The inclusion of the charge on C(5) of the dihydropyridine ring most probably is due to an inductive effect of the substituent on the phenyl ring.

Table 6 shows the predicted results based on the model for the entire data set compared to experimental data. The model has a tendency to underpredict the activity of the most active compounds and overpredict the activity of the least active compounds. This is probably due to lipophilic and steric factors, which AM1 calculations do not address. Notably, however, the model overpredicts the activity of the 2′-Br and 2′-I DHPs. Complementary pharmacological results obtained using guinea pig myocardial tissue (21, 22) are also included in Table 6. According to these results, the 2′-Br and 2′-I DHPs are the most active, in line with the predictions of the model.

The discriminant analysis yielded a model that is very effective at distinguishing more active from less active compounds using four descriptors. Again, the ubiquitous energy of the HOMO is included. The bond orders and lengths included are adjacent to the points of attachment of the substituents on the phenyl ring. These reflect the location of attachment and subsequent bond strengthening and weakening due to the ring substituents. The effectiveness of the model is indicated by its 97% success rate at classifying DHPs when using random training and test data sets.

These QSAR results have implications for the design of a neuronally active DHP. To be active in the central nervous system, DHP lipophilicity must be tailored so that the drug can cross the blood–brain barrier. Changing the phenyl substituent is a potentially effective way of doing this. In conjunction with previous QSAR studies (20, 38–40), the unfavourable effect of substitution at the 4′ position of the phenyl ring and of large substituents at the 3′ position is underlined. The energy of the HOMO has been shown to be important. DHPs with large *meta* and *para* substituents and with low ionization potentials are thus predicted to be weakly active. The development of an efficient discriminant model based solely on the results of semi-empirical calculations is also potentially useful. In conjunction with the regression models, it can be used to screen out unfavourable substitutions on the phenyl ring of the DHP. These QSAR correlations are therefore of utility in the rational design process.

5. Conclusions

The results reported in this study have shown that AM1-optimized structures closely match both crystal structures and geometries optimized at the *ab initio* level of calculation. There are only slight differences between the AM1 geometries and those obtained experimentally. However, in the case of ring pucker, both *ab initio* and AM1 calculations failed to reproduce the pucker observed in the crystal structures.

Various conformers were examined for each DHP; the preferred conformation had both ester groups oriented *syn-periplanar* to the double bond of the dihydropyridine ring. There was no consistent preference for an *sp* or *ap* phenyl conformation.

Correlation of biological data with AM1-calculated electronic and geometric descriptors yielded meaningful correlations for mono-substituted DHPs. A discriminant model was also developed that successfully distinguished between strongly and weakly active DHPs. The energy of the HOMO (negative energy of ionization potential) was shown to be the electronic descriptor that was most useful in evaluating DHP activity. This represents a refinement of previous QSAR investigation of the DHPs.

The information obtained from this study can also be used toward the rational design of novel antiepileptic DHPs. The tailoring of functionality can be constrained both by the requirement for a comparatively low energy *sp/sp* ester conformation and by the QSAR correlations. In this way, changes in DHP structure that improve its pharmacokinetic properties can be evaluated to ensure that its pharmacodynamic behaviour is not sacrificed.

PARIMAL PAUL, RAMPRASAD DAS, KAMALAKSHA NAG, ERIC J. GABE, and JEAN-PIERRE CHARLAND. Can. J. Chem. **70**, 2461 (1992).

The homodinuclear [$M_2L_2\mu$(CN)](ClO_4) complexes and the heterodinuclear [LPd-CN-NiL](ClO_4) and [LNi-CN-PdL](ClO_4) complexes of nickel(II) and palladium(II) have been synthesized with a tridentate ligand HL (methyl 2-[(2′-aminoethyl)amino]cyclopent-1-enedithiocarboxylate). In solution both the isomers dissociate, $[LNi\text{-}CN\text{-}PdL]^+$ much more rapidly than $[LPd\text{-}CN\text{-}NiL]^+$, and a steady state equilibrium between the $[LPd\text{-}CN\text{-}NiL]^+$, $[Pd_2L_2\mu\text{-}(CN)]^+$, and $[Ni_2L_2\mu\text{-}(CN)]^+$ species is established. The isomer $[LPd\text{-}CN\text{-}NiL]^+$ exhibits a band at 555 nm that is absent in the other isomer and homodinuclear complexes. The X-ray structure of [LPd-CN-NiL](ClO_4) has been studied. Crystals of the compound are monoclinic, a = 8.964(2), b = 23.852(2), c = 14.096(2) Å, β = 105.92(1)°, Z = 4, space group $P2_1/a$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.054 and R_w = 0.034 for 4426 reflections with $I \geq 2.5\sigma(I)$. The two metal centres are in a square-planar environment provided by the N_2S donor set of the ligand and cyanide bridge, but the metal atoms as well as C and N atoms of μ-CN could not be distinguished due to disorder. An alternate stacking of Pd-CN-Ni and Ni-NC-Pd units has been proposed to explain the 1:1 occupancy of the atoms concerned.

PARIMAL PAUL, RAMPRASAD DAS, KAMALAKSHA NAG, ERIC J. GABE et JEAN-PIERRE CHARLAND. Can. J. Chem. **70**, 2461 (1992).

On a synthétisé les complexes homodinucléaires [$M_2L_2\mu$(CN)](ClO_4) et les complexes hétérodinucléaires [LPd-CN-NiL] et [LNi-CN-PdL](ClO_4) du nickel(II) et du palladium(II) incluant le ligand tridentate HL (2-[(2′-aminoéthyl)-amino]cyclopent-1-ènedithiocarboxylate de méthyle). En solution, les deux isomères se dissocient, le $[LNi\text{-}CN\text{-}PdL]^+$ beaucoup plus rapidement que le $[LPd\text{-}CN\text{-}NiL]^+$, et il s'établit un état stationnaire entre les espèces $[LPd\text{-}CN\text{-}NiL]^+$, $[Pd_2L_2\mu\text{-}(CN)]^+$ et $[Ni_2L_2\mu\text{-}(CN)]^+$. L'isomère $[LPd\text{-}CN\text{-}NiL]^+$ présente une bande à 555 nm qui est absente dans l'autre isomère et dans les complexes homodinucléaires. On a déterminé la structure par diffraction des rayons X. Les cristaux sont monocliniques, groupe d'espace $P2_1/a$, avec a = 8,964(2), b = 23,852(2) et c = 14,096(2) Å, β = 105,92(1)° et Z = 4. On a résolu la structure par des méthodes directes et on l'a affinée par le méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,054 et R_w = 0,034 pour 4426 réflexions avec $I \geq 2{,}5\sigma(I)$. Les deux centres métalliques sont dans un environnement plan carré formé par l'ensemble donneur N_2S du ligand et le pont cyanure; toutefois, à cause du désordre, on ne peut distinguer ni les atomes métalliques ni les atomes de C et de N du μ-CN. On a proposé un empilement alternatif des unités Pd-CN-Ni et Ni-NC-Pd pour expliquer la présence 1 : 1 des atomes concernés.

[Traduit par la rédaction]

Introduction

The bridging ability of cyanide ion has been used to synthesize a large variety of dinuclear M-CN-M (1–6) or M-CN-M′ (7–12) complexes as well as trinuclear M-CN-M′-CN-M (13–15) complexes. Magnetic (16, 17), electrochemical (18, 19), spectroscopic (20), and intramolecular electron transfer (13, 14, 21–25) properties of these complexes have received considerable attention. Quite recently a novel -CN- linked molecular material whose structure resembles scaffolding was reported (26). Although linkage isomerism in homodinuclear or heterodinuclear cyano complexes could be expected to be a common phenomenon, surprisingly only a few such systems have been reported so far. These include $[(NH_3)_5Co\text{-}CN\text{-}Co(CN)_5]$ and $[(NH_3)_5Co\text{-}NC\text{-}Co(CN)_5]$ (12*a*, 12*b*), $[(H_2O)_5Cr\text{-}CN\text{-}Co(CN)_5]$ and $[(H_2O)_5Cr\text{-}NC\text{-}Co(CN)_5]$ (12*c*), *cis*-$(C_6F_5)_2Pd[(\mu\text{-}NC)$*trans*-$Pd(C_6F_5)(PPh_3)_2]$ and *cis*-$(C_6F_5)_2Pd[(\mu\text{-}CN)$*trans*-$Pd(C_6F_5)(PPh_3)_2]$ (1), and [CN(dpe)Ni-CN-Co$(dmgH)_2$Cl] and [CN-$(dmgH)_2$Co-CN-Ni(dpe)Cl] (7) (dpe = bis(diphenylphosphino)ethane; $dmgH_2$ = dimethylglyoxime); of which the first pair has been characterized by X-ray crystallography (27). While the heterodinuclear μ-CN complexes derived from kinetically inert metal ions can be expected to be thermodynamically stable in solution, the behaviour of similar complexes of labile metal ions may, however, be quite intriguing. The purpose of this study was to examine the stability of the linkage isomers obtained from labile metal ions

like nickel(II) and palladium(II). To this end, we synthesized the square-planar complexes [LPd-CN-NiL][ClO_4] and [LNi-CN-PdL](ClO_4)(HL = methyl 2-[(2′-aminoethyl)-amino]cyclopent-1-enedithiocarboxylate) and structurally characterized the isomer Pd-CN-Ni.

Experimental

Materials

Reagents were those available commercially and were used as received. The complexes [PdL(MeCN)][ClO_4] (28) and [NiL(MeCN)][ClO_4] (29) were prepared according to the previously published procedures.

Synthesis

*[MLCN] (M = Ni, Pd) **1**, **2***

To an acetonitrile solution (25 mL) of [ML(MeCN)](ClO_4) (5 mmol), an aqueous solution (5 mL) of NaCN (0.25 g, 5 mmol) was added in small portions with stirring. After additional stirring for 0.5 h the product was collected by filtration and washed successively with water, MeCN, and MeOH. The compound was recrystallized from boiling MeCN. Anal. calcd. for $C_{10}H_{15}N_3NiS_2$: C 40.04, H 5.00, N 14.01, Ni 19.59; found: C 40.18, H 5.14, N 13.92, Ni 19.45. Anal. calcd. for $C_{10}H_{15}N_3S_2Pd$: C 34.54, H 4.32, N 12.09, Pd 30.63; found: C 34.38, H 4.26, N 12.18, Pd 30.43.

*[LM-CN-ML](ClO_4)(M = Ni, Pd) **3**, **4***

To a suspension of [MLCN] (2 mmol) in MeCN (30 mL) was added an MeCN solution (20 mL) of [ML(MeCN)](ClO_4) (2 mmol). The mixture was stirred and heated at 80°C for 0.5 h, during which time a clear solution was obtained. After filtration, the solution was concentrated and cooled to deposit the crystalline product. The compound was recrystallized from MeCN. Anal. calcd. for $C_{19}H_{30}N_5O_4S_4ClNi_2$: C 33.88, H 4.46, N 10.40, Ni 17.45; found: C 33.88, H 4.55, N 10.58, Ni 17.58. Anal calcd. for $C_{19}H_{30}N_5O_4S_4ClPd_2$: C 29.67, H 3.90, N 9.11, Pd 27.70; found: C 29.52, H 4.12, N 9.25, Pd 27.52.

*[LPd-CN-NiL](ClO_4) **5***

To a vigorously stirred solution of [PdLCN] (0.35 g, 1 mmol) in MeCN (40 mL) was added rapidly a solution of [NiL(MeCN)][ClO_4] (0.41 g, 1 mmol) in MeCN (10 mL). The solution was filtered and immediately reduced to ca. 20 mL under reduced pressure. The crystalline product that was obtained on ice cooling was collected by filtration and washed with acetone. Anal. calcd. for $C_{19}H_{30}N_5O_4S_4ClNiPd$: C 31.64, H 4.16, N 9.71, Ni 8.15, Pd 14.76; found: C 31.48, H 4.25, N 9.85, Ni 8.22, Pd 14.58.

*[LNi-CN-PdL](ClO_4) **6***

To a cold solution (10°C) of [PdL(MeCN)](ClO_4) (0.46 g, 1 mmol) in MeCN (20 mL) was added solid [NiLCN] (0.3 g, 1 mmol) with vigorous stirring. The suspension momentarily became clear, but the product was immediately precipitated. This was collected by filtration and washed with cold MeCN and acetone. Anal. calcd. for $C_{19}H_{30}N_5O_4S_4ClNiPd$: C 31.64, H 4.16, N 9.71, Ni 8.15, Pd 14.76; found: C 32.08, H 4.11, N 9.93, Ni 7.97, Pd 14.97.

Caution ! Although the perchlorate salts reported here were found to be indefinitely stable at room temperature, they should be considered potentially explosive at elevated temperatures.

Physical measurements

IR spectra were recorded on a Perkin–Elmer model 783 spectrophotometer using KBr discs. Electronic spectra were recorded on a Jasco 7850 spectrophotometer. Room temperature magnetic susceptibility was measured on an EG & G PAR 155 vibrating sample magnetometer. C, H, N analyses were performed on a Perkin–Elmer 240C elemental analyzer.

Ni and Pd were estimated gravimetrically as their dimethylglyoximates.

*X-ray crystallographic analysis of [LPd-CN-NiL](ClO_4) **5***

Crystals suitable for X-ray diffraction were obtained by recrystallizing **5** from MeCN. A deep purple rod-shaped crystal of dimensions 0.104 × 0.038 × 0.041 mm was mounted on a glass fiber. Unit-cell parameters were refined by least squares on setting angles for 30 reflections (2θ = 100–115dg) measured on a diffractometer with CuK_α radiation (λ = 1.54178 Å). Crystal data are as follows:

$C_{19}H_{30}N_5O_4S_4ClPdNi$ f.w. 721.28

Monoclinic, a = 8.964(2), b = 23.852(2), c = 14.096(2) Å, β = 105.92(1)°, V = 2898.3(8) Å^3, Z = 4, ρ_c = 1.653 Mg m^{-3}, μ ($CuK\alpha$) = 97.62 cm^{-1}; space group $P2_1/a$ (alt. $P2_1/c$) was determined by systematic absences.

Diffraction intensities were measured on an Enraf–Nonius CAD4 diffractometer at 295 K using CuK_α radiation (λ = 1.54178Å). An ω–2θ scan mode at a scan speed of 2°/min was employed. Three standards were measured after every 100 reflections and no significant crystal decay was detected. Data were collected to 2θ = 156° (hkl, $\bar{h}kl$, $h\bar{k}l$). Lorentz and polarization factors were applied and absorption correction was made. Transmission factors ranged from 0.401 to 0.137. Of the 10 131 reflections measured, 6077 were unique (R_{merge} = 0.031) and 4426 having $I \geq 2.5\sigma(I)$ were used for structure analysis.

Direct methods (MULTAN)(30) were used to locate heavier atoms (Pd, Ni, S, Cl) followed by normal difference Fourier map for lighter atoms, including H atoms. The peak heights of the two highest peaks in the E-map were unexpectedly very similar. Other solutions were investigated and showed the same anomalous peak height results. Isotropic refinement of all non-hydrogen atoms except those of the μ-CN group, which were defined as carbons and refined on occupancy, was carried out by full-matrix least squares. The resulting occupancies of the -CN- atoms were such that it was impossible to distinguish between the C and N atoms. Furthermore, the two metal atoms had unusually low and high thermal parameters. This implied that the Pd site has a lower electron density than presumed and the opposite for the Ni site. Additional refinement of these occupancies established identical electron density midway between the number of electrons expected for Ni(II) and Pd(II), respectively, i.e., their occupancy of each site is 0.50 with a small uncertainty. Clearly, the structure of **5** is disordered in that the Pd and Ni, and C and N, atoms are statistically scrambled. A possible explanation would be the presence of equal amounts of superimposed -Pd-CN-Ni- and -Ni-NC-Pd- fragments (see later). Additional scattering curves were generated to take into account this 1:1 distribution for Pd/Ni and C/N. Anisotropic full-matrix refinement (H atoms isotropic) using the weighting scheme $w = 1/[\sigma^2(F_o) + 0.0009F_o^2]$ with (F_o) from counting statistics, gave satisfactory agreement factors R and R' of 0.054 and 0.034, where $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma\, w(|F_o| - |F_c|)^2/w|F_o|^2)^{1/2}$. All calculations were performed with the NRCVAX crystal structure programs (31). Scattering factors were taken from the *International tables for X-ray crystallography* (32). The final atomic positional parameters and equivalent isotropic temperature factors are listed in Table 2. Anisotropic thermal parameters, calculated hydrogen parameters, and calculated structure factors are available as supplementary data.[4]

[4]Tables of observed and calculated structure factor amplitudes, of temperature factors, of hydrogen parameters, and of detailed bond distances and angles may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen atom parameters and of bond lengths and angles have also been deposited with the Cambridge Crystallograph Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 IEZ, U.K.

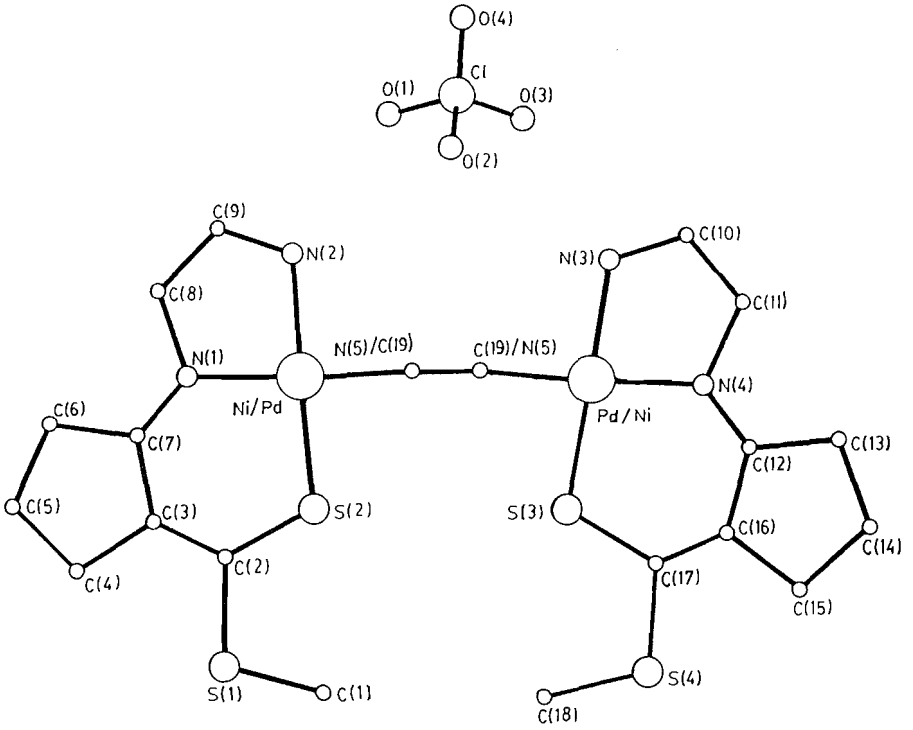

FIG. 1. Molecular structure of [LPd-CN-NiL] (ClO_4) with the atom labelling scheme.

Results and discussion

The cyano-bridged complexes were synthesized by reacting stoichiometric amounts of two different complementary mononuclear complexes, one containing the terminal cyano group and the other a weakly coordinating ligand. Thus, while for the preparation of the homodinuclear complexes [LM-CN-ML][ClO_4] (M = Ni, Pd) the reactants used were [MLCN] and [ML(MeCN)][ClO_4], the heterodinuclear [LM-CN-ML][ClO_4] complexes were obtained by reacting [MLCN] (M = Pd, Ni) with [ML(MeCN)][ClO_4] (M = Ni, Pd). We previously demonstrated (28, 29, 33) that HL is a potentially tridentate ligand with N_2S donors, and the fourth coordinating group (X) in the square-planar nickel(II) and palladium complexes $[MLX]^{n+}$ (n = 0 or 1) undergoes interesting chemical transformations. All the dinuclear complexes are soluble in polar solvents such as Me_2SO, *N*,*N*-dimethylformamide (DMF), and MeCN, less so in $MeNO_2$ and Me_2CO, but practically insoluble in MeOH or CH_2Cl_2. They are diamagnetic compounds and their salient IR and UV–vis spectral data are given in Table 1. The terminal νCN^- vibrations for the mononuclear complexes, which are observed at 2120 (**1**) and 2125 (**2**) cm^{-1}, are shifted to higher frequencies by ca. 40 cm^{-1} in the dinuclear complexes. This shift is also accompanied by similar changes in the NH stretching frequencies of the ligand. Thus, while for complexes **1** and **2** the νNH bands are observed at 3200 and 3230 cm^{-1}, they appear at about 3240 and 3285 cm^{-1} in complexes **3–6**. Clearly, this difference in νNH arises because of the stronger electron-withdrawing ability of the terminal cyanide. The dinuclear complexes in addition exhibit characteristic bands due to the ionic perchlorate at ca. 1100 and 630 cm^{-1}.

In the UV region all the complexes exhibit absorption bands more or less in the same positions indicating their origin belongs primarily to internal ligand transitions. Complex **1** shows a shoulder at 490 nm, which probably can be associated with its square-planar geometry. The isomer $[LPd\text{-}CN\text{-}NiL]^+$ also exhibits a fairly strong band in the visible region with the peak at 555 nm (ϵ = 90 dm^{3}mol^{-1}cm^{-1}). By contrast, the absorption of $[LNi\text{-}CN\text{-}NiL]^+$ and $[LNi\text{-}CN\text{-}PdL]^+$ continually goes on decreasing in the range 400–

′$1 - x, -y, 1 - z$

700 nm. Evidently, the band at 555 nm cannot be attributed to a nickel(II)-centered *d–d* transition; in that case complexes **3** and **6** would have exhibited a band or a shoulder in the visible region. While we are not sure about the exact nature of this band, it nevertheless appears to be a charge transfer transition involving the chromophore Pd-CN-Ni.

To find the stability of the dinuclear cyano complexes in solution, the time-dependent spectral changes that occurred in the DMF solutions for $[LPd\text{-}CN\text{-}NiL]^+$, $[LNi\text{-}CN\text{-}PdL]^+$, and a 1:1 mixture of $[Ni_2L_2\mu\text{-}(CN)]^+$ and $[Pd_2L_2\mu\text{-}(CN)]^+$ in the range 500–700 nm were recorded. The absorption spectrum of the Pd-CN-Ni isomer changed very slowly with time by the gradual transformation of the peak at 555 nm to a shoulder. It was noted that the spectral changes for complex **5** occurred very slowly before 0.5 h and after 20 h, but more quickly in the mid-period. In contrast, the spectrum of the Ni-CN-Pd isomer (**6**) began to change rapidly from the beginning and reached completion in about 10 h. In this case the successive absorption curves passed through an isosbestic point at 540 nm. The spectral change that occurred for the mixture of the two homodinuclear species is similar to that of complex **6**. The final spectrums for all three cases were identical, clearly indicating the establishment of the same steady state equilibrium. The greater stability of Pd-CN-Ni species relative to Ni-CN-Pd species is understandably due to the stronger Pd—C bond and lesser lability of Pd^{2+} ion. The gross reaction leading to the steady state equilibrium can be given by eq. [1]:

$$[1]\quad 2\text{Ni-CN-Pd} \xrightarrow{k_1} \text{Ni-CN-Ni} + \text{Pd-CN-Pd} \underset{k_3}{\overset{k_2}{\rightleftharpoons}} 2\text{Pd-CN-Ni}$$

Crystal structure analysis

A PLUTO (34) diagram of $[LPd\text{-}CN\text{-}NiL][ClO_4]$ **5** is shown in Fig. 1 together with the atom labelling scheme. As already noted, due to crystallographic disorder the two metal atoms as well as the C and N atoms of μ-CN could not be distinguished. Accordingly, they are alternately designated as Pd/Ni, Ni/Pd, C(19)/N(5), and N(5)/C(19). Final atomic coordinates for the non-hydrogen atoms and selected bond lengths and angles are given in Tables 2 and 3.

The structure for the cation of **5** consists of two ML (M = Pd, Ni) fragments linked by a cyanide ion. The metal atoms in the ML fragments are in distorted square-planar environments provided by the N_2S donor set of the ligand and the C or N atom of the cyanide. The two ligand moieties in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

the complex are in *cisoid* conformation. In the two ML fragments corresponding metal–donor bond lengths are quite similar. There are two sets of M—N distances in each ML fragment, of which the M—N(2) or M—N(3) distances are about 0.18 Å longer than the M—N(1) or M—N(4) distances. This difference is expected because M—N bonds to a 4-coordinate nitrogen (terminal) should be longer than to a 3-coordinate one (middle). Moreover, the M—N(terminal) bond is further elongated by the *trans* directing influence of S. The M—N(1) or M—N(4) distances are normal for square-planar nickel(II) and palladium(II) complexes. The two M—S distances in **5** differ by ca. 0.02 Å and the average distance 2.184(2) Å may be compared with the reported low-spin Ni—S distances ranging between 2.10 and 2.20 Å (35, 36) and the Pd—S distance of 2.24 Å observed in a closely related complex (33*c*). The M—C/N distance (avg. 1.89 Å) and the C—N distance (1.158(8) Å) are similar to the other cyano-bridged complexes (27). The *cis* angles in the ML fragments deviate to some extent from 90°. For example, the angles S(3)—M—N(4) (97.41(14)°) and N(3)—M—C/N (93.67(24)°) are wider compared with S(3)—M—C/N (85.09(15)°) and N(3)—M—N(4) (83.84(24)°). The *trans* angles N(3)—M—S(3) (178.39(19)°) and N(4)—M—C/N (177.50(20)°), however, are almost linear. It may be noted that the MCNM bridge angles (177.2(4)° and 175.0(4)°) are not perfectly linear. The displacements (Å) of the constituent atoms from the mean planes of N(2), N(1), S(2), C/N (plane 1) and N(3), N(4), S(3), C/N (plane 2) are: N(2)[−0.067(9)], N(1)[0.026(6)], S(2)[−0.003(2)], C/N[0.034(7)]; N(3)[−0.022(9)], N(4)[0.008(6)], S(3)[−0.001(2)], C/N[0.010(7)]. While in plane (2) the metal atom is displaced above the least-squares plane by 0.046(9) Å, in plane (1) this displacement (0.157(10) Å) is even more significant. It might appear that the two metal atoms are square-pyramidally distorted in the same direction, albeit to a different extent. However, for square-pyramidal d^8 metal ion complexes the basal angles (that is, the angles produced by atoms in the diagonal positions) should be less than 170° (37) as compared with 176–178° observed in the present case. The displacement of the two metal atoms from the mean planes may therefore be attributed to crystal packing forces. It may also be noted that the two ML fragments in the complex are not perfectly parallel; the dihedral angle between planes (1) and (2) is 5.85(12)°.

The packing diagram of **5** (Fig. 2) shows that stacking of the complex cations occurs roughly along the *a* axis of the unit cell. To account for 1:1 Pd:Ni and C:N occupancy, the presence of equal amounts of superimposed Pd-C-N-Ni and Ni-N-C-Pd fragments in the unit cell has already been considered. There are other possibilities also for disordering. For example, one may consider the superposition of Ni-C-N-Pd and Pd-N-C-Ni fragments. However, it has already been demonstrated that the $[Ni\text{-}CN\text{-}Pd]^+$ species is thermodynamically less stable than the $[Pd\text{-}CN\text{-}Ni]^+$ species. The possibility for the co-crystallization of the homodinuclear $[Pd\text{-}CN\text{-}Pd]^+$ and $[Ni\text{-}CN\text{-}Ni]^+$ species, according to eq. [1], may also be considered. However, the solubilities of these two homodinuclear complexes and the precursor complex **5** in MeCN, the solvent from which crystals were grown, are not identical. The decreased order of solubility is $[Ni_2L\ \mu\text{-}CN](ClO_4) > [Pd_2L\ \mu\text{-}CN](ClO_4) > [LPd\text{-}CN\text{-}NiL](ClO_4)$. In a situation like this the species which crystallizes is usually controlled by solubilities, not solution equilibria (38). Thus, stacking of Pd-CN-Ni, Ni-NC-Pd, and so on appears to provide a reasonable basis for the crystallographic observation.

The ClO_4^- ion in **5** is not disordered. From the molecular structure (Fig. 1) it is apparent that the O(1), O(2), and O(3) atoms of the ClO_4^- ion are amenable to H-bonding with the protons of the N(2) and N(3) atoms. The interatomic distances and angles involved in H-bonding are listed in Table 4.

A kinetic study of the thermal dehydration of calcium sulphite hemihydrate

CARL ANDERSON AND ANDREW K. GALWEY[1]

School of Chemistry and Questor Centre, The Queen's University of Belfast, Belfast BT9 5AG, Northern Ireland

Received February 20, 1992

CARL ANDERSON and ANDREW K. GALWEY. Can. J. Chem. **70**, 2468 (1992).

An isothermal kinetic study of the dehydration of orthorhombic calcium sulphite hemihydrate is reported:

$$CaSO_3 \cdot 1/2H_2O(s) \rightarrow CaSO_3(s) + 1/2H_2O(g)$$

Fractional reaction (α)–time curves exhibit the sigmoid shape characteristic of nucleation and growth reactions proceeding in the solid state. Yield–time data exhibit a very satisfactory obedience to the Avrami–Erofe'ev ($n = 2$) equation

$$[-\ln(1 - \alpha)]^{1/2} = kt$$

Rate studies were concerned with the temperature interval 573–673 K and the calculated activation energy was 173 ± 8 kJ mol^{-1}, showing the hydrate to be thermally relatively stable. The mechanism of dehydration is discussed and reference is made to the dehydration of calcium hydroxide with which it shows close similarities.

CARL ANDERSON et ANDREW K. GALWEY. Can. J. Chem. **70**, 2468 (1992).

On rapporte une étude cinétique isotherme de la déshydratation de l'hémihydrate du sulfite de calcium orthorhombique :

$$CaSO_3 \cdot 1/2H_2O(s) \rightarrow CaSO_3(s) + 1/2H_2O(g)$$

Les courbes de la réaction fractionnaire (α)–temps présentent la forme sigmoïde caractéristique des réactions de nucléation et de croissance se produisant dans l'état solide. Les données relatives au rendement–temps obéissent bien à l'équation de Avrami–Erofe'ev ($n = 2$) :

$$[-\ln(1 - \alpha)]^{1/2} = kt$$

On a réalisé des études de vitesses entre 573 et 673 K et l'énergie d'activation calculée, égale à 173 ± 8 kJ mol^{-1}, démontre que l'hydrate est thermiquement relativement stable. On discute du mécanisme de déshydratation et on fait référence à la déshydratation de l'hydroxyde de calcium avec laquelle il existe d'importantes similarités.

[Traduit par la rédaction]

Introduction

The present study is a further contribution to an extensive, systematic investigation of the kinetics and mechanisms of diverse solid state dehydration reactions. Previous work has been concerned with the release of water from alums (1, 2), lithium potassium tartrate monohydrate (3), lithium sulphate monohydrate (4), magnesium chloride dihydrate (5), and lignite (brown coal) (6). Conclusions based on dehydration studies have contributed significantly to our theoretical understanding of solid state reactions generally (7–10) and the reaction models developed have been applied to diverse chemical changes proceeding in varied crystalline reactants (7). In extending this approach we now report a study of the dehydration of $CaSO_3 \cdot 1/2H_2O$. This complements our previous investigations (1–6) by including the mechanism of a reaction that occurs within a relatively high-temperature interval, 570–670 K. Thus, in this process the participation of water, condensed within the reaction interface, can be excluded from consideration of the mechanism. This reaction feature contrasts with the chemical steps proposed for the low-temperature dehydration of alums (1, 2) where temporary retention of water at the reactant/product interface is believed to promote the difficult solid product recrystallization process.

It was also of interest to compare $CaSO_3 \cdot 1/2H_2O$ dehydration with the extensively studied dehydrations of $CaSO_4 \cdot 2H_2O$ and $CaSO_4 \cdot 1/2H_2O$, investigated in various temperature intervals within the overall range 341–425 K, and which are controlled both by phase boundary and diffusion processes, Ball *et al.* (11, 12) and Okhotnikov *et al.* (13). The present work shows that $CaSO_3 \cdot 1/2H_2O$ on decomposition yields water vapour, in contrast with the chemical changes that occur in a similar temperature interval (623–803 K) for $MgCl_2 \cdot 2H_2O$ where the water of crystallization interacts with the anion to yield hydrogen chloride as the principal product.

We are aware of no previous isothermal kinetic study of $CaSO_3 \cdot 1/2H_2O$ dehydration, though the reaction temperature (ca. 620 K) has been mentioned (14). To characterize the factors controlling the reaction rate, the present observations are discussed in the context of mechanistic proposals for water evolution from other crystalline solids.

$CaSO_3 \cdot 1/2H_2O$ exists in three crystallographic structures (14, 15); the present work was concerned with the α (orthorhombic) form. The dehydrated material undergoes dissociation ($CaSO_3 \Leftrightarrow CaO + SO_2$) and (or) decomposition ($4CaSO_3 \rightarrow 3CaSO_4 + CaS$) at temperatures well above (800 K) those of the present reaction (15–17). However, these subsequent reactions did not overlap with dehydration.

Experimental

Calcium sulphite hemihydrate

Reagent grade (Pfaltz and Bauer) $CaSO_3 \cdot 1/2H_2O$ in the form of a fine powder was used throughout the present study. Analytical results for the reactant supplied were as follows: Ca, 30.0, SO_3^{2-}, 56.2; and H_2O, 6.9% (theoretical $CaSO_3 \cdot 1/2H_2O$: Ca, 31.01; SO_3^{2-}, 62.01; and H_2O, 6.98%). Calcium was determined by complexometric titration, sulphite was determined by back titration with standard $Na_2S_2O_3$ after addition of excess standard iodine solution. Water was calculated from the hydrogen content of

the sample measured by combustion analysis. Powder X-ray diffraction confirmed the identity of the reactant as $CaSO_3 \cdot 1/2H_2O$ (orthorhombic) (14).

Isothermal kinetic studies

$CaSO_3 \cdot 1/2H_2O$ dehydration kinetics were measured from the water vapour pressure evolved at known times in an initially evacuated conventional glass apparatus using an absolute pressure diaphragm gauge. This Baratron MKS 222B gauge worked in the range 0–10 Torr (1 Torr = 133.3 Pa) and was read to ± 0.001 Torr. The output from this gauge, and that from a thermocouple junction positioned beside the heated reactant sample, was interfaced with a computer that automatically recorded (time, pressure, temperature) values at a preset time interval for subsequent kinetic analyses. New data were recorded only if a prespecified extent of reaction had occurred. The frequency of data collection was, therefore, related to reaction rate. The computer programme also included facilities for graphical testing of obedience of data to rate expressions applicable to solid state reactions and to print both plots and tabulated results. The apparatus has been described previously (18).

Each reactant sample, ca. 50 mg (weighed to ±0.2 mg), was retained in a small glass reactant tube by a loose glass-wool plug and placed in the vacuum apparatus before evacuation at <0.05 Torr for at least 1 h at ambient temperature. After isolation of the constant volume system from the pumps the reactant was introduced into the constant temperature (±1 K) heated zone.

Scanning electron microscopy

Samples of the unreacted salt, the fully reacted product, and material partially dehydrated to measured extents were observed and examined using a Jeol 35 CF scanning electron microscope. Each specimen was rendered conducting before examination by coating with a light evaporated film of Au/Pd.

Results and discussion

Electron microscopic examinations

Reactant

Figures 1*a–c* show representative textures of the reactant studied. The powder is composed of rectangular crystallites, the longest dimension being 5–10 μm, together with a small proportion of much finer particles. Approximately half of the material was in the form of crystal aggregates up to 100 μm diameter, Figs. 1*a* and *b*, and the remainder was composed of separate crystals of similar size. Most of the crystals exhibited flat surfaces but a small proportion had rounded faces: some are seen in Fig. 1*c* to left of centre.

Product

Representative textures of the dehydrated salt are shown in Figs. 2*a* and *b*. The sizes and shapes of the component crystallites are not perceptibly different from those of the original hydrate (compare with Figs. 1*a–c*). Large crystal aggregates remained together with a similar proportion of dispersed individual particles. There was no evidence that the salt melted during dehydration. Detailed examinations of reacted salt surfaces (Figs. 3*a* and *b*) showed that dehydration was accompanied by some surface roughening and an increase in the number of pores. Internal textures, exposed by crushing after reaction, Fig. 4, show the generation of an extensive internal pore structure permeating each crystallite. Such channels arise through reactant contraction after water loss and provide pathways for water loss.

Partially dehydrated salt

The textures of salt samples partially decomposed to various known extents were indistinguishable from appearances shown in Figs. 2–4. No systematic changes of texture with extent of reaction was discerned.

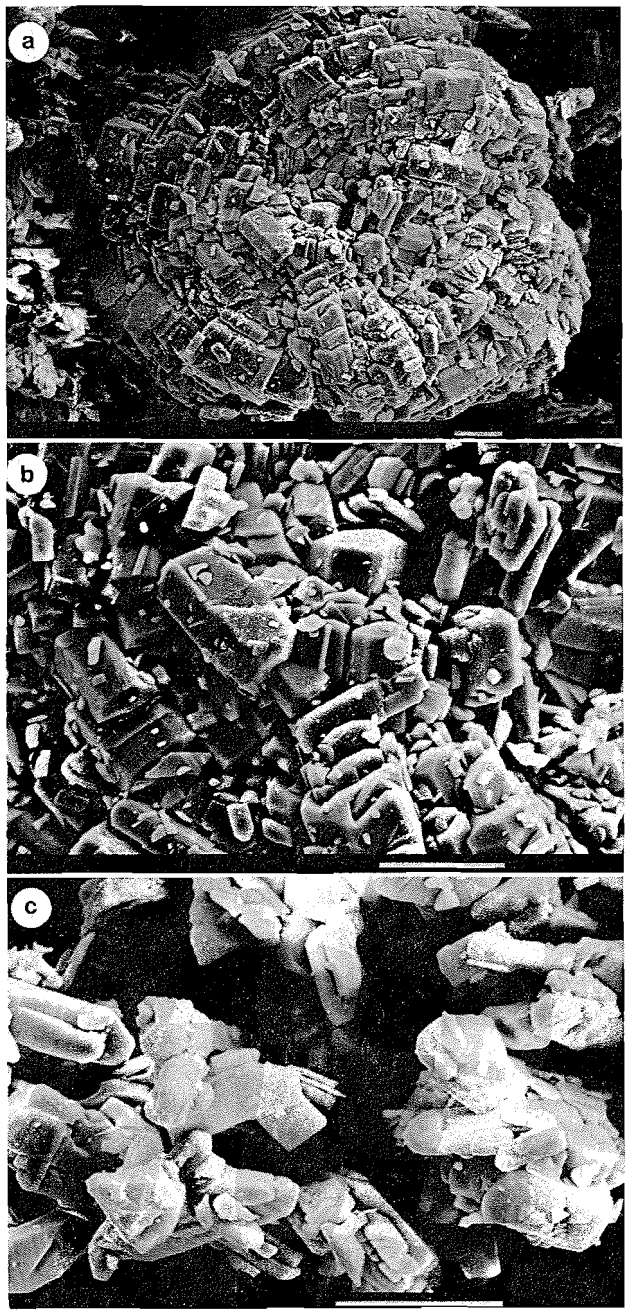

FIG. 1. Calcium sulphite hemihydrate reactant is composed of rectangular crystallites, longest edge 5–10 μm. About half of the reactant was agglomerates, diameters up to 100 μm (Figs. 1*a* and *b*) while a similar amount is dispersed, Fig. 1*c*. The latter also shows atypical rounded particles present in small proportion only. (Scale bars: all 10 μm.)

Comment

The most important microscopic observations were that dehydration was not accompanied by melting and that no structures identifiable as nuclei could be discerned. Dehydration resulted in surface roughening and pore development but textural features expected to be useful in elucidating

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

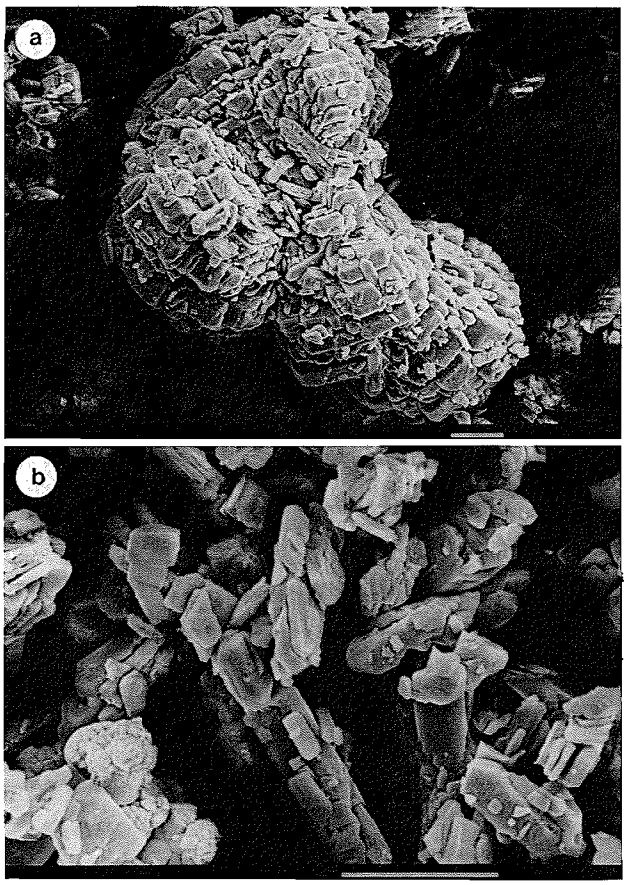

FIG. 2. Crystallites of calcium sulphite dehydrated in vacuum at 618 K. The sizes and shapes of product crystals are indistinguishable from those of the reactant: see Figs. 1*a–c*. (Scale bars: both 10 μm.)

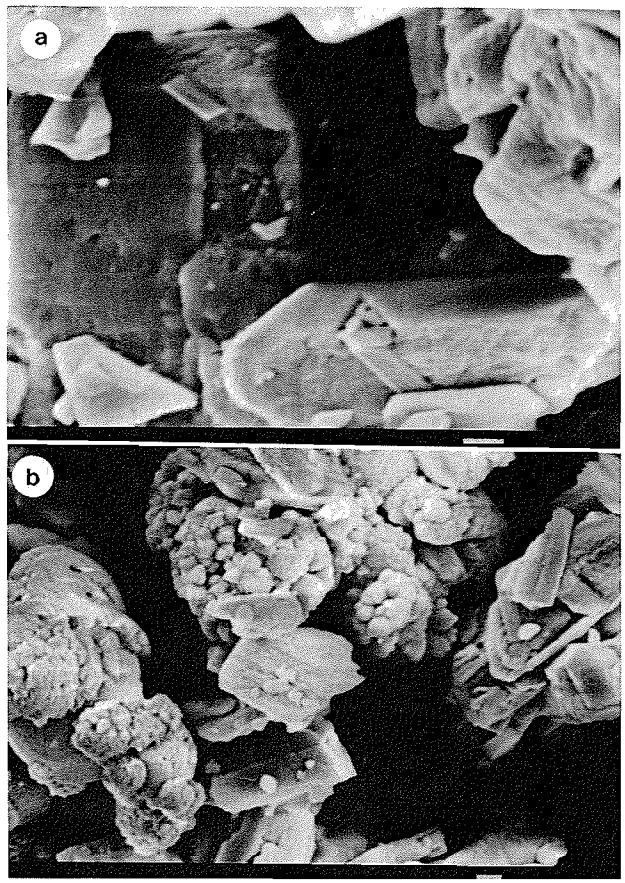

FIG. 3. Surface textures of salt dehydrated at 618 K were roughened and contained pores and (*b*) some rounded particles were generated. (Scale bars: both 1.0 μm.)

the reaction mechanism or kinetic controls were below the limits of resolution in these small crystallites.

Reaction stoichiometry

The reactant weight loss on dehydration (mean 7.1%, theoretical 6.98%) and product pressure measured in the calibrated volume of the apparatus agreed, within the limits of experimental error, with that expected for

$$CaSO_3 \cdot 1/2H_2O(s) \rightarrow CaSO_3(s) + 1/2H_2O(g)$$

It was confirmed by powder X-ray diffraction that the solid product was the orthorhombic form of $CaSO_3$ (14). Refrigerant traps (78 and 178 K) condensed the product water vapour and residual pressures corresponded to ca. 1% of the water pressure yield.

Kinetic measurements

The initial reaction

The main dehydration process was preceded by the rapid evolution of 2.0–2.5% of the constituent water during the heating of the sample to reaction temperature. (There was some evidence that an additional amount of water may have been lost during initial sample evacuation, before isolation from the pumps and heating.) Thereafter the rate of water evolution diminished and became approximately constant between $0.025 < \alpha < 0.05$ (α is the fractional reaction). The activation energy for the zero-order process was 130 ± 15 kJ mol^{-1}, at 570–650 K.

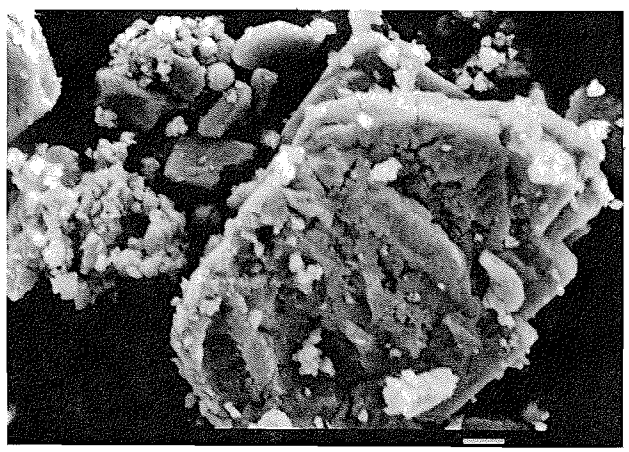

FIG. 4. A crystallite interior, exposed by crushing after dehydration at 618 K, shows evidence of irregular internal pore development during reaction. (Scale bar: 1.0 μm.)

The extent of this initial reaction was estimated to correspond to the superficial dehydration of crystal surfaces to a thickness of 10–20 nm. The approximately zero-order behaviour is ascribed to overlap between the deceleratory completion of the initial process and the acceleratory onset of the main reaction.

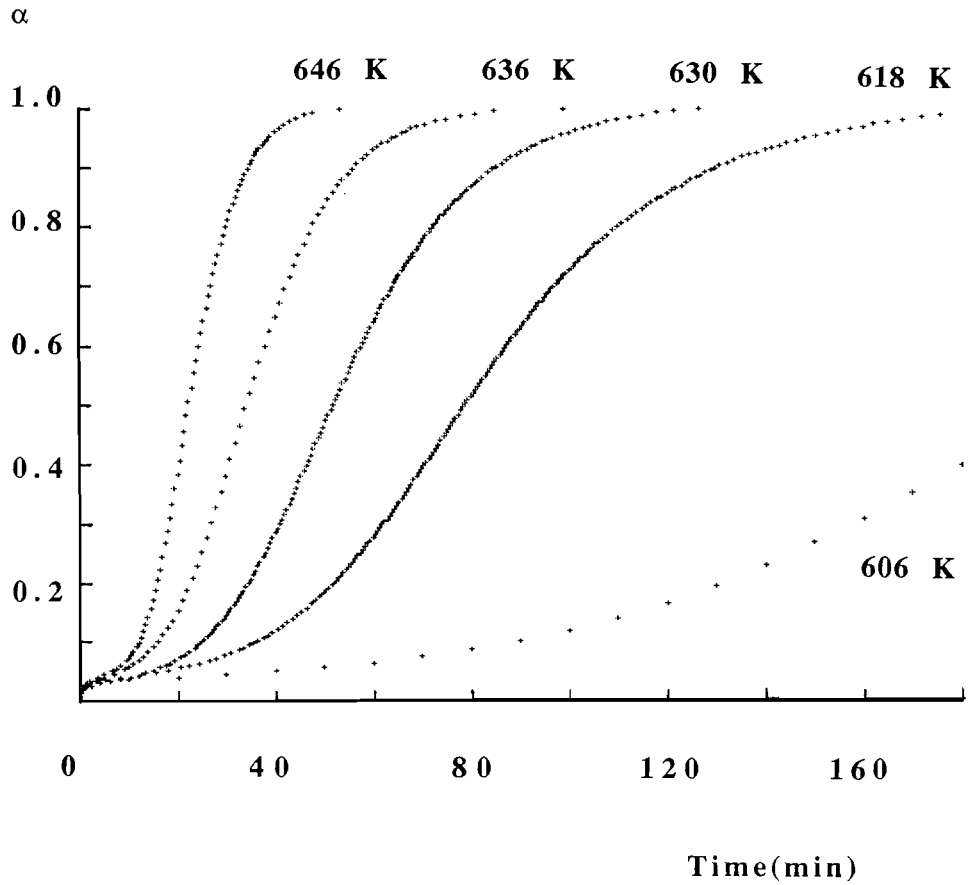

FIG. 5. Representative α–time plots for the isothermal dehydration of calcium sulphite hemihydrate at five temperatures 606–646 K. The characteristic sigmoid shaped curves are ascribed to a nucleation and growth reaction mechanism.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

The main reaction

Representative α–time plots for $CaSO_3 \cdot 1/2H_2O$ dehydrations are shown in Fig. 5. Following a short induction period the reaction exhibited the sigmoid shape yield–time relationship that is characteristic (7) of nucleation and growth processes. After subtracting the contribution from the initial reaction (α_i = ca. 0.04), the most satisfactory kinetic obedience was found for the Avrami–Erofe'ev (n = 2) equation (7):

$$[1] \quad [-\ln(1 - \alpha)]^{1/2} = kt$$

This equation was obeyed for $0.09 < \alpha < 0.96$; the fits of data from Fig. 5 are shown in Fig. 6. Rate constants from 17 experiments gave a calculated activation energy of 173 ± 8 kJ mol^{-1}, at 573–673 K.

Interruption of reaction

Dehydration reactions were interrupted at various α values and the salt cooled to ambient temperature before restoring conditions prevailing previously. Such interruption caused no appreciable change in the kinetic characteristics of the resumed reaction.

Reactant packing

The dehydration kinetics of salt loosely dispersed on glass wool (19) were identical with the behaviour of powder packed more densely in the reaction vessel. This is consistent with the expectation that the reverse reaction would not exert perceptible influence on rate characteristics at this relatively high reaction temperature.

Incorporation of a small proportion (10%) of previously dehydrated salt caused no change in dehydration behaviour. The onset of water loss was not promoted by the presence of the anhydrous product.

Crushed salt

The effect of reactant crushing with pestle and mortar on the rate of subsequent dehydration is shown in Fig. 7. In comparative experiments it was shown that this mechanical pretreatment significantly accelerated the onset of reaction, the induction period was reduced by about 50%, and the acceleratory period was subsequently completed at a lower α value (ca. 0.2). Plots of $[-\ln(1 - \alpha)]^{1/2}$ against time showed two linear regions. The first ($0.09 < \alpha < 0.62$) gave rate constants that were 1.5× values for the uncrushed powder and the second, following a short curved transition region, represented a rate similar to that of the uncrushed powder ($0.07 < \alpha < 0.97$). A more satisfactory kinetic obedience was given by the contracting cube equation (7), $[1 - (1 - \alpha)^{1/3}] = kt$, which fitted the data after completion of the acceleratory process, $0.20 > \alpha > 0.94$. This may be due to the initial establishment of the reactant interface during abrasion. The overall effect of crushing, a rate increase of about 50% during the early stages, was, however, relatively small.

Dehydration of rehydrated salt

Water uptake by the dehydrated salt was slow and strongly deceleratory. Preliminary experiments, in 5 Torr water vapour at 300, 400, and 500 K, identified no conditions under which a kinetic study of the rehydration proceeded at a rate

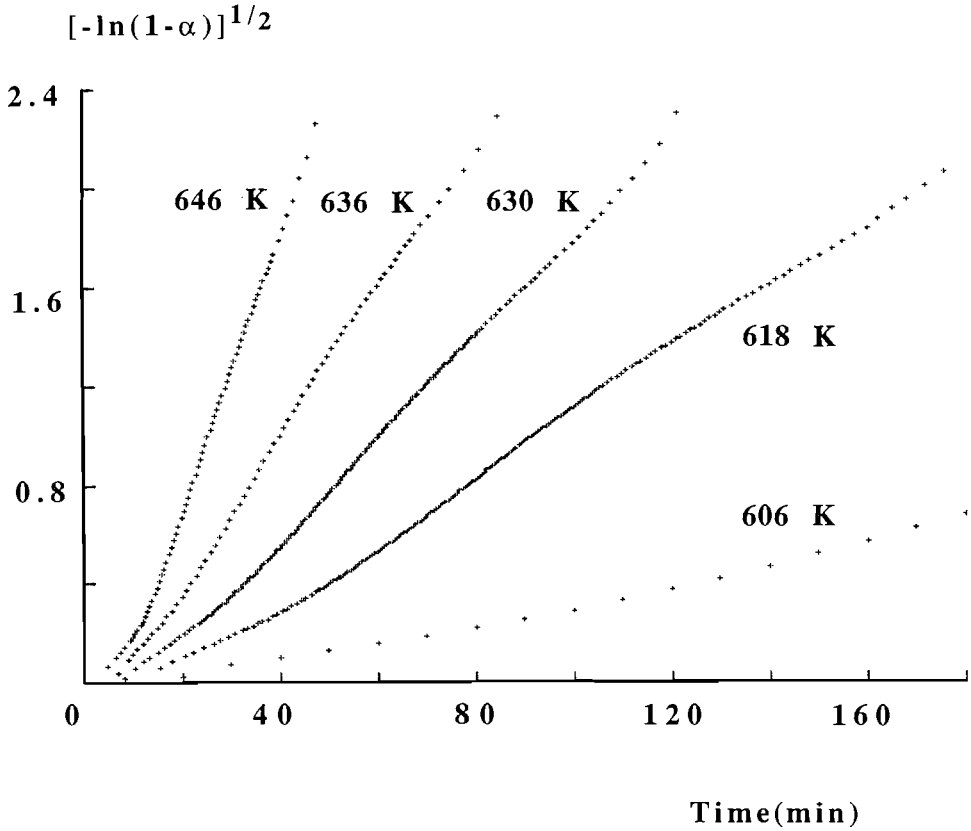

FIG. 6. Linear plots of $[-\ln(1 - \alpha)]^{1/2}$ against time for the data in Fig. 5 confirming kinetic obedience of the reaction to the Avrami–Erofe'ev equation ($n = 2$) (7).

suitable for kinetic measurements. Exposure of the dehydrated salt to saturated water vapour (ca. 14 Torr at 290 K) for 24 h resulted in a weight gain corresponding to the water uptake required for $CaSO_3 \cdot 1/2H_2O$. Water yields from successive (2nd, 3rd, and 4th) dehydrations were below theoretical expectation (75–80%), indicating losses during initial evacuation.

Figure 7 includes a typical α–time plot for a second dehydration (the most rapid of the three reactions shown) and can be compared with the curve for the first dehydration of the same reactant sample (the slowest of the curves shown) at 625 K. The following pattern of kinetic behaviour was identified in a series of comparative experiments (580–630 K) for rehydrated salt. An initial evolution of water was rapid to $\alpha = 0.20$ but kinetic studies were impracticable because this slightly deceleratory process overlapped with the reactant heating stage. The subsequent reaction obeyed eq. [1] for α between 0.2 and 0.7, rate constants were larger (×5–7) than those for the prepared salt, and this dehydration was completed in the approximate time required to initiate reaction in the original salt at the same temperature (see Fig. 7). Further kinetic analyses showed that the dehydration of rehydrated reactant fitted the contracting cube equation $0.4 < \alpha < 0.9$, with relatively slow completion of the last stages of dehydration. Precrushing the original reactant resulted in no detectable influence on the rate of water loss in second and subsequent dehydrations.

The relatively greater rate of water loss from the rehydrated salt may be explained by a reduction in effective crystallite size to ca. one sixth those of the original reactant. The contracting cube equation, $[1 - (1 - \alpha)^{1/3}] = 2\,kt/a$, includes the particle size dimension, a. This reaction model is consistent with the crack development found in the dehydrated product (Fig. 4). The increase in surface area ×6 is also consistent with the observed rise in extent of initial reaction, 2.5% in the original salt to 20% for a second reaction, though this ratio is somewhat greater, ×8.

Other experiments

Dehydration enthalpy

DSC studies, using a Perkin–Elmer DSC-7, detected only a single response at ca. 670 K, identified as dehydration, and no other thermal event between 300 and 800 K. From this peak the $CaSO_3 \cdot 1/2H_2O$ dehydration enthalpy was measured as 52 ± 5 kJ mol^{-1}.

Surface area measurements

Surface areas were measured by the BET method from nitrogen adsorption at 78 K. The surface area of the reactant was determined as 3 ± 1 m^2 g^{-1} and product 5 ± 2 m^2 g^{-1}. These correspond to assemblages of particles having an edge of ca. 1 μm, indicating the absence of extensive pore structures within the crystallites observed by electron microscopy.

Calcium sulphite and sodium metabisulphite

The dehydration kinetics of crushed mixtures ($CaSO_3 \cdot 1/2H_2O + Na_2S_2O_5$: 3:1 molar ratio) were identical with the reaction of $CaSO_3 \cdot 1/2H_2O$ alone. There was no evidence of fusion and the additive exerted no detectable influence on the dehydration.

The mechanism of reaction

The dehydration of calcium sulphite hemihydrate

$$CaSO_3 \cdot 1/2H_2O \rightarrow CaSO_3 + 1/2H_2O$$

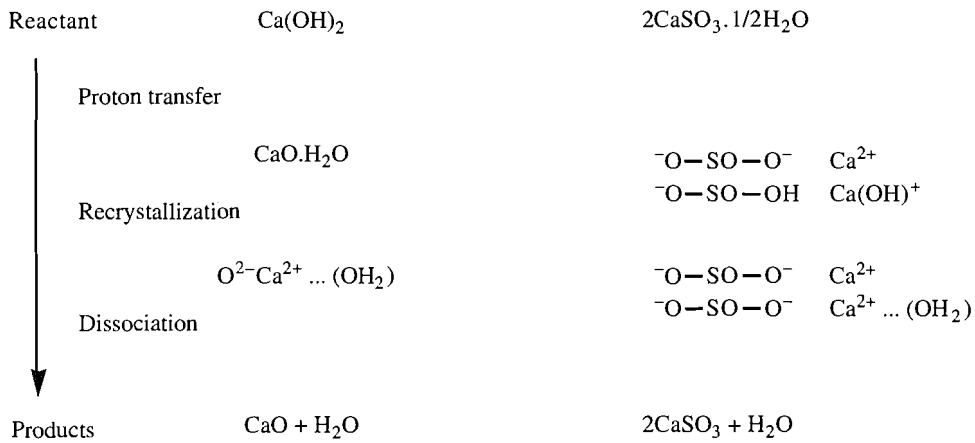
is accompanied by recrystallization (14) and we conclude, therefore, that the sigmoid shaped α–time curves result from a nucleation and growth reaction (7). Confirmation of this interpretation by microscopic observations was not possible because of the small size of the reactant crystallites and the absence of textural features that enabled the reactant and product phases to be distinguished.

The initial reaction (yielding 4% of the water from the prepared salt or 20% from the rehydrated salt) is ascribed to the facile loss of water from the less perfect crystallite surfaces. The calculated activation energy for this process was relatively low.

Onset of the main reaction is ascribed to the appearance of stable growth nuclei of product $CaSO_3$ in the reactant crystals. The promotion of nucleation by crushing is ascribed to (*i*) an increase in the surface area upon which nucleation can occur and (*ii*) increased ease with which the new phase can be formed within the damaged and imperfect crystal peripheries. The continued growth of the established reaction interface was not inhibited by interruption of the reaction by cooling. Water loss results in a contraction of the reactant (estimated to be 12% from crystallographic data (14)), thus accounting for the development of the extensive crack system within the anhydrous product particles that are pseudomorphic with the reactant crystallites (Fig. 4). This particle division also explains the more rapid dehydration rate observed in the finely divided crystallites for reactant samples of rehydrated salt.

The kinetic behaviour for $CaSO_3 \cdot 1/2H_2O$ dehydration was most satisfactorily expressed as obedience to eq. [1] with $n = 2$ and the fit with $n = 3$ was almost as good. Thus the rate characteristics are ascribed (7) to instantaneous nucleation followed by the growth of compact nuclei (three-dimensional growth) in the asymmetric reactant crystallites (one dimension longer than the other two). Unfortunately this geometric interpretation (10) of the kinetic characteristics could not be confirmed microscopically.

The considerable stability of $CaSO_3 \cdot 1/2H_2O$ is a consequence of the strong bonding of the oxygen atom in the water molecule to two (7 coordinated) Ca^{2+} ions: the Ca^{2+}—Ow bond length is 2.499 Å (16). (This structure may be contrasted with the linkage of water to a single Ca^{2+} in gypsum (16).) Dehydration is accompanied by recrystallization and the activation energy associated with the necessary bond reorganization is relatively large (173 kJ mol^{-1}), significantly greater than the dehydration enthalpy (52 kJ mol^{-1}). The activation energy clearly did not include a contribution from the nucleation step, which was rapidly completed at the onset of reaction ($n = 2$ or 3 for growth of nuclei, extrapolations of data in Fig. 6 are close to times required for sample heating). Although the lattice adopted by the anhydrous product may be influenced by the presence of a low relative vapour pressure of water (20), $CaSO_3 \cdot 1/2H_2O$ dehydration



SCHEME 1. Mechanisms of dehydrations of calcium hydroxide and of calcium sulphite hemihydrate

was certainly irreversible at these reaction temperatures. There was no evidence that water reacted with the anion, in contrast with the high-temperature dehydration of $MgCl_2 \cdot 2H_2O$ (5).

The rate of $CaSO_3 \cdot 1/2H_2O$ dehydration was closely similar to that of $Ca(OH)_2$ dehydration; at the same temperatures reaction velocities, measured from slopes of α–time plots across the median region of both reactions, usually agreed within $\times 2$. The α–time curves for the two systems showed a significant difference in that the calcium hydroxide reaction was predominantly deceleratory. Studies in this laboratory using the same apparatus and identical reaction conditions showed that for $Ca(OH)_2 \rightarrow CaO + H_2O$ the activation energy was 174 ± 20 kJ mol^{-1} (633–683 K) (21), which is in remarkably close agreement with the value calculated for the present reaction, 173 ± 8 kJ mol^{-1} (573–673 K). Various other studies of calcium hydroxide dehydration have given comparable values: 143–180 kJ mol^{-1} (22) and 161–188 kJ mol^{-1} (23), as well as lower values (24).

In considering this close coincidence of absolute reactivity, including activation energy, between these two reactants, we assessed the possibility that $Ca(OH)_2$ was formed as an intermediate during $CaSO_3 \cdot 1/2H_2O$ dehydration. Mechanisms such as

$$2CaSO_3 \cdot 1/2H_2O \rightarrow CaS_2O_5 + Ca(OH)_2$$

were discounted because the metabisulphite would be expected to decompose at lower temperatures, by comparison with the known (25) stabilities of $Na_2S_2O_5$ (decomposed at 500 K) and $K_2S_2O_5$ (decomposed at 550 K). $CaSO_3 \cdot 1/2H_2O$ dehydration was not accompanied by SO_2 evolution, which is the expected product of $S_2O_5^{2-}$ anion breakdown (SO_2 yields here were always $< 2\%$ of the evolved gases). The dehydration rate was not influenced by added $Na_2S_2O_5$ and no anion other than SO_3^{2-} was detected by infrared spectroscopic examination of the anhydrous $CaSO_3$ product.

The close reactivity similarities apparent between the dehydrations of $CaSO_3 \cdot 1/2H_2O$ and $Ca(OH)_2$ are, therefore, ascribed to common mechanistic features in the water elimination and recrystallization processes. The steps contributing to the overall chemical changes are proton transfer and the dissociation of a strong calcium to water (oxygen) bond. It is not known which of these is rate limiting for the dehydration reaction, but the essential steps in both reactions are compared in Scheme 1. We suggest that a proton transfer step in the dehydration of $CaSO_3 \cdot 1/2H_2O$ permits reorganization of the coordination shell around the Ca^{2+} ion, here represented as involving the temporary formation of a $^-O—SO—OH$ ion. Because the activation energy (173 kJ mol^{-1}) is much larger than the dehydration enthalpy (52 kJ mol^{-1}) we conclude that the water elimination mechanism is more complicated than a single bond rupture step. Thus the onset of dehydration occurs at the common temperature at which proton transfer becomes possible in both salts. This is one possible explanation of the similarity of reactivity. Alternatively, if the rupture of similar strong Ca^{2+} ---- (OH_2) bonds in both salts controls the dehydration rate, then again the similarities of behaviour are explained. We conclude, therefore, that the dehydration of $CaSO_3 \cdot 1/2H_2O$ is rate controlled by the recrystallization (reactant $\rightarrow$ product), which may be promoted by proton transfer or the Ca^{2+}—OH_2 bond rupture step.

Acknowledgements

We thank Miss C. Nolan for DSC measurements of the dehydration enthalpy and Dr. M. E. Brady for helpful discussions of the reaction mechanism. We also thank the staff of the Electron Microscope Unit, QUB, for help and advice in obtaining the electron micrographs. One of us (C. A.) thanks the Department of Education for Northern Ireland for the Award of a Postgraduate Scholarship held during the period of this work.

The aqueous reactions of K[Pt(DMSO)Cl_3] with nitriles were studied in different conditions of pH. At normal pH (≈2.4), the ligands RCN, where R is an alkyl group, produced the yellow complexes Pt(DMSO)(R-CN)Cl_2. Infrared spectroscopy suggested *cis* isomers. The ^{195}Pt NMR spectra of the compounds show a resonance around −3000 ppm. The same reactions in neutral medium (pH adjusted to ~7 with NaOH) produced acetamido-bridged dimers (DMSO)ClPt(μ-RCONH)$_2$Pt(DMSO)Cl with all the ligands studied: propionitrile, butyronitrile, dimethylacetonitrile, trimethylacetonitrile, fluoroacetonitrile, chloroacetonitrile, bromoacetonitrile, and dibromoacetonitrile. The results of ^{195}Pt NMR spectroscopy show a head-to-tail isomer, since only one signal around −2750 ppm is observed for each complex. These dimeric compounds are all blue or green depending on the ligand. The same dimers are obtained with all the haloacetonitrile ligands when the pH is not adjusted (≈2.4). The crystal structures of Cl(DMSO)Pt(μ-$C_4H_8NO)_2$Pt(DMSO)Cl (**1**) and Cl(DMSO)Pt(μ-$C_5H_{10}NO)_2$Pt(DMSO)Cl (**2**) were determined. The results confirm that the dimers are head-to-tail isomers with the DMSO ligands located in *trans* position to the *O*-acetamido atoms. The two crystals belong to the $Pna2_1$ space group with a = 11.112(4), b = 20.414(9), c = 10.161(4) Å for **1** and a = 11.607(6), b = 20.113(11), and c = 10.641(5) Å for **2**. The structures were refined to R = 0.054 for **1** and R = 0.056 for **2**. The Pt—Cl bond lengths are 2.328(10), 2.293(10) Å for **1** and 2.317(9), 2.317(10) Å for **2**, while the Pt—S bond lengths are 2.173(10), 2.193(10) for **1** and 2.180(9), 2.176(9) Å for **2**. The Pt—O bonds vary from 1.91(2) to 2.08(2) and the Pt—N from 1.88(2) to 2.03(2) Å. The dihedral angle between the two Pt(II) planes is 36°.

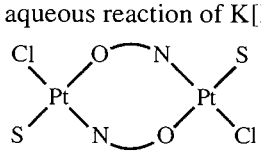
FERNANDE D. ROCHON, RADIA BOUGHZALA et ROBERT MELANSON. Can. J. Chem. **70**, 2476 (1992).

On a étudié les réactions aqueuses du K[Pt(DMSO)Cl_3] avec les nitriles à divers pH. À pH normal (pH ≈ 2,4) les ligands RCN, ou R est un groupe alkyle, donnent des complexes jaunes Pt(DMSO)(R-CN)Cl_2. La spectroscopie infrarouge révèle qu'il s'agit d'isomères *cis*. Les spectres RMN du ^{195}Pt présentent une résonance à environ −3000 ppm. Avec tous les ligands étudiés (propionitrile, butyronitrile, diméthylacétonitrile, triméthylacétonitrile, fluoroacétonitrile, chloroacétonitrile, bromoacétonitrile et dibromoacétonitrile) ces réactions, réalisées en milieu neutre (le pH est ajusté à 7 avec du NaOH), conduisent à des dimères avec le groupe acétamido en position de pont (DMSO)ClPt(μ-RCONH)$_2$(DMSO)Cl. Les résultats de la RMN du ^{195}Pt indiquent un isomère avec une structure tête-à-queue puisqu'on ne retrouve qu'un seul signal à environ −2750 ppm pour chacun de ces complexes. Tous ces dimères sont bleus ou verts dépendant du ligand. Tous les ligands haloacétonitriles donnent les mêmes dimères à pH normal (pH ≈2,4). On a déterminé la structure cristalline du Cl(DMSO)Pt(μ-$C_4H_8NO)_2$Pt(DMSO)Cl (**1**) et du Cl(DMSO)Pt(μ-$C_5H_{10}NO)_2$Pt(DMSO)Cl (**2**). Les résultats confirment que les dimères sont des isomères comportant une structure tête-à-queue dans laquelle le ligand DMSO est en position *trans* par rapport à l'atome d'oxygène du groupe acétamido. Les deux cristaux appartiennent au groupe d'espace $Pna2_1$ avec a = 11,112(4), b = 20,414(9), c = 10,161(4) Å pour le composé **1** et a = 11,607(6), b = 20,113(11) et c = 10,641(5) Å pour le composé **2**. On a affiné les structures jusqu'à des valeurs de R = 0,054 pour le composé **1** et de R = 0,056 pour le composé **2**. Les longueurs de liaison Pt—Cl sont de 2,328(10) et 2,293(10) Å pour le composé **1** et de 2,317(9), 2,317(10) Å pour le composé **2** tandis que la liaison Pt—S est de 2,173(10) et 2,193(10) Å pour le composé **1** et de 2,180(9) et 2,176(9) Å pour le composé **2**. La liaison Pt—O varie de 1,91(2) à 2,08(2) Å et la liaison Pt—N de 1,88(2) à 2,03(2) Å. L'angle dièdre entre les plans des deux Pt(II) est de 36°.

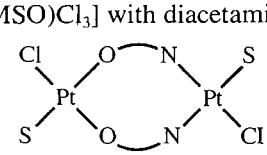
[Traduit par la rédaction]

Introduction

Recently, we started a study on the reactions of K[Pt(DMSO)Cl_3] with nitriles in aqueous medium. When K[Pt(DMSO)Cl_3] is dissolved in water, the pH of the solution is 2.35 (0.025 M), indicating some hydrolysis reactions. Its reaction with CH_3CN produced *cis*-Pt(DMSO)-(CH_3CN)Cl_2, which was studied by X-ray diffraction (1, 2). When the solution was neutralized with NaOH before adding CH_3CN, a dimer with acetamido bridges {Pt(DMSO)-Cl(μ-C_2H_4NO)}$_2$ (head-to-tail isomer) was isolated and characterized. The acetamido ligand was formed from the hydrolysis of CH_3CN. In this reaction, a blue solution was observed. The acetamido-bridged dimers can also be formed without adjusting the pH. If the reacting mixture (pH ~ 2.4) is left at room temperature for several weeks, a blue solution gradually forms and acetamido-bridged dimers can be eventually obtained. We also obtained the same dimers from the aqueous reaction of K[Pt(DMSO)Cl_3] with diacetamide.



head-to-tail isomer



head-to-head isomer

A similar study with no adjustment of pH (~2.4) with trichloroacetonitrile showed only the presence of *cis*-Pt-(DMSO)(H_2O)Cl_2 and its crystal structure has been reported (3). The presence of three chlorine atoms on the ligand lowers the donor properties of the N atom. At neutral pH, a monomer Pt(DMSO)Cl($C_4NO_2Cl_6$) containing a bidentate

deprotonated imide ligand, formed from the dimerization and hydrolysis of trichloroacetonitrile, was characterized by X-ray diffraction methods. No acetamido-bridged dimers were detected with this ligand.

When these reactions are done at neutral pH, a blue color is always observed after a few days. This blue compound, which is very soluble in water, is probably an analogue of *platinblau* reported in 1907 (4) and whose exact structure is still unknown. It was suggested that it contains deprotonated acetamido ligands bound to platinum(II), the acetamide being produced from the reaction of water with coordinated acetonitrile (5–7). But attempts to obtain *platinblau* by direct combination of platinum(II) with acetamide were not successful.

A systematic study of the aqueous reaction of K[Pt(DMSO)Cl_3] with no adjustment of pH(~2.4), and at neutral pH, was made with several alkyl and halo acetonitrile derivatives. Since trichloroacetonitrile is not a good ligand for Pt(II), we were interested to know if the monohaloacetonitriles would coordinate to Pt(II). The products of these reactions were analyzed by IR and by ^{195}Pt and ^{1}H NMR spectroscopy. The results of this study are described below.

Experimental section

The decomposition points were measured on a Fisher–Johns instrument. The pH values were measured on a Radiometre pHM 28 pH-meter with a Graphic-Controls microelectrode (13-620-253). The IR spectra were recorded in the solid state (KBr pellets) on a Perkin–Elmer 783 spectrometer. The ^{1}H NMR spectra were measured on a Bruker W-H 400 (400 MHz) with external TMS as reference. The ^{195}Pt NMR spectra were recorded on the same instrument (85.83 MHz), the external reference being K_2PtCl_4 adjusted to $\delta = -1628$ ppm from Na_2PtCl_6 ($\delta = 0$). The NMR spectra were measured in DMF-d_7 (^{1}H), in a mixture of DMF-d_7 and normal DMF (^{195}Pt), and occasionally in acetone-d_6. K_2PtCl_4 was bought from Johnson Matthey Inc. and was purified by crystallization from water before use. The nitrile ligands were obtained from Aldrich and the deuterated solvents from Cambridge Isotopes.

K[Pt(DMSO)Cl_3] was prepared by the published method (8). Yield: 90%; IR (cm^{-1}): ν(S=O) 1101, ν(Pt—Cl) 349m, 310m, 332s; NMR (ppm in D_2O): 3.50 (s + d), ^{3}J(Pt–H) = 24 Hz, δ(Pt) −2998; (ppm in DMF): 3.33 (s + d), ^{3}J(Pt–H) = 22 Hz, δ(Pt) −2965 (lit. (9) −2969 ppm in DMSO).

cis-Pt(DMSO)(CH_3CN)Cl_2 and Cl(DMSO)Pt(μ-$C_2H_4NO)_2$Pt(DMSO)Cl were prepared as already reported (1). *cis*-Pt(DMSO)(CH_3-CN)Cl_2: NMR (δ, ppm in DMF): CH_3 (DMSO) 3.50 s + d, $^{3}J(^{195}Pt-^{1}H)$ = 18 Hz, CH_3 2.79s, δ(Pt) −3010. Cl(DMSO)Pt(μ-$C_2H_4NO)_2$Pt(DMSO)Cl: δ(Pt) −2753 ppm in DMF.

The reactions of K[Pt(DMSO)Cl_3] with different nitriles were studied in water by two differents methods.

1. With no adjustment of pH

K[Pt (DMSO)Cl_3] (~0.5 mmol) was dissolved in a minimum quantity of distilled water, an excess of ligand (Pt:ligand = 1:4) was added to the solution, and the mixture was agitated and left at room temperature until a yellow precipitate was observed. The precipitate was then filtered, washed with water, and dried in vacuum. For the haloacetonitrile ligands, the isolated compounds were identical to those obtained at pH ~7 as described below. For the other ligands, the products were identified as Pt(DMSO)(RCN)Cl_2.

Pt(DMSO)(C_2H_5CN)Cl_2: Yield 50%; dec. 118–220°C; IR (cm^{-1}): 2318m, 1462w, 1428w, 1407m, 1378w, 1318w, 1305w, 1170s, 1155s, 1074m, 1030s, 987m, 928w, 918w, 776w, 737m, 692m, 447s, 381w, 360w, 340m, 322 sh.; NMR (δ, ppm in acetone-d_6): CH_3 (DMSO) 3.53s + d, $^{3}J(^{195}Pt-^{1}H)$ = 21Hz, CH_3 1.40t, ^{3}J = 7.5Hz, CH_2 3.05q, δ(Pt) −2997, δ(Pt) −3006 ppm in DMF.

Pt(DMSO)(n-C_3H_7CN)Cl_2: Yield 45%; dec. 115–220°C; IR (cm^{-1}): 2318w, 2310m, 1458m, 1408m, 1382w, 1315m, 1295m, 1147s, 1020s, 980m, 940m, 911m, 735s, 695w, 448s, 382m, 363m, 340s, 320w; NMR (δ, ppm in acetone-d_6): CH_3 (DMSO) 3.53s + d, $^{3}J(^{195}Pt-^{1}H)$ = 22Hz, CH_3 1.14t, ^{3}J = 7Hz, CH_2 3.04t, ^{3}J = 7Hz, CH_2 1.83m, δ(Pt) −2999 ppm in DMF.

Pt(DMSO)($CH(CH_3)_2CN$)Cl_2: Yield 73%; dec. 170–225°C; IR (cm^{-1}): 2190w, 1403m, 1316s, 1100vs, 1028s, 976m, 942m, 926m, 732m, 691m, 447m, 382m, 348m, 310m.

Pt(DMSO)($C(CH_3)_3CN$)Cl_2: Yield 18%; dec. 115–225°C; IR (cm^{-1}): 2308w, 2299w, 1477m, 1455m, 1414m, 1362m, 1240m, 1162s, 1147s, 1031s, 1018s, 982m, 938m, 928w, 913w, 734m, 692m, 442s, 378w, 362s, 320s, 312sh; NMR, δ(Pt) −3010 ppm in DMF.

2. With adjustment of pH

K[Pt(DMSO)Cl_3] (~0.7 mmol) was dissolved in 15 mL of distilled water and the pH of the solution was adjusted to about 7 with 0.1 M NaOH. The nitrile ligand (0.3–0.5 mL) was then added slowly with mixing and the solution was left at room temperature until a precipitate formed (1 day to 3 weeks). The precipitate, which proved to be the acetamido-bridged dimer, was either yellow, green, or blue depending on the ligand and on the time of standing. The precipitate was filtered, washed with water, and dried in vacuum.

{Cl(DMSO)Pt(μ-C_3H_6NO)}$_2$: Yield 20%; dec. 190–207°C; IR (cm^{-1}): 3317w, 3300s, 1590vs, 1495w, 1465w, 1420w, 1320w, 1258s, 1220s, 1148s, 1120s, 1022s, 920w, 900w, 735w, 697m, 608m, 450s, 380m, 340m; NMR (δ, ppm in DMF): CH_3 (DMSO) 3.33s, 3.47s, CH_3 0.85t, ^{3}J = 8Hz, CH_2 2.13q, NH 6.8, δ(Pt) −2763.

{Cl(DMSO)Pt(μ-nC_4H_8NO)}$_2$: Yield 15%; dec. 198–202°C; IR (cm^{-1}): 3318s, 1585vs, 1482m, 1430w, 1297m, 1237s, 1142vs, 1020s, 980w, 930w, 696m, 610w, 450s, 382m, 340m; ^{195}Pt NMR: −2752 ppm in DMF.

{Cl(DMSO)Pt(μ-C_2H_3NOF)}$_2$: Yield 30%; dec. 180–220°C; IR (cm^{-1}): 3330l 1625sh, 1610s, 1482m, 1438m, 1352m, 1215m, 1152s, 1142s, 1053s, 1038s, 935w, 722m, 699w, 602m, 458s, 385m, 342m; NMR (δ, ppm in acetone-d_6): CH_3 (DMSO) 3.63s, 3.62s, CH_2 4.88d, $^{2}J(^{19}F-^{1}H)$ = 48 Hz, NH 6.7, δ(Pt) −2715; (δ, ppm in DMF): CH_3 (DMSO) 3.64s, 3.60s, CH_2 4.94d, $^{2}J(^{19}F-^{1}H)$ = 44 Hz, NH 7.3, δ(Pt) −2723.

{Cl(DMSO)Pt(μ-C_2H_3NOCl)}$_2$: Yield 20%; dec. 182–240°C; IR (cm^{-1}): 3315l, 3000s, 1632w, 1612m, 1465w, 1420w, 1402m, 1315m, 1297w, 1210m, 1140vs, 1130sh, 1028s, 977w, 960w, 928w, 790m, 740m, 698m, 577m, 452s, 380m, 340s; NMR (δ, ppm in acetone-d_6): CH_3 (DMSO) 3.62s, 3.58s, CH_2 4.21s, NH 6.8, δ(Pt) −2725; (δ, ppm in DMF): CH_3 (DMSO) 3.65s, 3.58s, CH_2 4.26s, NH 7.5, δ(Pt) −2750.

Crystallographic measurements and structure resolution

The two blue crystals (synthesized by adjusting the pH at ~7) were selected after examination for homogeneity under a polarizing microscope. They were obtained directly from the reacting medium. The unit cell parameters were obtained by least-squares refinement of the angles 2θ (11–25°), ω, and χ for 15 well-centered reflections on a Syntex P1 diffractometer using graphite-monochromatized MoKα radiation. Crystal data and other information are summarized in Table 1. Scan rates and data treatment have already been described (10). Crystal (**1**) gradually decomposed during the data collection, as shown by a gradual decrease of the intensity of the three standard reflections. At the end of the collection, the intensity was reduced by about 20%. Scaling on the standard reflections was made as usual. Corrections were made for absorption and Lorentz–polarization effects. The anom-

alous dispersion terms of Pt, S, and Cl were included in the calculations (11).

The coordinates of the Pt atoms for the two crystals were determined from a three-dimensional Patterson map and the positions of all the other non-hydrogen atoms were found by the usual Fourier methods. The refinements of the two structures were done by using full-matrix least-squares calculations minimizing $\Sigma w(|F_o| - |F_c|)^2$. Interchanging the positions of the O and N atoms of the bidentate ligands resulted in abnormal thermal factors. The proposed positions are the most probable based on the size of the thermal factors. The H atoms could not be located (as often encountered for platinum complexes), and they were fixed at their calculated positions with $U_{eq} = 1.2 \times U_{eq}$ of the C to which they are bonded. Isotropic secondary-extinction corrections (12) were included in the calculations. Individual weights $w = 1/\sigma^2(F)$ were applied. The refinement of the scale factor, coordinates, and anisotropic temperature factors of all atoms converged to $R = 0.054$ and $wR = 0.046$ for **1** and to $R = 0.056$ and $wR = 0.050$ for **2**. Refinement of the enantiomorphic structures resulted in significantly higher R factors. There were a few residual peaks (<1.2e Å^{-3} for **1** and <1.3e Å^{-3} for **2**) in the close environment of the Pt atoms.[2]

[2]The following tables are available as supplementary material: anisotropic temperature factors (Table S1), coordinates of the H atoms (Table S2), weighted least-squares planes (Table S3), torsion angles (Table S4) (9 pages), observed and calculated structure factor amplitutes (Table S5) (17 pages). These tables may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 052.

Table S2 has also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

The scattering curves of Cromer and Waber (13) were used. Most of the calculations were done on a SHELXTL system and the others on a Cyber 830 with programs already described (10).

Results and discussion

The aqueous reactions of K[Pt(DMSO)Cl_3] with several nitriles were studied without adjusting the pH (~2.4) and at neutral pH (adjusted to ~7 with 1 M NaOH). The results were compared with those obtained with CH_3CN where *cis*-Pt(CH_3CN)(DMSO)Cl_2 (pH ~2.4) and Cl(DMSO)Pt(μ-$C_2H_4NO)_2$Pt(DMSO)Cl (pH ~7 or at pH ~2.4 after several weeks) were characterized (1) and with CCl_3CN where only *cis*-Pt(DMSO)(H_2O)Cl_2 (pH ~2.4) and Pt(DMSO)($C_4NO_2Cl_6$)Cl (pH ~7) were detected (3). In the present study, the nitriles propionitrile, butyronitrile, isobutyronitrile, trimethylacetonitrile, fluoroacetonitrile, chloroacetonitrile, bromoacetonitrile, and dibromoacetonitrile were used. Most of the products were characterized by IR and by ^{1}H and ^{195}Pt NMR spectroscopy.

Pt(RCN)(DMSO)Cl_2

The reaction of K[Pt(DMSO)Cl_3] with RCN, where R is an alkyl group, gave the yellow compound Pt(RCN)(DMSO)Cl_2.

$$K[Pt(DMSO)Cl_3] + RCN \xrightarrow[pH\sim2.4]{H_2O} Pt(DMSO)(RCN)Cl_2$$

This reaction is similar to the reactions with CH_3CN (1, 2) and $PhCH_2CN$ (14) where *cis*-Pt(DMSO)(RCN)Cl_2 was obtained. Under the same conditions, reactions with the haloacetonitriles (FCH_2CN, $ClCH_2CN$, $BrCH_2CN$, and Br_2CHCN) did not produce the nitrile complex as observed

For personal use only.

for CCl_3CN (3). These ligands all contain electron-attracting atoms, which decrease the donor properties of the molecule.

The IR spectra of the synthesized compounds Pt(DMSO)(RCN)Cl_2, where R = an alkyl group, were compared to that of *cis*-Pt(DMSO)(CH_3CN)Cl_2. The approximate skeleton symmetry of the complexes PtL_2X_2 is C_{2v} for the *cis* isomer and D_{2h} for the *trans* isomer. From group theory, two ν(Pt—Cl) vibrations are expected for *cis* isomers and only one for *trans* compounds (15). The IR spectrum of all the compounds showed two ν(Pt—Cl) bands between 310 and 348 cm^{-1}. We suggest, therefore, that the compounds Pt(DMSO)(RCN)Cl_2 are *cis* isomers like *cis*-Pt(DMSO)(CH_3CN)Cl_2, which also showed two ν(Pt—Cl) vibrations (1).

The formation of *cis* isomers might seem surprising because of the large *trans* effect of DMSO. The multiple nature of the Pt—S bond is probably an important factor. Besides the σ bond (S → Pt), there is a back-donation of electrons into a vacant $d\pi$-type orbital of the ligand (Pt → S). This π bond could be partially responsible for the large *trans* effect of DMSO, which is almost as large as that of C_2H_4 (16). The complexes Pt(DMSO)$_2Cl_2$ and Pt(CH_3CN)$_2Cl_2$ that are obtained in aqueous solution are also *cis* isomers (17, 18). For DMSO, it is now known that the first compound formed is *trans*-Pt(DMSO)$_2Cl_2$, which rapidly isomerizes to the *cis* compound. It was suggested that the enhanced $\pi(d$–$d)$ bonding is more efficient in the *cis* isomer than in the *trans* compound (19). Similarly, the reaction of K[Pt(DMSO)Cl_3] with the nitrile ligand could first produce the *trans* isomer, which would then isomerize to the more stable *cis* compound. For the compound *cis*-Pt(CH_3CN)$_2Cl_2$, the formation of a *cis* isomer can be explained by the same reasoning, but the nature of the π bond between platinum and CH_3CN is slightly different. The back-donation is made into a π^* molecular orbital of CH_3CN since N cannot use its high-energy *d* orbitals. Similarly, the formation of π bonds in the Pt—N and Pt—S bonds in Pt(DMSO)(RCN)Cl_2 would be more efficient in the *cis* configuration. We therefore suggest that the aqueous reaction of K[Pt(DMSO)Cl_3] with nitriles first produces the *trans* isomer, which then isomerizes to the *cis* compound. We intend to verify this hypothesis in the near future by changing the two ligands to more crowded ones, such as diphenyl sulfoxide and trimethylacetonitrile. With these ligands, the isomerization should be much slower and it should be possible to isolate the *trans* isomers. In a preliminary work, we studied the reaction of K[Pt(Ph_2SO)Cl_3] with CH_3CN. The ^{195}Pt NMR spectrum of the product showed the presence of several different Pt compounds, which have not yet all been identified. This project is being continued.

Some of the nitrile ligands show two bands in the infrared region at ~2250 cm^{-1}. There is a stretching vibration ν(C≡N) and a combination band $\partial(CH_3) + \partial$(C—C). These bands are observed for free CH_3CN at 2254 and 2290 cm^{-1}, respectively (20). Coordination of nitriles through the lone pair of electrons on the N atom increases the ν(C≡N) frequency because of kinematic coupling (with ν(Pt—N)) and the increased ionic character of the C—N bond (18). The ν(C≡N) vibrations in the complexes Pt(DMSO)(RCN)Cl_2 were observed around 2310 cm^{-1}, an increase in energy of about 55 cm^{-1}.

The ν(S=O) band in DMSO is observed at 1055 cm^{-1}. Upon coordination, the vibration is expected at higher energy since the binding site is the S atom. In K[Pt(DMSO)Cl_3], the band is observed at 1101 cm^{-1} while in the complexes *cis*-Pt(DMSO)(RCN)Cl_2 the vibration absorbs around 1150 cm^{-1}.

The ^{195}Pt NMR spectra of the four complexes *cis*-Pt(RCN)(DMSO)Cl_2, with R = CH_3, C_2H_5, *n*-C_3H_7, and $C(CH_3)_3$ measured in DMF, show signals at −3010, −3006, −2999, and −3010 ppm, respectively. These values are close to those reported for *cis*-Pt(DMSO)(RCN)Cl_2 where R = PhCN (−2994 ppm) and $PhCH_2CN$ (−3007 ppm) (14). The inductive repulsive effect follows the order $C(CH_3)_3$ > C_3H_7CN > C_2H_5CN > CH_3CN. The σ donating bond (N → Pt) bond should be stronger when R increases. We have observed that all complexes have almost the same chemical shifts (−3010 to −2999 ppm). The presence of π bonds in Pt–DMSO and Pt–NC-R complexes should not be neglected, but it is difficult to predict how the chemical shift will vary as R increases. An increase in the multiple nature of the Pt—N bond would decrease the electron density on Pt and therefore would produce a chemical shift towards lower field. The ^{195}Pt NMR spectrum of the compound *cis*-Pt(DMSO)(C_2H_5CN)Cl_2 was also measured in acetone-d_6. The resonance was observed at −2997 ppm, very close to the value (−3006 ppm) measured in DMF.

The ^{195}Pt NMR spectra of fresh DMF solutions of the complexes showed only one resonance, confirming the purity of the compounds. This is different from the synthesis of *cis*-Pt(DMSO)($PhCH_2CN$)Cl_2, which contained about 10% of an impurity assigned by the authors to the *trans* isomer (14). We believed that the signal observed at −2965 ppm in DMF might be caused by the presence of the starting material K[Pt(DMSO)Cl_3], which we observed at −2968 ppm in the same solvent. After about 1 h in DMF solution, the *cis*-Pt(DMSO)(RCN)Cl_2 compounds were shown to decompose slowly. A new peak was observed in the ^{195}Pt NMR spectrum at −2876 ppm. This signal is believed to be caused by the presence of Pt(DMSO)(DMF)Cl_2 as suggested for the decomposition of Pt(DMSO)($PhCH_2CN$)Cl_2 in DMF where the DMF species was observed at −2872 ppm (14).

The high-field ^{1}H NMR spectra were measured. The coupling constants $^3J(^{195}Pt$–$^1H)$ of DMSO and $^3J(^1H$–$^1H)$ were calculated when possible. These values are ~20 Hz and ~7 Hz respectively. The protons located on the carbon atom in the α position are more affected upon coordination than are the other protons. From the literature, the signals of the protons in DMSO in *cis*-Pt(CH_3CN)(DMSO)Cl_2 were observed at 3.41 ppm in acetonitrile-d_3 with a coupling constant ^3J(Pt–H) of 22.8 Hz (21). In our study, this resonance was observed around 3.50 ppm in DMF or acetone, with coupling constants between 18 and 22 Hz. A deshielding of about 0.9 ppm was observed for these protons upon coordination to platinum (pure DMSO, δ = 2.60 ppm).

Cl(DMSO) Pt(μ-RCONH)$_2$Pt(DMSO)Cl

The reaction of K[Pt(DMSO)Cl_3] in neutral solution (pH adjusted to ~7 with NaOH) with all the nitriles (R = alkyl or haloalkyl group) produced an acetamido-bridged dimer, similar to the reaction with CH_3CN, where in the same conditions Cl(DMSO)Pt(μ-$CH_3CONH)_2$Pt(DMSO)Cl was isolated and characterized by X-ray diffraction (1). We also determined the crystal structures of the compounds obtained with dimethylacetonitrile and trimethylacetonitrile. These results are discussed later in this publication.

$$K[(DMSO)Cl_3] + RCN \xrightarrow{pH\sim7} Cl(DMSO)Pt(\mu\text{-}RCONH)_2Pt(DMSO)Cl$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

The same compound was isolated without adjusting the pH (pH ~ 2.4) with the halonitriles, i.e., fluoroacetonitrile, bromoacetonitrile, chloroacetonitrile, and dibromoacetonitrile. These ligands do not form the compound *cis*-Pt(DMSO)(nitrile)Cl_2, as already mentioned. The formation of dimers with the halonitriles is faster at neutral pH than in acidic solution.

In organic chemistry, nitriles are known to hydrolyze but their conversion into amido ions usually requires acidic or basic conditions (22). In the presence of platinum, the reaction can be activated without the presence of acids or bases. The reaction is favored at neutral pH. With the ligands R-C≡N where R is an alkyl group, the hydrolysis reaction is quite slow in acidic medium (pH ~ 2.4) and *cis*-Pt(DMSO)(nitrile)Cl_2 is rapidly formed. This product is very insoluble and will precipitate immediately. If the mixture is not filtered and is left to stand at room temperature, acetamido-bridged dimers can be isolated after 1–2 months. In neutral solution, the dimers are formed more rapidly. For the nitrile ligands R-C≡N where R is a haloalkyl group like FCH_2CN, $ClCH_2CN$, $BrCH_2CN$, or Br_2CHCN, the compound *cis*-Pt(DMSO)(nitrile)Cl_2 is not stable and the dimer is isolated in acid or neutral solution, but the reaction is faster at neutral pH. Furthermore, for the halonitriles, the fastest reaction was with fluoroacetonitrile. The large electronegativity of fluorine drastically weakens the Pt—N (nitrile) bond, and the nitrile compound is the least stable. The hydrolysis of nitriles in the coordination sphere of metal ions has been known for several decades. It was first shown in 1967 that hydrolysis of 2-cyano-1,10-phenanthroline to the corresponding amide is strongly promoted by metal ions such as Cu^{2+}, Ni^{2+}, and Zn^{2+} (23). The rate acceleration was attributed to an entropy effect. A number of subsequent studies were reported and rate enhancements of 2×10^6 were observed in these reactions (24), including a report on hydration of nitriles to carboxamides catalyzed by platinum (25).

The structural analyses of Cl(DMSO)Pt(μ-C_2H_4NO)Pt(DMSO)Cl (1) and the two dimers described later show that the compounds are head-to-tail isomers, with the DMSO molecules in *trans* position to the *O*-acetamido atoms. The ^{195}Pt NMR signals of the synthesized compounds were observed between −2723 and −2773 ppm in DMF, very close to the value observed for the head-to-tail isomer obtained from CH_3CN (−2753 ppm in DMF). We suggest therefore that all the dimers synthesized in this project have the same configuration. The ^{195}Pt NMR spectrum of a head-to-head isomer would show two different signals of equal intensity around −2600 ppm for a Pt environment S Cl O O and around −3130 ppm for an environment S Cl N N similar to *cis* and *trans*-Pt(DMSO)$(NH_3)_2$Cl (δ = −3147 and −3126 ppm) (26). No ^{195}Pt NMR spectrum has yet been reported for this type of compound, but our values are close to that (δ = −2747 ppm) reported for Pt(DMSO)Cl($NH_2CH_2CO_2$) (26), which contains the same four donor atoms.

For the halonitriles, the chemical shifts follow the order of electronegativity of the halides. The observed values for the ligands FCH_2CN, $ClCH_2CN$, $BrCH_2CN$, and Br_2CHCN are −2723, −2750, −2762, and −2773 ppm, respectively, and the shielding increases with increase of the donor properties Br > Cl > F, covering a region of 50 ppm. For the ligands that do not contain any halogens, the δ(Pt) are constant (−2753, −2763, −2752, and −2756 ppm) for the complexes containing the hydrolyzed ligands of CH_3CN, C_2H_5CN, *n*-C_3H_7CN, and $C(CH_3)CN$, respectively. It was not possible to measure the ^{195}Pt NMR spectrum of the dimer with $CH(CH_3)_2CN$. The product obtained was deeply colored (green) and probably contains a small quantity of paramagnetic species. Nevertheless, a structure determination of one of the crystals showed it to be a head-to-tail acetamido-bridged dimer as described later in the text.

Fresh solutions of all the compounds except the product from trimethylacetonitrile (which showed a small signal at −2928 ppm) have shown only one resonance in ^{195}Pt NMR. But on standing in DMF, all the compounds decompose slowly. Figure 1 shows the ^{195}Pt spectrum of the dimer prepared with the ligand chloroacetonitrile at pH ~ 7, after 1 week in DMF. Nine peaks are observed. The signals at −2995, −2967, and at −2750 ppm can be assigned to *cis*-Pt(DMSO)(RCN)Cl_2 (~1%), $[Pt(DMSO)Cl_3]^-$ (~4%), and to the head-to-tail dimer Cl(DMSO)Pt(μ-$CH_2ClCNO)_2$Pt(DMSO)Cl (~18%), respectively. The other peaks observed at lower field (−2440, ~7%; −2426, ~7%; −2370, ~24%; −2312, ~2%; −2018, ~16%; and −1940 ppm, ~21%) are assigned to decomposed products containing DMF as ligand. DMF is a good O-donor ligand for platinum, producing species that would appear at lower field than species containing S- or N-donor ligands. These species have not yet been identified and the project is being continued.

The ^{1}H NMR spectra of these compounds have been measured and are listed in the experimental section. As ex-

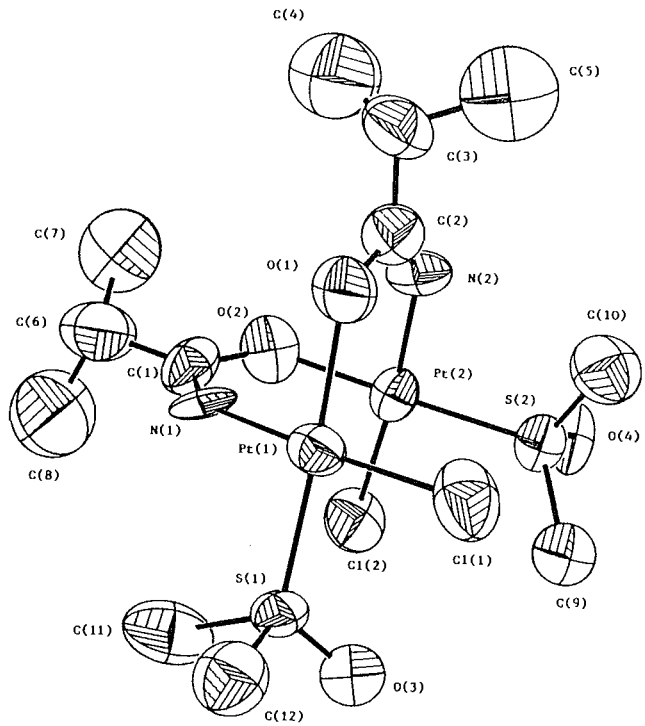

FIG. 2. Labeled diagram of Cl(DMSO)Pt(μ-$C_4H_8NO)_2$Pt-(DMSO)Cl (**1**).

pected, the protons located on a carbon atom in the α position of the acetamido ligands are the most affected upon coordination ($\Delta\delta \approx 0.6$ ppm). The protons in the β position are less deshielded ($\Delta\delta = 0.1$–0.2 ppm), while those in the γ position are not affected. All the dimeric species have shown two signals around 3.6 ppm for the protons of the DMSO ligands, indicating different environments for the two methyl groups, which differs from the compounds *cis*-Pt(DMSO)(nitrile)Cl_2 and $[Pt(DMSO)Cl_3]^-$ where only one signal was observed. Nevertheless, no $^3J(^{195}Pt-^1H)$ coupling was observed for the dimers, contrary to the two above monomers. The signal of the amide proton was observed around 7 ppm. Because of its width and its low intensity, it was not possible to observe a coupling with ^{195}Pt. The coupling constant $^2J(^{19}F-^1H)$ for the complex obtained from FCH_2CN is 46 Hz and agrees with similar reported values (44–81 Hz) (27).

The IR spectra of the dimers showed the absence of vibrations in the ν(C≡N) region, around 2300 cm^{-1}. One or two new bands around 1600 cm^{-1} were observed. These were assigned to the amido groups ν(C=O) and ∂(N—H). These complexes all show only one ν(Pt—Cl) band between 332 and 350 cm^{-1}. The ν(S—O) vibrations were observed between 1140 and 1156 cm^{-1}. An increase in the frequency of the vibration (S=O) of 85 cm^{-1} upon coordination confirmed that the binding site is the S atom. These values are close to those observed for the compounds *cis*-Pt(DMSO)(nitrile)Cl_2.

Most of the dimeric complexes obtained after adjusting the pH (~7) are green or blue. The same dimers obtained without adjusting the pH are usually yellow. The color is probably caused by the presence of a small quantity of a blue amorphous compound, not only on the surface (since it cannot be washed out) as suggested for the acetamido-bridged compound (1). The blue complex is believed to be an analogue of platinblau, which is probably an acetamido-bridged oligomer. A few research groups, especially those of Lippard and Lippert, have prepared several blue complexes with α-pyridone, uracil, and thymine derivatives (28–30). Several platinum blues were characterized crystallographically. These were found to be multinuclear species containing Pt in a fractional oxidation state (>2) with bridging α-pyridonate, uracilate, or thyminato ligands. It was suggested that the blue

*Crystal structures of Cl(DMSO)Pt(μ-$C_3H_8NO)_2$Pt-(DMSO)Cl (**1**) and Cl(DMSO)Pt(μ-$C_5H_{10}NO)_2$Pt-(DMSO)Cl (**2**)*

The dimers obtained with dimethylacetonitrile and trimethylacetonitrile gave crystals suitable for diffraction methods. The two analyzed crystals are isostructural. The refined atomic parameters are shown in Table 2. The structures of the two compounds are similar to that of the acetamido-bridged dimer synthesized from CH_3CN. Labeled diagrams of the two molecules are shown in Figs. 2 and 3. The bond distances and angles are reported in Table 3. The two compounds are acetamido-bridged dimers with a head-to-tail configuration. The DMSO ligands, which are S-bonded to Pt, are in *trans* position to the acetamido oxygen atoms. The relatively short Pt···Pt distances (2.989(2) Å for **1** and 2.983(2) Å for **2**) are produced by the geometric requirements imposed by the two bridging ligands.

The coordination around each platinum atom is square-planar, but there are some slight square-pyramidal distortions. For each crystal, the Pt atoms are out of the plane formed by the four coordinating atoms by −0.056 and −0.096 Å in crystal **1** and by −0.068 and 0.092 Å in crystal **2**. The tilt angles between the two Pt planes are 36° (**1**) and 35° (**2**).

The Pt—Cl bonds (2.328(10), 2.293(10) Å for **1** and 2.317(9), 2.317(10) Å for **2**) are normal. The Pt—S bonds (2.173(10)–2.193(10) Å) are slightly shorter than the average value (2.21 Å) reported for Pt–DMSO complexes (17, 32), but similar to those reported for Cl(DMSO)Pt(μ-$C_2H_4NO)_2$Pt(DMSO)Cl (2.185(2) and 2.198(2) Å) (1). The results on these dimers are different from those observed in α-pyridonate-bridged platinum complexes where the Pt—N (ammine or ethylenediamine) distances *trans* to pyridonate oxygen atoms were significantly longer than those *trans* to pyridonate nitrogen atoms, revealing a larger *trans* influence of the O atom. Lippard and co-workers suggested that this *trans* influence originated in more extensive σ-overlap of the Pt—N (pyridonate) bond relative to the Pt—O (amidate) bond (29, 31). For our compounds, the Pt—S bonds that are located in *trans* position to the Pt—O (acetamido) bonds are slightly shorter than normal, probably indicating a greater π-character of the Pt—S bond. The S atoms in the DMSO ligands are in an approximate tetrahedral environment.

The Pt—O (1.91(2)–2.08(2) Å) and Pt—N (1.88(2)–2.03(2) Å) bonds seem normal and agree well with values found in ref. 1 and in the pyridonate and uracilate complexes mentioned above. The bond lengths and angles in the two bridging acetamido ligands are also normal. The N—C bond distances are 1.25(4)–1.38(4) Å while the O—C bond lengths are 1.27(4)–1.36(4) Å. The angles around C(1) and C(2) are in the range 111(2)–129(2)°, indicating a sp^2 hybrid. The internal angles at N(1), N(2), O(1), and O(2) are similar, varying from 123(2)° to 135(2)°. The moieties N—C(C)—O are planar with the two amido planes almost perpendicular to each other. The thermal factors of the methyl groups are quite high, resulting in high standard deviations. The torsion angles have been calculated and the table is part of the supplementary material (see footnote 2).

The packing of the molecules for crystal **1** is shown in Fig. 4. The environment of the acetamide N atoms was closely examined for the presence of hydrogen bonds. There might be such an intermolecular interaction with N(2)···Cl(1) distance = 3.39(1) Å and angles Pt(2)—N(2)···Cl(1) = 102(1)° and C(2)—N(1)···Cl(1) = 123(2)°. The closest such contact around N(1) is O(3) with a distance of 3.38(2) Å (**1**). Therefore hydrogen bonding does not seem a very important stabilizing factor in these crystal structures.

Electrode-mediated Wacker oxidation of cyclic and internal olefins[1]

D. G. MILLER[2] AND D. D. M. WAYNER[3]

Steacie Institute for Molecular Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received February 18, 1992

D. G. MILLER and D. D. M. WAYNER. Can. J. Chem. **70**, 2485 (1992).

An improved method for the electrode-mediated oxidations of olefins by palladium(II) is described. Current efficiencies from 80% to 95% were obtained in oxidations of 1-decene, styrene, *trans*-2-octene, and cyclohexene in which perchloric acid was added to a chloride-free solution of a palladium(II) acetate catalyst. The palladium(0) was reoxidized to palladium(II) by reaction with catalytic amounts of benzoquinone, which was, in turn, regenerated by anodic oxidation. Addition of varying amounts of perchloric acid did not affect the current efficiency but accelerated the oxidation reaction, up to a concentration of approximately 0.15 M. The current efficiency remained high (>80%) over the course of the electrode-mediated oxidations of 1-decene, *trans*-2-octene, and cyclohexene. At the end of the reactions, when the substrate was depleted, a drastic decrease in the current was observed, indicating that the catalytic cycle leading to product was primarily responsible for the electrochemical reaction. It also was shown that the rates of the electrochemical reactions were generally slower than those of homogeneous reactions in which a stoichiometric amount of benzoquinone was used, indicating that the electrochemical regeneration of benzoquinone was mass transport limited at the highest concentrations of perchloric acid. This is in contrast to other reports in the literature that suggested that the homogeneous (non-electrochemical) reactions were actually slower. Reasons for the discrepancy between these results are discussed.

D. G. MILLER et D. D. M. WAYNER. Can. J. Chem. **70**, 2485 (1992).

On décrit une méthode améliorée d'oxydation des oléfines par le palladium(II), assistée par une électrode. On a obtenu des efficacités de courant allant de 80 à 95% lors d'oxydations du déc-1-ène, du styrène, du *trans*-oct-2-ène et du cyclohexène au cours desquelles on avait ajouté de l'acide perchlorique à une solution sans chlorure d'un catalyseur d'acétate de palladium(II). Le palladium(0) est ré-oxydé en palladium(II) par une réaction impliquant des quantités catalytiques de benzoquinone qui est, à son tour, régénéré par oxydation anodique. L'addition de quantités variables d'acide perchlorique n'affecte pas l'efficacité de courant; toutefois, la réaction d'oxydation est accélérée jusqu'à une concentration d'environ 0,15 M. Avec le déc-1-ène, le *trans*-oct-2-ene et le cyclohexène, l'efficacité du courant demeure élevée (>80%) pour l'ensemble des oxydations assistées par une électrode. À la fin de réactions, lorsqu'il ne reste plus de substrat, on observe une dramatique diminution du courant qui indique que le cycle catalytique conduisant au produit est le principal responsable de la réaction électrochimique. On a montré que la vitesse des réactions électrochimiques est généralement plus lente que les réactions homogènes dans lesquelles on utilise une quantité stoechiométrique de benzoquinone; ceci indique que, à des concentrations élevées d'acide perchlorique, la régénération électrochimique de la benzoquinone est limitée par un transport de masse. Cette situation est en opposition avec d'autres rapports parus dans la littérature qui suggéraient que les réactions homogènes (non-électrochimiques) sont de fait plus lentes. On discute des raisons pouvant expliquer ces différences.

[Traduit par la rédaction]

Introduction

The oxidation of olefins to ketones by Pd(II) salts, the Wacker oxidation (eq. [1]), is important from both an industrial and synthetic chemistry perspective. This process has been used in the industrial production of low molecular weight aldehydes and ketones (1), as well as in the selective oxidation of unsaturates in organic synthesis (2–4). The reaction itself is not catalytic in palladium so a secondary oxidation system that regenerates Pd(II) from Pd(0) is required (eq. [2]). Chemical oxidants (Ox) such as Cu(II), Fe(III), MnO_2, heteropolyacids, or quinones have been used for this purpose (4–11).

[1] $RCH{=}CH_2 + H_2O + Pd(II) \rightarrow RC(O)CH_3 + 2H^+ + Pd(0)$

[2] $Pd(0) + Ox \rightarrow Pd(II) + Red$

The commercial Wacker process originally used $CuCl_2$ to recycle the Pd(II) (eq. [3]), and molecular oxygen to regenerate Cu(II) from Cu(I) (eq. [4]). The process fell into disfavour in the 1970's as a result of corrosion problems caused by the copper chloride salts as well as the safety hazards associated with the use of high pressures of molecular oxygen. Alternative processes that are less corrosive and do not require molecular oxygen may lead to the reemergence of the Wacker oxidation as an efficient route to oxygenate production. One possibility is to replace one of the homogeneous oxidation reactions with an electrochemical reaction. Direct electro-oxidation of Pd(0) is not practical since the metal forms a mirror over the apparatus (12, 13). However, it is

[3] $Pd(0) + 2CuCl_2 \rightarrow PdCl_2 + Cu_2Cl_2$

[4] $CuCl_2 + 2HCl + 1/2O_2 \rightarrow 2CuCl_2 + H_2O$

feasible to consider using only catalytic amounts of a homogeneous chemical oxidant to recycle the palladium and to regenerate the chemical oxidant from its reduced form electrochemically (eq. [5]).

[5] $Red \xrightarrow{anode} Ox + ne^-$

Tsuji and Minato have reported the electrode-mediated oxidation of olefins using $Pd(OAc)_2$ and benzoquinone under galvanostatic conditions (10). While that study focused on the oxidation of terminal olefins, it was noted that the oxi-

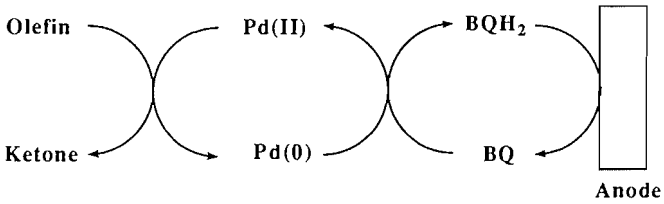

SCHEME 1

dation of cyclohexene and cyclopentene was possible even though no reaction occurred with these substrates in the absence of electrolysis. No explanation of this effect was offered.

In a similar study Horowitz (11) reported electrode-mediated olefin oxidations using $FeCl_3$ as the chemical oxidant. However, it is well known that chloride significantly inhibits the reaction (1, 6). Recent work in our laboratory (12) demonstrated that the homogeneous olefin oxidation was accelerated by as much as a factor of 40 by the addition of acid and the exclusion of chloride. Hence, we expected that improvements in the electrode-mediated oxidation process could be attained by using a completely chloride-free system in which a non-complexing (i.e., strong) acid was added.

In this paper, we have examined the controlled potential electrode-mediated oxidation of terminal, internal, and cyclic olefins, using this acid-enhanced, chloride-free method (12). Benzoquinone (BQ) has been used to reoxidize the Pd(0) (eq. [2]) since hydroquinone (BQH_2), the reduced form of benzoquinone (BQ), is easily oxidized to benzoquinone at the anode (Scheme 1). These data may have an impact on strategies for the large-scale production of cyclohexanone, an important intermediate for the production of caprolactam (one of the Nylon® monomers). In addition, Tsuji and Minato (10) reported that the palladium-catalysed oxidation of cyclic olefins was faster using electrode-mediated catalysis than it was in simple homogeneous reactions. Comparisons in this study of reaction with and without electrolysis will provide some insight into the reasons for those differences.

Results

Oxidations were carried out in solutions of acetonitrile/water (7:1v/v), containing benzoquinone (0.022 M, 20 mol% based on olefin), palladium acetate (0.0011 M, 1 mol% based on olefin), olefin (0.11 M), and perchloric acid (0.015–0.24 M). 1-Decene, styrene, *trans*-2-octene, and cyclohexene were oxidized to their corresponding ketones with current efficiencies consistently in the 75–90% range (Tables 1, 2).

The current efficiency (CE) is a measure of the fraction of the total number of moles of electrons used that result in the formation of the desired product (usually expressed as a percentage). The current efficiencies were calculated using eqs. [6]–[8].

$$[6] \quad CE = \frac{([\text{oxygenates}] - [\text{oxygenates}]_{\text{hom}}) \times 100}{[\text{oxygentates}]_{\text{theor}}}$$

where

$$[7] \quad [\text{oxygenates}]_{\text{theor}} = \frac{Q \times 100}{2FV[\text{olefin}]}$$

$$[8] \quad [\text{oxygenates}]_{\text{hom}} = \frac{[\text{Pd(II)}] + [\text{BQ}]}{[\text{olefin}]}$$

Q is the accumulated charge, V is the volume, and F is the faraday (96 487 coulombs/equiv.). The factor of 2 is necessary since the oxidation is an overall two-electron process (eqs. [1], [2], and [5]). Some of the product will form as a result of the homogeneous reaction (i.e., Pd(II) + benzoquinone) so the yield of product from the electrochemical reaction must be corrected for this contribution (eq. [8]).

High current efficiencies were obtained in electrode-mediated oxidations of 1-decene (Table 1, entries 1–3). Although the current efficiencies were about the same, the oxidation of 1-decene to 2-decanone was about ten times slower when $Cu(OAc)_2$ was the chemical oxidant compared to BQ (Table 1, entry 3). The homogeneous Wacker oxidations using a stoichiometric amount of $Cu(OAc)_2$ also were significantly slower than the oxidations using BQ.

Comparison of 1-decene oxidations in 0.015 M $HClO_4$ (Table 1, entry 1) and 0.12 M $HClO_4$ (Table 1, entry 2) confirmed, as was found for the homogeneous reaction (12), that the reaction rate increased as the concentration of perchloric acid increased. Once a steady state has been achieved the measured current is proportional to the overall rate. An average current of 220 mA was established during the reaction with the low $HClO_4$ concentration, whereas an average current of 415 mA was attained in the oxidation containing 0.12 M $HClO_4$. This rate enhancement of a factor of ca. 2 is less than that found in the homogeneous reaction using a stoichiometric amount of BQ (about a factor of 5) (12).

Data for the oxidation of styrene are shown in Table 1, entries 4–6. A decline in current efficiency from 83% at 700 C to 62% at 1400 C was observed, indicating that the conversion of the styrene had reached a maximum at ca. 60% (ca. 1000 C). After this point, continued electrolysis only served to decrease the current efficiency. The maximum conversion for the homogeneous reaction performed under the same conditions (12) was only 66%, demonstrating that the electrode-mediated oxidation is subject to limitations imposed upon it by the homogeneous reaction in this case.

trans-2-Octene was smoothly oxidized to a mixture of 4-, 3-, and 2-octanones (Table 1, entries 7–10). A small decrease in current efficiency (from 89 to 80%) was observed when the benzoquinone concentration was halved from 20 mol% (Table 1, entry 8) to 10 mol% (Table 1, entry 7); however, the average current remained relatively constant (ca. 190 mA). It is possible to use benzoquinone at concentrations even less than 10 mol% and still maintain high current efficiencies in electrode-mediated oxidations (this would ultimately simplify the isolation and purification of the products).

Rate enhancements with the addition of perchloric acid also were obtained in the *trans*-2-octene oxidations (Table 1, entries 8, 9). As was the case with 1-decene, the reaction was accelerated by about a factor of 2 when the concentration of acid was increased from 0.015 M to 0.12 M. The choice of electrolyte also influenced the rate. Comparison of *trans*-2-octene oxidations using 0.1 M tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte (Table 1, entry 9) with that using 0.1 M sodium perchlorate (Table 1, entry 10) indicated that high current efficiencies could be

attained using either electrolyte. However, the reaction rate (i.e., average current) was significantly lower when $NaClO_4$ was used; 440 mA in the reaction with 0.1 M TBAP as the supporting electrolyte, versus 245 mA was observed in the reaction with 0.1 M $NaClO_4$ (the latter has a higher solution resistance).

Electrode-mediated oxidations of cyclohexene also were investigated (Table 2). In general, the yields and current efficiencies were very good. Again, it was found that the rates (i.e., average currents) but not the current efficiencies depended on the concentration of perchloric acid. It is interesting to note that the oxidation of cyclohexene using $Cu(OAc)_2$ in the electrochemical experiment was unsuccessful. In addition, the twofold increase in the rate of the electrochemically mediated cyclohexene oxidations over the concentration range of perchloric acid was less than that found for the homogeneous reaction (12) using $Pd(OAc)_2$, $Pd(NO_2)_2$, or $PdSO_4$ (ca. a factor of 5).

Discussion

The unique ability of BQ to oxidize Pd(0) to Pd(II), compared to other chemical oxidants such as Cu(II) or MnO_2, also was observed for the catalyzed acetoxylation of olefins by Bäckvall *et al.* (14, 15). In that work the experimental evidence suggested that BQ was actually coordinated to the Pd(II). In addition, Hiramatsu et al. (16) prepared and characterized stable Pd(0)/quinone complexes in solution. In that study it was found that the oxidation potential of the Pd(0) depended on the electron demand of the quinone. It is likely that the regeneration of Pd(II) proceeds via an efficient inner-sphere electron transfer mechanism that is promoted by protonation of a Pd(0)/BQ complex. This explanation also is consistent with the acid catalysis that we have observed.

While the effect of acid concentration on the average rates is similar for the homogeneous and the electrode-mediated reactions, it is not identical. The average currents for the oxidation of 1-decene and *trans*-2-octene as a function of acid concentration were found to be about the same, reaching a plateau near 0.1 M (Fig. 1). The maximum current (ca. 420 mA) represents an average turnover rate of 0.025 s^{-1} (i.e., moles of ketone per mole of catalyst per second). For cyclohexene, the average currents were slightly smaller than those for 1-decene or *trans*-2-octene. In this case, the maximum current represents a turnover rate of 0.020 s^{-1}. The effect of acid concentration on the rates of oxidation of 1-decene and cyclohexene under the same conditions using a stoichimetric amount of BQ are shown in Fig. 2. For these reactions, the maximum average turnover rates (at 0.12 M $HClO_4$) for the oxidation of 1-decene and cyclohexene are 0.14 and 0.055 s^{-1} respectively.

Some comment on the nature of the acid catalysis is jus-

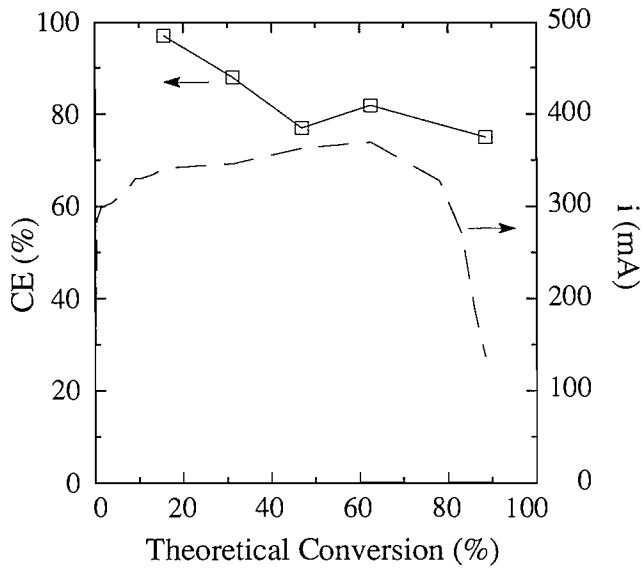

FIG. 3. Current (——) and current efficiency (□) as a function of the theoretical electrochemical conversion for the electrode-mediated oxidation of 1-decene in acetonitrile/water (7:1, v/v) with 1 mol% $Pd(OAc)_2$, 20 mol% benzoquinone at 0.9 V vs. SCE at 25°C.

tified. The Wacker oxidation is catalyzed by low concentration of acid. However, at higher concentrations some inhibition of the rate is evident (Fig. 2). We have suggested that the increased rate of ligand exchange is at least partly responsible for the acid catalysis (12). The rate of ligand exchange is acid catalysed at low acid concentration but approaches a limiting value at high acid concentration (17). Alternatively, the acceleration by low concentrations of acid may be a result of protonation of the ligand, which would increase the electrophilicity of the Pd(II) and increase its reactivity towards the olefin (18–20). The inhibition at high acid concentration can be understood from the simplified mechanism outlined in Scheme 2. In this scheme there are two reactions that result in the loss of a proton. At low acid concentration, the increased ligand exchange rate and the acid-catalysed decomposition of the Pd(0)/BQ complex are expected to control the overall kinetics. At higher concentrations, inhibition of reactions 2 and 4 in Scheme 2 become kinetically important, so the observed rates decrease.

It is clear that the oxidations are faster in the stoichiometric reactions by a factor of about six for 1-decene and about three for cyclohexene (the maximum currents for all three olefins at the highest acid concentration are about the same within the experimental uncertainty). The only obvious difference between the reactions (besides the electrode) is the concentration of BQ; 0.2 equivalents in the electrochemical reactions and 1.0 equivalent in the homo-

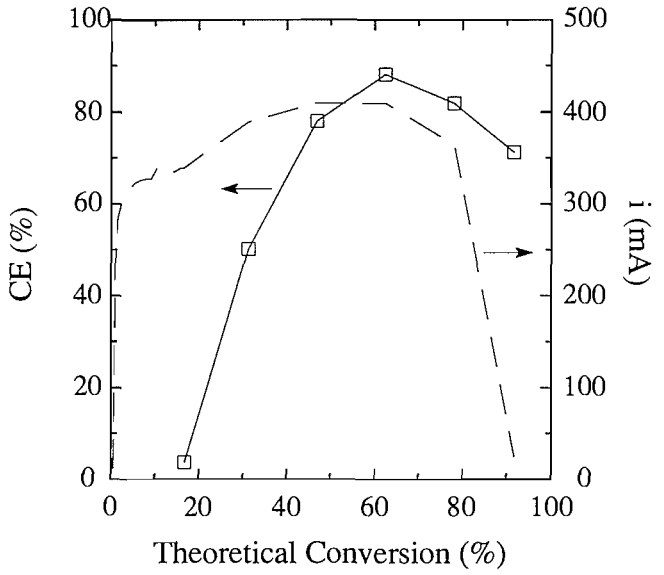

FIG. 4. Current (——) and current efficiency (□) as a function of the theoretical electrochemical conversion for the electrode-mediated oxidation of *trans*-2-octene in acetonitrile/water (7:1, v/v) with 1 mol% $Pd(OAc)_2$, 20 mol% benzoquinone at 0.9 V vs. SCE at 25°C.

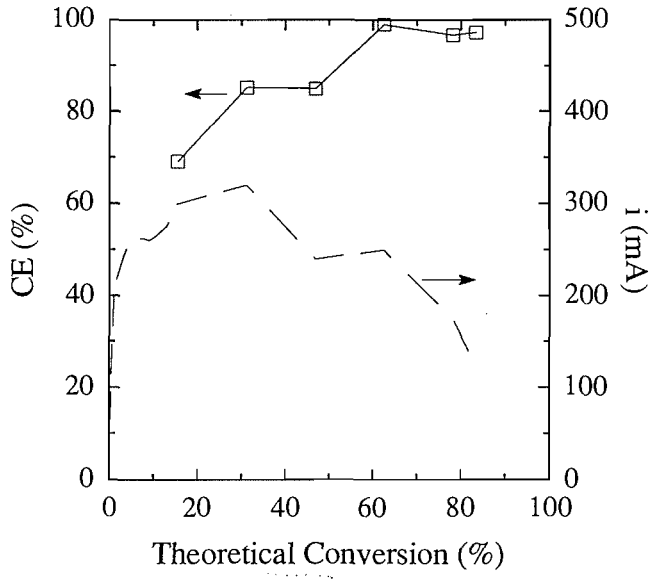

FIG. 5. Current (——) and current efficiency (□) as a function of the theoretical electrochemical conversion for the electrode-mediated oxidation of cyclohexene in acetonitrile/water (7:1, v/v) with 1 mol% $Pd(OAc)_2$, 20 mol% benzoquinone at 0.9 V vs. SCE at 25°C.

geneous reactions. It is tempting to attribute the difference in rates to the difference in concentration of BQ. However, this cannot be the case since the average current using only 0.1 equivalents of BQ (Table 1, entry 7) was the same as that using 0.2 equivalents (Table 1, entry 8). In this case, the evidence suggests that the reactions are limited by the rate of the electrochemical regeneration of BQ from BQH_2 (Scheme 1). This is clearly seen in Fig. 3–5 in which the cell current and current efficiencies for the oxidation of 1-decene, *trans*-2-octene, and cyclohexene have been plotted as a function of the theoretical electrochemical conversion. In general, a relatively constant plateau current was quickly established. A decrease in current only was observed near the end of the reaction when all of the olefin had been consumed (after about 80% of the olefin is consumed). At this point, the reaction can be restarted simply by adding more substrate. These figures also demonstrate the advantage of controlled potential electrolysis (as opposed to controlled current) since the reaction simply turns itself off when the substrate is depleted.

For *trans*-2-octene and cyclohexene induction periods for product formation were observed even though the currents had reached the limiting values (Figs. 4, 5). These induction periods are consistent with the work reported by Smidt *et al.* (1, 20) who demonstrated that the uptake of internal and branched olefins by Pd(II) salts is significantly slower than that of terminal olefins.

The use of potentiostatic (controlled potential) conditions is primarily responsible for the consistently high current efficiencies observed in the electro-oxidations. Under controlled potential conditions, the electrochemical oxidation is much more selective towards BQH_2; i.e., the current is determined by the concentration of BQH_2 only. Preliminary experiments performed under galvanostatic conditions were much less efficient, with current efficiencies <30%. Tsuji and Minato (10) also carried out controlled current oxidations and obtained current efficiencies only on the order of 50–60%. Under galvanostatic conditions, reasonable current efficiencies can only be attained when the rate of olefin oxidation (homogeneous) and the rate of the electrochemical regeneration of BQ (heterogeneous) are comparable. If the homogeneous reaction is too fast then the steady state concentration of BQ will be too low to prevent Pd(0) from precipitating. On the other hand, if the current is too high then the homogeneous oxidation rate is rate limiting and undesirable side reactions that sustain the high current result in a lowering of the overall current efficiency.

Tsuji and Minato (10) noted that cyclohexene and cyclopentene were oxidized readily under the electro-oxidation conditions (cyclohexanone yield 75%, current efficiency 59%; cyclopentanone yield 83%, current efficiency 53%), but almost no reaction occurred when a stoichiometric quantity of benzoquinone was added in lieu of electrochemical regeneration of benzoquinone. In contrast, we have found that the homogeneous reactions are actually faster than the electrochemically mediated reactions (*vide supra*). The discrepancy between the two sets of data is now easily explained. In the homogeneous oxidations carried out by Tsuji a suitable acid was not added. It is likely that under the galvanostatic conditions used in that work, the primary (perhaps the only) reaction at the initial stages of the reaction was the electrolysis of water, thus generating acid, since the Wacker oxidation is known to be slow. This electro-generated acid would then promote the homogeneous reaction and, consequently, appear to drive the reaction that was sluggish in the absence of electrolysis.

These data may have important implications in the large-scale synthesis of cyclohexanone, an important intermediate in the commercial caprolactam process (the monomer of Nylon 6®, Scheme 3). Virtually all industrial approaches to caprolactam go through cyclohexanone as an intermediate.

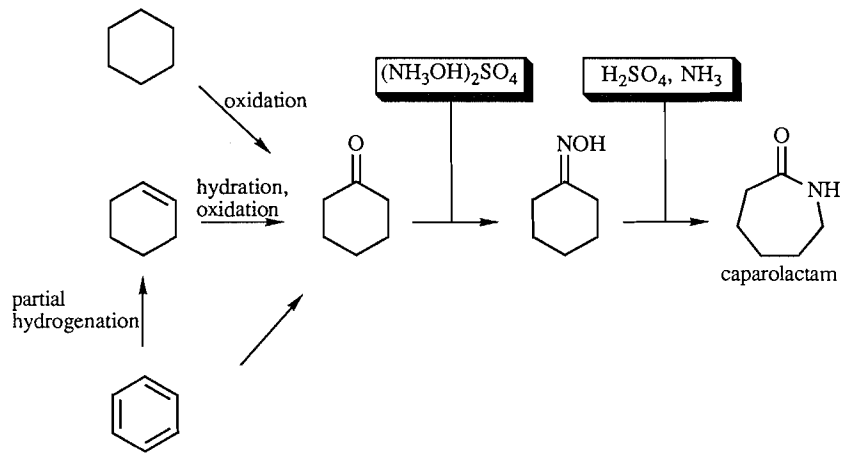

SCHEME 3

Most oxidation routes require high temperatures and pressures and generally give poor yields (21). The data presented in this work show, for the first time, that the oxidation of cyclohexene to cyclohexanone can occur at room temperature at commercially viable rates. Electrode-mediated catalysis is an attractive alternative if the high current efficiencies can be maintained in a scaled-up reactor. In addition, the catalytic amounts of quinone and Pd(II) would simplify the isolation and purification of products.

Experimental

All solutions were of spectroscopic quality. Olefins and palladium catalysts were commercially available (Aldrich) and were used as received. Tetrabutylammonium perchlorate (TBAP, Eastman) was recrystallized twice from ethylacetate/hexanes (9:1, v/v) and dried for 12 h in a vacuum oven (50°C, 5 Torr; 1 Torr = 133.3 Pa). Benzoquinone was passed through a silica gel column (chloroform as eluant) and recrystallized twice from hexane/ethyl acetate (10:1 v/v). A standard H-cell was used in all electro-oxidations (three-electrode configuration). An aqueous saturated calomel reference electrode was used for potential measurements. The potentiostat was a PAR model 173 equipped with a PAR model 176 digital coulometer. In all experiments both the working electrode and counter electrode were a platinum mesh (6 × 6 cm). All potentials are versus the saturated calomel electrode (SCE).

Olefin electro-oxidations

Palladium(II) acetate (0.1 mmol), benzoquinone (2 mmol), and perchloric acid (0.015–0.36 M) were dissolved in acetonitrite/water (7:1 v/v, 85 mL containing 0.1 M TBAP) in the anode compartment. Benzoquinone (3 mmol) and perchloric acid (0.015–0.36 M) were dissolved in 85 mL of the solvent/electrolyte, in the cathode compartment (the quinone in the cathodic compartment reduces the evolution of gases at the cathode). The electrochemical cell was deoxygenated by purging with argon for 30 min and stirred vigorously until the $Pd(OAc)_2$ was dissolved. The olefin (10 mmol) was added to the anode compartment (by syringe) and a potential of 0.9 V vs. SCE was applied until 1000 C had accumulated. After the reaction the contents of the anode compartment were removed (by pipette). Products were separated from the catalyst by extraction into diethyl ether, washed, and then analyzed by a capillary GC–internal standard method. *n*-Decane was the internal standard in the cylohexene reactions and *n*-tridecane was used in the internal standard in all other reactions.

Current efficiency versus theoretical conversion

The reactions were carried out as above, except that 2.0-mL samples were withdrawn (by syringe) periodically and were analyzed by the method described above. The reactions proceeded until the current decreased to a negligible value, after approximately 1700–1800 C had been accumulated.

Rearrangements in the acid-catalyzed formation of lactones from 2-hydroxynorbornane-2-acetic acid derivatives and related compounds

PETER YATES[1] AND MAGDY KALDAS
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received February 20, 1992

PETER YATES and MAGDY KALDAS. Can. J. Chem. **70**, 2491 (1992).

A mixture of the epimeric ethyl 2-hydroxynorbornane-2-acetates (**1**) on treatment with concentrated sulfuric acid is converted in turn to the lactones of *exo*-2-hydroxynorbornane-1-acetic acid (**4**), *endo*-6-hydroxynorbornane-*endo*-2-acetic acid (**5**), and *exo*-3-hydroxynorbornane-*exo*-2-acetic acid (**6**). With trifluoroacetic acid or 50% sulfuric acid, **1** gives **4**, but this does not react further. In concentrated sulfuric acid the parent acids of **1** (**7**) and (*E*)- and (*Z*)-(norborn-2-ylidene)acetic acids (**8** and **9**) and their ethyl esters (**10** and **11**) give **6** as the infinity product. A mixture of 5-norbornene-*endo*- and *exo*-2-acetic acid (**30** and **31**) on treatment with 50% sulfuric acid gives **4**, **5**, **6**, and *exo*-2-hydroxynorbornane-*syn*-7-acetic acid lactone (**33**). Routes are proposed for the formation of the lactones that involve protonation and carbocation formation followed by rearrangement via Wagner–Meerwein, *endo*-6,2-hydride, and *exo*-3,2-hydride shifts in decreasing order of preference. It is postulated that the usual inhibition of the rearrangement of tertiary to secondary norbornyl carbocations is not operative when the third substituent is a carboxymethyl group or its derivatives because of the electron-withdrawing properties of such groups relative to simple alkyl groups. A preliminary study has shown that *exo*-5-acetyloxy-*endo*-2-hydroxynorbornane-*exo*-2-acetic acid (**35**) with 50% sulfuric acid gives four products that are considered to be the γ-lactones of *endo*-5-acetyloxy- and *endo*-5-hydroxynorbornane-1-acetic acid (**38** and **39**) and *exo*-2-acetyloxy-1-hydroxy- and 1,2-dihydroxynorbornane-*syn*-7-acetic acid (**40** and **41**). Protonation of either the hydroxyl or acetyloxyl group is postulated, giving two carbocations that undergo rearrangements as in the case of **1**, together with 3,2-hydroxyl shifts. The structures of the lactones are assigned on the basis of spectroscopy, reactivity, and analogy. The reactions of the lactones, which lead to a variety of hydroxy- and oxonorbornaneacetic acids, illustrate their synthetic potential.

PETER YATES et MAGDY KALDAS. Can. J. Chem. **70**, 2491 (1992).

Un mélange d'épimères de 2-hydoxynorbornane-2-acétates d'éthyle (**1**) traité par de l'acide sulfurique concentré conduit aux lactones des acides *exo*-2-hydroxynorbornane-1-acétique (**4**), *endo*-6-hydroxynorbornane-*endo*-2-acétique (**5**) et *exo*-3-hydroxynorbornane-*exo*-2-acétique (**6**). Par traitement avec de l'acide trifluorbacetique ou de l'acide sulfurique à 50%, le composé **1** conduit au composé **4**, mais la réaction ne va pas plus loin. En milieu acide sulfurique concentré, les acides parents du composé **1**, soit les composés (**7**), les acides (*E*)- et (*Z*)-(norborn-2-ylidène) acétiques (**8** et **9**) ainsi que leurs esters éthyliques (**10** et **11**) ne conduisent qu'au composé **6** comme produit obtenu après un temps infini. Un mélange des acides 5-norbornène-*endo*- et *exo*-2-acétique (**30** et **31**) traité par de l'acide sulfurique à 50% permet d'obtenir les composés **4**, **5**, **6** ainsi que la lactone de l'acide *exo*-2-hydroxynorbornane-*syn*-7-acétique (**33**). On propose une voie d'accès à cette lactone qui implique une protonation et la formation d'un carbocation suivie d'une transposition de Wagner–Meerwein, des déplacements d'hydrures *endo*-6,2 et *exo*-3,2 dans cet ordre décroissant d'importance. On suggère que, en raison de leurs propriétés électroattractives relatives à celles des groupes alkyles simples, l'inhibition habituelle de la transposition des carbocations norbornyles tertiaire et secondaire disparait lorsque le troisième substituant est un groupe carboxyméthyle ou un de ses dérivés. Une étude préliminaire indique que, sous l'influence de l'acide sulfurique à 50%, l'acide *exo*-5-acétyloxy-*endo*-2-hydroxynorbornane-*exo*-2-acetique (**35**) conduit à quatre produits que l'on considère être les γ-lactones des acides *endo*-5-acétyloxy- et *endo*-5-hydroxynorbornane-1-acétique (**38** et **39**) et des acides *exo*-2-acétyloxy-1-hydroxy- et 1,2-dihydroxynorbornane-*syn*-7-acétique (**40** et **41**). On suggère que les protonations soit du groupe hydroxyle soit du groupe acétyloxyle conduisent à deux carbocations qui se transposent tous les deux, comme dans le cas du composé **1**, par le biais de déplacements 3,2 d'hydroxyle. On a établi les structures de ces lactones sur la base d'analogies des études spectroscopiques et d'études de réactivité. Les réactions des lactones, qui conduisent à divers acides hydroxy- et oxonorbornaneacétiques, illustrent leur potentiel en synthèse.

[Traduit par la rédaction]

The structures and rearrangements of 2-norbornyl cations have been the subjects of countless investigations during the past 50 years (1, 2). Many questions have been answered and these species are no longer the cynosures they were. However, the study of their chemistry still provides results of synthetic and mechanistic interest. We describe here one such study, which followed up observations we had made during the course of our synthetic work on norbornanes with functionalized carbon substituents at a bridgehead (3).

Reaction of 2-hydroxynorbornane-2-acetic acid derivatives with acids

In our earlier work we found that the epimeric mixture of ethyl 2-hydroxynorbornane-2-acetates (**1**), formed by the Reformatsky reaction of 2-norbornanone with ethyl bromoacetate (4),[2] gives on treatment with 32% hydrogen bromide in acetic acid at room temperature a mixture of the rearrangement product *exo*-2-bromonorbornane-1-acetic acid (**2**) and its ethyl ester **3** (3).[3] We have subsequently found that with 48% hydrobromic acid at room temperature **1** gives solely the lactone of *exo*-2-hydroxynorbornane-1-acetic acid

[1]Author to whom correspondence may be addressed.

[2]Lauria *et al.* (4) report that a single diastereomer is formed; however, their product may have undergone fractionation during purification since they hydrolyzed the crude ester, crystallized the resulting acid, and then re-esterified.

[3]All compounds prepared in our present and previous studies in this area are racemic, but are structurally represented as single enantiomers.

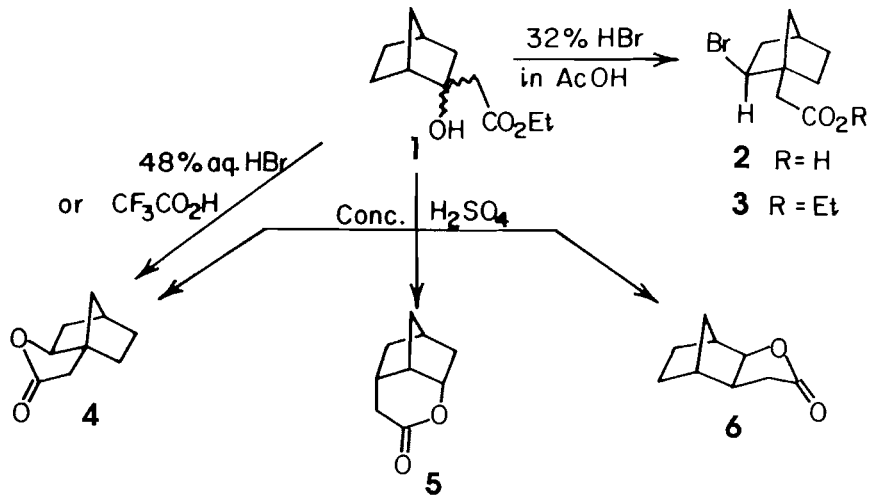
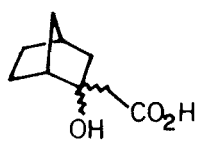
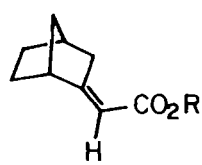


SCHEME 1

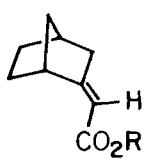
(**4**), as it does with trifluoroacetic acid (Scheme 1). Treatment of **1** with concentrated sulfuric acid at room temperature gives **4** and two isomeric lactones, **5** and **6**, derived from *endo*-6-hydroxynorbornane-*endo*-2-acetic and **exo**-3-hydroxynorbornane-*exo*-2-acetic acid, respectively, whose relative yields are time dependent (Table 1). Lactone **4** is formed first and is converted to lactones **5** and **6**; on longer standing **5** is converted to **6**, the infinity product. In accord with this, treatment of lactone **4** with concentrated sulfuric acid gives a mixture of **5** and **6**; after 10 min their ratio is 5:3 and after an extended reaction time **6** is the sole product. Treatment with weaker acids, e.g., 50% sulfuric acid returns **4** unchanged. We have also found that treatment of acids **7–9**[4] and esters **10** and **11** with concentrated sulfuric acid ultimately gives lactone **6**.



7



8 R = H
10 R = Et



9 R = H
11 R = Et

It is clear that **1** and compounds **7–11** all react in acids via a common carbocationic intermediate of type **12** (Scheme 2).[5] Simple secondary 2-norbornyl cations are well known to undergo rearrangement via three different pathways, which are, in order of decreasing preference: (*i*) Wagner–Meerwein shifts, (*ii*) *endo*-6,2 hydride shifts, and (*iii*) *exo*-3,2-hydride shifts (1, 2). In general these involve the conversion of a secondary cation to another secondary cation or to a tertiary cation. In the case of simple tertiary 2-norbornyl cations, such as the 2-methyl-2-norbornyl cation, rearrangement is disfavored because it would entail the conversion of a tertiary to a secondary cation (1). The case of the tertiary 2-norbornyl cation **12** is exceptional, however, since the presence of the carboxymethyl substituent, CH_2CO_2H, or its equivalent, at C-2 may be expected to destabilize the ion relative to the methyl-substituted ion owing to the electron-withdrawing inductive effect of such substituents (6). Thus the reversible rearrangement of the tertiary cation can be accounted for and the pathways for the formation of the lactones **4**, **5**, and **6** from **12** shown in Scheme 2[6] can be proposed.

The cation **12** is postulated first to undergo reversible

TABLE 1. Relative yields of lactones **4–6** from the reaction of **1** with concentrated sulfuric acid

Reaction time	Relative yield (%)		
	4	**5**	**6**
6 min	25	50	25
30 min	5	52	43
1 h	Trace	55	45
2 h	0	41	59
10 h	0	0	100

[4]Vaughan *et al.* (5) have reported that **8** (or **9**) is converted to lactone **4** by treatment with trifluoroacetic acid at room temperature.

[5]It is highly probable that both the secondary and tertiary norbornyl cations invoked in this work are at least partially bridged (1). However, the work of itself makes no contribution to the nonclassical – classical ion controversy, and we choose to represent the intermediates as classical ions to facilitate visualization of the rearrangements involved.

[6]WM, 6,2, and 3,2 represent Wagner–Meerwein, *endo*-6,2-hydride, and *exo*-3,2-hydride shifts, respectively.

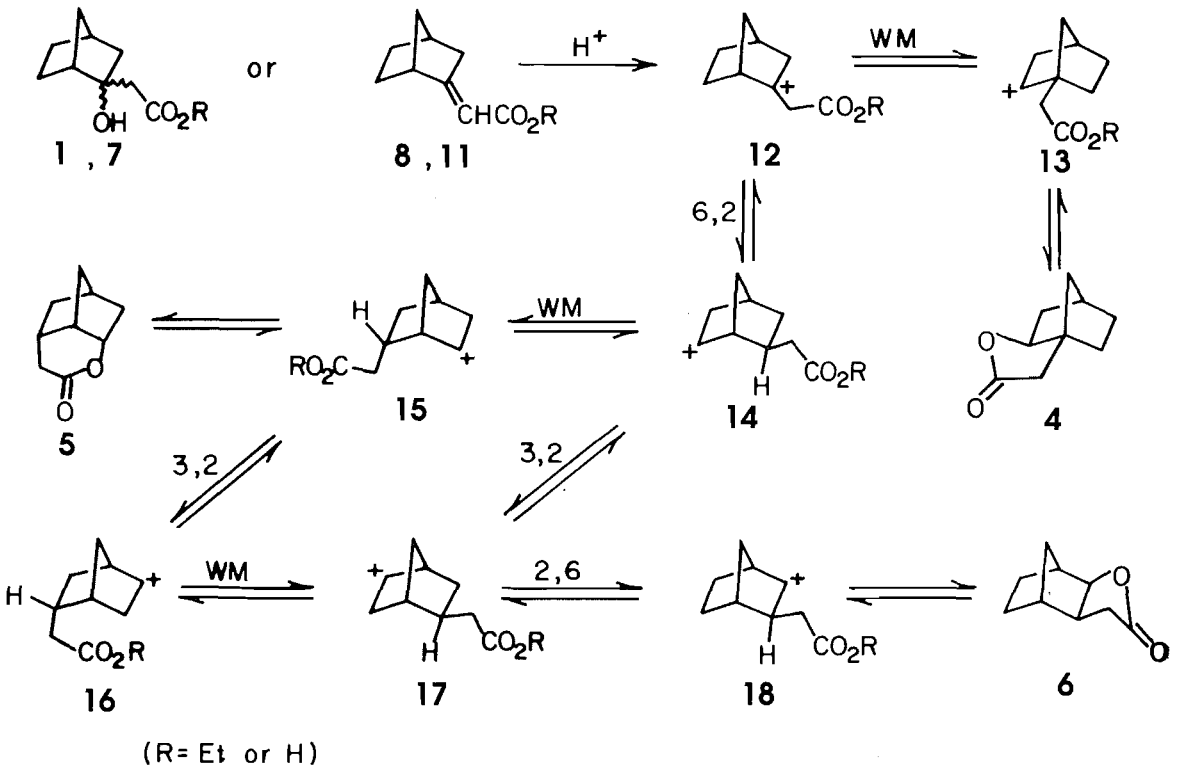
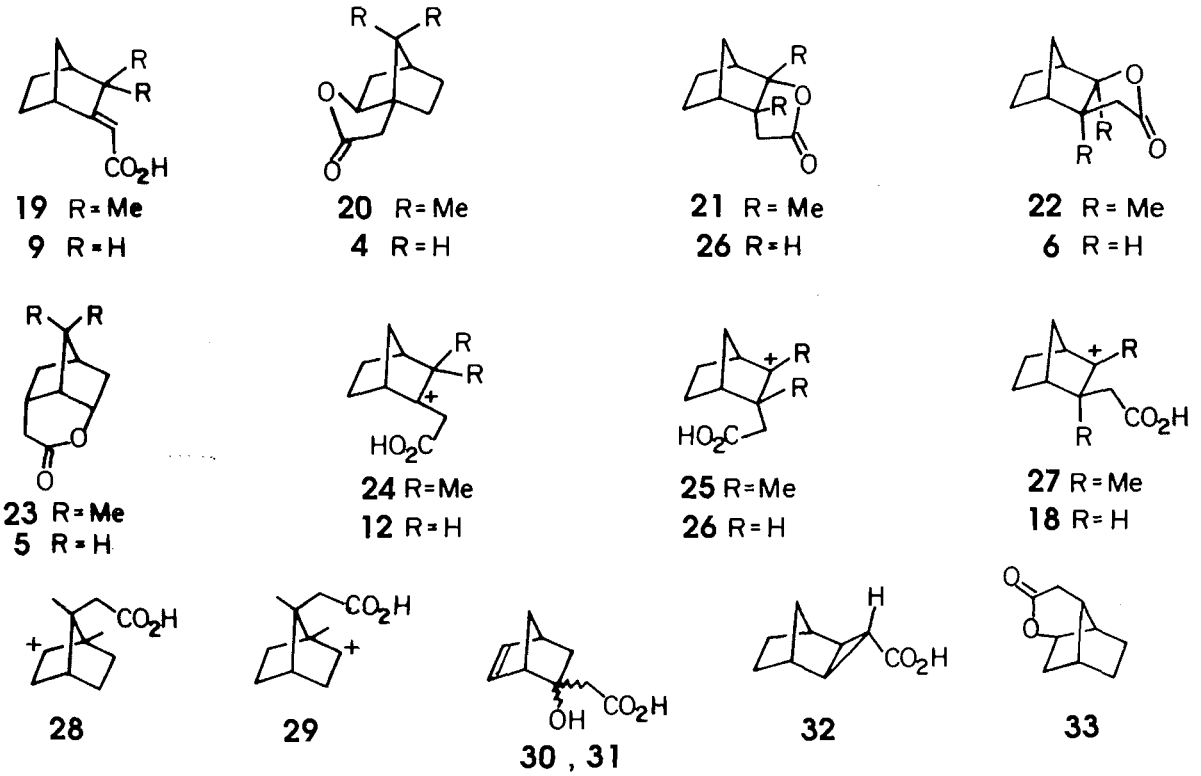


SCHEME 2



Wagner–Meerwein rearrangement to the cation **13** and lactone closure to **4** (in the cases where R = Et, the question of the timing of the loss of the ethyl group remains moot). The cation **12** is considered to undergo a slower, *endo*-6,2-hydride shift giving the cation **14**, followed by a Wagner–Meerwein shift to give the cation **15**, which closes to the lactone **5**; all of these steps are considered to be reversible. Finally, it is proposed that **15** and **14** undergo yet slower,

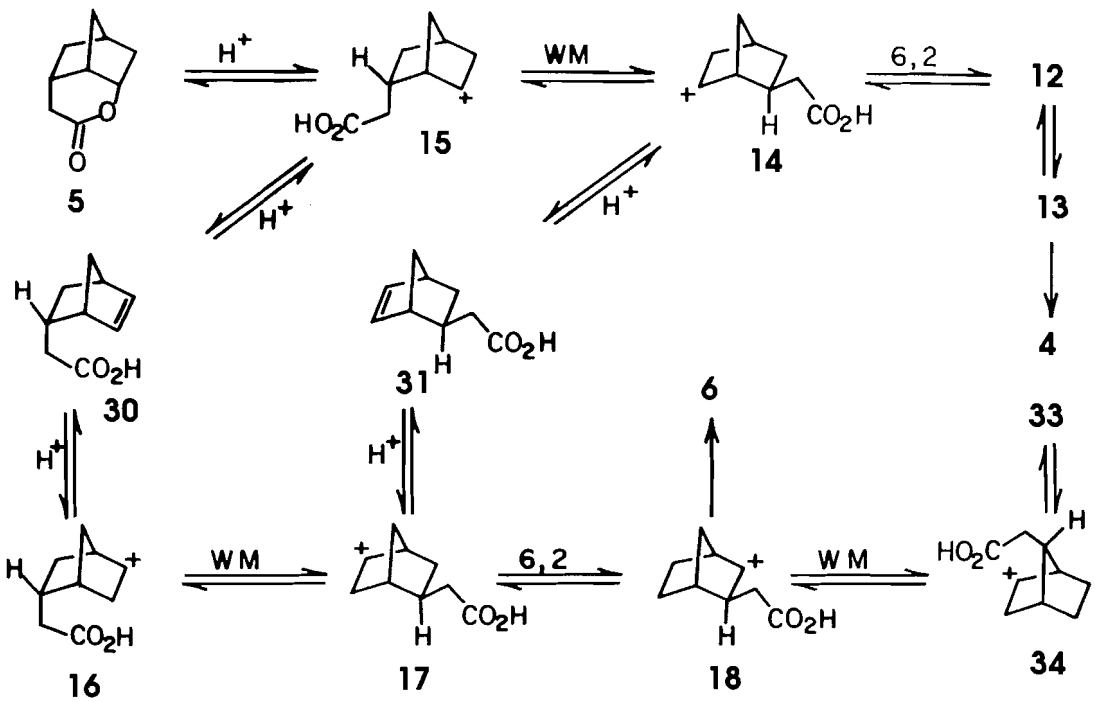

SCHEME 3

reversible, *exo*-3,2-hydride shifts to give **16** and **17**, respectively, which are interconvertible by Wagner–Meerwein shifts, and that **17** undergoes an *endo*-6,2-hydride shift to form the cation **18**, which closes to lactone **6**. The formation of **6** as the infinity product is attributed either to irreversible lactonization or to its being greatly favored at equilibrium. This interpretation may be oversimplified and additional pathways may well be involved (*vide infra*). However, it appears to us to be the most plausible one based on our postulates that rearrangement of tertiary cations of type **12** to secondary cations can occur, and that the commonly observed order of preference among the three types of shift is followed.

Vaughan and Wolinsky *et al.* (7) earlier examined the products formed by (*E*)-camphene-8-carboxylic acid (**19**), an analogue of **9**, under a variety of acid conditions. They found that lactone **20**, an analogue of **4**, is formed initially and that this can be converted in turn to lactone **21** and lactone **22**, the analogue of lactone **6**. In strong acids **22**, like **6**, is the infinity product. Their results differ from our own in the non-methyl series in the observation of the formation of the endo lactone **21** and the failure to observe the δ-lactone **23**, analogous to the δ-lactone **5**. The first difference can be accounted for in terms of an *exo*-3,2-methyl shift (Nametkin rearrangement (8)) in **24** leading to the formation of the stabilized, tertiary carbocation **25**; the formation of the corresponding series would require an *exo*-3,2-hydride shift in **12** to give the secondary carbocation **26**, a less energetically favored process. The second difference may be associated with the general circumstance that in multireaction manifolds the relative rates of the reactions are dependent on the nature of the substrate and that in a particular case an intermediate may be present in such low concentration that it fails to undergo detection. The same consideration can be invoked as a supplementary or alternative explanation of the failure to observe the formation of **23** from **12**. A further point of interest arises from this report (7). It concerns the origin of **22**, for which the authors propose ring closure of **27**, which arises from **25** by a Wagner–Meerwein shift to **28**, followed by an *endo*-6,2-hydride shift to **29** and another Wagner–Meerwein rearrangement to **27**. They note that the simplest pathway for the formation of **27** would be an *endo*-3,2-methyl shift in **24**, but disfavor this route because of the absence of established precedent for an *endo*-Nametkin rearrangement. However, there are difficulties with the lengthier route proposed, since the conversion of **25** to **28** involves an unfavorable Wagner–Meerwein rearrangement of a stabilized tertiary to a secondary carbocation (*vide supra*), and Haseltine and Sorensen (9) later reported that the *endo*-3,2-methyl shift occurs in related systems, albeit much more slowly than the corresponding *exo* shift. Thus the possibility of the formation of **27** by an *endo*-Nametkin rearrangement remains.

Reaction of 5-norbornene-2-acetic acids with acids

Sauers and Sonnet (10) were the first to examine the reaction of a mixture of racemic 5-norbornene-*endo*- and *exo*-2-acetic acids (**30** and **31**) with acids; in 75% sulfuric acid at 0°C for 22 h it gave the lactone **6** as the major product together with a second, unidentified lactone. They obtained the same major product from treatment of the isomeric tricyclic acid **32** with concentrated sulfuric acid for 18 days, accompanied by two other, unidentified lactones. Davies and Dowle (11) later investigated in greater detail the reaction of **30** and **31** with acids. They reported that in 50% sulfuric acid the *endo* isomer **30** or a mixture of this and the *exo* isomer **31** gave lactone **6** and the δ-lactone **33**; they did not observe the formation of lactones **4** and **5** and proposed a mechanistic scheme that took this into account. Since their results differed from ours with **1**, albeit in concentrated sulfuric acid,

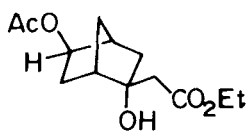
For personal use only.

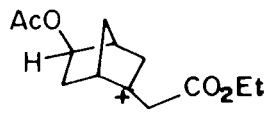
we have repeated the reaction of a mixture of **30** and **31** with 50% sulfuric acid, and now find that in addition to lactones **6** and **33**, lactones **4** and **5** are also formed under these conditions. Proposed routes for the formation of the various lactones are given in Scheme 3, which corresponds with Scheme 2, but differs in (*i*) the point of entry to the reaction manifold, (*ii*) the inclusion of lactone **33**, and (*iii*) the irreversible formation of lactone **4**, which we have shown does not react in 50% sulfuric acid. Our failure to observe the formation of **33** from **1** could again be attributable to the fact that it is present in such low concentration under the conditions we used as to be unobservable (cf. the δ-lactone **5**, above). The limiting case would be irreversible formation of lactone **6** from the carbocation **18** in concentrated sulfuric acid, but not in 50% sulfuric acid, inhibiting the conversion of **18** to **33** via **34**.

Reaction of exo-5-acetyloxy-2-hydroxynorbornane-2-acetic acids with acid

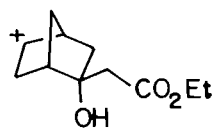
We discussed above lactone formation from 2-hydroxynorbornane-2-acetic acids via the carbocation **12**. We also carried out a preliminary investigation of lactone formation from *exo*-5-acetyloxy-2-hydroxynorbornane-2-acetic acids (**35**), which may be expected to give products via carbocation **36** that are analogous to those formed via **12**, and via carbocation **37**. In addition to a synthetic role (cf. ref. 3), the acetyloxyl group in **35** can serve as a marker and aid in mechanistic interpretations. Furthermore, the stereochemistry at the carbon atom bearing the acetyloxyl group in the products can provide information since a Wagner–Meerwein rearrangement of **35** will result in inversion in the relative configuration at this carbon (**35**–**37**, Scheme 4).



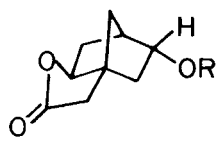
35



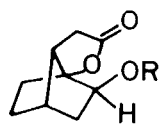
36



37



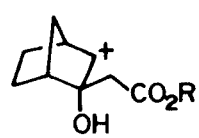
38 R = Ac
39 R = H



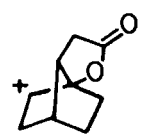
40 R = Ac
41 R = H

In the event, treatment of **35** with 50% sulfuric acid gave a mixture of four lactones. Two, the acetyloxy lactone **38** and hydroxy lactone **39**, had been obtained by us previously by a different route (3). The other two products are considered to be **40** and **41**, although the former was isolated only in admixture with **38**. We propose (Scheme 4) that lactone **38** is formed via **36** and **42** by a route analogous to that postulated for the formation of **4**, giving the *endo* acetyloxy lactone because of the involvement of a Wagner–Meerwein rearrangement in the formation of **42** (*vide supra*). Hydrolysis of **38** would lead to the hydroxy lactone **39**.

The other products from **35** are considered to arise via protonation of the acetyloxyl group and loss of acetic acid to give **37**,[7] which undergoes Wagner–Meerwein rearrangement to the carbocation **43**, which in turn undergoes an *endo*-6,2-hydride shift to give the cation **44**. An *exo*-3,2-hydroxyl shift to cation **45**, perhaps via a protonated epoxide, followed by an *endo*-3,2-hydride shift would then lead to the carbocation **46**. The occurrence of such an *endo* shift should be facilitated by electron donation from an unshared electron pair on the oxygen atom of the hydroxyl group. Cation **46** can give the protonated lactol **47**, which on loss of water followed by a Wagner–Meerwein rearrangement would give the carbocation **48** and thence the lactones **40** and **41** by *exo* nucleophilic attack (1). A closely related route for their formation could involve an *endo*-6,2-hydride shift in **37** to give the carbocation **49**,[8] and conversion of this by a series of steps analogous to the sequence **44** → **48** to **50**, the enantiomeric form of **48**.



49



50

Structural assignments and synthetic utilization and potential

Here we discuss the assignments of structure to the lactones **4**, **5**, **6**, **33**, **38**, **39**, **40**, and **41**. These were based on infrared and ^{1}H nmr spectroscopy[9] (see experimental sec-

[7]The *exo* acetyloxyl group in **35** is expected to be lost much faster than an *endo* acetyloxyl group (1), accounting for the fact that no products were observed that derived from loss of the *endo* acetyloxyl group in **38** (cf. the slow conversion of ethyl *endo*-3-acetyloxy-*exo*-6-bromo-norbornane-1-acetate to its *exo*-3-acetyloxy epimer by hydrogen bromide in acetic acid (3)).

[8]This would give **44** on Wagner–Meerwein rearrangement.

[9]The ^{13}C nmr spectra, which are also in accord with the assignments, will be discussed elsewhere.

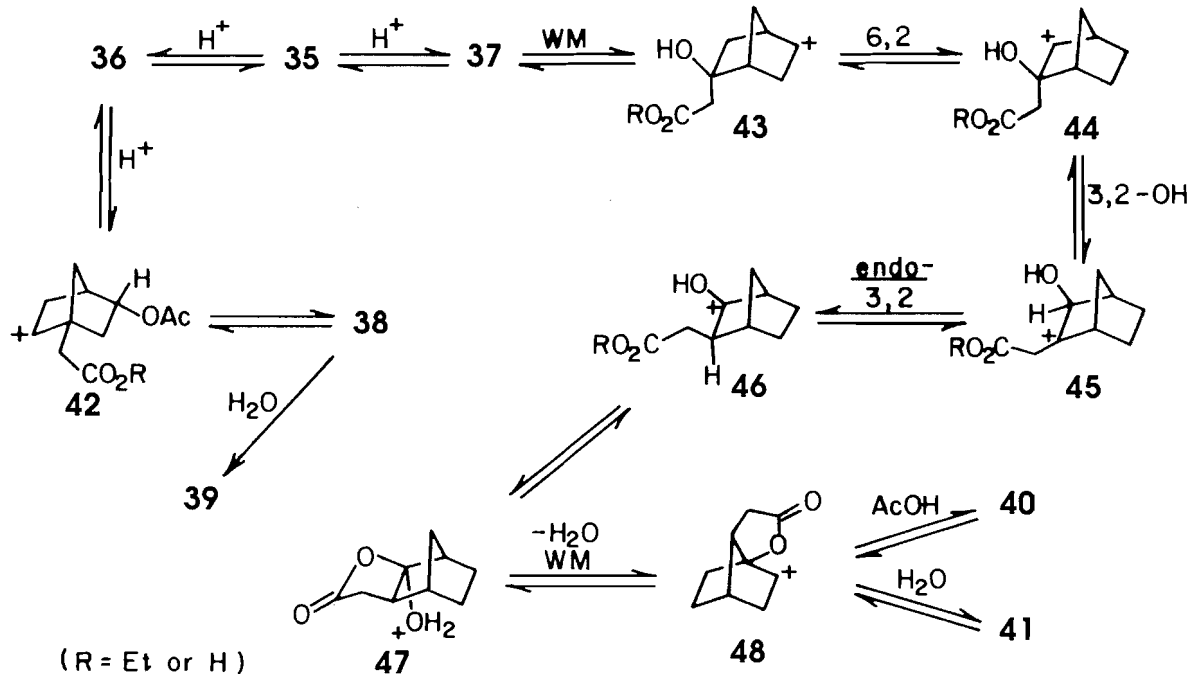
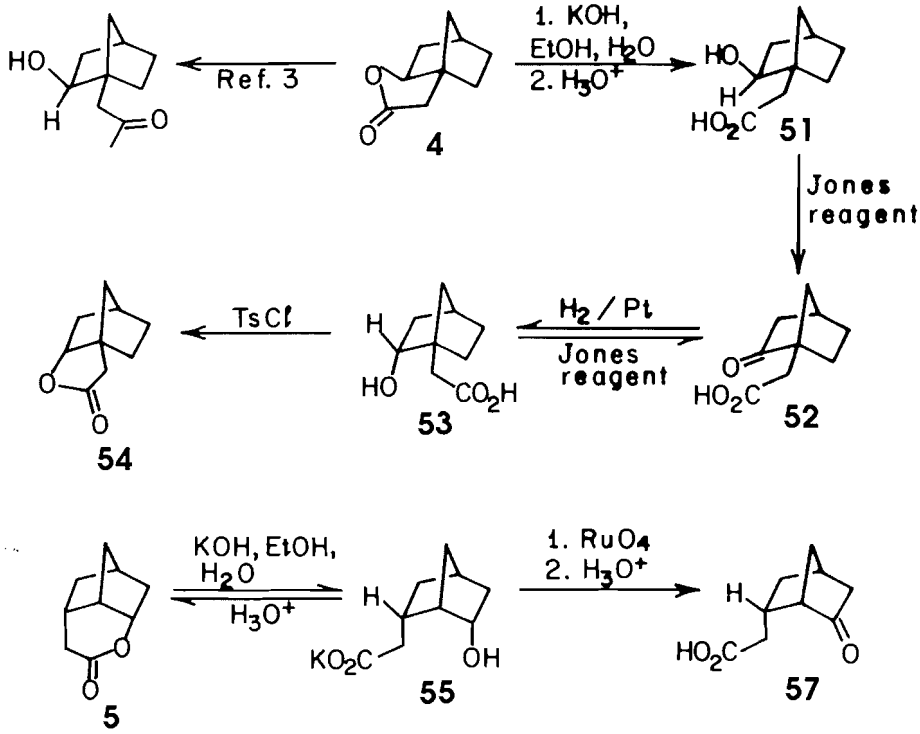


SCHEME 4



tion), on the reactions of the lactones, and on analogy with previous observations (2). The formation of the first four compounds has been reported by others, but in some cases their structures had not been rigorously established at the time much of the presently reported work was done. We refer briefly to some of their reactions here, both to confirm the structural assignments and to illustrate the synthetic potential of the lactones.

The structural assignments for the first six lactones were straightforward and we limit their discussion here to the schematic summary of their reactions below.

The assignments of structures **40** and **41** were less simple and we discuss these in more detail. Although **40** was obtained only as a mixture with **38**, it was possible to analyze its ir and ^{1}H nmr spectra because of the availability of the spectrum of pure **38**. The former showed it to be an acetyl-

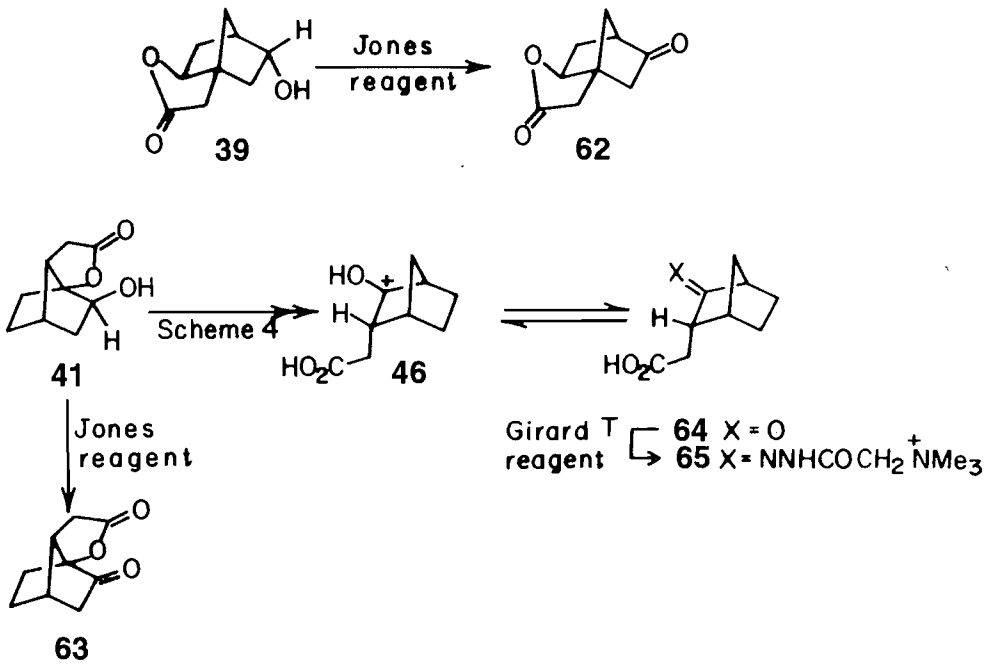
For personal use only.

oxy δ-lactone and the latter indicated that it contained only one proton on a carbon bearing an oxygen atom. Thus it must be either the δ-lactone of a tertiary alcohol and the acetate of a secondary alcohol or the δ-lactone of a secondary alcohol and acetate of a tertiary alcohol. Comparison of its ^{1}H nmr spectrum with that of **41** (*vide infra*) showed that the latter is the acetate of the former. Since **41** on oxidation with Jones reagent gives a keto δ-lactone, its hydroxyl group and the acetyloxyl group of **40** must be secondary. It follows that the lactone groups in **40** and **41** are tertiary. The ir spectrum of the oxidation product from **41** shows that the ketonic group is in a five-membered ring, strongly suggesting that the norbornane system is retained. Consideration of possible formulations in terms of these conclusions and the origin of the compounds leads to the assignment of structures **40** and **41**, with **64** as the structure of the oxidation product of the latter.



Compound **41** was obtained initially in a ca. 50:50 mixture with **39**; however, treatment of the mixture with Girard reagent T in the usual manner (12) resulted in removal of most of **41** from the organic layer and the isolation of a much enriched sample of **39** (85%). Acid hydrolysis of the aqueous layer gave a pure sample of **41**. It was thus possible to analyze the spectra of both **39** and **41**. Girard reagent T is normally used for the removal of aldehydes or ketones; since no such function is present in **41**, it must be generated from **41** under the conditions of the reaction. This is readily explicable in terms of structure **41** and the origin proposed for it in Scheme 4. Cation **46** could well be in equilibrium with a small amount of its parent ketone **65**, which could form the hydrazone **66** irreversibly with Girard reagent T; hydrolysis of this with acid would regenerate **46** and thence **41**.

These several transformations of the lactones illustrate their versatility, both observed and potential, in the synthesis of a variety of norbornane derivatives from 2-hydroxynorbornane-2-acetic acid and 5-norbornene-2-acetic acid derivatives. This potential is enhanced by the fact that the relative yields of the lactones can be controlled by variation of the reaction conditions for their formation.

Insofar as the routes for the formation of the lactones are concerned, definitive answers will require considerable further experimentation. In particular it will be of interest to determine the reactivities of all of the lactones under the several conditions of their formation, to observe the ionic intermediates by nmr spectroscopy, to undertake isotopic labeling studies, and to explore further the effect of CH_2CO_2R and related substituents on the stability of tertiary norbornyl cations relative to secondary and alkyl-substituted tertiary norbornyl cations.

Experimental

Melting points are uncorrected. Unless otherwise indicated infrared (ir) spectra were taken in chloroform solution and proton magnetic resonance (^{1}H nmr) spectra in deuteriochloroform solution. The ir peaks are strong unless otherwise described. Thin-layer chromatographic (tlc) analyses were carried out on Quanta/Gram precoated 20 × 20 cm silica plates (thickness 2 mm), activated for 30 min at 130°C. Organic solutions were dried with anhydrous magnesium sulfate unless otherwise stated.

exo-*2-Hydroxynorbornane-1-acetic acid lactone (4)*

(a) From treatment of 1 with hydrobromic acid

A solution of **1** (3.00 g, 15.00 mmol) in 48% hydrobromic acid (20 mL) was stirred at room temperature for 56 h, and the reaction mixture was extracted with dichloromethane (4 × 30 mL). The combined extracts were washed with aqueous 5% sodium bicarbonate (50 mL) and water (2 × 50 mL), and dried. The solvent was removed to give a yellow oil (2.20 g). This was subjected to molecular distillation (100–102°C/0.05 Torr; 1 Torr = 133.3 Pa) and the distillate was allowed to stand at 5°C for 2 weeks, by which time it had completely solidified. Sublimation gave lactone **4** (2.10 g, 92%) as plates, mp 69–70°C (lit. (5) mp 75–76°C)[10] ir (OCL_4) ν_{max}:

[10]The sample had $[\alpha]_D$ −0.72; it was possibly a single enantiomer (cf. ref. 5).

1773 cm^{-1}; ^1H nmr δ: 1.10–1.93 (m, 8H), 2.34 (m, 1H), 2.60 (s, 2H), 4.16 (t, J = 4 Hz; 1H); m/z: 152 (2) (M^+). Anal. calcd. for $C_9H_{12}O_2$: C 71.02, H 7.95; found: C 71.02, H 8.03.

(b) From treatment of ***1*** *with trifluoroacetic acid*

A solution of **1** (396 mg, 2.00 mmol) in freshly distilled trifluoroacetic acid (10 mL) was stirred at room temperature for 21 h. The reaction mixture was poured into ice-water (50 g) with stirring and extracted with chloroform (3 × 50 mL), and the combined extracts were dried (K_2CO_3–Na_2SO_4). The solvent was removed to give **4** (246 mg, 81%) as a colorless oil that solidified on cooling and had ir, ^1H nmr, and mass spectra and tlc behavior identical with those of the lactone **4** obtained from treatment of **1** with hydrobromic acid.

Treatment of ***1*** *with concentrated sulfuric acid. Formation of* ***4****,* endo*-6-hydroxynorbornane-*endo*-2-acetic acid lactone (****5****), and* exo*-3-hydroxynorbornane-*exo*-2-acetic acid lactone (****6****)*

(*i*) A solution of **1** (1.00 g) in concentrated sulfuric acid (15 mL) was stirred without external heating for 26 h. The reaction mixture was added slowly with stirring to a large amount of ice-water (ca. 300 g), and the mixture was extracted with dichloromethane (3 × 100 mL). The combined extracts were dried (K_2CO_3–Na_2SO_4), and the solvent was removed to give a brown oil (707 mg, 93%), which was purified by molecular distillation at 96°C/0.025 Torr onto a Dry Ice – acetone-cooled finger, giving **6** (10, 11, 13) (509 mg, 67%) as a colorless oil; ir ν_{max}: 1770 cm^{-1}; ^1H nmr δ: 1.08–1.65 (m, 6H), 1.88–2.84 (s, 5H), 4.46 (d of m, J = 4 Hz; 1H); m/z: 152 (27) (M^+).

(*ii*) In another run the reaction was followed by taking aliquots at intervals of 6 min, 30 min, 1 h, 2 h, and 10 h with work-up as above. Analysis by ^1H nmr spectroscopy showed the formation of lactones **4**, **5** (*vide infra*), and **6**; **4** and **5** in turn gave **6** irreversibly. The 6-min aliquot consisted of a mixture of **4**, **5**, and **6** in a ratio of 1:2:1, the 30-min aliquot showed a ratio of 1:11:9, the 1-h aliquot showed a ratio of **5** and **6** of 6:5 with only a trace of **4**, the 2-h aliquot showed a ratio of **5** and **6** of 7:10, and the 10-h aliquot showed only the lactone **6**. A column of silica gel that was packed in and eluted with dichloromethane was used in separating lactones **4**, **5**, and **6** from each other, lactone **4** being eluted first, followed by **5**, and finally **6**.

*Treatment of 2-hydroxynorbornane-2-acetic acid (****7****), (*E*)- and (*Z*)-(norborn-2-ylidene (****8*** *and* ***9****), and the ethyl esters of the latter (****10*** *and* ***11****) with concentrated sulfuric acid. Formation of* ***6***

Individual 5% solutions of **7** and mixtures of **8** and **9** and of **10** and **11** (3, 4) in concentrated sulfuric acid were stirred without external heating for 5, 10h, and 6 h, respectively. The reaction mixtures were quenched with large amounts of ice-water and extracted several times with dichloromethane. The combined extracts from each reaction mixture were dried (K_2CO_3–Na_2SO_4), and the solvent was removed giving brown oils, which were purified by molecular distillation to give almost quantitative yields (98, 94, and 99%, respectively) of lactone **6** as a colorless oil. Identifications were made by tlc and ir and ^1H nmr spectroscopic comparison with an authentic sample.

Treatment of ***4*** *with acids*

(a) Trifluoroacetic acid

(*i*) A solution of **4** (152 mg, 1.00 mmol) in freshly distilled trifluoroacetic acid (10 mL) was stirred at room temperature. After 10 days the reaction mixture was poured into ice-water (ca. 60 g) with stirring, and extracted with dichloromethane (3 × 50 mL). The combined extracts were dried (K_2CO_3–Na_2SO_4), and the solvent was removed to give a yellow oil (139 mg) that had ir and ^1H nmr spectra and tlc behavior identical with those of the starting material.

(*ii*) A solution of **4** (the material recovered from the treatment with trifluoroacetic acid above; 139 mg) in freshly distilled trifluoroacetic acid (10 mL) was boiled under reflux under nitrogen for 20 h. Work-up in the usual manner gave an oil that had ir and ^1H nmr spectra identical with those of the starting material.

(b) Formic acid – sulfuric acid

A solution of **4** in formic acid – sulfuric acid (9:1) was stirred at room temperature for 14 h. Work-up in the usual manner gave an oil that had ir and nmr spectra identical with those of the starting material.

(c) Sulfuric acid

(*i*) A solution of **4** (152 mg, 1.00 mmol) in 10% sulfuric acid (50 mL) was stirred at room temperature. After 36 h the reaction mixture was extracted with dichloromethane (3 × 50 mL). The combined extracts were dried (K_2CO_3–Na_2SO_4) and the solvent was removed to give a colorless oil (146 mg) that had ir and ^1H nmr spectra and tlc behavior identical with those of the starting material.

(*ii*) A solution of **4** in 50% sulfuric acid was found to return **4** unchanged after 6 days at room temperature.

(*iii*) A solution of **4** (760 mg, 5.00 mmol) in concentrated sulfuric acid (10 mL) was stirred at room temperature for ca. 24 h. Work-up in the usual manner gave a brown oil, which was purified by molecular distillation to give a colorless oil (48 mg, 67%) that had ir, ^1H nmr, and mass spectra and tlc behavior identical with those of lactone **6**.

(*iv*) A solution of **4** (1.52 g, 10.00 mmol) in concentrated sulfuric acid (20 mL) was stirred at room temperature for 10 min. Work-up in the usual manner gave a yellow oil which was dissolved in dichloromethane; the solution was washed with aqueous 5% sodium carbonate (5 × 50 mL), dried, and concentrated under reduced pressure to give a yellowish oil (1.31 g, 86%) that consisted of a mixture of **5** and **6** in a ratio of 5:3 with only a trace of **4**. The mixture was chromatographed on a column of silica gel that had been packed in dichloromethane. Lactone **5** was recovered and sublimed to give **5** (14) as plates, mp 68–69°C; ir ν_{max}: 1721 cm^{-1}; ^1H nmr δ: 0.84–1.60 (m, 4H), 1.74–2.60 (m, with a prominent s at 2.53; 7H), 4.79 (m, 1H). Exact Mass calcd. for $C_9H_{12}O_2$ (m/z): 152.0837; found: 152.0836. Anal. calcd. for $C_9H_{12}O_2$: C 71.02, H 7.95; found: C 71.04, H 7.95.

*Treatment of norborn-5-ene-endo-2-acetic acid (****30****) and norborn-5-ene-*exo*-2-acetic acid (****31****) with sulfuric acid. Formation of* ***4****,* ***5****,* ***6****, and* exo*-2-hydroxynorbornane-*syn*-7-acetic acid (****33****)*

A solution of a mixture of **30** and **31** (3, 11) (760 mg, 5.00 mmol) in 50% aqueous sulfuric acid (20 mL) was stirred at room temperature. After 2.5 h the reaction mixture was poured onto ice and extracted with dichloromethane (5 × 50 mL). The combined extracts were dried (K_2CO_3–Na_2SO_4) and the solvent was removed under reduced pressure to give the crude product as a yellow oil (729 mg). The crude product was chromatographed on a column of silica gel that had been packed in dichloromethane. Upon elution with dichloromethane four fractions were collected.

Concentration of the first fraction under reduced pressure and sublimation of the resulting oil afforded lactone **4** (121 mg, 16% as plates), mp 69–70°C. Mixture with an authentic sample of **4** did not depress the mp. Its ^1H nmr and ir spectra were identical to those of this sample.

The second fraction was concentrated under reduced pressure and the residue was molecularly distilled (94–97°C/0.02 Torr) to give **33** (11) (175 mg, 23%) as a colorless oil; ir ν_{max}: 1727 cm^{-1}; ^1H nmr δ: 1.10–2.73 (m, 11H), 4.38 (m, 1H); m/z: 152 (11) (M^+).

The third fraction was concentrated under reduced pressure. Thin-layer chromatography (silica gel/dichlormethane–benzene, 1:1) revealed it to be a mixture of **5** and **33**. This mixture was separated on a plate of silica gel eluted with dichloromethane–benzene (1:1) to give **5** (38 mg, 5%) as a colorless oil, which matched an authentic sample of **5** in every respect.

The last fraction was concentrated under reduced pressure. Distillation of the residue (97–98°C/0.025 Torr) afforded lactone **6** (220 mg, 29%) as a colorless oil, which was identified by ir, ^1H nmr, and tlc comparison with an authentic sample of **6**.

Treatment of ethyl exo-*5-acetyloxy*-endo-*2-hydroxynorbornane*-exo-*2-acetate (35) with sulfuric acid. Formation of* endo-*5-acetyloxy*-exo-*2-hydroxy- and* exo-*2*,endo-*5-dihydroxynorbornane-1-acetic acid γ-lactones (38 and 39) and* exo-*2-acetyloxy-1-hydroxy- and 1*,exo-*2-dihydroxynorbornane*-syn-*7-acetic acid γ-lactones (40 and 41)*

A solution of **35** (3) (2.56 g, 10.00 mmol) in 50% sulfuric acid (100 mL) was stirred at room temperature. After 60 h the reaction mixture was poured into ice-water (200 g) with stirring and extracted with dichloromethane (2 × 200 mL). The combined extracts were dried (K_2CO_3–Na_2SO_4), and the solvent was removed to give a yellow oil (1.99 g), which was chromatographed on a column of silica gel (ca. 60 g) that was packed in and eluted with dichloromethane. Two major fractions were collected. The first fraction was concentrated under reduced pressure and molecularly distilled (89–93°C/0.025 Torr) to give a colorless oil (630 mg, 30%). Thin-layer chromatography (silica gel/dichloromethane) revealed two unresolved spots. Further attempts to separate this mixture by tlc were unsuccessful. This mixture was identified as a 1:1 mixture of **38** and **40** (3); ir ν_{max}: 1770, 1736 cm^{-1}; ^1H nmr δ: 1.00–2.70 (m, with prominent s's at 2.03 and 2.56; 12H), 4.20 (d of m, 0.5H), 4.76 (m, 0.5H), 5.10 (m, 0.5H).

The second fraction (822 mg, 49%) was found to be a mixture of approximately equal amounts of **39** and **41**. To the mixture (822 mg, 4.90 mmol) Girard reagent T (12) (1.00 g) and acetic acid (1 mL) in 95% ethanol (10 mL) were added and the solution was boiled under reflux for 45 min, and then cooled. Ether (20 mL), water (20 mL), and saturated aqueous sodium chloride (10 mL) were added. The ether layer was separated, dried (K_2CO_3–$MgSO_4$), and concentrated under reduced pressure to give a yellowish oil (415 mg, 51%), shown by ^1H nmr spectroscopy to be an 85:15 mixture of **39** and **41**; ir ν_{max}: 3510 (w), 3355 (w), 1770, 1742 (w) cm^{-1}; ^1H nmr δ: 0.92–2.55 (m, with prominent ABq at 2.51, J = 16 Hz; 11H), 3.13 (s, 1.15H; absent after D_2O treatment), 4.04 (d of m, J_{app} = 3 Hz; 0.15H), 4.25 (d of d, J = 3 and 7 Hz; 1H), 4.35 (m, 1H).

The aqueous layer was separated, treated with concentrated hydrochloric acid (1 mL), and heated on a steam bath for 1 h. Additional ether (40 mL) was added and the ether extract was removed, dried (K_2CO_3–$MgSO_4$), and concentrated under reduced pressure. The residue was subjected to molecular distillation (103–104°C/0.025 Torr) to give **41** (271 mg, 33%) as a colorless, viscous oil; ir ν_{max}: 3510 (w), 3400 (w), 1776 cm^{-1}; ^1H nmr δ: 1.50–2.22 (m, 7H), 2.57, (m, 3H), 2.74 (br s, 1H; absent after D_2O treatment), 4.04 (d of m, J_{app} = 3 Hz; 1H). Anal. calcd. for $C_9H_{12}O_3$: C 64.27, H 7.19; found: C 64.38, H 7.15.

Hydrolysis of 4. Formation of exo-*2-hydroxynorbornane-1-acetic acid (51)*

To a solution of **4** (1.52 g, 10.0 mmol) in ethanol (30 mL) was added potassium hydroxide (5.60 g) with continuous swirling. The mixture was heated on a steam bath for 30 min followed by stirring without external heating for 3 h. Water (100 mL) was added, and the total volume was reduced on a rotary evaporator to ca. 75 mL. The concentrate was acidified to pH 4 with 6 N sulfuric acid while the temperature was maintained at 0–5°C. The solution was immediately extracted with dichloromethane (5 × 50 mL), and the combined extracts were washed with water (50 mL), and dried. The solvent was removed to give a white solid (1.50 g), which was crystallized from ether followed by sublimation at 67°C/0.125 Torr to give **51** (1.20 g, 70%), mp 93–94.5°C; ir ν_{max}: 3610–2410, 1706 cm^{-1}; ^1H nmr δ: 1.00–2.08 (m, 8H), 2.10–2.30 (m, 1H), 2.67 (ABq, J = 14 Hz; 2H), 3.66–3.92 (d of m, 1H), 6.50 (s, 2H; absent after D_2O treatment); m/z: 170 (2) (M^+). Anal. calcd. for $C_9H_{14}O_3$: C 63.51, H 8.28; found: C 63.41, H 8.25.

Oxidation of 51. Formation of 2-oxonorbornane-1-acetic acid (52)

A solution of **51** (170 mg, 1.00 mmol) in acetone was cooled to 5–10°C, stirred, and titrated with a freshly prepared solution of Jones reagent[11] until the orange color persisted for 1 h. The excess oxidant was destroyed by the dropwise addition of methanol. The solution was concentrated under reduced pressure and the residue was dissolved in chloroform. The solution was dried, and the solvent was removed. Molecular distillation (115–117°C/0.125 Torr) of the residue afforded **52** (166 mg, 99%) as a colorless oil that solidified on cooling to give **52** as needles, mp 57–59°C; ir ν_{max}: 3570–2440, 1739, 1706 cm^{-1}; ^1H nmr δ: 1.10–2.32 (m, 8H), 2.36–3.00 (m, with prominent ABq at 2.73, J = 17 Hz; 3H), 11.15 (s, 1H); m/z: 168 (M^+). Anal. calcd. for $C_9H_{12}O_3$: C 64.27, H 7.19; found: C 64.13, H 7.21.

Hydrogenation of 52. Formation of endo-*2-hydroxynorbornane-1-acetic acid (53)*

To a solution of **52** (210 mg, 1.20 mmol) in acetic acid (25 mL) was added platinum oxide (20 mg), and the mixture was shaken under hydrogen (3.5 atm; 1 atm = 101.3 kPa) at room temperature for 6 h. The reaction mixture was filtered and stripped of acetic acid by distillation under reduced pressure to give a yellow oil, which was crystallized from chloroform to give **53** (64 mg, 92%) as plates, mp 205–207°C (dec.), mixture mp with its *exo* isomer **51**, 39–68°C; ir ν_{max}: 3510–2325, 1704 cm^{-1}; ^1H nmr δ: 0.80–2.30 (m, 9H), 2.65 (s, 2H), 3.88–4.32 (d of m, 1H), 6.66 (br s, 2H; absent after D_2O treatment); m/z: 170 (4) (M^+). Anal. calcd. for $C_9H_{14}O_3$: C 63.51, H 8.28; found: C 63.69, H 8.23.

Reduction of 52 with sodium borohydride. Formation of 51 and 53

To a solution of **52** (183 mg, 1.10 mmol) in ethanol (10 mL) was added sodium borohydride (6.7 mg) portionwise over 5 min and the mixture was then poured into ice-water (ca. 50 g). The solution was saturated with sodium chloride and extracted with ether (4 × 50 mL). Evaporation of the ether under reduced pressure afforded a yellow oil (160 mg) that was shown to be a mixture of lactone **4** and the epimeric acids **53** and **51** in a 5:2 ratio by ir and ^1H nmr spectroscopic and tlc comparison with authentic samples.

Oxidation of 53. Regeneration of 52

A solution of **53** (50 mg) in acetone (25 mL) was cooled to 5–10°C, stirred, and titrated with a freshly prepared solution of Jones reagent[11] until the orange color persisted for 1 h. The excess oxidant was destroyed by dropwise addition of methanol. The acetone layer was separated and concentrated under reduced pressure. The residue was dissolved in chloroform, the solution was dried, and the solvent was removed to give **52** as a colorless oil, identified by ir and ^1H nmr spectroscopic comparison with an authentic sample.

Lactonization of 53. Formation of endo-*2-hydroxynorbornane-1-acetic acid lactone (54)*

To a solution of **53** (170 mg, 1.00) in dry pyridine (10 mL) was added benzenesulfonyl chloride (700 mg, 4.00 mmol), and the mixture was boiled under reflux under nitrogen for 15 min. The reaction mixture was cooled to room temperature and poured into ice-water (ca. 30.00 g). The mixture was extracted with chloroform (3 × 25 mL), and the combined extracts were washed with cold 10% hydrochloric acid (2 × 50 mL) to remove pyridine and then with water, dried (K_2CO_3–Na_2SO_4), and concentrated under reduced pressure to a viscous, pale yellow oil. Thin-layer chromatography (silica gel – dichloromethane) revealed one new spot in addition to that which corresponded to **53**. Analysis of the ^1H nmr and ir spectra indicated that this new compound is the *endo* lactone **54**, ir ν_{max}: 1776 cm^{-1}; ^1H nmr δ: 4.82 (m).

Hydrolysis of 5. Formation of endo-*6-hydroxynorbornane*-endo-*2-acetic acid and its potassium salt 56*

(*i*) To a solution of **5** (152 mg, 1.00 mmol) in ethanol (25 mL) was added potassium hydroxide (3.00 g) with continuous swirling. The mixture was heated on a steam bath for 30 min followed by stirring without external heating for ca. 5 h. Water (100 mL) was added and the total volume was reduced under reduced pressure to

[11]Reference 12, pp. 142–143.

For personal use only.

ca. 20 mL. The concentrate was acidified to pH 6 with concentrated hydrochloric acid while the temperature was maintained below 5°C. Solid sodium chloride was added to saturate the solution, which was immediately extracted with ethyl acetate (2 × 25 mL), and the combined extracts were dried. The solvent was removed under reduced pressure to give a pale yellow oil that was identified as **5** by ir, ^{1}H nmr, and tlc comparison.

(*ii*) The hydrolysis was repeated as in (*i*). The aqueous ethanolic solution was treated with ether (250 mL) and the precipitate was collected, washed with dry ether, and air-dried to give potassium *endo*-6-hydroxynorbornane-*endo*-2-acetate (**56**) as a white solid (186 mg, 97%); ir (KBr) ν_{max}: 1575, 1414 cm^{-1}; ^{1}H nmr δ(D_2O): 0.8–2.7 (m, 11H), 4.12–4.51 (m, 1H).

*Oxidation of **56**. Formation of 6-oxonorbornane-*endo*-2-acetic acid (**57**)*

To an aqueous solution of **56** (186 mg, 0.97 mmol, in 10 mL of water) ruthenium dioxide (6 mg) was added. The mixture was cooled to ca. 15°C and vigorously stirred while a solution containing ca. 10% of the stoichiometric amount of sodium periodate was added. The solution developed a yellow color indicating the presence of ruthenium tetroxide. Upon the precipitation of the black ruthenium dioxide another aliquot of sodium periodate was added. Each successive addition required more time for the disappearance of the yellow color of the tetroxide. After the addition of a slight excess of periodate the remaining ruthenium tetroxide was destroyed with isopropyl alcohol. The solution was acidified with 6 N hydrochloric acid to ca. pH 4 and extracted with ethyl acetate (5 × 20 mL). The combined extracts were dried, and the solvent removed under reduced pressure. The residue was crystallized from ether – ethyl acetate followed by sublimation to give **57** (125 mg, 77%), mp. 97–99°C (lit. (15) mp 96–97°C); ir ν_{max}: 3450–2355, 1742, 1715 cm^{-1}; ^{1}H nmr δ: 0.83–2.67 (m, 11H), 10.04 (br s, 1H; absent after D_2O treatment).

*Hydrolysis of **33**. Formation of* exo-*2-hydroxynorbornane*-syn-*7-acetic acid (**58**)*

To a solution of **33** (304 mg, 2.00 mmol) in ethanol (40 mL) was added potassium hydroxide (4.00 g) with continuous stirring. The mixture was heated on a steam bath for 30 min followed by stirring without external heating for 2 h. Water (100 mL) was added and the total volume was reduced under reduced pressure to ca. 15 mL. The concentrate was acidified to pH 4 with concentrated hydrochloric acid while the temperature was maintained below 5°C. The solution was saturated with sodium chloride and extracted with dichloromethane (3 × 50 mL). The combined extracts were dried and stripped of solvent under reduced pressure to give a pale yellow oil. Molecular distillation (106–109°C/0.02 Torr) afforded **58** (282 mg, 83%) as a colorless, viscous oil; ir ν_{max}: 3570–2380, 1695 cm^{-1}; ^{1}H nmrδ: 0:90–2.48 (m, 11H), 3.74 (d of d, J = 3 and 6 Hz; 1H), 7.10 (br s, 2H; absent after D_2O treatment). Anal. calcd. for $C_9H_{14}O_3$: C 63.51, H 8.28; found: C 63.45, H 8.21.

*Oxidation of **58**. Formation of 2-oxonorbornane-*syn-*7-acetic acid (**59**)*

A solution of **58** (255 mg, 1.50 mmol) in acetone was cooled in an ice-bath, stirred, and titrated with Jones reagent[11] until the orange color persisted for 10 min. The excess oxidant was destroyed by dropwise addition of methanol until the solution became colorless. The solution was concentrated under reduced pressure, and the residue was dissolved in dichloromethane (50 mL). The solution was dried, and the solvent was removed. Molecular distillation (117–119°C/0.025 Torr) of the residue gave **59** (232 mg, 92%) as a colorless oil; ir ν_{max}: 3579–2410, 1754, 1724 cm^{-1}; ^{1}H nmr δ: 0.92–2.60 (m, 11H), 11.67 (s, 1H; absent after D_2O treatment). Anal. calcd. for $C_9H_{12}O_3$: C 64.26, H 7.19; found: C 63.86, H 7.35.

*Hydrogenation of **59** in acetic acid. Formation of* endo-*2-acetyloxynorbornane*-syn-*7-acetic acid (**60**)*

To a solution of **59** (168 mg, 1.00 mmol) in acetic acid (15 mL) was added platinum oxide (10.00 mg), and the mixture was shaken under hydrogen (3.5 atm) at room temperature for 61 h. The reaction mixture was filtered, diluted with water (30 mL), and stripped of solvent by distillation under reduced pressure to give a yellow oil, which was molecularly distilled (85–88°C/0.02 Torr) to give **60** (201 mg, 95%) as a colorless oil; ir ν_{max}: 3570–2485, 1727 cm^{-1}; ^{1}H nmr δ: 0.85–2.54 (m, with a prominent s at 2.07; 14H), 4.76–5.15 (m, 1H), 10.32 (br s, 1H; absent after D_2O treatment). Exact Mass calcd. for $C_{11}H_{16}O_4$: 212.1049; found: 212.1068.

*Hydrolysis of **60**. Formation of* endo-*2-hydroxynorbornane*-syn-*7-acetic acid (**61**)*

To a solution of **60** (106 mg, 0.50 mmol) in ethanol (15 mL) was added potassium hydroxide (2.00 g) with continuous swirling. The mixture was heated on a steam bath for 30 min followed by stirring without external heating for 3 h. Water (30 mL) was added, and the total volume was reduced on a rotary evaporator to ca. 10 mL. The concentrate was acidified to pH 4 with 6 N sulfuric acid while the temperature was maintained at 0–5°C. The solution was immediately extracted with dichloromethane (5 × 10 mL), and the combined extracts were washed with water (2 × 10 mL) and dried. The solvent was removed under reduced pressure to give a colorless, viscous oil, which was molecularly distilled (64–68°C/0.005 Torr) to give **61** (51 mg, 60%) as a colorless, viscous oil; ir ν_{max}: 3570–2380, 1695 cm^{-1}; ^{1}H nmr δ: 0.77–2.48 (m, 11H), 4.06 (m, 1H), 7.30 (br s, 2H; absent after D_2O treatment). Exact Mass calcd. for $C_9H_{14}O_3$: 170.0947; found: 170.0943.

*Oxidation of **39**. Formation of* exo-*2-hydroxy-5-oxo-norbornane-1-acetic acid lactone (**62**)*

A solution of **39** (86% purity) (400 mg, 2.38 mmol) in acetone was cooled to 5–10°C, stirred, and titrated with a freshly prepared solution of Jones reagent[11] until the orange color persisted for 2 min. The excess oxidant was destroyed by dropwise addition of methanol. The acetone layer was concentrated under reduced pressure, and the residue was dissolved in dichloromethane. The solution was dried and the solvent was removed. Sublimation (65–67°C, 0.005 Torr) of the residue afforded **62** (291 mg, 73%) as white plates, mp 137–139°C; ir ν_{max}: 1776, 1751 cm^{-1}; ^{1}H nmr δ: 1.84 (s, 2H), 2.07 (m, 2H), 2.20 (ABq, J = 18 Hz; 2H), 2.73 (m, with sharp s at 2.73; 3H), 4.34 (t, J = 5 Hz; 1H). Exact Mass calcd. for $C_9H_{10}O_3$: 166.0629; found: 166.0634. Anal. calcd. for $C_9H_{10}O_3$: C 65.05, H 6.07; found: C 64.54, H 6.11.

*Oxidation of **41**. Formation of 1-hydroxy-2-oxonorbornane-*syn-*7-acetic acid lactone (**63**)*

A solution of **41** (168 mg, 1.00 mmol) in acetone was cooled to 0–5°C, stirred, and titrated with a freshly prepared solution of Jones reagent[11] until the orange color persisted for 2 min. The excess oxidant was destroyed by dropwise addition of methanol. The acetone layer was concentrated under reduced pressure, and the residue was dissolved in dichloromethane. The solution was dried and the solvent was removed. The oily residue was molecularly distilled (70–71°C, 0.005 Torr) to give **63** (118 mg, 71%) as a colorless oil; ir ν_{max}: 1772, 1751 cm^{-1}; ^{1}H nmr δ: 1.8–2.3 (m, 7H), 2.65 (m, 1H), 2.94 (m, 2H). Exact Mass calcd. for $C_9H_{10}O_3$: 166.0630); found: 166.0627.

Photodissolution of iron oxides. IV. A comparative study on the photodissolution of hematite, magnetite, and maghemite in EDTA media

MARTA I. LITTER AND MIGUEL A. BLESA[1]

Departamento Quimica de Reactores, Comision Nacional de Energia Atomica, Av. del Libertador 8250, 1429 Buenos Aires, Argentina

Received July 15, 1991[2]

MARTA I. LITTER and MIGUEL A. BLESA. Can. J. Chem. **70**, 2502 (1992).

The thermal and 254-nm photochemical dissolution reactions of magnetite (Fe_3O_4), maghemite (γ-Fe_2O_3), and hematite (α-Fe_2O_3) suspended in EDTA aqueous solutions were compared. γ-Fe_2O_3 and Fe_3O_4 are thermally and photochemically more reactive than α-Fe_2O_3. Both thermal and photochemical dissolution reactions are governed by an initiation step, which involves the production of Fe^{II}_{aq}, and a subsequent thermal reaction of these ions with the solid, to produce Fe^{III}_{aq}. The initiation step under UV irradiation involves the photoreduction of surface $>Fe^{III}$ – EDTA complexes to yield Fe^{II}_{aq} and the photooxidation of adsorbed EDTA to yield CH_2O and other oxidation products. After Fe^{III} – EDTA complexes build up in solution through the following step, homogeneous photolysis is the main source of Fe^{II} and CH_2O. Oxides with spinel type structure are characterized by faster rates in the two processes, and O_2 may inhibit the dissolution processes by changing the stoichiometry of the initiation step to that of the autooxidation of EDTA. The relative importance of autooxidation and photodissolution depends on the nature of the oxide and the experimental conditions. Photooxidation reaction rates parallel those of the photodissolution initiation steps, and long-term stability towards photocorrosion (dissolution) implies low photocatalytic activity for the oxidation of EDTA. The set of differential equations describing all the reaction rates is discussed and applied to the different cases.

MARTA I. LITTER et MIGUEL A. BLESA. Can. J. Chem. **70**, 2502 (1992).

On a comparé les réactions de dissolutions thermiques et photochimiques, à 254 nm, de la magnétite (Fe_3O_4), de la maghemite (γ-Fe_2O_3) et de l'hématite (α-Fe_2O_3) suspendues dans des solutions aqueuses d'EDTA. Le γ-Fe_2O_3 et le Fe_3O_4 sont thermiquement et photochimiquement plus réactifs que l'α-Fe_2O_3. Les réactions de dissolutions tant thermiques que photochimiques sont régies par une étape d'initiation, impliquant la production de Fe^{II}_{aq}, et une réaction thermique subséquente de ces ions avec le solide, conduisant à la formation de Fe^{III}_{aq}. L'étape d'initiation sous irradiation UV implique la photoréduction des complexes superficiels $>Fe^{III}$ – EDTA en Fe^{II}_{aq} et la photo-oxydation de l'EDTA adsorbé en CH_2O et en d'autres produits d'oxydation. Les oxydes dont la structure ressemble à celle de la spinnelle sont caractérisés par des vitesses de réactions des deux processus qui sont plus rapides, et l'O_2 peut inhiber les processus de dissolution en changeant la stoechiométrie de l'étape d'initiation vers celle de l'auto-oxydation de l'EDTA. L'importance relative de l'auto-oxydation et de la photo-dissolution dépend de la nature de l'oxyde et des conditions expérimentales. Les vitesses des réactions de photo-oxydation sont parallèles à celles des étapes de l'initiation de la photo-dissolution, et la stabilité à long terme vis-à-vis de la photocorrosion (dissolution) implique une faible activité photocatalytique pour l'oxydation de l'EDTA. On discute de l'ensemble des équations différentielles décrivant toutes les vitesses de réaction et on les applique aux differents cas.

[Traduit par la rédaction]

Introduction

The main kinetic features of the dissolution of magnetite in aqueous solutions have been established in a series of previous papers (see ref. 1 and references therein; see also refs. 2–9); analogous data for other iron oxides and oxohydroxides are less abundant (1, 5, 9–14). From the existing data it seems safe to conclude that the basic mechanisms are of general application to all iron oxides, but the actual rates of dissolution may span various orders of magnitude.

It is well known (15) that corrosion of semiconducting oxides may imply transfer of holes (h^+) from the valence band to the reductant and of electrons (e^-) from the conduction band, in the case of iron(III) oxides, as Fe^{II}. Because of this fact, photochemical dissolution is possible, and has been studied in a series of papers by others (13, 14, 16–25) and by us (26–28). It is well established that electron transfer reactions take place through localized sites of the semiconductor; the formation of surface complexes by adsorption of adequate ligands is equivalent in semiconductor terminology to the formation of extrinsic surface states. These surface complexes may trap e^- and (or) h^+ very efficiently (29), thus enhancing photodissolution and photocatalytic rates. The participation of individual Fe^{III} centers in the photochemical reactions of iron oxides has been considered (22, 30). Indeed, the usage of the surface complexation formalism leads to an adequate description of photocatalytic activity and photocorrosion, irrespective of whether primary light absorption involves the particle or the surface complex (25, 26). Spinel type oxides, such as γ-Fe_2O_3 or Fe_3O_4, are known to be more easily photocorroded than α-Fe_2O_3; it has been proved that this corundum structure is characterized by a fast surface recombination of the generated e^-/h^+ pairs (31, 32). Moreover, it has been shown that the existence of spinel phase inclusions in the α-Fe_2O_3 corundum structure enhances its photocatalytic reactivity for H_2 production (33). Hematite is called "photostable" because the optical transition that generates the electron-hole pairs is metal-ion centered (*d–d*) and does not affect Fe—O bonds (34). Consequently, because of the narrowness of *d*-bands and the consequent low mobility of holes, it has very poor photocatalytic properties. In this paper we show that the higher photocatalytic activity expected for spinel-type oxides derives easily in photodissolution, thus making these materials less promising for the photooxidation of organic matter.

Because of the electrochemical nature of the thermal dissolution of iron oxides, much can be learnt about these open circuit processes by studying the influence of light; in a pre-

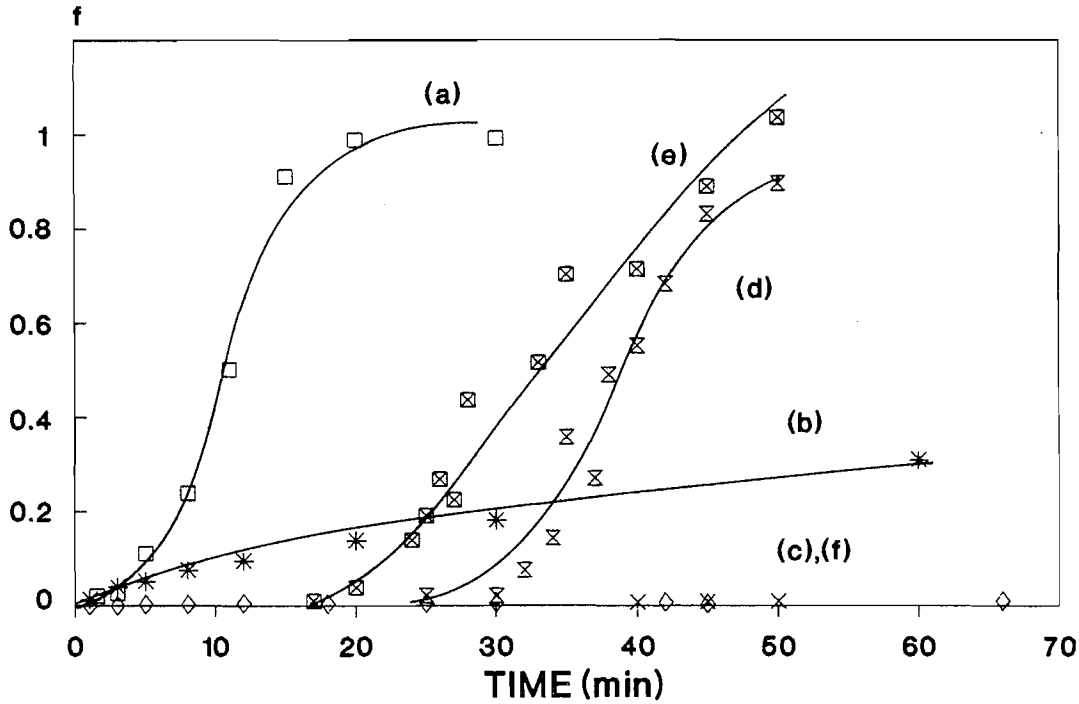

FIG. 1. Iron fraction dissolved from iron oxides by EDTA at 30°C and pH 3 as a function of time. [Oxide] = 1 g dm^{-3} in the thermal experiments and 0.5 g dm^{-3} in the photochemical experiments; [EDTA] = 2×10^{-2} mol dm^{-3}. (*a*): Fe_3O_4, thermal, $[Fe^{2+}]_0 = 5.6 \times 10^{-5}$ mol dm^{-3} (□); (*b*): γ-Fe_2O_3, thermal, $[Fe^{2+}]_0 = 5.1 \times 10^{-5}$ mol dm^{-3} (*); (*c*): α-Fe_2O_3, thermal, $[Fe^{2+}]_0 = 6.1 \times 10^{-5}$ mol dm^{-3} (◇); (*d*): Fe_3O_4, λ = 254 nm, $[Fe^{2+}] = 0$ (⧖); (*e*) γ-Fe_2O_3, λ = 254 nm, $[Fe^{2+}] = 0$ (⊠); (*f*) α-Fe_2O_3, λ = 254 nm, $[Fe^{2+}] = 0$ (×).

vious paper (28), we discussed the interrelationship between thermal and light-promoted maghemite dissolution in the presence of reductive ligands. This approach is extended in this paper to include other iron oxides; the results of a comparative study of the thermal and photochemical dissolution of α-Fe_2O_3, γ-Fe_2O_3, and Fe_3O_4 in aqueous solutions containing EDTA are presented here, and used to derive values of rate constants for the individual stages of the mechanism: the initial slow photochemical dissolution of reductive stoichiometry, and the following fast thermal dissolution by electron exchange between surface $>Fe^{III}$ centers and adsorbed Fe^{II} complexes.

The widespread interest in iron oxide dissolution reflects the relevance of these processes in fields such as transport of contaminants in waters, metal corrosion, decontamination of nuclear reactors, and mobilization of metals in aquatic systems (35–38).

Experimental

Maghemite (γ-Fe_2O_3) was a commercial sample and was the same as used in previous studies (26–28); its specific surface area was 25 m^2 g^{-1}. Hematite (α-Fe_2O_3) was a commercial sample (Mallinckrodt); its specific surface area was 9.8 m^2 g^{-1}. Magnetite (Fe_3O_4) was prepared as previously described (39); it was composed of cubo-octahedral particles of 0.26 μm average edge length, and its specific surface area was 5.5 m^2 g^{-1}.

The three oxides were characterized by chemical analyses, X-ray diffractometry, SEM, and BET surface area measurements.

Reagents were of analytical purity or better and were used without further purification. Water was bidistilled in a quartz apparatus. Dilute H_2SO_4 or NaOH were used for pH adjustment.

Thermal and photochemical experiments were carried out as in ref. 28. Thermal reactions were carried out under N_2 atmosphere; in the photochemical experiments, air-saturated suspensions were used in an effort to prevent formaldehyde losses from the system due to N_2 stripping. Furthermore, the effect of dissolved O_2 was of interest.

Total iron was determined by the thioglycolate method (40) and formaldehyde by the chromotropic acid technique (41).

Actinometry at 254 nm was performed by the ferrioxalate method (42), the total incident light intensity per unit solution volume (I_0) being 1.1×10^{-5} einstein s^{-1} dm^{-3}.

The reflectance spectra were obtained on a Shimadzu 210 A spectrophotometer equipped with an integrating sphere. Absorbances were measured in a Metrolab 2500 spectrophotometer.

Results

Spectral characteristics

The reflectance spectral features of α-Fe_2O_3, γ-Fe_2O_3, and Fe_3O_4 are in agreement with those reported previously in the literature (43–47). The three iron oxides present bands assigned to charge-transfer (260–390 nm), spin-flip (420–530 nm), and ligand-field (580–780 nm) transitions.

The principal difference between the reflectance spectra of Fe_3O_4 and the ferric oxides is the lack of the band edge in the visible region. For hematite and maghemite, a sharp increase of the absorptivity is observed below 600 nm, corresponding to a band gap of 2.0 eV, while for magnetite, the band edge is beyond 800 nm. Muret (46) reported a sharp increase in the absorption coefficient at 826 nm (1.5 eV).

Dissolution reactions

The dissolution profiles of Fe_3O_4, γ-Fe_2O_3, and α-Fe_2O_3 in EDTA at pH 3, brought about thermally by added ferrous ions and photochemically by irradiation at 254 nm, are shown in Fig. 1. The extent of dissolution under both experimental conditions is extremely low for hematite (curves *c* and *f*), but the two other iron oxides dissolve faster. In agreement with the results of previous studies of the thermal dissolution in EDTA and oxalic acid media (2, 4, 6), magnetite is

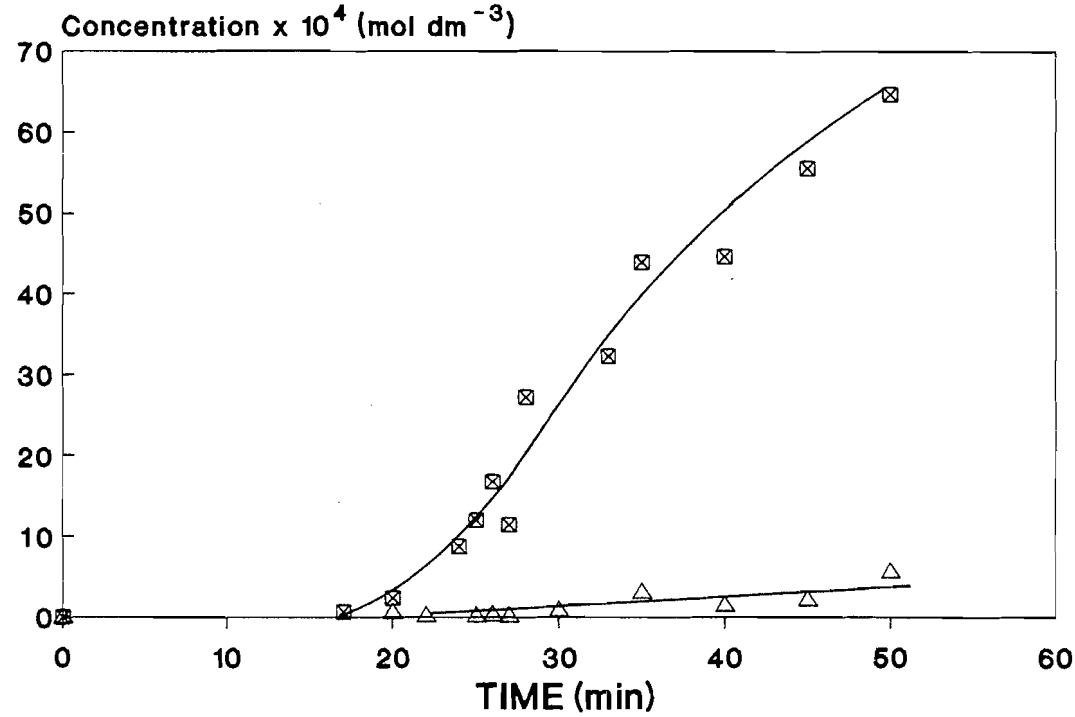

FIG. 2. Comparison of the production rates of iron (⊠) and formaldehyde (△) in the 254-nm photodissolution of γ-Fe_2O_3 (0.5 g dm^{-3}) in EDTA (2×10^{-2} mol dm^{-3}) at pH 3 and 30°C.

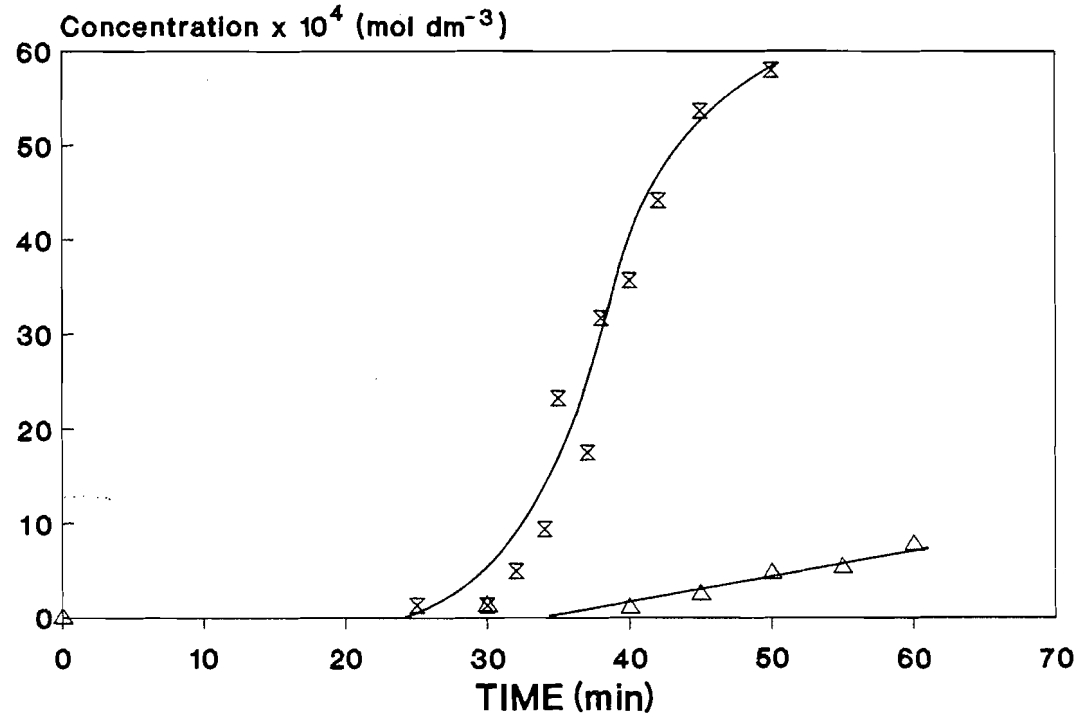

FIG. 3. Comparison of the production rates of iron (⧖) and formaldehyde (△) in the 254-nm photodissolution of Fe_3O_4 (0.5 g dm^{-3}) in EDTA (2×10^{-2} mol dm^{-3}) at pH 3 and 30°C.

characterized by sigmoidal f/t profiles (where $f = (m_0 - m)/m_0$ is the dissolved fraction of total iron and m_0 and m are the initial and instantaneous mass of the iron oxide; t is the reaction time). Practically no induction time is observed in the presence of Fe^{2+} under N_2 atmosphere (curve *a*), but under 254-nm irradiation, in O_2 atmosphere and with no added Fe^{2+} (curve *d*), the reaction presents an induction period. In the case of maghemite, the photodissolution (curve *e*) shows similar behavior to that observed with magnetite. The thermal (dark) dissolution profiles are similar only in the very

early stages: whereas magnetite dissolution is acceleratory, the maghemite dissolution rate decreases steadily with reaction time and, furthermore, total dissolution is not observed in the dark (see curve *b*). The dark reaction requires added Fe^{2+}; otherwise negligible dissolution is observed in time span of our experiments.

The formation of formaldehyde was observed only in the photolysis of γ-Fe_2O_3 and Fe_3O_4 suspensions at long reaction times (Figs. 2 and 3).

Discussion

Thermal dissolution

The mechanism of dissolution of iron oxides by reducing ligands in acid media can be described by the following steps (3–6):

(*a*) A fast preequilibrium adsorption step in which surface complexes are formed:

$$[1] \quad >Fe^{III} + L^{n-} \xrightarrow{H^+} >Fe^{III}\text{–}(L^{n-})(H^+)$$

where $>$ denotes the lattice surface of the oxide.

(*b*) Slow dissolution of $>Fe^{III}$–L surface complexes through acid (b_1) or reductive dissolution (b_2) parallel paths:

$$[2] \quad >Fe^{III}\text{–}(L^{n-})(H^+) \xrightarrow{k_1} (Fe^{III}\text{–}L)^{3-n}{}_{aq} (+ H^+) \qquad (b_1)$$

$$[3] \quad >Fe^{III}\text{–}(L^{n-})(H^+) \xrightarrow{k_2} >Fe^{II} + L^{(n-1)-} (+ H^+) \qquad (b_2)$$

$$\text{fast} \downarrow L^{n-}$$

$$(Fe^{II}\text{–}L)^{2-n}{}_{aq}$$

(*c*) A fast reductive reaction between Fe^{II} – L complexes and $>Fe^{III}$ surface centers:

$$[4] \quad >Fe^{III}\text{–}(L^{n-}) + (Fe^{II}\text{–}L)^{2-n}{}_{aq} \xrightarrow[H^+]{k_{Th}} >Fe^{II}\text{–}(L^{n-})(H^+) + (Fe^{III}\text{–}L)^{3-n}{}_{aq}$$

$$\downarrow$$

$$(Fe^{II}\text{–}L)^{2-n}{}_{aq}$$

The overall rate of dissolution can be expressed by the contribution of steps (*b*) and (*c*) by the following expression:

$$[5] \quad \frac{df}{dt} = R_0 + k\,[Fe^{II}]S$$

where $R_0 = (k_1 + k_2)\,[>Fe^{III}\text{–}(L^{n-})(H^+)]$ is a composite reaction rate term independent of $[Fe^{2+}]$, corresponding to the reaction steps mediated by Fe^{III} – L complexes (eqs. [2] and [3]), and the second term accounts for the reductive dissolution process promoted by aqueous Fe^{II} – L complexes[3] (eq. [4]); S is the instantaneous surface area, and k is related to k_{Th} (see below).

When no Fe^{II} is added to α-Fe_2O_3 or γ-Fe_2O_3 suspensions, the second term on the right-hand side of eq. [5] reflects essentially the buildup of Fe^{II} through b_2 (eq. [3]). In the case of magnetite, Fe^{II} is put in solution through b_1, b_2, and *c*; assuming congruent dissolution, pathway *c* produces 0.5 Fe^{II} for each dissolved Fe^{III}.

In the presence of added Fe^{2+}, the first term in eq. [5] is negligible and the expression becomes:

$$[6] \quad \frac{df}{dt} = k\,[Fe^{II}]\,S$$

For magnetite, $[Fe^{II}] = [Fe^{II}]_0 + [Fe^{II}]_{diss}$, where $[Fe^{II}]_0$ is the concentration of added ferrous salt, and $[Fe^{II}]_{diss}$ is the concentration of Fe^{II} arising from the dissolution of magnetite. As the main source of dissolved ions is pathway *c*,

$$[7] \quad [Fe^{II}]_{diss} = 1/3\,[Fe_T] = (m_0/3VM)f$$

where $[Fe_T]$ refers to dissolved Fe, exclusive of added Fe^{II} salts. In eq. [7], V is the suspension volume, and M the mass of oxide FeO_x, magnetite in this case, per mole of iron atoms. Therefore, eq. [6] can be changed to:

$$[8] \quad \frac{df}{dt} = k\,([Fe_T]/3 + [Fe^{II}]_0)\,S$$

$$= 3/2\,k_{Th}\,\{f/3 + (VM/m_0)\,[Fe^{II}]_0\}\,S$$

where $k_{Th} = 2/3\,(m_0/VM)\,k$. The 2/3 coefficient arises from the difference between the stoichiometry of the reaction and the rate-determining step, eq. [4].

Our sample of magnetite is composed of cubo-octahedral particles; the instantaneous surface area is therefore $S = S_0(1 - f)^{2/3}$ (contracting volume kinetic regime) (2*a*), and eq. [9] results:

$$[9] \quad \frac{df}{dt} = k_a f\,(1 - f)^{2/3} + k_b\,(1 - f)^{2/3}$$

where $k_a = k_{Th}\,S_0/2$ and $k_b = 3/2\,(VM/m_0)\,[Fe^{II}]_0\,k_{Th}\,S_0$.

Equation [9] can be easily integrated by casting it in the form [10]:

$$[10] \quad \frac{3dx}{dt'} = x^3 - c^3$$

where $t' = k_a t$, $x = (1 - f)^{1/3}$, and $c = (1 + k_b/k_a)^{1/3}$.

Integration of eq. [10] leads to the following expression:

$$[11] \quad t' = \frac{1}{c^2}\left\{\frac{1}{2}\ln\left[\frac{(x-c)^2}{(x^2+cx+c^2)}\right] - \sqrt{3}\tan^{-1}\left(\frac{2x+c}{\sqrt{3}c}\right) - \frac{1}{2}\ln\left[\frac{(1-c)^2}{(1+c+c^2)}\right] + \sqrt{3}\tan^{-1}\left(\frac{2+c}{\sqrt{3}c}\right)\right\}$$

Equation [11] fits the experimental values reasonably well (see Fig. 4, curve *a*), and the calculated value of k_{Th} for our sample of magnetite, derived from the fitting, is $2.3 \times 10^{-7}\ s^{-1}\ cm^{-2}$.

In the cases of maghemite and hematite, for $[Fe^{II}]_0 = 0$,

[3] Strictly, the rate should be first order on the surface concentration of Fe^{II} – L complexes adsorbed onto the oxide surface; this surface concentration is related to the concentration in the solution through some form of an adsorption isotherm, the simplest being the Langmuir expression:

$$[Fe^{II}]_{ads} = \frac{N_s\,K\,[Fe^{II}]_{sol}}{1 + K\,[Fe^{II}]_{sol}}$$

where N_s is the number of active surface sites on the oxide and K is the corresponding Langmuir constant for the adsorption of Fe^{II} – L complex. As the value of K reported (4*a*) for Fe^{II} – EDTA complexes in ca. 1200 $mol^{-1}\ dm^3$, and the concentration of Fe^{2+} added to the solution at the initial time of the reaction is ca. 10^{-5} mol dm^{-3}, in the early stages of dissolution $1 \gg K\,[Fe^{II}]_{sol}$, justifying the approximation $[Fe^{II}]_{ads} \cong N_s\,K\,[Fe^{II}]_{sol}$; the rate constant k (eq. [5]) embodies $N_s\,K$. Analogously, the rate terms for b_1 and b_2 can be written in the form $k_1\,S$ and $k_2\,S$.

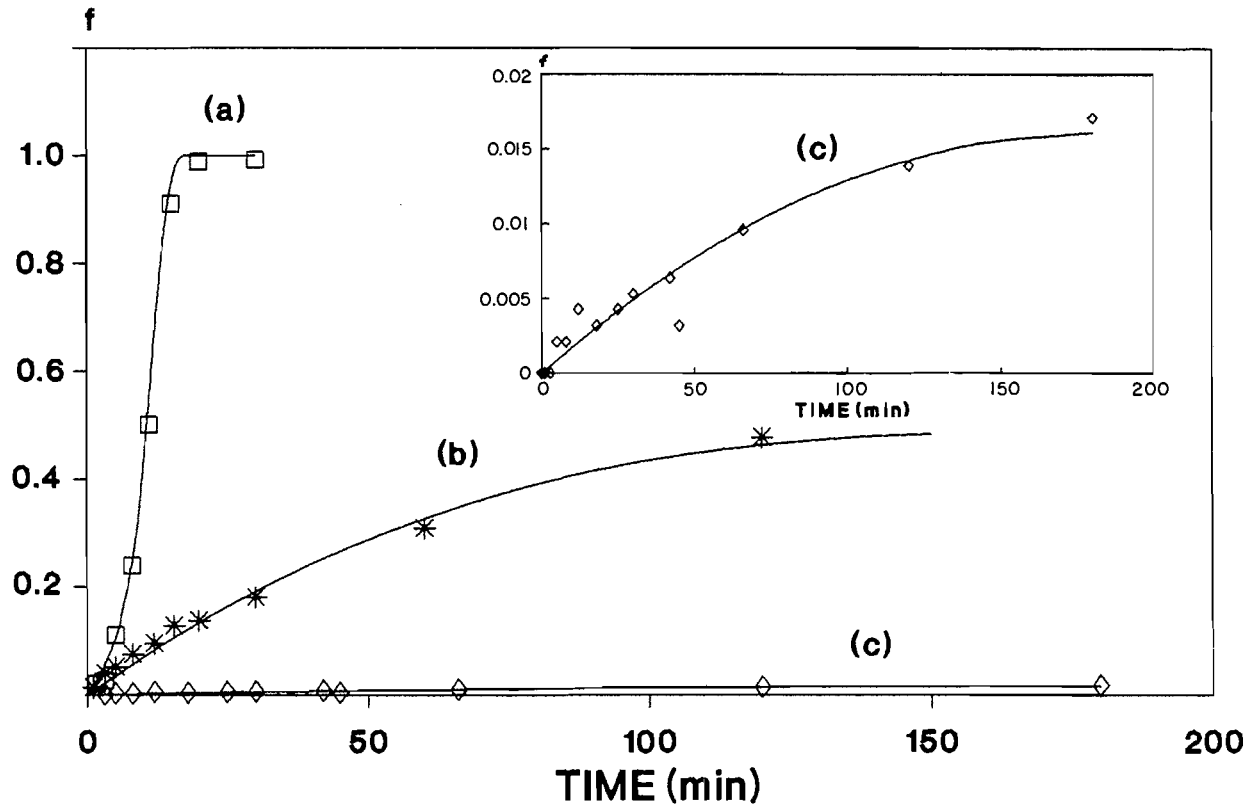

FIG. 4. Fitting of thermal dissolution curves for iron oxides in EDTA at 30°C and pH 3. Experimental data are those of Fig. 1. Calculated curve (*a*) for Fe_3O_4 was obtained through eq. [11]; calculated curve (*b*) for γ-Fe_2O_3, through integrated eq. [13], and calculated curve (*c*) for α-Fe_2O_3, through eq. [14]. Insert: enlargement of curve (*c*).

the lack of structural Fe^{II} makes dissolution slow at room temperature (6, 11, 28); the only source of Fe^{II} is reaction *b*. This reaction is very slow at low temperatures, and dissolution is observed at appreciable rates only when Fe^{II} is added to the suspension. For $[Fe^{II}] = [Fe^{II}]_0$, eq. [6] predicts a rate law of the form:

$$[12] \quad \frac{df}{dt} = k\,[Fe^{II}]_0\,S_0\,(1-f)^{1/n}$$

where n depends on the particle shape (see below). Equation [12] is the typical contracting geometry kinetic expression with a constant penetration rate (48). For low $[Fe^{II}]_0$ values, under our experimental conditions, the initial added Fe^{2+} is slowly consumed by the fast reaction with traces of oxygen that enter into the system. Assuming zero-order kinetics, eq. [6] takes the form [13]; note that the maghemite particles are acicular, the instantaneous surface area being therefore proportional to $(1-f)^{1/2}$ (49). In this case, $k_{Th} = (m_0/VM)\,k$.

$$[13] \quad \frac{df}{dt} = (VM/m_0)\,k_{Th}\,S_0\,(1-f)^{1/2}\,[Fe^{II}]_0\,(1-t/\tau)$$

In eq. [13], M is here the mass of maghemite (γ-Fe_2O_3) per mole of iron atoms, and $\tau = [Fe^{II}]_0/4\,R$ is the time required to consume the initial added Fe^{2+}, R being the rate of O_2 ingress into the system. Equation [13] is easily integrated, and the experimental points can be fitted reasonably well with a value of $\tau = 150$ min (curve *b*, Fig. 4). The slow dissolution regime in such a situation accounts for the arrest of dissolution at rather low values of f. This fitting procedure leads to $k_{Th} = 1.2 \times 10^{-7}\ s^{-1}\ cm^{-2}$.

For hematite, assuming spherical particles,[4] expression [14] applies:

$$[14] \quad \frac{df}{dt} = (VM/m_0)\,k_{Th}\,S_0\,(1-f)^{2/3}\,[Fe^{II}]_0\,(1-t/\tau)$$

Taking $\tau = 180$ min, the value of k_{Th} that fits the experimental results is $6.3 \times 10^{-9}\ s^{-1}\ cm^{-2}$ (curve *c*, insert of Fig. 4). The value of τ is better considered as a lower limit, due to the low measured amounts of iron.

From these results, we conclude that our sample of magnetite is twice as reactive as our sample of maghemite. The appreciably higher reactivity of these two spinel type oxides compared with the corundum type hematite can be related to the electronic and structural properties of the spinel octahedral iron sublattice, characterized by a fast electron-hopping (51).

Photochemical dissolution

Anaerobic systems

In ref. 28 we proposed a mechanism for the UV light promoted dissolution of maghemite in the presence of reductive ligands. Light provides an alternative initiation step (b_3) to the reaction sequence [2]–[4]:

[4]Although the sample of hematite is polydisperse, this assumption does not affect the f/t profiles, except in the latter stages of dissolution ($f > 0.6$) (50).

[15] $>Fe^{III}-(L)^{n-}(H^+) \xrightarrow{h\nu} >Fe^{II} + L^{(n-1)-}(+H^+) \quad (b_3)$
$\downarrow$
$(Fe^{II}-L)^{2-n}_{aq}$

Equation [15] is in fact the result of a series of events that include the creation of e^-, h^+ pairs, the trapping of e^- by surface $>Fe^{III}$ complexes, and the reaction of photoholes with adsorbed EDTA. As discussed below, the apparent quantum yield $\phi_1 = (d[Fe^{II}]/dt)/I_0$ for reaction [15] is very low, below 10^{-5} mol einstein $^{-1}$ (28). By itself, this quantum yield is too low to give rise to fast dissolution; the role of I_0 is therefore that of increasing the value of R_0 in eq. [5], thereby becoming the main source of $[Fe^{II}]$.

When aqueous Fe^{III} – L builds up in solution, its photolysis, either as a dissolved or adsorbed species, may provide an alternative to eq. [15] as the initiation step. If adsorption of Fe^{III} is large, the photodecomposition of $(Fe^{III} - L)_{aq}$ may be subjected to heterogeneous catalysis. No evidence for this phenomenon was found in this study. On the other hand, the photolysis of dissolved Fe^{III} – EDTA complexes, eq. [16], is the main photochemical reaction after a large fraction of dissolution is achieved, and accounts for the time dephasing observed between CH_2O production and iron oxide dissolution.

[16] $(Fe^{III}-L)_{aq} \xrightarrow{I_0\phi_2} Fe^{2+}$ + oxidation products of L

In the course of thermal dissolution, iron is put in solution essentially with negligible change in the oxidation state (except during the induction period). In the illuminated systems, it is better to write individual rate equations for Fe^{II} and Fe^{III}. These equations for hematite and maghemite are

$$[17] \quad \frac{d[Fe^{II}]}{dt} = k_1' S + k_2' [Fe^{III}]$$

$$[18] \quad \frac{d[Fe^{III}]}{dt} = -k_2'[Fe^{III}] + k_{Th} S [Fe^{II}]$$

In writing eqs. [17] and [18], the following assumptions were made: the amount of thermally produced Fe^{II} from the oxide, k_2S (eq. [3]), is negligible compared with the photochemical production, $k_1' S = I_0\phi_1$ (eq. [15]); the photochemical production (eq. [15]) is assumed to be proportional to the surface area, even though its contribution to $[Fe^{II}]$ is proportional to the surface area, even though its contribution to $[Fe^{II}]$ is important only at low conversions, and therefore the actual dependence on particle surface area is not important; at longer times, homogeneous photolysis dominates, with $I_0\phi_2 = k_2' [Fe^{III}]$ (i.e., the fraction of the total incident light absorbed by dissolved Fe^{III} is proportional to its concentration); $k_1S < k_{Th}S [Fe^{II}]$ (i.e., the amount of Fe^{III} produced by dissolution through reaction [2] is negligible in comparison to that produced by reaction [4]; this assumption breaks down only in the induction period, during which the extent of dissolution is below the detection limit in the short time interval required to trigger reaction [4]).

For magnetite, a factor 1.5 (due to the stoichiometry) must multiply the first term in eq. [17], and an additional term must be added to describe the contribution of Fe^{II} from the lattice, which goes into solution together with Fe^{III}:

$$[19] \quad \frac{d[Fe^{II}]}{dt} = 1.5\, k_1' S + k_2' [Fe^{III}] + 0.5\, k_{Th} S [Fe^{II}]$$

In general, for an oxide $Fe^{II}_n Fe^{III}_m O_p$,

$$[20] \quad \frac{d[Fe^{II}]}{dt} = \left(\frac{n+m}{2}\right) k_1' S + k_2' [Fe^{III}] + \left(\frac{n}{m}\right) k_{Th} S [Fe^{II}]$$

For Fe_2O_3, $\left(\frac{n+m}{2}\right) = 1$ and $(n/m) = 0$, and for Fe_3O_4, $\left(\frac{n+m}{2}\right) = 1.5$ and $(n/m) = 0.5$.

The equation for Fe^{III} production is the same for all the oxides.

The low extent of photodissolution of α-Fe_2O_3 in EDTA prevents the evaluation of the kinetic parameters corresponding to this oxide. The value of k_{Th} for hematite, obtained in the thermal experiments (6.3×10^{-9} s^{-1} cm^{-2}), is similar to the value calculated by us (28) to describe the photochemical dissolution of α-Fe_2O_3 by oxalic acid (25) (9.7×10^{-10} s^{-1} cm^{-2}). The following discussion refers to Fe_3O_4 and γ-Fe_2O_3.

In our previous paper we obtained the analytical solution of the set of kinetic equations [17] and [18] and the parameters $k_1' S_0$, k_2', and $k_{Th} S_0$ that fitted reasonably well the experimental data of the maghemite/EDTA system. In this paper, we have improved the analysis by introducing into the equations the thermal constant per unit area k_{Th} obtained from the thermal experiments described in the previous section, and we also sort out the two contributions lumped together in the empirical triggering kinetic parameter: the true photochemical initiation rate constant, called $k_1'S_0$ here, and the arresting effect of oxygen. As before, the requirement $S \cong S_0$ is maintained to simplify the mathematical treatment.

The influence of oxygen

In the presence of oxygen, eqs. [17], [18], and [19] must be modified:

$$[21] \quad \frac{d[Fe^{II}]}{dt} = k_1' S_0 - k_{ox} [O] [Fe^{II}] + k_2' [Fe^{III}]$$

$$[22] \quad \frac{d[Fe^{III}]}{dt} = -k_2' [Fe^{III}] + \{k_{ox} [O] + k_{Th} S_0\} [Fe^{II}]$$

$$[23] \quad \frac{d[Fe^{II}]}{dt} = 1.5\, k_1' S_0 - k_{ox} [O] [Fe^{II}] + k_2' [Fe^{III}] + 0.5\, k_{Th} S [Fe^{II}]$$

The simplest case corresponds to a fast scavenging of Fe^{II} by O_2; in such a case, an induction period ensues, corresponding to the time τ' required to generate enough Fe^{II} to suppress all oxidant.[5] The amount of Fe^{II} released through

[5]Note that τ' is given by $4\,[O_2]_0/k_1' S_o$, whereas the parameter τ used in the discussion of the thermal dissolution of γ-Fe_2O_3 is given by $[Fe^{II}]_0/4\,R$, (see eq. [13]). In both cases, the chemical reaction of Fe^{II} – EDTA and O_2 is fast, as expected (52).

TABLE 1. Comparison of the kinetic parameters for Fe_3O_4, γ-Fe_2O_3, and α-Fe_2O_3

Parameter	Fe_3O_4	γ-Fe_2O_3	α-Fe_2O_3
k_1'/mol dm^{-3} s^{-1} cm^{-2}	8.5×10^{-12}	3.5×10^{-12}	(Very low)
k_2'/s^{-1}	3.2×10^{-6}	3.2×10^{-6}	3.2×10^{-6}
k_{Th}/s^{-1} cm^{-2}	2.3×10^{-7}	1.2×10^{-7}	6.3×10^{-9}

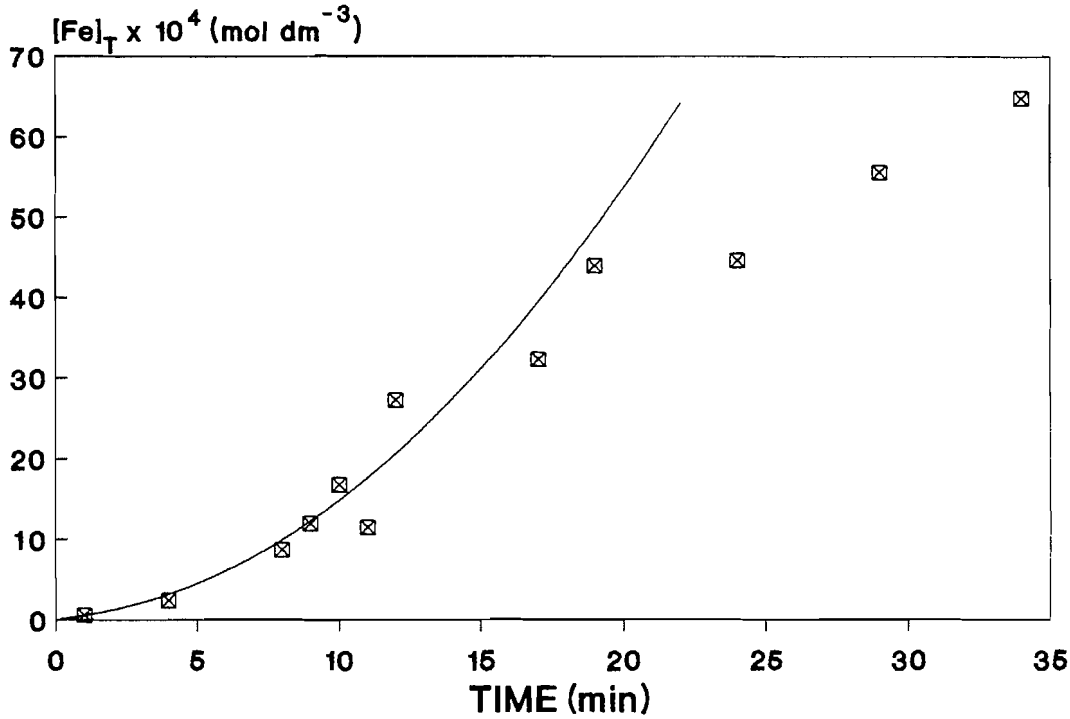

FIG. 5. Fitting of the 254-nm photodissolution curve for γ-Fe_2O_3 in EDTA at 30°C and pH 3. Experimental data (⊠) are those of Fig. 1. Solid curve was obtained through the analytical solution of eqs. [21] and [22], taking $\tau' = 16$ min.

the path defined by k_1' and required to scavenge all oxidant present is given by $k_1' S_0 \tau'$ in the case of maghemite and by $1.5\, k_1' S_0 \tau'$ in the case of magnetite. From our data, by setting τ' at approximately the beginning of the ascendant part of the curves *d* and *e* of Fig. 1, the values 26 min for magnetite and 16 min for maghemite are obtained. Combining these figures with the values of k_{Th} determined in the dark, and the value of k_2' found previously (28) (3.2×10^{-6} s^{-1}), the values $k_1' = 3.5 \times 10^{-12}$ mol dm^{-3} s^{-1} cm^{-2} (γ-Fe_2O_3), and $k_1' = 8.5 \times 10^{-12}$ mol dm^{-3} s^{-1} cm^{-2} (Fe_3O_4) are derived; Figs. 5 and 6 show the results of the fitting of the experimental points from Fig. 1 (converting f to [Fe_T]). The lower value of k_1' for γ-Fe_2O_3 indicates a somewhat lower photoreactivity, which may be explained by a faster recombination of the electron-hole pairs, facilitated by defects or vacancies in the oxide structure (29). Table 1 shows the comparison of the kinetic parameters for the three iron oxides.

This treatment implies that the low quantum yields for photodissolution also apply to heterogeneous photoassisted autooxidation, a result well in line with those described by Hoffmann and co-workers (30). Thus hematite, although more stable towards photocorrosion, is also less effective to photoinduce the degradation of organic matter. In agreement, Leland and Bard (53) reported that the rate of photoassisted autooxidation of oxalate on γ-Fe_2O_3 is ca. 14 times higher than on α-Fe_2O_3; EDTA shares with oxalate its ability to form surface complexes and thus it is also autooxidized in a photoassisted process at a rate that depends on the nature of the oxide; being less easily oxidizable, the low quantum yields seem reasonable. The differences in rates on γ-Fe_2O_3 and α-Fe_2O_3 are known to become much less marked in the case of relatively fast autooxidation reactions, such as that of SO_3^{2-}, which proceeds even in the dark (53). In this case, the quantum yield is appreciably higher, of the order of 0.1 (54). The low quantum yields may imply little importance of iron oxides as photocatalysts in the environmental degradation of organic matter; the mobilization of iron may, however, be strongly influenced.

Formaldehyde photoproduction

As indicated in ref. 28, formaldehyde is detected only after a sizeable fraction of the solid has dissolved (i.e. ≅20% for maghemite). This experimental result stresses the fact that the oxide dissolves essentially through pathway *c*, as Fe^{III} (eq. [4]), Fe^{II} being mainly produced at longer times by homogeneous photolysis.

The slopes of the curves for formaldehyde production (ca. 5×10^{-7} mol dm^{-3} s^{-1}) in both systems γ-Fe_2O_3 and Fe_3O_4 (Figs. 2 and 3), are in reasonable agreement with the calculated value of $\phi_2 I_0 = 1.8 \times 10^{-6}$ mol dm^{-3} s^{-1} (see eq. [16]), where ϕ_2 is the literature quantum yield of Fe^{2+} pro-

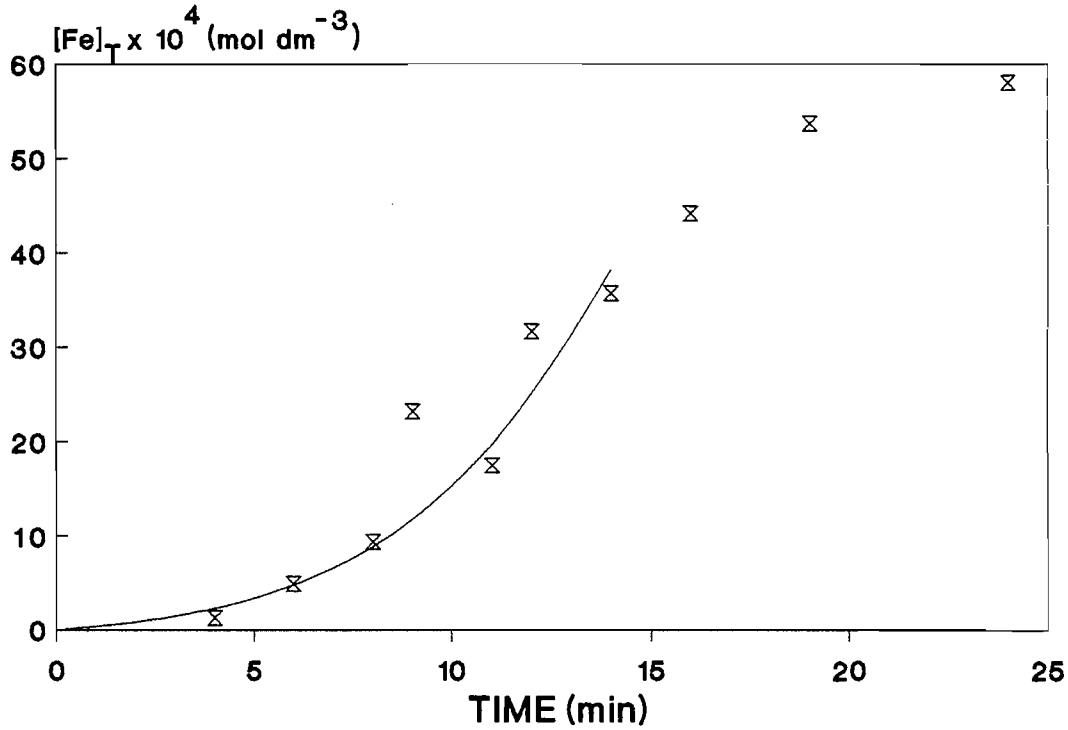

FIG. 6. Fitting of the 254-nm photodissolution curve for Fe_3O_4 in EDTA at 30°C and pH 3. Experimental data (⧖) are those of Fig. 1. Solid curve was obtained through the analytical solution of eqs. [22] and [23], taking $\tau' = 26$ min.

duction by homogeneous photolysis of Fe^{III} – EDTA (ca. 0.2 (55)); in agreement, k_2' is the same for all iron oxides.

Conclusions

1. The profiles f/t for the thermal and photochemical dissolution by carboxylic acids of the iron oxides studied in this paper exhibit different shapes, depending on the particular system. However, only one general mechanism is required to describe the dissolution of all the oxides, and the influence of dissolved ferrous ions and oxygen.

2. Oxygen inhibits the photodissolution in certain conditions: low rate of Fe^{II} production or any other case that warrants a high ratio of O_2/Fe^{II}. Conversely, a kinetic regime characterized by the fast production of high-surface Fe^{II} concentrations cannot be quenched by oxygen.

3. Spinel-type oxides are more reactive than α-Fe_2O_3, both in the direct reductive photodissolution and in the thermal dissolution by Fe^{II} complexes.

Appendix. List of symbols

c	dimensionless rate constant: $c = (1 + k_b/k_a)^{1/3}$ (eq. [10])
f	dissolved fraction of total iron (dimensionless); $f = (m_0 - m)/m_0$
I_0	total incident light intensity per unit solution volume (einstein s^{-1} dm^{-3})
k	rate constant (eq. [6]) (mol^{-1} dm^3 s^{-1} cm^{-2}); $k = \alpha\ (VM/m_0)\ k_{Th}$, where α is the adequate stoichiometric coefficient
k_a	(eq. [9]) (s^{-1}); $k_a = k_{Th}\ S_0/2$
k_b	(eq. [9]) (s^{-1}); $k_b = 3/2\ (VM/m_0)\ [Fe^{II}]_0\ k_{Th}\ S_0$
k_1	rate constant of Fe^{III}_{aq} production by phase transfer of Fe^{III} surface complexes (eq. [2]) (mol dm^{-3} s^{-1} cm^{-2})
k_2	rate constant of Fe^{II}_{aq} production by reduction and phase transfer of Fe^{III} surface complexes (eq. [3]) (mol dm^{-3} s^{-1} cm^{-2})
k_1'	photochemical initiation rate constant (eq. [15]) (mol dm^{-3} s^{-1} cm^{-2}); $k_1' = I_0\phi_1/S$
k_2'	homogeneous photolysis rate constant (eq. [16]) (s^{-1}); $k_2' = I_0\phi_2/[Fe^{III}]$
k_{ox}	second-order rate constant for the oxidation of Fe^{II} (eqs. [21], [22], and [23]) (mol^{-1} dm^3 s^{-1})
k_{Th}	rate constant of Fe^{III}_{aq} production by eq. [4] (s^{-1} cm^{-2})
K	Langmuir constant for the adsorption of Fe^{II} – EDTA complex (mol^{-1} dm^3)
m	instantaneous mass of the iron oxide (g)
m_0	initial oxide mass (g)
M	mass of oxide FeO_x per mole of iron atoms (g mol^{-1})
n	geometric parameter related to the shape of oxide particles (dimensionless)
N_s	total number of active sites per unit area (mol cm^{-2})
R	rate of O_2 ingress into the thermal system (mol dm^{-3} s^{-1})
R_0	dissolution rate (df/dt) independent of $[Fe^{II}]$ (eq. [5]) (s^{-1})
S	instantaneous surface area (cm^2)
S_0	initial surface area (cm^2)
t	reaction time (s)
t'	dimensionless time (eq. [10]); $t' = k_a\ t$
V	volume (dm^3)
x	(eq. [10]); $x = (1 - f)^{1/3}$ (dimensionless)
ϕ_1	apparent quantum yield for reaction [15] (mol $einstein^{-1}$); $\phi_1 = (d[Fe^{II}]/dt)/I_0$
ϕ_2	quantum yield of Fe^{II} production by homogeneous photolysis of Fe^{III}–EDTA (eq. [16]) (mol $einstein^{-1}$)
τ	time required to consume the initial added Fe^{2+} (eq. [13]) (s); $\tau = [Fe^{II}]_0/4R$
τ'	time required to generate enough Fe^{II} to suppress all oxidant (s); $\tau' = 4\ [O_2]_0/k_1'S_0$

CIC Medal address 1992[2]

It is nearly 50 years since I started a career in molecular spectroscopy as a graduate student with Dr. G. B. B. M. Sutherland at the University of Cambridge, England. I was given a Hilger D209 infrared spectrometer equipped with a rock salt prism and a Schwartz thermocouple. The output from the latter was fed into a galvanometer and amplified by means of an optical system consisting of a lamp, two mechanical grids, the galvanometer mirror, and a phototube. As the galvanometer mirror moved, the image of the first grid moved across the second grid and changed the current in the phototube. Several years later I saw a similar system in the laboratory of Professor R. V. Jones at Aberdeen who used it to measure the tilt of Scotland with the tides. Considerable work was going on at Cambridge (and Oxford) during the wartime years on the infrared spectra of hydrocarbons as a means for identifying the sources of fuel for enemy aircraft but I was asked to work on polymers. Finding the infrared spectra of substances like cellulose acetate difficult to interpret, I subsequently studied the spectra of a series of pyranose and furanose sugars. To simplify matters further I then studied the series cyclohexane (1), tetrahydropyran, 1:4 dioxane (2), and trioxane (3) in an attempt to understand the ring frequencies. There was also interest in whether the molecules exist in a chair or boat structure, which belonged to different symmetry groups with different numbers of infrared and Raman active fundamentals.

In July 1947 I commenced as a Junior Research Officer in the Organic Spectrochemistry group of the Division of Chemistry of the National Research Council. Dr. R. Norman Jones had compiled a catalogue of infrared spectra of a large number of ketosteroids and was working in collaboration with Dr. Konrad Dobriner of the Memorial Hospital in New York in an attempt to find a clue as to the origin of cancer. One interesting spectroscopic result was that the carbonyl frequency could be used as a fairly reliable diagnostic for the position of the carbonyl group in the ketosteroid framework (4). I decided to see if intensities could add any useful information. I made a study of methods which could be used to obtain accurate intensity measurements (to 1 or 2%) with infrared spectrometers of limited resolving power and produced a paper on the *Intensities and shapes of infrared absorption bands of substances in the liquid phase* (5), which later became a Citation Classic. We also published a paper on the intensities of carbonyl bands in the infrared spectra of steroids (6).

Two years later in July 1949, I transferred to the Division of Physics to work with Dr. G. Herzberg on the electronic spectra of free radicals. Dr. Herzberg was very keen to obtain a spectrum of CH_2 and suggested producing the radical by the photolysis of ketene or diazomethane and photographing the spectrum in absorption with a Lyman flash lamp. The importance of high resolution was also discussed since sensitive detection of absorption features requires a spectrograph with a resolving power similar to the widths of the lines being studied. So I built a flash photolysis apparatus and started looking for the spectra of free radicals using a 21 ft concave grating spectrograph. The first polyatomic free radical which we found was NH_2. Lines in the absorption spectrum matched features found in the emission spectrum of an oxy-ammonia flame. A Letter was promptly sent to the Journal of Chemical Physics (7) with a diagram and instructions that the spectral lines should show quite clearly in the final publication. Fortunately I received a proof, for I found that the spectral lines had been enhanced by hand without due regard for the relative intensities. In the meantime I had obtained stronger spectra and the journal agreed to accept a substitute diagram. In the final publication the lines appeared with about the same intensity as in the original diagram.

The next polyatomic free radical to be found was HCO, which has an extensive absorption system throughout the visible region (8, 9), a system quite different from the well-known hydrocarbon flame bands. Later, spectra of other polyatomic free radicals, e.g., PH_2 (10), NCO and NCS (11), CCO (12), HCCS (13), and C_5H_5 (14) were found as well as the spectra of several diatomic species. The technique has proved to be quite prolific and spectra of about 40 free radicals have been found over the years by workers in the Spectroscopy Group at Ottawa (15, 16).

The analysis of the NH_2 spectrum presented quite a challenge. The assignment of the spectrum to NH_2 was established by isotopic substitution using ^{15}N and D. The $^{14}N-^{15}N$ isotope shifts indicated that the angle in the upper state is approximately 160° (17) but in view of the alternation of band types in the spectrum the molecule was assumed to be linear. Subsequent work has now confirmed that the excited state is quasilinear with an equilibrium angle of 144° (18). By studying bands with similar rotational structures I was able to establish ground state combination differences and determine ground state rotational constants (19). The ground state of NH_2 has a structure very similar to the ground state of water. The spectrum consists of a very long progression of bands involving successive quanta of the bending vibration in the excited state. The rotational structures alternate, successive bands showing Σ and Π sub-bands respectively. The

[1]This article is based on the CIC Medal address delivered by Dr. Ramsay on June 1, 1992, at the 75th Annual Conference of the Canadian Society for Chemistry, Edmonton, Alberta.

[2]I wish to thank the CIC for awarding me this medal for 1992. I have been asked to record my address for posterity and do so in part here. The live address focussed more on recent research work which will appear in future publications; here I give an overview of my past activities, highlighting matters which I find particularly interesting, and filling in some of the details about what goes on behind the scenes.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

question remains, where are the other sub-bands which are expected? Eventually some Δ sub-bands were found by means of ground state combination differences but were found to lie about 110 cm^{-1} below the corresponding Σ sub-bands. Why this large separation? The clue was found in a comment in one of Mulliken's papers (20) which stated that "If $\Lambda = 1$, the Renner effect should, in general, cause relatively large energy differences between the different levels for a given v_2'." The two combining states of NH_2 are derived from a common $^2\Pi$ state in the linear configuration and large interactions may be expected between electronic and vibrational motions. Hence NH_2 was the first molecule in which the Renner effect was established (21, 22) although the magnitude of the effect was much larger than that considered by Renner (23). Work still continues on the spectrum of NH_2 and will do so for many years since there are numerous interactions between the rovibronic levels of the excited state and the high-lying levels of the ground state.

The HCO free radical provides another example of the Renner effect since the ground and excited states are derived from a common $^2\Pi$ state. All of the sub-bands, except for the Σ sub-bands, are diffuse, but by contour analysis of the latter the presence of the Renner effect has been established (24). One of the consequences is that bands with Σ sub-bands correspond to bands with *odd* values of the bending vibrational quantum number v_2'. In 1975 I had a 45 day visit from John Brown with the intention of finishing some work on magnetic rotation spectroscopy. On the third day we were discussing the HCO molecule and decided that we should try to confirm the vibrational numbering by attempting to observe the $H^{13}CO$ species in natural abundance. With our improved flash photolysis apparatus and path lengths up to 80 meters we did indeed observe the weak $H^{13}CO$ lines but in addition we found some weak lines of similar strength on the high-frequency side of the band head. These weak lines were produced by "axis-switching" (25) and enabled the determination of the *A*-rotational constant for the ground state for the first time. The work was completed within the 45 days and a paper submitted to the Herzberg issue of the Canadian Journal of Physics (26). Perhaps this illustrates the importance of allowing scientists the freedom to change course at short notice as ideas evolve.

I have had a number of summer students over the years with beneficial results. One of these was Ed Ballik who operated a King furnace and high-resolution infrared spectrometer with great skill. Our initial intention was to flow gases through the furnace rapidly and to look for transient species. We found a rich spectrum even when the furnace was evacuated and this turned out to be a new infrared band system of the C_2 molecule. One day Ed came to me with about a mile of chart paper and said that there was one line out of position. I confirmed his diagnosis and some time later was able to show that it was caused by a weak singlet–triplet perturbation. The outcome of this work was that it established that the ground state of the molecule is the lowest singlet state and not the lowest triplet state. This result was at first regarded as heresy since the Swan bands (a triplet system) are prominent in the spectra of comets. However the analysis of six singlet–triplet perturbations yielded the same result, namely, that the lowest singlet state lies below the lowest triplet state by 610 ± 5 cm^{-1} (27). The question remains, why are the Swan bands so prominent in the spectra of comets?

Another summer student was Maurice Clement. We decided to look for emission from the reaction of H atoms with NO. An apparatus was assembled in 2 days and the first exposure taken on a prism spectrograph showed a rich spectrum and a series of line-like features. Measurement of these features established them to be *R*-heads of sub-bands of the $\tilde{A}^1A'' - \tilde{X}^1A'$ system of HNO. The sub-bands involve much higher values of K' than seen in the absorption spectrum of HNO (28) and come to an abrupt halt after $K' = 13$ for the 000 level. This phenomenon is reminiscent of the well-known breaking-off in the rotational structures of diatomic molecules (29) and is caused by predissociation in the upper state. Breaking-off in the *K*-structures was observed at different K' values for two bands of HNO and three bands of DNO and gave consistent values for the upper limit for the dissociation energy of the molecule (30). This was the first example of breaking-off in the rotational structure of a polyatomic molecule and 30 years later is still the only example. Clement decided that experimental work was too easy and became a theoretician.

In 1962 I had the good fortune to meet Fraser Birss at the University of Alberta, Edmonton, and we forged a collaboration which lasted 25 years. He developed computer programmes for analysing singlet–singlet and triplet–singlet transitions of asymmetric top molecules of which only the former has been published (31). This programme was used initially for analysing many bands of the 4550 Å band system of *trans*-glyoxal and its isotopic derivatives (32–35). During these studies some weaker bands were found which gave the first evidence for the existence of the *cis* isomer (36). These results have had extensive applications in the field of photochemistry and the study of collisional processes (37).

The triplet–singlet programme has been used for obtaining rotational constants and spin constants of formaldehyde (38, 39), propynal (40), and glyoxal (41). By the application of electric fields, dipole moments were determined for formaldehyde (42) and propynal (43) in their triplet states as well as for CS_2 (44).

In 1970 we constructed a magnetic rotation apparatus and used it initially to detect triplet–singlet bands (45). However, we found that it also provided a sensitive method for detecting singlet–triplet perturbations in molecules and extensive studies were carried out on formaldehyde and its isotopic derivatives (46–50). These results were of direct interest to several groups of photochemists who at that time were carrying out lifetime measurements and fluorescence yields of single rovibronic levels of the $\tilde{A}^1A_2$ state (51). Further work on thioformaldehyde (H_2CS) led to the elucidation of the mechanism for the singlet–triplet perturbations observed in the zeroth level of the $\tilde{A}^1A_2$ excited state. The perturbations are caused by a vibronic spin-orbit interaction with a level of the $\tilde{a}^3A_2$ state and matrix elements have been evaluated (52).

The thioformaldehyde molecule has proved to be a valuable test molecule for many experiments. Advantages are that rotational analyses of bands of the $\tilde{a}^3A_2$–$\tilde{X}^1A_1$ and $\tilde{A}^1A_2$–$\tilde{X}^1A_1$ systems are available and that the bands lie in convenient regions for excitation with rhodamine dyes. Hang Fung carried out intermodulated fluorescence studies of some *K*-doublets and found that the measured splittings did not agree with the values calculated from the rotational constants. The discrepancies were in the range 10–300 MHz. We concluded that the excited state levels were perturbed by high

For personal use only.

rovibronic levels of the ground state (53). This result was confirmed by microwave–optical double resonance experiments (54). Similar results were obtained from microwave–optical double resonance measurements on HNO and DNO (55, 56). Two other interesting results emerged from the double resonance experiments. First, a large number of microwave lines were observed which could not be assigned to transitions in either the excited state or the ground state. These lines have been assigned to transitions from rovibronic levels of the $\tilde{A}^1A_2$ excited state to high rovibronic levels of the ground state (57, 58). Second, the technique has been found to provide a very powerful method for studying rotational "selection rules" in molecular collisions. A specific level in the electronically excited state can be monitored by means of a strong microwave transition to a high rovibronic level of the ground state. The optical laser can then be scanned to excite various rovibronic levels in the excited state and the efficiency by which these levels are converted by collisions to the level being monitored is measured by the intensity of the microwave signal. This technique provides a rapid coverage of a wide range of rotational levels (59).

I have had a continuing interest for many years in astrophysical problems. With Werner Goetz a 33 meter absorption tube was constructed and equipped with multiple reflection mirrors. By filling the tube with methane at pressures up to 1.6 atmospheres (1 atm = 101.3 kPa) and using path lengths up to 5 km it was possible to match some of the bands observed in the spectrum of the atmosphere of Uranus (60). Also by filling a similar tube of smaller volume with HD the 3–0, 4–0, 5–0, and 6–0 vibrational bands were observed and from the measured frequencies and intensities it was possible to determine a value for the D/H ratio in Jupiter (61). The larger tube was also filled with oxygen and several new bands of the Herzberg I, II, and III systems were found (62–64). I have also been able to record high-resolution spectra of the comets Halley and Wilson on the Anglo-Australian telescope; these data are still being evaluated.

Recently I entered into a fruitful collaboration with Professor Ewald Fink of the University of Wuppertal, Germany. Fink has shown that near-infrared emissions can be excited by energy exchange between $^1\Delta_g$ oxygen molecules and other species with low-lying excited states. So far the b–X systems of all the Group VI – Group VI diatomic molecules, and also some bands of the a–X systems, have been recorded at high resolution with a Fourier-transform spectrometer. Some of these results are already published (65–69). The spectrum of SeS was particularly strong, and weak magnetic dipole transitions were observed in the same band as the strong electric dipole transitions. In addition, the weak electric quadrupole transition of oxygen, $b^1\Delta_g$–$a^1\Sigma_g^+$, has been recorded at high resolution and the O and S branches observed in addition to the P, Q, and R branches (70). At higher pressures (up to 10 Torr; 1 Torr = 133.3 Pa) and with added gases a continuous absorption is seen underneath the discrete structure and is attributed to collision-induced emission (71). Other diatomic molecules which have been excited are those with a large spin-orbit splitting in the ground state. Examples are TeH (72) and BiH (73), which have $^2\Pi$ and $^3\Sigma$ ground states respectively. Also the series HO_2, HS_2, HSe_2, and HTe_2 has given extensive spectra.

In conclusion I wish to thank many persons who have had a beneficial influence on my career. My parents, though not scientists, always encouraged me follow my own inclinations as long as I considered that I was making progress. My chemistry master at school, Mr. G. F. Fowles, spent many hours giving me private tuition when I was in the Sixth Form. My undergraduate supervisor at University, Dr. F. S. Dainton (now Lord Dainton of Hallam Moors), worked me hard and effectively. My research supervisors, Dr. G. B. B. M. Sutherland and Professor E. K. Rideal, were always helpful and inspiring. At the National Research Council I have benefitted from the philosophies of Drs. E. W. R. Steacie and G. Herzberg, who believed that one should select persons carefully and give them the freedom and support to follow their own ideas. I have enjoyed the collaboration with numerous Postdoctoral Fellows, Research Associates, Summer Students, and Visiting Research Scientists. Finally I wish to acknowledge the highly professional and loyal support of two Technical Officers, Werner Goetz and Mike Barnett, each of whom has assisted me for more than 25 years.

Received March 6, 1992

SHARIFA S. ALKAABI and AHMAD S. SHAWALI Can. J. Chem. **70**, 2515 (1992).

The kinetics of the reactions of a series of (*Z*)-4-arylidene-2-phenyl-5(4*H*)oxazolones **1** with *n*-butylamine and piperidine were studied spectrophotometrically in dioxane, ethanol, and cyclohexane under pseudo-first-order conditions and at different temperatures. The relation $k_1(\text{obs}) = k_2[\text{amine}] + k_3[\text{amine}]^2$ was found applicable for all reactions studied in either dioxane or ethanol. However, in cyclohexane the *n*-butylaminolysis of **1** followed only third-order kinetics $k_1(\text{obs}) = k_3[n\text{-BuNH}_2]^2$. The kinetics of the reaction of **1** with *n*-butylamine in the presence of catalytic amounts of triethylamine in dioxane followed the equation: $k_1(\text{obs}) = k_2[n\text{-BuNH}_2] + k_3[n\text{-BuNH}_2]^2 + k_3'[n\text{-BuNH}_2]\,[\text{Et}_3\text{N}]$. The rate constants k_2 and k_3 correlated well with the Hammett equation and the corresponding activation parameters were determined. The results were interpreted in terms of a mechanism involving solvent- and amine-catalyzed processes.

SHARIFA S. ALKAABI et AHMAD S. SHAWALI. Can. J. Chem. **70**, 2515 (1992).

Faisant appel à des méthodes spectrophotométriques et opérant dans le dioxanne, l'éthanol et le cyclohexane, à différentes températures, dans des conditions de pseudo-premier-ordre, on a déterminé la cinétique des réactions d'une série de (*Z*)-4-arylidène-2-phényl-5(4*H*)oxazolones (**1**) avec la *n*-butylamine et la pipéridine. On a trouvé que la relation $k_1(\text{obs}) = k_2[\text{amine}] + k_3[\text{amine}]^2$ peut s'appliquer à toutes les réactions étudiées, soit dans le dioxanne ou l'éthanol. Toutefois, dans le cyclohexane, la *n*-butylaminolyse du produit **1** ne suit qu'une cinétique du troisième ordre, $k_1(\text{obs}) = k_3[n\text{-BuNH}_2]^2$. La cinétique de la réaction du produit **1** avec la *n*-butylamine en présence d'une quantité catalytique de triéthylamine dans le dioxanne suit l'équation : $k_1(\text{obs}) = k_2[n\text{-BuNH}_2] + k_3[n\text{-BuNH}_2]^2 + k_3'[n\text{-BuNH}_2]\,[\text{Et}_3\text{N}]$. Il existe une bonne corrélation entre les constantes de vitesse k_2 et k_3 et l'équation de Hammett et on a déterminé les paramètres d'activation. On interprète les résultats en fonction d'un mécanisme impliquant des processus catalysés par le solvant et l'amine.

[Traduit par la rédaction]

Although 4-arylidene-2-phenyl-5(4H)-oxazolones **1** were reported more than a century ago (1) and their reactions with various nucleophilic reagents have been extensively studied (2–9), the kinetics and mechanism of their ring cleavage by nitrogen nucleophiles have received little, if any, attention. Recently, in a study designed to determine the steric effect of remote substituents on peptide bond formation, it was reported that the reaction of (*Z*)-4-benzylidene-2-phenyl-5(4*H*)-oxazolone with benzylamine in acetonitrile followed second-order kinetics (10). This result seems surprising since the reaction of compounds **1**, being cyclic esters, with nitrogen nucleophiles in aprotic solvent would be expected to exhibit a kinetic pattern similar to that reported for aminolysis of acyclic esters. Extensive kinetic studies, in our laboratory and others, on the aminolysis of acyclic esters in aprotic solvents established that such reactions are subject to general base catalysis (11–23). Thus, under pseudo-first-order conditions the reactions of esters with primary amine (A) and in the presence of a tertiary amine (B) were found to follow the rate law: $k_1(\text{obs}) = k_2[\text{A}] + k_3[\text{A}]^2 + k_3'[\text{A}][\text{B}]$. In a few cases the k_2 term was not observed (16, 21, 22).

Since compounds **1** are versatile intermediates in the syntheses of peptides and didehydroamino acids (24), it was thought important to investigate in some detail the kinetics of their aminolysis to shed light on the mechanism of their ring cleavage by amines in both aprotic and protic solvents. For this purpose we studied the kinetics of the reactions of a series of (*Z*)-4-arylidene-2-phenyl-5-(4*H*)-oxazolones **1***a–i* with *n*-butylamine in dioxane, ethanol, and cyclohexane at different temperatures under pseudo-first-order conditions. The other objective of the present study was to determine both solvent and substituent effects on the aminolytic reactivity of **1**.

Results and discussion

(*Z*)-4-Arylidene-2-phenyl-5(4*H*)-oxazolones **1***a–i* were prepared from hippuric acid and the appropriate substituted benzaldehyde in the presence of acetic anhydride and anhydrous sodium acetate according to the Erlenmeyer method (25). The *Z* configuration indicated was based on the fact that the latter method of synthesis of **1** was reported to give the thermodynamically more stable *Z* isomer (6, 26–28). The *E* isomer of **1** is obtained by isomerization of the *Z* isomer with hydrobromic acid (6, 25).

The reaction of **1***d*, taken as a typical example of the **1***a–i* series studied, with *n*-butylamine in dioxane at 31°C takes place quantitatively according to eq. [1].

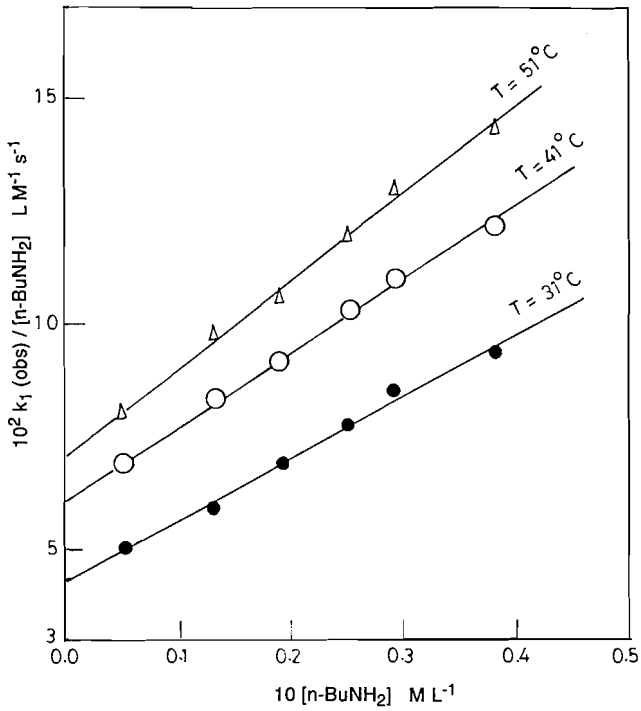

FIG. 1. Plots of k_1(obs)/[amine] against amine concentration for the reaction of azalactone **1***d* with n-butylamine in dioxane at different temperatures.

The reaction product was proved to be *N*-*n*-butyl-2-benzoylaminocinnamamide **2**. In anhydrous dioxane the reaction kinetics of each of **1***a–i* with tenfold excess or more of n-butylamine in the temperature range 31–51°C is pseudo-first-order with respect to **1** to at least 95% completion. The plot of the pseudo-first-order rate constant, k_1(obs), vs. n-butylamine concentration was not linear. However, the plot of k_1(obs)/[amine] against [amine] was, in each case, linear as shown in Fig. 1. Such plots indicate that the n-butylaminolysis of **1** in dioxane in the temperature range 31–51°C follows the rate equation [2]:

[2] $k_1(\text{obs}) = k_2[n\text{-BuNH}_2] + k_3[n\text{-BuNH}_2]^2$

Values of constants k_2 and k_3 were calculated, using the least-squares method, from the slopes and intercepts, respectively, of plots like those shown in Fig. 1. The data are summarized in Table 1. The correlation coefficients of such plots were in the range 0.986–0.990.

In ethanol the reaction of **1***a* with n-butylamine at 31°C followed eq. [2] as shown in Fig. 2. However, simple third-order kinetics were found for the reaction of **1***a* with n-butylamine in cyclohexane at 31°C (Fig. 2). In this case the reaction kinetics followed the rate equation [3].

[3] $k_1(\text{obs}) = k_3[n\text{-BuNH}_2]^2$

TABLE 1. Second- and third-order rate constants of the reactions of (*Z*)-4-arylidene-2-phenyl-5(4*H*)oxazolones **1***a–i* with n-butylamine in dioxane at 31°C

1*f*	0.90	2.75	1.13	2.00	1.40	3.18

[a] k_2, L mol^{-1} s^{-1}; k_3, L^2 mol^{-2} s^{-1}; ±0.06–0.25 and ±0.09, respectively.

$$[4]\quad k_1(\text{obs}) = k_2[n\text{-BuNH}_2] + k_3[n\text{-BuNH}_2]^2 + k_3'[n\text{-BuNH}_2][\text{Et}_3\text{N}]$$

The value of constant k_3' is given in Table 2.

The activation parameters, E_a and ΔS^*, were calculated from the least-squares fit of the data at different temperatures (Table 3) using eqs. [5] and [6], respectively, and the values are given in Table 4.

$$[5]\quad \ln k_1 = \ln A - (E_a/RT)$$

$$[6]\quad \ln A = \ln (RT/Nh) + (\Delta S^*/R)$$

The value of the term ln (RT/Nh) equals 29.53 at 314 K.

The present kinetic data obtained in dioxane or ethanol suggest that the *n*-butylaminolysis of **1** proceeds via concurrent second-order and third-order processes. The former process corresponds to a solvent-catalyzed reaction, whereas the latter represents an amine-catalyzed process. Another possibility for the quadratic third-order term in eq. [2] or [3] is that it may represent a reaction between **1** and an amine dimer. However, the present results exclude the involvement of such amine dimers in the aminolysis of **1**. This is because, if the amine dimer is catalytically active, it would be expected that as the amine concentration increases, the monomeric species would decrease and, in turn, the second-order term would disappear at high amine concentration. On the other hand, if the amine dimer were inactive a falloff in rate would be expected at high amine concentration. Neither expectation was observed experimentally.

The simplest stepwise mechanism that seems compatible with the present kinetic data is outlined in Scheme 1. Consistent with this mechanism are the following observations: (*i*) the disappearance of the k_2 term for the reaction of **1***d* with *n*-butylamine in cyclohexane; (*ii*) the rate acceleration observed when triethylamine is added to the reaction mixture; and (*iii*) the higher value of k_2 for the reaction of **1***d* with *n*-butylamine in ethanol as compared to that obtained for the same reaction in dioxane (Table 2).

The overall second-order and third-order rate constants (k_2 and k_3, respectively) were correlated with the Hammett substituent constant σ (29). The results of such correlations are summarized in Table 5. The ρ values indicate that both solvent- and amine-catalyzed reactions exhibit similar sensitivities towards substituent and that both are favoured by electron-withdrawing groups in the benzylidene moiety. The sensitivity is, however, small. This is because the ρ values for aminolysis comprise contributions from both steps of the indicated mechanism (Scheme 1). An electron-withdrawing substituent in the benzylidene moiety, while having a favorable effect on the first step, inhibits the ring opening. The net ρ value should be small, and this is what is observed experimentally. Furthermore, the similarity between the ρ values for the k_2 and k_3 processes indicates that both processes have a common intermediate whose collapse to products, by the help of either solvent or amine molecules, is rate determining. This is substantiated by the observation that the rate constant ratios (k_3/k_2) are approximately constant (Table 1). This finding is also consistent with the suggested mechanism outlined in Scheme 1.

The observed higher rate of aminolysis of **1***d* in ethanol as compared to that in dioxane may be viewed as a general acid catalysis. This rationalization is consistent with the re-

TABLE 4. Activation parameters for the second- and third-order processes of *n*-butylaminolysis of oxazolones **1** in dioxane[a]

ported rate acceleration by the hydroxyl group in the aminolysis of salicylate in nonhydroxylic solvents (19).

Table 4 lists Arrhenius activation energies and entropies of activation for the second- and third-order processes of *n*-butylaminolysis of three representative compounds of the series studied. As expected, the energy of activation of the amine-catalyzed process is lower than that of the corresponding solvent-catalyzed process. In addition, the data show that the energy of activation for both the second- and third-order processes exhibits a regular variation with the substituent in the benzylidene moiety: an electron-withdrawing group decreases the energy of activation and in turn increases the reaction rate, while the reverse is true for an electron-donating group.

The large negative entropies of activation are as expected for bimolecular and termolecular reactions (30). The small differences between the entropies of activation for the second-order and third-order processes probably reflect small variations in solvation of the corresponding transition states.

Experimental section

Melting points were determined on an Electrothermal capillary apparatus and are uncorrected. Infrared spectra were measured with a Pye–Unicam SP3-100 spectrophotometer. A Beckman DJ-70 spectrophotometer with electrically thermostated jacketed cell compartment was used for recording the electronic absorption spectra and kinetic measurements. The solvents, dioxane, ethanol, and cyclohexane, were BDH AnalaR grade and were used without further purification. *n*-Butylamine and piperidine were BDH reagents and purified before use as previously described (16). (*Z*)-4-Benzylidene-2-phenyl-5(4*H*)-oxazolone **1***d* and its substituted derivatives were prepared from *N*-benzoylglycine and the appropriate benzaldehyde in the presence of acetic anhydride and anhydrous sodium acetate according to the Erlenmeyer method (31). The compounds were crystallized from ethanol to constant melting points, which agreed with those previously reported (32).

TABLE 6. Characteristic ultraviolet maxima for (*Z*)-4-benzylidene-2-phenyl-5(4*H*) oxazolone and its substituted derivatives in dioxane

1*d*	360	**1***i*	378
1*e*	368		

Kinetics

The reactions were carried out in a 1-cm ground-glass stoppered, fused silica, absorption cell. The reference solution was that of the solvent used containing an amine concentration equal to that being used in the particular kinetic run. The reactions were followed by rate of disappearance of 4-arylidene-2-phenyl-5(4*H*)oxazolone absorption maximum (Table 6). The reaction products showed no absorption in the region of maximum absorption of **1***a–i*. For example, the complete spectrum of each kinetic run for the reaction of **1***d* with *n*-butylamine corresponded to the spectrum of *N*-*n*-butyl-2-benzoylaminocinnamamide solution of the same concentration. Beer's law was found to be obeyed within the concentration and wavelength ranges employed.

Stock solutions of **1***a–i*, usually about 10^{-2} M, were prepared. Stock amine solutions were prepared and the concentration determined by titration. Appropriate concentrations of amine and azalactone **1** were prepared by dilution of the stock solutions with the appropriate solvent. All azalactone concentrations were 5×10^{-4} M.

Reactions were followed up to 95% completion under pseudo-first-order conditions in which at least a tenfold excess of amine over azalactone was used. Duplicate or triplicate runs were performed for each concentration and readings taken in any kinetic run covered a range of 90% transmittance. The pseudo-first-order rate constants, k_1(obs), were calculated from log $(A_t - A_\infty)$ against time, t, data using the least-squares method. A_t and A_∞ are the absorbances of the reaction mixture at time t and infinite time, respectively. The average deviation from the mean value of the rate constant in duplicate or triplicate experiments was ±5% or less.

Identification of the reaction product

n-Butylamine (0.73 g, 0.01 mol) was added to a solution of **1***d* (0.002 mol) in dioxane (20 mL). The reaction mixture was immersed in a constant temperature water bath at 31 ± 0.1°C. After 24 h, the white solid that separated out was filtered. Crystallization from ethanol gave *N*-*n*-butyl-2-benzoylaminocinnamamide **2** in 85% yield, mp 190–191°C (lit. (33) mp 190°C); IR (KBr): 3265 (NH), 1640, 1667 (CO), 1520 (C=C) cm^{-1}; UV (dioxane), λ_{max} (log ε): 220 (4.292), 276 (4.218) nm; ^{1}H NMR ($CDCl_3$) δ: 0.72 (3H), 1.16 (2H), 1.34 (2H), 3.12 (2H), 6.85 (1H), 7.0–7.45 (5H), 7.78 (5H), 7.82 (1H), 9.10 (1H) ppm. Anal. found: calcd. for $C_{20}H_{22}N_2O_2$: C 74.51, H 6.88, N 8.69%; found: C 74.45, H 6.90, N 8.63%.

The reaction of boron trichloride – tertiary amine adducts with pseudohalide salts under phase transfer catalysis conditions

JEAN ATCHEKZAÏ, BERNARD BONNETOT, HENRI MONGEOT, SAMI BOUFI, AND BERNARD FRANGE[1]
Laboratoire de physicochimie minérale 1, 43 boulevard du 11 novembre 1918, 69622 Villeurbanne CEDEX, France

Received January 29, 1992

JEAN ATCHEKZAÏ, BERNARD BONNETOT, HENRI MONGEOT, SAMI BOUFI, and BERNARD FRANGE. Can. J. Chem. **70**, 2520 (1992).

The reaction of boron trichloride – tertiary amine adducts $D \cdot BCl_3$ with pseudohalide salts MX was investigated in a homogeneous medium or in two-phase systems under liquid/liquid or solid/liquid phase transfer catalysis conditions (PTC) as a potential route to the adducts $D \cdot BX_3$ (X = NCS, NCO). Best results were obtained with solid/liquid PTC with tetraglyme as catalyst. By suitable choice of the tertiary amine, solvent, and stoichiometry, the symmetric compounds $D \cdot BX_3$ were thus prepared with good yields, the same reaction leading either to mixed species $D \cdot BX_{3-n}Cl_n$ (n = 1, 2; X = NCS, NCO) or to the tetrapseudohaloborate anions BX_4^- (X = NCS, NCO). The mixed tetrahaloborates $BX_{4-n}Y_n^-$ could be obtained by exchange reaction from $BX_4^- + BY_4^-$ (X = NCS, Y = F, Cl, Br) or from BY_3 + Bu_4NX (X = NCS; Y = F, Cl, Br; X = NCO; Y = F). All these compounds were characterized by ^{11}B and, in one case, by ^1H and ^{13}C NMR. Pairwise additivity is observed for the ^{11}B NMR chemical shifts.

JEAN ATCHEKZAÏ, BERNARD BONNETOT, HENRI MONGEOT, SAMI BOUFI et BERNARD FRANGE. Can. J. Chem. **70**, 2520 (1992).

Nous avons étudié la réaction des complexes amine tertiaire – chlorure de bore $D \cdot BCl_3$ sur différents composés pseudohalogénés MX en opérant en milieu homogène ou hétérogène dans les conditions de la catalyse par transfert de phase (CTP) liquide/liquide ou solide/liquide. Les meilleurs résultats ont été obtenus par CTP solide/liquide avec le tetraglyme comme catalyseur. Les complexes symètriques $D \cdot BX_3$ (X = NCS, NCO) ont ainsi été préparés avec de bons rendements alors qu'en modifiant les conditions opératoires (solvant et stoechiomètrie), on obtient soit les dérivés mixtes $D \cdot BX_nCl_{3-n}$ (n = 1, 2; X = NCS, NCO) soit les ions tétrapseudohaloborates BX_4^- (X = NCS, NCO). Nous avons également obtenu les ions mixtes $BX_{4-n}Y_n^-$ par réaction d'échange entre BX_4^- et BY_4^- (X = NCS; Y = F, Cl, Br) ou BY_3 et Bu_4NX (X = NCS; Y = F, Cl, Br; X = NCO; Y = F). Tous ces dérivés ont été caractèrisés par RMN du ^{11}B et, dans un cas, par RMN du ^1H et du ^{13}C. Nous avons constaté que les déplacements chimiques du ^{11}B obéissent aux règles d'additivité.

Introduction

In a previous note (1), we reported our preliminary results concerning the reaction of KSCN with the adducts $C_6H_5CH_2NMe_2 \cdot BCl_3$, $BDMA \cdot BCl_3$, in an aromatic solvent with tetraglyme added as catalyst. In this paper, the scope of this new approach is investigated in a systematic way, aimed at preparing new adducts, mixed species, or tetrahaloborates anions by means of very simple methods. Thus, we were led to study the reaction of tertiary amine – boron trichloride adducts $D \cdot BCl_3$ (D = *N*,*N*-dimethylbenzylamine BDMA, *N*,*N*-dimethyloctylamine ODMA, and *N*,*N*-dilaurylamine LDMA) with thiocyanate and cyanate salts under various conditions, the relevant adducts being quite difficult (or impossible) to prepare by direct synthesis. The reaction was carried out in a refluxing aromatic solvent with a tetrabutylammonium salt, in two-phase liquid/liquid systems H_2O(NaOH)/organic solvent or in solid/liquid medium, a potassium (or sodium) salt being used in the latter case. The tertiary amines used are those whose adducts with boron halides are potential latent catalysts in the polymerization of epoxy resins (2). Further, these adducts are quite stable to moisture and could be kept in air for long periods of time without any degradation, at odds with the behaviour of related adducts that usually fume in air.

Experimental part

Physical measurements

NMR spectra were obtained with a Bruker AM 300 spectrometer at 96.28 MHz for ^{11}B with $BF_3 \cdot Et_2O$ as external reference (positive values downfield), and at 300 MHz for ^1H and 75 MHz for ^{13}C with TMS as reference in both cases. To obtain accurate values for the coupling constants, zero filling and Gaussian multiplication were applied prior to Fourier transformation, as reported earlier (3, 4). Typical ^{11}B NMR spectra were run with a spectral width of 20 000 Hz and 16 K data points. A least-squares fitting routine was used for the calculation of pairwise parameters $n_{i,j}$. Melting points were determined by differential scanning calorimetry (DSC). Elemental analyses were carried out by standard combustion at 1050°C for C, H, and N, the nitrogen oxides being reduced to nitrogen; S analysis was by combustion at 1400°C.

Materials

All reactions were performed under an atmosphere of dry argon. Tetraglyme was freshly distilled from sodium benzophenone; aromatic solvents were distilled over phosphorus pentachloride and stored over molecular sieves. Tetrabutylammonium cyanate was a commercial product (Fluka) and used as received. All reactions with the latter and with air-sensitive compounds were performed in an efficient dry-box.

Preparation of $D \cdot BX_3$ adducts

These were obtained by reaction of BX_3 with the suitable amine in hexane while stirring and cooling the mixture. The creamy slurry obtained was filtered, washed with several portions of hexane, and air dried. It was then thoroughly washed with cold water, dried again under vacuum at 100°C, and dissolved in dichloromethane. The solution was finally poured on a Florisil column (SiO_2/MgO 85:15) to remove any ionic impurity, providing analytical samples after recrystallization (CH_2Cl_2/hexane 1:1). The reaction was applied to $BDMA \cdot BX_3$ (X = F, Cl, Br, I), $ODMA \cdot BCl_3$, and $LDMA \cdot BCl_3$. The values reported for the ^1H, ^{13}C, and ^{11}B chemical shifts and coupling constants of $BDMA \cdot BX_3$ (X = F, Cl, Br, I, NCS) are summarized in Table 1.

[a]This long-range proton–boron coupling constant involves the methyl protons, consistent with earlier observations on $Me_3N \cdot BX_3$ adducts (5). In every case, the benzyl protons display an unresolved singlet.

[b]No $^2J(^{11}BC)$ could be detected with any of these compounds. Such behaviour is not uncommon with boron tetrahedral derivatives. Thus, in $B(C_6H_5)_4^-$, the $^2J(^{11}BC)$ is significantly smaller than the relevant ^3J, 1.5 vs. 2.7 Hz (6). For mixed tetraalkylborates, no $^2J(^{11}BC)$ has been found whereas a ^3J of about 4.0 Hz was measured (7). Further, similar trends are observed in organic chemistry, where $^2J(CH) << {}^3J(CH)$ for aromatic compounds.

[d]From ref. 9.

Preparation of BDMA · B(NCS)$_3$

This preparation was reported earlier (1). Anal. calcd. for $C_{12}H_{13}N_4S_3B$: C 45.00, H 4.09, N 17.50, S 30.03, found: C 44.87, H 4.11, N 17.73, S 29.35.

