PASCAL BOSSERAY, GÉRARD COUDERT, GÉRALD GUILLAUMET, GEORGES JEMINET, MADELEINE TISSIER, and JEAN JUILLARD. Can. J. Chem. **70**, 828 (1992).

We report here the synthesis of new polyoxygenated macrocyclic derivatives with a benzodioxinic subunit and a carboxylic side chain (**2**, **3**), along with some of their corresponding acyclic polyethers (**1**). Formation constants of sodium and potassium complexes with both the acid and anion forms of these compounds were obtained from potentiometric measurements. The enhancement of both complexing ability and selectivity afforded by the presence of a carboxylic side chain is discussed.

Key words: polyether carboxylic acids, macrocycles, benzo-1,4-dioxin, sodium and potassium complexes, solvent methanol.

PASCAL BOSSERAY, GÉRARD COUDERT, GÉRALD GUILLAUMET, GEORGES JEMINET, MADELEINE TISSIER et JEAN JUILLARD. Can. J. Chem. **70**, 828 (1992).

Nou avons réalisé la synthèse de nouveaux dérivés macrocycliques polyoxygénés porteurs d'un bras carboxylique (**2**, **3**) et de composés ouverts correspondants (**1**). Toutes ces molécules comportent un motif benzodioxinique 1-4. Les constantes de formation dans le méthanol des complexes des ions sodium et potassium avec les deux formes, acide et anion, de ces composés ont été obtenues par des mesures potentiométriques. On discute des améliorations des propriétés de complexation et de sélectivité déterminées par la présence du bras carboxylique.

Mots clés : acides carboxyliques de polyéthers, macrocycles, benzo-1,4-dioxine, complexes du sodium et du potassium, méthanol comme solvant.

Introduction

In previous work, some of us developed synthetic methods that enabled us to prepare benzodioxinic macrocyclic polyethers bearing a side chain on the carbon next to the benzodioxinic subunit (1–3). In a recent paper (3) we reported data on sodium and potassium ion interactions with some lariat-ethers obtained in this manner. Both their complexing ability and potassium–sodium selectivity were disappointing. These properties might be expected to improve with the introduction of side chains bearing a carboxylic group. For example, the preparation and testing of carboxylic acyclic and macrocyclic polyethers that are more or less efficient in extracting alkali-metal and alkaline-earth cations selectively have been reported by Wieranga *et al.* (4), Nakahama and co-workers (5), Hiratani (6), and Bartsch and co-workers (7). Such substances can be used for modeling the activity of naturally occurring carboxylic polyether ionophores such as monensin, nigericin, grisorixin, lasalocid, calcimycin, and their derivative compounds, which have been studied in Clermont for years. The compounds synthesized here were of three types, as shown in Fig. 1. They were tested for their complexing efficiency and selectivity for potassium and sodium cations in methanol. Preliminary extraction experiments in a biphasic system were also carried out in order to evaluate them as potential ionophores. Comparisons were made with analogs not bearing a carboxylic side chain (3).

Methods and results

Synthesis

The preparation of polyether compounds **1** has been described previously (2). The key intermediate **6** in the synthesis of **2** and **3** was prepared from 2-carboxy-benzo-1,4-dioxin **4** (8) in three steps (Scheme 1).

The first step was the functionalization of the heterocycle at C_3, which was achieved by treatment of 5-benzyloxy-2-pentanone (2) with the dianion of **4** (9). The lactone **5**, which was obtained after treatment with hydrochloric acid in aqueous dioxan, was then easily converted to diol **6** by reduction with lithium aluminium hydride. The syntheses of macrocycles **2** and **3** from diol **6** are shown in Schemes 2 and 3. Macrocyclic derivatives **7** were prepared by treatment of **6** with excess sodium hydride in tetrahydrofuran or in a tetrahydrofuran–hexamethylphosphoramide mixture (9:1) followed by reaction with the bistosylates of tetra-, penta-, and hexaethylene glycols (10). When potassium hydride was used as base the yield fell dramatically (20%). Diols **6**, in the presence of bis(2-chloroethyl) ether, tetrabutylammonium hydrogen sulfate, and 50% aqueous sodium hydroxide (11), were converted to the benzodioxinic dichloro polyethers **10**, which were subsequently cyclized with catechol and dry sodium hydroxide in *n*-butanol (12) to give compounds **11**.

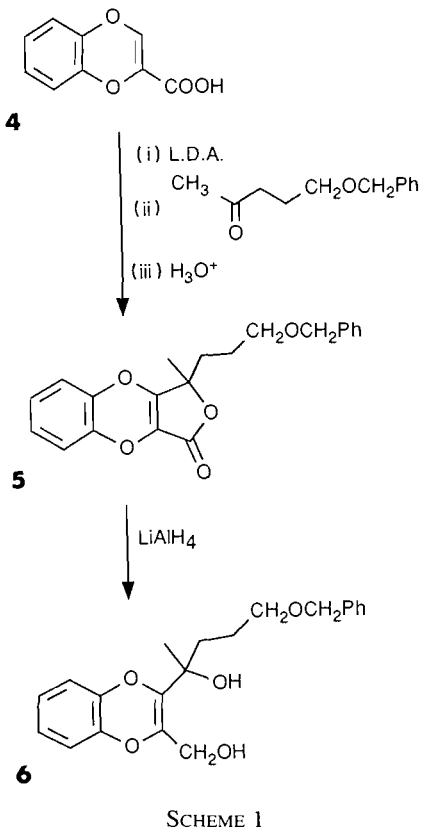

SCHEME 1

Hydrogenolysis of the benzyl protecting group of derivatives **7** and **11**, which was performed in ethyl acetate using a palladium-on-carbon catalyst (13), led to primary alcohols **8** and **12**.

Despite several attempts, the direct oxidation of **8** and **12** to the corresponding carboxylic acids failed. However, Swern oxidation (14) of **8** and **12** gave aldehydes **9** and **13**, which were then subjected to alkaline oxidation with silver nitrate (15) to afford the required acid derivatives **2** and **3**.

Complex formation in methanol

It has been shown (16) that polyether carboxylic ionophores (AH) are able to form both charged and neutral complexes with a cation M^+ in methanol: AHM^+ and AM. The presence of AHM^+ was therefore expected here and so the two formation equilibria [1] and [2]:

[1] $AH + M^+ \rightleftarrows AHM^+$

[2] $A^- + M^+ \rightleftarrows AM$

were included to take this into account, along with the corresponding deprotonation equilibria [a] and [a′]:

[a] $AH \rightleftarrows A^- + H^+$

[a′] $AHM^+ \rightleftarrows AM + H^+$

This system was studied by potentiometry using concurrently two sensitive glass electrodes, one responsive to H^+, the other to M^+, i.e., Na^+ or K^+. The pK_a's of the acidic polyethers were first determined using the usual procedures. Formation constants β_1 and β_2 were then obtained by measuring the activities of H^+ and M^+ when successive amounts of a basic solution of tetrabutylammonium methylate in methanol were added to a solution of the ligand and the alkali metal chloride at equimolar concentration. Procedures and processing of the data using Leden formation functions have been described elsewhere (16). Results thus obtained are set out in Table 1. With some of the non-carboxylic benzodioxinic polyoxygenated macrocycles previously studied, formation of A_2K^+ was observed (3). Formation of 2-ligand–1-cation complexes, i.e., $A_2H_2M^+$ or A_2M^-, is improbable here since good fits were obtained assuming formation of only AHM^+ and AM. Acid dissociation constants of the AHM^+ species in columns 2 and 3 of Table 1 were obtained by combining equilibrium constants for reactions [1], [2], and [a] according to eq. [3]:

[3] $pK_{a'} = pK_a - \log \beta_2 + \log \beta_1$

For comparison, previous data (16–18) for naturally occurring carboxylic polyether ionophores are given in Table 1. Also, some pK_a values of simple carboxylic acids obtained under the conditions described here are given in Table 2.

Complex formation in biphasic water – organic solvent system

The purpose of these measurements was to access the heterogeneous formation constants for reaction [4] in which the overlined species are in the organic phase and the others in the aqueous phase.

[4] $\overline{AH} + M^+ \rightleftarrows \overline{AM} + H^+$

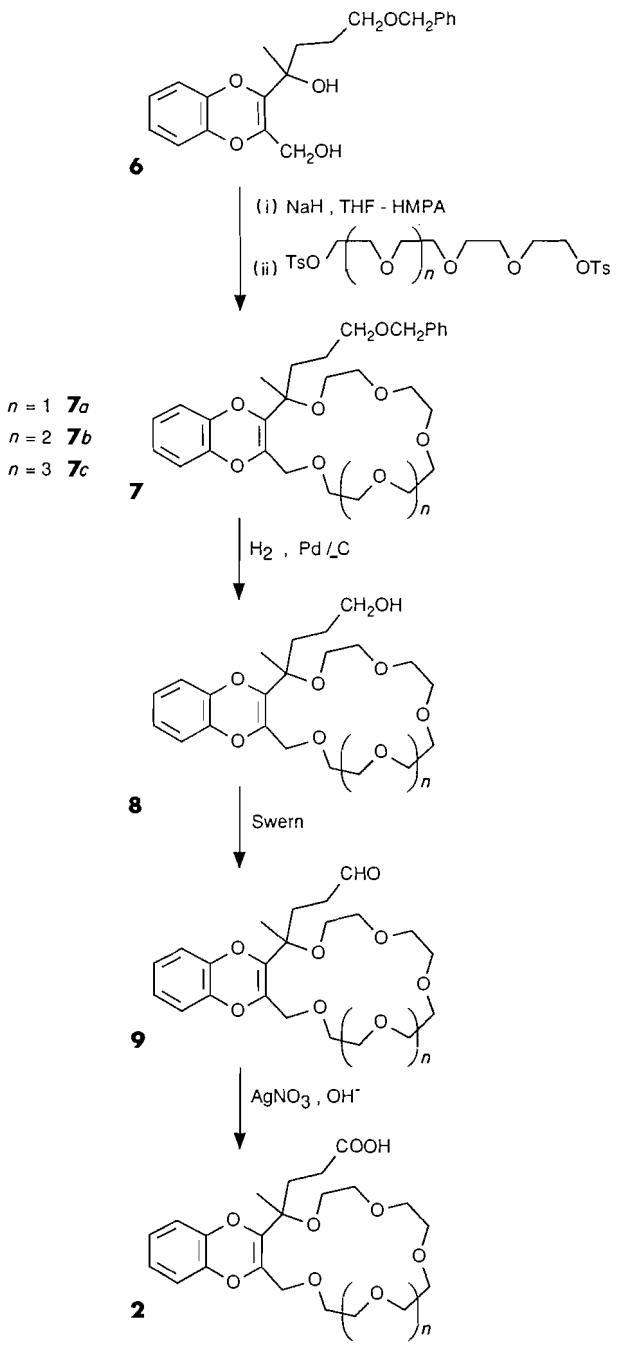
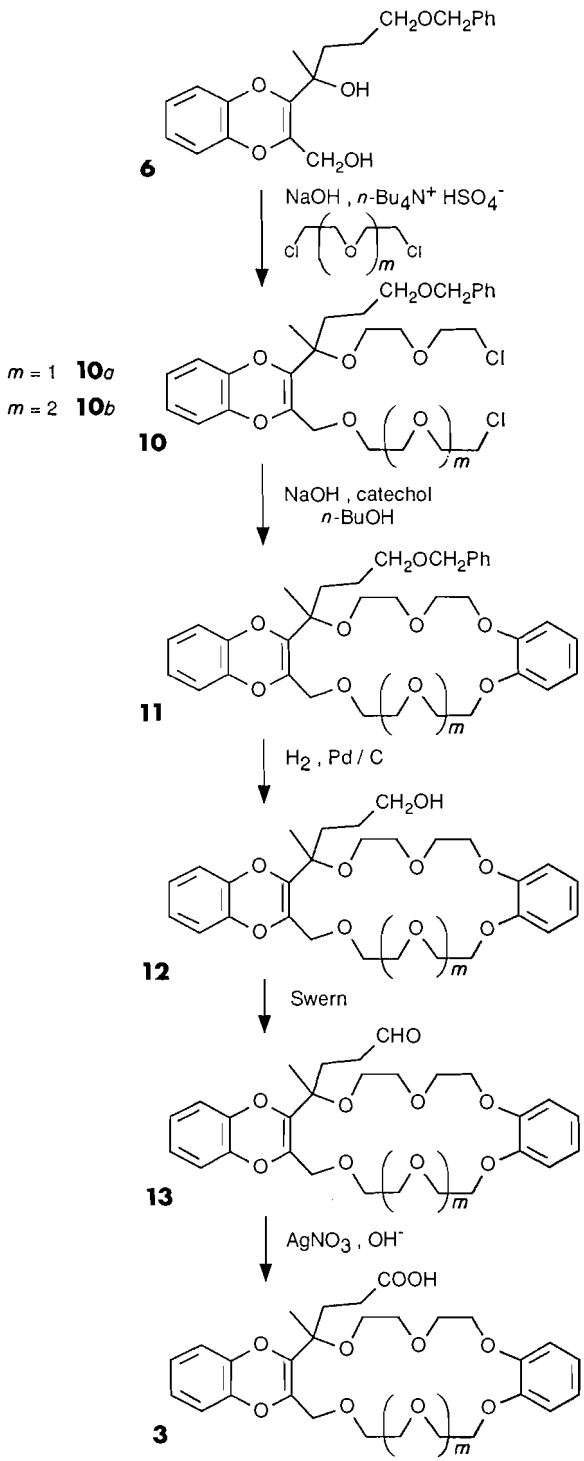


SCHEME 2



SCHEME 3

This was achieved by extracting the cation from the aqueous phase at variable pH by the ligand in the organic phase, using as the organic phase the *n*-butanol–toluene 30–70% mixture, according to a method first proposed by Pressman *et al.* (19) and developed by Pfeiffer and Lardy (20).

Experiments were limited to the 5–8 pH range. Under these conditions the distribution coefficient was rather small for all the products studied. This may be attributed to an observed partition in favor of water for most of the complex salts formed. Since they do not provide useful information, numerical data are not reported here for the sake of brevity.

Discussion

Synthesis

A new class of polyethers incorporating a benzodioxinic subunit and bearing a side chain with a terminal carboxylic acid group has been described. These compounds were obtained using a synthetic scheme with a limited number of steps, which should allow further developments to be made.

TABLE 1. Formation constants of acid, AHM^+, and neutral, AM, complexes of polyether carboxylic acid, AH, and metal cation, M^+, and acid dissociation of AH and AHM^+ in methanol at 25.0°C (molar scale of concentration)

Acid dissociation in methanol

In light of data on simple carboxylic acids, the acidity constants obtained for compounds **1–3** (Table 1) are within the expected range. In particular, judging from the large pK_a change from ethoxyacetic to β-ethoxypropionic acid, the inductive effect of the ethoxy group probably vanishes totally beyond four carbons. However, given that polyethers **1–3** are structurally similar in the vicinity of the carboxylic acid group, the significant variations observed in acid dissociation are a little surprising. The differences observed could be related to variations in the preferential conformation of the crown ring, which may or may not facilitate the interaction of the carboxylic hydroxyl with one of the oxygens of the ring through hydrogen bonding, thus more or less increasing the stability of the acid form. Such lowering of the acidity of a carboxylic group by the presence of a crown ether moiety in the molecule has already been observed (7*c*, 21).

The specificity of the interactions between the carboxylic acid and the oxygens of the crown should vanish on complexation with an alkali-metal cation. This is borne out by observation: the acidity differences are generally smooth; most of the $pK_{a'}$ values lie near 8.9, except in some particular cases. In addition, as expected, from AH to AHM^+ acidity is increased, but less than for the naturally occurring carboxylic ionophores, monensin and nigericin.

Complexation of Na^+ and K^+

As has been noted earlier (results) both the acid and anionic forms of the carboxylic polyethers are able to act as ligands of alkali-metal cations. Complexes of the neutral acid molecules can be compared to complexes of analogous benzodioxinic crown ethers without a carboxylic acid (3). This is done in Table 3 for compounds **2** and **3***a*. For complexation with potassium, differences are rather small, the trend being that the stabilization of the complex by the presence of the carboxylic acid increases as the size of the crown increases; the strongest complexation previously observed (3) for the seven-oxygen ring is probably retained. The same is not true for the sodium complexes, for which the presence of the carboxylic acid strengthens the complexation noticeably for the five-oxygen ring and even more so for the six-oxygen ring. The maximum observed with a simple crown ether, substituted or not, then recurs for the six-oxygen ring as shown in Fig. 2. Two of us have shown (25) that for one-chain polyethers, complexation increases with the number of oxygens, mainly for statistical reasons, this effect being more efficient for potassium than sodium cation as shown clearly in Fig. 1 from ref. 25. Table 1 shows that this is also true for **1**.

The complexation of a cation by polyethers possessing an anionic ligand is clearly more efficient than its complexation by polyethers with an acid ligand or by analogous monocarboxylic crown compounds. Differences in complexing ability range from 0.6 to 1.8 in terms of the logarithm of the formation constants. Such differences are smaller than those observed for natural polyether carboxylic ionophores, which range from to 2 to 4. With the latter substances the ionization of the carboxylic function corresponds mainly to the stabilization of the pseudo-ring and incidentally to the participation of this function in the coordination of the cation. Here, the carboxylate group acts mainly in coordinating the cation but also in creating a more closed space around the cation. This hemi-cage effect is more efficient in the case of small-size crown ether as observed for compound **3***a*, for example.

Conclusions

The complexing ability of some of these substances may then be considered as satisfactory but preliminary extraction experiments have shown that their lipophilic properties would have to be increased through appropriate chemical

modifications to obtain efficient ionophoric systems. The synthetic scheme used in this study can be easily adapted for such a purpose.

Experimental

Synthesis and purification

Infrared (ir) spectra were recorded on a Perkin Elmer 297 spectrometer. Nuclear magnetic resonance (nmr) spectra were obtained in $CDCl_3$ solution on Hitachi Perkin R 24 (60 MHz) and Bruker AM 300 (300 MHz) instruments. All samples that contained an OH group were back-exchanged in D_2O before analysis. Tetramethylsilane was used as an internal standard. Low-resolution mass spectra were recorded on a Nermag R 10.10 C mass spectrometer using a 70 eV ionization potential. Column chromatography was performed with 230–400 (flash chromatography) and 70–230 (gravity chromatography) mesh silica gel (E. Merck). Analytical thin-layer chromatography (tlc) was carried out on cut sections of E. Merck precoated aluminium sheets of silica gel 60 F_{254}. Chromatography solvents were distilled before use. Tetrahydrofuran (THF) was distilled from sodium benzophenone ketyl immediately prior to use. All reactions involving air- or moisture-sensitive reagents were performed under an argon atmosphere. Analyses of all new compounds, indicated by the symbols of the elements, were within ±0.4% of the theoretical values.

3-Methyl-3 [3-(phenylmethoxy)propyl]furo[3,4-b][1,4]benzodioxin-1-(3H)-one **5**

To a stirred solution of diisopropylamine (1.8 g, 17.6 mmol) in 8 mL of tetrahydrofuran was added *n*-butyllithium (11 mL, 17.6 mmol, 1.6 M in hexane) at −5°C. The pale yellow solution was stirred for 20 min at the same temperature. The reaction mixture was cooled to −78°C and a solution of 2-carboxy-benzo-1,4-dioxin **4** (8) (1.42 g, 8 mmol) in 7.5 mL of tetrahydrofuran was then added dropwise. The reaction mixture was stirred for a further 5 h at −78°C. 5-Benzyloxy-2-pentanone(2) (2.3 g, 12 mmol) dissolved in 3 mL of THF was added and the resulting solution was stirred at −78°C for 2 h. The reaction was quenched with water, and the mixture was warmed up to room temperature and extracted with Et_2O (2 × 20 mL). The aqueous layer was acidified with 10% HCl and extracted with CH_2Cl_2 (4 × 20 mL). This organic phase was dried over anhydrous $MgSO_4$, filtered, and evaporated.

A solution of the oily residue in dioxane (30 mL) and 10% HCl (30 mL) was stirred at room temperature. The reaction was monitored by tlc. After hydrolysis and extraction with CH_2Cl_2 (4 × 20 mL), the organic phase was washed with 5% aqueous sodium hydrogen carbonate solution (30 mL), with 10% HCl (10 mL), dried over anhydrous $MgSO_4$, and evaporated. The oily residue was chromatographed to give **5** as a colorless oil (87%); ir (film): 1780, 1710 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.3 (s, 3H, CH_3), 1.8 (m, 4H, CH_2), 3.3 (t, J = 6.5 Hz, 2H, CH_2O), 4.3 (s, 2H, OCH_2Ph), 6.7–6.8 (m, 4H, aromatic), 7.05 (s, 5H, aromatic). Anal. ($C_{21}H_{20}O_5$) C, H.

α-Methyl-2 [3-(phenylmethoxy)propyl]-benzo-1,4-dioxin-2,3-dimethanol **6**

To a solution of the lactone **5** (1.35 g, 4 mmol) in 20 mL of anhydrous ether was added an excess of hydride reagent ($LiAlH_4$) and the reaction was stirred for 2 h at room temperature. The reaction was monitored by tlc. Cold water was added cautiously; the salts were filtered through Celite and washed with ether. The organic phase was dried over anhydrous $MgSO_4$, filtered, and evaporated. The residue was purified by filtration through a short column of silica gel (petroleum ether – ether, 6:4) to leave **6** as a colorless oil (91%); ir (film): 3600–3100, 1680 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.4 (s, 3H, CH_3), 1.7–1.9 (m, 4H, CH_2), 3.7–3.5 (m, 2H, CH_2O), 4.2 (s, 2H, =C-CH_2O), 4.5 (s, 2H, OCH_2Ph), 6.5–7.0 (m, 4H, aromatic), 7.3 (s, 5H, aromatic). Anal. ($C_{21}H_{24}O_5$) C, H.

Synthesis of macrocycles 7

A suspension of sodium hydride (25.7 mmol, 50% dispersion in mineral oil, washed three times with dry tetrahydrofuran) in 40 mL of anhydrous tetrahydrofuran was refluxed and diols **6** (1.93 g, 5.8 mmol) dissolved in 48 mL of anhydrous tetrahydrofuran were added dropwise with stirring. The reaction mixture was

For personal use only.

refluxed for 2 h and a solution of bistosylate (5.8 mmol) of the relevant poly(ethylene glycol) in 48 mL of dry solvent was added. The heating and stirring were continued for another 36 h. After cooling, the reaction mixture was poured into water and extracted with ether (4 × 30 mL). The organic layer was dried over anhydrous $MgSO_4$ and concentrated *in vacuo* to give an oil, which was purified by flash chromatography. For the synthesis of **7***a* and **7***b*, the solvent used was a THF–HMPA mixture (9:1).

6,8,9,11,12,14,15,17,18,20-Decahydro-6-methyl-6-[3-(phenylmethoxy)propyl][1,4] benzodioxino[2,3-c] - [1,6,9,12,15]-pentaoxacycloheptadecin **7***a* (40%); oil; ir (film): 1680,1100 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.4 (s, 3H, CH_3), 1.7 (m, 4H, CH_2), 3.5–3.8 (m, 18H, CH_2O), 4.3 (s, 4H, CH_2O), 6.5–6.7 (m, 4H, aromatic), 7.1 (s, 5H, aromatic). Preparation of aldehydes ***9*** *and* ***13***

To a solution of dimethyl sulfoxide (0.546 g, 7 mmol) in dichloromethane (10 mL) at −60°C was added a solution of oxalyl chloride (0.4879 g, 4.1 mmol) in dichloromethane (10 mL) and the mixture stirred at −60°C for 30 min. A solution of alcohol **8** or **12** (2.6 mmol) in dichloromethane (10 mL) was then added to this mixture at −60°C. After stirring for 1 h, triethylamine (3 mL) was added. The stirring was continued at −60°C for another 10 min. The mixture was then allowed to warm up slowly to room temperature, quenched with saturated ammonium chloride, and extracted with dichloromethane (4 × 15 mL). The organic layer was washed with water, dried ($MgSO_4$), and evaporated to dryness. The product was purified by flash chromatography with ether – petroleum ether as eluent to yield pure **9** or **13**.

1,3,4,6,7,9,10,12,13,15-Decahydro-1-methyl-[1,4,7,10,13]-pentaoxacycloheptadecino[16,17-b]-[1,4]benzodioxin-1-propanal **9***a* (79%); oil; ir (film)-: 2720,1710 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.4 (s, 3H, CH_3), 2.0–2.2 (m, 2H, CH_2), 2.3–2.5 (m, 2H, CH_2-CHO), 3.5–3.7 (m, 16H, CH_2O), 4.3 (s, 2H, =C-CH_2O), 6.5–6.7 (m, 4H, aromatic), 9.4 (m, 1H, CHO). Preparation of acids **2** and **3**

To a solution of silver nitrate (0.1275 g, 0.75 mmol) in distilled water (6 mL) was slowly added a solution of aldehyde **9** or **13** (0.37 mmol) in ethanol (16.5 mL) and the mixture stirred at room temperature. A solution of sodium hydroxide (0.0596 g, 1.49 mmol) in distilled water (11 mL) was then added to this mixture at room temperature. The formation of a black precipitate was observed. The progress of the reaction was followed by tlc. After 30 min, the reaction mixture was filtered through Celite and the filter cake was washed with water and ether. The aqueous layer was separated, extracted with ether (1 × 10 mL), brought to pH 2 (pH paper), and reextracted with dichloromethane (4 × 15 mL). The combined organic extracts were dried ($MgSO_4$) and evaporated *in vacuo* to afford **2** or **3** as a syrup. Pure acids **2** and **3** were obtained by a rapid filtration through a short silica gel column.

Potentiometric measurement

Two glass indicator electrodes were used, one specific for the alkali-metal ion, either sodium (Jena er Glass) or potassium (Solea type pKV3), the other specific to hydrogen ion (Orion 91-01). The reference electrode was a two-stage model of the following type, the double junction being meant to prevent any contamination of the solution by potassium cations.

Hg, Hg_2Cl_2	KCl, Hg_2Cl_2 saturated in methanol	ClO_4NEt_4 8×10^{-2} M in methanol	Experimental solution

Potentials were recorded using an Orion research millivoltmeter model 701/A. Standardization of both electrodes was performed before measurements. For the pH standardization, buffers in methanol prepared according to De Ligny *et al.* (26) were used. Solutions of tetrabutylammonium methylate in methanol were prepared as previously described (27). All the data were obtained at 25.0°C.

Extraction measurement

These were conducted using procedures previously described (28).

Electrosynthesis of thiocyanato and mixed ligand thiocyanato complexes of transition metals by the sacrificial dissolution of metal anodes

M. C. CHAKRAVORTI[1] AND GAMPA V. B. SUBRAHMANYAM

Department of Chemistry, Indian Institute of Technology, Kharagpur-721 302, India

Received June 27, 1991

M. C. CHAKRAVORTI and GAMPA V. B. SUBRAHMANYAM. Can. J. Chem. **70**, 836 (1992).

A general method for the electrosynthesis of anionic and mixed ligand nonelectrolytic thiocyanato complexes of transition metals has been developed by the oxidation of sacrificial metal anodes in aqueous, or aqueous ethanolic, medium containing ammonium thiocyanate at room temperature and at an applied potential of 2–7 V. The method is rapid and gives good yield with high purity.

Key words: electrosynthesis, thiocyanato complexes, mixed ligand thiocyanato complexes.

M. C. CHAKRAVORTI et GAMPA V. B. SUBRAHMANYAM. Can. J. Chem. **70**, 836 (1992).

On a mis au point une méthode générale d'électrosynthèse de complexes thiocyanato anioniques et de complexes thiocyanato non-électrolytiques à ligands mixtes de métaux de transition; cette méthode fait appel à une oxydation d'anodes métalliques suicidaires, en solutions aqueuses ou dans un milieu éthanolique aqueux contenant du thiocyanate d'ammonium, à la température ambiante et à un potential appliqué de 2 à 7 V. La méthode est rapide et elle donne de bons rendements et les produits sont d'une grande pureté.

Mots clés : électrosynthèse, complexes thiocyanato, complexes thiocyanato à ligands mixtes.

[Traduit par la rédaction]

Introduction

In recent years there has been a growing interest in the synthesis of coordination compounds starting directly from metals (1–4). Electrochemical synthesis in which a sacrificial metal anode is dissolved in the presence of an electrolyte containing an appropriate ligand is an established way for the electrolytic synthesis of a variety of metal complexes in a single step (1). The process uses the metals directly and thus contamination of the product by the anions, which is often encountered in chemical methods using the metal salts, is absent. The method is rapid and highly selective. Oldham *et al.* recently reported the electrosynthesis of the anionic thiocyanato complexes of Zn, Cd, Ga, Co, and Au from a nonaqueous solution of thiocyanic acid using the metals as anode (5). In the present communication we describe a general method for the rapid and direct electrochemical synthesis of transition metal thiocyanato complexes and also mixed ligand thiocyanato complexes by the dissolution of sacrificial metal anodes in an aqueous (or aqueous ethanolic) solution of ammonium thiocyanate (also containing the appropriate ligand when mixed complexes are to be prepared).

Experimental

The metals were in the form of rods, lumps, chips, or foils and were mostly 99.8% pure. Other chemicals were of AR/GR quality from reputable manufacturers.

The electric power was supplied by a dc power supply (Aplab, India). The current was recorded from the scale of the power supply and checked by connecting a separate ammeter or milliammeter into the circuit. The electrolytic cell was a tall form of beaker (100 cm^3) fitted with a rubber stopper through which four holes were made. The appropriate metal rods (iron and molybdenum) formed the anode and were inserted through a hole. Other metals were used as lumps, foils, or chips. These were tied with a platinum wire, which was inserted through the hole. Chromium and manganese were previously deposited on a platinum foil sealed to a platinum wire that served as the anode. In all cases a platinum foil (about 1 × 1 × 0.15 cm) connected to a platinum wire served as the cathode and was introduced through the second hole. Two glass tubes were introduced through the other two holes. These allowed input and exit of nitrogen where it was necessary to carry out electrolysis in the absence of air.

Metals were analysed by standard titrimetric or gravimetric methods. Sulphur was determined gravimetrically as $BaSO_4$ after decomposing the complexes with nitric acid (6). Nitrogen was determined by the micro Dumas method. Reflectance spectra were recorded using a Shimadzu UV spectrophotometer (no. 3100) against $BaSO_4$. Infrared spectra were recorded in KBr pellet using a Perkin Elmer instrument (no. 883). Magnetic susceptibility was measured by the Gouy method using $Hg[Co(NCS)_4]$ as calibrant. Diamagnetic corrections were taken from standard sources (7).

Preparation of the complexes

$[(CH_3)_4N]_2[M(NCS)_4]$ where M = Mn, Fe, Co, Cu, Zn, and Cd; $[(CH_3)_4N]_3[Cr(NCS)_6]$; $[(CH_3)_4N]_4[Ni(NCS)_6]$ and $[(CH_3)_4N]_4[Mo_2O_4(NCS)_6]$

The electrolysis was carried out using 10 cm^3 of an aqueous solution containing 1 g NH_4SCN. The details of the experimental conditions are given in Table 1. After the electrolysis, the complexes were precipitated by adding a slight excess of tetramethylammonium chloride (or thiocyanate) dissolved in the minimum volume of water. The complexes were separated by filtering under suction within 30 min. These were dried by pressing between the folds of filter paper and then keeping in a desiccator over sulphuric acid.

Electrolysis using iron as anode was carried out in a stream of nitrogen. In all other cases electrolysis was carried out in air.

$[(CH_3)_4N]_3[Fe(NCS)_6]$

This was prepared by a two-step electrolysis. In the first step $[Fe(NCS)_4]^{2-}$ was generated *in situ* as described above, after which the iron anode was replaced by a platinum foil electrode and the electrolysis was continued in air for one more hour. Finally, the tetramethylammonium salt was obtained by the addition of a concentrated solution of tetramethylammonium chloride.

$[M(py)_4(NCS)_2]$, where M = Mn, Fe, Co, and Ni; $[M(py)_2(NCS)_2]$, where M = Cu, Zn and Cd; $[Mo_2O_4(py)_4(NCS)_2]$

The electrolysis was carried out using 10 cm^3 of an aqueous solution containing 3–4 cm^3 pyridine and 1 g NH_4SCN. Except for

Time of electrolysis in each case was 1 h.

molybdenum, in all cases the complexes precipitated during the electrolysis. The molybdenum complex was precipitated on concentrating the solution in a desiccator over dry $CaCl_2$. The complexes were separated by filtration under suction, washed with ethanol, and dried over sulphuric acid.

$[ML_2(NCS)_2]$, where M = Mn, Fe, Co, Ni, Zn, and Cd;
$[ML(NCS)_2]$, where M = Cu, Zn, and Cd; and
$[Mo_2O_4L_2(NCS)_2]$ where L = 2,2′-bipyridyl and 1,10-phenanthroline

The electrolysis was carried out in 60–70% aqueous ethanolic medium (10–12 cm^3) containing 1 g NH_4SCN and 0.2–0.3 g 2,2′-bipyridyl or 1,10-phenanthroline hydrate. The precipitates of the complexes appeared during the electrolysis. These were separated and dried as in the previous case. Electrolysis using iron as an anode was carried out in a stream of nitrogen. While zinc and cadmium gave $[ML(NCS)_2]$ with 0.2–0.3 g of the ligand, the complexes $[ML_2(NCS)_2]$ were obtained using 0.5 g of 2,2′-bipyridyl and 1,10-phenathroline hydrate.

All the mixed ligand complexes could also be prepared by first electrolysing in the presence of an aqueous solution of NH_4SCN (as in the case of the preparation of the anionic complexes), followed by the addition of the appropriate ligand (3–4 cm^3 pyridine as such, or 2,2′-bipyridyl or 1,10-phenanthroline hydrate in amounts as mentioned above and dissolved in a minimum volume of ethanol).

The experimental conditions along with the yields, etc. for the preparation of the 2,2′-bipyridyl complexes from aqueous ethanolic medium containing the ligand bipyridyl are given in Table 2. The same apply (with slight change in some cases) for the preparation of the pyridine and the 1,10-phenanthroline complexes.

Results and discussion

Our studies show that anionic thiocyanato complexes and also nonelectrolytic mixed ligand thiocyanato complexes of many transition metals can be easily and quickly prepared in a single step by anodic dissolution of the metals in aqueous or mixed solvent at room temperature. The applied voltage is low (2–5 V in aqueous medium and 5–7 V in mixed solvent) and the yield is very good (60–90% based on the amount of the metal oxidized). The main reactions taking place at the electrodes are

$$2H^+ + 2e \rightarrow H_2 \text{ (at cathode)}$$

$$M - ne \rightarrow M^{+n} \text{ (at anode)}$$

which is evident from the observed electrochemical efficiency. A slight deviation of the electrochemical efficiency (Tables 1 and 2) from the theoretical value of $1/n$ is ascribed to slight fluctuation of the current during the electrolysis and some other reactions taking place at the anode. In almost all cases a feeble foul smell was noted during electrolysis; this may be due to partial oxidation of thiocyanate at the anode.

An obvious advantage of the present method is the absence of any contamination of the products by the anions, which is often encountered in chemical methods using the metal salts. It was checked that tetramethylammonium chloride and tetramethylammonium thiocyanate gave the same product and there is no occlusion of chloride in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

product while using tetramethylammonium chloride. Another advantage of the method is that it uses an aqueous or mixed solvent at room temperature, while the common methods for the preparation of thiocyanato complexes often use nonaqueous solvents and sometimes involve reactions in the melt.

The compounds were characterized by chemical analysis and the measurement of the magnetic moments, ir spectra, and electronic spectra. The magnetic moments (8–13) and the important band positions in the ir spectra (9, 14–24) of most of the complexes are available in the literature. In all such cases our values agreed with the literature values. For other compounds also, these were as expected. The electronic spectral band positions of only a few compounds are available in the literature (9, 25–28) and our values are in agreement with these. For other compounds our data are in accordance with expectation.

All the analytical data have been deposited as Supplementary Material.[2]

Ion chemistry of aluminum and boron in methane–oxygen flames

PIERRE N. CROVISIER, J. HUGH HORTON, CARL S. HASSANALI, AND JOHN M. GOODINGS[1]

Department of Chemistry and Centre for Research in Earth and Space Science, York University, 4700 Keele Street, North York, Ont., Canada M3J 1P3

Received August 2, 1991

PIERRE N. CROVISIER, J. HUGH HORTON, CARL S. HASSANALI, and JOHN M. GOODINGS. Can. J. Chem. **70**, 839 (1992).

The ion chemistry of aluminum and boron, primarily in the +3 oxidation state, was studied by doping premixed, methane–oxygen flames of both fuel-rich and fuel-lean (oxygen-rich) composition with 1×10^{-6} mol fraction of $AlCl_3$ and 5×10^{-4} mol fraction of $B(OC_2H_5)_3$. Ions were observed by sampling the flames at atmospheric pressure through a nozzle into a mass spectrometer. At this low concentration level, aluminum exhibits two cation series: (*a*) $AlO^+.nH_2O$ (n = 2, 3) formed by proton transfer to AlO(OH) and $Al(OH)_3$ in which hydration reactions are involved; and (*b*) $Al^+.nH_2O$ (n = 0, 1) by protonation of AlOH with hydration/dehydration steps. At the higher concentration of the boron additive, four cation series were observed: (*a*) $B(OC_2H_5)_3H^+.nH_2O$ (n = 0, 1) based on proton transfer to the $B(OC_2H_5)_3$ additive; (*b*) $BO^+.nH_2O$ (n = 1–4) similar to aluminum; (*c*) $HB_2O_3^+.nH_2O$ (n = 1–3) involving the protonated dimer of metaboric acid, BO(OH); and (*d*) $B_3O_4^+.nH_2O$ (n = 2, 3) involving the protonated trimer of BO(OH) whose structures might be cyclic or linear. Other series members are formed by subsequent hydration or dehydration of the parent cations. The anions BO_2^- and BO^- previously studied by D. E. Jensen were also observed. The formation chemistry and probable structures of these ions are discussed, and compared with similar results obtained previously for flames doped with transition metals; notably Sc, Ti, V, and Cr in the +3 oxidation state.

Key words: aluminum, boron, ions, flame, gas phase.

PIERRE N. CROVISIER, J. HUGH HORTON, CARL S. HASSANALI et JOHN M. GOODINGS. Can. J. Chem. **70**, 839 (1992).

On a étudié la chimie ionique de l'aluminium et du bore, principalement dans leur état d'oxydation +3, en dopant des flammes prémélangées de méthane et d'oxygène, de compositions tant riches que pauvres (riches en oxygène) en combustibles, avec des fractions molaires de 1×10^{-4} de $AlCl_3$ et de 5×10^{-4} de $B(OC_2H_5)_3$. On a observé les ions en effectuant un échantillonnage des flammes, à pression atmosphérique, à l'aide d'un bec relié à un spectromètre de masse. À ces basses concentrations, l'aluminium présente deux séries de cations : (*a*) $AlO^+.nH_2O$ (n = 2, 3) formé par un transfert de proton vers le AlO(OH) et le $Al(OH)_3$ dans lequel des réactions d'hydratation sont impliquées; et (*b*) $Al^+.nH_2O$ (n = 0, 1) formés par la protonation du AlOH avec des étapes d'hydratation et de déshydratation. Aux concentrations plus élevées de l'additif de bore, on a observé quatre séries de cations : (*a*) $B(OC_2H_5)_3H^+.nH_2O$ (n = 0, 1) qui provient d'un transfert de proton à l'additif $B(OC_2H_5)_3$; (*b*) $BO^+.n(H_2O)$ (n = 1–4) semblables à ceux de l'aluminium; (*c*) $HB_2O_3^+.nH_2O$ (n = 1–3) impliquant le dimère protoné de l'acide métaborique, BO(OH); et (*d*) $B_3O_4.nH_2O$ (n = 2, 3) impliquant le trimère protoné du BO(OH) dont les structures peuvent être soit cycliques ou linéaires. D'autres membres de la série se forment par des réactions subséquentes d'hydratation ou de déshydratation des cations parents. On a aussi observé la présence des anions BO_2^- et BO^- qui avaient été étudiés antérieurement par D. E. Jensen. On discute de la chimie de la formation et des structures probables de ces ions et on les compare avec des résultats semblables obtenus antérieurement pour des flammes dopées avec des métaux de transitions, principalement le Sc, Ti, V et Cr dans leur état d'oxydation +3.

Mots clés : aluminium, bore, ions, flamme, phase gazeuse.

[Traduit par la rédaction]

Introduction

The motivation for this work on aluminum and boron arose out of our previous studies of the ion chemistry of the first row of 10 transition metals (Sc–Zn) in a hydrocarbon flame (1, 2). In these studies, the nude metallic oxide ion was observed for the first time in flames (2); i.e., AO^+, where A is the metal atom. Most of these metals form compounds with the metal in multiple oxidation states, including the +3 state for seven of them (Sc, Ti, V, Cr, Fe, Co, and Ni); it is the only state known for Sc. The oxide ion signals observed were large for VO^+ but considerably smaller for ScO^+, TiO^+, and CrO^+. However, members of the hydrated oxide ion series $AO^+.nH_2O$ (n = 0–3) accounted for 99% of the metallic flame ions observed for Sc and 81% for V, but only 6% for Ti and 0.2% for Cr.

The probable formation of these oxide ions in the flame is straightforward, involving the neutral trihydroxide, $A(OH)_3$, and oxide-hydroxide, AO(OH), which differ by a single water molecule

[1] $$A(OH)_3 + M \rightleftarrows AO(OH) + H_2O + M$$

where M is any other flame species. Oxide ion formation is initiated by proton transfer to these species followed by dehydration reactions

[2] $$HX^+ + A(OH)_3 \rightleftarrows X + A(OH)_3H^+$$
$$\text{or } A(OH)_2(H_2O)^+ \text{ or } AO^+.2H_2O$$

[3] $$A(OH)_2(H_2O)^+ + M \rightleftarrows H_2O + M + A(OH)_2^+$$
$$\text{or } AO^+.H_2O$$

[4] $$HX^+ + AO(OH) \rightleftarrows X + A(OH)_2^+ \quad \text{or } AO^+.H_2O$$

[5] $$A(OH)_2^+ \quad \text{or } AO^+.H_2O + M \rightleftarrows H_2O + M + AO^+$$

Here, HX^+ is a naturally occurring flame ion of the general type $C_xH_yO_z^+$ which functions as a proton donor for the chemical ionization of metallic species. From the promi-

nence of the signals observed for the oxide ion series, evidently the +3 oxidation state is emphasized for V, like Sc, but not for Ti nor Cr. These considerations provided our motivation for this study of Al and B, both main group III elements in the +3 oxidation state, in order to find out the degree to which their flame-ion chemistry is similar to that of Sc and V. We are not aware of any previous study of aluminum ions in flames. With regard to boron, Jensen (3, 4) studied the formation of alkali metal metaborates in fuel-rich, H_2–O_2–N_2 flames; he observed BO_2^- and BO^- mass spectrometrically and measured the corresponding electron affinities of BO_2 and BO. In similar fuel-rich hydrogen flames with added acetylene and doped with a trace of trimethylborate, $B(OCH_3)_3$, Burdett and Hayhurst (5) identified a "series of hydrates $H_2BO_2^+(H_2O)_n$," and "sets of borate and mixed borate/hydrate clusters, i.e., $H_2BO_2^+(HBO_2)_m$ and $H_2BO_2^+(H_2O)_x(HBO_2)_y$, with n, m, x, and y up to 5, were also found. In addition, borate clustering to H_3O^+ was observed in ions of the type $H_3O^+(HBO_2)_p(H_2O)_q$." However, there is no discussion of these ions beyond this statement of observations.

In this work, we studied primarily the cation chemistry of Al and B in the same, fuel-rich, CH_4–O_2 flame employed for the ion chemistry of transition metals. The ions were observed by sampling the flame at atmospheric pressure through a nozzle into a mass spectrometer. The nature of Al and B imposed limitations on the range of experimental conditions that could be examined. Thus, Al was added to the flame at the low concentration level of 10^{-6} mol fraction. Under this condition, no Al anions were observed, nor were any Al cations or anions seen in a fuel-lean (i.e., oxygen-rich) CH_4–O_2 flame. When B was admitted to the fuel-rich flame at the higher concentration of 5×10^{-4} mol fraction, an interesting variety of B_2 and B_3 cations as well as B_1 species was observed. In common with Jensen (3, 4), the anion chemistry revealed just BO_2^- and BO^-. Only very crude qualitative observations of B cations were made in the fuel-lean flame, however, because the nozzle of the mass spectrometer quickly clogged with solid boron oxides under fuel-lean conditions, and the results were not properly reproducible.

Experimental

The flame used in these experiments was a premixed, laminar, methane–oxygen flame of fuel-rich composition whose bulk characteristics are given in Table 1. It was conical in shape, ca. 3.5 mm in base diameter and 5 mm in height with a rounded tip, and with a bright blue reaction zone approximately 0.3 mm thick. It was stabilized at atmospheric pressure on a quartz capillary burner of inner diameter 2.3 mm, and surrounded by a flowing argon shield to minimize the entrainment of atmospheric air. The gases used were Matheson CP grade (CH_4 > 99.0%, O_2 > 99.6%, Ar > 99.9%) added directly from high-pressure cylinders without further purification.

With regard to the additives, all of the organometallic aluminum compounds that are commercially available and reasonably volatile are pyrophoric. In any case, the concentration of aluminum in the flame had to be kept low to avoid the excessive production of solid aluminum oxide (corundum), Al_2O_3, which would clog the orifice in the sampling nozzle of the mass spectrometer. Therefore, aluminum was added by spraying a 0.500 molar aqueous solution of $AlCl_3$ using a small part of the flame's oxygen supply to operate a tiny atomizer (6). It gave a small concentration of aluminum of 1×10^{-6} mol fraction in the equilibrium burnt-gas region of the flame. The presence of aluminum did not change the bulk characteristics of the flame nor its colour.

TABLE 1. Bulk characteristics of the fuel-rich flame

Flame parameter	
Equivalence ratio ϕ	2.15
Unburnt gas flow rates (mL s^{-1})	
CH_4	13.0
O_2	12.1
Adiabatic flame temperature (K)	2456
Measured flame temperature (K)	2200
Burnt-gas rise velocity (m s^{-1})	2.0
Equilibrium burnt-gas composition at 2200 K (mol fractions)	
H_2O	0.25144
H_2	0.41195
O_2	0.00000049
CO	0.29781
CO_2	0.034872
H	0.0036255
OH	0.00030488
O	0.00000191

Boron was added to the flame by flowing part of the flame's oxygen supply through a glass wool plug saturated with triethylborate, $B(OC_2H_5)_3$. This compound had a convenient vapour pressure at room temperature to provide a concentration of 5×10^{-4} mol fraction of boron in the equilibrium burnt gas. We have commented previously that this technique using a glass wool plug gives a much more even flow of the additive than bubbling oxygen through the liquid additive in a conventional gas saturator equipped with a glass frit (7). Although the concentration of boron is much higher than that of aluminum, a still higher boron concentration was avoided; a concentration of 1×10^{-3} mol fraction produced enough solid boron oxides to cause appreciable clogging of the orifice in the sampling nozzle. The addition of the boron additive imparted a bright green colour to the flame.

As an addition to the work done with the fuel-rich flame described in Table 1, some experiments were attempted using a similar fuel-lean, methane–oxygen flame (i.e., oxygen-rich) of equivalence ratio $\phi = 0.216$ whose bulk characteristics have been given previously (8). At the low aluminum concentration level of 1×10^{-6} mol fraction, no aluminum ions of any kind were unambiguously identified. Although boron ions were observed at the higher boron concentration of 5×10^{-4} mol fraction, the clogging problem of the nozzle with solid boron oxides was much more severe, such that stable quantitative measurements could not be made.

The flame-ion mass spectrometer has been described previously (9), and only a brief summary will be given here. The flame burner was mounted on a motorized carriage that provided accurate alignment of the flame axis with the sampling nozzle. A conical sampling nozzle of orifice diameter ca. 0.10 mm was employed, mounted in a water-cooled flange. The nozzle tip was an electron microscope lens made of platinum–iridium alloy described previously (10). Concentration profiles of individual or total ions as a function of axial distance, z, were traced out by advancing the flame onto the sampling nozzle of the mass spectrometer. Inside the nozzle, the sampled ions were focussed into a beam by an ion lens, and passed through two stages of differential pumping into a quadrupole mass filter. The mass-analyzed ions were detected with a parallel-plate Faraday collector connected to a vibrating reed electrometer having a grid-leak resistance of 10^{10} Ω.

The ion signal magnitudes in the profile figures are quoted in volts based on the detected ion current passing through 10^{10} Ω. A reproducible zero on the distance scale of the ion profiles, $z = 0$, was obtained from a fairly sharp minimum on the profile of pressure versus distance, z; pressure was measured by an ionization gauge mounted in the vacuum chamber housing the mass filter. The

pressure minimum corresponded to the downstream edge of the flame's bright, luminous reaction zone. The ion signal magnitudes reported below were corrected for mass discrimination in the ion lens and mass filter against ions of high mass number M (i.e., mass/charge ratio) measured at high resolving power. The correction procedure was given previously (11). The upper limit to the mass range of the mass spectrometer is 165 u.

The ion signals can be subject to distortion because the sampled flame gas is cooled in passing through the cold boundary layer surrounding the sampling orifice, and also in the adiabatic expansion to supersonic velocity that occurs downstream of the nozzle throat. These effects have been described in a series of papers by Hayhurst and co-workers, all of which are referenced in the latest work (5). Ion–molecule reactions having large rates can shift in the exothermic direction in response to the cooling during sampling. The effect is most likely to occur for hydrate formation because the rate involves the reagent water, a major product of combustion. Although this sampling effect may enhance certain hydrate ion signals to some extent, it is unlikely to falsify their existence.

Neutral aluminum and boron species

The background neutral aluminum and boron chemistry in the flame should be examined before considering the ion chemistry in detail. Although aluminum and boron are added as $AlCl_3$ and $B(OC_2H_5)_3$, respectively, these compounds will decompose to give a number of neutral species whose final equilibrium concentrations in the burnt gas will be independent of the chemical nature of the original additive. To calculate the concentrations of these species in the flame, ΔG_f^0 values at 2200 K for those aluminum and boron species listed in the JANAF tables were used (12). The ΔG^0 values and corresponding equilibrium constants for a number of reactions involving aluminum or boron species and the major neutral species present in the burnt gas of the fuel-rich flame could then be evaluated, again using data from the JANAF tables. Finally, the concentrations of the aluminum or boron species were calculated using the concentration data for the major flame species given in Table 1. The results of these calculations for the most important aluminum and boron species appear in Table 2, with concentrations given as fractions of the total aluminum or boron concentration in the flame. The AO_2^- anions are included since thermodynamic data are available.

In the case of the aluminum calculations, an important consideration arises because solid aluminum oxide, Al_2O_3, is stable under flame conditions. This was indicated by the formation of a solid white deposit, presumably aluminum oxide, which built up on the sampling plate when $AlCl_3$ was added to the flame. Since the activity for any solid is essentially unity, the equilibrium of Al_2O_3 with respect to its elements sets the concentration of gaseous atomic Al, and hence the concentrations of all other gaseous aluminum species in any particular flame (see, for example, ref. 13). Thus, no matter how much aluminum is added, the flame will contain constant concentrations of aluminum species at any given temperature provided the threshold for solid Al_2O_3 formation is exceeded. Such a result has implications for calibrating species concentrations or, conversely, for measuring flame temperatures. That is, the determination of the concentration of a major aluminum species such as AlO(OH) or AlOH in the flame can give a direct measure of the flame temperature, since the concentration is a function of the temperature only; the total amount of aluminum added is unimportant.

TABLE 2. Relative concentrations of aluminum and boron species present in the fuel-rich flame at equilibrium

Compound A = Al, B	Fraction of total additive present	
	Al[a]	B[b]
AO(OH)	0.726	0.977
AOH	0.267	[c]
HAO	3.93×10^{-6}	0.0172
AO	0.00520	0.00190
AO_2	8.16×10^{-6}	0.00153
A_2O	0.00241	2.53×10^{-11}
$(AO)_2$	2.92×10^{-4}	3.20×10^{-6}
A_2O_3	[c]	0.00119
A	3.02×10^{-5}	5.74×10^{-5}
AH	2.41×10^{-5}	[c]
$A(OH)_3$	[c]	8.80×10^{-4}
AO_2^-	4.76×10^{-8}	1.35×10^{-5}
Total	1.000	1.000

[a]Added as $AlCl_3$ to give 1×10^{-6} mol fraction in the burnt gas.

[b]Added as $B(OC_2H_5)_3$ to give 5×10^{-4} mol fraction in the burnt gas.

[c]Data were not available for these species in the gas phase.

The equilibrium calculations based on the JANAF tables (12) indicate that the aluminum chemistry is dominated by the oxide–hydroxide AlO(OH) with a significant contribution from the monohydroxide AlOH. The isomer of the latter, HAlO, is much less important. However, there are a number of gaps in the JANAF data. From emission spectra of Al and AlO in fuel-rich H_2–O_2–N_2 flames, Jensen and Jones (14) infer by an indirect method that the dominant neutral species is the radical dihydroxide $Al(OH)_2$; their conclusion is endorsed by Newman and Page (15). That the dominant neutral species involves aluminum in the +2 oxidation state is surprising. Unfortunately, the aluminum ions that were observed neither substantiate nor negate this conclusion. Also, no data are available for the trihydroxide $Al(OH)_3$ although the observed ions do imply the presence of this species in the flame.

In the boron case, the calculations given in Table 2 indicate that the oxide-hydroxide, metaboric acid BO(OH), accounts for nearly 98% of the boron present in the flame. No data are available for the mono- or dihydroxide or hydride, but the trihydroxide, orthoboric or boracic acid $B(OH)_3$, is given. The presence of neutral species based on the dimer and trimer of metaboric acid is implied by the ion chemistry. The dimer, $[BO(OH)]_2$, could rearrange to a stable linear structure, $O{=}BOB(OH)_2$. The trimer, $[BO(OH)]_3$, could lead to a linear structure, $O{=}BOB(OH)OB(OH)_2$, or a cyclic structure having a six-membered OBOBOB ring with each boron coordinated to an OH group. This latter structure is similar to that of metaboric acid in the solid phase (16).

Results and discussion

Aluminum ions

Only a low concentration level of 1×10^{-6} mol fraction of aluminum in the burnt gas of the fuel-rich flame was introduced by spraying a 0.500 molar aqueous solution of $AlCl_3$ using an atomizer. A total of four aluminum cations was

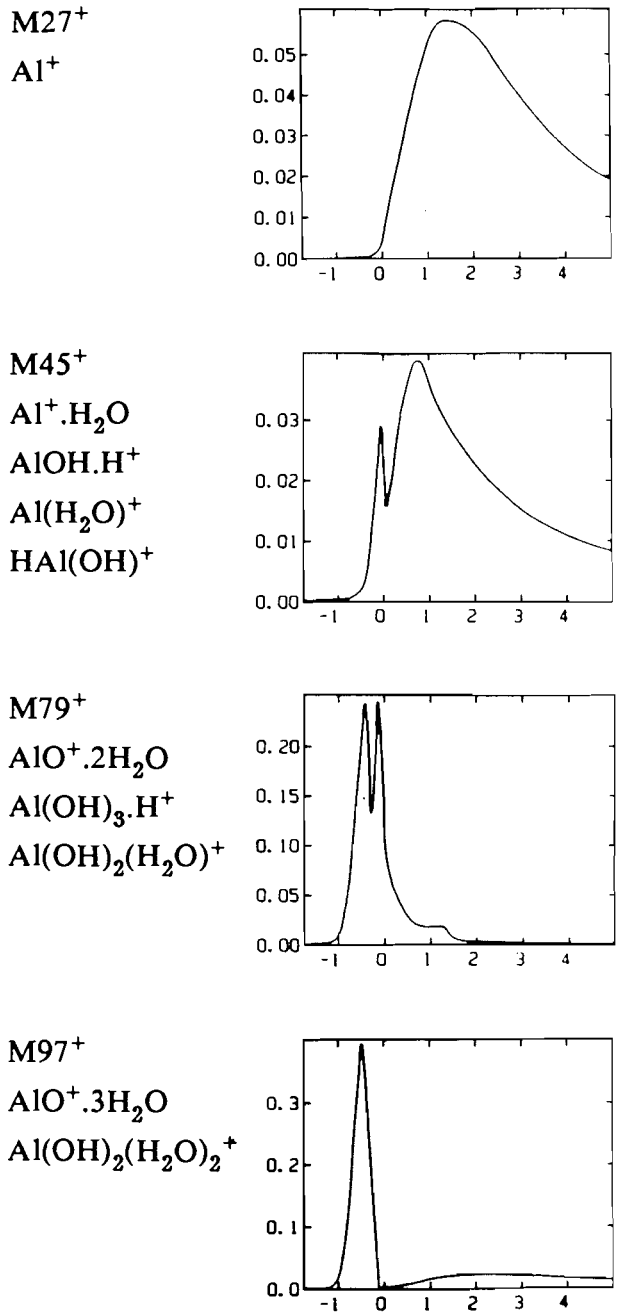

FIG. 1. Mass numbers, chemical assignments, and concentration profiles of aluminum cations observed in the fuel-rich flame below 165 u. The mass number of each cation is given first, then an empirical formula that identifies it as a member of a particular series, followed by its probable structural formula(e). All profile magnitudes are given in volts, plotted against distance along the flame axis, z, in mm. The reaction zone is located upstream of $z = 0$ (negative z).

observed, whose concentration profiles are given in Fig. 1 as a function of distance along the flame axis, z. They can be grouped as members of two cation series, $AlO^+.nH_2O$ and $Al^+.nH_2O$. The aluminum ion chemistry will be discussed in the following order: total ion profiles, anion chemistry, the two cation series, and fuel-lean flame considerations.

Total ion profiles

The total ion profiles for the fuel-rich flame did not differ, within experimental error, from those observed in the undoped flame (presented with the total ion profiles for boron in Fig. 2). Thus, aluminum does not appear to contribute any significant new ion source or sink to the naturally occurring ions already present in the undoped flame.

Aluminum anion chemistry

In marked contrast to the boron anions discussed later, no aluminum anions of any kind were identified in the fuel-rich flame. Assuming AlO_2^- to be the dominant anion, failure to observe it at this low concentration level of aluminum is not surprising in view of the small equilibrium concentration for AlO_2^- in Table 2. The fraction of total aluminum additive given as 4.76×10^{-8} corresponds to an AlO_2^- concentration of 1.6×10^5 ions cm^{-3}, just below the detection limit of the mass spectrometer. The experimental observation is consistent with the theoretical prediction.

$AlO^+.nH_2O$ series (n = 2, 3)

Unlike the Sc, Ti, and V cases where the ions $AO^+.nH_2O$ ($n = 0$–3) were identified (2), only the $n = 2$, 3 ions were observed unambiguously in the case of Al. Protonation of the oxide-hydroxide, the major aluminum neutral species listed in Table 2, would give $Al(OH)_2^+$ or $AlO^+.H_2O$ with $n = 1$ by reaction [4]. This ion at $M61^+$ was observed, but not reproducibly. A very small signal was seen in the burnt-gas region by increasing the voltage on the ion lens downstream of the sampling nozzle. Increasing the lens voltage imparts extra kinetic energy to the ions after they enter the mass spectrometer, and could cause hydrated molecules to break up. Thus, $AlO^+.H_2O$ is probably not a genuine flame ion but could appear if $AlO^+.2H_2O$ loses a water molecule on collision, as in reaction [3]. Failure to observe a regular signal for $AlO^+.H_2O$ could occur either if it rapidly hydrates to form $AlO^+.2H_2O$ at $M79^+$, or if it loses a water of hydration to form AlO^+ at $M43^+$ according to reaction [5]. However, if AlO^+ were present, it would probably have been masked by the very large signal due to protonated ketene, CH_3CO^+, a natural flame ion at the same mass number (9).

No signal was observed at $M62^+$ corresponding to the protonation of the radical dihydroxide $Al(OH)_2$ which Jensen and Jones (14) believe to be the dominant aluminum neutral species present in the flame. Alternatively, if the odd electron were weakly bound, it might ionize by electron transfer to give $Al(OH)_2^+$ at $M61^+$ (indistinguishable from the protonated oxide-hydroxide). If endothermic, this ionization process might also be enhanced by increased kinetic energy from the high voltage applied to the ion lens. Under the regular condition of the ion lens, however, the dihydroxide could be chemically ionized by the reaction

[6] $$H_3O^+ + Al(OH)_2 \rightarrow H + Al(OH)_2(H_2O)^+$$
$$\text{or } AlO^+.2H_2O$$

for the direct formation of the series member with $n = 2$ at $M79^+$. The large signal at $M79^+$ could also be produced by proton transfer to the trihydroxide $Al(OH)_3$ according to reaction [2]. Furthermore, $M79^+$ might arise by dehydration of the series member with $n = 3$ at $M97^+$, the largest signal observed with aluminum

[7] $$Al(OH)_2(H_2O)_2^+$$
$$\text{or } AlO^+.3H_2O + M \rightleftarrows M + H_2O + AlO^+.2H_2O$$

Certainly the profile at $M79^+$ in Fig. 1 is complex; it exhibits twin peaks in the reaction zone and a further one

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

downstream near $z = 1.3$ mm, indicative of several ion formation processes.

The $AlO^+.3H_2O$ ions at $M97^+$ could be produced from $Al(OH)_3$ in a three-body process

[8] $H_3O^+ + Al(OH)_3 + M \rightleftarrows M + Al(OH)_2(H_2O)_2^+$ or $AlO^+.3H_2O$

where the central Al atom is surrounded by a stable electron octet. Reaction [8] might be responsible for the maximum in the profile shown in Fig. 1, which occurs downstream where H_3O^+ is the major source ion. The three-body process would also be enhanced by any drop in temperature resulting from the entrainment of atmospheric air. The peak in the reaction zone could arise by proton transfer to neutral $Al(OH)_3(H_2O)$ having an electron octet if this species exists in the flame, or by hydration via the back reaction [−7]. In any case, the profile shape for $M97^+$ is indicative of two or more formation reactions. Much of this cation chemistry for aluminum could be clarified by measurements of the proton affinities for $Al(OH)_3$ and AlO(OH), and the ionization energy of $Al(OH)_2$.

$Al^+.nH_2O$ series (n = 0, 1)

The two ions in this series exist only downstream. The profile peak in the reaction zone at $M45^+$ in Fig. 1 is presumed to arise from protonated acetaldehyde, $CH_3CHO.H^+$, at the same mass number. The first hydrate, $Al^+.H_2O$ at $M45^+$, can be formed by protonation of the second-most important neutral aluminum species listed in Table 2, AlOH

[9] $H_3O^+ + AlOH \rightleftarrows Al(H_2O)^+ + H_2O$

A second isomer of $M45^+$, $HAl(OH)^+$, is also possible. Presumably this isomer would be formed by protonation of HAlO whose concentration in the flame is much lower, as seen in Table 2. In either case, the major proton source should be H_3O^+ since this is the dominant ion in the downstream portion of the fuel-rich flame.

Formation of the Al^+ ion at $M27^+$ could occur by dehydration of $M45^+$

[10] $Al(H_2O)^+ + M \rightleftarrows Al^+ + H_2O + M$

This mechanism is particularly attractive because it can be seen from the profiles in Fig. 1 that $M27^+$ appears to form after $M45^+$. However, it is also possible that a charge transfer mechanism previously invoked for the ionization of alkali metals is operative (17)

[11] $H_3O^+ + Al \rightarrow Al^+ + H_2O + H$

which is exothermic by 8.6 kJ mol^{-1} (12).

The Al^+ and $Al^+.H_2O$ ions account for 7.9% and 5.4% respectively, of the aluminum ions observed in the flame. As such, they are of greater importance than members of the same series for scandium and vanadium (2); as will be seen below, no boron members of this series were observed at all. Apparently the +3 oxidation state is, surprisingly, somewhat less emphasized in aluminum compared with scandium and vanadium.

Fuel-lean flame considerations

The fuel-lean flame (i.e., oxygen-rich) described in the experimental section was similarly doped with aluminum using the same atomizer techniques. However, no cations or anions of aluminum were observed with the mass spectrometer at the low concentration of aluminum obtainable. Calculations similar to those given in Table 2 were carried out for the fuel-lean flame, and revealed that AlO(OH) was the only important gas-phase species. Since the protonated form of this species, $Al(OH)_2^+$, was not observed in the fuel-rich flame under regular conditions, it is perhaps not surprising that it was not observed in the fuel-lean flame either. Thus, chemical ionization in the fuel-lean flame did not produce measurable ion signals.

Boron ions

Boron was added as $B(OC_2H_5)_3$ vapour to give 5×10^{-4} mol fraction of boron species in the burnt gas of the fuel-rich flame, a concentration 500 times greater than that used with aluminum. In this case, many more cations were observed, which can be organized into four cation series: $B(OC_2H_5)_3H^+.nH_2O$, $BO^+.nH_2O$, $HB_2O_3^+.nH_2O$, and $B_3O_4^+.nH_2O$. Clearly, a new dimension is added by the observation of B_2 and B_3 ions. The presentation of the results and discussion for boron will follow the same order employed for aluminum: total ion profiles, anion chemistry, the four cation series, and fuel-lean flame considerations.

Total ion profiles

Total ion profiles for the fuel-rich flame with and without the $B(OC_2H_5)_3$ additive are found in Fig. 2. The addition of boron to the flame results in a large increase in the total positive ion concentration, and an even larger relative increase in the total negative ion concentration. Since the flame is a quasi-neutral plasma, the difference between the total positive and negative ion signals gives the free electron concentration at any point on the flame axis. Thus, boron is an effective electron scavenger in the reaction zone; the total positive and negative ion concentrations are nearly equal there, such that the free electron concentration is effectively zero. On the other hand, boron is not an effective electron scavenger downstream. The initial large increase of both positive and negative ions upstream was observed previously with other additives (7, 8, 10, 18). It does not imply any new ion production process, but rather a decreased rate of ion loss. This occurs because relatively fast cation–electron recombination has been replaced by slower cation–anion recombination, resulting in a higher, steady-state level of ionization.

Boron anion chemistry

In the fuel-rich flame, only the BO_2^- and BO^- anions were detected, whose profiles are shown in Fig. 3. Our results for boron anions in a CH_4–O_2 flame clearly parallel those of Jensen in a H_2–O_2–N_2 flame (3, 4). The anions are derived from dissociative electron attachment to BO(OH) in the reaction zone

[12a] $e^- + BO(OH) \rightleftarrows BO_2^- + H$

[12b] $\rightleftarrows BO^- + OH$

The similarity in shape of the BO_2^- and BO^- profiles in Fig. 3 suggests that the two ions are equilibrated or nearly so

[13] $BO_2^- + H_2 \rightleftarrows BO^- + H_2O$

albeit with BO_2^- present in large excess. Reaction [13] mentioned by Jensen (4), in combination with the balanced flame radical reaction

[14] $H + H_2O \rightleftarrows OH + H_2$

would be indistinguishable from the reaction

[15] $BO_2^- + H \rightleftarrows BO^- + OH$

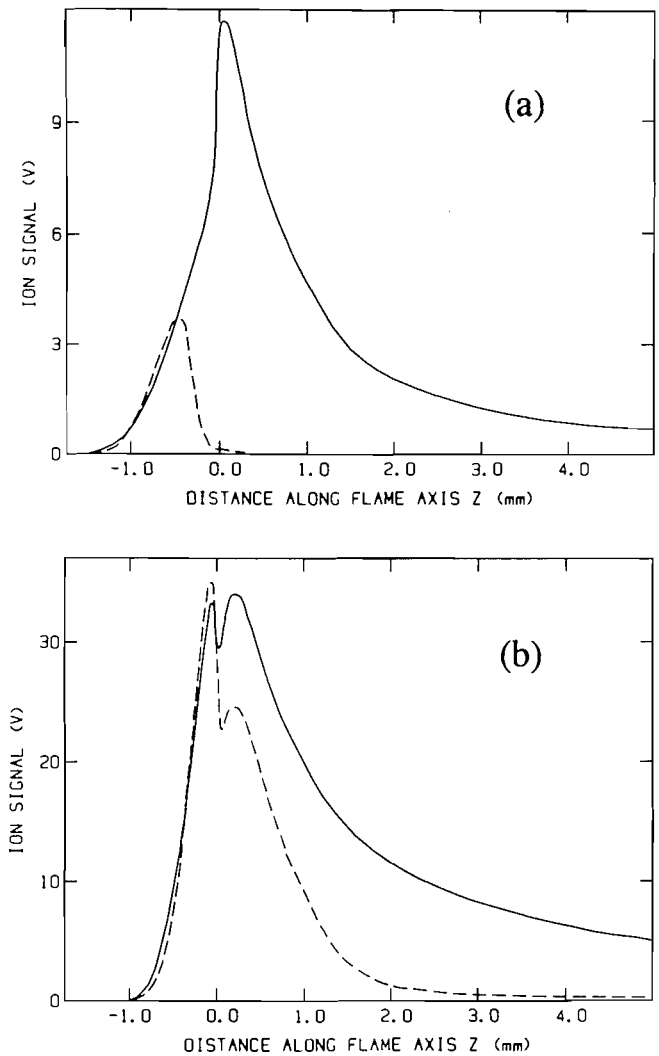

FIG. 2. Concentration profiles for the total ion signals (*a*) in the undoped fuel-rich flame and (*b*) in the fuel-rich flame doped with $B(OC_2H_5)_3$. Total positive ion signal is indicated by the solid line and total negative ion signal by the broken line. The flame reaction zone is located upstream of $z = 0$ (negative z).

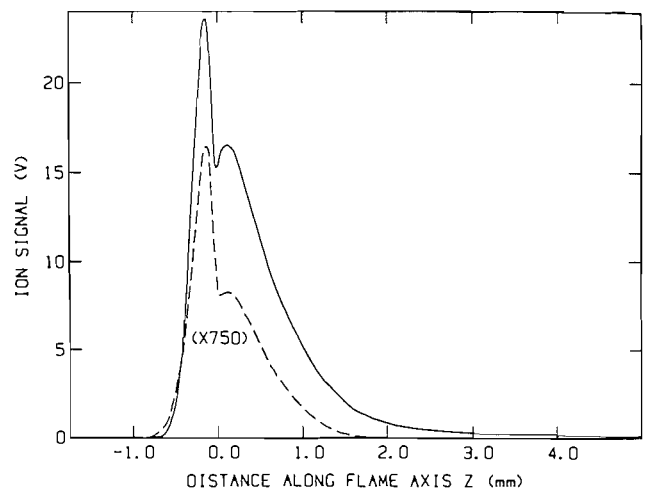

FIG. 3. Concentration profiles for the boron anions BO_2^- at $M43^-$ (solid line) and BO^- at $M27^-$ (broken line). The BO^- signal is multiplied by a factor of 750 in the figure. The reaction zone is located upstream of $z = 0$ (negative z).

It is also not surprising that the BO_2^- and the total negative ion profiles have similar shapes. Downstream in the fuel-rich flame where [H] becomes large, BO_2^- is destroyed by the back reaction [−12*a*] involving associative electron detachment. The signal minimum near $z = 0$ is caused by "H-atom overshoot" above its equilibrium concentration before [H] is reduced by the slow, neutral, three-body recombination reactions H + H + M and H + OH + M.

$B(OC_2H_5)_3H^+.nH_2O$(n = 0, 1)

Profiles for all 11 boron cations observed within the range of the mass spectrometer (165 u) are given in Fig. 4. It is clear from the mass numbers that two of the ions stem from protonation of the $B(OC_2H_5)_3$ additive, namely $B(OC_2H_5)_3H^+$ at $M147^+$ and its first hydrate, $B(OC_2H_5)_3H^+.H_2O$ at $M165^+$. It is just possible that the latter ion could also form directly by protonation of the hydrated additive, $(H_2O)B(OC_2H_5)_3$, with a filled valence shell around the B atom. As would be expected, both profiles exhibit a large peak in the flame reaction zone.

There are two aspects to this ion series that are somewhat surprising. The first is that both ion profiles show a tiny maximum near $z = 4$ mm downstream in the burnt gas; it is difficult to see in the $M165^+$ diagram, but it is definitely present in the original profile data. This would seem to indicate that a small amount of the additive survives into the burnt-gas region. The second aspect concerns the breakdown of the additive in the reaction zone. Initially, it might be expected to given orthoboric acid $B(OH)_3$ by three successive nucleophilic substitution (S_N2) reactions of OH for OC_2H_5 of the type

[16] $$B(OC_2H_5)_3 + OH \rightarrow B(OC_2H_5)_2(OH) + OC_2H_5$$

However, the protonated intermediates $B(OC_2H_5)_x(OH)_{3-x}H^+$ ($x = 2, 1$) were never observed. It would appear that the substitutions occur too rapidly to allow significant steady-state concentrations of the intermediates to build up.

$BO^+.nH_2O$ series (n = *1–4*)

Profiles for the four members of this series are given in Fig. 4 at $M45^+$, $M63^+$, $M81^+$, and $M99^+$. The BO^+ ion was not observed. This is perhaps not too surprising, given that boron is an electron-deficient element; BO^+ might be expected to be a strong Lewis acid, satisfying its empty valence orbitals by coordinating water molecules.

The ion signal for the first member of the series, $B(OH)_2^+$ at $M45^+$, is small and exists only in the downstream region; the peak in the reaction zone in Fig. 4 is due to protonated acetaldehyde, as mentioned in connection with $Al^+.H_2O$. Presumably $B(OH)_2^+$ is formed by proton transfer as in reaction [4] to the oxide-hydroxide or metaboric acid, BO(OH). From Table 2 it is the major boron species present in the flame at equilibrium. The *downstream* portions of the remaining members of the series are probably made by successive hydrations of this electron-deficient species, as in the back reaction [−3]. This is borne out by the fact that the downstream maxima occur progressively later in the flame as one goes down the series to the higher hydrates. Apparently $BO^+.2H_2O$ or $B(OH)_2(H_2O)^+$ at $M63^+$ is the preferred hydrate, since this signal is at least twice as large as that for any other member of the series in the downstream region. The shoulder on the downstream peak at $z = 0.5$ mm is due to a

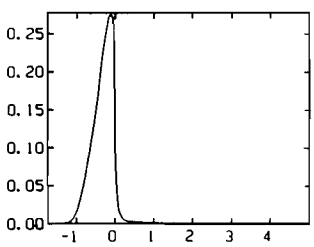

FIG. 4. Mass numbers, chemical assignments, and concentration profiles of boron cations observed in the fuel-rich flame at or below 165 u. The mass number of each cation is given first, then an empirical formula that identifies it as a member of a particular series, followed by its probable structural formula(e). All profile magnitudes are given in volts, plotted against distance along the flame axis, z, in mm. The reaction zone is located upstream of $z = 0$ (negative z).

naturally occurring flame ion at the same mass number. The final member of the series, $BO^+.4H_2O$ at $M99^+$, has a much smaller profile magnitude. A reasonable structure would be the true hydrate $B(OH)_2(H_2O)_2^+.H_2O$, with the water hydrogen-bonded in the outer coordination sphere to the two OH groups. It is probably not a true flame ion but arises due to cooling during sampling.

There is also signal present in the *reaction zone* for all these ions except possibly $BO^+.H_2O$, although naturally occurring flame ions at the same mass numbers may distort the peak magnitudes. In the reaction zone, formation of the series could well be initiated by protonation of orthoboric acid, $B(OH)_3$, formed by nucleophilic substitution of the additive as described in the previous section. Subsequent hydration could then form the remaining members of the series. This suggests that $B(OH)_3$ might be an important species in the reaction zone before its concentration drops off to a low equilibrium value in the downstream region of the flame. All of the ion chemistry of the $BO^+.nH_2O$ series, as well as that of the next two boron cation series, is summarized in Fig. 5.

$HB_2O_3^+.nH_2O$ series (n = *1–3*)

Both this ion series and the next one involving $B_3O_4^+.nH_2O$ represent ions arising from the polymerization of the additive in the flame. The relatively large concentration of boron additive in the flame must be responsible for this phenomenon. The first ion in the series, $HB_2O_3^+.H_2O$ at $M89^+$ shown in Fig. 4, has peaks in the reaction zone and downstream. The peak at $z = 0$ is again caused by a naturally occurring flame ion. The most reasonable structure involves a protonated form of the dimer, either $[BO(OH)]_2$ or $O{=}BOB(OH)_2$, to give $(HO)BOB(OH)_2^+$. The multiple peaks in the ion signal suggest that more than one ionization process is occurring. Thus, formation of the ion could take place by direct protonation of a dimer if it exists in the flame

[17] $HX^+ + [BO(OH)]_2$ or $O{=}BOB(OH)_2 \rightleftarrows (HO)BOB(OH)_2^+ + X$

or by an addition reaction with the first member of the $BO^+.nH_2O$ series

[18] $B(OH)_2^+ + BO(OH) + M \rightleftarrows (HO)BOB(OH)_2^+ + M$

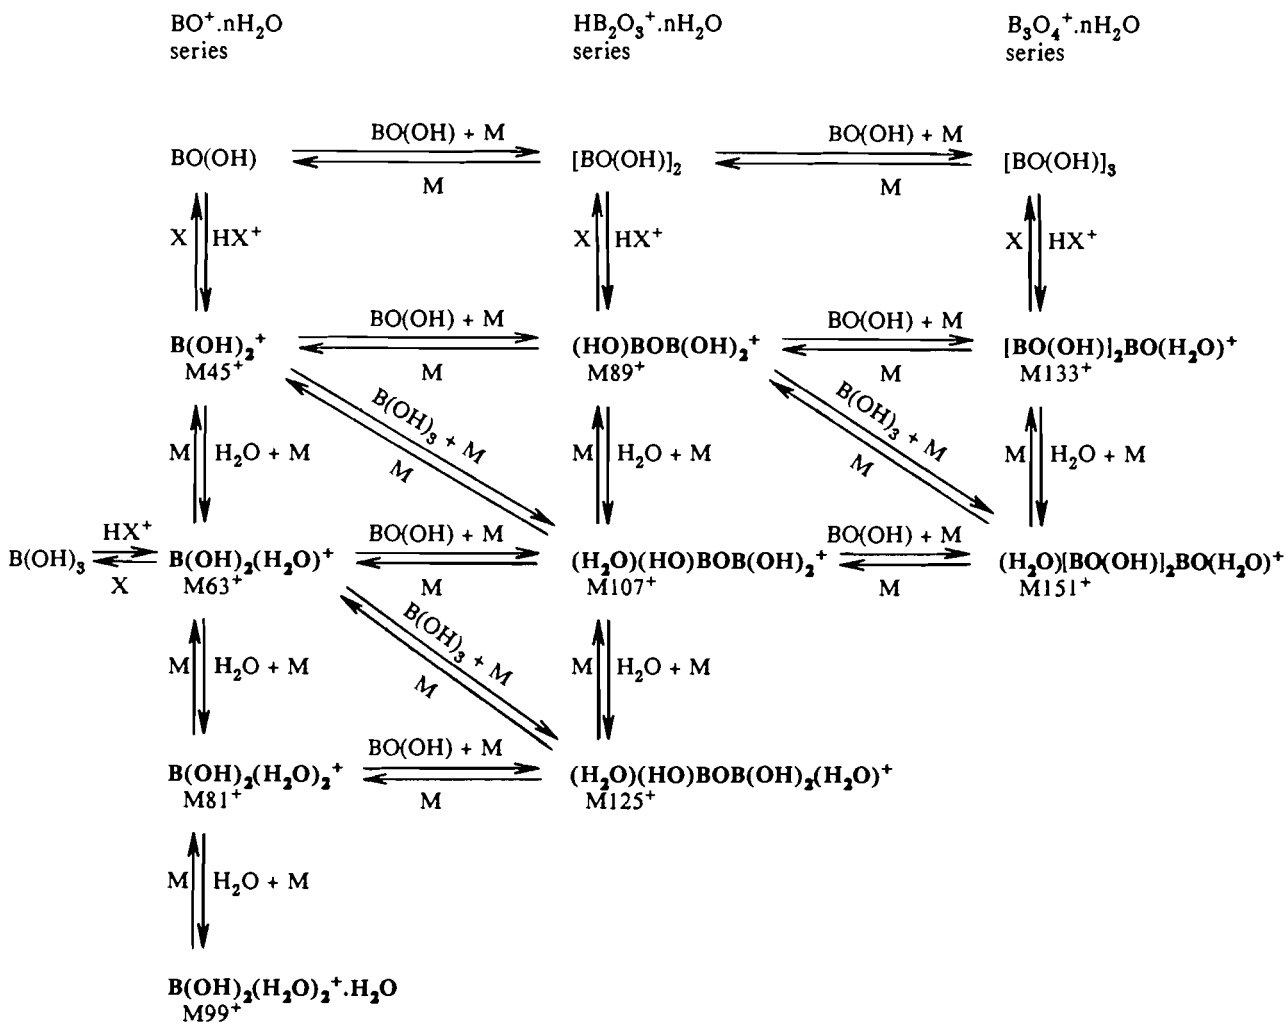

FIG. 5. Reaction flow diagram, which summarizes the boron cation chemistry leading to the three ionic series shown across the top of the figure. Probable structural formulae for the ions are given in bold, with their mass numbers written underneath. The ions of the $B_3O_4^+.nH_2O$ series could have either a linear or a cyclic structure. The symbols HX^+ and X represent flame species that are proton donors or proton receptors, respectively.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

This latter reaction would not appear to be important in the reaction zone, since $B(OH)_2^+$ was not observed there.

The next two ions in this series at $M107^+$ and $M125^+$ could be formed by successive hydrations of the parent ion at $M89^+$. The water molecules would tend to coordinate at the more electron-deficient B site, so that the ion at $M107^+$ would have a structure $(H_2O)(HO)BOB(OH)_2^+$, and the ion at $M125^+$ might be $(H_2O)(HO)BOB(OH)_2(H_2O)^+$. There are other possible structures such as ones in which the bridging O is protonated. The ion at $M107^+$ could also be formed from the $BO^+.nH_2O$ series, either by addition of metaboric acid or, in the reaction zone, orthoboric acid

[19] $B(OH)_2(H_2O)^+ + BO(OH) + M \rightleftarrows (H_2O)(HO)BOB(OH)_2^+ + M$

[20] $B(OH)_2^+ + B(OH)_3 + M \rightleftarrows (H_2O)(HO)BOB(OH)_2^+ + M$

Analogous reactions involving $B(OH)_2(H_2O)_2^+$ and $B(OH)_2(H_2O)^+$ could also form the ion at $M125^+$. All of this ion chemistry is summarized in Fig. 5.

$B_3O_4^+.nH_2O$ series (n = 2, 3)

Profiles of the two members of this cation series at $M133^+$ and $M151^+$ are given in Fig. 4. They show signals in the downstream region, and also in the reaction zone. The first ion may be derived by protonation of the trimer of metaboric acid

[21] $HX^+ + [BO(OH)]_3 \rightleftarrows B_3O_4^+.2H_2O + X$

As previously discussed in the section on neutral boron species, the neutral parent species could have a linear or a cyclic form, giving rise to two possible structures for $M133^+$; a linear one, *l*-$(HO)BOBO(OH)B(OH)_2^+$, or the protonated cyclic structure, *c*-$BO(OH)BO(OH)BO(H_2O)^+$. Protonation could occur either on one of the OH sites or possibly on a bridging O atom.

The other member of the series at $M151^+$ could arise by hydration of $M133^+$. Alternatively, it could be formed from the $HB_2O_3^+$ cation series, by addition either of metaboric or of orthoboric acid

[22] $(H_2O)(HO)BOB(OH)_2^+ + BO(OH) + M \rightleftarrows B_3O_4^+.3H_2O + M$

[23] $(HO)BOB(OH)_2^+ + B(OH)_3 + M \rightleftarrows B_3O_4^+.3H_2O + M$

Obviously, there are a number of structural possibilities for this ion, whether it is cyclic or linear. The ion chemistry of this series is also summarized in Fig. 5.

Clearly, the three boron cation series are strongly interlinked, chemically. The ion chemistry is interesting because it involves the formation of species that are precursors to the deposits of solid boron oxides that were eventually seen to coat the sampling plate of the mass spectrometer. Essentially all of these cations agree with those reported by Burdett and Hayhurst in their brief, four-line statement (5) quoted in our Introduction. Their "series of hydrates $H_2BO_2^+(H_2O)_n$" can be rewritten as $BO^+.(n + 1)H_2O$, the same as our B_1 series. Similarly, members of their other series are equivalent to ours: e.g., their "mixed borate/hydrate clusters . . . $H_2BO_2^+(H_2O)_x(HBO_2)_y$" give our $HB_2O_3^+.2H_2O$ with $x = 1$, $y = 2$; $HB_2O_3^+.3H_2O$ with $x = 2$, $y = 1$; and $B_3O_4^+.3H_2O$ with $x = 1$, $y = 2$. Their various series overlap to some extent, and they have not considered structure. Nevertheless, the agreement of their observations with ours is gratifying.

Fuel-lean flame considerations

It was not possible to measure quantitative profiles for boron ions in the fuel-lean flame (i.e., oxygen-rich) described in the experimental section. Solid boron oxides tended to clog the orifice in the sampling nozzle in the space of a few minutes. Nevertheless, a number of boron ions were detected qualitatively. With regard to the anions, evidence was obtained for both BO_2^- and BO^-, and also for BO_4^- and BO_6^-. The latter anion would require the coordination of at least two oxygen molecules at the B site. With regard to the cations, $M45^+$, $M63^+$, $M81^+$, $M107^+$, and $M133^+$ were all detected. Possibly the boron ion chemistry in the fuel-lean flame and fuel-rich flame has much in common.

Conclusions

The ion chemistry of aluminum and boron was studied by doping methane–oxygen flames with $AlCl_3$ and $B(OC_2H_5)_3$ to give 1×10^{-6} and 5×10^{-4} mol fraction, respectively, in the burnt gas. Measurements were made by sampling the flame through a nozzle into a mass spectrometer. The ions observed for both Al and B, elements in the +3 oxidation state, have aspects in common with ions observed previously for transition metals exhibiting the same oxidation state (1, 2), primarily Sc, Ti, V, and Cr.

A common theme for all of these elements is chemical ionization by proton transfer of their oxide-hydroxides, AO(OH), and trihydroxides, $A(OH)_3$, where A is the elemental atom. Subsequent hydration/dehydration of these ions gives rise to an oxide ion series $AO^+.nH_2O$ (n = 2, 3 for Al and 1–4 for B; large oxide ion signals were observed previously for Sc and V (n = 0–3), and small ones for Ti (n = 0–3) and Cr (n = 0, 1). The absence of AO^+ with Al and B probably reflects the electron-deficient nature of their valence shells.

The atomic ion series $A^+.nH_2O$ was not present with B but was observed with Al (n = 0, 1), arising by proton transfer to the monohydroxide, AOH, with subsequent dehydration. It was the dominant ion series observed with Cr (n = 0–3), major with Ti (n = 1–4), but minor with Sc (n = 1, 4) and V (n = 0, 1). It was also a dominant series with five other transition metals, Mn, Fe, Co, Ni, and Cu, but different chemical ionization mechanisms are possible, not necessarily associated with AOH.

Upper limits to the additive concentration in the flames for both Al and B were imposed by the formation of solid oxides that tended to clog the orifice in the sampling nozzle. This prevented the observation of Al ions in a fuel-lean flame; only qualitative measurements were possible in the flame doped with B. In a fuel-rich flame with the relatively high concentration of B additive, however, two polymeric ion series were observed: $HB_2O_3^+.nH_2O$ (n = 1–3) and $B_3O_4^+.nH_2O$ (n = 2, 3). These are formed by ion–molecule addition reactions of BO(OH) to single B ions, or proton transfer reactions to dimers and trimers of BO(OH). The B_3 series of ions can involve both cyclic and linear structures. A further ion series for boron, $B(OC_2H_5)_3H^+.nH_2O$ (n = 0, 1), arises by proton transfer to the additive with subsequent hydration. The ion chemistry of boron reveals a sequence in

the underlying neutral chemistry in which the $B(OC_2H_5)_3$ additive first converts to $B(OH)_3$ in the flame reaction zone by nucleophilic substitution (S_N2), and then to BO(OH) as the dominant species downstream in the burnt gas. The anion chemistry revealed only a very large BO_2^- signal and a much smaller one for BO^-, in line with the previous studies of Jensen (3, 4). As a general statement about the ion chemistry, boron had more in common with Si (19) than with the metallic elements, reflecting the nonmetallic character of B; its strong affinity for oxygen produces B—O—B structures in rings and chains.

Nuclear magnetic resonance studies of the methylammonium hexahalotellurates

MARK R. MACINTOSH, MARCO L. H. GRUWEL, KATHERINE N. ROBERTSON, AND RODERICK E. WASYLISHEN[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received May 28, 1991

MARK R. MACINTOSH, MARCO L. H. GRUWEL, KATHERINE N. ROBERTSON, and RODERICK E. WASYLISHEN. Can. J. Chem. **70**, 849 (1992).

A ^2H and ^{14}N NMR study of the solid methylammonium hexahalotellurates, $(MA)_2TeX_6$ (MA = $CH_3ND_3^+$ or $CD_3NH_3^+$, X = Cl, Br, and I), has been undertaken to characterize the dynamics of the methylammonium (MA) ion as a function of temperature. At room temperature, the MA ion in the hexachlorotellurate (solid II) is confined to C_3 jumps about the C—N axis while a small angle libration of the C—N axis is occurring. In the room temperature phase, solid I, of $(MA)_2TeBr_6$ and $(MA)_2TeI_6$ the MA ions are performing overall reorientations on the ps time scale, averaging the ^2H nuclear quadrupolar interactions to zero. Variable temperature ^2H NMR spin-lattice relaxation times, T_1, indicate an activation energy, E_A, for "isotropic" reorientations of the $CH_3ND_3^+$ ion of 5.2 ± 0.5 and 2.6 ± 0.3 kJ mol^{-1} for X = Br and I, respectively. Deuterium T_1 values for C-deuterated MA ion in the hexaiodotellurate indicate an E_A for whole-ion reorientation of 3.1 ± 0.3 kJ mol^{-1}. At any given temperature, the correlation time, τ_c, derived from the T_1 results was found to be the same for the two deuterium-labelled hexaiodotellurates. The similarity of both the E_A and the τ_c values implies correlated motion of the methyl and ammonium groups. The ^{14}N T_1 results for solid I of $(MA)_2TeI_6$ indicate that C—N axis motions, with an E_A = 5.6 ± 0.6 kJ mol^{-1}, are more hindered than N—D or C—D bond dynamics. The ^2H NMR spectra for $(MA)_2TeI_6$ (solid II) and $(MA)_2TeBr_6$ (solids II, III, and IV) are characterized by a Pake doublet line shape. The measured peak-to-peak splittings are less than what is predicted by C_3 motion about the molecular symmetry axis. It is possible to model these line shapes by postulating that C_3 rotations of the methyl and ammonium groups occur as the C—N axis librates in an effective cone about the position of the static molecular axis. For $(CH_3ND_3)_2TeBr_6$ and $(CD_3NH_3)_3TeBr_6$ the peak-to-peak splittings in the ^2H NMR spectra were measured as a function of temperature in solid phases II, III, and IV and were found to be similar. Finally, the ^2H NMR line shape relaxation for $(MA)_2TeBr_6$ (solid III) displays an orientation dependence indicating that rotations about the C—N axis are discrete rather than diffusive in nature. For solid phase II of $(MA)_2TeCl_6$, the line shape is observed to relax isotropically, implying that continuous C_3 rotations are taking place.

Key words: ^2H and ^{14}N NMR, methylammonium hexahalotellurates, molecular motion.

MARK R. MACINTOSH, MARCO L. H. GRUWEL, KATHERINE N. ROBERTSON et RODERICK E. WASYLISHEN. Can. J. Chem. **70**, 849 (1992).

On a réalisé une étude RMN du ^2H et du ^{14}N d'hexatellurates de méthylammonium solides, $(MA)_2TeX_6$ (MA = $CH_3ND_3^+$ ou $CD_3NH_3^+$, X = Cl, Br ou I), dans le but de caractériser la dynamique d l'ion méthylammonium (MA) en fonction de la température. À la température ambiante, l'ion MA présent dans l'hexachlorotellurate (solide II) est limité à des sauts C_3 autour de l'axe C—N alors qu'on note un faible angle de libration de l'axe C—N. Dans la phase présente à la température ambiante, solide I, des sels $(MA)_2TeBr_6$ et $(MA)_2TeI_6$, les ions MA subissent, à l'échelle de temps de la ps, des réorientations globales qui ramènent la moyenne des interactions quadrupolaires nucléaires du ^2H à zéro. Les temps de relaxation spin-réseau, T_1, en RMN du ^2H, à température variable, permettent de déterminer que l'énergie d'activation, E_A, pour les réorientations «isotropiques» de l'ion $CH_3ND_3^+$ sont égales à 5,2 ± 0,5 et 2,6 ± 0,3 kJ mol^{-1} respectivement pour X = Br et I. Les valeurs des T_1 du deutérium pour l'ion MA C-deutéré de l'hexaiodotellurate indiquent que la valeur de E_A pour la réorientation globale de l'ion est égale à 3,1 ± 0,3 kJ mol^{-1}. À n'importe quelle température donnée, on a trouvé que le temps de corrélation, τ_c, obtenu à partir des valeurs de T_1 est le même pour les deux hexaiodotellurates marqués au deutérium. La similarité des valeurs de E_A et de τ_c implique qu'il existe une corrélation entre les mouvements des groupes méthyle et ammonium. Les valeurs des T_1 obtenues par RMN du ^{14}N du solide I du $(MA)_2TeBr_6$ indiquent que les mouvements le long de l'axe C—N, avec une E_A = 5,6 ± 0,6 kJ mol, sont plus empêchés que ceux autour des liaisons N—D et C—D. Les spectres RMN du ^2H du $(MA)_2TeI_6$ (solide II) et du $(MA)_2TeBr_6$ (solides II, III et IV) sont caractérisés par une raie en forme de doublet de Pake. Les couplages entre sommets qui ont été mesurées sont plus faibles que ceux que l'on peut prédire sur la base du mouvement C_3 autour de l'axe de symétrie moléculaire. Il est possible de créer un modèle de la forme de ces raies en faisant l'hypothèse que les rotations C_3 des groupes méthyle et ammonium se produisent alors que l'axe C—N est en libration dans un cône effectif autour de la position de l'axe moléculaire statique. Pour les sels $(CH_3ND_3)_2TeBr_6$ et $(CD_3NH_3)TeBr_6$, on a mesuré les couplages entre sommets dans les spectres RMN du ^2H, déterminés en fonction de la température, pour les phases II, III et IV; on a trouvé qu'ils sont semblables. Enfin, la forme de raie de relaxation du spectre RMN du ^2H du $(MA)_2TeBr_6$ (solide III) présente une dépendance sur l'orientation qui indique que les rotations autour de l'axe C—N sont de nature discrète plutôt que diffuse. Pour le solide de la phase II du $(MA)_2TeCl_6$, on a observé que la forme de la raie subit une relaxation isotropique qui implique qu'il se produit des rotations C_3 continues.