Preparation of LDMA · B(NCS)$_3$

The reaction was carried out for 4 h in refluxing chlorobenzene with the molar ratio D · BCl_3/KNCS/TTG 1:9:0.2. After filtration, the clear solution was poured through a short column of Florisil, giving 60% of pure LDMA · $B(NCS)_3$, δ ^{11}B = −9.9 ppm (CH_2Cl_2), F = 30°C (DSC). Anal. calcd. for $C_{17}H_{31}N_4S_3B$: C 51.24, H 7.84; found: C 51.02, H 7.75.

Preparation of B(NCO)$_3$ adducts

The reaction was carried out in refluxing chlorobenzene for 8 h with a molar ratio D · BCl_3/NaNCO/TTG 1:9:0.2. After the same work-up as above, 80% of pure LDMA · $B(NCO)_3$ was obtained; δ ^{11}B = −6.1 ppm, F = 45°C. Anal. calcd. for $C_{17}H_{31}N_4O_3B$: C 58.29, H 8.92; found: C 57.92, H 8.75. ΔH_f = 90 J/g (DSC). The same reaction was applied to ODMA · BCl_3 in refluxing chlorobenzene for 5 h giving, after chromatographic treatment and recrystallization from CH_2Cl_2/hexane, 50% of pure ODMA · $B(NCO)_3$. Anal. calcd. for $C_{13}H_{23}N_4O_3B$: C 53.07, H 7.88; found: C 52.84, H 7.82. Finally, after refluxing BDMA · BCl_3 with NaNCO in chlorobenzene for 8 h, 95% BDMA · $B(NCO)_3$ was obtained together with 5% $B(NCO)_4^-$ (−6.0 and −11.6 ppm according to ^{11}B NMR). After the same work-up, 70% of pure BDMA · $B(NCO)_3$ was obtained. Anal. calcd. for $C_{12}H_{13}N_4O_3B$: C 52.97, H 4.81; found: C 52.72, H 4.67.

Preparation of NBu_4NCS

This was obtained according to a classical method (10) starting from NBu_4Br and KNCS in acetone, at room temperature for 12 h. After filtration of KBr (97%), the solution was evaporated to dryness and the solid residue twice recrystallized from hexane/

ethyl acetate 1:1 to give 60% of slightly yellow needles (F = 126–127°C (lit. (10) 123–125°C).

Preparation of tetrahaloborate anions

These were prepared by classical methods according to the reaction $BX_3 + NBu_4X$ (X = Cl, Br, I) performed in a dry-box with a suitable solvent. BF_4NBu_4 was obtained in the two-phase system $NaOH/CH_2Cl_2$ as already reported (3).

Reaction of $BF_3 \cdot Et_2O$ with NBu_4NCO

Mixing equimolar amounts of $BF_3 \cdot Et_2O$ and NBu_4NCO in dichloromethane, inside the dry-box, resulted in a slight precipitate with a broad signal in ^{11}B NMR spectroscopy ($\delta\ ^{11}B = -1.4$ ppm, $h_{1/2}$ = 150 Hz). After a few minutes, the signal became asymmetric and, after heating for short periods of time, a sharp signal appeared at −1.4 ppm, followed by broad, decreasing intensity signals at −2.4, −4.0, −7.4, and −11.5 ppm, consistent with the presence of the expected mixed species $BF_n(NCO)_{4-n}^-$. However, broad, unaccounted-for signals were also present downfield at −0.4 and +0.2 ppm. The compounds so obtained were quite stable in solution and could be recovered unchanged after several weeks.

Reaction of BCl_3 with NBu_4NCO

When bubbling BCl_3 in slight excess through a solution of NBu_4NCO in CH_2Cl_2, a slight precipitate was first observed, whereas a clear solution resulted if using the reverse order. The ^{11}B NMR spectrum of the fresh solution, besides the very sharp signal of BCl_4^- (7.2 ppm, $h_{1/2}$ about 4 Hz), contains two major signals at 30.4 and 22.4 ppm indicative of a substitution of BCl_3. With a larger excess of boron trichloride (6:1), the signal of free BCl_3 was also observed near 40 ppm, this latter signal being quite sensitive to concentration effects. Additional very small signals were also detected between 7.2 and 1.5 ppm in the ^{11}B NMR spectra but none could be attributed to $BCl_n(NCO)_{4-n}^-$ except for the one at 1.5 ppm (probably BCl_3NCO^-), still present in solution after several weeks.

Reaction of BBr_3 with NBu_4NCO

With boron tribromide and NBu_4NCO in CH_2Br_2, results obtained are still more complex. Adding the reactants in a 1:1 ratio, signals at 28.0 and 20.7 ppm denote the substitution reaction of BBr_3, whereas a very broad signal whose chemical shift ranges from −10 ppm to −14 ppm corresponds to an exchange reaction. Further, signals at −1.9, −7.6, and −9.2 ppm, still observed after several weeks, are clearly indicative of a reaction of BBr_3 on the NCO moiety. Adding BBr_3 in excess to NBu_4NCO in the same solvent resulted in a quite different ^{11}B NMR spectrum: a sharp signal (−25.4 ppm, $h_{1/2}$ = 6 Hz) pertains to BBr_4^- whereas a broad one (−19.7, $h_{1/2}$ = 29 Hz) is likely to belong to $BBr_2(NCO)_2^-$ originating from the disproportionation of BBr_3NCO^-, as deduced from the areas under the signals.

Results and discussion

Homogeneous vs. phase transfer reactions

Homogeneous medium

In this case, NBu_4NCS reacted with $LDMA \cdot BCl_3$ in xylene at different temperatures. Thus, in a typical run at 100°C, after 2 h a complex mixture was observed containing, according to ^{11}B NMR integration, $D \cdot BCl_3$ (27.6%), $D \cdot BCl_2NCS$ (23.0%), BCl_3NCS^- (9.4%), $BCl(NCS)_2^-$ (16.5%), $BCl_2(NCS)_2^-$ (10.4%), $D \cdot B(NCS)_3$ (4.7%), and $B(NCS)_4^-$ (8.3%) for a starting molar ratio $NBu_4NCS/LDMA \cdot BCl_3$ 1:1.3. Interestingly, the amounts of compounds deduced from ^{11}B NMR data point to a nucleophilic substitution of chlorine, followed by a breaking of the amine–boron bond, and thus leading to anionic species in a second step. Therefore, heating for longer periods (or at higher temperatures) results in increased yields of $B(NCS)_4^-$ and other anionic species while, conversely, the amount of substituted materials decreases. Although the "naked" NCS^- anion turns out to be a strong nucleophilic species, this reaction is of limited interest from a synthetic point of view.

Liquid/liquid PTC

The above reaction was also carried out in H_2O/organic solvent ($CHCl_3$ or CH_2Cl_2) under different conditions. In any case, at refluxing temperatures with such different catalysts as Aliquat 336 or TTG (see Table 2), no reaction at all could be detected. Similar reactions were performed with $BDMA \cdot BCl_3$ and several potassium salts in a slightly modified procedure using 10 N NaOH (instead of water) and benzene or toluene at refluxing temperatures with benzyltriethylammonium chloride as catalyst. The presence of concentrated aqueous NaOH is indeed quite attractive since it precludes further hydrolysis of the adducts. However, in refluxing benzene, no reaction was observed with $BDMA \cdot BCl_3$ and KNCS, whereas, with refluxing toluene, most of the adduct was destroyed. In one case, with $BDMA \cdot BCl_3$ and KBr, $BDMA \cdot BBr_3$ could be detected in very small amounts by ^{11}B NMR. This could be a way to perform the reverse reaction (11):

$$D \cdot BCl_3 + 3Y^- \rightarrow D \cdot BY_3 + 3X^-$$

Y standing for a heavier halogen than Cl, provided a suitable catalyst is found. Let us add that this order of reactivity is opposite to the ranking previously observed in solid/liquid PTC, that is to say, F > NCS > NCO, Cl > Br(1).

Solid/liquid PTC

Consistent with our earlier studies, the best results were obtained with solid/liquid PTC. To find the best catalyst the reaction $LDMA \cdot BCl_3/KNCS/$catalyst with molar ratios 1:9:0.25 was carried out for 4 h in refluxing benzene with different catalysts. The results are summarized in Table 2, the best results for the conversion being obtained with tetraglyme, which appeared as an even better catalyst than 18-crown-6. Interestingly, despite the formation of $B(NCS)_4^-$ in every case, no substituted derivative of the latter such as $BCl_n(NCS)_{4-n}^-$ could be observed by ^{11}B NMR, at variance with the above behaviour in a homogeneous medium. Similar yields were obtained with NaNCS (instead of KNCS). Thus it turned out that, by a suitable choice of the tertiary amine, stoichiometry, solvent, temperature, and reflux time, it was possible to direct the reaction towards the formation of any desired species. The relevant data with $D \cdot BCl_3/KNCO/TTG$ in molar ratios 1:9:0.15 are given in Table 3, enabling the synthesis of $LDMA \cdot B(NCO)_3$ in good yields with chlorobenzene as solvent. The adduct $LDMA \cdot B(NCS)_3$ could also be obtained in pure form (see experimental part).

Tetrapseudohaloborate anions and mixed species

The reaction of the previously prepared $B(NCS)_4^-\ K^+$ nTTG (n about 2.5) with BX_4^- (X = F, Cl, Br), NR_4^+ (R = Et, nBu) was carried out as a general route to the mixed anionic species $BX_{4-n}(NCS)_n^-$, the exchange, monitored by ^{11}B NMR, being rather slow (on the NMR time scale) and requiring previous heating of the solutions in CH_2Cl_2 or C_6H_5Cl. With BI_4^-, no exchange could be detected by ^{11}B NMR spectroscopy. However, such a reaction was difficult to perform for reasons of solubility. Hence, we were led to carry out the reaction of BX_3 with NCS^-, NBu_4^+ as an easier route to the same species. Thus, with $BF_3 \cdot Et_2O$ and $NCSNBu_4$ in a molar ratio 1:1 in CH_2Cl_2, the major compound was indeed $BF_3 \cdot NCS^-$ together with smaller amounts of BF_4^- and $BF_2(NCS)_2^-$. With $BF_3 \cdot Et_2O$ in excess (1.5:1 or 3:1) no

LDMA	chl.	8	0	0	2	98	0
LDMA	chl.	12	0	0	0	97	3[c]

Solvent: tol. = toluene, ben. = benzene, chl. = chlorobenzene. t = time of reflux (hours). The amounts of compounds (mol.%) were deduced from ^{11}B NMR spectra (ref. $BF_3 \cdot Et_2O$).

[a]Reaction carried out at 100°C.

[b]Important hydrolysis denoted by two broad signals in ^{11}B NMR spectra within the range 17–21 ppm belonging to unidentified three-coordinate species.

[c]The amount of $B(NCO)_4^-$ could be increased by use of diglyme as solvent at 140–150°C but additional unexplained ^{11}B NMR signals were also observed. Some of these signals could arise from cationic species $D_2BX_2^+$ and D_2BXY^+ as recently reported (12). However, the expected signal pertaining to $D_2BCl_2^+$, slightly downfield from D · BCl_3, could not be detected.

additional signals could be identified by ^{11}B NMR except for the 0 ppm signal pertaining to $BF_3 \cdot Et_2O$. Similar results could be observed with BCl_3 in the same solvent or BBr_3 in CH_2Br_2 to prevent a possible exchange reaction with CH_2Cl_2 (13). In the last example, with BBr_3/NCS^- in a molar ratio 1:1, an accurate measure of the areas under the broad ^{11}B NMR signals observed leads to the figures 1.7:1:0.91 for $BBr_3 \cdot NCS^-$, $BBr_2 \cdot (NCS)_2^-$, and BBr_4^-, respectively. Quite noteworthy is the fact that the amounts of $BBr_2(NCS)_2^-$ and BBr_4^- are identical within experimental error, giving strong support to the disproportionation reaction already observed with the fluoroanions BF_3A^- (14).

$$2\ BBr_3NCS^- \rightarrow BBr_2(NCS)_2^- + BBr_4^-$$

Similar results were observed with $BF_3 \cdot Et_2O$ and BCl_3. However, no exchange at all was observed when heating together mixtures of BX_4^- (X = F, Cl) and $NCSNBu_4$.

$B(NCO)_4^-$ was indeed detected by ^{11}B NMR, when the reaction of D · BCl_3 with NCO^- was carried out in homogeneous medium or solid/liquid systems ($\delta\ ^{11}B = -10.4$ to -11.5 ppm according to the solvent),[2] in any case but the overall yield of the latter in the mixture remains small although diglyme as solvent was instrumental in raising it, probably by formation of a solvate. Thus, the only possible route to mixed species was to carry out the reaction:

$$BX_3 + NCONBu_4 \rightarrow BX_3NCO^-,NBu_4^+$$

[2]Although few examples are available, the replacement of NCS by NCO in boron compounds appears to result in a shielding of the boron nucleus in ^{11}B NMR spectroscopy (15, 16).

However, the obtained results so far are quite different from those observed with NCS salts. Despite the literature data concerning the adducts $AlCl_3NCS^-$ and $AlCl_3NCO^-$, for which a $^1J(^{27}Al^{14}N)$ value of about 40 Hz was reported in both cases (17, 18), no coupling constant $^1J(^{11}B^{14}N)$ could be resolved in any of the three examples, at variance with our own results with the related adducts $BX_n(NCS)_{4-n}^-$ (X = F, Cl; n = 1, 2, 3) (3). Likewise, no $^1J(^{11}BF)$ could be resolved with the fluoro adducts $BF_n(NCO)_{4-n}^-$, consistent with earlier studies of $BF_3 \cdot NCO^-$ by ^{19}F NMR spectroscopy (14). In conclusion, the cyanate group has a behaviour quite different from the thiocyanate group. Besides the already quoted differences, the two nucleophilic sites of the ambidente cyanate ion do not have as large a difference in nucleophilicity as in the thiocyanate ion, the nitrogen atom being simultaneously the center of highest electron density and the most polarizable center (19), thus allowing the formation of cyanate compounds B-OCN as well as isocyanate compound B-NCO.

NMR data

^1H NMR data

The ^1H NMR spectra of the compounds BDMA · BX_3 (together with the ^{13}C and ^{11}B NMR spectra) are reported in Table 1. From the many ^1H NMR studies carried out with boron trihalide–amine adducts, the ^1H complexation shifts, i.e., the difference between the observed shift for the free amine and for the adduct, increase in the order $BF_3 < BCl_3 < BBr_3 < BI_3$, these complexation shifts being approximatively proportional to the heats of complexation (20). It is widely accepted that inductive effects explain this ranking although other factors can have an effect; for instance,

[a]D = BDMA as tertiary amine although no significant change was observed with other amines. The following set of parameters were deduced: $\eta_{D,Cl} = 2.29$, $\eta_{D,NCS} = -0.45$, $\eta_{NCO,NCO} = -1.92$, $\eta_{D,NCO} = -0.08$, $\eta_{NCO,Cl} = -0.69$.

changes in long-range shielding are likely to be important with heavier halogens (21) as well as steric interactions in some well-defined examples (22). Further, the chemical shifts measured for the NCS group are quite significant. Thus, whereas from a steric point of view NCS^- can be compared with I^-, as exemplified by the dissociation constant for NBu_4X in dichloroethane, which takes the values 0.8×10^{-4}, 10^{-4}, 1.4×10^{-4}, and 1.45×10^{-4} for X = Cl^-, Br^-, NCS^-, and I^-, respectively (23), the position of the complexation shift of the thiocyanate group, between that of F^- and Cl^-, brings strong support to the predominant influence of the electronegativity of the NCS^- group on the observed shift. It may be considered as an additional proof of the fact that NCS is bonded to boron through nitrogen.[3] Similar trends are observed for the coupling constants $^3J(^{11}BH)$ of the relevant adducts, in line with the data reported for the $^3J(^{11}BH)$ (28) and $^1J(^{11}B^{15}N)$ (29, 30) of the $Me_3N \cdot BX_3$ adducts (X = F, Cl, Br, I).

^{13}C NMR data

Once the amines are complexed to the boron trihalides the carbon shifts are consistently to lower fields as the Lewis acid becomes stronger, in accord with electron withdrawal from the amine by the stronger Lewis acid ($BF_3 < BCl_3 < BBr_3 < BI_3$). Therefore, the shift to high field of many amine ^{13}C resonances on complexation has features in common with protonation shifts of amines (31). Such trends are indeed observed for the CH_2 and $N(CH_3)_2$ of the series $BDMA \cdot BX_3$ (Table 1) but, for the aromatic carbons, these effects are small and negligible in the presence of solvent effects. The most striking feature of these ^{13}C NMR spectra lies in the presence of the previously reported $^3J(^{11}BC)$ (3), which remains constant or slightly increases with the heavier halogens. Furthermore, such coupling results in a significant broadening of the signal of the relevant carbon atom, thus enabling a ready assignment of the latter. With the compounds $ODMA \cdot BX_3$ and $LDMA \cdot BX_3$, although ^{13}C NMR spectroscopy is a good purity test, the correct assignment of the different carbon atoms is impossible unless sophisticated NMR techniques, such as $^{13}C-^{13}C$ correlated spectroscopy using the INADEQUATE sequence, are used or, possibly, T_1 measurements. Also, the ^{13}C chemical shifts so far reported for the long-chain aliphatic amines are unreliable (32, 33) as soon as more than four carbons are involved.

^{11}B NMR data

Although an upfield shift of the ^{11}B resonance is generally observed when the coordination number of boron increases from 3 to 4, this cannot be used as a criterion of the Lewis acid strength of the boron trihalide; one reason is that the ^{11}B chemical shift of trivalent boranes is controlled primarily by the π electron density at boron, while in tetracoordinated boron compounds the overall electron density has to be considered (34). Thus, from the values reported in Table 1, there is no obvious relationship between the adducts and the uncomplexed boron trihalides. Further, the δ ^{11}B value for the NCS derivative probably reflects the strong diamagnetic anisotropic shielding effect of the NCS group. The X-ray structure determination of related compounds (35, 36) proved a nearly linear B-NCS unit supporting this argument. It is a well-documented point that the ^{11}B chemical shifts for the adducts are determined primarily by the number and type of heavy halogens present, amine substituents having only small effects (37). In several types of compounds, chemical shifts of nuclei (38–40) were shown to be additive pairwise with respect to the substituent groups, the same kind of correlation being obeyed by the coupling constants between directly bonded atoms. Thus, the chemical shift (or spin–spin coupling) can be expressed as $\delta = \Sigma\eta_{i,j}$ where $\eta_{i,j}$ is a parameter associated with substituents i and j and independent of all other substituents. The sum is taken over all substituents about a central atom, excluding the nucleus observed in the NMR experiment. Such a correlation

[3]In most examples, boron gives rise to isothiocyanato compounds, B-NCS. The so-called thiocyanato derivatives, B-SCN, whose structure was deduced from IR data (24, 25) appear as doubtful, except for $(C_6H_5)_2BSCN$ for which two isomers were characterized (26, 27).

has been extensively applied to boron trihalide adducts (30, 41, 42) and mixed tetrahaloborate ions (13). We shall try to extend such correlations to the pseudohalogen compounds reported in this work, assuming for NCS and NCO groups a behaviour identical to the classical halogens X (X = F, Cl, Br, I). Thus, in the case of a complex such as $D \cdot BCl_2(NCS)$

$$\delta\,^{11}B = \eta_{Cl,Cl} + 2\eta_{Cl,NCS} + 2\eta_{Cl,D} + \eta_{D,NCS}$$

$$^1J(^{11}B\text{–}^{14}N) = \eta'_{Cl,Cl} + 2\eta'_{Cl,NCS}$$

where η is different in each of the above equations, D standing for the tertiary amine involved. Let us add that the set of parameters are the same for tertiary amine adducts or tetrapseudohaloborate ions and mixed species. The results of such calculations for the tetrapseudohaloborate ions $BX_n(NCS)_{4-n}^-$ (X = F, Cl, Br, n = 0, 1, 2, 3, 4) are summarized in Table 4, those for $D \cdot BCl_nY_{3-n}$ (D = BDMA, Y = NCS, NCO, n = 0, 1, 2, 3) in Table 5. The agreement between observed and calculated shifts is quite good, thus giving strong support to the validity of the hypothesis involved for the pseudohalogen group. Because of the paucity, and lack of accuracy, of data related to coupling constants $^1J(^{11}BF)$ and $^1J(^{11}B^{14}N)$ no correlations have been attempted. Furthermore, the above data are of interest from an heuristic point of view: thus, the extrapolated ^{11}B chemical shift for the compound BCl_3NCO^- is 1.47 ppm, in good agreement with the signal observed near 1.5 ppm. Using the same set of parameters and assuming $\eta_{F,NCO} = -0.54$, the calculated ^{11}B chemical shifts for $BF_n(NCO)_{4-n}^-$ are −2.3, −4.3, and −7.4 ppm for n = 3, 2, 1, respectively, instead of the observed values −2.4, −4.0, and −7.4 ppm.

Trichoderma longibrachiatum Rifai aggr. is a fungus reported to be antagonistic to the fungus *Mycena citricolor*, the causative agent of the American leaf spot disease of coffee. We have investigated the metabolites produced when *T. longibrachiatum* is grown in liquid culture and have isolated the known compounds sorbicillin (**2**), bisvertinol (**3**), and bisvertinolone (**4**) as well as several new compounds including trichodimerol (**1**), an interesting new natural product possessing a proper axis of symmetry. The structure of trichodimerol (**1**) was determined by a combination of spectroscopic techniques, including ^{1}H and ^{13}C nuclear magnetic resonance, infrared, ultraviolet, circular dichroism, optical rotatory dispersion, and mass spectrometry, and by transformation to octahydrotrichodimerol (**6**) and symmetrical and unsymmetrical derivatives thereof. The relative stereochemistry of bisvertinol (**3**) and bisvertinolone (**4**) has been revised. The metabolites described are not biologically active against *Mycena citricolor*.

ROMANO ANDRADE, WILLIAM A. AYER et PAUL P. MEBE. Can. J. Chem. **70**, 2526 (1992).

Le *Trichoderma longibrachiatum* Rifai aggr. est un champignon qui serait antagoniste du champignon *Mycena citricolor*, l'agent causant des taches sur les feuilles de café américain. On a examiné les métabolites produits par culture liquide du *T. longibrachiatum* et on a identifié la sorbicilline (**2**), le bisvertinol (**3**) et la bisvertinolone (**4**), des composés connus, ainsi que plusieurs nouveaux composés, dont le trichodiméral (**1**), un nouveau produit naturel intéressant possédant un axe de symétrie propre. On a déterminé la structure du trichodiméral (**1**) par une combinaison de techniques spectroscopiques, dont la résonance magnétique nucléaire du ^{1}H et du ^{13}C, l'infrarouge, l'ultraviolet, le dichroïsme circulaire, la dispersion rotatoire optique et la spectrométrie de masse ainsi que par la transformation de **1** en octahydrotrichodiméral (**6**) et en des dérivés symétriques et asymétriques de ce dernier. On a révisé la stéréochimie relative du bisvertinol (**3**) et de la bisvertinolone (**4**). Les métabolites décrits ne sont pas biologiquement actifs contre la *Mycena citricolor*.

[Traduit par la rédaction]

Introduction

Fungi of the genus *Trichoderma* Persoon are widespread and their taxonomical classification is difficult. This has led to the development of a *species aggregate* system of classification (1), which groups together several "species". It has been noted, for example, that under the name *Trichoderma hamatum* (Bon.) Bain aggr. there may be two or three or more different but morphologically very similar species, and "that isolates considered to belong to this species aggregate may behave quite differently under different conditions" (1). It is not surprising, then, that there is no clear pattern among the wide variety of secondary metabolites produced by *Trichoderma* strains (2, 3). In recent years considerable interest has been shown in the use of *Trichoderma* species as biological control agents (4). In spite of the importance of the genus, there are no studies reported of the metabolites of strains of *Trichoderma longibrachiatum* Rifai aggr., or of other "yellow" *Trichoderma* strains, although Rifai (1) has documented the existence of yellow pigments in *Trichoderma* strains of the species aggregates *T. aureoviride* Rifai aggr., *T. longibrachiatum*, and *T. harzianum*.

Our interest in the chemistry of the metabolites produced by *T. longibrachiatum* was stimulated by its potential use as a biocontrol agent for the American leaf spot disease of coffee (ojo de gallo), caused by the fungus *Mycena citricolor* (5). When grown in agar plate co-cultures, *T. longibrachiatum* caused lysis of the hyphae of *M. citricolor*.[3]

Unfortunately the antagonistic activity sometimes observed with *T. longibrachiatum* against *M. citricolor* was not observed with the extracts obtained when *T. longibrachiatum* was grown on liquid still or shake culture. However, the isolation of some colorful and apparently structurally unique compounds from these extracts prompted us to examine the compounds in more detail.

We describe herein the isolation of several new natural products, trichodimerol (**1**), trichodermolide, sorbiquinol, bislongiquinolide, and 5-hydroxyvertinolide, along with the known compounds sorbicillin (**2**), bisvertinol (**3**), and bisvertinolone (**4**). The details for the determination of the structure of trichodimerol, a unique natural product, are described and evidence for the revision of the structures of bisvertinol and bisvertinolone is presented.

Results and discussion

Trichoderma longibrachiatum was grown in both liquid shake and liquid still culture on a medium, developed by our collaborators in Costa Rica, containing yeast extract, malt extract, glucose (or lactose), peptone, and trace elements. Extraction of either the mycelium ($CHCl_3$:CH_2Cl_2) or the broth ($CHCl_3$) provided a similar mixture of metabolites in approximately equal amounts. Attempted separation by

chromatography over silica gel led to large losses of material and some metabolites were denatured as indicated by comparison of the ^{1}H nmr spectra of the fractions obtained using polar eluants with the ^{1}H nmr spectra of the initial mixtures. Sephadex LH20 chromatography proved to be a very useful tool in handling these silica-sensitive compounds. Sephadex LH20 chromatography of the extracts, followed by silica gel chromatography when possible, led to the isolation of the three known compounds, sorbicillin (**2**), bisvertinol (**3**), and bisvertinolone (**4**), and the five new polyketides trichodimerol (**1**), trichodermolide, sorbiquinol, bislongiquinolide, and 5-hydroxyvertinolide.

Sorbicillin (**2**), an orange crystalline compound, was first isolated as an impurity in penicillin by Cram and Tishler in 1948 (6) and chemical methods were used to determine its structure (7). It has also been isolated from *Verticillium intertextum* (8, 9) and has been synthesized (10). Compound **2** was converted by catalytic hydrogenation to tetrahydrosorbicillin, similar in all respects to the product described by Dreiding and co-workers (9).

Trichodimerol (**1**) is a pale yellow, optically active, crystalline compound. Its molecular formula, $C_{28}H_{32}O_8$, was obtained from the high-resolution electron impact mass spectrum (hreims) and the molecular ion was confirmed by fast atom bombardment mass spectrometry (fabms: *m/z* 497, $M^+ + 1$, 35%). Its ^{13}C nmr spectrum shows 14 signals, indicating an element of symmetry in trichodimerol.[4] The compound gives a positive ferric chloride test and its uv maximum (λ_{max} 362 nm) shows a bathochromic shift upon addition of base (λ_{max} 378 nm), showing the acidic character of the chromophore. The presence of an enolized β-diketone is suggested by the ir (hydroxyl 3420 cm^{-1} and strongly chelated carbonyl 1613 cm^{-1}) and ^{1}H nmr spectra (enolized β-diketone hydrogen at δ 16.33 ppm).

[4]The element of symmetry present in trichodimerol must be a proper axis of symmetry, not a plane or point of symmetry, since the compound is optically active.

The ^{1}H nmr spectrum of trichodimerol (Table 1) also displays methyl singlets (δ 1.43 and 1.46 ppm), a methine singlet (δ 3.00 ppm), a hydroxyl hydrogen (δ 3.20 ppm), and signals characteristic of a sorbyl chain (δ 1.89 (d, 6.5 Hz, 3H), 6.11–6.34 (m, 3H), 7.32 (dd, 10, 15 Hz, 1H)). Further evidence of the presence of the sorbyl chain is given by the hreims, which shows a base peak at *m/z* 95 (C_6H_7O, 100%). The stereochemistry of this unsaturated chain was assigned as *E,E* on the basis of the magnitude of the ^{1}H nmr coupling constants measured in benzene solution (J = 15 Hz between δ 5.55 and 5.88 and between δ 6.25 and 7.38).

The ^{13}C nmr spectrum (Table 2) of trichodimerol shows 14 signals: carbons of the sorbyl chain, the methyls, a methine (δ 57.6), and a series of quaternary carbons (δ 58.9, 78.9, 102.8, 104.1, and 176.0). The quaternary carbon signals are assigned as follows: δ 102.8 and δ 176.0 to oxygenated carbons of the enolized β-diketone, δ 58.9 to an

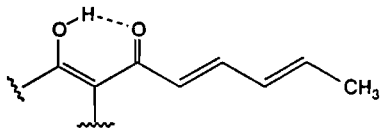
[d]Preparation to be described in Part 2.

aliphatic carbon, δ 78.9 to a monooxygenated aliphatic carbon, and δ 104.1 to a dioxygenated carbon. Since there are only two oxygen-bearing sp^2 carbons, we may conclude that the carbonyl of the sorbyl chain is part of the enolized β-diketone system. These data are consistent with the presence of fragment **5**, an enol-sorbyl system, in trichodimerol.

The molecular formula of trichodimerol indicates it has 13 unsaturations. Since trichodimerol is dimeric, eight unsaturations may be attributed to two enol-sorbyl systems (**5**), leaving five unassigned unsaturations and indicating that trichodimerol is pentacyclic. There are eight oxygen atoms present in trichodimerol, four forming part of the enol-sorbyl systems. Since the ^{13}C nmr spectrum of trichodimerol displays two other signals attributed to oxygen-bearing carbons (the monooxygenated and dioxygenated carbons at δ 78.9 and 104.1), the remaining four oxygens must be present as two hemiacetals.



5

To obtain information about the relative position of the groups further ^{1}H nmr experiments were carried out. Nuclear Overhauser effect (nOe) difference experiments (Table 3) show that there is a large nOe enhancement between the δ 3.00 methine, the sorbyl hydrogen at δ 6.12, and the methyl groups at δ 1.43 and 1.46, which suggests that the methine is in close proximity to these functionalities. In solvent studies with pyridine, the ^{1}H nmr spectrum of trichodimerol shows that the methyls, the methine, and the hydroxyl group are significantly shifted (by 0.44, 0.57, 0.64, and 1.87 ppm, respectively). These shifts are considerably larger than those observed when benzene is used as solvent, suggesting that the methyl groups are vicinal, 1,3-, or in some other way close to the hemiacetal hydroxyl (11).

Of the various "dimeric" structures that can account for the structural features outlined above, only one, structure **1**, has a proper axis of symmetry and can account for the observed optical activity of trichodimerol. The absolute stereochemistry of trichodimerol was determined to be as depicted in **1** by use of the exciton chirality method (12). The cd spectrum of trichodimerol shows a split Cotton effect (amplitude) (A) = $\Delta\varepsilon_1 - \delta\varepsilon_2 = -25$) with a negative first Cotton effect, corresponding to a negative chirality.

Trichodimerol is unstable, decomposing to an insoluble brittle solid upon standing. It may be transformed to a stable derivative, octahydrotrichodimerol (**6**), by hydrogenation over palladium on carbon. The molecular formula of compound **6**, $C_{28}H_{40}O_8$, was confirmed by hreims. Its uv spectrum, λ_{max} 340 (ε = 390) and 294 (14 000) nm, is consistent with the presence of a enolized β-diketone chromophore (13). In addition to the signals expected for a five-carbon saturated chain, the ^{1}H nmr spectrum of **6** (Table 1) shows signals for a methine hydrogen at δ 3.00 (s), a hydroxyl hydrogen at δ 3.28 (br s), a six-hydrogen singlet at δ 1.46 (which may be resolved into two singlets when either pyridine or benzene is used as solvent), an enolized β-diketone hydrogen at δ 16.66, and no olefinic absorptions. The product retained its symmetry as shown by its ^{13}C nmr spectrum (Table 2, only 14 signals).

Octahydrotrichodimerol (**6**) is much more stable than trichodimerol (**1**) and remains unchanged after long periods of time. As in trichodimerol the methyl groups and the methine hydrogen of octahydrotrichodimerol (**6**) display large

shifts in the ^1H nmr spectrum when pyridine is added. The methyl groups and the methine gave mutual nOe[5] enhancements, which are summarized in Table 3, together with the other observed enhancements. Because of its stability, compound **6** was used for additional spectroscopic studies and for the preparation of several derivatives.

Further evidence supporting the proposed structure of trichodimerol (**1**) was obtained from a $^{13}C[^1H]$ nOe enhancement experiment and a natural abundance ^{13}C INADEQUATE experiment on octahydrotrichodimerol (**6**). The location of the methine observed in the ^1H nmr spectrum relative to the non-hydrogen bearing carbons was investigated by the use of a $^{13}C[^1H]$ nOe difference experiment. Selective irradiation of H-1 of octahydrotrichodimerol gave enhancements to C-6, C-2, C-4, C-8, and a negative enhancement to C-3. The negative nOe must arise from an homonuclear nOe between H-1 and the two adjacent methyls (Me-13 and Me-14) followed by a heteronuclear nOe onto the carbons adjacent to the methyls. As well, the homonuclear nOe between the methine and the methyls is observed in the $^1H[^1H]$ nOe experiments. Indirect nOe enhancements of this type have been observed previously (14).

The abundant sample of octahydrotrichodimerol (**6**) justified a natural abundance ^{13}C two-dimensional INADEQUATE-type experiment (15). An INADSYM (16) spectrum was obtained and showed connectivities between C-3 and C-4, C-1 and C-6 and C-2, and between C-2 and C-3. These connectivities confirm that the structure of trichodimerol is as shown in **1**.

The formation of the different acetyl derivatives of octahydrotrichodimerol (**6**) demonstrates its interesting symmetry properties and confirms the presence of two

[5]Verified in benzene-d_6 where the two methyls give separate signals.

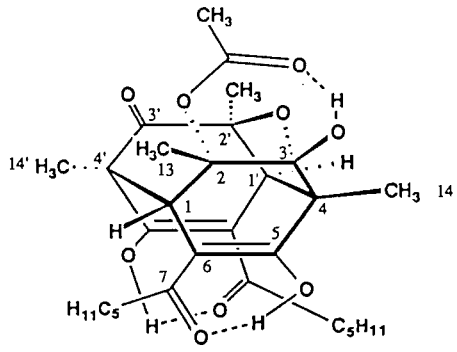
hemiacetals in trichodimerol. Treatment of octahydrotrichodimerol (**6**) with acetic anhydride in refluxing toluene or with acetic anhydride under reflux produced very complex product mixtures with at least 12 components as judged by tlc. When acetic anhydride, pyridine, and 4-*N*,*N*-dimethylaminopyridine (DMAP) in dichloromethane were used for acetylation of **6**, five acetylated products were isolated from the complex mixture formed.

Two different monoacetyl derivatives were obtained. The ir spectrum of monoacetate **7** shows the presence of a hydroxyl group (3400 cm^{-1}), a strongly chelated carbonyl (1605 cm^{-1}), and an acetoxyl carbonyl group (1728 cm^{-1}). The uv spectrum of monoacetate **7** is similar to that observed for octahydrotrichodimerol (**6**), indicating that the enolized β-diketone observed in **6** is unchanged in compound **7**.

The ^{1}H nmr spectrum of monoacetate **7** (Table 1) displays four methyl groups, enolized β-diketone hydrogens (δ 15.94 and 16.23), a hydroxyl hydrogen (δ 6.12 ppm), and methine hydrogens (δ 2.98 and 3.19), all as sharp singlets, indicating that compound **7** is not symmetrical. Accordingly, the ^{13}C nmr spectrum of **7** displays 29 signals, corresponding to 30 carbons. Five carbonyl-like absorptions are observed in the ^{13}C nmr spectrum (Table 2). It is apparent, however, from the integration of the signals that the signal at δ 188.4 corresponds to two carbons. One of the carbonyls can be assigned to the newly introduced acetyl group (δ 173.3), another four arise from the two enolized β-diketone systems (δ 188.4 × 2, 195.1, and 196.5), and the sixth may be assigned to a ketone (δ 202.2). The presence of only three signals in the region δ 100–110 indicates that compound **7** has a single hemiacetal group. Nuclear Overhauser experiments showed that there is a large nOe enhancement (12%) between the methyl hydrogens at δ 1.44 and the hydroxyl hydrogen at δ 6.12. Also, the chemical shift of the hydroxyl hydrogen occurs at unusually low field, suggesting it is chelated. The low-frequency absorption of the acetate carbonyl observed in the ir spectrum of **7** is consistent with this internal hydrogen bonding. These observations, together with the isolation of another monoacetate (**8**) (described below), lead us to conclude that one of the hemiacetals of octahydrotrichodimerol opens to the hydroxy ketone. The tertiary alcohol thus released is then acetylated to produce **7**. The acetyl carbonyl is conveniently located to allow hydrogen bonding with the hydroxyl group. This hydrogen bond explains the acetoxyl carbonyl absorption in the ir spectrum and the large nOe enhancement mentioned above.

The ^{13}C nmr chemical shifts of monoacetate **7** were compared with those of octahydrotrichodimerol (Table 2). A large

downfield shift for C-2 from δ 78.8 to 89.0 (10.2 ppm) is observed due to the acetylation of the tertiary alcohol. Other shifts observed are a downfield shift for C-4′ from δ 58.0 to 63.8 (5.8 ppm), and an upfield shift of C-1 and C-1′ from δ 57.3 to 53.3 and 56.8 (4.0 and 0.5 ppm, respectively) when **7** is compared with **6**. These downfield and upfield shifts are as expected for the change of a hemiacetal (in **6**) into a ketone (in **7**) (17). Furthermore, the nOe experiments (Table 3) allow the assignment of the methines and all the methyl hydrogen signals present in the ^{1}H nmr spectrum of monoacetate **7**.

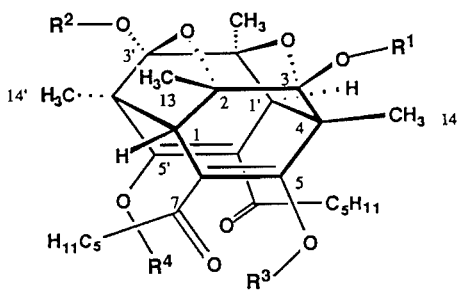


7

A second product obtained from the acetylation of octahydrotrichodimerol is monoacetyloctahydrotrichodimerol (**8**), $C_{30}H_{42}O_9$, which shows absorptions for a strongly chelated carbonyl (1600 cm^{-1}), hydroxyl (3440 cm^{-1}), and acetoxyl carbonyl (1752 cm^{-1}) in its ir spectrum. The ^{1}H nmr spectrum of **8** (Table 1) displays four methyl signals, (δ 1.36, 1.41, 1.43, and 1.48), methines (δ 2.96 and 3.00), acetyl methyl (δ 2.11), enolized β-diketone hydrogens (δ 16.40 and 16.69), and a hydroxyl hydrogen (δ 2.97). These signals indicate that compound **8** is not a symmetrical molecule.

Twenty-nine carbon signals were observed in the ^{13}C nmr spectrum of **8** (Table 2). There are five carbonyl-like carbon absorptions. One is attributed to the newly introduced acetyl carbonyl (δ 169.0) and four to the enolized β-diketone systems (δ 187.3, 191.8, 193.5, and 196.5). Furthermore, there are four carbon signals in the region 100–110 ppm, suggesting that compound **8** has two hemiacetals. Comparison of the ^{13}C nmr spectrum of **8** with that of **6** reveals that in **8** a hemiacetal carbon shifts from δ 103.9 to 109.5 (5.6 ppm). This shift is best explained if one hemiacetal hydroxyl of **6** has been acetylated to give the unsymmetrical acetate **8**.

A diacetate **9**, $C_{32}H_{44}O_{10}$, was also obtained upon acetylation of octahydrotrichodimerol. Its ir spectrum shows acetoxyl carbonyl (1753 cm^{-1}), a strongly chelated carbonyl (1599 cm^{-1}), but no free OH stretching absorption. The ^{1}H nmr spectrum of **9** (Table 1) displays the signals for hydrogens of methyls (δ 1.33 and 1.49), an enolized β-diketone hydrogen (δ 16.41), an acetyl methyl (δ 2.12), and a methine (δ 3.03), all as singlets. The ^{13}C nmr spectrum displays 16 signals, corroborating that compound **9** has an element of symmetry. Three carbon absorptions are carbonyl-like (Table 2): one is assigned to the acetate carbonyl (δ 169.0) and the other two to the enolized β-diketone system (δ 187.5 and 196.3). The hemiacetal carbon (δ 109.2) of **12** is shifted with respect to that observed in the ^{13}C nmr spectrum of octahydrotrichodimerol (**6**). From these data, the structure of the diacetate is assigned as the symmetrical hemiacetal diacetate **9**.



8 R^1 = Ac, R^2 = R^3 = R^4 = H
9 R^1 = R^2 = Ac, R^3 = R^4 = H
10 R^1 = R^2 = R^3 = Ac, R^4 = H
11 R^1 = R^2 = R^3 = R^4 = Ac

A fourth product isolated from the acetylation mixture is triacetate **10**, $C_{34}H_{46}O_{11}$, whose ir spectrum shows absorptions for acetoxyl carbonyl (1752 cm^{-1}), a conjugated ketone carbonyl (1699 cm^{-1}), a strongly chelated carbonyl (1612 cm^{-1}), but no free OH stretching. The uv spectrum of **10** differs from the uv spectrum of octahydrotrichodimerol (**6**) and the other acetates (**7**, **8**, **9**), suggesting that one of the enolized β-diketone systems of **6** has been acetylated.

The ^{1}H nmr spectrum of **10** (Table 1) shows signals for the acetate methyls (δ 2.11, 2.12, and 2.24), the quaternary methyls (δ 1.32, 1.35, 1.46, and 1.48), the methines (δ 3.02 and 3.11), and an enolized β-diketone hydrogen (δ 16.51) as singlets, as well as a one-hydrogen doublet of doublet of doublets at δ 3.40 (*J* 13, 8.5, 5 Hz) (Table 1) attributed to one of the side-chain H-8 hydrogens. Interestingly, in the ^{1}H nmr spectra of acetates **7**, **8**, and **9** the signal for the C-8 methylene hydrogens appears as a multiplet of two diastereotopic hydrogens. Although the chemical shift of the C-8 hydrogens is similar in the ^{1}H nmr spectra of compounds **7**, **8**, and **9**, one of the C-8 hydrogens has shifted more than 1 ppm in the ^{1}H nmr spectrum of **10**. This shift demonstrates that an enol system has been acetylated and suggests that the acetylated enol is endocyclic. If compound **10** had an exocyclic enol acetate, the side chain would retain its rigidity around the C-6, C-7 bond, and no significant change in any of the ^{1}H nmr signals of the C-8 hydrogens would be expected. The ^{13}C nmr spectrum of **10** (Table 2) is in agreement with the structure assigned.

A fifth acetate derivative was isolated from the acetylation of [1-^{13}C]acetate labelled octahydrotrichodimerol prepared during biosynthetic studies.[6] The ^{1}H and ^{13}C nmr

[6]Details of the biosynthetic studies will be presented in a subsequent paper.

spectra indicate it possesses structure **11**. The ir spectrum shows absorption for acetoxyl carbonyl (1751 cm^{-1}), conjugated carbonyl (1700 cm^{-1}), and double bond (1611 cm^{-1}) consistent with an enol acetate – ketone system.

The ^1H nmr spectrum of **11** (Table 1) shows absorptions corresponding to acetyl methyl hydrogens (δ 2.11 and 2.23), methyl hydrogens (δ 1.30 and 1.45), a methine hydrogen (δ 3.09), and a hexanoyl chain (δ 3.10 (m, 1H), 2.50 (m, 1H), 1.45 (m, 2H), 1.28 (m, 4H), and 0.88 (m, 3H). These characteristics indicate that tetraacetate **11** is symmetrical and that the enol acetates are endocyclic since, as indicated for triacetyloctahydrotrichodimerol (**10**), the chemical shift of the H-8 hydrogens changes to δ 3.11 and δ 2.50 in the ^1H nmr spectrum of tetraacetyloctahydrotrichodimerol (**11**). The ^{13}C nmr spectrum of **11** (Table 2) shows 18 signals and the assignment of these signals is in agreement with the proposed structure.

Octahydrotrichodimerol (**6**) is symmetrical and the progressive introduction of acetyl groups upon acetylation gives the following results. Introduction of one acetyl group, as in monoacetyloctahydrotrichodimerol (**7**) and monoacetyloctahydrotrichodimerol (**8**), destroys the symmetry present in octahydrotrichodimerol (**6**). Introduction of two acetyl groups, as in diacetyloctahydrotrichodimerol (**9**) yields a symmetrical product, while introduction of three acetyl groups, as in triacetyloctahydrotrichodimerol (**10**), destroys the symmetry again. The introduction of four acetyl groups restores the symmetry and gives tetraacetyloctahydrotrichodimerol (**11**).

As mentioned above, bisvertinol (**3**) and bisvertinolone (**4**), previously isolated by Dreiding and co-workers from *Verticillium intertextum* (18), were also obtained from *T. longibrachiatum*.[7] The previous workers favored a *trans* C-5a, C-9a ring junction and did not make a stereochemical assignment at the other ring junction (C-4a, C-9b).

We have investigated the stereochemistry of bisvertinol by nOe experiments with the following results: H-9a (δ 3.63) gave nOe enhancement to Me-17 and Me-25 (δ 1.26 (4%) and 1.42 (4%)), and to H-20 (δ 6.49 (18%)). H-3 (δ 2.44) gave an nOe enhancement to H-11 (δ 6.39 (7%)), to H-3′ (δ 2.71 (12%)), and to Me-16 (δ 1.19 (2%)). Furthermore, Me-16 gave enhancement to H-3 (1.4%) and Me-25 to H-20 (1.4%). Me-18 (δ 1.40 ppm) did not give rise to any nOe enhancement. These results allow us to assign the ^1H nmr signals of the quaternary methyls of bisvertinol.

The results of our nOe experiments and the cd spectrum (extrema of opposite sign at 410 and 353 nm (A = 75)) of bisvertinol indicate that the relative stereochemistry of Me-17, H-9a, and Me-25 in bisvertinol should be revised to an all-*cis* stereochemistry. The stereochemistry of the C-4a hydroxyl should then be *cis* on the basis of the enhanced stability of a *cis* 5–6 ring junction over a *trans* 5–6 ring junction, while the stereochemistry at C-4 should remain the same as proposed on biogenetic arguments (18). The stereochemistry of bisvertinol is thus as depicted in **3**. Application of the exciton chirality theory to the cd spectrum of bisvertinol indicates that its absolute stereochemistry is as shown in **3**.

Nuclear Overhauser enhancement experiments with bisvertinolone (**4**) showed similar results to the ones obtained for bisvertinol (**3**) and therefore the stereochemistry of bisvertinolone should also be revised from that proposed by Dreiding and co-workers (18).

The structures of the other new metabolites isolated from *T. longibrachiatum* will be described in Part 2 of this series.

[7]Identity was established by comparison of ^1H and ^{13}H nmr spectra with published values (9).

Experimental

General

High-resolution electron impact mass spectra (hreims) were recorded on an AEI MS-50 mass spectrometer coupled to a DS-50 computer. The hreims data are reported as m/z (relative intensity) except for the molecular ion, which is reported as m/z found (m/z calculated, relative intensity). Unless diagnostically significant, peaks with intensity less than 20% of the base peak are omitted. Chemical ionization mass spectra (cims) were recorded on an AEI MS-12 mass spectrometer with ammonia as the reagent gas. The data were processed using DS-55 software and a Nova-4 computer. The cims data are reported as m/z (assignment, relative intensity). Fourier transform infrared (ftir) spectra were recorded (as a cast from $CHCl_3$ solution unless otherwise noted) on a Nicolet FTIR 7199 interferometer. Ultraviolet (uv) spectra were recorded on a Hewlett Packard 8450A diode array spectrophotometer. Optical rotations were recorded on a Perkin Elmer 141 polarimeter. ^1H and ^{13}C nuclear magnetic resonance (nmr) spectra were measured (in $CDCl_3$ unless noted) on Brucker WM-360 and WH-300 (operating at 75.5 MHz for ^{13}C nmr) spectrometers, coupled to Aspect 2000 and Aspect 3000 computer systems, respectively. The multiplicity of the ^{13}C nmr signals was verified by APT experiments when possible. Chemical shifts are reported in parts per million (d value from tetramethylsilane (TMS)). The residual solvent signal was used as the internal standard, $CDCl_3$: ^1H: δ 7.262 ppm; ^{13}C: δ 77.00 ppm; acetone-d_6: ^1H: δ 2.04 ppm, ^{13}C: δ 29.0 ppm; MeOH-d_4: ^1H: δ 3.30 (methyl) ppm, ^{13}C: δ 49.00 ppm; C_6D_6: δ ^1H: 7.15 ppm, ^{13}C: δ 128.00 ppm relative to TMS.

Growth of Trichoderma longibrachiatum and isolation of the metabolites

Trichoderma longibrachiatum (UAMH 5068) was obtained from Professor Edgar Vargas of the University of Costa Rica and is deposited at the University of Alberta Microfungus Herbarium (UAMH 5068).

Trichoderma longibrachiatum (strain UAMH 4159) was obtained from the University of Alberta Mold Herbarium. It was originally deposited as *Trichoderma reesei* Simmons, mutant of ATCC 24449 (QM 9123). This strain (UAMH 4159) was previously deposited at the American Type Culture Collection (ATCC) as ATCC 26921, at the Commonwealth Mycological Institute (CMI) as CMI 192656, and at the Quatermaster Research and Development Center (QM) as QM 9414. *Trichoderma reesei* ATCC 24449 is a mutant of *T. reesei* ATCC 13631 (*T. viride* QM 6a) (CMI 45548), which was isolated from a "cotton duck shelter" by D. I. Fennell (19).

Slant cultures (PDA) of the fungi were stored in a refrigerator at 4°C. A small piece of mycelium and agar was removed from the slant culture and was used to inoculate an agar plate (PDA), and the plate culture was allowed to grow for 1 week. A portion of the plate culture was used to inoculate a liquid culture (potato dextrose media, 250 mL), which was allowed to grow with constant shaking (160 rpm) for 1 week. Inocula (20 mL) from the small shake culture were used to inoculate still cultures grown in Fernbach flasks (1 L, media composition: *vide infra*), while inocula (25 mL) were used to inoculate large shake cultures (500 mL of media).

Trichoderma longibrachiatum strain UAMH 5068 was grown on still and shake culture using the following media: glucose 2%, yeast extract 0.5%, malt extract 0.5%, K_2HPO_4 0.25%, $MgSO_4$ 0.2%,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

$(NH_4)_2SO_4$ 0.1%, bactopeptone 0.5%. The still culture was harvested after 26 days and the shake culture after 11 days of growth.

Trichoderma longibrachiatum strain UAMH 4159 was grown on still culture using the same media, but with lactose instead of glucose as the main carbon source. This growth was harvested after 27 days.

The mycelium was separated from the broth by gravity filtration through cheese cloth. The mycelial mass was dried for 24 h in a fume hood and then extracted for 24 h with $CHCl_3$:CH_2Cl_2 (1:1) in a percolator. The solvent was removed under reduced pressure to give the crude mycelial extract.

The broth was concentrated under reduced pressure to approximately one quarter of its original volume. Butanol was added to avoid excessive foaming during the evaporation. The concentrated broth was then extracted under stirring with chloroform (approx. 4 × 1/2 volume). The chloroform extract was concentrated under reduced pressure to give the crude broth extract as a gum.

Isolation of the metabolites of Trichoderma longibrachiatum

The crude mycelium extract (9.5 g) from a still culture of the *T. longibrachiatum* (UAMH 5068, 10 L) was separated in the following way. A Sephadex LH20 column (70 g, 36 × 2.8 cm i.d.) was packed in methanol, and increasing amounts of chloroform and petroleum ether were used to precondition the column and the column was rinsed with 250 mL of the least-polar solvent mixture to be used. Elution of the metabolites from the crude extract was accomplished using a stepwise increase in solvent polarity. The solvents used were petroleum ether:$CHCl_3$ 2:3 (500 mL), 1:2 (750 mL); petroleum ether:$CHCl_3$:acetone 1:2:1 (250 mL), 1:2:2 (250 mL); $CHCl_3$:acetone 1:1 (250 mL); and methanol. The first fraction (75 mL) was discarded, subsequent fractions (15–20 mL) collected, and like fractions (tlc) combined.

Trichodimerol (**1**) eluted in fractions 20–33 and 56–73 (0.86 g). Sorbicillin (**2**) eluted in fractions 33–44 as a 1:1 mixture with trichodimerol (0.26 g). Sorbiquinol coeluted with trichodimerol in fractions 45–55 (0.27 g). Crude bisvertinol (**3**) eluted in fractions 74–82 (3.5 g). Bisvertinol was purified further by column chromatography (Sephadex LH20, petroleum ether:$CHCl_3$:acetone 1:1:0.4) to give 470 mg of bisvertinol. An analytical sample, prepared by precipitation (twice) from petroleum ether:Et_2O gave bisvertinol, mp 151.5–152.5°C (82 mg). Column chromatography (silica gel; 1% EtOH:$CHCl_3$) of the fraction containing sorbicillin (60 mg) gave pure sorbicillin (20 mg). Column chromatography (silica gel; 2% EtOH:$CHCl_3$) of the fraction containing sorbiquinol (80 mg) afforded sorbiquinol, $C_{28}H_{32}O_7$ (19.4 mg), as a yellow solid, and, after increasing the polarity (6% EtOH:$CHCl_3$), trichodimerol (19.4 mg).

The broth extract (7.5 g) of the still culture of *T. longibrachiatum* (UAMH 5068) was separated as described above. Fractions 15–30 contained impure trichodimerol (0.76 g). Fractions 31–35 gave sorbicillin and trichodimerol (87 mg), 36–57 impure trichodimerol (0.6 g), and 58–69 impure bisvertinol (1.70 g). Sorbiquinol was not obtained. After repeating the Sephadex column with fractions 4–15 (3.25 g), 370 mg of bislongiquinolide, $C_{28}H_{32}O_8$, was obtained in fractions 79–85 as a yellow gum, and 100 mg of bisvertinolone (**4**) in fractions 87–90.

The crude broth extract (3.7 g) from the shake culture of *T. longibrachiatum* (UAMH 5068) was separated as before by Sephadex LH20 chromatography. Impure bisvertinolone (**4**) was obtained in fractions 56–65. This was precipitated from petroleum ether:Et_2O to give 350 mg of bisvertinolone as an amorphous powder, mp 153–155°C. The mycelial extract of the shake culture provided only trichodimerol.

The mycelium extract of *T. longibrachiatum* (UAMH 4159) (9.3 g) was separated by Sephadex LH20 chromatography as described above. Trichodermolide was found in fractions 1–3 and was purified by column chromatography (silica gel; Bz:Et_2O 10:1 to 5:1) to give 235 mg of pure trichodermolide, $C_{24}H_{28}O_4$, as a colorless wax. Fractions 11–18 contained almost pure trichodimerol (1.5 g), fractions 19–38 gave mainly a mixture (2.4 g) of trichodimerol, sorbicillin, and sorbiquinol, while fractions 58–66 contained impure bisvertinol (1.5 g).

The broth extract of *T. longibrachiatum* (UAMH 4159) (8 g) was separated by Sephadex chromatography as described above. Fractions 1–5 contained impure trichodermolide, which after column chromatography (silica gel; Bz:Et_2O 3:1) gave 71 mg of pure trichodermolide. Fractions 32–50 (1.2 g) were combined and subjected to further Sephadex LH20 chromatography using petroleum ether:$CHCl_3$:acetone (2:3:0.4) as eluant. The first 150 mL was discarded. 5-Hydroxyvertinolide, $C_{14}H_{18}O_5$, eluted in fractions 34–48, with fractions 39–40 containing pure 5-hydroxyvertinolide (40 mg).

*Hydrogenation of trichodimerol (**1**)*

Trichodimerol (**1**) (170 mg) in ethyl acetate was hydrogenated over palladium on carbon at room temperature for 1 h. The reaction mixture was filtered, concentrated, and purified by column chromatography (silica gel; Bz:Et_2O 1:1) to give octahydrotrichodimerol (**6**) (105 mg): mp 147–149°C (EtOAc: petroleum ether), 124–125°C (Bz:Et_2O); $[\alpha]_D$ +184 (*c* 0.70, MeOH); ftir ν_{max} (cm^{-1}): 3420, 2960, 2940, 2910, 1580, 1265, 1129, and 1130; uv (MeOH) λ_{max} nm (ε): 340 (390), 294 (14 100); cd (MeOH) $\lambda_{extremum}$ nm (Δε): 311 (+28), 281 (−4.9); A = +32.9; ord (MeOH) $\lambda_{extremum}$ nm ([ϕ]): 323 (+64 000), 296 (−65 000); ^{1}H nmr spectrum: see Table 1; ^{13}C nmr spectrum: see Table 2; hreims: 504.2727 (calcd. for $C_{28}H_{40}O_8$: 504.2724, 26%), 253 (65), 252 (33), 237 (17), 236 (35), 235 (25), 193 (53), 181 (76), 165 (52), 154 (73), 99 (100), 83 (19), 71 (53); cims: 502 (12%), 501 (32%), 252 (100%), 251 (73%), 233 (19%); tlc: R_f 0.17 (2% EtOH/$CHCl_3$), 0.46 (6%).

*Acetylation of octahydrotrichodimerol (**6**)*

Octahydrotrichodimerol (129 mg), acetic anhydride (1.5 mL), pyridine (0.5 mL), and dimethylaminopyridine (one crystal) were refluxed in dichloromethane (15 mL) for 7 days. Methanol (5 mL) was added, and the reaction mixture was filtered and evaporated *in vacuo*. Traces of pyridine were removed by azeotropic evaporation with toluene. Purification by column chromatography (silica gel; 12 to 33% ethyl acetate:petroleum ether) afforded the monoacetyl derivative of the keto form (**7**) (3.1 mg), diacetyloctahydrotrichodimerol (**9**) (51.2 mg), triacetyloctahydrotrichodimerol (**10**) (32.3 mg), and impure monoacetyloctahydrotrichodimerol (**8**) (7.7 mg). Compound **8** was purified further by preparative tlc on silica gel (eluant: 4% EtOH:$CHCl_3$) to give pure monoacetyloctahydrotrichodimerol (**8**) (3 mg).

*Monoacetyloctahydrotrichodimerol (**7**):* ftir ν_{max} (cm^{-1}): 3400, 2960, 2935, 2895, 2860, 1728, 1605, 1588, 1380, 1262, 1138, 1110, 1041, 948; uv (MeOH) λ_{max} nm (log ε): 295 (4.08); NaOH: 203 (4.53), 307 (4.08); HCl regenerated the original spectrum; ^{1}H nmr spectrum: see Table 1; ^{13}C nmr spectrum: see Table 2; hreims: 546.2834 (calcd. for $C_{30}H_{42}O_9$: 546.2830, 90%), 528 (19), 486 (37), 468 (14), 261 (27), 253 (42), 252 (12), 237 (22), 236 (81), 235 (52), 223 (19), 218 (21), 207 (22), 180 (33), 165 (60), 154 (21), 149 (40), 99 (100), 71 (80); cims: 564 (M^++18, 29%), 547 (M^++1, 14%), 504 (66), 295 (100); tlc: R_f 0.56 (EtOH:$CHCl_3$ 1%), 0.78 (2%), 0.92 (6%).

Natural abundance INADSYM

Octahydrotrichodimerol (600 mg) was dissolved in deuterated benzene (1.5 mL). Sixty-four FIDs of 2K points and 640 scans each were obtained with the program INADSYM of Bruker. The delays were optimized for a carbon–carbon coupling constant of 59 Hz. A relaxation delay of 2 s was used between scans. This required a total spectrometer time of 40 h. The spectral window used was of 4545 Hz, corresponding to 50 ppm at 90.56 MHz. A zero filling to 1024 W was done in F_1 and the spectra were Fourier-transformed with a Gaussian multiplication in F_1 (LB_1 = 100, GB_1 = 0.2), and a sinusoidal multiplication in F_2 followed by symmetrization.

Solvent effects in the metal interchange of crown ether – alkali metal cation complexes. Transition from an associative exchange in nitromethane to a dissociative exchange in acetonitrile studied by ^{23}Na nuclear magnetic resonance

KATHLEEN M. BRIÈRE[1] AND CHRISTIAN DETELLIER[2]

Ottawa–Carleton Chemistry Institute, University of Ottawa Campus, Ottawa, Ont., Canada K1N 6N5

Received March 27, 1992

KATHLEEN M. BRIÈRE and CHRISTIAN DETELLIER. Can. J. Chem. **70**, 2536 (1992).

The role of the solvent in the dissociation kinetics and cation exchange mechanisms of the complex sodium–monobenzo-15-crown-5 $(Na:B15C5)^+$ was examined by ^{23}Na NMR. In nitromethane (NM), the cationic exchange between the complexes takes place via an associative metal interchange mechanism, I_M. In acetonitrile (AN), it takes place via a dissociative (dissociation/recombination) mechanism. In AN–NM binary mixtures, the rate constant of the dissociative exchange (k_{-1}) increases with the AN molar fraction, X_{AN}, from 1.1×10^{-2} s^{-1} for $X_{AN} = 0$ to 89×10^{-2} s^{-1} for $X_{AN} = 0.400$ (corresponding to a decrease of the free energy of activation, $\Delta G_{di}^{\neq}$ from 62.1 to 51.1 kJ mol^{-1} respectively, at 301.5 K). The activation parameters were $\Delta H_{di}^{\neq} = 48$ kJ mol^{-1} and $\Delta S_{di}^{\neq} = -20$ J K^{-1}, mol^{-1} for $X_{AN} = 0.200$. This rate increase was related to the concentration increase in solution of the AN monosolvated complex $(AN:Na:B15C5)^+$. In the whole range of AN mole fractions studied, the rate constant of the associative exchange, k_2, was not dependent upon X_{AN} in the error limits: $k_2 \approx 9 \times 10^4$ M^{-1} s^{-1} at 301.5 K ($\Delta G_{as}^{\neq} = 45$ kJ mol^{-1}). The activation parameters were determined to be $\Delta H_{as}^{\neq} = 23$ kJ mol^{-1} and $\Delta S_{as}^{\neq} = -75$ J K^{-1} mol^{-1}. These findings are in good agreement with an associative exchange controlled mainly by the conformational changes of the ligand during the concerted partial decomplexation of a sodium cation and partial complexation of a second one, while solvation of the complexed cation plays a major role in the dissociative mechanism.

KATHLEEN M. BRIÈRE et CHRISTIAN DETELLIER. Can. J. Chem. **70**, 2536 (1992).

Par RMN du ^{23}Na, on a étudié le rôle du solvant sur les cinétiques de dissociation et sur les mécanismes d'échange de cation dans le complexe sodium–monobenzo-15-couronne-5. Dans le nitrométhane (NM), l'échange cationique entre les complexes se fait par un mécanisme associatif d'interchange du métal, I_M. Dans l'acétonitrile (AN), il se fait par un mécanisme dissociatif (de dissociation/recombinaison). Dans les mélanges binaires AN–NM, la constante de vitesse de l'échange dissociatif (k_{-1}) s'accroît avec la fraction molaire d'AN, X_{AN}, de 1.1×10^{-2} s^{-1} pour $X_{AN} = 0$ à 89×10^{-2} s^{-1} pour $X_{AN} = 0.400$ (ce qui correspond à une diminution de l'énergie libre d'activation $\Delta G_{di}^{\neq}$ de 62.1 à 51.1 kJ mol^{-1} respectivement, à 301.5 K). Les paramètres d'activation sont $\Delta H_{di}^{\neq} = 48$ kJ mol^{-1} et $\Delta S_{di}^{\neq} = -20$ J K^{-1} mol^{-1} pour $X_{AN} = 0.200$. Cet accroissement de vitesse se corrèle avec un accroissement de la concentration en solution du complexe monosolvaté par AN (AN : Na : B15C5)$^+$. Dans tout le domaine étudié des fractions molaires en AN, la constante de vitesse de l'échange associatif, k_2, ne dépendait pas de X_{AN}, dans les limites des erreurs de mesure : $k_2 \approx 9 \times 10^4$ M^{-1} s^{-1} à 301.5 K ($\Delta G_{as}^{\neq} = 45$ kJ mol^{-1}). Les paramètres d'activation étaient $\Delta H_{as}^{\neq} = 23$ kJ mol^{-1} and $\Delta S_{as}^{\neq} = -75$ J K^{-1} mol^{-1}. Ces résultats sont en accord avec un mécanisme associatif contrôlé par des changements conformationnels du ligand durant la décomplexation partielle du cation complexé allant de concert avec la complexation partielle d'un second cation, alors que c'est la solvatation du cation complexé qui joue le rôle prépondérant dans le mécanisme dissociatif.

Introduction

Since the report on crown ethers by Pedersen in 1967 (1), a wealth of information has been published concerning alkali metal cation – macrocyclic ligand complexes (see, for example, ref. 2). The structural and behavioral similarities of these macrocyclic ligands to the larger natural antibiotic ionophores make the simpler crown ethers a choice model for the study of transport of important biological cations, such as sodium or potassium, across lipophilic membranes. To gain insight into the underlying selectivities of these ligands towards the alkali metal cations, it is necessary to define their mechanisms of association and dissociation. Although thermodynamic and structural studies are relatively abundant, the kinetic and mechanistic aspects have received little attention and therefore are still not well understood (3). They were investigated in recent years by a few research groups, using alkali metal NMR (3–10). So far, two limiting mechanistic hypotheses (11) have accounted for the kinetic results obtained for alkali metal cations (M^+) in the presence of crown ethers or cryptands (C) in nonaqueous solvents: a *dissociative* (eq. [1]; with the steps of dissociation (1*a*) and recombination (1*b*)) and an *associative* exchange (eq. [2]).

$$[1a] \quad (M:C)^+ \underset{k_1}{\overset{k_{-1}}{\rightleftharpoons}} M^+ + C$$

$$[1b] \quad M^{+}* + C \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (M^*:C)^+$$

$$[2] \quad (M:C)^+ + M^{+}* \overset{k_2}{\rightleftharpoons} (M^*:C)^+ + M^+$$

For a given cation – macrocyclic ligand system, the nature of the counteranion (12, 13) and that of the solvent (14, 15) were shown to affect the competition between the above mechanisms. We previously reported that whereas the metal interchange in $(Na:B15C5^+)$[3] proceeds via the associative pathway (eq. [2]) in the poorly donating solvent nitromethane (NM; donor number (DN) = 2.7 (16)), in acetonitrile (AN; DN = 14.1) the preferred route is dissociative (eq. [1])

(4, 17). This was observed despite the many similarities between these two solvents: the dielectric constants are 35.9 for both solvents, the dipole moments are 3.53 and 3.56 D, and the solubility parameters (Hildebrand's δ) are 24.8 and 26.0 $MPa^{1/2}$ for AN and NM respectively (18). We therefore proceeded to investigate further this dramatic mechanistic difference by characterizing the exchange kinetics of sodium in $(Na:B15C5)^+$ in the binary solvent mixtures of AN and NM. The gradual change from the associative to the dissociative exchange in going from NM to AN is mainly controlled by the nature of the first coordination sphere of the complexed cation and by the organization of the solvation cage around the complex.

Experimental section

B15C5 (Aldrich 98%) was recrystallized from hexanes and vacuum-dried over P_2O_5 (303 K) for at least 24 h prior to use. $NaBPh_4$ (Aldrich 99%) was recrystallized from cyclohexane with a minimum amount of ethanol, and vacuum dried (353 K) over P_2O_5 for at least 24 h prior to use. NM (BDH, OmniSolv) and AN (BDH, certified ACS) were dried under reflux over calcium hydride for 3 h, distilled under nitrogen, and stored under argon. The NMR tubes containing the sample solutions were prepared under argon and sealed with Parafilm. All the spectra were recorded within 48 h after the preparation of the samples.

Binary mixtures of desired mole fraction composition were prepared by adding the appropriate mass of AN in preweighed amounts of NM. The mole fraction, X, of the minor component was calculated from the masses of each component. Since the volumes of the individual components were not actually measured, the concentration, in moles/litre, of the minor component was calculated using the density values for each solvent at ambient temperature (18) and assuming additive volumes in determining the total volume of the binary mixture.

^{23}Na NMR spectra and transverse and longitudinal relaxation times were obtained on a Varian XL-300 spectrometer, at 79.35 MHz. In the case of Lorentzian lineshapes, the transverse relaxation times (T_2) were determined directly from the linewidths. The longitudinal relaxation times (T_1) were determined using the inversion–recovery 180°–τ–90° pulse sequence and T_1 was obtained from a three-parameter nonlinear regression analysis on at least nine experimental data points. The 90° pulse width was systematically verified and depended upon the experimental conditions; it was in the range 20–30 μs. The temperature of the probe was measured with a thermocouple dipped in nitromethane in a nonspinning 10-mm NMR tube. For a temperature range between 240 and 310 K, the temperature of the sample was estimated to be reliable to ±0.5 K. Pseudo-first-order rate constants were obtained from a full line-shape analysis of the ^{23}Na NMR spectra for a two-site exchange (19, 21). This was carried out on an Amdahl mainframe system using a nonlinear regression procedure as described previously (20).

The errors reported on values that resulted from statistical regressions are the standard errors, σ, associated with the regressions: ±1σ reported for linear regressions and ±2σ for nonlinear regressions. The free energies of activation, $\Delta G^{\neq}$, and their respective errors (19) were calculated directly from the rate constants at 301.5 K.

The chemical shifts were referenced to sodium chloride (0.1 M NaCl) in 90:10 (v/v) $H_2O:D_2O$ and were corrected for differences in bulk magnetic susceptibilities between the sample solvent and aqueous reference (eq. [3]). The correction factors (c.f. = $(4\pi/3)(\chi_{ref} - \chi_{samp})$; χ_{ref} and χ_{samp} are the volume magnetic susceptibilities of the reference and sample solvents (22, 23)) were calculated to be respectively −1.374 ppm for NM and −0.775 ppm for AN.

$$[3] \qquad \delta = \delta_{obs} + \text{c.f.}$$

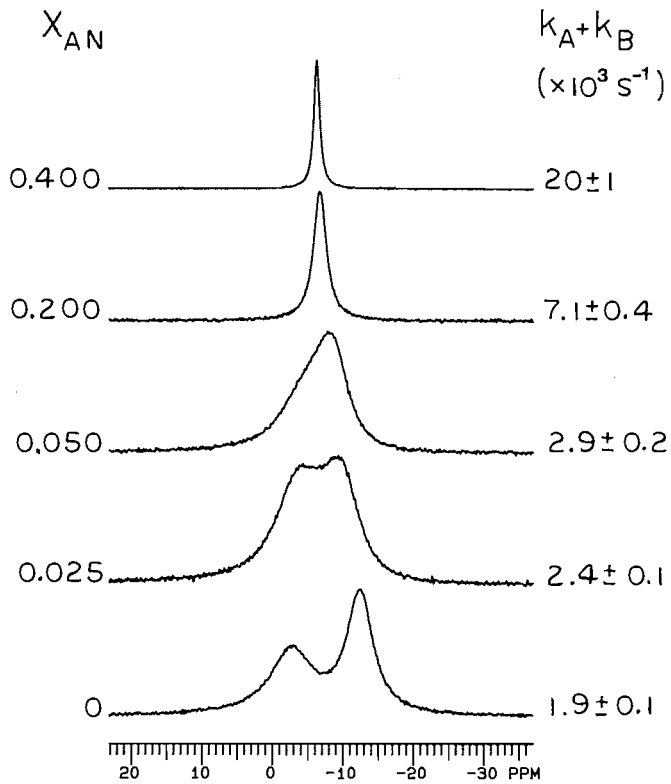

FIG. 1. ^{23}Na NMR spectra of samples containing equal populations of $(Na^+)_s$ and $(Na:B15C5)^+$ (ρ = 0.50) in AN–NM binary mixtures. $[NaBPh_4]_t$ = 20.0 mM and T = 301.5 ± 0.5 K. From top to bottom, the mole fraction of AN (X_{AN}) and ($k_A + k_B$) vary as shown.

For the binary solvent mixtures a weighted correction, determined from the values of the two neat solvents, was applied.

The viscosities of the binary mixtures were determined at 301 K using an Ostwald viscosimeter.

Results and discussion

In both AN and NM, the sodium cation forms quantitatively a 1:1 complex with B15C5 ($\log K_f > 4$) (4, 16, 24), so that it occupies two sites in solution (eq. [4]).

$$[4] \qquad A \underset{k_B}{\overset{k_A}{\rightleftharpoons}} B$$

Site A for the alkali metal cation is the solvated or "free" site, M^+, site B is the complexed alkali metal cation, $(M:C)^+$, and k_A and k_B are the pseudo-first order rate constants for the forward and reverse reactions respectively. In NM, at 300 K, this two-site exchange is slow on the ^{23}Na NMR chemical shift timescale, two separate peaks are observed, and a complete kinetic analysis from full lineshape analysis can be performed (4, 17). On the contrary, in AN, the exchange is very fast and a population weighted signal is observed, with no measurable exchange contribution to the linewidth (4). This can be observed in Fig. 1, which shows several ^{23}Na NMR spectra obtained at 301.5 K in a series of AN–NM binary solvent mixtures, for samples containing equal populations of solvated sodium (site A) and sodium complexed with B15C5 (site B). The bottom spectrum is that obtained in neat NM where a peak for each sodium site is observed (δ_A = −14.4 ppm; δ_B = −3.7 ppm). Upon in-

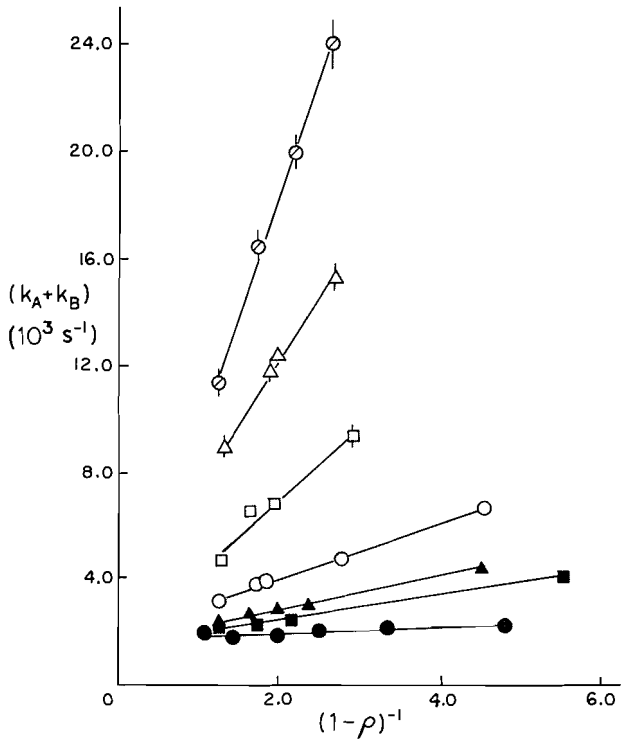

FIG. 2. $(k_A + k_B)$ as a function of $(1 - \rho)^{-1}$ for several AN–NM binary mixtures. $[NaBPh_4]_t$ = 20.0 mM and T = 301.5 ± 0.5 K. X_{AN}: (∅) 0.40; (△) 0.30; (□) 0.20; (○) 0.10; (▲) 0.050; (■) 0.025; (●) 0.

creasing the content of AN in the solvent, there is a coalescence of the two peaks around a mole fraction (X_{AN}) of 0.05, indicating an increase of the exchange rate.

For $X_{AN} < 0.2$, the pseudo-first-order rate constants were obtained from a complete lineshape analysis of the spectrum for an uncoupled two-site exchange case (19). The obtained lifetime (τ) is related to the pseudo-first-order rate constants as shown in eq. [5], since $P_A + P_B = 1$ (19, 21).

$$[5] \qquad \tau = P_A/k_B = P_B/k_A = (k_A + k_B)^{-1}$$

In eq. [5], P_A and P_B are the sodium populations in sites A and B respectively and τ is directly related to the lifetime of sodium in the two sites. For $0.2 \leq X_{AN} \leq 0.4$, the signal becomes Lorentzian, in the "moderately rapid" exchange limit, so that a comparison between the transverse relaxation rate (T_2^{-1}) and the longitudinal relaxation rate (T_1^{-1}) gives access to the pseudo-first-order rate constants (eq. [6]) (25–27).

$$[6] \qquad T_2^{-1} = 4\,P_A P_B\,\pi^2\,(\nu_A - \nu_B)^2\,(k_A + k_B)^{-1}$$

At $X_{AN} > 0.4$, a meaningful contribution to the exchange cannot be obtained.

The sum of the two pseudo-first-order rate constants, $(k_A + k_B)$, can be interpreted only if the corresponding mechanism of exchange is known. The two limiting mechanistic hypotheses (11), described in the introduction (eq. [1] and [2]), will be considered. They can be conveniently tested by the relationship between $(k_A + k_B)$ and the crown ether and salt concentrations, shown in eq. [7] (4, 21),

$$[7] \qquad k_A + k_B = k_{-1}(1 - \rho)^{-1} + k_2\,[Na^+]_t$$

where k_{-1} and k_2 are defined in eq. [1] and [2], $[Na^+]_t$ is the total concentration of sodium, and $\rho = [crown]_t/[Na^+]_t$.

Figure 2 shows plots of $(k_A + k_B)$ as a function of $(1 - \rho)^{-1}$ for several AN–NM binary mixtures varying in composition. In such linear plots, the slope is equivalent to k_{-1} whereas the intercept is related to k_2 (see eq. [7]) and one may thus separate the contributions of both mechanisms. In neat NM, this plot is near horizontal, indicating a mechanism predominantly associative. The slope increases as the content of AN in the solvent mixture increases, indicating a competition between both mechanisms. The linearity of all the plots is a good indication of the pertinence of this approach. It is noteworthy that all the plots extrapolate to the same value within experimental errors showing that k_2, the rate constant for the associative exchange, does not depend upon the nature of the solvent mixture, while k_{-1}, the rate constant for the dissociative exchange, displays a strong dependence upon X_{AN}. Table 1 contains the results obtained from linear regressions of the plots shown in Fig. 2, as well as the calculated free energies of activation, $\Delta G^{\neq}$, for the dissociative (di) and associative (as) exchange mechanisms: $\Delta G^{\neq}_{di}$ drops from 62 to 51 kJ mol^{-1} as X_{AN} increases to 0.40 while $\Delta G^{\neq}_{as}$ remains in the limits 44–46 kJ mol^{-1}. The extrapolation of the curve giving $\Delta G^{\neq}_{di}$ as a function of X_{AN} permits its estimation in neat AN: $\Delta G^{\neq}_{di} \sim$ 45–50 kJ mol^{-1}

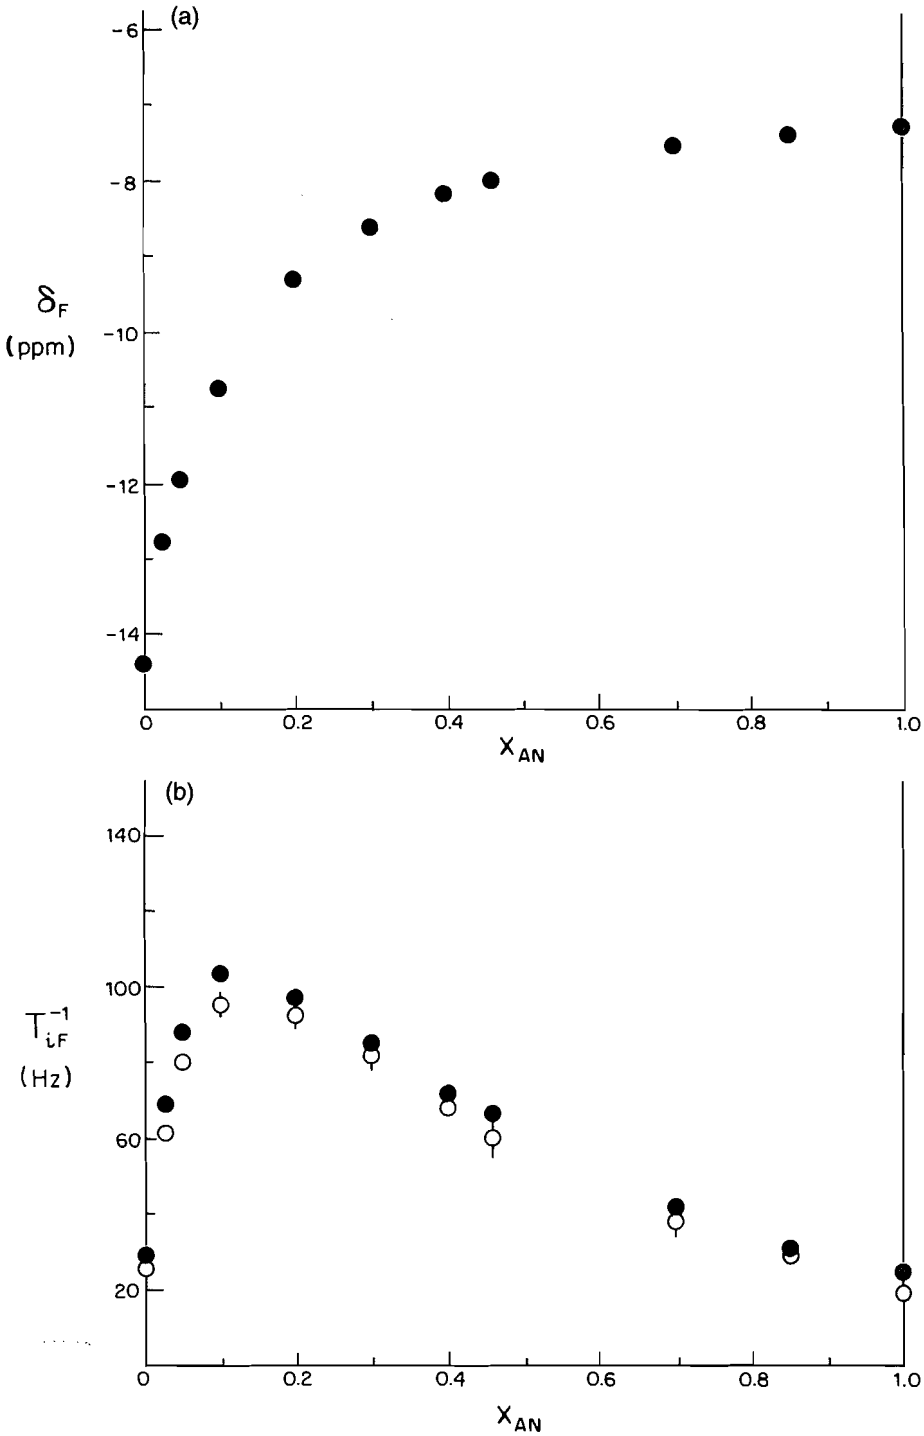

FIG. 3. (*a*) ^{23}Na NMR chemical shifts of $(Na^+)_s$, δ_F, as a function of the mole fraction of AN (X_{AN}). $[NaBPh_4]_t$ = 20.0 mM and T = 301.5 ± 0.5 K. (*b*) ^{23}Na NMR longitudinal (i = 1; ○) and transverse relaxation rate (i = 2; ●) of $(Na^+)_s$ as a function of the mole fraction of AN (X_{AN}). $[NaBPh_4]_t$ = 20.0 mM and T = 301.5 ± 0.5 K.

at 301.5 K. This can be compared with a value of 45.4 ± 0.4 kJ mol^{-1} previously reported at 258 K (4).

At this point, one should relate the exchange kinetics results with the nature of the various species in the binary mixtures. Figure 3 shows the variation of the solvated sodium cation, $(^{23}Na^+)_s$, chemical shift, δ_F, and of its transverse and longitudinal relaxation rates as a function of X_{AN}. The strong curvature of the chemical shift relationship towards low values of X_{AN} reflects a preferential solvation of the sodium cation by acetonitrile (28). The T_2^{-1} and T_1^{-1} values differ only by the instrumental inhomogeneities. While the relaxation rates are in the range 20–30 Hz in the neat solvents, a maximum value of 100 Hz is observed for X_{AN} ≅ 0.1. This value of X_{AN} (<0.5) indicates again a prefer-

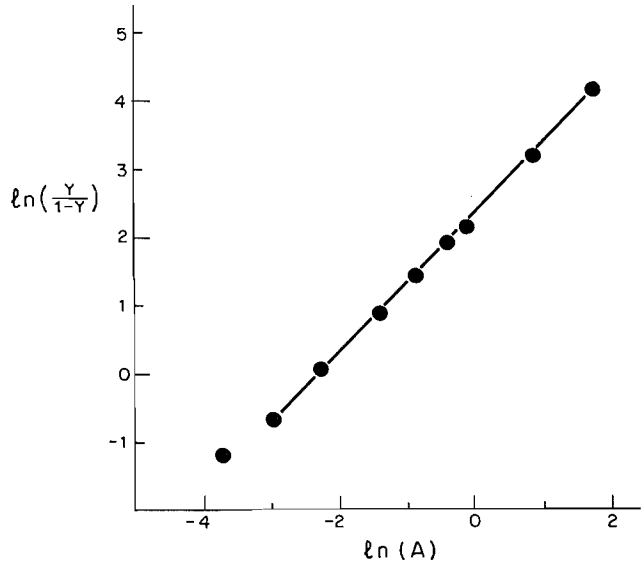

FIG. 4. Hill plot (see ref. 32) for AN–NM binary mixtures. $[NaBPh_4]_t$ = 20.0 mM and T = 301.5 ± 0.5 K.

ential solvation by AN (29). The maximum, as well as the general shape of the curve, reflects the dissymmetry of the sodium cation coordination sphere of the intermediate species $(Na^+(AN)_x(NM)_y)$ in the binary mixture (30). The application of the Hill formalism (31) has been extended to preferential solvation problems (32). Figure 4 gives the Hill plot for the ^{23}Na chemical shifts in the system AN–NM. The relationship is linear with a slope of 1.03 ± 0.03, indicating the absence of cooperativity (equality of the successive intrinsic constants) in the successive replacement of NM by AN molecules in the first sodium cation coordination sphere, as X_{AN} increases (32). This approach is based on the assumption that the ^{23}Na chemical shifts of the various solvates is additive (32–34). Since the process does not show any cooperativity, the Hill plot also yields the value of the intrinsic equilibrium constant of each step in the stepwise replacement of NM by AN molecules: K_s = 10.0 ± 0.3.

The ^{23}Na NMR parameters can also give information on the nature of the coordination sphere of sodium complexed with B15C5 (35). Figure 5 shows the relaxation rates corrected for the solvent viscosity, $R^* = T_2^{-1}/\eta$, as a function of X_{AN}. The simplicity of this curve is remarkable: no maximum, no inflection points are observed, and R^* decreases monotonically from 9.8×10^4 to 3.5×10^4 s^{-1} P^{-1}. For several binary solvent mixtures, the T_1^{-1} values were found to approximate the T_2^{-1} values within inhomogeneity, confirming the absence of any exchange contribution to the observed T_2^{-1}, which, except for inhomogeneity, has a purely quadrupolar origin ($T_2^{-1} = T_{2,inh}^{-1} + T_{2,q}^{-1}$; with $T_{2,inh}^{-1} << T_{2,q}^{-1}$) (30). In the case of a spin-3/2 nucleus, the quadrupolar relaxation rate in extreme narrowing conditions is given by eq. [8].

$$[8] \quad T_{2,q}^{-1} = T_{1,q}^{-1} = (2/5)\,\pi^2\chi^2\tau_c$$

where τ_c, which is related to the macroscopic viscosity through the Debye–Stokes–Einstein relationship (eq. [9]), is the correlation time characteristic of the quadrupolar relaxation and χ is the quadrupolar coupling constant (QCC) given by eq. [10].

$$[9] \quad \tau_c = 4/3\,\pi\,a^3\,(\eta/k_BT)f_r$$

$$[10] \quad \chi = (e^2qQ\,(1 + \gamma_\infty))/h$$

In eqs. [9] and [10], a is the molecular radius and f_r is a microviscosity coefficient, Q is the ^{23}Na nuclear quadrupole moment, q is the electric field gradient at the quadrupolar nucleus site, and $(1 + \gamma_\infty)$ is the Sternheimer antishielding factor. From eqs. [8]–[10], it appears that $T_{2,q}^{-1}$ is proportional to χ^2 and η. Since QCC is a very sensitive probe of the electronic distribution in the first coordination sphere

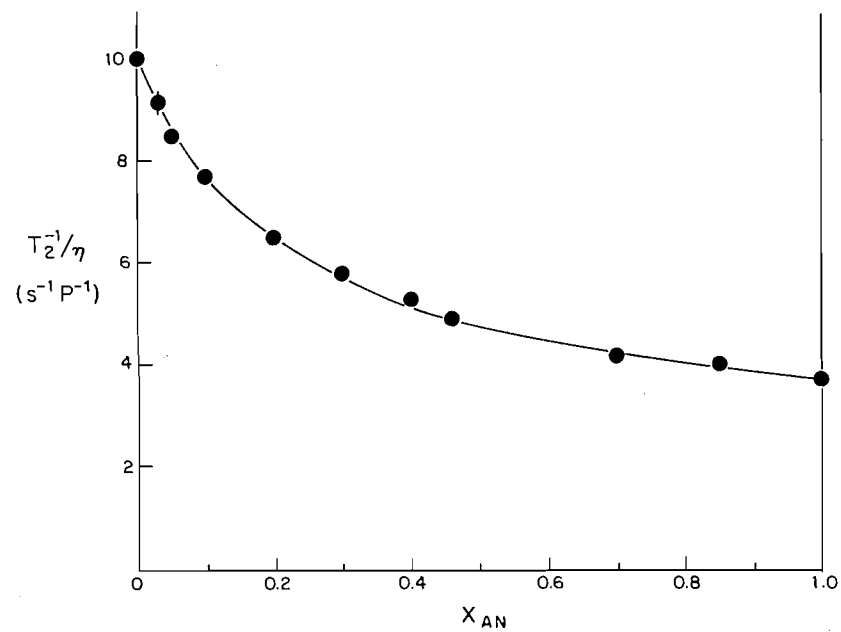

FIG. 5. ^{23}Na NMR transverse relaxation rates corrected for solvent viscosity, $R^* = T_2^{-1}/\eta$, of Na^+ complexed with B15C5 as a function of AN mole fraction in AN–NM binary mixtures. The data points are experimental and the curve is calculated (K_{CS} = 5.1; eq. [11]).

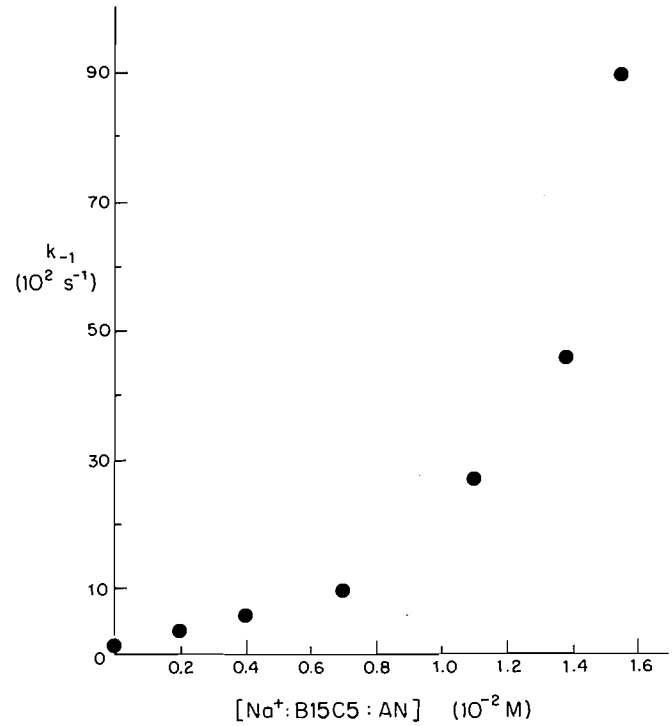

FIG. 6. The dissociative rate constant, k_{-1}, as a function of the concentration of the species $(AN:Na:B15C5)^+$.

of the sodium cation (30), R^* should be independent of X_{AN} if the environment of the sodium cation in the complex is invariant throughout the binary mixture range, as was shown previously for the systems $^{23}Na^+$–DB24C8 (36) and $^{39}K^+$–DB30C10 (37). So Fig. 5 shows the presence of more than one species in the binary mixtures. However, the smooth monotonic variation suggests no more than two species. Otherwise, one would expect the presence of a maximum such as that in Fig. 3*b*. The relationship between R^* and X_{AN} can be interpreted on the basis of a simple two-species model (eq. [11]):

$$[11] \quad (NM:Na:B15C5)^+ + AN \overset{K_{CS}}{\rightleftharpoons} (AN:Na:B15C5)^+ + NM$$

The observed T_2^{-1} is population averaged on the limiting values, obtained in neat solvents, for the two species shown in eq. [11]. Based on the above equilibrium, a nonlinear regression of the data shown in Fig. 5 gave the value 5.1 ± 0.5 for K_{CS}. This value is in the same order of magnitude as the intrinsic equilibrium constant for the replacement of one molecule of NM by one molecule of AN in the first coordination sphere of solvated sodium ($K_s = 10.0 \pm 0.3$). In Fig. 5, the data points are experimental and the curve is calculated. For any mole fraction, one can calculate the concentration of the species $(AN:Na:B15C5)^+$. Figure 6 shows a plot of the dissociative rate constant, k_{-1}, as a function of the concentration of $(AN:Na:B15C5)^+$. For values of $X_{AN} \leq 0.1$, corresponding to $[(AN:Na:B15C5)^+] \leq 7 \times 10^{-3}$ M (the total concentration of $Na^+ = 20.0 \times 10^{-3}$ M throughout this study), the relationship is linear. For higher values of X_{AN}, a strong increase of k_{-1} is observed. These results strongly suggest that the active species in the dissociative mechanism is the AN monosolvated complex (eq. [11]; $(AN:Na:B15C5)^+$) and that the first event in the dissociation process is the formation of this complex, governed by K_{CS}.

The global dissociation process is the result of a series of stepwise sodium–oxygen bond ruptures accompanied by sodium–solvent bond formations. This concept was recently discussed by Cox and Schneider (10). One can assume that the molecular composition of the solvation cage around the AN solvated complex (second solvation sphere of the sodium cation) roughly parallels the composition of the bulk solvent. Direct access to this information is not possible, since the ^{23}Na NMR parameters reflect the local solvent composition, at the $^{23}Na^+$ nucleus site. At low X_{AN} values, the solvation cage around the sodium complex is predominantly constituted of NM molecules. The general aspect of the plot shown in Fig. 6 is in good agreement with this model. Qualitatively, one should expect an increase of the rates in each of the discrete dissociative steps as the concentration of AN in the solvation cage of the complex increases, since AN is a stronger donor solvent than NM. Figure 6 is a reflection of this, since k_{-1} increases dramatically as X_{AN} increases. At low AN molar fractions, the nature of the solvation cage around the AN-solvated complex is mainly composed of NM molecules, and can be, at first approximation, considered as constant. The linear part of the plot, which one can visualize as the tangent to the plot at concentration 0, corresponds to a "clean" process in which the dissociating species can be identified to a supramolecular aggregate of a sodium cation complexed by a crown ether and coordinated by one acetonitrile molecule, encaged in a solvation shell of NM molecules. As the solvation cage is enriched in AN the global dissociation process is accelerated, in good agreement with Na^+—O bond ruptures concerted with Na^+–solvent bond formation.

To more completely characterize the competition between the dissociative and associative exchange mechanisms, variable temperature studies were performed in which values for the activation parameters of both competing mechanisms could be determined. Figure 7 shows four graphs of plots of $(k_A + k_B)$ as a function of $(1 - \rho)^{-1}$ (see eq. [7]) for four different values of X_{AN}. In each graph, the temperature is varied from 301.5 K (top) to 255.0 K (bottom). As in Fig. 2, the dissociative rate constant, k_{-1}, is obtained from the slope whereas the associative rate constant, k_2, is obtained from the *Y*-intercept. As expected, at each value of X_{AN}, both the k_{-1} and k_2 values increase with temperature. Reliable values of activation parameters for the dissociative process could be obtained only for $X_{AN} = 0.3$ and 0.2, since at the lower values of X_{AN}, the exchange is mainly controlled by the associative process. The results shown in Fig. 7 are also an illustration of an exchange process whose associative or dissociative nature is controlled by temperature. At the lower temperatures, the associative process, characterized by large negative entropies of activation, is favoured. As the temperature increases, the dissociative mechanism becomes competitive. A similar behaviour has been reported by Popoy and co-workers in the case of a diazacrown complex of sodium in tetrahydrofuran (38). Figure 8 shows the Eyring plots for the dissociative rate constant, k_{-1}. Table 1 gives the values of the activation parameters for both mechanisms at different values of X_{AN}. The activation

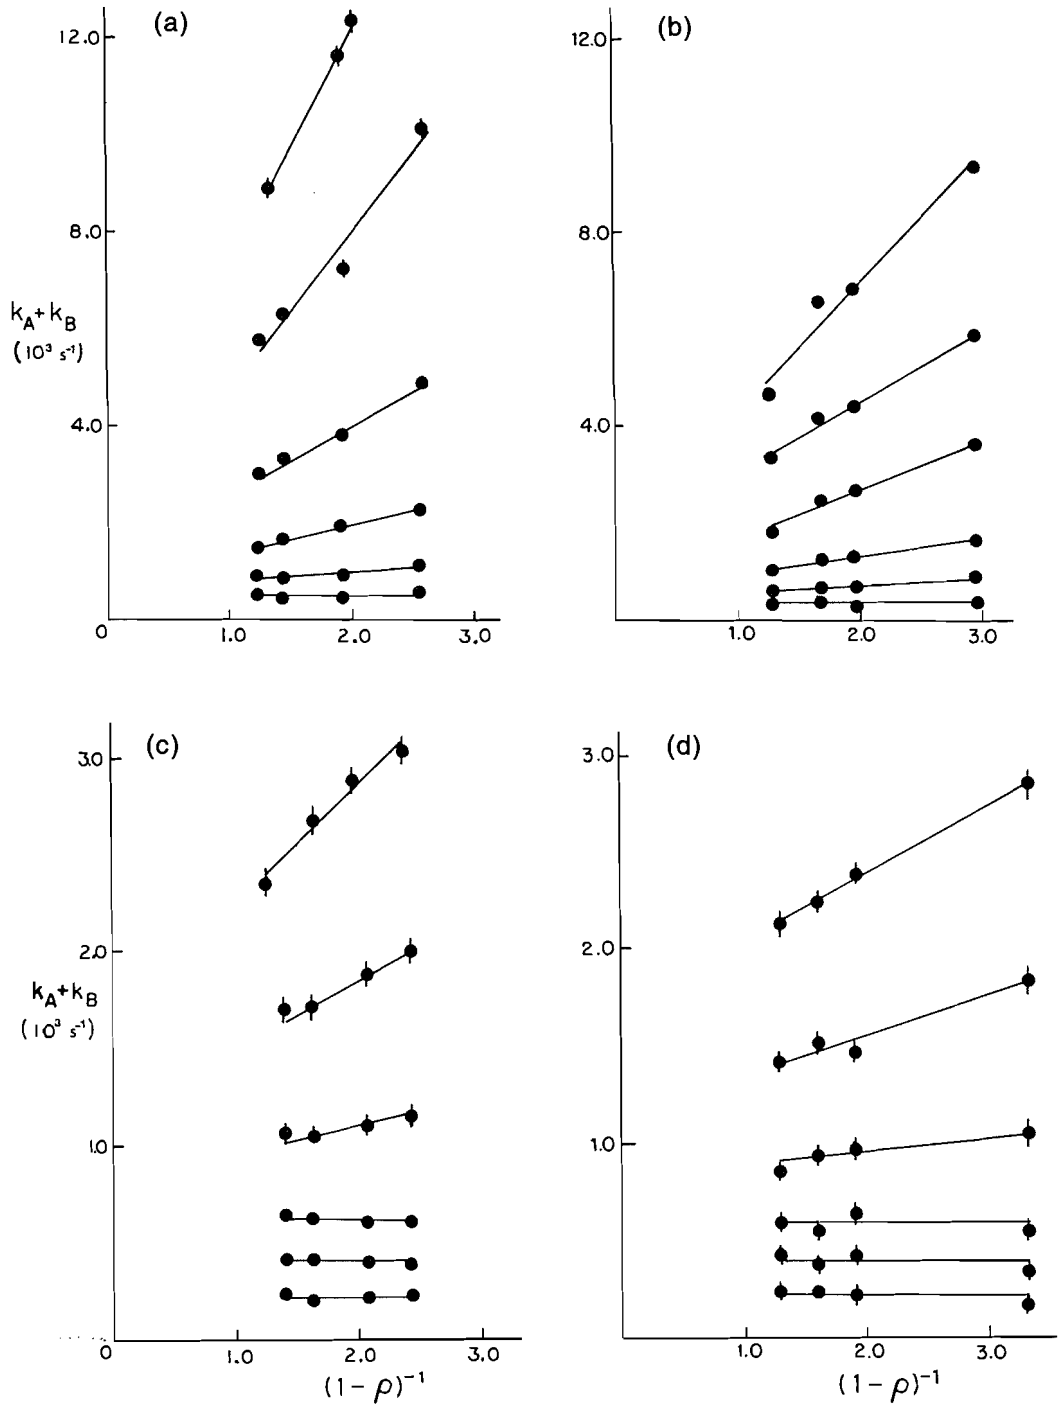

FIG. 7. (k_A + k_B) as a function of $(1 - \rho)^{-1}$ for a series of temperatures, at various mole fractions. (*a*) X_{AN} = 0.300; (*b*) X_{AN} = 0.200; (*c*) X_{AN} = 0.050; (*d*) X_{AN} = 0.025. In all four cases, from top to bottom, T = 301.5, 293.0, 284.0, 274.0, 264.5, 255.0 K.

parameters characterizing the associative process are essentially constant throughout the range of binary mixtures studied, in excellent agreement with our previous finding that this exchange process is mainly controlled by conformational factors (4, 5), which should be only slightly dependent upon the binary mixture composition. The large, negative value of $\Delta S^{\ddagger}_{as}$ is expected for an associative mechanism.

This study shows that the molecular role of the solvent in the kinetics and mechanisms of formation/dissociation of supramolecular entities in solution can be specified. The mechanistic difference that is observed between NM and AN could be related to the presence in solution of a species $(AN:Na:B15C5)^+$ strongly favoring the dissociation mechanism. A system in which a more strongly donating solvent molecule, such as dimethylformamide (DN = 26.6, compared to 14.1 for AN), would occupy the first coordination sphere of sodium in the solvent NM should permit us to specify further the nature and the role of the active species

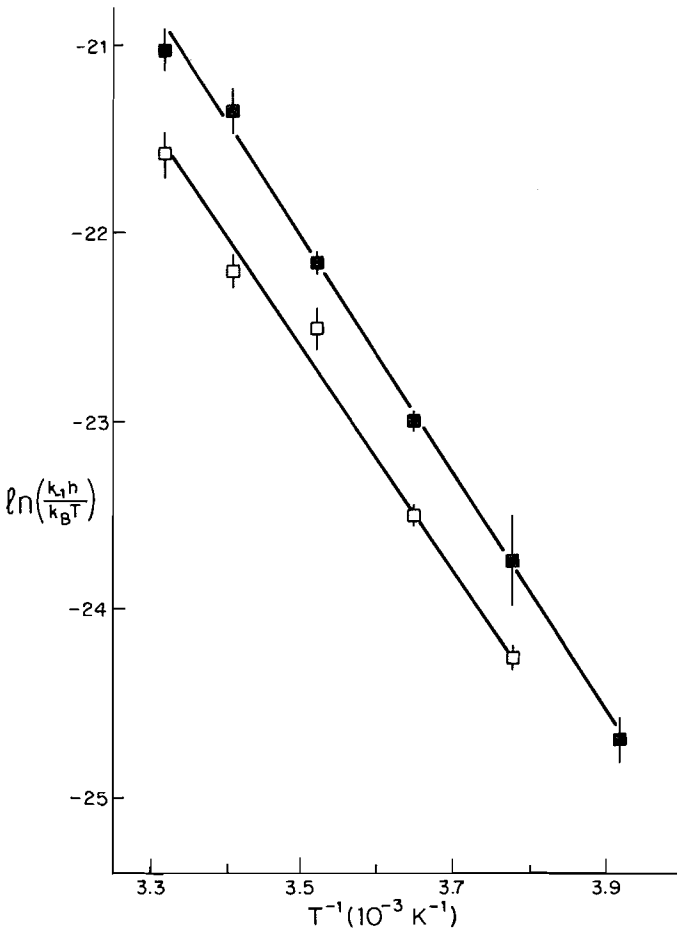

FIG. 8. Eyring plots for the dissociation rate constant of the complex $(Na:B15C5)^+$, k_{-1}, in AN–NM binary mixtures: X_{AN} = 0.300 (■); X_{AN} = 0.200 (□).

in the dissociation process. This work will be published in a forthcoming paper.

Synthesis, multinuclear NMR, and solution conformation of (η^5-indenyl)CoIR$_f$L complexes (L = CO, P-donor)

CHET R. JABLONSKI[1] AND ZHONGXIN ZHOU

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received December 4, 1991

CHET R. JABLONSKI and ZHONGXIN ZHOU. Can. J. Chem. **70**, 2544 (1992).

The preparation, spectroscopic characterization, and conformational analysis of a series of Co(III) indenyl complexes, (C_9H_7)CoIR$_f$L (R$_f$ = C_3F_7, C_6F_{13}, L = CO, P-donor), **2–8**, are described. ^{13}C and ^{1}H NMR parameters are consistent with a slightly distorted η^5-C_9H_7 coordination. ^{1}H nuclear Overhauser effect difference (nOed) spectra indicate a preferred solution conformation in which the perfluoroalkyl group is *trans* to the C_{3a}—C_{7a} ring junction.

CHET R. JABLONSKI et ZHONGXIN ZHOU. Can. J. Chem. **70**, 2544 (1992).

On décrit la préparation, la caractérisation spectroscopique et l'analyse conformationnelle d'une série de complexes du Co(III) indényle, (C_9H_7)CoR$_f$L (R$_f$ = C_3F_7 et C_6F_{13}; L = CO et P-donneur), **2–8**. Les paramètres RMN du ^{1}H et du ^{13}C sont en accord avec une coordination η^5-C_9H_7 légèrement déformée. Les spectres de différence d'effet Overhauser nucléaire du ^{1}H (deOn) suggèrent une conformation privilégiée en solution dans laquelle le groupe perfluoroalkyle est *trans* par rapport à la jonction C_{3a}—C_{7a}.

[Traduit par la rédaction]

Introduction

Transition metal π-indenyl complexes have attracted a great deal of attention, compared to their isostructural cyclopentadienyl derivatives, because of their enhanced reactivity toward ligand substitutions and related reactions (1–10). The "indenyl effect" has been explained on the basis of the ability of the π-indenyl ligand to undergo facile $\eta^5 \leftrightarrow \eta^3$ "ring-slippage" (5–9, 11–22).

Compared to other transition metals, the π-indenyl chemistry of cobalt remains relatively underdeveloped. π-Indenyl complexes are known for cobalt in formal oxidation states III, II, and I with the very air-sensitive Co(I) derivatives formulated as (η^5-indenyl)CoL$_2$ (L = ethylene (23, 24), CO (25, 26), PPh_3 (27), PMe_3 (28), $P(OR)_3$ (29) or L$_2$ = cyclic and acyclic dienes (3, 4, 23) or vinylketenes (27)) being the most numerous. Fewer Co(III) complexes have been reported (21, 27, 28, 30) and only one crystal structure ((η^5-indenyl)Co($C_2B_9H_{11}$)) has been determined (21). The homoleptic examples [(indenyl)$_2$Co]PF_6 (30) and (indenyl)$_2$Co (31) serve to delineate bonding extrema observed for cobalt and to illustrate the dependence of indene distortion and hapticity on electronic configuration (32). Structural studies (32) establish that the 19e$^-$ Co(II) indenyl complex significantly distorts towards an η^3 bonding mode. ^{13}C NMR data (30, 32, 33) confirm that the 18e$^-$ Co(III) complex, [(indenyl)$_2$Co]PF_6, is a "true" η^5-indenyl species.

During studies of chiral induction from the asymmetric metal centre of pseudo octahedral cyclopentadienyl complexes in the Arbuzov-like dealkylation of Scheme 1, we found that reactivity and optical selectivity are subtly related to the stereoelectronic properties of the ligand sphere (34–36). Reasoning that the lowered symmetry of piano-stool π-indenyl compared to their isostructural cyclopentadienyl Co(III) complexes might restrict rotamer populations and result in more efficient Co→P chiral induction for the chemistry outlined in Scheme 1, we reported (37, 38) the preparation and resolution of $(-)_{436}$-(η^5-C_9H_7)CoI(C_3F_7)-($PPh_2NHCH(CH_3)Ph$), **9**. To more clearly define the influence of ligand properties on conformation preferences of indenyl complexes, we prepared the series **2–8** (η^5-C_9H_7)-CoIR$_f$L (R$_f$ = C_3F_7, C_6F_{13}; L = CO, P-donor). Herein we report the synthesis, spectroscopic properties, and solution conformation of these new complexes.

Results and discussion

Synthesis and properties

Preparation of the title complexes was carried out according to Scheme 2. The known complex **1** was prepared (38) using a modification of the method originally described by Bönnemann (3) and Salzer and Taschler (26), which represents the most convenient route to **1**, the precursor for preparation of the new π-indenyl cobalt complexes. Oxidative additions of R$_f$I to **1** are slow but afford complexes **2** and **3** in good yield. Complexes **4–8** are then prepared by facile CO substitution in **2** and **3** by phosphorus donor ligands. Except for **7**, which decomposes at room temperature in the solid state within several days, all the π-indenyl cobalt(III) complexes prepared in this study are air stable in the solid state, but decompose gradually in solution at room temperature. They have been characterized by elemental analysis, infrared and multinuclear NMR spectroscopy, and, in the case of **3** and **6**, by X-ray diffraction.[2,3] Their physical properties are summarized in Table 1. The NMR spectra are discussed more fully below.

[2]Octahedral, slightly distorted η^5-structures for **3** and **6** were confirmed by X-ray crystallography. Problems encountered during data collection along with sample twinning resulted in relatively low-precision structures. The solid state and solution conformations were identical in the case of **3**. The solid state conformation of **6** places the $PPh(OCH_3)_2$ ligand *trans* to the indenyl 6-ring.

[3]Details of the structure refinements, crystal data, positional parameters, thermal factors, bond distances, intramolecular bond angles, Pluto diagrams, and intensity data have been deposited and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of crystal data, positional parameters, bond distances and angles, and the Pluto diagrams have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 IEZ, U.K.

NMR spectroscopy

The NMR spectra of transition-metal indenyl complexes have been extensively studied (7, 19, 30, 33, 39–41). Both electronic (15, 42) and steric (39, 41, 43, 44) factors can influence the extent of η^5-indenyl ring distortion as well as the preferred conformation of the ligands relative to the indenyl ring in solution.

^1H and ^{13}C NMR data are given in Tables 2 and 3, respectively. The presence of a chiral Co centre requires that the indenyl ring atoms (1,3; 4,7; 5,6) be diastereotopic and, in general, well-separated resonances were observed in both the 7.05 tesla ^1H and ^{13}C NMR spectra. ^1H NMR assignments (cf. Table 2) are supported by nuclear Overhauser effect difference (nOed) spectra shown in Fig. 1 for the representative case

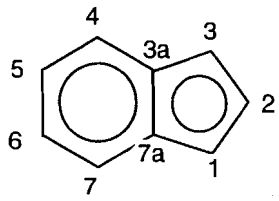

SCHEME 3

of complex **6**. Irradiation of the proton with δ = 4.88 ppm (Fig. 1*g*) results in enhancement of the peaks at δ = 5.68 and 7.16 ppm, but no enhancement of the peak at δ = 6.47 ppm. Irradiation of the proton with δ = 5.68 ppm (Fig. 1*f*) enhances the δ = 4.88 and 6.47 ppm signals. Irradiation of the proton at δ = 6.47 ppm (Fig. 1*e*) enhances the proton signals at δ = 5.68 and 7.53 ppm but no other enhancements were observed. Accordingly the three signals in the region of 4.5–7.0 ppm are assigned to H1 (4.88 ppm), H2 (5.68 ppm), H3 (6.47 ppm), respectively, and the higher-field doublet (δ = 7.16 ppm) is assigned to H7 while the lower-field doublet (δ = 7.53 ppm) corresponds to H4 (cf. Scheme 3 for numbering system). The ^{1}H NMR data for the remaining complexes were assigned on the basis of nOed data and by comparison with complex **6**. A similar method was employed by Coville and co-workers (39, 43, 44) to assign the ^{1}H NMR of a series of chiral indenyl ruthenium and iron complexes.

The ^{13}C spectra of complex **3** (cf. Table 3) were definitively assigned on the basis of 2-D ^{1}H/^{13}C ^1J heterocorrelation spectra, which correlate ^{13}C (95.37 ppm) with H2 (δ = 5.90 ppm), ^{13}C (87.95 ppm) with H3 (δ = 6.85 ppm), and ^{13}C (71.94 ppm) with H1 (δ = 5.80 ppm). Thus the indenyl carbon atoms are assigned as C1 (δ = 71.94 ppm), C2 (δ = 95.37 ppm), and C3 (δ = 87.95 ppm), respectively. Correlations of H4–H7 with C4–C7 were also clearly observed so that the assignments of the remaining indenyl carbons are unambiguous. Assignments for the remaining complexes in the series were made analogously.

The ^{19}F chemical shift assignments and coupling constants for the complexes investigated in this study are reported in Table 4. All compounds showed well-separated C_α–C_γ and C_α–C_ζ resonances for the perfluoropropyl and perfluorohexyl compounds, respectively. Due to the presence of the chiral Co centre and typically small vicinal couplings ($^3J_{FF}$ = 5–8 Hz), the ^{19}F spectra of the diastereotopic $(CF_2)_n$ groups are well approximated as a series of isolated AB spin systems. $^2J_{F_aF_b}$ values for F_a–C–F_b show a marked increase on passing from C_α to C_β but are relatively constant further along the perfluoroalkyl chain (cf. Fig. 2), pointing to a weakening of the C_α—F bond (45).

The ^{1}H and ^{13}C chemical shifts of η^5-indenyl are relatively insensitive to the perfluoroalkyl ligand in these complexes, suggesting that the electronic and steric requirements of C_3F_7 and C_6F_{13} are similar in determining the spectroscopic properties. However, the chemical shifts of the diastereotopic η^5-indenyl H1 and H3 protons correlate well with the electronic parameter (χ(cm^{-1})) (46, 47) of the phosphorus ligand (L) (cf. Fig. 3). The chemical shift of H1 decreases as the electronic donicity of L increases (the value of χ decreases) while the chemical shifts of H3 increase as the electronic donicity of L increases. The chemical shift of H2 is relatively insensitive to L. Thus, high donicity ligands result in a large difference of the chemical shifts for H1 and H3 (Δδ(H3–H1)) (cf. Fig. 3). Crabtree and coworkers (15, 42) argue that preferential weakening of the Co—C3a and Co—C7a bonds is expected to facilitate more significant stabilization via aromatization, hence strong *trans*-

[d]Cf. refs. 37, 38.

influence ligands will prefer a site *trans* to the indenyl 6-ring regardless of steric consequences. For complexes **2–8**, the strong *trans*-influence perfluoroalkyl ligands will then presumably select a conformation placing L between H1 and H7, *trans* to H3 of the indenyl ring as shown in Fig. 4.

The same conformational preference is deduced by examination of the ^{13}C NMR spectra. The C3 resonances (cf. Table 4) for complexes **4–9** are doublets with $^2J_{PC}$ equal to 10 ± 2 Hz while no coupling was observed for C1, which is *cis* to the phosphorus atom. In some cases coupling of C2 to phosphorus was also detected.

Support for these conformational preferences was ob-

FIG. 1. ^{1}H nOed spectra for **6**. (*i*) reference spectrum; (*a–h*) difference spectra (16x) for irradiation at the indicated (*) frequency; (*a*) H_{ortho}; (*b*) H4 and H_{meta}; (c) H5, H6, and H_{para}; (*d*) H7; (*e*) H3; (*f*) H2; (*g*) H1; (*h*) OCH_3.

tained from ^{1}H nOed (nuclear Overhauser effect difference spectra) experiments. The nOed spectra of complex **4** (cf. Fig. 5) unambiguously show that the $P(OCH_3)_3$ ligand bisects the H1 and H7 indenyl protons. Irradiation of the OCH_3 groups results in a strong enhancement to H1 and H7 and a very weak enhancement to H2, but *no* enhancement to H3 (cf. Fig. 5*f*). Successive irradiation of H1, H2, H3 reveal the proximal protons (Fig. 5*c*, *d*, *e*). Similar nOed results were observed for complex **5**.

The nOed spectra of complex **6** (cf. Fig. 1) are also in accord with the conformational arguments presented above.

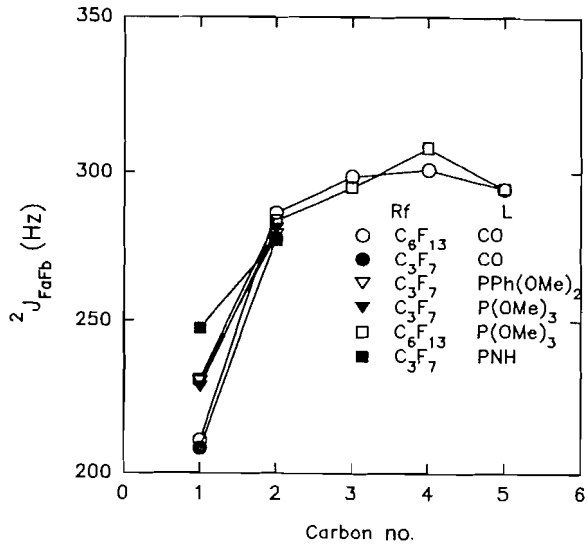

FIG. 2. Dependence of the ^{19}F coupling constants on position.

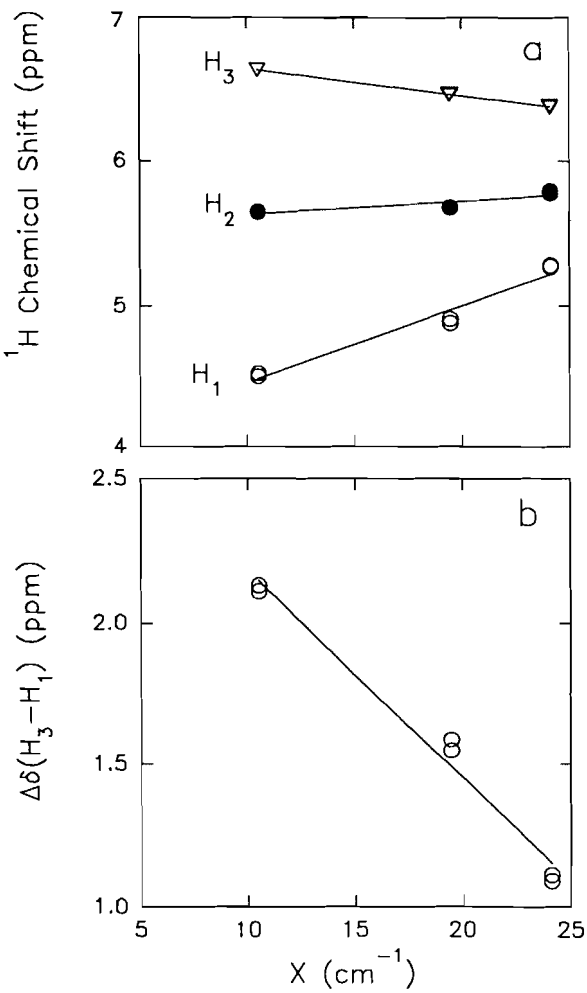

FIG. 3. Correlation of indenyl ^{1}H chemical shifts with χ.

Irradiation of the *ortho*-proton resonances of the $PPh(OCH_3)_2$ ligand results in strong enhancements for H7, H1, and OCH_3 (cf. Fig. 1*a*). Irradiation of H7 results in enhancement to the *ortho* protons and H1 (cf. Fig. 1*d*). Irradiation of OCH_3 (cf.

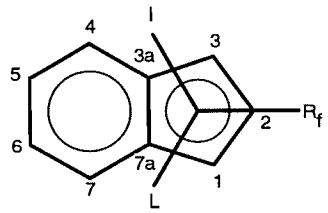

FIG. 4. Solution conformation of (η^5-indenyl)Co(R_f)(I)(L).

FIG. 5. ^{1}H nOed spectra for **4**. (*g*) reference spectrum; (*a–f*) difference spectra (32×) for irradiation at the indicated (*) frequency; (*a*) H4; (*b*) H7; (*c*) H3; (*d*) H2; (*e*) H1; (*f*) OCH_3.

Fig. 1*h*) affords a small but definitive enhancement to H1 and H7. The solution conformation of complex **9**, which was also determined by ^{1}H nOed, is the same as the complexes discussed above (37, 38).

Strong correlations between the indenyl ring junction (C3a, C7a) ^{13}C chemical shift and indenyl distortion have been reported (16, 18, 30, 32, 33). $\Delta\delta^{13}C_{3a,7a}$ ($\Delta\delta^{13}C_{3a,7a} = \delta^{13}C_{3a,7a}$(indenyl) $- \delta^{13}C_{3a,7a}$(Na^+indenyl$^-$)) has been demonstrated to be a reliable indicator of indene hapticity (16, 18, 32, 33) with values in the range -10 to -40 ppm and $+5$ to $+30$ considered diagnostic for η^5 and η^3 bonding, respectively (33). The calculated $\Delta\delta^{13}C_{3a,7a}$ parameters, determined from the chemical shifts of the diastereotopic ring junction carbons of the chiral complexes **2–9** (cf. Table 5), are in the range of -22 to -17 ppm, consistent with their description as slightly distorted η^5 complexes (32, 33), and are completely in accord with solid state results (see footnote 2).

[b] Cf. refs. 37, 38.

Summary

The preparation and spectroscopic characterization of a series of η^5-indenyl cobalt(III) complexes are described. Consistent with their 18e$^-$ configurations, the indenyl ring in these complexes is η^5-bonded but NMR parameters suggest a characteristic distortion towards η^3. ^{1}H nuclear Overhauser effect difference spectra show that all of these complexes prefer a solution conformation that places the perfluoroalkyl ligand *trans* to the indenyl 6-ring and the P-donor ligand *trans* to C3.

A good correlation is found for the ^{1}H chemical shift difference between H1 and H3 ($\Delta\delta$(H3–H1)) and the electron donicity (χ(cm^{-1})) of the *trans*-lying phosphorus ligand. The easily determined diastereotopic chemical shift difference ($\Delta\delta$(H3–H1)) reflects the extent of rotamer preference in the chiral-at-metal (η^5-indenyl)Co(III) complexes and, if ring-slip distortion is related to ligand electronic effects as has been suggested (15), may be a reactivity indicator.

Experimental section

Reagents and methods

All manipulations were performed under a dry, oxygen-free nitrogen or argon atmosphere using standard Schlenk techniques. Nitrogen gas was purified by passing through a series of columns containing DEOX (Alpha) catalyst heated to 120°C, granular P_4O_{10}, and, finally, activated 3A molecular sieves. THF, benzene, and hexane solvents were distilled under nitrogen from blue solutions of sodium benzophenone ketyl. Methylene chloride was distilled under nitrogen from P_4O_{10}. Anhydrous $CoCl_2$ was prepared by refluxing $CoCl_2 \cdot 6H_2O$ with thionyl chloride ($SOCl_2$, bp 77°C). Indene and 1,5-cyclooctadiene (COD) were vacuum distilled before use. C_3F_7I, $C_6F_{13}I$, and $PPh(OCH_3)_2$ were purchased from Aldrich and used as received. $P(OCH_3)_3$ (Strem) was distilled under vacuum before use. (*S*)-(−)-Diphenyl((1-phenylethyl)amino)phosphine (PNH) was prepared using the established procedure reported by Brunner and Doppelberger (48). Infrared spectra were measured on a Mattson Polaris Fourier transform spectrometer as solutions in KBr cells (0.1 mm) or as thin films deposited on a KBr

disk. Elemental analyses were performed by Guelph Chemical Laboratories Ltd. Melting points were determined in sealed capillaries and are uncorrected. NMR spectra were recorded on a GE 300-NB Fourier transform spectrometer operating at a proton frequency of 300.12 MHz. Complexes **1** and **9** were prepared as described previously (37, 38).

Proton nOed spectra were determined under steady state conditions on the GE 300-NB instrument. Data were collected using interleaved experiments of 16 or 32 transients cycled 12–16 times through the list of decoupling frequencies. In each experiment the decoupler was gated on in continuous wave (CW) mode for 6 s with sufficient attenuation to give an approximate 70–90% reduction in intensity of the irradiated peak. A 60 s delay preceded each frequency change. A set of four equilibrating scans was employed to equilibrate the spins prior to data acquisition. No relaxation delay was applied between successive scans of a given decoupling frequency. Difference spectra were obtained on 16 K or zero-filled 32 K data tables that had been digitally filtered with a 0.1 Hz exponential or Gaussian line broadening function. Quantitative data were obtained by integration.

Synthesis of (η^5-C_9H_7)$Co(CO)(I)(C_6F_{13})$, ***3***

Compound **1** (5.25 g, 22.8 mmol) was dissolved in 50 mL of benzene in an atmosphere of dry nitrogen. Perfluorohexyl iodide (10.8 g, 24.2 mmol) was injected into the solution via syringe and the solution stirred for 40 h at room temperature to afford a dark, red-brown solution containing some black precipitate. The reaction mixture was filtered through a Schlenk filter fitted with a 10 cm silica gel pad and washed with methylene chloride. TLC analysis (elution with benzene:hexane 2:1) showed the formation of a single product. Removal of solvent with the aid of a rotary evaporator left **3** as an air-stable, black powder (11.0 g, 75%). The crude product was dissolved in a small amount of methylene chloride and crystallized by slow diffusion of hexane at −20°C to give pure **3** as black, rectangular plates. Compound **2** was prepared from **1** and C_3F_7I using similar conditions.

Synthesis of (η^5-C_9H_7)$Co(R_f)(I)(L)$ ($R_f = C_3F_7$, C_6F_{13}; $L = P(OCH_3)$, $PPh(OCH_3)_2$, PNH) ***4–8***

All P-donor substituted complexes were synthesized using a procedure similar to that used for complex **6** described below. $PPh(OCH_3)_2$ (0.0912 g, 0.536 mmol) was added slowly via syringe with stirring to a solution of **2** (0.2547 g, 0.5102 mmol) in 10 mL benzene in a nitrogen atmosphere at room temperature. After stirring for 0.5 h, the solution was placed on an ice bath for 10 min. Removal of volatiles under oil-pump vacuum left the crude product as a dark powder (0.3043 g, 93%). The crude product was dissolved in a small amount of CH_2Cl_2 and crystallized by slow diffusion of hexane at −20°C to afford pure **6** as black prisms.

2-Chloro-2,4-dioxo-3-methyl-1,3,2-thiazaphospholidine. Comments on its phosphorylating properties

AGNES M. MODRO AND TOMASZ A. MODRO[1]
Department of Chemistry, University of Pretoria, Pretoria 0002, South Africa

Received March 6, 1992

AGNES M. MODRO and TOMASZ A. MODRO. Can. J. Chem. **70**, 2552 (1992).

2-Alkoxy-2,4-dioxo-3-methyl-1,3,2-thiazaphospholidines undergo facile ring-opening reactions with chloride ion, and, in particular, with water. This reactivity may limit their value as first intermediates in the sequential synthesis of phosphoric diesters from the parent 2-chloro-2,4-dioxo-3-methyl-1,3,2-thiazaphospholidine.

AGNES M. MODRO et TOMASZ A. MODRO. Can. J. Chem. **70**, 2552 (1992).

Les 2-alkoxy-2,4-dioxo-3-méthyl-1,3,2-thiazaphospholidines subissent des réactions d'ouvertures de cycle faciles sous l'influence de l'ion chlorure et, en particulier, avec l'eau. Cette réactivité peut s'avérer une limite à leur utilité comme premiers intermédiaires dans la synthèse séquentielle de diesters phosphorique à partir de la 2-chloro-2,4-dioxo-3-méthyl-1,3,2-thiazaphospholidine parente.

In a search for a versatile reagent for the synthesis of unsymmetrical dialkyl phosphates, Ugi and co-workers introduced 2-chloro-2,4-dioxo-3-methyl-1,3,2-thiazaphospholidine **1** as an ideal phosphorylating agent (1). Its value stemmed from a sequence of selective steps of the nucleophilic fission of the P—Cl, the P—N, and, finally, the P—S bond (Scheme 1).

The necessary conditions for the successful synthesis are that "the first phosphorylation step completely preserves the five-membered ring", and that "**2** does not react any further with alcohols, unless deliberately activated" (1); according to the reports, reagent **1** meets precisely these conditions. In our attempts to prepare dialkyl phosphates incorporating nitroimidazole drug moiety (2), we applied the above approach and found that it can present problems and requires very rigorous reaction conditions. We report here on some aspects of the reactivity of **1** that can complicate or limit its application as a multifunctional phosphorylating agent.

Results and discussion

Preparation of substrate **1** required some modification of the literature procedure, since under the reported conditions the reaction mixture solidifies due to freezing of the benzene solution. Compound **1** can, however, be prepared in benzene at 0°C (some frozen benzene serves as an internal cooling agent), or in CH_2Cl_2 at −30°C. We then reacted **1** with ethanol under conditions (1*a*) that should give pure 2-ethoxy-2,4-dioxo-3-methyl-1,3,2-thiazaphospholidine, **2***a* (**2**, R = Et) in 92% yield. The phosphorylation (the scale of the reactions was in the range of 1.5×10^{-4}–10^{-1} mol of **1**, and either pyridine or triethylamine was used as a base), however, repeatedly yielded a mixture consisting of three compounds (total yield 100%), that is, the required ester **2***a*, and the two ring-opened products, **4** and **5** (eq. [1]).

[1] $$\mathbf{1} \xrightarrow{\text{EtOH/amine}} \underset{78\text{–}80\%}{\mathbf{2}a} + \underset{\mathbf{4}}{\underset{2\text{–}4\%}{\text{MeNHC(O)CH}_2\text{SP(O)(OEt)Cl}}} + \underset{\mathbf{5}}{\underset{18\text{–}20\%}{\text{MeNHC(O)CH}_2\text{SP(O)(OEt)OH}}}$$

[1]Author to whom correspondence may be addressed.

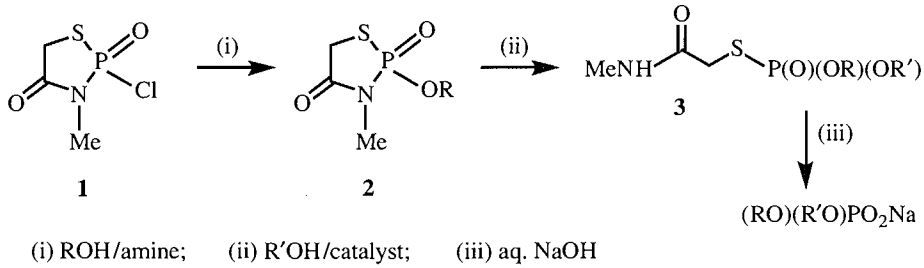
Analogous results were obtained with *n*-butanol, where the corresponding products, **2***b* (**2**, R = *n*-Bu), and the *O*-*n*-butyl analogues of **4** and **5** (**4**′ and **5**′) were formed in 68, 11, and 21% yields, respectively.[2] Phosphorochloridates **4**, **4**′ are *not* the result of the nonselective reaction of an alcohol with **1** (P—N instead of the P—Cl bond cleavage), but of the subsequent ring opening in **2** by the tertiary ammonium chloride present in the system. When the reaction mixture (eq. [1]), instead of being filtered off and evaporated, was stirred at room temperature for periods of 16, 24, and 72 h, the proportion of **4** increased to 22, 48, and 71%, respectively. When the reaction of **1** with ethanol (or *n*-butanol) was carried out without any base, **4** (or **4**′) was virtually the exclusive product, formed via the fast cleavage of the P—N bond in **2** by free HCl (3). It is worth noting that **4** did not undergo any appreciable hydrolysis when it was kept in aqueous solution over a period of several days.[3]

Cyclic ester **2***a*, free of any phosphorochloridate **4**, could be prepared by carrying out the phosphorylation at −65°C and the work-up at a temperature not higher than −5°C. NMR spectroscopy (^{31}P, ^{1}H) showed complete absence of **4**, but even under these conditions, up to 7% of the acid **5** could be observed in the reaction product. It is possible, however, that at least some of **5** was formed during the preparation and handling of the sample for spectroscopic determinations (*vide infra*).

The most remarkable property of the cyclic intermediate **2** is its susceptibility to hydrolysis. Irrespective of the care taken to remove water from solvents, reagents, and reaction atmosphere, we were never able to avoid to formation of some of the ring-opened acid **5**. When **1** was reacted with two mol-equivalents of ethanol and amine in benzene, the expected *O*,*O*-diethylphosphorothiolate **3***a* (**3**, R = R′ = Et) was formed in 87% yield. It was, however, contaminated with 13% of **5**, formed via the competitive hydrolysis of **2**

[2]Products **2***b* and **5**′ were not isolated and fully characterized, but they were identified by their ^{31}P nmr signals (**2***b*: δ_P 36.3; 5′: δ 20.9), in analogy with the respective ^{31}P nmr spectra of **2***a* (δ 36.1) and **5** (δ 21.9).

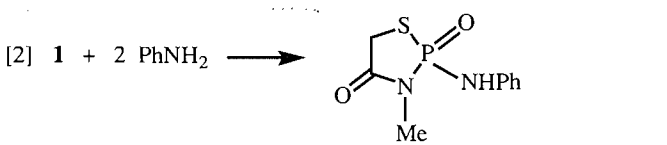
[3]As one of the referees pointed out, it should be possible to arrive at products **3** from substrates **1** via intermediates **4**. We are currently investigating this approach to the preparation of unsymmetrical phosphates.



SCHEME 1

in a second phosphorylation step (Scheme 1, step (ii)). It seems that the reactivity of **2** in the ring opening decreases rapidly with an increase in the steric bulk of the nucleophile. In the reaction of **1** with ethanol/pyridine (one mol-equivalent), followed by 2-propanol/pyridine, the expected mixed ester **3***b* (**3**, R = Et; R′ = *i*-Pr) was formed in only 50% yield, the remaining components being the intermediate cyclic ester **2***a* (36%), and its hydrolysis product, **5** (14%). The non-catalyzed hydrolytic opening of the 2,4-dioxo-3-methyl-1,3,2-thiazaphospholidine ring is a very facile reaction, irrespective of the nature of the 2-substituent. When the equimolar mixture of **1** and **2***a* was subjected to the competitive hydrolysis with water (half mol-equivalent) in $CDCl_3$ yielding a mixture of the respective products, $MeNHC(O)CH_2SP(O)(OH)Cl$ and **5**, we found (by examining the composition of the mixture by ^{31}P nmr spectroscopy) **1** to be only approximately two times more reactive than **2***a*. Ester **2***a* is, on the other hand, much more hygroscopic than substrate **1**, which may explain its very facile hydrolysis. When pure samples of **2***a* and **1** were exposed to the atmosphere, the absorption of moisture by **2***a* was found to be 11 times faster than that of **1**.

Reaction of **1** with amines also did not lead to a single substitution product. When a benzene solution of **1** was treated at 0°C with two mol-equivalents of aniline, the product consisted of the expected 2-phenylamino-2,4-dioxo-3-methyl-1,3,2-thiazaphospholidine, **6** (77%), and the corresponding chloride-promoted ring-opened derivative, **7** (23%) (eq. [2]). Since the cyclic product **6** is not hygroscopic, the hydrolysis product was in this case absent, but when **6** was dissolved in water, it gave instantly and quantitatively the corresponding amino acid, $MeNHC(O)CH_2SP(NHPh)O_2H$.



6

+ $MeNHC(O)CH_2S–P(O)(NHPh)Cl$

7

In conclusion, we demonstrated that cyclic ester **2**, the key intermediate in the phosphorylation sequence, is a less selective reagent than originally reported (1), and that it reacts smoothly without a catalyst with nucleophilic species, and with water in particular. The latter reaction can be highly detrimental from the synthetic point of view, as side-products of the type **5** can easily contaminate the final product of the phosphorylation. It is recommended, therefore, that step (ii) (Scheme 1) should be carried out immediately after the completion of the first step without isolation of **2**, at low temperature, and with the most rigorous exclusion of moisture.

Experimental section

Benzene (Merck, GR Grade) was stored and distilled over sodium wire and stored over molecular sieves (5A). Dichloromethane (Merck, GR Grade) was distilled from P_4O_{10} and stored over molecular sieves (4A). Pyridine (Merck, GR Grade) was stored over solid KOH for 2 weeks, fractionally distilled from KOH, and stored over molecular sieves (5A). Triethylamine (Aldrich, 99+%) was stored over solid KOH and distilled from P_4O_{10}. Ethanol, *n*-butanol, and 2-propanol (Merck, GR Grade) were purified with magnesium activated with iodine and fractionally distilled. Aniline (Aldrich, 99.5+%) was dried over KOH and distilled; sulfuryl chloride (Aldrich) was distilled immediately before use. *N*-Methylmercaptoacetamide was prepared in 83% yield from methyl mercaptoacetate following a literature procedure (4); bp 104–105°C (2 Torr; 1 Torr = 133.3 Pa). 2-Methoxy-3-methyl-4-oxo-1,3,2-thiazaphospholidine **8** was prepared as described by Richter and Ugi (1*a*) in 66% yield; bp 90–92°C (0.1 Torr); nmr (^1H and ^{31}P) spectra in full agreement with those reported (1*a*). The nmr spectra were recorded on a Bruker AC 300 MHz spectrometer and the chemical shift values are given relative to TMS (^1H) and 85% H_3PO_4 (^{31}P). Mass spectra were recorded on a Varian MAT-212 double-focusing direct-inlet spectrometer at an ionization potential of 70 eV. Only the molecular ion data are included.

2-Chloro-2,4-dioxo-3-methyl-1,3,2-thiazaphospholidine ***1***

Sulfuryl chloride (33.7 g, 0.25 mol) dissolved in CH_2Cl_2 (100 mL) was added slowly with stirring and cooling at −30°C to a solution of **8** (41 g, 0.25 mol) in CH_2Cl_2 (500 mL). Stirring was continued at room temperature for 10 h; the solution was concentrated under reduced pressure to approximately one-third volume and left overnight in a refrigerator. The product was collected by filtration, washed with dry CH_2Cl_2 and stored in a desiccator over P_4O_{10}. Yield 38.7 g (84%); δ_P 39.75 (lit. δ_P 39.06). ^1H nmr spectrum in full agreement with that reported (1*a*).

Reactions of ***1*** *with alcohols*

(*a*) Reactions were carried out under conditions reported in the literature. Pyridine or triethylamine was used as a base. After completion of the reaction and filtration, the solvent (benzene) was removed under reduced pressure and the crude product was examined by nmr (^1H, ^{31}P) spectroscopy. The proportions of individual components were determined from the relative intensities of the corresponding signals in the ^{31}P nmr spectra.

(*i*) Reaction with ethanol: 100%; **2***a* (78–80%), δ_P ($CDCl_3$) 36.1; ^1H nmr spectrum in full agreement with that given in ref. 1*a*; **4** (2–4%), δ_P 27.5; δ_H 2.72 (3H, br s, NMe), 3.35 (2H, d, J_{HP} 19.5 Hz, CH_2S), **5** (18–20%), δ_P 21.9; δ_H 2.83 (3H, br s, NMe), 3.50 (2H, d, J_{HP} 18.5 Hz, CH_2S).

(*ii*) Reaction with *n*-butanol: carried out as above, with pyridine

as a base. 100%; **2***b* (68%), δ_P ($CDCl_3$) 36.3; **4**′ (11%), δ_P 28.6; **5**′ (21%), δ_P 20.9.

(*iii*) Reaction with two mol-equivalents of ethanol in the presence of two mol-equivalents of triethylamine: 99%; **3***a* (87%), δ_P ($CDCl_3$) 24.2; δ_H 1.28 (6H, t, J_{HH} 7.1 Hz, 2 × Me of POEt), 2.75 (3H, br s, NMe), 3.37 (2H, d, J_{HP} 19.2 Hz, CH_2S), 4.09 (4H, quint, J_{HH}, J_{HP} 7.1 Hz, 2 × CH_2 of POEt), 7.04 (1H, br s, NH); spectral data in full agreement with those given in ref. 1*a*; **5** (13%), nmr (^1H, ^{31}P) spectra identical to those given above.

(*iv*) Reaction with ethanol, followed by 2-propanol: carried out as above using pyridine in both steps: 100%; **3***b* (50%), δ_P ($CDCl_3$) 20.7; ^1H nmr spectrum in full agreement with that given in ref. 1a; **2***a* (36%), δ_P 36.1; **5** (14%), δ_P 21.9.

(b) Modified synthesis of **2**a

A solution of equimolar quantities of ethanol and pyridine (or triethylamine) in CH_2Cl_2 (0.3 mL/mmol) was added slowly dropwise to a stirred solution of **1** in CH_2Cl_2 (7.5 mL/mmol) at −65°C. The mixture was then warmed to −10°C, evaporated at ca. 0°C and reduced pressure, benzene (5 mL/mmol) was added, and the mixture was filtered. After the evaporation of benzene under reduced pressure, **2***a* was obtained in 89% yield. The purity of the crude product (as determined by ^{31}P nmr spectroscopy) was 93–95%, the remaining 5–7% being product **5**.

Preparation of **4**

Ethanol (0.074 g, 1.62 mmol) in benzene (1 mL) was added slowly dropwise to a stirred solution of **1** (0.300 g, 1.62 mmol) in benzene (3 mL) at 0°C. The solution was left overnight in a refrigerator and evaporated under reduced pressure, yielding **4** as a viscous oil in quantitative yield. The nmr (^1H, ^{31}P) spectra were identical to those given above for the product of the experiment (*a*) (*i*); ms: *m/z* 231 (12%). The only other phosphorus containing product (≤5%) detected by ^{31}P nmr spectroscopy was **5** (δ_P 21.7).

When *n*-butanol was used instead of ethanol, **4**′ was obtained in almost quantitative yield. Oil; δ_P ($CDCl_3$) 28.5; δ_H 1.24 (3H, t, J_{HH} 7.1 Hz, Me of POBu), 1.36 (2H, m, γ-CH_2 of POBu), 1.68 (2H, m, β-CH_2 of POBu), 2.65 (3H, br s, NMe), 3.44 (2H, d, J_{HP} 19.0 Hz, CH_2S), 4.12 (2H, m, OCH_2 of POBu); ms: *m/z* 259 (1%).

Preparation of **5**

Compound **2***a* (0.70 g, 0.36 mmol) was dissolved in dioxane (7 mL), water (0.5 mL) was added to this solution, and the mixture was kept at room temperature for 43 h. The solution was evaporated to dryness under reduced pressure and the syrupy residue (98%) crystallized upon standing. It was purified by crystallization from chloroform/benzene (1:2); mp 81–83°C; nmr (^1H, ^{31}P) spectra identical to those given above; ms: *m/z* 213 (8%). Anal. calcd. for $C_5H_{12}NO_4PS$: C 28.2, H 5.6, N 6.6, S 15.0; found: C 29.1, H 5.8, N 6.6, S 14.8%.

Competitive hydrolysis of **1** *and* **2**a

Equimolar amounts (0.01 mmol) of **1** and **2***a* were dissolved in $CDCl_3$ (1.0 mL) and the ^{31}P nmr spectrum of this solution was recorded. A solution of water (0.11 mmol) in dioxane (0.1 mL) was added and the ^{31}P nmr spectra of this solution were recorded several times within a period of 1 h. The change in the **1**/**2***a* ratio (measured by the relative intensities of signals at δ_P 39.7 and 36.1) indicated that the disappearance of **1** was approximately two times faster than that of **2***a*.

Relative hygroscopic properties of **1** *and* **2**a

Samples of **1** and **2***a* (0.27 g each) were placed in identical containers and left exposed to the surrounding atmosphere. The increase of the mass of both samples was monitored periodically. The absorption of moisture by **2***a* was approximately 11 times faster than that by **1**; the ^{31}P nmr spectra of the samples, recorded after 72 h, corresponded mostly to the respective hydrolysis products.

Reaction of **1** *with aniline*

Aniline (0.10 g, 1.08 mmol) in benzene (5 mL) was added dropwise with stirring and cooling at 0°C to the solution of **1** (0.10 g, 0.54 mmol) in benzene (2 mL). The mixture was stirred at 0°C for 1.5 h, warmed up to room temperature, and filtered. After the evaporation of the solvent under reduced pressure, the crude product (0.087 g, 67%) was obtained as a yellow syrup. The ^{31}P nmr spectrum demonstrated the presence of two products: the major (77%, $CDCl_3$ δ_P 31.9) and the minor (23%, δ_P 25.7). Pure **6** was obtained by crystallization (ether/petroleum ether), mp 128–128.5°C; δ_P ($CDCl_3$) 31.9; δ_H 2.92 (3H, d, J_{HP} 7.7 Hz, NMe), 3.77 (1H, dd, J_{HH}, J_{HP} 16.3, 11.7 Hz, CH_AS), 3.92 (1H, dd, J_{HH}, J_{HP} 16.3, 6.5 Hz, CH_BS), 6.90–7.30 (5H, m, Ph), 7.73 (1H, br s, NH). Anal. calcd. for $C_9H_{11}N_2O_2PS$: C 44.6, H 4.6, N 11.6; found: C 44.4, H 4.5, N 11.3%.

When a sample of **6** was dissolved in D_2O, the nmr spectrum of this solution showed complete disappearance of **6** and the formation of the hydrolysis product, $MeNHC(O)CH_2SP(NHPh)O_2H$; δ_P (D_2O) 16.9; δ_H 2.67 (3H, s, NMe), 3.36 (2H, d, J_{HP} 14.4 Hz, CH_2S), 7.30–7.60 (5H, m, Ph).

The minor product obtained after crystallization of **6** (colorless oil) was identified as compound **7**: δ_P ($CDCl_3$) 25.7; δ_H 2.70 (3H, d, J_{HH} 6.9 Hz, NMe), 3.54 (2H, d, J_{HP} 9.2 Hz, CH_2S), 6.90–7.30 (5H, m, Ph); ms: *m/z* 278 (6%). Anal. calcd. for $C_9H_{12}ClN_2O_2PS$: C 38.7, H 4.3, N 10.0, Cl 12.7; found: C 38.1, H 4.4, N 9.6, Cl 11.9%.

The negative ^7J(CHO, CH_3) in 4-methylbenzaldehyde. Ionicity of the carbonyl bond

TED SCHAEFER AND RUDY SEBASTIAN
Department of Chemistry, University of Mannitoba, Winnipeg, Man., Canada R3T 2N2

Received April 7, 1992

TED SCHAEFER and RUDY SEBASTIAN. Can. J. Chem. **70**, 2555 (1992).

The spin–spin coupling constant over seven bonds between the formyl and methyl protons in 4-methylbenzaldehyde is −0.030 Hz in CS_2/C_6D_{12}/TMS, and (−)0.035 Hz in acetone-d_6, solutions at 297 K. This unexpected result is rationalized in terms of a spin–spin coupling mechanism attributed to the importance of a valence bond structure with an ionic carbonyl bond. The result again emphasizes the sensitivity to substituent perturbations of the six-bond coupling constant in quasi-planar benzaldehyde derivatives. It can have either sign and presents a challenge to its computation from first principles.

TED SCHAEFER et RUDY SEBASTIAN. Can. J. Chem. **70**, 2555 (1992).

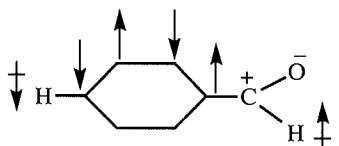
On a déterminé que, à 297 K, les constantes de couplage spin–spin à travers sept liaisons entre les protons du formyle et du méthyle du 4-méthylbenzaldéhyde sont de −0,030 Hz dans le CS_2/C_6D_{12}/TMS et de (−)0,035 Hz dans l'acétone-d_6. On rationalise ce résultat inattendu en fonction d'un mécanisme de couplage spin–spin attribué à l'importance d'une structure de liaison de valence avec une liaison carbonyle ionique. Ce résultat met à nouveau en relief la sensibilité des perturbations des substituants sur la constante de couplage à travers six liaisons dans des dérivés benzaldéhydes pratiquement plans. Elle peut prendre un signe ou l'autre et elle présente un défi pour ceux qui veulent la calculer à partir de principes fondamentaux.

[Traduit par la rédaction]

Introduction

The unprecedented properties of ^6J(H,CHO) ≡ ^6J, the coupling constant between the formyl and *para* ring protons, in benzaldehyde derivatives have been discussed recently (1, 2). While ^6J is negative in benzaldehyde itself, as expected for a σ–π mechanism dependent on $\sin^2\theta$, θ being the angle by which the formyl group twists out of the molecular plane, and while $^6J_0$ (θ = 0) most likely very nearly vanishes (2), it is as large as +0.086(3) Hz in the 3,5-difluoro derivative (1).

These positive ^6J values in some *meta*-substituted benzaldehydes are attributed (1) to a coupling mechanism associated with an ionic valence bond structure, here written[1] as **1**; crossed arrows denote proton spin states and the other



1

arrows refer to π electrons. In such derivatives, a linear relationship ^6J/Hz = 0.007 − 0.127 Σ $\sigma_{R,ST}$, exists (1) between ^6J and the standard residual resonance substituent constants (7) for *meta* substituents, $\sigma_{R,ST}$. It is therefore implied that substituents with residual π donor characteristics (7) at the *meta* position, such as F, Cl, OCH_3, CH_3, increase the importance of **1**. Although ^6J could not be determined for the 3,5-dimethyl derivative (1), a more recent determination of ^6J in 3-methylbenzaldehyde (8), possible because of the second-order and asymmetric properties of the spin system, gave +0.015(1) Hz via a very precise analysis of a highly resolved spectrum in acetone-d_6 solution. The linear regression yields +0.012(2) Hz. The considerable ionic character of the C=O bond in some molecules has been attested to recently by high-level molecular orbital computations (9).

The linear regression has ^6J as 0.007 Hz in the parent compound, yet ^6J is given as −0.018 (2) Hz in CS_2/C_6D_{12}/TMS and as −0.013 (1) Hz in acetone-d_6 solutions at 300 K (1). It is unlikely that, while unresolved, ^6J is positive in benzaldehyde (see below). Are the *meta* derivatives therefore unique in this respect? A measurement of ^7J(CHO,CH_3) in 4-methylbenzaldehyde (4MB) should provide a partial answer. For, if ^6J in benzaldehyde arises from the σ–π mechanism, proportional to $\sin^2\theta$, then, because $Q^H_{CH} = -Q^H_{CCH}$ in closed-shell aromatic molecules,[2] ^7J(CHO,CH_3) should be positive. If an unsuspected σ electron coupling mechanism accounts for ^6J in benzaldehyde, then ^7J should be severely attenuated relative to ^6J. Finally, if the methyl group enhances the importance of **1**, then ^7J may be negative.

Here we report that ^7J in 4MB is −0.030(0) Hz in CS_2/C_6D_{12} solution and is (−)0.035(0) Hz in acetone-d_6 solution at 297 K.

Experimental

Dilute solutions in CS_2/C_6D_{12}/TMS and (or) acetone-d_6/TMS solvent mixtures (see tables for details) were filtered into 5 mm o.d.

[1] Structure **1** is an alternative to that given previously (1); the present structure is a conflation that emphasizes the parallel spin states of the formyl proton and the π electron at the ipso carbon site. One way of picturing this arrangement is to note that the hyperfine parameter, $Q^H_{COH} < 0$, as based on the sign of isotropic shifts (3). Another way notes that $Q^C_{C'C} < 0$, where C′ is the ipso carbon atom (4), and that the hyperfine coupling constant is positive for the proton in the sigma radical, HCO (5, 6). In other words, positive spin density in the $2p_z$ orbital of the ipso carbon atom induces negative spin density in the sp^2 orbital near the formyl carbon atom, which, in turn, leads to negative spin density near the site of the formyl proton. In **1** the electron in the $2p_z$ orbital of the formyl carbon atom has moved to oxygen and is not involved in the spin polarization phenomena.

[2] ^6J(H,CH_3) is −0.602(2) Hz in toluene (10). In *p*-xylene, ^7J(CH_3,CH_3) is +0.60(3) Hz in a CS_2 solution (11, 12) and 0.596(9) Hz in acetone-d_6 solution (unpublished work in this laboratory). These coupling constants are proportional to $Q^H_{CH}Q^H_{CCH}$ and $(Q^H_{CCH})^2$, respectively (13–15).

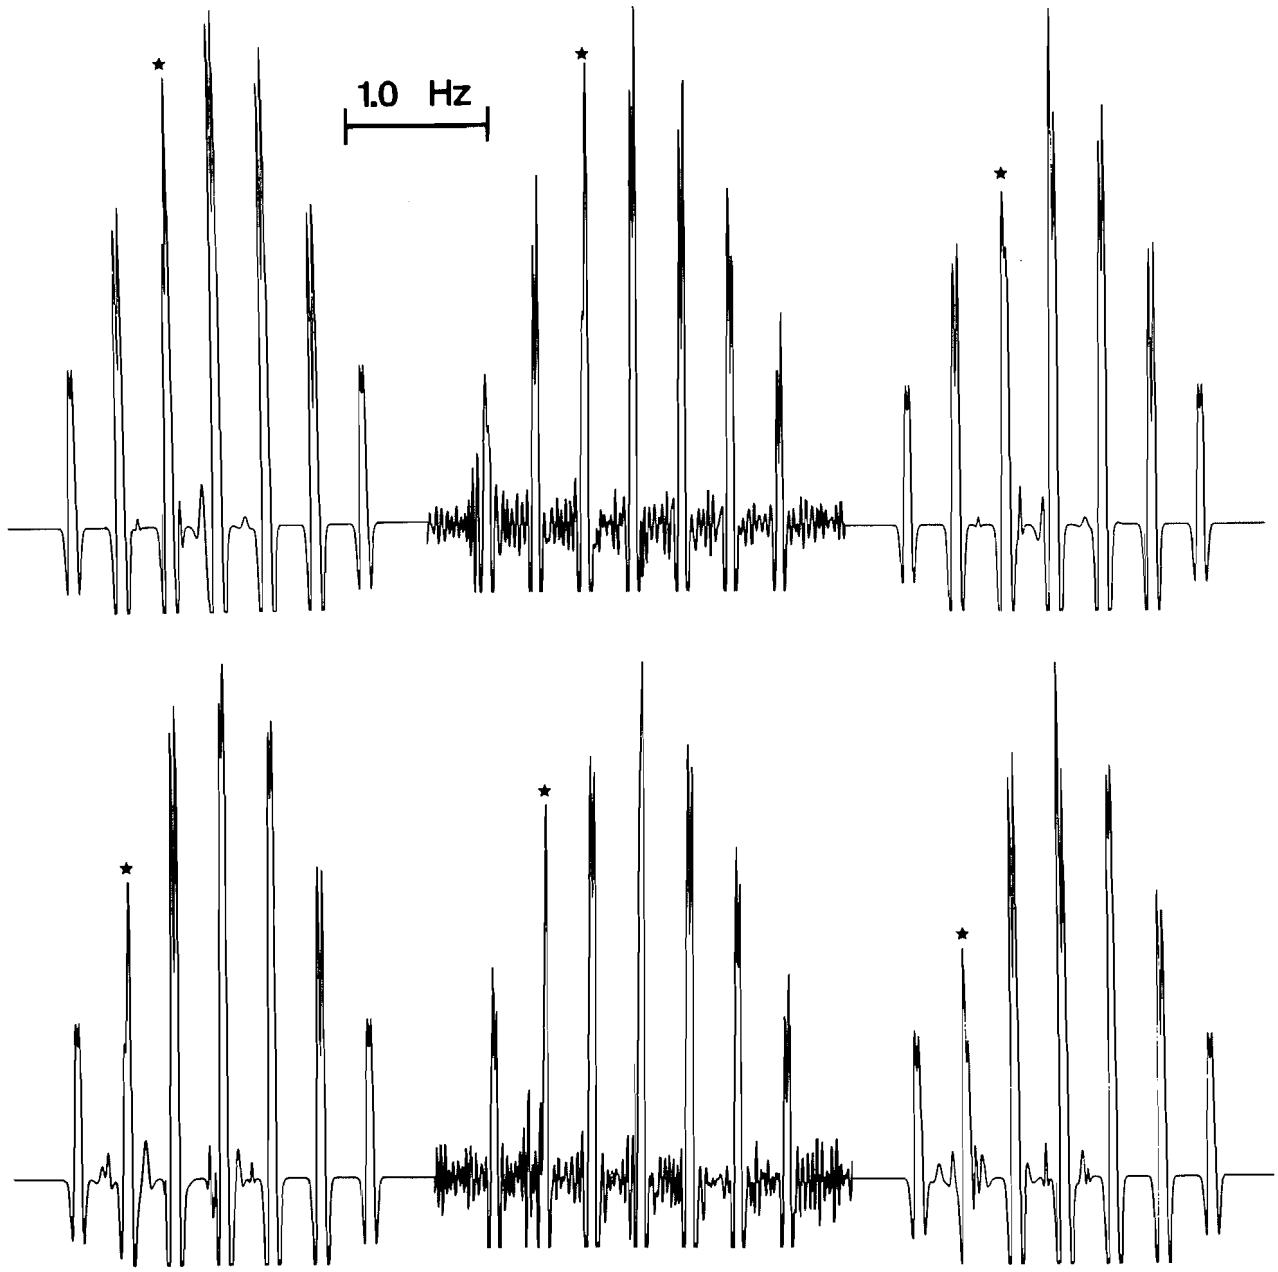

FIG. 1. Various $^1H\{^1H\}$ nmr spectra, experimental and theoretical, are displayed for the methyl protons of 4-methylbenzaldehyde as a 3.0 mol% solution in CS_2/C_6D_{12}/TMS at 300.135$_2$ MHz and 297 K. $^5J(H,CH_3)$ is 0.354(1) Hz and $^4J(H,CH_3)$ is −0.704(1) Hz, accounting for the gross pattern. The small splitting arises from $^7J(CHO,CH_3)$, which is 0.030(0) Hz in magnitude. The computed spectra on the left assume that $^7J < 0$ and those on the right, that $^7J > 0$, together with the spectral parameters in Table 1. In the top row, $\gamma B_2 \sim 0.2$ Hz at 2291.09 Hz relative to TMS, that is, a peak in the H-2 region is being weakly irradiated. In the experimental spectrum, shown to illustrate an artifact in addition to the expected perturbation of certain transitions, the doublet farthest to the left is distorted by interference between various frequencies (beats). The left-hand peak of the starred doublet has changed markedly in intensity (generalized Overhauser effect), as can be seen by comparison with the same doublet in the bottom row, for example. In the bottom row a weak irradiation field is applied in the H-3 region, at 2171.58 Hz; the theoretical spectra are consistent with $^7J < 0$. A series of 14 experiments confirmed this conclusion. The simulated and experimental spectra were processed with resolution enhancements of LB/GB = −0.190/0.625. Acquisition times were 45.5 s and digital resolution was 0.003–0.005 Hz/point. The resolution of the single-resonance spectra was somewhat better than that displayed here. The assumed linewidths above are 0.030 Hz.

nmr sample tubes. These were degassed by five cycles of the freeze–pump–thaw technique and were then sealed under vacuum to provide fairly symmetrical tops.

The ^1H nmr experiments utilized an AM300 Bruker spectrometer. Acquisition times for the free induction decays, acquired after final shimming on the decays of tetramethylsilane, were as long as 45.5 s. Data regions were set so as to provide, after zero-filling, a digital resolution of as high as 0.003 Hz/point when required or possible. Lower digital resolution, 0.005 Hz/point, was necessary in some $^1H\{^1H\}$ experiments.

The ^1H nmr spectra were analyzed with the computer program NUMARIT (16), extensively modified by R. Sebastian. Weak ir-

TABLE 1. The ^{1}H nmr spectral parameters for 4-methylbenzaldehyde in CS_2/C_6D_{12} and acetone-d_6 solutions at 297 K

Parameter	Solvent		Parameter	Solvent	
	CS_2/C_6D_{12}[a]	Acetone-d_6[b]		CS_2/C_6D_{12}[a]	Acetone-d_6[b]

[a]3.0 mol% in CS_2, containing also 10.0 mol% of C_6D_{12} and 0.5 mol% of tetramethylsilane (TMS)
[b]3.0 mol% in acetone-d_6, containing also 0.5 mol% of TMS.
[c]In Hz at 300.135$_2$ MHz to low frequency of internal TMS.
[d]The standard deviations in the spectral parameters were less than 0.001 Hz unless otherwise stated, as here. The solvent dependence of the intraring coupling constants is expected on the basis of experience with many molecules in this laboratory.

radiation experiments (17), ^{1}H{^{1}H}, were simulated with the program DOR (18), locally modified to deal with at least eight spin-$\frac{1}{2}$ nuclei.

Results and discussion

The ^{1}H nmr spectral parameters for 4MB are given in Table 1.

^7J(CHO,CH_3)

Figure 1 shows one example of a series of weak double irradiation or tickling experiments designed to determine the sign of ^7J(CHO,CH_3) ≡ ^7J. These experiments demonstrate that ^7J is −0.030(0) Hz in CS_2/C_6D_{12} solution at 297 K and, by inference from the data in Table 1, −0.035(0) Hz in acetone-d_6 solution at the same temperature.

A naive interpretation of these results combines $-Q^H_{CCH} = Q^H_{CH}$, the $\sigma_{R,ST}$ value of −0.19 for a *para* methyl substituent (7), and the linear relationship for *meta* substituents to give $^7J = -^6J = 0.007 - 0.127\sigma_{R,ST} = -0.031$ Hz, as measured. However, ^6J in benzaldehydye is certainly negative in these solutions (see below). As it happens, the sums of $-^6J$ in benzaldehyde and $-^7J$ in 4MB are +0.048(2) Hz in both solutions, perhaps implying that, in the 4-methyl derivative, the ionic mechanism has this magnitude. Whatever the true situation, it is clear that the methyl substituent enhances the importance of the coupling mechanism attributed to the ionic valence bond structure and that it dominates those mechanisms which contribute to a positive ^7J.

Remarks on ^{6}J *in benzaldehyde*

Further to discussions of the value of the unresolved ^6J in benzaldehyde (1, 2), a detailed reexamination of the spectral data (1) for an acetone-d_6 solution by iterative and simulative approaches has satisfied us that ^6J must indeed be negative. The present study emphasizes how sensitive ^6J in benzaldehydes is to substituent perturbations.

The minor constituents of toluene extracts of three fullerene-rich materials have been characterized by on-line LC–MS techniques, incorporating both positive and negative ion mass spectra obtained by atmospheric pressure chemical ionization. Two of the materials were soots, produced by resistive heating of graphite in an inert atmosphere, from different commercial suppliers. The third material was obtained as a condensate from a controlled laminar flame, and was shown previously (Anacleto *et al.*, Rapid Commun. Mass Spectrom. **6**, 214 (1992)) to contain significant quantities of compounds that behaved under the present LC–MS conditions as isomers of the C_{60} and C_{70} fullerenes, and which reverted to the latter upon heating. This finding was confirmed here, and extended to the higher clusters C_{76}, C_{84}, C_{90}, and C_{94}. One of the graphite-derived soots contained monoxides of the carbon clusters as the principal minor components, while the other soot contained hydrogenated species including $C_{60}H_2$, $C_{60}H_4$, $C_{70}H_2$, and $(C_{60} \cdot CH_4)$. The flame-generated material contained all of these minor constituents, together with complexes of C_{60} with larger aliphatic molecules as well as large quantities of polycyclic aromatic hydrocarbons and related species. Photo-oxidation of a purified C_{60} preparation, from the graphitic soot containing mostly monoxide impurities, was shown to lead to increased levels of the mono-, di-, and tri-oxides of C_{60}.

Faisant appel à des techniques de LC–MS incorporant des spectres de masse des ions tant positifs que négatifs obtenus par des ionisations chimiques réalisées à la pression atmosphérique, on a caractérisé les constituants mineurs obtenus par extraction au toluène de trois matériaux riches en fullerène. Deux des matériaux étaient des suies fournies par différents fournisseurs commerciaux et obtenue par chauffage de graphite par résistance dans une atmosphère inerte. Le troisième matériel a été obtenu sous forme de produit de condensation d'une flamme laminaire contrôlée; il a été démontré antérieurement (Anacleto *et al.*, Rapid Commun. Mass Spectrom. **6**, 214 (1992)) que ce matériel contient des quantités importantes de produits qui se comportent, dans les conditions actuelles de LC–MS, comme des isomères des fullerènes en C_{60} et en C_{70} et qui se transforment en ces derniers par chauffage. On a confirmé cette conclusion dans le présent travail et on l'a étendue aux agrégats plus importants C_{76}, C_{84}, C_{90} et C_{94}. L'une des suies provenant du graphite contient des monoxydes des agrégats carbonés comme constituants mineurs principaux alors que l'autre contient des espèces hydrogénées incluant le $C_{60}H_2$, le $C_{60}H_4$, le $C_{70}H_2$ et $(C_{60} \cdot CH_4)$. Le matériel généré par une flamme contient tous ces constituants mineurs en plus de complexes du C_{60} avec des molécules aliphatiques plus grosses ainsi que des quantités importantes d'hydrocarbures aromatiques polycycliques et d'espèces apparentées. On a montré que la photo-oxydation d'une préparation purifiée de C_{60}, obtenue à partir de suie graphitique contenant principalement des monoxydes comme impuretés, conduit à la formation de quantités de plus en plus grandes de mono-, di- et tri-oxydes de C_{60}.

[Traduit par la rédaction]

Introduction

The remarkably stable carbon cluster C_{60}, first discovered (1) in vapour from laser irradiation of graphite and subsequently produced in macroscopic quantities by resistive heating of graphite under an inert atmosphere (2–5),[3] is now established (6) as possessing a truncated icosahedron ("soccer ball") structure, while the homologue C_{70} is assigned (6) an ellipsoidal cage structure ("rugby ball"). In this paper the terms "buckminsterfullerene" and "fullerene" are taken to refer to these highly symmetrical stable closed-cage carbon clusters (1–6). Recently (7) it was shown that C_{60} and C_{70} fullerenes, found in samples of condensible compounds and soot collected from controlled combustion of benzene in premixed laminar flames, were spectroscopically indistinguishable from fullerenes prepared from graphite. Analysis of the flame samples by high-performance liquid chromatography with ultraviolet spectroscopic detection also revealed the presence of several additional components with fullerene-like characteristics (7).

The most abundant of these additional fullerene-like components (7) were tentatively identified (8) as isomers of the stable C_{60} and C_{70} fullerenes, using high-performance liquid chromatography coupled on-line to mass spectrometry (LC–MS). It was necessary to use mild LC–MS condi-

tions since it was also shown (8) that these compounds (putative fullerene isomers) were thermally converted to the corresponding stable fullerenes, with a half-life of about 1 h at 111°C (boiling toluene). The problem of converting relatively involatile and thermally labile analytes, in a condensed phase, into gaseous ions suitable for analysis by a mass spectrometer, is well known. Approaches include strategies whereby the analytes are pre-ionized in solution, and these analyte-derived ions are then transferred into the gas phase by mechanisms incorporating the effects of strong electric fields; the related techniques of electrospray and ionspray ionization (9–18) fall into this category. This approach will not be easily applicable to fullerenes and related compounds, although van Berkel *et al.* (19, 20) recently demonstrated ingenious methods whereby polycyclic aromatic hydrocarbons (PAHs) are ionized in solution via charge-transfer complex formation with appropriate electron acceptors or via electrochemical oxidation. A different approach was adopted in the LC–MS analysis of the flame-generated fullerenes (8). This approach exploits the fact that the equilibrium vapour pressure of a microscopic droplet, containing just a few molecules, can be many times greater than that of the same substance in the macroscopic bulk phase. This phenomenon reflects the much smaller binding forces exerted by its neighbours on a molecule in the surface layer of a microscopic droplet. While successful exploitation of this physical effect clearly requires that the analyte be somewhat volatile, it has proved effective for a wide variety of chemical compound types including polycyclic aromatic compounds (21) as well as the fullerenes of interest here (8). Briefly, the analyte solution (e.g., the effluent from an LC column) is nebulized at atmospheric pressure to form sub-micron sized droplets. When this is achieved in a pneumatic nebulizer surrounded by a heated tube, the solvent is rapidly evaporated from the droplets via interactions with the warm (100°C or so) gas, leaving behind extremely small particles of analyte. Remaining concerns (8), about identification of the thermally metastable compounds in the flame soot as C_{60} and C_{70} isomers, are centered on the question of whether the volatilization process was sufficiently mild and did not cause decomposition of unspecified labile adducts of the corresponding fullerenes. We believe that the subsequent ionization of the volatilized analytes (see below) was sufficiently soft that fragmentation of the gas-phase ions did not occur.

Soft-ionization of the volatilized analytes was achieved (8, 21) by atmospheric pressure chemical ionization (APCI) in a plasma sustained by a cold cathode discharge. In the absence of any other precautions, the dominant mechanism for formation of positive ions under these experimental conditions is proton transfer from protonated water clusters (21). However, it was found to be advantageous (8, 21), for the analytes of interest here, to separately introduce benzene at a controlled rate into the APCI source. In this way the dominant ionization mechanism for the fullerenes in positive-ion mode was found (8) to involve electron transfer to the $C_6H_6^{+\cdot}$ ions that dominated the APCI plasma. However, some degree of ionization via proton transfer from water clusters was also apparent (8). This competition between the two ionization mechanisms was even more apparent in the case of PAHs, for which the relative contributions of the two mechanisms were found (21) to reflect the trends in the ionization energies and proton affinities of the PAHs; protonation becomes relatively more important as PAH size increases. In negative-ion mode the benzene was omitted, and ionization mechanisms involved all of electron capture, proton abstraction (by OH^- and other anions present in the APCI plasma), and attachment of chloride ion derived from the dichloromethane used as one of the LC mobile phase components.

In the present work, additional details of the experimental arrangement are described. The power of the method is then illustrated by results obtained for minor constituents of the flame-generated material described previously (7, 8), and by comparable results obtained for extracts of two commercially available fullerene soots prepared by resistive heating of graphite in inert atmosphere (2–5 and footnote 3).

Experimental

Materials

The flame-generated soots and condensates were extracted with toluene at room temperature using low-power ultrasonic agitation (7). These solutions were the same as those characterized previously (7, 8). Samples of soot produced by resistive heating of graphite (2–5 and footnote 3), and of a purified extract of such a soot, containing C_{60} plus a few per cent of the C_{70} fullerene, were obtained from the Texas Fullerenes Corp. (TFC), Houston, Texas. A different soot was obtained separately from Materials and Electrochemical Research (MER) Corporation, Tucson, Arizona. Soot extracts were prepared by treatment with toluene, as described previously (7).

LC with UV–VIS spectroscopy

The column used was 25 cm long × 2.1 mm i.d., with Vydac 201TP C_{18} packing. The initial solvent was 100% acetonitrile for 5 min, then programmed linearly to 100% dichloromethane over 45 min, held for 5 min, then programmed back to initial composition over 5 min. The mobile phase flow rate was 0.2 mL/min, with an injection volume of 5 μL. A HP1090M liquid chromatograph (Hewlett Packard Co., Palo Alto, Calif.), equipped with a ternary DR5 solvent delivery system, a built-in HP1040A diode array detector, and a HP7994A data system, was used in all LC–UV–VIS analyses. As previously (8), the detector was configured for continuous full UV–VIS spectral acquisition (integrated over 220–600 nm) as well as for acquisition at 254 ± 2 nm.

LC with on-line mass spectrometry

The LC conditions were identical to those used in the LC–UV–VIS analyses. The LC–MS experiments employing APCI were conducted using an API III triple quadrupole instrument (SCIEX, Thornhill, Ontario), equipped with a heated pneumatic nebulizer interface (SCIEX). The pneumatic nebulizer is contained within a concentric quartz heating tube; itself located within the room temperature APCI source; the indicating thermocouple is located on the exterior surface of this heating tube, together with the heating element. Experiments conducted previously (8) on this nebulizer interface mounted on the bench but under conditions otherwise identical to those used in the LC–MS analyses, with a second thermocouple used to probe the gas temperatures within the interface, showed that the maximum temperatures experienced by the analytes under the conditions used fell in the range 80–100°C; estimates of analyte residence time in the warm gas indicate (8) a maximum of 5 s. A schematic illustration of the SCIEX heated nebulizer interface, as modified for the present work to permit post-column doping of the gas in the APCI source, is shown in Fig. 1. Medical quality air was normally used as the nebulizing gas, but was replaced by high-purity nitrogen for a few experiments; high-purity nitrogen was always used for the counter-current gas flow (the "gas curtain").

The APCI plasma was sustained by a cold corona discharge

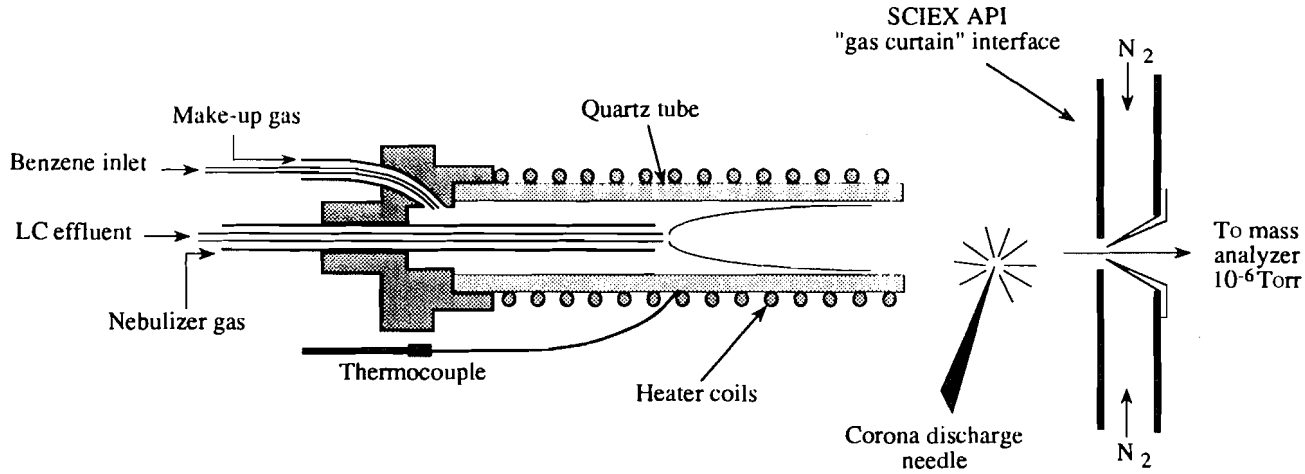

FIG. 1. Schematic illustration (not to scale) of modified heated pneumatic nebulizer interface used for LC–MS in conjunction with an APCI source. The microscopic droplets and particles of analyte are swept into the APCI plasma by the combined action of the nebulizer gas and make-up gas flows.

(stainless steel needle maintained at 3 kV). Introduction of 20 μL/min of benzene, as illustrated in Fig. 1, ensured that the dominant positive reactant ions in the plasma were $C_6H_6^{+\cdot}$, together with some water cluster ions from residual water in the system. Characterization of this APCI plasma in the absence of analytes also showed a significant population of benzene-derived ions at m/z 91, presumably $C_7H_7^+$ ions of tropylium structure. The benzene was not added when operating in negative-ion mode.

In preliminary survey experiments the mass spectrometer was usually scanned over a range m/z 600–1200, with a scan cycle time of 2 s. Having thus established the mass ranges of interest, improved signal/noise ratios could be achieved by scanning the quadrupole mass spectrometer in a piecemeal fashion, e.g., from m/z 1070 to 1090, then from m/z 1120 to 1140, in order to properly characterize the higher carbon clusters C_{90} and C_{94}. However, all of the other constituents described below could be characterized, with adequate ion statistics, in the full-scan mode (m/z 600–1200).

Mass spectrometric analyses of purified samples, without on-line HPLC, were obtained by flow-injection of a solution of the analyte into an acetonitrile–dichloromethane mobile phase with a composition and flow rate characteristic of conditions about halfway through an HPLC run, as specified above.

Results and discussion

A comparison of LC–UV–VIS chromatograms of extracts of three different fullerene materials is shown in Fig. 2. To exhibit the minor components, the intensity axes have been magnified so that LC peaks corresponding to the major components are well off-scale. The labelling of the major LC peaks in Fig. 2 is the same as that used previously (7, 8); peaks I and II were shown (8) to correspond to the stable C_{60} and C_{70} fullerenes, respectively, while peaks B and C are the compounds that have thus far behaved exactly as would be expected for thermally metastable C_{60} and C_{70} isomers (8). Peaks A and D were shown (8) to correspond to $C_{60}O$ and to C_{84}, respectively. The minor peaks labelled with Arabic numerals are those for which some information regarding the chemical nature of the eluting compounds could be obtained. The chemical identities of some of these compounds, e.g., those eluting after peak D in Fig. 2*c*, could not be satisfactorily determined due to a substantial degree of coelution of these high-mass compounds, and these peaks are therefore not numbered. To facilitate the discussion, Table 1 lists the annotated LC peaks together with their relative retention times and chemical identifications.

Major components: carbon clusters and their monoxides, and PAHs

As noted previously (7, 8) the flame-generated material is clearly very different from the two materials produced by resistive heating of graphite. The two extracts of graphite-derived soots (Fig. 2*a* and 2*b*) are very similar to one another with respect to their contents of C_{60} and C_{70} fullerenes (Peaks I and II), but show noticeable differences in the minor constituents.

Previously (8) it was shown that the flame-generated material contained significant proportions (0.5–1%) of the higher carbon clusters C_{76} and C_{84} (the former corresponding to peaks 10 and 11, and the latter to peak D). Figure 3 illustrates the dynamic range of the present LC–MS methodology in positive-ion mode, by comparing the reconstructed ion chromatograms (RICs) for m/z 720 and 840 (C_{60} and C_{70}, Figs. 3*a* and 3*c*) with those for even larger clusters C_{90} and C_{94} (m/z 1080 and 1128, Figs. 3*e* and 3*f*). Assuming equal LC–MS response factors for all of these carbon clusters, the data presented in Fig. 3 indicate that several chromatographically distinct forms of each of C_{90} and C_{94} are present in the extract of the flame-generated material (7), at levels 0.1% and 0.03% of those of the C_{60} clusters. The demonstrated dynamic range of 10^4, using piecemeal mass scanning (*not* selected ion monitoring, see experimental section), owes a great deal to the high molecular weights of the target analytes since there is almost no chemical noise in this mass range. It is worth noting that the same heat treatment (in boiling toluene under argon), which caused (8) conversion of peaks B and C (the putative metastable C_{60} and C_{70} isomers) to their stable fullerene counterparts (peaks I and II), also led to conversion of the early-eluting isomers of C_{76}, C_{90}, and C_{94} to later-eluting forms (data not shown). By way of contrast, the same heat treatment had almost no perceptible effect on the RIC for m/z 1008 ($C_{84}^{+\cdot}$) (8).

At m/z values above 700, the most important components in the flame-generated material, other than the carbon

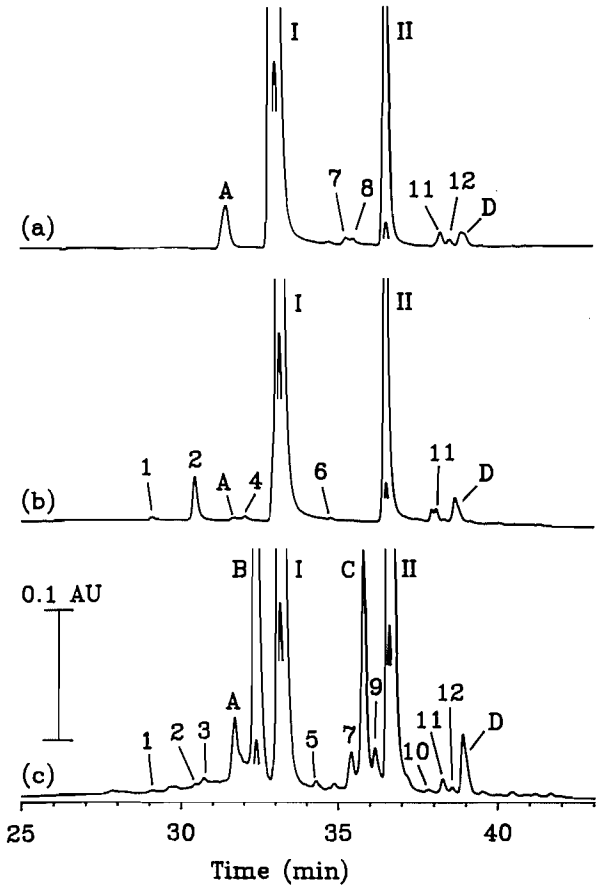

FIG. 2. LC–UV chromatograms (254 nm) of toluene extracts of fullerene-rich materials. The labelling of the LC peaks I and II (C_{60} and C_{70} fullerenes, respectively), and of peaks A–D, corresponds to that used previously (7, 8). Other annotations correspond to those in Table 1. In each case the complete chromatogram shown is a 10× expansion (vertical scale) of the chromatogram with all peaks on scale (shown as partial inserts for the major components). LC conditions are described in the text. (a) Graphite-derived soot, TFC, Houston. (b) Graphite-derived soot, MER, Tucson. (c) Flame-generated material (7, 8).

clusters themselves, were the monoxides (8). The complex RICs for *m/z* 736 and 856, corresponding to $C_{60}O^{+\cdot}$ and $C_{70}O^{+\cdot}$, respectively, are shown in Figs. 3*b* and 3*d*. The relevance of these complex chromatograms, as circumstantial evidence supporting the identification of peaks B and C as metastable isomers of the fullerenes, was discussed previously (8). Those peaks in the RICs for *m/z* 736 (Fig. 3*b*) and 856 (Fig. 3*d*), which apparently coelute with C_{60} and C_{70} compounds, were shown (8) to be APCI artifacts arising from oxidation of the carbon clusters in the APCI plasma. Replacement of air by high-purity nitrogen as the nebulizing gas resulted in a reduction of these oxide artifact peaks (annotated with asterisks in the appropriate figures) to negligible intensities, confirming previous observations (8) (see also discussion of Fig. 7, below).

At lower *m/z* values, and at elution times less than about 20 min, intense signals were observed in the chromatograms of the flame-generated material. Examples of these RICs are shown in Fig. 4, in the *m/z* range characteristic of PAHs. These RICs were computed to include the *m/z* values for both the molecular ions $M^{+\cdot}$ and the protonated molecules $(M + H)^+$, since it was shown previously (21) that both of these ionized forms are produced from PAHs under the present APCI conditions. The structures drawn in Fig. 4 are intended only to illustrate possible candidates for the compounds detected. At present no definite identifications of these PAHs have been made. Most of these constituents are present at apparently high levels relative to that of C_{60} (Fig. 4*g*), although it seems likely that the LC–MS response factors for these low-molecular weight components should be appreciably greater than for the large carbon clusters in view of their relative vapour pressures. At any rate, it is clear that formation of fullerenes and related compounds in the controlled flame (7) is accompanied by formation of large quantities of PAHs. It is worth noting here that the extracts of the two graphite-derived soots contained no detectable quantities of PAHs. The general increase in mass spectrometric background (chemical noise) at lower molecular weights can be seen in the RICs presented in Fig. 4. The increase in this background signal with increasing retention time reflects the gradient in mobile phase composition.

Each of the extracts of the two graphite-derived soots yielded evidence for fullerene monoxides. The appropriate evidence for the extract of the TFC soot is shown in Fig. 5. The RIC for *m/z* 736 (Fig. 5*b*, attributed to $C_{60}O^{+\cdot}$) shows an APCI artifact at the retention time for peak I (C_{60} fullerene). In addition to this artifact peak, only one other LC peak is observed in Fig. 5*b* (Peak A, Fig. 2) for *m/z* 736; this is in accord with expectations (8) based upon a unique monoxide structure for the fully symmetrical C_{60} fullerene (all carbon atoms equivalent). Recent work (22) has shown that an epoxide structure may be assigned to this unique monoxide of C_{60} fullerene. As emphasized previously (8), the flame-generated sample contains both the C_{60} fullerene plus the compound (peak B, Fig. 3*a*) postulated to be a necessarily less symmetrical isomer, and correspondingly also contains (Fig. 3*b*) several chromatographically distinguishable $C_{60}O$ isomers including peak A attributable to the fullerene monoxide (22). Similarly, the graphite-derived soot extract contains only the stable C_{70} fullerene (peak II, Fig. 5*c*) and correspondingly many fewer $C_{70}O$ isomers (Fig. 5*d*) than observed for the flame-generated material, which is known (8) to contain several forms of C_{70} including peak C (the putative metastable isomer) and the fullerene (peak II, Figs. 2 and 3*c*). The analytical results (not shown) for the other graphite-derived soot (obtained from MER) were similar to those shown in Fig. 5 except that the LC–MS peak A in the RIC for *m/z* 736, presumed to be due to the $C_{60}O$ monoxide, was only some 0.3% of the intensity of that of peak I (C_{60}) as compared with 6–7% in the case of the TFC soot extract (Fig. 5). The same trend was true of the RIC for $C_{70}O$ (*m/z* 856), i.e., the MER soot extract gave barely detectable signals for the monoxides, while that from the TFC soot (Fig. 5*d*) indicated the presence of at least two isomers. This suggests either that the soot obtained from MER was formed in a more reducing environment than that from TFC, or that the TFC soot had been exposed to light and air resulting in photo-oxidation (22, 23). This difference between the two graphite-derived soots will be referred to below. Small amounts of C_{76} and C_{84} were found in the extracts of both graphite-derived soots (Figs. 5*e* and 5*f*), as well as trace quantities of C_{90} (*m/z* 1080) and C_{94} (*m/z* 1128).

It was also of interest to analyse the solution of purified

C_{60} fullerene supplied by the Texas Fullerenes Corp. Figure 6*a* shows that the RIC for m/z 720 contains several small peaks with elution times shorter than that of C_{60} fullerene (peak I). One of these peaks has the same retention time (32 min) as peak B (Figs. 2*c* and 3*a*), and thus suggests the presence in this preparation of about 1% of the same putative metastable C_{60} isomer as was reported (8) in the flame-generated material. It is of interest that peak B was not observable in our own toluene extract of the TFC soot; this could reflect enrichment of the more soluble isomer (earlier retention time) during the TFC clean-up procedure used to prepare the fullerene solution, or possibly a different thermal history. Previous analyses of graphite-derived soots failed to observe peaks B and C due partly to the presumed low primary yields of these unstable compounds under the extreme conditions of the electrical discharge, and partly to the thermal conditions (boiling toluene for extended periods) used in most extraction procedures and which have been shown (8) to induce conversion of the putative isomers to the more stable fullerenes. The less intense peaks in the RIC for m/z 720 (Fig. 6*a* insert, peak annotated with #), at even earlier elution times, correspond to $C_{60}^{+\cdot}$ fragment ions of $C_{60}O^{+\cdot}$

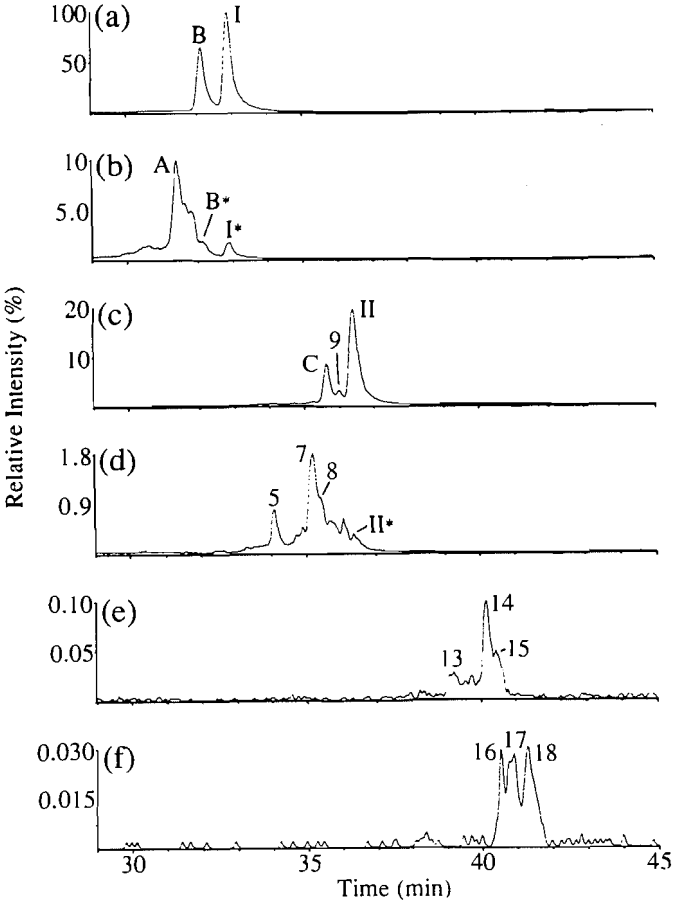

FIG. 3. Reconstructed ion chromatograms (RICs) from LC–MS analyses of a toluene extract of a fullerene-rich material generated by a controlled flame (7). Chromatographic conditions as described for Fig. 2. LC–MS coupling was by the heated pneumatic nebulizer interface (Fig. 1), and ionization was at atmospheric pressure and room temperature using electron transfer to $C_6H_6^{+\cdot}$ formed in a cold corona discharge (see text). Labelling of LC peaks is the same as in Fig. 2. Note the relative intensities of the various RICs. Peaks marked with asterisks in (*b*) and (*d*) are artifacts arising from oxidation of carbon clusters in the APCI:plasma. (*a*) *m/z* 720 ($C_{60}^{+\cdot}$); (*b*) *m/z* 736 ($C_{60}O^{+\cdot}$); (*c*) *m/z* 840 ($C_{70}^{+\cdot}$); (*d*) *m/z* 856 ($C_{70}O^{+\cdot}$); (*e*) *m/z* 1080 ($C_{90}^{+\cdot}$); (*f*) *m/z* 1128 ($C_{94}^{+\cdot}$).

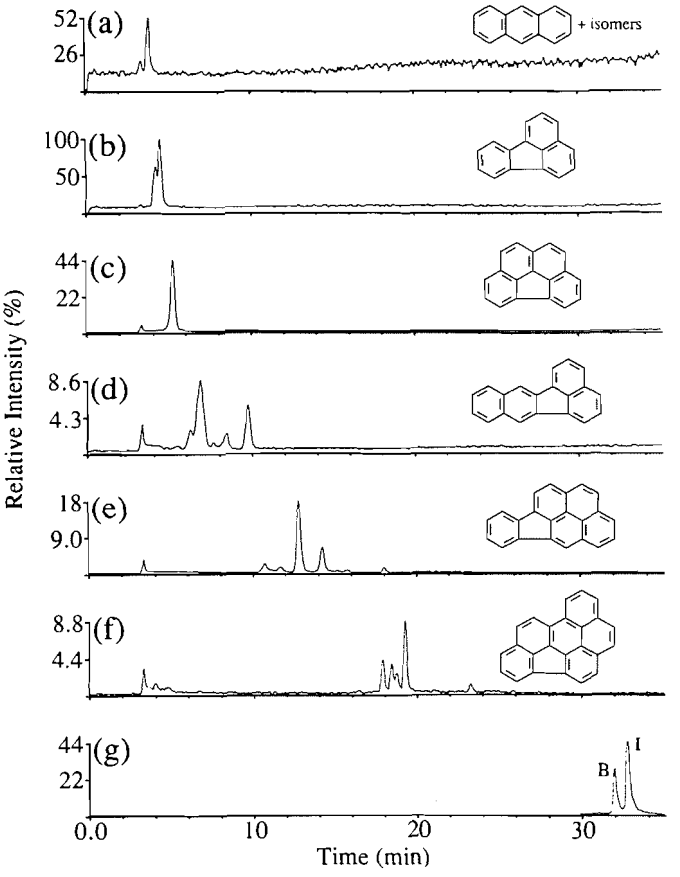

FIG. 4. RICs from LC–MS analyses of a toluene extract of a fullerene-rich material generated by a controlled flame (7). Chromatographic conditions as described for Fig. 2. LC–MS coupling was by the heated pneumatic nebulizer interface (Fig. 1), and ionization was at atmospheric pressure and room temperature using electron transfer to $C_6H_6^{+\cdot}$ formed in a cold corona discharge (see text). The structures shown are representative of the PAHs that possess the molecular masses detected in each case. Note the relative intensities of the various RICs: (*a*) *m/z* 178 plus 179; (*b*) *m/z* 202 plus 203; (*c*) *m/z* 226 plus 227; (*d*) *m/z* 252 plus 253; (*e*) *m/z* 276 plus 277; (*f*) *m/z* 300 plus 301; (*g*) *m/z* 720 plus 721 (C_{60} ions, for comparison of intensities). The t_0 is at 3.2 min, and can be observed in some of the RICs.

formed in the atmospheric pressure – vacuum interface region of the APCI mass spectrometer; this fragmentation reaction has been demonstrated previously (23) to occur at collision energies of a few tens of an electron volt. Comparison of Figs. 5*a*, 5*b*, and 5*c* with Fig. 6 shows that the purification procedure, used to obtain the commercial (TFC) purified solution, enriched $C_{60}O$ relative to C_{60}, but discriminated against C_{70}.

Minor components

The extract of the graphite-derived soot supplied by MER showed interesting differences from that of the TFC soot, other than the monoxide content discussed above. Mass spectra (Figs. 7*b* and 7*c*), acquired at retention times earlier than those of the corresponding fullerene, suggested the presence of $C_{60}H_2$ (peak 2) and of $C_{60}H_4$ (peak 1) at levels approximately 5% and 0.3%, respectively, of that of C_{60}. These constituents are well resolved chromatographically from peak I (C_{60}) and from each other. The patterns of mass peaks down to *m/z* 720 (Figs. 7*b* and 7*c*) are thus due to fragmentations induced in the APCI interface region, rather than to superimposed mass spectra of co-eluting $C_{60}H_2$ and $C_{60}H_4$ compounds. In the case where $C_{60}H_2$ was the dominant trace constituent (Fig. 7*b*), the $C_7H_7^+$ adduct ion was clearly observed at *m/z* 813 (compare the analogous adduct ion of C_{60} at *m/z* 811 in Fig. 7*a*).

Use of air as the nebulizing gas invariably resulted in greater sensitivity than use of high-purity nitrogen or argon, and for this reason air was used in most of the experiments reported here. This sensitivity effect was undoubtedly related to changes in the composition of the APCI plasma, which also resulted in marked changes in the APCI artifacts discussed above. These artifacts consisted of monoxides when air was present (see Fig. 3), but when air was excluded as far as possible the APCI artifacts changed from 16 Da adducts to 14 Da adducts; Fig. 7*a* exemplifies this general observation, in that *m/z* 734 now appears to replace *m/z* 736

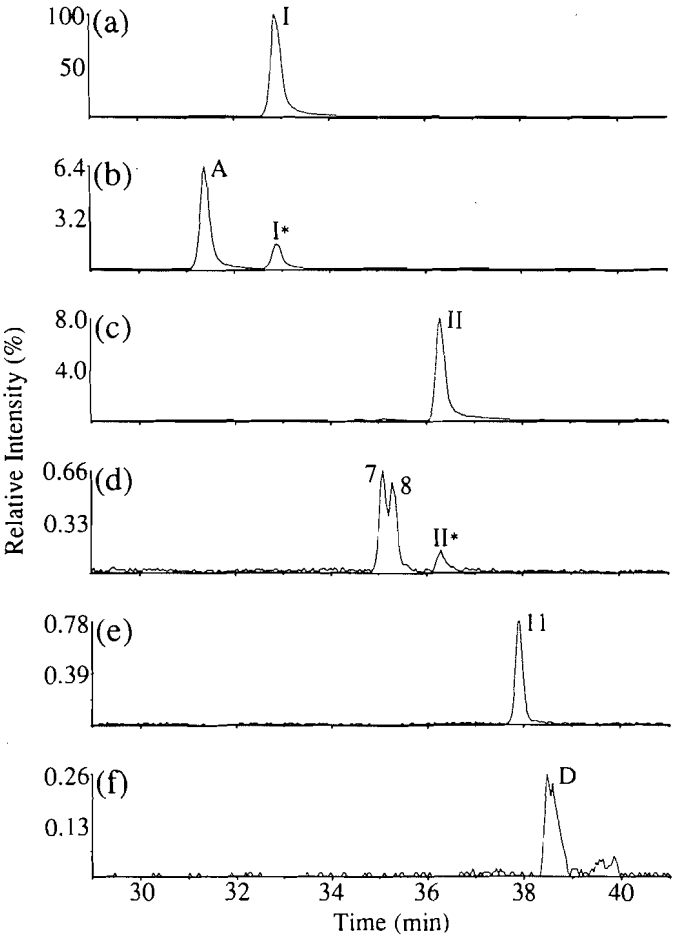

FIG. 5. RICs from LC–MS analyses of a toluene extract of a fullerene-rich material generated by resistive heating of graphite in an inert atmosphere (TFC). LC–MS conditions were identical to those used to obtain Fig. 4. Labelling of LC peaks is the same as in Fig. 2. Note the relative intensities of the various RICs. Peaks marked with asterisks in (*b*) and (*d*) are artifacts arising from oxidation of carbon clusters in the APCI plasma. (*a*) *m/z* 720 ($C_{60}^{+\cdot}$); (*b*) *m/z* 736 ($C_{60}O^{+\cdot}$); (*c*) *m/z* 840 ($C_{70}^{+\cdot}$); (*d*) *m/z* 856 ($C_{70}O^{+\cdot}$); (*e*) *m/z* 912 ($C_{76}^{+\cdot}$); (*f*) *m/z* 1008 ($C_{84}^{+\cdot}$).

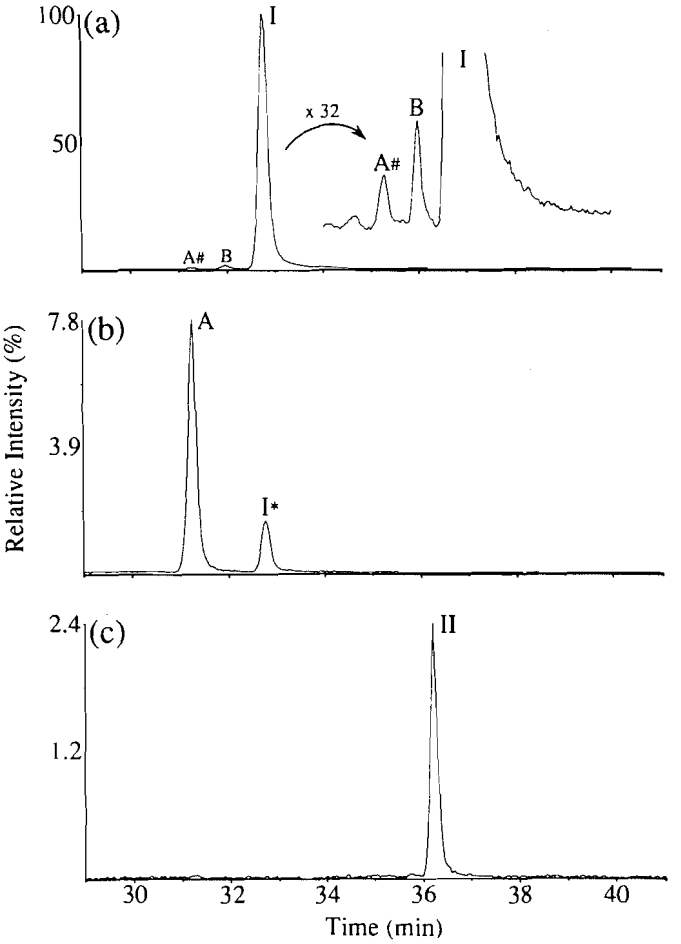

FIG. 6. RICs from LC–MS analyses of a commercial C_{60} solution (TFC) derived from a fullerene-rich material generated by resistive heating of graphite in an inert atmosphere. LC–MS conditions were identical to those used to obtain Fig. 4. Labelling of LC peaks is the same as in Fig. 2. Note the relative intensities of the various RICs. The peak marked with an asterisk in (*b*) is an artifact arising from oxidation of C_{60} in the APCI plasma, and that marked # in the insert in (*a*) is due to $C_{60}^{+\cdot}$ fragment ions formed by collision-induced dissociation of $C_{60}O^{+\cdot}$. (*a*) *m/z* 720 ($C_{60}^{+\cdot}$); (*b*) *m/z* 736 ($C_{60}O^{+\cdot}$); (*c*) *m/z* 840 ($C_{70}^{+\cdot}$).

in the spectrum of peak I. Attempts to establish that the APCI artifact at *m/z* 734 (Fig. 7*a*) had composition $C_{61}H_2^{+\cdot}$ (possibly the methylene adduct observed previously (23)), through flow-injection experiments on the purified fullerene extract obtained from TFC using perdeuterated versions of the mobile phase components (acetonitrile and dichloromethane) and of the benzene, yielded inconclusive results. The same was true of a corresponding experiment in which only the acetonitrile was replaced by its ^{15}N version, to investigate whether this minor component was $C_{60}N^{+\cdot}$, an ion for which some evidence has been presented previously (24). Interferences from other constituents in the sample were the cause of the ambiguity of the results obtained in both isotopic substitution experiments. Unfortunately use of the isotopically substituted mobile phases, in the corresponding experiments using LC–MS instead of flow-injection MS, was prohibitively expensive.

$C_{70}H_2$ was also observed (Fig. 7*d*) at extremely low levels, chromatographically well resolved (peak 6) from peak II (C_{70} fullerene). These hydrogenated carbon clusters were not detectable in the graphite-derived soot from TFC, supporting the above proposal that the MER material was produced in more reducing conditions than that from TFC. Possibly the graphite starting materials were significantly different. These hydrogenated forms were also observed, however, in the LC–MS analysis of the flame-generated material (Table 1).

The results described thus far are all derived from the positive-ion LC–MS data. The complementary negative-ion data did provide new insights. Figure 8 shows selected negative-ion mass spectra obtained by LC–MS analysis of the MER soot extract. The spectra in Fig. 8 should be compared to the corresponding positive-ion spectra for the same extract shown in Fig. 7. Figure 8*a* is similar to those shown previously (8) for LC peaks B and I in the LC–MS analysis of the flame-generated material; ionization of C_{60} by electron attachment (*m/z* 720) and by chloride attachment (*m/z* 755 and 757) are of comparable efficiencies. The fact that peaks B and I yield mass spectra indistinguishable from one

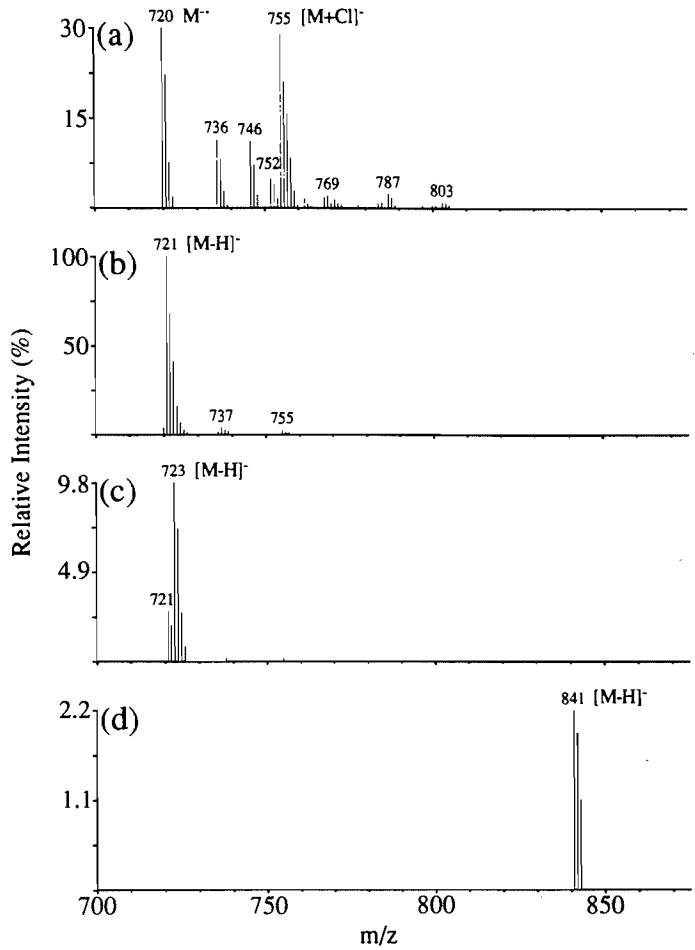

FIG. 8. Negative-ion mass spectra obtained during LC–MS analysis of the toluene extract of the graphite-derived soot from MER. LC–MS conditions were identical to those used to obtain Fig. 4, except that the post-column addition of benzene was omitted and negative ions were monitored. (*a*) Spectrum acquired at the crest of peak I (C_{60} fullerene). (*b*) Spectrum acquired at the crest of peak 2 ($C_{60}H_2$). (*c*) Spectrum acquired at the crest of peak 1 ($C_{60}H_4$). (*d*) Spectrum acquired at the crest of peak 6 ($C_{70}H_2$).

another in both positive- and negative-ion modes is strong evidence supporting the view (see Introduction) that, if peak B is *not* a C_{60} isomer, decomposition to C_{60} must have occurred prior to ionization in the APCI source. The corresponding negative-ion spectrum (not shown) for C_{70} (peak II) indicates that chloride attachment was about three times more efficient than electron attachment in this case. The ions at m/z 736 and 752 in Fig. 8*a* had greatly reduced relative intensities when high-purity nitrogen replaced air as the nebulizing gas (data not shown). This intensity dependence supports the interpretation of m/z 736 and 752 in Fig. 8*a* as being due to electron attachment ionization of $C_{60}O$ and $C_{60}O_2$ species formed as APCI artifacts. The electron capture efficiencies of these oxygenated species are expected to be higher than that of the parent C_{60} compound. The identity of the ion at m/z 746 could not be determined. Use of perdeuterated mobile phase components in flow-injection experiments again yielded disappointingly ambiguous results, and the corresponding LC–MS experiment, while desirable, was prohibitively expensive.

The hydrogenated species $C_{60}H_2$ (peak 2 and Fig. 8*b*) and $C_{60}H_4$ (peak 1 and Fig. 8*c*) appear to be efficiently ionized via proton abstraction to yield $C_{60}H^-$ and $C_{60}H_3^-$ ions at m/z 721 and 723. Note in Figs. 8*b* and 8*c* the reduced tendency of these anions to lose hydrogen atoms, compared with that of the corresponding cations (Figs. 7*b* and 7*c*). Identification of peak 5 as $C_{70}H_2$ (Table 1 and Fig. 7*d*) is based upon the negative-ion spectrum in Fig. 8*d*; the evidence for $C_{70}H^-$, derived from $C_{70}H_2$ by proton abstraction, is reasonably clearcut in Fig. 8*d* although this spectrum was obtained near the ion statistical limit.

The real surprise in the negative-ion data concerned the mass spectra acquired over LC peak A, thus far attributed solely to $C_{60}O$. While no direct evidence for this assignment was previously available (8), the only conceivable alternative ($C_{60} \cdot CH_4$) seemed much less appealing to chemical intuition. Nonetheless, the negative-ion spectra shown in Fig. 9 strongly suggest that both $C_{60}O$ and ($C_{60} \cdot CH_4$) can contribute to the signals at m/z 736 in the positive-ion spectra. The negative-ion spectrum in Fig. 9*a*, obtained for the graphite-derived soot from TFC, is consistent with ionization of $C_{60}O$ by competing electron-attachment and chloride-attachment mechanisms. In contrast, the corresponding

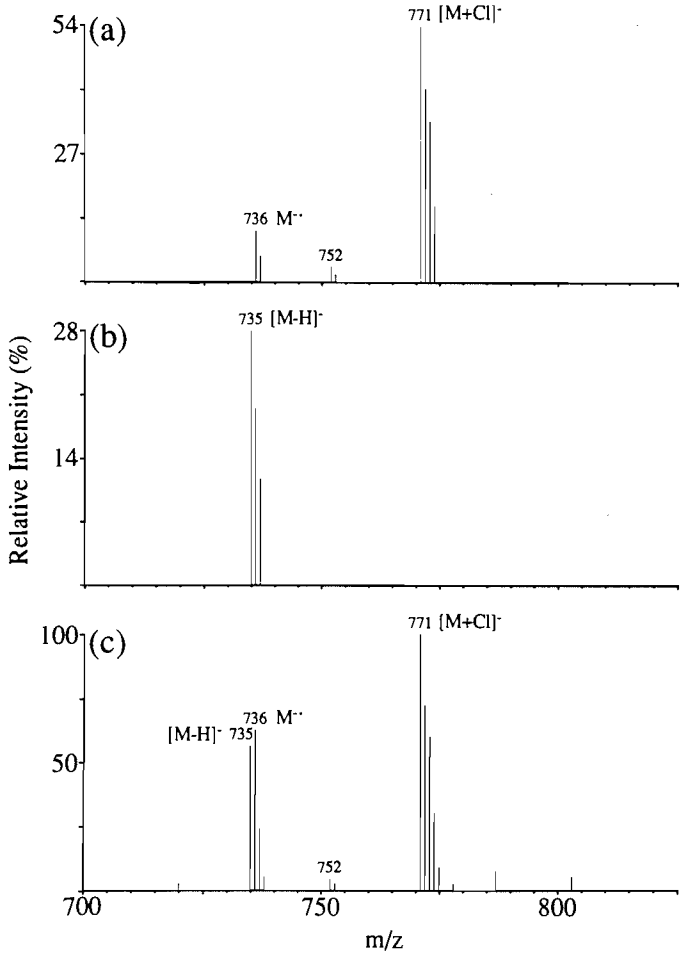

FIG. 9. Negative-ion mass spectra obtained during LC–MS analysis of the toluene extract of three fullerene-rich materials. LC–MS conditions were identical to those used to obtain Fig. 4, except that the post-column addition of benzene was omitted and negative ions were monitored. Spectra were acquired at the crests of LC peak A in each case. The relative intensities of the three spectra are not meaningful in this case. (*a*) Extract of graphite-derived soot from TFC. (*b*) Extract of graphite-derived soot from MER. (*c*) Extract of flame-generated material (8).

spectrum (Fig. 9*b*) for the graphite-derived soot from MER is precisely that which would be predicted for $(C_{60} \cdot CH_4)$ ionized via proton abstraction (e.g., by OH^-) to give a $C_{61}H_3^-$ anion with *no* observable $(M + Cl)^-$ ion. This difference between the two graphite-derived soots is again consistent with the suggestion that the material supplied by MER was produced in an atmosphere containing traces of hydrogen. It is interesting that the corresponding negative-ion mass spectrum for the flame-generated material (Fig. 9*c*) indicates significant quantities of both $C_{60}O$ (via m/z 736 and 771) and $(C_{60} \cdot CH_4)$ (m/z 735); the relative response factors are entirely unknown, and are quite possibly wildly different under these negative-ion conditions, so no definite conclusions concerning relative amounts can be drawn. However, comparison of the RIC for m/z 771 (negative-ion characteristic of Cl^- adduct of $C_{60}O$) with that shown in Fig. 3*b* (and previously (8)) for m/z 736 in the positive-ion analysis of the same flame-generated material, showed that the two traces were almost superimposable. On the other hand, the RIC for m/z 735 ($(M - H)^-$ ion characteristic of $C_{60} \cdot CH_4$) showed only a single peak co-eluting with peak A in the positive-ion RIC for m/z 736. These comparisons suggest that the CH_4 adduct was probably a minor constituent relative to the monoxides; ionization efficiencies of these compounds in positive-ion mode (electron transfer to $C_6H_6^{+\cdot}$) are not expected to differ wildly from one another, unlike those in negative ion mode (e.g., $C_{60}H_2^{+\cdot}$ at m/z 722 in Fig. 7*b* is only some 5% as intense as $C_{60}^{+\cdot}$ at m/z 720 in Fig. 7*a*, but the intensity of the corresponding $C_{60}H^{-\cdot}$ anion in Fig. 8*b* is three times as intense as $C_{60}^{-\cdot}$ at m/z 720 in Fig. 8*a*).

The nature of the $C_{60} \cdot CH_4$ complex is possibly analogous to that of the $C_{60}H_2$ species. It is possible to imagine the latter as being formed by a free-radical mechanism whereby two hydrogen atoms add successively across a C=C double bond. By analogy the $C_{60} \cdot CH_4$ complex could be formed by successive additions of a hydrogen atom and a methyl radical, and would thus be better described as $[C_{60}(H)(CH_3)]$. An alternative structure, described as $[C_{60}(CH_2)(H_2)]$, would correspond to a hydrogenated version of the methylene adduct of C_{60} (isoelectronic with $C_{60}O$) described previously (23); additions of monophenyl carbene (compare peak 4, Table 1), and of diphenylcarbene, to C_{60} have been characterized (25, 26). It is of interest that the flame-generated material also contained extremely low levels of a large number of constituents that appear to correspond to adducts of C_{60} and C_{70} with aliphatic molecules; these constituents were observed in the negative-ion LC–MS data as the corresponding anions formed by proton abstraction.

Finally, in view of the high ionization efficiency of the oxygenated fullerenes in negative-ion mode, a brief study of the photo-oxidation of the purified fullerene extract from TFC was conducted. Figure 10 shows selected mass spectra acquired, at well-resolved retention times, in the LC–MS analysis of an aliquot of this commercially purified solution, following exposure to daylight and air at room temperature for several weeks. The spectrum (not shown) acquired at the crest of peak I (C_{60}) was indistinguishable from that acquired prior to exposure (compare Fig. 8*a*). The same is true of the spectrum (Fig. 10*a*) acquired at the crest of peak A ($C_{60}O$, compare Fig. 9*a*). However, weak but well-resolved LC peaks corresponding to $C_{60}O_2$ and to $C_{60}O_3$ were observed in the exposed solution, but not in the original. Figures 10*b* and 10*c* show the mass spectra acquired at the crests of these LC peaks; that for $C_{60}O_3$ was obtained near the ion statistical limit, so the relative abundances of the isotopic variants are not in good agreement with predicted values. Comparison of these spectra suggests, interestingly, that electron attachment becomes progressively less competitive relative to chloride attachment as the degree of oxygenation increases. This trend cannot be accounted for by the different concentrations of dichloromethane in the mobile phase (and thus in the APCI reagent gas), since in fact the more highly oxygenated species eluted first. The RIC for m/z 736 ($C_{60}O^{-\cdot}$) showed only peak A in addition to the APCI artifact coincident with peak I, similar to Fig. 6*b* for this unexposed purified fullerene solution. However, the RIC for m/z 752 ($C_{60}O_2^{-\cdot}$, not shown) clearly indicated that two chromatographically distinguishable isomers were present, while that for m/z 768 ($C_{60}O_3^{-\cdot}$) demonstrated the presence of at least three isomers.

Estimate of absolute LC–MS sensitivity

The sensitivity of the LC–MS technique used here was estimated by calculating the concentration of the C_{60} fuller-

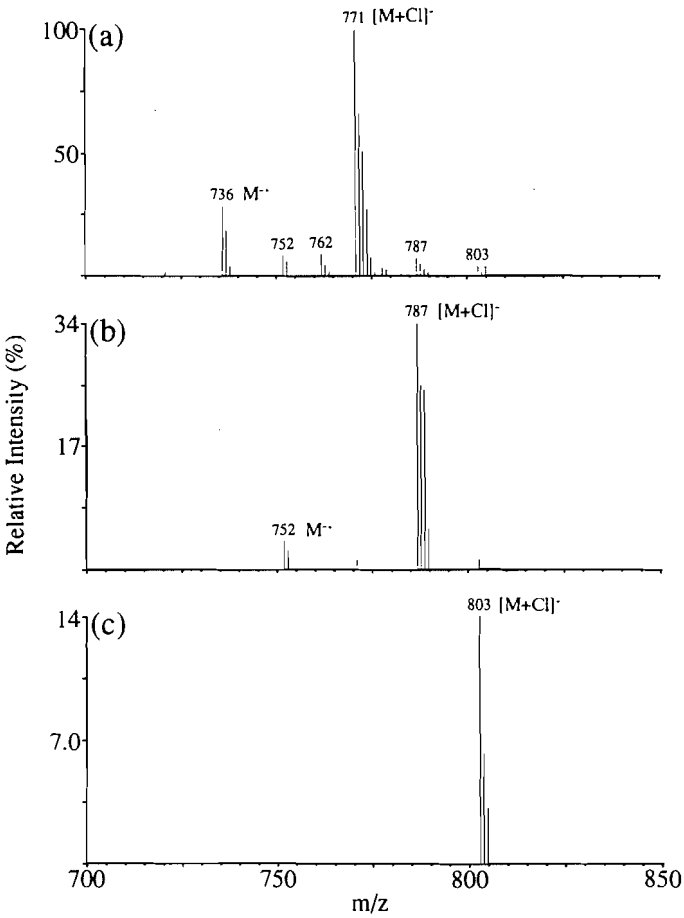

FIG. 10. Negative-ion mass spectra obtained during LC–MS analysis of the purified C_{60} solution prepared (TFC) from a graphite-derived soot, following prolonged exposure to light and air. LC–MS conditions were identical to those used to obtain Fig. 4, except that the post-column addition of benzene was omitted and negative ions were monitored. Spectra were acquired at the crests of the indicated LC peaks: (*a*) peak A ($C_{60}O$); (*b*) most intense peak in RICs for both m/z 752 (e^- attachment) and 787 (Cl^- attachment to $C_{60}O_2$); (*c*) most intense peak in RICs for both m/z 803 and 805 (Cl^- attachment to $C_{60}O_3$).

ene in the extracts analysed here by LC–UV. A value of the extinction coefficient at 257 nm is available (27), and this permitted an estimate of 500 ng as the amount of C_{60} fullerene injected on-column in the LC–MS experiment summarized in Figs. 3 and 4. This in turn implies that the quantity of C_{94} detected in Fig. 3*f* was less than 1 ng, assuming equal LC–MS response factors in positive-ion mode. In fact the volatilization efficiency within the heated nebulizer interface is likely to decrease with increasing size of the carbon clusters, so that the estimate of the amount of C_{94} is likely to be a lower limit.

Conclusions

It would be interesting to correlate the differences between the two commercially available graphite-derived soots, elucidated in the present work via analyses of the minor components, with details of their preparation. It is not surprising that the flame-generated material (7) is strikingly different from the other two, however. The presence in the flame-generated material of large quantities of polycyclic aromatic hydrocarbons, which were unobservable in the graphite-derived soots, reflects the different gaseous atmospheres under which compounds are formed in these two systems. This difference may lead to different mechanisms for control of formation of fullerenes, as might also be suggested by the discovery (7, 8) in the flame-generated material of large proportions of thermally labile compounds (peaks B and C), which revert to the C_{60} and C_{70} fullerenes on heating. The present work has added no further evidence for or against the proposal (8) that these thermally metastable compounds might be isomers of the C_{60} and C_{70} fullerenes, but has confirmed the conclusion that, if they are instead unstable adducts of some kind, dissociation to the fullerenes must have occurred *after* chromatographic separation but *before* ionization. Additional experiments designed to elucidate this problem are in progress.

The susceptibility of the fullerenes to form oxides upon photo-oxidation was confirmed here and shown to lead to mono-, di-, and tri-oxides of C_{60}. The presence of $C_{60} \cdot CH_4$ in some of these materials was masked by that of $C_{60}O$, and was revealed only through comparison of negative- and positive-ion mass spectra. It is probable that only a small amount of $C_{60} \cdot CH_4$, relative to that of $C_{60}O$, is present in the flame-generated material. This finding thus leaves unchanged the previous discussion (8) of the different multiplicities of the $C_{60}O$ isomers observed in the flame-generated material and in the TFC soot; this difference was presented (8) as circumstantial evidence supporting the tentative identification of peak B as a less symmetrical isomer of C_{60}.

The present work also illustrates the greatly superior power of the combined on-line LC–MS technique, relative to that of the two techniques applied separately. The LC–UV chromatograms of Fig. 2 clearly indicate that differences exist between the three solutions analysed, but the information content of the chromatograms and UV spectra (not shown) is very limited. Similarly, attempts to use mass spectrometry without pre-separation by HPLC failed to yield the desired information in the perdeuteration experiments conducted here, due to the obscuring effects of other more abundant constituents in the mixture.

Extension of the present technique, to other fractions of flame-derived materials, is in progress.

Second nearest-neighbor interactions in ternary regular solutions

MEGURU NAGAMORI
Centre de recherches minérales, Quebec Government, 2700 Einstein, Ste-Foy, Quebec, Canada G1P 3W8

Received January 21, 1992

MEGURU NAGAMORI. Can. J. Chem. **70**, 2569 (1992).

The concept of classical regular solutions has been expanded by considering both first and second nearest-neighbor interactions between randomly distributed molecules. While the present model requires an ideal entropy of mixing, as does the classic regularity model, its heat of mixing is expressed by a more flexible equation which attributes the second-order terms of the Margules formalism to first nearest-neighbor interactions, and the third-order terms to second nearest-neighbor interactions. The activity–composition relations have been expressed by a single equation of the grand partition function, which converges to that of the classical regularity with decreasing contributions from second nearest-neighbor molecules.

MEGURU NAGAMORI. Can J. Chem. **70**, 2569 (1992).

Le concept des solutions régulières classiques a été élargi en prenant en compte les interactions entre les paires moléculaires, non seulement les plus proches mais aussi les seconds plus proches, dans l'ensemble aléatoirement distribué. Bien que le présent modèle exige une entropie idéale de mélange, comme dans le modèle de régularité classique, l'enthalpie de mélange prend une expression qui attribue les termes de deuxième ordre de l'équation de Margules aux interactions moléculaires des plus proches voisins, et les termes de troisième ordre à celles des seconds plus proches voisins. La relation entre l'activité et la composition chimique a été exprimée par une grande fonction de partition, laquelle converge vers l'expression de la régularité classique à mesure que les contributions des seconds plus proches voisins diminuent.

1. Introduction

Despite the advent of many more sophisticated models, the classical regular solution model (regularity) is still in widest use for approximating organic, metallic, slag, and other solutions. In terms of statistical thermodynamics, the regularity is based on the configurational entropy of a random distribution of equal-sized spherical molecules (atoms) as well as on the internal energy of mixing of nearest-neighbor (nn) interactions (1, 2). Some attempts were made (3, 4) to improve the regularity model by including the contributions of second nn interaction energies as well. However, these models have not been put to practical use, because the obtained formulae were too complicated even for simple binary solutions.

The present note describes a novel method for counting first and second nn interactions, while remaining loyal to the classical regularity concept, yet dealing primarily with ternary and multicomponent solutions.

2. Configurational and vibrational complexions

Let us assume a ternary regular substitutional solution consisting of N_1 atoms (or molecules) of species 1, N_2 atoms of species 2, and N_3 atoms of species 3, which are randomly distributed over the lattice sites. The total number of complexions Ω for such a crystal may be expressed by the product of configurational and vibrational contributions (5): viz.

$$[1] \qquad \Omega = \frac{(N_1 + N_2 + N_3)!}{N_1!\, N_2!\, N_3!}\, q_1^{N_1}\, q_2^{N_2}\, q_3^{N_3}$$

where q_i refers to the vibrational partition function of an atom (or molecule) i, which remains unchanged in both pure solids and ternary mixtures in accordance with Neumann–Kopp's law.

3. Vectorial quartering of the second nn interactions

Let us consider, as an example, a face-centered cubic (fcc) solid solution whose lattice constants remain unchanged with varying composition. With respect to the central atom O, there are 12 first nn (or $z = 12$) and six second nn (or $s = 6$) atoms, as shown in Fig. 1. An atom in the second nn shell, say the atom X, has 4 nn atoms on the inner shell, or the atoms A, E, D, and J. Since the distance between the atoms O and X is 1.414 times the unit distance OA, the interaction energy between the second nn pair OX is 1/8 of that of the first nn pair OA, provided the interaction energy is inversely proportional to the sixth power of the distance of separation r (Lennard–Jones potential).

To take into account the interference of the second nn interaction (vector OX) by four window-forming atoms (A, E, D, and J) in the first nn shell, let us divide the vector OX into four equal portions and allocate a quarter each in the directions of OA, OE, OD, and OJ. Being of the same length in opposite direction, the vectors PQ and PR cancel out on the plane AOD, as shown in Fig. 1. A similar cancellation occurs on the plane EOJ as well.

4. Partial blockage of second nn interaction by first nn atoms

Let us single out the three atoms that are situated in the sites O, A, and X, and designate them by i, j, and k, respectively. By virtue of the vectorial quartering, the forces interacting between the atoms i, j, and k can be looked upon as being one-dimensional. The bond energy pertaining to an alignment ijk (called aligned energy E_{ijk}) may then be approximated as a sum of two interaction energy terms representing the atomic pairs i–j and i–k. It is convenient to first define both of the pairwise interaction energies, E_{ij} and E_{ik}, at a unit distance of $r = 1$, and then modify only the second nn pairwise energy E_{ik} by a multiplier compensating for a farther distance ($r > 1$) and the blockage effect of an intervening atom j. Under these conventions and the assumption of random distribution, the aligned atoms i, j, and k can now be either of species 1 or 2 or 3, independently.

The author tried and abandoned several different ideas for counting the second nn interaction energy before settling on the present method. The abandoned counting methods led to

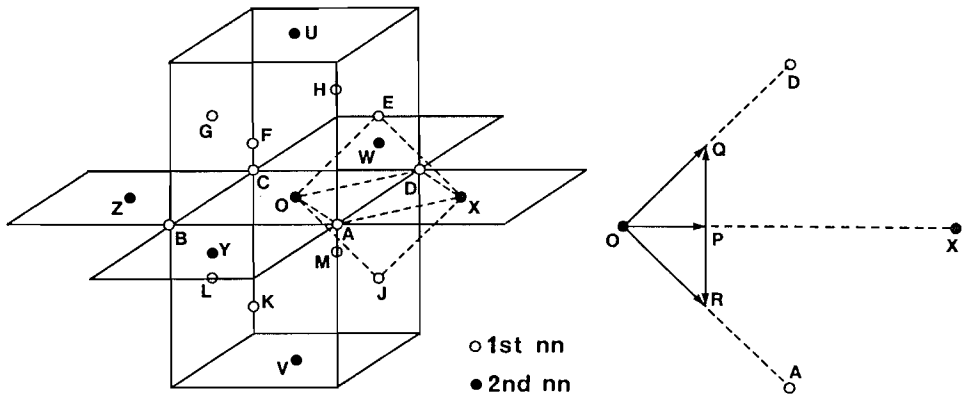

FIG. 1. The fcc structure and vectorial quartering.

complicated mathematical expressions of little practical merit. A simple expression for internal energy came about when the counting was made based on the following assumption: The force exerted upon the central atom i by a second nn atom k from the direction of OA is partially blocked by an intervening first nn atom j, and the extent of the blockage is a characteristic proper to the intervening atom j. The degree of such a partial blockage by an atom j, b_j, may be defined to range between 0 and 1; viz.

$$[2] \quad 0 < b_j < 1$$

It is to be noted that the classical regular solutions can be described as a limiting case where second nn interactions are totally blocked by the first nn shell, or $b_j = 1$.

The effects of the degree of blockage b_j and the distance r can be put together to define a new parameter f_j, which is named the permeation constant of atom j. If the potential energy beyond the first nn shell is proportional to r^{-6} in a fcc crystal, for example, its permeation constant f_j is expressed as

$$[3] \quad f_j = (1 - b_j)r^{-6} = (1 - b_j)/8$$

The interaction energy between the central atom i and the second nn atom k in an alignment ijk can then be given by $f_jE_{ik}/4$, where the coefficient 1/4 comes from the vectorial quartering.

As for the first nn interaction energy due to the atomic pair i–j, the same counting method as has been used in the traditional regularity theory is adopted here. Hence, only one half of the pairwise energy, or $E_{ij}/2$, is allocated to an alignment ijk, because the bond OA is counted twice as OAX and OAY, Fig. 1. Accordingly, the aligned energy E_{ijk} may be expressed by the following sum of first and second nn pairwise interaction energies:

$$[4] \quad E_{ijk} = 0.5(E_{ij}/2 + f_jE_{ik}/4) = E_{ij}/4 + f_jE_{ik}/8$$

where the coefficient 0.5 is to compensate for double counting of first nn (j) and second nn atoms (k) as central ones (i). The two pairwise components of an aligned energy E_{ijk} are shown schematically in Fig. 2.

5. Probability in random distribution

In a fcc regular crystal consisting of randomly distributed N_t ($=N_1 + N_2 + N_3$) atoms, the probability P_{ijk} of finding an atom i at the central site O, an atom j at the first nn site A, and an atom k at the second nn site X is given by

$$[5] \quad P_{ijk} = (N_i/N_t)\,(N_j/N_t)\,(N_k/N_t)$$

The number N_{ijk} of an alignment ijk over the sites OAX is given by the product of the total number of atoms N_t and the probability of occurrence P_{ijk}; viz.

$$[6] \quad N_{ijk} = N_t P_{ijk} = N_iN_jN_k/N_t^2$$

Each alignment ijk possesses an energy E_{ijk} as given by eq. [4]. Over the sites OAX, there are 27 possible different alignments ijk, as shown in Table 1. The bond energy of an alignment ijk is obtained by adding up the 27 aligned energies multiplied by each probabilistic weight, Table 1.

6. Internal energy of mixing

About the central site O, there is a total of $4s$ (=24) alignments equivalent to OAX, Fig. 1. Consequently, the internal energy η_{123} of the ternary fcc crystal is given by $4s$ times the weighted bond energy of the alignment OAX; viz.

$$[7] \quad \eta_{123} = 4s \Sigma (N_{ijk} E_{ijk})$$

For a fcc crystal of species 1 consisting of N_1 atoms, the internal energy, η_1, can be expressed by summing up the number of independent alignments 111, or $4sN_1$, times its aligned energy E_{111}; viz.

$$[8] \quad \eta_1 = 4s\,N_1(E_{11}/4 + f_1E_{11}/8)$$

Likewise, for pure fcc crystals of species 2 and 3 consisting of N_2 and N_3 atoms, respectively, we have

$$[9] \quad \eta_2 = 4s\,N_2(E_{22}/4 + f_2E_{22}/8)$$

$$[10] \quad \eta_3 = 4s\,N_3(E_{33}/4 + f_3E_{33}/8)$$

The internal energy of mixing ΔE can be given by the difference in internal energy before and after the mixing; viz.

$$[11] \quad \Delta E = \eta_{123} - \eta_1 - \eta_2 - \eta_3$$

The so-calculated expression of ΔE is shown in Table 2, where $z = 12$ and $s = 6$ for fcc crystals. The present solution, in which both first and second nn interactions are counted by using vectorial quartering, is called here the biregularity model, and the parameter e_{123} given by eq. [2.8] is named the biregular constant.

The internal energy of mixing for a biregular mixed crystal comprising 6×10^{23} ($=N_t$) atoms can be obtained by rewriting eq. [2.1], Table 2, as follows:

		3	N_t	×	(N_3/N_t)	(N_1/N_t)	(N_3/N_t)	×	$(E_{31}/4 + f_1 E_{33}/8)$
	2	1	N_t	×	(N_3/N_t)	(N_2/N_t)	(N_1/N_t)	×	$(E_{23}/4 + f_2 E_{31}/8)$
		2	N_t	×	(N_3/N_t)	(N_2/N_t)	(N_2/N_t)	×	$(E_{23}/4 + f_2 E_{23}/8)$
		3	N_t	×	(N_3/N_t)	(N_2/N_t)	(N_3/N_t)	×	$(E_{23}/4 + f_2 E_{33}/8)$
	3	1	N_t	×	(N_3/N_t)	(N_3/N_t)	(N_1/N_t)	×	$(E_{33}/4 + f_3 E_{31}/8)$
		2	N_t	×	(N_3/N_t)	(N_3/N_t)	(N_2/N_t)	×	$(E_{33}/4 + f_3 E_{23}/8)$
		3	N_t	×	(N_3/N_t)	(N_3/N_t)	(N_3/N_t)	×	$(E_{33}/4 + f_3 E_{33}/8)$

[12] $$\Delta E/N_t = x_1x_2(e_{12}x_1 + e_{21}x_2) + x_2x_3(e_{23}x_2 + e_{32}x_3) + x_3x_1(e_{31}x_3 + e_{13}x_1) + e_{123}x_1x_2x_3$$

where x_i refers to the atomic fraction of species i, or $x_i = N_i/N_t$. If volume change before and after the mixing is negligible, the internal energy ΔE becomes equal to the heat of mixing ΔH. Equation [12] can then be identified with the empirical Margules equation of the third order for the ternary heat of solution (6).

Equation [2.1] can also be derived for body-centered cubic (bcc) crystals with $z = 8$ and $s = 6$, as well as for ideal hexagonal close-packed (hcp) solids with $z = 12$ and $s = 6$. Liquids consisting of spherical molecules (atoms) of a similar size may be approximated by the coordination numbers

TABLE 2. Internal energy of mixing for ternary biregular solutions

$$\Delta E = (e_{12}N_1 + e_{21}N_2)N_1N_2/N_t^2 + (e_{23}N_2 + e_{32}N_3)N_2N_3/N_t^2 + (e_{31}N_3 + e_{13}N_1)N_3N_1/N_t^2 + e_{123}N_1N_2N_3/N_t^2 \quad [2.1]$$

where $$e_{12} = 2\left(\frac{z}{2} + f_1\frac{s}{2}\right)(E_{12} - E_{11}) + \left(\frac{z}{2} + f_2\frac{s}{2}\right)(E_{11} - E_{22}) \quad [2.2]$$

$$e_{21} = 2\left(\frac{z}{2} + f_2\frac{s}{2}\right)(E_{12} - E_{22}) + \left(\frac{z}{2} + f_1\frac{s}{2}\right)(E_{22} - E_{11}) \quad [2.3]$$

$$e_{23} = 2\left(\frac{z}{2} + f_2\frac{s}{2}\right)(E_{23} - E_{22}) + \left(\frac{z}{2} + f_3\frac{s}{2}\right)(E_{22} - E_{33}) \quad [2.4]$$

$$e_{32} = 2\left(\frac{z}{2} + f_3\frac{s}{2}\right)(E_{23} - E_{33}) + \left(\frac{z}{2} + f_2\frac{s}{2}\right)(E_{33} - E_{22}) \quad [2.5]$$

$$e_{31} = 2\left(\frac{z}{2} + f_3\frac{s}{2}\right)(E_{31} - E_{33}) + \left(\frac{z}{2} + f_1\frac{s}{2}\right)(E_{33} - E_{11}) \quad [2.6]$$

$$e_{13} = 2\left(\frac{z}{2} + f_1\frac{s}{2}\right)(E_{31} - E_{11}) + \left(\frac{z}{2} + f_3\frac{s}{2}\right)(E_{11} - E_{33}) \quad [2.7]$$

$$e_{123} = 2\left(\frac{z}{2} + f_1\frac{s}{2}\right)(E_{23} - E_{11}) + 2\left(\frac{z}{2} + f_2\frac{s}{2}\right)(E_{31} - E_{22}) + 2\left(\frac{z}{2} + f_3\frac{s}{2}\right)(E_{12} - E_{33}) \quad [2.8]$$

$z = 10$ and $s = 5$. Assuming a symmetrical distribution of molecules about the central site, the heat of mixing for such liquids can again be expressed by eq. [2.1].

7. Monoregular approximation for unknown biregular constant

As expressed by eq. [2.8], the biregular constant e_{123} contains terms involving all three species combined, such as the product $f_3(E_{12} - E_{33})$. Thus, e_{123} is a unique property of a given ternary system, and it cannot be calculated from the properties of the constituent binaries alone. Nonetheless, an approximate estimation of e_{123} may be attempted by assuming its regularity behavior; upon substituting $f_j = 0$ in eq. [2.8] only, we find

$$[13] \quad e_{123} = w_{12} + w_{23} + w_{31}$$

where

$$[14] \quad w_{mn} = z[E_{mn} - 0.5(E_{mm} + E_{nn})]$$

For a binary 1–2 solution, eq. [2.1] may be rewritten as

$$[15] \quad (\Delta E/N_t)/(x_1x_2) = e_{12}x_1 + e_{21}x_2 \equiv y$$

If the 1–2 binary is regarded as a regular solution, the value of w_{12} can be expressed by the average of y, eq. [15], over the entire 1–2 solution range; viz.

$$[16] \quad w_{12} = \int_0^1 y\, dx_2 = 0.5(e_{12} + e_{21})$$

Likewise, for the binary regular solutions of the systems 2–3 and 3–1, we have

$$[17] \quad w_{23} = 0.5(e_{23} + e_{32})$$

$$[18] \quad w_{31} = 0.5(e_{31} + e_{13})$$

Although eqs. [16], [17], and [18] are valid only for strictly regular solutions, they may be used to estimate approximately (called here monoregular approximation) an unknown value of e_{123}. Substituting them in eq. [13] yields

$$[19] \quad e_{123} = (e_{12} + e_{21} + e_{23} + e_{32} + e_{31} + e_{13})/2$$

The biregular constant e_{123} thus approximated assumes the same expression as that of Hillert (7), and it tends to provide better agreement with reality at middle concentrations than in terminal dilute solutions. The present biregular constant is slightly larger than the corresponding value given by the surrounded atom theory (7, 8), which has typically a coefficient of about $z/(3z - 1)$ as compared to $1/2$ in eq. [19].

8. Grand partition function for ternary biregular solutions

The grand partition function Ξ (GPF) can be constructed by combining the configurational and vibrational complexions Ω and the internal energy of mixing ΔE, as well as by introducing the absolute activity λ, as shown in Table 3. When a ternary biregular solution is in thermal equilibrium, the following conditions are satisfied (2, 5):

$$[20] \quad \partial \ln \Xi^0/\partial N_1 = 0; \qquad \partial \ln \Xi^0/\partial N_2 = 0; \qquad \partial \ln \Xi^0/\partial N_3 = 0$$

where Ξ^0 refers to the maximum term in the triple summation, Table 3. These partial differentiations may be carried out by using Stirling's formula $\ln N! = N \ln N - N$, and the results of such calculations are shown in Table 3.

When the Raoultian activity a_i is adopted (i.e., $a_i = 1$ for pure substance i), we find $a_i = q_i\lambda_i$. Each of the three conditions specified by eq. [20] then gives the expression for the Raoultian activity coefficient γ_i of constituent i, where $\gamma_i = a_i/x_i$ and $i = 1$, 2, or 3. When the internal energy of mixing is known for three constituent binaries, as each is expressed by a pair of e_{ij} values, together with an experimental (or monoregularly approximated) value of the biregular constant e_{123}, the Raoultian activities of all three components can be calculated from eqs. [3.3] through [3.5] for any ternary composition.

It is interesting to note that the GPF methodology entirely obliterates the Gibbs–Duhem integration, which is replaced by more straightforward partial differentiation, as given by eq. [20]. Thus, the problem of path dependence or

TABLE 3. Grand partition function of ternary biregular solutions and conditions for equilibrium

$$\Xi = \sum_{N_1}\sum_{N_2}\sum_{N_3}\frac{(N_1+N_2+N_3)!}{N_1!N_2!N_3!}\exp\left\{\frac{-1}{kT}\frac{1}{(N_1+N_2+N_3)^2}\{N_1N_2(e_{12}N_1+e_{21}N_2)+N_2N_3(e_{23}N_2+e_{32}N_3)+N_3N_1(e_{31}N_3+e_{13}N_1)\right.$$
$$\left.+e_{123}N_1N_2N_3\}\right\}(q_1\lambda_1)^{N_1}(q_2\lambda_2)^{N_2}(q_3\lambda_3)^{N_3} \quad [3.1]$$

$$\ln\Xi^0 = (N_1+N_2+N_3)\ln(N_1+N_2+N_3) - N_1\ln N_1 - N_2\ln N_2 - N_3\ln N_3 + N_1\ln(q_1\lambda_1) + N_2\ln(q_2\lambda_2) + N_3\ln(q_3\lambda_3)$$
$$-\frac{1}{kT}\frac{1}{(N_1+N_2+N_3)^2}\{N_1N_2(e_{12}N_1+e_{21}N_2)+N_2N_3(e_{23}N_2+e_{32}N_3)+N_3N_1(e_{31}N_3+e_{13}N_1)+e_{123}N_1N_2N_3\} \quad [3.2]$$

$$\frac{\partial\ln\Xi^0}{\partial N_1}=0 \quad ; \quad \ln\frac{q_1\lambda_1}{x_1}=\ln\gamma_1=-2A+x_2(D_{21}x_2+2D_{12}x_1)+x_3(D_{31}x_3+2D_{13}x_1)+D_{123}x_2x_3 \quad [3.3]$$

$$\frac{\partial\ln\Xi^0}{\partial N_2}=0 \quad ; \quad \ln\frac{q_2\lambda_2}{x_2}=\ln\gamma_2=-2A+x_3(D_{32}x_3+2D_{23}x_2)+x_1(D_{12}x_1+2D_{21}x_2)+D_{123}x_3x_1 \quad [3.4]$$

$$\frac{\partial\ln\Xi^0}{\partial N_3}=0 \quad ; \quad \ln\frac{q_3\lambda_3}{x_3}=\ln\gamma_3=-2A+x_1(D_{13}x_1+2D_{31}x_3)+x_2(D_{23}x_2+2D_{32}x_3)+D_{123}x_1x_2 \quad [3.5]$$

where $A \equiv x_1x_2(D_{12}x_1+D_{21}x_2)+x_2x_3(D_{23}x_2+D_{32}x_3)+x_3x_1(D_{31}x_3+D_{13}x_1)+D_{123}x_1x_2x_3$ [3.6]

NOTE: Ξ^0 = maximum term in Ξ; $x_i = N_i/(N_1+N_2+N_3)$; $D_{ij} = e_{ij}/kT$; $D_{123} = e_{123}/kT$; k = Boltzmann constant; T = temperature in Kelvin.

TABLE 4. Grand partition function of quaternary biregular solutions

$$\Xi = \sum_{N_1}\sum_{N_2}\sum_{N_3}\sum_{N_4}\frac{(N_1+N_2+N_3+N_4)!}{N_1!N_2!N_3!N_4!}(q_1\lambda_1)^{N_1}(q_2\lambda_2)^{N_2}(q_3\lambda_3)^{N_3}(q_4\lambda_4)^{N_4}\exp\left\{\frac{-1}{kT}\frac{1}{(N_1+N_2+N_3+N_4)^2}\right.$$
$$\times\{N_1N_2(e_{12}N_1+e_{21}N_2)+N_1N_3(e_{13}N_1+e_{31}N_3)+N_1N_4(e_{14}N_1+e_{41}N_4)+N_2N_3(e_{23}N_2+e_{32}N_3)$$
$$\left.+N_2N_4(e_{24}N_2+e_{42}N_4)+N_3N_4(e_{34}N_3+e_{43}N_4)+N_1N_2N_3e_{123}+N_1N_2N_4e_{124}+N_1N_3N_4e_{134}+N_2N_3N_4e_{234}\}\right\} \quad [4.1]$$

an arbitrary constant of integration is absent in the formulae derived based on the GPF method (2). All the thermodynamic functions of a ternary biregular solution can be derived from this sole equation of GPF, eq. [3.1].

Thermodynamically, eqs. [3.3]–[3.5] are valid for ternary solutions having an ideal entropy of mixing together with a weak intermolecular interaction. Mathematically, however, they are identical with the Margules formalism of the third order which has been used to approximate many real solutions having a non-ideal entropy of mixing. Equations [3.3]–[3.5] can be used, among others, in such applications as calculating the activity coefficients of the second and third constituents from the observed values of the first constituent, or estimating the activity coefficients at different temperatures. Biregularity can readily be applied to quaternary and multi-component solutions. As an example, the grand partition function of quaternary biregular solutions is shown in Table 4.

9. Conclusions

A solution model has been developed by taking into account the contributions of both first and second nearest-neighbor interactions, while observing faithfully the classical regularity concept. The present method of counting the second nearest-neighbor interactions did not lead to complicated mathematical relationships, differing from previous attempts, but it produced the same simple expression as the empirical Margules equation of the third order. The present biregularity model can be represented by a single equation, eq. [3.1], and it provides a slightly more flexible approximation for the heat of mixing than the classical regularity, although the entropy of mixing still has to be close to ideal.

Received April 15, 1992

OSVALD KNOP, S. C. CHOI, and DAVID C. HAMILTON. Can. J. Chem. **70**, 2574 (1992).

The *trans* effect (TE) in the present context refers to the electronic compensation which in collinear homoligand L—Z—L* *trans* bond pairs lengthens the Z—L* bond when the Z—L bond is shortened. The existence of a functional relation $d^* = f(d)$ between the conjugated bond lengths d(Z—L) and d^*(Z—L*) (d and d^* not equivalent by symmetry; population **A**) has been demonstrated for a variety of Z–L combinations, with Z mostly from Groups VI and V and L mostly a halogen. The two model functions investigated in detail are the empirical DPF (difference power fit), $d^* - d_0 = K(d - d_0)^{-c}$, and the semiempirical CSBO (constant sum of bond orders) based on a modified 3-centre 4-electron bond concept, $d^* - d_0 = -B \ln \{1 - \exp[-(d - d_0)/B]\}$, where $B = b_0 + b_1(d - d_0)$. Fitting DPF and CSBO to experimental d,d^* data sets involves 3-parameter nonlinear optimization; in this CSBO differs from the 2-parameter treatment of Sheldrick *et al.*, in which the limiting bond length d_0 was supplied externally. Modified versions of DPF and CSBO have been devised to accommodate, along with **A**, d,d^* pairs in which $d = d^*$ by symmetry (population **S**).

The relative merits of DPF and CSBO and the various aspects of TE quantification are discussed at length, among these the effect of the oxidation state of Z and of the presence of heteroligands on Z. The meaning of the parameters of optimization and the existence of "chemical" trends between them are examined as well as the importance of the symmetrically balanced bond length $d_e = d = d^*$ and of the total d range $\Delta = d_e - d_0$ resulting from the d,d^* regressions. Attempts to extend TE quantification to collinear heteroligand L_1—Z—L_2 *trans* bond pairs have provided insight into the nature of the bond-length variation in such systems. The very good DPF and CSBO fits to d,d^* sets obtained from 6-31G* optimizations of the equilibrium geometries of the OBOX, XOCN, and OCNY (X, Y = H, F, Cl, Li, Na, or no ligand) molecules and ions support the validity of the modified 3c4e model in accounting for the TE bond-length relationships.

OSVALD KNOP, S. C. CHOI et DAVID C. HAMILTON. Can. J. Chem. **70**, 2574 (1992).

Dans le présent contexte, l'effet *trans* (TE) se réfère à la compensation électronique qui, dans des paires de liaisons *trans* L—Z—L* d'homoligands colinéaires, provoque un allongement de la liaison Z—L* lorsque la liaison Z—L se raccourcit. On a démontré l'existence d'une relation fonctionnelle $d^* = f(d)$ entre les longueurs des liaisons conjuguées d(Z—L) et d^*(Z—L*) (d et d^* n'étant pas équivalents par symétrie; population **A**) d'une variété de combinaisons Z–L dans lesquelles Z représente principalement des éléments des groupes V et VI alors que L est généralement un halogène. Les deux fonctions modèles étudiées en détail sont la DPF empirique (ajustement de la différence des puissances), $d^* - d_0 = K(d - d_0)^{-c}$, et la CSBO constante (somme constante des ordres de liaison) semi-empirique basée sur un concept modifié de liaison à 4-électrons sur 3-centres, $d^* - d_0 = -B \ln \{1 - \exp[-d - d_0)/B]\}$ dans laquelle $B = b_0 + b_1(d - d_0)$. Un ajustement des DPF et CSBO avec les ensembles de données expérimentales pour d,d^* implique une optimisation non-linéaire de 3 paramètres; par cette procédure, la CSBO diffère du traitement à 2 paramètres de Sheldrick *et al.* dans lequel la valeur d_0 de la longueur de liaison limitante était fournit par une source extérieure. On a développé des versions modifiées de DPF et de CSBO pour accommoder, en plus de **A**, des paires d,d^* dans lesquelles $d = d^*$ par symétrie (population **S**).

On discute en détail des mérites relatifs des méthodes DPF et CSBO et de divers aspects de la quantification TE, en particulier de l'état d'oxydation de Z et de la présence d'hétéroligands sur Z. On a examiné la signification des paramètres d'optimisation et de l'existence de «tendances» chimiques entre ces paramètres ainsi que l'importance d'une longueur de liaison symétriquement balancée, $d_e = d = d^*$ et de l'ensemble de la plage $\Delta = d_e - d_0$ résultant des régressions d,d^*. Des essais dans le but d'étendre la quantification des TE à des paires de liaisons L_1—Z—L_2 d'hétéroligands colinéaires ont permis d'obtenir une compréhension de la nature de la variation de la longueur de liaison dans de tels systèmes. Les très bonnes corrélations des DPF et CSBO avec les ensembles d,d^* obtenues par optimisations 6-31G* des équilibres de géométrie des ions et molécules OBOX, XOCN et OCNY (X, Y = H, F, Cl, Li, Na ou aucun ligand) supporte la validité du modèle 3c4e modifié pour expliquer les relations entre le TE et les longueurs des liaisons.

[Traduit par la rédaction]

In this paper we investigate the presumed inherent connection (1) between the bond lengths d(Z—L) = d and d(Z—L*) = d^* ($d^* \geq d$) in collinear or nearly collinear L—Z—L* groups, where L and L* are atoms of the same element (here mostly a halogen). Unless the conjugated Z—L and Z—L* *trans* bonds are equivalent by symmetry at Z, $d \neq d^*$ except by accident. This inequality is commonly attributed to the existence of a compensating electronic mechanism (the *trans* effect, TE), which shortens Z—L and lengthens Z—L* relative to some real or supposed reference bond length $d = d^* = d_e$ (e, equal). The bond-length compensation is believed to be nonlinear.

Among the questions that can be asked are the following:

Q1. Are d and d^* connected through a functional relationship $d^* = f(d)$, i.e., to what extent can TE be quantified?

[1]Some of the results reported here were presented, in a much abbreviated form, at the 13th European Crystallographic Meeting, Trieste, 26–30 August, 1991.

Q2. If such a relationship exists, what is this function, and does the relationship hold regardless of the cause of the disproportionation $d_e,d_e \rightarrow d,d^*$?

Q3. If d_e is the lower bound of d^*, what is the *upper* bound of d^* beyond which $d^* = f(d)$ ceases to correspond to an effective bonding interaction between Z and L*?

Q4. Other circumstances being equal, what distinguishes TE for one Z–L combination from TE for another such combination? In particular, what is the effect of the oxidation state of Z?

Q5. How do other ligands on Z affect TE in the L—Z—L* homoligand bond pair?

Q6. What is the effect of deviations from collinearity on the quantification of TE?

TE can be investigated from a preconceived theory or in a purely empirical manner. In either case the success and validity of the investigation will depend on the reliability of the experimental bond-length values. We shall be concerned mainly with examination of primary evidence for TE, with a minimum of recourse to particular and ad hoc schemes that may have been advanced to deal with TE in specific circumstances.

Limits of detection and quantification of TE

To quantify TE with confidence, the total bond-length range should be large and the d,d^* pairs should be distributed over it as uniformly as possible. These requirements are not easily met, since for a given Z–L the d,d^* sampling is limited by the Z–L chemistry and in practice is almost always the result of historical, haphazard accumulation of bond-length values. In particular, as is often the case, bond lengths from certain classes of closely related compounds or structures may be overrepresented, resulting in distorted weighting.

Quite apart from limitations of their range and distribution, the individual bond-length values suffer from uncertainties associated with the method and procedure with which the bond lengths were determined. The majority of bond-length values by far come from crystal-structure determinations. In addition to the esd's of the refined atom coordinates and to inaccuracies in the unit-cell dimensions there is the uncertainty involved in correcting a bond length for the effects of thermal motion. The correction is model-dependent and thus only partially reliable (cf. ref. 1); where it has been applied it increases the bond length, typically, by 0.01–0.03 Å.[3] In principle, the total uncertainty in the bond-length value can be minimized by lowering as much as advisable the temperature of the crystal and by increasing the volume and accuracy of the diffraction data. In practice, however, one finds that the bulk of the reported bond-length values comes from room-temperature determinations and a large proportion of these bond lengths have not been corrected for thermal motion. Faced with the choice between attempting to supply, with questionable results, thermal corrections for the several hundred uncorrected bond lengths in our d,d^* data sets and using the uncorrected values throughout, we have opted for the latter. This means that, realistically, our investigation of the existence and nature of a d,d^* correlation depends on a body of uncorrected bond lengths that are estimated to be no closer to the "true" values than 0.01 Å at best.[4]

This uncertainty in the bond-length values interferes with the detection of TE in the region where the difference $d^* - d$ is small and, more seriously for the present investigation, with the assessment of the suitability of a trial $d^* = f(d)$ model function at large d^* values. Further uncertainty is introduced into the d,d^* correlation by deviations from collinearity, the effect of which on TE does not appear to have been investigated to date. Clearly, the relative merits of different model functions can only be tested and compared within the accuracy of the d,d^* values in a set.

A. Model functions

Visual inspection of d^* vs. d plots (ref. 1 and **B**) leads to a strong presumption that d and d^* are correlated and that the correlation is not linear. The function $d^* = f(d)$ representing the correlation will therefore have $f'(d) < 0$ and because of $d^* \geq d$ will cease to have a physical meaning beyond the point of intersection with the $d = d^*$ line. A further requirement is that $f(d)_{d \rightarrow d_0} \rightarrow N$ $(0 < d_0 \leq d_{min})$, the upper bound of N being infinity and the lower bound a d^* value corresponding to the cut-off distance for effective Z—L bonding interaction.

Stipulation of the lower bound of N presents a vexing problem. This bound is probably smaller than the sum ΣvdWr of the van der Waals radii of Z and L, but this statement may amount to no more than tautology, as the tabulated van der Waals radii are average estimates for atoms in neutral molecules, not necessarily applicable to situations in which TE is observed. However, assigning a finite value to N in advance would preempt **Q3** and lead to a circular argument. Furthermore, with increasing $|f'(d)|$ the experimental uncertainties in d increasingly influence the estimation of the lower bound of N (see **C3**). In these circumstances the most reasonable compromise is to assume $N \rightarrow \infty$, i.e., the $d^* = f(d)$ curve converges to a vertical asymptote at $d = d_0$, and to investigate the cut-off problem in terms of σ of the goodness of fit to the model function.

The presumed $d^* = f(d)$ relationship can be represented, within the limitations imposed by experiment, by various empirical functions satisfying the above requirements. The functions eventually investigated in detail (cf. also ref. 1) were

PF1 (simple power fit):

$$[1] \quad d^* = Kd^{-c}$$

PF2:

$$[2] \quad d^* = K(d - d_0)^{-c}$$

DPF (difference power fit):

$$[3] \quad d^* - d_0 = K(d - d_0)^{-c}$$

CSBO (constant sum of bond orders):

$$[4] \quad d^* - d_0 = -[b_0 + b_1(d - d_0)] \ln \{1 - \exp\{-(d - d_0)/[b_0 + b_1(d - d_0)]\}\}$$

[3] In some cases the disparity of the corrections for different Z—L bonds at Z may effectively wipe out the differences between the uncorrected $d(Z—L_{ax})$ and $d(Z—L_{eq})$, e.g., in the IF_5 square pyramid in $XeF_2 \cdot IF_5$ (2).

[4] For the effect of thermal corrections on TE correlations see **D5**.

The first three are purely empirical representations of the d,d^* correlation. They were chosen over polynomial representations because of convenience of manipulation and because the parameters d_0, K, and c can be assigned simple physical meaning. The fourth, semiempirical model function CSBO is based on the 3-centre 4-electron (3c4e) bond concept. Its suitability has been demonstrated previously (see **A4**) and CSBO is therefore discussed in detail below. All four model functions satisfy the asymptotic requirements $d^* \rightarrow \infty$ and $f' = \mathrm{d}d^*/\mathrm{d}d \rightarrow \infty$ as $d \rightarrow d_0$ ($d_0 = 0$ in PF1 and $d_0 > 0$ in the other three functions). In the following we shall write $d_e - d_0 = \Delta$, the total d range.

1. Function PF1

Setting $d^* = d = d_e$ yields $K = {d_e}^{c+1}$, hence $d^*/d_e = (d/d_e)^{-c}$ or ${d^*}_{red} = {d_{red}}^{-c}$. Furthermore, $f' = -cd^*/d; f' = -c$ for $d^* = d = d_e, f' = -1$ for $d^*/d = 1/c$.

2. Function PF2

Setting $d^* = d = d_e$ yields $K = d_e\Delta^c$. Hence $d^*/d_e = [(d - d_0)/\Delta]^{-c}, f' = -cd^*/(d - d_0); f' = -1$ for $d^*/d = (d - d_0)/dc, f' = cd_e/\Delta$ for $d^*/d = 1$.

3. Function DPF

Setting $d^* = d = d_e$ yields $K = \Delta^{c+1}$, hence

$$[5] \qquad (d^* - d_0)/\Delta = [(d - d_0)/\Delta]^{-c}$$

or $(d^* - d_0)_{red} = (d - d_0)_{red}{}^{-c}$ when the differences are normalized to Δ.[5] Further, $f' = -c(d^* - d_0)/(d - d_0), f' = -c$ for $d^* = d = d_e$, and $f' = -1$ for $(d^* - d_0)/(d - d_0) = 1/c$, i.e., at $d^*/d = [d + d_0(c - 1)]cd$.

In the statistical treatment of actual d,d^* sets the parameters chosen for the unconstrained nonlinear optimizations were d_0, K, and c. However, the difference Δ, which defines the total range of d implicit in TE for a given Z–L combination, is a fundamental property of the combination and is therefore readily visualized as a natural parameter of the d,d^* correlation. In the fitting of actual d,d^* data sets PF2 and DPF were sometimes reparametrized to d_0, Δ, and c.

4. Function CSBO

When contemplating the d,d^* plot for conjugate Sb—Cl *trans* bonds in Sb(III) species with octahedral coordination Lipka (3, 4) suggested, in accordance with earlier (5–8) notions on 3c4e bonds traceable to Rundle (9), that Pauling's (10) relation $D(n) = D(1) - B \log n = D(1) - \log n^B$ can be modified (our notation) to

$$[6] \qquad d(s) = d_0 - B \ln s, \qquad d^*(s^*) = d_0 - B \ln s^*$$

with the assumption that $s + s^* = 1$, i.e., the sum of the bond orders in the conjugate *trans* bond pair is constant; d_0 was taken as the shortest Sb—Cl bond length in the $SbCl_3$ crystal. From this, $\exp[-(d^* - d_0)/B] + \exp[-(d - d_0)/B] = 1$ and

$$[7] \qquad d^* = d_0 - B \ln \{(1 - \exp[-(d - d_0)/B]\}$$

Setting $d^* = d = d_e$, $B = \Delta/\ln 2$. A similar treatment has been applied to P(III)—Br (11), As(III)—Cl (12), As(III)—Br (13), and Sb(III)—Cl (14) d,d^* data sets.

Testing the validity of eq. [7] on more complete d,d^* sets, first for As(III)—Br (15) and subsequently for Sb(III)—Hal (16), and equating d_0 with the experimental Z—Hal bond lengths in gaseous $ZHal_3$ (i.e., $d_0 = d_0$(expt)), Sheldrick *et al.* found that B was not constant but varied with $d - d_0$. This variation was assumed to be linear, $B = b_0 + b_1 (d - d_0)$. On optimizing b_0 and b_1 they obtained (subject to certain restrictions on the d,d^* data sets, see **C3**) very satisfactory agreement for As—Br, Sb—Br, and Sb—I bonds, while for the Sb—Cl set they found that B and $d - d_0$ were uncorrelated.

Equation [4] is a rearranged form of Sheldrick's model function. The parameters b_0 and b_1 are related by

$$[8] \qquad b_1 = (1/\ln 2) - (b_0/\Delta)$$

However, the optimization procedure used by Sheldrick *et al.* and that in the present work are not the same. In Sheldrick's procedure $d_0 = d_0$ (expt) is fixed at an *external* value and b_0 and b_1 are fitted. In our treatment d_0 is a parameter of refinement; d_0, b_0, and b_1 are optimized *simultaneously* by a nonlinear three-parameter procedure. The legitimacy of the assumptions implicit in the two procedures is examined in **C2**.

5. Symmetric conjugate bond pairs

Conjugate homoligand Z—L *trans* bonds that are equivalent by molecular or crystallographic symmetry generate a special category of d,d^* pairs, $d_s = d_s{}^*$. They constitute a statistical population **S** different from the population **A** formed by the asymmetric $d_a \neq d_a{}^*$ pairs, which of course are subject to TE. For a particular Z–L combination the distribution of experimental d_s values is due to factors that undoubtedly operate also on the **A** population, but the effect of which cannot be separated there from the consequences of TE (see **C1**).

The **S** distribution in some cases is surprisingly wide, e.g., for Te(IV)—Cl, Bi(III)—Br, or Te(II)—S bonds; its apparent narrowness for other Z—L bonds may simply be due to insufficient sampling. Among the factors which contribute to the d_s spread are experimental accuracy, ionic charge and coordination number,[6] Coulombic compression in ionic crystals, Jahn–Teller effect, hydrogen bonding to L, ligation of Z to other atoms, and (for C_2 and C_s symmetries at Z) deviations from collinearity. Depending on the coordination number and symmetry, the Z atom can be shared by two or three such symmetric conjugate L—Z—L bond pairs, which in turn can be distinct or equivalent among themselves (e.g., in octahedral ${ZHal_6}^{n-}$ anions), or the symmetric conjugate pair can be unique (e.g., in trigonal-bipyramidal ${ZHal_5}^{n-}$ species of D_{3h} or C_{3h} symmetry).

The d_s values in an **S** set may be assumed normally distributed and have a mean $\bar{d}_s$. This mean may or may not be identical with the d_e value computed from the correlation function fitted to the **A** + **S** set or to the **A** set alone. This raises question

Q7, is $\bar{d}_s$ numerically the same as d_e?

In CSBO no special provision is made for the existence of a distribution of d_s values, since $s = s^* = \frac{1}{2}$ when $d^* = d$. However, if the variation in d_s is assumed to reflect changes in the bond order in the **S** population, then the spread of the bond orders about $s = \frac{1}{2}$ can be expressed, from $s + s^* = 1 + 2\delta s$, as $2\delta s = \exp[-(d - \bar{d}_s)/\bar{B}] - 1$, where $\bar{B} = (\bar{d}_s - d_0)/\ln 2$. The variance of this distribution can then be

[5] In its logarithmic form eq. [5] is naturally suited for graphical presentation.

[6] For the relative magnitude of the effect of coordination number and ionic charge in M(III)—Cl species see ref. 17.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

taken as a measure of the variability of the bond order in balanced (i.e., symmetric) conjugate *trans* bonds.

For each Z–L d,d^* set the sum $S[d^*(\text{obs})_i - d^*(\text{fit})_i]^2$ was minimized for the total **A** + **S** sample as well as for the **A** sample alone; for $n_S = 0$, of course, $S_{A+S} = S_A$. In addition to these **A** + **S** and **A** regressions, attempts were made to accommodate **S** as a separate population in the model functions. This was done (subject to the assumptions stated in **F**) by minimizing weighted combinations of $S_A[d_a^*(\text{obs})_i - d_a^*(\text{fit})_i]^2$ and $S_S[d_s(\text{obs})_i - d_c]^2$ in two ways, depending on the size of the **S** sample. For reasonably large n_S the combination to be minimized was

[9] $\quad n_A \log S_A + n_S \log S_S$

(regressions DPF(**A**,**S**) and CSBO(**A**,**S**)). For $n_S = 1$–4 the **S** sample is too small to estimate the **S** variance reliably. Assuming that the ratio of the **A** and **S** variances is λ, one can minimize the combination

[10] $\quad S_A + \lambda S_S$

(regressions DPF(**A**/**S**) and CSBO(**A**/**S**); initially λ was taken to be unity. Evaluation of r^2 and of error estimates is treated in **F**.

B. Individual Z–L combinations

Of the model functions investigated PF1 and PF2 (and even more so LIN, the linear function, cf. ref. 1) have generally been found inferior to or no better than DPF and CSBO, as judged by their respective r^2 and σ values. DPF and CSBO have therefore been adopted as the two standard model functions and evaluated (with the further elaboration allowing for **A** and **S** as separate populations) for the particular Z–L combinations considered in this work. The numerical results of the regressions are presented in Tables 1 and 2. Figures 1–4 contain plots of the experimental d,d^* pairs and the fitted DPF(**A** + **S**) curves. The corresponding CSBO(**A** + **S**) curves are not shown, as they are indistinguishable, on the scale of the drawings, from the DPF(**A** + **S**) curves. Sources of data are listed in **F**.

The Z–L data sets are for homoligand Z coordinations. The occasional d,d^* pairs in heterocoordinate Z species that are included in some of the sets are consistent with the body of the homoligand data (for the special case of Se(IV)—Cl(Ox) see below).

DPF(**A** + **S**) and CSBO(**A** + **S**) regressions have been obtained for all the Z–L data sets of Tables 1 and 2 except for Se(II)—Cl, As(III)—Cl, and As(III)—I (for the special case of P(III)—Br see below), which contain no d_s values and for which only the DPF(**A**) and CSBO(**A**) regressions are available. DPF(**A**,**S**) and CSBO(**A**,**S**) regressions were performed for data sets with $n_S \geq 2$. However, since the distribution of d_s values in very small **S** samples is likely to be unrepresentative, it would not be prudent to place too much confidence in the **A**,**S** regressions in such cases. For **S** samples with one to four d_s values, DPF(**A**/**S**) regressions (not listed in Table 1) were attempted as well, resulting in parameter values that did not differ from those obtained from the corresponding **A** or **A** + **S** regressions within the standard errors and that in most cases were numerically quite close to the latter.

Because of the incompleteness and deficiencies of some of the data sets it was thought most practical for comparison purposes to use the results of the **A** + **S** regressions throughout. While this is not the most logical choice when the different nature of the **A** and **S** populations is considered (see **A5**), it is justified by the fact that the parameter values from the **A** + **S** regressions are within at most 1.5σ of the corresponding values from the **A** or **A**,**S** regressions where the latter are available.

It should be noted that while each of the d,d^* data sets is adequately fitted by the regressions of Tables 1 and 2, the standard errors on the parameter estimates are large, at times comparable to or even exceeding the parameter value. In part, these large errors are the price to pay for universality, i.e., for the liberal inclusiveness of the data sets, both as concerns accuracy and chemical appropriateness of the bond lengths. This problem is illustrated by comparing the results of the present regressions for Se–Cl and Te–Hal with those for the much smaller but chemically homogeneous d,d^* sets for the μ_2–$Z_2Hal_{10}^{2-}$ dimers (Table III of ref. 1). The vintage of some of the literature d,d^* values is also a factor: older values, with larger than desirable esd's, tend to increase the scatter. However, the scatter is not the only factor responsible for the magnitude of the standard errors on the refined parameters (see **F**).

The comments below include (though not exhaustively) the bond lengths d_u for Z—L bonds with unopposed ligand (i.e., no *trans* ligand at an acceptable bonding distance, or a presumed lone pair, L—Z—LP). These bonds are often perpendicular or approximately perpendicular to the L—Z—L *trans* bond pair(s). Also cited are some "limiting" Z—L bond lengths, which may have bearing on the discussion of the d_0 values and which to some represent the "experimental" d_0 values, d_0(expt) (see **A4**).

Se(IV)–Cl(Ox). This set includes $Se_2O_2Cl_6^{2-}$, $SeOCl_3^-$, and $SeOCl_4^{2-}$. In all these species the Se—O bonds are perpendicular to the Se,Cl planes.

Se(II)–Cl, Se(II)–Br. The bond lengths in $SeCl_2$(g) and $SeBr_2$(g) are 2.157(3) and 2.32(2) Å, respectively (Table II of ref. 18).

Te(II)–S. This is the only experimental homoligand combination we have examined in which the ligand is not a halogen. The data set (Fig. 4) is interesting in several respects. Of the 107 d,d^* pairs 58 form the **S** sample (three of them corresponding to bond pairs of C_2 symmetry). Another 26 constitute an asymmetric **A1** sample, which corresponds to square-planar Te coordination with S—Te—S angles greater than 160° but which is skewed strongly toward 180° (mean S—Te—S angle, 172.2(56)°, $\gamma_1 = -0.77$, $\gamma_2 = 2.42$).[7] This is a true *trans* population, subject to TE. The remaining 23 pairs (population **A2**) correspond to quasi-*trans* S—Te—S* bonds associated with the trapezoidal-planar Te coordination.[8] In this sample the S—Te—S angle range is rather narrow, 145–152°, with a mean of 148.3(18)° and only a slightly skewed distribution ($\gamma_1 = 0.10$, $\gamma_2 = 1.88$). The existence of these two asymmetric populations with no angle overlap affords an opportunity to assess the effect of noncollinearity on TE. The regressions listed in Tables 1 and 2 are for **A1** and **S**. Regressions involving **A2** are discussed in **C5**.

P(III)–Br. There are only three d,d^* pairs in this set (points 2, 4, and 8 in Fig. 2 of ref. 11), so the parameter values in Tables 1 and 2 are for the exact fit. This set, although *statistically* not significant, has been included as a reference for tracing the effect of cyano heteroligands on the TE of P(III)—Br (see **C6**). Two of the three available d_u values, 2.217(1) Å (11), 2.221(3) Å (20), and 2.333(2) Å (11) (all three against LP), are marginally lower than the fitted d_0 values.

As(III)–Cl. This exclusively **A** data set does not contain d,d^* pairs sufficiently close to the expected d_c value and the point with the lowest d^* (and one that crucially affects the outcome of the d_c estimation)[9] appears to be spurious. Indeed, fitting this set to both DPF and CSBO ($r^2 = 0.917$, $\sigma = 0.045$ Å, $d_c = 2.443(25)$ Å) resulted in standard errors on the parameter values that were so large as to render the latter meaningless. A "synthetic" d_c value of

[7] γ_1, coefficient of skewness; $\gamma_1 < 0$, distribution skewed toward 180°, γ_2, coefficient of kurtosis; for a normal distribution $\gamma_2 = 3$.

[8] This coordination geometry is encountered with bidentate ligands of the $-CS_2$ type (cf. ref. 19).

[9] This point corresponds to a d,d^* pair in the heteroligand $As_2SCl_5^-$ anion (21).

[a]First line refers always to DPF(**A** + **S**); second, DPF(**A**, **S**); third line, DPF(**A**). Otherwise the line with $n < n$[DPF(**A** + **S**)] refers to DPF(**A**) and the line with n(**A**) + n(**S**) refers to DPF(**A**,**S**).
[b]45/9 etc. stands for $10^3\sigma$(**A**)/$10^3\sigma$(**S**).
[c]Refinement for DPF(**A**) gave unreasonable parameter values.
[d]DPF(**A1** + **S**); DPF(**A1**,**S**); DPF(**A1**).
[e]See **B**.
[f]Fit to three d,d* pairs only (see **B** and **C6**).

2.535 Å estimated from the d_e(Z—Hal) vs. $r(Hal^-)$ correlation (see **C5** and Fig. 5) was therefore added and the set was reoptimized, yielding parameter values with acceptable standard errors. The reported d_u values are 2.179 Å (22), 2.189 Å (12), and 2.204 Å (21). The bond length in $AsCl_3$(g) is 2.161 Å (23).

As(III)–Br. This set is among the most consistent investigated here, with all the d,d* values coming from one laboratory. The reported d_u values are 2.335 Å (15), 2.347 Å (13), and 2.366 Å (15). In $AsBr_3$(g), d(As—Br) = 2.33 Å (23).

As(III)–I. The values in this set, too, come from one laboratory and, as for As(III)–Br, from recent investigations. No d_s value is available, but there are d,d* pairs reasonably close to d_e. The solitary d_u value is 2.585 Å (24). The bond length in AsI_3(g) is 2.55 Å (23).

Sb(III)–Cl. The scatter in this large set may be in part attributable to the lower accuracy of the older structure determinations. It is reflected in the smallest r^2 and the largest σ value in Tables 1 and 2, and in the very large standard errors on the parameter values. It is noteworthy that Sheldrick and Martin (16), who used a somewhat smaller d,d* set in their CSBO regression with a d_0 fixed at d_0 (expt) in $SbCl_3$(g) (cf. Table 2), failed to obtain a meaningful correlation between B and $d - d_0$. Accumulation of additional, accurate d,d* should make it possible to formulate objective rejection criteria for cleaning up the existing Sb(III)–Cl set and to determine to what extent the scatter is inherent, i.e., arising from differences in bonding specific to the Sb(III)–Cl combination (as held in ref. 16). Many d_u values have been reported (7, 14, 25–27), ranging from 2.338 to 2.385 Å. In a $SbCl_3$[crown] complex (28) the Sb—Cl bond lengths are 2.405, 2.412, and 2.423 Å; in $SbCl_3$(g), d(Sb—Cl) = 2.333 Å (23).

Sb(III)–Br. This set is poorly defined at low d and the uniformity of the d,d* sampling leaves something to be desired. The reported d_u values are 2.505 and 2.529 Å (29). The bond length in $SbBr_3$(g) is 2.49 Å (23).

Sb(III)–I. The d_s distribution has a considerable width. The d_u bond lengths are 2.767 and 2.773 Å (30). In SbI_3(g), d(Sb—I) = 2.719 Å (23).

Bi(III)–Cl. The d_u reported recently in $Bi_2Cl_8^{2-}$ is 2.500(6) Å (31). In $BiCl_3$(g) the bond length is 2.48 Å (23); the average bond length in a $BiCl_3$[12]crown-4 complex (31) is 2.52(1) Å.

Bi(III)–Br. The scatter in this sample is appreciable; the d,d* distribution gives the impression of being bimodal. The bond length in $BiBr_3$(g) is reported as 2.63 Å (23).

Cl–Bi(III)–S. The appreciable scatter in this set comes from

[d]Reference 16 states that B and $d - d_0$ are uncorrelated.
[e]Fit to three d,d^* pairs only (see text).

limited experimental accuracy, from the involvement of the S ligands in other bonds, from the presence of other heteroligands on Bi, and from significant departures from collinearity. The shortest Bi—S distance in Bi_2S_3 is reported to be ~2.56 Å (32).

Xe(II)–F. The two *ab initio* $d = d^*$ values for XeF_2, 1.978 Å (33) and 1.985 Å (34), agree well with the d_e(**A** + **S**) = d_e[CSBO(**A** + **S**)] = 1.994(16) Å and d_e (**A**) = 1.998 (21) Å values calculated from the regressions. The *ab initio* (33) d,d^* pair for $Xe_2F_3^+$, 1.899 and 2.228 Å, is within 2σ of the regression. However, the *ab initio* d(Xe—F) estimates for XeF^+, 1.877 Å (33) and 1.886 Å (34), are higher than the asymptotic limit of the TE regressions, d_0(DPF) = 1.70 (13) Å and d_0(CSBO) = 1.76(6) Å, which seems to indicate that either the *ab initio* estimates are still too high or XeF^+ is not the correct asymptotic reference species for TE[Xe(II)–F], or both (see **C2** and Fig. 6).

B(III)–O. This combination was investigated only on 6–31G* *ab initio* values of d(B—O),d^*(B—O) in BO_2^-, OBO*X (X = H, F, Cl, Li), and B_2O_3 molecules. The data set for BO_2^- and OBO*X (n = 5) gave an almost exact fit to both DPF and CSBO; with *cis*-B_2O_3 and *trans*-B_2O_3 included (n = 7) the fit was considerably worse (see **D1**).

O–C–N. Like the preceeding, this combination was investigated only on 6–31G* *ab initio* values of the bond lengths, d(O—C),d(C—N), in OCN^-, XOCN, and OCNY (X, Y = H, F, Cl, Li, Na) species, and it too was found to give superior fits to the model functions (see **D3**).

Data sets with convergence problems

Fitting to DPF and CSBO was also attempted for the data sets assembled for Pb(II)–Br, Pb(II)–I, I(III)–Cl, and Ti(IV)–Cl. A significant fraction of the d,d^* pairs in these sets derives from entities that can only marginally be characterized as discrete. Although Figs. 1 and 3 show definite TE trends for these combinations, the data sets are small and ill-conditioned. Convergence could not be achieved for Pb(II)–Br (n = 5) and Ti(IV)–Cl (n = 17). For Pb(II)–I (n = 27) convergence was obtained for DPF (**A** + **S**) but the standard errors on the optimized parameter values were very large. The I(III)–Cl (n = 17) set contains a number of older d,d^* values of questionable accuracy. Regressions of the full set and of partial sets with some of the outliers omitted resulted in very large standard errors on the parameter values. However, the d_e values obtained in these regressions were reasonably consistent, with 2.508(13) Å as the best estimate.

Other Z–L combinations

The literature was searched also for d,d^* pairs of other Z–L combinations, especially in "planar" μ_2-bridged species. The results of our findings for TE in a number of transition-element μ_2-T_2Hal_{10} and μ_2-$T_2Hal_{10}^{2-}$ dimers are described in ref. 1. In planar Cu(II), Au(III), Pd(II), and Pt(II) μ_2-halogeno species the d,d^* inequality was found to be too small for a meaningful TE analysis; this is typical of T–Hal combinations in general. Scarcity of data was prohibitive for Ge(II) and Sn(II) combinations with the exception of Sn(II)–F where, however, other difficulties were encountered (see Sb(III)–F below). Such indications as there are point to the existence of TE ranges for Ge(II)–I and Sn(II)–I comparable to that for Pb(II)–I. For Pb(II)–Cl and Cd(II)–Cl the d,d^* pairs form ill-defined clusters with narrow d,d^* ranges, and the same seems true of Cd(II)–Br and Cd(II)–I.

Proper convergence could not be obtained for the Sb(III)–F set (n = 27). The scatter was large and difficult to trace to any one among the lower accuracy of the older structure determinations, large deviations from collinearity, and the lack of well-defined discrete character of the $Sb_pF_q^e$ entities. Indefiniteness of the Sb coordination and F–Sb–F "*trans*" angles as small as 130° are characteristic and inherent in crystal structures containing Sb(III)–F species. Similar problems are encountered with Sn(II)–F (cf. ref. 35 for an account of both Z–F combinations) and are endemic in oxide structures.[10]

C. Conclusions from data treatment

1. Examination of d_e *and* $\bar{d}_s$ *(Q7)*

The d_e (**A**) obtained from a DPF(**A**) regression represents the "best" estimate of the balanced Z—L bond length for the pertinent Z–L combination, provided the data set contains d,d^* pairs sufficiently close to the $d = d^*$ line. In that case the d_e(**A**) value has a remarkably small standard error and is very close to the d_e values calculated from the **A** + **S** and **A**,**S** regressions. When the d_e(**A**) values for the Z–Hal combinations are regressed linearly on Shannon's $r(Hal^-)$ radii, very good fits result. In the three series where all three halogens are represented, the regressions d_e(**A**) = a_0 + $a_1 r(Hal^-)$ give

[10]The d,d^* relationship for strongly angular *trans* bond pairs in oxides of Sb(III), Te(IV), and I(V) has been treated in terms of DPF with c = 1 in refs. 36 and 37 (cf. also ref. 38). Setting c = 1 implies $\Delta = d_e - d_0 = \sqrt{K}$. If $r(Cl^-) - r(O^{2-})$ is taken as 0.41 Å (Shannon's radii), d_e(Z—Cl) = $d_0 + \sqrt{K}$ + 0.41; using d_0 and K values from refs. 36 and 37 gives d_e estimates for Te(IV)—Cl and Sb(III)—Cl of 2.51 and 2.62 Å, respectively, in good agreement with the corresponding refined values in Table 1, 2.53 and 2.62 Å.

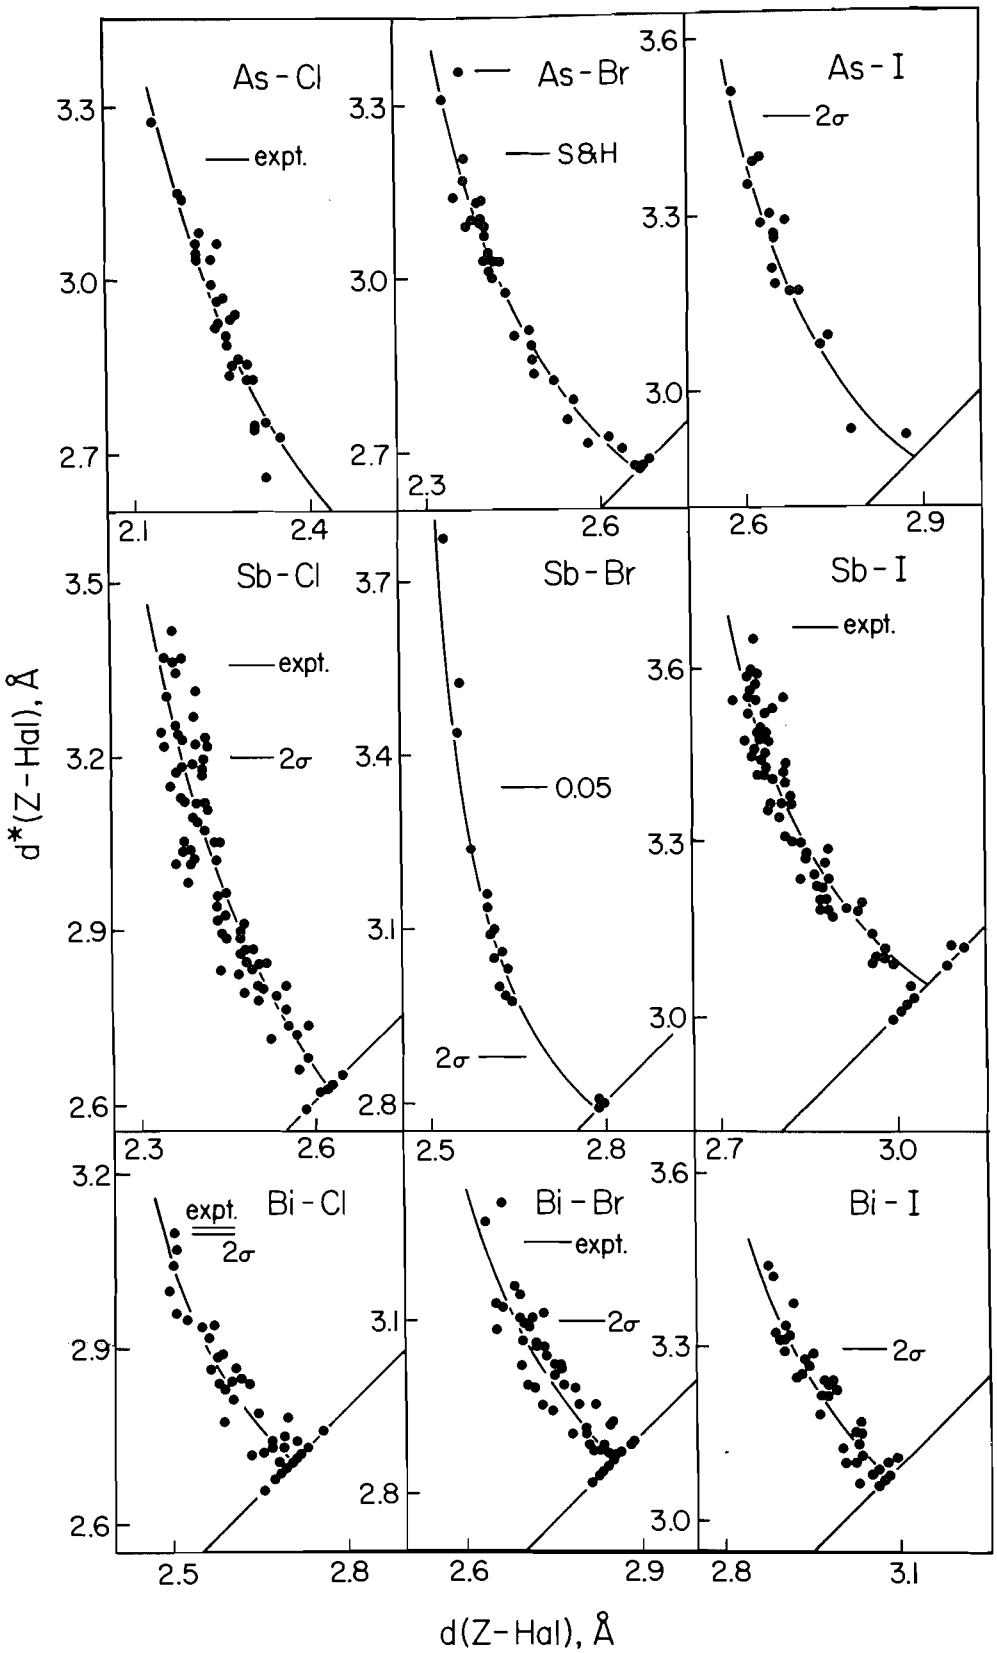

FIG. 2. d^* vs. d plots for conjugate Hal—Z—Hal* *trans* bonds in halogeno species of trivalent Group V elements (cf. caption of Fig. 1). The upper bar in the As–Br plot indicates d^* that corresponds to $d = d_0(\text{expt}) + 0.05$ Å.

Te(IV)–Hal:	$r^2 = 0.998$	$\sigma = 0.013$ Å,	$a_0 = 0.543(95)$ Å,	$a_1 = 1.091(48)$
Sb(III)–Hal:	1.000	0.001 Å	0.624(9) Å	1.102(5)
Bi(III)–Hal:	1.000	0.002 Å	1.023(13) Å	0.938(6)

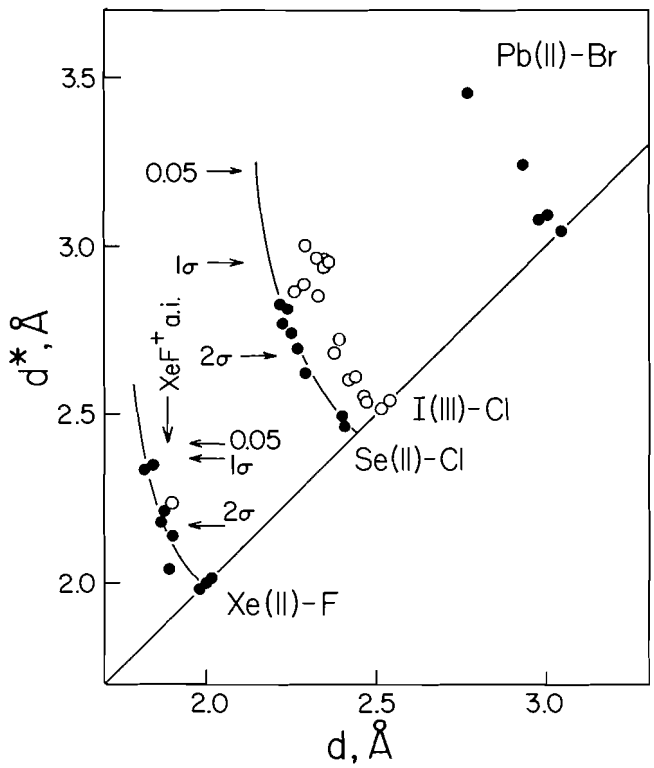

FIG. 3. d^* vs. d plots for conjugate Hal—Z—Hal* *trans* bonds in homoligand Se(II)–Cl, Xe(II)–F, I(III)–Cl, and Pb(II)–Br species (see caption of Fig. 1). Xe(II)–F: open circle, $Xe_2F_3^+$, *ab initio* value (33) not included in the regression.

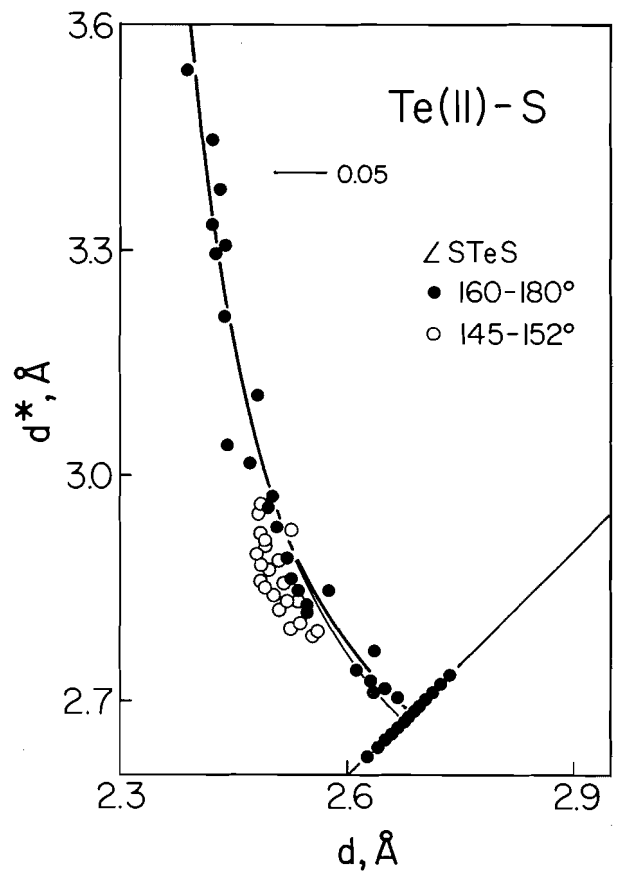

FIG. 4. d^* vs. d plot for conjugate S—Te—S *trans* bond pairs in Te(II)–S species. Full circles, **S** (on $d = d^*$ line) and **A1** data sets; open circles, **A2** data set. Thick line, DPF(**A1** + **S**) regression; thin line, DPF(**A1**) regression. For the 0.05 line see caption of Fig. 1.

Fits statistically indistinguishable from these are obtained when the d_e[CSBO(**A**)] or d_e(**A** + **S**) values are used; the latter give slightly lower error estimates. Since the regression lines for these three Z–Hal series are approximately parallel, one can roughly estimate the missing d_e values in those Z–Hal series where only two halogens are available (Fig. 5).

The estimated d_e(Z—F) obtained by extrapolation to $r(F^-)$ = 1.33 Å (Te(IV), 2.02–2.09 Å; Sb(III), 1.99–2.10 Å; Bi(III), 2.25–2.27 Å, depending on the TE regression used) all appear to be higher than the estimates from experiment (Fig. 5), but in view of the long extrapolation and of the various uncertainties involved these results should not be regarded as unreasonable.

The answer to **Q7** would be expected to be in the affirmative. By and large, the contributions to both **A** and **S** for the Z–Hal combinations examined originate in similarly-coordinate Z, although vagaries of uncontrolled sampling may be responsible for a disproportionate fraction of d_s values from discrete $ZHal_6^{n-}$ ions in some of the **S** sample populations. In the test of the d_e(**A**) and $\bar{d}_s$ values for equality (Table 3) a significance probability $P > 0.05$ indicates that the d_e(**A**) and $\bar{d}_s$ for that Z–L combination are statistically not distinct.[11] Inspection of the table reveals that with two exceptions P is always greater than the critical value, i.e., the test results confirm the above expectation of equality. The exceptions are Te(IV)–Cl and Bi(III)–Cl, for which P is very small. The reason for the low P values has not been investigated.

The statistical equivalence of d_e(**A**) and $\bar{d}_s$ thus legitimizes combining the **A** and **S** sample sets to one set, which can then be fitted to DPF(**A** + **S**) or DPF(**A**,**S**).

For the overall goodness of fit it is found that generally, for a given Z–L combination, $\sigma(\mathbf{S}) \sim \frac{1}{3}\sigma(\mathbf{A})$.

2. Problems involving d_0

In the empirical DPF model d_0 represents the asymptotic limit of d(Z—L) as defined by the Z–L sample used in the evaluation of TE(Z–L). Theoretically it should correspond to the limiting internuclear separation as determined by Z···L

[11]Hence d_e(**A** + **S**) and $\bar{d}_s$, too, must be statistically indistinguishable.

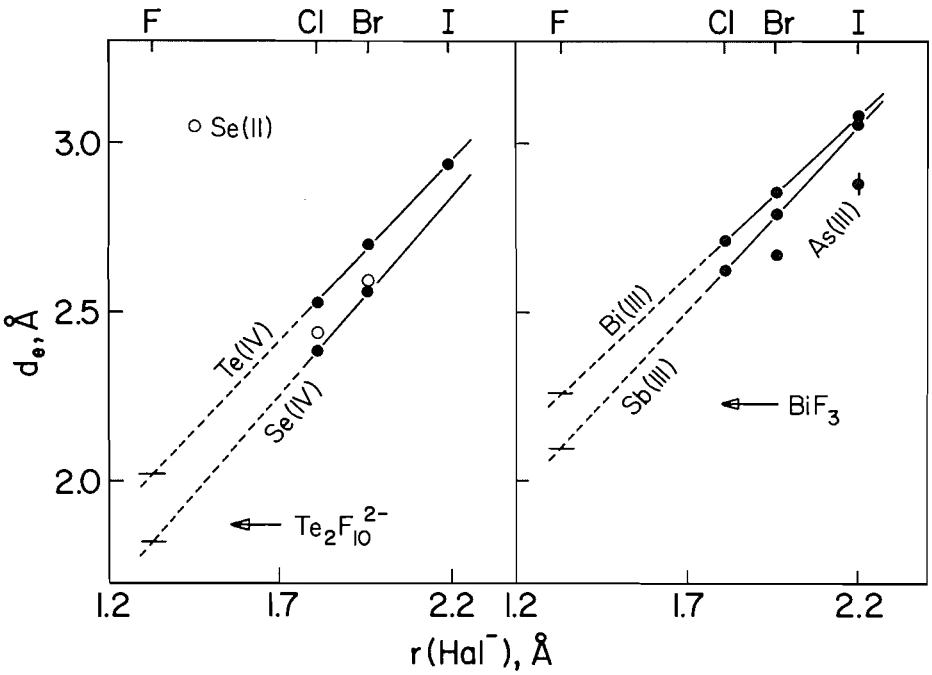

FIG. 5. Variation of d_e with the size of the halogeno ligand. BiF_3 indicates the smallest Bi—F bond length in BiF_3 (39) and $Te_2F_{10}^{2-}$ the smallest Te—F bond length in the pseudo μ_2-$[Te_2F_{10}]^{2-}$ dimer (18).

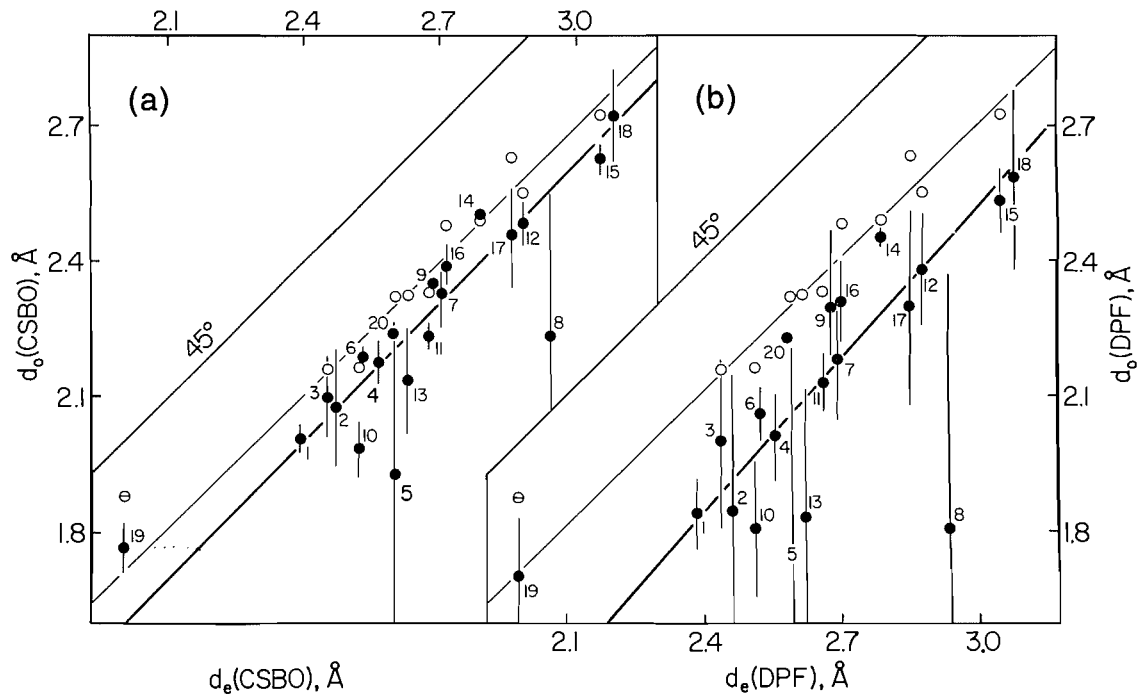

FIG. 6. Variation of d_0 with d_e for CSBO (*a*) and DPF (*b*). Full circles, optimized d_0; open circles, d_0(expt); circle with bar, *ab initio* d(Xe—F) in XeF^+ (not included in regressions). Thick line, regression of optimized d_0 on d_e with pairs 5, 8, and 19 excluded (see text). Thin line, regression of d_0(expt) on d_e. Numbering of Z–L combinations as in Tables 1 and 2.

repulsion at short range, but this is not possible to verify as we do not know how d(Z—L) in compounds of interest varies with external pressure. Clearly the confidence with which d_0 can be determined depends on the availability of d,d^* pairs at $d \rightarrow d_{0,\text{est}}$. The difficulty here is that in this region of the TE plot d^* increases steeply with d. Since all interatomic distances in a crystal are calculated from the same set of crystallographic parameters, the accuracy of d^* does not deteriorate as d^* increases. The problem is therefore one not of accuracy but of *eligibility* of large d^* for inclusion in the Z–L data set, especially in the presence of significant deviations from collinearity, i.e., when the coordination of Z at large Z · · · L distances is not sufficiently well defined. In doubtful cases one is therefore tempted to use extrapolation

[a]n, number of d,d^* pairs in sample; P, significance probability (see **F**).

from the well-defined portion of the TE curve as a guide for the acceptance or rejection of large d^* values, thus ending up in a circular argument without improving the estimate of d_0. This matter is discussed in **C3**.

In CSBO d_0 by definition corresponds to the length of a Z—L bond of order one. This bond length should be accessible from experiment, but the precise meaning of this quantity is not clear. The d_0 (expt) values, for a particular Z–L combination, obtained by different experimental methods and under different conditions of temperature and aggregation will not be the same, and there is the problem of choice, availability, and experimental accuracy of the reference values. Thus for Z(III)–Hal of Group V previous authors (see **A4**) have used as d_0 the d_u bond lengths in $ZHal_3$, in the gas phase where available, otherwise in the crystal. Again, in $SeCl_4$ and $TeCl_4$ monomers the bond lengths are not known (the other $SeHal_4$ and $TeHal_4$, Hal ≠ F, monomers do not appear to exist in the vapour state), and the $SeHal_4$ and $TeHal_4$ tetramers that occur in the crystals do not contain Z—Hal bonds with unopposed ligands. The bond length in XeF^+, the presumed reference species for the Xe(II)–F set, has not yet been determined and *ab initio* estimates of unknown accuracy (see **B**) must serve instead as external d_0. In the circumstances the optimized, internally consistent d_0(CSBO) defined by the d,d^* sample itself seem a more satisfactory choice than d_0 values supplied externally. The d_0 (expt), d_0(CSBO), and d_0(DPF) sets are compared below.

The refined d_0(CSBO) as well as the d_0(DPF) are consistently smaller than the corresponding d_0(expt). When the d_u in $ZHal_3$ (23) and in $SeCl_2$(g) and $SeBr_2$(g) (18) are taken as d_0(expt) and regressed linearly on d_e one obtains d_0(expt) = −0.274(235) + 0.993(87)d_e, r^2 = 0.943, σ = 0.046 Å (Fig. 6),[12] from which, for the midpoint of the d_e = 2.4–3.1 Å range, Δ(expt) = 0.274 − 0.007d_e ~ 0.26 Å. A similar regression of d_0(CSBO) on d_e including all the Z–L sets of Table 2 except Xe(II)–F and P(III)–Br resulted in r^2 = 0.741. The d_0(CSBO) of Se(II)–Br and Te(IV)–I, because of their very large standard errors, tend to obscure the observed trend. Omission of these two points improved the correlation considerably while still accommodating the omitted d_0(CSBO) within their respective 1σ limits: d_0(CSBO) = −0.446(221) + 1.023(82)d_e, r^2 = 0.917, σ = 0.066 Å (Fig. 6*a*);[13] Δ(expt) ~ 0.38 Å at d_e = 2.75 Å. On the average, the refined d_0(CSBO) values are thus about 0.09 Å smaller than the d_u in the reference species, and the Δ(CSBO) about 0.12 Å larger than the Δ(expt). The mean difference d_0(CSBO) − d_0(expt) is just outside the joint 1σ of the two regressions and therefore statistically not significant.

The scatter in the d_0(DPF) vs. d_e plot (Fig. 6*b*) is more appreciable than for d_0(CSBO) but the trends are the same. Linear regression with the points for Xe(II)–F, Se(II)–Br, and Te(IV)–I omitted gave d_0(DPF) = −0.889 (931) + 1.136 (145) d_e, r^2 = 0.813, σ = 0.116 Å.[14] The d_0(DPF) values are thus consistently smaller than the corresponding d_0(CSBO) values, on the average by about 0.13 Å, and by about 0.22 Å smaller than the corresponding d_0(expt) values.

Comparison of the regression lines shows that while the d_0(expt) on d_e and the d_0(CSBO) on d_e regressions are statistically equivalent, the d_0(DPF) regression on d_e is equivalent to neither. This raises the question, is the difference in the fitted d_0 values due to the difference in the rate of the asymptotic convergence of DPF and CSBO and thus an artefact of the model, or is the difference real and the collective information content of the observed variation of d^* with d such that d_0(DPF) in fact represents an estimate of the asymptotic limit of the Z—L bond length as determined by nuclear repulsion at short range? The latter naturally would be smaller than the d_0(expt) obtained from the d_u of the reference species at ordinary pressures. At present no answer can be given (but see **C7**). However, the *practical* consequences of the differences in d_0 are not serious, for the d,d^* data sets are adequately fitted over the observed d ranges by both model functions, and either function can be used for predictive or verificative purposes up to the limit of chemical bonding between Z and L.

3. *Cut-off distance for effective bonding (Q3)*

The distance limit for effective chemical bonding is usually taken as ΣvdWr, the sum of the van der Waals radii of the two atoms involved in the putative bond. Although by its very nature this sum is not a precise quantity, it does provide an independent check on the reasonableness of the refined asymptotic bond-length limit d_0: the d(ΣvdWr) value conjugated to d^* = ΣvdWr and calculated from a TE regression should not exceed d_0. That this indeed is the case is demonstrated in Fig. 7, where the differences d(ΣvdWr) − d_0(CSBO) as well as d(ΣvdWr) are plotted against d_0(CSBO).[15] Since d^* = ΣvdWr falls on the steep portion of the TE curve, the d(ΣvdWr) value is not overly sensitive to variation in d^* = ΣvdWr. For As(III)–Br, for example, for which ΣvdWr ~ 3.95 Å, a decrease of 0.4 Å in d^* from 4.15 to 3.75 Å produces an increase in d of only 0.024 Å. Still, all the d(ΣvdWr) − d_0(CSBO) differences in Fig. 7 are greater than zero; the d(ΣvdWr) are, on the average, about 0.05 Å from the corresponding d_0(CSBO).

Sheldrick and Horn (15) consider that "the wide scatter of

[12]If the *ab initio* value for XeF^+ is included, the regression gives d_0(expt) = 0.124(171) + 0.848(64)d_e, r^2 = 0.951, σ = 0.057 Å.

[13]If Xe(II)–F is included, the regression gives d_0(CSBO) = −0.167(182) + 0.921(68)d_e, r^2 = 0.923, σ = 0.071 Å.

[14]With Xe(II)–F included, d_0(PDF) = −0.360(327) + 0.943 · (123)d_e, r^2 = 0.796, σ = 0.129 Å.

[15]Pauling's van der Waals radii; the value for Bi is taken as 2.25 Å.

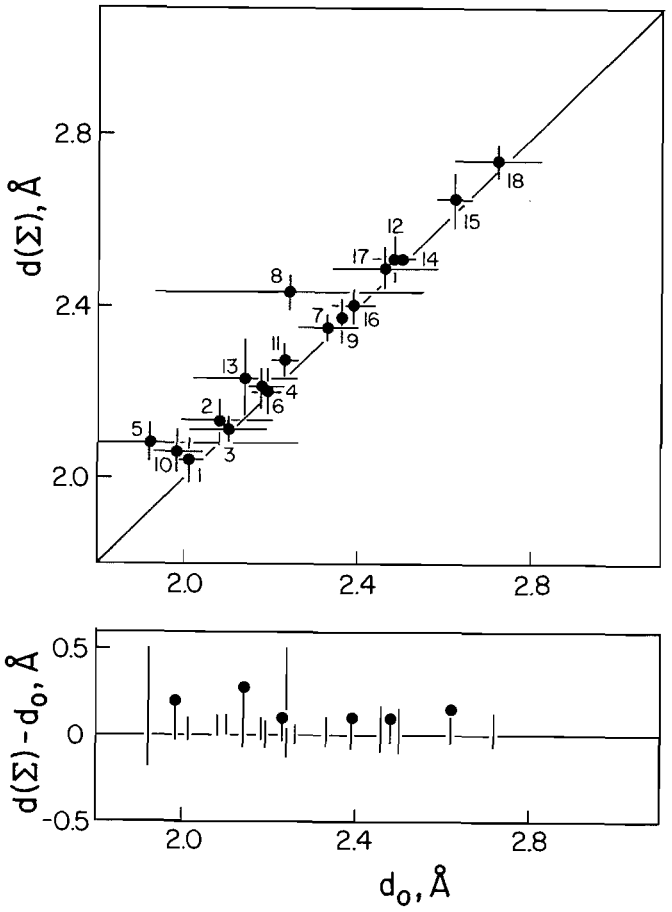

FIG. 7. Top: Comparison of d_0(CSBO) = d_0 with the bond length $d(\Sigma\text{vdWr}) = d(\Sigma)$ that results when d^* in the CSBO regression equation is equated with ΣvdWr, the sum of Pauling's van der Waals radii of Z and L. The uncertainty in $d(\Sigma\text{vdWr})$ does not include the uncertainty in the values of the radii themselves. Bottom: Variation of the difference $d(\Sigma\text{vdWr}) - d_0$(CSBO) with d_0(CSBO). Full circles, d_0(expt) values.

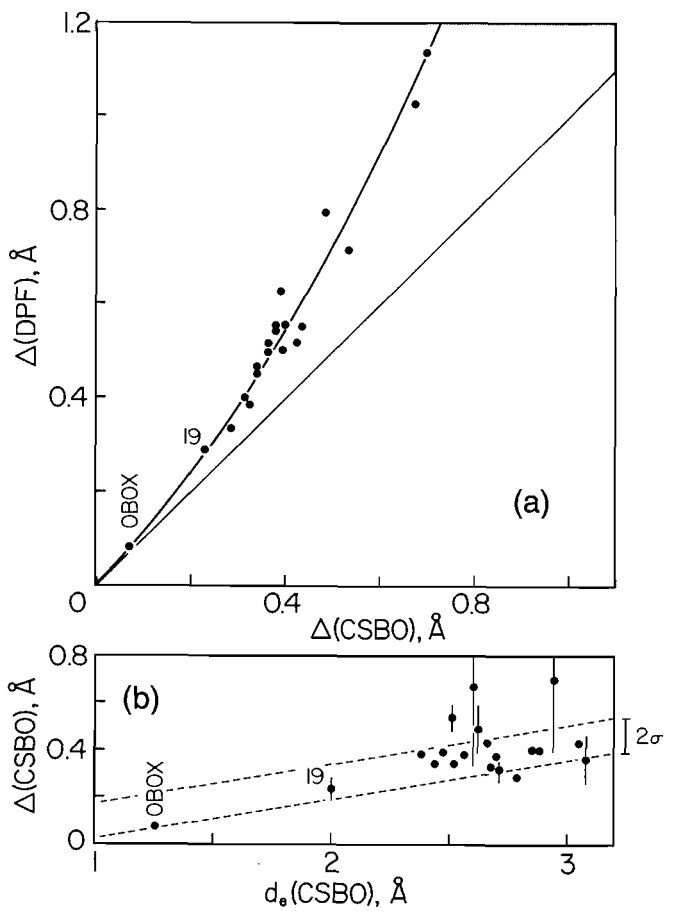

FIG. 8. (*a*) Comparison of Δ(DPF) and Δ(CSBO). (*b*) Variation of Δ(CSBO) with d_e(CSBO) over the extended d_e range.

d^* values observed for the extremely weak secondary bonds falsifies the observed [TE] trend."[16] In their treatment of the As(III)–Br set they therefore excluded d,d^* pairs for which $d - d_0(\text{expt}) \leq 0.05$ Å. Such truncation of course precludes in principle an answer to Q3, viz., can the cutoff for effective bonding be estimated from experimental data? Again, inclusion of d,d^* pairs that are only marginally governed by TE may vitiate this very endeavour.

To assess the effect of the above rejection criterion on a d,d^* sample set Figs. 1–4 indicate the d^* limits that correspond, respectively, to $d = d_0$(CSBO) + 0.05 Å, $d = d_0$(CSBO) + $\sigma[d_0(\text{CSBO})]$, $d = d_0$(CSBO) + $2\sigma[d_0(\text{CSBO})]$, and $d = d_0$(expt) + 0.05 Å, all as calculated from the CSBO regressions of Table 2; and, for As(III)–Br, also the d^* corresponding to $d = d_0$(expt) + 0.05 Å as calculated from the regression of ref. 15. The positions of these d^* limits vary from case to case and in several of the sets none of these limits is below the largest d^* value in the set (e.g., for Se(IV)–Cl, Se(IV)–Br, Sb(III)–I), but even where the limit is low, the scatter of the d,d^* points that are above the limit (i.e., candidates for rejection) is not appreciably worse than for the uncontested region of the TE curve. Rejection criteria based on such limits, if strictly applied, may therefore be unduly severe and may tend to eliminate much needed d,d^* pairs in the d region close to d_0.

4. Magnitude of TE and the involvement of lone pairs(s) on Z

As discussed in **C2**, the total variability Δ of d(Z—L) depends on d_0 and is therefore subject to the same uncertainty as the latter, with the result that Δ(DPF), Δ(CSBO), and Δ(expt) are not the same. The Δ(DPF) and Δ(CSBO) appear to be correlated: the difference between them increases with Δ and is satisfactorily represented by Δ(DPF) − Δ(CSBO) = $0.864[\Delta(\text{CSBO})]^2$ (Fig. 8*a*). Concomitant with this divergence of Δ(DPF) and Δ(CSBO), whether by accident or otherwise, is the general increase with Δ of the standard errors on the Δ values.

For Z–L combinations having d_e in the 2.4–3.1 Å range (i.e., all those in Fig. 4 except Xe(II)–F) Δ was found to vary only slightly with d_e (see **C2**). While this finding can be claimed to hold over that limited d_e range, given the large standard errors on d_0, its validity would not be expected to extend to low d_e values: the variability, for example, of d(Z—F) due to TE is significantly smaller than for other Z–Hal combinations (cf. ref. 1). In an attempt to elucidate this apparent discrepancy we have included, in the plot of

[16]As noted in **C2**, the accuracy of the large bond lengths is not significantly inferior to that of the short bond lengths, since all the interatomic distances in a crystal structure are calculated from the same set of atom coordinates and unit-cell dimensions. Hence by and large the scatter has other origins.

Δ(CSBO) against d_e(CSBO) (Fig. 8*b*), Xe(II)–F as well as the point for B(III)–O based on *ab initio* results for OBOX species (see **D1**). Although the trend that now emerges depends critically on the two additional points, it strongly suggests that, over a wider range of d_e, Δ increases with d_e. If a linear variation is assumed and the points for Se(II)–Br and Te(IV)–I are excluded from the regression because of their large errors (cf. **C2**), one obtains $\Delta(\text{CSBO}) = -0.067(113) + 0.166(44)d_e$, $r^2 = 0.474$, $\sigma = 0.075$ Å, from which it follows that $[\Delta(\text{CSBO})/d_e]_{\text{lim}} \sim 0.166$. This, qualitatively, is an important and plausible finding. For example, d_e for the N—N—N *trans* bond pair in azides and hydrazoic acid derivatives is 1.18 Å; the total variability of d(N—N) expected from Fig. 8*b* would be 0.13(8) Å. This is consistent with the experimental estimate of the upper bound of Δ(N—N), 0.08 Å (40); other examples can be adduced in support of this trend. The tentative conclusion thus is that the total spread Δ of d(Z—L) varies roughly linearly with d_e, the *strength* of TE then being determined by the magnitude of c (eq. [5]) or b_0 (eqs. [4] and [8]). The quasi-linear variation of Δ with d_e is also consistent with the variation of the bond-length difference $d_s - d_u$ with d_s observed in molecular species having certain geometries (see **D2**).

In mononuclear ZL_n^{ε} species an observable TE may arise from internal or from external causes. The bond length disproportionation in the discrete octahedral 14-valence-electron $ZHal_6^{n-}$ anions in asymmetric environments is largely (though not exclusively) the consequence of the stereochemical activity of the lone electron pair on Z (cf. ref. 41 and literature therein) and thus in the internal causes category. By contrast, in $XeF_2 \cdot MF_5$ and related adducts (Fig. 3) the Xe—F bond-length inequality is caused *externally*, by a weakening of one of the two Xe—F bonds through electron-abstracting interaction with MF_5, and with $[FXe]^+[FMF_5]^-$ as the extrapolation limit. The lone pairs on Xe are perpendicular to the F—Xe—F* *trans* bond pair and thus not involved in the bond-length compensation in any obvious way. Again, the TE in OBO*X (see **D1**), which results when $[OBO]^-$ forms a bond to X, cannot involve a lone pair as there are no lone pairs on the B atom. The conclusion would seem to be that TE depends on the stereochemical activity of a lone pair on Z only insofar as the lone pair is responsible for the formation of "secondary" bonds participating in conjugate *trans* bond pairs.

Let us now consider bridged halogeno species. Presence of a lone pair on Z seems to be essential in the discrete $[(\mu_2\text{-}Zi_2Hal_6)(Hal_\perp)_{0\text{-}4}]^{\varepsilon}$ dimers[17] in which large bridge asymmetry (and thus large TE) is observed. This is the case when Z is Se(IV), Se(II), Te(IV), I(III), or a Z(III) from Group V (15, 16; ref. 1 and literature therein). The bridge asymmetry decreases along the sequence Hal = (F), Cl, Br, I (1). When the lone pair is absent, the bridge asymmetry is generally small, sometimes negligible, and TE can vary considerably. Thus in the discrete $(Ti_2Cl_{10})^{2-}$ dimer (42, 43) the bridge asymmetry is small but the difference $\delta = d_{\text{bridge}} - d_{\text{terminal}}$ is ~0.23 Å (Fig. 1). In another $Z(d^0)$ species, $[Zr_2Cl_{10}]^{2-}$ (44), the bridge asymmetry is negligible and $\delta = 0.20$ Å (for other examples of and comments on μ_2-$[T_2Hal_{10}]^0$ and μ_2-$[T_2Hal_{10}]^{2-}$ dimers see ref. 1). In planar μ_2-$T_2Hal_6^{\varepsilon}$ (T = Au(III), Pd(II), Pt(II), Cu(II)) dimers the double bridge is practically symmetric and $\delta \leq 0.1$ Å, sometimes well below this value (45).[18]

*5. Effect of bond angle (**Q6**)*

Deviations from collinearity would be expected to play a rôle in TE, but this effect is difficult to establish with clarity. The bond angle in most of the Z–Hal data sets varies considerably, depending on the preponderance of the coordination geometries included in the sample. Typical distributions of the bond angles are illustrated by the following:[7]

			γ_1	γ_2
Se(IV)–Cl:	165.0–179.1°	⟨172.8(34)⟩°	−0.15	2.65
Se(IV)–Cl(Ox):	154.1–168.7°	⟨164.3(47)⟩°	−1.01	2.87
Se(II)–Cl:	169.7–178.8°	⟨174.4(26)⟩°	−0.10	2.41
As(III)–Br:	164.2–176.3°	⟨170.3(34)⟩°	−0.16	1.80
Bi(III)–Br:	161–179.9°	⟨173.5(47)⟩°	−0.79	2.87
Bi(III)–I:	163.9–176.7°	⟨171.8(33)⟩°	−0.63	2.45

(Centrosymmetric d_s, d_s pairs are not included in the range and means.)[19] These numbers indicate that unless the bond angle is constrained to 180° by symmetry at Z, it tends toward a mean value the difference of which from 180° reflects the stereochemical composition of the sample. This tendency is particularly noticeable in the Se(IV)–Cl(Ox) set, which is based on square-pyramidal $SeOCl_4$ units with O—Se—Cl angles greater than 90°.[20] All the above bond-angle distributions are skewed toward 180°, i.e., the tendency of the sample to noncollinearity is smaller than the mean would indicate.

Examination of several of the data sets for possible correlation between deviations from the fitted d^* values and the bond angles has so far proved inconclusive, although there appears to exist a very weak trend of the bond angle toward 180° as d tends toward d_e. On the whole, the less discrete the nature of the Z,Hal unit containing the *trans* bond pair(s), the larger the deviations of the bond angles from 180° and the greater their scatter, as evident in the Z–F sets, e.g., Sb(III)–F (35).

An unusual angle distribution is encountered for 4-coordinate Te in the Te(II)–S data set (see **B** and Fig. 4). The d,d^* pairs in the asymmetric **A1** subset are derived mostly from square-planar TeS_4 units with monodentate ligands, whereas those in the asymmetric **A2** subset come from trapezoidal-planar units in which the S atoms belong to two *cis*-S_2 pairs, each from a bidentate ligand molecule.[8] The latter arrangement is in fact an incomplete pentagonal-planar coordination, which accounts for the closeness of the S—Te—S angle in **A2** to $(360°/5) \times 2 = 144°$. The **A1** and **A2** angle distributions do not overlap.

Regressions for the **A1** + **S** subset show that this is a well-behaved d,d^* set, in fact one of the best examined here. The DPF(**A1**,**S**) and DPF(**A1**) regressions yield results that are statistically indistinguishable from DPF(**A1** + **S**). Keeping in mind that the goodness of fit σ for the reference regres-

[17]$Hal_\perp$ is perpendicular to the μ_2-Z_2Hal_6 bridge plane.

[18]Bonding in planar μ_2-$T_2Cl_6^{\varepsilon}$ d^8 dimers is considered in ref. 46, but its discussion there is unhelpful for understanding the magnitude of TE in these dimers.

[19]One of the noncentrosymmetric d_s pairs in the Bi(III)–Br set has an angle of 168.5° (C_2) and another, 178.0° (C_s); in the Bi(III)–I set, one d_s pair has an angle of 170.6° (C_2).

[20]The mean for 29 O—Se—Cl angles (ranging from 89.3 to 104.0°) in $SeOCl_4$ units (cf. ref. 1) is 98.0(40)°, $\gamma_1 = -0.47$, $\gamma_2 = 2.44$.

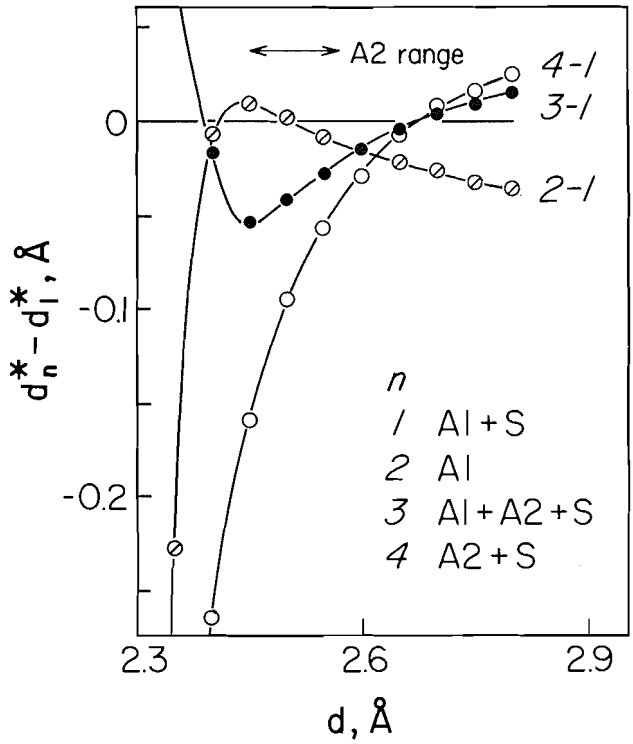

FIG. 9. Effect of bond angle on d,d^* correlations in Te(II)–S (see **B** and Fig. 4). **A1**, asymmetric *trans* population; **A2**, asymmetric quasi-*trans* population, S—Te—S = 145–152°; **S**, symmetric population. *2–1*, d^*[DPF(**A1**)] − d^*[DPF(**A1** + **S**]; *3–1*, d^*[DPF(**A1** + **A2**,**S**] − d^*[DPF(**A1** + **S**)]; *4–1*, d^*[DPF(**A2**,**S**)] − d^*[DPF(**A1** + **S**)]. Goodness of fit of the DPF(**A1** + **S**) regression, σ = 0.044 Å.

sion DPF(**A1** + **S**) is 0.044 Å, DPF(**A1**) and DPF(**A1**,**S**) are indistinguishable over the entire observed d,d^* range (Fig. 9). To test for the effect of the bond angle, regressions involving **A2** were attempted. Convergence was achieved for DPF and CSBO of **A2**,**S** (n_A = 23, n_S = 58) and **A1** + **A2**,**S** (n_A = 49, n_S = 58):

A2,**S**, σ_A = 0.033 Å, σ_S = 0.017 Å
DPF: r^2 = 0.957, d_0 = 2.329(110) Å, K = 0.198(71), c = 0.568(123), d_e = 2.685(2) Å, Δ = 0.356(110) Å
CSBO: r^2 = 0.957, d_0 = 2.358(77) Å, b_0 = 0.369(118) Å, b_1 = 0.314(98), d_e = 2.737(6) Å, Δ = 0.379(72) Å.

A1 + **A2**,**S**, σ_A = 0.072 Å, σ_S = 0.017 Å
DPF: r^2 = 0.931, d_0 = 2.337(11) Å, K = 0.168(5), c = 0.690(41), d_e = 2.684(2) Å, Δ = 0.347(11) Å
CSBO: r^2 = 0.922, d_0 = 2.370(5) Å, b_0 = 0.397(16) Å, b_1 = 0.181(36), d_e = 2.737(3) Å, Δ = 0.367(5) Å.

From Fig. 9 it is clear that the differences between the d^* calculated from DPF(**A1** + **S**) and the d^* calculated from DPF(**A1** + **A2**,**S**) are, over the observed d,d^* range, within 1σ of DPF(**A1** + **S**) and thus not significant. The d^* differences between DPF(**A2**,**S**) and DPF(**A1** + **S**) are large at small d values but quite small at large d; within the d(**A2**) range they are completely within 3σ of DPF(**A1** + **S**).

These comparisons and a statistical test (see **F**) lead to the conclusion that, statistically, the **A1** + **S** and **A2** populations are only marginally different, even though the two belong to different stereochemistries. This would be consistent with the visual impression of the *prima facie* evidence of Fig. 4 if one had no prior knowledge of the distinction between the **A1** and the **A2** points.

The lesson to be learnt here is that the *appearance* of a d,d^* plot may not, and probably will not, be sufficient to suggest the existence of two or more angle-differentiated populations in the d,d^* sample set if there is no *a priori* reason to suspect that the set is in fact composite. This would be so especially when the difference in the means of the stereochemically distinct angle distribution is relatively small or when the distributions significantly overlap. Inability to recognize and identify the d,d^* subsets may then lead to undifferentiated d,d^* regressions and to inferior TE correlations.

*6. Effect of heteroligands on TE (**Q3**)*

When the halogen coordination of Z in a Z–Hal species is not homoligand, the presence of non-halogen heteroligands (e.g., O, CH_3, CN) may affect TE in the conjugate Hal—Z—Hal *trans* bonds to a degree where the correlation equation for the pure homoligand species does not adequately accommodate the Z—Hal,Z—Hal* pairs in the heteroligand species. A case in point is TE for the homoligand Se(IV)–Cl species as compared to the square-planar $SeCl_4$ groupings with perpendicular Se—O bonds, specifically $Se_2Cl_{10}^{2-}$ (data set Se(IV)–Cl) vs. $Se_2O_2Cl_6^{2-}$ (data set Se(IV)–Cl(Ox)). In these centrosymmetric μ_2-dimers the bridge plane contains also four terminal Se—Cl bonds. The remaining four terminal Se—Cl bonds in $Se_2Cl_{10}^{2-}$ and the two Se—O bonds in $Se_2O_2Cl_6^{2-}$ are approximately perpendicular to the bridge plane (Fig. 1 of ref. 1). Statistical comparison of Se(IV)–Cl and Se(IV)–Cl(Ox) (see **F**) reveals that the Se—Cl,Se—Cl* bond-length pairs in these two sets *do not* come from the same population. This is not evident from the values of most of the regression parameters if their standard errors are taken into account, but for d_e (Se—Cl) the difference is immediately seen: the two d_e values differ by 0.085(19) Å, which is outside 3σ = 0.057 Å and thus clearly significant (but see **C7** for d_0).

A second example is TE in conjugate P(III)—Br *trans* bonds. Figure 2 of ref. 11 is a plot of $d^* - d_0$ vs. $d - d_0$ for PBr_4^-, PCl_4^-, and several heteroligand P(III)–Br anions. The $PBr_2(CN)_2^-$ anion in the solvated Na-[18]crown-6 salt (20) has C_2 symmetry (Br—P—Br, 171.4°), so that $d^* = d \sim d_e$ = 2.496(1) Å. The DPF and CSBO correlation curves defined by the three PBr_4^- pairs (see **B**) extrapolate to d_e = 2.588 Å, i.e., to a value ~0.09 Å higher. Because of the statistical inadequacy of this P(III)–Br set we have no error estimate for this value, but the difference of ~0.09 Å is believed to be significant.[21]

*7. Effect of oxidation state (**Q4**)*

A change in the oxidation state of Z entails the attendant changes in the coordination number and the effective size of Z. Since these changes are interdependent, differences in TE that may result on going from one oxidation state to another cannot be said to be specifically due to the change in the oxidation state. The overall effect on TE can at present be compared for the pairs Se(IV)–Cl/Se(II)–Cl and Se(IV)–Br/Se(II)–Br.

[21]This extrapolated d_e value is supported from a linear regression of d_e(CSBO) on d_0(expt) for Z(III)—Br (Z = P, As, Sb, Bi): r^2 = 0.922, σ = 0.013 Å, d_e(CSBO) = 1.117 + 0.665d_0(expt), from which d_e for P(III)—Br is 2.59 Å.

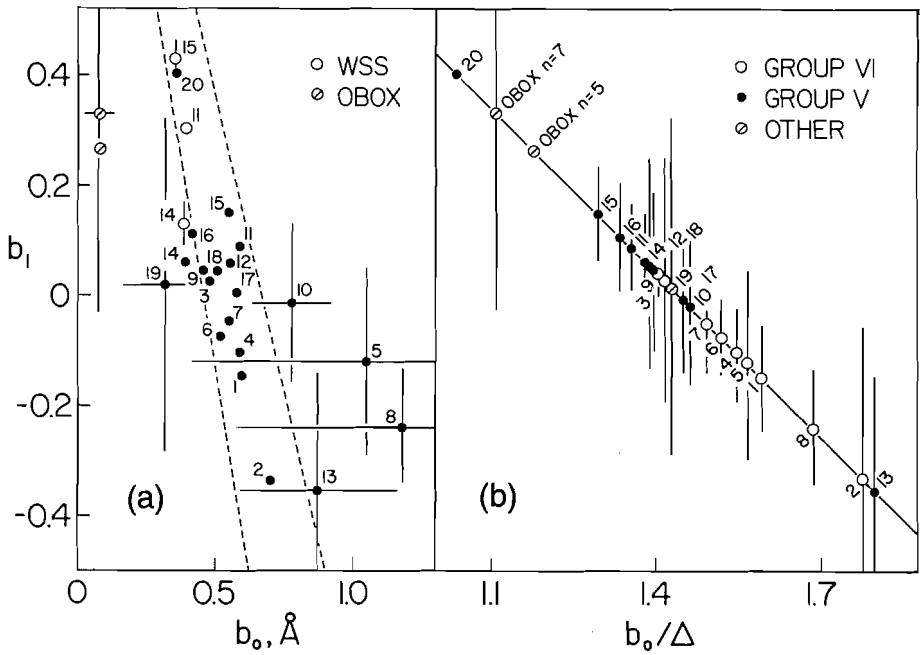

FIG. 10. Correlation of the optimized CSBO parameters b_0 and b_1. (*a*) WSS, Sheldrick *et al.* (15, 16); OBOX, *ab initio* values for OBO*X (see **D1**). For the broken lines see **C8**. Error bars shown only for points outside the region between the broken lines. (*b*) Plot of b_1 vs. b_0/Δ (eq. [8]). Standard error not available for P(III)–Br (no. 20, see text) and very small for OBOX, $n = 5$.

As would be expected, the d_e values are larger for Se(II) than for Se(IV). For the Cl pair the difference is 0.055(15) Å, i.e., ~0.06 Å > 3σ. For the Br pair the difference is smaller, 0.037(9) Å, i.e., ~0.04 Å > 3σ. However, the differences in the *refined parameters* are all smaller than the respective pooled esd's of the parameters and therefore statistically meaningless. This calls for testing the hypothesis that the Se(IV)–Cl and Se(II)–Cl samples come from the same population. Appropriate tests (see **F**) show that for the Cl pair this hypothesis can be rejected with considerable confidence and somewhat less strongly for the Br pair. The conclusion from the present data thus is that the change in the oxidation state affects TE in a significant way.

Closer scrutiny of the regression results for the three Se–Cl sets brings to light an additional interesting observation. The d_0(CSBO) values for Se(IV)–Cl, Se(IV)–Cl(Ox), and Se(II)–Cl are 2.006(29), 2.075(129), and 2.098(90) Å, respectively (Fig. 6*a*). All three are accommodated by the 1.5σ interval of the unweighted mean, 2.060(39) Å; a more comprehensive test (see **F**) shows that the three d_0 values are *not* significantly different even at the 0.10 level. This would suggest that, at least for the three cases considered, the *limiting* Se—Cl bond length as estimated by the CSBO treatment depends neither on the oxidation state nor on the presence of heteroligands on the Se atom. The same result is obtained with the Se(IV)–Br and Se(II)–Br sets, though less convincingly because of the very large standard errors on the d_0(CSBO) of Se(II)–Br. The implications of this finding are touched upon in **E**.

*8. Correlation of parameters (**Q4**)*

The values of the DPF and CSBO parameters would be expected to reflect the chemical regularities of the Z–L combinations. When b_1 is plotted against b_0 (Fig. 10*a*), the points for Z from Group VI appear to segregate roughly in the $b_1 < 0$ region of the plot and those for Z from Group V in the $b_1 > 0$ region, with most of the points falling within the area between the broken lines and defined, for $d_e = 2$ Å (right) and $d_e = 3$ Å (left), by the regression equations of **C2**. However, the expected consistency in the Cl, Br, I order in the Z–Hal triads is lacking. A similar situation is encountered in K vs. Δ(DPF) and log Δ(DPF) vs. log [K/Δ(DPF)] plots.

These observations are puzzling until it is realized that the three parameters each in the DPF and CSBO regressions are statistically very highly correlated. This correlation has its origin in the functional form of DPF and CSBO.[22] From eq. [8] we have $b_1 = (1/\ln 2) - (b_0/\Delta)$, which is the basis of the rectified plot, Fig. 10*b*. This plot displays the apparent segregation of the Group VI and Group V points, as well as the irregularities in the Z–Hal sequences, more dramatically than Fig. 10*a*. Because of the above algebraic constraint the triplet of b_0, b_1, and Δ values that results from a convergent CSBO optimization of any d,d^* sample set or subset will be accommodated on the straight line of Fig. 10*b*, regardless of how well the d,d^* sample represents the d,d^* population. For an *ideal* d,d^* population the regression would amount to a straightforward algebraic functional dependence: the positions of the Z–L points on the straight line would be exactly determined and presumably in the proper chemical order. The position of the point for a d,d^* *sample* set or subset, however, is determined by the requirement that the regression for that set converge to the model function, and the closeness of the point to the "true" position on the line thus depends on the magnitude of $\sigma(b_1)$. The order of the points in the sequence of Fig. 10*b* can then be changed by moving the points along the straight line within the projec-

[22]Very high correlations are to be expected for any model function in which the parameters of refinement are not separated.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

tions of their respective $\sigma(b_1)$ intervals. The uncertainty in the ordering can be decreased only by reducing the errors on the parameters, i.e., by improving the selfconsistency of the individual d,d^* data sets. Considering the present uncertainty in the b_1 values it is difficult to know whether special significance should be ascribed to the sign of b_1, i.e., whether $b_1 = 0$ corresponds to a boundary between two chemically distinguished regions of the b_1 vs. b_0/Δ plot.[23] Much the same situation as for CSBO is encountered in the rectified c vs. (log K)/log Δ(DPF) plot.

9. Comparison of DPF and CSBO

For a given Z–L data set the figures of merit, r^2 and σ, of the DPF(**A** + **S**) and CSBO(**A** + **S**) regressions are the same, i.e., the d,d^* pairs in an individual Z–L set are fitted equally well by both, and the same is true of the **A**,**S** regressions. Furthermore, the difference between the d_e values from DPF(**A** + **S**) and CSBO(**A** + **S**) is smaller than 0.005 Å and thus statistically negligible. Because of this and because of the smallness of its standard error, d_e is the regression parameter in which we can place most confidence, and with respect to which we can assess differences between the DPE and CSBO treatments.[24]

In Fig. 11 c and b_1 are plotted against d_e. By themselves these two plots do not enhance any trends that may have been suggested by the previous figures. However, their quasi-mirror symmetry seems to indicate the existence of a direct relationship between c and b_1, i.e., between DPF and CSBO. Indeed, the plot of c vs. b_1 (Fig. 12) mutually corroborates the consistency of the results obtained by independent fitting of the data sets to the two model functions. It can be shown from eqs. [3] and [4] that a c,b_1 correlation line must pass through the point $c = 0,b_1 = 0$. We also have the c and b_1 values for the OBO*X ($n = 5$) set, for which each fit is extremely close (see **D1**). A straight line passing through these two points is seen to accommodate all the Z–L points within their respective 1σ intervals but in most cases much more closely. This quasi-linearity of the c,b_1 correlation would have been difficult to predict from the complicated implicit function of the parameters that is obtained by combining eqs. [3] and [4]. The order of the c,b_1 points along the correlation line follows that of Fig. 10*b*.

The relationship between DPF and CSBO suggested by Fig. 12 leads one to expect that the conclusions formulated for Z–L combinations on the basis of the CSBO regressions will not differ from those obtained from DPF. This is certainly true of both the values and the order of d_e and essentially true of d_0. However, the standard error on d_0(CSBO) is consistently about half that of the standard error on d_0(DPF). On balance, while for practical purposes a Z–L d,d^* set is equally well fitted by DPF and CSBO, the latter function is to be preferred to DPF if only because it is not purely empirical. This said, DPF is more convenient for manipulation, and if eq. [3] is recast to eq. [5] it can be interpreted in chemical terms, with d_0 the limiting bond-length value, Δ the total d bond-length range, and c the curvature-determining exponent. By contrast, the b_0 and b_1 parameters have a more implicit, less intuitive meaning.[25]

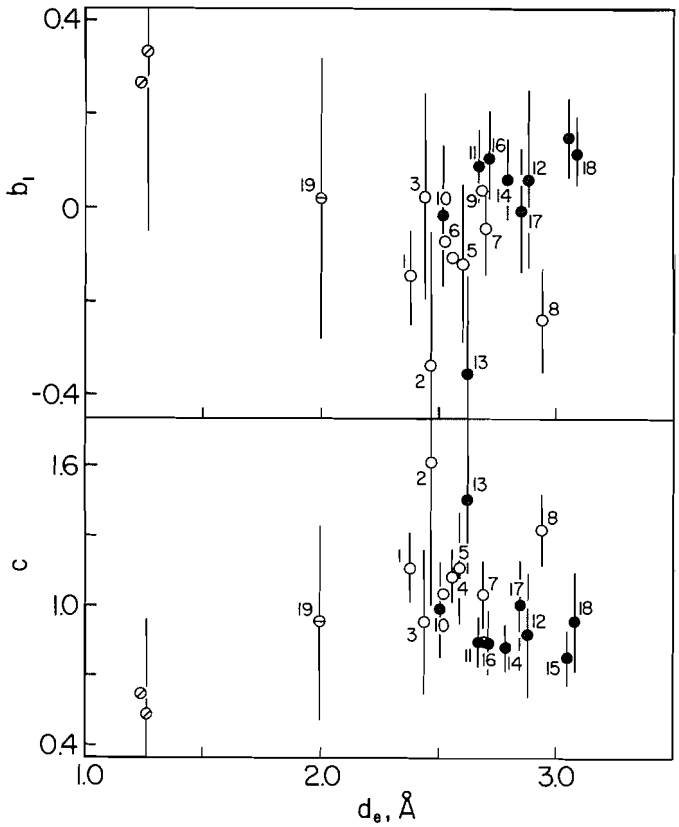

FIG. 11. Correlation of the parameters b_1 (top) and c (bottom) with d_e (**A** + **S** regressions). Open circles, Z from Group VI; full circles, Z from Group V; crossed circles, OBO*X.

D. General considerations

1. Support from ab initio *calculations (Q1, Q2)*

The existence and essential independence of the TE compensation and its regularity can be demonstrated on a centrosymmetric ZL_2 molecule in which the electron density in one of the bonds is decreased by formation of an L—X bond to a fourth atom, L—Z—L → L—Z—L*—X. An experimental LZL*X series suitable for the demonstration would be difficult to find, not to speak of interference from extraneous factors likely to confuse the expected trends. However, useful series can be generated by *ab initio* optimizations of the equilibrium ground-state geometries of LZL and LZL*X molecules, provided the calculations are self-con-

[23]For their As(III)–Br, Sb(III)–Br, and Sb(III)–I data sets Sheldrick *et al.* (15, 16) found $b_1 > 0$, in agreement with Table 2, but they failed to observe a $B,(d - d_0)$ correlation for their Sb(III)–Cl set (16). This presumably implies $b_1 \sim 0$. They explain this lack of correlation by an ad hoc argument involving the magnitude of the antibonding contribution of the Sb(5*s*) orbital. The result for our Sb(III)–Cl set is a negative, numerically large b_1, but the standard errors on b_1 and on the other refined parameters are large. A detailed reexamination of the Sb(III)–Cl d,d^* pairs seems desirable, especially if it is confirmed that in general b_1 can assume both negative and positive definite values, as found in our regressions.

[24]Sheldrick's (15, 16) d_e and Δ are not the same as ours. In the former, $d_e' - d_0(\text{expt}) = (b_0' \ln 2)/(1 - b_1' \ln 2)$, with b_0' and b_1' obtained from a linear optimization. In the latter, $d_e - d_0 = (b_0 \ln 2)/(1 - b_1 \ln 2)$, with d_0, b_0, and b_1 optimized simultaneously by a nonlinear regression (see **A4**).

[25]In this context even the meaning of B in Pauling's relation[4] ceases to be intuitive if the relation is written as $D(n) = D(1) - \ln n^B$, i.e., when B is formulated not as a scaling factor of ln n but as an empirical power of the bond order (cf. eq. [6]).

sistent within the series and at a level that is known to yield reasonably realistic geometries. Halogens as ligands are a poor choice for this purpose because of chemical restrictions on the L–X combinations, but the series deriving from the 16-valence-electron BO_2^- metaborate ion monomer (isoelectronic with CO_2) is well suited to illustrate the operation of TE in isolated homoligand species.

The conjugate B—O bond lengths obtained from 6-31G* optimizations for BO_2^-, OBO*X (X = H, F, Cl, Li), and *cis*- and *trans*-B_2O_3 = OBO*BO (Table 4) are plotted against each other in Fig. 13*a*. The OBO angle in these molecules is either 180° by symmetry or within 3° of 180°. It is immediately obvious that the disposition of the d,d* points in this plot resembles Figs. 1–4. To demonstrate the concomitant variation of the electron density, the density ρ_c at the bond critical point is plotted in Fig. 13*b* against the corresponding bond length d(O—B) or d*(B—O*). This plot is expected to conform to the functional dependence $\rho_c = sd^{-v}$ for B—O bonds (cf. ref. 47); to support and strengthen this contention we have included 6-31G* points for seven BO^ϵ diatomics[26] as well as the neutral BO_2, the BO_3^{3-} ion, and $B(OH)_3$. The power fit to these 22 d,ρ_c pairs gave $r^2 = 0.989$, $\sigma = 0.0077$ au = 0.052 e/Å^3 ~ 4% of ρ_c range, leaving no doubt about the internal consistency of the compensation in the OBO*X molecules or molecule-ions.

[26]S. C. Choi and O. Knop. Unpublished results.

The d,d* pairs in Fig. 13*a* were fitted to DPF (*i*) without any assumption about d_0, and (*ii*) assuming that d_0 corresponds to $d(B—O)_{6\text{-}31G^*} = 1.160$ Å in the singlet BO^+ (Table 4), on the premise that progressive lengthening of the B—O* bond would end up in the eventual removal of an O*X$^-$ unit. Regression *ii* of d* on d resulted in $r^2 = 0.913$, $\sigma = 0.014$ Å ~ 13% of range; with *cis*- and *trans*-B_2O_3 omitted, $r^2 = 0.998$, $\sigma = 0.002$ Å ~ 2% of range. The unconstrained regression *i* gave $r^2 = 0.865$ and $d_0 = 1.169(33)$ Å for $n = 7$ and an almost exact fit for $n = 5$, with $d_0 = 1.1677(4)$ Å (Table 5). The CSBO regressions gave very similar results save for a slight difference in d_0. The closeness of $d_0 = d(BO^+)_{6\text{-}31G^*}$ and the d_0 obtained from the unconstrained regressions supports the above assumption about the dissociative process.

The analytic treatment of TE is thus validated also for free molecular species, at least to the extent their equilibrium geometries are described by the 6-31G* calculations. This provides further support for the view of the general nature of the bond-length compensatory mechanism and for the 3c4e bond concept, as well as an affirmative answer to the second part of **Q2**.

The OBO*X series also provides an opportunity for estimating the effect of the bond angle on the TE correlation. The geometry of OBO*H was reoptimized with the OBO* angle constrained successively to 170°, 165°, and 160°. As would be expected, the closing-up of the bond angle from its unconstrained equilibrium value produced a lengthening of both the O—B and the B—O* bonds (d*(B—O*) = −1.1486 + 2.0616d(O—B), $r^2 = 0.999$), but the lengthening was so slight that it amounted to only ~0.0009 Å per 5° decrease in OBO*, a variation that would at best be only marginally recognizable in an experimental d,d* data set as arising from a departure from collinearity.

2. *"Self-TE-calibrating" stereochemistries*

Homoligand molecules or ions with stereochemistries such as those in Fig. 14 are of particular interest for the treatment of TE. They contain one or two symmetric pairs of balanced Z—L *trans* bonds with bond lengths d_s, and one or more Z—L bonds with unopposed ligands and bond lengths d_u. If d_s is taken as an estimate of d_e and d_u as an estimate of d_0, we have $\Delta_{est} = d_s - d_u$. This means that the total d bond-length range for the particular Z–L combination can in principle be estimated from the dimensions of a single molecular species. Equation [5] can then be written as $(d^* - d_u)/\Delta_{est} = [(d - d_u)/\Delta_{est}]^{-c}$, leaving c as the only parameter to be determined.

Although the molecular dimensions of many such species are known (e.g., type A, ClF_3, BrF_3; type B, SF_4, SbF_4^-; type C, BrF_5, IF_5, XeF_5^+, TeF_5^-, $SbCl_5^{2-}$; type D, PF_5, AsF_5, PCl_5, $SbCl_5$, $InCl_5^{2-}$), of all these combinations only Sb(III)–Cl can be checked against our TE treatment. In $SbCl_5^{2-}$ (25), the difference of the uncorrected bond lengths $d_s' - d_u = 0.33$ Å, $\frac{1}{2}(d_s + d_s') - d_u = 0.28$ Å; Δ(DPF) = 0.80(30) Å, Δ(CSBO) = 0.45(13) Å, $d_e - d_0[SbCl_3(g)] = 0.30$ Å. In view of what has been said in **C2** about d_0 as a parameter of refinement, these estimates of Δ from the bond lengths in the anion are of the right order of magnitude. For TeF_5^- the mean differences (8 determinations) are $d_s' - d_u = 0.11(3)$ Å. $\frac{1}{2}(d_s + d_s') - d_u = 0.09(2)$

Å, i.e., much smaller than for $SbCl_5^{2-}$. This is generally true of F as against Cl as a ligand. The range of bond lengths in the pseudo dimer $Te_2Cl_{10}^{2-}$ (cf. Table II of ref. 1) is in agreement with these estimates. The success of estimating the total d bond-length range from single geometries may well be worth investigating further.

3. Extension to dissimilar ligands

Because of the different nuclear charges on the ligands, in a heteroligand L_a—Z—L_b *trans* bond pair the two bonds are chemically nonequivalent. While for a homoligand L—Z—L bond pair $d^* \geq d$, $d^* = d = d_e$, for the heteroligand pair $d^b = d$(Z—L_b) can be greater or smaller than $d^a = d$(Z—L_a), with a crossover at $d^b = d^a$. However, the $d^b = d^a$ equality now does not characterize a symmetrically balanced pair of conjugate bond lengths, i.e., $d^b = d^a = d_e$ is not a limiting bond length, and the total bond-length range $\Delta = d_e - d_0$ now becomes, for Z—L_a and Z—L_b separately, infinite, with d_0^a and d_0^b as the respective lower bounds.

If it is assumed that TE for the L_a—Z—L_b bond pair can be represented by a single smooth correlation function, the regression equations for DPF and CSBO will have to be rewritten as

$$[11] \quad d^b - d_0^b = K(d^a - d_0^a)^{-c}$$

and

[a]$n = 5$ includes $[OBO]^-$ and OBO*X (X = H, F, Cl, Li); $n = 7$ includes in addition *cis*- and *trans*-OBO*BO.

[12] $$d^b - d_0^b = -B^b \ln\{1 - \exp[-(d^a - d_0^a)/B^a]\}$$

where B^a and B^b may be constants or $B^a = b_0^a + b_1^a(d^a - d_0^a)$, $B^b = b_0^b + b_1^b(d^b - d_0^b)$. The DPF thus becomes a 4-parameter regression and the CSBO a 4- or 6-parameter regression. The increase in the number of refinement parameters can be expected to place severe demands on the size and quality of the d^a, d^b data sets. However, simplification can be achieved by introducing certain assumptions.

If one accepts the tentative conclusion (see **C7**) that the refined limiting bond length d_0 for an L—Z—L d,d^* set is independent of the presence of other ligands on Z and of the oxidation state of Z, then d_0^a can be taken as the refined d_0 for the Z–L_a set and d_0^b as the refined d_0 for the Z–L_b set. When both d_0 values are available, the number of refinement parameters in eq. [11] will be reduced to two and that in eq. [12] to two and four, respectively.

As an indication of what may be expected from a generalization of the TE treatment we have examined the *trans* bond lengths in Cl—Bi(III)—S groupings (Fig. 15).[27] Attempts to obtain proper convergence for the 19 d^{Cl},d^S pairs in an unconstrained 4-parameter DPF regression (eq. [11]) were unsuccessful. However, a regression with d_0^{Cl} fixed at 2.35 Å gave $r^2 = 0.816$, $\sigma = 0.048$ Å, $K = 0.143(173)$, $c = 0.917(636)$, and $d_0^S = 2.457(200)$ Å.[28,29]

To test the above assumption that TE for L_a—Z—L_b obeys a single, smooth functional dependence a more selfconsistent d^a,d^b set is needed. To this end[27] we obtained a number of d(O—C),d(C—N) pairs in the isocyanate ion OCN^- and in XOCN and OCNY molecules from 6-31G* *ab initio* optimizations of the respective ground-state equilibrium geometries (Table 6). The optimized O—C—N angle in these species is either 180° or within 7° of 180°. A plot of d(C—N) against d(O—C) (Fig. 16) reveals that the bond-length variation in the *trans* bond pairs *cannot* be described by a single smooth DPF or CSBO function. Although the variation is monotonic, the OCNY and XOCN curves from a cusp at the OCN^- point. This unmistakable discontinuity owes its existence to the fact that the d,d^* correlation for the heteroligand bond pairs extends beyond $d^a = d^b$, and to the difference in the effect of bond formation on the OCN m.o. energy levels when X is added to $[OCN]^-$ on the O side in the one case and on the N side in the other, the nuclear charges on the O and N atoms not being the same. By contrast, the cusp that appears when a TE curve for a homoligand bond-pair set is folded symmetrically along the $d = d^*$ line on itself (e.g., OBOX, Figs. 13*a* and 16), arises from the termination of the TE curve at $d = d^* = d_e$ and is observed whenever the slope of the curve at d_e differs from -1 (for DPF this implies $c \neq 1$).

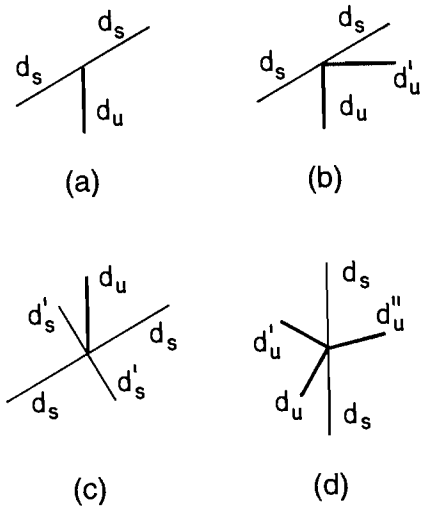

FIG. 14. Homoligand molecular geometries (schematic) containing balanced symmetric *trans* bond pairs as well as bonds with unopposed ligands. Symmetries: (*a*) and (*b*), C_{2v} or subgroups ($d_u \leq d_u'$); (*c*), C_{4v} or subgroups ($d_s \leq d_s'$); (*d*), D_{3h} or σ_h-retaining subgroups.

[27]Sufficiently extensive and selfconsistent Z–L_a,L_b sets are difficult to find. The appreciable scatter in the Bi(III)–Cl,S set comes from limited experimental accuracy, from the involvement of the S ligands in other bonds, from the presence of other heteroligands on Bi, and from significant deviations from collinearity. The data sets for Bi(III)–Br,S, Bi(III)–I,S, Sb(III)–I,S, and Te(II)–Cl,S are even worse in this respect. Paucity of data in any such series and the poor selfconsistency of the d^a,d^b pairs may in fact prove to be the greatest obstacle at present to a systematic investigation of TE in heteroligand *trans* bond pairs.

[28]The d^{Cl} bond length corresponding to point A in Fig. 15 (Cl—Bi—S, 165°; ref. 187, see **F**) is longer than any in the Bi(III)–Cl set. Points B and C correspond to bifurcated Cl—Bi—2S bonds, Cl—Bi—S ~ 144°. For point X see caption.

[29]A d,d^* regression for Bi(III)—S is not available. The mean of eight d_s[Bi(III)—S] values (refs. 188, 191, 192, and 258, see **F**) is 2.833(26) Å.

[b]OCO angle.
[c]NCN angle.

The presence of the cusp necessitates fitting the two branches of the TE correlation curve of Fig. 16 separately. However, there is no a priori reason to think that the limiting d_0^{CO} bond length for the two branches will not be the same, and similarly for d_0^{CN}. Consequently eqs. [11] and [12] are still applicable, subject to the condition that both branches pass through the cusp point at $[OCN]^-$. This requirement reduces the number of optimization parameters by two; for DPF the convenient parameters to eliminate are K^{OCNY} and K^{XOCN}. Fitting the two XOCNY branches to eq. [11] simultaneously without additional constraints gave a very satisfactory result (fit A, Table 7). Repeating the regressions with d_0^{CO} fixed at the d(C—O)$_{6\text{-}31G^*}$ value in CO (Table 6; the matching *ab initio* d_0^{CN} value in CN was unobtainable), and again without *any* constraint for the OCNY plus $[OCN]^-$ branch only, gave essentially the same results. The d_0^{CO} value obtained from the unconstrained regressions was somewhat higher than the *ab initio* value for CO. Proper convergence could not be achieved for an unconstrained DPF fit to the XOCN plus $[OCN]^-$ only branch.

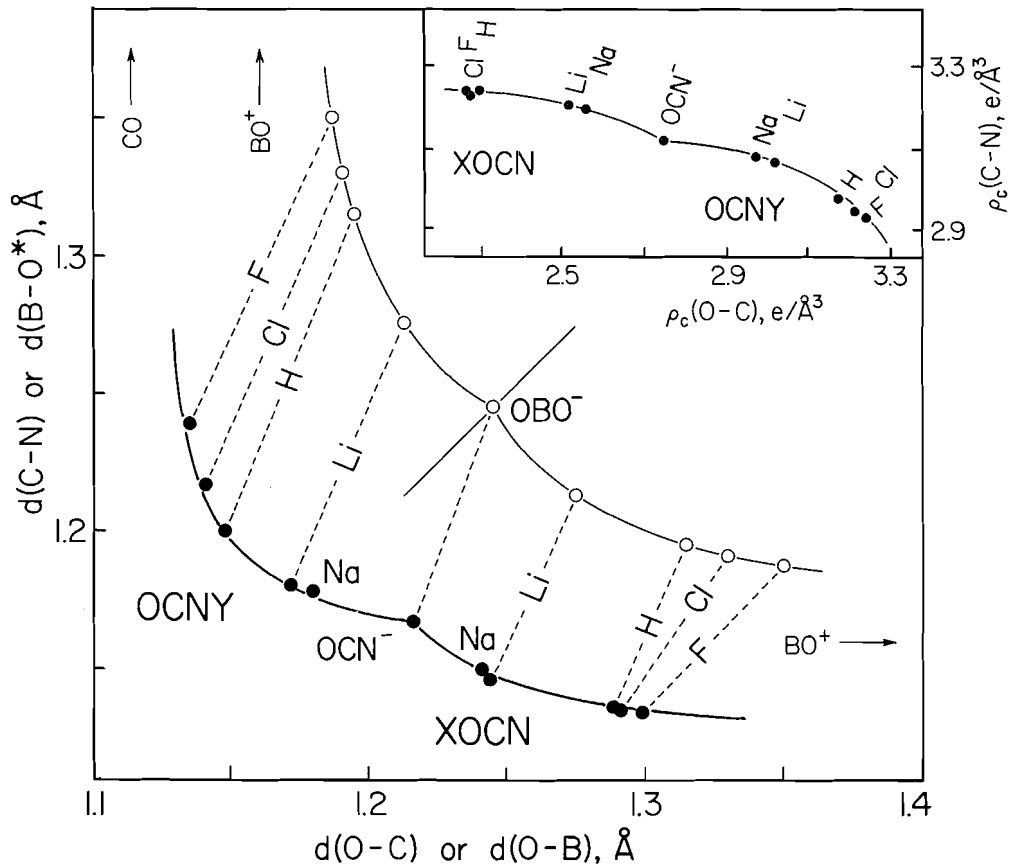

FIG. 16. Variation of d(C—N) with d(O—C) in $[OCN]^-$, XOCN, and OCNY (X, Y = H, F, Cl, Li, Na; 6-31G* *ab initio* bond lengths, see Table 7). The corresponding DPF curve for OBO*X (cf. Fig. 13*a*) is shown for comparison. Inset: correlation of the electron density ρ_c at the bond critical point in the O—C and the C—N bonds.

TABLE 7. DPF regressions of d(C—N) on d(O—C) for XOCN and OCNY (X, Y = H, F, Cl, Li, Na, or no substituent; cf. Table 6 and Fig. 16)[a]

Parameter	A[b]	B	C
r^2	0.9992	0.9745	0.9986
σ, Å	0.0013	0.0068	0.0016
d_0^{CO}, Å	1.125(4)	[1.114]	1.124(9)
d_0^{CN}, Å	1.127(1)	1.128(2)	1.144(26)
K^{OCNY}	[0.01474]	[9.220×10^{-3}]	$4.84(1117) \times 10^{-3}$
c^{OCNY}	0.416(39)	0.632(199)	0.668(565)
K^{XOCN}	[1.496×10^{-4}]	[5.357×10^{-5}]	—
c^{XOCN}	2.330(438)	2.887(308)	—

[a] $d^{CN} - d_0^{CN} = K(d^{CO} - d_0^{CO})^{-c}$; K^{OCNY}, c^{OCNY} refer to the OCNY branch, K^{XOCN}, c^{XOCN} to the XOCN branch of the correlation curve of Fig. 16. *A*, the OCNY and XOCN branches constrained to pass through the OCN^- point but otherwise unrestricted. *B*, d_0^{CO} fixed at 1.114 Å, otherwise as for the *A* regression. *C*, unrestricted fit to OCNY only (includes OCN^-).
[b] Smallest correlation matrix elements: d_0^{CO}–d_0^{CN}, −0.48; d_0^{CN}–c^{XOCN}, −0.51.

These results indicate that the d^{Cl},d^S data for Cl—Bi(III)—S should be refitted to take account of the presumed though not visible cusp. Point X in Fig. 15 represents the interatomic distances in the neutral BiSCl and may well correspond to the position of the cusp, but the overall quality of the existing Bi(III)–Cl,S data set is such that further treatment does not seem warranted at this time, in particular for the branch corresponding to large d(Bi—Cl) values.

4. Legitimacy of bond-length averaging

The problem with reporting a representative Z—L bond length when a significant TE is present is illustrated in the following two examples. In the centrosymmetric μ_2-$[Te_2Cl_{10}]^{2-}$ dimer there are three distinct d,d^* pairs at the 6-coordinate Te atom, the individual bond lengths ranging from ~2.34 to ~3.1 Å and clearly subject to TE (1). If these bond lengths are to be compared with other Te(IV)—Cl bond lengths, how is it to be done?

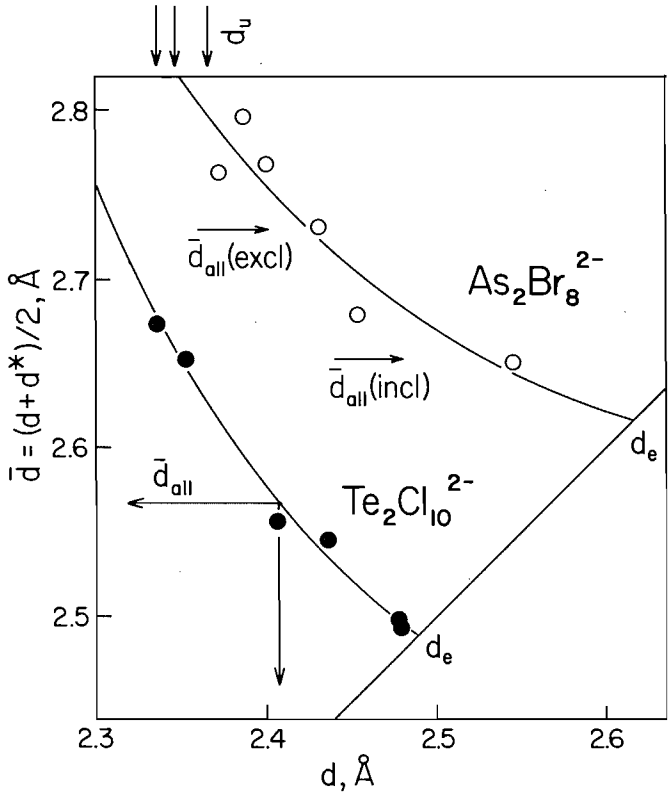

FIG. 17. Bond-length averaging in centrosymmetric μ_2-dimers $[Te_2Cl_{10}]^{2-}$ and $[As_2Br_8]^{2-}$ (see text). The curves represent the pairwise $\bar{d}_i = \frac{1}{2}(d_i + d^*_i)$ averages calculated from the DPF regressions. The d_u values are for $[As_2Br_8]^{2-}$.

A frequently encountered practice is to take the overall mean $\bar{d}_{all} = (\Sigma d_i)/n$, which is then assumed to be comparable to the bond length in a fully symmetric coordination, in the present case (as well as for strongly distorted $TeCl_6^{2-}$ anions) to the balanced d(Te—Cl) in $TeCl_6^{2-}$ of O_h symmetry.[30] This practice is justified when $d_i + d^*_i \sim 2d_e$, i.e., when the pairwise means $\bar{d}_i = \frac{1}{2}(d_i + d^*_i)$ are approximately the same, which would obtain when the d,d^* plot is approximately linear. However, this is generally not the case. In our example, the six available authentic d,d^* pairs for $Te_2Cl_{10}^{2-}$ can be fitted to DPF to $r^2 = 0.995$, $\sigma = 0.020$ Å (data set *a* of Table III, ref. 1).[31] As seen in Fig. 17, the d_i averages for these pairs are far from constant and at the far end considerably in excess of the $d_e = 2.489$ Å calculated from the regression. The $\bar{d}_{all}$ value is 0.08 Å above this d_e, i.e., significantly larger than the value that should be compared with d(Te—Cl) in $TeCl_6^{2-}(O_h)$. For other homoligand Te(IV)–Cl species the correlation line might be somewhat different as would $\bar{d}_{all}$, but the d_e calculated from the respective regressions would be essentially the same as for $Te_2Cl_{10}^{2-}$. All such d,d^* subsets would be contained in the global Te(IV)–Cl regressions, such as those of Table 1. In the overall context, there being only one d_e value for Te(IV)–Cl, viz. that from the global regression, the *trans* bond lengths in different Te(IV)–Cl species would differ from one another in the distribution of the $d_i,\bar{d}_i$ pairs but not in the d_e values. As long as the $d_i,\bar{d}_i$ pairs are consistent with the global regression line, no further comparisons are necessary, the bond-length differences between species being simply particular (but consistent) consequences of the operation of TE.

In the centrosymmetric μ_2-$[As_2Br_8]^{2-}$ dimer (13, 15) the situation is different in that the As atom is 5-coordinate. The As—Br bond approximately perpendicular to the bridge plane (actually the mean $Br_2As(Br)_2AsBr_2$ plane) is unopposed (Fig. 1 of ref. 1), of length d_u. It is thus shorter than either terminal As—Br bond (Fig. 17) and when included in $\bar{d}_{all}$ will result in a $\bar{d}_{all}$(incl.) value of ~2.654 Å, about 0.04 Å above the $d_e = 2.617$ Å calculated from the $As_2Br_8^{2-}$-only regression. However, when d_u is omitted, the $\bar{d}_{all}$ will increase to $\bar{d}_{all}$(excl.) = 2.730 Å. Neither $\bar{d}_{all}$ average is really satisfactory for comparisons. If the aim is to compare the d_u(As—Br) with other d_u(As—Br) bond lengths, there is no need for averaging, as these bond lengths can be compared directly. If the 5-coordination at As is regarded as an incomplete octahedral coordination, then $\bar{d}_{all}$(incl.) might be more appropriate for comparison with d_e.

5. Effect of thermal correction on TE parameters

So far the results and conclusions have been based on bond lengths uncorrected for the effect of thermal motion. The correction is typically in the 0.01–0.03 Å range and thus not negligible. We must now examine how it affects the quantification of TE.

For the purposes of this analysis let us assume that the corrected bond lengths can be written as

$$[13] \quad d^+ = pd + q, \quad d^{*+} = pd^* + q, \quad q > (1 - p)d$$

When the p,q pair is the same for every d,d^* pair in the Z–L set, the resulting DPF and CSBO fits for the d^+,d^{*+} set are entirely predictable, for the sums of squares functions for the corrected data $S_A{}^+(d_0{}^+, d_e{}^+, c)$ and $S_S{}^+(d_s{}^+)$ are made directly proportional to the sums of squares for the uncorrected data by simple transformations of the parameters. For DPF, choosing $d_0{}^+ = pd_0 + q$ and $d_e{}^+ = pd_e + q$ gives

$$S_A{}^+(d_0{}^+, d_e{}^+, c) = p^2 S_A(d_0, d_e, c)$$

and

$$S_S{}^+(d_s{}^+) = p^2 S_S(d_s)$$

Minimizing $S_A{}^+$ or $n_A \log S_A{}^+ + n_S \log S_S{}^+$ (see **A5**) therefore gives the same value for c, but for d_0 and d_e it gives values that are corrected in the same way as the data, viz. $d_0{}^+ = pd_0 + q$, $d_e{}^+ = pd_e + q$. The r^2 measure is the same for the corrected data, but the overall standard error σ now becomes $p\sigma$. For CSBO the same effect is achieved with the transformations $d_0{}^+ = pd_0 + q$, $b_0{}^+ = pb_0$.

In reality the thermal corrections are different for each d,d^* pair. However, the p and q can be considered to be mean values for the correction coefficients, and the resulting fit can be regarded as an approximate mean of the possible fits. Reliably corrected d,d^* values would be required to estimate $\langle p \rangle$ and $\langle q \rangle$ for each particular Z–L set.

Among the more important consequences of applying a correction for thermal motion is the reduction of the difference between d_0(expt) and d_0(CSBO) or d_0(DPF) (see **C2**). With the exception of BiI_3 the d_0(expt) in Fig. 6 are from the gas phase and therefore not subject to correction. The points

[30] The effect of ionic charge, though not negligible, is not dominant.

[31] The $Te_2Cl_{10}^{2-}$-only regression has a smaller dispersion than the global Te(IV)–Cl regression of Table 1, and similarly for the $As_2Br_8^{2-}$-only set.

For personal use only.

that represent these values, when replotted against d_e^+, will undergo horizontal shifts toward higher d_e, whereas the d_0(CSBO),d_e(CBSO) and d_0(DPF),d_e(DPF) will be displaced both horizontally and vertically to $d_0^+ (> d_0)$,$d_e^+ (> d_e)$. As a result the difference D^+ between d_0(expt) and $d_0^+ = a_0^+ + a_1^+ d_e^+$ will be smaller than the difference D between d_0(expt) and $d_0 = a_0 + a_1 d_e$: $D^+ - D \sim -a_1[(p - 1)d_e + q]$. Although we have not attempted a quantitative evaluation of this difference, it is clear that the thermal correction will tend to reduce the discrepancy between the optimized and the experimental d_0.

E. Summary

In terms of answers to questions **Q1–Q7** posed initially, our findings can be summarized as follows.

Q1, Q2. The existence of TE as a functional relation between the conjugated bond lengths d and d^* in collinear homoligand L—Z—L* *trans* bond pairs has been demonstrated or confirmed for a variety of Z–L combinations, at the experimental level for *trans* bond pairs in discrete or quasi-discrete species with Z mainly from Groups VI and V, and at the 6-31G* *ab initio* level for a number of isolated molecules or molecule-ions (OBOX, XOCN, OCNY; X,Y = H, F, Cl, Li, Na, or no ligand). In all these cases the TE correlation has been found to hold regardless of the specific cause of the bond-length disproportionation $d_e, d_e \rightarrow d, d^*$.

For the Z–L combinations examined it can be claimed that d,d^* in experimental homoligand *trans* bond pairs ($d \leq d^*$, d and d^* not related by symmetry; population **A**) are highly correlated. The model functions that have been adopted for the correlation and investigated in detail are the purely empirical DPF. (eq. [3]) and the 3-centre 4-electron (3c4e) based CSBO (eq. [4]), both involving 3-parameter nonlinear optimizations. For DPF (**A**) the r^2 values are between 0.80 and 0.98 and the average goodness of fit measure σ is about 9% of the total d range. For CSBO (**A**) the corresponding figures are 0.80–0.97 and ~13%.

To take account of d,d^* bond lengths equivalent by symmetry ($d = d^*$; population **S**) the DPF and CSBO functions were modified to combine the suitably weighted **A** and **S** samples. This was done in two ways, DPF(**A**,**S**) and CSBO(**A**,**S**) (eq. [9]), and DPF(**A**/**S**) (eq. [10]). In addition, DPF and CSBO were optimized for the straightforward **A** + **S** sum of the two samples; these two fits are available for all the Z–L data sets examined.

The individual d,d^* sets are equally well fitted by DPF and CSBO. In particular, the d_e values resulting from the two fits for a Z–L combination are practically identical and statistically indistinguishable. However, the rates of convergence of the two model functions to the asymptotic limit $d \rightarrow d_0$, $d^* \rightarrow \infty$ are not the same, which results in somewhat different estimates of d_0. This discrepancy is discussed at some length. The difference $\Delta = d_e - d_0$ represents the total range of d subject to TE and is surmised to vary quasi-linearly with d_e (Fig. 8*b*).

The equal (and high) success of the purely empirical DPF and of CSBO in fitting the d,d^* data sets validates the use of the modified 3c4e bond concept in accounting for the quantitative aspects of TE, not only for experimental d,d^* data to which the concept has been applied previously (e.g., As(III)–Br) and in this investigation, but also for much simpler situations involving 6-31G* optimized equilibrium geometries of isolated molecules or molecule-ions with collinear homoligand *trans* bond pairs. While the *absolute* values of the 6-31G* bond lengths should be treated with reserve, the self-consistency of the OBOX, XOCN, and OCNY sets is such that the observed conformity to the model functions cannot be dismissed as fortuitous or as an artefact of the basis set and the H–F method. The goodness of fit of the 6-31G* regressions thus corroborates, on the one hand, the validity of the calculated bond lengths relative to one another and, on the other hand, vindicates the suitability of the modified 3c4e model function CSBO for quantifying TE.

The problems arising from the extension of TE correlations to heteroligand L_1—Z—L_2 *trans* bond pairs are in part practical (insufficient data, appreciable scatter of d(Z—L_1),d(Z—L_2) points), in part theoretical (the bond-length variation over the observed range is not representable by a single smooth function). These matters are discussed in **D3**, in relation to Cl—Bi(III)—S and to *ab initio* bond pairs.

Q3. The upper bound of d^* beyond which $d^* = \text{DPF}(d)$ or $d^* = \text{CSBO}(d)$ in homoligand *trans* bond pairs ceases to correspond to an effective bonding interaction between Z and L is difficult to evaluate, but generally it appears to be somewhat lower than the sum ΣvdWr of the tabulated van der Waals radii of Z and L (Fig. 7).

Q4, Q5. The optimized parameter values of DPF and CSBO are different for different Z–L combinations. There are indications (Figs. 10 and 12) that these values may reflect chemical trends and regularities of Z–L. Statistical comparison of the Se(IV)–Cl, Se(IV)–Cl(Ox), and Se(II)–Cl data sets shows that while the d,d^* in the three sets come from different populations and the d_e values for the three sets are different and statistically distinguishable, the three d_0 values are similar and statistically indistinguishable. The three sets thus appear to have a common limiting d_0 bond length that is independent of the oxidation state of Se and of the presence of heteroligands on the Se atom. Lack of suitable and sufficiently extensive experimental d,d^* sets has prevented us from determining whether this conclusion for Se–Cl is true of other Z–L combinations. If it is, then the d_0 from the regressions will of necessity be smaller than d_u(Z—L) in the reference species, as d(Se—Cl) in $SeCl_2$(g) is not expected to be the same as the (as yet unknown) d_u(Se—Cl) in $SeCl_4$(g).

Q6. Departures from collinearity would be expected to increase both d and d^*, though not by equal amounts. As a result the d,d^* point would move away from the TE regression line established for essentially collinear bond pairs. The bond angles for the d,d^* sets examined are generally 170–180°, yet no significant systematic deviations from the TE lines have been detected that could be attributed specifically to lack of collinearity. For the special case of Te(II)–S see **C5**.

Q7. Where an **S** sample exists, the mean $\bar{d}_s$ value in most (though not all) of the cases examined is very close to and statistically indistinguishable from the d_e value obtained from the corresponding **A** sample. The d_e constitutes a well-defined basic parameter of a d,d^* set and, for Z–Hal combinations, has been shown to correlate well with the empirical ionic radius of the ligand (Fig. 5).

Among the various other aspects of TE discussed in this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

paper are the consequences of correcting d,d^* bond-length pairs for the effects of thermal motion.

F. Sources of data and statistical treatment

The data sets used in our treatment of the individual Z–L combinations are based on an extensive (though not exhaustive) search of the literature. All the d,d^* pairs from this search have been included in the regressions except for the very small number which gave *gross* visual misfits in the d^* vs. d plots and clearly did not belong to the respective sets. These were omitted from the final regressions and are not shown in Figs. 1–4.

To save space, papers cited previously in refs. 1 and 41 will be referred to only by the numbers under which the citations appear there; references marked *a* are from ref. 41 and those marked *b* from ref. 1. The very numerous additional papers not referred to in the text have been assigned running numbers between 100 and 300 and the citations have been deposited.[32]

Ab initio values (Tables 4 and 6): the total electronic energies, bond lengths and angles, net charges, critical radii, and electron densities at the bond critical points were obtained from in-house (see footnote 26) 6-31G* optimizations of the ground-state equilibrium molecular geometries. For methods see ref. 47.

Statistical treatment

The DPF and CSBO model functions are assumed to represent the conditional mean of d^* given d, and the variation of d^* about this mean is assumed to be Gaussian, with a standard deviation σ which is constant over the range of d values. With the additional assumption of statistical independence among the different d values, the method of nonlinear least squares (49, 50) is the appropriate technique for estimating the model parameters. An iterative algorithm minimizes the sum $S[d^*(\text{obs})_i - d^*(\text{fit})_i]^2$ and provides parameter estimates, standard errors for these estimates, and an estimate of the overall standard error σ. The latter and the proportion r^2 of the variation in d^* explained by the regression provide summaries that indicate the adequacy of the fit.

[32]The deposited material can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

The standard errors of the parameters derive from both σ and the model function and can be large even when the fit is adequate. For example, estimation of d_0 involves, for *any* suitable $d^* = f(d)$ model function, extrapolation to infinity and is inherently less accurate than estimation of d_e.

When **S** data are available, however, different methodology is required to accommodate possible differences between $\bar{d}_s$ and d_e and between σ_A and σ_S. Since in the **S** population $d^*_i = d_i$, it is only possible to consider the statistical fluctuations of d^* about its mean $\bar{d}_s$ rather than its variation about a conditional mean given d.

When $\bar{d}_s$ and d_e are assumed equal, a combined fit **A**,**S** is obtained by minimizing the weighted combination of eq. [9]. Estimates for σ_A^2 and σ_S^2 are then given by $\hat{S}_A/n_A$ and $\hat{S}_S/n_S$, respectively, $\hat{S}$ denoting evaluation at the optimal parameter values. Equation [9] is the negative of the maximized log likelihood function for the DPF and CSBO parameters, under the assumption that the **S** population is also Gaussian. For the **A**,**S** fit an r^2 measure was constructed using the **A** data only. The constrained or combined **A**,**S** fit is the appropriate one if estimates of $\bar{d}_s$ and d_e are deemed not to be significantly different. Standard errors on the parameter estimates will be smaller than for the fit to the **A** data only.

Test for equality of $\bar{d}_s$ *and* d_e

A statistical test for the equivalence of $\bar{d}_s$ and d_e was derived using the likelihood-ratio statistic, which is approximately distributed as a χ^2 with one degree of freedom. This statistic compares the fit to the data under the assumption that $\bar{d}_s = d_e$ to the unconstrained fit. The unconstrained fit involves fitting the model function to **A** data using nonlinear least squares and also estimating $\bar{d}_s$ and σ_S using the sample average and standard deviation from the **S** population. The test statistic is therefore

$$[14] \quad TI = n_A \log (S_{A,c}/S_{A,u}) + n_S \log (S_{S,c}/S_{S,u})$$

where c and u, respectively, indicate the constrained and unconstrained fit. Large values of TI, or small values of the significance probability P (cf. Table 3), suggest that the equality hypothesis may be untenable.

Testing for the effect of noncollinearity

The difference between the **A1**,**S** and **A2** Te(II)–S populations was assessed using the $n = n_{A2} = 23$ deviations $\mathbf{e} = (e_1, e_2 \ldots, e_{23})'$ of the d^*(**A2**) values from their corresponding predictions from DPF(**A1**,**S**). The quadratic form

$$[15] \quad Q = \mathbf{e}'\mathbf{M}\mathbf{e}/n = [\mathbf{e}'\mathbf{e} - \mathbf{e}'\mathbf{F}(\hat{\sigma}^2\mathbf{V}^{-1} + \mathbf{F}'\mathbf{F})^{-1}\mathbf{F}']/\hat{\sigma}^2$$

properly combines these deviations and is approximately distributed as a χ^2 with n degrees of freedom. Here $\mathbf{M} = [\hat{\sigma}^2\mathbf{I}_n + \mathbf{F}\mathbf{V}\mathbf{F}']^{-1}$ is the inverse of the estimated covariance matrix of the deviations, $\mathbf{V}$ is the estimated covariance matrix of the parameter estimates, $\hat{\sigma}^2$ is the estimated variance of the d^*(**A1**) values about the DPF curve, and $\mathbf{F}$ is the derivative matrix of DPF with respect to the parameters evaluated using the d(**A2**) values and the DPF(**A1**,**S**) parameter estimates of $\hat{K}$, $\hat{c}$, and $\hat{d}_0$.

The value of Q was calculated to be 32.34, which is exceeded with probability 0.09 in the χ^2_{23} distribution. We conclude that these results provide mild evidence of a difference between the **A1** and **A2** populations.

Testing for the effect of oxidation state and heteroligation

An overall test for comparing two populations can be constructed from the two sets of DPF parameter estimates $\hat{\Theta}_i = (\hat{d}_0, \hat{c}, \hat{d}_e)'$ and their covariance matrices $\hat{\Sigma}_i$ from each sample $i = 1,2$. The test statistic is given by

$$[16] \quad T2 = (\hat{\Sigma}_1^{-1} + \hat{\Sigma}_2^{-1})^{-1}(\hat{\Sigma}_1^{-1}\hat{\Theta}_1 + \hat{\Sigma}_2^{-1}\hat{\Theta}_2^{-1})$$

and has an approximate χ^2 distribution with three degrees of freedom under the hypothesis of equality of the population parameters.

Comparing Se(IV)–Cl and Se(IV)–Cl(Ox) in this way gives $T2 = 746.7$, while Se(IV)–Cl and Se(II)–Cl give 188.5. Both these values are much larger than $\chi^2_3(0.01) = 11.3$, so we conclude the population differences in both pairs are significant.

Similar tests for single parameter values indicate that d_e is significantly different at the 0.01 level in each pair: for the Se(IV)–Cl vs. Se(IV)–Cl(Ox) comparison, $T2 = 42.3$, and for Se(IV)–Cl vs. Se(II)–Cl $T2 = 15.5$. However, the values of d_0 in the three populations are *not* significantly different even at the 0.10 level, with $T2 = 0.5572$.

NOTE ADDED IN PROOF: In the recently reported $XeF_2 \cdot CrF_4$ (ref. 51; personal communication from Professor Leban), d(Xe—F) = 1.928 Å, d^*(Xe—F) = 2.123 Å. When this d,d^* pair is added to the Xe(II)–F set of Tables 1 and 2, the regressions ($n = 10$) give

DPF(**A**+**S**): $r^2 = 0.874$, $\sigma = 0.054$ Å, $d_0 = 1.690(142)$ Å, $K = 0.103(44)$, $c = 0.926(424)$, $d_e = 1.997(16)$ Å, $\Delta = 0.307(134)$ Å; for $d = 1.928$ Å, $d^*_{calc} = 2.079$ (54) Å.

CSBO(**A**+**S**): $r^2 = 0.872$, $\sigma = 0.055$ Å, $d_0 = 1.758(63)$ Å, $b_0 = 0.339(145)$ Å, $b_1 = 0.023(306)$, $d_e = 1.997(15)$ Å, $\Delta = 0.239(49)$ Å; for $d = 1.928$ Å, $d^*_{calc} = 2.080(550)$ Å.

With the d,d^* pair for $XeF_2 \cdot WOF_4$ (23) omitted ($n = 9$),

DPF(**A**+**S**): $r^2 = 0.957$, $\sigma = 0.033$ Å, $d_0 = 1.537(248)$ Å, $K = 0.182(165)$, $c = 1.200(357)$, $d_e = 1.998(9)$ Å, $\Delta = 0.461(244)$ Å; for $d = 1.928$ Å, $d^*_{calc} = 2.099(33)$ Å.

CSBO(**A**+**S**): $r^2 = 0.956$, $\sigma = 0.033$ Å, $d_0 = 1.690(117)$ Å, $b_0 = 0.494(252)$ Å, $b_1 = -0.163(247)$, $d_e = 1.998(9)$ Å, $\Delta = 0.309(113)$ Å; for $d = 1.928$ Å, $d^*_{calc} = 2.099(33)$ Å.

Acknowledgments

We are indebted to Professor H. Krebs and to the late Professor F. Lazarini for their generosity in providing us with details of a number of their crystal-structure determinations in advance of publication. This investigation was supported by grants from the Natural Sciences and Engineering Research Council of Canada.

TRISTRAM CHIVERS, ROBERT W. HILTS, IAN H. KROUSE, A. WALLACE CORDES, RANDAL HALLFORD, and SYRONA R. SCOTT. Can. J. Chem. **70**, 2602 (1992).

The reaction of $Ph_2PS_2N_3$ with $[Pt_2(\mu\text{-}Cl)_2(PEt_3)_4][BF_4]_2$ or $[PtCl_2(PEt_3)]_2$ in dichloromethane at 23°C produces the 1:1 adducts *cis*-$[PtCl(PEt_3)_2(Ph_2PS_2N_3)][BF_4]$, **3**, and *trans*-$[PtCl_2(PEt_3)(Ph_2PS_3N_2)]$, **4**, respectively, in good yields. The ^{31}P NMR data for **3** and **4** indicate that (*i*) the platinum is attached to a nitrogen atom adjacent to phosphorus in both these adducts, (*ii*) the PEt_3 ligands in **3** are in mutually *cis* positions, and (*iii*) the PEt_3 ligand in **4** is *trans* to the heterocyclic nitrogen. These structural features were confirmed by an X-ray analysis of **4**. Crystals of **4** are monoclinic, space group $P2_1/c$, with a = 14.920(3) Å, b = 8.966(5) Å, c = 19.103(5) Å, β = 109.32(2)°, V = 2411.6(16) Å^3, and Z = 4. The least-squares refinement with anisotropic thermal parameters for all non-hydrogen atoms converged at R = 0.050 and R_w = 0.053. The Pt—N bond length is 2.122(15) Å and the coordinated nitrogen atom is lifted ca. 0.63(2) Å out of the plane containing the other heterocyclic ring atoms. The attachment of a platinum(II) centre to the PN_3S_2 ring perturbs the S—N bond lengths significantly. The S—N distance involving the coordinated nitrogen is 1.672(16) Å, while the other S—N distances are 1.631(19), 1.555(19), and 1.562(19) Å, indicative of a localized sulfur diimide (-N=S=N-) structure. The UV–visible spectra of **3** and **4** in CH_2Cl_2 exhibit absorption bands at 514 and 528 nm, respectively, but dissociation of these adducts to give the free ligand $Ph_2PS_2N_3$ occurs readily in dilute solution.

TRISTRAM CHIVERS, ROBERT W. HILTS, IAN H. KROUSE, A. WALLACE CORDES, RANDAL HALLFORD et SYRONA R. SCOTT. Can. J. Chem. **70**, 2602 (1992).

Les réactions du $Ph_2PS_2N_3$ avec le $[Pt_2(\mu\text{-}Cl)_2(PEt_3)_4][BF_4]_2$ ou le $[PtCl_2(PEt_3)]_2$ effectuées dans la dichlorométhane, à 23°C, conduisent respectivement aux adduits 1 : 1 *cis*-$[PtCl(PEt_3)_2(Ph_2PS_2N_3)][BF_4]$, **3**, et *trans*-$[PtCl_2(PEt_3)(Ph_2PS_3N_2)]$, **4**, avec de bons rendements. Les données de la RMN du ^{31}P des composés **3** et **4** indiquent que (*i*) dans les deux cas, le platine est attaché à un atome d'azote adjacent de l'azote, (*ii*) les ligands PEt_3 du composé **3** sont dans des positions *cis* et (*iii*) le ligand PEt_3 du composé **4** se trouve en position *trans* par rapport à l'azote hétérocyclique. Ces caractéristiques structurales sont confirmées par une analyse du spectre de diffraction des rayons X du composé **4**. Les cristaux du composé **4** sont monocliniques, groupe d'espace $P2_1/c$, avec a = 14,920(3), b = 8,966(5) et c = 19,103(5) Å, β = 109,32(2)°, V = 2411,6(16) Å^3 et Z = 4. Un affinement, par la méthode des moindres carrés, des paramètres thermiques anisotropiques de tous les atomes qui ne sont pas des hydrogènes converge à R = 0,050 et R_w = 0,053. La longueur de la liaison Pt—N est égale à 2,122(15) Å et l'atome d'azote coordonné est déplacé de 0,63(2) Å au-dessus du plan contenant les autres atomes hétérocycliques du cycle. L'attachement d'un centre platine(II) au PN_3S_2 cycle perturbe fortement les longueurs des liaisons S—N. La distance S—N impliquant l'azote coordonné est égale à 1,672(16) Å alors que les autres distances S—N sont égales à 1,631(19), 1,555(19) et 1,562(19) Å et suggèrent l'existence d'une structure diimide de soufre (-N=S=N-) localisée. Les spectres UV–visible des composés **3** et **4**, déterminés dans le CH_2Cl_2, présentent des bandes d'absorption à 514 et 528 nm respectivement; toutefois, en solution diluée, la dissociation de ces adduits pour donner le ligand libre $Ph_2PS_2N_3$ se produit facilement.

Introduction

The phosphadithiatriazine ring system **1** is an eight π-electron system, which readily undergoes cycloaddition with norbornadiene (1) or oxidative-addition with halogens (2). The interaction of **1** with Lewis or Brønsted acids gives adducts of the type **2** in which the electrophile (E) is attached to a nitrogen atom attached to a phosphorus atom (3). *Ab initio* Hartree–Fock–Slater SCF calculations indicate that the regiospecificity of these reactions is governed by electrostatic effects. An X-ray structural determination of the methylated derivative, **2***a*, reveals that coordination of **1** to an electrophile also imposes a marked perturbation on both the conformation of the ring and the S—N bond lengths (3). Specifically, the S—N bond involving the coordinated nitrogen is weakened substantially suggesting that electrophiles might be used to promote ring-opening reactions. It was of interest, therefore, to investigate the reactions of **1** with other electrophiles in order to compare the deformation of ring geometry induced by adduct formation with that observed upon N-methylation. In this study we describe the

synthesis and ^{31}P NMR characterization of two platinum(II) adducts, viz. *cis*-$[PtCl(PEt_3)_2(Ph_2PS_2N_3)][BF_4]$, **3**, and *trans*-$[PtCl_2(PEt_3)(Ph_2PS_2N_3)]$, **4**, and the X-ray structure of **4**.

Experimental

Manipulations of air-sensitive reagents and products were performed under an atmosphere of prepurified nitrogen or argon using standard Schlenk or dry box techniques. Solvents (THF, diethyl ether, hexane, and dichloromethane) were dried with the appropriate desiccant and purged with argon. The compounds $Ph_2PS_2N_3$ (4), $[PtCl_2(PEt_3)]_2$ (5), and $[Pt_2(\mu\text{-}Cl)_2(PEt_3)_4][BF_4]_2$ (6) were prepared by the literature procedures.

Infrared spectra were obtained as Nujol mulls (KBr plates) on a Mattson 4030 FTIR spectrometer. UV–visible spectra were determined by using a Cary 219 spectrophotometer. The ^{31}P $\{^1H\}$ and ^1H NMR spectra were recorded on a Bruker AM-400 spectrometer operating at 161.978 and 400.13 MHz, respectively. The elemental analyses were performed by the microanalytical service within the chemistry department of the University of Calgary.

Preparation of cis-*[PtCl(PEt$_3$)$_2$(Ph$_2$PS$_2$N$_3$)][BF$_4$], 3*

A purple solution of $Ph_2PS_2N_3$ (0.100 g, 0.343 mmol) in dichloromethane (10 mL) was added dropwise to a solution of $[Pt_2(\mu\text{-}Cl)_2(PEt_3)_4][BF_4]_2$ (0.190 g, 0.172 mmol) in dichloromethane (10 mL) at 23°C with the immediate formation of a transparent red solution. The solution was stirred for 1 h and then solvent was removed under vacuum to give a purple-pink solid. Recrystallization of this product from deoxygenated diethyl ether – dichloromethane (1:1) solution at 23°C afforded *cis*-$[PtCl(PEt_3)_2(Ph_2PS_2N_3)][BF_4]$, (0.188 g, 0.222 mmol) in 65% yield. Infrared: 1060 cm^{-1} (s, br, ν_{as} BF_4^-); ^1H nmr ($CDCl_3$, 23°C), δ (ppm): 7.39–8.15 (m, C_6H_5, 10H), ca. 1.9 (m, CH_2CH_3, 12H), and ca. 1.2 (m, CH_2CH_3, 18H). The ^{31}P nmr data are discussed in the Results and discussion section. Anal. calcd. for $C_{24}H_{40}BClF_4N_3P_3PtS_2$: C 34.11, H 4.77, N 4.97; found: C 33.38, H 5.07, N 4.18.

Preparation of trans-*[PtCl$_2$(PEt$_3$)(Ph$_2$PS$_3$N$_2$)], 4*

This adduct was obtained as red crystals in 75% yield, after two recrystallizations from hexane at 23°C, from the reaction of $Ph_2PS_2N_3$ with $[PtCl_2(PEt_3)]_2$ by using a procedure similar to that described above for **3**. ^1H nmr ($CDCl_3$, 23°C); δ (ppm) 7.54–8.11 (m, C_6H_5, 10H), 1.68 (m, CH_2CH_3, 6H), 0.96 (dt, CH_2CH_3, 9H), $^3J(PH)$ = 18 Hz, $^3J(HH)$ = 9 Hz. The ^{31}P nmr data are discussed in the Results and discussion section. Anal. calcd. for $C_{18}H_{25}Cl_2N_3P_2PtS_2$: C 32.00, H 3.73, N 6.22; found: C 31.56, H 3.42, N 6.04.

X-ray crystallographic analysis of 4

Crystals of **4** were obtained from hexane solution. The crystal was attached to a glass fibre with epoxy. The structure was determined by the application of standard procedures, and pertinent crystallographic data are listed in Table 1.

The unit cell was determined from the setting angles of 25 reflections with $17° < 2\theta < 19°$. All measurements were made on an Enraf–Nonius CAD4 diffractometer with the $\omega/2\theta$ scan technique and calculations were done using the NRCVAX system of programs (7). Psi scan absorption corrections were made. No general correction was made for extinction.

The structure was solved by Patterson techniques. All non-H atoms were refined anisotropically. H atoms were constrained to idealized positions (C—H = 0.95 Å) with isotropic B values of 1.2 times the B value of the attached C atom. In the full-matrix least-squares refinement, the function minimized was $\Sigma w(|F_o| - |F_c|)^2$ where $w^{-1} = [\sigma^2(I) + 0.02\,I^2]/4F^2$. Conventional atomic scattering factors, corrected for anomalous dispersion, were used (8). Positional parameters are given in Table 2 and selected bond distances and angles are summarized in Table 3.

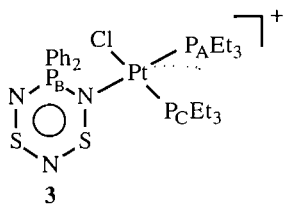
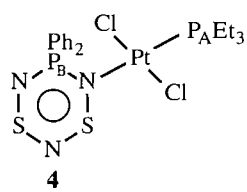
Results and discussion

Synthesis and ^{31}P nmr characterization of 3 and 4

The reaction of $Ph_2PS_2N_3$, **1**, with either $[PtCl(PEt_3)_2]_2[BF_4]_2$ or $[PtCl_2(PEt_3)]_2$ in dichloromethane at room temperature results in the cleavage of the chloro bridges to give the 1:1 adducts **3** and **4**, respectively, as air-stable, red crystals. By contrast **1** does not react with the palladium dimer $[PdCl_2(PEt_3)]_2$ even at reflux in chloroform.



3



4

The $^{31}P\{^1H\}$ nmr spectrum of **3** indicates that platinum is coordinated to a nitrogen atom adjacent to the phosphorus atom of the heterocyclic ring (Fig. 1). The resonances at 6.8 and 10.7 ppm are readily assigned to the inequivalent PEt_3 ligands (P_A and P_C, respectively) on the basis of their large couplings to platinum, 3269 and 3607 Hz, respectively. In addition, these resonances exhibit a mutual coupling of 21 Hz, indicating that the PEt_3 ligands are attached to platinum in mutually *cis* positions.[4] The signal for P_A appears as a doublet of doublets due to a three-bond coupling of 11 Hz to the heterocyclic phosphorus atom, P_B. The resonance for P_B is observed at 2.3 ppm, ca. 23 ppm downfield from that of **1** (1). For comparison the ^{31}P nmr chemical shifts of **2***a–d* occur in the range 29–41 ppm downfield from that of **1**. The resonance for P_B exhibits ^{195}Pt satellites with $J(PtP_B)$ = 30 Hz. The observation of this coupling and the P_A–P_B coupling strongly suggests that the platinum is coordinated to one of the equivalent nitrogen atoms (i.e., adjacent to P_B) rather than to the unique nitrogen in **1**.

The ^{31}P nmr spectrum of **4** also indicates that the platinum is attached to a nitrogen atom adjacent to phosphorus. Two mutually coupled resonances, $^3J(P_AP_B)$ = 11 Hz, are observed at 2.7 and 2.4 ppm, each with flanking ^{195}Pt satellites. The low-field signal with $^1J(PtP)$ = 3728 Hz is assigned to the PEt_3 ligand while the high-field signal with $J(PtP)$ = 28 Hz is ascribed to the heterocyclic phosphorus P_B. The structure of **4** was determined by X-ray crystallography.

X-ray crystal structure of trans-*[$PtCl_2(PEt_3)(Ph_2PS_2N_3)$], 4*

The X-ray analysis of **4** confirms that platinum is attached to a nitrogen atom adjacent to phosphorus. An ORTEP drawing of the structure with the atomic numbering scheme is displayed in Fig. 2. The pertinent endocyclic and exocyclic bond lengths and bond angles of **4** are compared with the corresponding values for the related adducts **2***a* and **2***d* in Table 3. The structural determination confirms that the $PtCl_2(PEt_3)$ is η^1-N-bonded to the PS_2N_3 ring with PEt_3 *trans* to nitrogen.

The structural trends for all three adducts are similar, although the perturbation of the geometry of the PS_2N_3 ring caused by coordination to platinum(II) is somewhat less than that observed for **2***a* and **2***d*. Thus the S(2)—N(1) bond distance in **4** is elongated from 1.575(3) Å in **1** (1) to 1.672(16) Å in **4** (cf. 1.707(5) and 1.712(3) Å in **2***a* and **2***d*, respectively (3)). The P—N bond lengths of ca. 1.63 Å in **4** are not significantly changed from the value of 1.62 Å observed for **1** (1) and the endocyclic bond angle at phosphorus is also little affected in **4**. The S(2)—N(3)—S(1)—N(2)—P(2) segment of the ring is planar to within 0.05(2) Å in **4** while the coordinated nitrogen N(1) is displaced from this plane by 0.63(2) Å (cf. 0.78 and 0.71 Å for **2***a* and **2***d*, respectively (3)). The angles sums at N(1) in **4** are 349.8° compared to values of 339° for **2***a* and 358.3° for **2***d*. As for **2***a* and **2***d*, the S(1)—N bond lengths of 1.55–1.56 Å are indicative of a localized sulfur diimide structure -N=S=N- in **4**.[5]

The geometry about platinum in **4** is essentially square-planar with d(Pt—N) = 2.122(15) Å. For comparison, the Pt—N bond lengths in platinum(II) complexes of chelating

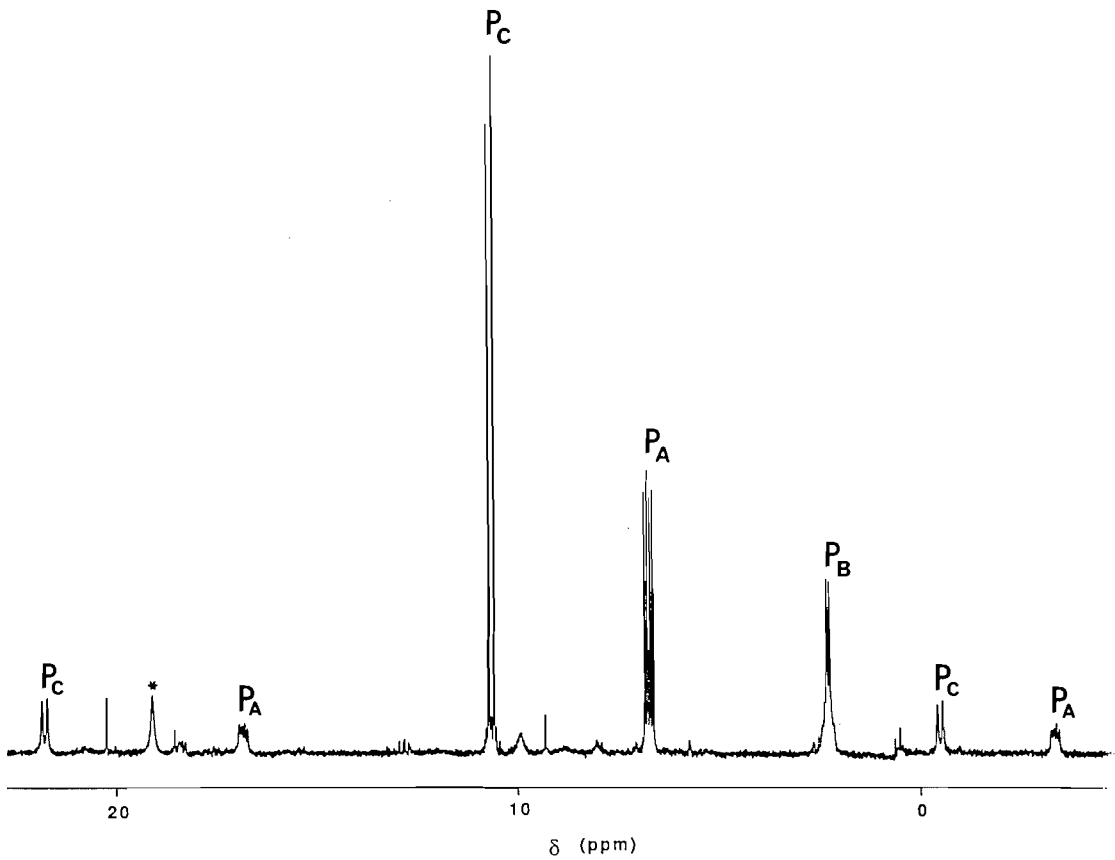

FIG. 1. ^{31}P NMR spectrum of *cis*-$[PtCl(PEt_3)_2(Ph_2PS_2N_3)][BF_4]$, **3**. Unreacted $[Pt_2(\mu\text{-}Cl)_2(PEt_3)_4][BF_4]_2$ is identified by an asterisk.

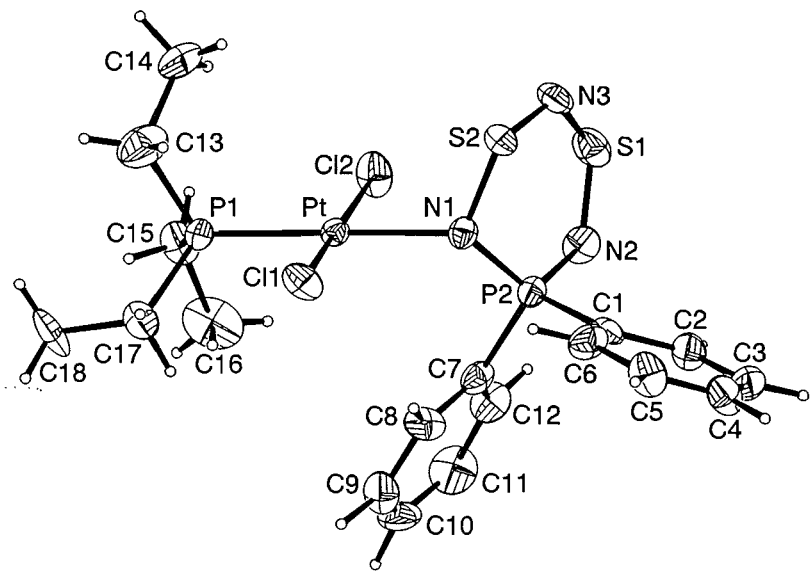

FIG. 2. ORTEP plot (30% probability ellipsoids) of *trans*-$[PtCl_2(PEt_3)(Ph_2PS_2N_3)]$, **4**.

S—N ligands are in the range 2.01–2.05 Å (11–13) and the Pt—N bond distance in the fluxional dimer $[Pt(PR_3)(1,5\text{-}Ph_4P_2N_4S_2)]_2$ is 2.089(7) Å (14). This centrosymmetric molecule undergoes a facile [1, 3] shift of platinum between vicinal nitrogen atoms of the $P_2N_4S_2$ ring. Thus the Pt—N bond length observed for **4** is indicative of a weak interaction as reflected in the ready dissociation of this adduct in solution (*vide infra*). The relatively large value (3728 Hz) for $^1J(Pt\text{–}PEt_3)$ in **4** is further evidence of the weakness of this interaction.[6]

[6] $^1J(Pt\text{–}P)$ values for closely related complexes with strong Pt—N bonds *trans* to PEt_3 are significantly smaller (3175–3355 Hz) (12, 13).

Electronic spectra of 3 and 4

The adducts **3** and **4** exhibit absorption bands at 514 and 528 nm, respectively, in methylene dichloride. The determination of an extinction coefficient for these absorptions was thwarted by the partial dissociation of the adducts to give **1** (λ_{max} 550 nm). The observed hypsochromic shift in the π^*(HOMO) $\rightarrow$ π^* (LUMO) transition of **1** upon coordination to platinum(II) is much less pronounced than that observed for the adducts **2***a–d*, for which absorption maxima are observed in the range 410–430 nm (3). Thus the visible spectroscopic data provide another manifestation of the relative weakness of the nitrogen–electrophile interaction in **4** compared to that in **2***a–d*.

Conclusions

The interaction of the phosphadithiatriazine **1** with platinum(II) electrophiles produces 1:1 adducts in which the metal is attached to a nitrogen atom adjacent to phosphorus in the PS_2N_3 ring. Coordination to platinum perturbs the conformation of the ring and the S—N bond lengths in a manner similar to that observed for other electrophiles. However, the interaction with platinum(II) is weaker than that observed for electrophiles such as $SnCl_4$ or upon methylation, as indicated by ^{31}P NMR and visible spectroscopic measurements and by the X-ray structural data.

The title disaccharide Manp(β1–4)GlcpNAcβ1-OCD$_3$ has been prepared by a short synthetic sequence through the inversion of configuration from *gluco* to *manno* involving benzyl Glcp(β1–4)GlcpNAc. The disaccharide was subjected to detailed high-field ^{1}H and ^{13}C NMR study. First, conventional and 2D spectra were run to afford a complete set of assigned spectral parameters. Next, steady-state ^{1}H–{^{1}H} NOE and ^{1}H, ^{13}C spin lattice relaxation experiments were performed to infer dynamic spectral data related to molecular conformation. Owing to tight couplings and signal overlaps in the ^{1}H spectrum, proton relaxation and selected NOE data were obtained via ^{13}C NMR after transfer of the actual, non-equilibrium, proton magnetization to the ^{13}C frequency domain. Using this experimental approach it has been found that T_1's for Manp H-4 and GlcpNAc H-2 were substantially longer than those of the other sugar ring protons, and that the principal interresidue dipolar contact in Manp(β1–4)GlcpNAcβ1-OCD$_3$ takes place between Manp H-1 and GlcpNAc H-4. Subsequently, a conformational analysis of the disaccharide was executed by means of a semiempirical method comparing Boltzman-averaged computed observables with experimental T_1 and NOE values. The results suggest that the disaccharide has substantial conformational flexibility. Its *exo*-anomeric-stabilized conformational minimum at approximately $\phi = +50°$ ($\psi = 0 \pm 10°$) of the glycosidic rotational angle is significantly populated but this global minimum does not represent the only rotational form available to the molecule.

HO HUAT LEE, LIGAYA N. CONGSON, DENNIS M. WHITFIELD, LAJOS R. RADICS et JIRI J. KREPINSKY. Can. J. Chem. **70**, 2607 (1992).

On a préparé le disaccharide Manp(β1–4)GlcpNAcβ1-OCD$_3$ mentionné dans le titre en utilisant une courte voie de synthèse impliquant une inversion de configuration de *gluco* à *manno* sur le Glcp(β1–4)GlcpNAc de benzyle. On a soumis le disaccharide à une étude détaillée par RMN du ^{1}H et du ^{13}C à haut champ. Dans un premier temps, on a déterminé les spectres conventionnels et en 2D afin d'obtenir un ensemble complet des paramètres spectraux. Par la suite, dans le but de relier les données spectrales avec une conformation moléculaire, on a effectué des expériences d'EON ^{1}H-{^{1}H} à l'état stationnaire et de relaxation spin-réseau du ^{1}H et du ^{13}C. À cause des faibles couplages et des recouvrements de signaux dans le spectre du ^{1}H, on a déterminé la relaxation du proton et les données sélectives d'EON à l'aide de la RMN du ^{13}C après un transfert de la magnétisation réelle, non-équilibrée, du proton vers le domaine de fréquence du ^{13}C. Utilisant cette approche expérimentale, on a trouvé que les T_1 du H-4 du Manp et du H-2 du GlcpNAc sont beaucoup plus longs que ceux des autres protons du cycle du sucre et que le principal contact dipolaire inter-résidu dans le Manp(β1–4)GlcpNAcβ1-OCD$_3$ se produit entre le H-1 du Manp et le H-4 du GlcpNAc. Par la suite, on a effectué une analyse conformationnelle complète du disaccharide à l'aide d'une méthode semi-empirique permettant de comparer les valeurs moyennes de Boltzman calculées et les valeurs experimentales de T_1 et d'EON. Les résultats suggèrent que la disaccharide possède beaucoup de flexibilité conformationnelle. La population de sa conformation *exo*, stabilisée par anomérie et correspondant à un minimum d'énergie pour un angle de rotation glycosidique $\phi = +50°$ ($\psi = 0 \pm 10°$), est importante, mais ce minimum global ne représente pas nécessairement la seule forme rotationnelle disponible pour cette molécule.

suitable sites on the carrier peptidic chain. NMR spectroscopy is the method of choice for the determination of conformations of these substances in solution (2). However, NMR spectra become increasingly crowded as the molecules become more complex and resulting ambiguity in certain assignments makes it more difficult to draw conformational conclusions based on analysis of the spectra. This is further aggravated by tight coupling involving several ^1H nuclei as in the case of GlcpNAc substituted in β1–4 fashion (3). Since the understanding of smaller components assists in the studies of the larger molecule, we have examined the disaccharide Manp(β1–4)GlcpNAcβ1-OCD_3 (**II**) with the objective to determine its preferred conformation. One of our aims has been to solve the problem of signal assignments, including NOE measurement, in tight coupling situations. Furthermore, we were interested in agreement between the conformational conclusions derived from the NMR measurements and potential energy calculations.

Results and discussion

Synthesis

The synthetic design is summarized in Scheme 1. The only major problem in the synthesis of this saccharide is the formation of the *cis* glycosidic bond, i.e., the β-mannopyranoside (4). This is a difficult problem and a number of solutions has been proposed for its solution. All direct methods using a non-participating group for protection of O-2 of mannose result in formation of both α and β anomers and, depending on circumstances, different ratios of α:β anomers are obtained. The β anomers are formed predominantly (sometimes exclusively) with reactive hydroxyl groups, such as those in aliphatic alcohols: this has been observed in the case of the 2,3-;4,6-dicyclohexylidene derivative (5) and the 2,3-carbonate of mannose (6). The hydroxyl group on C-4 of 2-acetamido-2-deoxyglucopyranosides is relatively unreactive and in glycosylation reactions the above derivatives yield predominantly the *trans* product, i.e., α-mannopyranoside. When O-2 of mannose is protected by a benzyl group, and heterogenous promotion is used (silver silicate, silver zeolite, thallium zeolite), analogous observations have been made. An indirect method of formation of β-mannopyranoside is based on the preparation of β-glucopyranoside with the assistance of a participating protecting group on O-2 of glucopyranoside, and converting anomerically pure β-glucopyranoside into β-mannopyranoside by an inversion of the C-2 configuration (*gluco* to *manno*). This has been done by either S_N2 displacement (7) or oxidation–reduction sequences (8). Although the last mentioned procedure from the Jeanloz laboratory involving oxidation of HO-2 to a carbonyl and reduction of the latter with sodium borohydride afforded the *manno* configuration with a very good specificity, some *gluco* configuration has usually been obtained as well (8). We have found that L-Selectride (lithium tri-*sec*-butylborohydride) gave a reduction product in which the *gluco* configuration was consistently undetectable.

The accepting partner in the glycosylation reaction often reacts differently when it is presented to a glycosylating agent as an α- or β-glycoside. To determine which anomer would give higher yield and better purity in the coupling reaction, we have prepared pure both α- and β-benzyl 2-acetamido-2-deoxy-3,6-di-*O*-benzyl-D-glucopyranosides. Comparison of glycosylation reactions using both acceptors separately did not show any noticeable difference.

The starting materials **2** and **3** were prepared as reported previously: orthoester **IV** was made according to Kochetkov *et al.* (9) and transformed into the bromide **V** by a modification of the procedure of Hindsgaul *et al.* (10). Acceptors benzyl 2-acetamido-2-deoxy-3,6-di-*O*-benzyl-D-glucopyranosides α (8, 11) (**III***a*) and β (12) (**III***b*) were known as well, but their preparation was somewhat lengthy or involved a chromatographic separation of a differently substituted carbohydrate moiety, which would be tedious on a larger scale. Regioselective reductive opening of the 4,6-benzylidine derivative described by Garegg *et al.* (13) was promising as a simplification for the synthesis of these acceptors. Moreover, purification of individual intermediates on the pathway leading to **III***a* and **III***b* was substantially helped by no need for chromatography since they were all crystalline. Benzylidine derivatives were synthesized from benzyl anomers (α prepared by Fischer glycosidation (11); β by Koenigs–Knorr glycosylation (12*a*, 14), separately benzylated, and subjected to reductive opening of the 1,3-dioxane ring system. Although the yields may seem low, they could be substantially improved by purification of mother liquors after crystallization. However, this would make the synthesis more tedious and time consuming and, in light of the simplicity of the design and low costs of materials involved, not justified. The synthesis of the title compound **II** is portrayed in Scheme 1, and the synthesis of intermediates **III***a* and **III***b* is summarized in Scheme 2.

NMR spectrometry

Conformational studies by NMR methods usually require a prior complete assignment of the ^1H and ^{13}C spectra (2). Assignments were made by standard 1D and 2D procedures: first, homonuclear 2D chemical shift correlation (COSY) experiment indicated proton–proton connectivities within the individual sugar moieties. Next, 2D heteronuclear (H,C-COSY) experiment afforded the assignment of ^{13}C resonances. The assigned spectral parameters, i.e., ^1H and ^{13}C chemical shifts, and ^1H–^1H coupling constants, are collected in the experimental section.

Conformational analysis of oligosaccharides relies on conformation-related NMR parameters, such as interresidue ^1H–$\{^1H\}$ nuclear Overhauser enhancement (NOE) data and spin-lattice relaxation times of hydrogen nuclei, T_1^H, and carbons, T_1^C. The 400 MHz spectrum of the disaccharide Manp(β1–4)GlcpNAcβ1-OCD_3 (cf. Fig. 1) as obtained in a dilute D_2O solution is displayed in Fig. 2. It can be seen that under these conditions protons H-2, H-3, and H-4 of the GlcpNAc unit appear tightly coupled (3) (cf. the additional splitting of the resonance at 4.63 ppm assigned to H-1 of this unit) while other resonances of GlcpNAc overlap with signals of Manp protons. Although such spectral complexity, typical for certain oligosaccharides, causes no major difficulties in the assignment procedure, it makes it impossible to measure the individual relaxation times of more than a fraction of protons in the system. Moreover, it obviates determining which of the resonances due to the GlcpNAc unit become enhanced upon selective preirradiation of an isolated proton, e.g., the anomeric proton H-1 of the Manp unit. However, resonances in decoupled ^{13}C spectra of molecules of this size are generally well separated at frequencies employed in this study (100 MHz), and consequently it becomes convenient to monitor proton relaxation processes and steady-state NOE enhancements after transferring proton magnetizations to the ^{13}C domain prior to observation. This may be easily achieved using one of the known polarization transfer pulse sequences, a possibility recognized in the early 1980's by Avent and Freeman (15), who described a related proton relaxation experiment using 2D spectroscopy. Indirect measurement of proton relaxation rates by INEPT polarization transfer to ^{13}C has been reported by Morris (16) and more recently by Bigler (17), who used this technique to infer relaxation parameters of protons directly bound to ^{13}C nuclei.

The accuracy of indirectly measured proton relaxation rates, $1/T_1^{H(indir)}$, is limited by the fact that its value is obtained as a difference

$$1/T_1^{H(indirect)} = 1/T_1^{H(pt)} - 1/NT_1^C$$

where $T_1^{H(pt)}$ is the proton relaxation time measured via polarization transfer method, T_1^C represents the dipolar portion of the ^{13}C relaxation time, and N is the number of protons directly attached to a given carbon atom. This relationship reflects the fact that proton longitudinal relaxation rates of the ^{12}C and ^{13}C obtained, respectively, from direct and indirect T_1 experiments differ by an amount determined by the dipolar interaction between the ^{13}C and ^1H nuclei. This amount is given by the dipolar ^{13}C relaxation rate divided by the number of directly bound protons. In all reported cases, the two right-hand side terms were determined in two separate experiments. To improve accuracy of the indirect proton relaxation data, in this study we made two modifications to the known technique. First, we used the DEPT sequence as the polarization transfer method (known to provide distortionless and J_{CH}-independent transfer, and, second, we acquired the two data sets ($T_1H^{(DEPT)}$ and T_1^C in *one single experiment*). The effects of these modifications were tested on a sample of methyl α-D-glucopyranoside. Three subsequent measurements were performed in a queued serial run and the pertinent data are reported in Table 1. It can be seen that the accuracy of the indirectly measured T_1^H is about 10%, which compares well with the overall estimated error of 5% for the directly measured relaxation time values. The accuracy of indirect measurements performed on the disaccharide **II** is estimated to be of the same order.

The proton relaxation data obtained for the disaccharide using the direct and indirect methods are collected in Table 2. It can be seen that the indirect T_1 data agree well with the values obtained by direct measurements for all protons that exhibit no overlapping with other resonances. The data summarized in Table 2 also show that Manp H-4 and GlcNAc H-2 protons have significantly longer T_1 values than the other ring protons of the disaccharide **II**. This fact may reflect the *trans diaxial* relationship of these protons to their (vicinal) neighbours.

The NOE difference spectrum obtained for disaccharide **II** upon selective preirradiation of the resonance due to Manp H-1 is displayed in Fig. 3. Intra-residue enhancements of resonances due to Manp H-2′, H-3′, H-4′, and H-5′, as well as H-6′ and H6″ are readily recognized. However, as can be seen from Fig. 3, the spectrum gives no unambiguous answer as to which of the closely spaced H-2, H-3, and H-4 resonances of the GlcpNAc unit is responsible for the interglycosidic enhancement, a question of prime importance for the conformational analysis. Fourier transformation of the

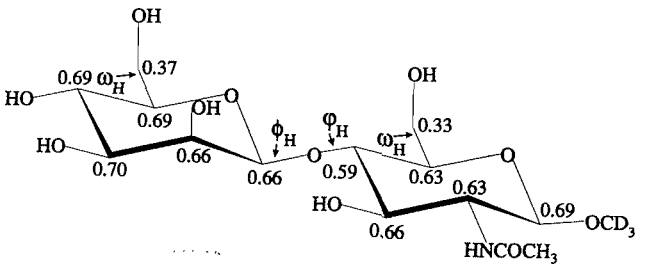

FIG. 1. Structure of the disaccharide **II** showing the glycosidic torsion angles ϕ_H and ψ_H, and the exocyclic ω_H hydroxymethylene torsion angles. Also shown are the direct ^{13}C T_1's measured with an accuracy of ±10%. The small variations between values is indicative of isotropic reorientation of the molecule as a whole.

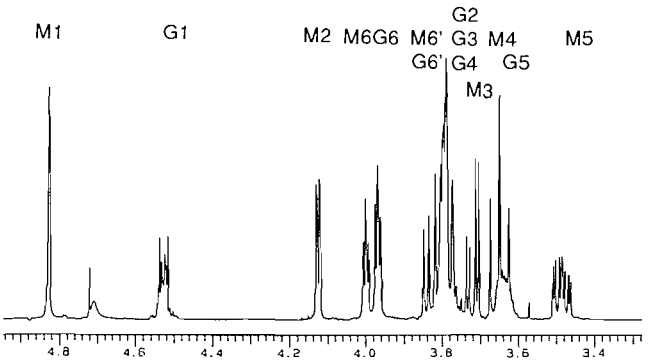

FIG. 2. Partial ^1H NMR spectrum of the disaccharide **II** in D_2O showing CH and CH_2 protons and their assignments. The virtual coupling in GlcpNAc H-1 and H-5 is readily apparent.

resolution-enhanced time-domain difference signal (cf. Fig. 4) suggested that most of the observed inter-glycosidic NOE is due to H-4 of the GlcpNAc unit.

To verify this conclusion, a method, analogous to the indirect T_1 experiment described above, was devised in which the non-equilibrium polarization of the proton spin system resulting from selective preirradiation of one of the proton resonances of interest was transferred to the ^{13}C domain via DEPT. The carbon spectrum measured with the unperturbed proton spin system was subtracted from the carbon spectrum thus obtained, and the difference spectrum obtained is displayed in Fig. 5 (for details, see the Experimental). It can be clearly seen that the NOE originating in the ^1H multiplet at 3.8 ppm (cf. Fig. 4) is mostly associated with GlcpNAc ^{13}C-4 at 80.2 ppm.

Conformational analysis

We used for conformational analysis the method, developed by Cumming and Carver, that compares Boltzman-averaged calculated observables, $\langle X \rangle$, with the experimental

[a]Direct proton relaxation times, $T_1^{H(dir)}$, were obtained with a relaxation delay of 10 s between subsequent scans, and 8 scans were accumulated for each of 15 variable delay values (varied between 0.025 and 8 s). In the polarization transfer experiment providing the $T_1^{H(DEPT)}$ and T_1^C data, 256 transients were accumulated for each pair of FID's using a relaxation delay of 8 s and 16 s values of variable delay ranging between 0.005 and 4 s. Prior to Fourier transformation, the time domain signals in both experiments were multiplied by an exponential window function with LB = 3 s. The three sets of data, (a), (b), and (c), were obtained in a queued serial experiment.

values (18). In this work we calculated P.E. surfaces considering the bonds of greatest flexibility, namely, the glycosidic torsion angles ϕ_H (H-1′, C-1′, O-1′, C-4) and ψ_H (C-1′, O-1′, C-4, H-4) and the exocyclic hydroxymethylene torsion angles ω_H (H-5, C-5, C-6, O-6) and (H-5′, C-5′, C-6′, O-6′). This simplification is usually invoked since the bonds of the pyranose rings are known to exhibit fluctuations of <10° (19). Thus the rings were fixed at their geometries determined by X-ray diffraction of model compounds (20, 21). This conformation is the $^4C_1$ chair conformation for both Manp and GlcpNAc and is supported by the observed coupling constants (see Experimental). Thus P.E. cubes were generated by calculating sixty 60 × 60 P.E. surfaces by varying ϕ_H, ψ_H, and ω_H in 6° intervals.

Three different P.E. equations were used. The first one, HS, has terms for van der Waals (Hard-Sphere) and the Exo-Anomeric (EA) effect only. The second uses these terms plus a Hydrogen bonding term and is denoted HH. The third uses Hard-Sphere but no EA term and it uses point charges to calculate an electrostatic term EL (dielectric = 1). The P.E. cubes HS, HH, or EL were then converted to probabilities using the Boltzman relation and subsequently to ⟨NOE⟩'s and $\langle T_1\rangle$'s by calculating the averaged $\langle 1/r^6\rangle$ distance matrix. The requisite isotropic correlation times were estimated to best fit the conformationally least-sensitive ^1H variables as 1.4×10^{-10} s, such as the ^1H T_1 of GlcpNAc H-1. In this way the isotropic relaxation matrix could be solved to yield ⟨NOE⟩'s and $\langle T_1\rangle$'s.

The results are tabulated in Tables 2 (T_1) and 3 (NOE) along with the experimental values. The reported values are for varying ϕ_H, ψ_H, and ω_H of the GlcpNAc residue. Similar values except for the NOE between Manp H-1′ and GlcpNAc H-6, H-6′ were calculated by varying the Manp ω_H instead of the GlcpNAc ω_H (not shown). Also shown in Tables 2 and 3 are values calculated using the correlation time 0.78×10^{-10} s calculated from the $^{13}CT_1$'s. The $^{13}CT_1$'s did not vary significantly among each other whereas the $^1HT_1$'s do so, suggesting that the $^{13}CT_1$'s are sensitive to the overall motion of the molecule while the $^1HT_1$'s are also sensitive to other motions. Figure 1 shows a drawing of disaccharide **II** with the direct $^{13}CT_1$'s marked on it, and the flexible torsion angles ϕ_H, ψ_H, and ω_H indicated.

The general agreement between calculated and experimental values is good considering the simplifications made in the calculations. The largest discrepancies are the T_1 of Manp H-4′ and the corresponding NOE to this proton from H-1′. This may reflect some bias caused by the crystal structure used to generate the coordinates. Small changes in

TABLE 2. 400 MHz ^1H NMR T_1's at 310 K for disaccharide **II** in s calculated with $\tau_c = 1.4 \times 10^{-10}$ or $\tau_c = 0.78 \times 10^{-10}$ (^{13}C in brackets)

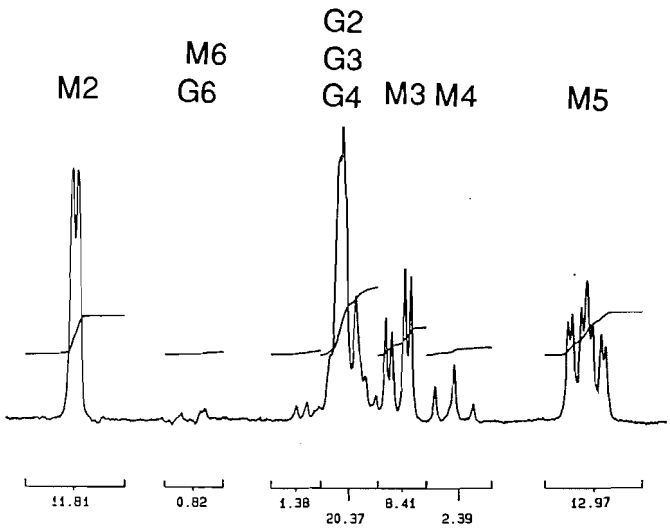

FIG. 3. The NOE of disaccharide **II** in D_2O showing the enhanced resonances after irradiation of Manp H-1′. The strongly coupled GlcNAc H-2, H-3, and H-4 at $\delta = 3.8$ ppm are readily apparent. The integral of irradiated Manp H-1′ was set to −100%.

either the ring dihedral angles or the C—H bond lengths will change the H—H separations. This factor was not further investigated since it should not markedly influence the glycosidic torsions.

To compare the various models, a statistical parameter Z (see eq. [1], where X_{obs} is the observed NMR observable, X_{calc} is the corresponding calculated NMR observable, and n is the number of observables) was determined for the variables sensitive to the glycosidic torsions, namely, the

$$[1] \quad Z = \left[\sum^{n} (X_{obs} - X_{calc}/X_{obs})^2 \right] \Big/ n$$

$^1HT_1$'s of Manp H-1′ and H-2′, and GlcpNAc H-4, and NOE's between Manp H-1′ and Manp H-2′ as well as across the linkage to GlcpNAc H-4 and H-6. The various values of Z are tabulated in Table 4, including those neglecting the NOE to GlcpNAc H-6. This last NOE depends on ω_H as well as ϕ_H and ψ_H, and ω_H is not well calculated by these P.E. surfaces. For example the coupling constants J_{56proR} and J_{56proS} of the GlcpNAc are calculated (22, 23) to be 5.3 ± 0.5 Hz and 5.9 ± 0.5 Hz by any of these P. E. surfaces compared to the experimental values of 5.2 Hz and 2.9 Hz respectively. The experimental values suggest averaging between the $\psi_H = -60°$ and 180° rotamers (24).

The HH surface with variation of GlcpNAc ω_H gives the best fit (lowest Z) to the experimental data although the distinction is small. If the NOE between Manp H-1′ and GlcNAc H-6 is neglected, then the HS model with variation of Manp ω_H gives the best fit. The EL model also fits the data well, suggesting that all three models give a satisfactory representation of the molecule. A contour plot of the EL surface, which shows the minimum and 10 1-kcal contours above the minimum, is shown in Fig. 6*a*. The corresponding probability plot, which shows contours for the minimum and the 10%, 25%, 50%, 90%, and 99.9% probability

contours is shown in Fig. 6*b*. This surface is entirely consistent with the results of Homans using the Amber force field (25). The more than 150° of ϕ_H and 80° of ψ_H occupied by the 99.9% probability contour suggests that this disaccharide is flexible. Figures 6*c* and 6*d* show the probability surfaces for the HS and HH surfaces respectively. These last two surfaces do not vary significantly from each other but do occupy a smaller volume of conformational space then the EL surface. The HH plot does suggest that a hydrogen bond can potentially stabilize the conformation. The plots in Fig. 6 are all taken at the minimum value of ω_H for the respective surface. The surfaces at different values of ω_H (not shown) do not differ qualitatively.

Taken together, these results suggest that the *exo*-anomeric (EA) stabilized minimum near $\phi_H = +50°$ ($\psi_H = 0 \pm 10°$) is significantly populated but is not the only conformation possible. These minima are also consistent with previous calculations for this linkage that did not implicitly consider flexibility (26–29). In two crystal structures of small molecules with this linkage this conformation is indeed found (20, 30). However, in a complex between an oligosaccharide containing the linkage in **II** and a lectin, the Manp(β1–4)GlcpNAc linkage is found in a second minimum (31). This result points to the importance of these other conformers. In fact, although not predicted to be populated in our "rigid" maps (22, 32) (which also neglect solvation), the EL PE surface in Fig. 6*a* shows that conformers with ψ_H near 180°

The minimum and the 10%, 25%, 50%, 90%, and 99.9% probability contours are plotted.

are only a few kilocalories above the global minimum and probably easily accessible to the molecule.

Conclusions

In conclusion, we have designed an efficient synthesis of Manp(β1–4)GlcpNAc glycosides. Furthermore, we have developed an NMR method for unambiguously assigning ^{1}H–^{1}H NOE's in tight coupling situations by monitoring the effect in the ^{13}C domain using DEPT transfer, and applied it to this disaccharide. This confirmed that the NOE across the glycosidic linkage is mostly between Manp H-1′ and GlcpNAc H-4. This value and the T_1 values were then compared to calculated values, demonstrating that models in which the glycosidic torsion angles vary substantially are entirely consistent with the NMR data. This result strongly suggests that conformations other than the global minimum need to be considered when modelling larger oligosaccharides of the N-linked family that contain this linkage. It has also been shown that T_1's of certain ^{1}H nuclei are considerably longer than expected (this has significance for the choice of experimental conditions for NOE measurements).

Experimental

General methods

Melting points were determined on a Reichert Thermovar melting point apparatus and are uncorrected. Optical rotations were

measured with a Perkin–Elmer polarimeter (model 243B) at 26 ± °C. Microanalyses were performed by the Micro Analytical Laboratory Ltd., Markham, Ontario. IR spectra were recorded on a Perkin–Elmer (model 1430) spectrometer using thin film on NaCl plates.

Fast Atom Bombardment mass spectra (FAB-MS) were recorded with a VG Analytical ZAB-SE mass spectrometer at the Mass Spectrometry Laboratory of the Carbohydrate Research Centre, University of Toronto. The samples in thioglycerol were bombarded by neutral xenon atoms (8 keV and 1 mA anode current) generated by an Ion-Tech Saddle Field Ion Gun.

Thin-layer chromatography (TLC) was performed on silica gel $60F_{254}$ (Merck) plastic plates and visualized by spraying with 50% sulfuric acid and (or) 1% orcinol acidic ferric chloride and heating at 200°C. Silica gel (230–400 mesh; Toronto Research Chemicals) was used for flash chromatography. All starting materials were dried overnight under vacuum (10^{-3} Torr; 1 Torr = 133.3 Pa) prior to use and the solvents were distilled from appropriate drying agents. Solutions were concentrated at water aspirator pressure.

^{1}H NMR spectra of the synthetic intermediates were obtained with a Bruker AM 500-spectrometer at 19 ± 2°C either in $CDCl_3$ containing a trace of TMS (0 ppm, ^{1}H and ^{13}C) as the internal standard or in D_2O (99.98%, Aldrich) containing a trace of acetone (2.225 ppm relative to internal DSS, ^{1}H) as the internal standard using the δ(ppm) scale. ^{13}C spectra in D_2O were referenced to external dioxane (67.4 ppm relative to TMS). Samples for NMR analyses in D_2O were passed through a Chelex 100 (Bio-Rad) ion-exchange resin in doubly distilled H_2O to remove paramagnetic impurities, lyophilized, and then lyophilized three times with D_2O.

A Varian Associates model VXR-400 instrument was used to obtain the NMR spectra of the title disaccharide (**II**). All experiments were made with undegassed samples (10 mg in 0.7 mL D_2O). Absence of paramagnetic impurities was tested qualitatively by measuring the proton T_1 value of the residual HDO signal of the solvent. In all samples this was found to be longer than 18 s.

NMR spectrometry

Relaxation time measurements

The T_1^H data for protons involved in tight couplings, and (or) exhibiting their resonances in crowded spectral regions, were also measured by an indirect method. The pulse sequence employed in this study was similar to that published by Bigler (17) except that the polarization transfer step was achieved by means of DEPT (cf. Pegg *et al.* (35)). To decrease the overall errors of the indirect proton relaxation data, $T_1^{H(ind)}$, acquisition of the time domain signal pertinent to $T_1^{H(DEPT)}$, and T_1^C were acquired alternately in one experiment. To test the reliability, the modified sequence was applied to a sample of methyl α-D-glucopyranoside (20 mg in 0.7 mL of $CDCl_3$). First, $T_1^{H(dir)}$ values were obtained in a conventional proton inversion recovery experiment, then the contribution of the dipolar mechanism in ^{13}C relaxation was examined using a {^{1}H}–^{13}C heteronuclear NOE measurement. The values obtained were close the theoretically expected maximum (2.98) for each ring carbon signal, attesting to the predominance of a dipolar mechanism in the longitudinal relaxation of the monosaccharide. Values of $T_1^{H(DEPT)}$ and T_1^C were obtained next (cf. Table 1 for the summary of the relaxation data).

Homonuclear NOE experiments

Steady-state Overhauser enhancements of proton resonances exhibiting their signals in crowded spectral regions were conveniently monitored via ^{13}C NMR spectroscopy. A pulse sequence was employed, in which the DEPT polarization transfer step was preceded by a selective proton preirradiation period analogous to that employed in steady-state {^{1}H}–^{1}H NOE experiments. The non-equilibrium magnetization of the proton spin system, resulting from the selective preirradiation, is thus transferred to the ^{13}C frequency domain and detected as ^{13}C signal enhancement. As in the proton NOE difference spectroscopy, the ^{13}C signal enhancement is conveniently monitored in the difference mode. The reference intensity required is provided by ^{13}C resonance obtained through polarization transfer from the unperturbed proton spin system. In practical terms such a pulse sequence requires fast switching between low-power, multiple frequency, selective preirradiation (NOE) mode, and high-power pulsing mode (DEPT) while observing ^{13}C NMR, a condition readily met by modern dual broadband spectrometers fitted with computer-controlled attenuators. As the spectrometer at our disposal was of an earlier generation, in which multiple-frequency, low-power selective irradiation is available only with the ^{1}H observe set-up, the above experiment was conveniently performed in the "reversed" mode, i.e., by deriving both soft and hard proton pulses from the decoupler channel. In the actual pulse sequence the selective preirradiation was achieved by frequency-cycled, low-power DANTE pulse trains (36). This segment, terminated with optional, hard 90° decoupler read pulse, was used to set up the NOE part of the experiment (level, duration, frequencies of selective preirradiation). With the NOE setup completed, the NOE part of the pulse sequence was connected to the standard DEPT segment, preceded by a train of 90° ^{13}C pulses to destroy eventual proton–carbon correlation effects. With alternate acquisition, a reference ^{13}C DEPT spectrum with no proton preirradiation was also accumulated and the resulting two time-domain signals were used to obtain the NOE difference spectrum. Running these experiments in D_2O, particular attention had to be given to minor changes in the sample temperature when switching from the NOE setup to the NOE DEPT experiment. Since this experimental sequence uses broad-band decoupling, the sample temperature rises a few degrees over the temperature during the NOE setup, and a readjustment of the preirradiation frequency is required.

Computational methods

The computational methods used have been described in detail previously (18, 33, 37). (BIGST and NEWSIG400 are modifications of the original CCM program developed by Carver and co-workers, which uses a full relaxation matrix approach to calculate NOE's and T_1's (23). All programs, except MONGO and MODEV were written in Fortran at the University of Toronto (37). Calculations were performed on a Microvax.) Briefly, they entail using the coordinates (X-ray) for these monosaccharides (20, 21) as starting conformations. Then PE cubes were calculated using the program BIGTST using 60 6° increments for each of the torsion angles ϕ_H, ψ_H, and ω_H (i.e., sixty 60 × 60 PE surfaces). Electrostatic calculations used point charges. These PE cubes were next used to calculate Boltzman-averaged relaxation matrices using the programs QSET and NEWSIG400. Finally, the relaxation matrix was solved to calculate for NOE's and T_1's. Contour plots were made using the program MONGO (38). Coupling constants were calculated employing the calculated torsion angles using the equation 8E of Haasnoot *et al.* (22) and data analysis was done utilizing the BASIC program MODEV (computer code available on request) (33).

Chemical synthesis

2-O-Acetyl-3,4,6-tri-O-benzyl-D-glucopyranosyl bromide (V)

Bromide **V** (refs. 1, 2) was prepared from the ortho ester **IV** (refs. 9, 10) by a method of Lemieux and co-workers (10) modified as follows. A mixture of orthoester **IV** (2.69 g, 5.17 mmol) and acetyl bromide (30 mL) was stirred at room temperature for 0.5 h. Then it was diluted with toluene (100 mL) and evaporated to dryness to give **V** (2.9 g) as a pale brownish solid. TLC indicated that it contained mainly bromide **V**, R_F 0.45 (ethyl acetate – hexane = 1:4). The crude product **V** was dried over P_2O_5 *in vacuo* before using for the coupling reaction.

Benzyl 2-acetamido-2-deoxy-3,6-di-O-benzyl-α-D-glucopyranoside (IIIa)

To a solution of benzyl 2-acetamido-2-deoxy-α-D-glucopyranoside, mp 186–187°C (11), (4.39 g) in acetonitrile (200 mL), benzaldehyde dimethylacetal (10.00 mL) and *p*-toluenesulfonic (0.5 g) were added at room temperature, and the reaction mixture was stirred at 60°C under argon for 60 h. After pouring the reaction mixture into an ice-cold saturated aqueous $NaHCO_3$ solution,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

the resulting benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside was extracted into CH_2Cl_2, and after evaporation of the solvent and recrystallization from dioxane and isopropanol it was obtained pure (mp 263–264°C, 3.59 g, 62%). This benzylidene derivative (3.05 g) in dry. THF (8 mL) was added to a solution of NaH (0.58 g) in dry THF (5 mL), and stirred under argon to homogeneity. A solution of α-bromotoluene (1.43 mL) in dry THF (8 mL) was added slowly and this mixture was stirred until all the benzylidene derivative was consumed. Then CH_2Cl_2 was added, solids were filtered off, the solution was washed with aqueous NaCl, dried over $MgSO_4$, and the solution after concentration gave white crystalline benzyl 2-acetamido-3-*O*-benzyl-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside, mp 267–269°C (3.67 g, 63%). To a solution of this latter compound (4.17 g) and $NaCNBH_3$ (2.95 g) in dry THF (300 mL) containing molecular sieves 3A (10 g) was added dropwise Et_2O saturated with gaseous HCl (50 mL). After completion of the reaction in about 45 min, CH_2Cl_2 (300 mL) was added, the mixture was poured onto ice, and extracted four times with CH_2Cl_2, dried over $MgSO_4$, and concentrated to dryness. The benzyl 2-acetamido-2-deoxy-3,6-di-*O*-benzyl-α-D-glucopyranoside crystallized from hexane–ethanol at 5°C (mp 145–146°C, 1.4 g, 33.5%). An additional equal amount was obtained after chromatography of the mother liquors on a silica gel column using a gradient of MeOH in CH_2Cl_2.

*Benzyl 2-acetamido-2-deoxy-3,6-di-*O*-benzyl-β-D-glucopyranoside (**III**b)*

2-Acetamido-2-deoxy-D-glucopyranose (50 g) gave after overnight stirring with acetyl chloride (100 mL) 2-acetamido-2-deoxy-3,4,6-tri-*O*-acetyl-α-D-glycopyranosyl chloride (mp 118–120°C, 29.7 g, 36%), which was dissolved in dry benzyl alcohol (100 mL) together with $Hg(CN)_2$ (18.37 g) and $HgBr_2$ (3.5 g). This reaction mixture was stirred overnight, then it was diluted with $CHCl_3$ (400 mL), washed with saturated aqueous $NaHCO_3$, water, dried over $MgSO_4$, and evaporated to dryness. Chromatography on silica gel of the residue afforded benzyl 2-acetamido-2-deoxy-3,4,6-tri-*O*-acetyl-β-D-glycopyranoside, which after crystallization from ethanol gave 9.15 g (26%) of the compound, mp 165°C. The latter compound (12.83 g) was dissolved in dry methanol (50 mL, and to this was added dropwise a solution of NaOMe prepared by dissolving Na (0.7 g) in dry MeOH (50 mL) at room temperature. White crystals that formed during the reaction were collected and recrystallized from EtOH to give benzyl 2-acetamido-2-deoxy-β-D-glucopyranoside, mp 199–202°C (6.88 g). From this precursor were sequentially prepared benzyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside, mp 267–270°C, benzyl 2-acetamido-3-*O*-benzyl-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside, mp 278–280°C, and benzyl 2-acetamido-2-deoxy-3,6-di-*O*-benzyl-β-D-glucopyranoside, mp 176–178°C, by the same procedures as described for the α anomer.

*Benzyl 2-acetamido-4-O-(2-O-acetyl-3,4,6-tri-O-benzyl-β-D-glucopyranosyl)-3,6-di-O-benzyl-2-deoxy-α-D-glucopyranoside (**VI**a) (ref. 8)*

To a mixture of acceptor **III***a* (500 mg, 1.02 mmol), $HgCl_2$ (500 mg), and molecular sieves (3A, 800 mg) in CH_3NO_2 (4 mL) stirred at room temperature under argon, a solution of crude bromide **V** (1.60 g, 2.88 mmol) in toluene (4 mL) was added (12*a*). The reaction mixture was stirred in the dark for an additional 46 h. Then another batch of $HgCl_2$ (300 mg) was added, and stirring continued for 71 h. The reaction mixture was diluted with CH_2Cl_2 (150 mL), filtered through Celite, the Celite cake was washed with additional CH_2Cl_2 (3 × 30 mL), and the combined filtrates after washing with H_2O (200 mL) were dried over $MgSO_4$ and evaporated to dryness. The residue was subjected to chromatography on silica gel (ethyl acetate – toluene = 1:2) and pure compound **VI***a* (719 mg, 73%) was obtained as a colorless solid, mp 128–129°C (from Et_2O–CH_2Cl_2); $[\alpha]_D$ + 79.9 (*c* 1.0, $CHCl_3$) (lit. (8) mp 128–129°C; $[\alpha]_D^{20}$ + 84 (*c* 3.0, $CHCl_3$)); R_f 0.32 (ethyl acetate – toluene, 1:2); IR (neat): 3300 and 1660 (NHCO), 1750 (RCOOR) cm^{-1}; ^1H NMR δ: 5.12 (d, 1H, *J* = 8.9 Hz, exchangeable with D_2O; N*H*); 4.98 (br t, 1H, *J* = 9.7 Hz, H-2′), 4.93 (d, 1H, *J* = 3.7 Hz, H-1), 4.46 (d, 1H, *J* = 10 Hz, H-1′), 4.17 = (t × d, 1H, *J* = 9.2 Hz and 3.7 Hz, H-2), 4.01 (t, 1H, *J* = 9.2 Hz, H-4) 3.48 (t, 1H, *J* = 9.3 Hz, H-3′), 3.30 (m, 1H, H-5′), 1.90 and 1.74 (2S, 6H, $COCH_3$).

*Benzyl 2-acetamido-4-O-(2-O-acetyl-3,4,6-tri-O-benzyl-β-D-glucopyranosyl)-3,6-di-O-benzyl-2-deoxy-α-D-glucopyranoside (**VI**a) and benzyl 2-acetamido-4-O-(2-O-acetyl-3,4,6-tri-O-benzyl-β-D-glucopyranosyl)-3,6-di-O-benzyl-2-deoxy-β-D-glucopyranoside (**VI**b): a comparison*

To assess the reactivity of acceptors **III***a* and **III***b* toward bromide **V**, control experiments were carried out under identical conditions (room temperature, 45 h). Two separate reactions were set up side by side, each using: acceptor (**III***a* or **III***b*, 60 mg), bromide **V** (205 mg of the same batch), $HgCl_2$ (60 mg), and molecular sieves (3A) (100 mg). Comparable yields of **VI***a* and **VI***b* (8, 12*a*) of similar purity were obtained.

*Benzyl 2-acetamido-3,6-di-O-benzyl-2-deoxy-4-O-(3,4,6-tri-O-benzyl-β-D-mannopyranosyl)-α-D-glucopyranoside (**VI**e) (ref. 8)*

A solution of crude ketone **VI***d* (70 mg. 0.076 mmol) (prepared from **VI***a* as described (8)) in THF (3 mL) (5) was added dropwise (34) to a 1 M solution of L-Selectride (lithium tri-sec-isobutylborohydride) in THF (Aldrich; 3 mL) under stirring at −78°C. After stirring the reaction mixture at this temperature for a further 5 h, the reaction was quenched by addition of MeOH (0.3 mL), followed by 30% aqueous H_2O_2 (0.5 mL). Then the solution was filtered through Celite, washed with CH_2Cl_2 (50 mL), and the solvent was evaporated to give a pale yellow syrup, which after chromatography on silica gel (ethyl acetate – toluene = 1:2) afforded pure **VI***e* (38 mg, 56%) as a colorless solid; mp 173.5–174.5°C (observable change into an amorphous wet solid started at 156°C); $[\alpha]_D$ +78.5 (*c* 1.0, $CHCl_3$); (lit. (8) mp 156–159°C; $[\alpha]_D^{20}$ + 80 (*c* 0.98, $CHCl_3$)); R_F 0.35 (fivefold development in the same solvent); ^1H NMR δ:7.27 (m, 30H, C_6H_5), 5.28 (d, 1H, *J* = 9.2 Hz, exchangeable with D_2O, N*H*), 4.93 (d, 1H, *J* = 4.0 Hz, H-1), 4.63 (br s, 1H, H-1′), 4.27 (br t × d, 1H, *J* = 9.6 Hz and 3.7 Hz, became a d × d after exchange with D_2O, H-2), 4.05(t, 1H, *J* = 9.2 Hz, H-4), 3.99 (br t, 1H, *J* = 2.8 Hz, became d after exchange with D_2O, H-2′), 3.35 (d × d, 1H, *J* = 9.2 Hz and 3.0 Hz, H-3′), 3.27 (m, 1H, H-5′), 2.50 (d, 1H, *J* = 2.9 Hz, exchangeable with D_2O, O*H*), and 1.79 (s, 3H, $COCH_3$). Anal. calcd. for $C_{56}H_{61}NO_{11}$ (924.090): C 72.79, H 6.65, N 1.52, found: C 72.68, H 6.53, N 1.46.

*Methyl-d_3 2-acetamido-2-deoxy-3,6-di-O-acetyl-4-O-(2,3,4,6-tetra-O-acetyl-β-D-mannopyranosyl)-β-D-glucopyranoside (**VI**g)*

Compound **VI***e* (327 mg, 0.354 mmol) in acetic acid – methanol (3:4, 70 mL) was stirred in an H_2 atmosphere with 10% Pd–C (250 mg) at room temperature for 23 h. After the usual work-up it gave a crude product that was subsequently treated with acetic anhydride (10 mL) in pyridine (10 mL) for 70 h. Ethyl acetate (100 mL) was added, the solution was washed with cold water (2 × 50 mL), dried over $MgSO_4$, and evaporated to give peracetylated compound **VI***f* (mixture of α and β, 263 mg) as an amorphous solid; R_F 0.52 (ethyl acetate – methanol = 20:1). Crude **VI***f* (263 mg) was dissolved in acetyl chloride – acetic acid (6:1, 35 mL) and the solution was saturated with HCl gas passing slowly through at 0°C for 6 h; stirring continued for another 85 h at room temperature. Then toluene (200 mL) was added, and the solvents were evaporated to give the chloride as a light-brown amorphous solid (R_F 0.58, ethyl acetate). The chloride, after drying over P_2O_5 *in vacuo*, was treated with $HgCl_2$ (300 mg), molecular sieves (3A; 600 mg), and methanol-d_3 (0.50 mL) in nitromethane–toluene (1:1, 5 mL) at room temperature for 6 h. It was diluted with ethyl acetate – dichloromethane (1:1, 100 mL); filtered through Celite, and washed with ethyl acetate (3 × 20 mL); the combined filtrates were evaporated to give a pale brown syrup. After chromatography on

a silica column (ethyl acetate), pure **VIg** (153 mg, 66% overall) was obtained as a colorless syrup; R_F 0.20 (same solvent); $[\alpha]_D$ −48.2 (*c* 0.57, $CHCl_3$); IR (neat): 3370 and 1670 (NHCO), 2210 and 2065 (CD), 1745 (RCOOR); ^{1}H NMR δ: 5.43 (d, 1H, *J* = 9.2 Hz, N*H*), 5.40 (d × d, 1H, *J* = 3.3 Hz and 0.6 Hz, H-2′), 5.21 (t, 1H, *J* = 9.9 Hz, H-4′), 5.12 (d × d, 1H, *J* = 10.4 Hz and 8.9 Hz, H-3), 5.03 (d × d, 1H, *J* = 10.4 Hz and 8.9 Hz, H-3), 5.03 (d × d, 1H, *J* = 9.9 Hz and 3.3 Hz, H-3′), 4.70 (d, 1H, *J* = 0.6 Hz, H-1′), 4.39 (d, 1H, *J* = 8.1 Hz, H-1), 3.97, (d × d × d, 1H, *J* = 10.3 Hz, 9.2 Hz, and 8.3 Hz, H-2), 3.85 (t, 1H, *J* = 9.1 Hz, H-4), 3.63 (m, 2H, H-5, H-5′), 2.14, 2.13, 2.10, 2.09, 2.04, 1.99, and 1.96 (7s, 21H, COC*H*$_3$). Anal. calcd. for $C_{27}H_{36}NO_{17}D_3$ (652.617): C 49.69, H 6.49, N 2.15; found: C 49.52, H 6.43, N 2.08.

*Methyl-*d$_3$ *2-acetamido-2-deoxy-4-*O*-β-*D*-mannopyranosyl-β-*D*-glucopyranoside (II)*

A solution of sodium methoxide in dry methanol (1%; 4 mL) was added to a solution of compound **VIg** (104 mg, 0.160 mmol) dissolved in dichloromethane–methanol (2:1, 6 mL). The reaction mixture was stirred for 25 min at room temperature, cooled to 0°C, and neutralized with acidic DOWEX 50 (H^+) resin (2.1 mL, 1.7 mg per mL). The resin was subsequently filtered off and washed with methanol (3 × 20 mL). The combined filtrates were evaporated to dryness, yielding a syrup that was taken up into distilled water (30 mL) and washed with hexane (30 mL). The aqueous solution was evaporated to give compound **II** (60 mg, 94%) as a colorless solid; mp 251–253°C (from methanol); R_F 0.25 ($CHCl_3$–MeOH = 1:1); $[\alpha]_D$ −48.5 (*c* 0.47, methanol–water, 2:1). ^{1}H NMR δ: 4.83 (d, 1H, *J* = 1.1 Hz, H-1′), 4.13 (d × d, 1H, *J* = 3.2 Hz and 1.1 Hz, H-2′), 3.72 (d × d, 1H, *J* = 9.6 Hz and 3.2 Hz, H-3′), 3.65 (d × d, 1H, *J* = 9.6 Hz and 9.6 Hz, H-4′), 3.49 (d × d × d, 1H, *J* = 2.4 Hz, 6.4 Hz, and 9.6 Hz, H-5′), 3.99 (d × d, 1H, *J* = 2.4 Hz and −12.3 Hz, H-6′), 3.80 (d, 1H, *J* = 6.4 Hz and −12.3 Hz, H-6″), 4.53 (d, 1H, *J* = 8.2 Hz, H-1), 3.8, (m, 3H, H-2, H-3, H-4), 3.64 (m, 1H, H-5), 3.95 (d × d, 1H, *J* = 2.9 Hz and −12.3 Hz, H-6), 3.83 (d × d, 1H, *J* = 5.2 Hz and −12.3 Hz, H-6′) 2.10 (s, 3H, NCOC*H*$_3$); ^{13}C NMR δ: 101.4 (C-1′), 71.8 (C-2′), 74.1 (C-3′), 67.9 (C-4′), 77.7 (C-5′), 62.2 (C-6′), 103.1 (C-1), 56.2 (C-2), 73.7 (C-3), 80.3 (C-4), 75.9 (C-5), 61.6 (C-6), 23.5 (CO*C*H$_3$), 170 (*C*OCH$_3$). *Anal.* calcd. for $C_{15}H_{24}NO_{11}D_3$ (400.395): C 45.00, H 7.55, N 3.50, found: C 44.83, H 7.45, N 3.46.

Stereoselective deprotonation of tropinone and reactions of tropinone lithium enolate

MAREK MAJEWSKI[1] AND GUO-ZHU ZHENG
Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received April 30, 1992

MAREK MAJEWSKI AND GUO-ZHU ZHENG. Can. J. Chem. **70**, 2618 (1992).

Tropinone (**6**) was deprotonated with lithium diisopropylamide and with chiral lithium amides (**18–24**) and the resulting enolates (two enantiomers) were treated with electrophiles. The aldol reaction with benzaldehyde and deuteration were both diastereoselective. The former yielded only one isomer (*exo*, *anti*) of the aldol **8***a*; the latter proceeded from the *exo* face. This selectivity permitted us to probe the deprotonation of tropinone with lithium amides; it was concluded that the reaction involves predominantly the *exo* axial protons. The reaction of tropinone enolate with ethyl chloroformate led, via a ring opening, to the cycloheptenone derivative **9**. The reaction with methyl cyanoformate yielded, in the presence of silver acetate and acetic acid, the β-ketoester **8***b*; however, in the absence of these additives, and especially when 12-crown-4 was added to the enolate, a ring opening leading to the pyrrolidine derivative **10** occurred instead. Deprotonation of tropinone with chiral lithium amides proceeded with modest enantioselectivity. A synthesis of non-racemic anhydroecgonine via this strategy allowed establishing the absolute stereochemistry of deprotonation.

MAREK MAJEWSKI et GUO-ZHU ZHENG. Can. J. Chem. **70**, 2618 (1992).

On a déprotoné la tropinone (**6**) à l'aide du diisopropylamidure de sodium et des amidures de lithium chiraux (**18–24**) et l'on a traité les énolates qui se sont formés (deux énantiomères) avec des électrophiles. La réaction aldolique avec le benzaldéhyde ainsi que la deutération sont toutes les deux diastéréosélectives; la première ne fournit qu'un isomère (*exo*, *anti*) de l'aldol **8***a* alors que la dernière se produit par la face *exo*. Cette sélectivité a permis d'examiner la déprotonation de la tropinone avec des amidures de lithium; on en a conclu que la réaction implique principalement les protons axiaux *exo*. La réaction de l'énolate de tropinone avec le chloroformate d'éthyle conduit, par le biais d'une ouverture de cycle, au dérivé cyclohepténone **9**. La réaction avec le cyanoformate de méthyle, réalisée en présence d'acétate d'argent et d'acide acétique, conduit au β-cétoester **8***b*; toutefois, lorsque cette addition est réalisée en l'absence de ces additifs et particulièrement lorsqu'on ajoute de l'éther 12-couronne-4 à l'énolate, il se produit plutôt une ouverture de cycle conduisant au dérivé de la pyrrolidine **10**. La déprotonation de la tropinone sous l'influence d'amidures de lithium se produit avec une énantiosélectivité modeste. Une synthèse de l'anhydroecgonine non-racémique à l'aide de cette stratégie a permis d'établir la stéréochimie absolue de la déprotonation.

[Traduit par la rédaction]

Introduction

Reactions that differentiate efficiently between two enantiotopic groups are often encountered in bioorganic chemistry when enzymes are used as reagents (1). In more classical synthetic organic chemistry such reactions are rare (2). Indeed the scarcity of group-enantioselective reactions has led some researchers to caution against complications of synthetic problems arising from symmetry in starting materials (3). Development of methods for achieving enantiotopic group selectivity is thus important; one such method that emerged recently as a promising new synthetic tool involves enantioselective deprotonation of ketones (4). The method is shown in general terms in Scheme 1; an achiral (or *meso*) ketone **1**, which has an internal plane of symmetry and thus belongs to the C_s point group, reacts with a chiral lithium amide **2** to yield a non-racemic mixture of lithium enolates (**3s**, **r**) which further react with an electrophile to give a number of products (**4**, **5**; only one enantiomer of each of these compounds is shown in Scheme 1). The goal is to achieve control over reaction selectivity, i.e., one of the products should predominate.

In this paper we describe our studies on the deprotonation of tropinone (**6**) (5); apart from theoretical interest in studying the scope and limitations of enantioselective deprotonation, we hoped that deprotonation of this *meso* ketone, followed by reactions of the resulting enolates with electrophiles, might lead to the development of a synthetic strategy suitable for the construction of a number of tropane alkaloids (6) in a stereoselective manner.

Results and discussion

A metal enolate of tropinone has three electron-rich centers that could be attacked by an electrophile: the α-carbon, the oxygen, and the nitrogen; depending on the character of the electrophile either one of these centers can participate in the reaction (*vide infra*).

Deprotonation of tropinone with LDA

Relatively little is known about generation and reactions of tropinone lithium enolates (6); for that reason, and also to find a suitable method of determination of the enantiomeric excess of tropinone deprotonation, we first investigated reactions of this ketone with lithium diisopropylamide (LDA) followed by electrophilic attack (Scheme 2). The racemic mixture of tropinone lithium enolates, generated by mixing tropinone with LDA in THF at −78°C, was treated with a number of electrophiles. The results are summarized in Table 1 (the differences between yields presented in Table 1 and these in ref. 5*a* reflect the changes in experimental procedures made since preliminary results of this work were published).

Chlorotrimethylsilane (entry 1) and acetic anhydride (entry 2) yielded the racemic mixtures of the O-silylated and O-acetylated products **7***a* (E = $SiMe_3$) and **7***b* (E = COMe), respectively. In the first case the quality of chlorotrimethylsilane proved crucial. Use of a chlorotrimethylsilane–triethylamine mixture, from which the amine hydrochloride was removed by centrifugation, a common procedure in silyla-

6	PhCOCl	8*c*	62
7	DEAD	8*d*	80
8	D_2O	8*e*	81

[a]Yields refer to isolated, pure products.

tion reactions, led to low yields both when Corey's internal quench (7) and the normal procedure of quenching the preformed enolate with one equivalent of chlorosilane were tried. This was, conceivably, due to triethylamine hydrochloride protonating the enolate. Good yield was achieved by purifying TMSCl by distillation from CaH_2 followed by storage over polyvinylpyridine (Reillex 402) (8), and using the internal quench procedure.

Benzaldehyde (entry 3), methyl cyanoformate (entry 5), benzoyl chloride (entry 6), and diethylazodicarboxylate (DEAD; entry 7) reacted at the carbon terminus. Interestingly, the reaction with benzaldehyde was highly stereoselective and gave only one diastereoisomer out of a possible four. Lithium enolates of cyclic ketones are known to give predominantly *anti* aldols (9); the vicinal coupling constant J_{AB} in the ^1H NMR of the aldol product **8***a* was, however, only 3 Hz, which suggested the *syn* configuration (9*a*). In agreement with both steric and stereoelectronic effects we expected this product to be the *exo* isomer; the *exo* face of tropinone should be less hindered sterically in analogy to norbornyl ring systems (10*a*). Alkylation of endocyclic six-membered enolates is known to proceed predominantly from the axial direction, which, in systems where steric constrains are absent, was rationalized by stereoelectronic effects (10, 11). We finally determined that the aldol **8***a* was indeed the *exo-anti* isomer by NMR studies on a cyclic derivative (5*a*) and by X-ray analysis of compound **8***a*, which fortunately was crystalline.[2] The low J_{AB} value is probably due to the fact that, in solution, the OH group of **8***a* is hydrogen-bonded to the nitrogen (similar hydrogen bonding is pseudotropine was reported before) (12).

To gain an entry into alkaloids related to cocaine we wanted to attach an ester synthon to the tropinone ring. Towards this end we treated the racemic mixture of tropinone lithium enolates with ethyl chloroformate, a reagent that was

[2]The X-ray data will be published elsewhere.

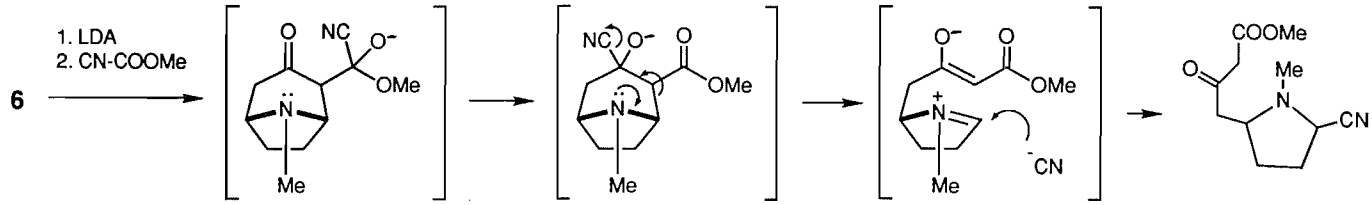

SCHEME 3

often used for carboethoxylation (13). Unexpectedly this led to formation of cycloheptenone **9** via ring opening.[3] Chloroformates are known to demethylate tropinone and other tertiary amines (14) but the reaction leading to **9** is clearly of a different type; it can be viewed as an electrophilic attack on nitrogen in tandem with E1cB elimination.

The reaction with chloroformate was thus unsuccessful as far as making of the β-ketoester was concerned. We next turned our attention to methyl cyanoformate, developed by Mander and co-workers as a reagent for α-carbomethoxylation of ketones (15*a*). Initially, reaction of tropinone lithium enolate with this reagent produced the desired β-ketoester **8***b*, which exists as a mixture of keto and enol forms, in low yield (45%). The major by-product isolated from this reaction was the substituted pyrrolidine **10** (Scheme 3, relative stereochemistry unknown). After a brief study of the reaction conditions we found that when, prior to addition of the cyanoformate reagent, one equivalent of 12-crown-4 was added to the enolate, the pyrrolidine derivative **10** became the major product (74% isolated yield) and only a small amount of the β-ketoester **8***b* was formed. When one equivalent of LiBr was added to the enolate, however, the amount of pyrrolidine **10** was much smaller and the yield of **8***b* increased to 70%. We rationalized these observations as follows:

Mander and Crabtree observed formation of ketone cyanohydrins of β-ketoesters in reactions of ketone enolates with cyanoformate (15). It seems, therefore, reasonable to envisage that intermediate **12** (Scheme 3) plays an important role in the reaction. This intermediate presumably undergoes Grob fragmentation (16), which leads to the undesired pyrrolidine **10**; to minimize this side reaction the formation of **12** has to be suppressed. The experiment with LiBr, addition of which increased the yield of the β-ketoester **8***b*, indicated that a Lewis acid retarded the Grob pathway; we attributed this to the LiBr complexation with the CN ion, which attenuated the nucleophilicity of this anion. In an effort to further decrease the ability of CN^- to attack the C=O, acetic acid was added to the reaction mixture instead of LiBr. The acid was expected to convert the cyanide to the less nucleophilic HCN: we subsequently added silver acetate to trap HCN as silver cyanide. This strategy worked; the desired β-ketoester **8***b* was now produced in 94% yield (82% after column chromatography).

Deuteration of tropinone lithium enolate with D_2O, using a second equivalent of *n*-BuLi to prevent "internal return" of the proton according to the procedure developed by Seebach and co-workers (17), showed the same face selectivity as the aldol reaction and yielded only one monodeuterated product **8***e*, the *exo* isomer. This allowed us to address the question: is the deprotonation of tropinone diastereoselective? Due to steric and stereoelectronic effects (*vide supra*) the axial *exo* protons should undergo abstraction faster than the equatorial ones.

Both ^1H and ^{13}C NMR spectra of tropinone were described before (18), however, there is some confusion in the literature concerning proton assignments (cf. difference in assignments in ref. 18*a* and ref. 18*b*). Since we intended to use NMR for the analysis of deuterated tropinones, we reinvestigated the proton NMR spectrum using nuclear Overhauser effects to help identify all the protons. The proton assignments and nOe's are shown in Fig. 1. It should be noted that the six-membered ring of tropinone is known to assume the chair conformation with the methyl group being equatorial (18).

Only one product (**8***e*) was isolated from lithiation of tropinone with LDA, followed by addition of one equivalent of *n*-BuLi and deuteration with D_2O (17). This product was the *exo* isomer, as evidenced by the 50% decrease in the intensity of the NMR signal at 2.69 ppm (the signal at 2.20 ppm remained unchanged). The *exo* **8***e* was then subjected to another deprotonation with LDA followed by treatment of the enolate with *n*-BuLi and then by quenching with D_2O. We envisaged that, if the base removed any of the equatorial protons, producing enolates **14** and (or) **15**, we should find the geminal bis-deuterotropinone **16** in the products (Scheme 4). The formation of the isomer **17**, with both deuterium atoms axial, could result from either axial or equatorial deprotonation. We did not detect compound **16** either by ^1H or by ^{13}C NMR which led us to the conclusion that the deprotonation of tropinone with LDA is highly diastereoselective: the axial (*exo*) protons are removed at least 12 times faster than the equatorial (*endo*) protons (assuming that deprotonation is not reversible and that NMR provides 5% detection level of **16**; if 5% of **16** was indeed produced this would indicate the relative rate of proton abstraction k_{Hax}/k_{Heq} of 12–17 depending on the magnitude of the primary deuterium isotope effect).

Deprotonation with chiral lithium amides

Abstraction of an α-proton from tropinone (**6**) with a chiral lithium amide (**18–24**), followed by quenching of the resulting non-racemic mixture of tropinone lithium enolates with benzaldehyde, yielded two enantiomers of the aldol product **8***a*. The enantiomeric excess (ee) was determined by NMR; when the ^1H and ^{13}C spectra of samples of **8***a* were taken in the presence of optically active shift reagent

[3]We later learned that this ring-opening reaction had also been observed by Simpkins, who reported it in a lecture, cf. ref. 4*b*.

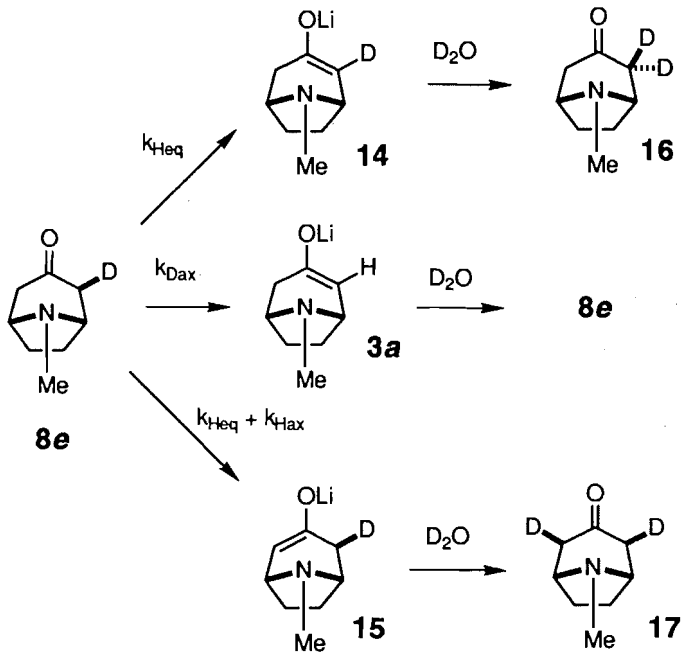

SCHEME 4

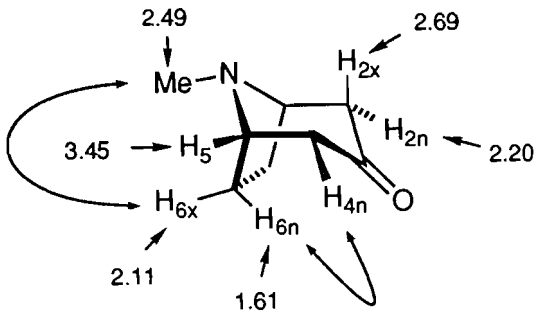

FIG. 1. Proton chemical shifts and nOe's (double-headed arrows) of tropinone (**6**).

(+)-Eu(tfc)$_3$, the splitting of the singlet corresponding to the N-Me group was observed. When the racemic **8***a*, obtained using LDA as the base, was analysed by this method the ratio of the peaks in the N-Me singlet split in the presence of Eu(tfc)$_3$ was 52:48, which provided some measure of the accuracy of this technique. The results of our enantioselective deprotonation experiments are shown in Table 2. The observed selectivities were modest with an optimum ee of 60%. We were able, however, to obtain an optically pure sample of compound **8***a* by fractional crystallization (19).

In an effort to improve enantioselectivity we investigated the effect of reaction conditions (bases **22** and **23** were used in this brief study). Lowering the reaction temperature to −100°C, as well as using two equivalents of base or an additional equivalent of *n*-BuLi, had no effect on enantioselectivity. Use of HMPA or sparteine as additives decreased the ee by up to three quarters (i.e., 10% ee instead 40% when base **23** was used in the presence of sparteine).

To establish the absolute stereochemistry of the proton abstraction with chiral lithium amides and also to highlight the potential practical utility of the method we synthesised non-racemic anhydroecgonine methyl ester (**27**), a natural product of known configuration (20*b*), via this enantioselective deprotonation strategy. The synthesis is shown in Scheme 5. A non-racemic sample of compound **8***b* was obtained in 95% yield according to the method described above (deprotonation of tropinone with base **22** followed by treatment with methyl cyanoformate, AcOH, and AcOAg). Due to tautomerism, compound **8***b* exists as a mixture of isomers with, presumably, the carboxymethyl group disposed equatorially in the major isomer. The keto group in **8***b* was reduced with sodium borohydride. It was found that under standard conditions ($NaBH_4$ in EtOH) only a small amount of **8***b* underwent reduction. However, upon lowering the reaction temperature to −60°C and addition of a small amount of aqueous NH_4Cl the reduction proceeded well (presumably due to the change in the keto–enol equilibrium of the starting material) and yielded a mixture of two products **25** and **26** in a ratio of 6:1 (80% yield). Compounds **25** and **26** were separated[4] and were then subjected to dehydration. It was found that compound **25** (but not **26**) underwent a facile dehydration with trifluoroacetic anhydride – triethylamine. Compound **26** (but not **25**) was easily dehydrated with triflic anhydride – triphenylphosphine oxide. Elimination of trifluoroacetate esters with Et_3N presumably proceeds via the E2 mechanism, hence compound **26**, in which the hydrogen atom and the OH group are *cis*, could not be easily dehydrated with the $(CF_3CO)_2O$–Et_3N mixture. The method utilizing triphenylphosphine and trifluoromethylsulfonic anhydride, developed by Hendrickson and Hussoin (21), presumably involves *syn* elimination. This would account for the easy dehydration of compound **26** under these conditions.

[4]The relative configurations of these compounds were assigned on the basis of the comparison of their NMR spectra with the spectra of cocaine and its isomers reported by Carroll *et al.*; cf. ref. 20*c*.

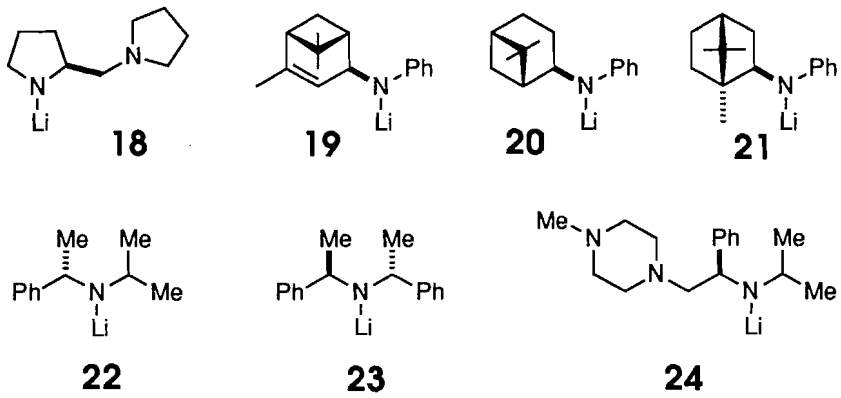
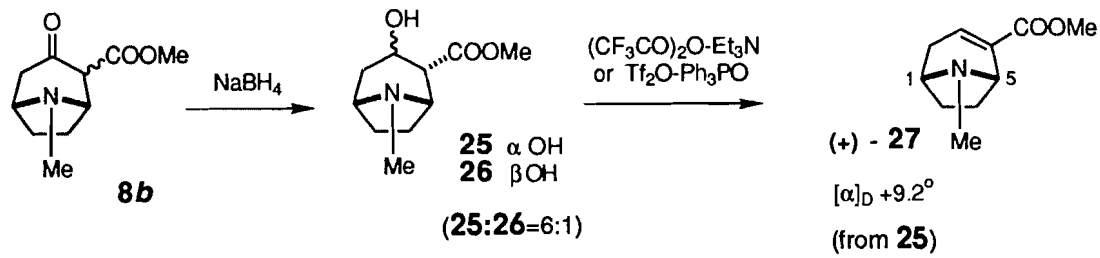
TABLE 2. Enantioselective deprotonation of tropinone with bases **18–24** followed by aldol addition



Entry	Base[a]	Yield (%)[b]	ee (%)[b]	Isomer[b,c]
1	**18**	85	8	(+)-2*R*
2	**19**	97	16	(−)-2*S*
3	**20**	70[d]	26	(−)-2*S*
4	**21**	75[d]	40	(−)-2*S*
5	**22**	88	34	(+)-2*R*
6	**23**	84	40	(−)-2*S*
7	**24**	64	60	(+)-2*R*

[a]Optically pure bases **18–24** were used (cf. Experimental).
[b]Yields and ee refer to compound **8***a*.
[c]The absolute stereochemistry was established by correlating the structure of **8***a* with that of ecgonine Me ester.
[d]A small amount (less than 5%) of the *endo-anti* isomer of **8***a* was observed.



SCHEME 5

The optically active **27** was thus obtained, via the sequence described above, in 71% yield from an achiral starting material (tropinone) and had the optical rotation of +9.2. Since the optically pure levorotatory anhydroecgonine methyl ester, derived from cocaine, was reported (20*a*) to have $[\alpha]_D^{20}$ of −43, the optical purity of our sample was calculated to be 21% (the optical purity of compound **27** could not be measured by NMR as no separation of peaks due to enantiomers in the presence of optically active shift reagents was observed).

The absolute configuration of levorotatory anhydroecgonine methyl ester is known (6, 20); this isomer has the carbomethoxy group at C-2 (Scheme 5; tropane alkaloid numbering). This allowed us to determine the absolute stereochemistry of proton abstraction: bases **18**, **22**, and **24** remove preferentially the pro-*S* proton of tropinone (from C-4) and bases **19–21** and **23** deprotonate faster at C-2 (pro-*R* axial hydrogen); this was in agreement with the results of Simpkins (4*b*).

In conclusion, we have established that: (*i*) deprotonation of tropinone with LDA is diastereoselective and involves the axial (*exo*) protons. (*ii*) The aldol addition of tropinone Li enolate is also diastereoselective and produces the *exo-anti* aldol. (*iii*) Chloroformates react with the Li-enolate of tropinone to give a product of ring opening (**9**). (*iv*) Tropinone can be deprotonated enantioselectively with chiral lithium amides. Although the optical yields observed so far were modest, we are pursuing the potential use of this strategy in the stereoselective synthesis of tropane alkaloids. The strategy was highlighted by a short synthesis of non-racemic anhydroecgonine methyl ester (**27**).

Experimental

All moisture-sensitive reactions were carried out under argon. THF was distilled from a dark-blue solution containing sodium benzophenone ketyl under nitrogen atmosphere. Diisopropylamine, triethylamine, pyridine, DMF, TMEDA, and dichloromethane were distilled from calcium hydride under nitrogen atmosphere, and then stored in 100-mL Sure-seal™ bottles containing 4Å molecular sieves under argon. TMSCl was twice dis-

tilled from calcium hydride under argon atmosphere, and then stored in a 100-mL Sure-seal™ bottle with Reillex™ 402 (8). Acetic anhydride was distilled from calcium carbide (22), then redistilled before storing over 4Å molecular sieves under argon. Benzoyl chloride was stirred with oven-dried calcium carbonate powder for 2 days; the filtered liquid was then dried over sodium sulfate. After distillation, the purified benzoyl chloride was stored with 4Å molecular sieves under argon. Benzaldehyde was washed with 10% aqueous calcium carbonate solution and dried over calcium chloride prior to fractional distillation (22). Butyllithium was titrated periodically using 2,5-dimethoxybenzyl alcohol as indicator. Lithum bromide was flame-dried under vacuum and stored in a sealed flask under an argon atmosphere; it was used as a stock solution in THF (~3 M). Flash column chromatographic separations were performed with Merck Kieselgel 60 (230–400 mesh ASTM). All thin-layer chromatography (TLC) was carried out using precoated glass plates with Silica Gel 60 F254. The spots were detected by using UV light, or phosphomolybdic acid/$Ce(SO_4)_2$ solution followed by charring on a hot plate.

Melting points are uncorrected. Gas chromatography was performed using a Hewlett Packard 5890A with a HP-1 column (methyl silica gum, 5 m × 0.53 mm × 2.65 mm film thickness). The CHN elemental analyses were done using a Perkin Elmer 2400 CHN elemental analyzer. Low-resolution mass spectra were obtained using a VG Analytical retro-fitted MS-12. All NMR spectra were recorded on a Brucker AM 300 (^{1}H at 300 MHz; ^{13}C at 75 MHz) using $CDCl_3$ as solvent and TMS (tetramethylsilane) as internal standard (δ_{TMS} = 0.00 ppm).

3-Trimethylsiloxy-8-methyl-8-azabicyclo[3.2.1]oct-2-ene (7a)

TMSCl (5.5 mmol; 0.7 mL) was added to a solution of LDA (1.1 mmol) in THF (3.2 mL) followed by the dropwise addition of a solution of tropinone (1.0 mmol; 0.139 g) in THF (2 mL) over 15 min at −78°C. After 5 min the mixture was quenched with triethylamine (1.5 mL) and was then warmed to room temperature; the remaining TMSCl, triethylamine, and THF were removed on a rotary evaporator. The pure product (185 mg, 88%) was obtained after distillation from Kugelrohr apparatus: bp 218°C; IR (KBr) 3045, 2958, 2937, 2844, 2794, 1651, 1251, 893, 845 cm^{-1}; ^{1}H NMR δ: 4.92 (d, J = 5.6 Hz, 1H), 3.28 (d, J = 5.3 Hz, 1H), 3.26 (d, J = 5.7 Hz, 1H), 2.53 (dd, J_1 = 20.0 Hz, J_2 = 9.7 Hz, 1H), 2.37 (s, 3H), 2.13 (m, 1H), 2.00 (m, 1H), 1.83 (m, 1H), 1.58 (m, 2H), 0.20 (s, 9H); ^{13}C NMR δ: 147.1 (OC), 106.5 (CH), 57.9 (CH), 57.2 (CH), 35.7 (NCH_3), 35.3 (CH_2), 34.9 (CH_2), 29.8 (CH_2), 0.1 ($SiCH_3$); MS (CI–NH_3) m/z: 214 (8.3), 213 (25.3), 212 (100.0), 211 (9.1), 183 (18.8), 182 (37.8). Anal. calcd. for $C_{11}H_{21}NOSi$: C 62.50, H 10.01, N 6.63; found: C 62.40, H 10.22, N 6.81.

General procedure for generation of tropinone lithium enolate and its reaction with electrophiles

Diisopropylamine (0.155 mL; 1.1 mmol) was dissolved in THF (3.2 mL), and cooled to 0°C. *n*-Butyllithium (1.1 mmol; 0.48 mL of a 2.3 M solution in hexane) was added to the solution. The resulting, colourless, solution of LDA was stirred for 25 min at 0°C and was then cooled to −78°C. Tropinone **6** (0.139 g; 1.0 mmol), dissolved in THF (2 mL), was added dropwise over 15 min to the solution. The resulting mixture was stirred for 45 min at −78°C and was then treated with an appropriate electrophile. After the reaction mixture was stirred for a specified period of time the reaction was quenched with saturated aqueous NH_4Cl solution at −78°C. The reaction mixture was then allowed to warm to room temperature and was extracted with CH_3Cl (3 × 10 mL). The combined organic layers were washed with water, then dried over sodium sulfate, and the solvents were removed on a rotary evaporator to give the crude product.

3-Acetoxy-8-methyl-8-azabicyclo[3.2.1]oct-2-ene (7b)

Acetic anhydride (5.3 mmol; 0.5 mL) was added to a solution of tropinone lithium enolate (1.0 mmol) in THF (3.2 mL) and the mixture was stirred at −78°C for 1 h. After the standard work-up, the crude product **7***b* was obtained as a yellow oil (117 mg; 64%). Purification by chromatography (SiO_2; 5% MeOH in CH_3Cl) and bulb-to-bulb distillation (50°C/0.5 Torr; 1 Torr = 133.3 Pa) afforded **7***b* as a colourless oil (97 mg, 54%). IR (KBr) 2939, 2798, 1757, 1676, 1432, 1212, 1116 cm^{-1}; ^{1}H NMR δ: 5.46 (dd, J_1 = 1.3, J_2 = 4.2 Hz, 1H), 3.37 (m, 2H), 2.67 (dd, J_1 = 3.7 Hz, J_2 = 17.1 Hz, 1H), 2.44 (s, 3H), 2.18 (m, 1H), 2.11 (s, 3H), 2.05 (m, 1H), 1.91 (dt, J_1 = 8.9 Hz, J_2 = 2.5 Hz, 1H), 1.71 (d, J = 17.0 Hz, 1H), 1.66 (m, 1H); ^{13}C NMR δ: 169.1 (CO), 145.1 (OC), 116.4 (CH), 57.9 (CH), 57.2 (CH), 35.3 (NCH_3), 34.6 (CH_2), 29.9 (CH_2), 21.0 (CH_3); MS (El) m/z: 183 (0.3), 182 (3.4), 181 (19.4), 138 (19.3), 111 (27.5), 110 (100.0), 96 (27.3).

(1R, 2S*, 1'R*)-2-(1'-Hydroxybenzyl)-8-methyl-8-azabicyclo[3.2.1]octan-3-one (8a)*

The general procedure was followed with PhCHO as electrophile. The reaction mixture was stirred at −78°C for 15 min. After standard work-up, a yellowish solid was obtained (216 mg; 88%).

The crude product was dissolved in a minimum amount of chloroform in a warm water bath. Hexane was then added dropwise until the solution became cloudy. A small amount of $CHCl_3$ was added until the mixture became clear again. The clear solution was cooled down slowly to room temperature, and white needles of the racemate were collected (183 mg, 75%); m.p. 132.7°C; IR (KBr) 3399, 3086, 2954, 2880, 2807, 1711, 1491, 1452, 1077, 760, 701 cm^{-1}; ^{1}H NMR δ: 7.19–7.40 (m, 5H), 5.21 (d, J = 3.1 Hz, 1H), 3.57 (d, J = 6.6 Hz, 1H), 3.43–3.48 (m, 1H), 2.84 (ddd, J_1 = 15.6 Hz, J_2 = 4.6 Hz, J_3 = 1.5 Hz, 1H), 2.44 (s, 3H), 2.39–2.42 (m, 1H), 2.30 (ddd, J_1 = 15.7 Hz, J_2 = 2.0 Hz, J_3 = 2.0 Hz, 1H), 2.07–2.25 (m, 2H), 1.44–1.65 (m, 2H); ^{13}C NMR δ: 208.0 (CO), 141.7 (C), 128.0 (CH), 127.3 (CH), 125.2 (CH), 76.5 (CHOH), 67.1 (CHN), 63.8 (CHN), 61.5 (CH), 51.6 (CH_2), 40.5 (CH_3N), 26.3 (CH_2), 26.1 (CH_2); MS (CI, NH_3) m/z: 247 (17.7), 246 (100.0), 140 (51.9), 82 (20.1). Anal. calcd. for $C_{15}H_{19}NO_2$: C 73.44, H 7.81, N 5.71; found: C 73.50, H 8.06, N 5.70.

The ee was measured by ^{1}H NMR. Small amounts of (+)-$Eu(tfc)_3$ were added to the sample in $CDCl_3$ solution until a sufficient separation of the peak corresponding to the N-Me group (originally at 2.44 ppm) was achieved.

(+)-(1S, 2R, 1'S)-2-(1'-Hydroxybenzyl)-8-methyl-8-azabicyclo[3.2.1]octan-3-one (8a)

A solution of tropinone (1.0 mmol; 0.139 g) in THF (2 mL) was added dropwise over 15 min, to the preformed yellowish solution of lithium amide **22** (1.1 mmol) in THF (3.2 mL) and the mixture was stirred for 45 min at −78°C. Benzaldehyde (1.2 mmol; 0.127 mL) in THF (1 mL) was added to the reaction mixture at −78°C and, after 15 min, the reaction was quenched with saturated NH_4Cl solution (2 mL). After standard work-up, the crude mixture was placed under high vacuum for 2 days. A yellow solid was obtained (212 mg; 86% yield).

Optical purity of the crude **8***a* was 34% as measured by ^{1}H NMR using (+)-$Eu(tfc)_3$. The compound was recrystallized from $CHCl_3$–hexane as described above. White needles of the racemate were collected first and the solvent from the mother liquid was removed, and the remaining solid was again subjected to recrystallization. After repeating this procedure several times, an enantiometrically pure product was obtained as yellow rhombic crystals: mp 132–133°C; $[\alpha]_D^{20}$ + 23 (c 0.0173 g/mL, $CHCl_3$).

Methyl 8-methyl-3-oxo-8-azabicyclo[3.2.1]octane-2-carboxylate (8b) (ref. 20b)

Methyl cyanoformate (1.3 mmol; 0.1 mL) was added dropwise to a solution of tropinone lithium enolate (1.0 mmol) in THF (3.2 mL) at −78°C. The mixture was stirred at −78°C for 20 min. Glacial acetic acid (1 mL), and then silver acetate (1 mmol; 0.168 g) in glacial acetic acid (1 mL) were added to the mixture at −78°C. The mixture was warmed to room temperature, stirred for 30 min, and concentrated NH_4OH solution was added until the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

mixture became clear. The resulting solution was extracted with $CHCl_3$ (5 × 30 mL), the combined organic extracts were washed with water, dried (Na_2SO_4), and the solvent was removed to give an off-white solid (187 mg; 95% yield).

Purification by flash chromatography (SiO_2, 5% MeOH in $CHCl_3$) yielded a white solid that was a mixture of keto and enol forms of **8***b* (161 mg, 82%): IR (KBr): 2951, 2851, 2799, 1741, 1718, 1652, 1615, 1443, 1227, 813 cm^{-1}; ^1H NMR δ: 3.78 (m, 1H), 3.76 (s, 64% 3H), 3.74 (s, 36% 3H), 3.37–3.66 (1H), 3.12–3.37 (1H), 2.67–2.93 (1H), 2.53 (s, 13% 3H), 2.38 (s, 22% 3H), 2.36 (s, 65% 3H), 2.03–2.32 (3H), 1.74–1.94 (1H), 1.48–1.66 (1H); MS (CI, isobutane) *m/z*: 198 (100), 166 (23). Anal. calcd. for $C_{10}H_{15}NO_3$: C 60.89, H 7.67, N 7.10; found: C 60.59, H 7.72, N 6.98.

2-Benzoyl-8-methyl-8-azabicyclo[3.2.1]oct-2-en-3-ol (8c)

The general procedure was followed with benzoyl chloride (2.6 mmol; 0.3 mL, 2.5 equivalents) as the electrophile. The mixture was stirred at −78°C for 30 min, before saturated NH_4Cl solution (2 mL) was added to the reaction mixture. Na_2CO_3 solution (40%) was added to the resulting yellow mixture until pH ~9. Extraction, followed by column chromatography (SiO_2, 5% MeOH in $CHCl_3$), yielded a yellow solid of **8***c* (150 mg; 62%); mp 75.2–77.2°C; IR (KBr) 3058, 2945, 2849, 2796, 1716, 1678, 1595, 1568, 1447, 1400, 1273, 1146, 697 cm^{-1}; ^1H NMR δ: 7.43–7.57 (m, 5H), 3.82 (d, J = 6.0 Hz, 1H), 3.41 (t, J = 6.1 Hz, 1H), 2.91 (ddd, J_1 = 19.3 Hz, J_2 = 5.5 Hz, J_3 = 1.9 Hz, 1H), 2.28–2.42 (m, 1H), 2.32 (s, 3H), 2.22 (t, J = 9.5 Hz, 2H), 2.02 (m, 1H), 1.70 (m, 1H); ^{13}C NMR δ: 195.6 (CO), 181.2 (OC=C), 135.6 (C), 130.6 (CH), 128.3 (CH), 128.1 (CH), 112.8 (C=C), 59.6 (CH), 58.0 (CH), 40.4 (CH_2), 37.1 (NCH_3), 33.9 (CH_2), 29.2 (CH_2); MS (EI) *m/z*: 245 (0.7), 244 (5.4), 243 (21.2), 215 (54.1), 214 (100.0), 136 (20.6), 110 (12.2), 105 (39.5), 82 (52.8). Anal. calcd. for $C_{15}H_{17}NO_2$: C 74.05, H 7.04, N 5.76; found: C 73.83, H 6.82, N 5.51.

2-(1, 2-Dicarbethoxyhydrazo)-8-methyl-8-azabicyclo[3.2.1]-octan-3-one (8d)

DEAD (1.9 mmol; 0.3 mL) was added to a solution of tropinone lithium enolate (1.0 mmol) in THF (3.2 mL) and the mixture was stirred at −78°C for 30 min. After standard work-up the yellowish, oily product **8***d* was obtained (295 mg, 94%). The product was purified by flash chromatography (SiO_2; 5% MeOH in $CHCl_3$). The purified product **8***d* was a yellow solid (250 mg, 80%): mp 81.2–82.2°C; IR (KBr) 3295, 3252, 2978, 2957, 2883, 2766, 1746, 1712, 1508, 1468, 1302, 1231, 1095 cm^{-1}; ^1H NMR δ: 6.81–7.09 (br, 1H), 4.99–5.21 (br, 1H), 4.13 (q, J = 7.0 Hz, 4H), 3.58–3.68 (br, 1H), 3.41 (br, 1H), 2.69 (d, J = 15.1 Hz, 1H), 2.52 (br, 3H), 2.23 (d, J = 15.3 Hz, 1H), 1.80–2.12 (br, 3H), 1.49 (m, 1H), 1.19 (two overlap. t, J = 7.0 Hz, 6H); ^{13}C NMR δ: 205.4 (CO), 204.9 (CO), 156.6 (COO), 156.0 (COO), 65.1 (CH), 64.8 (CH), 62.8 (OCH_2), 61.8 (OCH_2), 61.3 (CH), 61.0 (CH), 46.7 (CH_2), 46.4 (CH_2), 38.5 (CH), 37.4 (CH_3), 37.2 (CH_3), 27.9 (CH_2), 27.5 (CH_2), 24.5 (CH_2), 24.2 (CH_2), 14.4 (CH_3), 14.3 (CH_3); MS (CI (NH_3)) *m/z*: 316 (2.6), 315 (17.5), 314 (100.0), 313 (12.3), 225 (20.3), 85 (20.2), 83 (31.2), 82 (37.2). Anal. calcd. for $C_{14}H_{23}N_3O_5$: C 53.66, H 7.40, N 13.41; found: C 53.57, H 7.58, N 13.58.

(exo)-2-Deutero-8-methyl-8-azabicyclo[3.2.1]octan-3-one (8e)

n-Butyllithium (2.2 mmol; 1.05 mL of 2.1 molar solution in hexane), was added dropwise to a solution of tropinone lithium enolate (2.0 mmol) in THF (5.2 mL) at −78°C, and the mixture was then warmed to 0°C for 20 min. The reaction mixture was then cooled down to −78°C, D_2O (5 mL, 99% D) was added, and the mixture was warmed first to 0°C for 3 min, then to room temperature. Extraction and removal of the solvents using first a rotary evaporator and then high vacuum gave a greenish solid.

Pentane was added to the crude solid dropwise at 40°C until all the solid had dissolved. The solution was then cooled down to −30°C for several hours. The solvent was removed from the crystals at this low temperature via a syringe, and the crystals of the pure **8***e* were washed with cold pentane. Yield: 227 mg; 81%; mp 40.5–42.0°C; IR (KBr): 3387, 2934, 2882, 2855, 2802, 1714, 1592, 1476, 1348 cm^{-1}; ^1H NMR δ: 3.44 (br, 2H), 2.69 (dd, J_1 = 4.0 Hz, J_2 = 16.0 Hz, 1H), 2.49 (s, 3H), 2.20 (d, J = 15.3 Hz, 2H), 2.11 (m, 2H), 1.61 (m, 2H); ^{13}C NMR δ: 211.1 (CO), 60.7 (CH), 47.6 (CH_2), 47.3 (t, J = 18.2 Hz, CHD), 38.3 (CH_3), 27.6 (CH_2); MS (CI (NH_3)) *m/z*: 144 (18.0), 143 (20.3), 142 (69.8), 141 (100.0), 140 (84.2), 138 (17.0), 83 (91.9).

(exo, exo)-2,4-Dideutero-8-methyl-8-azabicyclo[3.2.1]octan-3-one (17)

2-Deuterotropinone (**8***e*) (1.0 mmol; 140 mg) in THF (1.2 mL) solution was added dropwise to a solution of LDA (1.1 mmol) in THF (3.2 mL) at −78°C. After 40 min, *n*-BuLi (1.1 mmol; 0.52 mL of 2.1 molar solution in hexane) was added slowly to the mixture at −78°C. The mixture was then warmed to 0°C for 20 min and cooled down to −78°C again. D_2O (5 mL, 99%D) was added to the reaction mixture at −78°C, and then warmed to 0°C for 3 min, then to room temperature. Extraction and removal of solvents by rotary evaporator, followed by high vacuum, gave a greenish solid (141 mg; 100%). The solid was purified by crystallization from pentane as described above. Yield: 110 mg (78%), mp 42–43°C; IR (KBr): 2932, 2882, 2856, 2802, 2216, 1702, 1475, 1344, 1146, 483, 453 cm^{-1}; ^1H NMR δ: 3.45 (br, 2H), 2.70 (dd, J_1 = 3.9 Hz, J_2 = 16.0 Hz, 33% of 2H), 2.50 (s, 3H), 2.20 (d, J = 15.4 Hz, 2H), 2.12 (m, 2H), 1.61 (m, 2H); ^{13}C NMR δ: 211.1 (CO), 60.7 (CH), 47.6 (CH_2), 47.3 (t, J = 18.2 Hz, CHD), 38.3 (CH_3), 27.6 (CH_2); MS (CI − NH_3) *m/z*: 145 (8.4), 144 (46.2), 143 (83.4), 142 (100.0), 141 (69.8), 140 (29.3).

6-(N-Carbethoxy-N-methyl)aminocyclohept-2-en-1-one (9)

Ethyl chloroformate (4.7 mmol; 0.45 mL) was added slowly to a solution of tropinone lithium enolate (1.0 mmol) in THF (3.2 mL) and stirred for 10 min at −78°C. Saturated NH_4Cl solution (2 mL) was added at −78°C, the mixture was warmed to room temperature, and 40% Na_2CO_3 solution (3 mL) was added to make the mixture basic. The organic layer was separated, and the aqueous layer was extracted with chloroform (4 × 5 mL). After drying (Na_2SO_4) and removal of the solvent from the combined organic layers the product was purified by chromatography (SiO_2, 4:1 hexane:AcOEt). Yellow oil (184 mg; 87%), bp 275°C; IR (KBr): 3022, 2978, 2936, 2872, 1693, 1667, 1483, 1405, 1314, 1155, 772 cm^{-1}; ^1H NMR δ: 6.64 (ddd, J_1 = 11.5 Hz, J_2 = 6.3 Hz, J_3 = 4.6 Hz, 1H), 6.04 (d, J = 12.1 Hz, 1H), 4.60 (br, 1H), 4.14 (q, J = 7.1 Hz, 2H), 2.84 (m, 2H), 2.80 (s, 3H), 2.42–2.68 (m, 2H), 1.87–2.14 (m, 2H), 1.26 (t, J = 7.1 Hz, 3H); ^{13}C NMR δ: 14.4 (OCH_2CH_3), 29.0 (CH), 30.4 (CH_2), 47.8 (CH_2), 50.9 (NCH_3), 61.0 (OCH_2CH_3), 132.2 (CH), 146.2 (CH), 155.6 (NCOO), 200.3 (CO); MS (EI, 20eV) *m/z*: 211 (60), 138 (66), 108 (95), 104 (100). Anal. calcd. for $C_{11}H_{17}NO_3$: C 62.54, H 8.11, N 6.63; found: C 62.70, H 8.38; N 6.76.

Methyl 4-[2'-(5'-cyano-1'-methylpyrrolidinyl)]-3-oxo-butyrate (10)

12-Crown-4 (1.1 mmol; 0.194 g) in THF (1 mL) was added to a solution of tropinone lithium enolate (1.0 mmol) in THF (3.2 mL) at −78°C. The mixture was warmed to 0°C for 10 min, and was then cooled to −78°C. Methyl cyanoformate (1.3 mmol; 0.1 mL) was added and the reaction mixture was stirred for 30 min at −78°C. After the standard work-up, and the removal of solvents, the crude product was purified by chromatography (SiO_2, 1:1 hexane:AcOEt), yielding a white solid (165 mg; 74%). Mp 78.8–79.8°C; IR (KBr): 2954, 2855, 2799, 2242, 1745, 1715, 1630, 1565, 1437, 1323, 1258, 1198, 1161, 1048 cm^{-1}; ^1H NMR δ: 3.93 (d, J = 6.7 Hz, 1H), 3.75 (s, 3H), 3.48 (s, 2H), 2.98 (m, 1H), 2.87 (dd, J_1 = 17.0 Hz, J_2 = 3.8 Hz, 1H), 2.58 (q, J = 8.5 Hz, 1H), 2.43 (s, 3H), 2.34 (m, 1H), 2.02–2.18 (m, 2H), 1.58 (m, 1H); ^{13}C NMR δ: 201.0 (CO), 167.4 (COO), 117.3 (CN), 58.3 (OCH3), 56.5 (CH), 52.4 (CH), 49.6 (CH_2), 47.0 (CH_2), 36.6 (NCH_3), 29.2 (CH_2), 28.0 (CH_2); MS (CI, NH_3) *m/z*: 227 (1.4), 226 (13.0), 225 (97.3), 224 (2.0), 198 (39.7), 109 (100.0), 82

(24.4), 225 (46.0), 198 (100.0), 109 (19.0), 82 (12.0). Anal. calcd. for $C_{11}H_{16}N_2O_3$: C 58.91, H 7.19, C 12.49; found: C 58.76, H 7.12, C 12.71.

*Methyl (*endo, endo*)-3-hydroxy-8-methyl-8-azabicyclo[3.2.1]-octane-2-carboxylate (**25**) and methyl (2-*endo, *3-*exo*)-3-hydroxy-8-methyl-8-azabicyclo[3.2.1]octane-2-carboxylate (**26**)*

Compound **8***b* (1.0 mmol; 0.197 g) was dissolved in absolute ethanol (2.5 mL) at room temperature, and the solution was then cooled down to −60°C. Sodium borohydride (5.3 mmol; 0.200 g) was added to the clear solution. A small amount of solid NH_4Cl was then added to the mixture followed by addition of saturated NH_4Cl solution (0.5 mL). The reaction mixture was stirred at −60°C for 3 h, was then allowed to warm to room temperature, and stirred overnight. The excess of $NaBH_4$ was destroyed by adding acetic acid (glacial) dropwise. The solvent and excess AcOH were removed on a rotary evaporator, and the residue was dissolved in $CHCl_3$ (10 mL). Na_2CO_3 (40% solution, 5 mL) was added and the mixture was then extracted with $CHCl_3$ (4 × 15 mL). After washing with water, the combined organic layers were dried (Na_2SO_4). The solvent was removed and the crude product was dried under high vacuum, yielding an oily solid (159 mg; 80%). ^{1}H NMR showed that the product contained 86% of **25** and 14% of **26**.

These two isomers were separated by flash chromatography (SiO_2, 5% MeOH in $CHCl_3$); **26** (20 mg; 10%) was eluted first followed by **25** (133 mg; 67%).

Compound **25**: IR (neat): 3700–3100, 1740 cm^{-1}; ^{1}H NMR δ: 4.28 (t, J = 4.5 Hz, 1H), 3.76 (s, 3H), 3.49 (br, 1H), 3.23 (br, 1H, OH), 3.17 (br, 1H), 3.00 (t, J = 3.5 Hz, 1H), 2.32 (s, 3H), 1.94–2.16 (m, 5H), 1.82 (m, 1H); ^{13}C NMR δ: 24.2 (CH_2), 25.8 (CH_2), 38.7 (CH_2), 40.0 (CH), 50.0 (CH), 52.0 (CH), 60.3 (NCH_3), 62.1 (CH), 64.9 (OCH_3), 173.9 (CO); MS (EI) *m/z*: 199 (15), 97 (58), 96 (78), 83 (58), 82 (100). *Anhydroecgonine methyl ester (**27**) (ref. 20*a*)*

(*a*) (±)-(**27**): Triphenylphosphine oxide (0.4 mmol; 0.111 g) was dissolved in anhydrous dichloromethane (0.5 mL) and placed in a septum-sealed 10-mL round-bottom flask at 0°C, under argon. Trifluoromethanesulfonic anhydride (0.2 mmol; 34 mL) in anhydrous dichloromethane (0.5 mL) was added dropwise to the reaction mixture with constant stirring. The reddish colour of triphenylphosphine oxide solution disappeared immediately after the triflic anhydride had been added. Racemic compound **26** (0.1 mmol; 20 mg) in dry dichloromethane (0.5 mL) was added slowly at 0°C, and the reaction mixture was then warmed to room temperature and stirred for 15 min. Anhydrous triethylamine (0.5 mL) was added to the reaction mixture and the reddish color appeared again. After 15 min, the reaction was quenched with water (2 mL), and then extracted with diethyl ether (5 × 5 mL). The combined organic layers were dried over anhydrous sodium sulfate. After removal of the solvent, the residue was subjected to separation on a short column (SiO_2, 3% MeOH in $CHCl_3$), which yielded the purified product (15 mg; 83%).

(*b*) (+)-(**27**): Non-racemic **25** (5.5 mmol; 1.1 g), was prepared as previously described using chiral base **22**, and dissolved in anhydrous dichloromethane (4 mL) in a septum-sealed 10-mL round-bottom flask at 0°C, under argon. Anhydrous triethylamine (15.8 mmol; 2.2 mL) was added, followed by a catalytic amount of 4-(dimethylamino)pyridine in dichloromethane (1.2 mL) solution. The solution was stirred and trifluoroacetic anhydride (7.1 mmol, 1.0 mL) in dichloromethane (2.5 mL) was added dropwise during 20 min. After stirring for an additional 2 h at 0°C, the reaction mixture was warmed to room temperature and stirred for another 30 h. The reaction mixture was then cooled down to 0°C again, and treated with dilute Na_2CO_3 solution until the solution became basic. The mixture was extracted with chloroform (5 × 30 mL), and the combined organic layers were washed (H_2O), and then dried (Na_2SO_4). After removal of the solvent, the mixture was subjected to flash chromatography (SiO_2, 3% MeOH in $CHCl_3$). A colorless oil was obtained (925 mg; 93%): $[\alpha]_D^{20}$ + 9.2 (*c* 0.1084 g/mL, MeOH), IR (KBr): 2949, 2876, 2843, 2793, 1711, 1639, 1436, 1253, 1084, 753, 728 cm^{-1}; ^{1}H NMR δ: 1.52 (m, 1H), 1.85 (t, J = 9.8 Hz, 1H), 1.88 (dd, J_1 = 19.6 Hz, J_2 = 4.7 Hz, 1H), 2.18 (m, 2H), 2.37 (s, 3H), 2.65 (m, 1H), 3.28 (m, 1H), 3.75 (s, 3H), 3.83 (m, 1H), 6.83 (m, 1H); ^{13}C NMR δ: 30.1 (CH_2), 31.6 (CH_2), 34.5 (CH_2), 36.8 (CH), 51.8 (NCH_3), 57.0 (OCH_3), 134.0 (C), 136.2 (CH), 166.7 (CO); MS (CI (NH_3)) *m/z*: 182 (100), 181 (15.6), 152 (15.3).

Synthesis of chiral amines

(*S*)-(+)-1-(2-Pyrrolidinylmethyl)pyrrolidine **18***a*, which was the precursor to base **18**, was purchased from Aldrich and dried prior to use (CaH_2). Amines used for generating **21–24** were synthesized by methods reported in the literature (23). Amines that were the source of compounds **19** and **20** were synthesized by reductive amination (see below).

*(+)-(1S, 2S, 5S)-N-Phenyl-4,6,6-trimethylbicyclo[3.1.1]hept-3-enylamine (**19**a)*

Aniline (9.0 mmol; 0.83 g), and glacial acetic acid (15 mL) were placed under argon. (1*S*)-(−)-Verbenone (1.0 mmol; 0.154 mL) was then slowly added to this solution at room temperature and the reaction mixture was stirred for 4 h. Sodium borohydride (5.3 mmol; 200 mg) was then added in small portions and the turbid mixture was stirred at room temperature overnight under argon. Aqueous HCl solution (10%) was added to acidify the mixture, and acetic acid was then removed on a rotary evaporator. The residue was dissolved in chloroform (10 mL) and aqueous sodium carbonate solution (40%) was added until the mixture became basic. The mixture was then extracted with chloroform (4 × 20 mL). After washing with water, the combined organic layers were dried over anhydrous sodium sulfate. The solvent was removed and the crude product was purified by chromatography (SiO_2, 4:1 *n*-hexane:ethyl acetate). Yield: 191 mg, $[\alpha]_D^{20}$ + 25.0 (*c* 0.0162 g/mL, $CHCl_3$); IR (KBr): 3429, 3049, 2922, 2867, 1600, 1502, 1428, 746, 691 cm^{-1}; ^{1}H NMR δ: 7.17 (td, J_1 = 7.4 Hz, J_2 = 1.0 Hz, 2H), 6.68 (t, J = 6.4 Hz, 1H), 6.60 (d, J = 7.7 Hz, 2H), 5.38 (br, 1H), 4.30 (br, 1H), 3.90 (br, 1H (NH)), 2.50 (m, 1H), 2.43 (m, 1H), 2.01 (t, J = 6.2 Hz, 1H), 1.74 (t, J = 1.8 Hz, 3H), 1.41 (d, J = 8.8 Hz, 1H), 1.32 (s, 3H), 1.07 (s, 3H); ^{13}C NMR δ: 147.8 (C), 147.5 (C), 130.1 (CH), 118.4 (CH), 117.5 (CH), 113.5 (CH), 56.5 (CH), 47.8 (CH), 45.2 (CH), 39.0 (CH_2), 35.0 (CH_2), 27.0 (CH_3), 23.0 (CH_3), 22.8 (CH_3); MS (CI (NH_3)) *m/z*: 229 (14.6), 228 (77.5), 227 (13.2), 135 (50.1), 94 (100.0). Anal. calcd. for $C_{16}H_{21}N$: C 84.53, H 9.31, N 6.16; found: C 84.40, H 9.02, N 6.15.

*(−)-(1R), 2R, 5S)-N-Phenyl-6,6-dimethylbicyclo[3.1.1]-heptanylamine (**20**a)*

Analogous procedure using (1*R*)-(+)-nopinone (1.0 mmol) and aniline yielded a yellowish oil, **20***a* (204 mg, 95%). After purification by flash chromatography, a colorless liquid was obtained (189 mg; 88%): bp 302°C; $[\alpha]_D^{20}$ −75.3 (*c* 0.1142 g/mL, $CHCl_3$); IR (KBr): 3421, 3050, 2911, 2867, 1601, 1502, 1465, 1315, 746, 691 cm^{-1}; ^{1}H NMR δ: 7.15 (t, J = 7.5 Hz, 2H), 6.65 (t, 7.3 Hz, 1H), 6.34 (d, J = 8.5 Hz, 2H), 3.94 (m, 1H), 3.81 (br, 1H (NH)), 2.28–2.48 (m, 2H), 2.19 (br, 1H), 1.98 (m, 2H), 1.88 (m, 1H), 1.61 (m, 1H), 1.21 (s, 3H), 1.12 (s, 3H), 1.03 (d, J = 10.0 Hz, 1H); ^{13}C NMR δ: 23.2 (CH_3), 24.7 (CH_2), 25.2 (CH_2), 27.8 (CH_3),

30.0 (C), 38.0 (CH_2), 41.1 (CH), 45.6 (CH), 54.9 (CH), 113.1 (CH), 116.9 (CH), 129.4 (CH), 147.6 (C); MS (CI (NH_3)) *m/z*: 217 (17.2), 216 (100); Anal. calcd. for $C_{15}H_{21}N$: C 83.67, H 9.83, N 6.50; found: C 83.77, H 9.71, N 6.47.

Lewis acid mediated Diels–Alder reactions of 2*H*-thiopyrans

DALE E. WARD[1] AND YUANZHU GAI

Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received April 13, 1992

DALE E. WARD and YUANZHU GAI. Can. J. Chem. **70**, 2627 (1992).

Lewis acid mediated Diels–Alder reactions of 2*H*-thiopyrans with acrylate, crotonate, and methacrylate dienophiles have been investigated. Modest to good yields of predominantly *exo* adducts are obtained with 4-substituted 2*H*-thiopyrans. With 5-substituted 2*H*-thiopyrans, high *endo* selectivity is observed. No adducts were produced with methacrylate dienophiles. Relative to the thermal reactions, the *exo* selectivity is enhanced in the presence of Lewis acids. Unusually high *exo* selectivity is observed using "wet" Et_2AlCl as the promoter.

DALE E. WARD et YUANZHU GAI. Can. J. Chem. **70**, 2627 (1992).

On a étudié les réactions de Diels–Alder catalysées par des acides de Lewis entre des 2*H*-thiopyranes et des acrylate, crotonate et méthacrylate agissant comme diénophiles. Avec les 2*H*-thiopyranes substitués en position 4, on a obtenu des rendements allant de modestes à bons d'adduits principalement *exo*. Avec les 2*H*-thiopyranes substitués en position 5, on observe une sélectivité élevée de produits *endo*. Il ne se produit aucun adduit lorsque le méthacrylate agit comme diénophile. Comparées aux réactions thermiques, la sélectivité *exo* est améliorée en présence d'acide de Lewis. On observe une sélectivité anormalement élevée en faveur de l'*exo* lorsque du Et_2AlCl «humide» est utilisé comme promoteur.

Introduction

The lack of reactivity associated with *cis*-substituted 1,3-dienes (1) is a significant limitation of the Diels–Alder reaction (2). In an effort to address this problem, we have recently investigated (3) a strategy involving the use of 2*H*-thiopyrans as functional equivalents to *cis*-dienes. Diels–Alder reactions of 2*H*-thiopyrans with dienophiles can provide adducts that, after desulfurization, are synthetically equivalent to an adduct derived from a *cis*-diene (3).

The reactions of various 2*H*-thiopyrans bearing electron-donating substituents with reactive dienophiles such as maleic anhydride or maleimide provide good to excellent yields of predominantly *endo* adducts. However, with less reactive dienophiles such as methyl acrylate or butenone the reactions are considerably slower and thermal decomposition of the dienes competes effectively with cycloaddition. Although the regioselectivity is high compared to reactions with related acyclic dienes (3*b*), the lower yields and poor stereoselectivity observed in the reactions of 2*H*-thiopyrans with less reactive dienophiles limits potential synthetic applications. In an attempt to improve yields and stereoselectivity by producing adducts at lower temperatures we have examined the effect of Lewis acids on these reactions (2, 4). The results are presented in Tables 1–3.

Results and discussion

Initially we investigated the reaction of **1***a* with methyl acrylate (**2***a*). The Diels–Alder reaction proceeds at 120°C in toluene (sealed tube) to give a 1.7:1 mixture of *endo* and *exo* adducts, **5***a* and **5***b* respectively, in 56% yield after 6 days (3) (Table 1, entry 1). The efficacy of various Lewis acids in promoting the reaction at lower temperatures was evaluated. The addition of various amounts of $TiCl_4$, $SnCl_4$, or Et_2AlCl to a solution of **1***a* and **2***a* in CH_2Cl_2 at −78°C or room temperature failed to produce the desired adducts; the only products resulted from hydrolysis of **1***a*. Eventually, we found that Diels–Alder adducts were produced at room temperature in the presence of $BF_3 \cdot Et_2O$ (Table 1, entry 5) or, better, $EtAlCl_2$ (Table 1, entries 6–9). The adducts obtained were a mixture of **5***a* and **5***b* together with their products of silyl enol ether hydrolysis, **7***a* and **7***b*. Analysis of the reaction products was simplified by employing an acidic work-up that effected the hydrolysis of **5***a* and **5***b* and resulted in the isolation of **7***a* and **7***b* as the only adducts.

The stereochemistry of **7** was readily determined, as previously (3*a*), by analysis of the coupling constants observed in the ^1H NMR spectra. The *endo* proton at C-5 was readily assigned based on its $^4J_{HH}$ with H-3_{anti} (2–2.5 Hz). The stereochemistry of the proton at C-6 was determined based on its $^3J_{HH}$ with H-5_{endo} (for **7***b*, J = 11 Hz; for **7***a*, J = 6 Hz) and its $^4J_{HH}$ with H-7_{exo} (for **7***b*, J = 0 Hz; for **7***a*, J = 2.5 Hz). Stereochemical assignments were independently confirmed by hydrolysis (CF_3CO_2H, CH_2Cl_2) of the individual isomers (3*a*) **5***a* and **5***b* to give **7***a* and **7***b*, respectively.[2]

The use of $EtAlCl_2$ was also effective in promoting the reaction of **1***a* with *N*-phenylmaleimide (**1***c*) to produce the *endo* adduct **11** in yields similar to that obtained in the thermal reaction (Table 1, cf. entries 10 and 12) (3*a*). Comparing with the reactions of **2***a*, the yield and stereoselectivity obtained in the reactions of *N*-phenylmaleimide were not as sensitive to the amount of Lewis acid employed. Other Lewis acids were not as effective in promoting the reaction. In contrast to the thermal reaction, the *exo* adduct could not be detected in the ^1H NMR spectrum of the crude product from the Lewis acid mediated reactions. Several attempts to effect reaction of **1***a* with methyl crotonate (**3***a*) or methyl methacrylate (**4***a*) were unsuccessful (Table 1, entries 15, 16).

In an effort to improve on both the scope and stereoselectivity of Diels–Alder reactions with acrylate derivatives we examined substrates incorporating an oxazolidone auxiliary (5). *N*-Alkenoyloxazolidones have been reported to be reactive acrylate equivalents (6) in Lewis acid mediated Diels–Alder reactions producing adducts with high stereoselectiv-

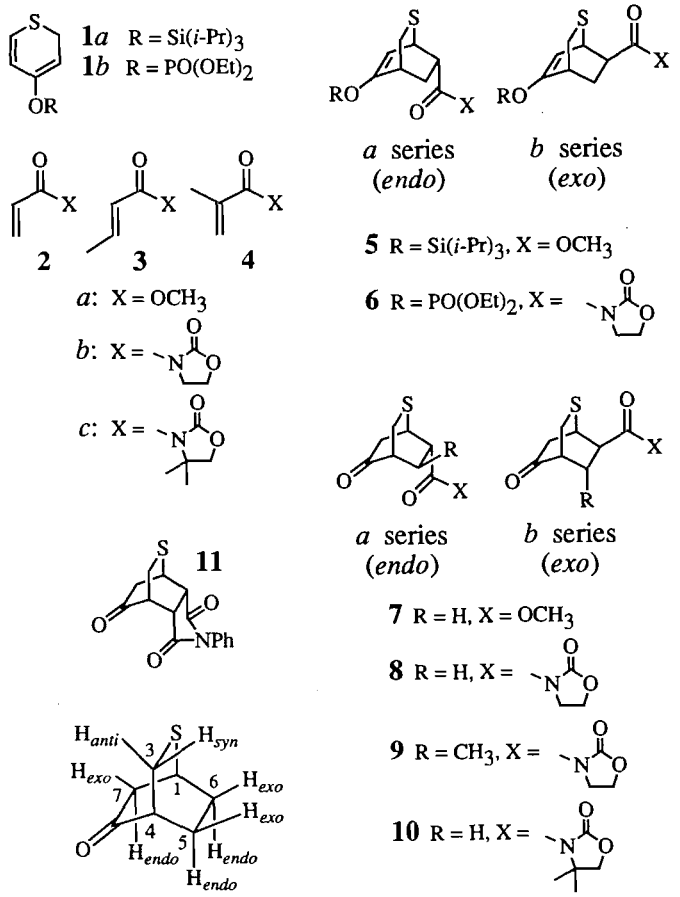
ity (7–9). The results are presented in Table 1 (entries 17–45).



Surprisingly, the reaction of **1***a* with **2***b* in the presence of excess Et_2AlCl under the published conditions[3] did not produce an adduct after 1 h at −78°C or at room temperature (Table 1, entry 18). A similar reaction mediated by Me_2AlCl at −78°C gave a 1.7:1 mixture of the adducts **8***b* and **8***a* in low yield after work-up (Table 1, entry 19). The stereochemistry of the adducts was assigned on the basis of ^1H NMR as outlined above. The difference in the results obtained with Et_2AlCl and Me_2AlCl might be due to the higher propensity of the former to add to **2***b* in a 1,4 sense in competition with cycloaddition of **2***b* to an unreactive diene (7, 10).

A survey of various Lewis acids eventually revealed that the reaction of **1***a* with **2***b* could be effectively promoted by $TiCl_4$ (Table 1, entries 22–31). Best results were obtained by "buffering" the $TiCl_4$ with $Ti(i\text{-}PrO)_4$ (11). The yield of adducts was sensitive to the amount of $TiCl_4$ (Table 1, cf. entries 25–28) as well to the ratio of $TiCl_4$ to **2***b* (Table 1, cf. entries 22 and 26). The degree of *exo* stereoselectivity was enhanced in reactions conducted at lower temperatures (Table 1, cf. entries 22 and 23), with more $TiCl_4$ (Table 1, cf. entries 25 and 28), or with added $Ti(i\text{-}PrO)_4$ (Table 1, cf. entries 26 and 30).

Under similar conditions, a modest yield of Diels–Alder adducts was obtained from the reaction of **1***a* with **3***b* (Table 1, entries 32–34). By contrast, adducts were not detected in attempted reactions of **1***a* and **4***b*. The stereochemistry of the adducts **9***a* and **9***b* was evident based on analysis of the coupling constants between H-7_{exo} and H-6 (for **9***b*, ^4J = 0 Hz; for **9***a*, ^4J = 1 Hz) and between H-3_{anti} and H-5 (for **9***b*, ^3J = 0 Hz; for **9***a*, ^3J = 1 Hz). The coupling constants observed between H-6 and H-5 (for **9***b*, ^3J = 6.5 Hz; for **9***a*, ^3J = 7.5 Hz) were consistent with a *trans* relationship between the C-5 methyl group and the C-6 acyl group.

The low stereoselectivity observed in reactions with **2***b* prompted us to examine the dimethyl derivative **2***c* (8*c*). The results are presented in Table 1 (entries 36–45). The thermal reaction of **1***a* with **2***c* modest *endo* selectivity. Reactions mediated by various Lewis acids were consistently *exo* selective. After considerable experimentation we were able to produce the *exo* adduct **10***b* with high stereoselectivity and in good yield using "wet" Et_2AlCl as the mediator (5). Reactions of **1***a* with **3***c* failed to produce any cycloaddition products under a variety of conditions.

The major by-products in the above reactions resulted from the decomposition of the diene. The use of dienol phosphates as stable analogues of dienol silyl ethers has recently been reported (12). Diels–Alder adducts were not obtained in thermal reactions of **1***b* with acrylate derivatives (3*a*). We briefly examined the reaction of **1***b* with **2***b* in the presence of $TiCl_4$ and the results are presented in Table 2. At best, a modest yield of Diels–Alder adducts was obtained as a 1.5:1 mixture of *exo*:*endo* isomers. No adducts could be detected in similar reactions of **1***b* with **3***b* or with **4***b*.

The thermal Diels–Alder reactions of **1***a* with **2***a*, **2***b*, or **2***c* are unselective or show modest *endo* selectivity. Interestingly, in all of the Lewis acid mediated reactions examined the *exo* adducts are the major diastereomers produced.[4] By contrast, both thermal (13) and Lewis acid mediated (14) Diels–Alder reactions of 1,3-cyclohexadienes typically give predominantly *endo* adducts with varying levels of diastereoselectivity. Similarly, Diels–Alder reactions of both 1,2-dihyropyridines (15) and 2-pyranones (16) are typically *endo* selective. With the exception of reactions with methacrylate derivatives (17), very few examples of *exo*-selective Diels–Alder reactions of 1,3-cyclohexadienes have been reported (13*g*, 18, 19). Specifically, Diels–Alder reactions of 1,3-bis(trialkylsilyloxy)-1,3-cyclohexadienes are highly *exo* selective both under thermal (18, 19) and Lewis acid mediated (18) conditions; the reason(s) for this unusual behavior is unknown.

To test the generality of this *exo* selective process with 2*H*-thiopyrans we examined the Diels–Alder reactions of 5-triisopropylsilyloxy-2*H*-thiopyran (**12**) (3*a*). The propensity for **12** to rearrange into the unreactive 3-substituted isomer **13** precluded thermal reactions with acrylate dienophiles (3*a*). Lewis acid mediated reactions of **12** with *N*-phenylmaleimide, **2***a*, **2***b*, and **2***c* were repeated under conditions that

[3]Under these conditions cyclopentadiene reacts with **2***b* at −100°C "within seconds" to produce the *endo* adduct in quantitative yield (7).

[4]We assume that the observed *endo*:*exo* ratios result from kinetic control since: (*i*) the *endo*:*exo* ratios do not appear to change during the course of the reactions; (*ii*) samples of **5***a* and **7***a* treated with $EtAlCl_2$ were shown to be configurationally stable; (*iii*) a 1:1 mixture of the triisopropylsilyl enol ethers corresponding to **10***a*,*b* was unchanged after treatment with Me_2AlCl at room temperature; (*iv*) samples of **10***a* and **17***a* were unchanged after treatment with Me_2AlCl at room temperature.

TABLE 2. Diels–Alder reactions of **1***b* with **2***b*, **3***b*, and **4***b*[a]

Entry	Dienophile[b]	Lewis acid[b]	Product	Yield (%)	*exo*:*endo*[c]
1.	**2***b* (1.5)	$TiCl_4$(0.7)	**6**	Trace	—
2.	**2***b* (1.5)	$TiCl_4$(1.0)	**6**	38	1.5:1
3.	**2***b* (1.5)	$TiCl_4$(1.0)[d]	**6**	49	1.4:1
4.	**2***b* (1.5)	$TiCl_4$(1.0) $Ti(i\text{-}PrO)_4$(0.2)	**6**	41	1.6:1
5.	**2***b* (1.5)	$TiCl_4$(1.0) $Ti(i\text{-}PrO)_4$(0.2)[d]	**6**	51	1.5:1
6.	**2***b* (1.5)	$SnCl_4$(0.7)	**6**	Trace	—
7.	**3***b* (1.5)	$TiCl_4$(1.0)	—	—	—
8.	**4***b* (1.5)	$TiCl_4$(1.0)	—	—	—

[a]Unless otherwise noted, reactions carried out with 0.1–0.15 mmol of **1***b* in CH_2Cl_2 (2 mL) at room temperature.
[b]The number of equivalents based on **1***a* indicated in parentheses.
[c]Measured by weight of isolated adducts.
[d]Reaction carried out at 40°C.

proved successful for **1***a*. The results are presented in Table 3.

Reaction of **12** with *N*-phenylmaleimide (**1***c*) mediated by $EtAlCl_2$ gave the *endo* adduct **14** in low yield along with **13** (60%). The stereochemistry of the product was assigned based on the coupling observed in the ^1H NMR spectrum between H-8_{exo} and H-5 (^4J = 2 Hz) and was confirmed by hydrolysis (CF_3CO_2H, CH_2Cl_2) of the known (3*a*) *endo* triisopropylsilyl enol ether.

Reaction of **12** with **2***a* in the presence of $EtAlCl_2$ at room temperature gave a good yield of adducts as a 1.4:1 mixture of stereoisomers **15** (Table 3, entry 3). Severe congestion of resonances in the ^1H NMR spectrum of the adducts prevented definitive assignment of stereochemistry. Alternatively, reaction of **12** with **2***b* in the presence of $TiCl_4$ gave a single adduct that was identified as **16***a* together with rearranged diene **13** (30%) (Table 3, entries 4, 5). In the ^1H NMR spectrum of **16***a*, H-5 was coupled to H-8_{exo} (^4J = 1.5 Hz) but not to H-3_{anti} (*dd*, *J* = 3, 10.5 Hz). The stereochemistry of the major adduct from the reaction of **12** and **2***a* was assigned as *endo* (**15***a*) based on the close correspondence of its ^{13}C NMR spectrum with that of **16***a*. Reactions of **12** and **2***c* in the presence of Me_2AlCl or $TiCl_4$ were also highly *endo* selective (Table 3, entries 8, 9). Surprisingly, the same reaction mediated by "wet" Et_2AlCl (5) resulted in poor stereoselectivity (Table 3, entry 11). Adducts were not detected in similar reactions of **1***a* with **3***c*.

endo Addition is generally the preferred mode of the Diels–Alder reaction (1). Various factors have been proposed to rationalize the *endo*:*exo* ratios in Diels–Alder reactions including secondary orbital interactions, steric effects, and dipole–dipole interactions (1). The small difference in the activation energy of *endo* and *exo* transition states, however, means that relatively subtle changes in the transition

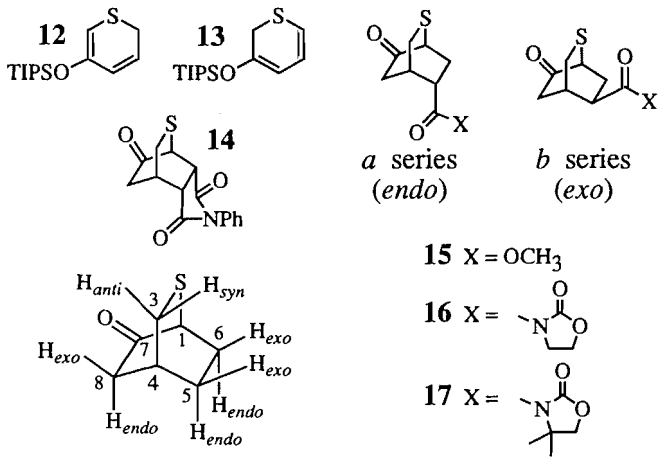
state structure can result in large changes in the *endo*:*exo* ratio (20). Lewis acid mediated Diels–Alder reactions typically display enhanced *endo* selectivity relative to their thermal counterparts (2, 4, 21). Compared to other cyclic dienes, **1***a* is unusual since the portion of *exo* adduct increases when reactions are conducted in the presence of Lewis acids.[4] This behavior is presumably due to structural and (or) mechanistic consequences resulting from the replacement of a methylene group in a 1,3-cyclohexadiene skeleton with a sulfur atom.



The 1,3-diene of 2*H*-thiopyran deviates significantly from planarity and shows little conjugation with the sulfur atom (22). Diels–Alder reaction with methyl acrylate (**2***a*), however, is completely regioselective and gives predominantly the *endo* adduct corresponding to **5***a* (i.e., **5***a* with OR = H) (23). The mechanism of Lewis acid mediated cycloaddition with silyloxy substituted 2*H*-thiopyrans **1***a* and **12** is uncertain. Several examples of cycloaddition reactions of both cyclic (14*c*–*e*) and acyclic (24; see also ref. 11*a*) silyloxy dienes with dienophiles in the presence of Lewis acids have been proposed to proceed through a stepwise double Michael reaction mechanism. The evidence presented in favor of the two-step mechanism typically involves the detection or isolation of an intermediate. We presume that a two-step mechanism for cycloaddition reactions with **1***b* is unlikely since, in contrast to silyl enol ethers (25), we are unaware of examples of Lewis acid promoted Michael reactions of enol phosphates. In no case have we detected or isolated any intermediate product in the Lewis acid mediated cycloaddition reactions of **1***a*, **1***b*, or **12**. The similar stereoselectivity observed in the $TiCl_4$ promoted reactions of **2***b* with **1***a* and **1***b* is consistent with similar reaction mechanisms. Interestingly, high *endo* stereoselectivity is typically observed in double Michael reactions both under acidic (14*c*–*e*, 24) and basic (26) conditions.

Several factors might be invoked to explain the increase in *exo* selectivity in the reactions of **1***a* with **2** under Lewis acid mediated conditions compared to the thermal reaction. The presence of the sulfur atom could result in reduced steric repulsions in the *exo* transition state.[5] Since coordination of the dienophile with a Lewis acid results in a larger effective size, the *exo* selectivity would increase under these conditions. Alternatively, secondary orbital interactions involving the sulfur atom might favor the *exo* transition state.[6] In the presence of Lewis acids these interactions become more important (21) and *exo* selectivity would be enhanced. Finally, the sulfur might act as a Lewis base. The *exo* mode of addition would be favored by the possibility of simultaneous coordination of the diene and the dienophile with a Lewis acid. With small revisions, all of these factors could be similarly applied to the second step in a double Michael reaction mechanism to rationalize *exo* selectivity.

Comparing the reactions of **1***a* with those of **12** is instructive. With both dienes reaction with *N*-phenylmaleimide is highly *endo* selective under thermal and Lewis acid mediated conditions. The reactions of **12** with acrylate derivatives are *endo* selective while the same reactions of **1***a* are *exo* selective. In general these results can be accommodated by a steric argument. Cases where the *exo* transition state develops a *gauche* interaction between a substituent on the dienophile and the CH_2 group on the diene (i.e., **1***a* with **1***c*, **12** with **1***c*, and **12** with **2**) favor the *endo* adduct. Cases where the only *gauche* interaction in the *exo* transition state is between a substituent on the dienophile and the sulfur atom on the diene (i.e., **1***a* and **1***b* with **2**) favor the *exo* adduct.

Rationalizing the differences in reactivity and stereoselectivity observed with different dienophile and Lewis acids combinations is difficult. The importance of the dienophile conformation (and the influence of the Lewis acid on dienophile conformation) on stereoselectivity has been discussed (6, 7, 8, 28). A major anomaly occurs in reactions mediated by aluminum Lewis acids, particularly "wet" Et_2AlCl. The reaction of water with Et_2AlCl is known (29) to produce $(ClEtAl)_2O$ (plus ethane). At present we feel that the unusual selectivity observed with this mediator is best rationalized by *exo* transition state with simultaneous coordination of the diene (via sulfur) and dienophile to a bidentate (or polydentate) Lewis acid related to $(ClEtAl)_2O$ (5).

Conclusion

Lewis acid mediated Diels–Alder reactions of 2*H*-thiopyrans are very sensitive to the nature of the dienophile and the Lewis acid. Under appropriate conditions, the reactions are highly stereoselective and can provide adducts that are unavailable in thermal reactions. Modest to good yields of predominantly *exo* adducts are obtained in Lewis acid mediated reactions of 4-triisopropylsilyloxy-2*H*-thiopyran (**1***a*) with acrylate and crotonate derivatives. Reactions of 5-triisopropylsilyloxy-2*H*-thiopyran (**12**) with acrylate derivatives give modest to good yields of predominantly *endo* adducts. In most cases the observed stereoselectivity can be rationalized by steric effects. Unusually high *exo* selectivity is observed in reactions of **2***c* in the presence of "wet" Et_2AlCl. We postulate that, in this case, the selectivity is due to simultaneous coordination of the diene (via sulfur) and dienophile to a bidentate (or polydentate) Lewis acid related to $(ClEtAl)_2O$.

Further experiments aimed at determining the nature of the *exo* selectivity and of the wet Et_2AlCl promoter are underway. Applications of the use of 2*H*-thiopyrans as surrogates

[5]In the *exo* transition state, a *gauche* interaction develops between the acyl group and the S while in the *endo* transition state the steric interaction is between the acyl group and an sp^2 CH. A sulfur atom is sterically much smaller than an sp^2 CH ($-SCH_3$, *A* value = 0.7; $-CH{=}CH_2$, *A* value = 1.35; ref. 27).

[6]For example, interaction of an occupied orbital on sulfur with the dienophile LUMO.

for *cis*-dienes are under active investigation and will be reported in due course.

Experimental[7]

The dienes **1***a*, **1***b*, and **12** were freshly prepared as described previously (*3a*). The ratio of **12**:**13** was 4.5–5:1. The dienophiles **2***b*, **2***c*, **3***b*, **3***c*, **4***b*, and **4***c* were prepared by acylation (*7*) of the corresponding oxazolidones (*30*). The dienophiles **2***a*, **3***a*, and **4***a* were distilled. CH_2Cl_2 was distilled from P_2O_5 and stored over 3Å molecular sieves under argon. The Lewis acids $EtAlCl_2$, Et_2AlCl, and Me_2AlCl were purchased as 1 M solutions in hexane and were of good quality as judged by calibration with a known example (*5*, *7*). $BF_3 \cdot Et_2O$ (neat) and $SnCl_4$ (1 M in CH_2Cl_2) were used as received. Solutions of $TiCl_4$ (0.2–0.25 M in CH_2Cl_2) were prepared from distilled (CaH_2) reagent. "Wet" Et_2AlCl (for reaction with 0.1 mmol of diene) was prepared as follows (*5*): a solution of H_2O in CH_2Cl_2 (0.11 M) was prepared by addition of H_2O (10 mg) to anhydrous CH_2Cl_2 (5 mL). Et_2AlCl (1 M in hexane, 0.1 mL) was added to an aliquot of this solution (0.23 mL, 0.25 mmol) in CH_2Cl_2 (1 mL). After stirring at ambient temperature for 15 min the dienophile was added, followed by the diene.

The IR spectra were obtained by diffuse reflectance infrared Fourier transform (DRIFT). Unless otherwise noted, the ^1H NMR and ^{13}C NMR spectra were obtained in $CDCl_3$ solution at 300 MHz and 75 MHz, respectively. Mass spectra were obtained at low resolution with ionization by electron impact at 70 eV (EI) or by chemical ionization (CI) using NH_3 as reagent gas.

General procedure for reactions

The Lewis acid was added via syringe to a stirred solution of the dienophile (0.11–0.25 mmol) in CH_2Cl_2 (1 mL) at the appropriate temperature. A solution of the diene (0.1–0.15 mmol) in CH_2Cl_2 (1 mL) was then added. The reactions were monitored by TLC and after 1 h the dienes typically were no longer detected. The reactions were quenched by addition of saturated $NaHCO_3$(aq) (ca. 1 mL). After extraction with CH_2Cl_2, the combined organic layers was dried over Na_2SO_4(s) and concentrated and the crude product analyzed by ^1H NMR for the presence of diene(s) and adducts. In successful reactions, various amounts of the silyl enol ether of the adduct(s) was detected. Addition of trifluoroacetic acid (ca. 2 drops) to a CH_2Cl_2 solution of the crude product gave complete hydrolysis of the enol ethers within 5–10 min. After concentration to dryness, the *endo*:*exo* ratio was determined by ^1H NMR. The crude products were fractionated by flash column chromatography and (or) by preparative thin-layer chromatography (ether/hexane mixtures as eluent) to give the individual adducts. Yields are based on isolated products.

*(1′*R*, 4′*R*, 5′R*, 6′R*)-3-(5′-Methyl-2′-thiabicyclo[2,2,2]-octan-8′-one-6′-carbonyl)-2-oxazolidinone (**9**b)*

IR: 1767, 1725, 1693 cm^{-1}; ^1H NMR δ: 4.48 (2H, dt, J = 7, 7 Hz, H-5), 4.12 (2H, m, H-4), 3.16 (1H, dd, J = 2.5, 6.5 Hz, H-6′), 3.49 (1H, m, H-1′), 3.12 (1H, dd, J = 3.5, 11 Hz, H-3′$_{syn}$), 3.03 (2H, m, H-5′, H-3′$_{anti}$), 2.82 (2H, d, J = 3.5 Hz, H-7′), 2.55 (1H, m, H-4′), 0.97 (3H, d, J = 7 Hz, C-5′ CH_3); ^{13}C NMR δ: 211.5 (s, C-8′), 171.6 (s, C-6′ C=O), 153.4 (s, C-2), 62.4 (t, C-5), 53.0 (d, C-6′), 48.6 (d, C-4′), 48.3 (t, C-4), 43.1 (t, C-7′), 37.8 (d, C-1′), 30.9 (d, C-5′), 27.7 (t, C-3′), 21.9 (q, C-5′ CH_3); MS (EI), m/z (relative intensity): 269 ([M]$^+$, 36), 222 (21), 135 (100).

(1′R, 4′R*, 6′S*)-3-(2′-Thiabicyclo[2.2.2]octan-8′-one-6′-carbonyl)-4,4-dimethyl-2-oxazolidinone (**10**a)*

IR: 1773, 1727, 1697 cm^{-1}; ^1H NMR δ: 4.48 (1H, dddd, J = 1.5, 1.5, 7, 10.5 Hz, H-6′), 4.03 (2H, s, H-5), 3.25 (1H, m, H-1′), 3.08 (2H, m, H-3′), 2.98 (1H, dd, J = 3, 19 Hz, H-7′$_{endo}$), 2.76 (1H, m, H-4′), 2.73 (1H, ddd, J = 1.5, 3, 19 Hz, H-7′$_{exo}$), 2.36 (1H, ddd, J = 3, 10.5, 14 Hz, H-5′$_{exo}$), 2.21 (1H, dddd, J = 1.5, 2.5, 7, 14 Hz, H-5′$_{endo}$), 1.56 (6H, s, C4-CH_3); ^{13}C NMR δ: 211.7 (s, C-8′), 174.1 (s, C-6′ C=O), 153.4 (s, C-2) 75.3 (t, C-5), 60.8 (s, C-4), 45.0 (t, C-7′), 44.3 (d, C-6′), 42.2 (d, C-4′), 35.7 (d, C-1′), 27.3 (t, C-3′), 25.5 (t, C-5′), 24.8 (q, C4-CH_3), 24.7 (q, C4-CH_3); MS (CI), m/z (relative intensity): 301 ([M + 18]$^+$, 100), 284 ([M + 1])$^+$, 11), 133 (45).

(1′R, 4′R*, 6′R*)3-(2′-Thiabicyclo[2.2.2]octan-8′-one-6′-carbonyl)-4,4-dimethyl-2-oxazolidinone (**10**b)*

IR: 1768, 1727, 1703 cm^{-1}; ^1H NMR δ: 4.17 (1H, ddd, J = 3, 5, 11 Hz, H-6′), 4.03 (1H, d, J = 8.5 Hz, H-5), 4.00 (1H, d, J = 8.5 Hz, H-5), 3.39 (1H, ddd, J = 3, 3, 6.5 Hz, H-1′), 3.07 (1H, dd, J = 3, 11 Hz, H-3′$_{syn}$), 2.93 (1H, ddd, J = 2.5, 3, 11 Hz, H-3′$_{anti}$), 2.80 (2H, m, H-7′), 2.76 (1H, ddd, J = 2.5, 5, 14 Hz, H-5′$_{exo}$), 2.67 (1H, m, H-4′), 1.88 (1H, dddd, J = 2.5, 4, 11, 14 Hz, H-5′$_{endo}$), 1.59 (3H, s, C4-CH_3), 1.58 (3H, s, C4-CH_3); ^{13}C NMR δ: 212.2 (s, C-8′), 172.8 (s, C-6′ C=O), 154.0 (s, C-2), 75.4 (t, C-5), 61.1 (s, C-4), 48.4 (t, C-7′), 44.4 (d, C-6′), 41.5 (d, C-4′), 37.4 (d, C-1′), 27.5 (t, C-3′), 25.0 (q, C4-CH_3), 24.5 (q, C4-CH_3), 22.6 (t, C-5′); MS (CI, NH_3), m/z (relative intensity): 301 ([M + 18]$^+$, 90), 284 ([M + 1]$^+$, 100), 268 (14), 133 (34).

(1S, 4S*, 5R*,6R*)-N-Phenyl-2-thiabicyclo[2.2.2]octan-7-one-5,6-dicarboxylic acid imide (**14**)*

IR: 1711, 1494 cm^{-1}; ^1H NMR δ: 3.81 (1H, dd, J = 3.5, 10 Hz, H-6), 3.60 (1H, d, J = 3.5 Hz, H-1), 3.24 (2H, m, H-5, 4), 3.05 (2H, m, H-3), 2.68 (1H, ddd, J = 2, 2, 20 Hz, H-8$_{exo}$), 2.34 (1H, ddd, J = 1.5, 2, 20 Hz, H-8$_{endo}$); ^{13}C NMR δ: 199.7 (s, C-7), 176.1 (s, imide C=O), 174.1 (s, imide C=O), 129.4 (d × 2, N-C_6H_5), 129.2 (d, N-C_6H_5), 126.2 (d × 2, N-C_6H_5), 45.6 (d, C-6), 41.9 (d, C-5), 41.4 (d, C-1), 39.4 (t, C-8), 31.2 (d, C-4), 28.9 (t, C-3); MS (CI, NH_3), m/z (relative intensity): 305 ([M + 18]$^+$, 100).

(1S, 4S*, 5S*)-2-Thiabicyclo[2.2.2]octan-7-one-5-carboxylic acid, methyl ester (**15**a)*

IR: 1723 cm^{-1}; ^1H NMR δ: 3.72 (3H, s, OCH_3), 3.03 (1H, t, J = 3 Hz, H-1), 2.87 (4H, m, H-3, 4, 5), 2.55 (4H, m, H-8, 6); ^{13}C NMR δ: 204.2 (s, C-7), 174.3 (s, C-5 C=O), 52.3 (q, OCH_3), 40.6 (d, C-5), 39.5 (d, C-1), 39.4 (t, C-8), 32.0 (d, C-4), 30.4 (t, C-3), 28.9 (t, C-6); MS (CI, NH_3), m/z (relative intensity): 218 ([M + 18]$^+$, 85), 201 ([M + 1]$^+$, 100).

(1S, 4S*, 5R*)-2-Thiabicyclo[2.2.2]octan-7-one-5-carboxylic acid, methyl ester (**15**b)*

IR: 1719 cm^{-1}; ^1H NMR δ: 3.76 (3H, s, OCH_3), 2.99 (2H, m), 2.88 (2H, m), 2.75 (3H, m), 2.46 (2H, m); ^{13}C NMR δ: 204.5 (s, C-7), 173.5 (s, C-5 C=O), 52.4 (q, OCH_3), 42.7 (t, C-8), 40.3 (d, C-5), 39.9 (d, C-1), 31.7 (d, C-4), 28.3 (t, C-6), 24.9 (t, C-3); MS (CI, NH_3), m/z (relative intensity): 218 ([M + 18]$^+$, 36), 201 ([M + 1]$^+$, 100).

(1′S, 4′S*, 5′S*)-3-(2′-Thiabicyclo[2.2.2]octan-7′one-5′-carbonyl)-2-oxazolidinone (**16**a)*

IR: 1773, 1720, 1691 cm^{-1}; ^1H NMR δ: 4.45 (2H, t, J = 7 Hz, H-5), 4.04 (3H, m, H-4, 5′$_{exo}$), 3.09 (1H, ddd, J = 2, 3, 10.5 Hz, H-3′$_{syn}$), 3.06 (1H, m, H-1′), 2.88 (1H, dd, J = 3, 10.5 Hz, H-3′$_{anti}$), 2.76 (1H, m, H-4′), 2.70 (1H, ddd, J = 2.5, 6.5, 14 Hz, H-6′$_{endo}$), 2.65 (1H, ddd, J = 2, 3, 19 Hz, H-8′$_{endo}$), 2.53 (1H, m, H-6′$_{exo}$), 2.43 (1H, ddd, J = 1.5, 3, 19 Hz, H-8′$_{exo}$); in C_6D_6, δ: 3.82 (1H, m, H-5′$_{exo}$), 3.16 (2H, m, H-5), 2.92 (3H, m, H-4,1′), 2.77 (1H, ddd, J = 2, 3, 10.5 Hz, H-3′$_{syn}$), 2.56 (1H, ddd, J = 2.5, 6.5, 14 Hz, H-6′$_{endo}$), 2.46 (1H, ddd, J = 2, 3, 19 Hz, H-8′$_{endo}$), 2.39 (1H, dd, J = 3, 10.5 Hz, H-3′$_{anti}$), 2.17 (3H, m, H-8′$_{exo}$, 6′$_{exo}$, 4′); ^{13}C NMR δ: 204.3 (s, C-7′), 173.9 (s, C-5′ C=O), 153.2 (s, C-2), 62.2 (t, C-5), 42.9 (t, C-4), 40.7 (d, C-5′), 38.9 (t, C-8′), 38.2 (d, C-1′), 32.6 (d, C-4′), 30.3 (t, C-3′), 27.9 (t, C-6′); MS (EI), m/z (relative intensity): 255 ([M]$^+$, 100), 211 (26), 182 (44), 168 (98).

(1′S, 4′S*, 5′S*)-4,4-Dimethyl-3-(2′-thiabicyclo[2.2.2]octan-7′one-5′-carbonyl)-2-oxazolidinone (**17**a)*

Characterized as a 10:1 (^1H NMR) mixture of **17***a* and **17***b* IR: 1770, 1721, 1697 cm^{-1}; ^1H NMR δ: 4.03 (2H, s, H-5), 4.03 (1H, m, H-5′), 3.06 (1H, ddd, J = 1.5, 3, 10.5 Hz, H-3′$_{syn}$), 3.04 (1H, m, H-1′), 2.87 (1H, dd, J = 3, 10.5 Hz, H-3′$_{anti}$), 2.73 (1H, m, H-4′), 2.66 (1H, ddd, J = 3, 6.5, 14 Hz, H-6′$_{endo}$), 2.56 (1H, ddd, J = 1.5, 3, 19 Hz, H-8′$_{endo}$), 2.47 (1H, m, H-6′$_{exo}$), 2.43 (1H, ddd, J = 1, 3, 19 Hz, H-8′$_{exo}$), 1.56 (3H, s, CH_3), 1.54 (3H, s, CH_3); ^{13}C NMR δ: 204.3 (s, C-7′), 174.8 (s, C-5′ C=O), 153.7 (s, C-2), 75.2 (t, C-5), 60.8 (s, C-4), 40.9 (d, C-5′), 39.5 (d, C-1′), 38.8 (t, C-8′), 32.5 (d, C-4′), 30.4 (t, C-3′), 28.1 (t, C-6′), 24.9 (q, CH_3), 24.8 (q, CH_3); MS (EI), m/z (relative intensity): 283 ([M]$^+$, 100), 210 (88), 168 (95).

(1′S, 4′S*, 5′R*)-4,4-Dimethyl-3-(2′-thiabicyclo[2.2.2]octan-7′one-5′-carbonyl)-2-oxazolidinone (**17**b)*

A 1.5:1 mixture of **17***a* and **17***b* was fractionated by PTLC (ether, multiple elution) to give a sample that was a 0.2:1 mixture (^1H NMR) of **17***a* and **17***b*. IR: 1770, 1721, 1698 cm^{-1}; ^1H NMR (C_6D_6) δ: 3.73 (1H, m, H-5′; coupled to H-3′$_{anti}$, J = 1.5 Hz), 3.11 (2H, s, H-5), 2.79 (3H, m, H-1′, 3′$_{syn}$, 6′$_{exo}$), 2.42 (1H, dd, J = 3.5, 19 Hz, H-8′$_{exo}$), 2.31 (2H, m, H-4′, 8′$_{endo}$), 2.19 (1H, ddd, J = 1.5, 3.5, 11 Hz, H-3′$_{anti}$), 1.97 (1H, ddd, J = 4, 10.5, 15 Hz, H-6′$_{endo}$), 1.14 (3H, s, CH_3), 1.10 (3H, s, CH_3); ^{13}C NMR δ: 204.5 (s, C-7′), 173.9 (s, C-5′ C=O), 153.7 (s, C-2), 75.2 (t, C-5), 61.0 (s, C-4), 42.8 (d, C-8′), 40.5 (d, C-5′), 40.3 (d, C-1′), 31.9 (d, C-4′), 27.6 (t, C-6′), 24.8 (q, CH_3), 24.7 (q, CH_3), 24.2 (t, C-3′); MS (EI), m/z (relative intensity): 301 ([M + 18]$^+$, 100), 284 ([M + 1]$^+$, 88).

The acidities of 4-arylsulfonylmethylpyridines and *N*-methyl and *N*-benzyl 4-arylsulfonylmethylpyridinium cations in aqueous solution

STEFAN WODZINSKI AND JOHN W. BUNTING[1]

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received March 23, 1992

STEFAN WODZINSKI and JOHN W. BUNTING. Can. J. Chem. **70**, 2635 (1992).

The pK_a values for the deprotonation of a series of 4-(X-phenylsulfonylmethyl)pyridines (**6**) (pK_a = 19.89 (X = H); ρ = 3.0) were determined in aqueous dimethyl sulfoxide solutions at 25°C using the H_0^q acidity function. The pK_a values were also measured for the corresponding series of *N*-methyl 4-(X-phenylsulfonylmethyl)pyridinium cations (**2**) (pK_a = 11.27 (X = H); ρ = 1.45) and also for a series of *N*-(X-benzyl) 4-phenylsulfonylmethylpyridinium cations (**7**) (pK_a = 10.70 (X = H); ρ = 0.65) in aqueous solution (ionic strength 0.1 at 25°C). Comparison of the substituent effects upon the pK_a values of the sulfonyl-activated carbon acids **2**, **6**, and **7** with the substituent effects upon the pK_a values of the corresponding three series of ketones gives insight into the electron-density distribution in the carbanionic conjugate bases of sulfone and ketone carbon acids. Extrapolation of a linear free energy relationship between the pK_a values of neutral sulfones and ketones allows the estimation of pK_a = 28.7 for the deprotonation of methyl phenyl sulfone in aqueous solution.

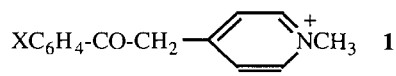
STEFAN WODZINSKI et JOHN W. BUNTING. Can. J. Chem. **70**, 2635 (1992).

Opérant à 25°C, dans des solutions de diméthylsulfoxyde aqueuses et faisant appel à la fonction d'acidité H_0^q, on a déterminé les valeurs de pK_a pour la déprotonation d'une série de 4-(X-phénylsulfonylméthyl)pyridines (**6**) (pK_a = 19,89 (X = H); ρ = 3,0). On a aussi mesuré les valeurs des pK_a pour la série correspondante des cations *N*-méthyl 4-(X-phénylsulfonylméthyl)pyridinium (**2**) (pK_a = 11,27 (X = H); ρ = 1,45) ainsi que pour une série de cations *N*-(X-benzyl) 4-(X-phénylsulfonylméthyl)pyridinium (**7**) (pK_a = 10,70 (X = H); ρ = 0,65) en solution aqueuse (force ionique de 0,1 à 25°C). Une comparaison des effets de substituants sur les valeurs de pK_a des acides carbonés **2**, **6** et **7**, activés par le sulfonyle, avec les effets de substituants sur les valeurs des pK_a des trois séries de cétones correspondantes éclaire notre compréhension de la distribution de la densité électronique dans les bases carbanioniques conjuguées des acides carbonés de sulfones et de cétones. Une extrapolation de la relation d'énergie libre linéaire entre les valeurs de pK_a des sulfones et des cétones neutres permet d'évaluer à 28,7 la valeur du pK_a pour la déprotonation de la méthyl phényl sulfone, en solution aqueuse.

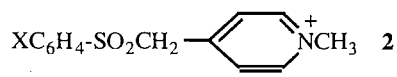
[Traduit par la rédaction]

There have been relatively few quantitative measurements of the thermodynamic acidities of sulfonyl-activated carbon acids in aqueous solution. The acidities of bis(methylsulfonyl)methane ($(CH_3SO_2)_2CH_2$, pK_a = 12.5 (1–3)) and bis(phenylsulfonyl)methane ($(C_6H_5SO_2)_2CH_2$, pK_a = 11.21 (1)) have been measured in water, and related cyclic 1,3-disulfones have been found, depending upon ring size, to be up to 1.5 pK_a units more acidic (eight-membered ring) or less acidic (five-membered ring) than these acyclic sulfones (1). α-Methylation of disulfones leads to a significant decrease in acidity ($(C_2H_5SO_2)_2CHR$, pK_a = 12.20 for R = H, pK_a = 14.56 for R = CH_3 (3*a*); $(C_6H_5SO_2)_2CHR$, pK_a = 11.21 for R = H, pK_a = 13.76 for R = CH_3 (3*b*)); α-phenylation results in only a slight increase in acidity ($(C_2H_5SO_2)_2CHC_6H_5$, pK_a = 12.12 (3*a*)); α-bromination leads to a significant increase in acidity ($(C_2H_5SO_2)_2CHBr$, pK_a = 10.71 (3*a*)).

All of the above disulfones are significantly less acidic than the corresponding diketones (e.g., $(CH_3CO)_2CH_2$, pK_a = 8.87 (4); $(CH_3CO)_2CHCH_3$, pK_a = 10.9 (5); $(CH_3CO)_2CHBr$, pK_a ≈ 7.0 (6)). Greater thermodynamic acidity for a ketone than for the corresponding sulfone is also found for the picolinium cations **1** (pK_a = 7.66 for X = H (7)) and **2** (pK_a = 11.34 for X = H (8)), and for β-keto sulfones (e.g., $CH_3SO_2CH_2COCH_3$, pK_a = 9.90 (6, 9)) relative to disulfones (see above). Ketones are also known to be more acidic than the corresponding sulfones in dimethyl sulfoxide solution (10).



1



2

Apart from the examples quoted above, the only other sulfone-activated carbon acids for which we have been able to locate pK_a values in aqueous solution are six examples of cyclic β-keto sulfones (both exocyclic and endocyclic sulfones) (9), the α- and β-picolinium isomers of **2** (8), 3-phenyl-2*H*-thiopyran 1,1-dioxide (pK_a = 10.79 (11)) and its 6-methyl derivative (pK_a = 12.36 (11)), a variety of ring-substituted phenyl esters of methylsulfonylmethanesulfonic acid (e.g., $CH_3SO_2CH_2SO_3C_6H_5$, pK_a = 9.99 (12)), 3-methylsulfonyl-2,4-pentanedione ($(CH_3CO)_2CHSO_2CH_3$, pK_a ≈ 4.7 (6)), tris(methylsulfonyl)methane ($(CH_3SO_2)_3CH$, pK_a ≈ 0 (6, 13)), and a bicyclic trisulfone containing an acidic bridgehead hydrogen atom (pK_a = 3.30 (13)). In addition, data are available for several acyclic β-keto sulfones in 50% ethanol – 50% water (9), six ethoxycarbonyl-activated sulfones and disulfones in 60% acetonitrile – 40% water (14, 15), and also for a variety of ring-substituted phenacyl phenyl sulfones (**3**) in 95% ethanol – 5% water (16).

3

Substituent effects upon the acidities of 4-phenacylpyridines (**4**) and 4-phenacylpyridinium cations (**1** and **5**) have been shown (7) to be useful probes of the delocalization of

electron density in the carbanionic conjugate bases of these species. We felt that similar insight into the electronic structure of the conjugate bases of the corresponding sulfonyl-activated carbon acids (**2**, **6**, and **7**) would also be of interest in view of the wide use of sulfonyl-stabilized carbanions as reagents in synthetic organic chemistry. Furthermore, in conjunction with our previous study of substituent effects upon the acidities of the ketones **1**, **4**, and **5** (7), such data would allow a detailed comparison of substituent effects upon the acidities of these two closely related series of carbonyl- and sulfonyl-activated carbon acids in aqueous solution. In particular, we felt that such a comparison might provide quantitative insight into the saturation of resonance effects that is commonly observed upon the acidities of carbon acids when successive activating substituents are introduced.

The current paper reports the synthesis and acidities of a wide range of ring-substituted 4-arylsulfonylmethylpyridines (**6**) and their *N*-methyl cations (**2**) and also *N*-(substituted benzyl) 4-phenylsulfonylmethylpyridinium cations (**7**). In addition, the pK_a values were measured for several other sulfonylmethylpyridinium cations (**8**–**11**) in aqueous solution. These data allow the estimation of the pK_a value of methyl phenyl sulfone in aqueous solution. To the best of our knowledge, this is the first estimate of the aqueous acidity of a simple sulfone, unactivated by other acidifying functional groups, on the basis of a linear free energy relationship that does not resort to assumptions (17) regarding the rates of the deprotonation reaction.

Experimental

*4-arylsulfonylmethylpyridines (**6**)*

All 4-arylsulfonylmethylpyridines (**6**), with the exception of the 4-bromo-3-nitrophenyl derivative (**6***j*) which is described below, were prepared from 4-picolyl chloride and the sodium salt of the appropriate arylsulfinic acid by a method based upon that described by Golding *et al.* (8). This method is outlined below for 4-phenylsulfonylmethylpyridine. In some cases the appropriate sodium arylsulfinate was commercially available; in other cases these salts were prepared from the appropriate arylsulfonyl chloride as described below for sodium 4-bromobenzenesulfinate.

Sodium 4-bromobenzenesulfinate

4-Bromobenzenesulfonyl chloride (10.0 g) was added to a solution of sodium sulfite (7.4 g) in water. The mixture was stirred at 70°C, with periodic addition of aqueous NaOH to maintain an alkaline solution. After complete dissolution of the sulfonyl chloride, the solution was heated at 100°C for 5 min, and then strongly acidified with concentrated hydrochloric acid. Upon cooling this solution in an ice bath, white crystalline 4-bromobenzenesulfinic acid was obtained. This product (5.4 g) was collected, washed with dilute hydrochloric acid, press-dried with filter paper, and immediately dissolved in aqueous NaOH (1 equivalent). All water was removed on the rotatory evaporator, whereupon sodium 4-bromobenzenesulfinate was obtained as a white powder.

Sodium salts of the following substituted benzenesulfinic acids were also prepared by this same general route: 4-methoxy; 4-nitro; 3-nitro; 3-chloro; 3,4-dichloro; 3,5-dichloro. The 4-nitrobenzenesulfinic acid did not precipitate from the acidified solution, and was extracted into diethyl ether, which was subsequently dried over magnesium sulfate and removed on the rotatory evaporator.

*4-Phenylsulfonylmethylpyridine (**6**a)*

4-Picolyl chloride hydrochloride (8.0 g), sodium benzenesulfinate (8.2 g), and sodium acetate trihydrate (13.3 g) were refluxed in 1-butanol (35 mL) for 6 h. The reaction mixture was poured into water (800 mL). The product (6.8 g), which precipitated as brown crystals was collected and recrystallized twice from ethanol to give white crystals; mp 202–203°C (lit (8) mp 203–204°C).

The other sulfones (**6***b*–**6***i*) were also prepared via this same general method in yields of 30–60%. The melting points and ^1H NMR spectra of all **6** are listed in Table 1. All **6** were also characterized by elemental analyses (C, H, N) (Huffman Laboratories, Golden, Colorado), which in all cases were within experimental error of the theoretical predictions.

*4-Bromo-3-nitrophenylsulfonylmethylpyridine (**6**j)*

Direct reduction of 4-chloro-3-nitrobenzenesulfonyl chloride to the sulfinic acid by the above method was unsuccessful. However, the 4-bromo-3-nitrophenylsulfonylmethylpyridine was readily prepared, based upon a method given by Nunn and Schofield (18), via direct nitration of the previously prepared 4-bromophenylsulfonylmethylpyridine (**6***d*).

4-Bromophenylsulfonylmethylpyridine (0.83 g) was shaken for 15 min with a solution containing 70% nitric acid (0.3 mL) in water (10 mL) that had been saturated with sodium nitrate. The reaction mixture was then kept at 0°C for 3 h. The white crystalline N-nitrate was collected by vacuum filtration, and then slowly added to ice-cooled concentrated sulfuric acid (20 mL). This mixture was heated to 50°C for 5 min, and then poured onto ice. Upon careful basification with aqueous ammonia, a yellow precipitate was obtained. The product (**6***j*; 0.64 g) was recrystallized from aqueous ethanol, and characterized as usual (Table 1).

*N-Methyl 4-arylsulfonylmethylpyridinium bromides (**2** · Br^-)*

The appropriate sulfone (**6**) was stirred with excess methyl bromide in acetone solution in a pressure bottle for 24 h. The precipitated products were collected and recrystallized from ethanol in 70–

90% yields. The melting points and ^{1}H NMR spectra of all **2**.Br^- are collected in Table 2.

N-*(Substituted benzyl) 4-phenylsulfonylmethylpyridinium bromides (7 · Br^-)*

4-Phenylsulfonylmethylpyridine (1.0 g) was refluxed with the appropriate substituted benzyl bromide (1.1 equivalents) in acetone for 24 h. The products that precipitated were collected and recrystallized from ethanol in 65–85% yields. The melting points and ^{1}H NMR spectra of all **7** · Br^- are collected in Table 3.

Other sulfones

2-Phenylsulfonylmethylpyridine (mp 111–112°C (lit. (8) mp 111.5–112.5°C)) was prepared by a similar route to that described above for its 4-pyridyl isomer. This species was methylated and benzylated by the above general routes to give the bromide salts of **8** and **9**, respectively. 4-Methylsulfonylmethylpyridine (mp 137–138°C (lit. (19) mp 133.5–134.5°C)) and its 2-pyridyl isomer (mp 122–124°C (lit. (20) mp 121–122°C)) were prepared by the above route from the appropriate picolyl chloride and sodium methanesulfinate. The bromide salts of **10** and **11** were then prepared by methylation by the above procedure. The characterization of the bromide salts of **8**–**11** is reported in Table 4.

pK_a values

The pK_a values of all *N*-methyl and *N*-benzyl sulfonylmethylpyridinium cations (**2**, **7**–**11**) were measured spectrophotometrically in aqueous solution at ionic strength 0.1 and 25°C by the general method of Albert and Serjeant (21). Buffer solutions contained KOH + KCl for pH > 10.7 and Na_2CO_3 + $NaHCO_3$ for pH 9.4–10.7. pK_a values were evaluated from the pH-dependence of the absorbance of temperature-equilibrated solutions prepared by mixing equal volumes of a stock aqueous solution of the cationic sulfone (usually 0.06 mM) with double strength buffer solutions. Absorbances at λ_{max} in the spectrum of the conjugate base species were used for the evaluation of pK_a values.

As discussed below, the neutral sulfones (**6**) are quite weak acids and required the use of the acidity function (H_0^q) developed by Cox *et al.* (22) for mixtures of dimethyl sulfoxide and water containing a constant concentration of tetramethylammonium hydroxide (0.047 M). A stock solution of tetramethylammonium hydroxide (0.77 M) in water was prepared from a freshly opened bottle of the solid pentahydrate (99% purity as supplied by Aldrich Chemical Co., Milwaukee, Wisconsin). The exact hydroxide ion concentration of this stock solution was determined by titration with standard hydrochloric acid (0.1 M). Solutions of known H_0^q were prepared according to the compositions given in the table in ref. 22 using analytical grade dimethyl sulfoxide (BDH Chemicals, Toronto, Ontario), and were temperature-equilibrated for at least 10 min before the addition of a small aliquot (0.1 mL) of a stock solution of the sulfone (**6**) (3.0 mM). Absorbances of these basic solutions were then monitored for 5 min at λ_{max} of the conjugate base species, and extrapolated to the mixing time (t = 0) to correct for a slow decomposition of the carbanionic conjugate base species. The pK_a values of **6** were then calculated by fitting the initial absorbance (A) at H_0^q to eq. [1] by an iterative procedure based upon the Marquardt algorithm. The pK_a value, the absorbance (A_C) of the conjugate base, and the absorbance of the conjugate acid (A_{CH}) are treated as parameters to be evaluated in this iterative method. In all cases A_{CH} = 0 within experimental error, which is consistent with the observed transparency of the sulfone at wavelengths in the vicinity of the absorbance maximum in the spectrum of its conjugate base (e.g., Fig. 1).

$$[1] \quad H_0^q = pK_a + \log((A - A_{CH})/(A_C - A))$$

Results

4-Arylsulfonylmethylpyridines (6)

The electronic absorption spectra of the 4-arylsulfonylmethylpyridines (**6**) do not change between pH 7 and 14 in aqueous solution. To investigate the acidities of these weak carbon acids, we resorted to the acidity function (H_0^q) defined by Cox *et al.* (22) for aqueous solutions of 0.047 M tetramethylammonium hydroxide containing varying concentrations of dimethyl sulfoxide. The electronic absorption

spectrum of **6***a*: X = H as a function of H_0^q is shown in Fig. 1. Although such solutions are unstable, the initial spectrum of each of these basic solution is readily measured. The initial intensity (*A*) of the band of λ_{max} = 350 nm is clearly dependent upon H_0^q; this band can be assigned to the carbanionic conjugate base **12***a*: X = H. The dependence of *A* upon H_0^q can be described by eq. [1], with the parameters A_{CH}, A_C, and pK_a being defined by fitting the data to this equation via an iterative regression analysis based upon the Marquardt algorithm. Similar observations were made for five other 4-arylsulfonylmethylpyridines. Spectral parameters and pK_a values that have been calculated for the deprotonation of each **6** are collected in Table 5. This table also includes individual pK_a values calculated from each absorbance measurement using the value of A_{CH} derived in the iterative fit to eq. [1].

Two of the 4-arylsulfonylmethylpyridines (**6***i* and **6***j*) underwent reactions in these highly basic solutions to give intensely colored species having absorption spectra that were quite different from the $\lambda_{max} \approx 350$ nm that are listed in Table

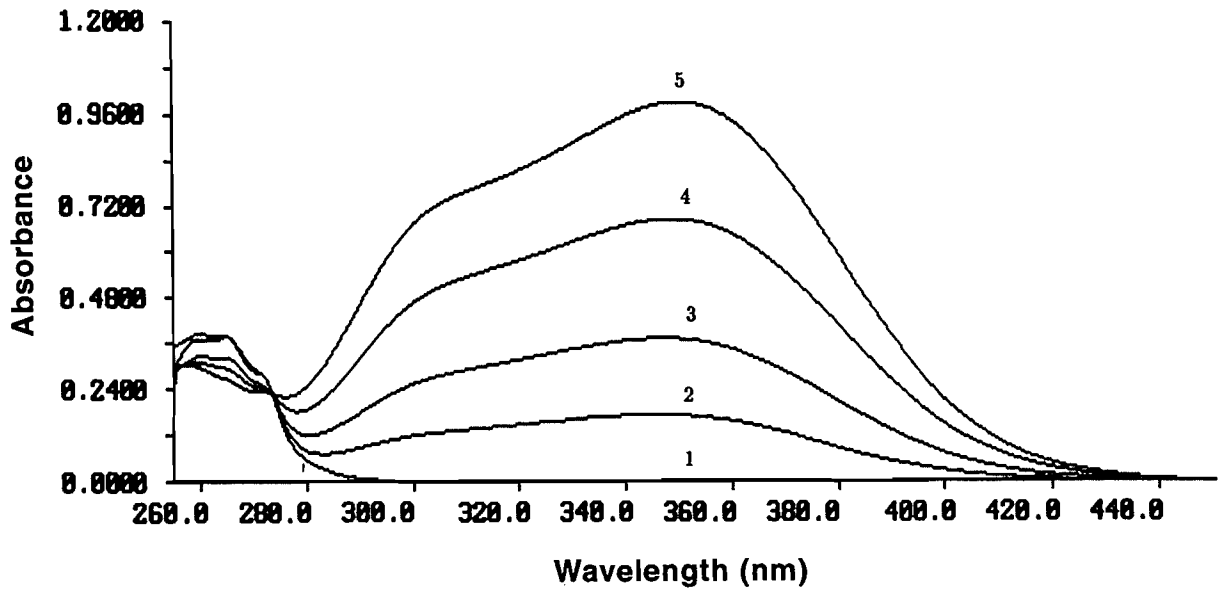

FIG. 1. Variation of the electronic absorption spectrum of **6***a* (0.1 mM) as a function of H_0^q in dimethyl sulfoxide – water solutions containing 0.047 M tetramethylammonium hydroxide. Curve 1, neutral dimethyl sulfoxide; 2, H_0^q = 18.81, 3, H_0^q = 19.41; 4, H_0^q = 20.10; 5, H_0^q = 20.97. Spectra were recorded immediately after mixing a neutral stock solution of **6***a* with each of the basic media.

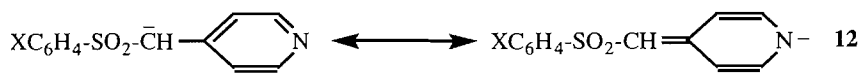

12

5. An example of this phenomenon is shown in Fig. 2 for **6***i* at H_0^q = 18.12, which displays an absorption maximum at 632 nm. We have not investigated these atypical reactions in detail. However, it seems significant that such species are only observed for phenyl rings having a 1,3-orientation of the nitro and sulfonyl substituents. This substitution pattern is well established as promoting nucleophilic addition reactions in these electron-deficient aromatic rings; i.e., Meisenheimer complex formation (23, 24). We suggest that a similar nucleophilic addition to the substituted phenyl ring probably occurs for **6***i* and **6***j* in these basic media. Our observations suggest that in these two cases the formation of Meisenheimer-type σ-adducts is thermodynamically more favourable than carbanion formation via the deprotonation of the α-methylene group of these two sulfones (**6***i* and **6***j*).

4-Arylsulfonylmethylpyridinium cations (2 and 7)

The pH-dependence of the electronic absorption spectrum of **2***a*: X = H is shown in Fig. 3. These spectra are cleanly reversible to the spectrum of **2***a* in neutral solution upon acidification of these basic solutions. The pH-dependent spectrum in Fig. 3 is quite typical of that observed for all **2** and **7**. The pH-dependence of the absorbance at constant wavelength describes a clean acid–base titration curve for all X-substituents. The pK_a value for each substituted derivative of **2** and **7**, and also the spectral characteristics of the absorption maximum of the corresponding conjugate base species, are collected in Table 6.

Other sulfones

Similar spectral observations to those described above for **2***a* were also made for the cationic sulfones **8**–**11**. The pK_a values for each of these species and spectral data for their conjugate bases are also included in Table 6. The *N*-benzyl cation is more acidic than the corresponding *N*-methyl cation in both the 2-pyridyl (ΔpK_a = 1.01) and 4-pyridyl (ΔpK_a = 0.57) cases, and the 4-phenylsulfonylmethyl de-

[a]Absorption maximum (nm) in the spectrum of the conjugate base; log ϵ is calculated from A_C, which is evaluated as described in the text.

[b]pK_a values in this column were calculated for each individual solution from eq. [1] using A_C evaluated as described in the text.

[c]pK_a values in this column are from the iterative fit to eq. [1] that is described in the text.

rivative is more acidic than the corresponding 4-methylsulfonylmethyl derivative in both the *N*-methyl 2-pyridyl (ΔpK_a = 0.57) and 4-pyridyl (ΔpK_a = 0.63) cations. The 2-pyridyl cations are 0.96 to 1.40 pK_a units more acidic than their 4-pyridyl isomers.

Discussion

Each of the sulfones that were investigated in the present work displays a pH-dependent electronic absorption spectrum that is consistent with the equilibration of the sulfone with its conjugate base. Whereas the spectra of the sulfones contain only the ultraviolet absorption maxima that are expected for simply substituted benzene and pyridine chromophores, the conjugate bases display long-wavelength absorption maxima that are typical of more highly conjugated non-aromatic systems. Delocalization of carbanionic electron density into the pyridine (or pyridinium) ring as described in **12** is expected to be of considerable importance in these conjugate base species.

The weakly acidic neutral sulfones (**2**) only undergo deprotonation in highly basic media. We have found that the H_0^q acidity function that was developed (22) for the exocyclic deprotonation of ring-substituted pyridinium cations appears to be applicable to the deprotonation of these 4-arylsulfonylmethylpyridines. A major concern in the use of this acidity function is the question of whether the activity coefficient postulates that are inherent in the definition of H_0^q for pyridinium cations will also be applicable to neutral pyridines. The lack of any trend in individually calculated pK_a values as a function of H_0^q in Table 5 suggests that the inherent activity assumptions in H_0^q must be at least approximately applicable to the deprotonation of neutral pyridine carbon acids. The extensive electron delocalization into the pyridine ring in the conjugate base species is similar for both neutral and cationic pyridines, as exemplified by the similar λ_{max} in the absorption spectra of the conjugate bases of **2** and **7** (Tables 5 and 6). Such delocalization may be a major factor in determining the applicability of H_0^q to the neutral sulfones (**2**).

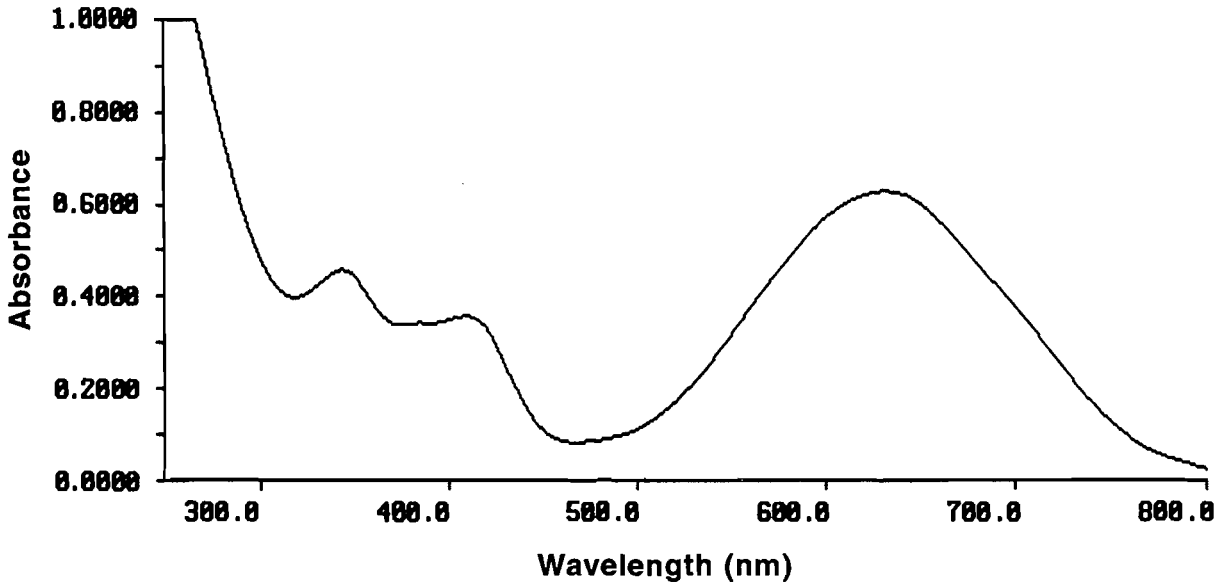

FIG. 2. The electronic absorption spectrum of **6*i*** (0.09 mM) in dimethyl sulfoxide – water containing 0.047 M tetramethylammonium hydroxide at $H_0^q = 18.12$.

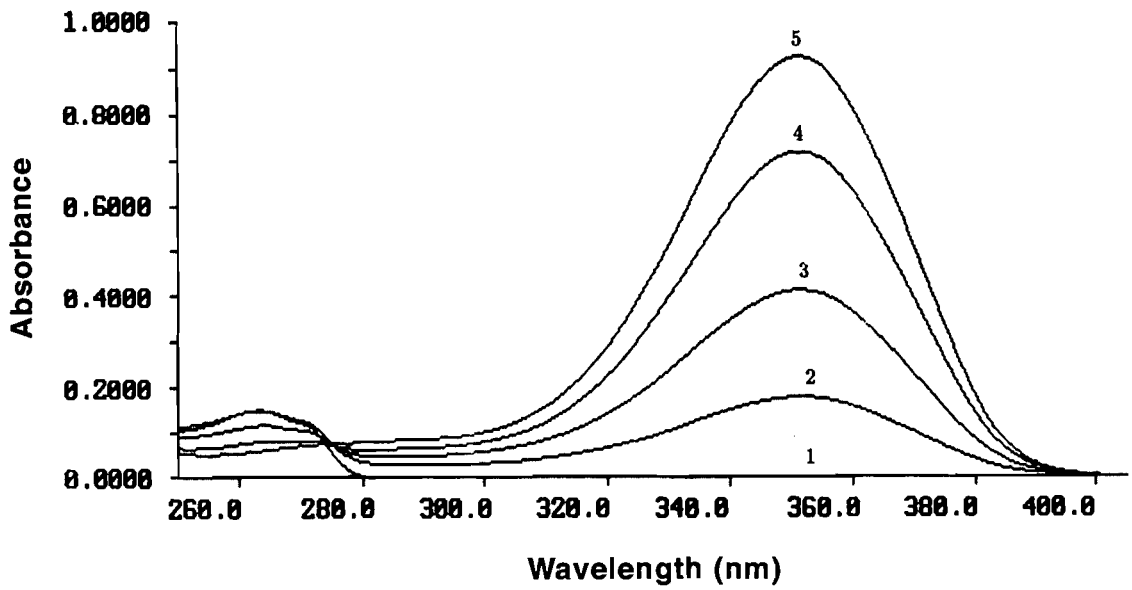

FIG. 3. Variation of the electronic absorption spectrum of **2*a*** (0.03 mM) as a function of pH in aqueous solution. Curve 1, pH = 10.0; 2, pH = 11.1; 3, pH = 11.55; 4, pH = 12.0; 5, pH = 13.0.

The reasons for the somewhat different λ_{max} that are observed for the 4-nitro derivatives than for all other X-substituents in the spectra of the conjugate bases of both **2** and **6** must reside in phenomena other than resonance effects (see below). The λ_{max} = 317 nm that is observed for **6*h***: X = 4-NO_2 appears to be a logical extension of the shoulder that is apparent in the vicinity of 310 nm in the spectrum of the conjugate base of **6*a*** (Fig. 1), and the maxima at 307 and 311 nm in the carbanions from **6*e*** and **6*f*** (Table 5). It seems likely that the spectra in Table 5 are influenced by the variation in solvent composition that is involved in the generation of the conjugate base species. One wonders whether preferential solvation of the pyridine nitrogen atom and (or) the sulfone group by dimethyl sulfoxide and water, similar to that established for the nitro group (25), may play a role in the observed λ_{max} of the spectra of the carbanions of **6** in Table 5. The conjugate base of **2*h*** in Table 6 is the only 4-arylsulfonylmethylpyridinium cation in this table to display a double maximum. The possibility of intramolecular charge-transfer complexation in the conjugate base of **2*h*** should be considered as a source of the unusual spectrum in this case.

Substituent effects upon the pK_a values of **2** (Fig. 4), **6** (Fig. 5), and **7** are closely correlated with Hammett σ constants for the X-substituents. Correlation equations are given in eqs. [2]–[4].

[a]In aqueous solution, ionic strength 0.1, at 25°C.
[b]Absorption maximum (nm) in the spectrum of the conjugate base.

[3] $pK_a(\mathbf{6}) = -3.0(\pm 0.1)\,\sigma + 19.80(\pm 0.06)$, $r = 0.996$

[4] $pK_a(\mathbf{7}) = -0.65(\pm 0.02)\,\sigma + 10.68(\pm 0.01)$, $r = 0.995$

The clean correlation of substituent effects (eq. [3] and Fig. 5) that is obtained for **6** provides further support for the adequacy of H_0[9] for the evaluation of the acidities of these neutral sulfones. Equation [2] was evaluated using the σ constants recommended by Hansch *et al.* (26) for the 3,4-dichloro (**2***f*) and 4-bromo-3-nitro (**2***j*) derivatives. In each of these cases, the assumption of strict additivity of *meta* and *para* substituent constants for these 3,4-disubstituted rings leads to significant deviations from the correlation line established for the other X-substituents (Fig. 4).

It seems clear that the X-substituent effects upon the acidities of **2** and **6** do not contain contributions from resonance interactions between X and the carbanionic centre, since neither σ^+ parameters for the 4-methoxy or 4-methyl substituents nor the σ^- parameter for the 4-nitro substituent are appropriate. This result contrasts with the X-substituent effects upon the pK_a values for the corresponding ketones (**1**) in which both the 4-methoxy and 4-nitro substituents deviate significantly from the correlation line defined by other substituents (7).