Mots clés : RMN du ^2H et du ^{14}N, méthylammonium hexahalotellurates, mouvement moléculaire.

[Traduit par la rédaction]

Introduction

Several studies have been completed in an effort to characterize the dynamic, structural, and thermodynamic properties of the methylammonium hexahalotellurates, $(MA)_2TeX_6$ (X = Cl, Br, and I) (1–5). These complexes are all solids at room temperature and undergo solid–solid phase transitions as they are cooled. These phase transitions were first revealed by differential thermal analysis (DTA) and

nuclear quadrupole resonance (NQR) studies of the halogen nuclei (1). More recently, investigators also used NQR (2) and DTA (4) as well as adiabatic calorimetry (3) to demonstrate the existence of additional phases. A summary of the transition temperatures and the corresponding molar entropy changes with provisional phase designations is given below. Notice the dramatic temperature decrease of the solid I ↔ II phase transition on going from $(MA)_2TeCl_6$ to

$(MA)_2TeCl_6$	VI	$\xleftrightarrow[0.77\,R]{73\text{ K}}$	V	$\xleftrightarrow[1.79\,R]{137\text{ K}}$	IV	$\xleftrightarrow[0.30\,R]{\sim 155\text{ K}}$	III	$\xleftrightarrow[0.20\,R]{226\text{ K}}$	II	$\xleftrightarrow[1.18\,R]{439\text{ K}}$	I
$(MA)_2TeBr_6$					IV	$\xleftrightarrow[1.56\,R]{129\text{ K}}$	III	$\xleftrightarrow[0.65\,R]{164\text{ K}}$	II	$\xleftrightarrow[1.91\,R]{289\text{ K}}$	I
$(MA)_2TeI_6$							III	$\xleftrightarrow[0.73\,R]{66\text{ K}}$	II	$\xleftrightarrow[2.66\,R]{116\text{ K}}$	I

$(MA)_2TeBr_6$ ($\Delta T_{I\leftrightarrow II}$ = 150 K) and from $(MA)_2TeBr_6$ to $(MA)_2TeI_6$ ($\Delta T_{I\leftrightarrow II}$ = 173 K). In each case, the high-temperature phase transition, from solid I to solid II, involves a change from a cubic crystal structure to a less symmetric lattice, i.e., a structural phase transition takes place.

Proton NMR second moments, $M_2(^1H)$, provide a measure of the motional averaging of the ^1H dipolar interaction and were reported for the $(MA)_2TeX_6$ salts by Kume *et al.* (1). For temperatures between 77 and about 300 K, $M_2(^1H)$ for $(MA)_2TeCl_6$ was essentially independent of temperature ($\approx 6\ G^2$). This value is much less than the calculated static intramolecular $M_2(^1H)$ value of 30 G^2 and is in fair agreement with the value calculated (7.8 G^2) using a model that assumes rapid C_3 jumps about the C—N axis of an isolated MA ion. For the other $(MA)_2TeX_6$ salts (X = Br and I), $M_2(^1H)$ is approximately 0.5 G^2 at 300 K, implying that at this temperature there is substantially more rotational freedom for the MA ions than is present in the hexachlorotellurate. Note that at 300 K the hexabromo- and hexaiodotellurates are in the high-temperature phase, solid I, where the MA ions effectively occupy crystal sites of spherical symmetry. The small observed $M_2(^1H)$ values indicate that the C—N axis is performing effectively "isotropic" rotations or jumps at a rate that is much faster than the ^1H–^1H dipolar interaction in Hz. At temperatures below the solid I ↔ II phase transition, the ^1H second moment of $(MA)_2TeBr_6$ steadily increases from 3.8 G^2 in solid II to a value of 7.8 G^2 in solid IV. A similar trend is observed for the MA ion in the hexaiodotellurate. This increase in $M_2(^1H)$ reflects an increased hindrance of C—N axis reorientations and is consistent with the continued presence of rapid C_3 rotations about the C—N axis.

The high-temperature cubic solid phase I of the $(MA)_2TeX_6$ distinguishes them from the other methylammonium hexahalometallates, $(MA)_2MX_6$ (M = tetravalent Sn, Pt, Se, Pd, and Pb; X = Cl, Br, and I), which are all rhombohedrally distorted from cubic crystal symmetry (6). As a result of the structural differences among the $(MA)_2MX_6$, the dynamics of the cation in the $(MA)_2TeX_6$ are predictably different than for the other $(MA)_2MX_6$ salts. The MA ions in the rhombohedral $(MA)_2MX_6$ have been or are predicted to be characterized by anisotropic motion (7) and do not undergo "isotropic" rotations as they do in the $(MA)_2TeX_6$ salts. The unique variation of the MA ion dynamics in the $(MA)_2TeX_6$ is deserving of further investigation by the NMR of spin-one nuclei (8). Both ^2H and ^{14}N NMR spin-lattice relaxation and line-shape studies have been used to probe the motional characteristics of the MA cation in the $(MA)_2TeX_6$ salts as a function of temperature. The use of two different NMR-active nuclei as probes allows for the separation of the C—D or N—D bond dynamics and the C—N bond reorientations (*vide infra*). Where possible, line-shape simulations have been included to model the experimental results.

Theory

Deuterium and ^{14}N are quadrupolar nuclei (I = 1) and their solid-state NMR spectra are dominated by nuclear quadrupolar interactions (9–15). These interactions arise from coupling between the nuclear quadrupole moment, eQ, and the electric field gradient (efg) at that nucleus. In general, the spin-one NMR spectrum of a polycrystalline sample in a strong magnetic field, $\boldsymbol{B}_0$, is characterized by a Pake powder pattern that is symmetric about the isotropic resonance frequency, ν_0 ($\nu_0 \approx \gamma\boldsymbol{B}_0/2\pi$). The observed line shape is the resultant superposition of doublets corresponding to all possible orientations of crystallites in the applied field, $\boldsymbol{B}_0$. The doublet splittings are given in frequency units by eq. [1]

$$[1]\quad \Delta\nu(\theta,\phi) = \left(\frac{3}{2}\right)\chi\left[\frac{(3\cos^2\theta - 1)}{2} - \frac{(\eta\sin^2\theta\cos^2 2\phi)}{2}\right]$$

where χ is the nuclear quadrupolar coupling constant, $eq_{zz}eQ/h$, q_{zz} is the largest component of the efg tensor, θ and ϕ orient $\boldsymbol{B}_0$ in the principal axis system of the efg tensor, and η is the asymmetry parameter. For η = 0, the ϕ-dependence vanishes and eq. [1] is reduced to

$$[2]\quad \Delta\nu(\theta) = \left(\frac{3}{2}\right)\chi\left(\frac{3\cos^2\theta - 1}{2}\right)$$

where θ is the angle between q_{zz} and $\boldsymbol{B}_0$. Typically, the spectral asymmetry for the N—D and C—D bonds of the methylammonium ion is $\leq$0.1, which indicates that eq. [2] is a reasonable approximation of eq. [1] for the purposes of this study.

The ^2H NMR time scale is defined with respect to the quadrupolar coupling constant, χ. Dynamics are considered fast when τ_c, the correlation time that describes q_{zz} vector dynamics, is much shorter than the reciprocal of the coupling constant, χ^{-1}. Fast motion of appropriate symmetry can average the traceless quadrupolar interaction to zero. This is generally observed in the liquid state and also in solids for nuclei at crystal sites of high symmetry. Fast exchange involving three or more sites about one symmetry axis will attenuate the breadth of the observed line shape, producing an

For personal use only.

effective efg tensor with axial symmetry even if $\eta_{static} \neq 0$. The appropriate scaling factor, S, is given by eq. [3],

$$[3] \quad S = \left(\frac{3\cos^2\beta - 1}{2}\right)$$

where β is the angle between q_{zz} and the axis of fast rotation. Thus, for either $CD_3NH_3^+$ or $CH_3ND_3^+$, rapid C_3 jumps or diffusion about the C—N bond axis lead to $S = 1/3$ assuming an NCD or CND bond angle of 109.5°. If an additional motion about a C_n axis ($n \geq 3$) is present the reductive effect of the two motions on the spectral width is multiplicative.

The NMR spin-lattice relaxation time constant, T_1, can also provide useful dynamical information (12–16). For quadrupolar nuclei such as ^2H and ^{14}N, the quadrupolar mechanism is the dominant relaxation mechanism and is given by eq. [4]

$$[4] \quad \frac{1}{T_1} = \left(\frac{3}{10}\right)\pi^2\chi^2\left(1 + \frac{\eta^2}{3}\right)f(\omega_0,\tau_c)$$

where $\omega_0 = 2\pi\nu_0$ and $f(\omega_0,\tau_c)$ describes the ω_0 and τ_c dependence of the rate of spin-lattice relaxation. If isotropic reorientation is occurring and the dynamics of the observed nucleus can be adequately described by one effective correlation time, τ_c, $f(\omega_0,\tau_c)$ is given by eq. [5].

$$[5] \quad f(\omega_0,\tau_c) = \frac{\tau_c}{(1 + \omega_0^2\tau_c^2)} + \frac{4\tau_c}{(1 + 4\omega_0^2\tau_c^2)}.$$

In the extreme narrowing regime $\tau_c << \omega_0^{-1}$, and $f(\omega_0,\tau_c)$ is $5\tau_c$. Generally, the temperature dependence of τ_c exhibits simple Arrhenius behaviour (eq. [6]), thus,

$$[6] \quad \tau_c = \tau_0 \exp\left(\frac{E_A}{RT}\right)$$

where τ_0 corresponds to the correlation time at infinite temperature and E_A is the effective barrier to the motion described by τ_c.

Spin-lattice relaxation experiments on powder line shapes can also discern free diffusion (continuous rotation) from rotational jumps. Torchia and Szabo (16) have described rigorous T_1 relaxation expressions for both three-site jumps and continuous diffusion. In the extreme narrowing limit, their expressions predict an orientational dependence of the relaxation for the "jump" model. Specifically, there is a $\cos^2\theta$ dependence to the relaxation; T_1 increases from $\theta = 0°$ to 90°. In contrast, there is no T_1 anisotropy expected for continuous diffusive motions; that is, all parts of the powder pattern relax synchronously. This analysis is complicated by spectral overlap of the two transitions that are possible for an $I = 1$ nucleus. For example, the singularities at the $\theta = 90°$ orientations overlap with the $\theta = 35.3°$ orientations from the other subspectrum. As a result, the observed difference in line-shape anisotropy between the $\theta = 0°$ and "90°" orientations is less than predicted by theory but is still discernible. In general, any fast flipping motion that occurs is expected to produce an orientational dependence of the spin-lattice relaxation, which can be observed by examining partially relaxed spectra.

Experimental

The $(MA)_2TeX_6$ salts (X = Cl, Br, and I) were prepared by dissolving tellurium dioxide in a solution of aqueous hydrogen halide and adding to this the appropriate aqueous methylammonium halide solution (17). The solids were recovered from the reaction mixture and dried under vacuum. Deuteration of the ammonium group was achieved by successive recrystallization of the complexes from deuterium oxide (99.9%). The methyl deuterated hexachlorotellurate salt was prepared from aqueous CD_3NH_3Cl. For X = Br and I, the corresponding CD_3NH_3X salts were prepared by neutralizing CD_3NH_3Cl, isolating the methylamine, and then adding the appropriate hydrogen halide, prior to reaction with TeO_2 and HX.

Once the solids were recovered under vacuum, the samples were allowed to dry further in a vacuum desiccator before they were sealed in NMR tubes. These methylammonium salts fit the literature description (3) (yellow crystals for $(MA)_2TeCl_6$, deep orange crystals for $(MA)_2TeBr_6$, and shiny black crystals for $(MA)_2TeI_6$) and were observed via NMR line-shape studies to undergo reversible phase transitions at temperatures very close to those established in previous studies (1, 3).

NMR measurements for ^2H and ^{14}N were recorded at 55.4 and 26.1 MHz, respectively, on a Nicolet 360 NB spectrometer ($\boldsymbol{B}_0$ = 8.48 T). The deuterium $\pi/2$ pulse lengths were 7.2–8.2 μs. A Bruker MSL-200 spectrometer was used to perform some of the ^2H NMR measurements on the noncubic phases of the $(MA)_2TeX_6$. The ^2H NMR frequency is 30.7 MHz ($\boldsymbol{B}_0$ = 4.70 T) and $\pi/2$ pulse lengths of 4.5 μs were used with a quadrupole echo pulse sequence to measure line shapes and relaxation times (18). Spin-lattice relaxation times were measured using the inversion–recovery technique with either a compensating one-pulse or a quadrupole echo pulse program (19). Typically, ten variable delays were used. A three-parameter fit of the intensity of a peak at a particular delay was used to determine T_1 values.

The peak-to-peak or quadrupolar splitting, $\Delta\nu_{pp}$, in the ^2H NMR spectra was measured directly from the spectrum or with a peak picking routine. This splitting represents the frequency difference between the two most intense points in a ^2H NMR line shape. In the limit of zero line broadening, $\Delta\nu_{pp} = \Delta\nu$ provided there is axial symmetry of the efg tensor (20). The effect of artificial or natural line broadening is to change the line shape such that $\Delta\nu_{pp} < \Delta\nu$. This implies that values of χ derived from the apparent quadrupolar splitting will be underestimated in cases where line broadening is considerable.

The experimental spectra were simulated using the FORTRAN program, MXQET (21), which ran on a VAX 8800 main-frame computer.

Results and discussion

NMR line shapes

In the cubic phase (solid I) of $(MA)_2TeI_6$ a single "isotropic" peak is observed for both ^2H and ^{14}N NMR spectra with line widths at half height, $\Delta\nu_{1/2}$, of <1 and 3 kHz, respectively. Typical line shapes are shown in Fig. 1 and indicate an effectively cubic reorientation potential for each of the observed nuclei. Both rapid C_3 exchange about the molecular symmetry axis and fast overall reorientation of the C—N axis must be taking place in order to observe the isotropic line shapes.

Similar ^2H NMR spectra were observed for the solid I phase of $(MA)_2TeBr_6$. Nitrogen-14 NMR spectra of the hexabromotellurate salt were not observed, probably because of dipolar coupling to $^{79/81}Br$, which broadens the line shape relative to those observed for $(MA)_2TeI_6$ (solid I). Note that NQR transitions are observed for both the TeI_6^{2-} and $TeBr_6^{2-}$ salts; therefore, it is unlikely that either of the halides would be self-decoupled from ^{14}N. We do not believe

For personal use only.

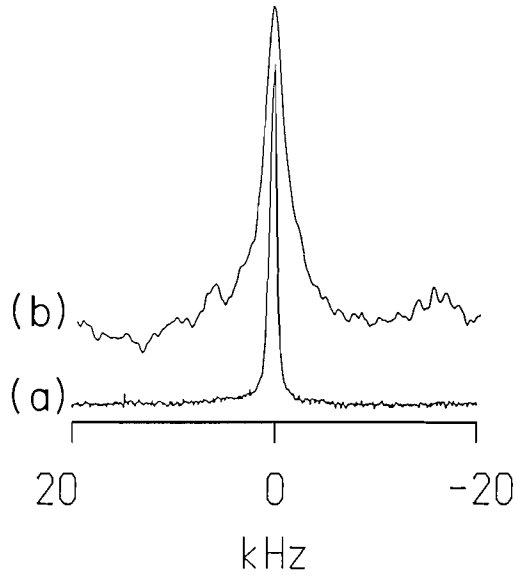

FIG. 1. NMR spectra for $(MA)_2TeI_6$ (solid I): (*a*) ^2H spectrum at 153 K ($\Delta\nu_{1/2} < 1$ kHz), which is similar to line shapes for $(MA)_2TeBr_6$ (solid I); (*b*) the ^{14}N NMR spectrum at 174 K ($\Delta\nu_{1/2} < 3$ kHz).

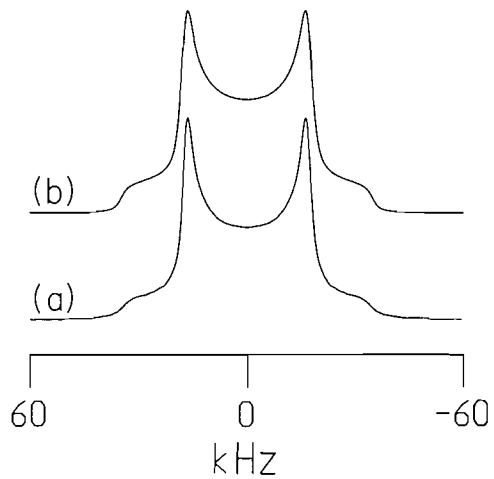

FIG. 2. Experimental (*a*) and simulated (*b*) ^2H NMR lines shapes for $(MA)_2TeCl_6$ at 293 K. The simulation was based on a model assuming C_3 jumps about the C—N axis with diffusion of the symmetry axis about a cone with a half angle of 22 ± 1° and the following input parameters: χ = 170 kHz, β = 109.5°, η = 0, $\pi/2$ = 4.5 μs, echo delay = 40 μs, and Lorentzian and Gaussian line broadening of 2.0 and 1.0 kHz, respectively.

that the increased ^{14}N NMR line width results from restricted motion of the C—N axis. Instead, the inability to obtain a spectrum is a manifestation of the relatively weak ^{14}N $\boldsymbol{B}_1$ radio frequency pulses available on the Nicolet 360 NB spectrometer which are incapable of uniformly exciting spectral lines with $\Delta\nu_{1/2} > 5$ kHz. In addition, long probe dead times at 26.1 MHz using the Nicolet high resolution "liquids" probe preclude observation of broad peaks.

The experimental ^2H NMR spectrum for $(MA)_2TeCl_6$ at 293 K (solid II) is shown in Fig. 2. The line shape has a peak-to-peak splitting, $\Delta\nu_{pp}$, of 32.8 kHz. This line shape is similar to those obtained for the solid phases II, III, and IV of $(MA)_2TeBr_6$ and solid phase II of $(MA)_2TeI_6$. The MA ions no longer experience the isotropic potential of solid I and are

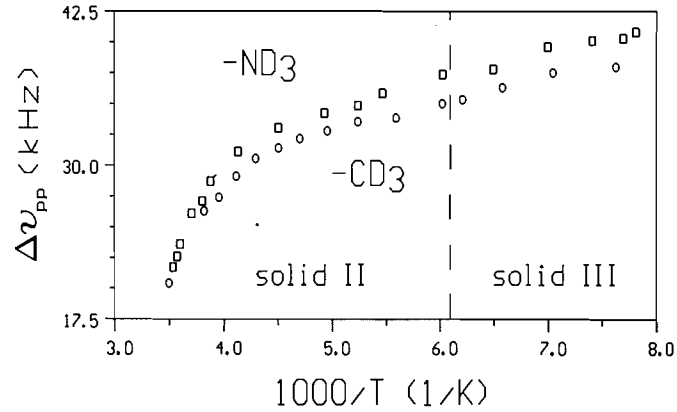

FIG. 3. The $\Delta\nu_{pp}$ for the N- and C-deuterated $(MA)_2TeBr_6$ (solids II and III) as a function of inverse temperature.

characterized by a nonzero reduction factor ($S \neq 0$). Assuming tetrahedral geometry about the C and N atoms of the MA ion, eq. [3], with β = 109.47°, gives S = 1/3 for pure C_3 rotations. From the observed quadrupolar splitting of 32.8 ± 1 kHz, eq. [2] predicts a static quadrupolar coupling constant of 131 ± 4 kHz. This value of χ is smaller than the expected static value, e.g., ≈175 kHz from ref. 22, indicating that the C—N axis is not static in the solid II phase of $(MA)_2TeCl_6$.

The observed peak-to-peak splittings, $\Delta\nu_{pp}$, were measured for the ^2H NMR line shapes of $CH_3ND_3^+$ and $CD_3NH_3^+$ in the hexabromotellurate as a function of temperature below the solid I ↔ II phase transition. The temperature dependence of these splittings is shown in Fig. 3. For the N-deuterated $(MA)_2TeBr_6$, $\Delta\nu_{pp}$ varies from 21.7 ± 1 to 42.5 ± 1 kHz for temperatures between 280 and 99 K. In the case of the carbon-labelled salt, $CD_3NH_3^+$, $\Delta\nu_{pp}$ increases from 20.4 kHz at 286 K to 36.6 kHz at 122 K. This variation in splitting with temperature demonstrates the gradual onset of C—N axis reorientational freedom with increasing temperature. The temperature dependence of the splittings for the N- and C-deuterated MA in $(MA)_2TeBr_6$ (solids II and III) is not quite the same at low temperatures. At any given temperature, the peak-to-peak splitting, $\Delta\nu_{pp}$, arising from the ND_3^+ group is slightly larger than $\Delta\nu_{pp}$ due to the CD_3 moiety. This difference could result if one end of the MA ions was undergoing librational motion to a greater extent than the other. Our results suggest that the amplitude of the librational motion of the ND_3^+ group is smaller than that of the CD_3 group at any given temperature. This is entirely reasonable since the ammonium groups are expected to hydrogen-bond more strongly with the neighbouring TeX_6^{2-} anions. Alternatively, the larger peak-to-peak splittings observed for the ammonium-labelled $(MA)_2TeBr_6$ could imply that its static value of the quadrupolar coupling constant, χ, is larger than for $(CD_3NH_3^+)_2TeBr_6$. This second explanation is less likely, since it has been determined (22, 23) that the value of χ decreases as the strength of the hydrogen bonding increases.

The anisotropy of the solid II NMR line shapes indicates that some of the motions present in the solid phase I have become slow on the ^2H NMR time scale. Intuitively, whole-ion (C—N axis) reorientations are expected to be more hindered than the C_3 rotational motion. Solid II ^2H NMR line shapes are consistent with a slowing of the C—N axis reorientations while the C_3 rotations of the methyl and ammo-

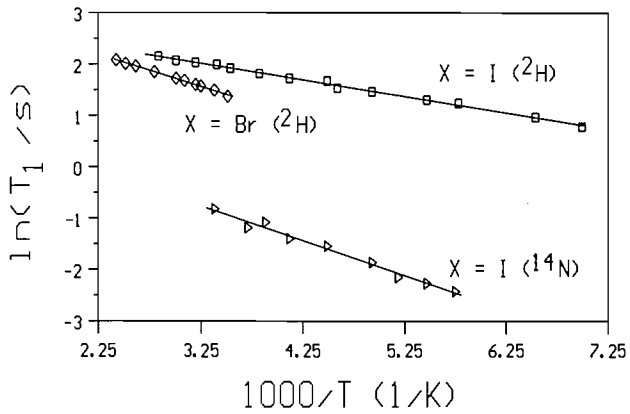

FIG. 4. The ^2H and ^{14}N NMR spin-lattice relaxation times for solid I of some N-deuterated $(MA)_2TeX_6$ (X = Br and I) as a function of inverse temperature.

nium groups continue. That is, the motion of the C—N axis in solid II is highly hindered relative to that in the solid I phase. The observed ^2H NMR line shapes for solid II of $(MA)_2TeCl_6$ and solids II and III of $(MA)_2TeBr_6$ can be simulated with a model based on C_3 jumps of the methyl and ammonium groups about the C—N axis while the C—N axis is librating. Figure 2 shows the line shape simulated for the spectrum of $(MA)_2TeCl_6$ at 293 K. The simulation was performed assuming C_3 rotations take place while the C—N axis diffuses around a cone with a half angle of 22 ± 1°. Other details of the simulation are given in the figure caption.

This model of a wobbling C_3 axis tracing out a cone is a practical physical model making it convenient to quantify the extent of the librational motion. As the temperature is increased, the C—N axis gains motional freedom, which can be measured by the simulation-derived angle of the effective librational axis about which C_3 rotations continue to occur. As the temperature is increased the effective cone made by the wobbling C—N axis also increases. As a result, this model is consistent with the observed quadrupolar splittings and the ^1H NMR second moment results (1). As the temperature is decreased the angle of the half-cone decreases and $\Delta\nu_{pp}$ and $M_2(^1H)$ increase.

NMR spin-lattice relaxation results

The ^2H and ^{14}N NMR spin-lattice relaxation results for $(MA)_2TeI_6$ (solid I) and the ^2H NMR spin-lattice relaxation of $(MA)_2TeBr_6$ (solid I) are displayed in Fig. 4. The results given are for the N-deuterated methylammonium salts. A ^2H NMR T_1 study of $(CD_3NH_3)_2TeI_6$ (solid I) was also performed but is not shown as it displayed essentially the same temperature dependence as the corresponding N-deuterated analogue. The negative slope of the $\ln(T_1)$ versus reciprocal temperature plots indicates "extreme narrowing" conditions, validating the use of $f(\omega_0,\tau_c) = 5\tau_c$ in eq. [4]. Equation [4] may be used to establish the time scale of the motions effective in relaxing the ^2H and ^{14}N nuclei, respectively. However, note that for the methylammonium ion, the ^2H and ^{14}N nuclear relaxation times will probe different motions. The ^{14}N nuclei relax by the motion of the C—N bond axis since the largest principal component of the nitrogen efg tensor lies along this axis. For the same reason ^2H nuclei are relaxed by motion of the C—^2H or N—^2H bond; hence, the effective deuterium correlation time, τ_c (^2H), reflects internal motions of the $CD_3(ND_3)$ group as well as the overall motion of the C—N axis. At 183 K, the ^2H and ^{14}N T_1 values are 3.7 ± 0.4 and 0.10 ± 0.02 s, respectively. Substitution of the respective T_1 values in eq. [4] along with the quadrupolar coupling constants for methylammonium chloride ($\chi(^2H)$ = 175 kHz and $\chi(^{14}N)$ = 900 kHz from ref. 22) results in correlation times of 0.60 ps for ^2H and 0.80 ps for ^{14}N. These are incredibly short correlation times for the methylammonium cation in the solid state at 183 K. The slightly longer effective correlation time for motion of the C—N bond is intuitively what one would anticipate. As temperature increases our results indicate that the bond vector dynamics for ^2H and ^{14}N occur at comparable rates. We suspect the ^2H correlation times are more reliable than the corresponding ^{14}N values because the value of $\chi(^2H)$ is probably more reliable than $\chi(^{14}N)$. Any uncertainty in χ strongly influences the accuracy of a calculated correlation time as a result of the χ^2 dependence of τ_c (eq. [4]). Despite these uncertainties in the value of χ the error in the ^{14}N correlation times is probably less than 50%.

The ^2H spin-lattice relaxation times for the N- and C-deuterated $(MA)_2TeI_6$ are the same within experimental error. Again it is difficult to make precise comparisons of the correlation times when accurate values of χ are not known. Considering the similarity of the T_1 temperature dependence, the correlation times describing C—D and N—D bond dynamics will be the same if the two quadrupolar coupling constants are comparable. This will be assumed for two reasons. First, the values of χ for MA ions in other compounds show only a small dependence on the site of deuteration. For example, Jurga and Spiess (24) studied methylammonium perchlorate using ^2H NMR spectroscopy. They examined motionally averaged spectra and found χ for $CH_3ND_3^+$ and $CD_3NH_3^+$ to be 168 and 166 kHz, respectively.[2] Also the $\Delta\nu_{pp}$ dependence on reciprocal temperature shown in Fig. 3 demonstrates the similarity of χ for the differently deuterium-labelled $(MA)_2TeBr_6$ salts. As a result, the values of χ for the two $(MA)_2TeI_6$ should be similar and support a model based on correlated motion of the ammonium and methyl groups.

An activation barrier to the motion described by τ_c (eq. [6]) can be obtained from the T_1 dependence on inverse temperature. Such Arrhenius plots are shown in Fig. 4 from which E_A for N—D, C—D, and C—N dynamics can be determined. Table 1 lists the E_A values determined in this study. For the sake of comparison the results from the ^1H NMR (2) and the infrared spectroscopy (3) studies are included in Table 2. Several comments can be made about these derived activation energies. First, the E_A values for ND_3^+ and CD_3 overall reorientation in $(MA)_2TeI_6$ (solid I) are small (≈ 3 kJ mol^{-1}) and are the same within the estimated error of this analysis (±10%). These activation energies correspond closely to the values obtained in previous studies (2, 3). The E_A for internal rotations of the methyl and ammonium groups of a MA ion is expected[3] to be about 10 kJ mol^{-1}, implying that the much smaller values derived for $(MA)_2TeI_6$ (solid I) do not describe the independent motion of the labelled groups. This suggests that there is correlated motion of the two groups,

[2]We obtained motionally averaged spectra for methylammonium chloride at 293 K to provide another comparison; $\Delta\nu_{pp}$ = 32.6 ± 1 and 34.1 ± 1 kHz for CH_3ND_3Cl and CD_3NH_3Cl, respectively.

[3]The potential barrier to internal rotation of ethane is determined by infrared spectroscopy to be 12.25 kJ mol^{-1} (25).

i.e., both sets of T_1 results seem to describe the same motion. Correlated motion of the two groups is further supported by the previous comparison of correlation times derived from the ^2H NMR T_1 results for the N- and C-deuterated MA ions. The near identity of the correlation times implies that the dynamics of the two groups occur at the same rate. Secondly, the "isotropic" reorientation of the MA ion is more restricted in the $TeBr_6^{2-}$ lattice compared to the TeI_6^{2-} as a result of two considerations: (1) the void between the hexabromotellurate complex anions is slightly smaller, allowing less volume for the MA ion to move about, and (2) the ND_3^+ moiety should hydrogen-bond more strongly to the $TeBr_6^{2-}$ ions than to the TeI_6^{2-} ions as a result of the relative electronegativities of the two halide atoms. Lastly, within the $(MA)_2TeI_6$ lattice, the deuterium bond vector dynamics are shown to be energetically less demanding than the C—N motions. This reflects the relative ease with which the C_3 motion about the C—N axis occurs compared with whole-ion reorientation. However, as previously mentioned, it should be emphasized that relaxation of the ^2H nuclei occurs by C_3 rotations of the methyl and ammonium groups and through C—N axis reorientations while the ^{14}N nuclei are relaxed only by whole-ion motion. Note that $q_{zz}(^{14}N)$ lies along the C—N axis. As a result, it is expected that the E_A values derived from ^2H T_1 studies will always be less than or equal to those determined from the analogous ^{14}N results.

Finally, it is determined from the ^2H NMR relaxation spectra for $(MA)_2TeBr_6$ (solid III) at 150 K that the motion the MA ion performs consists of jumps between three equivalent sites. For nuclei that relax by rotational jumps the two orientational extremes provide the largest difference in the T_1 values of the line shape. If the T_1 values for these two positions are determined experimentally to be different, then

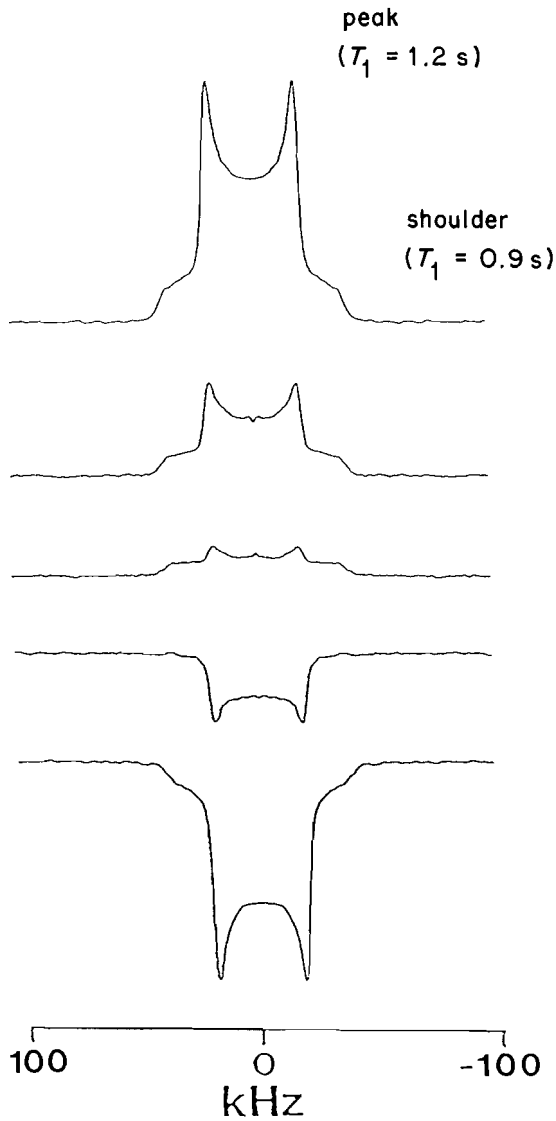

FIG. 5. A stacked plot of partially relaxed ^2H NMR spectra for $(MA)_2TeBr_6$ at 150 K (solid III) demonstrating T_1 anisotropy and establishing that the MA ions are undergoing discrete motions. The variable delays from the bottom to the top of the figure are: 0.01, 0.4, 0.8, 1.2, and 3.0 s; the respective T_1 values for $\theta = 0°$ and "90°" are 0.9 and 1.2 s.

discrete motion is occurring. By inspecting the recovery of the signal intensity for the shoulder and peak positions of the spectra in Fig. 5 the orientational dependence of the relaxation of the MA ion in $(MA)_2TeBr_6$ can be observed. As expected for jump motions, the shoulders ($\theta = 0°$) relax more efficiently than the peaks (θ = "90°"). The respective T_1 values are approximately 0.9 and 1.2 s.

The T_1 anisotropy observed for solid III of the hexabro-

motellurate salt contrasts with the result obtained for solid phase II of $(MA)_2TeCl_6$ (Table 3). The line shape in this case does not display an orientational dependence to the relaxation. As a result, the rotational motion about the molecular axis is diffusive rather than discrete in nature. Note that the T_1 values increase with increasing temperature, indicating extreme narrowing conditions apply ($\tau_c << \omega_0^{-1}$).

Conclusions

Both ^2H and ^{14}N NMR line-shape and relaxation studies are shown to be useful probes of the dynamics of the MA ion in the $(MA)_2TeX_6$ as a function of temperature. In summary, room temperature $(MA)_2TeCl_6$ (solid II) is characterized by an anisotropic line shape that is typical of C_3 rotation about a librating C—N axis. The other $(MA)_2TeX_6$ (X = Br and I) have a room temperature phase (solid I) characterized by "isotropic" line shapes. Both the ^2H and ^{14}N NMR results clearly demonstrate that the cation is performing overall reorientations on the ps time scale. The activation energies for the MA ion reorientation for X = Br and I are different, possibly due to both hydrogen bonding and steric effects. Both N- and C-deuterated $(MA)_2TeI_6$ have the same E_A and τ_c within experimental error, indicating that rotations of the ammonium and methyl groups are probably strongly coupled and are not two independent motions. Also the E_A values derived are much less than would be expected for the internal rotation of the methyl and ammonium groups. Nitrogen-14 NMR relaxation results for the iodotellurate indicate the E_A value for C—N axis reorientation is higher than the corresponding E_A value obtained from ^2H NMR relaxation results. This implies that the dynamics of the C—D and N—D bond vectors are energetically more favourable than reorientation of the C—N axis. In the lower-temperature phases of the hexahalotellurates the motion of the C—N axis gradually becomes more restricted resulting in an anisotropic ^2H NMR line shape. The quadrupolar splitting increases as the temperature is decreased. These spectra are simulated with coupled C_3 jumps of the methyl and ammonium groups that occur while the C—N axis librates. Finally, the orientational dependence of the T_1 measurements for $(MA)_2TeBr_6$ at 150 K (solid III) demonstrates that the C_3 motion of the MA ion involves three-site jumps rather than continuous diffusion about the molecular symmetry axis. In solid II of $(MA)_2TeCl_6$, the partially relaxed NMR line shapes do not show an orientational dependence, implying that the C_3 motion is diffusive.

GRAZYNA WENSKA, BOHDAN SKALSKI, and ZOFIA GDANIEC. Can. J. Chem. **70**, 856 (1992).

1-Methyluracil and 1-methylthymine are converted into *N*-(1-methylpyrimidin-2-one-4-yl)- and *N*-(1,5-dimethylpyrimidin-2-one-4-yl)-pyridinium chlorides, respectively. The pyrimidinyl-pyridinium salts were then reacted with various nucleophiles under very mild conditions to give high yields of the desired 4-substituted pyrimidinones. In a similar manner 2′,3′,5′-tri-*O*-acetyluridine is efficiently converted into new 4-substituted pyrimidinone nucleosides.

GRAZYNA WENSKA, BOHDAN SKALSKI et ZOFIA GDANIEC. Can. J. Chem. **70**, 856 (1992).

On a transformé respectivement le méthyl-1-uracile et la méthyl-1-thymine en chlorure de *N*-(méthyl-1-pyrimidinone-2-yl-4-)-pyrimidinium et en chlorure de *N*-(diméthyl-1,5-pyrimidinone-2-yl-4)-pyrimidinium. Les sels de pyrimidinyl-pyrimidinium, par réaction subséquente avec divers nucléophiles, dans des conditions très douces, donnent avec des rendements élevés, les pyrimidinones substituées en position 4 attendues. D'une façon analogue, on a transformé efficacement la tri-*O*-acétyl-2′,3′,5′-uridine en des nouveaux nucléosides contenant la pyrimidinone substituée en position 4.

Introduction

The conversion of 1-alkyluracils and uridine to various 4-substituted 2-pyrimidinone derivatives requires activation of the C-4 position and is often achieved with 4-chloro or thio derivatives (1). The C-4 position can also be activated by trimethylsilylation (2) or by treatment with various phosphorylating or condensing agents in the presence of 1-methylimidazole (3), 1,2,4-triazole (4), or 3-nitro-1,2,4-triazole (5) to give appropriate, reactive 4-(3-methyl-imidazolium), 4-(1,2,4-triazol-1-yl), and 4-(3-nitro-1,2,4-triazol-1-yl) derivatives. The latter method was developed in recent studies of oligonucleotide synthesis by Reese and Ubasawa (6) and is now the most frequently used method in the conversion of uridines to cytidines (4, 7, 8). Recently, the synthesis of 4-substituted pyrimidine nucleosides involving a displacement of the 4-*O*-triisopropylphenylsulfonyl group in uridine and thymidine with malonate-type nucleophiles was reported (9).

Adamiak *et al.* showed previously (10, 11) that nucleosides having per-*O*-acetylated sugar residues, such as uridine, thymidine, guanosine, and inosine, undergo quantitative transformation into the corresponding water-soluble, fluorescent pyrimidin-4-yl and purin-6-yl pyridinium salts, when treated with 4-chlorophenylphosphorodichloridate in the presence of pyridine. The purinyl-pyridinium salts have already proven very useful as intermediates in purine nucleoside chemistry (12, 13). A preliminary study in the case of pyrimidinyl-pyridinium salts has demonstrated that they can serve as intermediates in various side processes during oligonucleotide synthesis using the phosphotriester method, including formation of the 4-triazolyl derivatives mentioned above (11).

In this work the reactivity of pyrimidyn-4-yl pyridinium salts towards various *O*-, *N*-, or *S*-nucleophiles was tested by using 1-methyl derivatives **2***a*,*b* and tri-*O*-acetyl riboside **2***c*. Based on the results of these experiments the synthetic procedures yielding new 4-substituted pyrimidin-2(1*H*)-ones from 1-methyluracils (**1***a*,*b*) and uridine (**1***c*) have been developed.

Results and discussion

1-Methyluracil (**1***a*), 1-methylthymine (**1***b*), and 2′,3′,5′-tri-*O*-acetyluridine (**1***c*) were converted to the respective *N*-(pyrimidin-2-one-4-yl)-pyridinium chlorides **2***a*, **2***b*, and **2***c*, respectively, by treatment with 4-chlorophenylphosphorodichloridate in the presence of pyridine (Scheme 1), i.e., under conditions used previously for similar transformations in purine and pyrimidine nucleosides (10, 11). Pure salts were obtained either as concentrated aqueous solutions (**2***a* and **2***c*) or as lyophilizates (**2***b*). The samples were stable when stored at 0°C for several weeks.

The salts **2***a*,*b* were subjected to reaction with imidazole, histidine, 1-methylimidazole, 4,5-diphenylimidazole, in-

dole, glycine, 3-chlorophenol, 7-hydroxycoumarin, mercaptoethanol, and azide ions. The reactions were carried out at room temperature in water or in a mixture of water and organic solvent (1,4-dioxane or chloroform) at pH ca. 6, i.e., the natural pH of the solutions. In the case of 7-hydroxycoumarin the pH of the reaction medium had to be adjusted to 7.5 in order to make the reaction go to completion (Table 1; entries 11, 12). The extent of the reactions was monitored by measuring the loss of pyridinium salts using a sensitive, spectrophotometric Zincke reaction test (11, 14). Among the nucleophiles listed above, 4,5-diphenylimidazole, indole, and glycine appeared to be unreactive towards **2***a,b*, whereas all the others reacted with **2***a,b* to give the appropriate C-4 substituted pyrimidine derivatives **3***a,b*–**10***a,b*. The products **3***a,b*–**10***a,b* were isolated by a combination of extraction and (or) chromatography on silica gel and identified by means of ^1H and ^{13}C NMR and mass spectral techniques. The synthetic procedures developed for the preparation of **3***a,b*–**10***a,b* were then applied to similar transformations of uridine. Thus, the pyridinium salt **2***c* derived from uridine was treated with some of the above-listed nucleophiles, imidazole, 3-chlorophenol, mercaptoethanol, and sodium azide, to give 4-substituted nucleoside derivatives **2***c*, **7***c*, **9***c*, and **10***c*, respectively. The results are summarized in Table 1, and the structures of the products are shown in Scheme 2. Some of the products are fluorescent. In these cases the emission parameters (λ_{max} and fluorescence quantum yield) are included in the experimental section.

In the case of the reaction of **2***a* with imidazole a quantitative conversion into **3***a* was also achieved with dimethylformamide or 1,4-dioxane as solvents instead of water or a water – organic solvent mixture, indicating that a broad range of solvents can be used in these transformations.

Attempts were also made to introduce the imidazol-1-yl substituent into the C-4 position of uridine as well as the synthesis of **3***a*, **4***a*, and **8***a* according to the method described by Matsuda *et al.* (3) as a possible alternative to our method. However, all these attempts were unsuccessful. The HPLC analyses of the reaction mixtures after 3 h revealed almost exclusive presence of the methylimidazolium salts instead of the expected substitution products. Prolongation of the reaction time (18 h) had no effect on the progress of the reactions, except for significant deacetylation in the case of the per-*O*-acetylated nucleoside salt.

Reactions of **2***a,b* with histidine (Table 1; entries 4, 5) were less efficient than those with other nucleophiles. They are of interest, however, since they may offer the possibility of selective, chemical modification of histidine residues in proteins.

In the case of the reaction of **2***a,b* with 1-methylimidazole (Table 1; entries 6, 7) products derived from the imidazole ring opening, **6***a,b*, were isolated in addition to the expected 1-methylimidazolium salts **5***a,b*. This observation and the fact that 1-methylimidazolium salts derived from pyrimidine nucleosides were previously identified as potential side products in oligonucleotide synthesis when the 2,4,6-triisopropylbenzenesulfonyl chloride/1-methylimidazole system was used as condensing reagent (11) prompted us to examine the chemical stability of salts **5***a,b* in acidic and basic conditions. They appeared to be stable in acidic media (0.05 N HCl, room temperature, 24 h) whereas, at pH > 7 a partial transformation into ring-opened products **6***a,b* occurred as a result of hydrolytic opening of the imidazolium ring of **5***a,b* (cf. Scheme 3). In the case of **5***a* the ring opening reaction occurred to a small extent (4%, HPLC) at pH 7.1 (TRIS buffer, room temperature, 24 h). When more basic conditions (TRIS, pH = 9.0, 24 h) were applied, the HPLC analysis revealed the presence of **5***a* (19%), **6***a* (75%), and **1***a* (6%). The ratio of **6***a*/**1***a* (14:1) remained unchanged after almost all of **5***a* disappeared (3 days), indicating that **5***a* also undergoes a nucleophilic attack of hydroxide ion at C-4 under these conditions to give **1***a*. 5-Methyl derivative **5***b* appeared to be less susceptible towards hydrolytic opening of

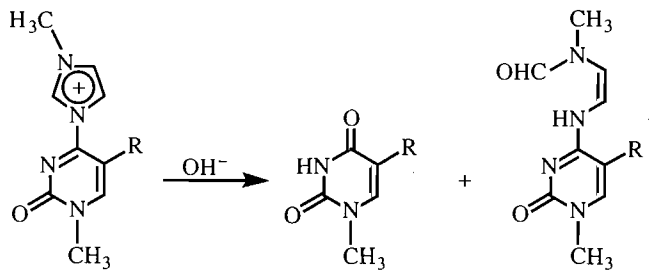
a: R = CH_3, R′ = H
b: R = CH_3, R′ = CH_3
c: R =  , R′ = H

SCHEME 2



SCHEME 3

the imidazolium ring, reflecting its diminished electron deficiency compared with **5***a*. Under analogous conditions of pH and temperature only 49% of **5***b* disappeared, after 24 h, to give **6***b* (27%) and **1***b* (22%). Both **6***a* and **6***b* were stable within the pH range $1 < pH < 9$. Thus, one can conclude that formation of imidazolium salts during oligonucleotide synthesis and their further transformation into relatively stable analogs of **6***a*,*b* may result in a point mutation in the synthetic oligomer.

The structures of the compounds **6***a*,*b* were unequivocally determined with the aid of ^1H and ^{13}C NMR spectrometry. The signal assignments based on the conventional one-dimensional technique (chemical shifts and decoupling) were confirmed by two-dimensional ^1H–^1H COSY spectra. In the case of **6***a*,*b* all the resonances except for N-CHO and pyrimidine C6-H and N1-CH_3 are doubled indicating the existence of an amide *cis–trans* equilibrium due to restricted N-C=O bond rotation (15). As could be expected, increasing temperature resulted in significant broadening of these signals. However, coalescence did not occur within the temperature range studied (298–373 K).

The mode of methylimidazolium ring opening, determining the site of attachment of the formyl group to the methylamino nitrogen in **6***a*,*b*, was deduced from the following observations. In the long-range ^1H–^1H COSY spectrum of **6***a* in DMSO the formyl proton signal (δ 8.06 ppm) is coupled with N-CH_3 proton signals (δ 3.26 and 3.10 ppm). Moreover, the N-H signals (δ 9.33 and 8.77 ppm) were correlated with C=C-H proton resonances whereas no correlation with the N-CH_3 signal was observed. The resonance of the N-CH_3 group of the opened imidazolium ring appears as a singlet in ^1H spectra measured in aprotic solvents ($CDCl_3$, CD_3CN, DMSO-d_6) in which H/D exchange does not occur. These observations are consistent with the proposed structures of **6***a*,*b*.

Aryl groups were proposed by Reese and Skone for protection of uracil on O-4 in oligoribonucleotide synthesis and several 4-*O*-phenyl derivatives were synthesized via 4-triazolyl derivatives (16). We found that similar derivatives can be obtained via pyrimidinyl-pyridinium salts. Treatment of **2***a*,*b*,*c* with 3-chlorophenol in a chloroform–water two-phase system gave the desired 4-*O*-(3-chlorophenyl) derivatives **7***a*,*b*,*c* with 94, 92, and 85% yields, respectively.

Mercaptoethanol and azide ion appeared to be the most reactive among all the nucleophiles used. Addition of mercaptoethanol to aqueous solutions of **2***a*,*b*, and **2***c* caused complete loss of pyridinium salts after ca. 30 min, whereas in the case of sodium azide the reaction was completed within 15 min to give, respectively, 4-(2-hydroxythioethyl) derivatives **9***a*,*b*,*c* and 4-azido derivatives **10***a*,*b*,*c* with excellent yields (cf. Table 1; entries 13–18). The 4-(2-hydroxyethylthio) derivative **9***c* was also obtained directly from *O*-protected uridine in a one-pot manner with an overall yield 78% (*vide infra*).

It has been observed previously that 4-azido substituted pyrimidine (3, 17) and 6-azido substituted purine (18) nucleosides tend to form tetrazolo structures in solution. In the purine series the azidoazomethine–tetrazole equilibrium was shown to be influenced by the nature of the solvent (18). In the case of **10***a*,*b*,*c* the infrared spectra in DMSO exhibit the presence of an absorption at ca. 2230 cm^{-1} due to the azido group while no such absorption could be observed in chloroform solutions. The ^1H and ^{13}C NMR spectra, on the other

hand, show the existence of a single tautomeric form in each of these solvents. Thus, one can conclude that in DMSO **10***a*,*b*,*c* exist in the azido form whereas in chloroform the tautomeric tetrazolo form exists, exclusively.

In conclusion, we have demonstrated that pyrimidin-4-yl pyridinium salts are highly reactive towards various nucleophiles to give the appropriate, 4-substituted derivatives. The very mild conditions required for both the activation and substitution steps and the high yields of the products make these compounds attractive intermediates for modification of uracils.

Experimental

Pyridine and dioxane were purified and dried as described previously (10). 1-Methyluracil and 1-methylthymine were synthesized according to the reported procedure (19). Synthesis of **2***c* was described previously (11). All the other reagents (Merck, Aldrich, and Fluka) were used as received. Thin-layer chromatography was performed on Merck F_{254} and Merck RP silica gel plates. Merck PSC 60-F_{254} silica gel plates were used for preparative separations. Column chromatography was performed on H60, MN 100–200 mesh, and RP silica gels (Merck) and NM 300 cellulose (Macherey Nagel). The following solvent systems were used for TLC: chloroform/methanol, 30:1 (A); chloroform/methanol, 20:1 (B); chloroform/methanol, 10:1 (C); ethyl acetate (D); ethyl acetate/methanol, 15:1 (E); water (F); ethanol (G); ethanol/30% aqueous acetic acid, 2:1 (H); ethanol/water, 3:1 (I); all v/v.

HPLC separations in the case of the stability studies of **5***a*,*b* were performed on a Waters 600E instrument using an ODS column eluted isocratically with a mixture of $CH_3CN/H_2O/CH_3COOH$, 25:74.9:0.1 (v:v:v). Melting points were taken on a Boetius apparatus and are uncorrected. UV-absorption and fluorescence emission spectra were measured on a Zeiss UV–VIS M-40 spectrophotometer and a Perkin Elmer MPF 44 spectrofluorometer. Fluorescence quantum yields were determined relative to quinine bisulfate (ϕ = 0.55, 1 N H_2SO_4) (20). Mass spectra were obtained by using a Jeol JMS-D-100 mass spectrometer. A Varian Gemini 300 VT instrument was used to obtain ^1H and ^{13}C NMR spectra. The chemical shifts δ_H and δ_C are reported in ppm relative to TMS and dioxane as internal standards. Microanalyses were performed on a Perkin Elmer 2400 CHN analyser.

N-[1-Methylpyrimidin-2(1H)-one-4-yl]pyridinium chloride, **2**a *and N-[1,5-dimethylpyrimidin-2(1H)-one-4-yl]pyridinium chloride,* **2**b

A dry sample of 1-methyluracil or 1-methylthymine (3 mmol) was dissolved in anhydrous pyridine (50 mL) and treated with 4-chlorophenylphosphorodichloridate (0.73 mL, 4.5 mmol). The mixture was stirred for 18 h. The precipitate formed was filtered, dissolved in ice-cold water, and neutralized to pH ca. 6.2–6.5 with Dowex-1 resin (HCO_3^-). The resin was filtered, and the filtrate concentrated under vacuum to ca. 10 mL and passed through a Dowex-1 (Cl^-) column. The eluates were concentrated (<30°C) to give ca. 0.1 M aqueous solutions of **2***a* and **2***b*. In the case of the more stable **2***b* the solution was lyophilized to give a yellow solid (86% yield). Some selected spectral data for **2***a*,*b* are presented below.

2*a*: UV (H_2O) λ_{max}: 268 nm, 310 nm; ^1H NMR (D_2O) δ: 9.53 (m, 2, pyridine Cα-H), 8.91 (m, 1, pyridine Cγ-H), 8.73 (d, J = 6.9 Hz, 1, C6-H), 8.34 (m, 2, pyridine Cβ-H), 7.34 (d, J = 6.9 Hz 1, C5-H), 4.68 (s, 3, N-CH_3); ^{13}C NMR δ: 163.24, 157.61, 151.64, 142.60, 129.21, 98.82, 40.31.

2*b*: UV (H_2O) λ_{max}: 263 nm (ϵ 5300), 334 nm (ϵ 5000); ^1H NMR (D_2O) δ: 9.18 (m, 2, pyridine Cα-H), 8.93 (m, 1, pyridine Cγ-H), 8.61 (s, 1, C6-H), 8.36 (m, 2, pyridine Cβ-H), 4.75 (s, 3, N-CH_3), 2.13 (s, 3, C-CH_3); ^{13}C NMR δ chemical shifts were identical with those reported previously (21).

General procedure for the syntheses of ***3–10***

Water was used as a solvent unless otherwise specified. 0.1 M aqueous solutions of **2***a*,*b* or **2***c* (aliquots corresponding to 1–5 mmol samples of the salts) were treated with the appropriate nucleophile (3 equiv.) and the reaction mixture kept at room temperature until almost complete loss of pyridinium salt was detected by the Zincke test (14). The reaction times and yields are summarized in Table 1. Isolation procedures and spectral data for the products are presented below.

1-Methyl-4-(imidazol-1-yl)pyrimidin-2(1H)-one, **3**a *(Table 1; entry 1)*

Water was removed under reduced pressure. The solid residue was chromatographed twice on SiO_2 (systems D and A) and the product crystallized from isopropanol: mp > 260°C; UV (H_2O) λ_{max}: 304 nm (ϵ 9400), 239 nm (ϵ 8800); fluorescence emission λ_{max}: 363 nm (ϕ = 0.002); ^1H NMR (TFA-*d*/acetone-d_6) δ: 9.66 (m, 1, imidazole C2-H), 8.55 (d, J = 7.1 Hz, 1, C6-H), 8.27, 7.72 (2m, 2, imidazole C4-H and C5-H), 7.30 (d, J = 7.1 Hz, 1, C5-H), 3.91 (s, 3, N-CH_3); ^{13}C NMR (TFA-*d*/acetone-d_6) δ: 160.15, 159.31, 150.67, 136.48, 123.53, 120.93, 97.68, 41.12; MS *m*/*z* (relative intensity): M^+ 176(88), 175(100), 149(10), 134(18), 107(9). Anal. calcd. for $C_8H_8N_4O$: C54.53, H 4.58, N 31.80; found: C 54.47, H 4.54, N 31.84.

1,5-Dimethyl-4-(imidazol-1-yl)pyrimidin-2(1H)-one, **3**b *(Table 1; entry 2)*

The aqueous solution was extracted with chloroform. The organic layer was dried and the solvent evaporated. The crude product was chromatographed (SiO_2, system D) and then recrystallized from isopropanol; mp 151–153°C (dec.); UV (H_2O) λ_{max}: 316 nm (ϵ 8700), 238 nm (ϵ 7000); fluorescence emission λ_{max}: 376 nm (ϕ = 0.002); ^1H NMR ($CDCl_3$) δ: 8.27 (s, 1, imidazole C2-H), 7.73 (s, 1, C6-H), 7.65 and 7.16 (2m, 2, imidazole C4-H and C5-H), 3.60 (s, 3, N-CH_3), 2.31 (s, 1, C5-CH_3); ^{13}C NMR ($CDCl_3$) δ: 159.34, 155.49, 151.05, 137.02, 130.41, 118.16, 104.35, 38.46; MS *m*/*z* (relative intensity): M^+ 190(69), 189(100), 163(6), 148(8), 140(6). Anal. calcd. for $C_6H_{10}N_4O$: C 56.83, H 5.30, N 29.45; found: C 56.67, H 5.27, N 29.32.

1-(2′,3′,5′-Tri-O-acetyl-β-D-ribofuranosyl)-4-(imidazol-1-yl)-pyrimidin-2-(1H)-one, **3**c *(Table 1; entry 3)*

The aqueous solution was extracted with chloroform. The organic layer was dried and then concentrated under reduced pressure. The residue was chromatographed on SiO_2 (system D). Fractions containing pure product were collected and evaporated under vacuum to give **3***c* as a foam. UV (H_2O) λ_{max}: 305 nm (ϵ 7800), 242 nm (ϵ 8700); fluorescence emission λ_{max}: 374 nm (ϕ = 0.002); ^1H NMR ($CDCl_3$) δ: 8.41 (br s, 1, imidazole C2-H), 8.13 (d, J = 7.3 Hz, 1, C6-H), 7.70 and 7.19 (2s, 2, imidazole C4, C5-H), 6.58 (d, J = 7.3 Hz, 1, C5-H), 6.14 (d, 1, Cl′-H), 5.51–5.26 (m, 2, sugar C-H), 4.53–4.42 (m, 3, sugar C-H), 2.15, 2.13 and 2.12 (3s, 9, $COCH_3$); ^{13}C NMR ($CDCl_3$) δ: 170.12, 169.53, 158.96, 154.41, 145.57, 131.82, 128.35, 116.32, 94.60, 89.72, 80.35, 73.85, 70.00, 62.85, 20.75, 20.42; high resolution MS, *m*/*z*: M^+ 420.12781 ($C_{18}H_{20}N_4O_8$ requires 420.12796 amu).

Reaction of **2**a *with histidine (Table 1; entry 4)*

The reaction mixture was concentrated and chromatographed on a reversed phase silica gel column (system F). The fractions containing **4***a* were collected, the solvent evaporated to dryness, and the solid residue recrystallized from a mixture of isopropanol–water: mp 233–240°C (dec.); UV (H_2O) λ_{max}: 305 nm (ϵ 8700), 238 nm (sh); fluorescence emission λ_{max}: 363 nm (ϕ = 0.0007); ^1H NMR (D_2O) δ: 7.80 (br s, 1, histidine C2-H), 7.23 (d, J = 7.3 Hz, 1, C6-H), 6.93 (br s, 1, histidine C5-H), 5.78 (d, J = 7.3 Hz, 1, C5-H), 3.57 (m, 1, CH-CO), 3.19 (s, 3, N-CH_3), 3.07 (m, 2, CH_2); ^{13}C NMR (D_2O) δ: 174.99, 164.98, 159.94, 154.03, 137.07, 135.88, 118.60, 97.05, 55.69, 38.40, 29.52. Anal. calcd. for $C_{11}H_{13}N_5O_3$: C 50.18, H 4.97, N 26.60; found: C 49.87, H 4.85, N 26.33.

Reaction of **2**b *with histidine (Table 1; entry 5)*

A work-up utilizing the same procedure as for **2***a* (see above) gave a crystalline sample of **4***b*: mp 194–197°C; UV (H_2O) λ_{max}: 318 nm (ϵ 8800), 240 nm (sh); fluorescence emission λ_{max}: 376 nm (ϕ = 0.0007); ^{1}H NMR (D_2O) δ: 8.22 (s, 1, histidine C2-H), 8.15 (s, 1, C6-H), 7.55 (s, 1, histidine C5-H), 4.00 (m, 1, CH-CO), 3.55 (s, 3, N-CH_3), 3.12 (m, 2, CH_2), 2.21 (s, 3, C-CH_3); ^{13}C NMR (D_2O) δ: 174.18, 159.99, 158.04, 154.68, 138.86, 137.40, 117.95, 108.46, 55.37, 39.44, 29.42, 15.38. Anal. calcd. for $C_{12}H_{15}N_5O_3$: C 51.98, H 5.45, N 25.25; found: C 51.67, H 5.41, N 25.11.

Reaction of pyridinium salt **2**a *with 1-methylimidazole (Table 1; entry 6)*

The reaction mixture was extracted with $CHCl_3$. The organic layer was dried, concentrated under vacuum, and chromatographed on an SiO_2 column (B) to yield a pure sample of **6***a*: mp 200°C; UV (H_2O) λ_{max}: 301 nm (ϵ 20 700), 225 nm (sh); ^{1}H NMR ($CDCl_3/CD_3OD$, 5:1) δ: 8.09 (s, 1, CHO), 7.55 (d, J = 7 Hz, 1, C6-H), 7.15 and 6.88 (2m, total 1, C=CH), 6.08 and 5.94 (2d, J = 7.1 and 7.3 Hz, total 1, C5-H), 5.50 and 5.26 (2d, J = 7.1 and 6.6 Hz, total 1, C=CHO), 3.44 (s, 3, N-CH_3), 3.19 and 3.03 (2s, total 3H, *cis* and *trans* CO-N-CH_3); ^{13}C NMR ($CDCl_3/CD_3OD$) δ: 164.16 and 162.48 (aldelhyde C=O), 162.11 and 160.96 (C4), 157.82 (C=O), 147.09 (C6), 121.36 and 116.38 (C=C), 110.74 and 109.38 (C=C), 95.51 (C5), 37.87 (N-CH_3), 37.49 and 31.89 (N-CH_3); MS m/z (relative intensity): M^+ 208(37), 180(18), 164(25), 151(15), 150(100), 144(20), 138(29), 136(12), 126(6). Anal. calcd. for $C_9H_{12}N_4O_2$: C 51.91, H 5.80, N 26.90; found: 51.84, H 5.79, N 26.85.

The aqueous layer remaining after extraction with $CHCl_3$ was concentrated and chromatographed on cellulose (systems G, I). The fractions containing imidazolium salt **5***a* were concentrated to remove ethanol and then passed through a Dowex (Cl^-) column. The aqueous eluate was treated with charcoal and evaporated to dryness. The sample of **5***a* was stored at 5°C and was stable for over 2 weeks: UV (H_2O) λ_{max}: 313 nm (ϵ 4800), 242 nm (sh); fluorescence emission λ_{max}: 371 nm (ϕ = 0.14); ^{1}H NMR (D_2O) δ: 9.56 (s, 1, imidazole C2-H), 8.32 (d, J = 7.3 Hz, 1, C6-H), 8.04 and 7.53 (2d, 2, imidazole C4-H and C5-H), 6.90 (d, J = 7.3 Hz, 1, C5-H), 3.88 (s, 3, N-CH_3), 3.48 (s, 3, N-CH_3); ^{13}C NMR (D_2O) δ: 158.20 (C4), 156.25 (imidazole C3), 137.02 (C2), 126.02 (C6), 120.60 (imidazole C4 and C5), 96.71 (C5), 40.10 (N-CH_3), 37.60 (N-CH_3). Anal. calcd. for $C_9H_{11}N_4OCl{\cdot}xH_2O$: C 44.17, H 5.35, N 22.89; found: C 41.10, H 5.27, N 22.71.

Reaction of pyridinium salt **2**b *with 1-methylimidazole (Table 1; entry 7)*

Extraction of the reaction mixture with chloroform and column chromatography of the organic layer over SiO_2 (C) gave **6***b*: mp 192°C; UV λ_{max} (H_2O): 308 nm (ϵ 18 700), 224 nm (sh); ^{1}H NMR ($CDCl_3/CD_3OD$ 5:1) δ: 8.10 (s, 1, CHO), 7.41 (d, J = 1 Hz, 1, C6-H), 6.84 and 6.98 (2d, J = 7.5 and J = 7.2 Hz, total 1, C=CH), 5.20 and 5.70 (dd, J = 5.7 Hz and J = 1 Hz; and d, J = 7.2 Hz, total 1, C=CH), 3.41 (s, 3, N-CH_3), 3.22 and 3.09 (2s, total 3, CO-N-CH_3), 1.99 and 2.05 (2d, total 3, C-CH_3); ^{13}C NMR ($CDCl_3/CD_3OD$ 5:1) δ: 161.99, 159.9, 157.66, 144.33, 115.62, 109.60, 103.05, 38.02, 37.54, 12.40; MS m/z (relative intensity): M^+ 222(27), 194(19), 178(16), 164(100), 163(25), 152(21), 150(11), 140(10). Anal. calcd. for $C_{10}H_{14}N_4O_2$: C 54.04, H 6.34, N 25.10; found: C 53.97, H 6.26, N 25.02.

The aqueous layer obtained after extraction with $CHCl_3$ was concentrated under vacuum and chromatographed over cellulose (systems G, I). Fractions containing **5***b* were concentrated and passed through a Dowex (Cl^-) column. The eluate was evaporated to dryness under vacuum to give **5***b* as a white solid: UV (H_2O) λ_{max}: 324 nm (ϵ 4700); fluorescence emission λ_{max}: 387 nm (ϕ = 0.104); ^{1}H NMR (D_2O) δ: 9.27 (s, 1, imidazole C2-H), 8.24 (s, 1, C6-H), 7.86 and 7.51 (2m, 2, imidazole C4-H and C5-H), 3.87 (s, 3, N-CH_3), 3.48 (s, 3, N-CH_3), 2.11 (s, 3, C-CH_3); ^{13}C NMR (D_2O) δ: 156.58, 144.93, 137.81, 125.10, 122.33, 108.90, 39.87, 37.43, 14.30. Anal. calcd. for $C_{10}H_{13}N_4OCl{\cdot}xH_2O$: C 46.42, H 5.84, N 21.65; found: C 46.27, H 5.83, N 21.49.

*1-Methyl-4-(3-chlorophenoxy)pyrimidin-2(1*H*)-one,* **7**a *(Table 1; entry 8)*

3-Chlorophenol (0.933 g, 7.26 mmol) and triethylamine (0.35 mL, 2.5 mmol) were added to a two-phase system composed of an aqueous solution of pyridinium salt **2***a* (20 mL, 2.42 mmol) and chloroform (20 mL). The mixture was stirred vigorously for 2 h in the absence of light. The chloroform layer was separated and fractionated on a silica gel column (system E) to give **7***a*: mp 146–148°C; UV (H_2O) λ_{max}: 280 nm (ϵ 7800); ^{1}H NMR ($CDCl_3$) δ: 7.61 (d, J = 7.1 Hz, 1, C6-H), 7.15 (m, 4, aromatic H), 6.04 (d, J = 7.1 Hz, 1, C5-H), 3.48 (s, 3, N-CH_3); ^{13}C NMR ($CDCl_3$) δ: 171.04, 156.31, 152.29, 149.37, 134.80, 130.30, 126.13, 122.44, 120.28, 94.81, 38.08; high resolution MS m/z: 236.03518 ($C_{11}H_9N_2O_2Cl$ requires 236.03519 amu). Anal. calcd. for $C_{11}H_9N_2O_2Cl$: C 55.82, H 3.83, N 11.84; found: C 55.80, H 3.85, N 11.63.

*1,4-Dimethyl-4-(3-chlorophenoxy)pyrimidin-2(1*H*)-one,* **7**b *(Table 1; entry 9)*

This compound was obtained according to the procedure described for **7***a*. Fractions from a silica-gel column (system E) were collected and evaporated to dryness. The residue was dissolved in methanol and decolorized with charcoal. Crystallization from ethyl acetate gave **7***b* as white needles: mp 211°C; UV (H_2O) λ_{max}: 289 nm (ϵ 7300); ^{1}H NMR (DMSO-d_6/$CDCl_3$) δ: 7.99 (d, J = 1.0 Hz, 1, C6-H), 7.30 (m, 4, aromatic H), 3.34 (s, 3, N-CH_3), 2.03 (d, J = 1.0 Hz, 3, C-CH_3); ^{13}C NMR (DMSO-d_6/$CDCl_3$) δ: 169.31, 155.22, 152.57, 148.61, 133.28, 130.62, 125.53, 122.39, 120.87, 101.96, 36.89, 11.43; high resolution MS, m/z: 250.05066 ($C_{12}H_{11}N_2O_2Cl$ requires 250.05083 amu). Anal. calcd. for $C_{12}H_{11}N_2O_2Cl$: C 57.49, H 4.42, H 11.18; found: C 57.46, H 4.42, N 11.21.

*1-(2′,3′-5′-Tri-*O*-acetyl-*β*-D-ribofuranosyl)-4-(3-chlorophenoxy)pyrimidin-2(1*H*)-one,* **7**c (Table 1; entry 10)

The pyridinium salt **2***c* was reacted with 3-chlorophenol under conditions analogous to those used for synthesis of **7***a*. The chloroform layer was separated and chromatographed on SiO_2 ($CHCl_3$ and system A). Appropriate fractions were collected and the solvent evaporated to give **7***c* as an oil. UV (H_2O) λ_{max}: 278 nm (ϵ 7700); ^{1}H NMR ($CDCl_3$) δ: 7.91 (d, J = 7.4 Hz, 1, C6-H), 7.20 (m, 4, aromatic H), 6.18 (d, J = 7.4 Hz, 1, C5-H), 6.11 (d, 1, C1′-H), 5.39, 5.32, and 4.38 (3m, 5, sugar C-H), 2.15, 2.14, and 2.10 (3s, 9, $COCH_3$); ^{13}C NMR ($CDCl_3$) δ: 170.88. 169.94, 169.37, 154.85, 151.51, 143.58, 134.52, 130.09, 126.18, 122.07, 120.00, 96.00, 89.00, 79.74, 73.49, 69.68, 62.75, 20.76, 20.46. High resolution MS m/z: M^+ 480.09340 ($C_{21}H_{21}N_2O_9Cl$ requires 480.09313 amu).

*1-Methyl-4-(coumarin-7-oxy)pyrimidin-2(1*H*)-one,* **8**a *(Table 1; entry 11)*

The reaction of **2***a* with 7-hydroxycoumarin was carried out in a mixture of dioxane/water 4:1 (v/v) at pH 7.5 adjusted with $NaHCO_3$. Crystals of pure **8***a*, precipitated from the reaction mixture, were filtered: mp 161°C; UV (CH_3OH) λ_{max}: 305 nm (ϵ 13 100, sh), 285 nm (ϵ 16 500); fluorescence emission λ_{max}: 378 nm (ϕ = 0.002); ^{1}H NMR (TFA-*d*/acetone-d_6) δ: 8.67 (d, J 7.6 Hz, 1, C6-H), 8.15 (d, J = 9.4 Hz, 1, coumarin C3-H), 7.9 (m, 1, aromatic H), 7.42 (m, 2, aromatic H), 6.75 (d, J = 9.4 Hz, 1, coumarin C4-H), 6.45 (d, J = 7.6 Hz, 1, C5-H), 3.86 (s, 3, N-CH_3); ^{13}C NMR (TFA-*d*/acetone-d_6) δ: 173.36, 166.06, 161.13, 156.14, 154.19, 151.27, 146.93, 132.90, 121.36, 119.63, 118.05, 111.56, 94.97, 40.41; MS m/z (relative intensity): M^+ 270(100), 200(8), 188(19), 187(97), 159(43), 149(8), 109(6). Anal. calcd. for $C_{14}H_{10}N_2O_4$: C 62.22, H 3.72, N 10.37; found: C 62.07, H 3.69, N 10.18.

1,5-Dimethyl-4-(coumarin-7-oxy)pyrimidin-2(1H)one, **8**b *(Table 1; entry 12)*

The solvent and pH were the same as for synthesis of **8***a*. The reaction mixture was concentrated under vacuum, and the crystalline product was filtered off and separated from unreacted 7-hydroxycoumarin by chromatography on SiO_2 plates (system E): mp 238°C; UV (CH_3OH) λ_{max}: 307 nm (ε 12 700), 288 nm (ε 12 600); fluorescence emission λ_{max} 376 nm (φ = 0.001); ^{1}H NMR (TFA-*d*/acetone-d_6) δ: 8.34 (s, 1, C6-H), 8.13 (d, *J* = 9.5 Hz, 1, coumarin C3-H), 7.86 (m, 1 aromatic H), 7.38 (m, 2, aromatic H), 6.71 (d, *J* = 9.5 Hz, 1, coumarin C4-H), 3.89 (s, 3, N-CH_3), 2.40 (s, 3, C-CH_3); ^{13}C NMR (TFA-*d*/acetone-d_6) δ: 171.93, 166.45, 157.38, 155.94, 155.03, 153.66, 147.19, 132.05, 120.56, 117.30, 114.29, 112.07, 40.53, 11.94; MS *m/z* (relative intensity): (M^+ + 1) 285(18), M^+ 284(100), 270(6), 214(7), 187(19), 159(15), 149(10), 146(7), 134(9). Anal. calcd. for $C_{15}H_{12}N_2O_4$: C 63.37, H 4.25, N 9.85. Found: C 63.14, H 4.21, N 9.73.

1-Methyl-4-(2-hydroxyethylthio)pyrimidin-2(1H)one, **9**a *(Table 1; entry 13)*

The reaction mixture was extracted with $CHCl_3$. The extract was chromatographed on silica gel plates (system E). Product **9***a* was obtained as an oil that solidified upon addition of ethyl acetate: mp 70–72°C; UV (H_2O) λ_{max}: 301 nm (ε 20 700), 225 nm (sh); ^{1}H NMR ($CDCl_3/CH_3OD$) δ: 7.46 (d, *J* = 6.9 Hz, 1, C6-H), 6.30 (d, *J* = 6.9 Hz, 1, C5-H), 3.70 (t, *J* = 6.5 Hz, 2, CH_2), 3.49 (s, 3, N-CH_3), 3.30 (t, *J* = 6.5 Hz, 2, CH_2); ^{13}C NMR ($CDCl_3/CH_3OD$) δ: 177.87, 156.04, 145.47, 104.46, 61.11, 32.35, 32.02. MS *m/z* (relative intensity): M^+ (186(1), 166(4), 156(18), 142(45), 141(35), 127(12), 126(100). Anal. calcd. for $C_7H_{10}N_2O_2S$: C 45.14, H 5.41, N 15.04; found: C 45.03, H 5.37, N 14.94.

1,5-Dimethyl-4-(2-hydroxyethylthio)pyrimidin-2(1H)one, **9**b *(Table 1; entry 14)*

The reaction mixture was extracted with $CHCl_3$ and the organic layer was dried and concentrated under reduced pressure. The residue was separated on an SiO_2 column (system E): mp 110°C; UV (H_2O) λ_{max}: 308 nm (ε 18 700), 224 nm (sh); ^{1}H NMR ($CDCl_3/CD_3OD$) δ: 7.29 (d, *J* = 0.8 Hz, 1, C6-H), 3.76 (t, 2, CH_2), 3.48 (s, 3, N-CH_3), 3.33 (t, 2, CH_2), 2.04 (d, *J* = 0.8 Hz, 3, C-CH_3); ^{13}C NMR ($CDCl_3/CD_3OD$) δ: 178.19, 155.92, 143.30, 113.07, 61.11, 38.08, 32.02, 13.81; MS *m/z* (relative intensity): M^+ 200(5), 183(5), 170(13), 156(100), 155(64), 140(11). Anal. calcd. for $C_8H_{12}N_2O_2S$: C 47.98, H 6.04, N 13.99; found: C 47.76, H 5.98, N 13.87.

*1-(2′,3′,5′-Tri-*O*-acetyl-β-D-ribofuranosyl)-4-(2-hydroxyethylthio)-pyrimidin-2(1H)one,* **9**c *(Table 1; entry 15)*

The product was isolated as described above. System E was used for chromatography. UV (H_2O) λ_{max}: 301 nm (ε 19 600); ^{1}H NMR $CDCl_3$) δ: 7.64 (d, *J* = 7.0 Hz, 1, C6-H), 6.44 (d, *J* = 7.0 Hz, 1, C5-H), 6.19 (d, 1, C1′-H), 5.42, 5.35, and 4.38 (3m, 5, sugar C-H), 3.73 (t, *J* = 6.5 Hz, 2, CH_2), 3.30 (t, *J* = 6.5 Hz, 2, CH_2), 2.16, 2.14, and 2.10 (3s, 9, $COCH_3$); ^{13}C NMR δ: 177.56, 169.96, 169.59, 169.50, 156.82, 146.12, 103.81, 88.89, 80.06, 73.36, 69.88, 62.77, 61.13, 32.47, 20.67, 20.36, 20.23; high resolution MS, *m/z*: M^+ 430.10427 ($C_{17}H_{22}N_2O_9S$ requires 430.10444 amu).

One-pot synthesis of **9**c

The solution of 2′,3′,5′-tri-*O*-acetyluridine (1 mmol) in dry pyridine (10 mL) was treated with 4-chlorophenylphosphorodichloridate (1.5 mmol) and left overnight at room temperature followed by addition of mercaptoethanol (7 mmol). The Zincke test indicated 9% conversion of the pyridinium salt after ca. 1 h. The reaction mixture was evaporated to dryness, and the residue was dissolved in aqueous sodium bicarbonate and then extracted with chloroform. Chromatography on SiO_2 (system E) gave **7***c* in 78% overall yield.

1-Methyl-4-azidopyrimidin-2(1H)-one, **10**a *(Table 1; entry 16)*

The aqueous solution containing 2 mmol of **2***a* was evaporated (<30°C) to dryness. The solid residue was dissolved in dry dimethylformamide (20 mL) and sodium azide (0.195 g, 3 mmol) was added. The resulting mixture was stirred for 15 min and then the solvent was evaporated under vacuum at 35°C. The residue was treated with water (30 mL) and the aqueous solution extracted with chloroform. The organic layer was dried over Na_2SO_4, concentrated, and treated with hexane to give crystals of **10***a*: mp 206–208°C; UV (H_2O) λ_{max}: 270 nm (ε 8500, sh), 258 nm (ε 10 000); ^{1}H NMR (DMSO-d_6) δ: 7.73 (d, *J* = 7.3 Hz, 1, C6-H), 6.94 (d, 1, C5-H), 3.73 (s, 3, N-CH_3); ^{13}C NMR (DMSO-d_6) δ: 151.42, 143.62, 141.52, 92.26, 36.62; high resolution MS, *m/z*: 151.04932 ($C_5H_5N_5O$ requires 151.04936 amu). Anal. calcd. for $C_5H_5N_5O$: C 39.73, H 3.33, N 46.34; found: C 39.60, H 3.28, N 46.49.

1,5-Dimethyl-4-azidopyrimidin-2(1H)-one, **10**b *(Table 1; entry 17)*

This compound was obtained according to the procedure described for **10***a*. The crude product was chromatographed on an SiO_2 column (system B): mp 178–180°C; UV (H_2O) λ_{max}: 273 nm (ε 7500, sh), 257 nm (ε 9500); ^{1}H NMR (DMSO-d_6) δ: 7.76 (d, *J* = 1.2 Hz, 1, C6-H), 3.56 (s, 3, N-CH_3), 2.28 (d, *J* = 1.2 Hz, 3, C-CH_3); ^{13}C NMR (DMSO-d_6) δ: 152.19, 143.30, 138.05, 101.64, 36.46, 12.19; high resolution MS, *m/z*: 165.06494 ($C_6H_7N_5O$ requires 165.06498 amu). Anal. calcd. for $C_6H_7N_5O$: C 43.63, H 4.27, N 42.40; found: C 43.41, H 4.25, N 42.27.

*1-(2′,3′,5′-Tri-*O*-acetyl-β-D-ribofuranosyl)-4-azidopyrimidin-2(1H)-one,* **10**c *(Table 1; entry 18)*

The aqueous solution of **2***c* was treated with sodium azide. Pure **10***c*, which precipitated from the reaction mixture, was filtered off. An additional amount of the product was isolated from the filtrate by extraction ($CHCl_3$) and chromatography on SiO_2 (system D). UV (H_2O/CH_3OH, 9:1) λ_{max}: 265 nm (ε 7000, sh), 251 nm (ε 7600); ^{1}H NMR ($CDCl_3$) δ: 7.71 (d, *J* = 7.8 Hz, 1, C6-H), 6.98 (d, *J* = 7.8 Hz, 1, C5-H), 6.29 (d, 1 C1′-H), 5.45, 5.39, and 4.39 (3m, 5, sugar C-H), 2.17, 2.14, and 2.09 (3s, 9, $COCH_3$); ^{13}C NMR ($CDCl_3$) δ: 169.99, 169.59, 169.50, 150.53, 142.58, 133.85, 94.70, 88.78, 80.69, 73.24, 69.95, 62.75, 20.68, 20.37, and 20.23; high resolution MS, *m/z*: M^+ 395.10757 ($C_{15}H_{17}N_5O_8$ requires 395.10749 amu).

A phosphorus-31 NMR study of solid carbonylhydridotris(triphenylphosphine)rhodium(I). Unusual MAS sideband intensities in second-order NMR spin systems

GANG WU, RODERICK E. WASYLISHEN,[1] AND RONALD D. CURTIS
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received July 25, 1991

GANG WU, RODERICK E. WASYLISHEN, and RONALD D. CURTIS. Can. J. Chem. **70**, 863 (1992).

The CP/MAS ^{31}P NMR spectrum of carbonylhydridotris(triphenylphosphine)rhodium(I), $RhH(CO)(PPh_3)_3$ (**1**), can be described as a tightly coupled ABMX spin system (X = ^{103}Rh). In contrast to the solution ^{31}P NMR spectrum, the three equatorial phosphorus nuclei are nonequivalent in the solid state and this structural feature allows us to measure the two-bond spin–spin couplings, $^2J(^{31}P,^{31}P)$. A new method is proposed for extracting the principal components of the chemical shift tensor from slow MAS NMR spectra in a tightly *J*-coupled two-spin system. For compound **1**, the principal components of the ^{31}P chemical shift tensors calculated using this method are in good agreement with those obtained from NMR spectra of a static sample. The principal components of the ^{31}P chemical shift tensors determined for **1** are compared with those reported previously for Wilkinson's catalyst, $RhCl(PPh_3)_3$. The δ_{22} component of the ^{31}P chemical shift tensors in **1** shows the largest variation with structure. This is ascribed to differences in the orientation of the P—C_{ipso} bond about the equatorial plane of the trigonal bipyramidal structure.

Key words: rhodium–phosphine compounds, AB spin system, ^{31}P chemical shift tensor, magic-angle spinning, molecular structure.

GANG WU, RODERICK E. WASYLISHEN et RONALD D. CURTIS. Can. J. Chem. **70**, 863 (1992).

On peut décrire le spectre RMN CP/MAS du ^{31}P du carbonylhydrido (triphénylphosphine)rhodium(I), $RhH(CO)(PPh_3)_3$ (**1**), par un système de spin ABMX (X = ^{103}Rh) fortement couplé. Contrairement à ce qui a été observé dans le spectre RMN du ^{31}P en solution, les trois noyaux des phosphores équatoriaux ne sont pas équivalents à l'état solide et cette caractéristique structurale nous a permis de mesurer les couplages spin–spin à travers deux liaisons, $^2J(^{31}P,^{31}P)$. On propose une nouvelle méthode pour extraire les principales composantes du tenseur du déplacement chimique à partir de spectres RMN, mesurés lentement par la technique de rotation à l'angle technique, dans un système *J* à deux spin couplés. Pour le composé **1**, les principales composantes des tenseurs du déplacement chimique du ^{31}P, calculées par cette méthode, sont en bon accord avec celles obtenues à partir de spectres RMN d'un échantillon statique. On a comparé les principales composantes des tenseurs du déplacement chimique du ^{31}P du composé **1** avec celles rapportées antérieurement pour le catalyseur de Wilkinson, $RhCl(PPh_3)_3$. La composante δ_{22} des tenseurs du déplacement chimique du ^{31}P du composé **1** est celle qui varie le plus avec la structure. On attribue cette propriété aux différences dans l'orientation de la liaison P—C_{ipso} autour du plan équatorial de la structure trigonale bipyramidale.

Mots clés : composés rhodium–phosphine, système de spin AB, tenseur du déplacement chimique du ^{31}P, rotation à l'angle technique, structure moléculaire.

[Traduit par la rédaction]

Introduction

Carbonylhydridotris(triphenylphosphine)rhodium(I), $RhH(CO)(PPh_3)_3$ (**1**), is one of the most important commercial homogeneous catalysts (1–3). In solution, ^{31}P NMR studies indicate that **1** is capable of undergoing dissociation to generate $RhH(CO)(PPh_3)_2$ as indicated in eq. [1].

$$[1] \quad RhH(CO)(PPh_3)_3 \underset{-PPh_3}{\overset{+PPh_3}{\rightleftharpoons}} RhH(CO)(PPh_3)_2$$

The latter species is an active catalyst for alkene hydrogenation and hydroformylation (4). The dissociation of a triphenylphosphine ligand from **1** is apparent from ^{31}P NMR ligand exchange studies in toluene solution (5). For example, when a large excess of triphenylphosphine is added to a toluene solution of **1**, the doublet at $\delta(^{31}P)$ = 39.8 ppm ($^1J(^{103}Rh,^{31}P)$ = 155 Hz) arising from $RhH(CO)(PPh_3)_3$ broadens and shifts to a lower frequency ($\delta(^{31}P) = -7.2$ ppm for free triphenylphosphine ligands). Typical exchange rates for dissociation are on the order of 50 s^{-1} at 25°C for a solution containing a 6:1 excess of PPh_3. The observation of a simple doublet in the ^{31}P NMR spectrum of **1** in toluene solution suggests that all three PPh_3 groups are chemically equivalent and that they occupy the equatorial sites of a trigonal bipyramid as deduced from X-ray diffraction studies (6).

The yellow crystals of $RhH(CO)(PPh_3)_3$ are monoclinic and belong to the space group $P2_1/n$ (C_{2h}^5). Examination of the X-ray diffraction results indicates that each of the three PPh_3 ligands is nonequivalent due to slight variations in structure (see Fig. 1). One of the primary objectives of the present study is to demonstrate that the ^{31}P cross-polarization (CP) magic-angle spinning(MAS) NMR spectrum of **1** is sensitive to these subtle structural differences. As well, we describe a general procedure for analyzing the AB portion of a slow MAS NMR spectrum to obtain average principal components of the A and B spin chemical shift tensors. The CP/MAS ^{31}P NMR spectrum of **1** is analyzed as the ABM portion of a general ABMX spectrum where X = ^{103}Rh ($I = \frac{1}{2}$). The NMR parameters obtained from our solid-state study are compared with corresponding solution NMR studies (5) and with related solid-state NMR studies on Wilkinson's catalyst, $RhCl(PPh_3)_3$ (7).

Theory

For an isolated or uncoupled spin-1/2 nucleus, it is well-known that the analysis of slow MAS NMR spectra is ca-

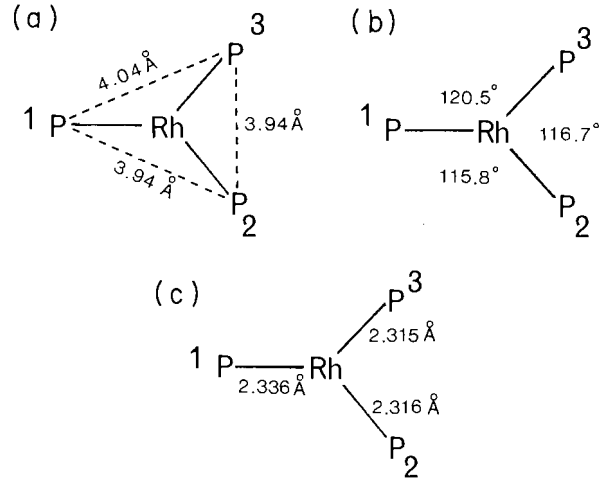

FIG. 1. Selected structural parameters of the RhP_3 moiety in **1**. Phosphorus sites are numbered as in ref. 6.

pable of yielding the principal components of the chemical shift (CS) tensor and, hence, the chemical shift anisotropy (8–14). Such techniques are particularly attractive in cases where the MAS spectrum consists of several isotropic peaks, making the analysis of the corresponding static powder NMR spectrum very difficult. The most widely used procedure for analyzing slow MAS NMR spectra is the well-known Herzfeld–Berger technique (9). In cases where the spin under observation is coupled to a heteronuclear spin through direct dipole–dipole and indirect spin–spin (J) interactions, the relative intensity of the peaks in the J-coupled multiplet in each spinning sideband is modulated by the dipolar and J interactions as well as the chemical shift anisotropy (10, 15). If the dipolar coupling and the anisotropy in J (ΔJ) are negligible, then the heteronuclear J-coupled multiplet observed with MAS NMR will show regular fine structure similar to that observed in solution NMR spectra. However, this is not generally true if two nuclei are strongly J-coupled, i.e., an AB spin pair. In such a case, even if the dipolar coupling and ΔJ are zero, it is still possible to have AB multiplets with different relative intensity in each spinning sideband because the mixing between the $|\alpha\beta\rangle$ and $|\beta\alpha\rangle$ states becomes orientation dependent in an AB spin system.

Consider a strongly J-coupled spin pair, A and B, each with anisotropic chemical shift and isotropic J coupling (the dipolar interaction between the two spins is assumed to be negligible). The resulting four transitions, ν_i, and their relative intensities, P_i, are given by eq. [2]:

$$[2a] \quad \nu_1 = \frac{1}{2}(\nu_A + \nu_B) - \frac{1}{2}J - \frac{1}{2}D, \qquad P_1 = 1 - J/D$$

$$[2b] \quad \nu_2 = \frac{1}{2}(\nu_A + \nu_B) + \frac{1}{2}J - \frac{1}{2}D, \qquad P_2 = 1 + J/D$$

$$[2c] \quad \nu_3 = \frac{1}{2}(\nu_A + \nu_B) - \frac{1}{2}J + \frac{1}{2}D, \qquad P_3 = 1 + J/D$$

$$[2d] \quad \nu_4 = \frac{1}{2}(\nu_A + \nu_B) + \frac{1}{2}J + \frac{1}{2}D, \qquad P_4 = 1 - J/D$$

where $D = [(\nu_A - \nu_B)^2 + J^2]^{1/2}$. If (θ_A, ϕ_A) and (θ_B, ϕ_B) are used to define the orientation of the applied magnetic field B_0 in the principal axis system of the two chemical shielding tensors, A and B, respectively, then ν_A and ν_B are

$$[3a] \quad \nu_A = \nu_0[1 - (\sigma_{11}{}^A \sin^2\theta_A \cos^2\phi_A + \sigma_{22}{}^A \sin^2\theta_A \sin^2\phi_A + \sigma_{33}{}^A \cos^2\theta_A)]$$

$$[3b] \quad \nu_B = \nu_0[1 - (\sigma_{11}{}^B \sin^2\theta_B \cos^2\phi_B + \sigma_{22}{}^B \sin^2\theta_B \sin^2\phi_B + \sigma_{33}{}^B \cos^2\theta_B)]$$

It is clear from eqs. [2] and [3] that because of the term D each transition characterizes a more complicated powder line shape than that of an isolated nucleus with anisotropic chemical shift. Therefore, the previous method of analyzing spinning sidebands in a slow MAS NMR spectrum (9) is not directly applicable to a tightly J-coupled AB spin pair, since in this case the envelope of spinning sidebands associated with each transition cannot be characterized by three distinct principal components of a chemical shift tensor.

Fortunately, if we take the average of the four transitions in eq. [2], the term D can be removed and the expressions of both transition frequency and intensity become very simple:

$$[4a] \quad \nu_0 = \frac{1}{4}(\nu_1 + \nu_2 + \nu_3 + \nu_4) = \frac{1}{2}(\nu_A + \nu_B)$$

$$[4b] \quad P_0 = \frac{1}{4}(P_1 + P_2 + P_3 + P_4) = 1$$

The transition ν_0 is not observable, but can be easily constructed in a slow MAS NMR spectrum. Its calculated position appears at the centre of a J-coupled AB multiplet and its intensity is the average of all four peaks. It should be noted, however, that the intensity distribution of such constructed spinning sidebands still cannot be characterized by a single chemical shift tensor, since each constructed sideband equals the average of sidebands due to the two different CS tensors of spin A and B. Only when the magnitudes of the principal components of the two CS tensors are approximately the same (not necessarily in their orientations) can one analyze the constructed sidebands with the usual methods (9, 11, 12) and recover the elements of the chemical shift tensor.

Theoretical justification of the above procedure can be made by applying the Floquet Hamiltonian theory to a homonuclear spin-1/2 pair in rotating solids (16). Assuming that the sample spinning rate is much greater than the isotropic J coupling between the two nuclei of an AB spin pair, one can rewrite eq. 17 in ref. 16 and obtain the intensities of the four transitions in the ith order spinning sideband, P^i, as follows (dipolar interactions and ΔJ are ignored):

$$[5a] \quad P_1^i = Y_1 I_A^i + Y_4 I_B^i$$

$$[5b] \quad P_2^i = Y_2 I_B^i + Y_3 I_A^i$$

$$[5c] \quad P_3^i = Y_2 I_A^i + Y_3 I_B^i$$

$$[5d] \quad P_4^i = Y_1 I_B^i + Y_4 I_A^i$$

where

$$Y_1 = \frac{1}{2}(1 - \cos\Psi - \sin\Psi)$$

$$Y_2 = \frac{1}{2}(1 + \cos\Psi + \sin\Psi)$$

$$Y_3 = \frac{1}{2}(1 - \cos\Psi + \sin\Psi)$$

$$Y_4 = \frac{1}{2}(1 + \cos\Psi - \sin\Psi)$$

and $\sin\Psi = J/D$. I_A^i and I_B^i are the intensities of the ith order spinning sideband due to the chemical shift tensors of spin A and spin B, respectively, in the absence of any spin–spin interaction. From eq. [5], it is easy to show that the average intensity of the J-coupled multiplet in the ith order spinning sideband becomes independent of the J interaction, i.e.,

$$[6] \quad \frac{1}{4}(P_1^i + P_2^i + P_3^i + P_4^i) = \frac{1}{2}(I_A^i + I_B^i)$$

Furthermore, it is interesting to note in eq. [5] that the relative intensity of peaks in the J-coupled multiplet deviates from that obtained in solution NMR studies. For example, the relative intensity of P_1^i and P_2^i is given as

$$[7] \quad \frac{P_1^i}{P_2^i} = \frac{(1 - \sin\Psi)(I_A^i + I_B^i) - \cos\Psi(I_A^i - I_B^i)}{(1 + \sin\Psi)(I_A^i + I_B^i) - \cos\Psi(I_A^i - I_B^i)}$$

Obviously, if $I_A^i \neq I_B^i$, this ratio is different from $(1 - \sin\Psi)/(1 + \sin\Psi)$, which is the ratio expected for an AB spin pair in the solution NMR spectrum.

Inspection of eqs. [5] and [7] reveals the following general features regarding the MAS NMR spectrum of two tightly J-coupled spins: (1) the relative intensities of the four peaks in an AB multiplet vary depending on the order of the spinning sidebands, (2) the relative intensities of the AB multiplets become distorted in comparison with those obtained in solution NMR studies, and (3) only in the case where the spinning rate is so high that all spinning sidebands are of negligible intensity (i.e., $I_A = I_B = 1$ for the isotropic peaks) do the MAS spectra restore the normal AB patterns observed in solution.

Experimental

Carbonylhydridotris(triphenylphosphine)rhodium(I), **1**, was purchased from Aldrich Chemical Company and was used for the present NMR study without further purification. The yellow crystals of **1** were ground and packed into a zirconium oxide rotor (7 mm o.d.). Phosphorus-31 CP/MAS NMR spectra were obtained on a Bruker MSL-200 NMR spectrometer (B_0 = 4.70 T) operating at 81.033 MHz. All spectra were acquired at 20°C with high-power proton decoupling during data acquisition. Cross polarization was accomplished under the Hartmann–Hahn match condition using 90° pulses of 4 μs. Typical values of the contact time were 2–5 ms and the recycle time was 10 s. Sample spinning rates ranged from 2 to 4 kHz. The magic angle was adjusted by examining the ^{79}Br NMR signal of KBr (17). All ^{31}P spectra were referenced to 85% H_3PO_4(aq) by using solid $NH_4H_2PO_4$ as a secondary reference. The latter compound has a chemical shift of +0.81 ppm with respect to 85% H_3PO_4(aq). The acquisition time was 106 ms and the 8 K FID was zero-filled to 16 K prior to Fourier transformation. The line widths at half-height in the MAS NMR spectra were approximately 25 Hz. No improvement in the line width was observed by using longer acquisition times.