Substituent effects upon the acidities of the neutral sulfones **6** (ρ = 3.0) are much larger than for the more strongly acidic *N*-methyl cation analogs **2** (ρ = 1.45). The reduced ρ value for **2** relative to **6** suggests much lower electron density on the formal carbanionic atom in the conjugate base of **2** than in the conjugate base of **6**. This observation is consistent with the ρ = 0.65 that is found for the *N*-(substituted benzyl) cations (**7**). This ρ = 0.65 indicates significant neutralization of the cationic charge upon the ring nitrogen atom as a result of electron delocalization from the carbanionic

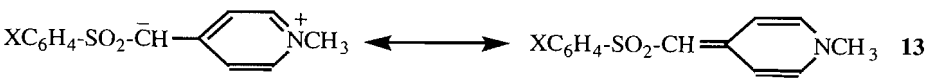
[e]From ref. 7.

centre into the pyridinium ring (**13**). Relative to ρ = 1.14 for the deprotonation of *N*,*N*-dimethylbenzylammonium cations (27), the ρ = 0.65 for **7** suggests approximately 60% neutralization of the formal charge upon the pyridinium nitrogen atom of **7** upon deprotonation of the methylene group. Such extensive delocalization of negative charge into the pyridinium ring requires predominant sp^2-hybridization for the carbanionic carbon atom in **13**, and leaves little doubt that in the present case the carbanionic centre is planar rather than pyramidal (32).



13

The cationic sulfones **2** with ρ = 1.45 are of similar acidity to phenacylsulfones (**3**) for which X-substituent effects have been reported (16) to have ρ = 2.01 in 95% ethanol – 5% water. This latter value may be corrected to ρ = 2.01/1.63 = 1.23 for aqueous solutions using ρ = 1.63 for the deprotonation of substituted benzoic acids in ethanolic solution (28). Substituent effects upon the pK_a values for ring-substituted benzenesulfonamides ($XC_6H_4SO_2NH_2$, pK_a 10.00 (X = H), ρ = 1.06) and benzenesulfonanilides ($XC_6H_4SO_2NHC_6H_5$, pK_a 8.31 (X = H), ρ = 1.15) are also of similar magnitude in aqueous solution (29) to those found for **2** in the current study.

Substituent effects upon the aqueous acidities of analogous series of pyridine and pyridinium activated sulfones and ketones are compared in Table 7. In all cases the ketones are more acidic than the corresponding sulfones, although the difference in acidity of these two series of carbon acids decreases with increasing acidity from ΔpK_a = 7.42 for the neutral species to only 3.42 for the N-benzyl cations. In all cases the ρ values are also smaller for the ketones than for the corresponding sulfones, although $\Delta\rho$ = 0.97 for the neutral species is reduced to only 0.07 for the N-methyl cations. The ΔpK_a = 4.81 observed upon N-methylation of the ketone is also considerably smaller than ΔpK_a = 8.62 that is found upon N-methylation of the sulfone. The ρ values of 0.65 and 0.47 for the sulfones (**7**) and ketones (**5**), respectively, suggest that delocalization of carbanionic charge into the pyridinium ring is more important for the conjugate bases of the sulfones than of the ketones. This latter result is presumably attributable to the much greater importance of enolate ion stabilization in the conjugate bases of the ketones, than the analogous delocalization of electron density into the sulfonyl group in the sulfone carbanions.

Combination of the Hammett correlation (eq. [3]) for substituent effects upon the acidity of the neutral 4-arylsulfonylmethylpyridines with the analogous Hammett correlation (eq. [5]) previously established (7) for the corresponding 4-phenacylpyridines (**4**) leads to eq. [6]. Extrapolation of this relationship to pK_a = 18.31 for acetophenone in aqueous solution (30) allows the estimation of pK_a = 28.7 for methyl phenyl sulfone in water. This appears to be the first estimate of the acidity of this sulfone in aqueous media, and is comparable with pK_a = 29.05 reported for this same sulfone (10) in dimethyl sulfoxide solution.

[5] $pK_a(\mathbf{4}) = 2.03\,\sigma + 12.50$

[6] $pK_a(\text{sulfone}) = 1.5\,pK_a(\text{ketone}) + 1.3$

The only previous estimate that we have been able to locate for the pK_a of a simple sulfone in aqueous solution is the value of 23 proposed by Pearson and Dillon (17) for dimethyl sulfone. This estimate was based on two separate assumptions regarding the kinetic acidity of this compound, including the assumption that the rate–equilibrium correlation for the deprotonation of ketones is also applicable to sulfones. This latter assumption almost certainly leads to a large overestimation of the acidity of dimethyl sulfone (i.e., too low pK_a) since the kinetic acidities of sulfones are known (2, 3, 17) to be considerably greater than those of ketones of similar thermodynamic acidity. Since we have shown above that methyl sulfones (**10** and **11**) are less acidic than their phenyl sulfone analogues (**2***a* and **8**) in aqueous solu-

For personal use only.

tion, the above estimate for methyl phenyl sulfone requires $pK_a > 28.7$ (probably ≈ 30) for dimethyl sulfone in aqueous solution. The pK_a of dimethyl sulfone in dimethyl sulfoxide solution is reported to be 31.1 (10).

Viscosities and thermodynamics of viscous flow of binary liquid mixtures of 2-(2-butoxyethoxy)ethanol with aniline and *N*-alkyl anilines

PAUL WISEMAN,[1] MURRAY HEGGIE, AND RAMAMURTHY PALEPU[2]

Department of Mathematics and Natural Sciences, University College of Cape Breton, Sydney, N.S., Canada B1P 6L2

Received December 5, 1991

PAUL WISEMAN, MURRAY HEGGIE, and RAMAMURTHY PALEPU. Can. J. Chem. **70**, 2645 (1992).

Viscosities and densities of binary mixtures containing 2-(2-butoxyethoxy)ethanol with aniline and *N*-alkyl-substituted anilines have been determined at five different temperatures over the complete concentration range. Excess volumes, viscosities, and excess molar free energy of activation of flow were calculated and the departure from ideal behavior is explained on the basis of specific interactions between the components in these mixtures. McAllister's approach correlates the viscosity data with a significantly high degree of accuracy for all these systems.

PAUL WISEMAN, MURRAY HEGGIE et RAMAMURTHY PALEPU. Can. J. Chem. **70**, 2645 (1992).

Opérant à cinq températures différentes et sur l'ensemble des plages de concentration, on a déterminé les viscosités et les densités de mélanges binaires contenant du 2-(2-butoxyéthoxy)éthanol avec de l'aniline et des anilines *N*-alkylées. On a calculé les volumes et les viscosités en excès ainsi que l'énergie libre molaire d'activation en excès et on explique la déviation par rapport au comportement idéal en se basant sur des interactions spécifiques entre les composants de ces mélanges. Pour tous ces systèmes, l'approche de McAllister permet d'obtenir une très bonne corrélation entre toutes les données de viscosité.

Introduction

In this work, viscosities of five nonelectrolyte binary mixtures at five different temperatures were measured. These mixtures were composed of 2-(2-butoxyethoxy)ethanol with aniline (ANL), *N*-methylaniline (MEA), *N*,*N*-dimethylaniline (DMA), *N*-ethylaniline (EAN), and *N*,*N*-diethylaniline (DEA).

Excess molar viscosities, volumes, and the free energies of activation for viscous flow were evaluated from the experimental data to examine the type and strength of interactions between the components in these mixtures.

Experimental

The methods used in our laboratory have been described previously (1–6). Densities were determined with a digital densimeter DMA 45 (Anton-Parr, Austria). A Sodev temperature controller bath (constant to 0.001°C) was used. Calibration was carried out with air and nanopure water with an error of $\pm 1 \times 10^{-4}$ g cm^{-3}. Viscosities at different temperatures were measured using modified Ostwald viscometers and a viscosity bath (Koehler instrumentation). The estimated error in the viscosity measurements was within ±0.005 cP.

Anilines used were the same as in earlier studies (1–6). 2-(2-Butoxyethoxy)ethanol, an Aldrich product, was purified by distillation under reduced pressure and stored over molecular sieves. The experimental density of 0.9521 g cm^{-3} at 298 K agrees well with the literature value of 0.9528 g cm^{-3} (7).

Results and discussion

The excess functions V^E, η^E and ΔG^{*E}, were calculated from the experimental values[3] using the following equations:

$$[1] \quad V^E = [(X_1M_1 + X_2M_2) \div \rho] - [X_1V_1 + X_2V_2]$$

$$[2] \quad \eta^E = \eta - \exp(X_1 \ln \eta_1 + X_2 \ln \eta_2]$$

$$[3] \quad \Delta G^{*E} = RT[\ln \eta V - (X_1 \ln \eta_1 V_1 + X_2 \ln \eta_2 V_2)]$$

where ρ, η, and V are the density, viscosity, and volume of the mixture, M_1, M_2, V_1, V_2, η_1, η_2, X_1, and X_2 are molar masses, volumes, viscosities, and mole fractions of the pure components 1 and 2, respectively.

The excess function (Y^E) for the binary systems could be represented by Redlich–Kister equation (8):

$$[4] \quad Y^E = X_1X_2 \sum_{j=1}^{n} a_j(1 - 2X_1)^{j-1}$$

where Y^E and a_j represent the excess functions V^E, η^E, ΔG^{*E} and the polynomial coefficients. The values of the coefficients were determined by the method of least squares. In each case, the optimum number of coefficients was ascertained from an examination of the variation of the standard error of estimate with n:

$$[5] \quad \sigma_y = [\Sigma(X^E_{ob} - X^E_{cal})^2 \div (n_{ob} - n)]^{1/2}$$

where n_{ob} is the number of measurements. The values of these coefficients along with standard error of estimate at 298 K are presented in Table 1. Figures 1–3 show the values of η^E, V^E, and ΔG^{*E} as a function of the mole fraction of the alcohol. The continuous curves were generated with the aid of the coefficients in Table 1.

Viscosity data for the liquid mixtures were used to test the empirical approach of McAllister (9). The McAllister correlation is based on a model proposed by Eyring and coworkers (10) which considers that interaction between layers of molecules as if the molecules were undergoing a chemical reaction and have to overcome a potential barrier of this

process. For a binary mixture of A and B in which the molecular interactions of 1-1-1, 1-2-1, 1-1-2, 1-2-2, 2-1-2, and 2-2-2 types can be visualized, this approach yields the following equation for a three-body interaction.

$$[6] \quad \ln \nu = X_1^3 \ln \nu_1 + 3X_1^2X_2 \ln \nu_{12} + 3X_1X_2^2 \ln \nu_{21} + X_2^3 \ln \nu_2 + R_0$$

where

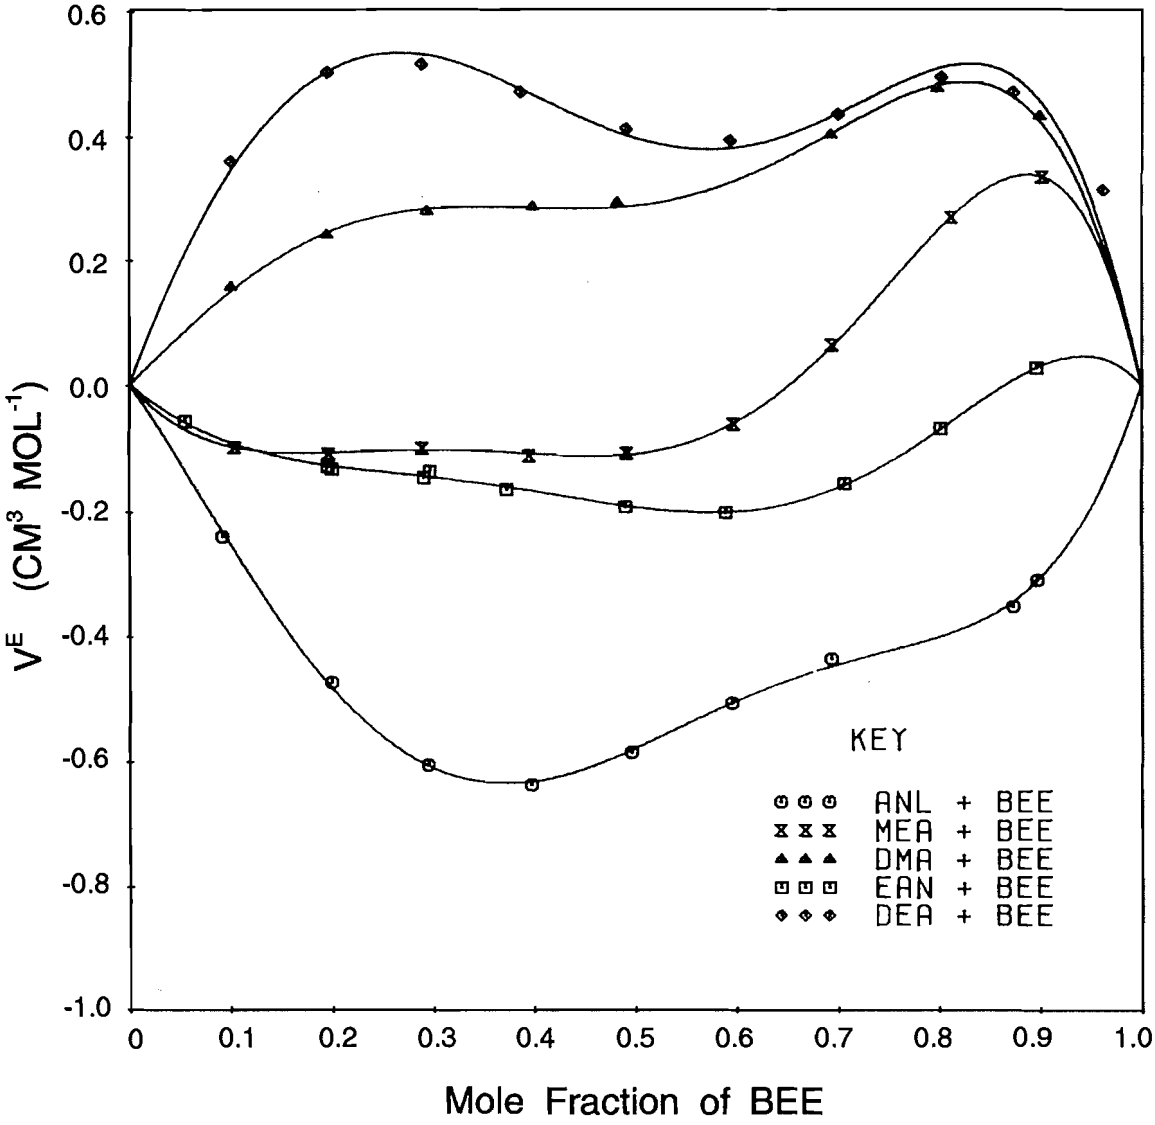

FIG. 2. Molar excess volumes of the systems at 298.15 K.

$$[7]\quad R_0 = -\ln\left[X_1 + \frac{X_2M_2}{M_1}\right] + 3X_1^2X_2\ln\left[\frac{2}{3} + \frac{M_2}{3M_1}\right] + 3X_1X_2^2\ln\left[\frac{1}{3} + \frac{2M_2}{3M_1}\right] + X_2^3\ln\left[\frac{M_1}{M_2}\right]$$

In eq. [6], ν_1, ν_2 and ν refer to the kinematic viscosities of the pure components 1, 2 and the mixture respectively. The interaction parameters ν_{12} and ν_{21} were determined by the methods of least squares from the experimental viscosity data. The values of ν_{12}, ν_{21}, absolute average error, and the ratio of radii r_2/r_1 at different temperatures are presented in Table 2. The use of a cubic equation is justified only if the ratio of the molecular radii of the two components in the mixture is less than 1.5. The interaction parameters ν_{12} and ν_{21} may be represented in terms of specific interactions between unlike molecules. It is possible in a simplified model to associate the parameter ν_{12} with the 1-1-2, 2-1-2 type and ν_{21} with the 1-2-1, 1-2-2 type of interaction. The relative intensities of these interactions between a central unit and the surrounding molecules or any other aggregates in any direction may be different for different neighboring arrangements. It is not unreasonable to expect the nature of these specific interactions to be about the same either for the 1 or 2 central species. Therefore the specific interaction terms ν_{12} and ν_{21} should have the same statistical weight at a given temperature. From the examination of the values of ν_{12} and ν_{21} in Table 2, it is obvious that the values are of the same order of magnitude but they do differ slightly from each other. However, McAllister's treatment proved to be reasonably accurate in predicting the viscosity data of the binary mixtures.

The excess viscosity values (Fig. 1) are positive for BEE with ANL, MEA, EAN and slightly negative for the DMA and DEA systems. The algebraic values of η^E may be represented in the following order: DMA < DEA < EAN < MEA < ANL. The sign and magnitude of η^E depend on the combined effect of factors such as molecular size, shape, and intermolecular forces (11). The positive values of η^E indicate the presence of a specific interaction such as the formation of weak hydrogen bonding of the type O—H---N or N—H---O. The negative values of η^E in the systems of BEE with DEA and DMA suggest that mutual loss of specific in-

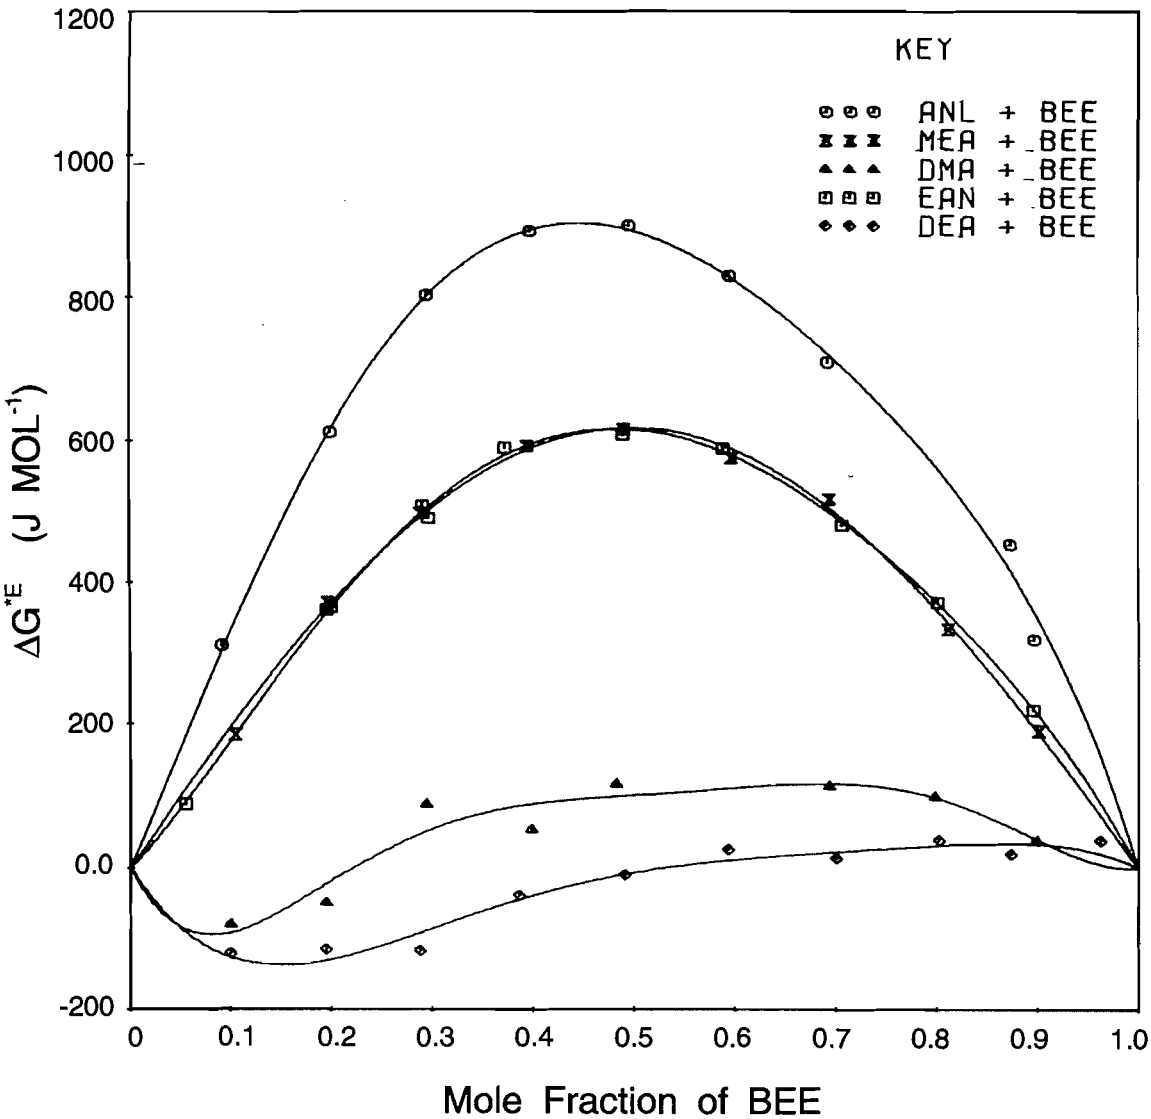

FIG. 3. Molar excess free energies of viscous flow for the systems at 298.15 K.

teractions in like molecules outweigh the specific interactions between unlike molecules (12, 13). The symmetric curve of η^E and ΔG^{*E} vs. mole fraction for ANL + BEE indicates that the energy necessary to break the hydrogen bonds in the mixing process for the pure liquids is similar for both components. For the systems BEE with MEA and EAN the excess viscosity becomes less positive and the maxima shifts toward the higher mole fraction of BEE. This indicates that the breaking energy of hydrogen bonding in BEE, when mixing with MEA and EAN, is not compensated by the weak N---H bonding of the base (14). In systems whose excess viscosity shows a well-marked maximum, the composition of the complex formed can be fixed at least to a first approximation from the mole ratio at the maximum (15). One can conclude from the analysis of Fig. 1 that, for the system ANL + BEE, there is evidence of a complex formation in the mole ratio of 1:1. For the other two systems, we can not find a molar relation because the maxima do not coincide.

The observed excess volume (V^E) values result from the balance of dipole–dipole interaction contributions leading to an expansion in volume and geometrical packing or free volume effects leading to contraction in volume (16). The curves in Fig. 2, indicate that the excess volumes are positive for BEE with DEA, DMA and negative for ANL, EAN systems in the entire concentration range and change sign for the MEA system. A negative value of V^E indicates strong interaction between the components of the mixture. The positive ΔG^{*E} values (Fig. 3) can be seen in binary systems as an indication of strength of interactions between molecules (17, 18). From the values of excess functions, one can conclude that the strength of specific interactions varies in the order ANL + BEE > MEA + BEE > EAN + BEE > DMA + BEE > DEA + BEE.

The anomeric effect in thio derivatives of benzocycloheptene

S. DÉSILETS AND M. ST-JACQUES[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Québec), Canada H3C 3J7

Received January 30, 1992

S. DÉSILETS and M. ST-JACQUES. Can. J. Chem. **70**, 2650 (1992).

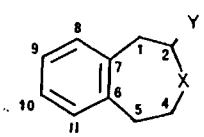
The conformational properties of six thio derivatives of benzocycloheptene were studied by ^1H and ^{13}C high-field NMR spectroscopy in solution at low temperature. Both parent compounds **2** and **6**, with sulfur at positions 3 and 1, respectively, were found to exist in the chair conformation. The 2-substituted derivatives of **2** (**3**: Y = OCH_3 and **4**: Y = Cl) revealed the presence of the Ca form only. In contrast, the 2-substituted derivatives of **6** (**7**: Y = OCH_3 and **8**: Y = Cl), with sulfur at position 1, showed mixtures of three conformers, namely Ca:Ce:TB (Ca = axial chair, Ce = equatorial chair, and TB = twist-boat), whose populations in CHF_2Cl were, respectively, 93:5:2 and 85:12:3. The predominance of the Ca form in both series argues in favour of a strong anomeric effect in spite of the large departure from coplanarity (~35°) in the :—S—C—Y fragment of both **7** and **8**. This noncoplanarity appears to weaken only slightly the n–σ^* overlap characteristic of the *endo*-anomeric effect, contrary to earlier observations for the :—O—C—Y fragment in **5**. The differences between the effects of O and S are discussed.

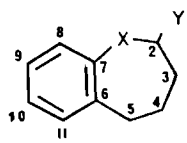
S. DÉSILETS et M. ST-JACQUES. Can. J. Chem. **70**, 2650 (1992).

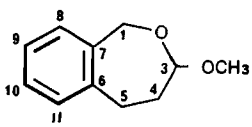
Faisant appel à la RMN du ^1H et du ^{13}C à haut champ, on a étudié les propriétés conformationnelles à basse température de six dérivés sulfurés du benzocycloheptène en solution. On a trouvé que les deux composés parents **2** et **6** contenant du soufre respectivement dans les positions 3 et 1 existent dans la conformation chaise. Les spectres des dérivés du composés **2** substitués en position 2 (**3** : Y = OCE_3 et **4** : Y = Cl) ne révèlent la présence que de la forme Ca. Par ailleurs, les spectres des dérivés du composé **6** substitués en position 2 (**7** : Y = OCH_3 et **8** : Y = Cl) et portant un atome de soufre en position 1 montrent la présence des trois conformères suivants : Ca, Ce et TB (Ca = chaise axiale, Ce = chaise équatoriale et TB = bateau croisé) dont les populations dans le CHF_2Cl sont respectivement de 93 : 5 : 2 et 85 : 12 : 3. La prédominance de la forme Ca dans les deux séries suggère l'existence d'un effet anomère important malgré le fait que la molécule est loin d'être coplanaire (déviation de ≈35°) dans le fragment :—S—C—Y des deux composés **7** et **8**. Contrairement à ce qui a été observé antérieurement avec le segment :—O—C—Y du composé **5**, ce manque de coplanéité ne semble pas diminuer beaucoup le recouvrement n–σ^* caractéristique de l'effet anomère *endo*. On discute des différences dans les effets du O et du S.

[Traduit par la rédaction]

Stereoelectronic concepts are of fundamental importance in modern organic chemistry (1). Among these, the anomeric effect (2) is best known. It refers to the preference of an electronegative substituent for the axial rather than the sterically preferred equatorial position at the anomeric carbon in the tetrahydropyran ring (3). The major experimental results (4) used to characterize this effect were generated by studies of five- and six-membered heterocyclic compounds such as tetrahydrofuran and tetrahydropyran derivatives substituted on the α-carbon. Analogous studies were carried out (5) on the seven-membered cyclic molecules **1**, **5**, and **9** for which the electronegative α-substituent is OCH_3. These benzocycloheptene derivatives revealed the stabilization of the twist-boat (TB) conformer with large variations resulting from changes in the oxygen position of the seven-membered ring. Hence, this ring system is useful to probe conformational effects of stereoelectronic origin.







1 X=O , Y=OCH_3 **5** X=O , Y=OCH_3 **9**

2 X=S , Y=H **6** X=S , Y=H

3 X=S , Y=OCH_3 **7** X=S , Y=OCH_3

4 X=S , Y=Cl **8** X=S , Y=Cl

The anomeric effect for second-row atoms such as sulfur has received relatively little attention. Interesting work on six-membered molecules was reported by Pinto and co-workers (6) but none for seven-membered cyclic molecules. We therefore wish to report herein the conformational results of a low-temperature NMR investigation of six derivatives of thiobenzocycloheptene (**2**, **3**, and **4** constituting series 3 and **6**, **7**, and **8** referred to as series 1) whose substituents (Y) are all located at the anomeric carbon. The observed conformational differences will be discussed in light of interactions at the origin of the anomeric effect.

[a]Chemical shifts in CH_3OCH_3 are similar.
[b]Uncertainties on conformer populations were ±0.5.
[c]Low S/N or superposed with the major signals.
[d]Superposed with the majors signals.

compounds **2**–**4** (series 3) and **6**–**8** (series 1) were obtained at different temperatures between 0 and −143°C in two different solvent systems (CHF_2Cl and CH_3OCH_3).

The 100.6 MHz ^{13}C NMR decoupled spectrum of the parent compound **2** (Y = H) of series 3 shows five well-resolved signals at −20°C. No spectral change was observed when the temperature was lowered to −120°C.

This result clearly establishes that **2** exists as a single conformer. In support of this conclusion, the 400.1 MHz ^1H NMR spectrum at −143°C shows splittings characteristic of axial and equatorial protons of the single conformer. After assignment of the ^1H and ^{13}C signals at 25°C using normal (7) and long-range (8) HETCOR 2D spectra as summarized in Tables 1 and 2, the following proton–proton vicinal coupling constants were obtained for the C4—C5 bond at −20°C ($^3J_{aa}$ = 11.2 Hz; $^3J_{ee}$ = 7.0 Hz; $^3J_{ae}$ < 1.0 Hz). A comparison with similar benzocycloheptene derivatives (9) indicates that these parameters are characteristic of a chair conformation. The activation energy of the chair inversion determined (10) at the coalescence temperature of the H-2 signal (T_c = −127°C), is $\Delta G^{\neq}$ = 7.0 ± 0.3 kcal mol^{-1} in CHF_2Cl.

The 100.6 MHz ^{13}C and 400.1 MHz ^1H NMR spectra of derivatives **3** (Y = OCH_3) and **4** (Y = Cl) showed a slight broadening of the signals when lowering the temperature to −140°C. This observation is in accord with the presence of a single conformer. The assignment of the proton signals for these two compounds was readily made using the ^1H–^1H COSY 2D experiment (11) at −120°C, while the ^{13}C signal assignment was made by comparison with the chemical shifts of the parent compound **2**. The pertinent parameters are given in Tables 1 and 2.

The single conformer for each of **3** and **4** is found to have a chair geometry from consideration of the vicinal proton–proton coupling constants about the C4—C5 bond ($^3J_{aa}$ = 11.0 and 11.6 Hz; $^3J_{ee}$ = 6.6 and 6.8 Hz for both **3** and **4**; $^3J_{ae}$ < 1.0 Hz) obtained at −120°C. These values are similar to those determined for the chair form of compound **2**. The orientation of the polar substituents (OCH_3 for **3** and Cl for **4**) is then deduced as axial by the characteristic equatorial–equatorial vicinal coupling constants about the C1—C2 between H-2 and the two H-1 ($^3J_{ee}$ = 6.6 Hz for **3** and 6.2 Hz for **4**). The substituent chemical shift effects (12) α, β, γ were determined from the ^{13}C data at −120°C for the Ca forms of **3** and **4** as summarized in Table 1.

Decoupled 100.6 MHz ^{13}C NMR spectra of the parent compound **6** (Y = H) at variable temperature are also characteristic of a single conformer; indeed no spectral change is observed down to −120°C. Normal (7) and long-range (8) HETCOR 2D experiments at 25°C were used to assign the carbon peaks reported in Table 1.

As for compound **2**, the 400.1 MHz ^1H NMR spectrum of **6** at low temperature (−120°C) also shows splitting of the axial and equatorial proton signals that were assigned using COSY 2D data (11). The chair conformer is then deduced from the values of the vicinal coupling constants between H-4 and H-5, namely $^3J_{4a-5a}$ = 11.8 Hz; $^3J_{4e-5e}$ = 7.6 Hz; $^3J_{ae}$ < 1.0 Hz, which are found to be similar to those obtained for compounds **2**–**4**. $\Delta G^{\neq}$ is calculated for the inversion of the chair at the coalescence temperature (10) of H-2 (T_c = −45°C) and is equal 10.8 ± 0.3 kcal mol^{-1}.

On lowering the temperature, both the methoxy and chloro derivatives (**7** and **8**) showed changes in the 100.6 MHz ^{13}C NMR and also in the 400.1 MHz ^1H NMR spectra. For example, Fig. 1 shows that the aliphatic carbon signals (C-2 to C-5) of **7** split into three components of unequal intensities (93:5:2) at −120°C, while for compound **8** the intensities are 85:12:3 at −120°C, both in CHF_2Cl.

To show that for **7** the less abundant of the three peaks (2%) in CHF_2Cl is not an impurity but a real conformer signal, the saturation transfer technique (13) was used with selective excitation of the C-2 signals using the DANTE

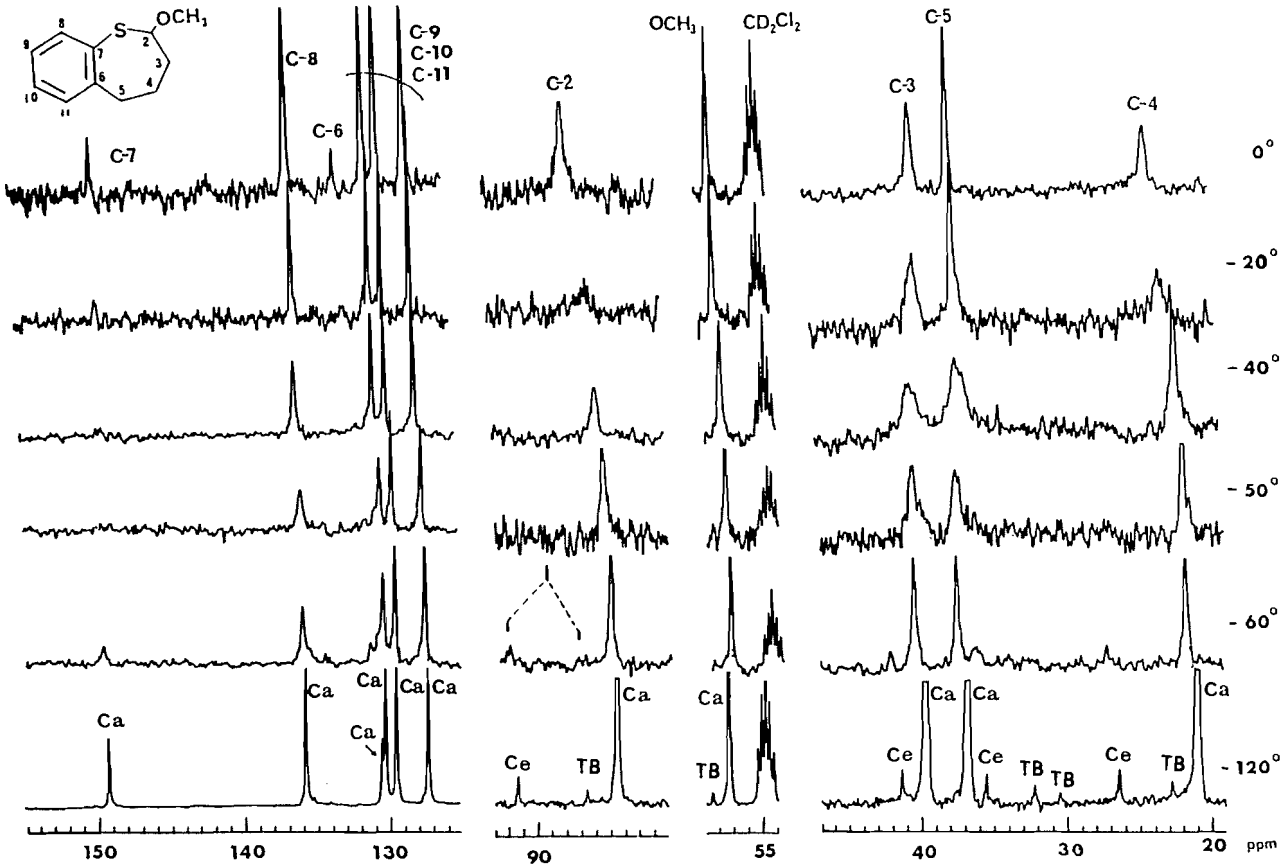

FIG. 1. Variable temperature 100.6 MHz ^{13}C NMR spectra of **7**, in CHF_2Cl (Ca = axial chair, Ce = equatorial chair, TB = twist-boat).

sequence (14) as illustrated in Fig. 2. At −85°C in CHF_2Cl, selective saturation of the minor peak at 86.3 ppm (Fig. 2*b*) effectively reduced the relative intensity of the other two peaks located at 84.1 and 91.0 ppm. Saturation of the major peak (84.1 ppm) was also accompanied by transfer of saturation that, as Fig. 2*c* shows, modified the other two signals. This transfer of saturation between the three signals confirms the presence of three equilibrating conformers.

The ^{13}C NMR spectrum of compound **8** at −120°C shows that the chemical shifts of the minor peaks (C-3 to C-5) are similar to those of **7** and therefore in accord with the presence of three conformers. The ^{13}C aliphatic signals for the two most abundant conformers of compounds **7** and **8** have been assigned by selective double irradiation of H-5 and H-4 respectively. A comparison with ^{13}C chemical shifts of the parent compound **6** was made to assign the aromatic carbons. From these results, the α, β, γ chemical shift parameters (12) were calculated and are summarized in Table 1. The γ parameter is the most reliable diagnostic (15) of the Ca or Ce forms. It is observed that this parameter for **7** is negative, larger for Ca (−6.4 ppm) than for Ce (−0.9 ppm), in accord with the value already observed (5) for the Ca (−6.8 ppm) and Ce (−2.2 ppm) forms of the reference methoxy derivative **5**. The chloro compound **8** also possesses a greater negative γ value for Ca (−6.3 ppm) than for Ce (+0.5 ppm) as commonly observed in many other analogs (16).

To support the conformational results obtained from the ^{13}C parameter analysis, the ^{1}H NMR spectra of **7** and **8** were also analyzed at −120°C. However, because the majority of the signals of the two less-populated conformers (namely the second and third conformer in order of decreasing population) overlap with those of the major conformer (namely the first conformer), complete spectral assignment for **7** was made using the ^{1}H–^{1}H COSY 2D experiment (11) at −120°C. Figure 3 shows the contour plot obtained at −120°C from the COSY 2D experiment together with the normal one-dimensional ^{1}H spectrum above it. The diagonal peaks correspond to the chemical shifts of the various signals in the normal spectrum while the off-diagonal peaks result from coherence transfer via *J* coupling.

The downfield signal H-2e at 4.6 ppm was taken as starting point for the assignment. This signal numbered 1 on the diagonal of the contour plot shows two correlations (2 and 3) that identify H-3e and H-3a. Next, the H-3e peak at 2.4 ppm gives rise to the two correlations 4 and 5 that identify H-4e and H4a. Finally, the two protons H-5a and H-5e were assigned using the two correlations 6 and 7. The assignment of axial and equatorial protons for **8** was similarly made and the data are presented in Table 2.

For the major conformer of **7** and **8**, the vicinal coupling constants between H-4 and H-5 agree with chair forms for which the substituent orientation is deduced as axial using the vicinal proton–proton coupling constant between H-2 and the two H-3 protons ($^{3}J_{2e-3e}$ = 3.7 Hz; $^{3}J_{2e-3a}$ = 2.6 Hz for **7** and $^{3}J_{2e-3e} = {}^{3}J_{2e-3a}$ = 3.0 Hz for **8**). The minor H-2 signals at 4.09 and 4.66 ppm for the second conformer of both compounds **7** and **8** showed only one large coupling con-

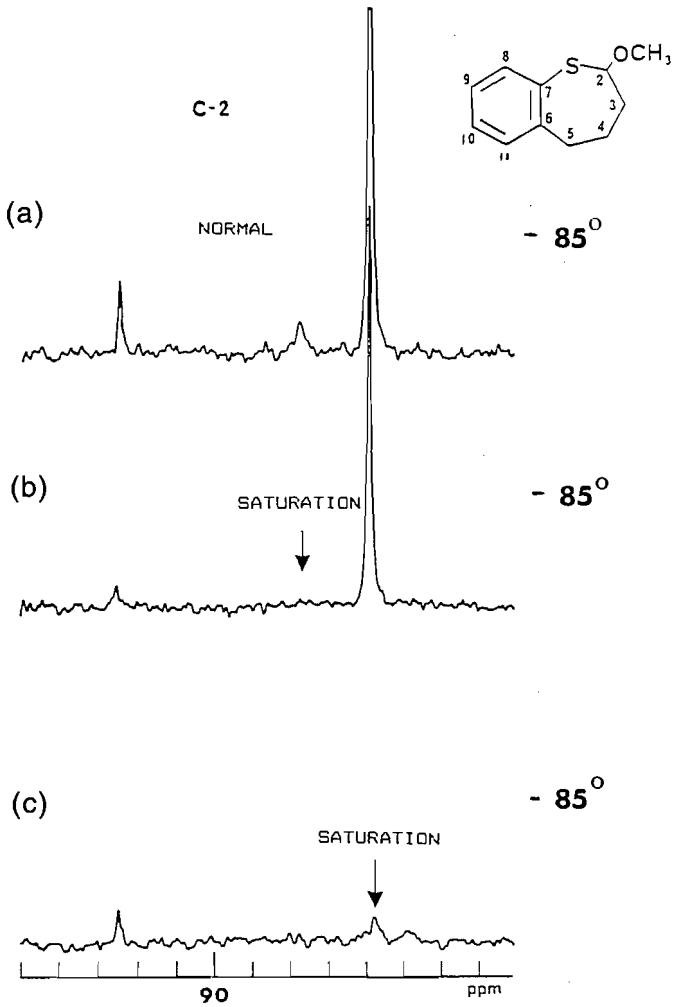

FIG. 2. Partial 100.6 MHz ^{13}C NMR spectra of **7** at −85°C with saturation transfer between the three conformers. (The intensities are normalized with the solvent signal.)

stant between H-2 and one of the two H-3 protons ($^3J_{2a-3a}$ = 11.3 Hz for **7** and 11.5 Hz for **8**) which is indicative of an equatorial orientation of the polar substituents (Y = OCH_3 for **7** and Y = Cl for **8**).

For the third and less populated conformer, no signal was detected in the ^1H spectra because of overlap with the major signals. However, based on the general behaviour for this family of compounds, the most likely conformer possible is the twist-boat form (TB).

In conclusion, the ^1H and ^{13}C NMR parameters for **7** and **8** are in accord with the presence of the three conformers, namely, Ca, Ce, TB, in the ratios summarized in Table 1.

The $\Delta G^{\neq}$ values were estimated (17) at the coalescence temperatures of signals in the ^{13}C NMR spectra. The results for **7** are $\Delta G^{\neq}$(Ca–TB) = 12 ± 1 kcal mol^{-1} (T_c = −20°C) and $\Delta G^{\neq}$(Ce–TB) = 9 ± 1 kcal mol^{-1} (T_c = −50°C), while for the chloro compound **8**, $\Delta G^{\neq}$(Ca–TB) = 10.7 ± 0.5 kcal mol^{-1} (T_c = 35°C) and $\Delta G^{\neq}$(Ce–TB) = 10.2 ± 0.5 kcal mol^{-1} (T_c = −40°C).

Discussion

Conformation of the parent compounds 2 and 6

The ^1H and ^{13}C NMR spectra of the parent compounds **2** and **6** revealed exclusively the presence of the chair (C) conformation. This large preference for C over TB is totally in accord with that observed for analogous benzoxepins (5) and is in accord with the relative conformational energies calculated for TB using the MM2 Molecular Mechanics computer program (18) (2.8 kcal mol^{-1} for **2** and 3.1 kcal mol^{-1} for **6**).

Conformational dynamics

The activation energies for the conformational exchange processes of the sulfur compounds are summarized in Table 3. While compound **2** (Y = H), with sulfur at the 3 position, shows a low barrier for the C ⇄ C* inversion (ΔG^* = 7.0 kcal mol^{-1}), the three derivatives with sulfur at the 1 position (**6**, Y = H; **7**, Y = OCH_3; **8**, Y = Cl) possess a higher free energy barrier for the C ⇄ C* process (10.7–12.0 kcal mol^{-1}). The observation that the 1,5-benzodithiepin series (19) showed a similar high free energy barrier (10.9–12.9 kcal mol^{-1}) suggests that rotation about the phenyl–S bond contributes to raise the barrier for conformational interconversion.

Anomeric effect in the methoxy derivatives 3 and 7

In a previous publication (20), Wolfe *et al.* using the theoretical PMO method for sulfur derivatives confirmed the large preference for the *gauche* form in the :—S—C—Y moiety (dihedral angle θ = 60°) over the *anti* form (θ = 180°). The stabilization energy resulting from an interaction between the occupied (n_s) and unoccupied (σ^*_{C-Y}) molecular orbitals is proportional to $S^2/\Delta E$ (where S is the overlap between the two orbitals and ΔE is the energy difference between these two orbitals). The analysis of the n_x–σ^*_{C-Y} orbital interaction within this framework (20) predicts better overlap for the n_O than the n_S free electron pair and it is suggested that this term should dominate over the energy gap term (ΔE). Consequently, the anomeric effect is expected to be greater for the :—O—C—Y than for :—S—C—Y moiety. *Ab initio* studies (21) made on the O—C—O and S—C—O fragments are in accord with the above *n*-σ* analysis. Furthermore, assuming that a longer C—Y bond is a reflection of a stronger anomeric effect (22), the observation that the C—Cl bond lengths in some six-membered rings (23) are longer for :—O—C—Cl (1.84 Å) than for :—S—C—Cl (1.80 Å), supports the above prediction on the relative strength of the anomeric effect.

In spite of these considerations, it is found that the axial conformer is more favored in cyclic six-membered sulfur compounds because the C—S (1.84 Å) bond is longer than C—O (1.45 Å) and this reduces steric repulsion in Ca. For example, the results for both the six-membered 2-methoxytetrahydropyran (3*a*) **10** and 2-methoxytetrahydrothiopyran (24) **11** showed an identical Ca:Ce population ratio at 25°C in the nonpolar solvent CCl_4 (83:17), while in the more polar acetonitrile the Ca:Ce ratio is 68:32 for **10** and 79:21 for the sulfur analog **11**.

Comparison of our results for the two methoxy benzothiepins (**3** and **7**) to the analogous methoxy benzoxepins (**1** and **5**, whose results are also reported in Table 3) show similar axial preference in the 3-hetero series (>98% for **3** and 94% for **1** at −120°C), while for the 1-hetero series the Ca amounts are strikingly different, 93% for **7** and 5% for **5**. This low Ca population for **5** was explained (5) by a weakening of the *endo*-anomeric effect produced by a large departure from coplanarity in the :—O—C—OMe fragment as revealed by calculated torsional angles. A stronger

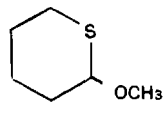
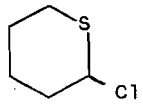
10



11



12

exo-anomeric effect was also expected to further stabilize the Ce form of **5**. In contrast, the departure from coplanarity in the :—S—C—OMe fragment of **7** does not appear to appreciably attenuate the n–σ* overlap from the *endo*-anomeric effect. In terms of free energy, the axial conformer of **7** is stabilized over the equatorial form by ΔG^0(a − e) = −1.0 kcal mol^{-1} while in **5** the situation is reversed with a destabilization ΔG^0(a − e) = 0.9 kcal mol^{-1}. Thus, the total energy difference between the Ca and Ce forms of **5** and **7** is estimated at about 1.9 kcal mol^{-1}. It would appear that the larger and more diffuse character of the n_S orbital relative to n_O orbital allows it to contribute more favorably to n–σ* overlap in spite of the appreciable departure from coplanarity as suggested by the torsion angle near 35° that is estimated for both **5** and **7** by the MM2 computer program (18).

Finally it appears that the stereoelectronic stabilization of the TB in compound **7**, mainly by the anomeric effect, is sufficient to lead to observable NMR signals (2%), while for compound **5** the attenuation of the anomeric effect (n–σ*$_{C—O}$) was not sufficient to lead to observable signals for the TB form (5*b*).

*Anomeric effect in the chloro derivatives **4** and **8***

The advantage of the chloro substituent over the methoxy group is that it has no particular rotamer favouring the *exo*-anomeric interaction (25). Now, without this contribution,

TABLE 3. Thermodynamic and kinetic data for compounds **1–8**

Compound	Solvent	Conformer	Population, %[a,b]	$-\Delta G^0$, kcal/mol (T, °C)	$\Delta G^{\neq}$, kcal/mol (T, °C)
1[c]	CHF_2Cl	Ca	94	0.84 (Ca/Ce, −120)	8.8 (Ca→Ce, −85)
		Ce	6		
2	CHF_2Cl	C	>98	>1.2 (C/TB, −143)	7.0 (C→C*, −127)
3	CHF_2Cl	Ca	>98	>1.2 (C/TB, −140)	—
4	CHF_2Cl	Ca	>98	>1.2 (C/TB, −120)	—
5[c]	CHF_2Cl	Ca	5	0.89 (Ce/Ca, −120)	8.4 (Ce→Ca, −90)
			95		
6	CHF_2Cl	C	>98	>1.2 (C/TB, −120)	10.8 (C→C*, −45)
7	CHF_2Cl	Ca	93	1.0 (Ca/Ce, −120)	12.0 (Ca→TB, −20)
		Ce	5	1.2 (Ca/TB, −120)	9.0 (Ce→TB, −50)
		TB	2	0.3 (Ce/TB, −120)	
8	CHF_2Cl	Ca	85	0.6 (Ca/Ce, −120)	10.7 (Ca→TB, −35)
		Ce	12	1.0 (Ca/TB, −120)	10.2 (Ce→TB, −40)
		TB	3	0.4 (Ce/TB, −120)	

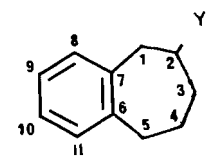
[a]Populations in CH_3OCH_3 are similar for **2–6**, while for **7** and **8** populations are Ca:Ce:TB, 91:6:3 and Ca:Ce:TB, 80:17:3, respectively.
[b]Uncertainties on conformer populations were ±0.5.
[c]Data taken from ref. 5*b*.

the Ca/Ce ratio should be representative of the strength of *endo*-anomeric effect alone (25). Furthermore, the relative steric effect of both the methoxy and the chloro groups is expected to be similar as indicated by the similar conformational *A* values in the cyclohexane series (26).

Considering the relative energies of the σ^*_{C-Y} orbitals (lower for Y=Cl than for Y=OCH_3) (27), the energy gap ΔE for the n_S–σ^*_{C-Y} interaction suggests a better anomeric stabilization for the chloro substituent than for the methoxy group. Considering the similar electronegativity of Cl and OCH_3, it is expected (28) that both σ^*_{C-Cl} and σ^*_{C-OCH3} would provide the same overlap (S^2) with the n_S orbitals. Consequently for a six-membered ring, the 2-chlorotetrahydrothiopyran **12** shows a larger axial preference[2] with ΔG^0(a − e) = −1.75 kcal mol^{-1} than the methoxy analogue **11** for which ΔG^0(a − e) = −1.53 kcal mol^{-1}.

Our results for the thio derivatives **3** and **4** (>98% of Ca) are not sufficiently sensitive to show differences between the chloro and methoxy substituents. However, in compounds **7** and **8** a larger axial preference is observed for the methoxy derivative **7** relative to the chloro derivative **8**. This result is opposite to that reported earlier for six-membered rings.[2] An electrostatic interaction between the polar substituent (Cl or OCH_3) and the benzo group favouring the Ce form has been identified in the past (9) for the methoxy and chloro derivatives **13** and **14** of benzocycloheptene. Such an electrostatic interaction might also be responsible for the stronger axial preference for **7** (Y = OCH_3) than for **8** (Y = Cl).

Considering that in both compounds **4** and **8** the chloro group is located at the same ring position, then the difference in the Ca amounts should arise mainly from the change in the S-atom position in the seven-membered ring. With sulfur located at that 3 position (as in **4**), the large preference for the Ca (Ca/Ce > 49) is controlled by the *endo*-anomeric effect, while with sulfur at the 1 position (as in **8**) the preference for the axial form is reduced slightly (Ca/Ce = 7.7) and, possibly, as the result of a departure from coplanarity in the :—S—C—Cl moiety in **8**, which could lead to a slight reduction of the *endo*-anomeric effect and therefore shift the equilibrium towards the Ce conformer.



13 Y=OCH_3
14 Y=Cl

Finally, the *endo*-anomeric effect n_S–σ^*_{C-Cl} contributes to the stabilization of TB (3%) in **8** but not in **4**. This trend was also observed for the methoxy derivatives **3** and **7**.

Experimental

High-field variable temperature ^1H, ^{13}C, and COSY 2D NMR spectra were recorded with a Bruker WH-400 spectrometer equipped with a B-VT-100 variable temperature unit. Calibration using a copper–constantan thermocouple inside an NMR tube containing a solvent indicates that the temperatures reported are precise within ±3°C.

The samples used in the variable temperature ^1H experiment were prepared as a CHF_2Cl solution (15–20 mg in 0.55 mL of solution) containing 18% of CD_2Cl_2 (for locking purposes), 82% of CHF_2Cl, and a small quantity of Me_4Si in 5-mm tubes that were degassed and sealed. The degassed carbon-13 samples were prepared in CHF_2Cl or CH_3OCH_3 (120–180 mg in 2.2 mL of solution) containing 18% of CD_2Cl_2 (for locking purposes) and a small quantity of Me_4Si.

Reliable integrations from the ^{13}C spectra were obtained using a 0.1–0.2 s delay between pulses and by averaging at least three sets of carbon signals for each compound.

Normal and long-range HETCOR 2D NMR spectra were performed on a Varian VXR-300 spectrometer in $CDCl_3$, using the published pulse sequence (7, 8), for which 128 FID of 2K were recorded. A Gaussian function was applied and the final matrix was zero-filled to 256 × 2K. The digital resolution obtained was between 5–10 Hz/pt (F2, ^{13}C) and 2–4 Hz/pt (F1, ^1H).

Typical parameters for the COSY 2D spectra are as follows:

[2]Reference 2, p. 24.

128FID × 1K of 16 scans were acquired and the final matrix was treated with Gaussian multiplication and zero-filled to 1K × 1K matrix. The digital resolution was between 2 and 4 Hz/pt.

The high-resolution mass spectra were taken on a modified MS-50 spectrometer at 70 eV.

The molecular mechanics (MM2) calculations were obtained on an IBM/AT computer, using the PCMODEL program (18) purchased from Serena Software, Box 3076, Bloomington, IN 47402-3076.

Compounds **2–4** and **6–8** were prepared as follows:

1,2,4,5-Tetrahydro-3-benzothiepin (2)

This compound was prepared by the reaction of ditosylated 1,2-benzenediethanol (*5b*) (10 g, 24.4 mmol) in 150 mL of ethanol with sodium sulfide nonanhydrate (5.9 g, 24.5 mmol). The suspension was stirred vigourously for 6 h at room temperature and then filtered. The solvent was removed under vacuum and the remaining liquid was purified by flash chromatography on silica gel (230–400 mesh) using a mixture of CH_2Cl_2:hexanes/50:50 as eluant. The solid compound **2** (2.4 g), reported in the literature (29), was confirmed by the ^1H and ^{13}C NMR spectra listed in Tables 1 and 2. Mass spectrum EI, Exact Mass calcd. for $C_{10}H_{12}S$: 164.066; found: 164.066.

2-Chloro-1,2,4,5-tetrahydro-3-benzothiepin (4)

This compound was prepared by the reaction of 1,2,4,5-tetrahydro-3-benzothiepin (**2**) (0.78 g, 4.75 mmol) at −20°C for 2 h with *N*-chlorosuccinimide (0.65 g, 4.86 mmol) in 30 mL of carbon tetrachloride. The mixture was then filtered and the solvent evaporated under vacuum to give 0.93 g of liquid, identified by its proton NMR spectrum as a mixture (50:50) of compound **4** and 1,2-dihydro-3-benzothiepin. Many purification attempts by distillation, flash chromatography (silica, alumina, basic alumina), or gas chromatography were unsuccessful and led to 1,2-dihydro-3-benzothiepin. The ^1H and ^{13}C NMR parameters were obtained on the mixture and those of **4** are reported in Tables 1 and 2. Mass spectrum CI, *m/e*: 199 (M + 1); 163 (M − Cl).

2-Methoxy-1,2,4,5-tetrahydro-3-benzothiepin (3)

At −80°C, the chloro derivative (**4**) freshly prepared as above (0.54 g, 2.72 mmol) was dissolved in 100 mL of methanol and the solution was neutralized with $NaHCO_3$ (0.28 g of $NaHCO_3$ was added in excess). The solution was then stirred vigourously at −80°C and a solution of silver trifluoromethanesulfonate (0.7 g, 2.72 mmol) in 5 mL of methanol at −80°C was added dropwise. After 0.5 h, the mixture was filtered, poured into 100 mL of water, and extracted with 3 × 150 mL of ether. The organic layers were dried with magnesium sulfate, filtered, and evaporated under vacuum. Purification by flash chromatography on silica gel (230–400 mesh) eluting with (10% CH_2Cl_2/hexane) yielded 0.32 g of pure 2-methoxy-1,2,4,5-tetrahydro-3-benzothiepin (**3**). The ^1H and ^{13}C NMR parameters are reported in Tables 1 and 2. Mass spectrum EI, Exact Mass calcd. for $C_{11}H_{14}OS$: 194.076; found: 194.073; CI, *m/e*: 195 (M + 1), 163 (M − OCH_3).

2,3,4,5-Tetrahydro-1-benzothiepin (6)

This compound was prepared using thiophenol as starting material by a published method (30). The compound was purified by flash chromatography on silica gel (230–400 mesh) using a mixture of CH_2Cl_2 and hexane as eluant.

The ^1H and ^{13}C NMR parameters are reported in Tables 1 and 2. Mass spectrum EI, Exact Mass calcd. for $C_{10}H_{12}S$: 164.066; found: 164.063.

2-Chloro-2,3,4,5-tetrahydro-1-benzothiepin (8)

N-Chlorosuccinimide (0.68 g, 5.09 mmol) was added to a solution containing compound **6** (0.8 g, 4.87 mmol) in 15 mL of carbon tetrachloride. The mixture was stired overnight, filtered, and evaporated under vacuum to give 0.95 g of compound **8** as a liquid. The ^1H and ^{13}C data listed in Tables 1 and 2 showed the compound to be pure. Mass spectrum CI, *m/e*: 199 (M + 1), 163 (M − Cl).

2-Methoxy-2,3,4,5-tetrahydro-1-banzothiepin (7)

A solution of silver trifluoromethanesulfonate (0.65 g, 2.52 mmol) in 4 mL of methanol was added dropwise to a stirred solution of the chloro compound **8** (0.5 g, 2.52 mmol) in 30 mL of methanol. After 0.5 h the acid mixture was neutralized with $NaHCO_3$, filtered, and added to 10 mL of water. Extractions were made with 3 × 100 mL of ether and the organic fractions were dried with $MgSO_4$, filtered, and evaporated under vacuum. The mixture was purified on flash chromatography eluting with a mixture of 20% CH_2Cl_2:hexane to give 0.39 g of compound **7** as liquid. The ^1H and ^{13}C NMR data are listed in Tables 1 and 2. Mass spectrum EI, Exact Mass calcd. for $C_{11}H_{14}OS$: 194.076; found: 194.073; CI, *m/e*: 195 (M + 1), 163 (M − OCH_3).

Received September 19, 1991[2]

JAMES V. DAVIES, FRANKIE W. LAU, LOANNE T. N. LE, JOHN T. W. LAI, and YOSHIKATA KOGA. Can J. Chem. **70**, 2659 (1992).

Thermal expansivities of aqueous solutions of 2-butoxyethanol (BE) were measured at concentrations of $x_{BE} < 0.04$, where x_{BE} is the mole fraction of BE. Thermal expansivity is a second derivative of the Gibbs free energy. The composition derivatives of thermal expansivities, the third derivatives, show peak anomalies at the same loci as the other third derivatives of the Gibbs free energy reported earlier from this laboratory (Can. J. Chem. **67**, 671 (1989); J. Phys. Chem. **94**, 3879 (1990); J. Phys. Chem. **95**, 4119 (1991)). The loci of such anomalies form a boundary that separates two regions of totally different mixing schemes. The mixing scheme in the water-rich region seems to be consistent with the "iceberg formation," the "structure enhancement of H_2O by hydrophobic solute," and the "hydrophobic attraction." In the intermediate composition region, the hydrogen bond network of H_2O collapses due to the presence of too many molecules of BE, and H_2O and BE molecules interact with each other as normal liquid molecules.

JAMES V. DAVIES, FRANKIE W. LAU, LOANNE T. N. LE, JOHN T. W. LAI et YOSHIKATA KOGA. Can. J. Chem. **70**, 2659 (1992).

On a mesuré l'expansibilité thermique de solutions aqueuses du 2-butoxyéthanol (BE) à des concentrations de $x_{BE} < 0.04$ où x_{BE} est la fraction molaire du BE. L'expansibilité thermique est égale à la deuxième dérivé de l'énergie libre de Gibbs. Les dérivés de l'expansibilité thermique en fonction de la composition, les troisièmes dérivés, présentent des anomalies dans les pics aux mêmes endroits que les autres troisièmes dérivés de l'énergie libre de Gibbs rapportées antérieurement par ce laboratoire (Can. J. Chem. **67**, 671 (1989); J. Phys. Chem. **94**, 3879 (1990); J. Phys. Chem. **95**, 4119 (1991)). Les locations de ces anomalies forment une frontière qui sépare deux régions dans lesquelles les processus de mélange sont totalement différents. La processus dans la région riche en eau semble être en accord avec les concepts de «formation d'iceberg», de «rehaussement de la structure de l'eau par le soluté hydrophobe» et d'«attraction hydrophobe». Dans la région de composition intermédiaire, la présence d'une trop grande quantité de molécules de BE provoque une désagrégation du réseau de liaisons hydrogènes de l'eau et les molécules d'eau et de BE interagissent les unes avec les autres comme des molécules liquides normales.

[Traduit par la rédaction]

Introduction

In previous thermodynamic studies from this laboratory on aqueous solutions of 2-butoxyethanol (BE), the excess partial molar enthalpies, $H_m^E(i)$ (1, 2), entropies, $S_m^E(i)$ (3), and volumes, $V_m^E(i)$ (4, 7), were reported. Here i stands for BE or H_2O. These quantities were determined accurately and at small increments in mole fraction. Thus the derivatives of these quantities with respect to the amount of the ith species were evaluated with a reasonable accuracy, within several per cent. These derivatives signify the effect of an additional ith species on the respective partial molar quantity of the existing ith species. Thus, it was argued (1–4, 7) that they provide a measure of the ith species – ith species interaction in terms of enthalpy, entropy, or volume, respectively.

With the aid of these quantities, we pointed out that there are three composition regions in the single phase domain, in each of which the mixing scheme is qualitatively different from those in the other regions. Furthermore, we pointed out (1–4, 7) that the crossovers between the neighbouring regions are associated with anomalies in the third or the fourth derivatives of the Gibbs free energy. In particular, the transition from the water-rich to the intermediate composition regions was accompanied by peak anomalies in the third derivatives of the Gibbs free energy.

This work is a part of continuing efforts of learning how the other third derivatives behave across this boundary in mixing scheme. To this end we measured thermal expansivities of the BE–H_2O mixtures.

Experimental

2-Butoxyethanol (BE) used was supplied by Aldrich (99+%, spectroscopic grade). H_2O was freshly distilled. The mixtures were prepared by weighing. BE was weighed out, at least 3 g, to within 0.0001 g and H_2O, about 300 g, to 0.01 g for series I (see below), or to 0.1 g for series II. Thus the mole fraction was determined at worst within 0.05%, taking account of the effect of degassing noted below.

A home-made dilatometer is shown in Fig. 1. It is made of Pyrex glass with a volume of about 270 mL. A capillary of 1 mm diameter is fitted through a B19 ground joint. A standard wooden meter stick was fixed to the capillary by means of two plastic cord holders. The cross-sectional areas of the capillary at various positions of the meter stick were calibrated by using a small amount of mercury. It was found necessary to degas the sample immediately before filling the dilatometer. Otherwise, gas bubbles formed in the dilatometer. Degassing was accomplished by connecting the flask containing a sample solution to a 2 L flask evacuated to approxi-

mately 10 Torr (1 Torr = 133.3 Pa) and then immersing the flask in an ultrasonic bath for 3 min. The decrease in mass following this procedure was less than 0.03%, which was judged to cause a negligible change in solution composition. No problems associated with dissolved gases were subsequently detectable.

The dilatometer filled with a sample was immersed in a bath the temperature of which was controlled within ±0.001°C. The temperature of the bath was measured to 0.01°C by a mercury-in-glass thermometer, which had been calibrated at the ice point and the melting point of $Na_2SO_4 \cdot 10H_2O$, 32.383°C. After thermal equilibration, which was attained within an hour, the temperature of the bath was raised and the volume change was measured by the rise of the meniscus in the capillary.

Two series of measurements were performed. At lower mole fraction regions, the thermal expansivities turned out to be smaller than those at higher concentrations. Therefore, in the first series, after thermal equilibration at 20°C the temperature was raised successively by 2°C up to 30°C for the concentration region $x_{BE} < 0.026$. In the second series, $x_{BE} > 0.01$, the temperature was changed by 1°C from about 23.5 up to 26.5°C. In this way the meniscus rise for both series was typically from 10 to 20 cm, depending on the concentration of the sample. The meniscus rise was read to 0.01 cm by a magnifying glass. The temperature change was determined with a Beckmann thermometer to within 0.001°C. Thus with stem corrections for both the Beckmann thermometer and the

capillary of the dilatometer, the uncertainties were estimated to be less than 0.5%. Taking into account the thermal expansivity of Pyrex glass, we could indeed reproduce the thermal expansivity of pure H_2O within 0.25% of the literature values (6) in the temperature range from 20 to 30°C.

Results and discussion

The definition of thermal expansivity, α_p, is given by

$$[1] \quad \alpha_p = (1/V)(\partial V/\partial T)_p$$

As mentioned above, we used a dilatometer with its total volume, V_0, being kept constant. Thus, we actually measure the following quantity, α_p', given by

$$[2] \quad \alpha_p' = (1/V_0)(\partial V/\partial T) = (1/V_0)(\partial^2 G/\partial p \partial T)$$

which is therefore a second derivative of the Gibbs free energy. Thus, we wish to measure the values of α_p' in small increments in composition and to determine the following derivative, the third derivative of the Gibbs free energy:

$$[3] \quad (\partial \alpha_p'/\partial n_{BE})_{n_W} = (\partial x_{BE}/\partial n_{BE})_{n_W}(\partial \alpha_p'/\partial x_{BE})$$
$$= (1/N)(1 - x_{BE})(\partial \alpha_p'/\partial x_{BE})$$
$$= (1/V_0)(\partial^3 G/\partial p \partial T \partial n_{BE})$$

Here, $N = n_{BE} + n_W$, and n_{BE} and n_W are the amounts of BE and H_2O in the mixture.

Table 1 lists the results for series I. A typical plot of α_p' vs. temperature at a given mole fraction is shown in Fig. 2. The curve in the figure is a quadratic equation fit to the five values of α_p' determined at 21, 23, 25, 27, and 29°C. From such a curve fitting, the values of α_p' at 20.00, 25.00, and 30.00°C were obtained and are also listed in Table 1. For series II, since there are only three values, determined at 24, 25, and 26°C, a linear fit was used to estimate the value of α_p' at 25.00°C and the uncertainty for each mole fraction. Such values of α_p' at 25.00°C are listed in Table 2 together with all the measured values.

All of these data for α_p' are plotted against x_{BE} in Fig. 3. Inflection points are clearly apparent. The derivatives of eq.

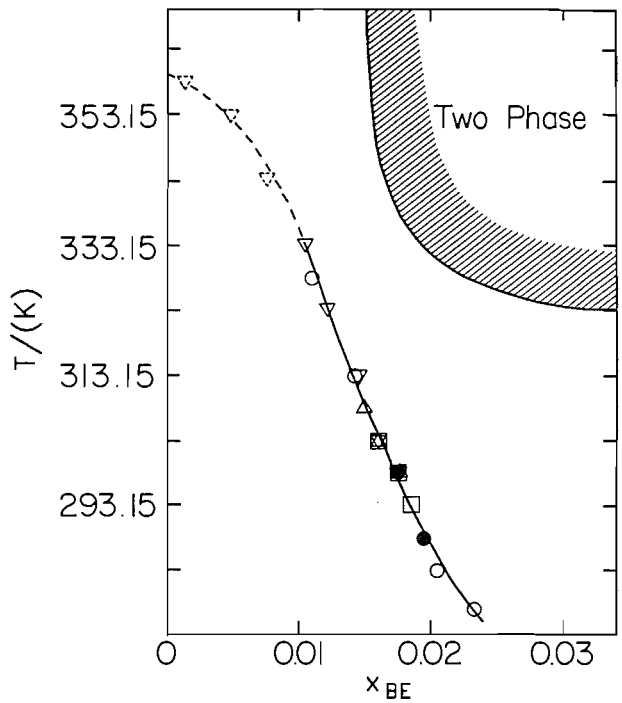

FIG. 5. The loci of peak or cusp anomalies in various third derivatives of Gibbs free energy: $\Delta\nabla$ ▽, $(\partial H_m^E(BE)/\partial n_{BE})$, refs. 1–3; ○, $C_p^E(BE)$, ref. 5; ●, $(\partial V_m^E(BE)/\partial n_{BE})$, ref. 7; □, $(\partial\alpha_p'/\partial n_{BE})$, this work.

[3] are graphically evaluated from Fig. 3. The results are plotted in Fig. 4 for N taken to be unity. An estimated uncertainty is shown in Fig. 4. The loci of the peak anomalies shown in Fig. 4 are plotted in Fig. 5 together with those of other third derivatives mentioned in the Introduction. They all seem to fall on the same boundary.

According to the discussion presented in the previous papers (1–4, 7), in the region to the left of the boundary shown in Fig. 5, the hydrogen bond network of H_2O is enhanced by BE molecules in the solution. In the intermediate concentration region, to the right of the boundary, H_2O loses its hydrogen bond network and behaves as a normal liquid. The fact that the values of α_p' are smaller in the water-rich region

than those in the intermediate region, as is apparent from Fig. 3, is perfectly consistent with the above interpretation. In the water-rich region, the volume increase due to thermal motion is compensated for by the volume decrease due to the breakage of hydrogen bonds on heating.

The acidic specific capsular polysaccharide of *Rhodococcus equi* serotype 3. Structural elucidation and stereochemical analysis of the lactate ether and pyruvate acetal substituents[1]

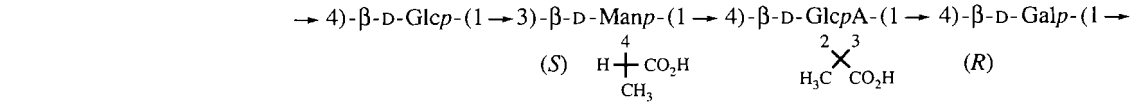
WAYNE B. SEVERN[2] AND JAMES C. RICHARDS

Institute for Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received May 1, 1992

WAYNE B. SEVERN and JAMES C. RICHARDS. Can. J. Chem. **70**, 2664 (1992).

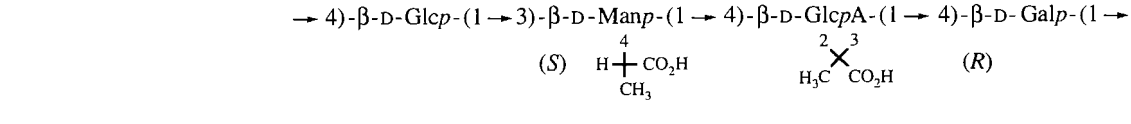
The specific capsular polysaccharide produced by *Rhodococcus equi* serotype 3 was found to be a high-molecular-weight acidic polymer composed of D-glucose, D-galactose, D-glucuronic acid, 4-*O*-[(*S*)-1-carboxyethyl]-D-mannose, and pyruvic acid in equal molar proportions. Structural analysis, employing a combination of chemical and nuclear magnetic resonance techniques, established that the polysaccharide is composed of linear repeating tetrasaccharide units,



in which (*R*)-1-carboxyethylidene groups bridge the O-2 and O-3 positions of the β-D-glucuronic acid residues. The ^1H and ^{13}C NMR resonances of the native and depyruvulated serotype 3 polysaccharides were fully assigned by homo- and heteronuclear chemical shift correlation methods. The absolute configurations of the lactate-substituted mannopyranosyl residues and the pyruvate acetals were determined from ^1H–^1H NOE measurements on the intact polysaccharide. Unequivocal determination of the absolute chirality of the 4-*O*-[(*S*)-1-carboxyethyl]-β-D-mannopyranose residues was achieved by ^1H–^1H NOE measurements on an acetylated lactone derivative of the glycose.

WAYNE B. SEVERN et JAMES C. RICHARDS. Can. J. Chem. **70**, 2664 (1992).

On a trouvé que le polysaccharide capsulaire spécifique produit par le *Rhodococcus equi* du sérotype 3 est un polymère acide de poids moléculaire élevé, composé de D-glucose, de D-galactose, d'acide D-glucuronique, de 4-*O*-[(*S*)-1-carboxyéthyl]-D-mannose et d'acide pyruvique présents en proportions molaires égales. Une analyse structurale faisant appel à une combinaison de techniques chimiques et de la résonance magnétique nucléaire a permis d'établir que le polysaccharide est formé d'unités linéaires tétrasaccharides qui se répètent,



dans lesquelles des groupes (*R*)-1-carboxyéthylidènes forment un pont entre les positions O-2 et O-3 des résidus d'acide β-D-glucuronique. Les spectres RMN du ^1H et du ^{13}C des polysaccharides du sérotype 3, tant naturel que dépourvu d'acide pyruvique, ont été attribués par des méthodes de corrélation des déplacements chimiques homo- et hétéronucléaires. Les configurations absolues des résidus mannopyranosyles substitués par un lactate ainsi que les acétals pyruviques ont été déterminés par des mesures d'eOn ^1H–^1H sur le polysaccharide intact. On a réalisé une détermination univoque de la chiralité absolue des résidus 4-*O*-[(*S*)-1-carboxyéthyl]-β-D-mannopyranose grâce à des mesures d'eOn sur un dérivé lactone acétylé du glycose.

[Traduit par la rédaction]

Introduction

Rhodococcus equi (1) is a Gram-positive bacterial pathogen that causes serious, and often fatal, respiratory disease in 4 to 12 week old foals (2). The bacteria are encapsulated by negatively charged, carbohydrate polymers that are serotype specific (3, 4). By using a double immunodiffusion precipitation test (4) seven serotypes of the *R. equi* are currently recognised.

Capsular polysaccharide (CPS) is identified as a potential virulence factor of both Gram-positive and Gram-negative bacteria (5). In pathogenic bacteria, the capsular layer provides protection from the nonspecific host defense mechanisms, although the relationship between the presence of capsule and pathogenesis in *R. equi* has not been established.

In an attempt to understand the molecular basis for the antigenic diversity of the *R. equi* CPS, we have employed a combination of NMR and MS based strategies for their structural elucidation (6). The specific CPS's of serotypes 1 and 2 have been fully characterized (7, 8). Both were found to be high-molecular-weight heteroglycans composed of linear tetrasaccharide units containing D-glucuronic acid residues. In addition, the two polysaccharides contained acidic, non-carbohydrate components that could be related to their serological specificities. The serotype 1 polysaccharide was found to contain 1-carboxyethylidene (pyruvic acid) acetal groups while the serotype 2 polysaccharde carries biosynthetically related (9) 1-carboxyethyl (lactic acid) ether substituents.

Pyruvic acid acetals occur widely in bacterial polysaccharides (9) and are recognised (10) as immunodominant structural features. Although less frequently encountered, lactic acid ether substituted sugars have been reported as components of both lipo- and extracellular polysaccharides (9). The structural variability of the antigenic determinants

is influenced by: (1) the nature of the substituted monosaccharide residue, (2) the position(s) of substitution, and (3) the chirality of the substituent. These features were completely assigned for the components present in the *R. equi* serotype 1 and 2 polysaccharides. NMR spectroscopy led to the identification of (*S*)-1-carboxyethylidene acetal groups linked to the O-4 and O-6 positions of β-D-mannopyranosyl residues in the serotype 1 polysaccharide (7). For the serotype 2 CPS, a chemical approach was employed to establish the presence of 3-*O*-[(*S*)-1-carboxyethyl]-α-L-rhamnopyranosyl residues (8).

In the present investigation, the structural elucidation of the specific capsular polysaccharide produced by *R. equi* serotype 3 is reported. This polysaccharide is unusual in that it contains both the pyruvic acid and lactic acid moieties in a D-glucuronic-acid-containing tetrasaccharide repeating unit. The absolute stereochemistry of these chiral antigenic determinants was determined by proton nuclear Overhauser enhancement based methods.

Results and discussion

Isolation and purification

The specific capsular polysaccharide produced by *R. equi* serotype 3 was isolated from plate-grown cells by mechanical dissociation from the cellular material into 4 M sodium chloride solution. Following enzymatic digestion with ribonuclease, deoxyribonuclease, and proteinase K, the polysaccharide was purified via its insoluble cetyltrimethyl ammonium salt (8). Pure capsule was obtained by ion exchange chromatography on DEAE–Sephacel as a discrete band at the beginning of the sodium chloride gradient and was judged to be free from nucleic acids and proteins since neither ribose nor amino acids were detectable in its acid hydrolysis products. The polysaccharide had $[\alpha]_D$ −5.5 (*c* 1.2, water); Anal. found: C 40.76, H 5.45, N 0.00, ash 0.8%; and gave a single sharp precipitin line in immunodiffusion against rabbit antisera to *R. equi* serotype 3 cells (4). All subsequent analyses were made on the DEAE–Sephacel purified product.

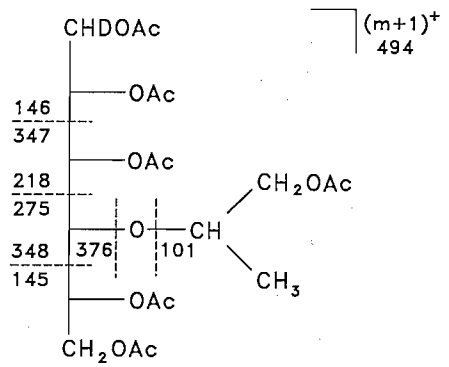
Composition

The native serotype 3 CPS eluted as a sharp band at the void volume (K_{av} 0.09) of a Sephadex G-200 gel filtration system, indicating it to be a high-molecular-weight polymer. Qualitative analysis of the eluant revealed that the polysaccharide contained both neutral glycose (11) and hexuronic acid components (12).

Analysis of the polysaccharide hydrolysis products (2 M trifluoroacetic acid, 100°C, 16 h) by high-performance anion exchange (HPAE) chromatography (13) indicated the neutral glycoses to be galactose (R_G 0.95) and glucose (R_G 1.0) (eluant A), while pyruvic acid (R_G 2.6), glucuronic acid (R_G 3.9), and a fifth component (R_G 3.2) were identified (eluant B) as the acidic constituents in the hydrolyzate.

The pyruvic acid moiety could be easily released from the native *R. equi* serotype 3 CPS by treatment of the polymer with dilute acetic acid (2%, 100°C, 2 h), indicating that the substituent was linked as an acetal to a glycosyl residue (10). The depyruvulated polysaccharide had $[\alpha]_D$ −4.8 (*c* 1.25, water); Anal. found: C 40.20, H 5.39, N 0.00, ash 0.9%.

GLC analysis of the reduced and acetylated hydrolysis products (14), derived from the *R. equi* serotype 3 polysaccharide, indicated that the neutral glycosyl residues, which were identified as 1,2,3,4,5,6-hexa-*O*-acetyl derivatives of glucitol (T_{GA} 1.0) and galactitol (T_{GA} 1.1), were present in approximately equimolar proportions. Sequential treatment of the polysaccharide with methanolic HCl (1 M, 85°C, 14 h) and sodium borohydride was employed to effect carboxyl group reduction. Subsequent hydrolysis and formation of the alditol acetates indicated the presence of glucose and galactose in the ratio of 2:1. When carboxyl group reduction was carried out with sodium borodeuteride, MS analysis confirmed that the glucuronic acid component, identified as 1,2,3,4,5,6-hexa-*O*-acetyl glucitol-6,6-d_2, represented approximately one half of the derived glucitol hexaacetate. A molar equivalent of an additional component was identified by using the methanolysis procedure (T_{GA} 1.5). The EI-MS fragmentation pattern for the carboxyl-reduced ($NaBH_4$) alditol acetate derived from this component is depicted below (**1**).



1

The primary fragment ion at *m/z* 101 is indicative of an acetoxypropyl moiety (15) and the shift of this fragment by two mass units to *m/z* 103 when carboxyl reduction was effected with $NaBD_4$ indicated it to be derived from a carboxyethyl moiety. Furthermore, peaks at *m/z* 145, 146, 218, 275, 347, 348, and 376 place this substituent at the 4-position of the alditol, establishing that the residue is a 4-*O*-(1-carboxyethyl)-hexose.

The absolute configurations of the unsubstituted glycoses were established from the characteristic GLC retention times of their trimethylsilylated *R*-2-butyl glycosides (16). In this way the glucosyl, galactosyl, and glucuronic acid residues were all assigned to the D-series.

Glycosyl linkage analysis

The methylated (17), reduced ($NaBH_4$) (18), and hydrolyzed, pyruvate-free, *R. equi* serotype 3 CPS afforded products that, after reduction ($NaBD_4$) and acetylation, furnished valuable mass spectral data on the positions of the linkages of the component glycosyl residues (Table 1). From this analysis it can be inferred that the capsular polysaccharide is composed of →4)-D-Glc*p*-(1→, →4)-D-Gal*p*-(1→, →4)-D-Glc*p*A-(1→ and a →3)-4-*O*-(1-carboxyethyl)-hex*p*-(1→, which form a linear tetrasaccharide unit. The hydrolysis products, analogously derived from the permethylated native polysaccharide, contained the same *O*-methylated derivatives for D-glucose, D-galactose, and the (1-carboxy-

[b]Retention times relative to that of 1,4,5-tri-*O*-acetyl-2,3,6-tri-*O*-methyl-D-glucitol-1-*d*, using GLC program A.

ethyl)-hexose. However, D-glucose was obtained instead of 2,3-di-*O*-methyl-D-glucose, indicating that the pyruvate acetals were linked to the O-2 and O-3 positions of the O-4 substituted D-glucuronic acid units in the native polysaccharide.

Glycosyl sequence determination

High-resolution NMR techniques were employed to establish the sequence of the glycosyl residues. The general approach involved the initial complete assignment of the ^{1}H and ^{13}C NMR spectra of the intact polysaccharide from which the relative stereochemistry, ring size, and anomeric configuration of the component glycoses were identified and the location of the 1-carboxyethylidene substituent confirmed.

Solubilization of the native polysaccharide in D_2O produced viscous solutions (pD $\approx$ 2) that gave broad lines in the NMR spectra. Although better resolution was obtained at higher temperatures, autohydrolysis of the pyruvic acid acetals was observed. To reduce the extent of degradation, all NMR spectra of the native polysaccharide were recorded at 62°C in D_2O buffered at pD $\approx$ 6.2.

Examination of the ^{1}H and ^{13}C NMR spectra of the type 3 polysaccharide confirmed the polymer to be composed of a regular repeating tetrasaccharide unit. The ^{1}H NMR spectrum of the native polysaccharide exhibited anomeric ^{1}H resonances corresponding to the four glycosyl residues in the low-field region of the spectrum at 5.03 (d, ca. 1H, J = 7.5 Hz), 4.73 (s, ca. 1H, J = 1.2 Hz), 4.58 (d, ca. 1H, J = 7.5 Hz), and 4.49 ppm (d, 1H, J = 7.8 Hz). Four ^{13}C resonances were observed in the proton-decoupled ^{13}C NMR spectrum between 110 and 100 ppm (Fig. 1*a*). The lowest-field resonance in this grouping (109.88 ppm) could be attributed to the acetal carbon of the pyruvic acid moiety from the ^{1}H coupled or DEPT (19) ^{13}C NMR spectra, while the intensity of the peak at 100.73 ppm suggested it to be composed of two coincident resonances. The magnitude of the heteronuclear one-bond ^{13}C–^{1}H coupling constants ($^1J_{C,H}$) was found to be ca. 160 Hz for each of the anomeric resonances, which indicates that the anomeric configurations of all the linkages were β (20). In accord with compositional analysis, diagnostic ^{13}C resonances were observed at 19.08 and 23.87 ppm from the methyl carbons of the carboxyethyl and carboxyethylidene groups, respectively; and three signals at low field, 182.4, 177.2, and 175.6 ppm, indicated the presence of the three carboxyl groups within the repeating unit. Correspondingly, characteristic high-field resonances at 1.61 (s, 3H) and 1.40 ppm (d, 3H, J = 7.7 Hz) in the ^{1}H NMR spectrum could be assigned to the methyl protons of the respective carboxyethylidene and carboxyethyl groups. The methyl singlet from the carboxyethylidene moiety was absent in the ^{1}H NMR spectrum of the pyruvate-free polysaccharide.

Assignment of the proton resonances from the native and pyruvate-free polysaccharides was made from two-dimensional homonuclear chemical shift correlation (COSY (21) and Relayed COSY (22)) experiments. Subspectra corresponding to each of the four glycosyl residues were identified from the chemical shift (23) and the vicinal ^{1}H–^{1}H coupling constant values (24). The residues were labelled **a**, **b**, **c**, and **d** according to decreasing order of the chemical shifts from the H-1 resonances (25). The observed chemical shifts and coupling constants for the native and pyruvate-free polysaccharide are given in Tables 2 and 3. Unambiguous assignment of the corresponding ^{13}C resonances was effected by correlation with the ^{1}H resonances of the directly attached protons by heteronuclear ^{13}C–^{1}H chemical shift correlation experiments (26) and the data are recorded in Tables 4 and 5.

The contour plot of the ring proton region of the COSY spectrum obtained on the native polysaccharide is shown in Fig. 2. Five ^{1}H resonances were associated with the subspectrum from residue **a** and, from the large observed ring proton coupling constants ($^3J \approx 10$ Hz), it could be identified as the β-D-glucopyranosyluronic acid unit. Analogously, the subspectrum arising from residue **c** could be attributed to a pyranosyl residue having the β-gluco configuration. The spin system associated with this residue comprised seven ^{1}H resonances and was assigned to the β-D-glucopyranosyl unit.

The connectivity pathway relating H-1, H-2, H-3, and H-4 of residue **d** was readily discernible from the cross-peaks, and the ^3J-values (Table 2) were typical of a pyranoside unit possessing the β-D-*galacto* configuration.

Residue **b** could be identified as a *manno*-pyranosyl unit from the observed small magnitude of the vicinal cou-

a	→4)-β-D-Glc*p*A-(1→ 2 3 (*R*) × H_3C CO_2H	5.03 (7.5)	3.48 (9.3)	3.75 (9.6)	4.17 (9.9)	3.79					1.61
b	→3)-β-D-Man*p*-(1→ 4 (*S*) H + CO_2H CH_3	4.73 (1.2)	4.16 (2.8)	4.03 (9.6)	3.66 (9.5)	3.48	3.79 (2.4)	3.97 (5.3, 12.5)	1.40 (7.7)	4.30	
c	→4)-β-D-Glc*p*-(1→	4.58 (7.5)	3.39 (9.0)	3.65 (9.6)	3.70 (9.6)	3.50	3.77 (2.3)	3.97 (5.3, 12.5)			
d	→4)-β-D-Gal*p*-(1→	4.49 (7.8)	3.67 (9.0)	3.76 (3.5)	4.21 (1.2)	3.76	3.76 (7.7)	3.76 (3.9, 10.7)			

[a]Observed first-order chemical shifts and coupling constants (Hz) measured at 62°C in D_2O/phosphate buffer (pD ≈ 6.2).

plings, $J_{1,2}$ (0.5 Hz) and $J_{2,3}$ (2.8 Hz). However, mannose was not detected in the polysaccharide acid hydrolysis products, which suggested this residue to be the *O*-(1-carboxyethyl)-substituted hexose. The AX_3 spin system associated with the carboxyethyl substituent of residue **b** was identified from cross-peaks in the full-scale COSY spectrum relating the methyl doublet at 1.40 ppm (J = 7.7 Hz) to the lactic acid H-2 quartet at 4.30 ppm. The low intensities of the cross peaks relating H-1 to H-2 of residue **b** and those relating H-4 to H-5 of residue **d** (Fig. 2) are attributed to the small values (ca. 1–3 Hz) for the scalar couplings, $J_{1,2}$ and $J_{4,5}$, typical of the *manno*- and *galacto*-pyranosyl configurations, respectively (18).

The ^{1}H NMR spectrum of the pyruvate-free polysaccharide lacked the characteristic signal due to the carboxyethylidene methyl protons that was observed for the native polysaccharide. In addition, H-1**a** and H-4**a** showed substantial upfield shifts (0.3–0.4 ppm) upon removal of the pyruvate group. With the exception of the protons associated with the glucopyranosyl uronic acid (residue **a**), the chemical shifts from residues **b**, **c**, and **d** (Table 3) were closely similar (within 0.1 ppm) to those observed for the native polysaccharide (Table 2).

In the ^{13}C NMR spectrum of the native polysaccharide, resonances at 182.40, 109.88, and 23.87 ppm were attributed to the respective carboxyl, acetal, and methyl carbons of the pyruvic acid moiety (Fig. 1*a*). These signals were absent in the spectrum of the depyruvulated polysaccharide (Fig.

1*b*). The low-field value of the acetal carbon (≈110 ppm) is indicative of the pyruvic acid acetal forming a five-membered ring system (27). A comparison of the ^{13}C NMR data from the native and the pyruvate-free polysaccharides (Tables 4 and 5) indicates that the β-D-glucopyranosyl uronic acid residue is substituted by the pyruvic acid moiety at the O-2 and O-3 positions, a result that is in accord with the methylation analysis data (Table 1). Following removal of the pyruvate, the corresponding carbon resonances, C-2 and C-3, showed significant upfield shifts of 2.7 and 3.3 ppm,

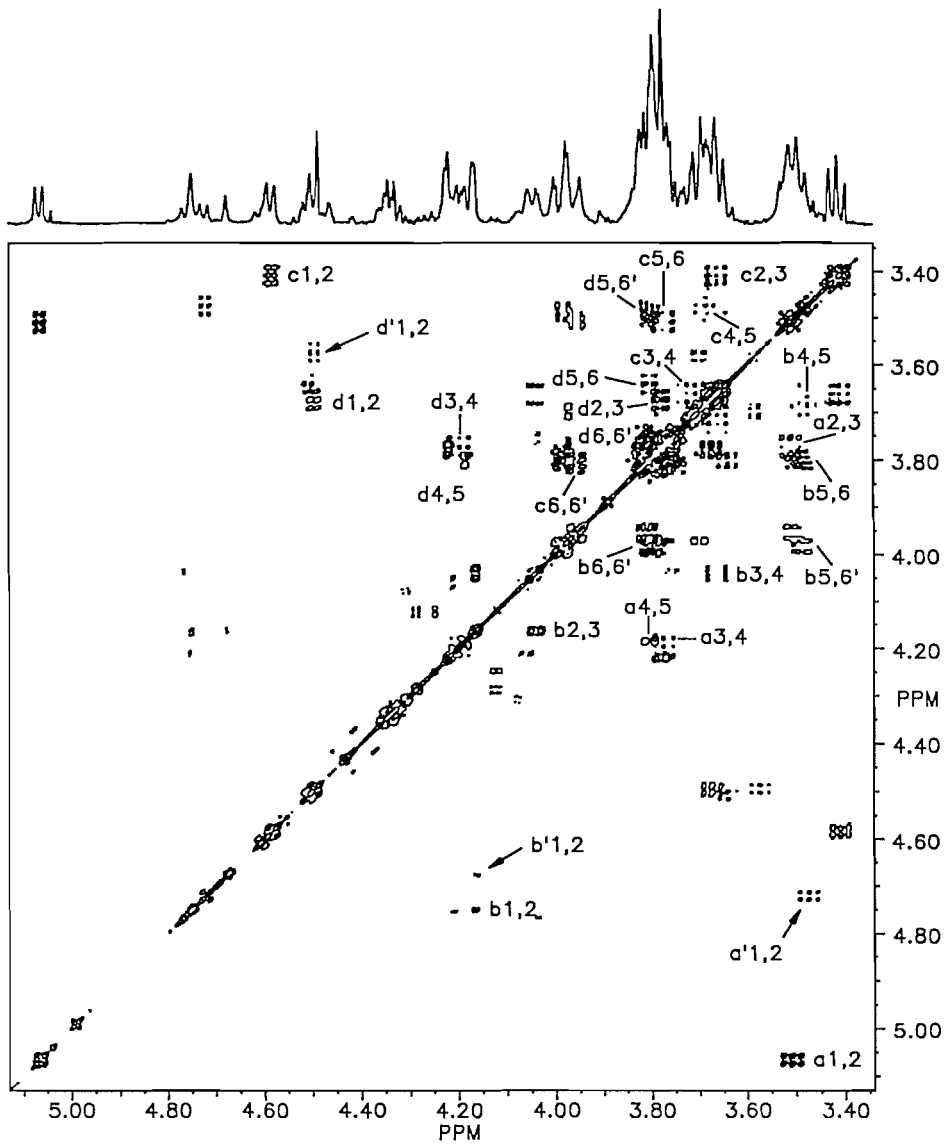

FIG. 2. Partial phase-sensitive COSY contour map of the native *R. equi* serotype 3 capsular polysaccharide recorded at 62°C, showing correlations of the ring protons from 3.3 to 5.1 ppm. Cross-peak assignments are indicated. **a**'1,2, **b**'1,2, **d**'1,2, and other minor peaks arise from partial depyruvulation of the polysaccharide.

respectively, while the adjacent carbons, C-1 and C-4, were shifted downfield by approximately 2.2 ppm. In addition, shielding effects experienced by C-3 and C-4 of residue **b**, i.e., upfield shifts of ≈1.0 and 1.6 ppm, respectively, may be attributed to conformational changes accompanying removal of the acetal substituent.

The arrangement of the four glycosyl residues within the repeating unit was determined from interresidue ^1H–^1H NOE measurements (28), which also served to confirm the positions of the glycosidic linkages (Table 6). NOE measurements were made using difference spectroscopy (29) (Fig. 3). The NOE were employed qualitatively to establish short (≥3 Å) through-space connectivities between the anomeric and aglyconic protons of the adjacent glycosidically linked residues. In addition, the occurrence of intraresidue NOE between H-1 andd H-3 and between H-1 and H-5 within the pyranose ring systems of each of the glycosyl residues was

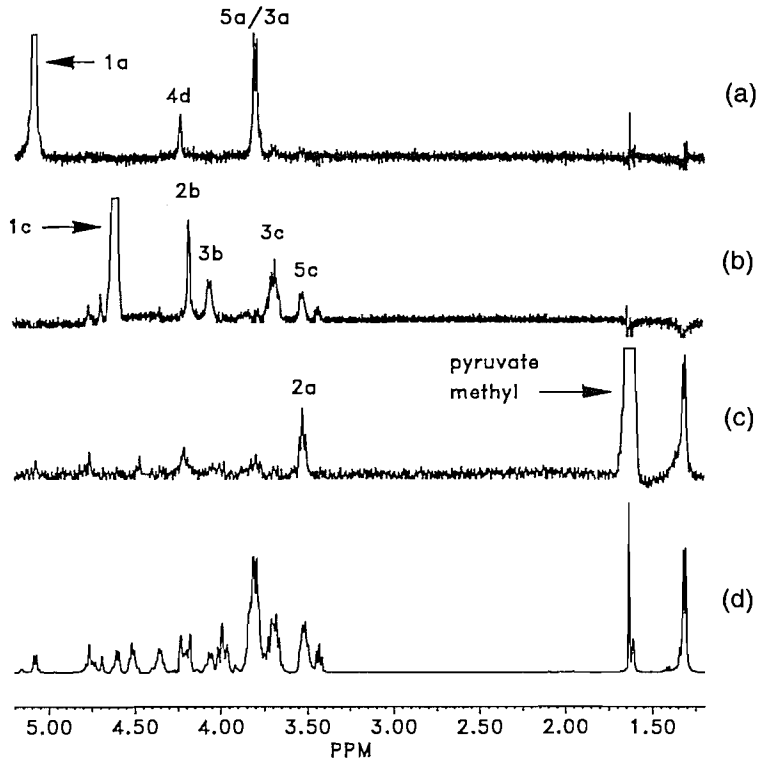

FIG. 3. NOE difference spectra measured on the native *R. equi* serotype 3 capsular polysaccharide. Spectrum arising from the irradiation of (*a*), H-1 of glucuronic acid unit (1**a**); (*b*), H-1 of glucosyl unit (1**c**); and (*c*), the methyl group of the pyruvate substituent. The off-resonance control spectrum is shown in (*d*).

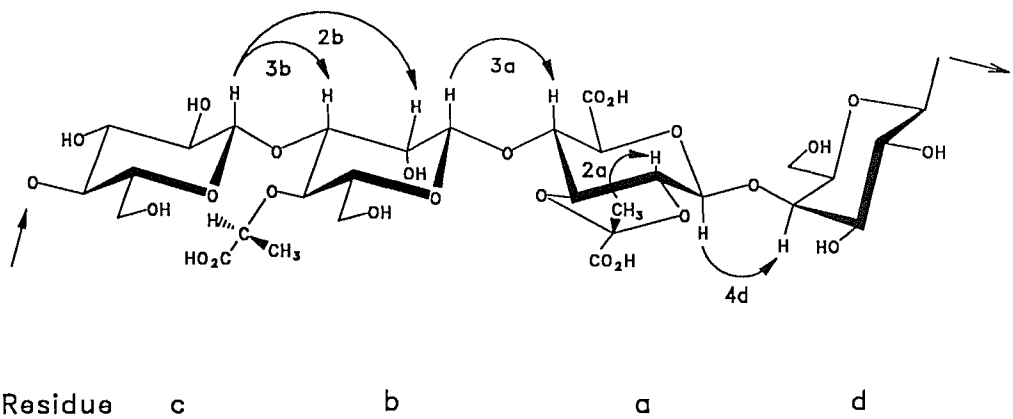

FIG. 4. The tetrasaccharide repeating unit of the *R. equi* serotype 3 capsular polysaccharide showing some of the observed NOE's.

indicative of their assigned β-configurations. Thus irradiation of the anomeric proton resonance (5.03 ppm) of the β-D-glucopyranosyluronic acid residue **a** showed strong NOE within the pyranose ring system to H-5**a** and (or) H-3**a** (≈3.79 ppm), and across the glycosidic bond to H-4**d** (4.21 ppm) of the D-galactopyranosyl residue (Fig. 3*a*). The connectivity established by the transglycosidic NOE (H1-**a**/H-4**d**), indicates the partial sequence **a**→**d** and further suggests that the β-D-glucopyranosyl uronic acid is linked to the O-4 position of the β-D-galactopyranosyl unit. The occurrence of interresidue NOE relating the H-1**d**/H-4**c**, H-1**c**/H-3**b**, and H-1**b**/H4**a** resonance pairs established the linear sequence of glycoses within the repeating tetrasaccharide unit as

[→**a**→**d**→**c**→**b**→]

The NOE connectivities are as shown in Fig. 4 and the indicated linkage positions (Table 6) are in agreement with the results from methylation analysis. Furthermore, the relatively deshielded values of the ^{13}C NMR resonances (≥79 ppm) from C-4**a**, C-3**b**, C-4**c**, and C-4**d** (Table 4) would indicate that the respective positions are glycosylated.

The conformation about the glycosidic linkage is to a large extent governed by the *exo*-anomeric effect (30). Thus, for a disaccharide in its minimum energy conformation, the internuclear distance between the anomeric and aglyconic protons of adjacent pyranose residues is of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

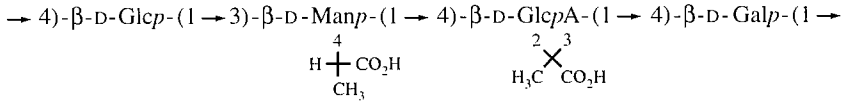
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

order of 3 Å, leading to a detectable NOE. In certain instances, interresidue NOE can be transferred to other protons on the aglycone. This can be realised when aglycone protons adjacent to the site of substitution occupy equatorial positions, viz., in 3-*O*-substituted mannopyranosyl or galactopyranosyl residues. Whether an NOE will be observed at an adjacent equatorial proton is dependent on the stereochemistry (D or L) of the two glycosyl residues (glycone and aglycone) and the configuration (α or β) of the adjoining glycosidic linkage. In the present context, significant NOE's were observed between H-1 of the β-D-glucopyranosyl residue **c** and both H-2 and H-3 of the lactate-substituted mannopyranosyl residue **b** (Fig. 3*b*). The absolute stereochemistry of the D-glucose residue was determined by chemical correlation with a standard of known chirality. The chirality of the 4-*O*-(1-carboxyethyl)-mannose residue was not evident by this method since appropriate standards were not available, but could be determined relative to that of the D-glucose residue from the observed $^1H-^1H$ NOE values.

The minimum energy conformations of the two disaccharide units, β-D-Glc*p*-(1→3)-β-D-Man*p* and β-D-Glc*p*-(1→3)-β-L-Man*p*, were calculated using the HSEA method (31) and the minimum energy molecules are shown in Fig. 5. A transglycosidic NOE would be expected between Glc H-1 and Man H-2 only in the disaccharide in which both glycosyl units possess the D-configuration (internuclear separation 2.8 Å) and not in the diastereoisomeric D-L disaccharide (separation 3.9 Å). The observation of an NOE between H-1**c** and H-2**b** of the β-D-1,3-linked **c**→**b** disaccharide unit of the native polysacchardie (Fig. 3*b*, Fig. 4) establishes that the 4-*O*-(1-carboxyethyl)-β-mannopyranose has the D-absolute configuration. A similar pattern of NOE was observed for the →4)-β-D-Glc*p*-(1→3)-β-D-Man*p*-(1→ unit in the *R. equi* serotype 1 polysaccharide in which the chirality of the mannose residue was established independently by chemical correlation (7).

Considerations of the conformation about the glycosidic bond of 1,3-linked disaccharides as a means of stereochemical assignment have previously been reported (32, 33).

Thus the tetrasaccharide unit of the *R. equi* S3 polysaccharide can be assigned the sequence shown in **2**.



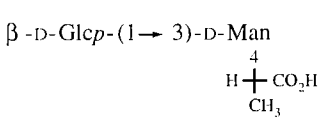
2

Partial acid hydrolysis

The foregoing structural conclusions were supported by analysis of the oligosaccharide fragments produced upon mild acid hydrolysis (2% TFA, 3 h, 100°C) of the CPS. Subsequent purification on Sephadex G-15 gave the disaccharides **3** (K_{av} 0.61) and **4** (K_{av} 0.53), and the trisaccharide **5** (K_{av} 0.23). Methanolysis followed by quantitative analysis of the carboxyl-reduced ($NaBD_4$) acid hydrolysis products gave the results recorded in Table 7. Structural information was obtained from the GLC–MS analysis of the methylated oligosaccharide alditol derivatives. The disaccharide **3** was composed of glucuronic acid and galactose. Methylation of the reduced **3** and subsequent GLC–EI-MS analysis showed diagnostic ions at *m/z* 233 (aA_1), 201 (aA_2), and 169 (aA_3), indicative of a hexopyranosyl uronate end group (34). Abundant fragment ions at 296 (J_1), 236 (bA_1), and 204 (bA_2) confirm the presence of a terminal hexitol, allowing **3** to be identified as

β-D-Glc*p*A-(1→4)-D-Gal

Glycose analysis indicated oligosaccharide **4** to contain 4-*O*-(1-carboxyethyl)-D-mannose and D-glucose. The EI-MS fragmentation pattern of the reduced, methylated disaccharide indicated nonreducing hexose (*m/z* 219, aA_1) and (1-carboxyethyl)-hexitol (*m/z* 308, bA_1) monomeric units consistent with **4** being assigned the structure



Identification of the two disaccharide fragments confirms the partial sequences, **a**→**d** and **c**→**b**, in the repeating unit **2** of the polysaccharide. The trisaccharide **5** was composed of GlcA, Gal, and Glc. The reduced methylated trisaccharide showed abundant ions in its EI-MS characteristic of terminal HexA (*m/z* 233, aA_1), HexA-Hex (*m/z* 437, abA_1), and hexitol end group (*m/z* 236, cA_1) fragments that permitted **5** to be identified as

β-D-Glc*p*A-(1→4)-β-D-Gal*p*-(1→4)-D-Glc

representative of the trisaccharide sequence **a**→**d**→**c** in the polysaccharide.

Absolute configuration of the carboxyethylidene and carboxyethyl substituents

Pyruvic acid acetals bridging the O-2 and O-3 positions of D-glucuronic acid residues are known as components of a number of *Klebsiella* polysaccharides, but the chiralities of these components has not been reported (35). The absolute configuration of the acetal carbon of cyclic pyruvate acetals involving 1,3-dioxane ring systems linked to the O-4 and O-6 positions of hexopyranosyl residues (Glc*p*, Man*p*, and Gal*p*) can be readily determined by comparison of ^{13}C NMR chemical shifts of the pyruvate methyl resonance with those of model compounds (27). However, assignment of the absolute configuration of cyclic pyruvate acetals involving 1,3-dioxolane ring systems is not as straightforward. When a 1-carboxyethylidene substituent is linked to the O-3 and O-4 positions of D-Gal*p*, no significant difference is observed for ^1H or ^{13}C chemical shifts of the methyl resonances in the *R* and *S* acetals (27). By analogy, the methyl resonances from the *R*- or *S*-2,3-(1-

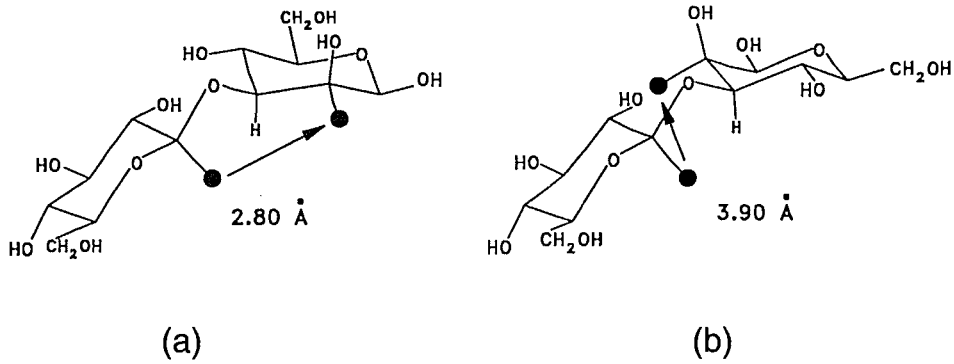


FIG. 5. The minimum energy conformation of the two disaccharide units, (*a*) β-D-Glc*p*-(1→3)-β-D-Man*p* ($\phi = 55°$, $\psi = 10°$) and (*b*) β-D-Glc*p*-(1→3)-β-L-Man*p* ($\phi = 55°$, $\psi = -5°$), calculated using the HSEA method. Internuclear distances between Glc H-1 and Man H-2 are indicated. A transglycosidic NOE would be expected only in the disaccharide in which both glycosyl units possess the D-configuration.

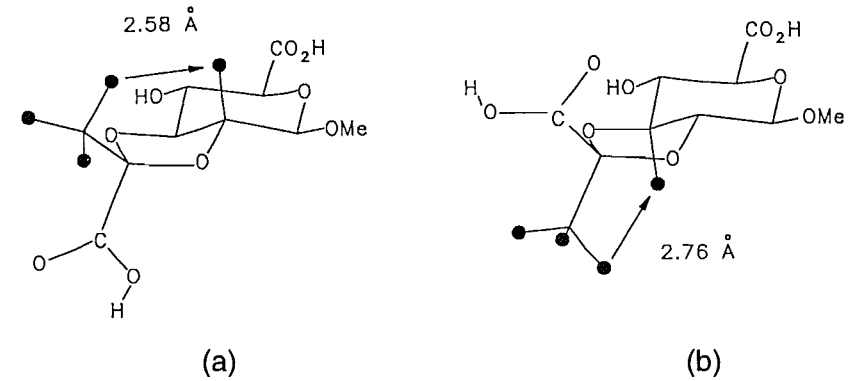

FIG. 6. Computer-generated models for the (*a*), *R*- and (*b*), *S*-2,3-pyruvate acetals of β-D-Glc*p*A. An NOE would be expected between the pyruvate methyl group and H-2 of the pyranose ring in the *R* isomer, whereas an NOE would be expected at the β-D-Glc*p*A H-3 in the *S* isomer.

TABLE 7. Sugar analysis data for the oligosaccharides obtained on partial hydrolysis of the *R. equi* serotype 3 polysaccharide

Compound	Derivatives[a]	T_{GA}	Mole ratio
3	Glucitol-6,6-d_2[b]	1.00	0.80
	Galactitol	1.01	1.00
4	Glucitol	1.00	1.00
	4-*O*-(1-Hydroxypropyl)-mannitol	1.48	0.95
5	Glucitol[b]	1.00	1.00
	Glucitol-6,6-d_2[b]	1.00	0.92
	Galactitol	1.01	0.95

[a]Determined as their carbonyl reducued alditol acetates.
[b]Determined by mass spectrometry.

carboxyethylidene) derivatives of D-Glc*p*A would not be expected to show significant stereochemical shift differences. Furthermore, suitable reference compounds are not readily available and chemical correlation is further complicated by the extreme acid lability of the *trans*-fused 1,3-dioxolane ring system (35).

It was envisaged that results from ^1H–^1H NOE experiments on the intact polysaccharide would provide a diagnostic indication of the orientation of the pyruvate methyl group and thereby lead to the desired stereochemical assignment (Fig. 6). This approach was recently applied to the stereochemical analysis of pyruvate acetals substituted at the O-2 and O-3 positions of α-D-Gal*p* residues (36).

Saturation of the pyruvate methyl resonance in the native polysaccharide resulted in an NOE at H-2 of the D-glucopyranosyl uronic acid residue **a** (Fig. 3*c*); no detectable NOE was observed at the H-1**a** or H-3**a** resonances. This result is consistent only with the pyruvate acid acetal

having the *R* configuration in which the methyl group occupies a position on the same face of the D-glucopyranosyl ring system as the axial H-2 (Fig. 4, Fig. 6*a*).

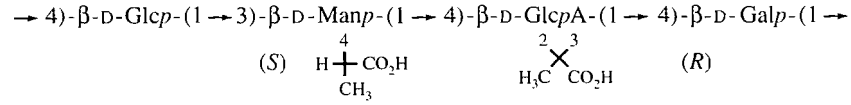
The absolute configuration of the lactic acid moiety was determined from an NOE-based method that involved a conformationally rigid lactone derivative of the 4-*O*-(1-carboxyethyl)-α-D-mannopyranose.[3]

Periodate oxidation of the pyruvate-free polysaccharide followed by $NaBH_4$ reduction and acid hydrolysis (2 M TFA, 100°C, 12 h) afforded 4-*O*-(1-carboxyethyl)-D-mannose (**6**), which was obtained by Biogel P2 gel filtration. Treatment of the 4-*O*-(1-carboxyethyl) sugar ether (**6**) with acetic anhydride in the presence of pyridine afforded the 1,2,6-tri-*O*-acetyl lactone derivative (**7**), which was obtained pure by silica gel chromatography (see Experimental).

The chirality of the lactone α-carbon was correlated to that of the D-mannose residue from the observed $^1H-^1H$ NOE's in the acetylated lactone derivative (**7**) (Fig. 7). The ^1H NMR resonances were fully assigned (Fig. 7*a*) from a COSY experiment. Irradiation of the lactate α-proton resulted in an NOE at H-4 of the D-mannopyranosyl ring (Fig. 7*b*). Correspondingly, irradiation of the D-mannose H-4 resulted in an NOE at H-α (Fig. 7*c*), establishing the lactate moiety to have *S* chirality (as in **6**).

Conclusion

The accumulated evidence permits the repeating unit of the native *R. equi* S3 polysaccharide to be assigned the structure **8**.



8

Immunodiffusion studies suggest that the 1-carboxyethylidene acetals are part of the immunodeterminant region of the serotype 3 polysaccharide. The native polysacchride (8) gave a strong positive precipitin reaction, whereas no precipitin line against serotype 3 specific rabbit antisera was obtained with the pyruvate-free polysaccharide. The stereochemistry of these substituents is undoubtedly important in determining the serological specificity (37). The stereochemistry of the 1-carboxyethylidene acetals was firmly established from $^1H-^1H$ NOE measurements in the intact polysaccharide.

An NOE-based strategy involving prior lactonization of

For personal use only.

the lactone-substituted sugar enabled configurational analysis of this substituent. It is possible that the (*S*)-1-carboxyethyl substituents are also major epitopic features of the serotype 3 antigen.

Experimental

Bacterial culture

Rhodococcus equi serotype 3 (ATCC 33703), obtained from Dr. J. F. Prescott, University of Guelph, Guelph, Ontario, was grown on plates as previously described (8).

Capsular polysaccharide

The capsular polysaccharide was isolated from the cells (123 g, wet weight) by mechanical dissociation from the cellular material into 4 M sodium chloride solution. The cellular material was removed by centrifugation and the supernatant dialyzed until salt-free. Following enzymic digestion with ribonuclease, deoxyribonuclease, and proteinase K, the crude polysaccharide was precipitated with cetyltrimethyl ammonium bromide (38). The insoluble Cetavlon–polysaccharide complex was collected by centrifugation, redissolved in aqueous NaCl (4 M), and the polysaccharide component was recovered after precipitation with ethanol. Extensive dialysis afforded the sodium salt of the serotype 3 CPS (yield 490 mg, 0.4%).

Pure capsule was obtained by ion exchange chromatography. A sample (20 mg), dissolved in water, was applied to a column (1 × 40 cm) of DEAE–Sephacel (Pharmacia) equilibrated with 0.05 M Tris-HCl buffer (pH 7.2). The column was eluted with the same buffer (50 mL) followed by a 0–1 M NaCl gradient in the same buffer. Fractions (2 mL) were collected and assayed colourimetrically for neutral glycose (11) and hexuronic acid (12). Material purified in this way was deionized with Rexyn 101 (H^+ form) ion exchange resin followed by lyophilization of the eluant.

Polysaccharide samples (20 mg) were subjected to gel chromatography on columns (1 × 40 cm) of Sephadex G-200 (Pharmacia) eluted with pyridinium acetate (0.05 M, pH 4.5). Column eluants were continuously monitored for changes in refractive index by a Waters R403 differential refractometer and fractions were assayed colourimetrically (11, 12).

Polysaccharide samples were tested for serological activity by the gel diffusion test described by Prescott (4). Serotype 3 *R. equi* antisera was a gift from Dr. J. F. Prescott, University of Guelph.

Analytical methods

Quantitative colourimetric methods were used to analyse the column chromatography eluants for (*i*) neutral glycoses (11), (*ii*) hexuronic acids (12), and (*iii*) lactic-acid-containing glycoses (39).

Glycoses were determined directly by HPAE (13) or by GLC of their alditol acetate derivatives (14). Carbohydrate samples (0.2–0.5 mg) were hydrolyzed with trifluoroacetic acid (2 M, 0.5 mL) for 15 h at 100°C and evaporated to dryness *in vacuo* to obtain the free glycoses. For the GLC–MS estimation of acidic glycoses, polysaccharide samples (0.5 mg) were treated with methanolic HCl (1 M, 1 mL) for 15 h at 85°C. Excess methanolic HCl was removed *in vacuo* and the residues, in water (1 mL), were treated with $NaBD_4$ or $NaBH_4$ (15 mg) for 6 h at 25°C. Following neutralization with aqueous acetic acid (10% v/v), the mixtures were concentrated *in vacuo*, and borate was removed by repeated distillation of methanol (5 × 5 mL) from the residue. The products were deionized by passing the aqueous solution (2 mL) through a column containing Rexyn 101 (H^+ form) and then hydrolyzed (as stated). The free glycoses were reduced ($NaBH_4$) and borate was removed before the resultant alditols were acetylated by treatment with acetic anhydride (0.5 mL, 2 h, 115°C).

Absolute configurations of the glycoses were determined by GLC–MS of the corresponding trimethylsilyl *R*-2-butyl-glycoside derivatives (16). The identity of the glycose derivatives was established by comparison of their GLC retention times and mass spectra with those of authentic reference compounds.

Methylation analysis was performed on polysaccharide samples (2 mg) with methyl iodide in dimethyl sulfoxide containing an excess of sodium methylsulfinylmethanide (17). The methylated products were recovered by partitioning the reaction mixture between water and methylene chloride, followed by concentration of the organic phase. The methylated polysaccharide was treated with $NaBH_4$ in an ethanol:water mixture (1:4) at 25°C for 15 h and the carboxyl-reduced products were hydrolyzed, concentrated to dryness, reduced with $NaBD_4$, and acetylated (as stated).

GLC was performed with a Hewlett Packard model 5710A chromatograph fitted with a hydrogen flame detector and a model 3380A electronic integrator using a fused-silica capillary column (0.3 mm × 25 m) containing 3% OV17 with the following temperature programs: A, 2 min at 180°C, then 2°C/min to 240°C (methylated and acetylated alditols); B, isothermally at 175°C (trimethylsilyl 2-butyl-glycosides); and C, 2 min at 200°C, then 10°C/min to 320°C (methylated oligosaccharides). The carrier gas was dry nitrogen at 30 mL/min and retention times are quoted relative to D-glucitol hexaacetate (T_{GA}) or 1,4,5-tri-*O*-acetyl-2,3,6-tri-*O*-methyl-D-glucitol (T_{GM}).

GLC–MS was performed using a Hewlett Packard 5958B system employing the GLC program conditions A or C, by electron impact (EI) employing an ionization potential of 70 eV, or by chemical ionization (CI) with ammonia as the reagent gas.

HPAE was carried out using a Dionex BioLC carbohydrate system equipped with a column (4.6 × 250 mm) of Dionex Carbopac AS-6 pellicular anion exchange resin, and a AG-6 guard column with pulsed amperometric detection. Isocratic elution was performed using the following eluants: A, 15 mm sodium hydroxide, or B, 150 mM sodium hydroxide and 150 mM sodium acetate, at a flow rate of 1 mL/min at ambient temperature. Retention times are quoted relative to that of D-glucose (R_G).

Depyruvulation of the polysaccharide

The pyruvate acetal substituents were removed from the native capsular polysaccharide by heating a sample (120 mg) in aqueous acetic acid (2% v/v, 120 mL) at 100°C for 2 h. The modified polysaccharide was concentrated to dryness and purified by gel filtration on a G-200 column.

Partial acid hydrolysis

The serotype 3 CPS (50 mg), dissolved in 2% trifluoroacetic acid, was kept at 100°C for 3 h, then concentrated *in vacuo*. The hydrolyzate was fractionated by gel chromatography on a column (2.5 × 70 cm) of Sephadex G-15 with pyridinium acetate (0.05 M, pH 4.5) as eluant. The three oligosaccharides isolated, **3** (K_{av} 0.61), **4** (K_{av} 0.53), and **5** (K_{av} 0.23), were reduced ($NaBH_4$) and methylated before undergoing GLC–MS analysis (program C).

Isolation of the lactone derivative of 1,2,6-tri-O-acetyl-4-O-[(S)-1-carboxyethyl]-D-mannopyranose (7)

The depyruvulated *R. equi* serotype 3 polysaccharide (100 mg) was treated, in the dark, with aqueous sodium metaperiodate (0.12 M, 100 mL) at 4°C for 7 days. Following destruction of excess periodate with ethylene glycol (1 mL), the oxidized polysaccharide was reduced with $NaBH_4$ (200 mg) (6 h, 25°C); excess borohydride was then decomposed with aqueous acetic acid. The modified polysaccharide was purified by gel filtration on a column (1.6 × 100 cm) of Biogel P2 (-400 mesh) by using water as the eluant. The product was detected by assaying fractions (1 mL) colourimetrically for lactate-containing sugars (39).

A sample of the modified polysaccharide (40 mg) was hydrolyzed with trifluoroacetic acid (2 M, 100 mL) for 12 h at 100°C and concentrated to dryness, followed by repeated distillation from

water. Acetic anhydride (2 mL) was added to a suspension of the hydrolyzate in THF (10 mL). After the mixture had been stirred for 13 h, pyridine (2 mL) was added and the mixture stirred for an additional 8 h. The acetylated product (**7**) was purified on a column of silica gel (60 Å) eluted with ethyl acetate:hexane (4:1); yield, 10 mg (10%). ^{1}H NMR ($CDCl_3$): 6.05 (1H, d, J = 1.9 Hz, H-1), 5.31 (1H, dd, J = 9.7 Hz, H-3), 5.10 (1H, d, J = 2.3 Hz, H-2), 4.36 (1H, dd, J = 5.8 Hz, H-6′), 4.29 (1H, dd, J = 1.7, 12.5 Hz, H-6), 4.22 (1H, q, J = 6.8 Hz, H-α), 4.03 (1H, m, H-5), 3.83 (1H, t, J = 9.7 Hz, H-4), 2.13–2.00 (9H, s, Ac), 1.40 (3H, d, CH_3). ^{13}C NMR ($CDCl_3$): 90.8(C-1), 77.1 (C-α), 73.3 (C-2), 71.9 (C-4), 71.6 (C-3), 71.3 (C-5), 62.7 (C-6), 20.8 (Ac), 19.1 (CH_3).

NMR spectroscopy

Unless otherwise stated, nuclear magnetic resonance spectra were obtained on a Bruker AM-500 spectrometer equipped with an Aspect 3000 computer, using standard Bruker software. Solutions of polysaccharide samples in deuterium oxide (Merck, Sharp and Dohm, 99.8 at.%) or D_2O/phosphate buffer were prepared at a concentration of 10–40 mg/mL subsequent to lyophilization from D_2O. Proton and carbon-13 measurements were made on solutions (0.4 mL) of the polysaccharides (pD ≈ 2.0, or 6.5) in 5 mm tubes at 62°C.

^{1}H NMR spectra at 500 MHz were recorded using a spectral width of 2.5 kHz, an acquisition time of 3.2 s, and a 90° pulse. Resolution enhancement was achieved by using a Gaussian lineshape transformation (40). Chemical shifts are expressed relative to internal acetone (2.225 ppm).

NOE difference spectra were obtained using a selective low-power presaturation pulse applied to the proton resonance for 200 ms followed by a 90° observation pulse, where each line of a multiple resonance was irradiated sequentially for 25 ms during the presaturation delay (29).

Broad-band proton-decoupled ^{13}C NMR spectra were obtained at 125 MHz using a spectral width of 25 kHz and a 90° pulse, employing composite pulse proton decoupling (WALTZ) (41). Proton-coupled ^{13}C NMR spectra were determined by gated coupling (42). Chemical shifts are referenced to internal acetone (31.07 ppm).

Two-dimensional homonuclear proton correlation experiments, COSY (21), Relayed COSY (22), and NOESY (43), were measured with solvent suppression employing the conventional pulse sequences as previously described (8). A mixing time of 200 ms was employed for the NOESY experiment.

Heteronuclear ^{1}H–^{13}C chemical shift correlations were made using the CHORTLE pulse sequence (8, 26).

^{1}H and ^{13}C NMR spectra of the lactone **7** were obtained on a sample in $CDCl_3$ at 600 MHz and 150 MHz, respectively, using a Bruker AMX-600 spectrometer (see footnote 3). ^{1}H–^{1}H NOE measurements were made by selective irradiation of each line of the multiplet resonance for a total irradiation time of 1 s.

Molecular modeling

Molecular modeling was performed by using the PC-based program, Alchemy (Tripos Associates, Inc.). The minimum energy conformation about the glycosidic bond of the disaccharides was estimated by the HSEA method (30, 31). Structures were optimized by the MM2 algorithm (Allinger, QCPE, Indiana University) optimized for carbohydrates (44).

General methods

Commercial reagents and solvents were analytical grade. Concentrations were made under reduced pressure at bath temperatures below 40°C. Optical rotations were determined at 22°C in 10 cm microtubes using a Perkin–Elmer model 243 polarimeter.

Dielectric enrichment in binary solvent mixtures. The intramolecular hydrogen bond in *N*-alkyl-substituted *o*-nitroanilines. Substituent effects

ROSA CATTANA, JUANA J. SILBER, AND JORGE ANUNZIATA[1]

Departamento de Química y Física, Universidad Nacional de Río Cuarto, Estafeta Nro 9, Río Cuarto, Argentina

Received January 2, 1992

ROSA CATTANA, JUANA J. SILBER, and JORGE ANUNZIATA. Can. J. Chem. **70**, 2677 (1992).

In this work we report solvatochromism studies on *o*-nitroaniline and several *N*-alkyl-*o*-nitroaniline derivatives used as solutes in solvent mixtures of an "inert" nonpolar cosolvent, cyclohexane, and THF as a solvent with hydrogen bond acceptor ability. These studies allowed us to establish the competition between inter- and intramolecular hydrogen bond in solutes. This was done by comparing the magnitude of the local inhomogeneity induced by the solute-in-solvent mixture, that is, "preferential solvation," using Suppan's dielectric enrichment model as modified by us to be applied to electronic transitions. Since preferential solvation accounts for dielectric as well as specific interactions while dielectric enrichment only for the former, it was shown by comparison that it is possible to separate both effects and even quantify them. It was deduced that *N*-alkyl-*o*-nitroanilines form a strong intramolecular hydrogen bond, which remains unbroken even in polar solvents and hydrogen bond acceptors such as dimethyl sulfoxide. This was also confirmed by solvatochromic studies in pure solvents. On the other hand, a symmetrical dependence of the effects of alkyl substituents and solvents on the shifts of the absorption spectra was observed.

ROSA CATTANA, JUANA J. SILBER et JORGE ANUNZIATA. Can. J. Chem. **70**, 2677 (1992).

On a effectué des études de solvatochromisme sur des dérivés de l'*o*-nitroaniline et de plusieurs *N*-alkyl-*o*-nitroanilines utilisées comme solutés dans des mélanges d'un co-solvant non-polaire «inerte», le cyclohexane, et de THF agissant comme solvant capable d'accepter des liaisons hydrogènes. Ces études ont permis d'établir les quantités relatives de liaisons hydrogènes inter- et intramoléculaires dans les solutés. Ces conclusions ont été obtenues en comparant l'amplitude de l'inhomogénéité locale induite par le solvant dans le mélange, soit la «solvatation préférentielle», avec le modèle d'enrichissement diélectrique de Suppan tel que nous l'avons modifié pour l'appliquer aux transitions électroniques. Comme la solvatation préférentielle explique les interactions diélectriques et spécifiques alors que l'enrichissement diélectrique n'explique que les premières, on montre que, par comparaison, il est possible de différencier les deux effets et même de les quantifier. On a déduit que les *N*-alkyl-*o*-nitroanilines forment une forte liaison hydrogène intramoléculaire qui n'est pas brisée même dans des solvants polaires et accepteurs de liaisons hydrogènes comme le diméthylsulfoxyde. Cette conclusion a aussi été confirmée par des études solvatochromiques dans des solvants purs. Par ailleurs, on a observé une dépendance symétrique des effets de substituants alkyles et de solvants sur les déplacements du spectre d'absorption.

[Traduit par la rédaction]

Introduction

Solvent effects on the electronic spectrum of a molecule are due to the usually weak interactions between the solute and solvent molecules. These can be classified into nonspecific and specific interactions. Although it has been recognized that when specific interactions are present they tend to dominate the total effect (1), the greatest difficulty is usually to determine which is the predominating solvent effect.

To unravel this problem, empirical parameters are commonly used (1, 2). One of the most successful approaches is the solvatochromic comparison method of Kamlet, Taft, and co-workers (3). This allows us to quantify specific interactions and to separate them from polarity–polarizability effects.

Another useful approach to this problem might be the use of a binary mixture of solvents. As expected, the solute preferentially surrounds itself with the component in the mixture that leads to the most negative Gibbs energy of solvation (ΔG^0). The observation that the solvent shell has a composition other than the macroscopic ratio is termed selective or preferential solvation (4). These terms are generally used to describe molecular–microscopic local-solute-induced nonhomogeneity in a multicomponent solvent mixture. They include both (*i*) nonspecific solute–solvent association caused by dielectric enrichment in the solvent shell (5) and (*ii*) specific solute–solvent association such as hydrogen bonding or electron donor–acceptor (EDA) interactions.

The importance of such phenomena has been recognized not only for spectroscopic studies but also for the interpretation of equilibrium and kinetic data (6–9).

Perhaps the first thermodynamic treatment of the problem of preferential solvation was presented by Grunwald *et al.* (10), who were interested in the solvation of ions in mixtures of water and dioxane. This approach was further developed by Covington and Newman (11), who studied the immediate chemical environment of solute ions by measuring the NMR chemical shifts of alkali metal ions in binary solvent mixtures.

Although preferential solvation effects have been attributed mostly to specific interactions, Nitsche and Suppan (12) suggested that there is also a complete general mechanism, the "dielectric enrichment" model, to explain nonadditive polarity effects. Taking into consideration that the absorption band position depends on both the solute ground state dipole moment and the associated change by excitation (13), we have introduced a modification of this model. To distinguish pure dielectric effects from other specific solute–solvent interactions, we compared the preferential solvation approach with the theoretical results obtained by the dielectric enrichment model for *p*-nitroanilines (13).

On the other hand, there has been some controversy about solutes such as *o*-nitroanilines. There may be a competition between inter- and intramolecular hydrogen bond interactions in these solutes. Studies of the IR spectra of these

compounds in different proton-accepting solvents (14) led to the conclusion that there is a moderately strong intramolecular hydrogen bond in *o*-nitroaniline that is completely broken in such solvents as dioxane, ethers, and amines. However, it was shown by UV–visible spectroscopy (15) that the intramolecular hydrogen bond in *o*-nitroaniline and *N*-methyl-*o*-nitroaniline does not break to form intermolecular hydrogen bonds in bases as strong as *N*-methylpyrrolidin-2-one. NMR and IR studies (16) have shown that *m*- and *p*-nitroanilines form dimers in carbon tetrachloride and chloroform by hydrogen bonding between the hydrogen of one molecule of amine and the nitro group of the other. This is not observed for *o*-nitroaniline, where the intramolecular hydrogen bond reduces the possibility of intermolecular interaction.

A set of hydrogen-bond rules from crystal chemistry and crystallographic data has recently been developed for organic compounds including nitroanilines. This is valid for solids and solutions (17). However, it is emphasized that the expected or typical hydrogen bonds may not occur for several reasons, including the presence of multiple competitive hydrogen-bond sites, steric overcrowding, or competing dipolar or ionic forces.

In this work we report solvatochromism studies in *o*-nitroaniline (**1**) and *N*-alkyl-*o*-nitroaniline derivatives (**2**–**10**) used as solutes in solvent mixtures of an "inert" nonpolar cosolvent, cyclohexane, and THF as a solvent with hydrogen-bond acceptor ability. These results are compared with those obtained for *p*-nitroaniline (13).

The studies were performed on a series of pure solvents and the data analyzed by the solvatochromic comparison method. We also considered the effect that the substituents may have upon the type or strength of the solute–solvent interactions. It is known (18) that solvent and substituent effects on the acidity of *p*-substituted anilines are mutually symmetrical. Thus, for a series of solvents, each solvent yields a regression coefficient for the acidity vs. the substituent, σ^*, and these coefficients subsequently correlate with solvent basicity. On the other hand, when the acidity of the amino group is correlated with solvent basicity the regression coefficient now correlates with the substituent constant.

These studies aim through the analysis of solute–solvent interactions, to yield further insight into the structure of those compounds which, having inherently large second-order polarizabilities, are good candidates for nonlinear optical materials (19).

Theoretical section

Model used in studies in binary solvent mixtures

(a) Preferential solvation

Following the model of Frankel *et al.* (20) for a solute in a binary mixture, the solvent is considered to be distributed between two phases, the bulk solvent and the solvation shell of the solute. It is assumed that the solvation shell is made up of independent sites that are always occupied. If the solvation number is considered to be the same for both solvents, there is a one to one replacement of solvent molecules. Considering that the solvation shell obeys the laws of regular solutions, eq. [1] can be derived (20).

$$[1] \quad Y_a/Y_b = K\,X_a/X_b$$

where Y_a and Y_b represent the mole fractions of solvents a and b in the solvation shell, respectively, and X_a and X_b refer to the bulk solvent.

The solvents a and b are considered to contribute in an additive manner to the total solvation energy. Then, if the frequency of the absorption maximum (ν_m) is a representative value for the mixture in the solvation phase, it can be assumed that (21):

$$[2] \quad \nu_m = \nu_a\,Y_a + \nu_b\,Y_b$$

and then:

$$[3] \quad \Delta\nu_m = \Delta\nu\,Y_a$$

where $\Delta\nu_m = \nu_m - \nu_b$; $\Delta\nu = \nu_a - \nu_b$; and $Y_b = 1 - Y_a$.

Since the experimentally known values are the molar fractions of the bulk solvents, a linear relation between $\Delta\nu_m$ and X_a is predicted only when $X_a = Y_a$. Any deviation from this relation ($K \neq 1$) may indicate preferential solvation effects.

(b) Dielectric enrichment

The initial model proposed by Suppan (5, 12), which we modified (13) for a better application to the study of solvent effects in electronic transitions, is described by the local thermodynamic equilibrium in a solvent under the influence of a polar, nonpolarizable solute.

Considering in the solvent mixture an element of volume dv, in which an electric dipole moment $d\boldsymbol{p}$ is induced by the permanent dipole moment $\boldsymbol{\mu}$ of the solute, the dielectric interaction energy dE is given by eq. [4] (22, 23).

$$[4] \quad dE = -\boldsymbol{F}(\boldsymbol{r}) \cdot d\boldsymbol{p} = \frac{3\mu^2 f(D)}{8\pi} \frac{(3\cos^2\theta + 1)}{r^6}\,dV$$

where $\boldsymbol{F}(\boldsymbol{r})$ is the dipolar electric field generated by the solute, $\boldsymbol{r}$ is the position vector of the element of volume with respect to the solute, and $f(D) = 2(D-1)/2D + 1$ is Onsager's function for the mixture (eq. [5])

$$[5] \quad f(D) = Y_p(\boldsymbol{r})\,f(D_p) + Y_N(\boldsymbol{r})\,f(D_N)$$

where D_p and D_N are the static bulk dielectric constants and $Y_p(\boldsymbol{r})$ and $Y_N(\boldsymbol{r})$ are the "*local*" molar fractions of the polar and nonpolar solvent, respectively.

Suppan derived an expression based on the ground state dipole moment of the solute from which it is possible to calculate the stabilization energy and, consequently, $Y_p(\boldsymbol{r})$ (5, 12).

However, since the absorption band position depends on

the ground state dipole moment (μ_g) and its associated change by excitation according the Franck–Condon principle (24), we have proposed that the dielectric enrichment energy (E_{en}) should be, for this purpose, better expressed by

$$[6] \quad E_{en} = (E_{ex} - E_g)_{local} - (E_{ex} - E_g)_{bulk}$$

where $E = -\int \boldsymbol{F}(\boldsymbol{r})\, d\boldsymbol{p}$ and the subscripts "ex" and "g" refer to excited and ground state, respectively.

To evaluate E_{ex} and E_g, eq. [4] is used. The value of $f(D)$ for the *local* is given in eq. [5] while $f(D)$ for *bulk* is calculated from the experimental values of X_p and X_N. Then, E_{en} is given explicitly by eq. [7].

$$[7] \quad E_{en} = -\frac{3}{4}\mu_g(\mu_{ex} - \mu_g)\int_a^{\infty} dr \int_{\phi}^{\pi} d\theta\, [(Y_p - X_p)f(D_p) + (Y_N - X_N)f(D_N)]\frac{(3\cos^2\theta + 1)\sin\theta}{r^4}$$

$$= \frac{-X_N X_P \Delta E_{lineal}}{8}\int_{-1}^{1} d\rho \int_{-1}^{1} du\, \frac{G(u)[1 - \exp(-G(u)\, z\rho^2)]}{X_p + X_N \exp(-G(u)\, z\rho^2)}$$

where

$$\frac{Y_N(r)}{Y_p(r)} = \frac{X_N}{X_p}\exp - [Z\, G(u)/r^6]$$

$$\Delta E_{lineal} = \frac{\mu_g(\mu_{ex} - \mu_g)\,\Delta f}{a^3}$$

a = cavity radius; the preferential solvatochromic index (5) is

$$Z = \frac{3\mu_g^2 \bar{M}\,\Delta f}{8\pi\, T\, \bar{\delta}\, R\, a^6}$$

where $\bar{M}$ is the average molecular weight and $\bar{\delta}$ the average density of the solvents in the mixture; $\Delta f = f(D_p) - f(D_N)$; $\rho = (a/r)^3$; $u = \cos\theta$; and $G(u) = 3u^2 + 1$.

Knowing a, μ_g and μ_{ex} for the solute and $f(D)$ for the corresponding solvents it is possible to evaluate, from eq. [7], the dielectric enrichment energy (E_{en}) for each pair of experimental values of X_N and X_p in every mixture studied. From these data a theoretical curve can be constructed. This curve gives an idea of the deviation from linearity of the solvatochromic shifts due only to dielectric enrichment.

Experimental section

o-Nitroaniline (**1**) from Carlo Erba was purified by sublimation under vacuum; mp 71.6°C (lit. (25) mp 71.5°C). Compounds **2–8** were synthesized and purified following the method already reported (26). Compounds **9** and **10** were synthesized and purified by a method reported elsewhere (27).

The solvents used: *n*-hexane (Hx), cyclohexane (CHx), benzene (Bz), dimethyl sulfoxide (DMSO), dimethylformamide (DMF), methanol (MeOH), ethanol (EtOH), isopropyl ether (iPE), acetonitrile (ACN), ethyl acetate (EtAc), and tetrahydrofuran (THF), were purified to spectroscopic quality by standard methods (28). The UV cutoff point in a UV cell of 10 mm against air was used as purity criterion.

The spectroscopic measurements were performed in a Cary 17 spectrophotometer at a temperature of 25 ± 0.2°C.

ν_{max} was measured by taking the midpoint between the two positions of the spectrum where the absorbance is equal to 0.90 A_{max} (29). Thus, the uncertainties in ν_{max} are ca. 100 cm^{-1}.

The least-squares correlation coefficients between π^* vs. α, π^* vs. β, and α vs. β for the solvent set used are 0.0327, 0.6439, and 0.3702 with high significance level. Thus, they may be considered mutually independent.

Data processing for the dielectric enrichment model as carried out using an IBM 3031 computer.

Results and discussion

(a) Studies in binary solvent mixtures

The behavior of *o*-nitroaniline (**1**) and *N*-alkyl-*o*-nitroanilines (**2–8**) was compared by measuring the position of the maximum of the longest wavelength absorption band in several solvent mixtures. This band, corresponding to a transition polarized in the *z* axis, has a strong charge transfer character and consequently, it is greatly influenced by polar solvents (30, 31).

Preferential solvation

The results for **1** and **2** in THF–CHx mixtures are shown in Figs. 1 and 2. As can be observed, the experimental points deviate from linearity, so preferential solvation for both solutes is detected in the solvent mixtures studied. The behavior for the other *N*-alkyl-*o*-nitroanilines is very similar.

It should be taken into account that the observed deviations are produced not only by the dielectric factors but also by the specific interactions that could be involved, mainly hydrogen bond formation. These global interactions may be quantified by calculating the preferential solvation constant, K, which according to eqs. [1]–[3] can be calculated by eq. [8].

$$[8] \quad K = X_{THF}(\nu_m - \nu_{CHx})/X_{CHx}(\nu_{THF} - \nu_m)$$

The results are shown in Table 1.

Dielectric enrichment

Solving eq. [7] by numerical integration with Gauss–Legendre quadrature (32), we calculated a theoretical curve for **1**, which represents the deviation from linearity due to dielectric enrichment (Fig. 1). The solute parameters used in these calculations are a = 3.36 Å and μ_g = 4.35 D (33). It is not necessary to know the value of μ_{ex} since it can be inferred from the experimental values of ΔE_{lineal}, a, Δf, and μ_g (eq. [7]).

There exists an extra energy of stabilization for **1**, as shown by a curvature of the experimental points greater than that predicted by dipolar effects (Fig. 1). To interpret these results we have considered that THF is a good hydrogen-bond acceptor solvent, as predicted by its β value (β = 0.55).

Moreover, **1** is capable of being a hydrogen bond donor (14, 18, 34) and, in fact, it has a value of α_2^H = 0.367 on the solute hydrogen-bond acidity scale of Abraham *et al.* (35). Thus it is expected that hydrogen bond formation with the solvent should be responsible for at least a part of the observed preferential solvation of THF toward **1**, as was observed for *p*-nitroaniline (13).

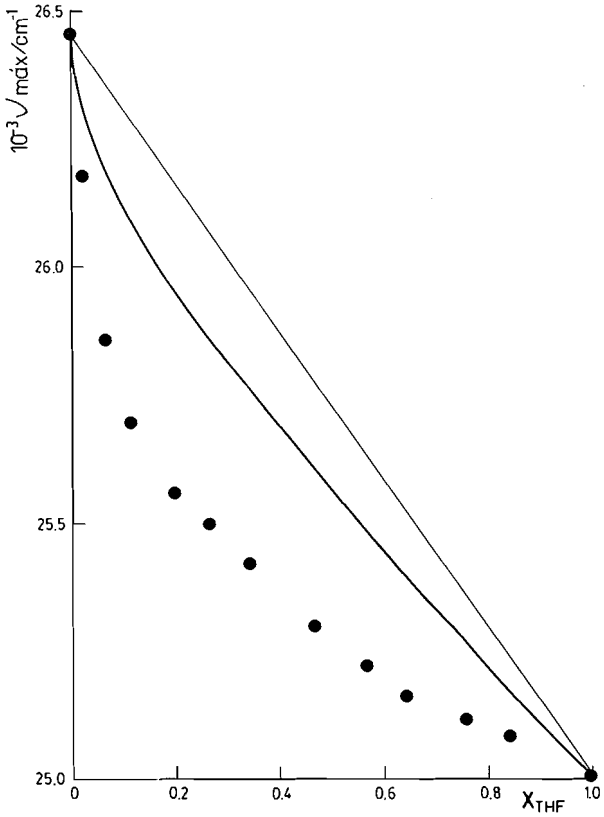

FIG. 1. ν_{max} vs. X_p for *o*-nitroaniline in THF–CHx solvent mixture. (——) Theoretical linear dependence for no preferential solvation; (——) curve predicted by dielectric enrichment model; (●) experimental data.

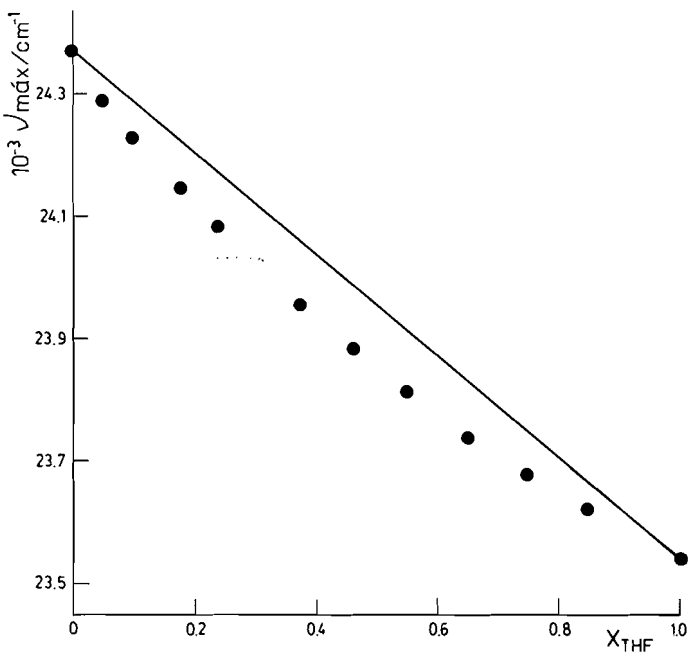

FIG. 2. ν_{max} vs. X_p for *N*-propyl-*o*-nitroaniline in THF–CHx solvent mixture. (——) Theoretical linear dependence for no preferential solvation; (●) experimental data.

TABLE 1. Preferential solvation constants (K) for compounds **2**–**8** in the CHx–THF solvent mixture

Compound	K
2	1.47 ± 0.03
3	1.49 ± 0.02
4	1.48 ± 0.04
5	1.48 ± 0.02
6	1.50 ± 0.03
7	1.52 ± 0.02
8	1.49 ± 0.04

To obtain a more quantitative picture of the dielectric effect of the solvent mixtures, we calculated the solvation constant, K_D, from the theoretical curve (Fig. 1), applying the same procedure used to calculate K in the preferential solvation model. This constant may be considered a measure of the dielectric enrichment in the polar solvent within the solvation shell.

The values of K_D for **1** and *p*-nitroaniline (13) are 1.44 ± 0.02 and 1.70 ± 0.02, respectively, while the corresponding values of K are 3.74 ± 0.03 and 4.09 ± 0.02.

As can be observed, the values of K_D for *p*-nitroaniline are higher than for **1**, as expected, since the former has a higher value of μ_g (33). The greater values of K for *p*-nitroaniline also reflect not only the higher dielectric effects but also a higher degree of intermolecular hydrogen bond formation than for **1** (α_2^H (*p*-nitroaniline) = 0.421).

The values of K for *N*-alkyl-*o*-nitroanilines are very similar to the value of K_D for **1**, which could indicate that the preferential solvation is mainly due to dipolar interaction of these solutes with THF and that there is no breaking of the intramolecular hydrogen bond in this medium.

On the other hand there is no significant variation of K with the *N*-alkyl substituents (R). This may be because of the relatively high polarity of THF that gives such strong dipole–dipole interactions with the solutes and that is insensitive to the small changes produced by the change of the substituent.

(b) Studies in pure solvents

The absorption maxima measured for the solutes **1**–**10** in different solvents are reported in Table 2. The correlations obtained by Taft and Kamlet's solvatochromic comparison method (3) are shown in eqs. [9]–[18]:

[9] $\nu(\mathbf{1}) = (26.57 \pm 0.03) - (1.75 \pm 0.06)\pi^* - (1.05 \pm 0.06)\beta, \quad r = 0.9987$

[10] $\nu(\mathbf{2}) = (24.50 \pm 0.05) - (1.65 \pm 0.08)\pi^* - (0.14 \pm 0.06)\alpha, \quad r = 0.9918$

[11] $\nu(\mathbf{3}) = (24.45 \pm 0.04) - (1.62 \pm 0.06)\pi^* - (0.14 \pm 0.05)\alpha, \quad r = 0.9945$

[12] $\nu(\mathbf{4}) = (24.41 \pm 0.05) - (1.58 \pm 0.07)\pi^* - (0.11 \pm 0.06)\alpha, \quad r = 0.9924$

[13] $\nu(\mathbf{5}) = (24.37 \pm 0.04) - (1.62 \pm 0.06)\pi^* - (0.13 \pm 0.04)\alpha, \quad r = 0.9899$

[14] $\nu(\mathbf{6}) = (24.28 \pm 0.04) - (1.55 \pm 0.07)\pi^* - (0.14 \pm 0.06)\alpha, \quad r = 0.9931$

[15] $\nu(\mathbf{7}) = (24.20 \pm 0.06) - (1.51 \pm 0.09)\pi^* - (0.13 \pm 0.07)\alpha, \quad r = 0.9866$

[16] $\nu(\mathbf{8}) = (24.17 \pm 0.05) - (1.52 \pm 0.07)\pi^* - (0.07 \pm 0.04)\alpha, \quad r = 0.9914$

[17] $\nu(\mathbf{9}) = (26.06 \pm 0.04) - (2.39 \pm 0.08)\pi^* - (0.10 \pm 0.04)\alpha, \quad r = 0.9954$

[18] $\nu(\mathbf{10}) = (25.20 \pm 0.06) - (2.00 \pm 0.07)\pi^* - (0.17 \pm 0.03)\alpha, \quad r = 0.9900$

There is a strong effect of the β parameter on **1** (eq. [9]), which coincides with literature data (14) and is interpreted as due to the hydrogen bond donor ability of the H amino group not involved in the intramolecular hydrogen bond.

On the contrary there is no effect on β in the solutes **2–8**. The values of *b* are smaller than its standard deviation and with a significance level higher than 40% according to the Student t-test. This means that the *b* values can be considered equal to zero.

This may indicate that there is no breaking of the intramolecular hydrogen bond in these *N*-alkyl-*o*-nitroanilines. Consequently, they have a similar behavior to solutes **9** and **10**, which do not have an H in the amino group.

The high and negative values of the π* sensitivity coefficients, *s*, are as expected, considering the important increase of dipole moment upon excitation for these solutes (36).

The value of *s* is higher for *N*,*N*-dialkyl-*o*-nitroanilines than for **1** and *N*-alkyl-*o*-nitroanilines. This has been explained by considering that polar solvents favor the coplanarity of the *ortho* group, producing a marked bathochromic effect (15). However, it is believed that this effect is due to the fact that, in the *N*-alkyl-*o*-nitroanilines, the intramolecular hydrogen bond aids in stabilizing, particularly, the excited state of these solutes and makes them less sensitive to the solvent polarity.

On the other hand, a negative value of the coefficient for α, *a*, in compounds **2–10** indicates the formation of an intermolecular hydrogen bond to the oxygen of the nitro group in protic solvents (37). However, the values of *a*, although statistically significant, are low. It is evident that for compounds **9** and **10** the non-coplanarity of the *ortho* groups weakens the intramolecular charge transfer from the amine to the nitro group. Thus the latter is a weak hydrogen bond acceptor. In the case of the *N*-alkyl-*o*-nitroanilines (compounds **2–8**), which are coplanar, *inter*molecular hydrogen bond formation competes unfavorably with the *intra*molecular bond formation. Moreover, it might be considered that the charge transfer from the amine to the nitro group (classical through-resonance) is only partial, as was calculated recently for *p*-nitroaniline (38).

(c) Substituent effects in the solvatochromism of N-*alkyl*-o-*nitroanilines*

Equations [9]–[16] show a variation of the sensitivity to solvent polarity, when the R group is changed.

To quantify the influence of inductive and steric effects, the values of the coefficient *s* were intended to be correlated with σ* and E_s (39) parameters, respectively.

Although the correlation of *s* with σ* is very poor ($r = 0.8368$), it shows the trend that the greater the inductive electron donor effect of the R substituent, the lesser the sensitivity to the solvent polarity. There is also no significant dependence on the steric parameters.

On the other hand, it was possible to determine for each solvent the dependence of the absorption band in *N*-alkyl-*o*-nitroanilines upon substituent parameters by a general equation such as:

[19] $\nu = \nu_0' + \rho \Sigma \overset{*}{\sigma} + a_1 E_s(R)$

This equation accounts for the effect exerted by the alkyl substituent on the stabilization of the positive charge on amine nitrogen in the excited state. The results are shown in Table 3.

As can be observed, only the inductive effect of the substituent is significant. The positive sign of ρ shows that, when the electron donor effect of the alkyl substituents increases, the excited state is more stable.

Also, by considering the correlations in Table 3, a dependence of ρ upon the solvent parameters was found, as shown in eq. [20]:

[20] $\rho = (3.24 \pm 0.07) - (0.25 \pm 0.13)\pi^* - (1.50 \pm 0.16)\beta, \quad r = 0.9818$

It is evident that when the polarity of the solvent increases, and consequently its interaction with the solutes, the dependence on the substituent is smaller. Moreover, the

TABLE 3. Correlation terms obtained by application of eq. [19] to compounds **1–8**[a]

Solvent	ν_0'	ρ	r
Hx	24.96 ± 0.07	3.31 ± 0.28	0.9788
Bz	23.92 ± 0.07	2.93 ± 0.27	0.9751
DMSO	23.04 ± 0.04	1.82 ± 0.18	0.9722
DMF	23.29 ± 0.04	2.01 ± 0.17	0.9800
MeOH	23.67 ± 0.04	2.27 ± 0.17	0.9836
EtOH	23.77 ± 0.05	2.03 ± 0.19	0.9750
iPE	24.41 ± 0.05	2.38 ± 0.20	0.9797
ACN	23.56 ± 0.05	2.66 ± 0.22	0.9795
EtAc	23.97 ± 0.05	2.37 ± 0.22	0.9760
THF	23.85 ± 0.06	2.08 ± 0.24	0.9622

[a]Confidence level of every correlation greater than 99.99%, according to Student *t*-test.

negative sign of the β coefficient can be explained by considering that the higher the β value for the solvent, the closer inductive effect of the H on **1** gets to the alkyl groups.

Summarizing, there seems to be a symmetrical dependence of the substituent and solvent effects on the shifts of the absorption band (18).

(d) Substituent effects on N,N-*dialkyl* o-*nitroanilines*

The results obtained by the solvatochromic comparison method for compounds **9** and **10** are compared with the correlations for the corresponding *p*-nitroaniline isomers from literature data (40). For *p*-nitropyrrolidino benzene (Pyr) eq. [21] is obtained:

$$[21]\quad \nu(\text{Pyr}) = (27.39 \pm 0.04) - (3.13 \pm 0.06)\pi^* - (0.56 \pm 0.08)\alpha, \qquad n = 9, \qquad r = 0.9873$$

and for *p*-nitropiperidino benzene (Pip) eq. [22]:

$$[22]\quad \nu(\text{Pip}) = (27.68 \pm 0.05) - (3.13 \pm 0.05)\pi^* - (0.49 \pm 0.06)\alpha, \qquad n = 9, \qquad r = 0.9901$$

When the values of the solvatochromic terms *s* and *a* are compared with those for the *ortho* isomers (eqs. [17] and [18]), it is clear that the *para* isomers are much more sensitive in both nonspecific and specific (hydrogen bond) solvent interactions. This could be attributed to the lack of planarity of the *ortho* compound, which implies lower charge delocalization and, thus, lower effect of solvent polarity and hydrogen bond formation capability.

Y. C. TOONG, S. P. TAI, M. C. PUN, ROSEMARY C. HYNES, L. E. KHOO, and F. E. SMITH. Can. J. Chem. **70**, 2683 (1992).

Methods of synthesis, elemental analyses, and IR and NMR spectroscopic data are reported for a series of triphenyltin esters of *N*-salicylidene-ω amino acids of the general formula: $Ph_3SnOCO(CH_2)_nN{=}CHAr$ (Ar = 2-HOC_6H_4- and 2-$HOC_{10}H_6$-; n = 1, 2, 3, and 5). The crystal structure of triphenyltin *N*-salicylidene-6-aminohexanoate was determined. The crystals are monoclinic, space group $P2_1/a$, with a = 16.3493(8) Å, b = 9.0675(7) Å, c = 18.8562(14) Å, β = 100.493(5)°, V = 2748.6(3) Å^3, Z = 4, and D_{calc} = 1.427 Mg m^{-3}. The final discrepancy factors are R_F = 0.033, and R_W = 0.036 for 2339 significant reflections. This compound, believed typical of the series described, adopts a polymeric *trans*-O_2SnC_3 trigonal bipyramidal geometry with the axial positions occupied by a carboxylate oxygen and the phenolic oxygen of an adjacent molecule. These compounds appear to be the first reported triphenyltin(IV) carboxylates with phenolic oxygen bridges.

Y. C. TOONG, S. P. TAI, M. C. PUN, ROSEMARY C. HYNES, L. E. KHOO et F. E. SMITH. Can. J. Chem. **70**, 2683 (1992).

On rapporte les méthodes de synthèse, les analyses élémentaires et les données spectroscopiques d'une série d'esters triphénylstanniques d'acides *N*-salicylidène-ω-aminés de formule générale : $Ph_3SnOCO(CH_2)_nN{=}CHAr$ (Ar = 2-HOC_6H_4- et 2-$HOC_{10}H_6$-; n = 1, 2, 3 et 5). On a déterminé la structure cristalline du *N*-salicylidène-6-aminohexanonate de triphénylétain. Les cristaux sont monocliniques, groupe d'espace $P2_1/a$, avec a = 16,3493(8), b = 9,0675(7) et c = 18,8562(14) Å, β = 100,493(5)°, V = 2748,6(3) Å^3, Z = 4 et D_{calc} = 1,427 Mg m^{-3}. On a affiné la structure jusqu'à des facteurs R_F = 0,033 et R_W = 0,036 pour 2339 réflexions significatives. Ce composé, considéré comme typique de la série décrite, adopte une géométrie bipyramidale trigonale polymérique du *trans*-O_2SnC_3 dans laquelle les positions axiales sont occupées par un oxygène du carboxylate et par l'oxygène phénolique d'une molécule adjacente. Ces composés semblent être les premiers carboxylates de triphénylétain(IV) comportant des ponts phénoliques oxygénés.
[Traduit par la rédaction]

Introduction

Structural studies on a range of triphenyltin carboxylates have yielded examples of monomeric and polymeric forms. For the monomers, depending on whether the chelating carboxylate group functions as a uni- or bi-dentate ligand, the tin atoms are found to be either four- or five-coordinate (1). However, in the polymeric forms the carboxylate ligands behave as bridging bidentate ligands and the pentacoordinate tin atoms have distorted trigonal bipyramidal geometries (1). Alternatives to carboxyl bridging have been sought in compounds containing either donor substituent groups or labile phenolic groups in the ester function. Among the earliest compounds successfully investigated was trimethyltin(IV) glycinate (2) whose crystal structure revealed a polymeric network built of Sn—N linkages. Polymeric triphenyltin(IV) carboxylates that contain unidentate carboxylate groups are rare. There are only three compounds reported, namely, triphenyltin(IV) pyridine-3-carboxylate (3), triphenyltin(IV) 3-ureidopropionate (4), and the triphenyltin(IV) ester of citraconic acid monopyrrolidide (5). The first compound involves an Sn—N linkage, while for the last two structures the Sn—O bridges occur through the uriedo and amido carbonyl oxygens, respectively, and not the carboxyl oxygen. X-ray structural analyses for $Ph_3SnOCOR$ where R contains a phenolic functional group as in $Ph_3SnOCOC_6H_4$-OH-*o* (6), $Ph_3SnOCOC_6H_4OCH_3$-*o* (6), $Ph_3SnOCOC_6H_4$-OPh-*o* (7), $Ph_3SnOCOC_6H_4(N_2C_6H_3MeOH)$ (the ligand in this complex is *o*-(2-hydroxy-5-methylphenylazo)-benzoate (8) failed to firmly establish the presence of an Sn—O(phenolic) linkage even though such a network was reported for the trimethyltin(IV) analogue, $Me_3SnOCOC_6H_4OH$-*o* (9). We describe here the synthesis and characterization by IR and NMR spectroscopic techniques of a series of triphenyltin derivatives of *N*-salicylidene-ω-amino acids, 2-HOC_6H_4-$CH{=}N(CH_2)_nCOOH$, and *N*-2-hydroxynaphthylidene-ω-amino acids, 2-$HOC_{10}H_6CH{=}N(CH_2)_nCOOH$ (n = 1, 2, 3, and 5). Each ligand contains a potential binding site in its phenolic fragment in addition to the carboxyl function that could engage the tin atom in either intra- or inter-molecular (polymeric) coordination. Since definitive establishment of the bonding behaviour in these situations must come from X-ray diffraction studies, we carried out an X-ray crystal structure determination on a representative compound in

this series, namely, triphenyltin *N*-salicylidene-6-aminohexanoate. The results confirmed the presence of an Sn—O(phenolic) bridge with the carboxylate group functioning in the unidentate mode.

Experimental

Reagents

Bistriphenyltin oxide and other chemicals were purchased from the Aldrich Chemical Company, and used without further purification.

Preparation of ligands

Triphenyltin(IV) esters of *N*-arylidene-ω-amino acids were prepared by refluxing in absolute ethanol (ca. 90 mL) a mixture of bistriphenyltin oxide (10 mmol), ω-amino acid (20 mmol), and salicylaldehyde or 2-hydroxynaphthaldehyde (20 mmol). After refluxing for 6–8 h the reaction mixture was cooled and the product (if there was precipitation) was isolated via filtration, otherwise the reaction mixture was concentrated under reduced pressure before either toluene or petroleum ether (60–80°C) was added to induce precipitation. The isolated solid was recrystallized from benzene, petroleum ether, or ethanol to give the pure triphenyltin carboxylates whose yields and melting points are listed in Table 1.

A slowly evaporating solution (95% ethanol, 30 mL) of triphenyltin(IV) *N*-salicylidene-6-aminohexanoate (4 g) yielded crystals (1.2 g), mp 118–119°C, from which a thin yellow plate of dimensions 0.40 × 0.25 × 0.03 mm was selected for X-ray analysis.

gen, and nitrogen microanalyses were performed at the Chemistry Department, National University of Singapore, Singapore.

X-ray analysis

Space group and cell dimensions

Empirical formula: $SnC_{31}H_{28}O_3N$ FW = 590.33

Monoclinic $P2_1/a$, a = 16.3493(8) Å, b = 9.0675(7) Å, c = 18.8562(14) Å, β = 100.493(5)°, V = 2748.6(3) Å^3. Cell dimensions were obtained from 25 reflections with 2θ in the range 90.00°–100.00°. Crystal dimensions: 0.40 × 0.25 × 0.03 mm. Z = 4, $F(000)$ = 1215.85, D_{calc} = 1.427 Mg m^{-3}, μ = 7.80 mm^{-1}, λ = 1.54056 Å (Cu Kα), $2\theta_{max}$ = 99.8°.

Data collection, structure solution and refinement

The intensity data were collected at 295 K on a Nonius diffractometer run by the NRCCAD diffractometer control program (10), using the θ/2θ scan mode and profile analysis (11). A total of 3027 reflections were measured, of which 2803 were unique. Of these, 2339 had $I > 2.5\sigma I_{net}$. Absorption corrections were made from 4 psi scans. The structure was solved by locating the tin from a Patterson synthesis. The inner coordination sphere was identified using the DIRDIF (12) programme. Hydrogen atoms were calculated. The remaining non-hydrogen atoms were located from a difference Fourier. The final least-squares cycle was calculated with 68 atoms, 326 parameters, and 2339 out of 2803 reflections. Unit weights were used. Final residuals are R_F = 0.033, R_W = 0.036 for data with $I_{net} > 2.5\sigma I_{net}$, R_F = 0.043, R_W = for all data. The goodness of fit was 1.35. Maximum shift/error was 0.006. In the last D-map, the top peak was 0.410 e/Å^3, and the deepest hole was −0.470 e/Å^3. Scattering factors were taken from the literature (13). All computation was performed using the NRCVAX system of crystal structure solving programmes (14).

Results and discussion

The triphenyltin carboxylates, $Ph_3SnOCO(CH_2)_nN{=}CHAr$ (n = 1, 2, 3, and 5), listed in Table 1, can be prepared by refluxing a mixture of bistriphenyltin oxide, an ω-amino acid, and the appropriate hydroxyaldehyde in absolute alcohol as shown by the equation below:

The melting points and analytical data for the range of carboxylates synthesized are shown in Table 1. All the carboxylates listed in Table 1 were isolated as yellow solids that were stable in air.

The NMR signal from the azomethine proton in each of the free ligands (δ = 8.40–8.80 ppm) did not shift significantly on complex formation. For all the complexes, a broad signal observed at δ = 11–14 ppm was assigned to the phenolic proton. This assignment was substantiated by the broad infrared absorptions in the region 2600–3400 cm^{-1} which are reported to be due to intramolecular hydrogen bonding between the phenolic proton and the azomethine nitrogen (15).

The observed infrared absorption frequencies for the carboxylic antisymmetric, ν_{asym}(OCO), and symmetric, ν_{sym}(OCO), stretching vibrations are shown in Table 2. The assignment of the ν_{asym}(OCO) band is complicated by the presence of the ν(C=N) stretching vibration, which is observed in the region 1615–1625 cm^{-1}. Nevertheless, the magnitude of the ν_{asym}(OCO) − ν_{sym}(OCO) (i.e., Δν) separation is of interest. The observed values of Δν, which are in the range 230–350 cm^{-1}, indicate a unidentate bonding mode for the carboxylate moiety (16). For a bridging or chelating carboxylate group Δν would be expected to be ≤ 150 cm^{-1} (17), as widely observed in the infrared spectra of triorganotin carboxylates (18). This suggests that it is the phenolic group which occupies the fifth coordination site at the tin atom (19). Furthermore, the strong intramolecular hydrogen bonding between the imino nitrogen atom and the phenolic group would increase the likelihood of coordination by the phenolic oxygen to the tin atom. Thus the spectroscopic data suggest that the structures of these triphenyltin carboxylates may well involve bridging by phenolic oxygen atoms. This conclusion was confirmed by the the results of an X-ray structural analysis for triphenyltin(IV) *N*-salicylidene-6-aminohexanoate. Figure 1 is an ORTEP plot illustrating the coordination around the tin atom. The final fractional coordinates of non-hydrogen atoms with equivalent isotropic thermal parameters are listed in Table 3 while the bond lengths and bond angles for the complex are in Tables 4 and 5, respectively. Calculated and observed structure factors, calculated hydrogen atom parameters, and anisotropic thermal parameters have been deposited as Tables S-1, S-2, and S-3, respectively. The atom-numbering scheme and a stereo pair showing the packing arrangement in the unit cell have been deposited as Figs. S-1 and S-2.[2]

The tin is five-coordinate with the axial positions of the trigonal bipyramid being occupied by a carboxylate oxygen, O(1), and the phenolic oxygen, O(3), of an adjacent symmetry-related molecule. The sum of the carbon–tin–carbon angles in the trigonal plane of triphenyltin *N*-salicylidene-6-aminohexanoate is 358.2(3)° (114.2° + 133.8° + 110.2°). The apical angle subtended at tin is 176.20(17)°. The short tin–oxygen distances are Sn—O(1) = 2.148(4) Å and Sn—O(3) = 2.328(4) Å and are well within the range of Sn—O bond distances usually observed for triorganotin carboxylates (1). It is interesting to compare the phenolic oxygen–tin distance of 2.33 Å observed here with that of 3.04 Å reported for triphenyltin salicylate (6), which clearly corresponds to a much weaker interaction.

The Sn—O(2) distance is 2.973(5) Å, which explains the opening-up of the C(14)—Sn—C(26) angle to 133.8°. Such non-uniformity in CSnC angles has been observed before, and attributed to weak Sn...O contacts (20).

In contrast to the Sn—O(1)—C(1) angle of 113.3(4)° the Sn—O(3)—C(13) angle of the bridging oxygen atom is opened up to 132.2(4)° to accommodate the bulk of the salicylidene moiety. Even larger Sn—O′—C′ angles (where O′ refers to the bridging oxygen atom) have been observed for $Ph_3SnOCOCH_2CH_2NHCONH_2$, 144.1(2)° (4), $Ph_3SnOCOCH_3$, 142.7° (20), and $Ph_3SnOCOC_6H_4Cl$-2, 146.4 (21).

The short C=O distance of 1.222(9) Å indicates that the free carbonyl group on the ligand is not involved in coordination with another tin atom. Similar C=O bond lengths have also been reported for corresponding non-bridging carbonyl groups in the compounds $Ph_3SnOCOCH_2CH_2NHCONH_2$, 1.224(4) Å (4), and $Ph_3SnOCOCME{=}CHCON(CH_2)_4$, 1.222(5) Å (5). The *cis* configuration adopted by the salicylidene moiety is similar to that reported for 2-bromo-*N*-salicylidene aniline (22). Proton transfer from oxygen to nitrogen atoms via hydrogen bonding and the formation of zwitterion intermediates in similar molecules to those discussed here is quite commonly encountered (19, 23, 24). Thus the labile phenolic oxygen is rendered susceptible to coordination with the tin atom. This makes possible the formation of a series of Sn—O(phenolic) bridges leading to the zigzag polymeric structure of triphenyltin *N*-salicylidene-6-aminohexanoate, which has a repeat distance of 4.7140 Å (25, 26). Similarities in the spectroscopic data suggest that the other compounds in the series adopt similar structures.

This series appears to be the first reported example of such an arrangement in triphenyltin carboxylates.

[2]These tables and diagrams may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

The diagrams and table of hydrogen atom parameters have also been deposited with the Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Lambertellin, a metabolite of *Ciboria gordonii* Funk

GERALD ARTHUR POULTON,[1] GORDON WILLIAM BUSHNELL, AND YUN-LONG LI
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 3P6

Received January 7, 1992

GERALD ARTHUR POULTON, GORDON WILLIAM BUSHNELL, and YUN-LONG LI. Can. J. Chem. **70**, 2688 (1992).

Lambertellin, 9-hydroxy-3-methyl-2*H*-naphtho[2,3-*b*]pyran-2,5,10-trione, previously identified from species of *Lambertella* and *Pseudospiropes*, has been isolated from the discomycete *Ciboria gordonii* Funk, identified on needles of the western hemlock *Tsuga heterophylla*. Spectral data and a crystal structure are given for lambertellin, confirming the structure in the literature.

GERALD ARTHUR POULTON, GORDON WILLIAM BUSHNELL et YUN-LONG LI. Can. J. Chem. **70**, 2688 (1992).

On a isolé lambertelline, la 9-hydroxy-3-méthyl-2*H*-naphto[2,3-*b*]pyran-2,5,10-trione (antérieurement identifiée à partir d'espèces de *Lambertella* et de *Pseudospiropes*), à partir du discomycète *Ciboria gordonii* Funk, identifié sur les aiguilles de la ciguë *Tsuga heterophylla*. On rapporte les données spectrales de la lambertelline et on a déterminé sa structure cristalline, confirmant ainsi la structure proposée dans la littérature.

[Traduit par la rédaction]

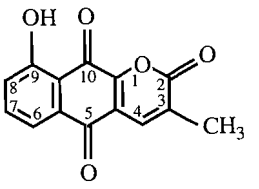
Introduction

Funk (1) has identified the fungus *Ciboria gordonii* Funk from needles of the Western hemlock *Tsuga heterophylla* (Raf.) Sarg. Cultures of this fungus produce visible quantities of the metabolite lambertellin, 9-hydroxy-3-methyl-2*H*-naphtho-[2,3,*b*]-pyran-2,5,10-trione, **1**, production being best at 10°C. Lambertellin has been previously isolated from *Lambertellin hicoriae* Whetzel (2, 3), from *L. corni maris* (4), and later from *Pseudospiropes simplex* (5), and a synthesis reported (6). As our preliminary spectral data were not in agreement with literature data for lambertellin, a crystal structure determination was conducted to confirm identity.

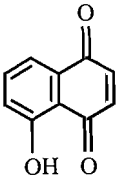
Results and discussion

Lambertellin was first isolated and identified as a constituent of a number of different fungi more than 20 years ago (2–4). It is of low solubility in organic solvents and thus the ^{1}H NMR data reported in the literature (in CF_3COOH (6) or as the sodium salt in D_2O (4)) did not permit a simple comparison with spectra obtained on current FT machines in $CDCl_3$ or DMSO-d_6. Differences between our observed chemical shifts of the coupled grouping of methyl and olefinic proton (2.16 and 7.84 ppm in $CDCl_3$) and published data (2.71 and 6.77 ppm in D_2O (4); 2.41 and 7.85–8.4 ppm in CF_3COOH (6)), plus the unavailability of comparison ^{13}C data, prompted us to confirm the structure of our isolate through X-ray crystal structure determination.

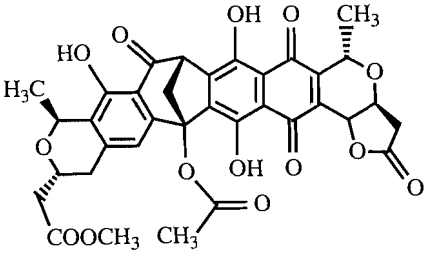
Figure 1 is an ORTEP drawing of lambertellin, giving the atomic labelling scheme and a display of the thermal motion ellipsoids scaled to enclose 50% probability. Table 1 summarizes the crystal data for lambertellin. The fractional atomic coordinates are presented in Table 2 together with equivalent isotropic temperature parameters. The interatomic distances are given in Table 3. The A ring is aromatic, with a mean bond length of 1.39(2) Å. Ring B is distinctly quinonoid, with the four carbon–carbon bonds α to the carbonyl showing an average bond length of 1.476(10) Å and the two central partial double bonds being 1.348(3) Å and 1.418(3) Å, typical of naphthoquinone-type structures (7–10). Ring C exhibits C—O single bonds (1.397(3), 1.356(2) Å), C—C single bonds (1.426(3), 1.452(3) Å), and the isolated C=C double bond (1.344(3) Å) typical (11) of an α-pyrone ring.



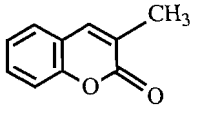
1



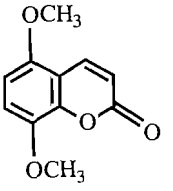
2



3



4



5

The carbonyl bond C(13)—O(4) is longer (1.228(2) Å) than the other two (1.216(2) Å, 1.202(2) Å), characteristic of a carbonyl group which is intramolecularly hydrogen bonded to a neighbouring hydroxyl group. Juglone (**2**) exhibits an analogous difference between the hydrogen-bonded carbonyl bond length (1.26(2) Å) and that of the non-hydrogen-bonded carbonyl (1.20(2) Å) (7).

Bond angles are listed in Table 4. As might be expected from a peri-naphthalene-type interaction, the C(11)—O(5) and C(13)—O(4) bonds are forced apart by steric interactions, the external angle of the C—O bond facing the carbonyl group being enlarged to 123.3(2)°, resulting in a

[a]Estimated standard deviations are given in parentheses.

compression of the angle on the opposite side to 117.1(2)°. Analogous effects have been reported, e.g., for juglone (**2**) (7) and γ-naphthoquinone (**3**) (8). Least-squares plane calculations were done for the atoms in the three six-membered rings and for the atoms in each individual six-membered ring. These four calculations were repeated with the attached peripheral non-hydrogen atoms included in the set of atoms defining the plane. Not one of these calculations indicated planarity for the set of atoms considered, judged by the esd's of the fractional atomic coordinates. The plane defined by the 14 atoms of the three rings gives a concise description of the structure, and these results have been deposited (see footnote 3). The maximum deviation from this plane by an atom belonging to the defining set was 0.063 Å by C(8). The peripheral O atoms deviated from the plane slightly more, up to 0.130 Å for O(3). This plane of the molecule lies at a perpendicular distance of 0.034 Å from the centre of inversion (at 0.5, 0.5, 0.5 for the coordinates given).

Selected intermolecular distances have been deposited as supplementary Table 4 (see footnote 3). The shortest intermolecular distance is O(4)···O(4′) across an inversion centre. Figure 2 shows this intermolecular contact to be part of a bifurcated hydrogen bond which is repeated by the inversion centre to give a double bifurcation. Bifurcated hydrogen bonds are relatively rare (12).

The packing of the molecular structure can be explained in terms of the molecular pairs just described. Pairs of molecules are arranged across each origin and across points like (0.5, 0.5, 0.5), as shown in Fig. 2. This results in layers of parallel obliquely slanted molecules with differing orientations at the x = 0 and x = 0.5 levels. Since the unit cell angle β is close to 90°, the layers are approximately at right angles to the a axis. The short lengths of b and c are related to the packing efficiency of the almost planar structure of the molecular pairs. The three-dimensional methyl groups do not lie within the layers, but are located on their surfaces. C(1) lies at 0.003(3) Å from the principal mean plane described above and has no close intermolecular contacts.

Table 5 summarizes the ^{1}H NMR data obtained in this

[a]Estimated standard deviations are given in parentheses.

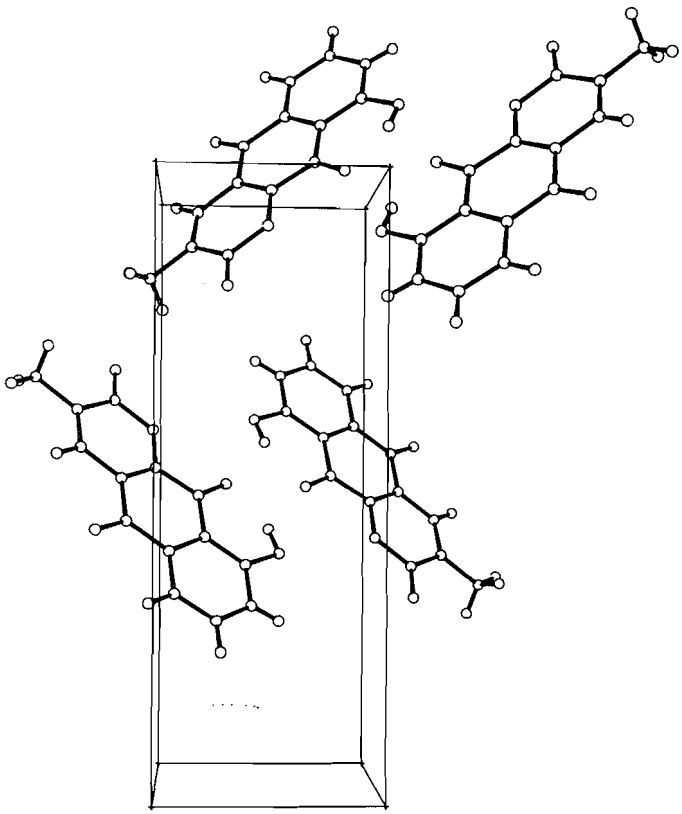

FIG. 2. Packing diagram for lambertellin. Unit cell outline is given with the origin at the lower, back, on the right-hand side. The *a* axis is vertically up, the *b* axis is across the page, right to left, and the *c* axis is toward the viewer. The molecules drawn are x, y, z; $1 - x, 1 - y, 1 - z$; $1.5 - x, -0.5 + y, 1.5 - z$; $0.5 + x, 0.5 - y, 0.5 + z$.

study and compares them with data reported in the literature for lambertellin and its methyl ether. In both $CDCl_3$ and DMSO, the methyl signal is observed upfield from all previously reported values, more in line with the values obtained for 3-methylcoumarins (e.g., 2.18 ppm for 3-methylcoumarin (**4**) itself (13)). Coupling constants and proton chemical shifts of the three coupled aromatic protons of ring A were confirmed by spectral simulation, and are in line with previously reported assignments (14).

Table 6 shows the ^{13}C data and assignments which are supported by 2D-COSY, DEPT, HETCOR, and HMBC data (15). Juglone (**2**) may be taken as an appropriate model for rings A and B, whereas 3-methylcoumarin (**4**) and 5,8-dimethoxycoumarin (**5**) are less accurate models for chemical shifts in an α-pyrone ring fused to a quinonoid ring.

Experimental

General

Melting points were determined on a Kofler hot stage and are uncorrected. Proton NMR spectra were obtained on a Perkin–Elmer R32 spectrometer at 90 MHz, a Bruker WM250 spectrometer at 250 MHz, or a Varian XL-300 spectrometer at 300 MHz. Carbon NMR spectra were determined on the Bruker WM250 spectrometer at 62.9 MHz, Varian XL-300 spectrometer at 75.4 MHz, or Varian VXR-500 spectrometer at 125.8 MHz. Infrared spectra were obtained on a Perkin–Elmer 283 spectrometer and ultraviolet spectra on the Beckman DU-8 spectrophotometer. Accurate mass measurements were kindly provided by the University of British Columbia Mass Spectrometry Centre using the Kratos MS-50 instrument.

Culture and extraction

Ciboria gordonii (1) was cultured on 2% malt extract (DIFCO) in Petri dishes at 10°C in the dark for 4 weeks. Mycelium and agar from 50 dishes were extracted by stirring with dichloromethane at room temperature (3 × 800 mL). The crude extract (120 mg) was washed with small amounts of acetone and the product recrystallized from acetone–hexane. Lambertellin was isolated as orange–red needles, mp 251–252°C (lit. (4) mp 253–254°C). Lambertellin showed ν_{max} (KBr): 3450, 3200–2500 br, 1750, 1650, 1610 cm^{-1}; λ_{max} (CH_3OH): 299 (log ϵ = 3.98), 270 nm (4.07); ^{1}HMR (250 MHz, $CDCl_3$): 11.8 (1H, s, OH, D_2O exchangeable), 7.84 (1H, q, J = 1.5 Hz, H4), 7.72 (1H, dd, J = 8.4, 7.5 Hz, H7), 7.65 (1H, dd, J = 7.5, 1.2 Hz, H6), 7.32 (1H, dd, J = 8.4, 1.2 Hz, H8), 2.29 (3H, d, J = 1.5 Hz, Me); ^{13}CMR: see Table 6; in a gated spectrum run in $CDCl_3$, the peaks at 137.4, 133.3, 125.3, and 119.9 ppm appeared as doublets; ms *m/z* (relative intensity, formula): 256.0370 (M+, 100, calculated for $C_{14}H_8O_5$ 256.0372), 228

(35, $C_{13}H_8O_4$), 200 (98, $C_{12}H_8O_3$), 199 (96, $C_{12}H_7O_3$), 172 (12, $C_{11}H_8O_2$), 144 (12, $C_{10}H_8O$), 115 (30, C_9H_7), 92 (20, C_6H_4O).

X-ray measurements

The crystal was mounted on a glass fibre in the direction of its greatest length and photographed using Weissenberg and precession cameras with CuK_α radiation. The symmetry was found to be monoclinic and an approximate unit cell was established. The crystal was then transferred to a Picker 4-circle diffractometer using MoK_α radiation and automated with a PDP-11/10 computer on which all further work was done. The unit cell was refined by least squares from 14 pairs of reflections (at $\pm 2\theta$) in the range 2θ = 8–45°. The crystal data are presented in Table 1.

Intensity measurements were done for 1 quadrant ($k,l \geq 0$) in the range 2θ = 0–50°, using a stepped scan of 120 steps of 0.01° in 2θ counting for 0.50 s per step. Background counting was for 30 s at each end of the scan. A set of standards 043;406;216 were measured before each batch of 50 reflections; 2164 measurements consisting of 129 standards and 2035 reflections were obtained. Lorentz and polarisation corrections were applied and equivalent measurements were averaged to obtain a final file with 1901 unique reflections. Weak reflections were included. No absorption correction was applied.

Structure solution and refinement

The programs used were SHELX-76 (19) and ORTEP (20). The atomic scattering factors were those given in the SHELX-76 program (19, 21). The structure was solved using direct methods and refined by standard Fourier synthesis techniques and by least-squares minimizing $\Sigma w\Delta^2$ (where w is a weight derived from the counting statistics ($w = 1/(\sigma^2(F) + 0.001F^2)$ and $\Delta = ||F_o| - |F_c||$). Initially carbon atomic scattering factors were used for all the ring atoms. The O atoms were identified as such by abnormally low temperature parameters. The hydrogen atoms of the C(1) methyl group were first calculated and then the group as a whole was refined as a rigid body. The hydrogen atoms were treated as isotropic scatterers and the heavier atoms were allowed the freedom of anisotropic thermal motion. U_{iso} was refined for those hydrogen atoms whose positional coordinates were refined. The final residuals were R = 0.0599, R_w = 0.0715.[2] The convergence was good with the final maximum (shift/esd) = 0.009. The final difference map had no important features, maximum 0.22 e Å^{-3}, minimum −0.28 e Å^{-3}. The number of measurements, 1901, was sufficient to determine the 204 parameters well.

Supplementary tables containing hydrogen-atom fractional atomic coordinates and isotropic temperature parameters, interatomic distances for the hydrogen atoms, bond angles involving hydrogen atoms, selected intermolecular distances, anisotropic temperature parameters, least-squares plane results, and observed and calculated structure factor amplitudes have been deposited.[3]

Spatial and temporal visualization of a pH-dependent complexation equilibrium by nuclear magnetic resonance imaging

B. J. BALCOM, T. A. CARPENTER, AND L. D. HALL[1]

Herchel Smith Laboratory for Medicinal Chemistry, Cambridge University School of Clinical Medicine, University Forvie Site, Robinson Way, Cambridge, CB2 2PZ, U.K.

Received June 8, 1992

B. J. BALCOM, T. A. CARPENTER, and L. D. HALL. Can. J. Chem. **70**, 2693 (1992).

Alteration of a chemical equilibrium, ethylenediaminetetraacetic acid chelation of aqueous copper, in response to a pH gradient that protonates the complexing agent, has been observed spatially and temporally by ^{1}H nuclear magnetic resonance. Protonation of the complexing agent shifted the complexation equilibrium towards free copper ion. Free and bound copper ions alter the spin lattice relaxation time (T_1) of water in the host polyacrylamide gel to different extents. Based on this difference, a T_1 weighted (fast repetition time, short echo time) two-dimensional spin-warp imaging sequence mapped out the distribution of the free and bound species. Addition of a pH 3 aqueous solution to the gel was insufficient to alter the equilibrium; a pH 1 aqueous solution liberated the complexed copper. Quantitative one-dimensional experiments gave a T_1 weighted profile that showed the reaction front is displaced a distance proportional to the square root of time.

B. J. BALCOM, T. A. CARPENTER et L. D. HALL. Can. J. Chem. **70**, 2693 (1992).

Utilisant la RMN du ^{1}H, on a pu observer la modification spatiale et temporale d'un équilibre chimique, la chélation du cuivre aqueux par de l'acide éthylènediaminetétraacétique sous l'influence d'un gradient de pH qui protone l'agent complexant. La protonation de l'agent complexant déplace l'équilibre de la complexation vers l'ion cuivre libre. Les ions de cuivre libres et liés altèrent de façons différentes les temps de relaxation spin-réseau (T_1) de l'eau du gel de polyacrylamide hôte. En se basant sur cette différence, une valeur moyenne de T_1 (temps de répétition rapide et temps d'écho court), il a été possible d'établir des séquences bidimensionnelles d'images déformées des spins qui définissent les contours de distribution des espèces libres et liées. L'addition d'une solution aqueuse de pH 3 n'est pas suffisante pour altérer l'équilibre; à un pH de 1, la solution aqueuse libère le cuivre complexé. Des expériences unidimensionnelles quantitatives ont permis de déterminer un profil moyen de T_1 qui montre que la front de la réaction se déplace d'une distance qui est proportionnelle à la racine carrée du temps.

It is a fundamental tenet of the majority of chemical transformations that the reaction medium is spatially and temporally homogeneous. In practise this is generally ensured by dissolving the reagents in a suitable solvent, which is then stirred. However, fast reactions often cannot be stirred briskly enough to ensure that the reaction is homogeneous. This is commonly observed for many acid/base titrations. Recently we examined two irreversible chemical reactions (1) where the rate of reaction was limited in a controlled manner by diffusion of reagents in a gel medium. In this communication we examine by Nuclear Magnetic Resonance Imaging (2–6) (NMRI), the spatial and temporal behaviour of a chemical equilibrium in a gel matrix perturbed by a pH gradient. This experiment is effectively a spatial titration.

Ethylenediaminetetraacetic acid (EDTA) has a very high affinity for divalent cations; for example, the log stability constant of EDTA and aqueous Cu^{2+} is approximately 18 (7). The effective stability constant, however, is pH dependent (7, 8); decreasing the pH of the reaction medium protonates the binding sites of EDTA and shifts the equilibrium towards free Cu^{2+} ions. Relaxation of the Cu^{2+}–EDTA system to a new equilibrium is very rapid upon addition of acid[2] and therefore it can be anticipated that progress of the "titration" will be limited by the rate at which reagents diffuse together.

A time-varying pH gradient was induced in the reaction sample by adding an acidic solution (pH 1.2, sulfuric acid) to the axial void of a right cylinder formed from cross-linked polyacrylamide gel[3] doped with EDTA chelated Cu^{2+} (15 mM). The gel network acts to limit long-range convective mixing of the reagents (9) so that the concentration profile of migrating protons in this medium is predominantly controlled by aqueous diffusion (9, 10). Thus the polyacrylamide gel behaves in many respects like pure water but with a well-defined ultrastructure determined by the casting geometry.

[1]Author to whom correspondence may be addressed.

[2]Homogeneous test reaction at concentrations representative of this work. Colour of the Cu^{2+}–EDTA complex was the indicator.

[3]Polyacrylamide gels were formed, over 24 h, from a 90:9.5:0.5 mixture of water, acrylamide, and bis-acrylamide (9) employing ammonium persulphate as the initiator and *N*,*N*,*N*′,*N*′-tetramethyethylenediamine as the accelerator. Gels were cast as right cylinders (*i*) diameter 26 mm in a Perspex cylinder sealed at the bottom, with a 5-mm NMR tube placed concentric with the cylinder axis, (*ii*) diameter 16 mm in a Perspex cylinder sealed at the bottom. Water-soluble by-products of the reaction were removed by equilibration over several days in a large reservoir of distilled deionized water. Gels were doped with 15 mM Cu^{2+} (sulphate salt) and 15 mM EDTA (disodium salt) by a similar equilibration. The dopant solution was adjusted to pH 7 with aqueous NaOH prior to equilibration. Small diameter samples (1-D experiments) were cut to a square edge with a sharp wire and guide.

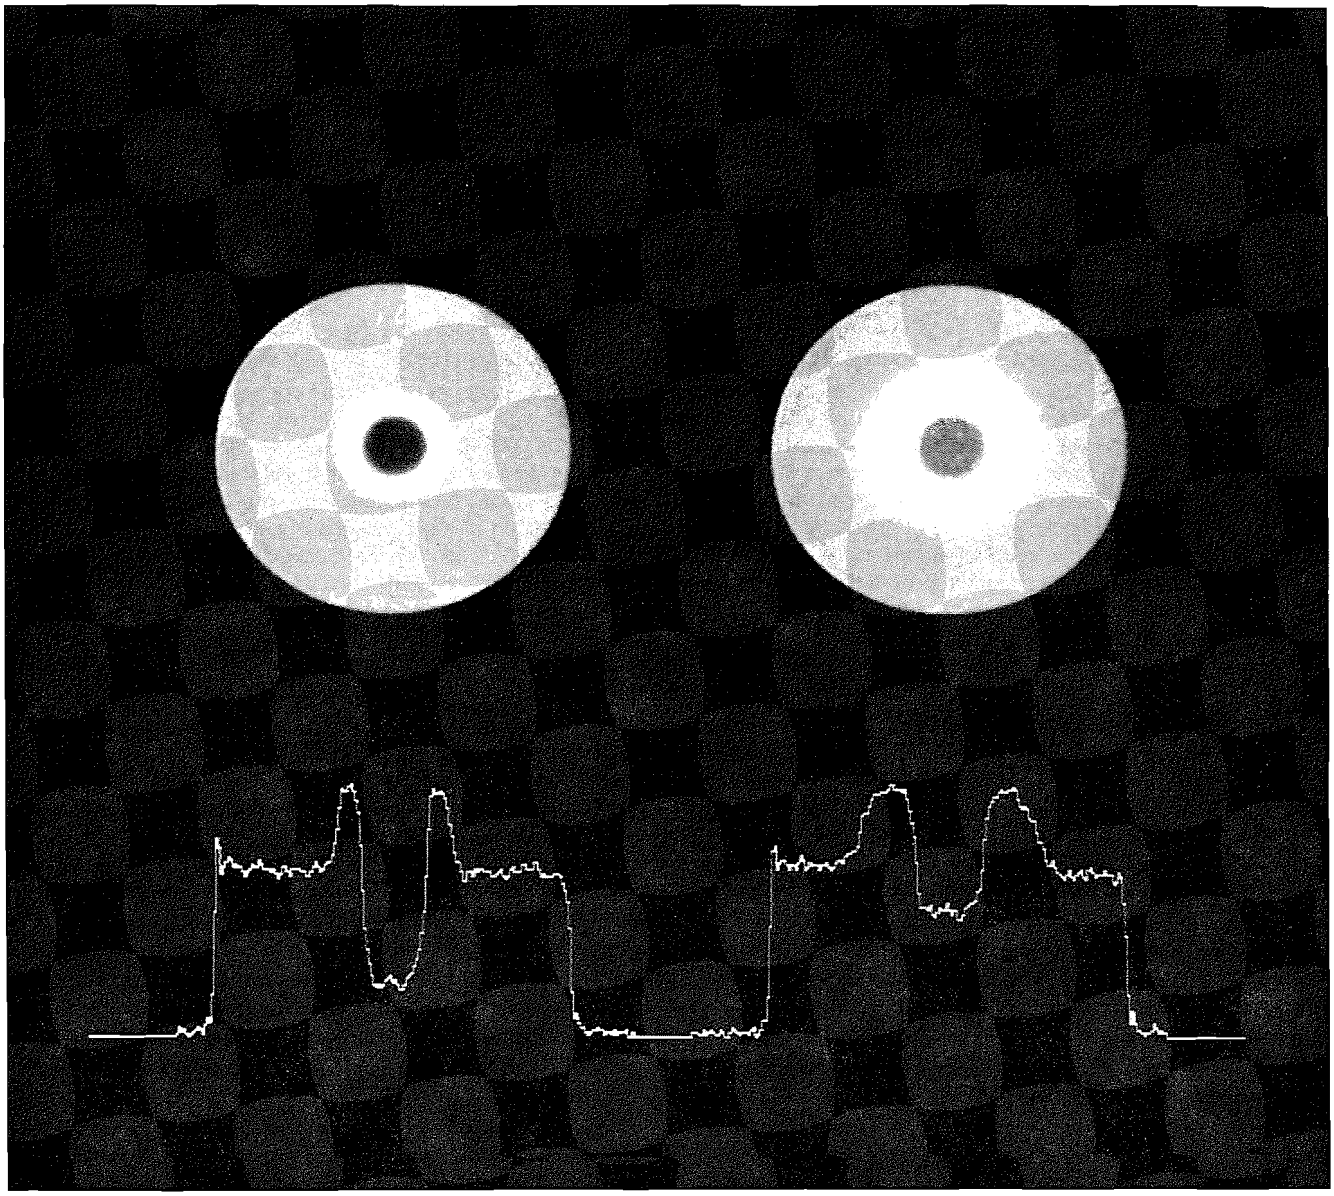

FIG. 1. Two-dimensional image illustrating the shift in complexation equilibrium Cu^{2+}–EDTA under the influence of a pH gradient. Areas of high image intensity map unbound Cu^{2+}. The left image corresponds to 4 min after addition of acid to the axial void, the right image 25 min. Profiles below both images reflect the intensity distribution along a line that bisects the center of each image horizontally.

As the local concentration of H^+ increases, the resultant, spatially dependent, shift in equilibrium can be imaged by utilizing the differential effect of complexed and free Cu^{2+} on the spin lattice relaxation time (T_1) of water in the gel media. Previously we examined contrast engendered through an alteration in the electronic structure of a contrast agent (1). In this work signal contrast is created through an alteration in the solvation of a contrast agent. Such effects with other paramagnetic metals are well known (11) and are presumed to reflect the reduced contact of the metal with its hydration sphere. Inversion recovery measurements of the proton spin lattice relaxation time at pH 7 (Cu^{2+} = 15 mM, EDTA = 15 mM) gave a T_1 of 0.38 s, whereas at pH 1.2 the T_1 was 0.19 s in the same system.

A conventional T_1 weighted spin-warp imaging sequence was employed (2) to visualize the molecular processes occurring in the gel. The analytical expression for the signal intensity at any point in the image is given by eq. [1], where TE is the time at which the spin echo is detected, TR is the repetition time, T_2 is the spin–spin relaxation time, and ρ is proton density. Since the gels under study are primarily water (90%), the proton density is very high and signal-to-noise in the resultant images is good.

$$[1] \quad S = \rho \exp(-TE/T_2)(1 - \exp(-TR/T_1))$$

The relaxation times for this system and the imaging parameters chosen (fast repetition rate, short TE) result in an image where contrast is strongly T_1 weighted and translates, to a first approximation, into a map of free and bound Cu^{2+}. Figure 1 shows two transverse slice images of the gel sys-

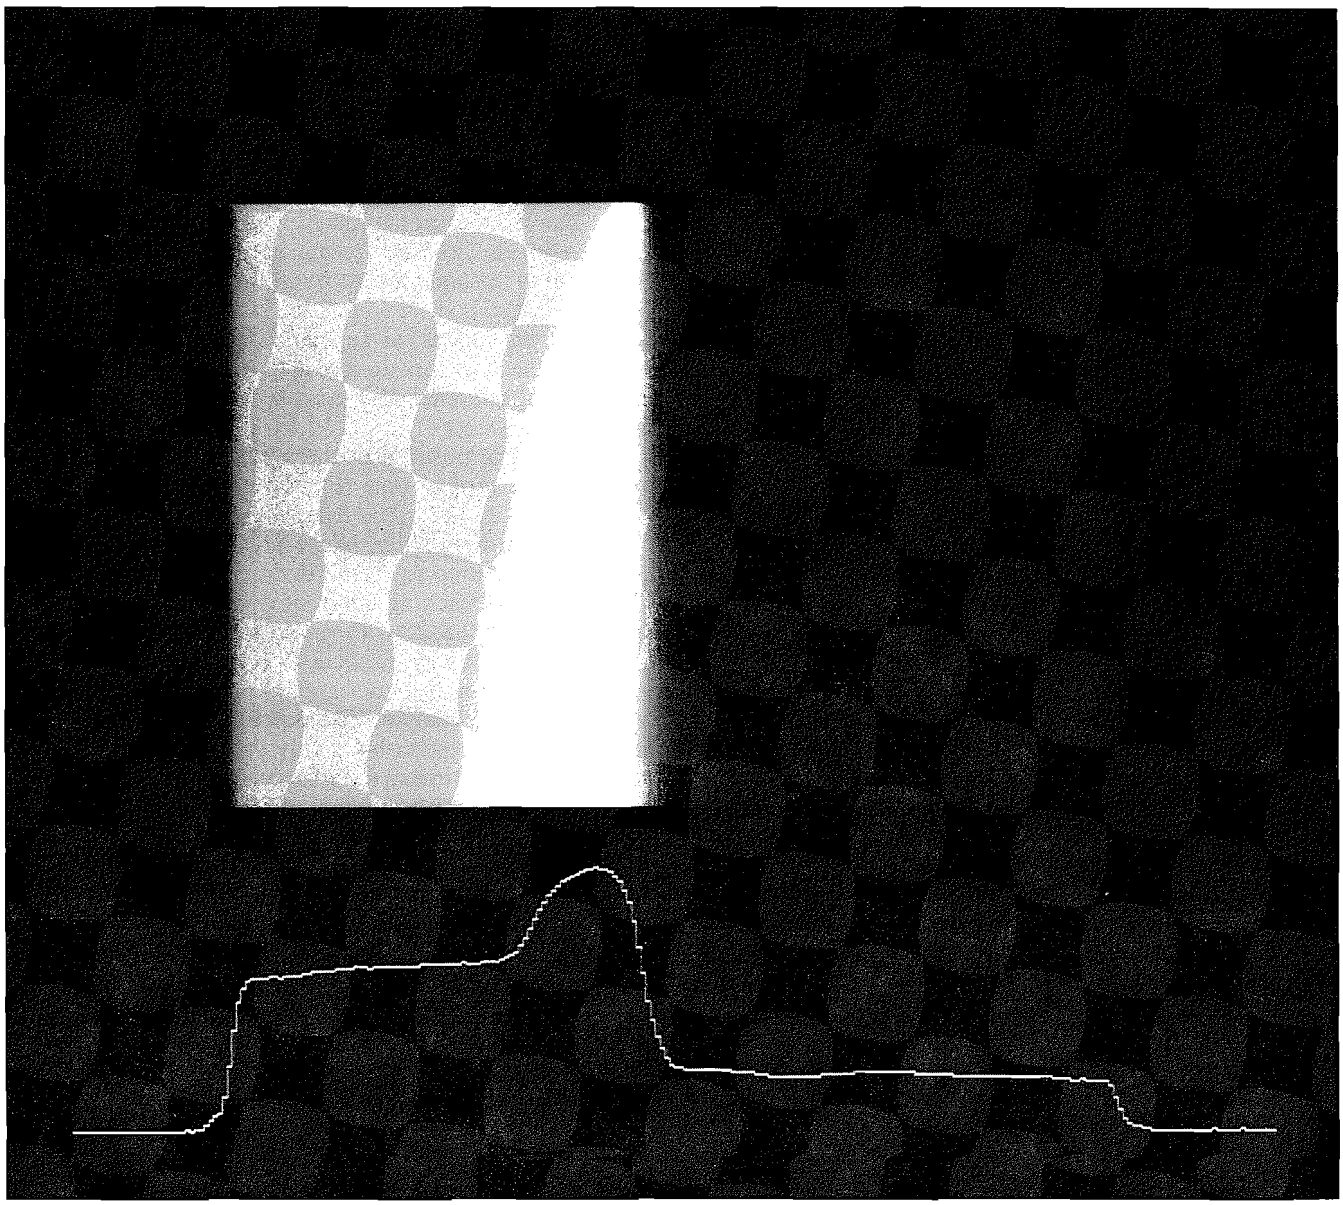

FIG. 2. One-dimensional magnetization profiles (x direction) acquired as a function of time (y direction) demonstrating the shift in complexation equilibrium Cu^{2+}–EDTA under the influence of a pH gradient. The reaction front moves right to left into the pre-doped aqueous gel as time increases. High signal intensities map unbound Cu^{2+}. The discrete profile shown is midway through the stack of 128. The uniform signal intensity in the aqueous reservoir shows it remains well mixed throughout the experiment.

tem,[4] acquired 4 and 25 min after addition of the acidic solution to the axial void. Regions of the sample without significant concentrations of free Cu^{2+} have weaker signal intensities due to partial saturation of their longitudinal magnetization under the influence of a fast repetition rate. Initially, bound copper and, therefore, low signal, predominates everywhere except in the immediate vicinity of the axial void.

With increasing time, the region of enhanced signal intensity spreads as the wave of aqueous protons migrates radially from the central void shifting the equilibrium between complexed and free Cu^{2+}. Back-diffusion of liberated Cu^{2+} into the axial void increases the signal from this part of the sample. Visual examination of the sample subsequent to imaging confirms that unbound copper predominates in the annular region of enhanced intensity. EDTA chelated copper in this sample displays a distinctive blue colour, which is diminished in the region of the sample corresponding approximately to the intense signal observed in Fig. 1. Cloudiness of the polyacrylamide gel (12), however, precludes more than a qualitative examination of the gel system based

[4]The NMR probe was a modified split-ring resonator (15) of 6.3 cm diameter. The imaging experiment was performed using an ORS Biospec 1 (83.7 MHz) instrument with a horizontal bore (31 cm) magnet and 20 cm home-built gradient set. The 2-D spin-warp sequence, with a hard 90° pulse and a slice-selective 180° pulse, had a repetition time of 0.3 s and an echo time of 15 ms. Slice thickness was 1 cm and the acquisition time 80 s for each 256 × 256 image. Field of view was 6 cm and pixel size 0.2 mm.

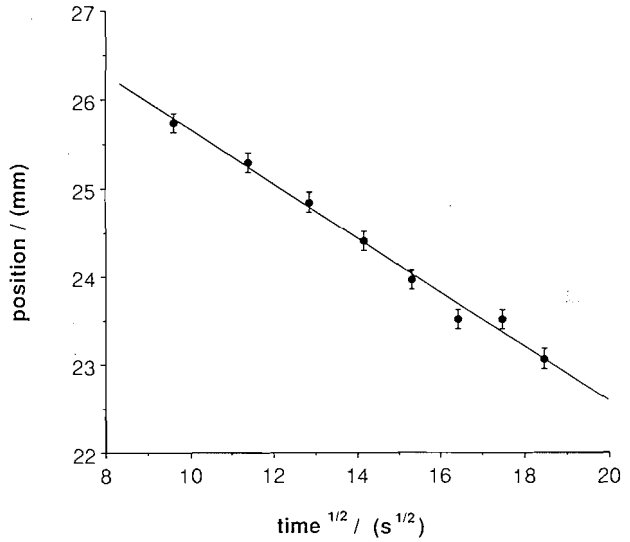

FIG. 3. Plot of the interface position as a function of the square root of time. The plot is linear in accord with theory. The uncertainty in each point is $\pm 1/2$ pixel (0.1 mm).

on colour changes. A less acidic solution (pH 3) added to the axial void gave no enhancement of NMR signal from the gel, which accords with the expectation that a pH 3 solution should be insufficient to manifest a substantial alteration in the Cu^{2+}–EDTA equilibrium. The Cu^{2+}–EDTA complex is known to be stable at approximately pH 3 (8).

The experiment shown in Fig. 1 illustrates that we are able to follow the moving boundary between free and bound Cu^{2+} that results from diffusion of H^+. The spread of the reaction front in this experiment, however, is difficult to quantify for two reasons: (1) The front moves a finite distance during data acquisition, which leads to a smearing of the front. The exact nature of this smearing in the image (frequency) domain is difficult to predict *a priori* because the image is reconstructed, via a Fourier transform, from data collected in the time domain (2). (2) H^+ in the axial void is of finite concentration. Most simple solutions to the reaction–diffusion equation presume a constant concentration reservoir. Both of these difficulties, along with the attendant mathematical complications of radial geometry (Bessel functions), are avoided if one works with a simple one-dimensional sample.

Roughton (13) has shown that fast reaction kinetics, in a one-dimensional sample, lead to the propagation of reaction fronts a distance proportional to the square root of time. To investigate the Cu^{2+}–EDTA system more thoroughly, we performed the one-dimensional analog to the experiment in Fig. 1. The sample was a cylinder of polyacrylamide, in a Perspex former, pre-doped with chelated copper; A roughly equivalent volume of pH 1.2 sulfuric acid was added to the top of the polyacrylamide gel. The reaction front moving into the gel was imaged by rapid repetition of a simple spin-echo imaging sequence[5] without a phase encode step (2). This sequence produced a one-dimensional magnetization profile of the sample along the cylinder axis. The signal intensity at a point is governed, as before, by eq. [1].

The experiment is shown in Fig. 2 where we have synthesized an image from a series of profiles acquired at 30-s intervals. In this composite image the discrete profiles (x direction) are displayed as a function of time (y direction). As before, regions of high intensity correspond to unbound Cu^{2+}. The left side of the image, with moderate intensity, is the gel with chelated Cu^{2+} while the dark right-hand side of the image is the aqueous reservoir. A representative profile from the image is displayed at the bottom of the figure. The reaction front moves, as expected, from the aqueous reservoir into the gel; the shorter acquisition time of the one-dimensional sequence (5 versus 80 s) freezes movement of the reaction zone.

A plot of the position of the reaction front as a function of the square root of time (Fig. 3) is a straight line as predicted by theory (13). The front position is chosen to be the point of maximum slope in the advancing wave; a difference approximation to the derivative (14) yields this point. This method of tracking the front is valid provided the front shape does not change with time. We have plotted only the first quarter of the experiment in Fig. 3 because the reservoir concentration does not greatly exceed the total amount of EDTA in the sample. The boundary condition outlined above (constant reservoir) is only valid early in the experiment. At longer times, the observed reaction front broadens, probably because the flux of H^+ has decreased.

Further studies with other reactions and imaging sequences are planned to investigate in more detail moving boundaries of chemical reactivity by NMRI. We conclude by noting this work provides a simple precedent for using paramagnetic chelates as a novel class of NMR-active indicators whereby the spatial variation of various chemical equilibria may be examined. It is conceivable that the approach can be used to study systems such as ion exchange beds where it may be impossible to sample aliquots or to insert any form of instrumental probe.

[5]The 1-D spin-echo sequence, with hard 90° and 180° pulses (16 per profile), had a repetition time of 0.3 s and an echo time of 10 ms. Profiles (128) of 256 pixels were collected every 30 s. The field of view and pixel size were approximately the same as the two-dimensional experiment.

The thermodynamics of the vaporization of liquid indium(I) iodide by modified entrainment

PETER J. GARDNER AND STEVE R. PRESTON

Department of Chemistry, Royal Holloway and Bedford New College, University of London, Egham Hill, Egham, Surrey, TW20 0EX, U.K.

Received March 3, 1992

PETER J. GARDNER and STEVE R. PRESTON. Can. J. Chem. **70**, 2699 (1992).

The transport of gaseous In(I)I in an argon carrier gas was studied in the temperature range 723–887 K by the modified entrainment method. Combination of the entrainment results with a literature equation for the total vapour pressure above the liquid gave the following expressions for the temperature dependence of the vapour pressures of the monomer (InI) and dimer (In_2I_2) respectively: $\ln[p^0_1/p^0] = -(12\ 866 \pm 141)/T + (12.99 \pm 0.51)$ (720–810 K) and $\ln[p^0_2/p^0] = -(18\ 370 \pm 700)/T + (15.8 \pm 1.2)$ (720–790 K); $p^0 = 10^5$ Pa. The dimer concentration is ca. 2% and nearly constant from 720 to 810 K.

PETER J. GARDNER et STEVE R. PRESTON. Can. J. Chem. **70**, 2699 (1992).

Faisant appel à la méthode d'entrainement modifiée et opérant entre 728 et 887 K, on a étudié le transport du In(I)I gazeux dans de l'argon agissant comme gaz porteur. Une combinaison des résultats de l'entraînement avec une équation tirée de la littérature pour la pression de vapeur totale au-dessus du liquide a permis de tirer les expressions suivantes pour la relation entre la température et respectivement les pressions de vapeur du monomère (InI) et du dimère (In_2I_2) : $\ln[p^0{}_1/p^0] = -(12\ 866 \pm 141)/T + (12{,}99 \pm 0{,}51)$ (720–810 K) et $\ln[p^0{}_2/p^0] = -(18\ 370 \pm 700)/T + (15{,}8 \pm 1{,}2)$ (720–790 K); $p^0 = 10^5$ Pa. La concentration de dimère est approximativement égale à 2% et elle est pratiquement constante de 720 à 810 K.

[Traduit par la rédaction]

Introduction

There is considerable current interest in the thermodynamics of the complexation and polymerization of gaseous metal halides (1). Much of this interest is engendered by the lamp industry (2), which makes extensive use of these halides, e.g., of In, Na, Sc, Sn, etc., as dopants within the envelope of the current generation of "metal halide" mercury discharge lamps. Their presence improves significantly the spectral distribution and colour rendition of the discharge. Before the discharge is struck, the halide is present as a condensed phase and knowledge of its vaporization thermodynamics is crucial to proper lamp design. There has been a recent study (3) of the total vapour pressure over liquid indium(I) iodide from 646 to 958 K by quasi-static vapour pressure manometry. The results from this study have been used in combination with an examination of In(I)I(l) from 723 to 887 K by modified entrainment to yield separate vapour pressure equations for the monomer and dimer species. The techniques and data analysis are similar to those used in a recently reported study (4) of indium(I) bromide.

Experimental

Materials

Indium(I) iodide, an opaque purple crystalline material, was from the same batch (3) as that used for vapour pressure manometry; its synthesis and analysis have been reported (3). The material was handled in a dry-nitrogen-filled glove bag.

Argon was purified by passage through a commercial rare gas purifier (model RGP-4, B.O.C. Ltd.)

Apparatus

The modified entrainment apparatus has been described before (4). The principal difference between the modified entrainment method (MEM) and conventional entrainment is that in MEM the sample and the vapour in equilibrium with it are insulated from the irreproducible effects of the carrier gas (argon) by a narrow capillary (20 mm long × 1 mm diameter). This capillary acts as a diffusive resistance to the egress of sample vapour which is swept away by the carrier at the capillary orifice. The equilibrium vapour pressure obtains at the bottom of the capillary (5) above the sample surface and consequently the transport kinetics in the capillary may be formulated readily. The experimental parameter is the rate of mass loss ($\dot{w}$) at a preset temperature (T); the range studied was from 4.2×10^{-11} kg s^{-1} (at 723 K) to 1.6×10^{-9} kg s^{-1} (at 887 K). The diffusive resistance (length over cross-sectional area) of the channel was 24 120 ± 12 m^{-1}. Eighty-three data points were recorded using a modified protocol compared to that used in earlier work (4). The sample was allowed to cool from its maximum temperature of 887 K at 2 K min^{-1} and the rate of mass loss ($\dot{w}$) was logged digitally at 1 min intervals. Several points throughout the temperature range were repeated under isothermal conditions to confirm that thermal equilibrium is established during the dynamic recording protocol. The apparatus is operated at near atmospheric pressure.

Results and discussion

High-temperature mass spectroscopy, at 590 K, of the vapour above solid In(I)I (T_m = 632 K) indicates the presence of a low concentration (a few percent) of the dimer, In_2I_2 (3). The vapour composition was also examined by absorption spectroscopy (6, 7) but only the presence of the monomer was noted. Accordingly, our results were interpreted assuming the following equilibria

[1] $\quad InI(l) \rightleftharpoons InI(g) \qquad \Delta H_1, \Delta S_1$

[2] $\quad 2InI(g) \rightleftharpoons In_2I_2(g) \qquad \Delta H_2, \Delta S_2$

The solution to the flux equations for these equilibria is identical to that for the corresponding $InBr/In_2Br_2$ system, which has been described in detail (4) and will not be repeated here. Briefly, if the ratio of the dimer to monomer flux in the capillary (see Experimental) is β, then the partial pressures of the monomer (p^0_1) and dimer (p^0_2) are given by eqs. [3] and [4]

$$[3] \quad p_1^0 = \frac{P}{(1+\beta)}\left(1 - \exp\left(\frac{-\dot{w}RTl(1+\beta)}{D_1AM_1P(1+2\beta)}\right)\right)$$

$$[4] \quad p_2^0 = \frac{P\beta}{(1+\beta)}\left(1 - \exp\left(\frac{-\dot{w}RTl(1+\beta)}{D_2AM_1P(1+2\beta)}\right)\right)$$

In these equations, P is the argon carrier gas pressure (near atmosheric), $\dot{w}$ is the rate of mass loss at temperature T, l/A is the diffusive resistance, and M_1 is the monomer molecular mass. For the limiting cases of zero dimer ($\beta = 0$ in eqs. [3] and [4] and $i = 1$ in eq. [5]) or zero monomer ($\beta = \infty$ in eqs. [3] and [4] and $i = 2$ in eq. [5]), eqs. [3] and [4] reduce to eq. [5]

$$[5] \quad p_i^0 = P\left(1 - \exp\left(\frac{-\dot{w}RTl}{\mathcal{D}_iM_iAP}\right)\right)$$

In these equations D_i are ternary (InI, In_2I_2, Ar) diffusion coefficients and $\mathcal{D}_i$ are binary (InI or In_2I_2, Ar) diffusion coefficients. The total vapour pressure (p_T) is given by eq. [6].

$$[6] \quad p_T/\text{Pa} = p_1^0 + p_2^0 = \exp(-16\,683/T + 62.716 - 5.001 \ln T)$$

which was obtained by a weighted three-parameter regression of the experimental points (3) from quasi-static vapour pressure manometry; the weighting factor is p_T^2 (8). The temperature range for the study by Brumleve *et al.* (3) was 645–960 K, which encompasses our experimental range (723–887 K). The total vapour pressure above In(I)I has been reported many times in the past and the relative merits of these earlier determinations have been discussed (3). The presence of higher halides in the sample is a frequent cause of high results. We prefer to use the results of Brumleve *et al.* because they were obtained with a sample from the same batch as used in our work, and because of our first-hand knowledge of the experimental procedure of Brumleve *et al.*

If the diffusion coefficients (D_i) are known, then eqs. [3], [4], and [6] contain three unknowns, p_1^0, p_2^0, and β. The estimation of the diffusion coefficients is described in the Appendix. The equations were solved numerically at each experimental temperature using a bisections algorithm (9) to find the root of $F(\beta) = 0$ where

$$[7] \quad F(\beta) = p_T - p_1^0 - p_2^0$$

with an initial guess $0 < \beta < 10$. $F(\beta)$ is a monotonically increasing function from $\beta = -0.5$, approaches asymptotically a positive limit at large values of β and with one root in this range. During data processing it was noted that the proportion of dimer (and hence β) was small throughout the experimental range. Consequently, because of random error in $\dot{w}$, several negative roots for β (and hence p_2^0) were found; this problem has been noted before (4). This was circumvented by using analytic values of $\dot{w}$ from a weighted linear regression of the experimental data points, eq. [8]. This has the effect of smoothing the input data.

$$[8] \quad \ln[\dot{w}/\text{kg s}^{-1}] = -(4.74 \pm 0.19) - \frac{(13\,782 \pm 150)}{T}$$

Having found values for β at the experimental temperatures, values for p_1^0 and p_2^0 follow from eqs. [3] and [4]. These were used to generate vapour pressure equations, [9] and [10], for the monomer and dimer ($p^0 = 10^5$ Pa).

$$[9] \quad \ln[p_1^0/p^0] = (12.99 \pm 0.51) - (12\,866 \pm 141)/T \quad (720\text{–}810\ \text{K})$$

$$[10] \quad \ln[p_2^0/p^0] = (15.8 \pm 1.2) - (18\,366 \pm 698)/T \quad (720\text{–}790\ \text{K})$$

The uncertainty intervals in the coefficients of the vapour

[a]These derived quantities were obtained from smoothed values of $\dot{w}$, eq. [8], see text.
[b]1 Torr = 133.3 Pa.
[c]β is the ratio of the fluxes of dimer to monomer in the capillary and is approximately equal to $p_2^0D_1/p_1^0D_2$; values of D_1 and D_2 may be estimated from eqs. [A2] and [A3].
[d]Redundant significant figures are included in these columns; the precision of these pressures is discussed in the text and shown in the figure.

Dimer pressure fraction, 800 K, %	Small(3)	4	2

[a]A third law result from ref. 15 combined with an enthalpy of fusion from ref. 3 where the wide range of reported values for this function is discussed.
[b]Observed directly by DeFoort *et al.* (15), reaction(4) in his Table 7.
[c]From eq. [12].
[d]These literature values are not mutually self-consistent via eq. [12] because, although they come from the same authors, they were reported independently (3, 14).

pressure equations are 68% confidence intervals and are composite terms that include the effect of the random fluctuations in $\dot{w}$, the uncertainty in the diffusive resistance, and an estimated (5%) uncertainty for the diffusion coefficients (see Appendix). Some experimental values of $\dot{w}(T)$ and the derived values of p_1^0, p_2^0, and β are collected in Table 1.

The vapour pressures are given in Fig. 1 with the error bars calculated using an estimated cross-correlation coefficient as in the earlier work (4). The pressure fraction of the dimer is small, changing from 0.9% (at 730 K) to 1.4% (at 780 K); the difference is not statistically significant and the conclusion is that the dimer concentration is approximately con-

stant and less than 2% in the range 720–810 K. Equation [10] refers to the equilibrium

[11] $2InI(l) \rightleftharpoons In_2I_2(g) \qquad \Delta H_{11}, \Delta S_{11}$

and the thermodynamic constants for this expression are related to those for eqs. [1] and [2] by eq. [12]; Table 2 summarizes our thermodynamic constants for these reactions.

[12] $\Delta H_2 = \Delta H_{11} - 2\Delta H_1$

Table 3 compares thermodynamic constants for the same three reactions for InX (X = Cl, Br, I) and includes some literature results. To permit comparison with literature results, the data in Table 2 and the corresponding earlier results (4) for InBr have been converted to apply to 298.15 K. The source of the C_p data for this conversion was as follows: for the liquid halides (10, 11), for InX(g) standard statistical thermodynamic routines with known (12) molecular parameters were used, and for $In_2X_2(g)$ scaling with $2.2C_p(InX)$ was used; this scaling factor is nearly temperature independent and is valid for the alkali metal halides and their dimers (13).

The enthalpy changes for reaction [1] given in Table 3 show a predictable trend and the agreement between various sources is satisfactory. For eqs. [2] and [11] there is agreement with literature sources only for InI; the disagreement for InBr is quite marked, especially for eq. [11].

The proportion of dimer in the vapour at 800 K is higher for InBr than for the other halides and InBr has a relatively high dimerization bond energy: In_2Cl_2 (47 kJ mol^{-1}), In_2Br_2 (72 kJ mol^{-1}), In_2I_2 (32 kJ mol^{-1}). As noted before (4), the dimerization bond energy for the bromide fits satisfactorily with the trend in this function vs. molecular mass for the alkali metal halide dimers but is clearly out of step with the other indium(I) halides; we can offer no explanation for this surprising fact.

Diffusion coefficients

The simultaneous solution of eqs. [3], [4], and [6] at each experimental temperature to yield β and then p_1^0 and p_2^0 assumes that the ternary diffusion coefficients for the system $InI/In_2I_2/Ar$ are known. There are no experimental diffusion coefficients for this system but a second-order treatment (16) of ternary diffusion in the context of modified entrainment permits the effective ternary coefficients ($D_{i,mix}$) to be written in terms of the corresponding binary diffusion coefficients ($\mathcal{D}_{ij}$) with respect to the majority component, argon

[A1] $$D_{i,\text{mixture}} = \frac{\mathcal{D}_{i,Ar}}{\gamma_i}$$

In eq. [A1], γ_i is a function of β, molecular masses, and temperature; the analytical form has been given before (4) along with computational details. Numerical values commonly lie in the range $0.8 < \gamma_i < 1.1$. The binary diffusion coefficients were calculated from the Chapman–Enskog equation (17). Use of this equation requires collision diameters for the interdiffusing species, and for the indium iodides these were estimated from an empirical correlation between Lennard Jones (LJ) collision diameters and moments of inertia (18). To calculate moment of inertia, it is necessary to know the molecular structure and the problem of estimating $\mathcal{D}_{ij}$ reduces to the estimation of the molecular structure of In_2I_2. The corresponding structure for InI is known (r_e = 2.754 Å (12)) and there are well-established correlations between structural constants for the alkali metal halides and their dimers (19, 20). The structure of In_2I_2 was

assumed to be D_{2h} and the In—I bond length was interpolated (2.99 Å) from a plot of $r(\text{M—X})_{\text{mon}}$ vs. $r(\text{M—X})_{\text{dim}}$ for the alkali metal halides using $r(\text{In—I})_{\text{mon}}$ = 2.754 Å. The bond angle θ(I—In—I) was interpolated at 107.2° from a linear plot of θ(X—M—X) vs. $(R_M - R_X)$ for the alkali metal halides where R_i are covalent radii (21); a similar correlation has been noted by Welch *et al.* (22). The covalent radius for In was estimated from the bond lengths in InX (X = Cl, Br, I) as 1.38 Å. Using the moments of inertia calculated from the structures and the σ_{LJ} vs. $I^{1/2}$ correlation in ref. 18, $\sigma_{LJ}(\text{InI})$ = 4.92 Å and $\sigma_{LJ}(\text{In}_2\text{I}_2)$ = 5.99 Å. The Chapman–Enskog equation contains a collision integral, which is a weak function of k_BT/ϵ_{ij}, where ϵ_{ij} is the well-depth of the interdiffusing species and k_B is the Boltzmann's constant. Svehla's correlation (23) with normal boiling point was used to estimate ϵ/k_B, InI = 1173 K and ϵ/k_B, In_2I_2 = 1821 K. Values for the LJ constants for argon were taken from a tabulation by Reid *et al.* (24). With the Lorentz–Berthelot (25) combining rules for ϵ_{ij} and σ_{ij} and Neufeld's expression (26) for the collision integral, the diffusion coefficients were calculated and regressed to a power law in T (ϵ_{ij} and σ_{ij} are the Lennard–Jones intermolecular potential parameters). From 700 to 950 K, the expressions [A2] and [A3] apply.

$$[\text{A2}] \quad \mathcal{D}(\text{InI, Ar})/\text{m}^2\,\text{s}^{-1} = 5.70 \times 10^{-6}\left(\frac{T}{273}\right)^{1.805}$$

$$[\text{A3}] \quad \mathcal{D}(\text{In}_2\text{I}_2\text{, Ar})/\text{m}^2\,\text{s}^{-1} = 3.83 \times 10^{-6}\left(\frac{T}{273}\right)^{1.851}$$

The choice of molecular parameters for In_2I_2 will clearly influence the result, and a range of estimated parameters was explored to investigate the effect. Values for the In—I bond length in the dimer were varied by ±5% and the theoretically estimated parameters of Solomonik (27), r(In—I) = 3.078 Å and θ(I—In—I) = 95.9°, were also studied.[1] The effect of these changes is to alter $\sigma_{LJ}(\text{In}_2\text{I}_2)$ to within the range 5.86–6.12 Å and this in turn affects $\mathcal{D}(\text{In}_2\text{I}_2)$, β, and the proportion of dimer. For all these modifications, the percentage of dimer remained less than 2% throughout the experimental temperature range. The procedure described in this appendix, that of estimating diffusion coefficients from empirical LJ parameters, has been validated for the SnBr_2–Ar and SnI_2–Ar systems (28).

The substituted arylhydrazonomesoxalonitriles and *N*-methyl phenylhydrazonomesoxalonitrile are studied electrochemically in benzonitrile (BN) employing different voltammetric and coulometric techniques. They are oxidized in a single irreversible one-electron transfer leading to a dimerization reaction. The reduction process occurs in two irreversible one-electron uptakes followed by proton abstraction from the solvent to give the saturated azomethine linkage.

G. M. ABOU-ELENIEN, N. A. ISMAIL, M. M. HASSANIN et A. A. FAHMY. Can J. Chem. **70**, 2704 (1992).

Opérant en milieu benzonitrile et faisant appel à des techniques voltammétriques et coulométriques, on a étudié le comportement électrochimique d'arylhydrazonomesoxalonitriles substitués et du *N*-méthyl phénylhydrazonomesoxalonitrile. Ces produits sont oxydés par un transfert unique irréversible d'un électron conduisant à une réaction de dimérisation. Le processus de réduction se produit par le biais de deux acceptations irréversibles d'un électron, suivies de l'arrachement d'un proton du solvant pour conduire à la formation d'une liaison azométhine saturée.

Introduction

The electrochemical behaviour of α-arylhydrazononitriles and their *N*-methylated derivatives has recently been reported in the literature (1–8). The increase of interest in the chemistry of this class of compounds arose from their reported biological activity (9–13). It was found that these compounds are more effective than cyanides in the uncoupling oxidative phosphorylation in mitochonderial systems (14, 15).

Despite the considerable interest in the polarographic reduction of these compounds at the DME in aqueous buffers (1, 2, 16, 17), little has been reported (5) about their electrochemical behaviour in nonaqueous media at solid electrodes. In the present work we report the reduction and oxidation properties of some *para*-substituted α-arylhydrazonomesoxalonitriles (**1***a–g*) and their unsubstituted *N*-methyl derivative (**2**) at a rotating platinum disc electrode and the effects of substituents on their redox characteristics.

Experimental

Reagents

Benzonitrile (BN) (Rotitainerm, West Germany) was purified by, first, distillation under vacuum from orthophosphoric acid, followed by repeated distillations from phosphorus pentoxide and final fractional distillation from potassium metal. The supporting electrolyte, tetra-*n*-butylammonium perchlorate (TBAP) (Fluka–Swiss), was crystallized several times from ethanol–water (9:1 v/v) mixture and dried *in vacuo* before use.

Organic syntheses

Compounds **1***a–g* were prepared following the procedure described by Lax (18). Compound **2** was prepared according to the procedure described by Cauquis *et al.* (5). The products obtained were purified by repeated crystallization from ethanol and the purity was checked by TLC. The structures of all the prepared compounds were confirmed by elemental analyses as well as by spectral data.

Apparatus and instruments

The voltammetric measurements were carried out using a potential scan generator VSG 72 as a potential source, potential control amplifier PCA 72C (Bank Electronic, Gottingen, West Germany) as a potentiostat, servogor XY (Metrawatt, Nurnberg, West Germany) as *X–Y* recorder, and a coulometer manufactured by Bank Electronic, Gottingen, West Germany. The rotating platinum disc electrode (RDE), was mounted to a rotating motor (750 rpm) (Metrohm, Swiss).

Measurements

The electrochemical measurements were carried out in dry benzonitrile (BN) containing 0.1 M tetra-*n*-butylammonium perchlorate (TBAP) as supporting electrolyte. The steady state voltammetry was carried out using a rotating platinum disc electrode (RDE), the cyclic voltammetry using a stationary platinum disc electrode. The number of electrons participating in each electrode process was obtained by controlled potential coulometry (CPC) in the same electrolyte using a platinum sheet electrode. Controlled potential electrolysis (CPE) experiments were carried out using a platinum net electrode either in dry benzonitrile or in acetonitrile with lithium perchlorate as supporting electrolyte.

The electrode potentials were measured against a saturated Ag/AgCl/Cl^- (BN) electrode, which was occasionally calibrated against the redox potential of the cobaltocenium/cobaltocene system (19). The standard potential of the Ag/AgCl/sat. Cl^- (BN)

electrode against the normal hydrogen electrode (NHE) is −176 mV (20, 21).

Controlled potential electrolysis (CPE)

Electrolysis of phenylhydrazonomesoxalonitrile (**1***b*) was carried out with 250 mg amounts of the starting material in both acetonitrile and benzonitrile. The potential was adjusted to a value corresponding to the limiting current plateau (+1.9 V for oxidation and −1.3 V for reduction). The electrolysis was stopped after the passage of a quantity of electricity corresponding to the uptake of 1 mole of electrons per mole of product for the oxidation and 2 moles for the reduction. In each case, after electrolysis, the resulting solution was evaporated at reduced pressure and the product was extracted with ethyl acetate, which was subsequently removed by evaporation. The mixture obtained was chromatographed on thin-layer silica gel plates using chloroform as solvent.

The oxidation product of CPE

Two main products with R_f = 0.71 and 0.84 were obtained. The zone with R_f value 0.71 was scraped off the plate, extracted with acetonitrile, filtered, and evaporated at reduced pressure. The resulting brownish solid compound (yield 60%; mp 250°C (dec.)) was identified as **3**; ir, cm^{-1} (KBr): 3200, 3300 (two NH); 2220 (CN); 1600 (C=N); 1220 (ClO_4); ^1H nmr ($CDCl_3$, TMS) δ, ppm: 7.2–7.4 (m, 8H, aromatic protons), 10.0 (s, br, 2H, two NH). Anal. calcd.: C 39.71, H 1.84, Cl 26.10, N 20.59%; found: C 39.68, H 1.75, Cl 25.66, N 20.37%.

The zone with R_f 0.84 was scraped and extracted as above. The faint orange-yellowish product obtained (yield 23%; mp 83°C) was identified as **4**; ir, cm^{-1} (KBr): 3200–3300 (two NH), 2220 (CN), 1600 (C=N); ^1H nmr ($CDCl_3$, TMS) δ, ppm: 7.25–7.44 (m, 6H, aromatic protons), 10.0 (s, br, 2H, two NH). Anal. calcd.: C 53.07, H 1.97, Cl 17.44, N 27.52%; found: C 53.15, H. 1.90, Cl 17.31, N 27.35%.

The reduction product of CPE

A quantitative yield of the original compound **1***b* was obtained (mp 102°C) when the reduction product was exposed to air; ir, cm^{-1} (KBr): 3240 (NH), 2220 (CN), 1600 (C=N); ^1H nmr ($CDCl_3$, TMS) δ, ppm: 7.2–7.5 (m, 4H, aromatic protons), 10.0 (s, br, 1H, NH). Anal. Calcd.: C 52.81, H 2.44, Cl 17.36, N 27.38%; found: C 52.63, H 2.38, Cl 17.28, N 27.25%.

Results and discussion

The electrochemical data for compounds **1***a–g* and **2** are summarized in Table 1. Figure 1 shows typical steady state voltammograms of these compounds, while Figs. 2*a* and *b* illustrate the corresponding cyclic voltammograms of the oxidation and reduction processes respectively, which are similar for compounds **1***a–f*. The oxidation occurs in a single irreversible one-electron process coupled with a consecutive chemical reaction (an EC mechanism). On the other hand, the reduction process occurs in two irreversible one-electron processes following an ECEC mechanism.

Compound **1***g* with an amino substituent is reduced similarly to the other members of the series, but the oxidation is accompanied by a second irreversible process corresponding to the oxidation of a primary aromatic amine. The reduction of the *N*-methylated derivative (**2**) occurs in a single two-electron wave instead in two irreversible one-elec-

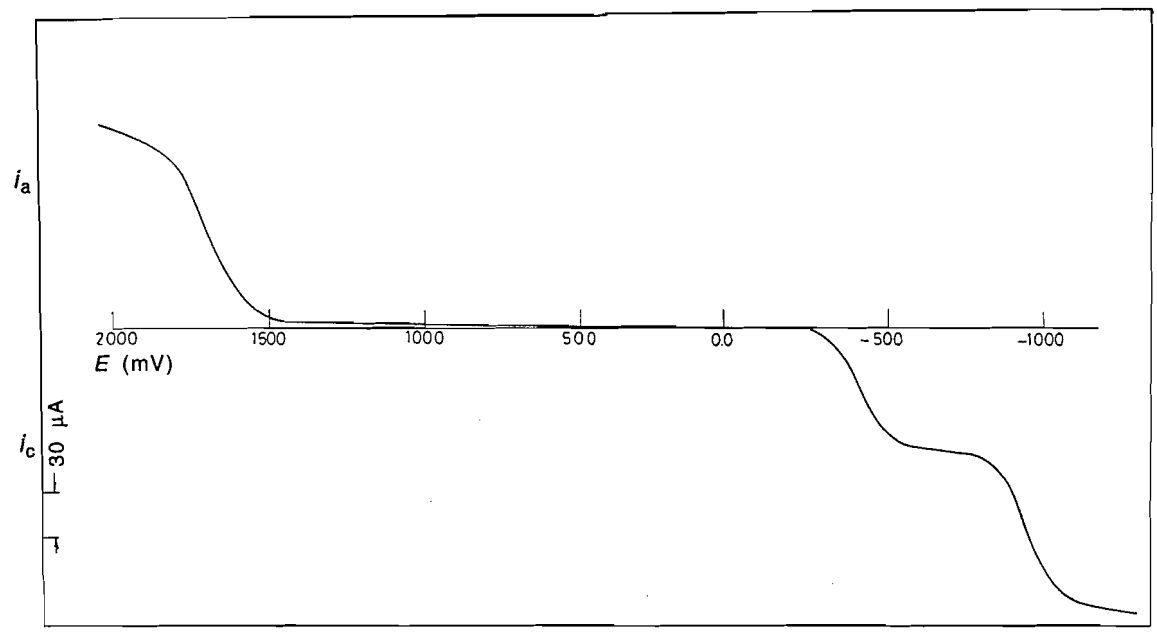

FIG. 1. DC voltamogram of compound **1***a* in BN.

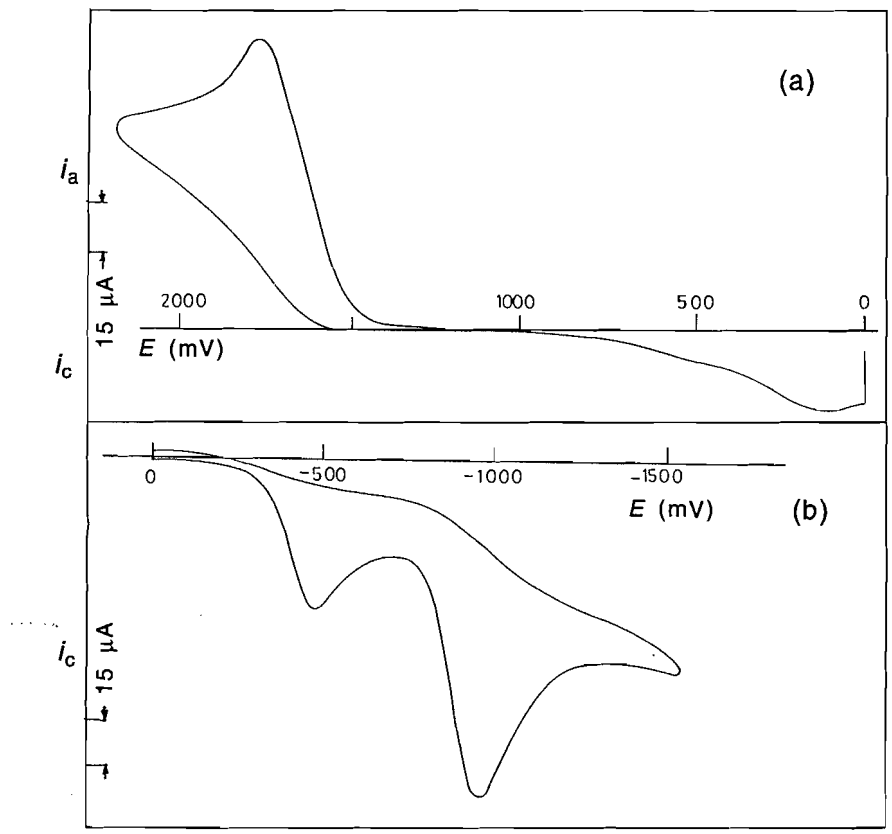

FIG. 2. Cyclic voltamogram of compound **1***a* in BN. (*a*) Oxidation. (*b*) Reduction. Scan rate = 100 mV/s.

tron waves. This two-electron process is accompanied by a chemical reaction (EC mechanism).

The substituted arylmesoxalonitriles **1***a–g* and (**2**) are thus oxidized in a single irreversible one-electron transfer process. This assumes that the coupled chemical reaction is dimerization. This is supported by isolation of 60% of the dimer **3** in the CPE (Scheme 1). The presence of 23% of the other dimeric species **4** indicates that under conditions of CPE, using a larger electrode over a prolonged period of time, the electrooxidation involves more than one electron per molecule of compound **1**.

The reduction of compounds **1***a–g* is assumed to occur on

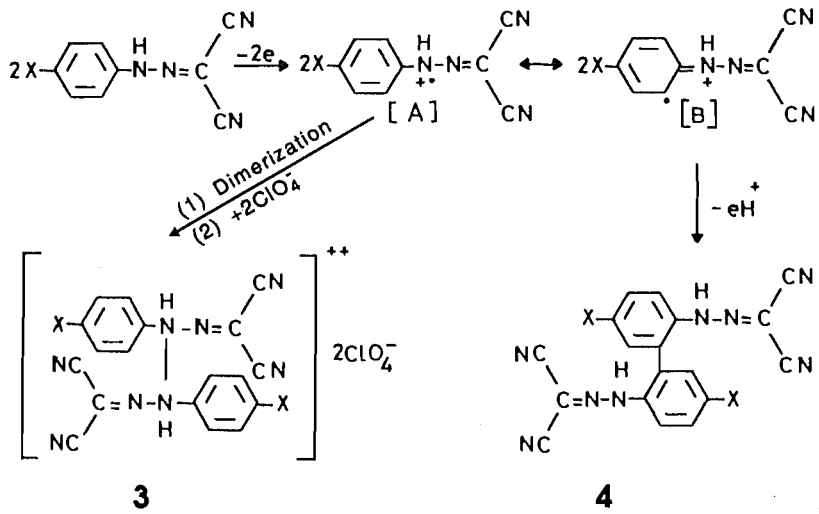
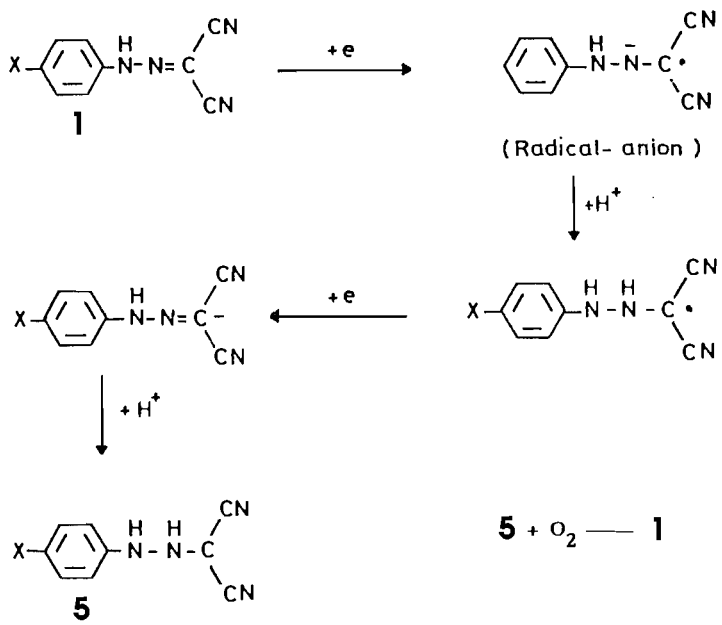


SCHEME 1



SCHEME 2

the -N=C double bond in two irreversible consecutive one-electron transfers, the potentials of which, for compound **2**, overlap. It is assumed that chemical reactions accompanying both electron transfers are proton abstractions — either from residual water in the solvent, from ions of the supporting electrolyte, or from the parent compound. Such a sequence is indicated in Scheme 2. The resulting hydrazine derivative **5** is unstable, especially in air, and is readily oxidized with air oxygen to the starting substance. This was the product obtained by CPE under aerobic conditions.

The introduction of the nitro group (Table 1, compound **1***d*) makes both reduction processes more difficult when compared with the unsubstituted parent compounds. This is contrary to the fact that usually the electron-attracting property of the nitro group lowers the electron density at the reduction centre. Also the presence of the electron-donating methoxy group has an effect opposite that usually observed (22) for electroreductions; it facilitates the first reduction process by 40 mV. Similar behaviour of the nitro and methoxy substituents was also found by Kass (23) in the reduction of different substituted arylaziridinium salts. The substitution by a methyl group on nitrogen (compound **2**) makes both oxidation and reduction processes more difficult than that of compound **1***a*. This may be explained by a steric effect of the methyl group at the reduction centre, which would hinder the approach of the reduction centre to the electrode surface.

Coordination chemistry of thioether–pyridazine macrocycles II. Synthesis, structural and spectroscopic studies of dinuclear copper(II) and polynuclear copper(I) and silver(I) complexes of a tetrathiapyridazinophane macrocyclic ligand

LIQIN CHEN, LAURENCE K. THOMPSON,[1] AND JOHN N. BRIDSON
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received May 19, 1992

LIQIN CHEN, LAURENCE K. THOMPSON, and JOHN N. BRIDSON. Can. J. Chem. **70**, 2709 (1992).

The preparation and properties of the thioether–pyridazine macrocycle (L3; $C_{11}H_{16}N_2S_4$) containing one pyridazine subunit, and its copper(II), copper(I), and silver(I) complexes are described. Magnetic susceptibility data (5–300 K) for the binuclear complexes $[CuL3Cl_2]_2$ (**I**) and $[CuL3Br_2]_2$ (**II**) have been fitted to the Friedberg magnetization expression with a molecular field correction. Intradimer antiferromagnetic exchange is weak ($-2J < 18$ cm^{-1}), with even weaker interdimer exchange ($-zJ' < 0.3$ cm^{-1}). The complexes $[CuL3Cl]_x$ (**III**) and $[AgL3ClO_4]_x$ (**V**) have been characterized by X-ray crystallography. **III** crystallizes in the triclinic system, space group $P\bar{1}$, with a = 9.410(2) Å, b = 10.291(2) Å, c = 9.208(2) Å, α = 108.56(1)°, β = 91.82(2)°, γ = 68.04(1)°, V = 780.1(2) Å^3, and $Z = 2$(R = 0.035, R_w = 0.031 for 1856 reflections). The ligand acts as a bidentate, S_2, bridge between dinuclear Cu_2Cl_2 units in a double stranded polymer. **III** crystallized in the monoclinic system, space group $P2_1/n$, with a = 9.382(4) Å, b = 19.274(4) Å, c = 10.190(3) Å, β = 106.35(3)°, V = 1768(1) Å^3, and $Z = 4$ (R = 0.036, R_w = 0.029 for 1776 reflections). The structure consists of a polymeric, two dimensional sheet structure, involving pseudo-tetrahedral silver ions linked by *exo*-bidentate, S_2, ligands and bidentate perchlorates.

LIQIN CHEN, LAURENCE K. THOMPSON et JOHN N. BRIDSON. Can. J. Chem. **70**, 2709 (1992).

On décrit la préparation et les propriétés du macrocycle thioéther-pyridazine (L3; $C_{11}H_{16}N_2S_4$) contenant une sous-unité pyridizane et de ses complexes avec le cuivre(II), le cuivre(I) et l'argent(I). On a ajusté les données de susceptibilité magnétique (5–300 K) des complexes binucléaires $[CuL3Cl_2]_2$ (**I**) et $[CuL3Br_2]_2$ (**II**) avec l'expression de magnétisation de Friedberg en faisant appel à une correction moléculaire du champs. L'échange antiferromagnétique intradimère est faible ($-2J < 18$ cm^{-1}) et l'échange interdimère est encore plus faible ($-zJ' < 0{,}3$ cm^{-1}). On a caractérisé les complexes $[CuL3Cl]_x$ (**III**) et $[AgL3ClO_4]_x$ (**V**) par cristallographie par rayons X. Le composé **III** cristallise dans le système triclinique, groupe d'espace $P\bar{1}$, avec a = 9,410(2), b 10,291(2) et c = 9,208(2)Å, α = 108,56(1), β = 91,82(2) et γ = 68,04(1)°, V 780,1(2)Å^3 et $Z = 2$ (R = 0,035 et R_w = 0,031 pour 1856 réflexions). Le ligand agit comme un pont bidentate, S_2, entre des unités dinucléaires Cu_2Cl_2 dans un polymère bicaténaire. Le composé **III** cristallise dans le système monoclinique, groupe d'espace $P2_1/n$, avec a = 9,382(4), b = 19,274(4) et c = 10,190(3) Å, β = 106,35(3)°, V = 1768(1) Å^3 et $Z = 4$ (R = 0,036 et R_w = 0,029 pour 1776 réflexions). La structure consiste en une feuille polymérique bidimensionnelle impliquant des ions argent pseuduo-tétraédriques liés entre eux par des ligands *exo*-bidentates, S_2, et des perchlorates bidentates.

[Traduit par la rédaction]

Introduction

Numerous studies have been carried out on homoleptic thioether complexes of copper (1–11). The coordination chemistry of chelating ligands with built in thioether and azole groups (12), and macrocyclic ligands with thioether and amino, amido, pyridine, furan and thiophene subunits have also been explored (13–23).

Our interest in mixed sulfur–nitrogen ligands involving thioether and diazine linkages stems from our earlier studies on open chain tetradentate (N_4) thioether–pyridazine ligands (24–29), which involved non-coordinating thioether linkages and formed binuclear copper(II) complexes with, in some cases, positive (0 → +0.5 V vs. SCE) reduction potentials. The combination of pyridazine and thioether groups, suitably disposed for simultaneous coordination, might be expected to produce binuclear copper(II) complexes with more positive reduction potentials, due to the softer nature of the sulfur donors and their affinity for copper(I). Our initial studies in this area have involved the synthesis and structural and spectroscopic studies of a series of copper(II) and copper(I) complexes of two oligomeric macrocyclic thioether–pyridazine ligands (L1, L2, Fig. 1) (30). For the copper(II) complexes the ligands act as nitrogen (pyridazine) donors only, while for the copper(I) derivatives coordination appears to involve just the sulfur atoms. The present paper describes the copper and silver coordination chemistry of the simple 1:1 macrocyclic ligand L3

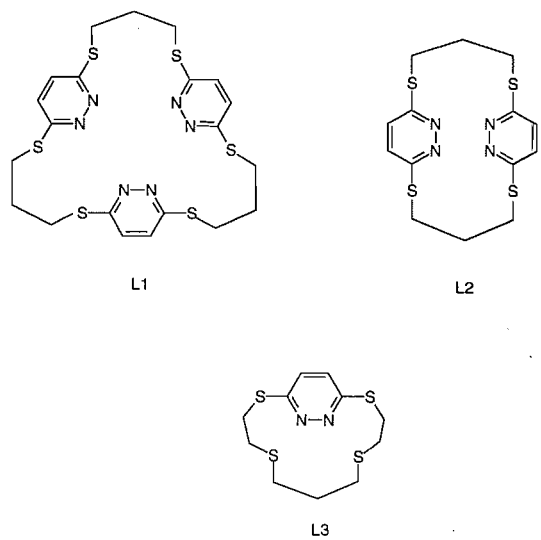

FIG. 1. Structural representation of the ligands.

(Fig. 1), which produces unusual polymeric copper(I) and silver(I) derivatives.

Experimental section

Commercially available reagents (Aldrich) were used without further purification. Infrared spectra were recorded using a Mattson Polaris FT instrument and electronic spectra with a Cary 17 spectrometer. EPR spectra were recorded with a Bruker ESP 300 X-band spectrometer at room temperature and 77 K. Mass spectra were obtained using a VG Micromass 7070 HS spectrometer and nmr spectra using a GE 300 MHz instrument. X-ray diffraction data were collected using a Rigaku AFC6S instrument and room temperature magnetic susceptibility data were measured by the Faraday method using a Cahn 7600 magnetic susceptibility system. Variable temperature (5–300 K) magnetic data were obtained with an Oxford Instruments superconducting Faraday magnetometer with a Sartorius 4432 microbalance. A main solenoid field of 1.5 T and a gradient field of 10 T m^{-1} were employed. Elemental analyses were performed by Canadian Microanalytical Service, Delta, British Columbia, Canada.

Synthesis of ligand and complexes

Safety note

Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small amounts of material should be prepared and these should be handled with caution. The complexes described in this report have, so far, been found to be safe when used in small quantities.

L3

3,7-Dithianonane-1,9-diol (31) (5.70 g, 25.0 mmol) was added to anhydrous ethanol (100 mL) in which sodium metal (1.15 g, 50.0 mmol) had been dissolved, and the resulting solution was stirred for 30 min. 3,6-Dichloropyridazine (3.73 g, 25.0 mmol) was then dissolved in anhydrous ethanol (100 mL) and both solutions were added dropwise simultaneously to anhydrous ethanol (500 mL) by using pressure equalizing funnels, over a period of 6 h during which time a white precipitate formed. The mixture was stirred overnight and then filtered. The white solid was washed with ethanol and deionized water, dried *in vacuo*, and recrystallized from $CHCl_3$ to give white crystals. Yield 5.5 g (72%). MP 234–236°C. Mass spectrum, major mass peaks (*m/e* (relative intensity)) 304(20) P, 271(5), 202(8), 170(40), 133(100), 105(28), 41(42). ^1H nmr ($CDCl_3$) (δ (relative intensity)): 1.88(2) (multiplet, CH_2), 2.65(4) (multiplet, CH_2), 2.85(4) (multiplet, CH_2), 3.53(4) (multiplet, CH_2), 7.11(2) (singlet, pyridazine).

[CuL3Cl$_2$] (I) and [CuL3Br$_2$]$_2$ (II)

A solution of L3 (182 mg, 0.6 mmol) in $CHCl_3$ (20 mL) was added to a solution of $CuCl_2 \cdot 2H_2O$ (255.6 mg, 1.5 mmol) in MeOH (20 mL). The resulting solution was filtered and then refluxed for 20 min whereupon dark brown crystals formed. Yield 200 mg (76%). Anal. calcd. for $(C_{11}H_{16}N_2S_4CuCl_2)_2$: C 30.10, H 3.67, N 6.38; found: C 29.80, H 3.48, N 6.28. $[CuL3Br_2]_2$ (**II**) was prepared similarly by reaction of L3 with $CuBr_2$ and was obtained as dark brown crystals. Yield 210 mg (66%). Anal. calcd. for $(C_{11}H_{16}N_2S_4CuBr_2)_2$: C 25.02, H 3.05, N 5.31; found: C 24.98, H 3.00, N 5.29.

[CuL3Cl]$_x$ (III)

Cu powder (190.5 mg, 3.0 mmol) was added to a solution of $CuCl_2 \cdot 2H_2O$ (51.2 mg, 0.30 mmol) in CH_3CN (20 mL). The mixture was stirred for 6 h under N_2 and the resulting colourless solution filtered into a solution of L3 (91.2 mg, 0.3 mmol) in $CHCl_3$ (20 mL) under a nitrogen atmosphere. The pale yellow solution was left at room temperature overnight and colourless crystals formed. Yield 105 mg (87%). Anal. calcd. for $(C_{11}H_{16}N_2S_4CuCl)_x$: C 32.74, H 3.99, N 6.94; found: C 32.87, H 3.97, N 6.98.

[AgL3(ClO$_4$)]$_x$ (IV), [AgL3(ClO$_4$)]·CH$_3$CN (V) and [AgL3(NO$_3$)] (VI)

A solution of L3 (152 mg, 0.5 mmol) in $CHCl_3$ (20 mL) was added to a solution of $AgClO_4$ (250 mg, 1.2 mmol) in CH_3CN (20 mL). The combined solution was filtered and then allowed to stand at room temperature overnight. Colourless crystals formed which were filtered, washed with CH_3CN and $CHCl_3$, and dried in air. Yield 150 mg (63%). Anal. calcd. for $(C_{11}H_{16}N_2S_4AgClO_4)_x$: C 25.81, H 3.15, N 5.47; found: C 25.92, H 3.09, N 5.52. When the colourless crystals were kept in contact with the solution for several days they gradually become yellow crystals (**V**), which were found to contain one molecule of acetonitrile. Anal. calcd. for $(C_{11}H_{16}N_2S_4AgClO_4)\cdot CH_3CN$: C 28.24, H 3.46, N 7.60; found: C 28.06, H 3.35, N 7.53. $[AgL3(NO_3)]$ (**VI**) was prepared similarly by using $AgNO_3$ and obtained only as colourless crystals. Yield 127 mg (54%). Anal. calcd. for $C_{11}H_{16}N_2S_4AgNO_3$: C 27.85, H 3.40, N 8.86; found C 27.76, H 3.26, N 8.87.

X-ray crystallographic analysis of [CuL3Cl]$_x$ (III)

The diffraction intensities of a colourless parallelepiped crystal of $[CuL3Cl]_x$ of approximate dimensions 0.35 × 0.35 × 0.10 mm were collected using a Rigaku AFC6S diffractometer with graphite monochromatized MoKα radiation. Cell constants and the orientation matrix were obtained by the least squares refinement of the setting angles of 24 carefully centred reflections in the range $48.12° < 2\theta < 49.88°$. Based on a statistical analysis of the intensity distribution, and the successful solution and refinement of the structure, the space group was determined to be $P\bar{1}$. Machine and data collection parameters and crystal data are given in Table 1. The data were collected at 25 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 50.0°. Omega scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.28° with a take-off angle of 6.0°. Scans of $(1.37 + 0.30 \tan\theta)°$ were made at a speed of 16.0°/min (in ω). The weak reflections ($I < 10.0\ \sigma(I)$) were rescanned (maximum of two rescans) and the counts were accumulated to assure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1.

A total of 2932 reflections were collected. The intensities of three representative reflections, which were measured after every 150 reflections, remained constant during data collection (no decay correction applied). An empirical absorption correction was applied, using the program DIFABS (32), which resulted in transmission factors ranging from 0.75 to 1.36. The data were corrected for Lorentz and polarization effects.

The structure was solved by direct methods (33, 34). The non-hydrogen atoms were refined anisotropically. The final cycle of full-matrix least-squares refinement was based on 1856 observed reflections ($I > 3.00\ \sigma(I)$) and 173 variable parameters and converged with unweighted and weighted agreement factors of $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.035$ and $R_w = [(\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2]^{1/2} = 0.031$. The standard deviation of an observation of unit weight was 1.63. The weighting scheme was based on counting statistics and included a factor ($p = 0.01$) to down weight the intense reflections. Plots of $\Sigma w(|F_o| - |F_c|)^2$ versus $|F_o|$, reflection order in data collection, $\sin\theta/\lambda$, and various classes of indices showed no unusual trends. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.36 and −0.48 electrons/Å^3, respectively, and have no chemical significance. Neutral atom scattering factors (35) and anomalous dispersion terms (36, 37) were taken from the usual sources. All calculations were performed using the TEXSAN (38) crystallographic software package using a VAX 3100 workstation. Hydrogen atoms were located in a difference map but not refined. Thermal parameters were set at 1.2 times the isotropic thermal parameter of the bonded C atoms.

Atomic positional parameters are given in Table 2 and selected

bond distances and angles are given in Table 4. Thermal parameters (Table S-1), hydrogen atom parameters (Table S-2) a full listing of bond distances and angles (Table S-3) and observed and calculated structure factors ($10|F_o|$ and $10|F_c|$) (Table S-4) are deposited as supplementary material.[2]

*X-ray crystallographic analysis of [AgL3(ClO$_4$)]$_x$ (**IV**)*

The diffraction intensities of a colourless, irregular crystal of **V** of approximate dimensions 0.40 × 0.20 × 0.15 mm were collected in a similar manner to **III**. Crystal data, intensity collection and refinement details are summarized in Table 1. Atomic positional parameters are given in Table 3 and selected bond distances and angles are given in Table 5. Thermal parameters (Table S-5), hydrogen atom positional parameters (Table S-6), a full listing of bond distances and angles (Table S-7), and observed and calculated structure factors ($10|F_o|$ and $10|F_c|$) Table (S-8) are deposited as supplementary material.[2]

Results and discussion

The synthesis of L3 was achieved in high yield by a traditional high dilution cyclization reaction and no trace of any 30-membered macrocycle containing two pyridazine subunits was detected. The copper and silver complexes of L3 did not dissolve appreciably in any solvent and so were studied exclusively in the solid state.

[2]Supplementary Tables S-1 to S-8 may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables S-2, S-3, S-6, and S-7 have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

*Description of the structures of [CuL3Cl]$_x$ (**III**) and [AgL3(ClO$_4$)]$_x$ (**V**)*

The structure of [CuL3Cl]$_x$ (**III**) is illustrated in Figs. 2, 3. The overall structure is that on an infinite double stranded polymer with two *exo*-bidentate macrocyclic ligands bridging the dinuclear chloro-bridged copper groups. The ligands are bonded only by sulfur donor atoms and these include S1, which is attached to the pyridazine ring and S3.

		S(2)—Ag(1)—O(1)	90.5(1)
		O(2)—Ag(1)—O(1)	104.2(2)

Each repeating unit of the polymer can be envisaged as a tetranuclear copper(I) entity, with the two ligands and the four coppers forming a most unusual metallocyclic arrangement. The copper atoms have a slightly distorted tetrahedral geometry with angles at copper in the range 102.90(5) to 120.54(5)°. The bond distances to sulfur (Cu1—S1 2.367(2) Å, Cu1—S3 2.280(1) Å) are within the range of other Cu(I) complexes of homoleptic thioether ligands (4, 5, 7, 9–11). The long Cu1—S1 bond may be associated with an inductive effect resulting from the proximity of S1 to the pyridazine ring. S1—C1 (1.772(4) Å) is significantly shorter than S3—C6 and S3—C7 (1.815(5) Å). The two copper chlorine distances are very similar (Cu1—Cl1 2.340(2), 2.350(1) Å) and can be compared with those in the polymeric complex $(C_3H_6S_3)_2$ $(CuCl)_3$ (2.30 to 2.413 Å) (39) which involves a canted $Cu_2S_4Cl_2$ dinuclear centre.

Homoleptic crown thioether complexes of silver(I) usually involve high coordination numbers. Examples include six-coordinate $[Ag([18]aneS_6)]^+$ (40) and $[Ag([9]aneS_3)_2]^+$ (41, 42), five-coordinate $[Ag_2L_2]^{2+}$ (L = 2,5,7,10-tetrathia[12](2,5)-thiophene) (43) and four-coordinate $[Ag_3([9]aneS_3)]^{3+}$ (44), $[Ag_2([15]aneS_5)_2]^{2+}$ (45), and $[Ag(16S6)]^+$ (16S6 = 1,3,6,9,11,14-hexathiacyclohexadecane) (46) species. Part of the structure of **IV** is illustrated in Fig. 4 and it involves a polymeric chain structure in which distorted tetrahedral silver(I) ions are bridged by *exo*-bidentate, macrocyclic ligands, that involve sulfur atoms S1 and S2 only as donors. The silver–sulfur distances (Ag1—S1 2.452(2) Å, Ag1—S2 2.463(2) Å) are about 0.1 Å shorter than those found in other Ag(I) thioether complexes with high coordination numbers (40–46), and about 0.1 Å longer than those in two-coordinate Ag(I) complexes (47, 48). Unlike the situation for **III**, where one thioether sulfur adjacent to the pyridazine ring was involved in coordination, only aliphatic thioether sulfurs act as donors in **IV**. The other two donor sites are provided by perchlorate oxygens (O1,O2) with relatively long silver oxygen bonds (Ag1—O1 2.659(5) Å, Ag1—O2 2.655(6) Å). However, the overall structure is most unusual and involves bidentate perchlorates, which cross link the polymeric S_2 chains with the formation of a 2-dimensional, polymeric sheet (Fig. 5). Bonded perchlorates involving silver thioether complexes are not common and in the case of the ligand cyclo(L-methionyl-L-methionyl) the distant silver–perchlorate contacts of 3.00 and 3.03 Å are questionable in terms of bonding interactions. Other silver–perchlorate bonds in, for example, isothiocyanate (49) and dimethyl sulfoxide (50) complexes of silver fall in the range 2.40–2.75 Å. The tetrahedral distortion at the silver ion is dominated by a large S1—Ag1—S2 angle of 148.82(6)°, with the smallest angle S2—Ag1—O1 of 90.5(1)°.

The coordination of L3 to both copper(I) and silver(I) by sulfur atoms only is clearly a reflection on the soft donor preferences of these ions. The exobidentate nature of the coordination of L3 to both copper(I) and silver(I) ions is consistent with the general trend for *exo*-dentate coordination observed for homoleptic, macrocyclic thioether complexes, which is related to the preferred "gauche" placement of the C—S linkages (51, 52). However, the incorporation of the rigid pyridazine subunit into the macrocycle sets ligands of this type apart from the symmetric, ethane bridged, homoleptic macrocyclic thioethers, and could lead to departures from the general trend of exodentate coordination. Molecular models indicate that L3 could encapsulate two metals acting as a tetradentate N_2S_2 ligand with endodentate aliphatic sulfur donors. Clearly more examples of structures of complexes of ligands of this sort are required to make reasonable comparisons with the aliphatic, macrocyclic thioethers.

Spectral and magnetic properties

The ligand L3 has an infrared absorption at 1568 cm^{-1}, associated with CN stretch in the pyridazine ring. A very

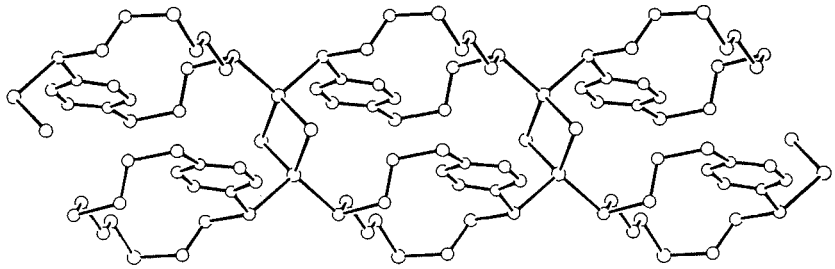

FIG. 2. Molecular structure of $[CuL3Cl]_x$ (**III**) illustrating the double stranded polymer.

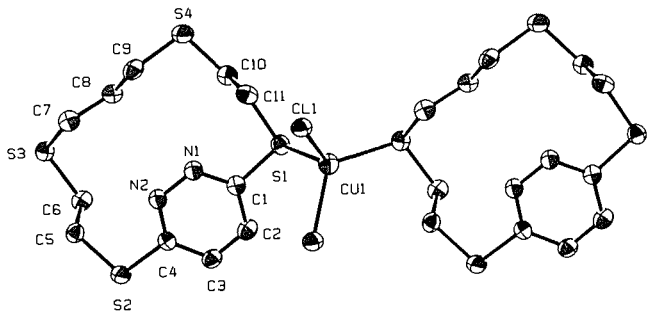

FIG. 3. Molecular structure of a fragment of $[CuL3Cl]_x$ (**III**).

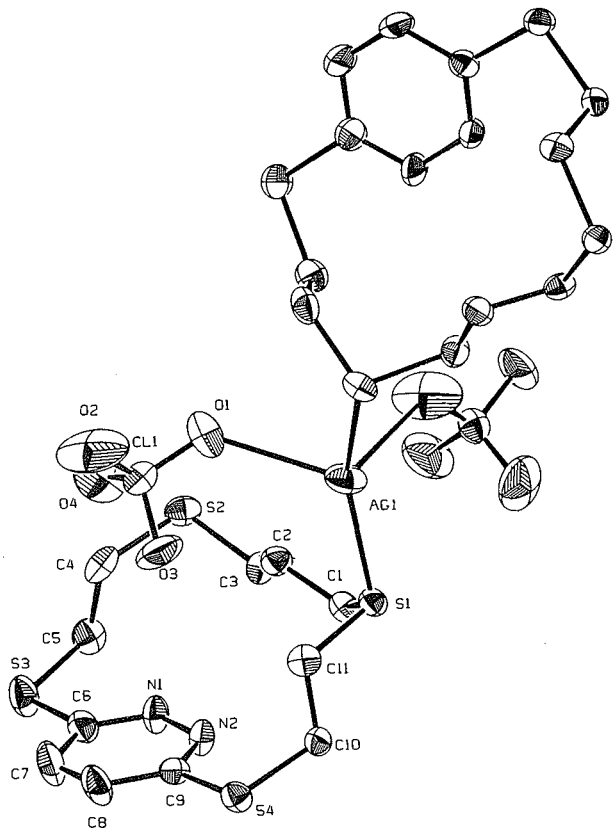

FIG. 4. Molecular structure of a fragment of $[AgL3(ClO_4)]_x$ (**IV**).

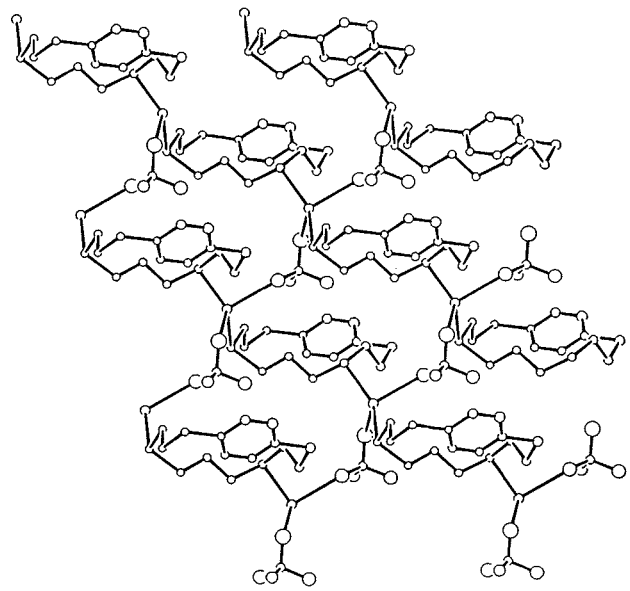

FIG. 5. Molecular structure of $[AgL3(ClO_4)]_x$ (**IV**) illustrating the 2-dimensional polymeric arrangement.

small shift is observed in this band by 7 cm^{-1} or less, in all the complexes (Table 6). The absence of pyridazine coordination in **III** and **IV** and the similarity in the position of this absorption in all the complexes suggests that pyridazine nitrogen atoms are not involved in coordination in the other complexes. Far infrared absorptions for **I** at 355 and 350 (sh) cm^{-1} are assigned to terminal copper–chlorine stretch, while bands at 280 and 260 cm^{-1} are assigned to bridging copper–chlorine bonds. Similar absorptions for **II** at 208 and 252 cm^{-1} are assigned to terminal copper–bromine stretch. In the range 4000–400 cm^{-1} the spectra of **I** and **II** are virtually identical, indicating structurally similar complexes.

The ν_3 perchlorate vibration for **IV** appeared as a strong, broad absorption centred at 1078 cm^{-1}, with little peak resolution. This might not have been anticipated based on the bidentate bridging nature of the perchlorate groups. A similar broad, strong absorption is observed for **V**. Overall the infrared spectra of **IV** and **V** are very similar, suggesting a similar structural arrangement. The presence of two CN stretching bands at 2293 and 2255 cm^{-1} suggests that the CH_3CN occupies a lattice position only and is not coordinated to silver. The nitrate complex **VI** has an overall infrared spectrum similar to the perchlorate complex, and in the nitrate combination band region an expanded spectrum reveals four bands at 1748, 1741, 1738, and 1731 cm^{-1}. The fairly narrow range of this group of bands (17 cm^{-1}) is probably indicative of two slightly different monodentate nitrate groups (53). Structurally **VI** maybe similar to **IV** with a polymeric exobidentate ligand bridging the Ag(I) ions,

which are three coordinate with coordinated, monodentate nitrate.

Compounds **I**, **II** are dark brown in colour and are insoluble in common solvents. Solution can be effected in strong donor solvents like DMF, but decomposition occurs with the release of the ligand. Consequently the electronic spectra of **I** and **II** were only examined in the solid state as mulls. Intense high energy absorptions were observed in both cases (Table 6), which are clearly associated with charge transfer, rather than *d–d* transitions. Infrared data indicate that the ligand does not involve pyridazine–nitrogen coordination and that both complexes contain terminal and bridging halogen ligands. A reasonably structural suggestion for **I** and **II** would be a square-pyramidal dihalogen bridged dimer with L3 behaving as a bidentate S_2 donor in the square-pyramidal basal plane, with an axially bound halogen. The intense visible absorptions at 20 400 cm^{-1} (**I**) and 19 000 cm^{-1} (**II**) are associated with halogen to metal charge transfer because of their difference in energy, while the higher energy bands are likely to be associated with $\sigma S \rightarrow Cu$ charge transfer. A comparable ligand, 2,5,9,12-tetrathia[13]-(2,5)-thiophenophane (L), which involves the same S_4 thioether fragment bound to the 2- and 5-positions of a thiophene ring, formed a dinuclear, dichloro-bridged, square-pyramidal complex $[LCuCl_2]_2$ involving bidentate chelating S_2 ligands (54). Similar, intense visible and ultraviolet bands for this, and related complexes, were assigned to charge transfer transitions associated with the sulfur and chlorine donor atoms.

Magnetic moments for **I** and **II**, measured at room temperature (Table 6), exceed the spin only value for copper and do not give any clear indication of spin coupling and support for the proposed dimeric structures. Variable temperature magnetic measurements were therefore carried out on both **I** and **II** in the temperature range 4.5–300 K. Susceptibility/temperature profiles are both similar (see Fig. 6 for **I**) with a pronounced susceptibility maximum at low temperatures ($T_N \sim 18$ K for **I**; $T_N \sim 8$ K for **II**). Such behaviour is typical of weakly antiferromagnetically coupled copper(II) dimers, thus supporting the dimeric structures for **I** and **II**.

Magnetic interactions between copper(II) centres in isolated dinuclear species are described by the Bleaney–Bowers expression (eq. [1]) (55)

$$[1] \quad \chi_M = \frac{N\beta^2 g^2}{3k(T-\theta)}[1 + (1/3)\exp(-2J/kT)]^{-1} + N\alpha$$

using the isotropic (Heisenberg) exchange Hamiltonian ($H = -2J\mathbf{s}_1 \cdot \mathbf{s}_2$) ($\chi_M$ is expressed per mole of copper atoms and $N\alpha$ is the temperature-independent paramagnetism). Interdimer exchange can be accounted for by the inclusion of a Weiss-type correction (θ) (56). A non-linear regression analysis (57) of the magnetic data for **I** and **II** using eq. [1] indicated the presence of weak intradimer antiferromagnetic coupling ($-2J < 16$ cm^{-1} (**I**); $-2J < 5$ cm^{-1} (**II**)), but also significant interdimer exchange as well ($\theta \sim -5$ K). For weakly coupled copper(II) dimers where the singlet–triplet splitting is comparable with the Zeeman energy, $g\beta H$, the magnetization expression (eqs. [2], [3]) is considered to be more appropriate (58, 59).

Equation [2] can be corrected, in the molecular field approximation, for the presence of magnetic interactions between neighbouring dimers (eq. 4),

$$[2] \quad M = \frac{Ng\beta \sinh(g\beta H/kT}{\exp(-2J/kT) + 2\cosh(g\beta H/kT) + 1}$$

$$[3] \quad \chi_M = M/H + N\alpha$$

where z is the

$$\chi'_{Cu} = \frac{\chi_{Cu}}{1 - (2zJ'\chi_{Cu}/Ng^2\beta^2)}$$

number of nearest neighbor dimers and J' the interdimer exchange parameter. The variable temperature susceptibility data for **I** and **II** were fitted to an equation which combined eqs [2], [3], and [4] and was corrected for the presence of simple Curie law paramagnetic impurity components. The results are given in Table 6. Both compounds show weak intradimer antiferromagnetic coupling ($-2J = 17.77(7)$ cm^{-1} (**I**); $-2J = 8.08(4)$ cm^{-1} (**II**)). Very weak interdimer antiferromagnetic coupling is also apparent ($zJ' = -0.51(1)$ cm^{-1} (**I**); $zJ' = -0.29(1)$ cm^{-1} (**II**)), but because no structural details are available for these compounds little can be said concerning the mechanism of this exchange component, or how many dimers are involved. Comparable values of g and $-2J$ were obtained from both methods of data fit-

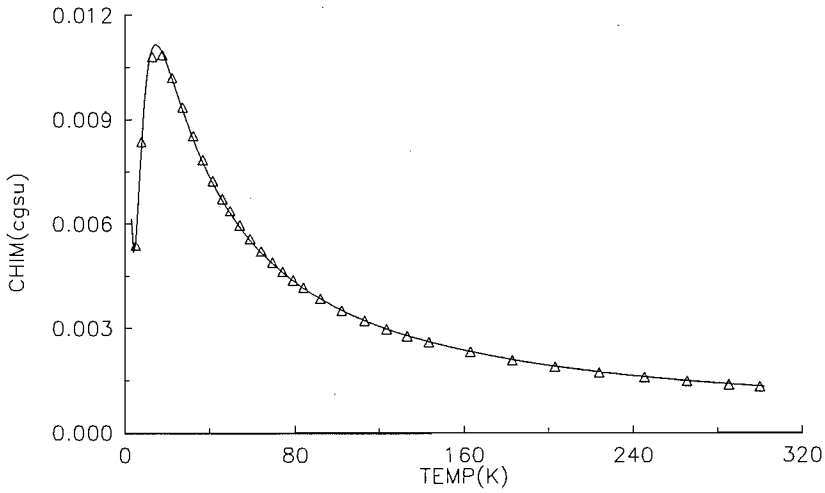

FIG. 6. Variable temperature magnetic data for $[CuL3Cl_2]_2$ (**I**). The solid line was calculated from eqs. [2], [3], [4] with $g = 2.061(3)$, $-2J = 17.77(7)$ cm^{-1}, $zJ' = -0.51(5)$ cm^{-1}, $\rho = 0.045$.

ting, but since lower residual factors were obtained with the magnetization equation, combined with the inherent problems of using the Bleaney–Bowers fit for weakly coupled copper(II) dimers, a more confident assessment of the exchange situation can be realised by the use of eqs. [2], [3], and [4]. Small amounts of Curie law paramagnetic impurities were necessary for reasonable data fits and these show up in the solid state EPR spectra of **I** and **II**. No half-field EPR transitions were observed that sometimes typify weakly coupled dinuclear copper(II) complexes. The experimental data and the theoretical line for **I**, calculated using eqs. [2], [3], and [4] for $g = 2.061(3)$, $-2J = 17.77(7)$ cm^{-1}, $zJ' = -0.51(5)$ cm^{-1}, $\rho = 0.045$ are shown in Fig. 6.

Weak antiferromagnetic coupling is typical for halogen bridged dimeric copper(II) complexes and in the case of dichloro-bridged square-pyramidal, $[LCuCl_2]_2$ (S_2) (54) and octahedral $[L'CuCl_2]_2$ (S_3) (54) complexes of some thiophenophane ligands $-2J$ values of 20.8 and 7.4 cm^{-1} are found for Cu—Cl—Cu bridge angles of 90.94° and 86.87°, respectively (22). The magnetic properties of **I** and **II** are therefore consistent with dimeric halogen bridged structures. The smaller exchange integral for the bromo-complex(II) would not be anticipated if **I** and **II** had similar structures, with comparable bridge angles, because of the demonstrated ability of bridging and terminal halogen ligands to modify exchange based on their electron polarizing effects (60, 61). On this basis a somewhat smaller bridge angle might be anticipated for **II**.

FT-infrared study of the interaction between all-*trans* retinylidene isopropylamine and model proton donors

P. MIGCHELS AND TH. ZEEGERS-HUYSKENS[1]

Department of Chemistry, University of Leuven, Celestijnenlaan 200F, B-3001 Heverlee, Belgium

Received March 10, 1992

P. MIGCHELS and TH. ZEEGERS-HUYSKENS. Can. J. Chem. **70**, 2717 (1992).

The interaction between all-*trans* retinylidene isopropylamine (*t*RiPA) and phenols covering a large pK_a domain is investigated by FT-infrared spectrometry. For phenols having pK_a between 10.2 and 8.18, only normal OH...N hydrogen bonds are formed. The thermodynamic parameters (K, $-\Delta H$, $-\Delta S^0$) determined in carbon tetrachloride solution show that *t*RiPA possesses a good proton acceptor ability. The spectral characteristics (frequency and integrated intensity) of the $\nu_{C=N}$ vibration are also investigated. From a pK_a of 6, proton transfer takes place. The proton transfer constants determined in 1,2-dichloroethane are linearly related to ΔpK_a (pK_a of the protonated base minus pK_a of the phenol). Comparison with previously studied imine systems shows that the proton transfer constant increases with the number of C=C double bonds in the base.

P. MIGCHELS et TH. ZEEGERS-HUYSKENS. Can. J. Chem. **70**, 2717 (1992).

L'interaction entre la toute-*trans* retinylidène isopropylamine (*t*RiPA) et des phénols couvrant un large domaine de pK_a est étudiée par spectrométrie infrarouge à transformée de Fourier Pour les phénols caractérisés par des pK_a variant de 10.20 à 8.18, seuls les complexes à liaison hydrogène normale OH...N sont formés. Les paramètres thermodynamiques (K, $-\Delta H$, $-\Delta S^0$), déterminés dans la tétrachlorure de carbone, montrent que la *t*RiPA possède un bon pouvoir accepteur de proton. Les caractéristiques spectrales de la vibration $\nu_{C=N}$ (fréquence, intensité intégrée) sont aussi étudiées. À partir d'un pK_a de 6, il y a formation de complexes par transfert de proton. Les constantes de transfert déterminées dans le 1,2-dichloroéthane sont linéairement correlées aux ΔpK_a (pK_a de la base protonée moins pK_a du phénol). La comparaison avec des systèmes d'imine étudiés antérieurement montre que la constante de transfert augmente avec le nombre de doubles liaisons présentes dans la base.

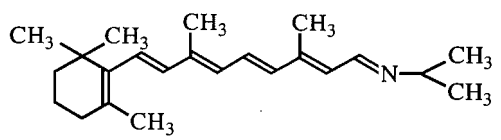
Introduction

In the light transduction mechanisms of both rhodopsin and bacteriorhodopsin, the bond between the retinal Schiff base nitrogen and a proton donor group in the opsin deserves particular attention and it is essential to know if the Schiff base is initially protonated or not (see, for example, ref. 1). Although resonance Raman spectra of rhodopsine indicate that the N atom is protonated (2–6), ^{13}C NMR (7) and differential kinetic IR measurements (8) oppose this view. Both extreme views can be reconciled by admitting a strong hydrogen bond with a double minimum potential function (9–15). This is in agreement with *ab initio* calculations (16, 17) on retinal chromophore modelling systems such as the alkylimine – formic acid system. It is thus essential to know the shape of the potential function governing the proton motion. In this work, the interaction between *trans* retinylidene isopropylamine (*t*RiPA) and phenol derivatives covering a large pK_a range (10.20–0.5) is investigated by FT-infrared spectroscopy.



(*t*RiPA)

The phenols have been chosen as proton donors because they can serve as models for tyrosine (18) and, in this large pK_a domain, the following equilibria can be studied:

$$C{=}N + HO \overset{K_{HB}}{\rightleftharpoons} C{=}N...HO \overset{K_{PT}}{\rightleftharpoons} C{=}N\text{-}H^+...O^-$$

where K_{HB} refers to normal hydrogen bonds and K_{PT} to proton transfer complexes. There are some literature data on the interaction between *trans* retinylidene isobutylamine (*t*RiBu) and phenols. Kristoforov *et al.* have shown that *t*RiBu forms normal hydrogen bonds with *p*-cresol and that proton transfer complexes can be detected in excess of proton donor. The proton transfer equilibria have been studied in carbon tetrachloride for some phenol–*t*RiBu systems by Rastogi and Zundel (20). In methylcyclohexane, the ΔG^0_{PT} values at 295 K vary from +10.5 to 13.5 kJ mol^{-1} (K_{PT} from 0.013 to 0.004) and are not correlated with the pK_a of the proton donors (21). There seems, however, to exist a correlation between the enthalpies and entropies for the proton transfer processes and the proton donor ability of the phenols (20). In a recent work, the thermodynamic constants for hydrogen bonding and proton transfer were extensively discussed for the phenol–*t*RiBu system (22).

This literature overview shows that there is no systematic study on hydrogen bonding between retinal Schiff bases and phenols. Furthermore, the proton transfer constants are not always reliable. The present study was undertaken in order to investigate systematically the influence of the proton donor acidity on the K_{HB} and on the K_{PT} values, to discuss the characteristics of the $\nu_{C=N}$ vibration, and to establish the influence of the number of C=C bonds on the proton transfer constants.

Experimental

The infrared spectra were recorded on the Perkin Elmer 883 and on the Bruker FT-IR 88 spectrophotometers. The formation constants K were determined in carbon tetrachloride from the absorbance of the ν_{OH} stretching vibration at concentrations of proton donors ranging from 5 to 8 × 10^{-3} mol L^{-1}. The base was in excess. The proton transfer constants K_{PT} were determined in 1,2-dichloroethane from the intensity of the $\nu_{C=N}$ band. The intensity of the $\nu_{C=N\text{-}H^+}$ band of *t*RiPA picrate observed at 1651 cm^{-1}, where 100% proton transfer was supposed to occur, was taken as refer-

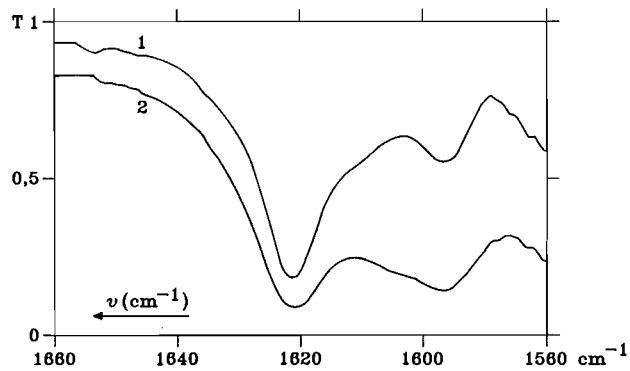

FIG. 1. FT–infrared spectra (1660–1580 cm^{-1}) of 1 *t*RiPA (c = 0.032 mol L^{-1}); 2 *t*RiPA (c = 0.032 mol L^{-1}) and 3,4-dichlorophenol (c = 0.034 mol L^{-1}). Solvent = carbon tetrachloride. Cell thickness = 0.1 cm.

ence. The total concentration of complexes was calculated from the intensity of the ν_{OH} stretching vibration in the same solvents.

*t*RiPA was synthesized by condensation of isopropylamine and all-*trans* retinal (19). The product was held at 5°C, in the dark and under nitrogen atmosphere. The solvents and the phenols were carefully dried and purified by the standard methods.

Results and discussion

1. Normal hydrogen bonds

For phenols having pK_a between 10.20 and 8.18, only one band at 1620–1621 cm^{-1} was observed. This suggests that only normal hydrogen bonds are formed. The thermodynamic parameters (K, $-\Delta H$, $-\Delta S^0$) determined in carbon tetrachloride solution are listed in Table 1.

The logarithms of the formation constants are linearly related to the pK_a of the proton donors:

$$\log K^{298K} = 7.80 - 0.58\ pK_a\ (r = 0.996)$$

$$\log K^{323K} = 6.72 - 0.51\ pK_a\ (r = 0.995)$$

It must be pointed out here that the thermodynamic data for the interaction between the *n*-butylamine retinal Schiff base and phenols having pK_a between 6 and 8 were measured in methylcyclohexane. The ΔG^0 values at 295 K vary from -8.7 to -13 kJ mol^{-1} (K_{HB} from 35 to 200 L mol^{-1}) but are not correlated to the acidity of the proton donors (21). The lowest value is obtained for the 2,4,6-trichlorophenol complex (K = 35 L mol^{-1}, pK_a = 6) and the highest one for the 2,4,5-trichlorophenol complex (K = 200 L mol^{-1}, pK_a = 6.72), the weakest proton donor 2,4-dichlorophenol (pK_a = 6.0) being characterized by a stability constant of 92 L mol^{-1}. These data were obtained in methylcyclohexane.

The thermodynamic data reported in Table 1 show that *t*RiPA possesses a good proton acceptor ability. The equilibrium constants have been recently reported for systems involving the same proton donors and other Schiff bases such as isobutylidene isopropylamine (iBiPA) (23), 2,4-hexadienylidene isopropylamine (HiPA) (24), and *trans*-butenylidene isopropylamine (*t*BiPA) (25). The K values are markedly higher for the *t*RiPA than for the iBiPA complexes where the Schiff base has no C=C double bond. There is, however, no systematic correlation between the thermodynamic data and the number of C=C double bonds.

The $\nu_{OH...N}$ band is broad and characterized by several submaxima. These spectroscopic features have also been

TABLE 2. Wavenumbers, integrated intensity (A), intensification factor (A^c/A^f), and dipole moment derivative ($\partial\mu/\partial Q$) of the $\nu_{C=N}$ vibration of *t*RiPA complexed with phenols. Solvent = carbon tetrachloride

Phenol	$\nu_{C=N}$ (cm^{-1})	A^a (L mol^{-1} cm^{-2})	A^c/A^f	$\pm\partial\mu/\partial Q$ (esu amu$^{-1/2}$)
None	1620	7250	—	101.6

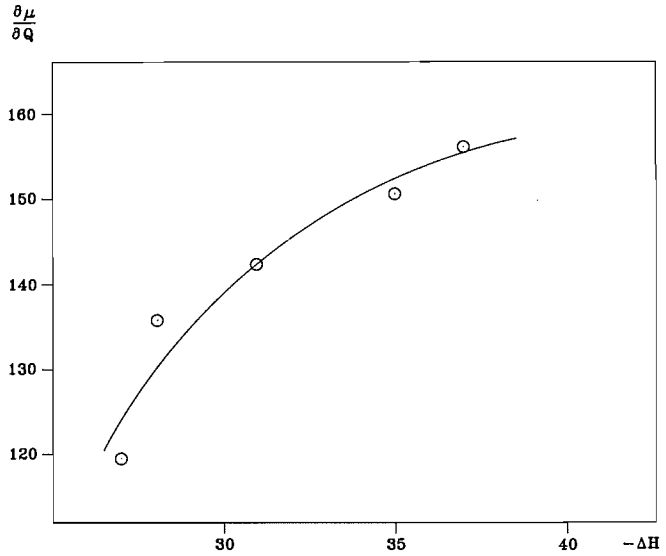

FIG. 2. $\partial\mu/\partial Q$ (esu amu$^{-1/2}$) as a function of $-\Delta H$ (kJ mol^{-1}).

observed for other complexed Schiff bases (22). Owing to the overlapping with the strong ν_{CH_3} and ν_{CH} bands, the maximum could not be estimated with precision. For the *t*RiPa–phenol complex, the maximum was localized at 3050 ± 50 cm^{-1}.

Characteristics of the $\nu_{C=N}$ vibration

The $\nu_{C=N}$ vibration is observed at 1620 cm^{-1} in carbon tetrachloride. As shown in Fig. 1, the frequency of this vibration is very insensitive to hydrogen bond formation. The $\nu_{C=N}$ band is indeed observed at 1621 cm^{-1} in the phenol complex and at 1620 cm^{-1} in the 3,4-dichlorophenol complex. A broadening of the band can be observed. This behaviour is in complete contrast with the $\nu_{C=O}$ vibration, which is shifted to lower frequencies by about 10–25 cm^{-1}. The insensitivity of the $\nu_{C=N}$ vibration to normal hydrogen bond formation has been explained by the fact that the perturbation induced by the formation of the bond is transmitted to the terminal group implanted on the double bond rather than on the double bond itself (23).

The integrated intensity (A) of the $\nu_{C=N}$ band in free *t*RiPA (A^f) and in some complexes (A^c) was obtained by deconvolution of the bands, because of the overlapping with the $\nu_{C=N}$ band of *t*RiPA and with $\nu_{8a,b}$ vibrations of the phenols. The values are indicated in Table 2, along with the intensity enhancement A^c/A^f.

The dipole moment derivatives with respect to the normal coordinate obtained by the relation

$$\frac{\partial\mu}{\partial Q} = \pm\left(\frac{3000\,C^2\,A}{\pi\,N}\right)^{1/2}$$

are also indicated in Table 2. As shown in Fig. 2, this derivative increases with the enthalpy of complex formation.

It is noteworthy that in the complexes involving the same proton donors and saturated Schiff bases, the intensity of the $\nu_{C=N}$ vibration does not increase upon hydrogen bond formation (23). The difference can be ascribed to the electronic delocalization in the retinylidene system, which increases upon complex formation.

3. Proton transfer complexes

From a pK_a value of 6, proton transfer takes place. This can be evidenced by the frequency increase of the $\nu_{C=N}$ vibration, which is observed at 1655 cm^{-1}. As shown in Fig. 3, the intensity of this band increases with the acidity of the proton donor. The proton transfer constant K_{PT}

$$K_{PT} = \frac{[O^-...H^+N]}{[OH...N]}$$

$[O^-...H^+N]$ and [OH...N] being the concentrations of the ionic pair and of the normal hydrogen bonds, is calculated from the intensity of the band at 1655 cm^{-1}. This method seems better than that based on the intensity decrease of the $\nu_{C=N}$ vibration, which strongly overlaps with the $\nu_{C=C}$ vibrations. The observation of both the $\nu_{C=N}$ and $\nu_{C=N\text{-}(H^+)}$ vibrations indicates a double minimum potential for the proton motion.

The proton transfer constants are usually discussed as a function of ΔpK_a, the difference between the pK_a of the acid conjugated to the base and that of the proton donor (24). The pK_a value of *t*RiPA is estimated from the shift of the ν_{OH} band

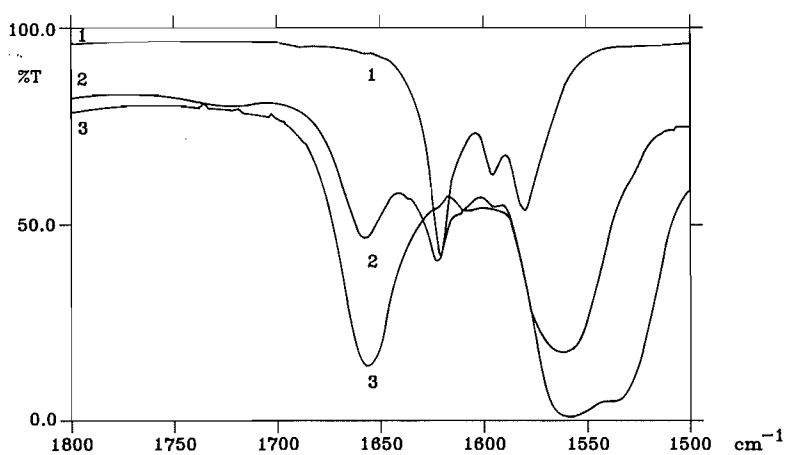

FIG. 3. FT–infrared spectra (1800–1500 cm^{-1}) of 1 *t*RiPA (c = 0.17 mol L^{-1}); 2 *t*RiPA (c = 0.17 mol L^{-1}) and 2,4,6-trichlorophenol (c = 0.19 mol L^{-1}); 3 *t*RiPA (c = 0.17 mol L^{-1}) and 2,4,5,6-tetrachlorophenol (c = 0.24 mol L^{-1}). Solvent = 1,2-dichloroethane. Cell thickness = 0.01 cm.