The static ^{31}P NMR spectrum of a powdered sample of **1** was obtained on a Varian Unity-400 NMR spectrometer (B_0 = 9.40 T) using a slightly modified Varian 7-mm MAS probehead. Proton and phosphorus 90° pulse lengths for cross polarization were 5 μs with a decoupling field strength in excess of 90 kHz. The contact time was 2.5 ms with an acquisition time of 35 ms and a recycle time of 20 s. The audiofrequency filters were opened to their maximum values, 100 kHz, in order to observe the ^{31}P NMR signal approximately 12 μs after the cross-polarization period. This was found to help alleviate spectral distortions associated with a loss of information in the first few data points. A sensitivity enhancement corresponding to 50 Hz of line broadening was applied to the FID prior to Fourier transformation.

The phosphorus-31 NMR spectrum of a toluene solution of **1** (50 mg in 2.0 mL) was obtained at 146.12 MHz on a Nicolet 360 NB NMR spectrometer with broadband proton decoupling. The solution sample was prepared under a nitrogen environment and sealed in a 10-mm NMR tube. The NMR spectrum was recorded at room temperature (20°C) and was referenced to external 85% H_3PO_4(aq).

Simulation of the isotropic portion of the MAS NMR spectra was accomplished by the LAME8 program (18). All the spinning sideband analyses were performed using a Simplex program based on the Herzfeld–Berger method (9). The static powder line shape was calculated by simply overlapping three independent CS powder patterns.

Results and discussion

The ^{31}P CP/MAS NMR spectra of **1** is shown in Fig. 2. The presence of intense first and second-order spinning sidebands indicates that the ^{31}P chemical shift anisotropies are large compared with the sample spinning frequency, 4.0 kHz. The isotropic portion of the ^{31}P CP/MAS spectrum of **1** is given in Fig. 3*a*. Since the three ^{31}P nuclei are nonequivalent in the solid state, all the possible J couplings between ^{31}P–^{31}P and ^{31}P–^{103}Rh are readily resolved in the high-resolution, solid-state NMR spectrum. The calculated spectrum is also shown in Fig. 3*b* and best-fit parameters are summarized in Table 1. The resultant pattern suggests an ABMX spin system in **1** (A, B, and M represent the three ^{31}P nuclei; X = ^{103}Rh). The three isotropic chemical shifts were determined to be 45.35, 34.34, and 33.84 ppm compared to the single chemical shift (41.15 ppm) obtained from a solution NMR spectrum. The assignment of three phosphorus chemical shifts to P1, P2, and P3 shown in Fig. 1 is based on arguments regarding the relative magnitudes of the principal components of the chemical shift tensors (*vide infra*). It is readily seen from Fig. 3 that, although all the observed line positions are well reproduced (rms deviation < 0.8 Hz), the intensities of the outer peaks of the AB portion in the simulated spectrum are significantly smaller than the observed intensities. As discussed in the theory section, this is due to the strong J coupling and the orientation-dependent chemical shifts in the solid state, so that the AB pattern in the MAS spectrum of **1** differs from that expected in solution.

The one-bond ^{103}Rh–^{31}P coupling constants, $^1J(^{103}\text{Rh},^{31}\text{P})$, in **1** fall in the normal range reported for related rhodium(I) compounds (19, 20) and agree well with the value observed for the same compound in toluene solution. The three essentially equal $^1J(^{103}\text{Rh},^{31}\text{P})$ values confirm that the three phosphorus atoms are at equatorial sites, since $^1J(^{103}\text{Rh},^{31}\text{P}_{ax})$ has been found to be smaller than $^1J(^{103}\text{Rh},^{31}\text{P}_{eq})$ (19). Following previous solution NMR investiga-

tions of rhodium(I) complexes (21), the sign of $^1J(^{103}Rh,^{31}P)$ in **1** is assigned as negative.

Since the three triphenylphosphine ligands in **1** are equivalent in solution, $^2J(^{31}P,^{31}P)$ cannot be measured. The values of $^2J(^{31}P,^{31}P)$ in solid **1** are comparable to those reported for five-coordinate rhodium(I) compounds (22). This two-bond coupling was intermediate between the magnitudes of $^2J(^{31}P,^{31}P)_{cis}$ and $^2J(^{31}P,^{31}P)_{trans}$ reported for four-coordinate rhodium(I) compounds (19, 20) where $^2J(^{31}P,^{31}P)_{cis} < {}^2J(^{31}P,^{31}P)_{trans}$. Similar to the discussion of $^1J(^{103}Rh,^{31}P)$, the values of $^2J(^{31}P,^{31}P)$ also provide evidence that the three phosphorus atoms are at approximately equivalent equatorial sites; otherwise a much smaller $^2J(^{31}P,^{31}P)$, characteristic of a $^2J(^{31}P_{ax},^{31}P_{eq})$, would be observed (23). The sign of $^2J(^{31}P,^{31}P)$ was assumed to be positive (19), although no difference could be introduced in the simulated spectrum by varying the relative sign of $^2J(^{31}P,^{31}P)$ and $^1J(^{103}Rh,^{31}P)$.

In addition to the isotropic peaks, several spinning sidebands also appear in the MAS NMR spectrum of **1**, as shown in Fig. 2. Inspection of the relative intensities of the *J*-coupled multiplet in each spinning sideband indicates that both heteronuclear ($^{103}Rh,^{31}P$) and homonuclear ($^{31}P,^{31}P$) dipolar interactions are small. Based on the X-ray crystal structure (6), the direct dipolar coupling constants

$$R_{AX} \equiv \left(\frac{\mu_0}{4\pi}\right) r_{AX}^{-3} \gamma_A \gamma_X \left(\frac{\hbar}{2\pi}\right)$$

are as follows: $^1R_{P-Rh} \leq 125$ Hz and $^2R_{P-P} \leq 325$ Hz. These values are small with respect to the sample spinning frequency (ca. 4 kHz), confirming that the relative intensities of the spinning sidebands are primarily governed by the anisotropic chemical shift and the J_{AB} coupling.

Unusual AB patterns also appear in the different order spinning sidebands as observed in the isotropic part of the slow MAS NMR spectrum. In Fig. 4 several spinning sidebands are shown for easy comparison. It is clear that the relative intensities of peaks within the high-frequency multiplet (M spin) remain essentially unchanged in the different order spinning sidebands, while the relative intensities of peaks within the AB part vary dramatically.[2]

It is straightforward to recover the principal components of the CS tensor for the M spin. The relative intensities of the central peak of the high-frequency triplet were measured at three different sample spinning rates and the three principal components of the CS tensor were obtained by implementing the Herzfeld–Berger method (9). For the A and B spins, the intensity of the AB multiplet due to the strong $^{31}P-^{31}P$ *J* coupling was averaged in each spinning sideband, as described in the theory section. Assuming that the chemical shift anisotropies at the two tightly *J*-coupled spins are approximately the same, the principal components of the two CS tensors can be recovered by using the averaged intensities. If the two CS tensors differ, then the averaged principal components are obtained, provided that the difference between the corresponding principal components of the two CS tensors is small compared to their anisotropies.

The principal components of phosphorus CS tensors in **1**, obtained from analysis of the MAS NMR spectrum, are given in Table 2. To confirm the accuracy of these values, a static powder spectrum was obtained at a high magnetic field (B_0 = 9.40 T). Analysis of the static powder spectrum (shown in Fig. 5*a*) permits the determination of the principal components for all three ^{31}P chemical shift tensors in **1**. Since the dipolar couplings and *J* couplings (ca. 150 Hz) are much

[2]In fact, the relative intensities of peaks within the M-spin multiplet do change very slightly, presumably due to the small deviation from first-order *J* coupling between the M spin and the other two spins, or due to the residual homonuclear dipolar interactions among the ^{31}P nuclei in **1**.

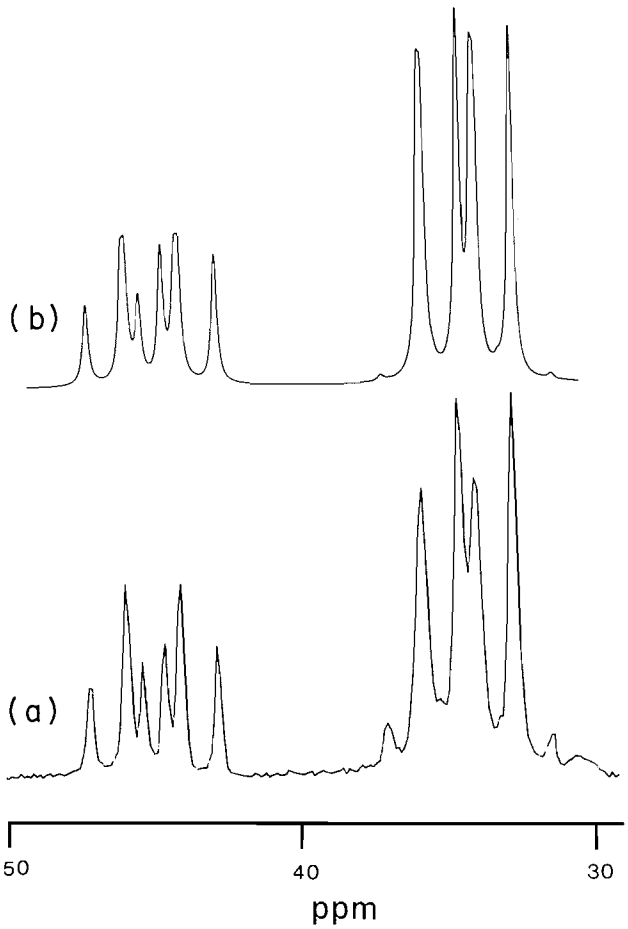

FIG. 3. (*a*) The isotropic part of the CP/MAS ^{31}P NMR spectrum of **1**. (*b*) Calculated spectrum with parameters given in Table 1. A Lorentzian line shape with the half-height width of 20 Hz was used.

smaller than the chemical shift anisotropies in Hz ($\Delta\nu = \nu_{11} - \nu_{33} \approx 24$ kHz at $B_0 = 9.40$ T), it is reasonable to analyze the static powder line shape by simple overlapping of the three independent chemical shift powder patterns. The calculated ^{31}P NMR static powder line shape is also shown in Fig. 5*b*. It is evident that all of the main shoulders of the experimental line shape are reproduced in the calculated spectrum. The anomalous features at the low-frequency end of the static line shape were also observed at $B_0 = 4.70$ T. These features may be attributed to the second-order J coupling effect between P1 and P3, or to the homonuclear dipolar coupling between the three ^{31}P nuclei. Nonetheless, the effect is small and does not influence the determination of the principal components in the present case. The results obtained from analysis of the static powder line shape (also shown in Table 2) clearly indicate that analysis of the MAS NMR spectrum gives reasonable estimates of the principal components for P2 (M spin), while for P1 and P3 (A and B spins) it yields the averaged values of the corresponding principal components. Also, it is clear that the principal components of the CS tensors for P1 and P3 differ by less than 15 ppm.

In Table 2 the values of the chemical shift anisotropy ($\Delta\delta = \delta_{11} - \delta_{33}$) observed for the three ^{31}P nuclei of **1** are comparable to those reported previously (7) for the mutually *trans* phosphorus nuclei in the approximately square planar $RhCl(PPh_3)_3$, Wilkinson's catalyst, the only rhodium–phosphine complex for which complete ^{31}P shielding data are available (24). It is interesting to note that the variation of the δ_{33} components of the three ^{31}P chemical shift tensors in **1** is relatively small: furthermore, the three δ_{33} components in **1** are similar to the corresponding components at the mutually *trans* ^{31}P nuclei in $RhCl(PPh_3)_3$. Since the orientation of δ_{33} has been determined to be almost parallel to the Rh—P bond in $RhCl(PPh_3)_3$ (7), it is reasonable to expect that δ_{33} of the ^{31}P chemical shift tensor also lies along the Rh—P bond for each ^{31}P nucleus in **1**. Thus, the chemical shieldings along the Rh—P bond in compound **1** are probably similar to those at the two mutually *trans* phosphorus nuclei in $RhCl(PPh_3)_3$. Also, the three δ_{11} components in **1** have approximately the same values as those of the mutually *trans* ^{31}P nuclei in $RhCl(PPh_3)_3$.

In contrast to δ_{11} and δ_{33}, the δ_{22} component of the ^{31}P CS tensors in **1** shows large variations and all three δ_{22} components deviate from the corresponding values in $RhCl(PPh_3)_3$. From Table 2 it is readily seen that the unique high-frequency isotropic chemical shift at P2 in **1** is mainly due to the significant deshielding of the δ_{22} component. From a solution ^{31}P NMR study, significantly different isotropic chemical shifts have been found in different conformers associated with rotation of the phenyl groups about the Rh—P bond in *trans*-$[RhX(CO)L_2]$ complexes (X = halogen; L = tertiary phosphine) (25). Therefore, two distinct isotropic shifts (ca. 45 and 34 ppm) observed in **1** may also reflect the local orientation of the phenyl groups with respect to the trigonal bipyramidal structure in the solid state. Since the unique

[a]All principal components are in ppm and estimated errors are less than ±5 ppm.
[b]All principal components are in ppm and estimated errors are ±2 ppm.
[c]From ref. 7.

isotropic shift at 45.15 ppm results from deshielding of the δ_{22} component that is perpendicular to the Rh—P bond, it is reasonable to associate the variations in δ_{22} with the different orientations of the P—C_{ipso} bonds at each of the three phosphorus sites. This argument is supported by the X-ray crystal structure of **1** where the dihedral angles of (OC)—Rh—P—C_{ipso} for the three phosphorus sites are P1(−64, +55, +176), P2(+7, +129, −112), and P3(−177, −54, +64) (6). The relative orientation of the phenyl groups is unique at P2. Since the principal components of the ^{31}P CS tensors at P1 and P3 are similar, the assignment of P1 and P3 remains ambiguous.

It is worth noting that in a recent ^{31}P NMR study of a series of solid cyclic and acyclic phosphorus–metal complexes, δ_{22} was reported to be much more sensitive to the local geometry at the phosphorus atoms than δ_{11} and δ_{33} (26). Similarly, we have found evidence that the δ_{22} component of the ^{31}P chemical shift tensors in **1** is sensitive to the local orientation of the phenyl groups. However, work on ^{31}P chemical shielding in phosphine–metal complexes is just

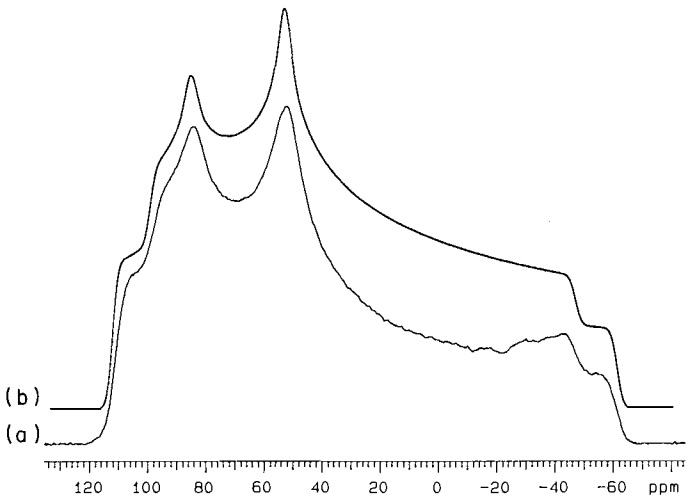

FIG. 5. (*a*) Observed static powder spectrum of **1** at B_0 = 9.40 T. (*b*) Calculated static powder line shape of **1** using the parameters listed in Table 2.

beginning and details of how the principal components of chemical shift tensors correlate with the structural parameters are still not fully understood. Therefore, our assignment must be regarded as tentative. Further investigations of phosphorus shift tensors in metal phosphine compounds are in progress in our laboratory.

Summary

We have shown that the relative intensities of the NMR transitions observed for tightly coupled spin systems in the high-resolution MAS NMR spectra of solids do not correspond to those calculated using the conventional high-resolution Hamiltonian applicable to second-order spectra in isotropic solutions. The Herzfeld–Berger method cannot be used directly to recover the principal components of a chemical shift tensor when one of the spins is a part of an AB spin system. Here, we have proposed and successfully applied a simple procedure to recover the average ^{31}P chemical shift tensors for the AB spin pair in $RhH(CO)(PPh_3)_3$. The δ_{11} and δ_{33} components are similar to those obtained for the two mutually *trans* ^{31}P nuclei in the square planar complex, $RhCl(PPh_3)_3$. The intermediate components of the ^{31}P chemical shift tensors in $RhH(CO)(PPh_3)_3$, $RhCl(PPh_3)_3$, and related compounds (26) show the largest variation with molecular structure and it is this component that is mainly responsible for variations of δ_{iso} in these compounds.

Acknowledgements

We are grateful to the Natural Sciences and Engineering Research Council of Canada for financial support. We thank Mr. Bill Kenny of Varian for making it possible for us to obtain ^{31}P NMR spectra of **1** at 9.40 T, and Dr. F. Morin, McGill University, for obtaining ^{31}P NMR spectra at 7.05 T. Finally, we thank Professors T. S. Cameron and O. Knop for helpful discussions concerning the reported X-ray results of compound **1**.

En vue de déterminer le degré de substitution de matrices complexes, la bromation de différents carbazoles par le tribromure de tétrabutylammonium a été envisagée en tant que modèle de réaction de substitution. Elle nous a permis de tester la validité d'une méthode de dosage voltampérométrique des ions tribromures et des espèces libérées, les ions Br^- et H^+. Les résultats obtenus pour différents rapports substrat/réactif sont en excellent accord avec ceux obtenus en chromatographie liquide hautes performances. La technique électrochimique constitue une méthode fiable, rapide et facile à mettre en oeuvre pour suivre la cinétique de la bromation ou déterminer le degré de substitution de matrices organiques complexes.

Mots clés : bromation, tribromure de tétrabutylammonium, dosage voltampérométrique (Br_3^-, Br^-, H^+), degré de substitution.

ANNIE DESBENE-MONVERNAY, OUZAMA KARAZOUN, JACQUES BERTHELOT, and PAUL-LOUIS DESBENE. Can. J. Chem. **70**, 870 (1992).

To determine the degree of substitution of complex matrices, the bromination of various carbazoles by tetrabutylammonium tribromide has been used as a model of a substitution reaction. This has allowed us to test the validity of the voltamperometric titration of tribromide ions and species formed (Br^- and H^+ ions). The results obtained for various substrate/reagent ratios are in excellent agreement with those of high performance liquid chromatography. The electrochemical titration can be considered as reliable, fast, and very easy to use. It permits us to follow the bromination kinetics and to determine the degree of substitution of complex organic matrices.

Key words: bromination, tetrabutylammonium tribromide, voltamperometric titration (Br_3^-, Br^-, H^+), degree of substitution.

Introduction

Le tribromure de tetrabutylammonium ($TBABr_3$) a déjà été utilisé comme nouvel agent de bromation des doubles et triples liaisons (1, 2) ainsi que comme réactif pour substituer un atome de brome à un hydrogène dans les aromatiques activés (phénols (3) et amines (4)). Les avantages de $TBABr_3$ comme réactif de bromation sont nombreux : caractère non toxique et non corrosif; composé très stable à degré de brome constant; produit donnant lieu à une réaction douce, à température ordinaire.

Par ailleurs le dosage des ions Br_3^- et Br^-, mis au point dans le cas de la bromation d'alcènes (5, 6), a permis d'appréhender pour la première fois l'indice de brome d'un milieu complexe : les résidus lourds des pétroles (7).

Afin de poursuivre notre modélisation de la bromation par $TBABr_3$ de cette matrice organique complexe, l'usage de ce réactif, associé à la technique de dosage électrochimique précédemment élaborée, est maintenant appliqué à une réaction de substitution, la bromation de carbazoles, ce type de composé offrant l'avantage de présenter plusieurs sites d'attaque électrophile.

Le degré de substitution déterminé électrochimiquement est comparé avec celui obtenu en chromatographie liquide à hautes performances, technique qui permet en outre de préciser le nombre, la nature et les proportions des composés formés.

Partie expérimentale

Réactifs

Un certain nombre des composés étudiés sont des produits commerciaux utilisés directement : c'est le cas du perchlorate de tétrabutylammonium (TBAP) puriss Fluka, du bromure et du tribromure de tétrabutylammonium (TBABr et $TBABr_3$) Janssen Chimica et de l'acide perchlorique normapur 70% Prolabo. Le carbazole, le *N*-éthyl-carbazole et le *N*-éthyl, 3-carboxaldéhyde-carbazole provenant de chez Aldrich ont été recristallisés avant usage. Le *N*-méthyl, le 3-chloro, le 3-bromo, le 3,6-dibromo et le 3,6-dichloro-carbazoles ont été synthétisés selon le processus décrit dans la référence 8.

En ce qui concerne les solvants, le chloroforme Spectrosol SDS, l'acétonitrile, le nitrométhane, le diméthylformamide et le diméthylsulfoxyde, qui sont de qualité spectroscopique et pro-

viennent de chez Aldrich, ont été utilisés sans purification ultérieure. Le carbonate de propylène Aldrich a été distillé sous vide avant usage. Enfin pour la chromatographie liquide nous avons utilisé du *n*-heptane et de l'acétate d'éthyle Chromasol SDS.

Électrochimie

L'étude voltampérométrique a été effectuée à l'aide d'électrodes à disque de Pt (diamètre = 2 mm), Au (diamètre = 5 mm) et C Vitreux (diamètre = 3 mm), de type Tacussel EM-EDI, commandées par une unité d'asservissement Contravit Tacussel et tournant à la vitesse de 500 t/min. La cellule contenant 25 mL de solvant 0,1 M en perchlorate de tétrabutylammonium comprend, outre l'électrode tournante, une grille de Pt cylindrique comme électrode auxiliaire et se trouve reliée par l'intermédiaire d'un pont électrolytique à une électrode de référence de type $Ag–Ag^+$ 10^{-2} M dans l'acétronitrile.

Les courbes *i–E* enregistrées à l'aide d'une table traçante Ifelec (IF 3802) ont été obtenues avec un potentiostat Par EGG 173 piloté par un générateur de signaux Par EGG 175.

Bromation

La bromation des composés a été réalisée à température ambiante en faisant réagir sous agitation magnétique 5 mL d'une solution de chloroforme contenant 0,5 mmol de carbazole avec 5 mL d'une solution de chloroforme 0,1 M en $TBABr_3$. Les prises d'essais, opérées à la seringue (250 μL), ont été transférées directement du mélange réactionnel dans la cellule électrochimique.

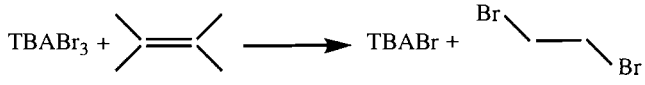
Les produits de bromation du carbazole, 3-bromo et 3,6-dibromo carbazole ont été identifiés par comparaison de leurs caractéristiques physiques (point de fusion) et spectrales (IR, RMN ^1H et masse) avec celles d'un échantillon authentique.

Chromatographie

L'analyse du milieu réctionnel a été effectuée en chromatographie de partage en phase normale sur une installation Beckman comportant deux pompes 112 gérées par un controleur modèle 421, un injecteur Altex équipé d'une boucle de 20 μL et un détecteur UV modèle 165. La séparation des carbazoles est obtenue en moins de 10 min sur une colonne de silice (300 × 4,6 mm; dp = 7 μm) avec comme phase mobile un mélange *n*-heptane/acétate d'éthyle 85 : 15, et pour un débit de 1 mL/min. La longueur d'onde de détection est fixée à 254 nm. Dans ces conditions les temps de rétention du carbazole, du 3-bromo et du 3,6 dibromo-carbazole sont respectivement de 4,8, 6,0 et 8,0 min.

Résultats et discussion

$TBABr_3$ est un agent de bromation qui peut donner lieu soit à des réactions d'addition dans le cas de composés insaturés :



soit à des réactions de substitution sur des composés aromatiques :

$$x\ TBABr_3 + \text{substrat} \rightarrow x\ TBABr + \text{substrat bromé} + x\ HBr \quad (x \text{ fois})$$

Dans les réactions d'addition il y a libération d'un ion Br^- par double liaison ou par ion Br_3^- consommé, alors que pour les réactions de substitution il se forme deux ions Br^- pour un atome de brome fixé ou encore pour un ion tribromure disparu. De plus, dans ce dernier cas, chaque atome de brome fixé se substitue à un atome d'hydrogène entrainant l'apparition d'un proton en solution. Aussi le dosage des ions Br_3^-, Br^- et H^+ doit-il permettre de suivre la réaction de substitution lors de la bromation par $TBABr_3$ de composés aromatiques. En outre, dans le cas plus complexe d'une compétition entre les réactions d'addition et de substitution, il apparait possible d'opérer la discrimination entre ces deux types de réaction.

Étude voltampérométrique des espèces considérées

Le comportement voltamétrique en milieu organique des halogénures a été considéré depuis longtemps (9), notamment celui des ions qui nous intéressent à savoir, Br^- (10–12) et Br_3^- (11, 13). Afin d'optimiser le dosage de ces ions au sein de matrices complexes, nous avons reconsidéré leur comportement en voltamétrie stationnaire, dans plusieurs solvants organiques, en opérant avec des microélectrodes tournantes de Pt, d'Au et de C vitreux. Les courbes intensité–potentiel obtenues dans l'acétonitrile avec ces différents matériaux d'électrode sont représentées sur la figure 1 pour le bromure de tétrabutylammonium (TBABr) et le tribromure de tétrabutylammonium ($TBABr_3$). C'est avec une électrode à disque de Pt, qui présente le domaine d'électroactivité le plus étendu et le courant résiduel le plus faible, que les vagues sont les mieux définies et les processus d'oxydoréduction :

$$6\ Br^- \underset{I}{\overset{I'}{\rightleftharpoons}} 2\ Br_3^- + 4e^-$$

$$2\ Br_3^- \underset{II,II'}{\rightleftharpoons} 3\ Br_2 + 2e^-$$

les plus réversibles.

Par ailleurs la hauteur des paliers de diffusion est proportionnelle à la concentration en ion pour les différentes vagues I, II, I′ et II′. Les pentes des droites de calibration qui représentent la sensibilité *S* de la réponse de l'électrode à la concentration en espèce électroactive varient sensiblement d'un métal à l'autre (tableau 1). Le Pt offre la sensibilité maximum pour l'oxydation des ions Br^- (vagues I et II) et l'oxydation des ions Br_3^- (vague II′), tandis que l'Au est le plus favorable pour la réduction des ions tribromure (vague I′).

L'influence du solvant sur la sensibilité de la réponse en courant a été considérée uniquement dans le cas du Pt, matériau qui offre les meilleures performances. Le choix des solvants est limité du fait des conditions à remplir simultanément : conductivité élevée, caractère aprotique, domaine d'électroactivité étendu, inertie chimique vis à vis de $TBABr_3$. La nature du solvant influe sur la hauteur des paliers de diffusion, qui néanmoins varie proportionellement à la concentration en espèce électroactive dans tous les milieux considérés. La sensibilité de la réponse *S* évolue avec la viscosité (η) du solvant et s'avère maximum dans l'acétonitrile (tableau 2). Si on se réfère à l'expression du courant limite atteint en régime stationnaire :

$$i_l = \text{const} \cdot n \cdot A \cdot D^{2/3} \cdot \omega^{1/2} \cdot \nu^{-1/6} \cdot C$$

n : nombres d'électrons échangés
A : surface de l'électrode
ω : vitesse de rotation de l'électrode
D : coefficient de diffusion de l'espèce électroactive
C : concentration de l'espèce électroactive
ν : viscosité cinématique du milieu ($\nu = \eta/d$; d : densité)

En considérant *D* inversemment proportionnel à η, ce qui semble vérifié pour les ions Br^- et Br_3^-, i_l s'avère proportionnel à $\eta^{-5/6}$, ce qui est effectivement observé (fig. 2).

Par ailleurs les réactions de bromation à l'aide de $TBABr_3$

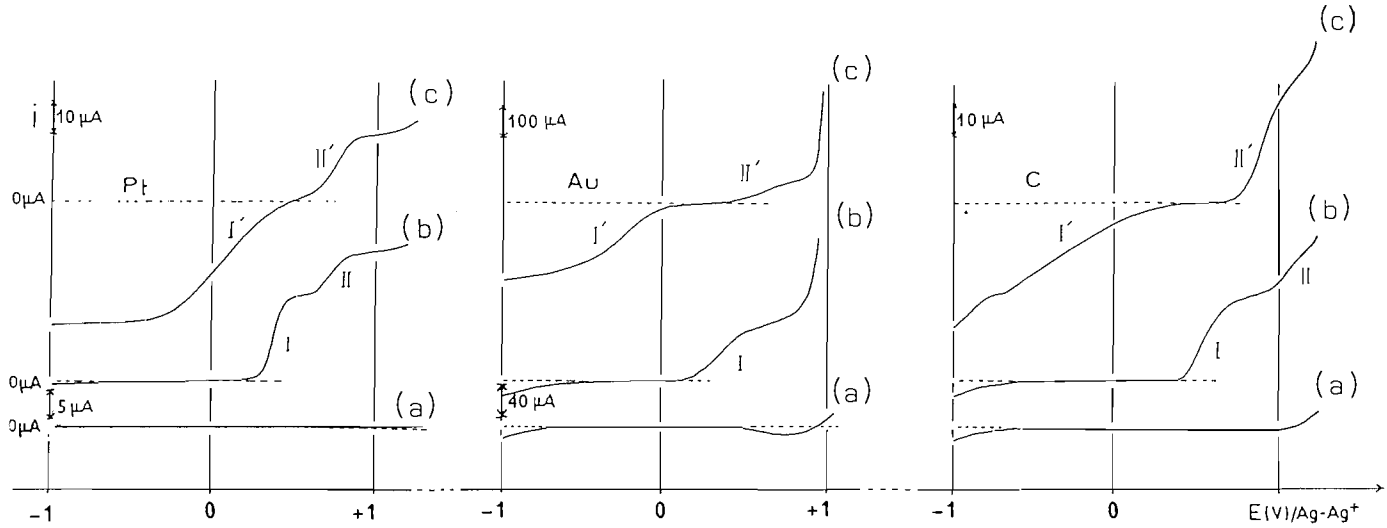


FIG. 1. Voltammogrammes obtenus sur électrode tournante à disque de Pt, Au et C vitreux en milieu CH_3CN perchlorate de tetrabutylammonium (TBAP) 0,1 M (ω = 500 t/min; V = 100 mV/s). (*a*) courbe support; (*b*) TBABr 8×10^{-4} M; (*c*) $TBABr_3$ 8×10^{-4} M.

TABLEAU 1. Pente des droites de calibration $i_D = f(\text{conc})$ pour différents matériaux d'électrode

Ion	Matériau	Pente (mA cm^{-2} $mmol^{-1}$ L)	[coefficient de régression]
Br^-		Vague I	Vague II
	Pt	0,53[0,999]	0,26[0,998]
	Au	0,36[0,999]	—
	C vitreux	0,49[0,999]	—
Br_3^-		Vague I'	Vague II'
	Pt	1,45[0,999]	0,78[0,999]
	Au	1,53[0,999]	0,38[0,995]
	C vitreux	0,53[0,997]	0,67[0,999]

sont effectuées préferentiellement dans le chloroforme, où elles sont rapides et totales. Malheureusement ce solvant de faible constante diélectrique, solubilisant mal les sels supports, est difficilement utilisable en électrochimie. Aussi avons nous considéré l'évolution de la sensibilité de la réponse d'une électrode à disque de Pt dans CH_3CN en fonction de la quantité de chloroforme ajoutée (tableau 3). On observe une décroissance linéaire de la sensibilité avec la concentration en chloroforme pour les vagues I et I'. Néanmoins en présence de 90% de $CHCl_3$ la sensibilité n'est divisée que par 2, ce qui permet des ajouts importants de mélange réactionnel dans la cellule électrochimique, sans diminution considérable du signal relatif à l'oxydation des ions Br^- et à la réduction des ions Br_3^-.

En conclusion le dosage des ions Br^- et Br_3^- présente une sensibilité optimale en milieu CH_3CN, avec une électrode de Pt. Il est à souligner que la présence d'oxygène ne modifie pas les différentes vagues considérées et que le dosage peut avoir lieu sous air. Par contre l'état de surface de l'électrode et le sens de balayage du potentiel influent de façon sensible sur l'allure, la position et la hauteur de la vague de réduction des ions tribromures et doivent être contrôlés.

En ce qui concerne les carbazoles, ils s'oxydent dans les mêmes conditions d'analyse aux environs de 1 volt, à des potentiels qui varient légèrement en fonction de leur structure (tableau 4). Le potentiel de demi-vague des carbazoles augmente dans l'ordre *N*-alkyl carbazole, carbazole, 3-halogénocarbazole, carbazoles 3,9-disubstitués et carbazoles 3,6-disubstitués, c'est à dire avec le caractère inductif accepteur du ou des substituants. L'oxydation du carbazole est représentée à titre d'exemple sur la figure 3*a*.

Quant aux protons, ils présentent une vague de réduction caractérisée par un potentiel de demi-vague de −200 mV/$Ag-Ag^+$ (Fig. 3*c*), qui se déplace vers les potentiels plus négatifs en présence d'ions tribromures. Ainsi pour les carbazoles disubstitués il est impossible d'opérer une quantification à partir du signal obtenu en réduction.

La courbe intensité–potentiel obtenue après bromation du

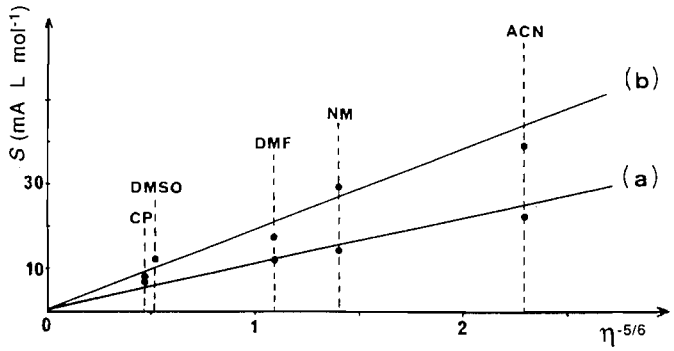

FIG. 2. Variation de la sensibilité de la réponse d'une électrode de Pt (S) à l'oxydation des ions Br^- (a) et à la réduction des ions Br_3^- (b) en fonction de la viscosité (η) du solvant.

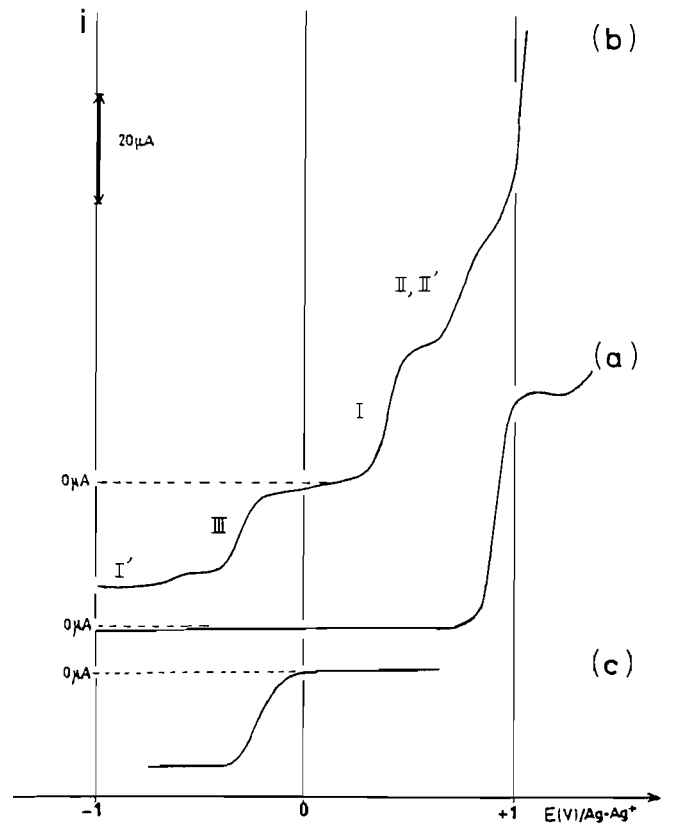

FIG. 3. Voltammogrammes obtenus sur électrode tournante à disque de Pt en milieu CH_3CN + TBAP 0,1 M (ω = 500 t/min; V = 100 mV/s). (a) carbazole $1{,}5 \times 10^{-3}$ M; (b) mélange réactionnel (carbazole 5×10^{-2} M + $TBABr_3$ 5×10^{-2} M) (250 μL) après 3 min de réaction; (c) $HClO_4$ $0{,}95 \times 10^{-3}$ M.

carbazole par $TBABr_3$ est représentée sur la figure 3*b*. L'étude voltampérométrique des différentes espèces mises en jeu permet à partir d'une telle courbe d'évaluer le degré d'avancement de la réaction de substitution d'un atome d'hydrogène par un atome de brome en exploitant : (*i*) l'évolution de la vague de réduction de Br_3^- (I'), qui diminue au fur et à mesure de la consommation du réactif $TBABr_3$; (*ii*) l'évolution de la vague d'oxydation de Br^- (I), qui augmente lors de la libération d'ions Br^- à raison de 2 Br^- formés par Br_3^- consommé; (*iii*) l'évolution de la vague de réduction des ions H^+ (III), qui sont libérés à la suite de la substitution sur le substrat d'un atome d'hydrogène par un atome de brome.

La vague située à +700 mV/Ag–Ag^+ qui résulte des vagues d'oxydation de Br_3^- (II') et de Br^- (II), s'avère moins nette pour les composés s'oxydant plus facilement, c'est à dire les carbazoles *N*-alkyl substitués. Elle peut néanmoins être utilisée pour déterminer la teneur en ions tribromure dans les cas délicats, où la vague de réduction des protons interfère avec celle des ions Br_3^-, comme c'est le cas notamment avec les carbazoles disubstitués.

Bromation des carbazoles

La bromation des carbazoles par $TBABr_3$ a été réalisée dans le chloroforme, solvant donnant des réactions rapides et complètes. Les résultats obtenus en voltampérométrie avec des carbazoles différemment substitués sont rassemblés dans le tableau 4.

En ce qui concerne le carbazole, il ressort que :

(*i*) La réaction du carbazole avec $TBABr_3$ en mélange équimoléculaire (10^{-1} M) est une réaction quasi instantanée et totale comparable à celle des amines aromatiques (4).

(*ii*) Pour deux équivalents de $TBABr_3$, la bromation est rapide mais pas tout à fait totale puisqu'il reste 13% de réactif. Une évolution se manifeste après une demi-heure, se traduisant par une diminution des concentrations en ions H^+ et Br^-, due vraisemblablement en partie à la libération de HBr dans l'atmosphère.

(*iii*) Avec 3 équivalents de $TBABr_3$ la réaction de bromation est rapide mais s'avère limitée à la fixation de deux atomes de brome par mole de substrat. On note également une diminution des pourcentages en ions H^+ et Br^- correspondant à un dégagement de HBr, par ailleurs mis en évidence par piégeage et dosage acido basique.

Pour les carbazoles substitués il s'avère que :

(*i*) La substitution de l'azote par un groupe alkyle (Me ou Et) ralentit légèrement la réaction de bromation par rapport au carbazole non substitué puisqu'après 3 min il reste encore, dans le cas du *N*-méthyl et du *N*-ethyl carbazole, respectivement 27 et 24% de tribromure qui n'a pas réagi au lieu de 6% dans le cas du carbazole. La réaction apparaît cependant totale au bout d'une demi-heure. L'attaque de Br_3^-, se faisant par les atomes de brome terminaux chargés négativement (14), est rendue plus difficile dans le cas des carbazoles *N*-alkyl substitués pour lesquels la densité électronique en position 3 est augmentée. On conçoit que, dans de telles conditions, la cinétique de bromation des *N*-alkyl carbazoles soit ralentie par rapport à celle du carbazole.

(*ii*) Avec un substituant halogène en position 3, cas du 3-chloro ou du 3-bromo carbazole, la bromation du carbazole est instantanée et complète.

(*iii*) Enfin, la disubstitution en position 3,6 (cas du 3,6-dichloro ou du 3,6-dibromo carbazole) et en position 3,9 (cas du 9-éthyl 3-formyl carbazole) limite la réaction de bromation à environ 15%.

Ce dernier résultat qui peut paraître surprenant, les carbazoles, 3,9-disubstitués conservant un hydrogène en position 6 dégagé du point de vue stérique, doit trouver son origine au niveau des densités électroniques.

On doit de plus noter que le degré de substitution calculé à partir de la concentration en protons (tableau 4 colonne 5) est généralement inférieur à celui déterminé à partir des ions Br^- (tableau 4 colonne 9) lui même inférieur à celui obtenu

à partir des ions tribromures (tableau 4 colonne 10). Ces écarts s'expliquent principalement par le fait que la vague de réduction des protons se situe à proximité de la vague de réduction des ions Br_3^- et en raison du dégagement de HBr.

Afin de valider les résultats de l'étude électrochimique, la bromation du carbazole non substitué à été suivie par chromatographie liquide à hautes performances. Les courbes d'étalonnage établies, en chromatographie de partage en phase normale, pour chacun des composés ont permis l'analyse quantitative du milieu réactionnel après bromation du carbazole par $TBABr_3$ et conduit, pour différents rapports molaires $TBABr_3$/carbazole, aux résultats rassemblés dans le tableau 5.

Ces résultats appellent les commentaires suivants :

(*i*) Dans le cas d'un mélange équimoléculaire, la bromation est terminée après 30 min du fait de la consommation

[d] ([Bromo carb.]/[carb.]$_{initiale}$ + 2[Dibromocarb.]/[carb.]$_{initiale}$) × 100.

totale de $TBABr_3$, mais il reste 21% de carbazole. La monosubstitution s'avère majoritaire par rapport à la disubstitution. Le degré de substitution global atteint 96%, en bon accord avec ceux déterminés électrochimiquement (cf. tableau 4).

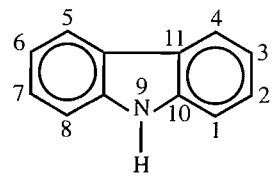
(*ii*) Pour un mélange correspondant à des proportions $TBABr_3$/carbazole égales à 2 : 1, la réaction de bromation est pratiquement complète, puisqu'il ne subsiste plus qu'une faible proportion de carbazole (2%). On observe une faible quantité de carbazole monobromé à côté du dibromocarbazole largement majoritaire. Le degré de substitution s'élève à 190%, c'est à dire à une valeur comparable à celles obtenues à l'aide du dosage électrochimique.

(*iii*) Avec un gros excès de $TBABr_3$ (3 : 1), la bromation est totale et conduit exclusivement au dibromocarbazole. Le degré de substitution atteint 200%, résultat à rapprocher de ceux calculés par la technique électrochimique à partir de la teneur du milieu réactionnel en ions Br^-, Br_3^- et H^+.

Conclusion

La bromation du carbazole par $TBABr_3$ est une réaction rapide, qui sous certaines conditions peut être totale. Elle conduit préférentiellement au dérivé monosubstitué dans le cas d'un mélange équimoléculaire et exclusivement au composé disubstitué en présence d'un excès égal ou supérieur à deux équivalents de $TBABr_3$. Les atomes de brome se fixent en positions 3 et 6, reconnues depuis longtemps comme étant les plus réactives. En effet les densités électroniques sur le noyau carbazolyle calculées à l'aide des coefficients (C^2) des orbitales atomiques obtenues à partir de la théorie de Hückel (15) indiquent que les sites réactifs sont les positions 1, 3, 6, 8 et 9.

Il est à noter que les positions 1 et 8 sont défavorisées stériquement. Quant à l'azote il doit être protoné par les H^+ libérés par la réaction de substitution. Ces deux remarques expliquent que la substitution se limite à deux atomes de brome fixés en positions 3 et 6 sur la molécule de carbazole.



1	0,133
2	0,001
3	0,118
4	0,073
9	0,202
10	0,051
11	0,024

En présence d'un halogène en position 3, la réaction de substitution est également instantanée et totale alors qu'elle se trouve ralentie du fait de l'existence d'un groupement alkyle sur l'azote.

Pour les dérivés disubstitués son rendement diminue et s'annule quasiment lorsque les positions 3 et 6 ne sont pas disponibles, ce qui confirme que ces pôles 3 et 6 sont bien les sites de la substitution électrophile.

D'un point de vue analytique on note un bon accord entre l'analyse en chromatographie liquide et les différentes possibilités offertes par les dosages voltampérométriques pour la détermination du degré de substitution (cf. tableau 6). La technique électrochimique ne donne pas d'indication sur les produits formés. Elle ne différencie pas la mono, la di, la trisubstitution et ne précise pas les sites réactionnels. Néanmoins elle permet de suivre facilement le degré d'avancement de la réaction de bromation par $TBABr_3$ et de faire rapidement un bilan global de la substitution. Rappelons également qu'elle est apte à discriminer entre réaction d'addition et de substitution. Aussi cette approche simple, d'application générale, semble particulièrement appropriée au cas des matrices complexes pour lesquelles les constituants exacts ne sont pas connus et qui ne peuvent donner lieu qu'à un bilan global.

On se propose donc d'appliquer cette méthode fiable,

For personal use only.

rapide et facile à mettre en oeuvre, que constitue la réaction de bromation par $TBABr_3$ associée au dosage voltampérométrique des ions Br_3^- et Br^-, à des cas plus complexes : composés donnant lieu à la fois à des réactions d'addition et de substitution, composés se trouvant au sein de matrices complexes, dans la mesure où celles-ci ne donnent pas de vagues d'oxydo-réduction dans le domaine de potentiel [−1 V; +1 V], films polymères, dérivés notamment du carbazole, pour préciser, à partir du degré de substitution, leur état de réticulation.

A stability and equilibrium study on Cd – salicylidene tris(hydroxymethyl) methylamine – chloride binary and ternary complexes

REFAT ABDEL-HAMID[1] AND MOHAMED T. EL-HATY[2]
Department of Chemistry, Faculty of Science, Sohag, Egypt

Received June 19, 1991

REFAT ABDEL-HAMID and MOHAMED T. EL-HATY. Can. J. Chem. **70**, 877 (1992).

Binary and ternary complexes of Cd(II) with salicylidene tris(hydroxymethyl) methylamine and chloride ion at 298 K were studied polarographically at I = 0.1 mol dm^{-3} $NaClO_4$ in 30% (v/v) DMF – aqueous medium at pH 10.2. The overall formation constants were found to be, for the binary system, log β_1 = 3.55 ± 0.03 and log β_2 = 5.40 ± 0.07 and, for the ternary one, log β_{11} = 7.64 ± 0.06 and log β_{12} = 9.56 ± 0.06.

Key words: formation constants, binary and ternary complexes of Cd(II).

REFAT ABDEL-HAMID et MOHAMED T. EL-HATY. Can. J. Chem. **70**, 877 (1992).

Faisant appel à la polarographie et opérant à 298 K, à un pH de 10,2, à I = 0,1 mol dm^{-3} de $NaClO_4$, dans un milieu à 30% (v/v) de DMF/eau, on a étudié les complexes binaires et ternaires du Cd(II) avec le salicylidène tris(hydroxyméthyl) méthylamine et l'ion chlorure. On a trouvé que les constantes globales de formation du système binaire sont log β_1 = 3,55 ± 0,03 et log β_2 = 5,40 ± 0,07 alors que celles du système ternaire sont log β_{11} = 7,64 ± 0,06 et log β_{12} = 9,56 ± 0,06.

Mots clés : constantes de formation, complexes binaires et ternaire du Cd(II).

[Traduit par la rédaction]

Introduction

In view of the confusing results of Sreenivasulu *et al.* (1) for the cadmium(II) – salicylidene tris(hydroxymethyl) methylamine binary system in different supporting electrolytes it was thought worthwhile to undertake a further polarographic study of these complexes using a more sophisticated computerized analysis (2) for the estimation of the stability constants. The investigation was extended to include a study of ternary complexes of Cd(II) with the title Schiff base and chloride.

Experimental

Salicylidene tris(hydroxymethyl) methylamine was synthesized following the method described elsewhere (3), and purified by repeated crystallization from methanol or ethanol (mp 134°C). The results of the elemental microanalysis of the compound were in agreement with its structure ($C_{11}H_{15}O_4N$; calcd.(found)%: C 58.66(58.72), H 6.71(6.60), N 6.22(6.31)).

All reagents used were of analytical (B.D.H. or Merck) grade. Fresh 0.10 mol dm^{-3} $NaClO_4$/30% dimethylformamide – aqueous stock solution was prepared by dissolving sodium perchlorate in carbon dioxide free bidistilled water. Fresh Schiff base stock solution (2.00 mol dm^{-3}) was prepared from the fresh electrolyte solution (0.10 mol dm^{-3} $NaClO_4$) on the same day that measurements were performed. The stock solution (0.10 mol dm^{-3}) of cadmium(II) was prepared using cadmium chloride, and standardized (4).

All experiments were performed in 30%(v/v) dimethylformamide – aqueous medium at 298 K. A 0.01% Triton-X100 was used as a maximum suppressor.

DC and cyclic polarograms were performed using an EG & G PAR model 364A polarographic analyzer. The measurements were carried out using a conventional three-electrode configuration. An EG & G PAR model SMDE 303 mercury-drop system in small dropping mode was used as working electrode. The electrode area was 1.05 mm^2. The reference electrode was a $Ag/AgNO_3$ (0.01 mol dm^{-3}) electrode in 0.10 mol dm^{-9} sodium perchlorate/30%(v/v) dimethylformamide – aqueous solution. A 1.0 cm^2 platinum sheet auxilliary electrode was used throughout. Solutions were purged with pure nitrogen before measurements and an atmosphere of nitrogen was maintained above the working solution.

Calculations were performed using the POLAG computer program on a CROMEMCO CS 500 computer.

Results and discussion

The most common method of extracting stability constants from polarographic data is that of DeFord and Hume (5, 6). The method is based on the following equations:

$$[1] \quad F = \exp\left[nF/RT\,(E_{1/2(s)} - E_{1/2(c)})\right] + \ln\,(I_{ds}/I_{dc})$$

$$[2] \quad F = 1 + C_L\beta_1 + C_L^2\beta_2 + \ldots C_L^n\beta_N$$

where $E_{1/2(s)}$ and $E_{1/2(c)}$ are the half-wave potentials for the uncomplexed and complexed metal ion, respectively, I_{ds} and I_{dc} are the diffusion currents of the uncomplexed and complexed metal ion, C_L is the analytical concentration of the ligand, and β_N is the overall stability constant of the Nth complex.

If a second ligand is present, the method of Schaap and McMasters (7, 8) is used.

POLAG is a nonlinear least-squares iterative program that seeks to minimize U, the sum of squares of the residual, i.e.,

$$[3] \quad U = \sum_{1}^{K} (F_{calc} - F_{obs})^2$$

where K is the number of data points; F_{obs} is given by eq. [1] and represents the experimental data; F_{calc} is obtained from eq. [2].

A solution of 1.0 mmol dm^{-3} cadmium(II) in 0.10 mol dm^{-3} $NaClO_4$/30% dimethylformamide – aqueous medium exhibits a reversible cyclic voltammetric two-electron diffusion-controlled wave at a peak current potential, E_p, of 0.586 volt versus Ag/Ag^+. The reduction of Cd(II) binary and ternary complexes of the system under investigation in the pH range 7–12 gives a cyclic voltammetric two-electron reversible diffusion-controlled wave as revealed from the

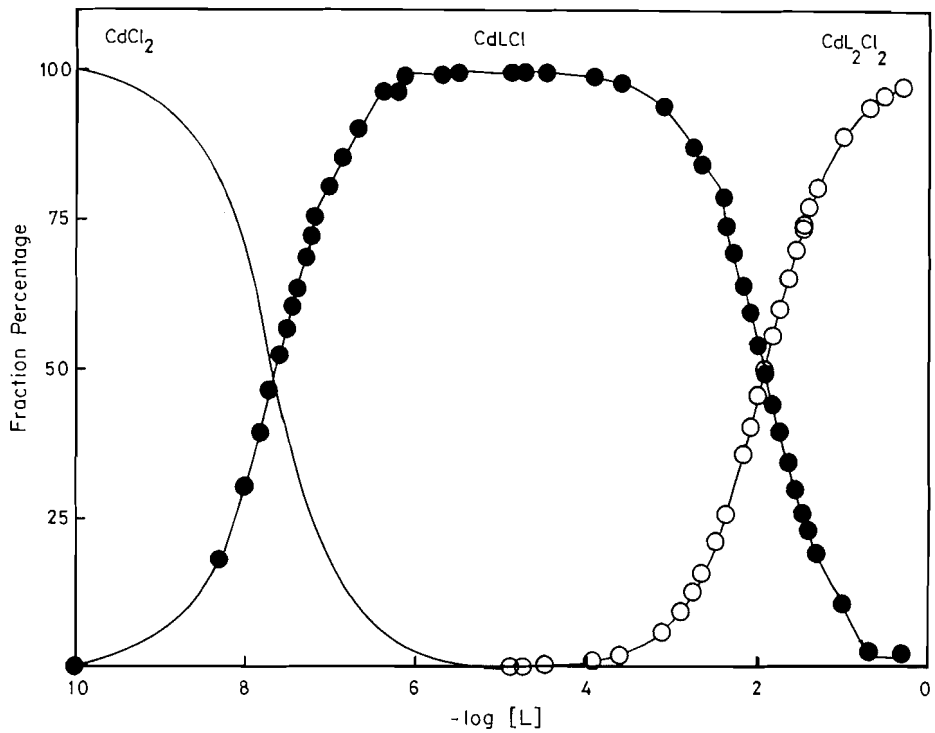

FIG. 1. Distribution diagram for the ternary system.

TABLE 1. Cyclic voltammetric data for Cd(II) – Schiff base binary system in 0.1 mol dm^{-3} $NaClO_4$/30%(v/v) DMF – aqueous medium at pH 10.2, [Cd(II)] = 1.0 mmol dm^{-3}, [Schiff base] = 0.05 mol dm^{-3}

Scan rate (mV s^{-1})	$-E_p^c$ (V)	$-E_p^a$ (V)	i_p^c (μA)	$E_p - E_{p/2}$ (mV)	i_p^a/i_p^c
20	0.704	0.674	5.85	28.0	1.00
50	0.702	0.676	6.70	28.5	1.02
100	0.705	0.672	7.66	29.0	0.98
200	0.706	0.673	9.01	29.0	0.96
500	0.706	0.677	11.70	29.5	0.98

cyclic voltammetric data obtained (cf. Table 1). These anodic and cathodic peak current potentials, E_p^a and E_p^c, were independent of scan rate (9), $E_p^a - E_p^c$ and $E_p - E_{p/2}$ were 30 ± 2 and 29 ± 2 mV, respectively, and the anodic to cathodic peak current ratio, i_p^a/i_p^c, approaches unity. The diffusion-controlled nature is confirmed by the linear dependence of the peak current, i_p^c, on the square root of the scan rate, $\nu^{1/2}$.

Binary system

The stability constants of binary complexes of Cd(II) with the title Schiff base were evaluated separately prior to those of the ternary complexes. Identical conditions were maintained in both binary and ternary systems.

A plot of $-E_{1/2}$ versus log C (logarithm of concentration of the Schiff base) gives a smooth curve, suggesting the formation of overlapping complexes. The POLAG computer program data suggest that the most likely model corresponds to the presence of ML and ML_2 species with overall stability constants, log β, of 3.55 ± 0.03 and 5.40 ± 0.07, respectively. These values are in good agreement with those previously reported for this system (1).

TABLE 2. DC polarographic data for the Cd(II) – Schiff base binary and ternary systems in 0.1 mol dm^{-3} $NaClO_4$/30%(v/v) DMF – aqueous medium at pH 10.2, [Cd(II)] = 1.0 mmol dm^{-3}

Ternary system

The ternary system was studied by keeping the concentration of the weaker ligand (chloride) constant (0.1 mol dm^{-3}) while varying the concentration of the subject Schiff base (cf. Table 2).The shift in the half-wave potentials is greater in the presence of chloride than in its absence, indicative of formation of a mixed ligand complex. From the data obtained, the most likely model shows the presence of both CdLCl and $CdLCl_2$ with stability constants, log β_{11} = 7.64 ± 0.06 and log β_{12} = 9.56 ± 0.06, respectively.

A typical species-distribution graph for the ternary system is shown in Fig. 1.

Studies of the effect of hydrogen bonding on the absorption and fluorescence spectra of all-*trans*-retinal at room temperature

S. ALEX, H. LE THANH, AND D. VOCELLE[1]

Département de chimie, Université du Québec à Montréal, C.P. 8888, Succ. A, Montréal (Québec), Canada H3C 3P8

Received June 18, 1991

S. ALEX, H. LE THANH, and D. VOCELLE. Can. J. Chem. **70**, 880 (1992).

Ultraviolet (UV)–visible and fluorescence spectra were obtained for complexes of ATR and TFA at different ratios and in four different solvents: hexane, chloroform, dichloromethane, and methanol. In the first three solvents, a large excess of TFA generates retinylic cations that absorb from 459 to 600 nm. Also, in $CHCl_3$, Raman spectroscopy and fluorescence indicate that some aggregated species like ATR:$(TFA)_n$, with a λ_{max} of ca. 470 nm, are present. In methanol, TFA protonates the solvent and it is $CH_3O^+H_2$ which interacts with ATR so that only blue-shifted H-bonded ATR is present. From these results, it is shown that in the tautomeric equilibrium C=O. . .HOOC-(1) ⇋ C=O$^+$H. . .$^-$O$_2$C-(2), form (1) is always favored in the ground state whatever the solvent. In the excited state in hexane and in methanol, (1) is rapidly transformed into (2). In CH_2Cl_2 and $CHCl_3$, this transformation is absent so that there is no energy dissipation, with the result that the retinal complexes become more unstable.

Key words: all-*trans*-retinal, fluorescence, H-bonds, trifluoroacetic acid, UV–vis spectroscopy.

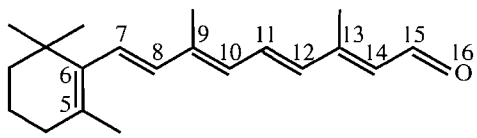
S. ALEX, H. LE THANH et D. VOCELLE. Can. J. Chem. **70**, 880 (1992).

Les spectres UV–visible et de fluorescence ont été obtenus pour des complexes d'ATR et de TFA à des concentrations variées et dans quatre solvants différents : l'hexane, le chloroforme, le dichlorométhane et le méthanol. Dans les trois premiers solvants, un grand excès de TFA génère des cations rétinyliques qui absorbent de 459 à 600 nm. Aussi, dans le $CHCl_3$ la spectroscopie Raman et la fluorescence indiquent que des espèces associées du genre ATR : $(TFA)_n$ sont présentes. Dans le méthanol, TFA protonne le solvant et c'est $CH_3O^+H_2$ qui interagit avec ATR de telle sorte que seulement de l'ATR lié par des liaisons hydrogènes et absorbant dans le bleu, est présent. De ceci, il est démontré que dans l'équilibre tautomérique C=O. . .HOOC-(1) ⇋ C=O$^+$H. . .$^-$O$_2$C-(2), la forme (1) est toujours privilégiée dans l'état fondamental quel que soit le solvant. Dans l'hexane et le méthanol, dans l'état excité, (1) se transforme rapidement en (2). Dans le CH_2Cl_2 et $CHCl_3$, cette dernière transformation est absente ce qui empêche la dissipation de l'énergie absorbée avec pour conséquence de rendre les complexes de rétinal plus instables.

Mots clés : rétinal tout *trans*, fluorescence, liaisons hydrogènes, acide trifluoroacétique, spectroscopie UV–visible.

Introduction

This paper relates to room-temperature absorption and fluorescence spectra of H-bonded all-*trans*-retinal (see formula below), a polyene aldehyde of photochemical interest in the field of vision (1, 2, and refs. cited therein).



It is also important because of the unique properties of the electronic excited states of polyene analogs (1–9), properties that have often been used by nature in pigments (1, 2). For many years, the excited singlet state manifold of retinal has provided a challenging system because it can occupy three low-lying states (viz. $^1B_u^+$, $^1A_g^-$, and $^1n\pi^*$), which are very close in energy (1, 5, 8). Generally speaking, it is admitted now that the strongly allowed $^1B_u^+$–^1A_g and the weaker $^1n\pi^*$ electronic transition required a higher energy than the symmetry forbidden $^1A_g^-$–^1A_g electronic transition (1, 4, 8, 9). However, there are examples to demonstrate that this relative level ordering is dependent on the solvent, the temperature, and the conformation of retinal (3–6), these conferring on this molecule unusual fluorescence properties (10–12).

Hydrogen-bonding interactions between an acid such as trifluoroacetic acid (TFA hereafter) and all-*trans*-retinal (ATR hereafter) can be of different types depending on the polarity of the solvents in which the systems are studied and may lead to a simple hydrogen bond or (and) a hydrogen-bonded ion pair (13–15). In other words, this can be summarized by the following tautomeric equilibrium (eq. [1]) between a hydrogen-bonded and a proton transfer complex, written using a symbolic notation as:

$$\underset{\text{(hydrogen-bonded complex)}}{C{=}O\ldots HOOC} \rightleftharpoons \underset{\text{(hydrogen-bonded ion pair)}}{C{=}OH^+\ldots {}^-OOC} \quad [1]$$

In general, the potential representing the motion of the proton betwen the C=O and the $^-$OOC ends is unsymmetrical and is regulated by two minima (14). The proton populations of these two minima are determined by the acid and base strength of the proton donor and acceptor, the polarity of the medium, and by other factors such as the specific solvation of the species, etc. (14, 15). In addition, these molecules are generally differently H-bonded in the ground and in the excited states and it is believed that the nature of these H-bonds may govern their photochemical behavior.

To determine the exact nature of these H-bonds in the ground and excited states, the absorption and emission spectra of all-*trans*-retinal mixed with increasing amounts of TFA were measured in various solvents. This study was carried out at room temperature rather than at low temperatures in order to provide a model system that can be used to understand the photochemistry of Schiff bases in visual and bacterial pigments. Also, at this temperature, one can take advantage of the fact that all-*trans*-retinal does not fluoresce unless it is strongly hydrogen-bonded (10, 11) or aggregated (16).

Materials and methods

All-*trans*-retinal was purchased from Aldrich Chemical Company (Milwaukee, Wis.) and used without further purification. All solvents were spectrograde (Fisher-Canada, Ont.) and were dried over molecular sieves. The formation of the hydrogen-bonded system was carried out by simply adding the desired amount of trifluoroacetic acid (Aldrich Chemical Company) to the stock solution of all-*trans*-retinal dissolved in the proper solvent. In this work, the simple association of hydrogen with the oxygen of the C=O link in eq. [1] (viz. C=O + HOOC $\leftrightharpoons$ C=O . . .HOOC) was not considered, its association constant K being 5000 M^{-1} in hexane (K has been calculated using the Chignell and Gratzer approach (13)). It is worth noting that this reaction is complete as in similar H-bonded Schiff bases (17). This was one reason to select TFA (pK_a = 0.23 in water) since the association ability abides by a linear relationship to the pK_a of the H-bonder in both states (2, 9). ATR:TFA complexes with a molecular ratio ranging from 1:1 to 1:∞ were made and tested in four solvents, which were hexane (C_6H_{14}, dielectric constant D = 1.89), chloroform ($CHCl_3$, D = 4.81), dichloromethane (CH_2Cl_2, D = 9.08), and methanol (MeOH, D = 32.80). The initial ATR concentration selected was in the range of $2 \times 10^{-5} - 2 \times 10^{-4}$ M for UV measurements and about ten times more dilute for emission measurements. It should be noted that a phase separation occurred between hexane and TFA for large concentrations of the latter, therefore measurements reported here correspond only to the organic phase. No fluorescence is detected in chloroform and dichloromethane if the starting ATR concentration is below ca. 10^{-5} M and in these solvents the complexes form aggregates and (or) carbocations. Time-resolved fluorescence experiments were also done for an ATR:TFA molecular ratio equal to 1:50 and in the same four solvents using a 45° illumination–collection geometry and an average accumulation time of 2 h. Raman spectra of these compounds were collected using a 488 nm excitation wavelength in order to take advantage of the preresonance effect.

The absorption spectra were collected on a Cary 2200 UV–visible spectrometer set at a 2-nm resolution. The fluorescence measurements were acquired on a Perkin–Elmer MPF-44 fluoremeter using a 8 nm bandpass slit. The spectra were not corrected for the spectral response of the detection system. The fluorescence lifetime of retinal complexes was measured using Photochemical Research Associates Inc. International model 3000 fluorescence lifetime, single photon counting equipment (PRA, London, Ont.). The excitation light was generated by nitrogen flash lamp PRA model 510. Fluorescence excitation and emission were detected using appropriate band pass interference filters. Data were analyzed by a PRA statistical deconvolution program. The Raman spectra were recorded on a Spex Triplemate spectrograph coupled to an EG & G Princeton Applied Research detector, model 1422, and samples were excited with 20 mW of the 488.8 nm laser line (Spectra-Physics CW Ar^+ laser, model 2016). The sealed capillary was mounted on a thermally regulated sample holder and maintained at a temperature of 5°C. The spectra were recorded with a 5 cm^{-1} slit width during 15 min. The ATR concentration used for these experiments was ca. 10^{-4} M.

Results and discussion

UV–visible

UV–visible spectra were obtained for complexes of ATR and TFA at different ratios. The spectra of these products were collected in four different solvents and the electronic transition positions are quoted, *vide supra,* in Figs. 1 and 2. Depending on the nature of the solvent, the complexes are differently affected by the hydrogen-bonding agent TFA. Two types of results are noted: (*i*) those obtained in hexane and in methanol where the maximum of the absorption band

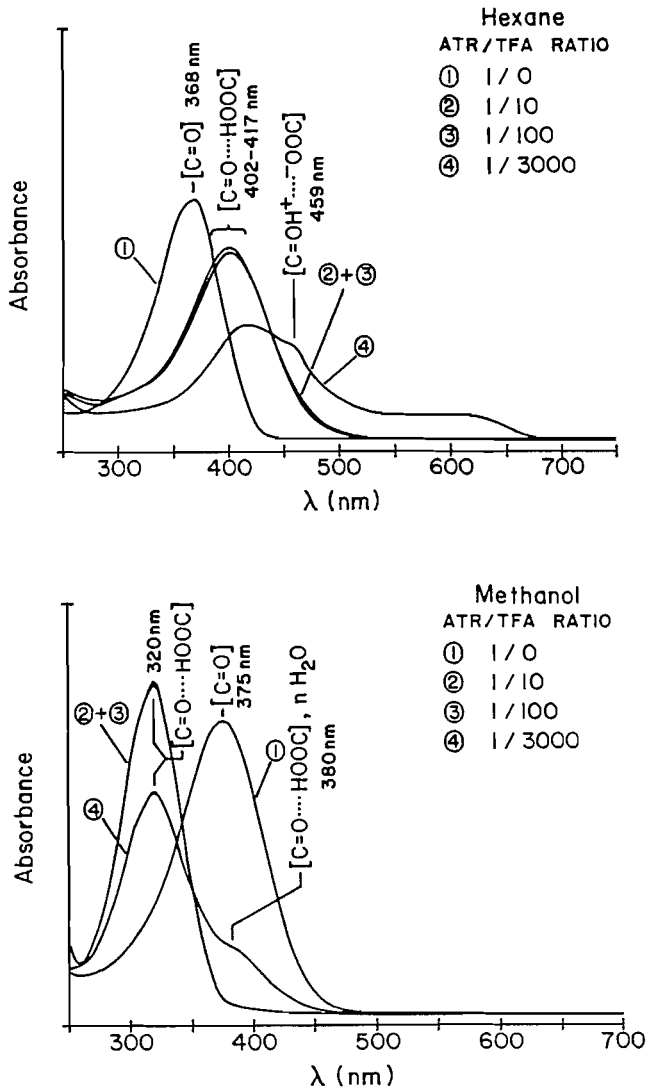

FIG. 1. UV–visible spectra of all-*trans*-retinal (2×10^{-4} M) mixed with various quantities of trifluoroacetic acid in hexane and methanol.

is shifted and the absorbance modified while these two parameters remain almost independent of the TFA quantity over a wide range of concentrations (see Fig. 1); (*ii*) those obtained in dichloromethane and chloroform where the maximum of the absorption band is also shifted and the absorbance modified but these are a direct function of the TFA concentration (Fig. 2).

In hexane and methanol solutions, both the π–π^* and the n–π^* transitions of ATR appear as one band, which is centered at ca. 368 nm in hexane and 375 nm in methanol (see Fig. 1). In hexane solutions, upon addition of TFA in ratios of 1:10–1:100 (Fig. 1), the band is red shifted to 402–417 nm. This band must be due to some H-bonded complexes of ATR and TFA and the shift is explained by a better stabilization of the π^* excited state. When a very large excess of TFA is used (1:3000), Fig. 1 shows that the spectrum is now composed of at least two bands, the first one being ca. 417 nm with an apparent shoulder at 459 nm and the second appearing at ca. 600 nm. The band at 417 nm is attributed to ATR–TFA complexes as previ-

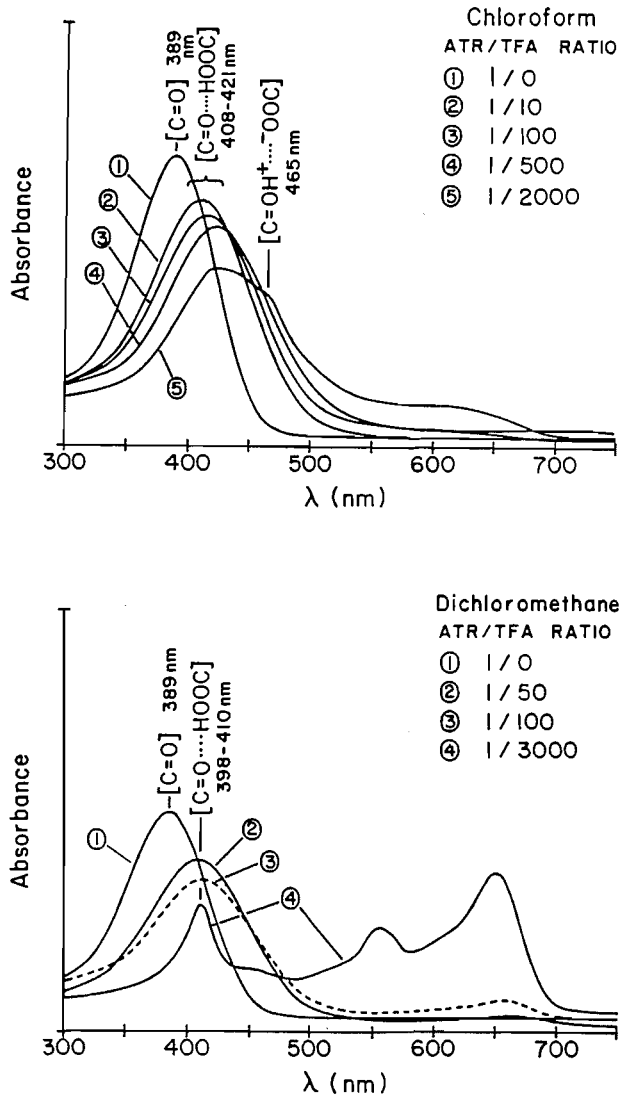

FIG. 2. UV–visible spectra of all-*trans*-retinal (2×10^{-4} M) mixed with various quantities of trifluoroacetic acid in chloroform and dichloromethane.

ously indicated, while the others at ca. 459 and ca. 600 nm must be due to protonated forms of ATR. In the 600-nm region, the spectra obtained here show a close resemblance to those acquired by Blatz *et al.* (18, 19) using retinol and acids. Hence, the spectral features are assigned to cationic forms of retinal since Blatz *et al.* (18, 19) invoked the presence of retinylic cations to explain the bands at ca. 600 nm (viz.: C=C—C=C—$\overset{+}{C}$H$_2$). In the present study, it is possible to obtain two kinds of charged species. First, by simple protonation of the retinal carboxyl function as indicated in eq. [2] and previously in eq. [1], where Ret indicates the polyenic part of retinal:

$$\text{Ret—CHO} + \text{HO}_2\text{CCF}_3 \rightleftharpoons \text{Ret—}\overset{\text{H}}{\underset{|}{\text{C}}}\text{=}\overset{+}{\text{O}}\text{H}\cdots{}^{-}\text{O}_2\text{CCF}_3 \quad [2]$$

$$\text{other resonance forms} \longleftrightarrow \text{Ret—}\overset{\text{H}}{\underset{|}{\overset{|}{\underset{+}{\text{C}}}}}\text{—OH}\cdots{}^{-}\text{O}_2\text{CCF}_3$$

Being in hexane, the counterion must remain close to the retinylic carbocation and thus forms an ion pair that absorbs at ca. 459 nm, as seen with protonated Schiff bases (17).

The second form of protonated retinal could come from a reaction of protonated retinal with a trifluoroacetate anion as shown in eq. [3].

$$\text{Ret—}\overset{\text{H}}{\underset{|}{\text{C}}}\text{=}\overset{+}{\text{O}}\text{H} + {}^{-}\text{O}_2\text{CCF}_3 \rightleftharpoons \left[\text{Ret—}\overset{\text{H}}{\underset{|}{\overset{|}{\text{C}}}}\text{—O}_2\text{CCF}_3 \atop \text{OH}\right]$$

$$\Big\Updownarrow \text{TFA} \qquad [3]$$

$$\text{Ret—}\overset{\text{H}}{\underset{+}{\overset{|}{\text{C}}}}\text{—O}_2\text{CCF}_3 \rightleftharpoons \left[\text{Ret—}\overset{\text{H}}{\underset{|}{\overset{|}{\text{C}}}}\text{—O}_2\text{CCF}_3 \atop \overset{+}{\text{O}}\text{H}_2\right]$$

$$\Big\Updownarrow$$

other resonance forms

This of course follows the same line of reasoning used by Blatz *et al.* (18), who advocated the following reaction (eq. [4]):

$$\text{Ret—CH}_2\text{OH} + \text{HO}_2\text{C-} \rightleftharpoons \text{Ret—}\overset{+}{\text{C}}\text{H}_2\text{OH}_2\cdots{}^{-}\text{O}_2\text{C-} \quad [4]$$

$$\Big\downarrow$$

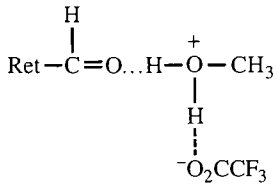
$$\text{Ret—}\overset{+}{\text{C}}\text{H}_2\cdots{}^{-}\text{O}_2\text{C-}$$

Hence, a species like Ret—$\overset{+}{\text{C}}$H—O_2CCF_3 could also absorb at ca. 600 nm since it is structurally close to Ret—CH_2^{+}. . .$^{-}$O$_2$C-. It does not preclude the possibility that the bands at 459 and 600 nm could belong to the same entity. However, if this was indeed the case, the fluorescence results (see below) would be difficult to explain. As indicated in Materials and methods, there is a phase separation occurring at such a high ratio of TFA and the spectrum was taken in the phase containing ATR, TFA, and hexane.

In methanol, with ratios of 1:10 and 1:100, the ATR:TFA systems present a band at 320 nm (Fig. 1) that is blue-shifted relative to the 375-nm band of ATR. This band must represent some H-bonded ATR complexes, but of a different kind since it is blue-shifted. Since the hydroxyl function is a better acceptor than the oxygen of the carbonyl group, methanol must be partly protonated by TFA. This protonated methanol ($\text{CH}_3\text{O}^{+}\text{H}_2$) could then form effective H-bonds with ATR (viz.: Ret—CHO. . .H$_2^{+}$OCH$_3$). Papanikolas *et al.* (9) noted a similar blue-shifted system in using decatetraenal hydrogen-bonded to hexafluoroisopropyl alcohol, and this was explained by a better stabilization of the ground state. The shape of the absorption band (see Fig. 1) partly confirms that, as there might exist a better coincidence between the n–π^* and π–π^* electronic transitions, as a consequence of the well-established blue shift of the n–π^* transition upon H-bonding (20).

In the presence of a very large excess of TFA, Fig. 1 shows that the band at 320 nm is still there but quite reduced in intensity and there is a new band at ca. 380 nm, almost coincidental with the band obtained for retinal alone in methanol.

However, this does not seem to be an equilibrium since no isobestic point is detected in the spectra. This new band probably indicates that the H-bonded retinal is now surrounded by trifluoroacetate ions; this can be illustrated as follows:



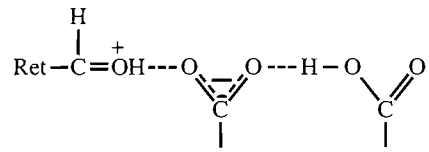
The large excess of TFA must make the presence of its anion around the retinal moiety more likely and, in doing so, it would neutralize the positive charge on the oxonium ion, consequently restoring a kind of "neutral" methanol. That this could indeed be the case is inferred by the following experiment. When different amounts of water are added to the methanolic solutions of ATR and TFA, the spectra are altered and a new band grows at 375–380 nm. This means that $CH_3OH_2^+$ is replaced in part by H_3O^+, which implies that retinal is now mostly solvated by neutral methanol molecules (CH_3OH) that are in very large excess compared to the water molecules.

In chloroform, the spectra presented in Fig. 2 show a marked similarity to those obtained in hexane. Upon addition of TFA, a red shift occurs and the band slowly moves first to 402 nm (ATR:TFA, 1:10), then to 421 nm (1:500). During this red shift the band intensity decreases and broadens, probably indicating that aggregates are formed. In a very large excess of TFA (1:2000), as previously seen in hexane, the spectrum exhibits two bands: one at ca. 410 nm with a shoulder at 465 nm, the other at 600 nm. The bands at 465 and 600 nm are ascribed to the same cations as described for hexane solutions.

These similarities between the results obtained in hexane and chloroform could be an oversimplification of the results in chloroform, which are, in fact, more complex. This stems from the following experiment. It is well known that the carbon–carbon double-bond stretching mode ($\nu_{C=C}$) of retinal can be related to the wavelength of its electronic transition by the following expression (eq. [5]) (21).

$$[5] \quad \lambda_{max} = 7002.22 - 4.20 \times \nu_{C=C}$$

where λ_{max} is the maximum absorption wavelength and $\nu_{C=C}$ the carbon–carbon stretching mode frequency observed in the Raman spectrum. This equation has already been tested by us on similar systems (22). When Raman measurements of $\nu_{C=C}$ were conducted on ATR alone in all four solvents (hexane, methanol, $CHCl_3$, and CH_2Cl_2), the λ_{max} calculated using eq. [5] was the same, within experimental error, as those actually found by means of UV–visible spectroscopy. The same applies for ATR:TFA complexes in hexane and methanol. However, in $CHCl_3$, eq. [5] no longer holds. For instance, for a ATR:50 TFA system, application of eq. [5] gives a λ_{max} of ca. 470 nm, which does not correspond with the actual value of 410 nm found in the UV–visible spectrum. This lack of agreement must be attributed to a difference in the nature of the hydrogen bonds in chloroform. Two explanations can be given. As suggested by a referee, it could arise from modifications of relative energies and ordering in the excited state since the ground state frequency of the C=C stretching vibration is also a function of these electronic states.[2] The second explanation implies the formation of new hydrogen-bonded complexes with a λ_{max} of 470 nm, which is not seen clearly by UV–vis spectroscopy but which resonates fully with the 488-nm laser line and is probably more Franck–Condon active. The structure of the new species could be a trimer such as described below:



With Schiff bases of retinal, this trimer has effectively been seen to exist at room and low temperatures (22–24) and consequently, in these cases, eq. [5] also did not hold. Whichever explanation is right, both demonstrate that the hydrogen bonds in chloroform are different from those in the other solvents.

In dichloromethane, the UV–vis results are similar to those found in chloroform (see Fig. 2) for a low molar ratio of ATR:TFA. When the TFA concentration is large, more than one band appears in the 550–700 nm region, indicating that several cationic complexes are present. Equation [5] remains valid for Raman measurements of a 1 ATR:50 TFA molecular ratio, but at higher TFA concentrations laser-induced fluorescence becomes intense and makes Raman measurements impossible to achieve.

From these results it is possible to elucidate the role played by the intermolecular hydrogen bonds and their influence on the stability of these systems. For instance, it is seen from the absorption measurements that as long as the TFA concentrations are kept moderately low (i.e., 1–100 TFA for 1 ATR), the equilibrium between the molecular associated species and the ionic one in eq. [1] is displaced to the left. When large excesses of TFA are used, some proton transfer is observed in three solvents, C_6H_{14}, $CHCl_3$, and CH_2Cl_2, but not in methanol. The lack of evidence of proton transfer in methanol solutions is ascribed to the fact that, in such a solvent, the proton may retain some association with its environment, meaning that the medium competes quite effectively against ATR. In addition, from Raman data, there are indications that, at least in $CHCl_3$, some aggregations do occur in the ground state. Finally, it appears that the equilibrium of eq. [1] must be governed by a strongly asymmetric double well, where the H-bonded species are in the deeper well while the protonated species, always in the minority, are in the higher well.

Fluorescence

The fluorescence results behave somewhat the same way as those obtained in UV–visible spectroscopy except that it is more practical to present and discuss the results for each solvent.

In hexane

Stationary fluorescence results of ATR–TFA complexes are presented in Fig. 3 and Table 1. They show the excitation and emission spectra for a mixture of one molecular equivalent of ATR to 50 molecular equivalents of TFA. Such

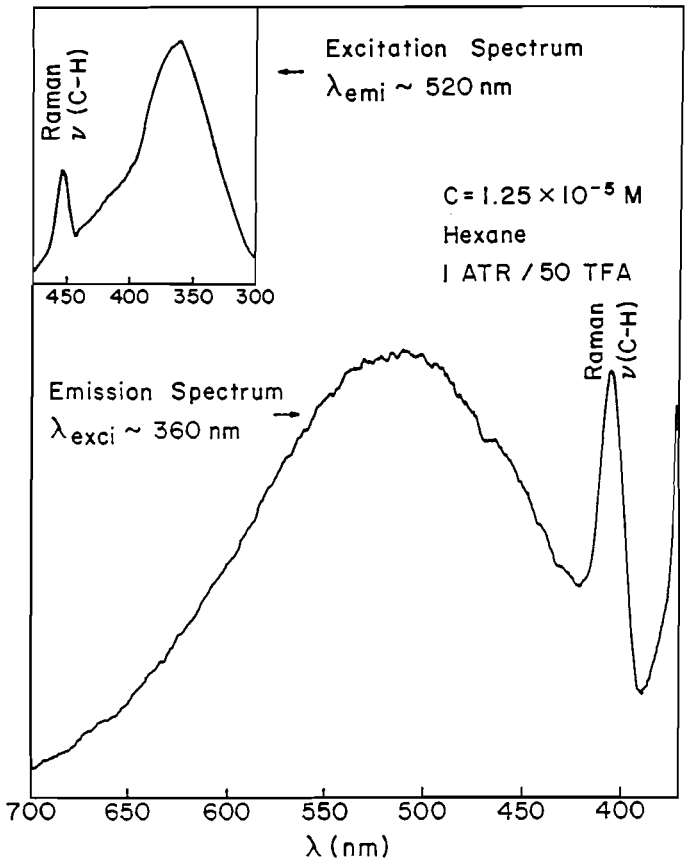

FIG. 3. Emission and excitation spectra of a 1 ATR:50 TFA complex in hexane (concentration 1.25×10^{-5} M).

a ratio has been selected in order to prevent the complexed retinal being significantly dissociated in dilute solutions. The excitation spectrum is displayed in the upper left corner in Fig. 3. The quantum yield at room temperature is about 4.0×10^{-4} (determined by using quinine sulfate as internal standard, assuming a quantum yield of 0.55 (25)), and this is consistent with previously published quantum yields (3, 10, 17). Strong Raman interferences are seen in both spectra and are pointed out, *vide supra*, in Fig. 3. The excitation wavelengths fall at 360–370 nm while the emission is seen at 520–530 nm, leading to an average Stokes shift of ca. 8200 cm^{-1}. The emission bandshape is almost independent of the ATR:TFA molecular ratio provided that this ratio remains below 1:100. For higher ratios, the spectra are characterized by a profile that suggests the presence of unresolved components, which yield a broad band between 500 and 620 nm. These emissions cannot be related to precise excitation wavelengths due to a strong inner filter effect.

For a very large ratio of ATR:TFA (viz. 1:∞), a new fluorescence band is detected at ca. 670 nm, which is associated with a maximum excitation energy of 620 nm (more precisely, the excitation band appears as a continuum with a maximum located at 620 nm) and is assigned to retinylic cations as quoted before in the UV–visible section. Time-resolved experiments were also carried out in hexane for a mixture of ATR:TFA with a ratio of 1:50 and the fluorescence decay curves can be fitted by using a biexponential model that is characterized by two time constants equal to 5.72 and 1.33 nanoseconds (ns). The relative intensities related to the slow and the fast components are 43 and 57% respectively. These results are summarized in Table 1.

Upon isotopic substitution using deuterated TFA, the fluorescence decreases by a factor of 1.7–1.8 and this cannot be explained by a simple difference between the H and D bond strength in the ground state (26, 27). This fact, combined with the large Stokes shift, suggests that the emission may originate from another species generated in the excited state rather than from the radiative relaxation of the excited hydrogen-bonded species.

In methanol

The data obtained in methanol resemble, to a certain point, those recorded in hexane solutions. For an excitation wavelength centered at ca. 320–325 nm, an emission spectrum is obtained for the 1 ATR:50 TFA system with a maximum at ca. 490 nm, affording a Stokes shift of ca. 10 800 cm^{-1}. This is similar to what was observed in hexane and the spectrum shows little dependence on the variations of the concentration of ATR or of TFA or of their respective ratios. Upon a large addition of TFA, fluorescence quenching occurs and no emission is detected even if the excitation wavelength is shifted to 380 nm. It is believed that quenching is due to some water molecules (almost always associated with TFA) present in the solution. That this could be the case is indicated by the following experiment: when water is purposely added to the methanol solution of ATR:TFA, quenching is considerably amplified. As expected, no evidence of the presence of highly emitting retinylic cations was found whatever the experimental conditions chosen. As in hexane, time-resolved experiments were done and the fluorescence decay curves are also biexponential, with two time constants at 3.60 and 0.56 ns associated with relative intensities of 38 and 62% respectively (see Table 1).

In chloroform

In this solvent, the excitation and emission spectra are very sensitive to the concentration of ATR, and a concentration of ca. 2×10^{-5} M was found most useful. Under this condition, for an ATR:TFA ratio of 1:50, the excitation spectrum looks like a continuum with a maximum located at ca. 460–470 nm while the emission spectrum has its maximum at ca. 640–650 nm. No fluorescence is detected following the excitation in the absorption band of the H-bonded complex whatever the concentration chosen. When the concentration of TFA is increased, the spectra become rather complex since there are continua for both the excitation and the emission spectra.

The red-shifted band that absorbs at ca. 470 nm and leads to emission is probably the same one that was already identified by resonance Raman spectroscopy. Nevertheless, the complexity of the excitation emission spectra cannot be explained by invoking the presence of only a single molecular association ATR:TFA but rather by a multitude of forms, which could be polymeric forms such as either ATR:$(TFA)_n$ or $(ATR)_n$:TFA. In these adducts the proton can be located anywhere between the carboxylic and the C=O aldehyde ends. In addition, chloroform may participate in these structures since its hydrogen atom could also form hydrogen bonds. Time-resolved fluorescence measurements carried out on these systems are characterized by a biexponential model having two time constants equal to 3.85 and 0.22 ns, the faster component explaining 94% of the decay curve (Table 1). This leads to quite distinct data, when compared to previous solvents.

In dichloromethane

The results are very similar to those obtained in chloroform: visualize an emission maximum at ca. 640–700 nm with an excitation maximum at ca. 460–470 nm for the same ATR:TFA ratio and concentration. The only difference is that in dichloromethane, fluorescence at 690–700 nm, which was only occasionally seen in chloroform (for high ratios of TFA to ATR), is now almost always present and dominant. The signal at 690–700 nm is optimal for an excitation wavelength centered between 620 and 660 nm. This feature, which dominates the spectrum, is assigned to retinylic cations, is quite intense, and must probably hide the fluorescence coming from other entities. All the results are displayed in Table 1. Also, contrary to the other three solvents, in dichloromethane the ATR:TFA complexes are less stable and more time-sensitive. This generates secondary products of unknown structures, which are unfortunately difficult to identify. This comment can be verified in the following experiment: when ATR is dissolved in neat TFA, at least three different electronic transitions (at 418, 616, and 660 nm) are seen just after TFA addition and, within 1 h, five new and relatively sharp bands grow and replace the previous ones. The new bands are located at 410, 464, 506, 555, and 608 nm and the spectrum possesses a large number of excitation/emission pairs. This must result from the high proportion of retinylic cations formed in chlorinated solvents, compared to hexane where it was minimal and to methanol where it was completely absent. Fluorescence decays are modelized with two time constants: 4.24 and 0.31 ns, the faster component being the dominant part of the decay curve as seen previously in chloroform (see Table 1).

Therefore, depending on the solvents, two fluorescence regimes describe the behavior of these complexes. From these results and theoretical considerations, the data can be understood as follows: recent experiments carried out on similar systems (9) unambiguously demonstrated that the fluorescence detected in a long polyene aldehyde has a $^1B_u^+$ character. This implies that the two low-lying $^1A_g^-$ and $^1n\pi^*$ states need to be inverted with respect to the $^1B_u^+$ state and protonation could be the simplest way to achieve this requirement. Protonation will convert the n orbital to a bonding orbital and, therefore, the n–π^* transition is blue-shifted in vacuum (1). Also, protonation is known to stabilize the "*ionic*" $^1B_u^+$ energy level (1, 4, 9, 28), and, concomitantly, it can destabilize the "*covalent*" $^1A_g^-$ state, thus providing the changes necessary for state inversion in going from the free (or H-bonded) to the protonated adduct (1, 4, 9, 28). It should be noted that the simple association of the aldehyde with hydrogen does not induce a state inversion even if the resulting $^1B_u^+$–$^1n\pi^*$ and $^1B_u^+$–$^1A_g^-$ energy gaps are somehow narrowed. Since no protonated complexes are observed in the ground state, fluorescence in hexane and methanol has to originate from the protonated form induced after an H-transfer in the excited state. A reverted potential in this state is conceivable, as ATR molecules are known to be more basic in the excited state (29) and therefore should favor the right-hand side of eq. [1].

Incidentally, the excited state lifetimes for complexed or protonated ATR are in the nanosecond range and therefore sufficiently long to allow proton transfer since this reaction occurs on a shorter time scale (26, 27). In that sense, these two arguments support evidence for a reverted potential in the excited state. Furthermore, the influence of isotopic substitution and the quenching phenomenon corroborate this hypothesis. This is also consistent with the large Stokes shift observed in these systems. However, care should be taken because large Stokes shifts are not a priori sufficient proof to support this hypothesis according to previous work done

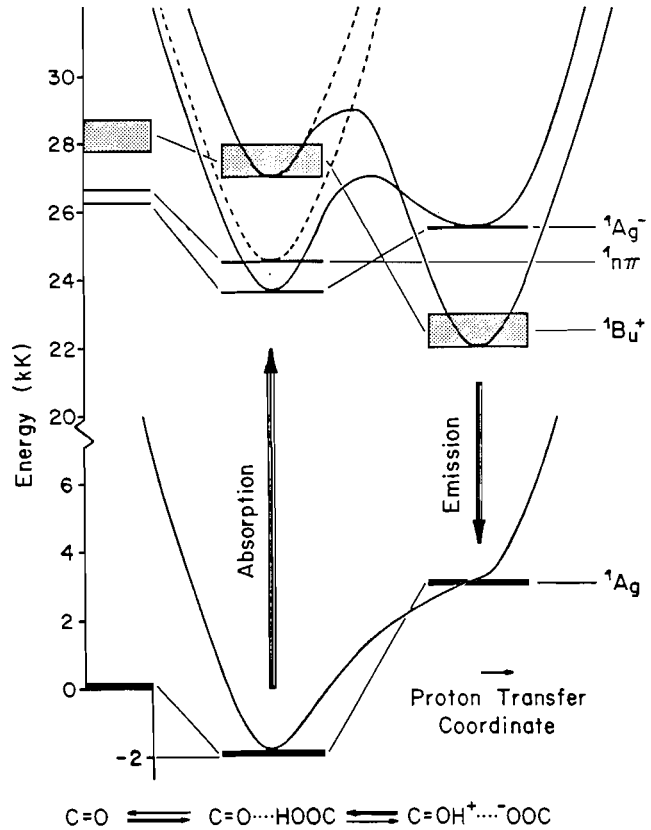

FIG. 4. Potential energy curves as a function of the proton position for the ground and the lowest excited states of H-bonded all-*trans*-retinal.

in this field on retinal or its analogs (3, 5, 12, 17), and the observed lifetimes may only derive from a solvent relaxation effect.

A *qualitative* energy diagram giving an illustration of the level ordering for the H-bonded and protonated ATR:TFA complexes is shown in Fig. 4. The values used in the graph are adapted from refs. 1, 4, 9, and 28 and completed by experimental data collected in this work. The potential energy surface curves are hypothetical, as are also some stabilization and destabilization energies for the ground and the excited states.

In chloroform, no proton transfer is detected, either because it is not favored in both states or simply because the emission from the protonated species is self-absorbed by the absorption band of the red-shifted species seen at ca. 470 nm, or else fluorescence is quenched due to extensive ground state complexation. So far, the so-called red-shifted species has not been identified, but the formation of a complex like $ATR(TFA)_2$ is strongly suspected since this structure is rather common with these types of compounds (22–24, 30, 31) and by the tendency of organic acids to self-associate in organic solvents (32). Coordination using a polymeric acid as a proton source should generate a more "acidic" proton (22, 30, 31), which then could form a protonated or a more tightly H-bonded system, both of them being able to fluoresce. This hypothesis is supported by the fact that when the TFA concentration is gradually increased, the excitation spectrum becomes broader and broader, meaning that successive equilibria may be present in the medium, such as:

[6] $ATR(TFA)_n \leftrightharpoons ATR(TFA)_{n+1} \leftrightharpoons ATR(TFA)_{n+2}$ with $n > 2$

This concept is not new as Blatz *et al.* (30) and Baasov *et al.* (31) came to the same conclusions in other studies. Emission deriving after excitation of the main electronic transition shows that the medium is complex. This applies for chloroform and also for dichloromethane, except that in the latter case the situation deteriorates rapidly due to the irreversible conversion of ATR into carbocations.