Phenol	ΔpK_a	K_{PT}	%PT
3-CF_3,4-NO_2 phenol	6.10	0.32	24
2,4,6-Trichlorophenol	5.99	0.39	28
2,3,4,5,6-Tetrachlorophenol	4.90	2.29	69
Pentachlorophenol	4.75	2.52	79
2,6-Dichloro-4-NO_2 phenol	3.55	10.19	91

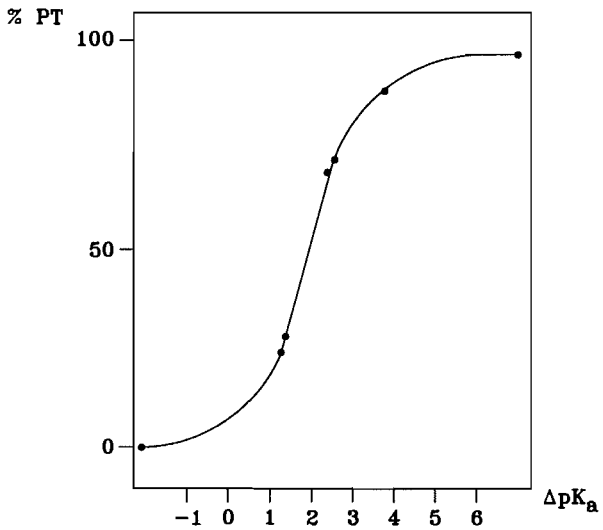

FIG. 4. %PT as a function of ΔpK_a

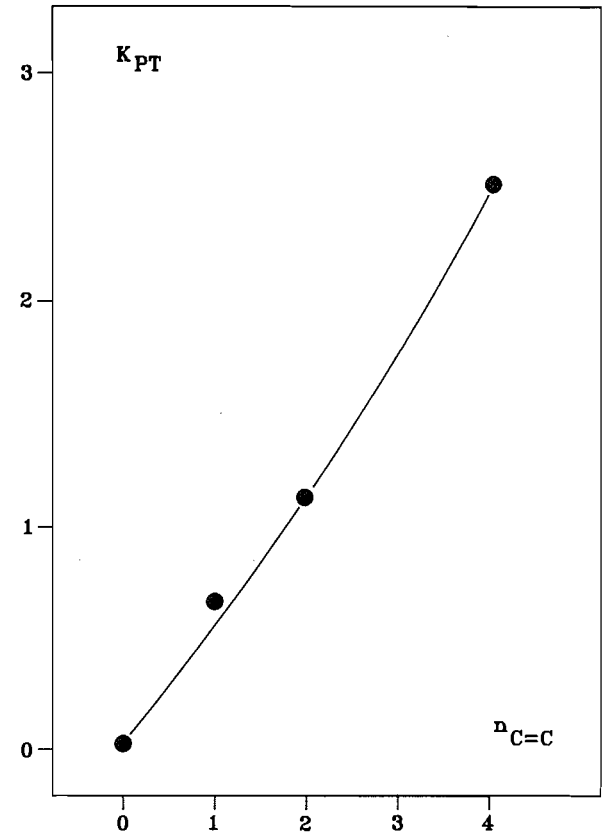

FIG. 5. K_{PT} as a function of the number of C=C bonds in the Schiff bases.

in the methanol complex (350 cm^{-1}) and the correlation between the $\Delta\nu_{OH}$ values and the pK_a for OH...N(sp^2) hydrogen bonds. The pK_a of *t*RiPA computed from this relation is 7.36.

Table 3 lists the ΔpK_a values, the proton transfer constants, and the percentage of proton transfer for the investigated systems. It must be pointed out here that for the interaction between *t*RiBu and phenols having pK_a between 6 and 8, Zundel and co-workers (21) obtained very low proton transfer constants (K_{PT}^{295K} between 0.004 and 0.013) in methylcyclohexane. These values are not correlated to the acidity of the phenol derivative but a linear correlation was obtained between the enthalpies and entropies for the proton transfer process. Although these experimental results are hardly explainable, the K_{PT} values are, as expected, much weaker in methylcyclohexane than in 1,2-dichloroethane (26).

The logarithms of the proton transfer constants are linearly related to ΔpK_a

$$\log K_{PT} = -1.20 + 0.60\ \Delta pK_a\ (r = 0.995)$$

Typical slopes between 0.4 and 1 have been obtained for the OH...N $\rightleftarrows$ O^-...H^+N equilibria. The slopes and intercepts of the above correlation depend on the nature of the interacting molecules, the solvents, and the temperature (26). Figure 4, where the percentage of proton transfer is plotted versus ΔpK_a, shows that 50% proton transfer is achieved for ΔpK_a = 2 or, in other words, when the pK_a of the proton donor is 5.35. For the interaction between the *n*-butylamine retinal Schiff base and carboxylic acids in carbontetrachloride, 50% proton transfer occurs at the same ΔpK_a value of 2 (27). For systems involving all-*trans* retinylidene *tert*-butylamine and substituted acetic acids, 65% proton transfer is achieved when the pK_a of the proton donor is about 4 (28).

In previous works (23–25) the proton transfer constants of various Schiff bases – phenol systems were determined in the same solvent and at the same temperature. It seemed to us interesting to investigate the influence of the number of C=C bonds on the proton transfer constants. The K_{PT} values for the pentachlorophenol and various Schiff bases are as follows:

	iBiPA	*t*BiPA	*t*HiPA	*t*RiPA
K_{PT}	0	0.69	1.13	2.52
$n_{C=C}$	0	1	2	4

Figure 5 shows that the K_{PT} values clearly increase with the number of C=C bonds in the Schiff base or, in other words, with the electronic delocalization in the polyene chain. It must be pointed out here that these results do not agree with those of Bissonnette *et al.* (13). These authors investigated the interaction of various carboxylic acids with *trans* heptadienylidene 2,4-*tert*-butylamine and all-*trans* retinylidene *tert*-butylamine by electronic and ^{1}H NMR spectroscopy. The percentage of protonation was very similar for the two imines. The results of the present work show that the K_{PT} values are higher for the *t*RiPA than for the *t*HiPA systems.

Sedum alkaloids XII. Synthesis of the new piperidine alkaloids homosedinone and dihomosedinone

ALEX DURANT AND CLAUDE HOOTELÉ[1]

Service de chimie organique, Faculté des sciences, Université Libre de Bruxelles, B-1050 Bruxelles, Belgium

Received April 14, 1992

ALEX DURANT and CLAUDE HOOTELÉ. Can. J. Chem. **70**, 2722 (1992).

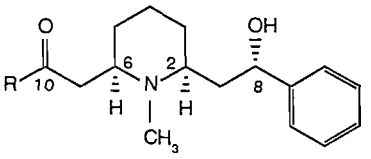
The new piperidine alkaloids homosedinone **2** and dihomosedinone **3**, isolated from *Sedum acre*, have been synthesized from (−)-norsedamine **7** by application of the sequence: anodic methoxylation – elimination – nucleophilic addition.

ALEX DURANT et CLAUDE HOOTELÉ. Can. J. Chem. **70**, 2722 (1992).

La synthèse de deux nouveaux alcaloïdes pipéridiniques, l'homosédinone **2** et la dihomosédinone **3**, isolés de *Sedum acre*, est décrite au départ de la (−)-norsédamine **7** par application de la séquence : méthoxylation anodique – élimination – addition nucléophile.

Introduction

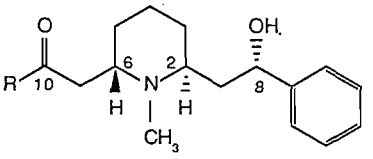
Sedum acre constitutes a rich source of piperidine alkaloids (1). During a search for new bases from this species, we isolated two fractions, after repetitive counter-current and chromatography separations, whose spectral properties indicated two homologs of sedinone **1**. These fractions contained, respectively, homosedinone **2** and dihomosedinone **3** accompanied by their C-6 epimers **4** and **5**. The separation of the diastereoisomers was complicated owing to the facile epimerization (2, 3) of this type of base (β-amino ketones); **2** and **3** were eventually isolated in very minute amounts by TLC.[2] Definite evidence for structures **2** and **3**, which also represent the absolute configuration of the new alkaloids (2*S*,6*R*,8*S*), rests on the synthesis we describe in this paper.



1 R = CH_3

2 R = CH_2-CH_3

3 R = CH_2-CH_2-CH_3



4 R = CH_2-CH_3

5 R = CH_2-CH_2-CH_3

6 4,5-dehydro, R = CH_3

Results and discussion

We have shown recently that the sequence of anodic methoxylation – elimination – nucleophilic addition (4) provides an efficient route for the synthesis of 2,6-disubstituted piperidine alkaloids (3) and we used this procedure for the synthesis of sedinone **1** and sedacrine **6**. The sedinone homologs **2** and **3** have now been obtained by application of the same methodology.

The α-methoxy carbamate **8** was prepared by anodic oxidation of the *N*-carbomethoxy derivative of (−)-norsedamine **7** as reported previously (3). Replacement of the 6-methoxy group in **8** by the desired side chain was carried out by treatment with an excess of 2-trimethylsilyloxybut-1-ene and 2-trimethylsilyloxypent-1-ene, respectively (synthesized according to the procedure of Corey and Gross (5)), at −78°C in dichloromethane in the presence of $TiCl_4$ as a Lewis acid. After chromatography two fractions containing at least 95% (by ^1H NMR) of the *cis*-2,6-disubstituted carbamates **9** and **10** were isolated in 78 and 85% yield, respectively; the principal by-product of these substitutions is the enecarbamate resulting from elimination of methanol from **8** (3).

The high stereoselectivity observed in the reactions of α-methoxy-*N*-acylpiperidines with nucleophiles is now well documented (3, 7, 8): the *cis* stereochemistry results from stereoelectronically preferred axial attack of the nucleophile on the iminium intermediate that contains the phenethyl chain in the axial orientation due to $A^{1,3}$ strain.

Without further purification **9** and **10** were transformed into the corresponding acetals **11** and **12**. Reduction of the acetals **11** and **12** with $LiAlH_4$ in THF gave the *N*-methyl derivatives **13** and **14**; acid hydrolysis of the acetal groups furnished two 85:15 mixtures of *cis*- and *trans*-piperidines **2**:**4** and **3**:**5** in 70% overall yield from the carbamates **9** and **10** respectively. The presence of 15% of the *trans* isomers **4** and **5** results from the epimerization at C-6 during the basic work-up after the deprotection step. Fractional crystallization of the above mixtures from hexane yielded pure homosedinone **2** and dihomosedinone **3**. The spectral properties and optical rotation of the synthetic compounds were identical to those of the alkaloids **2** and **3** from the natural source.

13 R = CH_2-CH_3

14 R = CH_2-CH_2-CH_3

Structure **2** (without stereochemical implications) was recently assigned to a base isolated from *Lobelia davidii*; comparison of the physical and spectral values reported (6) with those of **2** and **4** do not allow its stereochemistry to be established and we have not been able to obtain a specimen of the natural product for direct comparison with the synthetic material.

The facile epimerization of the β-amino ketones sedinone **1** and the homologs **2** and **3** deserves some comments. In methanol at room temperature these bases epimerize at C-6; the equilibrium (*cis*:*trans* ca. 1:1) is reached after a few hours, while the corresponding hydrochlorides (and the *N*-acyl derivatives **9** and **10**) are stereochemically stable under the same comditions. Epimerization is also fast in chloroform/ammonia and chloroform/MacIlvaine buffer pH 6 (precluding the use of these last conditions for the separation of the C-6 epimers by counter-current distribution) but much slower in pure chloroform. It is likely that the epimerization involves a reversible retro-Michael reaction by way of the six-membered ring chelate of an enol tautomer as depicted in Fig. 1 (3, 9).

Given the propensity for β-amino ketones to undergo epimerization in the conditions used during isolation of the bases, it is not established which epimers are present in *Sedum acre*.

Experimental

Melting points were determined on a Kofler microscope and are uncorrected. Mass spectral data were obtained on a Micromass 7070 spectrometer. Nuclear magnetic resonance spectra were recorded in $CDCl_3$ with TMS as internal standard on a Bruker WM 250 spectrometer. Optical rotations were measured on a Perkin Elmer 141 polarimeter.

Preparation of **9**

To a stirred solution of $TiCl_4$ (108 mg) in CH_2Cl_2 (2 mL) at −78°C, under a nitrogen atmosphere, was added dropwise a solution of **8** (172 mg) in the same solvent (2 mL). A solution of 2-trimethylsilyloxybut-1-ene (738 mg) was then added and the resulting reaction mixture was stirred for 1 h at −78°C and then allowed to reach room temperature (1 h). After addition of water and NH_4OH the mixture weas extracted twice with $CHCl_3$. The combined organic layers were evaporated and the residue was purified by chromatography on alumina ($CHCl_3$) to afford **9** (149 mg, 78% yield) and the enecarbamate resulting from elimination of methanol from **8** (26 mg, 17% yield), with spectral data as previously reported (3). **9** (oil): ^{1}H nmr δ: 7.3 (5H, m), 5.77 (1H, dd, J = 4 and 10 Hz, H8), 4.64 (1H, m, H6), 4.28 (1H, m, H2), 3.69 (3H, s), 2.61 (2H, m, H9), 2.45 (2H, m, H11), 2.09 (3H, s), 2.2–1.5 (8H, m), 1.03 (3H, t, J = 7 Hz); ^{13}C nmr δ: 209.3 (C10), 170.4, 156.3 (NCO), 140.7, 128.7, 128.2, 126.6, 73.8 (C8), 52.7 (CH_3), 47.6, 47.2 and 46.7 (C2, C6, C9), 41.4 (C7), 36.2 (C11), 28.1 and 27.4 (C3, C5), 21.3 (CH_3), 14.0 (C4), 7.8 (C12); ms, m/z: 375 (<0.5%), 315, 256, 212, 154, 140 (100).

Preparation of the acetal ***11*** *from* ***9***

A solution of **9** (126 mg), ethylene glycol (105 mg), and $TsOH \cdot H_2O$ (4 mg) in 20 mL of benzene was heated under reflux for 20 h in a Dean–Stark apparatus. After evaporation of the solvent, the residue was dissolved in water, basified with NH_4OH, and extracted with $CHCl_3$. The combined organic layers were evaporated and the residue was filtered through a short column of alumina ($CHCl_3$) to yield the acetal **11** (117 mg, 83%); **11** (oil): ^{1}H nmr δ: 7.3 (5H, m), 5.76 (1H, dd, J = 4 and 10 Hz, H8), 4.3 (2H, m, H2 and H6), 3.9 (4H, m), 3.69 (3H, s), 2.09 (3H, s), 2.2–1.3 (12H, m), 0.91 (3H, t, J = 7 Hz); ^{13}C nmr δ: 170.6, 156.1, 141.0,

$LiAlH_4$ reduction of ***11***

To a solution of the acetal **11** (108 mg) in THF (15 mL) was added $LiAlH_4$ (106 mg). The mixture was heated under reflux for 17 h. The excess of hydride was carefully destroyed by water and the mixture was filtered through Celite and evaporated to dryness. The residue was dissolved in 0.2 N aqueous HCl and washed twice with $CHCl_3$. The aqueous phase was then basified (NH_4OH) and extracted twice with $CHCl_3$. Evaporation of the organic phase afforded the *N*-methyl derivative **13** (75 mg, 88% yield). **13** (oil): ^1H nmr δ: 7.3 (5H, m), 4.94 (1H, dd, J = 3 and 9 Hz, H8), 3.9 (4H, m), 3.2–3 (2H, m, H2 and H6), 2.26 (3H, s), 2–1 (12H, m), 0.92 (3H, t, J = 7 Hz); ^{13}C nmr δ: 145.3, 128.1, 126.9, 125.6, 111.5, 76.1, 64.9, 64.8, 64.6, 58.8, 40.5, 40.4, 30.2, 26.3, 25.3, 24.1, 23.2, 7.5; ms, *m/z*: 333 (4%), 290, 218, 212 (100), 170, 101, 96.

Homosedinone ***2*** *from* ***13***

A solution of the acetal **11** (288 mg) in 0.12 N aqueous HCl (50 mL) was heated under reflux for 30 min. The mixture was then cooled, basified (NH_4OH), and extracted twice with $CHCl_3$. Evaporation of the combined organic layers afforded a 85:15 mixture (248 mg, 96% yield) of homosedinone **2** and 6-epihomosedinone **4**. Crystallization of the mixture from hexane afforded pure homosedinone **2** : mp 62–63°C; $[\alpha]_D^{20}$ −41 ($CHCl_3$, c = 1.5); ^1H nmr δ: 7.3 (5H, m), 4.93 (1H, dd, J = 3 and 11 Hz, H8), 3.6–3.1 (2H, m, H2 and H6), 2.7–2.3 (4H, m, H9 and H11), 2.26 (3H, s), 2–1 (8H, m), 1.06 (3H, t, J = 7 Hz); ^{13}C nmr δ: 209.5, 145.2, 128.3, 127.1, 125.7, 75.9 (C8), 64.6 (C6), 59.0 (C2), 47.7 (C9), 40.5 (C7), 36.3 (C11), 27.1 (NCH_3), 24.8, 23.5, and 23.4 (C3, C4, and C5), 7.9 (CH_3); ms, *m/z*: 289 (10%), 218, 168 (100), 96. These spectral values are virtually identical with those of **2** from *S. acre*: mp 62–63°C (mixture mp without depression), $[\alpha]_D^{20}$ −40 ($CHCl_3$, c = 0.2).

6-Epihomosedinone **4** : ^1H nmr δ: 7.3 (m), 4.89 (dd, J = 3 and 11 Hz), 2.48 (s); ^{13}C nmr δ: 209.3, 145.2, 128.3, 127.1, 125.7, 75.8 (C8), 60.7 (C6), 51.3 (C2), 46.6 (C9), 39.0 (C7), 36.3 (C11), 35.7 (NCH_3), 23.3 and 23.1 (C4 and C5), 20.5 (C4), 7.8 (CH_3); ms, *m/z*: 289; (these values were extracted from the spectra of a 1:1 mixture of **2** and **4**).

Preparation of ***10*** *and* ***8***

By use of a procedure similar to that described for the preparation of **9**, **8** (346 mg) was treated with $TiCl_4$ (241 mg) and 2-trimethylsilyloxypent-1-ene (1537 mg) to afford **10** (342 mg, 85% yield) and the enecarbamate resulting from the elimination of methanol (48 mg, 15% yield); **10** (oil): ^1H nmr δ: 7.3 (5H, m), 5.77 (1H, dd, J = 4 and 10 Hz, H8), 4.66 (1H, m, H6), 4.29 (1H, m, H2), 3.69 (3H, s), 2.62 (2H, m, H9), 2.41 (2H, m, H11), 2.09 (3H, s), 2.2–1.9 (2H, m, H7), 1.7–1.5 (8H, m), 0.90 (3H, t, J = 7 Hz); ^{13}C nmr δ: 209.4, 170.8, 156.7, 141.2, 129.2, 128.7, 127.3, 74.3, 53.2 (CH_3), 48.1 and 47.1 (C2 and C6), 48.0 and 45.4 (C9 and C11), 41.9 (C7), 28.6 and 27.9 (C3 and C5), 21.7 (CH_3), 17.7 (C12), 14.4 (C4), 14.2 (CH_3); ms, *m/z*: 389 (<0.5%), 329, 270, 142, 141; 140 (100), 85, 83.

Preparation of the acetal ***12*** *from* ***10***

The acetal **12** (386 mg, 81% yield) was prepared by a procedure similar to that described for **11** from **10** (428 mg), ethylene glycol (468 mg), and $TsOH \cdot H_2O$ (12 mg); **12** (oil): ^1H nmr δ: 7.3 (5H, m), 5.76 (1H, dd, J = 4 and 10 Hz, H8), 4.3 (2H, m, H2 and H6), 3.9 (4H, m), 3.69 (3H, s), 2.09 (3H, s), 2.2–1.3 (14H, m), 0.91 (3H, t, J = 7 Hz); ^{13}C nmr δ: 170.9, 156.7, 141.4, 129.1, 128.6, 127.1, 111.6, 74.4, 65.4, 65.0, 53.0, 48.2, 47.6, 42.0, 41.6, 39.9, 28.9, 28.1, 21.7, 17.5, 14.9, 14.6; ms, *m/z*: 433 (<0.5%), 390, 373, 304, 270, 244, 140 (100), 115.

$LiAlH_4$ reduction of ***12***

By use of a procedure similar to that described for the preparation of **13**, **12** (358 mg) was treated with $LiAlH_4$ (340 mg) in THF to afford the *N*-methyl derivative **14** (oil, 259 mg, 90% yield): ^1H nmr δ: 7.3 (5H, m), 4.94 (1H, dd, J = 2 and 9 Hz, H8), 3.9 (4H, m), 3.2–2.9 (2H, m, H2 and H6), 2.25 (3H, s), 2–1.1 (14H, m), 0.93 (3H, t, J = 7 Hz); ^{13}C nmr δ: 145.9, 128.8, 127.5, 126.2, 111.8, 76.7, 65.5, 65.4, 65.3, 59.4, 41.7, 41.1, 40.4, 26.9, 25.9, 24.7, 23.8, 17.8, 15.0; ms, *m/z*: 347 (8%), 304, 226, 218, 115, 98 (100), 96.

Dihomosedinone ***3*** *from* ***14***

By use of a procedure similar to that described for the preparation of **2**, a 85:15 mixture (204 mg, 94% yield) of **3** and **5** was obtained after hydrolysis of **14** (256 mg) in 0.12 N aqueous HCl. Crystallization from hexane afforded pure dihomosedinone **3**: mp: 67–68°C, $[\alpha]_D^{20}$ −43 ($CHCl_3$, c = 1.4); ^1H nmr δ: 7.3 (5H, m), 4.93 (1H, dd, J = 3 and 11 Hz, H8), 3.6–3.1 (2H, m, H2 and H6), 2.7–2.3 (4H, m, H9 and H11), 2.26 (3H, s), 2–1.1 (10H, m), 0.91 (3H, t, J = 7 Hz); ^{13}C nmr δ: 209.4, 145.7, 128.8, 127.6, 126.2, 76.4 (C8), 65.1 (C6), 59.3 (C2), 48.7 (C9), 45.8 (C11), 41.1 (C7), 27.8 (NCH_3), 25.4, 24.0, and 23.9 (C3, C4, and C5), 17.9 (C12), 14.3 (CH_3); ms, *m/z*: 303 (17%), 218, 182 (100), 98, 97, 96. These spectral values are virtually identical with those of dihomosedinone **3** from *S. acre* ($[\alpha]_D^{20}$ −42 ($CHCl_3$, c = 0.3)).

A concise synthesis of (+)-muscarine

T. H. CHAN[1] AND C. J. LI
Department of Chemistry, McGill University, Montreal, Que., Canada H3A 2K6

Received March 31, 1992

T. H. CHAN and C. J. LI. Can. J. Chem. **70**, 2726 (1992).

(+)-Muscarine was synthesized from *S*-(−)-ethyl lactate in five steps with the application of a zinc-mediated allylation reaction in aqueous media. Reversal of chelation-control stereoselectivity was observed in the allylations of chiral α-alkoxy aldehydes in aqueous media.

T. H. CHAN et C. J. LI. Can. J. Chem. **70**, 2726 (1992).

Appliquant une réaction d'allylation réalisée en milieu aqueux et faisant intervenir du zinc, on a effectué la synthèse de la (+)-muscarine en cinq étapes à partir du *S*-(−)-lactate d'éthyle. Lors des allylations en milieu aqueux des α-alkoxy aldéhydes chiraux, on a observé un renversement du contrôle de stéréosélectivité de la chélation.

Introduction

Muscarine (**1**, OH^- instead of I^-) is an alkaloid first isolated from the poisonous mushroom, *Amanita muscaria* (fly agaric) in 1954 (1). Its structure, chemistry and physiological activities have been extensively investigated (2). Muscarine acts as a selective agonist of the neurotransmitter acetylcholine on smooth muscles of the gastrointestinal tract, eye exocrine glands, and heart. As a consequence, the receptor responses in those tissues are termed muscarinic receptors. More recently, with the use of selective antagonists, distinct subtypes of muscarinic receptors were distinguished (3).

Synthesis of muscarine has been accomplished a number of times from different precursors (2–6). Recently, a chemoenzymatic synthesis of muscarine and its stereoisomers has been reported (7). The renewed interest in this molecule is due in part to the recent suggestion that various subtypes of muscarinic receptors may be implicated in Alzheimer disease (8). Because of our interest in this area, we report here an efficient synthesis of (+)-muscarine from the readily available *S*-(−)-ethyl lactate by taking advantage of a zinc-mediated allylation reaction in aqueous media (9, 10).

Results and discussion

S-(−)-Ethyl lactate (**2**) was converted into the 2,6-dichlorobenzyl ether **3** in 90% yield (Scheme 1). DIBAL reduction of **3** gave the aldehyde **4**. Treatment of the crude aldehyde **4** with allyl bromide and zinc powder in water with NH_4Cl as catalyst resulted in a *anti*:*syn* (71:29) mixture of diastereomers **5***a* and **5***b* in 85% combined yield. The two diastereomers were easily separated by flash chromatography (eluent: hexane:ethyl acetate, 20:1). Treatment of **5***a* with iodine in CH_3CN at 0°C gave the cyclized product **6***a* stereospecifically in 85% yield (for previous study of the iodocyclization reaction, see ref. 11). Finally, treatment of **6***a* with excess trimethylamine in ethanol gave (+)-muscarine (2*S*,4*R*,5*S*). A similar reaction sequence with **5***b* gave (+)-epimuscarine **7**. Compared to the previously reported syntheses in the literature, the present synthesis of muscarine offers the advantages of simplicity, good overall yield, and high optical purity of the product from a readily available chiral precursor.[2]

The stereoselectivity in the conversion of **4** and **5** deserves some comments. Normally, the stereoselectivity observed in the addition of *C*-nucleophiles such as organometallic reagents to chiral α-alkoxy aldehydes (and ketones) has been rationalized on the basis of chelation control (12, 13). The carbonyl compound **8** forms the chelate **9** as shown in Scheme 2. The *C*-nucleophile (R^-) attacks from the less-hindered side as indicated by the arrow, giving the chelation-controlled product **10** in preference to the non-chelation product **11** (Scheme 2). The chelation-control approach provides a useful and convenient synthesis of **10**. When this presumed chelation is diminished by the use of a bulky protecting R^2 or by the use of a non-chelating reagent, the non-chelation product **11** can predominate.[3]

Indeed, the reaction of **4** with allylmagnesium bromide in ether afforded the two diastereomers **5***a* and **5***b* in a ratio of 40:60 (*anti*:*syn*) as predicted by the chelation-control model. A similar reaction with diallylzinc in ether (15) resulted in a complicated mixture. The reversal in diastereoselectivity between organic and aqueous media appears to be a general result for several α-alkoxy aldehydes **8***a*, *b*, and *c*. The effects of solvent on diastereoselectivity are summarized in Table 1. We attribute this change to the disruption of chelation in the aqueous media. In support of this, it should be noted that in the case of α-methylphenylacetaldehyde (**12**), where there is no possibility of chelation, there was no significant difference in the diastereoselectivity between allylations in organic or aqueous media (16). However, it is possible that the observed stereoselectivity in the aqueous organometallic-type reactions may be due to factors associated with the metal surface in such heterogenous reactions (10).

The present synthesis of muscarine demonstrates that organometallic-type reactions in aqueous media can make a meaningful contribution to organic synthesis. Further applications of such reactions can be anticipated.

[1]Author to whom correspondence may be addressed.

[2]Synthesis of muscarine from lactate ester was not reported previously, presumably because of the difficulty in obtaining the intermediate **5***a* in the conventional organometallic allylation due to chelation control.

[3]Non-chelation-controlled additions can be achieved with alkyltitanium reagents of low Lewis acidity (see ref. 14*a*). For effects of protecting group on chelation control, see ref. 14*b*.

Experimental section

Melting points are uncorrected. Infrared spectra were obtained from films on NaCl plates for liquids and as a KBr pellet for solids on an Analect FTIR AQS-18 spectrophotometer. The ^1H NMR and ^{13}C NMR spectra were recorded on Varian XL-200, XL-300, and Gemini-200 instruments. Mass spectra were determined on a DuPont 21-492B spectrometer. High-resolution mass spectra were obtained on a VG ZAB-HS instrument. Optical rotations were measured on a JASCO DID-140 polarimeter. Column chromatography was performed on silica gel 60 (Merck and EM Science). Acetonitrile was dried by refluxing over CaH_2.

Ethyl (S)-2-(2',6'-dichlorobenzyloxy)-propionate (3)

Dry powdered silver oxide (1.3 g, 5.25 mmol) was added to a solution of ethyl *S*-(−)-lactate (559 mg, 5 mmol) and 2,6-dichlorobenzyl bromide (1.2 g, 5 mmol) in dry ether (50 mL) over a period of 40 min while stirring. The reaction was kept refluxing for 6 h until TLC showed complete disappearance of the starting lactate. Then the reaction mixture was filtered through Celite. Evaporation of the solvent resulted in a crude material, which was purified by flash chromatography (hexane:ethyl acetate, 20:1) to give 1.25 g (90%) of **3** as a colorless oil. IR(neat) *v*: 2986, 2901, 2886, 1746, 1581, 1564, 1436, 1373, 1268, 1197, 1139, 1116, 766 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.30(t, *J* = 7.1, 3H), 1.41(d, *J* = 6.9, 3H), 4.1(q, *J* = 7.1, 1H), 4.2(q, *J* = 7.1, 2H), 4.7(d, *J* = 10.6, 1H), 5.02(d, *J* = 10.61, 1H), 7.25(m, 3H)ppm; HRMS, Exact Mass for $C_{12}H_{14}O_3Cl_2$ + H^+, calcd.: 277.0399; found: 277.0398.

[a]For Method, see experimental section.
[b]The ratio of *syn*:*anti* isomers was determined by ^{1}H nmr. See refs. 17 and 21.

1.0 M in hexane) was added dropwise by syringe over 40 min at −78°C. After stirring for 2 h, saturated aqueous ammonium chloride (10 mL) was added to quench the reaction, followed by the addition of 10% HCl (2 mL). The organic layer was separated and dried ($MgSO_4$). Evaporation of the solvent afforded the crude aldehyde **4**, which was used directly without purification. The crude aldehyde was transferred into a 100-mL flask and mixed with H_2O (50 mL). To the suspension was added allyl bromide (360 mg, 3 mmol) and zinc powder (192 mg, 3 mmol), followed by 1 mL of saturated aqueous ammonium chloride solution to catalyze the reaction. The reaction was continued until no aldehyde could be detected by TLC. The reaction mixture was extracted with ether. The ether extract was dried ($MgSO_4$). Evaporation of the solvent gave a mixture of diastereomers (2–3:1). Separation of the diastereomers was achieved by flash chromatography (hexane:ethyl acetate, 20:1). The major isomer proved to be **5***a*. ^{1}H NMR ($CDCl_3$) δ: 1.21(d, J = 6.3, 3H), 2.21(br, 3H), 3.50(m, 1H), 3.71(m, 1H), 4.75(AB, J = 10.2, 2H), 5.1(m, 2H), 5.8(m, 1H), 7.25(m, 3H) ppm; ^{13}C NMR ($CDCl_3$) δ: 13.9, 36.8, 65.3, 72.2, 77.7, 117.3, 128.3, 129.8, 133.3, 134.9, 136.6 ppm.

*(2S,3S)-2-(2′,6′-Dichlorobenzyloxy)-5-hexen-3-ol (**5**b)*

The minor product from the above reaction proved to be **5***b*. ^{1}H NMR ($CDCl_3$) δ: 1.23(d, J = 6.0, 3H), 2.21(br, 2H), 2.77(d, OH, J = 2.6, 1H), 3.41(m, 2H), 4.80(AB, J = 10.2, 2H), 5.1(m, 2H), 5.8(m, 1H), 7.25(m, 3H) ppm; ^{13}C NMR ($CDCl_3$) δ: 15.2, 37.1, 65.2, 74.2, 77.9, 116.9, 128.3, 129.9, 133.1, 134.6, 136.6 ppm.

*(2S,4R,5S)-2-Iodomethyl-5-methyl-tetrahydrofuran-4-ol (**6**a)*

A solution of **5***a* (266 mg, 0.97 mmol) in acetonitrile (15 mL) was treated with iodine (254 mg, 1.0 mmol) in small portions under an atmosphere of nitrogen at −5°C. After stirring for 3 h at 0°C, the mixture was diluted with ether, and washed with water and 10% sodium thiosulfate aqueous solution. After drying ($MgSO_4$), **6***a* was isolated by flash chromatography (hexane: EtOAc, 2:1) as a colorless oil (234 mg, 85%). IR(neat) ν: 3399(br, OH), 2970, 2930, 1733, 1445, 1358, 1249, 1096, 1063, 984, 992, 905 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.21(d, J = 6.4, 3H), 1.88(m, 1H), 2.0(m, 1H), 2.6(s, br, 1H), 3.25(m, 2H), 3.9–4.2(m, 3H) ppm; ^{13}C NMR ($CDCl_3$) δ: 10.4, 19.7, 40.8, 77.0, 77.2, 83.2 ppm.

*(2S,4S,5S)-2-Iodomethyl-5-methyl-tetrahydrofuran-4-ol (**6**b)*

The compound was obtained from **5***b* by the same procedure as described above as a colorless needle crystal, mp 60–62°C (lit. (11) mp 62°C); IR(KBr) ν: 3435(br, OH), 2885, 1716, 1539, 1179, 1164, 1065, 1039, 1013 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.28(d, J = 6.4, 3H), 1.75(br, 2H), 2.4(m, 1H), 3.35(m, 2H), 3.8–4.0(m, 2H), 4.16(m, 1H) ppm; ^{13}C NMR ($CDCl_3$) δ: 79.9, 76.7, 73.4, 41.4, 14.1, 11.8 ppm.

*(+)-Muscarine iodide (**1**)*

The iodoalcohol **6***a* (170 mg, 0.7 mmol) and excess of trimethylamine (~500 mg) were dissolved in 2 mL of ethanol, and heated to 80°C in an ampule for 4 h. On cooling, (+)-muscarine iodide (**1**) crystallized from solution as colorless needles. Recrystallization of the crude material twice from 2-propanol furnished colorless crystals (124 mg, 60%), mp 141–143°C; (lit. (7) mp 138–142°C); $[\alpha]_D^{20}$ +6.3 (*c* 1.0, EtOH) (lit. (7) $[\alpha]_D^{20}$ +6.36 (*c* 0.346, EtOH); IR(KBr) ν: 3374(br, OH), 3016, 2969, 2923, 2906, 2741, 1651, 1486, 1465, 1183, 1100, 1008, 970, 929 cm^{-1}; ^{1}H NMR (D_2O) δ: 1.23(d, J = 6.5, 3H), 2.1(m, 2H), 2.9(br, 1H), 3.25(s, 9H), 3.55(m, 2H), 4.15(m, 2H), 4.65(m, 1H) ppm; ^{13}C NMR (D_2O) δ: 86.9, 78.0, 74.8, 73.4, 56.9, 40.3, 22.0 ppm.

*(+)-Epimuscarine iodide (**7**)*

By the same procedure as described above, (+)-epimuscarine iodide (**7**) was obtained from **6***b* as colorless crystals, mp 169–170°C (lit. (11) mp 175°C); $[\alpha]_D^{20}$ +41.9 (*c* 0.34, EtOH) (lit. (11) $[\alpha]_D^{20}$ +43.23 (*c* 0.636, EtOH); IR(KBr) ν: 3428(br, OH), 2969, 2885, 1653, 1558, 1458, 1065, 1013 cm^{-1}; ^{1}H NMR (D_2O) δ: 1.25(d, J = 6.4, 3H), 1.65(m, 1H), 2.65(m, 1H), 3.20(s, 9H), 3.55(m, 2H), 3.96(m, 1H), 4.25(m, 1H), 4.45(m, 1H) ppm; ^{13}C NMR (D_2O) δ: 83.54, 74.23, 74.04, 73.03, 56.70, 47.55, 16.14 ppm.

Allylation studies

Method O(Mg): To a solution of the aldehyde (1 mmol) in ether (20 mL) at −78°C, allylmagnesium bromide (1 M, 3 mmol) was added dropwise. The mixture was worked up in the usual manner to give the product.

Method A(Zn): A mixture of the aldehyde (1 mmol), allyl bromide (1.5 mmol), and zinc powder (1.5 mmol) in water (20 mL) was stirred at room temperature for 3 h. A few drops of aqueous NH_4Cl was added at the beginning to initiate the reaction. The product was extracted with ether and purified in the usual manner.

*1-Benzyloxy-1-phenyl-5-penten-2-ol (**10**a, **11**a)*

The compound was obtained by Method A(Zn) or Method O(Mg). ^{1}H NMR ($CDCl_3$) δ: (*syn*) 2.05(m, 2H), 2.95(br, 1H), 3.8(m, 1H), 4.2(d, J = 7.7, 1H), 4.35(dd, J = 11.4, 39.3, 2H), 5.0(m, 2H), 5.8(m, 1H), 7.35(m, 10H) ppm; (*anti*) 2.5(m, 2H), 3.9(m, 1H), 4.3(d, J = 1.2, 1H) ppm. The stereochemistry was deduced from ^{1}H NMR spectra of the diols based on the empirical rule of J(CH-OH, *syn*) > J(CH-OH, *anti*) (17) on comparison with similar compounds (18).

*5-Benzyloxy-1-nonanen-4-ol (**10**b, **11**b)*

The compound was obtained by Method A(Zn) or Method O(Mg). ^{1}H NMR ($CDCl_3$) δ: (*syn*) 0.9(t, 3H), 1.35(br, 4H), 1.6(m, 2H), 2.1(br, 1H), 2.3(m, 2H), 3.3(q, J = 5.4, 1H), 3.65(m, 1H), 4.56(dd, J = 11.3, 21.2, 2H), 5.1(m, 2H), 5.85(m, 1H), 7.35(m, 5H) ppm; (*anti*) 3.4(m, 1H), 3.85(m, 1H), 4.6(br, 2H) ppm (19).

*2-Benzyloxy-5-hexen-3-ol (**10**c, **11**c)*

The compound was obtained by Method A(Zn) or Method O(Mg). ^{1}H NMR ($CDCl_3$) δ: (*syn*) 1.20(d, J = 6.0, 3H), 2.2–2.5(m, 2H), 3.5(m, 2H), 4.6(dd, 2H), 5.15(m, 2H), 5.85(m, 1H), 7.35(m, 5H) ppm; (*anti*) 1.19(d, J = 6.3, 3H), 2.25(m, 2H), 3.5(m, 1H), 3.8(m, 1H) ppm (20).

Competitive Diels–Alder and ene addition of *N*-arylmaleimides to 7-dehydrocholesteryl acetate

WILLIAM J. LEIGH,[1] DONALD W. HUGHES, AND D. SCOTT MITCHELL[2]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received April 21, 1992

WILLIAM J. LEIGH, DONALD W. HUGHES, and D. SCOTT MITCHELL. Can. J. Chem. **70**, 2730 (1992).

Thermolysis of *N*-phenyl, *N-para*-biphenyl, and *N-para,para'*-terphenylmaleimide with 7-dehydrocholesteryl acetate in benzene solution at 200°C yields mixtures of four cycloadducts in relative yields that are essentially independent of the maleimide substituent. The three major products are those of ene addition to C_7 of the steroid with abstraction of the proton at C_9 or C_{14}. The α-*endo*-Diels–Alder adduct is formed as a minor product. The structures of the adducts have been elucidated on the basis of one- and two-dimensional ^1H and ^{13}C NMR spectroscopic techniques, including homonuclear ^1H decoupling, NOE, ^1H–^1H COSY, heteronuclear ^1H–^{13}C shift correlation, and TOCSY 2-D experiments, and the results of molecular mechanics (MMX) calculations. The combination of these techniques has made it possible to almost completely assign the ^1H and ^{13}C NMR spectra for two of the ene adducts and the Diels–Alder adduct from reaction of 7-dehydrocholesteryl acetate with *N*-phenyl maleimide.

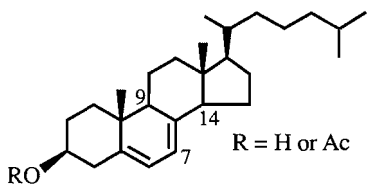
WILLIAM J. LEIGH, DONALD W. HUGHES et D. SCOTT MITCHELL. Can. J. Chem. **70**, 2730 (1992).

La thermolyse des *N*-phényl, *N-para*-biphényl et *N-para,para'*-terphénylmaléimides en présence d'acétate du 7-déhydrocholestéryle, en solution dans le benzène, à 200°C, fournit des mélanges de quatre cycloadduits dont les rendements relatifs sont essentiellement indépendants du substituant de la maléimide. Les trois produits principaux correspondent à une addition ène sur la position C_7 du stéroïde, accompagnée d'un enlèvement de proton en C_9 ou en C_{14}. L'adduit de Diels–Alder α-*endo* se forme comme produit mineur. On a déterminé les structures à l'aide de techniques de RMN du ^1H et du ^{13}C, uni- et bidimensionnelles, comprenant des expériences de découplage homonucléaire du ^1H, d'eOn, de COSY ^1H–^1H, de corrélation hétéronucléaire de déplacements ^1H–^{13}C et des expériences TOCSY en 2-D, et de résultats de calculs de mécanique moléculaire (MMX). Grâce à l'ensemble de ces techniques, il a été possible d'attribuer pratiquement tous les spectres RMN du ^1H et du ^{13}C de deux des adduits ène et de l'adduit de Diels–Alder obtenus par la réaction de l'acétate du 7-déhydrocholestéryle avec la *N*-phénylmaléimide.

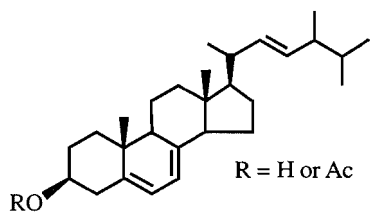
[Traduit par la rédaction]

Introduction

The reactions of steroidal dienes such as 7-dehydrocholesterol (**1**) and ergosterol (**2**) with common dienophiles have been studied in some detail (1–13). Acyclic dienophiles such as dialkyl azocarboxylates (1–3), dimethyl acetylenedicarboxylate (4), acrylonitrile (5), and carbonyl dicyanide (6) have been reported to undergo ene addition with **1** (1–5), **2** (6), and the corresponding acetate esters to the complete exclusion of Diels–Alder cycloaddition. Evidently, Diels–Alder addition is preferred only with particularly powerful dienophiles such as *N*-phenyltriazolinedione (7, 8), 1,4-phthalazinedione (9), or singlet oxygen (10), or with acyclic alkenes when the steroidal diene moiety is part of a higher conjugated system (11).



1



2

The reaction of maleic anhydride with ergosteryl acetate, which was first investigated almost 60 years ago (12), has been the subject of some confusion over the years (12–14). The reaction is now known to yield a mixture of the ene and Diels–Alder adducts shown in eq. [1] (14). The structures of the four products (**3–5**) have been assigned on the basis of derivativization studies and ^1H NMR spectroscopy (14), following the pioneering studies of Huisman and co-workers on the reactions of dienophiles with 7-dehydrocholesteryl acetate (**1**) (1, 3).

As part of our continuing studies of the effects of thermotropic liquid crystals on the reactivity of guest molecules (15), we have investigated the reaction of **1** with a series of *N*-aryl maleimides (**6–8**). A preliminary account of the reaction of **7** with **1** in isotropic and steroidal liquid crystalline solvents has been published (16). As is the case with maleic anhydride and **2**, a mixture of Diels–Alder and ene adducts are obtained as the major products from this reaction (eq. [2]). The three ene adducts were originally identified on the basis of diagnostic similarities between their ^1H NMR spectra and those of the ene adducts of **1** with acyclic dienophiles (1, 3).

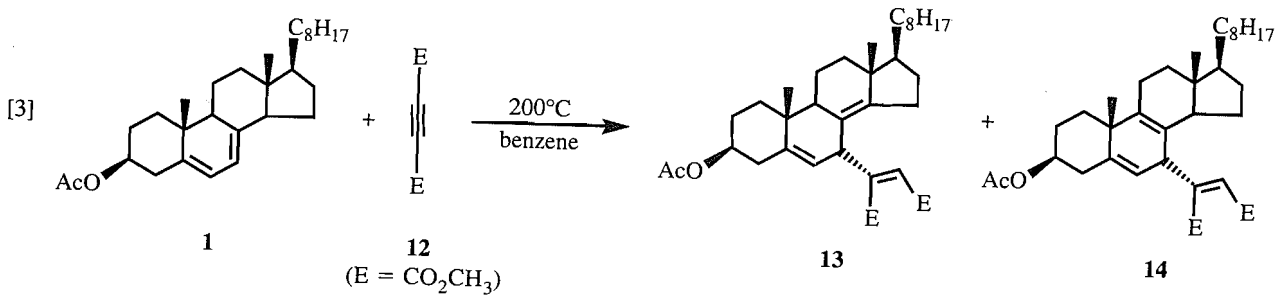
In this paper, we report the results of a study of the reaction of **6–8** with **1** in benzene solution. We were particularly interested in rigorously verifying our structural assignments for **9** and **10**, which were made on the basis of ^{1}H chemical shift arguments following the rationale developed by Huisman and co-workers in identifying the ene adducts of **1** with dimethyl acetylenedicarboxylate (**12**) (eq. [3]) (4). The chemical shifts of the 18- and 19-methyl protons are very different in the ^{1}H NMR spectra of **13** and **14**. From examination of molecular models, Huisman and co-workers reasoned that the geometry of 18-CH_3 in relation to the C_8—C_9 double bond in **14** should result in its protons experiencing greater shielding than the corresponding ones in **13**. The methyl-proton regions of the ^{1}H NMR spectra of **9***a*,*b* and **10** (Ar = *para*-biphenyl) bear marked similarities to those of **13** and **14**, and our initial structural assignments were made on this basis. This same rationale has been used by numerous other workers in assigning the

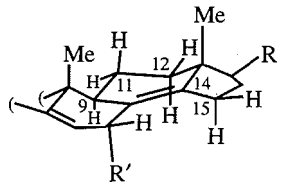


1 12 ($E = CO_2CH_3$) 13 14

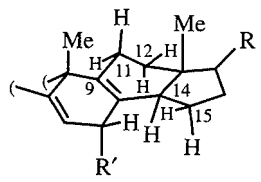
structures of the products of ene additions to steroidal dienes (1–3, 5, 6, 14), but has evidently never been verified using modern NMR techniques.

In the present work, we attempted to verify our initial assignments using a more rigorous spectroscopic approach. We carried out various two-dimensional chemical shift correlation experiments, in order to assign the individual resonances in the rather complex ^1H and ^{13}C NMR spectra of these molecules. For three of the adducts, we also carried out homonuclear proton decoupling, NOE, and TOCSY 2-D experiments to help identify individual protons whose assignments on the basis of the other 2-D experiments are inconclusive. Molecular mechanics (MMX) calculations were also carried out in order to assist in our assignments in some cases. In particular, we wondered if it might be possible to conclusively identify the differences in the structures of the B and C rings in the two adduct types, through complete assignment of the B-, C-, and D-ring carbon and proton resonances. As shown in the partial structures below, differentiation of the two adduct structures is possible if the protons at C-11, C-12, C-15, and C-9/14 can be rigorously identified. We also employed these methods to establish the stereochemistry in the Diels–Alder adduct **11**, in order to verify the assignment made by Jones *et al.* for the Diels–Alder adduct (**3**) obtained from the reaction of ergosteryl acetate (**2**) with maleic anhydride (14).

The reaction of **1** and **6–8** in liquid crystalline solvents, which was the reason for our initial interest in this system, is described in a separate publication (17).



9



10

Results and discussion

N-Biphenyl- and *N*-terphenylmaleimide (**7** and **8**, respectively) were synthesized by condensation of the appropriate aromatic amine with maleic anhydride, following the method of Crivello (18).

Reaction of **6–8** with equimolar **1** was carried out at 200°C in benzene solution in sealed tubes. Monitoring the progress of small-scale runs in deuteriobenzene by ^1H NMR and high-performance liquid chromatography (HPLC) showed that the reaction proceeds to ca. 70% completion after 4 h under these conditions in each case. The products were isolated and purified by semi-preparative medium-pressure chromatography, using a combination of normal- and reverse-phase conditions. The reaction produced four main products in each case (eq. [2]), and one minor product in yields that were too low (6–7%) to enable isolation. The distribution of adducts is independent of the aryl substituent in **6–8**, within experimental error. Ene adducts **9***a* and **9***b* are formed in ca. 34 and 25% yield, respectively, ene adduct **10** is formed in ca. 13% yield, and the Diels–Alder adduct **11** is formed in ca. 20% yield. Product yields were determined by quantitative HPLC analyses. It is interesting to note that the distributions of adducts obtained from reaction of **1** with the series of *N*-aryl maleimides are very similar to that reported for the reaction of **2** with maleic anhydride (14).

Preliminary structure assignments for **9–11** (Ar = *para*-biphenyl) were made on the basis of their high-field ^1H and ^{13}C NMR spectra in deuteriochloroform solution, as well as their infrared and chemical ionization mass spectra. For each adduct, DEPT ^{13}C NMR spectra were recorded to distinguish between C/CH_2 and CH/CH_3 resonances. Heteronuclear ^1H-^{13}C shift correlated spectra, ^1H–^1H COSY, and TOCSY experiments were then recorded to establish ^1H–^{13}C and ^1H–^1H connectivities (19). The high-field ^1H and ^{13}C NMR spectra of the adducts were essentially independent of the *N*-aryl substituent, except of course in the aromatic regions.

The ^1H NMR spectra of ene adducts **9***a* and **10** and the Diels–Alder adduct **11** (Ar = phenyl) were investigated in greater detail, in an attempt to establish the differences in the structures of the B and C rings for the first two molecules, and to rigorously establish the stereochemistry of addition in the case of the third. Figure 1 shows the 500 MHz ^1H NMR spectra of **9***a* and **10**, illustrating the pronounced differences in the methyl proton resonances in the 0.8–1.3 ppm region for the two adduct types, and the slightly more subtle differences that occur elsewhere in the spectra. Figures 2 and 3 show contour plots obtained from the ^1H–^1H COSY and the ^1H–^{13}C shift-correlated spectra of adduct **9***a*, respectively. The pertinent details of our spectral assignments for compound **9***a* are presented below, along with a brief description of the assignments for **9***b*, **10**, and **11** where they differ from those of **9***a*. The ^1H and ^{13}C NMR spectra of **1** (which have been completely assigned (20)) and those of other, similar cholestane steroids (21–23) were especially helpful in deriving the spectral assignments for these compounds. It should be noted that while eq. [2] specifically identifies **9***a* as having *R* stereochemistry at C-1′ of the maleimide ring, we are actually not able to distinguish between the two diastereomers on the basis of our NMR data.

The TOCSY 2-D experiment provides a means of reveal-

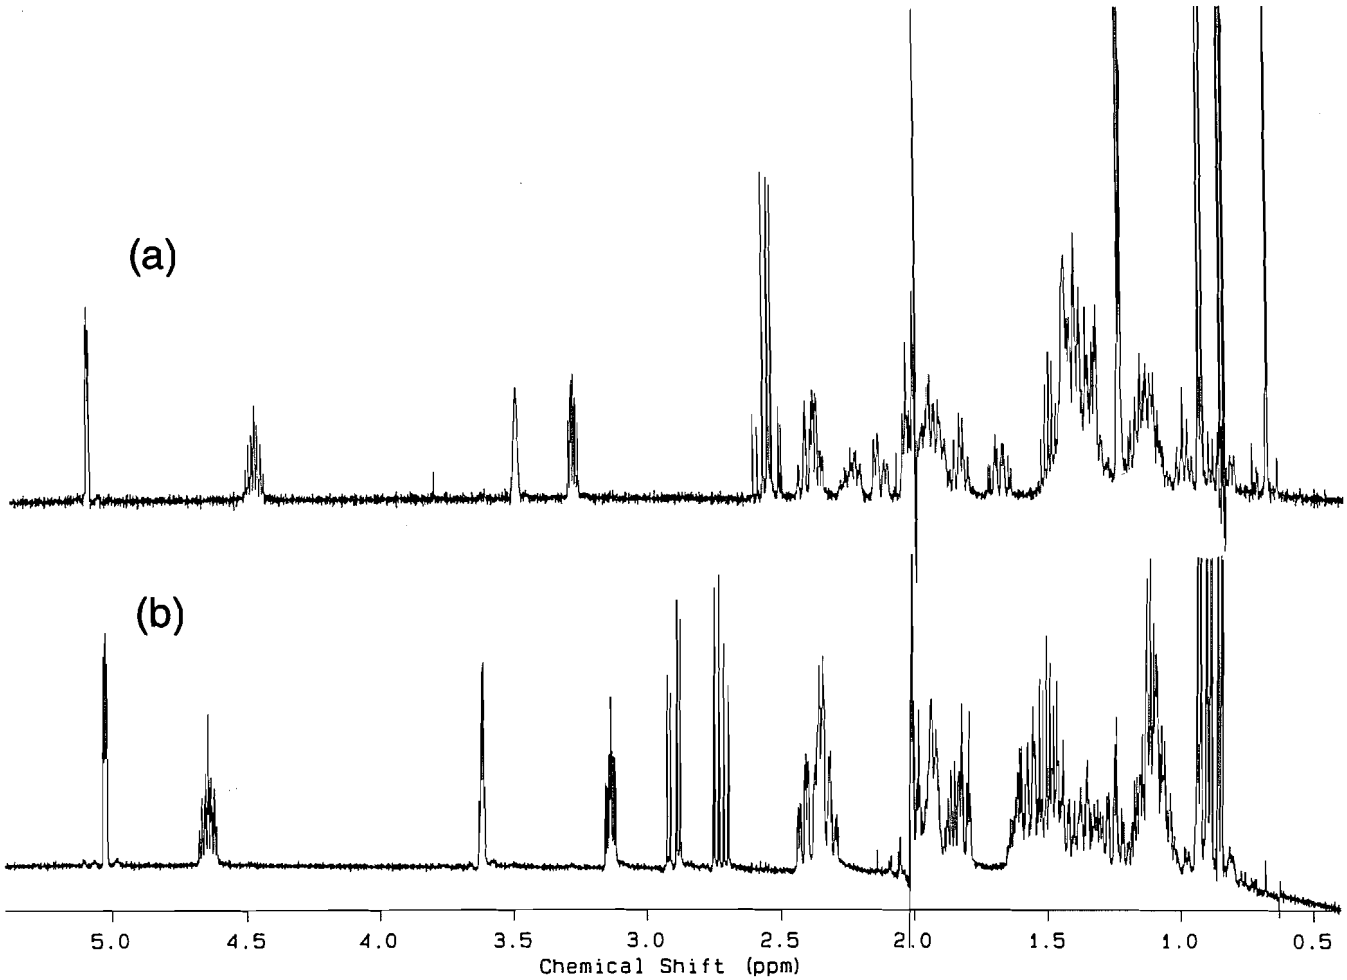

FIG. 1. High-field (500 MHz) ^{1}H NMR spectra (0–5.1 ppm region) of (*a*) **9***a* (Ar = phenyl) and (*b*) **10** (Ar = phenyl) in $CDCl_3$ solution.

ing coherence transfer throughout a spin system and will produce cross-peaks between protons that are not spin-coupled but belong to the same spin system. In principle, this technique should be able to resolve entire spin systems for specific steroid rings. To illustrate the application of the TOCSY method, Fig. 4 displays cross sections taken through the C-15 and C-3 protons of steroid **9***a*. For the former, correlations are observed not only to all the other ring-D protons but also to H-20 (overlapped by H-16α) and the 21-CH_3 protons. Similarly, all the A-ring protons were resolved by the observation of TOCSY correlations between H-3α and the C-1 protons. Figure 5 displays the TOCSY contour plot of Diels–Alder adduct **11**, obtained with an 80 ms spin-lock time.

The ^{1}H and ^{13}C NMR chemical shifts and ^{1}H–^{1}H spin coupling constants for **9***a*, **10**, and **11** (Ar = phenyl) are tabulated in Tables 1 and 2, respectively, while the results of the ^{1}H–^{1}H NOE experiments are listed in Table 3. The proton chemical shifts and coupling constants presented in Tables 1 and 2 were not refined by iterative spectral simulation. Interpretation of the information obtained from the NOE experiments was assisted by consideration of energy-minimized structures of the adducts determined from molecular mechanics (MMX) calculations. The results of these calculations are shown in Figure 6. Vicinal ^{1}H–^{1}H coupling constants, calculated from the energy-minimized structures of **9–11** using the equation included in the molecular mechanics software package (see experimental section), are included in Table 2 for comparison to the experimentally determined values. All of the adducts exhibited IR and mass spectral properties that were consistent with their proposed structures. ^{1}H and ^{13}C NMR assignments for **9***b* (Ar = *p*-biphenyl) are collected in the experimental section.

(i) Spectral assignments: ene adduct **9**a

The general strategy for assigning the ^{1}H spectrum was to begin with the olefinic proton H-6 at 5.03 ppm and H-3α at 4.65 ppm and establish both through-bond and through-space connectivities with neighbouring protons and then proceed into the adjacent ring spin systems. Through-space connectivity was provided by NOE difference experiments and this information was examined in relation to the energy-minimized structure of the molecule (Fig. 6*a*). In the COSY-45 contour plot of **9***a*, H-6 displayed cross-peaks with protons at 3.62 and 2.31 ppm. The 3.62 ppm multiplet correlates with a signal at 3.14 ppm that appears as the X part of an isolated ABX spin system arising from the C-1′ and C-2′ protons (3.14 and 2.90, 2.73 ppm, respectively) of the *N*-phenyl substituted imide ring. This dictates that the 3.62 ppm multiplet must be assigned to H-7.

For personal use only.

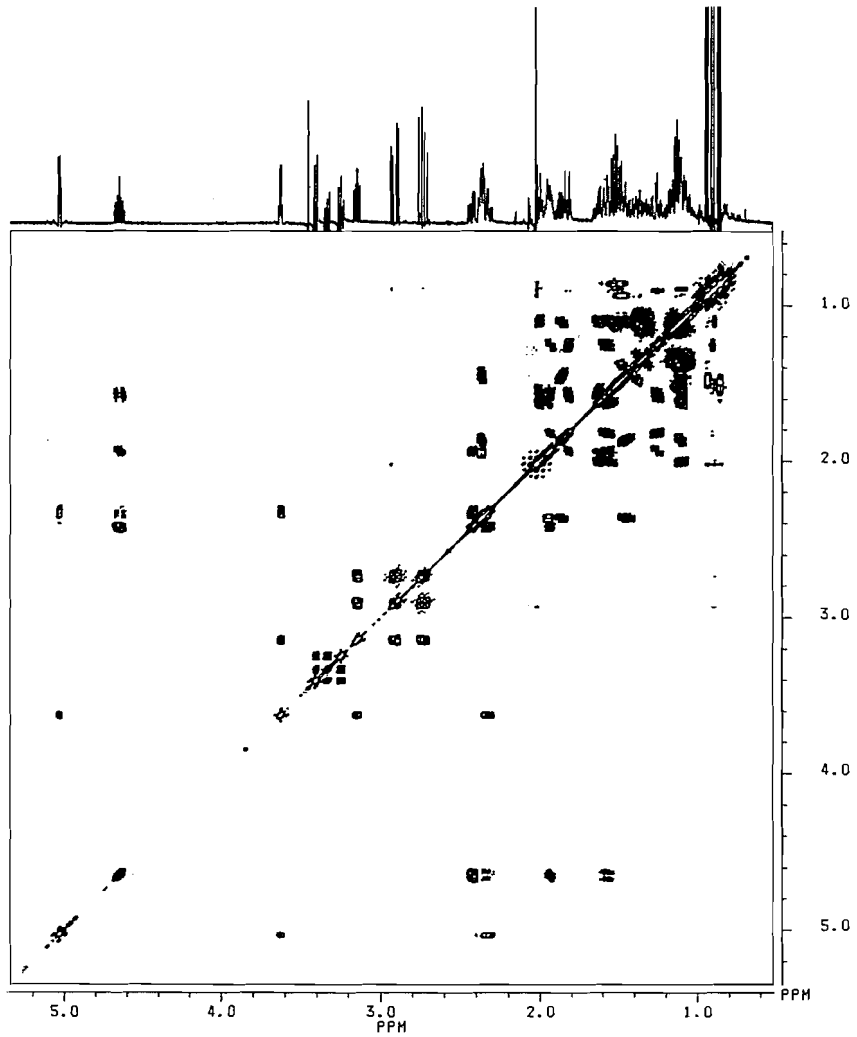

FIG. 2. COSY-45 spectrum of **9***a* in $CDCl_3$ solution.

Proton H-7 also shows a correlation with the complex multiplet at 2.31 ppm. Closer examination of the 2.31 ppm signal revealed that it overlaps with a two-proton multiplet and that it is coupled to the signal at 2.49 ppm as well as to H-3α at 4.65 ppm. Proton H-3α was also coupled to the signal at 2.49 ppm. These COSY connectivities suggest that the 2.31 and 2.49 ppm signals arise from the protons on C-4. Presumably, the cross-peaks between 2.31 ppm and H-6 and H-7 are due to long-range coupling over four and five bonds, respectively. Differentiation of the C-4 protons was achieved by NOE experiments. Saturation of the 19-CH_3 signal at 0.90 ppm resulted in an enhancement of the C-4 proton at 2.31 ppm, allowing it to be assigned to H-4β. Similarly, saturation of H-3α enhanced the H-4α signal at 2.49 ppm.

The identification of H-4β provided a means for determining if H-7 occupies an α or β position by using the stereochemical dependence of the five-bond homoallylic coupling between these protons. Maximum homoallylic coupling is observed when both coupled nuclei are 90° above or below the plane of the double bond (24). In this case with the geometry of H-4β being fixed, the 3.5 Hz five-bond coupling can only arise with H-7 being in a β position as shown in Fig. 6*a*. Furthermore, in an NOE experiment where H-7 was saturated there was an enhancement of a multiplet later identified as H-15α,β. This NOE result can be accounted for provided H-7 is in the β position. The structure in Fig. 6*a* indicates an average internuclear distance of 2.4 Å between H-7β and H-15α,β. During this NOE experiment H-6 and H-1′ were also enhanced.

The assignment of the A-rings protons was completed by following the cross-peaks in the COSY-45 spectrum from H-3α to the multiplets corresponding to the C-2 protons (1.93 and 1.57 ppm) and then from the C-2 protons to the C-1 methylene protons at 1.25 and 1.82 ppm. The α and β protons were identified in an NOE experiment where the 19-CH_3 was saturated (Tables 1 and 3). Additional confirmation of the H-2α assignment was provided by the observation of a four-bond W-type coupling (2.2 Hz) between H-4α and H-2α. A four-bond coupling was also detected between H-1α and the 19-CH_3 in the COSY spectrum.

Only a limited number of protons on the C and D rings and on the C-17 side chain could be identified from the ^1H spectrum because of the high degree of signal overlap in the 0.5–1.7 ppm region. A four-bond coupling resulted in a cross-peak being observed in the COSY-45 between the 18-CH_3 and H-12α (1.10 ppm) protons. Methyls 26 and 27 correlated with the H-25 multiplet centred at 1.51 ppm. Proton

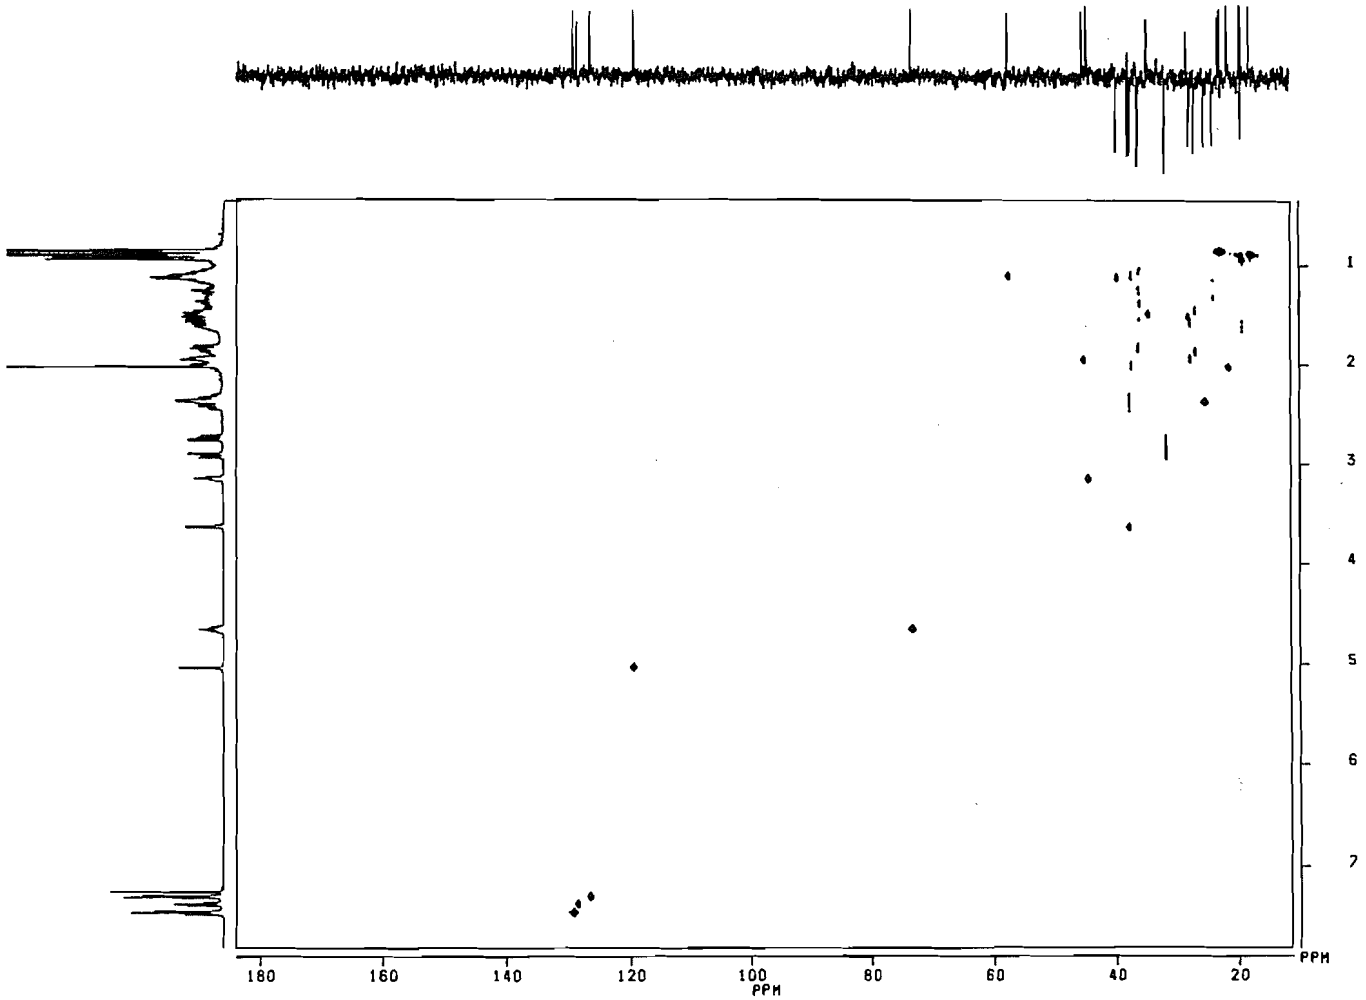

FIG. 3. $^{1}H-^{13}C$ shift correlation spectrum of **9***a* in $CDCl_3$ solution. The ^{13}C spectrum is shown as the DEPT spectrum.

H-20 was assigned to 1.48 ppm on the basis of its correlation with the 21-CH_3 doublet at 0.93 ppm.

The $^{1}H-^{13}C$ 2-D shift correlation experiment allows assignment of the remaining proton resonances and facilitates the analysis of the ^{13}C spectrum. A preliminary assignment of the ^{13}C NMR spectrum (Table 1) was achieved by the DEPT technique and by comparison with literature data (22, 23). Olefinic carbons 5 and 6 could be readily assigned by these methods to 145.9 and 119.3 ppm, respectively. However, the assignment of carbons 8 and 14 remains tentative.

Cross sections from the shift correlation spectra were particularly useful for assigning both the aliphatic carbons and their corresponding directly bonded protons. Since the A-ring protons were already identified, this simplified the assignment of carbons 1 through 4 (Table 1). There was an overlap of the C-4 and C-7 resonances. In the C ring, the previously assigned H-12α (1.10 ppm) was correlated with the carbon at 37.3 ppm. The cross section through this carbon resonance located H-12β (2.00 ppm), which was overlapped by the acetate methyl singlet. The C-11 methylene protons (1.63 and 1.53 ppm) were revealed in the COSY-45 spectrum by the cross-peaks with the C-12 protons. The C-11 carbon (19.1 ppm) was difficult to assign because of overlap with the 19-CH_3.

The resolution of the methine carbon signals between 40 and 75 ppm made it possible to assign the H-17α and H-9α protons (Table 1), which were obscured in the ^{1}H NMR spectrum. Identification of H-17α provided the means for assigning the other D-ring protons since a cross-peak was detected in the COSY spectrum to the multiplet eventually assigned to H-16β (1.83 ppm). The combination of the COSY and shift correlation data indicated that the C-16 methylene protons were at 1.83 and 1.46 ppm. Their designation as α (1.46 ppm) and β (1.83 ppm) is tentatively based on the coupling constants estimated from these multiplets (Table 3) (19, 22). However, it should be noted that this method of assignment is considered controversial (21). Both C-16 protons show correlations with an unresolved multiplet overlapping H-4β at 2.36 ppm; by elimination, this multiplet can be assigned to the H-15α,β protons. In the cross section through the shift correlation spectrum, H-15α,β appeared as a singlet connected to the carbon at 25.2 ppm, indicating that these methylene protons are in fact equivalent. The assignment of the C-17 side-chain protons and carbons relied on the COSY and shift correlation spectra and comparisons with literature data.

The TOCSY 2-D experiment, which produces cross-peaks between protons that are not coupled but belong to the same spin system, provided additional confirmation of some of the ^{1}H assignments. In particular, all the A-ring protons

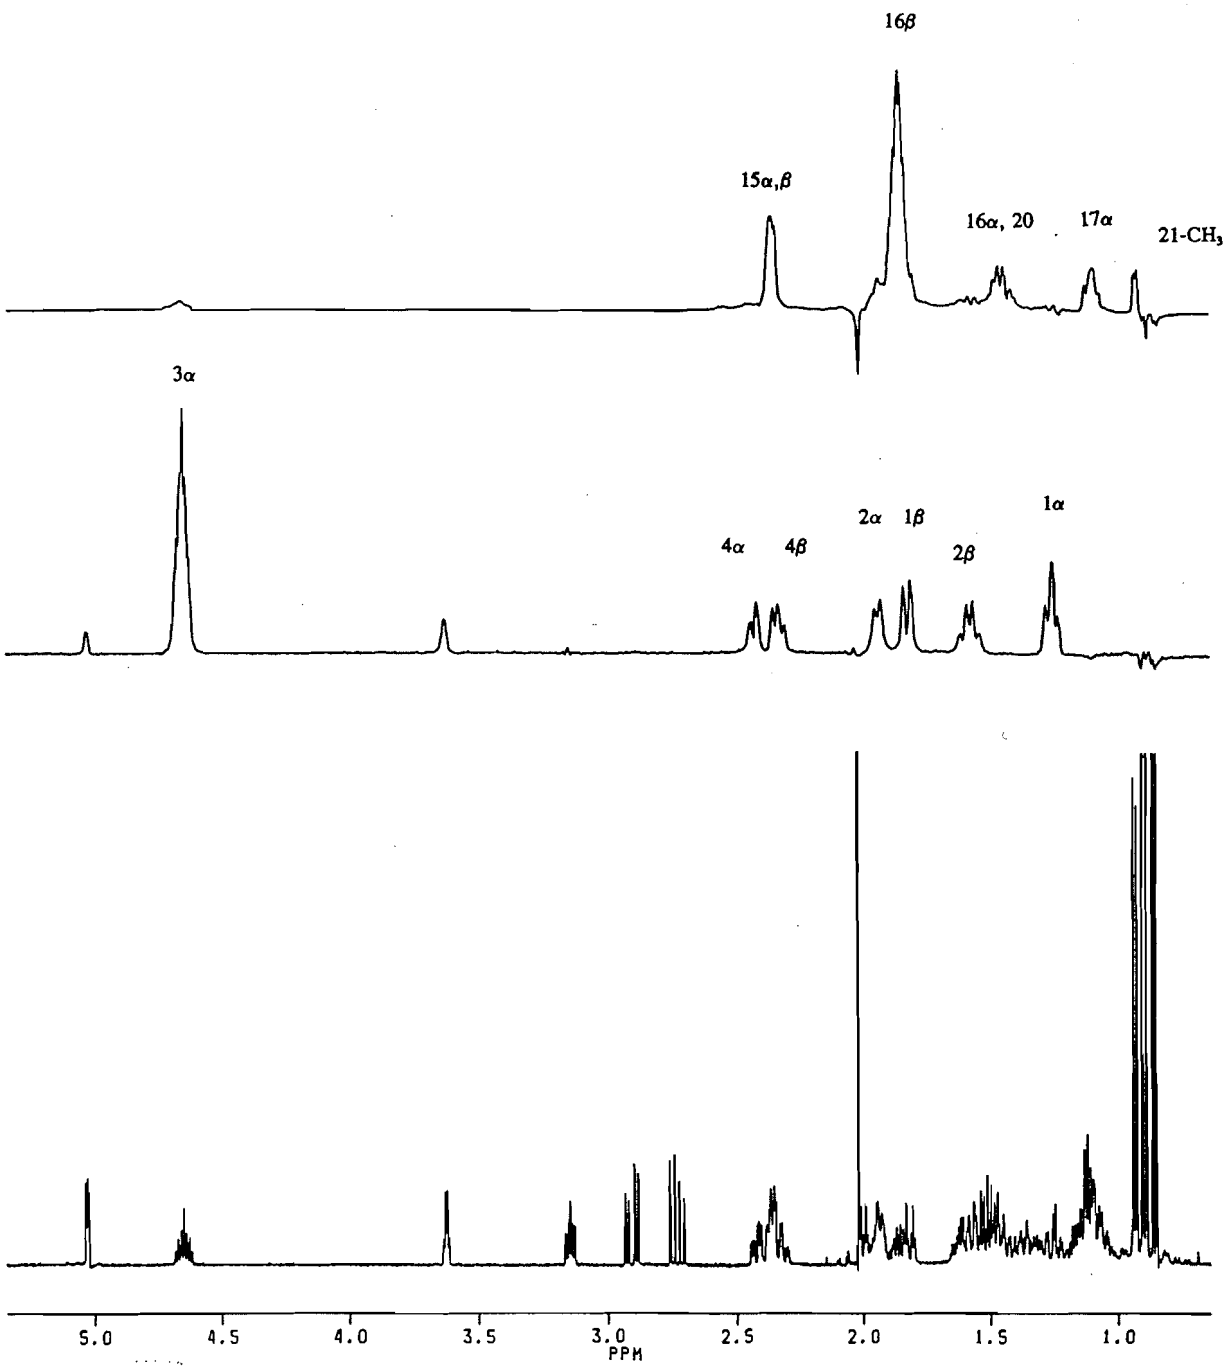

FIG. 4. Cross sections taken from the TOCSY spectrum of adduct **9***a* showing the resolution of the protons in rings A and D (middle and top spectra, respectively). The correlation between H-15α,β and the 21-CH_3 indicate coherence transfer occurring over six bonds.

could be identified by taking a cross section through the H-3α signal. In addition to the normal correlations with the C-2 and C-4 protons, H-3α also shows TOCSY cross-peaks to the C-1 protons at 1.25 and 1.82 ppm. An interesting result was the observation of TOCSY correlations through the entire D-ring spin system between 21-CH_3 and the C-15 protons (Fig. 4, top). In the cross section through 21-CH_3, the only proton not clearly observed was H-20, which was overlapped with the multiplet from H-16α. The H-15 to 21-CH_3 proton correlation indicates coherence transfer occurring between nuclei separated by six bonds. Unfortunately, the H-9/H-11/H-12 correlation could not be clearly observed due to overlap of the broad H-9 proton resonance with other signals.

(ii) Spectral assignments: ene adduct **9**b

The ^1H and ^{13}C spectra of **9***b* appear to be somewhat different from those of **9***a*, though they are essentially identical in the 0.8–1.0 ppm (methyl) regions. ^1H–^1H COSY and ^1H–^{13}C shift-correlated spectra of **9***b* (Ar = biphenyl), made in identical fashion to those for **9***a* (*vide supra*), allow sufficiently detailed assignment of the ^1H spectrum to conclude that the main differences between the spectra of **9***a*,*b* are associated with the B-ring carbons (C-6–C-9) and their corresponding protons. This is consistent with the identifi-

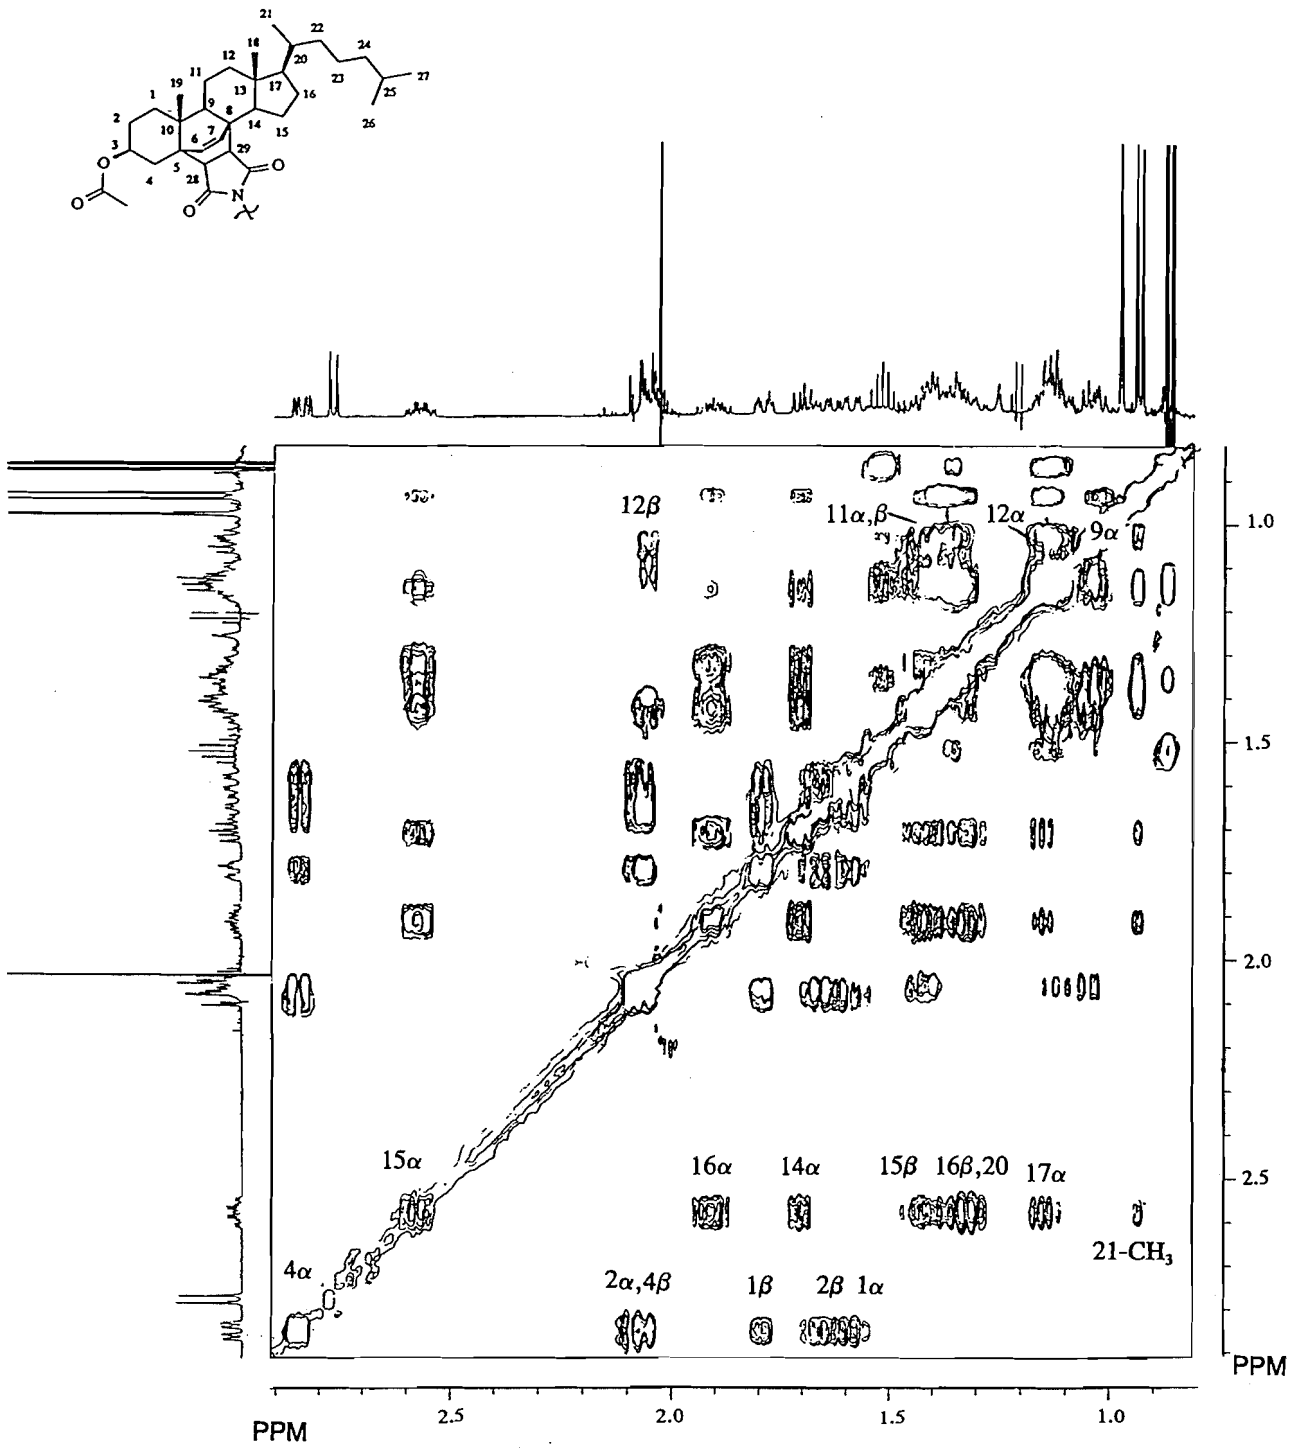

FIG. 5. TOCSY contour plot of the region from 0.8 to 2.9 ppm for adduct **11** (Ar = phenyl), recorded with an 80 ms spin-lock time.

cation of **9*a*** and **9*b*** as diastereomers differing only in the stereochemistry at the 1′-position of the maleimide ring. In the ^{1}H NMR spectrum of **9*b***, H-6 appears at 5.51 ppm (cf. 5.03 ppm in **9*a***), H-7β appears at 3.16 ppm (cf. 3.62 ppm in **9*a***), and H-9α appears at 2.25 ppm (cf. 1.94 ppm in **9*a***). Also, the H-15 protons are shifted to 2.17 and 2.27 ppm, from their position of 2.36 in **9*a***. The remaining protons in **9*b*** appear within 0.06 ppm of their positions in the spectrum of **9*a***.

The main differences in the ^{13}C spectrum are due to C-5 (143.6 ppm), C-6 (121.5 ppm), C-7 (39.9 ppm), C-8 (125.9 ppm), and C-9 (44.0 ppm), to be compared with the corresponding resonances in **9*a*** (145.9, 119.3, 37.6, 132.0, and 45.1 ppm, respectively). Also, the C-1′ and C-2′ resonances are shifted to 45.7 and 33.9 ppm, respectively, from their positions in the spectrum of **9*a***. The remaining resonances in the ^{13}C NMR spectrum of **9*b*** are within 0.4 ppm of their positions in the spectrum of **9*a***.

The assigned ^{1}H and ^{13}C resonances for this compound are listed in the experimental section.

[a]Aromatic protons appeared in the 7.29–7.44 ppm range; aromatic carbons in the 126.4–147 ppm range.
[b]Assignments may be reversed.
[c]Signals not observed due to low sample concentration.
[d]Assignments tentative.

*(iii) Spectral assignments: ene adduct **10***

The chemical shifts and coupling constants for **10** were determined using procedures similar to those used for **9***a*. The ^1H and ^{13}C spectral assignments presented for this compound in Table 1 should be viewed with greater caution than those for **9***a*, since there was considerably greater overlap of signals in the ^1H spectrum of **10** and only a small number of coupling constants could be determined reliably. However, sufficient resolution was obtained to confirm the stereochemistry at C-7 and to give an indication of the change in position of the second double bond in ring B.

By analogy with the data for **9***a*, the homoallylic coupling (2.1 Hz) is consistent with H-7 occupying a β position. Therefore, the stereochemistry at C-7 in **10** appears to be the same as that in **9***a*.

The position of the C-8/C-9 double bond was determined by locating the C-11 protons and examining their geminal coupling. These protons (11α, 2.26 and 11β, 2.13 ppm) were identified in the COSY-45 spectrum and were differentiated in an NOE experiment where the 19-CH_3 was saturated. An evaluation of the geminal coupling from the H-11α multiplet showed it to be approximately −18.1 Hz. The substantial increase in the magnitude of the geminal coupling is consistent with the plane of the π-system bisecting the angle between the C-11 methylene protons (25–27). This result confirms that the double bond is in fact located between C-8 and C-9.

*(iv) Spectral assignments: Diels–Alder adduct **11***

The gross structure of the Diels–Alder adduct (**11**) is particularly easy to identify because of the AX patterns in the ^1H NMR spectrum due to the vinylic protons at C-6 and C-7 (5.81 and 6.22 ppm, respectively) and the maleimide protons at C-1′ and C-2′ (2.75 and 3.38 ppm, respectively). Assignment of the A- and C-ring protons (Table 1) was achieved by a combination of COSY-45 and TOCSY (Fig. 5) 2-D techniques as well as NOE difference spectra (Table 3). The C-ring assignments were complicated by the overlap of H-11α and H-11β.

The B-ring vinyl proton chemical shifts were assigned with the aid of NOE difference spectra in which the methyl signals at 0.73 and 0.96 ppm were saturated. In the experiment where the 0.93 ppm methyl resonance was irradiated, an enhancement of the 5.81 ppm doublet was observed.

[a]Calculated from the energy minimized structures (Fig. 6), using the equation supplied with PCModel Version 4.0. Calculated values are in parentheses following the observed values.
[b]Overlapping multiplets; coupling not resolved.
[c]Assignment uncertain.

Several other protons arising mainly from ring A were also enhanced (Table 3). Thus, the 0.93 ppm singlet must be assigned to the 19-CH_3 while the vinylic doublet at 5.81 ppm can be attributed to H-6. Saturation of the 18-CH_3 resonance (0.73 ppm) produced the corresponding enhancement of H-7 (6.22 ppm) (Table 3). These NOE results provide experimental verification of the agreement of our assignments of the C-18 and C-19 methyl resonances with those of Jones *et al.* for the Diels–Alder adduct from **2** and maleic anhydride (14). In addition, the NOE data also confirm the *endo*- stereochemistry of adduct **11** as shown in the MMX-derived structure in Fig. 6*c*. Methyl-19 is close to H-6 while the 18-CH_3 is in the proximity of H-7. Further support for this geometry was provided by NOE experiments that involved the saturation of H-1′ and H-2′ protons of the succinimidyl ring. Saturation of the 3.38 ppm signal produced an enhancement of H-3α at 5.30 ppm, thereby allowing the 3.38 ppm resonance to be assigned to H-1′. The neighbouring H-2′ proton (2.75 ppm) was enhanced along with the 1.56 ppm H-1α multiplet. Saturation of H-2′ resulted in NOE's to H-1′ and to the 1.03 ppm multiplet assigned to H-9α.

The D-ring protons were identified from the COSY-45 and TOCSY (Fig. 5) spectra. The isolated multiplet at 2.55 ppm correlates with the doublet of doublets at 1.68 ppm and with the multiplets at 1.89, 1.40, and 1.30 ppm. Measurement of the coupling constants for the 2.55 and 1.68 ppm multiplets indicated a 7.2 Hz coupling between these protons. The remaining 12.3 Hz coupling associated with the 1.68 ppm signal arises from an interaction with the proton at 1.40 ppm. These results were interpreted with H-14α being assigned to 1.68 ppm with an axial/pseudo-equatorial coupling (7.2 Hz) to H-15α (2.55 ppm), and an axial/pseudo-axial coupling (12.3 Hz) to H-15β (1.40 ppm). The 1.89 and 1.30 ppm signals were shown by NOE experiments involving saturation of H-15α (Table 3) to arise from H-16α and H-16β, respectively. The D-ring proton H-15β was also affected by saturation of the olefinic proton H-7 (6.22 ppm). This enhancement is consistent with the spatial geometry of these protons as shown in the MMX structure (Fig. 6*c*).

The TOCSY contour plot (Fig. 5) allowed the completion of the D-ring assignments by the observation of the correlation between H-15α and H-17α. The longer-range correlation was also detected between H-15α and the 21-CH_3 protons. The multiplet for H-20 was not observed because of overlap with the H-15β and H-16β signals.

	15α (2.55)	15β (17.9%), 16α[b]

[a]Intensities measured from the difference spectrum are reported relative to the saturated signal where the intensity was assigned to −100 for a single proton multiplet; the peaks of interest were then integrated. Since the samples were not degassed, these results cannot be considered quantitative and serve only as a general indication of the observed enhancement of the signals. For the applications in this study, the determination of a numerical value for the NOE was not critical since the detection of an enhancement in itself is sufficient to provide the required structural information (40).

[b]The percent change in peak intensity is not considered accurate due to overlap with other signals or baseline distortions resulting from incomplete subtraction of adjacent peaks.

Only a partial assignment of the alkyl side-chain protons was possible from the 2-D spectra. The 26,27-CH_3 protons displayed TOCSY cross-peaks to contours centered at 1.35 and 1.12 ppm. These cross-peaks are considered to arise from the protons on carbons 22, 23, and 24, but no further differentiation of these signals was possible.

Summary and conclusions

The reaction of 7-dehydrocholesteryl acetate (**1**) with *N*-aryl maleimides yields mixtures of ene and Diels–Alder adducts. There is very little variation in the relative yields of the adducts with *N*-aryl substituent throughout the series **6–8**, and the product distributions are similar to that reported previously for the reaction of ergosteryl acetate with maleic anhydride (14).

The structures of the ene-adducts **9** and **10** and Diels–Alder adduct **11** from the reaction of **1** and **6–8** have been elucidated by high-field ^1H and ^{13}C NMR spectroscopic techniques, employing 2-D chemical shift correlation experiments and molecular mechanics calculations to assist in the spectral assignments. The accuracy with which the latter is able to predict coupling constants in these systems is quite remarkable. In all cases, the present assignments verify the conclusions of previous workers, who employed differences in the chemical shifts of the C-18 and C-19 methyl protons to identify the structures of the various adduct types (1–4).

TOCSY spectra have been reported previously for a triterpenoid (39). However, to our knowledge, the present work represents one of the first demonstrations of the power of the TOCSY pulse sequence for resolving entire spin systems in steroids. This technique will undoubtedly find increasingly frequent use in the analysis of the ^1H NMR spectra of complex natural products.

Experimental

Melting points were determined using a Mettler FP82 hot stage (controlled by a Mettler FP80 central processor) mounted on an Olympus BH-2 microscope, and are corrected. Routine ^1H NMR spectra were recorded with Varian EM390 or Bruker AC200 NMR spectrometers, and referenced with internal tetramethylsilane. Infrared spectra were recorded as KBr pellets (except where noted otherwise) using a Perkin–Elmer model 283 infrared spectrometer, calibrated with the 1601.8 cm^{-1} polystyrene absorption. Mass spectra and exact masses were determined by electron impact (70 eV), using a VG analytical ZAB-E mass spectrometer with a source temperature of 200°C and direct probe injection. Combustion analyses were performed by Galbraith Laboratories, Inc.

Analytical high-performance liquid chromatographic analyses employed a Gilson Isocratic HPLC system consisting of a model 302 pump and 5-mL head, a model 802B manometric module, Holochrome variable wavelength detector, and a Rheodyne model 7125 loop injector. A detector wavelength of 235 nm was used for analysis of product mixtures from reaction of **1** and **6**. Analyses of those from reaction of **1** with **7** and **8** employed a detector wavelength of 280 nm. The detector was interfaced with a Unitron microcomputer (Apple II+ clone) through an Adalab® data acquisition/control card (Interactive Microware, Inc.). The 0–10 mV signal was amplified to 0–1 V using an Adaamp® analog amplifier (Interactive Microware, Inc.). Chromatogram acquisition and storage was performed using Chromatochart® (Interactive Microware, Inc.). Product yields were determined from the HPLC peak areas (calculated by triangulation), assuming identical detector responses for each set of adducts and are the averages of two runs each analysed in triplicate. Normal-phase separations employed a Merck Hibar (4.6 × 220 mm) Si60 (10 μm) column, while reverse-phase separations employed Alltech (4.6 × 250 mm) C18 (10 μm) or Brownlee (4.6 × 220 mm) RP-18 Spheri-10 columns.

Semi-preparative LC separations were performed with the above system equipped with a 50-mL recycling pump head and an Isco 254-nm single wavelength detector. Normal-phase separations were performed with an EM Lobar Si60 (2.5 × 25 cm) silica column,

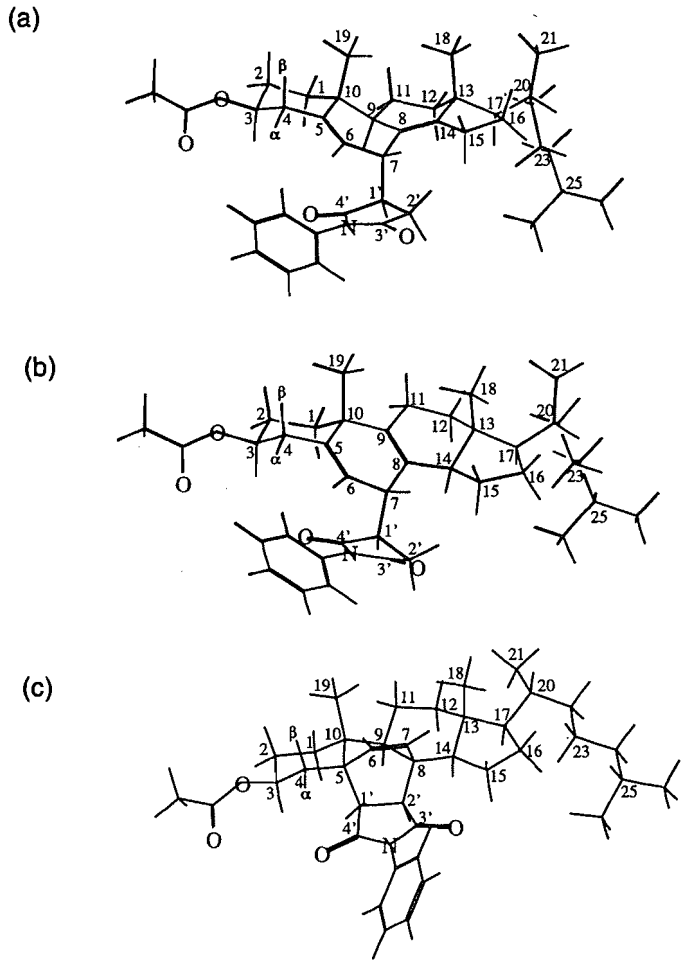

FIG. 6. Energy-minimized (MMX) structures of adducts **9***a* (*a*), **10** (*b*), and **11** (*c*).

while reverse-phase separations were performed using a Whatman Partisil M9 10/50 ODS-2 column.

High-resolution ^1H and ^{13}C NMR spectra were recorded on a Bruker AM500 spectrometer. Proton spectra were acquired at 500.135 MHz using a 5-mm dual frequency ^1H–^{13}C probe. Spectra were obtained in 64–88 scans in 32K data points over a 2.415–3.012 kHz spectral width (5.439–6.783 s acquisition times). The sample temperature was maintained at 30°C by a Bruker BVT-1000 variable temperature unit. The free induction decay (FID) was processed using Gaussian multiplication (line broadening: −2.0 Hz, Gaussian broadening factor: 0.15) for resolution enhancement and was zero-filled to 64K before Fourier transformation.

Absolute value proton COSY 2-D NMR spectra were recorded using the pulse sequence 90°–t_1–45°–ACQ. Spectra were acquired in 32 scans for each of the 512 FID's that contained 2K data points in F2 over the previously mentioned spectral widths. The ^1H 90° pulse width was 18.6 μs. A 2.0 s relaxation delay was employed between acquisitions. Zero-filling in F1 produced a 1K × 1K data matrix with a digital resolution of 2.359 or 2.941 Hz/point in both dimensions. During 2-D Fourier transformation a sine-bell squared window function was applied to both dimensions. The transformed data were then symmetrized.

TOCSY 2-D NMR spectra were acquired in the phase-sensitive mode using the MLEV-17 pulse sequence (28). Phase-sensitive data were obtained using time-proportional phase incrementation (TPPI) (29, 30). In the F2 dimension, 2K data points were used during the acquisition of the 256 FID's. Each FID was acquired in 16 scans for adduct **9***a* and 176 scans for **10**. A 2.415 kHz spectral width in the F2 dimension was used for both samples. The relaxation delays were 1.0 s for **9***a* and 0.7 s for **10**. The 90° ^1H pulse width used in the 5-mm broadband inverse probe was 26.0 μs. The length of the spin-lock mixing time was 80 ms plus two trim pulses of 2.5 ms. Zero-filling in the F1 dimension to 2K data points resulted in a digital resolution of 2.359 Hz/point in both dimensions. During the 2-D Fourier transformation, a sine-bell squared window function shifted by $\pi/2$ was applied to both dimensions. The transformed data were not symmetrized.

Proton–proton NOE difference spectra were acquired by subtraction of a control FID from an on-resonance FID. The decoupler in the control FID irradiated a position in the spectrum where there were no proton signals. The on-resonance FID was obtained with the proton of interest being selectively saturated. In both cases the same decoupler power and duration of saturation (5.0 s) were used. This saturation period also served as the relaxation delay for both the control and on-resonance FID's. The decoupler was gated off during acquisition. Eight scans were acquired for both the control and on-resonance FID's. The cycle of alternate acquisition of control and on-resonance FID's was repeated 8 times for a total of 64 scans for the complete difference FID. A 90° ^1H pulse width of 18.6 μs was used. The difference FID was processed using exponential multiplication (line broadening: 4.0 Hz) and was zero-filled to 32K before Fourier transformation. Samples were not degassed.

Carbon-13 NMR spectra were recorded at 125.759 MHz using the 5-mm dual frequency ^1H–^{13}C probe. The spectra were acquired over a 21.739 or 30.0 kHz spectral width in 16K or 32K data points (0.377–0.557 s acquisition time). Single pulse spectra used a ^{13}C pulse width of 2.5 μs (30° flip angle) and a 0.5 s relaxation delay. The DEPT pulse sequence was used for editing. The ^{13}C 90° pulse width was 6.4 μs while the ^1H 90° pulse width through the decoupler channel was 18.6 μs. The delays used in the DEPT pulse sequence were a 1.0 s relaxation delay and $1/2^1J_{CH}$ delay of 0.003571 s. The FID's were processed using exponential multiplication (line broadening: 4.0–5.0 Hz).

The ^{13}C–^1H 2-D chemical shift correlation spectra of **9** and **10** (Ar = phenyl) were acquired using the standard pulse sequence incorporating the BIRD pulse during the evolution period for ^1H–^1H decoupling in F1 (31–33). The spectra in the F2 (^1H) dimension were recorded over a spectral width of 3.106 kHz in 2–4K data points. The 256–512 FID's in the F1 (^{13}C) dimension were obtained over a 19.231 kHz spectral width. Each FID was acquired in 32 scans. The fixed delays in the pulse sequence were a 0.75–1.0 s relaxation delay, BIRD pulse and polarization transfer delays ($1/2^1J_{CH}$) of 0.003571 s, a refocussing delay ($1/4^1J_{CH}$) of 0.001786 s, and a 0.3 s delay between the BIRD pulse and the inverse pulse sequence. The 90° ^1H pulse was 9.2 μs while the 90° ^{13}C pulse was 10.1 μs. The data for **9** and **10** (Ar = phenyl) were processed using exponential multiplication (line broadening: 11.0 Hz) in F2 and unshifted sine bell in F1. Zero-filling in F1 resulted in a 2K × 1K data matrix.

The ^1H–^{13}C inverse detected shift correlation spectrum of **11** was acquired by using the HMQC pulse sequence with the BIRD pulse (34) in a 5-mm broadband inverse probe. The data were obtained in the phase sensitive mode using time-proportional phase incrementation (TPPI) (29, 30). The spectra in F2 were recorded over a spectral width of 2.415 KHz in 2K data points. In F1, each of the 186 FID's was acquired in 144 scans over the ^{13}C spectral width of 14.286 KHz. The fixed delays in the pulse sequence were a relaxation delay of 0.6 s, a BIRD pulse delay ($1/2^1J_{CH}$) of 0.003571 s, and the delay between the BIRD pulse and the HMQC pulse sequence was 0.35 s. The 90° ^1H pulse was 8.5 μs while the ^{13}C 90° pulse was 10.3 μs. Carbon-13 decoupling during acquisition was achieved by the GARP method (35). The data were processed using a sine-bell squared window function shifted by $\pi/2$ in both dimensions. In F1, the 2-D data were zero-filled to 2K.

The compounds used in the NMR experiments were dissolved in $CDCl_3$ (MSD Isotopes) to a concentration of about 0.05 M. Chemical shifts for the ^1H and ^{13}C spectra are reported in ppm relative to TMS using the residual solvent signals at 7.24 and 77.0 ppm as internal references for the ^1H and ^{13}C spectra, respectively.

Molecular mechanics calculations employed the MMX package supplied with PCModel Version 4.0 (Serena Software, Inc). Vicinal ^1H–^1H coupling constants were calculated using the equation supplied with the same software package, from the energy-minimized structures.

HPLC solvents acetonitrile (Caledon HPLC), dichloromethane (Caledon HPLC), ethyl acetate (BDH Reagent), and hexane (Caledon HPLC) were used as received from the suppliers, as were methanol (Mallinckrodt anhydrous), acetic anhydride (BDH Reagent), 1-nitropropane (Eastman), chlorobenzene (Fisher Reagent), toluene (Caledon Reagent), and carbon tetrachloride (Caledon Reagent or Fisher Spectroscopic). Absolute ethanol was prepared by refluxing 95% ethanol over magnesium turnings and iodine for 24 h followed by distillation. Benzene-d_6 and deuteriochloroform were used as received from MSD Isotopes. *N*-Phenylmaleimide (Sigma) was recrystallized twice from acetone and dried over phosphorus pentoxide (mp 89.5–90°C). 4-Aminobiphenyl, maleic anhydride, and *para*-terphenyl were used as received from Aldrich Chemical Co.

7-Dehydrocholesteryl acetate (**1**) was prepared from 7-dehydrocholesterol (Sigma) and acetic anhydride by the method of Prichard (36). The product was recrystallized thrice from acetone and washed with cold methanol (mp 125–127°C; lit. (37) mp 129–130°C).

N-Biphenylmaleimide (**7**) was prepared by the method of Crivello (18). The crude product was purified by column chromatography (silica; 2% acetonitrile – methylene chloride) followed by two recrystallizations from acetone, and obtained as bright yellow needles (mp 190.0–190.5°C; lit. (18) mp 189–190°C).

N-Terphenylmaleimide (**8**) was prepared by a modification of the procedure employed for the synthesis of **7** (18). Maleic anhydride (0.3 g, 3.1 mmol) was dissolved in acetone (4 mL) and 4-amino-*p*-terphenyl (38) (0.5 g, 2.04 mmol) was added, resulting in the immediate formation of a yellowish precipitate. The precipitate was collected by vacuum filtration, dried over phosphorus pentoxide in a vacuum desiccator for several hours, and then dissolved in a solution of acetic anhydride (5 mL) and anhydrous sodium acetate (0.1 g). The mixture was heated for 4 h at 90°C, during which time a yellow precipitate was formed. The mixture was cooled and the resulting solid collected and washed with acetone–water. Two recrystallizations from acetone yielded **8** as a pale yellow solid (0.55 g, 1.7 mmol, 83%); mp 293–303°C (dec.). IR (KBr) (cm^{-1}): 3095 (w), 1705 (s), 1503 (w), 1481 (m), 1394 (m), 1153 (w), 1139 (w), 1009 (w), 939 (w), 822 (m), 812 (m), 757 (w), 751 (w), 718 (w), 676 (m); ^1H NMR (200 MHz; $CDCl_3$) δ: 6.88 (s, 2H), 7.46 (m, 4H), 7.68 (s, 5H), 7.69 (m, 4H); ^{13}C NMR ($CDCl_3$) δ: 126.28, 127.02, 127.52, 127.74, 128.80, 130.29, 134.26, 139.00, 140.48, 169.50; MS *m/e*(*I*): 69(13), 169(9), 255(10), 271(11), 325(100), 326(6). Exact Mass calcd. for $C_{22}H_{15}NO_2$: 325.1103; found: 325.1105.

*Preparation and isolation of adducts from reaction of **1** and **6–8***

Preparative-scale thermolyses of **1** with **6** and **7** were carried out in the following fashion. 7-Dehydrocholesteryl acetate (**1**; 0.30 g, 0.7 mmol) and an equimolar amount of **6** or **7** were dissolved in benzene (35 mL). The resulting solution was divided among three 5/8-in. thick-walled Pyrex tubes which had been soaked in 10% aqueous sodium hydroxide for ca. 8 h, rinsed several times with distilled water, and oven-dried. The samples were degassed using three freeze–pump–thaw cycles, and the tubes were sealed under vacuum. They were then placed in a Parr model 4914 Pressure Reaction Apparatus and heated at 200°C for 4 h. The tubes were opened and the solvent was removed on the rotary evaporator.

Preparative-scale thermolysis of **1** and **8** was carried out using cholesteryl 4-chlorobenzoate (a cholesteric liquid crystal at 200°C) as solvent, in order to obtain a higher yield of adduct **10** than is afforded from the reaction in benzene solution (17). The diene **1** (0.15 g, 0.35 mmol), **8** (0.113 g, 0.35 mmol), and cholesteryl 4-chlorobenzoate (15 g) were dissolved in methylene chloride (15 mL). The volatile solvent was removed on the rotary evaporator, and the solid mixture which remained was placed in a 5/8-in. Pyrex tube, sealed under vacuum, and heated at 200°C for 4 h. The resulting mixture was flash-chromatographed on a silica gel column. The liquid crystal was eluted with 3:2 dichloromethane:hexanes, while the products were subsequently eluted as a mixture with starting materials with 2% acetonitrile in dichloromethane.

Isolation of the products from the thermolyses described above was carried out by cyclic semi-preparative liquid chromatography, using flow rates of 8–10 mL/min. The crude reaction mixtures were placed on the column. Three chromatographic cycles with methylene chloride as eluant separated the mixture into three fractions, which were collected and stripped of solvent. The first fraction, which consisted of the starting materials, was discarded. The second fraction consisted of a mixture of **9*a*** and **10**, while the third consisted of a mixture of **9*b***, **11**, and small quantities of a fifth (unidentified) adduct. Adducts **9*a*** and **10** were separated after three further cycles of the second fraction on the same column using methylene chloride as eluant. For the reaction with **6**, adducts **9*b*** and **11** were separated from the third fraction after two further cycles on the same column using 2% acetonitrile in dichloromethane as eluant. For the reaction with **7** and **8**, adducts **9*b*** and **11** were isolated by reverse-phase chromatography using 5% water in acetonitrile as eluant (7 mL/min) and a single pass through the column. The solvents were stripped from the purified adducts, and they were then recrystallized several times from methanol or chloroform–methanol mixtures. Analytical, physical, and spectroscopic data for each of the adducts are described below.

Product yields for the reaction of **1** with **6–8** in benzene solution were determined by HPLC analysis of small-scale (ca. 0.01 mmol) mixtures, which were thermolysed in base-washed, sealed 7-mm Pyrex tubes for 4 h in an oil bath at 200°C. After cooling to room temperature, the tubes were opened and aliquots were injected into the HPLC.

*Thermolysis of **1** and **6***

The adducts were separated on silica using 2% acetonitrile–dichloromethane as eluant and a flow rate of 1 mL/min. Under these conditions, the starting materials and products elute as follows: **1** (4 min); **6** (6 min); **9*a*** (13 min; 36%); **10** (14 min; 13%); **9*b*** (19 min; 25%); **11** (23.5 min; 19%); unidentified adduct (27 min; 6%).

The aryl regions in the ^1H and ^{13}C NMR spectra of the adducts were essentially identical (see **9*a*** (Ar = phenyl)).

*Thermolysis of **1** and **8***

The adducts were separated on silica using 2% acetonitrile–dichloromethane as eluant and a flow rate of 1 mL/min. Under these conditions, the starting materials and products elute as follows: **1** (4 min); **8** (5.0 min); **10** (6 min; 15%); ***9a*** (7 min; 32%); ***9b*** (10 min; 26%); and **11** (10 min; 21%), unidentified adduct (13 min; 7%). Thermolysis of **1** and **8** in the cholesteric liquid-crystalline phase of cholesteryl-4-chlorobenzoate for 4 h at 200°C yields the same products, but in the following yields: **10** (40%), ***9a*** (21%), ***9b*** (13%), **11** (10%), unidentified adduct (16%).

The aryl regions in the ^1H and ^{13}C NMR spectra of the adducts were essentially identical (see ***9a*** (Ar = *para,para′*-phenyl)).

The HLM method: a simple way to get the solid–liquid phase diagrams and enthalpies of transition of pure components and mixtures

FRANÇOIS QUIRION,[1] DANIEL LAMBERT, AND GÉRALD PERRON

Institut national de la recherche scientifique – Energie et matériaux, 1650 Montée Ste-Julie, Varennes (Qué.), Canada J3X 1S2

Received November 6, 1991[2]

FRANÇOIS QUIRION, DANIEL LAMBERT, and GÉRALD PERRON. Can. J. Chem. **70**, 2745 (1992).

A simple method of thermal analysis is described which gives the same information as differential scanning calorimetry. The method is based on the Heat-Leak-Modulus, HLM, of a sample cell placed in a constant temperature reservoir. In the present study, the HLM method is used for the investigation of pure components and mixtures from −190 to 50°C. The method allows the determination of glass-transition, crystallizations, solid–solid transition, eutectic, and melting temperatures with a reproducibility better than ±0.1°C. The enthalpy of a transition can be determined with a reproducibility of ±5%. The simplicity, the low cost, and the precision of the HLM method fills the gap between standard cooling curves and sophisticated differential scanning calorimetry experiments. The HLM method has numerous applications in physical chemistry, polymer science, metallurgy, and chemical engineering.

FRANÇOIS QUIRION, DANIEL LAMBERT et GÉRALD PERRON. Can. J. Chem. **70**, 2745 (1992).

Nous présentons une méthode d'analyse thermique donnant essentiellement la même information que la calorimétrie différentielle à balayage. La méthode est basée sur le «heat-leak-modulus» d'un échantillon placé dans un réservoir gardé à température constante et elle est utilisée pour l'étude des solvants et des mélanges de solvants entre −190 et 50°C. La méthode permet de déterminer les températures de transition vitreuse, de cristallisation, de transition solide–solide, d'eutectique et de fusion avec une reproductibilité meilleure que ±0.1°C. L'enthalpie associée à une transition peut être obtenue avec une reproductibilité de ±5%. La simplicité, la précision et le faible coût de la méthode en font une technique intermédiaire entre les courbes simples de refroidissement et la calorimétrie différentielle à balayage.

Introduction

In the past years, we have been involved in the optimization of aprotic solvent mixtures for low-temperature applications of lithium batteries. To identify systems that remain liquid at very low temperatures, solid–liquid phase diagrams were determined for numerous mixtures and many of them showed unusual heating curves that were difficult to interpret in terms of solid–liquid and solid–solid transitions. Consequently, we developed a simple method to analyse the time dependence of the temperature of the sample in term of the Heat-Leak-Modulus, HLM, of a sample cell placed in a reservoir kept at a constant temperature.

As will be shown, the HLM method provides essentially the same information as differential scanning calorimetry, DSC, the major difference being that DSC is more sensitive. However, the HLM setup is much less expensive and is as effective for the analysis of systems having heats of transition greater than 1 joule per gram of sample. This condition is almost always satisfied for the investigation of the solid–liquid phase diagrams of mixtures.

The present paper describes the HLM method and its application to the determination of phase diagrams and enthalpies of transition of pure components and mixtures.

Theoretical background

The heating rate of a cooled sample placed in a heat reservoir will depend on the thermal conductivity, k (J s^{-1} K^{-1} cm^{-1}), of the material between the reservoir and the sample. With air, the heating rate will be small and the temperature of the sample, T_S, will increase slowly. If the heat required to warm the sample is small compared to the amount of heat in the reservoir then the temperature of the reservoir, T_R, will remain constant. In these conditions, the time dependence of the temperature of the sample can be described by (1)

$$[1] \quad c_P \frac{dT_S}{dt} = k\,G(x)\,(T_R - T_S)$$

where $G(x)$ is a geometrical factor (cm) and c_P (J K^{-1}) is the heat capacity of the cell containing the sample. This equation can be rearranged in term of the Heat-Leak-Modulus, HLM, a parameter that varies less with the temperature of the sample.

$$[2] \quad \mathrm{HLM} = \frac{dT_S}{dt} \Big/ (T_R - T_S)$$

In the absence of transitions involving heat, the unperturbed Heat-Leak-Modulus, HLM_0 (s^{-1}), becomes (2)

$$[3] \quad \mathrm{HLM}_0 = \frac{k\,G(x)}{c_P}$$

Both the thermal conductivity of air and the heat capacity of the cell containing the sample increase with temperature, so that HLM_0 should not vary much with temperature. If the sample goes through an endothermic transition, $dH_S > 0$, the heat will be taken from the cell and the sample because of the poor thermal conductivity of the air layer surrounding the cell. In these conditions, the transition is assumed to proceed adiabatically and the contribution to the time dependence of the temperature of the sample becomes

$$[4] \quad \frac{dT_S}{dt} = -\frac{dH_S}{dt} \Big/ c_P$$

Adding this contribution to HLM gives

$$[5] \quad \mathrm{HLM} = \mathrm{HLM}_0 - \frac{1}{c_P\,(T_R - T_S)} \frac{dH_S}{dt}$$

[2]Revision received May 11, 1992.

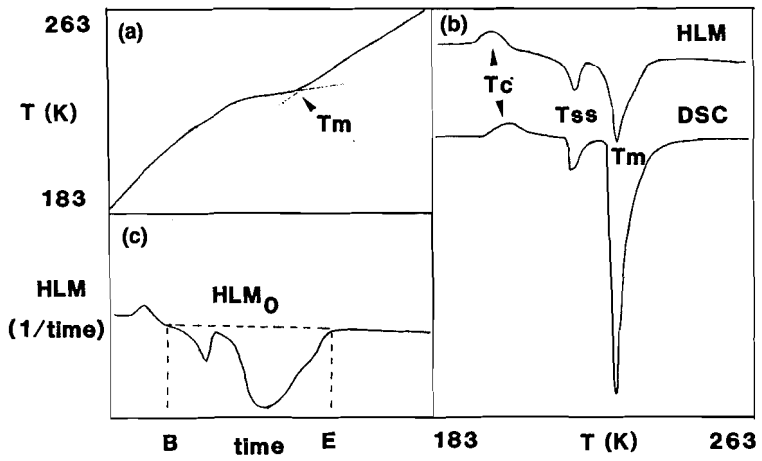

FIG. 1. Comparison of three representations of the time dependence of the temperature, for a sample of 0.25 cm^3 of acetonitrile. In (*a*), the usual temperature vs. time; in (*b*), the HLM vs. temperature curve is compared with a scan obtained by differential calorimetry using a DuPont calorimeter (model DSC 2910); in (*c*), the values of HLM shown in (*b*) are plotted against time and the beginning, B, and end, E, of the region of transition are shown.

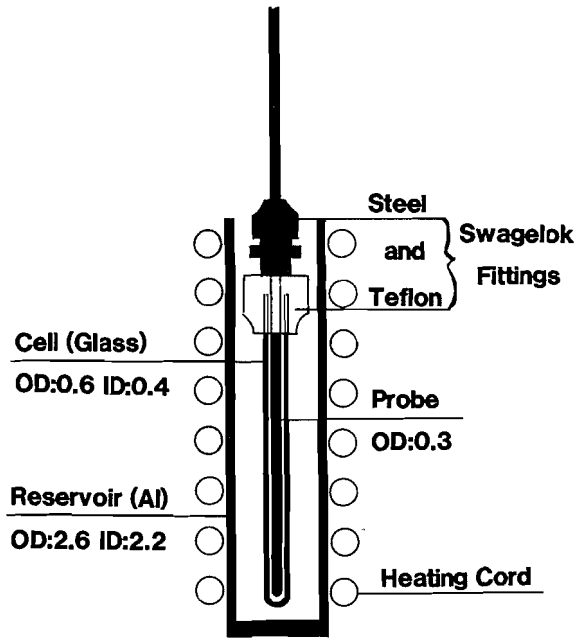

FIG. 2. Apparatus used in the present investigation. OB and ID stand for outer and inner diameter in cm, respectively. In the present work, the aluminum reservoir was 17 cm high and the length of the glass cell was about 8 cm.

Thus, an endothermic transition will produce a minimum in HLM while an exothermic transition will produce a maximum. The resulting dependence of HLM on temperature will essentially be identical to the one obtained with a more sophisticated differential scanning calorimeter. This is illustrated in Fig. 1 where three different approaches to the thermal analysis of acetonitrile are compared. First, the typical temperature vs. time curve shown in Fig. 1*a* allows a rough estimate of the melting temperature. In Fig. 1*b*, the same data are plotted as HLM vs. temperature and the resulting curve is compared to a DSC scan obtained with a Dupont calorimeter (DSC 2910). In both cases, the crystallization peak, the solid–solid transition, and the melting point of acetonitrile were detected.

In addition to the detection of a transition, one can also determine the heat associated with the transition through an appropriate analysis of the time dependence of the temperature of a sample as it is cooled or heated. Integration of eq. [5] leads to

$$[6] \quad g_S \Delta H_S = \int dH = -c_P \int (\mathrm{HLM} - \mathrm{HLM}_0)(T_R - T_S)\, dt$$

where ΔH_S (J g^{-1}) and g_S (g) are the enthalpy of transition and the mass of the sample. As with other calorimeters, the heat capacity of the system must be determined experimentally in the range of temperature of the investigation.

Experimental section

Chemicals

The origin and purity of the chemicals used are as follows: octane, nonane, dodecane, tetradecane, hexadecane, octadecane, and eicosane from Produits Chimiques Américain, >>99%; methanol and benzene from Produits Chimiques Américain, reagent anhydrous; heptane, decane, 1,4-dioxane, acetonitrile, and carbon tetrachloride from Caledon, distilled in glass; chloroform from Caledon, ACS spectro grade; toluene from Aldrich, ACS reagent; dichloromethane from Aldrich, HPLC grade.

Metholology

Figure 2 is a representation of the apparatus that was used in this investigation. The temperature probe (Omega, 100 ohm, platinum) is fixed to the glass cell with Swagelok fittings. In this configuration, the liquid sample is trapped as a film (~0.05 cm thick) between the temperature probe and the cell. The heat reservoir is an aluminum cylinder heated at a constant power with a powercord. The data acquisition unit consists of a multimeter (Keithley no. 196) driven by a compuer through an IEEE interface. This setup is flexible and other types of temperature probe, heating device, materials, or acquisition unit can be used.

The methodology consists of three very simple steps; loading, cooling, and analysis of the sample.

Loading

A volume of 0.25 cm^3 is weighed and placed into the glass cell. This fairly large volume reduces significantly the effect of humidity and evaporation encountered in differential scanning calorimetry when very small quantities of sample, ≈10 mg are weighed. The temperature probe is introduced into the glass cell, forcing the

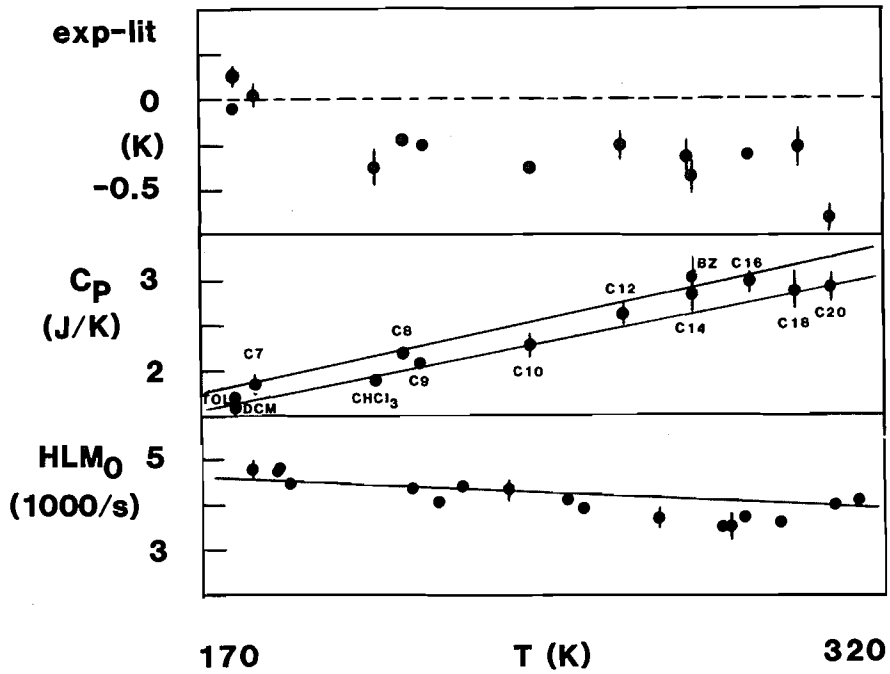

FIG. 3. Top; temperature dependence of the difference between the experimental and literature values of the temperature of transition. Middle; temperature dependence of the calibration constant, c_p, of the apparatus shown in Fig. 2. C*i* stands for aliphatic hydrocarbons with *i* carbon atoms and TOL, DCM, $CHCl_3$, and BZ stand for toluene, dichloromethane, chloroform, and benzene, respectively. Bottom; temperature dependence of the heat-leak-modulus in the absence of transition, HLM_0, as determined from the values of HLM_E. The solid line was calculated as described in the text.

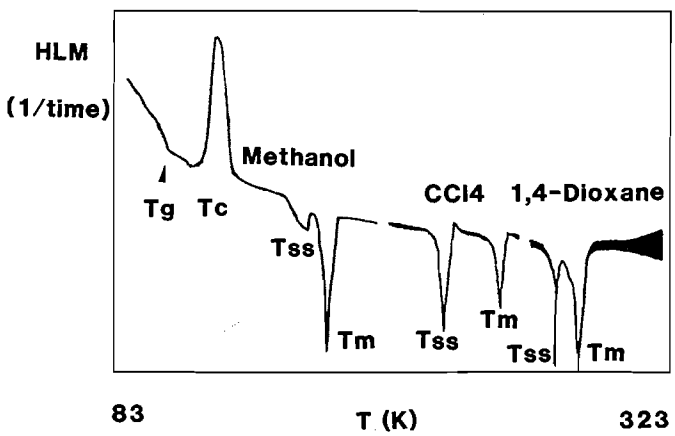

FIG. 4. HLM vs. temperature diagram showing portions of the curves obtained for methanol, carbon tetrachloride, and 1,4-dioxane. T_C, T_M, T_G, and T_{SS} stand for crystallization, melting, glass, and solid-solid transitions, respectively.

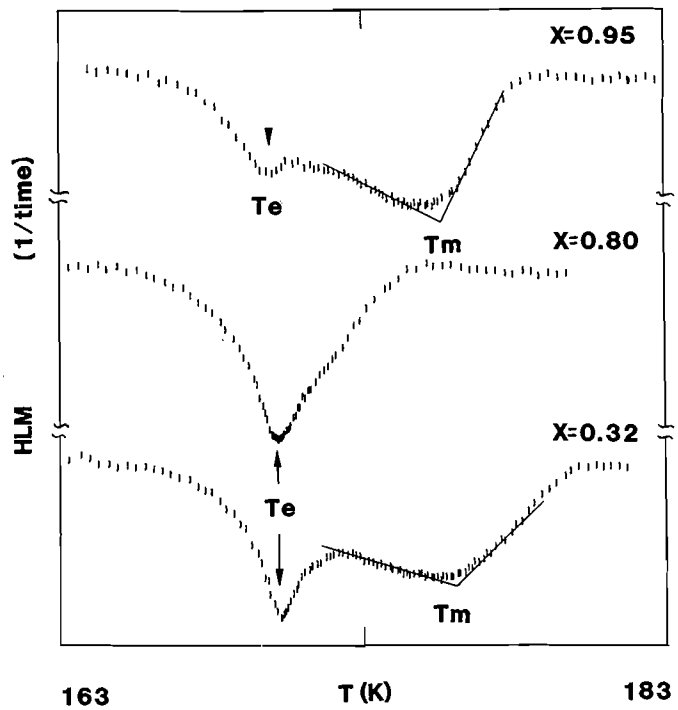

FIG. 5. Example of HLM vs. temperature curves obtained for three mixtures of heptane and toluene. The values of X is the mole fraction of toluene in the mixture. The eutectic temperature, T_E, is determined at the minimum of its corresponding peak while the melting temperature, T_M, is determined graphically.

volume of the liquid to rise as a film (thickness = 0.05 cm) between the probe and the glass cell.

Cooling

The cell is hermetically closed with Teflon and steel fittings to avoid evaporation and contamination of the sample. Then it is frozen by immersion in liquid nitrogen or another cryogenic mixture.

Analysis

The cell is transferred and fixed to the heat reservoir. The temperature of the sample is read at predetermined time intervals. Starting at the second value, the HLM is calculated and plotted on the screen. At the end, the scan can be analysed, printed, and saved for further analysis.

With the HLM method, it is not necessary to determine the absolute value of time because the array containing the temperature of the sample contains data that are equally spaced in time. That time interval, dt, is set to unity and HLM is calculated with eq. [2] where dT_S is the temperature difference between two successive

readings. The same arbitrary unit of time is used for the determination of the enthalpies of transition.

For integration purpose, HLM is plotted as a function of time (in arbitrary units) and the values are smoothed (3) over three equally spaced data with

$$[7] \quad HLM_I^{NEW} = HLM_{I-1}/4 + HLM_I/2 + HLM_{I+1}/4$$

Then the user selects the beginning and the end of a transition where HLM_B and HLM_E are determined, respectively. The baseline, HLM_0, is calculated by linear interpolation between HLM_B and HLM_E, as shown in Fig. 1*c*. The integral of eq. [6] is approximated (3) by a summation assuming linearity between equally spaced values of HLM. The integration becomes

$$[8] \quad \text{Area} = 1/2\,(A_B + A_E) + \sum_{I=B+1}^{E-1} A_I\,\Delta t$$

where $A(t) = (\text{HLM-HLM}_0)(T_R\text{-}T_S)$ and Δt is the arbitrary unit of time set to unity. With the resulting area (K), and knowing the calibration constant (J K^{-1}) and the mass of sample (g), the enthalpy of the transition (J g^{-1}) is calculated with the area resulting from the integration.

Results and discussion

Reproducibility of experiments

The temperatures and enthalpies of transition reported in this paper are values averaged over at least three runs with typical standard deviations of ±0.05 K and ±5%, respectively. From one sample to another, the reproducibilities of these results are ±0.1 K and ±3%, respectively.

Varying parameters such as the thickness of the reservoir, the cooling rate of the sample, and the period of acquisition does not affect the calibration constant, c_P, within the reproducibility limit of ±5%. The calibration is also independent of the temperature of the reservoir as long as it is at least 40 K higher than the temperature of the transition to be studied.

One very important parameter for the reproducibility of the data is the volume of sample in the cell since it determines the height of the liquid film and, consequently, the amount of cell material that contributes to the heat capacity. For instance, on going from 0.15 to 0.25 cm^3 of heptane, the calibration constant increases linearily with a slope of 8 J K^{-1} cm^{-3}. This value is much higher than the heat capacity of heptane because it also contains contributions from the glass cell and the probe. These contributions are very difficult to evaluate and, for that reason, it is important to always use the same volume of sample from one experiment to another to keep the calibration as constant as possible.

The melting temperatures of mixtures were determined graphically. The eutectic temperature and the temperature of

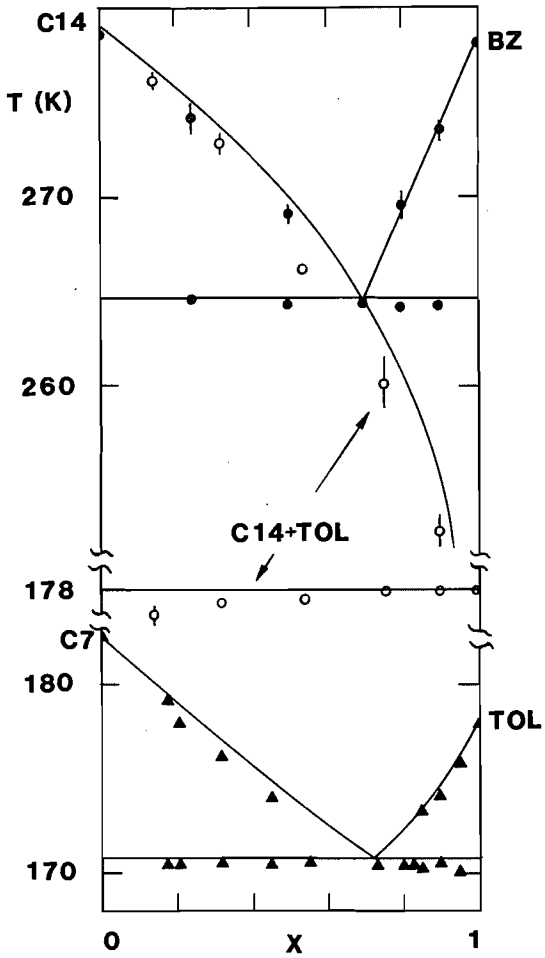

FIG. 6. Comparison of the solid–liquid phase diagram obtained with the HLM method with the results of Guieu et al. (5) (solid lines). Empty and filled circles are the melting and eutectic temperatures, respectively. C14, BZ, C7, and TOL stand for tetradecane, benzene, heptane, and toluene, respectively.

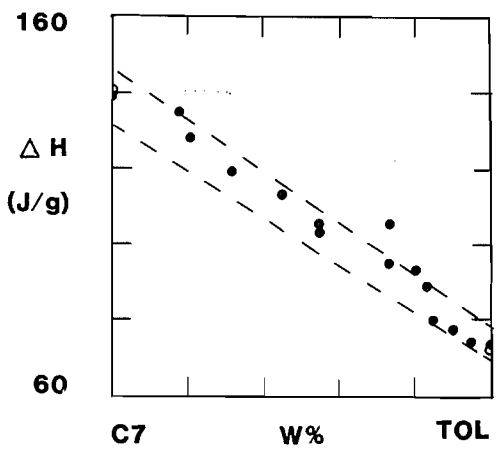

FIG. 7. Total enthalpy of melting, in joules per gram, of the mixtures of heptane and toluene as a function of the weight fraction of toluene. Dashed lines represent the +5% and −5% limits of the reproductibility. The calibration constant was taken as the average of the calibrations obtained with heptane and toluene.

melting of the pure components were defined as the temperatures at the minimum of the smoothed HLM vs. T curves. This procedure may lead to temperatures of transition that are different from the expected one because the minimum is not always symmetrical. This is shown in Fig. 3 where a difference of about −0.25°C is observed between the experimental and the literature values of the melting temperature. That small difference is rather systematic and it may also be the consequence of a miscalibration of the temperature probe. Nevertheless, the use of the minimum for the determination of the melting temperature is fast and convenient.

Temperature dependence of the calibration constant, c_P

The determination of the enthalpy of transition requires the calibration of the apparatus in term of its heat capacity (eq. [6]) in the temperature range to be investigated. We have determined the calibration constant of the present apparatus, c_P, with the literature value of the enthalpy of fusion, ΔH_F, and the experimental area (eq. [7]) of the peak at the melting point. The results are reported in Table 1 and plotted in Fig. 3 as a function of the melting temperature. The increase of the calibration constant with temperature is in accordance with the general temperature dependence of the heat capacity of materials. Moreover, most of the values fall within the ±5% limits of the linear trend. Thus, using the linear trend that describes the temperature dependence of the calibration constant, $c_P(T) = 1.54 + 0.0103(T\text{-}160)$, it is possible to measure the enthalpy of transition of an unknown within 5%.

Temperature dependence of HLM_0

Equation [3] shows that HLM_0 depends on a geometrical factor, $G(x)$, independent of the temperature, and on c_P and k, the heat capacity and the thermal conductivity of the system, which both depend on temperature. Thus, provided that the values of $G(x)$, c_P, and k are known, the temperature dependence of HLM_0 could be determined quantitatively. The geometrical factor was calculated with the value of HLM_0 just after the melting of heptane, and the values of c_P and k were also available at that temperature.

With the present geometry, the heat flux is normal to the surface of the components, so that the overall thermal conductivity of the system is limited by the component having the lowest thermal conductivity according to (1)

$$[9] \quad k^{-1} = \Sigma \Phi_i k_i^{-1}$$

where Φ_i is the volume fraction of component i. For the apparatus described in Fig. 2, the air layer accounts for about 93% of the volume while the remaining space is occupied by the sample cell. The thermal conductivity was calculated using the reported values of k for dry air, and the contribution of the sample cell was assumed to be negligible (less than 1%). Taking $G(x)$ as a constant, the temperature dependence of HLM_0 was calculated with eqs. [3] and [9] and the temperature dependence of c_P. The resulting curve is plotted as a solid line in Fig. 3 and it is in good agreement with the experimental values of HLM_E, which correspond to the values of HLM_0 after the melting of the samples. This shows that HLM_0 can be calculated quantitatively as a function of temperature provided that the geometry and the characteristics of the materials are well known.

Transitions in the solid state

The presence of transitions in the solid state is often difficult to observe with typical temperature vs. time curves. This was shown for acetonitrile in Fig. 1 and there exist many

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

other components that present solid–solid transitions. Figure 4 presents the experimental HLM vs. T curves of methanol, carbon tetrachloride, and 1,4-dioxane where such transitions are observed in the solid state.

The glass transition, T_G, corresponds to an increase of the heat capacity due to additional molecular motions in the solid state, and from eq. [3] it will appear as a sudden decrease of HLM_0. These molecular motions often lead to the exothermic crystallization, T_C, of the solid glass. For instance, see the curve for methanol in Fig. 4. Another type of transition in the solid state is the reorganization of the solid structure or the solid–solid transition, T_{SS}, that occurs at a temperature lower than the solid–liquid transition, T_M. As for acetonitrile, the HLM vs. temperature curves of Fig. 4 all show the presence of a solid–solid transition.

Solid–liquid phase diagram

In addition to the characterization of pure components, the HLM method is very effective for the investigation of the solid–liquid phase diagram of mixtures. This is shown in Fig. 5 where the scans obtained with the HLM method are presented for three mixtures of heptane and toluene. The shape of the curves obtained for the thermal analysis of that system is very similar to the scans obtained by DSC (4). For that single eutectic system, the eutectic mixture, as for the pure components, shows a single peak that has its minimum at the temperature of the transition. The HLM curves of the mixtures on both sides of the eutectic composition show a sharp peak at the eutectic temperature and a broad and asymmetric peak corresponding to the range of the solid–liquid equilibrium of the mixtures. Because of the asymmetry of the melting range, the melting temperature is determined by extrapolation.

The HLM method was used to determine the solid–liquid phase diagram of the systems heptane–toluene, tetradecane–benzene, and tetradecane–toluene. The resulting phase diagrams are shown in Fig. 6 and compared to those obtained by Guieu *et al.* (5). For the three systems, the difference between our value of the eutectic temperature and the literature value is within the experimental error. This is quite good, considering the fact that the thermal analyses reported in the literature were performed at a heating rate of 0.2 K min^{-1} while, in our case, the heating rate varied from 35 K min^{-1} at 170 K to about 20 K min^{-1} at room temperature.

The investigation of mixtures with the HLM method is not only a fast and accurate method for the determination of solid–liquid phase diagrams but it is also reliable for the determination of the total enthalpy of melting of a mixture. For instance, the method was applied to mixtures of heptane and toluene. The enthalpy of mixing should be small for these monpolar solvents so that the enthalpy of melting of that single eutectic system is expected to be linear from one component to the other. The calibration constant, c_P, was determined with the pure components, and the total enthalpy of melting of the mixture was determined with the integration procedure described using eqs. [6]–[8]. The results are shown in Fig. 7 and they are in accord with the expected behavior within the ±5% limits shown by the two straight lines.

Conclusions

The HLM method is a technique of thermal analysis based on the Heat-Leak-Modulus of the system. This parameter is not very dependent on the temperature and it provides a reproducible baseline from one experiment to another. The HLM method allows the identification of the glass-transition, crystallization, solid–solid transition, eutectic, and melting temperatures of a system with a precision better than 0.1 K. The apparatus is easy to calibrate in term of its heat capacity and the enthalpies of transition can be determined with a precision of ±5%.

The main difference between the HLM method and differential scanning calorimetry is the limit of detection, which is lower in the case of DSC. However, a wide variety of investigations do not require the high sensitivity of DSC. Moreover, the high sensitivity of DSC often forces the use of a very small amount of sample, which increases the relative error in the weight of sample and emphasizes the effect of evaporation and humidity.

The simplicity, low cost, and precision of the HLM method fill the gap between standard cooling curves and the sophisticated differential scanning calorimetry experiments. The HLM method has numerous applications in physical chemistry, polymer science, metallurgy, and chemical engineering.

The percentages of protonation were determined for a conjugated Schiff base *trans,trans*-2,4-heptadienylidene *tert*-butylamine in the presence of 3-chloropropionic acid (CPR) and dichloroacetic acid (DCA) in three solvents of different polarities. In dioxane, a solvent of low polarity, protonation is only important for the strong acid DCA (50–60%). By using solvents of higher polarities, protonation is seen to increase and is almost complete for DCA in ethanol. When water molecules are added to these systems, hydrolysis of the Schiff base, measured inside the time span of the experiments (10 min), occurs readily in dioxane, is very slow in a chloroform–dioxane mixture (9:1), and is totally absent in a mixture of ethanol–dioxane (1:9). Results indicate that water does not mediate protonation in all three sets of solvent combinations. The results are also discussed in terms of the possible role that water molecules could have in the visual and bacterial pigments.

P. TURCOTTE, S. ALEX et D. VOCELLE. Can. J. Chem. **70**, 2751 (1992).

Les pourcentages de protonation ont été déterminés pour le cas d'une base de Schiff conjuguée, la *trans,trans*-2,4-heptadiénylidène *tert*-butylamine, en présence de l'acide 3-chloropropionique (CPR) et de l'acide dichloroacétique (DCA) dans trois solvants de différentes polarités. Dans le dioxane, un solvant de faible polarité, la protonation n'est importante que pour l'acide fort DCA (50–60%). En utilisant des solvants de polarité plus élevée, la protonation augmente et est à peu près complète pour le DCA dans l'éthanol. Quand de l'eau est ajoutée à ces systèmes, l'hydrolyse de la base de Schiff, mesurée à l'intérieur du temps d'enregistrement des spectres (10 min), est rapide dans le dioxane, est beaucoup plus lente dans un mélange de chloroforme–dioxane (9:1) et est totalement absente dans un mélange d'éthanol–dioxane (1:9). Les résultats indiquent que l'eau ne favorise aucunement la protonation et cela vaut pour les trois ensembles de solvants utilisés. Les résultats sont aussi discutés en terme du rôle que pourrait jouer l'eau dans les pigments visuels et bactériens.

Introduction

Protonation and deprotonation of a retinal Schiff base are essential events in the mechanism of proton translocation in visual and bacterial pigments. These two aspects have received wide interest on both theoretical and experimental grounds (1–10). It is now known that the protonating agent of the chromophore of rhodopsin (11-*cis* retinal linked to lysine 296 of the apoprotein) is glutamic acid 113 (11–13), whereas for the related bacterial pigment bacteriorhodopsin, it is a combination of three amino acids that are responsible for the protonation of the chromophore: Asp-85, Asp-212, and Arg-82 (14, 15). One of the most important features of these pigments that is still not fully understood is their capacity to absorb light in the 500–570 nm region. Model studies of Schiff base in organic solvents have shown that an unprotonated Schiff base has its maximum absorption (λ_{max}) at ca. 360 nm while protonated model Schiff bases (SB) are red-shifted to λ_{max} ca. 440–450 nm (16, 17). Considering that bovine rhodopsin (as an example) has its λ_{max} at 500 nm (18), it implies that the protonated chromophore is again red-shifted by about another 50 nm by interactions with the protein. This last bathochromic shift is called the opsin shift (19). Several hypotheses have been advanced to explain this shift (2, 16, 18), but lately, the emphasis has been placed on the relationship between the protonated Schiff base and its counterion; visualize $RetCH{=}N(R)H^{+}\cdots{}^{-}OOCR$, where Ret is the retinylidene portion of the Schiff base that could well explain totally or in part the opsin shift. Yet, model studies conducted in our laboratory (20–25) have indicated that a retinylidene Schiff base in nonpolar solvents or in methanol could not be fully protonated by acids having pK_a's in the 3–5 region as measured in water, which is the region where Glu or Asp have their pK_a's (4.25 and 3.89 respectively). Hence, some stabilizing factors must be present in the protein so that the system Schiff base/acid could be fully protonated ($SBH^{+}\cdots{}^{-}OOC^{-}$). We have suggested (26) and partly demonstrated (21, 25) that the concomitant presence of several molecules of acid acting like a proton relay transfer and (or) the presence of water molecules could possibly help the system to reach full protonation. In particular the role of water, apart from its obvious involvement in the hydrolysis of metarhodopsin II, remains intriguing, since pigments which have been made dry react quite differently than normal "wet" pigments (9, 10). However, these hypotheses are still controversial and more data must be gathered to confirm or invalidate these postulates.

At this moment, two schools of thought exist on this question. One favors the presence of water next to the Schiff base (2, 6–10), the other (27) rather promotes the excitonic model of Kriebel and Albrecht (1). Both models have advantages and drawbacks but neither one nor the other can rationalize all the physical and chemical properties of these pigments.

Furthermore, if water molecules are present near the protonated Schiff base, some additional factors must also be present to prevent these water molecules from reaching the protonated imine before the metarhodopsin II stage, since hydrolysis will occur readily. So far, the mechanism of hydrolysis of Schiff bases have received little attention. Cooper *et al.* (28) have reported a full kinetic analysis of the hydrolysis of a model of rhodopsin consisting of *N*-retinylidene

n-butylamine in aqueous anionic, cationic, and neutral detergent micelle systems.

In the present study, the role of water, especially its ability to favor protonation and hydrolysis, will be explored. Since Papadopoulos *et al.* (29) have shown that four molecules of water are likely present near the chromophore, different ratios of water in the system, from 0 up to 4, will be added. To do this, a simpler model will be used. It consists of *trans,trans*-2,4-heptadienylidene *tert*-butylamine (SB hereafter) that will be protonated by two acids: dichloroacetic acid (DCA, pK_a 1.26) and 3-chloropropionic acid (CPR, pK_a 3.99). The SB and the acid will be dissolved in a solvent or mixtures of solvents (dioxane, chloroform, or ethanol) to which different amounts of water will be added. Protonation and the unwanted hydrolysis will be monitored by Raman spectroscopy. These experiments are expected to give a better knowledge of the behavior of such systems in various electrostatic media. In addition, these tests are meant to stress the importance of electrostatic interactions on the physical and chemical properties of protonated Schiff bases.

Experimental

The synthesis of *trans,trans*-2,4-heptadienylidene *tert*-butylamine ($CH_3CH_2CH{=}CHCH{=}CHCH{=}NC(CH_3)_3$, called SB) was carried out according to a well-established method (22). The aldehyde and amine were supplied by the Aldrich Chemical Co. (Milwaukee, Wis., U.S.A.). Since this SB is somewhat unstable, it must be used freshly prepared or redistilled. All experiments were done quickly, especially when water and acids were present so as to minimize hydrolysis. Solutions for Raman spectra were prepared by mixing 0.025 M of the SB with an equimolar quantity of the organic acid in a given solvent. The concentration of the imine was selected to reduce to a minimum the self-absorption on Raman intensities deriving from the tail of the $\pi-\pi^*$ electronic transition of the protonated imine seen at ca. 308 nm in chloroform (30). The $\pi-\pi^*$ electronic transition of the unprotonated form absorbs at 267 nm. Dioxane, chloroform, and ethanol were all of a spectrograde quality and were dried, as well as the acids, over molecular sieves for liquids and in a desiccator over anhydrous calcium chloride for solids. Chloroform was also eluted three times on a basic alumina column to remove traces of ethanol and hydrochloric acid.

In the experiments using water (HPLC grade), spectra were taken immediately after water addition in the solution. UV spectra were recorded on a Pye Unicam PU 8800 instrument while Raman spectra were obtained on a Spex Triplemate spectrograph coupled to an EG&G Princeton Applied Research detector, model 1422. Samples were excited with the 25–50 mW of the 488.8 nm laser line (Spectra Physics CW A^+, model 2016) to take full advantage of the preresonance effect. To improve the preresonance effect, attempts to use the 457.9 nm laser line were tried but were inconclusive because of the poor detector efficiency in this spectral region. The samples were put in a sealed capillary mounted on a thermally regulated sample holder maintained at 10°C. Resolution was 5 cm^{-1} at 1600 cm^{-1}. The spectra were recorded in 10 min and the fluorescence background was routinely substracted with an appropriate *n*th-order polynomial when necessary.

Results and discussion

In a first approximation, the SB/acid system obeys the simple equation written below, using symbolic notation:

[1] $C{=}C{-}C{=}C{-}C{=}N{-}R + HOOC{-}R_1 \rightleftharpoons C{=}C{-}C{=}C{-}C{=}N(R)H^+\cdots{}^-OOCR_1$

Depending on the acids and solvents used, the percentage of protonated SB (or PSB) varies and this particular point has already been investigated in pure chloroform and methanol solutions by means of FT-IR spectroscopy (23, 24). As a rule, the protonation is almost complete, providing that the proton source has a pK_a value less than to 2 units, especially when the solvents are polar and protic. Upon water addition, the PSB is known to hydrolyse to give irreversibly the parent aldehyde (2):

[2] $R{-}CH{=}N(R_1)H^+ + H_2O \rightleftharpoons R\text{-}CH{=}O + R_1\text{-}NH_3^+$

This is particularly true for the protonated SB since the unprotonated SB is expected to be more stable in the presence of water according to standard organic chemistry rules. Thus, hydrolysis is believed to be dependent on both the protonation state of the imine moiety and the electrostatic properties of the solvents. In the present work, the water effect will be tested to differently solvated PSB in order to characterize its action. Several solvents and combinations of solvents can be tested to carry out this study, but for this work we have chosen dioxane, chloroform, and ethanol for reasons that are explained later.

Generally speaking, in the actual pigments, the protonated chromophore may be located in a protein cavity falling into one of the following three categories.

(*1*) The protonated Schiff base lies in a nonpolar cavity and does not form H bonds within this pocket.

(*2*) The protonated Schiff base rests in a nonpolar but interactive cavity. For simplicity, the term interactive cavity will be used in the text when interactions are presumed to exist between the chromophore and the cavity.

(*3*) The protonated Schiff base is surrounded by a polar and interactive cavity.

To mimic the situations (*1*), (*2*), and (*3*), three solvents or mixtures of solvents could be used. For case (*1*), pure dioxane was selected even though some interactions are possible by the use of the lone pairs of electrons located at the two oxygen atoms. However, it is the only suitable nonpolar solvent (dielectric constant 2.21) that is able to dissolve the SB, the acid, and the water without inducing a phase separation. In case (*2*), a mixture of 90% of chloroform and 10% of dioxane was used, whereas for (*3*), a mixture of 10% ethanol and 90% dioxane was used. In the last case, ethanol was chosen instead of the customary methanol because fluorescence, always a nuisance in Raman, is less intense in that solvent. A few combinations of solvents were also tested and will be mentioned in the text when necessary.

First, Raman spectra of unprotonated and protonated model SB were collected in dioxane, chloroform, and ethanol in the absence of water in order to characterize their spectroscopic behaviour. Spectra of the SB and differently protonated SB in chloroform are displayed in Fig. 1. As can be seen, they are dominated by the C=C double bond stretching mode ($\nu_{C=C}$) of the conjugated system centered at ca. 1624 cm^{-1} and the C=N double bond stretching mode of the imine link ($\nu_{C=N}$) located at ca. 1641 cm^{-1} when unprotonated. Following addition of any organic acids, the $\nu_{C=N}$ vibration gradually disappears and is replaced by the weak $C{=}N^+$ stretching mode ($\nu_{C=N^+}$) detected at ca. 1679 cm^{-1}. Simultaneously, the Raman intensity of the $\nu_{C=C}$ band is enhanced, while its frequency position remains almost unchanged. It should be noted that when protonated, the intensity of the $\nu_{C=C}$ mode of the PSB gains intensity because the energy of its electronic transition becomes more coinci-

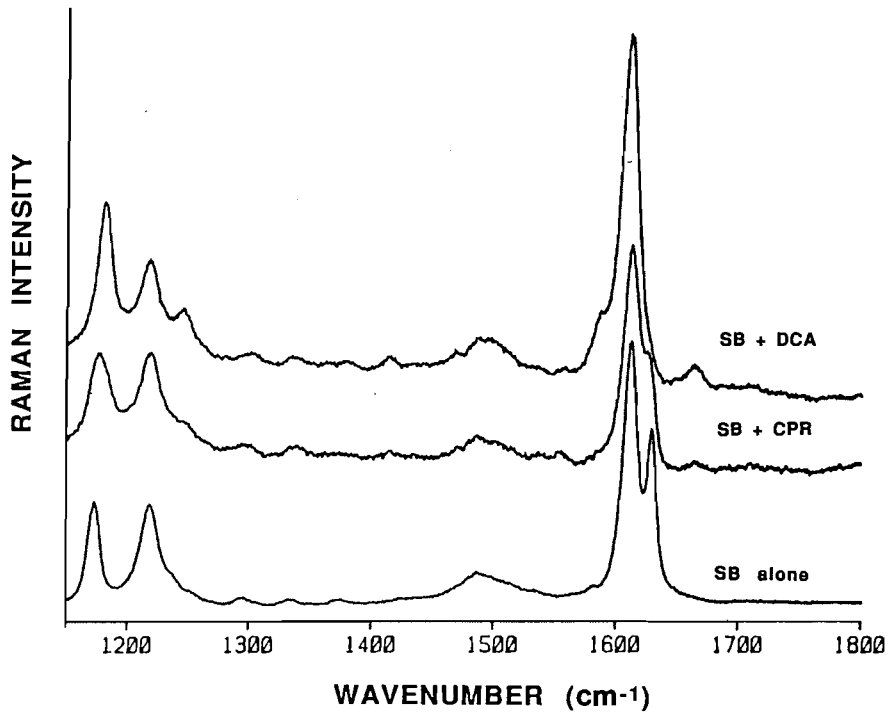

FIG. 1. Raman spectra of the SB (bottom trace) and of the SB complexed to organic acids (top traces) in chloroform excited with the 488 nm laser line at a concentration of 0.025 M.

TABLE 1. Percentages of protonation of several SB/acid systems in dioxane, chloroform, and ethanol

SB/acid	Dioxane (%)	Chloroform (%)	Ethanol (%)
SB/CPR	0–10	40–50	50–60
SB/MCA[a]	35–45	60–70	80–100
SB/DCA	50–60	80–90	100

[a]MCA stands for monochloroacetic acid.

dent with the energy of the 488 nm laser line, leading to a better preresonance Raman effect (viz. λ_{max} 308 nm for the PSB compared with λ_{max} 267 nm for the SB). This Raman regime also leaves the spectra of the complexes free of the contribution of the $\nu_{as\ COO^-}$-mode of the deprotonated organic acids, detected in the same spectral region. This makes the measurements of the percentage of protonation easily accessible and they are reported in Table 1 for chloroform, dioxane, and ethanol. The percentages of protonation have been calculated simply by measuring the peak heights of the $\nu_{C=N}$ of the SB that remains after protonation compared with the peak heights of the $\nu_{C=N}$ of the SB without the acid system, since all spectra have been obtained using the same concentration of the SB. This method is applicable as long as the $\nu_{C=N}$ band is visible, that is, for systems where the SB is moderately protonated. When protonation becomes large, the height of the $\nu_{C=N^+}$ band (at 1679 cm^{-1}) can be measured and compared with the height of this band for the fully protonated system. From Table 1, it can be seen that protonation increases with the strength of the acid used and the polarity of the solvent (dielectric constants of these three solvents are dioxane 2.21, chloroform 4.81, and ethanol 24.3). Maximum protonation occurs for DCA in ethanol, whereas the minimum is reached for CPR in dioxane. These results are comparable to those obtained by means of FT-IR for the same system in chloroform (23) and in methanol (24). Knowledge of the initial degree of protonation is important, as the reactions taking place following water addition are governed by its relative concentration compared with the one of either the PSB or the SB.

Addition of water

When water is added to the system, part of the protonated SB is destroyed and turned into its aldehyde form. The aldehyde (*trans,trans*-2,4-heptadienal) has two characteristic bands: the very intense $\nu_{C=C}$ at ca. 1637 cm^{-1} and the weaker $\nu_{C=O}$ at ca. 1681 cm^{-1}, which are unfortunately coincident with the $\nu_{C=N}$ band of SB (at 1641 cm^{-1}) and the $\nu_{C=N^+}$ band of PSB (at 1679 cm^{-1}), with the result that this study is less straightforward. The effect of the presence of the aldehyde in the SB spectrum can be seen in Fig. 2, corresponding to 30, 70, and 100% of hydrolysis. The spectra corresponding to 30 and 70% of hydrolysis are computerized versions using the pure SB and pure aldehyde spectra and correspond to the situations where respectively 30 and 70% of the SB would have been hydrolyzed. As can be seen, the intense $\nu_{C=C}$ of the dienal completely overlaps the $\nu_{C=N}$ of the SB. This deteriorates even more when the PSB is present, because then three products having almost the same Raman signature appear as shown experimentally in Fig. 3 for hydrated PSB and SB adducts in dioxane. As can be seen, the overlapping contribution from the aldehyde considerably alters the usual spectral response in the 1600–1700 cm^{-1} region. This makes it difficult to evaluate the percentage of protonation using the method quoted earlier, as well as the measurement of the extent of hydrolysis. It is not possible to solve this problem by substracting the alde-

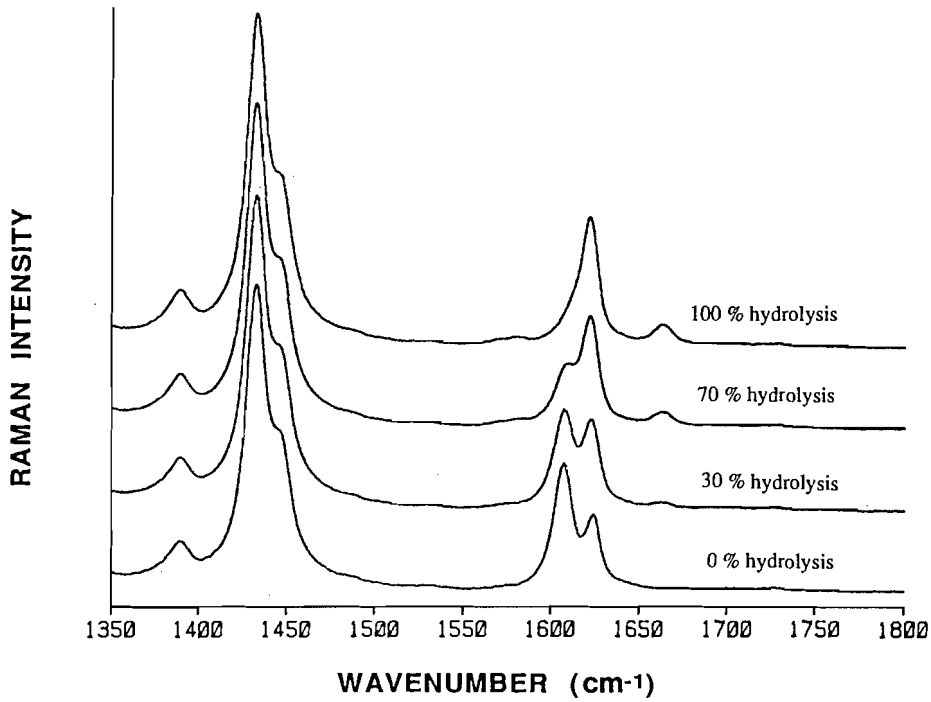

FIG. 2. Raman spectra of a 0.025 M dioxane solution of SB (bottom trace) and of a 0.025 M dioxane solution of its parent aldehyde (top trace) excited at 488 nm. Middle traces represent computer mixing of both spectra in various proportions as quoted (*vide infra*).

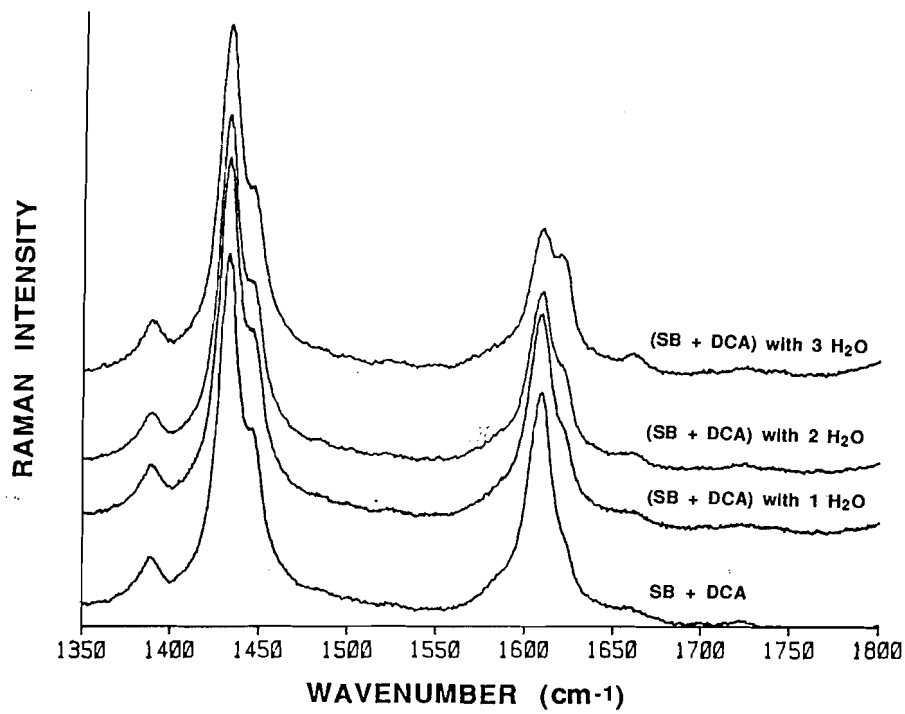

FIG. 3. Raman spectra of a 0.025 M solution of the SB complexed to dichloroacetic acid in the absence (bottom trace) and in the presence of water (top three traces) in dioxane (excitation wavelength 488 nm).

hyde contribution, firstly because all the aldehyde vibrations are coincident with either the SB or the PSB spectral response and secondly, because of a lack of an internal standard, an unmatched mass balance will result leading to a false estimation of the degree of protonation.

However, it is not necessary to monitor the exact changes in the degree of protonation of the SB in the presence of water; it is sufficient to have an indication of how the protonation state varies under the different conditions. Hence, the relative change in the percentage of protonation of the SB

TABLE 2. Calculation of the ratio R of an equimolar mixture of SB/acid in dioxane (0.025 M) in the presence of 0 to 4 times water compared with the initial concentration of SB

in the presence of water can be evaluated by considering the evolution of the different bands in the 1600–1700 cm^{-1} region. If protonation is favoured by water, the $\nu_{C=N}$ band at 1641 cm^{-1} will decrease, whereas the $\nu_{C=C}$ band at 1624 cm^{-1} will increase. Thus the intensity ratio of the $\nu_{C=C}$ band measured at 1624 cm^{-1} divided by the intensity of the $\nu_{C=N}$ at 1641 cm^{-1} will increase according to an increase of the degree of protonation. This ratio R can then be used as an indicator reflecting the protonation state of the SB. For 0% protonation, R ranges between 1.4 and 1.8, depending on the solvent, whereas for 100% protonation, R tends to infinity. However, when hydrolysis is present, R is directly affected since the dienal produced has its $\nu_{C=C}$ located at 1637 cm^{-1}, as previously described, and thus R is expected to decrease. This can be seen in Fig. 3 where four spectra of a SB/DCA in dioxane are shown. The first spectrum (bottom line) shows a band at ca. 1624 cm^{-1} and a shoulder at ca. 1641 cm^{-1}; the ratio R is 2.4, indicating that protonation is indeed present (R 2.4 compared with R 1.8 for 0% protonation). The other spectra relate to the addition of 1, 2, and 3 molecules of water. It shows that the 1620–1625 cm^{-1} band decreases whereas the ca. 1635 cm^{-1} band increases. R, measured always at 1624 and 1641 cm^{-1}, takes the value of 1.8, 1.6, and 1.3 respectively. This time, the denominator of R mostly represents the contribution (at 1641 cm^{-1}) of the $\nu_{C=C}$ of the dienal plus the contribution of the $\nu_{C=N}$ of the SB. The Raman signal deriving from the bending mode of water can also be detected in this same region, but its contribution is negligeable because, at the concentration range used, its signal is very weak. Thus R does not reflect the exact degree of protonation because of the presence of the aldehyde formed after hydrolysis. However, if an x% protonation of the SB is followed by the same x% hydrolysis, R can again be used by utilizing an experimentally derived equation (3):

$$[3] \quad \% \text{ of protonation} = \% \text{ of hydrolysis} = 114.0 - 70.4R$$

As an example, for R = 1.62, eq. (3) gives 0% hydrolysis; for R 0.2, a 100% hydrolysis. Therefore after water addition, if the value R corresponds to the initial percentage of protonation, then it means that water does not promote protonation. Table 2 reports the results obtained in dioxane using 0 to 4 molecules of water and Tables 3 and 4 refer respectively to chloroform–dioxane (9:1) and ethanol–dioxane (1:9) solvents.

In all three cases, as can be seen in Tables 2–4, results show that the heptadienylidene Schiff base without acids, but in the presence of water, is quite stable (R does not vary).

For 3-chloropropionic acid, a weak acid, Table 2 shows that R is very slightly different from the "standard" value (R 1.8), indicating that protonation, if any, is very small and that water molecules have, at the most, a very weak effect in promoting protonation in dioxane. With DCA, protonation is higher (R 2.4) and water molecules affect R directly (from 2.4 to 0.9). Using eq. [3], in the case of four molecules of water, the degree of protonation reaches around 50%, which corresponds to the initial degree of protonation, thus indicating that water has no effect in promoting protonation. In the time span of the experiments (some 10 min for each spectrum), these results indicate that it takes four molecules of water to cause the complete hydrolysis of one molecule of the protonated Schiff base.

In a chloroform–dioxane (9:1) mixture, CPR is more effective as a protonating agent (R 1.8 compared with 1.4). With water, R reaches only 1.6 (from 1.8), indicating that in the time span of the experiments water has almost no effect. For DCA, in the absence of water, R reaches 3.6, indicating some 80–90% protonation and showing that chloroform favors more protonation than dioxane (50–60%). Again, with water present, R drops only slightly from 3.5 to 2.8. For a protonation of 80% followed by complete hydrolysis, R should reach ca. 0.48 (as calculated using eq. [3]) instead of 2.8. From Table 3 then, it must be concluded that chloroform is rather effective in shielding the PSB from water and only a small fraction of the molecules of water can hydrolyze the PSB. Chloroform is known to cause the formation of tight ion-pairs (thus favoring protonation) and this has been described before (20, 24). Finally, the ratio of chloroform to dioxane was varied from 1:1 to 1:9 and the same results were obtained, that is, R was identical or greater than R obtained in pure dioxane.

In an ethanol–dioxane (1:9) mixture, only DCA was used. Table 4 shows that DCA gives only 60–70% protonation (R

2.9), that is, more than in dioxane (R 2.4) and less than in chloroform–dioxane (R 3.6). Other ratios of ethanol and dioxane were tested. Usually R increased with an increase in the ratio of ethanol to dioxane. Unfortunately, severe experimental limitations exist in this case because of the unavoidable fluorescence background present with alcoholic solutions. Upon water addition, R remains constant, meaning that the system is chemically stable: no hydrolysis is occurring as well as no additional protonation. This is quite different from the results obtained in pure dioxane where hydrolysis readily occurred. In fact, hydrolysis became important in this ethanol–dioxane mixture only when the concentration of water was at least 1% v/v water/solvent. The presence of ethanol promotes protonation when compared with dioxane alone and prevents hydrolysis. This means that some ethanol molecules lie close to the imine function and interact with the SB and the acid probably through hydrogen bonding, helping protonation to occur. Also, other ethanol molecules must interact with water, again through hydrogen bonding, and this time preventing water from diffusing near the protonated Schiff base.

This is not too surprising when one considers the action that water has when interacting either with dioxane or ethanol. Cennamo and Tartaglione (31) have studied by X-ray spectroscopy the behavior of water mixed with either dioxane or ethanol. In that work, they show that whatever the concentrations of water used, its structure is different from one solvent to the other. This can also be seen by examining the Raman spectra of mixtures of water–ethanol and water–dioxane. Figure 4 shows the spectrum obtained with a mixture of water–dioxane in a ratio of 1:9 (curve 1). This must be compared with the spectrum of pure water (also shown, curve 2). Dioxane is then seen to disturb greatly the structure of water with an enhancement of the 3420 cm^{-1} band relative to the 3260 cm^{-1} band. This is well documented and is assigned to a decrease of the in-phase intermolecular coupling of the OH oscillators (ref. 32 and references therein). It is believed that in such cases water is dispatched into micro domains. The spectrum of a 1:10 water–ethanol mixture is quite different from that obtained with a 1:10 water–dioxane mixture. The water vibrations in this region are again perturbed but the variation of the 3420 and 3260 cm^{-1} band system is less pronounced. However, in the case of the water–ethanol mixture, the analysis becomes more complex because of the presence of the stretching vibration mode of OH of the alcohol. Some information can be found in the region of the OH bending mode which appears in the 1600–1700 cm^{-1} region. For pure water, in the IR spectrum (this signal is too weak in the Raman spectrum), the band appears at ca. 1645 cm^{-1}. In a water–ethanol mixture (1:10), the band is at ca. 1656 cm^{-1} whereas for a 1:10 water–dioxane mixture, it is at ca. 1648 cm^{-1}. The 1648 cm^{-1} band being close to the 1645 cm^{-1} band implies that water molecules prefer to associate with themselves in dioxane in the same way they do in pure water, whereas in ethanol water molecules are seen to associate with molecules of ethanol, creating stronger H bonds; it must be noted that H bonding tends to increase the vibration frequency of a bending mode. This being so, the results obtained in dioxane and in an ethanol–dioxane mixture are perfectly understandable. Hydrolysis of the PSB is fast in dioxane since water does not associate with it and is very slow in ethanol–dioxane because water associates itself to ethanol and in doing so does not reach the PSB easily.

If we now look globally to the three systems, the addition of water does not seem to promote protonation. Of course, the water content is quite low compared with the solvents, but nevertheless it indicates that water is not attracted by the PSB/counterion system and hence plays no role.

These results also demonstrate that the protection of a

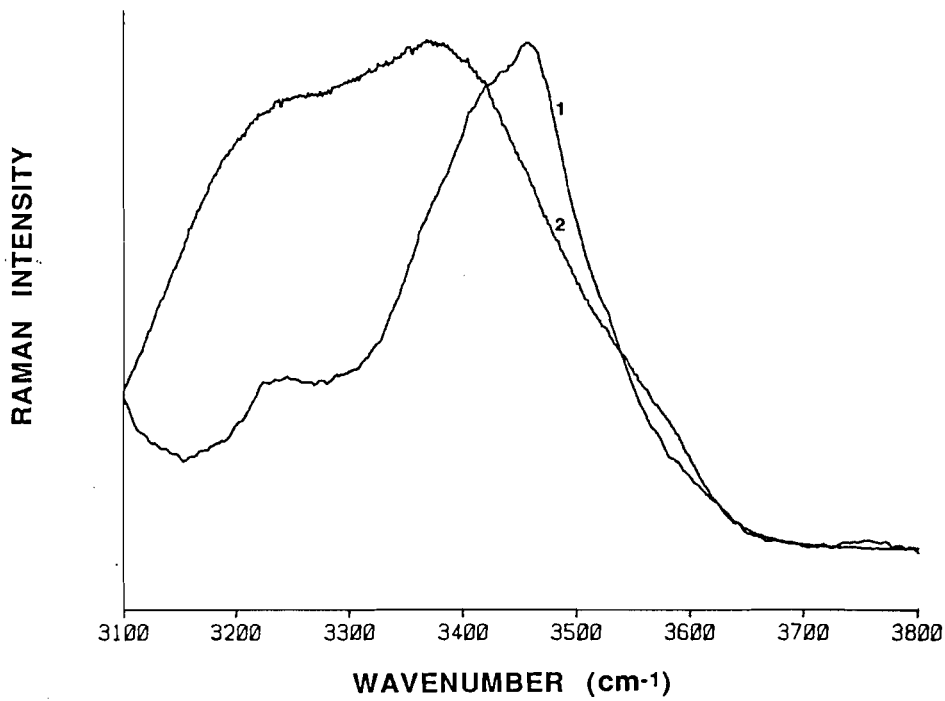

FIG. 4. Raman spectra of a 10:90 mixture of water in dioxane (1) and of neat water (2) in the region 3100–3800 cm^{-1} (excitation wavelength 488 nm).

protonated Schiff base from hydrolysis is assured by a protic medium and this protection is greater as the dielectric constant of the medium is large.

Our system has been devised to shed some light on how water molecules could react with the chromophore in the host cavity. It is evident that this model is quite different from the protein; dioxane, chloroform, and ethanol cannot mimic the protein moiety as such. However, the polarity of the cavity hosting the Schiff base portion of the chromophore is not known. Recently, the protonating agent has been found. It is Glu-113 (15), a rather weak acid which, as we have shown in the past (22–25), is unlikely to protonate fully the Schiff base chromophore unless some stabilizing factors are also present in the protein. Furthermore, water molecules are now known to be present near the chromophore (9, 10) and only very recently (33) their possible role in protonation has been advocated, much in the same way as we have predicted in the past. The present model, given all its shortcomings, can nevertheless show, we believe, some interesting inferences. In particular, our results indicate that the host cavity lodging the protonated Schiff base in the pigments could possibly be rich in groups that will be able to form an extensive hydrogen-bond network so as to offer a propitious environment for protonation. That is, the environment would stabilize the PSB, its counterion, and the water molecules. These groups could be Tyr, Ser, His, Glu, Asp, Arg and they could act in a fashion similar as the one found by Khorana *et al.* (14, 15) in bacteriodopsin where protonation of the SB seems to be due to the combined action of three amino acids. At different stages, especially for metarhodopsin II, it is possible to invoke the fact that the environment surrounding the chromophore could change from a protic medium to an aprotic one, thus liberating the water molecules that can now hydrolyze the Schiff base.

An efficient and general synthesis of alkyl alkynyl sulfoxides

SIDIMA T. KABANYANE AND DAVID I. MAGEE[1]
Department of Chemistry, University of New Brunswick, Bag Service No. 45222, Fredericton, N. B., Canada E3B 6E2

Received March 31, 1992

SIDIMA T. KABANYANE and DAVID I. MAGEE. Can. J. Chem. **70**, 2758 (1992).

A convenient one-step method for the preparation of alkynyl phenyl sulfides using diphenyl disulfide has been developed. The oxidation of the corresponding sulfides to the sulfoxides, and not sulfones, was achieved by using *trans*-(phenylsulfonyl)-3-phenyloxaziridine. A variety of other oxidizing reagents was also investigated.

SIDIMA T. KABANYANE et DAVID I. MAGEE. Can. J. Chem. **70**, 2758 (1992).

On a mis au point une méthode de préparation simple qui conduit en une étape du disulfure de diphényle aux sulfures d'alkynyle et de phényle. On a réalisé l'oxydation des sulfures en sulfoxydes correspondants — et non pas en sulfones — en utilisant de la *trans*-(phenylsulfonyl)-3-phényloxaziridine. On a aussi examiné une série d'autres agents d'oxydation.

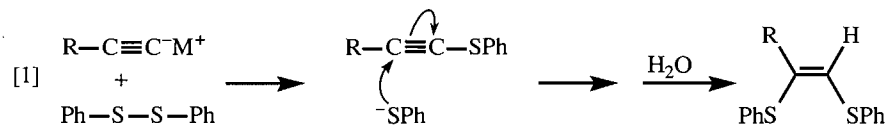
[Traduit par la rédaction]

Introduction

In the course of our studies on the chemistry of acetylenic sulfoxides, the development of a general, high-yielding method for their preparation became necessary. A survey of the literature showed numerous methods for the preparation of acetylenic sulfides that, in turn, were oxidized to the required sulfoxides: dehydrohalogenation of olefinic compounds (1), elimination of mercaptans (2), isomerization with migration of multiple bonds (3), and the reaction of metal acetylides on alkyl or phenyl sulfenyl halides and thiosulfinates (4). The only direct method involved the reaction of an alkynyl anion with sulfinate esters (5). However, for our purposes these methods proved to be either low yielding, or incompatible with another functionality in our system. As a result of these difficulties, we investigated other means of synthesizing these compounds that would not only serve our purposes, but be of general utility.

Results and discussion

Our first attempt was the reaction of an acetylide anion with diphenyl disulfide; however, the sole product observed (85% yield) was a bis-sulfide (eq. [1]). The structural geometry of this compound was supported by a 5.5% nOe between the olefinic proton and the allylic methylene. This product, we believe, arose from nucleophilic attack of the lithium thiophenolate generated during the course of the reaction upon the acetylenic sulfide. This mechanism was further corroborated by the fact that treatment of pure acetylenic sulfide, synthesized via a different procedure, with lithium thiophenolate under identical reaction conditions gave the same bis-sulfide product. This result is not without precedent (4). Alkyl cuprates (6), sodium stannanes (7), trialkyl phosphites (8), tertiary amines (9), and a variety of other reagents (10) all undergo nucleophilic additions to this class of compounds as well. It then became quite evident that a successful approach required an efficient removal of the unwanted lithium thiophenolate.



[1]

The conversion of sulfur compounds to stable sulfonium ions via S-alkylation is a well-known biological and chemical process used for the activation of certain centers towards nucleophilic addition. It occurred to us that we may utilize this property of sulfur for our purposes in the following way. Pretreatment of the disulfide with one equivalent of methyl iodide would generate the S-alkylated product that, in turn, should yield only the desired product and methyl phenyl sulfide on treatment with an alkynyl anion (path a, eq. [2]).

As a test of this hypothesis we treated diphenyl disulfide with methyl iodide in tetrahydrofuran (THF) at room temperature for 1 h, followed by cooling to −78°C and addition of the lithium alkynyl anion generated from MEM-protected propargyl alcohol. *As predicted, the crude ^{1}H NMR spectrum revealed only the alkynyl phenyl and methyl phenyl sulfides after a normal work-up procedure.* Silica gel chromatography provided the desired compound in 87% yield. Clearly methyl iodide was beneficial, but was its role as postulated (path a, eq. [2]), or simply as an efficient thiophenolate trap (path b, eq. [2])? We favor the latter explanation for the following reasons: (1) separate, simultaneous addition of methyl iodide and diphenyl disulfide to the alkynyl anion gave the same result as the premixed solution, and (2) ^{1}H NMR analysis of the premixed solution over various periods of time (i.e., 5 min – 1 h) showed no evidence of any intermediates.

Encouraged by this result, we investigated its generality and our results are presented in Table 1. As can be seen from the table, a variety of functional groups tolerate the reaction conditions. Notable examples are entries 2 and 4 where the phenyl sulfenyl group was only incorporated at the alkyne.

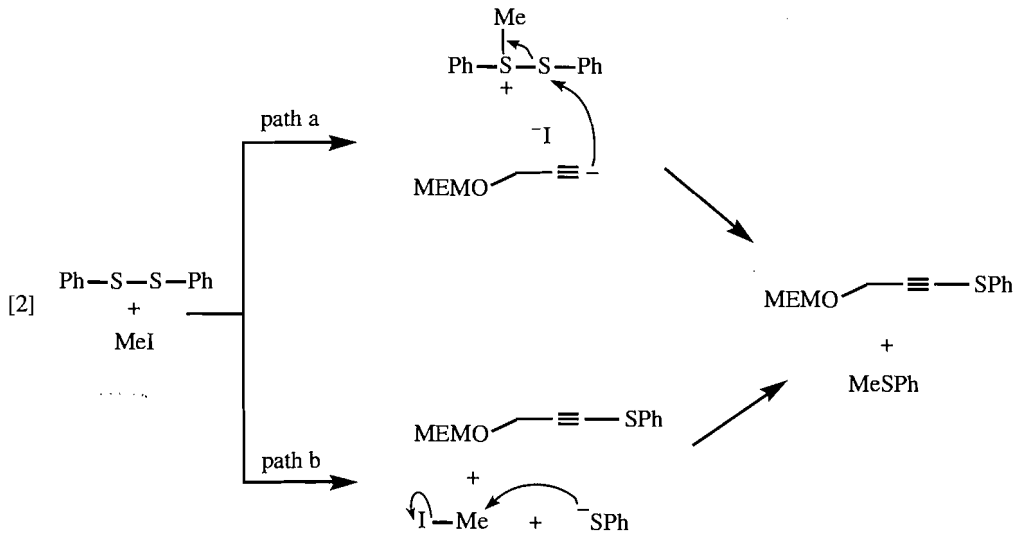
[a]All new compounds gave satisfactory ^1H NMR, IR, and high-resolution mass spectra.



With the preparation of the sulfides in hand, the only task remaining was their oxidation to the corresponding sulfoxides. We anticipated no particular problems since there is ample literature precedent for performing this transformation (11). However, we decided to undertake a more rigorous investigation since the oxidation of sulfides to sulfoxides, and not sulfones, can be rather troublesome. The reagents chosen were the standard oxidants *m*CPBA, Oxone® (12), and sodium periodiate ($NaIO_4$) (13), as well as the recently introduced Davis reagent, *trans*-2-(phenylsulfonyl)-3-phenyloxaziridine (14). Our results are presented in Table 2.

Unexpectedly, neither phenylsulfonyloxaziridine nor $NaIO_4$ showed any reactivity towards the sulfides under normal oxidation conditions, even after extended periods of time (24 h at room temperature). Both of these reagents are known to oxidize alkyl and phenyl sulfides very readily and, in the case of oxaziridine, very cleanly and rapidly (14*a*). This result suggests that the alkyne plays a pivotal role in decreasing the nucleophilicity of the sulfur atom and thus its

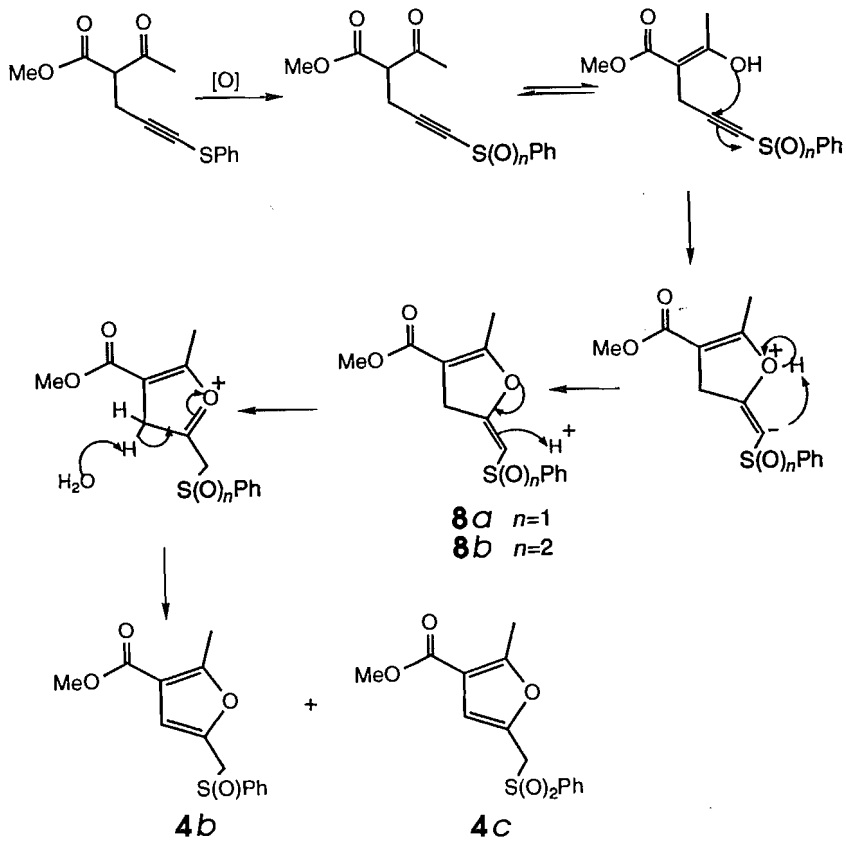
susceptibility towards oxidation. The reason for this reduced reactivity is not readily apparent. While one can argue that a sulfur lone pair may be delocalized into the π orbitals of the alkyne, Davis *et al.* showed that diphenyl sulfide oxidizes instantaneously at 0°C with oxaziridine (14*a*). The neighbouring acetylene thus exerts a very specific deactivating effect.

We were, however, pleased to find that reactions with the Davis reagent at 60°C provided the desired products in high yields, Table 2. *In all cases attempted, no overoxidation was observed.* Surprisingly, olefin **6** showed no reaction of the double bond even though these are the conditions reported for epoxidation (14*b*). This method of oxidation solves the dilemma that we encountered with the use of *m*CPBA and (or) Oxone®. Although uniformly good yields of oxidized products were obtained, there was difficulty in achieving complete specificity (contrast the results for compound **1***a* with those for **4***a* and **5***a*, Table 2).

The oxidation of compound **4**, under any of the conditions, gave a more complicated result, which could prove of use for the synthesis of highly substituted furans. Treatment of **4** with oxaziridine gave, as expected, a sulfoxide, but spectroscopic investigations (i.e., $^1H-^1H$ decoupling, ^{13}C NMR, low-resolution MS, UV, IR) revealed the structure to be the vinyl ether **8***a*, Scheme 1. This product presumably arises by enolization of the β-keto ester, followed by Michael addition of the oxygen atom onto the acetylenic sulfoxide. Acid-catalyzed isomerization (*p*TSA, MeOH) of the exocyclic double bond cleanly furnished furan **4***b*, Scheme 1.

Since it was clear that an acid source was required to induce isomerization, we felt that treatment of acetoacetate **4***a* with either *m*CPBA or Oxone® should produce the furans directly. In the case of Oxone®, furan **4***b* could be obtained directly (see Table 2). However, the reaction could be intercepted to give compound **8***a*, the same vinyl ether as in the oxaziridine oxidation. *m*CPBA, as shown in Table 2, gave only compounds **8***a* and **8***b*, with the sulfone product predominating. Both of these products, when treated with *p*-



SCHEME 1

toluenesulfonic acid in methanol, isomerized to give furans **4***b* and **4***c*.

In conclusion, we have demonstrated that alkynyl sulfides can be prepared in generally high yields by treating a premixed solution of diphenyl disulfide and methyl iodide with various lithium alkynyl anions. The sulfides can then be oxidized exclusively to their sulfoxides by *trans*-2-(phenylsulfonyl)-3-phenyloxaziridine. Other oxidants such as *m*CPBA or Oxone® are also effective but, in some instances, mixtures or sulfones predominate. Further studies in this area, including the potential use of the resulting alkynyl sulfoxides (and sulfones) for intra- and intermolecular nucleophilic additions, are currently being pursued.

Experimental

All commercial reagents were purchased from Aldrich Chemicals (Milwaukee) and used without any further purification. Reaction solvents were dried according to established procedures (15). All reactions were performed in oven-dried glassware (120°C) under an atmosphere of nitrogen unless otherwise stated. Reaction temperatures refer to external baths.

Column chromatography was carried out according to the procedure of Still *et al.* (16), using Merck silica gel (230–400 mesh). Thin-layer chromatographic analyses were performed on Merck F_{254} 0.25 mm plates. Infrared (IR) spectra were recorded on a Bruker IFS25 FTIR and are reported in wave numbers (cm^{-1}). Low- and high-resolution mass spectra were measured on a Kratos MS50TC. All nuclear magnetic resonance (NMR) spectra were recorded on an XL200 (200 MHz) spectrometer with chemical shifts reported in ppm (δ) with tetramethylsilane as an internal standard. All coupling constants (J) are reported in Hz. Ultraviolet (UV) spectra were recorded on a Beckmann model 25 spectrometer with 4.5 mL capacity quartz cuvets and 95% ethanol as solvent.

General method for alkynyl sulfide preparation: 3-(methoxyethoxymethyl)-1-propynyl phenyl sulfide **1***a*

A solution of 3-(2-methoxyethoxymethyl)-1-propynyl ether (250 mg, 2.2 mmol) in 5 mL THF was cooled to −78°C. To this was added *n*-butyllithium (1.4 mL, 2.2 mmol) and the reaction was stirred for 30 min. A premixed solution (1 h at RT) of diphenyl disulfide (480 mg, 2.2 mmol) and methyl iodide (0.14 mL, 2.2 mmol) in THF (8 mL) was then added dropwise, and was stirred for 1 h at room temperature. It was then quenched with 20 mL of dilute aqueous NH_4Cl solution and extracted with diethyl ether (2 portions). The organic phase was dried with magnesium sulfate ($MgSO_4$) and concentrated *in vacuo*. The crude product was purified by SiO_2 chromatography (3:1 hexane:EtOAc) to give sulfide **1***a* (384 mg, 87%) as a colorless oil. IR (neat) cm^{-1}: 3075 (s), 2929 (s), 2183 (s), 1583 (s), 849 (s); ^1H NMR ($CDCl_3$) δ: 7.35 (m, 5H), 4.82 (s, 2H), 4.46 (s, 2H), 3.70 (t, 2H, J = 3.9), 3.55 (t, 2H, J = 3.9), 3.37 (s, 2H); HRMS: m^+/z_{obs} = 252.0814 (m^+/z_{calc} = 25.0821).

3-Hydroxy-1-propynyl phenyl sulfide **2**a

A solution of proparyl alcohol (200 mg, 3.5 mmol) and THF (10 mL) was cooled to −30°C. *n*-Butyllithium (4.7 mL, 7.5 mmol) was added dropwise and the reaction was stirred for 30 min. A premixed solution (1 h, RT) of diphenyl disulfide (785 mg, 3.6 mmol) and methyl iodide (0.3 mL, 3.8 mmol) in THF (5 mL) was then added dropwise. The reaction mixture was allowed to warm to room temperature and stir for 1 h. Aqueous work-up followed by SiO_2 chromatography (3:1 hexane:EtOAc) afforded sulfide **2***a* (530 mg, 90%) as a colorless oil. IR (neat) cm^{-1}: 3371 (b), 3020 (s), 2919 (s), 2186 (s), 1583 (s), 678 (s); ^1H NMR ($CDCl_3$) δ: 7.33 (m, 5H), 4.48 (s, 2H); HRMS: m^+/z_{obs} = 164.0296 (m^+/z_{calc} = 164.0296).

1-Nonynyl phenyl sulfide **3**a

1-Nonyne (200 mg, 1.6 mmol) was treated as described in the general procedure. SiO_2 chromatography (20:1 hexane:EtOAc) afforded sulfide **3***a* (252 mg, 68%) as a colorless oil. IR (neat) cm^{-1}: 3131 (w), 2927 (s), 2359 (w), 1583 (s); ^1H NMR ($CDCl_3$) δ: 7.26 (m, 5H), 2.48 (t, 2H, J = 6.7), 1.60 (m, 2H), 1.35 (m, 8H), 0.88 (t, 3H, J = 6.7); HRMS: m^+/z_{obs} = 232.1284 (m^+/z_{calc} = 232.1286).

Methyl-2-acyl-5-phenylthio-pentynoate **4**a

A suspension of sodium hydride (83.6 mg, 2.1 mmol) in THF (20 mL) was cooled to 0°C. To this was added β-keto acetylene **4** (300 mg, 1.9 mmol) in THF (5 mL). After complete addition and stirring for 10 min, the temperature was lowered to −30°C and *n*-butyllithium (1.3 mL, 2.1 mmol) was added dropwise. Stirring was continued for 30 min at this temperature. A premixed solution (1 h, RT) of diphenyl disulfide (414 mg, 1.9 mmol) and methyl iodide (0.14 mL, 2.3 mmol) in THF (5 mL) was added dropwise. The reaction mixture was stirred for 1 h at room temperature. Aqueous work-up followed by purification on SiO_2 chromatography (3:1 hexane:EtOAc) gave sulfide **4***a* (413 mg, 81%) as a colorless oil. IR (neat) cm^{-1}: 3063 (m), 2189 (w), 1744 (s), 1719 (s), 1583 (m); ^1H NMR ($CDCl_3$) δ: 7.32 (m, 5H), 3.75 (t, 1H, J = 7.5), 3.75 (s, 3H), 2.98 (d, 2H, J = 7.5), 2.29 (s, 3H); HRMS: m^+/z_{obs} = 262.0654 (m^+/z_{calc} = 262.0644).

4-(Methoxymethoxymethyl)-5-(1,3-dioxolane)-1-hexynyl phenyl sulfide **5**a

MOM-(1,3-dioxolane)-1-hexyne (300 mg, 1.4 mmol) was treated as described in the general procedure. Purification by SiO_2 chromatography (3:1 hexane:EtOAc) afforded sulfide **5***a* (374 mg, 83%) as a colorless oil. IR (neat) cm^{-1}: 3073 (m), 2984 (s), 2201 (w), 1583 (s), 1441 (m), 899 (s); ^1H NMR ($CDCl_3$) δ: 7.28 (m, 5H), 4.63 (s, 2H), 3.94 (m, 4H), 3.76 (dd, 2H, J = 6.0, J = 2.2), 3.35 (s, 3H), 2.73 (dd, 2H, J = 6.0, J = 2.2), 2.11 (m, 1H), 1.34 (s, 3H); HRMS: m^+/z_{obs} = 322.1245 (m^+/z_{calc} = 322.1239).

*4-*n*-Butoxymethyl-5-ethylene-1-hexynyl phenyl sulfide* **6**a

The corresponding alkyne (200 mg, 1.11 mmol) was treated as described in the general procedure. Chromatography on SiO_2 (3:1 hexane:EtOAc) afforded sulfide **6***a* (229 mg, 72%) as a colorless oil. IR (neat) cm^{-1}: 3087 (m), 2998 (s), 2929 (s), 2203 (w), 1648 (m), 1584 (m), 1449 (m); ^1H NMR ($CDCl_3$) δ: 7.30 (m, 5H), 4.91 (p, 1H, J = 1.5), 4.85 (p, J = 1.5), 3.48 (m, 4H), 2.65 (m, 3H), 1.77 (bs, 3H), 1.50 (m, 5H), 0.91 (t, 3H, J = 8.2); HRMS: m^+/z_{obs} = 288.1561 (m^+/z_{calc} = 288.1598).

3-Tetrahydropyranoxyl-1-propynyl phenyl sulfide **7**a

The corresponding alkyne (200 mg, 1.42 mmol) was treated as described in the general procedure. Chromatography on SiO_2 (20:1 hexane:EtOAc) gave sulfide **7***a* (318 mg, 90%) as a colorless oil. IR (neat) cm^{-1}: 3060 (m), 3005 (s), 2739 (s), 2136 (m), 1583 (s), 1441 (s); ^1H NMR ($CDCl_3$) δ: 7.29 (m, 5H), 4.87 (t, 1H, J = 3.1), 4.50 (s, 2H), 3.85 (m, 1H), 3.65 (m, 1H), 1.71 (m, 6H); HRMS: m^+/z_{obs} = 248.0864 (m^+/z_{calc} = 248.0871).

3-(Methoxyethoxymethyl)propynyl phenyl sulfoxide **1**b

General method 1

To a stirred solution of sulfide **1***a* (100 mg, 0.39 mmol) in methylene chloride (10 mL) at 0°C was added a solution of *m*-chloroperoxybenzoic acid (82 mg, 0.47 mmol) in methylene chloride (5 mL). The solution was stirred for 1 h at 0°C, added to 20 mL of $NaHCO_3$ solution, shaken, and separated into two layers. The aqueous layer was extracted with methylene chloride (2 portions) and the combined extracts washed with brine. The organic phase was dried with $MgSO_4$ and the solvent evaporated under reduced pressure. The crude product was purified by SiO_2 chromatography (3:1 hexane:EtOAc) to afford sulfoxide **1***b* (100 mg, 96%) as a colorless oil. IR (neat) cm^{-1}: 2926 (s), 2184 (m), 1445 (m), 1200 (b); UV λ_{max}: 226 (ϵ_{max} 6400); ^1H NMR ($CDCl_3$) δ: 7.75 (m, 2H), 7.53 (m, 3H), 4.72 (s, 2H), 4.39 (s, 2H), 3.34 (s, 3H); HRMS: $(m^+/z - CH_3OCH_2CH_2O)_{obs}$ = 209.0269 ($(m^+/z - CH_3OCH_2CH_2O)_{calc}$ = 209.0273).

3-Hydroxy-1-propynyl phenyl sulfoxide **2**b *and sulfone* **2**c

General method 2

Oxone® ($2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$, 132 mg, 0.44 mmol of $KHSO_5$) in water (4 mL) was added to a solution of sulfide **2***a* (60 mg, 0.36 mmol) in methanol (4 mL) at 0°C with vigorous stirring. A white precipitate formed immediately. The reaction mixture was allowed to warm to room temperature and was stirred until TLC showed complete disappearance of starting material. The solvent was removed *in vacuo* and the mixture was extracted with chloroform (3 portions). The organic phase was washed with water (10 mL) and brine (10 mL) and dried with $MgSO_4$. The solvent was removed and the crude product purified by SiO_2 chromatography (1:3 hexane:EtOAc) to give 45 mg (68%) of sulfoxide **2***b* and 5 mg of sulfone **2***c* as colorless oils.

2*b*: IR (neat) cm^{-1}: 3372 (b), 2182 (s), 1445 (s), 1048 (s); UV λ_{max}: 223 (ϵ_{max} 9300); ^1H NMR ($CDCl_3$) δ: 7.75 (m, 2H), 7.50 (m, 3H), 4.39 (s, 2H); HRMS: m^+/z_{obs} = 180.0234 (m^+/z_{calc} = 180.0245).

2*c*: IR (neat) cm^{-1}: 3296 (b), 3066 (s), 2957 (s), 2203 (s), 1312 (s); UV λ_{max}: 224 (ϵ_{max} 8100); ^1H NMR ($CDCl_3$) δ: 8.00 (m, 8H), 7.60 (m, 3H), 4.41 (s, 2H), 1.9 (bs, 1H); HRMS: m^+/z_{obs} = 196.0189 (m^+/z_{calc} = 196.0194).

1-Nonynyl phenyl sulfoxide **3**b

Oxidation of sulfide **3***a* according to general procedure 2 and purification on SiO_2 (3:1 hexane:EtOAc) gave sulfoxide **3***b* (96%) as a colorless oil. IR (neat) cm^{-1}: 3060 (s), 2953 (s), 2180 (s), 1457 (s); UV λ_{max}: 226 (ϵ_{max} 9200); ^1H NMR ($CDCl_3$) δ: 7.79 (m, 2H), 7.54 (m, 3H), 2.42 (t, 2H, J = 9.7), 1.53 (m, 2H), 1.25 (m, 8H), 0.87 (t, 3H, J = 5.9); HRMS: $(m^+/z + H)_{obs}$ = 249.1244 ($(m^+/z + H)_{calc}$ = 249.1250).

Methyl-(2-phenylthiomethyl sulfoxide)-5-methyl-furanoate **4**b *and methyl-(2-phenylthiomethyl sulfone)-5-methyl-furanoate* **4**c

General method 3

A solution of sulfide **4***a* (50 mg, 0.19 mmol) and *trans*-2-(phenylsulfonyl)-3-phenyloxaziridine (65 mg, 0.25 mmol) in 5 mL of chloroform was refluxed (60°C) for 3 h. The reaction mixture was then cooled and the solvent was removed *in vacuo*. The residue was purified by SiO_2 chromatography (1:1 hexane:EtOAc) to afford 30 mg of sulfoxide **8***a* (57%) as a colorless oil.

Sulfoxide **8***a* was then dissolved in 2 mL of MeOH and a catalytic amount of *p*-toluenesulfonic acid was added. The mixture was stirred at room temperature for 12 h and then diluted with 10 mL of water and extracted with ether (3 × 20 mL). The combined organic phases were dried ($MgSO_4$), filtered, and the solvent was evaporated under reduced pressure to furnish 30 mg of sulfoxide **4***b* (100%) as a colorless oil.

8*a*: IR (neat) cm^{-1}: 3057 (m), 2956 (s), 1717 (s), 1652 (s), 1049 (s); UV λ_{max}: 271 (ϵ_{max} 20 000); ^1H NMR ($CDCl_3$) δ: 7.66 (m, 2H), 7.51 (m, 3H), 5.63 (t, 1H, J = 2.3), 3.76 (s, 3H), 3.71 (dt, 2H, J = 2.2, J = 2.3), 2.41 (t, 3H, J = 2.2); MS (relative intensity): 246 (m^+ − 32, 2), 153 (100), 125 (7), 77 (8).

4*b*: IR (neat) cm^{-1}: 2986 (s), 1717 (s), 1615 (s), 1447 (s), 1052 (s), 636 (s); UV λ_{max}: 244 (ϵ_{max} 12 400); ^1H NMR ($CDCl_3$) δ: 7.49 (s, 5H), 6.43 (s, 1H), 4.00 (d, 2H, J = 6.4), 3.78 (s, 3H), 2.43 (s, 3H); HRMS: $(m^+/z - C_6H_5SO)_{obs}$ = 153.0560 ($(m^+/z - C_6H_5SO)_{calc}$ = 153.0552).

Oxidation of sulfide **4***a* according to general procedure 1 gave sulfone **8***b* (70%) as a colorless oil. Acid-catalyzed isomerization as above followed by SiO_2 chromatography (1:1 hexane:EtOAc) yielded furan sulfone **4***c* (100%) as a colorless oil.

8*b*: IR (neat) cm^{-1}: 3033 (s), 2950 (s), 1720 (s), 1651 (s), 1325

(s); ^{1}H NMR ($CDCl_3$) δ: 8.10 (m, 2H), 7.66 (m, 3H), 5.31 (s, 1H), 3.74 (s, 3H), 3.72 (s, 2H), 2.28 (s, 3H).

4*c*: IR (neat) cm^{-1}: 2988 (m), 1719 (s), 1647 (s), 1447 (s), 1324 (s), 1178 (m); UV λ_{max}: 226 (ϵ_{max} 12 900); ^{1}H NMR ($CDCl_3$) δ: 7.66 (m, 5H), 6.52 (s, 1H), 4.34 (s, 2H), 3.79 (s, 3H), 2.42 (s, 3H); HRMS: m^+/z_{obs} = 294.0571 (m^+/z_{calc} = 294.0562).

5-(1,3-Dioxolane)-4-methoxymethoxymethyl-1-hexynyl phenyl sulfoxide **5**b *and sulfone* **5**c

Oxidation of sulfide **5***a* according to general procedure 1, followed by SiO_2 chromatography (3:1 hexane:EtOAc), furnished sulfoxide **5***b* and sulfone **5***c* (78%, 7:1 ratio) as colorless oils.

5*b*: IR (neat) cm^{-1}: 3058 (s), 2984 (s), 2182 (s), 1048 (s), 896 (s); UV λ_{max}: 227 (ϵ_{max} 5200); ^{1}H NMR ($CDCl_3$) δ: 7.80 (m, 2H), 7.53 (m, 3H), 4.56 (d, 2H, J = 2.9), 3.90 (m, 4H), 3.64 (m, 2H), 3.28 and 3.27 (s, 3H, -OMe diastereoisomers), 2.70 (d, 2H, J = 6.5), 2.13 (m, 1H), 1.28 (s, 3H); HRMS: $(m^+/z - CH_3OCH_2O)_{obs}$ = 277.0896 ($(m^+/z - CH_3OCH_2O)_{calc}$ = 277.0899).

5*c*: IR (neat) cm^{-1}: 3016 (m), 2923 (s), 2202 (s), 1310 (s), 1111 (s); UV λ_{max}: 237 (ϵ_{max} 5300); ^{1}H NMR ($CDCl_3$) δ: 7.96 (m, 2H), 7.54 (m, 3H), 4.51 (s, 2H), 3.87 (m, 4H), 3.60 (m, 2H), 3.27 (s, 3H), 2.62 (d, 2H, J = 6.3), 2.10 (m, 1H), 1.22 (s, 3H); HRMS: $(m^+/z - CH_3)_{obs}$ = 339.0912 ($(m^+/z - CH_3)_{calc}$ = 339.0902).

*4-*n*-Butoxymethyl-5-ethylene-1-hexynyl phenyl sulfoxide* **6**b *and sulfone* **6**c

Oxidation of sulfide **6***a* according to general procedure 2, and SiO_2 chromatography (3:1 hexane:EtOAc) furnished sulfoxide **6***b* and sulfone **6***c* (50%, 1:4 ratio) as colorless oils.

6*b*: IR (neat) cm^{-1}: 2926 (s), 2202 (s), 1458 (s), 1032 (s); UV λ_{max}: 228 (ϵ_{max} 8500); ^{1}H NMR ($CDCl_3$) δ: 7.74 (m, 3H), 7.45 (m, 3H), 4.88 (bs, 1H), 4.75 (bs, 1H), 3.26 (m, 4H), 2.51 (m, 3H), 1.6 (s, 3H), 1.25 (m, 4H), 0.9 (t, 3H, J = 2.8); HRMS: $(m^+/z - C_4H_9OCH_2)_{obs}$ = 217.0688 ($(m^+/z - C_4H_9OCH_2)_{calc}$ = 217.0687).

6*c*: IR (neat) cm^{-1}: 3070 (m), 2926 (s), 2202 (s), 1309 (s), 1115 (s); UC λ_{max}: 227 (ϵ_{max} 8800); ^{1}H NMR ($CDCl_3$) δ: 7.92 (m, 2H), 7.50 (m, 3H), 4.74 (s, 1H), 4.73 (s, 1H), 3.31 (m, 4H), 2.45 (m, 3H), 1.58 (s, 3H), 1.42 (m, 4H), 0.84 (t, 3H, J = 4.1); HRMS: $(m^+/z - C_4H_9OCH_2)_{obs}$ = 233.0629 ($(m^+/z - C_4H_9OCH_2)_{calc}$ = 233.0636).

3-Tetrahydropyranyloxy-1-proprynyl phenyl sulfoxide **7**b *and sulfone* **7**c

Oxidation of sulfide **7***a* according to general procedure 2, followed by SiO_2 chromatography (1:2 hexane:EtOAc), afforded sulfoxide **7***b* and sulfone **7***c* (71%, 19:1 ratio) as colorless oils.

7*b*: IR (neat) cm^{-1}: 3384 (b), 2943 (s), 2189 (s), 1036 (s), 612 (m); UV λ_{max}: 227 (ϵ_{max} 6800); ^{1}H NMR ($CDCl_3$) δ: 7.82 (m, 2H), 7.56 (m, 3H), 4.76 (m, 1H), 4.48 (s, 2H), 3.79 (m, 1H), 3.52 (m, 1H), 1.70 (m, 6H); HRMS: $(m^+/z - OH)_{obs}$ = 247.0781 ($(m^+/z - OH)_{calc}$ = 247.0793).

7*c*: IR (neat) cm^{-1}: 3030 (m), 2945 (s), 2203 (s), 1311 (s), 1123 (s); UV λ_{max}: 226 (ϵ_{max} 7100); ^{1}H NMR ($CDCl_3$) δ: 8.00 (m, 2H), 7.63 (m, 3H), 4.70 (s, 1H), 4.39 (s, 2H), 3.74 (m, 1H), 3.50 (m, 1H), 1.62 (m, 6H); HRMS: $(m^+/z - H)_{obs}$ = 279.0687 ($(m^+/z - H)_{calc}$ = 279.0691).

The formation of heterobicycles by condensation of (1*R*, 2*R*)-(−)-pseudoephedrine or (1*R*, 2*S*)-(−)-ephedrine with glyoxal is reported. In the case of pseudoephedrine, the nuclear magnetic resonance data of the crude reaction mixture indicate the presence of three isomeric compounds (**5**, **6**, and **7**), which were separated by fractional crystallization, while ephedrine afforded the oxazino-oxazine **8** and the known (5*S**,6*R**)-4,5-dimethyl-6-phenyl-1,4-oxazin-2-one (**9**). Conclusive spectroscopic evidence for the structures of the new compounds having the *cis*-[1,4]oxazino[3,2-*b*]-1,4-oxazine (**5** and **8**) and the 2,2′-bioxazolidine type structures (**6** and **7**) was obtained by measurement of the ^{13}C satellite coupling constants in the 300 MHz ^1H nmr spectra, combined with the evaluation of dihedral angles using a modified Karplus type relationship. Unequivocal ^1H and ^{13}C nmr spectral assignments for all new compounds were done using two-dimensional carbon–proton correlation experiments. Syntheses of the known 5a,6,11a,12-tetrahydro[1,4]benzoxazino[3,2-*b*]benzoxazine (**3***a*) whose crystal structure has been previously determined, as well as of its *N*,*N*′-diisopropyl derivative **3***b*, allowed us to corroborate the above observations for the six-membered ring heterocycles. Moreover, the structures of **3***b* and **7** were independently verified by single crystal X-ray diffraction studies, thus validating the structural conclusions deduced from nmr satellite multiplicity measurements.

NORBERTO FARFÁN, ROSA L. SANTILLAN, DOLORES CASTILLO, REYNA CRUZ, PEDRO JOSEPH-NATHAN et JEAN-CLAUDE DARAN. Can. J. Chem. **70**, 2764 (1992).

La formation d'hétérocycles par condensation de l'(1*R*,2*R*)-(−)-pseudoéphédrine et de l'(1*R*,2*S*)-(−)-éphédrine avec le glyoxal a été étudiée. Dans le cas de la pseudoéphédrine les données de la RMN sur le produit brut de la réaction sont en accord avec un mélange de trois isomères (**5**, **6** et **7**) qui ont été séparés par cristallisation fractionnée, alors que l'éphédrine conduit à l'oxazino-oxazine **8** et à la (5*S**,6*R**)-4,5-diméthyl-6-phényl-1,4-oxazin-2-one (**9**) déjà connue. La détermination des structures des *cis*-[1,4]oxazino[3,2-*b*]-1,4-oxazines (**5** et **8**) et des 2,2′-bioxazolidines (**6** et **7**) a été réalisée par la mesure des constantes de couplage observées sur les satellites ^{13}C des spectres RMN ^1H à 300 MHz, et par évaluation des angles dièdres au moyen d'une relation de type Karplus modifiée. L'attribution des signaux dans les spectres RMN ^1H et ^{13}C de tous les composés nouveaux a été déterminée sans ambiguïté par des expériences de corrélation à deux dimensions carbone–proton. La synthèse de la 5a,6,11a,12-tétrahydro[1,4]benzoxazino[3,2-*b*]-benzoxazine (**3***a*) dont la structure cristalline est connue, et son dérivé *N*,*N*′-diisopropyle **3***b* a permis de corroborer les observations précédentes relatives aux hétérocycles à six chainons. Les structures de **3***b* et **7** ont été verifiées par diffraction des rayons X sur monocristaux et vérifient les conclusions structurales déduites des mesures des constantes de couplage satellites.

Introduction

The condensation of *o*-aminophenol and glyoxal was initially thought (1) to provide glyoxal *bis*-(2-hydroxyanil) (**1**), but a structural reinvestigation (2) suggested that a 2,2′-bioxazolidine (such as **2**) is formed. Further studies (3) using various *o*-aminophenols, several α-dicarbonyl compounds and varying the molar ratio of the reactants revealed that the ease of condensation and the type of condensation products depend on the steric factors of the α-dicarbonyl compounds, as well as on the basicity of the amino group and the acidity of the hydroxyl group of the *o*-aminophenols; the 2 ,2′-bioxazolidines (**2**) being the condensation products of two moles of *o*-aminophenol with one mole of the α-dicarbonyl compounds.

Subsequent studies (4) showed that there were two additional conceivable structures (**3***a* and **4**) for the reaction of glyoxal with *o*-aminophenol. Structure **4** was excluded, based on the 270 MHz ^1H nmr spectrum, since for this isomer the two central C-H protons are not equivalent and should provide a complex signal pattern. However, since the proton spectrum does not allow a distinction between structures **2** or **3***a*, and photochemical experiments did not permit establishing the structure, the condensation product was definitively established as 5a,6,11a,12-tetrahydro-*cis*-[1,4]-benzoxazino[3,2-*b*][1,4]-benzoxazine (**3***a*) by a single crystal X-ray diffraction study (4).

Closely related studies report the reaction of 2-propyn-1-ols with 2-aminoalcohols and mercury(II) chloride (5), the reaction of 2-methylaminoethanol with glyoxal (6), and the reaction of 2-methylaminoethanol with *gem*-dibromoketones (7), which have been shown to proceed by highly stereoselective processes leading to *cis*-[1,4]oxazino[3,2-*b*]-[1,4]-oxazine derivatives. However, in all these cases the authors conclude that nmr techniques do not allow unequivocal distinction between the 2,2′-bioxazolidines (like **2**) or the actual *cis*-fused oxazino-oxazine structures (like **3**), and therefore the structures were established by single crystal X-ray analyses.

4

The aim of this study is to demonstrate that nmr techniques indeed allow unequivocal distinction between the *cis*-fused oxazino-oxazines (like **3**) and the bioxazolidine structures (like **2**) using the $^3J_{HH}$ values extracted from the ^{13}C satellites in the ^1H nmr spectra.

Experimental section

The ^1H and ^{13}C nmr spectra were recorded on Varian XL-300GS, Jeol GSX-270, and Jeol 90Q spectrometers in deuteriochloroform solutions containing internal TMS. The HETCOR standard pulse sequence, which incorporates quadrature detection in both domains, was used. The spectral windows of HETCOR experiments were adjusted in order to perform separate measurements for the aromatic and aliphatic regions. Mass spectra were obtained with a LKB 9000S/11E10 spectrometer and infrared spectra with a Nicolet MX-1 FT spectrophotometer. Melting points were determined in open capillaries and are uncorrected. Elemental analyses were performed by Oneida Research Services, Inc., New York.

(1*R*,2*R*)-(−)-Pseudoephedrine, (1*R*,2*S*)-(−)-ephedrine, and glyoxal (40%) were commercially available.

*5a,6,11a,12-Tetrahydro[1,4]benzoxazino[3,2-*b*]benzoxazine (**3**a)* was prepared as described in the literature (4); ^1H nmr ($CDCl_3$, 300 MHz): 6.84 (ddd, J = 7.5, 6.7, 2.0 Hz, 1H, H-3), 6.81 (dd, J = 8.2, 1.9 Hz, 1H, H-1), 6.79 (ddd, J = 8.1, 6.6, 1.5 Hz, 1H, H-2), 6.69 (ddd, J = 7.6, 1.7, 0.6 Hz, 1H, H-4), 5.33 (d, J = 3.7 Hz, 1H, H-5a), 4.88 (bd, J = 2.9, 1H, NH); ^{13}C nmr ($CDCl_3$, 75 MHz): 141.53 (C-12a), 128.52 (C-4a), 122.05 (C-3), 120.61 (C-2), 117.11 (C-1), 114.92 (C-4), 75.89 (C-5a).

*N,N'-Diisopropyl-5a,6,11a,12-tetrahydro[1,4]benzoxazino-[3,2-*b*]benzoxazine (**3**b)* was prepared from *N*-isopropyl-*o*-aminophenol (8) using the procedure described for the preparation of **3***a*, mp 195–198°C; ^1H nmr ($CDCl_3$, 90 MHz): 6.93–6.69 (m, 4H, H-1,2,3,4), 5.23 (s, 1H, H-5a), 4.17 (septet, J = 6.6, $CH(CH_3)_2$), 1.41 and 1.32 (d ea, J = 6.6, $CH(CH_3)_2$; ^{13}C nmr ($CDCl_3$, 22.5 MHz): 142.2 (C-12a), 130.5 (C-4a), 121.7 (C-3), 118.9 (C-2). 117.2 (C-1), 112.0 (C-4), 76.0 (C-5a).

Condensation of pseudoephedrine with glyoxal

To a solution of (1*R*,2*R*)-(−)pseudoephedrine (1 g, 6.05 mmol) in 50 mL benzene were added 0.5 g (3.0 mmol) of 40% aqueous glyoxal and a few iodine crystals and the solution was refluxed for 2 h using a Dean–Stark head. The solvent was evaporated and the solid residue (1.25 g, 2.6 mmol) consisting of a mixture of **5**, **7**, and **6** in a 6:3:1 ratio was recrystallized several times using methanol–hexane mixtures. The less soluble crystals afforded 454 mg (43%) of pure *(2R*,3R*,6R*,7R*)-2,6-diphenyl-3,4,7,8-tetramethyl-*cis*-perhydro[1,4]oxazino[3,2-*b*]-1,4-oxazine (**5**)*, mp 121–123°C; ir ν_{max} (KBr): 2955, 2876, 1641, 1451, 1378, 1332, 1232, 1090, 1052, 978, 891 cm^{-1}; ms, m/z (%): 352 (M^+, 7%), 353 (M^+, +1,1), 219(4), 190(11), 189(100), 176(12), 148(7), 118(39), 117(12), 91(4), 86(7), 84(11), and 49(17); Anal. calcd. for $C_{22}H_{28}N_2O_2$: C 74.97, H 8.01, N 7.95; found: C 75.07, H 7.75, N 7.90

Further crystallization yielded 191 mg (18%) of *(4R*,4'R*,5R*,5'R*)-5,5'-diphenyl-3,3',4,4'-tetramethyl-2,2'-bioxazolidine (**7**)*, mp 119–121°C; ir ν_{max} (KBr): 2965, 2927, 1453, 1378, 1222, 1177, 1051, 1013 cm^{-1}; ms, m/z (%) 352(M^+, 5%), 353(M^+ +1,1), 301(2), 219(7), 190(11), 189(100), 177(6), 176(42), 148(20), 133(3), 119(6), 118(42), 117(16), 91(10), 86(19), 84(28), and 49(18); Anal. calcd. for $C_{22}H_{28}N_2O_2$: C 74.97, H 8.01, N 7.95; found: C 75.21, H 7.85, N 7.97.

The final crystals yielded 21 mg (2%) of *(4R*,4'R*,5R*,5'R*)-5,5'-diphenyl-3,3',4,4'-tetramethyl-2,2'-bioxazolidine (**6**)*, mp 181–183°C; ir ν_{max} (KBr) 2969, 2844, 1452. 1357, 1221, 1776, 1092, 1073, 995 cm^{-1}; ms, m/z (%): 352 (M^+, 4%), 353(M^+ + 1,1), 219(9), 190(10), 189(100), 176(3), 148(5), 118(44), 117(13), and 91(4).

Condensation of ephedrine with glyoxal

Condensation of ephedrine with glyoxal was carried out using the procedure described in the case of pseudoephedrine. The reaction affords a mixture of **8** and **9** in a 7:3 ratio. The residue was evaporated to dryness and the solid dissolved in hexane–methanol mixtures to afford *(2R*,3S*,6R*,7S*)-2,6-diphenyl-3,4,7,8-tetramethyl-*cis*-perhydro[1,4]oxazino-[3,2-*b*]-1,4-oxazine (**8**)* (662 mg, 61%), which was recrystallized several times using methanol–hexane mixtures, mp 102–103°C; ir ν_{max} (KBr): 3292, 2887, 2865, 1439, 1378, 1156, 1128, 1068, 1006, 962 cm^{-1}. The remaining liquid was distilled under vacuum to give *(5S*,6R*)-4,5-dimethyl-6-phenyl-1,4-oxazin-2-one (**9**)* (284 mg, 26%), bp 135°C (0.5 Torr; 1 Torr = 133.3 Pa) (9). ^1H nmr ($CDCl_3$, 300 MHz): 7.27–7.40 (m, 5H, arom), 5.62 (d, J = 3.8 Hz, 1H, H-6), 3.43 and 3.49 (AB, J = 18.3 Hz, 2H, CH_2-3), 3.10 (dq, J = 6.8, 3.4 Hz, 1H, H-5), 2.36 (s, 3H, N-CH_3), 0.74 (d, J = 6.8 Hz, CH_3).

Results and discussion

In continuing our studies on the reaction of glyoxal with aminoalcohols (11) we decided to look more carefully into the reaction conditions for the condensation of pseudoephedrine or ephedrine with 40% aqueous glyoxal. The reaction of pseudoephedrine with glyoxal in a 2:1 ratio was carried out in benzene under reflux for 2 h. The crude reaction product is a mixture of (2R*,3R*,6R*,7R*)-2,6-diphenyl-3,4,7,8-tetramethyl-*cis*-perhydro[1,4]oxazino[3,2-*b*]-1,4-oxazine (**5**), mp 121–123°C, and two isomeric (4*R**,

For personal use only.

4′*R**,5*R**,5′*R**)-5,5′-diphenyl-3,3′,4,4′-tetramethyl-2,2′-bioxazolidines, mp 181–183°C (**6**) and 119–121°C (**7**), which were separated by fractional crystallizations using hexane–methanol mixtures.

In contrast, reaction of ephedrine with glyoxal, under the same reaction conditions, affords a mixture of (2*R**,3*S**,6*R**,7*S**)-2,6-diphenyl-3,4,7,8-tetramethyl-*cis*-perhydro-[1,4]oxazino[3,2-*b*]-1,4-oxazine (**8**) and (5*S**,6*R**)-4,5-dimethyl-6-phenyl-1,4-oxazin-2-one (**9**) (9).

Contrary to all previous reports, differentiation between the two types of ring fusion can indeed be achieved by observation of the ^{13}C satellites of the ring fusion protons in the ^1H nmr spectra. This removes the equivalence of any pair of CH residues since one of the protons couples strongly to the ^{13}C atom and the probability that the other proton is also attached to a ^{13}C atom is very small. Thus the A_2 system, consequent to symmetry, gives rise to an ABX spin–spin system, with the ^{13}C atom as the X part. These experiments show that the H-2 signals at 4.06 (s) in **6** and at 4.31 (s) in **7** undergo additional splitting ($^3J_{HH}$ = 3.85 Hz), while in the case of the six-membered heterocycles the same protons, at 4.34 in **5** and 4.30 in **8**, respectively, show coupling constants of 0 and 1.28 Hz, respectively.

To establish a generalization of the above observations, compounds **3***a* and **3***b* were prepared and subjected to nmr studies. Comparison of the $^3J_{HH}$ values for 5a,6,11a,12-tetrahydro[1,4]benzoxazino[3,2-*b*][1,4]benzoxazine ($^3J_{HH}$ = 0.89) (**3***a*) and its *N*-isopropyl derivative ($^3J_{HH}$ = 0.95) (**3***b*) with those of compounds **5** and **8** shows reasonable agreement and allows definite attribution of the ring-type fusion based on the satellite spectrum (Fig. 1). Furthermore, the use of a generalized Karplus type relationship (12) in the latter compounds allows us to establish a *cis*-type fusion of these derivatives, since the corresponding *trans* derivatives should exhibit coupling constants in the order of 7 Hz, while for compounds of type **2** one would expect $^3J_{HH}$ around 3–4 Hz. The structure of **3***a* has already been established (4) by single crystal X-ray analysis and those of **3***b* and **7** were determined in this work. Perspective views of the molecular structures are depicted in Figs. 2 and 3, respectively, while the atom coordinates are given in Tables 1 and 2, respectively.

Unequivocal ^1H and ^{13}C nmr assignments for compounds **5–8** to the values shown in Tables 3 and 4, respectively, were achieved by 2D carbon–proton correlated experiments and comparison with model compounds (13). In general, the assignment of the ^1H spectra is trivial and the fact that the proton signal can be recognized readily allows attribution of the corresponding signals in the ^{13}C nmr spectra. Observation of Tables 3 and 4 shows that neither the ^1H nor the ^{13}C chemical shifts of the ring fusion atoms may be of diagnostic value to establish the ring size in these fused heterocycles. This is in contrast to previous reports on bidioxolane and tetraoxodecalin mixtures (14, 15) where it has been found that dioxalane acetal methine protons absorb at lower field relative to dioxane acetal methine protons.

Complete assignment of the ^{13}C and ^1H nmr spectra of **3***a* (see experimental) was achieved by 2D carbon–proton correlated experiments. The distinction between the C-1 and C-4 carbons was achieved by comparison of the coupled spectrum with that obtained after addition of D_2O, which shows increased intensity of the dd signal at 114.92 ppm, thus allowing attribution of this resonance to C-4; the corresponding H-4 proton appears as a double doublet of doublets at 6.69 ppm (J = 7.6, 1.7, 0.6 Hz) in the ^1H nmr spectrum. In turn C-1 resonates at 117.11 and is observed as dd in the ^1H nmr spectrum (J = 8.2, 1.9) at 6.81 ppm. The remaining

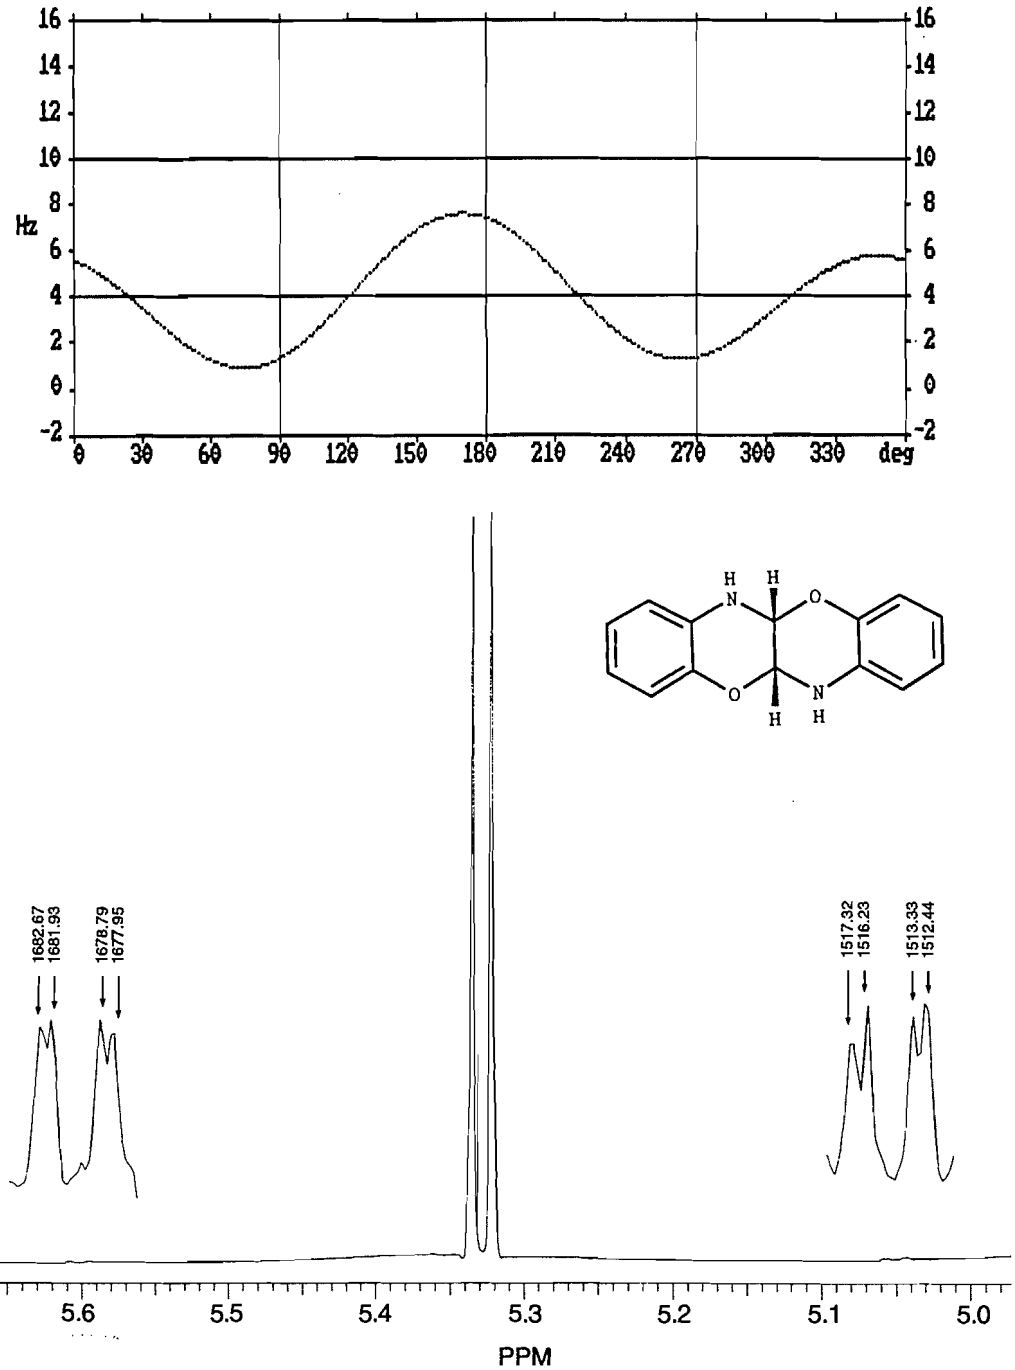

FIG. 1. ^{13}C satellite spectrum for the H—C(5a)—C(11a)—H fragment of **3***a* and plot generated by Altona. The program Altona (12) uses the relative stereochemistry of the fragment and electronegativity of atoms.

aromatic signals were assigned from the ^1H nmr spectrum, based on observation of the coupling pattern that allows us to distinguish the *meta* relationship. Thus the ddd (J = 7.5, 6.7, 2.0) at 6.84 ppm was attributed to H-3, which correlates to the carbon signal at 122.05, while the ddd (J = 8.1, 6.6, 1.5) at 6.79 corresponds to H-2, which is assigned to the carbon at 120.61 ppm.

The spectra of the *N*-isopropyl derivative **3***b* were assigned by comparison with those of **3***a*.

Assignment of the configuration of the 2,2′ protons in bioxazolidines **6** and **7** from nmr measurements was not possible due to the fact that the central -CH-CH- protons give rise to singlets at 4.06 and 4.31 ppm. These could not be resolved by addition of optically active shift reagents, by which one would expect two singlets for a *d,l* mixture or an AB system for a *meso* compound (16). However, the structure of **7** was established by X-ray analysis as the *meso* form.

Although it has been described that mass spectrometry provides a criterion for the differentiation of 1,4,5,8-tetraoxadecalin and bi(dioxolan-2-yl) derivatives (17) based on the observation of the molecular peak, which appears in the tetraoxadecalins but is virtually absent in the bi(dioxolanyl)

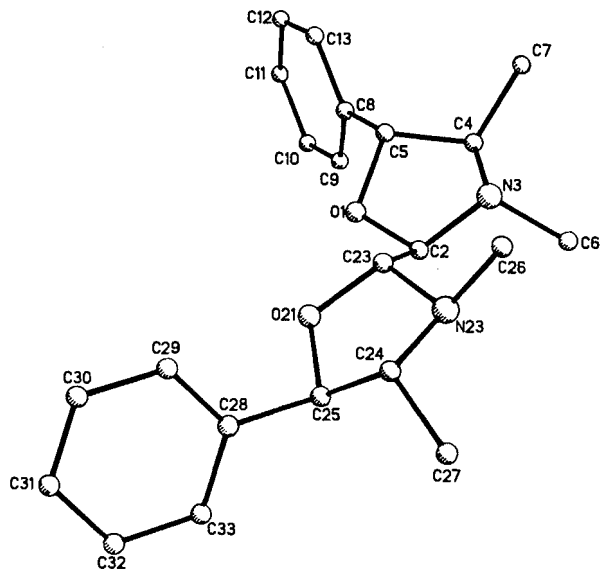

FIG. 3. Perspective view of the molecular structure of **7**.

derivatives, we are not aware of analogous mass spectral studies in the case of the bioxazolidines and oxazino-oxazine derivatives. However, we have found that this criterion has been used to establish the structure in the case of isomeric bibenzothiazole and [1,4]benzothiazino[3,2-*b*]-benzothiazine (18), based on the fact that the mass spectrum of the latter exhibits in addition to the M^+ and $M^+/2$ ions, two fragments that are 13 mass units above or below the $M^+/2$ peak, and such fragments have only been observed in ring systems like **3***a*.

In the case of the isomeric structures **5**, **6**, and **7** described in this study, the mass spectra show the M^+ and $M^+/2$ peaks in all cases. However, the most important fragment is at m/z 189, corresponding indeed to 13 mass units above the $M^+/2$ peak. The fact that this fragment was observed in all three isomers cast some doubts on the validity of such an approach to the general application of this methodology for

the differentiation of the type of isomers described in the present study.

The current interest in the study of the anomeric effect in ring systems containing the X-C-Y grouping, both experimentally and by computational studies (19–21), evidences the need to establish an unequivocal and simple approach for identifying and differentiating between isomeric systems.

Excepting an isolated report (22), the reaction of aminoalcohols with glyoxal (4, 6) as well as with various other compounds (5, 7, 23) have been shown to yield *cis*-oxazino-oxazine structures after X-ray analyses. These results, which imply a high degree of stereoselectivity, have been rationalized in terms of an anomeric effect (5) that favors those structures having the non-bonding lone pairs of the nitrogen atoms antiperiplanar to the C—O bonds.

Conclusions

It is apparent that neither the formation nor the ratio of the isomeric oxazino-oxazine (such as **3**) and bioxazolidine (such as **2**) products can be predicted. In the case of both ephedrine and pseudoephedrine, oxazino-oxazine type structures (as **3**) having the *cis* ring fusion are formed, while bioxazolidine (as **2**) formation occurred only in the latter aminoalcohol at higher temperatures. These results show that in addition to the reaction conditions, to the basicity of the amine and the acidity of the alcohol, the reaction outcome is also sensitive to stereochemical changes at the aminoalcohol portion.

The fact that the compounds having the bioxazolidine type structure (as **2**) isomerize in solution, or during chromatographic procedures, to the *cis*-oxazino-oxazine type structures (as **3**) gives evidence that the latter are thermodynamic products.

Detailed evaluation of the ^{1}H, ^{13}C, and mass spectral data for the isomeric five- and six-membered ring bis-heterocycles described in this study allows us to conclude that in the case of the bioxazolidine (as **2**) and oxazino-oxazine (as **3**) derivatives with hydyrogen atoms at the ring fusion, measurement of the ^{13}C satellites in the ^{1}H nmr spectra constitutes the simplest and most adequate criterion for their differentiation, as validated in the present study by the X-ray diffraction studies of **3***b* and **7**.

Received May 26, 1992

SANTOKH S. TANDON, LAURENCE K. THOMPSON, JOHN N. BRIDSON, and JOHN C. DEWAN. Can. J. Chem. **70**, 2771 (1992).

The ligand BTIM (1,2,4,5-tetrakis(4,5-dihydro-imidazol-2-yl)benzene) reacts with cobalt(II) salts to form two series of complexes. The 1:1, dinuclear, metallocyclic derivatives $[Co_2(BTIM)_2X_2]X_2$ (X = Cl (**I**), Br (**II**)) involve two bis-dentate ligands in a metallocyclic structure with a large unoccupied cavity. The 2:1, binuclear derivatives $[Co_2(BTIM)X_4]$ (X = Cl (**III**), Br (**IV**)) involve two metals bound to a single, bis-bidentate ligand. The crystal and molecular structures of **II** and **III** are reported. Compound **II** crystallized in the monoclinic system, space group $P2_1/c$, with a = 13.642(6) Å, b = 11.560(3) Å, c = 18.406(7) Å, β = 101.73(3)° and four formula units per unit cell. Refinement by full-matrix least squares gave final residuals of R = 0.060 and R_w = 0.062. Compound **III** crystallized in the triclinic system, space group $P\bar{1}$, with a = 8.367(2) Å, b = 14.254(3) Å, c = 7.649(2) Å, α = 100.99(2)°, β = 101.44(2)°, γ = 106.85(1)° and one formula per unit cell. Refinement by full-matrix least squares gave final residuals of R = 0.052 and R_w = 0.045. In the metallocyclic structure (**II**) the square-pyramidal cobalt(II) centres are separated by 7.599(4) Å, while in the 2:1 derivative the two tetrahedral cobalt(II) centres have a much larger separation (8.736(3) Å).

SANTOKH S. TANDON, LAURENCE K. THOMPSON, JOHN N. BRIDSON et JOHN C. DEWAN. Can. J. Chem. **70**, 2771 (1992).

Le ligand BTIM (1,2,4,5-tétrakis(4,5-dihydroimidazol-2-yl)benzène) réagit avec les sels de cobalt(II) pour former deux séries de complexes. Les dérivés métallocycliques dinucléaires 1 : 1 $[Co(BTIM)_2X_2]X_2$ (X = Cl (**I**) et Br (**II**)) impliquent deux ligands bis-dentates dans une structure métallocyclique et une cavité vide importante. Les dérivés binucléaires 2 : 1 $[Co_2(BTIM)X_4]$ (X = Cl(**III**) et Br (**IV**) impliquent des liaisons de deux métaux à un seul ligand bis-dentate. On a déterminé et on rapporte les structures moléculaires des composés **II** et **III**. Le composé **II** cristallise dans le système monoclinique, groupe d'espace $P2_1/c$, avec a = 13,642(6), b = 11,560(3) et c = 18,406(7) Å, β = 101,73(3)° et quatres molécules par unité. On a affiné la structure par la méthode des moindres carrés jusqu'à des valeurs finales de R = 0,060 et R_w = 0,062. Le composé **III** cristallise dans le système triclinique, groupe d'espace $P\bar{1}$, avec a = 8,367(2), b = 14,254(3) et c = 7,649(2) Å, α = 100,99(2), β = 101,44(2) et γ = 106,85(1)° et une molécule par unité. On a affiné la structure par la méthode des moindres carrés jusq'à une valeur de R = 0,052 et de R_w = 0,045. Dans la structure métallocyclique **II**, les centres en pyramide carrée du cobalt(II) sont séparés par 7,599(4) Å alors que dans le dérivé 2 : 1 les deux centres tétraédriques du cobalt(II) sont beaucoup plus séparés (8,736(3) Å).

[Traduit par la rédaction]

Introduction

The ligand BTIM (1,2,4,5-tetrakis(4,5-dihydroimidazol-2-yl)benzene) (Fig. 1) behaves in a tetradentate fashion in its copper coordination chemistry forming mainly 1:1 metallocyclic derivatives, e.g. $[Cu_2(BTIM)_2X_2]X_2$ (X = Cl, N_3), $[Cu_2(BTIM)_2(H_2O)_2](ClO_4)_4$, with two square pyramidal copper(II) centres bridged by two bis-dentate ligands, with large copper–copper separations (7.30, 7.42 Å) (1,2). The copper(II) centres were shown to be very weakly antiferromagnetically coupled with $-2J < 2$ cm^{-1}.

Reaction of BTIM with cobalt(II) salts led to the formation of two types of dinuclear complex, one similar to the copper derivatives with a 1:1 stoichiometry and the other with a 2:1 (metal:ligand) stoichiometry. The complexes have been characterized by infrared, electronic spectra and variable temperature magnetism and the structures of one example of each type of dinuclear complex have been confirmed by X-ray crystallography. The complex $[Co_2(BTIM)_2Br_2]$-$Br_2 \cdot 2CHCl_3 \cdot 4MeOH$ (II) has a dinuclear, metallocyclic (2:2) structure with dimensions comparable to the metallocyclic copper derivatives. The 2:1 complex $[Co_2(BTIM)Cl_4] \cdot$ 2DMF (**III**) involves a unique, open chain, dinuclear structure with the two tetrahedral cobalt(II) centres bridged by one ligand, with a much larger metal–metal separation (8.736(3) Å)). Variable temperature magnetic studies have been carried out on compounds **I**–**IV**, but are not really conclusive in terms of the presence of significant magnetic exchange between the cobalt centres.

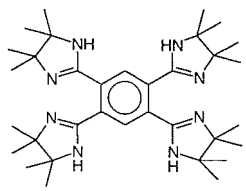

FIG. 1. Structural representation of the ligand BTIM.

Experimental section

Synthesis of the ligand and cobalt complexes

BTIM

A low yield synthesis of the ligand has already been reported (2). An improved synthesis is now described.

Tetracyanobenzene (3) (6.0 g; 0.034 mol) was dissolved in hot (100°C) nitrobenzene (150 mL). A solution of ethane-1,2-diamine (25.0 mL) in nitrobenzene (50 mL) was added dropwise over a period of 2 h and the mixture stirred at 100°C for three days. A reddish brown solution formed, followed by the formation of a light brown solid, which was filtered off, after cooling and washed with nitrobenzene (2 × 20 mL) and acetone (3 × 50 mL). The solid was recrystallized from methanol/chloroform (3:1) mixture. Yield 50%, *m/e* 350, mp dec. 270–300°C.

$[Co_2(BTIM)_2Cl_2]Cl_2 \cdot 4H_2O$ (I)

BTIM (0.35 g, 0.001 mol) was dissolved in a boiling mixture of methanol (200 mL) and chloroform (200 mL) and the solution filtered into a solution of $CoCl_2 \cdot 6H_2O$ (0.48 g, 0.002 mol) in methanol (50 mL). The reaction mixture was boiled gently in a conical flask for 1–2 h so that some solvent evaporated. A brown solid separated from the hot solution, which was filtered, washed with methanol, and dried under vacuum. The blue filtrate was concentrated to a volume of about 100 mL and allowed to stand at room temperature overnight. More product appeared on standing as well formed red–brown crystals, which were filtered and washed with methanol and chloroform. The crystals crumble and lose solvent on exposure to air and are only stable in the presence of the mother liquor. The crystalline sample was dried under vacuum and analysed. Anal. calcd. for $[Co_2(C_{18}H_{22}N_8)_2Cl_2]Cl_2 \cdot 4H_2O$: C 41.87, H 5.04, N 21.71, Co 11.42; found: C 41.86, H 4.16, N 21.52, Co 11.23.

$[Co_2(BTIM)_2Br_2]Br_2 \cdot 2CHCl_3$ (**II**) was prepared in a similar manner. Anal. calcd. for $[Co_2(C_{18}H_{22}N_8)_2Br_2]Br_2 \cdot 2CHCl_3$: C 33.12, H 3.34, N 16.27, Co 8.56; found: C 32.78, H 3.24, N 16.11, Co 8.27. Crystals of **II** suitable for X-ray analysis were unstable and lost solvent on exposure to air, and so were kept in contact with the mother liquor. Both methanol and chloroform solvent molecules were found in the X-ray sample.

$[Co_2(BTIM)Cl_4]$ (III) and
$[Co_2(BTIM)_2Br_4] \cdot 0.5MeOH \cdot 0.5CHCl_3$ (IV)

The blue (**III**) and greenish blue (**IV**) filtrates obtained after separation of **I** and **II** were concentrated further to a small volume. Acetonitrile (50 mL) was added to the hot solutions and the mixtures boiled gently in an open conical flask for about 15 min. Dark blue (**III**) or greenish blue (**IV**) crystals separated on standing at room temperature and were filtered off, washed with acetonitrile (2 × 5 mL) and methanol (2 × 5 mL), and dried under vacuum. Anal. calcd. for $[Co_2(C_{18}H_{22}N_8)Cl_4]$: C 35.42, H 3.61, N 18.37, Co 19.32; found: C 35.21, H 3.65, N 17.93, Co 18.88. Crystals of **III** suitable for X-ray analysis were obtained by slow, vapour diffusion of ether into a DMF:MeOH (1:1) solution of the complex, and the sample was shown to have the composition $[Co_2(C_{18}H_{22}N_8)Cl_4] \cdot 2DMF$. Anal. calcd. for $[Co_2(C_{18}H_{22}N_8)Br_4] \cdot 0.5CHCl_3 \cdot 0.5MeOH$ (**IV**): C 26.40, H 2.84, N 12.97, Co 13.64; found: C 26.11, H 2.81, N 12.87, Co 13.20.

Physical measurements

Infrared spectra were recorded using a Mattson Polaris Fourier transform spectrometer and electronic spectra using a Cary 17 spectrometer. Room temperature magnetic moments were measured by the Faraday method using a Cahn 7600 magnetic susceptibility system. Variable temperature magnetic data were obtained in the temperature range 5–305 K with an Oxford Instruments superconducting Faraday magnetic susceptibility system with a Sartorius 4432 microbalance. A main solenoid field of 1.5 T and a gradient field of 10 T m^{-1} were employed. C, H, and N analyses were carried out by the Canadian Microanalytical Service, Delta, and cobalt was determined by EDTA titration.

Crystallographic data collection and refinement of the structures

$[Co_2(BTIM)_2Br_2]Br_2 \cdot 2CHCl_3 \cdot 4MeOH$ (II)

Crystals of **II** dried out, crumbled, and ceased to diffract X-rays if removed from their mother liquor. Accordingly, a red–brown crystal was mounted at the end of a glass fiber under a stream of cold nitrogen gas and coated with high vacuum grease. The crystal was then transferred to the nitrogen cold stream of a low temperature device mounted on the diffractometer, and maintained at −110 ± 1°C throughout the data collection. The crystal was quite stable under these conditions and the intensities of three standard reflections showed no decay during data collection.

The diffraction intensities of an approximately 0.48 × 0.40 × 0.25 mm crystal were collected with graphite monochromatized MoKα radiation and a 1.5 kW sealed tube X-ray source using a Rigaku AFC6S diffractometer. The data were collected at low temperature using the ω–2θ scan technique to a maximum 2θ value of 55.2° and a scan rate of 8.0°/min. Cell constants were obtained by the least-squares refinement of the setting angles of 25 carefully centred reflections with 2θ in the range 27.23–29.97°. A total of 7190 reflections were measured, of which 6910 were unique (R_{int} = 0.086), and 3277 were considered significant with $I_{net} > 2.0\sigma(I_{net})$. An empirical absorption correction was applied using the program DIFABS (4) and the data were corrected for Lorentz and polarization effects.

The structure was solved by direct methods and refined by full-matrix least squares using TEXSAN (5) to final residuals of R and R_w of 0.060 and 0.062 respectively ($R = \Sigma(|F_o| - |F_c|)/\Sigma(|F_o|)$; $R_w = [\Sigma(|F_o| - |F_c|)^2/\Sigma wF_o^2)]^{1/2}$), with weights based on counting statistics. Hydrogen atoms were placed in calculated positions (temperature factor 1.2 times B(eq) of atom to which they are bound) and the non-hydrogen atoms were refined anisotropically. Neutral atom scattering factors were taken from ref. 6. The final difference map had no peaks greater than 0.7 e/Å^3. One chloroform molecule (C(90), Cl(90), Cl(91), Cl(92)) and two methanol molecules (C(50), O(50); C(60), O(60)) have been identified in the asymmetric unit and included in the refinement. A summary of crystal data is given in Table 1 and atomic positional parameters are given in Table 2. Anisotropic thermal parameters (Table S1), hydrogen atom positional parameters (Table S2), a full listing of bond distances and angles (Table S3), a listing of structure factors (Table S4), and least-squares planes data (Table S9) are included as supplementary material.[2]

$[Co_2(BTIM)Cl_4] \cdot 2DMF$ (III)

The diffraction intensities of a blue needle of approximate dimensions 0.35 × 0.10 × 0.08 mm were collected on a Rigaku AFC6S diffractometer, with graphite monochromatized MoKα radiation. The data were collected at a temperature of 26 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 50.0° at a scan speed of 4.0°/min. Cell constants were obtained by the least-squares refinement of the setting angles of 25 carefully centred reflections with 2θ in the range 22.75–31.97°. A total of 3111 reflections were measured, of which 2893 were unique (R_{int} = 0.043), and 1558 were considered significant with $I_{net} > 3.0\sigma(I_{net})$. An empirical absorption correction was applied using the program DIFABS (4) and the data were corrected for Lorentz and polarization effects. The structure was solved by direct methods and refined by full matrix least squares using TEXSAN (5) to final residuals of R and R_w of 0.052 and 0.045, respectively, with the non-hydrogen atoms refined anisotropically. Neutral atom scattering factors were taken from ref. 6. The final difference map had no peaks greater than 0.44 e/Å^3. A summary of crystal data is given in Table 1 and atomic positional parameters are given in Table 3. Anisotropic thermal parameters (Table S5), hydrogen atom positional parameters (Table S6), a full listing of bond distances and

angles (Table S7), a listing of structure factors (Table S8), and least-squares planes data (Table S9), are included as supplementary material.[2]

Results

Description of the structures of
$[Co_2(BTIM)_2Br_2]Br_2 \cdot 2CHCl_3 \cdot 4MeOH$ (II) and
$[Co_2(BTIM)Cl_4] \cdot 2DMF$ (III)

The structure of **II** is shown in Fig. 2 and bond lengths and angles relevant to the cobalt coordination spheres are listed in Table 4. Structurally **II** is analogous to several previously reported copper(II) complexes (2), where two BTIM molecules act as bridging, binucleating, tetradentate ligands and hold the two square-pyramidal metal centres in such a way as to create a large metallocyclic structure, with an unoccupied cavity bounded by the two parallel and eclipsed benzene rings and the MN_4 equatorial planes. **II** has a centre of symmetry at the centre of the cavity. The Co—N distances are essentially equal (ave. 2.006 Å) and compare

TABLE 4. Interatomic distances (Å) and angles (deg) relevant to the cobalt coordination spheres in $[Co_2(BTIM)_2Br_2]Br_2 \cdot 2CHCl_3 \cdot 4MeOH$ (**II**)

Atoms	Distance	Bonds	Angle
Co···Br(1)	2.555(2)	Br(1)—Co—N(1)	99.8(2)
Co···N(1)	2.010(7)	Br(1)—Co—N(3)	98.1(2)
Co···N(3)	2.001(7)	Br(1)—Co—N(5)	99.4(2)
Co···N(5)	2.007(7)	Br(1)—Co—N(7)	97.1(2)
Co···N(7)	2.014(8)	N(1)—Co—N(3)	86.1(3)
		N(1)—Co—N(5)	90.5(3)
		N(1)—Co—N(7)	163.1(3)
		N(3)—Co—N(5)	162.5(3)
		N(3)—Co—N(7)	91.5(3)
		N(5)—Co—N(7)	86.7(3)

closely with those reported for the copper derivatives (2). The equatorial donor atoms N(1), N(3), N(5), N(7) form an almost perfect plane (least-squares plane 1), with the cobalt displaced by 0.301 Å towards the apical bromine. The cobalt bromine distance of 2.555(2) Å compares closely with that found in the analogous copper chloride complex (2.504(3) Å) (2). The two cobalt atoms are separated by 7.599(4) Å and the benzene ring separation is 4.062 Å, thus creating a cavity of similar dimensions to that found in $[Cu_2(BTIM)_2Cl_2]Cl_2 \cdot 7H_2O$ (1, 2). The hydroimidazole rings (least-squares planes *4*, *5*) are twisted relative to the N_4 plane (plane *1*) and the benzene ring (least-squares plane *2*) (Fig. 2; dihedral angles between least-squares planes *1–2*, 90.2°; *1–4*, 69.7°; *2–4*, 133.6°; *1–5*, 68.6°; *2–5*, 135.0°; *4–5*, 77.0°). There are no close contacts between the solvent molecules in the lattice and the complex cation.

The structure of **III** is shown in Fig. 3 and bond lengths and angles relevant to the cobalt coordination spheres are listed in Table 5. The molecule is centrosymmetric, with the center of inversion at the center of the benzene ring of the BTIM ligand. The two cobalt atoms are four coordinate,

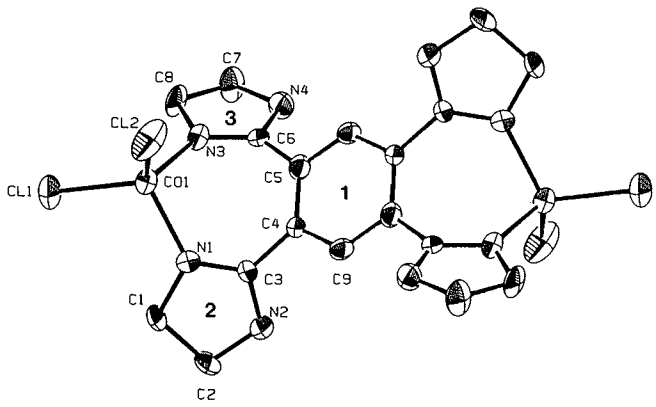

FIG. 3. Molecular structure of $[Co_2(BTIM)Cl_4] \cdot 2DMF$ (**III**).

TABLE 5. Interatomic distances (Å) and angles (deg) relevant to the cobalt coordination spheres in $[Co_2(BTIM)Cl_4] \cdot 2DMF$ (**III**)

Atoms	Distance	Bonds	Angle
Co(1)···Cl(1)	2.252(3)	Cl(1)—Co(1)—Cl(1)	112.6(1)
Co(1)···Cl(2)	2.232(3)	Cl(1)—Co(1)—N(1)	107.0(2)
Co(1)···N(1)	1.999(6)	Cl(1)—Co(1)—N(3)	110.9(2)
Co(1)···N(3)	1.988(6)	Cl(2)—Co(1)—N(1)	116.8(2)
		Cl(2)—Co(1)—N(3)	112.1(2)
		N(1)—Co(1)—N(3)	96.2(2)

bound to two nitrogen atoms and two chlorines on each side of the ligand. Each cobalt centre has a slightly distorted tetrahedral stereochemistry with angles at cobalt ranging from 96.2(2)° (N(3)—Co(1)—N(1)) to 116.8(2)° (Cl(2)—Co(1)—N(1)). The Co—N distances are almost equal (ave. 1.99 Å) and compare closely with those in **II**. The Co—Cl distances (Co(1)—Cl(1) 2.252(3) Å, Co(1)—Cl(2) 2.232(3) Å) are considered normal. The consequences of the 1,2-arrangement of the hydroimidazole rings is to create seven-membered chelate rings, with the result that the hydroimidazole rings themselves are mutually twisted and also twisted relative to the central benzene ring (Fig. 3; dihedral angles between least-squares planes *1–2*, 48.8°; *1–3*, 49.6°; *2–3*, 73.5°). Each half of the structure can be compared with that of the complex $Cu(OBT)Cl_2$, involving the related ligand 2,2′-*o*-phenylenebisbenzothiazole, which has a slightly distorted *cis*-square-planar structure involving very similar Cu—N and Cu—Cl distances (7). The DMF solvent molecule is hydrogen bonded via O(1) to hydrogen atom H(2), attached to the hydroimidazole nitrogen N(4), (N(4)—H(2) 1.067 Å; H(2)—O(1) 1.873 Å; N(4)—O(1) 2.829(9) Å).

Spectroscopy and magnetism

Characteristic infrared absorptions were observed for these complexes, associated with the ligand, in the range 3220–3320 cm^{-1}, due to the hydroimidazole N—H stretch, and in the range 1581–1606 cm^{-1} due to the hydroimidazole CN stretch. In the far infrared metal–nitrogen (hydroimidazole) stretching absorptions were identified in the range 290–310 cm^{-1}. For complexes **I** and **II** single absorptions associated with cobalt–halogen stretch were observed at 307 cm^{-1} (**I**) and 232 cm^{-1} (**II**), while for the 2:1 derivatives **III** and **IV** two clearly defined bands (308, 330 cm^{-1} (**III**); 215, 240 cm^{-1} (**IV**)) are assigned to cobalt–halogen stretch (Cl, Br, respectively) in a local C_{2v} environment. The solid state, mull transmittance, spectra (Table 6) of compounds **I**, **II** are characterized by the presence of two bands in the range 17 000 – 20 000 cm^{-1} and much weaker absorptions in the near infrared, which are assigned to *d–d* transitions in a square-pyramidal cobalt(II) centre. The higher overall absorption energies associated with **I** are consistent with an axially coordinated chlorine ligand. The general infrared and electronic spectral similarities between compounds **I** and **II** suggests a dinuclear metallocyclic structure for **I** similar to **II**. Compounds **III** and **IV** exhibit major solid state absorptions in the visible and near infrared regions, each clearly resolved into three components, and associated with the ν_3 and ν_2 transitions, respectively, in a C_{2v} distorted tetrahedral cobalt(II) centre. The lower energy absorptions in these regions associated with **IV** confirm the presence of coordinated bromine and suggest a structure similar to that in **III**. These spectral bands are typical of pseudo-tetrahedral cobalt(II) complexes with CoN_2X_2 chromophores and the absorption energies compare closely with bands observed for analogous, mononuclear complexes involving the ligands 1,2-bis(4,5-dihydroimidazol-2-yl)benzene(LP) and 1,2-bis(benzothiazol-2-yl)ethane(BBTE), which have very similar donor groups producing equivalent, seven membered chelate rings (8, 9). In DMF solution **III** and **IV** exhibit ν_3 and ν_2 transitions with almost identical absorption energies.

The 2:2 metallocyclic complexes **I**, **II** have high magnetic moments at room temperature (Table 6), typical of square-pyramidal or octahedral cobalt(II) compounds. The lower values observed for the 2:1 dinuclear complexes **III**, **IV** (4.47, 4.71 BM, respectively) are typical of pseudo-tetrahedral cobalt(II) species (10). Variable temperature magnetic studies were carried out on **I–IV** in the temperature range 5–305 K. Reciprocal susceptibility versus temperature plots showed that the Curie–Weiss law was obeyed in all cases over the full temperature range, with very small Weiss constants(θ = 0 to −7K). Such small values clearly do not signal the presence of very significant exchange interactions. For compounds **I** and **II** magnetic moments at 5 K exceeded 5.0 BM and so were not considered to have significant spin coupling between the cobalt(II) centres. The 1:1 metallocyclic, dinuclear copper(II) complexes of BTIM (2), which have the same structure as **II**, are very weakly antiferromagnetically coupled ($-2J < 2$ cm^{-1}), consistent with this observation. As a consequence the variable temperature magnetic data for these compounds were not analysed with respect to an exchange equation. A more pronounced decrease in magnetic moment (μ_{eff}) was observed for **III** and **IV** at low temperatures, and in the case of $[Co_2(BTIM)Br_4]$ (**IV**) the moment goes below the spin only value at about 7 K. The magnetic moment of cobalt(II) with a regular or slightly distorted tetrahedral geometry ($^4A_2$ ground state for T_d) is temperature independent, except at very low temperatures where zero field splitting may lead to some temperature dependence (11). Distinguishing such a situation from one involving very weak antiferromagnetic coupling is clearly difficult.

The magnetic data for **III** and **IV** were fitted to an exchange equation derived from the Van Vleck expression (12) for an isotropic, Heisenberg $S = 3/2,3/2$ pair. Very small negative J values ($-J$ = 0.432(8) cm^{-1} (**III**), $-J$ = 0.635(5) cm^{-1} (**IV**)) were obtained. However, since these J

Nature and characterization of the singlet and triplet excited states of the dibenzylideneacetone and di-3-(*N*-ethylcarbazoylidene)acetone bridging ligands[1]

PIERRE D. HARVEY[2] AND BENOIT DAOUST

Département de chimie, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Received March 13, 1992

PIERRE D. HARVEY and BENOIT DAOUST. Can. J. Chem. **70**, 2777 (1992).

The lowest energy singlet state in di-3-(*N*-ethylcarbazoylidene)acetone (dNECa), a luminescent model compound at room temperature for dibenzylideneacetone (dba), has been assigned to a charge transfer (CT) state using the medium polarity effect on $\lambda_{max}(F)$ and the fluorescence polarized spectra of dNECa at 77 K. The dNECa fluorescence quantum yields (ϕ_F) and lifetimes (τ_F) are solvent sensitive where both ϕ_F and τ_F tend to increase with polarity. The very weak and moderately structured phosphorences have been located for the first time for both dba and dNECa in the 550–800 nm range and are also assigned to a CT state. In this case the CT interactions are less pronounced than $\lambda_{(0\text{-}0)}P$ and τ_P are much less solvent sensitive. Finally, EHMO type calculations confirm that the CT transition is the lowest energy transition in dba and di-3-(*N*-methylindoylidene)acetone (a model compound for dNECa), but also suggest that the $n\pi^*$ state must lie near the CT state in dba.

PIERRE D. HARVEY et BENOIT DAOUST. Can. J. Chem. **70**, 2777 (1992).

En se basant sur l'effet de polarité du milieu sur le $\lambda_{max}(F)$ et sur les spectres de fluorescence polarisée de la dNECa à 77 K, on a attribué l'état singulet de base énergie de la di-3-(*N*-éthylcarbazoylidène)acétone (dNECa), un composé modèle de la dibenzylidèneacétone (dba) qui est luminescent à la température ambiante, à un état de transfert de charge (TC). Les rendements quantiques (Φ_F) et les temps de vie (τ_F) de la fluorescence de la dNECa dépendent tous les deux du solvant alors que Φ_F et τ_F ont tous les deux tendance à augmenter avec une augmentation de la polarité. Pour la première fois, on a pu localiser les phosphorescences très faibles et relativement bien structurées de la dba et de la dNECa dans la plage allant de 550 à 800 nm et on les a aussi attribuées à un état de TC. Dans ce cas, les interactions de TC sont moins prononcées et il en résulte $\lambda_{(0\text{-}0)}P$ et τ_P sont beaucoup moins sensibles aux effets de solvant. Enfin, des calculs du type orbitales moléculaires de HE confirment que la transition de TC est la transition de plus basse énergie dans la dba et la di-3-(*N*-méthylindoloylidène)acétone (un composé modèle de la dNECa) et suggèrent aussi que, pour la dba, l'état $n\pi^*$ doit se trouver près de l'état de TC.

[Traduit par la rédaction]

Introduction

The dibenzylideneacetone compound (dba) is a remarkable ligand that is particularly easy to synthesize and is capable of stabilizing Pd(0) and Pt(0) metals via coordination with the olefinic groups for preparing either mono- or binuclear species (1–6). In the free state the ligand adopts primarily the *s,cis–s,cis* conformation (7) and appears to be particularly photoreactive (8). Electron transfer and *cis,trans* isomerization reactions have been observed in the lowest-energy singlet (9) and triplet excited states, respectively (8). The luminescing singlet excited state has been assigned to a charge transfer (CT) state from the aryl groups to the ketone (9). There has been no spectroscopic evidence for an $n \rightarrow \pi^*$ transition associated with the presence of the carbonyl group although the molecule is closely related to benzophenone for which the lowest energy $n\pi^*$ singlet and triplet excited states are well known (10).

As mentioned, the dba ligand is photoreactive in solution. In the complexed state, our unreported results on the $M_2(dba)_3$ complexes (M = Pd, Pt) picosecond flash photolysis studies[3] have shown that the photoexcited binuclear complexes are efficiently deactivated, in part, via processes involving the bridging ligand. This investigation has an impact on the ongoing research on binuclear complexes substituted with electroactive pendant groups (11) in our laboratory. We recently showed that the excited state for $Pd_2(dba\text{-}Fc)_3$(dba-Fc = $(C_6H_5)CH{=}CH_2(CO)CH_2{=}CH(C_6H_4)(C_5H_4)Fe(C_5H_5)$) is due to metal-to-ligand charge transfer (MLCT) as in the $M_2(dba)_3$ complexes (M = Pd, Pt) (12), but appears to be ferrocenium localized in the oxidized form $[Pd_2(dba\text{-}Fc)_3]^{3+}$. Since the ferrocene molecule is an efficient deactivating agent for the triplet excited state (13), it became important to further investigate the nature of the dba excited states at this stage.

In this work we wish to report a number of experimental and theoretical results in order to address both singlet and triplet excited states, and the MO picture of the dba ligand. Since dba is not luminescent in solution at 298 K, the closely related model compound di-3-(*N*-ethylcarbazoylidene)acetone (dNECa) will be investigated (see Scheme 1 for structure). The CT fluorescence assignment will be spectroscopically demonstrated by polarity effects and polarization studies using dNECa. Furthermore, the very weak phosphorescences for dba and dNECa will be presented and assigned to a process arising from a CT state. The photophysical characterization of these two molecules is also made. Finally a qualitative MO analysis (via extended Hückel type calculations) will be examined for dba and di-3-(*N*-methylindoylidene)acetone (a model compound for dNECa) confirming the existence of the expected $n \rightarrow \pi^*$ and CT electronic transitions for both *s,cis–s,cis* and *s,cis–s,trans* conformations.

Experimental section

Materials

Dba (14) and dNECa (9) were prepared according to standard procedures. All the solvents: methanol (BDH), acetone (Fisher Scientific Company), acetonitrile (BDH), dimethyl sulfoxide (Fisher Scientific Company), dichloromethane (Fisher Scientific Com-

pany), dimethylformamide (BDH), chloroform (BDH), tetrahydrofuran (Aldrich Chemical Company), toluene (Mallinckrodt), benzene (Fisher Scientific Company), carbon tetrachloride (BDH), ehtyl acetate (BDH), dimethoxyethane (BDH), pyridine (BDH), butyronitrile (Aldrich Chemical Company), and 2-methyltetrahydrofuran (Aldrich Chemical Company), were purified according to standard procedures (15).

Apparatus

The absorption spectra were acquired on a Hewlett Packard 8452 A diode array spectrophotometer. The emission and excitation spectra were obtained using a Spex Fluorolog II spectrometer. The phosphorescence spectra and lifetime measurements were performed on a Spex 1934D phosphorimeter coupled with the Spex Fluorolog spectrometer. The fluorescence lifetimes were measured with a FL900 single photon counting fluorometer (Edinburgh Inst.) using a nF 900-ns flash-lamp source under the following conditions: electrode gap, 1.0 mm; gas, 0.5 bar of H_2(g) (1 bar = 100 kPa); applied EHT, 7.0 kV; repetition rate, 40 kHz.

Experimental procedures

The Φ_F values were measured using 9,10-diphenylantracene as standard (16). The polarization ratios (*N*) were measured according to literature procedures (see for examples ref. 17).

Computational details

All MO calculations were of the extended Hückel type (EHMO) using a modified version of the Wolfsberg–Helmholz formula (18). The atomic parameters used for C, O, and H are taken from ref. 19. The C—O, C—H, C=C, and C—C distances used for the computations are 1.23, 1.05, 1.31, and 1.46 Å as found crystallographically for the 2,2′-dimethyldibenzylideneacetone derivative in its *s,cis–s,cis* conformation. All angles were taken to be 120°, except for the torsional angle which was taken to be 0°. A detailed description of the graphic programs used in this work can

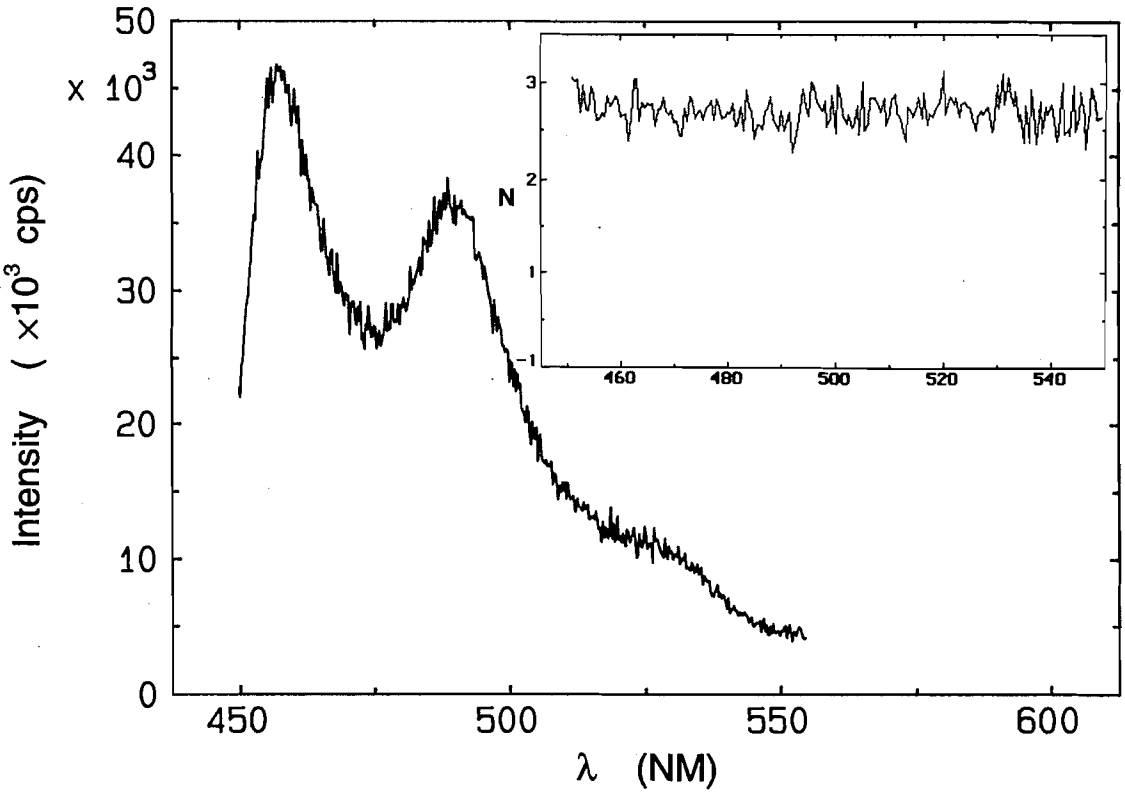

FIG. 2. Fluorescence spectrum of dNECa in 2-MeTHF at 77 K (concentration ~1 × 10^{-6} M). Insert: polarization ratio (N) as a function of λ using λ_{exc} = 447 nm (0-0 of the CT absorption band).

be found in ref. 20. Tables of atomic orbital contributions of the MO 41–45 for dba and 60–65 for di-3-(*N*-methylindoylidene)-acetone are provided as supplementary data.[4] Solution NMR studies proved that dba and dNECa have the *s,cis–s,cis* conformation (8, 9). The di-3-(*N*-methylindoylidene)acetone compound was used as a computational model for dNECa because the EHMO package (20) did not permit calculations for molecules exhibiting large numbers of MO's, and because the MO diagram would become more complicated than necessary for this work.

Results and discussion

1. CT Fluorescence assignment

The dNECa fluorescence appear as structureless symmetric bands that are sensitive to medium polarity. Table 1 lists the λ_{max}(F) values, the solvent dielectric constants (ε), and the Φ_F's for dNECa in various solvents at 298 K. The variation of λ_{max}(F) plotted against ε in the ln scale (Fig. 1) shows a clear increase in λ_{max}(F) (ranging from 476 to 525 nm = ~2070 cm^{-1}) with the medium polarity. For comparison purposes one should examine the spectroscopic data for some related monomeric compounds, particularly for 3-cyano-*N*-ethylcarbazole and 3-carboxyethyl-*N*-ethylcarbazole for which $\pi \rightarrow \pi$ fluorescences have been assigned (21). For the later, 60 and 170 cm^{-1} red shifts of the fluorescence bands for 3-cyano- and 3-carboxyethyl-*N*-ethylcarbazole, respectively, are reported for solvents going from 3-methylpentane to ethanol at 296 K (21). The particularly large polarity effect for dNECa is conclusively indicative of a CT fluorescence, and rules out the $n \rightarrow \pi^*$ emission. This CT assignment should be considered as a $\pi \rightarrow \pi^*$ transition in which a large charge separation is induced in the singlet excited state. The fluorescence quantum yield (Φ_F) also increases with the solvent polarity, but this increase is not as regular. The 77 K spectra are moderately vibrationally structured (Fig. 2) where the 0-0 band is easily recognized. Again the medium polarity induces large shifts in the fluorescence spectra as the 0-0 band shifts from 458 (toluene), to 462 (2-MeTHF), to 488 (butyronitrile), and to 492 nm (ethanol).

The second set of experiments involves the measurement of the polarization ratios (N). The CT assignment for the lowest energy absorption band has been established (9). The variation of the dipole moment should be polarized along the main (z) axis of dNECa in the C_{2v} point group (*s,cis–s,cis* conformation). According to the absorptivity data, ε ~21 000 M^{-1} cm^{-1} (9), this CT transition is allowed, and mixing of non-totally symmetric vibrational modes due to vibronic coupling is very unlikely. Theoretically, a value of N = 3 indicates that the emission is polarized parallel to the dipole moment change involved in the absorption process, while when N = 0.5, the luminescence is polarized perpendicular to the absorption. Figure 2 shows the fluorescence spectrum of dNECa at 77 K along with the polarization. The N values approach 3 all along the spectrum, clearly demonstrating that the emission does rise from the absorbing CT state and that no non-totally symmetric vibrational modes contribute to the intensity of the fluorescence, contrary to the substituted derivatives of carbazole

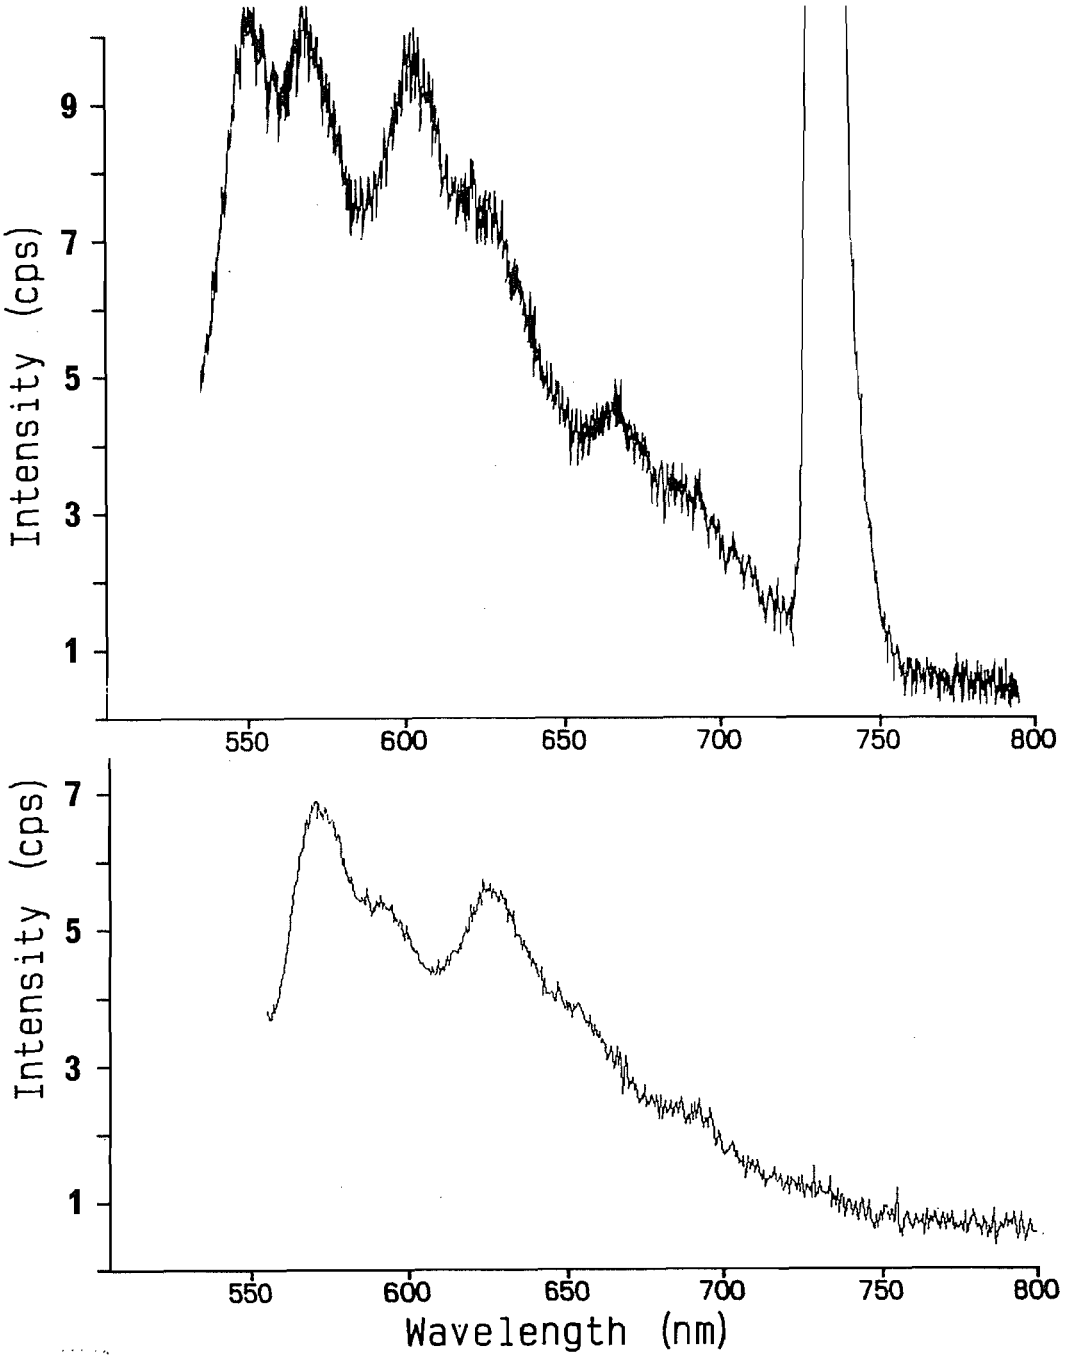

FIG. 3. Top: phosphorescence spectrum of dba in 2-MeTHF at 77 K (concentration $\sim 1 \times 10^{-4}$ M, λ_{exc} = 370 nm using a 450-W Xe lamp). Bottom: phosphorescence spectrum of dNECa in 2-MeTHF at 77 K (concentration $\sim 1 \times 10^{-5}$ M, λ_{exc} = 447 nm (0-0 of the CT absorption band) using a 450-W Xe lamp).

(17). The fact that N does not reach 3.0 (but rather ~2.7) for the 0-0 band is due to depolarization induced by glass imperfection and by solvent-induced depolarization.

The dba molecule could not be investigated as no emission was observed at 298 K and luminescence is very weak at 77 K ($\Phi_F < 0.01$). On the basis of the structural similarities (and the molecular orbital analysis; see the text below), the emissive singlet excited state is undoubtedly a CT state.

2. CT phosphorescence assignment

Very weak and moderately structured phosphorescence spectra were observed for dba and dNECa (Fig. 3) for which both band shapes and positions are very similar. The band positions are reported in Table 2. From the structured phosphorescence bands, two vibrational modes can be depicted, $\Delta\nu$ and $\Delta\nu'$ (Table 2) where the low- and high-frequency modes average ~540 ± 70 and ~670, and 1530 ± 70 and ~1540 cm^{-1} for dba and dNECa, respectively. The high-frequency modes are easily assigned to ν(C═C), not ν(C═O) (ν(C═O) = 1673 and 1694 cm^{-1} for dba and dNECa, respectively (9)). The IR and Raman spectra exhibit strong signals in this range where the closest frequencies are found at 1577 and 1576, and 1575 and 1550, for dba and dNECa,

respectively (9). The lower-frequency mode could be associated to ring deformation coupled with ν(C=C). No polarization measurement was attempted due to the weakness of the phosphorescence.

The 77 K phophorescence spectra do not appear to be especially sensitive to solvent polarity as a moderate 6-nm red shift is observed for dNECa going from toluene (570), to 2-methyltetrahydrofuran (574), to butyronitrile (576), and to ethanol (575 nm). The possibility of an $n \rightarrow \pi^*$ triplet excited state is also ruled out, and a CT assignment is preferred. The rather small red shift in the phosphorescence spectra in the polarity implies that this CT interaction is somewhat less extensive than that of the singlet excited state. The triplet state appears to possess significant $\pi\pi^*$ character, which is consistent with the *cis–trans* photoinduced isomerization in dba (8).

3. *Photophysical characterization*

As was the case for Φ_F (Table 1), the 298K τ_F values for dNECa in aprotic solvents vary with the medium polarity. The τ_F values are rather short as they range from 0.27 ± 0.07 to 0.51 ± 0.04 ns. Since the measurements are near the limit of the instrument, large uncertainties are induced. The radiative rate constants for fluorescence, $k_F(\Phi_F/\tau_F)$, and the non-radiative rate constants, k_{nr} ($(1 - \Phi_F)/\tau_F$), are listed in Table 3. Considering the experimental uncertainties, both k_F and k_{nr} are only weakly solvent dependent. The k_F values (ranging from (1.2 ± 0.4) × 10^8 to (3.3 ± 1.2) × 10^8 s^{-1}) compare reasonably with the theoretical value reported pre-

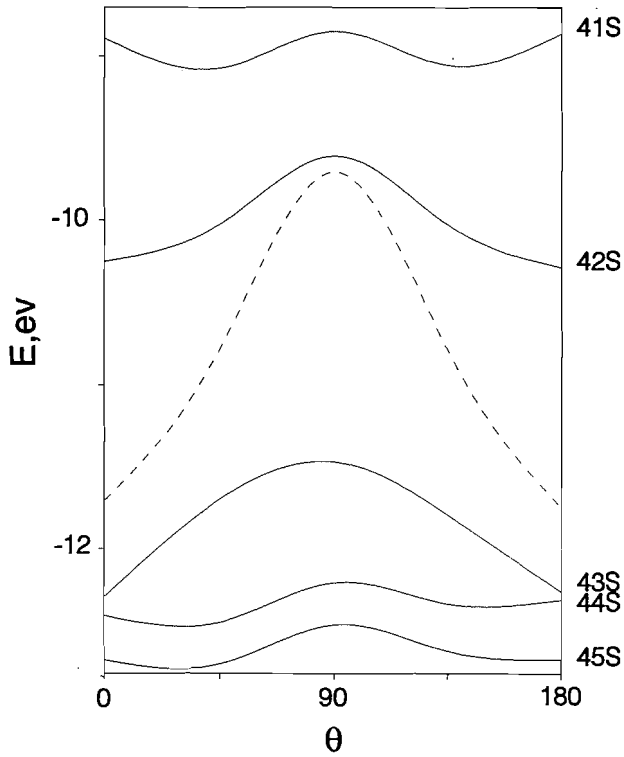

FIG. 4. Walsh diagram for the *s,cis–s,trans* (0°) → *s,cis–s,cis* (180°) conversion of dba around one of the (CO)—(C=C) bonds. MO no. 43 is the HOMO. The broken line is the total energy (1 div = 3 eV on this scale).

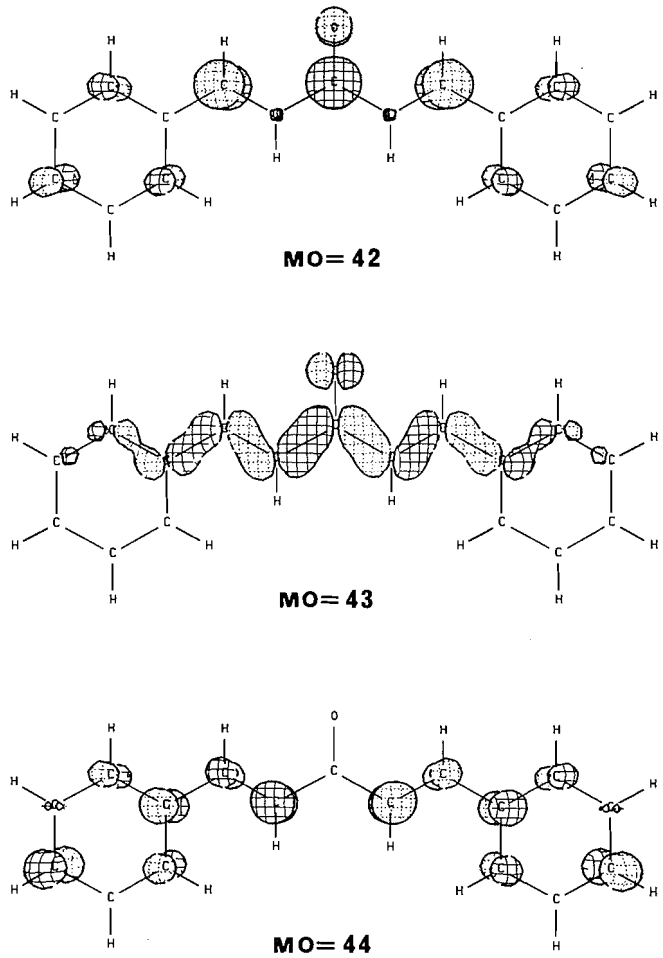

FIG. 5. MO diagram of the LUMO (no. 42), HOMO (no. 43), and HOMO-1 (no. 44) of *s,cis–s,cis* dba.

viously (3.9×10^8 s^{-1}) (9). At 77 K, both Φ_F and τ_F are also solvent dependent (Table 4) with the complication that the fluorescence decays exhibit biexponential kinetics. These biexponential kinetics were previously observed (9, 22) and tentatively interpreted in terms of *s,cis–s,cis* and *s,cis–s,trans* conformers (9). These conformers are in equilibrium, depending on both temperature and solvent (in the ground state) (6). The *s,cis–s,cis* form is the predominant form although a minor and non-negligible concentration of the second conformer exists (7). In this work no temperature dependence of the photophysical parameters is observed because one form is dominant over a very large temperature range. The dNECa phophorescence lifetimes (77 K; Table 5) are (like the $\lambda_{(0-0)}$P values) essentially solvent insensitive (and vary from 22.5 ± 0.3 to 24.8 ± 0.3 μs). The dba lifetime is similar but harder to measure; τ_p is 20 ± 2 μs in the same 77 K glasses. Interestingly, the low-energy triplet excited states in the diarylideneacetone compounds are not very sensitive to the meedium and do not appear to be strongly influenced by the nature of the aryl groups either.

4. MO Analysis

Assuming that the bond distances remain constant, a Walsh diagram is computed for dba undergoing the *s,cis–s,cis* (C_{2v}) ↔ *s,cis–s,trans* (C_s) conversion, via a rotation from 0° to 180° around one of the (CO)—(C=C) bonds (Fig. 4). In this graph the total energy (---) is plotted where a ~6.1 eV barrier to rotation is calculated with a maximum at θ = 90°. The *s,cis–s,cis* form is more stable (by only a few milli-electron volts), in agreement with previous observations (7). More importantly, the MO atomic contributions were also computed for both forms (Figs. 5 and 6). The LUMO's (no. 42; b_2 symmetry in the C_{2v} point group) have essentially the same atomic contributions and are delocalized π systems involving the C=O group. One other feature is that C_α and C_γ make little or no contribution to the MO. The MO contributions for the HOMO's and HOMO-1's (nos. 43 and 44, b_1 and a_2 symmetry in the C_{2v} point group, respectively) are inverted in the two conformers. This inversion does not appear as an MO crossing in the Walsh diagram, but rather appears as a gradual conversion from one set of atomic contributions to the other under the rotation. In the *s,cis–s,cis* form, the HOMO (no. 43) exhibits atomic contributions involving C—C σ-bonding and the nonbonding *p* orbital of the

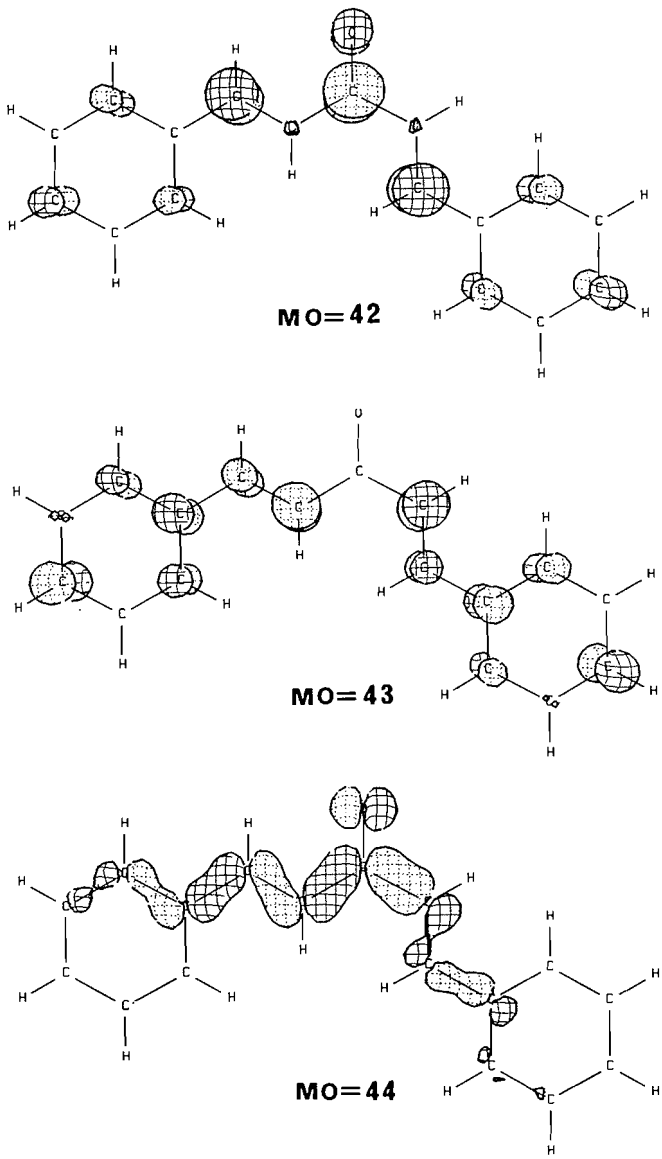

FIG. 6. MO diagram of the LUMO (no. 42), HOMO (no. 43), and HOMO-1 (no. 44) of *s,cis–s,trans* dba.

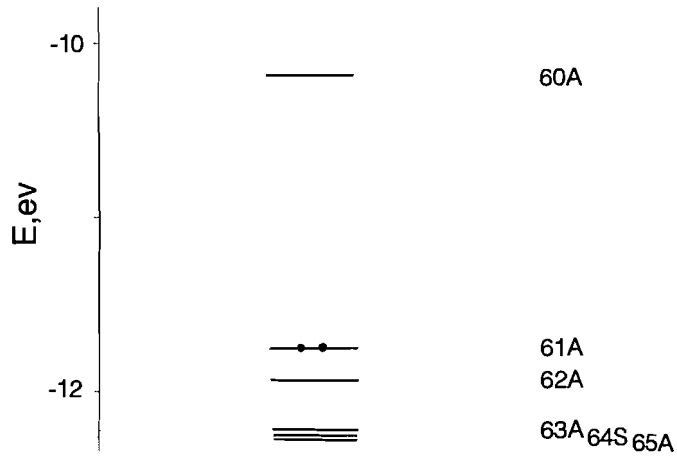

FIG. 7. Energy diagram for *s,cis–s,cis*-di-3-(*N*-methylindoylidene)acetone showing MO nos. 60 (LUMO) – 65. The atomic contributions for MO nos. 60–65 are provided as supplementary material (see footnote 3).

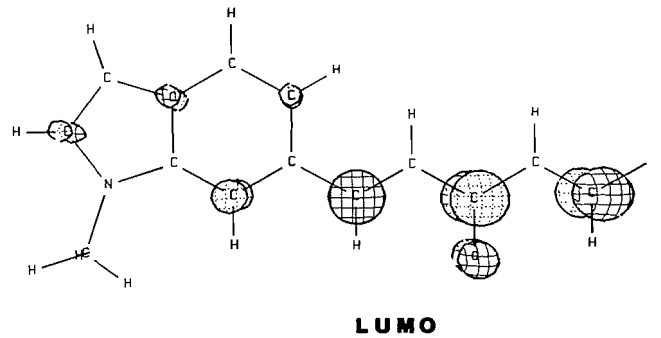

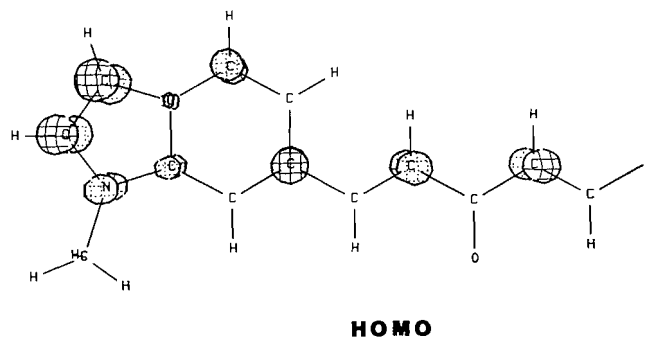

FIG. 8. MO diagram of the LUMO and HOMO for di-3-(*N*-methylindoylidene)acetone. The molecule is not shown completely since the LUMO exhibits a perpendicular miror plane at the C—O while the HOMO possess a C_2 axis along the C—O bond as is the case for dba.

O-atom, while the HOMO-1 is a π-delocalized system with no C=O contribution.

In the *s,cis–s,cis* form, the two lowest-energy transitions (HOMO → LUMO and HOMO-1 → LUMO; $^1A_1 \rightarrow {}^{1,3}A_2$ and $^1A_1 \rightarrow {}^{1,3}B_1$) are essentially the unobserved and orbitally forbidden $n \rightarrow \pi^*$ and a $\pi \rightarrow \pi^*$ type transition, respectively. In the latter case, the transition is polarized along the long axis of the molecule and induces a shift of the electronic density from the C_α-C_β-C_γ's to the C=O group and the C_β atoms that is indicative of a CT transition (from the ring to the C=O group), in agreement with our experimental observation. In the *s,cis–s,cis* form, the computed energy gap between the two MO's (nos. 43 and 44) is very small (0.047 eV) and is only indicative that they are close in energy.

To confirm that the luminescent dNECa is an appropriate model for dba, the *s,cis–s,cis* di-3-(*N*-methylindoylidene)-acetone compound (also C_{2v} point group; Fig. 7) is analyzed. The MO diagram (Fig. 7) exhibits a smaller LUMO (no. 60; b_1)–HOMO (no. 61; a_2) gap as expected, and the atomic contributions (Fig. 8) are very similar to the corresponding MO nos. 42 and 44 in *s,cis–s,cis* dba (Fig. 5). The two key features in this analysis are that the CT interaction during the lowest-energy electronic transition appears more

pronounced than in the dba case, and the energy gap between the HOMO and the MO corresponding to MO no. 43 in *s,cis–s,cis* dba (C—C σ-bonding + O nonbonding; no. 64 in this case) is now much greater (0.505 eV). The first result is perfectly consistent with the very large medium polarity effect on $\lambda_{max}(F)$ for dNECa, which appears not to be due to the presence of the heteroatom, but rather to extended π-delocalization. The second result implies that the $n\pi^*$-type excited states should definitely lie above the CT states in this case, as confirmed by the polarization experiments on dNECa.

Concluding remarks

While the lowest energy singlet excited state in dba is a CT state in nature, the triplet excited state possesses significant $\pi \rightarrow \pi^*$ character. These results are consistent with the photoinduced electron transfer and the typical *cis,trans*-isomerization reactivities of the dba singlet and triplet excited state, respectively. Since the τ_F and τ_P values are particularly short, excited state deactivation in their corresponding $M_2(dba)_3$ complexes (M = Pd, Pt) can be promoted if the process involve these (intraligand) states. Picosecond flash photolysis investigations on the $M_2(dba)_3$ (M = Pd, Pt) and $Pd_2(dba\text{-}Fc)_3$ complexes are in progress.

Received February 6, 1992

ROBERT I. HAINES and SANDRA J. NORTHCOTT. Can. J. Chem. **70**, 2785 (1992).

The kinetics of oxidation of several nickel(II) tetraazamacrocycles by the peroxydisulphate anion have been studied in water and in binary aqueous mixtures. The reactions proceed via an ion-pairing pre-equilibrium, followed by metal ion-assisted peroxy-bond fissure within the ion-pair solvent shell. The derived rate law is

$$\text{rate} = \frac{2k_4k_{ip}[S_2O_8^{2-}]\,[Ni(II)L]_{tot}}{1 + K_{ip}[S_2O_8^{2-}]}$$

Ion-pairing constants have been determined and have been found to be little influenced by steric factors, but do depend on solvent composition. Rate constants have been extracted using the rate expression and activation energies have been estimated from temperature dependences.

ROBERT I. HAINES et SANDRA J. NORTHCOTT. Can. J. Chem. **70**, 2785 (1992).

Opérant en milieux dans l'eau et dans des mélanges binaires aqueux, on a étudié la cinétique de l'oxydation, par l'anion peroxydisulfate, de plusieurs complexes de tétraazamacrocycles avec le nickel(II). Les réactions se produisent par le biais d'un pré-équilibre de paires d'ions, suivis d'un bris de la liaison peroxy assisté par l'ion métallique, à l'intérieur de la couche de solvant de la paire d'ions. La loi de vitesse qui en dérive est

$$\text{rate} = \frac{2k_4K_{ip}[S_2O_8^{2-}]\,[Ni(II)L]_{tot}}{1 + K_{ip}[S_2O_8^{2-}]}$$

On a déterminé les constantes de formation des paires d'ions et on a trouvé qu'elles ne sont pratiquement pas influencées par des facteurs stériques; elles dépendent toutefois de la composition du solvant. On a extrait les constantes de vitesse en utilisant une expression de vitesse et on a évalué les énergies d'activation à partir des dépendances sur la température.

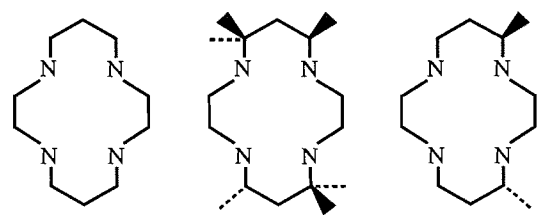
[Traduit par la rédaction]

Introduction

There have been many kinetic studies of oxidations by the peroxydisulphate anion, $S_2O_8^{2-}$ (1). Although $S_2O_8^{2-}$ is a very strong two-electron oxidant (E^0 = 2.2 V vs SHE), its redox reactions are usually slow. This is because the rate-determining step is thermal dissociation of the peroxy anion into SO_4^- radicals. Examples include the oxidation of thallium(I) (2), manganese(II) (3), and cerium(III) (4). The SO_4^- radical is known to be a very electrophilic species that can undergo H-atom abstractions (5) and addition reactions (6) and acts as an efficient one-electron oxidant with many substrates (7). Peroxydisulphate oxidations are, however, catalyzed by the presence of silver(I) ions (1, 3, 8), where a silver(I)-peroxydisulphate complex is postulated. The reduction of $S_2O_8^{2-}$ by a disilver(I) porphyrin complex (9) was found to be first order in both reactants. The porphyrin complex was labile and catalytic decomposition of the oxidant by free Ag(I) was suggested. Reaction of $S_2O_8^{2-}$ with Ag^+ alone is thought to proceed by a chain mechanism involving Ag^{2+}, AgO^+, SO_4^-, and OH^- intermediates, with the production of molecular oxygen (10). Intramolecular electron-transfer-assisted decomposition of peroxydisulphate has been found for a binuclear iron/ruthenium system (11).

As an oxidant, the peroxydisulphate anion has been used to prepare aqueous solutions of nickel(III) polyazamacrocycles (12), but no mechanistic studies of these reactions have been published to date. Xu and McAuley have used $S_2O_8^{2-}$ preparatively to oxidize macrobicyclic nickel(II) complexes, but found the kinetics intractible due to side reactions of the SO_4^- radicals (A. McAuley, personal communication).

In this paper, the kinetics of oxidation of nickel(II) tetraazamacrocycles, $[Ni(II)L]^{2+}$, by $S_2O_8^{2-}$ in aqueous and binary aqueous mixtures are examined. The ligands L_1–L_3 used in this work are described structurally in the schematic.



L_1 L_2 L_3

The mechanism of the reaction is described and the effects of added cosolvent are discussed in relation to solvent studies in other inorganic reaction mechanisms.

Experimental

Materials

The ligand L_1 (1,4,8,11-tetraazacyclotetradecane, 'cyclam') was used as received (Aldrich). L_2 (*meso*-5,7,7,12,14,14-hexamethyl 1,4,8,11-tetraazacyclotetradecane) and L_3 (2,3-dimethyl 1,4,8,11-tetraazacyclotetradecane) were synthesized according to the literature (13).

The nickel(II) complexes were prepared as the perchlorate salts by standard literature methods (13) and recrystallized from water prior to use. AnalaR grade potassium peroxydisulphate (BDH) was first washed several times with distilled water, then recrystallized four times from cold water, rinsed with ice-water, and dried over P_4O_{10} *in vacuo*. This procedure was found necessary to obtain reproducible, clean kinetics. Lithium perchlorate was prepared by neutralization of perchloric acid with lithium carbonate and was thrice recrystallized from water. All other reagents and solvents were of AnalaR grade and were used without further purification. All solutions were prepared using double-distilled, deionized water.

Kinetics

Kinetics were performed under pseudo-first-order conditions, using an excess of peroxydisulphate. The concentration of the nickel(II) complexes used in all experiments was 5.00×10^{-6} mol dm^{-3}. Absorbance changes with time were measured using 1 cm path length quartz cells in the thermostatted cell compartment of a Beckman DU-65 recording spectrophotometer. Data were collected using Beckman Datacapture software on a Wise AT-compatible microcomputer. First-order rate constants, k_{obs}, were calculated from the slopes of linear regression plots of $\ln(A_\infty - A_t)$ versus time. Reported values of k_{obs} are the means of at least three measurements. For any given set of conditions, repetitive measurements gave observed rate-constant values invariant within 1%.

A constant perchloric acid concentration of 0.0100 mol dm^{-3} was maintained to help stabilize the nickel(III) products. The stabilization of nickel(III) complexes in acidic media, as well as in the presence of coordinating ligands, is well known from kinetic studies (12, 14). Decomposition of the tervalent species at low acidity has been attributed to intramolecular electron transfer involving nickel(II)-ligand radical species. Ionic strength was kept constant at 0.300 mol dm^{-3} for all kinetic runs, using lithium perchlorate. Absorbance measurements were made at wavelengths chosen between 370 and 400 nm, to avoid interference by some of the co-solvents.

Results

Stoichiometric titration of the nickel(II) L_2 complex with $S_2O_8^{2-}$ in aqueous solution gave a ratio of 2.02 ± 0.05 : 1. The same stoichiometry was found for the reaction in the binary aqueous solvent mixtures used. The UV/visible spectrum of the product corresponded to the monosulphatonickel(III) species, $[Ni(III)L_2(SO_4)]^+$ (15). In aqueous solution, a clean isosbestic point was observed at 256 nm, indicating no observable intermediates. Furthermore, the product precipitated on addition of an aqueous solution of $NaBPh_4$. No precipitate was formed on addition of Ph_4AsCl to the product solution. These observations indicate the Ni(III) species to be cationic and the overall reaction may be described as

$$[1] \quad 2[Ni(II)L]^{2+} + S_2O_8^{2-} \rightarrow 2[Ni(III)L(SO_4)]^+$$

Excellent first-order kinetics were observed over at least five half-lives for the appearance of the nickel(III) products, in all solvents studied. This is remarkable in light of the well-known deviations from first-order behaviour in oxidations by peroxydisulphate that arise from reactions of SO_4^- radicals generated during the reaction (16). Thus the rate law

$$[2] \quad \text{rate} = +\frac{1}{2}\frac{d[Ni(III)L]}{dt} = k_{obs}[Ni(II)L]$$

is obeyed.

Table 1 lists the observed first-order rate constants for oxidation of the three nickel(II) complexes studied, in water as a function of temperature and $S_2O_8^{2-}$ concentration. Oxidation of $[Ni(II)L_2]^{2+}$ was much slower than that of the L_1 and L_3 complexes, as expected from the difference in electrode potentials for the nickel(II/III) complex couples (+0.67, +0.87, and +0.68 V (versus $Ag/AgNO_3$ (0.1 M) in acetonitrile) for the L_1, L_2, and L_3 complexes respectively) (17). Rates were independent of acid between pH 4 and 2, indicating no protonation of the oxidant in this range. This observation is consistent with the known lack of hydrogen-ion dependence in the oxidation of iron(II) by $S_2O_8^{2-}$ up to an acid concentration of 0.010 mol dm^{-3} (18). The addition of a radical scavenger, allyl acetate (19), caused no change in rates, within experimental error. This suggests that the rate-determining step does not likely involve the SO_4^- species.

Figure 1 shows the dependence of k_{obs} on $S_2O_8^{2-}$ concentration for the L_2 complex at several temperatures. The marked curvature in the plots (found for all systems studied) suggests an equilibrium pre-association of the ionic reactants prior to a rate-determining electron transfer. The general pattern bears resemblance to the classic Eigen–Wilkins (I_D) mechanism (20). A simplified mechanism (ignoring, for the moment, interchange between possible inner-sphere solvent at the nickel(II) complex and peroxydisulphate) may be described schematically as

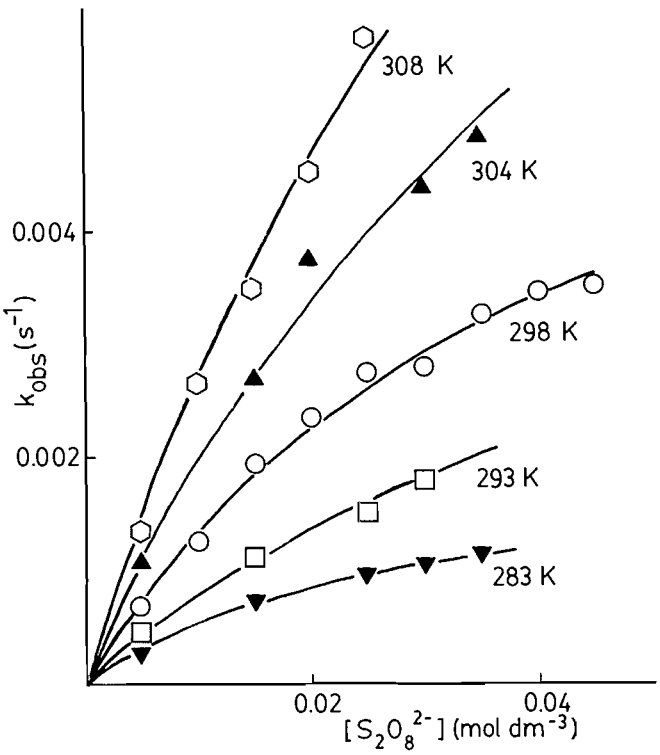

FIG. 1. Dependence of observed first-order rate constants on peroxydisulphate concentration for oxidation of the $[Ni(II)L_2]^{2+}$ cation at various temperatures.

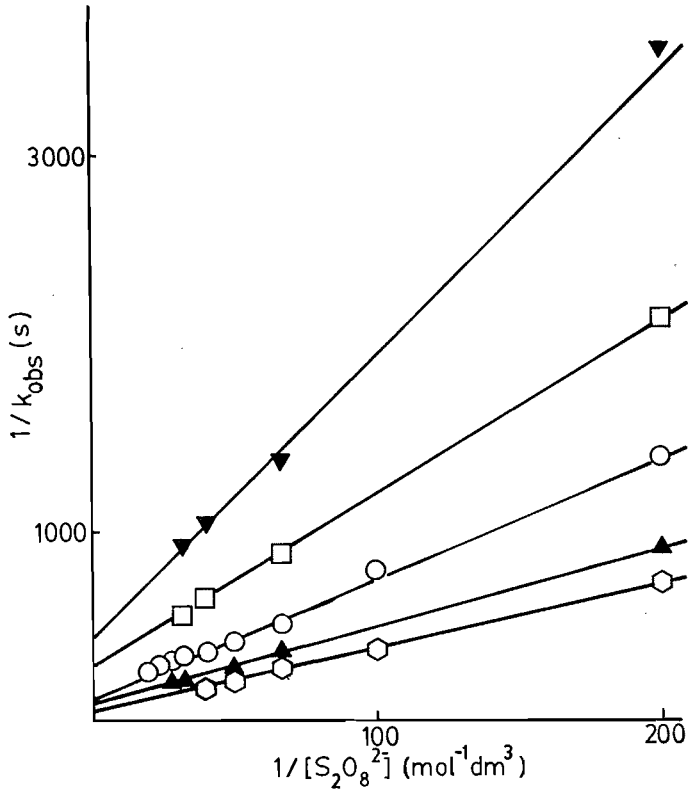

FIG. 2. Reciprocal plots for the data shown in Fig. 1.

$$[3] \quad [Ni(II)L]^{2+} + S_2O_8^{2-} \overset{K_3}{\rightleftharpoons} \{Ni(II)L^{2+}, S_2O_8^{2-}\} \quad \text{ion-pair}$$

$$[4] \quad \{Ni(II)L^{2+}, S_2O_8^{2-}\} \overset{k_4}{\rightarrow} [Ni(III)L(SO_4)]^+ + SO_4^-$$

$$[5] \quad [Ni(II)L]^{2+} + SO_4^- \overset{\text{fast}}{\rightarrow} [Ni(III)L(SO_4)]^+$$

The rate law derived from this scheme is

$$[6] \quad \text{rate} = \frac{2k_4K_{ip}[S_2O_8^{2-}]}{1 + K_{ip}[S_2O_8^{2-}]}[Ni(II)L]_{tot}$$

From eqs. [2] and [6], a plot of $1/k_{obs}$ versus $1/[S_2O_8^{2-}]$ should be linear, with a slope of $1/(2k_4K_{ip})$ and an intercept of $1/2k_4$. Figure 2 shows the inverse relationship for the L_2 complex at different temperatures. From such plots, the derived second-order rate constants, k_4, and ion-pairing constants, K_{ip}, for all reactions studied were computed using a linear least-squares fit. Table 2 lists these parameters for reaction of the three complexes in water as a function of temperature. From the temperature dependencies of the k_4 values, activation energies of 41.1 ± 1.3 and 34.9 ± 2.7 kJ mol^{-1} were calculated for the L_2 and L_3 complexes respectively.

Since the rates of reactions of the L_1 and L_3 complexes are near the measurable limit for the conventional kinetic equipment available to us, the L_2 complex was chosen for further study of solvation effects on the kinetics of the re-

0.0400			4.20 ± 0.06		

action. Table 3 lists k_{obs} for oxidation of the L_2 complex in a range of binary aqueous mixtures at 298 K. Figures 3 and 4 illustrate the effect of the added cosolvents methanol and acetone on the observed first-order rate constants. At first glance the data seem erratic, but reciprocal plots analogous to those in Fig. 2 yield the ion-pairing constants, K_{ip}, and second-order rate constants, k_4, listed in Table 4. The observed trend in these parameters with added cosolvent is consistent with that expected for increasingly hydrophobic media.

The magnitudes of the ion-pairing constants in all media studied are consistent with those expected for a 2+/2− pair (see Table 5), indicating the $S_2O_8^{2-}$ anion, not $HS_2O_8^-$, to be the reacting species.

Discussion

Mechanism

Reduction of peroxydisulphate characteristically proceeds via rate-determining fission of the peroxy bond (1), a step that may be assisted by the presence of a metal ion. In the present study, formation of an ion-pair provides a catalytic pathway for reduction of $S_2O_8^{2-}$ by the Ni(II) centre.

In the classic Eigen–Wilkins mechanism for complex formation, a rapid pre-equilibrium outer-sphere association (or ion-pairing) followed by rate-determining exchange of inner-sphere solvent with the incoming ligand obtains. This mechanism is summarized as

$$[7]\quad M(OH_2)_6^{n+} + L \overset{K_{os}}{\rightleftharpoons} \{M(OH_2)_6^{n+}, L\} \overset{k_{ex}}{\rightarrow} \{M(OH_2)_5L^{n+}\} + H_2O$$

The derived rate law for this scheme is

$$[8]\quad \frac{+d[ML^{n+}(aq)]}{dt} = \frac{K_{os}k_{ex}[M^{n+}][L]}{1 + K_{os}[L]}$$

Nickel(II) tetraazamacrocycles exist in aqueous solution as a mixture of low-spin square planar $[Ni(II)L]^{2+}$ and high-spin tetragonal $[Ni(II)L(OH_2)_2]^{2+}$ ions (21):

$$[9]\quad NiL^{2+}(aq) + 2H_2O(l) \overset{K_9}{\rightleftharpoons} NiL(OH_2)_2^{2+}$$

Electrostatic interaction of the peroxydisulphate anion with the square planar nickel(II) complex will occur according to eq. [3], and with the tetragonal bis-aquo species:

$$[10]\quad NiL(OH_2)_2^{2+} + S_2O_8^{2-} \overset{K_{10}}{\rightleftharpoons} \underset{\text{ion-pair}}{\{NiL(OH_2)_2^{2+}, S_2O_8^{2-}\}}$$

For intimate ion-pair formation, exchange between the inner-sphere solvent and $S_2O_8^{2-}$ must occur, analogous to that in eq. [7]:

$$[11]\quad \{NiL(OH_2)_2^{2+}, S_2O_8^{2-}\} \rightarrow \{NiL, S_2O_8^{2-}\} + 2H_2O$$

Estimated values of the rate of interchange of inner-sphere water with a variety of incoming ligands of varying charge have been tabulated by Burgess (22). The values fall in the range of 3–30 × 10^3 s^{-1}, which is close to the solvent exchange rate for water at $Ni^{2+}(aq)$ of 3 × 10^4 s^{-1} (23). It is reasonable to assume that like $Ni^{2+}(aq)$, interchange at the bis-aquo nickel(II) tetraazamacrocycle will be dissociative, with an exchange rate that is fast relative to the rate-

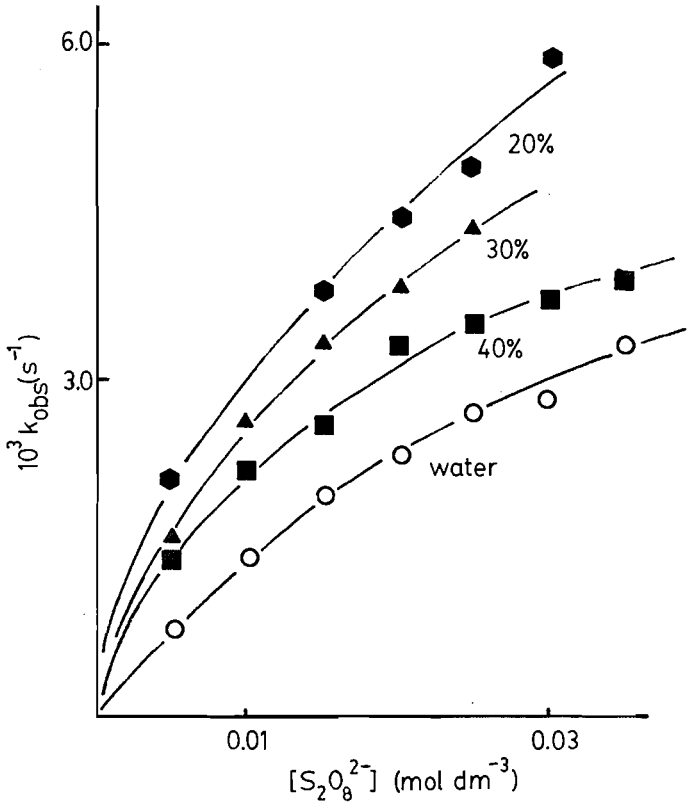

FIG. 3. Dependence of observed first-order rate constants on peroxydisulphate concentration for oxidation of the $[Ni(II)L_2]^{2+}$ cation in methanol–water mixtures (T = 298 K). Aqueous data are included for comparison.

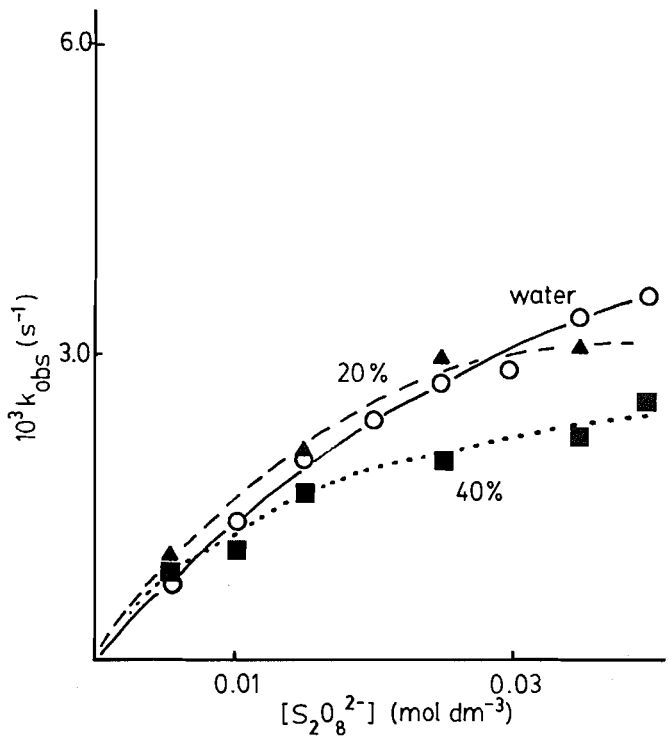

FIG. 4. Dependence of observed first-order rate constants on peroxydisulphate concentration for oxidation of the $[Ni(II)L_2]^{2+}$ cation in acetone–water mixtures (T = 298 K). Aqueous data are included for comparison.

determining peroxy-bond fissure in our system. The interchange rate at $Ni^{2+}(aq)$ for sulphate has been estimated as 1.0×10^4 s^{-1} at 20°C (24).

After formation of the intimate ion-pair, the redox step results in the formation of a sulphatonickel(III) complex. The lack of rate dependence on radical scavengers suggests that peroxy-bond fissure and Ni(III)–SO_4^{2-} bond formation occur concomitantly, according to eq. [4].

A rate law can be derived for the reaction, from eqs. [3]–[5] and [9]–[11]:

$$[12] \quad \text{rate} = \frac{2k_4K'[S_2O_8^{2-}]\,[Ni(II)L]_{tot}}{1 + K'[S_2O_8^{2-}]}$$

where $K' = (K_9K_{10} + K_3)$. The value of K_9 is small compared with K_3, whence $K' \approx K_3$ (which we have designated K_{ip}).

It is seen in Table 2 that the values of K_{ip} are little affected by the presence of substituents on the macrocyclic ligands. This indicates that the macrocycle does not impede the approach of the dianion to the metal centre, suggesting axial approach of the oxidant to the nickel in the ion-pair. The K_{ip}'s for the complexes agree well with that for pairing of aquonickel(II) with sulphate ion (Table 5), further supporting close approach of the $S_2O_8^{2-}$ to the nickel centre in the complexes without steric interference by the macrocyclic ligands. The precision of measuring K_{ip}'s is not good enough to detect subtle effects in the primary/secondary solvation shells of the complex (22). The activation energies (Table 2) are high for outer-sphere redox processes, but are approximately half the value expected for rate-determining peroxy-bond fissure (25). This is further evidence for assistance to peroxy-bond fissure by the macrocyclic complexes.

TABLE 4. Solvent effects on rate and equilibrium constants for the $[Ni(II)L_2]^{2+}/S_2O_8^{2-}$ system at 298 K

Solvent (% v/v)	k_4 (s^{-1})	K_{ip}
Water	0.00393 ± 0.00005	20 ± 6

40%	0.0017 ± 0.0002	61

Electrochemical and pulse radiolysis studies (26) have shown that in sulphate media nickel(III) tetraazamacrocycles are stabilized by axially coordinated sulphate(s). Axial proximity of the oxidant to the metal centre is expected to facilitate electron transfer from Ni(II) to the dianion, with concomitant peroxy-bond elongation in the transition state. Pennington and Haim (27) have shown that an inner-sphere mechanism obtains in the oxidation of chromium(II) by peroxodisulphate, with the formation of a mixture of $CrSO_4^+(aq)$ and $Cr^{3+}(aq)$.

TABLE 5. Ion-pairing constants for M^{n+}/X^{y-} systems in water at 298 K

M^{n+}	X^{y-}	K_{ip}	Reference
$Ni^{2+}(aq)$	$ImidH^+$	0.02	39
$Ni^{2+}(aq)$	$N\text{-Me-imid}^+$	0.02	39
$Ni^{2+}(aq)$	Histidine	0.15	39
$Ni^{2+}(aq)$	Imidazole	0.15	39
$Ni^{2+}(aq)$	HF	0.15	39
$Ni^{2+}(aq)$	$Hoxalate^-$	2	40
$Ni^{2+}(aq)$	$Oxalate^{2-}$	13	40
$[Ni(II)L_1]^{2+}$	$S_2O_8^{2-}$	24	This work
$[Ni(II)L_2]^{2+}$	$S_2O_8^{2-}$	20	This work
$[Ni(II)L_3]^{2+}$	$S_2O_8^{2-}$	19	This work

There appears to be little temperature dependence for the estimated values of K_{ip} (Table 2). However, the errors associated with their estimation precludes any confident interpretation of trends. The apparent lack of temperature dependence of K_{ip} on temperature indicates a near zero enthalpy for ion-pair formation. The entropy change for this process may be calculated as $+6.0\ J\ K^{-1}\ mol^{-1}$, using a value of 20 for K_{ip}. These values are not dissimilar to those obtained for ion-pair formation between the aquopentamminecobalt(III) cation and sulphate anion ($\Delta H = 0$ and $\Delta S = +68\ J\ K^{-1}\ mol^{-1}$ at zero ionic strength; $-1.3\ kJ\ mol^{-1}$ and $+14\ J\ K^{-1}\ mol^{-1}$ at ionic strength 1.0 mol L^{-1}) (28). The small entropy value is consistent with ion-pair formation rather than complexation, since fewer solvent molecules are released in the former case. Comparison of entropies of association for a series of ions forming inner- and outer-sphere associations has been made (29), showing significantly lower entropies for outer-sphere (ion-pairing) couples than inner-sphere (complexing) ones. Enthalpies of association for ion-pairing in these systems was also small, despite large charge neutralisations ($|z_+z_-| = 9$ or 10).

The most significant feature of our results is that within an order of magnitude the values of K_{ip} correspond to ion-pairing constants for $Ni^{2+}(aq)$–X^{2-}. Again, this supports the contention that the peroxydisulphate anion approaches the nickel(II) centre axially.

Solvent effects

Peroxydisulphate is known to oxidize organic solvents such as alcohols (30, 31), dimethyl sulphoxide (32), and acetone (33), particularly in the presence of metal-ion catalysts. These reactions have been shown to proceed by radical chain mechanisms, but are exceedingly slow compared with the rate of oxidation of the nickel complexes in this work and offer no interference.

Ion-pairing constants were found to increase with increasing organic content of the solvent mixture (Table 4). This behaviour is in accord with the electrostatic model of ion-pairing, where K_{ip} is dependent on the charge product of the component ions, the distance between the centres of the ions, and the dielectric constant of the medium (22).

The second-order rate constants, k_4, are relatively insensitive to bulk solvent composition, although there is a slight decrease in k_4 with increased organic component. For a second-order reaction between oppositely charged ions, it is expected that increasing the hydrophobic character of the medium would stabilize the free energy of the transition state relative to that of the initial state (34). Hence a reduction in the activation energy for the reaction in the more hydrophobic medium is expected relative to water. This would result in an increase in rate constants in the binary mixtures relative to those in water. Such effects have been observed, for example in the mixed-solvent study of the mercury(II)-catalysed aquation of hexachlororhenate (35).

In the present study, the slight changes in rate constants with increasing hydrophobicity of the medium suggests that the system has undergone any major electrostatic rearrangements that are likely, prior to the rate-determining step. Only slight solvation differences are apparent in the system before and after electron transfer. This agrees with the proposed mechanism, where concomitant nickel(II) oxidation peroxy-bond fissure occurs within the solvent cage of the ion-pair, oblivious to the solvation effects of the bulk medium. Retardation of rates on going from water to binary aqueous mixtures has been observed previously (36) for oxidation of tris-diimine iron(II) complexes. In those cases, trends in reaction rates with solvent composition were explained in terms of changes in initial-state versus transition-state energies.

Recently, there has been a series of reports on solvent effects on peroxydisulphate oxidations of transition-metal complexes (37, 38). In all of the systems studied, decreases in rates with increasing organic cosolvent were observed, in agreement with the present study. Holba *et al.* (36, 37) did not detect ion-pairing, which is not unexpected since their cationic complexes were singly charged.

Azetinone formation is not competitive with intermolecular reactions of a β-lactam-4-ylidene

MICHEL ZOGHBI AND JOHN WARKENTIN[1]
Department of Chemistry, McMaster University Hamilton, Ont., Canada L8S 4M1

Received May 1, 1992

MICHEL ZOGHBI and JOHN WARKENTIN. Can. J. Chem. **70**, 2792 (1992).

3-Phenoxy-1-phenyl-2-azetidinon-4-ylidene (β-lactam-4-ylidene) **2***a*, was generated by thermolysis of a spiro-fused β-lactam oxadiazoline precursor (**1**). Fast 1,2-H migration, a characteristic reaction of singlet carbenes that would convert **2***a* to 3-phenoxy-1-phenyl-3-azetin-2-one (**4***a*) could not be demonstrated. Added 1, 3-diphenylisobenzofuran (**6**) did not afford the [4+2] cycloadduct (**7**) expected from **4***a* but, instead, the isomeric *E*- and *Z*-4-[1-(2-benzoylphenyl)-1-phenyl]-methylene-3-phenoxy-1-phenylazetidin-2-ones (**9**). Those compounds can be rationalized as the products of rearrangement of first-formed [2+1] adducts of **6** and the ylidene. The structure of the *Z* isomer of **9** was established by means of single crystal X-ray diffraction. Generation of **2***a* in methanol-d_4, either neat or 3.3 M in benzene, afforded the isomeric products of carbene insertion into the OD bond of methanol-d_4. Structural isomers expected from addition of methanol-d_4 to **4***a* could not be detected. The results suggest that 1,2-H migration in **2***a* is relatively slow, with $k_H \leq 1.4 \times 10^6$ s^{-1} at 100°C, which is slower than analogous rearrangement of benzylchlorocarbene by 200-fold or more.

MICHEL ZOGHBI et JOHN WARKENTIN. Can. J. Chem. **70**, 2792 (1992).

La thermolyse d'une oxadiazoline spiro-condensée à une β-lactame (**1**) conduit au 3-phénoxy-1-phényl-2-azétidon-4-ylidène (β-lactam-4-ylidène) (**2***a*). On n'a pas pu mettre en évidence de migration rapide 1,2-H, une réaction caractéristique des carbènes singulets qui permettrait de transformer le composé **2***a* en 3-phénoxy-1-phényl-3-azétin-2-one (**4***a*). L'addition de 1,3-diphénylisobenzofurane (**6**) n'a pas permis d'isoler le cycloadduit [4+2] (**7**) que l'on pourrait attendre à partir du produit **4***a*; on a plutôt obtenu les *E*- et *Z*-4-[1-(2-benzoylphényl)-1-phényl]-méthylène-3-phénoxy-1-phénylazétidin-2-ones isomères (**9**). On peut rationaliser la formation de ces produits par une transposition des adduits [2+1] du produit **6** et de l'ylidène qui se forment en premier. On a déterminé la structure de l'isomère *Z* du composé **9** grâce à la diffraction des rayons X par un cristal unique. La génération du composé **2***a* dans du méthanol-d_4, soit à l'état pur ou en solution 3,3 M dans le benzène, fournit des produits d'insertion du carbène dans la liaison OD du méthanol-d_4. On n'a pas pu détecter les isomères de structure que l'on pourrait attendre lors de l'addition du méthanol-d_4 sur le composé **4***a*. Les résultats suggèrent que la migration 1,2-H dans le composé **2***a* est relativement lente, alors que $k_H \leq 1{,}4 \times 10^6$ s^{-1}, à 100°C; cette valeur est 200 fois plus faible que celle observée lors de la transposition analogue du benzylchlorocarbène.

Despite intense interest and activity in the area of β-lactam chemistry (for post-1980 reviews, see ref. 1), β-lactam-4-ylidenes, **2**, were described only recently (2). They can be generated efficiently and conveniently by heating spiro-β-lactam oxadiazolines (**1**) at ca. 100°C in solution, Scheme 1, and they have considerable potential for elaboration of the β-lactam system by both intramolecular and intermolecular reactions (2). Two potential intramolecular reactions of **2** include 1,2-H migrations leading to azetinones, **3** and **4**. With **1***a* (R^1 = Ph, R^2 = OPh, R^3 = H) in hand (2) we were in a position to generate **2***a* (R^1 = Ph, R^2 = OPh, R^3 = H) and to examine its fate. Azetinones are not stable species: An azetinone of type **4** has been observed at −5°C by spectroscopic methods (3) but none has ever been isolated despite attempts by several groups (4–6). Azetinones **3** have not been isolated either, but their existence as transients is a facet of postulated mechanisms of nucleophilic substitutions on β-lactams (7) bearing a leaving group (L) at C4, Scheme 2, and of the hetero-Diels–Alder reactions, to form **5**, reported by Meyers' group (8).

Methods, results, and discussion

In view of the limited stabilities of azetinones **4**, diphenyl isobenzofuran (**6**) was included to trap **4***a*, *in situ*, as the [4π+2π] cycloadduct **7**, Scheme 3.

Thermolysis of **1***a* in benzene containing **6** (0.5 M) did not take the course leading to **7**. Instead of **7**, two 1:1 adducts of **2***a* and **6** were isolated, each in 16% yield. Spectroscopic data (ir, ^{1}H nmr, ^{13}C nmr) indicated not only a higher β-lactam carbonyl frequency (1800 cm^{-1}) than in **1***a* (1792 cm^{-1}) and the presence of another carbonyl group (ca. 1665 cm^{-1}), but also a high probability of geometric isomerism. Single crystal X-ray diffraction showed that one of the products was *Z*-4-[1-(2-benzoylphenyl)-1-phenyl]-methylene-3-phenoxy-1-phenylazetidin-2-one, **9***a*.[2] The other product could then be identified, from its spectra, as the corresponding *E* isomer, **9***b*. In view of the fact that **2***a* and its analogues have been shown to add to CC double bonds, as in styrene (2) and 4-bromo-1-butene,[3] we propose an analogous cyclopropanation in the first step, to form **8**, presumably as a mixture of all possible isomers (Scheme 4). As a special divinylcyclopropane, with heteroatom substituents and phenyl groups as well, isomers **8** are not expected to be stable at 100°C. A reasonable mechanism for formation of **9** (Scheme 5) begins with an expected vinylcyclopropane bond cleavage in **8**, leading to diradical **10**, which undergoes β-scission to form **9***a* and **9***b*.

We were unable to find a precedent in the literature for formation of a 4-methylene-β-lactam by a carbene route. A few members of the family are known (9) but molecular structures of compounds containing that interesting ring

[1]Author to whom correspondence may be addressed.

[2]Full details of the crystal and molecular structures of **9***a* will be published elsewhere.

SCHEME 3

system have not been reported. Major structural features of the β-lactam portion of **9***a* (bond lengths and bond angles) are given in Fig. 1.[2]

Reactions of singlet carbenes with 1,3-diarylisobenzofurans, including 1,3-diphenylisobenzofuran (10, 11), are known. Thus dichloro, dibromo, and diiodocarbene react with **6** to afford the appropriate β,β-dihalo-[2-benzoyl]-styrenes (10). The authors (10) also proposed initial [2+1] cycloaddition and subsequent rearrangement of vinylcyclopropane systems analogous to **8**.

A second test for azetinone **4***a* involved generation of **2***a* in methanol-d_4. If carbene **2***a* were to rearrange to **4***a* in competition with its insertion into the OD bond of methanol-d_4, then geometric isomers **11***a* and **11***b* would be expected as well as their structural isomers, **12***a* and **12***b*, Scheme 6.

The system was calibrated by generating **2***a* in neat CH_3OH by thermolysis of **1***a* at 100°C. Insertion products **11***c* and **11***d* were formed quantitatively in the ratio **11***c* (*trans*): **11***d* (*cis*) = 2.6:1. Chemical shifts (δ) for the proton at C3 were: *trans*, 5.26 (s, br); *cis*, 5.30(J = 3.6 Hz). Three experiments with CD_3OD were then carried out with concentrations of CD_3OD (in benzene) at 0.06, 0.40, and 3.30 M as well as one experiment in neat CD_3OD. Products from the low-concentration runs (0.06 and 0.40) were very complex and inconclusive because products of insertion into CD_3OD (if any) could not be identified or isolated. However, the

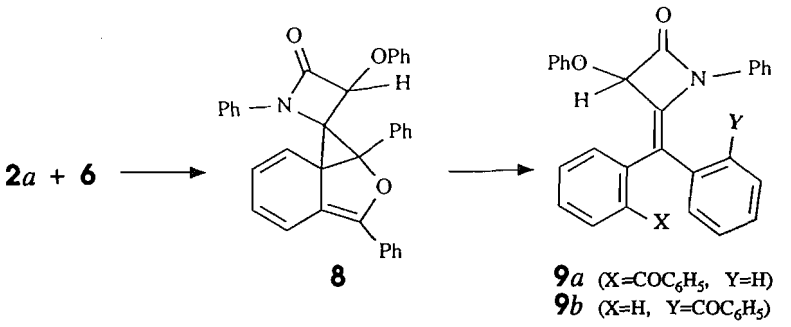
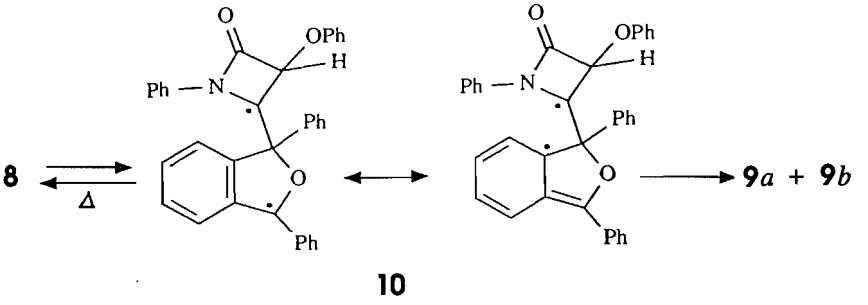


SCHEME 4



SCHEME 5

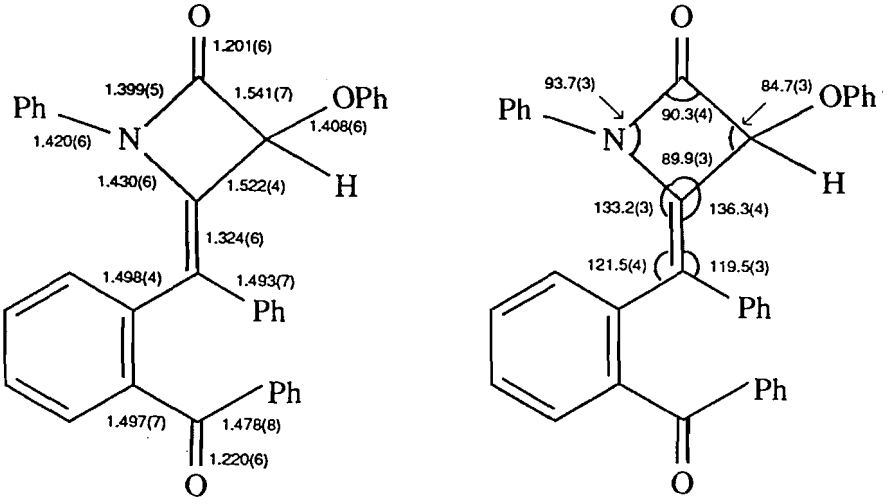


FIG. 1. Bond lengths (Å) and bond angles (degrees) of **9a**.

experiment with 3.30 M CD_3OD afforded **11***a* and **11***b* in ca. 70% yield and that with neat CD_3OD afforded the same products in quantitative yield. In both cases, the isomer ratio was 2.6:1 and the signals at δ 5.27 (*trans*) and 5.30 (*cis*) were singlets. Moreover, the signals from C4-H (*trans*, δ = 5.44, J = 0.63 Hz; *cis*, δ = 5.68, J = 3.6 Hz) in the ^{1}H nmr spectra of **11***c* and **11***d*, respectively, were absent from spectra of products formed in CD_3OD. Therefore, perdeuteromethanol afforded **11***a* and **11***b* from carbene **2***a* and not **12***a* and **12***b* from azetinone **4***a*.

Rearrangement of carbene **2***a* to azetinone **4***a* is probably slower than analogous 1,2-H migrations in other carbenes, because of strain in the azetinone. A rough estimate of the increase in strain (in units of displacement from ideal angles, in degrees) was obtained by assuming that actual internal bond angles in the carbene are 90° (N1), 93° (C2), 87° (C3), and 89° (C4) and that those in the azetinone are all 90°. The inherent carbene bond angle in an unconstrained singlet carbene was assumed to be that of singlet methylene, 102° (12), and inherent bond angles at the sp^2 and sp^3 carbons were taken to be 120° and 109°, respectively. Given these assumptions, the angle strain increase accompanying the rearrangement **2***a* → **4***a* is about 28°.[4] Some fraction of that increase in angle strain must be present at the transition state for migration, to reduce the rate constant for that step. Nevertheless, the absolute value of that rate constant could still be substantial, given that rearrangement of benzyl-

[4]Small changes in the assumed bond angles do not affect the sense of the change of angle strain.

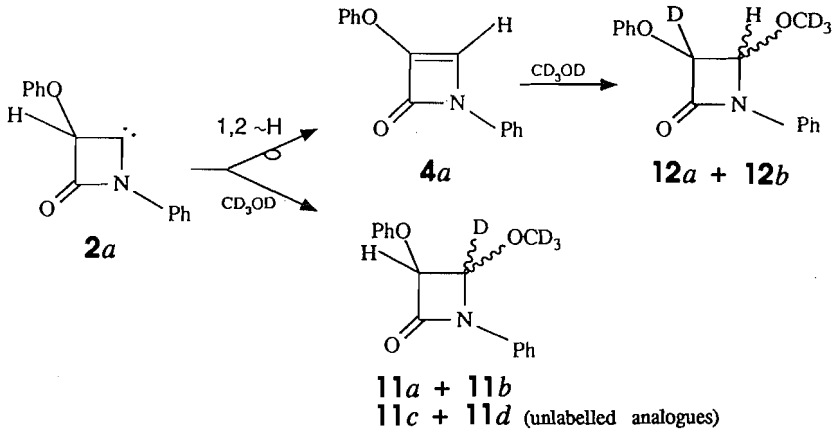

SCHEME 6

chlorocarbene occurs with k (100°C) $\simeq 2.9 \times 10^8$ s^{-1} (calculated from $A = 10^{11.1}$ s^{-1} and $E_a = 4.5$ kcal mol^{-1}) (13). If 1,2-H migration in **2***a* were slower by a factor of 100, bimolecular reaction of **2***a* with **6** would consume half of the carbene at [**6**] = 5×10^{-3} M, assuming that the rate constant for trapping of **2***a* with **6** is about the same as that for trapping of benzylchlorocarbene with tetramethylethylene (6×10^8 M^{-1} s^{-1} (13). Experiments with [**6**] = 5×10^{-3} M are out of the question, given that the yield was only 32% with 100-fold more concentrated **6**

The rate constant for trapping of singlet dimethoxycarbene with methanol has a value $\simeq 10^5$ M^{-1} s^{-1} at 20°C (14). Assuming that dimethoxycarbene is an adequate model for **2***a* and that the rate constant at 100°C would be about 10^6 M^{-1} s^{-1}, the experiment with 3.3 M methanol suggests that the rate constant for 1,2-H migration in **2***a* has a value $\leq 1.4 \times 10^6$ s^{-1} at 100°C. Those results also have a bearing on the lifetime of the carbonyl ylide precursor of carbene **2***a*, as discussed below.

A question that remains is the fate of the fraction of carbene **2***a* that is not trapped by **6** (0.5 M) or by methanol (≤3.3 M). In view of the fact that trapping by neat methanol was quantitative, bimolecular reactions of the carbonyl ylide (Scheme 7) are unlikely. Although **14** could be converted to the observed products in methanol, analogous compounds from genuine trapping of carbonyl ylides by methanol survive similar conditions (15). We assume, therefore, that the lifetime of the carbonyl ylide intermediate (Scheme 1) is very short. There are then two explanations for the fact that carbene trapping can be surprisingly inefficient without competition from azetinone formation. First, the carbene may undergo fast alternative unimolecular reactions, such as fragmentations or insertions (Scheme 8). Second, it is conceivable that some azetinone (**4***a*) is actually formed and that it undergoes unimolecular reactions (Scheme 9) fast enough to escape trapping by the reagents that were chosen. Azetinones **4** can rearrange rapidly to iminoketenes (6) and *N*-phenyliminoketenes undergo efficient electrocyclization (16) to 4-(1*H*)-quinolinones. Electrocyclic ring opening of cyclobutenones to ketenes is also well known (17) and serves as a second model for the potential ring opening of **4***a*. We were not able to isolate any 3-phenoxy-4-(1*H*)-quinolinone (Scheme 9) and fragmentation to phenylisocyanate can be ruled out, at least in the reactions where methanol was present, because methyl-*N*-phenylcarbamate was not obtained.

In summary, the potential 1,2-H migration that would rearrange β-lactam-4-ylidene **2***a* to azetinone **4***a* is slowed because of increased angle strain in the product and possibly because of reduced electrophilicity imparted by the nitrogen substituent. Moss *et al.* (18) recently reported that the methoxy group of cyclopropylmethoxy carbene retards ring expansion of that carbene. Although evidence for the intermediacy of **4***a* could not be obtained, it must be recognized that the high reactivity of the carbene precursor (**2***a*), not only in unimolecular reactions but also toward suitable traps for **4***a*, imposes severe restrictions on the choice of conditions.

The reaction of ylidene **2***a* with 1,3-diphenylisobenzofuran to form **9** constitutes the first example of the construction of the rare **4**-methylenazetidin-2-one unit by a carbene route. In view of the known reactions of rhodium carbenoids with simpler furans (19) there is some potential for the synthesis

of additional 4-methylenazetidin-2-ones from **2***a* and its analogues.

Experimental

*1,7,8-Triaza-6,6-dimethyl-5-oxa-2-oxo-3-phenoxy-1-phenylspiro-[3·4] oct-7-ene (**1**)*

This compound, a spiro-fused β-lactam oxadiazoline (2), was synthesized by formal [2+2] cycloaddition of phenoxyketene to 5,5-dimethyl-2-phenylimino-Δ^3-1,3,4-oxadiazoline (**13**) (7*a*, 20).

Phenoxyacetyl chloride (0.51 g, 3.0 mmol) in dry CH_2Cl_2 (10 mL) was added, drop by drop and with stirring, to a solution of **13** (0.47 g, 2.5 mmol) and triethylamine (6.0 mmol) in dry CH_2Cl_2 (20 mL) under N_2 at −23°C. When addition was complete, the cold bath was removed but stirring was maintained overnight. The reaction solution was washed with saturated aqueous bicarbonate and with brine. Those aqueous layers were extracted twice with CH_2Cl_2 and the organic layers were combined. Removal of the solvent after drying over $MgSO_4$, and chromatography on silica (Chromatotron, 2-mm plate), afforded **1** as a white solid (98%), one diastereomer only, presumably *trans*, mp 95–96°C; ir (KBr) cm^{-1}: 1792 (CO), 1594 (N=N); ^1H nmr (200 MHz, $CDCl_3$) δ: 1.48 (s, 3H), 1.56 (s, 3H), 5.49 (s, 1H), 7.0–7.4 (m, 10H); ^{13}C nmr (126 MHz, $CDCl_3$) δ: 23.93 (CH_3), 24.35 (CH_3), 88.21 (C3), 122.85 (C6), 129.66 (C4), 116.14, 121.91, 123.13, 127.33, 129.30 (5 CH, aryl), 133.24 (N-C1, aryl), 156.99 (O-C1, aryl), 162.13 (CO); ms (ci) *m/z*: 267 ($M-N_2-CO$, 4%), 209 ($M-N_2-CO-C_3H_6O$, 87%), 180 (76%), 134 (20%), 105 (70%), 77 (100%); ms (ci, CH_4) *m/z*: 324 (M+1, 10%), 254 (9%), 230 (40%), 209 (100%), 180 (42%), 132 (46%), 104 (24%), 71 (75%). The *trans* geometry was confirmed by means of single crystal X-ray diffraction.

A minor fraction from the plate (ca. 1% yield) was a thick yellow oil to which the corresponding *cis* structure was assigned on the basis of its spectra; ir (film) cm^{-1}: 1785 (CO), 1595 (N=N); ^1H nmr (200 MHz, $CDCl_3$) δ: 1.38 (s, 3H), 1.56 (s, 3H), 5.79 (s, 1H), 6.96–7.40 (m, 10H); ^{13}C nmr (50.3 MHz, $CDCl_3$) δ: 24.08 (CH_3), 24.35 (CH_3), 84.20 (C3), 122.37 (C6), 122.57 (C4), 115.50, 121.14, 123.00, 127.14, 129.36, 129.75 (6 CH, aryl), 133.51 (N-C1, aryl), 156.75 (O-C1, aryl), 162.48 (CO); ms (ei) *m/z*: 209 ($M-N_2-CO-C_3H_6O$, 95%), 180 (100%), 132 (18%), 105 (33%), 77 (34%); ms (ci, NH_3) *m/z*: 341 ($M+NH_4$, 50%), 326 (7%), 308 (11%) 210 ($M+1-N_2-CO-C_3H_6O$, 100%), 180 (32%), 118 (11%).

Thermolysis in benzene

For attempted trapping with 1,3-diphenylisobenzofuran a solution of β-lactam oxadiazoline **1***a* (*trans* isomer, 27.6 mg, 0.085 mmol) and diphenylisobenzofuran **14** (70.0 mg, 0.256 mmol) in benzene (0.4 mL) was sealed into a glass tube after three cycles of freeze–pump–thaw degassing. The tube was then immersed in an oil bath (100 ± 0.2°C) for 1 h. Removal of the solvent afforded a yellow oily residue, which was chromatographed on silica (Chromatotron, 2-mm plate) with ether (5%) in hexane as eluent. Excess **14** was eluted first followed by **9***b* and **9***a*.

E-*4-[1-(2-Benzoylphenyl)-1-phenyl]-methylene-3-phenoxy-1-phenylazetidin-2-one,* **9**b

Yellow oil; ir (film) cm^{-1}: 1800 (CO, lactam), 1665 (CO, ketone); ^1H nmr (200 MHz, $CDCl_3$) δ: 5.61 (s, 1H), 6.72–7.58 (m, 24H); ^{13}C nmr (126 MHz, $CDCl_3$) δ: 84.68 (C3, −ve), 128.14 (C4), C5 not assigned, 117.24, 121.77, 123.01, 126.09, 127.09, 127.35, 127.79, 127.99, 128.31, 128.84, 129.44, 129.56, 129.84, 130.02, 132.32, 132.98 (16 CH, aryl, −ve), 130.02, 130.32, 139.85 (3 C, aryl, +ve), 162.10 (CO, lactam); ms (ei) *m/z*: 507 (M, 10%), 414 (6%), 388 (M-PhNCO, 34%), 370 (8%), 311 (10%), 270 (M−β-lactam, 100%), 241 (20%), 193 (9%), 165 (26%), 144 (27%), 116 (9%), 105 (56%), 77 (92%); ms (ci, NH_3) *m/z*: 508 (M+1, 100%), 388 (M−PhNCO, 12%), 270 (M−β-lactam, 10%).

Z-*4 [1-(2-Benzoylphenyl)-1-phenyl] methylene-3-phenoxy-1-phenylazetidin-2-one,* **9**a

Yellow oil; ir (film) cm^{-1}: 1800 (CO, lactam), 1740 (C=C, tentative), 1670 (CO, ketone); ^1H nmr (200 MHz, $CDCl_3$) δ: 6.07 (br s, 1H), 6.86–7.72 (m, 24H); ^{13}C nmr (126 MHz, $CDCl_3$) δ: 84.82 (C3), 118.10 (C5 or C4), 123.22 (C4 or C5), 122.39, 126.13, 126.57, 126.70, 127.79, 128.13, 128.33, 128.90, 129.29, 129.85, 130.02, 131.90, 132.67 (13 CH, aryl), 136.53 (C1, aryl), 137.14 (C1, aryl), 137.93 (2 C1, aryl), 157.34 (O-C1, aryl), 166.96 (CO, β-lactam), 189.28 (CO, ketone); ms (ei) *m/z*: 507 (M, 10%), 414 (12%), 388 (M−PhNCO, 69%), 311 (15%), 270 (M−lactam, 100%), 241 (10%), 209 (18%), 144 (30%); structure confirmed by single crystal X-ray diffraction on a crystal grown from hexane.

Thermolysis in methanol

Reactions were carried out in sealed nmr tubes of medium wall thickness. In a typical experiment, oxadiazoline **1***a* (32 mg,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

0.1 mmol) in methanol (0.25 mL) was degassed by means of three freeze–pump–thaw cycles (10^{-2} Torr; 1 Torr = 133.3 Pa) before the tube was sealed. The tube was then immersed in oil (100 ± 0.2°C) for 55 min before it was opened and the excess solvent was removed by bulb-to-bulb distillation on the vacuum line. Reactions in which benzene was used to dilute the methanol were run in the same way.

The residue remaining after solvent removal was taken up in $CDCl_3$ for ^1H nmr and ^{13}C nmr spectroscopy. Those spectra were clean, indicating two isomeric products only, except for the cases where dilute methanol-in-benzene solutions were used. In those cases the nmr spectra were very complex and both assignments of the spectra and attempts to separate components of the product mixture failed.

4-Methoxy-3-phenoxy-1-phenylazetidin-2-one

The only product observed by ^1H nmr spectroscopy, following thermolysis of **1***a* in neat methanol were the *trans* and *cis* isomers **11***a* and **11***b* (*trans*: *cis* = 2.6:1) as a yellow oil. Spectra were obtained with the mixture; ir (film, cm^{-1}): 1770 (C=O); ^1H nmr (200 MHz, $CDCl_3$, *trans* isomer) δ: 3.55 (s, OCH_3), 5.28 (d, J = 0.8 Hz), 5.46 (d, J = 0.8 Hz), 7.06–7.57 (m); *cis* isomer, δ: 3.55 (s, OCH_3), 5.33 (d, J = 3.6 Hz), 5.71 (d, J = 3.6 Hz), 7.06–7.57 (m), total integrals (Σ doublets : Σ OMe : Σ ArH) in satisfactory ratios; ^{13}C nmr (50.3 MHz, $CDCl_3$, *trans* isomer) δ: 53.83 (OCH_3), 83.67 (C4, tent.), 84.61 (C3, tent.), 160.94 (CO); *cis* isomer, δ: 54.53 (OCH_3), 81.79 (C3, tent.), 88.23 (C4, tent.), 163.07 (CO), observed signals not assigned to a particular isomer, 115.56, 115.70, 117.47, 117.57, 122.55, 125.31, 125.34, 129.31, 129.65, 129.76 (10 CH, aryl, 136.70 (N-C1, aryl, both isomers), 157.07 and 157.40 (OC1, aryl); ms (ei), *m/z*: 269 (M, 13%), 150 (M−PhNCO, 100%), 135 (15%), 104 (15%), 84 (15%), 77 (60%); ms (ci, NH_3) *m/z*: 287 (M + NH_4, 100%), 270 (M + 1, 90%), 178 (18%), 150 (28%), 138 (5%), 136 (14%), 94 (11%); ms (high resolution) *m/z*: 269.1056; calcd. for $C_{16}H_{15}NO_3$: 269.1052.

Computational and ultraviolet photoelectron spectroscopic studies of 5-substituted cyclopentadienes. Evidence that $n-\pi$ orbital mixing in the HOMO is not the source of the *syn* π-facial selectivity in Diels–Alder reactions

Received April 14, 1992

NICK H. WERSTIUK, JIANGONG MA, JOHN B. MACAULAY, and ALEX G. FALLIS. Can. J. Chem. **70**, 2798 (1992).

A series of C5 monomethyl (**1***a*–**1***f*) and pentamethylcyclopentadienes (**2***a*–**2***f*) bearing stereogenic C5 heteroatom substituents (-NH_2, -OH, -OCH_3, and -SCH_3) have been studied computationally (*ab initio* and AM1) and with ultraviolet photoelectron (pe) spectroscopy. In the case of compounds **1***d*–**1***f* and **2***d*–**2***f*, the conformations **3** and **4** of C_s symmetry with the lone paris *anti* to the cyclopentadiene ring are computed to be the most stable geometries. On the other hand, the twisted-*anti* conformers **5***a* and **5***b* are the most stable geometries of **1***c* and **2***c*. Analysis of the computed MO eigenvalues (orbital energies), MO eigenvectors (orbital coefficients), and the pe spectra of cyclopentadienes **2***a*–**2***f* established that $n-\pi$ orbital mixing is not important in the HOMO's of **1***c*–**1***d* or **2***c*–**2***d*. That the ionization energy of the HOMO is found to be virtually independent of the substituent at C5 in the series **2***a*–**2***f*, provides support for the computational results. Because **2***c*–**2***d* undergo Diels–Alder reactions selectively, *syn* to the heteroatom substituent, $n-\pi$ orbital mixing in the HOMO cannot be the source of the π-facial selectivity observed for these compounds.

NICK H. WERSTIUK, JIANGONG MA, JOHN B. MACAULAY et ALEX G. FALLIS. Can. J. Chem. **70**, 2798 (1992).

Utilisant des calculs (*ab initio* et AM1) et la spectroscopie photoélectronique ultraviolette, on a étudié une série C5 de monométhyl (**1***a*–**1***f*) et de pentaméthylcyclopentadiènes (**2***a*–**2***f*) portant des substituants hétéroatomiques stéréogéniques en C5 (-NH_2, -OH, -OCH_3 et -SCH_3). Dans les cas des composés **1***d*–**1***f* et **2***d*–**2***f*, les calculs ont permis d'établir que les conformations **3** et **4** de symétrie C_s, dans lesquelles les paires libres sont *anti* par rapport au cycle cyclopentadiène, possèdent les géométries les plus stables. Par ailleurs, les conformères *anti* déformés, **5***a* et **5***b*, correspondent aux géométries les plus stables des composés **1***c* et **2***c*. Une analyse des valeurs propres calculées pour les OM (énergies des orbitales), des vecteurs propres des OM (coefficients des orbitales) et des spectres pe des cyclopentadiènes **2***a*–**2***f* a permis d'établir qu'un mélange d'orbitales $n-\pi$ n'est pas important dans les OM hautes occupées des produits **1***c*–**1***d* ou **2***c*–**2***d*. Le fait que l'énergie d'ionisation de l'OM haute occupée soit virtuellement indépendante de la nature du substituant en C5, dans la série **2***a*–**2***f*, confirme les résultats des calculs. Compte tenu du fait que les composés **2***c*–**2***d* subissent des réactions de Diels–Alder sélectivement *syn* par rapport au substituant hétéroatomique, on en conclut que le mélange d'orbitals $n-\pi$ dans l'OM haute occupée ne peut pas être la source de la sélectivité π-faciale observée pour ces composés.

[Traduit par la rédaction]

Introduction

The origin of the π-facial diastereoselectivity observed in Diels–Alder (DA) reactions of C5 heteroatom-substituted cyclopentadienes is still imperfectly understood. Consequently, to determine the key factors responsible, a wide range of substrates have been studied both experimentally (1–11) and computationally (11–18). These investigations revealed that a number of interrelated factors are important. Various suggestions have been advanced as possible sources for the pattern observed. These include steric effects, complexation between the diene and the dienophile, secondary orbital interactions, polarizability, electrostatic interactions, orbital mixing, and transition-state hyperconjugation. This latter interpretation, proposed originally by Cieplak (19) for reactions of cyclohexanones, is based on the concept of transition-state stabilization by σ-electron donation from the adjacent bond into the vacant σ orbital associated with the incipient bond. This explanation accounted for the *syn* approach of a butadiene to 5-fluoroadamantane-2-thione where the electrostatic model failed (20). Macaulay and Fallis and co-workers extended these ideas to Diels–Alder reactions of 2,5-dimethylthiophenes oxides (21) and C-5 substituted cyclopentadienes (22) to rationalize the preference observed for cycloaddition *anti* to the antiperiplanar σ bond that is the better donor.

The synthetic utility of the Diels–Alder reaction is well established (23). Nevertheless, the ability to control the facial selectivity without the use of a chiral auxiliary is often limited. Complete facial control renders the reaction enantioselective and with asymmetric, planar 1,3-dienes there exists a latent capacity to establish five or more chiral centres in one operation. Thus it is desirable to identify the factors that affect the π-facial diastereoselectivity so the stereochemistry of Diels–Alder reactions of C5 substituted cyclopentadienes can be predicted with certainty and the adducts utilized for the total synthesis of complex natural products.

We undertook a study of two groups of substituted cyclopentadienes. One group consisting of the C5 disubstituted cyclopentadienes **1***a*–**1***e* was studied computationally with *ab initio* and semiempirical methods. The other class, **2***a*–**2***f*, were synthesized earlier (9, 22) to establish experimentally the diastereoselective preferences in this series. The

results are shown in Table 1. This group has been examined both computationally and experimentally with the aid of ultraviolet photoelectron spectroscopy (UPS) measurements. The objectives of the combined computational/UPS study were to determine the conformational preferences of the heteroatom substituents at C5 and gain information on the magnitude of the n–π orbital mixing in the HOMO in both series of compounds. This is important since it has been postulated that the latter effect is important in determining the *syn*-facial selectivity observed for reactions of cyclopentadienes bearing oxygen and chlorine substituents at C5 (13). According to the orbital mixing rule (13), for cyclopentadienes bearing heteroatom substituents at C5 the π-HOMO combines out of phase with the n- and σ-orbitals in such a way that the n-orbital mixes with the π-HOMO (Scheme 1). This produces a nonequivalent extension of the π-MO in the direction of the substituent and leads to preferential *syn* attack of the incoming dienophile. In view of the facial diastereoselectivities observed for **2***c*–**2***f* (9, 22), we anticipated that a computational study of compounds **1***a*–**1***f* and **2***a*–**2***f*, coupled with a UPS study of **2***a*–**2***f*, would establish whether n–π orbital mixing occurs in the HOMO of these compounds and thereby establish its importance in determining the π-facial selectivity of DA reactions of C5 heteroatom-substituted cyclopentadienes (cp's). Methyl substitution at C1, C2, C3, and C4 of the cp ring should differentially destablize the HOMO and lead to an increase in the ϵ_{HOMO}, ϵ_n gap ($\epsilon_{HOMO} > \epsilon_n$) in the series of compounds **2***c*–**2***f* relative to the 5,5-disubstituted cp's, **1***a*–**1***f*. In principle, this should reduce the magnitude of the n–π_{HOMO} interaction and, according to the orbital mixing model, result in a loss of facial diastereoselectivity.

In this paper we document and discuss the results of the *ab initio* and semiempirical calculations and analyze the

photoelectron (pe) spectra of **2***a*–**2***f*. From the pe spectral data and the results of the *ab initio* and semiempirical computational studies, information was gained on the magnitude of the n–π interactions in dienes **2***c*–**2***f*. This has led to new insights and improved our predictive capability.

Results and discussion

Ab initio *calculations on 5,5-disubstituted cyclopentadienes*

Ab initio calculations (24, 25) were carried out on cyclopentadienes **1***a*–**1***e* (i) to determine the preferred orientation, *syn* or *anti* to the cp ring, of the lone pairs of X (Scheme 2), and (*ii*) to gain information on the degree of the interaction of the lone pairs with the π-system from computed eigenvectors (orbital coefficients) and eigenvalues (orbital energies) with no methyl substituents on the carbons of the π-system. Calculations were first carried out on conformations with the lone pair(s) *syn* and *anti* to the cp ring, with forced C_S symmetry in both cases. Optimizations were carried out with 3-21G and 4-31G basis sets, but the geometries obtained with the 4-31G calculations were used for single point calculations at the 4-31G** level. This was so because the differences in energy between the C_S *anti* and C_S *syn* conformers were computed to be smaller (in the order of 1 kcal mol^{-1}) with the 4-31G basis set than the 3-21G basis set. In fact, this led to a switch in the computed relative stabilities of the C_S *anti* and C_S *syn* conformers in the case of **1***c*. When the 3-21G basis set was used the C_S *anti* conformer was found to be slightly lower in energy (0.03 kcal mol^{-1}) than C_S *syn* conformer; with the 4-31G basis set the C_S *syn* conformer was 0.1 kcal mol^{-1} lower in energy than the *anti* conformer. Single point calculations at the 4-31G** level on the 4-31G geometries gave the results documented in Table 2. Polarization functions were added to hydrogens in addition to the heavy atoms simply to balance the basis set. When the 4-31G C_S geometries of the *anti* conformations of **1***d*, **1***e*, and **1***f* were used as starting points for full optimizations in the absence of the symmetry constraint, C_S symmetry was maintained. To establish with certainty that the C_S *anti* conformation is the global minimum for **1***d*–**1***f*, the CH_3—C(5)—O—CH_3 dihedral angle of **1***e* was set at 170° and the geometry was optimized with the 4-31G basis set without any symmetry constraints. That the dihedral angle was 179.9° in the optimized geometrical structure indicates that the C_S *anti* conformation is the global minimum of **1***e*. Furthermore a FORCE calculation on the 4-31G geometry gave no imaginary frequencies. Because the C_S *anti* conformations are computed to be the most stable geometrical structures of **1***d* and **1***f* as well, frequency calculations were not carried out on these compounds. When the *syn* conformations of these compounds were optimized without the C_S symmetry constraint, twisting occurred about the C5—X bond to relieve torsional strain. Table 2 lists the total and relative energies of three conformations of **1***c*, **1***d*, **1***e*, and **1***f*. Table 3 lists the torsional angles of the twist conformations and Table 4 documents the orbital energies of **1***a*–**1***f*. As is seen from the data in Table 2, except for the amino compound, the C_S *anti* conformers of **1***d*, **1***e*, and **1***f* are computed to be more stable than the C_S *syn* and twisted-*syn* conformers, which would be considered to be the most reactive in the orbital mixing model. For the amino compound **1***c*, the twisted-*syn* conformer **5***a* was computed to be

lower in energy than the C_S *anti* conformer with the 4-31G**//4-31G basis sets.

Of importance is the nature of the three highest occupied MO's of **1***c*, **1***d*, **1***e*, and **1***f*. According to the *ab initio* (4-31G**) calculations, there is no significant interaction between the nitrogen and the π-system in the HOMO of the C_S *syn* conformer of **1***c*; the orbital coefficients at N are <0.03.[2] A plot of the HOMO that is diene π-type is given in Fig. 1(*a*). This plot, as well as the others obtained from *ab initio* calculations, was generated with PSI/88(26) and GAUSSIAN 90° checkpoint files; in this and all other examples, the 0.025 au contour is plotted. Because PSI/88 uses only STO-3G, 3-21G, and 6-31G basis sets, the MO's were obtained from single point calculations with the 3-21G(*) basis set on the 4-31G optimized geometry. It is important to note here that the orbital coefficients of the heavy atoms were virtually identical to the coefficients obtained with the 4-31G and 4-31G** basis sets. While the HOMO-1 is predominantly localized on N (coefficient 0.49) there are sizeable coefficients on the methyl carbon (0.20) and C5 (0.17) of the cp ring. There is little mixing with the cp π orbitals; the coefficients at C1, C2, C3, and C4 are less than 0.06. HOMO-2 predominantly cp π-type (orbital coefficients at C1(C4), 0.17; at C2(C5), 0.23), with a sizeable coefficient on N (0.11). For the twisted-*anti* conformer of **1***c* there is mixing of the N lp and the π orbitals in the HOMO as is seen in Fig. 1(*b*). The coefficients on N, C1(C4), and C2(C3) are 0.12, 0.28, and 0.23, respectively. For HOMO-1 the coefficients are 0.44 on N, 0.20 on the carbon (C1) *anti* to the lp, 0.14 on C4, and 0.1 on C5. As was the case for the C_S *syn* conformer, the HOMO-2 is predominantly cp ring π-type. The presence of an *n*–π interaction in the twisted conformation is supported by the fact that the HOMO is destabilized (0.16 eV) and the N lp is stabilized (0.29 eV) relative to the C_S *anti* conformer (Table 4). For the C_S *anti* conformer there is no significant mixing between the N l*p* and the π system in the HOMO. In accord with this result is the fact that the orbital energies (Table 4) do not change significantly relative to the *syn* conformer.

In the case of the C_S *anti* conformer of alcohol **1***d*, a weak interaction between the oxygen (orbital coefficient = 0.1) and the π-system in the HOMO is indicated by the *ab initio* calculations with the 4-31**//4-31G basis sets. This interaction is purely π-type. HOMO-1 is predominantly diene π_+ with some involvement of the oxygen (0.12) and CH_3 orbitals. The third MO involves mixing of oxygen (0.42) with the σ orbitals of the C1—C5 and C4—C5 bonds of the cp ring; at the 4-31G**//4-31G level $\epsilon_{\pi-} > \epsilon_{\pi+} > \epsilon_n$. A plot of the HOMO of **1***d* computed with the 3-21G(*) basis set (the orbital coefficients were virtually identical to the coefficients computed with the 4-31G**//4-31G basis sets) is given in Fig. 2(*a*). For the *anti* conformer the coefficients on oxygen and the carbons of the HOMO are virtually identical to the coefficients of the HOMO of the *syn* conformer, as is seen from a comparison of Fig. 2(*a*) and Fig. 2(*b*).

In going from the C_S *syn* conformer of **1***d* to the C_S *syn* conformer of the methoxy compound **1***e*, the computed energy of the HOMO increases only by 0.08 eV. Based on the magnitude of the coefficients on oxygen (0.12) and carbon, the interaction of the lp with the π-system of the diene (see Fig. 3(*a*)) is similar to the interaction in **1***d*. The HOMO-1 of **1***e* involves mixing of the oxygen orbitals within the framework of the cp ring (see Fig. 3(*b*). The shift of the HOMO-1 from 11.65 to 10.96 eV (Table 3) is as expected for methyl substitution on oxygen. For **1***e*, HOMO-2 is

[2]Since 4-31G** is a split-valence basis set, only the largest coefficient of the pairs of orbitals is given in each case.

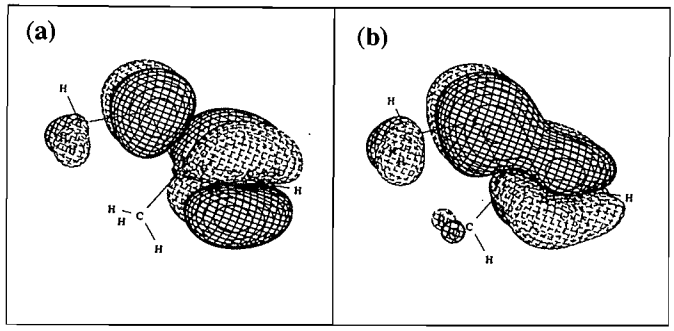

FIG. 4. Plots of the 0.025 au contours of the HOMO (*a*) and HOMO-1 (*b*) of the C_S *syn* conformer of **1***f*.

TABLE 5. AM1 relative energies of 5,5-disubstituted cyclopentadiene conformers

Diene	Relative heat of formation (kcal mol^{-1})		
	C_S *syn*	C_S *anti*	Twisted-*syn*
1*c*	1.61	1.15	0(40.52)[a]
1*d*	2.78	0(−6.68)	1.60
1*e*	3.08	0(0.02)	1.31
1*f*	1.77	0(39.24)	0.52
1	1.63	0(41.70)[b]	0.48

[a]This is the heat of formation of the twisted-*anti* conformation of **1***c*.
[b]These values were obtained using mixed parameters (C,H(AM1), S(MNDO)).

similar to the HOMO-2 of **1***d*: there is a minor degree of mixing of the oxygen and π carbon orbitals with the carbon coefficients predominating. For the C_S *anti* conformer, the oxygen orbital coefficient is reduced (0.06) relative to the C_S *syn* conformation. This is seen in a comparison of the HOMO's given in Fig. 3(*a*) and Fig. 3(*c*). The HOMO and HOMO-2 are stabilized by 0.24 and 0.22 eV, respectively and the HOMO-1 is stabilized by 0.13 eV.

For the C_S *syn* conformer of **1***f* the orbital coefficients define a significant interaction between the sulfur lone pair and the π-system of the cp ring in the HOMO (S, 0.37), and HOMO-1 (S, 0.5) (see Figs. 4(*a*) and 4(*b*). HOMO-2 and HOMO-3 also show considerable mixing of S and cp ring orbitals. An interaction between S and the cp ring is also computed for HOMO, HOMO-1, HOMO-2, and HOMO-3 of the *anti* conformer, as indicated by the coefficients on S and the ring carbons. In fact, based on the coefficients, the mixing is virtually identical to the mixing in the *syn* conformer.

AM1 calculations on 5,5-disubstituted cyclopentadienes

AM1 calculations (27) were also carried out on cyclopentadienes **1***c*–**1***f* as well as **1***a* and **1***b*. As seen from the data in Table 5, the conformational preferences of X-R computed by AM1 are the same as those computed for the series at the 4-31G** level. The *anti* conformations are the lowest-energy geometrical structures of **1***d*, **1***e*, and **1***f*, but the twisted-*anti* conformer of **1***c* is lower in energy than the *anti* or *syn* conformations. The orbital energies are given in Table 6.

TABLE 9. AM1 relative energies of pentamethylcyclopentadiene conformers

	Relative energies (kcal mol^{-1})[a]		
Diene	*syn*	*anti*	Twisted-*syn*
2*c*	1.98	1.15	0(8.15)[b]
2*d*	3.16	0(−38.95)	1.58
2*e*	3.29	0(−31.79)	2.05
2*f*	2.01	0(8.31)	0.82
2	1.86	0(10.92)	0.94[c]

[a]The heat of formation of the most stable conformer is given in parentheses.
[b]The heat of formation of the twisted-*anti* conformation.
[c]These values were obtained with mixed AM1 parameters (C, H(AM1); S(MNDO)).

anti conformation the coefficient on oxygen is smaller (0.06) than the coefficient for the *anti* conformation of **1***d* (0.10). Figures 6(*a*)–6(*c*) give the plots of HOMO, HOMO-1, and HOMO-2 of the C_S *syn* conformer of **2***d* and clearly show that there is no appreciable n–π orbital mixing in the HOMO and HOMO-1. On the other hand, the plot of HOMO-2 also shows that the mixing of the lp orbitals is n–σ, not n–π. Figures 7(*a*)–7(*d*) show the plots of the HOMO, HOMO-1, HOMO-2, and HOMO-3 of the *syn* conformer of **2***f*. In this case there is n–π mixing in the HOMO (S, 0.20; C1(C4), 0.26; C2(C3), 0.20). HOMO-1 is essentially n_S (S, 0.62; C1(C4), 0.098). HOMO-2 and HOMO-3 show a substantial amount of n–π mixing. The coefficients of the four highest occupied MO's of **2***f* are virtually identical to the coefficients of the HOMO, HOMO-1, HOMO-2, and HOMO-3 (plots not shown) of *syn*-**2***f*, as are the orbital energies (Table 8).

AM1 calculations on pentamethylcyclopentadienes

As is seen from the data in Table 9, the twisted-*anti* conformer of **2***c* was computed as the most stable geometry with AM1, in keeping with the results of the *ab initio* and AM1 calculations on **1***c*. The orbital energies given in Table 10 are shown graphically in Fig. 8. For **2***d*, **2***e*, and **2***f* the *anti* conformations are computed to be the most stable geometrical structures. These results are in accord with the *ab initio*/AM1 calculations on **1***d*, **1***e*, and **1***f* and the *ab initio* calculations on **2***d* and **2***f*. Plots of HOMO, HOMO-1, and HOMO-2 of twisted-*anti* - **2***c* (not shown), *syn*-**2***d* (Figs. 9(*a*)–9(*c*), and *syn*-**2***c* (not shown) were obtained with PSI/88 and the AMPAC gpt files. It is seen that the MO's (the 0.025 au contours are plotted) of *syn*-**2***d* are indistinguishable from

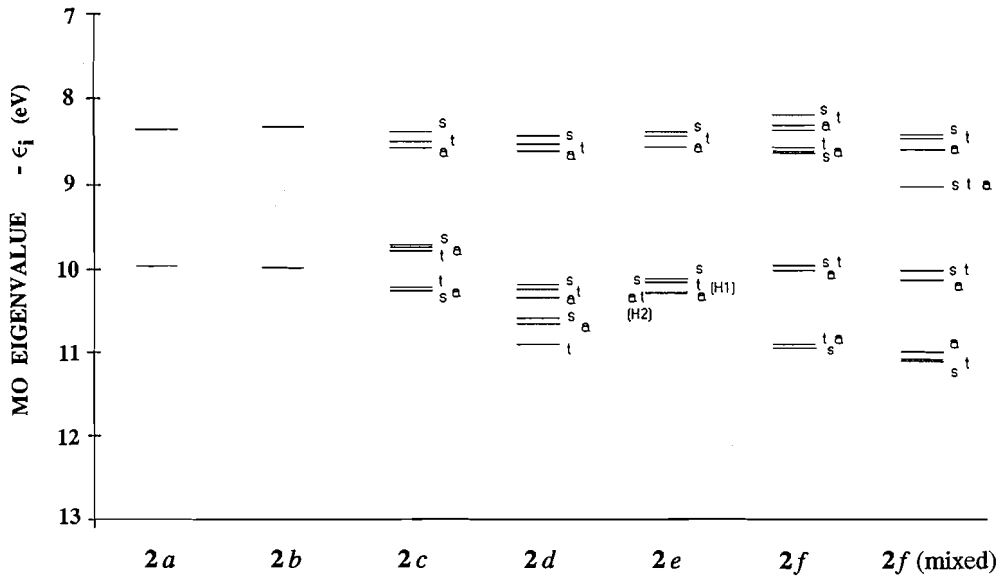

FIG. 8. Orbital energies of **2***a* (HOMO and HOMO-1), **2***b* (HOMO and HOMO-1), and the *syn* (s), *anti* (a), and twist (t) conformers of **2***c* (HOMO, HOMO-1, and HOMO-2), **2***d* (HOMO, HOMO-1, and HOMO-2), **2***e* (HOMO, HOMO-1, and HOMO-2), and **2***f* (HOMO, HOMO-1, HOMO-2, and HOMO-3) computed with AM1. H1 and H2 are the values for HOMO-1 and HOMO-2 of **2***e*. The values for **2***f* (mixed) were obtained with mixed parameters (C,H(AM1); S(MNDO)).

TABLE 10. AM1 orbital energies of pentamethylcyclopentadiene conformers

Diene	Orbital energies (eV) HOMO	HOMO-1	HOMO-2	HOMO-3
2*a*	8.35	9.95		
2*b*	8.33	9.99		
2*c syn*	8.38	9.71	10.26

[a]These values were obtained using mixed AM1 parameters (C, H(AM1): S(MNDO)).

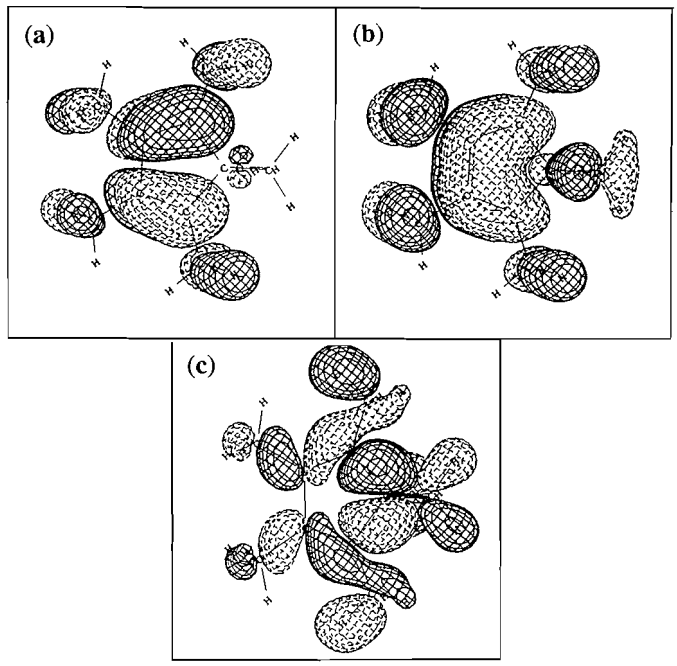

FIG. 9. Plots of the 0.025 au contours of the HOMO (*a*), HOMO-1 (*b*), and HOMO-2 (*c*) of the C_S *syn* conformer of **2***d* computed with AM1.

the 3-21G(*) MO's (Figs. 6(*a*)–6(*c*)). This is the case (not shown) for *syn*-**2***e* as well. The HOMO and HOMO-1 of **2***f* computed with AM1 parameters for C, H, and S are shown in Figs. 10(*a*) and 10(*b*). Based on the orbital energies (Fig. 5) and MO's computed with the 4-31G**//4-31G and 3-21G(*) basis sets, these AM1 calculations overestimate the n_S–π interaction, primarily because the n_S orbital energy is too high. This analysis is supported by the pe spectrum of **2***f* (*vide infra*). On the other hand, calculations with mixed AM1/MNDO parameters (C,H(AM1);S(MNDO) yielded results that compare closely to those obtained with *ab initio* calculations. The HOMO, HOMO-1, HOMO-2, and HOMO-3 or *syn*-**2***f* are shown in Figs. 11(*a*)–11(*d*). The π-type S lp is localized more when mixed parameters are used and the MO's closely resemble the 3-21G(*) MO's shown in Figs. 7(*a*)–7(*d*). This study was carried out to ascertain which set of parameters gives the best description of the orbital energies and MO's of **2***f* before a comprehensive AM1

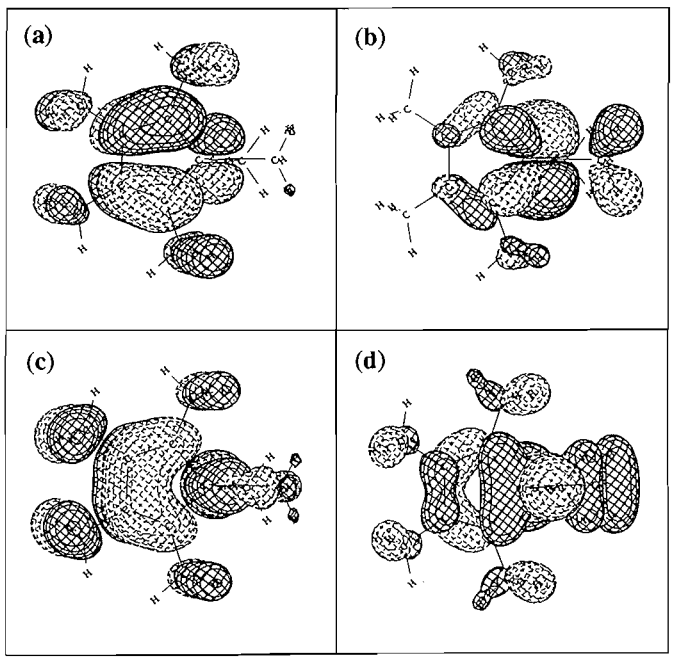

FIG. 11. Plots of the 0.025 au contours of the HOMO (*a*), HOMO-1 (*b*), HOMO-2 (*c*), and HOMO-3 (*d*) of the C_S *syn* conformer of **2***f* computed with AM1 using mixed parameters.

computational study[3] of the Diels–Alder addition of maleic anhydride to **2***a*, **2***c*, **2***d*, **2***e*, and **2***f* was initiated.

The *ab initio* and semiempirical computational studies clearly establish that n–π mixing is not important in the HOMO of **2***c*, **2***d*, and **2***e*. Furthermore, a comparison of the *ab initio* and semiempirical results shows that AM1 calculations give conformational preferences, eigenvalues (orbital energies), and eigenvectors (MO's) that compare favourably with the *ab initio* calculations at the 4-31G** level. This result suggests that AM1 calculations will be useful for studying conformational preferences, n–π orbital mixing in other heteroatom substituted cp's, and the DA reactions of **2***a*–**2***e* with maleic anhydride.

Photoelectron spectra of cyclopentadienes

The pe spectra of **2***a*–**2***f* are given in Figs. 12(*a*–12(*f*), respectively. The IE's are tabulated in Table 11 and shown graphically in Fig. 13. The π_+, π_- splittings of **2***a* and **2***b* are 2.07 ± 0.05 and 2.04 ± 0.05 eV, respectively. These values are similar to the splitting of 2.10 eV observed for 5,5-dimethylcyclopentadiene (28). In going from **2***a* to **2***b* there is a decrease of 0.08–0.10 eV in the π IE's. Relative to cyclopentadiene (28) the IE's of the HOMO and HOMO-1 decrease by 1.20 and 1.28 eV for **2***a* and 1.27 and 1.38 for **2***b*. Relative to 5,5-dimethylcyclopentadiene the shifts of the π_- and π_+ IE's of **2***b* are 1.17 and 1.23 eV, respectively. These results show that the addition of five or six methyls to the cyclopentadiene ring does not produce a significant differential destabilization of π_+ or π_-. According to the *ab initio*/AM1 calculations the HOMO's of **2***a* and **2***b* are basically diene π-type mixed with π-type orbitals of the methyl groups at C1, C2, C3, and C4. No On the other hand, the HOMO-1 does involve orbital mixing with the C—H and C—C bonds at C5.

For the amino compound **2***c*, the IE of the HOMO does not shift significantly relative to **2***a*, but HOMO-2 is stabilized by 0.23 eV (Fig. 12(*c*)). According to the *ab initio*/AM1 calculations, the band at 8.88 eV is due to the nitrogen lone pair. These experimental results are in accord with the AM1 calculations, which showed that there is no significant interaction between the lone pair and the π-system in the HOMO of **2***c* in either of the three conformations studied computationally.

For alcohol **2***d* the HOMO is stabilized relative to **2***a* and **2***b* by 0.17 and 0.24 eV (Fig. 12(*d*)). This is due to an inductive stabilization by oxygen. That the HOMO is stabilized is in accord with the calculations, which showed that there is no significant n–π interaction in the HOMO. The next two bands are closely spaced, as predicted by the *ab initio* calculations. According to the *ab initio*/AM1 calculations there is no significant n–π mixing in the HOMO-1, but HOMO-2 involves mixing of the lone pair orbitals and the σ (C1—C5 and C4—C5) orbitals of the cp ring. This explains why the bands due to HOMO-1 and HOMO-2 overlap rather than being split.

In going from **2***d* to **2***e*, the HOMO (Fig. 12(*e*)) is slightly destabilized (0.1 eV), in keeping with the results of the computational studies. HOMO-2 is stabilized by 0.28 eV relative to **2***a*, a consequence of an indictive effect and a weak n–π interaction with the oxygen lone pairs.

In the case of **2***f*, the lowest IE band (Fig. 12(*f*) is destabilized by 0.09 eV relative to the HOMO of **2***a*. This result is in keeping with the *ab initio*/AM1 calculations, which showed that there is an n–π interaction in the HOMO of **2***f*. Confirmation that this interaction is weak is provided by the fact that the second band, computed to be predominantely n_S, remains sharp (FWHM = 0.2 eV) like the n_S band of $(CH_3)_2S$ (FWHM = 12 eV) (29). The other sulfur lone-pair band is at 10.19 eV.

Because the computed orbital energies, both *ab initio* and AM1 (Tables 8 and 10) are insensitive to the dihedral angle as shown graphically in Figs. 5 and 8, the predicted confor-

[3]We (N.H.W. and J.M.) have found that *syn* approach of maleic anhydride to **2***f* is preferred when AM1 parameters are used for C, H, and S; on the other hand, when mixed parameters are used, *anti* addition is computed to be the low-energy pathway in keeping with the experimental results (Table 1). A manuscript documenting an AM1 computational study of the DA reaction of **2***b*–**2***f* with maleic anhydride is being written.

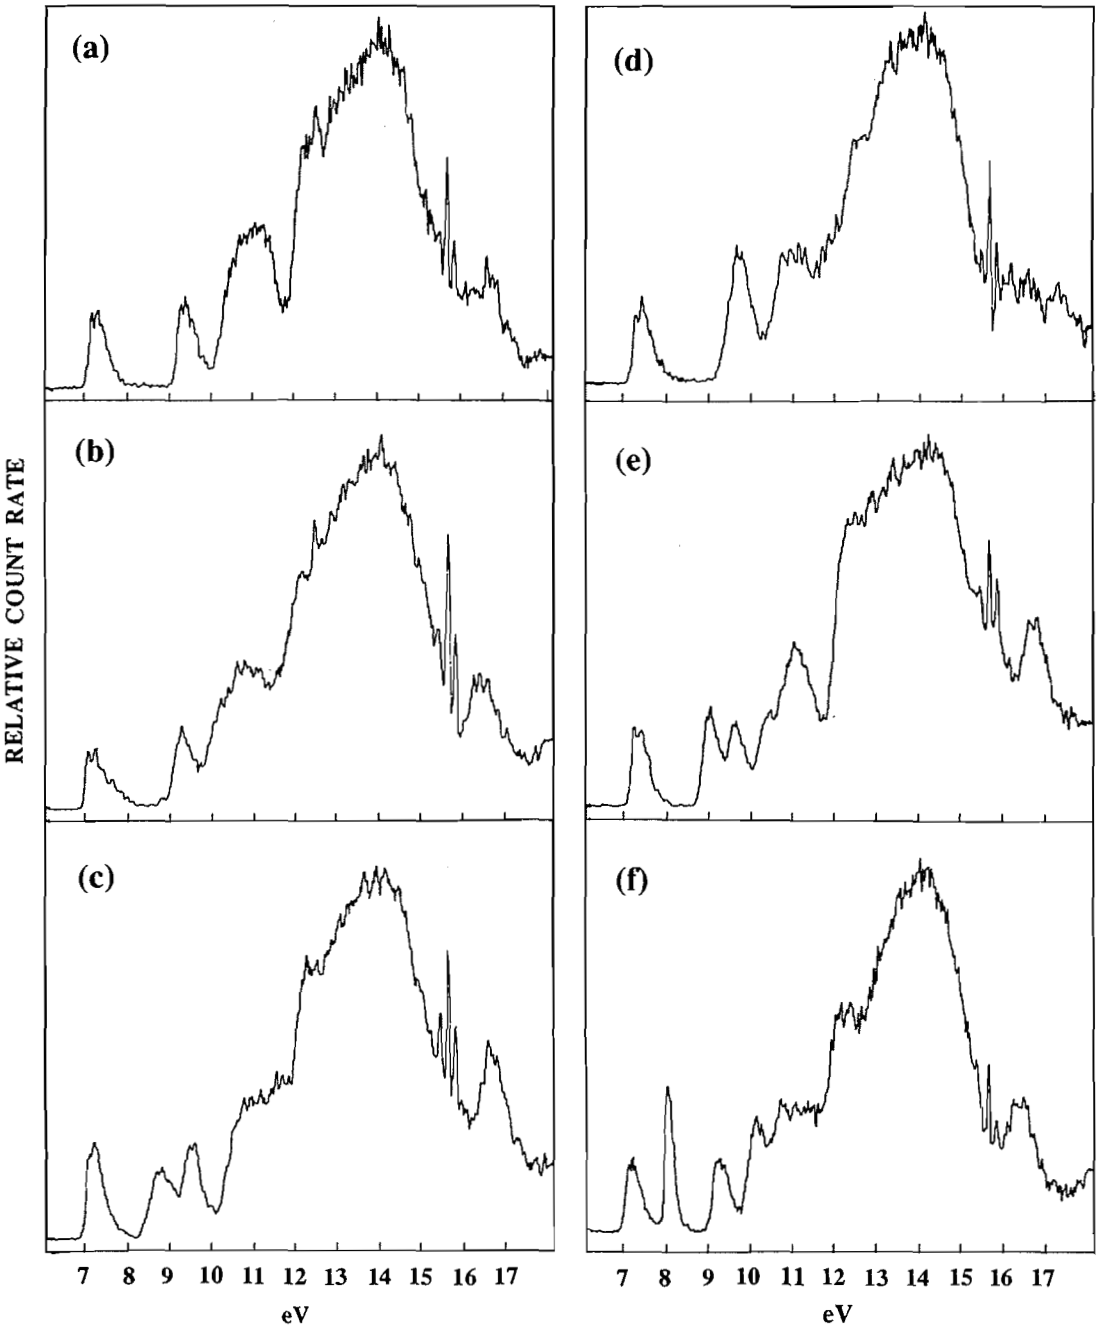

FIG. 12. Ultraviolet photoelectron spectra of **2***a* (*a*), **2***b* (*b*), **2***c* (*c*), **2***d* (*d*), **2***e* (*e*), and **2***f* (*f*).

mational preferences, twisted-*anti* for **2***c* and *anti* for **2***d*, **2***e*, and **2***f*, cannot be corroborated with the pes data.

As far as the correlation between the computed and experimental π_-,π_+ splittings of the dienes is concerned (Table 12), the *ab initio* calculations overestimated the splittings. Nevertheless, the IE's of the HOMO's are computed with good accuracy (Tables 8 and 11). AM1 overestimated the IE's of the HOMO's and underestimated the splittings by 0.4–0.5 eV. The key point is that both methods, assuming that Koopmans' theorem (30) holds, computed the insensitivity of energy of the HOMO to the nature of X at C5 of the cp ring, and this was corroborated by experiment.

Conclusions

The results of the computational studies on **1***a*–**1***f* and **2***a*–**2***f*, the pes studies on **2***a*–**2***f* and the study of the stereochemistry of the DA reactions with maleic anhydride/N-phenylmaleimide clearly show that $n-\pi$ orbital mixing in the HOMO proposed by Inagaki *et al.* (13) cannot be the source of the π-facial selectivity observed in the reactions of cyclopentadienes **2***c*–**2***f*. According to *ab initio*/AM1 calculations and pe spectroscopy there is no significant mixing of the lone-pair orbitals and the π-system in the HOMO's of **2***c*, **2***d*, and **2***e*, a requirement in the orbital mixing model, yet *syn* π-facial selectivity is observed in the DA reactions

of these compounds (Table 1). Moreover, *anti* and not *syn* facial selectivity is observed for the sulfur compound **2***f* where the n_S orbital energy is close to π and $n-\pi$ mixing occurs in the HOMO.

Experimental

Computational studies

Calculations were carried out with the *ab initio* packages GAUSSIAN 90 (24) and GAMESS (25) running on Multiflow Trace 14/300 and IBM RS/6000 computers, respectively. AM1 calculations were carried out with AMPAC version 2.1 (27) ported to an IBM RS/6000 computer. The keyword PRECISE was used to tighten the convergence criteria. The MO plots were obtained with PSI/88 (26) ported to a SUN 3/60 computer.

Ultraviolet photoelectron spectroscopic studies

The pe spectra of the dienes synthesized previously (9, 22) were obtained on a non-commercial spectrometer described previously (31) by signal averaging 20–50 scans. The spectra were calibrated with argon.

Acknowledgements

We thank the Natural Sciences and Engineering Research Council of Canada for financial support. The PS/2, 70/486, 80/386, and RS/6000 computers used in this study were obtained under the auspices of an IBM Canada – McMaster University cooperative project. We also thank Professor W. L. Jorgensen for providing the PSI/88 computational package and Mr. S. Urqhart for porting the software to a Sun 3/60 computer.

Received December 9, 1991

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **70**, 2809 (1992).

The preparation of the *N*-(2-hydroxypropyl)-*N*-alkylhydroxylamines, **6***a* (R = CH_3) and **6***b* (R = CH_2Ph), and their reactions with phenylboronic acid are described. Regardless of the molar ratios of reactants employed, the reaction with **6***b* leads to the 1:2 condensate 1-benzyl-7-methyl-3,5-diphenyl-2,4,6-trioxa-1-azonia-3-bora-5-boratabicyclo[3.3.0]-octane, **7**, while that with **6***a* gives rise to the 1:1 condensate 1,4,6,9-tetramethyl-2,7-diphenyl-3,8,11,12-tetraoxa-1,6-diazonia-2,7-diboratatricyclo[5.3.1.1^{2,6}]dodecane, **11** (the cyclic BONBON dimer of 4,6-dimethyl-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane, **9**). Compounds **7** and **11** both crystallize in the triclinic space group $P\bar{1}$: for **7**; a = 13.126(1), b = 15.337(1), c = 10.9469(5) Å, α = 91.727(5), β = 104.647(5), γ = 72.922(7)°, Z = 4; and for **11**; a = 9.0807(4), b = 9.1653(3), c = 6.4876(2) Å, α = 97.708(3), β = 108.830(3), γ = 89.188(4)°, Z = 1. The structures were solved by direct methods and were refined by full-matrix least-squares procedures to R = 0.038 and 0.032 for 5879 and 1827 reflections with $I \geq 3\sigma(F^2)$, respectively. Compound **7** has the expected bicyclic pyroboronate structure, but represents the first reported *N*-substituted example of this type of compound. Bond lengths involving boron in **7** are (C) O—B(sp^3) = 1.428(2) and 1.420(2), (B)O—B(sp^3) = 1.472(2) and 1.468(2), N—B(sp^3) = 1.737(2) and 1.762(2), C(phenyl)—B(sp^3) = 1.588(2) and 1.584(2), (N)O—B(sp^2) = 1.402(2) and 1.404(2), (B)O—B(sp^2) = 1.331(2) and 1.329(2), C(phenyl)—B(sp^2) = 1.555(3) and 1.553(2) Å. The X-ray analysis establishes a centrosymmetric, twofold N→B coordinated, dimeric structure in the solid state for **11** in which each B—O—N segment of a central six-membered BONBON ring is bridged by an O—C—C moiety. Compound **11** represents the first fully characterized example of a new type of "BONBON" compound. Bond distances involving the boron atom are (N)O—B = 1.465(1), (C)O—B = 1.428(1), N—B = 1.695(2), and C(phenyl)—B = 1.607(2) Å. Spectroscopic evidence indicates that in solution and in the gas phase this material exists predominantly as the monomer **9**.

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **70**, 2809 (1992).

On décrit la préparation des *N*-(2-hydroxypropyl)-*N*-alkylhydroxylamines (**6***a*, R = CH_3 et **6***b*, R = CH_2Ph) et leurs réactions avec l'acide phénylboronique. Quels que soient les rapports molaires de réactifs utilisés, la réaction du composé **6***b* conduit à une condensation 1:2 et à la formation du 1-benzyl-7-méthyl-3,5-diphényl-2,4,6-trioxa-1-azonia-3-bora-5-boratabicyclo[3.3.0]octane (**7**) alors que celle du composé **6***a* fournit une condensation 1:1 donnant naissance au 1,4,6,9-tétraméthyl-2,7-diphényl-3,8,11,12-tétroxa-1,6-diazonia-2,7-diboratatricyclo[5.3.1.1^{2,6}]dodécane (**11**) (le dimère cyclique BONBON du 4,6-diméthyl-2-phényl-1,3-dioxa-4-aza-2-boracyclohexane, **9**). Les composés **7** et **11** cristallisent tous les deux dans le groupe d'espace triclinique $P\bar{1}$; pour **7**, a = 13,126(1), b = 15,337(1) et c = 10,9469(5) Å, α = 91,727(5), β = 104,647(5) et γ = 72,922(7)° et Z = 4 alors que pour **11**, a = 9,0807(4), b = 9,1653(3) et c = 6,4876(2) Å, α = 97,708(3), β = 108,830(3) et γ = 89,188(4)° et Z = 1. On a résolu les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,038 et 0,032 respectivement pour 5879 et 1827 réflexions avec $I \geq 3\sigma(F^2)$. Le composé **7** possède la structure pyroboronate bicyclique attendue, mais elle représente le premier exemple rapporté d'un composé de ce genre qui est *N*-substitué. Les longueurs de liaisons impliquant le bore du composé **7** sont (C)O—B(sp^3) = 1,428(2) et 1,420(2), (B)O—B(sp^3) = 1,472(2) et 1,468(2), N—B(sp^3) = 1,737(2) et 1,762(2), C(phényl)—B(sp^3) = 1,588(2) et 1,584(2), (N)O—B(sp^2) = 1,402(2) et 1,404(2), (B)O—B(sp^2) = 1,331(2) et 1,329(2) et C(phényl)—B(sp^2) = 1,555(3) et 1,553(2) Å. L'analyse par rayons X permet d'établir que dans le composé **11**, à l'état solide, il existe une structure dimère, centrosymétrique, comportant une coordination N→B binaire dans laquelle chaque segment B—O—N du cycle à six chaînons BONBON central est lié par un pont O—C—C. Le composé **11** représente le premier cas complètement caractérisé d'un nouveau type de composé "BONBON." Les distances impliquant l'atome de bore sont (N)O—B = 1,465(1), (C)O—B = 1,428(1), N—B = 1,695(2) et C(phényl)—B = 1,607(2) Å. Les données spectroscopiques indiquent que, en solution et en phase gazeuse, ce composé existe préférentiellement sous la forme du monomère **9**.

[Traduit par la rédaction]

Introduction

N-(2-Hydroxyalkyl)hydroxylamines, **1**, react with phenylboronic acid in a ratio of 1:2 resulting in a bicyclic condensation product **2** (1), the molecular structure of which has been confirmed by an X-ray crystallographic analysis of **2** (R^1 = R^2 = Me, R^3 = R^4 = H) (2). A similar bicyclic structure with a transannular N→B coordinative bond, **4**, has been established for the 1:2 condensates of *N*,*N*′-dialkyl-*N*,*N*′-dihydroxyaminals **3** with phenylboronic acid (3, 4).

As an extension of our studies in this area we have synthesized the *N*-(2-hydroxypropyl)-*N*-alkylhydroxylamines **6** by reduction of the nitrones **5** (*a*: R = CH_3; *b*: R = CH_2Ph), obtained from 2-hydroxypropanal and *N*-methyl- or *N*-benzylhydroxylamine, respectively. Compounds **6** represent analogues of the bishydroxylamine **3** in which one of the nitrogen atoms has been replaced by a carbon atom. The condensation reaction of **6** with phenylboronic acid, however, gives (dependent on the nature of the *N*-alkyl substituent) differently composed crystalline products having elemental analyses and ^1H nmr spectra consistent with 1:1 and 1:2 condensates, respectively. The latter reaction product, obtained from **6***b* (R = CH_2Ph), could possess the bicyclic structure **7** analogous to the type **2** compounds that can be synthesized from various *N*-unsubstituted *N*-(2-hydroxyalkyl)hydroxylamines. The bicyclic ring system in **7**, like that in **2**, would be formed by intramolecular N→B coordination. This is confirmed by the ^{11}B nmr spectrum of **7** in $CDCl_3$ which displays two signals of nearly equal peak area at $\delta(Et_2OBF_3)$ = 13.3 and 28.0 ppm, indicating the presence of both tetracoordinate (sp^3) and trivalent (sp^2) boron species (5). The 1:1 reaction product,[2] obtained from **6***a* (R = CH_3), gives a ^1H nmr spectrum consistent with both of the cycloboronate structures **8** and **9**. The latter structure, having the potential for twofold O—B $pp(\pi)$ back donation, should be more stable than the five-membered cycloboronate **8** containing a borinic amide *N*-oxide function, presumably an unstable moiety expected to rearrange to the more stable six-membered boronate ring **9**. Cycloboronates of "1,3-diols" are well-documented in the literature (6).

The primary signal in the ^{11}B nmr spectrum of the product in $CDCl_3$ solution at $\delta(Et_2OBF_3)$ = 27.2 ppm indicates the presence of a trivalent boron species like **9** (or **8**). A second weak signal (3% of the total peak area) in the ^{11}B nmr spectrum at 13.6 ppm, however, suggests the presence of a small amount of a tetracoordinate boron compound. Two separate ^{11}B nmr signals indicating the presence of both tri- and tetracoordinate boron have also been observed in the spectra of the supposed BONBON dimers of borinic acid esters of oximes (7, 8). The tetracoordinate boron species in this case could originate from the dimerization of **8** to give the tricyclic compound **10** that resembles the dimerization product of salicylaldoxime phenylboronate, **12**, having a similar BONBON ring system (9). On the other hand, a stable six-membered cycloboronate **9** could dimerize to a tricyclic compound **11** containing tetracoordinate boron if there were stabilizing forces to overcompensate for the loss of O—B $pp(\pi)$ resonance energy. Another hint at a possible dimerization process comes from the infrared spectrum (KBr pellet) and provides further evidence in support of a tetrahedral boron atom, at least in the solid state. The characteristic ν_{16} phenyl ring stretching vibration at 1600 cm^{-1} which is normally found in the spectra of trigonal planar phenylboronates is very weak in this case, and the decrease in the intensity of the ν_{16} band corresponds to an increasing degree of "tetracoordination" at phenylboron centres (10).

In both the EI and FAB mass spectra the highest mass feature with highest abundance is the molecular ion of the monomer **8** or **9**. This could also be interpreted as a complete dissociation of the respective dimers **10** or **11**. Similar dissociations of BONBON dimers in the gas phase have been reported for various borinic acid esters of oximes (7, 8, 11). In view of the somewhat ambiguous spectroscopic data, an X-ray crystallographic analysis has been carried out to provide a definitive assignment to one of the monomer structures **8** or **9**, or to one of the dimeric structures **10** or **11**, at least in the solid state. In addition, an unambiguous proof of the bicyclic structure **7** was desirable and has been provided by an X-ray analysis.

Experimental

N-(2-Hydroxypropylidene)methanamine-N-oxide, **5**a *(R = CH_3)*

2-Hydroxypropanal (1.48 g, 20 mmol) and *N*-methylhydroxylammonium chloride (1.66 g, 20 mmol) are dissolved in 20 mL of ethanol (96%) and are mixed with a solution of K_2CO_3 (1.38 g, 10 mmol) in 5 mL of water. After 48 h the solvent is distilled off *in vacuo*. The remaining oil is not purified further. Yield: 1.85 g (90%). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.36 (d, *J* = 7 Hz, C—CH_3), 3.65 (s, N—CH_3), 4.70 (m_c, O—CH), 5.23 (s, broad, exchangeable, OH), 6.81 (d, *J* = 5 Hz, N=CH).

N-(2-Hydroxypropylidene)phenylmethanamine-N-oxide, **5**b *(R = CH_2Ph)*

2-Hydroxypropanal (1.11 g, 15 mmol) and *N*-benzylhydroxylammonium chloride (2.39 g, 15 mmol) are reacted as described above for **5***a*. The residue remaining after removal of the solvent is recrystallized from ethanol/ether. Yield: 2.55 g (95%); mp 97°C. Anal. calcd. for $C_{10}H_{13}NO_2$: C 67.02, H 7.31, N 7.82; found: C 67.14, H 7.34, N 7.69. Infrared (KBr): 3250 (O—H), 1600 cm^{-1} (—C=N). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.34 (d, *J* = 7 Hz, CH_3), 4.86 (m_C, O—CH and OH), 4.83 (s, N—CH_2), 6.76 (d, *J* = 5 Hz, N=CH), 7.39 (s, 5 aromatic H).

1-(N-Hydroxy-N-methylamino)-2-propanol, **6**a

N-(2-Hydroxypropylidene)methanamine-*N*-oxide, **5***a* (crude product, 1.03 g, 10 mmol), is dissolved in 30 mL of methanol. A solution of KBH_4 (1.08 g, 20 mmol) in 15 mL of water is added dropwise and the mixture is stirred for 24 h at room temperature. Excess KBH_4 is decomposed with tartaric acid, and the solution is brought to pH 9–10 by the addition of an aqueous solution of Na_2CO_3. After the removal of methanol *in vacuo*, the aqueous solution is extracted with dichloromethane (4 × 50 mL). The dichloromethane solution is dried over $MgSO_4$, and the solvent is then distilled off *in vacuo*. The residual oil is taken up in a small volume of absolute ethanol and cooled down until crystallization yields 0.60 g (57%) of colorless needles; mp 71°C (from absolute

[2]The equimolar ratio of the components in the condensation product still results even when a large excess of phenylboronic acid is employed in the reaction.

ethanol). Anal. calcd. for $C_4H_{11}NO_2$: C 45.70, H 10.55, N 13.32; found: C 45.65, H 10.66, N 12.96. Infrared (KBr): 3400 and 3160 cm^{-1} (O—H). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.20 (d, J = 7 Hz, C—CH_3), 2.72 (m_c, N—CH_3 and N—CH_2—C), 4.08 (m_c, O—CH), 6.25 (s, broad, exchangeable, 2 OH).

1-Benzyl-7-methyl-3,5-diphenyl-2,4,6-trioxa-1-azonia-3-bora-5-boratabicyclo[3.3.0]octane, 7

1-(*N*-Benzyl-*N*-hydroxyamino)-2-propanol, ***6b*** (0.36 g, 2 mmol), and phenylboronic acid (0.49 g, 4 mmol) are dissolved in 20 mL of benzene and refluxed for 1 h using a Dean–Stark trap for continuous removal of water. After evaporation of the solvent *in vacuo* the crystalline residue is recrystallized from CH_2Cl_2. Yield: 0.55 g (74%) of colorless crystals; mp 114–116°C. Anal. calcd. for $C_{22}H_{23}B_2NO_3$: C 71.21, H 6.25, B 5.83, N 3.78; found: C 71.22, H 6.31, B 5.98, N 3.79. Infrared (KBr): 1605 cm^{-1} (phenyl C=C). ^1H nmr (400 MHz, $CDCl_3$/TMS): δ (ppm) = 1.38 (d, J = 6 Hz, CH_3), 2.58 and 2.61 (d, J = 12 Hz and d, J = 11 Hz, 1/2 (O—C)—CH_2), 3.45 (d, J = 15 Hz, 1/2 Ph—CH_2), 3.92 (d, J = 15 Hz, 1/2 Ph—CH_2), 4.30 (m_c, O—CH), 7.30–7.50 (m, 11 aromatic H), 7.75–7.80 (m, 2 aromatic H), 7.92–7.98 (m, 2 aromatic H). ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$): δ (ppm) = 28.0 ($w_{1/2}$ = 960 Hz) and 13.3 ($w_{1/2}$ = 770 Hz); ratio of peak areas: 1:1. Crystals suitable for X-ray analysis were obtained by slow crystallization form CH_2Cl_2.

*1,4,6,9-Tetramethyl-2,7-diphenyl-3,8,11,12-tetraoxa-1,6-diazonia-2,7-diboratatricyclo[5.3.1.$1^{2,6}$]dodecane, **11** (cyclic BONBON dimer of 4,6-dimethyl-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane, **9**)*

1-(*N*-Hydroxy-*N*-methylamino)-2-propanol, **6** (0.21 g, 2 mmol), and phenylboronic acid (0.25 g, 2 mmol) are dissolved in 20 mL of benzene and refluxed for 1 h using a Dean-Stark trap for continuous removal of water. The solvent is distilled off *in vacuo*, and the remaining oil is taken up in a small volume of absolute ethanol. Cooling down the ethanolic solution yields 0.26 g (68%) of colorless crystals; mp 107–108°C (from absolute ethanol). Anal. calcd.

EI-Mass spectrum (70 eV, 250°C): m/z = 191 (100%, 1/2 M$^+$), 176 (11%, 1/2 M$^+$ − CH_3), 104 (28%, C_6H_5BO). FAB-Mass spectrum (3-nitrobenzylalcohol [NBA], positive ion mode); m/z = 191 (100%, 1/2 M$^+$), 136 (47%, NBA − 17), 114 (34%, M$^+$ − 77), 105 (44%, PhBOH), 104 (24%, PhBO), 77 (34%, Ph), 72 (58%, M$^+$ − 77 − 42). Crystals suitable for X-ray analysis were obtained by slow crystallization from absolute ethanol.

X-ray crystallographic analyses of 7 and 11

Crystallographic data for **7** and **11** appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 93.8–101.9° for **7** and 106.2–112.6° for **11**. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, showed a linear decays of 5.3% for **7** and 7.3% for **11**. The data were processed,[3] corrected for Lorentz and polarization effects, decay, and absorption (empirical, based on azimuthal scans for four reflections).

Both structure analyses were initiated in the centrosymmetric space group $P\bar{1}$ on the basis of E-statistics, the choices being confirmed by the subsequent successful solutions and refinements of the structures. The asymmetric unit of **7** contains two molecules. The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from E-maps or from subsequent difference Fourier syntheses. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (C—H = 0.98 Å, $B_H = 1.2B_{bonded\ atom}$) for **7** and were refined with isotropic thermal parameters for **11**. Corrections for secondary extinction were applied for both structures, the final values of the extinction coefficients being 1.02×10^{-5} for **7** and 4.62×10^{-3} for **11**. Neutral atom

scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International tables for X-ray crystallography (12). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, and bond angles appear in Tables 2–4, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, and least-squares planes, and measured and calculated structure factor amplitudes for the both structures are included as supplementary material.[4]

Results and discussion

The X-ray analyses establish structure **11** (Fig. 1) for the 1:1 reaction product of **6***a* and phenylboronic acid, and structure **7** (Fig. 2) for the 1:2 condensate of **6***b* and phenylboronic acid. It is not yet understood why the *N*-benzyl substituted educt **6***b* gives the expected bicyclic pyroboronate **7**, analogous to **2** and **4**, whereas the *N*-methyl derivative **6***a* leads to the six-membered cycloboronate **9** which associates to the dimer **11** in the solid state but appears to be present predominantly as the monomer in the $CDCl_3$ solution used for obtaining the ^{11}B nmr spectrum. Varying the molar ratios of the reactants does not change the results in either reaction. Several competitive factors such as O—B $pp(\pi)$ interactions, rehybridization energy ($sp^2 \rightarrow sp^3$) of N—B coordination, steric effects, hydrogen bonding, and crystal packing effects seem to control the formation of the particular crystalline product in each case.

Compound **7** is characterized by the bicyclo[3.3.0]octane ring skeleton, formed by a transannular N—B interaction in the eight-membered BOBONCCO ring which has a boat-boat ("saddle") conformation. Folding about the N—B bond divides the ring system into a pair of *cis*-fused five-membered rings. The angles between the normals to the mean planes of the nearly planar BOBON rings and the BOCN planes of the BOCCN rings (that have envelope conformations) are 113.7 and 114.0° in the two independent molecules of **7**, representing the "folding angle" of the bicyclic system. Similar "folding" of bicyclo[3.3.0]octane ring systems has been reported for the compounds **2** ($R^1 = R^2 =$ Me, $R^3 = R^4 =$ H) (2) and **4** (R = Me) (4). Until now, type **2** compounds had only been obtained from *N-un*substituted *N*-(2-hydroxyalkyl)hydroxylamines. Thus, the *N*-benzyl derivative **7** is the first example of an *N*-substituted type **2** compound.

There are two crystallographically independent molecules of **7**. Figure 2 depicts the 1*R*,5*S*,7*R*-enantiomer of the molecule containing B(1) and the 1*S*,5*R*,7*S*-enantiomer of the molecule containing B(3). Since this material crystallizes in a centrosymmetric space group, the respective enantiomers of each of the two independent molecules are also present in the crystal.

The N—B bonds in the two independent molecules of **7** are significantly different from one another, presumably as a result of packing effects. The N—B bonds of 1.737(2) and 1.762(2) Å observed for **7** are longer than the transannular N—B bond in the *N*-unsubstituted derivative **2** (1.688(2) Å) (2), probably a result of the steric requirements of the benzyl substituent, and are similar to those of 1.729(3) and 1.736(3) Å reported for the two independent molecules of **4**

[a] Symmetry operation: $1 - x, 1 - y, 1 - z$.

(4). As expected, the coordination about N(1)/N(2) and B(2)/B(4) is approximately tetrahedral, whereas the coordination at the trivalent boron atom B(1)/B(3) is planar within experimental error. The partial double bond character of both O—B bonds involving the trivalent boron atom in **7** is documented by the short bond lengths (O(2)—B(1) = 1.331(2), O(1)—B(1) = 1.402(2), O(5)—B(3) = 1.329(2), O(4)—B(3) = 1.404(2) Å) which further suggest O—B *pp*(π) interactions of differing strengths for the two bonds. The *B*-phenyl ring is nearly coplanar with the boronate group, an orientation which could facilitate a possible conjugation between the π-systems of the phenyl and boronate moieties. The (sp^2)B—C(phenyl) bonds are shorter by about 0.03 Å than the (sp^3)B—C(phenyl) bonds at B(2)/B(4), resulting from a combination of steric and hybridization effects and a weak π-interaction between the phenyl ring and the "vacant" p_z orbital of the adjacent sp^2-boron atom.

In the (sp^2)B—O—B(sp^3) anhydridic moiety, the characteristic difference between the very short (sp^2)B—O bond (1.331(2) and 1.329(2) Å) and the long (sp^3)B—O bond (1.472(2) and 1.468(2) Å) is consistent with that observed for other compounds of type **2** (2), **4** (4), and similar cyclic "pyroboronates" involving one trigonal boronate and one tetracoordinated borinic (13) or boronic acid group (14–17).

The 7-methyl substituent at C(1)/C(23) is positioned in a pseudo-equatorial orientation at the "flap" of the BOCCN ring "envelope." The hydrogen atom at C(1)/C(23) occupies the pseudo-axial position, but the distance between this hydrogen atom and the facing oxygen atom O(1)/O(4) is too long for an intramolecular C—H···O interaction that could play a role in the stabilization of the structure.

Structure **11**, a centrosymmetric twofold N→B coordinated dimer of the six-membered BONCCO ring **9**, represents the solid state structure of the simple cyclic phenylboronate **9**. A pair of enantiomers of **9** comprises the centrosymmetric dimer **11**, forming an "internal racemate." The chiral centres of the molecule depicted in Fig. 1 have the configurations B(1): *S*, C(2): *R*, N(1): *S*, B(1)*: *R*, C(2)*: *S*, N(1)*: *R*. The tricyclic ring system of **11** is composed of a central six-membered BONBON ring having O—C—C bridges spanning both of the B—O—N segments. This is a new type of "BONBON" compound. In addition to the simple BONBON dimers of open-chain B—O—N compounds (7, 8, 11, 15 and references therein, 18), the ring system **12** having two —O—C=C—C= anellations (one at each side of the central BONBON ring) (9) and two other types of bridged BONBON compounds **13** (15) and **14** (19) are known. The tricyclic ring system of **13** has an O—B—O bridge across the B—O—N—B fragment and a C—C bridge across the N—B—O—N fragment of the central BONBON ring. The bicyclic compound **14** contains a B—O—B bridge across the six-membered BONBON ring. Whereas the BONBON ring in **11** has a strain-free, nearly undistorted chair conformation, those in **12**, **13**, and **14** have more or less distorted boat conformations. To the best of our knowledge, compounds **11–14** are the only "BONBON" compounds which have as yet been structurally characterized by X-ray analysis with the exception of a preliminary communication of some crystallographic data (without details on the molecular structure) for the oxime derivative $Me_2C{=}N{-}O{-}BMe_2$ (11). These data, together with spectroscopic studies, led to the conclusion that the boron compound probably has a dimeric structure in the crystal, but is partially dissociated in solution and fully dissociated in the gas phase into the monomeric $Me_2C{=}N{-}O{-}BMe_2$.

The N—B bond length in **11** (1.695(2) Å) is similar to those observed for several cyclic N—B coordinated com-

pounds like **2** ($R^1 = R^2 = Me$, $R^3 = R^4 = H$) (1.688(2) Å) (2) and the "BONBON" derivative **14** (1.703(3) Å) (19), but is somewhat shorter than the N—B bonds in other tetrahedral "$PhBO_2N$" compounds having sterically hindered N—B bonds like **4** (R = Me) (1.729(3) and 1.736(3) Å) (4) and **7** (1.737(2) and 1.762(2) Å) (this work) and similar bicyclic systems with N—B bond lengths ranging from 1.706(2) to 1.759(3) Å (14, 16, 17). Shorter N—B bonds than those in the BONBON dimer **11** are found in the polycyclic BONBON compounds **12** (mean 1.586(3) Å) (9) and **13** (mean 1.654(8) Å) (15). The sum of the bond lengths about the boron atom in **11**, 6.170 Å, is at the lower end of the range 6.191–6.297 Å observed previously for compounds of the type "$PhBO_2N(sp^3)$" (15, 20). This is consistent with a relatively low overall strain about the boron atom (15).

The dimeric structure of **11** in the solid state is additionally stabilized by weak transannular C—H···O hydrogen bonds between C(2)—H(3) of one of the BONCCO rings and O(1) of the second such ring. The intramolecular C···O distance of 2.853(1) Å is significantly shorter than the sum of van der Waals radii (about 3.3 Å). The existence of short C—H···O interactions in crystals is well-documented, these interactions being considered attractive (21–23). Spectroscopic (24) and crystallographic evidence (25) document the influence of intramolecular C—H···O interactions on the conformational preferences and on the general geometry of both open-chain and cyclic compounds. The distance between the transannular hydrogen H(3) and the BON oxygen atom O(1) in the eight-membered BONBOCCN ring portion of **11** is 2.37(1) Å. A similar distance (2.34 Å) has been observed for the transannular C—H···O interaction in the ten-membered ring system of nonanolactone (25). The C—H···O angle of 108.0(8)° in **11** is similar to the corresponding value of 109.5° in nonanolactone (25). Including these C—H···O hydrogen bonds, the complete three-dimensional array of the crystalline form of **11** has an approximate diamond-lattice conformation resembling the skeleton of "diamantane" ("congressane") (26). There is also a second pair of weaker intramolecular C—H···O interactions present in **11**: C(3)—H(4)···O(2)*, H···O = 2.47(2) Å, C···O = 2.911(2) Å, and C—H···O = 106(1)°. All intermolecular distances correspond to normal van der Waals interactions.

To assign unidentified ESR signals obtained in a Fenton system with a spin trap, 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO), fundamental reactions of DMPO have been thoroughly investigated. When the concentration of Fe^{2+} in Fenton systems exceeded 1% of that of DMPO, background ESR signals totally distinguishable from 2-hydroxy-5,5-dimethyl-1-pyrrolidinyloxy (DMPO-OH) appeared, and simultaneously absorbance at 520 nm increased, which was characteristic of hydroxamic acids complexed with Fe^{3+}. To prove the postulated formation of hydroxamic acid as a key intermediate, DMPO was subjected to Fenton reaction or was treated with Fe^{3+} in aqueous solution to produce DMPO-OH (Makino *et al.* Biochem. Biophys. Res. Commun. **172**, 1073 (1990)), and a major product was isolated by RPLC. Based on ^1H, ^{13}C NMR and MS measurements, the structure of the major product was assigned to 1-hydroxy-5,5-dimethyl-1-pyrrolid-2-one (HDMPN) having a hydroxamic acid structure. Temperature dependence of NMR spectra and careful analysis of the fragmentation patterns in MS further revealed that HDMPN was present in equilibrium with 2-hydroxy-5,5-dimethyl-1-pyrroline-*N*-oxide (HDMPO), a tautomer of HDMPN. It has also been shown that the oxidation of DMPO yielding HDMPN and HDMPO occurs via DMPO-OH and is driven by Fe^{3+}. These oxidation products (HDMPN and HDMPO) were readily converted to the corresponding ESR visible aminoxyl radicals by oxidation and $^{\cdot}OH$ addition in aqueous solution, respectively, and superimposition of the ESR signals arising from these radicals accounts for the background signals observed in Fenton systems with DMPO as a spin trap.

Dans le but d'attribuer les signaux RPE non-identifiés obtenus dans un système de Fenton avec un piège à spin, le *N*-oxyde de 5,5-diméthyl-1-pyrroline (DMPO), on a étudié à fond les réactions fondamentales du DMPO. Lorsque la concentration de Fe^{2+} dans les systèmes de Fenton dépasse 1% de celle du DMPO, des signaux RPE totalement différents de ceux du 2-hydroxy-5,5-diméthyl-1-pyrrolidinyloxy (DMPO-OH) apparaissent avec une augmentation simultanée de l'absorption à 520 nm, caractéristique des acides hydroxamiques complexés par le Fe^{3+}. Afin de prouver la formation postulée d'acide hydroxamique comme intermédiaire clé, on a soumis le DMPO à une réaction de Fenton ou on l'a traité par du Fe^{3+} en solution aqueuse pour obtenir du DMPO-OH (Makino *et al.* Biochem. Biophys. Res. Commun. **172**, 1073 (1990)) et on a isolé le produit principal par RPLC. En se basant sur la RMN du ^1H et du ^{13}C et des mesures de spectrométrie de masse, on conclut que le produit majeur est la 1-hydroxy-5,5-diméthyl-1-pyrrolidin-2-one (HDMPN) possédant une acide hydroxamique dans sa structure. La relation entre la température et les spectres RMN ainsi qu'une analyse soigneuse des patrons de fragmentation de SM ont aussi permis de démontré que le HDMPN est présent à l'équilibre avec l'oxyde de 2-hydroxy-5,5-diméthyl-1-pyrroline (HDMPO), un tautomère du HDMPN. On a aussi montré que l'oxydation du DMPO, conduisant à la HDMPN et au HDMPO, se produit par l'intermédiaire du DMPO-OH et que cette réaction est provoquée par le Fe^{3+}. L'oxydation du HDMPN et l'addition de $^{\cdot}OH$ à une solution aqueuse de HDMPO permettent de transformer ces deux produits d'oxydation en radicaux aminoxyl correspondants, visibles par RPE; la superposition des signaux RPE qui résultent de ces réactions explique les signaux de fond qui sont observés dans les systèmes de Fenton avec du DMPO comme piège à spin.

[Traduit par la rédaction]

Introduction

The method of spin trapping is a powerful tool to detect short-lived free radicals that are not detectable by conventional ESR.[2] In this method, through reaction with spin traps, short-lived free radicals are converted to relatively stable aminoxyl radicals (spin adducts) that are ESR detectable (1). Recently this method has been widely applied to the detection of free radicals in biological systems in attempts to correlate the free-radical formation to the initiation of various diseases (2) since a large body of accumulated evidence indicates that free-radical-induced damage of cellular constit-

uents such as DNA and membrane is critical to such initiation steps. In these studies, 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO, **1** in Fig. 1) has been used almost exclusively as a spin trap since its solubility in water is sufficiently high that the high concentration of the spin trap can be used to detect short-lived free radicals present in very low concentrations. Another advantage is that this spin trap is sufficiently potent to trap oxygen-centered free radicals, especially hydroxyl radicals ($^{\cdot}OH$) and superoxide anion radicals (O_2^{-}) (3). Furthermore, compared to other spin traps (4), it exerts relatively low toxicity to cells.

It is known, however, that ESR spectra obtained with DMPO are often difficult to assign due to coexistence of unidentified signals (1*c*, 5). This is particularly the case when systems containing metal ions (for example, the Fenton reaction) are utilized to initiate free-radical reaction. These undesirable background ESR signals have hampered accurate analysis of ESR spectra and the origin of the spectra remains unidentified. Thus, to make the spin trapping method more accurate and reliable, it is extremely important to characterize all of the species giving rise to the background signals and to clarify the mechanism of their production.

To address these questions, we have conducted basic studies regarding the type of impurities contained in commercial preparations of DMPO that lead to undesirable artifactual ESR signals, and the reactions DMPO undergoes in the presence of metal ions to yield ESR detectable species. For the first question, we have shown that a DMPO derivative, a hydroxyl amine having an epoxy ring (**2** in Fig. 1), is contained in commercial DMPO preparations and this compound is readily oxidized to give an aminoxyl radical whose characteristic ESR spectrum is composed of six lines with equal intensities (6). For the second question, we have reported a preliminary study demonstrating that DMPO is converted to 2-hydroxy-5,5-dimethyl-1-pyrrolidinyloxy (DMPO-OH, **3** in Fig. 1), which is the same compound as a hydroxyl radical adduct of DMPO via the nucleophilic addition of a water molecule to the double bond of DMPO complexed with Fe^{3+} (7).

In the present study, we have carried out further detailed studies to elucidate the entire mechanism for the reaction of DMPO in the presence of iron ions. The present results will be useful not only for accurate assignment of complicated ESR spectra obtained with DMPO in biological studies, but also for designing improved spin traps that do not undergo the undesirable side reactions.

Materials and methods

Materials

High purity DMPO was obtained from Mitsui-Toatsu Co. (Tokyo, Japan) and used without further purification (6). Other reagents of reagent grade were purchased from Wako Pure Chemicals (Osaka, Japan). Water was purified sequentially by Milli R/Q and Milli QII (Millipore, Mass. U.S.A.).

1-Hydroxy-5,5-dimethyl-1-pyrrolid-2-one (HDMPN) was synthesized by modification of the procedure reported previously (8): a mixture of methyl acrylate (1.12 mol) and 2-nitropropane (3.35 mol) was stirred at 30°C for 14 days in the presence of triethylamine (0.56 mol). The methyl 4-methyl-4-nitropentanate obtained was distilled under reduced pressure (69–71°C at 0.7 Torr; 1 Torr = 133.3 Pa) (yield, 80%). To the 50% aqueous ethanol solution (300 mL) containing distilled 4-methyl-4-nitropentanate (0.25 mol) and NH_4Cl (0.25 mol), Zn powder (1.0 mol) was added at 10°C for 3 h with stirring. This mixture was filtered and the solvent was removed by evaporation. The remaining oil was dissolved in 2 N HCl (100 mL) and extracted with chloroform (100 mL, 5 times). After drying the chloroform layer over $MgSO_4$, the solvent was removed by evaporation. Crude HDMPN was purified by column chromatography on silica (Wakogel C-300) with $CHCl_3$:methanol (10:1) as eluent, and subsequently recrystallized from ether:petroleum ether (yield, 50%). This product was identified and examined for its purity by ^1H NMR and RPLC and no additional lines or peaks due to impurities were detected.

2,5,5-Trimethyl-1-pyrroline-*N*-oxide (M_3PO, **4** in Fig. 1) was synthesized by the modification of reported procedures (8*a*, 9). An ether solution (300 mL) of 3-butene-2-one (0.3 mol), 2-nitropropane (0.6 mol), and Triton B (24 mL) was refluxed for 5 h and subsequently shaken sequentially with 0.5 N HCl (100 mL), 10% Na_2CO_3 (100 mL), water (100 mL), and water saturated with NaCl (100 mL). The ether layer containing 5-methyl-5-nitro-2-hexanone was dried over Na_2SO_4 and the ether was then removed by evaporation. The residue was distilled under reduced pressure (59–60°C at 1 Torr). To an aqueous NH_4Cl solution (0.8 M, 300 mL) was added prepared 5-methyl-5-nitro-2-hexanone (0.225 mol). Zn powder (0.9 mol) was added to this suspension under vigorous stirring for 1 h at 0°C and then this solution kept at 20°C for 2 h with vigorous stirring. The reaction mixture was condensed *in vacuo* and was extracted with chloroform. After drying the chloroform layer over Na_2SO_4, chloroform was removed. The crude product was purified by column chromatography similar to that used above for the synthesis of HDMPN (yield, 50%). This product was identified and examined for its purity by ^1H NMR and RPLC and no additional lines or peaks due to impurities were observed.

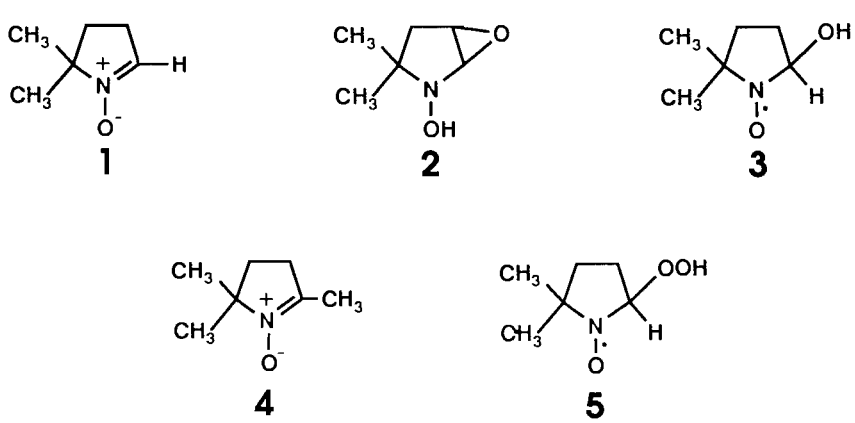

FIG. 1. DMPO and its derivatives appearing in this paper. For HDMPN and HDMPO, see Scheme 1.

Methods

Free radicals were generated by sonolysis or photolysis, except for Fe^{3+}-catalyzed DMPO-OH formation in the dark. For sonication, a Bransonic model B-2200 cleaning bath was used. A sample tube was set in the center of the bath and argon gas was bubbled (500 mL/min) during the sonication to enhance ESR signals (10). Photolysis was carried out on an XC-500 tunable irradiator (Koken Kogyo, Saitama, Japan) equipped with a 500-W xenon lump. These experiments were performed at room temperature.

ESR spectra were measured at room temperature on a Jeol model PE-3X spectrometer (X-band, 100-kHz field modulation, Jeol, Tokyo). Mn^{2+} was used as a marker for the measurements of hyperfine splitting constants (hfsc) and *g*-values. An aqueous flat quartz cell (1.6 mm in thickness, 10.0 mm in width, and 180.0 mm in length) was used. ESR settings used are represented in the figure legends. Spin concentrations were calculated with 2,2,6,6-tetramethylpiperidine-*N*-oxyl as a standard.

^1H and ^{13}C NMR spectra were obtained on a JNM GSX-400 NMR spectrometer (400 MHz, Jeol) coupled with a variable temperature unit. Standards used for the measurements of chemical shifts were tetramethylsilane (TMS) in $CDCl_3$ (internal reference) and 3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid, sodium salt (TSP-d_4) in D_2O (external reference).

A JMS DX-300 MS spectrometer (Jeol) was used to measure *m/z* values. The electron ionization mass spectrometry (EIMS) was coupled with a temperature rise in the sample probe. The conditions for MS measurements were as follows: ionization energy, 30 eV; temperature rise, 16°C/min from 25°C; pressure, 10^{-6} Torr.

For RPLC analyses, a combination of Hitachi L-6000 and L-6200 pumps equipped with a photodiodearray L-3000 detector (Hitachi, Tokyo) was utilized. An Inertsil ODS column (GL Science, Tokyo) was used. The chromatographic conditions are shown in the figure legend.

Absorption spectra were obtained on a Shimadzu UV 260 spectrophotometer (Shimadzu, Kyoto, Japan). Concentrations of Fe^{2+} and Fe^{3+} were measured with 1,10-phenanthroline (ε_{510} = 9720 cm^{-1} M^{-1}) and potassium thiocyanate (ε_{480} = 9100 cm^{-1} M^{-1}) as coloring reagents, respectively.

All experiments were carried out in the dark to avoid photochemically induced reactions of DMPO (11).

Results and discussion

Background ESR signals in Fenton systems

The reaction of DMPO (0.01, 0.1, or 1 M) in Fenton systems (eqs. [1]–[3]) consisting of H_2O_2 and $FeSO_4$ was investigated by ESR at room temperature under atmospheric conditions.

$$[1]\quad Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + {}^{\cdot}OH + OH^-$$

$$[2]\quad {}^{\cdot}OH + H_2O_2 \rightarrow {}^{\cdot}OOH + H_2O$$

$$[3]\quad Fe^{3+} + {}^{\cdot}OOH \rightarrow Fe^{2+} + O_2 + H^+$$

The concentrations of H_2O_2 and $FeSO_4$ were varied from 1 mM to 1 M and 10 μM to 10 mM, respectively. When the concentration of Fe^{2+} was less than 1% of that of DMPO, an ESR spectrum composed of a 1:2:2:1 quartet attributable to a spin adduct of hydroxyl radicals (DMPO-OH, a_N = $a_{\beta H}$ = 1.50 mT) was obtained (Fig. 2*A*) (12). On the other hand, additional lines appeared when the concentration of Fe^{2+} exceeded 1% of that of DMPO. Figure 2*B* shows an ESR spectrum taken immediately after the sample preparation. The additional lines consisted of a 1:1:1 triplet of 1:1 doublets further split into a 1:1 doublet, and was assigned as a spin adduct of the hydroperoxyl radical of DMPO (DMPO-OOH, a_N = 1.43 mT, $a_{\beta H}$ = 1.15 mT, and $a_{\gamma H}$ = 0.13 mT, **5** in Fig. 1) (12). With increasing storage time, the ESR spectrum obtained immediately after the sample preparation (storage time ca. 1 min) changed further, and two sets of ESR lines appeared consisting of a 1:1:1 triplet (a_N = 1.53 mT, signal (*i*)) and a 1:1:1 triplet of 1:2:1 triplet

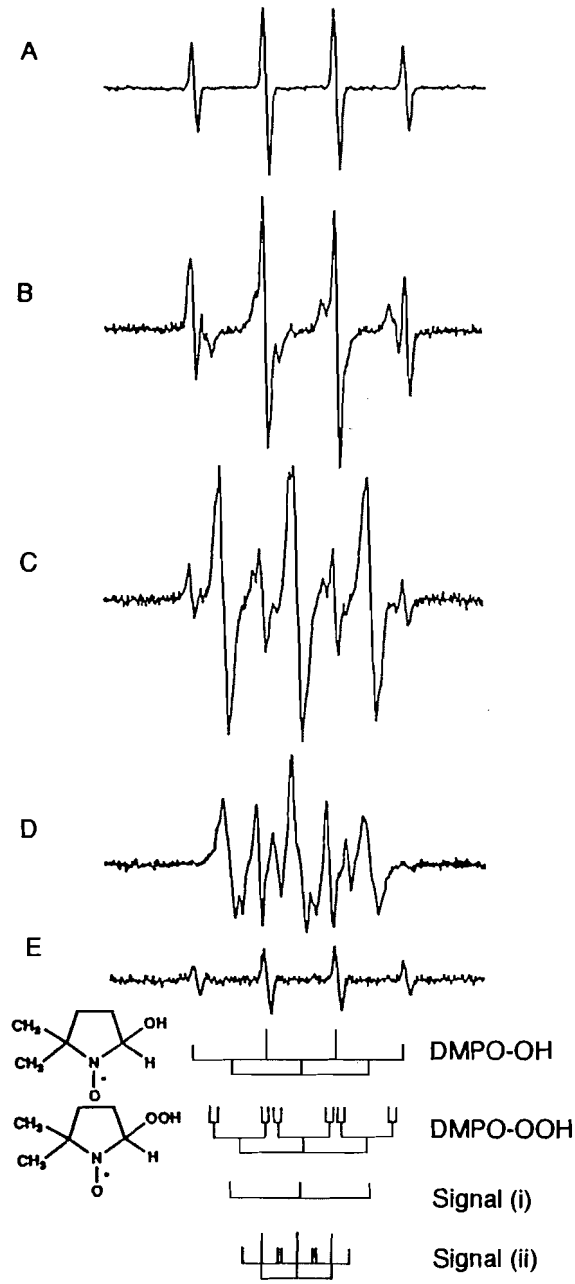

FIG. 2. ESR spectra obtained from aqueous DMPO solutions (100 mM) containing (*A*, *B*, *C*, and *D*) $FeSO_4$ (10 μM for *A* and 3 mM for *B*, *C*, and *D*) and H_2O_2 (900 mM), and (*E*) $FeNH_4(SO_4)_2$ (1 mM). Storage time was (*A*) 2 h, (*B*) 3 min, (*C*) 2 h, (*D*) 3 h, and (*E*) 1 min. Each component is explained by the stick diagrams in this figure. Hyperfine splitting constant values obtained for each of the ESR components are as follows: a_N = $a_{\beta H}$ = 1.50 mT for DMPO-OH, a_N = 1.43 mT, $a_{\beta H}$ = 1.15 mT, and $a_{\gamma H}$ = 0.13 mT for DMPO-OOH, a_N = 1.53 mT for signal (*i*), and a_N = 0.72 mT and $a_{\gamma H}$ = 0.41 mT (2H) for signal (*ii*). ESR settings are as follows: modulation amplitude, 0.05 mT; receiver gain, ×500 for *A*, *B*, *C*, and *D* and ×1000 for *E*; time constant, 0.3 s; sweep time, 16 min for *B*, *C*, and *D* and 8 min for *A* and *E*.

(a_N = 0.72 mT and a_H = 0.41 mT, signal (*ii*)) after 1 h (Fig. 2*C*) and 3 h (Fig. 2*D*), respectively. All the ESR components appearing in Figs. 2*A–D* are explained by the stick diagrams illustrated in Fig. 2. In the present study, the unidentified signals (*i*) and (*ii*) have been studied in detail to clarify their origin and formation mechanisms.

First we explored the possibility that the background signals (*i*) and (*ii*) might arise through reactions between DMPO and Fe^{2+} or Fe^{3+} oxidized from Fe^{2+} in Fenton systems. No reaction was observed for an aqueous DMPO solution containing Fe^{2+} (as $FeSO_4$). In an aqueous DMPO solution (100 mM) containing Fe^{3+} (as $FeNH_4(SO_4)_2$, 1 mM), an ESR spectrum consisting of a 1:2:2:1 quartet appeared (Fig. 2*E*) and diminished over several 10-min intervals. This species has been assigned to the same compound as a DMPO spin adduct of $^{\cdot}OH$ (DMPO-OH), and is formed by the nucleophilic addition of a water molecule to DMPO (7). These results suggest that other reactions, probably involving conversion of initially formed DMPO-OH, are responsible for the production of the background ESR signals.

Absorption spectra were also measured for Fenton systems that gave rise to the background ESR signals (*i*) and (*ii*). As shown in Fig. 3*A*, a Fenton system ($FeSO_4$ (3 mM) and H_2O_2 (900 mM)) containing DMPO (100 mM) showed an absorption at 520 nm, which increased with increasing storage time. A similar spectrum was obtained from an aqueous solution containing $FeNH_4(SO_4)_2$ (10 mM) and DMPO (10 mM) (Fig. 3*B*). These results imply that the same species absorbing at 520 nm is formed in both systems, and that the appearance of the background ESR signals may be related to the increment of the absorbance.

A possibility that the species absorbing at 520 nm is a complex between DMPO and Fe^{3+} has been ruled out since we already demonstrated that the formation of a DMPO–Fe^{3+} complex occurs instantly at room temperature (7, 13), while the complex absorbing at 520 nm formed slowly at a rate in the order of 1 h. Elsworth and Lamchen (14) have reported that cyclic nitrones including DMPO undergo two-electron reduction in the presence of $FeCl_3$ to yield directly the corresponding hydroxamic acids, and that a hydroxamic acid derivative of DMPO (1-hydroxy-5,5-dimethyl-1-pyrrolid-2-one, HDMPN) complexed with Fe^{3+} has absorption at 544 nm (ε = 1075 cm^{-1} M^{-1}). Although the absorption maximum observed in this study was slightly blue-shifted (520 nm) relative to that reported (544 nm), HDMPN was likely to be produced in the present systems. Accordingly, we decided to reexamine in more detail the formation of the hydroxamic acid (HDMPN) from DMPO or DMPO-OH to clarify the relation with the generation of background ESR signals.

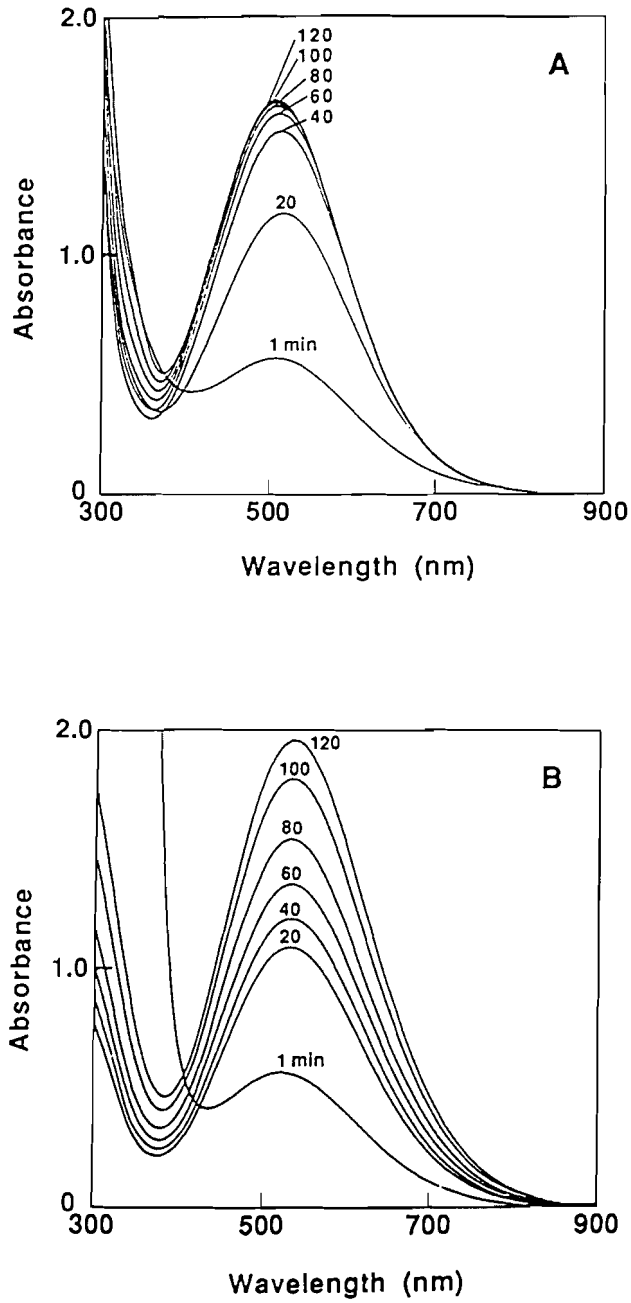

FIG. 3. Progressive change in the absorbance at 520 nm occurring in aqueous solutions containing (*A*) DMPO (100 mM), $FeSO_4$ (3 mM), and H_2O_2 (900 mM) and (*B*) DMPO (10 mM) and $FeNH_4(SO_4)_2$ (10 mM). The path length of the cell used was 0.5 cm for *A* and 1.0 cm for *B*.

Characterization of intermediates giving rise to background ESR signals

To examine the formation of HDMPN from DMPO or DMPO-OH, ^1H NMR measurements were first performed in a D_2O solution containing $FeNH_4(SO_4)_2$ (10 mM) and DMPO (10 mM), and the time course of the reaction was followed. A typical spectrum obtained is depicted in Fig. 4. Similar spectra were obtained from Fenton systems that gave the absorbance maximum at 520 nm. A set of lines with chemical shifts of 8.43 (CH at C2), 4.06 (CH_2 at C3), 3.37 (CH_2 at C4), and 2.57 (CH_3 at C5) ppm was assigned to DMPO: the chemical shifts were low-field shifted and line shapes broadened due to the presence of paramagnetic Fe^{3+}, in comparison with those for DMPO in D_2O free of ferric ions (7.23 (CH at C2), 2.76 (CH_2 at C3), 2.24 (CH_2 at C4), and 1.42 (CH_3 at C5) ppm). The rest of the signals with chemical shifts of 3.58, 3.13, and 2.43 ppm were probably due to the postulated complex between HDMPN and Fe^{3+}. The signal intensities of DMPO (asterisked) decreased as that of the complex increased. This conversion proceeded in the order of 1 h, corresponding to the slow change of the ESR lines appearing in Fig. 2.

Product analysis was also carried out for a system com-

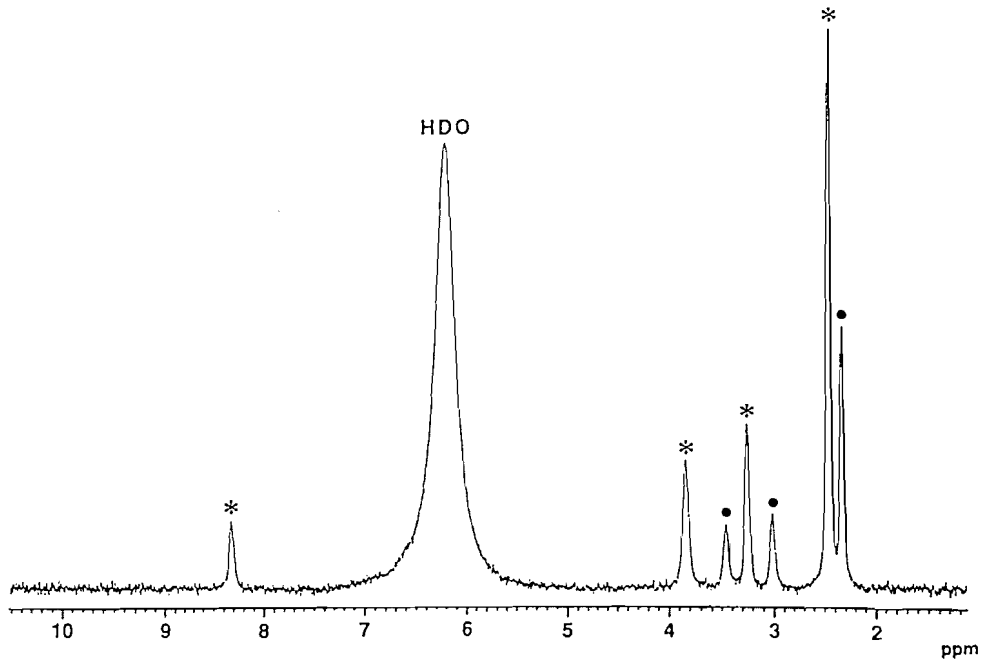

FIG. 4. A typical ^1H NMR spectrum obtained from a D_2O solution containing DMPO (10 mM) and $FeNH_4(SO_4)_2$ (10 mM). The peaks indicated by asterisks and closed circles are due to DMPO and a product from DMPO, respectively.

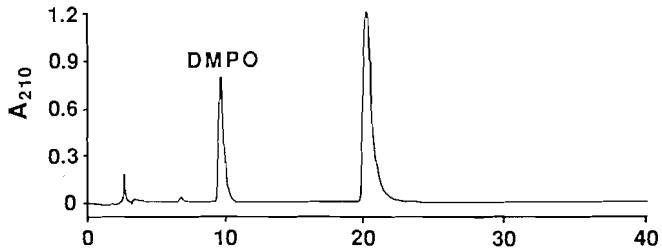

FIG. 5. An RPLC chromatogram obtained from an aqueous DMPO solution (10 mM) containing $FeNH_4(SO_4)_2$ (10 mM). Reaction time was 3 h. The first peak, eluted at 9.5 min, is due to DMPO. Chromatographic conditions are as follows: column, Inertsil ODS (4.6 mm i.d. × 250 mm long); eluent, (*a*) $CH_3CN:H_2O$ (5%) and (*b*) $CH_3CN:H_2O$ (25%); gradient, held in (*a*) for 10 min, linear from (*a*) to (*b*) for 20 min, and held in (*b*); flow rate, 1.0 mL/min; detection, 210 nm.

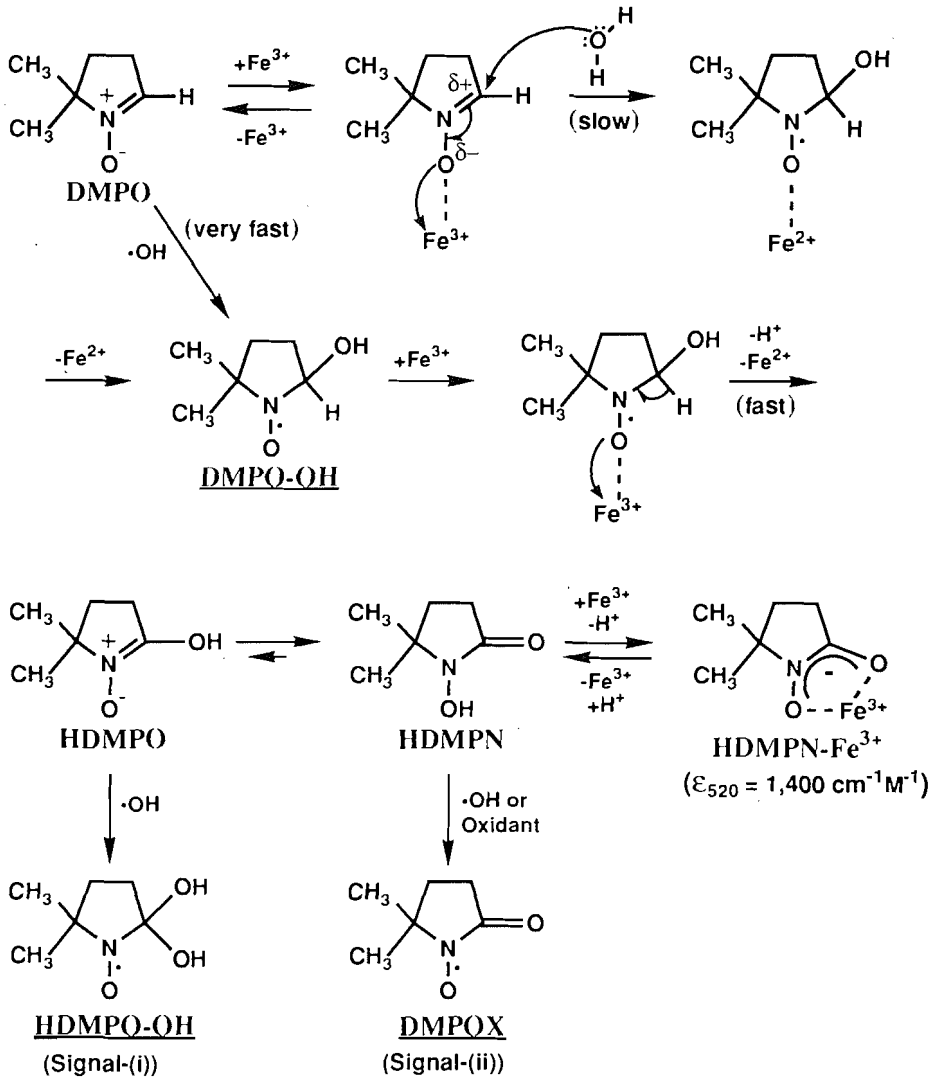
prising DMPO and ferric ions. DMPO (10 mM) was allowed to react in an aqueous solution containing $FeNH_4(SO_4)_2$ (10 mM) for 1 day at room temperature, and product analysis was performed periodically by RPLC. A typical chromatogram is shown in Fig. 5. Analogous chromatograms were obtained for the Fenton system containing DMPO. The intensity of the peak due to the major reaction product eluted at 20.5 min increased with the decrease in the peak of DMPO eluted at 9.5 min. The stoichiometry between DMPO and the major product was consistent with that obtained by the ^1H NMR measurement. The major product eluted at 20.5 min was collected and measured by ^1H NMR and MS. Fe^{3+} that disturbed the measurements was separated during the elution from the RPLC column. By the EIMS coupled with temperature rise, two peaks appeared at 170 and 194°C in the MS chromatogram and the major MS peaks were obtained from these peaks as follows: (*m/z*) 36, 98, 114, and 129 (M^+) at 170°C and 86, 114, and 129 (M^+) at 194°C. The second set of *m/z* values indicates the formation of HDMPN, which has a mass number of 129 and has methyl (15 amu) and carbonyl (28 amu) groups. The first set indicates that this molecule has a mass number of 129 and has methyl (15 amu) and hydroxyl (16 amu) groups. This compound is tentatively assigned to 2-hydroxy-5,5-dimethyl-1-pyrroline-*N*-oxide (HDMPO), a tautomer of HDMPN (see Scheme 1 for the structures of HDMPN and HDMPO). To confirm these assignments, ^1H and ^{13}C NMR spectra of the isolated product were measured in $CDCl_3$ and D_2O, respectively. The ^1H NMR spectrum of the major product consisted of signals with chemical shifts of 10.02 (N-OH), 2.40 (CH_2 at C3), 1.90 (CH_2 at C4), and 1.31 (CH_3 at C5) ppm (Fig. 6*A*). These values coincide exactly with those of authentic HDMPN. Consistent assignment was also obtained from the ^{13}C NMR spectrum (Fig. 6*B*): 174.73 (C=O at C2), 64.75 (C5), 32.79 (CH_2 at C4), 28.80 (CH_2 at C3), and 26.91 (CH_3 at C5) ppm. From these results, the major product is assigned to HDMPN. Since HDMPO is a tautomer of HDMPN, an equilibrium between HDMPN and HDMPO may exist. To elucidate the possibility, ^1H NMR measurements were performed in $CDCl_3$ by lowering the temperature to suppress structural exchange between HDMPN and HDMPO. As shown in Fig. 6*C*, at −20°C and below a broad singlet emerged around 5.5 ppm, which is characteristic of an enolic OH group, and the signal is attributed to an OH proton of HDMPO. The ratio of HDMPN:HDMPO calculated from the spectrum obtained at −60°C was roughly 8:1.

Since HDMPN is a hydroxylamine as well as a hydroxamic acid that can be converted to an aminoxyl radical under oxidative conditions, and HDMPO is a nitrone spin trap, ESR signals should arise when these compounds are oxidized by $^{\cdot}OH$. Thus an aqueous solution of authentic HDMPN (100 mM) was photo-irradiated at 260 nm in the presence of



SCHEME 1. Overall reaction mechanism of DMPO spin trapping in Fenton systems. ESR detectable species are underlined.

H_2O_2 (100 mM). An ESR spectrum obtained from the sample is represented in Fig. 7*A*: the stick diagrams indicate that this spectrum is composed of two sets of lines (Fig. 7*B*). One is a 1:1:1 triplet (a_N = 0.72 mT) of a 1:2:1 triplet ($a_{\gamma H}$ = 0.41 mT, 2H). It should be noted that this spectrum was previously assigned to an aminoxyl radical referred to DMPOX (5*d*, 15). The other spectrum consists of a 1:1:1 triplet (a_N = 1.53 mT) of a 1:3:3:1 quartet ($a_{\gamma H}$ = 0.12 mT, 3H). The quartet that is not clear in Fig. 2 is obvious in this spectrum because of line sharpening in the absence of paramagnetic iron ions, and this spectrum is tentatively assigned to an HDMPO spin adduct of •OH. We suspect that the three hydrogen atoms of the two methyl groups at C5 fit the structural coordination of the W plan (16), with which hfsc values are relatively large via long-range interaction. A computer simulation (Fig. 7*B*) using the above hfsc values nicely reproduced the observed spectrum (Fig. 7*A*). Accordingly the two sets of ESR lines arising from HDMPO-OH and DMPOX are consistent with the background signals (*i*) and (*ii*) in Fig. 2. It was also confirmed that addition of Fe^{3+} to an aqueous HDMPN solution led to an absorption spectrum identical with that represented in Fig. 3. Assuming that both HDMPN and HDMPO form the complex (for convenience, referred to here as HDMPN–Fe^{3+}) with Fe^{3+} in the presence of excess Fe^{3+}, the molar absorption coefficient (ε) of the complex was revised here to be 1400 cm^{-1} M^{-1}, which was slightly higher than that reported previously (1075 cm^{-1} M^{-1}) (14*b*).

In summary, when DMPO is used in a solution containing Fe^{3+}, HDMPN and HDMPO are produced, which are ESR silent (the reactions to yield HDMPN and HDMPO are discussed below). However, when •OH is generated in solutions such as Fenton systems, HDMPN is converted to the corresponding aminoxyl radical (DMPOX), and HDMPO traps •OH to form an HDMPO spin adduct (HDMPO-OH), both of which are ESR detectable (Scheme 1). The absorption at 520 nm observed in the presence of Fe^{3+} is due to the complex between Fe^{3+} and HDMPN (and (or) HDMPO).

Precursor of HDMPN and HDMPO

As mentioned earlier in this text, the formation of DMPO-OH was detected by ESR in a solution containing DMPO and Fe^{3+}. Therefore, it is very likely that DMPO-OH is a pre-

cursor of HDMPN and HDMPO. To prove this, DMPO-OH (ca. 50 μM based on ESR measurement) was generated by sonolysis in an aqueous DMPO solution (10 mM). Sonolysis of water gives rise to $^{\bullet}OH$ and $^{\bullet}H$ by homolytic cleavage of water molecules and thus DMPO-OH and DMPO-H are formed (10). It is noted that possible involvement of DMPO-H in the reactions discussed below was ruled out since essentially the same results were obtained in photolysis of an aqueous DMPO solution containing H_2O_2 and Fe^{3+}. After addition of Fe^{3+} (1 mM as $FeNH_4(SO_4)_2$) to the sonicated solution, the absorption at 520 nm increased for the first 30 min and reached a plateau, then decreased slightly (Fig. 8). The absorbance (520 nm) of the sonicated sample was always larger than that of non-sonicated one by 0.07 (in absorbance units). Using the ε value of the HDMPN–Fe^{3+} complex determined here (1400 cm^{-1} M^{-1}), the absorbance difference can be translated into 50 μM of the complex, which is in good agreement with the concentration of the ligand (HDMPN) expected from the initial yield of DMPO-OH (ca. 50 μM). The amount of Fe^{2+} reduced from Fe^{3+} was also monitored by colorimetric analysis and an analogous difference (ca. 50 μM) in the amount of Fe^{2+} was found between the samples with and without sonication. This result strongly supports that the precursor for HDMPN (and HDMPO) is DMPO-OH. The plateau and slight decrease in the concentration of the HDMPN–Fe^{3+} complex observed for both solutions after 30 min (Fig. 8) is probably due to the consumption of Fe^{3+} in these systems.

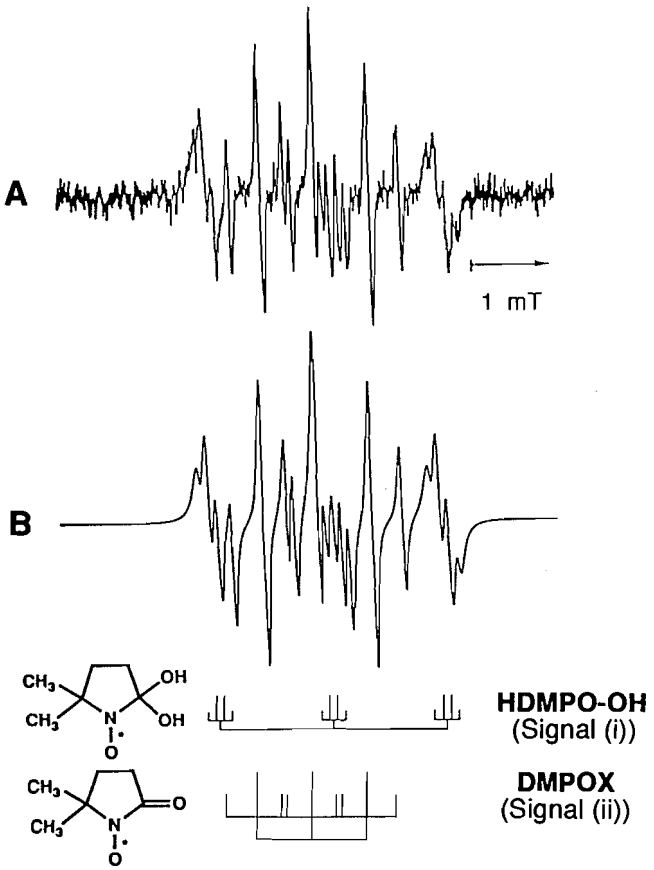

FIG. 7. (*A*) An ESR spectrum obtained from a UV-irradiated (at 260 nm for 3 s) HDMPN solution (100 mM) in the presence of H_2O_2 (100 mM) and (*B*) a computer simulation spectrum for *A*. ESR parameters used for the simulation are as follows: a_N = 1.53 mT, $a_{\gamma H}$ = 0.12 mT (3H), and g = 2.0063 for HDMPO-OH (denoted as signal (*i*) in Fig. 2), and a_N = 0.72 mT, $a_{\gamma H}$ = 0.41 mT (2H), and g = 2.0072 for DMPOX (denoted as signal (*ii*) in Fig. 2). The line width (ΔH_{pp}) taken was 0.05 mT for DMPOX and 0.08 mT for HDMPO-OH and the intensity ratio of DMPOX:HDMPO-OH was 1:1. ESR settings are follows: modulation amplitude, 0.025 mT; receiver gain, ×2000; time constant, 1.0 s; sweep time, 32 min.

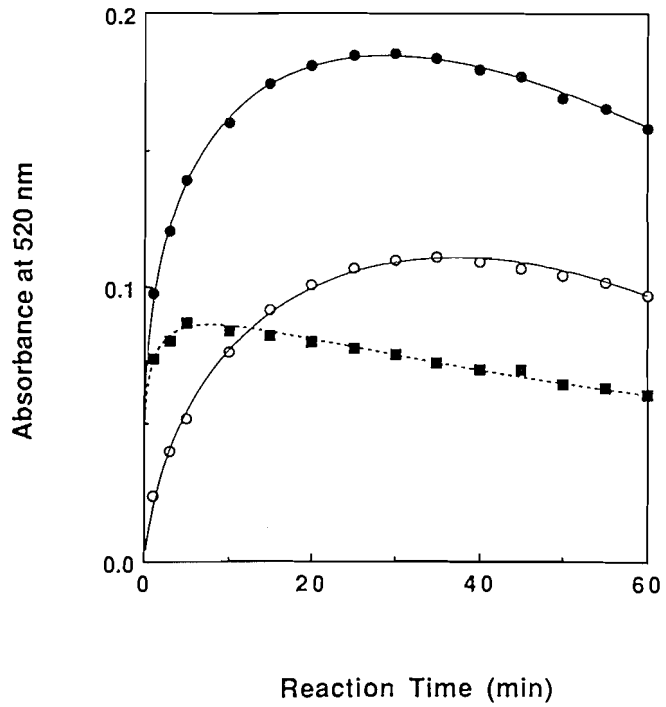

FIG. 8. Time courses for the formation of the HDMPN–Fe^{3+} complex in aqueous DMPO solutions (10 mM) containing (●) DMPO-OH (ca. 50 μM) and $FeNH_4(SO_4)_2$ (1 mM) and (○) $FeNH_4(SO_4)_2$ (1 mM). A broken line (□) representing a concentration of HDMPN–Fe^{3+} originating from the sonication was obtained by subtracting the concentration of the complex in the non-sonicated solution (○) from that in the sonicated one (●). DMPO-OH was generated immediately prior to the sample preparation by sonicating (for 5 min) an aqueous DMPO solution (10 mM) with Ar bubbling (500 mL/min). The concentration of the complex is calculated using the molar extinction coefficient (ε) of 1400 cm^{-1} M^{-1} (at 520 nm).

In the sonicated solution, DMPO-OH produced both by the sonication and the dark reaction is involved in the formation of the HDMPN–Fe^{3+} complex, while only the latter is responsible in the non-sonicated solution. Accordingly, the apparent rate of formation of the complex from DMPO-OH initially formed by the sonication can be roughly estimated by the initial slope of a curve (broken line) obtained by subtracting the concentration of the complex in the non-sonicated solution from that in the sonicated one (Fig. 8). The calculated rate is 53 μM/min. It should be noted that the calculated value is obviously a minimum estimate of a real rate: the first data point of the curve obtained is already in a late stage of the conversion reaction of DMPO-OH produced by the sonication and, additionally, the lifetime of DMPO-OH at pH 3 has been estimated to be several minutes in a γ-irradiated aqueous DMPO solution (17). The rate of complex formation by the dark reaction in the non-sonicated solution is also estimated as 17 μM/min. It follows that the formation of the HDMPN–Fe^{3+} complex from DMPO-OH initially formed by the sonication occurred at least 3-fold faster than that in the dark reaction. Assuming that the formation of DMPO-OH is a rate-determining reaction for the formation of the HDMPN–Fe^{3+} complex, the rates of formation of the complex in the conversion of DMPO-OH and in the dark reaction should be approximately proportional to k_1[DMPO-OH][Fe^{3+}] and k_2[DMPO][Fe^{3+}], respectively, where k_1 and k_2 are apparent rate constants. Using [DMPO-OH] = 50 μM, [DMPO] = 10 mM, [Fe^{3+}] = 1 mM, and k_1[DMPO-OH][Fe^{3+}]/k_2[DMPO][Fe^{3+}] ≃ 3, k_1/k_2 is roughly estimated as 660. This result implies that the reaction between DMPO-OH and Fe^{3+} to produce HDMPN proceeds at least two or three orders of magnitude more efficiently than that between DMPO and Fe^{3+} to produce DMPO-OH.

The reactions for the formation of HDMPN and HDMPO from DMPO in the presence of Fe^{3+} are summarized in Scheme 1. According to the scheme, the amount of the reduced Fe^{3+} should be twice as large as that of converted DMPO. To see if this is the case, the changes in the concentrations of Fe^{3+} and DMPO were measured for a sample consisting of equimolar $FeNH_4(SO_4)_2$ (10 mM) and DMPO (10 mM). The time profile for the conversion of Fe^{3+} and DMPO is shown in Fig. 9. It is evident from Fig. 9 that the amount of reduced Fe^{3+} is twice as large as that of the converted DMPO throughout the course of the reaction. This result is consistent with the proposed scheme.

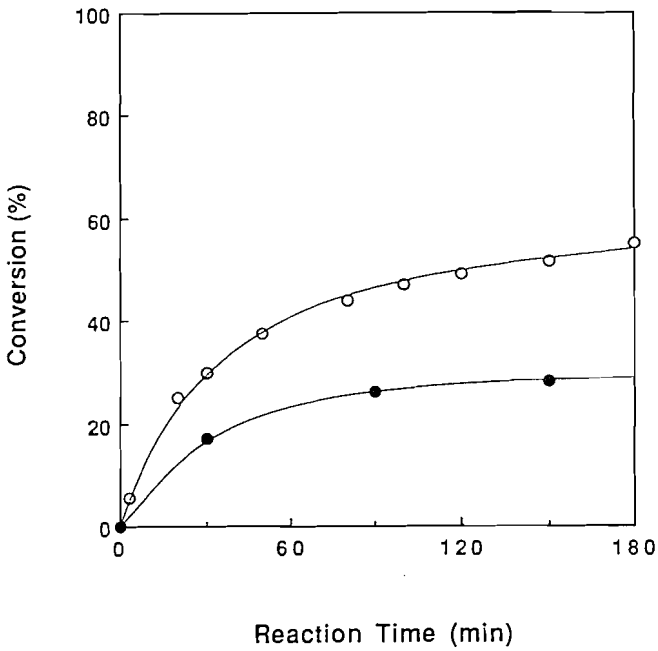

FIG. 9. Time courses for the decreases of (●) DMPO and (○) ferric ions in an aqueous DMPO solution (10 mM) containing $FeNH_4(SO_4)_2$ (10 mM). The contents of DMPO and ferric ions were measured by RPLC analysis and colorimetric determination with potassium thiocyanate, respectively.

Effect of methyl substitution at C2 on the formation of HDMPN and HDMPO

In the proposed scheme, elimination of a hydrogen atom from C2 in DMPO-OH is involved. This suggests that if the hydrogen atom is replaced by an alkyl group at C2, no reaction should take place after the hydroxylation of the double bond. To confirm this, reaction of M_3PO (18) having a methyl group at C2 was investigated in the presence of Fe^{3+}. M_3PO (10 mM) was allowed to stand in an aqueous solution in the presence of $FeNH_4(SO_4)_2$ (10 mM) at room temperature. However, no absorption appeared around 520 nm in up to 50 h, implying that compounds analogous to HDMPN and HDMPO for DMPO were not formed. From the same sample, an ESR spectrum composed of a 1:1:1 triplet (a_N = 1.52 mT) was obtained, indicating the formation of M_3PO-OH. Probably, as for DMPO-OH, M_3PO-OH is produced by the nucleophilic addition of a water molecule to the double bond. Also, RPLC analysis showed an extremely slight decrease in the concentration of M_3PO: this decrease may correspond to the amount of the produced spin adduct (in the order of 1 μM). These results indicate that M_3PO-OH does not undergo further proton elimination.

In summary, in the presence of Fe^{3+}, DMPO is initially converted to ESR detectable DMPO-OH by the addition of a water molecule and subsequently, through hydrogen elimination from DMPO-OH, HDMPN and HDMPO are formed. When $^{\bullet}OH$ is present, HDMPN is converted to the corresponding aminoxyl radical (DMPOX) and HDMPO traps $^{\bullet}OH$ to yield HDMPO-OH. These two species give rise to the background ESR signals (*i*) and (*ii*) in Fig. 2. This makes it difficult to analyze the ESR signals obtained. Since a series of reactions shown in Scheme 1 are accelerated when H_2O_2 coexists in the systems to produce DMPO-OH by $^{\bullet}OH$ addition, assignment of ESR signals obtained in biological systems should be carried out with great care. Such undesirable side reactions can be avoided by using spin traps having CH_3 groups at C2 in a pyrroline ring.

Acknowledgments

We thank Dr. Hiroaki Ohya-Nishiguchi for valuable discussion and Dr. Yashige Kotake for useful suggestions for the synthesis of M_3PO. Additions covalentes de nucléophiles sur les pyrido-as-triazines

NELLY PLÉ, ALAIN TURCK ET GUY QUEGUINER[1]

Laboratoire de chimie organique fine et hétérocyclique, Institut de recherches en chimie organique fine, Institut national des sciences appliquées, Unité de recherche associée au Centre national de la recherche scientifique, n° 1429, BP 08, 76131 Mont Saint Aignan CEDEX France

Reçu le 26 février 1991[2]

NELLY PLÉ, ALAIN TURCK et GUY QUEGUINER. Can. J. Chem. **70**, 2828 (1992).

L'addition covalente de divers nucléophiles sur les pyrido-as-triazines a été étudiée; la structure des σ-adduits a été determinée par RMN. Nous avons decelé une exceptionnelle réactivité des pyrido-as-triazines comportant un atome d'azote pyridinique en β vis-à-vis des nucléophiles carbonés. Cette aptitude à former des σ-adduits avec ces réactifs est comparable à celle des ptéridines. Nous avons observé une régiosélectivité de l'attaque nucléophile sur le cycle pyridinique en péri du cycle triazinique.

NELLY PLÉ, ALAIN TURCK, and GUY QUEGUINER. Can. J. Chem. **70**, 2828 (1992).

Covalent addition of various nucleophiles to pyrido-as-triazines was studied and the σ-adduct structures were determined by NMR. A remarkable reactivity toward carbon nucleophiles has been highlighted for pyrido-as-triazines bearing a pyridinic nitrogen in the β position: only in the pteridine series has a similar reactivity been encountered. Complete regioselectivity of the nucleophilic attack on the pyridine nucleus peri to the triazine was observed.

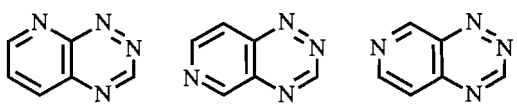
Introduction

L'addition covalente de réactifs nucléophiles est une réaction caractéristique des systèmes polyazaaromatiques (1–4). Divers exemples d'hydratations covalentes observés avec des composés naturels comportant un hétérocycle polyazoté comme la xanthoptérine (5) ont suscité un vif intérêt pour l'étude de cette réaction. Parmi les polyazanaphtalénes, les pyrazino[2,3-*d*]pyrimidines ou ptéridines présentes dans un grand nombre de composés naturels ont été plus largement étudiées (15).

Les pyrido-as-triazines que nous avons synthétisées (13*c*) ont des structures proches de celle des ptérines et il apparait intéressant d'essayer de cerner leur réactivité vis-à-vis des nucléophiles. Dans la série des pyrido-as-triazines il existe quatre hétérocycles différents comportant un cycle as-triazine condensé à la pyridine par une liaison carbone–carbone. Notre étude porte sur trois d'entre eux, les hétérocycles **1**, **2** et **3**.



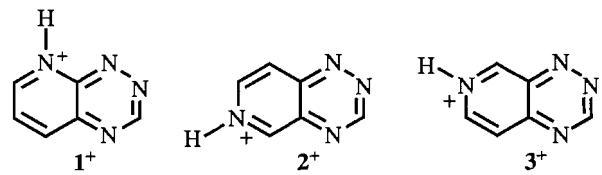
1 **2** **3**

Hydratation

Milieu neutre et acide

Les spectres RMN ^1H de ces hétérocycles restent inchangés dans D_2O et CD_3OD pendant un laps de temps supérieur à 1 semaine à température ambiante. En milieu neutre les pyrido-as-triazines étudiées, **1**, **2** et **3**, sont donc stables dans l'eau et dans le méthanol. Cependant l'addition de DCl provoque une perte très rapide de résolution du spectre RMN ^1H vraisemblablement due à des équilibres rapides entre formes protonées et neutres.

En milieu acide et anhydre (CF_3COOD) aucune modification du spectre RMN ^1H des pyrido-as-triazines n'a été observée à température ambiante pendant un temps relativement long (96 h). Ce résultat traduit une stabilité des cations anhydres $\mathbf{1}^+$, $\mathbf{2}^+$ et $\mathbf{3}^+$ dont la structure a pu être établie par ailleurs à l'aide de spectres RMN ^{13}C (14).



$\mathbf{1}^+$ $\mathbf{2}^+$ $\mathbf{3}^+$

L'addition d'eau ou de méthanol à une solution de pyrido-as-triazine dans l'acide trifluoroacétique entraîne la formation de nouvelles espéces comme le démontre en RMN la diminution des signaux des pyrido-as-triazines et l'apparition de nouveaux signaux dans une région de champs plus forts. La complexité des spectres ne nous a cependant pas permis d'établir la structure des composés obtenus.

En présence d'eau l'évolution des spectres se fait plus rapidement pour $\mathbf{3}^+$ ($t_{1/2}$ = 10 min) et $\mathbf{2}^+$ ($t_{1/2}$ = 30 min) que pour $\mathbf{1}^+$ ($t_{1/2}$ = 2 h 30),

Milieu basique

L'addition d'une base forte comme $NaOCD_3$ ou NaOD à température ambiante à des solutions de pyrido-as-triazines dans D_2O provoque la disparition progressive en 1 h à 1 h 30 des signaux des spectres RMN ^1H et ^{13}C. En RMN ^1H la disparition totale des signaux se fait avec une quantité de base équivalente à 1/10 de la quantité stoéchiométrique.

L'extraction par $CDCl_3$ de la solution basique (D_2O/NaOD) pour laquelle nous n'obtenons plus de signal RMN permet d'obtenir une phase organique dont le spectre RMN ^1H est identique à celui de l'hétérocycle initial. Nous avons pu vérifier ainsi que la disparition des signaux en RMN ^1H ou ^{13}C n'était pas due à la destruction de l'hétérocycle mais vraisemblablement à l'existence d'équilibres relativement rapides entre l'hétérocycle et des formes hydratées.

Nous avons tenté de déterminer la nature des produits d'addition formés en déplaçant ces équilibres par oxydation des σ-adduits par un excès de ferricyanure de potassium à température ambiante. Cette méthode a été précisément utilisée pour déterminer le site d'hydratation de triazanaphtalènes (6).

Dans ces conditions nous avons pu isoler les composés **6**

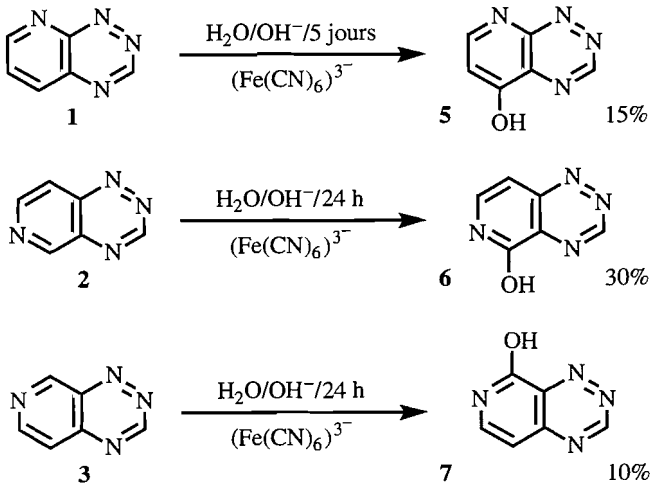
[a]Solvant $CDCl_3$.
[b]Solvant DMSO-d_6.

et **7** après un temps de réaction de 24 h tandis que le composé **5** est obtenu en 5 jours.

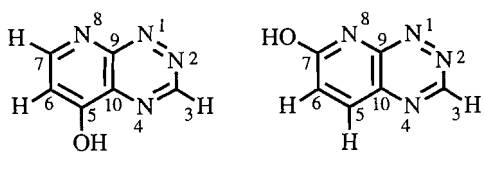


L'analyse des spectres RMN ^{1}H des composés **5–7** (tableau 1) révèle pour chacun de ces composés l'existence d'un proton mobile attribuable à un OH ou un NH. On observe également la présence d'un singulet dans la région des champs forts (δ 10–9, 8 ppm) que nous pouvons attribuer au proton H3.

Nous observons pour chacun des composés l'existence d'un spectre AB avec un déplacement chimique plus faible ($\Delta\delta \sim 1$ ppm vers les champs forts) que celui des protons équivalents dans l'hétérocycle de départ.

Ces remarques nous permettent d'envisager une attaque nucléophile sur le cycle pyridinique exclusivement. Pour les hétérocycles **2** et **3** l'attaque nucléophile se fait sans ambiguïté en α de l'azote pyridinique pour donner les composés **6** et **7** (en équilibre tautomère entre formes lactame–lactime).

Dans le cas du composé **5** deux structures ***5a*** et ***5b*** sont compatibles avec un spectre RMN ^{1}H comportant un AB et correspondent à une attaque nucléophile en C5 ou C7.



5a ***5b***

L'étude du spectre RMN ^{13}C du composé **5** (tableau 2) effectué à 400 MHz nous permet de lever l'indétermination.

Parmi les valeurs des constantes de couplage $^1J_{CH}$ et $^3J_{CH}$ du cycle pyridinique données dans la littérature (7) on observe les valeurs $^3J_{C2-H4} = 7$ Hz et $^3J_{C4-H2} = 4$ Hz ainsi qu'une valeur particulièrement élevée $^3J_{C2-H6} = 12$ Hz caractéristique de la présence d'un hydrogène sur un carbone en α de l'atome d'azote. L'étude comparative des constantes $^3J_{C-H}$ des composés **5** et **6** (tableau 2) nous permet d'observer 12 Hz pour la constante $^3J_{C5-H7}$ du composé **6** et 14 Hz pour la constante $^3J_{C9-H7}$ pour le carbone quaternaire C9 à 153,0 ppm du composé **5**. Cette forte valeur de la constante de couplage de ce carbone (situé en α de l'atome d'azote pyridinique en raison de son déplacement chimique) ne peut être expliquée que par une structure de type ***5a***. On note par ailleurs que les autres constantes de couplage observées sont en accord avec les valeurs données dans la littérature (7).

Cette étude nous permet de conclure que l'hydratation covalente des pyrido-as-triazines en milieu basique se fait exclusivement sur le cycle pyridinique. On observe que la position de l'atome d'azote pyridinique influe sur la vitesse de la réaction et la régiosélectivité : les composés **2** et **3** pour lesquels l'azote pyridinique est en β s'hydratent plus vite que **1**, l'attaque nucléophile se fait alors en α de l'azote pyridinique et en péri du cycle triazine. Pour le composé **1** dont l'azote pyridinique est en position α l'addition est plus lente et l'hydratation a lieu également sur le sommet péri libre (addition 1–4). Il est remarquable que le cycle monoazoté soit plus réactif que la triazine dans ces trois hétérocycles.

Action de différents nucléophiles

Action du bisulfite de sodium

Des nucléophiles soufrés comme le bisulfite de sodium, l'acide thiobarbiturique et les thiophénols forment des σ-adduits avec certains dérivés des ptéridines qui sont inactifs avec l'eau ou les alcools (3*a*, 8).

L'action du bisulfite de sodium dans l'eau à température ambiante a été étudiée sur les hétérocycles **1** et **2**. Seul le composé **2** fournit après un long temps de réaction (5 jours) un dérivé d'addition. Nous observons la précipitation d'un solide rouge **8**; la microanalyse nous permet d'établir pour ce composé la formation d'un adduit 1 : 1.

TABLEAU 3. Données spectrales ^1H des composés **8–15**. Les protons échangeables par D_2O sont indiqués par un astérisque

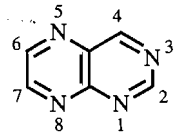
Composé	H3	H5	H6	H7	H8	CH_3	CH_2	CH	NH	$J_{7,8}$	$J_{5,6}$	$J_{6,8}$
8	9,4	6,16	7,5*	7,1	5,46	—	—	—	—	6	3	—
9	8,5	6,16	7,3*	7.6	5.4	1.83	—	—	—	6	3	—
10	8,6	6,3	7,15*	7,4	5,66	—	—	—	9,7	6	3	—
11	9,45	—	7,2*	7,0	6,45	1,3	4,2	6,2	—	7	—	—
12	9,85	—	8,1*	7,85	7,1	1,25	4,2	—	—	7	—	—
13*a*	10,1	—	—	8,9	8,3	3,8	—	6*	—	6	—	—
13*b*	9,6	—	7,3*	7,4	6,75	3,8	—	—	—	—	—	1–2
14*a*	10,1	—	—	8,9	8,3	1,3	4,2	6*	—	6	—	—
14*b*	9,52	—	7,3*	7,35	6,7	1,3	4,2	—	—	7	—	1–2
15*a*	10,1	7,9	9,0	—	—	3,7	—	6,2*	—	—	5	
15*b*	9,5	6,33	7,56	7,33*	—	3,7	—	—	—	—	7	

Le spectre RMN ^1H du composé **8** révèle la présence d'un spectre AB à 5,46 et 7,1 ppm avec une constante de couplage de 6 Hz attribuée aux protons H7 et H8.

Le glissement des déplacements chimiques de ces protons vers les champs forts ainsi que la constante de couplage voisine de celle observée dans les dihydro-1,2 pyridines (9) indique la formation d'un σ-adduit sur la liaison C5—N6. Ici encore, l'hétérocycle **2** qui présente un atome d'azote en β est plus réctif que l'isomére **1** qui lui a l'azote pyridinique en α.

Action de nucléophiles carbonés

L'addition de nucléophiles carbonés sur la ptéridine **16** (3*b*) et sur divers dérivés de cet hétérocycle (3*a*, 3*c*, 8*a*) conduit à deux types d'adduits différents, sans que toutefois une rationalisation de la régiosélectivité ait été proposée.



16

*Adduits 1 : 1 en N_3–C_4 du cycle pyridinique avec dans certains cas un réarrangement conduisant à des dérivés de la pyrido[2,3-*b*]pyrazine (10)

*Adduits 2 : 1 en N_5–C_6 et C_7–N_8 du cycle pyrazinique (11)

Nous avons fait agir sur les pyrido-as-triazines **1**, **2** et **3** les différents nucléophiles carbonés actifs avec la ptéridine et ses dérivés. Dans les conditions opératoires indiquées seuls les composés **2** et **3** ont conduit à la formation de σ-adduits.

Action de l'acide barbiturique et de l'acétylacétone

L'action de l'acide barbiturique et de l'acétylacétone sur la pyrido[3,4-*e*]as-triazine **2** dans l'eau à température ambiante nous a permis d'isoler deux adduits 1 : 1 possédant des caractéristiques voisines en RMN ^1H (tableau 3).

Les microanalyses établies pour les composés **9** et **10** permettent de conclure à la formation d'adduits 1 : 1.

Les spectres RMN ^1H de **9** et **10** présentent des analogies avec celui du composé **8** et nous permettent de conclure à une addition sur la liaison C5—N6.

Dans le cas des composés **9** et **10** nous n'avons pas pu observer le proton aliphatique H_α et nous notons par ailleurs l'absence de couplage du proton H5. Ces données RMN peuvent s'expliquer par l'existence d'un équilibre cétone–énol; nous n'avons toutefois pas pu confirmer l'existence de cet équilibre par RMN ^{13}C.

Action de l'acétylacétate d'éthyle et du cyanacétate d'éthyle

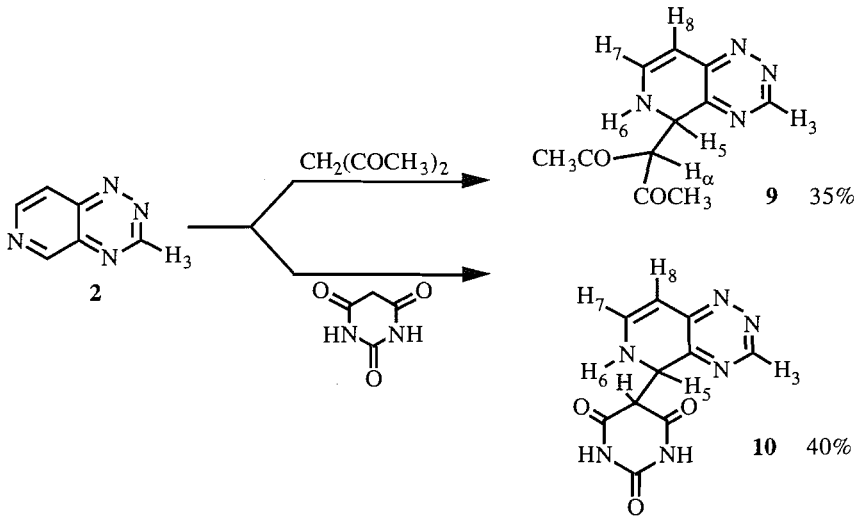
L'action de l'acétylacétate d'éthyle sur l'hétérocycle **2** conduit au composé **11**. Sa composition centésimale permet de lui attribuer la formule brute $C_{10}H_{10}N_4O_2$.

Le spectre IR présente un pic intense à 1660 cm^{-1} attribuable à un ν(C=O) associé, correspondant à une configuration *Z*.

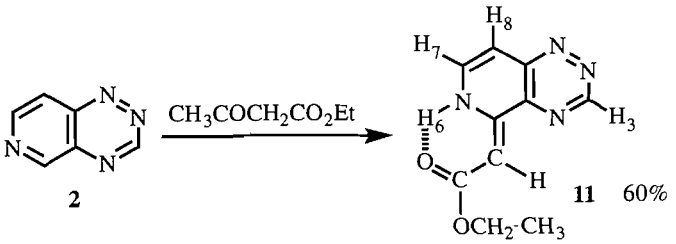
Le spectre RMN ^1H dans le chloroforme deutérié (tableau 3) révèle l'absence de groupement méthyle non couplé, qui peut s'expliquer par une réaction de désacylation.

Les déplacement chimiques de H7 et H8 et leur constante de couplage $J_{8,7}$ sont comparables à ceux du système AB observé dans les pyridones-2 (12). Une étude comparative des spectres RMN ^1H de **11** avec ceux des σ-adduits **8–10** précédemment décrits révèle pour **11** l'absence de signal du proton H5 et un déblindage des protons H3 et H8. Ces éléments plaident en faveur d'une structure de type pyrilidène. Cette hypothèse est confirmée par le spectre RMN ^{13}C

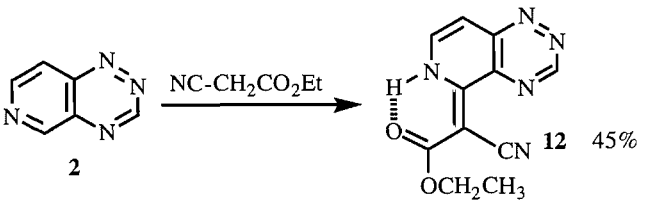
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.



qui présente un carbone vinylique à 86,9 ppm ($^1J_{CH}$ = 167 Hz).



Les données spectrales RMN ^1H du composé **12** obtenu par action du cyanacétate d'éthyle sur l'hétérocycle **2** sont très voisines de celles décrites pour le composé **11** et permettent de lui attribuer également une structure pyrilidène. Le spectre IR révèle la présence d'un pic à 1635 cm^{-1} attribuable à un ν(C=O) associé, indiquant l'existence d'une configuration *Z*.

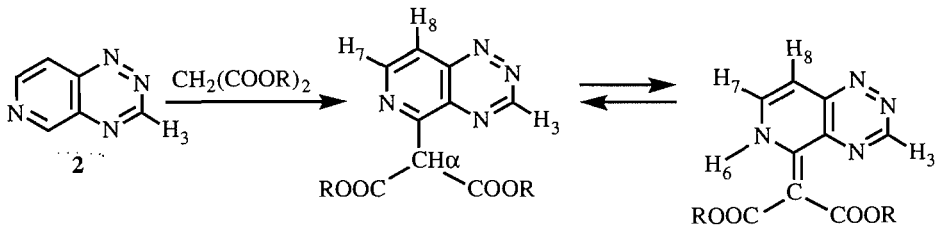


Action du malonate de diéthyle et de diméthyle

L'action des esters maloniques sur la pyrido[3,4-*e*]-as-triazine **2** conduit à la formation de dérivés dont la composition centésimale indique qu'il s'agit d'adduit 1 : 1.

Les spectres IR présentent deux bandes ν(C=O), l'une à 1730–1720 cm^{-1} et une autre moins intense à 1685–1670 cm^{-1}

Les spectres RMN ^1H relativement complexes révèlent l'existence de deux formes tautomères pour l'adduit formé.



R = C_2H_5 **13***a* **13***b* 60%

R = CH_3 **14***a* **14***b* 65%

Dans la forme **13***a*, le spectre RMN ^1H indique que le cycle pyridinique est aromatique; en effet nous observons pour les protons H3, H8 et H7 de la pyrido-as-triazine des déplacements chimiques voisins de ceux de l'hétérocycle **2** (tableau 3). Dans la forme **13***b*, le cycle pyridinique est sous forme pyrilidène : nous observons un glissement des déplacements chimiques des protons H3, H8 et H7 vers les champs forts comparables à ceux observés dans les composés **11** et **12** précédemment décrits. L'addition de D_2O entraîne la disparition assez rapide du signal à 7,3 ppm et de la petite constante de couplage (*J* = 1–2 Hz) du signal à 6,75 ppm, ce qui permet d'attribuer le signal à 7,3 ppm au proton H6 de la forme **13***b*.

Par action de D_2O le singulet situé à 6 ppm disparaît également lentement au cours du temps (55 h pour une disparition totale) et peut être attribué au proton CH_α de la forme **13***a*.

Afin de vérifier l'existence d'une tautomérie entre les

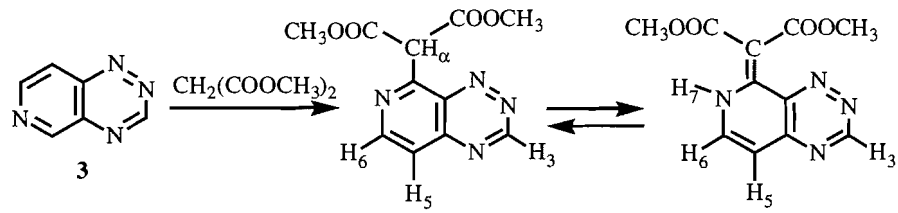
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

formes **13***a* et **13***b* nous avons réalisé les spectres RMN ^{1}H dans le DMSO-d_6 et $CDCl_3$ et évalué le pourcentage de l'une et l'autre forme par intégration des différents signaux.

Solvant	**13***a*	**13***b*
$CDCl_3$	40%	60%
DMSO-d_6	24%	76%

La forme non aromatique **13***b* majoritaire est vraisemblablement stabilisée par une liaison hydrogène entre l'hydrogène H6 et les doublets libres des oxygènes de la fonction ester proche.

L'action du malonate de diméthyle à température ambiante sur la pyrido[4,3-*e*]-as-triazine **3** permet d'obtenir avec l'hétérocycle **2** la formation d'un adduit 1 : 1 **15** dont le spectre RMN ^{1}H révèle également l'existence de deux formes tautomères.

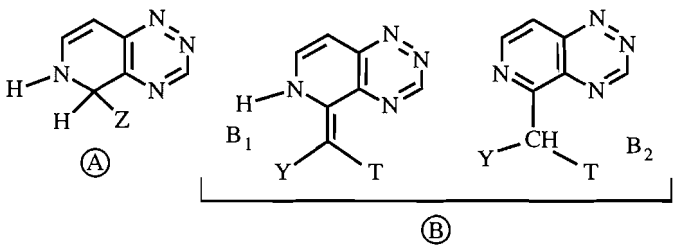


3 **15***a* 30% **15***b* 70%

L'analyse du spectre de RMN ^{1}H du composé **15** à température ambiante dans le chloroforme deutérié permet d'établir un pourcentage de 30% pour la forme aromatique **15***a* et 70% pour **15***b*.

Conclusion

L'action des nucléophiles carbonés sur la pyrido[3,4-*e*]-as-triazine **2** conduit essentiellement à deux types de composés.



Les composés de type A résultent de l'addition primaire sur la liaison 5–6 et sont des dérivés de la dihydro-5,6 pyrido[3,4-*e*]-as-triazine. Les composés de type B résultent également d'une addition suivie d'une oxydation. Nous avons pu mettre en évidence des équilibres tautomères pour certains composés de type B.

Si la littérature relate l'existence de plusieurs polyazanaphtalènes capables de donner des σ-adduits avec des nucléophiles comme l'eau, les thiophénols ou les ions amidures, on peut noter l'exceptionnelle réactivité des ptéridines seules capables d'établir des σ-adduits avec des nucléophiles carbonés désignés dans la littérature en terme de réactifs de Michaël.

Cette étude de réactivité des pyrido-as-triazines vis-à-vis de divers nucléophiles permet de mettre en évidence pour les composés **2** et **3** une exceptionnelle aptitude à former des σ-adduits qui est comparable à celle des ptéridines.

Dans les pyrido-as-triazines la présence du cycle triazinique orthocondensé semble activer le cycle pyridinique vis-à-vis des nucléophiles et lui conférer cette remarquable réactivité.

On observe pour les pyrido-as-triazines étudiées une régiosélectivité totale des attaques nucléophiles sur le cycle pyridinique en péri du cycle triazinique. On peut également noter une réactivité accrue pour les composés possédant l'azote pyridinique en position β.

Partie expérimentale

Les points de fusion ont été déterminés sur un banc de Kofler et ne sont pas corrigés. Les spectres infrarouges ont été enregistrés sur un spectrographe Beckman IR 4250 à réseau. Les spectres de RMN de ^{1}H ont été enregistrés à l'aide de spectromètre Varian A60 et EM360, Varian XL 100-12 WG et Bruker AM 400 (Aspect 3000). Les déplacements chimiques (ppm) sont mesurés par rapport au tétraméthylsilane (TMS) dans $CDCl_3$ et par rapport à l'hexaméthyldisiloxane (HMDS) dans DMSO-d_6. Les spectres de RMN de ^{13}C ont été enregistrés sur un spectromètre Bruker WH 90 à 22,69 MHz et AM 400. Les déplacements chimiques sont reportés en ppm vers les champs faibles par rapport au TMS ou au HMDS. Les spectres de masse ont été enregistrés sur un spectromètre Jeol JMS-D 100. Les microanalyses ont été effectuées sur un appareil Technicon CHN par Monsieur Ecolivet au laboratoire d'analyse de l'Institut National des Sciences Appliquées.

Préparation des pyrido-as-triazines

Les composés **1**–**3** ont été préparés selon le mode opératoire donné dans la littérature (13).

Hydroxypyrido-as-triazines

À une solution de 0.5 g (3,78 mmol) de pyrido-as-triazine **1**, **2** ou **3** dans 10 mL d'ammoniaque (d = 0,9), on ajoute une solution de 1,62 g (5 mmol) de ferricyanure de potassium dans 15 mL d'eau. On laisse sous agitation à température ambiante pendant 48–60 h. Il apparait un précipité rouge orangé d'hydroxypyrido-as-triazine qui est isolé par filtration.

4-Hydroxypyrido[3,2-e]-as-triazine **5** : Rdt = 15%; F = 265°C; IR (KBr) : 3300, 3180, 2960, 1650 cm^{-1}; RMN ^{1}H (DMSO-d_6) δ ppm : 6,9 (d, 1H, $J_{6,7}$ = 6 Hz, H6), 7,6 (s, 1H, mob. NH), 8,6 (d, 1H, H7), 9,9 (s, 1H, H3); RMN ^{13}C (DMSO-d_6) δ ppm : 156.4 (d, C5, $^3J_{CH}$ = 7.5), 155,9 (d, C7, $^1J_{CH}$ = 177 Hz), 153.0 (d, C9, $^3J_{CH}$ = 14), 151,6 (d, C3, $^1J_{CH}$ = 207.2), 129.2 (d, C10, $^3J_{CH}$ = 6), 106,6 (dd, C6, $^1J_{CH}$ = 162 Hz, $^3J_{CH}$ = 9 Hz). Anal. calc. pour $C_6H_4N_4O$: C 48,64; H 2,70; N 37,83; trouvé : C 48,21; H 2,9; N 38,1%.

5-Hydroxypyrido[3,4-e]-as-triazine **6** : Rdt = 30%; F = 215°C; IR (KBr) : 3320, 3100, 1650, 1580 cm^{-1}; RMN ^{1}H (DMSO-d_6) δ ppm : 7,25 (d, 1H, $J_{7,8}$ = 6 Hz, H8), 7,7 (s, 1H, mob.), 8,1 (d, 1H, H7), 10 (s, 1H, H3); RMN ^{13}C (DMSO-d_6) δ ppm : 159.1 (d, C5, $^3J_{CH}$ = 12), 153,6 (d, C3, $^1J_{CH}$ = 210.2), 150.1 (d, C10,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

$^3J_{CH}$ = 3), 147.7 (d, C7, $^1J_{CH}$ = 177), 127.1 (d, C9, ^3J = 2), 106,1 (d, C8, $^1J_{CH}$ = 170.6 Hz). Masse : 148 (M^+), 147 (100%, $M^+ - H$), 120 ($M^+ - N_2$), 93 (95%, $M^+ - N_2 - HCN$). Anal. calc. pour $C_6H_4N_4O$: C 48,64; H 2,70; N 37,83; trouvé : C 48,4; H 2,8; N 38,0%.

8-Hydroxypyrido[4,3-e]-as-triazine **7** : Rdt = 10%; *F* = 240°C; IR (KBr) : 3310, 3100, 2900, 1710, 1680, 1540; RMN ^{1}H (DMSO-d_6) δ ppm : 6,85 (d, 1H, $J_{5,6}$ = 6 Hz, H5), 8,15 (s, 1H mob.), 8,2 (d, 1H, H6), 9,8 (s, 1H, H3); RMN ^{13}C (DMSO-d_6) δ ppm : 157,1 (C3), 157,1 (C6), 106,6 (C5). Anal. calc. pour $C_6H_4N_4O$: C 48,64; H 2,70; N 37,83; trouvé : C 48,4; H 3,0; N 38,2%.

Action des nucléophiles

Combinaison bisulfitique **8**

À une solution de 0,90 g de bisulfite de sodium dans 10 mL d'eau, on ajoute 0,35 g de pyrido[3,4-*e*]-as-triazine **2**. Le mélange est agité pendant 30 min à température ambiante, filtré, puis à nouveau laissé sous agitation à température ambiante pendant 5 jours. Il apparait un précipité qui est séparé par filtration; Rdt = 20%; *F* > 260°C; IR (KBr) : 3340, 3240–3150, 1640, 1580, 1565, 1500 cm^{-1}; RMN ^{1}H (DMSO-d_6) δ ppm : 5,46 (d, 1H, $J_{7,8}$ = 6 Hz, H8), 6,16 (d, 1H, $J_{5,6}$ = 3 Hz, H5), 7,1 (d, 1H, H7), 7,5 (m, 1H, H6), 9,4 (s, 1H, H3); RMN ^{13}C (DMSO-d_6) δ ppm : 141,6 (s, C3), 141,2 (d, C7, J_{CH} = 178 Hz), 100,6 (dd, C8, $^1J_{CH}$ = 168 Hz, $^3J_{CH}$ = 7 Hz). Anal. calc. pour $C_6H_5N_4SO_3Na$: C 30,50; H 2,11; N 23,72; trouvé : C 30.1; H 2,4; N 23,2%.

Condensation avec l'acétylacétone **9**

À une solution de 0,35 g (2,6 mmol) de pyrido-as-triazine **2** dans 10 mL d'eau, on ajoute 0,4 g (3 mmol) d'acétylacétone. Le mélange est agité à température ambiante pendant 3 jours. Il apparait un précipité qui est filtré, puis lavé au chloroforme et à l'éthanol; Rdt = 35%; *F* = 245°C (dec); IR (KBr) : 3100, 2900, 1650, 1580, 1500 cm^{-1}; RMN ^{1}H (DMSO-d_6) δ ppm : 1,85 (s, 6H, CH_3), 5,85 (d, 1H, $J_{7,8}$ = 6 Hz, H8), 6,16 (d, 1H, $J_{5,6}$ = 3 Hz, H5), 7,3 (s large, 1H, H6), 7.7 (d, 1H, H7), 8.05 (s, 1H, H3). Anal. calc. pour $C_{11}H_{12}N_4O_2$: C 56,89; H 5,21; N 24,12; trouvé : C 56,8; H 5,2; N 24,2%.

Condensation avec l'acide barbiturique **10**

Une suspension de 0,35 g de pyrido[3,4-*e*]-as-triazine **2** et 0,5 g de dimédone dans 20 mL d'eau est portée 1 h à 50°C, puis agitée à température ambiante pendant 2 jours. On obtient un précipité brun clair isolé par filtration puis lavé à l'eau; Rdt = 40%; *F* = 260°C (dec.); IR (KBr) : 3200–3000 (large), 1730, 1580 cm^{-1}; RMN ^{1}H (DMSO-d_6) δ ppm : 5,66 (d, 1H, $J_{7,8}$ = 6 Hz, H8), 6,3 (d, 1H, $J_{5,6}$ = 3 Hz; H5), 7,15 (d, 1H, *J* = 3 Hz, H6), 7,4 (m, 1H, H7), 8,6 (s large, 1H, H3); 9,7 (s large, 2H, NH); RMN ^{13}C (DMSO-d_6) δ ppm : 163,6; 151,0; 149,8 (C=O); 142,0 (C3); 138,7 (C7); 98,9 (C8); 129,7; 123,5; 80,5 (C_{4aires}). Anal. calc. pour $C_{10}H_8N_6O_3 \cdot H_2O$: C 43,13; H 3,59; N 30,21; trouvé : C 43,5; H 3,4; N 30,0%.

Condensation avec l'acétylacétate d'éthyle **11**

Une solution de 0,35 g de pyrido[3,4-*e*]-as-triazine **2**, 0,40 g d'acétylacétate d'éthyle dans 20 mL d'eau est agitée à température ambiante pendant 2 jours. On obtient un précipité rouge vif, recristallisé dans l'éther éthylique; Rdt = 60%; *F* = 210°C; IR (KBr) : 3200, 1660, 1640 cm^{-1}; RMN ^{1}H($CDCl_3$) δ ppm : 1,3 (t, 3H, *J* = 7 Hz, CH_3), 4,2 (q, 2H, CH_2), 6,2 (s, 1H, =CH), 6,45 (d, 1H, $J_{7,8}$ = 7 Hz, H8), 7,1 (d, 1H, H7), 7,2 (s, 1H, H6), 9,45 (s, 1H, H3); RMN ^{13}C ($CDCl_3$) δ ppm : 14,1 (CH_3), 59,9 (CH_2O), 86,9 (d, =CH, J_{CH} = 157 Hz), 100,9 (d, C8, J_{CH} = 167 Hz), 134,4 (d, C7, J_{CH} = 184 Hz), 154,7 (d, C3, J_{CH} = 202 Hz), 154,2 (s, C5), 146,9 (s, C10), 119,4 (s, C9), 170 (s, C=O). Masse : 218 (90%, M^+), 190 ($M^+ - C_2H_5$), 172 ($M^+ - C_2H_5$), 144 ($M^+ - COOC_2H_5$), 116 (100%, $M^+ - COOC_2H_5$-N_2). Anal. calc. pour $C_{10}H_{10}N_4O_2$: C 55,04; H 4,62; N 25,67; trouvé : C 54,5; H 4,5; N 24,8%.

Condensation avec le cyanacétate d'éthyle **12**

Une suspension de 0,35 g de pyrido[3,4-*e*]-as-triazine **2**, 0,40 g de cyanacétate d'éthyle dans 20 mL d'eau est agitée à température ambiante pendant 24 h. On obtient un solide rouge vif qui est séparé par filtration, puis lavé au chloroforme et à l'éthanol; Rdt = 45%; *F* = 240°C; IR (KBr) : 3100, 3000, 2200, 1635, 1530 cm^{-1}; RMN ^{1}H (DMSO-d_6) δ ppm : 1,25 (t, 3H, *J* = 7 Hz, CH_3), 4,2 (q, 2H, CH_2), 7,1 (d, 1H, $J_{7,8}$ = 7 Hz, H8), 7,85 (d, 1H, H7), 8,1 (s, 1H, H6), 9,85 (s, 1H, H3). Masse : 243 (85%, M^+), 215 ($M^+ - CN$), 198 ($M^+ - OC_2H_5$), 188 ($M^+ - CN - N_2$), 160 (100%). Anal. calc. pour $C_{11}H_9N_5O_2$: C 54,32; H 3,73; N 28,79; trouvé : C 54,7; H 3,6; N 28,3%.

Condensation avec les esters maloniques

Une suspension de 0,35 g de pyrido-as-triazine, 0,5 g d'ester malonique et 20 mL d'eau est agitée à température ambiante pendant 24 h. Le précipité obtenu est filtré, lavé au chloroforme puis à l'éther froid. Recristallisation dans l'éther éthylique.

Condensation avec le malonate de diéthyle **13** : Rdt = 60%; *F* = 240°C; IR (KBr) : 3140, 3040, 2920, 1720, 1685, 1615 cm^{-1}. Anal. calc. pour $C_{13}H_{13}N_4O_4$: C 53,97; H 4,49; N 19,37; trouvé : C 54,5; H 4,6; N 19,8%.

Condensation avec le malonate de diméthyle **14** : Rdt = 65%; *F* = 230°C; IR (KBr) : 3100, 2980, 1730, 1680, 1615, cm^{-1}. Anal. calc. pour $C_{11}H_{10}N_4O_4$: C 50,38; H 3,84; N 21,37; trouvé : C 49,9; H 3,6; N 21,0%.

Condensation de la pyrido[4,3-e]-as-triazine avec le malonate de diméthyle **15** : Rdt = 30%; *F* = 234°C; IR (KBr) : 3140, 2960, 1730, 1670, 1605, 1540 cm^{-1}: Masse : 262 (40%, M^+); 231 ($M^+ - OCH_3$); 207 (100%). Anal. calc. pour $C_{11}H_{10}N_4O_4$: C 50,38; H 3,84; N 21,37; trouvé : C 50,7; H 3,7; N 21,0%.

Introduction

During the past few years, our project has focused on the replacement of one or several carbon atoms of cyclopropane by heteroatoms such as phosphorus, following the work of Baudler and co-workers (1). It is now well established that the stability of small strained rings such as diphosphiranes depends mainly on the influence of the substituent (2). We report here a comparative study of the stereochemistry of diphosphiranes, carried out by MNDO calculations (energies, dipole moments, charges) and experimental investigations.

Experimental

Diphosphiranes **3***a–f*, bearing bulky substituents on the phosphorus atoms, were prepared according to the procedure already described (3). For the theoretical approach, we used more simplified models, i.e., diphosphiranes **1***a–g* with methyl substituents, and **2***a* and **2***h* with a phenyl group on the phosphorus atom instead of the bulky tris-2,4,6-*tert*-butylphenyl substituents, which are too large for computational approaches (Scheme 1).

Calculations were carried out on diphosphiranes **1***a–g*, **2***a*, and **2***h*. The basic approximations of the MNDO (modified neglect of diatomic overlap) method included a semi-empirical model for the two-center integrals (4). We used a Control Data Cyber 860-180 NOS/VE system of the CICT (Centre Inter-Universitaire de Calcul de Toulouse). For the purpose of this paper, we collected energy values (eV), dipole moments (D), net atomic charges, and optimized parameters (Table 1).

The dipole moments of **3***a–f* were measured in benzene at 25°C by a WTW dipole meter (Table 2). The Debye formula was used, as in the Halverstadt and Kumler extrapolation method, for calculation of total polarization (5), with $\alpha = (d\varepsilon/d\omega_2)_{\omega_2 \to 0}$, $\beta = (dv/d\omega_2)_{\omega_2 \to 0}$, and $0.001 < \omega_2 < 0.050$. ε is the dielectric constant, ω_2 the mass fraction of the sample, and v the density. Electronic polarizations can be replaced by the molecular refractions R_{MD}.

Results

To accomplish stabilization of unstable and unusual organophosphorus compounds in a low coordination state (6), the use of sterically bulky moieties as protective groups is extremely effective. Diphosphiranes **3***a–f* in refluxing toluene solution undergo a ring-opening reaction by preferential P—P bond rupture, leading to 1,3-diphosphapropenes (7). The determination of the kinetic parameters of the ring-opening reactions at 100°C in C_7D_8 was carried out by ^{31}P NMR. The free enthalpy of activation for the ring-opening reactions is in the range of 30 kcal mol^{-1} (Table 3) (8), so that the stabilities of diphosphiranes **3***a–f* can be established according to the following order: **3***e* > **3***c* > **3***d* > **3***a* > **3***f*.

This order of stability concerns solely the thermal ring-opening reactions of diphosphiranes **3***a–f* in the *trans* configuration. Calculations show that the *trans* configuration is thermodynamically the most stable isomer (about 4 kcal mol^{-1}) for **1***a–c* and **2***a*, while the preferential *cis* configuration is obtained for **1***d*, **1***f*, and **1***g*. Notable effects are observed in the case of **1***e*, in which the change of the intracyclic carbon configuration involves a change of the *cis/trans* stability.

Experimentally, the reaction of carbenoids with *trans* diphosphene was used as a stereoselective synthesis of diphosphiranes **3** (3). In each case, only the *trans* isomer was obtained. The $^{31}P\{^1H\}$ NMR spectra, reported as a singlet for **3***a*, **3***c*, and **3***f* and as an AB system for **3***d*, **3***e*, are consistent with a *trans* configuration. The X-ray analysis confirms this configuration (9).

Dipole moment calculations of **1** and **2** show a large difference between the *cis* and *trans* configurations. As expected, generally higher values (≅ 2D) are observed for the *cis* configuration. Substitution of a methyl by a phenyl group (**1***a* and **2***a*, respectively) does not induce a substantial modification of the dipole moment values.

Experimental values for **3** are in the range 0.46–1.81 D (Table 2). Higher values (1.81 and 1.75 D) correspond to

monohalogenated diphosphiranes **3***d*, **3***e*, whereas the value observed in the case of *gem*-dichlorodiphosphirane **3***c* (0.46 D) is close to that for spirodiphosphirane **3***f* (0.60 D).

Discussion

Since the results of Lutsenko and co-workers (10) and Baudler and Saykowski (11), it is well established that diphosphiranes substituted by isopropyl or *tert*-butyl on the phosphorus atoms are somewhat unstable and susceptible to dimerization reactions. This dimerization, arising from biradical intermediates, is never observed for **3***a–f*, whatever the substituents on the intracyclic carbon atoms (3, 12). In the case of **3***f*, we have demonstrated that the diphosphanyl biradical intermediate leads to the ring extension product (diphosphacyclobutane) and the rearrangement product (diphosphanorbornadiene), without any dimerization (13).

We commonly notice a small difference in energy between *cis* and *trans* structures (≅ 4 kcal mol^{-1}); however, the *trans* forms are usually the more stable. Comparison between measurements performed on **3** and calculations carried out on **1***a–c* and **2***a* provides further support for the presence of *trans* isomers as the main products.

For the diphosphiranes **1***d* and **1***e*, the *cis* forms, in which

TABLE 4. Influence of the rotation of the phenyl substituent on the dipole moment values

θ(°):	160	40	−77 (optimized value)
μ (D):	1.15	1.30	1.24

the chloride atom is *syn* with respect to the methyl substituents of the phosphorus atoms, are the more stable isomers. Such stabilization resulting from an attractive interaction between the methyl group and the negative dipole C–Cl has been reported for rotational isomerism of 1,2-dichloroethane (14). On the other hand, for **3***d* and **3***e*, the presence of bulky substituents (2,4,6-tri-*tert*-butylphenyl) induces a large steric hindrance, which involves a *trans* configuration.

For the spiro derivative, the large difference between *cis* and *trans* calculated energy values is probably the consequence of the particular strain energy of the spiro derivative **1***f* (15). Our method does not allow any accurate evaluation of the different ring-strain energies. Recently, Liu and Bachrach have estimated, by *ab initio* studies, the ring-strain energy of the parent diphosphirane (15 kcal mol^{-1}) using homodesmic reactions (16). For the same model, we obtain an energy value of 50 ± 20 kcal mol^{-1}, by MNDO calculations. Consequently, taking into account the inherent uncertainty in the calculated values, the energy levels for **1***f* cannot be adequately interpreted. Nevertheless, comparisons can be realized for the calculated and experimental dipole moments.

Thus the experimental dipole moment of **3***a* (1.51 D) is close to the calculated value for *trans* **1***a* (1.32 D) whereas the *cis* isomer has a much higher calculated dipole moment (3.07 D). The calculated dipole moment for *trans* **1***c* (0.96 D) is also in good agreement with the experimental value for **3***c* (0.46 D). For **1***d*, calculation of the dipole moment of the *cis* isomer in the *A* and *B* configurations excludes the *B* configuration (Scheme 2). In the case of **3***d*, the experimental dipole moment is nearly the same as the value calculated for *trans* **1***d*. In contrast to **3***d*, the two calculated values for *cis* and *trans* **1***e* are close to the experimental dipole moment determined for **3***e*. In this case, to determine the exact configuration of **3***e*, the dipole moment measurements must be completed by other appropriate methods.

Replacement of a methyl by a phenyl group on either a phosphorus atom or an intracyclic carbon atom affects the dipole moment slightly: 1.32 D for **1***a* (*trans*) and 1.24 D for **2***a* (*trans*) or 1.75 D for **3***e* (*trans*) and 1.81 D for **3***d*, respectively. The variation of μ induced by the possible boat conformation of the aryl substituents was estimated by MNDO calculations as 0.4 D. The θ angle value (dihedral angle CCPC), corresponding to the rotation of a phenyl group around the P—C bond, has almost no influence on the dipole moment values ($1.15 < \mu < 1.30$ D) (Table 4).

The optimized value of the angle (θ = −77°) corresponds quite well to the value given by X-ray structural analysis of **3***c* (θ = −72°) (9). This preferential conformation in the solid state disappears when compounds **3***a–f* are in solution. Thus variable temperature ^{1}H NMR studies clearly demonstrate a free rotation of the aryl groups. The rotation-barrier energy depends on the intracyclic carbon atom substituents. The lower rotation barriers measured for **3***a* and **3***f* are 10.9 and 10.0 kcal mol^{-1}, respectively, whereas the barrier for **3***c* is 17 kcal mol^{-1}. In diphosphirane **3***d*, only the aryl substituent in a *cis* position vs. the chlorine atom is able to rotate with a barrier equal to 19.6 kcal mol^{-1}. This rotation, occurring in solution at room temperature, has no noticeable effect on the experimental dipole moment measurements (Table 4).

In conclusion, the calculated dipole moments correspond to the *trans* geometry. Similarly, the experimental dipole moment values show the presence of preferential *trans* isomers, probably due to the stereoselective cyclopropanation reaction (17), but also to the presence of bulky substituents attached to each phosphorus atom. However, the calculations allow us to predict the formation of *cis* isomers for the sterically less-hindered diphosphiranes. Recently we have shown that, under ultrasonic irradiation, **3***d* undergoes a substitution of the aryl group by a chlorine atom on the phosphorus atom without ring opening (18). For **3***c*, under the same conditions, we observe the formation of two cyclic isomers (^{31}P NMR data: δ −12; −76; $^1J_{P-P}$ = 80 Hz, and δ −16; −59; $^1J_{P-P}$ = 143 Hz) in what are, most probably, the *trans* and *cis* configurations. This hypothesis will be experimentally investigated in the future.

The 1992 Alcan Award Lecture
Excursions around the periodic table: ligand design in inorganic chemistry[1]

MICHAEL D. FRYZUK[2]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B. C., Canada V6T 1Z1

Received June 23, 1992

MICHAEL D. FRYZUK. Can. J. Chem. **70**, 2839 (1992).

An overview is given on the strategy used to come up with the design of a new type of ligand that is appropriate for coordination to both the late metals and the early metals. The coordination chemistry of the potentially tridentate ligand $^{-}N(SiMe_2CH_2PR_2)_2$ is developed starting with the Ni triad and then the heavier members of group 9, namely rhodium and iridium. It is with iridium that reactive fragments such as methylene and vinylidene have been stabilized and their chemistry examined. Extension to groups 3, 4, and the lanthanides is also discussed. With these elements, phosphine coordination imparts new reactivity patterns such as alkane elimination with group 3 and dinitrogen activation with group 4. In addition, the side-on binding mode for N_2 attached to a dinuclear zirconium system is also presented.

MICHAEL D. FRYZUK. Can. J. Chem. **70**, 2839 (1992).

On présente une vue d'ensemble de la stratégie utilisée pour mettre au point un nouveau ligand pouvant donner une coordination avec les derniers et les premiers métaux. On a développé la chimie de coordination du ligand potentiellement tridentate $^{-}N(SiMe_2CH_2PR_2)_2$ en utilisant au départ la triade du nickel et ensuite les membres de masse plus élevée du groupe 9, soit le rhodium et l'iridium. Avec l'iridium, les fragments réactifs, tels le méthylène et le vinylène, sont stabilisés et on a examiné leur chimie. On discute aussi de l'extension aux groupes 3 et 4 et aux lanthanides. Avec ces éléments, la coordination avec la phosphine provoque de nouveaux types de réactivité, tels l'élimination d'alcane avec le groupe 3 et l'activation du diazote avec le groupe 4. De plus, on a passé en revue le mode de fixation par lé côté du N_2 attaché à un système dinucléaire du zirconium.

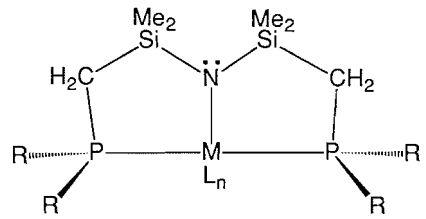
[Traduit par la rédaction]

Introduction

An invitation by the editors of the Canadian Journal of Chemistry to submit a personal account of some of our research presented in the ALCAN Award Lecture is a welcome one since it will give me an opportunity to thank many of the people who have enthusiastically carried this work to its present state. This particular project involves some very straightforward ideas but does need some background to set them in perspective.

When I arrived at UBC in 1979 there were so many projects that I wanted to tackle that I had to make some decisions on which avenues to concentrate given the limited manpower available for a new assistant professor. Although there was an apparently unfettered choice of research projects available to me, there were a few unwritten rules to abide by. The most important one was to avoid at all costs what you did for your Ph.D. work. For me that meant staying away from chiral chelating phosphine ligands and their associated rhodium complexes and catalytic asymmetric hydrogenation (1–3). Another related rule was to avoid what you did while you were a postdoctoral fellow. For me that meant staying away from zirconium and hafnium hydrides stabilized by pentamethylcyclopentadienyl ligands (4). As it turns out I probably ended up disobeying both of these rules, but I'm getting ahead of myself.

In 1979 a paper appeared which I found astounding (5). It reported the preparation of the three-coordinate rhodium complex $Rh(PPh_3)_2[N(SiMe_3)_2]$. What made this short communication so interesting was the claim that this was the first ever preparation of an amide ligand bound to rhodium. Even more important was the claim that amide ligands were still not known for complexes of Pd, Os, and Ir (and a few other metals). The amide ligand, defined as a deprotonated amine of the general formula $^{-}NR_2$ (R = alkyl, aryl, silyl, or H), is well known to bind to the early metals (groups 3–5) and the lanthanides (6) but the fact that its coordination chemistry with the later transition elements (groups 8–10) was so lacking was intriguing.



I

SCHEME 1

About this same time I had also noticed that phosphine ligands (PR_3) were not generally associated with complexes of the early transition metals and the lanthanides. In contrast, phosphine complexes of the later transition elements are ubiquitous. This observation was probably my way of disobeying the two unwritten rules for a new assistant professor, namely that I wanted to apply some of the expertise in phosphine chemistry obtained from my Ph.D. work to the experience with early metal chemistry picked up in my postdoctoral stint.

It was the dichotomy in the coordination behavior of these two ligand types, the amide group and the phosphine donor, that provided the incentive to develop a hybrid ligand system that incorporated both ligand types into one chelating array. The ligand system aimed for is shown in Scheme 1. It seemed possible that such a ligand would allow us to

[1]This is an invited personal review article based on Professor Fryzuk's Alcan Award lecture, presented at the 1992 Annual Conference of the Canadian Society for Chemistry, Edmonton, Alberta.

[2]E. W. R. Steacie Fellow (1990–1992).

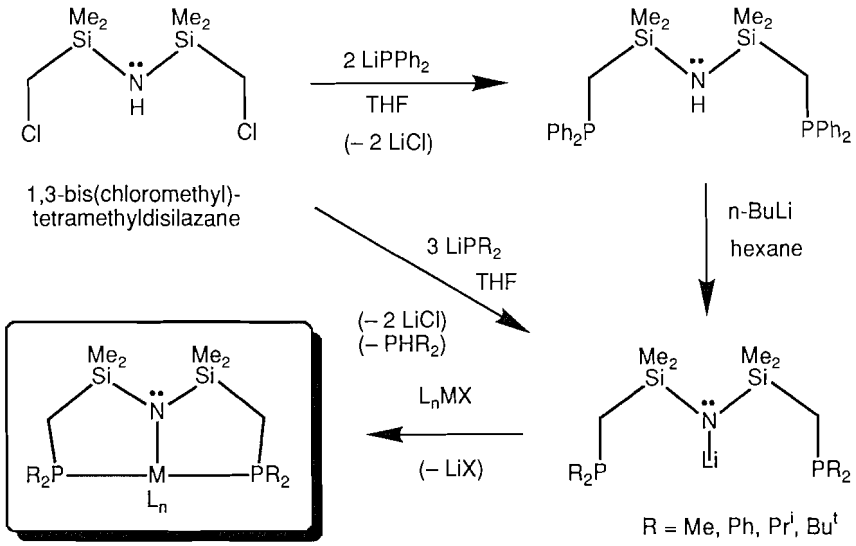
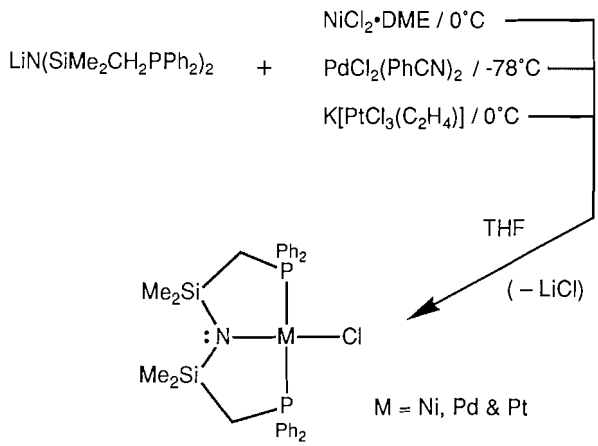


SCHEME 2



SCHEME 3

overcome the apparent coordination chemistry mismatches in the following way: phosphine complexes of the early metals and the lanthanides would be accessible since the amide portion of the tridentate ligand would anchor the ligand to the metal and force coordination of the phosphine donor by virtue of the chelate effect; in addition, amides of the later transition elements would also be accessible with this ligand system since now the phosphine interaction would help stabilize the amide ligation. More importantly, if the reactivity patterns of a metal complex are a function of its coordination environment then it was hoped that this ligand system would result in the observation of new and unusual chemistry because this was a brand new type of ligand.

A few final words of introduction are in order. The preparation of the actual target ligand was facilitated by the discovery that the proposed starting material was commercially readily available at reasonable prices. If at some point luck had to rear its head, why not at the beginning of a new project? In our excursion around the periodic table the vehicle will be the coordination complex **I** shown in Scheme 1. The rest of the account will summarize aspects of the coordination chemistry of this ligand with various metals across the periodic table, hopefully giving due credit to my co-workers.

Ligand synthesis

The preparation of various forms of the ligand is shown in Scheme 2; the range of substituents at phosphorus from phenyl to *tert*-butyl has provided some limited variability in steric and electronic effects. In general we use the lithium form of the deprotonated amide as the starting material in concert with some halide precursor complex containing the metal of choice; in a few cases the corresponding potassium salt has also been used.

Coordination chemistry: late metals

My first graduate student at UBC, Patricia MacNeil, was the person who initiated work on this ligand system. She began this trip around the periodic table at the nickel(II) complex $NiCl[N(SiMe_2CH_2PPh_2)_2]$ prepared by the reaction of the lithium salt with $NiCl_2 \cdot DME$ (DME = 1,2-dimethoxyethane); she then prepared the analogous Pd(II) and Pt(II) derivatives as outlined in Scheme 3 (7, 8). The palladium complex was the first mononuclear palladium amide to be structurally characterized, based on what was claimed earlier (5, 6). Interestingly, a review undertaken by ourselves did uncover some prior palladium amide complexes (9), but there are, to our knowledge, no other crystal structural analyses. Aside from some peculiar CO migratory insertion behavior for the Ni derivatives (10), the chemistry of the group 10 derivatives was rather predictable; however, this work did provide the groundwork for our later studies.

Patricia MacNeil then went on to synthesize rhodium and iridium derivatives using this ligand system (11–17). The preparation mirrors that for the group 10 triad; as shown in Scheme 4 the key starting material for the heavier members of group 9, namely rhodium and iridium, is the cyclooctene complex $M(\eta^2\text{-}C_8H_{14})[N(SiMe_2CH_2PPh_2)_2]$ since this allows access to a variety of derivatives in both the +1 and +3 oxidation states. Without a doubt it has been the iridium derivatives stabilized by this tridentate ligand system that have provided the enduring chemistry for the late metals. As outlined in Scheme 4, access to iridium(I) species incorporating

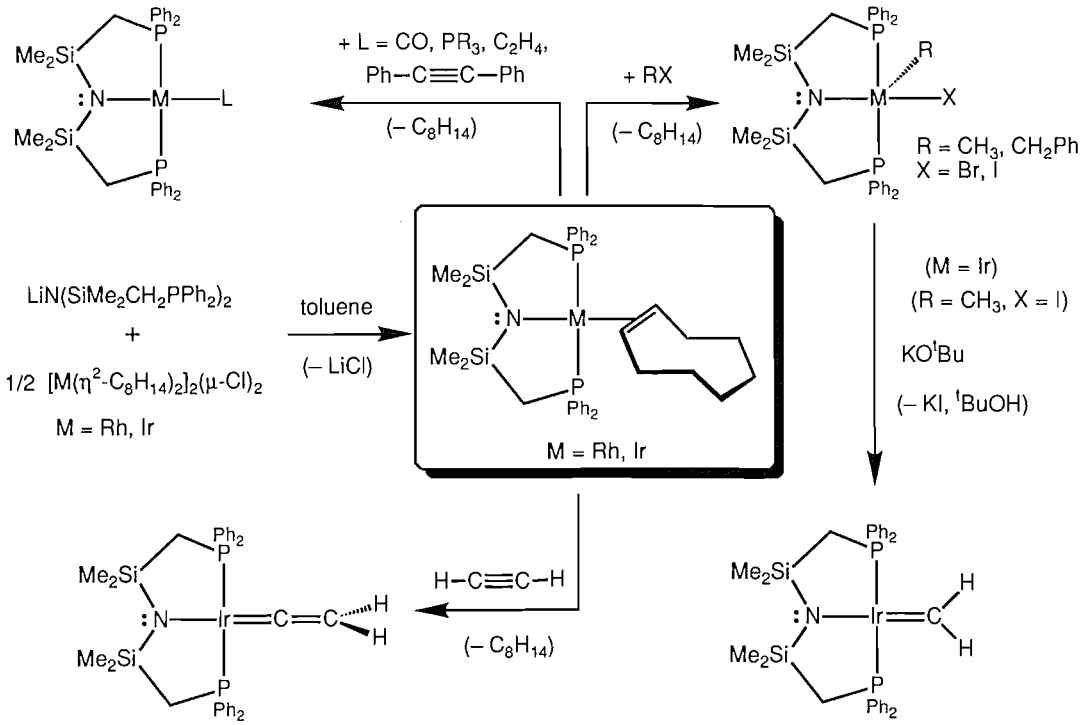
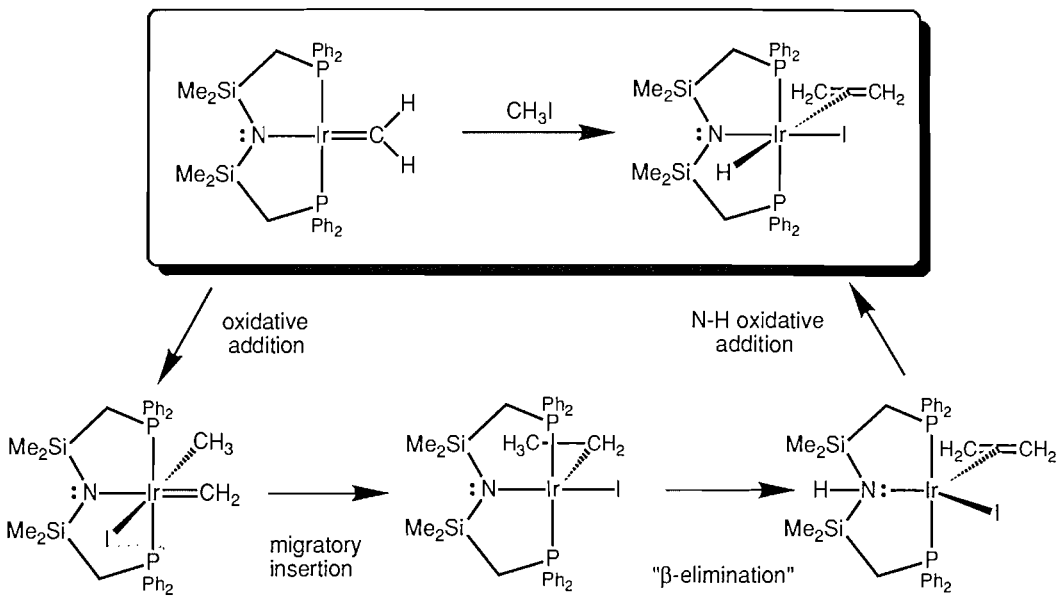


SCHEME 4



SCHEME 5

the very reactive methylene (=CH_2) (14) and vinylidene (=C=CH_2) (18) fragments has allowed the chemistry of these very unstable moieties to be examined. For example, Kiran Joshi showed that addition of CH_3I to the methylene complex resulted in the generation of the ethene-hydride derivative as a result of a carbon–carbon bond formation via migratory insertion; similarly, Dr. Neil McManus and Dr. Graham White showed that the vinylidene derivative also underwent migratory insertion with CH_3I to generate the corresponding allyl derivative (19). These reactions are shown in Schemes 5 and 6 respectively. What is significant in this work is that we have identical metals and ligand environments with which to compare the relative reactivity of the methylene and the vinylidene moieties. As shown by their reactivity with CH_3I there are intriguing similarities as well as differences and these are still being evaluated in my group. For example, in both of Schemes 5 and 6, the amide donor is shown to be involved in the mechanism by formation of amine derivative via intramolecular proton abstraction from a coordinated hydrocarbyl group; this "β-elimination" to the amide donor has precedent in some of our earlier work in the heterolytic activation of H_2 by related group 9 complexes (16).

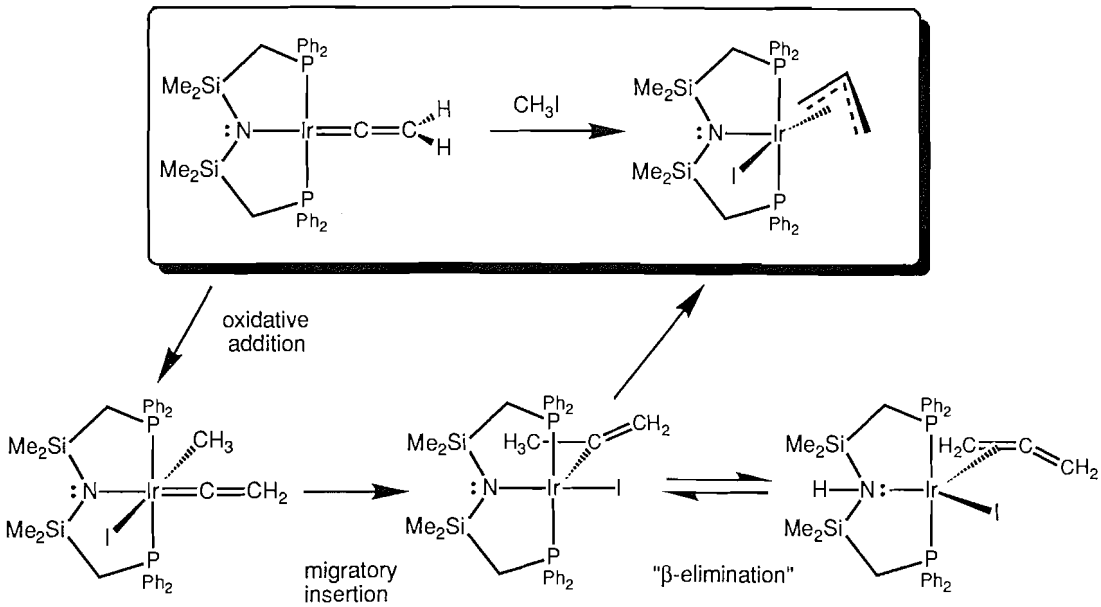
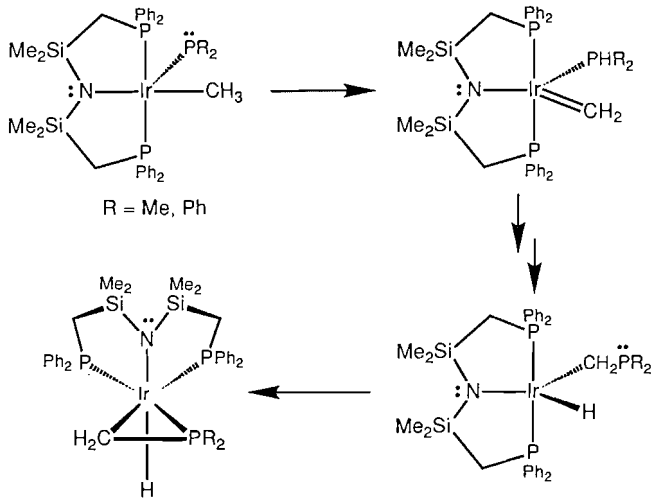
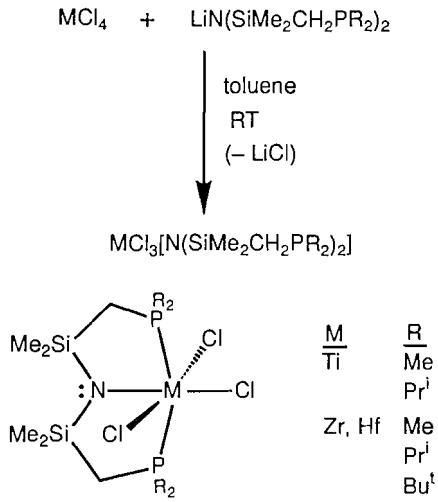


SCHEME 6



SCHEME 7



SCHEME 8

We have found that iridium–carbon double-bonded species occur in other chemistry involving the iridium fragment $Ir[N(SiMe_2CH_2PPh_2)_2]$ as well. Both the thermal transformation of, and the reaction of hydrogen with, phosphido-alkyl iridium species would appear to involve iridium–methylene type intermediates at crucial points in the sequence (20, 21). For example, Kiran Joshi showed (20) that in the thermal decomposition of iridium phosphido–methyl complexes, the formation of cyclometalated hydride derivatives can be rationalized by proton abstraction from the methyl ligand by the coordinated phosphide to generate an intermediate phosphine methylene; as shown in Scheme 7, subsequent rearrangement (by a number of hypothetical steps) produces the cyclometalated phosphine hydride.

It would appear that the combination of iridium and this ligand system is special since we have been able to access a variety of reactive organic fragments such as methylene and vinylidene and study their chemistry. In future, our efforts will be the focused on other reactive fragments such as silylene (=SiR_2), and silene (η^2-SiR_2SiR_2).

Coordination chemistry: early metals and the lanthanides

The other aspect of our ligand design was the use of this system to generate phosphine complexes of the early metals (22). In 1981, my second graduate student, Hugh Williams, was the first person to try bonding this ligand type to the early metals. His first success was in the preparation of bis(ligand) derivatives of zirconium(IV) and hafnium(IV), $MCl_2[N(SiMe_2CH_2PR_2)_2]_2$ (M = Zr, Hf; R = Me, Ph) (23); although these complexes were of stereochemical interest, they showed little reactivity. Hugh did find that hydride complexes of hafnium(IV) could be prepared (24) via the formation of a monoligand starting material having the approximate formula $HfCl_3[N(SiMe_2CH_2PMe_2)_2] \cdot HfCl_4$. A German post-

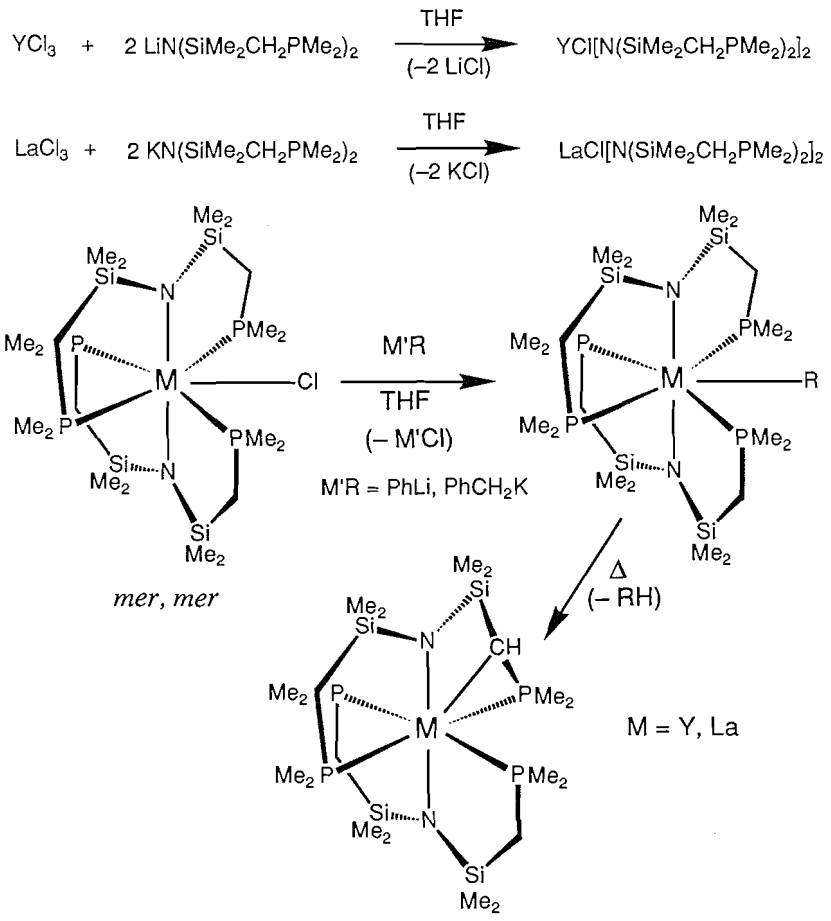
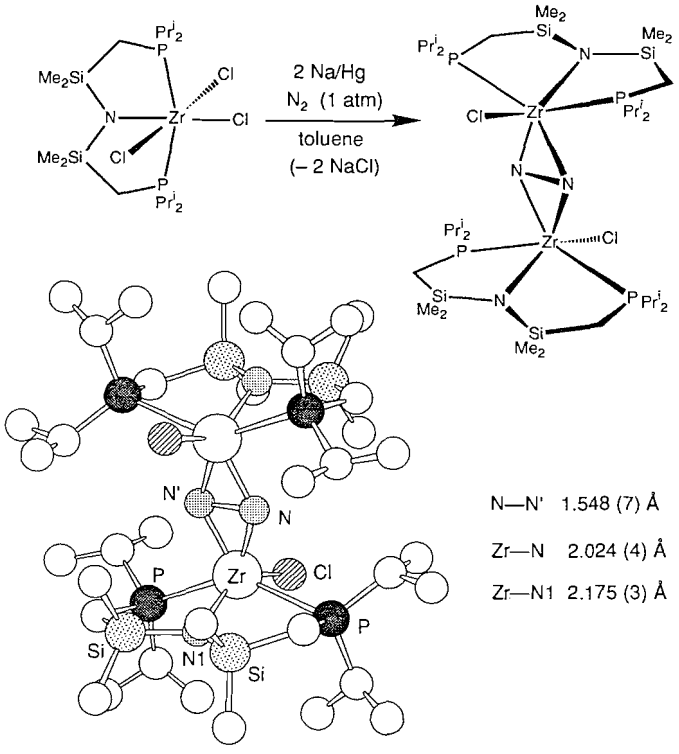


SCHEME 9

doctoral fellow, Dr. Axel Westerhaus, solved a lot of our problems in this area by coming up with straightforward syntheses of monoligand staring materials for Zr(IV) and Hf(IV) with a variety of substituents at phosphorus (25); this is outlined in Scheme 8. These monoligand derivatives turned out to be exceedingly versatile as we were able to prepare dinuclear hydride complexes (26), derivatives containing the η^4-butadiene moiety (27, 28), and trimethyl complexes of Zr and Hf (29). Tim Haddad prepared the η^4-butadiene complexes as part of his M.Sc. thesis and showed that the butadiene-allyl derivatives, $M(\eta^4\text{-}C_4H_6)(\eta^3\text{-}C_3H_5)[N(SiMe_2CH_2PR_2)_2]$ (M = Zr, Hf, R = PR^i, Me), underwent carbon–carbon coupling to generate a new hydrocarbon fragment bound $\eta^4{:}\eta^1$ to the group 4 metal centre (27). For his Ph.D., Tim moved the coordination chemistry of this ligand even further to the left in the transition series by preparing group 3 complexes (30, 31). Here again, we started off by preparing the bis(ligand) derivatives $MCl[N(SiMe_2CH_2PMe_2)_2]_2$ for M = Y and La; $^{31}P\{^1H\}$ NMR spectroscopy has turned out to be quite crucial in these systems since it can provide information on stereochemistry. We anticipated that these seven-coordinate derivatives would be rather unreactive in analogy to the group 4 complexes; however, we were pleasantly surprised to find that the remaining chloride could be metathesized by PhLi and $PhCH_2K$ to generate the corresponding hydrocarbyl derivatives, $YR[N(SiMe_2CH_2PMe_2)_2]_2$ (32). These hydrocarbyl complexes were found to thermally eliminate hydrocarbon to generate cyclometalated



SCHEME 10

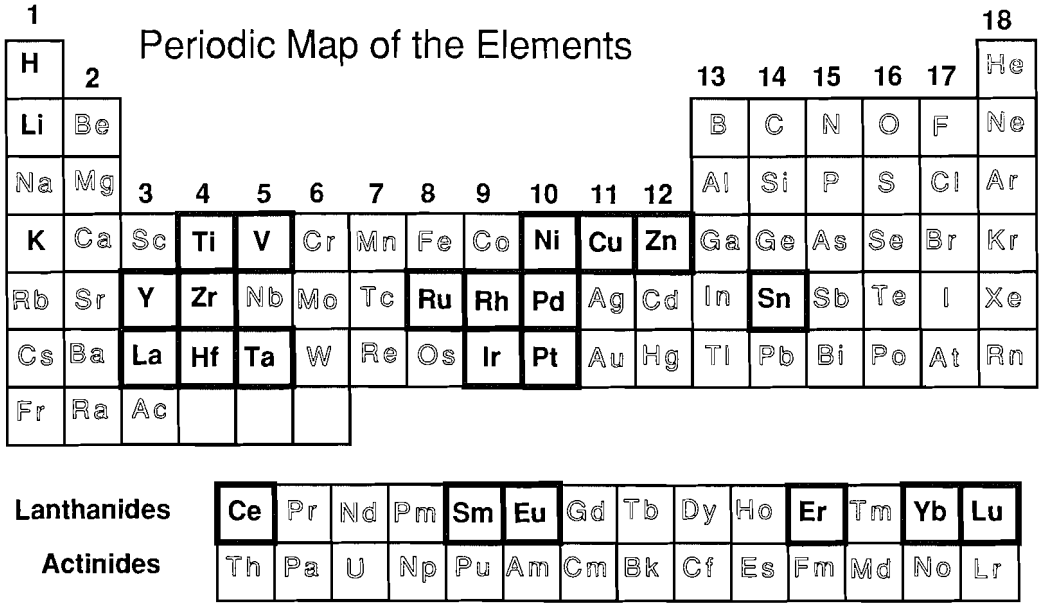
For personal use only.



SCHEME 11

complexes; in fact, the lanthanum hydrocarbyl derivative could not be isolated, as it spontaneously formed the cyclometalated complex. The group 3 chemistry is summarized in Scheme 9.

Because of the similarity between the chemistry of the group 3 elements and the lanthanide metals, Dr. David Berg was able to open up the corresponding chemistry of the rare earth elements using this ligand system. He was able to prepare the bis(ligand) derivatives $MCl[N(SiMe_2CH_2PR_2)_2]_2$ for M = Ce, Sm, Er and Yb with R = Me and Ph; he also prepared bis(ligand) derivatives $M[N(SiMe_2CH_2PMe_2)_2]_2$ for the divalent metals M = Sm(II), Eu(II), and Yb(II). Noteworthy is the $^{31}P\{^1H\}$, NMR spectrum of the diamagnetic, divalent ytterbium derivative $Yb[N(SiMe_2CH_2PMe_2)_2]_2$, which shows a singlet with ^{171}Yb satellites (^{171}Yb has $s = 1/2$ and 14.3% natural abundance); the $^1J_{Yb-P}$ of 665 Hz is the first ever one-bond coupling recorded for these spin-active nuclei (22).

Phosphine complexes of group 4 are still being pursued in our group. One of the final accomplishments of Tim Haddad for his Ph.D. degree was to make a dinitrogen complex of zirconium. The reduction of $ZrCl_3[N(SiMe_2CH_2PPr^i_2)_2]$ with two or more equivalents of Na/Hg under an atmosphere of dinitrogen generates a deep blue material, which we have characterized as $\{[(Pr^i_2PCH_2SiMe_2)_2N]ZrCl\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)$ (33). This complex is remarkable since it contains the dinitrogen in the very rare side-on mode bridging between the two zirconium centres (Scheme 10). Even more remarkable is the extremely long N—N bond distance of 1.548(7) Å for the bridging N_2 unit; this is by far the longest N—N bond length ever recorded for dinitrogen complexes (34–36).

In an attempt to try and gain a deeper understanding of this side-on mode of bonding for a dinitrogen ligand, David McConville and M. Mylvaganam carried out semi-empirical molecular orbital calculations, backed up by synthetic studies (37). What they discovered was that the side-on mode is a direct result of the tridentate ligand's bonding requirements since the amide donor binds to one of the *d*-orbitals that would normally be used to form a π-bond with the end-on form of the N_2 ligand. This was verified by the preparation of a variety of derivatives; for example, the cyclopentadienyl derivative $\{[(Pr^i_2PCH_2SiMe_2)_2N]Zr(\eta^5\text{-}C_5H_5)\}_2(\mu\text{-}N_2)$ shows a linear end-on mode of coordination that is consistent with the molecular orbital analysis. Pauline Chow has recently extended the dinitrogen chemistry to titanium and vanadium (38); in these dinuclear systems, $\{[(Pr^i_2PCH_2SiMe_2)_2N]MCl\}_2(\mu\text{-}N_2)$ (M = Ti, V), the dinitrogen bridges in a linear end-on fashion due to steric constraints as a result of the smaller metal centres and the rather bulky ancillary ligand.

Future prospects

In Scheme 11, a periodic table is shown with those elements highlighted that have been studied with this ligand system. I have not discussed all of our efforts; rather I have tried to detail how this excursion got started and then travel across the periodic table with minimal stopovers at particular elements. However, it should be obvious that there are destinations in the periodic map of the elements that must be visited; for example, it is rumored that adventures will abound in the main group elements. And what about the actinides? This excursion is certainly not over.

Acknowledgments

The support of the Natural Sciences and Engineering Research Council of Canada (NSERC) since 1980 is gratefully acknowledged. Acknowledgment is also made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for partial support of this work. Johnson Matthey is thanked for their generous loans of precious metals (Pd, Pt, Ru, Rh, and Ir). I would also like to thank ALCAN International for their continued support of chemistry in Canada. Dr. Steven J. Rettig is also thanked for his enthusiastic expertise in solving crystal structures.

Preparation and structure of chloro-copper(II) complexes of 7-azaindole

JACQUES POITRAS AND ANDRÉ L. BEAUCHAMP[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal, Qué., Canada H3C 3J7

Received April 6, 1992

JACQUES POITRAS and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **70**, 2846 (1992).

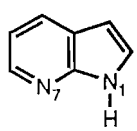
The light green *trans*-$CuCl_2(Haza)_2$ adduct precipitates immediately from mixtures of $CuCl_2 \cdot 2H_2O$ with excess 7-azaindole (Haza) in methanol. Upon standing in azaindole-rich solution, this solid is replaced by a deep green $Cu_2Cl_4(Haza)_6$ compound, whose crystal structure (orthorbombic, *Fdd*2, a = 26.558, b = 23.750, c = 12.727 Å, Z = 8, R = 0.068, R_w = 0.066) shows the presence of square-planar $[Cu(Haza)_4]^{2+}$ and *trans*-$[CuCl_2(Haza)_2]$ units connected by bridging Cl^- ions, making each Cu atom (4 + 2)-coordinated. Azaindole is bonded to the metal via the pyridine N7 site, whereas the five-membered ring retains its N1—H proton. The azaindole ligands are disordered over two orientations in the $[CuCl_2(Haza)_2]$ unit. The square-planar Cu species and apical Cl^- ions lie on a twofold axis and define along c an infinite chain based on the $\cdots Cl\cdots[Cu(Haza)_4]\cdots Cl\cdots[CuCl_2(Haza)_2]\cdots$ pattern. Equimolar mixtures of azaindole and $CuCl_2 \cdot 2H_2O$ yield a brown $Cu_4OCl_6(Haza)_4$ compound. The crystal structure of its ethyl acetate solvate (monoclinic, $P2_1/c$, a = 11.661, b = 22.415, c = 15.077 Å, β = 109.85°, Z = 4, R = 0.048, R_w = 0.054) shows the presence of a tetranuclear cluster consisting of a μ_4-oxide ion surrounded by a tetrahedron of Cu(II) atoms bridged in pairs by chlorine atoms. The trigonal-bipyramidal coordination of each copper atom is completed by a monodentate N7-bonded azaindole molecule hydrogen bonded to bridging chlorines via N1—H. The influence of complexation on the infrared spectrum of azaindole is discussed.

JACQUES POITRAS et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **70**, 2846 (1992).

Le composé d'addition vert clair *trans*-$CuCl_2(Haza)_2$ précipite immédiatement lors du mélange de $CuCl_2 \cdot 2H_2O$ avec le 7-azaindole (Haza) en excès dans le méthanol. En le laissant reposer dans une solution riche en azaindole, ce solide est remplacé par un composé vert foncé $Cu_2Cl_4(Haza)_6$, pour lequel la structure cristalline (orthorhombique, *Fdd*2, a = 26,558, b = 23,750, c = 12,727 Å, Z = 8, R = 0,068, R_w = 0,066) indique la présence d'espèces planes carrées $[Cu(Haza)_4]^{2+}$ et *trans*-$[CuCl_2(Haza)_2]$ reliées par des ions Cl^- pontants, qui confèrent à chaque atome de Cu une coordination (4 + 2). L'azaindole est lié au métal par l'intermédiaire de l'azote pyridinique N7, alors que le cycle à cinq chaînons conserve son proton N1—H. Les ligands azaindole sont désordonnés selon deux orientations dans le motif $[CuCl_2(Haza)_2]$. Les espèces planes carrées du cuivre et les ions Cl^- axiaux se trouvent sur un axe de rotation d'ordre deux et définissent selon c une chaîne infinie basée sur la séquence $\cdots Cl\cdots[Cu(Haza)_4]\cdots Cl\cdots[CuCl_2(Haza)_2]\cdots$. Le mélange équimolaire d'azaindole et de $CuCl_2 \cdot 2H_2O$ conduit au composé brun $Cu_4OCl_6(Haza)_4$. La structure cristalline du solvate d'acétate d'éthyle (monoclinique, $P2_1/c$, a = 11,661, b = 22,415, c = 15,077 Å, β = 109,85°, Z = 4, R = 0,048, R_w = 0,054) indique la présence d'un agrégat tétranucléaire comprenant un ion μ_4-oxyde entouré d'un tétraèdre d'atomes Cu(II) pontés deux à deux par des atomes de chlore. La coordination bipyramidale trigonale de chaque atome de cuivre est complétée par une molécule d'azaindole monodentate liée par N7, dont le proton N1—H participe à des liaisons hydrogène avec des chlores avoisinants. L'influence de la coordination sur le spectre infrarouge de l'azaindole a également été étudiée.

Introduction

The ligating properties in 7-azaindole (Haza, scheme 1)[2] have attracted relatively little attention. Previous reports from this laboratory described the preparation and structural characterization of three types of complexes with the CH_3Hg^+ cation (1, 2). In most of the remaining compounds structurally characterized so far, the azaindole anion acts as a bi-



SCHEME 1

nucleating agent by bridging a pair of metal atoms as carboxylate ligands do. However, in contrast with carboxylates and other common assembling ligands, the two donor sites of azaindole are not equivalent, being part of five- and six-membered rings, respectively. For this reason, we often get mixtures of many stereoisomers which are difficult to separate and crystallize. Furthermore, when crystalline materials are obtained, structural studies are complicated by the fact that the ligands generally show disorder due to ring orientation. Peng and co-workers (3, 4) have shown that Cu and Ni compounds originally prepared by Brookes and Martin (5) are indeed "windmill" tetra(azaindolate)dimetal units. A similar binding mode has recently been reported for a dichromium system (6). Azaindole anions can be used to stabilize metal–metal bonds, as observed in quadruply-bonded dimolybdenum compounds (7, 8). Bridging is also observed in the $Cu_4O(aza)_4(OCH_3)_4(dmf)_2$ and $Co_4(aza)_6$ clusters (3).

In the neutral form, the lone pair of N7 in the six-membered ring is the only one available. The presence of the N1—H bond in the other ring, roughly parallel to the N7 lone pair, results in very unusual hydrogen-bonding features for the free ligand, which has recently been shown to exist in the solid state as a unique hydrogen-bonded tetramer (1). Complexes of formally neutral azaindole have been described for CH_3Hg^+ (1, 2) and Zn^{2+} (9). An adduct of dirhodium tetrapropionate has also been reported (10). When the ligand is

bonded via N7, the adjacent N1—H bond points inside the metal coordination sphere, where it can interact with other ligands. While exploring the coordinating ability of azaindole, the reactions with copper(II) chloride in methanol were examined under conditions that did not lead to ligand deprotonation. Three compounds were isolated and characterized. The crystallographic work carried out on two of these compounds shows that hydrogen bonding has a particular influence on the structure of these materials.

Experimental section

Reactants and methods

$CuCl_2 \cdot 2H_2O$ (BDH) and 7-azaindole (Aldrich) were used as received. The solvents were of reagent grade. Chlorine was analyzed by potentiometric titration with $AgNO_3$.

Infrared spectra (4000–220 cm^{-1}) were recorded as KBr or CsI pellets with a Perkin-Elmer 783 spectrophotometer. Magnetic susceptibilities were measured at room temperature with a Johnson-Matthey balance, calibrated with $HgCo(SCN)_4$ ($\chi = 16.44 \times 10^{-6}$ c.g.s.e.m.u.). The data were corrected for diamagnetism of the ligands using Pascal's constants (11).

Reactions

$CuCl_2(Haza)_2$

To a solution of $CuCl_2 \cdot 2H_2O$ (0.49 g, 2.9 mmol) in methanol (30 mL) was added a solution of 7-azaindole (1.01 g, 8.5 mmol) in methanol (30 mL) at room temperature. A light green precipitate formed immediately. The resulting mixture was stirred for several minutes and the product was collected by filtration, washed with methanol, and dried *in vacuo* at room temperature Yield: 0.78 g (73%). Anal. calcd. for $C_{14}H_{12}CuCl_2N_4$: Cl 19.14; found: 19.21. $\mu = 2.02$ BM. The same compound also formed in lower yields when the reaction was run at room temperature with a 2:1 or 1:1 ligand:Cu ratio.

$Cu_2Cl_4(Haza)_6$

A solution of 7-azaindole (1.00 g, 8.5 mmol) in methanol (30 mL) was added to a solution of $CuCl_2 \cdot 2H_2O$ (0.36 g, 2.1 mmol) dissolved in methanol (20 mL). The above light green precipitate of $CuCl_2(Haza)_2$ appeared immediately. The mixture was heated near the boiling point until the precipitate redissolved to give a clear dark green solution. Dark green prismatic crystals were obtained upon cooling. Yield: 0.94 g (91%); $\mu = 1.95$ BM (per copper atom).

$Cu_4OCl_6(Haza)_4$

A solution of 7-azaindole (2.00 g, 16.9 mmol) in methanol (30 mL) was added dropwise to a hot solution of $CuCl_2 \cdot 2H_2O$ (2.88 g, 16.9 mmol) in methanol (50 mL). The green solution gradually darkened and a brown solid formed. Heating was continued for several minutes. After cooling to room temperature, the product was collected by filtration, washed with methanol, and dried *in vacuo* at room temperature. Yield: 2.90 g (73%). Anal. calcd. for $C_{28}H_{24}Cu_4Cl_6N_8O$: Cl 22.26; found: 21.65. $\mu = 1.81$ BM (per cooper atoms). Single crystals were obtained as the ethyl acetate solvate $Cu_4OCl_6(Haza)_4 \cdot 0.5C_4H_8O_2$ by recrystallization from a chloroform – ethyl acetate mixture.

Crystallographic measurements and structure determination

The crystallographic work was done with an Enraf-Nonius CAD-4 diffractometer. A set of 25 centered reflections was used to determine the reduced cell, which was checked with axial photographs. A primitive monoclinic cell was obtained for $Cu_4OCl_6(Haza)_4 \cdot 0.5C_4H_8O_2$. The systematic absences ($h0l$, $l \neq 2n$; $0k0$, $k \neq 2n$), agreed with the intensity data set, uniquely defining $P2_1/c$ as the space group. For $Cu_2Cl_4(Haza)_6$, the Niggli matrix indicated an F-centred orthorhombic cell, which agreed with the axial photographs. The systematic absences (hkl, $h + k$, $h + l$, $k + l \neq 2n$; $0kl$, $k + l \neq 4n$; $h0l$, $h + l \neq 4n$) uniquely defined its space group as $Fdd2$.

Crystal data are given in Table 1. The intensities were measured as described earlier (12). Six standard reflections were monitored for crystal decay every hour and for misorientation every 200 reflections. For $Cu_4OCl_6(Haza)_4 \cdot 0.5C_4H_8O_2$, four octans ($hkl$, $hk\bar{l}$, $h\bar{k}l$, $h\bar{k}\bar{l}$ were collected (15883 reflections). Averaging ($R_{av} = 0.041$) yielded a set of 7020 independent hkl and $hk\bar{l}$ data. For $Cu_2Cl_4(Haza)_6$, 3941 hkl and $h\bar{k}l$ reflections were measured. Averaging yielded a set of 1997 unique hkl data ($R_{av} = 0.040$). The raw data were corrected for the effects of Lorentz, polarization and absorption (Gaussian integration, grid $10 \times 10 \times 10$).

Similar strategies were applied to solve and refine both structures. Details specific to each compound are provided in the supplementary material.[3] The Cu atoms were first located from a Patterson map or direct methods. The non-hydrogen atoms were then found from ΔF maps. Full-matrix least squares were used to refine all non-hydrogen atoms isotropically. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with individual weights w based on counting statistics. The Cl and Cu atoms were first allowed to refine anisotropically, while the remaining non-hydrogen atoms were kept isotropic. Disorder was found to occur for an azaindole ligand in $Cu_2Cl_4(Haza)_6$ (Fig. 1) and the lattice ethyl acetate molecule in $Cu_4OCl_6(Haza)_4 \cdot 0.5C_4H_8O_2$. Occupancy factors were determined at this stage and fixed for the rest of the refinement. Hydrogens were introduced at idealized positions (C—H = 0.95 Å, N—H = 0.87 Å). Their parameters were not refined, but their coordinates were recalculated after each least-squares cycle. In the last stage, anisotropic temperature factors were refined for the non-hydrogen atoms.

The scattering curves were taken from standard sources (13, 14). The anomalous dispersion terms of Cu and Cl were taken from Cromer (15). The calculations were done with NRCVAX (16), SHELX-76 (17), and local utility programs (18). The refined coordinates for the two structures are listed in Tables 2 and 3, respectively.

Result and discussion

In the absence of a good proton acceptor, the very poorly acidic N1—H proton of 7-azaindole is not expected to dissociate or to be displaced by the metal in methanol. The ligand is indeed found to behave as a typical monodentate aromatic *N*-heterocycle like pyridine. Mixing methanol solutions of $CuCl_2 \cdot 2H_2O$ and a threefold excess of azaindole at room temperature produces a dark green solution from which a good yield of light green needles of composition $CuCl_2(Haza)_2$ precipitates immediately. The compound ex-

[3]The supplementary material includes details on structure determinations, tables of refined temperature factors, hydrogen coordinates, distances and angles in the disordered azaindole rings, distances and angles for hydrogen bonds, least-squares plane calculations and structure factor amplitudes for both structures, diagrams (disordered ethyl acetate and unit cell) for $Cu_4OCl_6(Haza)_4 \cdot 0.5C_4H_8O_2$, together with a list of infrared frequencies (62 pages). Complete set of data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Structure resolution and refinement, Figure S-1 (disordered ethyl acetate molecule), Figure S-2 (stereoview of the unit cell), Table S-2 (idealized coordinates of the hydrogen atoms), Table S-3 (distances and angles in the azaindole ligands), Table S-4 (distances and angles for the hydrogen bonds) for $Cu_4OCl_6(Haza)_4 \cdot 0.5C_4H_8O_2$, and structure resolution and refinement, Table S-9 (idealized coordinates of the hydrogen atoms), Table S-10 (distances and angles in the azaindole ligands), Table S-11 (distances and angles for the hydrogen bonds) for $Cu_2Cl_4(Haza)_6$ have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

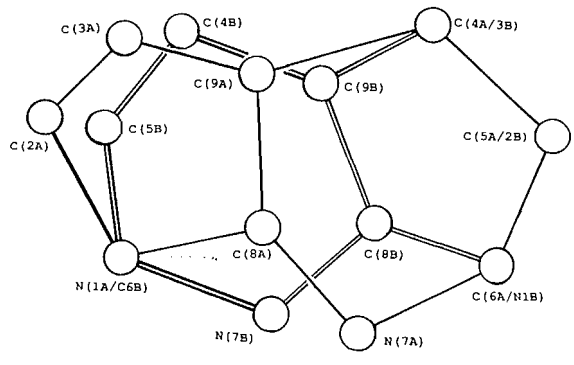

FIG. 1. Disorder of the coordinated azaindole ligand in the *trans*-$[CuCl_2(Haza)_2]$ unit of $Cu_2Cl_4(Haza)_6$ (occupancies 0.50/0.50).

hibits a normal magnetic moment of 2.02 BM. A similar green solid was isolated with imidazole (19) and found to consist of square-planar *trans*-$CuCl_2L_2$ units with one of the Cl ligands bridging the units into an infinite chain of (4 + 1)-coordinated Cu centres. The structure of $CuCl_2(Haza)_2$ was not determined, but it very likely corresponds to the same *trans*-square-planar structure, which is also found for pyridines (20–23), dimethylnaphthyridine (24) and related ligands (25).

The light green compound could also be isolated as a pure material from azaindole–$CuCl_2 \cdot 2H_2O$ mixtures with ratios between 6:1 and 1:1, provided the precipitate initially formed was filtered immediately. When attempts were made to grow single crystals by leaving the dark green filtrate of the above preparations to stand overnight in closed container at room temperature, deep green prismatic crystals were obtained instead of the needles. A quicker way to obtain the dark green prismatic solid is by boiling a 6:1 mixture. The composition of this material was shown by X-ray diffraction (see below) to be $CuCl_2(Haza)_3$, which should be formulated as $[CuCl_2(Haza)_2][Cu(Haza)_4]Cl_2$. The magnetic moment of 1.95 BM (per Cu atom) is consistent with this structure. This same compound was eventually prepared from a 3:1 ligand:metal mixture from which the fluffy precipitate initially formed was not filtered. After several hours, the precipitate had redissolved, to be replaced by the prismatic deep green solid. Interestingly, even when the reaction was carried out with four- to six-fold excess of ligand, the same $CuCl_2(Haza)_3$ compound was the only complex isolated. We were unable to obtain $[Cu(Haza)_4]Cl_2$, even though such $[CuL_4]X_2$ compounds are known with imidazoles (26–30) and pyridines (31).

Neither of the above green compounds formed when the reaction was carried out with excess copper. Under stoi-

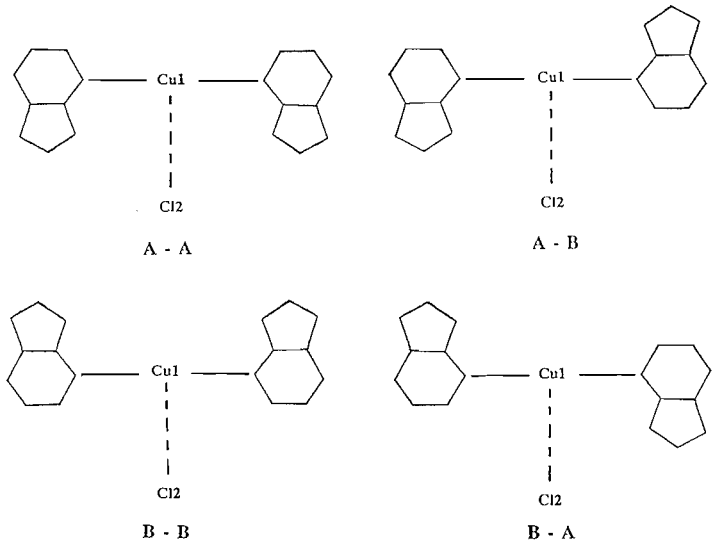
chiometric conditions, a brown solid shown to be the tetranuclear cluster $Cu_4OCl_6(Haza)_4$ (see X-ray work below) was isolated when a hot solution of the ligand was slowly added to a hot solution of $CuCl_2 \cdot 2H_2O$. Fast addition of mixing in the opposite order resulted in immediate formation of some light green $CuCl_2(Haza)_2$ material. The magnetic moment (1.81 BM per Cu atom) similar to those found for this type of cluster (32) indicates that the copper atoms are not appreciably coupled. The central μ_4-oxide ligand undoubtedly originates from the relatively large amount of water introduced via the $CuCl_2 \cdot 2H_2O$ reactant, the two expelled protons being quenched by azaindole molecules (pK_a of $H_2aza^+ = 4.6$) (33). Infrared bands characteristic of the azaindolium ion are found in the spectrum of the residue obtained from filtrate evaporation.

Crystal structure of $Cu_2Cl_4(Haza)_6$

Two features commonly encountered in Cu(II) complexes (34) are observed in this crystal structure: (*1*) the primary coordination of the metal consists of four strong bonds in an roughly square-planar arrangement; and (*2*) one or two weaker axial bonds with halogen atoms belonging to adjacent units provide bridging interactions between the square planes, resulting in square-pyramidal (4 + 1) or elongated octahedral (4 + 2) overall coordinations.

The asymmetric unit includes two symmetry-independent copper atoms, both lying on a crystallographic twofold axis and belonging to square-planar *trans*-$[CuCl_2(Haza)_2]$ and $[Cu(Haza)_4]^{2+}$ species, respectively (Fig. 2). The azaindole



SCHEME 2

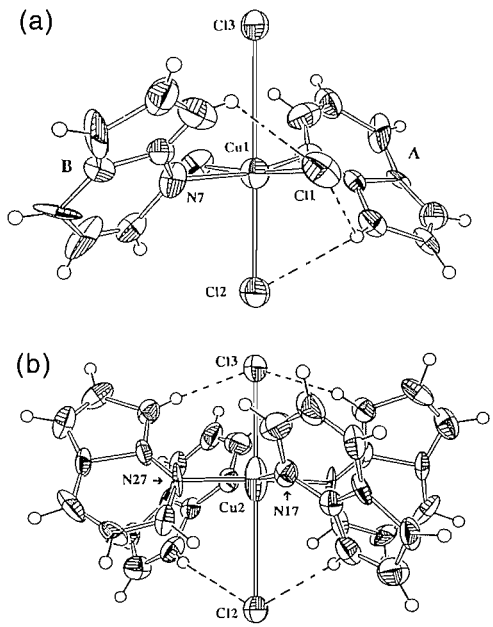


FIG. 2. Coordination of the metal atoms in $Cu_2Cl_4(Haza)_6$. (*a*) $CuCl_2(Haza)_2$ unit formed by Cu(1) and (*b*) $[Cu(Haza)_4]^{2+}$ ion formed by Cu(2). In $CuCl_2(Haza)_2$, the azaindole ligands are disordered over two orientations A and B (see text). About both Cu atoms, longer apical Cu···Cl bonds are formed with bridging Cl(2) and Cl(3) ions. Thermal ellipsoids correspond to 50% probability. Hydrogens are shown as spheres of arbitrary size. Dashed lines represent hydrogen bonds.

ligands are all formally neutral and coordinated to copper via N7. The square planes, roughly perpendicular to the twofold axis, are bridged by chloride ions lying on the same axis, which complete an overall (4 + 2)-coordination about the metal. Selected interatomic distances and bond angles are listed in Table 4.

(a) Environment of Cu(1): trans-*[$CuCl_2(Haza)_2$]*

The azaindole ligand is involved in a twofold disorder (Fig. 1) leading to two equally populated orientations of the five-membered ring with respect to the coordination plane: labels A and B (Fig. 2*a*) correspond to five-membered rings pointing toward Cl(2) and away from Cl(2), respectively. The crystallographic results are consistent with the presence of four possible combinations of these two orientations, namely A–A, B–B, A–B, and B–A (Scheme 2), which all possess a roughly square-planar *trans*-$CuCl_2N_2$ coordination. The B–A/A–B pair actually corresponds to the same molecule rotated by 180° about the Cu(1)–Cl(2) direction (crystallographic twofold axis). As chlorine is not disordered, the Cl(1)—Cu(1)—Cl(1) is 172.7(1)° in all cases. The N7 donor atoms are not coincident in A and B, so that different patterns of distances and angles are obtained around Cu(1) (Table 5). Departure from planarity is large and the bond angles deviate very significant from ideality. We tend to prefer the A–B/B–A structure, because all molecules would then show a small square-pyramidal distortion displacing Cu(1) by 0.121 Å toward the relatively close Cl(2) bridging atom. Also, the A–B/B–A molecule is statistically twice as probable as either A–A or B–B.

The ORTEP drawing (Fig. 2*a*) shows an A–B molecule. The Cu(1)—Cl(1) distance (2.270(2) Å) (Table 4) compares well with those reported for *trans*-$CuCl_2N_2$ molecules with 2,3- and 2,6-dimethylpyridine (2.254(2) and 2.264(2) Å, respectively), where the chlorines do not participate in bridging (20, 21). Because of the disorder, the Cu(1)—N7 bond lengths are less reliable. The Cu(1)—N(7A) distance (2.02(2) Å) is similar to those found in analogous complexes with related ligands (19–22, 24). The long Cu(1)—N(7B) distance is undoubtedly an artifact due to disorder. Individual distances and angles for the disordered Haza ligand are listed in the supplementary material.

(b) Environment of Cu(2): $[Cu(Haza)_4]^{2+}$ (Fig. 2b)

The Cu—N bonds in the square plane (mean 2.030 Å) are comparable with those stated above and they lie in the range (1.98–2.05 Å) found for imidazole complexes (26, 35, 36) containing CuN_4 units. The N—Cu—N *cis* bond angles are essentially equal to the ideal 90° value for a square-planar geometry. The *trans* angles (176.4(4), 177.3(4)°) show significant, but small, departure from 180°, indicating a

small tetrahedral distortion. The atom-to-plane distances are as follows: Cu(2), 0.003(7); N(17), −0.058(10); N(27), 0.053(11) Å.

The bond lengths for the two independent azaindole ligands in the $[Cu(Haza)_4]^{2+}$ moieties (supplementary material) show differences greater than the experimental error. Appreciable differences are also noted with respect to the free ligand (1) or other N7-bonded complexes (9, 10). This suggests that some disorder, milder than above, might be present in this case as well, in spite of the fact that it has not been possible to identify resolved atomic positions.

(c) Molecular packing

A view of an *ac* layer of the unit cell is given in Fig. 3. The ···Cl(3)···Cu(1)···Cl(2)···Cu(2)···Cl(3)··· chain is perfectly linear, all atoms lying on the crystallographic twofold axis. The CuN_4 and $CuCl_2N_2$ planes are roughly perpendicular to this chain and occur in alternance. They are bridged by Cl^- ions, but bridging is highly dissymmetric. Cl(2) forms a normal "semi-bond" of 2.819(5) Å with Cu(1), but its contact with Cu(2) is very long (3.429(8) Å). Similarly, Cl(3) is more strongly bonded to Cu(2) (2.941(8) Å) than to Cu(1) (3.538(4) Å). Similar features have been encountered in various alkylammonium salts of chlorocopper(II) anions containing linear Cu···Cl···Cu bridging units (37). Thus, although each Cu atom is surrounded by six neighbours in an octahedral arrangement, a square-pyramidal (4 + 1)-coordination including only one axial chlorine would be a more appropriate description from the electronic point of view.

All azaindole N1—H protons are hydrogen bonded to Cl atoms.[3] If the ligands were in the $CuCl_2N_2$ plane, extremely short H1···Cl(1) distances would result. This strain is relieved by rotating the ligand ~45° around the Cu—N7 bond, leading to a reasonably strong N1—H···Cl(1) hydrogen bond (N···Cl = 3.177(12) Å for A, 3.114(15) Å for B) (38). In this orientation, weaker hydrogen bonding can simultaneously take place with an apical chloride ion: N1···Cl(2) = 3.343(12) Å for ligands A, N1···Cl(3) = 3.545(14) Å for ligands B. In the $[Cu(Haza)_4]^{2+}$ unit, the ligands make angles of ~58° with the coordination plane. Two of these ligands form hydrogen bonds of 3.283(11) Å with Cl(2) on one side of the square plane, whereas the other two interact with Cl(3) at 3.013(10) Å on the other side.

This compound presents two unusual features: the chain is built up from two types of Cu(II) species and the ···Cl···Cu(1)···Cl···Cu(2)···Cl··· backbone is perfectly linear. These peculiarities can be regarded as a conse-

For personal use only.

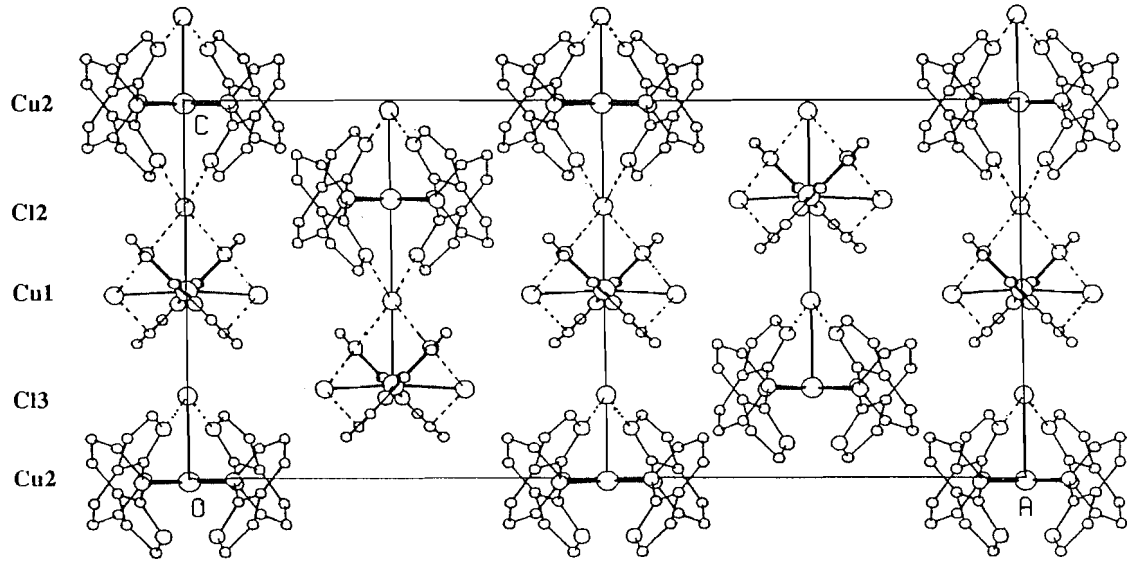

FIG. 3. View of a layer of the unit cell of $Cu_2Cl_4(Haza)_6$ down the *b* axis (thickness *b*/2). The Cu atoms and bridging Cl ions lie on crystallographic twofold axes. The labels on the left hand side refer to the Cl and Cu atoms on the *c* axis. The square planes around copper are perpendicular to these axes and seen edgewise in the figure. Hydrogen bonds are shown as dashed lines.

quence of the roughly parallel orientation of the N7 lone pair with the N1—H bond, which restricts the hydrogen bonding capability of coordinated azaindole to the regions just above and below the coordination plane. Figure 3 indeed shows that hydrogen bonding occurs only inside the chains, all inter-chain interactions consisting of normal van der Waals contacts. The ligands in the $[Cu(Haza)_4]^{2+}$ unit can rotate about the Cu—N7 bond so as to make efficient hydrogen bonds with chloride ions forming the apical Cu···Cl semi-bonds with the metal. This takes place without appreciably disturbing the Cu—N7 bond, the difference between the C6—N7—Cu(2) and C8—N7—Cu(2) angles remaining below 10° (Table 4). Other heterocyclic ligands like pyridine or imidazoles would be unable to give a similar stabilizing effect. Steric crowding would even destabilize the system with α-alkylated imidazoles and pyridines, or with a two-ring system like benzimidazole, which are devoid of properly oriented hydrogen-bond donors. In contrast, in the $[Cu(Haza)_4]^{2+}$ unit, two of the rings are rotated above the square plane and two are rotated below, thereby stabilizing a chloride ion on each side of the plane. The chain can then be propagated by approaching extra square planar species at each end of this ···Cl···$[Cu(Haza)_4]$···Cl··· nucleus, since the terminal Cl^- ions are not sterically crowded. However, if the stoichiometry were $[Cu(Haza)_4]Cl_2$, only half of the Cl^- ions could be part of such a chain, so that the remaining ions would have to sit elsewhere in the unit cell, where they would have to interact via van der Waals contacts with hydrophobic regions of azaindole in the outer part of the chain. In the present compound, a neutral $[CuCl_2(Haza)_2]$ unit is inserted between ···Cl···$Cu(Haza)_4$···Cl··· segments, allowing the system to use the residual basicity of the sterically accessible Cl^- ions to fill the apical positions of the $[CuCl_2(Haza)_2]$ unit and favour chain propagation. This could explain the unusual stoichiometry found for this deep green complex and the fact that the $[Cu(Haza)_4]Cl_2$ salt known with other ligands could not be obtained.

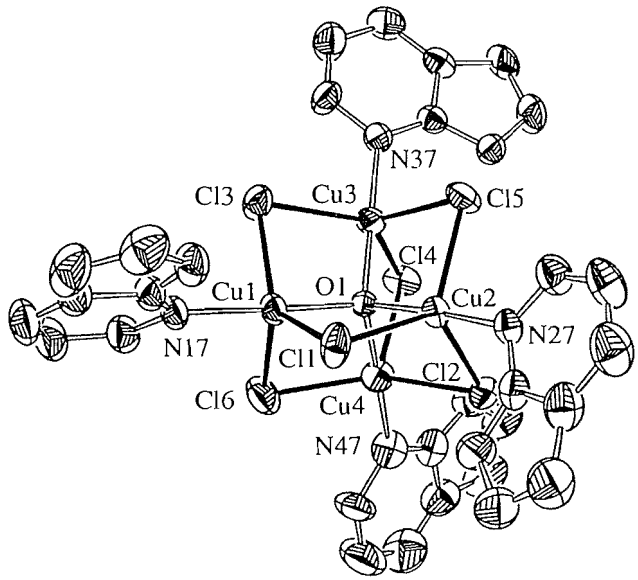

FIG. 4. ORTEP drawing of the $Cu_4OCl_6(Haza)_4$ molecule. Thermal ellipsoids correspond to 50% probability. Hydrogens are omitted for clarity.

Crystal structure of $Cu_4OCl_6(Haza)_4 \cdot 0.5C_4H_8O_2$

The molecule contains the Cu_4OCl_6 core consisting of a μ_4-oxygen atom coordinated tetrahedrally to four Cu atoms, which are bridged in pairs by six chlorine atoms (Fig. 4). A trigonal-bipyramidal coordination about each of these four Cu atoms is completed by 7-azaindole ligands bonded via the N7 lone pair. Disordered ethyl acetate molecules not bonded to the cluster are also present (Fig. S-1).[3] Selected distances and angles are listed in Table 6.

Structural results are available for similar clusters containing pyridines (32, 39), imidazoles (40–42) and other ligands (40, 43–45). Norman and co-workers (40) have

Cu(1)—Cl(6)—Cu(4)	81.70(8)	Cu(3)—O(1)—Cu(4)	112.5(2)

collected these data and noted that the geometry of the Cu_4O tetrahedron is relatively constant. The departure from tetrahedral geometry about oxygen is usually small: the O—Cu—O angles have been found to lie in the range 106.3–115.8°, with a mean value of 109.4°. Our Cu—O—Cu angles (105.8(2)–112.5(2)°, mean 109.5°) fit well with these earlier results. The Cu—O bond lengths are not very sensitive to the external ligand present: our results (1.912(4)–1.925(4) Å, mean 1.918 Å) are in good agreement with the literature (1.869–1.939 Å, mean 1.908 Å) (40). The Cu—N bond lengths show greater variation. Our distances (1.983(6)–2.016(7) Å, mean 1.998(6) Å) suggest that azaindole has steric requirements similar to pyridines (mean 1.98 Å) (32, 39) and greater than imidazoles (mean 1.94 Å) (40, 41).