Therefore the only question left unanswered is why these complexes are so sensitive to solvent properties. In a first approximation, this has nothing to do with their respective polarity and another reason has to be found. In alkane solvents, it is seen that an H-transfer in the excited state takes place, and this is understandable as it is generally admitted that this case resembles the kinetics of unsolvated molecules, which are well known to induce ultrafast H-atom translocations (see ref. 26 and refs. therein) because the barrier to H-transfer is zero. In methanol, the 10 000 cm^{-1} Stokes shift is also explained by a proton transfer occurring in the excited state, from the associated species ([Ret—CHO. . .HOOC]*) to the protonated species ([Ret—CHO^+-H. . .^-O_2C-]*). Then fluorescence occurs from the excited protonated form into the protonated form in the ground state, which immediately reverts to the most stable associated species (see Fig. 4). However, this holds as long as the TFA concentration is not too large and in the absence of water, since then a large decrease of H-transfer is found due to H-intermolecular competition between all molecules present.

In chloroform and dichloromethane, TFA is present in polymeric form and they therefore generate a certain number of ATR H-complexes, depending on the concentration of the H-donor and the solvent. The H-complexes show more instability towards illumination and are easily converted into red-shifted species. The formation of carbocations is easier in these solvents since the absence of proton transfer in the excited state reduces its rate of relaxation and, in consequence, produces an energy buildup making these complexes more susceptible to photochemical transformations (26, 27).

Conclusion

H-bonded ATR complexes have unique optical properties and are stable when a proton transfer reaction occurs in the excited state. This may answer questions about the mechanism of vision, as it involves wavelength regulation in photointermediates for visual and bacterial pigments. But it mainly demonstrates that the H-bond strength is a critical parameter defining the stability of H-bonded retinal, and this cannot be predicted by simply looking at the solvent polarity but rather by measuring the solvent ability to favor an even distribution of the acceptor–donor molecules in the medium.

Received April 2, 1991

SULIMAN N. BASAHEL and EL-HUSSIENY M. DIEFALLAH. Can. J. Chem. **70**, 888 (1992).

DTA–TG techniques were applied to study the thermal decomposition and reactivity in intimately mixed powders of barium or strontium carbonate and titanium dioxide. The results showed that the temperature for the thermal decomposition of $BaCO_3$–TiO_2 mixtures precedes the decomposition of pure $BaCO_3$ by about 250°C, whereas the decomposition of $SrCO_3$–TiO_2 mixtures precedes the decomposition of pure $SrCO_3$ by about 60°C. Kinetic analysis of the isothermal data in view of various solid-state reaction models showed that the reaction is best described by the phase boundary models. The effects of ^{60}Co γ irradiation and of doping the metal oxide with Li^+ or Cu^{2+} ions on the thermal decomposition reactions were investigated.

Key words: titanates, thermal decomposition, doping, irradiation effects.

SULIMAN N. BASAHEL et EL-HUSSIENY M. DIEFALLAH. Can. J. Chem. **70**, 888 (1992).

On a appliqué les techniques de l'ATD–TG à l'étude de la décomposition thermique et de la réactivité de poudres intimement mélangées de carbonates de baryum ou de strontium et de dioxyde de titane. Les résultats montrent que la température de décomposition thermique de mélanges de $BaCO_3$–TiO_2 précède celle de la décomposition du $BaCO_3$ pur par environ 250°C; par ailleurs, la décomposition de mélanges de $SrCO_3$–TiO_2 ne précède la décomposition du $SrCO_3$ pur que par 60°C. Une analyse cinétique des données isothermiques en relation avec les divers modèles de réactions à l'état solide montrent que les meilleurs modèles pour décrire la réaction sont les phases limites. On a aussi examiné les effets d'irradiation par des rayons γ du ^{60}Co et du dopage de l'oxyde métallique par des ions Li^+ ou Cu^{2+} sur les réactions de décompositions thermiques.

Mots clés : titanates, décomposition thermique, dopage, effets d'irradiation.

[Traduit par la rédaction]

Introduction

Processes involving the chemical transformations of solids play an increasingly important role in modern technology, as sophisticated and costly solids can be produced by reaction of other, precursory solids (1). Solid state reactions between metal carbonates and metal oxides are carried out to obtain more important solids and to gain understanding of some of the factors influencing these reactions (1–7). The processes of forming titanates in crystalline mixtures have become very important in the ceramic industry and other technologies (2, 3). The thermoanalytical behaviour of $CaSO_4$ – metal oxide and $CaCO_3$ – metal oxide systems was discussed by Ishii *et al.* (4). The formation of $CaTiO_3$ in the $CaSO_4$–TiO_2 system was shown to proceed in two steps (5). The role of CO_2 removal in the $BaCO_3$–TiO_2 system was described by Dell (6) and the effects of dispersion and mixing conditions of reactant particles on reactivity in this system was studied by Yamaguchi *et al.* (7).

The chemical and catalytic reactivity of a solid depends on its method of preparation, so that structural and electronic imperfections may have important effects on the behaviour of a solid state reaction. Irradiation of a solid might alter the kinetics of a reaction and help to clarify the reaction mechanism (1, 8). Doping with metal ions or other pretreatment of samples may have important effects on the reactivity of solids (1).

In the present study, the reactivity in $BaCO_3$–TiO_2 and $SrCO_3$–TiO_2 systems, which are potentially suitable for conversion to $BaTiO_3$ and $SrTiO_3$, were investigated. The kinetics of the thermal decomposition of $BaCO_3$–TiO_2 and $SrCO_3$–TiO_2 reactions were studied and compared with the kinetic equations that give the best fit to the experimental data to find out whether the reaction is phase boundary or transport controlled. The effects of increasing γ radiation dose and of doping the metal oxide with Li^+ or Cu^{2+} ions, on the kinetics and the activation parameters of the solid state reactions, were investigated.

Experimental

Analar barium carbonate (BDH Chemicals Ltd.), C.P. grade strontium carbonate (Fluka AG), and titanium dioxide (Hering–Kahlbaum AG) were used in this study. Mixtures of metal carbonate – TiO_2 (each with particle size less than 125 μm) were prepared by thoroughly mixing the powders in a 1:1 molar ratio by first tumbling the dry powders together for 3 h and then grinding them with a mortar and pestle. The mixtures were dried in a thermostated oven at 120°C for few hours.

DTA–TG behaviour of the $BaCO_3$–TiO_2 and $SrCO_3$–TiO_2 systems was investigated using a Shimadzu model 30 thermal analyzer. The kinetics of the isothermal decomposition and formation of titanate were studied in the temperature range 820–950°C under 1 atm (101.3 kPa) pressure in air flow (50 mL/min). The X-ray diffraction patterns for samples calcined at selected temperatures were performed using a Philips instrument model 1700, with nickel-filtered Cu Kα radiation.

Samples were irradiated using ^{60}Co-Gammacell and were exposed to successively increasing doses at a dose rate of 1.01 ± 0.05 kGy h^{-1}.

Doping of TiO_2 with Li^+ or Cu^{2+} ions was carried out using the impregnation technique at dopant metal ion concentrations of 0.5

Results and discussion

Figures 1 and 2 show the DTA–TG curves obtained for the $BaCO_3$ and $BaCO_3$–TiO_2 (anatase) system, respectively. At room temperature, barium carbonate belongs to the orthorhombic system and high-temperature X-ray analysis (9) has shown that at 805°C it undergoes transformation to the hexagonal form and, at 976°C, it transforms to the cubic form. The DTA curve of $BaCO_3$ (Fig. 1) shows, in addition to the two endothermic peaks corresponding to these two phase transitions, a third highly endothermic and broad peak at 1100–1200°C due to the decomposition of $BaCO_3$. In the $BaCO_3$–anatase system (Fig. 2) the DTA curve shows two endothermic peaks, the first at 805°C due to the first phase transition of $BaCO_3$ and a second, relatively more broad endothermic peak, at about 900°C, which results from the overlap of the second phase transition in $BaCO_3$ and the endothermic peak due to the decomposition of $BaCO_3$ and the formation of $BaTiO_3$. The titanate formation reaction starts at a temperature that is about 250°C below that required to start the decomposition of pure $BaCO_3$.

At room temperature $SrCO_3$ belongs to the orthorhombic system and it undergoes transformation to the hexagonal system at 912°C. Figure 3 shows the DTA–TG curves for pure $SrCO_3$. The DTA curve shows, in addition to the peak at 912°C due to phase transition, a peak at 1030°C due to decomposition of $SrCO_3$. The DTA–TG curves obtained for the $SrCO_3$–anatase system (Fig. 4) showed that the phase transition peak remains at 912°C, but the decomposition peak is shifted to lower temperatures due to the formation of strontium titanate.

The remarkable decrease in the decomposition temperature of the metal carbonate – metal oxide mixtures could be attributed to the formation of the single phase product. It is also evident that the TG traces of the intimately mixed powders do not reveal intermediate curve breaks either at the fast or at the slow heating rates. X-ray diffraction patterns for $BaCO_3$–TiO_2 and $SrCO_3$–TiO_2 mixtures (in 1:1 molar ratio) calcined at 950°C for 15 min showed the formation of $BaTiO_3$ and $SrTiO_3$, respectively. Yamaguchi *et al.* (7) pointed out that the particle size ratio of $BaCO_3$ to TiO_2 in the reaction mixture is closely related to the formation of intermediate phases. It was suggested that the reaction between $BaCO_3$ and coarse TiO_2 to form $BaTiO_3$ proceeds in three steps with the formation of Ba_2TiO_4 during the reaction, whereas in equimolar mixtures of $BaCO_3$ – fine TiO_2, the reaction leads directly to $BaTiO_3$.

Reaction isotherms were obtained by isothermal gravimetry in air and the degree of reaction was calculated from the weight loss of the mixtures. Figures 5 and 6 show typical fractional reaction (α) vs. time (t) curves obtained for the isothermal decomposition of a 1:1 molar ratio of crystalline powdered mixtures of $BaCO_3$–TiO_2 and $SrCO_3$–TiO_2, with the formation of barium titanate and strontium titanate, respectively. It is evident that the α/t curves are not sigmoidal and that the formation reactions do not follow the exponential growth model.

The fractional reaction – time curves obtained under var-

System	log *A* (min^{-1})	*E* (kJ mol^{-1})
$BaCO_3$–TiO_2	7.9 ± 0.7	196 ± 14
$SrCO_3$–TiO_2	8.7 ± 0.2	221 ± 5

TABLE 2. Effect of γ irradiation on the activation parameters of the isothermal reaction in the barium carbonate – anatase system

Radiation dose (MGy)	log *A* (min^{-1})	*E* (kJ mol^{-1})
Non-irradiated	7.9 ± 0.7	196 ± 14
0.60	9.2 ± 1	226 ± 20
1.17	8.6 ± 0.6	212 ± 14
1.64	8.2 ± 1	201 ± 25
2.26	7.3 ± 0.8	183 ± 18

ious conditions were analyzed by linear regression (LR) analysis according to the different heterogeneous solid state reaction models (10–14). The results of the kinetic data analysis showed that the phase boundary models and the first-order kinetics give the best fit. The reactivities of the $CaSO_4$–TiO_2 and $BaSO_4$–TiO_2 systems (5) examined by isothermal TG studies were found to fit Jander's diffusion equation. However, analysis of the results obtained under the present experimental conditions in $BaCO_3$–TiO_2 and $SrCO_3$–TiO_2 systems have shown that the diffusion functions give a much less satisfactory fit to the experimental data. Rate constants calculated for the solid state reaction between $BaCO_3$ and ZnO according to the diffusion models showed a pronounced drift with time, indicating that these models are invalid for analyzing the reaction (10). The results obtained here show that the phase boundary models give the best representation of the reaction.

TABLE 3. Effect of doping on the activation parameters of the isothermal reaction in the barium carbonate – anatase system

% M-doped TiO_2	log *A* (min^{-1})	*E* (kJ mol^{-1})
Non-doped TiO_2	7.9 ± 0.7	196 ± 14
0.5% Li-doped	7.8 ± 0.6	194 ± 14
5.0% Li-doped	8.0 ± 0.9	197 ± 21
0.5% Cu-doped	7.0 ± 0.6	174 ± 13
5.0% Cu-doped	11.1 ± 1.4	264 ± 32

The activation energies of solid state reactions could vary between relatively large limits depending on the nature and the method of preparing the starting materials (15, 16). Table 1 shows the activation energies and frequency factors ob-

For personal use only.

tained for the solid state reactions in MCO_3–TiO_2 calculated according to the Arrhenius equation by LR analysis using rate constants calculated on the basis of the phase boundary contracting area model. The results show that the titanate formation reaction has higher activation energy and frequency factor with $SrCO_3$ than with $BaCO_3$. The radius of Ba^{2+} (1.35 Å) is higher than that of Sr^{2+} (1.13 Å) and, based on Coulombic attractions, the Sr^{2+} ions will have a stronger oxygen-to-carbon bond than the Ba^{2+} ions. This should increase the energy needed to liberate CO_2 and thus increase the activation energy for the reaction. It was reported that in the $BaCO_3$–TiO_2 system the activation energy could change between 200 and 280 kJ/mol depending on particle size and method of mixing (7).

The results of the kinetic data analysis of the thermal decomposition of irradiated mixtures of $BaCO_3$–TiO_2 showed that radiation did not introduce a change in the reaction model and mechanism. The effects of radiation dose on the activation energy and the frequency factor of the reactions are shown in Table 2. Although the changes in the activation parameters are within experimental errors, there is a regular decrease in both the activation energy and the frequency factor of the reaction with increasing radiation dose. However, the values in the non-irradiated mixtures are lower than those obtained for mixtures having low radiation doses, which may be due to the effects of small dose radiation annealing. Since radiation introduces defects into the solid and at crystal surfaces (8), and these defects may act as important sites for reaction nucleation and initiation of decomposition, this could result in a lowering of activation energy at the higher doses where internal radiolytic reactions and the generation of defects and their catalytic effects compete with radiation annealing.

The results for thermal decomposition and titanate formation reaction of doping the anatase with Li^+ or Cu^{2+} ions showed that doping did not change the model for the reaction interface. Table 3 summarizes the results of the effects of doping on the activation parameters calculated by LR analysis. Doping with Li^+ seems not to have a significant effect on the activation parameters of the reaction, whereas doping with Cu^{2+} causes a lowering in the activation parameters at low concentration and an increase at the higher concentration. At low concentration Cu^{2+} facilitates electron transfer reactions in the solid and the release of CO_2. At the higher dopant concentration, copper titanate could form in high enough yield and this may lead to an increase in the activation parameters. The results here showed that Cu^{2+} dopant effects are not additive but are interactive for the system studied, and that more detailed investigation of the effects of copper is required to confirm the kinetic consequences of the presence of the additive.

LESLIE W. TARI and ANTHONY S. SECCO. Can. J. Chem. **70**, 894 (1992).

Pyranosyl nucleosides are among the most recent modifications of natural nucleosides to receive attention as potential HIV inhibitors. As part of our studies involving modified nucleosides, the crystal structure of 1-(2′,3′-dideoxy-β-D-*erythro*-hex-2′-enopyranosyl)thymine was determined and its molecular structure and conformation compared with AZT in an effort to assess the title compound's potential activity against HIV. The compound crystallizes in the monoclinic space group $P2_1$ with cell dimensions a = 7.966(3), b = 18.004(3), c = 8.346(3) Å, β = 91.29(3)°. The crystal structure, solved by direct methods and refined to R = 0.032 and wR = 0.041 for 1285 observed data, contains two independent molecules in the asymmetric unit, each displaying different torsion angles, χ (64.5(6)° and 72.7(6)°) and γ (62.0(7)° and 178.6(5)°). Molecular conformations, described as slightly distorted chairs with O5′ *endo* and C5′ *exo* and with equatorial substituents, are stabilized by a network of hydrogen bonds throughout the crystal. Despite the substantial difference in χ values with respect to AZT in the solid state, molecules appear to exhibit sufficient structural overlap with AZT to expect a similar capacity for binding to the active site of phosphorylation; the barrier to rotation about the *N*-glycosidic bond is only slightly greater for the title compound. The significant difference, on comparison with AZT, appears at the primary hydroxyl, which is so oriented as to probably preclude activity of this pyranosyl compound as an anti-HIV agent. The conformational parameters given are in accordance with the IUPAC–IUC Joint Commmission on Biochemical Nomenclature (Pure Appl Chem. **55**, 1273 (1983)).

Key words: crystal structure, modified nucleoside, pyranosyl nucleoside, anti-HIV drugs.

LESLIE W. TARI et ANTHONY S. SECCO. Can. J. Chem. **70**, 894 (1992).

Les nucléosides de pyranosyle font partie des plus récentes modifications des nucléosides naturels à recevoir de l'attention comme inhibiteurs potentiels du HIV. Dans le cadre de nos études impliquant des nucléosides modifiés et dans le but d'évaluer l'activité potentielle du composé mentionné dans le titre contre l'HIV, on a déterminé la structure cristalline de la 1-(2′,3′-didésoxy-β-D-*erythro*-hex-2′-énopyranosyl)thymine et on a comparé sa structure moléculaire ainsi que sa conformation avec celles de l'AZT. Le composé cristallise dans le groupe d'espace monoclinique, groupe d'espace $P2_1$, avec a = 7,966(3), b = 18,004(3) et c = 8,346(3) Å et β = 91,29(3)°. On a résolu la structure par des méthodes directes et on l'a affinée jusqu'à des valeurs de R = 0,032 et R_w = 0,041 pour 1285 réflexions observées; elle contient deux molécules indépendantes par unité asymétrique et chacune présente des angles de torsion χ (64,5(6) et 72,7°) et γ (62,0(7) et 178,6(5)°) différents. Les conformations moléculaires, que l'on peut décrire comme des chaises légèrement déformées avec l'O5′ *endo*, le C5′ *exo* et les substituants équatoriaux, sont stabilisées par un réseau de liaisons hydrogènes dans tout le cristal. Malgré des différences substantielles, par rapport à l'AZT, dans les valeurs de χ à l'état solide, les molécules semblent présenter des recouvrements structuraux suffisants avec l'AZT pour s'attendre à une capacité similaire à se lier au site actif de phosphorylation; la barrière à la rotation autour de la liaison *N*-glycosidique n'est que légèrement supérieure pour le composé mentionné dans le titre. Lorsqu'on le compare à l'AZT, la seule différence importante se rapporte à l'hydroxyle primaire qui est orienté d'une façon telle qu'une activité de ce composé pyranosyle comme agent anti-HIV est peu probable. Les paramètres conformationnels sont conformes aux recommendations de la commission conjointe de l'UICPA et de l'UIC relativement à la nomenclature biochimique (Pure Appl. Chem. **55**, 1273 (1983)).

Mots clés : structure cristalline, nucléoside modifié, nucléoside de pyranosyle, médicaments anti-HIV.

[Traduit par la rédaction]

Introduction

As part of our ongoing studies of modified nucleosides, we have synthesized the title compound. The compound was first synthesized by Yamazaki, Matsudo, Sugiyama, Seto, and Yamaoka (1) to demonstrate a new method of preparing 2′,3′-unsaturated pyranosyl nucleosides. Several hexeno- and hexano-pyranosyl nucleosides, like their pento-furanosyl analogs, have long been known to exhibit significant biological activity. Only in the past year have the pyranosyl compounds been investigated as potential anti-Human Immunodeficiency Virus (HIV) drugs (2). Presently, the most effective acquired immunodeficiency syndrome (AIDS) chemotherapy involves 3′-azido-3′deoxythymidine (AZT), the structural characteristics of which have been well documented (3–5) and their relationship to its activity been inferred (4–6). However, the adverse side effects of AZT have necessitated the search for drugs with an equal or greater efficacy but lower toxicity. The difficulty in designing nucleosides as therapeutic agents for AIDS patients is the lack of detailed structural knowledge of the active sites of (*i*) the cellular kinases responsible for phosphorylation and of (*ii*) the viral reverse transcriptase that incorporates the resulting nucleotide into the growing DNA strand. Using AZT as the best available model, we may be able to effectively screen the pyranosyl compounds for anti-HIV activity by comparing the structural parameters of these strategically modified nucleosides with those of AZT. In this context, we have undertaken the present crystallographic study in an attempt to investigate the conformational features of the title compound for

comparison with those of AZT, as a predictive tool for its activity.

Crystal data

$C_{12}H_{14}O_5N_2$ fw = 254.24

Monoclinic, a = 7.966(3), b = 18.004(3), c = 8.346(3) Å, β = 91.29(3)°, V = 1196.6(6) Å^3, Z = 4, D_x = 1.411, Mg m^{-3}, μ = 9.13 cm^{-1}, $F(000)$ = 536(298 K; CuKα,λ = 1.54178 Å), space group $P2_1$ (from absent reflections condition and structure analysis).

Experimental

The title compound was synthesized by condensation of the pertrimethylsilylated thymine with the 3,4,6-tri-*O*-acetyl-D-glucal according to the method reported by Kondo, Nakai, and Goto (7) for uracil. Crystals were obtained by slow evaporation of a methanol/ethyl acetate solution of the compound. Data were collected using a colorless crystal of dimensions 0.30 × 0.25 × 0.40 nm on a Rigaku AFC6S diffractometer equipped with an evacuated beam collimator and detector tunnel. Graphite monochromated CuKα radiation was employed with the intensities measured 400 mm from the crystal. Measured data to 2θ = 106° included reflections h (0–8), k (0–18), l (−8–8). Scans were of the ω–2θ type, where the ω scan speed was 32° min^{-1}. The scan width in ω was (1.57 + 0.30 tan θ)° and weak reflections were rescanned up to four times and the counts accumulated. Of the 1582 reflections measured, 1460 were considered unique; for averaged data R_{int} = 0.035; 1285 reflections (88%) were classified as observed, having $F^2 \geq 3\sigma(F^2)$. Three standard reflections monitored throughout data collection showed less than 1% change in their intensities over the period of the experiment, indicating no decay correction was required. Lorentz–polarization corrections were applied and an empirical absorption correction was included in the data processing step (transmission factors, 0.875–1.000, based on ψ-scans of three reflections).

The structure was solved by direct methods.[2] The phase set with the highest combined figure of merit yielded an E-map showing the complete heavy-atom framework of two independent molecules in the asymmetric unit. The non-H atoms were refined to conver-

gence and subsequent difference Fourier maps revealed 21 of the hydrogens. Full-matrix least-squares refinement continued to convergence with all non-H atoms assigned anisotropic thermal parameters, and available H's assigned isotropic temperature factors. At this stage, a difference map indicated positions for four of the six methyl H's, but attempts to refine them were unsuccessful. However, these positions were used in orienting all six methyl hydrogens in ideal positions. The H of O44′A was difficult to locate. Difference maps showed two very small peaks, both in chemically reasonable positions to be the hydrogen of O44′A. When each peak position was refined individually as the hydrogen, the refinement tended to shift the hydrogen toward the other peak coordinates. This difficulty in refining the H position, in combination with the development of a large temperature factor associated with the atom, suggested the possibility that the hydrogen was disordered. Therefore, the H6A occupancy was assigned 0.5 at each of the two observed peak positions on the difference map and refined along with all other atoms. Their coordinates and isotropic temperature factors were allowed to vary in subsequent refinement cycles. No attempt to determine the occupancies of the disordered hydrogen was made. From this point, convergence of the entire structure was reached within three cycles and yielded $R = 0.0322$ and $wR = 0.0413$ for 1285 observed data where $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $wR = \Sigma w||F_o| - |F_c||^2/\Sigma w|F_o|^2$. The maximum parameter shift was 0.16σ on the final cycle of refinement and the standard deviation in an observation of unit weight was 1.831 for 417 variables. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2/\sigma^2(F_o^2)$; a weighting analysis confirmed the suitability of the chosen weights by showing uniform average values of $\Sigma w(|F_o| - |F_c|)^2$ over ranges of index classes, F_o, and sin θ/λ. Following convergence, the peaks on the difference Fourier map had densities corresponding to ± 0.16 e Å^{-3} randomly scattered throughout the cell. When the complete data set was used $R = 0.0387$ and $wR = 0.0486$. The enantiomer refined was chosen on the basis of the chirality of the starting sugar (*vide supra*). Scattering factors and anomalous dispersion corrections for non-hydrogen atoms were from ref. 11, and from ref. 12 for the scattering factors of hydrogen. Final atomic positional parameters and equivalent isotropic thermal parameters are given in Table 1.[3] Molecules in the asymmetric unit are displayed in Fig. 1 along with the atom labels.

Results and discussion

Molecular geometry

Bond lengths and bond angles are given in Table 2. The two independent molecules in the asymmetric unit possess similar molecular dimensions, with bond lengths and angles that are within the normal range (13). The two molecules differ, most notably, in their *N*-glycosidic torsion angles (23) (χ, O5′—C1′—N1—C6), which are 64.5(6)° (+*sc*) in **I** and 72.7(6)° (+*sc*) in **II**, as well as in the values of their torsion angles (γ) C4′—C5′—C55′—O55′, which are 62.07(7)° (+*sc*) in **I**, and 178.6(5)° (+*ap*) in **II**. The value of γ adopted by **I** represents a more sterically hindered (close O55′A···C4′A contact), thus less energetically favorable, conformation than the value found in **II**, the attainment of which may be ascribed to the fact that the O55′A hydrogen, H1A, is involved in an intermolecular hydrogen bond (Table 3). The γ torsion angle in **II** is stabilized by an intramolecular hydrogen bond between H1B and O5′B (Table 3).

The O5′—C1′ bond differs in length from the O5′—C5′ bond in **I**, with the O5′—C5′ bond length being shorter by 0.04(1) Å. An analogous trend is observed in other pyranosyl nucleosides, e.g., amicetin (14), cytosamine triacetate (15), and 1-(2′,3′-dideoxy-β-D-*erythro*-hexopyranosyl)thymine (16). However, the same is not true in **II**, where the O5′—C1′ and O5′—C5′ bond lengths are not significantly different (at $p > 0.05$). The C1′—N1 glycosyl bond distances for **I** and **II** are identical within experimental error, with values of 1.468(8) and 1.470(7) Å, respectively.

The dimensions of the thymine moiety in **I** and **II** are in good agreement with those of 1-methyl thymine (17), thymidine (18), and 1-(2-hydroxyethyl)thymine (19). The thymine rings in both **I** and **II** are essentially planar, with average deviations of ±0.005 Å and ±0.013 Å from their respective mean planes through N1, C2, N3, C4, C5, and C6.

Puckering parameters (20) for the pyrenose rings were found to be $\varphi = 80.2°$, $\theta = 129.1°$, $Q = 0.485$ Å in **I** and $\varphi = 88.6°$, $\theta = 130.9°$, $Q = 0.494$ Å in **II**. These parameters are structurally manifested in both molecules as slightly distorted half-chair conformations (distorted toward twist boats), with O5′ *endo* and C5′ *exo*. The three substituents on the pyrenose rings adopt the less sterically hindered equatorial positions.

Molecules of the title compound form an extensive network of intermolecular hydrogen bonds (Table 3). A packing diagram is given in Fig. 2, in which the disordered hydrogen bonded to O44′A is shown at only one position, viz. H6A′. It is interesting to note (although not shown in Fig. 2) that in both positions H6A and H6A′ the disordered hydrogen is involved in hydrogen bonding interactions (Table 3). The ability to bond in both environments provides an explanation for the observed disorder in H6A. Despite the apparent overlap of the thymine rings in the asymmetric unit, their interplanar spacing of 3.65 Å and their 9.8° dihedral angle indicate that π–π stacking interactions do not have a significant influence on the crystal packing.

Biological implications

Currently, AZT has the highest therapeutic index of the nucleoside analogs that are known to inhibit the replication of HIV-I in vivo. AZT has a well-defined mode of action. It becomes activated, like natural nucleosides, through phosphorylation by cellular kinases, and is subsequently combined with the HIV's reverse transcriptase, resulting in either blockage of the active site as a competitive inhibitor of natural nucleotides, or incorporation into viral DNA leading to premature chain termination. The structural features of AZT, implicated as crucial in recognition by phosphorylating enzymes, are twofold. Firstly, the relative position of the electron-rich terminus of the azido group with respect to the thymine moiety is deemed important (4, 5) from the perspective of hydrogen bonding and potential electrostatic interactions within the active site. Secondly, it is important that the rotation of the base about the *N*-glycosyl bond be energetically feasible, so that the potential for hydrogen bonding interactions between the base and the cognate enzyme can be fully realized, while maintaining the integrity

of the interaction between the terminal azido nitrogen and the enzyme (5).

It may be suggested that any active analog of AZT must display similar structural features. The structure of the title compound, in both forms **I** and **II**, has been compared to the structure of the purported active conformer of AZT (4, 5), as illustrated in Fig. 3. The relative position of the O44′ hydroxyl (the azido counterpart) and the thymine moiety in the title compound is described by the intramolecular distances listed in Table 4; analogous distances in AZT are included in the table for comparison. Considering the results in Table 4, and the fact that the *inter*atomic distances (Fig. 3) from the terminal azido nitrogen to O44′ in the title structure are only 1.30(1) Å (**I**) and 1.16 (1) Å (**II**), it appears that the title compound exhibits enough structural similarity with AZT to possess a similar capacity for binding within the active site of enzymatic phosphorylation. Although a spatial correspondence between the title compound and AZT exists, the *N*-glycosidic torsion angle χ differs by approximately 70° and 79° when comparing AZT with **I** and **II**, respectively. To ascertain the importance of the differences in χ, the energy required to rotate the base 360° around the *N*-glycosyl bond was calculated at 10° intervals (for both the title compound and AZT), and found to be less than 1 kcal/mol higher for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

the title compound than for AZT.[4] Furthermore, the energy/χ-angle profile is virtually identical in both systems. As this small difference in rotational energy would indicate, the relative values in the crystal of the *N*-glycosidic torsion angle, χ, in AZT and the title structure are not important features in this comparison.

The completion of the enzymatic phosphorylation process requires that at least the following two conditions be met. Firstly, recognition of and binding to the active site must occur. Secondly, it is critical that, once bound, the nucleoside analog presents the oxygen atom to be phosphorylated to the appropriate enzymatic site with positional specificity. Phosphorylation will not likely occur in any nucleoside analog that has its phosphorylation site oriented significantly differently from that in AZT. Figure 3 clearly shows that the sites of phosphorylation in AZT (O5′) and in the title compound (O55′) are oriented quite differently in the superimposed structures. These oxygens, i.e., O5′ and O55′, can only be brought into proximity with each other by having the pyrenose ring undergo the unlikely ring-flip to an alternative conformation with O5′A (or B) *exo* and C5′A (or B) *endo*, which would result in severe steric clashes between the thymine and the C6′ hydrogens. The distances between O5′ in AZT and O55′ in the title structure are 2.336(9) Å **I** and 4.02 (1) Å **II** in the respective comparisons.

On the basis of the above structural comparisons with AZT, the inference is that the title compound would not effectively inhibit the HIV virus. As corroborating evidence for this conclusion, it is interesting to note that, while this work was in progress, the study cited as ref. 2 appeared in the literature indicating that the title compound possesses little activity against the HIV-1 virus in vitro.

Structural study in the oligomethylene dithiobenzoate series, *n*DBS, where *n*, the number of methylene groups, is odd

CLAUDE LEBLANC AND FRANÇOIS BRISSE[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Que.), Canada H3C 3J7

Received December 21, 1989[2]

CLAUDE LEBLANC and FRANÇOIS BRISSE. Can. J. Chem. **70**, 900 (1992).

Model compounds of the poly(oligomethylene thioterephthalates) have been synthesized and characterized by X-ray diffraction analyses. The pink *n*-methylenedithiobenzoates, obtained for $n = 3, 5, 7$, and 9, all have a low melting point of about 320–330 K. They all crystallize in the monoclinic system, space group $P2_1/c$. The *a* and *b* unit cell dimensions vary little while the *c* dimension increases monotonically as *n* changes from 3 to 9. The crystal structure of the four compounds were established from low-temperature X-ray intensities. Except for the lengthening of the methylenic sequence, the four molecules studied here are isostructural. One of the thiobenzoate groups of the molecules is coplanar with all the methylenic carbons, while the other thiobenzoate group is at 90° from the above plane of atoms. The methylenic sequence has the same conformation. It may be described by $g^+(t)_n$, where *n* is the number of methylene groups. Thus, the four compounds belong to a crystallographically homologous series. The molecules form centrosymmetric "dimers," which, in turn, are herring-bone packed in their respective unit cells. In each "dimer" two aromatic rings are across from one another while being mutually perpendicular. On the basis of the above results, one proposes three potentially acceptable structures for the parent poly(oligomethylene thioterephthalates).

Key words: dithiobenzoate, methylene sequence, crystal structure, poly(oligomethylene thioterephthalate).

CLAUDE LEBLANC et FRANÇOIS BRISSE. Can. J. Chem. **70**, 900 (1992).

On a synthétisé des composés modèles des poly(thiotéréphtalates d'oligométhylène) et on les a caractérisés par diffraction des rayons X. Les points de fusion des dithiobenzoates de *n*-méthylène, $n = 3, 5, 7$ et 9, sont tous relativement bas (320–330 K). Ils cristallisent tous dans le système monoclinique, groupe d'espace $P1/c$. Les dimensions *a* et *b* de la maille varient très peu, mais la valeur de *c* augmente d'une façon monotone alors que *n* passe de 3 à 9. On a déterminé les structures cristallines des quatre composés à partir d'intensités mesurées à basse température. À l'exception de l'allongement de la séquence méthylénique, les quatre molécules étudiées sont isostructurales. L'un des groupes thiobenzoates des molécules est coplanaire avec les carbones méthyléniques, alors que l'autre groupe thiobenzoate fait un angle de 90° avec le plan mentionné plus haut. La conformation de la séquence méthylénique est la même dans toutes les molécules. Elle peut être décrite par $g^+(t)_n$, où *n* est le nombre de groupes méthyléniques. D'un point de vue cristallographique, les quatre composés appartiennent donc tous à une série homologue. Les molécules forment des «dimères» centrosymétriques qui s'entassent en chevron dans leurs mailles respectives. Dans chaque «dimère» deux noyaux aromatiques se trouvent placés face à face, tout en étant perpendiculaires l'un à l'autre. Sur la base de ces résultats, on propose trois structures potentiellement acceptables pour les poly(thiotéréphtalates d'oligométhylène) parents.

Mots clés : dithiobenzoate, séquence méthylénique, structure cristalline, poly(thiotéréphtalate d'oligométhylène).

[Traduit par la rédaction]

Introduction

To establish what the geometrical and conformational characteristics of a linear polymer are, we analyzed the constancies and the variations of the bond distances and the bond and torsion angles of small molecules that are chemically and, presumably, structurally related to the parent polymer. This was done by X-ray diffraction from single crystals. We chose this approach since polymer single crystals, suitable for an X-ray structural determination, cannot usually be obtained. However, X-rays interact with a partially crystalline, or ordered, polymer to produce a fiber diffraction pattern containing a limited amount of information. Thus, the structural data derived from the model compounds is very useful in the interpretation of the fiber pattern.

The structures of the poly(*n*-methylene terephthalates) or *n*GT's were investigated in this laboratory for $n = 2$–6 through the use of their model compounds, the oligomethylene dibenzoates and their di-*para*-substituted analogs: 3 GT(1), 4 GT(2), 6 GT(3, 4).

However, very little has been reported so far on the synthesis or the structure of dicarboxylic dithiol polyesters (5). We have undertaken a systematic study of such polymers where the diacid is terephthalic acid. The present work deals with model compounds of the poly(*n*-methylene thioterephthalates), the sulfur relatives of the above-mentioned *n*GT's. The model compounds chosen to represent the poly(*n*-methylene thioterephthalates) are the *n*-methylene dithiobenzoates (or *n*DBS). It is the synthesis and the analysis of the properties of the odd members of this series (3 DBS, 5 DBS, 7 DBS, and 9 DBS) which are reported here.

Experimental

The *n*-methylene dithiobenzoates are prepared in a two-step process. First, potassium thiobenzoate is obtained by reacting thiobenzoic acid and KOH at 0°C in the presence of MeOH. In the second step, the potassium salt is made to react with the dibromoalkane of interest, in the presence of MeOH, and refluxed for 6 h at 65°C.

$$2C_6H_5COS^- K^+ + Br(CH_2)_nBr \rightarrow C_6H_5COS(CH_2)_nSCOC_6H_5 + 2KBr$$

At the end of the reaction the product precipitates. It is filtered and purified by recrystallization in MeOH. All the compounds

prepared in this manner are pink and are obtained in high yields (80–90%).

Crystals, in the form of thin platelets suitable for X-ray analysis, were obtained by slow evaporation of their respective methanolic solutions. The unit-cell dimensions were obtained with the Enraf–Nonius CAD4 diffractometer by least-squares analysis of the diffractometer setting angles of 25 well-centered reflections in the range $30° < 2\theta < 44°$ for 3 DBS, 5 DBS, and 7 DBS, and $40° < 2\theta < 45°$ for 9 DBS. The low temperature required for the X-ray data collection of all four compounds was maintained using a modified Nonius cooling system. The temperature achieved was stable to ±4°. The crystal data of interest are given in Table 1. The intensity data were recorded using the $\omega/2\theta$ scan technique with a scan range calculated by $\Delta\omega = (1.00 + 0.35 \tan \theta)°$ and the graphite monochromatized Mo radiation, $\lambda(\text{MoK}\bar{\alpha}) = 0.71069$ Å. For 9 DBS, the X-ray intensities were obtained with the graphite monochromatized copper radiation, $(\text{CuK}\bar{\alpha}) = 1.54178$ Å, while the scan range was calculated by $\Delta\omega = (0.80 + 0.14 \tan \theta)°$. The intensities of seven reference reflections were monitored every hour and showed no significant decay of the crystals. The orientation of the crystals was verified every 100 measurements. The intensity data were reduced to a common scale using standard procedures.[3] Lorentz and polarization corrections, as well as an absorption correction based on the geometrical description of the crystal, were applied in all cases.

The structures were solved by direct methods. All the non-hydrogen atoms were found on E-maps calculated with the set of phases having the highest combined figure of merit. The structures were refined at first by a full-matrix least-squares procedure minimizing $\Sigma w(|F_o| - |F_c|)^2$. The weights applied were derived from the counting statistics of the measured intensities. After all H atoms were localized, the final refinements proceeded in the block-diagonal approximation, with anisotropic temperature factors for the non-hydrogen atoms and isotropic for H atoms. The refinements all converged satisfactorily. The details of the data collection and least-squares refinements are summarized in Table 2. The scattering curves for the non-hydrogen atoms were taken from ref. 9 and those for H atoms from ref. 10. The anomalous scattering contributions of the S atoms were included in the structure factor calculations (11). The atomic coordinates are listed in Tables 3 (*a*)–(*d*) while the structure factor tables have been deposited as part of the Supplementary Material.[4]

Results and discussion

All the *n*DBS compounds remain pink even after four recrystallizations. Their melting points are low and in a relatively narrow range of temperatures, 320–330 K. The melting points do not seem to be correlated with either the methylene chain length or its parity, as these values are also in the neighbourhood of those found when the number of methylene groups is even.[5] The unit-cell dimensions (a, b, c, β, V) vary regularly with n, the number of methylene groups (see Table 1 and Fig. 1). The two dimensions a and b change only slightly while c, the product $c \sin \beta$, and the unit-cell volume, V, increase significantly as n changes from 3 to 9. These linear variations have been parametrized, as follows, as a function of n:

$$a(\text{Å}) = 6.280 \times 10^{-2}\, n + 8.840 \quad (\sigma = 0.032)$$

$$b(\text{Å}) = -4.440 \times 10^{-2}\, n + 6.001 \quad (\sigma = 0.008)$$

$$c(\text{Å}) = 1.6377\, n + 25.550 \quad (\sigma = 0.286)$$

$$c \sin \beta\ (\text{Å}) = 1.8517\, n + 23.738 \quad (\sigma = 0.111)$$

$$V\ (\text{Å}^3) = 95.710\, n + 1267.4 \quad (\sigma = 2.67)$$

As will be seen later, such a regular evolution of the unit-cell parameters is an indication that the molecules are very sim-

ilar in conformation and in crystal packing. A similar pattern was reported (12) in the *N,N′*-oligomethylene bisbenzamide series when, however, the number of methylene groups is even.

Structural results

The atomic numbering of the *n*DBS molecules is reported in Fig. 2 while drawings of the molecules are shown in Fig. 3. It is apparent that the molecules in the series have the same conformation. The main feature of these molecules, which are chemically symmetrical, is their lack of symmetry in the solid state. An examination of Fig. 3 reveals that the two thiobenzoate groups of a given molecule have totally different orientations with respect to the methylenic sequence. To establish this quantitatively, the bond distances, bond angles, and torsion angles are compared in Tables 4 and 5. In each aromatic ring, the average value of the intracyclic bond angles is 120°. However, the usual narrowing of the bond angle at C(1), due to the conjugation between the thioester group and the aromatic ring, is observed (13). Indeed, the average value of the C(6)—C(1)—C(2) angles is 118.9°, while the individual values are in the range of 118.3(3)°–119.6(3)°. Concurrently the C(1)—C(7) bond distance is slightly shorter; its average is 1.493 Å. The average C(sp^2)—C(sp^2) distance is 1.383(3) Å in 3 DBS, 1.380(5) Å in 5 DBS, 1.385(4) Å in 7 DBS, and 1.386(8) Å in 9 DBS,

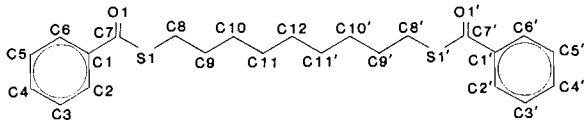

FIG. 2. Atomic numbering adopted for the *n*DBS molecules.

in good agreement with the compilation found in *Molecular structures and dimensions* (14). The thioester groups are planar. However, the bond angles show the same deviation from 120° as was reported for the ester groups. The C(1)—C(7)—O, O—C(7)—S, C(1)—C(7)—S bond angles have average values of 122.5(4), 121.5(3), and 115.9(3)° respectively. The C(sp^2)—S and C(sp^3)—S distances, with averages of 1.769(4) and 1.808(5) Å, agree well with their respective published values of 1.76 and 1.80 Å (14). The two S—C(8)—C(9) bond angles behave unusually since they systematically take significantly different values depending upon which end of the molecule is considered (Table 5). At the unprimed end, the S—C(8)—C(9) angles average 114.9(3)°, while at the primed end of the molecules the average is 111.4(3)°. In the methylenic sequence itself, the C—C bond distances vary over a large interval, from 1.499(5) to 1.530(4) Å, and average 1.515 Å. The C—C—C bond angles behave in a similar way: average 112.7°, range 109.8(3)°–114.9(3)°. It should be pointed out that the first and the last angles in the sequence, C(8)—C(9)—C(10), are always smaller than any of the others and show little variation. Their range is only from 109.8(3)° to 111.7(3)°. In other words, it seems that the central part of the chain is a bit more flexible or deformable than its ends, which are attached to S atoms. The torsion angles within the aliphatic sequence are all *trans*. However, the unusual behavior noted for the θ = S—C(8)—C(9) angles is also reflected in the τ = C(7)—S—C(8)—C(9) torsion angles. The primed values are in the range 173.8°–179.8°, while the unprimed ones range from 89.6° to 91.8°. Thus, at the unprimed end of the molecule, a "pseudo" *gauche* torsion angle corresponds to a large θ = S—C(8)—C(9) bond angle, while at the primed end a *trans* conformation is associated with a smaller value of θ. This observation may be rationalized when one compares the schematic representation and the Newman projections, along the C(8)—S bond, of the two ends of the molecules (Fig. 4). At the primed end of the molecule, the carbonyl group is *gauche* to two hydrogen atoms and the C(8′)—C(9′) bond is in the ester plane, τ′ = C(7′)—S′—C(8′)—C(9′) ~ 180°, and thus does not interact with the p_z orbital on the sulphur atom. However, at the other end (the unprimed end) of the molecule, the carbonyl is "pseudo" *gauche* to the first bond of the aliphatic segment, and also "pseudo" *gauche* to one hydrogen atom. It can be seen that in this case the C(8)—C(9) bond is in the plane containing the large p_z orbital of sulphur (τ =

1/1'	82.5		78.3		72.8		70.6	

[a]A: unprimed atoms; B: primed atoms.

C(7)—S—C(8)—C(9) ~ 90°). As a consequence there is a strong interaction, which results in an enlargement of the θ = S—C(8)—C(9) bond angle. Experimentally we observe that for τ ~ 90° the angle θ is 110°–111° while for τ' ~ 180°, θ' is 114°–115°.

The conformation of the C(7)-S-C(8)...C(8')-S'-C(7') sequence of atoms is the same for all the odd *n*DBS compounds. It may be described as g^+ttt for 3 DBS, g^+tttt for 5 DBS, and so on, or abbreviated as $g^+(t)_n$, (*g* = *gauche*, $g^+ \approx +60°$, *t* = *trans* ≈ 180°).

As a first approximation the molecules can be seen (Fig. 3) as made up of two nearly planar groups of atoms. The first group is the unprimed thiobenzoate; the second group includes the primed thiobenzoate group, all of the methylenic C atoms, and S. This is clearly appreciated when one compares the primed and unprimed values of the τ = C(7)—S—C(8)—C(9) torsion angles (Table 5). At the unprimed end, this angle is close to 90° while at the primed end its value is nearly 180°, a difference of about 90°. Energetically these two conformations must be very similar. Since there is no chemical reason for this behavior, it is attributed to packing effects. On closer inspection, the previous planes of atoms may be subdivided again since the aromatic rings (plane **1**, made up of C(1) → C(6)) and the thioester groups (plane **2**, C(1), C(7), O, S) are not exactly coplanar although each is individually planar. The dihedral angle, ε, between planes **1** and **2** is small and varies between 2° and 6° and is of the same order of magnitude as that reported in benzoates (15). The methylenic C atoms, between the primed and unprimed thiobenzoates, are nearly coplanar (plane **3**). The dihedral angles between all these planes are given in Table 6 for all odd *n*DBS.

Packing of the molecules

Stereopairs are shown in Fig. 5 (*a*)–(*d*). In all *n*DBS molecules, two centrosymmetrically related molecules adopt a head-to-tail type of disposition (Fig. 6). These "nonbonded dimers" form a layer parallel to the *ab* plane in which the individual molecules are at about 45° from *ab*. In the next layer, observed at *c*/2, the molecules are at −45° from *ab*. Thus when seen in the *bc* projection, the molecules form a herring-bone pattern. This type of packing is reminiscent of that adopted by the *N*,*N*'-oligomethylene dibenzamides with an even number of methylene groups. However, in the latter case, each molecule was H-bonded to two neighboring ones (12). Since the *n*DBS molecules with *n* odd have comparable unit cell dimensions, belong to the same space group, have the same conformation and the same mode of packing,

they constitute a crystallographically homologous series. Surprisingly there is no such relationship among the *n*DBS molecules with *n* even (see footnote 5).

Extension to the parent polythioester

A reasonably sound structure for the parent polymers, the poly(oligomethylene thioterephthalates), may be proposed using the information derived from the present study of their model compounds. The relation between the polythioester and its model compound is shown in Fig. 7. The fiber repeat, p_o, which is the distance measured along the chain axis between two consecutive crystallographically equivalent units, may be experimentally accessible from measurements of an X-ray fiber pattern of the oriented polymer. Thus, if a polymer and its model compound have the same conformation, the polymer's fiber repeat is also the distance between the centers of the aromatic rings in the model compound. It is expected that the reverse is also true. Many crystal structures of non-chiral synthetic polymers belong to centrosymmetric space groups and, quite often, the polymer chain itself is crystallographically centrosymmetric (3, 16). Assuming that this situation applies here and that the number of methylene groups is odd, the only centers of symmetry will be found in the middle of each terephthaloyl group. However, if the aliphatic segment possesses an even number of methylenes, a further center of symmetry will be found at the mid-point of the central CH_2—CH_2 bond. Consequently, the polymer's fiber repeat is the distance between the centers of two consecutive aromatic rings for an even number of methylenes in the model compounds. It is twice that distance when there is an odd number of methylenes (Fig. 7).

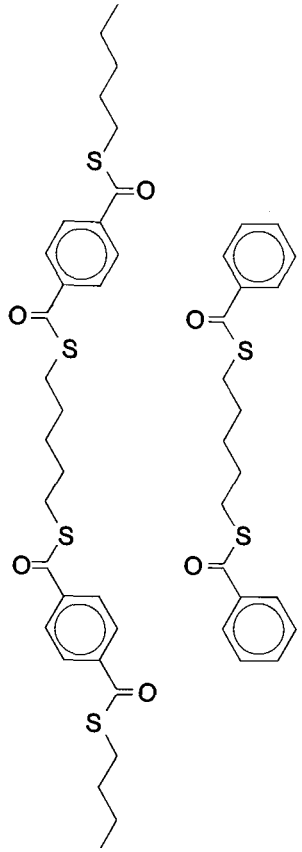

FIG. 7. Relation between a polymer, poly(pentamethylene thioterephthalate), and its model compound, pentamethylene dithiobenzoate.

TABLE 7. Values of the fiber repeat, p_0 (Å), calculated for the three possible conformations of the poly(oligomethylene thioterephthalates)

	n			
	3	5	7	9
Case I[a]	25.08	30.82	34.83	40.50
Case II	26.90	31.96	37.24	42.24
Case III	25.99	31.39	36.03	41.37

[a]See text and Fig. 8.

Since in the *n*DBS molecules two conformations are equally represented ($\tau \approx 90°$ and $\tau \approx 180°$), it is reasonable to expect that the parent polymer will adopt one or the other or even a combination of the two. For an ordered polymer, i.e., a crystalline one, only a few combinations need to be considered. These are schematically described in Fig. 8. Apart from the bond distances and angles, three types of torsion angles are required to describe the conformation of the poly(oligomethylene thioterephthalates). The torsion angles to be specified are ε, τ, and ϕ_i's. In the model compounds the angle ε is always small and stays in the range of 2°–6°, while τ may be either 90° or 180° and the ϕ_i's are all 180°. The fiber repeat may be evaluated according to the schemes shown in Fig. 8. Assuming that the methylenic sequence remains in the fully extended conformation three cases are possible:

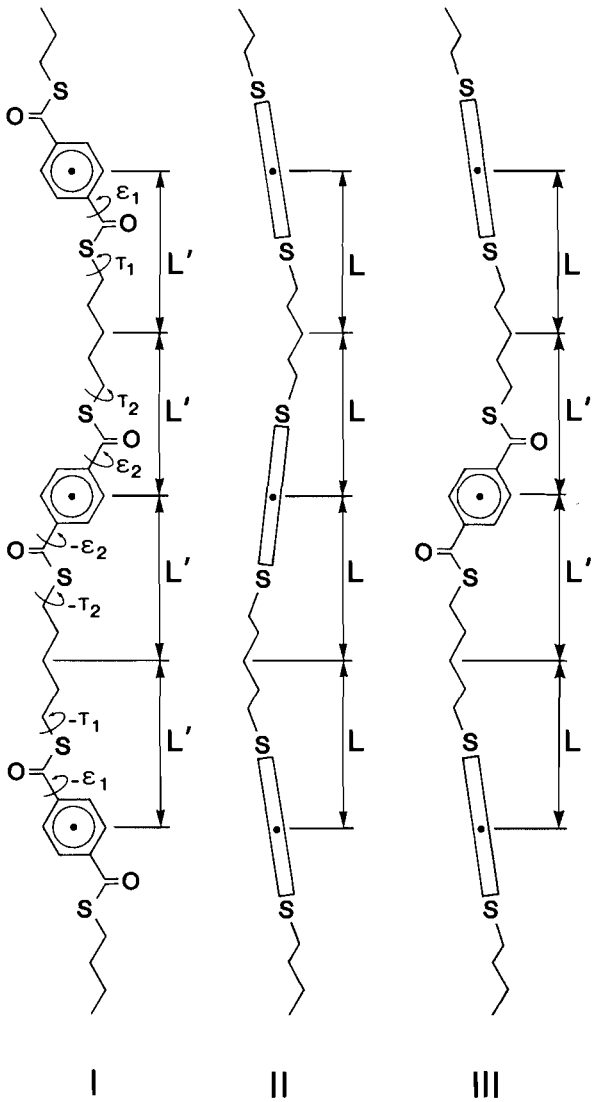

FIG. 8. Three possible conformations of poly(pentamethylene thioterephthalate). The τ torsion angle may take the values of ~90° or ~180° while all the ε and ϕ_i torsion angles are kept equal to 0° and 180° respectively. Thus the terephthaloyl groups are shown either in the plane of the page or perpendicular to it (long rectangles), while the S-$(CH_2)_5$-S sequence is only in the plane of the page. The black dots indicate the centers of symmetry.

Case I. All τ's are 180°. This corresponds to the all-*trans* conformation, then the fiber repeat, $p = 4L'$.

Case II. All the τ's are 90°. Because of the centers of symmetry $\tau_1 = \tau_2 = 90°$ and $\tau_1' = \tau_2' = -90°$, then $p = 4L$.

Case III. Here $\tau_1 = -\tau_1' = 90°$ while $\tau_2 = \tau_2' = 180°$. The fiber repeat is $p = 2L + 2L'$.

The quantities L and L' are the distances from the central atom to the center of the unprimed and primed aromatic rings corresponding to $\tau = 90°$ and $\tau' = 180°$ respectively. The fiber repeats calculated for each situation are given in Table 7.

Received June 21, 1991

N. T. KAWAI, D. F. R. GILSON, J. F. BRITTEN, I. S. BUTLER, and P. G. FARRELL. Can. J. Chem. **70**, 910 (1992).

The crystal structure of 1,4-dibromocubane has been determined by X-ray diffraction. The crystal is monoclinic, $P2_1/n$, a = 6.878(1), b = 6.960(7), c = 8.793(2) Å, β = 113.08(2)°, Z = 2, R = 0.055. The C—Br bond length, at 1.926 Å, is shorter than usual and the carbon framework is probably distorted by longer bonds along the edges. The direct dipole coupling constants between protons, obtained from the partially oriented NMR spectrum, show that a distortion of the proton positions from the ideal cube occurs in the bromo compound but not in diiodocubane, presumably because of the higher strain energy in the former.

Key words: halocubanes, crystal structures, NMR spectroscopy, molecular modelling calculations.

N. T. KAWAI, D. F. R. GILSON, J. F. BRITTEN, I. S. BUTLER et P. G. FARRELL. Can. J. Chem. **70**, 910 (1992).

On a déterminé la structure cristalline du 1,4-dibromocubane par diffraction des rayons X. Les cristaux sont monocliniques, groupe d'espace $P2_1/n$, avec a = 6,878(1), b = 6,960(7) et c = 8,793(2) Å, β = 113,08(2)°, Z = 2 et R = 0,055. La longueur de la liaison C—Br, à 1,926 Å, est plus courte que d'habitude et la structure carbonée fondamentale est probablement déformée par des liaisons plus longues à la périphérie. Les constantes de couplage dipolaires directes entre les protons, obtenues à partir de spectres RMN partiellement orientés, montrent que, dans le composé bromé, il existe une déformation de la position des protons par rapport à un cube idéal; cette situation n'existe pas dans le diiodocubane, probablement à cause de l'énergie de tension plus élevée dans le premier.

Mots clés : halocubanes, structures cristallines, spectroscopie RMN, calculs par modélisation moléculaire.

[Traduit par la rédaction]

Introduction

The possibility of distortions of the cubic framework of substituted cubanes was first examined by Tracey (1), who studied the proton magnetic resonance spectra of the mono- and 1,4-dicarboxylic acid derivatives oriented in lyotropic liquid crystal solutions. The protons vicinal to the carboxylic acid groups were displaced in the direction of the substituent such that the HCCH dihedral angle is non-zero, suggesting that the cage structure was elongated along the symmetry axis. The crystal structures of several derivatives of cubane (pentacyclo[4.2.0^{2,5}.0^{3,8}.0^{4,7}]octane) have now been reported (2–6). The differences in carbon–carbon bond lengths in these compounds has become a topic of considerable interest, in particular, the changes in the exocyclic bond lengths. The crystal structure of cubane-1,4-dicarboxylic acid showed that these bonds were shorter than normal, when compared with analogous bonds in bicyclooctane and adamantane carboxylic acid derivatives (4). The cage–cage bond lengths found for cubylcubane and 2-*tert*-butylcubylcubane, 1.458 and 1.474 Å, respectively, are significantly shorter, by 0.114 Å, than the average value of C—C bonds derived from the Cambridge Crystallographic Database for connected carbon atoms each bonded to three other carbons (5). In related, but much earlier, studies, a comparison of the bond lengths of carbon–halogen compounds (7, 8) showed that there is a significant shortening of the carbon–halogen bond length in the adamantyl halides compared with *tert*-butyl analogues.

In the present study we report the results of a crystal structure investigation of 1,4-dibromocubane, and of the hydrogen atom positions derived from the analysis of the dipole–dipole coupling constants of the proton magnetic resonance spectra of the dibromo and diiodo compounds, oriented in a nematic liquid crystal solvent. A crystallographic study of 1,4-diiodocubane was discontinued when the structure of this compound was reported (6). The results obtained, however, were in agreement with the published study.

Experimental

Preparation

Pentacyclo[4.2.0.0^{2,5}.0^{3,8}.0^{4,7}]octane-1,4-dicarboxylic acid (0.9 g) and mercuric oxide (2.6 g) were stirred together in refluxing dibromomethane (50 mL). A solution of bromine (2.0 g) in dibromomethane (25 mL) was added dropwise over 30 min and the mixture refluxed overnight. After cooling and filtering, the solvent was removed to leave a solid material, which was extracted several times with hot hexanes. Evaporation yielded the crude dibromocubane, which was purified by recrystallization from hexanes followed by sublimation, mp 196–198°C (0.90 g, 72%). For the diiodo derivative, the dicarboxylic acid (0.9 g), (diacetoxyiodo)benzene (3.3 g), and iodine (2.5 g) were stirred together in refluxing carbon tetrachloride (150 mL) under irradiation from a 200-W tungsten lamp for 8 h. A second addition of the same amounts of (diacetoxyiodo)benzene and iodine was then made and the reaction continued for a further 24 h. After cooling, the reaction mixture was thoroughly washed with sodium thiosulphate solution, dried, and the solvent removed to leave a solid that was purified as described above for the dibromo derivative, mp 225°C (dec.) (0.75 g, 42%).

X-ray crystallography

Diffraction data on a single crystal of dibromocubane, approximately 0.2 mm in all directions, were collected at room temperature on an Enraf–Nonius CAD4 diffractometer with Mo-Kα radiation ($K\alpha_1$ = 0.70930, $K\alpha_2$ = 0.71359) using θ/2θ scans. Unit cell parameters were refined with 24 reflections (2θ = 40–50°). Crystal data are

TABLE 1. Atomic coordinates and equivalent isotropic temperature factors (B_{iso} in Å^3) for dibromocubane

Atom	x	y	z	B_{iso}
Br	0.2758(2)	0.3117(2)	0.1522(2)	4.52(9)
C1	0.411(2)	0.126(2)	0.063(1)	2.7(6)
C2	0.518(2)	0.180(2)	−0.054(2)	3.4(7)
C3	0.292(2)	−0.046(2)	−0.050(1)	3.2(6)
C4	0.595(2)	−0.007(2)	0.168(2)	3.4(7)
H1	0.49(2)	0.32(2)	−0.09(1)	5(3)
H2	0.14(2)	−0.14(2)	−0.04(1)	6(3)
H3	0.65(1)	−0.00(1)	0.28(1)	1(2)

in aqueous zinc bromide solutions was 2.13 Mg m^{-3}. Systematic absences occurred at: $h,0,1$: $h + 1 = 2n + 1$; $0,k,0$:$k = 2n + 1$, indicating the space group $P2_1/n$ ($P2_1/c$ with an alternate choice of cell, no. 14), with molecules located at special positions. Intensity data were collected using the $\theta/2\theta$ scan mode up to $2\theta = 44.7°$. Two octants were measured within the index range $h,k,l = -6$ to 6, 0 to 6, and 0 to 9. Three standard reflections, measured 46 times during the data collection, showed a maximum instability of 2.83%, and were used to make corrections in the data reduction. Of the 475 unique reflections measured, 415 had intensities greater than $2.5\sigma(I)$.

The structure was solved by Patterson methods using the NRCVAX software (9). Halogen positions were determined from a Patterson map, and the carbon atoms were positioned from an electron density difference map. Hydrogen positions were initially located according to the carbon atom framework. Spherical absorption corrections were performed. Refinement of the non-hydrogen atoms was made with anisotropic temperature factors, while the hydrogen atoms were refined with isotropic factors. Final atomic coordinates are given in Table 1, and the thermal parameters are listed in Table 2. The lowest and highest peaks in the final difference map were −1.4 e Å^{-3} and 0.65 e Å^{-3}. The final extinction coefficient was 0.1867. Convergence was reached at $R = 0.055$, $R_W = 0.063$, for the 415 significant reflections, where $R = \Sigma(F_o - F_c)/\Sigma F_o$, $R_W = [\Sigma(K(F_o - F_c)^2)/\Sigma(KF_o^2)]^{1/2}$. Refinement was based on 59 variables, weight based on counting statistics with a modifier K in KF_o^2 of 0.00005. Bond lengths and angles are presented in Table 3.

Nuclear magnetic resonance

The NMR spectra were obtained on a Varian XL-300 spectrometer for dilute solutions (about 3 mol%) of dibromo- and diiodocubane in the solvent 1132, a mixture of phenylcyclohexylcyanides (Merck). The spectra were analyzed using a version of the LAOCOON program modified for dipolar coupling.

Results and discussion

The molecular structure and numbering system is shown in Fig. 1, and the packing diagram in Fig. 2. The structure is isomorphous with 1,4-diiodocubane (6) and also with the 1,4-dinitro derivative (3).

The search for substituent-induced variations in the carbon–carbon bond lengths in cubane derivatives is complicated by the observation that the crystallographically inequivalent C—C bond lengths show considerable variation. The average "edge" bond distance, C2—C3, in five cubane derivatives is 1.556 ± 0.006 Å (5), and dibromocubane at 1.567 Å is at the longer limit but within the error. The average bond length at C1 appears to be slightly shorter than the edge distance, and the bond angles at C1 are slightly larger, at 91.8°. In the diiodo compound, the averaged C—C distances were the same, and the bond angles closer to 90°. Thus the cage structure of dibromocubane may be slightly compressed along the symmetry axis. Recently, the gas phase structure of cubane itself was studied by electron diffraction (10). A vibrationally averaged C—C distance, r_g, of 1.573 Å was obtained. The value reported from the crystal structure determination (2) was 1.551 Å (averaged over the different distances in the crystal).

To accommodate the ring strain in the cubyl system, the C—C bonds become more p in character and the exocyclic bonds acquire more s-character. Thus these bonds are usually shorter than expected. The carbon–halogen bond lengths in the cubanes can be compared with those reported (7, 8) for *tert*-butyl and adamantyl derivatives, Table 4. The expected trend is observed.

The structures of the dibromo- and diodocubanes were calculated using the MM2 method (11) and the results for dibromocubane are included in Table 3. Interestingly, the deviations from a symmetric structure are in the same direction as observed in the X-ray study, but much larger; the edge C—C distance is much longer than the bonds to C1 and the angles at C1 greater than 90°. The predicted structure of diiodocubane is very close to the reported structure, i.e., the angles in the ring are close to 90° and the C—C bond lengths are the same. In both cases, however, the calculated C1–halogen bond lengths are even shorter than observed, 1.913 and 2.105 Å, for the dibromo and diiodo compounds, respectively.

To fit the results of the oriented NMR spectra to the structure, it is necessary to adopt coordinates for the carbon

cage and this was done for those averaged from the X-ray data and those derived from the MM2 calculations.

For a molecule with threefold molecular symmetry the dipole–dipole coupling constants (12) are given by eq. [1],

$$[1]\quad D_{ij} = -k\left\{C_{3z^2-r^2}\left[-2\frac{(\Delta z_{ij})^2}{r^5_{ij}} + \frac{(\Delta x_{ij})^2}{r^5_{ij}} + \frac{(\Delta y_{ij})^2}{r^5_{ij}}\right]\right\}$$

where $k = -\hbar\gamma_i\gamma_j/2\sqrt{5}\pi$. Assuming C_3 axial symmetry, there are three different proton–proton distances in the 1,4-dihalocubane structure, along the cube edge, across the face, and across the cube diagonal, and the oriented NMR spectrum is determined by three direct dipole coupling constants, three indirect couplings, and a single order parameter describing the orientation. For a perfect cube, the angle between the H-H direction along the edge of the cube and the C_3 axis, which is assumed to be the axis of orientation in the liquid crystal solvent, is 54.7°, which reduces this direct di-

$x_2 = x_4; x_3 = x_5; y_2 = y_3 = -y_1/2; y_4 = y_5 = y_1/2; y_6 = -y_1; z_2 = z_3 = z_1; z_4 = z_5 = z_6 = -z_1.$

pole coupling constant to zero. If a displacement of the proton positions occurs, then a small coupling constant results and the effect upon the spectrum is to produce a slight splitting of certain lines, shown in Fig. 3. The results of the spectral analysis are given in Table 5. The absence of the splitting (or a splitting small enough to be within the line width) in the case of the diiodo derivative indicates that little or no distortion occurs for this compound.

With the assumption of C_3 symmetry, the geometric relationships between the coordinates are; $x_1 = 0.0$, $x_2 = \sqrt{3}/2\ y_1$, $y_2 = -y_1/2$, thus the y_1 and z_1 coordinates and the motional constant $C_{3z^2-r^2}$ remain to be fitted to the three dipole–dipole coupling constants. To fit the structure to the carbon framework, the adjustable parameters were modified so that $y_1 = y(\mathrm{C1}) + r_H \cdot \sin(\alpha)$, and $z_1 = z(\mathrm{C1}) + r_H \cdot \cos(\alpha)$, where r_H is the C—H bond length and α is the angle made by the C—H bond to the z-axis. The carbon coordinates derived by (*i*) averaging the crystal coordinates and (*ii*) from the MM2 calculations were then used for y(C1) and z(C1). C—H bond lengths of 1.096 and 1.093 Å were obtained for the dibromo and diiodo compounds, respectively, and the angles α were identical at 70.3°. The proton coordinates are listed in Table 6. The occurrence of non-zero dipolar couplings in the case of dibromocubane results from a distortion of the cubic carbon framework and not as a result of a displacement of the proton positions. It should be emphasized, however, that comparisons of structural information derived by different experimental methods should include vibrational corrections. The MM2 calculations do show that the strain energy in the dibromo compound is about 66 kJ mol^{-1} higher than in the diiodo compound. The two main contributions to this increased strain energy are the C—C—Br bend and the C—C—C—Br torsion and, in attempting to relieve this extra strain, the dibromo molecule distorts.

Electron thermalization distance distribution and ion mobility in n-C_6F_{14}

TAKEHISA YOSHINARI[1] AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received July 16, 1991

TAKEHISA YOSHINARI and GORDON R. FREEMAN. Can. J. Chem. **70**, 915 (1992).

Electron thermalization distances in liquid n-C_6F_{14} were estimated from the electric field dependence of the free-ion yields at $0.3 \leq E$ (MV/m) ≤ 3.7 and densities $1564 \leq d$ (kg/m^3) ≤ 1951; the latter correspond to $335.4 \geq T$ (K) ≥ 191.3. The distance distribution function that best fits the data has a Gaussian body and power tail (*YGP*), the same as in n-alkanes and in C_6F_6 and SF_6, but different from those in the liquids N_2, CO, and CS_2. The latter apparently capture electrons at higher energies than do the fluorine compounds. The static relative permittivity of liquid n-C_6F_{14} was measured as a function of temperature and compared with the square of the refractive index and the Debye and Clausius–Mosotti equations. Atomic polarization appears to contribute 6% to the refractive index in the far infrared. Cation mobilities at temperatures $335.4 \geq T$ (K) ≥ 191.2 are fitted by the free volume model, with $v_0 = 1.71 \times 10^{-4}$ m^3/mol and $E_v = 3.24$ kJ/mol.

Key words: electron, ion, liquid density, permittivity, mobility, n-C_6F_{14}, thermalization distance.

TAKEHISA YOSHINARI et GORDON R. FREEMAN. Can. J. Chem. **70**, 915 (1992).

En se basant sur la relation entre le champ électrique et les rendements en ions libres à $0,3 \leq E$ (MV/m) $\leq 3,7$ et à des densités de $1564 \leq d$ (kg/m^3) ≤ 1951 (qui correspondent à $335,4 \geq T$ (K) $\geq 191,3$), on a évalué les distances de thermalisation des électrons dans le n-C_6F_{14}. La fonction de la distribution de la distance qui caractérise le mieux les données possède un corps gaussien et un queue en puissance (*YGP*); il s'agit de la même distribution que pour les n-alcanes, le C_6F_6 et le SF_6, mais elle est différente de celle observée dans le N_2, le CO et le CS_2 liquides. Ces derniers liquides semblent capturer les électrons à des énergies plus élevées que les composés fluorés. On a mesuré la permittivité relative statique du n-C_6F_{14} en fonction de la température et on l'a comparée au carré de l'indice de réfraction et aux équations de Debye et de Clausius–Mosotti. Il semble que, dans l'infrarouge lointain, la polarisation atomique fasse une contribution de 6% à l'indice de réfraction. On a justé les mobilités cationiques aux températures $335,4 \geq T$ (K) $\geq 191,2$ avec le modèle du volume libre, avec $v_0 = 1,71 \times 10^{-4}$ m^3/mol et $E_v = 3,24$ kJ/mol.

Mots clés : électron, ion, densité de liquide, permittivité, mobilité, n-C_6F_{14}, distance de thermalisation.
[Traduit par la rédaction]

Introduction

The shape of the electron thermalization distance distribution depends on the electron scattering (1) and capture (2) properties of the liquid. In the present work the search for different distribution functions was continued by studying a liquid that captures electrons to form anions, perfluoro-n-hexane (3, 4). The electron-capturing efficiency of n-C_6F_{14} is greater than that of C_6F_6 (3*b*), which was studied earlier (5).

Experimental

Materials

Perfluoro-n-hexane (Aldrich, 99%) was further purified by putting Davison molecular sieves 3A into it for 4 days, then transferring it onto phosphorus pentoxide (2–5 mm mesh, Baker, Granusic) where it was stored for about 2 months before being transferred into the conductance cell. All treatments and transfers were done under vacuum. The molecular sieves had been heated at 210°C under vacuum for 6 days, then cooled before transferring the fluorocarbon onto it. The phosphorus pentoxide had been evacuated for 2 weeks at room temperature, then for 3 min at 100°C, then cooled.

The liquid was degassed by trap-to-trap distillation while pumping on the receiver at 77 K, during each transfer.

Measurements

A conductance cell for low-pressure liquids (6) was used, with 2.97-mm electrode spacing.

The free-ion yield at a given applied field strength was determined by dividing the integrated ion current from the sample by that from the accelerator target, and multiplying by an appropriate factor that included the electron density of the sample (7). A 100-ns pulse of 1.7 MeV X-rays deposited ~1 μJ/kg in the fluorocarbon.

The cooling (8) and heating (9) systems and temperature measurement were as described in the references cited. The temperature uncertainty was 0.3 K.

Ion mobilities were measured by time of flight (10). The mobilities were independent of applied field strength up to the highest field used, 2.7 MV/m. Each reported mobility value is the average of six measurements, three made with different positive applied voltages and three with different negative voltages.

Liquid permittivities, densities, and viscosities

Values of the static relative permittivities ϵ of n-C_6F_{14} were obtained from the measured capacitance of the empty conductance cell at 295 K and of the filled cell at various temperatures (11). They are plotted in Fig. 1.

Values of the liquid density d at 273–323 K are reported in ref. 12. At $273 < T/\text{K} < 323$ the densities were calculated from ϵ and the Clausius–Mosotti equation (13)

$$[1] \quad P\frac{(\epsilon - 1)M}{(\epsilon + 2)d}$$

where $P = 40.2 \times 10^{-6}$ m^3/mol is the molar polarization, calculated from the values of ϵ and d at 294.6 K, and $M = 0.338$ kg/mol is the molar mass. Values of ϵ and d are listed in Table 1.

The value $\epsilon = 1.759$ at 293.2 K is much larger than $n_D^2 = 1.566$ (12). The low value of the refractive index was confirmed by measurements here. The difference is not due to a permanent dipole moment (it would have to be 2.1×10^{-30} C m, or 0.64 D), because the measured temperature dependence of ϵ is much smaller than that calculated from the Debye equation (13) and the measured values of d (12). We suggest that the refractive index at far-

Results and discussion

Free-ion yields and electron thermalization distances

The electric field strength dependences of free-ion yields in n-C_6F_{14} at temperatures from 191.3 to 335.4 K are shown in Fig. 2; G_{fi}^E is the number of pairs of free ions formed per 16 aJ (100 eV) of energy absorbed by the sample when the electric field strength across it is E.

The competition between geminate recombination of the initial electron–ion pairs, driven by mutual Coulombic attraction, and free-ion formation, driven by thermal energy and the external electric field, is a stochastic process (14).

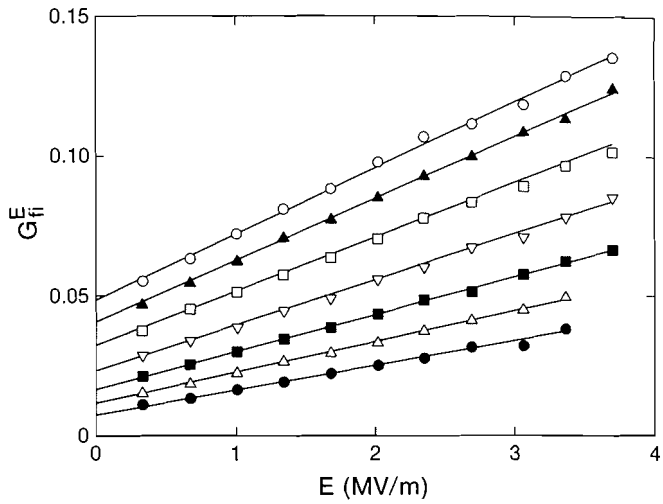

FIG. 2. Electric field strength dependence of free ion yields in n-C_6F_{14} at T(K): ○, 335.4; ▲, 315.3; □, 295.2; ▽, 269.7; ■, 245.3; △, 220.3; ●, 191.3. The curves were calculated from eqs. [2]–[5], using the parameter values in Table 2.

The free-ion yields and their field and temperature dependences can be calculated from an extended (14) model of Onsager's (15). The probability ϕ_{fi}^E of free-ion formation is

$$[2]\quad \phi_{fi}^E = G_{fi}^E/G_{tot} = \int_0^\infty \phi_{fi}^0(y)[1 + f(E,y,T)]F(y)dy$$

where G_{tot} is the total yield of initial ionization, and

$$[3]\quad \phi_{fi}^0(y) = \exp(-\xi^2/4\pi\epsilon_0\epsilon k_B T y) = \exp(-r_c/y)$$

where $-\xi$ is the electron charge, ϵ_0 is the permittivity of vacuum, k_B is Boltzmann's constant, T is the temperature, r_c is the "critical" Onsager radius, and the fractional increase of $\phi_{fi}^0(y)$ caused by the field E is

$$[4]\quad f(E,y,T) = e^{-\beta y}\sum_{n=1}^{\infty}\frac{(\beta y)^n}{(n+1)!}\sum_{j=0}^{n-1}(n-j)\frac{(r_c/y)^{j+1}}{(j+1)!}$$

where $\beta = \xi E/k_B T = 11\ 600\ E/T$ in SI units, and $F(y)dy$ is the fraction of electrons that have thermalization distances between y and $y + dy$.

The distribution function $F(y)$ in many liquids has a 3-dimensional Gaussian body and a power tail (14), and is designated YGP:

$$[5]\quad F(y) = \begin{cases} 0.96\ \mathrm{YG}, & y < 2.4\ b_{GP} \\ 0.96\ \mathrm{YG} + 0.48\ (b_{GP}^2/y^3), & y > 2.4\ b_{GP} \end{cases}$$

where 0.96 is a normalization factor and $\mathrm{YG} = (4y^2/\pi^{1/2}b_{GP}^3)\exp(-y^2/b_{GP}^2)$, and b_{GP} is the dispersion parameter and the most probable value of y. Other types of distribution function that have been tried are given in refs. 2 and 14.

For n-C_6F_{14} the value $G_{tot} = 3.0$ was taken to be the same as that for C_6F_6 (5). The best fitting $F(y)$ for n-C_6F_{14} over

[d]Normal bp = 330.3 K.
[e]Normal fp = 186.06 K.

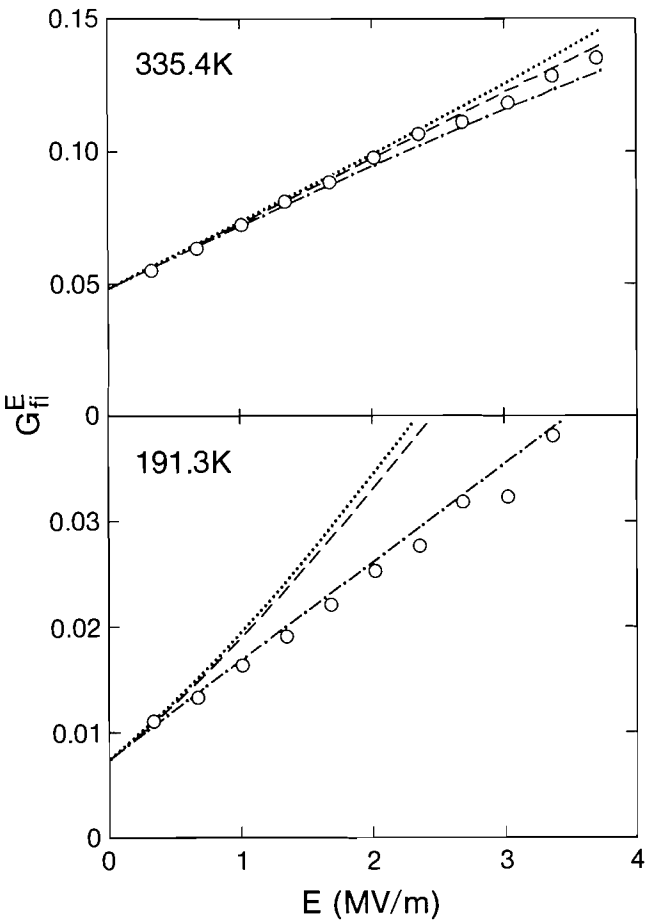

FIG. 3. Free ion yields (O) at 335.4 and 191.3 K compared to those calculated for $F(y)$ = YEP (–·–), YE (– – –), and YEC (····), using the parameter values in Table 3.

the ranges of d and E used was YGP, and this function was used to calculate the curves in Fig. 2. The parameter values are listed in Table 2. The value of $b_{GP}d$ is nearly constant over the 25% variation of liquid density.

The distribution YGP fits the G_{fi}^E data in liquid C_6F_6 and SF_6 (5) as well as that in n-C_6F_{14}, in spite of the fact that these compounds attach electrons to form anions. This distribution is characteristic of most liquids such as n-alkanes, which do not attach electrons (14). On the other hand, data for the liquids N_2 (2), CO (16), and CS_2 (5) cannot be fitted by YGP, but require the modified exponential function YEP:

TABLE 3. Electron thermalization distance distribution parameters for the curves in Fig. 3[a]

	b_{Ex} (nm)[b]	
	335.4 K	191.3 K
YEP	3.0	2.0
YE	3.9	3.2
YEC	2.6	2.2

[a]G_{tot} = 3.0, y_0 = 1 nm, ϵ as in Table 2.
[b]Attenuation coefficient.

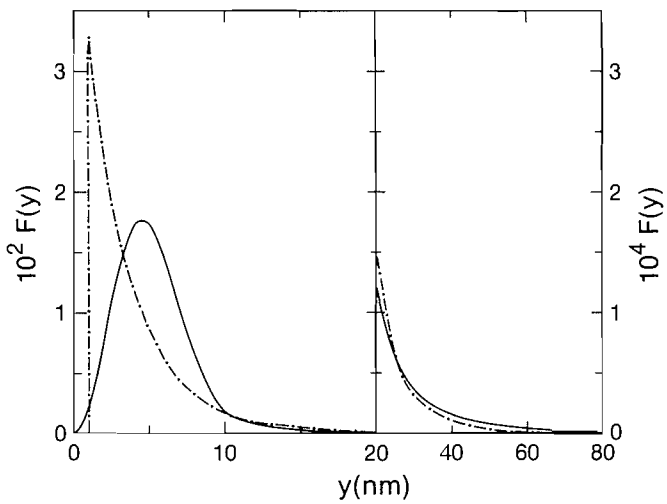

FIG. 4. Electron distribution functions. $F(y)$ = YGP (—) and YEP (–·–), for T = 335.4 K.

$$[6]\quad F(y) = \begin{cases} 0.97\ \mathrm{YE}, & 0 < (y - y_0) < 3.5\ b_{EP} \\ 0.97\ \mathrm{YE} + 0.72\ [b_{EP}^2/(y - y_0)^3], & \end{cases}$$

$$(y - y_0) > 3.5\ b_{EP}$$

where 0.97 is a normalization factor, $\mathrm{YE} = b_{EP}^{-1} \exp[(y - y_0)/b_{EP}]$, y_0 is taken as 1 nm, and b_{EP} is the attenuation coefficient. It appears that the liquids N_2, CO, and CS_2 capture electrons well before thermalization, and that n-C_6F_{14}, C_6F_6, and SF_6 capture electrons at a later, lower energy stage.

The extents to which YE and YEP fail to fit the n-C_6F_{14} data at 335.4 K and 191.3 K are shown in Fig. 3. Another modification of an exponential function, designated YEC (2), was also tried. None fits the data as well as does YGP. The parameter values for the curves in Fig. 3 are listed in Table 3.

The shapes of the distribution functions YGP and YEP are compared in Fig. 4. Both functions have a y^{-3} tail, which extends the distributions to larger separation distances. The tail is an artifact of the single-pair microzone model, attributed to the single ion–electron pairs that survive after the rapid neutralization of the innermost $(n - 1)$ pairs in micro-

[a]Liquid viscosity (12).

zones (spurs) that initially contain n pairs (14). A y^{-3} distribution by itself gives a reasonable fit to the data at 191.3 K, but not those at the higher temperatures. The core of the distribution contributes progressively more to the free-ion yields at higher fields (Fig. 5 in ref. 17) and at higher temperatures (Figs. 7 and 8 in ref. 2).

A Gaussian core is attributed to randomization of the direction of motion of the slowing-down electrons by the scattering in the final stages of de-energization. An exponential core is attributed to capture of the electrons by molecules before the electrons have become thermalized, and before the ion–electron separation distances have been Gaussianized.

Cation mobility

An Arrhenius plot of the cation mobilities μ is given in Fig. 5. The curve is not linear at $T \leq 230$ K, but it is adequately fitted by the free volume model (10, 18):

$$[7] \quad \mu = \frac{A}{T^{1/2}}\left(\frac{v - v_0}{v_0}\right)\exp(-E_v/RT)$$

where A is a constant, v is the molar volume, v_0 is the molar volume at which diffusion ceases, and R is the gas constant. The best fitting values are $E_v = 3.24$ kJ/mol and $v_0 = 1.71 \times 10^{-4}$ m^3/mol.

The product of the mobility and the liquid viscosity, μη, is nearly constant over the temperature region for which viscosity values are available (Table 4).

The preparation and solid state characterization of the bifunctional radical furan-2,5-bis(1,2,3,5-dithiadiazolyl) 2,5-[$(S_2N_2C)OC_4H_2(CN_2S_2)$] and the related monofunctional radical 2-cyanofuran-5-(1,2,3,5-dithiadiazolyl) 2,5-[$(S_2N_2C)OC_4H_2(CN)$] are described. The crystal structure of 2,5-[$(S_2N_2C)OC_4H_2(CN_2S_2)$] is orthorhombic, space group $Pna2_1$, and consists of interleaved arrays of dimers, for which the mean interannular S···S contact is 3.137 Å. The crystal structure of the monofunctional radical 2,5-[$(S_2N_2C)OC_4H_2(CN)$] is monoclinic, space group $P2_1/n$, and consists of a ribbon-like network of dimers (mean interannular S···S = 3.126 Å) interconnected by close head-to-tail CN···S contacts. The dimer units form stacks parallel to z, with a mean interdimer S···S separation of 3.956 Å. The similarities and differences between these two crystal structures and those of related benzene-substituted systems are discussed.

Key words: dithiadiazolyl radicals, furan-based diradicals, cyanofuran-based radicals, radical dimers, crystal structures.

On décrit la préparation et la caractérisation à l'état solide du radical bifonctionnel furane-2,5-bis(1,2,3,5-dithiadiazolyl) 2,5-[$(S_2N_2C)OC_4H_2(CN_2S_2)$] et du radical monofonctionnel apparenté 2-cyanofurane-5-((1,2,3,5-dithiadiazolyl) 2,5-[$(S_2N_2C)OC_4H_2(CN)$]. La structure cristalline du 2,5-[$(S_2N_2C)OC_4H_2(CN_2S_2)$] est orthorhombique, groupe d'espace $Pna2_1$ et elle comporte des arrangements intercalés de dimères pour lesquels le contact interannulaire S···S moyen est de 3,137 Å. La structure cristalline du radical monofonctionnel 2,5-[$(S_2N_2C)OC_4H_2(CN)$] est monoclinique, groupe d'espace $P2_1/n$ et elle est formée d'un ensemble en forme de ruban de dimères (distance S···S interannulaire moyenne = 3,126 Å) reliés par des contacts tête à queue CN···S rapprochés. Les unités de dimère s'empilent d'une façon parallèle à z et la séparation S···S interdimère moyenne est de 3,956 Å. On discute des similarités et des différences entre ces deux structures cristallines et celles de systèmes apparentés comportant des benzènes substitués.

Mots clés : radicaux dithiadiazolyles, diradicaux de dérivés furaniques, radicaux de cyanofuranes, dimères radicalaires, structures cristallines.

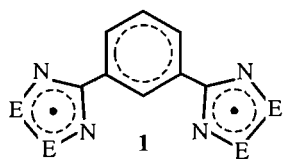
Introduction

Our interest in the design of molecular conductors based on neutral heterocyclic thiazyl and selenazyl building blocks (1) led us to investigate the solid state properties of 1,3- and 1,4-phenylene bridged 1,2,3,5-dithiadiazolyl and 1,2,3,5-diselenadiazoyl biradicals [$(E_2N_2C)C_6H_6(CN_2E_2)$] **1** (2, 3) and **2** (4) (E = S, Se). These bifunctional radicals associate in the solid state, but both the packing patterns and the mode of association are significantly different. The 1,4-derivatives **2** (E = S, Se) form dimers that adopt a herring-bone-like packing pattern, while in the α-phase of the 1,3-derivatives (E = S, Se) the molecules stack in vertical arrays, with association occurring through alternate ends of sequential diradical units (2). The selenium-based 1,3-phenylene system also crystallizes in a second (or β) phase, in which the crescent-shaped dimers link together in chain-like arrays (3). All the structures, particularly the selenium



1

derivatives, are characterized by short inter-radical E···E

contacts. The results of variable temperature single-crystal conductivity studies on both phases of the selenium-based 1,3-derivatives are consistent with intrinsic semiconductor behaviour (3).

As a continuation of this work we are constructing diradical systems that are similar in shape to the phenylene-bridged systems already studied. As a first step we synthesized and structurally characterized the furan-bridged diradical system 2,5-[$(S_2N_2C)OC_4H_2(CN_2S_2)$] **3**, in the hope that this system would opt for a packing pattern similar to that found for the 1,3-phenylene bridged material (2). In addition we also prepared and characterized a monofunctional radical possessing a 5-cyanofuryl substituent, i.e., **4**, to see if the crystal structure of this system would resemble that found in the α-phase of the recently reported 3-cyanophenyl compound (5). Herein we provide a full account of the preparation and crystal structures of **3** and **4**.

Results and discussion

Preparation of radicals

Our synthetic methodology for generating both mono- and bifunctional dithia- and diselenadiazolyls is now well established (2–5). The condensation of a persilylated amidine with sulphur (or selenium) dichloride affords the corresponding dithiadiazolium (or diselenadiazolium) chloride, which can then be reduced, typically by triphenylantimony, to the radical. In the present paper we extend this approach to include both the monofunctional and bifunctional furan-substituted dithiadiazolyls **3** and **4** (Scheme 1). As before, purification and crystal growth can be effected by vacuum sublimation methods (see Experimental).

Crystal structure of 3

Dark, blue-black blocks of **3**, grown by sublimation at 160°C/10^{-2} Torr (1 Torr = 133.3 Pa), are not isomorphous with crystals of the 1,3-phenylene-bridged diradical **1** (E = S) (tetragonal, space group $I4_1/a$); instead they belong to the orthorhombic space group $Pna2_1$. In contrast to the vertical columns of diradicals found in the structure of **1** (E = S), the crystal structure of **3** consists of discrete dimer units linked internally at both ends, as found in **2**. An ORTEP drawing, showing the atom numbering scheme, is given in Fig. 1. Non-hydrogen atom coordinates are given in Table 1. The internal bond lengths and angles summarized in Table 2 are typical of those seen in dithiadiazolyls (6, 7). The mean intradimer S····S separation, 3.137 Å, is also similar to those seen in the related bifunctional dimers, e.g., **1** (3.140 Å) and **2** (3.121 Å). As in the structure of 1,4-phenylene derivative **2**, there is a slight bowing of the dimer units, so that the mean centroid-to-centroid distance between the two furan rings (3.388 Å) is significantly longer than the terminal S····S links.

Within the unit cell (Fig. 2) the dimers generate a herring-bone network in the *xz* plane, with four dimers per unit cell. As such the packing pattern is reminiscent of that observed for **2** but, as a result of the reduction of the (approximate) D_{2h} symmetry of the molecular unit found in **2**, the "ribs" within each herring-bone assembly curve inwards or outwards with respect to the plane of the network. The space group propagates this alternation of curvatures along sets of "ribs" in both the *x* and *z* directions. Within each sheet there are three interdimer S····S interactions d_1–d_3 (Table 2) that are closer than the expected van der Waals contact (8). Of these, the two perpendicular approaches d_2 and d_3 (mean 3.221 Å) are remarkably close, significantly more so than

the corresponding contacts in the structure of **2** (mean 3.500 Å).

Although the contacts d_1–d_3 between dimers are strong, indeed more so than in **2** (E = S), the curvature of the molecular skeleton leads to an isolation of neighbouring sheets. As illustrated in Fig. 3, the outside edge of one furan ring is forced into the pocket formed by the curvature of its neighbour; this eliminates the possibility of any close intersheet S----S contacts (along *y*) of any consequence.

Crystal structure of ***4***

Crystals of **4**[2] belong to the monoclinic space group $P2_1/n$, and consist of radical dimers linked in a cofacial manner through S----S contacts (mean 3.126 Å). An ORTEP drawing, showing the atom numbering scheme, is given in Fig. 1. Non-hydrogen atom coordinates are given in Table 3 and internal structural parameters summarized in Table 2. In many ways the crystal structure closely resembles that of the α-phase of the 3-cyanophenyl-substituted dithiadiazolyl **5** (5). As in this latter structure, which is also monoclinic, $P2_1/n$, with a = 7.295(3), b = 20.488(2), c = 11.367(2) Å, β = 95.54(2)°, the dimers form snake-like ribbons connected by head-to-tail CN----S contacts (mean 3.048 Å, cf. 3.075 Å in α-**5**) (Fig. 4).

Despite the similarity in the ribbon-like networks there are subtle but important differences between the structures of **4** and α-**5**. As in **5**, individual dimers of **4** form stacks running parallel to *z* (in α-**5** the stacking direction is *x*, which is equivalent to *z* in these $P2_1/n$ cells), but the interdimer S----S separation of 3.956 Å (mean of d_1 and d_2) is much shorter (4.26(5) Å in α-**5**). Also, while the benzene and CN_2S_2 rings in **5** display a significant torsion about the phenyl–CN_2S_2 bond (12(4)°),[3] the furan and CN_2S_2 rings in **4** are more nearly coplanar (mean furyl–CN_2S_2 torsion angle = 7(5)°).[3] The origins of this difference may arise from the greater size of the benzene ring in α-**5**, which forces the observed twisting in order to allow adjacent ribbons to approach one another. This point can be better appreciated after consideration of the fact that the angle between the 2,5-substituents on a furan ring (144° in a pentagon) is substantially larger than between the 1,3-substituents on a benzene core (120° in a hexagon). This difference forces a more severe curvature on the ribbon-like backbone of α-**5**, which, when coupled with greater peripheral spread of the phenyl group, induces a twisting of the phenyl rings about the ligand–CN_2S_2 linkage. The twisting also introduces a sheer effect between the two phenyl groups in a dimer unit, which reduces intradimer phenyl–phenyl contacts.

Perhaps as a consequence of the features noted above, the stacking patterns of the ribbons in **4** and α-**5**, and the number and nature of inter-stack contacts are very different. The principal differences are illustrated in Figs. 5 and 6, which show the stacking of the dimer S_4 subunits in the two structures, as viewed parallel to the *y* axis. In **4** adjacent S_4 stacks are out of register (Fig. 5), so that there are significant S----S

[2]We have not observed any tendency of **4** to form a second crystalline phase, as does **5**.

[3]This is the mean of the four 4-atom 3-bond torsion angles; the number in parentheses is the range.

contacts between the dimers both above and below to either side. By contrast, the S_4 stacks in α-**5** (Fig. 6) are in register, so that only S····S contacts d_3 (4.170 Å) and d_4 (4.168 Å), which are notably longer than those in **4**, are maintained between neighbours immediately to either side.

Summary and conclusions

The seemingly minor differences in the molecular structures of 2,5-furan- and 1,3-benzene-based dithiadiazolyl radicals lead to major differences in crystal structure. In the case of the bifunctional system **3**, the relatively wide angle (in comparison to the 1,3-phenylene structure **1**) between the two radical rings forces the crystal structure into a pseudo 1,4-phenylene instead of a pseudo α-1,3-phenylene packing pattern. The same issues work to advantage in the cyano-substituted derivative **4**. The smaller (than cyanobenzene) cyanofuran ring, coupled with a more obtuse angle between

the 2- and 5-substituents, produces flatter, less-ruffled ribbons, that can stack in a pseudo-interleaved (out-of-register) manner, thereby producing a much more tightly packed (in terms of S····S contacts) arrangement than in the 3-cyanophenyl-substituted system **5**. The selenium analogue to **4** should have conductivity characteristics significantly greater than that of the selenium counterpart of **5**.

Experimental

Starting materials and general procedures

Furan-2,5-dimethanol, lithium bis(trimethylsilyl)amide, sulphur dichloride, and triphenylantimony were all obtained commercially (Aldrich). Sulfur dichloride was distilled (at 1 atm (= 101.3 kPa)) before use and $LiN(SiMe_3)_2$ was converted into its diethyl etherate in order to facilitate amidine synthesis (9). Acetonitrile (Fisher HPLC grade) was purified by distillation from P_2O_5. All reactions were performed under an atmosphere of nitrogen. 2,5-Dicyanofuran was prepared by oxidation of furan-2,5-dimethanol to the corresponding dialdehyde (10) and conversion of the latter to the dioxime (11); subsequent dehydration with acetic anhydride (12) then afforded the dinitrile. Selenium tetrachloride was prepared by direct oxidation of selenium with chlorine gas (13). Mass spectra were recorded on a Kratos MS890 mass spectrometer. ^1H NMR spectra were recorded at 200 MHz on a Varian Gemini 200 MHz spectrometer. Infrared spectra (CsI optics, Nujol mulls) were obtained on a Nicolet

20XS/C FTIR instrument. Elemental analyses were performed by MHW laboratories, Phoenix, Arizona.

*Preparation of furan-2,5-bis(*N,N,N′*-tris(trimethylsilylamidine), DIFURADS*

A solution of 2,5-dicyanofuran (6.02 g, 0.51 mmol) in 30 mL diethyl ether was added dropwise to a slurry of $LiN(SiMe_3)_2 \cdot Et_2O$ (25.0 g, 10.3 mmol) in 100 mL diethyl ether and the resulting dark-brown solution stirred under nitrogen for 16 h. The solvent was then removed *in vacuo* to leave a dark-brown solid, to which was added Me_3SiCl (1.6. mL, 12.7 mmol) in 100 mL of toluene. This mixture was heated at reflux for 5 h, then filtered to remove LiCl, and the solvent distilled off to leave a dark-brown solid, which was crystallized from hot acetonitrile/toluene to give colourless needles of furan-2,5-bis(*N,N,N′*-tris(trimethylsilylamidine),DIFURADS (12.7 g, 2.2 mmol, 43%), mp 112–115°C. ^1H NMR (δ, $CDCl_3$): 0.14 (Me_3Si, 54H, s), 6.56 (H_2C_4O, 2H, s). Anal. calcd. for $C_{24}H_{56}N_4OSi_6$: C 49.43, H 9.33, N 9.61; found: C 49.53, H 9.35, N 9.65.

Preparation of 2,5-[$(S_2N_2C)OC_4H_2(CN_2S_2)$], 3

An excess of SCl_2 (1.6 mL, 25 mmol) was injected via syringe into a slurry of DIFURADS (2.94 g, 5.00 mmol) in 60 mL acetonitrile, and the resulting red/orange slurry stirred and heated to gentle reflux for 1 h. The mixture was filtered to remove the crude product 2,5-[$(S_2N_2C)OC_4H_2(CN_2S_2)]Cl_2$ (a brick-red solid). This material was dried *in vacuo*, then reduced with triphenylantimony (1.8 g, 5.2 mmol) in a slurry of 50 mL acetonitrile for 6 h at room temperature. The mixture was filtered, and the residual black solid washed with 2 × 20 mL acetonitrile and pumped dry *in vacuo*. This crude product was purified by sublimation at 160°C/10^{-2} Torr to give lustrous black (green to reflected light) blocks of 2,5-[$(S_2N_2C)OC_4H_2(CN_2S_2)$] **3** (E = S) (0.60 g, 2.2 mmol, 44%), mp 275–278°C. IR (1600–250 cm^{-1} region): 1355 (br, s), 1259 (m), 1166 (s), 1044 (w), 1037 (w), 978 (m), 818 (m), 799 (m), 771 (s), 695 (w), 597 (w), 520 (w), 505 (s), 429 (w), 379 (w) cm^{-1}. Mass spectrum (EI, *m/e*): 274 (M^+, 80%) 228 ($(M - NS)^+$, 28%), 196 ($(M - S_2N)^+$, 57%), 150 ($(NC(C_4H_2O)CNS)^+$, 15%), 118 ($(NC(C_4H_2O)CN)^+$, 12%), 78 ($(S_2N)^+$, 33%), 64 (S_2^+, 100%). Anal. calcd. for $C_6H_2N_4OS_4$: C 26.27, H 0.73, N 20.42; found: C 26.25, H 0.90, N 20.39.

*Preparation of 5-cyanofuran-2-(*N,N,N′*-tris(trimethylsilylamidine),CNFURADS*

Powdered $LiN(SiMe_3)_2 \cdot Et_2O$ (12.08 g, 50.0 mmol) was slowly added to a solution of 2,5-dicyanofuran (5.90 g, 50.0 mmol) in 100 mL diethyl ether, producing a dark-brown solution. The mixture was stirred overnight under nitrogen, and the solvent removed *in vacuo* to leave a dark-brown solid. A solution of Me_3SiCl (8.0 mL, 6.3 mmol) in 100 mL toluene was then added, and the mixture heated at reflux for 5 h. Filtration of the mixture, and removal of the solvent from the filtrate, afforded a dark-brown oil that was distilled *in vacuo* to give 5-cyanofuran-2-(*N,N,N′*-tris(trimethylsilylamidine), CNFURADS (11.0 g, 31.3 mmol, 63%), as a colourless waxy solid, bp 114–116°C/10^{-2} Torr, which was recrystallized from acetonitrile as colourless flakes, mp 68–70°C. ^1H NMR (δ, $CDCl_3$): 0.13 (Me_3Si, 27H, s), 6.50 and 7.07 (H_2C_4O, 2H, J_{AB} 3.6 Hz). Anal. calcd. for $C_{15}H_8N_3OSi_3$: C 51.23, H 8.31, N 11.95; found: C 51.43, H 8.28, N 12.15.

Preparation of 2,5-[$(S_2N_2C)OC_4H_2(CN)$], 4

Sulphur dichloride (2.5 mL, 39 mmol) was injected into a slurry of CNFURADS (3.55 g, 10.0 mmol) in 50 mL acetonitrile, and the resulting mixture stirred and heated to gentle reflux under nitrogen for 30 min. The resulting red precipitate was filtered off and dried *in vacuo*. This crude dithiadiazolium chloride was then reduced wth Ph_3Sb (1.8 g, 5.0 mmol) in 50 mL acetonitrile to give a khaki-brown solid (1.60 g), which was purified by vacuum sublimation at 160°C to give blue-black crystals of 2,5-[(S_2N_2C)-$OC_4H_2(CN)$] **6** (E = S) (1.60 g, 81%), mp > 244°C (dec.). IR: ν(CN) 2234 cm^{-1} and (1600–250 cm^{-1} region) 1346 (s), 1298 (s), 1219 (m), 1155 (m), 1023 (m), 986 (m), 964 (m), 833 (w), 812 (m), 804 (m), 773 (s), 696 (w), 596 (w), 588 (w), 558 (w), 504 (s), 463 (w), 448 (w) cm^{-1}. Mass spectrum (EI, *m/e*): 196 (M^+, 100%), 150 ($(M - NS)^+$, 30%), 132 ($(M - S_2)^+$, 20%), 118 ($(NC(C_4H_2O)CN)^+$, 42%), 94 (70%), 78 (S_2N^+, 90%). Anal. calcd. for $C_6H_2N_3OS_2$: C 24.85, H 0.70, N 14.49; found: C 25.00, H 0.55, N 14.41.

X-ray measurements

All X-ray data were collected on an ENRAF–Nonius CAD-4 at 293 K with monochromated Mo K_α (λ = 0.71073 Å radiation). Crystals were mounted on glass fibers coated with epoxy. Crystals of **3** belong to the orthorhombic space group $Pna2_1$, and have unit cell parameters a = 19.545(4), b = 5.913(2), c = 16.242(2) Å. Crystals of **4** are monoclinic, space group $P2_1/n$, with a = 10.455(5), b = 20.645(3), c = 7.060(4) Å, β = 104.44(4)°. Data were collected using a θ/2θ technique with a scan width of (1.0 + 0.3 tan θ). Both structures were solved using MULTAN and refined by full-matrix least squares which minimized $\Sigma w(\Delta F)^2$. The final R and R_w values of 0.034 and 0.036 (for **3**) and 0.049 and 0.051 (for **4**) were based respectively on refinements of 270 and 152 parameters with 1164 and 767 unique data with $F_o^2 > 3\sigma(F_o^2)$. Crystals of **4** were extremely thin plates (the data crystal was 0.03 mm thick), which led to a low number of $I > 3\sigma(I)$ reflections, and the consequent need to refine carbon atoms isotropically. Data collection, structure solution, and refinement parameters for all structures have been deposited.[4]

Sorption of magnesium–picolinate complexes on a macroporous styrene–divinylbenzene copolymer containing immobilized 8-hydroxyquinoline and on the copolymer itself

GOCOOL PERSAUD AND FREDERICK F. CANTWELL[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received July 31, 1991

GOCOOL PERSAUD and FREDERICK F. CANTWELL. Can. J. Chem. **70**, 926 (1992).

The sorbent XAD-OXINE was prepared by covalently binding 8-hydroxyquinoline onto the surface of the macroporous copolymer Amberlite XAD-2 to give about 20% surface coverage. Sorption, onto both XAD-2 and XAD-OXINE, of the magnesium-containing species that are present in solutions of magnesium ion and picolinic acid was studied by the column equilibration/atomic absorption technique at solution pH of 6.00 and 7.50 and ionic strength of 0.25. By using solutions containing various amounts of added magnesium and picolinic acid, in which the ratio of the two metal–ligand complex species, MgP^+/MgP_2, varied greatly (P^- is the ligand picolinate), it was shown that neither the species Mg^{2+} nor the species MgP^+ sorb to an appreciable extent onto the parent polymer XAD-2, but the neutral species MgP_2 sorbs strongly and exhibits a linear isotherm. Then, by measuring the sorption isotherm of the species Mg^{2+} on XAD-OXINE in the absence of picolinic acid, by measuring the overall sorption of magnesium-containing species on XAD-OXINE in the presence of picolinic acid, and by assuming that the sorption of the species MgP_2 onto XAD-OXINE was about the same as it was on XAD-2, it was possible to show that the species MgP^+ sorbs strongly onto XAD-OXINE, and exhibits linear sorption isotherms. Thus, XAD-OXINE sorbs all three species Mg^{2+}, MgP^+, and MgP_2.

Key words: Amberlite XAD-2, immobilized oxine, magnesium ion.

GOCOOL PERSAUD et FREDERICK F. CANTWELL. Can. J. Chem. **70**, 926 (1992).

On a préparé l'adsorbant XAD-OXINE en liant d'une façon covalente de la 8-hydroxyquinoléine sur la surface du copolymère macroporeux Amberlite XAD-2 de manière à couvrir environ 20% de la surface. Faisant appel à la technique de l'équilibration sur colonne/absorption atomique et opérant à un pH de 6,00 et 7,50 et à une force ionique de 0,25, on a étudié la sorption, sur du XAD-2 ainsi que sur du XAD-OXINE, d'espèces contenant du magnésium contenues dans des solutions d'ion magnésium et d'acide picolinique. Utilisant des solutions contenant diverses quantités de magnésium et d'acide picolinique ajoutés, dans lesquelles les rapport des deux espèces métalliques/complexes ligands, MgP^+/MgP_2, varient beaucoup (P = ligand picolinate), on a montré que ni l'espèce Mg^{2+} ni l'espèce MgP^+ ne s'adsorbe d'une manière appréciable sur le polymère parent XAD-2; toutefois, l'espèce neutre MgP_2 s'adsorbe fortement et elle présente une isotherme linéaire. En mesurant l'isotherme de sorption des espèces Mg^{2+} sur le XAD-OXINE en l'absence d'acide picolinique, en mesurant la sorption globale des espèces contenant du magnésium sur le XAD-OXINE en présence d'acide picolinique et en faisant l'hypothèse que la sorption du MgP_2 sur le XAD-OXINE est pratiquement égale à celle observée sur le XAD-2, il est alors possible de démontrer que l'espèce MgP^+ s'adsorbe fortement sur le XAD-OXINE et qu'elle présente des isothermes d'adsorption linéaires. Le XAD-OXINE adsorbe donc les trois espèces Mg^{2+}, MgP^+ et MgP_2.

Mots clés : Amberlite XAD-2, oxine immobilisé, ion magnésium.

[Traduit par la rédaction]

Macroporous copolymers of styrene and divinylbenzene (DVB) find many uses in analytical chemistry. They are routinely used to concentrate trace components from both biological and environmental samples (1, 2). They have been used as packings for moderate efficiency liquid chromatography columns (3, 4) and, in the form of microparticles, as reverse-phase packings for high-efficiency liquid chromatography columns (5–7). These polymers are essentially nonionic and tend to strongly adsorb hydrophobic, nonionic sample molecules from aqueous solution. However, they also sorb ionic sample species (8). They have been used as HPLC packings for "dynamic ion exchange" chromatography of lanthanide ions (9). In this latter type of application a large surfactant ion is reversibly sorbed onto the surface of all of the packing in the column and lanthanide sample ions are chromatographed on this reversibly modified packing.

Macroporous styrene–DVB copolymers have also been derivatized by covalently attaching various groups to the polymer surface. Low-capacity cation and anion exchangers have been prepared by attaching sulfonate or quaternary ammonium groups. They have been used as liquid chromatographic column packings for separating both organic and inorganic ions (10, 11). A physico-chemical model has been developed to explain the retention of organic ions on such low-capacity ion exchangers (12, 13). Ligands have also been covalently bound to macroporous styrene–DVB copolymers in order to prepare "chelating sorbents" suitable for preconcentrating trace-metal ions from aqueous sample solutions (14–17).

Chelating sorbents have been used not only to preconcentrate metal ions but also to achieve metal ion "speciation" measurements, in which the concentration of a free (hydrated) metal ion species M^{n+} is measured in solutions containing metal–ligand complexes of the ion M^{n+}, even when the complexes are kinetically labile (18). These measurements of free-metal ion concentration are made by the column equilibration/atomic spectroscopy method in which a sample solution is equilibrated with a small bed of chelating sorbent and then the sorbed metal ion M^{n+} is eluted into an atomic absorption spectrophotometer. The underlying principles of the method have been presented in detail (18–21). An essential requirement of the method is that, of all the M^{2+} containing species that are present, the sorbent will se-

lectively sorb M^{n+} but will not sorb its metal–ligand complexes. Recently a chelating sorbent, XAD-OXINE, which was prepared by covalently binding the ligand oxine (8-hydroxyquinoline) to the macroporous styrene–DVB copolymer Amberlite XAD-2, was investigated for use in measuring free magnesium ion concentration (22). It was found that in the presence of ligands that form rather hydrophilic complexes with Mg^{2+}, such as EDTA and oxalate, it is possible to measure accurately the concentration of the species Mg^{2+} at concentrations as low as 10^{-6} M, even though the complexes are kinetically labile and even when the species Mg^{2+} represents only a few percent of total dissolved magnesium in solution. However, in contrast, it was found that in the presence of the ligand picolinate, P^-, which forms more hydrophobic complexes with Mg^{2+} because of the presence of an aromatic ring on the ligand, the measured values of $[Mg^{2+}]$ were erroneously high. Preliminary studies suggested that this is because one or both of the magnesium–picolinate complexes, MgP^+ and MgP_2, is sorbed by XAD-OXINE (Table V, ref. 22).

In the present work, sorption of the species Mg^{2+}, MgP^+, and MgP_2 onto XAD-OXINE and onto the parent copolymer XAD-2 is investigated quantitatively. Because macroporous styrene–DVB copolymers and their derivatives are used extensively for chromatography, for preconcentration of both organic and metal ions, and for speciation studies, the resultant quantitative description is broadly relevant in analytical chemistry.

Experimental section

Reagents

Sodium chloride (BDH), which was used to adjust ionic strength, piperazine *N,N'* bis(2-ethanesulfonic acid) (PIPES; Sigma Chemical Co.), which was used to prepare the buffers, oxalic acid (Fisher), disodium ethylenediamine tetraacetic acid (EDTA; Fisher), and picolinic acid (2-pyridinecarboxylic acid; Sigma) were all reagent grade and were used as received. Magnesium stock solutions were prepared by dissolving the metal powder in 6 M nitric acid and diluting.

Purified water, prepared by passing the laboratory distilled water through a mixed-bed ion exchange resin column (Amberlite MB-1; Rohm and Haas) was used in preparing all solutions. The 1 M NaCl stock solution was passed through a 16 cm × 2.5 cm bed of Dowex Chelating Resin (Sigma) to reduce the level of trace Mg^{2+} before using this solution in the preparation of samples and standards.

All solutions containing Mg^{2+}, both standards and samples, were buffered with 0.0010 M PIPES, a noncomplexing buffer (22), to pH 6.00 or 7.50 and all had their ionic strengths adjusted to 0.25_0 M with NaCl. Complexation of Mg^{2+} by Cl^- is small enough to be neglected (22).

Sorbents

The sorbent "XAD-2" is the parent polymer. It is the macroporous styrene–DVB copolymer Amberlite XAD-2 (Rohm and Haas). The 100–200 mesh (75–150 μm) cut was used. It was obtained by grinding and sieving. Fines were removed by sedimentation and decantation in methanol, and soluble impurities were removed by cycling it through washes with 1.2 M HCl, water, 1 M NaOH, water, and methanol.

The chelating sorbent "XAD-OXINE" was prepared from XAD-2 by covalently binding oxine to its surface via a methylene group linkage, as described elsewhere (22, 23). It has a complexing capacity, based on Cu^{2+} uptake, of 264 ± 2 μmol/g of dry sorbent (22).

Apparatus

The column equilibration/atomic absorption apparatus is described elsewhere (22). The column design was the same for both XAD-2 and XAD-OXINE and was similar to that used previously (20). For each sorbent the column consisted of a 1.0-cm length bed packed in a 1.5-mm i.d. Teflon tube with small sintered glass frits inserted into the tube at each end of the sorbent bed. The weight of sorbent was 5.2 mg in each case.

Due to space restrictions imposed by efforts to minimize the holdup volume of the system, it was not practical to thermostat the column. However, experiments were run at ambient temperature in a controlled temperature room (25 ± 2°C) and calibrating standards of Mg^{2+}, containing no ligand, were always run along with sample solutions containing ligand so that operating at ambient temperature introduced minimal errors.

Column equilibration procedure

Sample and standard solutions were pumped via the peristaltic pump through the small column of XAD-2 or XAD-OXINE at a constant flow rate (±0.1 mL/min) at nominal values of 4.5–5.0 mL/min.

In a typical experiment the solution of interest was pumped through the column for 20 min in the "loading" step, in order to bring the sorbent to equilibrium with the solution. Next the column was eluted for 2.0 min with 1.0 M HNO_3 and the eluate was directed into the nebulizer of an atomic absorption spectrophotometer (Perkin–Elmer, model 4000). The measured atomic absorption signal was a peak, the area of which, $(P.A.)_{total}$, was proportional to the sum of magnesium-containing species sorbed and magnesium-containing species in the solution present in the holdup volume of the system. The holdup volume was measured experimentally (22). The peak area associated with magnesium-containing species sorbed, $(P.A.)_{sorbed}$, in a particular experiment was then calculated from $(P.A.)_{total}$ and from the peak area associated wtih the holdup of the particular magnesium-containing solution of interest, $(P.A.)_{holdup}$, using the expression:

$$[1] \quad (P.A.)_{sorbed} = (P.A.)_{total} - (P.A.)_{holdup}$$

For both the standard solution and the sample solution a correction was made for the presence of a very small amount of magnesium impurity that had not been removed by the Dowex Chelating Resin column cleanup. Details of this small correction were previously given (22). For comparison with results reported in ref. 22, it may be noted that all experiments in the present report were performed by the "without washing" procedure described in that reference.

Results and discussion

Picolinic acid has three conjugate acid–base species, H_2P^+ (pK_{a1} = 1.03), HP (pK_{a2} = 5.21), and P^-, the picolinate anion. The pK_a values are from the critical compilation of Martell and Smith (24) at 25°C and c = 0.1. The ligand species is P^-.

Because peak area (P.A.) is the quantity obtained directly from the atomic absorption spectrophotometer and because P.A. is directly proportional to the total moles of all of the magnesium-containing species sorbed on the column and is therefore proportional to the total adsorbed concentration (mol/kg) on that column, it is convenient to plot P.A. as the vertical-axis variable in the measured isotherms reported below.

Sorption of Mg^{2+}

Sorption isotherms are plots of concentration sorbed versus concentration in solution, at equilibrium. Sorption isotherms of the species Mg^{2+} on XAD-OXINE (not shown) have been measured in the absence of added picolinate at c = 0.25_0 for pH 6.00 and 7.50 (23). The isotherm obtained

at pH 7.50 is about four times steeper than that obtained at pH 6.00, consistent with a greater degree of ionization of the immobilized ligand oxine at higher pH, and both isotherms exhibit a slight concavity toward the [Mg^{2+}] axis, which is generally similar to that seen in Fig. 1 of ref. 22.

When the parent polymer, XAD-2, was used as the sorbent in the absence of picolinate, it was found that no sorption of Mg^{2+} was detectable on XAD-2 in these experiments. This is consistent with the view that the sorption of Mg^{2+} on XAD-OXINE results from complexation of Mg^{2+} by immobilized oxinate ligand.

Picolinate complexes

Picolinate forms the complex species MgP^+ and MgP_2, with stepwise formation constants of 1.6×10^2 (at $c = 0.1$) and 8.9×10^3 (at $c = 0$) (24). Evaluation of the experimental sorption data requires theoretical calculation of the concentrations of the magnesium-containing species Mg^{2+}, MgP^+, and MgP_2. These multiple-equilibrium calculations were performed with the aid of the speciation program COMICS (23, 25). In the calculations the acidity constants and metal–ligand formation constants were corrected to ionic strength $c = 0.25_0$ using activity coefficients obtained with the Davies equation (26), and uncertainties in theoretically calculated species concentrations were obtained by error propagation (23).

Results of these theoretical species distribution calculations at pH 5.00, 6.00, 7.00, and 7.50, for added picolinic acid concentrations, $C_{\text{picolinic acid}}$, of 0.001 M, 0.01 M, and 0.05 M, are presented in Table 1. In the table are shown values of α_i, the fraction of the total magnesium in solution that is present as species i, where i is either Mg^{2+}, MgP^+, or MgP_2. Since these calculations were performed assuming a very small added magnesium concentration, the α_i values in Table 1 are independent of C_{Mg} and will apply to other added magnesium concentrations provided that $C_{Mg} << C_{\text{picolinic acid}}$. Information from Table 1 is needed to determine which of the complex species MgP^+ and MgP_2 is sorbed, and to what extent.

Sorption on XAD-2

Examination of Table 1 reveals two important relationships. First, examination of any horizontal row shows that, for a constant $C_{\text{picolinic acid}}$ and for pH $\geq$ 6, the fraction of magnesium that is present in the form of any particular species is nearly constant, independent of pH. Second, examination of the vertical columns shows that the relative fractional contribution of any species varies markedly with $C_{\text{picolinic acid}}$ and, more importantly, the ratio $(\alpha_{MgP_2}/\alpha_{MgP^+})$ also changes markedly. At any pH $\geq$ 6 this ratio has values of approximately 0.05, 0.4_5, and $2._5$ for $C_{\text{picolinic acid}}$ of 0.001, 0.01, and 0.05, respectively.

Study of the sorption of magnesium–picolinate complexes on the parent polymer XAD-2 is aided by the above relationships and is simplified even more by the fact that the species Mg^{2+} does not sorb significantly on XAD-2. Thus, any magnesium sorbed on XAD-2 will be due to only MgP^+ and (or) MgP_2. Furthermore, the fact that the ratio $(\alpha_{MgP_2}/\alpha_{MgP^+})$ varies so greatly with $C_{\text{picolinic acid}}$ makes it possible to determine the extent to which each of these two species is adsorbed on XAD-2 by studying the amount of magnesium sorbed for constant C_{Mg} and varied $C_{\text{picolinic acid}}$. The results of these two studies, one at pH 6.00 and the other at pH 7.50, are presented in Table 2.

Interpretation of the information in Table 2 is achieved by making plots of $(P.A.)_{sorbed}$ versus the concentrations of individual magnesium–picolinate complex species at a particular pH. Such plots were made for $(P.A.)_{sorbed}$ versus [MgP_2] at pH 6.00 and at pH 7.50. The former is shown in Fig. 1. Linear regression yields a slope of 0.13 ± 0.01, intercept of -0.01 ± 0.04, and correlation coefficient of 0.997 for the plot at pH 6.00 and a slope of 0.14 ± 0.02, intercept of -0.02 ± 0.03, and correlation coefficient of 0.989 for the plot at pH 7.50. In contrast to the linearity of these plots, plots of $(P.A.)_{sorbed}$ versus [MgP^+] (not shown) are nonlinear. Correlation coefficients of 0.37 and 0.78 were obtained at pH 6.00 and 7.50, respectively. These results reveal the following: (*i*) The neutral species MgP_2 is sorbed on the hydrophobic surface of the parent polymer XAD-2 while the cationic species MgP^+ either is not sorbed or is sorbed to a much smaller extent than MgP_2. This is shown by the good linearity of the plots of $(P.A.)_{sorbed}$ versus [MgP_2]. (*ii*) The sorption of MgP_2 on the polymer surface is independent of pH. This is shown by the fact that the slopes of the plots of $(P.A.)_{sorbed}$ versus [MgP_2] at pH 6.00 and pH 7.50 are equal to one another. Since XAD-2 is a nonionic polymer with very few acid–base groups (27) this lack of pH dependence is consistent with expectations.

Sorption on XAD-OXINE

If XAD-OXINE sorbs all three species, Mg^{2+}, MgP^+, and MgP_2, then when a solution containing magnesium and picolinate is equilibrated with XAD-OXINE the measured peak area $(P.A.)_{sorbed}$ will be the sum of peak areas due to three sorbed species:

$$[2] \quad (P.A.)_{sorbed} = (P.A.)_{sorbed,Mg^{2+}} + (P.A.)_{sorbed,MgP^+} + (P.A.)_{sorbed,MgP_2}$$

Since sorption isotherms for the species Mg^{2+} have been measured on XAD-OXINE, as discussed above, and since [Mg^{2+}] can be theoretically calculated for a sample solution containing both magnesium and picolinate, then it is a simple matter to read, from the appropriate Mg^{2+} sorption isotherm, the value of $(P.A.)_{sorbed,Mg^{2+}}$ to be used in eq. [2].

In addition, the value of $(P.A.)_{sorbed,MgP_2}$ to be used in eq. [2] for sorption on XAD-OXINE can be estimated from the sorption of MgP_2 on the parent polymer XAD-2. The sorbent XAD-OXINE has a relatively small fraction of its sur-

[a] From eq. [2]: $(P.A.)_{\text{sorbed},MgP^+} = (P.A.)_{\text{sorbed}} - (P.A.)_{\text{sorbed},Mg^{2+}} - (P.A.)_{\text{sorbed},MgP_2}$.
[b] $[MgP^+]$ calculated from theory using COMICS program.

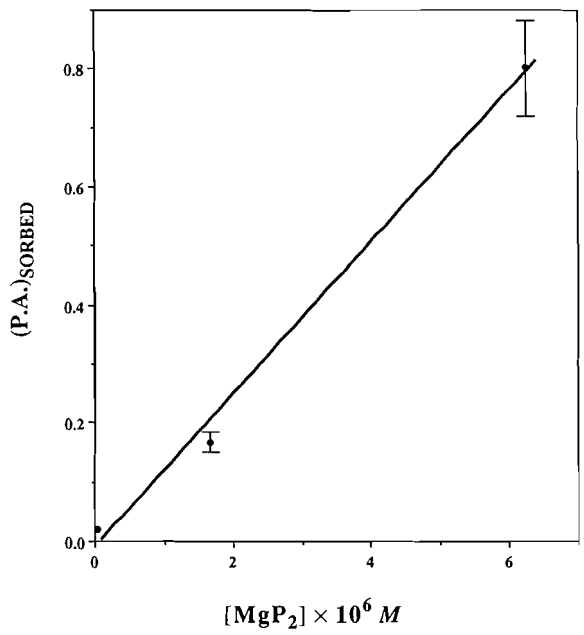

FIG. 1. Sorption of magnesium-containing species, as peak area (P.A.) of sorbed magnesium, on the parent polymer XAD-2 as a function of the concentration of the species MgP_2 in solution, at pH = 6.00 and ionic strength 0.25_0.

face occupied by covalently attached oxine groups, (i.e., for a complexing capacity of 264 μmol/g, only about 20% of the benzene rings at the surface of the styrene–DVB copolymer have attached oxine). Therefore, in terms of its adsorption of the neutral species MgP_2, the XAD-OXINE is expected to behave quantitatively much like XAD-2 (12, 13). As a consequence, if identical sample solutions containing magnesium and picolinate are passed through columns of XAD-OXINE and XAD-2, containing the same amount of sorbent, then the value of $(P.A.)_{\text{sorbed},MgP_2}$ to be used in eq. [2] for XAD-OXINE can be taken to be the same as the value found for XAD-2, because the latter sorbs MgP_2 but not MgP^+ or Mg^{2+}.

Since it is possible, independently, to know the values of $(P.A.)_{\text{sorbed, } Mg^{2+}}$ and $(P.A.)_{\text{sorbed},MgP_2}$ to be used in eq. [2], then it is possible to know whether and to what extent the species MgP^+ is sorbed on XAD-OXINE. Presented in column 3 of Table 3 are experimentally measured values of $(P.A.)_{\text{sorbed}}$ that were obtained at two different pH's when solutions containing constant $C_{\text{picolinic acid}} = 0.050_0$ M and varied C_{Mg} were equilibrated with XAD-OXINE; presented in column 4 are values of $(P.A.)_{\text{sorbed},Mg^{2+}}$ that were read from the experimentally measured Mg^{2+} isotherms on XAD-OXINE at the appropriate $[Mg^{2+}]$; and presented in column 5 are values of $(P.A.)_{\text{sorbed},MgP_2}$ that were obtained by equilibrating the sample solution with the XAD-2 column. The sixth column presents values of $(P.A.)_{\text{sorbed},MgP^+}$ obtained by subtracting $(P.A.)_{\text{sorbed},Mg^{2+}}$ and $(P.A.)_{\text{sorbed},MgP_2}$ from $(P.A.)_{\text{sorbed}}$, as per eq. [2]. The last column shows $[MgP^+]$ values for the solution, obtained by theoretical calculations. Plots were made of $(P.A.)_{\text{sorbed},MgP^+}$ versus $[MgP^+]$ at pH 6.00 and 7.50, respectively. The former plot is shown in Fig. 2. These plots correspond to sorption isotherms for the species MgP^+ on XAD-OXINE.

Both isotherms for MgP^+ are linear. At pH 6.00 the slope is 0.25 ± 0.01 (intercept 0.01 ± 0.02; $r = 0.998$) and at pH

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12

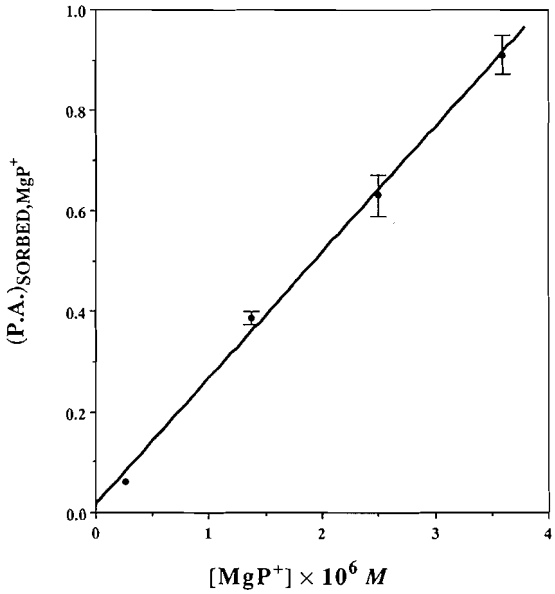

FIG. 2. Sorption of MgP^+, as peak area (P.A.) due to sorbed MgP^+ on XAD-OXINE as a function of the concentration of MgP^+ in solution, at pH 6.00 and ionic strength 0.25_0.

7.50 it is 0.92 ± 0.04 (intercept 0.03 ± 0.03; r = 0.998). A greater slope for the isotherm at higher pH means that the cationic species MgP^+ is sorbed more strongly on XAD-OXINE as a result of an increase in the degree of ionization of the covalently bound oxine to form its anion oxinate. Increased sorption of a cationic sample species as the result of an increase in negative surface-charge density is qualitatively consistent with the theoretical predictions of the "double-layer ionic adsorption and exchange model" (13, 28, 29). *Quantitative* evaluation of the sorption of MgP^+ on XAD-OXINE in terms of this theoretical model is not possible at this time because it was not possible accurately to measure the surface-charge density on XAD-OXINE (22).

Conclusions

On the parent polymer, XAD-2, the hydrophobic, neutral species MgP_2 is sorbed (undoubtedly by the process of surface adsorption) while the charged species Mg^{2+} and MgP^+ are not significantly sorbed compared to MgP_2.

On the derivatized polymer, XAD-OXINE, all three magnesium-containing species Mg^{2+}, MgP^+, and MgP_2 are sorbed. Sorption of the hydrophilic metal ion Mg^{2+} on XAD-OXINE is likely the result of complexation by the bound ligand oxinate. Sorption of the hydrophobic, neutral species MgP_2 is very likely due to the process of surface adsorption on the extensive styrene–DVB polymer surface that is available in XAD-OXINE. Sorption of the hydrophobic cationic species MgP^+ on XAD-OXINE is probably due to a combination of adsorption on the polymer surface and cation exchange in the diffuse part of the electrical double layer (13, 28, 29). However, the possibility of sorption of MgP^+ as a result of the formation of a mixed-ligand complex of magnesium with picolinate and bound oxine cannot be ruled out.

The relative strengths of sorption on XAD-OXINE for the species Mg^{2+}, MgP^+, and MgP_2 at ionic strength c = 0.25 and pH 6.00 and 7.50 can be seen from the relative (P.A.) values in Table 3. Sorption strength for MgP_2 will be relatively independent of c and pH but sorption strength for both Mg^{2+} and MgP^+ will increase markedly with increasing pH and with decreasing ionic strength.

The $\tilde{a}^3A'' \leftarrow \tilde{X}^1A'$ electronic spectra of acetaldehyde-h_4 and -d_4

N. N. YAKOVLEV AND I. A. GODUNOV[1]

The Laboratory of Molecular Spectroscopy, Department of Chemistry, Moscow M. Lomonosov State University, Moscow W-234, 119899, Russia

Received July 11, 1991

N. N. YAKOVLEV and I. A. GODUNOV. Can. J. Chem. **70**, 931 (1992).

The $\tilde{a}^3A'' \leftarrow \tilde{X}^1A'$ electronic absorption spectra of acetaldehyde-h_4 and -d_4 were recorded in the vapour phase at room temperature. The major experimental requirement was a high pressure × path length (650 Torr × 140 m). The vibrational structure of these electronic transitions was interpreted in terms of the torsional modes ν'_{15} and ν''_{15} attached to the ν'_{14} out-of-plane bending mode. The main CH_3CHO results agreed with those obtained earlier (Moule and Ng); the values of the 0_0^0 transition and torsional barrier height were 27240.1 and 590 cm^{-1} respectively. Three inversion (out-of-plane bending) energy levels in the excited $\tilde{a}^3A''$ state were found and the inversion potential function was determined with a barrier height of 1110 cm^{-1}. The CD_3CDO spectrum confirmed the CH_3CHO analysis. The values of the 0_0^0 transition and torsional barrier height were equal to 27270 and 610 cm^{-1}.

Key words: vibronic spectrum, acetaldehyde, molecular structure.

N. N. YAKOVLEV et I. A. GODUNOV. Can. J. Chem. **70**, 931 (1992).

Opérant à la température ambiante, on a déterminé les spectres d'absorption électronique $a^3A'' \leftarrow X^1A'$ des acétaldéhydes-h_4 et -d_4 en phase gazeuse. La condition expérimentale principale est une valeur élevée de la pression × longueur de parcours (650 Torr × 140 m). On a interpréte la structure vibrationnelle de ces transitions électroniques en fonction des modes de torsion ν'_{15} et ν''_{15} attachés au mode de déformation hors-plan ν'_{14}. Les principales caractéristiques du spectre du CH_3CHO sont en bon accord avec celles obtenues antérieurement (Moule et Ng); les valeurs de la transition 0_0^0 et la hauteur de la barrière de torsion sont respectivement égales à 27240,1 et 590 cm^{-1}. On a observé trois niveaux d'inversion de l'énergie (déformation hors-plan) dans l'état excité a^3A'' et on a trouvé que le hauteur de la barrière de la fonction du potentiel d'inversion est égale à 1110 cm^{-1}. Le spectre du CD_3CDO confirme l'analyse du spectre du CH_3CHO. Les valeurs de la transition 0_0^0 et de la hauteur de la barrière de torsion sont égales à 27270 et 610 cm^{-1}.

Mots clés : spectre de vibration, acétaldéhyde, structure moléculaire.

[Traduit par la rédaction]

Introduction

The $\tilde{a}^3A'' \leftarrow \tilde{X}^1A'$ electronic absorption spectrum of acetaldehyde-h_4 in the vapour phase at room temperature was investigated earlier by Moule and Ng (1). This spectrum was interpreted in terms of the torsional modes ν'_{15} and ν''_{15} attached to the ν'_{14} out-of-plane C—H bending mode. Both modes were highly Franck–Condon active and their intensity distributions suggested that: (*i*) the methyl group undergoes a rotation from an $\tilde{X}^1A'$ eclipsed conformation to an $\tilde{a}^3A''$ staggered conformation and (*ii*) the aldehyde -CHO group is nonplanar in the $\tilde{a}^3A''$ state. The 0_0^0 band at 27240.4 cm^{-1} was not directly observed because of low intensity.

However Moule and Ng (1) failed to determine the inversional potential because of insufficient experimental data. Because they used a cell with a large volume, it was not possible for them to record the spectra of the isotopic species. Therefore we have investigated the $\tilde{a}^3A'' \leftarrow \tilde{X}^1A'$ spectra of both CH_3CHO and CD_3CDO.

Experimental

The CH_3CHO and CD_3CDO used were of 99.0 and 99.5% purity, respectively. CD_3CDO contained ≥98% of deuterium. Both samples were purified by vacuum trap-to-trap distillation.

The spectra were photographically recorded on a DFS-452 spectrograph in the 1st order of holographic grating (2400 lines per mm) at a modest resolution of 120 000. Pathlengths of up to 140 m at 20°C were obtained with a 2.5 m stainless steel Whytetype multipath cell for vapour pressures up to 650 Torr (1 Torr = 133.3 Pa). A XBO-250 W xenon arc was the light source and a BS-10 glass filter was used to isolate the far-UV radiation. Calibration was made with the iron lines of an iron–neon hollow cathode lamp. Absorption intensities were estimated from tracings of the spectra recorded with a IFO-451 microdensitometer. Line positions were directly measured on spectograms with a IZA comparator. The accuracy of the measurements was ~0, 5 cm^{-1} for CH_3CHO and ~1.0 cm^{-1} for CD_3CDO. The CH_3CHO bands are fairly sharp and single-headed. The CD_3CDO bands are less intense, broader, and double-headed with a separation of ~7 cm^{-1}. The heads of the lower frequency components were measured.[2]

Results and discussion

The key to the analysis of the acetaldehyde-h_4 and -d_4 spectra was the same as in ref. 1. Using the torsional transitions in $\tilde{X}^1A'$ states from microwave and far infrared (2, 3) spectra, we assigned selected bands to the torsional $15^0_{v''}$ vibronic transitions. Then taking into account the results of the analyses of acetaldehyde $-h_4$ and $-d_4$ $\tilde{A}^1A'' \leftarrow \tilde{X}^1A'$ spectra (4, 5) we assigned some bands to the torsional $15_0^{v'}$ and $15^{v'}_{v''}$ transitions. After that we established the 0_0^0 transition wavenumbers of acetaldehyde-h_4 and -d_4 as 27240.1 and 27270 cm^{-1}, respectively, using the 15^{0A}_{2A}, 15^{2A}_{2A}, and 15^{2A}_{0A} transitions for CH_3CHO and also the 15^{0E}_{1E}, 15^{1E}_{1E}, and 15^{1E}_{0E} transitions for CD_3CDO (the 0_0^0 transitions were not directly observed). Thus for each isotopic species we found the group of strong bands ("pattern") that accompanied the "origin"

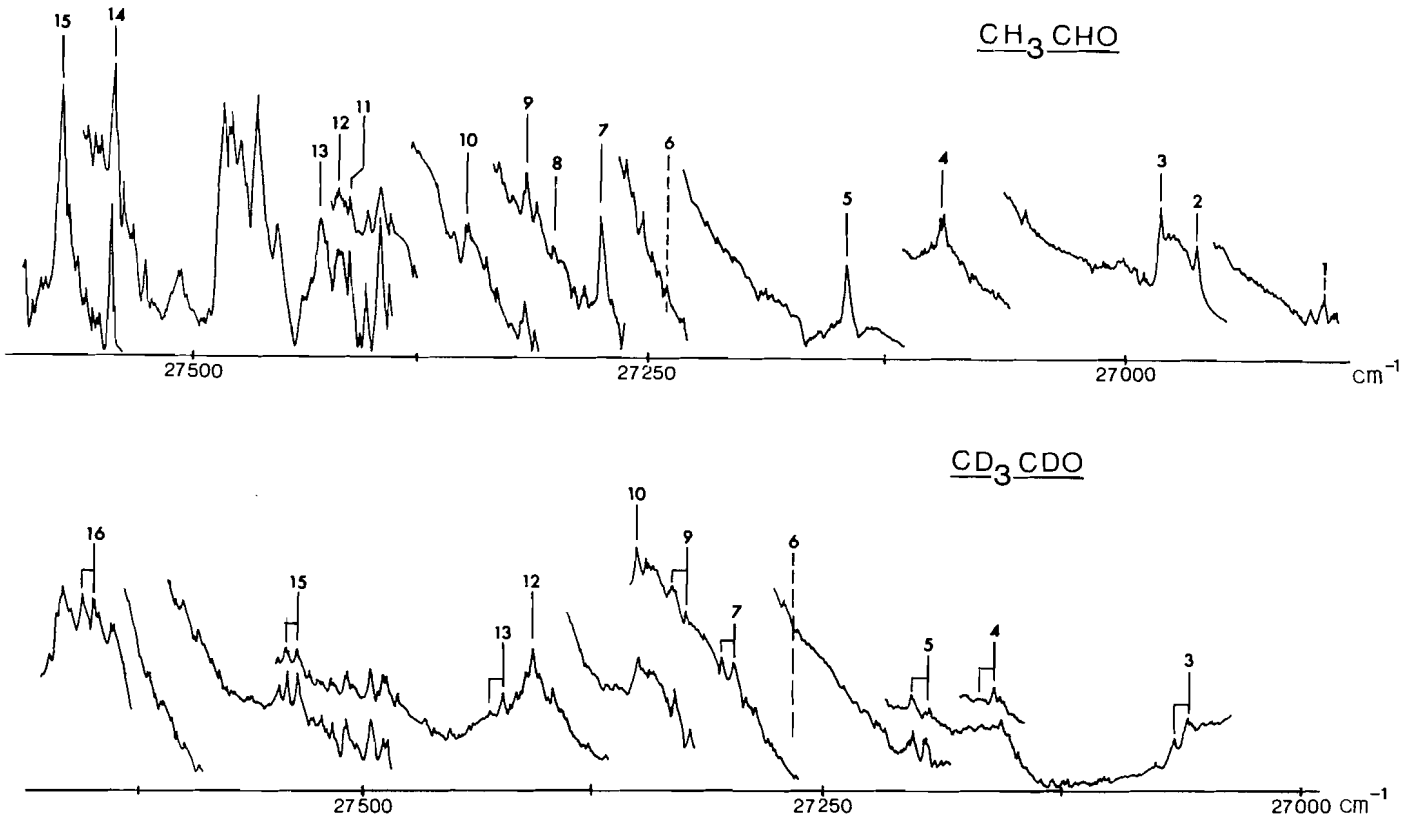

FIG. 1. The UV absorption spectra of acetaldehyde-h_4 and -d_4 near the 0_0^0 transitions. (Band numbers are the same as in Table 1)

(0_0^0) of the electronic $\tilde{a}^3A'' \leftarrow \tilde{X}^1A'$ transition (see Table 1 and Fig. 1). The figure shows that the most intensive bands correspond to the 15_{0A}^{2A} transition in the CH_3CHO spectrum and the 15_{0E}^{1E} transition in the CD_3CDO spectrum.

We also found several of the same patterns that accompany the "pseudoorigins" listed in Table 2 with their possible assignments. One can see from Table 2 that three inversion energy levels in the excited triplet electronic state have been found for CH_3CHO and it is rather difficult to assign these "pseudoorigins" differently (the possibility of their assignments to the $A^1A'' \leftarrow \tilde{X}^1A'$ system has also been considered).

[b]$K_1 = 855.36\ cm^{-1}\ Å^{-2}$, $k_1 = 2688.69\ cm^{-1}$, $k_2 = 1.31\ Å^{-2}$, see potential, eq. [1].
[c]Calculated with the data from ref. 4 using the method presented in ref. 10.
[d]The out-of-plane angle Θ corresponds to the minima of the potential, eq. [1].

The parameters of the inversional potential

$$[1] \quad V(Z) = K_1Z^2 + k_1 \exp(-k_2Z^2)$$

where Z is the out-of-plane oxygen displacement, have been determined by the method of Ueda and Shimanouchi (7) for this molecule. Strictly speaking, the -CHO group has a pyramidal structure in the acetaldehyde equilibrium configuration in the lowest excited singlet S_1 and triplet T_1 electronic states. Such -CHO group "deformation" of the planar structure in the ground S_0 electronic state of acetaldehyde was approximated by an out-of-plane C—H bond displacement (1, 4). In this case the CCH angle was decreased and the CCO angle was fixed. But we could not obtain the rotational constants listed in ref. 4 for acetaldehyde-h_4 in the S_1 state with geometric parameters from "model *ii*" (4). Instead of $A' = 1.649$, $B' = 0.338$, and $C' = 0.300\ cm^{-1}$ (4) we obtained $A' = 1.842$, $B' = 0.317$, and $C' = 0.288\ cm^{-1}$, but the rotational contours of the acetaldehyde-h_4 vibronic bands 0_0^0, 14_0^1 (A_1, E), 15_0^2 (A_1, E) calculated with these rotational constants were far from the experimental ones listed in ref. 4. However, calculated and experimental vibronic band rotational contours of CH_3CHO and CH_3CDO spectra (4) agree well if we use the geometric parameters derived from the microwave spectrum (8), except r(C=O) = 1.316 Å and the out-of-plane C=O bond displacement angle $\Theta = 37.5°$ (with $\angle CCO = 116.2°$). In fact, only the planar $CCH_{ald.}$ and CCO angles differ from those of "model *ii*" (4).

For acetaldehyde in the T_1 state, we assume the geometric parameters to be the same as in the S_1 state, except for the Θ angle. We take this angle as the minimum of the potential, eq. [1]. The calculated parameters of the potential, eq. [1], are listed in Table 3. The inversion potentials of acetaldehyde-h_4 and -d_4 in the S_1 state and those of formaldehyde-h_2 and -d_2 in the S_1 and T_1 states (9) are also listed in Table 3. We assume that the inversion potentials of acetaldehyde-h_4 and -d_4 in the T_1 state are approximately the same, and we calculate the inversion energy levels of CD_3CDO, Table 3. Using the data, we assign the 441 cm^{-1} frequency found in the CD_3CDO spectrum (Table 2) to the inversion level 14^{1+} or 14^{1-}. Taking into account that the 14_0^{1+} transition is more intense than the 14_0^{1-} transition in the CH_3CHO spectrum, we tentatively assigned the CD_3CDO 441 cm^{-1} frequency to the 14^{1+} level. Because of low intensity, we could not observe the transitions to higher inversional levels in the CD_3CDO spectrum and thus could not assign this frequency definitely.

One can see from Table 3 that the acetaldehyde inversion barrier in the T_1 state is approximately twice that in the S_1 state

[b]Assumed.

and the Θ equilibrium value in the T_1 state is about 8° larger than in the S_1 state. Similar relations are observed for formaldehyde, see Table 3.

We mentioned above that the vibronic bands in the CD_3CDO spectrum were double-headed with a separation of about 7 cm^{-1}. Such contours seem to be part of the vibronic band rotational contours. We also investigated the possibility of assigning the 7 cm^{-1} frequency to the inversion splitting $14^{0-}(0^{0-}) - 0^{0+}$. From the T_1 inversion potentials for CH_3CHO and CD_3CDO and the assignment of the 503 cm^{-1} frequency in the CH_3CHO spectrum to the 14^{1+} level (Table 2), we calculate an inversion splitting of 41–45 cm^{-1} for CH_3CHO by the method of Coon *et al.* (10). As such intervals are not observed in the CH_3CHO spectrum, this hypothesis has been rejected.

Using the torsional levels obtained from the spectral analysis, we determined the T_1 internal rotation potential functions

$$[2] \quad V(\varphi) = \frac{1}{2}[V_3(1 - \cos 3\varphi) + V_6(1 - \cos 6\varphi)]$$

for acetaldehyde-h_4 and -d_4 by the method of Lewis *et al.* (11), Table 4. The reduced rotational constants F listed in Table 4 are calculated with the help of geometric parameters obtained for the inversional potential (microwave parameters (7) but r(C=O) = 1.316 Å, ∠ Θ = 45° with ∠CCO = 113.2°). One can see from Table 4 that these internal rotational potentials are in good agreement both with each other and with the potential determined for CH_3CHO by Moule and Ng (1).

Conclusions

The results of the $\tilde{a}^3A'' \leftarrow \tilde{X}^1A'$ spectral analysis for acetaldehyde-h_4 and -d_4 agree well with each other and confirm the earlier analysis (1) reported for acetaldehyde-h_4. We obtain three inversion levels and determine the inversion potential of CH_3CHO in the excited T_1 triplet state. The T_1 state inversion barrier is approximately twice that of the S_1 state. A similar result was obtained earlier for formaldehyde (9).

Study of the dissociation of the products of some proton transfer reactions in acetonitrile solvent

WLODZIMIERZ GALEZOWSKI[1] AND ARNOLD JARCZEWSKI
Faculty of Chemistry, A. Mickiewicz University, Grunwaldzka 6, 60-780 Poznan, Poland

Received April 17, 1991

WLODZIMIERZ GALEZOWSKI and ARNOLD JARCZEWSKI. Can. J. Chem. **70**, 935 (1992).

The conductometric study of the products of the proton transfer reactions of C-acids (nitriles, nitroalkanes, and 2,4,6-trinitrotoluene) with the strong amine bases (1,1,3,3-tetramethylguanidine (TMG), 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), 1,8-bis(dimethylamino)naphthalene (DMAN), and piperidine) in acetonitrile shows their large degree of dissociation into free ions. The dissociation constant values have been estimated at 25°C to be larger than 1×10^{-4} M. This weakens the formalism commonly accepted in spectrophotometric kinetic studies of these systems of reactions, based on the assumption that the product is an ion pair. Spectrophotometric equilibrium and kinetic measurements provided evidence that reverse reaction is a second-order process (pseudo-first order because cation concentration is controlled by side reactions). The influence of the common cation ($TMGH^+$) on the equilibria of the proton abstraction from 2-methyl-1-(4-nitrophenyl)-1-nitropropane and 4-nitrophenylcyanomethane with TMG base in acetonitrile at 25°C was examined and was found to be compatible with the assumption of large dissociation of the reaction product for free ions. "Equilibrium constants" estimated by the Benesi and Hildebrand method (which assumes an ion-pair product) decreased with increasing concentration of added $TMGH^+$ cation, but these "equilibrium constants" multiplied by $[TMGH^+]$ are constant. The observed pseudo-first-order rate constants of the proton transfer reaction, measured at large excess of the base over C-acid, grow with the cation concentration due to the increase of the backward reaction rate. The concentration of added common cation shows a negligible influence on the observed rate constants of deuteron transfer reaction. Thus, as a result of side reactions, in which extra amounts of cation are formed, some second-order rate constants k_f^H and also kinetic isotope effects (KIEs) (k_f^H/k_f^D) that have been measured in acetonitrile can be substantially overestimated.

Key words: ion-pair dissociation, proton transfer reactions, kinetic isotope effects.

WLODZIMIERZ GALEZOWSKI et ARNOLD JARCZEWSKI. Can. J. Chem. **70**, 935 (1992).

Une étude conductométrique des produits de réactions de transfert de protons d'acides C (nitriles, nitroalcanes et 2,4,6-trinitrotoluène) avec des bases fortes aminées (1,1,3,3-tétraméthylguanidine (TMG), 1,8-diazabicyclo[5.4.0]undéc-7-ène (DBU), 1,8-bis(diméthylamino)naphtalène (DMAN) et pipéridine) dans l'acétonitrile montre qu'ils sont fortement dissociés en ions libres. À 25°C, on a évalué que les constantes de dissociation sont plus grandes que 1×10^{-4} M. Ces résultats affaiblissent le formalisme généralement accepté dans les études cinétiques spectrophotométriques de ces systèmes de réactions, qui est basé sur l'hypothèse que le produit est une paire d'ions. L'équilibre spectrophotométrique et les mesures cinétiques fournissent des données suggérant que la réaction inverse est du deuxième ordre (pseudo-premier ordre parce que la concentration des cations est contrôlée par des réactions parasites). Opérant à 25°C, dans l'acétonitrile, on a examiné l'influence du cation commun ($TMGH^+$) sur l'équilibre de la réactions d'enlèvement du proton du 2-méthyl-1-(4-nitrophényl)-1-nitropropane et du 4-nitrophénylcyanométhane par la base TMG et on a trouvé que cette influence est compatible avec l'hypothèse d'une importante dissociation des produits de réaction en ions libres. Les «constantes d'équilibre» évaluées par la méthode de Benesi et Hildebrand (qui fait l'hypothèse que le produit est une paire d'ions) diminuent avec une augmentation de la concentration de cation $TMGH^+$ ajoutée; toutefois, ces «constantes d'équilibre» multipliées par $[TMGH^+]$ sont constantes. Les constantes de vitesse du pseudo-premier-ordre observées pour la réaction de transfert de proton, mesurées avec un grand excès de base par rapport à l'acide C, augmentent avec la concentration de cation; ce résultat est dû à l'augmentation de la vitesse de la réaction en retour. La concentration du cation commun ajouté ne présente qu'une influence négligeable sur les constantes de vitesse observées pour la vitesse de transfert de deutéron. À cause de réactions secondaires dans lesquelles il se forme des quantités supplémentaires de cations, il est donc possible que les constantes de vitesse du deuxième ordre, k_f^H, qui ont été mesurées ainsi que les effets isotropiques cinétiques (EIC) (k_f^H/k_f^D) qui ont été mesurés dans l'acétonitrile soient substantiellement surestimées.

Mots clés : dissociation de paires d'ions, réactions de transfert de proton, effets isotropiques cinétiques.

[Traduit par la rédaction]

Introduction

The proton transfer reactions between C-acids of various structures and strong amines in aprotic solvents have been extensively studied for many years (1–10). The kinetics of these systems of reactions were mostly carried out spectrophotometrically, taking advantage of the fact that the ionic products formed after abstraction of the proton have large absorption coefficients in the visible range of the spectrum. The particularly important parameter obtained from these kinetic studies was the primary deuterium kinetic isotope effect (KIE), which appeared to be a useful tool in determining the mechanism of the proton transfer and also the magnitude of the tunnel effect (2, 3, 10, 11).

The kinetic studies of these reactions were performed in a variety of solvents, mostly aprotic solvents, of different polarity (2, 10–13), since Caldin and Mateo predicted that the value of KIE is strongly dependent on the polarity of the solvent in which the proton transfer reaction has been carried out (2, 12). They predicted that in high-polarity solvents the proton transfer was coupled with the motion of the molecules of the solvent, which reduced the effective deuteron/proton mass ratio, consequently decreasing the KIE value (2). Therefore, low-polarity solvents seemed to fa-

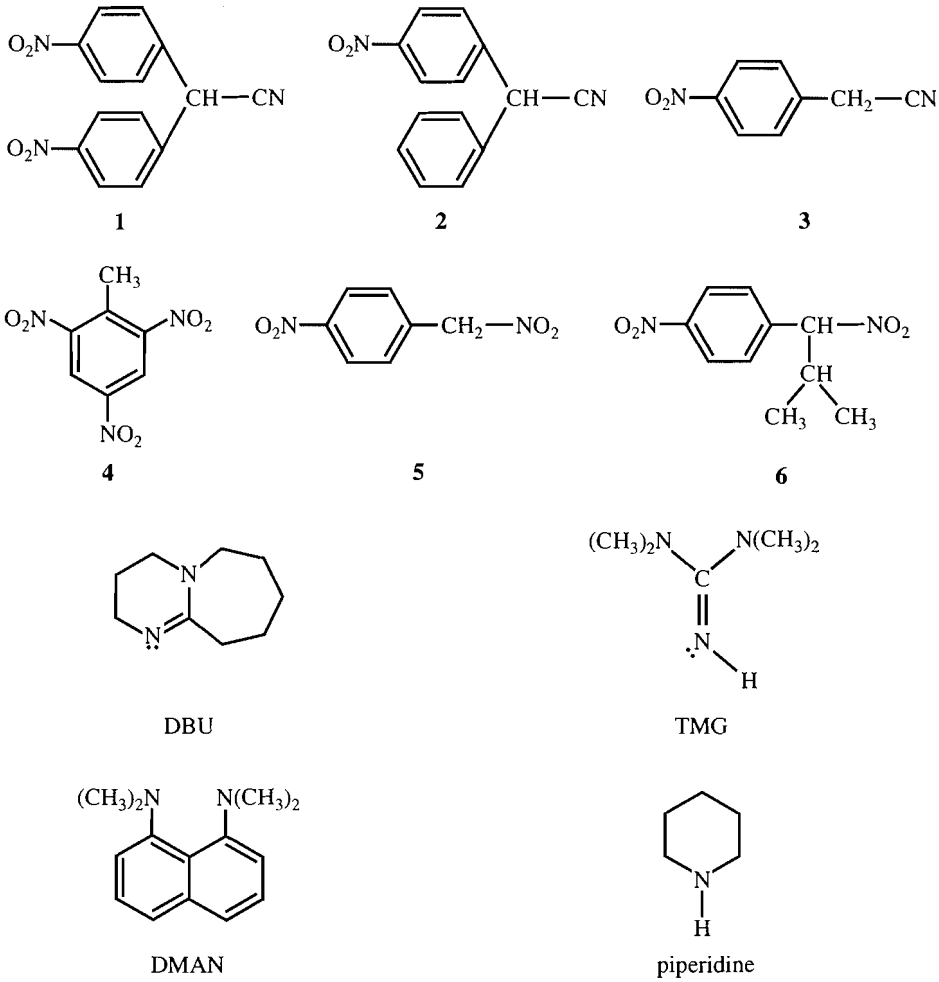
For personal use only.

vour large KIE values by the "uncoupled mechanism" (14, 15). Consequently for comparison, kinetic experiments were performed in both low- and high-polarity aprotic solvents (10, 14, 16). However, very frequently, the equilibrium constants for the ionogenic proton transfer reactions were too small in low-polarity solvents, constraining kinetic measurements to high-polarity solvents, mostly acetonitrile (8–10).



On the basis of the fit of the experimental equilibrium data to the Benesi and Hildebrand equation (1) the products were claimed to be ion pairs, unexpectedly for both groups of low- and high-polarity solvents (1, 2). However, in our previous paper (14) we proved that the products of some proton transfer reactions between 1-(4-nitrophenyl)-1-nitroalkanes and DBU or TMG carried out in acetonitrile solvent are dissociated to free ions, showing that the Benesi and Hildebrand method is frequently not reliable in these systems of reactions.

The estimation of the degree of dissociation of the product for a reaction of a C-acid with a strong organic base in acetonitrile is crucial for determining the kinetic equation. This is of particular importance for the reactions of nitrophenylcyanoalkanes, which have relatively large pK_a values in comparison with nitrophenylnitroalkanes, reacting with a similar rate constant (8–10, 17). The reactions of nitriles, with small equilibrium constants, present an interesting system in which the KIE values are close to a maximum around $\Delta G_0 = 0$.

The use of the correct kinetic equation has a fundamental significance for the results of kinetic experiments and their interpretation. Therefore, the intention of this work is to estimate the degree of dissociation of the products of some proton transfer reactions for a larger number of C-acids and bases in acetonitrile solvent, and also to discuss the possible implications on the results of spectrophotometric equilibrium and kinetic measurements, as we believe that the effect of the common cation derived from the reacting base has a considerable impact on kinetic and equilibrium parameters.

Results and discussion

Conductometric measurements

Proton transfer reactions between C-acids and amines give ion-pair products that can dissociate to free ions depending

$$AH + B \underset{}{\overset{K_r}{\rightleftharpoons}} A^-, BH^+ \overset{K_d}{\rightleftharpoons} A^- + BH^+$$

SCHEME 1

TABLE 1. Results of conductance studies of proton transfer between various C-acids and amine bases in acetonitrile at 25°C showing very large ionization and dissociation of the reaction product

System	$10^2 C_B$ (mol dm^{-3})	Onsager slope	Λ_0 (Ω^{-1} cm^2 mol^{-1})
1 + DBU	2.67–9.64	293–394	134–138
1 + TMG	2.58–9.33	329–414	145–150
1 + piperidine	2.58–9.33	357–448	139–145
2 + DBU	2.67–9.64	407–735	140–155
2 + TMG	2.62–9.48	560–659	155–160
4 + DBU	2.67–9.64	294–363	149–155
4 + TMG	2.63–9.48	376–525	160–164

on the polarity of the solvent used (1, 16) (Scheme 1),[2] where AH = C-acid, B = base, A^-, BH^+ = ion pair, A^- and BH^+ are free ions. Kinetic measurements on these reactions are always carried out in a large excess of the base concentration over the reacting C-acid, to assure pseudo-first-order conditions (1–10, 12–14). Therefore in the present work conductometric experiments were performed under similar conditions.

For all reactions of **1**, **2**, and **4** with DBU and TMG and the reaction of **1** with piperidine in a given concentration range (Table 1) the plots of Λ vs. $C_{AH}^{1/2}$ gave reasonable values of Λ_0. As an example, for the reaction of **4** with TMG the Λ_0 ranging between 160 and 164 is close to that of tetramethylguanidinium picrate, which is equal 161 (18). The experimental Onsager slopes (18) shown in Table 1 are not far from theoretical values, indicating both a very extensive ionization of C-acid and dissociation of the resulting salt into free ions. (Those theoretical Onsager slopes in acetonitrile at 25°C vary from 320 to 380 depending on particular Λ_0.)

No correction for conductivity of contaminants or solvolysis products of amine bases was applied. A simple subtraction of the conductivity of the base solution was not satisfactory, leading in some cases even to a slight increase in Λ with C-acid concentration. The specific conductivity κ_0 of the solutions of the bases in MeCN solvent increases with base concentration and is larger for the stronger bases DBU (pK_a in acetonitrile at 25°C = 23.9 (19), $\kappa_0 = (5–10) \times 10^{-6}$ Ω^{-1} cm^{-1} in the concentration range 0.02–0.08 M) and TMG (pK_a = 23.3 (20); $(2–4) \times 10^{-6}$ Ω^{-1} cm^{-1}, 0.03–0.1 M) and smaller for weaker bases DMAN (pK_a = 18.3;[3] $(2–3) \times 10^{-7}$ Ω^{-1} cm^{-1}, 0.05–0.18 M) and piperidine (pK_a = 18.9 (21); $(4–10) \times 10^{-7}$ Ω^{-1} cm^{-1}, 0.04–0.13 M)).

Conductometric measurements in the solutions of strong amine bases in acetonitrile show poor reproducibility due to unavoidable contaminants (22). We also found in our study

[2]The alternative scheme, in which free ions are initially formed from reactants (with following ion-pairing), is experimentally indistinguishable from Scheme 1 presented in this paper and leads to basically the same conclusions.

[3]K. T. Leffek and P. Pruszynski, personal communication.

that, despite of all precautions taken, these specific conductivities varied with a new batch of solvent or amine base used (the κ_0 values shown above are the lowest we achieved). Therefore, although a correction for solvolysis of amine bases could be made by employing pK_a values of amine base and the autoprotolysis constant of acetonitrile (22), it is hard to account for variable amounts of unknown impurities, that unfortunately affect the conductivity of the systems under study quite strongly.

Accordingly, for data analysis of systems behaving like weak electrolytes, not listed in Table 1, a simple treatment was applied in which effects of interionic forces on mobility and thermodynamic potential were neglected. Under these assumptions the conductivity of the reaction products is described by eq. [1], which is analogous to the Kraus and Bray equation (14, 23):

$$[1] \quad 1/\Lambda = 1/\Lambda_0 + C_{AH}\,\Lambda/(K_{ef}\Lambda_0^2)$$

where C_{AH} is the total concentration of C-acid, Λ is the equivalent conductivity, and Λ_0 is the limiting equivalent conductance. The effective equilibrium constant, K_{ef}, is described by eq. [2]:

$$[2] \quad 1/K_{ef} = 1/K_d + 1/(K_r K_d C_B)$$

where K_r and K_d are defined in Scheme 1, and C_B is the base concentration in large excess over C_{AH}. From eq. [2], K_d and K_r values can be estimated using the relation $1/K_{ef}$ vs. $1/C_B$.

The K_{ef} values obtained from the Kraus and Bray formalism (plot $1/\Lambda$ vs. $C_{AH}\Lambda$) are collected in Table 2. They represent the lower limit of dissociation constants of the ion pairs, K_d (14).

The values of K_r and K_d for the reaction of **3** with DBU (Table 3) were estimated using the relation $1/K_{ef}$ vs. $1/C_B$. In the case of the reactions of **2** and **5** with DMAN the plot of $1/(K_{ef}\Lambda_0^2)$ vs. $1/C_B$ was used (eq. [3]), due to the large standard deviations of Λ_0 affecting the accuracy of K_{ef}.

$$[3] \quad 1/(K_{ef}\Lambda_0^2) = 1/(K_d\Lambda_0^2) + 1/(K_d\Lambda_0^2 K_r C_B)$$

The experimental data fitted to eq. [3] showed excellent correlation coefficients. The K_d values were then calculated from the initial intercepts and the mean values of Λ_0.

The reactions of **2** and **4** with piperidine (Table 2) show some irregularities as compared to other systems, since their

effective constants K_{ef} increase considerably faster than could be expected from the increase of the base concentration, which is not consistent with eq. [2]. This is particularly evident for the reaction of **2** over a wide range of piperidine concentration.

The simplest explanation of this phenomenon seems to be the interaction of the second molecule of piperdine with the cation, as shown in Scheme 2.

The formation of BHB^+ ions, known as a homoconjugation, is favoured by two factors: the low steric demands of the base, and by hydrogens available for hydrogen bonding (24). From the set of amines under investigation, piperidine demonstrates the strongest tendency to form homoconjugates. The homoconjugation constant for piperidinium cation, which is 25 M^{-1} (25), indicates that in the range of piperidine concentration (0.0186–0.623 M, Table 2) used, the equilibrium between piperidinium cation and its homoconjugated form can be observed. Both forms exist in comparable amounts for a concentration of piperidine equal to 1×10^{-2} M. With increasing concentration of piperidine above 10^{-2} M, the bulk of the piperidinium cation exists as the homoconjugate. Collaterally, the increase of the equilibrium constant and also a larger extent of dissociation of the ion pairs formed in the proton transfer reactions have been observed (Scheme 2) (24). Homoconjugation was a reason to omit the K_r and K_d values for the reactions of piperidine base with C-acids (Table 3). However, in these cases the considerable dissociation of the ion-pair product can be deduced from the K_{ef} values shown in Table 2.

The examination of the results leads to the conclusion that the smallest value of dissociation constant K_d found in this study is equal to 6.7×10^{-5} M (Table 3), which is comparable with the largest values of C-acid concentrations commonly used in kinetic or equilibrium experiments carried out by means of spectrophotometric methods (1–17, 26). Hence, the assumption that the products of these proton transfer reactions in acetonitrile solvent are ion pairs in the spectrophotometric range of C-acid concentration is not justified.

We would like to emphasize here that direct kinetic measurements are suitable only for reactions with fairly large equilibrium constants, which means the systems involving a rather strong C-acid and a strong base, such as those shown in Tables 1–3.

We believe that in acetonitrile solvent most proton transfer reactions from nitro or cyano group activated C-acids give products that are mostly dissociated into free ions; however, in the cases where the ability of charge delocalization is smaller, comparable amounts of both forms (ions and ion pairs) exist in equilibrium. This last case is particularly difficult with respect to interpretation of kinetic data. Both extreme cases, with the product fully dissociated to free ions or entirely in the form of ion pairs, are worthy of study.

Effect of common cation on the equilibria and kinetics of proton transfer reactions

Equilibria

The equilibrium data for the reaction of C-acids with amines (in a large excess over C-acid) in acetonitrile often fulfill the Benesi and Hildebrand eq. [4] (14).

$$[4] \quad C_{AH}/A = 1/\epsilon + 1/(\epsilon K_{Ben} C_B)$$

where A is the absorbance of the product (optical path length 1 cm), ϵ the molar absorptivity of the product, and K_{Ben} the "equilibrium constant" estimated by the Benesi and Hildebrand method. This agreement suggests that the product of the proton transfer reaction exists mainly as the ion pair, in contrast to the conclusions derived from conductometric measurements.

We partly discussed the possible reason for this discrepancy (14), indicating the effect of the common cation BH^+, which was formed in side reactions of strong amines with acetonitrile solvent and its acidic contaminants or brought in with amine base. In the present paper the spectrophotometric results supporting our assumptions are presented.

The concentration of BH^+ cations of a strong amine base (B) in acetonitrile solution increases with the concentration of the amine as can be seen from conductometric measurements of solutions of amines (κ_0 values quoted in preceding paragraph). However, it is difficult to estimate the real concentration of the BH^+ cations under conditions of spectrophotometric equilibrium or kinetic measurements. Therefore, the addition of a well-dissociated salt of the BH^+ cation allows control of its concentration over the whole range of measurements. For this purpose we used 1,1,3,3-tetramethylguanidinium picrate ($TMGH^+$ Pi^-) which is well dissociated in acetonitrile solvent (18).

As a working model we chose the reaction between 2-methyl-1-(4-nitrophenyl)-1-nitropropane (**6**) and TMG due to its moderate rate and the great resistance of the product to oxidation. The conductometric measurements show a large degree of dissociation of the product of this reaction in acetonitrile solvent.[4]

The equilibrium data for reactions of TMG with both **6** and **3**, with and without additions of tetramethylguanidinium picrate, fulfilled fairly well the Benesi and Hildebrand equation [4] (Tables 4 and 5), which could, as already mentioned, suggest a small degree of dissociation of the product into free ions. However, the resulting "equilibrium constants" K_{Ben} decreased considerably with increasing

[TMGH$^+$]. It is worthy of notice that the product of K_{Ben} and $C_{TMGH^+Pi^-}$ is constant. This result is in excellent agreement with the assumption of full dissociation of the ion pairs since in this case K and K_{Ben} are

$$[5] \quad K = \frac{[BH^+][A^-]}{[AH][B]}$$

and

$$[6] \quad K_{Ben} = \frac{K}{[BH^+]} = \frac{[A^-]}{[AH][B]}$$

The reason that eq. [6] is also fulfilled without the addition of common cation is that [BH$^+$] (the sum of BH$^+$ concentrations derived from both sources: the measured reaction, and from the environment) changes relatively slowly with the concentration of the base.

Employing the pK_a of TMG and K values from Tables 4 and 5, pK_a for **3** and **6** can be calculated. They are 25.4 and 25.9, respectively.

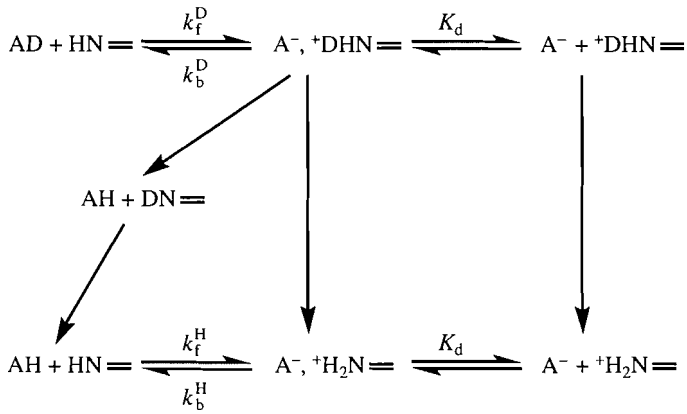
Kinetic experiments

Kinetics of the proton transfer reaction between **6** and TMG in acetonitrile without additions of tetramethylguanidinium picrate, for different concentrations of the TMG base (Table 6), fulfill the following equation:

$$[7] \quad k^H_{obs} = (k^H_f)_{app}C_{TMG} + k^*_b$$

where k^H_{obs} is the pseudo-first-order rate constant and $(k^H_f)_{app}$ the apparent second-order rate constant. The relation of k^H_{obs} against C_{TMG} showed relatively large intercepts, k^*_b; on the other hand the plots of k^D_{obs} vs. C_{TMG} for the deuteron transfer reaction (Table 7) pass through the origin, indicating that the A$^-$,TMGD$^+$ is a short-lived intermediate (Scheme 3) and D/H exchange in the C-acid is irreversible (k^D_b is much smaller than the sum of rate constants of all protonation reactions of the carbanion).

The reaction medium contains a sufficient excess of exchangeable protons over concentration of deuterated C-acid (C_{AD} = 2.5 × 10^{-5} M) to make the D/H exchange in C-acid



SCHEME 3

irreversible (27). There exist a number of sources of exchangeable protons, taking into account that well-dried TMG base still contains ca. 1% of water (28), and that the TMG molecule itself has an easily exchangeable proton, and also that well-dried acetonitrile solvent still contains 0.001% of water, which makes the concentration of exchangeable protons equal to ca. 1 × 10^{-3} M.

The assumption that the D/H isotopic exchange is much faster than internal return seems to be well justified, since the rate constants of internal return for the ion-pair products of the reactions of nitrophenylnitroalkanes in low-polarity solvents are relatively small, e.g., for the reaction of **6** with DBU in THF and chlorobenzene solvents they are about 1 s^{-1} (16). Since the rate constants of the reactions of C-acids with amines, as well as the equilibrium constant for ion-pair formation, are poorly dependent on the polarity of the solvent (14, 16), we can assume that the rate constant k^D_b(Scheme 3) of the reaction of **6** with TMG is of the same order of magnitude. Furthermore, when thermodynamic barriers are low, dissociation of the ion pairs, as well as D/H exchange in the TMGD$^+$ cation, are very fast processes (11). Therefore we can expect that the kinetics of the reaction of **6**-*d* with

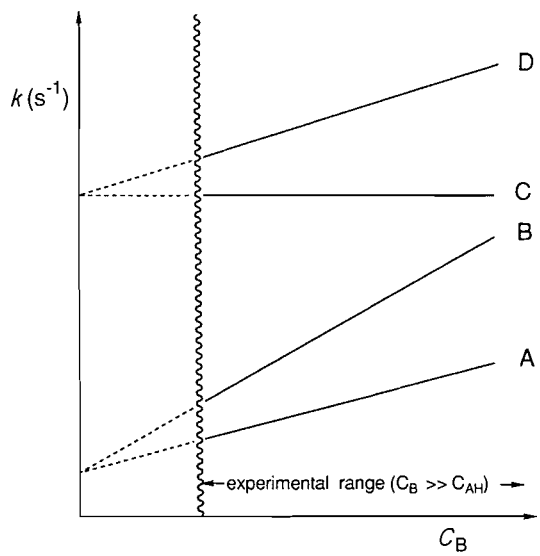

FIG. 1. The influence of BH^+ cations originating from side reactions on the measured values of second-order rate constants. A: $k = k_b = k^H_b K_d^{-1}[BH^+]$, eq. [10], no addition of common cation BH^+; $[BH^+]$ increases considerably with C_B (an arbitrary chosen linear function); B: $k = k^H_{obs} = k^H_f C_B + k_b$, eq. [9], otherwise as in A; slope = $(k^H_f)_{app} > k^H_f$; C: $k = k_b$, $[BH^+]$ = const. (the common cation BH^+ added, and assuming that side reactions contribute negligibly to $[BH^+]$ as a result of full suppression of dissociation of their products); D: $k = k^H_{obs} = k^H_f C_B + k_b$, otherwise as in C; slope = k^H_f.

TMG follows the scheme described by Melander and Saunders (27), with the Guggenheim or end-point method plots curved initially.

These small curved parts were discarded, and the resulting k^D_{obs} values plotted against C_B gave good straight lines with slopes k^D_f, fulfilling the following equation:

$$[8] \quad k^D_{obs} = k^D_f C_{TMG}$$

Melander and Saunders (27) assumed that $[BH^+]$ does not vary with time. This condition was fulfilled in our experiments with the addition of $TMGH^+Pi^-$ and was approximately true for experiments without this addition, since the common cation BH^+ is formed not only in the reaction between C-acids and TMG base, but also in the reaction of strong TMG base with acetonitrile solvent and acidic contaminants (22).

The effect of the common cation $TMGH^+$ on the kinetics of the proton transfer reaction

The data presented in Tables 6 and 7 support our assertion of a large dissociation of the products of proton transfer reactions in acetonitrile into free ions. The values of the apparent rate constants for backward reaction k^*_b increase with $C_{TMGH^+Pi^-}$ (Table 6). The increase of $C_{TMGH^+Pi^-}$ from 1×10^{-4} M to 2×10^{-4} M caused almost twofold increase of k^*_b, as was expected for complete dissociation of the ion pairs into free ions. Therefore, when k^H_{obs} is now described in terms of true, not apparent, rate constants, eq. [9] is valid:

$$[9] \quad k^H_{obs} = k^H_f C_{TMG} + k_b$$

where k^H_f is the second-order rate constant, and the rate constant of the reverse reaction k_b varies with $[BH^+]$ according to eq. [10]

$$[10] \quad k_b = k^H_b K_d^{-1}[TMGH^+]$$

where k^H_b is the rate constant of internal return within the ion pair (see Scheme 3). It is noteworthy that k_b depends on C_{TMG}, in contrast to k^*_b. The latter is simply an experimental initial intercept (eq. [7]), which has been erroneously considered to be equal to k^H_b.

The lack of a significant dependence of the second-order rate constant for the forward, deuteron transfer reaction, k^D_f, on $C_{TMGH^+Pi^-}$ (Table 7) suggests that the concentration of the salt does not particularly influence the rate constants. However, the data collected in Table 6 show that estimated rate constants $(k^H_f)_{app}$ decrease with increasing $C_{TMGH^+Pi^-}$.

This phenomenon seems to be a consequence of the salt effect on the rate of the backward reaction. The rate constant $(k^H_f)_{app}$ measured as a slope of the plot of k^H_{obs} against C_B without addition of $TMGH^+Pi^-$ is overestimated since $[TMGH^+]$ increases with the increase of TMG base concentration, amplifying k_b (Fig. 1).

As a consequence of too large values of $(k^H_f)_{app}$, and no influence of the backward reaction on the measured value of the rate constant of the deuteron transfer reaction, k^D_f, the values of the kinetic isotope effects $(k^H_f)_{app}/k^D_f$, entry for $C_{TMGH^+Pi^-} = 0$ in Table 7, are too large. The addition of $TMGH^+Pi^-$ reduces the error in k^H_f because dissociation of the side-reaction products is suppressed.

In conclusion, the spectrophotometrically measured equilibrium and rate constants for proton transfer reactions in acetonitrile show definite dependence upon the $TMGH^+$ cation concentration, which is in good agreement with our

previous assumption of a large degree of dissociation of the product for free ions (14). In the case of a proton transfer reaction characterized by a moderate equilibrium constant, the large excess of the base over C-acid is applied; then $[BH^+]$ from sources other than the examined reaction is dependent upon the concentration of the base. Hence, the measured second-order rate constants k^H_f can be overestimated. Since $[BH^+]$ does not affect significantly the estimated rate constants for the deuteron transfer reaction, k^D_f, the primary deuterium kinetic isotope effects k^H_f/k^D_f are overestimated.

The addition of the common cation BH^+ should make the rate constant of the backward reaction virtually independent of the concentration of the base. However, the resulting large increase in the rate constant of the reverse reaction is not very favourable to the accuracy of the k^H_f estimation. On the other hand, if the proton transfer reaction is characterized by a very large equilibrium constant, then the addition of a common cation is redundant, since in this case the backward reaction has a negligible influence on the observed rate constant k^H_{obs}.

Experimental

Acetonitrile

The commercial product, purchased from Apolda, was purified by the O'Donnell method (29) with a final, fractional distillation over P_2O_5. The distillation apparatus was flushed with argon to eliminate air. The quality of the solvent was characterized by the following parameters: absorbance at 200 nm < 0.1 (optical path length 1 cm), $\kappa < 1 \times 10^{-7}\ \Omega^{-1}\ cm^{-1}$.

C-acids

Bis(4-nitrophenyl)cyanomethane (**1**), 4-nitrophenylphenylcyanomethane (**2**), 2,4,6-trinitrotoluene (**4**), 4-nitrophenylnitromethane (**5**), and 2-methyl-1-(4-nitrophenyl)-1-nitropropane (**6**) were synthesized according to procedures already described (8, 17, 26, 14, respectively); 4-nitrophenylcyanomethane (**3**) was a commercial product from Eastman. The melting points and the spectra after recrystallization from ethanol were in accordance with the literature, except for bis(4-nitrophenyl)cyanomethane, mp 96.5–98°C, which was recrystallized from 1,2-dichloroethane/hexane mixture (lit. (8) mp 93–94.5°C).

2-Methyl-1-(4-nitrophenyl)-1-nitropropane-1-*d* was prepared as described earlier (16). The deuteration was completed to at least 99%, as judged from the NMR spectrum.

Amines

1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU), 1,1,3,3-tetramethylguanidine (TMG), and piperidine, commercial products (Aldrich), were dried over KOH pellets and then distilled in the apparatus flushed with argon. Both DBU and TMG were distilled under vacuum. 1,8-Bis(dimethylamino)naphthalene (DMAN), a commercial product (Aldrich), was recrystallized from ethanol; mp 48–49°C.

1,1,3,3-Tetramethylguanidinium picrate ($TMGH^+Pi^-$) was prepared according to a procedure described by Leffek *et al.* (19) (mp 128.5–129.5°C). The solutions of both C-acid and base were prepared from freshly purified reagents just before measurements. In the kinetic and equilibrium experiments $TMGH^+\ Pi^-$ was added to the C-acid solutions.

Conductivity measurements were carried out using a Tesla BM-484 semiautomatic conductivity bridge operating at 1592 Hz with a conventional, calibrated cell with platinum electrodes. The cell constant was 0.8744 cm^{-1}, determined in normal way (14). The cell was sealed to exclude atmospheric moisture and gases. The temperature was maintained at 25.0 ± 0.1°C. For each concentration of base, conductivity was typically measured for six concentrations of C-acid in the concentration range $(4–24) \times 10^{-4}$ M.

Spectrophotometric measurements of equilibria were performed at 515 and 532.5 nm for **6** and **3** respectively with the solutions of $TMGH^+Pi^-$ as a reference. Each K_{Ben} value resulted from absorbance values for at least five base concentrations.

Kinetic measurements were performed with a stopped flow spectrophotometer using a C-acid concentration of ca. 2.5×10^{-5} M and base concentrations shown in Tables 6 and 7. The observed first-order rate constants were calculated according to the Guggenheim method. In the case of the deuteron transfer reaction, the initial curved part of the Guggenheim plot, corre-

For personal use only.

sponding to a time less than 0.2 half-life, was discarded (27). The second-order rate constants were calculated according to eqs. [7] and [8]. The addition of $TMGH^+$ Pi^- to the products of the proton transfer reactions did not change the λ_{max}, molar absorptivity ϵ, or the shape of absorption band of the anion of C-acid under investigation.

Preparation and structure of silver complexes with 4-nitroimidazole

ISABELLE SÉGALAS AND ANDRÉ L. BEAUCHAMP[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Québec), Canada H3C 3J7

Received June 25, 1991

ISABELLE SÉGALAS and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **70**, 943 (1992).

The reaction of 4-nitroimidazole (NO_2ImH) with $AgNO_3$ and $AgBF_4$ in neutral or weakly acidic aqueous media yielded the insoluble [$Ag(NO_2Im)$] compound, whose infrared and ^{13}C NMR spectra are consistent with a polymeric chain of deprotonated ligands bridging silver atoms via the endocyclic nitrogen atoms. In strongly acidic solution, [$Ag(NO_2ImH)_2$]X salts (X = NO_3, BF_4) were obtained and their crystal structures were determined. [$Ag(NO_2ImH)_2$]NO_3: monoclinic, $P2/n$, a = 14.214(1), b = 12.571(2), c = 14.222(1) Å, β = 111.38(7)°, Z = 8, R = 0.021, 3443 observed reflections; [$Ag(NO_2ImH)_2$]BF_4: monoclinic, $P2_1/c$, a = 9.543(4), b = 6.478(2), c = 20.869(9) Å, β = 90.84(3)°, Z = 4, R = 0.027, 1646 observed reflections. In both compounds, the two-coordinated metal forms roughly collinear bonds to two neutral ligands via the endocyclic nitrogen atom adjacent to the nitro group. One oxygen of each nitro group makes a secondary Ag—O bond near the equatorial plane. The anions are hydrogen bonded to the ligand N—H groups and do not directly interact with the metal. Solution ^1H and ^{13}C NMR spectra show that the cationic complexes dissociate in DMSO. The infrared and CP-MAS ^{13}C NMR spectra are discussed in connection with the coordination patterns observed.

Key words: silver, imidazole, crystal structure, infrared spectroscopy, nuclear magnetic resonance.

ISABELLE SÉGALAS et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **70**, 943 (1992).

Le 4-nitroimidazole (NO_2ImH) réagit avec $AgNO_3$ et $AgBF_4$ en solution aqueuse neutre ou peu acide pour former le composé insoluble [$Ag(NO_2Im)$], dont les spectres infrarouge et RMN ^{13}C sont en accord avec une chaîne polymère constituée du ligand déprotoné pontant deux atomes d'argent par l'intermédiaire des atomes d'azote endocycliques. En solution très acide, les sels [$Ag(NO_2ImH)_2$]X (X = NO_3, BF_4) sont obtenus et leur structure cristalline a été determinée. [$Ag(NO_2ImH)_2$]NO_3 : monoclinique, $P2/n$, a = 14,214(1), b = 12,571(2), c = 14,222(1) Å, β = 111,38(7)°, Z = 8, R = 0,021, 3443 réflexions observées; [$Ag(NO_2ImH)_2$]BF_4 : monoclinique, $P2_1/c$, a = 9,543(4), b = 6,478(2), c = 20,869(9) Å, β = 90,84(3)°, Z = 4, R = 0,027, 1646 réflexions observées. Dans les deux cas, la métal bicoordonné est lié de façon à peu près linéaire à deux ligands neutres par l'atome d'azote endocyclique adjacent au groupe nitro. L'un des oxygènes de chaque groupe nitro forme une liaison secondaire Ag—O près du plan équatorial. Les anions établissent des liaisons hydrogène avec les groupes N—H des ligands, sans interagir directement avec le métal. Les spectres RMN ^1H et ^{13}C montrent que les complexes cationiques se dissocient dans DMSO. Les spectres infrarouges et RMN ^{13}C à l'état solide sont discutés en relation avec les modes de coordination observés.

Mots clés : argent, imidazole, structure cristalline, spectroscopie infrarouge, résonance magnétique nucléaire.

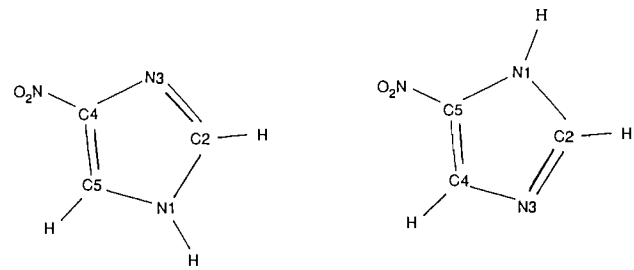
Introduction

Nitroimidazoles are known to be effective radiosensitizers and chemotherapeutic agents both as free molecules (1–3) and when coordinated to metals like Pt, Ru, and Rh (4–6). The role played by the nitro groups in the coordination of these molecules has so far attracted little attention. As part of our current interest for metal complexes of nitroimidazoles, we recently described the structure of a CH_3Hg^+ complex with 4-nitroimidazole (7), in which the nitro oxygens, although only weakly bonded to the metal, had a determining influence on the overall structure. We wish to report here on the interaction of this ligand with the Ag^+ ion, another soft, low-coordinated, Lewis acid. The endocyclic N donors are anticipated to be the preferred target for this metal (8), but coordination with the neutral ligand could in principal take place with either of the two tautomeric forms (Scheme 1).[2] Even though the 4-nitro tautomer has been shown to be present in the solid state (9) and to predominate in water solution (10), coordination to the 5-nitro tautomer could be favoured in systems where the nitro group would create steric hindrance. On the other hand, nitro groups could exhibit weak donor properties and directly participate in bonding with silver, as do the carbonyl-like oxygens adjacent to the main nitrogen coordination sites in complexes with thymine (11), cytosine (12), succinimide (13), and glutarimide (14). Thus, it was of interest to determine if the nitro oxygens in 4-nitroimidazole would bind to silver and if the ligand geometry would be affected by coordination.



SCHEME 1

Experimental

Reagents and methods

$AgNO_3$ (BDH), Ag_2CO_3 (Alfa), 4-nitroimidazole (Aldrich), and HBF_4 (48% aqueous solution, Alfa) were used as received.

The infrared spectra (4000–250 cm^{-1}) were recorded on a

[1]Author to whom correspondence may be addressed.

[2]Ring numbering conventionally starts with the N—H(R) position and the tautomers are usually referred to as the 4-nitro and 5-nitro forms, respectively.

Perkin–Elmer 783 spectrophotometer. KBr pellets were used for the free ligand and $[Ag(NO_2Im)]$. Since the $[Ag(NO_2ImH)_2]X$ compounds reacted with KBr, the spectra were taken with Nujol and hexachlorobutadiene mulls between KRS-5 windows.

The NMR spectra were recorded with a Varian VXR-300 spectrometer at 300 MHz for ^1H and 75.43 MHz for ^{13}C. The solution spectra were taken in $(CD_3)_2SO$ and referenced to the residual solvent signal. The chemical shifts were converted to the standard TMS scale by assigning $\delta = 2.49$ (^1H) or 39.6 ppm(^{13}C) to these signals. The solid-state ^{13}C CP/MAS spectra were obtained under the following conditions: spin rate ~4100 Hz, contact time = 2.5 ms, relaxation delay = 25 s, 150–250 scans. The aromatic signal of hexamethylbenzene powder at 132.0 ppm was used to calibrate the chemical shifts.

Preparations

$[Ag(NO_2Im)]$

To 0.68 g (6.0 mmol) of 4-nitroimidazole dissolved in hot water (50 mL) was added 1.02 g (6.0 mmol) of $AgNO_3$. The yellowish precipitate immediately formed was filtered from the cooled solution and dried *in vacuo*. Yield: 1.20 g, 91%. Anal. (Guelph Microanalytical Lab.) calcd. for $C_3H_2AgN_3O_2$: C 16.38, H 0.92, N 19.11; found: C 16.65, H 1.08, N 19.89.

$[Ag(NO_2ImH)_2]NO_3$

To a hot solution of 4-nitroimidazole (0.68 g, 6.0 mmol) in water (60 mL) was added $AgNO_3$ (1.02 g, 6.0 mmol) dissolved in a minimum of warm water. The $[Ag(NO_2Im)]$ precipitate initially formed was redissolved by adding a minimum of concentrated HNO_3 to the hot solution. The complex started to precipitate while the mixture was cooling down to room temperature. After 2 days at room temperature, colourless platelets were filtered and dried *in vacuo*. Yield: 0.74 g, 63%. Crystals from this homogeneous batch were used for X-ray work. When the reaction was conducted under stoichiometric conditions (M:L = 1:2), the infrared spectrum of the product indicated substantial contamination by free ligand.

$[Ag(NO_2ImH)_2]BF_4$

Ag_2CO_3 (0.41 g, 1.5 mmol) was added to 0.44 mL (3.3 mmol) of 48% HBF_4. After evolution of CO_2, the greyish, syrupy solution of $AgBF_4$ was poured into a solution of 0.68 g (6.0 mmol) of 4-nitroimidazole in 60 mL of hot water. The yellowish precipitate initially formed was redissolved with a minimum of concentrated HBF_4 solution. Air-stable needles were isolated as above. Yield: 0.65 g, 52%. Crystals from this homogeneous batch were used for X-ray work. The sample obtained from a 1:1 M:L mixture showed the same infrared spectrum, but the solid was sticky and more difficult to isolate, probably because it could not be completely freed from small amounts of hygroscopic HBF_4 and (or) $AgBF_4$.

Crystallographic measurements and structure determination

The crystallographic work was done with an Enraf–Nonius CAD-4 diffractometer, following similar procedures for the two compounds. The reduced cell was determined from 25 randomly distributed reflections ($13° < \theta < 18°$) generated by the automatic search routine of the CAD-4 software and centered in the counter aperture. Indexing yielded in both cases a primitive monoclinic cell, which was checked with axial photographs taken about each of the axes. These oscillation photographs showed the expected layer–line separations, and a Laue mirror was present for oscillations about *b*. The crystal data are provided in Table 1.

$[Ag(NO_2ImH)_2]BF_4$

The Niggli matrix was not consistent with a symmetry higher than monoclinic. Space group $P2_1/c$ was uniquely defined from the systematic absences ($h0l$, $l \neq 2n$; $0k0$, $k \neq 2n$) revealed by the full data set.

The intensity data were collected by using the $\omega/2\theta$ scan mode, over a $\Delta\omega$ range of $(0.80 + 0.35 \tan\theta)°$. Five standard reflections were monitored for crystal decay every hour and for misorientation every 200 reflections. A complete sphere of data ($2\theta \leq 50°$, MoK$\bar{\alpha}$) was collected. An absorption correction based on crystal geometry was applied (Gaussian integration, grid $10 \times 10 \times 10$). Averaging equivalent reflections yielded a standard two-octant (hkl, $hk\bar{l}$) data set consisting of 2263 unique reflections, of which 1646 had intensity above background. These data were corrected for the effects of Lorentz and polarization.

The Ag atom was located from a Patterson map. The remaining non-hydrogen atoms were then found from a difference Fourier (ΔF) map. The structure was first refined isotropically by full-matrix least-squares procedures. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with weights w based on counting statistics. The hydrogen atoms were fixed at idealized positions ($U_{iso} = 0.05$ Å^2). Their parameters were not refined, but their coordinates were recalculated after each cycle. All non-hydrogen atoms were finally refined anisotropically. The final ΔF map showed a general background below ± 0.52 e Å^{-3}.