The coordination of copper is best described as a distorted trigonal bipyramid. The O—Cu—N angles (174.2(2)–179.1(2)°) are close to the ideal 180° value. As found for similar molecules (40), the O—Cu—Cl angles (mean 84.2°) are ~10° less than the N—Cu—Cl angles (mean 95.9°). Thus, the Cu atom is displaced ~0.24 Å from the plane of the three Cl atoms, toward N7. Angular distortions in the equatorial plane are large. The Cu—Cl distances and Cl—Cu—Cl angles can vary over a broad range in such systems (40). Around Cu(1), Cu(2), and Cu(3), the Cl—Cu—Cl angles range from 111.8(1) to 130.1(1)° (mean 119.0°), whereas the Cu—Cl distances are found between 2.340(2) and 2.467(2) Å (mean 2.397 Å). Such variations can be regarded as normal for this type of framework. In contrast, the more severe distortions around Cu(4) are somewhat unusual. The Cl(2)—Cu(4)—Cl(6) angle (141.5(1)°) is much larger, although not quite as large as some of those found in Cu_4OCl_6(2-methylpyridine)$_4$ (32), where the metal coordination has been described as intermediate between a trigonal bipyramid and a square pyramid. The less regular environment of Cu(4) also includes an unusually long Cu(4)—Cl(4) bond of 2.619(2) Å, almost as long as the

2.679(8) Å bond found in the 2-methylpyridine complex. In spite of this long bond, the mean Cu—Cl distance (2.432 Å) about Cu(4) is not much greater than about the three other Cu atoms, since one of the bonds to Cu(4) (2.329(2) Å) is the shortest in the structure. Large distortions in similar clusters have been ascribed to packing effects (39, 40) and they probably have the same origin here (see below).

The geometry of the four non-equivalent azaindole ligands (see supplementary material) is normal (1, 9, 10). If coordination took place exactly along the lone pair direction, the metal would lie in the plane of the ligand and the two Cu—N7—C angles would be equal. The copper-to-plane distances are relatively small (Cu(1), 0.042(1) Å; Cu(2), 0.175(1) Å; Cu(3), 0.046(1) Å; Cu(4), 0.024(1) Å), whereas the maximum in-plane distortion corresponds to 3.8° (ligand 1).

Coordination of azaindole to the axial site of the trigonal bipyramid places the N1—H bond in a suitable orientation to form hydrogen bonds with the equatorial Cl atoms. Five of the six Cl atoms participate in such intramolecular interactions.[3] Ligands 1 and 4 each form one moderately strong (38) hydrogen bond (N···Cl < 3.13 Å) with a single chlorine. This corresponds to relatively small N(11)—N(17)—Cu(1)—Cl(1) and N(41)—N(47)—Cu(4)—Cl(4) torsion angles of 39.1(3) and 33.7(3)°, respectively. For ligands 2 and 3, the torsion angles are close to 60°, so that the N—H bonds are roughly equidistant from two chlorines, with which they form bifurcated hydrogen bonds.

A packing pattern is given in Figure S-2.[3] The molecules are held in the crystal mainly by normal van der Waals contacts. Contribution from hydrogen bonding is restricted to the N(21)—H···Cl(3) bond of 3.289(7) Å. The cavity occupied by the ethyl acetate molecule is delimited by azaindole rings and Cl(6) atoms of various cluster molecules. It is probably to make room for the solvent that Cl(6) is the only chlorine not participating in hydrogen bonding and this part of the cluster is distorted. Also, since the ethyl acetate molecule is disordered, it possibly induces minor disorder in the Cu(4)—Cl(6) region, leading to greater temperature factors for these atoms.

Infrared spectra of the azaindole complexes

The infrared spectrum of 7-azaindole has been discussed elsewhere (2, 7). A list of frequencies and tentative assignments is provided in the supplementary material. Since the state of protonation is not changed, the spectra of the complexes are not drastically different. Various shifts are noted in the 1600–1400 cm^{-1} region of the ring stretching modes. The best diagnostic for coordination to netural azaindole via N7 is provided by the well-defined ring out-of-plane vibrations at 428/419 cm^{-1}, which are replaced in the complexes by a weak component at 449 cm^{-1} and a stronger band at ~434 cm^{-1}.

The complexes can be differentiated from the 700–800 cm^{-1} region: 789/762/715 cm^{-1} for Haza, 781/746/699 cm^{-1} for $CuCl_2(Haza)_2$, 794/781/735/711/701 cm^{-1} for $Cu_2Cl_4(Haza)_6$, and 799/786/723 cm^{-1} for $Cu_4OCl_6(Haza)_4$. Differences in hydrogen bonding also introduce noticeable spectral variations for N1—H bands. The strong multi-component ν(N—H) region (2300–3200 cm^{-1}) of free Haza is replaced in $CuCl_2(Haza)_2$ by a better defined strong band at 3330 cm^{-1}. The weak N1—H out-of-plane bending band, observed near 850 cm^{-1} in the free ligand, shifts to 530 cm^{-1} and becomes much stronger in the complex. These displacements are indicative of weaker hydrogen bonding than in the free ligand. The same effect has been noted for azaindole adducts of $TaCl_5$ and $NbCl_5$ (46). For the N1—D derivatives, obtained by dissolution in CD_3OD, these N—H vibrations are shifted down to 2490 and 400 cm^{-1}, respectively, as expected. The greater number of independent ligands in $Cu_2Cl_4(Haza)_6$ leads to extra components at 3200 and 3145 cm^{-1}. For $Cu_4OCl_6(Haza)_4$, the ν(N—H) band occurs at 3110 cm^{-1}, but the γ(N—H) band expected at 530 cm^{-1} is masked by a metal-centered band (see below).

The ligand shows no vibrations in the 240–400 cm^{-1} range. The single broad band of medium intensity observed at 289 cm^{-1} for $CuCl_2(Haza)_2$ and $Cu_2Cl_4(Haza)_6$ originates from Cu–ligand motion, but it cannot be safely assigned. A strong ν(Cu—N) band has been found at this frequency for $[CuL_4]^{2+}$ species with pyridines (47) and imidazoles (27–30, 47, 48). For various $CuCl_2L_2$ compounds with the same ligands, the ν(Cu—N) and ν(Cu—Cl) bands are believed to occur in the same region (28–30, 49, 50). Our band at 289 cm^{-1} probably includes both vibrations. The low-frequency region also exhibits a band at ~230 cm^{-1}, mentioned for many similar systems. There is no consensus concerning its assignment, but it undoubtedly originates from a metal-centered mode. $Cu_4OCl_6(Haza)_4$ produces a new strong band at 558 cm^{-1}, observed for other clusters containing the Cu_4O core (32, 45, 51) and assigned to Cu—O stretching. The 289 cm^{-1} band mentioned above seems to have shifted down to ~250 cm^{-1}, where three components are observed at 263, 249, and 239 cm^{-1}. A similar pattern has been noticed for the 2-methylpyridine cluster (32) and assigned to general M-ligand stretching. It probably correspond mainly to Cu—N motion, since the comparison of a pair of analogous chloro and bromo compounds (45) identified the 225 cm^{-1} band as due to cluster ν(Cu—Cl) vibration.

Acknowledgments

We wish to thank M. Leduc for preparing the compounds, and M. Simard and F. Bélanger-Gariépy for their assistance in solving the X-ray structures. The support of the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged.

Basicity of substituted 2-pyridyl-1,1,3,3-tetramethylguanidines and aminopyridines in acetonitrile and water solvents

NASER FOROUGHIFAR,[1] KENNETH T. LEFFEK, AND YONG GU LEE[2]
Department of Chemistry, Dalhousie University, Halifax, N. S., Canada B3H 4J3

Received June 17, 1992

NASER FOROUGHIFAR, KENNETH T. LEFFEK, and YONG GU LEE. Can. J. Chem. **70**, 2856 (1992).

A series of substituted 2-pyridyl-1,1,3,3-tetramethylguanidines has been synthesized and the pK_a of each has been measured in acetonitrile and water solvents, together with the pK_a of the corresponding aminopyridine. A relationship between the pK_a's in these two solvents has been derived that allows the estimation of a pK_a in acetonitrile from that in water. The results were fitted to the Hammett equation, giving $\rho = 2.31 \pm 0.14$ and 1.64 ± 0.11 for the pyridylguanidines in acetonitrile and water, respectively, and 6.16 ± 0.4 and 5.24 ± 0.2 for the aminopyridines in the same solvents.

NASER FOROUGHIFAR, KENNETH T. LEFFEK et YONG GU LEE. Can. J. Chem. **70**, 2856 (1992).

On a synthétisé une série de 2-pyridyl-1,1,3,3-tétraméthylguanidines substituées et on a mesuré les pK_a de chacune dans l'acétonitrile et dans l'eau ainsi que les pK_a des aminopyridines correspondantes. On a établi une corrélation entre les pK_a dans ces deux solvants; elle permet d'évaluer un pK_a dans l'acétonitrile à partir de celui dans l'eau. On a ajusté les résultats avec l'équation de Hammett, obtenant des valeurs de $\rho = 2{,}31 \pm 0{,}14$ et $1{,}64 \pm 0{,}11$ pour les pyridylguanidines dans l'acétonitrile et l'eau, respectivement, et de $6{,}16 \pm 0{,}4$ et $5{,}24 \pm 0{,}2$ pour les aminopyridines dans les mêmes solvants.

Introduction

The basicity of a series of phenyl-substituted 2-phenyl-1,1,3,3-tetramethylguanidines was measured (1) in order to provide a series of strong organic bases to complement the weaker aniline and pyridine bases for use in physical-organic research. Acetonitrile was chosen as the solvent since it is an aprotic solvent that is easy to purify and has a wide range of applicability in physical-organic measurements. The present work extends the range of strong bases to 1,1,3,3-tetramethylguanidines (TMG) substituted with various pyridyl groups at the N-2 position and also provides pK_a values of the conjugate acids of a series of aminopyridine bases in both acetonitrile and water solvents. The first objective is to provide a quantitative relationship between the pK_a in the solvents to allow a more reliable estimate of the pK_a of the conjugate acid of a particular base in acetonitrile from that in water. Coetzee and Padmanabhan (2) found no such quantitative relationship for a series of amines consisting mainly of aliphatic bases, but they did find that the pK_a's of the conjugate acids correlated with the Taft substituent constants, $\Sigma\sigma^*$, with the same slopes in acetonitrile solvent as those determined by Hall (3) in water.

It has been known for a long time (4) that Hammett σ constants, determined using phenyl-substituted substrates, could be used to correlate substituted pyridines. The second objective of the pK_a determinations for the aminopyridines is to demonstrate the validity of Hammett correlations in multiply-substituted pyridines and provide a body of data that will allow the standard methods of predicting pK_a's in water (5) to be used directly in acetonitrile.

Results and discussion

Table 1 presents the pK_a values of the conjugate acids of the bases in acetonitrile and water solvents, together with the pK_a differences between the two solvents. All the bases are stronger in acetonitrile than in water, as previously observed (1, 2), probably due to the weaker proton acceptor power of acetonitrile relative to water (2). It was shown (1) that the procedure of simply averaging the ΔpK_a values was not a satisfactory method of estimating the pK_a in one solvent from a measurement in the other, since the error may be more than half a pK_a unit. Uncertainties of this magnitude are usually too large for meaningful discussion of kinetic or other data.

The relationship between the pK_a values in acetonitrile and water for the bases in the present study is represented by eq. [1], with a correlation coefficient (c.c.) of 0.994.

$$[1] \quad pK_a^{AN} = (1.23 \pm 0.03)pK_a^{W} + 6.2 \pm 0.2$$

This relationship is complementary to the phenylTMG series previously published (1) and gives a range of bases in acetonitrile from a pK_a of 3.0 up to 23.9 (for DBU (1)). Schesinger (8) reported a value for DBU (1,8-diazabicyclo[5.4.0]undec-7-ene) of 24.32 in acetonitrile and also two 2,4-diaminovinamidines with pK_a values of 26.22 and 26.92 in the same solvent. Thus there is a wide range of nitrogen bases of known pK_a in acetonitrile over a scale of about 24 pK_a units.

If the 22 bases reported for the phenylTMG series (1) are combined with the 16 bases in Table 1, the relationship (c.c. 0.982) between pK_a^{AN} and pK_a^{W} is given by eq. [2].

$$[2] \quad pK_a^{AN} = (1.11 \pm 0.03)pK_a^{W} + 7.0 \pm 0.3$$

It is interesting to note that all the bases fall on the same correlation line despite the fact that the aminopyridine bases are protonated on the ring nitrogen atom, while the pyridylTMG bases are protonated on the N-2 atom of the TMG group, although no doubt considerably delocalized onto the N-1 and the N-2 atoms (9). Thus the solvent effect does not depend on the environment of the proton in the conjugate acid of the base, nor does it depend upon specific solvation of the picrate anion, since Coetzee and Padmanabhan (2) found

For personal use only.

virtually the same pK_a values for picrates and perchlorates. This confirms that the solvent effect must be due to the poorer proton-accepting ability of acetonitrile relative to water.

Equation [2] may be used to estimate pK_a values in water for strong bases that are affected by the levelling effect in water. We previously estimated the pK_a of DBU in water as 14.3 from a pK_a^{AN} of 23.9, but the application of eq. [2] gives a value of 15.2±0.5. If the Schesinger value of 24.3 in acetonitrile is used, DBU would have a pK_a in water of 15.7. Since DBU has a similar structure to the bases correlated by eq. [2], these values should be better estimates than our previous one. The large uncertainty in such an estimate demonstrates the need to measure pK_a values directly whenever this is possible.

Hammett plots may be constructed for all of the pyridylTMG compounds in Table 1 using the σ values for the =N— group of the pyridine ring given by Perrin *et al.* (ref. 5, p. 139) and the normal σ values (1, 5) for the substituents on the pyridine ring, both relative to the position of the TMG group, to give Σσ in Table 1. These are described by eqs. [3] (c.c. 0.989) and [4] (c.c. 0.987) for acetonitrile and water solvents, respectively.

$$[3] \quad pK_a^{AN} = -(2.31\pm0.14)\sigma + 20.7\pm0.1$$

$$[4] \quad pK_a^{W} = -(1.64\pm0.11)\sigma + 11.5\pm0.1$$

The intercepts of eq. [3] and eq. [4] should be equal to the pK_a of phenylTMG in acetonitrile and water, respectively. The agreement in acetonitrile, between 20.7±0.1 from eq. [3] and the literature value of 20.6±0.1(1) is very good, but in water eq. [4] gives 11.5±0.1, whereas Pruszynski found 12.18±0.02 (10). In acetonitrile, at least, the pK_a of a substituted pyridylTMG could, therefore, be predicted with good accuracy from that of phenylTMG. The ρ values are very similar to those found for the substituted phenylTMG compounds, i.e., ρ = 2.18±0.16 in CH_3CN (1) and 1.84±0.05 in water (10). Within ±σ they are the same in CH_3CN and differ by only a little more than this in water. The ρ values are clearly different in the two solvents, unlike the observation for aliphatic bases (2, 3).

It is concluded that the electronic effects governing the base strengths of pyridyl-substituted tetramethylguanidines generally parallel those of the phenyltetramethylguanidines.

Hammett plots for the aminopyridines in Table 1 are described by eqs. [5] and [6], with correlation coefficients of 0.983 and 0.999 respectively.

$$[5] \quad pK_a^{AN} = -(6.16\pm0.40)\sigma + 12.8\pm0.2$$

$$[6] \quad pK_a^{W} = -(5.24\pm0.20)\sigma + 5.34\pm0.08$$

The correlation found in water confirms earlier work of Charton (11), who obtained ρ = 5.70 and an intercept of 5.39, and also that of Clark and Perrin (12), who found ρ = 5.90 and an intercept of 5.25 for pyridinium ions in water. The pK_a of pyridine in water is 5.23 (6). The ρ value of 6.16 in acetonitrile shows that the sensitivity of this reaction constant to solvent change is less for pyridinium ions than it is for the tetramethylguanidinium ions. The intercept of 12.8 is somewhat higher than the pK_a of pyridine in acetonitrile, which was reported by Coetzee and Padmanabhan (2) as 12.33. Thus the pyridine bases are not as well correlated in acetonitrile as they are in water and also not as well correlated as the TMG bases in acetonitrile. Therefore, the prediction of the pK_a of a pyridine base in acetonitrile can be done only with moderate accuracy.

Experimental

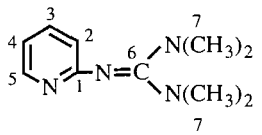
Substituted 2-pyridyl-1,1,3,3-tetramethylguanidines were synthesized using a modification of the procedure of Bredereck (13). A solution of 1,1,3,3-tetramethylurea (0.1 mol) (Aldrich, dried over 4A molecular sieve) in dry benzene (100 mL) was treated dropwise with a solution of $POCl_3$ (0.2 mol) in dry benzene (30 mL). The reaction was stirred at room temperature overnight and a solution of the appropriate aminopyridine (0.15 mol) in dry benzene (80 mL) was added in several portions. The reaction mixture was stirred for 20 h at 75–80°C, after which the solid was separated and washed several times with benzene. The solid was then dissolved in water and 2 N NaOH solution was added to bring the pH to about 14, followed by extraction with benzene, drying over anhydrous sodium sulphate, evaporation, and vacuum distillation under reduced pressure. In some cases further purification was carried out

by tlc. The amount of $POCl_3$ used was larger than that reported by Bredereck (13) and this increased the yield calculated on the amount of tetramethylurea used.

2-Amino, 3-amino, and 4-aminopyridine were commercially availale (Aldrich) and were dried and further purified as necessary.

Picrates of the bases under study were obtained by mixing equimolar amounts of the bases and picric acid in 95% ethanol. This mixture was refluxed for 30 min, cooled to room temperature, and poured into an excess of water. The fine yellow crystals that precipitated were crystallized from ethanol and were dried in a vacuum desiccator. These preparations were carried out on a small scale and the picrates were handled carefully with due regard to the fact that ammonium picrate has been used in the explosive warhead of some naval shells.

The melting points were measured using a Fisher–Johns melting point apparatus and are uncorrected. The ^1H and ^{13}C nmr spectra were run in chloroform-*d*, unless otherwise stated, with TMS as the internal reference, using a Nicolet 360 NMR spectrometer with Fourier transform, at the Atlantic Resonance Centre, Dalhousie University. The mass spectra were recorded on a modified Du Pont CEC model 21-104 mass spectrometer at 70 eV. The ^{13}C nmr signals are reported in the sequence presented on structure I, followed by the signals for substituents on the heterocyclic part of the molecule.



I

2-(2'-Pyridyl)-1,1,3,3-tetramethylguanidine

Yield 38%; bp 110–115°C/0.3 Torr (1 Torr = 133.3 Pa); ^1H nmr δ: 8.2(1H, d, 5.0 Hz), 7.4(1H, t, 6.0 Hz), 6.68(2H, m), 2.7(12H, s); ^{13}C nmr δ: 162.0, 114.7, 137.1, 116.7, 148.4, 163.7, 39.7; ms. (rel. int., %): 193(8), 177(4), 148(61), 78(100). Picrate: mp 148–150°C; ^1H nmr N^+H δ: 10.05(1H, bs).

2-(3'-Pyridyl)-1,1,3,3-tetramethylguanidine

Yield 36%; bp 112–115°C/0.3 Torr; ^1H nmr δ: 8.07(1H, d, 5.0 Hz), 7.99 (1H, s), 7.12 (1H, t, 5.0 Hz), 7.03 (1H, d, 6.0 Hz), 2.8(12H, s); ^{13}C nmr δ: 140.9, 148.1, 128.1, 123.5, 143.7, 160.7, 39.7; ms (rel. int., %): 193(6), 192(46), 177(10), 148(100), 78(25). Picrate: mp 141–144°C; ^1H nmr N^+H δ: 10.00(1H, bs).

2-(4'-Pyridyl)-1,1,3,3-tetramethylguanidine

Yield 30%; bp 118–120°C/0.3 Torr; ^1H nmr δ: 8.15(2H, d, 5.0 Hz), 6.41(2H, d, 5.0 Hz), 2.57(12H, s); ^{13}C nmr δ: 149.9, 116.8, 158.8, 116.8, 149.9, 161.2, 39.7; ms. (rel. int., %): 193(7), 192(37), 177(7), 148(100), 78(26). Picrate: mp 153–155°C; ^1H nmr N^+H δ: 10.41 (1H, s).

2-(5'-Methyl-2'-pyridyl)-1,1,3,3-tetramethylguanidine

Yield 40%; bp 115–120°C/0.3 Torr; ^1H nmr δ: 7.9(1H, d, 2.0 Hz), 7.2(1H, dd, 2 and 8 Hz), 6.6(1H, d, 8 hz), 2.8(12H, s); ^{13}C nmr δ: 161.3, 116.1, 138.0, 123.5, 148.1, 161.6, 39.6, 17.6; ms. (rel. int., %): 206(88), 162(71), 148(100), 119(12), 92(79). Picrate: mp 146–147°C; ^1H nmr N^+H δ: 8.4(1H, bs).

2-(5'-Chloro-2'-pyridyl)-1,1,3,3-tetramethylguanidine

Yield 42%; bp 120–125°C/0.3 Torr; ^1H nmr δ: 8, 9(1H, d, 2 Hz), 7.3(1H, dd, 2 and 8 Hz), 6.6(1H, d, 8 Hz), 2.8(12H, s); ^{13}C nmr δ: 162.0, 117.5, 136.9, 121.8, 146.6, 162.4, 39.7; ms (rel. int., %): 226(65), 182(80), 139(10), 127(43), 112(100), 77(38). Picrate: mp 138–139°C; ^1H nmr N^+H δ: 11.4(1H, bs).

2-(5'-Bromo-2'-pyridyl)-1,1,3,3-tetramethylguanidine

Yield 45%; bp 120–125°C/0.3 Torr; ^1H nmr δ: 8.2(1H, d, 2 Hz), 7.6(1H, dd, 2 and 8 Hz), 6.6 (1H, 8 Hz), 2.8(12H, s); ^{13}C nmr δ: 162.3, 118.2, 139.6, 109.7, 148.9, 162.4, 39.7; ms (rel. int., %): 271(92), 227(97), 211(100), 190(80), 157(95), Picrate: mp 135–136°C; ^1H nmr N^+H δ: 10.7(1H, bs).

2-(5'-Nitro-2'-pyridyl)-1,1,3,3-tetramethylguanidine

Yield 38%; bp 130–138°C/0.3 Torr; ^1H nmr δ: 9.1(1H, d, 2 Hz), 8.2(1H, dd, 2 and 8 Hz), 6.6(1H, d, 8 Hz), 2.8(12H, s); ^{13}C nmr δ: 164.9, 115.5, 132.3, 136.1, 146.6, 167.4, 40.0; ms. (rel. int., %) 237(100), 193(88), 179(99), 147(66), 124(7). Picrate: mp 123–125°C; ^1H nmr N^+H δ: 9.6(1H, bs).

2-(4',6'-Dimethyl-2'-pyridyl)-1,1,3,3-tetramethylguanidine

Yield 45%; bp 118–125°C/0.3 Torr; ^1H nmr δ: 6.3(1H, s), 6.2(1H, s), 2.6(12H, s), 2.3(3H, s), 2.1(3H, s); ^{13}C nmr δ: 161.2, 113.6, 147.8, 115.7, 156.3, 162.6, 39.7, 24.5, 20.8; ms (rel. int., %) 220(82), 176(42), 162(100), 121(36), 106(55). Picrate: mp 141–142°C; ^1H nmr N^+H δ: 8.9(1H, bs).

Tetraethylammonium perchlorate was recrystallized from benzene and dried in a vacuum oven at 60°C.

Acetonitrile was prepared by the method of O'Donnell *et al.* (14), followed by fractional distillation from P_2O_5 and calcium hydride.

The pK_a measurements in acetonitrile solvent were carried out using the potentiometric method of Coetzee and Padmanabhan (2, 15). The H-type cell and the detailed method have been described previously (1).

The pK_a measurements in water were carried out spectrophotometrically using a Cary 219 uv–vis instrument equipped with a thermostated cell, as previously described by Pruszynski (10).

Excess properties for acetylacetone + pentanols systems at 298.15 K

ROQUE RIGGIO,[1] HECTOR E. MARTINEZ, AND NORMA Z. DE SALAS
Facultad de Ciencias Naturales, Universidad Nacional de Salta, Buenos Aires 177, 4400 Salta, Repūblica Argentina

Received October 17, 1991[2]

ROQUE RIGGIO, HECTOR E. MARTINEZ, and NORMA Z. DE SALAS. Can. J. Chem. **70**, 2859 (1992).

From experimental densities, viscosities, and refractive indexes for the acetylacetone + 1-pentanol, + 2-Pentanol, + isoamyl alcohol, and + *tert*-amyl alcohol systems at 298.15 K, the excess molar volumes, excess viscosities, excess molar free energies of activation of flow, and excess internal pressures were calculated over the whole concentration range. Conclusions about the molecular interactions in these mixtures were drawn from the variations of the excess functions with the composition.

ROQUE RIGGIO, HECTOR E. MARTINEZ et NORMA Z. DE SALAS. Can. J. Chem. **70**, 2859 (1992).

Utilisant les densités, les viscosités et les indices de réfractions expérimentaux des systèmes acétylacétone + pentan-1-ol, + pentan-2-ol, + alcool isoamylique et + alcool *tert*-amylique, à 298,15 K, on a calculé les volumes molaires en excès, les viscosités en excès, les énergies libres d'activation molaires en excès de l'écoulement et les pressions internes en excès, pour l'ensemble des concentrations. En se basant sur les variations des fonctions en excès en fonction de la composition, on a pu tirer des conclusions relativement aux interactions moléculaires présentes dans ces mélanges.

Introduction

The excess properties of binary liquid solutions are fundamental for the design of industrial equipment and for the interpretation of the liquid state, particularly when polar–polar liquids are the components of the mixtures. Continuing our study on these types of systems (alcohols + ketones) (1–3) we report here the excess properties: molar volumes (V^E), viscosities (η^E), molar free energies of activation of flow (G^{*E}), and internal pressures (Pi^E), for the following mixtures: (*i*) acetylacetone (AA) + *n*-pentanol (P_1), (*ii*) acetylacetone (AA) + 2-pentanol (P_2), (*iii*) acetylacetone (AA) + isoamyl alcohol (IA), and (*iv*) acetylacetone (AA) + *tert*-amyl alcohol (TAA).

Experimental

Materials

Acetylacetone, *n*-pentanol, 2-pentanol, isoamyl alcohol, and *tert*-amyl alcohol (all Merck Darmstadt p.a.) were dried over anhydrous K_2CO_3 and fractionally distilled under a nitrogen atmosphere. In each case the middle fraction was collected and stored over 0.3 nm molecular sieve for alcohols and 0.4 nm molecular sieve for acetylacetone to prevent water absorption. The mixtures were prepared by mixing accurately weighed quantities of the pure liquids. Caution was taken to prevent evaporation.

Density (ρ)

Densities were determined with an Anton Paar DMA46 calculating density meter with a built-in thermostat. We estimated that the reported densities were accurate to within ± 0.1 kg m^{-3}.

Viscosity (η)

The measurements were carried out with a Cannon–Fenske viscosimeter calibrated with doubly distilled water and benzene (accuracy $\pm 0.5\%$).

Refractive index (n_D)

The refractive indexes of the pure components (sodium D line) were measured with a Jena dipping refractometer with an accuracy of ± 0.00002. For viscosity and refractive index, a thermostatically controlled bath, constant to ± 0.01°C, was used.

[2]Revision received June 26, 1992.

Results

The experimental physical properties of the pure liquids are reported in Table 1, along with the literature values for comparison. Densities, viscosities, and refractive indexes of the binary mixtures can be calculated from the experimental data, knowing the mole fraction, by the following equation:

$$[1] \quad A = x_iA_i + x_jA_j + x_ix_j \sum_{\substack{k=0 \\ i<j}}^{n} a_k(x_i - x_j)^k$$

where A_i and A_j are the properties of the pure components. Table 2 shows the values of the coefficients a_k as well as their standard deviation, calculated by the method of least squares.

The excess functions of the binary systems can be represented by a Redlich–Kister form of the type:

$$[2] \quad X^E = x_ix_j \sum_{k=0}^{n} a_k(2x_i - 1)^k$$

where X^E represents V^E, η^E, G^{*E}, and Pi^E, x_i and x_j the mole fractions of the components *i* and *j*, respectively, and a_k the polynomial coefficients. The least-squares method was used to determine the values of the coefficients. In each case, the optimum number of coefficients was ascertained from an examination of the variation of the standard error of estimate with *n*:

$$[3] \quad \sigma_y = [\Sigma(X^E_{obs} - X^E_{cal})^2/(n_{obs} - n)]^{1/2}$$

where n_{obs} is the number of measurements.

The excess functions were calculated with the following equations:

$$[4] \quad V^E = V - (x_1V_1 + x_2V_2) = [(x_1M_1 + x_2M_2)/\rho] - (x_1V_1 + x_2V_2)$$

$$[5] \quad \eta^E = \eta - \eta^{id} = \eta - \exp(x_1 \ln \eta_1 + x_2 \ln \eta_2)$$

$$[6] \quad G^{*E} = RT[\ln \eta V - (x_1 \ln \eta_1V_1 + x_2 \ln \eta_2V_2)]$$

$$[7] \quad Pi^E = \frac{2^{1/6}RT}{2^{1/6}V - dN^{1/3}V^{2/3}} - \left[x_1 \frac{2^{1/6}RT}{2^{1/6}V_1 - d_1N^{1/3}V_1^{2/3}} + x_2 \frac{2^{1/6}RT}{2^{1/6}V_2 - d_2N^{1/3}V_2^{2/3}}\right]$$

[a]Units: ρ, kg m^{-3}; η, mPa s.

where V and η are the molar volumes and the viscosities of the mixtures; V_1, V_2, η_1, and η_2 are the molar volumes and viscosities of the pure components, respectively; η^{id} is the viscosity of ideal mixture. The excess internal pressures (Pi^E) of the liquid mixture have been obtained (4) by the equation:

$$[8] \quad Pi^E = P_i - (x_1 Pi_1 + x_2 Pi_2)$$

where Pi, Pi_1 and Pi_2 are the internal pressures of the mixture and the pure components, respectively, and can be obtained from the Buchler–Hirschfelder–Curtis equation of state (5):

$$[9] \quad Pi = \frac{2^{1/6}RT}{2^{1/6}V - dN^{1/3}V^{2/3}}$$

N is Avogadro's number and d the molecular diameter of the mixture or the pure components, calculated by following relation (6):

$$[10] \quad d = 2\left[\frac{n_D^2 - 1}{n_D^2 + 2} V \frac{3}{4\pi N}\right]^{1/3}$$

n_D are the refractive indexes of the mixtures or the pure components.

Table 3 shows the values of the coefficients a_k for the excess functions of the binary systems and their standard deviation, calculated by the method of least squares.

Discussion

All the alcohols are considered to be associated substances (7, 8), but when the alcohols are mixed with polar solvents (in our case a ketone), a breakdown of the alcohol's associated structure occurs and specific interactions could be present (9). In this paper, we report the values of the following excess properties: molar volumes (V^E), viscosities (η^E), free energies of viscous flow (G^{*E}), and internal pressures (Pi^E).

For the excess molar volumes, there are two factors that explain the behavior of this property as related to the composition in these mixtures. (*a*) The disruption of the hydrogen-bonded alcohol structure gives rise to a positive contribution to V^E. The positive contribution depends on the dielectric constant of the ketone (10), and on the chain length (11) and the degree of branching in the alcohol (12). (*b*) The fact that the interactions between unlike molecules in all the systems are weaker than the interactions between like molecules also produces a positive contribution to V^E.

Factors that make a negative contribution to V^E are (*a*) the geometrical fitting of the ketone into the remaining alcohol structure (13, 14) and (*b*) unlike specific interactions due to formation of new chemical species in the mixtures.

The excess volumes V^E measured at 298.15 K are plotted vs. composition in Fig. 1. V^E are positive for all systems and we can conclude that in all cases the positive contributions to V^E arise from the breaking of the self-associated alcohol structure with the ketone acting as a diluent. From the analysis of Fig. 1, we observe that V^E's are greater when the said

compounds are mixed with secondary and tertiary alcohols than when mixed with primary alcohols, it being evident from our results that the (OH) alcohol function at the secondary or tertiary carbon and the branched alcohols produces a less negative contribution to V^E on mixing. The typical contributions appearing in these types of systems are due to those

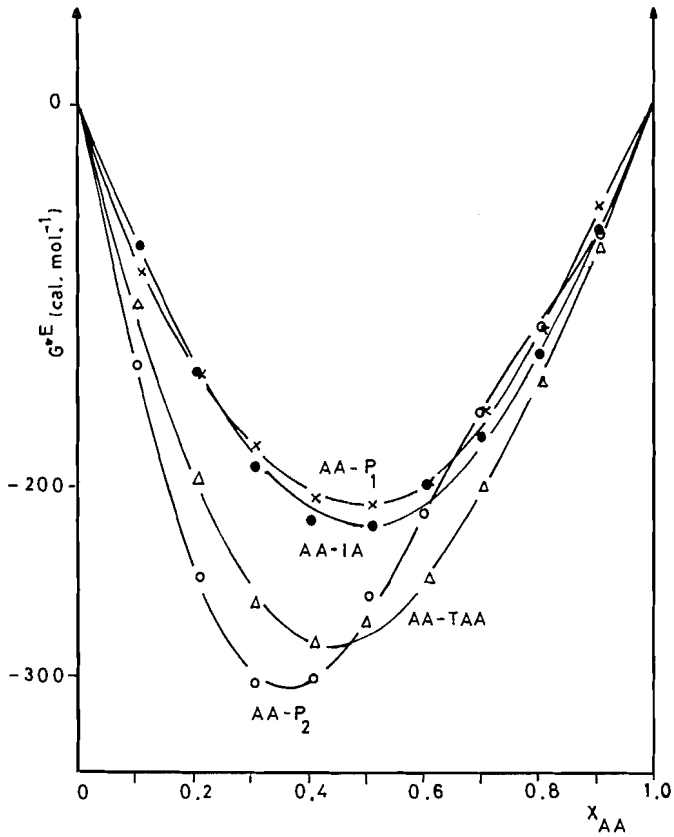

FIG. 3. Molar excess free energies of viscous flow activation by the systems at 298.15 K.

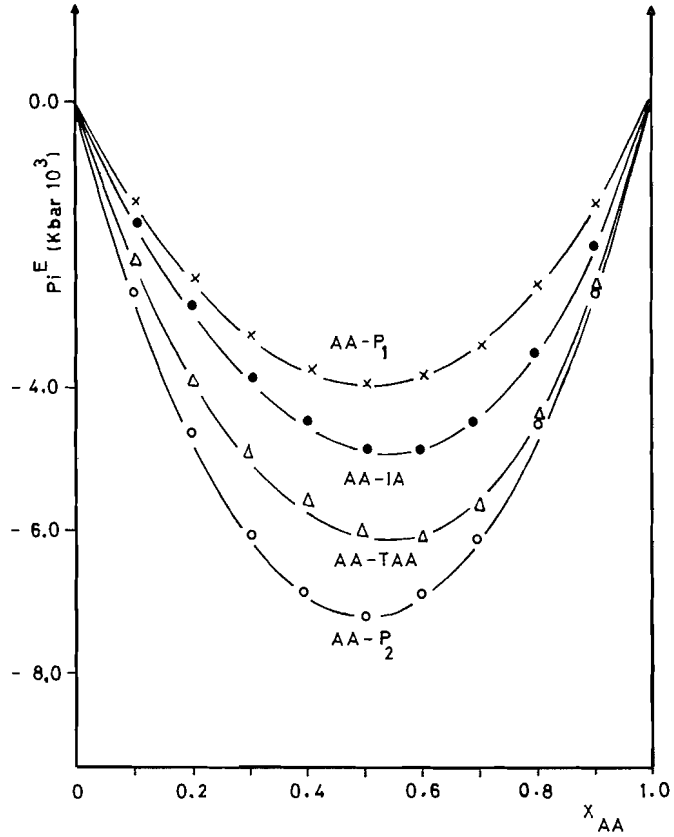

FIG. 4. Excess internal pressures of the systems at 298.15 K.

caused by the dipole–dipole interaction and, on the other hand, that caused by the effect of the self-association of the alcohol. This self-association effect seems to predominate over the former when the alcohol is not primary. The increments for the V^E's, with respect to the negative contribution, are in the following order:

$$AA + P_1 > AA + IA > AA + TAA > AA + P_2$$

which are according to ref. 15.

The smooth representation of the η^E values is presented in Fig. 2 and shows negative values for the excess viscosities for all the systems, which are interpreted in terms of dominant dispersion forces (16). The values obtained for η^E show the following decreasing order:

$$AA + P_1 < AA + IA < AA + TAA < AA + P_2$$

Such an excess function lets us draw conclusions about interactions present in the mixtures. Negative deviations occur when dispersion forces are responsible, according to the order given above, which is in complete agreement with the conclusions reached for the V^E's.

From the analysis of the dependence of G^{*E} upon composition (Fig. 3), we observed an increment of negative deviations in the following order:

$$AA + P_2 < AA + TAA < AA + IA < AA + P_1$$

It is known that the strength of interactions increases as G^{*E} diminishes, and the data obtained indicate that interactions decrease in the given order, in total accord with the conclusions pointed out previously.

Figure 4 shows negative deviations for the Pi^E's over the whole concentration range, for all the systems, in this sequence:

$$AA + P_2 < AA + TAA < AA + IA < AA + P_1$$

The negative values of the Pi^E's indicate in a qualitative way that the repulsion forces are greater than the forces of attraction, on the other hand, positive Pi^E values imply the forces of attraction are greater than those of repulsion. The values obtained for excess internal pressures present good agreement with the Dunlap and Scott (17) prediction that the systems with a positive maximum in the V^E will exhibit a minimum in the Pi^E.

If we compare the V^E and η^E values in this study with those of methylisobutylketone (MIK), already published for the same alcohols (1–3), we conclude: (*a*) V^E for the mixtures with MIK are less positive than V^E for the mixtures with AA; (*b*) η^E for the mixtures with MIK are less negative than the η^E for the mixtures with AA. This shows that more interaction exists between the alcohols and MIK than with AA. In principle, three types of interactions appear when mixing an alcohol + AA. These are (*a*) keto–enol, (*b*) keto–alcohol, and (*c*) enol–alcohol effects. The more predominant effects in our systems are the keto–enol interactions.

Solubility measurements and determination of Setschenow constants for the pesticide carbaryl in seawater and other electrolyte solutions

MIGUEL ANGEL HUERTA-DIAZ[1] AND SILVIO RODRIGUEZ
Department of Chemistry, University of the Pacific, Stockton, CA 95211, U.S.A.

Received February 21, 1992

MIGUEL ANGEL HUERTA-DIAZ and SILVIO RODRIGUEZ. Can. J. Chem. **70**, 2864 (1992).

Accurate solubility measurements covering the range 278–318 K were obtained for the carbamate pesticide carbaryl (1-naphthyl-*N*-methylcarbamate) in water, natural and artificial seawater, and NaCl, Na_2SO_4, $CaCl_2$, and $(CH_3)_4NBr$ electrolyte solutions. Carbaryl solubilities were determined using a combination of a generator column method and spectrophotometric techniques. In all cases the solubility of carbaryl in water and in the electrolyte solutions increased with an increase in temperature. The salt effect on the pesticide solubility as a function of temperature was obtained by calculating the Setschenow constants for each one of the electrolyte solutions. Salting-out was observed in solutions prepared with NaCl, Na_2SO_4, and $CaCl_2$ as well as in natural and artificial seawater, whereas salting-in was observed with $(CH_3)_4NBr$ solutions.

MIGUEL ANGEL HUERTA-DIAZ et SILVIO RODRIGUEZ. Can. J. Chem. **70**, 2864 (1992).

Opérant à des températures allant de 278 à 318 K, on a déterminé avec précision la solubilité du carbaryl (1-naphtyl-*N*-méthylcarbamate), un pesticide de la famille des carbamates, dans l'eau, dans des eaux de mer naturelle et artificielle et dans des solutions de NaCl, de Na_2SO_4, de $CaCl_2$ et de $(CH_3)_4NBr$ agissant comme électrolytes. On a déterminé les solubilités du carbaryl en utilisant une combinaison d'une méthode de colonne génératrice et de techniques spectrophotométriques. Dans tous les cas, la solubilité du carbaryl dans l'eau et dans les solutions d'électrolytes augmente avec une augmentation de la température. On a déterminé l'effet de sel sur la solubilité du pesticide en fonction de la température en calculant les constantes de Setschenow pour chacune des solutions d'électrolytes. On a observé un relargage dans les solutions préparées avec du NaCl, du Na_2SO_4 et du $CaCl_2$ ainsi qu'avec les eaux de mers naturelle et artificielle; l'inverse a été observé avec les solutions de $(CH_3)_4NBr$.

[Traduit par la rédaction]

Introduction

The extent to which aquatic biota are exposed to a toxicant such as a pesticide is largely controlled by its aqueous solubility (1). Solubility measurements can also be used to predict or extrapolate such parameters as transfer coefficients from residence in soils into runoff and ground water, systemic penetration into aqueous tissues, and distributions from formulations into aqueous spray carriers (2). In addition, solubilities are of thermodynamic interest since they can provide information fundamental in understanding hydrophobic interactions and in calculating the transfer properties of solutes between various solvents.

Since most pesticides are organic compounds of low molecular weight they show a hydrophobic character, having water solubilities in the ppm or even ppb range (3). Solubility measurements can be affected either by the temperature or by the ionic strength of the dissolving medium. Hence, the presence of a third component such as an electrolyte may substantially change the solubility of nonpolar molecules. This is the case of the salting-out effect of sodium chloride and other salts present in seawater (1). The magnitude of this effect can be calculated by using the empirical relationship developed by Setschenow (4)

$$[1] \quad \log(S_0) - \log(S) = k_S C_e$$

where k_S is the Setschenow constant, and S_0 and S represent the solubilities in mol kg^{-1} of the nonelectrolyte in water and in the electrolyte solution of concentration C_e, respectively. A positive value for k_S indicates salting-out and a negative one indicates salting-in.

Salt effect studies provide considerable information of theoretical importance concerning the complex interactions of ions and neutral molecules and the unique nature of water as a solvent. Additionally, knowledge of salting-out effects can have practical applications on the separation of nonelectrolytes from water solutions (5).

Carbaryl, the common name for the carbamate pesticide 1-naphthyl-*N*-methylcarbamate, is a white crystalline solid soluble in most polar solvents (6). It was introduced in 1956 under the trade name "Sevin" and since then its toxicity (refs. 7–11) as well as its physicochemistry (refs. 12–20) has been documented by several researchers. Carbaryl is currently used as a preharvest pesticide for the protection of fruits, vegetables, and field crops and is one of the most widely used carbamate insecticides (21). Carbaryl has also been employed in the aquatic environment to control the pests and predators of oysters (e.g., starfish, oyster drills (6)). However, some deleterious secondary effects have been observed. For example, Brown (22) noted that concentrations as low as 1 ppb of carbaryl could inhibit the development of clam eggs. Other studies (23) have indicated that carbaryl may be teratogenic. It is thus important to have reliable information on the solubility of this pesticide in natural water systems in order to make a proper assessment of its toxic implications for the aquatic fauna and the environment.

This paper reports solubility data of the pesticide carbaryl in water, natural and artificial seawater, and in solutions prepared with the major seawater salt components NaCl, Na_2SO_4, and $CaCl_2$. In addition, the quaternary salt $(CH_3)_4NBr$ (tetramethylammonium bromide) was utilized to investigate the salting-in effects of this compound on the solubility of carbaryl. All solubilities were measured as a function of temperature and electrolyte concentration and

were subsequently used to evaluate salt-induced effects through the calculation of Setschenow constants.

Experimental

All reagents used were analytical grade or better and were used as received without further purification. Carbaryl was obtained from Chem Service as an analytical standard. All solutions were prepared with deionized water distilled in an all-glass still with a dissolved organic carbon content of <0.2 ppm (<0.02 μmol mL^{-1}). Natural seawater was IAPSO standard seawater (Institute of Oceanographic Sciences, Surrey, England) with a stated chlorinity of 19.3770‰. Artificial seawater was prepared according to the recipe given by Kester *et al.* (24). The maximum electrolyte concentrations utilized were selected based on their abundance in natural seawater.

The concentration of carbaryl in the different solutions was determined spectrophotometrically using a Varian model Cary 219 UV–VIS spectrophotometer equipped with a double beam, with a nominal slit of 0.5 nm and a special attachment to the cell holder that allowed the use of a thermoregulated bath. All measurements were made using 1-m matched quartz cells. Temperature measurements were done with a digital telethermometer (Bailey, model BAT-12) with a resolution of 0.1°C.

The solubilities of carbaryl at different temperatures in water and in electrolyte solutions of varying concentrations were measured using the method developed by May *et al.* (25, 26). This method has successfully been used by other researchers (1, 27–31) and, briefly, it consists in the generation of saturated solutions of nonelectrolytes produced by passing the solution acting as solvent through a column packed with glass beads previously covered with the nonelectrolyte. In this way the surface area is greatly increased and the time necessary for reaching saturation is decreased substantially.

For our analyses 4.0 g of carbaryl were dissolved with approximately 200 mL of methylene chloride. The resulting solution was then mixed with 100 g of glass beads 60–80 mesh and rotoevaporated to dryness. The beads were then packed into a 100-cm^3 Allihn condenser with a water jacket 300 mm in length. The condenser was connected to a thermoregulated circulating bath (Lauda, model B-1) with an operating range of 30–100°C and an accuracy of 0.03°C. An immersion cooler (Neslab, Cryocool model CC-60II) was used to lower the temperature of the circulating water below 30°C. Water or electrolyte solutions were pumped through the column at an estimated flow rate of 2 mL min^{-1}.

Each new column was initially conditioned by passing 500 mL of distilled water at 50°C. After this initial step the column could be reset to any desired temperature and solutions could be passed through and collected in the quartz cell for measurement. It was found by experience that after this initial equilibration step 100 mL of each new solution had to be pumped through before collecting the first sample. Each time a new temperature was set, 30–35 mL of the solution had to be passed through the column before taking a sample for analysis.

Results

Carbaryl shows two distinct peaks in the absorbance spectrum, one at 269 nm and the maximum at 279 nm. Values for the solubility concentrations were obtained by constructing a standard calibration curve (linear up to 0.5 μmol kg^{-1}) and reading at 279 nm. These values were corrected for temperature-induced volume changes by using the equation developed by Lo Surdo *et al.* (32). The estimated standard error ($\sigma \times 10^{-6}$) of this equation over the molality range zero to saturation and temperature range 273–323 K are 20.3 and 14.8 for NaCl and Na_2SO_4, respectively. In the special case of $CaCl_2$ and $(CH_3)_4NBr$, for which no high-accuracy density data as a function of temperature are available, the correction factors used were the same as those used for Na_2SO_4. This assumption seems supported by the findings of Ikono (33), who showed that the difference in density between two 0.5 molal solutions, one of $MgCl_2$ and the other of $CaCl_2$, was less than 0.6% in the temperature range 15–45°C, and this difference was even smaller for more dilute solutions. Furthermore, the magnitude of the correction in all our data in no case exceeded 0.8% of the value. Similar corrections were made for seawater (SW) and artificial seawater (ASW) following the equations developed by Leyendekkers (34).

Table 1. Solubility of carbaryl in water between 278 and 318 K

T (K)	$S \times 10^4$ (mol kg^{-1})
278	2.71 ± 0.08
283	3.15 ± 0.09
288	3.74 ± 0.11
293	4.45 ± 0.13
298	5.21 ± 0.18
303	6.52 ± 0.19
308	7.86 ± 0.24
313	8.99 ± 0.27
318	10.06 ± 0.31

Salinity of standard seawater was calculated using the equation recommended by UNESCO (35). The "molality" m_s of seawater, defined as the sum of the molalities of each one of the electrolyte components, was calculated using the equation (34):

$$[2] \quad m_s = \frac{S'}{M' - 10^{-3} M'S}$$

where S' stands for salinity and M' can be considered as the "corrected" molecular mass of sea salt. For convenience, seawater can be considered as a solution constituted of different electrolytes according to a specific "recipe." In this work, the recipe chosen for ASW was the one developed by Kester *et al.* (24) in which $M' = 68.08$ g "mol^{-1}."

All solubilities represent the mean of at least three measurements for each temperature, with the estimated experimental error expressed as one standard deviation. Error propagation methods (36) were used throughout this work along with the usual standard statistical techniques.

Table 1 shows that, as expected, the solubility values obtained for carbaryl in water increased with temperature from $(2.71 \pm 0.08) \times 10^{-4}$ mol kg^{-1} at 278 K to $(10.06 \pm 0.31) \times 10^{-4}$ mol kg^{-1} at 318 K. Solubility values at different temperatures taken from the literature (37–41) show a wide range of values, probably reflecting the lack of reliable solubility data for this pesticide. Swann *et al.* (41), who used the same generator column method, obtained a value of 82.6 ppm at 298 K. The difference between their value and the corresponding solubility determined in this work ($5.21 \times 10^{-4} \approx$ 105 ppm) might be attributed to the different amounts of glass beads and pesticide used in each experiment. During the course of this work it was observed that the carbaryl concentration values increased each time larger amounts of glass beads and pesticide were used. This trend continued up to a

certain point at which further increases in their respective amounts did not change the solubility values obtained. Furthermore, concentrations similar to those reported by Swann *et al.* (41), within experimental error, were obtained each time their glass beads/pesticide ratio was used.

Tables 2–4 show the solubilities of carbaryl as a function of temperature and electrolyte concentration for the solutions made of NaCl, $(CH_3)_4NBr$, Na_2SO_4, $CaCl_2$ and for natural and artificial seawater. As a rule, carbaryl solubilities increased with increasing temperature and decreased with increasing electrolyte concentration. Only the tetramethylammonium bromide solutions showed an increase in carbaryl solublity with increasing electrolyte concentration (Table 2). These results were as expected since the solubility of nonelectrolytes in water is generally reduced by common inorganic salts, whereas the tetramethylammonium salts often have the opposite effect.

To measure the magnitude of the salting-in or the salting-out effect of the different electrolytes, the Setschenow constants (k_S) were calculated by fitting the different solubilities to eq. [1] using least squares. The results as a function of temperature are given in Figs. 1*a*–1*e*. As expected, the values of the Setschenow constant for carbaryl were positive in all the electrolyte solutions except in tetramethylammonium bromide where salting-in was observed.

The Setschenow constants for NaCl (Fig. 1*a*) generally decreased with increasing temperature. Similar results but opposite in trend were obtained for the salting-in of carbaryl in tetramethylammonium bromide as shown in Fig. 1*d*. The k_S values for sodium sulfate and tetramethylammonium bromide (Figs. 1*b* and 1*d*) remained essentially constant throughout the temperature range considered. Calcium chloride values for k_S (Fig. 1*c*) showed a maximum at 288

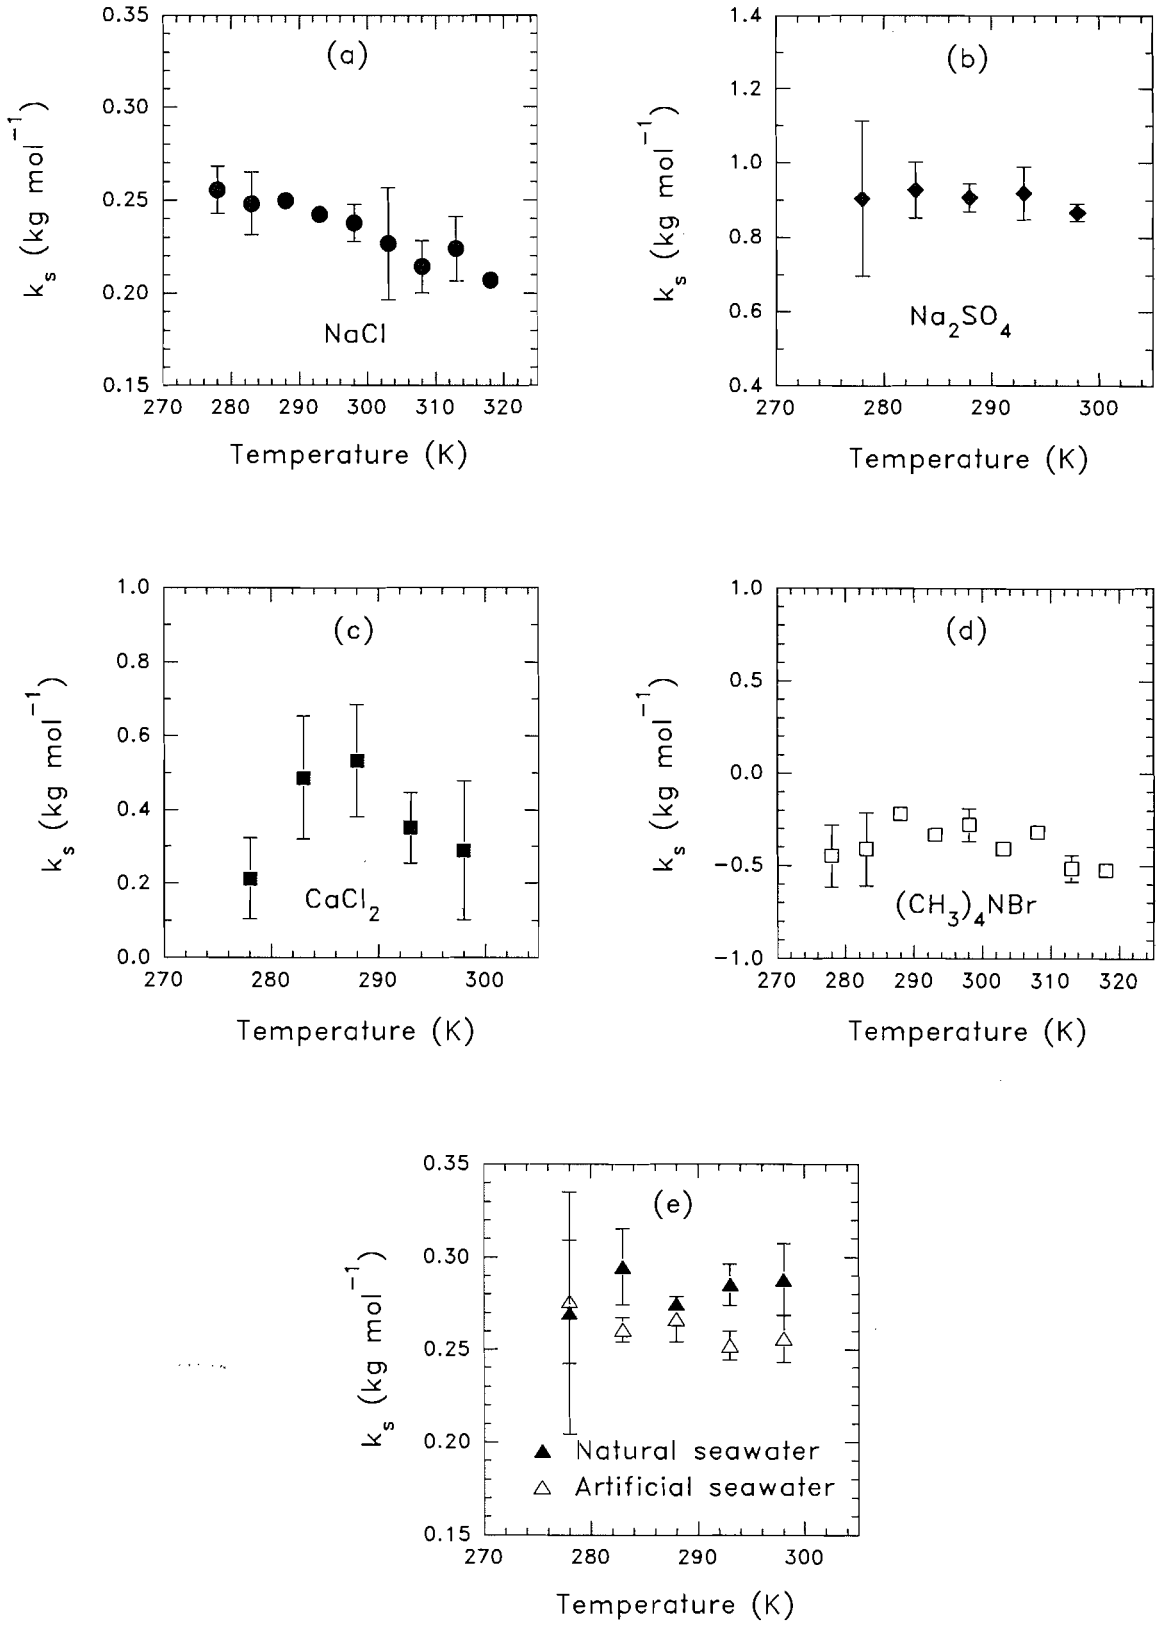

FIG. 1. Setschenow constants (k_S) as a function of temperature for (*a*) sodium chloride, (*b*) sodium sulfate, (*c*) calcium chloride, (*d*) tetramethylammonium bromide, and (*e*) natural and artificial seawater. Error bars correspond to ± (one standard deviation).

K but no conclusion can be reached due to the high uncertainty associated with each value.

As shown in Fig. 1*e*, the Setschenow constants for natural and artificial seawater were approximately constant for the measured temperature range (average of 0.282 ± 0.010 and 0.262 ± 0.009 kg mol^{-1}, respectively). They were also

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

similar to those obtained for sodium chloride (average of 0.247 ± 0.007 kg mol^{-1}), the dominant ionic species in seawater, although the trend of the values is somewhat different, reflecting perhaps the combined contributions of the other major constituents of seawater. Setschenow constants in natural and artificial seawater were determined in order to find if there was any effect due to organic matter that might be present in natural seawater. Considering the experimental uncertainty of the individual k_S values, the observed difference between the temperature variation of the Setschenow constant in natural and artificial seawater (Fig. 1*e*) was not clearly established.

Conclusions

Accurate solubility measurements for carbaryl in water, seawater, and different electrolyte solutions were obtained using a generator column system. This method was demonstrated to be a simple, reliable, and reproducible method for determining solubilities of nonpolar molecules like the pesticide carbaryl.

Setschenow parameters of carbaryl were measured as a function of temperature for several salts. We found that generally an increase in temperature decreased the k_S values for sodium chloride solutions and remained essentially constant for sodium sulfate, tetramethylammonium bromide, and natural and artificial seawater. General trends in the Setschenow constants for calcium chloride solutions were not clear due to the high uncertainty associated with each value.

Because sodium chloride is the dominant ionic species in seawater, we would expect a decrease in the solubility of the pesticide carbaryl (and other similar toxic compounds) once it reaches more saline, carbonate-enriched waters like coastal areas. However, this effect could be neutralized in organic-enriched natural waters or waters in which highly polarizable compounds, similar to $(CH_3)_4NBr$ (e.g., borates) are present. To have a better understanding of the behavior of pesticides in our environment more research must be done on this subject.

A physicochemical study on organic eutectics and addition compound; benzidine–pyrogallol system

U. S. Rai and Santhi George

Chemistry Department, Banaras Hindu University, Varanasi - 221 005, U.P. India

Received July 8, 1991[1]

U. S. Rai and Santhi George. Can J. Chem. **70**, 2869 (1992).

The phase diagrams of the binary organic system of benzidine–pyrogallol was determined by the thaw–melt method. The solidification behaviour of the pure components, their eutectics, and the addition compound were studied by measuring the movement of growth front in a capillary. From the data on X-ray diffraction, thermal and microscopic investigations it can be inferred that the eutectics are not simple mechanical mixtures of the components involved. The IR and NMR spectral investigations were carried out to throw light on the nature of bonding between the two components forming the addition compound.

U. S. Rai et Santhi George. Can. J. Chem. **70**, 2869 (1992).

Faisant appel à la méthode de fusion, on a déterminé les diagrammes de phase du système organique binaire benzidine/pyrogallol. En mesurant le mouvement de croissance du front dans la capillaire, on a étudié le comportement lors de leur solidification des composants purs, de leurs eutectiques et de leur composé d'addition. En se basant sur des études thermiques, microscopiques et de diffraction des rayons X, on peut déduire que les eutectiques ne sont pas de simples mélanges des composants impliqués. Des études par spectroscopies IR et RMN ont été entreprises afin de faire la lumière sur la nature des liaisons entre les deux composants formant le composé d'addition.

[Traduit par la rédaction]

1. Introduction

The past decade has witnessed (1–6) an immense activity both in the fundamental understanding of the solidification and properties of polyphase alloys and in the technological developments of *in situ* composites for particular applications. Owing to the low transformation temperature, ease in purification, transparency, minimised convection effects and wider choice of materials, the organic systems (7–12) are being used as model systems for a detailed investigation of the parameters which control solidification, which in turn, govern the properties of materials. As the organic eutectics and the molecular complexes are analogues of metal eutectics and intermetallic compounds, respectively, a systematic physicochemical study of a model system involving organic compounds may be of potential importance in unravelling the mysteries of solidification, bonding, and microstructure, among others. In view of this, a binary organic system involving benzidine (BZ) and pyrogallol (PG) has been chosen to study its phase diagram, linear velocity of crystallization, thermochemistry, microstructure, X-ray diffraction, and spectral behaviour.

2. Experimental

2.1 Materials and purification

AR grade benzidine (CDH, India) was directly used in the present investigation. Pyrogallol (S.d. Fine-Chem Pvt Ltd., India) was purified by repeated distillation under reduced pressure and was stored in a coloured bottle to avoid exposure to light. The melting point of each compound (benzidine, 127°C and pyrogallol, 134°C) was compared with its literature value (benzidine, 128°C and pyrogallol, 134°C) to assess its purity.

2.2 Phase diagram

The phase diagram of the benzidine–pyrogallol system was determined by the thaw–melt method (13, 14). In this method, mixtures of two components covering the entire range of composition were prepared in different long-necked test tubes. These mixtures were homogenized by melting in silicone oil followed by chilling in ice. Their thaw and melting temperatures were determined using a Toshniwal melting point apparatus equipped with a precision thermometer which could read correctly up to ±0.5°C.

2.3 Linear velocity of crystallization

The linear velocity of crystallization data for the pure components, the eutectics, and the addition compound were determined (15, 16) at different undercooling temperatures by measuring the movement of the solid-liquid interface in the capillary tube of 15 cm length and 0.5 cm inner diameter.

2.4 Heat of fusion

Heats of fusion of the pure components, the eutectics, and the addition compound were determined (17) by using a Dupont-9900 thermal analysis DSC apparatus.

2.5 Microstructure

Microstructures of the eutectics and the addition compound were recorded (18, 19) by placing the slide containing unidirectionally solidified sample on the platform of a Leitz Labourlux D optical microscope attached with a camera.

2.6 X-ray diffraction

X-ray diffraction patterns of the pure components, the eutectics, and the addition compound were recorded (20, 21) on a computerized X-ray diffraction unit, PW 1710 model, using CuK_α radiation.

2.7 Spectral studies

Infrared spectra of the pure components, the eutectics, and the addition compound were recorded (22) in the region 4000–625 cm^{-1} in Nujol mull using a Perkin-Elmer 783 infrared spectrometer. $CDCl_3$ was used as a solvent for recording the PMR spectra on Jeol FX 90 Q Fourier Transform NMR spectrometer.

3. Results and discussion

3.1 Phase diagram

The solid–liquid equilibrium data on the BZ–PG system are given in Fig. 1 in the form of a temperature–composition curve. The plot shows the formation of a 1:1 addition compound with congruent melting point surrounded by two eutectics E_1 and E_2, containing 0.902 and 0.139 mole fractions of benzidine, respectively. The melting point of pure benzidine is 127.0°C and it decreases continuously with the

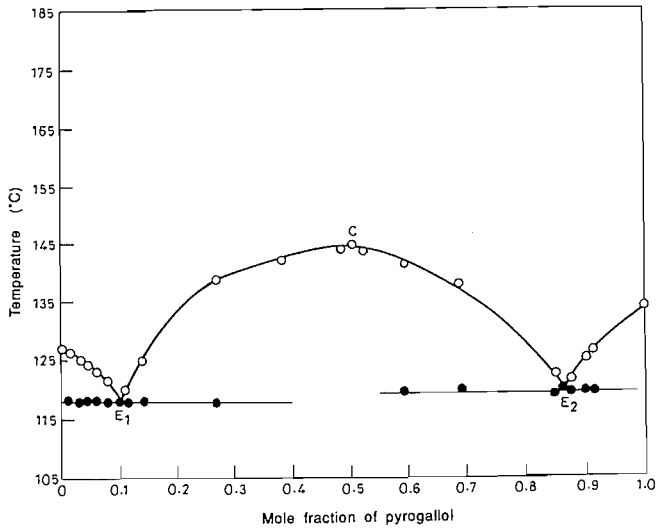

FIG. 1. Phase diagram of the benzidine–pyrogallol system. ○, Melting temperature; ●, thaw temperature.

addition of pyrogallol and attains a minimum at E_1 (118.0°C). With continued addition of pyrogallol the melting point rises to a maximum of 145.0°C at C after which it decreases to a minimum of 120.5°C at E_2. At point C the solid and the corresponding liquid have identical composition. This phase diagram may be viewed as consisting of two simple eutectic type phase diagrams placed side-by-side. The flatness in the maximum at C suggests that the addition compound is dissociated (23, 24) in the molten state.

3.2 Linear velocity of crystallization

According to Hillig and Turnbull (25), the linear velocity of crystallization (v) of each of the pure components, the eutectics, and the addition compound is related to the undercooling (T) by the equation

$$[1] \quad v = u(\Delta T)^n$$

where u and n are constants. The constants u and n are calculated from the linear plots (Fig. 2) of log v versus log ΔT and the values are reported in Table 1. It is evident from the table that most of the n values are close to 2, thereby suggesting a square relationship between v and ΔT. However, the deviations in the values of n from 2, observed in some cases, may be due to the difference in the bath temperature and the temperature of the growing interface. In the present investigation, both components have a high enthalpy of fusion, consequently each crystallization step results in a release of heat causing the interface to attain a higher temperature than the bath.

From the values of u (Table 1) for the pure components and the addition compound, it can be inferred that the crystallization rate of the addition compound of the BZ–PG system is less than that of the parent components. Studies on the crystal morphology of the addition compounds indicate that they crystallize as a definite chemical entity. However, during crystallization, the two components of the melt have to enter the crystal lattice simultaneously in such a way that the composition of the melt conforms to the respective molar ratios of the components. Thus the linear velocity of crystallization of the addition compound may be expected to be of the order of the growth velocity of the species crystallizing with the lower rate. The value of u for E_1 (formed between benzidine and the addition compound) is higher than that of either component while for E_2 (formed between the addition compound and pyrogallol) it lies between the corresponding components. These results may be explained on the basis of the mechanism proposed by Winegard *et al.* (26) and substantiated by others. Accordingly, the solidification of both the eutectics of BZ–PG system takes place by the side-by-side growth of the two components. In the eutectics under investigation the addition compound behaves as one of the components, and its melting point is higher than those of the components it nucleates first.

Eutectic-2	0.006918	1.50
1:1 Addition compound	0.000005	3.33

3.3 Thermochemical studies

One may get an idea on the mode of crystallization, structure of eutectic melt, and the nature of interaction between two components forming the eutectics and the addition compound from their heats of fusion. For the purpose of comparison, the experimental and calculated values of heat of fusion for the eutectics are reported in Table 2. It is evident from the data in the table that the calculated (27) values of the heat of fusion are higher than the experimental

values. If an eutectic is a simple mechanical mixture of two components involving no heat of mixing or any type of association in the melt, the heat of fusion will be simply given by the mixture law (19). However, when a solid eutectic melts there is considerable likelihood of association and mixing, both causing violation of the mixture law. The difference between the experimental and calculated values can be attributed to the formation of clusters in the eutectic melt. In the present eutectic system where one component has an $—NH_2$ group and the other contains an —OH group, both the end members have a tendency for hydrogen bond formation, resulting in a favourable condition for cluster (28) formation in the melt. The values of heat of mixing (29) (ΔH_m), which is the difference between the experimental and calculated values of the heat of fusion, were calculated for both eutectics and the data are reported in Table 2. It is clear that the values are highly negative. According to thermochemical studies (13) the structure of the eutectic melt depends on the sign and magnitude of the enthalpy of mixing. Three types of structures are suggested; quasieutectic $\Delta H_m > 0$, clustering of molecules for $\Delta H_m < 0$, and molecular solution for $\Delta H_m = 0$. The negative values of ΔH_m for the eutectics of the BZ–PG system suggest clustering of molecules in the eutectic melt. To see a small value of heat of mixing in the case of E_2 of the system, one might be tempted to consider the formation (30) of a molecular solution instead of a weak interaction. It may be noted that this system is quite different from simple eutectic systems where merely ordering of the parent phases has been suggested in the melts. It seems that there is considerable enhancement in the interactions due to the presence of molecular complex in the melt.

The experimental values of the heat of fusion of the addition compound determined by the DSC method are reported in Table 2. Its theoretical value was calculated by a method reported earlier (28). It is evident from Table 2 that the heat of mixing is highly negative. This suggests (30) that the presence of an addition compound enhances the attraction among the components. The association is also favoured by the presence of hydroxyl and amino groups in the components.

The deviation from ideal behaviour can best be expressed in terms of excess thermodynamic functions which give more quantitative ideas about the nature of the molecular interactions. It is defined as the difference between the thermodynamic function of mixing for a real system and the corresponding value for an ideal system at the same temperature and pressure. To understand the nature of interaction between two components forming the eutectics, some thermodynamic functions such as excess free energy (g^E), excess enthalpy (h^E) and excess entropy (S^E) were calculated by a method reported earlier (27). The positive g^E values (Table 3) suggest (31) that the interaction between like molecules is stronger than that between unlike molecules. The values of h^E and s^E correspond to the excess free energy and are a measure of the excess enthalpy of mixing and excess entropy of mixing, respectively.

TABLE 3. Excess thermodynamic functions for benzidine–pyrogallol system

Material	g^E (J mol^{-1})	h^E (J mol^{-1})	S^E (J mol^{-1} K^{-1})
Eutectic-1	580.02	1201.28	1.62
Eutectic-2	712.32	4383.36	9.34

3.4 Microstructure

It is well known that in a polyphase material the microstructure provides data on the size, shape and orientation of the grains in addition to the distribution of the phases involved. The arrangement of grains and phases in a material controls its mechanical properties and decides its various applications. The shape (32) that a crystal adopts in the melt subsequent to nucleation is controlled by the way in which atoms molecules are added onto the solid, which in turn is determined by the atomic/molecular structure of the solid–liquid interface. However, the interface structure depends upon the chemical character of the material in question and also upon the thermal environments in which the crystal is growing. For a material with entropy of fusion less than $2R$ (where R is the gas constant), the interface which is about 50% populated is atomically rough and results in non-faceted growth. On the other hand, for a material with entropy of fusion greater than $2R$, the interface is perfect with a few atoms missing from it, and results in faceted growth. In the present investigation, the pure components have their entropy of fusion greater than $2R$, thereby resulting in faceted growth. The morphology of eutectics developed in each case is influenced by the entropy of fusion of the phases involved. The microstructures of the eutectics under investi-

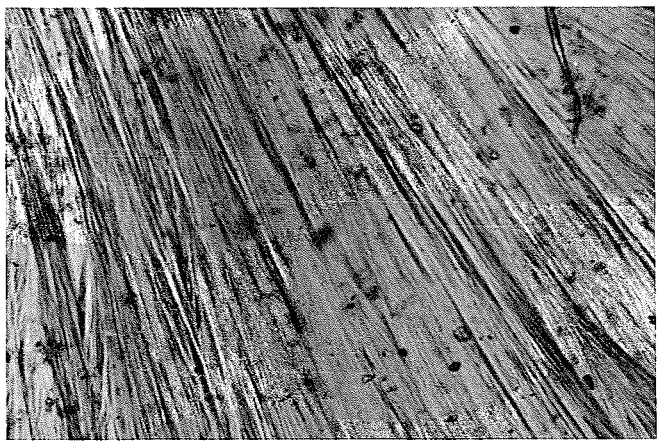

FIG. 3. Microstructure of the benzidine–pyrogallol eutectic (E_1) × 100.

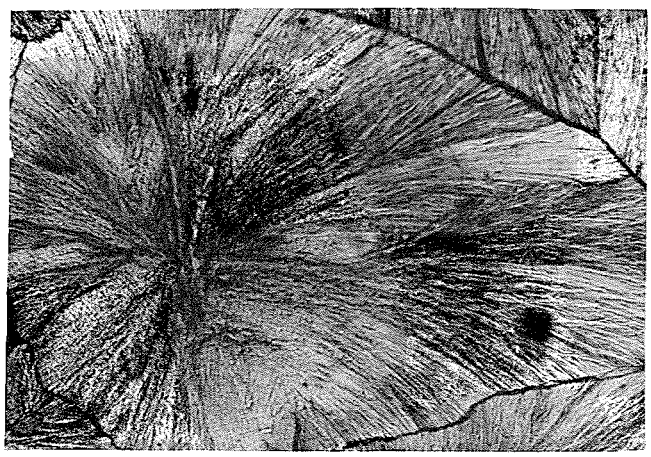

FIG. 4. Microstructure of the benzidine–pyrogallol eutectic (E_2) × 100.

gation are given in Figs. 3 and 4. While the eutectics E_1 of the BZ–PG system given in Fig. 3 shows lamellar growth, the second eutectic E_2 (Fig. 4) of this system indicates that one of the phases nucleates first and the other phase radiates outward perpendicularly. The microstructure of the addition compound (Fig. 5) shows faceted growth like pure components.

3.5 X-ray diffraction

A critical scanning of the current literature (19) reveals that there are two conflicting ideas about the nature and bonding in eutectics. While one group of workers believes that a binary eutectic is a mixture of two kinds of crystals, favourably oriented with respect to each other, the other group is of the opinion that the eutectic grains do not exhibit a fixed orientational relationship. To clarify this, the X-ray diffraction patterns of the pure components, the eutectics, and the addition compounds were recorded and the results are reported in Tables 4 and 5. It is evident from the reported data that the number of reflections of pure components and the addition compounds is comparable with the number of reflections of their corresponding eutectics. It can be inferred from this observation that they belong to the same crystal system and have similar lattices. It is evident from the results reported in Table 4 that for the BZ–PG system strong reflections of benzidine and the addition compound are either absent in the eutectic E_1 or show a variation of intensity. Accordingly, reflections of benzidine and *d* values 4.82, 4.45, 3.12 Å show an increase in intensity and those at 4.23, 3.83, and 3.35 Å show a decrease in intensity in the eutectic E_1. Similarly, reflections of the addition compound at *d* values 5.25, 4.47, 4.35, 3.94, 3.84, 3.30, and 3.14 Å show a decrease in intensity and those at *d* values 4.58, 3.53, and 3.10 Å show an increase in intensity in the eutectic E_1.

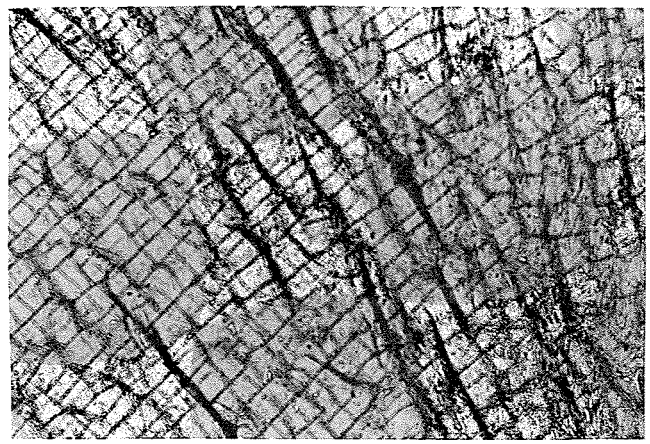

FIG. 5. Microstructure of the benzidine–pyrogallol addition compound (A) × 100.

The X-ray patterns of the two components should be exactly superimposed on the eutectic composite if a eutectic is a simple mechanical mixture of two components. From the diffraction data on the pure components, the eutectics, and the addition compound, it can be inferred that there is a marked difference in the interplanar distance and the relative intensity. The variation in relative intensity of the reflections of pure components in the eutectics and the absence of reflections of pure components in eutectics and those of eutectics in pure components suggest that the eutectics are not simply a mechanical mixture of two components. There is orientation of some atomic planes during the formation of the eutectics.

3.6 Spectral studies

The IR spectrum of benzidine in Nujol shows three bands at (*i*) 3190, (*ii*) 3320, and (*iii*) 3400 cm^{-1} due to NH stretching vibrations. The IR spectrum of the pyrogallol in Nujol exhibits four bands at (*i*) 3280, (*ii*) 3250, (*iii*) 3380, and (*iv*) 3480 cm^{-1} due to OH stretching vibration in the compound. The addition compound gives four peaks: (*i*) 3300, (*ii*) 3355, (*iii*) 3380, and (*iv*) 3485 cm^{-1}. This may be attributed to the merging of a peak of benzidine at 3190 cm^{-1} and that of pyrogallol at 3280 cm^{-1} resulting a new peak at 3300 cm^{-1} in the addition compound because of intermolecular interaction between the two components. However, no definite conclusion can be drawn from the IR data. The proton NMR spectrum of benzidine shows a peak at δ 3.52 due to NH proton, and the ring protons are obtained as multiplets in the range δ 6.48 – δ 7.37. Pyrogallol gives a proton signal at δ 1.6. The molecular complex of the BZ–PG system gives a broad band in the range δ 1.58 – δ 1.14 and shows the disappearance of the OH proton signal which may

Vibrational spectroscopic study of the interaction of metal ions with diethyl phosphate, a model for biological systems

JANUSZ STANGRET[1] AND RODRIGUE SAVOIE[2]
Department of Chemistry, Laval University, Québec (Qué.), Canada G1K 7P4

Received June 3, 1991

JANUSZ STANGRET and RODRIGUE SAVOIE. Can. J. Chem. **70**, 2875 (1992).

We have studied, using Raman and infrared spectroscopy, the interaction of various monovalent, divalent, and trivalent metal cations with the PO_2^- group of diethyl phosphate in aqueous solution, at metal:phosphate ratios ranging from 1:40 to 6:1. The results show that the metal cations interact with the phosphate groups in various ways and to different extents. Spectral characteristics for some specific types of interactions are presented, namely, for direct metal binding by one of the oxygen atoms in the PO_2^- group, the formation of water-separated ion pairs, and non-specific electrostatic interactions.

JANUSZ STANGRET et RODRIGUE SAVOIE. Can. J. Chem. **70**, 2875 (1992).

Nous avons étudié par spectroscopie Raman et infrarouge l'interaction de divers cations métalliques monovalents, divalents et trivalents avec le groupe chargé PO_2^- du phosphate de diéthyle en solution aqueuse, à des rapports métal : phosphate variant de 1 : 40 à 6 : 1. Les résultats démontrent que les ions se distinguent tant par leur affinité pour le groupement phosphate que par leur façon d'interagir avec celui-ci. On présente diverses caractéristiques spectrales permettant d'identifier certains types d'interaction, notamment la fixation directe par l'un des atomes d'oxygène du groupement phosphate, la formation de paires d'ions séparées par molécules d'eau et les interactions non spécifiques de nature électrostatique.

Introduction

Phosphate groups are of prime importance in biological systems, as they are present in major classes of compounds, such as nucleic acids, phospholipids, etc. In DNA, they play a structural role in the linking of subunits through a phosphodiester bridge of the type $R_1O—PO_2^-—OR_2$. They can also interact with positively charged species, such as basic proteins and metal ions, through the negative charge on the PO_2^- groups. Although many metal cations can interact with the bases as well as with the phosphate groups in nucleic acids, the latter type of interaction is particularly important as it stabilizes the DNA double helix (1, 2). From theoretical considerations (3), phosphate groups also appear to be the most likely association sites for water in nucleic acids. Furthermore, the manner in which water molecules are organized around DNA through PO_2^-–metal–water interactions seems to be an important factor in the stabilization of specific DNA conformations (4).

Vibrational spectroscopy, particularly Raman spectroscopy, has been used extensively for the study of nucleic acids (5–8). The symmetric stretching vibration of the PO_2^- groups gives a moderately strong and sharp band near 1090 cm^{-1} in the Raman spectrum of DNA. This peak is relatively insensitive to the conformation of the polynucleotide and many investigators have followed the suggestion of Tsuboi *et al.* (9) that it be used as an internal standard in conformational studies. On the other hand, Raman studies of aqueous DNA solutions have shown that this band can be affected in intensity as well as in frequency when metal ions are present in the solution (10–12). Just how these changes are related to the extent and type of metal binding by the phosphate groups is not completely understood. It is the purpose of the present study to investigate this behavior with a very simple model compound, the diethyl phosphate anion ($(C_2H_5O)_2PO_2^-$), in the presence of different types of metal cations. The vibrational spectra of various salts of DEP have been reported previously (13–16) and they have been the subject of force constant calculations (14, 15, 17). This molecule has also been used as a model for the calculation of the vibrational frequencies of the DNA backbone (14, 18) and of the phosphate group in phospholipids (2).

Experimental

Diethyl phosphate (DEP, acid form) was purchased from Eastman Kodak and used without further purification. Metal salts were reagent grade and used as supplied. Stock solutions were prepared by mixing weighted amounts of diethyl phosphate in demineralized water and neutralizing with aqueous NaOH (or LiOH or KOH). The pH was measured with a micro-electrode and an Orion Research Model 721 pH-meter. These DEP solutions, at 0.1 or 0.3 M concentration, were used to obtain the reference spectra. Weighted amounts of the solid metal chlorides were dissolved in the reference solutions to prepare mixed samples at various metal:DEP ratios. The series of $NiCl_2$ solutions at appropriate Ni^{2+} concentrations were prepared by mixing equal volumes of a DEP reference solution and solutions of $NiCl_2$ (from the same original stock solution) at the appropriate molar concentration. The pH was not adjusted following the mixing; it varied from 7.5 for the pure DEP solution to 5.5 for a solution at 6:1 Ni:DEP molal ratio.

The Raman spectra were obtained from the aqueous samples contained in sealed capillary cells placed in a temperature-regulated holder (19). These spectra were recorded on a microcomputer-controlled Spex Model 1400 spectrometer, with either a conventional photomultiplier detection system or a multichannel detector (CCD9000 system from Photometrics Ltd., with 1152 × 298 pixels Thompson TH7895 detector). The spectra were excited by the 514.5 nm line from a Spectra Physics Model 2020 argon ion laser at an average power of 300 mW at the sample. The dispersive spectra were obtained at a spectral resolution of 5 cm^{-1}, the data being collected at 2 cm^{-1} intervals. The total integration time was 25s per point, resulting from the summation of 5 spectra obtained at 5s per point. The spectra obtained with the multichannel detector (1152 data points) covered a spectral region of ca. 500 cm^{-1} with 1200 grooves/mm gratings or ca. 2000 cm^{-1} with

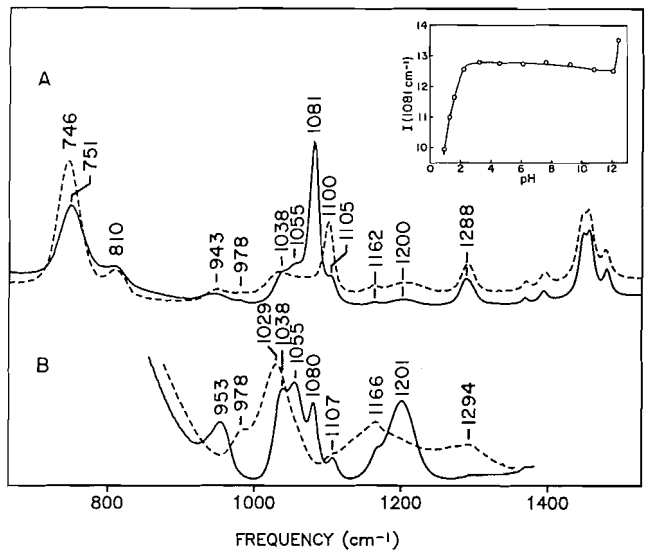

FIG. 1. (*A*) Raman and (*B*) infrared spectra of an aqueous solution of diethyl phosphate at 20°C; (—) 0.3M solution at pH 7 and (- - -) 1M solution in 4M HCl (pH < 0). Insert: variation in intensity of the 1081 cm^{-1} Raman band of the anion as a function of pH.

300 grooves/mm gratings. Intensity corrections were made for the transmission of the spectrometer and of the filter (holographic edge filter from Physical Optics Corporation, Torrance, CA, U.S.A.). The frequency calibration was achieved using emission lines from a neon spectral lamp (20), with an estimated accuracy of 1 cm^{-1} or better. The entrance slit of the spectrometer was adjusted to yield the maximum resolution consistent with channel separation in the detector (ca. 0.5 and 2 cm^{-1}, respectively, with the two types of gratings). The acquisition time was 10 min on the average.

The infrared spectra were obtained from samples contained between two BaF_2 windows separated by a 10 μm-thick Mylar spacer. They were recorded on a commercial BOMEM Model DA3.02 interferometer with MCT detector. These spectra were typically taken at a spectral resolution of 2 cm^{-1} by summation of 1000 interferograms and using a Bartlett apodisation function.

Spectral manipulations were performed with the *SpectraCalc* program (Galactic Industries Corporation, Salem, New Hampshire, U.S.A.).

Results

The Raman and infrared spectra of neutral (sodium salt) and strongly acidic aqueous solutions of diethyl phosphate are reproduced in Fig. 1. At neutral pH, the phosphate group of this molecule is ionized, giving the $(C_2H_5O)_2PO_2^-$ anion. Previous studies (13, 17) have shown that the stretching vibrations of the phosphate group in this species occur in two different regions: the charged PO_2^- group gives a symmetric mode (ν_s) responsible for the strong Raman band and medium intensity infrared peak near 1080 cm^{-1}, whereas the antisymmetric mode (ν_a) gives a strong infrared band, with little corresponding Raman activity, at ca. 1200 cm^{-1}. The phosphodiester —O—P—O— group is also characterized by symmetric and antisymmetric components, which give, respectively, a strong maximum near 750 cm^{-1} and a weaker band at 810 cm^{-1} in the Raman spectrum. The two strong bands at 1038 and 1055 cm^{-1} in the infrared, with relatively weak Raman counterparts, are usually assigned to C—O vibrations, and that at 953 cm^{-1} to a C—C stretching mode (2, 13, 14, 16). The weak band at 1105 cm^{-1}, present in both types of spectra, has generally been identified as a component of the $\nu_s(PO_2^-)$ vibration in the solid phase spectra. Its presence in the solution spectra, its absence in the spectra of dimethyl phosphate, and the fact that it is only weakly active in the spectra of methyl ethyl phosphate (15, 16) suggest that the band corresponds to a fundamental vibration of the ethyl group. Most of the weaker bands at frequencies higher than 1100 cm^{-1} arise from vibrations of alkyl groups.

Normal coordinate calculations have indicated that vibrational frequencies of the phosphate group in DEP vary with the molecular conformation (14, 15, 17). However, these effects are small and we have assumed that the spectral changes resulting from the addition of metal cations to DEP were not caused by changes in the distribution of these structures in the solutions.

Protonation of DEP causes important changes in the vibrations of the PO_2^- group. The infrared and Raman bands at 1080 cm^{-1}, caused by the ν_s vibration of this group, are practically absent from the spectra of a strongly acidic solution (Fig. 1). Similarly, the strong infrared band at 1201 cm^{-1}, assigned to ν_a, and that at 1055 cm^{-1} show an appreciable loss in intensity, whereas the band at 1105 cm^{-1} in the Raman spectrum displays the opposite behaviour. It seems that the addition of another single P—O bond to the system affects the mixing of P—O, C—O, and C—C stretching vibrations, displacing the 1080 and 1055 cm^{-1} bands of the anion to 1030 cm^{-1}, while the C—C vibrational band at 953 cm^{-1} loses most of its intensity. The composite band at 1029 cm^{-1} in the infrared spectrum of the acid solution has appreciable intensity, but the corresponding band in the Raman spectrum is quite weak. In a previous study on the interaction of Ag^+ ions with dialkylphosphates (13), it was proposed that the ν_a vibrational band of the anion at 1200 cm^{-1} in neutral solution is displaced to ca. 1150 cm^{-1} upon covalent neutralisation of the phosphate group. We rather believe that the 1200 cm^{-1} band is displaced, with reduced intensity, to ca. 1270 cm^{-1} in the infrared spectrum of the acid solution, the increased intensity in the 1150 cm^{-1} region being due, at least in part, to the ν_2 vibration of H_3O^+ ions (21). One also notes that the Raman band due to the symmetric stretching mode of the phosphodiester —O—P—O— group is shifted to 746 cm^{-1} at low pH, its intensity being enhanced in the process. The relative height of the 1081 cm^{-1} Raman band of the DEP anion shows that this species remains ionized in the pH range 2.5–12 (see insert, Fig. 1).

The changes occurring in the infrared and Raman spectra of DEP as a result of interaction with metal ions are usually small, especially at low metal concentration. Minor spectral modifications are more easily seen in the difference spectra, which are obtained by subtracting the spectrum of DEP from that of the corresponding solutions in the presence of metal ions. This can be done in a straightforward manner with infrared spectra if the sample thickness and concentration are very accurately known, which is seldom the case. In Raman spectroscopy, to determine the proper value of the constant to be used in the subtraction operation ([DEP + metal] − $K\times$[DEP]), a band present in both spectra and insensitive to the effect of the metal ions is needed as a reference intensity standard. We have used the Raman bands of the alkyl groups in the 1280–1500 cm^{-1} range for this purpose, since they should not be affected by perturbations of the PO_2^- group. In what follows, we will use a *normalized multiplication constant, K*, which is chosen in each case to yield the value

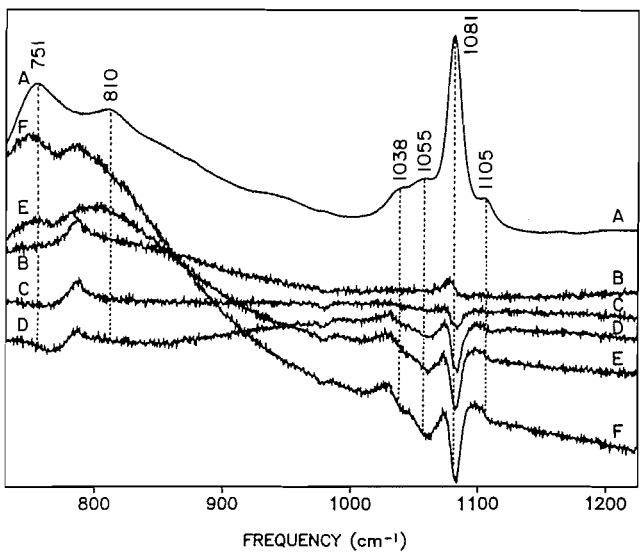

FIG. 2. (*A*) Raman spectrum of an aqueous solution of diethyl phosphate (0.1M, pH 7.5) at 20°C. (B–F) Difference spectra (intensity multiplied by 6) obtained in the presence of $NiCl_2$ at a Ni:DEP molar ratio of (*B*) 0.025, (*C*) 0.25, (*D*) 1.5, (*E*) 3.0, and (*F*) 5.0.

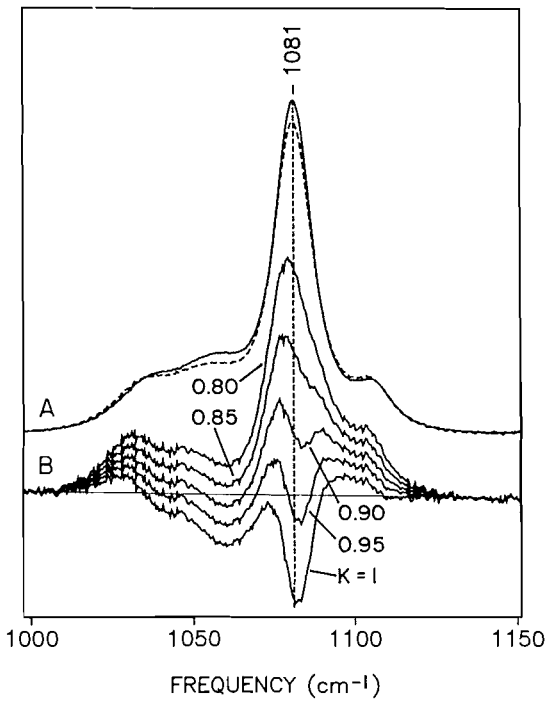

FIG. 3. (*A*) Raman spectrum of an aqueous solution of (—) diethyl phosphate (DEP) (0.1M, pH 7.5) and (- - -) the same solution with added $NiCl_2$ (DEP + metal) at a Ni:DEP molar ratio of 6:1. (*B*) Subtracted spectra (intensity multiplied by 5) ([DEP + metal] − K × [DEP]) for different values of the normalized multiplication constant K (see text).

1 (100%) when the reference bands used as intensity standards are completely annulled in the difference spectrum.

As an example of the use of difference spectra, the curves obtained from aqueous solutions of DEP in the presence of Ni(II) at metal:DEP ratios varying from 0.025:1 to 5:1 are given in Fig. 2. These difference spectra show that the spectral changes depend on the relative metal concentration. At very low metal:DEP ratio, one observes a slight shift to lower frequency of the $\nu_s(PO_2^-)$ band at 1081 cm^{-1} and a weak perturbation in the phosphodiester vibrational region near 800 cm^{-1}. At higher metal concentration, on the other hand, the $\nu_s(PO_2^-)$ band is shifted to higher frequency, with some loss in intensity. Band shifts and intensity changes are also apparent in the 1020–1060 cm^{-1} region (C-O stretching vibrations).

Another way in which spectral changes can be more easily visualized is through the "affected spectrum" (22–24), obtained by incompletely subtracting the reference spectrum to yield a positive difference curve in the region of interest. This is illustrated in Fig. 3, which shows the difference spectra obtained by subtracting the spectrum of an aqueous solution of DEP (0.1M) from that of the same solution in the presence of Ni(II) at a Ni:DEP molar ratio of 6:1, for various values of the normalized multiplication constant K. In the present study, the retained affected spectrum for the mixed solution with Ni(II) was the positive difference spectrum, obtained with the maximum value of K, which could be fitted with calculated band components. The program used for curve fitting was the FIT program from Spectrum Square Associates, Inc. (Ithaca, NY, U.S.A.), run under SpectraCalc (Galactic Industries Corporation, Salem, NH, U.S.A.). The difference between calculated and experimental spectra was taken to be:

$$\chi^2 = \frac{\sum_{i=1}^{N} [(\text{data}\ (\nu_i) - \text{calc}\ (\nu_i))/\text{Rms}]^2}{N - F}$$

in which N is the number of data points, F is the number of degrees of freedom, ν is the frequency, and Rms is a measure of the noise in the spectrum.

Taking Fig. 3 as an example, it was observed that negative peaks occurred in the difference curves for values of K approximately higher than 0.88. To fit the difference spectra for this value of K and lower, five components (of mixed Gaussian and Lorenztian shape) were needed. The fit between calculated and experimental spectra, as determined from the value of χ^2, decreased by an order of magnitude as K was lowered from 0.88 to 0.85. At this point the value of χ^2 as a function of K passed through a minimum, and the difference spectrum obtained with $K = 0.85$ was therefore taken as the affected spectrum. This procedure worked well in general, although in some cases the function $\chi^2 = f(K)$ gave a very broad minimum or merely levelled off with decreasing K. The calculated spectrum for the example given above is compared with the affected spectrum in Fig. 4-*D*. It is obvious that the manipulations of the spectral data needed for the complete analysis of the effect of a particular type of metal ion on the spectrum of DEP were very time-consuming, so that the whole procedure was used only in the case of Ni(II) in the present study. In the other cases, qualitatively affected spectra chosen by visual inspection were retained.

The affected spectrum can be very meaningful for a system limited number of discrete components. In this case, the above example is interpreted as follows. Since the final value of K was 0.85, we surmise that 85% of the spectrum of DEP remained unaffected by the metal ions under our experimental conditions. We also conclude that the affected spec-

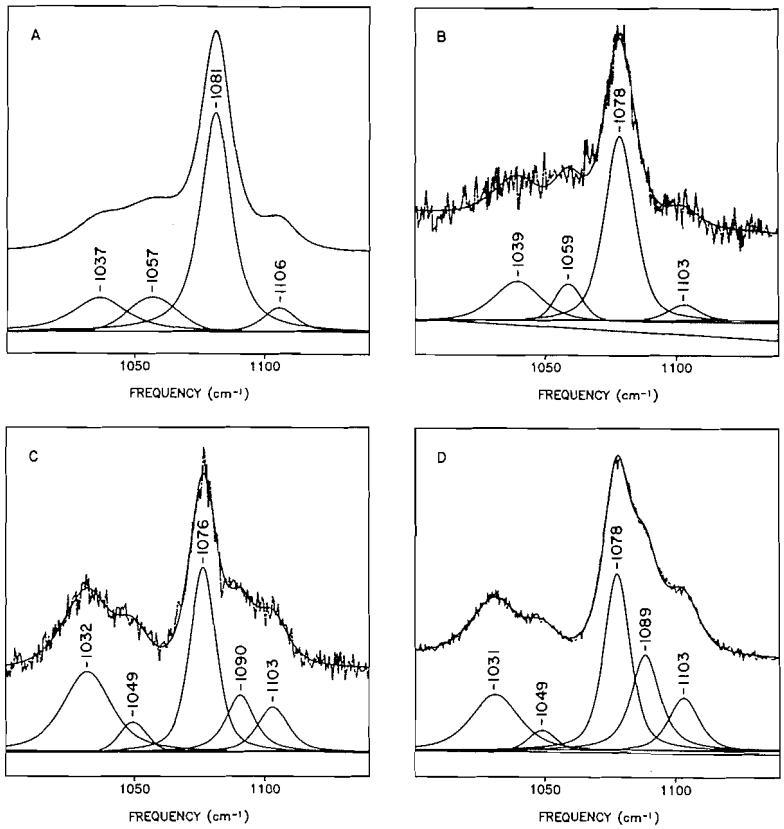

FIG. 4. Band fitting of (*A*) the Raman spectrum of aqueous diethyl phosphate (DEP) (0.1M, pH 7.5) and of (B–D) the affected spectra obtained from solutions of DEP containing $NiCl_2$ at a Ni:DEP molar ratio of (*B*) 0.1:1, (*C*) 2:1, and (*D*) 6:1. (—) Calculated spectra.

trum obtained by the subtraction procedure (at $K = 0.85$) represents 15% of DEP molecules. This interpretation can be questionable, particularly in the case of weak band shifts caused by bulk effects in the solution and affecting all solute molecules. It remains, however, that the affected spectrum in these conditions constitutes a very sensitive indicator of the band shift.

The affected Raman spectra in the 1000–1150 cm^{-1} of solutions of DEP in the presence of Ni(II) at various metal:DEP ratios (Fig. 4) are particularly revealing. Theoretical band fitting of the spectrum in aqueous DEP alone necessitates four components, the major one being associated to the $\nu_s(PO_2^-)$ vibration at 1081 cm^{-1} (Fig. 4-*A*). For the affected spectrum from the solution at Ni:DEP ratio of 1:40 (Fig. 4-*B*), the same number of components is needed, but the main band is shifted to a lower frequency by 3 cm^{-1}, which is consistent with the effect observed in the difference spectrum (Fig. 2-*B*). At higher metal:DEP ratio (Fig. 4-*C*, *D*), an extra component is needed at 1089 cm^{-1} to fit the affected spectra. This extra band becomes progressively more important as the metal concentration is increased. A shift to lower frequency of the 1037 and 1056 cm^{-1} bands of DEP, with enhancement of the lower frequency peak, is also observed in the affected spectra, in accordance with the derivative features present in the different spectra for these solutions (Fig. 2). This behavior, which will be discussed more fully below, indicates that DEP interacts with Ni(II) in different ways, depending on the concentration of the metal cation in the solution. In an attempt to determine the number of components required to explain the spectral data, we have performed a factor analysis using the 1000–1140 cm^{-1} region of the Raman spectra of 16 solutions of DEP (0.1 M) in the presence of Ni^{2+}, at metal:DEP ratios ranging from 6:1 to 0 (pure DEP). (The analysis was done using the PLSPLUS option of SpectraCalc; see ref. 25 for details on factor analysis.) The results of this analysis suggested that four major components are necessary to adequately describe the chosen ensemble.

Difference and affected Raman spectra for solutions of DEP (0.3M) in the presence of the cations K^+, Ca^{2+}, and Cu^{2+}, at a metal:DEP ratio of 1:1, are illustrated in Fig. 5. The corresponding curves for a solution at pH = 1 (effect of the H_3O^+ ion) are also reproduced. (The affected spectra for these mixtures are qualitative only, as they were not subjected to the band fitting procedure used with the Ni(II) solutions.) The subtracted spectra generally consist of a differential feature in the 1080 cm^{-1} region, indicative of a shift to higher frequency of the $\nu_s(PO_2^-)$ vibrational mode, and a slight positive peak at 750 cm^{-1}, resulting from an increased intensity of the band due to the symmetric phosphodiester stretch. The difference spectra of the divalent metal cations also show a decreased intensity in the 1081 cm^{-1} region and extra components on the low-frequency side of the main peak. The difference spectrum obtained with a solution at pH 1 versus that at pH 7, which shows the effect of protonation, is very similar to that obtained from a $CaCl_2$ solution, although the intensity loss at 1080 cm^{-1} is much larger for the acid solution. The affected spectrum, on the other hand, closely resembles the raw spectrum of a DEP solution at very low pH (Fig. 1), as expected.

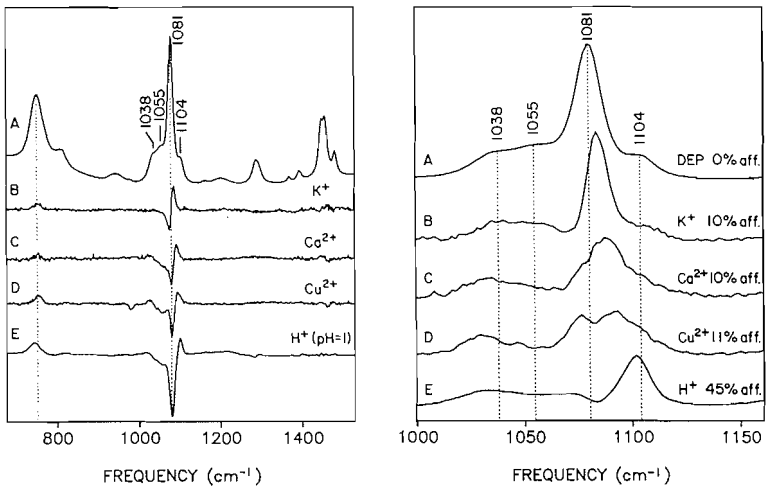

FIG. 5. (*A*) Raman spectrum of an aqueous solution of diethyl phosphate (DEP) (0.3M, pH adjusted to 7 with NaOH). Difference (left) and affected (right) spectra (intensity multiplied by 3) obtained from solutions of DEP in the presence of (*B*) KCl, (*C*) $CaCl_2$, and (*D*) $CuCl_2$ at a cation:DEP ratio of 1:1. (*E*) Corresponding curves (intensity multiplied by 1) for a solution of DEP at pH 1. The % values indicate the amount of affected spectrum (see text).

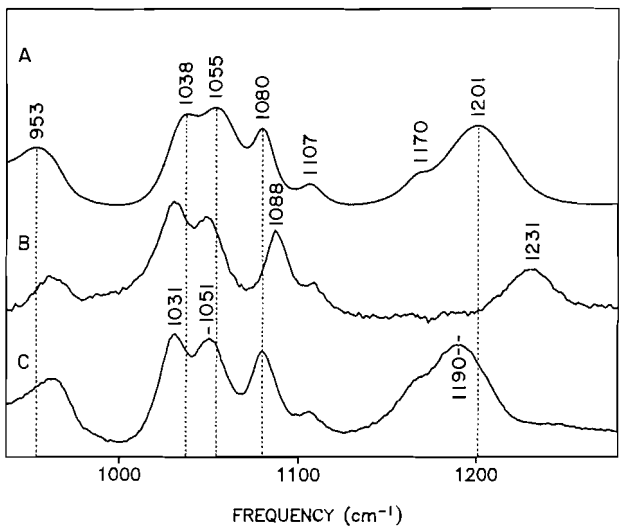

FIG. 6. (*A*) Infrared spectrum of an aqueous solution of diethyl phosphate (DEP) (0.1M, pH 7). Affected spectra obtained from solutions of DEP in the presence of (*B*) $CaCl_2$ and (*C*) $NiCl_2$ at a metal:DEP ratio of 1:1.

The information provided by the affected spectra in infrared are complementary to those provided by the Raman technique. An example of application is shown in Fig. 6, which shows the PO_2^- stretching vibrational region of the affected spectra obtained from DEP (0.1M) in the presence of Ca^{2+} and Ni^{2+} at a metal:DEP ratio of 1:1. The Ca^{2+}-affected spectrum is typical in that it shows a shift to lower frequency of the bands at 1038 and 1055 cm^{-1}, whereas the peaks at 1080 and 1201 cm^{-1}, arising from the stretching vibrations of the PO_2^- group, are shifted in the opposite direction. The effect of Ni^{2+} is clearly different, the $\nu_s(PO_2^-)$ mode at 1080 cm^{-1} remaining essentially invariant, while the $\nu_a(PO_2^-)$ mode at 1201 cm^{-1} is shifted to a lower frequency.

The pH of the solution has some effect on the frequency and intensity of the bands of DEP within the range in which the phosphate group is ionized. The effect of metal ions also differ from that at neutral pH. This is illustrated in Fig. 7, where the spectra of solutions brought to pH near 12 by addition of LiOH, NaOH, and KOH are compared with a solution adjusted to pH 7 with the same base. Increasing the pH to 12 results in a shift to lower frequency of the $\nu_s(PO_2^-)$ band.

Discussion

As shown in Fig. 5, the difference and affected spectra obtained from a series of solutions of DEP in the presence of different metal ions indicate that the complexation of this type of cations by ionized phosphate groups depends on the nature of the metals. As our measurements have been particularly extensive on the DEP–Ni^{2+} system, this particular case will be discussed first, so that the conclusions can be extended to other systems.

DEP – Ni^{2+} system

The vibrational spectroscopic results gathered in this study indicate that the interaction of Ni^{2+} cations with the phosphate group of DEP is a function of metal concentration. This is particularly evident when one compares the difference and affected spectra (Figs. 2 and 4) obtained from solutions at metal:DEP ratios of 0.025:1 and 6:1. We believe that the four spectral components indicated by the factor analysis for this ensemble reflect the existence of phosphate groups of DEP in four different types of environment, which we tentatively identify as follows:

Species A:

These are ionized PO_2^- groups as they are found in neutral aqueous DEP (Na^+ salt). They are for the most part hydrogen-bonded to water molecules and they interact electrostatically with their neighboring Na^+ counterion. These interactions are, on average, symmetrical with respect to the two oxygen atoms of the charged phosphate groups. Such a system is characterized by an intense $\nu_s(PO_2^-)$ Raman band at 1081 cm^{-1} (Fig. 4-*A*).

Species B:

These species consist of ionized PO_2^- groups interacting with Ni^{2+} ions through water molecules (outer-sphere inter-

For personal use only.

actions or, more generally, formation of water-separated ions pairs). The effect of the metal cation in this $Ni^{2+}\cdots O(H)—H\cdots {}^{-}O_2P(OEt)_2$ type of aggregate is to increase the acidity of the water molecule and to strengthen the hydrogen bond affecting the phosphate group, causing a decrease in frequency of the $\nu_s(PO_2^-)$ vibration. Typically, the spectrum of such species corresponds to the affected spectrum obtained at very low metal:DEP ratio, such as in Fig. 4-*B*. Note that this spectrum is very similar to that of aqueous DEP alone, except for the displacement of the $\nu_s(PO_2^-)$ vibrational band to 1078 cm^{-1}. Another noteworthy difference is the absolute intensity of this peak, which is increased considerably in the presence of the metal cation. This causes a positive peak to appear in the difference spectrum, as in Fig. 2-*B*. The effect is also apparent when the intensity of the $\nu_s(PO_2^-)$ band of DEP near 1080 cm^{-1} is plotted as a function of the relative metal concentration, which shows a maximum at a Ni:DEP ratio of 0.25:1 (Fig. 8-*B*).

The increased intensity of the 1078 cm^{-1} band for the B-type species, compared to that of the corresponding band at 1081 cm^{-1} for the A-type variety, has to be taken into account when attempts are made to relate the intensity of the 1078 cm^{-1} component (see Fig. 8-*C*) to the actual concentration of the B-type species in solutions of various metal:DEP ratios. Even so, this curve displays a very peculiar shape in low metal concentrations, an effect which is reflected in the graph giving the total proportion of DEP affected by Ni^{2+} ions (Fig. 8-*A*), as determined by the band-fitting procedure described in the "results" section above. These findings, which are even more striking when one takes into account the total amount of affected DEP (Fig. 8-*D*), clearly show that the number of DEP molecules linked to Ni^{2+} ions by outer-sphere coordination is proportionally much larger at low metal concentrations. This can be explained by the fact that this type of bonding is favored on an entropy basis: when the metal concentration is small, it is relatively easy for the Ni^{2+} ions to find, within a few layers of water molecules, one or several phosphate groups with which it can interact through these solvent molecules. As the metal concentration is increased, more and more metal ions find their way close to the phosphate groups, and more direct interactions take place, at the expense of outer-sphere coordination.

Species C:

These are $Ni^+—O—P(=O)(O—Et)_2$ species, analogous to protonated DEP, with the acid proton replaced by the metal cation. The Raman spectrum of these unsymmetrically bound ion pairs are likely similar to that of protonated DEP (see Fig. 1), which is characterized by a 90% reduction in intensity at 1081 cm^{-1} and a 40% reduction at 1055 cm^{-1}, a shift to 1031 cm^{-1} of the band at 1038 cm^{-1} in DEP solution at pH 7, and an increase by a factor of 2.3 of the intensity of the peak at 1105 cm^{-1}, which is shifted to 1100 cm^{-1}. The frequency shift of the low-frequency band from 1039 to 1031 cm^{-1}, and the increased intensity of this band and of that near 1100 cm^{-1} when the Ni:DEP ratio is raised from 0.025 to 1 (Fig. 4-*B*, *C*), are likely due to the formation of these metallated species. Even more characteristic is the negative component at ca. 1081 cm^{-1} in the difference spectra (Fig. 2), which shows the decrease in intensity of the $\nu_s(PO_2^-)$ band as the metal:DEP ratio is raised. Also apparent in these spectra are the reduced intensity at 1055 cm^{-1} and the shift to lower frequency of the 1038 cm^{-1} band.

Species D:

The existence of these species has to be inferred to account for the component growing at 1090 cm^{-1} in the affected spectra at high metal concentrations (Fig. 8-*C*, *D*). The intensity of this band grows more slowly than that of the other components of the affected spectra at low metal:DEP ratios, but it does not level off at Ni:DEP ratios >3 as the others do. This suggests that the concentration of the species responsible for the 1090 cm^{-1} band become proportionally more important at high metal concentrations. We believe that species of this type are ionized phosphate groups which interact in a non-specific electrostatic way with metal cations. A partial disruption of the hydrogen bond network with water molecules in the neighborhood of the phosphate groups probably results from these interactions at increased metal concentrations. The effect is then equivalent to a partial dehydration of the PO_2^- groups, which is known to displace the $\nu_s(PO_2^-)$ vibrational frequency to higher values (17, 26). It is also possible that the PO_2 angle of the charged

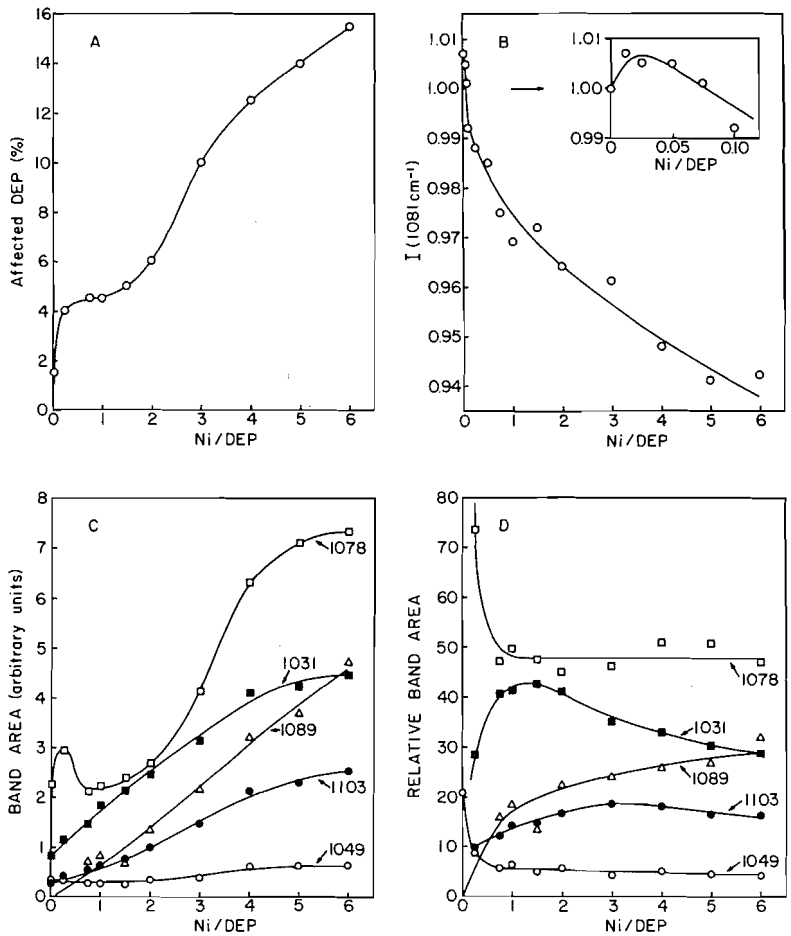

FIG. 8. Variation of spectral parameters obtained from a 0.1M aqueous solution of DEP with added $NiCl_2$ as a function of the Ni:DEP ratio. (*A*) Fraction of the spectrum affected, (*B*) relative peak-height intensity of the 1081 cm^{-1} Raman band, (*C*) intensity of calculated spectral components, and (*D*) intensity of calculated spectral components (given in *C*) divided by the fraction of affected spectrum (given in *A*).

phosphate group in DEP is modified by the presence of the metal cations, causing a modification of the vibrational frequencies of this group (17). Note that type-A species are equivalent to those of type D, except that the statistically symmetrical interactions involved in the latter case are more important or consequential than with the Na^+ counterions used in the reference solution (DEP-Na solution at pH 7).

DEP – other metal-ion systems

The conclusions from our analysis of the Ni^{2+}–DEP spectra can now be extended to the other metal–DEP systems. Unless otherwise specified, the spectra discussed below are for a 1:1 metal chloride:DEP ratio; indicated pH values refer to the cation/DEP solutions. The simplest metal ions to be considered are those of the alkaline metals: Li^+ (pH = 6.4), Na^+ (pH = 7.4) and K^+ (pH = 7.2). As shown in Fig. 5, the difference and affected Raman spectra for K^+ are indicative of a mere shift, with no loss in intensity, of the $\nu_s(PO_2^-)$ vibrational band. This is corroborated by the shape of the affected spectrum, which is very similar to that of the original DEP spectrum. The frequency shift is rather small (ca. 2 cm^{-1}) for K^+ and Na^+ (as determined from a Na^+ solution at 2:1 Na:DEP ratio), and slightly larger (ca. 4 cm^{-1}) for Li^+. These results show that the alkaline-metal ions interact electrostastically in a general manner with charged phosphate groups, these interactions being essentially symmetrical with respect to the two oxygen atoms. It is interesting to note that in a solution at a much larger Na^+:DEP ratio of 18, the frequency of the $\nu_s(PO_2^-)$ band (spectrum not shown) is essentially identical to that at a metal:DEP ratio of 2:1 (ca. 1083 cm^{-1}). The affected spectrum at high metal ion content, however, shows an increased scattering at 1031 cm^{-1}, with corresponding intensity decrease at 1055 cm^{-1}. This observation, together with the decrease in intensity (by approximately 5%) at 1081 cm^{-1}, suggests that unsymmetrical interactions (analogous to those yielding type-C species) take place to some extent at high salt concentrations.

Alkaline-earth metal ions appear to have an intermediate behavior towards DEP, by comparison with alkaline and transition metal ions. As shown in Fig. 5-*C* for Ca^{2+} (pH = 6.7), the frequency shift of the $\nu_s(PO_2^-)$ band is positive, but larger than with K^+ (1088 versus 1083 cm^{-1}), indicating generally stronger interactions with the PO_2^- groups. A slight overall decrease in intensity is also revealed in the $\nu_s(PO_2^-)$ region of the difference spectrum, suggesting some degree of asymmetrical interaction with the oxygen atoms of the phosphate groups. The decrease intensity at 1055 cm^{-1} in the affected spectrum supports this conclusion. Note that the difference spectrum in this case bears some resemblance to that for a solution of DEP at pH 1 (Fig. 5-*E*), for which a

good proportion of the phosphate groups are protonated. The affected spectrum (not shown) for a Mg^{2+}–DEP solution (pH = 6.8) shows an extra component at 1077 cm^{-1}, indicating that this metal cation is more involved than Ca^{2+} ions in the formation of water-separated ion pairs with the phosphate groups.

Transition metal ions, such as Ni^{2+} (pH = 6.2) (Figs. 3 and 4), Cu^{2+} (pH = 3.4) (Fig. 5-*D*), Zn^{2+} (pH = 5.1), and Cd^{2+} (pH = 6.3) (spectra not shown) behave in the same manner. Their affected spectrum contains a high-frequency component at ca. 1092 cm^{-1}, characteristic of symmetric electrostatic interactions with the PO_2^- groups, as well as a low-frequency band resulting from outer-sphere coordination. Their difference spectrum further shows a decrease in intensity in the $\nu_s(PO_2^-)$ region, indicating asymmetric interactions with the oxygen atoms of the phosphate groups. This contrasting behavior compared to alkaline-earth metal ions is especially obvious in the $\nu_a(PO_2^-)$ region of the affected infrared spectrum (Fig. 6), where the band at 1201 cm^{-1} in aqueous DEP is shifted to 1231 cm^{-1} in the presence of Ca^{2+} and 1190 cm^{-1} in a Ni^{2+} solution.

The affected spectra (not shown) of DEP solutions in the presence of Ag^+ (from $AgClO_4$; pH = 6) and Pb^{2+} (pH = 4.2) unexpectedly display a low-frequency component only, at ca. 1078 cm^{-1}. This is particularly surprising in the case of Ag^+, as the infrared spectrum for the solid silver salt of DEP is suggestive of the formation of a partly covalent (therefore asymmetrical) bond with PO_2^- groups (13). The present results suggest that both Ag^+ and Pb^{2+} in solution have a relatively high affinity for water molecules, and that they interact with the phosphate groups through the solvent molecules, forming water-separated ions pairs (type-B species).

The trivalent cations La^{3+} (pH = 3.5) and Al^{3+} (pH = 6,1) also behave in a peculiar way, their affected spectrum (not shown) containing mainly a high-frequency component at 1090 cm^{-1} with very weak accompanying peak at 1078 cm^{-1}. However, the fraction of affected spectrum with these cations (25–30%) is much higher than with monovalent and divalent metal ions. Furthermore, a considerable intensity loss occurs at 1081 cm^{-1}, suggesting that these ions can also interact directly, in an asymmetric way with the oxygen atoms of the PO_2^- groups. Otherwise, the interactions of the phosphate groups with these highly charged species, which are no doubt extensively solvated, appear to be non specific. It is also worth mentioning that the mixture with $AlCl_3$ at pH = 3.3 yields an affected spectrum which is quite similar to that obtained with DEP at pH 1 (Fig. 5-*E*). This probably results from a partial protonation of DEP under these circumstances.

Effect of high pH

The neutralization of aqueous solutions of DEP with either LiOH, NaOH, or KOH has the same effect on the vibrational spectra of this compound. In particular, the frequency of the $\nu_s(PO_2^-)$ in the resulting solutions is the same (within 1 cm^{-1}). However, raising the pH of such solutions to ca. 12 has a marked influence on this frequency, even though the concentration of OH^- ions is much lower than that of DEP. As shown in Fig. 7, the effect depends on the nature of the cation.

The frequency shift of the $\nu_s(PO_2^-)$ vibrational mode in the affected spectrum from the LiOH solution is quite large (14 cm^{-1}), suggesting a strong perturbation of the phosphate groups in the ca. 5% affected DEP molecules. We tentatively explain this behavior by the formation of $OH^- \cdot Li^+ \cdot {}^-O{-}P(=O)(O{-}Et)_2$ species, in which a LiOH molecule comes in close contact with one of the two oxygen atoms of the charged phosphate group. The effect is different in the KOH solution, which causes only a small frequency shift (3 cm^{-1}) of the $\nu_s(PO_2^-)$ mode. This minor effect probably results from small changes in the distribution of charged species in the vicinity of phosphate groups, as the affinity of K^+ cations for OH^- ions is not expected to be exactly the same as that for the negatively charged phosphate groups. The affected spectrum from the NaOH solution shows peaks at both 1067 and 1078 cm^{-1}, indicating that both types of structures are present in the mixture.

Conclusion

The present results indicate that metal cations have different affinities for charged phosphate groups and also that they interact in different ways with these groups. The vibrational spectra show that such interactions can have different and even opposite effects on the intensity and frequency of the vibrational bands of the PO_2^- unit. These changes can be interpreted in terms of direct metal binding by one of the oxygen atoms of the PO_2^- groups, non-specific electrostatic interactions, and formation of water-separated ion pairs with the phosphate groups. It can be concluded from these observations that the decrease in intensity of the band due to the symmetrical stretching mode of charged phosphate groups, which is prominent near 1080 cm^{-1} in the spectra of several types of biomolecules (phospholipids, nucleic acids. . .), is only partially characteristic of the extent of metal binding by these groups, as it arises mainly from interactions of the first kind.

Tetrakis(trimethylgermyl)silane and tris(trimethylgermyl)silyllithium

KIM M. BAINES,[1] KEVIN A. MUELLER, AND TSUN K. SHAM
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 20, 1992

KIM M. BAINES, KEVIN A. MUELLER, and TSUN K. SHAM. Can. J. Chem. **70**, 2884 (1992).

Tetrakis(trimethylgermyl)silane can be synthesized by the addition of four equivalents of trimethylgermyllithium to tetrachlorosilane. Treatment of tetrakis(trimethylgermyl)silane with methyllithium gives tris(trimethylgermyl)silyllithium, which was trapped with aqueous hydrochloric acid, chlorotrimethylsilane or methyl iodide to yield tris(trimethylgermyl)silane, tris(trimethylgermyl)(trimethylsilyl)silane, or methyltris(trimethylgermyl)silane, respectively. Chlorination of tris(trimethylgermyl)silane affords dichlorobis(trimethylgermyl)silane.

KIM M. BAINES, KEVIN A. MUELLER et TSUN K. SHAM. Can. J. Chem. **70**, 2884 (1992).

On peut synthétiser le tétrakis(triméthylgermyl)silane par addition de quatre équivalents de triméthylgermyllithium au tétrachlorosilane. Le traitement du tétrakis(triméthylgermyl)silane avec du méthyllithium fournit du tris(triméthylgermyl)silyllithium que l'on a piégé avec de l'acide chlorhydrique aqueux, du chlorotriméthylsilane ou de l'iodure de méthyle pour obtenir respectivement du tris(triméthylgermyl)silane, du tris(triméthylgermyl)(triméthylsilyl)silane ou du méthyltris(triméthylgermyl)silane. La chloration du tris(triméthylgermyl)silane fournit du dichlorobis(triméthylgermyl)silane.

Introduction

Over the last decade, tris(trimethylsilyl)silyllithium has been used extensively for the synthesis of a variety of main group (for example, see ref. 1) and transition metal (for example, see ref. 2) silyl compounds. The tris(trimethylsilyl)silyl group is often the substituent of choice when a sterically encumbered ligand is required. The silyllithium reagent is readily prepared by the treatment of tetrakis(trimethylsilyl)silane (3) with MeLi in tetrahydrofuran (THF) and can be used either in situ (4) or isolated as its THF adduct (5) before use.

In addition to being a convenient precursor to $(Me_3Si)_3SiLi$, $(Me_3Si)_4Si$ has been used as a molecular model compound of a silicon surface (6) and proposed as a chemical shift standard for solid-state NMR spectroscopy (7).

Recently, the synthesis of tris(trimethyl*stannyl*)silyllithium, by the treatment of tetrakis(trimethyl*stannyl*)silane with MeLi, and its use in the synthesis of transition metal silyl complexes was reported (8). Given the interest shown in the $(Me_3M)_3Si$— (M = Si or Sn) group as a ligand in organometallic chemistry, we decided to investigate the synthesis of tetrakis(trimethyl*germyl*)silane and its conversion to tris(trimethyl*germyl*)silyllithium. In addition, $(Me_3Ge)_4Si$ was of interest because of possible applications in metal-organic chemical vapour deposition (MO–CVD) where, recently, compounds containing a silicon–$(carbon)_n$–germanium chain have been synthesized as potential CVD precursors (9). $(Me_3Ge)_4Si$ may also aid in the structural analysis of Si–Ge atomic layer superlattices (10).

Results and discussion

To investigate the synthesis of $(Me_3Ge)_4Si$, a high yield route to chlorotrimethylgermane was required. Although the synthesis of Me_3GeCl has been reported to occur in good yield by the demethylation of tetramethylgermane using concentrated sulfuric acid, followed by treatment with ammonium chloride (11); in our hands, yields significantly lower than that reported in the literature were consistently obtained. Thus, an alternative route to Me_3GeCl utilizing the redistribution reaction between tetraalkylgermanes and tetrachlorostannane was developed. Tetramethylgermane and tetrachlorostannane, when heated at 150°C for several hours in a Carius tube, yield Me_3GeCl quantitatively. This procedure is similar to that employed by Grobe and Hendriock (12) except that a catalyst is not required.

Analogous to the one-pot synthesis of $(Me_3Si)_4Si$ (3) from $SiCl_4$, Me_3SiCl, and lithium, the one-pot coupling reaction between $SiCl_4$ and Me_3GeCl using lithium metal seemed to be a viable route to $(Me_3Ge)_4Si$. However, attempts at the one-pot procedure gave hexamethyldigermane as the major product and only a trace amount of the desired compound (0.4% yield). Apparently, the formation of Me_3GeLi followed by coupling to Me_3GeCl occurs much more readily than the formation of Cl_3SiLi, leading to the formation of significant amounts of Me_6Ge_2.

$$[1]\quad SiCl_4 + 4Me_3GeCl + 8Li \xrightarrow{THF} \underset{\text{major}}{(Me_3Ge)_2} + \underset{\text{trace}}{(Me_3Ge)_4Si}$$

We therefore attempted the synthesis of $(Me_3Ge)_4Si$ by the addition of a solution of Me_3GeLi to $SiCl_4$. Two commonly used methods for the preparation of Me_3GeLi are the treatment of either Me_3GeCl or Me_6Ge_2 with two equivalents of lithium metal in hexamethylphosphoramide (HMPA) (13). More recently, HMPA/THF (14) or HMPA/Et_2O (15) has been used as the solvent. It was found that the preparation of Me_3GeLi in 1/1.2 HMPA/Et_2O from Me_3GeCl, followed by coupling to $SiCl_4$ in pentane, gave the best yield of $(Me_3Ge)_4Si$ (19%). Hexamethyldigermane, however, was still the major product formed (30%).

$$[2]\quad Me_3GeCl + 2Li \xrightarrow{HMPA/Et_2O} Me_3GeLi + LiCl$$

$$[3]\quad 4Me_3GeLi + SiCl_4 \xrightarrow{pentane} (Me_3Ge)_4Si + (Me_3Ge)_2$$

Tetrakis(trimethylgermyl)silane is a colourless, waxy solid. The ^{29}Si NMR chemical shift of the central silicon atom of $(Me_3Ge)_4Si$ (−104.62 ppm) falls between that of $(Me_3Si)_4Si$ (−135.5 ppm) (16) and $(Me_3Sn)_4Si$ (−69.2 ppm) (8).

The reaction between $(Me_3Ge)_4Si$ and MeLi gives $(Me_3Ge)_3SiLi$, analogous to the synthesis of $(Me_3Si)_3SiLi$ (4) and

[1]Author to whom correspondence may be addressed.

$(Me_3Sn)_3SiLi$ (8). Although this compound was not isolated, its presence was confirmed by trapping reactions with the following electrophiles: aqueous acid, Me_3SiCl, and MeI to give tris(trimethylgermyl)silane, tris(trimethylgermyl)(trimethylsilyl)silane, and methyltris(trimethylgermyl)-silane, respectively. In this way, $(Me_3Ge)_3SiLi$ proved to be a convenient reagent for the preparation of new compounds containing the $(Me_3Ge)_3Si$— group.

[4] $(Me_3Ge)_4Si + MeLi \xrightarrow{THF} (Me_3Ge)_3SiLi + GeMe_4$

[5] $(Me_3Ge)_3SiLi \xrightarrow{H_3O^+} (Me_3Ge)_3SiH$

$(Me_3Ge)_3SiLi \xrightarrow[pentane]{Me_3SiCl} (Me_3Ge)_3Si\text{-}SiMe_3$

$(Me_3Ge)_3SiLi \xrightarrow[pentane]{MeI} (Me_3Ge)_3Si\text{-}Me$

$(Me_3Ge)_3SiH$, the product resulting from the acidic hydrolysis of $(Me_3Ge)_3SiLi$, can be readily chlorinated to give $(Me_3Ge)_2SiCl_2$, in much the same manner as $(Me_3Si)_3SiH$ (17).

[6] $(Me_3Ge)_3SiH \xrightarrow[-78°C]{Cl_2/pentane} (Me_3Ge)_2SiCl_2$

The dichlorosilane will allow for further functionalization at the silicon centre using nucleophilic reagents.

Conclusions

The one-pot coupling reaction involving $SiCl_4$, Me_3GeCl, and Li metal in THF was not a satisfactory method for the preparation of $(Me_3Ge)_4Si$. However, a moderate yield of $(Me_3Ge)_4Si$ is obtained when four equivalents of Me_3GeLi are added to $SiCl_4$. As expected, the treatment of $(Me_3Ge)_4$-Si with MeLi gave $(Me_3Ge)_3SiLi$ which, when trapped with electrophiles, gave new compounds containing the $(Me_3Ge)_3Si$— group. The chlorination of $(Me_3Ge)_3SiH$ afforded $(Me_3Ge)_2SiCl_2$, which is a precursor to other new compounds containing silicon–germanium bonds.

Experimental

All glassware was thoroughly flame-dried and the apparatus kept under a dry argon atmosphere over the course of each reaction. THF and Et_2O were distilled from sodium and benzophenone immediately before use. Pentane and HMPA were distilled from $LiAlH_4$ and CaH_2, respectively, and stored under an atmosphere of dry argon prior to use. $SiCl_4$, Me_3SiCl, and MeI were distilled from $CaCl_2$ immediately before use. Me_4Ge was used as received from Toronto Research Chemicals Inc. Chromatography was performed on silica gel plates using a Chromatotron (Harrison Research Co.; model 8924) or by dry column flash chromatography (18). Acidic work-up refers to the slow addition of 1 M HCl to the reaction mixture, followed by separation of the two layers and extraction of the aqueous layer with Et_2O. The organic layers were subsequently combined, washed successively with water and brine, and dried over $MgSO_4$. When HMPA was used in the reaction, the organic layer was initially extracted several times with 1 M HCl.

Infrared spectra were recorded on a Bruker IFS 32 FTIR spectrometer, controlled by an IBM System 9000 computer. Nuclear magnetic resonance spectra were recorded on either a Gemini 200, Varian XL-200 or XL-300 NMR spectrometer, using C_6D_6 as the solvent. Electron impact mass spectra were recorded on a Finnegan MAT model 8230 spectrometer, using an ionizing voltage of 70 eV. Elemental analyses were performed by Galbraith Laboratories Inc., Knoxville, TN. A Hewlett-Packard 5830 GC, equipped with a DB 5 capillary column, was used to obtain the gas chromatographs. The yield of hexamethyldigermane given is based on the amount of chlorotrimethylgermane used.

Chlorotrimethylgermane

Me_4Ge (6.96 g, 52.5 mmol) and $SnCl_4$ (13.65 g, 52.4 mmol) were introduced into a Carius tube. The Carius tube was then sealed under vacuum and heated for 46 h at 150°C. Simple distillation (under a dry argon atmosphere) of the reaction mixture gave a quantitative yield of Me_3GeCl (8.02 g, 52.4 mmol) as a clear, colourless liquid (bp 102°C, atmospheric pressure; lit. (11) 102–103°C, 760 Torr; 1 Torr = 133.3 Pa). ^1H NMR (ppm) 0.35 (s) (lit. (11) (C_6D_6) 0.39 (s)).

Tetrakis(trimethylgermyl)silane

(a) One-pot Synthesis

Me_3GeCl (3.00 g, 19.6 mmol), THF (25 mL), and pounded lithium (0.39 g, 56 mmol) were mechanically stirred at −78°C. To this stirred suspension, was added a solution of $SiCl_4$ (0.75 g, 4.4 mmol) in THF (10 mL) from a pressure-equalizing funnel. After stirring at −78°C for 3 h, the cold bath was removed and the reaction mixture was left to stir overnight. As the reaction proceeded, the reaction mixture went from light-green to dark-brown and opaque in appearance. After filtration through Celite and acidic work-up; dry column flash chromatography (silica gel; hexanes), followed by Kugelrohr distillation (pot temperature: 100°C, 0.4 Torr), a crude, white solid was obtained. This was then sublimed (90°C, 0.5 Torr) to give $(Me_3Ge)_4Si$ (0.008 g, 0.4%) as a white, waxy solid.

(b) Using trimethylgermyllithium prepared from chlorotrimethylgermane

Lithium metal (0.21 g, 30 mmol), pounded into small, flat pieces (ca. 1 cm in diameter), was placed into a 100 mL three-neck round-bottom flask. HMPA (5 mL) was then added and the resulting HMPA/Li mixture was stirred vigorously until the solution turned from clear to blue-grey in colour. At this point, a solution of Me_3GeCl (1.65 g, 10.8 mmol) in Et_2O (6 mL) was added, dropwise. The resulting solution gradually acquired a dark-brown colour, with a yellow tinge. After 3.5 h of stirring at room temperature, the germyllithium solution was added dropwise (ca. 1 drop every 3 s) to a solution of $SiCl_4$ (0.44 g, 2.59 mmol) in pentane (50 mL) at −78°C. After the addition was complete, the reaction mixture was allowed to warm to room temperature and stirred overnight. Acidic work-up of the chocolate-brown solution, followed by removal of the solvents by simple distillation, resulted in a crude reaction mixture containing HMPA, $(Me_3Ge)_2$, and $(Me_3Ge)_4Si$. The residual HMPA was removed by dry column flash chromatography (silica gel, pentane). The $(Me_3Ge)_2$ and $(Me_3Ge)_4Si$ were then separated by trap-to-trap distillation (room temperature, 0.7 Torr) to yield $(Me_3Ge)_2$ (0.38 g, 30%) as a clear, colourless liquid. The pot residue, $(Me_3Ge)_4Si$, was purified by sublimation (62°C, 0.7 Torr) to yield 0.24 g (19%) of a white, waxy solid; mp 245°C (dec., sealed tube); IR (KBr pellet, cm^{-1}) 2969 (s), 2905 (s), 2797 (m), 1404 (s), 1229 (s); ^1H NMR (ppm) 0.38 (s); ^{13}C NMR (ppm) 1.98 (q, J = 126 Hz); ^{29}Si NMR (ppm) −104.62; MS m/e (%) 500 (15, M^+), 485 (36, $M^+ - Me$), 381 (41, $M^+ - GeMe_3$), 279 (26), 177 (36), 119 (30, $GeMe_3$), 73 (100, $SiMe_3$); Anal. calcd. for $C_{12}H_{36}Ge_4Si$: C 28.89, H 7.29, found: C 29.07, H 7.08.

Tris(trimethylgermyl)silyllithium and tris(trimethylgermyl)silane

Methyllithium (2.3 mL of a 1.3 M solution in Et_2O) was added, via pipet,[2] to a stirred solution of $(Me_3Ge)_4Si$ (0.21 g, 0.43 mmol)

[2]A glass pipet fitted with a 3-valve pipet filler (Aldrich Cat. no. Z13,647-6) is repeatedly flushed with argon in the following manner: the gas in the bulb is expelled by pressing simultaneously on the bulb and valve "A" on top of the bulb, followed by drawing argon up into the pipet and bulb by pressing the "S" valve on the stem. After expelling argon from the bulb, the liquid is then drawn up into the pipet by pressing valve "S" and, after transfer to the appropriate flask, the liquid is expelled from the pipet by squeezing the argon-filled bulb and then pressing valve "S."

in THF (12 mL). After stirring overnight at room temperature, the light-yellow $(Me_3Ge)_3SiLi$ solution was added dropwise to 15 mL of a rapidly stirring 1 M HCl solution. After the addition was complete, the aqueous layer was extracted with Et_2O. The combined organic layers were then washed with water, followed by brine, dried over $MgSO_4$, and the solvent removed by rotary evaporation. Purification by chromatography (Chromatotron; hexanes) yielded 0.12 g (72%) of $(Me_3Ge)_3SiH$ as a clear, colourless liquid. IR (neat, cm^{-1}) 2068 (s, Si—H); ^1H NMR (ppm) 0.37 (s, 27 H, Ge—CH_3), 3.10 (s, 1 H, Si—H); ^{13}C NMR (ppm) 1.05 (q, J = 126 Hz); ^{29}Si NMR (ppm) −96.95; MS *m/e* (%) 382 (6, M^+), 367 (8, M^+ − Me), 293 (22), 177 (20), 119 (24, $GeMe_3$), 73 (100, $SiMe_3$); high resolution MS: calcd. for *m/e* $C_9H_{28}{}^{28}Si^{72}Ge_2{}^{74}Ge$ 381.9614; found: 381.9662.

Tris(trimethylgermyl)(trimethylsilyl)silane

MeLi (0.4 mL of a 1.3 M solution in Et_2O) was added to a stirred solution of $(Me_3Ge)_4Si$ (0.09 g, 0.18 mmol) in THF (12 mL). After stirring overnight at room temperature, the light-yellow silyllithium reagent was transferred to a pressure-equalizing funnel and added, dropwise, to a solution of Me_3SiCl (0.13 g, 1.2 mmol) in pentane (35 mL) at −78°C. The cold bath was then removed and the reaction mixture stirred overnight. Acidic work-up and removal of the solvent by rotary evaporation gave a crude, white solid. Sublimation (55°C, 1.15 Torr) resulted in the isolation of 0.043 g (53%) of $(Me_3Ge)_3Si(SiMe_3)$ as a white, waxy solid. IR (KBr, cm^{-1}) 2967 (s), 2905 (s), 2797 (m), 1404 (m), 1260 (m), 1244 (s), 1229 (s), 814 (s), 687 (m), 625 (m), 586 (s), 558 (s); ^1H NMR (ppm) 0.24 (s, 9 H, Si—CH_3), 0.39 (s, 27 H, Ge—CH_3); ^{13}C NMR (ppm) 2.02 (q, Ge—CH_3, J = 126 Hz), 2.46 (q, Si—CH_3, J = 119 Hz); ^{29}Si NMR (ppm) −8.44 (sextet, $SiMe_3$, J = 7 Hz), −112.45 (m, $(Me_3Ge)_3Si$); MS *m/e* (%) 454 (4, M^+), 439 (10, M^+ − Me), 335 (12, M^+ − $GeMe_3$), 235 (12), 177 (8), 119 (11, $GeMe_3$), 73 (100, $SiMe_3$); high resolution MS: calcd. for *m/e* $C_{12}H_{36}{}^{28}Si_2{}^{72}Ge_2{}^{74}Ge$: 454.0009; found: 453.9991.

Methyltris(trimethylgermyl)silane

$(Me_3Ge)_3SiLi$ was prepared, as described previously, by the addition of MeLi (0.7 mL of a 1.3 M solution in Et_2O) to a stirred solution of $(Me_3Ge)_4Si$ (0.09 g, 0.19 mmol) in THF (12 mL) and stirring the resulting mixture overnight at room temperature. The light-yellow silyllithium reagent was then added dropwise to a solution of MeI (0.23 g, 1.6 mmol) in pentane (40 mL) at −78°C. The reaction mixture was then allowed to warm to ambient temperature and stirred overnight. After acidic work-up, purification by chromatography (Chromatotron; hexanes) gave 0.05 g of a white, waxy solid which contained a mixture of $(Me_3Ge)_3Si$—Me and $(Me_3Ge)_4Si$ in a 4:1 ratio (by GC). These two compounds could not be separated; however, preparative GC allowed for the isolation of a mixture containing 91% $(Me_3Ge)_3Si$—Me (by GC). Characterization for $(Me_3Ge)_3Si$—Me, containing approximately 20% $(Me_3Ge)_4Si$: ^1H NMR (ppm) 0.22 (s, 3 H, Si—CH_3), 0.31 (s, 27 H, $GeCH_3$); ^{13}C NMR (ppm) −0.53 (q, Ge—CH_3, J = 126 Hz), −11.26 (q, Si—CH_3, J = 124 Hz); ^{29}Si NMR (ppm) −63.18; MS *m/e* (%) 396 (31, M^+), 381 (56, M^+ − Me), 279 (83, M^+ − $GeMe_3$), 177 (75), 119 (30, $GeMe_3$), 73 (100, $SiMe_3$); high resolution MS: calcd. for *m/e* $C_{10}H_{30}{}^{28}Si^{72}Ge_2{}^{74}Ge$: 395.9770; found: 395.9796.

Dichlorobis(trimethylgermyl)silane

Chlorine gas was bubbled (ca. 1 bubble every 5 s) through a stirred solution of $(Me_3Ge)_3SiH$ (0.053 g, 0.14 mmol) in pentane (15 mL) at −78°C. The reaction was monitored by gas chromatography and was found to be complete after 16 min of chlorination. The solvent was then removed by rotary evaporation and the product purified by trap-to-trap distillation (room temperature, 0.5 Torr). This afforded 0.043 g (92%) of $(Me_3Ge)_2SiCl_2$ as a clear, colourless liquid. IR (neat, cm^{-1}) 2965 (s), 2936 (s), 2876 (m), 1458 (m), 1381 (m), 1237 (w), 822 (s), 652 (m), 600 (s); ^1H NMR (ppm) 0.28 (s); ^{13}C NMR (ppm) −3.27 (q, J = 128 Hz); ^{29}Si NMR (ppm) 40.83; MS *m/e* (%) 334 (5, M^+), 319 (4, M^+ − Me), 197 (15), 119 (100, $GeMe_3$), 73 (69, $SiMe_3$); high resolution MS: calcd. for *m/e* $C_6H_{18}{}^{28}Si^{72}Ge^{74}Ge^{35}Cl_2$: 333.8987; found: 333.8965.

J. K. KAUPPINEN, D. J. MOFFATT, and H. H. MANTSCH. Can. J. Chem. **70**, 2887 (1992).

The nonlinear behavior of the filter-type Maximum Entropy Method (MEM) was investigated from a theoretical and a practical point of view. The integrated intensity of the output spectral lines of MEM was probed as a function of the input intensity pattern, the filter length, and the S/N ratio of the input spectrum. The nonlinear behavior of MEM has been explained and the results compared with those derived by another method, LOMEP (Lineshape Optimized Maximum Entropy linear Prediction). The study was carried out with the aim of resolution enhancement of spectra that have high signal-to-noise ratio.

J. K. KAUPPINEN, D. J. MOFFATT et H. H. MANTSCH. Can. J. Chem. **70**, 2887 (1992).

On a étudié le comportement non-linéaire de la Méthode d'Entropie Maximale d'un point de vue tant théorique que pratique. On a examiné l'intensité intégrée des raies spectrales de sortie MEM en fonction du patron de l'intensité à l'entrée, de la longueur du filtre et du rapport signal/bruit du spectre d'entrée. On a expliqué le comportement non-linéaire du MEM et on a comparé les résultats avec ceux obtenus à l'aide d'une autre méthode, LOMEP (prédiction linéaire à partir de l'information sur l'entropie maximale et la forme de la courbe). On a réalisé l'étude afin d'augmenter la résolution de spectres ayant des rapports signal/bruit élevés.

[Traduit par la rédaction]

Introduction

The basic principle of the Maximum Entropy Method (MEM) (1–3) is to perform a least-squares fit with an extra constraint, maximization of the information entropy. Simpler techniques, which use as the only constraint the standard deviation of a least-squares fit, will not yield a unique solution. The most probable solution will be the one that has a maximum information entropy. Thus, by maximizing the entropy of the spectrum for a given standard deviation one obtains the best solution for a given set of data. This operation, known as iterative MEM, has been shown to be suitable for *fitting* a spectrum (1–8); however, it is not well suited for resolution enhancement.

There exists another type of MEM, based on filter theory, in which the output spectrum is computed simply from a maximum entropy power spectral estimator, which is proportional to the power spectrum of the transfer function of the filter. There are many variations of this MEM that differ only in the model of the filter and in the method used to solve the resulting equations. Most common (1–3, 9) are the autoregression (AR), moving-average (MA), and autoregression/moving-average (ARMA) models. As this type of MEM has been used for resolution enhancement, we will make it the focus of our discussion. In a previous report (10) we tested the use of the AR method of Burg's MEM (11, 12) as a resolution enhancement technique; we now explain why it should never be used for this purpose. We show that in AR, MA, and ARMA information regarding the intensity of the input lines is highly degraded. Moreover, other methods in which the power spectral estimator is proportional to the power of a transfer function, such as MUSIC (13, 14) or MINIMUM NORM (14), will also suffer from this disadvantage.

Theory

Part A. Filter-type maximum entropy method

In the ARMA method (1–3, 9) the time domain model is given by

$$[1] \qquad I_j = -\sum_{k=1}^{M} a_k I_{j-k} + \sum_{k=0}^{P} b_k e_{j-k}, \qquad b_0 = 1$$

where, using an interferometric notation, $I_j = I(j\Delta x)$ is the time domain data point at $j\Delta x = j/(2\nu_{max})$, and e_j is the corresponding error at this point. The ARMA model in eq. [1] can be considered as a filter with a transfer function given by

$$[2] \qquad H(z) = \frac{1 + \sum_{k=1}^{P} b_k z^{-k}}{1 + \sum_{k=1}^{M} a_k z^{-k}}$$

where

$$[3] \qquad z = \exp\left(-i\frac{\pi\nu}{\nu_{max}}\right)$$

The power spectral estimation (2, 9) has been defined as

$$[4] \qquad P(\nu) = \sigma_M^2 H^*(\nu) H(\nu)$$

where σ_M is the standard deviation of the errors e_j and H^* stands for a complex conjugate of H.

In a spectrum with a high signal-to-noise ratio the $b_k e_{j-k}$ terms can be approximated to zero (for $k > 0$) and the method

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

becomes the autoregression AR model. Thus eq. [1] reduces to

$$[5] \quad I_j = -\sum_{k=1}^{M} a_k I_{j-k} + e_j$$

or

$$[6] \quad I_j - e_j = I'_j = -\sum_{k=1}^{M} a_k I_{j-k} = \sum_{k=1}^{M} h_k I_{j-k}$$

where $a_k = -h_k$ $(k > 0)$. Thus eqs. [2]–[4] yield

$$[7] \quad H(z) = \frac{1}{1 + \sum_{k=1}^{M} a_k z^{-k}}$$

and

$$[8] \quad P(\nu) = \frac{\sigma_M^2}{\left| \sum_{k=0}^{M} a_k \exp\left(\frac{i\pi\nu k}{\nu_{max}}\right) \right|^2}, \qquad a_0 = 1$$

$P(\nu)$ is referred to as the maximum entropy power spectral estimator. It has been demonstrated (15) that the information entropy has a maximum for $P(\nu)$ if the prediction-error coefficients $\{a_k\}$ are derived from eq. [5], i.e., by fitting the data I_j according to eq. [5].

The procedure known as Burg's MEM is based on eqs. [5] and [8]. Because under certain conditions the power spectrum $P(\nu)$ defined by eq. [8] produces narrow spectral lines this method is sometimes referred to as "super-resolution MEM." However, the method is highly nonlinear and therefore often misleading. If line narrowing were to take place correctly in eq. [8] then this would be equivalent to linear prediction in the time domain. We will show that this is never the case.

Part B. True linear prediction and LOMEP

Let us now consider a new approach to the problem of linear prediction. Instead of using Burg's method we derive a theoretical impulse response $\{h_k\}$ of the linear prediction based on eq. 5.[3] Equation [6] can be rewritten as a convolution:

$$[9] \quad I_p(x) = [D(x)h(x)] * I(x) = \int_{-\infty}^{\infty} D(x')h(x')I(x - x')\,dx'$$

where $I_p(x)$ is a predicted signal and $D(x)h(x)$ is the desired impulse response, if

$$[10] \quad D(x) = \begin{cases} 1 & 0 < x \leq M\Delta x \\ 0 & \text{elsewhere} \end{cases}$$

Let us assume that we know the true signal $I(x)$ in the interval $(0, M\Delta x)$ and that it consists of *noise-free* undamped cosine waves, i.e.,

$$[11] \quad I(x) = \sum_i A_i \cos(2\pi\nu_i x)$$

where A_i is the integrated intensity of a line at ν_i. A true linear prediction is possible if and only if we have a stationary case where the theoretical coefficients $\{a_k\}$ do not depend on the shift of the input data (see below). It can be shown[3] that if $e_j = 0$, then the simplest solution of eq. [5] is given by

$$[12] \quad h(x) = \sum_i \alpha_i \cos(2\pi\nu_i x + \phi_i)$$

where the scaling constants α_i and the phase adjustments ϕ_i can be derived from the constraint:

$$[13] \quad \mathcal{H}(\nu) = \mathcal{F}\{D(x)h(x)\} = 1 \qquad \text{at} \qquad \nu = \nu_i$$

where $\mathcal{F}\{\ \}$ is the Fourier transform operator. This is a necessary and sufficient condition for $h(x)$ to be a solution of eq. [5]. Furthermore, it can be shown[3] that the constants α_i and ϕ_i depend only on the frequencies ν_i of the spectral lines and on M; thus the filter coefficients $a_k = -h_k = -h(k\Delta x)$ *do not contain information concerning the line intensities* A_i. Hence, under these ideal conditions (a noise-free input spectrum) eq. [8] will not contain any intensity information and therefore the *filter-type MEM cannot give correct intensities of the spectral lines and eqs. [4] and [8] cannot be accurate estimates of the power spectrum* $P(\nu)$.

The only way to realize significant resolution enhancement with correct line intensities A_i is to perform a true linear prediction. This is accomplished by applying eq. [5] inductively (with the assumption $e_j = 0$) to extrapolate the time domain starting with the $M + 1$ known (measured) data I_j $(j = 0, 1, 2, \ldots M)$. We have given this resolution enhancement method the name "LOMEP" (10, 16) (Lineshape Optimized Maximum Entropy linear Prediction). LOMEP consists of three procedures: Fourier Self-Deconvolution FSD (17), Burg's MEM, and this true linear prediction, LP. Now, maximum resolution enhancement can only be achieved by extrapolation of undamped cosine waves as assumed in eq. [11]. In practice, the intrinsic lineshape of spectroscopic lines (e.g., Lorentzian or Gaussian) corresponds to damped cosine waves in the time domain. Therefore the first step in LOMEP is the use of FSD to change the damped cosine waves to undamped ones according to the following equation:

$$[14] \quad E(\nu) = \mathcal{F}\left\{\frac{\mathcal{F}^{-1}\{W_0(\nu)\}\,\mathcal{F}^{-1}\{E_{in}(\nu)\}}{\mathcal{F}^{-1}\{W(\nu)\}}\right\}$$

where $E_{in}(\nu)$ is the input spectrum with lineshape function $W(\nu)$, $\mathcal{F}\{\ \}$ and $\mathcal{F}^{-1}\{\ \}$ are the Fourier transform and inverse Fourier transform, respectively. Line narrowing will be achieved if the imposed output lineshape $W_0(\nu)$ is narrower than $W(\nu)$. The line-narrowing factor K, loosely referred to as the "resolution enhancement factor," is given by

$$[15] \quad K = \frac{\text{FWHH}(W)}{\text{FWHH}(W_0)}$$

where FWHH(W) and FWHH(W_0) are the full width at half-height of $W(\nu)$ and $W_0(\nu)$, respectively. In practice K is limited by the signal-to-noise ratio (S/N) of $E_{in}(\nu)$, i.e., $K < \log_{10}(\text{S/N})$. In LOMEP the output lineshape $W_0(\nu)$ is a sinc function meaning that FSD changes the damped time-domain signals to undamped ones. This lineshape optimization is the key step in LOMEP, enabling it to achieve resolution enhancement (10).

The next step in LOMEP is to compute the prediction-error coefficients $\{a_k\}$ ($k = 1, 2, 3, \ldots M$) of a prediction-error filter. This is done by using Burg's method (11, 12) and $M + 1$ known data I_j ($j = 0, 1, 2, \ldots M$). After this we are able to predict new data I_j($j > M$) by using eq. [5] and $M + 1$ known data I_j ($j = 0, 1, 2 \ldots M$) assuming that $e_j = 0$. In principle, Burg's MEM gives $\{a_k\}$ so that the error power $\Sigma^M |e_j|^2$ has a minimum. Unfortunately, this minimum error power depends very strongly and chaotically on the filter length M. The innovation in LOMEP is to optimize the filter length M using a simple test of the prediction coefficients a_k. This can be done by predicting backward the data I'_{-j} ($j = 1, 2, 3 \ldots M$) using the input data I_j ($j = 0, 1, 2, \ldots M$). From those predicted data I'_{-j} we are able to compute the quality factor of prediction given by:

$$[16] \quad q(M) = 1 - \sqrt{\frac{\sum_{j=1}^{M} (I'_{-j} - I_{-j})^2}{\sum_{j=1}^{M} (I_{-j})^2}}$$

This is possible, because $I_{-j} = I_j$ and the forward and backward prediction coefficients are the same, if the input signal consists of undamped cosine waves. Unfortunately, in all but the most trivial cases, the theoretical minimum M for which $q(M) = 1$ is larger than the number of usable data points in the time-domain signal. The practical solution is to search for an optimum filter length M_0 for which $q(M_0)$ has a maximum. The choice of M_0 can greatly affect the quality of the LOMEP output in terms of lineshape.

The next step of LOMEP is a linear prediction applying eq. [5] inductively to the initial input signal I_j ($j = 0, 1, 2, \ldots M_0$). The final signal is the input signal plus the predicted one I_j ($j = M_0 + 1, M_0 + 2, \ldots, N$) where the practical limit, N, to extrapolation is determined mainly by $q(M_0)$ and the degree of distortion allowable in the output spectrum. To obtain a more desirable lineshape than sinc we apodize the final signal. Thus the lineshape ($W_L(\nu)$) of the LOMEP output spectrum is simply the Fourier transform of the apodization function. The line-narrowing factor K of LOMEP is FWHH(W)/FWHH(W_L) and it is proportional to N.

Comparison of Burg's MEM with LOMEP as methods for resolution enhancement

The only step common to both MEM and LOMEP is the use of Burg's MEM to compute the coefficients $\{a_k\}$ using the same model eq. [5]. Thereafter LOMEP and MEM differ substantially, the former once again using eq. [5] to accomplish a true linear prediction, with the latter using the maximum entropy power spectral estimator given by eq. [8]. Therefore LOMEP output spectra are amplitude (true) spectra whereas MEM spectra are power spectra. In LOMEP, lineshape optimization is always performed with the help of FSD, while MEM is applied to spectra without use of any lineshape information. In this work we apply FSD before MEM, because in this case MEM works better (10). Further, in LOMEP we optimize the filter length and use the quality factor $q(M_0)$ to guarantee the reliability of the final prediction. The closer $q(M_0)$ is to 1, the less distorted are the output lines. In LOMEP the output lineshape and the line narrowing factor K are easily adjusted by apodization and the length (N) of the final signal, whereas in MEM lineshape and linewidth are not under our control.

Let us now compare the properties of Burg's MEM with the true linear prediction of LOMEP, by applying eq. [5] to synthesized data. This comparison was carried out by varying (*i*) the integrated intensity of the individual input spectral lines (see Fig. 1), (*ii*) the filter length M (see Fig. 2), and (*iii*) the S/N ratio of the input spectrum (see Fig. 3). The test spectra are comprised of Lorentzian lines (FWHH = 40) at positions $\nu_1 = 600$, $\nu_2 = 900$, $\nu_3 = 1600$, and $\nu_4 = 1650$ with a sampling interval of 1. The integrated intensities of the input spectra and those of the various output spectra are listed in Table 1; measured intensities were integrated 25 points to either side of the input line positions. In all three figures, the MEM spectra are magnitude spectra and the LOMEP spectra have a Bessel lineshape.

Figure 1 shows the FSD, LOMEP, and MEM output spectra with $M = 152$, $N = 153$. Because the theoretical impulse response $D(x)h(x)$, defined in eqs. [10] and [12], depends only on M and the frequencies ν_i, we may compute the $\{a_k\}$ coefficients for the input spectrum of Fig. 1A only, and then use these coefficients to compute LOMEP outputs for all four input spectra. The LOMEP spectra, even with a high K (resolution enhancement factor) value of 10, are quite reasonable, both in terms of lineshape (lack of distortion) and integrated intensity. As evident from Table 1-I, the intensities are accurate to within 0.1%. The output lineshape is controlled by apodization of the extrapolated signal. The fact that the impulse response calculated from spectrum 1A can be successfully employed for the linear prediction of all four spectra proves that the impulse response does not contain intensity information. It is to be noted that LOMEP also gives correct intensities in the case of negative lines.

On the other hand, the relative integrated intensities of the MEM spectra in Fig. 1 deviate from the input values by as much as two orders of magnitude. Furthermore, some lines have undergone splitting and even those that did not, do not possess uniform lineshapes. This clearly demonstrates that neither the impulse response nor the magnitude spectrum $(P(\nu))^{1/2}$ in eq. [8] contains significant intensity information. In this simulation the ratio M/N is approximately one. As it has been shown (2, 3), this is not an optimal situation for MEM. Figure 2 illustrates the behavior of LOMEP and MEM as a function of the filter length (M), using spectrum 1B as input. Again, the intensities of the spectral lines are retained in the LOMEP output while MEM produces a variation of between +3 and −51% around the input values (see Table 1-II). Spurious lines are also evident in the MEM output, and the lines at 1600 and 1650 often appear split. In this example the number of points, N, used in MEM was 153, while for LOMEP this number was $M + 1$. The discrete M values used in the calculations are given in Fig. 2. Now the M to N ratio is closer to the optimal value (2, 3) for MEM but not for LOMEP. For small values of M ($M << M_0$), the LOMEP procedure appears to suffer from lack of information, which results in lineshape distortions, but no degradation of the integrated intensity information.

Figure 3 compares the output of LOMEP with that of MEM as a function of S/N using again the intensities and frequencies in spectrum 1B as a model. The measured integrated intensities of the output spectra are given in Table

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12

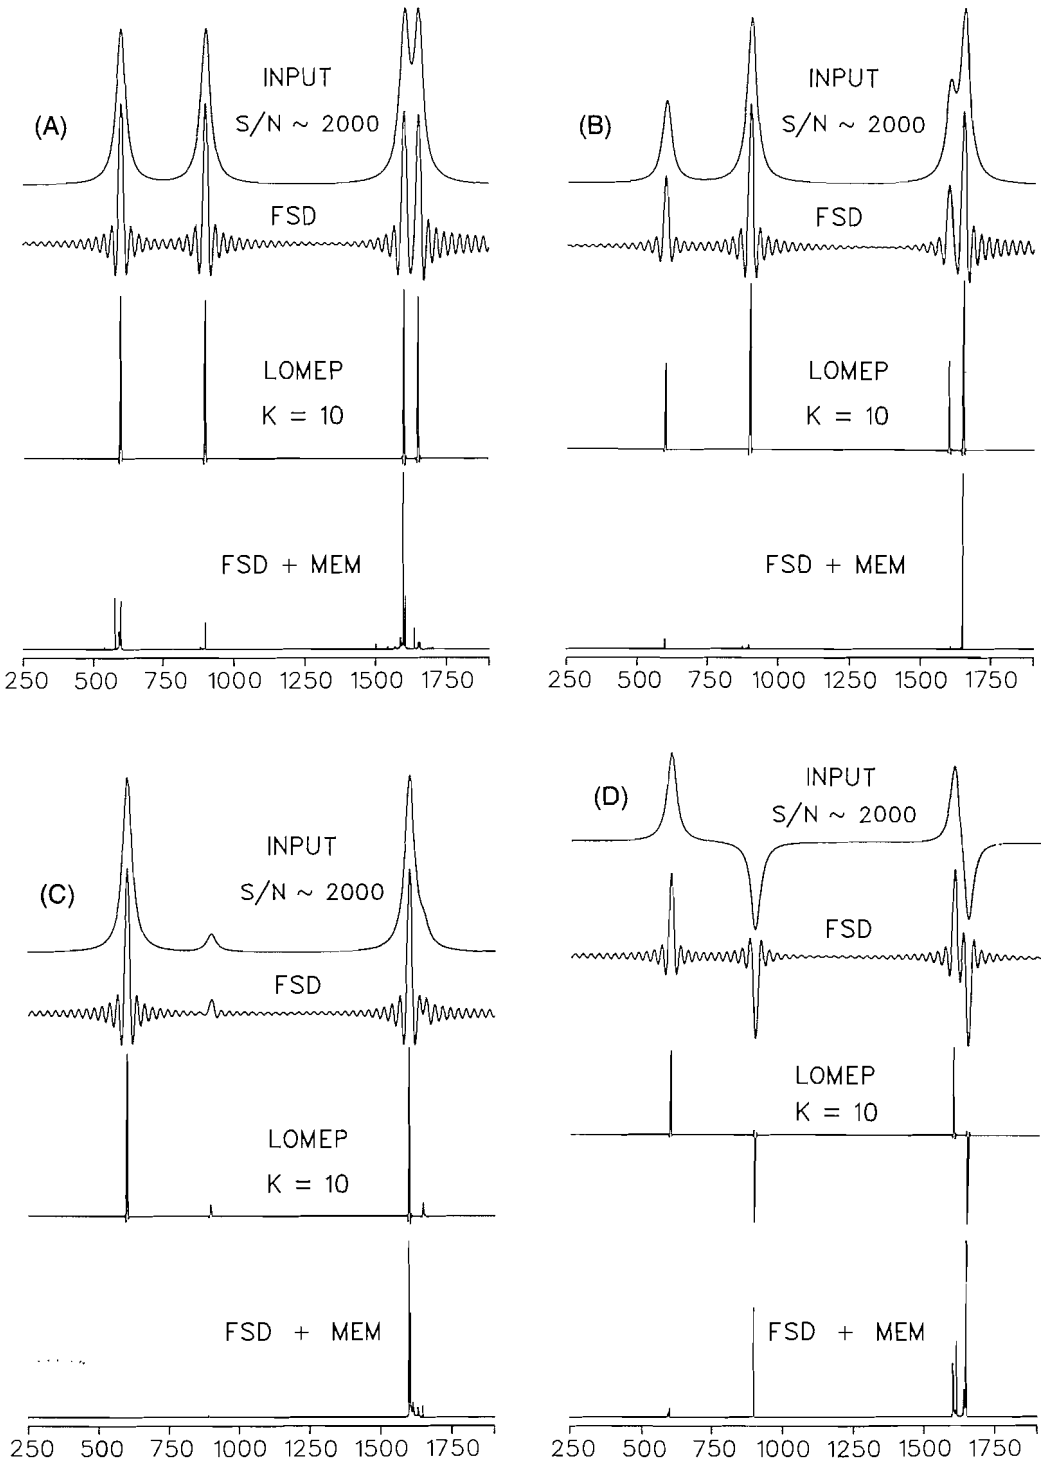

FIG. 1. Burg's MEM and LOMEP output spectra at various input line intensity patterns. The input lines at 800, 900, 1600, and 1650 have the following relative integrated intensities (A) 1, 1, 1, 1; (B) 1/2, 1, 1/2, 1; (C) 1, 1/10, 1, 1/10; (D) 1, −1, 1, −1. The peak-to-peak S/N was 2000.

1-III. Once more it is evident that LOMEP performs well, giving accurate intensities and output lineshapes even in the examples with low input S/N, though some output noise is evident in these cases. The MEM output spectra on the other hand have quite inaccurate intensities. In addition, this figure demonstrates a peculiar characteristic of filter MEM: its output appears to improve as the input S/N decreases. For example, with S/N = 2 or 20 the intensity errors are ~25%, while at S/N = ∞ the intensity errors are almost two orders of magnitude. This is further evidence that the maximum entropy power spectral estimator given in eqs. [4] and [8] is incorrect. Another odd characteristic of MEM is the apparent absence of noise in the output, regardless of the input S/N. This is because the link between the input spectrum and the output is very tenuous, depending only upon a smooth Fourier transform of the filter coefficients, $\{a_k\}$. Comparing

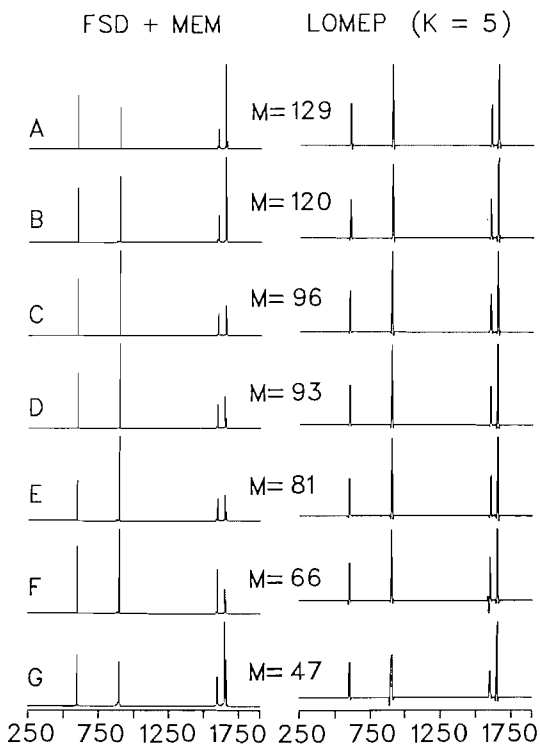

FIG. 2. Illustration of the effect of filter length, $M\Delta x$, on MEM and LOMEP output spectra. The input spectrum is that from Fig. 1B with $N = 153$ for MEM and $N = M + 1$ for LOMEP.

the LOMEP and MEM output at low S/N (Fig. 3E), MEM gives a better looking spectrum while LOMEP gives a more accurate representation of the input along with some output noise.

Discussion

Part A. Why can LOMEP perform a true linear prediction?

In LOMEP one uses a linear filter, as in eqs. [5] and [9], applied to the measured time domain signal, $I(x)$, after FSD. Upon Fourier transformation eq. [9] becomes:

$$[17] \quad E_p(\nu) = \mathcal{H}(\nu)E(\nu)$$

where the transfer function of the filter is given by

$$[18] \quad \mathcal{H}(\nu) = \mathcal{F}\{D(x)h(x)\}$$

According to eq. [11], $I(x)$ consists of infinitely long cosine waves even though only a short segment of this signal is known (between 0 and $M\Delta x$). Now if the condition in eq. [13], i.e., $\mathcal{F}\{D(x)h(x)\} = \mathcal{H}(\nu) = 1$, is exactly valid, at least at all the frequencies (ν_i) where lines occur in the spectrum $E(\nu)$, one can continue $I_p(x)$ ad infinitum, $I_p(x) = I(x)$, and eq. [17] can be rewritten:

$$\begin{aligned}[19] \quad E_p(\nu) &= \mathcal{H}(\nu)E(\nu) \\ &= \mathcal{H}(\nu) \sum_i A_i \{(1/2)\,\delta(\nu + \nu_i) \\ &\quad + (1/2)\,\delta(\nu - \nu_i)\} \\ &= \sum_i A_i \{(1/2)\,\delta(\nu + \nu_i) \\ &\quad + (1/2)\,\delta(\nu - \nu_i)\} = E(\nu)\end{aligned}$$

because $\mathcal{H}(\nu) = 1$ at $\pm \nu_i$ and $E(\nu) = \mathcal{F}\{I(x)\}$. This means that LOMEP gives an exactly correct spectrum including the intensities A_i and the frequencies ν_i. Though $h(x)$ may include frequencies that are not in $I(x)$, the LOMEP result will not contain lines at these frequencies. LOMEP is inherently a more reliable method because it will produce an output line at a given frequency, ν_ω, if and only if $\mathcal{H}(\nu_\omega) = 1$, and the spectrum, $E(\nu_\omega)$, has significant intensity at ν_ω according to eq. [19]. This practically eliminates the possibility of spurious lines, which are quite common in MEM. Moreover, LOMEP will in general yield more accurate frequencies than MEM because in linear prediction both the input signal and the impulse response contain frequency information.

Part B. What's wrong with MEM?

Burg's MEM is based on the maximum entropy power spectral estimator given by eq. [8]. Its predecessor, eq. [5], can be expressed in a continuous form as

$$[20] \quad I(x) = [D(x)h(x)]*I(x) + e(x)$$

or as

$$[21] \quad E(\nu) = \mathcal{H}(\nu)\,E(\nu) + \varepsilon(\nu)$$

where $\varepsilon(\nu)$ is an error spectrum that includes noise. Hence,

$$[22] \quad E(\nu) = \frac{\varepsilon(\nu)}{1 - \mathcal{F}\{D(x)h(x)\}} = \frac{\varepsilon(\nu)}{1 - \mathcal{H}(\nu)}$$

In Burg's MEM one first derives the impulse response $\{a_k\}$ of the so-called prediction-error filter by minimizing errors. If $\varepsilon(\nu)$ were known, the output spectrum could then be computed by direct application of the transfer function $1/(1 - \mathcal{H}(\nu))$. Because the absolute value of the error spectrum, $|\varepsilon(\nu)|$, is not known, the constant value, σ_M, has been used instead, i.e.,

$$[23] \quad |\varepsilon(\nu)| \approx \sigma_M = \sqrt{\frac{1}{2\nu_{\max}} \int_{-\nu_{\max}}^{\nu_{\max}} |\varepsilon(\nu)|^2 d\nu}$$

Using this approximation the power spectrum becomes:

$$[24] \quad P(\nu) = |E(\nu)|^2 \approx \frac{\sigma_M^2}{|1 - \mathcal{H}(\nu)|^2} = \frac{\sigma_M^2}{\left|\sum_{k=0}^{M} a_k e^{i2\pi\nu k\Delta x}\right|^2}$$

which is the well-known maximum entropy power spectral estimator. However, it turns out that this approximation in eq. [23] is very poor, especially at the line positions, ν_i, where the difference between σ_M and $|\varepsilon(\nu_i)|$ can be several orders of magnitude. Also, the error spectrum, $|\varepsilon(\nu)|$, is not merely noise, but contains intensity information not contained in the prediction-error constants. Rearranging eq. [22],

$$[25] \quad \varepsilon(\nu) = E(\nu)[1 - \mathcal{H}(\nu)]$$

we see that $\varepsilon(\nu)$ depends not only on $E(\nu)$, but also on how close $\mathcal{H}(\nu)$ is to unity, i.e., the validity of the linear prediction condition.

We will now explore how this erroneous approximation explains much of the anomalous behavior of MEM. Let us take a few numerical examples. For convenience, we rewrite eq. [24] as follows:

[26] $$P(\nu) = |E(\nu)|^2 \approx \frac{\sigma_M^2}{|1 - \mathcal{H}(\nu)|^2}$$

$$= \frac{\sigma_M^2}{[1 - \mathrm{Re}(\nu)]^2 + [\mathrm{Im}(\nu)]^2} = \frac{\sigma_M^2}{|\Delta(\nu)|^2}$$

where $\mathrm{Re}(\nu)$ and $\mathrm{Im}(\nu)$ are the real and imaginary parts, respectively, of $\mathcal{H}(\nu)$. Assuming the linear prediction condition (eq. [13]) is exactly valid, i.e., $\mathrm{Re}(\nu) = 1$ and $\mathrm{Im}(\nu) = 0$ at all the line positions, then, according to eq. [26], all the corresponding peak heights in MEM will be infinite. It is now easy to understand why on average the closer $[\Delta(\nu)]^2$ is to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

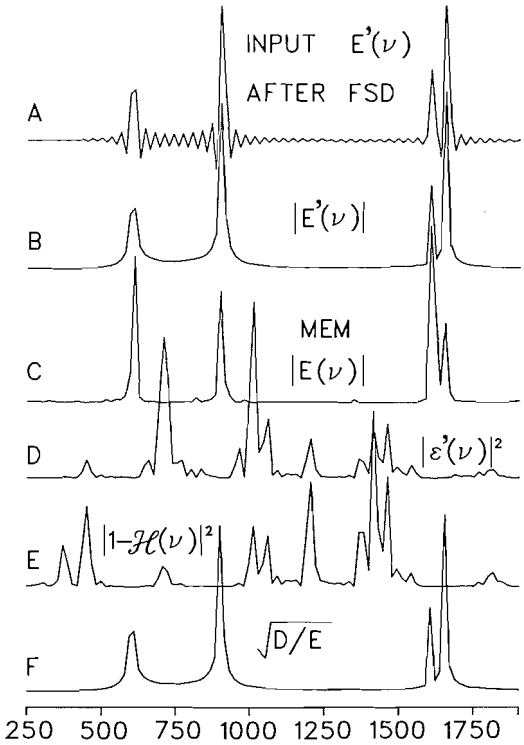

FIG. 4. Demonstration of the inaccurate approximation $|\epsilon(\nu)| \approx \sigma_M$ using eq. [22].

zero, the narrower will be the output line (compare Figs. 3A and 3E).

Figure 4 illustrates the behavior of the function $\Delta(\nu)$ and demonstrates eq. [22]. Figure 4A shows the FSD spectrum of the input spectrum from Fig. 3C with a S/N of 200, Fig. 4B is the corresponding magnitude spectrum $|E'(\nu)|$, and Fig. 4C is Burg's MEM spectrum with $M = 127$, $N = 128$. Again, the MEM output spectrum exhibits degradation of intensity information. Figures 4D and 4E show the power spectra of $\varepsilon'(\nu)$ and $1 - \mathcal{H}(\nu)$, respectively. An estimate, $\varepsilon'(\nu)$, is computed as the discrete Fourier transform of

$$e_j = \sum_{k=0}^{M} a_k I'_{j-k}$$

which means that $\varepsilon'(\nu) = E'(\nu)[1 - \mathcal{H}(\nu)] \approx E(\nu)[1 - \mathcal{H}(\nu)] = \varepsilon(\nu)$ with $E'(\nu) = \mathcal{F}^{-1}\{I'(x)\}$. This approximation, necessary because neither the fitted $I(x)$ nor $E(\nu)$ is known, is quite valid, because, at this S/N, $E'(\nu)$ and $E(\nu)$ differ by less than 1%. According to eq. [22], taking the square root of the ratio of spectrum D to E should yield $|E'(\nu)|$; this is shown to be the case in Fig. 4F. Hence we can conclude that the reason for the erroneous intensities in MEM spectra is the fact that $|\varepsilon(\nu)|^2$ is not a constant (σ_M). In this example, the measured values of $|\varepsilon'(\nu)|^2$ at 600, 900, 1600, and 1650 are 1.01×10^{-11}, 1.30×10^{-10}, 1.33×10^{-11}, and 2.90×10^{-10}, respectively. This represents a change of more than one order of magnitude from line to line.

A study of the value $|\Delta(\nu)|^2$ at the known line positions will further clarify the behavior of the filter-type MEM. For example, if one follows the MEM output spectra as a function of S/N in Fig. 3, it is clear that, at high S/N, $|\Delta(\nu)|^2$ is so small that slight changes in $\mathrm{Re}(\nu)$ and $\mathrm{Im}(\nu)$ can modulate the quantity $1/|\Delta(\nu)|^2$ by a few orders of magnitude. In extreme cases, e.g., Fig. 3A where $\log(|\Delta(\nu)|^2)$ ranges from -10 to -13, the peak height may even be markedly affected by small computational errors. As the S/N decreases, the value $|\Delta(\nu)|^2$ increases, resulting in smaller changes in the output; the range for $\log(|\Delta(\nu)|^2)$ in Fig. 3C is -5.7 to -6.6 and at S/N = 2 it is -2.2 to -4.2. From Table 1–III one can see that at very low S/N (2 and 20) there exists a slight correlation between the integrated intensities of MEM lines and the true intensities. The reason is that the transfer function $\mathcal{H}(\nu)$ is distorted by the noise. Statistically, the stronger the line is at ν_i, the closer $\mathcal{H}(\nu_i)$ is to unity. In other words, $|\Delta(\nu_i)|^2$ is statistically proportional to $(\mathrm{S/N})^{-2}$ at ν_i, resulting in a smaller intensity distortion at low S/N.

Part C. The importance of lineshape

Throughout this discussion the input signal has been assumed to be composed of undamped cosine waves corresponding to a sinc lineshape in the frequency domain. The filter-type MEM has been used for fitting the observed data in cases where the lineshape is not a sinc function, with the goal of increased S/N with any resolution enhancement as a serendipitous bonus. In such cases, where the time domain signal will consist of damped cosine waves, the AR model in eq. [5] is not generally applicable. According to the AR model, eq. [5] should hold for any M contiguous data points, $I_j, I_{j+1}, I_{j+2}, \ldots, I_{j+M-1}$, regardless of the starting point, j. The only function that can satisfy this criterion is the exponential: $A_i(x) = A_i \exp(-2\pi\tau x)$. This means that the AR model, eq. [5], may be applied only to spectra composed of Lorentzian lines. Now eq. [8] can be seen as being applicable only to the special case (implied by eq. [3]) where the Lorentzian lines have zero width with the sinc lineshape resulting from the time domain truncation inherent in all discrete sample data. Attempts to apply eq. [8] directly to Lorentzian lines (or any other lineshape) that correspond to damped cosine waves in the time domain, while not exhibiting as much degradation of intensity information as discussed herein, will often result in inaccurate output frequencies and the splitting of component lines that is a well-known characteristic of Burg's MEM.

Concluding remarks

Herein we have made a comparison between Burg's MEM and LOMEP as resolution enhancement techniques by examining their effect on line intensities. We compare the two techniques in three different ways, by varying the pattern of line intensities, the filter length (M), and the S/N ratio of the input. These trial tests demonstrate that MEM completely degrades intensity information, except at low-input S/N where there is a loose correlation between input and output intensities. At low S/N the coefficients $\{a_k\}$ will be degraded, resulting in the possibility of at least a statistical relationship between $\Delta(\nu_i)$ and the input intensity A_i.

By calculating an approximate error spectrum $|\varepsilon(\nu)|^2$, we have demonstrated the large inaccuracy in the approximation $|\varepsilon(\nu)|^2 \approx (\sigma_M)^2$ in eq. [8]. Furthermore, we point out that this approximation accounts for all the anomalous behavior of MEM. We conclude that for data having a high S/N ratio (>100) treatments such as Burg's MEM, and similar techniques that approximate the power spectral estimator as being proportional to the power spectrum of the transfer function, will retain little, if any, information of line intensities. The

prediction-error coefficients $\{a_k\}$, which are quite efficiently calculated by the Burg's algorithm, can be much better utilized for a true linear prediction as is accomplished in the LOMEP technique, which is shown to retain intensity information.

Static dielectric constants of the *N,N*-dimethylformamide/2-methoxyethanol solvent system at various temperatures

FULVIO CORRADINI, LUIGI MARCHESELLI, LORENZO TASSI,[1] AND GIUSEPPE TOSI
Department of Chemistry, University of Modena, via G.Campi, 183 41100 Modena, Italy

Received April 2, 1992

FULVIO CORRADINI, LUIGI MARCHESELLI, LORENZO TASSI, and GIUSEPPE TOSI. Can. J. Chem. **70**, 2895 (1992).

Measurements of static dielectric constants (ε) have been made for binary liquid mixtures of *N,N*-dimethylformamide (DMF)/2-methoxyethanol (ME) at 19 temperatures ranging from −10 to +80°C. Some empirical equations of the type $\varepsilon = \varepsilon(T)$, $\varepsilon = \varepsilon(X_1)$, and $\varepsilon = \varepsilon(T,X_1)$ have been applied to check their validity. The ε^E values, which refer to the deviation of the dielectric constants of the binaries from the values arising from mole fraction mixture law, have been calculated. Deviations from ideal behaviour have been found to be positive at all temperatures. The positive ε^E values are attributed to a specific interaction between unlike molecules, which leads to the formation of complexes between DMF and ME in the liquid state. These *n*DMF·*m*ME complex moieties were found to have the stoichiometric ratios 2:1, 1:1, and 1:2 in the temperature range of −10 to +80°C.

FULVIO CORRADINI, LUIGI MARCHESELLI, LORENZO TASSI et GIUSEPPE TOSI. Can. J. Chem. **70**, 2895 (1992).

On a déterminé les constantes diélectriques statiques (ε) de mélanges liquides binaires *N,N*-diméthylformamide(DMF)/2-méthoxyéthanol(ME), à 19 températures allant de −10 à +80°C. Dans le but d'évaluer leur validité dans le cas présent, on a appliqué quelques équations empiriques du type $\varepsilon = \varepsilon(T)$, $\varepsilon = \varepsilon(X_1)$ et $\varepsilon = \varepsilon(T,X_1)$. On a calculé les valeurs de la quantité ε^E qui se réfère à la déviation des constantes diélectriques des binaires par rapport aux valeurs découlant de la loi de mélange des fractions molaires. On a trouvé que, à toutes les températures étudiées, le déplacement par rapport au comportement idéal est positif. On a attribué les valeurs positives de ε^E à l'existence d'une interaction spécifique, entre les molécules dissemblables, conduisant à la formation de complexes entre le DMF et le ME, à l'état liquide. On a détecté que les rapports stoechiométriques de ces entités complexes *n*DMF·*m*ME passent de 2:1 à 1:1, puis à 1:2 lorsqu'on fait varier la température de −10 à +80°C.

[Traduit par la rédaction]

Introduction

The static dielectric constant of materials in the liquid state represents a measure of polarization character. When working with polar liquids, this property can provide much useful information about the local structure due to the orientation of the molecules and to reciprocal interactions between neighbouring units. Furthermore, the dielectric data over a wide temperature range for pure liquids, and binary or more complex mixtures employed as solvents, are required to estimate the electrostatic ion–solvent interactions on the basis of the electrostriction theory for ionic solutions, the Debye–Hückel law coefficients for volumes, and other thermodynamic properties (1).

Although dielectric constants as a function of temperature and composition of binary mixtures have been measured for a lot of solvent systems, there are very few available experimental data in the literature on amido-alcholic solvent systems. Thus this study was designed to extend our knowledge on the dielectric behaviour of *n,n*-dimethylformamide (DMF)/2-methoxyethanol (ME) binaries in the temperature range −10 to +80°C, and covering the whole miscibility field expressed in mole fraction of DMF ($0 \leq X_1 \leq 1$).

This solvent system could also be used in electroanalytical chemistry, e.g., for measuring acid–base dissociation constants. In a recent paper, we reported the dissociation constant of picric acid, obtained experimentally using the conductometric method under the same experimental conditions as above (2).

N,N-Dimethylformamide is a nonaqueous solvent of particular interest because it has no hydrogen bonding in the pure state. It therefore acts as an aprotic protophilic medium with a large dipole moment (μ = 3.86 D at 25°C) (3) and a high dielectric constant (ε = 37.51 at 25°C). Consequently, according to Charlot (4) DMF may be classified as a dissociating solvent. Thus DMF and its binary mixtures with hydroxy compounds may be useful to study the effect of the solvent structure on the solvation properties of solutes.

2-Methoxyethanol is amphiprotic, a potentially acidic medium with a low autoprotolysis constant ($pK_{autoprot}$ = 20.5 at 20°C) (5) and a low dielectric constant (ε = 16.94 at 25°C). It is therefore hardly a dissociating solvent (6–10) either for ionogen or ionophore solutes. Because of its dipolar character (μ = 2.36 D) (11), ME shows a tendency to polymerize and form a hydrogen-bonded network.

Based on the arguments above, we are able to study the properties of this binary solvent system systematically, using a range of mixtures ranging from the very structured solvent (pure ME) to a solvent with no structural effects (pure DMF) (12).

Chemists often study the variation of thermomechanical parameters versus solvent composition to characterize liquid mixtures. In a strongly interacting system, this is not a linear relationship. Thus if one merely interpolates the ε values, one may incur serious errors, particularly if there were not a lot of experimental data used in the interpolation.

This paper reports on our findings of the relationship between dielectric constant, temperature, and mole fraction of one component in the system (X_1).

Experimental section

Materials

N,N-Dimethylformamide and 2-methoxyethanol (containing both <0.10% and 0.05% water by weight, respectively, found by Karl-Fischer titrations) were of Carlo Erba (Milan) high purity grade. The solvents were purified by passage through neutral almuina

L	0.1025	10/90
M	0.0000	0/100

column before use, and the final purity was checked by gaschromatography (99.8% DMF, 99.7% ME), confirming that no other significant organic components were present.

Apparatus and procedures

The solvent mixtures were prepared by weight using a Mettler PM 4800 Δ-range balance in dry nitrogen to avoid contact with atmospheric moisture, and then preserved on 3A molecular sieves. The probable error in the DMF mole fraction (X_1) is estimated to be less than 1.5×10^{-4}.

Dielectric constant measurements were carried out at 2 MHz by the heterodyne beat method using a Wissenschaftlich, Technischen Werkstätten GMBH dipolmeter Model DM01 (WTW, Weilheim Oberbayern, Germany). The thermostated stainless steel measuring cells were of MFL 2 ($7 < \varepsilon < 21$) and MFL 3 ($21 < \varepsilon < 90$) type. The sample cells are of the covered coaxial capacitor type with vacuum capacitances of 2 pF (MFL 2) and 0.5 pF (MFL 3). These are adequate to cover the dielectric constant range of DMF/ME mixtures over the whole temperature range studied ($-10 \leq t/°C \leq 80$).

It was checked that good overlap was obtained when passing from the MFL 2 to MFL 3 measuring cell, the difference always lies within the experimental accuracy of the equipment. The cells were calibrated with standard pure liquids, such as dichloromethane, pyridine, butan-1-ol, and acetone (MFL 2); methanol, ethanol, glycerol, and deionized water (MFL 3). With the exception of the Millipore deionized water, all these solvents were of spectrograde quality or more higher. The dielectric constants for the standards were taken from literature (13).

All experiments were performed at least for 10 replicate runs for each composition and at each temperature the confidence level was 95%; the results were averaged.

The measurements were reproducible to within ±0.02 dielectric constant unit. The thermostated measuring cells were embodied in a polyurethane protective jacket, and a Lauda K2R controlled the temperature of the thermostatic bath to ±0.02°C. A thermoresistance Pt 100 (Tersid, Milan) immersed in the sample inside the measuring cells ensured that the temperature was constant and a Wayne Kerr 6425 Precision Component Analyzer measured the resistance. An automatic titration system (Crison model KF 431) equipped with a digital buret (Crison model 738) was used for Karl-Fischer titrations.

Results and discussion

We measured the dielectric constants of the two pure solvents and nine binary mixtures at 19 temperatures in the $-10 \leq t/°C \leq +80$ at 5°C intervals. The compositions are identified by the letters A,B,C,...M, and their ε values are presented in Table 1.

Table 2 reports the experimentally determined dielectric constants and ln ε was fitted to a linear equation in T (13)

$$[1] \quad \ln \varepsilon = \alpha_0 + \alpha_1 T \qquad T/K$$

The above procedure yields the results summarized in Table I, which includes the standard deviation σ(ln ε) at each temperature, has been supplied as supplementary material.[2] The average uncertainty $\overline{\Delta\varepsilon}$, as calculated by

$$[2] \quad \overline{\Delta\varepsilon} = \frac{\sum_N |\varepsilon_{calcd} - \varepsilon_{exptl}|}{N}$$

where N is the number of data points, equals $\pm 0.02\varepsilon$ units, this shows eq. [1] to be an adequate representation of the experimental data.

Figure 1 shows the nonlinear nature of ε as a function of X_2.

An early attempt to express ε as a function of X_1 was in the form of a polynomial:

$$[3] \quad \ln \varepsilon = \beta_0 + \beta_1 X_1 + \beta_2 X_1^2 + \ldots + \beta_n X_1^n$$

Here our best results were obtained for $n = 2$. The relative coefficients β_j are listed in Table II (supplementary material),[2] along with the corresponding standard deviations σ(ln ε) at each experimental temperature. The average uncertainty $\overline{\Delta\varepsilon}$ of the ε values estimated by eq. [3] was approximately ±0.03 ε unit.

The rational equation suggested by King and Queen (14) ε takes the form:

$$[4] \quad \ln \varepsilon = \frac{a_0 + a_1 X_1 + a_2 X_1^2 + \ldots + a_m X_1^m}{b_0 + b_1 X_1 + b_2 X_1^2 + \ldots + b_n X_1^n}$$

with some limiting conditions. Firstly, mole fraction X_1 is defined in the range [0,1] that corresponds to a likely optimum condition on the number of terms provided by $m = n$, and also the sum of the quantities in the denominator can never be zero. Reduced forms of the rational equation [4] are used by imposing the condition $b_0 = 1$ (known as the Padè approximant (14)), and improved by making $a_0 = 1$ (15) (the reciprocal Padè approximant). Thus rational equation becomes

$$[5] \quad \ln \varepsilon = \frac{a_0 + a_1 X_1}{b_0 + b_1 X_1}$$

It is noteworthy that eq. [5] reproduces the dielectric constant values of the two pure components, at the respective limits $X_1 = 0$ and $X_1 = 1$, being assumed $a_0 = 1$, and b_0 necessarily equal to $(\ln \varepsilon_2)^{-1}$ at each investigated temperature. Thus we only needed to determine two coefficients a_1 and b_1, which are the true adjustment parameters (Table III of supplementary material).[2] The experimental ε values in Table 2 are reproduced with an average uncertainty $\overline{\Delta\varepsilon}$ of $\pm 0.02\varepsilon$ unit.

Finally we suggest that rational functions like [5] fit experimental ε values for the DMF/ME binary solvent system better than the polynominal [3], even both are within experimental uncertainly and both have two adjustable coefficients. Equation [3] has two true adjustment coefficients because $\beta_0 = \ln \varepsilon_2$.

The dielectric constant and all thermomechanical properties of a binary system are functions of two variables:

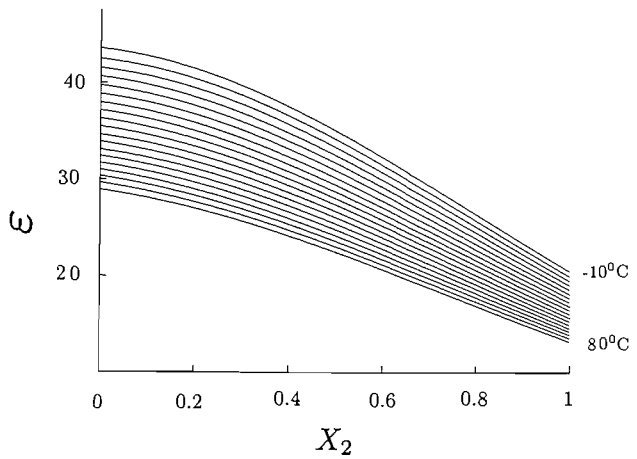

FIG. 1. Isothermal best-fit curves of the static dielectric constant for the *N*,*N*-dimethylformamide/2-methoxyethanol binary system calculated by eq. [5] at various composition.

temperature and composition. A general expression of this dependence is

$$[6] \quad \varepsilon = \varepsilon(T,X_1)$$

By algebraic manipulation of eqs. [1] and [5], eq. [6] may be expressed as

$$[7] \quad \ln \varepsilon(T,X_1) = \left[\frac{\sum_{i=0}^{1}\sum_{j=0}^{1} \gamma_{ij} T^i X_1^j}{(\ln \varepsilon_2)^{-1} + \gamma_{0\bar{1}} X_1} \right]^{1/2}$$

This three-dimensional correlation model, whose coefficients (Table 3) were evaluated by the least-squares method on a TSP computer package (16), fits the experimental data to within $\overline{\Delta\varepsilon} = \pm 0.08$ ε unit over the entire experimental temperature ($-10 \leq t/°C \leq +80$) and composition ($0 \leq X_1 \leq 1$) ranges.

11	TX_1	-3.63106×10^{-2}
0$\bar{1}$	X_1	0.90008

The excess function

The dielectric behaviour of the DMF/ME system is far from ideal. This deviation from ideal behaviour may be measured by assuming a linear dependence of ε on composition for an ideal mixture. Payne and Theodorou (17) used the following equation for this measurement:

$$[8] \quad \varepsilon = \varepsilon^E + \varepsilon_1 X_1 + \varepsilon_2 X_2$$

where ε^E is the excess function; $\varepsilon_1,\varepsilon_2$ represent the values for the pure components at each experimental temperature; and X_1,X_2 are the mole fractions, respectively.

Table 4 lists the ε^E values that have been extensively used (18, 19).

Figure 2 shows plots of ε^E versus X_2, in which the data were obtained by fitting ε^E values in the following equation (20):

$$[9] \quad \varepsilon^E = X_1 X_2 \sum_{k=0}^{6} c_k (X_2 - X_1)^k$$

Table IV in the Depository of Unpublished Data[2] lists the c_k values in eq. [9] and the standard deviations $\sigma(\varepsilon^E)$ at each experimental temperature. Values of ε^E calculated from Eq. [9] are in good agreement with the experimental values listed

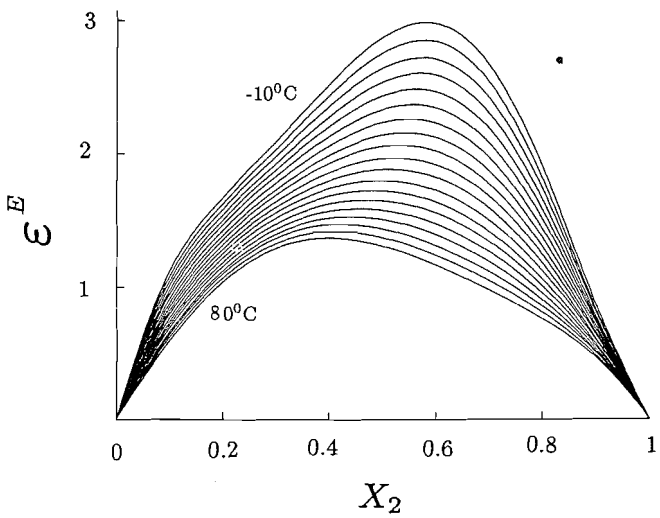

FIG. 2. Isothermal best-fit curves of the excess dielectric constant for the *N*,*N*-dimethylformamide/2-methoxyethanol binary system calculated by eq. [6] at various temperatures.

in Table 4, with $\overline{\Delta\varepsilon^E} = \pm 0.04\varepsilon$ units.

Figure 2 shows that the ε^E values are always positive. At the lower temperatures, ε^E reaches a maximum at $X_2 \simeq 0.65$. As the temperature increases, the maximum becomes more flattened and shifts to $X_2 \simeq 0.5$ at about 50°C. Above this temperature, the maximum becomes pronounced and shifts to $X_2 \simeq 0.35$ at 80°C.

It has been pointed out in literature that small shifts of dielectric behaviour of mixed solvents from ideality ($\varepsilon^E \leq 5$) may be attributed to two causes: (*i*) weak depolar associations between unlike molecules and (or) (*ii*) homoconjugations of the highest dipole moment component induced by the presence of the apolar or quasi-apolar cosolvent (17). Since we have two very polar components, it is less likely that there are homoconjugations between similar molecules but more likely that there are weak dipolar associations between unlike molecules.

Petersen (21) agreed with our opinion. He pointed out that the hydrogen bonds between the water molecules and the carbonyl oxygen atoms are stronger than those formed between the water molecules themselves. In the case of DMF, this effect may be enhanced by the presence of a nitrogen atom in the α-position of the carbonyl group, and by the negative charge on the oxygen in a resonance form:

The maxima values in Fig. 2 may also serve as an index of thermostability of the adducts formed in solution.

We therefore conclude that the probable compositions of the adducts are in DMF:ME = 1:2, 1:1, and 2:1 mole ratios over the temperature range of −10 to +80°C.

A solid-state NMR study of mixtures of poly(ethyl acrylate) (PEA) or poly(ethyl acrylate-co-sodium acrylate) (PEA-i) with sodium palmitate (SP) shows that (1) there is a change in the electron density of the carboxylate carbons of SP in the mixtures compared to pure SP; (2) the $T_{1\rho H}$ value for SP in the mixtures with PEA or PEA-i is depressed in comparison with pure SP for mixtures containing over 4 mol% SP. This can be interpreted as a result of interfacial magnetization transfer from the protons of PEA or PEA-i to the protons of SP; (3) deuterated SP (D-SP) shows a similar growth in magnetization as a function of contact time when pure or when mixed with PEA. The growth is significantly slower in its mixtures with PEA-i. All these findings can be explained by a PEA-i:SP mixture morphology involving bilayers of carboxylate ions at the interface; the same tendency exists in the PEA:SP mixtures, only in this case the ester groups of PEA are preferentially located at the interface.

A. NATANSOHN, C. G. BAZUIN et X. TONG. Can. J. Chem. **70**, 2900 (1992).

Une étude, par spectroscopie RMN à l'état solide, de mélanges de poly(acrylate d'éthyle) (PEA) ou de poly(acrylate d'éthyle-co-acrylate de sodium) (PEA-i) avec du palmitate de sodium (SP) montre que : (1) dans le SP en mélange comparé au SP à l'état pur, il y a un changement dans la densité électronique des atomes de carbones des groupements carboxylate; (2) pour des mélanges avec le PEA et le PEA-i contenant plus de 4% molaire de SP, les valeurs de $T_{1\rho H}$ du SP sont plus faibles que celles du SP à l'état pur. On peut interpréter ce fait comme resultant d'un transfert interfacial de magnétisation des protons de PEA ou de PEA-i vers les protons du SP; (3) le SP deutérié (D-SP), tant à l'état pur qu'en mélange avec du PEA, présente une augmentation semblable de la magnétisation en fonction du temps de contact; par contre, l'augmentation est nettement plus lente dans les mélanges avec le PEA-i. On peut expliquer tous ces résultats par une morphologie du mélange PEA-i/SP impliquant des bicouches d'ions carboxylate à l'interface. La même tendance existe dans les mélanges de PEA/SP; toutefois, dans ce cas, les groupes esters du PEA se retrouvent préférentiellement à l'interface avec les ions carboxylate du SP.

[Traduit par la rédaction]

One of the more recent methods used to analyze the phase structure in polymer blends, mixtures, and composites is high-resolution solid-state NMR obtained with cross-polarization and magic angle spinning. A recent review of its applications to heterogeneous materials (1) emphasizes that spin diffusion can be used to obtain information on a scale between 1 and 200 nm. A variety of experimental techniques are available in solid-state NMR for obtaining information about spin diffusion (2), and the literature making use of them is constantly growing. Two of those techniques are employed in this paper to investigate mixtures of sodium palmitate with poly(ethyl acrylate) and poly(ethyl acrylate-co-sodium acrylate). This is part of a more general effort taking place in our laboratory to investigate the phase structure of polymer blends, mixtures, and composites by solid-state NMR.

The first technique is measurement of $T_{1\rho H}$, the rotating frame proton spin-lattice relaxation time constant. It is now well established that $T_{1\rho H}$ is a reliable probe for the phase structure of various materials based on polymers (3). A recent review of the literature on polymer blends is included in one of our previous publications (4). $T_{1\rho H}$ can be directly related to the distance the spin travels during the spin-lattice relaxation process, hence it may be used as an indirect measure of proton density in the analyzed phase (5). Our investigations on charge transfer interacting polymer blends confirmed that the physical distance between protons is more important for $T_{1\rho H}$ than are mobility factors (6).

The second technique is polarization transfer between nonbonded regions in a sample. This is usually employed in mixtures in which one of the components lacks protons, and hence its magnetization has to come from the other component, the protonated one, by physical proximity and nonbonding interactions. Another condition that must be satisfied for the magnetization to be transmitted is a relatively low mobility of both components. Except for very low T_g rubber materials, this condition is usually satisfied in the solid state. There are many examples of such studies, some of them reviewed in ref. 1. We have employed this technique in a study of compatibilization of a polymer pair through ionic interactions (7).

In a previous paper (8), mixtures of sodium palmitate (SP) with poly(ethyl acrylate) (PEA), and with an ionomer of PEA, namely poly(ethyl acrylate-co-sodium acrylate) (PEA-i), obtained by partial saponification of PEA, were investigated by differential scanning calorimetry (DSC) and dynamic mechanical thermal analysis. The fact that the DSC transitions of the pure soap phase are not perturbed in the mixtures shows that the soap remains phase-separated in the mixtures, and that the soap phase is virtually identical to that

of pure soap. Furthermore, neither the glass transition of either polymer nor the biphasic morphology of the ionomer was affected by the presence of the soap. On the other hand, there were certain indications that there may be physical interfacial interactions between the soap phase and either polymer. In particular, the rubbery region was significantly reinforced in modulus by addition of SP, roughly to the same extent for both polymers, leading to the supposition that there are interactions between SP carboxylate groups at the surface of the crystalline domains of the soap and the ester groups of either polymer. In the case of the ionomer, although the total effect of the interfacial interactions is similar to that obtained for PEA, it was supposed that interactions between carboxylate groups of the ionomer and those of the soap may also take place, but without significantly affecting the ionomer microdomain structure. However, no indication of interactions between the two components was observed through infrared spectroscopy. We will show in this paper that the two NMR techniques mentioned above provide new evidence for interfacial interactions.

Experimental

Synthesis of the polymer and ionomer and preparation of the mixtures are described in previous publications (6, 8). Briefly, the mixtures were prepared by dissolving the two components in a 1% benzene/methanol (50:50 v/v) solution, stirring for about 15 h, freeze-drying, and further drying at about 70°C under reduced pressure for several days. The PEA-i used in the present study is a poly(ethyl acrylate) ionomer containing 10 mol% sodium acrylate co-units. Deuterated palmitic acid (MSD Isotopes, 97.7 at.% D) was converted to deuterated sodium palmitate.

Sodium palmitate was prepared for NMR measurements by being subjected to the same processing procedures as were its mixtures with PEA or PEA-i. Thermal history, especially in a crystalline substance, can produce changes in the relaxation behaviour; hence all samples analyzed have a similar thermal history. Deuterated sodium palmitate (D-SP) was mixed with PEA and PEA-i, respectively, following the same general procedures.

The NMR spectra were recorded on a Bruker CXP-200 spectrometer operating at 50.307 MHz. A typical cross-polarization pulse sequence had a preparation delay of 10 s, a proton 90° pulse of 3.7 μs, a contact time of 1 ms, a decoupling time of 0.09 s, and an acquisition time of 0.1024 s. Two hundred scans were recorded for each spectrum and spinning was performed at ca. 4 kHz, leading to the complete absence of spinning side-bands. Proton spin-lattice relaxation in the rotating frame time constants and intermolecular cross-polarization rates were monitored by increasing contact times. Depending on the sample, contact times were varied between 0.2 and 200 ms. No external reference for the chemical shift was employed; all signals were measured in comparison to the sharp CH_3 peak (15 ppm).

Results and discussion

The spectrum of sodium palmitate is presented in Fig. 1, along with the assignments. There are three groups of signals. The carboxylate carbon resonates in a sharp peak at 187 ppm. The methyl carbon resonates at 15 ppm, while the various CH_2 carbons give a signal centered around 32 ppm, which is the resonance of all-*trans* methylene carbons, similar to polyethylene (9). The spectrum of PEA-i is presented in Fig. 2 together with its assignments. The backbone resonates at about 40 ppm in a broad peak, and the CH_3 peak (at 15 ppm) is again sharp, due to significant motional averaging. The glass transition temperature of this ionomer is 5°C according to DSC heating scans of 20°C/min (8), which

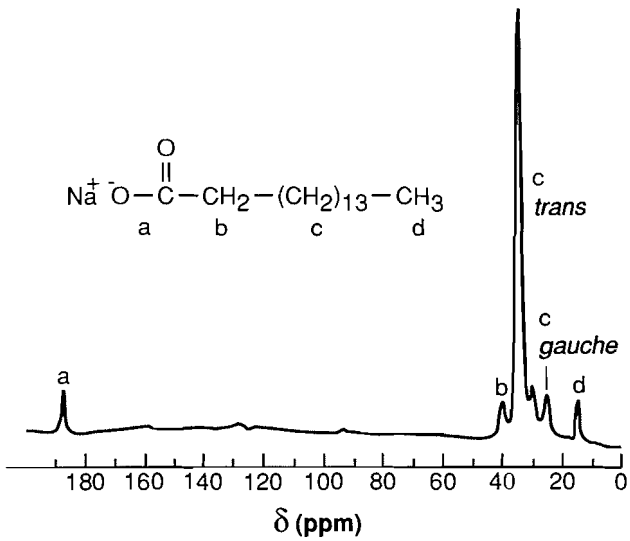

FIG. 1. CP-MAS ^{13}C NMR spectrum of sodium palmitate.

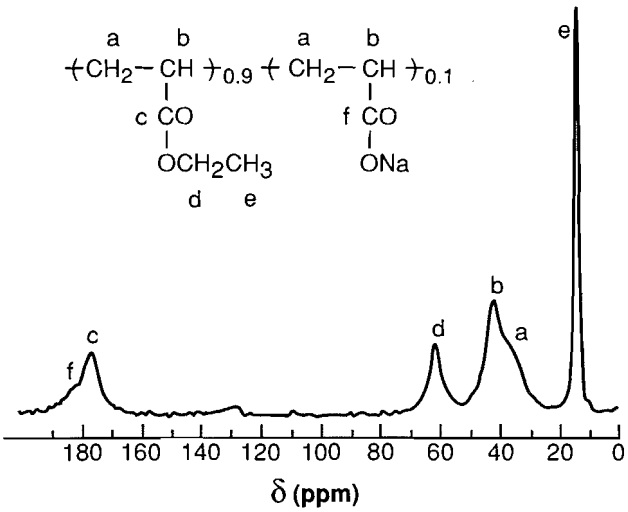

FIG. 2. CP-MAS ^{13}C NMR spectrum of a copolymer of ethyl acrylate with 10 mol% sodium acrylate (PEA-i).

means that even the segmental motion is significant at room temperature. The ester CH_2 resonates at about 60 ppm and the ester carbonyl at about 177 ppm. The carboxylate carbon appears as a shoulder on the low-field side of the carbonyl. Its chemical shift in the ionomer is 182 ppm, much higher than that in the sodium palmitate. A spectrum of PEA, not presented here, is very similar to the spectrum in Fig. 2. The main difference is the absence of the carboxylate carbon signal.

Figure 3 presents the ^{13}C NMR spectrum of a mixture of PEA-i and sodium palmitate (SP) containing 35 wt.% SP. As expected, the spectrum is essentially a weighted average sum of the spectra presented in Figs. 1 and 2. The CH_3 groups of the two components resonate together at 15 ppm, while the CH_2 signal of SP overlaps with the backbone resonances of PEA-i. The carboxylate carbons of the two components also seem to resonate together at 183 ppm. Two of the PEA-i signals resonate separately: the ester carbonyl at 177 ppm and the ester CH_2 at 60 ppm.

Although the carboxylate carbon signal, which belongs

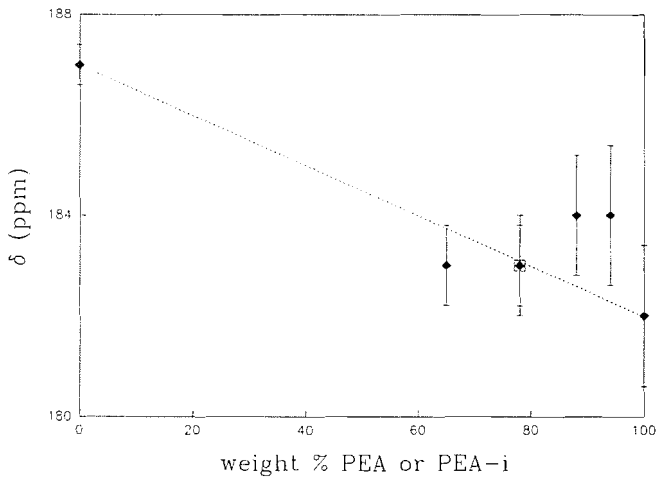

FIG. 4. Chemical shift of the carboxylate carbons as a function of composition for various mixtures of PEA-i with SP (◆) and for one mixture of PEA containing 22 wt.%. SP (□).

mainly to SP, overlaps the carbonyl signal of PEA-i, the resonance of the former can be readily identified and measured because of its rather sharp signal. A plot of its chemical shift as a function of the mixture composition is presented in Fig. 4. The principal result is that the carboxylate carbon soap signal in all of the mixtures resonates upfield from the signal of the pure soap. The dashed line suggests that this signal moves linearly upfield toward the pure ionomer signal as a function of composition. However, it is obvious that this cannot be confirmed by our data, since the error in measuring the chemical shift is relatively large and increases as the soap content decreases.

A PEA:SP mixture containing 22 wt.% SP is included in the five mixtures reported in Fig. 4. The chemical shift of its carboxylate carbons is seen to be identical to that in the PEA-i:SP mixture of the same composition. In both cases, this apparent chemical shift can be interpreted as a change in the electronic environment of the carboxylate carbon in going from the pure soap to the mixture with the polymer or ionomer. This is assuming, of course, that the chemical shift is dictated primarily by the electron density around the resonating nucleus, and does not take into account other factors that can affect carbon chemical shifts. If this assumption is accepted, one could explain the shift in the ionomer mixtures by considering the composition and resulting morphology of the ionomer. PEA-i, like many ionomers, shows two-phase behaviour (8). It is generally accepted that the ionic groups of the ionomer tend to aggregate to form ion-rich domains that lead to the appearance of the second phase (10). When SP is mixed with the ionomer, it is possible that at least some of its carboxylate groups tend to be in close proximity to the ion-rich domains, perhaps even mixed preferentially with carboxylate groups of the ionomer. The SP carboxylate groups would thus be surrounded by more electron density and therefore resonate at higher field when mixed with the ionomer than in pure SP. On the other hand, the chemical shift data in Fig. 4 also suggest that the SP carboxylate groups are as shielded in the polymer without carboxylate groups (PEA) as they are in the ionomer. The shielding of the SP carboxylate groups in the PEA mixture may indicate a preference for neighbouring ester carbonyl groups. If neighbouring ester groups have similar effects on the SP carboxylate groups as do neighbouring carboxylate groups, then, based on the chemical shift data, one cannot rule out that the SP groups may be mixed preferentially with ester groups in the ionomer mixtures as well.

One factor to be considered in the above is that the chemical shift of the carboxylate carbons in all soap mixtures contains a distribution of many possible shifts at the interfaces, in various environments, and in a bulk phase. Hence it is reasonable to suppose that the actual chemical shift of the soap carboxylate carbons present at the interface with PEA or PEA-i is much lower than the average read in the spectrum. Possibly this indicates the presence of carboxylate–carboxylate or carboxylate–ester bilayers.

To measure the proton spin-lattice relaxation time constant in the rotating frame ($T_{1\rho H}$), the contact time can be increased systematically and the spectrum monitored for magnetization decay. Figure 5 shows an example of a plot of ln(magnetization) as a function of contact time for a mixture of PEA-i and SP containing 22 wt.% SP. The numbers on each curve correspond to the signals in Fig. 3 and represent the magnetization decays for each of those signals. The only "pure" signals in Fig. 3, numbers 2 and 3, belong to PEA-i. They decay very fast, as fast as in the pure ionomer, and from the slope one can determine a $T_{1\rho H}$ of 2.8 ms. The remaining three signals contain both components and, consequently, their decay is nonexponential. Nevertheless, one can clearly distinguish a long relaxation time component (48 ms for this sample) and subtract this component from the overall decay to obtain the fast component, which is similar to that of the "pure" PEA-i signals. The contribution of PEA-i to signals 1 and 4 is minor, as one would expect from the intensity ratios in Fig. 2. For CH_3 (signal 5), however, PEA-i has the most important contribution, and this explains why the nonexponential decay is the most obvious here.

The most important conclusion to be drawn from Fig. 5 is that, as expected (8), the two components do not mix at the molecular level. They form separate phases, which relax independently, and there is a hindrance to magnetization transfer across phase boundaries. The actual $T_{1\rho H}$ values as a function of the composition of the mixtures were also determined. Figure 6 presents the results. However, some caution must be exercised when interpreting them. Two points in particular must be dealt with.

First, it is to be noted from the figure that, for a given composition, more than one $T_{1\rho H}$ values are obtained from

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

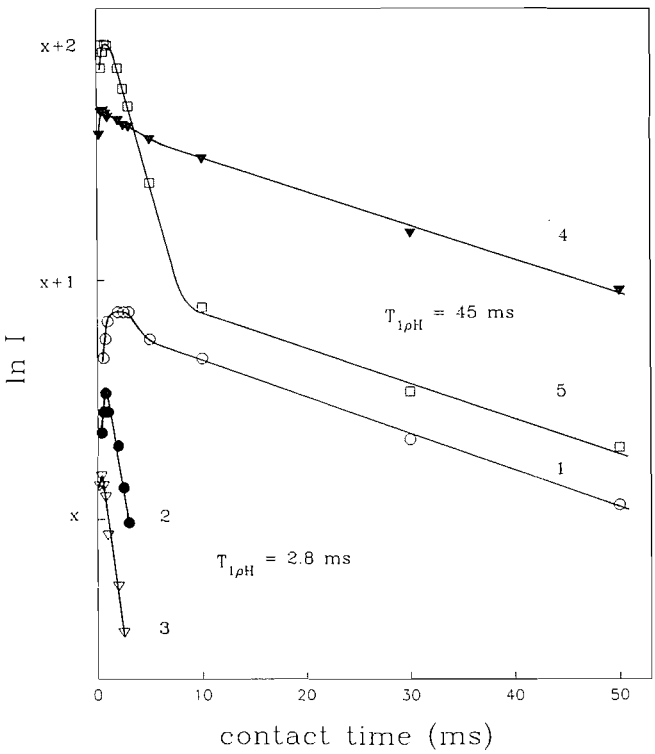

FIG. 5. Magnetization decay as a function of contact time for a mixture of PEA-i containing 22 wt.% SP. The numbers correspond to the signal numbers in Fig. 3.

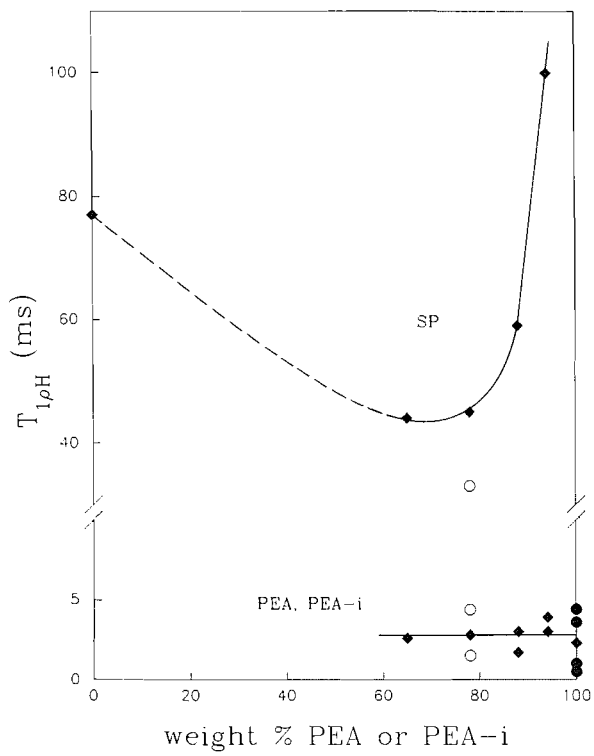

FIG. 6. $T_{1\rho H}$ values as a function of concentration for several PEA-i/SP mixtures (◆) and one PEA/SP mixture (○). The upper symbols are for the values obtained from SP signals, the lower symbols from PEA-i or PEA signals. The $T_{1\rho H}$ values for the signals of pure PEA are also shown (●). See text for more detailed explanation.

the polymer or ionomer signals in some cases. Mixtures containing PEA-i with 35 wt.% and 22 wt.% soap show the same slope for all signals, as does the pure ionomer. However, the two PEA-i mixtures of lower soap content, the only PEA mixture, and PEA itself show different slopes for different signals. This is, in fact, a well-known phenomenon for polymers above their T_g (11); and PEA, PEA-i, and all of the mixtures have glass transitions below room temperature (8). In this situation, the presence of different slopes does not mean that there are various phases within the polymer domains.

Second, care must be taken when measuring $T_{1\rho H}$ values for crystalline substances, which SP is. The presence of spin–spin relaxation mechanisms can prevent measurement of the actual $T_{1\rho H}$ value. To avoid errors in the measurements, especially to eliminate the local dipolar field, a spin-lock experiment can be used only with relatively high spin-locking fields. Analyzing other soaps at higher temperatures, Bonekamp *et al.* (12) demonstrated that there is a minimum acceptable field for this experiment. A variable field experiment confirmed that for our sample at room temperature the minimum admissible field is 4.5 G, clearly well below the 16 G field (corresponding to the 90° pulse of 3.7 μs) used by us. As supportive evidence, the $T_{1\rho H}$ values plotted in Fig. 6 are of the same order of magnitude as those measured on sodium *n*-butyrate (12).

Now, the data in Fig. 6 show that PEA and PEA-i are not influenced very much by the presence of the soap. Their $T_{1\rho H}$ values stay more or less constant. SP, on the other hand, undergoes significant changes when mixed with the polymer or ionomer. Except for the sample containing 6 wt.% SP, which shows an increase in the $T_{1\rho H}$ value, all mixtures have lower $T_{1\rho H}$ values than SP itself. It is generally accepted that in miscible systems $T_{1\rho H}$ takes a value that is intermediate between the values of the two components. Phase-separated systems can show some kind of "communication" at the interface, which affects the $T_{1\rho H}$ value of the slower relaxing component (4). This means that, if the two components of a system present some kind of physical interaction at the interface that separates the two phases, and that if this interaction can translate into a limited diffusion of spins across the interface, then, at the interface, the slowest-relaxing component will be partly relaxed by the fastest-relaxing component. This will translate into an overall decrease of $T_{1\rho H}$ for the slow-relaxing component. Such occurrences have been observed for charge-transfer interacting polymer blends (4), as well as for interpenetrating epoxy composites containing lignin (13).

If this is true in the case studied here, Fig. 6 indicates that there is some communication at the interface if the amount of soap in the mixture with PEA-i exceeds ca. 10 wt.% (ca. 4 mol%). Furthermore, there seems to be more communication in the mixture with PEA than in the mixture with the ionomers.

One explanation for the data in both Figs. 4 and 6 may be related to how the soap molecules arrange themselves at the interface with the polymer or ionomer. Soaps such as SP generally form a solid phase bilayer structure with interdigitated ionic groups; i.e., the ion pairs form an ionic double layer, where each half contains anions and cations that are arranged alternately both within the half-layer and between

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

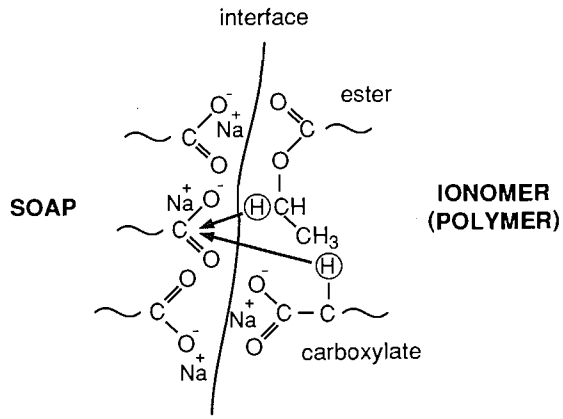

FIG. 7. Schematic view of the interface between the polymer (ionomer) and the soap domains. Arrows indicate the distance the spin is required to travel to allow for magnetization transfer.

the two half-layers (14). The DSC studies of the mixtures of SP with PEA and PEA-i indicated that the bulk structure of the SP phase is essentially unperturbed in the mixtures (8). However, given the tendency of the ionic groups to form bilayers, it is reasonable to assume that in the mixtures with PEA and PEA-i, which are polar media, the SP molecules at the surface of the soap domains are arranged such that the sodium carboxylate ion pairs face the surrounding polymer or ionomer. In the case of the ionomer, this allows for direct contact between its carboxylate groups and those at the SP surface; in fact, the SP and PEA-i carboxylate groups may even tend to form an interfacial ionic double layer. If the proportion of soap in the mixture is very low, the SP domains would be very small in size and number; under these conditions the interfacial separation between the soap and ionomer domains may consist solely of soap and ionomer carboxylate groups. This could explain why, in Fig. 6, a composition with the lowest amount of SP shows an increase in $T_{1\rho H}$ compared with the pure soap, unlike all other compositions, which present a depression of $T_{1\rho H}$. With the addition of more soap, ester carbonyl groups are likely to replace ionomer carboxylate groups at the interface with the soap phase. This would allow more contacts between the protonated part of the ionomer and the soap, and probably also some communication of the carbons in the soap with the protons in the ionomer.

In the mixtures with PEA, the carboxylate surface of the soap domains would be primarily in contact with the ester carbonyl groups of PEA, which are less polar than the carboxylate groups and may allow for more contact with the soap than in the case of PEA-i. This would explain why the $T_{1\rho H}$ of the soap is more depressed in the presence of 78 wt.% PEA than in the presence of 78 wt.% PEA-i. This hypothesis is also consistent with the chemical shifts in Fig. 4, as noted above. A schematic illustration to clarify the possible contacts at the interface is presented in Fig. 7.

To test this hypothesis, experiments were carried out using deuterated SP. In the same experimental conditions as were employed for the $T_{1\rho H}$ measurements, the magnetization of the carbon nuclei increases with increasing contact time, because now the protons are a diluted species and the physical distance between two protons is greater than the distance previously measured for spin diffusion. Figure 8*a*

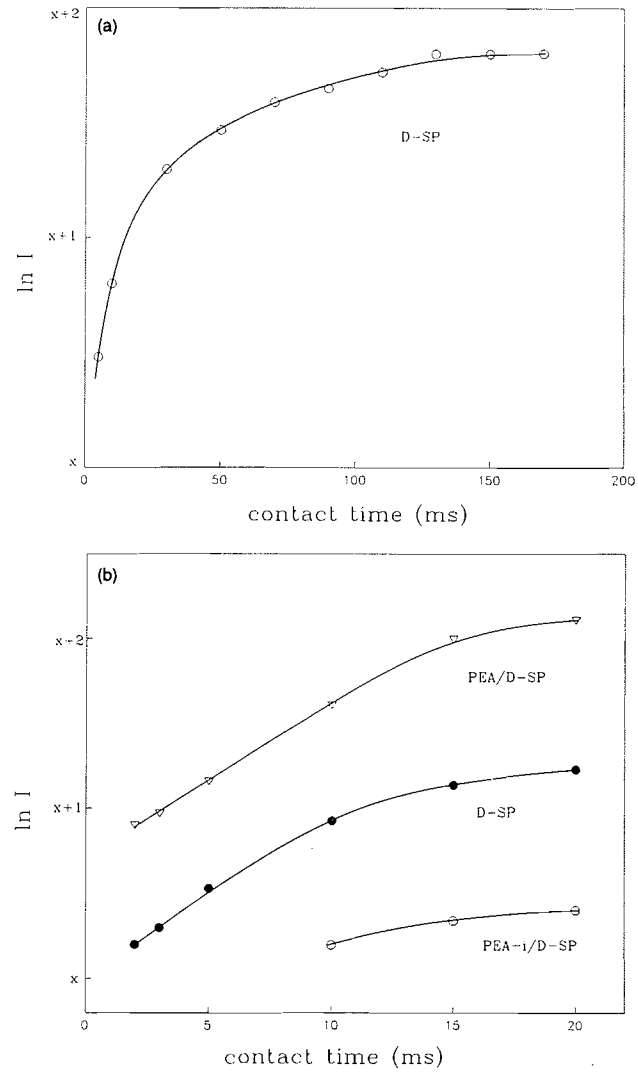

FIG. 8. Buildup of magnetization (*a*) in deuterated soap and (*b*) in D-SP, PEA:D-SP, and PEA-i:D-SP as a function of contact time. The vertical axis is shifted arbitrarily.

shows the magnetization buildup for one of the D-SP signals. There are small differences in this buildup for various carbons, due to different distances from protons. Figure 8*b* shows the initial part of this magnetization buildup curve for D-SP in comparison with two mixtures containing 22 wt.% D-SP: one with PEA and the other with PEA-i. The first obvious conclusion is that there are no significant changes in the buildup pattern for the mixtures as compared to the pure D-SP, which confirms phase separation and lack of spin diffusion across interfaces. Intimate molecular mixing would have allowed magnetization transfer from the protons of PEA or PEA-i to the carbons of D-SP, and the signals of D-SP carbons would have grown much faster.

Because the vertical scale in Fig. 8*b* is arbitrarily drawn, a better comparison between the samples can be made using Table 1, which presents the signal/noise ratios for the methylene carbons of D-SP at various contact times. The signal/noise ratio depends on several factors, the most important in our case being sample quantity. The same spinner is filled with pure D-SP or with a mixture containing only 22 wt.% D-SP (lines 2 and 3). One would expect a decrease

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12

TABLE 1. Signal/noise ratios for the deuterated soap and its mixtures at various contact times

Sample	Signal/noise ratio			
	10 ms	15 ms	20 ms	10 ms/20 ms
D-SP	6.7	9.8	10.6	1.6
PEA-D-SP	7.5	8.4	15.8	2.1
PEA-i-D-SP	2.5	3.3	3.9	1.6

of the signal/noise ratio for the mixed samples, but this happens only for the mixture with the ionomer. This last mixture has such a weak signal that it cannot be measured out of the noise at contact times lower than 10 ms. The fact that the mixture with PEA has a higher signal/noise ratio than the pure D-SP suggests that there is some cross-polarization transferred through the soap–polymer interface. From Fig. 7, the closest contacts can be achieved with the ester methylene protons. They are not nearly as efficient in transmitting magnetization in the ionomer samples, which suggests that, in the ionomer mixtures, the carboxylate groups rather than the ester groups dominate at the interface with the soap domains. A carboxylate–carboxylate interface would have very few protons present, thus being an effective barrier for magnetization transmission.

The last column in Table 1 compares the signal/noise ratios at 10 and 20 ms contact times, and is an indication of growth during this interval. All samples are behaving similarly, as shown in Fig. 8*b*, with the mixture containing PEA showing a higher growth.

In conclusion, all three findings presented above can be explained by the presence of separated soap domains dispersed within a continuous polymer or ionomer phase. The soap molecules at the surface of the soap domains are arranged such that the carboxylate groups preferentially face the polymer phase. The carboxylate groups of the ionomer and the ester groups of the polymer are closer than the less polar groups to the soap domains, thus causing a chemical shift of the carboxylate carbon signal to a higher field in the mixtures than in pure soap. In the ionomer mixtures, a carboxylate–carboxylate bilayer tends to form at the interface separating the two domains, probably supplemented by a carboxylate–ester layer; this decreases or prevents magnetic communication between the protons of the ionomer and the carbons of the soap. If the amount of soap is very small, no communication is noted between even the protons of the two phases. In the polymer mixtures, the carboxylate–ester bilayer allows for more communication between the magnetic nuclei of the two phases than in the ionomer mixtures. Thus, although the bulk phase of neither component is significantly perturbed in the mixtures, as was shown in ref. 8, the above results strongly indicate the presence and type of interfacial interactions between the two components for both the polymer and ionomer mixtures.

Received January 13, 1992

BHAMIDI SRINIVAS and PANTHAPPALLY S. ZACHARIAS. Can. J. Chem. **70**, 2906 (1992).

Different series of heterodinuclear complexes, viz., $[CuNiL](ClO_4)_2 \cdot nH_2O$, $[CuZnL](ClO_4)_2 \cdot nH_2O$, $[NiCuL](ClO_4)_2 \cdot nH_2O$, and $[NiZnL](ClO_4)_2 \cdot nH_2O$ complexes where L is a dinucleating Schiff base ligand derived from the condensation of 1 mole of 2-hydroxy-5-methylbenzene-1,3-dicarbaldehyde, 1 mole of 1,3-diaminopropane, and 2 moles of *ortho*- or *para*-substituted aniline, have been synthesized and investigated. The μ_{eff} values of the CuNiL and NiCuL series of complexes suggest presence of weak antiferromagnetic coupling in them. In MeCN and DMF the CuNiL and NiCuL series of complexes exhibit two reversible one-electron redox couples at two different potentials. The large separation between the two redox couples is attributed to the antiferromagnetic interaction between the metal centres in the complexes. In the NiCuL series of complexes, the observed shift of 100–150 mV in E_1 to more negative values in complexes with potential donor groups such as OMe, OEt, SMe, etc. in the *ortho* position of the phenyl group of L is explained on the basis of weak bonding interactions of these groups with the copper centre. The CuNiL series of complexes do not exhibit such shift in E_1 values since there is no significant change in the square planar geometry of the copper centre. The CuZnL and NiZnL series of complexes exhibit only single one-electron redox couple as could be anticipated.

BHAMIDI SRINIVAS et PANTHAPPALLY S. ZACHARIAS. Can. J. Chem. **70**, 2906 (1992).

On a synthétisé et étudié différentes séries de complexes hétérodinucléaires, comme $[CuNiL](ClO_4)_2 \cdot nH_2O$, $[CuZnL](ClO_4)_2 \cdot nH_2O$, $[NiCuL](ClO_4)_2 \cdot nH_2O$ et $[NiZnL](ClO_4)_2 \cdot nH_2O$, dans lesquels L est un ligand bidentate formé d'une base de Schiff provenant de la condensation d'une mole de 2-hydroxy-5-méthylbenzène-1,3-dicarbaldéhyde, une mole de 1,3-diaminopropane et deux moles d'anilines *ortho* ou *para* substituées. Les valeurs de μ_{eff} des complexes des séries CuNiL et NiCuL suggèrent la présence d'un faible couplage antiferromagnétique. Dans le MeCN et le DMF, les complexes des séries CuNiL et NiCuL présentent deux couples rédox réversibles à un électron, à deux potentiels différents. La grande séparation entre les deux couples rédox est attribuée à l'interaction antiferromagnétique entre les centres métalliques des complexes. Le déplacement de 100–150 mV observé vers des valeurs plus négatives de E_1 pour les complexes de la série NiCuL portant des groupes donneurs, comme OMe, OEt, SMe, etc., dans la position *ortho* du groupe phényle L est expliqué par les faibles interactions de liaison de ces groupes avec les centres cuivriques. Les complexes des séries CuNiL ne présentent pas de déplacement dans les valeurs de E_1 puisqu'il n'y a pas de changements significatifs dans la géométrie plan carré du centre cuivrique. Comme on pouvait s'y attendre, les complexes des séries CuZnL et NiZnL ne présentent qu'un seul couple rédox à un électron.

[Traduit par la rédaction]

Introduction

Dinuclear metal complexes are important in the investigation of interactions between metal ions in dinuclear metal centres of proteins (1–4) and that of multimetallic species at active bio sites (5–9). Various types of dinucleating ligands have been used in the preparation of dimetallic complexes, of which Schiff base ligands derived from 2-hydroxy-5-methylbenzene-1,3-dicarbaldehyde are of considerable interest since they provide two metal ions in close proximity (<3.0 Å) for direct metal–metal interaction. Dinuclear copper(II) complexes of these ligands show interesting magnetic and redox behaviour (10–19). The dicopper complex of macrocyclic Schiff base ligand obtained from the condensation of 2-hydroxy-5-methylbenzene-1,3-dicarbaldehyde and 1,3-diamino-propane exhibits reversible one-electron transfers at two different potentials, although both copper centres are identical with respect to ligand environment and geometry (20). This has been ascribed to the magnetic exchange coupling between the copper(II) centres and its resultant stabilizing influence on $Cu^{I}Cu^{II}$ intermediate complex species (20). Compared to the bulk of literature available on dicopper(II) complexes, very little has been reported on heterodimetallic complexes of these ligands, probably due to the difficulties involved in the syntheses of such complexes (21, 22). The heterodimetallic complexes, having copper(II) as one metal centre and the other metal centre varying among Mn(II), Fe(II), Co(II), and Ni(II), have been shown to exhibit considerable antiferromagnetic coupling between the metal centres. In this article we wish to report the syntheses, characterization of a series of heterodinuclear Cu(II), Ni(II), and Zn(II) complexes (general structure is shown in **2** of Scheme 1), and their spectral, magnetic, and redox properties.

SCHEME 1

It can be seen from the structure that the ligands provide two nonequivalent O_2N_2 coordination sites, which share two phenolato groups. While the substitution on the phenylazomethine group can be expected to influence the redox behaviour of the metal at the M_B site, it is not likely to do so at the M_A sites.

Experimental

Syntheses of complexes

All reagents and solvents were purchased from commercial sources and utilized after distillation or recrystallization. 2-Hydroxy-5-methylbenzene-1,3-dicarbaldehyde was prepared according to a reported procedure (13). For electrochemistry, MeCN was treated successively with $CaCl_2$ and P_2O_5 and DMF was dried over CaH_2 and distilled. They were stored on type 4A molecular sieves. The heterodinuclear Cu(II), Ni(II), and Zn(II) complexes, $CuNiL(ClO_4)_2\cdot 3H_2O$, $CuZnL(ClO_4)_2\cdot H_2O$, $NiCuL(ClO_4)_2\cdot 3H_2O$, and $NiZnL(ClO_4)_2\cdot 2H_2O$ were prepared from the precursor complexes CuL′ and NiL′ as shown in the Scheme 1.

The precursors CuL′ and NiL′ complexes were prepared according to reported procedure (21). In a typical preparation, a suspension of CuL′ (0.420 g, 1 mmol) in MeOH (20 cm^3) was added to the respective aniline (3 mmol) and solid $Ni(ClO_4)_2\cdot 6H_2O$ (0.365 g; 1 mmol) and stirred. The stirring was continued for 2 h, and the yellowish green product of $CuNiL(ClO_4)_2\cdot H_2O$ was collected by filtration, washed with diethyl ether, and dried *in vacuo* for 12 h. $NiCuL(ClO_4)_2\cdot 3H_2O$ complexes were prepared from NiL′ complex, the respective anilines and $Cu(ClO_4)_2\cdot 6H_2O$ by following a similar procedure adopted for the preparation of $CuNiL(ClO_4)\cdot 3H_2O$. The $CuZnL(ClO_4)_2\cdot H_2O$, $NiZnL(ClO_4)_2\cdot 2H_2O$ type complexes were also prepared by the same procedure.

Caution: The perchlorate salts are potential explosives and should be handled with care.

Physical measurements

The CHN analyses were carried out on a Perkin–Elmer 240 C Elemental Analyser. Metal estimations were carried out on an inductively coupled plasma spectrometer (Labtem-Australia). Infrared spectra were recorded on a Perkin–Elmer IR 283 spectrophotometer in the range 4000–200 cm^{-1} in KBr pellets. Electronic absorption spectra were recorded on a Perkin–Elmer Lambda 3B UV-Vis spectrophotometer in the 900–200 nm wavelength region and on a Cary 17D spectrophotometer in the near ir region in MeCN and DMF. Magnetic susceptibility measurements were made by the Faraday method, at ambient temperature using a CAHN magnetic balance setup. Diamagnetic corrections were made using Pascal's constants (23).

Cyclic voltammetric experiments were carried out on a PAR electrochemistry system consisting of a 174 A polarographic analyzer and a single compartment cell. Solutions of the strengths (1×10^{-3} mol dm^{-3}) in MeCN (acetonitrile) or DMF (*N*,*N*-dimethylformamide) were used. The supporting electrolyte was 0.1 mol dm^{-3} tetraethylammonium perchlorate (TEAP), which was prepared as described (24), recrystallised twice from H_2O, and dried under vacuum at 40°C. All experiments were performed under a blanket of dry nitrogen at 27°C, using a three-electrode assembly, a hanging mercury drop electrode (hmde) as working electrode, Pt wire as auxiliary electrode, and standard calomel electrode (sce) as reference electrode. All potentials are referred to the sce and are uncorrected for liquid junction potential.

Results and discussion

Synthesis and characterisation

Synthetic details of the heterodinuclear copper(II), nickel(II), and zinc(II) complexes are given in the experimental section and are outlined in Scheme 1. Syntheses of pure heterodinuclear complexes of these series are often difficult because of the presence of homodinuclear species. However, by maintaining proper experimental conditions such as reaction time, stoichiometry, etc., analytically pure complexes could be synthesised. All the complexes are soluble in common organic solvents and most of the complexes are obtained as hydrates.

The complexes discussed here will be abbreviated as CuNiL, NiCuL, CuZnL, and NiZnL. The first and the second metal centres are represented as M_A and M_B sites in the general structure of the complexes shown in Scheme 1. L represents the generalised ligand structure. Depending upon the substituents on the anilines these ligands are represented as L^1, L^2, and L^3, etc., and are shown in Scheme 1. A special feature of the present set of complexes is that the metal centres are in different ligand environments while in the case of heterodinuclear complexes derived from 2-hydroxy-5-methylbenzene-1,3-dicarbaldehyde and diamines reported in the literature, the metal centres have equivalent ligand environment.

Infrared spectra of the present complexes are similar since the ligand systems do not differ much from one another. For most of the complexes, the presence of water molecules is evident from the broad bands observed in the region 3550–3400 cm^{-1}. All the complexes exhibit two strong absorptions at 1620 and 1550 cm^{-1} characteristic of metal coordinated C=N and C---O (phenolato) groups. Presence of ionic perchlorate is evident from the observation of ir bands at 1100 and 625 cm^{-1}. Analytical data for the complexes are presented in Table 1 and they agree with the structure shown in **2** of Scheme 1.

Electronic spectra and magnetic moments

Electronic spectra were recorded in MeCN and DMF. Better spectral profiles are obtained for most of the complexes in MeCN. For all the complexes, a strong band in the wavelength region 430–400 nm is observed and is attributed to a combination of ligand to metal or interligand charge transfers. From the general structure of the dinuclear complexes shown in Scheme 1 it is apparent that the M_A site is close to planar geometry while the M_B site is more nonplanar. However, they can assume square pyramidal or octahedral geometry depending upon the number of co-ordinated water molecules.

The CuNiL complexes exhibit spectral bands at 590 nm, a shoulder at 750 nm, and another band at 960 nm. For

	(45.02)	(4.10)	(6.00)	—	(6.08)	(6.77)

CuZnL complexes there is only one band at 625 nm with a shoulder at 750 nm. The mononuclear copper complex CuL′ of the same ligand system where copper is in planar geometry has an absorption band at 598 nm. Therefore, the origin of the 590 nm band and 750 nm shoulder in CuNiL complex is due to the inner copper centre. The 990 band originates from the *d–d* transition of the nickel centre. The spectral pattern of CuNiL complexes suggests square-pyramidal geometry for the metal centre (25, 26) arising from the possible coordination of water molecules. It may be pointed out that all the dinuclear complexes discussed here have at least two water molecules (Table 1). The NiCuL complexes exhibit a band at 748 nm with a broad shoulder at ca. 1000 nm. The 748 nm band corresponds to the *d–d* transition of the copper(II) centre in square pyramidal geometry and the 1000 nm band to the nickel centre. These bands may be compared with the spectral bands of $[CuNiL_2Cl_2] \cdot 2H_2O$ type complexes which have bands at 1000

[a]Magnetic moment per molecule for heterodinuclear complexes; values are uncorrected for TIP; error limits ±0.02 μ_B; field strength 7 K Gauss.
[b]Peaks absent.

and 725 nm. The 725 nm band is reported to originate from square pyramidal geometry for the copper(II) center (27) arising from the possible coordination of water molecules. The NiZnL complexes show an absorption band at 980 nm which can be attributed to a square pyramidal nickel centre (25).

Room temperature magnetic moments obtained for CuNiL and NiCuL complexes are in the range 2.86–3.09 μ_B per complex molecule against the spin-only value of 3.31 μ_B per complex molecule for noninteracting CuNiL and NiCuL complexes. The lower μ_{eff} values indicate the presence of antiferromagnetic coupling between Cu(II) and Ni(II) centres in these series of complexes. Antiferromagnetic interactions exists in heterodinuclear CuNi complexes derived from 3-formylsalicylic acid and diamines and are reflected in their μ_{eff} values (3.05 μ_B). The CuZnL and NiZnL complexes exhibit magnetic moments in the ranges 1.84–1.93 μ_B and 3.5–3.8 μ_B, corresponding to square-planar copper(II) and high-spin nickel(II) centres, respectively. Magnetic interactions are not expected in these complexes because of the presence of a zinc atom with a d^{10} configuration. The magnetic moment values for the complexes are collected in Table 2.

Electrochemical data

Cyclic voltammetric data for the complexes were collected in MeCN and DMF in the potential range +0.4 to −1.6 V vs. sce using the hmde working electrode at various scan rates (20–200 mV/s) (Table 3). In general, better cyclic voltammetric profiles were obtained in MeCN. In MeCN, CuNiL complexes exhibit two redox couples, one at ca. −0.48 V, which is close to reversible ($\Delta E_1 \approx 70$ mV) at higher scan rates, with the second redox couple in the potential range −1.29 to −1.33 V. The i_c/i_a ratio is close to unity for both redox couples. The CuZnL complexes exhibit only one redox couple in the potential range −0.35 to 0.39 V in MeCN with ΔE values of 160–220 mV. The first

[a] E_1 values obtained after immediately reversing the scan after the first reduction peak.
[b] Peak absent.

redox couple of CuNiL complexes (E_1) therefore corresponds to a copper-centred redox process, $Cu^{II}Ni^{II}$–$Cu^{I}Ni^{II}$. The observation that this couple is reversible only at higher scan rates indicates that $Cu^{I}Ni^{II}L$ species is not very stable. At low scan rates (<50 mV/s) large current in the range −0.90 to −1.10 V implies decomposition of the $Cu^{I}Ni^{II}L$ species. The instability of the electrogenerated $Cu^{I}Ni^{II}L$ complex species should be related to square-planar based geometry of the copper environment which destabilises the intermediate species. It is observed that if the forward scan is reversed immediately after the first reduction peak (at −0.60 V), the E_1 redox couple becomes more reversible in behaviour. These features are shown in Fig. 1. The second redox couple (E_2) corresponds to a nickel-centred redox

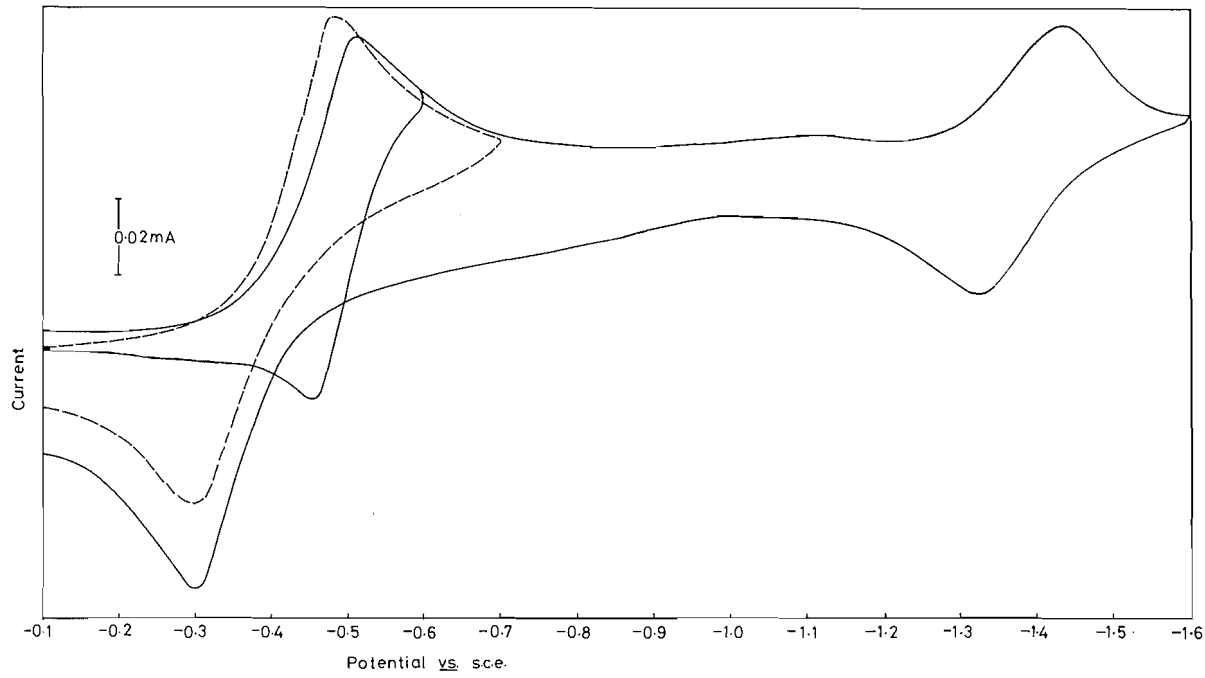

FIG. 1. Cyclic voltammograms of the complexes $CuNiL^2(ClO_4)_2 \cdot 3H_2O$ (—) and $CuZnL^2(ClO_4)_2 \cdot H_2O$ (----) in MeCN using a hmde working electrode at the scan rate 100 mV s^{-1}. Concentration of complex: 1×10^{-3}; supporting electrolyte: NEt_4ClO_4 (0.1 M).

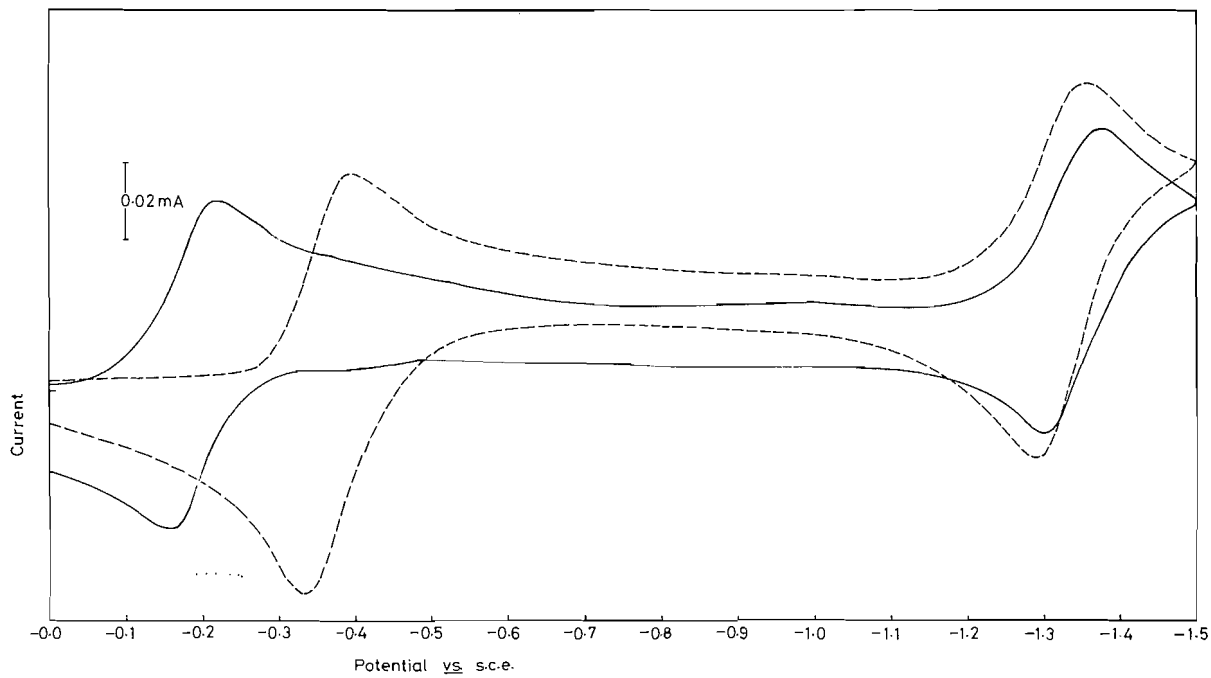

FIG. 2. Cyclic voltammograms of $NiCuL^1(ClO_4)_2 \cdot 3H_2O$ (—) $NiCuL^4(ClO_4)_2 \cdot 3H_2O$ (----) in MeCN, using a hmde working electrode at the scan rate 100 mV s^{-1}. Concentration of complex: 1×10^{-3} M; supporting electrolyte: NEt_4ClO_4 (0.1 M).

process, $Cu^{I}Ni^{II}$–$Cu^{I}Ni^{I}$, and is also close-to-reversible only at high scan rates. In DMF both redox couples are observed at high scan rates (>100 mV/s) at −0.48 and −1.30 V with ΔE_p at ca. 70 mV. The quasireversibility of the redox couple at ca. 0.35 V in CuZnL complexes can be explained to arise from the instability of the intermediate species because of the square-planar based geometry around the copper(II) ion. These complexes also exhibit a strong current in the potential range −0.90 to −1.10 V similar to CuNiL complexes, indicating decomposition/demetallation of the electrochemically generated $Cu^{I}Zn^{II}$ species. In DMF the redox couple is observed at a more negative potential (ca. −0.50 V). A cyclic voltammetric profile for a representative CuZnL complex is also shown in Fig. 1.

The NiCuL complexes in MeCN exhibit two reversible one-electron redox couples in the potential range −0.20 to −0.39 V (E_1) and −1.37 to −1.42 V (E_2). The redox couple E_1 corresponds to the copper-centred reduction $Ni^{II}Cu^{II}$–

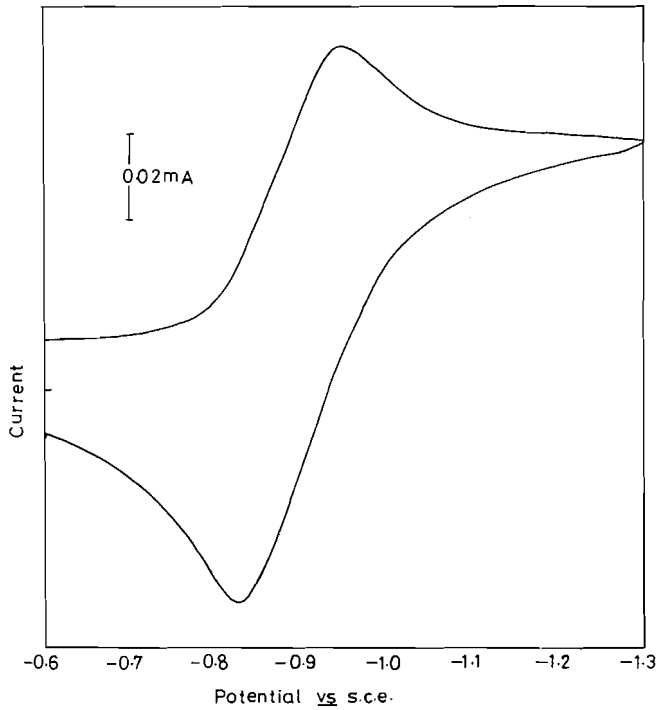

FIG. 3. Cyclic voltammogram of $NiZnL^1(ClO_4)_2 \cdot 2H_2O$ in MeCN using a hmde working electrode at the scan rate 100 mV s^{-1}. Concentration of complex: 1×10^{-3} M; supporting electrolyte: $NEt_4 \cdot ClO_4$ (0.1 M).

$Ni^{II}Cu^{I}$ and the other couple E_2 corresponds to the nickel-centred reduction $Ni^{II}Cu^{I}L$–$Ni^{I}Cu^{I}L$. The NiZnL complexes exhibit only a nickel-centred redox couple at ca. −0.90 V. These features are shown in Fig. 3. For both series, good cyclic voltammetric profiles are obtained at both low and high scan rates which suggests that the electrogenerated species are more stable on a cyclic voltammetric time scale against decomposition/demetallation. In DMF the first redox couple for NiCuL complexes is observed in the −0.13 to −0.36 V potential range and the second at ca. −1.32 V. It has been reported for the dicopper complexes of ligands L^1 and L^3 with strong antiferromagnetic interaction ($\mu_{eff} \sim 0.90\mu_B$) (28) the first reduction of $Cu^{II}Cu^{II}$–$Cu^{I}Cu^{II}$ is close to reversible and occurs at −0.05 and −0.07 V in DMF. The observed shift of ca. 120 mV towards more negative potentials for $NiCuL^1(ClO_4)_2 \cdot 3H_2O$ and $NiCuL^3(ClO_4)_2 \cdot 3H_2O$ complexes in comparison to their dicopper analogues can be explained by the weak antiferromagnetic coupling in the NiCuL complexes. The copper-centred reduction in complexes where there is no magnetic interaction occurs at more negative potential, ca. −0.50 V.

The NiCuL complexes of ligands L^2, L^4, L^5, and L^6 which have *ortho* substituents on the phenylazomethine group, viz., Me, OMe, OEt, and SMe, respectively, can be influenced by inductive, steric, and other effects due to substitutions. If steric is the only factor influencing the redox behaviour, all these complexes should show a shift of similar magnitude for the copper-centred electron transfer potential (E_1) to less negative values, since Cu(I) species become more stable in tetrahedral geometry, resulting from the presence of *ortho* substituents. The E_1 value for $NiCuL^2$ (2-Me) is −0.13 V while the other complexes have the following E_1 values: $NiCuL^4$ (2-OMe), −0.36; $NiCuL^5$ (2-OEt), −0.33 V; $NiCuL^6$ (2-SMe), −0.30 V. While the $NiCuL^2$ complex may attain pseudotetrahedral geometry for the copper centre because of steric interaction, the copper centre in $NiCuL^4$, $NiCuL^5$, and $NiCuL^6$ will be of different geometry because of the coordinating ability of the *ortho* substituents. The negative shift in E_1 potentials in $NiCuL^4$, $NiCuL^5$, and $NiCuL^6$ complexes can be attributed to this change in geometry. Cyclic voltammetric profiles for representative *ortho*- and *para*-substituted complexes in dmf are shown in Fig. 2. A similar behaviour has also been observed for the corresponding dicopper(II) complexes (29). Another significant observation is that for all the complexes, the second electron transfer, $Ni^{II}Cu^{I}$–$Ni^{I}Cu^{I}$, occurs in the narrow potential range −1.31 to −1.34 V, unlike the E_1 values. This is due to the similarity of the nickel–ligand environment in all the complexes. Although the general features are unchanged, the E_1 and E_2 values in MeCN are shifted by ca. 70–80 mV towards more negative values, compared to the corresponding values in DMF, possibly due to variation in solvent interaction with the central metal ions.

Comparison of the nickel-centred redox potentials in NiZnL complexes with those of CuNiL and NiCuL complexes reveals a shift of the potential to less negative values for NiZnL complexes. This arises from the difference in the charge of the reduced species, since for CuNiL and NiCuL complexes, the reduction at the nickel centre occurs after the first electron-transfer at the copper centre, i.e., reduction occurs from $Cu^{+}NiL$ and $NiCu^{+}L$ species, respectively.

Conclusion

In conclusion, it can be pointed out that the magnetic moments of the CuNiL and NiCuL series of complexes indicate weak antiferromagnetic coupling between the metal centres. The copper-centred reduction (E_1) occurs at −0.45 V for CuNiL and −0.38 V for NiCuL complexes. These E_1 values are in between the E_1 values observed for the strongly coupled dicopper system ($E_1 \sim 0.05$ V) and the noninteracting copper centres ($E_1 \sim -0.54$ V). In NiCuL complexes, ligands with donor groups such as OMe, OEt, and SMe influence the E_1 values. Magnetic and cyclic voltammetric results of our complexes show that weak magnetic interaction can exist even in heterodinuclear complexes analogous to the homodinuclear systems.

NATHALIE DUFOUR, ANNE-MARIE LEBUIS, MARIE-CLAUDE CORBEIL, ANDRÉ L. BEAUCHAMP, PASCAL DUFOUR, YVES DARTIGUENAVE, and MICHÈLE DARTIGUENAVE. Can. J. Chem. **70**, 2914 (1992).

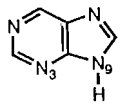
Complexes of the types $[CH_3Hg(aza)]$, $[CH_3Hg(Haza)]X$, and $[(CH_3Hg)_2(aza)]X$ are obtained by reacting CH_3HgOH and/or CH_3HgX (X = NO_3, ClO_4) with 7-azaindole (Haza). The weakly acidic N1-H proton on the pyrrole ring is displaced by the hydroxide, whereas the perchlorate and nitrate salts lead to CH_3Hg^+ coordination to the N7 lone pair on the pyridine ring. Detailed analysis of the infrared spectra of the complexes and their *N*-deuterated derivatives provides diagnostic regions for eventual prediction of the coordination mode in other systems. All compounds are characterized by means of ^1H, ^{13}C, and ^{199}Hg NMR spectra in DMSO solution and solid-state CP-MAS ^{13}C spectra. Comparison of the solution and solid-state ^{13}C spectra show that the species present in the solids remain undissociated in DMSO. Each type of complex can be identified from a characteristic pattern of large displacements of the ligand ^{13}C signals. The ^1H spectra are less informative because substitution of the N1-H proton by CH_3Hg^+ induces only minor shifts. Metal solvation appears to have a major influence on the ^{13}C and ^{199}Hg chemical shifts of the CH_3Hg^+ groups.

NATHALIE DUFOUR, ANNE-MARIE LEBUIS, MARIE-CLAUDE CORBEIL, ANDRÉ L. BEAUCHAMP, PASCAL DUFOUR, YVES DARTIGUENAVE et MICHÈLE DARTIGUENAVE. Can. J. Chem. **70**, 2914 (1992).

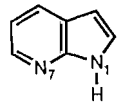
Les complexes $[CH_3Hg(aza)]$, $[CH_3Hg(Haza)]X$ et $[(CH_3Hg)_2(aza)]X$ sont obtenus par réaction de CH_3HgOH et/ou CH_3HgX (X = NO_3, ClO_4) avec le 7-azaindole (Haza). L'hydroxyde déplace le proton peu acide N1-H du cycle pyrrolique, alors que le perchlorate et le nitrate conduisent à une coordination de CH_3Hg^+ au doublet libre de l'atome N7 du cycle pyridinique. L'analyse détaillée des spectres infrarouges des complexes et de leurs dérivés N-deutérés permet d'identifier les régions caractéristiques du mode de coordination, résultat qui pourra être étendu à d'autres systèmes. Tous les composés sont caractérisés au moyen des spectres RMN ^1H, ^{13}C et ^{199}Hg en solution dans le DMSO et RMN ^{13}C CP-MAS à l'état solide. La comparaison des spectres ^{13}C des solutions et des solides montre que les espèces présentes dans les solides demeurent intactes dans le DMSO. Chaque type de complexe peut être identifié d'après un ensemble caractéristique de déplacements importants des signaux ^{13}C du ligand. Les spectres ^1H sont moins révélateurs, parce que la substitution du proton N1-H par CH_3Hg^+ ne produit que de faibles déplacements. La solvatation autour du métal semble exercer une grande influence sur les déplacements chimiques ^{13}C et ^{199}Hg des groupes CH_3Hg^+.

Introduction

Our interest has been attracted by the ability of multidentate nitrogen donors in rigid ligands like purines (**I**) to stabilize dinuclear metal–metal bonded systems. Since 7-azaindole[2] (**II**) consists of fused six- and five-membered rings with a pair of nitrogen atoms having the same arrangement as N3 and N9 in purines, the reactions with this simple model ligand were examined in the first place.



I



II

We previously reported (1) the crystal structures of a substitution product of dimolybdenum tetraacetate in which two carboxylates have been replaced by deprotonated azaindole units bridging the molybdenum atoms. The related $Mo_2Cl_2(aza)_2(PEt_3)_2$ complex has also been studied by Cotton and coworkers (2). Compounds of the type $M_2(aza)_4$ have been prepared for M = Ni(II) and Cu(II) by Brookes and Martin (3, 4), who proposed in both cases the presence of discrete dimeric units of the "copper acetate" or "paddle-wheel" type. This structure was confirmed for copper and nickel by Peng and co-workers (5), who also examined azaindole-containing clusters of copper and cobalt. The structure of a similar dinuclear chromium(II) compound has been recently reported (6). On the other hand, azaindole can act in a unidentate manner, for instance as axial ligand in dirhodium tetracarboxylates (7, 8). The crystal structure of a monodentate zinc complex has also been described by Sheldrick (9).

In the crystal structures containing bridging deprotonated azaindole, ligand disorder is almost always found to occur, because the two rings, although not identical, are sufficiently similar to lead to a random distribution of ligand direction in the crystal. Probably for this reason, getting crystals of dinuclear compounds suitable for X-ray work is difficult. Thus, reliable spectroscopic diagnostics are needed to establish the binding mode of this ligand.

Our previous work on nucleobases (10, 11) has revealed that the CH_3Hg^+ cation is a useful probe to evaluate the relative coordinating ability of the various sites in multidentate ligands. The three anticipated types of methylmercury complexes of azaindole were prepared and used to "calibrate" the NMR and vibrational spectroscopic results. The crystal structures of two of these complexes have been reported in a previous paper (12).

Experimental

Preparations

CH_3HgOH was obtained from Alfa as 1 M aqueous solution. 7-Azaindole was used as received from Aldrich. All other

chemicals were reagent grade. C, H, N analyses were done by Schwazkopf Laboratories, New York.

[$CH_3Hg(aza)$], 1

CH_3HgOH (1.0 mL, 1.0 mmol) was added at room temperature to a solution of 118 mg (1.0 mmol) of azaindole in 13 mL methanol. After slow evaporation at room temperature to 2–3 mL in a well ventilated hood, a colourless precipitate appeared, which was filtered, quickly washed with methanol, and dried *in vacuo* at room temperature. Yield: 237 mg (71%). Anal. calcd. for $C_8H_8HgN_2$: C 28.88, H 2.42, N 8.42; found: C 29.07, H 2.57, N 8.28.

*[$CH_3Hg(Haza)$]NO_3, 2*a

CH_3HgOH (1.0 mL, 1.0 mmol) was added to a solution containing 118 mg (1.0 mmol) of azaindole in 13 mL methanol and 1.0 mL 1 M (1 mmol) aqueous HNO_3. Volume was reduced to 2–3 mL by slow evaporation at room temperature and the white solid was treated as above. Yield: 363 mg (92%). Anal. calcd. for $C_8H_9HgN_3O_3$: C 24.28, H 2.29, N 3.00; found: C 24.42, H 2.11, N 2.88.

*[$CH_3Hg(Haza)$]ClO_4, 2*b

Same procedure as for **2***a*, $HClO_4$ was used instead of HNO_3. Yield: 386 mg (89%). Anal. calcd. for $C_8H_9ClHgN_2O_4$: C 22.18, H 2.09, N 6.46; found: C 22.29, H 2.01, N 6.42.

*[$(CH_3Hg)_2(aza)$]NO_3, 3*a

CH_3HgOH (2.0 mL, 2.0 mmol) was added to a solution of 118 mg (1.0 mmol) of azaindole in 13 mL methanol and 1 mL 1 M (1.0 mmol) aqueous HNO_3. Volume was reduced to 2–3 mL by slow evaporation at room temperature. The white solid was isolated as above. Yield: 485 mg (79%). Anal. calcd. for $C_9H_{11}Hg_2N_3O_3$: C 17.71, H 1.82, N 6.88; found: C 17.98, H 1.77, N 6.81.

*[$(CH_3Hg)_2(aza)$]ClO_4, 3*b

Same procedure as for **3***a*, except that $HClO_4$ was used instead of HNO_3. Yield: 568 mg (87%). Anal. calcd. for $C_9H_{11}ClHg_2N_2O_4$: C 16.69, H 1.71, N 4.32, Cl 5.47; found: C 16.65, H 1.77, N 4.26, Cl 5.40. The unit cell parameters of this compound were determined with a CAD-4 diffractometer, following the standard procedure used for single crystals (12): monoclinic, space group *Cc* or *C2/c*, a = 19.292(7), b = 10.840(5), c = 14.002(7) Å, β = 114.78(4)°, Z = 8, D_{calcd} = 3.25 g cm^{-3}.

Instruments

The solution NMR spectra were recorded at ambient probe temperature using DMSO-d_6 (Silanor, from Merck, Sharp & Dohme Canada) as solvent. The ^1H spectra were recorded at 90 MHz with a Bruker WH-90 spectrometer, and the ^{13}C spectra at 20.17 MHz with a Bruker WP-80 instrument. Me_4Si (δ = 0) was used as internal standard in both cases. The ^1H–^{13}C heteronuclear shift-correlation experiment was done on a Varian VXR spectrometer (^1H frequency = 300 MHz, ^{13}C frequency = 75.43 MHz, spectral width = 4825 Hz, Mixing time = 1 s). The ^{199}Hg spectra were obtained at 72.57 MHz with the Bruker WH-400 instrument of the Laboratoire Régional de Résonance Magnétique Nucléaire, located at the Université de Montréal. The chemical shifts were referenced to an external 1.0 M CH_3HgCl solution in DMSO (δ = −848 ppm) (13).

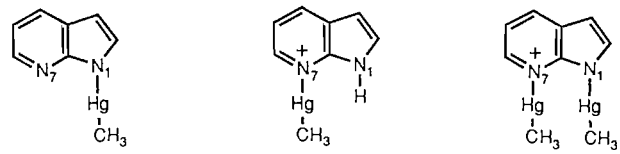
The solid-state CP-MAS ^{13}C NMR spectra were recorded at ambient probe temperature on a Varian VXR instrument (^{13}C frequency = 75.43 MHz), using external hexamethylbenzene as reference (δ = 132.1 ppm). Relaxation delays were 80 s for Haza, 20 s for [CH_3Hg(aza)], 12 s for [CH_3Hg(Haza)]NO_3, and 40 s for [$(CH_3Hg)_2$(aza)]ClO_4. Spectra were recorded using a sideband suppression routine. Spinning rates were typically ~4 kHz.

The infrared spectra (4000–400 cm^{-1}) were recorded as KBr pellets with a Perkin–Elmer 783 spectrophotometer.

Results and discussion

The reactions are carried out in methanol, in which CH_3HgOH and the acid (HNO_3 or $HClO_4$) are introduced as 1 M aqueous solutions. Under the mild conditions used, no substitution occurs on azaindole carbon atoms and three types of *N*-bonded complexes are isolated.

The neutral [CH_3Hg(aza)] complex (**1**) is prepared by using CH_3HgOH as the metal reactant, whereby the weakly



acidic proton of azaindole is neutralized and replaced by the metal on the five-membered ring, as indicated by X-ray work (12). This same compound has been reported by Kline and co-workers (14). On the other hand, if CH_3HgNO_3 or CH_3HgClO_4 (from the hydroxide + HNO_3 or $HClO_4$) is used in the reaction, the proton is not removed and a [CH_3Hg(Haza)]$^+$ salt (**2**) is obtained. In this case, the crystallographic results (12) show that the proton remains on the five-membered ring, whereas the CH_3Hg^+ group is bound to the lone pair of the pyridine nitrogen. Finally, if the reaction is conducted with one mole of each CH_3HgOH and CH_3HgNO_3 (or CH_3HgClO_4) per mole of azaindole, salts of the [$(CH_3Hg)_2$(aza)]$^+$ complex (**3**) are isolated, in which both nitrogens bear a metal atom.

Infrared spectroscopy

To obtain fingerprints for these three complexation patterns in the solid state, infrared spectra (4000–400 cm^{-1}) were recorded. The wavenumbers are listed in Table S-1 (supplementary material)[3] and compared with those of azaindole. The N1—D deuterated compounds are also included for the free ligand and the [CH_3Hg(Haza)]X complexes. The tentative assignments used are those proposed previously (1) by comparison with earlier work on indole by Lautié and co-workers (15) and Takeuchi and Harada (16).

Since complexation is accompanied by deprotonation or changes in hydrogen bonding, the vibrations involving the N—H bond were first identified by means of *N*-deuteration. Azaindole gives rise to a broad ν(N—H) absorption at ~2900 cm^{-1}, displaced to ~2300 cm^{-1} in the N1—D derivative. The δ(N1—H) vibration is expected at ~1150 cm^{-1}. The 1230–1100 cm^{-1} region includes four bands (1205, 1193, 1121, and 1103 cm^{-1}), one of which, probably at 1193 cm^{-1}, should correspond mainly to δ(N—H) motion. Only three bands (1220, 1174, and 1115 cm^{-1}) are left in the deuterated derivative, and the relatively large effect of deuteration suggests that appreciable coupling with N—H motion is present for all these modes in non-deuterated azaindole. Also, the new band at 1392 cm^{-1} in the deuterated compound is probably one of the ring modes at 1400–1450 cm^{-1} shifted to lower wavenumber by loss of N—H coupling. The δ(N—D) band is found at 850 cm^{-1}. The out-of-plane γ(N—H) vibration gives rise to the broad feature around 850 cm^{-1} for azaindole. The γ(N—D) vibration could correspond to the very broad absorption underlying other li-

[3]Table of infrared data for azaindole, the CH_3Hg^+ complexes, and N—D deuterated derivatives (four pages) may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

For personal use only.

gand bands between 550 and 600 cm^{-1}, or to the very weak feature at 535 cm^{-1}.

In the spectra of the complexes, the CH_3Hg^+ groups produce the usual distinctive features: sharp ν(C—H) bands at 2930 cm^{-1}, strong $\delta(CH_3)$ bands at ~1195 cm^{-1}, and broader $\rho(CH_3)$ absorptions near 790 cm^{-1}. The weak ν(Hg—C) vibrations normally occur at 555 cm^{-1}, but ligand bands interfere in this region.

For the charged complexes, nitrate and perchlorate salts were studied to reveal all the ligand and CH_3Hg^+ bands, some of which are masked by the anion. The nitrate bands occur where they are expected (17): strong and broad ν_3 absorption at 1370 cm^{-1} and weaker doublet for ν_2 at ~820 cm^{-1}. Low site symmetry probably imparts some intensity to the normally IR-inactive ν_1 mode that seems to appear weakly at ~1050 cm^{-1}. For the perchlorate, the very strong ν_3 band is found at ~1080 cm^{-1}, as well as the weaker ν_4 vibration at 625 cm^{-1}. Weak features are also observed at 920 cm^{-1} for ν_1 and probably at 455 cm^{-1} for ν_2 in $[(CH_3Hg)_2(aza)]ClO_4$.

For the N1-protonated/N7-mercurated $[CH_3Hg(Haza)]X$ complexes, the most important perturbations in the ligand bands are probably due to changes in hydrogen bonding. The high-wavenumber region clearly shows that hydrogen bonding is much weaker in the perchlorate than in the nitrate: the ν(N1—H) mode produces a massif centred at ~3100 cm^{-1} (2300 cm^{-1} after deuteration) for the nitrate, but the absorption is sharper and at higher energy (3320 cm^{-1} N—H, 2480 cm^{-1} N—D) for the perchlorate. The γ(N—H) band is shifted to 880 cm^{-1}.

A few spectral changes can be used to distinguish between the free ligand and the complexes. The strong ligand band at 1422 cm^{-1} loses most of its intensity, whereas the barely visible 1450 cm^{-1} absorption is replaced by a sharp and strong band at 1441 cm^{-1}. In addition, the following significant shifts occur on ligand bands: 1498 (+12), 428 (+12), and 419 (+11) cm^{-1}.

Substitution of the N1—H proton leads to more spectacular changes for $[CH_3Hg(aza)]$ and the $[(CH_3Hg)_2(aza)]X$ salts. The high-frequency region is simplified by the disappearance of the broad ν(N—H) band. The weak γ(N—H) band at 850 cm^{-1} is also removed. No clear indication can be extracted from the δ(N—H) region, because the strong δ band of CH_3Hg^+ interferes. In the low-frequency region, where the spectra are particularly clear, the ring out-of-plane vibrations of azaindole at 428 and 419 cm^{-1} are shifted to 474 and 442 cm^{-1}, respectively. The 952/917/897 cm^{-1} set is displaced to 964/940/911 cm^{-1}. The strong 878 cm^{-1} band loses most of its intensity, whereas the equally strong 789 cm^{-1} band is displaced to 810 cm^{-1}. These characteristics common to $[CH_3Hg(aza)]$ and $[(CH_3Hg)_2(aza)]X$ can be regarded as good diagnostics for N1—H substitution.

The two kinds of *N*1-substituted compounds show a number of spectral differences (Table S-1). The in-plane azaindole ring mode at 1583 cm^{-1} is displaced to 1585 cm^{-1} in the 1:1 and to 1563 cm^{-1} in the 2:1 complexes. Also, the band at 1468 cm^{-1} for $[(CH_3Hg)_2(aza)]^+$ occurs 12 cm^{-1} higher for $[CH_3Hg(aza)]$. Between 1250 and 1350 cm^{-1}, the three bands occur at 1304 (vs), 1285 (s) and 1242 (vw) for the 1:1 compound, but at 1342 (s), 1272 (sh), and 1263 (s) cm^{-1} for the 2:1 complexes. Various other differences are found at lower wavenumbers, namely at 630 cm^{-1}, where the 2:1 nitrate compound is displaced −20 cm^{-1} with respect to the 1:1 complex.

These diagnostic regions in the infrared spectra can be used to identify the type of coordination taking place on 7-azaindole.

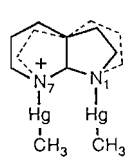
Solution NMR spectroscopy

^1H, ^{13}C, and ^{199}Hg NMR spectra were obtained with DMSO solution. The data are collected in Tables 1–3.

The ^1H and ^{13}C spectra of 7-azaindole were assigned by Cox and Sankar from data in $CDCl_3$ (18). Their assignments can be applied directly to our results, since the chemical shifts and coupling constants are not greatly affected by the change of solvent. An extra broad signal is observed at 11.6 ppm for the N1—H proton. The mutually coupled (^3J = 3.3 Hz) resonances of H2 (7.49 ppm) and H3 (6.45 ppm) show further coupling with this proton (^3J(H1—H2) = 1.5, ^4J(H1—H3) = 2.6 Hz). These features due to the N1—H proton, also observed in DMF (1), have not been mentioned for $CDCl_3$ solution (18).

For the complexes, the ^1H signals can be safely identified by comparison with the ligand chemical shifts and coupling constants. The three protons of the six-membered ring are mutually coupled and H5 is readily recognized as a doublet of doublets with ^3J couplings of ~7.7 Hz with H4 and ~5 Hz with H6. The difference in coupling constants makes it possible to identify H4 and H6. This is particularly useful for the N7-mercurated complexes, where the H4 and H6 signals are close together. In the five-membered ring, the H3 resonance always occurs ~1 ppm upfield from H2. For the $[CH_3Hg(Haza)]X$ salts, they both consist of doublets of doublets similar to those of the free ligand. For $[CH_3Hg(aza)]$ and the $[(CH_3Hg)_2(aza)]X$ compounds, substitution of the N1—H proton removes the broad low-field signal at 11.6 ppm, whereas H2 and H3 appear as simple doublets, due to loss of coupling with H1. In the ^{13}C spectra, the quaternary carbons C8 and C9 give low-intensity signals sufficiently separated as not to be confused. The remaining resonances can usually be identified by comparison with the free ligand. The ^1H and ^{13}C spectra also include high-field signals for the CH_3Hg^+ groups.

Coordination of CH_3Hg^+ to the N7 lone pair is expected to render the N1—H proton more acidic. This is reflected by the shift of the corresponding signal to 12.6 ppm for the $[CH_3Hg(Haza)]^+$ ions (Table 1). The positive charge on this complex displaces all azaindole resonances downfield. The largest shifts are found for H4 (+0.47 ppm) and H5 (+0.40 ppm), whereas the resonance of H6, adjacent to the coordination site, is displaced by only +0.28 ppm. Thus, the H2 and H3 protons on the other ring, both shifted by +0.25 ppm, are almost as sensitive as H6 to N7-coordination. A similar pattern of shifts is noted when azaindole is



IV

7-methylated (**III**),[4] but the $\Delta\delta$ values are ~40% greater (18). Another similarity with the 7-methyl derivative is the ~1 Hz

[4]7-Methyl-1*H*-pyrrolo[2,3-*b*]pyridinium.

increase of the ^3J(H5—H6) coupling constant. In the ^{13}C spectra, CH_3Hg^+ coordination induces a pattern of shifts similar to methylation, but much smaller (Table 2). For instance, the adjacent carbons undergo shifts of −1.0 ppm (C6) and −3.6 ppm (C8) upon N7-mercuration, whereas the shifts are −5.3 and −9.2 ppm, respectively, for 7-methylation. The greatest displacements for this type of complex are found for C4 (+5.3 ppm) and C9 (+4.1 ppm).

Substitution of the N1—H proton in [CH_3Hg(aza)] removes the low-field ^1H resonance for this atom, but introduces only small shifts on the other signals. Surprisingly, the H2 proton, next to the substitution site, has not moved (7.49 ppm), even though an appreciable shift of −0.21 ppm has been noted for this complex in $CDCl_3$ (14). The largest shifts in DMSO are found for the protons most remote from the substitution site, that is, H5 (−0.14 ppm) and H6 (−0.12 ppm). The ^{13}C assignments given in Table 2 are based on a 2D ^1H–^{13}C experiment. Large downfield shifts are noted for the adjacent atoms C8 (+6.1 ppm) and C2 (+9.6 ppm).

Combined N1—H substitution and N7-coordination in the [$(CH_3Hg)_2$(aza)]X salts lead to roughly additive effects for both the ^1H and ^{13}C spectra. Large ^{13}C upfield shifts with respect to azaindole are observed for C2 (+12.1 ppm), C9 (+6.8 ppm), and C4 (+4.4 ppm). In the ^1H spectra, the chemical shifts are relatively close to those of [CH_3Hg-(Haza)]$^+$. This is normal, since N7-complexation introduces much larger shifts than N1—H substitution. As expected for [$(CH_3Hg)_2$(aza)]$^+$, the low-field N1—H signal is absent and simple doublets are found for H2 and H3.

The resonances of the CH_3Hg^+ groups are collected in Table 3. The two non-equivalent groups in [$(CH_3Hg)_2$(aza)]$^+$ produce two well-resolved signals in the ^1H, ^{13}C, and ^{199}Hg spectra, indicating slow exchange of the two types of groups.

The ^1H signal of [CH_3Hg(aza)] (0.79 ppm) occurs in the 0.7–0.8 ppm range found for complexes with monoanionic imidazoles (19) and purines (10, 11, 20, 21) in DMSO. Solvent effect is appreciable, since the signal is displaced to 0.93 ppm in $CDCl_3$ (14). Coordination to the less basic pyridine-type nitrogen results in a downfield shift to 0.97 ppm for the [CH_3Hg(Haza)]$^+$ compounds. For [$(CH_3Hg)_2$(aza)]$^+$, the two resonances get closer together than those of the above 1:1 compounds. The same behaviour is shown by the $^2J(^{199}Hg—^1H)$ coupling constants, which are generally regarded as good probes for the nucleophilic character of the mercuration site. Various workers (10, 19, 22–24) proposed linear equations relating this ^2J constant with either the log of the complex formation constant or the pK_a of the corresponding protonated ligand. The relationship $^2J = 248.5 - 3.88$ pK_a, based on complexes with heterocyclic nitrogen ligands in DMSO solutions (19), seems to be the most appropriate for the present system. When applied to the [CH_3Hg(Haza)]$^+$ species (^2J = 234 Hz), the predicted pK_a values for the N7-protonated $(H_2aza)^+$ ion is ~4, which is reasonably close to the value of 4.6 reported earlier (25), considering the anticipated reliability of such a crude relationship. Using this same equation with the 192 Hz constant for [CH_3Hg(aza)], a pK_a of ~15 is predicted for the N1—H proton of neutral azaindole, an acceptable value since the electro-attracting N7 atom should make the N1—H proton more acidic than in indole (pK_a ~17) (26). In the [$(CH_3Hg)_2$(aza)]$^+$ ion, the coupling constants, like the chemical shifts, have moved together. With a ^2J constant of 199 Hz, N1 behaves as though its pK_a had decreased by ~2 units, whereas that of N7 (222 Hz) had increased by ~3 units. Thus, electron density transferred from the five- to the six-membered ring has diminished the basicity difference between the two sites. However, this effect alone cannot account for the ^{13}C and ^{199}Hg results.

From data on a series of purine complexes, it was concluded (27) that the ^{13}C chemical shift of CH_3Hg^+ decreases as the $^2J(^{199}Hg—^1H)$ constant increases. Combining this with the above ^2J vs. pK_a relationship, it is predicted that $\delta(^{13}C)$ should *increase* with pK_a. Therefore, the ^{13}C data in Table 3 for [CH_3Hg(aza)] (1.5 ppm, pK_a ~15) and [CH_3Hg(Haza)]$^+$ (1.9 ppm, pK_a 4.6) are not in the expected order. In addition, the two signals of [$(CH_3Hg)_2$(aza)]$^+$ are displaced downfield by ~1 ppm compared with the corresponding 1:1 compounds, instead of moving together as observed for the ^1H resonances. Similarly, the ^{199}Hg chemical shifts cannot be rationalized solely from considerations on donor basicity. In this case, the 1:1 complexes occur in the order expected from earlier studies on purines and imidazoles (28): [CH_3Hg(Haza)]$^+$ (−902 ppm) is observed at higher field than [CH_3Hg(aza)] (−732 ppm). For [$(CH_3Hg)_2$(aza)]$^+$, the two signals are closer together than those of the 1:1 compounds, but the predominant effect is the very large downfield shift of both resonances.

The [$(CH_3Hg)_2$(aza)]$^+$ cation undoubtedly adopts structure **3**, similar to those of various adenine complexes (29, 30), with two roughly parallel CH_3Hg^+ groups lying in the molecular plane. The obvious peculiarity of this structure is the presence of two Hg atoms lying close together. The $^4J(^{199}Hg—^{199}Hg)$ coupling, detected for a dinuclear compound with bridging bis(diphenylphosphino)methane (31), could give an idea of the extent of interaction between the metals, but our compound was not soluble enough to produce observable features for the small population (<3%) of $^{199}Hg/^{199}Hg$ isotopomer. Metal–metal bonding is ruled out, because the Hg–Hg separation, probably similar to those observed in the adenine complexes (~3.2 Å), should be greater than the sum of the van der Waals radii. Even at this distance, the electric field of one Hg atom could be felt by the other nucleus, but the magnitude of this effect on the ^{199}Hg chemical shifts is hard to predict. On the other hand, direct interaction is not required to explain the large downfield shifts observed, since solvent effect was invoked to rationalize anomalies in ^{199}Hg data for other systems, namely for [CH_3Hg(py)]$^+$ complexes examined by Canty and co-workers (32). The −1159 ppm[5] signal of the pyridine complex was found to be drastically shifted in the compounds with 2-methylpyridine (−1014 ppm) and 2,6-dimethylpyridine (−975 ppm), even though ligand basicity had not changed appreciably. This was ascribed to reduced solvation of Hg due to the steric effect of the *ortho* methyl groups, restricting access of the good donor solvent molecules to the "equatorial" region around mercury. Similarly, data on a series of $(CH_3)_2Hg$ solutions in various solvents showed that replacing coordinating solvents like DMSO or DMF by hydrocarbons produced ~100 ppm downfield shifts, also ascribed to desolvation (33). In the case of [$(CH_3Hg)_2$(aza)]$^+$, the presence of two adjacent CH_3Hg^+ groups in near van der Waals contact is anticipated to severely perturb solvation

[5]These results, referenced to CH_3HgNO_3, were converted to the convention used here (δ = 0 for $(CH_3)_2Hg$) by subtracting 1146 ppm (39).

[c]Not resolved.

around the metal, since each Hg atom blocks access of solvent molecules to one side of the other Hg atoms. This effect likely makes a significant contribution to the observed downfield shifts in $[(CH_3Hg)_2(aza)]^+$, compared with the 1:1 compounds where no similar steric hindrance to solvation is present. Although centred on the metal, this effect is probably transmitted to some extent to the carbon atom and could explain the small downfield shift of the ^{13}C resonances.

Solid-state NMR

The ^{13}C signals for the solid compounds (Table 4) have been interpreted by comparison with the solution spectra.

For free azaindole, the resonances are relatively broad, often dissymmetric, and splitting in two resolved components is visible for C3 and C5. These effects are not due to poor spectrum quality or artefacts of data acquisition. They result from the presence of eight symmetry-independent azaindole molecules in the crystal. X-ray work (12) has shown that the solid contains two crystallographically non-equivalent types of hydrogen-bonded tetramers, in which the azaindole molecules are in similar, but not identical, environments. Thus, each peak can be regarded as resulting from eight close, but not exactly coincident, components. The mild disorder observed in the crystal can also contribute to signal broadening. The mean chemical shifts for the solid differ by <2 ppm from those observed for DMSO solution.

Similarly, for $[CH_3Hg(aza)]$, the mean chemical shifts of the ring carbons deviate by <1.5 ppm from those found in DMSO, confirming that the same species is present in both phases. The signals are much sharper than those of the free ligand, but most of them are split in two or three resolved components (Table 4). This is consistent with the crystal structure reported earlier (12), since the unit cell contains three non-equivalent monomeric molecules with appreciable differences in intermolecular interactions.

The high-field region of $[CH_3Hg(aza)]$ includes two CH_3Hg^+ peaks at 4.4 and −1.4 ppm (Table 4) in a roughly 2:1 ratio. The strongest component is shifted downfield by 2.9 ppm with respect to the DMSO solution. $[CH_3Hg(Haza)]NO_3$ and $[(CH_3Hg)_2(aza)]ClO_4$ also exhibit downfield shifts of 2–4 ppm in the solid state. It is tempting to relate this trend to the desolvation effect mentioned above, since the metal in the solid is presumably not as efficiently surrounded by good donors as in DMSO. Weak equatorial Hg—O(nitrate) contacts of ~2.95 Å in $[CH_3Hg(Haza)]NO_3$ should play a role similar to solvation and shift the resonance back to high field, but this does not seem to balance efficiently the effect of desolvation, since the signals remain downfield in the solid. Similarly, in the case of $[CH_3Hg(aza)]$, where moderately strong Hg···N7 "semi-bonds" of ~2.85 Å with adjacent molecules are found for *two* of the three independent molecules, the stronger signal remains downfield. Therefore, such dipolar interactions cannot explain the presence of the high-field signal at −1.4 ppm. The unit cell was carefully examined for other differences that would single out one of the groups. Molecule A (Fig. 1) was found to differ from the other two not only by the lack of intermolecular Hg···N contacts within 3.3 Å, but also by the position of its CH_3Hg^+ carbon at ~3.4 Å, just above the six-membered ring of a molecule B, where the anisotropic effect of the aromatic system is expected to be maximized. This could displace the corresponding signal for A upfield from those of the other two molecules, which do not overlook an aromatic ring. A recent study on CH_3Hg^+ complexes with amino acids supports this assumption. The ^{13}C signal (in water) of the amino-coordinated CH_3Hg^+ group appears at −1.9 ppm for serine (34), but it is shifted upfield to −4.3 ppm in presence of the aromatic substituent in tryptophan (35). This was ascribed to the anisotropic effect of the aromatic system, since the conformation observed in the solid, with the CH_3Hg^+ group above the indole ring, was shown to be predominant in solution (36).

In cationic complexes, the solid-state and the DMSO solution spectra show greater differences for some of the ring signals. For instance, with $[CH_3Hg(Haza)]NO_3$, differences of +5.3, +3.5, and +2.0 ppm are found for C3, C4, and C2, respectively. At the moment, these various shifts cannot be individually interpreted in terms of detailed structural effects. However, the presence of the charged NO_3^- ion can

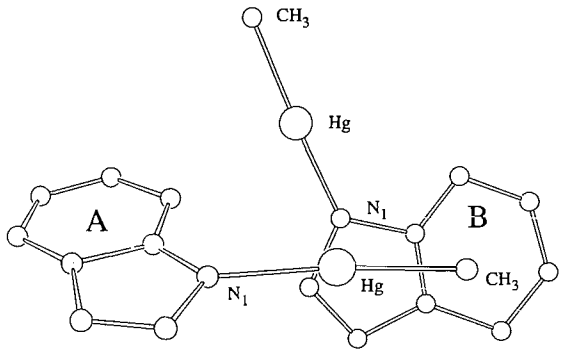

FIG. 1. Position of the CH_3Hg^+ group of molecule A above the azaindole ring of molecule B (in the plane of the figure) in the unit cell of [CH_3Hg(aza)]. The drawing is based on the X-ray work of ref. 12. Hydrogens are omitted for simplicity.

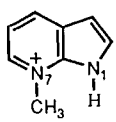
conceivably give rise, in the solid, to strong, localized, dipolar interactions that would not survive in solution.

The crystal structure of the $[(CH_3Hg)_2(aza)]ClO_4$ salt has not been determined, but the cation certainly adopts structure **3** similar to those found for adenine complexes (29, 30). This compound belongs to space group *C2/c* (assuming that it is centric, which is very likely). Thus the eight molecules in the unit cell should all be symmetry equivalent. Despite this fact, shoulders are found for almost all resonances, particularly for C5. This is probably due to crystal disorder, which is expected for this type of compound. Indeed, even though the two halves of the $[(CH_3Hg)_2(aza)]^+$ ion are different, the van der Waals envelope of this planar species is not greatly modified if it is rotated by 180° about the common C8—C9 bond (**IV**). As a result, the cation is probably randomly distributed over the two orientations in the crys-



III

tal, as found whenever the two N atoms have similar environments, such as in neutral 7-azaindole (12), salts containing the azaindolium cation (37), and various complexes in which azaindole is bridging two metal atoms (1, 5, 38). Disorder in $[(CH_3Hg)_2(aza)]ClO_4$ would create non-uniform environments at the molecular level and introduce local non-equivalencies, which would explain the splitting shown by the solid-state spectrum.