$[Ag(NO_2ImH)_2]NO_3$

The auto-indexing procedure yielded a reduced cell with parameters corresponding to a primitive monoclinic lattice: $a = 14.214(1)$, $b = 12.571(2)$, $c = 14.223(1)$ Å, $\alpha = 90.01(1)$, $\beta = 111.38(1)$, and $\gamma = 90.00(1)°$. The Laue mirror on the oscillation photograph about *b* was consistent with this cell. The systematic absences ($h0l$, $h + l \neq 2n$) noted in a fast precollection suggested Pn and $P2/n$ as possible space groups. However, since *a* and *c* were roughly equal, an orthorhombic cell with one face centred would also fit the lattice. Oscillation photographs about the potential orthorhombic axes failed to reveal the extra mirror planes. Thus, a primitive monoclinic lattice was used to collect the data. Nevertheless, a whole sphere of data ($2\theta < 50°$, MoK$\bar{\alpha}$) was collected as above. Before starting the structure resolution, the Laue symmetry was checked on the full data set. The intensities were first corrected for absorption. An orthorhombic *C*-centred cell was then defined from the *P*-monoclinic cell: $\mathbf{a}_0 = -\mathbf{a}_m - \mathbf{c}_m$, $\mathbf{b}_0 = \mathbf{a}_m - \mathbf{c}_m$, $\mathbf{c}_0 = -\mathbf{b}_m$. The Laue mirror already found in the monoclinic cell (now perpendicular to c_0) was confirmed by the low *R* factor (0.01) and mean Δ/σ value (0.6) when the $hkl/hk\bar{l}$ pairs were compared. Orthorhombic Laue symmetry was clearly ruled out by the *R* and Δ/σ values for the $hkl/\bar{h}kl$ (0.26, 16.9) and $hkl/\bar{h}k\bar{l}$ pairs (0.25, 16.6). A *C*-centred monoclinic cell with β accidentally equal to 90° was also rejected as inconsistent with the systematic absences: beside the *C*-centring condition (hkl, $h + k \neq 2n$), absences were noted for the $hk0$ reflections with $h \neq 2n$ and $k \neq 2n$, indicating that a glide plane was present *perpendicular* to *c*. In a *C*-centred monoclinic cell (space groups Cc or $C2/c$), only a *c* glide plane (perpendicular to *b*) is allowed, with an extinction condition $h0l$, $l \neq 2n$. The glide plane detected is actually the *n* plane of the $P2/n$ or P/n cell.

The data set obtained after averaging the equivalent reflections consisted of 4153 independent hkl and $hk\bar{l}$ reflections, of which 3443 had intensities significantly above background. These data were corrected for the effects of Lorentz and polarization.

The asymmetric unit of the $P2/n$ cell corresponds to two formula units. The two Ag atoms were located from a Patterson map. The remaining non-hydrogen atoms were then positioned from a ΔF map. Refinement was carried out as above. Atomic coordinates showed no correlation coefficients >0.5. Hydrogens were handled as in the previous case. The general background in the final ΔF map was below $\pm$ 0.29 e Å^{-3}. This model showed no abnormally large thermal motion or artificial disorder that could indicate that the space group would be Pn instead of $P2/n$.

TABLE 1. Crystallographic data

	$[Ag(NO_2ImH)_2]NO_3$	$[Ag(NO_2ImH)_2]BF_4$
Formula	$C_6H_6AgN_7O_7$	$C_6H_6AgBF_4N_6O_4$

Goodness-of-fit ratio	1.54	1.52

The scattering curves used were from Cromer and Mann (15), except for hydrogen (16). Anomalous dispersion was taken into account for Ag (17). The refined coordinates for the NO_3^- and the BF_4^- salts are listed in Tables 2 and 3, respectively.[3]

Results and discussion

Unsubstituted imidazole (ImH) has been known for many years to form a very stable silver imidazolate [Ag(Im)]

[1] $Ag^+ + LH \rightleftharpoons AgL\downarrow + H^+$

[2] $H^+ + LH \rightleftharpoons LH_2^+$

[3] $Ag^+ + 2LH \rightleftharpoons AgL\downarrow + LH_2^+$

(8). This insoluble compound precipitates when the pH of an equimolar mixture of ligand and $AgNO_3$ is raised to ~10 with NaOH (18). The very low solubility of the product and the addition of OH^- help to remove the weakly acidic proton (pK_a = 14.4) (19) of imidazole, displacing equilibrium [1] to the right. Since imidazole is also a Brønsted base (eq. [2], pK_a of ImH_2^+ = 7.0) (19), it can also act as proton quencher, leading to disproportionation reaction [3]. Thus, without added NaOH, half of the ligand in a 1:1 Ag:imidazole mixture would be used to neutralize the released proton and the yield in [Ag(Im)] would probably not exceed 50%.

With 4-nitroimidazole, the corresponding insoluble $[Ag(NO_2Im)]$ complex is formed essentially quantitatively without adding NaOH. The electron-attracting nitro group increases ligand acidity (pK_a = 9.3) (19) and makes the proton easier to displace in aqueous media. On the other hand, because of its very low Brønsted basicity (pK_a of $NO_2ImH_2^+$ = 0.0) (19), the ligand does not efficiently bind the expelled proton and has no levelling effect on the yield. Thus, large excess of ligand should be avoided, since its low solubility in water would result in samples contaminated with unreacted ligand.

The $[Ag(ImH)_2]NO_3$ complex containing the formally neutral ligand was obtained from a mixture of $AgNO_3$ and excess imidazole, by addition of HNO_3 to reduce the pH to 5.5 (20) or 4 (21). The pH was kept low enough to avoid reaction [1], but not so low as to completely displace equilibrium [2] toward LH_2^+. With 4-nitroimidazole, the preparation of the NO_3^- and BF_4^- salts of $[Ag(NO_2ImH)_2]^+$ required much higher (1–2 M) acid concentrations to prevent the formation of $[Ag(NO_2Im)]$ via reaction [1].

[3]The supplementary material includes tables of refined temperature factors, distances and angles in the ligands, distances and angles for hydrogen bonds, least-squares plane calculations, and structure factor amplitudes for both structures, as well as a table of infrared wavenumbers for 4-nitroimidazole, its *N*-deuterated derivative, and the three Ag complexes (39 pages). Complete set of data may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

The tables of hydrogen atom coordinates and geometry of the hydrogen bonds have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

[a]Atomic position numbering as described in footnote to Table 2.

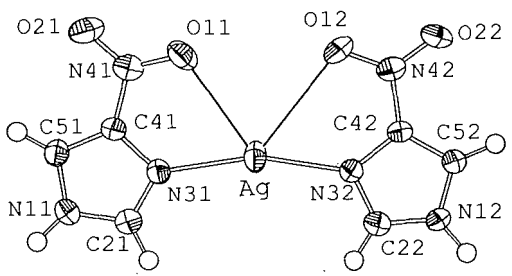

FIG. 1. ORTEP drawing of the [Ag(4-nitroimidazole)$_2$]$^+$ ion in the NO_3^- salt (cation B). Cation A is almost identical. Ellipsoids correspond to 50% probability. Hydrogens are shown as spheres of arbitrary size. Lines correspond to Ag—O secondary bonds.

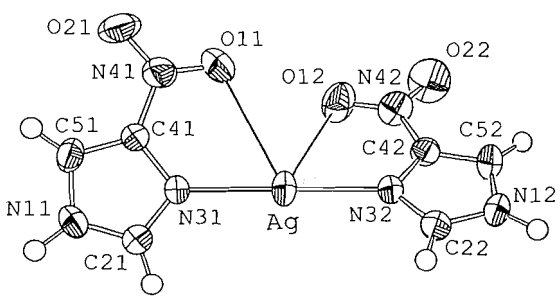

FIG. 2. ORTEP drawing of the [Ag(4-nitroimidazole)$_2$]$^+$ ion in the BF_4^- salt. Conditions as in Fig. 1.

[Ag(NO_2Im)] is a powdery, probably polymeric, material, from which single crystals could not be grown. The [Ag(NO_2ImH)$_2$]$^+$ salts were isolated as suitable crystalline solids and their structures were determined by X-ray diffraction.

X-ray diffraction

The NO_3^- and the BF_4^- salts contain the roughly linear two-coordinate [Ag(NO_2ImH)$_2$]$^+$ cation shown in Figs. 1 and 2, respectively. The ligand retains its N1—H proton[4] and binds to the metal via the ring nitrogen atom N3 adjacent to the nitro group, whereas one of the nitro oxygens, directed toward the equatorial plane (perpendicular to N—Ag—N), forms secondary Ag—O bonds. The two symmetry independent cations present in the NO_3^- salt (one shown in Fig. 1) have very similar conformations: the imidazole rings are

[4]When the ligands are discussed collectively, the atoms are represented by the unparenthesized one-digit symbols shown for the 4-nitro tautomer in Scheme 1. To designate one particular ligand, the individual parenthesized symbols of Tables 2 or 3 are used in the text.

[a] $-x, -\frac{1}{2} + y, \frac{1}{2} - z$.

nearly coplanar, making dihedral angles of 4.9(2)° (molecule A) and 3.4(2)° (molecule B). In the BF_4^- compound (Fig. 2), the rings are 44.2(4)° apart. The nitro groups have mutually *syn* orientations in these three independent complex cations.

An analogous two-coordinate species was found in $[Ag(imidazole)_2]NO_3$ (20, 21) whereas a more complex hexanuclear pattern was observed for the perchlorate (22). The Ag—N distances observed here (Table 4) (mean 2.135 Å, NO_3^-; 2.172 Å, BF_4^-) are slightly longer than those found by these authors (2.075(3) and 2.089(3) for ClO_4^-, 2.120(8) and 2.132(8) Å for NO_3^-), but comparable with those reported for silver atoms bonded to similar rings in purines (23).

Departure from linearity is significant (Table 4), but not uncommon for Ag(I). In the NO_3^- salt (cation A), the O(11A)···O(12A) separation (3.044(3) Å) is just above the normal van der Waals distance (3.0 Å). Therefore, the N(31A)—Ag(A)—N(32A) unit (169.9(1)°) could not be made more linear without producing steric hindrance between the nitro groups, *if the ligands were kept coplanar*. On the other hand, the greater departure from linearity for cation B (162.3(1)°) cannot be ascribed to O(11B)···O(12B) steric hindrance, since the separation is 3.400(3) Å. At any rate, there should be free rotation about the Ag—N bonds in solution, and the *syn*-nitro coplanar arrangement found for the nitrate salt is probably due to crystal packing, because the ligands are not coplanar in the BF_4^- salt, where the N—Ag—N angle is 175.2(1)°.

Since the sum of the van der Waals radii is 3.2 Å (24), the intramolecular Ag···O distances (2.7–3.0 Å, Table 4) should correspond to some bonding, but much weaker than a normal covalent bond, for which distances <2.45 Å are expected (11, 25). As the ligand is not flexible, the Ag—O distance is directly correlated with the Ag—N3—C angles, which should be equal if coordination took place along the

[a]Mean values for the six symmetry-independent ligands in the NO_3^- and BF_4^- salts. Details in the supplementary material, Table S-11.

expected N3 lone-pair direction. For the six independent ligands in these two structures, the differences between Ag—N3—C4 and Ag—N3—C2 are large and of different signs: +6.5° (ligand 1A), −2.5° (2A), −3.1° (1B), and +7.8° (2B) for NO_3^-, −0.9° (ligand 1) and −7.3° (ligand 2) for BF_4^-. This shows again that secondary bonding, although providing stabilization, does not impose strict structural requirements to the "chelate" ring and to the metal coordination geometry.

Details on the distances and angles in the individual ligands are provided in the supplementary material. The ligand geometry is not appreciably perturbed by coordination, as shown in Table 5, where the mean values for the complexes are compared with the data for free 4-nitroimidazole (9). There are no appreciable differences in bond lengths. Angles are usually more sensitive to coordination, but only two angles are possibly affected here. The mean C2—N3—C4 angle of 104.3° (range 103.9–104.6°) in the complexes, slightly greater than in the free ligand (103.4(2)°), would be consistent with the usual increase resulting from the smaller size of the N3 "lone pair" after coordination. The other difference is found for C4—N4—O2 (complexes: 117.7°, range 116.8–118.2°; free ligand: 118.4°). This angle involves external nitro oxygens, and it should be sensitive to intermolecular effects. Details on the weighted least-squares planes are also given in the supplementary material. The five-membered rings are planar within 1.2 σ (0.005 Å). As previously noted in the structure of $[Ag(imidazole)_2]NO_3$ (20), displacement of the metal from this plane is usually large, reaching 0.29 Å in the BF_4^- compound. Combination of torsion about C4—N4 and out-of-plane bending of the NO_2 unit leads to the following dihedral angles between the nitro groups and their respective rings: 0.9(3) and 0.7(3)° (NO_3^-, molecule A), 8.2(3) and 3.9(3)° (NO_3^-, B), 3.8(4), and 2.7(4)° (BF_4^-). Most of these distortions are highly significant, but still small compared with the ~45° twist about the C2—NO_2 bond observed in $PtCl_2L_2$ complexes with 2-nitroimidazole derivatives (4).

The unit cell of the BF_4^- salt is shown in Fig. 3. The anions lie close to planes parallel to the *ab* face at $z = 0$ and $\frac{1}{2}$. Between these planes are found the complex cations, with their N—Ag—N direction roughly parallel to the *ac* plane and making a ~45° angle with the *a* and the *c* axes. Within the cationic regions, cohesion is achieved by normal van der Waals contacts and by an intermolecular Ag···O(12) interaction of 2.984(3) Å. Both ends of each cation are anchored to BF_4^- ions in different layers by means of hydrogen bonding with the N1—H groups. F(3) takes part in a standard N(11)—H···F(3) bond (N···F separation = 2.856(4) Å), whereas F(1) is involved in a bifurcated hydrogen bond with two different N(12)—H groups (N···F = 2.924(4) and 3.003(4) Å).

A different packing pattern is found for the nitrate salt (Fig. 4). There are no intermolecular Ag···O contacts in this case. Furthermore, in contrast with $[Ag(imidazole)_2]NO_3$ (20), the anions have no direct interactions with the metal. The building units of the structure are infinite ribbons in which flat complex cations are bridged by NO_3^- ions forming hydrogen bonds with ligand N1—H groups. One such ribbon contains cations of type A, roughly parallel to the *ab* plane, with their N(31A)—Ag(A)—N(32A) direction parallel to the *a* axis at $y \sim 0$ (or 1). The N1—H groups at both ends of the cation form strong hydrogen bonds to two symmetry equivalent nitrate ions of type B:N(11A)···O(3B) = 2.873(3) Å and N(12A)···O(2B) = 2.790(3) Å. The crystallographic twofold axis generates a second ribbon, next to the first and running in the same direction, thereby optimizing van der Waals contacts between parallel planar components. Similar ribbon pairs, oriented along *c*, centred at $y = \frac{1}{2}$, and parallel to the *bc* face, contain cations B and anions A, also linked by N1—H···O(nitrate) hydrogen bonds: N(11B)···O(2A) = 2.806(3) Å and N(12B)···O(1A) = 2.755(3) Å. The nitro groups do not participate in hydrogen bonding. The only intermolecular contacts of the nitro groups occur with the C2—H region of ligands in the other type of ribbons.

Infrared spectroscopy

The frequencies are provided in Table S-12 (supplementary material) for 4-nitroimidazole, the *N*-deuterated derivative, and the three silver complexes.

The spectrum of the 4-nitro compound contains most of the bands of unsubstituted imidazole with only small shifts. Our assignments are made by comparison with those deduced from systematic studies on imidazole (26) and 4-methylimidazole derivatives (27). In the present case, one set of ν, δ, and γ(C—H) modes should be replaced by nine vibrations involving the nitro group. Four internal modes are located in well-defined regions identified for nitrobenzenes (28–30): ν_{as}, 1510; ν_s, 1375; δ, 860; γ, 745 cm^{-1}. The normally weak ρ(NO_2) vibration, observed at ~530 cm^{-1} for nitrobenzenes, could produce the very weak feature at 470 cm^{-1}. The torsion mode is not expected to lie above 200 cm^{-1}. The ν(C—NO_2) mode probably corresponds to the strong band at 982 cm^{-1}, which replaces the imidazole δ(C—H) mode at 1050 cm^{-1} in this region. The δ(C—NO_2) mode is tentatively assigned to a clear band at 435 cm^{-1}, absent from the spectrum of imidazole.

The two δ(C—H) bands are readily recognized, since they are not appreciably shifted from their positions in imidazole (26). The γ(C—H) bands are more difficult to locate. One of these modes gives rise to a doublet at 819/811 cm^{-1}, close to the position found for imidazole. The 920 cm^{-1} region, where one such mode is found for imidazole, retains only the

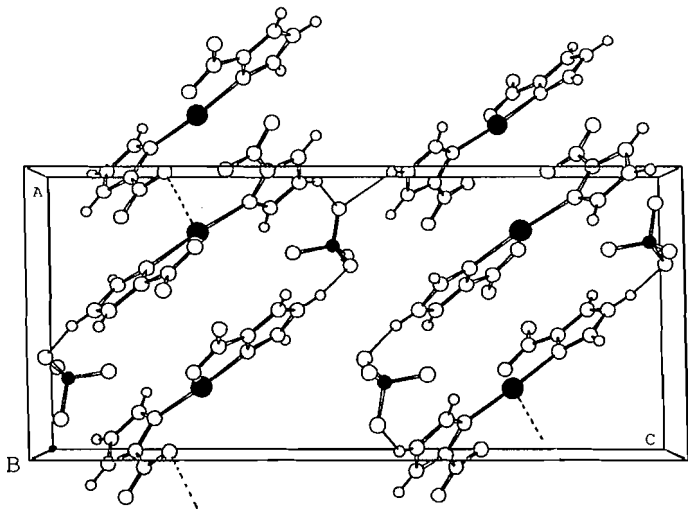

FIG. 3. Unit cell of $[Ag(4\text{-nitroimidazole})_2]BF_4$. Atoms are shown as spheres of arbitrary sizes: Ag (black) < C ~ N ~ O ~ F < B (black) < H. Full lines correspond to hydrogen bonds, and dashed lines to intermolecular Ag···O contacts. The unit cell origin is indicated by a black dot.

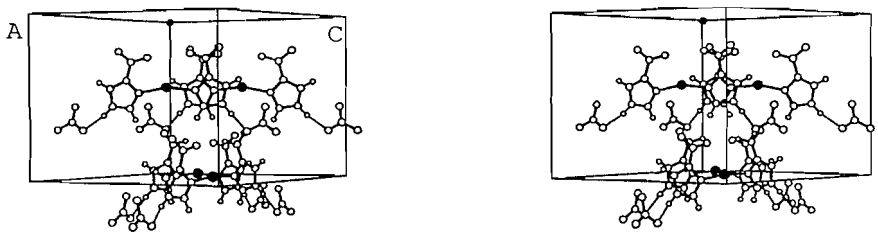

FIG. 4. Stereoview of molecular packing for $[Ag(4\text{-nitroimidazole})_2]NO_3$. Conditions as for Fig. 3.

922 and 906 cm^{-1} components, which are likely due to ring vibrations. Similarly, the γ(C—H) doublet of imidazole at 749/730 cm^{-1} is replaced here by the single 749 cm^{-1} feature assigned to the $\gamma(NO_2)$ vibration. The best candidate for the second γ(C—H) vibration of 4-nitroimidazole is found at 834 cm^{-1}, next to the other.

The spectral regions sensitive to N—H motion are identified by comparison with the *N*-deuterated derivative. The broad ν(N—H) massif centred at 2800 cm^{-1} is replaced by a less complex feature for ν(N—D) near 2180 cm^{-1}. Deuteration gives rise to new bands at 888/873 and 668 cm^{-1}, also found for imidazole (26, 27) and assigned to δ(N—D) and γ(N—D), respectively. The corresponding N—H vibrations can thus be identified at 1240 (δ) and 950 (γ) cm^{-1}, respectively. Deuteration removes the 1150/1135 cm^{-1} doublet, which is possibly shifted to 1210 cm^{-1} with considerable loss of intensity: this doublet originates from a ring mode found to be sensitive to ring substitution in imidazole derivatives (26, 27). The $\nu(C—NO_2)$ mode, also expected to be coupled with the ring, is displaced from 982 to 1003 cm^{-1}. Both of these effects could be related to loss of coupling with δ(N—H) motion upon deuteration.

The most obvious spectral changes for the $[Ag(NO_2ImH)_2]X$ complexes arise from anion bands. They are found at the typical wavenumbers for uncoordinated anions (31), and low site symmetry imparts some intensity to certain IR-forbidden bands: for NO_3^-, 1360 (vs, br), 1035 (vw), 710 (m), 830 cm^{-1} (masked); BF_4^-: 1020 (vs, br), 512 (m). Among the ligand bands, the ν(N—H) mode in the BF_4^- salt is shifted from 2800 to 3320 cm^{-1}, probably because of weaker H-bonding. This band remains unshifted in the nitrate, where the crystallographic work shows that hydrogen bonding is stronger. As the ligand stays formally neutral in these compounds, the remaining ligand modes do not undergo drastic changes. The following bands are found to undergo appreciable shifts: 1510 (+10), 1330 (+10), 982 (+14), 435 (+10) cm^{-1}.

As expected, the spectrum of $[Ag(NO_2Im)]$ contains no anion bands and ligand deprotonation introduces drastic spectral changes. The strong ν(N—H) massif near 2800 cm^{-1} is completely washed out. Loss of coupling with N—H motion and changes in ring bond orders displace many of the ligand vibrations. The high wavenumber ring band at 1565 cm^{-1} is probably displaced to ~1500 cm^{-1} and overlaps with the $\nu(NO_2)$ band. The 1150/1135 cm^{-1} doublet for the ring mode sensitive to deuteration moves toward 1200 cm^{-1}. Other bands undergo large changes: 1075 (+43), 982 (+35), 922 (+36), 906 (−43), 599 (−47) cm^{-1}. The shift from 435 to ~460 cm^{-1} with considerable loss of intensity of the low-frequency band assigned to $\delta(C—NO_2)$ seems to be another good diagnostic for complexation of 4-nitroimidazole in the anionic form.

Nuclear magnetic resonance

No solvent could be found to dissolve the $[Ag(NO_2Im)]$ compound. DMSO is the only common solvent in which the $[Ag(NO_2ImH)_2]X$ complexes were soluble enough to obtain ^1H and ^{13}C NMR spectra. In both kinds of spectra, the chemical shifts were found to coincide with those reported

for free 4-nitroimidazole in this solvent (32–34), indicating that the ligands had been displaced from the coordination sphere.

The solid-state ^{13}C spectra (Table 6) proved to be more informative. Since the solid (9) contains the tautomeric form found to be highly dominant in solution (10), the assignments proposed for solution spectra are used directly (32–34).

In $[Ag(NO_2ImH)_2]NO_3$, coordination to the N3 lone pair of a formally neutral ligand induces relatively small shifts of 3.1 ppm downfield on C2 and 2.5 ppm upfield on C4, whereas C5 is not displaced. For $[Ag(NO_2Im)]$, the shifts are larger for C2 and C5 (+7.0 and +9.3 ppm, respectively), whereas C4 is displayed by only +0.2 ppm. For comparison, Table 6 includes data for a complex containing two uniligating square-planar RNi^+ units (R = 7-amino-4-methyl-5-aza-3-hepten-2-one) bonded to N1 and N3 of a deprotonated imidazole ring (35). To determine the peak shifts produced by this type of binding, comparison with the solution spectrum of imidazole would not be informative, since fast tautomeric exchange of the N—H proton between N1 and N3 renders C4—H4 and C5—H5 equivalent on the NMR time scale. The data from the solid-state spectrum (36) are more appropriate, since fast exchange does not occur in the crystal. Table 6 reveals that for this complex containing an imidazole monoanion bridging two metal atoms, large downfield shifts of 5.8 and 9.8 ppm are noted for C2 and C5, respectively, whereas C4 does not move very much. Considering the similitude of the $\Delta\delta$ values, it can safely be concluded that 4-nitroimidazole in $[Ag(NO_2Im)]$ also plays a bridging role via N1 and N3.

Conclusion

Under neutral or weakly acidic conditions, 4-nitroimidazole forms the insoluble $[Ag(NO_2Im)]$ compound, in which the ligand is shown to be bridging via N1 and N3 by solid-state ^{13}C NMR. Since the metal exhibits a marked preference for linear two-coordination, this compound likely consists of metal atoms and ligand monoanions alternating along an infinite chain. The formation of this compound can be opposed by using very high concentrations of acid. Then, discrete $[Ag(NO_2ImH)_2]^+$ salts, containing two-coordinate silver and neutral imidazole ligands, are isolated. In these compounds, the metal has a linear N—Ag—N coordination, and since the heterocyclic N atom used to coordinate is the one adjacent to the nitro group, the latter is in a suitable position to close a loose chelate ring by weaker Ag···O semi-bonding near the metal equatorial plane. The latter interaction is not very strong, but it contributes to binding and helps stabilizing the 4-nitro tautomer in the complex.

The particular effects of the nitro group in this system can be related to two main points. Its electron-attracting effects decreases the pK_a of both the neutral ligand and its conjugated acid, increasing the domain of existence of the neutral complex $[Ag(NO_2Im)]$, which does not have to compete with the protonation equilibrium of the free ligand, as was the case for the complex with unsubstituted imidazole. On the other hand, the polar NO_2 group of free 4-nitroimidazole participates in dipolar interactions in the solid state, which considerably reduces water solubility compared to unsubstituted imidazole and renders the preparation of pure, ligand-free, samples more difficult.

MARK L. J. REIMER, JOHN B. WESTMORE, and MANORANJAN DAS. Can. J. Chem. **70**, 952 (1992).

Electron ionization positive ion mass spectra of 15 substituted cobalt(III) β-diketonates and monothio-β-diketonates, $Co^{III}L_3$, where L = RCXCHCOR′, R = phenyl, 2-thienyl, or 2-naphthyl; X = O or S; and R′ = CHF_2, CF_3, C_2F_5, or n-C_3F_7, show a marked dependence on the ligand. Molecular ions, $[Co^{III}L_3]^{+\bullet}$, are observed only for some of the more highly fluorinated complexes (R′ = C_2F_5 or n-C_3F_7). The $[Co^{III}L_2]^{+\bullet}$ ion, possibly generated by ionization of $Co^{II}L_2$ formed by thermal degradation, or by electron ionization of $Co^{III}L_3$, typically decomposes by elimination of a radical, i.e., $L^{\bullet}$ or $R'^{\bullet}$, to yield ions containing Co(II); subsequent decompositions proceed preferentially by loss of even-electron neutral species, also to yield ions containing Co(II). Cobalt-containing ions in which fluorine has rearranged to the metal decrease in variety and abundance for the ligands with higher fluorine content. When metal-bonded oxygen is replaced by sulfur, fluorine migration to Co(III), rather than to Co(II), is preferred. These trends are consistent with a combination of several different concepts including the ability of the metal to undergo valency change, the principle of Hard and Soft Acids and Bases, and the inductive capabilities of the ligand donor atoms and of the R and R′ groups. Ion decomposition pathways are proposed.

Key words: mass spectrometry, cobalt complexes, β-diketonates, fluorinated chelate complexes.

MARK L. J. REIMER, JOHN B. WESTMORE et MANORANJAN DAS. Can. J. Chem. **70**, 952 (1992).

Les spectres de masse des ions positifs obtenus par ionisation électronique de 15 β-dicétonates et de monothio-β-dicétonates de cobalt(III) substitués, $Co^{III}L_3$ [L = RCXCHCOR′, R = phényle, 2-thiényle ou 2-naphtyle, X = O ou X et R′ = CHF_2, CF_3, C_2F_5 ou n-C_3F_7], dépendent grandement de la nature du ligand. On n'observe les ions moléculaires $[Co^{III}L_3]^{+\bullet}$ que pour quelques-uns des complexes les plus fluorés (R′ = C_3F_5 ou n-C_3F_7). L'ion $[Co^{III}L_3]^{+\bullet}$ qui provient peut-être d'une ionisation du $Co^{II}L_3$ formé par une dégradation chimique ou par une ionisation électronique du $Co^{III}L_3$ se décompose d'une façon typique par l'élimination d'un radical, soit $L^{\bullet}$ ou $R'^{\bullet}$, pour fournir des ions contenant du Co(II); les dégradations subséquentes se produisent préférentiellement par la perte d'espèces neutres avec un nombre pair d'électrons et elles conduisent aussi à des ions contenant du Co(II). La variété et l'abondance des ions contenant du cobalt dans lesquels le fluor s'est déplacé vers le métal diminuent avec une augmentation du contenu en fluor. Lorsqu'on remplace de l'oxygène lié à un métal par un soufre, la migration du fluor vers le Co(III) est préférée à une migration vers le Co(II). Ces tendances sont en accord avec une combinaison de plusieurs concepts différents comprenant : l'habilité du métal à subir un changement de valence, le principe des acides et des bases dures et molles et les capacités inductives des atomes du ligand donneur et des groupements R et R′. On propose des voies de décompositions pour les ions.

Mots clés : spectrométrie de masse, complexes du cobalt, β-dicétonates, complexes de chélates fluorés.

Introduction

The significant volatility and stability of metal β-diketonates and their derivatives make them suitable for gas chromatography (1). When this technique is combined with mass spectrometry, analytical methods, based upon the use of isotopic tracers, can be devised for metals. Recently, metal β-diketonates were used as precursors for chemical vapor deposition (2–4), a promising technique for the preparation of thin films of high T_c superconducting oxides (5), and the application of mass spectrometry to characterize the alkaline earth complexes for this purpose has been described (6).

The mass spectra of these complexes are of interest in their own right because their wide variety permits assessment of the influence exerted by bonding and structure factors, i.e., (*i*) the central metal atom, (*ii*) the ligand donor atoms, and (*iii*) the wide variety of organic substituents attached to the ligand. Conversely, because of this, the mass spectra can often be used to draw conclusions about the condensed phase chemistry of the metals. Much of the early mass spectral work starting from the first extended study (7), has been reviewed (8–11).

In the electron ionization (EI) mass spectrum of an organic compound an odd-electron positive ion ($OE^{+\bullet}$) typically decomposes to an even-electron positive ion (EE^{+}) and an odd-electron neutral ($OE^{\bullet}$) (or, occasionally, to $OE^{+\bullet}$ and an even-electron neutral (EE^{0})), but an even-electron cation preferentially decomposes to another EE^{+} and an EE^{0} (ref. 12, or other texts on mass spectrometry). Many exceptions to this generalization are known, the majority being explicable by aromatic stabilization of the radical cations formed in the reaction: $EE^{+} \rightarrow OE^{+\bullet} + OE^{\bullet}$ (13). To interpret the mass spectra of metal complexes, which also frequently violate this generalization, it is useful to invoke the concept of metal valency change (14, 15) to alter the "odd" or "even" electron character of a metal-containing ion. This character is controlled by the capacity of the complexed metal atom

either to accept one or more electrons from the ligands (valence decrease in metal) or to donate one or more electrons to the ligands (valence increase in metal). The mass spectra of metal complexes are often best explained if valence changes in the bonded metal are assumed to occur during some ion dissociation reactions, while metal valence is maintained during others. In fact, many ion decompositions appear to depend upon the oxidation states normally accessible to the metal. This is true of the mass spectra of metal β-diketonates and monothio-β-diketonates, which can be understood, in part, from the dependence of ion stability upon relative stabilities of metal oxidation states (10).

Rearrangements involving transfer of an atom (or group of atoms) to the metal in the formation of a metal-containing fragment ion or neutral species are also observed (16). A plausible explanation for such rearrangements, and the reasons behind the bonding preferences shown by various metals towards the migrating species, is given by the principle of Hard and Soft Acids and Bases (HSAB) (17–21), an empirically derived relationship that correlates the relative affinities of acceptor metals (ions or atoms: Lewis acids) for donor atoms (ligands: Lewis bases) on the basis of their respective electronic properties. This principle has been extended to the mass spectra of fluorinated β-diketonate complexes to explain the rearrangement of fluorine to the metal (22). Formation of ions or neutrals containing Met—F bonds (Met = metal) occurs for Co(II), Fe(III), Fe(II), Cr(III), Al(III), Zn(II), Ni(II), and Mn(II) complexes of 1,1,1,5,5,5-hexafluoro-2,4-pentanedione. All of these metal ions can be considered as hard, or borderline-hard, acids while fluorine can be considered as a hard base. Fluorine migration to these centres is therefore in keeping with HSAB predictions (the two electron-withdrawing CF_3 groups on the ligand would be expected to harden the borderline-hard metals, making them more receptive to a fluorine transfer). Fluorine rearrangement is notably absent, however, in the spectrum of the copper(I) complex with this ligand; Cu(I) is considered to be a soft acid and so would not be expected to bind with fluorine. A comparison (22) of these results with those obtained when a CF_3 group is replaced by methyl, ethyl, isopropyl, *tert*-butyl, phenyl, or 2-thienyl revealed a striking dependence of the abundances of the rearrangement ions on the substituent. Thus, replacement of a CF_3 group by a more electron-releasing species softens the metal, so fluorine rearrangement becomes less prevalent. This phenomenon was also noted for reactions in which HF is eliminated. When one of the CF_3 groups is replaced by a methyl or phenyl group, the relative abundances of the ions resulting from HF loss increase dramatically; softening the metal environment decreases its ability to compete for fluorine.

In the present study we examine the positive ion EI mass spectra of a series of fluorinated cobalt(III) complexes, CoL_3, having the general form $Co^{III}(RCXCHCOR')_3$, where R = phenyl, 2-thienyl, or 2-naphthyl; X = O or S; and R′ = CHF_2, CF_3, C_2F_5, or *n*-C_3F_7, as listed in Table 1. Except for **3***a*, mass spectral studies of these complexes have not been reported previously. The complexes are of interest because of the accessibility of the (III), (II), and (I) valence states of cobalt, which have varying hard/soft acid character. Furthermore, both the X = O, and X = S series of complexes are stable and easily prepared (this is not so for several other metal ions). We relate the trends in observed ion abundances to the ability of the metal to undergo change in valency, to the HSAB principle, and to the inductive effects of the ligand donor atoms and of the R and R′ groups, in a more comprehensive way than has been reported heretofore.

Experimental

Mass spectrometry

All mass spectra were acquired on a VG 7070E-HF double-focusing (EB) mass spectrometer (VG Analytical Ltd.; Manchester, England) equipped with a DEC Micro PDP-11/73 data system (Digital Equipment Corp.; Maynard, Mass.). Reproducible mass spectra were obtained by introducing samples on a direct insertion probe, which was heated to produce an even rate of volatilization. The low resolution EI conditions were as follows: accelerating voltage, 6 kV; ionizing energy, 70 eV; trap current, 200 μA; source temperature, 200°C; scan rate, 1.0 s/decade; resolution, 1400 (10% valley definition).

Ion decomposition spectra were recorded by linked scanning as follows: (*a*) product ion spectra at constant magnetic field/electric field ratio (i.e., B/E constant; accelerating voltage (V) fixed), and (*b*) constant neutral loss spectra ($B[1 - (E/E_0)]^{1/2}/E$ constant; V fixed), on selected ions in the spectra of **4***a* and **7***b* at a scan rate of 5.0 s/decade. Parent ions were collisionally activated in the first field-free region of the instrument by adjusting the helium pressure in the collision cell to attenuate the parent ion signal by approximately 50%.

Ligand syntheses

The fluorinated β-diketones used in the syntheses of **3***a* and **4***a* were purchased from Aldrich Chemical Co. (Milwaukee, Wis.), and of **5***a* from Eastman Kodak Co. (Rochester, N.Y.). The remaining β-diketones were synthesized by a Claisen condensation of the appropriate methyl ketone ($RCOCH_3$) with the fluorinated ethyl ester ($R'COOC_2H_5$), as previously described (23, 24). The fluorinated monothio-β-diketones were synthesized from their corresponding β-diketones (24–28).

Syntheses of cobalt(III) β-diketonates

These syntheses were based on the procedure of Fay and Piper (29). Sodium tris-carbonatocobaltate(III) trihydrate (0.3 mmol; prepared as described below) and 6 M nitric acid (0.15 mL) were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

added to a solution of the ligand (0.9 mmol) in 1.5 mL of aqueous alcohol (40% ethanol). After refluxing the mixture for 30 min, the precipitated green product was filtered off under suction, washed with cold water, and air dried. Its purity was monitored by TLC and, if warranted, it was further purified by column chromatography (30% methylene chloride/petroleum ether on silica gel).

Following a reported procedure (30), sodium tris-carbonatocobaltate(III) trihydrate, $Na_3[Co(CO_3)_3] \cdot 3H_2O$, was prepared by adding 50 mL of an aqueous solution of cobalt(II) nitrate hexahydrate (0.10 mol) and 30% hydrogen peroxide (10 mL) dropwise, with stirring, to an ice-cold slurry of sodium bicarbonate (0.50 mol) in water (50 mL). The mixture was stirred in an ice bath for 1 h. The precipitated green product was filtered off under suction, washed with 30 mL of cold water, then washed with cold absolute ethanol and allowed to air dry.

Syntheses of cobalt(III) monothio-β-diketonates

As reported previously (28), cobalt (II) acetate tetrahydrate (4 mmol) in absolute ethanol (150 mL) was added to a solution of the ligand (12 mmol) in ethanol (50 mL). After aerating the brown solution for 4 h the resulting precipitate was filtered off and washed with ethanol. (In the cases of **6***b* and **9***b* a solid did not form after aeration, so the solution volume was reduced to 75 mL by evaporation and then cooled. After addition of 5 mL of water, the mixture was refrigerated overnight to obtain a precipitate of the desired product. This was filtered off and washed with cold ethanol.)

Results and discussion

Discussion will focus on the major cobalt-containing ions observed; metal-free fragments will be referred to only when necessary to elucidate decompositions involving metal-containing species.

Co(III) β-diketonates

Mass spectra of the nine Co(III) β-diketonates are given in Table 2, with representative spectra depicted in Fig. 1. (Except where the mass spectral peaks were too small to measure accurately, the isotopic patterns were consistent with the ion assignments proposed in Tables 2 and 4.) The mass spectrum of **3***a* is in good agreement with a previous report (31). To assist in assignment of fragmentation pathways, collisionally activated decompositions of selected ions obtained from **4***a* are listed in Table 3.

Difluoromethyl-substituted ligands (R′ = CHF_2)

In the mass spectra of complexes **1***a* and **2***a*, $[Co^{III}L_3]^{+\bullet}$ ions, or ions unequivocally formed from them, were not detected. The observed ion of highest m/z is the EE^+ species $[Co^{III}L_2]^+$. Since we could not tell from these results whether $[Co^{III}L_2]^+$ is formed by loss of a ligand radical from $[Co^{III}L_3]^{+\bullet}$ or by ionization of $Co^{II}L_2$ formed by thermal degradation of $Co^{III}L_3$, we operated the ion source under ammonia chemical ionization (NH_3CI) conditions for complex **1***a*. Strong signals corresponding to $[CoL_2+H]^+$ and $[CoL_2+NH_4]^+$ were obtained, but the analogous signals for $[CoL_3+H]^+$ and $[CoL_3+NH_4]^+$ could not be detected. This result is consistent with thermal decomposition of CoL_3. Thus, ion decomposition pathways originating from $[Co^{III}L_2]^+$ are shown in Scheme 1. Initially, elimination of a radical, either $R'^{\bullet}$ to give $[Co^{II}L(L - R')]^+$ or $L^{\bullet}$ to give $[Co^{II}L]^+$, suggests reduction of cobalt(III). Subsequently, the relative stability of cobalt(II) towards reduction results, predominantly (but not exclusively), in EE^0 losses (i.e., (L − R′), (L − R), (L − F), CO, CHF), each leading to a fragment ion containing Co(II). Observation of a low yield of $[Co^I]^+$ confirms that further reduction of cobalt is, indeed, possible. (Linked scanning indicates that, for **4***a* at least, $[Co^I]^+$ can form through loss of (L − R′) plus $F^{\bullet}$ from $[Co^{II}F(L - R')]^+$.) Reduction of cobalt(II) is entirely in keeping with the established chemistry of cobalt. With the exception of copper, the +1 oxidation state is better known for cobalt than for any other first transition series metal (32).

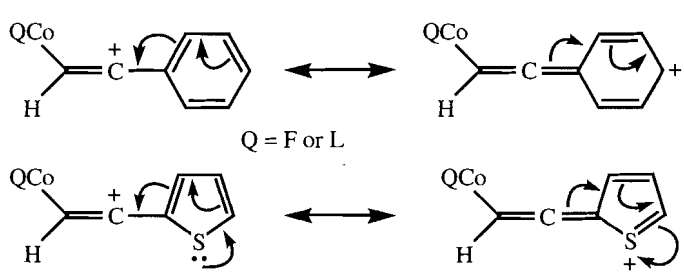
A number of decompositions involving fluorine transfer to cobalt are inferred by analogy with results for **4***a* and **7***b*. Thus, losses of the neutral species $Co^{II}F_2$ in the fragmentations $[Co^{II}F(L - COF]^+ \rightarrow [L - COF_2]^+$, and $[Co^{II}L]^+ \rightarrow [L - 2F]^+$ confirm that fluorine rearrangement to cobalt has, in fact, taken place. (The decompositions $[Co^{II}L]^+ \rightarrow [L - COF_2]^+ + Co^{II}F_2 + CO$, and $[Co^{II}L]^+ \rightarrow [L - 2F]^+ + Co^{II}F_2$, were confirmed by linked scanning for **4***a* and **7***b*, respectively. The first of these is probably the sum of the two steps: $[Co^{II}L]^+ \rightarrow [Co^{II}F(L - COF]^+ \rightarrow [L - COF_2]^+$. These conclusions are also consistent with those noted in the introduction.)

Elimination of (L − F) from $[Co^{II}L(L - R')]^+$ to give $[Co^{II}F(L - R')]^+$ also requires fluorine transfer, as do losses of :CHF from $[Co^{III}L_2]^+$ and $[Co^{II}L]^+$. (Corresponding losses of (L − F) and of CF_2 from $[Co^{II}L(L - R')]^+$ and $[Co^{II}L]^+$, respectively, were confirmed by linked scanning for the trifluoromethyl analogue **4***a*.)

Finally, migration of the aryl (R) group to the metal in $[Co^{II}L]^+$ results in the loss of the EE^0 species (L − R) and the formation of the EE^+ fragment $[Co^{II}R]^+$. Concerted mechanisms based on four- and six-membered transition states have been suggested for this process (33).

Trifluoromethyl-substituted ligands (R′ = CF_3)

As above, $[Co^{III}L_3]^{+\bullet}$ ions were not detected in the mass spectra of **4***a* and **5***a*, though a small peak was observed for this ion in the spectrum of **3***a*. The most abundant cobalt-containing fragment ions are $[Co^{III}L_2]^+$ and $[Co^{II}L(L - R')]^+$. Many of the fragmentation pathways proposed in Scheme 2 have been confirmed by linked scanning. Some are similar to those discussed for Scheme 1 and, subsequently, will be referred to only in passing. Eliminations of the EE^0 species CO_2, RC_2H, and CF_2 occur in the decomposition sequence: $[Co^{II}L(L - R')]^+ \rightarrow [LCo^{II}CHCR]^+ \rightarrow [Co^{II}L]^+ \rightarrow [FCo^{II}(L - R')]^+ \rightarrow [FCo^{II}CHCR]^+$. (Note: the 44 dalton neutral fragment eliminated was identified as CO_2 in the very similar mass spectrum of the perdeuterated Fe(III) analogue of **3***a*. The proposed 1,3 shift of an oxygen to carbon of the other, electron-deficient, carbonyl group imparts to the product ion vinyl ion character that "is compensated by the aromatic group α to the charge" (34).) Specifically, for the present complexes, resonance stabilization by the adjacent aromatic group could promote formation of the $[LCo^{II}CHCR]^+$ and $[FCo^{II}CHCR]^+$ ions:



It is also conceivable to regard these species as QCo^+ bonded to the π system of HC≡CR.

Two routes to the ion $[Co^{II}R]^+$ from $[Co^{II}L]^+$ are shown

in Scheme 2. A direct route invokes migration of the ligand aryl group to cobalt, followed by loss of (L − R), as discussed above for **1***a* and **2***a*. The second route, established for **4***a* by linked scanning, proceeds by elimination of the EE^0 species CF_2, HF, and C_3O_2 in the fragmentation sequence: $[Co^{II}L]^+ \rightarrow [Co^{II}F(L - R')]^+ \rightarrow [[Co^{II}(L - CF_2 - HF)]^+ \rightarrow [Co^{II}R]^+$. (Deuterated Fe(III) analogues of **3***a* and **4***a* were used to establish the origin of hydrogen in HF as the central CH position of the ligand (31). After loss of HF the aryl group migrates to the positive cobalt centre, accompanied by expulsion of the neutral fragment C_3O_2.

Complex **4***a* (R = 2-thienyl) gives a low abundance ion of m/z 363, of a type observed only for this compound; linked scanning confirms that its parent is $[Co^{III}L_2]^+$. Two assignments, i.e., $[Co^{II}L_2 - 2R']^+$ or $[Co^{III}RL]^+$, appear possible. Successive losses of two R′· radicals seem unlikely, because the second loss involves the energetically unfavorable elimination of an $OE^{\cdot}$ species ($CF_3^{\cdot}$) from the EE^+ species ($[Co^{II}L(L - R')]^+$). In contrast, the decomposition $[Co^{III}L_2]^+ \rightarrow [Co^{III}RL]^+$, by elimination of (L − R), has a parallel in the reaction $[Co^{II}L]^+ \rightarrow [Co^{II}R]^+$, discussed in the previous paragraph. The very low abundance of $[Co^{III}RL]^+$ in the spectrum of **4***a* is probably a reflection of the greater ease of reduction of cobalt(III) relative to cobalt(II), which opens up alternative decomposition channels for cobalt(III) species. The assignment as $[Co^{III}RL]^+$ is supported by the following measurement. The mass difference, 2.4 mmu, between the alternative assignments requires an instrumental resolution, $M/\Delta M$, of ~150 000 to separate them, about 5–10 times greater than the specified resolution of our mass spectrometer. By software peak matching, at a nominal resolution of 6,300, the mass of the ion was determined as 362.9167 u compared to calculated masses of 362.9172 u for $[Co^{III}RL]^+$ and 362.9196 u for $[Co^{II}L_2 - 2R']^+$. This result, coupled with no detectable broadening of the ion peak, suggests that the contribution of $[Co^{II}L_2 - 2R']^+$ to the signal is minimal, at best.

Pentafluoroethyl- and n-*heptafluoropropyl-substituted ligands (R′ = C_2F_5 and* n-C_3F_7)

Whereas the abundances of $[Co^{III}L_3]^{+\cdot}$ have been very small or not observable for all complexes discussed so far, these ions are all detectable in the spectra of complexes **6***a*, **7***a*, **9***a*, and **10***a* (Table 2). (Despite this, the NH_3 CI mass spectrum of **6***a* is also consistent with extensive thermal decomposition to CoL_2.) Thus, increasing fluorine content increases the abundance of $[Co^{III}L_3]^{+\cdot}$ but, interestingly, the

abundance is smaller when R′ = C_3F_7 than when R′ = C_2F_5. Also, the abundance of $[Co^{III}L_3]^{+\cdot}$ is greater when R = phenyl than when R = 2-thienyl. The net effect of the various substituents is probably not simple. Up to a point, increasing fluorine content decreases polar interactions between molecules of the complexes (depending upon how they are packed in the solid), and increases the volatility. Beyond this point, increasing molecular mass and dispersion forces decrease the volatility. If the rate of thermal decomposition of CoL_3 is comparable to the sublimation rate at the temperature of the probe, then the observed spectrum could be sensitive to the probe temperature required for volatilization of the complexes. Perhaps these competing effects are optimized when R′ = C_2F_5. As noted above, these observations

⟶ reaction step for which reduction of cobalt is proposed

SCHEME 2. Fragmentation pathways proposed for β-diketonates **3***a*, **4***a*, and **5***a* (R′ = CF_3).

may also be influenced by the stability of $[Co^{III}L_3]^{+\bullet}$, if it is formed.

The ions $[Co^{III}L_2]^+$, $[Co^{III}L(L - 32)]^+$ (except for **6***a*), $[Co^{II}L(L - R')]^+$, and $[Co^{II}L]^+$ are prominent metal-containing ions. Since loss of the 32 dalton neutral fragment is not confined to sulfur-containing complexes its composition is probably :CHF, rather than S, in all cases.

Almost all of the fragmentation routes proposed in Scheme 3 are similar to those discussed above. Though still observed, ions formed by fluorine transfer to cobalt have declined in both number and significance, but the elimination of C_2F_4 (or 2 :CF_2 by analogy with the spectra of **7***b* and **8***b*, see below), observed only when R′ = C_2F_5 (**6***a* and **7***a*) in the decomposition $[Co^{II}L]^+ \rightarrow [Co^{II}F(L - R')]^+$, is a new reaction here.

Co(III) Monothio-β-diketonates

Mass spectra of the six monothio-β-diketonates **6***b*, **7***b*, **8***b* (R′ = C_2F_5), **9***b*, **10***b*, and **11***b* (R′ = *n*-C_3F_7) are given in Table 4, and representative spectra are shown in Figure 2. To aid in elucidation of fragmentation pathways, the results of collisionally assisted decompositions of selected ions obtained from **7***b* are listed in Table 3.

The low abundance of $[Co^{III}L_3]^{+\bullet}$ ions in the mass spectra of analogues of these complexes having a CF_3 substituent and various aryl substituents was attributed to thermal degradation to reduced complexes, $Co^{II}L_2$ (27, 35). However, we detected low abundances of $[Co^{III}L_3]^{+\bullet}$ and $[Co^{III}L_2(L - F)]^+$ for several of these more highly fluorinated complexes indicating, as above, that increasing fluorine content increases the yield of $[Co^{III}L_3]^{+\bullet}$.

Decomposition pathways observed for these complexes are shown in Scheme 4. Reduction of the metal in $[Co^{III}L_2]^+$ results in the $OE^{+\bullet}$ species $[Co^{II}L_2]^{+\bullet}$, which in turn can lose either F·, to yield $[Co^{II}L(L - F)]^+$, or R′· to give $[Co^{II}L(L - R')]^+$. (These processes are confirmed by linked scanning.) The EE^0 species CO and $R(C_2S)H$ are eliminated from $[Co^{II}L(L - R')]^+$ in the fragmentation sequence $[Co^{II}L(L - R')]^+ \rightarrow [Co^{II}L(L - R'CO)]^+ \rightarrow [Co^{II}L]^+$. Alternative decomposition routes originating from $[Co^{II}L(L - R')]^+$ and leading to $[Co^{II}L]^+$ proceed either by the stepwise elimination of the EE^0 species COS and RC_2H, or by direct loss of (L − R′). From a mechanistic viewpoint, the loss of COS corresponds to the loss of CO_2 in the mass spectra of Co(III) β-diketonates, as discussed above. Loss of the OE· species R′CO· from $[Co^{I}L]^{+\bullet}$ (assuming a further reduction of cobalt) results in the EE^+ species $[Co^{I}SC(R)CH]^+$, which can then eliminate sulfur to give $[Co^{I}CHCR]^+$.

The only ion resulting from fluorine-to-metal transfer that is common to all complexes of this group is $[Co^{III}FL(L - CF_3)]^+$ formed by elimination of :CF_2 from $[Co^{III}L_2]^+$. In addition, for **7***b* and **8***b*, this ion decomposes further by loss of :CF_2 to yield $[Co^{III}FL(L - C_2F_5)]^+$. (This result does not exclude a competing elimination of C_2F_4 from $[Co^{III}L_2]^+$.) We note that fluorine transfer to cobalt(III) is involved in this reaction. In contrast, transfer of fluorine to cobalt(II) is not observed.

All observed spectra of the monothio-β-diketonates ex-

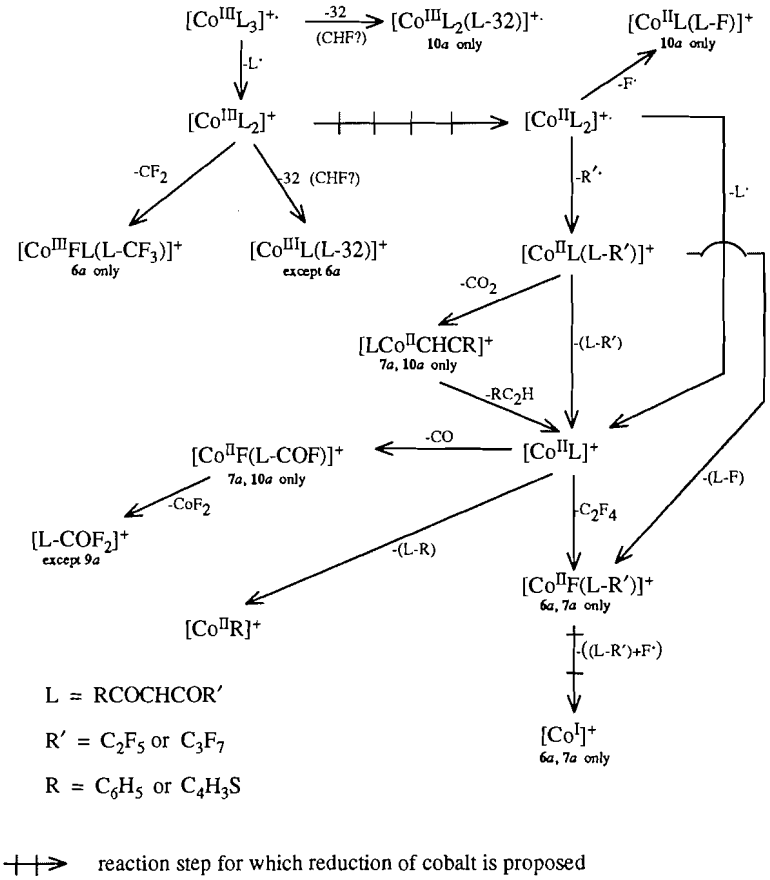
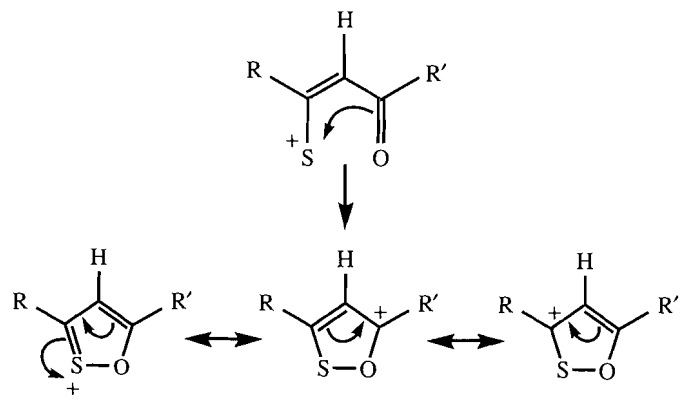


SCHEME 3. Fragmentation pathways proposed for β-diketonates **6***a*, **7***a* (R′ = C_2F_5), **9***a*, and **10***a* (R′ = C_3F_7). Pathways are common to all complexes, except where noted.

hibit metal-free ions that have no analogues in the spectra of the β-diketonates. We attribute their formation to the respective losses of CoS and S in the sequence: $[Co^{II}L(L - R'CO)]^+ \rightarrow [2L - S - R'CO]^+ \rightarrow [2L - 2S - R'CO]^+$. We could confirm only the second step by linked scanning, but the corresponding loss of MetS has been documented previously in the mass spectra of trifluoromethyl-substituted monothio-β-diketonates of Ni(II), Pd(II), Pt(II), Fe(III), Ru(III), Co(III), and Rh(III) (27, 36).



The high abundance of $[L]^+$ observed here also occurs generally for monothio-β-diketonates (27, 36)[4] suggesting that it has a very stable structure, perhaps the resonance-stabilized cyclic structure shown in the diagram.

Influence of ligands and metal on the mass spectra

Effect of fluorine content on ions formed by fluorine-to-metal transfer

Ions attributable to formation by fluorine-to-metal transfer reactions decline in both number and significance in the sequence $CF_3 > CHF_2 > C_2F_5 > n\text{-}C_3F_7$. This is best illustrated by the mass spectra of the β-diketonates, for which the Σ%TIC carried by these ions (i.e., the sum of the %TIC values for $[Co^{II}F(L - COF)]^+$, $[Co^{II}FL(L - R')]^+$, $[Co^{II}F(L - R')]^+$, $[FCo^{II}CHCR]^+$, $[L - 2F]^+$, and $[L - COF_2]^+$, where %TIC is the current for an ion expressed as a percentage of the total metal-containing ion current) when R = phenyl and 2-thienyl (the common aryl groups) has a striking dependence on the R′ group. (The respective Σ%TIC values for CF_3 : CHF_2 : C_2F_5 : C_3F_7 substituents are 6.4 : 6.3 : 2.4 : 0 and 6.3 : 4.3 : 2.9 : 1.2 for R = C_6H_5 and C_4H_3S substituents.) Probably there are several energetic and kinetic factors influencing the extent of the fluorine transfer reactions, including (*a*) hardness of the metal centre, (*b*) relative hardness of each carbon atom of the fluoroalkyl group, (*c*) relative stabilities of the products, and (*d*) conformational/steric factors. If we argue, for simplicity, that the inductive effect of CF_3 is similar to that of F then we predict the hardening effect of the fluoroalkyl groups on cobalt to be $CHF_2 < CF_3 \cong C_2F_5 \cong n\text{-}C_3F_7$, and the relative hardness of their carbon atoms to be $\alpha(CHF_2) < \alpha(CF_3, C_2F_5,$

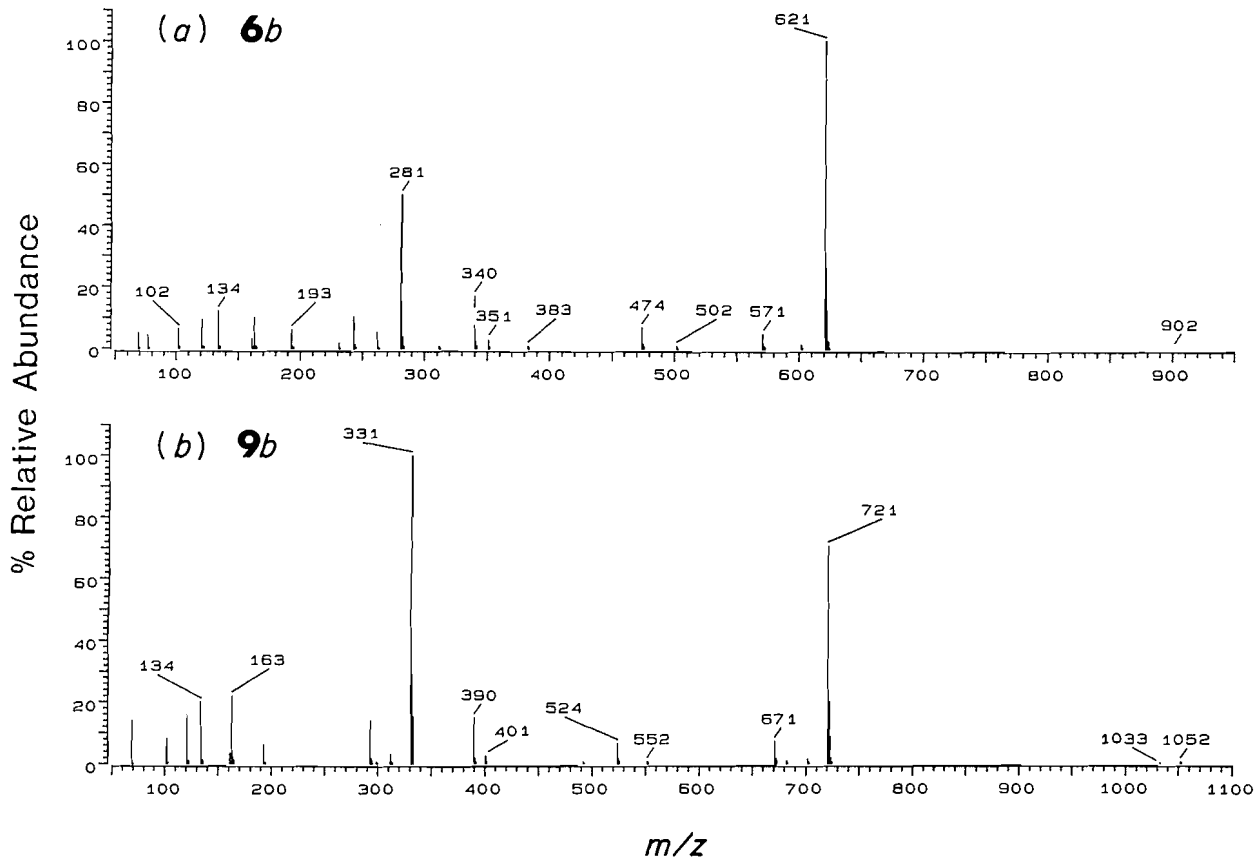

FIG. 2. Low-resolution EI mass spectra of (*a*) tris(1,1,1,2,2-pentafluoro-5-mercapto-5-phenyl-pent-4-en-3-onato)cobalt(III), **6***b*; and (*b*) tris(1,1,1,2,2,3,3-heptafluoro-6-mercapto-6-phenyl-hex-5-en-4-onato)cobalt(III), **9***b*.

n-C_3F_7) < β(C_2F_5, n-C_3F_7) ≅ γ(n-C_3F_7). A variety of neutral species can be lost. For example, considering fluorocarbon and hydrofluorocarbon species only, the possibilities are the following: from CHF_2, loss of :CHF; from CF_3, loss of :CF_2; from CF_2CF_3, loss of α-F gives :$CFCF_3$, loss of β-F gives CF_2:CF_2 or two :CF_2; from $CF_2CF_2CF_3$, loss of α-F gives :$CFCF_2CF_3$, loss of β-F gives CF_2:$CFCF_3$ or CF_2 + :$CFCF_3$, loss of γ-F gives :CF_2 + CF_2:CF_2 or three :CF_2. From factors (*a*)–(*c*) we predict the relative ease of fluorine transfer to cobalt from carbon to be: (*a*) n-C_3F_7 ≅ C_2F_5 ≅ CF_3 > CHF_2, (*b*) CHF_2 > CF_3 ≅ C_2F_5 ≅ n-C_3F_7 (in the competition for fluorine between carbon and cobalt, transfer from the softest carbon should be easiest), (*c*) CF_3 > (CHF_2, C_2F_5, n-C_3F_7) (because :CF_2 has a strongly resonance stabilized structure (23)). To assess factor (*d*) we note that transfer of α, β, or γ fluorines involve five-, six-, or seven-membered cyclic transition states, respectively, with the probability of fluorine being in the correct place for transfer decreasing with increasing ring size. The results suggest that factors (*c*) and (*d*) are the most important, but it is clear that the observance (or absence) of metal–fluorine bonded fragments in the mass spectra of these compounds is highly susceptible to the electronic environment associated with each chelate structure.

Effect of the aryl group on ions formed by fluorine-to-metal transfer

The influence of the aryl (R) substituents can be tentatively assessed from the abundances of ions arising from fluorine-to-metal transfer. (The total abundance of these ions is small owing to the low tendency for fluorine migration, an observation consistent with HSAB theory, which predicts a minimal attraction between a borderline-hard acid, such as Co(II), and a hard base, such as F.) Nevertheless, in the mass spectra of the CF_3-substituted β-diketonates, the ion current carried by $[Co^{II}F(L - R')]^+$ (the only fluorine-transfer ion common to all three complexes studied) is greater for **4***a* (R = 2-thienyl) than for **3***a* (R = phenyl) or **5***a* (R = 2-naphthyl). The respective %TIC values are 4.8 (R = 2-thienyl) > 2.1 (R = phenyl) ≈ 2.3 (R = 2-naphthyl), which we have taken as an approximate ordering of ease of fluorine transfer to cobalt. This is consistent with the greater variety of ions formed by fluorine-to-cobalt transfer (i.e., $[Co^{II}F(L - COF)]^+$, $[Co^{II}F(L - R')]^+$, and $[FCo^{II}CHCR]^+$) in the spectrum of **4***a*, compared to only $[Co^{II}F(L - R')]^+$ in those of **3***a* and **5***a*. The 2-thienyl substituent is known to be more electron releasing than is phenyl because thiophene reacts approximately three orders of magnitude faster than does benzene with electrophilic reagents (37). However, it can release electron density not only to cobalt but also efficiently to the CF_3 substituent in the same ligand through the conjugated system. These results suggest that the latter release is more effective.

Effect of cobalt oxidation state on ions formed by fluorine-to-metal transfer

An examination of metal–fluorine bond formation in the mass spectra of the monothio-β-diketonates reveals an interesting dichotomy. While fluorine transfer in the reaction $[Co^{III}L_2]^+ \rightarrow [Co^{III}FL(L - CF_3)]^+$ can be rationalized on the

basis of the hard-acid character of Co(III), the process is otherwise suppressed. HSAB theory rationalizes this behavior: (*i*) after metal reduction, fluorine transfer to the borderline-hard acid Co(II) center is less favored, (*ii*) the replacement of metal-bonded oxygen by sulfur in the chelate ring results in further softening of the cobalt center and a further lowered probability for fluorine migration.

Effect of donor heteroatom

The replacement of oxygen by sulfur in the chelate ring has a marked effect. For example, ions retaining Co—S bonds are observed more frequently than are ions retaining Co—O bonds in the mass spectra of the respective complexes. Typically, $[Co^{II}Aryl]^+$ ions are present in the spectra of β-diketonates and are absent in the spectra of monothio-β-diketonates; this reflects the stronger Co—S interaction since the mechanism proposed for the formation of $[Co^{II}R]^+$ involves breaking of metal–donor bonds.

Summary

Cobalt(III) chelates generally fragment by elimination of two OE$^\bullet$ radicals from $[CoL_3]^{+\bullet}$. Reduction of cobalt upon loss of the second radical species is presumed. Subsequent decomposition occurs through loss of either an EE^0 neutral without reduction of cobalt(II) (preferred) or loss of a third OE$^\bullet$ radical, indicating a further reduction to cobalt(I). In contrast, molecular ions of complexes of these ligands with metals that are resistant to change in oxidation state (e.g., Al(III), Ga(III), Pd(II), and Zn(II)) fragment by elimination of an OE$^\bullet$ species, followed by losses of one or more EE^0 species (37).

The HSAB principle provides a rationale for variations in abundance and variety of ions arising from fluorine-to-metal migration, based on the prediction that a hard base such as fluorine should bind preferentially with a hard acid. Cobalt is difficult to categorize; although Co(III) is a hard acid and as such should bind with fluorine, it is so readily reduced to the softer Co(II) state that relatively few ions involving F—Co(III) bonding are observed. Other results[4] have shown that fluorine migration is widespread in generation of fragment ions from Al(III) and Ga(III) β-diketonates (both metal ions are classified as hard acids), but is suppressed in generation of ions from chelates of Pd(II), a soft acid.

Fluorine transfer is much less significant in the fragmentation of ions from monothio-β-diketonates. The presence of the sulfur donor presumably softens the metal, thereby making the migration of fluorine a less-favored process.

Resonance stabilization by proximate aryl groups is also crucial to the formation of $[LCo^{II}CHCR]^+$ and $[FCo^{II}CHCR]^+$ ions for several of the Co(III) β-diketonates; the lone pair resonance provided by the heterocyclic 2-thienyl group appears to be particularly important.

α-Oxosulfines: reactions with alkenes and alkynes[1,2]

IAN W. J. STILL[3] AND DONNA KAYE T. WILSON[4]

J. Tuzo Wilson Research Laboratories, Erindale Campus, University of Toronto, Mississauga, Ont., Canada L5L 1C6

Received April 26, 1991

IAN W. J. STILL and DONNA KAYE T. WILSON. Can. J. Chem. **70**, 964 (1992).

Thiochroman-4-one 1,1-dioxide has been successfully converted into 3-sulfinylthiochroman-4-one 1,1-dioxide and the reactions of this α-oxosulfine with a series of alkenes have been carefully investigated. The α-oxosulfine was found to react as a Diels–Alder diene with 2-methylpropene, *Z*- and *E*-2-butene, 2-ethyl-1-butene, 1-pentene, *Z*-2-pentene, and cyclopentene and cyclohexene to produce a new group of heterocyclic compounds, the 2,3-dihydro-5*H*-1,4-oxathiino[3,2-*c*][1]benzothiopyrans, in yields ranging from 21 to 42%. In all cases, formation of the Diels–Alder adduct was accompanied by a second type of product, identified as the product of electrophilic addition (EA) of a sulfenium species to the alkene, in lesser yields, ranging from 9 to 18%. When the trapping dienophile used was 3,3-dimethyl-1-butene, only the EA adduct was obtained, in 28% yield. Formation of only the EA type of adduct was also observed in reactions of the α-oxosulfine with 2-butyne (21%) and with the thione 2,2,4,4-tetramethylpentane-3-thione (di-*tert*-butyl thioketone) (16%). Attempts to prepare the α-oxosulfines corresponding to the following ketones are also described: thiochroman-4-one 1-oxide, isothiochromanone and isothiochromanone 2,2-dioxide, tetrahydrothiophen-3-one 1,1-dioxide, 3,3,5,5-tetramethylcyclohexanone, and 2-indanone.

Key words: Diels–Alder, electrophilic addition, sulfenic acid.

IAN W. J. STILL et DONNA KAYE T. WILSON. Can. J. Chem. **70**, 964 (1992).

On a transformé avec succès le 1,1-dioxyde de thiochroman-4-one en 1,1-dioxyde de 3-sulfinylthiochroman-4-one et on a examiné avec soin les réactions de cette α-oxosulfine avec une série d'alcènes. On a trouvé que l'α-oxosulfine réagit comme un diène de Diels–Alder avec le 2-méthylpropène, les (*Z*)- et (*E*)-but-2-ènes, le 2-éthylbut-1-ène, le pent-1-ène, le (*Z*)-pent-2-ène, le cyclopentène et le cyclohexène pour conduire à la formation d'un nouvel ensemble de composés hétérocycliques, les 2,3-dihydro-5*H*-1,4-oxathiino[3,2-*c*][1]benzothiopyranes, avec des rendements allant de 21 à 42%. Dans tous les cas, la formation de l'adduit de Diels–Alder est accompagnée par un second type de produit, identifié comme le produit d'addition électrophilique (AE) d'une espèce sulfénium sur l'alcène, avec des rendements plus faibles, allant de 9 à 18%. Lorsqu'on a utilisé le 3,3-diméthylbut-1-ène comme diénophile, on n'a obtenu que du produit d'AE, avec un rendement de 28%. On n'a aussi observé que la formation du produit d'AE dans les réactions de l'α-oxosulfine avec le but-2-yne (rendement de 21%) et avec la thione 2,2,4,4-tétraméthylpentane-3-thione (di-*tert*-butyl thiocétone) (rendement 16%). On décrit aussi les essais effectués dans le but de préparer les α-oxosulfines correspondant aux cétones suivantes : 1-oxyde de la thiochroman-4-one, isothiochromanone et 2,2-dioxyde de l'isothiochromanone, 1,1-dioxyde de la tétrahydrothiophèn-3-one, 3,3,5,5-tétraméthylcyclohexanone et indan-2-one.

Mots clés : Diels–Alder, addition électrophilique, acide sulfénique.

[Traduit par la rédaction]

Introduction

In our earlier study (1) of the reactivity of α-oxosulfines we reported that the α-oxosulfines **1***a* and **2***a*, derived from cyclohexanone and thiochroman-4-one respectively, did not react as heterodienes in Diels–Alder trapping reactions with alkenes and alkynes. This represented behaviour quite in contrast to our preliminary finding (2) that the related α-oxosulfine **2***b* did act as a diene in Diels–Alder reactions, with both 2-methylpropene and norbornene. We were anxious to further investigate this apparent dichotomy and to seek to identify the electronic, steric, or other factors responsible, as well as to establish the generality of such inverse electron-demand Diels–Alder reactions as a potential synthetic route to various heterocyclic compounds.

Generally, α-oxosulfines are unstable, with a few notable exceptions reported by Zwanenburg and co-workers (3), and thus are generated *in situ*. They are conveniently prepared by reaction of the trimethylsilyl enol ether of the parent ketone with thionyl chloride, usually in the presence of a non-nucleophilic base such as 2,6-lutidine or 2,2,6,6-tetramethylpiperidine (1, 3). Interestingly, two alternative procedures for generating α-oxosulfines, using a completely different approach, have been reported very recently (4, 5). The role of the C=S bond in simple sulfines in Diels–Alder reactions is well documented (6, 7). In our present study, it was our intention initially to synthesize a series of α-oxosulfines of different structural types in order to explore their reactivity as (hetero) dienes in the Diels–Alder reaction with standard alkene or alkyne trapping agents. Later, we explored the reactivity of the model α-oxosulfine diene **2***b* towards a variety of structural types of alkene and alkyne. We now present the results of these studies.

Results and discussion

We decided to initiate this part of our study of the reactivity of α-oxosulfines with alkenes and alkynes by reexamining the reactivity of the oxosulfine system **2***b* with a wider range of trapping agents. This, we felt, would be important not only from the point of view of establishing the scope of the Diels–Alder reaction of α-oxosulfines but also in illuminating the rather puzzling dichotomy of behaviour between **2***a* and **2***b* already alluded to in the Introduction.

The starting point for **2***b* involved initial preparation of the keto-sulfone **3***c* by oxidation of **3***a* with peroxyacetic acid (8),

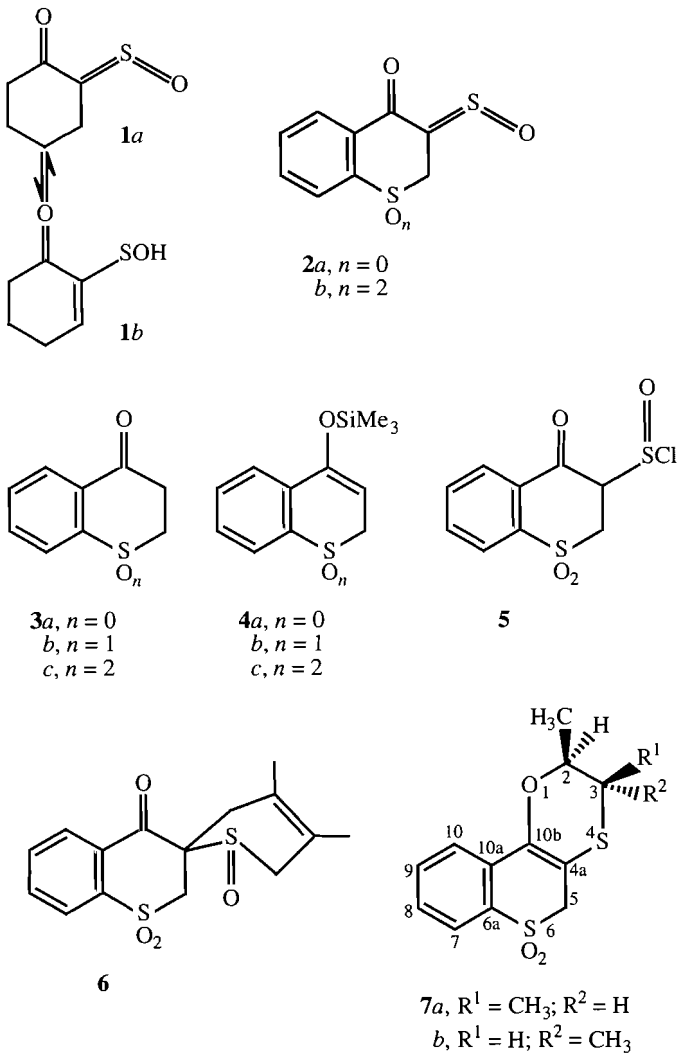
followed by conversion to the trimethylsilyl enol ether **4***c* (9), in an overall yield of 80%. As described earlier (1, 2) the silyl enol ether is converted into the α-oxosulfine **2***b* at low temperatures, via the intermediate β-oxosulfinyl chloride **5** and subsequent loss of HCl. Thionyl chloride was used for many of the sulfinylation reactions but on occasion was replaced with the milder *N*-(chlorosulfinyl)imidazole (10). The loss of HCl to produce **2***b* occurred even in the absence of added base, although addition of 2,6-lutidine was often effective.

The reaction of **2***b* with the isomeric alkenes *Z*-2-butene and *E*-2-butene will be described in detail and serves as a model for the analogous reactions of **2***b* with 2-methylpropene, 2-ethyl-1-butene, 1-pentene, *Z*-2-pentene, cyclopentene and cyclohexene, and 3,3-dimethyl-1-butene, the results of which are summarized in Table 1. The existence of **2***b* as an intermediate in the Diels–Alder trapping reactions was verified using 2,3-dimethyl-1,3-butadiene to afford the adduct **6** (2). Two alkene trapping agents that were totally without success in the trapping of **2***b* were the enol ether systems 2,5-dihydrofuran and ethyl vinyl ether.



Before describing our results with **2***b* in detail, it is very important to emphasize that, as observed in our preliminary communication (2) but in contrast to the results obtained by Zwanenburg and co-workers (3), *all* of the Diels–Alder adducts (**7***a*,*b*, **10***a*–*c*, **12***a*–*d*) obtained from the reaction of

2*b* as a (hetero) diene had suffered deoxygenation at the 1,4-oxathiin sulfur atom. We think that this arises from the fact that **2***b* has not proved to be isolable and therefore that all such Diels–Alder reactions were carried out as *in situ* trapping experiments. Inevitably, this means that thionyl chloride, and the by-product chlorotrimethylsilane, are present in such reaction mixtures, either agent being capable of effecting the deoxygenation of sulfoxides (11, 12). The facile deoxygenation is a consequence of the fact that the *S*-oxides of **7** and its cogeners are expected to be strongly activated towards electrophilic attack by such reagents, due to conjugative electron release from the oxathiin ring oxygen atom. Deoxygenation by $SOCl_2$ probably proceeds via electrophilic attack to produce intermediates such as **9***a*,*b*, with subsequent reduction being effected by the Cl^- counterion. It should be noted that no deoxygenation of **6** was ever observed. Compound **6** is, for both electronic and steric reasons, expected to be much less reactive towards such electrophilic deoxygenation than the 1,4-oxathiin *S*-oxides corresponding to **7***a*,*b* and their analogues.

Reaction of **2***b* with *Z*-2-butene *in situ* was conducted at −23°C in CH_2Cl_2 solution, with the reaction mixture finally being allowed to warm to 25°C. Two products were isolated after careful chromatography, along with some ketosulfone **3***c*, as was generally observed in this series. The first product (30%) was a beige solid and showed a C=C stretching vibration in the IR at 1608 and sulfone bands at 1314 and 1151 cm^{-1}. The ^1H NMR spectrum (400 MHz) showed the expected two doublets of doublets and two triplets of doublets for the aromatic ring protons. The C-5 CH_2 appeared as a very characteristic doublet of doublets at δ 3.78 and 3.86. Two quartets of doublets at δ 3.30 and 4.51 are assigned to the C-3 and C-2 methine hydrogens, respectively. Doublets were observed at δ 1.35 and 1.38 for the two methyl groups. The presence of a molecular ion at m/z = 282, the ^{13}C NMR data (see Table 2), and elemental analysis confirmed the formula $C_{13}H_{14}O_3S_2$ and led us to assign the (deoxygenated) Diels–Alder adduct structure **7***a* to this product.

The second product (14%) was also obtained as a (yellow) solid with a carbonyl stretching band in the IR at 1675 and SO_2 bands at 1295 and 1154 cm^{-1}. A molecular ion was detected at m/z = 317 and elemental analysis confirmed the composition $C_{13}H_{13}ClO_3S_2$. The most characteristic feature

in the ^{1}H NMR spectrum of this product was a singlet at δ 6.85, assigned to the lone vinylic proton in structure **8***a*. This structural assignment was further confirmed by the ^{13}C NMR data listed in Table 3. Compound **8***a* represents the electrophilic addition (EA) mode of reaction that was observed in the cyclohexanone and thiochroman-4-one series described previously (1) but which we now encountered for the first time from the α-oxosulfine **2***b*, albeit as a minor product.[5]

We were interested to discover if the Diels–Alder reaction so observed with *Z*-2-butene was stereospecific with respect to the alkene. Accordingly, a trapping experiment was carried out on **2***b*, under identical reaction conditions, using *E*-2-butene. Products analogous to **7***a* and **8***a* were again obtained. The Diels–Alder adduct **7***b* (26%) was very similar to, but clearly not identical with, **7***a*. In particular, **7***b* showed two very characteristic *quintets* in the ^{1}H NMR spectrum at δ 3.16 and 4.08 (J = 6.8, 6.4 Hz, respectively), assigned to the C-3 and C-2 protons. Clearly the much smaller (C-2)H/(C-3)H vicinal coupling constant of 2 Hz found in **7***a* is in accord with the *cis* adduct, with **7***b* as the *trans* isomer.[6] Only a single diastereomer was detected in each case and hence the Diels–Alder addition does show the expected stereospecificity. A second product (10%) obtained from the trapping experiment with *E*-2-butene was shown to have a structure consistent with the EA adduct **8***b*. Once again, this was a single diastereomer and thus, as predicted by the mechanism proposed earlier (1), the electrophilic addition must also proceed by a stereospecific pathway. ^{13}C NMR data for both adducts are listed in Tables 2 and 3.

In using 2-ethyl-1-butene (1,1-diethylethylene) as a dienophile we wished to investigate the regiochemical aspect of the above reactions. While the regiochemistry predicted for the Diels–Alder reaction can be predicted from bond polarities in the ground and transition states and would presumably follow the pattern already observed for 2-methylpropene (2), the situation may not be so clear-cut in the electrophilic addition pathway, where an intermediate (thiiranium ion) species **11** is presumed to be formed (1). Two adducts were again obtained. The Diels–Alder adduct (25%) was assigned structure **10***a* on the basis of IR, ^{1}H NMR, ^{13}C NMR, mass spectral, and elemental analysis and confirmed unambiguously by a single-crystal X-ray structure determination.[7] The minor product (14%), again a single isomer, had spectral properties consistent with the EA product **8***h*. The determination in favour of **8***h*, rather than its regioisomer, is based on the analysis of the ^{1}H and ^{13}C NMR spectra and comparative data from model compounds such as *tert*-butyl chloride and *tert*-butyl mercaptan and from similar adducts in the series derived from α-oxosulfine **2***a* (1). This result suggests that in the (presumed) intermediate thiiranium ion **11** there is a considerable degree of "open" or carbocation-like character, leading normally to nucleophilic trapping by Cl^- at the (more hindered) tertiary site and hence to the Markovnikov regioisomer actually observed. When we reexamined the reaction of **2***b* with 2-methylpropene as trapping agent, a small amount of the minor EA adduct **8***i* (9%) could be isolated, accompanying the expected Diels–Alder addition product **10***b* (37%) (2). The spectral similarities between the EA adducts **8***h*,*i* derived from these two 1,1-disubstituted ethylenes, and in particular the ^{13}C NMR data (Tables 2, 3), are quite striking. Regiochemical results from the EA pathway were not always so clear-cut, however (see

[5]An alternative route to the electrophilic addition product via an intermediate α-chlorosulfenyl chloride cannot be ruled out, cf. ref. 13.

[6]Molecular models show that the 1,4-oxathiin ring probably adopts a boat conformation although a half-chair conformation is also possible.

[7]Crystals of **10***a* were obtained by recrystallization from ethyl acetate/hexane as pale yellow needles. All work was performed on an Enraf–Nonius CAD4 diffractometer using graphite monochromatized MoKα radiation, λ = 0.71073 Å. A crystal of dimensions 0.24 × 0.36 × 0.28 gave the following data: $C_{15}H_{18}O_3S_2$, M_r = 310.4, triclinic, space group $P\bar{1}$ with a = 9.127(2), b = 10.330 (2), c = 8.972(1) Å, α = 106.36(2), β = 112.04(1), γ = 81.11(2)°, V = 751.2 Å^3, D_x = 1.37 g cm^{-3} for Z = 2, μ = 3.4 cm^{-1}, F(000) = 328, room temperature. Full details of the crystallographic structure will be published elsewhere.

1-pentene and *Z*-2-pentene cases, in Table 1), suggesting that, as noted by others (14–16), nucleophilic opening of thiiranium species is sensitive to many factors that may override simple structural considerations.

The pattern of results already described is followed, for the most part, by the remaining trapping experiments summarized in Table 1. For example, the symmetrically substituted cycloalkenes cyclopentene and cyclohexene gave the analogous Diels–Alder adducts (**12***a*,*b*) and EA adducts (**13***a*,*b*), again in a roughly 2:1 ratio. When the unsymmetrically disubstituted alkene *Z*-2-pentene was used, regioisomeric mixtures of both the Diels–Alder (**12***c*,*d*) and EA adducts (**8***c*,*d*), the latter in almost equal amounts, were obtained. This is a not unexpected outcome. With the unsymmetrically substituted alkene, 1-pentene, the expected product **10***c* was the sole Diels–Alder adduct isolated but, interestingly, *two* regioisomeric EA adducts (**8***e*,*f*) were again obtained, although the Markovnikov adduct **8***e* was predominant (2.5:1). The exclusive formation of the expected regioisomeric Diels–Alder adducts **10***a*,*b* and Markovnikov-governed EA adducts **8***h*,*i* from the strongly disymmetric alkenes 2-ethyl-1-butene and 2-methylpropene has already

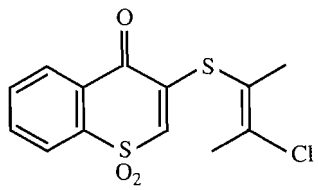
been described. Thus, a well-marked trend towards regiospecificity of both Diels–Alder adduct and EA adduct formation is revealed in Table 1 as the disymmetry of the trapping alkene is increased.

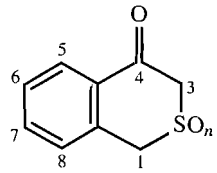
The other results in Table 1 deserve brief comment. With 3,3-dimethyl-1-butene (*tert*-butylethylene) *only* the EA adduct **8***g* was isolated, in almost 30% yield. The failure to form a Diels–Alder adduct in this instance may simply be due to failure to achieve the necessary coplanarity in the transition state, due to the presence of the bulky *tert*-butyl unit. The *anti*-Markovnikov regiospecificity in the EA adduct is more surprising in the light of other data in Table 1. It is possible, however, that in the presumed intermediate thiiranium ion **11** (R = *tert*-butyl, R′ = H) there is very little "open" carbocation character, because this would involve only a *secondary* carbocation, in contrast to those situations where R and R′ are both methyl (or ethyl) groups. Accordingly, attack of Cl^- on **11** (R = *tert*-butyl, R′ = H) may occur by the S_N2, rather than S_N1, mode, leading to preferred attack at the CH_2 site and hence to the *anti*-Markovnikov adduct observed. The failure of the one alkyne trapping agent used (2-butyne) to lead to any Diels–Alder adduct may be due to the (expected) lower reactivity of alkynes as dienophiles in the inverse electron-demand Diels–Alder reaction. Again in this case a reasonable yield (21%) of the EA adduct **14** was, however, observed.

An alternative approach to the synthesis of α-oxosulfines that had not yet been examined for their Diels–Alder reactivity emphasized the creation of α-oxosulfine units that would be *incapable* of undergoing tautomerization to the corresponding vinylsulfenic acids and hence would not be capable of undergoing the competing electrophilic addition (EA) reaction. For this reason, we selected as target molecules isothiochromanone **15***a* and its 2,2-dioxide **15***b*, tetrahydrothiophen-3-one 1,1-dioxide, 3,3,5,5-tetramethylcyclohexanone, and 2-indanone.

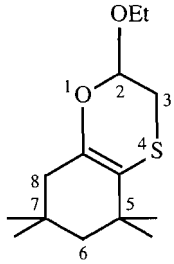
Isothiochromanone was readily prepared by the Friedel–Crafts cyclization of 2-benzylthioacetic acid (17). Reaction of the trimethylsilyl enol ether of **15***a* with thionyl chloride, followed by trapping with 2,3-dimethyl-1,3-butadiene, however, gave no conclusive evidence for the presence of the expected α-oxosulfine. We reasoned that the analogous sulfone **15***b* might be a better choice, particularly since the presence of the sulfone group should enhance the electron deficiency of the α-oxosulfine and hence its ability to undergo inverse electron-demand Diels–Alder reactions. Surprisingly, all attempts to prepare the trimethylsilyl enol ether of **15***b* by any of the methods we had employed previously met with utter lack of success, the ketone **15***b* being recovered in all cases. Since it seemed unlikely that either steric or electronic factors could account for this failure, we suspected that the silyl enol ether had actually formed but was extremely labile to hydrolysis. This view was subsequently confirmed by the conversion of **15***b* into its stable *tert*-butyldimethylsilyl enol ether in 79% yield. Unfortunately, this more hindered silyl enol ether did not react with thionyl chloride to produce the desired α-oxosulfine, even when anhydrous caesium fluoride was used in an attempt to cleave the O—Si bond. Tetrahydrothiophen-3-one 1,1-dioxide was next synthesized from 2,5-dihydrothiophene 1,1-dioxide by a three-step literature procedure (18). Like **15***b*, this compound is a β-ketosulfone, however, and when preliminary attempts to make its trimethylsilyl enol ether were unsuccessful, based upon our experience with **15***b*, we elected not to pursue this avenue farther.



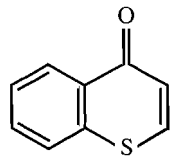
14



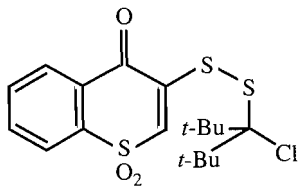
15*a*, *n* = 0
b, *n* = 2



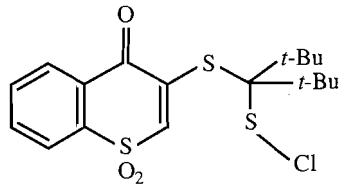
16



17



18



19

We next turned our attention to the α-oxosulfine derived from 3,3,5,5-tetramethylcyclohexanone. Formation of the trimethylsilyl enol ether was readily accomplished and, following reaction with *N*-(chlorosulfonyl)-imidazole, trapping experiments were conducted with 2-methylpropene, 2,3-dimethyl-2-butene, ethyl vinyl ether, and 2-butyne. Only in the case of ethyl vinyl ether was spectroscopic evidence obtained for the formation of the expected Diels–Alder adduct **16**, albeit in only 10% yield. In addition to other expected spectral features, the mass spectrum of **16** showed the presence of both a molecular ion (m/z = 256) and a major fragment ion (m/z = 184) corresponding to retro-Diels–Alder cleavage.

Zwanenburg and co-workers (19) showed that 2-sulfinyl-1-indanone is one of a very small number of stable, isolable α-oxosulfines and that it reacts with ethyl vinyl ether to produce the 1,4-oxathiin type of Diels–Alder adduct. We accordingly prepared 2-inandone from 1-indene (20), in 35% yield. Although the methylene protons in this case are also acidic ($pK_a \sim 12$; see discussion above), the trimethylsilyl enol ether could be readily prepared, contaminated by a small amount of the starting ketone. Reaction of the enol silyl ether with thionyl chloride, however, followed by attempted trapping with ethyl vinyl ether, gave none of the desired Diels–Alder adduct.

One other α-oxosulfine system that we wished to examine was that derived from thiochroman-4-one 1-oxide **3***b*. Since we have observed quite different patterns of reactivity for the α-oxosulfines derived from the corresponding sulfide (1) and sulfone it was important to establish where

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

the α-oxosulfine derived from **3***b* fitted in this series. The sulfoxide **3***b* was readily prepared from thiochroman-4-one by oxidation with peroxyacetic acid (21). Unfortunately, all attempts to convert **3***b* into its trimethylsilyl enol ether failed, producing only starting material accompanied by varying amounts of thiochromone, **17**. Several Pummerer-type dehydration reactions of sulfoxides using chlorotrimethylsilane have been described previously (22, 23). This reaction in our case presumably results from preferential *O*-silylation of the (more nucleophilic) sulfoxide site, followed by loss of $HOSiMe_3$ and deprotonation. Attempts to selectively oxidize the enol silyl ether **4***a* with *m*-chloroperoxybenzoic acid (*m*-CPBA) in buffered solution led only to complex mixtures of the ketones **3***a* and **3***b*, accompanied by their respective trimethylsilyl enol ethers. One final attempt to prepare the trimethylsilyl enol ether **4***b* was made, by treating the 3-bromo analogue of **3***b* (24), with zinc and chlorotrimethylsilane by the method of Joshi and Pande (25). Since this procedure again gave no useful result we reluctantly abandoned our attempt to prepare the α-oxosulfine in the sulfoxide series.

Attempts were also made to carry out Diels–Alder type reactions on the α-oxosulfine **2***b*, using heterodienophiles in place of alkenes or alkynes. In some cases (6), neutral imines were found to react with electron-deficient dienes via the inverse electron-demand Diels–Alder reaction. *N*-Methylbenzaldimine was accordingly prepared by a literature procedure (26). In the course of several attempts, however, to react the aldimine with **2***b* under our usual conditions no Diels–Alder adduct could be obtained and only traces of benzaldehyde and the keto-sulfone **3***c* were recovered. In similar trapping experiments using di-*tert*-butyl thioketone (27) a yellow solid adduct (16%) was isolated. The product showed a strong C=O band in the IR at 1653 cm^{-1} characteristic of an EA adduct and was established from ^1H and ^{13}C NMR and mass spectral evidence to have the structure **18** or **19**. The available evidence does not allow us to distinguish between these two possibilities. Disappointingly, when we attempted to extend this reaction to the aryl thioketone 4,4′-dimethoxythiobenzophenone no adduct of either the Diels–Alder or the EA type could be obtained and only **3***c* and unreacted thioketone were recovered.

Experimental

Infrared spectra were recorded using KBr pellets (if solid) or NaCl discs (if liquid), on a Nicolet 5DXB FTIR spectrometer. The ^1H NMR spectra were obtained on a Varian EM-360L spectrometer in $CDCl_3$ solution, unless otherwise indicated. High-field ^1H NMR spectra were obtained on a VXR 400 spectrometer and ^{13}C NMR spectra on a Varian XL-400 spectrometer, operating at 100.53 MHz. The ^{13}C NMR spectra were recorded in $CDCl_3$ solution. High- and low-resolution mass spectra were recorded on a VG-70-250S mass spectrometer. Column chromatography was carried out on grade 60, 60 Å silica gel supplied by Toronto Research Chemicals. Elemental analyses were performed by the Scandinavian Microanalytical Laboratory, Box 25, 2730 Herlev, Denmark.

Dichloromethane and chloroform were dried by distillation over phosphorus pentoxide and stored over 3 Å molecular sieves. Diethyl ether was dried by distillation from sodium benzophenone ketyl. Triethylamine was dried by distillation over calcium hydride and thionyl chloride was purified by distillation over triphenyl phosphite. Potassium iodide was dried at ~140°C for 3 h.

X-ray crystallography[7,8]

Unit cell dimensions based on 25 reflections ($10 < \Theta < 19°$). Intensity data collection (ω–2Θ scans, ω scan width $(0.60 + 0.35 \tan \Theta)°$, max. scan time = 60 s, octants $\pm h$, $\pm k$, l with $2 < 2\Theta < 54°$) gave a total of 3266 data. Variable scan rates (1.65–5.4°/min). Intensities of three standard reflections measured every 2 h showed no evidence of crystal decay.

Data are corrected for Lorentz and polarization effects but not for absorption. Exclusion of 345 zero F_{obs} data gave a final data set of 2921 reflections. The structure was solved by direct methods. Refinement was by full-matrix least-squares calculations, initially with isotropic and then with anisotropic thermal parameters for non-hydrogen atoms. The hydrogen atoms were positioned on geometric grounds and a general hydrogen thermal parameter was refined (final $U_{iso} = 0.057(3)$ Å^2). Final rounds of least-squares refinement included 182 parameters, $R = 0.040$, $wR = 0.043$ for 2131 reflections with $I > 3\sigma(I)$ and weights $(w) + 1/(\sigma^2(F_o) + 0.00036 (F_o)^2)$. Max. shift/esd in final refinement cycle 0.01; density in final difference map in range ±0.45 e/Å^3; there were no chemically significant features.

General procedure for the preparation of trimethylsilyl enol ethers

Dry chloroform (60 mL) was added to potassium iodide (65.70 g, 0.40 mol) with stirring under nitrogen. The mixture was cooled to 0°C and chlorotrimethylsilane (18.0 mL, 0.14 mol) was added. A solution of the ketone (0.059 mol) and triethylamine (33.1 mL, 0.24 mol) in dry chloroform (50 mL) was then added dropwise. The mixture was allowed to warm to room temperature, the flask was covered with foil paper, and the solution refluxed in the dark for 16 h. The reaction mixture was diluted with diethyl ether and the precipitated solid was removed by vacuum filtration and the filtrate dried ($MgSO_4$). Removal of the solvents on the rotary evaporator yielded the crude silyl enol ether, which was distilled (Kugelrohr) or used without further purification.

1-Trimethylsilyloxy-3,3,5,5-tetramethylcyclohexene

The crude silyl enol ether (98%) was obtained as a pale yellow oil. ^1H NMR, δ: 0.2 (s, 9H), 1.0 (br s, 12H), 1.3 (s, 2H), 1.8 (s, 2H), 4.7 (s, 1H).

*cis-2,3-Dihydro-2,3-dimethyl-[5H]-1,4-oxathiino[3,2-c-][1]-benzothiopyran 6,6-dioxide, 7*a

(+/−)-(1′S, 2′S*)-3-(2′-Chloro-1′-methylpropylthio)thiochromone 1,1-dioxide, 8*a

A solution of **4***c* (0.60 g, 2.23 mmol) in dry dichloromethane (5 mL) was stirred at −23°C under nitrogen. A solution of thionyl chloride (0.16 mL, 2.23 mmol) in dichloromethane (1 mL) was added dropwise and *Z*-2-butene was bubbled into the reaction mixture for 5 min. The mixture was stirred at −23°C for 2–3 h and then allowed to warm to 25°C and stirred for a further 16 h. The reaction mixture was washed (satd. $NaHCO_3$) and dried ($MgSO_4$). After filtration and removal of the solvent, a dark oil was obtained as the crude product.

Column chromatography on silica gel using dichloromethane/diethyl ether (99:1) as the eluent produced a brown oil (14%). Crystallization from dichloromethane/pentane yielded **8***a* as yellow needles, mp 137–138°C. IR, ν: 1675 (C=O), 1295, 1154 (SO_2)

[8]A complete set of tables comprising positional and thermal parameters, bond distances, and bond angles for **10***a* may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

These tables have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

*2,3-Dihydro-2,2-diethyl-[5*H*]-1,4-oxathiino[3,2-c][1]-benzothiopyran 6,6-dioxide,* **10**a

3-(2′-Chloro-2′-ethylbutylthio)thiochromone 1,1-dioxide, **8**h *(use of* N*-(chlorosulfonyl)imidazole (10) in place of $SOCl_2$)*

A solution of imidazole (0.58 g, 8.60 mmol) in dry dichloromethane (15 mL) was stirred under nitrogen at −15°C (CO_2(s) + ethylene glycol). Thionyl chloride (0.16 mL, 2.15 mmol) was added and the mixture was stirred at 25°C for 10 min. The white solid that precipitated was allowed to settle and the supernatant was transferred via a double-tipped needle to a three-necked flask equipped with a magnetic stirrer, gas-inlet adapter, and addition funnel. The solution was stirred under nitrogen at −15°C before adding more thionyl chloride (0.16 mL, 2.15 mmol). The mixture was then stirred at 25°C for 10 min and finally cooled to −23°C. A solution of **4***c* (1.05 g, 3.91 mmol) in dichloromethane (10 mL) was added dropwise to the solution of *N*-chlorosulfinylimidazole (4.30 mmol). 2-Ethyl-1-butene (1.0 mL, 8.19 mmol) was then added and the reaction mixture was stirred at −23°C for 4 h, allowed to warm to 25°C, and stirred an additional 15 h. The reaction mixture was washed (water, 5% $NaHCO_3$) and dried ($MgSO_4$). Filtration and removal of the solvent yielded a dark oil, which was purified by column chromatography. Dichloromethane eluted a yellowish-brown solid, **10***a* (25%), which on recrystallization from ethyl acetate/hexane yielded tan crystals, mp 115–116°C. IR, ν: 1610 (C=C), 1306, 1140 (SO_2) cm^{-1}; ^1H NMR, δ: 0.95 (t, J = 7.5 Hz, 6H), 1.8 (m, 4H), 2.91 (s, 2H), 3.85 (s, 2H), 7.40 (td, J = 7.6, 1.2 Hz, 1H), 7.57 (td, J = 7.7, 1.3 Hz, 1H), 7.68 (dd, J = 8.0, 1.2 Hz, 1H), 7.87 (dd, J = 7.7, 1.3 Hz, 1H); MS, m/z (% rel. int.): 310 (100), 228 (43), 162 (63), 134 (42), 83 (72), 55 (58). Another brown oil (30%), a mixture of **12***c* and **12***d* (2.8:1.0), was also eluted from the column. Crystallization from ethyl acetate/petroleum ether (30–60°C) gave initially a pale yellow solid and later a white solid, mp 183–184°C, was obtained. IR, ν: 1610 (C=C), 1314, 1153 (SO_2) cm^{-1}; ^{1}H NMR[10] (**12***c*), δ: 1.08 (t, J = 7.4 Hz, 3H), 1.39 (d, J = 6.5 Hz, 3H), 1.54 (m, 2H), 3.18 (ddd, J = 10.1, 4.3, 2.3 Hz, 1H), 3.84 (s, 2H), 4.59 (qd, J = 6.5, 2.2 Hz, 1H), 7.40–7.87 (m, 4H); ^{1}H NMR[10] (**12***d*), δ: 1.08 (t, J = 7.4 Hz, 3H), 1.36 (d, J = 7.0 Hz, 3H), 1.74 (m, 2H), 3.30 (qd, J = 7.0, 1.8 Hz, 1H), 3.78, 3.89 (ABq, J = 16.2 Hz, 2H), 4.20 (ddd, J = 9.0, 4.6, 1.8 Hz, 1H), 7.40–7.87 (m, 4H); MS, *m/z* (% rel. int.): 296 (82), 164 (30), 162 (100), 134 (91), 76 (30), 69 (51), 55 (38). High resolution MS, Exact Mass calcd. for $C_{14}H_{16}O_3S_2$: 296.0541; found: 296.0534. Anal. calcd. for $C_{14}H_{16}O_3S_2$: C 56.73, H 5.44; found: C 56.44, H 5.69.

[9]The number of assigned protons is doubled because of the presence of the two regioisomers. Many of the splitting patterns could not be ascertained because of the resulting overlapping. Signals that were clearly distinguishable are underlined.

[10]Serious overlapping of signals for **12***c,d* occurred only in the aromatic region.

*2,3-Dihydro-2-propyl-[5*H*]-1,4-oxathiino[3,2-c][1]-benzothiopyran 6,6-dioxide,* ***10***c

3-(2'-Chloropentylthio)thiochromone 1,1-dioxide, ***8***e

3-(1'-Chloromethylbutylthio)thiochromone 1,1-dioxide, ***8***f

The enol silyl ether **4***c* (0.60 g, 2.23 mmol) in dry dichloromethane (4 mL) was stirred at −78°C under nitrogen. A solution of thionyl chloride (0.16 mL, 2.23 mmol) in dichloromethane (4 mL) was added dropwise over 5 min and 1-pentene (1.2 mL) was added in one portion. The mixture was stirred at −78°C for 2 h, then allowed to warm to room temperature and stirred for a further 16 h. The reaction mixture was washed (satd. $NaHCO_3$) and dried ($MgSO_4$). The crude product was obtained as a dark oil.

Column chromatography on silica gel using dichloromethane yielded a brown oil (**8***e,f*) (2.5:1, 11%). Crystallization from dichloromethane/pentane gave pale yellow crystals, mp 116–117°C. IR, ν: 1669 (C=O), 1296, 1151 (SO_2) cm^{-1}; ^{1}H NMR,[9] δ: 0.9 (t, 6H), 1.4–2.8 (m, 8H), 3.14 (**8***e*) (m, 2H), 3.22 (**8***f*) (m, 1H), 3.58 (**8***f*) (dd, J = 11.6, 8.4 Hz, 1H), 3.73 (**8***f*) (dd, J = 11.6, 3.9 Hz, 1H), 4.11 (**8***e*) (m, 1H), 6.81 (s, 1H), 6.86 (s, 1H), 7.74 (td, J = 7.7, 1.2Hz, 2H), 7.87 (td, J = 7.8, 1.3 Hz, 2H), 8.02 (dd, J = 7.9, 1.1 Hz, 2H), 8.22 (m, 2H); MS, *m/z* (rel. int.): 294 (86), 265 (69), 227 (48), 201 (72), 153 (70), 76 (90), 69 (100).

Further elution with dichloromethane yielded a brown oil (**10***c*) (21%). Crystallization from ethyl acetate/hexanes gave tan crystals, mp 119.5–120.5°C. IR, ν: 1615 (C=C), 1317, 1147 (SO_2) cm^{-1}; ^{1}H NMR, δ: 0.98 (t, J = 7.2 Hz, 3H), 1.5–1.9 (m, 4H), 3.02 (d, J = 5.8 Hz, 2H), 3.79, 3.91 (ABq, J = 16.1 Hz, 2H), 4.23 (m, 1H), 7.41 (td, J = 7.6, 1.2 Hz, 1H), 7.56 (td, J = 7.7, 1.3 Hz, 1H), 7.66 (dd, J = 8.0, 1.1 Hz, 1H), 7.87 (dd, J = 7.8, 1.2 Hz, 1H); MS, *m/z* (% rel. int.): 296 (75), 162 (100), 134 (89), 76 (29), 58 (38). High resolution MS, Exact Mass calcd. for $C_{14}H_{16}O_3S_2$: 296.0541; found: 296.0540.

3-(1'-Chloromethyl-2',2'-dimethylpropylthio)thiochromone 1,1-dioxide, ***8***g

3,3-Dimethyl-1-butene (1.0 mL) was used as the trapping reagent for **2***b*. The crude product, a dark oil, was column chromatographed on silica gel. Dichloromethane eluted a yellowish-brown solid (28%). Recrystallization from dichloromethane/pentane yielded **8***g* as a yellow solid, mp 164–165°C. IR, ν: 1668 (C=O), 1300, 1157 (SO_2) cm^{-1}; ^{1}H NMR, δ: 1.14 (s, 9H), 3.08 (dd, J = 6.4, 5.3 Hz, 1H), 3.59 (dd, J = 12.1, 6.5 Hz, 1H), 3.97 (dd, J = 12.2, 5.3 Hz, 1H), 7.07 (s, 1H), 7.74 (td, J = 7.7, 1.2 Hz, 1H), 7.86 (td, J = 7.7, 1.3 Hz, 1H), 8.02 (dd, J = 7.9, 1.2 Hz, 1H), 8.21 (dd, J = 7.9, 1.3 Hz, 1H); MS, *m/z* (% rel. int.): 347 (49), 345 (100), 227 (32), 137 (25), 136 (21), 107 (13). High resolution MS, Exact Mass calcd. for $C_{15}H_{18}ClO_3S_2$ (MH^+): 345.0385; found: 345.0385.

E-*3-(2'-Chloro-1'-methyl-1'-propenylthio)thiochromone 1,1-dioxide,* ***14***

2-Butyne (0.50 mL) was used as the trapping reagent for **2***b*. The crude product was obtained as a dark brown oil (0.48 g). Column chromatography on silica gel, using dichloromethane, yielded a yellow solid (0.15 g, 21%). Recrystallization from dichloromethane/pentane gave green crystals of **14**, mp 189.5–190.5°C. IR, ν: 1665 (C=O), 1307, 1156 (SO_2) cm^{-1}; ^{1}H NMR, δ: 2.19 (m, 3H), 2.38 (m, 3H), 6.68 (s, 1H), 7.75 (td, J = 7.7, 1.2 Hz, 1H), 7.87 (td, J = 7.7, 1.3 Hz, 1H), 8.03 (dd, J = 7.9, 1.2 Hz, 1H), 8.22 (dd, J = 7.9, 1.2 Hz, 1H); MS, *m/z* (% rel. int.): 316 (24), 314 (53), 279 (100), 215 (61), 162 (23), 136 (35), 76 (47), 59 (61). High resolution MS, Exact Mass calcd. for $C_{13}H_{11}ClO_3S_2$: 313.9838; found: 313.9834. Anal. calcd. for $C_{13}H_{11}ClO_3S_2$: C 49.60, H 3.52, Cl 11.26, S 20.37; found: C 49.32, H 3.62, Cl 11.26, S 20.26.

Isothiochroman-4-one 2,2-dioxide, ***15***b

A solution of isothiochromanone (0.35 mmol) in dry dichloromethane (5 mL) was stirred at 25°C under nitrogen. A solution of *m*-CPBA (0.79 mmol) in dichloromethane (5 mL) was added

dropwise to the solution, which was stirred at 25°C for 20 h. The organic phase was then washed (10% Na_2SO_3, 10% $NaHCO_3$, satd. NaCl) before being dried ($MgSO_4$). Filtration and subsequent removal of the solvent gave **15***b* as a pale yellow solid (60%). Recrystallization from 95% EtOH afforded pale yellow crystals, mp 157–158°C. IR, ν: 1686 (C=O), 1315, 1119 (SO_2) cm^{-1}; ^1H NMR (acetone-d_6), δ: 4.5 (m, 2H), 4.8 (br s, 2H), 7.4 (m, 3H), 8.2 (m, 1H).

*4-*tert*-Butyldimethylsilyloxyisothiochrom-3-ene 2,2-dioxide*

Diisopropylamine (0.11 mL, 0.76 mmol) and 2.5 M *n*-butyllithium in hexanes (0.32 mL, 0.81 mmol) were added to dry THF (3 mL) with stirring under nitrogen at −78°C. The mixture was stirred for 30 min. A solution of **15***b* (0.15 g, 0.75 mmol) in dry THF (6 mL) was added dropwise over 15 min to the LDA solution. The mixture was stirred for 30 min at −78°C and 4-*tert*-butyldimethylchlorosilane (0.49 g, 3.25 mmol) in THF (5 mL) was then added. After stirring at −78°C for 30 min and then at room temperature for 1.5 h, the solution was concentrated and a light brown solid was obtained. The solid was washed with diethyl ether and the mixture was filtered. Concentration of the yellow filtrate gave a yellow solid (0.19 g, 79%), mp 96–100°C. ^1H NMR, δ: 0.3 (s, 6H), 1.0 (s, 9H), 4.4 (s, 2H), 6.0 (s, 1H), 7.5 (m, 4H).

*2,3-Dihydro-2-ethoxy-5,5,7,7-tetramethylcyclohexeno [1,2-*b*]-1,4-oxathiin,* ***16***

N-(Chlorosulfinyl)imidazole (10) prepared as before from imidazole (0.30 g, 4.40 mmol) and thionyl chloride (0.16 mL, 2.20 mmol) in dry dichloromethane (10 mL) was added dropwise under nitrogen to a cooled solution (−23°C) of 1-trimethylsilyloxy-3,3,5,5-tetramethylcyclohexene (0.50 g, 2.21 mmol), 2,2,6,6-tetramethylpiperidine (0.37 mL, 2.21 mmol), and ethyl vinyl ether (1.0 mL, 10.5 mmol) in dry dichloromethane (5 mL). The mixture was stirred at −23°C for 5 h and then at 25°C for a further 16 h. The reaction mixture was diluted with diethyl ether and filtered. The filtrate was washed (satd. $NaHCO_3$, water) and dried ($MgSO_4$). After filtration and removal of the solvent, a yellow oil (0.42 g) was obtained. Purification by flash chromatography on silica gel (CH_2Cl_2/CCl_4 70:30) yielded **16** as a colourless oil (0.069 g, 10%). IR, ν: 1646 (C=C), 1124 (C—O) cm^{-1}; ^1H NMR, δ: 1.3 (m, 15H), 1.5 (s, 2H), 2.0 (s, 2H), 2.9 (d, J = 3 Hz, 2H), 3.8 (m, 2H), 5.2 (m, 1H); MS, m/z (% rel. int.): 256 (66), 241 (30), 211 (9), 184 (30), 72 (18).

*3-(1'-Chloro-2',2'-dimethyl-1'-*tert*-butylpropyldithio)thiochromone 1,1-dioxide,* ***18****/ 3-(1'-chlorosulfenyl-2',2'-dimethyl-1'-*tert*-butylpropylthio)thiochromone 1,1-dioxide,* ***19***

Di-*tert*-butylthioketone (0.8 mL) was used as the trapping reagent for **2***b*. The crude product was isolated as a reddish-brown oil (1.22 g). Dichloromethane eluted a yellow solid (0.15 g, 16%). Recrystallization from dichloromethane/pentane gave yellow crystals of **18/19**, mp 177–179°C. IR, ν: 1653 (C=O), 1309, 1153 (SO_2) cm^{-1}; ^1H NMR, δ: 1.4 (s, 18H), 8.0 (m, 5H); MS, m/z (% rel. int.): 416 (1), 384 (1), 258 (17), 194 (7), 161 (8), 57 (100). High resolution MS, Exact Mass calcd. for $C_{18}H_{23}O_3S_3$ (M − Cl): 383.0809, found: 383.0782.

Received August 15, 1991

N. H. WERSTIUK, S. YEROUSHALMI, and HONG GUAN-LIN. Can J. Chem. **70**, 974 (1992).

A group of bicyclic ketones and thiones have been synthesized for homenolization studies. Bicyclo[2.2.1]heptane-2,5-dione (**6**) undergoes unusually rapid tetramethylation giving 3,3,6,6-tetramethylbicyclo[2.2.1]heptane-2,5-dione (**1**) in good yield. Treatment of **1** with P_2S_5 in xylene gave 3,3,6,6-tetramethylbicyclo[2.2.1]heptane-2,5-dithione (**2**) and 3,3,6,6-tetramethyl15-oxo-bicyclo[2.2.1]heptane-2-thione (**3**), which was converted into **4** with Raney nickel. Bicyclo[2,2,2]octane-2,5-dione (**7**), prepared via a Diels–Alder reaction between 2-trimethylsilyloxy-1,3-cyclohexadiene and and α-acetoxyacrylonitrile followed by a one-step desilylation/hydrolysis, also undergoes facile tetramethylation giving 3,3,6,6-tetramethylbicyclo[2.2.2]octane-2,5-dione (**5**) in good yield. AM1 calculations were carried out on the α-enolates of bicyclo[2.2.1]heptan-2-one, **6**, 5-methylidenebicyclo[2.2.1]heptan-2-one, and 4-acetylbicyclo[2.2.1]-heptan-2-one in an attempt to gain information on the source of the enhanced acidity of the C-3 hydrogens of **6** and **7**.

Key words: bicyclic ketones, thiones, synthesis.

N. H. WERSTIUK, S. YEROUSHALMI et HONG GUAN-LIN. Can. J. Chem. **70**, 974 (1992).

Dans le but d'étudier leur homo-énolisation, on a synthétisé une série de cétones et de thiones bicycliques. La bicyclo[2.2.1]heptane-2,5-dione (**6**) subit une tétraméthylation inhabituellement rapide pour conduire à la 3,3,6,6-tétramethylbicyclo[2.2.1]heptane-2,5-dione (**1**) avec un bon rendement. Soumise à l'action du P_2S_5 dans le xylène, la cétone **1** fournit la 3,3,6,6-tétraméthylbicyclo[2.2.1]heptane-2,5-dithione (**2**) et la 3,3,6,6-tétraméthyl-5-oxo-bicyclo[2.2.1]heptane-2-thione (**3**) qui a été transformée en cétone **4** par action du nickel de Raney. La bicyclo[2.2.2]octane-2,5-dione (**7**), préparée par une réaction de Diels–Alder entre le 2-triméthylsilyloxycyclohexa-1,3-diène et l'α-acétoxyacrylonitrile suivie par une réaction combinée de désilylation et d'hydrolyse, subit aussi une réaction facile de tétraméthylation conduisant à la 3,3,6,6-tétraméthylbicyclo[2.2.2]octane-2,5-dione (**5**) avec un bon rendement. On a effectué des calculs AM1 sur les énolates α des bicyclo[2.2.1]heptan-2-one (**6**), 5-méthylidènebicyclo[2.2.1]heptan-2-one et 4-acétylbicyclo[2.2.1]heptan-2-one dans le but de déterminer la source de l'acidité accrue des protons en C-3 des composés **6** et **7**.

Mots clés : cétones bicycliques, thiones, synthèse.

[Traduit par la rédaction]

Introduction

Our interest in determining the rate enhancement of α-enolization and homoenolization (β- and γ-enolization) by carbonyl and thiocarbonyl groups positioned β and γ to α-enolizable and homenolizable C-H's (1–7) necessitated the synthesis of a group of bicyclic ketones and their thione analogues. To this end, we undertook the synthesis of 3,3,6,6-tetramethylbicyclo[2.2.1]heptane-2,5-dione (**1**), 3,3,6,6-tetramethylbicyclo[2.2.1]heptane-2,5-dithione (**2**), 3,3,6,6-tetramethyl-5-oxo-bicyclo[2.2.1]heptane-2-thione (**3**), 3,3,6,6-tetramethylbicyclo[2.2.1]heptan-2-one (**4**), and 3,3,6,6-tetramethylbicyclo[2.2.2.]octane-2,5-dione (**5**), compounds required for a study of H/D exchange under homoenolization conditions (1 M KO*t*Bu/*t*BuOD, 150–180°C).

In the case of **1**, all C—H bonds are located either α, β, or γ to at least one activating carbonyl group. The hydrogens at C-7 are β to two carbonyl groups; the bridgehead hydrogens at C-1 and C-4 are α and β, and the hydrogens of the *exo* and *endo* methyls are β and γ to these groups. In this latter case, a two-site, through-space interaction with two carbonyl groups is only possible for the carbanion derived from an *endo* methyl. In **2**, the C-H's are activated by two thiocarbonyl groups. In this series of compounds, **3** is an ideal substrate to study because the relative activating effects of carbonyl and thiocarbonyl groups can be determined directly by intramolecular competitive H/D exchange. To establish the degree to which a second carbonyl group exhances the acidity of the C-H's at C-1 (C-4), C-7, and the methyl groups relative to the parent monoketone, it was also necessary to synthesize and study H/D exchange of 3,3,6,6-tetramethylbicyclo[2.2.1]heptan-2-one (**4**). Studies on [2.2.2]-dione **5** would establish the degree to which introduction of a second carbonyl group enhances homoenolization and bridgehead α-enolization relative to the monoketone 3,3-dimethylbicyclo[2.2.2]octan-2-one (8). In the case of **5**, the second carbonyl group is γ to a β-enolizable methylene and β to an α bridgehead hydrogen; the C-7 and C-8 methylenes are identical as are the bridgehead hydrogens and the pairs of *exo* and *endo* methyls.

Our plan was to synthesize and tetramethylate diones **6** and **7**, convert **1** into **2** and **3**, and desulfurize **3** to prepare **4**. This approach would also establish whether methylation of 2,5-diones **6** and **7** is enhanced over the corresponding bicyclic monoketones, which would require repeated treatments with $NaNH_2/CH_3I$ in order to be dimethylated (8).

In this publication, we document the preparation of **1**, **2**, **3**, **4**, and **5**, describe an improved three-step synthesis of **7**, and report on the facile methylation of **6** and **7**. The results of AM1 (9, 10) calculations on **1**–**7**, bicyclo[2.2.1]heptan-2-one (**BH**), 5-methylidenebicyclo[2.2.1]heptan-2-one-(**MBH**), and 4-acetylbicyclo[2.2.1]heptan-2-one (**ABH**) and the enolates of **6**, **BH**, **MBH**, and **ABH** are presented and

discussed. The ^1H and ^{13}C nmr spectra of **1**, **2**, **3**, **4**, **5**, and **7** are interpreted and resonances are assigned. These spectral assignments are important because nmr spectroscopy is the best way to determine the selectivity of H/D exchange in these compounds.

Results and discussion

Synthesis and methylation of **6**

Dione **6** was prepared from norbornadiene by the method of Meinwald *et al.* (11). When dione **6** was reacted with KO*t*Bu/CH_3I in ether at ambient temperature, tetramethylation was complete in 3 h; tetramethyldione **1** was isolated from several reactions in yields that ranged between 55 and 60%. Analysis of the reaction mixtures by gc showed that only minor amounts (<10%) of lower-retention-time products, assumed to be di- and trimethylated diones, were present. This facile tetramethylation contrasts the low reactivity of bicyclo[2.2.1]heptan-2-one, which must be treated several times with fresh $NaNH_2/CH_3I$ to achieve full dimethylation. That **6** is alkylated more readily than the monoketone is certainly due to the enhanced acidity of the hydrogens α to the carbonyl groups. In fact, previous studies established that **6** undergoes H/D exchange in NaOD/D_2O/dioxane faster (the H_{exo} and H_{endo} enhancements are 1200 and 600, respectively) than bicyclo[2.2.1]heptan-2-one (3). In our view, the enhanced acidity of **6** leads to a higher equilibrium concentration of the potassium enolate, relative to the monketone, and this results in an increase in the rate of methylation.

Synthesis and methylation of **7**

Although the synthesis of **7** was reported previously (12), a Diels–Alder reaction between 2-trimethylsilyloxy-1,3-cyclohexadiene (13, 14) and α-acetoxyacrylonitrile was used to construct the [2.2.2] skeleton (15). We reasoned that if the D–A reaction proceeded with good regioselectivity as indicated in Scheme 1, hydrolysis of the D–A adduct would yield **7** in an efficient three-step synthesis (Scheme 1). In fact, this was realized. Nuclear magnetic resonance analysis of the D–A product showed that there was a 4:1 preference for formation of the 2,5-substituted [2.2.2] adduct. In our initial studies, the D–A adduct was desilylated with KF and the ketocyanoacetate (**KCA**), identified on the basis of its ms, nmr, and ir spectra, was isolated as the major product. The **KCA** was hydrolyzed to **6** with aqueous NaOH. To simplify this synthesis, the D–A adduct was desilylated and converted to the ketone with 1 M $NaOCH_3/CH_3OH$ at ambient temperature. This one-pot desilylation–hydrolysis gave **6** in good yield and purity. Any 2,6-dione formed from the regioisomeric D–A adduct presumably was ring-opened to the keto ester, which was separated from **6** by crystallization. This three-step synthesis, which gave **6** in 25% overall yield from the cyclohexadiene and α-cyanovinyl acetate, is an improvement over the route described by Hill *et al.* (12) who used a five-step synthesis that began with a D–A reaction of maleic anhydride and hydroquinone. Dione **7**, like **6**, was readily tetramethylated with KO*t*Bu/CH_3I at ambient temperature; **5** was obtained in 55–60% yield from a number of reactions. This facile tetramethylation of **7** is in accord with the enhanced kinetic acidities of the α hydrogens relative to bicyclo[2.2.2]octan-2-one. Initial H/D exchange studies of **7** in NaOD/D_2O/dioxane have established that the rate enhancements of exchange of H_{exo} and H_{endo} relative to the monoketone are 20 and 15, respectively.[2]

Computational studies

Full geometry optimizations were carried out on **1**, **2**, **3**, **4**, **5**, **6**, and **7** with AM1 (9, 10) and the keyword PRECISE was used to tighten the covergence criteria. The computed geometrical structures of these compounds are given in Fig. 1. Enthalpies of ionization of **BH**, **MBH**, and **6** obtained by computing the heat of formation of the corresponding enolates (16) are given in Table 1. In each case, the enolates were found to be planar. The increase in acidity of the *exo* and *endo* hydrogens of **6** over the monoketone predicted from the computed ΔH_i's is seen in the relative rates of H/D exchange at the α C-3 sites. The second carbonyl group of **6** can enhance the acidity of these C-H's by polar (through-space and through-bond) and homoconjugative effects. It appears from the nature of the HOMO (Fig. 2) of the enolate of **6** that a π-type homoconjugative interaction does not occur although hyperconjugation with the C4—C5 bond is indicated by orbital contributions at C5—O9. The low *exo*

[2]The rates of *exo* and *endo* H/D exchange relative to the *endo* hydrogen of bicyclo[2.2.1]heptan-2-one are 10 400 and 7800, respectively. These experiments were carried out by W. Gunn at McMaster University, 1990.

selectivity[2] observed for H/D exchange of **7** shows that this is the case for the [2.2.2] system as well. If the transition state is achieved early, a larger *exo* selectivity would be expected if homoconjugative stabilization of the enolate was important because *exo* deprotonation would lead to better orbital overlap between the incipient anion at C-3 and the π-system of the carbonyl group at C-5.

To probe possible ring strain and hybridization effects of

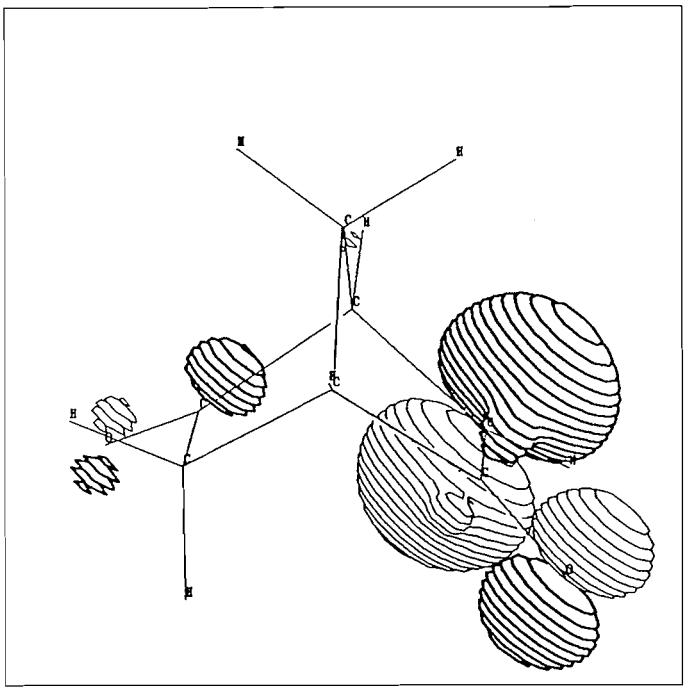

FIG. 2. Plot of the 0.2 au contours of the HOMO of the α-enolate of **6** obtained with AM1/DEN3D calculations.

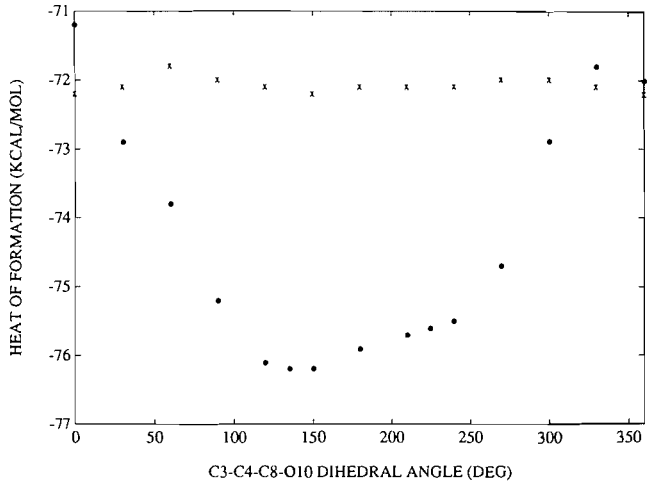

FIG. 3. Plot of the heats of formation of **ABH**(x) and its enolate **8** (·) versus the C3—C4—C5—O10 dihedral (twist) angle.

an sp^2 center at C5 of **BH**, ΔH_i of **MBH** was also computed. As seen from the data in Table 1, introduction of a carbon–carbon double bond at C5 results in a decrease ($\Delta\Delta H_i$ = 2.6 kcal) in the computed ΔH_i, but the decrease is considerably smaller than $\Delta\Delta H_i$ (11.0 kcal) computed for **BH** and **6**. Since the double bond is expected to stabilize the enolate through an inductive/field effect, the calculations suggest that these effects, if present, must be small. It is important to note that the computational results on **MBH** and its enolate are in accord with H/D exchange studies on **MBH** that established that the *exo*-H and *endo*-H rate enhancement are 8.9 and 2.1, respectively, relative to **BH** (2).

To establish how the spatial orientation of a β-carbonyl group affects the stability of an α-enolate, an AM1 computational study was carried out on 4-acetylbicyclo[2.2.1]-heptan-2-one (**ABH**) and its α-enolate. Structure **8** is the most stable geometry of this enolate. Figure 3 shows how the computed ΔH_f of **ABH**(X) and its enolate **8**(·) changes as the C3—C4—C8—O10 dihedral angle is driven through 360° beginning with an angle of 0°. Since the computed ΔH_f of the parent dione **ABH** is essentially independent of this dihedral angle, the computed enthalpy of ionization, ΔH_i, exhibits a dependence on angle nearly identical to ΔH_f of the enolate. On the basis of these results, maximum stabilization of an enolate derived from a 1,4-diketone should be expected when this dihedral angle lies between 105° and 240°. It is noteworthy that this dihedral angle is 110.9° for the enolate of **6**, and **6** exhibits an enhanced kinetic acidity over the parent monoketone. It is also interesting to note that on the basis of the ΔH_i's (Table 1) computed for **6** and 4-acetylbicyclo[2.2.1]heptan-2-one(**ABH**), **6** should show a higher acidity than **ABH**. Although H/D exchange of **ABH** has not yet been studied, Casadevall and co-workers have published the results of a study of 4-acetylcamphor(4-acetyl-1,7,7-trimethylbicyclo[2.2.1]heptan-2-one) and its 4-methyl, 4-chloro, 4-bromo, and 4-nitro analogues (17). The rate enhancements of H/D exchange of H-3-*exo* and H-3-*endo* of 4-acetylcamphor over camphor are 16.4 and 32.3, respectively. These enhancements are significantly lower than those observed for *exo* (1200) and *endo* (600) exchange of **6**, in keeping with the predictions made on the basis of the ΔH_i's computed for **6** and **ABH**. It should be pointed out here that since there is no conformational preference for the acetyl group of **ABH** (*vide supra*), a lower reactivity, relative to **6**, than that expected on the basis of the computed ΔH_i of the 135° conformer should be seen for **ABH**. If homoconjugative stabilization of the α-enolate **6** is not important, the question of why **6** is more acidic than **ABH** arises. If a field effect of the β-carbonyl group is important in stabilizing this α-enolate, then the C3, C=O distance may be the determining factor. That these distances for the α-enolates derived from **6** and **ABH** are 2.39 and 2.54 Å, respectively, is in accord with this hypothesis.

Nuclear magnetic resonance spectral assignments of ketones and thiones

^{13}C spectra

Table 2 documents the assignments of the ^{13}C resonances of **1**, **2**, **3**, **4**, **5**, **6**, and **7**.

^1H spectra

To assign the ^1H resonances of **1**, **2**, **3**, **5**, and **7**, nOe difference spectra were obtained and analyzed. Table 3 lists the resonances irradiated and the assignments made on the basis of the observed enhancements. In the case of **1**, irradiation of the signal at 1.18 ppm resulted in the enhancement of signals at 2.60 and 2.22 ppm. Irradiation of the signal at 1.02 ppm resulted in enhancement of only the signal at 2.60 ppm due to the bridgehead hydrogens. In the case of **2**, irradiation of the signals at 1.33 and 1.10 ppm again led to the assignment of all ^1H resonances. The resolution-enhanced spectrum of **3** showed a multiplet — an AB quartet split into triplets — for the hydrogens at C-7 (Fig. 4). That the upfield portion of this signal, as well as the one at 2.73 ppm, were enhanced when the singlet at 1.29 ppm (the *exo* methyl adjacent to the C=S group) was irradiated, established with certainty the assignment of the resonance of C7-H *syn* to the C=S group and the bridgehead C-H adja-

cent to the C=O group. Irradiation of the singlet at 1.22 ppm due to *exo* methyls adjacent to the C=O group led to an enhancement of the signals of C7-H *syn* to the C=O group (*anti* to C=S) and the bridgehead C-H adjacent to the C=S group. That the resonances due to the C7-H's *syn* and *anti* to the C=S group are separated and assignable at 500 MHz will facilitate the determination of the selectivity of H/D exchange under homoenolation conditions. Irradiation of the singlets at 0.99 and 1.14 ppm due to the *endo* methyls resulted in enhancement of only one signal, the bridgehead hydrogen, in each case and corroborated both the methyl group and bridgehead assignments. Irradiation of the singlet at 1.06 ppm of **5** resulted in an enhancement of only the resonance at 2.36 ppm, the bridgehead hydrogens, and established that this singlet at 1.06 ppm is due to the *endo* methyls at C-3 and C-6. That the resonances at 2.36 and 2.18 are enhanced when the *exo* methyls (1.22 ppm) are irradiated established that the multiplet at 2.18 is due to the hydrogens at C-7 and C-8 that are *anti* to the carbonyl groups at C-2 and C-5, respectively. In this case, the signal due to the *syn*-H's is also enhanced but only one-third the amount that the bridgehead and *anti* hydrogens are enhanced. These results are in accord with the distances between the *exo*-methyl carbon(s) and the bridgehead hydrogen(s) (2.37 Å), the *anti* C7 (C8)-H (2.82 Å) and the *syn* C7(C8)-H (3.28 Å) obtained from the AM1 optimized geometry of **5**. It is interesting to note that, according to AM1, dione **5**, unlike its parent **7**, is twisted (see **5'**). Presumably this is due to a steric interaction of the *endo* methyls. In the case of **7**, irradiation of the multiplet at 2.05 ppm resulted in enhancement of signals at 2.74 and 2.52 ppm. When the resonance at 1.94 was irradiated, only the broad singlet at 2.74 ppm was enhanced. These two experiments led to a definitive assignment of the resonances at 2.74 (bridgehead C-H's), centered at 2.53 (*exo* C3(C6)-H's), centered at 2.47 (*endo* C3(C6)-H's), 2.05 (C7(C8)-H's *syn* to the carbonyl groups at C2 and C5), and 1.94 (C7(8)-H's *anti* to the carbonyl groups) ppm of **7**.

Experimental

General

Melting points were measured with a Kofler Hot-Stage apparatus and all uncorrected nuclear magnetic resonance (nmr) spectra were recorded on Varian EM-390 and Bruker WM-250 and AM-500 spectrometers with $CDCl_3$ or CCl_4 as solvents. Tetramethylsilane (TMS) was used as an internal standard and chemical shifts are reported as parts per million downfield from internal TMS. Mass spectra were recorded on CEC-21-110B, VG Micromass 7070F, and VG ZAB spectrometers. Elemental analyses were carried out by Gailbraith Laboratories Inc., Knoxville, Tenn. Preparative gas–liquid chromatographic separations were performed on Varian Associates A-90-P and A-700 gas chromatographs. Helium was used as a carrier gas and samples were collected manually.

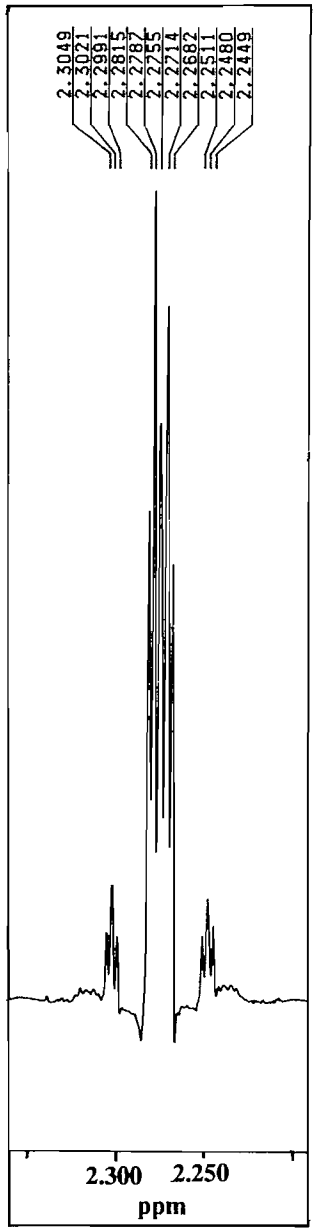

FIG. 4. A section (*syn*- and *anti*-C7-H's) of the resolution-enhanced 500 MHz ^{1}H nmr spectrum of **3**.

Preparation of 3,3,6,6-tetramethylbicyclo[2.2.1]heptane-2,5-dione (1)

Bicyclo[2.2.1]heptane-2,5-dione (5.28 g, 42.5 mmol) prepared by the method of Meinwald *et al.* (11) was placed in a round-bottom flask (1500 mL) containing dry ether (800 mL) and potassium-*tert*-butoxide (30.4 g, 270 mmol) was added. This solution was stirred for 0.5 h and CH_3I (60 mL) in an equal volume of ether was slowly aded over 0.5 h. After the solution was stirred for 3 h, analysis by analytical gc showed that the methylation was complete; only traces of the dione remained and only one major peak was evident. The solid was filtered off and solvent was removed by distillation. Recrystallization of the residue from ether gave **1** (4.2 g, 56%), mp 114–115°C; ^{1}H nmr ($CDCl_3$) δ: 2.60 (t, 2H, bridgehead H-1,H,4), 2.20 (t, 2H, H-7) 1.15 (s, 6H, *exo* CH_3) 1.10 (s, 6H, *endo* CH_3); ^{13}C nmr ($CDCl_3$) δ: 217.8 (C-2, C-5), 70.1 (C-1, C-4), 45.9 (C-3, C-6) 23.5 (*exo* CH_3's, C-9, C-11) 22.3 (C-10, C-12 *endo* CH_3's). Anal. calcd. for $C_{11}H_{12}O_2$: C 73.23, H 8.95; found: C 73.58, H 8.89.

Preparation of bicyclo[2.2.2]octane-2,4 dione (7)

2-Trimethylsiloxy-1,3-cyclohexadiene (1.81 g, 10.7 mmol), prepared by the method of Rubottom and Gruber (14), and 1-cyanovinyl acetate (1.11 g, 10 mmol) were combined in a dry Pyrex tube. The tube was sealed under vacuum and heated at 150°C for 15 h. The viscous product was dissolved in 1 N sodium methoxide/methanol (30 mL); the solution was stirred at room temperature for 3 h and poured into 150 mL of ice-water. The aqueous solution was extracted with methylene chloride, the combined extracts were dried over anhydrous $MgSO_4$, and the solvent was removed by rotoevaporation to yield 1.1 g of crude **7**. Recrystallization from benzene gave 0.70 g of **7** (51%), mp 203–205°C (lit. (10) mp 203–205°C); ^{1}H nmr ($CDCl_3$) δ: 2.75 (bm, 2H, H-1, H-4), 2.52 (q, 4H, H-3 *exo*, H-3 *endo*, H-6 *exo*, H-6 *endo*), 2.06 (bm, 2H, H-7(8) *syn*) 1.94 (bm, 2H, H-7(8) *anti*).

Preparation of 3,3,6,6-tetramethylbicyclo[2.2.2]octane-2,5-dione (5)

Dione **7** (0.83 g, 6.0 mmol) and potassium-*tert*-butoxide (5.38 g, 48.0 mmol) were mixed in dry ether (160 mL) in 3-necked flask (500 mL) fitted with a condenser, drying tube, and dropping funnel. After this mixture was stirred for 30 min, CH_3I (10 mL, 22.8 g, 161 mmol) dissolved in an equal volume of dry ether was added dropwise over a 10-min interval. The mixture was stirred at room temperature for 3 h, then filtered. Removal of the solvent by rotoevaporation gave 0.91 g of crude **5**. Recrystallization from pentane yielded 0.67 g of **5** (58%), mp 69–70°C; ^{1}H nmr ($CDCl_3$) δ: 2.36 (2H, H-1, H-4), 2.18 (m, 2H, H7(8) *anti*), 1.86 (m, 2H, H-7(8) *syn*), 1.22 (s, 6H, *exo* CH_3's), 1.06 (s, 6H, *endo* CH_3's). Mol. Wt. (high resolution ms), calcd. for $C_{12}H_{18}O_2$: 194.1313; found: 194.1312.

Preparation of 3,3,6,6-tetramethylbicyclo[2.2.1]heptane-2,-5-dithione (2) and 3,3,6,6-tetramethyl-5-oxo-bicyclo[2.2.1]heptane-2-thione (3)

A round-bottom flask (250 mL) containing 100 mL of xylene was fitted with a Soxhlet extractor, a condenser, and a drying tube. The extractor was charged with 10.0 g of P_2S_5 in the thimble. After the xylene was refluxed for 2 h to obtain a solution saturated with P_2S_5, dione **1** (3.0 g, 16.7 mmol) was added and the mixture was stirred, refluxed, and monitored by analytical gc. After 5.5 h the solution was cooled, the P_2S_5 removed by filtration, and the xylene distilled under reduced pressure. The concentrate was extracted (5 × 75 mL) with ether/petroleum ether (30–60°C) (50:50 v/v). The combined extracts were filtered and concentrated by distillation. Compounds **1**, **2**, and **3** were separated by column chromatography on neutral alumina (activity 7, mesh size 80–200) beginning with petroleum ether (30–60°C) as the solvent and gradually increasing the polarity by addition of ether. The chromatography was monitored by analytical gc and the appropriate fractions were combined. The order of elution was **2**, **3**, and **1**. Thione **2**, mp 25–30°C; ir (CCl_4) ν_{max}: 1167 (C=S) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 3.42 (s, 2H, H-1, H-4), 2.30 (s, 2H, H-7 *syn* and *anti*), 1.27 (s, 6H, *exo* CH_3's), 1.06 (s, 6H, *endo* CH_3's); ^{13}C ($CDCl_3$) δ; 2.68.6 (C-2, C-5), 74.1 (C-1, C-4), 56.1 (C-3, C-6), 35.6 (C-7), 29.5 (*exo* CH_3's), 25.6 (*endo* CH_3's); Mol. Wt. (high resolution ms) calcd. for $C_{11}H_{12}S_2$: 212.0704O; found: 212.06930. **3**, mp 50–53°C; ^{1}H nmr ($CDCl_3$) δ: 3.23 (1H, H-1), 2.70 (1H, H-4), 2.23 (2H, H-7 *syn* and *anti*), 1.21 (s, 3H, *exo* 3-CH_3), 1.21 (s, 3H, *exo* 6-CH_3), 1.06 (s, 3H, *endo* 3-CH_3), 0.94 (s, 3H, *endo* 6-CH_3). ^{13}C nmr ($CDCl_3$) δ: 268.4 (C=S), 217.5 (C=O), 72.7 (C-1), 61.8 (C-4), 55.2 (C-3), 33.7 (C-7), 46.0 (C-6), (*exo* and *endo* CH_3's), 28.9, 25.7, 23.6, and 21.5. Mol. Wt. (high resolution ms) calcd. for $C_{11}H_{16}O_2S$: 196.09320; found: 196.09210.

Preparation of 3,3,6,6-Tetramethylbicyclo[2.2.1]heptan-2-one (4)

Monothione **3** (1.47 g, 7.5 mmol) was dissolved in super dry ethanol (25 mL) in a round-bottom flask (100 mL) fitted with a condenser and a drying tube, and Raney nickel W-2 (10 g) was added. This mixture was stirred and refluxed for 10 h and moni-

tored by analytical gc. The catalyst was filtered off using a sintered-glass funnel containing Celite and washed with ethanol (10 mL). After most of the ethanol was removed by distillation, 0.86 g of ketone **4** was isolated from the concentrate by preparative gc on a 15% Carbowax on Chromosorb W (60–100 mesh) column maintained at 195°C. **4**, ^{1}H nmr (CCl_4) δ: 2.13 (m, 1H, H-4, $J_{4,5x}$ = 4.4 Hz, $J_{4,5n}$ ~0.3 Hz, $J_{4,7a}$ 1.3 Hz, $J_{4,7s}$ = 0.4 Hz), 2.01 (dd, 1H, H-1, $J_{1,7a}$ = 0.8 Hz), 1.96 (m, 1H, H-7 *syn*, $J_{7s,7a}$ = 10.8 Hz, $J_{7s,5n}$ = 2.6 Hz, $J_{7s,4}$ = 0.7 Hz, $J_{7s,1}$ = 1.3 Hz), 1.85 (m, 1H, H-7 *anti*, $J_{7a,7s}$ = 10.8 Hz, $J_{7a,1}$ = 0.8 Hz, $J_{7a,4}$ = 1.8 Hz), 1.63 (bdd, 1H, H-5 *endo*, $J_{5n,5x}$ = 12.8 Hz, $J_{5n,7s}$ = 2.6, $J_{5n,4}$ ~0.3), 1.42 (dd, H-5 *exo*, $J_{5x,5n}$ = 12.8, $J_{5x,4}$ = 4.4), 1.11 (s, 3H, CH_3), 1.04 (s, 3H, CH_3), 1.00 (s, 3H, CH_3), 0.97 (s, 3H, CH_3); ^{13}C nmr ($CDCl_3$) δ: 222.0 (C=O), 62.4 (C-4), 47.2 (C-1), 46.5 (C-3), 36.8 (C-6), 38.7 (C-7), 34.3 (C-5), 30.9 (CH_3), 27.4 (CH_3), 20.8 (CH_3). Anal. calcd. for $C_{11}H_{14}O$: C79.46, H 10.91; found: C 79.27, H 11.03.

Computational studies

RHF calculations were carried out with AM1, Version 2.1, of the general purpose molecular orbital computational package AMPAC (10) that was ported to IBM RT, IBM RS/6000, and MIPS 2030 workstations. Optimizations were carried out with the AM1 default parameters and the keyword PRECISE was used to tighten the convergence parameters. The MO density plot was obtained with the package AM1/DEN3D/DRAW3D (18) and printed as a SUN 3/60 rasterfile on a Laser Jet II printer.

G. W. BUCHANAN, S. MATHIAS, C. BENSIMON, and J. P. CHARLAND. Can. J. Chem. **70**, 981 (1992).

The structures of the title materials have been determined via X-ray crystallography. In the free crown ether, there is effectively a plane of symmetry that bisects the molecule. In the NaNCS complex, ring inversion of one of the cyclohexane moieties has occurred, giving a distorted pentagonal pyramidal coordination geometry about the sodium ion. For the free crown, two conformers, whose free energies differ by ca. 0.5 kJ/mol in solution can be detected via ^{13}C NMR at 168 K. Limiting low-temperature solution spectra are compared to those which have been obtained in the solid phase using the ^{13}C CPMAS technique.

Key words: crown ethers, stereochemistry, X-ray, NMR.

G. W. BUCHANAN, S. MATHIAS, C. BENSIMON et J. P. CHARLAND. Can. J. Chem. **70**, 981 (1992).

On a déterminé les structures des produits mentionnés dans le titre par diffraction des rayons X. Dans l'éther couronne à l'état libre, il existe un plan de symétrie qui bissecte la molécule. Dans le complexe NaNCS, il se produit une inversion des cycles des portions cyclohexaniques; il s'ensuit que la coordination autour du sodium est de type pyramide pentagonale déformée. Pour la couronne libre, à 168 K, la RMN du ^{13}C permet de détecter deux conformères dont les énergies libres diffèrent par environ 0,5 kJ/mol, en solution. On a comparé les spectres obtenus à la limite inférieure de température supportée par la solution avec ceux qui ont été obtenus en phase solide à l'aide de la technique du CPMAS du ^{13}C.

Mots clés : éthers couronnes, stéréochimie, rayons X, RMN.

[Traduit par la rédaction]

Introduction

In crown ether chemistry, the 15-crown-5 system is of interest because of its efficiency for internal encapsulation of the sodium ion. For benzo-15-crown-5, the structures of the free crown as well as the hydrated NaI complex have been determined via X-ray crystallography (1, 2). The solid phase ^{13}C NMR spectrum of the free crown has also been published (3). Recently we reported the X-ray structures, ^{13}C CPMAS NMR, and solution NMR behaviour of dibenzo-15-crown-5 and its NaNCS complex (4). With respect to the derived dicyclohexano 15-crown-5 systems, however, nothing has appeared in the literature to date.

Presently, we report the synthesis, X-ray structures, and solution conformational dynamics for the *cis-syn-cis* isomer of dicyclohexano-15-crown-5 and its NaNCS complex. The limiting low-temperature solution spectra of these materials are compared to solid phase ^{13}C spectra. Results are discussed with respect to those for the analogous dicyclohexano-14-crown-4 molecules (5, 6) and *cis*-cyclohexano-15-crown-5 (7).

Results and discussion

The structures and numbering schemes for the systems examined are presented in Fig. 1. The dispositions of the cyclohexane rings are consistent with those determined via X-ray crystallography. Bond lengths and angles are listed in

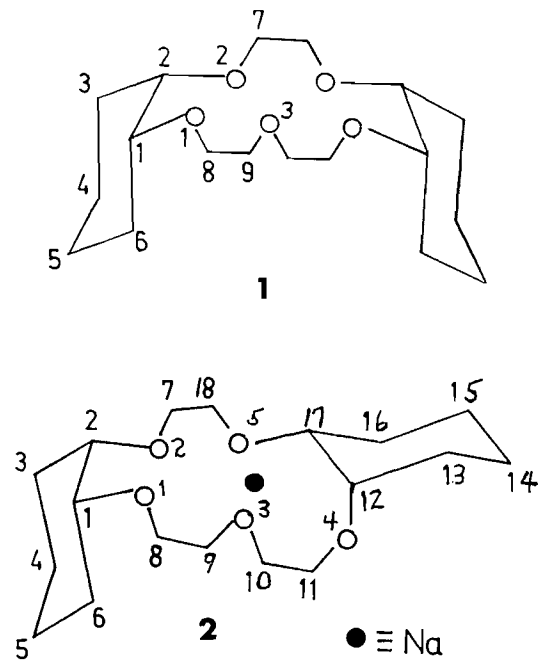

FIG. 1. Structures and numbering schemes for *cis-syn-cis*-dicyclohexano-15-crown-5, **1**, and its NaNCS complex **2**.

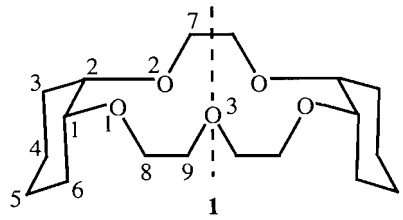
Table 1 for the free crown ether **1** and its NaNCS complex **2**. Torsion angles involving ring skeletal atoms are provided in Table 2 while the crystallographic data are collected in Table 3. Atomic parameters are reported in Table 4 and ^{13}C NMR chemical shifts are collected in Table 5. Figure 2 shows stereoviews of **1** and **2**.

For **1** and **2** the initial point of interest from the X-ray data concerns the conformations of the cyclohexane rings. In **1**, since there is disorder present at the C7 site, the molecule effectively possesses a plane of symmetry as depicted below.



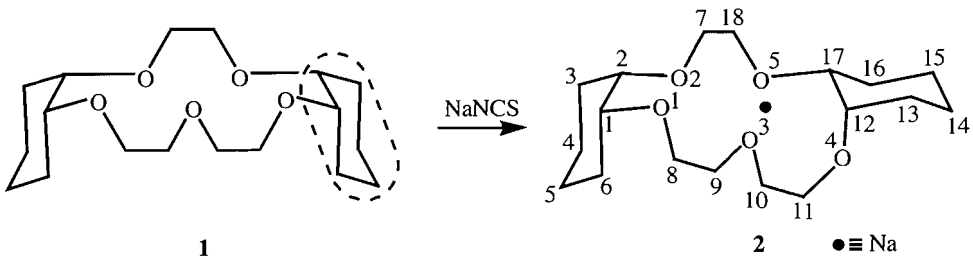
1

In contrast, for the NaNCS complex **2** one of the cyclohexane rings has undergone an inversion process (below).

This behaviour is opposite to that found by X-ray crystallography for the analogous dicyclohexano-14-crown-4 system (5), where the free crown ether lacks any true symmetry element while the LiNCS complex has a plane of symmetry. Further discussion of X-ray structures will be presented in Sect. (*iii*).

(i) Solid phase ^{13}C NMR spectra

Figure 3 contains the solid phase ^{13}C spectra of **1** and **2**. For a system such as **1**, which possesses a plane of symmetry, nine resonances are expected in the solid phase ^{13}C spectrum in the absence of crystal packing effects, multiple conformations, or non-identical molecular environments in the unit cell (3). Indeed the spectrum of solid **1** is consistent with expectations, there being four non-oxygenated resonances of approximately equal intensity in the range of 20–30 ppm and five oxygenated resonances in the range of 69–80 ppm.



1 **2** ●≡ Na

By analogy with our earlier work (5, 6) and the known influence of axial and equatorial oxygen on chemical shifts of cyclohexyl carbons (8, 9), assignments of the six clearly resolved lines can be made with some confidence. The largest shift difference is apparent for the methine carbons bearing oxygen, where C2, bearing an axial oxygen, is shielded by 7.66 ppm relative to C1 bearing an equatorial moiety. A 4.51 ppm difference is apparent between the resonance for C4 (γ-*gauche* to O2) relative to C5 (γ-*trans* to O1), with C4 being the more shielded. The C3 and C6 sites, being β to oxygen, show only a minor shift difference (28.70 vs. 29.89 ppm) with the C3 site, which is β to axial oxygen, being the more shielded. The three closely spaced CH_2O resonances (69.90–70.82 ppm) cannot be assigned unambiguously.

In the case of **2**, the lack of symmetry in the crystal structure is reflected in the appearance of the solid phase ^{13}C spectrum, there being six clearly discernible resonances in the oxygenated carbon region as well as highly skewed intensities for the four resolved aliphatic carbon lines present in the range of 20–30 ppm.

C8′—O1′—C1′—C6′	143.5(2)			C11—O4—C12—C13	76.6(4)

One notable difference in the chemical shifts for solid **1** vs. **2** concerns the CH_2-O carbons. In **2**, the resonances for C8, 9, 10, and 11 are all shielded by at least 3.6 ppm relative to C8 and C9 of **1**. Examination of the torsional angles present in the X-ray structures provides an explanation based on the O—C—C—O networks. For **2**, these angles are 58.4° for the O4—C11—C10—O3 network and 61.8° for the O3—C9—C8—O1 case. In **1**, however, the O3—C9—C8—O1 network has a dihedral angle of 73.7°. Based on the known experimental (8, 9) and theoretical (10, 11) angular dependence of the γ-*gauche* effect in ^{13}C NMR, one expects the expansion of the O—C—C—O dihedral angle from ca. 60° to 75° to lead to substantial deshielding in **1** as observed.

From the spectrum of **2** it is evident that one of the methine carbons bearing axial oxygen appears at 74.32 ppm and the other is part of the overlapping broad signal centered at 70.85 ppm. Comparison of the torsional angle environ-

ments for C2 vs. C12 shows that there are two pairs of networks in which significant dihedral angle differences exist. In the C8—O1—C1—**C2** case, θ = 85.5°, while for C18—O5—C17—**C12**, θ = 166.0°. For the C7—O2—**C2**—C3 case, θ = 68.3°, while for C11—O4—**C12**—C13, θ = 76.6°. Based on the aforementioned angular dependencies of ^{13}C steric shifts (8–11), and considering these geometrical differences, the expectation is that C12 would be the more deshielded of this pair of carbons and is thus assigned the resonance at 74.32 ppm.

(ii) Solution ^{13}C spectra

For **1** at 298 K, nine resonances are observed, in accord with the effective twofold symmetry of the molecule induced by rapid cyclohexane inversion on the NMR timescale. Two closely spaced methine carbon resonances appear at 77.90 and 77.72 ppm, since C1 and C2 remain in slightly different environments even in the presence of rapid ring inversion. For the CH_2-O carbons, three lines are observed, as expected, in the range of 68–71 ppm. Due to extensive overlap in the ^1H spectrum of **1** (even at 500 MHz) one cannot use COSY methods for clear distinction between CH_2-O resonances and hence the HETCOR experiment for ^{13}C assignments cannot be employed. For the C3,6 sites again a closely spaced pair of ^{13}C resonances is present, in this case at 27.91 and 27.76 ppm. Finally, two resonances are seen for the C4 and C5 sites at 22.87 and 22.05 ppm, in agreement with its effective symmetry at 298 K in solution.

It is of interest to compare the solid state conformation with that in solution under conditions where cyclohexane ring inversion is slow on the NMR timescale. Reduction of the temperature of the CD_2Cl_2 solution of **1** induced broadening followed by the emergence of a much more complex spectrum at the slow exchange limit of 168 K (Fig. 4). A closer examination of the methine carbon region (Fig. 5) gives an

insight into the conformational processes that have occurred with respect to the cyclohexane moieties.

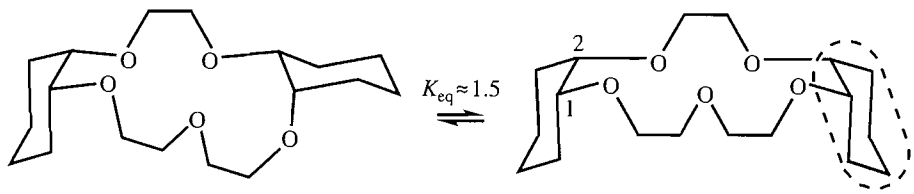
From the aforementioned doublet near 77.8 ppm have emerged six CH-O resonances in the range of 79.92–73.13 ppm. We attribute the high-intensity pair at 79.33 and 74.51 ppm to the C1 and C2 sites, respectively, of the symmetrical conformation of **1** illustrated above. The two minor lines of equal intensity at 79.92 and 78.56 ppm are attributed to methine carbons bearing equatorial oxygen in an asymmetric conformation of **1**. Similarly, the pair of lines at 75.60 and 73.13 ppm is deemed to arise from methine carbons bearing axial oxygen in the asymmetric conformation of **1**. Such a conformation could arise as a result of a single cyclohexane inversion depicted below.

Such a duality of conformations has previously been elucidated in the dicyclohexyl-14-crown-4 ether series (12). From the integrated intensities one can calculate K_{eq} and hence the ground state free energy difference ($-\Delta G^0$) between the symmetric and the asymmetric conformations at 168 K using the equation $-\Delta G^0 = RT \ln K_{eq}$. The result is that the symmetric conformation is calculated to be more stable by only 0.50 ± 0.20 kJ/mol.

For **2**, the ^{13}C spectrum at 298 K again shows nine resonances, consistent with rapid conformational averaging on

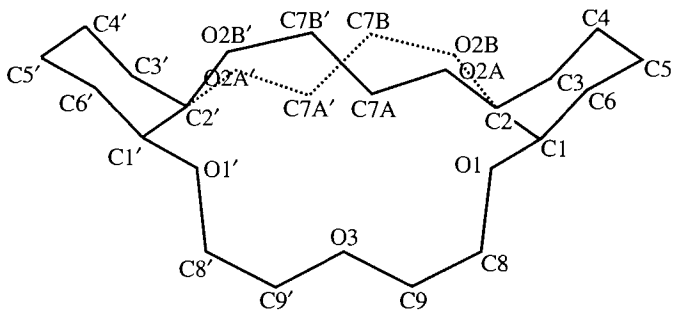
the NMR timescale. From $^1H-^{13}C$ HETCOR and $^1H-^1H$ COSY spectra at 500 MHz, assignment of the ^{13}C CH_2-O lines is possible in this case since there is less resonance overlap in the ^1H spectrum than is the case for **1**. It is useful to note that all geminal protons are magnetically nonequivalent in these systems, so that rather complex ^1H spectra are observed. Figure 6 shows a HETCOR spectrum.

The low-temperature ^{13}C spectra of **2** also exhibit decoalescence phenomena and the number of resonances increases markedly from the nine observed at 298 K. One cannot rule out the existence of multiple conformations here as well; however, sufficient peak resolution is not present to enable unravelling of the nature of the conformational processes that are occurring.



(iii) X-ray crystallographic structures

The ORTEP diagram for **1** is presented in Fig. 2*a*. In this depiction there are no symmetry elements. In fact, however, there is disorder (as illustrated below) at the C7 and O2 sites, with the disordered sites C7A, C7B, O2A, and O2B being equally populated. The crystallographic mirror plane passes through the mid-point of the C7A—C7B′ and C7A′—C7B bonds and the O3 site.



1

The solid phase ^{13}C NMR spectrum of **1** (Fig. 3), which contains nine lines, is consistent with the presence of this symmetry plane. Although there is some overlap of the three CH_2-O resonances near 70 ppm, there are six other clearly resolved resonances observed.

Normal torsion angles in crown ethers are such that O—C—C—O networks are *gauchoid* (dihedral angle ca. 60°) and all other four-atom moieties (ignoring hydrogens) are *transoid* (dihedral angle ca. 180°). In the case of **1**, the C8—O1—C1—C2 angle of 92.8° represents a major deviation, as do the C7A—O2A—C2—C3 and C7B—O2B—C2—C3 angles of 155.4° and 99.0° respectively. Other notable differences from "ideal" geometry are the C8—O1—C1—C6 network (143.5°), C7A—O2A—C2—C1 (77.4°), and C7B—O2B—C2—C1 (144.2°). For the O—C—C—O networks, the O1—C8—C9—O3 case shows significant expansion from pure *gauche* to 73.7°.

In the NaNCS complex **2**, the sodium ion is hexacoordinated to the five oxygen atoms of the crown ether and to the N atom of the SCN anion, resulting in a distorted pentagonal pyramidal coordination polyhedron. The five oxygens are not coplanar, the mean deviation from the least-squares plane connecting them being 0.27 Å. The cross-ring diagonal distances between "opposite" oxygens range from 3.855 to 4.586 Å, the average being 4.295 Å. As expected, the binding cavity is smaller than that found in the X-ray structure of the NaNCS · H_2O · 18-crown-6 complex (13), where the diagonal O—O distances in the 18-membered ring are ca. 5.100 Å on the average.

Data in Table 2 show that there is some distortion in the 15-membered ring from "ideal" conformations of crown ethers. This is particularly evident in the C8—O1—C1—C2 network where the torsion angle of 85.5° departs significantly from the "normal" value of near 180°. Similar types of distortions were observed in the LiNCS complexes of a related dicyclohexano-13-crown-4 system (14).

Figure 2*b* shows that the five ether oxygens are pointing towards the concave side of the crown ether, with the cyclohexane rings and the SCN^- side by side or with the anion coming in the concave side of the 15-membered ring. Hence the Na^+ appears to complex preferentially from the concave direction. Again there is similarity in the orientations of the anion and alkaline cation in the present case with that observed for LiNCS complexes in the analogous 13-crown-4 series (14).

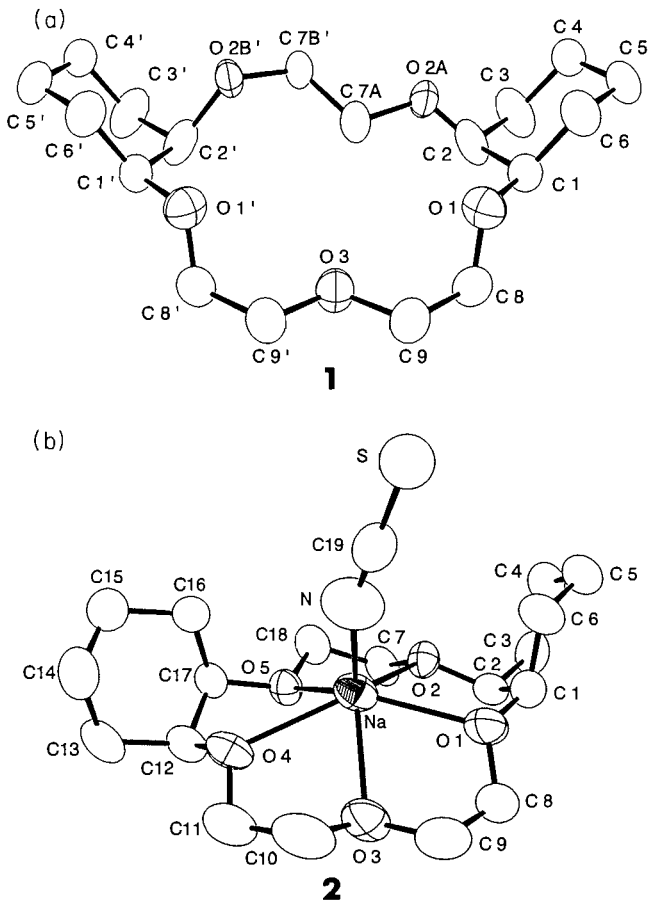

FIG. 2. (*a*) ORTEP diagram of **1**. (*b*) ORTEP diagram of **2**.

As noted earlier, the average diagonal distance between opposite oxygen atoms of **2** is 4.295 Å. By subtraction of twice the van der Waals radius of O (i.e., 2 × 1.4 Å) one can obtain the adjusted diameter of the binding cavity, 1.495 Å. Since the effective diameter of the Na^+ ion is 1.9–2.4 Å (15), the cavity is clearly too small to accommodate the Na^+ ion and hence this cation is found 0.84 Å out of the least-squares plane. By contrast, in the 18-crown-6 complex (13) the longer O—O distances result in an enlarged binding cavity diameter (ca. 2.3 Å) and hence the Na^+ lies only 0.27 Å out of the least-squares plane.

Finally, the Na—O distances listed in Table 1 are shorter when involving equatorial O's than when axial oxygens are bound (2.401 and 2.342 Å vs. 2.515 and 2.494 Å respectively). The Na—O3 distance of 2.412 Å falls in between. In the present 6-coordinate case, the average Na—O bond length of 2.433 Å is somewhat shorter than that in the 7-coordinate $NaNCS \cdot H_2O \cdot$ 18-crown-6 system (13).

Experimental

Crystallographic measurements, structure solution and refinement

Single crystals of **1** and **2** were mounted on glass fibres and measured on a Nonius CAD-4 diffractometer. Accurate cell parameters and intensity data were obtained at room temperature using graphite-monochromated CuKα radiation for **1** and MoKα radiation for **2**. Crystal data are provided in Table 3.

The space group $P2_1/n$ (alternate setting of $P2_1/c$) was uniquely defined from the systematic absences noted in the data of **2**. The intensity data for **1** revealed systematic absences consistent with two possible space groups. These are *Pbnm* (alternate setting *Pnma*) and $Pbn2_1$ (alternate setting of $Pna2_1$). Intensity data were corrected in the usual fashion for Lorentz and polarization-ratio factors but not for absorption. Other details pertaining to the data reduction step are listed in Table 3.

The positions of the non-H atoms of **2** were determined by direct methods with MULTAN (16). At this stage, isotropic refinement of all non-H atoms was carried out by full-matrix least squares. A subsequent difference map revealed the positions of the H atoms. They were included and refined isotropically while non-H atoms were refined anisotropically. The structures were refined to convergence by full-matrix least squares; $\Sigma w(|F_o| - |F_c|)^2$ was minimized with $w^{-1} = \sigma^2(F_o) + 0.0003F_o^2$. Details of the structure refinement of **2** and final *D*-map are given in Table 3.

The structure of **1** was solved in the space group $Pbn2_1$. As in **2**, positions of non-H atoms were derived from direct methods. A close inspection of the electron density maps based on the two possible space groups revealed positional disorder in the $-O-CH_2-CH_2-O$ bridge linking the two cyclohexane rings. Refinement of the occupancy factors of the disordered positions confirmed that this bridge was disordered over two equally populated positions. Least-squares refinement was continued with half-occupied C positions for the disordered bridge and isotropic thermal parameters for C and O atoms. There was further evidence of disorder. Results of refinement at this stage showed O atoms of the disordered bridge with thermal amplitudes much larger than the other non-H atoms of **1**. C—O and C—C distances in the disordered group were similar to those for analogous crown ethers (13, 14). However, two of the four $C_{cyclohexyl}—O—CH_2$ angles were unusually large (ca. 135°), which are highly improbable values.

The refinement of **1** in space group $Pbn2_1$, including H atoms at calculated positions and non-H atoms refined with anisotropic thermal parameters, would have made the number of reflections per refined parameter unacceptably low. As the space group of **1** could be *Pbnm*, cell symmetry was checked with the program MISSYM, which finds all metric symmetry elements from the atomic coordinates of any crystal structure and builds the generators in the unit cell (17). In addition to the *b* and *n* glide planes perpendicular to the *a* and *b* axes respectively, MISSYM detected mirror symmetry perpendicular to the *c* axis of the unit cell. Refinement of **1** was pursued in space group *Pbnm*.

H atoms bonded to non-disordered C atoms were added at calculated positions (C—H bond of 1.08 Å, sp^3 hybridized). Non-H atoms were defined anisotropically and H atoms isotropically. H atoms next to disordered positions C7A and C7B were successfully located in the next *D*-map and refined in the next least-squares cycles. At this stage, the *R* and R_w factors were ca. 1% higher than the final values quoted in Table 3. As the anisotropic thermal parameters of O2 described a highly and abnormally elongated 3D shape, this atom was removed from the structure and relocated in a subsquent *D*-map. The map revealed two positions. These were refined anisotropically as O atoms with half occupancies. This attempted refinement led to the lower residuals listed in Table 3. The high bond angle of ca. 135° centered at the formerly nondisordered O2 site has been replaced by more reasonable values averaging ca. 117°. However, the previous C2—O2 distance of ca. 1.4 Å is now showing systematically short and long C2—O2A and C2—O2B distances (see Table 1). Despite these geometrical distortions, the latter structural description with two partially (and equally) occupied $-O-CH_2-CH_2-O$ bridges linking the two cyclohexane rings has been used. It is of interest to note that similar structural distortions have been found in the X-ray structure of a related dicyclohexano-13-crown-4 ether (14). Details of the structure refinement of **1** and *D*-map are given in Table 3.

All computations were performed with the NRCVAX crystal package (17). The scattering curves were from the International Tables for X-ray Crystallography (18). Bond lengths and angles involving non-H atoms are presented in Table 1 while torsion angles involving ring skeletal atoms are given in Table 2. Refined coordinates of the non-H atoms of **1** and **2** are reported in Table 4.

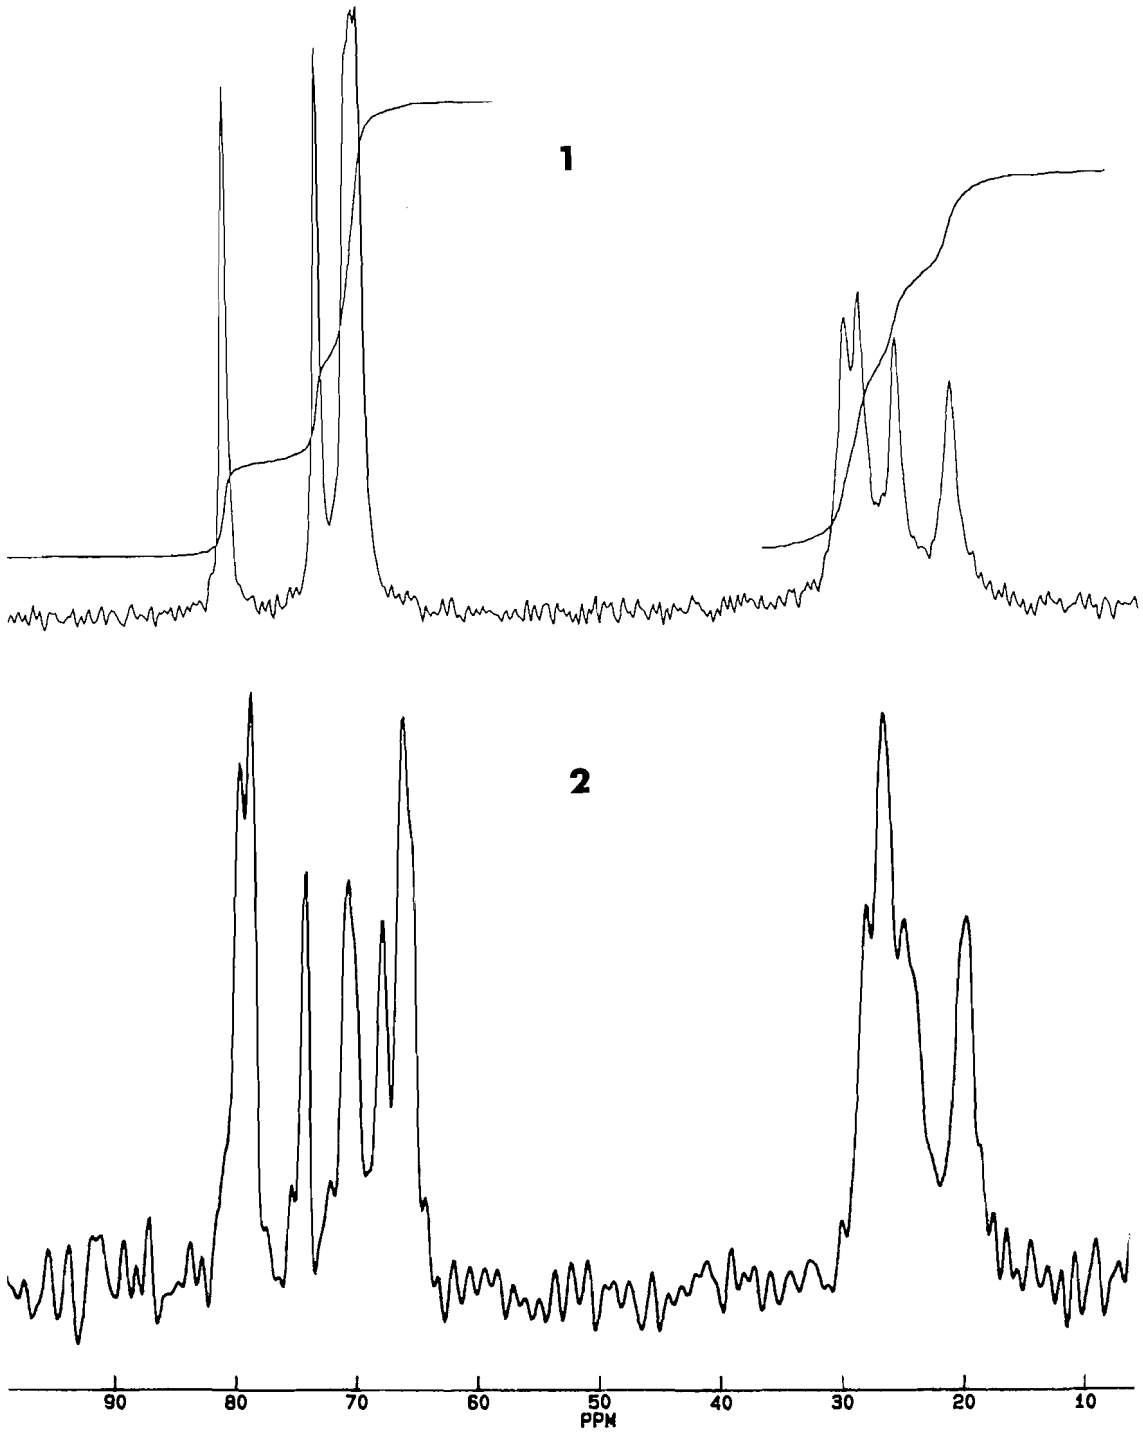

FIG. 3. 45.3 MHz solid phase ^{13}C NMR spectra.

Lists of anisotropic temperature factors, H atomic parameters, all bond lengths and angles, all torsion angles, and calculated, observed, and unobserved structure factors are deposited as Supplementary Material.[3]

[3]These data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen atom parameters and bond lengths and angles have also been deposited with The Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

Spectra

The ^{13}C CPMAS NMR spectra were recorded at 45.3 MHz on a Bruker CXP-180 spectrometer using techniques described previously (5). Chemical shifts were measured relative to external solid hexamethylbenzene (HMB) and converted to the TMS scale by the factor of 16.9 ppm, the chemical shift of the CH_3 group of HMB. The solution phase ^{13}C spectra were recorded at 100.6 MHz on a Bruker AM 400 system using conditions of complete ^1H noise decoupling. Typical spectral widths were 10 kHz with 32K data points for acquisition and zero filling to 64K. Normal pulse widths were 30° with a pulse delay of 2 s. Samples were ca. 0.1 M in CD_2Cl_2 solutions. The $^1H^{13}C$ HETCOR spectra were obtained on a Bruker AM 500 spectrometer using low decoupler power in the CW mode

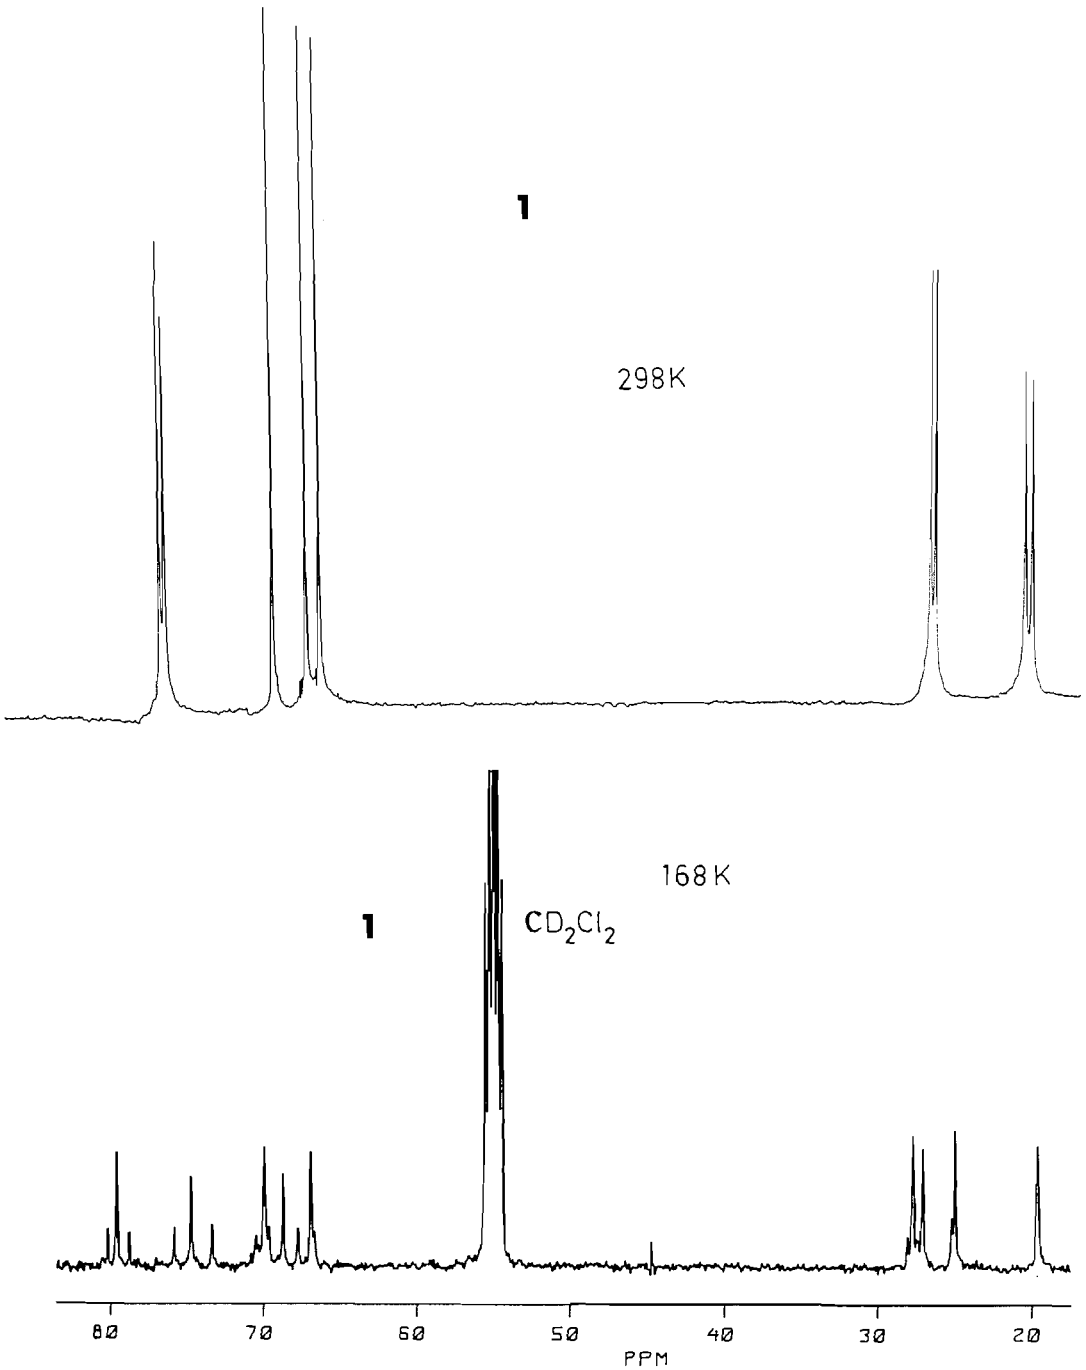

FIG. 4. 100.6 MHz ^{13}C solution spectra of **1** at 298 and 168 K.

(composite phase decoupling), with polarization transfer from ^{1}H to ^{13}C.

The FID's were acquired over 4096 data points for each of the 128 or 256 values of the evolution time, with digital resolution of 7 Hz/point in $F2$ and 5–10 Hz/point in $F1$. The raw data were zero-filled in $F1$ prior to Fourier transformation using the sine bell window function. Proton relaxation delays of 3–5 s were utilized.

Materials

Dibenzo-15-crown-5 was prepared as previously described (4). Hydrogenation of this material to a mixture of **1** and the *cis-anti-cis* isomer was accomplished using an American Instrument Co. 50 000 psi (1 psi = 6.9 kPa) maximum pressure high-pressure apparatus. In 60 mL of 1-butanol were dissolved 2.2 g (0.007 mol) of dibenzo-15-crown-5 and 0.40 g of 5% ruthenium on alumina catalyst. A pressure of 1200 psi was used and the reaction was allowed to proceed for 12 h at a temperature of 120°C. The catalyst was removed via filtration and the butanol by rotary evaporation to yield 2.1 g of a viscous yellow oil. From ^{13}C NMR there appeared to be two configurational isomers present in the ratio of ca. 2:1. Separation of these isomers was accomplished via column chromatography on activated silica gel of mesh size 100–200 using as initial eluent a mixture of 60:40 CH_2Cl_2–hexanes and a ratio of 50:1 silica gel to crude crown ether. Gradual introduction of diethyl ether in place of hexanes yielded **1** as the first isomer eluted, with 5% diethyl ether, 35% hexanes, and 60% CH_2Cl_2. Recrystallization from hexanes yielded the pure *cis-syn-cis* isomer **1**, as subsequently determined by X-ray crystallography, mp 67–68°C. The latter column fractions contained the minor, presumably *cis-anti-cis*, isomer, which remained an oil.

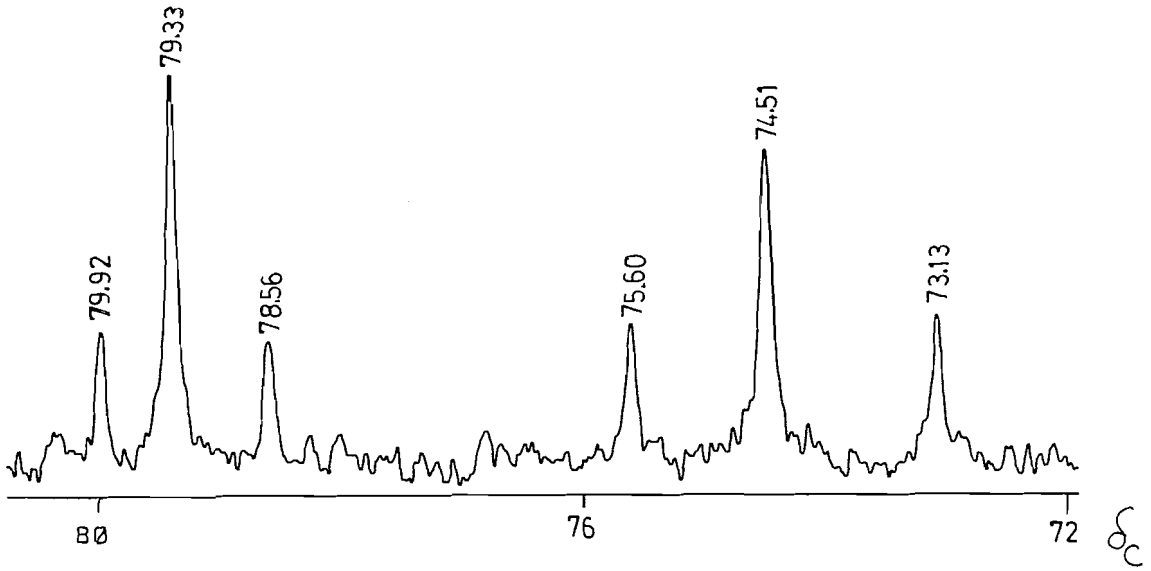

FIG. 5. Methine carbon region of 100.6 MHz spectrum of **1** at 168 K.

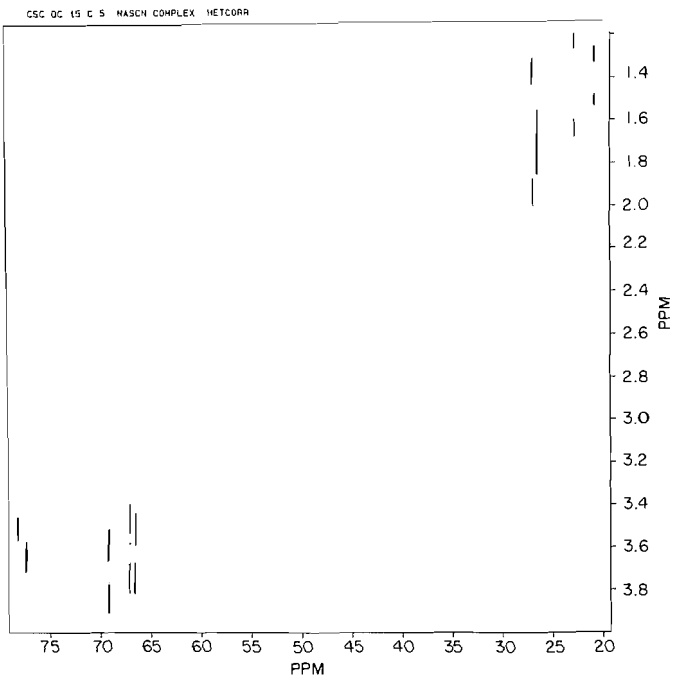

FIG. 6. $^{1}H^{13}C$ HETCOR spectrum of **2** at 500 MHz.

For preparation of the complex **2**, equimolar amounts of **1** and NaNCS were dissolved in a minimum volume of dry methanol. After allowing the mixture to stand for 2–3 h, the solvent was removed by rotary evaporation. Subsequent recrystallization from ethanol–hexanes yielded pure **2**, mp 140–141°C.

Received January 9, 1991[2]

G. W. BUCHANAN, S. MATHIAS, C. BENSIMON, and J. P. CHARLAND. Can. J. Chem. **70**, 981 (1992).

The structures of the title materials have been determined via X-ray crystallography. In the free crown ether, there is effectively a plane of symmetry that bisects the molecule. In the NaNCS complex, ring inversion of one of the cyclohexane moieties has occurred, giving a distorted pentagonal pyramidal coordination geometry about the sodium ion. For the free crown, two conformers, whose free energies differ by ca. 0.5 kJ/mol in solution can be detected via ^{13}C NMR at 168 K. Limiting low-temperature solution spectra are compared to those which have been obtained in the solid phase using the ^{13}C CPMAS technique.

Key words: crown ethers, stereochemistry, X-ray, NMR.

G. W. BUCHANAN, S. MATHIAS, C. BENSIMON et J. P. CHARLAND. Can. J. Chem. **70**, 981 (1992).

On a déterminé les structures des produits mentionnés dans le titre par diffraction des rayons X. Dans l'éther couronne à l'état libre, il existe un plan de symétrie qui bissecte la molécule. Dans le complexe NaNCS, il se produit une inversion des cycles des portions cyclohexaniques; il s'ensuit que la coordination autour du sodium est de type pyramide pentagonale déformée. Pour la couronne libre, à 168 K, la RMN du ^{13}C permet de détecter deux conformères dont les énergies libres diffèrent par environ 0,5 kJ/mol, en solution. On a comparé les spectres obtenus à la limite inférieure de température supportée par la solution avec ceux qui ont été obtenus en phase solide à l'aide de la technique du CPMAS du ^{13}C.

Mots clés : éthers couronnes, stéréochimie, rayons X, RMN.

[Traduit par la rédaction]

Introduction

In crown ether chemistry, the 15-crown-5 system is of interest because of its efficiency for internal encapsulation of the sodium ion. For benzo-15-crown-5, the structures of the free crown as well as the hydrated NaI complex have been determined via X-ray crystallography (1, 2). The solid phase ^{13}C NMR spectrum of the free crown has also been published (3). Recently we reported the X-ray structures, ^{13}C CPMAS NMR, and solution NMR behaviour of dibenzo-15-crown-5 and its NaNCS complex (4). With respect to the derived dicyclohexano 15-crown-5 systems, however, nothing has appeared in the literature to date.

Presently, we report the synthesis, X-ray structures, and solution conformational dynamics for the *cis-syn-cis* isomer of dicyclohexano-15-crown-5 and its NaNCS complex. The limiting low-temperature solution spectra of these materials are compared to solid phase ^{13}C spectra. Results are discussed with respect to those for the analogous dicyclohexano-14-crown-4 molecules (5, 6) and *cis*-cyclohexano-15-crown-5 (7).

Results and discussion

The structures and numbering schemes for the systems examined are presented in Fig. 1. The dispositions of the cyclohexane rings are consistent with those determined via X-ray crystallography. Bond lengths and angles are listed in

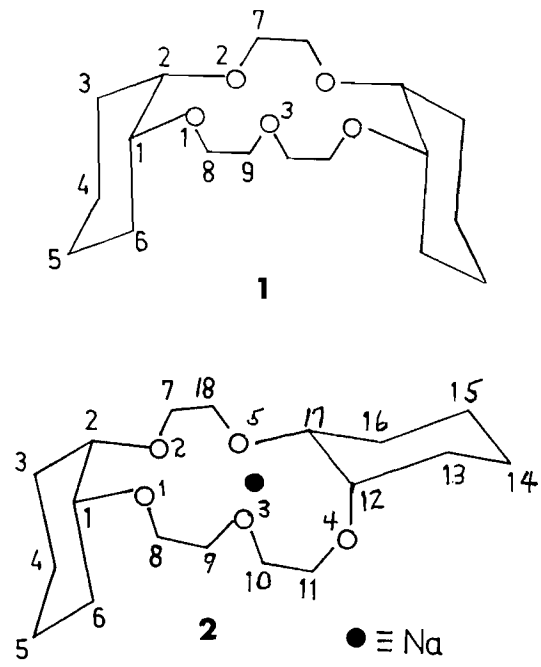

FIG. 1. Structures and numbering schemes for *cis-syn-cis*-dicyclohexano-15-crown-5, **1**, and its NaNCS complex **2**.