Concluding remarks

The structures proposed for [CH_3Hg(aza)] and the [CH_3Hg(Haza)]X salts in the solid-state are based on X-ray diffraction work published earlier (12). As to the $[(CH_3Hg)_2$-(aza)]X salts, full X-ray diffraction was not deemed worthwhile, but structure **3** is very likely in view of the presence of the similar structure observed for related ligands. In our detailed analysis of the infrared spectra, the vibrations due to the anions and the CH_3Hg^+ groups were first identified. Patterns of spectral changes in the ligand bands were then proposed to provide characteristic diagnostics for each of the three types of coordination. While interpreting the ^1H spectra in DMSO, it was found that a large shift is not a reliable indication that coordination takes place at a nearby site, since the H5 and/or H4 signals are the most affected for all coordination patterns. Thus, the largest displacements observed upon N1—H substitution in the five-membered ring of [CH_3Hg(aza)] are found for protons of the other ring. Moreover, it is difficult to differentiate between $[(CH_3Hg)_2(aza)]^+$ and $[CH_3Hg(Haza)]^+$ from the ^1H spectra. The ^{13}C ligand signals are better suited to identify the binding mode, large displacement being noted on a specific set of carbons for each type of complex. On the other hand, the CH_3Hg^+ resonances seem to be very sensitive to metal solvation, so that relationships between donor basicity and ^{13}C or ^{199}Hg chemical shifts should be used with great care. The infrared and NMR diagnostics developed here are hoped to be useful to identify the coordination mode in non-crystalline materials for which X-ray diffraction information could not be obtained.

Acknowledgments

We wish to thank R. Mayer for assistance in recording solid-state NMR spectra, and the Natural Sciences and Engineering Research Council of Canada for financial support. A travel grant for P. Dufour provided by the Programme d'Échange Interuniversitaire Franco-québecois is also acknowledged.

ALLAN W. REY, WALTER A. SZAREK, and DAVID B. MACLEAN. Can. J. Chem. **70**, 2922 (1992).

A highly convergent synthesis of the pentacyclic indole alkaloid (+)-mostueine (**1**) is described. The key step involved the coupling of the dianion derived from (1′*S*)-3-(1′-hydroxyethyl)-4-methylpyridine (**4**) with the iminium salt 3,4-dihydro-2-methyl-9-(*p*-toluenesulfonyl)-β-carbolinium iodide (**3**). Low asymmetric induction (15% de) at the C-1 position of the β-carboline ring system (C-3 of mostueine) was obtained. The nonfermenting baker's yeast-mediated reduction of 3-acetyl-4-methylpyridine provided the hydroxyethylpyridine component in acceptable yield (67%) and high optical purity (99.0% ee). This synthesis of **1** has established that the absolute stereochemistry of mostueine is (3*S*,19*R*).

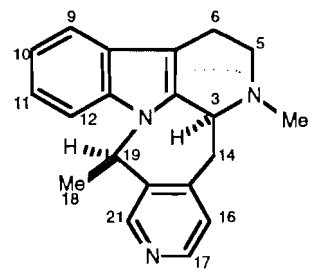
ALLAN W. REY, WALTER A. SZAREK et DAVID B. MACLEAN. Can. J. Chem. **70**, 2922 (1992).

On décrit une synthèse hautement convergente de l'alcaloïde indolique pentacyclique (+)-mostuéine (**1**). L'étape clé implique le couplage du dianion dérivé de la (1′*S*)-3-(1′-hydroxyéthyl)-4-méthylpyridine (**4**) avec le sel iminium (**3**), l'iodure de 3,4-dihydro-2-méthyl-9-(*p*-toluènesulfonyl)-β-carbolinium. On a obtenu une faible induction asymétrique (15% de) à la position C-1 du système cyclique β-carboline (C-3 de la mostuéine). La réduction de la 3-acétyl-4-méthylpyridine, sous l'influence de la levure pâtissière qui ne fermente pas, fournit la portion hydroxyéthylpyridine avec un rendement acceptable (67%) et une grande pureté optique (99,0% ee). Cette synthèse du composé **1** a établi que la stéréochimie absolue de la mostuéine est (3*S*,19*R*).

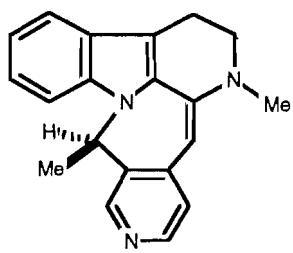
[Traduit par la rédaction]

Introduction

The structurally interesting pentacyclic indole alkaloid mostueine (**1**) (also referred to as 3,14-dihydrodecussine) is composed of a β-carboline skeleton possessing an azepino ring attached to a pyridine ring. Mostueine, a weak muscle relaxant, was originally isolated from the leaves of *Mostuea brunonis* (2). It has also been found to be a constituent in the root and stem bark of *Strychnos decussata, S. dale, S. elaecarpa* (3) and, most recently, *S. johnsonii* (4). The pharmacologically more active compound decussine (**2**) is identical with mostueine except for a site of unsaturation at C-3—C-14. It is noteworthy that mostueine has been reported to be converted into decussine (3, 5) on storage (3).



1



2

The total synthesis of (±)-mostueine was accomplished by McGee *et al.* (6) and by Onanga and Khuong-Huu (7), and their combined studies have established the relative configuration at C-3 and C-19 to be 3*SR*,19*RS*. These syntheses are strategically similar in that they both rely upon the alkylation of the indole nitrogen to close the azepino ring as the last step. Herein we report another more convergent and enantioselective synthesis of mostueine.

The addition of nucleophiles to iminium salt electrophiles has been effectively exploited by us and others for the synthesis of a variety of alkaloids (8). It became apparent that this reaction may permit an efficient synthesis of mostueine as shown retrosynthetically in Scheme 1. Furthermore, this strategy would establish the absolute stereochemistry at C-3. Another more general and synthetically interesting question was the extent of asymmetric induction at the C-1 position of the β-carboline ring system (C-3 of mostueine) upon addition of the chiral nucleophile **4**. In any event, the diastereomeric-adduct mixture should be readily resolvable by chromatography, thereby providing an enantioselective route to mostueine.

Results and discussion

Synthesis of **4**

The synthesis of (1′*S*)-3-(1′-hydroxyethyl)-4-methylpyridine (**4**) is outlined in Scheme 2. The starting material, 3-cyano-4-methylpyridine (**6**), was prepared in gram quantities using the 3-step procedure developed by Bobbitt and Scola (9). The conversion of **6** into 3-acetyl-4-methylpyridine (**8**) was originally accomplished by Webb and Corwin (10). However, this transformation necessitated 3 steps and the overall yield was 30%. Another higher-yielding but longer sequence involved conversion of **6** into 4-methylnicotinaldehyde (3 steps, 71% yield) (10, 11). This aldehyde was then converted into the desired methyl ketone **8** by way of its trimethysilylcyanohydrin derivative in 63% yield (12). In

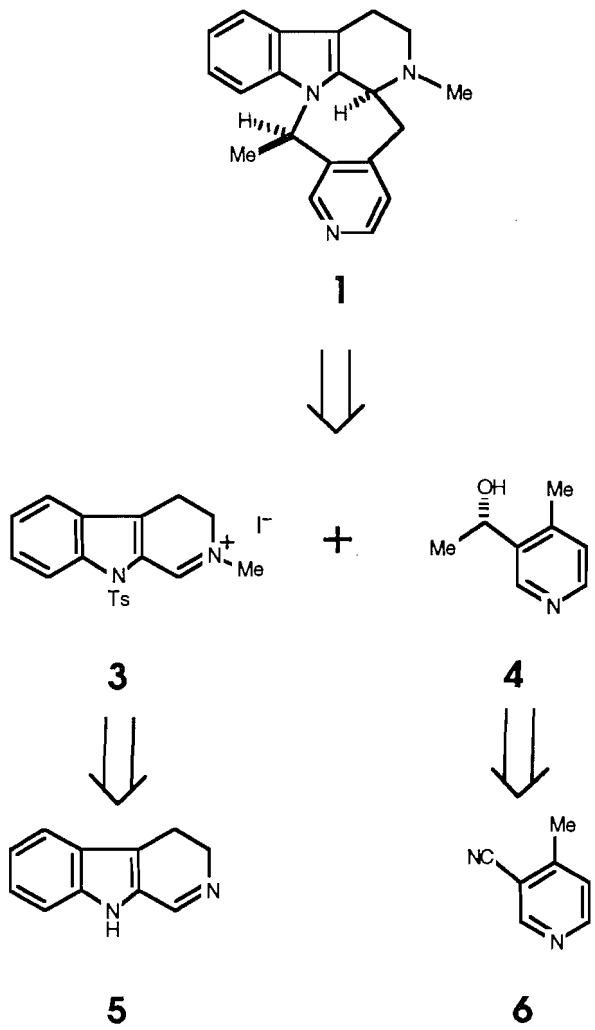
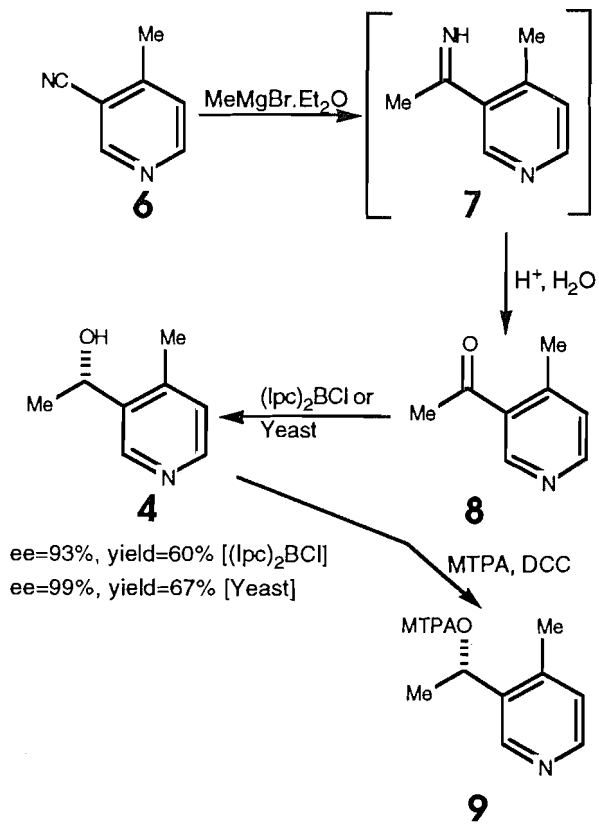


SCHEME 1



SCHEME 2

contrast to these methods, we have found that a more direct route was the Grignard addition of methylmagnesium bromide (3.0 M solution in diethyl ether) to the nitrile **6** followed by *in situ* acid-catalyzed hydrolysis of the presumed imine intermediate **7**. This protocol, based upon work done by Canonne *et al.* (13), conveniently furnished 3-acetyl-4-methylpyridine in 83% yield.

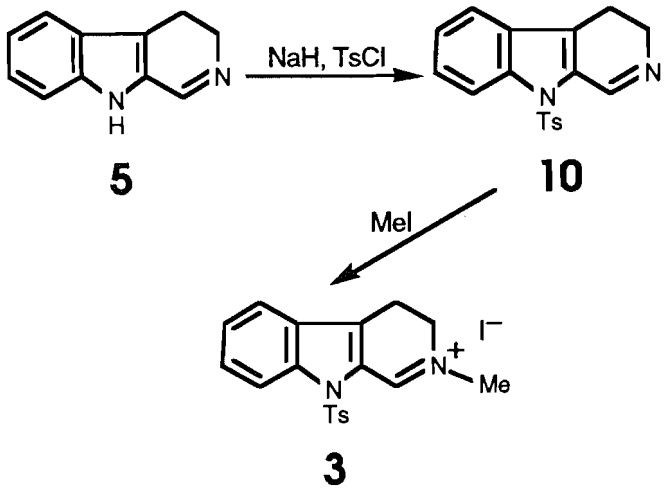
With acetylpyridine **8** in hand, the next challenge was the stereoselective reduction to form the (*S*)-alcohol **4**. Our initial notion was to employ methodology developed by Brown and co-workers (14) for the asymmetric reduction of aralkyl ketones. Thus, treatment of 3-acetyl-4-methylpyridine with (−)-*B*-chlorodiisopinocampheylborane [(−)-$(Ipc)_2BCl$], and subsequent removal of the boron moiety with diethanolamine, gave (1′*S*)-3-(1′-hydroxyethyl)-4-methylpyridine (**4**). The overall yield was 60% and the enantiomeric excess was 93%. This result is consistent with Brown and co-workers' (14) reduction of 3-acetylpyridine (65% yield and 92% ee). It is pertinent to note that, in each case, 2.3 equivalents of the (−)-$(Ipc)_2BCl$ reagent were required, presumably because of complex formation.

Owing to the expense of the (−)-$(Ipc)_2BCl$ reagent, we examined the possibility of a yeast-mediated reduction. Thus, treatment of the substrate **8** with Fleischmann's Baker's yeast (170:1 yeast to **8** ratio (w/w)) for 4 days at 32°C provided **4** in 67% yield and 99.0% ee ($[\alpha]_D$ −53.5; *c* 1.0, $CHCl_3$). The product was isolated by extractive processing, and the reaction was performed on a 5-gram scale. Another salient feature was that this reduction was accomplished using nonfermenting yeast (i.e., glucose or sucrose was *not* added), thereby facilitating processing. This modification was based upon work done by Bucciarelli *et al.* (15) and by Rasor and Rüchardt (16). An interesting point is that, under almost identical conditions, Takeshita *et al.* (17) found that the yeast-mediated reduction of 3-acetylpyridine gave (1′*S*)-3-(1′-hydroxyethyl)pyridine in 40% yield and 67% ee. Clearly, the 4-methyl group in substrate **8** has a profound effect on the stereochemical outcome of this reduction.

The enantiomeric excesses were determined by conversion of the crude alcohol products into their corresponding diastereomeric (*S*)-α-methoxy-α-(trifluoromethyl)phenylacetate derivatives (**9**) using *S*-MTPA (Aldrich) and *N*,*N*′-dicyclohexylcarbodiimide as the coupling agent. The ee was then assessed by high-resolution ^1H nmr (400 MHz) integration of the well-resolved signals ($\Delta\delta$ = 20 Hz) of the diastereomeric 4-methyl protons.

The absolute stereochemistry of **4** was ascertained to be *S* by ^1H nmr analysis of its *S*-MTPA and *R*-MTPA esters (18). This conclusion is consistent with Brown and co-workers' observation (14) that reduction of similar compounds with (−)-$(Ipc)_2BCl$ leads to the *S* enantiomer. Furthermore, yeast reductions of aralkyl ketones give predominantly the *S*-alcohol (19).

It has not escaped our attention that the enantiopure compound, (1′*S*)-3-(1′-hydroxyethyl)-4-methylpyridine, may be of value as a synthetic intermediate in the synthesis of various pyrido-alkaloids and other natural products. Further-



SCHEME 3

more, its *N*-benzyl salt may be of therapeutic value (20) as a possible antineoplastic agent.

Synthesis of ***3***

The synthesis of the intermediate of which the β-carboline portion of mostueine is comprised, specifically the iminium salt, 3,4-dihydro-2-methyl-9-(*p*-toluenesulfonyl)-β-carbolinium iodide (**3**), is depicted in Scheme 3. The starting material was the known 3,4-dihydro-β-carboline (or norharmalan) (**5**), which is readily accessible by way of the Bischler–Napieralski reaction of N^b-formyltryptamine (21). Protection of the indole nitrogen as its tosylamide presented some difficulty. Initially, phase-transfer catalytic methods (22) were examined; however, the yields were low (<30%) owing to formation of side products. Finally, reproducible yields (65%) of the desired 3,4-dihydro-9-(*p*-toluenesulfonyl)-β-carboline (**10**) were obtained by formation of the sodium salt of the indole (sodium hydride, DMF, −10°C, 30 min) followed by addition of *p*-toluenesulfonyl chloride (−60°C, 1.5 h). The major by-product resulted from sulfonylation at the C-3 position of the indole nucleus (C-7 of mostueine). This procedure is an adaptation of a method developed by Langlois *et al.* (23) for the *N*-benzylation of **5**. Methylation of the imine nitrogen of **10** by treatment with iodomethane (THF, room temperature, 12 h) and subsequent filtration provided the iminium salt **3** in 91% yield.

Coupling of ***3*** *and* ***4*** *and completion of the synthesis of* ***1***

The remaining steps in this convergent synthesis of mostueine are shown in Scheme 4. The critical coupling of **3** and **4** went as predicted and afforded adducts **11***a* (3*S*, 19*S*) and **11***b* (3*R*, 19*S*) as a 1.35:1.00 mixture, respectively, and in 62% yield. Considerable effort was spent optimizing this reaction and it was found that the use of a combination of potassium *tert*-butoxide and lithium diisopropylamide afforded the highest yield. A 30-min reaction time at −78°C was found to be sufficient; longer reaction periods led to a reduced yield. The diastereomeric compounds **11***a* and **11***b* were readily separable by silica gel flash chromatography.

We were somewhat disappointed by the low degree of asymmetric induction (de = 15%) obtained for the addition of enantiopure **4** to the iminium salt **3**. Preliminary efforts were made to improve the diastereoselection of this process by varying the hydroxyl protecting group (*tert*-butyldimethylsilyl ether and methoxymethyl ether) on **4** and the indole protecting group (benzyl and free indole). No improvement in the asymmetric induction was obtained for the coupling of these modified compounds (all combinations were tried). These results suggest that the stereocenter on **4** is too remote to offer significant stereoinduction upon addition of this nucleophile.

Compounds **11***a* and **11***b* in racemic form were also isolated by McGee *et al.* (6) in their synthesis of (±)-mostueine. Of significance is that our high-resolution ^{1}H nmr data obtained for (+)-**11***a* and (−)-**11***b* correspond exactly with the literature (6). Their work demonstrated that the racemic modifications of the (3*S*,19*S*) diastereomer **11***a* can be cyclized under forcing conditions (potassium *tert*-butoxide in THF) to provide (±)-mostueine. Mechanistically, this reaction is consistent with the transfer of the *p*-toluenesulfonyl group from the indole nitrogen to the C-19 alkoxide followed by S_N2 displacement of the *p*-toluenesulfonyloxy group by the indole nitrogen (for a related example of this type of cyclization, see ref. 24). Thus, treatment of **11***a* with potassium *tert*-butoxide in anhydrous THF provided (+)-mostueine in 13.5% yield. The major product of the reaction was the imine **12** (40% yield) presumably formed by *C*-alkylation of the intermediary C-19 tosylate. Our results are consistent with those obtained by others (6, 7). The relative (and in this case the absolute) configuration of **12** was established by ^{1}H nmr nOe experiments. For instance, a significant enhancement (6.8%) of the H-14ax signal was observed upon presaturation at the signal for H-19. Additionally, presaturation at the signal for the H-18 methyl protons gave a 7.5% intensity enhancement of the H-21 signal.

Attempts to improve the yield of mostueine were unsuccessful. For instance, the adduct corresponding to **11***a* deprotected at N-9 was oxidized (MnO_2, CH_2Cl_2, reflux, 36 h, 42%) at C-19 to provide the ketone. Unfortunately, conditions to reductively aminate the indole nitrogen with the ketone were not found.

The spectral data for the synthetically prepared (+)-mostueine were identical with the data for a sample of the natural product that was kindly provided by Prof. F. Khuong-Huu. Also, the optical rotation for mostueine synthesized by this method was +186 (*c* 1.0, $CHCl_3$), a value that closely corresponds to the optical rotation of natural mostueine (+196 (2)). This result unambiguously demonstrates that the absolute stereochemistry of **1** is (3*S*,19*R*), an assignment that is consistent with the proposed biosynthesis (4) of mostueine from strictoside.

In summary, the enantioselective synthesis of the indole alkaloid mostueine has been accomplished in a convergent and efficient manner. This work shows that the absolute configuration of mostueine is (3*S*,19*R*) as depicted.

Experimental

Apparatus, materials, and methods

The ^{1}H nmr spectra were recorded at 200 MHz and 400 MHz (as indicated) on Bruker AC-F200 and AM-400 spectrometers, respectively. The samples were dissolved in either $CDCl_3$ or DMSO-d_6 (as indicated). The proton chemical shifts are quoted in parts per million (ppm) downfield relative to the internal standard, tetramethylsilane (δ scale). The ^{13}C nmr spectra were recorded at 50.3 MHz on a Bruker AC-F200 spectrometer. The carbon chemical shifts are quoted in ppm with reference to $CDCl_3$ (77.00 ppm). The multiplicities of signals were determined by JMOD experiments. The analyses were done as a first-order ap-

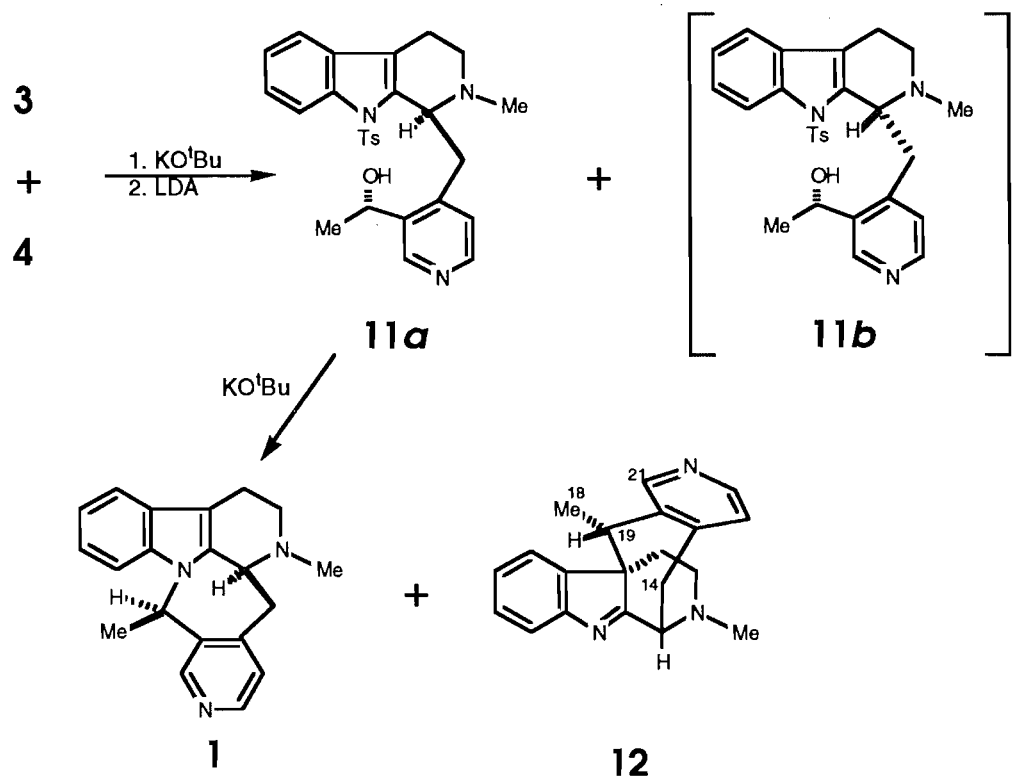

SCHEME 4

proximation. The ir spectra were determined using KBr disks or taken from films on sodium chloride plates (as indicated) on a BOMEM MB-120 ft-ir spectrophotometer at room temperature.

EI (electron ionization) mass spectra were recorded at 70 eV on a VG Analytical ZAB-E mass spectrometer equipped with a VG 11-250 data system. CI (chemical ionization) spectra were recorded on the same instrument using NH_3 at ~1 Torr (1 Torr = 133.3 Pa) as reagent gas. The peak intensities are given as a percent of the base peak (100%) intensity. High-resolution mass spectra (hrms) measurements were performed on the above instrument under EI conditions.

Melting points were determined using a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured on a Perkin–Elmer 241 polarimeter and were run at room temperature (~23°C). Thin-layer chromatography was performed using silica gel 60-F_{254} plates (E. Merck No. 5714) of 0.25 mm thickness. Preparative-layer chromatographic (ptlc) separations were accomplished on silica gel 60-F_{254} plates (E. Merck No. 5717) of 2 mm thickness. For flash chromatography, silica gel 60 (230–400 mesh, E. Merck No. 9385-5) was employed.

All reactions involving lithiation were performed in apparatus dried in the oven at 140°C for at least 12 h and assembled hot under a stream of argon. Septa and syringes were used for transfer of reagents. Solvents and reagents were reagent grade and, when required, further purifications were accomplished following published procedures (25). Titrations of the organolithium reagents were done using diphenylacetic acid (26).

3-Acetyl-4-methylpyridine (8)

To a stirred solution of 3-cyano-4-methylpyridine (**6**) (5.01 g, 42.5 mmol) (prepared according to ref. 9) in benzene (30 mL) at 0°C and under an argon atmosphere was added a 3.0 M solution of MeMgBr in diethyl ether (42.0 mL, 126 mmol). The solution was stirred at 0°C for 2 h, the temperature was then raised to room temperature, and the stirring was continued a further 16 h. The mixture was cooled to 0°C, the excess of MeMgBr was carefully quenched, and the solution acidified to pH ~2 by addition of 4 M HCl. This solution was stirred for 2 h, at which point it was basified to pH ~10 using concentrated NH_4OH solution (aq.). The aqueous layer was extracted with ethyl acetate (6 × 60 mL), the combined organic extracts were dried over $MgSO_4$ (anhydrous), and the solvent was removed *in vacuo*. The crude red oil (5.14 g) was purified by silica gel flash chromatography (ethyl acetate – hexane (2:3, v/v)) to furnish the acetylpyridine **8** (4.75 g, 83% overall yield from **6**) as a colorless oil (this material is slightly volatile and, thus, should not be exposed to reduced pressure for prolonged periods); bp 57–58°C (1–2 Torr); ν_{max} (film): 3052, 2979, 2928, 1687, 1592, 1358, 1270 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 2.53 (3H, s, CH_3CO), 2.62 (3H, s, CH_3 at C-4), 7.17 (1H, d, J = 5.0 Hz, H-5), 8.51 (1H, d, J = 5.0 Hz, H-6), 8.92 (1H, s, H-2); ^{13}C nmr (50.3 MHz, $CDCl_3$) δ: 20.8 (CH_3 at C-4), 29.1 (CH_3CO), 126.6 (C-5), 132.8 (C-4), 147.8 (C-3), 150.2 (C-6), 151.5 (C-2), 199.2 (CH_3CO); ms (EI), m/z (%): 135 (52) $[M]^+$, 120 (100), 92 (82), 65 (37). Exact Mass calcd. for C_8H_9NO $[M]^+$: 135.0684; found (hrms): 135.0692.

(1′S)-3-(1′-Hydroxyethyl)-4-methylpyridine (4)

Method 1. (−)-(Ipc)$_2$BCl reduction

To a solution of (−)-*B*-chlorodiisopinocampheylborane ((−)-(Ipc)$_2$BCl, Aldrich, 5.95 g, 18.5 mmol) in THF (20 mL) at −20°C and under an argon atmosphere was added 3-acetyl-4-methylpyridine (**8**) (1.00 g, 7.41 mmol). The reaction mixture was stirred for 17 h and the volatiles were removed under vacuum. The residue was dissolved in diethyl ether (30 mL) and diethanolamine (4.29 g, 40.8 mmol) was added. This mixture was stirred for 3 h and the solid that precipitated was removed by filtration through a sintered-glass funnel (medium porosity). The filter cake was washed twice with pentane and the combined filtrate and washings were concentrated *in vacuo*. To remove the remaining α-pinene, the oil was taken up in 0.2 M HCl (40 mL) and washed with ethyl acetate (60 mL). The aqueous layer was basified with $NaHCO_3$ (s) and extracted with ethyl acetate (5 × 50 mL). The combined extracts

For personal use only.

were dried over $MgSO_4$ and the solvent removed *in vacuo*. The remaining oil was purified by silica gel flash chromatography (ethyl acetate – methanol (95:5, v/v)) to yield 0.61 g (60% yield) of the chiral alcohol **4** (ee = 93.0%) as a colorless oil; $[\alpha]_D$ −50.2 (*c* 1.0, $CHCl_3$).

Method 2. Yeast reduction

Six 500-mL side-arm Erlenmeyer flasks, each containing a mixture of the ketone **8** (0.85 g, 6.3 mmol) and dry baker's yeast (Fleischmann's Yeast Limited, "Traditional Active Dry Yeast") (145 g) in tap water (250 mL), were shaken on a wrist-action shaker for 4 days at 32°C. The solutions were combined and centrifuged (13,000 rpm, 10 min, 4°C). The supernatant aqueous layers were decanted, more water was added to the centrifuge tubes, and the yeast re-suspended. This mixture was centrifuged as above and the supernatant aqueous layers were collected. All aqueous extracts were combined and passed through a 2-cm bed of Celite. Extraction of the aqueous phase with ethyl acetate (6 × 400 mL), followed by drying of the combined organic layers over Na_2SO_4 and removal of the solvent *in vacuo*, gave a slightly-yellow oil. This material was further purified by silica gel flash chromatography (ethyl acetate – methanol (95:5, v/v)) to provide 3.45 g (67% yield) of the (*S*)-alcohol **4** (ee = 99.0%) as a colorless oil; $[\alpha]_D$ −53.5 (*c* 1.0, $CHCl_3$); ν_{max} (film): 3296, 2975, 2926, 1603, 1449, 1416, 1373, 1096, 1071 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 1.46 (3H, d, *J* = 6.5 Hz, C-2′ H's), 2.30 (3H, s, CH_3 at C-4), 4.80 (1H, br s, D_2O-exchangeable, OH), 5.06 (1H, q, *J* = 6.5 Hz, H-1′), 6.98 (1H, d, *J* = 4.8 Hz, H-5), 8.18 (1H, d, *J* = 4.8 Hz, H-6), 8.51 (1H, s, H-2); ^{13}C nmr (50.3 MHz, $CDCl_3$) δ: 18.1 (C-2′), 23.4 (CH_3 at C-4), 64.5 (C-1′), 125.0 (C-5), 140.0 (C-4), 144.3 (C-3), 145.7 (C-6), 146.3 (C-2); ms (EI), *m/z* (%): 137 (28) $[M]^+$, 122 (100), 94 (50), 93 (13), 92 (12), 65 (14). Exact Mass calcd. for $C_8H_{11}NO$ $[M]^+$: 137.0841; found (hrms): 137.0851.

(1′S)-3-[1′-O-(S-MTPA)ethyl]-4-methylpyridine (9)

To *S*-(+)-α-methoxy-α-(trifluoromethyl)phenylacetic acid (101 mg, 0.430 mmol) in dichloromethane (15 mL) were added *N*,*N*′-dicyclohexylcarbodiimide (114 mg, 0.553 mmol), 4-dimethylaminopyridine (10 mg, 0.082 mmol), and the chiral alcohol **4** (42.0 mg, 0.306 mmol), and the solution was stirred for 16 h. The white precipitate was removed by filtration through a sintered-glass funnel (fine porosity) and washed with pentane (2 × 15 mL). The filtrate was diluted with dichloromethane (20 mL) and sequentially washed with saturated aqueous solutions of $NaHCO_3$ and NaCl (15 mL of each). The organic layer was dried over $MgSO_4$ and the solvent removed *in vacuo* to afford 76.8 mg (71% yield) of the acetate **9** as a colorless oil (the spectral data for the (1′*S*,*R*) diastereomer are given in parentheses if they are different from those of the (1′*S*,*S*) diastereomer); ^1H nmr (400 MHz, $CDCl_3$) δ: 1.56 (1.63) (3H, d, *J* = 6.7 Hz, C-2′ H's), 2.38 (2.33) (3H, s, CH_3 at C-4), 3.45 (3.55) (3H, q, *J* = 1.2 Hz, OCH_3), 6.27 (6.23) (1H, q, *J* = 6.7 Hz, H-1′), 7.06 (7.03) (1H, d, *J* = 5.0 Hz, H-5), 7.30–7.45 (5H, m, Ph), 8.39 (8.37) (1H, d, *J* = 5.0 Hz, H-6), 8.53 (8.35) (1H, s, H-2); ^{13}C nmr (50.3 MHz, $CDCl_3$) δ: 18.4 (18.3) (C-2′), 21.1 (21.0) (CH_3 at C-4), 55.3 (55.5) (OCH_3), 70.5 (70.4) (C-1′), 120.4 (*C*CF_3), 125.4 (125.2) (C-5), 126.2 (CF_3), 127.2, 128.3, 129.6, 131.8 (127.0, 128.4) (Ph), 134.4 (134.3) (C-3), 144.2 (C-4), 147.6 (147.4) (C-6), 149.1 (149.0) (C-2), 165.6 (165.8) (R*C*O_2R′); ms (EI), *m/z* (%): 354 (5) $[M + H]^+$, 224 (12), 189 (65), 143 (14), 120 (100); ms (CI), *m/z* (%): 354 (100) $[M + H]^+$, 120 (15). Exact Mass calcd. for $C_{18}H_{19}NO_3F_3$ $[M + H]^+$: 354.1316; found (hrms): 354.1322.

4,9-Dihydro-9-(p-toluenesulfonyl)-3H-pyrido-[3,4-b]indole (10)

At −10°C, the 3,4-dihydro-β-carboline **5** (see ref. 21 for preparation, 1.40 g, 8.23 mmol) was added slowly to a suspension of NaH (0.58 g, 60% in mineral oil, 14.6 mmol) in DMF (20 mL) and under an argon atmosphere. (**Caution**: various 3,4-dihydro-β-carbolines and 3,4-dihydro-2-methyl-β-carbolinium salts have recently been implicated in provoking the neuronal degeneration underlying idiopathic Parkinson's disease (27).) The mixture was stirred for 30 min and then cooled to −60°C at which time *p*-toluenesulfonyl chloride (3.15 g, 16.5 mmol) was added. The reaction mixture was acidified after 1.5 h using 0.2 M HCl (40 mL) and extracted with diethyl ether (2 × 30 mL). The combined organic layers were extracted with 0.2 M HCl (25 mL) and the combined aqueous extracts made basic with concentrated NH_4OH solution (aq.). Extraction with dichloromethane (2 × 60 mL) and subsequent drying over $MgSO_4$ and removal of the solvent *in vacuo* provided a solid amorphous material. This solid was purified by silica gel flash chromatography (ethyl acetate – hexane (7:3 v/v)) to yield 1.74 g (65%) of the tosylamide **10**, which was recrystallized from ethyl acetate – hexane; mp 143–145°C; ν_{max} (KBr): 3048, 2936, 2849, 1596, 1554, 1444, 1365, 1230, 1167 cm^{-1}; ^1H nmr (200 MHz, $CDCl_3$) δ: 2.31 (3H, s, Ts-CH_3), 2.75 (2H, app t, *J* = 8.7 Hz, H-4), 3.84 (2H, td, *J* = 2.2, 8.8 Hz, H-3), 7.16 (2H, d, *J* = 8.2 Hz, Ts), 7.28 (1H, t, *J* = 7.5 Hz, H-6), 7.43 (1H, t, *J* = 7.8 Hz, H-7), 7.47 (1H, d, *J* = 7.9 Hz, H-5), 7.65 (2H, d, *J* = 8.2 Hz, Ts), 8.18 (1H, d, *J* = 8.3 Hz, H-8), 8.99 (1H, app s, H-1); ^{13}C nmr (50.3 MHz, $CDCl_3$) δ: 18.7 (C-4), 21.4 (Ts-CH_3), 47.1 (C-3), 115.1 (C-8), 120.1 (C-5), 124.1 (C-6), 125.6 (C-4a), 126.5 (Ts), 127.3 (C-7), 127.8 (C-4b), 128.6, 129.8 (Ts), 134.7 (C-9a), 136.8 (C-8a), 145.1 (Ts), 150.9 (C-1); ms (EI), *m/z* (%): 324 (24) $[M]^+$, 169 (100), 142 (22), 115 (21), 91 (19). Exact Mass calcd. for $C_{18}H_{16}N_2O_2S$ $[M]^+$: 324.0932; found (hrms): 324.0926.

4,9-Dihydro-2-methyl-9-(p-toluenesulfonyl)-3H-pyrido-[3,4-b]indolinium iodide (3)

To a solution of the tosylamide **10** (501 mg, 1.54 mmol) in tetrahydrofuran (25 mL) was added iodomethane (0.49 mL, 7.7 mmol) with stirring and at room temperature, and the mixture was allowed to stand overnight. The solid precipitate **3** was isolated by filtration through Whatman filter paper (hardened) and the filter cake washed with hexane (2 × 20 mL) to provide 0.653 g (91% yield) of the bright-yellow crystalline 3,4-dihydro-2-methyl-β-carbolinium salt **3**; mp 195–197°C; ν_{max} (KBr): 3077, 3035, 2994, 2970, 1640, 1540, 1434, 1370, 1171, 1096 cm^{-1}; ^1H nmr (200 MHz, DMSO-d_6) δ: 2.31 (3H, s, Ts-CH_3), 3.37 (2H, app t, *J* = 9.0 Hz, H-4), 3.89 (3H, s, *N*-CH_3), 4.16 (2H, t, *J* = 9.1 Hz, H-3), 7.16 (2H, d, *J* = 8.4 Hz, Ts), 7.45 (1H, app t, *J* = 7.9 Hz, H-6 or H-7), 7.70 (1H, app t, *J* = 7.9 Hz, H-6 or H-7), 7.87 (1H, d, *J* = 7.9 Hz, H-5), 7.99 (2H, d, *J* = 8.4 Hz, Ts), 8.07 (1H, d, *J* = 8.6 Hz, H-8), 9.47 (1H, s, H-1); ^{13}C nmr (50.3 MHz, DMSO-d_6) δ: 19.0 (C-4), 21.0 (Ts-CH_3), 47.7 (*N*-CH_3), 49.8 (C-3), 114.6 (C-8), 123.2 (C-5), 125.4 (C-6), 125.8, 125.9 (C-4a, C-4b), 127.4, 130.4 (Ts), 131.6 (C-7), 132.5 (C-9a), 134.1 (Ts), 138.7 (C-8a), 146.5 (Ts), 155.1 (C-1); ms (EI), *m/z* (%): 340 (17) $[M - I + H]^+$, 185 (100), 184 (73), 183 (36), 157 (18), 156 (18), 142 (61), 139 (24), 92 (51), 91 (64). Exact Mass calcd. for $C_{19}H_{20}N_2O_2S$ $[M - I + H]^+$: 340.1245; found (hrms): 340.1234.

Tosylamide adducts 11a[(1S,1″S)-2,3,4,9-tetrahydro-1-{[3′-(1″-hydroxyethyl)-4′-pyridinyl]methyl}-2-methyl-9-(p-toluenesulfonyl)-1H-pyrido[3,4-b]indole] and 11b[(1R,1″S)-2,3,4,9-tetrahydro-1-{[3′-(1″-hydroxyethyl)-4′-pyridinyl]methyl}-2-methyl-9-(p-toluenesulfonyl)-1H-pyrido[3,4-b]indole]

Under an argon atmosphere and at −10°C, the hydroxypyridine **4** (228 mg, 1.66 mmol) in tetrahydrofuran (20 mL) was treated with potassium *tert*-butoxide (1.5 M in tetrahydrofuran, 1.44 mL, 2.16 mmol). The solution was stirred at this temperature for 10 min at which time it was cooled to −78°C and lithium diisopropylamide (1.5 M in tetrahydrofuran, 1.44 mL, 2.16 mmol) was added; the solution became yellow. After 25 min, the solution was added dropwise using a cannula to a vigorously stirred suspension of the 2-methyl-β-carbolinium salt **3** (519 mg, 1.11 mmol) in tetrahydrofuran (20 mL) at −78°C. The reaction was quenched after 0.5 h by addition of saturated NaCl (aq.) (2 mL) and then diluted with dichloromethane (40 mL). This mixture was washed sequentially with saturated $NaHCO_3$ (aq.) (15 mL) and saturated NaCl (aq.) (15 mL), dried over $MgSO_4$, and the solvent removed *in vacuo*. The

The effect of Lewis acids on the intramolecular Diels–Alder reaction of the furan diene

CHRISTINE ROGERS AND BRIAN A. KEAY[1]

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received May 15, 1992

CHRISTINE ROGERS and BRIAN A. KEAY. Can. J. Chem. **70**, 2929 (1992).

A general method is described for effecting the intramolecular Diels–Alder reaction of the furan diene in which the side arm connecting the diene to the dienophile contains four carbon atoms. The use of 1.1 equivalents of methylaluminum dichloride at −78°C for 2–8 h shifts the Diels–Alder equilibrium towards the products and provides the oxatricyclo adducts in good to excellent yield. Catalytic quantities of methylaluminum dichloride (10 mol%) provided a higher quantity of adduct than excess Lewis acid when the enone was substituted with alkyl groups. The scope was extended to include a precursor containing a five carbon atom side arm, and two examples containing acetylenic dienophiles that were activated by a carbonyl moiety on the side arm. Precursors having a four carbon atom side arm provided only oxatricyclo adducts having the side arm *syn* to the oxygen bridge. The assignment of the stereochemistry of the oxatricyclo adducts is discussed in detail.

CHRISTINE ROGERS et BRIAN A. KEAY. Can. J. Chem. **70**, 2929 (1992).

On décrit une méthode générale d'effectuer une réaction intramoléculaire de Diels–Alder avec des dièmes furaniques portant une chaîne latérale de quatre atomes de carbone qui relie le diène au diénophile. L'utilisation de 1,1 équivalent de dichlorure de méthylaluminium, à −78°C, pendant 2–8 h, déplace l'equilibre de Diels–Alder vers les produits et les adduits oxatricyclo avec des rendements allant de bons à excellents. Lorsqu'on substitue l'énone avec des groupes alkyles, les quantités d'adduit formées lorsqu'on utilise des quantités catalytiques de dichlorure de méthylaluminium (10 mol%) sont plus grandes que celles obtenues avec un excès d'acide de Lewis. On a étendu le champ d'application à un précurseur contenant une chaîne latérale de cinq atomes de carbone et à deux exemples contenant des diénophiles acétyléniques activés par une portion carbonyle sur la chaîne latérale. Les précurseurs portant une chaîne latérale contenant quatre atomes de carbone ne fournissent que les adduits oxatricyclo dans lesquels la chaîne latérale est *syn* par rapport au pont oxygène. On discute en détail de l'attribution de la stéréochimie des adduits oxatricyclo.

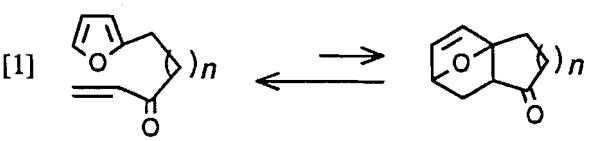
The intramolecular Diels–Alder (IMDA) reaction is a widely utilized synthetic strategy for the simultaneous formation of two rings with high stereo- and regio-control (1). The use of a furan moiety as the diene component in the IMDA reaction leads to the creation of an oxygenated cyclohexane ring in a rigid cycloadduct that has potential application for the synthesis of natural products. The intramolecular Diels–Alder reaction of the furan diene (IMDAF) has been studied extensively both when the tether connecting the diene and dienophile consists of three carbon atoms (1, 2), and when the tether contains a heteroatom and is either three (n = 1) or four (n = 2) atoms in length (eq. 1) (1, 3). The IMDAF reaction of precursors that have a side arm containing four (n = 2) (1, 4) or five (n = 3) (1, 5) carbon atoms have been studied to a lesser extent, and are generally reported to have equilibria that lie toward starting material. Methods employed to overcome the unfavourable equilibrium have included heat (4*a*), β-cyclodextrin (6), aqueous solutions (4*h*, 7), substituted side arms (3*g*, 3*h*, 4*k*, 4*m*, 4*n*, 5*b*, 8) and high pressure (4*b*, 4*c*, 4*j*). The success of these methods has been variable. The first four methods have produced increased starting material:adduct (SM:A) ratios for precursors with unsubstituted dienophiles but usually required long reaction times (2–14 days). High pressure (1.0–1.2 GPa) has been successful in overcoming the unfavourable equilibrium with both unsubstituted and substituted dienophiles; however, the isolated yields of the adducts have been poor, the reaction scale is limited, and access to specialized equipment is necessary. We therefore sought a generally applicable method for performing the IMDAF reaction that would overcome these limitations.



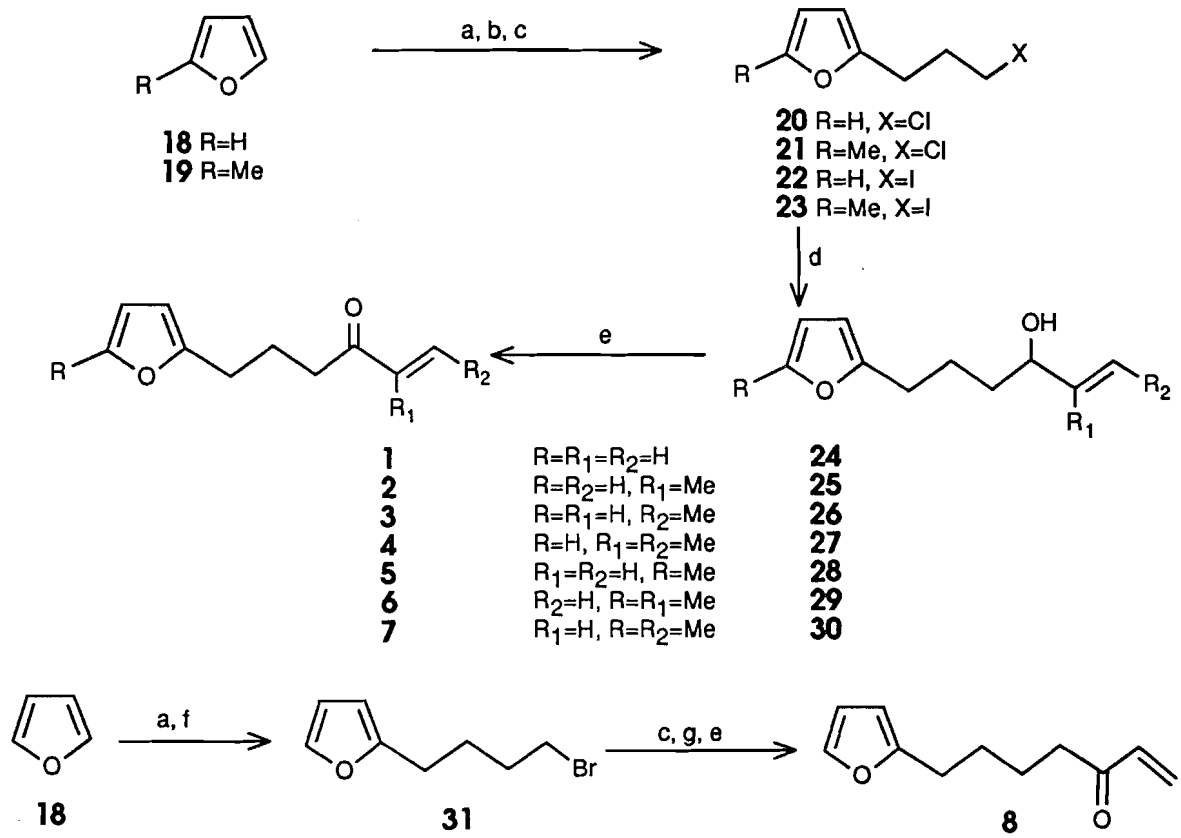
***n*=1 (a CH_2 may be substituted by an S, O, or N atom)**
***n*=2 (a CH_2 may be substituted by an O or N atom)**

Lewis acids have been used extensively in the *intermolecular* Diels–Alder reaction of the furan diene (9) to increase both the regioselectivity and the rate of reaction. Lewis acids have also been used to accelerate the rate of the *intramolecular* Diels–Alder reaction (10); however, their successful use in the IMDAF reaction (4*i*, 5*a*, 11) has been limited to only two reports: one employing an internally coordinated magnesium salt (12), and the second an application of zinc iodide (13). The paucity of examples of Lewis acid-mediated IMDAF reactions may be due to competing side reactions such as: (*a*) the polymerization of the furan ring or the dienophile (14), (*b*) the susceptibility of the furan ring to Friedel–Crafts-type reactions (14), and (*c*) the aromatization of the oxatricyclo adducts (15). We recently reported that the IMDAF reaction, in which the side arm contained four or five carbon atoms, is accelerated by the Lewis acid methylaluminum dichloride at low temperatures to provide the oxatricyclo adducts in good to excellent yield (16). We herein provide a full account of this work.

Preparation of IMDAF precursors ***1–17***

Precursors **1–8** were prepared as outlined in Scheme 1. Lithiation of either furan **18** or 2-methylfuran **19** under

[1]Author to whom correspondence may be addressed.



Reagents: (a) 1.2 equiv. n-BuLi, THF, 0°C, 1.5h; (b) 1-bromo-3-chloropropane; (c) NaI, acetone, reflux; (d) 2.2 equiv. t-BuLi, Et_2O, -78°C; then, acrolein, methacrolein, crotonaldehyde or tiglic aldehyde; (e) Swern [O]; (f) 1,4-dibromobutane; (g) 2.2 equiv. t-BuLi, Et_2O, -78°C; then acrolein

SCHEME 1

standard conditions (17) followed by trapping of the resultant anion with 1-bromo-3-chloropropane, afforded alkylated furans **20** (63%) and **21** (95%), respectively. Conversion of the chlorides **20** and **21** into the iodides **22** and **23** was accomplished in excellent yield under Finkelstein conditions (18). Halogen–metal exchange of the iodides **22** and **23** with *tert*-butyllithium (19) followed by quenching of the resulting carbanion with acrolein, methacrolein, crotonaldehyde, or tiglic aldehyde provided allylic alcohols **24–30**. Swern oxidation (20) of the allylic alcohols **24–30** yielded the IMDAF precursors **1–7** respectively. Furan **8** was prepared by reaction of the anion of furan **18** with 1,4-dibromobutane to provide bromide **31**, which was converted to furan **8** by the identical sequence described above (Scheme 1).

The synthesis of IMDAF precursors **9–15** is summarized in Scheme 2. Ismail and Hoffman (21) have reported that Friedel–Crafts alkylation of either furan **18** or 2-methylfuran **19** with 4-methyl-2-oxo-3-pentenenitrile **32** (22) in the presence of aluminum trichloride in benzene provided esters **33** and **34**, respectively, in reasonable yield after the reaction mixture was quenched with methanol. Our attempts to repeat this reaction provided esters **33** and **34** in poor yield (<20%) due to the competing Friedel–Crafts alkylation of the solvent benzene. Changing the solvent to carbon disulfide provided esters **33** and **34** in 30 and 66% yield, respectively. The yield of ester **33** was diminished due the formation of the 2,5-dialkylated product **35**. Attempts to prevent formation of **35** by blocking one α-site of furan with a *tert*-butyldimethylsilyl moiety were unsuccessful; the silylated furan did not undergo Friedel–Crafts reactions when subjected to a variety of Friedel–Crafts conditions.

Although Lipshutz and co-workers (23*a*) reported successful 1,4 additions of the higher-order cyanocuprate of 2-lithiofuran to α,β-unsaturated ketones, we were unsuccessful in effecting the same reaction on 3-methyl-2-butenal, methyl 3-methyl-2-butenoate, or dimethyl isopropylidenemalonate. The failure of these reactions may be due to both the low reactivity of the cuprate reagent (23*b*), and to the hindered nature of the position to be attacked.

Reduction of esters **33** and **34** with lithium aluminum hydride provided alcohols **36** and **37**, respectively, which were converted to the corresponding iodides **38** and **39** via the tosylates (18). The iodides **38** and **39** were then converted to precursors **9–12** and **13–15** via: (*a*) halogen–metal exchange, (*b*) quenching the anion with an α,β-unsaturated aldehyde to give allylic alcohols **40–46**, and (*c*) Swern oxidation.

The acetylenic precursors were prepared by treating the anion formed by halogen–metal exchange of iodide **38** with either 3-(trimethylsilyl)propynal **47** (24) or 2-butynal **48** (Scheme 2) (25). Swern oxidation provided compounds **16** and **17** in good yield.

Results and discussion

Compound **2** was treated with a number of Lewis acids (26) that had been reported to accelerate both inter- (9*c*, 27)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12

Reagents: (a) oxalyl choride, hexane; (b) CuCN, MeCN; (c) 0.25 equiv. $AlCl_3$, CS_2, furan **18** or 2-methylfuran **19**; (d) MeOH; (e) $LiAlH_4$, Et_2O; (f) TsCl, DMAP, CH_2Cl_2; (g) NaI, acetone, reflux; (h) 2.2 equiv. t-BuLi, Et_2O, -78°C; then acrolein, methacrolein, crotonaldehyde, or tiglic aldehyde; (i) Swern [O]; (j) 2.2 equiv.t-BuLi, Et_2O, -78°C; then TMSC≡CCHO (**47**) or MeC≡CCHO (**48**).

SCHEME 2

and intra-molecular (10*m*, 13, 28) Diels–Alder reactions (Table 1). Compound **2** was chosen for this model study since it had previously shown reluctance to undergo the IMDAF reaction when treated with Florisil either in methylene chloride or aqueous 2.0 M $CaCl_2$ solutions (entries 9 and 10) (4*h*). In each example, 1.1 equivalents of Lewis acid was added to a dilute solution (0.02–0.03 M) of compound **2** in methylene chloride at −78°C. Aliquots were removed from the reaction mixture and their ^{1}H NMR spectra were measured. The reaction was stirred at a particular temperature until there was no further change in the starting material to adduct (SM:A) ratio by ^{1}H NMR. The reaction was then warmed another 10 or 15°C, and the process repeated until a temperature was reached at which decomposition was detected. The aliquots removed from the reaction mixture were quenched with cold 10% sodium bicarbonate to prevent re-equilibration and to neutralize acidic by-products. The SM:A ratios were measured by integration of the ^{1}H NMR spectrum of the crude reaction mixture, in particular by comparison of the integral of the vinyl protons of the adduct **50** (δ 6.48 and 6.14) and that due to the β-furan protons of the starting material **2** (δ 6.28 and 6.00).

The results are summarized in Table 1. Zinc iodide (entry 1) was the least effective Lewis acid examined, which was surprising in light of its proven synthetic utility for accelerating both the intermolecular Diels–Alder reaction of the furan diene (9*c*) and an IMDAF reaction in which the side arm contained three carbon atoms (13). Although some adduct was produced within 3 h at room temperature, the equilibrium still favoured starting material. The ratio of SM:A did not change significantly after 39 h and decomposition products were detected by ^{1}H NMR. These findings are attributed to the unfavourable heterogeneous nature of the reaction mixture when zinc iodide is used. Tin(IV) chloride (entry 2) provided a favourable SM:A ratio of 24:76 within 1 h at −78°C; however, extensive decomposition was also observed (by ^{1}H NMR). The remaining Lewis acids (entries 3–8) provided SM:A ratios favouring adduct after only 2 h at either −78 or −50°C; decomposition was evident at temperatures above −50°C for all Lewis acids examined. The yields of the adduct were in excess of 95% (based on recovered starting material) after flash chromatography (29), indicating that decomposition below −50°C was insignificant. For ease of handling and reaction work-up, methylaluminum dichloride was chosen as the Lewis acid to continue the study.

[a]Some decomposition after 64 h (by ^{1}H NMR).
[b]Extensive decomposition (by ^{1}H NMR).
[c]Some decomposition after 3.5 h (by ^{1}H NMR).
[d]Decomposition occurred above −50°C.

The effect of solvent on the Lewis acid-mediated IMDAF reaction was also examined. Treatment of compound **2** in hexane with methylaluminum dichloride resulted in the formation of a gummy precipitate. Both ^{1}H NMR and TLC indicated that no IMDAF reaction had occurred. Toluene was also unsuitable as a solvent because many unidentified products formed even at −78°C. All subsequent reactions were therefore performed in methylene chloride.

The results from treating precursors **1–7** and **9–15** with methylaluminum dichloride at −78°C are summarized in Tables 2 and 3 respectively. Previous results from our lab (4*h*) using Florisil are also included for comparison purposes. Several observations are noteworthy. The use of 1.1 equivalents of methylaluminum dichloride with precursors **1**, **2**, **5**, and **6** provided their corresponding oxatricyclo adducts in excellent yields. Both compounds **1** and **5**, which have unsubstituted dienophiles, provided adducts **49** and **53** in 99% yield after only 1 h at −78°C. Compounds **2** and **6**, which were unreactive with Florisil, gave adducts **50** and **54** in 63 and 80% yields, respectively. In contrast, precursors **3**, **4**, and **7**, which have substitution at the terminus of the dienophile, had SM:A ratios in favour of starting material. The unreactive nature of these dienophiles in the IMDAF reaction is well precedented in the literature (4*i*), and may be a result of both increased steric interactions in the transition state as well as increased electron density of the carbon–carbon double bond.

The geminally substituted precursors **9** and **13** (Table 3) provided adducts **56** and **60** in 88% yield, respectively, upon treatment with Florisil alone after only 1 day at room temperature, and therefore were not treated with methylaluminum dichloride. Compounds **10**, **11**, **14**, and **15** provided varying SM:A ratios when Florisil was employed; however, in all cases adduct was detected and isolated. This finding is in contrast to the results from the corresponding unsubstituted precursors **2**, **3**, **6**, and **7** (Table 1) in which no adduct was detected after 6 days. The increased reactivity of the substituted precursors may be due to the *gem*-dialkyl effect (3*g*, 3*h*, 4*m*, 8, 30).

Treatment of compounds **10**, **11**, **14**, and **15** with 1.1 equivalents of methylaluminum dichloride provided SM:A ratios in favour of starting material; increased quantities of adduct were formed relative to the results from using Florisil, except for compound **14**. The lower SM:A ratios for compounds **10** and **14** (Table 3) when compared to the SM:A ratios for compounds **2** and **6** (Table 2) can be explained by unfavourable 1,3-diaxial methyl interactions present in adducts **57** and **61**, which are absent in adducts **50** and **54**. Thus the 1,3-diaxial interactions may be promoting the retro Diels–Alder reaction. Compound **12** provided no adduct with 1.1 equivalents of methylaluminum dichloride.

We then sought a means of overcoming the unfavourable equilibrium for precursors containing more hindered dienophiles. A survey of the literature revealed very few examples in which catalytic quantities of Lewis acids had been employed to accelerate IMDA reactions (10*h*, 10*j*, 10*k*, 28*c*, 31) and no examples involving the IMDAF reaction. Dramatic improvements in the SM:A ratios were observed when compounds **3**, **6**, **7** (Table 2), **10**, **11**, and **14** (Table 3) were exposed to 0.1 equivalents of methylaluminum dichloride at −78°C. In all cases the SM:A ratios favoured the adducts (SM:A ratios ranged from 40:60 to 0:100) and provided the oxatricyclo adducts in good to excellent yield. The SM:A ratios of compound **4** and **15** improved only slightly when compared to the results from the use of 1.1 equivalents of Lewis acid, and the tiglic precursor **12** did not react at all. These findings therefore represent the first examples of Lewis acid-catalyzed IMDAF reactions. In addition, these are also the first examples of Lewis acid-catalyzed IMDA reactions involving systems containing an internally activated dienophile.

The greatly improved SM:A ratios obtained when 0.1 equivalents of methylaluminum dichloride was employed, when compared with 1.1 equivalents, were rationalized by considering the effect that the amount of Lewis acid present has on the reaction equilibria. Our IMDAF reactions were shown to be under thermodynamic control: the reaction of pure adduct **50** with 1.1 equivalents of methylaluminum dichloride at −78°C for 2.5 h provided the same ratio of compounds **2**:**50** (35:65) that was obtained when pure precursor **2** was treated under the identical conditions (Scheme 3). The proposed equilibria are illustrated in Scheme 4. In the presence of 1.1 equivalents of Lewis acid the starting material and adduct are essentially complexed with Lewis acid and therefore both the forward and reverse Diels–Alder reactions are accelerated, leading to a thermodynamic ratio of Lewis acid complexed starting material **A*** and adduct **B***. Treatment of the reaction mixture with a bicarbonate quench at −78°C destroys the Lewis acid and provides, in the case of compound **3**, a SM:A ratio of 78:22 (Table 2). This ratio

[a]Yield in parentheses is based on recovered starting material.

is therefore indicative of the **A***:**B*** ratio in solution, since it has been shown that compound **3** and adduct **51** do not interconvert in the absence of Lewis acid or upon work-up at room temperature. When catalytic quantities of methylaluminum dichloride are employed, the Lewis acid should preferentially complex with the more basic enone in the starting material **A** (Scheme 4) rather than with the saturated ketone in the adduct **B** (32). The dissociation of the Lewis acid from the adduct **B*** and complexation with **A** thus not only slows the rate of the reverse Diels–Alder reaction but accelerates the forward reaction, leading to a shift in the equilibrium towards adduct. The SM:A ratio for compound **3**:**51** increased to 31:69 (Table 2) with 0.1 equivalents of Lewis acid. Attempts to probe the nature of the species in solution by ^1H NMR studies have been inconclusive to date. Further work is in progress to establish support for the above hypothesis.

The utility of mild Lewis acids in the IMDAF reaction was not limited to either a four carbon atom side arm or dienophiles comprising enones. Compound **8**, containing a five carbon atom side arm, provided two oxatricyclo adducts **63** and **64** in a ratio of 84:8 in favour of the *endo* isomer in addition to unreacted starting material when treated with 0.1 equivalents of methylaluminum dichloride at −78°C for 2 h (Table 4). The stereochemistry of the major isomer (**63**) was determined by comparison of the ^1H NMR spectrum of **63**

[a]Yield in parentheses is based on recovered starting material.

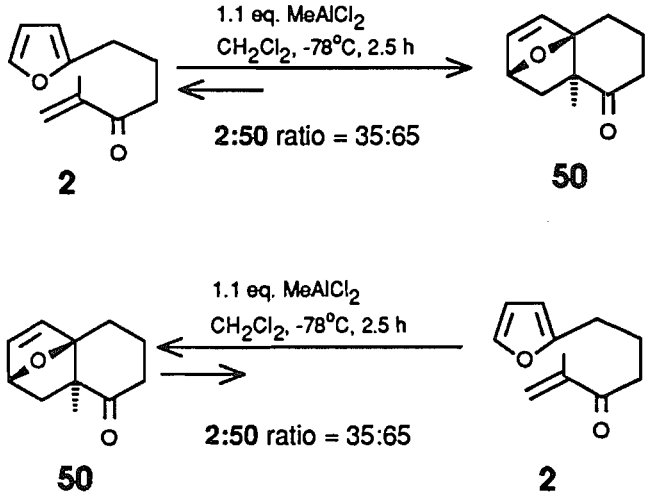
with that reported by Harwood and co-workers (5*a*). Interestingly, compound **8** has been previously reported to provide adducts **63** and **64** only at 1.2 GPa and in a ratio of 1:1 (5*a*).

Acetylenic precursors **16** and **17** provided the strained adducts **65** (88%) and **66** (97%), respectively, when treated with 1.1 equivalents of dimethylaluminum chloride at −50°C for 2.5 h (Scheme 5). The weaker Lewis acid dimethylaluminum chloride (26) was employed to minimize possible side reactions such as aromatization of the adducts. The use of internally activated acetylenic dienophiles in either the IMDA or IMDAF reaction is rare (1, 33), and no successful examples have been reported with the IMDAF reaction (4*l*). Usually the acetylene has been activated from the terminus by an ester moiety (1, 10). Thus, the reactions of compounds **16** and **17** are the first successful IMDA reactions involving internally activated acetylenic dienophiles. Adduct **65** was easily purified by flash chromatography, while adduct **66** was not as stable and partially isomerized to compound **67**, which contains an exocyclic double bond, upon standing.

Stereochemistry of the adducts

The stereochemistry of all the adducts formed in the Lewis acid accelerated IMDAF reactions containing a four-carbon

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.



SCHEME 3

side arm had the side arm orientated *syn* with respect to the oxygen bridge resulting from an *exo* mode of attack. This is not surprising since (1) the calculated $\Delta G^0 = +12.9$ kJ/mol (PCModel 4), for the equilibration between the *exo* adduct **49** and the corresponding *endo* adduct, favours the *exo* adduct and (2) the reactions are under thermodynamic control (*vide supra*). This stereochemistry is consistent with that reported by others in the literature for tethers consisting of four carbon atoms with an internally activated dienophile (4*a*,*f*). The delineation of the stereochemistry in adducts **49–51** and **53–55** (Scheme 6) will be described in detail as representative examples. The stereochemistry of the remaining adducts arising from either acrolein-, methacrolein-, or crotonaldehyde-type dienophiles were determined in a similar manner.

The stereochemistry of adducts **49** and **53** was determined by ^{1}H NMR based on the coupling constants of protons H-6α, H-7α, and H-7β (Scheme 6). The bridge proton in adduct **49** H-8 (δ 4.91) was coupled to both H-7β (3.8 Hz) and H-9 (0.9 Hz). Coupling of H-8 to H-7α was not observed since the dihedral angle of H-8—C-8—C-7—H-7α was 90°. Proton H-7β (δ 2.49) was a multiplet with couplings of 3.0 Hz, 3.8 Hz, and 11.8 Hz to protons H-6α (δ 2.28), H-8, and H-7α (δ 1.49), respectively. The 3.0 Hz coupling constant observed between H-7β and H-6α was indicative of a 60° dihedral angle, thereby placing the side arm *syn* to the oxygen bridge. If the side arm was orientated *anti* to the oxygen bridge then the C-6 proton would have a dihedral angle of 0°C to the C-7α proton and a coupling constant of approximately 8 Hz would be expected (34). The 8.3 Hz coupling observed between H-7α and H-6α therefore confirmed our assignment of the relative stereochemistry. Since compound **53** has a methyl group at C-8, proton H-7α was identified by its upfield shift as the doublet of doublets at δ 1.61. This upfield shift was observed in compound **49** for H-7α, and was probably due to the diamagnetic anisotropy of the carbon–carbon double bond. The coupling constants of 11.8 Hz to H-7β and 8.2 Hz to H-6α again confirmed the *syn* orientation of the side arm to the oxygen bridge in compound **53**.

The determination of the stereochemistry of the side arm with respect to the oxygen bridge in adducts **50** and **54** could not be directly related to coupling constants since a methyl group is attached at C-6 (Scheme 6). If the adducts were formed from the mode of cyclization in which the side arm was orientated *exo*, the C-6 methyl substituent would be *anti* (i.e., *endo*) to the oxygen bridge and be shielded by the C-9—C-10 double bond. The methyl group at C-6 had an upfield chemical shift of δ 1.11 and δ 1.08 for adducts **50** and **54**, respectively, which is indicative of *endo* orientated methyl groups in oxatricyclo adducts (35). The proton H-7β was a doublet of doublets at δ 2.86 in compound **50**, due to vicinal coupling with the bridge proton H-8 (5.1 Hz) and geminal coupling to H-7α (11.8 Hz). Proton H-7α coupled only geminally to H-7β (11.8 Hz), and was highly shielded at δ 1.00 due to the anisotropy of the carbon–carbon double bond. Similarly, protons H-7α and H-7β appeared as an AB quartet (11.8 Hz) at δ 1.12 and δ 2.55, respectively, in compound **54**.

The crotonaldehyde-derived adducts **51** and **55** contain an additional stereocenter at C-7. Since IMDAF reactions catalyzed by Lewis acids have a concerted mechanism (36), the

SCHEME 5

methyl group at C-7 should be *anti* to the oxygen bridge (Scheme 6) if an *exo* mode of cyclization had occurred. Proton H-8 (δ 4.69) in adduct **51** was a doublet of doublets coupled to H-9 (1.6 Hz) and H-7β (4.7 Hz), indicating that the methyl group at C-7 was indeed *anti* to the oxygen bridge. If the C-7 methyl group was *syn* to the oxygen bridge, the protons H-8 and H-7 would form a 90° dihedral angle, and would therefore show no coupling (34). This stereochemical assignment was also supported by the highly shielded chemical shift of the C-7 methyl doublet (δ 0.93) due to the anisotropy of the C-9—C-10 carbon–carbon double bond. Proton H-6 was a doublet (4.0 Hz, δ 1.73) and coupled to H-7β (δ 2.79). The 4.0 Hz coupling constant was indicative of a 60° dihedral angle, thereby placing H-6 *anti*, and the side arm *syn*, with respect to the oxygen bridge. The stereochemistry of compound **55** was assigned in a similar manner. The C-7 methyl group appeared as an upfield doublet at δ 0.95, consistent with the moiety being *anti* to the oxygen bridge. Proton H-6 (δ 1.89) was a doublet with 4.2 Hz coupling to H-7, indicating the side arm was *syn* with respect to the oxygen bridge.

Conclusions

We have shown that Lewis acids are effective reagents for promoting the IMDAF reaction in which the diene and dienophile are connected by four or five carbon atoms. The reaction conditions are also applicable to acetylenic dienophiles internally activated by a carbonyl moiety. The use of methylaluminum dichloride makes the IMDAF reaction a viable synthetic transformation since: (1) the time for the reaction to reach equilibrium is reduced to a few hours from 4 to 14 days; (2) the isolated yields of adducts are very high, and (3) only one adduct is formed with up to four asymmetric centres of known relative stereochemistry. Synthetic applications of this methodology are currently in progress.

Experimental

General methods

Melting points were determined using an Electrothermal melting point apparatus and are uncorrected. Boiling points refer to the air-bath temperature using Kugelrohr distillation apparatus, and are also uncorrected. Infrared spectra were obtained as either thin films (oils) on either NaCl or KBr plates, or as KBr pellets (solids). The infrared spectra were recorded on either a Nicolet 5-DX FT-IR spectrophotometer or a Mattson model 4030 FT-IR.

Nuclear magnetic resonance spectra were obtained on one of three instruments: Bruker AC-300 (^1H 300 MHz, ^{13}C 75 MHz), Bruker ACE-200 (^1H 200 MHz, ^{13}C 50 MHz), or a Bruker AM-400 spectrometer (^1H 400 MHz). Deuterochloroform was used both as the solvent, and the internal standard (^1H, δ 7.27; ^{13}C, δ 77.0) un-

less otherwise stated. All ^{1}H NMR spectra listed will have the following format: chemical shift (in ppm), (multiplicity, number of protons, coupling constants (Hz), assignment). The abbreviations used to describe the multiplicities are as follows: br = broadened, s = singlet, d = doublet, t = triplet, q = quartet, qu = quintet, and ABq refers to a quartet due to an AB spin system. The ^{13}C NMR spectra listed will have the following format: chemical shift (in ppm), (number of attached protons as determined by DEPT experiments).

Low-resolution mass spectra were recorded using either a Varian CH5 spectrometer, or a VG 7070 instrument. The data are listed as mass (*m/e*), (relative intensity, assignment). The spectra were obtained either by the electron-impact (EI) method or field ionization (FI), and the method will only be listed if FI was used. High-resolution mass spectra were recorded on a Kratos MS80 spectrometer. Microanalyses were performed either by Guelph Chemical Laboratories Limited, Guelph, Ontario, or by Mrs. D. Fox, Department of Chemistry, University of Calgary.

Solvents were either dried by standard methods (37), then distilled prior to use, or were purchased as anhydrous solvents in Sure-Seal® bottles from the Aldrich Chemical Company. THF was dried over sodium and benzophenone, as was diethyl ether. Methylene chloride, diisopropyl amine, and triethylamine were dried over CaH_2. Methanol was refluxed with Mg^0 metal for 12 h, then distilled. DMSO was dried over NaOH. Acetonitrile, DMF, and diethyl ether were purchased as anhydrous solvents, and HPLC-grade acetone was used.

The Lewis acids employed in this study were used as purchased, with no further purification. Boron trifluoride etherate and titanium(IV) chloride were used as neat liquids. The aluminum-containing reagents were purchased as molar solutions in hexane from Aldrich.

All glassware and syringes were dried in a 120°C oven for at least 4 h, then cooled under a stream of Ar, or in a desiccator containing Drierite. Reactions that were sensitive to moisture or atmospheric conditions were performed under an Ar atmosphere.

General procedure 1: conversion of tosylate or chloride to iodide

The tosylate or chloride (10 mmol) and NaI (25 mmol) were dissolved in HPLC-grade acetone (75 mL) and heated to reflux for 24 h under Ar. The reaction was cooled, and the solvent removed *in vacuo*. Diethyl ether (100 mL) and water (75 mL) were then added to dissolve the crude material. The aqueous layer extracted with Et_2O (3 × 100 mL) and the combined organic layers were dried over Na_2SO_4 (anhydrous), filtered, and the solvent removed *in vacuo* to provide the crude iodide. The iodide was purified either by flash chromatography, or distillation.

General procedure 2: coupling of iodide with unsaturated aldehydes

The iodide was purified by filtration through basic alumina, then distillation just prior to use. The iodide (1.0 mmol) was dissolved in anhydrous Et_2O (10 mL), and the solution was cooled to −78°C in a Dry Ice – acetone bath. *tert*-Butyllithium (2.2 mmol) was added dropwise to the cooled solution by syringe, and the reaction was stirred for 1 h at −78°C. The α,β-unsaturated aldehyde was distilled from Na_2SO_4 under Ar, and was added neat (1.5 mmol) by syringe to the reaction. The reaction was continued for a further 30 min (or until monitoring by TLC showed no starting material was present), then was quenched at low temperature with saturated NH_4Cl (10 mL). After warming to room temperature, the aqueous layer was extracted with Et_2O (3 × 25 mL) and CH_2Cl_2 (2 × 25 mL). The combined organic layers were dried over Na_2SO_4, filtered, and the solvent removed *in vacuo* to provide the crude coupled product, which was purified by flash chromatography, then distillation.

General procedure 3: Swern oxidation

The method of Swern (20) was used to oxidize the allylic alcohols to the enones. Oxalyl chloride (11 mmol) was dissolved in dry CH_2Cl_2 (25 mL) and cooled to −60°C (Dry Ice – chloroform) in an Ar-purged 3-neck round-bottom flask equipped with a dropping funnel. Freshly distilled alcohol (10 mmol) was dissolved in dry CH_2Cl_2 (10 mL) and placed in the dropping funnel. DMSO (22 mmol) was added neat (by syringe) to the oxalyl chloride solution, the reaction was stirred for 2 min, and then the alcohol solution was added within 5 min. The mixture was stirred an additional 15 min, then Et_3N (50 mmol) was added and stirring was continued for another 5 min before warming the reaction to room temperature. Water (50 mL) was added, and the aqueous layer was extracted with CH_2Cl_2 (5 × 25 mL). The combined organic layers were washed with 5% HCl (15 mL), 5% Na_2CO_3 (15 mL), and water (15 mL), dried over Na_2SO_4, filtered, and the solvent removed *in vacuo* to provide the crude bad-smelling product, which was purified by flash chromatography, then distilled.

General procedure 4: IMDAF reactions in Florisil

The freshly distilled enone (1 mmol) was dissolved in dry CH_2Cl_2 (15 mL) and placed in an Ar-purged round-bottom flask. To this was added Florisil (100–200 mesh, 10 weight equivalents to the enone). The reaction was wrapped in foil and stirred at the appropriate temperature for the required length of time. The reaction was then filtered, the Florisil washed well with EtOAc (20 mL), and the solvent removed *in vacuo* without external heating to provide the crude product, which could be purified by flash chromatography.

General procedure 5: IMDAF reactions using Lewis acid

The freshly distilled enone (0.2 mmol) was dissolved in dry CH_2Cl_2 (10 mL), placed in an Ar-purged 3-necked flask, and cooled to the appropriate temperature. Methylaluminum dichloride (1.0 M in hexane) was added to the cooled enone solution, and the reaction was stirred for the appropriate length of time. The reaction was quenched with 10% $NaHCO_3$ (10 mL), and warmed until no frozen material remained. The aqueous layer was extracted with CH_2Cl_2 (4 × 10 mL), then the organic layer was washed with H_2O (15 mL), dried over Na_2SO_4, filtered, and the solvent removed *in vacuo* without external heating to provide the crude product, which was purified by flash chromatography.

*3-(2-Furyl)-1-chloropropane (**20**)*

Furan **18** (6.0 mL, 82.5 mmol) was dissolved in dry THF (140 mL) under Ar and cooled to −78°C. Butyllithium (2.5 M in hexanes, 39.6 mmol) was added, then the solution was warmed to 0°C and stirred for 2 h. The 1-bromo-3-chloropropane (15.5 g, 98.7 mmol) was passed through basic alumina, then distilled before being added dropwise to the yellow anion solution. The reaction was stirred at room temperature overnight. The solvent was removed *in vacuo*, then ether (100 mL) and saturated NH_4Cl (100 mL) were added to the oily residue. The aqueous layer was extracted with ether (3 × 100 mL), dried over Na_2SO_4, and the solvent removed *in vacuo*. Distillation under aspirator provided compound **20** as a clear, colourless oil (9.1 g, 63.1 mmol), 76% yield; bp 60–70°C/20 Torr (1 Torr = 133.3 Pa); IR (neat) cm^{-1}: 2959–2850(C-H), 735(C-Cl); ^{1}H NMR (200 MHz): 2.12(qu, 2H, J = 7.0 Hz), 2.82(t, 2H, J = 7.0 Hz), 3.57(t, 2H, J = 7.0 Hz), 6.05(dd, 1H, J = 0.8 Hz, J = 3.0 Hz), 6.30(dd, 1H, J = 1.8 Hz, J = 3.0 Hz), 7.33(dd, 1H, J = 0.8 Hz, J = 1.8 Hz); ^{13}C NMR (50 MHz): 25.07(t), 30.86(t), 44.01(t), 105.55(d), 110.09(d), 141.13(d), 154.29(s); mass spectrum: 144(15, $M^{+\cdot}$), 81(100, M − $(CH_2)_2Cl$). Exact Mass calcd. for C_7H_9ClO: 144.0342; found: 144.0352.

*3-(2-(5-Methylfuryl))-1-chloropropane (**21**)*

2-Methylfuran **19** (7.9 mL, 80.0 mmol) was dissolved in dry THF (140 mL) under Ar and cooled to −78°C. Butyllithium (2.5 M in hexanes, 38.4 mmol) was added, then the solution was warmed to 0°C and stirred for 2 h. The 1-bromo-3-chloropropane (17.0 g, 108.2 mmol) was passed through basic alumina, then distilled before being added dropwise to the yellow anion solution. The reaction was stirred at room temperature overnight. The solvent was removed *in vacuo*, then ether (100 mL) and saturated NH_4Cl (100 mL) were added to the oily residue. The aqueous layer was

For personal use only.

extracted with ether (3 × 100 mL), dried over Na_2SO_4, and the solvent removed *in vacuo*. Distillation under aspirator provided chloride **21** as a clear, colourless oil (12.3 g, 77.5 mmol), 97% yield, bp 75–85°C/20 Torr; IR (neat) cm^{-1}: 2956–2867(C-H), 653(C-Cl); ^1H NMR (200 MHz): 2.10(qu, 2H, J = 6.9 Hz), 2.27(s, 3H), 2.76(t, 2H, J = 7.2 Hz), 3.58(t, 2H, J = 6.5 Hz), 5.87(d, 1H, J = 3.0 Hz), 5.92(d, 1H, J = 3.0 Hz); ^{13}C NMR (50 MHz): 13.27(q), 25.02(t), 30.87(t), 43.96(t), 105.66(d), 106.02(d), 150.43(s), 152.25(s); mass spectrum: 158(11, $M^{\cdot+}$), 95(100, M − $(CH_2)_2Cl$). Exact Mass calcd. for $C_8H_{11}OCl$: 158.0498; found: 158.0501.

3-(2-Furyl)-1-iodopropane (22)

Using general procedure 1, chloride **20** (9.1 g, 63.1 mmol) was converted to iodide **22** (14.1 g, 59.7 mmol) in 95% yield after distillation; bp 20–30°C/0.04 Torr; IR (neat) cm^{-1}: 3144–3001(C-H), 2953–2843(C-H); ^1H NMR (200 MHz): 2.15(qu, 2H, J = 7.0 Hz), 2.77(t, 2H, J = 7.0 Hz), 3.20(t, 2H, J = 7.0 Hz), 6.06(dd, 1H, J = 0.8 Hz, J = 3.1 Hz), 6.29(dd, 1H, J = 1.8 Hz, J = 3.1 Hz), 7.32(dd, 1H, J = 0.8 Hz, J = 1.8 Hz); ^{13}C NMR (50 MHz): 5.79(t), 28.57(t), 31.61(t), 105.70(d), 110.09(d), 141.16(d), 153.92(s); mass spectrum: 236(51, $M^{\cdot+}$), 81(100, M − $(CH_2)_2I$). Exact Mass calcd. for C_7H_9IO: 235.9697; found: 235.9704.

3-(2-(5-Methylfuryl))-1-iodopropane (23)

Using general procedure 1, chloride **21** (3.75 g, 23.6 mmol) was converted to the iodide **23** (5.60 g, 22.4 mmol) in 95% yield after distillation; bp 100°C/20 Torr; IR (neat) cm^{-1}: 3102(C-H), 2942–2845(C-H); ^1H NMR (300 MHz): 2.13(qu, 2H, J = 6.8 Hz), 2.26(s, 3H), 2.71(t, 2H, J = 6.8 Hz), 3.21(t, 2H, J = 6.8 Hz), 5.85 and 5.89(ABq, 2H, J = 3.0 Hz); ^{13}C NMR (50 MHz): 5.88(t), 13.42(q), 28.63(t), 31.72(t), 105.78(d), 106.28(d), 150.50(s), 151.94(s): mass spectrum: 250(51, $M^{\cdot+}$), 95(100, M − $(CH_2)_2I$). Exact Mass calcd. for $C_8H_{11}IO$: 249.9855; found: 249.9857.

6-(2-Furyl)-1-hexen-3-ol (24)

Using general procedure 2, iodide **22** (0.59 g, 2.50 mmol) was treated with *tert*-butyllithium (3.23 mL, 5.5 mmol) and acrolein (0.25 mL, 3.74 mmol) to produce compound **24** (0.22 g, 1.32 mmol) as a clear, colourless oil in 53% yield after purification by flash chromatography (5:1) and distillation; bp 60–68°C/0.04 Torr; IR (neat) cm^{-1}: 3385 (O-H); ^1H NMR (200 MHz): 1.52–1.84(overlapping m, 6H), 2.67(t, 2H, J = 7.1 Hz), 4.13(m, 1H, J = 6.2 Hz), 5.12(ddd, 1H, J = 1.3 Hz, J = 1.3 Hz, J = 10.3 Hz), 5.23(ddd, 1H, J = 1.3 Hz, J = 1.3 Hz, J = 17.2 Hz), 5.90(ddd, 1H, J = 6.2 Hz, J = 10.3 Hz, J = 17.2 Hz), 6.00(dd, 1H, J = 0.8 Hz, J = 3.1 Hz), 6.28(dd, 1H, J = 1.8 Hz, J = 3.1 Hz), 7.30(dd, 1H, J = 0.8 Hz, J = 1.8 Hz); ^{13}C NMR (50 MHz): 23.87(t), 27.80(t), 36.39(t), 72.93(d), 104.85(d), 110.05(d), 114.72(t), 140.77(d), 141.09(d), 155.98(s); mass spectrum: 166(9, $M^{\cdot+}$), 148(10, M − H_2O), 94(100, M − CH_2=C(OH)CH=CH_2). Exact Mass calcd. for $C_{10}H_{14}O_2$: 166.0994; found: 166.0994.

6-(2-Furyl)-2-methyl-1-hexen-3-ol (25)

Using general procedure 2, iodide **22** (0.51 g, 2.18 mmol) was treated with *tert*-butyllithium (2.82 mL, 4.79 mmol) and methacrolein (0.27 mL, 3.26 mmol) to produce compound **25** (0.22 g, 1.20 mmol) as a clear, colourless oil in 55% yield after purification by flash chromatography (5:1) and distillation; bp 130°C/0.1 Torr; IR (neat) cm^{-1}: 3397(OH); ^1H NMR (200 MHz): 1.55–1.80(m, 5H), 1.72(t, 3H, J = 1.1 Hz, J = 1.1 Hz), 2.67(t, 2H, J = 7.2 Hz, H-4), 4.08(br q, 1H), 4.85(qu, 1H, J = 1.6 Hz), 4.95(m, 1H, J = 1.0 Hz, J = 1.6 Hz), 5.99(dd, 1H, J = 0.8 Hz, J = 3.1 Hz), 6.28(dd, 1H, J = 1.8 Hz, J = 3.1 Hz), 7.30(dd, 1H, J = 0.8 Hz, J = 1.8 Hz); ^{13}C NMR (50 MHz): 17.45(q), 24.06(t), 27.76(t), 34.22(t), 75.85(d), 104.82(d), 110.03(d), 111.10(t), 140.75(d), 147.40(s), 156.00(s); mass spectrum: 180(10, $M^{\cdot+}$), 94(100, M − $CH_2CH(OH)C(Me)$=CH_2, McLafferty rearr.). Exact Mass calcd. for $C_{11}H_{16}O_2$: 180.1151; found: 180.1150.

(E-7-(2-Furyl)-2-hepten-4-ol (26)

Using general procedure 2, iodide **22** (0.60 g, 2.56 mmol) was treated with *tert*-butyllithium (3.32 mL, 5.64 mmol) and crotonaldehyde (0.32 mL, 3.84 mmol) to produce compound **26** (0.31 g, 1.72 mmol) as a clear, colourless oil in 67% yield after purification by flash chromatography (9:1) and distillation; bp 52–68°C/0.035 Torr; IR (neat) cm^{-1}: 3443(O-H); ^1H NMR (200 MHz): 1.47–1.84(m, 5H), 1.70(dd, 3H, J = 0.9 Hz, J = 6.0 Hz), 2.65(t, 2H, J = 7.1 Hz), 4.06(br q, 1H, J = 6.3 Hz), 5.48(ddq, 1H, J = 0.9 Hz, J = 6.0 Hz, J = 15.3 Hz), 5.67(ddq, 1H, J = 1.5 Hz, J = 6.8 Hz, J = 15.3 Hz), 5.99(dd, 1H, J = 0.8 Hz, J = 3.1 Hz), 6.28(dd, 1H, 1.9 Hz, J = 3.1 Hz), 7.30(dd, 1H, J = 0.8 Hz, J = 1.9 Hz); ^{13}C NMR (50 MHz): 17.62(q), 24.00(t), 27.81(t), 36.63(t), 72.84(d), 104.78(d), 110.02(d), 126.97(d), 134.11(d), 140.72(d), 156.05(s); mass spectrum: 180(8, $M^{\cdot+}$), 162(39, M − H_2O), 94(100, M − $CH_2CH(OH_2)$-CH=CHMe). Anal. calcd. for $C_{11}H_{16}O_2$: C 73.30, H 8.95; found: C 73.10, H 9.02.

(E)-7-(2-Furyl)-3-methyl-2-hepten-4-ol (27)

Using general procedure 2, iodide **22** (1.56 g, 6.63 mmol) was treated with *tert*-butyllithium (8.58 mL, 14.58 mmol) and tiglic aldehyde (0.96 mL, 9.94 mmol) to produce compound **27** (0.58 g, 3.00 mmol) as a clear, colourless oil in 45% yield after purification by flash chromatography (7:1) and distillation; bp 72–78°C/0.1 Torr; IR (neat) cm^{-1}: 3365(O-H); ^1H NMR (200 MHz): 1.49(br, s, 1H), 1.50–1.80(m, 10H), 2.65(t, 2H, J = 5.0 Hz), 4.01(br m, 1H), 5.47(br q, 1H), 5.99(dd, 1H, J = 0.7 Hz, J = 3.1 Hz), 6.28(dd, 1H, J = 1.9 Hz, J = 3.1 Hz), 7.30(dd, 1H, J = 0.7 Hz, J = 1.9 Hz); mass spectrum: 194(23, $M^{\cdot+}$), 176(42, M − H_2O), 94(100, M − $CH_2CH(OH)C(Me)$=CHMe). Anal. calcd. for $C_{12}H_{18}O_2$: C 74.19, H 9.34; found: C 73.91, H 9.32.

6-(2-(5-Methylfuryl))-1-hexen-3-ol (28)

Using general procedure 2, iodide **23** (0.59 g, 2.34 mmol) was treated with *tert*-butyllithium (3.03 mL, 5.15 mmol) and acrolein (0.24 mL, 3.51 mmol) to produce compound **28** (0.25 g, 1.40 mmol) as a clear, colourless oil in 60% yield after purification by flash chromatography (5:1) and distillation; bp 130–135°C/12 Torr; IR (neat) cm^{-1}: 3400(C-O), 1021(C-O); ^1H NMR (200 MHz): 1.53–1.81(overlapping m, 6H), 2.26(s, 1H), 2.61(t, 2H, J = 7.2 Hz), 4.13(br, m, 1H, J = 6.2 Hz), 5.12(dt, 1H, J = 1.3 Hz, J = 1.3 Hz, J = 10.3 Hz), 5.23(dt, 1H, J = 1.3 Hz, J = 1.3 Hz, J = 17.2 Hz), 5.85(ABq, 2H), 5.87(ddd, 1H, J = 6.2 Hz, J = 10.3 Hz, J = 17.2 Hz); ^{13}C NMR (50 MHz): 13.41(q), 23.96(t), 27.85(t), 36.42(t), 72.93(d), 105.40(d), 105.73(d), 114.73(t), 141.10(d), 150.16(s), 154.08(s); mass spectrum: 180(31, $M^{\cdot+}$), 162(7, M − H_2O), 108 (100, M − CH_2=C(OH)CH=CH_2). Anal. calcd. for $C_{11}H_{16}O_2$: C 73.30, H 8.95; found: C 73.08, H 9.21.

6-(2-(5-Methylfuryl))-2-methyl-1-hexen-3-ol (29)

Using general procedure 2, iodide **23** (0.52 g, 2.07 mmol) was treated with *tert*-butyllithium (2.67 mL, 4.55 mmol) and methacrolein (0.26 mL, 3.10 mmol) to produce compound **29** (0.28 g, 1.45 mmol) as a clear, colourless oil in 70% yield after purification by flash chromatography (5:1) and distillation; bp 69–77°C/0.04 Torr; IR (neat) cm^{-1}: 3405 (O-H); ^1H NMR (200 MHz): 1.55–1.70(m, 5H), 1.72(dd, 3H, J = 0.9 Hz, J = 1.2 Hz), 2.25(s, 3H), 2.61(t, 2H, 7.0 Hz), 4.08(br t, 1H, J = 7.5 Hz), 4.84(m, 1H, J = 1.7 Hz), 4.95(m, 1H, J = 0.8 Hz, J = 1.7 Hz), 5.85(ABq, 2H); ^{13}C NMR (50 MHz): 13.42(q), 17.44(q), 24.19(t), 27.84(t), 34.35(t), 75.66(d), 105.40(d), 105.79(d), 110.99(t), 147.48(s), 150.13(s), 154.16(s); mass spectrum: 194(14, $M^{\cdot+}$), 108(100, M − $CH_2CH(OH)C(Me)$=CH_2). 6-(2-Furyl)-1-hexen-3-one (1)

Compound **24** (0.19 g, 1.18 mmol) was oxidized according to general procedure 3 to provide compound **1** (0.18 g, 1.10 mmol) as a clear, colourless oil in 93% yield after purification by flash chromatography (20:1) and distillation; bp 50–55°C/0.08 Torr. The ^1H NMR spectrum always contained >10% bridged adduct **49**, therefore compound **1** was not analyzed but treated with either Florisil or methylaluminum dichloride to provide adduct **49**.

6-(2-Furyl)-2-methyl-1-hexen-3-one (2)

Compound **25** (0.65 g, 3.58 mmol) was oxidized according to general procedure 3 to provide compound **2** (0.60 g, 3.36 mmol) as a clear, colourless oil in 94% yield after purification by flash chromatography (20:1) and distillation; bp 58–60°C/0.045 Torr; IR(neat) cm^{-1}: 1677(C=O); ^1H NMR (200 MHz): 1.87(dd, 3H, J = 0.8 Hz, J = 1.4 Hz), 1.97(qu, 2H, J = 7.3 Hz), 2.67(t, 2H, J = 7.3 Hz), 2.72(t, 2H, J = 7.3 Hz), 5.75(dq, 1H, J = 0.8 Hz, J = 1.4 Hz), 5.92(m, 1H, J = 1.4 Hz), 6.00(dd, 1H, J = 0.8 Hz, J = 3.0 Hz), 6.28(dd, 1H, J = 2.0 Hz, J = 3.0 Hz), 7.30(dd, 1H, J = 0.8 Hz, J = 2.0 Hz); ^{13}C NMR(50 MHz): 17.55(q), 22.80(t), 27.27(t), 36.44(t), 105.18(d), 110.06(d), 124.27(t), 140.91(d), 144.53(s), 155.46(s), 199.52(s); mass spectrum: 178(21, $M^{+\cdot}$), 94(100, M − $CH_2{=}C(OH)C(Me){=}CH_2$, McLafferty rearr.). Exact Mass calcd. for $C_{11}H_{14}O_2$: 178.0994; found: 178.0998.

(E)-7-(2-Furyl)-2-hepten-4-one (3)

Compound **26** (0.27 g, 1.48 mmol) was oxidized according to general procedure 3 to provide compound **3** (0.23 g, 1.29 mmol) as a clear, colourless oil in 88% yield after purification by flash chromatography (20:1) and distillation; bp 60–70°C/0.05 Torr; IR (neat) cm^{-1}: 1672 and 1696(C=O); ^1H NMR (200 MHz): 1.89(dd, 3H, J = 1.6 Hz, J = 6.8 Hz), 1.96(qu, 2H, J = 7.2 Hz), 2.57(t, 2H, J = 7.2 Hz), 2.66(t, 2H, J = 7.2 Hz), 6.00(dd, 1H, J = 0.6 Hz, J = 3.1 Hz), 6.11(dq, 1H, J = 1.6 Hz, J = 15.7 Hz), 6.28(dd, 1H, J = 1.9 Hz, J = 3.0 Hz), 6.83(dq, 1H, J = 6.8 Hz, J = 15.7 Hz), 7.30(dd, 1H, J = 0.6 Hz, J = 1.9 Hz); ^{13}C NMR (50 MHz): 18.09(q), 22.50(t), 27.26(t), 38.92(t), 105.18(d), 110.04(d), 131.91(d), 140.89(d), 142.31(d), 155.44(s), 199.74(s); mass spectrum (FI): 178(100, $M^{+\cdot}$). Anal. calcd. for $C_{11}H_{14}O_2$: C 74.13, H 7.92; found: C 74.18, H 7.98.

(E)-7-(2-Furyl)-3-methyl-2-hepten-4-one (4)

Compound **27** (0.69 g, 3.55 mmol) was oxidized according to general procedure 3 to provide compound **4** (0.62 g, 3.24 mmol) as a clear, colourless oil in 91% yield after purification by flash chromatography (20:1) and distillation; bp 60–70°C/0.045 Torr; IR (neat) cm^{-1}: 1666 (C=O); ^1H NMR (200 MHz): 1.77(d, 3H, J = 1.1 Hz), 1.84(d, 3H, J = 6.9 Hz), 1.96(qu, 2H, J = 7.2 Hz), 2.66 and 2.68(overlapping t, 4H, J = 7.2 Hz), 5.99(dd, 1H, J = 0.7 Hz, J = 3.1 Hz), 6.27(dd, 1H, J = 1.8 Hz, J = 3.1 Hz), 6.69(qq, 1H, J = 1.1 Hz, J = 6.9 Hz), 7.29(dd, 1H, J = 0.7 Hz, J = 1.8 Hz); ^{13}C NMR (50 MHz): 10.78(q), 14.51(q), 22.92(t), 27.19(t), 35.90(t), 104.94(d), 109.90(d), 136.88(d), 138.02(s), 140.68(d), 155.40(s), 200.94(s); mass spectrum (FI): 192(51, $M^{+\cdot}$), 94(100 − CH=C(OH)C(Me)=CHMe, McLafferty rearrangement). Anal. calcd. for $C_{12}H_{16}O_2$: C 74.97, H 8.39; found: C 74.85, H 8.43.

6-(2-(5-Methylfuryl)-1-hexen-3-one (5)

Compound **28** (0.24 g, 1.34 mmol) was oxidized according to general procedure 3 to provide compound **5** (0.15 g, 0.84 mmol) as a clear, colourless oil in 63% yield after purification by flash chromatography (20:1) and distillation; bp 60–70°C/0.04 Torr; IR (neat) cm^{-1}: 1684(C=O); ^1H NMR (200 MHz): 1.96(qu, 2H, J = 7.5 Hz), 2.25(s, 3H), 2.59–2.70(t, 2H each, J = 7.5 Hz), 5.85(m, 2H), 6.19(dd, 1H, J = 1.5 Hz, J = 16.5 Hz), 6.38(dd, 1H, J = 10.1 Hz, J = 16.5 Hz); ^{13}C NMR (50 MHz): 13.42(q), 22.33(t), 27.24(t), 38.57(t), 105.74(d), 105.86(d), 127.87(t), 136.50(d), 150.36(s), 153.36(s), 200.34(s); mass spectrum: 178(13, $M^{+\cdot}$), 108(100, M − $CH_2{=}C(OH)CH{=}CH_2$, McLafferty rearrangement).

6-(2-(5-Methylfuryl))-2-methyl-1-hexen-3-one (6)

Compound **29** (0.28 g, 1.45 mmol) was oxidized according to general procedure 3 to provide compound **6** (0.27 g, 1.42 mmol) as a clear, colourless oil in 98% yield after purification by flash chromatography (20:1) and distillation; bp 60–68°C/0.045 Torr; IR (neat) cm^{-1}: 1680(C=O); ^1H NMR (200 MHz): 1.87(dd, 3H, J = 0.7 Hz, J = 1.3 Hz), 1.94(qu, 2H, J = 7.3 Hz), 2.24(s, 3H), 2.61(t, 2H, J = 7.3 Hz), 2.73(t, 2H, J = 7.3 Hz), 5.75(m, 1H, J = 0.7 Hz, J = 1.4 Hz), 5.84(ABq, 2H), 5.93(m, 1H, J = 1.3 Hz, J = 1.4 Hz); ^{13}C NMR (50 MHz): 13.41(q), 17.54(q), 22.95(t), 27.37(t), 36.52(t), 105.78(d), 124.19(t), 144.57(s), 150.33(s), 153.56(s), 201.61(s); mass spectrum: 192(62, $M^{+\cdot}$), 108(100, M − $CH_2{=}C(OH)C(Me){=}CH_2$, McLafferty rearrangement). Exact Mass calcd. for $C_{12}H_{16}O_2$: 192.1150; found: 192.1158.

(E)-7-(2-(5-Methylfuryl))-2-hepten-4-one (7)

Compound 30 (0.30 g, 1.54 mmol) was oxidized according to general procedure 3 to provide compound **7** (0.24 g, 1.23 mmol) as a clear, colourless oil in 80% yield after purification by flash chromatography (20:1) and distillation; bp 70–82°C/0.045 Torr; IR (neat) cm^{-1}: 1695–1670(C=O); ^1H NMR (200 MHz): 1.89(dd, 3H, J = 2.5 Hz, J = 7.5 Hz), 1.95(qu, 2H, J = 7.0 Hz), 2.25(s, 3H), 2.55(t, 2H, J = 7.0 Hz), 2.60(t, 2H, J = 7.0 Hz), 5.84(ABq, 2H), 6.11(dq, 1H, J = 1.6 Hz, J = 15.8 Hz), 6.83(dq, 1H, J = 6.8 Hz, J = 15.8 Hz); ^{13}C NMR (50 MHz): 13.39(q), 18.08(q), 22.59(t), 27.38(t), 38.96(t), 105.74(d), 105.78(d), 131.90(d), 142.24(d), 150.28(s), 153.49(s), 199.88(s); mass spectrum: 192(10, $M^{+\cdot}$), 108(100, M − $CH_2{=}C(OH)CH{=}CHMe$, McLafferty rearrangement). Exact Mass calcd. for $C_{12}H_{16}O_2$: 192.1151; found: 192.1138.

1-Bromo-4-(2-furyl)butane (31)

Furan **18** (5.0 mL, 68.7 mmol) was dissolved in dry THF (80 mL) in an Ar-purged flask and cooled to −78°C in a Dry Ice – acetone bath. To this solution was added *n*-butyllithium (20.0 mL, 50.0 mmol), then the reaction was stirred at room temperature for 1 h. Freshly distilled 1,4-dibromobutane (10.0 g, 46.3 mmol) was added to the orange anion, and the reaction was stirred overnight. Saturated NH_4Cl (50 mL) was used to quench the reaction. The aqueous layer was extracted with ether (3 × 100 mL), then the combined organic layers were dried over Na_2SO_4, filtered, and the solvent removed *in vacuo*. The crude product was distilled using a fractionating column under aspirator pressure, collecting the fraction boiling from 95 to 100°C to give compound **31** (2.54 g, 12.5 mmol) in 25% yield; IR (neat) cm^{-1}: 2943–2864(C-H); ^1H NMR (200 MHz): 1.67–2.08(m, 4H), 2.68(t, 2H, J = 7.1 Hz), 3.43(t, 2H, J = 7.1 Hz), 6.02(dd, 1H, J = 0.8 Hz, J = 3.0 Hz), 6.30(dd, 1H, J = 1.7 Hz, J = 3.0 Hz), 7.33(dd, 1H, J = 0.8 Hz, J = 1.7 Hz); ^{13}C NMR (50 MHz): 26.56(t), 27.00(t), 32.04(t), 33.34(t), 105.03(d), 110.06(d), 140.88(d), 155.38(s); mass spectrum: 202 (6, $M^{+\cdot}$), 81(100, M − $(CH_2)_3Br$). Exact Mass calcd. for $C_8H_{11}BrO$: 201.9993; found: 201.9982.

7-(2-Furyl)-1-hepten-3-one (8)

General procedure 1 was used to convert bromide **31** (3.55 g, 17.5 mmol) to the corresponding iodide (4.16 g, 16.6 mmol) in 95% yield after distillation; bp 60–68°C/0.08 Torr; IR (neat) cm^{-1}:

For personal use only.

2936–2860(C-H); ^{1}H NMR (200 MHz): 1.64–2.01(m, 4H), 2.68(t, 2H, J = 7.5 Hz), 3.21(t, 2H, J = 7.5 Hz), 6.02(dd, 1H, J = 0.7 Hz, J = 3.1 Hz), 6.29(dd, 1H, J = 1.7 Hz, J = 3.1 Hz), 7.31(dd, 1H, J = 0.7 Hz, J = 1.7 Hz); ^{13}C NMR (200 MHz): 6.50(t), 26.80(t), 28.87(t), 32.78(t), 105.03(d), 110.06(d), 140.88(d), 155.35(s); mass spectrum: 250(22, $M^{\cdot+}$), 123(30, M-I), 81(100, M − $(CH_2)_3$I). Exact Mass calcd. for $C_8H_{11}IO$: 249.9851; found: 249.9851.

Using general procedure 2, the above iodide (0.58 g, 2.32 mmol) was treated with *tert*-butyllithium (3.0 mL, 5.09 mmol) and acrolein (185 μL, 2.78 mmol) to produce the corresponding allylic alcohol (0.29 g, 1.61 mmol) as a clear, colourless oil in 69% yield after purification by flash chromatography (7:1) and distillation; bp 50–60°C/0.05 Torr; ^{1}H NMR (200 MHz): 1.39–1.75(m, 7H), 2.64(t, 2H, J = 7.2 Hz), 4.11(br, m, 1H), 5.11(dt, 1H, J = 1.2 Hz, J = 1.2 Hz, J = 10.3 Hz), 5.22(dt, 1H, J = 1.2 Hz, J = 1.2 Hz, J = 17.2 Hz), 5.91(ddd, 1H, J = 6.2 Hz, J = 10.3 Hz, J = 17.2 Hz), 5.99(dd, 1H, J = 0.7 Hz, J = 3.0 Hz), 6.28(dd, 1H, J = 1.9 Hz, J = 3.0 Hz), 7.30(dd, 1H, J = 0.7 Hz, J = 1.9 Hz).

The above allylic alcohol (133.9 mg, 0.74 mmol) was oxidized according to general procedure 3 to provide compound **8** (113.3 g, 0.64 mmol) as a clear, colourless oil in 86% yield after purification by flash chromatography (20:1) and distillation; bp 80°C/0.06 Torr; ^{1}H NMR (200 MHz): 1.56–1.83(overlapping m), 2.50–2.76(overlapping m), 5.83(dd, 1H, J = 2.5 Hz, J = 10.1 Hz), 5.98(dd, 1H, J = 0.7 Hz, J = 3.0 Hz), 6.20(d of ABq, 1H, J = 2.5 Hz, J = 17.5 Hz), 6.25(dd, 1H, J = 1.8 Hz, J = 3.0 Hz), 6.37(d of ABq, 1H, J = 10.1 Hz, J = 17.5 Hz), 7.30(dd, 1H, J = 0.7 Hz, J = 1.8 Hz).

4-Methyl-2-oxo-3-pentenenitrile (32)

Freshly distilled acid chloride of 3-methyl-2-butenoic acid (2.19 g, 18.5 mmol) was dissolved in dry acetonitrile (15 mL) under Ar. To this solution was added anhydrous CuCN (2 equiv.), and the suspension was heated to reflux (oil bath, 90°C) for 30 min, during which time a clear, brown solution was formed. The solution was cooled to room temperature, and the solvent was removed using a rotary evaporator (no heat), followed by an Ar back-purge. The desired compound was then distilled from the remaining brown solid, along with some acetonitrile. Conversion was confirmed by ^{1}H NMR, then the acyl cyanide **32** was used directly for the next step, bp 70–80°C/20 Torr; ^{1}H NMR (200 MHz): 2.07 and 2.30(s, 3H each), 6.25(s, 1H).

Methyl 3-(2-furyl)-3-methylbutanoate (33)

A modification of the method of Ismail and Hoffmann (21) was used for the preparation of furan **33**. The acyl cyanide **32** (3.52 g, 32.3 mmol) was dissolved in CS_2 (120 mL) under Ar and cooled in an ice bath. To this solution was added $AlCl_3$ (1.08 g, 8.10 mmol), resulting in a gummy precipitate. After stirring for 1 h at room temperature, furan **18** (12.0 mL, 165.0 mmol) was added neat, and the reaction was stirred for 24 h, after which time anhydrous methanol (100 mL) was added to the solution. The reaction was then stirred for an additional 24 h. Evaporation of the CS_2, followed by removal of methanol *in vacuo*, resulted in a viscous brown material. The crude product was taken up in ether (200 mL) and water (100 mL) followed by washing with 10% Na_2CO_3 (2 × 100 mL), then water (2 × 100 mL), dried (Na_2SO_4), and the ether removed *in vacuo*. Distillation of the crude brown oil provided **33** (27% from 3-methyl-2-butenoic acid), bp 40–44°C/0.03 Torr (lit. (21) bp 40°C/0.03 Torr); IR (neat) cm^{-1}: 1738 (C═O), 1077 (C—O); ^{1}H NMR (200 MHz): 1.40(s, 6H), 2.61(s, 2H), 3.58(s, 3H), 6.01(dd, 1H, J = 0.8 Hz, J = 3.2 Hz), 6.26(dd, 1H, J = 1.9 Hz, J = 3.2 Hz), 7.32 (dd, 1H, J = 0.8 Hz, J = 1.9 Hz); ^{13}C NMR (50 MHz): 2 × 28.70(q), 34.96(s), 45.73(t), 51.11(q), 103.12(d), 108.80(d), 140.66(d), 161.27(s), 171.58(s); mass spectrum: 182(58, $M^{\cdot+}$), 109(100, M − CH_2CO_2Me). Exact Mass calcd. for $C_{10}H_{14}O_3$: 182.0942; found: 182.0935.

Methyl 3-(2-(5-methylfuryl))-3-methylbutanoate (34)

The acyl cyanide **32** (1.82 g, 16.7 mmol) was dissolved in CS_2 (60 mL) under Ar and cooled in an ice bath. To this solution was added $AlCl_3$ (0.56 g, 4.2 mmol), resulting in a gummy precipitate. After stirring for 1 h at room temperature, 2-methylfuran **19** (7.0 mL, 70.5 mmol) was added neat, and the reaction was stirred for 24 h, after which time anhydrous methanol (70 mL) was added to the crimson solution. The reaction was then stirred for an additional 24 h. Evaporation of the CS_2, followed by removal of methanol *in vacuo*, resulted in a viscous brown material. The crude product was taken up in ether (200 mL) and water (100 mL), followed by washing with 10% Na_2CO_3 (2 × 100 mL), then water (2 × 100 mL), dried (Na_2SO_4), and the ether removed *in vacuo*. Distillation of the crude brown oil provided **34** (66%), bp 100–120°C/15 Torr; IR (neat) cm^{-1}: 1738(C═O), 1385,1365(CMe_2) 1198(C—O); ^{1}H NMR (200 MHz): 1.37(s, 6H), 2.25(d, 3H, J = 0.75 Hz), 2.58(s, 2H), 3.60(s, 3H), 5.87(d of ABq, 2H, J = 0.8 Hz, J = 3.1 Hz); ^{13}C NMR (50 MHz): 13.43(q), 2 × 26.69(q), 34.89(s), 45.82(6), 71.08(q), 103.64(d), 105.57(d), 150.33(s), 159.568s), 171.77(s); mass spectrum: 196(53, $M^{\cdot+}$), 123(100, M − CH_2CO_2Me). Anal. calcd. for $C_{11}H_{16}O_3$: C 67.32, H 8.22; found: C 66.84, H 8.18.

3-(2-Furyl)-3-methyl-1-butanol (36)

To $LiAlH_4$ (0.51 g, 9.3 mmol), suspended in ether (25 mL) at 0°C under Ar, was added dropwise a solution of freshly distilled **33** (1.42 g, 7.8 mmol) in ether (8 mL). The reaction was warmed to room temperature and stirred for 12 h. After cooling to 0°C, the reaction was quenched using water (0.5 mL), 15% NaOH (0.5 mL), then water (1.5 mL). The white mixture was then filtered through Celite, and the solvent removed *in vacuo* to provide a clear, colourless oil. The oil was purified by flash chromatography (1:1), then distilled to yield compound **36** (92%), bp 48°C/0.07 Torr; IR (neat) cm^{-1}: 3333(OH), 1385,1363(CMe_2), 1077, 1059(C—O); ^{1}H NMR (200 MHz): 1.30(s, 6H), 1.51(s, 1H), 1.89(t, 2H, J = 7.2 Hz), 3.54(t, 2H, J = 7.2 Hz), 5.99 (dd, 1H, J = 0.9 Hz, J = 3.2 Hz), 6.28(dd, 1H, J = 1.5 Hz, J = 3.2 Hz) 7.32(dd, 1H, J = 0.9 Hz, J = 1.5 Hz); ^{13}C NMR (50 MHz): 2 × 27.20(q), 34.57(s), 44.61(t), 59.92(t), 103.24(d), 108.61(d), 140.64(d), 163.32(s); mass spectrum: 154(35, $M^{\cdot+}$), 109(100, M − $(CH_2)_2OH$). Anal. calcd. for $C_9H_{11}O_2$: C 70.09, H 9.15; found: C 69.66, H 9.00.

3-(2-(5-Methylfuryl))-3-methyl-1-butanol (37)

Compound **34** (2.03 g, 10.4 mmol) was reduced to alcohol **37** (1.76 g, 10.1 mmol) by the method described for compound **36** in 97.5% yield after distillation, bp 60–70°C/0.1 Torr; IR (neat) cm^{-1}: 3334(OH), 1384,1365(CMe_2), 1059,1021(C—O); ^{1}H NMR (200 MHz): 1.28(s, 6H), 1.38(br s, 1H), 1.87(t, 2H, J = 7.1 Hz), 2.26(d, 3H, J = 0.8 Hz), 3.58(t, 2H, J = 7.1 Hz), 5.85(ABq, 2H); ^{13}C NMR(50 MHz): 13.45(q), 2 × 27.22(q), 34.36(s), 44.55(t), 59.97(t), 103.62(d), 105.51(d), 150.31(s), 160.46(s); mass spectrum: 168(60, $M^{\cdot+}$), 123(100, M − $(CH_2)_2OH$). Anal. calcd. for $C_{10}H_{16}O_2$: C 71.39, H 9.59; found: C 71.37, H 9.43.

3-(2-Furyl)-1-iodo-3-methylbutane (38)

Distilled compound **36** (1.05 g, 6.80 mmol) was dissolved in dry CH_2Cl_2 (20 mL), and cooled in an ice bath. To this solution was added *p*-toluenesulfonyl chloride (2.59 g, 13.6 mmol) and DMAP (1.66 g, 13.6 mmol), and the reaction was stirred for 12 h. The mixture was poured into water (50 mL), then the organic layer was washed with 5% HCl (2 × 50 mL), and water (3 × 50 mL), then dried over Na_2SO_4. The solvent was removed *in vacuo* to yield a viscous clear oil, which was then purified by flash chromatography (7:1) to provide the tosylate of compound **36** (2.03 g, 6.58 mmol) in 98% yield. This decomposed when stored at room temperature; IR (neat) cm^{-1}: 3093–3035(C—H), 1364, 1187(SO_2st.); ^{1}H NMR (200 MHz): 1.25(s, 6H), 1.97(t, 2H, J = 7.3 Hz), 2.45(s, 3H), 3.93(t, 2H, J = 7.3 Hz), 5.91(dd, 1H, J = 0.7 Hz, J = 3.3 Hz), 6.22(dd, 1H, J = 1.8 Hz, J = 3.3 Hz), 7.25(d, 1H, J = 0.7 Hz, J = 1.8 Hz), 7.33 and 7.74(AA′XX′, 4H);

C-7), 60.35(s, C-6), 81.92(d, C-8), 92.68(s, C-1), 137.11(d, C-9 and C-10), 214.25(s, C-5).

(6α-H)-8α-Methyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (53)

General procedure 5 was used to perform the Lewis acid-mediated reaction of compound **5**. Thus, enone **5** (58.9 mg, 0.33 mmol) was treated with $MeAlCl_2$ (0.36 mL, 0.36 mmol) at −78°C for 1 h to provide adduct **53** (58.9 mg, 0.33 mmol) in >99% yield as yellow oil (no bp due to decomposition on heating); IR (neat) cm^{-1}: 1710(C=O); ^{1}H NMR (400 MHz): 1.58(s, 3H, -CH_3), 1.61(dd, 1H, $J_{6\alpha,7\alpha}$ = 8.2 Hz, $J_{7\alpha,7\beta}$ = 11.8 Hz, H-7α), 1.88–2.04(m, 2H), 2.20(dd, 1H, $J_{7\beta,6\alpha}$ = 3.5 Hz, J_{gem} = 11.8 Hz, H-7β), 2.23(dt, 1H, $J_{2\alpha,3\alpha}$ = 5.2 Hz, $J_{2\alpha,3\beta}$ = 12.4 Hz, J_{gem} = 12.4 Hz, H-2α), 2.39(dd, 1H, $J_{6\alpha,7\beta}$ = 3.5 Hz, $J_{6\alpha,7\alpha}$ = 8.2 Hz, H-6α), 2.35–2.44(m, 2H), 2.52(dddt, 1H, $J_{4\beta,2\beta}$ = 1.6 Hz, $J_{4\beta,3\alpha}$ = 3.6 Hz, $J_{4\beta,3\beta}$ = 3.6 Hz, J_{gem} = 14.1 Hz, H-4β), 6.15 and 6.25(ABq, 1H, J = 5.6- Hz, H-9 and H-10); ^{13}C NMR (50 MHz): 18.71(q, -CH_3), 21.68, 28.54, 35.42, and 41.86(t, C-2, C-3, C-4, and C-7), 53.77(d, C-6), 85.96 and 90.83(s, C-1 and C-8), 137.69 and 141.18(d, C-9 and C-10), 209.70(s, C-5); mass spectrum (FI): 178. Exact mass calcd. for $C_{11}H_{14}O_2$: 178.0994; found: 178.0986.

6α,8α-Dimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (54)

General procedure 5 was used to perform the Lewis acid-mediated reactions of compound **6**. 1.1 Equivalents of $MeAlCl_2$ reaction: precursor **6** (80.5 mg, 0.419 mmol) was treated with $MeAlCl_2$ (461 μL, 0.461 mmol) at −78°C for 8 h to provide a SM:A ratio of 19:81 with quantitative recovery of material. Flash chromatography (9:1) provided starting material (12.6 mg) and adduct **54** (59.0 mg). Catalytic reaction: enone **6** (37.4 mg, 0.192 mmol) was treated with $MeAlCl_2$ (19 μL, 0.019 mmol) at −65°C for 2 h to provide a SM:A ratio of <1:>99 with 99% recovery of material. Flash chromatography (9:1) provided precursor **6** (2.6 mg) and **54** (34.6 mg) as a clear, colourless oil; IR (neat) cm^{-1}: 1708(C=O); ^{1}H NMR (400 MHz): 1.08(s, 3H, C-6-CH_3), 1.10(d, 1H, $J_{7\alpha,7\beta}$ = 5.5 Hz, H-7α), 1.50(s, 3H, C-8-CH_3), 1.82–2.04(m, 2H), 2.16–2.23(m, 2H), 2.38(dt, 1H, $J_{3\beta,4\beta}$ = 3.2 Hz, $J_{3\alpha,4\beta}$ = 3.2 Hz, $J_{4\alpha,4\beta}$ = 14.4 Hz, H-4β), 2.51–2.67(m, 1H), 2.55(d, 1H, $J_{7\alpha,7\beta}$ = 11.8 Hz, H-7β), 6.13(d, 1H, $J_{10,9}$ = 5.6 Hz, H-10), 6.27(d, 1H, $J_{9,10}$ = 5.6 Hz, H-9); ^{13}C NMR (50 MHz): 18.87 and 22.24(q, -CH_3's), 20.84, 25.86, 38.22, and 43.66(t, C-2, C-3, C-4, and C-7), 57.41(s, C-6), 85.69 and 92.09(s, C-1 and C-8), 135.87 and 141.65(d, C-9 and C-10), 213.33(s, C-5); mass spectrum: 192(5, M$^{\cdot+}$), 108(100, M − CH_2=C(OH)C(Me)=CH_2, retro IMDAF–McLafferty rearr.). Exact Mass calcd. for $C_{12}H_{16}O_2$: 192.1150; found: 192.1141.

(6α-H)-7α,8α-Dimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (55)

General procedure 5 was used to perform the Lewis acid-mediated reaction of compound **7**. Quantitative reaction: enone **7** (63.7 mg, 0.331 mmol) was treated with $MeAlCl_2$ (364 μL, 0.364 mmol) at −78°C for 8 h to provide a SM:A ratio of 82:18 with 98% recovery of material. Flash chromatography (7:1) provided enone **7** (46.9 mg) and adduct **55** (15.2 mg). Catalytic reaction: compound **7** (51.4 mg, 0.267 mmol) was treated with $MeAlCl_2$ (27 μL, 0.027 mmol) at −65°C for 2 h to provide a SM:A ratio of 24:76 (92% recovery, 47.5 mg). Starting material **7** (10.7 mg) could be separated from the product **55** (32.1 mg), a yellow solid, using flash chromatography (9:1), mp 28–30°C; IR (KBr) cm^{-1}: 1709(C=O), 1136(C—O); ^{1}H NMR (400 MHz): 0.95(d, 3H, J = 7.1 Hz, C-7-CH_3), 1.52(s, 3H, C-8-CH_3), 1.89(d, 1H, $J_{6\alpha,7\beta}$ = 4.3 Hz, H-6α), 1.90–1.99(m, 2H), 2.17(ddd, 1H, $J_{2\alpha,3\alpha}$ = 5.3 Hz, $J_{2\alpha,3\beta}$ = 12.1 Hz, J_{gem} = 14.7 Hz, H-2α), 2.29–2.38(m, 2H), 2.46(dq, 1H, $J_{7\beta,6\alpha}$ = 4.1 Hz, J = 7.0 Hz, H-7β), 2.5(dddt, 1H, $J_{4\beta,2\beta}$ = 1.6 Hz, $J_{4\beta,3\alpha}$ = 3.7 Hz, $J_{4\beta,3\beta}$ = 3.7 Hz, J_{gem} = 14.3 Hz, H-4β), 6.20(d, 1H, $J_{9,10}$ = 5.6 Hz, H-10), 6.26(d, 1H, $J_{9,10}$ = 5.6 Hz, H-9); ^{13}C NMR (50 MHz): 17.07(q), 17.12(q), 21.38, 28.62, and 41.53(t, C-2, C-3, and C-4), 43.10(d, C-7), 61.51(d, C-6), 88.63 and 90.09(s, C-1 and C-8), 138.80 and 138.87(d, C-9 and C-10), 210.14(s, C-5); mass spectrum: 192(13, M$^{\cdot+}$), 108(100, M − CH_2=C(OH)CH=CHMe, retro IMDAF–McLafferty rearr.). Exact Mass calcd. for $C_{12}H_{16}O_2$: 192.1151; found: 192.1132.

(6α,8α-H)-2,2-Dimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (56)

The IMDAF reaction of compound **9** (52.9 mg, 0.275 mmol) was performed according to general procedure 4 to provide adduct **56** (46.5 mg, 0.242 mmol) after 12 h in 88% yield as a white solid, mp 57–60°C; IR (KBr) cm^{-1}: 1705(C=O), 1663(C=C), 1390, 1369(*gem*-Me); ^{1}H NMR (400 MHz): 1.08 and 1.36(s, 6H, 2 × CH_3), 1.55(dd, 1H, $J_{7\alpha,6\alpha}$ = 8.5 Hz, J_{gem} = 11.8 Hz, H-7α), 1.61(ddd, 1H, $J_{3\alpha,4\beta}$ = 2.7 Hz, $J_{3\alpha,4\alpha}$ = 5.8 Hz, J_{gem} = 13.9 Hz, H-3α), 1.99(dt, 1H, $J_{3\beta,4\beta}$ = 4.3 Hz, $J_{3\beta,4\alpha}$ = 13.9 Hz, J_{gem} = 13.9 Hz, H-3β), 2.27(dd, 1H, $J_{6\alpha,7\beta}$ = 3.2 Hz, $J_{6\alpha,7\alpha}$ = 8.5 Hz, H-6α), 2.37–2.42(overlapping m, 2H, H-4β and H-7β), 2.58(dt, 1H, $J_{4\alpha,3\alpha}$ = 5.8 Hz, $J_{4\alpha,3\beta}$ = 15.1 Hz, $J_{4\alpha,4\beta}$ = 15.1 Hz, H-4α), 4.88(dd, 1H, $J_{8,9}$ = 1.5 Hz, $J_{8,7\beta}$ = 4.9 Hz, H-8), 6.24(d, 1H, $J_{10,9}$ = 5.8 Hz, H-10), 6.43(dd, 1H, $J_{9,8}$ = 1.5 Hz, $J_{9,10}$ = 5.8 Hz, H-9); ^{13}C NMR (50 MHz): 24.24 and 25.96(q, -CH_3), 30.98, 34.88, and 37.84(t, C-3, C-4, and C-7), 31.98(s, C-2), 47.90(d, C-6), 77.90(d, C-8), 95.90(s, C-1), 133.47, 138.83(d, C-9 and C-10), 210.20(s, C-5); mass spectrum: 192(48, M$^{\cdot+}$), 109(100, M − $(CH_2)_2$C(O)CH=CH_2). Exact Mass calcd. for $C_{12}H_{16}O_2$: 192.1150; found: 192.1148.

(8α-H)-2,2,6α-Trimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (57)

The IMDAF reaction of compound **10** (221.2 mg, 1.07 mmol) was performed according to general procedure 4 to provide after 96 h precursor **10** (186.4 mg, 0.903 mmol) and adduct **57** (19.8 mg, 0.096 mmol) after purification by flash chromatography (9:1) in 93% total recovery.

General Procedure 5 was used to perform the Lewis acid-mediated reactions of compound **10**. Thus, enone **10** (55.3 mg, 0.268 mmol) was treated with quantitative $MeAlCl_2$ (295 μL, 0.295 mmol) at −78°C for 8 h to provide a SM:A ratio of 68:32 with a quantitative recovery of material. Enone **10** (161.9 mg, 0.785 mmol) was treated with catalytic $MeAlCl_2$ (79 μL, 0.079 mmol) (according to general procedure 5) at −65°C for 2 h to provide a SM:A ratio of 40:60 with quantitative recovery. Flash chromatography (9:1) provided enone **10** (64.5 mg) and adduct **57** (92.3 mg) in 97% recovered yield. Adduct **57** was characterized as a white solid, mp 44–55°C; IR (KBr) cm^{-1}: 3078, 3021(C-H), 2982–2858(C-H), 1699(C=O), 1389, 1369(*gem*-Me); ^{1}H NMR (200 MHz): 0.99(d, 1H, J = 11.7 Hz, H-7α), 1.03(s, C-6-CH_3), 1.16 and 1.39(s, 3H each, 2 × CH_3), 1.61(ddd, 1H, $J_{3\alpha,4\beta}$ = 2.8 Hz, $J_{3\alpha,4\alpha}$ = 5.8 Hz, $J_{3\alpha,3\beta}$ = 13.4 Hz, H-3α), 2.01(dt, 1H, $J_{3\beta,4\beta}$ = 4.1 Hz, $J_{3\beta,4\alpha}$ = 14.3 Hz, $J_{3\beta,3\alpha}$ = 13.6 Hz, H-3β), 2.35(ddd, 1H, $J_{4\beta,3\alpha}$ = 2.8 Hz, $J_{4\beta,3\beta}$ = 4.0 Hz, $J_{4\beta,4\alpha}$ = 15.3 Hz, H-4β), 2.82(dt, 1H, $J_{4\beta,3\beta}$ = 5.8 Hz, J_{gem} = 14.5 Hz, H-4α), 2.85(dd, 1H, $J_{7\beta,8}$ = 3.8 Hz, $J_{7\beta,7\alpha}$ = 11.8 Hz, H-7β), 4.77(dd, 1H, $J_{8,9}$ = 1.6 Hz, $J_{8,7\beta}$ = 5.2 Hz, H-8), 6.33(d, 1H, $J_{10,9}$ = 5.9 Hz, H-10), 6.48(dd, 1H, $J_{9,8}$ = 1.7 Hz, $J_{9,10}$ = 5.9 Hz, H-9); ^{13}C NMR (50 MHz): 23.85(q), 24.44(q), 27.48(q), 32.70(s, C-2), 35.10, 35.29, and 39.78(t, C-3, C-4, and C-7), 54.18(s, C-6), 77.39(d, C-8), 97.10(s, C-1), 132.15 and 138.70(d, C-9 and C-10), 213.94(s, C-5); mass spectrum: 206(10, M$^{\cdot+}$), 109(100, M − $(CH_2)_2$C(O)CMe=CH_2). Exact Mass calcd. for $C_{13}H_{18}O_2$: 206.1307; found: 206.1290.

(6α,8α-H)-2,2,7α-Trimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (58)

The IMDAF reaction of compound **11** (54.9 mg, 0.266 mmol) was performed according to general procedure 4 to provide a SM:A ratio of 87:13 with quantitative recovery of material after 192 h. General procedure 5 was used to perform the Lewis acid–mediated reactions of compound **11**. Thus, enone **11** (104.1 mg, 0.504 mmol) was treated with quantitative $MeAlCl_2$ (555 μL, 0.555 mmol) at −78°C for 8 h to provide a SM:A ratio of 73:27

*2,2,6α,8α-Tetramethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (**61**)*

The IMDAF reaction of compound **14** (58.4 mg, 0.265 mmol) was performed according to general procedure 4 to provide a SM:A ratio of 88:12 in 82% recovery of material after 336 h. Starting material (40.9 mg) and adduct (6.8 mg) were isolated by flash chromatography (9:1). General procedure 5 was used to perform the Lewis acid-mediated reactions of compound **14**. Thus, enone **14** (48.8 mg, 0.222 mmol) was treated with quantitative $MeAlCl_2$ (244 μL, 0.244 mmol) at −78°C for 8 h to provide a SM:A ratio of 78:22 with quantitative recovery of material. Enone **14** (30.1 mg) and adduct (9.0 mg) were isolated by flash chromatography (9:1). Enone **14** (32.7 mg, 0.148 mmol) was treated with catalytic $MeAlCl_2$ (15 μL, 0.015 mmol) (according to general procedure 5) at −65°C for 2 h to provide a SM:A ratio of 23:77 with quantitative recovery. Adduct **61** was characterized as a solid; IR (KBr) cm^{-1}: 2986–2873(C—H), 1708(C=O), 1384,1371(*gem*-Me); ^1H NMR (300 MHz): 1.01(s, 3H, C-6-CH_3), 1.09(d, 1H, $J_{7\alpha,7\beta}$ = 11.7 Hz, H-7α), 1.12 and 1.33(s, 3H each), 1.46(s, 3H, C-8-CH_3), 1.56(ddd, 1H, $J_{3\alpha,4\beta}$ = 2.7 Hz, $J_{3\alpha,4\alpha}$ = 5.8 Hz, $J_{3\alpha,3\beta}$ = 13.6 Hz, H-3α), 1.99(dt, 1H, $J_{3\beta,4\beta}$ = 4.1 Hz, $J_{3\beta,3\alpha}$ = 13.6 Hz, $J_{3\beta,4\alpha}$ = 14.4 Hz, H-3β), 2.32(ddd, 1H, $J_{4\beta,3\alpha}$ = 2.7 Hz, $J_{4\beta,3\beta}$ = 4.1 Hz, $J_{4\beta,4\alpha}$ = 15.3 Hz, H-4β), 2.53(d, 1H, J = 11.7 Hz, H-7β), 2.77(ddd, 1H, $J_{4\alpha,3\alpha}$ = 5.8 Hz, $J_{4\alpha,3\beta}$ = 14.4 Hz, $J_{4\alpha,4\beta}$ = 15.3 Hz, H-4α), 6.25(d, 1H, $J_{10,9}$ = 5.7 Hz, H-10), 6.30(d, 1H, $J_{9,10}$ = 5.7 Hz, H-9); ^{13}C NMR (75 MHz): 18.93(q), 23.75(q), 24.27(q), 27.51(q), 32.78(s, C-2), 35.00 and 35.31(t, C-3 and C-7), 46.21(t, C-4), 57.37(s, C-6), 84.76 and 97.29(s, C-1 and C-8), 132.76 and 141.69(d, C-9 and C-10), 214.39(s, C-5); mass spectrum: 220(18, $M^{\cdot+}$), 123(100, M − $(CH_2)_2C(O)CMe{=}CH_2$). Exact Mass calcd. for $C_{14}H_{20}O_2$: 220.1464; found: 220.1462.

*(6α-H)-2,2,7α,8α-Tetramethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (**62**)*

General procedure 5 was used to perform the Lewis acid-mediated reactions of compound **15**. Thus, enone **15** (14.6 mg, 0.066 mmol) was treated with catalytic $MeAlCl_2$ (6.6 μL, 0.066 mmol) at −65°C for 2 h to provide a **15**:**62** ratio of 69:31 with 72% recovery; IR (KBr) cm^{-1}: 2960–2868(C-H), 1706(C=O), 1384,1368(*gem*-Me); ^1H NMR (400 MHz): 0.97(d, 3H, $J_{14,7\beta}$ = 7.0 Hz, H-14), 1.08 and 1.28(s, 3H each), 1.50(s, 3H, C-8-CH_3), 1.56(ddd, 1H, $J_{3\alpha,4\beta}$ = 2.8 Hz, $J_{3\alpha,4\alpha}$ = 6.0 Hz, $J_{3\alpha,3\beta}$ = 13.5 Hz, H-3α), 1.88(d, 1H, $J_{6\alpha,7\beta}$ = 4.1 Hz, H-6α), 2.01(dt, 1H, $J_{3\beta,4\beta}$ = 4.8 Hz, $J_{3\beta,4\alpha}$ = 13.6 Hz, $J_{3\beta,3\alpha}$ = 13.6 Hz, H-3β), 2.35(dq, 1H, $J_{7\beta,6\alpha}$ = 4.1 Hz, $J_{7\beta,14}$ = 7.0 Hz, H-7β), 2.40(ddd, 1H, $J_{4\beta,3\alpha}$ = 2.8 Hz, $J_{4\beta,3\beta}$ = 4.8 Hz, $J_{4\beta,4\alpha}$ = 16.2 Hz, H-4β), 2.51(ddd, 1H, $J_{4\alpha,3\alpha}$ = 6.0 Hz, $J_{4\alpha,3\beta}$ = 13.6 Hz, $J_{4\alpha,4\beta}$ = 16.2 Hz, H-4α), 6.20(d, 1H, $J_{10,9}$ = 5.7 Hz, H-10), 6.37(d, 1H, $J_{9,10}$ = 5.7 Hz, H-9); ^{13}C NMR (50 MHz): 17.20(q), 17.40(q), 24.06(q), 25.86(q), 31.94(s, C-2), 34.40 and 37.55(t, C-3 and C4), 45.65(d, C-7), 59.21(d, C-6), 88.25 and 95.38(s, C-1 and C-8), 135.41 and 139.34(d, C-9 and C-10), 211.59(s, C-5); mass spectrum: 220(8, $M^{\cdot+}$), 123(100, M − $(CH_2)_2C(O)CH{=}CHMe$). Exact Mass calcd. for $C_{14}H_{20}O_2$: 220.1464; found: 220.1465.

*(7β,9α-H)-12-Oxatricyclo[7.2.1.0^{1,7}]dodec-10-en-6-one (**63**)*

General procedure 5 was used to perform the Lewis acid-mediated reaction of compound **8**. Thus, enone **8** (63.5 mg, 0.356 mmol) was treated with $MeAlCl_2$ (36 μL, 0.036 mmol) at −78°C for 2 h to provide a SM:A ratio of 8:92 with 98% recovery of material. Some retro-IMDAF reaction occurred upon attempted purification by flash chromatography (9:1). Adduct **63** was characterized as a white crystalline solid; ^1H NMR (200 MHz): 1.38–1.67(m, 2H), 1.75–2.30(overlapping m, 6H), 2.38–2.70(overlapping m, 2H), 3.20(dd, 1H), 4.90(dd, 1H, H-9), 6.02(d, 1H, $J_{11,10}$ = 6.2 Hz, H-11), 6.41(dd, 1H, $J_{10,9}$ = 1.2 Hz, $J_{10,11}$ = 6.2 Hz, H-10).

*2,2-Dimethyl-7-(trimethysilyl)-11-oxatricyclo[6.2.1.0^{1,6}] undec-6,9-dien-5-one (**65**)*

General procedure 5 was used for the Lewis acid-mediated IMDAF reaction of compound **16**. Thus, enone **16** (100.9 mg, 0.384 mmol) was treated with $MeAlCl_2$ (423 μL, 0.423 mmol) at −50°C for 2.5 h to provide a SM:A ratio of 12.88. Adduct **65** (76.4 mg, 0.482 mmol) was obtained in 89% yield (based on recovered starting material) as a golden crystalline solid, after purification by flash chromatography; mp 85–94°C; IR (Kbr) cm^{-1}: 1660(C=O); ^1H NMR (200 MHz): 0.19(s, 9H), 1.09 and 1.22(s, 3H each, C-2-CH_3's), 1.79(ddd, 1H, $J_{3\alpha,4\beta}$ = 2.6 Hz, $J_{3\alpha,4\alpha}$ = 6.6 Hz, J_{gem} = 14.2 Hz, H-3α), 1.95(ddd, 1H, $J_{3\beta,4\beta}$ = 5.6 Hz, $J_{3\beta,4\alpha}$ = 12.5 Hz, J_{gem} = 14.2 Hz, H-3β), 2.43(ddd, 1H, $J_{4\beta,3\alpha}$ = 2.6 Hz, $J_{4\beta,3\beta}$ = 5.6 Hz, J_{gem} = 19.1 Hz, H-4β), 2.63(ddd, 1H, $J_{4\alpha,3\alpha}$ = 6.6 Hz, $J_{4\alpha,3\beta}$ = 12.5 Hz, J_{gem} = 19.1 Hz, H-4α), 5.60(d, 1H, $J_{8,9}$ = 1.9 Hz, H-8), 6.98(dd, 1H, $J_{9,8}$ = 1.9 Hz, $J_{9,10}$ = 5.4 Hz, H-9), 7.05(d, 1H, $J_{10,9}$ = 5.4 Hz, H-10); ^{13}C NMR (50 MHz): −2.15(q), 25.76(q), 22.29(q), 31.63(s, C-2), 34.20 and 36.16(t, C-3 and C-4), 86.48(d, C-8), 99.87(s, C-1), 144.16 and 144.44(d, C-9 and C-10), 160.77 and 174.23(s, C-6 and C-7), 195.64(s, C-5); mass spectrum: 262(15, $M^{\cdot+}$), 247(50, M − Me), 109(100, M − $C_8H_{16}OSi$). Exact Mass calcd. for $C_{15}H_{22}O_2Si$: 262.1389; found: 262.1376.

*2,2,7-Trimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-6,9-dien-5-one (**66**)*

General procedure 5 was used for the Lewis acid-mediated IMDAF reaction of compound **17**. Thus, enone **17** (99.1 mg, 0.485 mmol) was treated with $MeAlCl_2$ (553 μL, 0.553 mmol) at −60°C for 0.5 h to provide adduct **66** (98.5 mg, 0.482 mmol) in

99% recovery as a white, crystalline solid, which could not be purified by flash chromatography without isomerization of the C-6, C-7 double bond; IR (neat) cm^{-1}: 1666(C=O); ^1H NMR (200 MHz): 1.10 and 1.21(s, 3H each), 1.75(ddd, 1H, $J_{3\alpha,4\beta}$ = 3.0 Hz, $J_{3\alpha,4\alpha}$ = 6.7 Hz, J_{gem} = 12.9 Hz, H-3α), 1.89(dt, 1H, $J_{3\beta,4\beta}$ = 3.0 Hz, $J_{3\beta,4\alpha}$ = J_{gem} = 12.9 Hz, H-3β), 2.31(s, 3H, C-8-CH_3), 2.43(ddd, 1H, $J_{4\beta,3\alpha}$ = 3.0 Hz, $J_{4\beta,3\beta}$ = 3.0 Hz, J_{gem} = 16.3 Hz, H-4β), 2.50–2.75(m, 1H, H-4α), 5.10(d, 1H, $J_{8,9}$ = 1.8 Hz, H-8), 7.04(dd, 1H, $J_{9,8}$ = 1.8 Hz, $J_{9,10}$ = 5.4 Hz, H-9), 7.09(d, 1H, $J_{10,9}$ = 5.4 Hz, H-10); ^{13}C NMR (50 MHz): 15.63(q), 22.02(q), 25.44(q), 31.64(s, C-2), 34.20(t), 36.16(t), 86.12(d, C-8), 99.28(s, C-1), 142.04 and 145.57(d, C-9 and C-10), 171.98(s, C-6 and C-7), 196.32(s, C-5); mass spectrum: 204(14, $M^{\cdot+}$), 163(24, M − HC≡CH), 109(100, M − $(CH_2)_2C(O)C{\equiv}CCH_3$). Exact Mass calcd. for $C_{13}H_{16}O_2$: 204.1150; found: 204.1146.

The effect of tensioactive agents on the kinetics of hydrogen evolution at a nickel electrode

RICHARD MENINI,[1] PIOTR K. WRONA,[2] HUGUES MÉNARD, AND OLIVIER VITTORI[1]
Département de chimie, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received November 29, 1991

RICHARD MENINI, PIOTR K. WRONA, HUGUES MÉNARD, and OLIVIER VITTORI. Can. J. Chem. **70**, 2948 (1992).

The effect of tensioactive agents (TSA = SDS, BRIJ35, BRIJ78, BRIJ99, and CTAB) on the kinetics of hydrogen evolution at a rotating nickel electrode in 0.2 M solutions of Na_2SO_4 was investigated. It was found that at higher concentrations of TSA, their presence inhibited the reaction although their adsorption behaviour at the nickel electrode is different. We concluded that BRIJ35 and CTAB should show better performance in the hydrogenation of organic compounds than SDS.

RICHARD MENINI, PIOTR K. WRONA, HUGUES MÉNARD et OLIVIER VITTORI. Can. J. Chem. **70**, 2948 (1992).

On a étudié l'influence de divers agents tensioactifs (STA = SDS, BRIJ35, BRIJ78, BRIJ99 et CTAB) sur la cinétique de la réaction d'évolution d'hydrogène à une électrode tournante, dans des solutions 0,2 M de Na_2SO_4. On a trouvé que, à des concentrations élevées de TSA, leur présence inhibe cette réaction de façons semblables, même si leur comportement d'adsorption à l'électrode de nickel est différent. On en conclut que, lors de l'hydrogénation de composés organiques, le BRIJ35 et le CTAB devraient donner de meilleures performances que le SDS.

[Traduit par la rédaction]

Introduction

Tensioactive agents (TSA) are frequently used in electrochemistry. Since these compounds usually show strong adsorption at the mercury electrode, they have been widely used in polarography as maxima suppressors (1). It has also been found (2) that TSA (gelatin and methyl red) show significant influence on the kinetics of reactions occurring at the electrodes. Many TSA show self-organization and at higher concentrations they spontaneously form micelles (3). Micellized TSA (4) were used by Proske to solubilize nonpolar organic compounds in water for electrochemical measurements. This idea was similar to that described (5) by Behr and Dojlido. These authors have found that the adsorption of benzene at mercury electrodes increased many times in the presence of small (5%) amounts of ethyl alcohol, although in the bulk of solution, ethyl alcohol had very small effect (an increase of less than 3%) on the solubility of benzene.

At present the TSA micelles are used widely to modify organic chemical and electrochemical reactions (6, 7). For example, it has been found (8) that after the addition of a nonionic surfactant (BRIJ35), a single four-electron polarographic wave of the reduction of substituted nitrobenzene at pH $\geq$ 9 splits into two waves. The product of the first one-electron wave has been identified as a nitrobenzene free radical. Similar results were obtained (9) in 1952 by Holleck and Exner, who used camphor and triphenylphosphine. They also obtained a single, one-electron reduction wave of nitrobenzene to nitrobenzene radical (see also ref. 10).

The use of cationic micelles of cetyltrimethylammonium bromide to reduce 4-bromobiphenyl to biphenyl by 9-phenylanthracene radical has been recently described (11).

TSA may also enhance the hydrogenation of organic compounds. Many organic, and mostly aromatic compounds, after reduction, could be used as a source of hydrogen. Various applications of this idea have been described by Lessard and co-workers (12). For hydrogenation reactions these authors used mostly nickel, copper, and other composite electrodes. Recently, Ménard *et al.* have described (13, 14) the use of composite nickel powder electrodes bonded with $AlPO_4$ and $LaPO_4$ polymers. These electrodes have very large active surfaces and have been used successfully in many electrochemical organic syntheses. The long-range purpose of our work was to determine the effect of TSA micelles on the hydrogenation of organic compounds at composite nickel electrodes. Since in the presence of TSA the organic substances are often reduced at higher overvoltages, our first problem is to find a TSA with as little effect as possible on the electrode kinetics, and that is strongly adsorbed at the electrode surface. This paper describes the first part of our work, i.e., to measure the effect of TSA micelles on the kinetics of hydrogen evolution reaction (HER) at nickel electrodes. We found that all TSA used anionic, cationic, and non-ionic, inhibit the HER in a similar way, but their adsorption at the nickel electrode is markedly different.

Experimental

The rotating disk electrode was made from high purity nickel rod, mounted in KEL-F. The surface of the electrode was 0.126 cm^2. The electrode was polished by alumina before every experiment, later rinsed in 1 M H_2SO_4 for 15 s or introduced into the cell without washing. When the electrode was not washed, its potential was 100 mV more negative than the formal potential of the Ni/Ni^{2+} redox couple. The pH of the solution was measured before every experiment.

The cell was made of Pyrex glass and the anodic compartment was separated by a Nafion membrane M-901 CATH/MD (DuPont). A Luggin capillary was used to minimize the ohmic drop. Since the current was of the order of 0.2 mA, and the resistivity did not exceed 40 Ω, the *IR* was smaller than 10 mV.

The reference electrode was a calomel electrode with saturated KCl. The electrode was separated from the experimental cell by a salt bridge containing the solution under study. The counter electrode was a graphite rod with a high surface area.

Most experiments were conducted in 0.2 M solution of Na_2SO_4

TABLE 1. Characteristics of the tensioactive agents used in this work

Type	Chemical formula and abbreviation	Critical micelles concentration (M)	Kraft temperature (°C)
Anionic	Sodium dodecylsulfate (SDS) $CH_3—(CH_2)_{11}—SO_3^-Na^+$	8.1×10^{-3}	23
	0.05 M Na_2SO_4[a]	1.5×10^{-3}	
	0.2 M Na_2SO_4[a]	4.2×10^{-4}	
Cationic	Cetyltrimethylammonium bromide $CH_3—(CH_2)_{15}—N(CH_3)_3^+Br^-$ (CTAB)	9.2×10^{-3}	26
	0.2 M Na_2SO_4[a]	1×10^{-5} (est)	
Non-ionic	Polyethylene oxide dodecanol $CH_3—(CH_2)_n—(OCH_2CH_2)_k—OH$		
	BRIJ-35 ($n = 11$, $k = 23$)	$(6–9) \times 10^{-5}$	
	0.05 M Na_2SO_4[a]	9.5×10^{-4}	
	BRIJ-78 ($n = 17$, $k = 20$) $CH_3(CH_2)_n—CH=CH—(OCH_2CH_2)_kOH$		
	BRIJ-99 ($n = 15$, $k = 20$)		
	0.05 M Na_2SO_4[a]	5.6×10^{-4}	

[a]Values determined in this work using the surface tension method (15).

at pH 3.4. The sodium sulfate used was of high purity (Na_2SO_4, anhydrous, BDH). In the case of Na_2SO_4 manufactured by Anachemia (Na_2SO_4, anhydrous) and $Na_2SO_4 \cdot 10H_2O$ (BDH) the current–potential wave appeared at potentials ~100 mV more negative. This shift can be explained by the presence of Cl^- ions in solutions prepared from $Na_2SO_4 \cdot 10H_2O$. The concentration of chlorine ions was 10 times higher in $Na_2SO_4 \cdot 10H_2O$ than in Na_2SO_4. Similar shift in potential occurred when a 10 mg/L solution of sodium chloride was added to the 0.2 M Na_2SO_4 solution. However, this phenomenon needs additional studies. Solutions were prepared using deionized water (Barnstead Nanopure). Oxygen was removed by passing nitrogen through the cell. All experiments were carried out at 25°C.

Results

Description of the surface active agents

The TSA used in this work are listed in Table 1. Physicochemical properties of these compounds in water and in organic solvents have been described by Lardet and Thomalla (15) and Berthod (16). Berthod has found that for ionic TSA, the critical micelles concentration (CMC) depends on the type of the salt, and decreases linearly with the salt concentration. The lowest CMC was found for Na_2SO_4. In the case of BRIJ, almost no dependence of CMC on salt concentration was found. Values of CMC corresponding to $\mu = 0$ M are presented in Table 1. We therefore measured the CMC at higher concentrations of Na_2SO_4 using the surface tension method (15). In all cases one observed the CMC at much lower concentrations of TSA.

Measurements of the formal potentials of the H^+/H_2 redox couple

The formal potentials of the electrode reaction

$$[1] \quad H_3O^+ + e \rightarrow 1/2\, H_2 + H_2O$$

were measured in Na_2SO_4 solutions at $\mu = 0.2$ M in the range of pH from 2.6 to 3.4 at a large Pt electrode kept in a stream of H_2. The dependence of E_f^0 on pH was described by a linear relation:

$$[2] \quad E_f^0 = -0.246\ (\mp 0.002) + 0.058(\mp 0.004)\ \text{pH}$$

with correlation coefficient $R = 0.989$. Both the slope and the E_f^0 value for pH = 0 were in accord with theoretical predictions.

Stability of the nickel electrode

Typical cyclic current–potential curves recorded with the use of the nickel-rotating electrode in 0.2 M solution of Na_2SO_4 at pH 3.4 are presented in Fig. 1. In the region of potentials more negative than −0.4 V (SCE), one observes a very well developed wave of H^+ ion reduction, and at more negative potentials, the reduction of water.

At potentials more positive, one observes a small oxidation peak. Since at these pH's the formal potential of the Ni^{2+}/Ni redox couple is close to 0 V/SCE (−0.25 V vs. SHE) (17), it follows from the Pourbaix diagrams (17) that the nickel electrode should be oxidized to Ni^{2+} ions. Interpretation of these small peaks is difficult. Formation of these peaks was also observed by Reshetnikov (18) and Kesten and Feller (19). Probably the peaks correspond to the formation of a monolayer of nickel hydroxide.

Though the electrode potential was always more negative than −0.4 V (when it was dipped into the solution), we have experienced some problems with the reproducibility of the *I–E* curves. For example, the second curve, recorded immediately after the first one, was usually located at potentials more negative. This can not be attributed to the formation of NiO which facilitates the reduction of hydrogen (20). Therefore some poisoning of the electrode surface has occurred. To achieve reproducibility, we have analyzed the effect of several electrochemical pre-treatments on the *I–E* curves under the following conditions: (*i*) no additional electrochemical pre-treatment; (*ii*) by passing a cathodic current 2 mA for 30 min; (*iii*) by imposing a potential in the region of limiting current of H^+ for 15 min; (*iv*) by keeping the electrode in solution at the open circuit for 30 min; and (*v*) by cycling the potential from zero current to reduction of water.

Before every experiment the electrode was polished on alumina and washed in 1 M solution of H_2SO_4 for 15 s.

Reproducible results were obtained only in case (*ii*). Here when the cathodic current was flowing through the nickel

electrode, its potential slowly changed towards more negative values, and later stabilized. This behaviour was similar to that observed by Bockris and Conway (21) and Amosé and Barbieri (22). These authors have also reported a loss in the activity of the nickel electrode during cathodic polarization, and ascribed this effect to the adsorption of traces of impurities (Bockris and Conway) or the dissolution of hydrogen

in the electrode (Amosé and Barbieri). We are unable to distinguish between these two possibilities. Our earlier results seem to confirm the first version (23). Undoubtedly freshly prepared electrodes have slightly higher activity than those that have undergone pre-treatment, since the reduction wave of the H^+ ions appeared at fresh electrodes at potentials more positive by ~50 mV (Fig. 2*a*). However, we decided to sacrifice a higher activity of the electrode to achieve reproducible results. An example of the *I–E* curves obtained is shown in Fig. 2*b*.

The dependence of limiting current on the concentration of H^+ ions for f = 3000 rev min^{-1} is described by the fol-

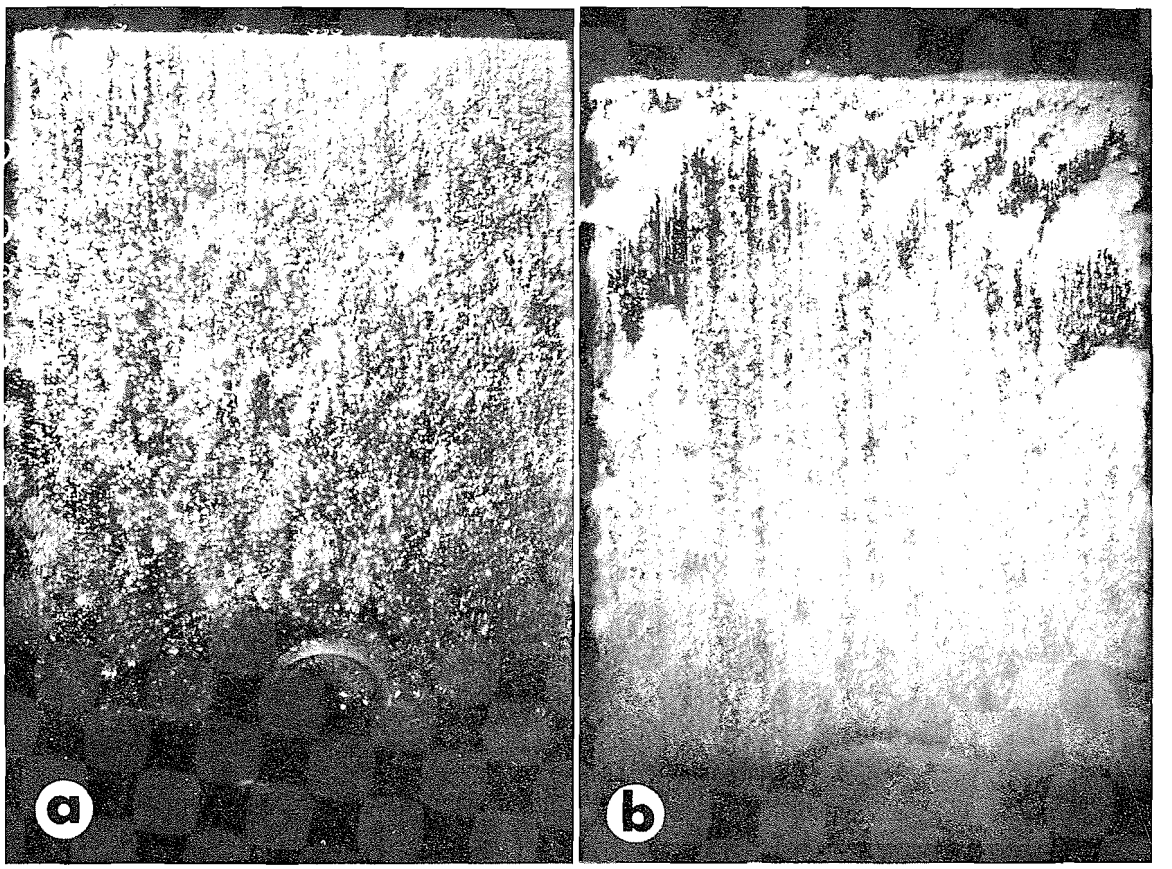

FIG. 3. Evolution of hydrogen at Ni electrode in 0.2 M solution of Na_2SO_4 (*a*) without and (*b*) in the presence of SDS (10^{-2} mol L^{-1}).

lowing equation: I_{lim} (mA) = (6.0 ± 2.7) × 10^{-2} + (4.96 ± 0.25) × 10^{-1} $C(H^+)$ (mM). From the Levich equation (24):

$$[3] \quad I_{lim} = 0.62nFAD_{H^+}^{2/3}\,\omega^{0.5}\,\delta^{-1/6}\,C_{H^+}$$

one may calculate the diffusion coefficient of the H^+ ions. The value obtained (D_{H^+} = (7.2 ± 0.5) × 10^{-5} cm^2 s^{-1}) was in good agreement with that reported (25) by Vielstich and Jahn (7.5 × 10^{-5} cm^2 s^{-1}).

Influence of various TSA on the kinetics of H^+ ion reduction at the nickel electrode

The experiments were conducted in 0.2 M solution of Na_2SO_4. The TSA was introduced to deoxygenated solution and its concentration was increased up to the moment when visible turbidity appeared. Up to 10 mM concentration of SDS could be obtained. Other TSA had much lower solubilities: 3.6 mM (CTAB), 1.4 mM (BRIJ35), and ~0.35 mM (BRIJ78 and BRIJ99).

The half-wave potentials, determined from the semi-logarithmic analysis (log $(i/(i_l - i)) - E$) are presented in Table 2. Table 2 also lists the kinetic parameters (logarithm of the formal rate constants and the cathodic transfer coefficients α) of reaction [1]. Since hydrogen evolution was in all cases irreversible, we could calculate the formal rate constants using the following equation (24):

$$[4] \quad k_{fh} = \frac{I_{lim}}{nFAC_{H^+}} \times \frac{I}{I_{lim} - I}$$

From the dependence of log k_{fh} on E, the α values were calculated. The log k_{fh}^0 values correspond to log k_{fh} at E_f^0.

Most of the TSA caused a shift of $E_{1/2}$ towards more negative potentials. In the presence of SDS, at lower concentrations almost no change in $E_{1/2}$ was observed, and at higher concentrations they shifted slightly towards more positive values. At the same time, in the region of intermediate concentrations, one observed an increase in α from 0.5 to 0.66.

All TSA (including SDS) significantly affect the sizes of the evolving hydrogen bubbles. In the absence of TSA, hydrogen evolved as large bubbles, causing erratic variations in the limiting currents. Occasionally, large bubbles of hydrogen formed and sticked to the nickel electrode, causing the current to drop to almost zero. In the presence of TSA, hydrogen evolved uniformly in the form of very small bubbles, which could be easily removed from the electrode. In these cases the limiting current did not show any irregularities. Changes of the form of bubbles in the presence of the TSA are presented in Fig. 3.

Changes in capacities of the nickel electrode caused by TSA at potentials more positive than the reduction of the H^+ ions

To measure the effect of TSA on capacities of the nickel electrode we attempted to measure the ac impedance in the region of hydrogen evolution. Since the ac measurements lasted for 10 min, we did our measurements while recording the current–time curves at various potentials. The results showed that the current slowly dropped with time for more than 5% of its original value, indicating a slow decrease in the activity of this electrode. We were therefore unable to measure the ac impedance in these potentials re-

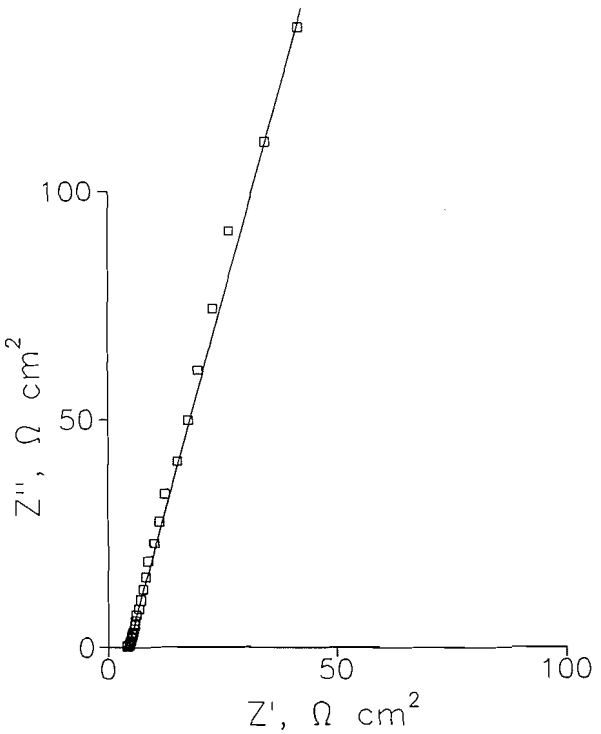

FIG. 4. The Nyquist plot for the Ni RDE in 0.4 M solution of Na_2SO_4 at pH 3.4.

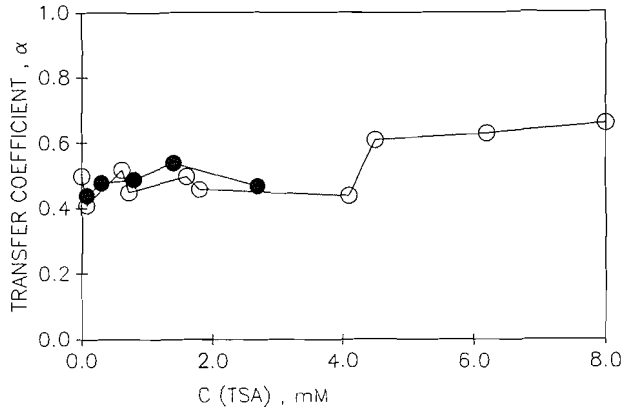

FIG. 5. Dependence of the transfer coefficient α on C_{TSA} for SDS at two pH values; ●, 3.1; ○, 3.4.

gion, since a change in activity affected the ac impedance. The ac impedance was therefore measured in a region of potentials more positive than the wave of the H^+ reduction, at zero current and $E = -450$ mV.

The impedance of the nickel electrode showed frequency dispersion (Fig. 4) which is typical for a solid electrode (26). Appearance of the frequency dispersion is most probably the result of electrode inhomogenity (27). In such a case one may use (28) the equivalent circuit consisting of the solution resistivity (R_s) and the constant phase element (CPE) in series. The total impedance ($\hat{Z}$) could be described by the following equation:

$$[5] \quad \hat{Z} = R_s \frac{1}{(j\omega)^{\alpha} T}$$

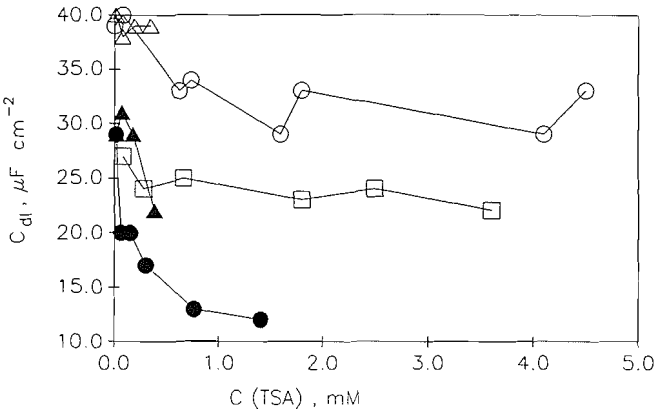

FIG. 6. Changes in the double layer capacity of the Ni RDE in the presence of various concentrations of TSA (pH = 3.4 and 0.2 M Na_2SO_4): ●, BRIJ 35; △, BRIJ 78; ▲, BRIJ 99; □, CTAB; ○, SDS.

The capacity of the double layer was calculated from the equation given by (29) Brug *et al.*:

$$[6] \quad T = C_{dl}^{\phi} \left(\frac{1}{R_s}\right)^{(1-\phi)}$$

The calculated capacities are given in Table 2.

Discussion

Changes in the formal rate constant of the hydrogen evolution reaction at nickel electrode, observed during the additions of increasing amounts of TSA, are presented in Table 2. All these changes have similar character. In regions of small concentrations of TSA, the formal rate constants increase by a factor of 2 and later decrease almost by a factor of 3. Changes in pH has small effect on the kinetic parameters and the adsorption of SDS on the nickel electrode.

Changes in the transfer coefficient α are presented in Fig. 5 for SDS and Table 2 for the other TSA. Results presented in Fig. 5 indicate that in the presence of SDS, in the region of intermediate concentrations, one observes an increase in α from 0.5 to 0.66, whereas the effect of all other TSA on this parameter is rather small (Table 2). Thus we may conclude that the presence of SDS facilitates the evolution of hydrogen to a greater degree than other substances.

Usually, the changes in the kinetics of electrode reactions in the presence of various organic compounds have been explained by different adsorption behaviours of these compounds. The changes in capacity of the nickel electrode caused by increasing amounts of TSA are presented in Fig. 6. All capacity measurements have been conducted in a region slightly more positive than the potential of zero charge for the nickel electrode (17) (E_{pzc}(Ni) = −0.55 V). Results presented in Fig. 6 indicate that SDS has small effect on capacity. Higher concentrations of CTAB lower the capacity of the nickel electrode by about 25%, whereas the maximum lowering in C_{dl}, equal to about 60%, was observed in the case of BRIJ35.

Thus we expect that these two compounds to have maximum effect on hydrogenation of organic substances, since they do not change much the kinetic of the hydrogen evolution, but they should facilitate adsorption of organic substances at the vicinity of the electrode and improve their hydrogenation.

SDS should not show similar properties. However, since in its presence one observes some increase in the transfer coefficient, it is possible that it could be used for the evolution of hydrogen.

The compounds (β-diketonate)Cu(PR_3)$_n$, where β-diketonate = 1,1,1,5,5,5-hexafluoroacetylacetonate, hfac; 1,1,1-trifluoroacetylacetonate, tfac; and acetylacetonate, acac; R = *n*-butyl (*n*-Bu), phenyl (Ph), and cyclohexyl (Cy); n = 1 and 2, have been prepared. The monotriorganophosphine adducts were prepared in high yield by the reaction of the sodium salt of the corresponding β-diketonate with [ClCu(PR_3)] with elimination of sodium chloride. The bis(triorganophosphine) adducts were prepared by the reaction of (β-diketonate)Cu(PR_3) with one equivalent of triorganophosphine. These species were characterized by ^{1}H, ^{13}C, and ^{31}P NMR spectroscopy, FTIR spectroscopy, mass spectroscopy, and by combustion elemental analysis. Four examples were structurally characterized by single crystal X-ray diffraction in the solid state. (acac)CuPCy_3 crystallizes in the triclinic crystal system, space group $P\bar{1}$, where a = 13.502(6) Å, b = 13.691(6) Å, c = 5.781(6) Å, α = 71.05(3)°, β = 67.50(3)°, γ = 64.81(3)°, Z = 4, and R = 5.42%. (tfac)CuPCy_3 crystallizes in the monoclinic crystal system, space group $P2_1/n$, where a = 9.639(3) Å, b = 22.717(7) Å, c = 12.045(5) Å, β = 111.67(3)°, Z = 4, and R = 7.22%. (hfac)CuPCy_3 crystallizes in the monoclinic crystal system, space group $P2_1/c$, where a = 9.870(2) Å, b = 17.314(4) Å, c = 15.586(3) Å, β = 99.74(2)°, Z = 4, and R = 5.29%. (hfac)Cu(PCy_3)$_2$ crystallizes in the monoclinic crystal system, space group $P2_1/n$, where a = 13.645(6) Å, b = 19.252(13) Å, c = 16.875(9) Å, β = 102.02(4)°, Z = 4, and R = 7.20%. The compounds (β-diketonate)Cu(PCy_3) are all monomeric in the solid state and possess approximately trigonal-planar copper coordination environments, although (tfac)Cu(PCy_3) is significantly distorted from trigonal geometry. The Cu—O bond distances are significantly different in this species. The compound (hfac)Cu(PCy_3)$_2$ is monomeric in the solid state and possesses a distorted tetrahedral copper coordination environment. The distortion is believed to be due to the large steric demands of the PCy_3 ligands that result in long Cu—P bond distances of 2.251(3) and 2.277(3) Å, a large P—Cu—P angle of 141.3(1)°, long Cu—O distances of 2.213(5) and 2.251(5) Å, and a small O—Cu—O angle of 80.8(2)° compared to the corresponding values for (hfac)Cu(PCy_3). No trends in Cu—O bond distances between the compounds can be discerned, within the limits of error on the data, that would clearly enable a comparison of thermodynamic parameters such as bond length – bond strength relationships as a function of the β-diketonate substituents. However, the spectroscopic data revealed a number of trends as a function of the β-diketonate substituents, including an increase of ν(C=O and ν(C=C) in the order acac < tfac < hfac, analogous to the increase in their Lewis acidity. An increase in shielding of the ^{31}P resonance of the triorganophosphine ligands was observed in the order hfac < tfac < acac, consistent with expected inductive effects based on the electronegativity of the β-diketonate substituents.

H.-K. SHIN, M. J. HAMPDEN-SMITH, E. N. DUESLER et T. T. KODAS. Can. J. Chem. **70**, 2954 (1992).

On a préparé les composés (β-dicétonate)Cu(PR_3)$_n$ dans lesquels β-dicétonate = 1,1,1,5,5,5-hexafluoroacétylacétonate (hfac), 1,1,1-trifluoroacétylacétonate (tfac) et acétylacétonate (acac); R = *n*-butyle (*n*-Bu), phényle (Ph) et cyclohexyle (Cy); n = 1 et 2. On a préparé les adduits monotriorganophosphines avec d'excellents rendements par la réaction du sel de sodium du β-dicétonate correspondant avec le [ClCu(PR_3)], avec élimination de chlorure de sodium. On a préparé les adduits bis(triorganophosphine) par la réaction des (β-dicétonate)Cu(PR_3) avec un équivalent de triorganophosphine. On a caractérisé ces espèces par RMN du ^{1}H, du ^{13}C et du ^{31}P, par spectroscopie infrarouge par transformée de Fourier, par spectroscopie de masse et par analyse élémentaire par combustion. On a caractérisé les structures de quatre exemples par le biais de la diffraction des rayons X par un cristal unique à l'état solide. Les cristaux du (acac)CuPCy_3 sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 13,502(6), b = 13,691(6) et c = 5,781(6) Å, α = 71,05(3), β = 67,50(3) et γ = 64,81(3)°, Z = 4 et R = 5,42%. Ceux du (tfac)CuPCy_3 sont monocliniques, groupe d'espace $P2_1/n$, avec a = 9,639(3), b = 22,717(7) et c = 12,045(5) Å, β = 111,67(3)°, Z = 4 et R = 7,22%. Ceux du (hfac)CuPCy_3 sont monocliniques, groupe d'espace $P2_1/c$, avec a = 9,870(2), b = 17,314(4) et c = 15,586(3) Å, β = 99,74(2)°, Z = 4 et R = 5,29%. Les cristaux du (hfac)Cu(PCy_3)$_2$ sont monocliniques, groupe d'espace $P2_1/n$, avec a = 13,645(6), b = 19,252(13) et c = 16,875(9) Å, β = 102,02(4)°, Z = 4 et R = 7,20%. À l'état solide, tous les composés (β-dicétonate)Cu(PCy_3) sont monomériques et leurs environnements de coordination du cuivre sont approximativement plan trigonal même si la géométrie trigonale du (tfac)Cu(PCy_3) est très déformée. Dans ces espèces, les distances Cu—O sont très différentes. Le composé (hfac)Cu(PCy_3) est monomérique et l'environnement de coordination du cuivre est tétraédrique déformé. On croit que la distorsion est causée par les grandes demandes stériques des ligands PCy_3 qui

allongent les distance Cu—P (2,251(3) et 2,277(3) Å), élargissent l'angle P—Cu—P (141,3(1)°), allongent les distances Cu—O (2,213(5) et 2,251(5) Å) et amenuisent l'angle O—Cu—O (80.8(2)°) par rapport aux valeurs correspondantes du (hfac)Cu(PCy_3). Aux limites expérimentales près, on n'a pas observé de tendances dans les distance Cu—O entre les divers composés qui auraient pu permettre d'établir une comparaison avec des paramètres thermodynamiques comme les relations longueur de liaison/force de liaison en fonction des substituants des β-dicétonates. Toutefois, les données spectroscopiques ont révélé un certain nombre de tendances en fonction des substituants des β-dicétonates, y compris une augmentation de ν(C=O) et ν(C=C) dans l'ordre acac < tfac < hfac, analogue à celui de la variation de leur acidité de Lewis. On a observé une augmentation dans le blindage de la résonance ^{31}P des ligands triorganophosphines dans l'ordre hfac < tfac < acac qui est en accord avec les effets inductifs attendus sur la base de l'électronégativité des substituants des β-dicétonates.

[Traduit par la rédaction]

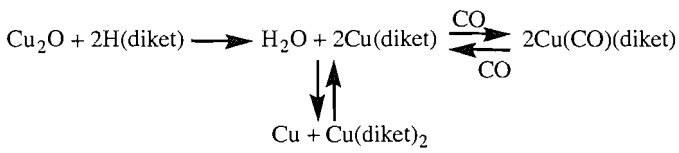
Introduction

It has been demonstrated that β-diketonate complexes of copper(I) and copper(II) exhibit suitable physical properties to be precursors for the Chemical Vapor Deposition (CVD) of copper metal. Copper(II) β-diketonate complexes have been studied extensively (1–5). However, while their volatility is high (Cu(hfac)$_2$ exhibits an equilibrium vapor pressure of ~250 mTorr (1 Torr = 133.3 Pa) at 60°C) (6), they do not thermally decompose below 340°C and, above 390°C, significant incorporation of carbon impurities into copper films is observed. The presence of hydrogen gas during deposition increases the purity of the deposit, but drastically alters the selectivity (4, 5).

On the other hand, it has recently been shown that copper(I) β-diketonate complexes, (β-diketonate)CuL_n, where L = a Lewis base such as a triorganophosphine, an olefin, or an alkyne, undergo thermally induced disproportionation reaction (Eq. [1]) (7–9) over a temperature range 80–400°C and, in some cases, deposit copper selectively (7–15). Selective copper deposition from (β-diketonate)CuL compounds onto the metals Pt, W, and Cu in the presence of SiO_2 and the minimum deposition temperature are strongly influenced by the nature of the β-diketonate substituents and Lewis base ligands, L. For example, (hfac)CuPMe_3 selectively deposits copper onto W and not SiO_2 in the temperature range 150–300°C. Above 300°C, selectivity is lost and deposition is observed on SiO_2 as well. However, (tfac)Cu(PMe_3) and (acac)Cu(PMe_3) selectively deposit copper at 100–150°C and <80°C, respectively, on W in the presence of SiO_2 (7, 16). Above these temperatures selectivity is lost. In contrast, (hfac)Cu(1,5-COD) and (hfac)Cu(2-butyne) deposit copper on both W and SiO_2 over the temperature range 120–200°C. Below 120°C, no deposition is observed (16, 17). Furthermore, the compounds (hfac)Cu(PR_3)$_2$, R = Me, Et, show substantially higher thermal stability than their monophosphine counterparts and do not deposit copper below 350°C (16). To gain a better understanding of those factors that affect the bonding of β-diketonate ligands to the copper(I) center and that play a crucial role in CVD, we have undertaken studies of the structural chemistry and reactivity of (β-diketonate)CuL_n complexes.

[1] $2(\beta\text{-diketonate})Cu^{(I)}L \rightarrow Cu^{(0)} + Cu^{(II)}(\beta\text{-diketonate})_2 + 2L$

Despite the enormous amount of work devoted to synthesis and characterization of copper(II) β-diketonate complexes, there are relatively few reports devoted to the corresponding Cu(I) complexes. Reports of monotriorganophosphine adducts, (β-diketonate)Cu(PR_3), are particularly rare. Copper(I) acetylacetonate was reported previously (18–20) and shown to undergo disproportionation to copper metal and copper(II) bisacetylacetonate compounds in the absence of stabilizing ligands (19). A number of stable complexes of general formula (β-diketonate)CuL_n (L = isonitriles, ammonia, and phosphines; n = 2 or 2.5) were synthesized and characterized by Nast and Lepel (21). In early 1970, Carty and co-workers (22, 23) also prepared a number of copper(I) β-diketonate complexes containing two triorganophosphine ligands bonded to each copper. Doyle et al. (24) reported preparation of (β-diketonate)Cu(CO) from Cu_2O and β-diketones, and observed that only one CO is absorbed per copper atom. The yellow-green solution of (hfac)Cu(CO) is only stable if stored under a CO atmosphere; otherwise, it disporportionates to form copper metal and copper(II) β-diketonate according to Scheme 1. These β-diketonate copper(I) carbonyl complexes react with triorganophosphines, amines, and isonitriles to produce the corresponding bis(Lewis base) species, (β-diketonate)CuL_2.



SCHEME 1

It was also shown previously that the addition of triorganophosphine ligands to the copper(I) coordination sphere can displace a uninegative oxygen donor ion. For example, the copper(I) nitrate complexes (NO_3)CuL_2, (NO_3)CuL_3, and (NO_3)CuL_4 exhibit bidentate, monodentate, and ionic nitrate ligand binding modes, respectively (22, 25). Furthermore, we recently demonstrated that addition of an excess of PMe_3 to the mononuclear, distorted trigonal-planar complex (β-diketonate)Cu(PMe_3) results in displacement of the β-diketonate ligand from the copper coordination sphere to form [β-diketonate]$^-$[Cu(PMe_3)$_4$]$^+$ (26). In this work we report the syntheses and characterization of a number of (β-diketonate)Cu(PR_3)$_n$ species, where R = Bu, Ph, and Cy; n = 1 and 2. Included is a solid state structural study of (β-diketonate)Cu(PCy_3), where β-diketonate = 1,1,1,5,5,5-hexafluoroacetylacetonate (hfac), 1,1,1-trifluoroacetylacetonate (tfac), and acetylacetonate (acac); Cy = cyclohexyl and (hfac)Cu(PCy_3)$_2$, to probe the changes in β-diketonate coordination as a function of the β-diketonate ligand and the degree of substitution with a sterically demanding phosphine ligand.

Experimental section

General procedures

All manipulations were carried out under an atmosphere of dry (molecular sieves) dinitrogen using standard Schlenk techniques. All hydrocarbon and ethereal solvents were dried and distilled from

sodium benzophenone ketyl and stored over 4 Å molecular sieves. Copper(I) chloride, sodium hydride, and tertiary phosphines were purchased from Aldrich Chemical Co. and used without further purification. Copper(I) chloride was obtained from Fischer Scientific Company and recrystallized by the literature method (27) prior to use. The β-diketone starting materials were purchased from Aldrich Chemical Co. and were distilled under nitrogen and stored over 4 Å molecular sieves before use. Sodium salts of β-diketones were prepared by the reaction of the free acid with sodium hydride, as previously described (28). The compounds [ClCu(PR_3)] were prepared by methods previously described in the literature (28). Elemental analyses were performed by Ms. R. Ju at the Department of Chemistry, University of New Mexico. NMR data were recorded on a Bruker AC-250P NMR spectrometer by using the protio impurities of the deuterated solvents as references for the ^{1}H NMR, and the ^{13}C resonance of the solvents as the reference for ^{13}C NMR spectroscopy. Temperatures were calibrated with either ethylene glycol or methanol. ^{31}P NMR data were recorded on the same instrument using phosphoric acid as reference. ^{31}P NMR chemical shifts are quoted using the high frequency = positive sign convention. Infrared data were recorded on a Perkin–Elmer model 1620 FTIR spectrophotometer. Mass spectra were recorded on a Finnegan GC mass spectrometer. The melting points were determined using a digital melting point apparatus purchased from Electrothermal England Ltd.

Syntheses

Similar synthetic procedures were employed to prepare the two classes of compounds described here, (β-diketonate)Cu(PR_3)$_n$, n = 1 and 2. A typical example of an experimental procedure is given for each, followed by the spectroscopic data.

(acac)CuPBu$_3$

The liquid ClCuPBu_3 (4.26 g, 14.14 mmol) and 2.30 g (18.84 mmol) of Na^+(acac$^-$) were placed in a 250 mL Schlenk flask, and 100 mL of dry pentane was added under dry nitrogen. The white solution immediately turned pale yellow. After stirring at room temperature for 2 h, the solution was filtered, the white precipitant was washed with two 10-mL portions of pentane, and the filtrates were combined. The volatile components were removed *in vacuo* to give 4.83 g (94% yield) of very pale yellow liquid, which was characterized as Cu(acac)(PBu_3).

(hfac)Cu(PCy_3)$_2$

PCy_3 (0087 g, 0.31 mmol) and 0.155 g (0.31 mmol) of (tfac)Cu(PCy_3) were placed in a 100 mL Schlenk flask, and 10 mL of dry pentane was added under dry nitrogen. The light yellow solution was stirred at room temperature for 2 h. The volatile components were removed *in vacuo* to give 0.221 g (91.7% yield) of greenish yellow powder, which was characterized as Cu(hfac)(PCy_3)$_2$. Chartreuse crystalline (hfac)Cu(PCy_3)$_2$ was prepared by cooling a pentane solution in the freezer (−30°C), overnight.

Spectroscopic and analytical data

Representative spectroscopic data are provided here for (hfac) compounds. ^{1}H, ^{13}C{^{1}H}, and ^{31}P{^{1}H} NMR data, IR and mass spectral data for the other compounds are available as supplementary materials (see footnote 2).

(hfac)CuP^{n}Bu$_3$

Orange liquid. Yield: 90%. IR data (KBr disc, cm^{-1}): 2962(s), 2934(s), 2875(m), 1642(s), 1590(w), 1549(m), 1522(m), 1483(s), 1467(m), 1415(w), 1381(w), 1342(w), 1256(s), 1198(s), 1147(s), 1096(m), 1051(w), 1007(w), 969(w), 946(w), 910(w), 794(m), 765(w), 741(w), 727(w), 668(s), 583(m), 527(w). ^{1}H NMR δ: 6.30 (s, 1H, CH), 1.10 (m, 18H, P($C_3H_6CH_3$)$_3$), 0.78 (t, 7 Hz, 9H, P($C_3H_6CH_3$)$_3$); ^{13}C{^{1}H} NMR δ: 177.4 (q, 34 Hz, CO), 118.6 (q, J(C–F) = 286 Hz, CF_3), 89.5 (s, CH), 27.5 (d, J(C–P) = 3 Hz, PBu_3), 24.8 (d, J(C–P) = 26 Hz, PBu_3), 24.4 (d, J(C–P) = 14 Hz, PBu_3), 13.7 (s, PBu_3); ^{31}P{^{1}H} NMR δ: −8.57 (s, br). Mass spectral data (70 eV, m/e): 472, 7%, [(hfac)CuPBu_3]$^{+\cdot}$; 467, 5%, [Cu(PBu_3)$_2$]$^{+\cdot}$; 403, <1%, [($O_2C_2CHCF_3$)CuPBu_3]$^{+\cdot}$; 265, 100%, [CuPBu_3]$^{+\cdot}$; 209, 7%, [CuP(H)Bu_2]$^{+\cdot}$; 202, 44%, [PBu_3]$^{+\cdot}$; 201, 2%, [Cu($O_2C_2CHCF_3$)]$^{+\cdot}$ or [(O_2C_2CH)$_2$Cu]$^{+\cdot}$; 187, 3%, [PBu_2(C_3H_6)]$^{+\cdot}$; 173, 14%, [PBu_2(C_2H_4)]$^{+\cdot}$; 160, 28%, [PBu_2(CH_3)]$^{+\cdot}$; 151. 5%, [CuPBu]$^{+\cdot}$; 146, 53%, [P(H)Bu_2]$^{+\cdot}$; 131, 5%, [P(H)Bu(C_3H_6)]$^{+\cdot}$; 118, 19%, [P(H)Bu(C_2H_5)]$^{+\cdot}$; 109, 12%, [CF_3COCH]$^{+\cdot}$; 104, 12%, [P(H)Bu(CH_3)]$^{+\cdot}$; 103, 7%, [(OCCH)Cu]$^{+\cdot}$; 89.7%, [P(H)Bu]$^{+\cdot}$; 69, 1%, [CF_3]$^{+\cdot}$; 63.3%, [Cu]$^{+\cdot}$; 57, 1%, [C_4H_9]$^{+\cdot}$. Anal. calcd. for $C_{17}H_{28}O_2F_6PCu$ (mol. wt. 472.93): C 43.18, H 5.97; found: C 43.55, H 6.19.

(tfac)CuP^{n}Bu$_3$

Chartreuse liquid. Yield: 98%. Anal. calcd. for $C_{17}H_{31}F_3O_2PCu$ (mol. wt. 418.96): C 48.74, H 7.46; found: C 49.14, H 7.55.

(acac)CuP^{n}Bu$_3$

Light-yellow liquid. Yield: 94%. Anal. calcd. for $C_{17}H_{34}O_2PCu$ (mol. wt. 364.99): C 55.94, H 9.39; found: C 56.24, H 9.31.

(hfac)CuPPh$_3$

Color: orange. Yield: 93%; mp 145°C. IR data (KBr disc, cm^{-1}): 3057(w), 3020(w), 2987(w), 1646(s), 1585(w), 1576(w), 1548(s), 1519(s), 1488(s), 1457(w), 1436(s), 1419(w), 1387(w), 1337(m), 1310(m), 1257(s), 1211(s), 1150(s), 1102(s), 1097(s), 1090(s), 1073(w), 1028(m), 998(m), 980(w), 973(w), 944(w), 927(w), 852(w), 846(w), 807(w), 792(s), 753(s), 738(s), 708(s), 696(s), 670(s), 618(w), 586(m), 537(s), 509(s), 493(s), 443(w), 436(w), 420(w). ^{1}H NMR δ: 7.32 (m, 6H, PPh_3(o)), 6.90 (m, 9H, PPh_3(m/p)), 6.31 (s, 1H, CH); ^{13}C{^{1}H} NMR δ: 177.6 (q, 33 Hz, CO), 134.0 (d, 13 Hz, PPh_3(b)), 131.5 (d, 43 Hz, PPh_3(a)), 130.7 (s, PPh_3(d)), 129.1 (s, br, PPh_3(c)$^+$), 118.6 (q, J(C–F) = 288 Hz, CF_3), 89.8 (s, CH); ^{31}P{^{1}H} NMR δ: 9.22 (s, br). X-ray crystallographic studies

Single crystal X-ray difffraction studies of (acac)Cu(PCy$_3$), (tfac)Cu(PCy$_3$), (hfac)Cu(PCy$_3$), and (hfac)Cu(PCy$_3$)$_2$ were carried out for comparative purposes. A summary of the crystal data and experimental details for the X-ray diffraction studies of these compounds is presented in Table 1. A general description of the experimental procedure is presented here, with more details available as supplementary material.[2]

Crystals of each compound were grown from *n*-pentane solution at −30°C. Suitable crystals were selected and sealed in glass capillaries at room temperature in a glove box under nitrogen atmosphere. X-ray data were collected on a Nicolet R3m/V diffractometer and the structures solved by direct methods using Shelxtl Plus and refined by the full-matrix least-squares method.

(acac)Cu(PCy$_3$)

Refinement of the non-hydrogen atoms showed that the cyclohexane ring corresponding to C(18)–C(23) had large anisotropic U's. This is indicative of some positional disorder. Attempts to refine the ring as two disordered cyclohexanes with isotropic U's on the disordered ring positions yielded higher R-factors than by simply refining all these ring positions anisotropically. In the final model, all non-hydrogen atoms were treated anisotropically, and all hydrogen atoms were included in idealized positions (riding model) with their isotropic U's set to 1.25 times the U(equiv) of their parent atoms.

(tfac)Cu(PCy$_3$)

Refinement of the non-hydrogen atoms showed that the F's had very large anisotropic U's. Close inspection of a difference Fourier map showed two sets of F's corresponding to two CF_3 positions rotated slightly from one another. All the F's share one isotropic U, which was not varied at first to determine the relative occupancies of the two sets of F's. The occupancies refined to 0.6767 and 0.3233 for the sets F(1)–F(3) and F(1′)–F(3′), respectively. Fixing the occupancies on the disordered F's, the final refinement model used anisotropic U's on all non-hydrogen atoms except the disordered F's, which were refined isotropically with a common U. All hydrogens were included in idealized positions (riding model) with isotropic U's set to 1.25 times U(equiv) of their parent atoms.

(hfac)Cu(PCy$_3$)

Refinement of the model went smoothly without any problems. The final model: anisotropic refinement on all non-hydrogen atoms, all hydrogen atoms included in idealized positions (riding model) with isotropic U's set to 1.25 times U(equiv) of their parent atoms.

(hfac)Cu(PCy$_3$)$_2$

Refinement of the non-hydrogen atoms showed large anisotropic U's for F(2), F(3), F(4), F(5), F(6), and particularly C(17). Study of difference Fourier maps showed that C(17) could be disordered over two sites, while no other sites for the F's could be picked out except for their original positions. Fixing a common isotropic U for C(17) and its other site C(17′), varying the relative occupancies, gave the resulting site occupancies for C(17) and C(17′) as 0.675 and 0.325. The final model refined all non-hydrogen atoms anisotropically except for C(17) and C(17′), which had fixed occupancies and a common, but variable isotropic U, and included all hydrogen atoms (allowing for disorder on C(17) and C(17′)) in idealized positions (riding model) with isotropic U's set to 1.25 times U(equiv) of parent atom, except for those on C(17) and C(17′), which were set to 1.25 times the common isotropic U of C(17) and C(17′).

[a]Details in common: radiation, Mo-K_α (λ = 0.71069Å); weighting scheme, $w^{-1} = \sigma^2(F) + g F^2$ (see supplementary materials for value of g).

Final difference Fourier maps were essentially featureless at the end of final refinements for all structures. Atomic coordinates are presented in Tables 2–5, and bond lengths and angles are presented in Tables 6–9. Full details of the structural data are available as supplementary materials (footnote 2).

Results and discussion

Synthesis

The complexes (β-diketonate)Cu(PR_3), where β-diketonate = hfac, tfac, and acac, R = Bu, Ph, and Cy, were prepared by the reactions of [Cu(Cl)(PR_3)] with the corresponding sodium β-diketonate salt according to eq. [2]. This method avoided the problems of formation of the bis(triorganophosphine) complexes described in the Introduction. The complexes (β-diketonate)Cu(PR_3)$_2$ were prepared from *n*-pentane or diethyl ether solutions of (β-diketonate)CuPR_3 by reaction with PR_3, in 1:1 molar ratio as shown in eq. [3]. These reactions resulted in the formation of the desired product in high yield.

[2] $[ClCuPR_3] + Na^+\beta\text{-diketonate}^- \rightarrow (\beta\text{-diketonate})CuPR_3 + NaCl$

[3] $(\beta\text{-diketonate})CuPR_3 + PR_3 \rightarrow (\beta\text{-diketonate})Cu(PR_3)_2$

In addition to the methods described in the Introduction, several other methods of preparing triorganophosphine adducts copper(I) compounds have been described in the literature. However, these methods do not result in formation of mono(triorganophosphine) species. The reduction of β-diketonate copper(II) complexes with the tertiary phosphine (22, 23, 29) results in formation of bis(triorganophosphine) adducts, and the reduction of copper(II) acetate with Grignard reagents in the presence of a triorganophosphine results in the formation of either tris(triorganophosphine) complexes or ionic salts when small phosphines such as PMe_3 and PMe_2Ph are used, as described by eq. [4] (30).

[4] $Cu_2(O_2CMe)_4 + 2MgR_2 + \text{excess L} \rightarrow$ [Cu(L)$_4$][CuR_2], L = PMe_3, PMe_2Ph; or CuRL_3, L = $PMePh_2$

The reaction of $ClCuPPh_3$ with the thallium(I) β-diketonate (1:1 molar ratio) led surprisingly to the formation of bisphosphine complexes (31) as shown in Eq. [5], and not to the expected monophosphine adduct.

[5] $Tl^+\beta\text{-diketonate}^- + ClCuPPh_3 \rightarrow 0.5(\beta\text{-diketonate})Cu(PPh_3)_2 + TlCl + ?$

Recently, Doyle *et al.* (24) prepared a number of β-diketonate copper(I) olefin and carbonyl complexes, but reported that displacement of the carbonyl ligand, with L = triorganophosphines, amines, or isonitriles, gave derivatives of the type (β-diketonate)CuL_2. The reaction of eq. [2] seems to be a convenient, high-yield, general route to a variety of (β-diketonate)Cu(PR_3) complexes.

The reaction of eq. [3] resulted in formation of the bis(triorganophosphine) products, generally in high yields. However, where PR_3 = PMe_3, the addition of an excess of phosphine ligand resulted in displacement of the β-diketonate ligand from the copper(I) coordination sphere to form the salt [(β-diketonate)]$^-$[Cu(PMe_3)$_4$]$^+$ (26), analogous to the observations of Dempsey and Girolami (30). Unexpectedly, the very sterically hindered species (β-diketonate)Cu(PCy_3)$_2$ (PCy_3, cone angle = 170°C) was prepared and isolated by reaction of eq. [3], and one example, (hfac)Cu(PCy_3)$_2$, was structurally characterized by single crystal X-ray diffrac-

tion. This molecule is of interest because the bulky tricyclohexylphosphine groups are likely to exert a large steric effect on the copper(I) coordination environment.

The addition of other Lewis base ligands such as pyridine, NEt_3, THF, and H_2O to electronically unsaturated complexes (β-diketonate)$CuPR_3$ in greater than tenfold excess did not lead to any reaction. This observation is not surprising, since these ligands, although less sterically demanding than PCy_3, are weaker (hard) lewis bases with respect to the "soft" copper(I) cation. However, the result of a proton NMR study in which pyridine-d_5 was reacted with (hfac)$CuPMe_3$ revealed that addition of one drop of pyridine-d_5 to a benzene-d_6 solution of (hfac)$CuPMe_3$ caused the ^1H resonance of the coordinated PMe_3 to be deshielded by 0.41 ppm, and dissolution of (hfac)$CuPMe_3$ in pyridine-d_5 resulted in further deshielding of 0.72 ppm. We previously observed that the coordination of the Lewis bases to the copper(I) center is dominated by the σ-donor ability, not the π-acceptor ability, as evidenced by the small change in carbon–carbon bond lengths of olefin and alkyne ligands on coordination to the (β-diketonate)Cu(I) moiety (8, 32).

Depending on the particular phosphine and β-diketonate groups, the complexes have varying stability with respect to air oxidation, but all are moisture insensitive. In general the complexes derived from hfacH are more stable with respect to aerial oxidation and thermolysis than those prepared from tfacH and acacH. For example (acac)$CuP(n\text{-}Bu)_3$ thermally decomposed during attempted sublimation. The compounds (hfac)$Cu(PR_3)_n$, (tfac)$Cu(PR_3)_n$, and (acac)$Cu(PR_3)_n$, in general, are orange-yellow, chartreuse, and light-yellow solids or liquids, respectively. The complexes (β-diketonate)$Cu(PBu_3)_n$, where $n = 1$ and 2, are viscous liquids at room temperature, whereas the other derivatives are solids with melting points that vary from 92°C to 148°C as described in the experimental section. In general (β-diketonate)$Cu(PR_3)_2$ compounds are more thermally stable than their (β-diketonate)$Cu(PR_3)$ analogues.

Characterization and trends

The compounds (β-diketonate)CuL that were characterized previously were shown to be monomeric in the solid state and in solution (8, 28, 32, 33), and thus the (β-diketonate)$Cu(PR_3)$ complexes described here were expected to exhibit a similar trigonal-planar arrangement of ligands about the central copper(I) atom. The species (β-diketonate)$Cu(PR_3)_2$ were expected to be monomeric, four-coordinate, and tetrahedral by comparison to the literature data for analogous complexes, assuming that the β-diketonate ligand remains chelating (22, 25). β-Diketonate ligands can exhibit a great variety of coordination modes in metal-organic complexes. The solution phase ^1H, ^{13}C, and

^{31}P NMR and solid state IR spectral data were consistent with chelation through both oxygen atoms in these phases. Table 10 lists the IR spectroscopic data of some (β-diketonate)Cu(PR_3)$_n$ species in the double bond stretching region (1500–1700 cm^{-1}).[3] The β-diketones themselves exist in keto–enol tautomerism where electron-withdrawing substituents, such as CF_3 and C_6H_5, displace the equilibrium in favor of the enol tautomer, while electron-donating substituents (CH_3) favor the keto form (35). The observed increase in ν(C=C) frequency in the order acac < tfac < hfac is consistent with the increasing Lewis acidity of β-diketones (36, 37). It is also noteworthy that when CH_3 groups in β-dikeotnate complexes are replaced by CF_3 groups, the carbonyl stretching frequency increases (i.e., acac < tfac < hfac). These observations have previously been interpreted in terms of weakening of the Cu—O bond on complexation as the frequency of the perturbed carbonyl band was raised in the case of Cu(II) β-diketonate complexes (38–40). Comparison of the ν(C—O and ν(C—C) bands in (β-diketonate)Cu(PR_3)$_n$, n = 1 and 2, compounds show that ν(C—O) is higher and ν(C—C) is lower for n = 2 than for n = 1. These changes are consistent with a greater contribution of the keto form to (β-diketonate)Cu(PR_3)$_2$ compounds.

In the ^{1}H and ^{13}C NMR data of (β-diketonate)Cu(PR_3)$_n$, the downfield chemical shifts of the central methine protons and carbons of the β-diketonate ring, the upfield shifts of the phosphine protons, and the increasing $^2J_{P-H}$ in the order hfac > tfac > acac may be ascribed to the rehybridization of phosphorus (more electron-withdrawing substituents on the β-diketonate may cause the Cu(β-diketonate) moiety to be more electron withdrawing), as expected on the basis of Bent's rules (41). The ^{31}P NMR chemical shifts of phosphine ligands in the title species are generally quite broad and follow the order of shielding hfac < tfac < acac-. This trend could reasonably be interpreted in terms of inductive effects (more electron-withdrawing substituents on the β-diketonate ligand result in more deshielding of the ^{31}P resonance) due to the highly electronegative CF_3 group. The observation of broadened singlet ^{31}P NMR resonances may be the result of quadrupolar broadening (42, 43) due to the presence of ^{63}Cu or ^{65}Cu (44) or the possibility of an exchange process (45) involving either the triorganophosphine or β-diketonate ligands. Solutions containing excess triorganophosphines also exhibit a broad single resonance at the weighted-average resonance of the complexed and free phosphine at room temperature. These results are indicative of reversible

[3]There has been some discussion about these band assignments in the literature. For a normal coordinate analysis, see ref. 34.

triorganophosphine dissociation that is rapid on the NMR time scale at room temperature.

The mass spectral data of the title compounds were studied to investigate the oligomerization in the vapor phase since these species have potential to exist as oligomers bridged through the β-diketonate oxygen as a result of steric crowding (46). As we observed previously, ions corresponding to [(β-diketonate)$Cu_2(PR_3)_2]^+$ were observed with low intensities. Molecular ions were observed for (β-diketonate)-Cu(PR_3) compounds in every case, and the highest intensity ion was attributed to either $[Cu(PR_3)]^+$ or $[PR_3]^+$. The mass spectra were generally dominated by fragmentation of the PR_3 ligands. However, molecular ions were not observed for (β-diketonate)Cu$(PR_3)_2$ compounds, and their fragmentation was

[a]Equivalent isotropic U defined as one third of the trace of the orthogonalized U_{ij} tensor.
[b]C(17) and C(17′) represent disordered positions of C(17) with occupancies of 0.675 and 0.325, respectively. The positions of H(12a), H(16a), H(16b) are the idealized hydrogen atom positions for C(17) and its corresponding hydrogens H(17a) and H(17b). The positions of H(12b), H(16c), and H(16d) are the idealized hydrogen atom positions for C(17′) and its corresponding hydrogens H(17c) and H(17d).

similar to that of their monophosphine analogues. Variation in the mass spectral parameters, such as reducing the ionization potential (70 to 30 eV), increasing the sample size, and decreasing the sample heating rate, did not result in the observation of the expected monomeric parent ion, (β-diketonate)Cu(PCy_3)$_2^+$. These observations probably result

from weak coordination of the second phosphine ligand, consistent with the observed lengthening (weakening) of the Cu—P bonds in the solid state structure of (hfac)Cu(PCy_3)$_2$ compared to that observed for (β-diketonate)CuPCy_3 compounds.

Solid state structural data

The solid state structures of (hfac)Cu(PCy_3), (tfac)Cu(PCy_3), and (acac)Cu(PCy_3) were determined by single crystal X-ray diffraction and the ORTEP plots are shown in Figs. 1–3 respectively. All three compounds are monomeric with three-coordinate copper in the solid state. The copper coordination environment is distorted trigonal planar and none of molecules possesses any symmetry elements in the solid state. The compound (tfac)Cu(PCy_3) is most distorted from trigonal-planar geometry with O—Cu—P angles of 156.3(2)° and 112.7(2)°. The two Cu—O bond distances are significantly different, within the limits of error

on the data, with Cu—O(1), close to the CF_3 substituent, 1.942(6) Å, shorter than Cu—O(2), close to the CH_3 substituent, 2.068(5) Å. However, no trends in Cu—O bond distances between the compounds can be discerned, within the limits of error on the data, that would clearly enable a comparison of thermodynamic parameters such as bond length – bond strength relationships as a function of the β-diketonate substituents. The bite angles of the β-diketonate ligands of ~91°–~94° and the Cu—O bond lengths of ~2.00 Å are similar to other copper(I) β-diketonate complexes bearing one Lewis base adduct (8, 28, 32, 33). Similarly, no unambiguous trends in Cu—P bond lengths or C—O and C—C bond lengths and angles, within the limits of error of the data, were observed that would enable comparison to the spectroscopic trends observed.

The crystal structure of (hfac)Cu(PCy_3)$_2$ was determined by single crystal X-ray diffraction. The ORTEP drawing is shown in Fig. 4 and the structural data confirm that this compound is monomeric and adopts a distorted tetrahedral geometry, although the bulky tricyclohexylphosphine ligands exert a large steric effect. The steric effects are evident from the long Cu—P bond distances of 2.251(3) and 2.277(3) Å (hfacCu(PCy_3) derivative = 2.15 Å), the large P—Cu—P angle of 141.3(1)°, the long Cu—O distances of 2.213(5) and 2.251(5) Å (~2.01 Å for (hfacCu(PCy_3)), and the small O—Cu—O angle of 80.8(2)° (90.7(2)° for (hfacCu(PCy_3)) compared to the monotricyclohexylphosphine-substituted derivative (Tables 6 and 9). The Cu—P bond lengths are analogous to those observed in other tetrahedrally coordinated copper(I) compounds with two-phosphine ligands (47). The P—Cu—P bond angle, 141.3(1)°, is close to that of the four-coordinate nitrate complex (NO$_3$)Cu(PCy_3)$_2$, 140(1)°, but it is significantly larger than those typically reported for systems with the less bulky PPh_3 groups: 127(1)° in (tfac)Cu(PPh_3)$_2$ (25), 131.2(1)° in (NO$_3$)Cu(PPh_3)$_2$ (22), and 123.26(6)° in (BH_4)Cu(PPh_3)$_2$ (23). Furthermore, the O—Cu—O angle, 80.8(2)°, of the hexafluoroacetylacetonate ligand is significantly smaller than

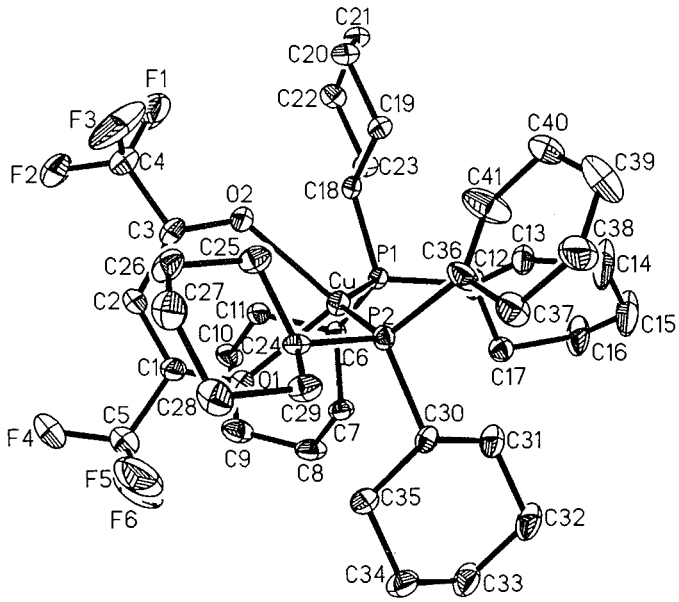

FIG. 4. ORTEP plot for (hfac)Cu(PCy_3)$_2$.

that of (hfac)CuPCy_3 (90.7(2)°). Since the tricyclohexylphosphine is very bulky, steric factors exert a strong influence on the coordination environment of copper in the compound (hfac)Cu(PCy_3)$_2$. These results are consistent with the cone angle data derived for PPh_3 (145°) and PCy_3 (170°) (46). Within the limits of error on the X-ray diffraction data, the changes in tautomerism predicted for the β-diketonate ligands in (hfac)Cu(PCy_3) compared to (hfacCu(PCy_3)$_2$, based on the spectroscopic data, could not be unambiguously established.

Conclusions

A general synthesis of a variety of new monotriorganophosphine adducts of copper(I) β-diketonates of general formula (β-diketonate)Cu(PR_3), prepared by the salt elimination reaction between [ClCu(PR_3)] and Na (β-diketonate), results in high purity and high yields. These species can then be reacted with one equivalent of the corresponding triorganophosphine to yield the adducts (β-diketonate)Cu(PR_3)$_2$ in virtually quantitative yield. Trends in the NMR and FTIR data suggested that the strength of binding of the β-diketonate and phosphine ligands to the copper(I) center increases in the order acac < tfac < hfac. This trend is also consistent with the observed qualitative trends in thermal and oxidative stability of these species. The ν(C—O) band is weakened markedly along the series hfac > tfac > acac. On addition of PR_3 to (β-diketonate)Cu(PR_3) compounds, the FTIR data are consistent with a stronger contribution of the keto form of the β-diketonate ligand compared to the starting material.

Attempts were made to confirm these trends by comparison of the metrical parameters of the species (hfac)Cu(PCy_3), (tfac)Cu(PCy_3), and (acac)Cu(PCy_3). However, while the Cu—O bond lengths in (tfac)Cu(PCy_3) were significantly different within the limits of error of the X-ray diffraction data, with Cu—O adjacent to the CF_3 substituent being shorter, the compounds (hfac)Cu(PCy_3) and (acac)Cu(PCy_3) exhibited values that covered a larger range of bond distances and did not exhibit any trends. As a result, care should be taken when interpreting these data as dependent on crystal packing forces (although no short intermolecular distances were observed).

The species (hfac)Cu(PCy_3)$_2$ was also characterized by single crystal X-ray diffraction in the solid state and revealed a distorted, tetrahedral copper(I) coordination environment. The distortion was believed to be the result of the two sterically demanding PCy_3 groups, which resulted in significant lengthening of the Cu—O bonds. These results are valuable for comparison to the thermally induced disproportionation of (β-diketonate)CuL compounds that is being examined as a method for the CVD of copper. The trends in FTIR data can be compared to the changes observed in coordination of these species on silica surfaces to provide insight into the mode of adsorption. Steric overcrowding of the copper(I) center resulting in lengthening of the Cu—O bonds of the β-diketonate ligand until it is finally completely displaced from the copper(I) coordination sphere, as in the case of [(β-diketonate)]$^-$ [CuL_4]$^+$ compounds, may provide insight into the β-diketonate ligand transfer during thermally induced disproportionation. Further studies are in progress.

MICHEL ZOGHBI and JOHN WARKENTIN. Can. J. Chem. **70**, 2967 (1992).

Δ^3-1,3,4-Oxadiazolines (**1**) that share their C2 with C4 of a β-lactam ring in a spiro fusion were prepared. The structures were established through single crystal X-ray diffraction of **1***a* and by infrared, ^{1}H, and ^{13}C nuclear magnetic resonance spectroscopies. Thermolysis of **1** at 100°C, in benzene containing dimethyl acetylenedicarboxylate, afforded spiro-fused β-lactam cyclopropene **12** in 33% yield. Similar thermolysis of **1***b* in the presence of ethyl phenylpropiolate gave spiro-fused β-lactam cyclopropene **13** (32%). The molecular structure of **12**, determined by single crystal X-ray diffraction, has the two ester carbonyl carbons out of the plane of the cyclopropene ring by about 0.17 Å, indicating substantial nonbonded steric interactions and suggesting unusually high strain energy. At 154.5°C, **12** underwent isomerization to **19**, presumably through a vinyl carbene intermediate.

MICHEL ZOGHBI et JOHN WARKENTIN. Can. J. Chem. **70**, 2967 (1992).

On a préparé les Δ^3-1,3,4-oxadiazolines (**1**) qui partagent leur carbone-2 avec le carbone-4 d'un cycle β-lactame pour donner une fusion spiro. On a déterminé leurs structures par diffraction des rayons X par un cristal unique de **1** et par spectroscopies infrarouge et résonance magnétique nucléaire du ^{1}H et du ^{13}C. La thermolyse de **1**, à 100°C, dans du benzène contenant de l'acétylènedicarboxylate de diméthyle, fournit le cyclopropène spiro-condensé à un β-lactame, **12**, avec un rendement de 33%. Une thermolyse semblable de **1***b* en présence de phénylpropiolate d'éthyle conduit au cyclopropène spiro-condensé à un β-lactame, **13**, avec un rendement de 32%. La structure moléculaire de **12**, déterminée par diffraction des rayons X par un cristal unique, montre que les carbones des deux groupes carbonyles des esters sont à 0,17 Å du plan du cyclopropène, indiquant qu'il existe des interactions stériques non-liées importantes et suggérant la présence d'une énergie de tension anormalement élevée. À 154,5°C, le composé **12** s'isomérise en **19**, probablement par l'intermédiaire d'un carbène vinylique.

[Traduit par la rédaction]

Introduction

Recently we reported the preparation and thermolysis of some spiro β-lactam oxadiazolines, **1** (1). Such compounds undergo thermal decomposition to afford β-lactam-4-ylidene intermediates (**2**) that can be trapped by intermolecular cycloaddition to alkenes and alkynes (1). The product from reaction with an alkyne (Scheme 1) is a novel species (**3**) embodying not only the ring strains of a β-lactam and a cyclopropene but also the additional strain engendered by virtue of the spiro ring fusion. The latter feature prevents the bond angle between substituents at the tetracoordinate carbon of the cyclopropene from adopting the large value characteristic of small ring compounds.

We now report details of the synthesis and characterization of two compounds of the families **1** and **3** and the thermolysis chemistry of one of the spiro β-lactam cyclopropenes (**3**).

Methods, results, and discussion

Spiro β-lactam oxadiazolines **1***a* and **1***b* were prepared by the route outlines in Scheme 2. The preparation of 4-substituted ketone semicarbazones, including **4**, has been described (2) and their cyclization by oxidizing agents, including Pb^{IV}, to 2-imino-Δ^3-1,3,4-oxadiazolines (e.g., **5**) is well known (2, 3). Only the *Z* isomers of **5** were obtained, as shown in Scheme 2 (3*a*, 4). On treatment with diphenylacetyl chloride and triethylamine at −20°C, **5***a* was converted to **1***a* in 90% yield. Similarly, **5***b* afforded **1***b* in 80% yield.

While the structures of **1***a* and **1***b* could be inferred from their infrared and nmr spectra, an unequivocal proof of the connectivity was needed to rule out isomeric structures as well as compounds derived from **1** through loss of N_2. To that end, the structure of **1***a* was confirmed by X-ray diffraction. The main features of the molecular structures are illustrated in Fig. 1.[2] Bond lengths and bond angles for the β-lactam ring of **1***a* are not significantly different from those reported (4) for 1-(2-bromophenyl)-azetidinone.

Oxadiazoline **1***a* is stable at room temperature but it decomposes in benzene solution at 100°C (sealed tube) with a half-life of 41 min. Its decomposition was followed conveniently by ^{1}H nmr spectroscopy, which showed the decay of the methyl singlets of **1***a* (δ = 1.42 and 1.44) and the growth of the singlet from acetone at δ = 1.95, relative to the internal toluene reference signal at δ 2.50. By analogy to the mechanism of thermolysis of other Δ^3-1,3,4-oxadiazolines (5, 6) we propose that the first step is a concerted, suprafacial, 1,3-dipolar cycloreversion to N_2 and a carbonyl ylide (**6**), Scheme 3. Again, on the basis of analogy, **6** might be expected to undergo 1,4-sigmatropic rearrangement to **7** (7, 8), electrocyclization to oxirane **8** (9–11), and fragmentation to carbonyl compounds and carbenes (8, 9, 12), Scheme 3. Compound **7**, which should be stable under the reaction conditions, was not detectable by ^{1}H nmr spectroscopy. Oxirane **8**, which might survive at 100°C, was also not observed. Oxiranes spiro-fused to C4 of a β-lactam ring have not been reported, to the best of our knowledge, but a thiirane analogue is known (13). Imide **10** was not obtained either, nor was there any evidence for the formation of propene, the expected product from fast rearrangement of 2-propylidene (**11**) (12*b*). On the other hand, the high yield of acetone (>95%) implies that **6** fragments rapidly, and essentially unidirectionally, to **9** and acetone. That fragmen-

tation, potentially reversible (12*b*), is presumably driven by two factors. First, **6** is heavily substituted in the β-lactam ring and must be twisted out of the planar conformation (14) to accommodate nonbonded interactions. Such twisting must reduce the bond order of at least one of the ylide O—C bonds. Second, the higher ground state energy of **6** is complemented by enhanced transition state stabilization from partial formation of the strong carbonyl double bond and a singlet aminocarbene (**9**).

Ylidene **9** probably undergoes a number of unimolecular reactions as well as reactions with **1***a* and with itself in the absence of good carbenophiles. The numerous products from thermolysis of **1***a* in benzene were not characterized[3] because of our greater interest in trapping **9** by cycloaddition.

Thermolysis of **1***a* at 100°C in benzene containing dimethyl acetylenedicarboxylate (3.1 M) and of **1***b* in the presence of ethyl phenylpropiolate (3.0 M) afforded **12** and **13** in 33 and 32% yields, respectively (Scheme 4). Both were characterized by means of ir spectroscopy, ^{13}C nmr spectroscopy, and mass spectrometry. A single crystal of **12** was used to confirm its structure, by X-ray diffraction.

Major aspects of the molecular structure of **12** are shown in Fig. 2.[2] The most striking feature is the distortion of the bonds holding the ester groups to the cyclopropene ring. The carbonyl carbons of these ester groups are out of the cyclopropene ring plane (0.180 Å for one, 0.155 Å for the other) in the direction toward the lactam nitrogen, as emphasized in the drawing (Fig. 2). Presumably nonbonded repulsions between those ester groups and the phenyl groups at C6 are responsible.

Thermolysis of **12** at 154.5°C in benzene afforded a product to which structure **19** could be assigned. Formation of **19** can be rationalized as depicted in Scheme 5. The well-known ring opening of cyclopropenes to vinyl carbenes (15) is the first step, forming **17** and its geometric isomer, not shown. Both carbenes presumably revert to **12** (15*a*) but **17**

[3]Except to exclude **7**, **8**, and **10** as reaction products and to confirm that a major product was acetone.

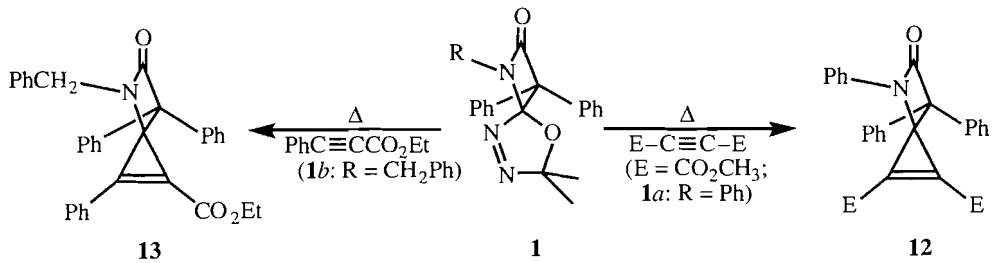

SCHEME 4

also inserts into a phenyl CH bond to form **18**, which undergoes allylic rearrangement to the more stable **19**. That carbene attack had occurred on a *C*-phenyl and not on the *N*-phenyl group was clear from the mass spectrum, which did not contain the signal for diphenylketene radical cation characteristic of **1**, **12**, and **13**. The infrared spectrum showed that the β-lactam ring had remained intact (1810 cm^{-1}) and both the uv spectrum as well as the ^1H and ^{13}C nmr spectra indicated that the product cannot have structure **18**. Although **18** would appear to be a necessary intermediate, isomerization to the more stable **19** is not surprising given that the H moiety that migrates is allylic, benzylic, and ester-activated in **18**.

Experimental

2-Phenylimino-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline, **5**a, *and 2-benzylimino-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline,* **5**b

These compounds were prepared from the appropriate 4-substituted semicarbazones of acetone as described in the literature (2).

*1,7,8-Triaza-6,6-dimethyl-5-oxa-2-oxo-1,3,3-triphenyl-spiro[3.4]oct-7-ene (**1**a)*

To a solution of **5***a* (0.96 g, 2.5 mmol) and triethylamine (6.0 mmol) in dry methylene chloride (20 mL) under nitrogen at ca. −23°C was added, drop by drop, a solution of diphenylacetyl chloride (0.69 g, 3.0 mmol) in dry methylene chloride (10 mL). The cold solution was stirred during the addition and, thereafter, overnight after the cold bath had been removed. The solution was washed with saturated sodium bicarbonate solution and with brine and the aqueous layers were extracted twice with methylene chloride. The combined organic layers were dried over $MgSO_4$. Filtration and evaporation of the solvent afforded β-lactam **1***a* in nearly pure form. Centrifugal chromatography (Chromatotron, 2-mm silica-coated plate, elution with ether (1 part) in hexanes (4 parts)) afforded pure **1***a* (90%), mp 154°C; ir (KBr) cm^{-1}: 1770 (C=O), 1595 (N=N); ^1H nmr (500 MHz, $CDCl_3$) δ: 1.38 (s, 3H), 1.39 (s, 3H), 7.10–7.50 (m, 15H); ^{13}C nmr (126 MHz, $CDCl_3$) δ: 24.30 (CH_3), 24.40 (CH_3), 76.13 (C3), 122.61 (C6), 125.17 (C4), 123.27, 127.57, 128.02, 128.33, 128.42, 128.69, 128.75, 129.39 (8 aryl CH), 133.38 (C1 of Ar), 134.61 (C1 of Ar), 136.39 (N-C1 of Ar), 166.80 (C=O); ms (ei, low resolution) *m/z*: 355 (M − N_2, 1%), 269 (M − N_2 − C_3H_6O, 68%), 236 (M − N_2 − PhNCO, 7%),

194 (Ph_2CCO, 60%), 119 (PhNCO, 35%), 165 ($C_{13}H_9$ = 9-fluorenyl, 100%); ms(ci, NH_3) *m/z*: 384 (M + 1, 100%); structure confirmed by single crystal X-ray diffraction.

*1,7,8-Triaza-1-benzyl-6,6-dimethyl-5-oxa-2-oxo-3,3-diphenylspiro[3.4]oct-7-ene (**1**b)*

The procedure described above gave, from **5***b* and diphenylacetyl chloride, spiro-β-lactam oxadiazoline **1***b* in 80% yield as a white solid, mp 101–102°C; ir (KBr) cm^{-1}: 1770 (C=O), 1600 (N=N); ^1H nmr (500 MHz, $CDCl_3$) δ: 1.35 (s, 3H), 1.45 (s, 3H), 4.53 (d, *J* = 15 Hz, 1H), 4.66 (d, *J* = 15 Hz, 1H), 7.20–7.55 (m, 15H); ^{13}C nmr (126 MHz, $CDCl_3$) δ: 24.32 (CH_3), 24.67 (CH_3), 76.03 (C3), 122.31 (C6), 124.82 (C4), 127.65, 127.80, 128.00, 128.36, 128.41, 128.60, 128.73 (7 aryl CH), 135.13 (C1 of Ar), 135.36 (C1 of Ar), 136.80 (C1 of Ar), 168.53 (CO); ms (ei) *m/z*: 397 (M, 3%), 341 (M − N_2 − CO, 11%), 265 (9%), 236 (18%), 194 (Ph_2CCO, 100%), 165 ($C_{13}H_9$, 9-fluorenyl, 83%), 132 (30%), 91 ($PhCH_2$, 87%); ms (ci, NH_3) *m/z*: 415 (M + NH_4, 28%), 398 (M + 1, 100%), 360 (11%), 345 (27%), 302 (71%), 267 (20%), 206 (32%), 194 (Ph_2CCO, 17%), 167 (43%), 108 (15%), 99 (40%).

*Thermolysis of β-lactam oxadiazolines in presence of alkynes. Preparation of **12** and **13***

For the preparation of **12**, a solution of spiro-β-lactam oxadiazoline **1***a* (0.038 g, 0.10 mmol) and dimethyl acetylenedicarboxylate (0.14 g, 1.0 mmol) in benzene (0.25 mL), in a medium-walled nmr tube sealed to a ground glass joint, was degassed by means of three freeze–pump–thaw cycles at 10^{-2} Torr (1 Torr = 133.3 Pa). The tube was sealed and immersed in an oil bath, maintained at 100 ± 0.2°C, for 10 h. Bulb-to-bulb transfer of the excess alkyne and benzene (vacuum line) left a residue that was chromatographed on silica (Chromatotron, 2-mm plate) using ether (25%) in hexane for elution.

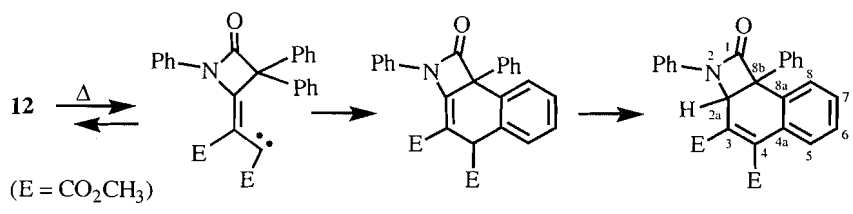
Compound **13** was prepared by the same procedure, from **1***b* and ethyl phenylpropiolate.

*4-Aza-1,2-bis(methoxycarbonyl)-5-oxo-4,6,6-triphenylspiro[2.3]hex-1-ene (**12**)*

Yellow solid, 33% yield; mp 128–129°C; ir (KBr) cm^{-1}: 1720, 1730 (2 × CO, ester), 1750 (CO, lactam); uv (CH_2Cl_2), λ_{max}: 248 nm (log ε = 4.32); ^1H nmr (500 MHz, $CDCl_3$), δ: 3.75 (s, 6H), 7.11–7.46 (m, 15H); ^{13}C nmr (126 MHz, $CDCl_3$) δ: 53.43 (OCH_3), 64.13 (C3 or C6), 66.03 (C6 or C3), 119.81 (C1, C2); 125.55, 127.24, 127.79, 128.02, 128.53, 129.46 (6 aryl C), 135.82 (N − C1, Ar), 137.00 (2C1, Ar), 158.33 (2CO, ester), 167.63 (CO, lactam); ms (EI) *m/z*: 439 (M, trace), 411 (M − CO, 11%), 379 (13%), 348 (18%), 320 (M − PhNCO, 100%), 293 (24%), 249 (13%), 178 (31%), 165 ($C_{13}H_9$ = 9-fluorenyl, 73%), 119 (PhNCO, 15%), 77 (47%), ms (CI, NH_3), *m/z*: 457 (M + NH_4, 16%), 440 (M + 1, 100%), 410 (23%), 382 (5%), 352 (6%), 323 (7%), 294 (6%), 246 (5%), 167 (28%), 119 (10%), 94 (12%); confirmation of structure by single crystal X-ray diffraction.

*4-Aza-4-benzyl-1-ethoxycarbonyl-5-oxo-2,6,6-triphenylspiro[2.3]hex-1-ene (**13**)*

Yellow oil, 35% yield; ir (film) cm^{-1}: 1710 (CO, ester), 1745 (CO, lactam); ^1H nmr (200.1 MHz, $CDCl_3$) δ: 1.26 (t, *J* = 7.2 Hz, 3H), 4.04–4.41 (m, 4H, CH_2Ph and CH_2CH_3), 701–7.46 (m, 20H); ^{13}C nmr (50.32 MHz, $CDCl_3$) δ: 14.08 (CH_3), 43.02 ($PhCH_2$), 60.92 (C6), 61.45 (OCH_2), 70.97 (C3), 112.51 (C1), 125.00 (C2); 127.16, 127.29, 127.32, 127.50, 127.67, 128.29, 128.35, 128.56, 128.69, 131.50, 131.70, (11 aryl C); 135.97, 137.24, 138.20, 138.69 (4 × C1 of Ar), 159.46 (CO, ester), 169.55 (CO, lactam); ms (EI), *m/z*: 485 (M, 6%), 457 (M − CO, 9%), 384 (M − CO − CO_2Et, 7%), 352 (M − $PhCH_2NCO$, 19%), 322 (12%), 194 (Ph_2CCO, 11%), 165 ($C_{13}H_9$ = 9 − fluorenyl, 27%), 133 (Ph-CH_2NCO, 29%), 105 (22%), 91 ($PhCH_2$, 100%); ms (CI, NH_3), *m/z*: 503 (M + NH_4, 3%), 486 (M + 1, 100%), 353 (M − Ph-CH_2NCO − H, 5%), 167 (17%), 108 (18%), 91 (20%); ms (HR), *m/z*: calcd. for $C_{33}H_{27}NO_3$: 485.1991; found: 485.2000.



SCHEME 5

*3,4-bis(Methoxycarbonyl)-2,8b-diphenyl-2a,8b-dihydro-[2,1-b]azet-1(2H)one (**19**)*

Thermolysis of **12** (0.86 g, 1.95 mmol) was carried out in dry degassed benzene (5 mL) in a sealed tube. The tube was heated with refluxing anisole (154°C). After about 3 min the solution turned from pale yellow to dark green but the yellow colour returned on cooling the contents of the tube to room temperature. After 4 h of heating, the green colour, presumably from a reactive intermediate, faded, and the solution was again yellow. After heating for 4 additional hours the tube was opened, the solvent was evaporated, and the residue was examined by tlc to reveal two fluorescent spots and some highly polar material. Centrifugal chromatography (Chromatotron, 2-mm silica plate) using ether (25%) in hexane gave the least polar fluorescent material as a white solid, mp 165–166°C, in 25% yield; ir (KBr) cm^{-1}: 1685 (C=C), 1712 (CO, ester), 1732 (CO, ester), 1810 (CO, lactam); uv (λ_{max}, CH_2Cl_2) nm: 232 (log ε = 4.16), 258 (log ε = 4.05); ^1H nmr (200.1 MHz, $CDCl_3$) δ: 3.50 (s, 3H, OMe), 3.73 (s, 3H, OMe), 4.96 (s, 1H, CH), 7.22–7.56 (m, 14H); ^{13}C nmr (126 MHz, $CDCl_3$) δ: 44.11 (C2a), 51.11 (OMe), 52.74 (OMe), 78.12 (+ve, C8b), 98.87 (+ve, C3), 121.16 (+ve, Ar), 117.18 to 130.94 (series of 10 −ve Ar peaks), 130.26 (+ve, C4), 135.18 (+ve, Ar), 135.69 (+ve, Ar), 150.64 (+ve, C4a), 164.70 (+ve, CO), 165.41 (+ve, CO), 171.89 (+ve, CO lactam; ms (EI), *m/z*: 439 (M, 3%), 411 (M − CO, 5%), 380 (M − CH_3CO_2, 26%), 352 (M − CO − CH_3CO_2, 100%), 320 (M − PhNCO, 38%), 291 (15%), 160 (8%), 84 (35%); ms (CI, NH_3), *m/z*: 457 (M + NH_4, 100%), 440 (M + 1, 40%), 412 (M + 1 − CO, 40%), 380 (22%), 352 (40%), 320 (9%),; ms (HR), *m/z*: calcd. for $C_{27}H_{21}NO_5$: 439.1420; found: 439.1418.

Cycloaddition reactions of $SNSAsF_6$ with aryl nitriles and diphenylacetylene; the preparation and characterization of aryl 1,3,2,4- and 1,2,3,5-dithiadiazole radicals

JACK PASSMORE,[1] XIAOPING SUN, AND SIMON PARSONS
Department of Chemistry, University of New Brunswick, Bag Service no. 45222, Fredericton, N. B., Canada E3B 6E2

Received June 2, 1992

JACK PASSMORE, XIAOPING SUN, and SIMON PARSONS. Can. J. Chem. **70**, 2972 (1992).

The SNS^+ cation (in $SNSAsF_6$) underwent symmetry-allowed concerted cycloadditions with the aryl nitriles RCN (R = 2,5-$Me_2C_6H_3$, Ph, *p*-$O_2NC_6H_4$, and 3,5-$(O_2N)_2C_6H_3$) and diphenylacetylene. The cycloadducts $RCNSNSAsF_6$ (R = 2,5-$Me_2C_6H_3$, Ph, *p*-$O_2NC_6H_4$, and 3,5-$(O_2N)_2C_6H_3$) and $PhCSNSCPhAsF_6$ were characterized by elemental analyses and IR and NMR (^1H, ^{13}C, ^{14}N) spectroscopies. The reduction of $RCNSNS^+$ gave the corresponding 1,3,2,4-dithiadiazoles RCNSNS·, which in turn rearranged to the corresponding 1,2,3,5-dithiadiazoles RCNSSN·. The rate of this rearrangement was correlated with the ionization potentials of the corresponding nitriles. The radicals RCNSNS· (R = Ph, *p*-$O_2NC_6H_4$) were isolated as pure compounds, and characterized by mass spectrometry, IR, FT-Raman, and ESR spectroscopies. The reduction of $PhCSNSCPh^+$ led to neutral radical PhCSNSCPh·, which is stable in solution up to ca. 0.5 M, but decomposes at higher concentrations.

JACK PASSMORE, XIAOPING SUN et SIMON PARSONS. Can. J. Chem. **70**, 2972 (1992).

Le cation SNS^+ (du $SNSAsF_6$) donne des cycloadditions concertées, permises par la symétrie, avec les nitriles aromatiques RCN (R = 2,5-$Me_2C_6H_3$, Ph, *p*-$O_2NC_6H_4$ et 3,5-$(O_2N)_2C_6H_3$) et le diphénylacétylène. On a caractérisé les cycloadduits $RCNSNSAsF_6$ (R = 2,5-$Me_2C_6H_3$, Ph, *p*-$O_2NC_6H_4$ et 3,5-$(O_2N)_2C_6H_3$) et $PhCSNSCPhAsF_6$ grâce aux analyses élémentaires et par spectroscopies IR et RMN du ^1H, du ^{13}C et du ^{14}N. La réduction des cations $RCNSNS^+$ fournit les 1,3,2,4-dithiadiazoles RCNSNS· correspondants qui, à leur tour, se réarrangent en 1,2,3,5-dithiadiazoles RCNSSN· correspondants. Il existe une corrélation entre la vitesse de cette transformation et les potentiels d'ionisation des nitriles correspondants. On a isolé les radicaux RCNSNS· (R = Ph, *p*-$O_2NC_6H_4$) à l'état pur et on les a caractérisé par spectrométrie de masse et par spectroscopie IR, Raman-TF et RPE. La réduction du cation $PhCSNSCPh^+$ conduit au radical neutre PhCSNSCPh· qui est stable en solution jusqu'à une concentration d'environ 0,5 M; toutefois, à des concentrations plus élevées, il se décompose.

[Traduit par la rédaction]

Introduction

We previously showed (1–5) that SNS^+ (as the AsF_6^- salt) undergoes extensive, quantitative, symmetry-allowed cycloaddition reactions with aliphatic alkynes, nitriles, alkenes, and SN^+. In this paper we report the cycloaddition reactions of SNS^+ with aryl nitriles and diphenylacetylene, which give $RCNSNSAsF_6$ (R = 2,5-$Me_2C_6H_3$, Ph, *p*-$O_2NC_6H_4$, and 3,5-$(O_2N)_2C_6H_3$) and $PhCSNSCPhAsF_6$. The quantitative kinetic aspects of these reactions have been reported elsewhere (5).

Reduction of the alkyl derivatives of $RCNSNS^+$ led to the corresponding neutral 7π radicals RCNSNS·, but at higher concentrations RCNSNS· rearranged to the thermodynamically more stable 7π radicals RCNSSN· (2, 6, 7). However, we were able to isolate small amounts of CH_3CNSNS· at low temperature (6) and the paramagnetic liquid Bu^{t}CNSNS· in the dark (7). Since then, some related diradicals have been prepared (8). We were interested in understanding RCNSNS· and its novel rearrangement to RCNSSN·. Therefore we attempted the preparation and isolation of the aryl derivatives of RCNSNS· and investigated the dependence of the rearrangement rate on the nature of the substituent. The results are reported below.

Reduction of alkyl derivatives of $R'CSNSCR''^+$ in dilute solution gave the corresponding 7π radicals R′CSNSCR″· (1, 9). At higher concentrations a large number of diamagnetic products were detected (1, 9), except in the case of $CF_3CSNSCCF_3$, which was isolated as a thermally stable green liquid under a blue gas (10). Since then NCCSNSCCN· has been prepared (11) by a different route. The related radical benzo-1,3,2-dithiazole is stable (12), as well as other more complex derivatives (e.g., benzobisdithiazole) (13). The preparation of PhCSNSCPh· in solution at high concentration and a study of its stability is reported below.

Experimental

Unless otherwise specified, reagents and techniques used are as described in ref. 5. The purity of the reagents RCN (R = 2,5-$Me_2C_6H_3$, Ph, *p*-$O_2NC_6H_4$, and 3,5-$(O_2N)_2C_6H_3$) and PhCCPh (Aldrich Chemical Company) was established by their infrared and NMR (^1H, ^{13}C and ^{14}N) spectra. $SNSAsF_6$ and $H_2CSNSCH_2AsF_6$ were prepared as described (3, 14). The multinuclear NMR (^1H, ^{13}C, ^{14}N) spectra were obtained as described (15). IR spectra were obtained as Nujol mulls with KBr plates in the 4000–200 cm^{-1} region using a Perkin–Elmer 683 IR spectrometer. ESR spectra were recorded at room temperature with a locally modified version of the Varian E-4 spectrometer using DPPH as a field marker. The FT-Raman spectra were acquired on solid samples in a 5-mm NMR

tube using the FT-IR spectrometer IFS 66 (Bruker) equipped with the FT-Raman accessory FRA 101 using the 1.064 μm exciting line of a Nd: YAG laser (70 mW; resolution: 2 cm^{-1}; 300 scans). The mass spectra were obtained at room temperature in the electron-impact mode using 70 eV ionizing voltage on a Kratos MS-50TC instrument.

All the reactions were performed in liquid SO_2 in a two-bulbed reaction vessel, incorporating a sintered glass frit and J. Young Teflon valve. ESR spectra were obtained using a rigorously dried 4-mm quartz tube connected via a J. Young valve. Reactions carried out *in situ* were quickly warmed up to room temperature to prevent tube breakage.

Preparation of aryl $\overline{RCNSNS}AsF_6$ *(R = 2,5-*$Me_2C_6H_3$*, Ph, p-*$O_2NC_6H_4$*, and 3,5-*$(O_2N)_2C_6H_3$*) and* $\overline{PhCSNSCPh}AsF_6$ *by the reactions of* $SNSAsF_6$ *with RCN or PhCCPh*

Liquid nitriles RCN (R = 2,5-$Me_2C_6H_3$ and Ph) were dissolved in SO_2, and the solutions poured onto $SNSAsF_6$; in the case of solid nitriles RCN (R = *p*-$O_2NC_6H_4$ and 3,5-$(O_2N)_2C_6H_3$) and PhCCPh, SO_2 was condensed onto the solid mixtures of $SNSAsF_6$ and the corresponding nitriles or PhCCPh at −196°C, and the mixtures warmed up to room temperature. These five reactions led to intensely coloured solutions as shown in Table 1. The colour change for 2,5-$Me_2C_6H_3CN$ and PhCCPh took place within the specified apparent reaction times (Table 1). In the case of PhCN, the first colour change from clear yellow to dark green took place quickly after the two reactants were mixed at room temperature, the second colour change from dark green to brown occurred in 2 h. For *p*-$O_2NC_6H_4CN$ and 3,5-$(O_2N)_2C_6H_3CN$, the colour change took place immediately with rapid dissolution of the nitriles after the reactants were mixed at room temperature. However, the $SNSAsF_6$ did not completely dissolve until the indicated reaction times (Table 1). All the products (except $\overline{PhCSNSCPh}AsF_6$) were recrystallized *in situ* as previously described (1, 5), giving purified crystals of $\overline{RCNSNS}AsF_6$ with different colours in the different yields (Table 1), which were characterized by chemical analyses (Table 1), IR (Table 2), and multinuclear NMR (Table 3). In the case of $\overline{PhCNSNS}AsF_6$, the trace amounts of dark green and brown impurities were removed by more than 10 recrystallizations, leading to a pure bright yellow product.[2] In other cases, fewer recrystallizations were needed to remove the intensely coloured impurities. The decomposition points of the first four products are all ca. 213 ± 3°C. The IR and ^1H NMR spectra of the impure fractions were identical to those of the corresponding pure fractions except that NH_4 peaks (only ca. 0.1 wt.%) were also observed in the ^1H NMR spectra (6.07 ppm, 1:1:1 triplet, $^1J(H-^{14}N)$ = 109.1 Hz) of the impure fractions. Traces of other impurities were not observed (^1H NMR) in reactions carried out *in situ*. The gross yields (pure + impure) for all the five preparations were higher than 95%.

The preparation of $\overline{PhCSNSCPh}AsF_6$ *by the reaction of PhCCPh with* $\overline{H_2CSNSCH_2}AsF_6$

SO_2 (5.35 g) was condensed onto a mixture of PhCCPh (0.089 g, 0.5 mmol) and $\overline{H_2CSNSCH_2}AsF_6$ (0.296 g, 1.0 mmol), giving a brown solution, which was stirred for 24 h. The volatiles were removed, leaving a brown solid (0.391 g) (^1H NMR in SO_2 with CH_2Cl_2 internal concentration standard: 7.8 ($\overline{PhCSNSCPh}^+$, multiplet, 10H), 3.7 and 3.1 ($S_2N(C_2H_4)_2^+$, d, *J* = 6.6 Hz, 8H). The brown solid was extracted four times with CH_2Cl_2 (4.66 g). After removal of the solvent it gave a brown soluble amorphous solid and a white insoluble solid (identified as $S_2N(C_2H_4)_2^+$ by IR). The brown solid was identified as $\overline{PhCSNSCPh}AsF_6$ by its IR spectrum: 1596(mw), 1578(w), 1496(mw), 1437(sh), 1421(m), 1311(vw), 1291(mw), 1181(w), 1151(w), 1095(w), 1088(sh), 1078(m), 1046(vw), 1032(vw), 1024(w), 1002(w), 969(w), 836(w), 794(m), 769(m), 757(ms), 690(s,$\nu_3AsF_6^-$), 679(sh), 669(sh), 626(w), 579(w), 541(w), 524(w), 464(w), 390(s,

[2] $\overline{PhCNSNS}AsF_6$ was simultaneously prepared elsewhere, but reported (16) to be green.

[b]Based on the assignments of the symmetric stretches, the asymmetric stretches are then assigned according to Banister's equation (17) $\nu_{asym} = 1.51\ \nu_{sym} - 73.1$.

$\nu_4AsF_6^-$). The ^{13}C NMR spectrum of a similar reaction carried out in 1:1 stoichiometry in a 10-mm NMR tube showed resonances at 183.9, 134.4, 131.2, 130.3, 123.3 (Ph$\overline{CSNSC}Ph^+$, see Table 3); 132.5, 129.8, 129.7, 123.5, 91.5 (PhCCPh), and 46.8 ppm ($S_2N(C_2H_4)_2^+$ (3)).

The generation and ESR study of 4-aryl-1,3,2,4-dithiadiazoles $R\overline{CNSNS}\cdot$ *(R = 2,5-$Me_2C_6H_3$, Ph, p-$O_2NC_6H_4$, 3,5-$(O_2N)_2C_6H_3$)*

SO_2 (0.100 g) and $CFCl_3$ (0.500 g) were successively condensed onto a mixture of $R\overline{CNSNS}AsF_6$ (7 mg), $SbPh_3$ (7 mg), and NMe_4Cl (7 mg) in an ESR tube, giving a blue solution of $R\overline{CNSNS}\cdot$ ($(3.0 \pm 0.5) \times 10^{-2}$ M) at room temperature. A duplicate set of samples was also prepared. One set of the samples was continuously exposed to room light, while the other set was kept in the dark. ESR spectra of both sets of samples were recorded at room temperature once every 1 or 2 days until the rearrangement was completed as indicated by the yellow colour of all the solutions. The results are given in Table 4, and the data for the rearranged disulfides are given in Table 5.

ESR study of the rearrangement of $R\overline{CNSNS}\cdot$ *(R = 2,5-$Me_2C_6H_3$, Ph, p-$O_2NC_6H_4$, 3,5-$(O_2N)_2C_6H_3$) to* $R\overline{CNSSN}\cdot$ *in the solid state*

SO_2 (0.5 g) was condensed onto a solid mixture of $R\overline{CNSNS}AsF_6$ (7 mg), $SbPh_3$ (7 mg), and NMe_4Cl (7 mg) at −196°C. The samples were rapidly warmed up to room temperature and after 3 min the solvent was quickly removed under dynamic vacuum with solutions kept in the dark at all times. The solid mixtures (containing $R\overline{CNSNS}\cdot$) were exposed to room light for 1 or 2 days and then dissolved in a mixture of SO_2 (0.100 g) and $CFCl_3$ (0.500 g) (in the dark). Their ESR spectra were recorded immediately. The solvent was quickly removed (in the dark) and the above procedure was repeated on each of the samples until the rearrangement was completed. The spectral data are shown in Table 4.

Preparation of $R\overline{CNSNS}\cdot$ *(R = Ph, p-$O_2NC_6H_4$) by reduction of* $R\overline{CNSNS}^+$

$Ph\overline{CNSNS}\cdot$: SO_2 (6.30 g) was condensed onto the solid mixture of $Ph\overline{CNSNS}AsF_6$ (0.881 g, 2.38 mmol) and $Na_2S_2O_4$ (0.873

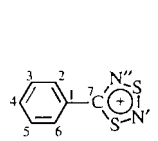
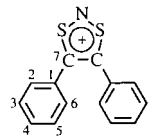
[a]Actual spectra deposited (see footnote 3). The ^{1}H NMR spectra of the aryl derivatives of $R\overline{CNSNS}^+$ and $Ph\overline{CSNSCPh}^+$ exhibit complex second-order multiplets due to aryl ring protons with the exception of 3,5-$(O_2N)_2C_6H_3\overline{CNSNS}^+$, which has a simple AX_2 type of coupling between *ortho* and *para* protons. These spectra indicate that both H2, H6 and H3, H5 are equivalent, respectively. Correspondingly, the ^{13}C spectra show the equivalence between C2 and C6 and between C3 and C5 (except 2,5-$Me_2C_6H_3\overline{CNSNS}^+$). The results suggest that the aryl rings of all the cycloadducts can freely rotate about C—C single bonds in solution at room temperature.

[b]C7 stands for the carbon atoms in the -$\overline{CNSNS}^+$ or -$\overline{CSNSC}^+$- rings. The carbon and hydrogen atoms in the aryl rings are numbered in accordance with IUPAC rules as shown, e.g., for $Ph\overline{CNSNS}^+$ and $Ph\overline{CSNSCPh}^+$:



$Ph\overline{CNSNS}^+$



$Ph\overline{CSNSCPh}^+$

g, 5.01 mmol) at −196°C and then the reactants warmed up to room temperature and stirred overnight in the dark. The colour of the solution became near-black. The soluble material was poured through a frit into the other bulb and the SO_2 was removed by evacuation at −15°C. Black crystalline $Ph\overline{CNSNS}\cdot$ (0.375 g, 2.07 mmol) was recovered with a yield of 87%. IR:[3] 1597w, 1502vw, 1406vw, 1334w, 1227w, 1178w, 1152vw, 1099w, 1074w, 1056vw, 1027m, 1000w, 984w, 970w, 929m, 914m, 825w, 800w, 776s, 765s(sh), 757s, 705s, 680vs, 650m, 634m, 605w, 595m, 542w, 508m, 395s cm^{-1}. EI mass spectrum (*m/e* (int%)>7%): 181 (M^+, 70), 135 ($PhCNS^+$, 27), 103 ($PhCN^+$, 100), 78 (SNS^+, 47). ESR: identical to that of $Ph\overline{CNSNS}\cdot$ generated in 4-mm ESR tube *in situ* (see Table 4).

p-*$O_2NC_6H_4\overline{CNSNS}\cdot$*: SO_2 (12.9 g) was condensed onto the solid mixture of *p*-$O_2NC_6H_4\overline{CNSNS}AsF_6$ (1.288 g, 3.10 mmol), $SbPh_3$ (1.011 g, 2.86 mmol), and Me_4NCl (0.989 g, 9.02 mmol) at −196°C. The contents were warmed up to room temperature. The colour of the solution, which contained $SbPh_3Cl_2$ and Me_4NCl, became brown very quickly, and a black solid (insoluble in SO_2, $CFCl_3$, and C_6H_6) was formed. The reactants were stirred for 10 min at room temperature in the dark to allow the reduction to be completed, but to avoid any rearrangement taking place. The black powder was washed five times with SO_2 to remove the coloured solubles and then the colour of the solution became very light. The SO_2 was removed by evacuation and the black powdered *p*-$O_2NC_6H_4\overline{CNSNS}\cdot$ (0.589 g, 2.60 mmol) was recovered in the yield of 84%. IR:[3] 3100w, 3070w, 3053vw, 2722w, 2351vw, 1912vw, 1682vw, 1605ms, 1595ms, 1574w, 1524vs, 1503w, 1487w, 1408m, 1342vs, 1322m, 1310m, 1298w, 1227w, 1113m, 1105m, 1008w, 961w, 933ms, 855s, 850s, 824w, 792m, 751s, 705s, 683s, 651m, 613w, 592m, 542vw, 461m, 393vw cm^{-1}. FT-Raman:[3] 654.0vw, 721.9vw, 796.3s, 1105.3vw, 1181.6m, 1341.7w, 1405.7s, 1478.9m, 1506.5vs, 1515.4vs, 1595.5vs, 2392.6vw, 2819.0vw, cm^{-1}. EI mass spectrum (*m/e* (int%)>4%): 226 (M^+, 24.4), 180 ($M^+ - NO_2$, 5.4), 148 (*p*-$O_2NC_6H_4CN^+$, 4.2), 134 (*p*-$O_2NC_6H_4C^+$, 4.8), 102 ($C_6H_4CN^+$, 12.3), 78 (SNS^+, 100). Elemental anal. (%) calcd.: C 37.2, H 1.8, N 18.6, S 28.3; found: C 37.1, H 1.9, N 18.6, S 28.5. ESR: The spectrum was obtained in

saturated $CFCl_3$ solution at room temperature, and was identical to that of p-$O_2NC_6H_4$CNSNS· generated in a 4-mm ESR tube *in situ* (see Table 4).

Preparation of RCNSSN· (R = Ph, 3,5-$(O_2N)_2C_6H_3$) by the rearrangement of RCNSNS·

PhCNSSN·: SO_2 (5.24 g) was condensed onto $Na_2S_2O_4$ (0.325 g, 1.87 mmol) and PhCNSNSAsF_6 (R = Ph) (0.343 g, 0.927 mmol). The colour of the solution changed from yellow to dark brown after 10 min at room temperature, but the solution was stirred for 20 h to allow complete reduction and rearrangement. The SO_2 was then removed by evacuation and the soluble material extracted with dry benzene into the second bulb, giving a black crystalline product PhCNSSN· (0.13 g) in 81% recovered yield (IR and mass spectrum (19), ESR (18)). FT-Raman:[3] 3064.1s, 3010.7vw, 2136.2vw, 1915.4vw, 1673.8vw, 1599.4vs, 1553.6w, 1498.6m, 1375.2s, 1363.0m, 1325.0m, 1268.3w, 1159.1w, 1140.4vw, 1026.9w, 1003.3s, 805.6m, 777.2m, 662.9m, 618.5w, 508.7w, 473.0w, 430.5m (S–S stretch),[4] 310.8m, 263.5w, 219.6m, 152.9m, 116.9s cm^{-1}.

3,5-$(O_2N)_2C_6H_3$CNSSN·: SO_2 (4.33 g) was condensed onto the solid mixture of 3,5-$(O_2N)_2C_6H_3$CNSNS AsF_6 (0.518 g, 1.12 mmol), $SbPh_3$ (0.285 g, 1.86 mmol), and Me_4NCl (0.265 g, 2.43 mmol) at −196°C. The contents were warmed up to room temperature, the colour of the solution (which contained $SbPh_3Cl_2$ and Me_4NCl) became brown very quickly, and black solid was precipitated. The reactants were stirred for 10 min at room temperature to allow the reduction to be completed. The black powder was washed five times with SO_2 to remove the coloured solubles and then the colour of the solution became very light. The SO_2 was pumped off and the black powder of rearranged 3,5-$(O_2N)_2C_6H_3$CNSSN· was recovered. Mass spectrum (*m/e* (int%)): 271 (M^+, 100), 225 (M^+ − SN or NO_2, 70), 193 (3,5-$(O_2N)_2C_6H_3CN^+$, 44), 179 ($M^+ - N_2S_2$, 75), 147 ($O_2NC_6H_3CN^+$, 16), 101 ($C_6H_3CN^+$, 33), 78 (SNS^+, 66). ESR: the spectrum was acquired in $CFCl_3$ solution at room temperature and was identical to that of 3,5-$(O_2N)_2C_6H_3$CNSSN· generated *in situ* (see Table 5).

Preparation and stability of PhCSNSCPh·

In an initial experiment, SO_2 was condensed onto a mixture of PhCSNSCPhAsF_6 (ca. 1 mg), $SbPh_3$, and NMe_4Cl in an ESR tube. After allowing the reduction to proceed for 4 min the SO_2 was removed by dynamic vacuum, and replaced with degassed $CFCl_3$. The ESR spectrum at room temperature was the same as reported previously for PhCSNSCPh· (hyperfine coupling constants: ^{14}N, 10.71 G: ^{15}N, 15.02 G; ^{33}S, 3.92 G: g = 2.0065).

PhCSNSCPh· is transparent royal blue in dilute $CFCl_3$ solution, but opaque deep green when concentrated. In an attempt to prepare 1 M solution of PhCSNSCPh·, SO_2 was condensed onto a

[4]ν_{S-S} = 432.3 cm^{-1} based on Steudel's equation (20): d_{S-S} = 2.53 − (1.041 × 10^{-3}) ν_{S-S} ($300 < \nu_{S-S} < 530$); d_{S-S} = 2.08 Å for PhCNSSN· (23).

mixture of $PhCSNSCPhAsF_6/S_2N(C_2H_4)_2AsF_6$ (1.549 g, containing 2.0 mmol of $PhCSNSCPhAsF_6$), $SbPh_3$ (0.708 g, 2.01 mmol), and NMe_4Cl (0.538 g, 4.91 mmol), giving a brown solution, which was stirred in the dark for 30 min. The SO_2 was removed, leaving a brown solid lump, which was stirred in the dark with $CFCl_3$ (20 mL) overnight to extract the $PhCSNSCPh\cdot$. The deep green solution was filtered into a second bulb (where several flakes of a black precipitate began to form), and then into an NMR tube (containing 0.015 g of CH_2Cl_2 as an internal concentration standard), and an ESR tube. The samples were kept frozen at −196°C until the first spectra were acquired (at room temperature). Then on storing at −20°C, a thin grey film slowly formed on the walls of the tubes. The ESR spectrum of the solution was monitored over 600 h. The intensities (arbitrary units) of the ESR signal (determined by double integration of the spectra) varied with time (after the addition of SO_2): 15.5 h, 7.1; 88.9 h, 6.0; 155.9 h, 4.5; 256.4 h, 4.1; 417.4 h, 4.1; 615.8 h, 4.1. The ^1H NMR spectrum of the solution exhibited resonances due to $SbPh_3Cl_2$ (8.4 ppm, multiplet), $SbPh_3$ (7.9 ppm, multiplet), NMe_4^+ (1.8 ppm, singlet), and some radical decomposition products (7.6 ppm, multiplet). The intensities of these resonances did not change relative to that of the CH_2Cl_2 internal standard over 49 days.

Results and discussion

The cycloaddition reactions between SNS^+ and aryl nitriles and PhCCPh

The reactions of $SNSAsF_6$ with the aryl nitriles RCN (R = 2,5-$Me_2C_6H_3$, Ph, *p*-$O_2NC_6H_4$, and 3,5-$(O_2N)_2C_6H_3$) and PhCCPh gave analytically and spectroscopically pure cycloaddition products $RCNSNSAsF_6$ and $PhCSNSCPhAsF_6$, which were established by good elemental analyses (Table 1) and IR (CN, SN, CS, and AsF_6^- vibrations, Table 2) and multinuclear NMR (^1H, ^{13}C and ^{14}N, Table 3) spectroscopies. Although the initial unpurified products were highly coloured, the experimental results show that only traces of impurity were formed.[5] Therefore the aryl rings in $RCNSNS^+$ (R = 2,5-$Me_2C_6H_3$, Ph, *p*-$O_2NC_6H_4$ and 3,5-$(O_2N)_2C_6H_3$) and $PhCSNSCPh^+$ essentially remain intact during the cycloaddition reactions, and the cycloadditions between SNS^+ and aryl nitriles and PhCCPh are essentially quantitative symmetry-allowed cycloaddition reactions (5).

The NMR spectra of the cycloadducts showed aryl substituent resonances at higher frequency than in the corresponding unreacted nitrile due to the formation of the cationic rings. However, the identity of the ring systems is best established by the ^{13}C chemical shifts of C7 (202–205 ppm for the aryl derivatives of $RCNSNS^+$ and 184 ppm for $PhCSNSCPh^+$), which are characteristic for $-CNSNS^+$ and $-CSNSC-^+$ by comparison with the ^{13}C chemical shift values of related cations (5). The ^{14}N NMR spectrum of $PhCNSNS^+$ shows two broad peaks at −46 and 20 ppm, assignable to the two inequivalent nitrogen atoms in the five-membered ring. The peaks in the ^{14}N spectrum of 2,5-$Me_2C_6H_3CNSNS^+$ are broad and they appear to be superimposed. In the cases of $RCNSNS^+$ (R = *p*-$O_2NC_6H_4$ and 3,5-$(O_2N)_2C_6H_3$), the ^{14}N spectrum shows only one narrow asymmetric peak, presumably due to the superimposition of the resonances due to NO_2, N′, and N″. The ^1H and ^{13}C NMR spectra also show that there is free rotation of the aryl groups in solution at room temperature (see footnote (*a*) in Table 3).

We were unable to remove the traces of black impurity present in $PhCSNSCPhAsF_6$ given by the reaction of PhCCPh and $SNSAsF_6$. However, the material was analytically pure with IR and NMR (^1H, ^{13}C) identical to the pale brown material produced according to eq. [1]:

$$[1]\quad 2\,S_2N(C_2H_4)AsF_6 + PhCCPh \rightarrow PhCSNSCPhAsF_6 + S_2N(C_2H_4)_2AsF_6$$

Reaction [1] was shown to proceed quantitatively by an *in situ* ^{13}C NMR experiment. However, the isolated yield of $PhCSNSCPhAsF_6$ was lower than that in the direct cycloaddition reaction (100%) because of separation problems using CH_2Cl_2 as a solvent.

Aryl 1,3,2,4-dithiadiazole radicals and their rearrangements to 1,2,3,5-dithiadiazoles

Dilute solutions (ca. 10^{-2} M) of $RCNSNS\cdot$ (R = 2,5-$Me_2C_6H_3$, Ph, *p*-$O_2NC_6H_4$, 3,5-$(O_2N)_2C_6H_3$) were prepared according to reaction [2]:

$$[2]\quad RCNSNSAsF_6 + 1/2\,SbPh_3 + Me_4NCl \xrightarrow{SO_2/CFCl_3} RCNSNS\cdot + 1/2\,Ph_3SbCl_2 + Me_4NAsF_6$$

The radicals were identified by their ESR spectra, which showed *g* and a^N values very similar to those reported for the alkyl derivatives (6, 7); the spectral data are given in Table 4. Like the alkyl derivatives, they also undergo rearrangements to the corresponding disulfide isomers, the ESR parameters of which are given in Table 5. $RCNSNS\cdot$ (R = 2,5-$Me_2C_6H_3$ and Ph) (like the Bu′ derivative) only rearrange in the light. However, $RCNSNS\cdot$ (R = *p*-$O_2NC_6H_4$, 3,5-$(O_2N)_2C_6H_3$) (like the CF_3 derivative) rearrange in the dark, although at a much slower rate than in the light. The rates of rearrangement given in Table 4 can be correlated with the ionization potential of the RCN nitrile, and the electronegativity of R. This kind of correlation is also obtained for the aliphatic derivatives of $RCNSNS\cdot$ (R = CH_3, Bu′, CF_3, and I), i.e., the rearrangement rates of $RCNSNS\cdot$ follow the order Bu′ < CH_3 < CF_3 < I (6, 9). It is likely that the higher the electronegativity of R (which corresponds to a higher ionization potential of RCN and also of $RCNSNS\cdot$), the faster the rate of rearrangement of $RCNSNS\cdot$ to $RCNSSN\cdot$ (although on this basis the CF_3 derivative would have been expected to rearrange faster than the iodo derivative). This rearrangement has been quantitatively determined to be a bimolecular process for $RCNSNS\cdot$ (R = Ph,

[5]The highly coloured impurities may be produced from the slow side reaction of SNS^+ with the aryl rings of $RCNSNS^+$ (R = 2,5-$Me_2C_6H_3$, Ph, *p*-$O_2NC_6H_4$, and 3,5-$(O_2N)_2C_6H_3$) and $PhCSNSCPh^+$. A slow reaction is observed between SNS^+ and benzene to give highly coloured products (J. Passmore, M. J. Schriver, and X. Sun, unpublished results) (cf. reaction of ONO^+ with C_6H_6 (21)). The related cycloaddition reactions of SNS^+ with aliphatic nitriles and alkynes led to either colourless or yellow cycloadducts (1, 2, 5).

p-$O_2NC_6H_4$), which will be reported elsewhere).[6] Further studies of the rearrangement of RCNSNS· to RCNSSN· are in progress. We have prepared spectroscopically (IR, Raman, and ESR) pure PhCNSSN· by the quantitative rearrangement of PhCNSNS·. PhCNSSN· was first synthesized by Banister and co-workers (16, 19, 23) by the reduction of the corresponding cation. Since then various other RCNSSN· (e.g., CF_3 (24) and Me_2N (25)) have been synthesized by the same route. We have also synthesized RCNSSN· (R = Bu^t and CF_3) on a preparative scale by the quantitative rearrangement of the corresponding RCNSNS· (6). The rearrangement of 3,5-$(O_2N)_2C_6H_3$CNSNS·, like CF_3CNSNS·, was rapid, and we were unable to isolate it. The reduction of 3,5-$(O_2N)_2C_6H_3$CNSNS$^+$ on a preparative scale led directly to the precipitation of rearranged radical 3,5-$(O_2N)_2C_6H_3$CNSSN·, which was identified by ESR and mass spectrometry.

Isolation and properties of solid RCNSNS· (R = Ph, p-$O_2NC_6H_4$)

Although RCNSNS· undergoes facile rearrangement to RCNSSN·, we were able to isolate unrearranged radicals RCNSNS· (R = Ph, p-$O_2NC_6H_4$) as pure solid materials on a preparative scale by allowing them to quickly form in the solid state. Their identity was established by the combination of several experimental techniques, including mass spectrometry, ESR, IR and FT-Raman spectroscopies, and X-ray crystallographic analysis. The mass spectra of RCNSNS· (R = Ph, p-$O_2NC_6H_4$) showed intense SNS^+ (47% for Ph and 100% for p-$O_2NC_6H_4$ derivatives) and (or) RCN^+ (100% for Ph and 4% for p-$O_2NC_6H_4$[7] derivatives) peaks from the fragments for both of the radicals. This characteristic fragmentation pattern for RCNSNS· is supported by the observation of their photolysis into RCN and SNS· (22). Although the mass spectra of RCNSSN· gave peaks due to the fragments SSN (same m/e as SNS) and RCN, they were less intense than those of the corresponding molecular ions. The X-ray crystallographic analysis for PhCNSNS·[8] showed that its unit cell parameters and crystal system are completely different from those of the disulfide PhCNSSN· (23). In addition, PhCNSNS· also has different IR data from those of PhCNSSN· (19). The FT-Raman spectrum of p-$O_2NC_6H_4$CNSNS· did not give an S–S stretch, which was strong in PhCNSSN· at 430.5 cm^{-1}. This is, as far as we are aware, the first report of Raman spectra of these or related highly coloured radicals, now obtainable by using FT-Raman spectroscopy, which is likely to prove very useful in this and related areas. RCNSNS· (R = Ph, p-$O_2NC_6H_4$) are unambiguously characterized by their ESR spectral data (1:1:1 triplet for both derivatives) in solution, showing that the isolated solid compounds were unrearranged radicals RCNSNS· (R = Ph, p-$O_2NC_6H_4$). The crystallographic studies also showed that PhCNSNS· and PhCNSSN· possess essentially the same volumes of the molecular unit (389.9(1) Å^3 for PhCNSNS· and 382.4(1) Å^3 for PhCNSSN· (23)). This suggests that PhCNSNS· forms similar sulfur-based π^*–π^* dimers in the solid state as observed for PhCNSSN· (23). The attempted reduction of 2,5-$Me_2C_6H_3$CNSNS$^+$ resulted in an intractable tar.

RCNSNS· (R = 2,5-$Me_2C_6H_3$, Ph, p-$O_2NC_6H_4$, and 3,5-$(O_2N)_2C_6H_3$) not only undergo photochemical rearrangement in dilute solution, but also rearrange to RCNSSN· in the solid state in the light at room temperature. PhCNSNS· even completely rearranges to its disulfide isomer PhCNSSN·· in the solid state in the dark at −20°C after a week. We have also found that Bu^{t}CNSNS· completely rearranges to Bu^{t}CNSSN· in the liquid state in the dark at room temperature after ca. 20 h (7). Banister and co-workers (26) recently reported that p-C_6H_4(CNSNS)$_2$·· undergoes thermal rearrangement to its disulfide isomer p-C_6H_4(CNSSN)$_2$·· in the solid state at 150°C. All of these results suggest that this rearrangement is a general process for 1,3,2,4-dithiadiazoles in the solid state. Energetic difference obviously exists between the rearrangement of RCNSNS· to RCNSSN· in the light and in the dark. This suggests that the thermal rearrangement (low-energy process) may be related to a different reaction pathway from that of the photochemical rearrangement (high-energy process). p-$O_2NC_6H_4$CNSNS· is infinitely stable in the solid state in the dark at room temperature. However, the attempted crystal growth by sublimation at 90°C resulted in thermolysis to p-$O_2NC_6H_4$CN (detected by IR), presumably due to the loss of SNS· (22).

Generation and stability of PhCSNSCPh·

The PhCSNSCPh· was previously prepared in dilute solution by Sutcliffe and co-workers by the reaction of PhCCPh with S_4N_2, and characterized in dilute CCl_4 solution by ESR (27–31). We prepared it by the reduction of PhCSNSCPhAsF$_6$ with $SbPh_3$/NMe_4Cl according to eq. [3]:

$$[3]\quad \text{PhCSNSCPhAsF}_6 + 1/2\ \text{SbPh}_3 + \text{NMe}_4\text{Cl} \rightarrow \text{PhCSNSCPh·} + \text{NMe}_4\text{AsF}_6 + 1/2\ \text{SbPh}_3\text{Cl}_2$$

The ESR parameters obtained in this study were in good agreement with those obtained by Sutcliffe and co-workers (29–31).

PhCSNSCPh· decomposed to an insoluble diamagnetic solid when an attempt was made to isolate it. It is also unstable as a 1 M solution, decomposing to some soluble (^{1}H NMR) and insoluble products. The decomposition appeared

[6]N. Burford, J. Passmore, and X. Sun. Manuscript in preparation. See also ref. 22.

[7]The very low intensity of the p-$O_2NC_6H_4CN^+$ peak is conceivably attributed to the lower intensity of the M^+ peak than that of the Ph derivative and the more branched fragmentations of M^+ and p-$O_2NC_6H_4CN^+$ due to the existence of the nitro group.

[8]Crystallographic unit cell parameters for PhCNSNS·: monoclinic, a = 6.156(5) Å, b = 15.581(5) Å, c = 8.659(5) Å, $\alpha = \gamma = 90°$, β = 110.13(6)°, V = 779.8(1) Å^3, Z = 2, volume of molecular unit 389.9(1) Å^3. Determination of the full crystal structure was unsuccessful because of its crystallinity loss during attempted data collection, possibly due to the rearrangement on an irradiation by the X-ray beam.

to cease (in this case after 70 h) when the radical concentration reached a certain critical level, which we estimated to be about 0.5 M, by monitoring the intensity of the ESR signal of a 1 M solution of PhCSNSCPh· as a function of time in the dark. The stability of R′CSNSCR″· is comparable with that of its nitroxide analogue R′R″NO·. R_2NO· (R = Bu^t, CF_3) is a stable species (32, 33). Ph_2NO· is unstable and not isolable (33, 34), but it decomposes to diphenylamine and *N*-phenyl-*p*-benzoquinonime *N*-oxide in solution under normal preparative concentrations (34). This suggests that the stability of R′CSNSCR″· parallels that of the nitroxides R′R″NO·.

Conclusions

We previously showed the generality of quantitative symmetry-allowed cycloaddition reactions of SNS^+ with aliphatic alkynes and nitriles (1–5). This generality has now been extended to simple aryl derivatives to give the corresponding pure cycloadducts RCNSNS$^+$ (R = 2,5-$Me_2C_6H_3$, Ph, *p*-$O_2NC_6H_4$, and 3,5-$(O_2N)_2C_6H_3$) and PhCSNSCPh$^+$.

Reduction of RCNSNS$^+$ in dilute solution gives the neutral 7π radical RCNSNS·. We were able to isolate solid RCNSNS· (R = Ph, *p*-$O_2NC_6H_4$). The novel rearrangement of RCNSNS· to RCNSSN· was previously studied for some alkyl derivatives (6, 7). In this work, we determined the relative rates of this rearrangement for some related aryl derivatives and found that the lower the electronegativity of R, the slower the rearrangement. This discovery may lead to a better understanding of the mechanism of this rearrangement. It also aids us in the planned syntheses of more stable RCNSNS· mono- and multi-radical containing species that are of interest in their own right and as potentially useful materials.

The study of the stability of PhCSNSCPh· showed that PhCSNSCPh· is stable in solution up to ca. 0.5 M. It seems to be intermediate in stability between $CH_3CSNSCCH_3$·, which is only detectable by ESR spectroscopy in very dilute solution (1), and RCSNSCR· (R = CF_3 (10), CN (11)), which are isolable as stable materials.

Received June 12, 1992

J. F. HARROD, YING MU, and E. SAMUEL. Can. J. Chem. **70**, 2980 (1992).

As previously described, organosilanes react with dimethyltitanocene (DMT) to give three reduced titanium intermediates, $Cp_2Ti(\mu\text{-}SiRR'H)(\mu\text{-}H)TiCp_2$, **1**, $[Cp_2Ti(\mu\text{-}SiRR'H)]_2$, **2**, and $[Cp_2Ti(H)]_2(\mu\text{-}H)$, **3**. When R = Me and R′ = *n*-Bu, the DMT is quantitatively converted to **1**, which is persistent at room temperature. When R′ = H, DMT is initially converted quantitatively to **1**, which then rapidly declines to give an equilibrium mixture of **1**, **2**, and **3**, with **2** as the dominant species. When R = Ph and R′ = Ph or Me, **1** is again produced quantitatively, but it rapidly declines to produce an unidentified paramagnetic product, rather than **2** or **3**. It is believed that **2** is unstable with respect to dissociation in these cases due to the steric bulk of the substituents.

J. F. HARROD, YING MU et E. SAMUEL. Can. J. Chem. **70**, 2980 (1992).

Comme on l'a démontré antérieurement, les organosilanes réagissent avec le diméthyltitanocène (DMT) pour donner trois intermédiaires réduits du titane, $Cp_2Ti(\mu\text{-}SiRR'H)(\mu\text{-}H)TiCp_2$, **1**, $[Cp_2Ti(\mu\text{-}SiRR'H)]_2$, **2**, et $[Cp_2Ti(\mu\text{-}SiRR'H)]_2(\mu\text{-}H)$, **3**. Lorsque R = Me et R′ = *n*-Bu, le DMT est transformé quantitativement en **1** qui est persistant à la température ambiante. Lorsque R′ = H, le DMT est initialement converti quantitativement en **1** qui disparaît alors rapidement pour donner un mélange à l'équilibre des composés **1**, **2** et **3** dans lequel le composé **2** prédomine. Lorsque R = Ph et R′ = Ph ou Me, **1** est encore une fois produit d'une façon quantitative, mais sa concentration diminue rapidement pour donner un produit paramagnétique inconnu plutôt que les produits **2** ou **3**. Dans ce cas, on croit que le composé **2** est instable et qu'il se dissocie à cause de l'encombrement stérique des substituants.

[Traduit par la rédaction]

Introduction

The intermediates in the group 4 metallocene-catalyzed dehydrocoupling reactions of organosilanes are quite different for titanium (1, 2) and for zirconium (3, 4). In a number of studies, we have used the dimethylmetallocenes of group 4 as the catalyst precursor (1, 3, 5). In these cases, the chemistry of the transformation of the precursor into the active catalytic species constitutes an important part of the chemistry. Tilley and Woo have carried out extensive studies with pre-synthesized silylzirconocene(IV) and hafnocene(IV) complexes that provide convincing evidence for the role of silylhydridozirconocenes(IV) as the key catalytic species (4). They also showed that the induction periods typical of dimethylmetallocene catalysts are not observed with silylhydridozirconocene catalysts. Finally, all studies have concluded that the zirconium remains mainly in the oxidation state IV throughout the reaction and only small amounts of Zr(III) species are detected.

The titanocene-catalyzed reaction differs in two important ways from the zirconocene and hafnocene systems. In the first place, one cannot use either dihydrotitanocene(IV) or hydridosilyltitanocene(IV) complexes as catalysts, since such compounds are too unstable to isolate and manipulate (6, 7). Secondly, once the induction period for transformation of DMT into the active catalyst is complete, all of the detectable titanium is in the form of Ti(III) (1, 2). Despite this fact, it was concluded from a study of the kinetics of a number of DMT-catalyzed reactions that the most probable species for the true catalyst was the hydridosilyltitanocene(IV), **4** (8). In no case has **4** ever been directly observed. However, Buchwald and his collaborators have recently succeeded in isolating and structurally characterizing trimethylphosphine coordinated **4** (R = R′ = Ph).[2] From these results, it appears likely that the true catalyst is generated by an equilibrium splitting of the dimer **1** by silane as shown in eq. [1].

[1] $$\underset{\mathbf{1}}{Cp_2Ti(\mu\text{-}H)(\mu\text{-}SiHRR')TiCp_2} + RR'SiH_2 \rightarrow 2\,\underset{\mathbf{4}}{Cp_2Ti(SiHRR')H}$$

In earlier reports, we described the manner in which DMT reacts rapidly with organosilanes, following an induction period, to give **1** initially, then $[Cp_2Ti(SiRR'H)]_2$, **2**, and finally the mixed valence hydride $Cp_2Ti_2H_3$, **3** (1, 2). We have now systematically followed these species in the course of the reactions of several organosilanes, by monitoring their ^1H NMR spectra.

Results and discussion

The reactions of primary silanes

The profile of a reaction of a catalytic amount of DMT with phenylsilane is shown in Fig. 1. The amounts of **1***a* and **2***a*

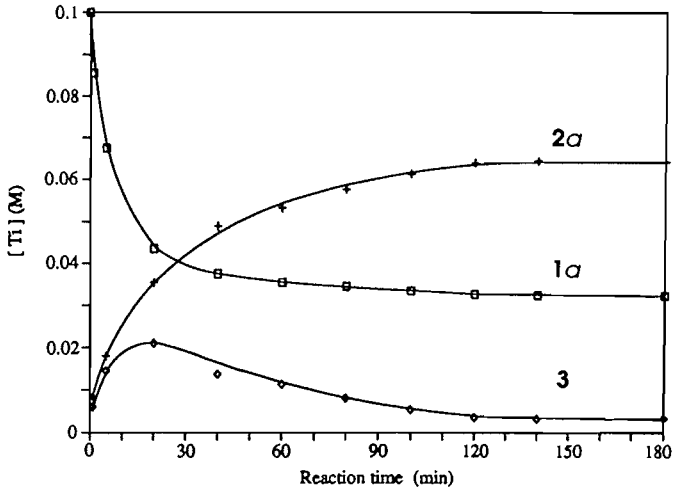

FIG. 1. Evolution of the concentrations of compounds **1***a*, **2***a*, and **3** with time. $[DMT]_i = 0.1$ M; $[PhSiH_3]_i = 1.0$ M in benzene-d_6 at 20°C.

were calculated directly from integration of NMR spectra. The third curve, believed to be mainly due to the presence of **3**, was obtained by subtraction of the amount of **1***a* + **2***a* from the total amount of titanium. The zero of time in this figure corresponds to the time at which the blue colour, signalling the end of the induction period, was first observed. It is evident from these results that DMT is transformed rapidly and completely to **1***a* in the first few seconds of the reaction. The concomitant formation of one equivalent of $PhMeSiH_2$, some oligophenylsilane, and some CH_4 was also evident from the ^1H NMR spectra. The initial reaction in the presence of excess silane is then:

$$[2] \quad 2\,Cp_2TiMe_2 + 4\,PhSiH_3 \rightarrow Cp_2Ti(H)(HPhSiH)TiCp_2 + 3\,MeH + PhMeSiH_2 + 2/n\,H(PhSiH)_nH$$

Immediately following its rapid formation, **1***a* begins to decay to the other two products. The decay continues until a steady state of all species is reached after about 2 h. At the steady state, under ambient conditions, the dominant species is **2***a* (ca. 65%) and **1***a* is about 30% of the total titanium present.

When isolated, **1***a* is used as a catalyst for phenylsilane polymerization, there is no induction period, and the rate of dehydrocoupling is initially high. The rate then declines as the **1***a* is converted into **2***a*. When isolated, **2***a* is used a catalyst, the reaction is initially very slow, but accelerates as the **2***a* is converted to **1***a*. This conversion is evident from the change in colour from the dark greenish-grey of **2***a* to the royal blue of **1***a*. The ^1H NMR spectrum of the reaction mixture shows that about 30% of **2***a* is converted to **1***a* over a period of several hours. Thus, the same steady state composition is achieved irrespective of the starting complex.

The course of a reaction of methylsilane with DMT is very similar to that of phenylsilane. At the steady state, which was achieved after ca. 3 h with 0.1 M DMT and 1.0 M $MeSiH_3$ in C_6D_6, the concentrations of **1***b* and **2***b* were again ca. 35% and 60% of the total titanium.

The reaction of n-*butylmethylsilane*

The reaction of *n*-butylmethylsilane is somewhat different from those of the primary silanes. Following the induction period, the reaction mixture does turn royal blue and the ^1H NMR spectrum shows the formation of CH_4, $BuMe_2SiH$, and the complex **1***c*. There is, however, no evidence for transformation of **1***c* into any other species and its concentration remains constant for at least several hours.

The ^1H NMR spectrum of **1***c* is similar to that of **1***a* (1). At room temperature, the four resonances of the inequivalent Cp groups are already sharp in **1***c*, while the bridging hydride resonances only sharpen up at lower temperature, as illustrated in Fig. 2. The presence of a paramagnetic species in solutions of **1***c* is signalled by a marked paramagnetic broadening of the resonances of the metal complex, excess $BuMeSiH_2$, and the solvent. The effect of concentration on the Cp resonances of **1***c* is shown in Fig. 3.

Studies by EPR of a solution of **1***c* in toluene showed a broad featureless singlet at room temperature with $g_{iso} = 1.984$, and did not provide further clarification as to the structure of the paramagnetic species responsible for the line broadening of the NMR signal.

The reactions of diphenylsilane and methylphenylsilane

The initial reactions of diphenylsilane and phenylmethylsilane with DMT gave CH_4, the methylated silanes, and quantitative conversion of DMT to **1***d* and **1***e*, respectively. In both cases, **1** begins to decay immediately, but there is no evidence in the NMR spectrum for the formation of **2**. The EPR spectra of reacting solutions reveal the presence of **3**, together with an intense broad singlet of unassigned origin. When the reactions are carried out in hexane as solvent, a black microcrystalline precipitate is recovered after several hours, which from its EPR spectrum and chemical analysis appears to be mainly **3**. Curves showing the disappearance of **1***d* and **1***e* with time are shown in Fig. 4.

The mechanism of formation of **1** *and* **2** *and their implication in DMT-catalyzed dehydrocoupling*

In earlier reports we described some aspects of the reactions of DMT with organosilanes and organogermanes (1,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

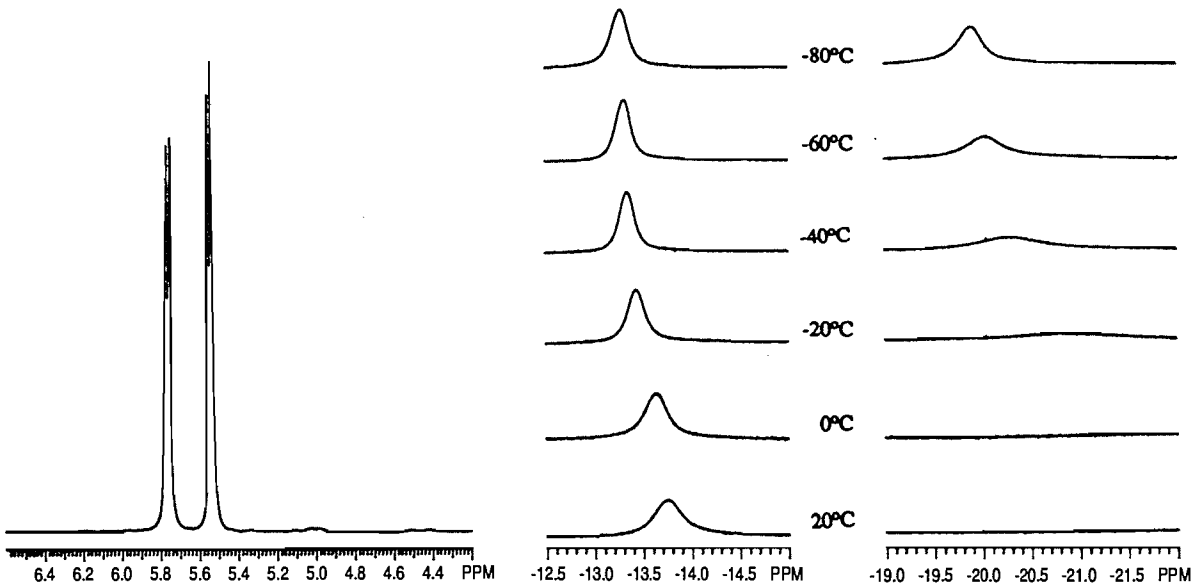

FIG. 2. ^{1}H spectrum of **1***c* at different temperatures. [**1***c*] = 0.1 M in toluene-d_8.

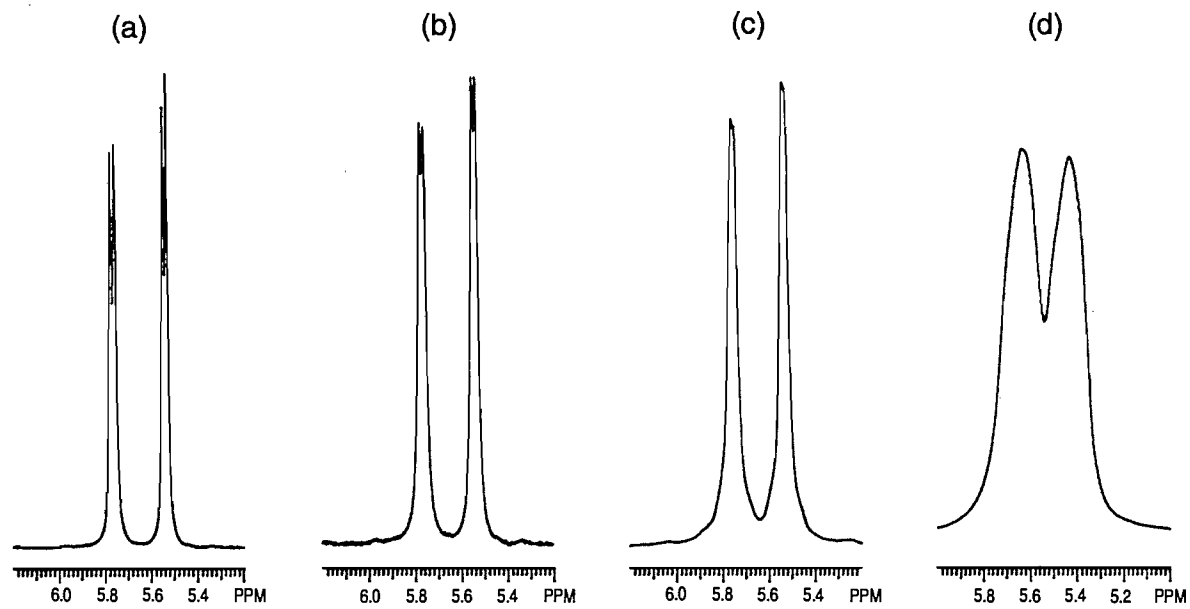

FIG. 3. ^{1}H NMR spectrum of **1***c* in the Cp region at different concentrations of the complex. (*a*) 0.1 M; (*b*) 0.2 M; (*c*) 0.3 M; (*d*) 0.6 M.

9). The critical feature of the DMT reactions, and one which distinguishes DMT from its zirconium and hafnium analogues, is the explosive nature of the reaction that leads to reduced titanium species. In its strongly autocatalytic nature and its spatially inhomogeneous propagation, this reaction is very similar to the reaction of H_2 with DMT (6, 10). It is likely in both cases that titanocene is the chain carrier that is responsible for the branched chain character of these reactions. Bercaw *et al.* were able to show unequivocally that this was the case for the reaction of H_2 with $Cp^*_2TiMe_2$ (11). We have shown that the explosive reduction, in the case of silanes, is suppressed by CO (1). When CO is present, instead of the catastrophic reduction to Ti(III) dimers, there is a slow, non-autocatalytic formation of $Cp_2Ti(CO)_2$. If there is only a small amount of CO available, the slow accumulation of the dicarbonyl continues until the CO is exhausted and then the catastrophic reduction to Ti(III) dimers occurs.

When a sterically undemanding, basic phosphine, such as Me_3P, is added to the DMT/silane reaction mixture, the product is not (as might be anticipated from the CO result) the titanocene(II)bis(phosphine) (12), but a titanocene(III)-silyl(phosphine) complex (2). The same products are observed on reaction of **1** or **2** with Me_3P or CO. Since **1** and **2** interconvert, it is not easy to distinguish whether these reactions involve specifically **1** or **2**.

The new results described above confirm that complexes **1** are the initial products of the reduction reactions of silanes with DMT. They also indicate that the origin of the low activities of secondary silanes with respect to catalyzed dehydrocoupling is different in the case of butylmethylsilane from

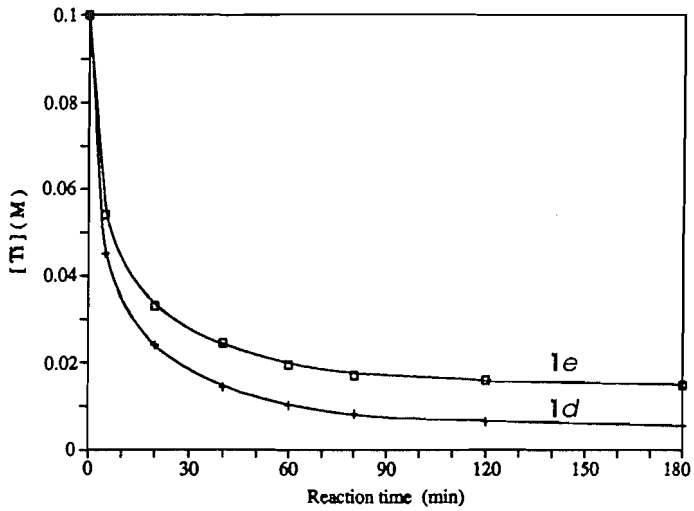

FIG. 4. Evolution of the concentrations of **1***d* and **1***e* with time. $[DMT]_i = 0.1$ M; $[Ph_2SiH_2] = 0.7$ M; $PhMeSiH_2 = 0.9$ M. At 20°C in benzene-d_6.

the cases of diphenyl- and phenylmethyl-silanes. The inactivity of the former is due to the inordinate stability of **1***c*, while that of the secondary arylalkylsilanes seems related to the inordinate labilities, or instabilities, of **1***d* and **1***e*. The abnormal stability of **1***c* may arise from the greater electron-releasing character of the alkyl substituents, giving rise to stronger bridging bonds. It may also be partly due to steric inhibition of reaction [1]. By the same reasoning, it may be concluded that the arylalkyl- and diaryl-silanes dissociate more readily into mononuclear species, due to the greater electron deficiency of the bridges, but that the formation of **4** (eq. [1]) is slowed down, perhaps by steric effects, to the point that the mononuclear intermediate decomposes via an unproductive channel. The more rapid disappearance of **1***d* and **1***e*, relative to **1***a*, may also be linked to a more facile dissociation of these bimetallic into monometallic complexes. In this case, however, the dissociation may be a disproportionation into titanocene(II) and a hydridosilyltitanocene(IV) complex (1, 8).

The failure to observe **2***d* and **2***e* by NMR does not prove that they are absent, since they may dissociate into paramagnetic monomers, according to eq. [3]. Even a small

[3] $[Cp_2Ti(SiRR'H)]_2 \rightleftharpoons 2\ Cp_2Ti(SiRR'H)$

amount of dissociation could cause extreme broadening of NMR resonances, provided the equilibrium was rapid. There is also ample evidence that dissociation of **2** can occur in the presence of donor ligands (2). This explanation is still not very convincing, however, when it is recognised that **2***a* and **2***b* have unbroadened resonances at room temperature, while neither **2***d* nor **2***e* can be detected in reaction mixtures down to −80°C.

The activity of primary silanes can then be rationalized in terms of an optimum ease of dissociation of **1** and a rate of conversion of the resulting mononuclear complex into **4** that precludes its decomposition by a nonproductive reaction. Although **2** is not an efficient source of the primary catalyst, its formation correlates with high catalytic activity. This is presumably because the processes that are prerequisite to the formation of **4** are also prerequisite to the formation of **2**. All of this leads to the conclusion that only a small fraction of the titanium is in the form of primary catalytic species and that the true activity of the primary catalyst is very much higher than the apparent activity. We are therefore concentrating our continuing efforts on the development of Cp-related ligands that inhibit dimerization of the hydride and silyl intermediates, and slow down their spontaneous decomposition, without unduly slowing down the dehydrocoupling process.

Experimental

The general procedures for the purification of solvents, synthesis of reactants and catalysts, and carrying out reactions, are the same as described previously (1).

Reactions of primary and secondary silanes with DMT

All of the reactions were followed by ^{1}H NMR. The standard conditions, except for methylsilane, were as follows. To a solution of DMT (10 mg; 0.048 mmol) in degassed benzene-d_6, containing one drop of cycylohexane as calibrant, was added the reactant silane (0.06 mL). The mixture was sealed in an NMR tube and placed in the temperature-controlled cavity of a 300 MHz NMR spectrometer. The concentrations of **1** and **2** were monitored periodically by comparison of the integrals of their Cp resonances with the cyclohexane standard. In the case of methylsilane, the same amount of DMT was dissolved in benzene-d_6 (0.48 mL) containing a drop of cyclohexane. The methylsilane gas was bubbled into the solution until it turned deep blue. The NMR tube was then sealed and the reaction was followed by the same method as for the other silanes.

Synthesis of $[Cp_2Ti(\mu\text{-}SiH_2Me)]_2$, **2**b

Methylsilane was bubbled into a solution of DMT (100 mg; 0.48 mmol) in toluene (2 mL). Within a few minutes a rapid colour change from orange to deep blue occurred, accompanied by a vigorous gas evolution. The solution was left under an atmosphere of methylsilane for 24 h to complete the conversion of **1***b* to **2***b*. The supernatant liquid was then decanted and the crystalline product was washed three times with 2-mL portions of cold toluene and dried under vacuum (yield: 34 mg; 35% based on **2***b*). The ^{1}H NMR spectrum of the product, in toluene-d_8, revealed only peaks due to the two isomers of **2***b*, in a ratio of 1.2:1. Major isomer (ppm): Cp: 4.594 (s) and 4.492 (2); Si-H terminal: 4.777 (m), $^2J_{H,H}$: 4.48 Hz; $^3J_{H,H}$: 4.50 Hz; CH_3: 0.765 (dd), $^3J_{H,\mu\text{-}H}$: 1.85 Hz; Si-H-Ti: −10.16 (br s). Minor isomer (ppm): Cp 4.586 (s) and 4.518 (s); Si-H (terminal): 4.866 (m), $^2J_{H,H}$: 4.48 Hz; $^3J_{H,H}$: 4.50 Hz; CH_3: 0.739 (dd), $^3J_{H,\mu\text{-}H}$: 1.85 Hz.; Si-H-Ti: −10.16 (br s). The spectral parameters for Si-H (terminal) and CH_3 resonances are cited for the spectra observed while decoupling at 0.765, 0.739, and −10.16 ppm respectively. The major isomer is tentatively assigned the *cis* structure on the basis of the larger difference in chemical shift between the two Cp resonances for this isomer. Although the NMR spectrum indicated only the presence of **2***b* in solution, satisfactory analyses for this compound were not obtained (Anal. calcd. for $C_{22}H_{30}Si_2Ti_2$: C 59.19, H 6.77, Si 12.58, Ti 21.46; found: C 55.57, H 6.25, Si 9.94, Ti 21.87). The poor analysis can be attributed in part to the presence of **3**, which is NMR silent, but it is also common for compounds containing Ti and Si to give poor analyses due to the formation of refractory titanium silicide. Although the mass spectra of the products contained many expected fragments, parent peaks were not observed and it was concluded that the compounds are not in general stable enough to carry out structure confirmation by high-resolution MS.

Several attempts to isolate **1***b* in a relatively pure state were frustrated by the facile decomposition of **1***b* into **2***b*. However, **1***b* was readily observed in solution by its ^{1}H NMR spectrum. At room temperature, all resonances were very broad, including the Cp resonances. Contrary to the spectra of all other complexes of **1** so far observed, **1***b* only exhibits three separate Cp resonances in the

ratio of 1:1:2, due to the accidental degeneracy of the two higher field resonances. ^{1}H NMR data for **1***b* at different temperatures are summarized in Table 1.

*Synthesis of $Cp_2Ti(\mu\text{-}SiBuMeH)(\mu\text{-}H)TiCp_2$, 1*c

DMT (150 mg) was dissolved in pure degassed *n*-$BuMeSiH_2$ (1.0 mL). The solution changed colour rapidly from orange to dark blue with a vigorous gas evolution. After about 30 min, the supernatant liquid was decanted and the residual precipitate was washed three times with 2-mL portions of cold hexane and dried under vacuum to give a black powder (102 mg, 63% based on **1***c*). Satisfactory analyses were not obtained (calcd. for $C_{25}H_{34}SiT_2$: C 65.50, H 7.48, Si 6.13, Ti 20.9; found: C 62.7, H 7.01, Si 5.31, Ti 20.64). The ^{1}H NMR spectrum of the product gave only resonances in the Cp and hydride regions that were attributable to **1***c*. The *n*-C_4H_9 and CH_3 resonances of the complex were slightly obscured by small amounts of free $BuMeSiH_2$, also apparent from its Si-H resonance. The ^{1}H NMR spectrum of **1***c* is described in detail in the discussion. No parent peak for **1***c* was observed in the mass spectrum.