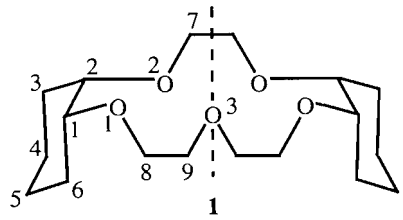
Table 1 for the free crown ether **1** and its NaNCS complex **2**. Torsion angles involving ring skeletal atoms are provided in Table 2 while the crystallographic data are collected in Table 3. Atomic parameters are reported in Table 4 and ^{13}C NMR chemical shifts are collected in Table 5. Figure 2 shows stereoviews of **1** and **2**.

For **1** and **2** the initial point of interest from the X-ray data concerns the conformations of the cyclohexane rings. In **1**, since there is disorder present at the C7 site, the molecule effectively possesses a plane of symmetry as depicted below.



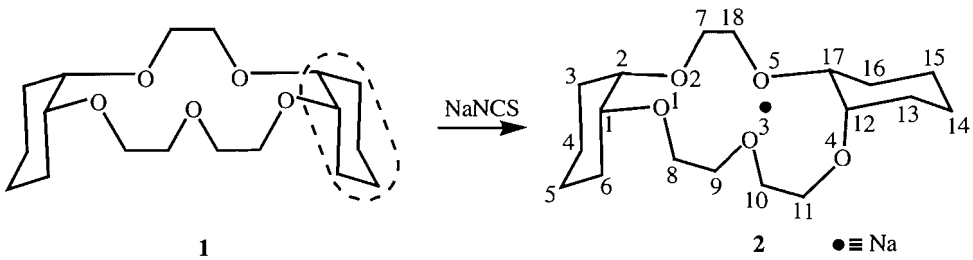
1

In contrast, for the NaNCS complex **2** one of the cyclohexane rings has undergone an inversion process (below).

This behaviour is opposite to that found by X-ray crystallography for the analogous dicyclohexano-14-crown-4 system (5), where the free crown ether lacks any true symmetry element while the LiNCS complex has a plane of symmetry. Further discussion of X-ray structures will be presented in Sect. (*iii*).

(i) Solid phase ^{13}C NMR spectra

Figure 3 contains the solid phase ^{13}C spectra of **1** and **2**. For a system such as **1**, which possesses a plane of symmetry, nine resonances are expected in the solid phase ^{13}C spectrum in the absence of crystal packing effects, multiple conformations, or non-identical molecular environments in the unit cell (3). Indeed the spectrum of solid **1** is consistent with expectations, there being four non-oxygenated resonances of approximately equal intensity in the range of 20–30 ppm and five oxygenated resonances in the range of 69–80 ppm.



1 **2** ●≡ Na

By analogy with our earlier work (5, 6) and the known influence of axial and equatorial oxygen on chemical shifts of cyclohexyl carbons (8, 9), assignments of the six clearly resolved lines can be made with some confidence. The largest shift difference is apparent for the methine carbons bearing oxygen, where C2, bearing an axial oxygen, is shielded by 7.66 ppm relative to C1 bearing an equatorial moiety. A 4.51 ppm difference is apparent between the resonance for C4 (γ-*gauche* to O2) relative to C5 (γ-*trans* to O1), with C4 being the more shielded. The C3 and C6 sites, being β to oxygen, show only a minor shift difference (28.70 vs. 29.89 ppm) with the C3 site, which is β to axial oxygen, being the more shielded. The three closely spaced CH_2O resonances (69.90–70.82 ppm) cannot be assigned unambiguously.

In the case of **2**, the lack of symmetry in the crystal structure is reflected in the appearance of the solid phase ^{13}C spectrum, there being six clearly discernible resonances in the oxygenated carbon region as well as highly skewed intensities for the four resolved aliphatic carbon lines present in the range of 20–30 ppm.

One notable difference in the chemical shifts for solid **1** vs. **2** concerns the CH_2-O carbons. In **2**, the resonances for C8, 9, 10, and 11 are all shielded by at least 3.6 ppm relative to C8 and C9 of **1**. Examination of the torsional angles present in the X-ray structures provides an explanation based on the O—C—C—O networks. For **2**, these angles are 58.4° for the O4—C11—C10—O3 network and 61.8° for the O3—C9—C8—O1 case. In **1**, however, the O3—C9—C8—O1 network has a dihedral angle of 73.7°. Based on the known experimental (8, 9) and theoretical (10, 11) angular dependence of the γ-*gauche* effect in ^{13}C NMR, one expects the expansion of the O—C—C—O dihedral angle from ca. 60° to 75° to lead to substantial deshielding in **1** as observed.

From the spectrum of **2** it is evident that one of the methine carbons bearing axial oxygen appears at 74.32 ppm and the other is part of the overlapping broad signal centered at 70.85 ppm. Comparison of the torsional angle environ-

ments for C2 vs. C12 shows that there are two pairs of networks in which significant dihedral angle differences exist. In the C8—O1—C1—**C2** case, θ = 85.5°, while for C18—O5—C17—**C12**, θ = 166.0°. For the C7—O2—**C2**—C3 case, θ = 68.3°, while for C11—O4—**C12**—C13, θ = 76.6°. Based on the aforementioned angular dependencies of ^{13}C steric shifts (8–11), and considering these geometrical differences, the expectation is that C12 would be the more deshielded of this pair of carbons and is thus assigned the resonance at 74.32 ppm.

(ii) Solution ^{13}C spectra

For **1** at 298 K, nine resonances are observed, in accord with the effective twofold symmetry of the molecule induced by rapid cyclohexane inversion on the NMR timescale. Two closely spaced methine carbon resonances appear at 77.90 and 77.72 ppm, since C1 and C2 remain in slightly different environments even in the presence of rapid ring inversion. For the CH_2-O carbons, three lines are observed, as expected, in the range of 68–71 ppm. Due to extensive overlap in the ^1H spectrum of **1** (even at 500 MHz) one cannot use COSY methods for clear distinction between CH_2-O resonances and hence the HETCOR experiment for ^{13}C assignments cannot be employed. For the C3,6 sites again a closely spaced pair of ^{13}C resonances is present, in this case at 27.91 and 27.76 ppm. Finally, two resonances are seen for the C4 and C5 sites at 22.87 and 22.05 ppm, in agreement with its effective symmetry at 298 K in solution.

It is of interest to compare the solid state conformation with that in solution under conditions where cyclohexane ring inversion is slow on the NMR timescale. Reduction of the temperature of the CD_2Cl_2 solution of **1** induced broadening followed by the emergence of a much more complex spectrum at the slow exchange limit of 168 K (Fig. 4). A closer examination of the methine carbon region (Fig. 5) gives an

insight into the conformational processes that have occurred with respect to the cyclohexane moieties.

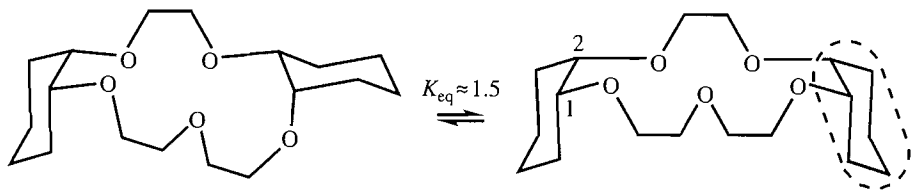
From the aforementioned doublet near 77.8 ppm have emerged six CH-O resonances in the range of 79.92–73.13 ppm. We attribute the high-intensity pair at 79.33 and 74.51 ppm to the C1 and C2 sites, respectively, of the symmetrical conformation of **1** illustrated above. The two minor lines of equal intensity at 79.92 and 78.56 ppm are attributed to methine carbons bearing equatorial oxygen in an asymmetric conformation of **1**. Similarly, the pair of lines at 75.60 and 73.13 ppm is deemed to arise from methine carbons bearing axial oxygen in the asymmetric conformation of **1**. Such a conformation could arise as a result of a single cyclohexane inversion depicted below.

Such a duality of conformations has previously been elucidated in the dicyclohexyl-14-crown-4 ether series (12). From the integrated intensities one can calculate K_{eq} and hence the ground state free energy difference ($-\Delta G^0$) between the symmetric and the asymmetric conformations at 168 K using the equation $-\Delta G^0 = RT \ln K_{eq}$. The result is that the symmetric conformation is calculated to be more stable by only 0.50 ± 0.20 kJ/mol.

For **2**, the ^{13}C spectrum at 298 K again shows nine resonances, consistent with rapid conformational averaging on

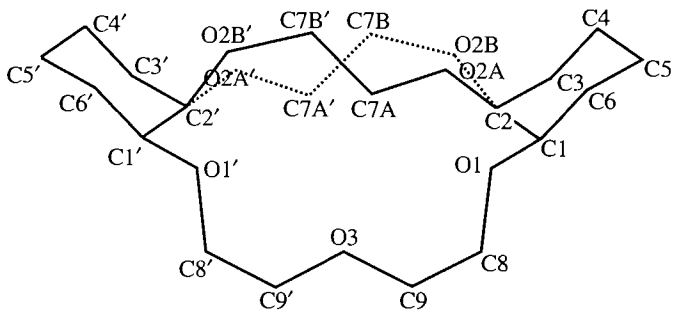
the NMR timescale. From $^1H-^{13}C$ HETCOR and $^1H-^1H$ COSY spectra at 500 MHz, assignment of the ^{13}C CH_2-O lines is possible in this case since there is less resonance overlap in the ^1H spectrum than is the case for **1**. It is useful to note that all geminal protons are magnetically nonequivalent in these systems, so that rather complex ^1H spectra are observed. Figure 6 shows a HETCOR spectrum.

The low-temperature ^{13}C spectra of **2** also exhibit decoalescence phenomena and the number of resonances increases markedly from the nine observed at 298 K. One cannot rule out the existence of multiple conformations here as well; however, sufficient peak resolution is not present to enable unravelling of the nature of the conformational processes that are occurring.



(iii) X-ray crystallographic structures

The ORTEP diagram for **1** is presented in Fig. 2*a*. In this depiction there are no symmetry elements. In fact, however, there is disorder (as illustrated below) at the C7 and O2 sites, with the disordered sites C7A, C7B, O2A, and O2B being equally populated. The crystallographic mirror plane passes through the mid-point of the C7A—C7B′ and C7A′—C7B bonds and the O3 site.



1

The solid phase ^{13}C NMR spectrum of **1** (Fig. 3), which contains nine lines, is consistent with the presence of this symmetry plane. Although there is some overlap of the three CH_2-O resonances near 70 ppm, there are six other clearly resolved resonances observed.

Normal torsion angles in crown ethers are such that O—C—C—O networks are *gauchoid* (dihedral angle ca. 60°) and all other four-atom moieties (ignoring hydrogens) are *transoid* (dihedral angle ca. 180°). In the case of **1**, the C8—O1—C1—C2 angle of 92.8° represents a major deviation, as do the C7A—O2A—C2—C3 and C7B—O2B—C2—C3 angles of 155.4° and 99.0° respectively. Other notable differences from "ideal" geometry are the C8—O1—C1—C6 network (143.5°), C7A—O2A—C2—C1 (77.4°), and C7B—O2B—C2—C1 (144.2°). For the O—C—C—O networks, the O1—C8—C9—O3 case shows significant expansion from pure *gauche* to 73.7°.

In the NaNCS complex **2**, the sodium ion is hexacoordinated to the five oxygen atoms of the crown ether and to the N atom of the SCN anion, resulting in a distorted pentagonal pyramidal coordination polyhedron. The five oxygens are not coplanar, the mean deviation from the least-squares plane connecting them being 0.27 Å. The cross-ring diagonal distances between "opposite" oxygens range from 3.855 to 4.586 Å, the average being 4.295 Å. As expected, the binding cavity is smaller than that found in the X-ray structure of the NaNCS · H_2O · 18-crown-6 complex (13), where the diagonal O—O distances in the 18-membered ring are ca. 5.100 Å on the average.

Data in Table 2 show that there is some distortion in the 15-membered ring from "ideal" conformations of crown ethers. This is particularly evident in the C8—O1—C1—C2 network where the torsion angle of 85.5° departs significantly from the "normal" value of near 180°. Similar types of distortions were observed in the LiNCS complexes of a related dicyclohexano-13-crown-4 system (14).

Figure 2*b* shows that the five ether oxygens are pointing towards the concave side of the crown ether, with the cyclohexane rings and the SCN^- side by side or with the anion coming in the concave side of the 15-membered ring. Hence the Na^+ appears to complex preferentially from the concave direction. Again there is similarity in the orientations of the anion and alkaline cation in the present case with that observed for LiNCS complexes in the analogous 13-crown-4 series (14).

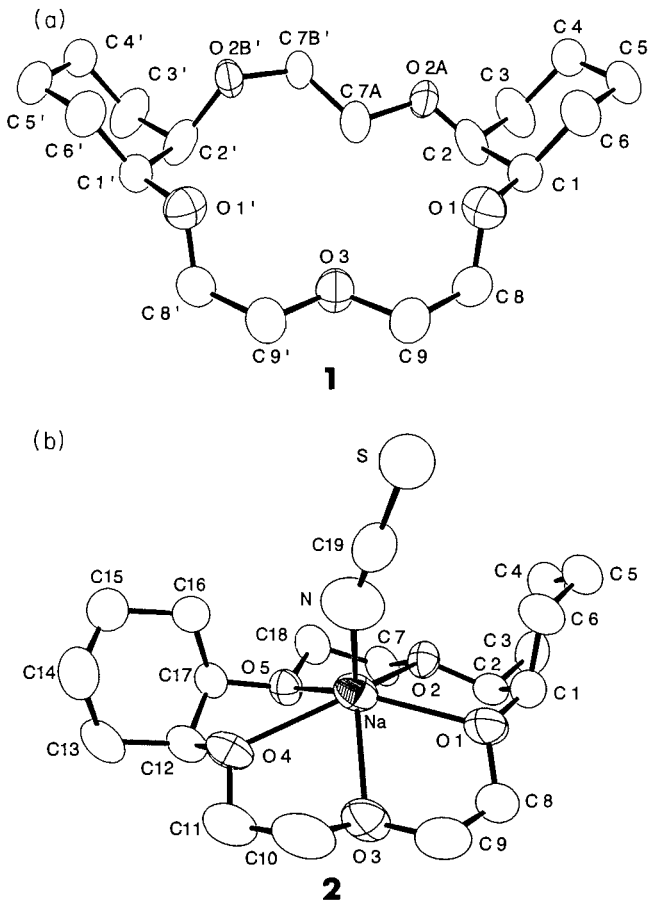

FIG. 2. (*a*) ORTEP diagram of **1**. (*b*) ORTEP diagram of **2**.

As noted earlier, the average diagonal distance between opposite oxygen atoms of **2** is 4.295 Å. By subtraction of twice the van der Waals radius of O (i.e., 2 × 1.4 Å) one can obtain the adjusted diameter of the binding cavity, 1.495 Å. Since the effective diameter of the Na^+ ion is 1.9–2.4 Å (15), the cavity is clearly too small to accommodate the Na^+ ion and hence this cation is found 0.84 Å out of the least-squares plane. By contrast, in the 18-crown-6 complex (13) the longer O—O distances result in an enlarged binding cavity diameter (ca. 2.3 Å) and hence the Na^+ lies only 0.27 Å out of the least-squares plane.

Finally, the Na—O distances listed in Table 1 are shorter when involving equatorial O's than when axial oxygens are bound (2.401 and 2.342 Å vs. 2.515 and 2.494 Å respectively). The Na—O3 distance of 2.412 Å falls in between. In the present 6-coordinate case, the average Na—O bond length of 2.433 Å is somewhat shorter than that in the 7-coordinate $NaNCS \cdot H_2O \cdot$ 18-crown-6 system (13).

Experimental

Crystallographic measurements, structure solution and refinement

Single crystals of **1** and **2** were mounted on glass fibres and measured on a Nonius CAD-4 diffractometer. Accurate cell parameters and intensity data were obtained at room temperature using graphite-monochromated CuKα radiation for **1** and MoKα radiation for **2**. Crystal data are provided in Table 3.

The space group $P2_1/n$ (alternate setting of $P2_1/c$) was uniquely defined from the systematic absences noted in the data of **2**. The intensity data for **1** revealed systematic absences consistent with two possible space groups. These are *Pbnm* (alternate setting *Pnma*) and $Pbn2_1$ (alternate setting of $Pna2_1$). Intensity data were corrected in the usual fashion for Lorentz and polarization-ratio factors but not for absorption. Other details pertaining to the data reduction step are listed in Table 3.

The positions of the non-H atoms of **2** were determined by direct methods with MULTAN (16). At this stage, isotropic refinement of all non-H atoms was carried out by full-matrix least squares. A subsequent difference map revealed the positions of the H atoms. They were included and refined isotropically while non-H atoms were refined anisotropically. The structures were refined to convergence by full-matrix least squares; $\Sigma w(|F_o| - |F_c|)^2$ was minimized with $w^{-1} = \sigma^2(F_o) + 0.0003F_o^2$. Details of the structure refinement of **2** and final *D*-map are given in Table 3.

The structure of **1** was solved in the space group $Pbn2_1$. As in **2**, positions of non-H atoms were derived from direct methods. A close inspection of the electron density maps based on the two possible space groups revealed positional disorder in the $-O-CH_2-CH_2-O$ bridge linking the two cyclohexane rings. Refinement of the occupancy factors of the disordered positions confirmed that this bridge was disordered over two equally populated positions. Least-squares refinement was continued with half-occupied C positions for the disordered bridge and isotropic thermal parameters for C and O atoms. There was further evidence of disorder. Results of refinement at this stage showed O atoms of the disordered bridge with thermal amplitudes much larger than the other non-H atoms of **1**. C—O and C—C distances in the disordered group were similar to those for analogous crown ethers (13, 14). However, two of the four $C_{cyclohexyl}—O—CH_2$ angles were unusually large (ca. 135°), which are highly improbable values.

The refinement of **1** in space group $Pbn2_1$, including H atoms at calculated positions and non-H atoms refined with anisotropic thermal parameters, would have made the number of reflections per refined parameter unacceptably low. As the space group of **1** could be *Pbnm*, cell symmetry was checked with the program MISSYM, which finds all metric symmetry elements from the atomic coordinates of any crystal structure and builds the generators in the unit cell (17). In addition to the *b* and *n* glide planes perpendicular to the *a* and *b* axes respectively, MISSYM detected mirror symmetry perpendicular to the *c* axis of the unit cell. Refinement of **1** was pursued in space group *Pbnm*.

H atoms bonded to non-disordered C atoms were added at calculated positions (C—H bond of 1.08 Å, sp^3 hybridized). Non-H atoms were defined anisotropically and H atoms isotropically. H atoms next to disordered positions C7A and C7B were successfully located in the next *D*-map and refined in the next least-squares cycles. At this stage, the *R* and R_w factors were ca. 1% higher than the final values quoted in Table 3. As the anisotropic thermal parameters of O2 described a highly and abnormally elongated 3D shape, this atom was removed from the structure and relocated in a subsquent *D*-map. The map revealed two positions. These were refined anisotropically as O atoms with half occupancies. This attempted refinement led to the lower residuals listed in Table 3. The high bond angle of ca. 135° centered at the formerly nondisordered O2 site has been replaced by more reasonable values averaging ca. 117°. However, the previous C2—O2 distance of ca. 1.4 Å is now showing systematically short and long C2—O2A and C2—O2B distances (see Table 1). Despite these geometrical distortions, the latter structural description with two partially (and equally) occupied $-O-CH_2-CH_2-O$ bridges linking the two cyclohexane rings has been used. It is of interest to note that similar structural distortions have been found in the X-ray structure of a related dicyclohexano-13-crown-4 ether (14). Details of the structure refinement of **1** and *D*-map are given in Table 3.

All computations were performed with the NRCVAX crystal package (17). The scattering curves were from the International Tables for X-ray Crystallography (18). Bond lengths and angles involving non-H atoms are presented in Table 1 while torsion angles involving ring skeletal atoms are given in Table 2. Refined coordinates of the non-H atoms of **1** and **2** are reported in Table 4.

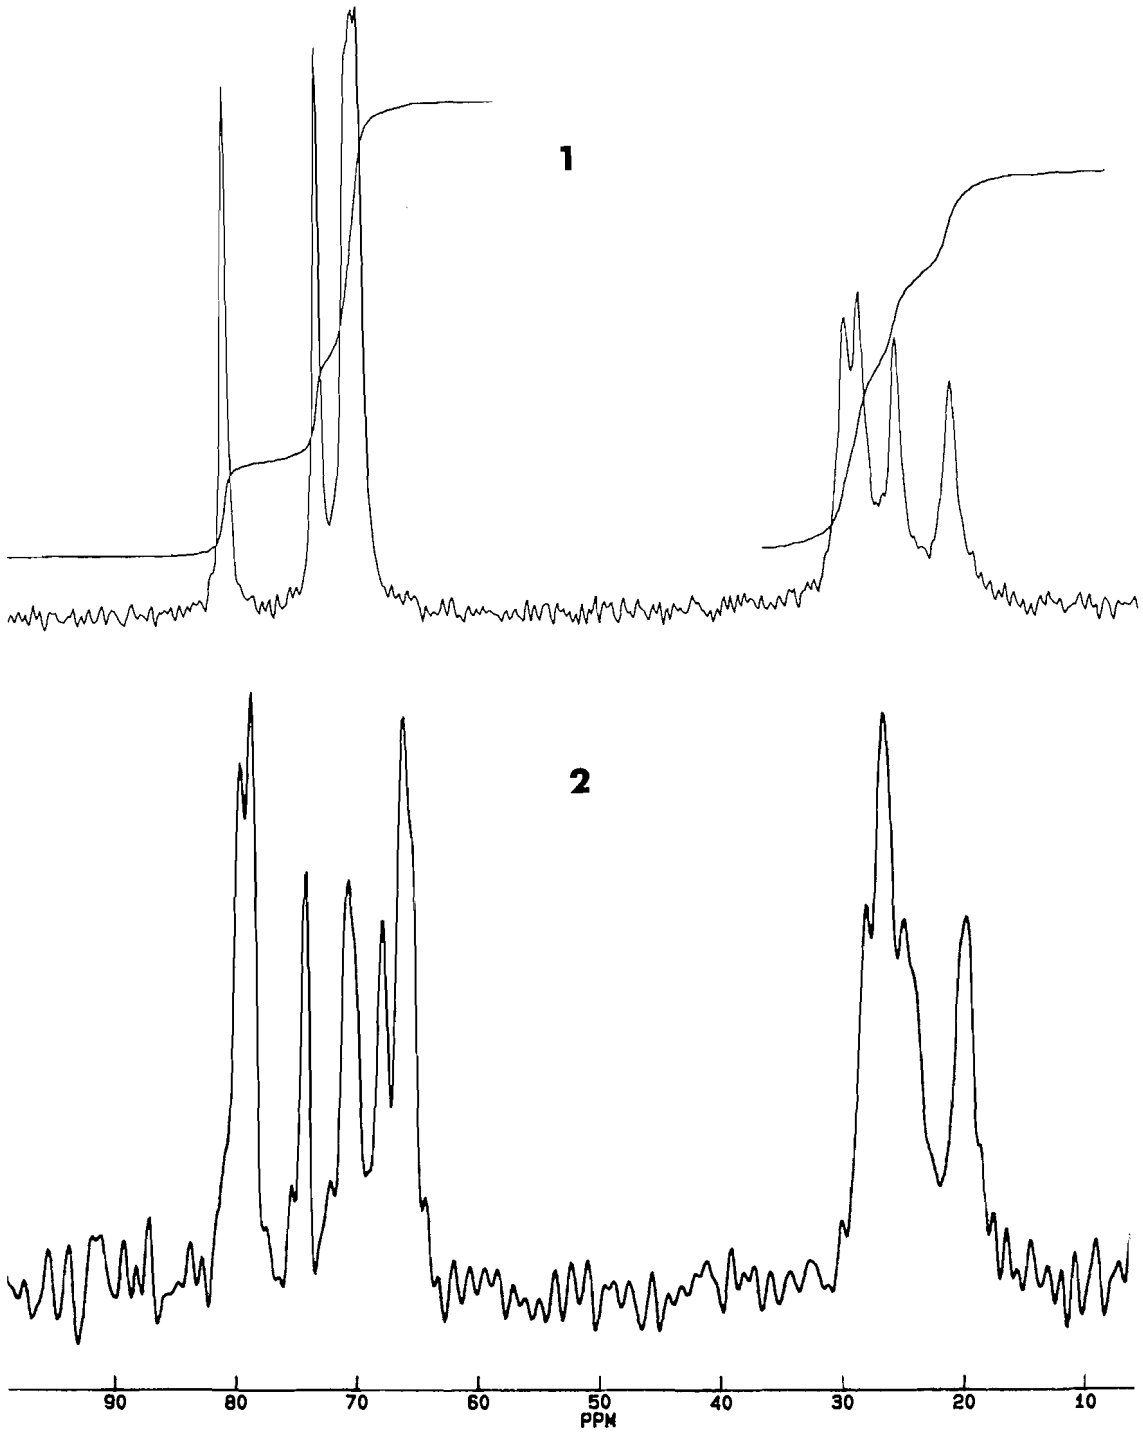

FIG. 3. 45.3 MHz solid phase ^{13}C NMR spectra.

Lists of anisotropic temperature factors, H atomic parameters, all bond lengths and angles, all torsion angles, and calculated, observed, and unobserved structure factors are deposited as Supplementary Material.[3]

[3]These data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen atom parameters and bond lengths and angles have also been deposited with The Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

Spectra

The ^{13}C CPMAS NMR spectra were recorded at 45.3 MHz on a Bruker CXP-180 spectrometer using techniques described previously (5). Chemical shifts were measured relative to external solid hexamethylbenzene (HMB) and converted to the TMS scale by the factor of 16.9 ppm, the chemical shift of the CH_3 group of HMB. The solution phase ^{13}C spectra were recorded at 100.6 MHz on a Bruker AM 400 system using conditions of complete ^1H noise decoupling. Typical spectral widths were 10 kHz with 32K data points for acquisition and zero filling to 64K. Normal pulse widths were 30° with a pulse delay of 2 s. Samples were ca. 0.1 M in CD_2Cl_2 solutions. The $^1H^{13}C$ HETCOR spectra were obtained on a Bruker AM 500 spectrometer using low decoupler power in the CW mode

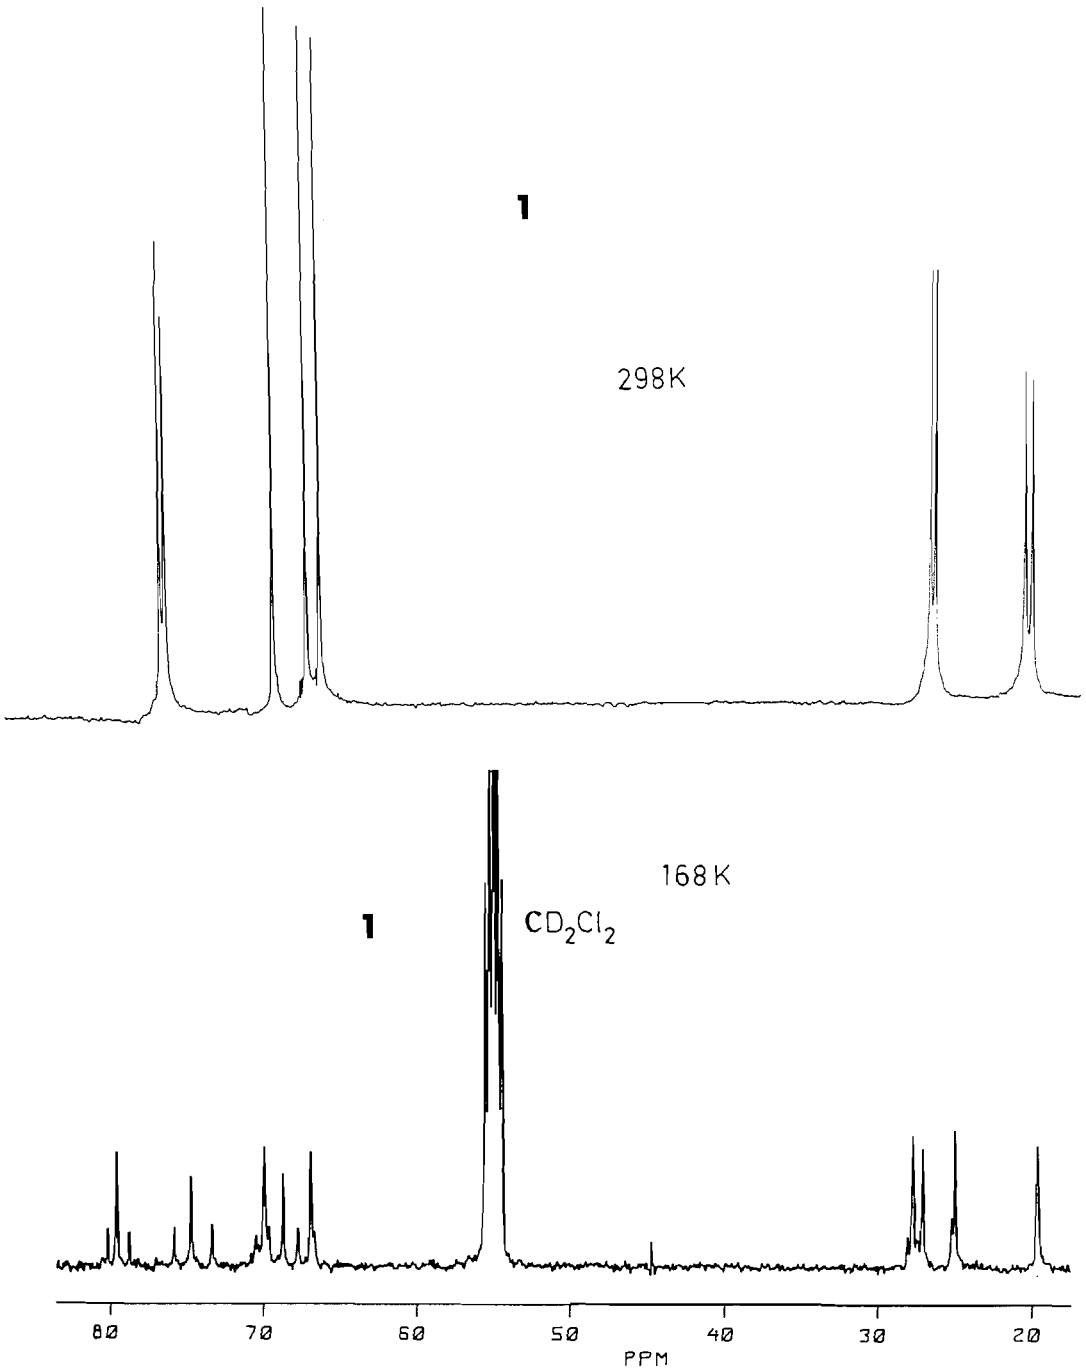

FIG. 4. 100.6 MHz ^{13}C solution spectra of **1** at 298 and 168 K.

(composite phase decoupling), with polarization transfer from ^{1}H to ^{13}C.

The FID's were acquired over 4096 data points for each of the 128 or 256 values of the evolution time, with digital resolution of 7 Hz/point in $F2$ and 5–10 Hz/point in $F1$. The raw data were zero-filled in $F1$ prior to Fourier transformation using the sine bell window function. Proton relaxation delays of 3–5 s were utilized.

Materials

Dibenzo-15-crown-5 was prepared as previously described (4). Hydrogenation of this material to a mixture of **1** and the *cis-anti-cis* isomer was accomplished using an American Instrument Co. 50 000 psi (1 psi = 6.9 kPa) maximum pressure high-pressure apparatus. In 60 mL of 1-butanol were dissolved 2.2 g (0.007 mol) of dibenzo-15-crown-5 and 0.40 g of 5% ruthenium on alumina catalyst. A pressure of 1200 psi was used and the reaction was allowed to proceed for 12 h at a temperature of 120°C. The catalyst was removed via filtration and the butanol by rotary evaporation to yield 2.1 g of a viscous yellow oil. From ^{13}C NMR there appeared to be two configurational isomers present in the ratio of ca. 2:1. Separation of these isomers was accomplished via column chromatography on activated silica gel of mesh size 100–200 using as initial eluent a mixture of 60:40 CH_2Cl_2–hexanes and a ratio of 50:1 silica gel to crude crown ether. Gradual introduction of diethyl ether in place of hexanes yielded **1** as the first isomer eluted, with 5% diethyl ether, 35% hexanes, and 60% CH_2Cl_2. Recrystallization from hexanes yielded the pure *cis-syn-cis* isomer **1**, as subsequently determined by X-ray crystallography, mp 67–68°C. The latter column fractions contained the minor, presumably *cis-anti-cis*, isomer, which remained an oil.

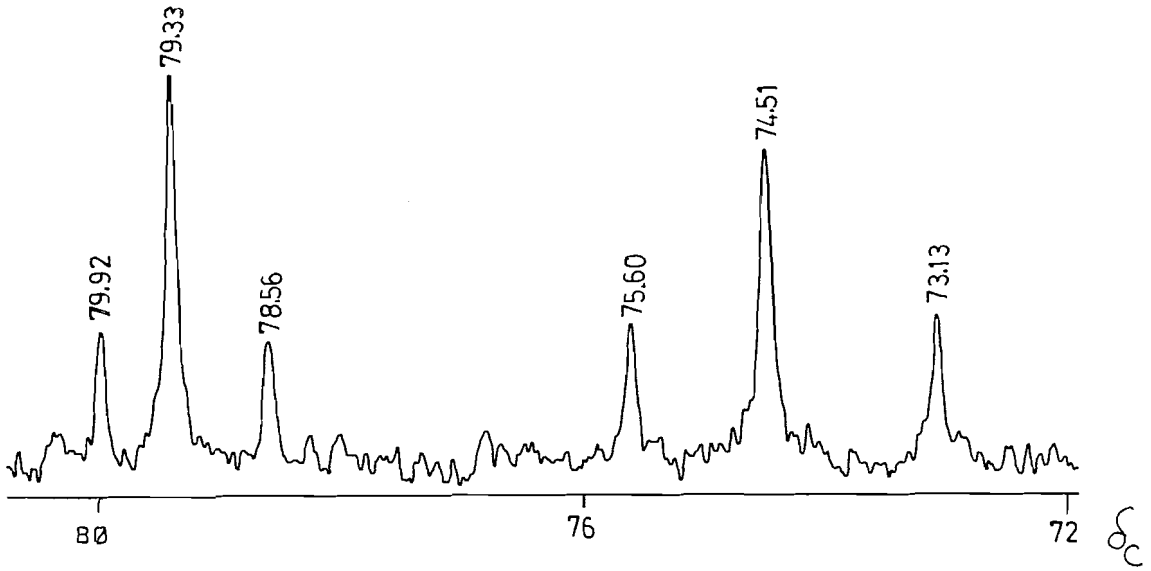

FIG. 5. Methine carbon region of 100.6 MHz spectrum of **1** at 168 K.

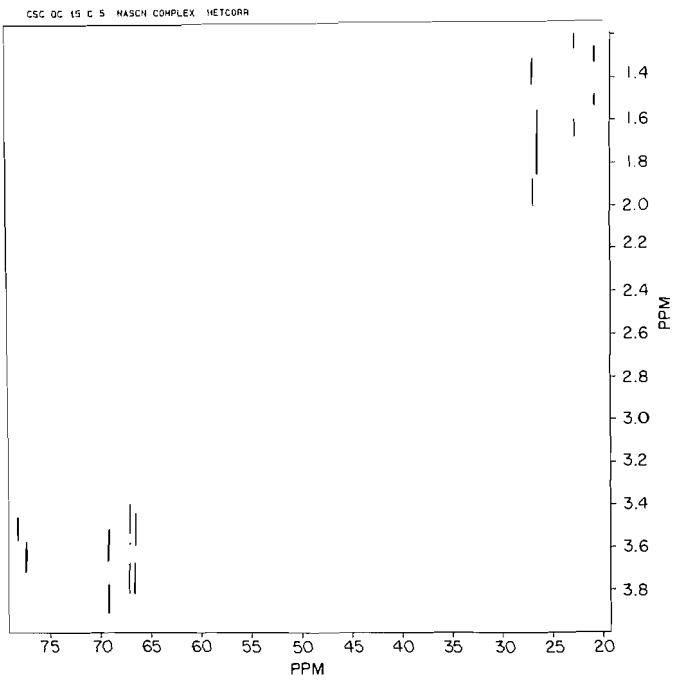

FIG. 6. $^{1}H^{13}C$ HETCOR spectrum of **2** at 500 MHz.

For preparation of the complex **2**, equimolar amounts of **1** and NaNCS were dissolved in a minimum volume of dry methanol. After allowing the mixture to stand for 2–3 h, the solvent was removed by rotary evaporation. Subsequent recrystallization from ethanol–hexanes yielded pure **2**, mp 140–141°C.

Photolysis of the 1-naphthylmethyl ester of substituted phenylacetic acids: intramolecular charge transfer and rates of decarboxylation of arylacyloxy radicals

JAMES W. HILBORN AND JAMES A. PINCOCK[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received July 24, 1991

JAMES W. HILBORN and JAMES A. PINCOCK. Can. J. Chem. **70**, 992 (1992).

The photolysis of esters **6** and **8** in methanol leads to products resulting from both naphthylmethyl cations and radicals. The product distribution is nearly independent of X for the esters **6** except when X equals methoxy. A mechanism involving initial homolytic cleavage of the carbon–oxygen bond in the excited singlet state of the ester is proposed. Competition between electron transfer in the radical pair to form the ion pair and decarboxylation of the arylacyloxy radical allows calculations of the rates for this decarboxylation process. The ρ value versus σ is close to zero. When X equals methoxy, intramolecular electron transfer occurs with the naphthalene ring serving as the acceptor and the methoxyaromatic as the donor. This exciplex fragments to carbon dioxide and 1-(1-naphthyl)-2-arylethane.

Key words: acyloxy radical, decarboxylation, photolysis of benzylic esters.

JAMES W. HILBORN et JAMES A. PINCOCK. Can. J. Chem. **70**, 992 (1992).

La photolyse des esters **6** et **8** dans le méthanol conduit à la formation de produits résultant à la fois de cations et de radicaux naphtylméthyles. Pour les esters **6**, la distribution des produits est indépendante de la nature de X, excepté lorsque X est un groupe méthoxyle. On propose un mécanisme impliquant un clivage initial homolytique de la liaison carbone–oxygène dans l'état singulet excité de l'ester. Une compétition entre le transfert d'électrons dans la paire de radicaux pour former la paire d'ions et la décarboxylation du radical arylacyloxy permet de calculer les vitesses de ce processus de décarboxylation. La valeur de ρ versus σ s'approche de zéro. Lorsque X est un groupe méthoxyle, il se produit un transfert intramoléculaire d'électrons avec le noyau naphtalénique servant de accepteur et le fragment méthoxyaromatique agissant comme donneur. Cet exciplexe se fragmente en dioxyde de carbone et 1-(1-naphtyl)-2-aryléthane.

Mots clés : radical acyloxy, décarboxylation, photolyse des esters benzyliques.

[Traduit par la rédaction]

Introduction

Benzylic substrates occupy a central place in the study of electronic effects on organic reactions. This is because variation of substituents along with application of linear free energy relationships (i.e., Hammett correlations) is an excellent probe of the charge changes that occur going from starting material to transition state. Moreover, the usual *meta* and *para* substituents are remote enough from the reaction site that steric effects are generally negligible. Even for radical reactions where charged intermediates are not involved, the decision of which σ scale to use and the sign and magnitude of the small, but measurable, ρ values have been valuable probes of reaction mechanism (1).

Recently, we showed (2) that the singlet photochemistry of 1-naphthylmethyl esters, **1**, in methanol solvent leads to the formation of three major products, as shown in eq. [1].

[1] $$\underset{\mathbf{1}}{ACH_2{-}O_2C{-}R} \xrightarrow[CH_3OH]{h\nu} \underset{\mathbf{2}}{ACH_2{-}OCH_3} + \underset{\mathbf{3}}{H{-}O_2C{-}R} + \underset{\mathbf{4}}{ACH_2{-}R}$$

The mechanism proposed to rationalize the product yields as a function of substituents on the naphthalene ring and changes in the structure of R is outlined in Scheme 1. The ether **2** and the acid **3** are formed by trapping of the 1-naphthylmethyl cation and carboxylate anion respectively. The hydrocarbon is formed from the radical pair that results after loss of carbon dioxide from the alkanoyloxy radical. Since mass balance for the reactions was excellent and only very small amounts of other radical derived products were detectable, essentially all the radical chemistry is occurring in-cage.

There has been considerable recent interest in the partitioning between heterolytic and homolytic pathways in benzylic photochemistry (3, 4). We have been able to rationalize the product yields for substrates **1** by a mechanism involving initial excited-state carbon–oxygen bond cleavage to form a singlet radical pair (i.e., $k_R^X >> k_I^X$). The product partitioning is then controlled by competition between k_{ET}^X, the electron transfer rate that converts the radical pair to the ion pair, and k_{CO_2} as a function of R. This is a quite different suggestion from the usual one that product yields are controlled, at least in part, by competition between k_R^X and k_I^X. Although there is no reason, in principle, why this would not also be true for substrates **1**, the simpler mechanism rationalizes all the cases that we have examined.

We now report results that allow a determination of the effect of substitutents on the rates of decarboxylation of the series of arylacetyloxy radicals, **5**, obtained by photolysis of the corresponding esters, **6**. In addition, we have examined the esters, **8**, in order to assess the effect of substituents directly attached to the developing radical center that results from decarboxylation of **7**.

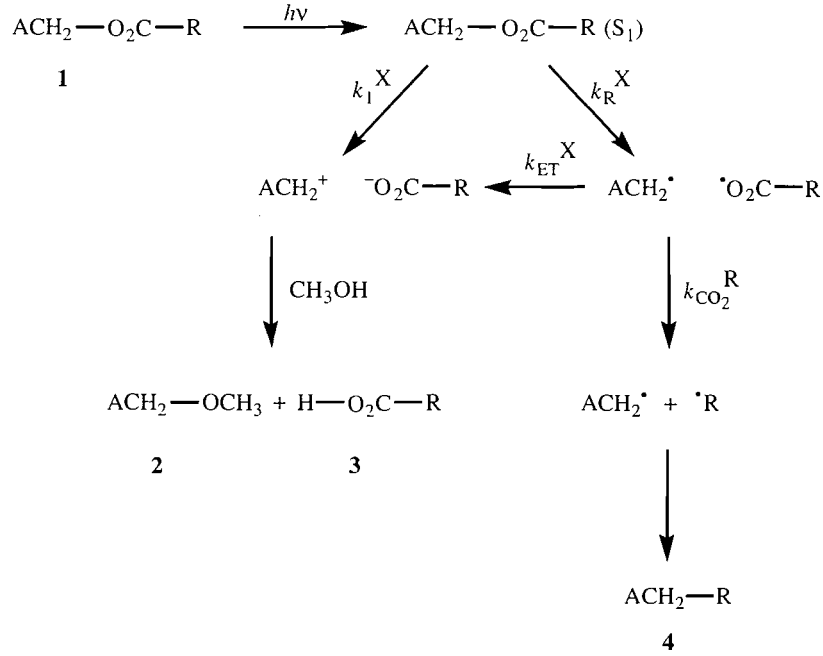

SCHEME 1. Mechanism of the photolysis of 1-naphthylmethyl esters in methanol solvent.

Results

The esters **6** and **8** were all synthesized by reaction of the corresponding acid chloride with 1-naphthylmethanol. Details of the procedure and data for characterization of the compounds are given in the experimental section.

Photolysis of the esters in methanol with a 200-W Hanovia medium-pressure Hg lamp using a Pyrex filter led to clean conversion to the products shown in eq. [1]: A = $C_{10}H_7$; R = X-$C_6H_4CH_2$ and R = X-CH_2. Reactions were monitored by HPLC and taken to completion for preparative scale runs. Photoproducts were isolated, purified, and used to make calibration standards for quantitative runs, which were run to lower conversion (<50%). No changes in product ratios as a function of photolysis time were detected and dark samples taken before and during irradiation were stable. No attempt was made to quantify the yield of the carboxylic acids, **9** (**3**, R = X-$C_6H_4CH_2$) and **10** (**3**, R = X-CH_2), but they could be cleanly isolated by acidification of basic extracts of the reaction mixture. Details of the photolysis procedure are in the experimental section. Values for the product yields in calibrated runs are shown in Table 1.

Also included in Table 1 are values for the quantum yield of fluorescence and the singlet lifetime for all the substrates in methanol.

Discussion

As the results in Table 1 indicate, the products shown in eq. [1] (i.e., the ether **2** and the coupling products, **11** (**4**, R = X-$C_6H_4CH_2$) or **12** (**4**, R = X-CH_2)), are formed and the mass balance is excellent. Since the yield of the ether is the easiest to quantify, we again (6) made the simplifying approximation that all starting material not accounted for by its formation has formed products from the radical pathway. Therefore, according to Scheme 1, k_{CO_2}/k_{ET}^X = yield of **2**/(100 − yield of **2**). As in our previous work (2, 6), we assume that k_{ET}^X is independent of the structure of the acyloxy radical and only dependent on the structure of the naphthalene ring. This assumption about k_{ET}^X is very reasonable for these substituted phenylacetyloxy radicals. A value of ρ = 0.5 has been measured (7) for the equilibrium acidities of substituted phenylacetic acids. If the substituent effect for the development of negative charge on the phenylacetyloxy radical as it is reduced to the corresponding anion is similar to this, then a ρ value equal to 30 mV/σ can be calculated for the reduction potentials. This gives a range in the reduction potentials of only 28 mV going from the best electron-donating group (4-CH_3O) to the best electron-withdrawing one (4-CN). The plot (2) of log k_{ET}^X as a

[d]Errors in parentheses are estimated assuming ±2% error in determination of product yields and ±10% error in the rate of decarboxylation of **15**.
[e]These values are not the correct rates of decarboxylation because the competing intramolecular electron transfer pathway leads to high yields of the decarboxylation product.

function of the oxidation potential change going from the radical pair to the ion pair indicates that this would only lead to a 20% change in k_{ET}^X, which is almost within the expected experimental error for determining k_{CO_2}. Of course, for the compounds studied here, the naphthalene side is constant so k_{ET}^X will equal k_{ET}^H. Using our previously estimated value (2) of 2.6×10^{10} s^{-1} for k_{ET}^H allows calculation of k_{CO_2} as a function of R. These values are listed in Table 1.

Turning first to the benzylic substrates, **6**, the values for k_{CO_2} are all clustered around 9.9×10^9 s^{-1} with the exception of the radicals **5***b* (X = 4-CH_3O) and **5***c* (X = 3-CH_3O) derived from substrates **6***b* and **6***c* respectively. This is made more obvious by the Hammett plot in Fig. 1, which shows that, within experimental error, the slope is close to zero if the two methoxy compounds are excluded. They have estimated rates of decarboxylation that are 10–20 times faster than the others. Clearly, then, the results for the arylacetate esters present two points for discussion: first, the lack of substituent effect for the rates of decarboxylation of the arylacetyloxy radicals, **5**, for all cases except the methoxy-substituted ones and, second, the anomalous behaviour of the methoxy compounds. The first point will be discussed next.

In general, of course, radical reactions have smaller substituent effects then ionic reactions. However, benzylic radicals certainly often have measurable ρ values, indicating the polarity of the transition state. In fact, there have been many quite successful correlations with σ^+ of benzylic rate data for abstraction of hydrogen from toluenes with various electronegative radicals (1, 8). Attempts to assess true radical stabilizing effects in benzylic systems (i.e., σ scales) have relied on studying reactions that have no polarity in the transition state (1*b*) or by measuring ESR hyperfine coupling constants of substituted benzyl radicals (1*a*). These scales indicate that even in completely nonpolar cases, substituents can stabilize benzyl radicals significantly, particularly by conjugation from the *para* position. Our observation of no measurable effect on the rate of loss of carbon dioxide from the arylacetyloxy radicals, **5**, was therefore a surprise.

Two closely related reactions deserve discussion for comparison. The first of these, oxidative decarboxylation of arylacetyl anions by persulfate gave a Hammett correlation with a $\rho^+ = -0.43$, suggesting, as expected, positive charge on the benzylic carbon as in **13** (9). However, later work (10) demonstrated that the electron transferred during the oxidation was probably from the aromatic ring, giving the expected high $\rho^+ = -2.9$. The second example involves the pyrolysis of substituted *tert*-butyl phenyl peracetates (11). Here, the evidence indicates that the cleavage of the O—O bond and the C—C bonds is concerted, producing benzyl and *tert*-butoxy radicals and carbon dioxide in one activated step. The transition state was drawn as in **14** and the reaction again

$$ArCH_2CO_2^- SO_4^{\bullet -} \longleftrightarrow ARCH_2CO_2^{\bullet} SO_4^{2-} \longleftrightarrow ArCH_2^+CO_2^{\bullet -}SO_4^{2-}$$

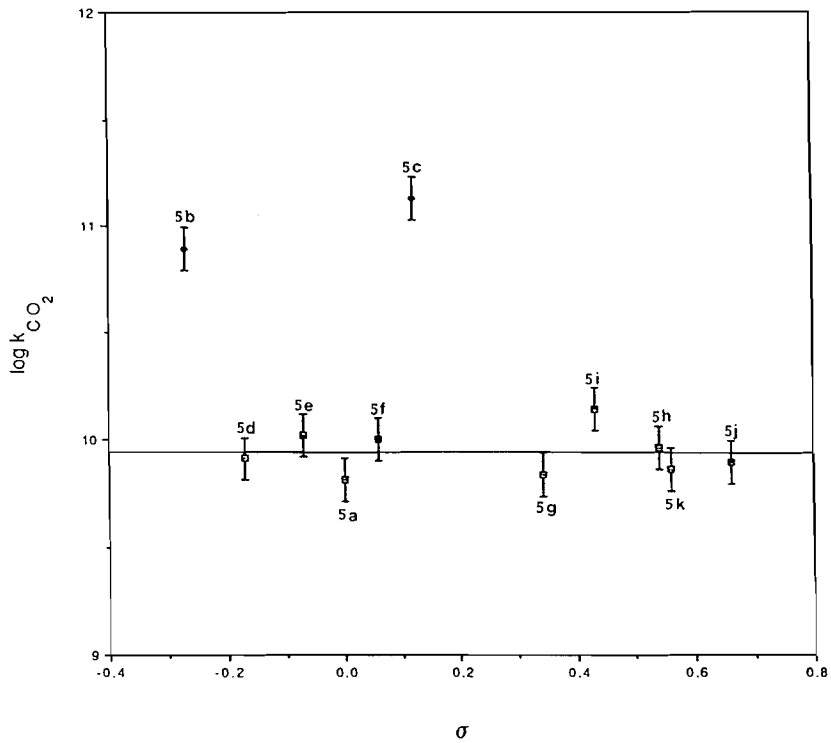

FIG. 1. Hammett plot of log k_{CO_2} versus σ for the decarboxylation of arylacyloxy radicals.

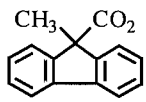
correlates with $\rho^+ = -1.0$ to -1.2 depending on temperature. A suggestion was made that perhaps arylacetyloxy radicals were too reactive to have a discrete lifetime. However, the observation that the 9-methylfluorenylcarboxylate radical, **15**, has a short but measurable lifetime (55 ps) at room temperature (12) makes this unlikely.



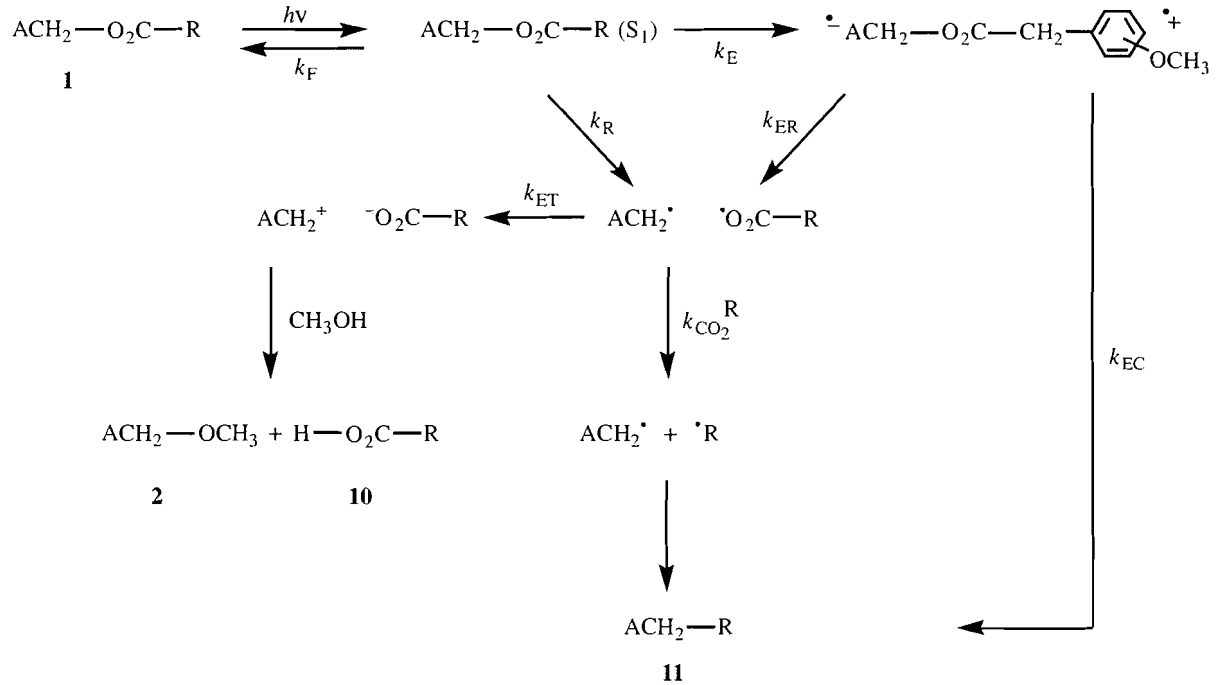
15

There are several differences between our method of determining rates of decarboxylation of arylacetyloxy radicals and that of Bartlett and Rüchardt (11). First, our results are obtained at 20°C as opposed to the higher temperatures (55–100°C) required for the perester decomposition. Thus, the radical has a better chance of having a discrete existence in the shallow energy well that separates it from the arylmethyl radical and carbon dioxide. Second, the counter radical is the carbon-centered radical, 1-naphthylmethyl, so that the polarity in the transition state should be minimized relative to **14** above. Finally, we presented evidence previously (6) that the loss of carbon dioxide from the arylacetyloxy radical may be controlled by the entropy rather than enthalpy of activation. This is true because the stabilization of the incipient benzyl radical requires a freezing of the conformation of the benzene ring to allow overlap with the breaking σ bond. Such entropic effects have been observed before for the much slower loss of carbon monoxide from phenylacetyl ($PhCH_2CO$) radicals (13). For the arylacetyloxy radical, where the enthalpic barrier will be extremely low, this entropic effect may dominate the activation process. If this is true, substituent effects would be expected to be small, i.e., radical stability effects are unimportant in determining the rate of loss of carbon dioxide.

The second major feature in the decarboxylation rates of the arylacetyloxy radicals, **5**, is the enhanced rate of decarboxylation for **5***b*, X = 4-OCH_3 and **5***c*, X = 3-OCH_3. This effect is easily explained when it is also noted that the quantum yield of fluorescence, ϕ_f, and the singlet excited state lifetime, τ_s, are also significantly different for these two substrates. As shown in Table 1, both values for both substrates are about a factor of two lower than for all the other substrates. This is true even though the chromophore and excited-state energy results from the same structural unit, the naphthalene ring. Clearly, another excited singlet-state process has been added to the mechanism for these methoxy-substituted substrates. Our suggestion is that this additional pathway is intramolecular exciplex formation by electron transfer from the methoxy aromatics to the naphthalene ring (Scheme 2). This process, with rate constant k_E, competes with the normal homolytic cleavage pathway, k_R, as well as with fluorescence, k_F. Therefore, both ϕ_F and τ_s will be decreased.

There are many examples of intramolecular exciplexes of this type and many, though not all, are emissive (14). We have looked carefully for excimer emission and have not been able to observe any in either methanol or cyclohexane solvent. However, the Rehm–Weller relationship (15), eq. [2], provides a convincing argument for exciplex formation. Values for the oxidation potential of anisole (1.76 V vs. SCE in CH_3CN) (16), the reduction potential of naphthanlene (−2.6 V vs. SCE in CH_3CN) (16), and the singlet excitation energy, $E_{0,0}$, for these substrates (376 kJ mol^{-1} from the wavelength of the 0,0 band in CH_3OH) gives ΔG_E = 43 kJ mol^{-1}. The electrostatic term in eq. [2] is less certain because the distance between the two charged rings is un-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.



SCHEME 2. Mechanism of the photolysis of 1-naphthylmethyl esters including the intramolecular electron transfer pathway.

[2] $\Delta G_E = E^0(D/D^+) + E^0(A^-/A) - e_0^2/\epsilon r - \Delta E_{0,0}$

known. If the two aromatics interact strongly, they could be quite close. Molecular models indicate that if the rings are coplanar in the exciplex, the maximum distance of separation is 5 Å with no geometric inhibition to shorter distances. Assuming the dielectric constant to be used is that of the bulk medium, methanol, the value of this term is 9 kJ mol^{-1} at 5 Å and 22 kJ mol^{-1} at 2 Å. Thus ΔG_E is probably somewhere between 34 kJ mol^{-1} and 21 kJ mol^{-1}. Using the graph produced by Rehm and Weller (15) for intermolecular charge transfer a value of k_E around 10^7 s^{-1} can be estimated.

The conclusion of this discussion is that intramolecular exciplex formation in **6***b* and **6***c* can compete with the normal singlet excited rate processes: $1/\tau_s = 1/40$ ns $= 2.5 \times 10^7$ s^{-1}.

From the fluorescence data, an estimate of the rate constant of exciplex formation can be made. Equation [3] indicates that the ratio of either lifetimes of the singlet excited states or fluorescence quantum yields for those substrates that do not form exciplexes relative to those that do is simply re-

[3] $\tau_F/\tau_F^E = \phi_F/\phi_F^E = 1 + k_E\tau_F$

lated to the required rate constant. This equation assumes that τ_F^E is the same as τ_F except for the addition of k_E, eq. [4]. On the average, the values of τ_F/τ_F^E and δ_F/ϕ_F^E are about 2.

[4] $1/\tau_F^E = k_F + k_D + k_R + k_E$

Therefore the product of $k_E\tau_F$ is close to unity or in other words, $k_E \approx k_F + k_D + k_R = 2.5 \times 10^7$ s^{-1} as required for exciplex formation to compete with but not dominate other singlet-state processes.

Finally, a value for the oxidation potential of toluene (2.28 V vs. SCE in CH_3CN) (16) used in eq. [2] leads to a value for ΔG_E for electron transfer (without including the electrostatic term) in the methyl-substituted esters **6***d* and **6***e* of +188 kJ mol^{-1}. This is obviously too endoergonic to lead to a rate that would be competitive with other excited singlet-state chemistry.

From the product ratios in Table 1, it is clear that the two methoxy-substituted substrates, **6***b* and **6***c*, give lower yields of the cation-derived product, the methyl ether **2**, and corresponding higher yields of the radical-derived coupling product **11**. The previous discussion suggests strongly that the formation of the intramolecular exciplex is creating another pathway of reactivity for the singlet excited state. The obvious conclusion is that this exciplex then gives preferentially the coupling product **11**. The electronic structure of the charge transfer complex represented by a contributor like **16**, eq. [5], seems ideal for concerted bond cleavage involv-

ing loss of CO_2 and formation of the precursors required for coupling. Note that the decarboxylation must be concerted in order to avoid formation of the arylacyloxy radical, which would then lead to the normal chemistry of the radical pair. In Scheme 2, as shown, $k_{EC} >> k_{ER}$. In conclusion, the calculated rates of decarboxylation in Table 1 for **5***b* and **5***c*, which are based on the ratio of the products **2** and **11** (**4**, R = X-$C_6H_4CH_2$), are clearly incorrect because an alternate pathway for formation of **11** is occurring.

The effect of substituents on the rates of decarboxylation of the arylacetyloxy radicals, **5**, are negligibly small. We therefore chose to look briefly at the effect of substituents more closely attached. The substrates **8** generate the radicals **7**. Since the fluorescence is normal (Table 1), the yield of **2** (eq. [1]) is now a measure of the decarboxylation rate again. The rates of decarboxylation of $RCO_2^{\cdot}$ are now significantly changed: R, $k_{CO_2} \times 10^{-9}$; H-CH_2, <1.3; NC-CH_2, 3.2; CH_3O-CH_2, 3.5; Ph-CH_2, 5.0; CH_2=$CHCH_2$, 7.7. With the obvious caution that these reactions are so fast that any rate–substituent correlation will be highly compressed, this order does make sense based on radical stability or bond-strength arguments. Clearly, since both the cyano and methoxy substituents give a rate increase relative to hydrogen, polar effects cannot be too important. However, the fact that methoxy is slightly faster than cyano is not in agreement with most scales of radical stabilizing effects (17). This may indicate a slight amount of polar character in the transition state for decarboxylation with the carboxyl oxygens negative and the methylene carbon positive.

Experimental

General

Ultraviolet (UV) spectra were obtained in methanol on a Varian Cary 219 spectrophotometer. Proton (^{1}H NMR) and carbon (^{13}C NMR) nuclear magnetic resonance spectra were obtained in $CDCl_3$ with TMS as an internal standard on a Nicolet NB 360 spectrometer. Mass spectra were obtained on a Hewlett Packard 5890 GC/MS using a 5% phenylsilicone capillary column. Infrared spectra were obtained on a Pye Unicam SP 1000 spectrophotometer. Fluorescence spectra were obtained on a Perkin Elmer MPF 66 spectrophotometer using samples in methanol that were degassed by three freeze–pump–thaw cycles; the optical density of the samples was always less than 0.2 and quantum yields were obtained relative to a value of 0.21 for 1-methylnaphthalene (5). Fluorescence lifetimes were obtained on the same samples using a PRA System 3000 instrument with a hydrogen flash lamp of pulse width 0.8 ns. Microanalysis were by Canadian Microanalytical Service Ltd., Delta, B.C., Canada.

Irradiations

Irradiations were done with a 200-W medium-pressure Hanovia mercury lamp in a standard immersion well with a Pyrex filter. Solutions were degassed with a slow nitrogen stream. Progress of the reaction was monitored by HPLC using a Waters system, operating in isocratic conditions (80:20 methanol:water), equipped with a Brownlee Spheri-10 reverse-phase column (25 × 0.46 cm). Detection was at 280 nm. Complete conversion of 200 mg of the esters took approximately 3 h for the most reactive esters while the unreactive esters took approximately 24 h. Product ratios remained constant throughout the course of the irradiation and dark samples taken either before or during the irradiation showed no conversion. Yields were obtained by calibrating the HPLC detector with samples of the products of known concentration in methanol. For preparative runs the photolyzed solution was concentrated under vacuum to approximately 10 mL and then 30 mL of water and 30 mL of CH_2Cl_2 were added. The CH_2Cl_2 layer was separated and extracted with 2 × 15 mL of a 5% aqueous NaOH solution. The CH_2Cl_2 layer was dried ($MgSO_4$), filtered, and rotoevaporated to give an oil that was subjected to flash chromatography through silica gel using 80:20 hexane:CH_2Cl_2 as the eluent. The aqueous alkaline layer was acidified with concentrated HCl, and extracted with 2 × 25 mL of CH_2Cl_2. Evaporation of this CH_2Cl_2 layer gave products that were identified as the corresponding acids.

Methoxyacetyl chloride, phenylacetyl chloride, 1-naphthylmethanol, cyanoacetic acid, 3-butenoic acid, 4-methoxyphenylacetic acid, 3-methoxyphenylacetic acid, 4-methylphenylacetic acid, 3-methylphenylacetic acid, 4-fluorophenylacetic acid, 3-fluorophenylacetic acid, 4-α,α,α-trifluorophenylacetic acid, 3-α,α,α-trifluorophenylacetic acid, were purchased from the Aldrich Chemical Company. All solvents were distilled prior to use. The acid chlorides were obtained by refluxing three molar equivalent of thionyl chloride with the acid (18). Cyanoacetyl chloride was prepared from cyanoacetic acid using the method of Ireland and Chaykovsky (19). The 4- and 3-cyanophenylacetic acids were obtained by the method of Richter *et al.* (20). The esters generated were hydrolyzed in aqueous base to give the corresponding acids. 1-Methoxymethylnaphthalene, **2**, was obtained by the previous procedure (6).

*Synthesis of substituted and 1-naphthylmethyl phenylacetates (**6**a–k) and 1-naphthylmethyl acetates (**8**a–c)*

To a well-stirred solution of 1-naphthylmethanol (1.56 g, 0.01 mol) and 1 mL of pyridine in 50 mL of dry benzene was slowly added the corresponding acid chloride (0.01 mol) in 30 mL of benzene at room temperature. The pyridinium hydrochloride salt precipitated and after all of the acid chloride was added the solution was stirred overnight. Then 50 mL of water was added and the two layers were separated. The benzene layer was washed twice with 10% aqueous HCl, once with 5% aqueous NaOH, and finally with water. The organic layer was dried ($MgSO_4$), filtered, and rotoevaporated to yield the crude esters. The ester was then column chromatographed over silica gel using 50:50 hexane:methylene chloride as the eluent. The ester fractions were identified by TLC, then combined and concentrated. The esters that were oils were distilled under vacuum and those that were solids were recrystallized from hexane for purification.

Characterization of esters

*1-Naphthylmethyl phenylacetate (**6**a)*: yield 62%; bp 196–200°C at 0.5 Torr[2] (lit. (21) bp 212°C at 4–5 Torr); UV: λ_{max} 265 (ϵ 6.37 × 10^3), 275 (7.39 × 10^3), 284 (5.29 × 10^3); IR (neat): 3010, 2930, 1740 (C=O), 1600, 1520, 1495, 1455, 1240, 1145, 940, 785, 765 cm^{-1}; ^{1}H NMR δ: 7.73–7.75 (m, 1H), 7.62–7.68 (m, 2H), 7.30–7.33 (m, 3H), 7.22 (t, 1H, J = 7.6 Hz), 7.09 (s, 5H), 5.39 (s, 2H, CH_2O), 3.47 (s, 2H, CH_2C(=O)); ^{13}C NMR δ: 171.4 (s, C=O), 133.8 (s), 133.6 (s), 131.5 (s), 131.2 (s), 129.2, 128.6, 128.5, 127.4, 127.0, 126.4, 125.9, 125.2, 123.5, 65.0 (t, CH_2O, J = 147.8 Hz), 41.3 (t, CH_2C(=O), J = 129.8 Hz); GC/MS: 277 (7, M + 1), 276 (39, M^+), 142 (18), 141 (100), 115 (24), 91 (24).

*1-Naphthylmethyl 4-methoxyphenylacetate (**6**b)*: yield 48%; bp 118–120°C at 0.5 Torr; UV: λ_{max} 266 (ϵ 8.16 × 10^3), 275 (8.52 × 10^3), 286 (5.15 × 10^3); IR (neat): 3080, 2980, 1740 (C=O), 1615, 1515, 1250, 1150, 1040, 980, 795, 780 cm^{-1}; ^{1}H NMR δ: 7.89–7.91 (m, 1H), 7.79–7.85 (m, 2H), 7.46–7.49 (m, 3H), 7.40 (t, 1H, J = 7.6 Hz), 7.16 (d, 2H, J = 8.4 Hz), 6.81 (d, 2H, J = 8.4 Hz), 5.55 (s, 2H, CH_2O), 3.74 (s, 3H, OCH_3), 3.57 (s, 2H, CH_2C(=O)); ^{13}C NMR δ: 171.4 (s, C=O), 158.8 (s), 133.7 (s), 131.6 (s), 131.4 (s), 130.1 (d, J = 153.3 Hz), 129.1, 128.5, 127.1, 126.3, 126.0 (s), 125.7, 125.1, 123.5, 114.0 (d, J = 158.7 Hz), 64.7 (t, CH_2O, J = 148.2 Hz), 55.2 (q, OCH_3, J = 143.5 Hz), 40.4 (t, CH_2C(=O), J = 130.0 Hz); GC/MS: 307 (6, M + 1), 306 (29, M^+), 142 (8), 141 (58), 121 (100), 115 (16), 78 (8). Synthesis of the hydrocarbons

1-(2-Methoxyethyl)naphthalene was prepared by the method of Todesco and Put (22). 1-Naphthalenepropanenitrile was synthesized from 2-(1′-naphthyl)ethanol. The alcohol was converted to the mesylate, which was then reacted with potassium cyanide in DMF. The ^1H NMR of these compounds were consistent with the those reported earlier (22, 23). The hydrocarbons (**11***a–k*, **12***c*) were isolated from preparative photolysis and had ^1H NMR that were consistent with their structure.

A mixture of glycosidic acids, each of which consisted of a tetrasaccharide unit linked by an anomeric carbon to 11-hydroxypalmitic acid and containing short-chain fatty acids ester-linked to the sugar units, was isolated from *Ipomoea stans*. Basic hydrolysis allowed isolation of a single compound whose structure was determined by two-dimensional NMR methods to be (*S*)-11-hydroxypalmitic acid 11-*O*-β-quinovopyranosyl-(1-4)-α-rhamnopyranosyl-(1,2)-β-glycopyranosyl-(1-2)-β-quinovopyranoside. Further HPLC separation of the original mixture allowed separation of a compound that was shown, by 2D NMR, to have 2-methylbutanoic acid molecules linked to C-4 of the terminal quinovose and C-2 of rhamnose, 3-hydroxy-2-methyl butanoic acid linked to C-6 of glucose, and with the palmitic acid forming a lactone at C-3 of rhamnose. Closer inspection revealed that this compound was actually a mixture of diastereomers involving different ((2*R*,3*R*) and (2*S*,3*S*)) enantiomers of 3-hydroxy-2-methylbutanoic acid bonded to the chiral tetrasaccharide core.

Key words: tetrasaccharide, two-dimensional NMR.

RAUL G. ENRIQUEZ, ISMAEL LEON, FIDEL PEREZ, FERNANDO WALLS, KATHERINE A. CARPENTER, FRANK V. PUZZUOLI et WILLIAM F. REYNOLDS. Can. J. Chem. **70**, 1000 (1992).

À partir de l'*Ipomoea stans*, on a isolé un mélange d'acides glycosidiques qui contiennent chacun une unité tétrasaccharide liée par un carbone anomérique à l'acide 11-hydroxypalmitique et qui contiennent des esters d'acides gras à chaines plus courtes liés à des unités de sucre. De leur hydrolyse basique on a pu isoler qu'un seul composé dont on a déterminé la structure par des méthodes de RMN bidimensionnelles; il s'agit du 11-*O*-β-quinovopyranosyl-(1,4)-α-rhamnopyranosyl-(1,2)-β-glucopyranosyl-(1,2)-β-quinovopyranoside de l'acide (*S*)-11-hydroxypalmitique. Une séparation plus poussée du mélange original par CHLP a permis de séparer un composé qui, selon la RMN en 2D, contiendrait des molécules d'acide 2-méthylbutanoique liées au C-4 du quinovose terminal et au C-2 du rhamnose, de l'acide 3-hydroxy-2-méthylbutanoique lié au C-6 du glucose et de l'acide palmitique formant une lactone en C-3 du rhamnose. Un examen plus minutieux a révélé que ce composé est en réalité un mélange de diastéréoisomères impliquant différents ((2*R*,3*R*) et (2*S*,3*S*)) énantiomères de l'acide 3-hydroxy-2-méthylbutanoique liés à un noyau tétrasaccharide chiral.

Mots clés : tétrasaccharide, RMN bidimensionnelle.

Introduction

During the course of a phytochemical investigation of *Ipomoea stans* (Convulvulaceae), a plant used in Mexican traditional medicine for treatement of epileptic seizures (1), we isolated two polysaccharide samples from the roots of this plant. Preliminary characterization indicated that each sample was an oligosaccharide linked to a hydroxylated long-chain fatty acid via an acetal linkage at an anomeric center. Other short-chain fatty acids were ester-linked to the oligosaccharide core. The major difference between the two samples appeared to be the extent of esterification, with the more polar compound containing fewer ester linkages. However, the ^{13}C spectra suggested that neither sample was pure. Instead, each sample appeared to be a mixture of several compounds that apparently were isomers involving different sites of esterification and (or) different short-chain fatty acids. Initial attempts at further chromatographic separation were unsuccessful. Consequently, a portion of each sample was subjected to mild basic hydrolysis to cleave the ester linkages. After purification, the two new compounds were found to be identical. The characterization of this compound, primarily by two-dimensional NMR spectroscopy, is reported below. In addition, subsequent purification via high-pressure liquid chromatography allowed isolation of one pure compound from the less polar fraction. Characterization of this compound is also reported.

Results and discussion

Initial characterization

Initial characterization of the hydrolyzed glycosidic acid was carried out using normal ^1H NMR and normal and DEPT-edited (2) ^{13}C NMR. Measurements were carried out in CD_3OD since this solvent gave the best-resolved ^1H spectrum. The observation of four methine ^{13}C peaks in the region expected for anomeric carbons (δ100–105) suggested that the compound was a tetrasaccharide. Consistent with this, 17 additional methine ^{13}C peaks were observed in the region δ67–84, one of which was assumed to be the oxygen-bearing carbon of the fatty acid. Only one methylene carbon was observed in the sugar region. However, there were four methyl ^{13}C peaks in the region δ14–19. Inspection of the ^1H spectrum also revealed four methyl signals, three showing doublet splitting and a fourth appearing as a broadened triplet. This indicated that three of the four monosaccharides were 6-deoxy (e.g., 6-methyl) sugars. Finally, the ^{13}C spectrum showed a CO_2H signal and 13 further CH_2 signals (the latter in the region δ21–37). Combined with the previously mentioned

-CHO- and $-CH_3$ signals, this suggested that the fatty acid was a hydroxypalmitic acid isomer. The ^1H spectrum showed a triplet at δ2.22 characteristic of a CH_2 group adjacent to CO_2H and coupled to another CH_2 group, ruling out C-2 and C-3 as sites of hydroxylation. Similarly the observation of a broadened CH_3 triplet, suggesting virtual coupling to more than one CH_2 group, rules out C-14 to C-16 as the site of hydroxylation. No further conclusions could be drawn at this point since the remaining methylene ^1H signals appeared as a broad, poorly resolved envelope in the range δ1.1–1.7.

Assignment of individual monosaccharide units

Initial assignments were carried out by obtaining a COSY spectrum (3). This allowed tentative assignment of the protons of the four monosaccharide units. Inspection of the one-dimensional NMR spectrum then allowed determination of the individual $^1H-^1H$ coupling constants. The latter data suggested that the four monosaccharide units were one β-glucose unit, G, two β-quinovose units, Q_1 and Q_2, and probably one α-rhamnose unit, R. However, there was some ambiguity on the latter point since the equatorial orientation of H-2 in rhamnose makes it difficult to distinguish α and β anomers of rhamnose on the basis of coupling between H-1 and H-2.

Some of the individual ^1H assignments were unclear due to partial spectral overlap. However, expansion of the COSY spectrum for the region δ2.9–4.3 (see Fig. 1) showed that, for each monosaccharide unit, a peak assigned as either H-3 or H-4 was resolved. This suggested the possibility of using a homonuclear relayed coherence transfer experiment (4) to confirm ^1H assignments. Results of this experiment are illustrated in Fig. 2. This shows f_1 cross sections through peaks assigned as H-3 or H-4 for each monosaccharide. In effect, they provide a low-resolution edited ^1H spectrum with each monosaccharide unit appearing as a separate subspectrum.

The spectra in Fig. 2 are somewhat surprising in that they show relay of information along sequences of four protons on different carbons. Normally the basic relay sequence (4) only transmits information along a three-proton sequence (5). However, Otter and Kotovych have observed similar long-range relay peaks in spectra of polypeptides (6). Multi-exponential relaxation effects may contribute to long-range relay peaks involving methyl protons (7) and this may partially account for our observations for Q_1, Q_2, and R. Strong coupling effects can also cause long-range relay peaks (8) but this is unlikely to be important in this case since most monosaccharide protons are only weakly coupled. The fact that there is only one proton per carbon in most cases and usually similar vicinal $^1H-^1H$ coupling constants should promote the efficiency of at least the original relay stage (5, 9). In any case, regardless of the origins of the long-range peaks, they are obviously very helpful for spectral assignments.

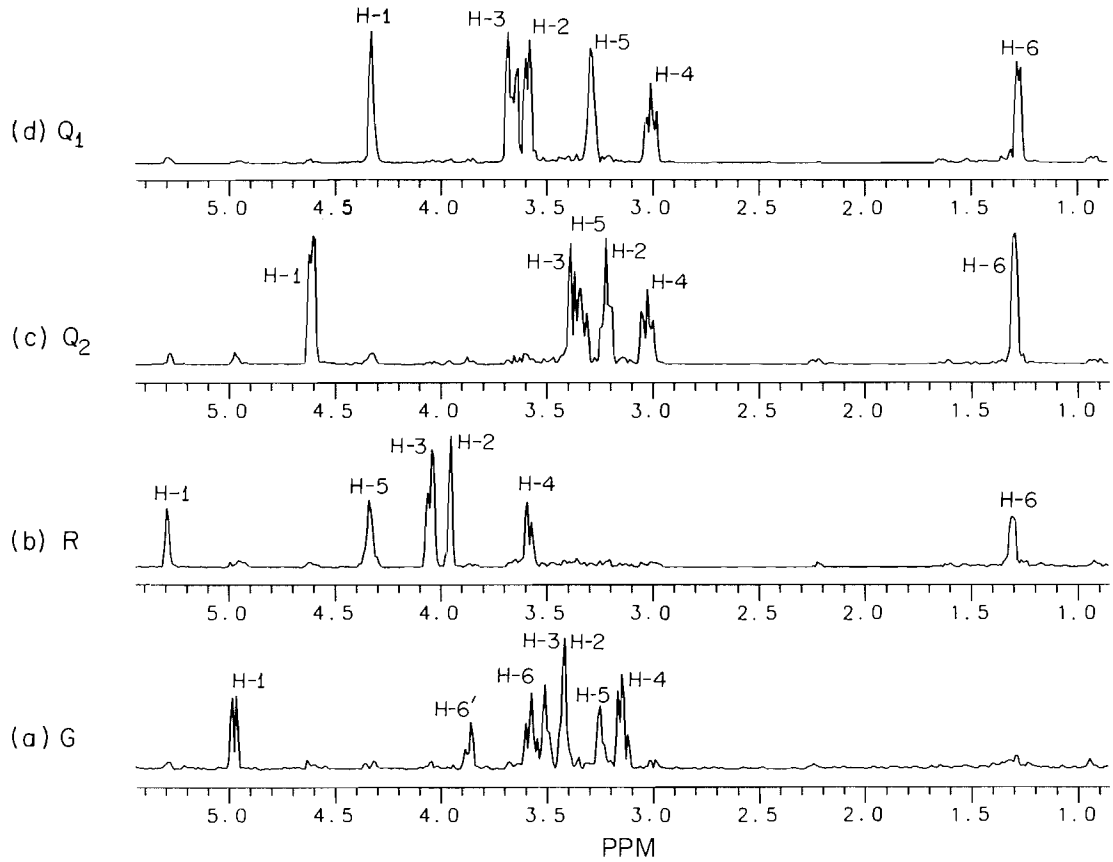

FIG. 2. Edited subspectra of individual monosaccharide units obtained from relay spectrum.

One-bond $^{13}C-^{1}H$ shift-correlated spectra (10) were used to assign ^{13}C chemical shifts, based on the ^{1}H assignments. Complete assignments of sugar protons and carbons are given in Table 1.

Assignment of linkage sites between different monosaccharide units and to the hydroxypalmitic acid chain

The first approach used to determine this information was to obtain nuclear Overhauser effect (nOe) difference spectra with and without irradiation of individual anomeric protons. However, there were three problems with this approach. First and most serious, the molecule is fortuitously tumbling at a rate almost corresponding to the cross-over from positive to negative nOe effects, resulting in very small intensity changes. Second, partial overlap of H-1 of Q_1 and H-5 of R complicated the interpretation of the results of irradiating the former hydrogen. Finally, strong spectral overlap near δ3.6 also hindered interpretation of some of the results. Nevertheless, the nOe results suggested inter-ring nOe's between H-1 of Q_2 and H-4 of R, H-1 of R and H-2 of G, and H-1 of G and H-2 of Q_1, plus an nOe between H-1 of Q_1 and the -CHO- proton assigned to the hydroxylated fatty acid.

To confirm these assignments, $^{13}C-^{1}H$ shift correlation spectra between indirectly bonded carbons and hydrogens (INCH) were measured, using our XCORFE sequence (11). The actual spectra were obtained on a peracetylated sample of the tetrasaccaride in $(CD_3)_2CO$. This was chosen because ^{13}C and ^{1}H relaxation times were significantly longer in the peracetylated compound, minimizing signal loss due to relaxation during the lengthy fixed delays necessary in INCH experiments. ^{1}H and ^{13}C spectra for the peracetylated sample were assigned in the same way as discussed above (see Table 1). Key cross-sectional spectra from the INCH experiment are shown in Fig. 3. Spectra 3*a*–3*g* show all six $^{1}H—C—O—^{13}C$ inter-ring connectivities plus the three-bond connectivity between H-1 of Q_1 and the methine carbon of the fatty acid. Many of the cross sections also show two-bond ($^{1}H—C—^{13}C$) connectivities, which are usually easily recognized by the presence of vicinal $^{1}H-^{1}H$ coupling. Three-bond intra-ring ($^{1}H—C—C—^{13}C$) cross-peaks are generally not observed, presumably because $^{3}J_{CH}$ coupling involving an axial hydrogen is relatively small due to the *gauche* dihedral angle (12). However, a strong three-bond connectivity is observed between the equatorial H-2 and C-4 of R (Fig. 3*e*), reflecting the larger *anti* $^{3}J_{CH}$ coupling (12). This suggests a method for determining the anomeric configuration of R, since C-3 and C-5 of R should show strong cross-peaks with H-1 only if H-1 is equatorial. In fact, these cross-peaks are observed (see Figs. 3*h*, 3*i*), confirming that R exists as its α-anomer. Alternatively, the same information could have been obtained by measuring anomeric $^{1}J_{CH}$ coupling constants (13).

Characterization of fatty acids

Two short-chain fatty acids were isolated from the hydrolysis of each of the two original samples. These were identified from their ^{1}H and ^{13}C spectra as 2-methylbutanoic acid and 3-hydroxy-2-methylbutanoic acid. The former was

[a] ^{13}C chemical shifts (relative to internal $(CH_3)_4Si$) for **1** in CD_3OD and (in parentheses) for the peracetylated derivative of **1** in $(CD_3)_2CO$.

[b] ^{1}H chemical shifts (relative to internal $(CH_3)_4Si$) for **1** in CD_3OD and (in parentheses) for the peracetylated derivative of **1** in $(CD_3)_2CO$.

[c] Vicinal $^{1}H-^{1}H$ couplings (in Hz) for **1** in CD_3OD.

[d] Denotes a carbon that is a linkage site to another monosaccharide or to hydroxypalmitic acids. Note that the ^{1}H chemical shifts for the attached protons generally show smaller shifts between **1** and its peracetylated derivative than protons attached to carbons whose hydroxyl groups are peracetylated.

the major component (ca. 60%) of the mixture in each case. Based on a comparison of coupling constants with those previously reported (14), the 3-hydroxy-2-methylbutanoic acid is apparently the (2*S*,3*S*) isomer or its (2*R*,3*R*) enantiomer.

Identification of the hydroxypalmitic acid isomer proved more difficult. From ^{13}C chemical shifts and T_1 relaxation times, it seemed improbable that the hydroxyl group was attached to a carbon that was within five carbons of either chain end. However, this still left six possible isomers. To determine the actual structure, the hydroxypalmitic acid was isolated from the glycosidic acid by mild acid hydrolysis. It was esterified (as the methyl ester), then converted to the trimethylsilyl ether. Gas chromatography/mass spectrometry indicated that the compound was 11-hydroxypalmitic acid and the observed rotation indicated that it was the *S* enantiomer (see Experimental). Thus the isolated pure compound has the structure (*S*)-11-hydroxypalmitic acid 11-*O*-β-quinovopyranosyl-(1-4)-α-rhamnopyranosyl-(1,2)-β-glucopyranosyl-(1-2)-β-quinovopyranoside. By analogy with earlier results (14), the quinovose and glucose units are assumed to have the D configuration while the rhamnose unit has the L configuration.

Assigned ^{13}C and ^{1}H chemical shifts and relaxation times for the hydroxypalmitic acid group are given in Table 2.

Determination of the complete structure of one component of the less polar fraction

With the aid of HPLC, a single, apparently pure, component was isolated from the less polar mixture. The ^{1}H spectrum of this compound is exceedingly complicated even at 500 MHz (Fig. 4). Nevertheless, by a combination of COSY, relay, and one-bond and long-range $^{13}C-^{1}H$ shift-correlation spectra it was possible to assign the entire structure and ^{1}H and ^{13}C spectra. The only difference in technique was that we used our recently developed FLOCK sequence (15) for the long-range $^{13}C-^{1}H$ shift correlation experiment, since this sequence gives a wider range of cross-peaks from a single experiment. These experiments indicated that one 2-methylbutanoic acid molecule was attached at C-4 of Q_2, a second 2-methylbutanoic acid was attached at C-2 of R, while a 3-hydroxy-2-methylbutanoic acid molecule was attached at the methylene group of G (C-6). Finally, the carboxylic acid function of the hydroxypalmitic acid formed a lactone ring at C-3 of R. This leads to the final structure **2**. However, one puzzling feature was

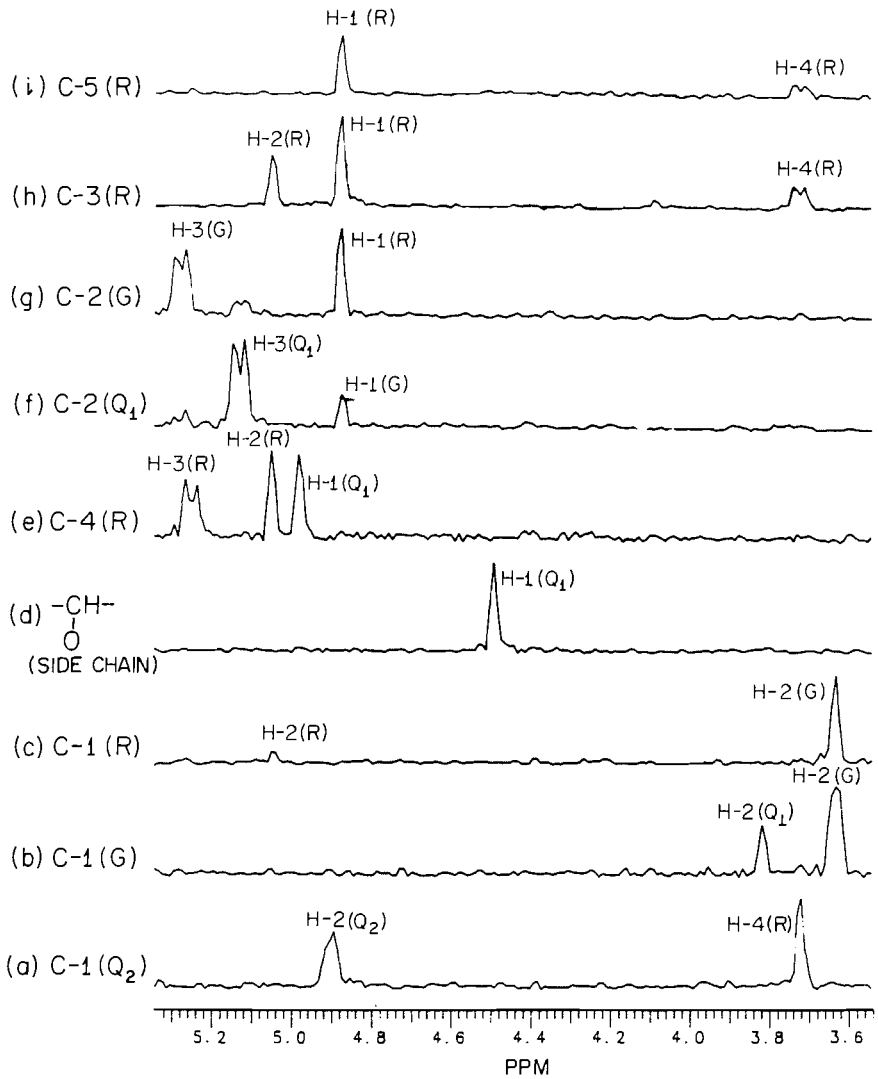

FIG. 3. f_1 cross-sectional spectra through indicated carbon (f_2) frequencies. The sample is a peracetylated sample of **1** in $(CD_3)_2CO$ and spectra were obtained with the XCORFE sequence.

an apparent doubling of ^{13}C peaks for all carbons of G, as well as carbons 1–3 of R and carbons 1, 2, and 5 of Q_1. The chemical shift difference was typically very small (0.03–0.06 ppm) with C-6 of G showing a splitting of 0.10 ppm. The carbons of the 3-hydroxy-2-methylbutanoic acid also showed splittings. This led us to suspect that the apparently pure compound was actually an almost equimolar mixture of two diastereomers, involving bonding of either of a pair of enantiomers ((2*R*,3*R*) or (2*S*,3*S*)) of 3-hydroxy-2-methylbutanoic acid to the chiral tetrasaccharide core. In fact, further very careful HPLC separation allowed isolation of a mixture that was approximately 85:15 in favour of one component. The data in Tables 3 and 4 correspond to the major component of this mixture. In view of the very small amount of sample available, no attempt was made to hydrolyze off the short-chain fatty acids and to determine the chirality of these acids. However, based on previous work on similar compounds (16), the 2-methylbutanoic acid is most likely present as the *S* enantiomer.

^{13}C spin-lattice relaxation times were also determined for **2**, mainly as an aid for assigning as many of the hydroxypalmitic acid carbons as possible. However, they also provide some useful information about mobility within the tetrasaccharide. The shortest relaxation times, corresponding to the slowest molecular motions, are observed for Q_1 and R. This is logical because these groups are linked to opposite ends of the hydroxypalmitic acid. The longest relaxation times are observed for the carbons of Q_2, the terminal quinovose unit. This is also logical since this is the only group that has linkages at C-1 and C-4, allowing for considerable freedom for rotation about the C-1/C-4 axis.

Comparison with related structures

After completion of the characterization of **1**, search of the literature revealed that Miyahara and co-workers had reported the isolation, from *Ipomoea orizabensis* (Convolvulaceae), of a series of four tetrasaccharide derivatives whose core structure differed from our core structure by replacement of Q_1 by a D-fucose unit (14). They also differed from our structure in that all four compounds had a tiglic acid group forming an ester link to the hydroxyl group at C-2 of rhamnose. Each of them contained two additional short-chain fatty acids with each containing a 3-hydroxy-1-meth-

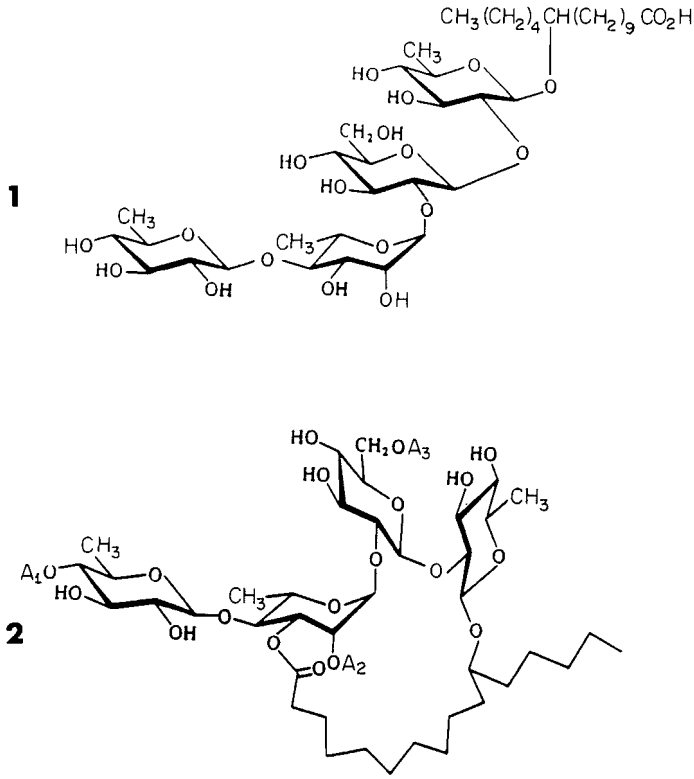
ylbutanoic acid group linked to C-6 of glucose (as we observed in **2**) plus an additional short-chain acid (either 3-hydroxy-2-methylbutanoic acid, 2-methylbutanoic acid, or methylpropanoic acid) at either C-3 or C-4 of the terminal quinovose group. The same group has reported a series of other tetrasaccharide derivatives (17, 18) but these differ even more in their monosaccharide units from the structure of the compound that we isolated. However, after our completion of the structure elucidation of **2** (other than the separation of diastereomers), Miyahara and co-workers reported a pair of compounds, isolated from the roots of *Convolvulus scammonia*, which had the identical core structure, **1** (16). However, these differed from our compound in having only one or two short-chain fatty acids. Both compounds have a 2-methylbutanoic acid group at C-2 of R (as in our case) while one of the compounds has a tiglic acid group at C-4 of Q_2. It should be noted that Miyahara and co-workers generally relied on indirect evidence (e.g., ^{1}H shifts after ester hydrolysis) to assign sites of esterification while we have unambiguous evidence from INCH experiments. We have also provided much more complete assignments for the acid carbons and protons. The observation of two compounds differing only in the stereochemistry of an ester-linked fatty acid also is a new observation. Overall, this investigation has provided further support for earlier work demonstrating the great power of 2D NMR for investigations of polysaccharide structures (19).

Based on the results of this and earlier investigations, there appears to be a wide variety of related compounds containing a tetrasaccharide unit linked by an anomeric carbon to 11-hydroxypalmitic acid. However, there appears to be considerable diversity in both the individual monosaccharide units as well as in the numbers, positions, and types of ester-linked short-chain fatty acids. In our case, the basic hydrolysis of both original samples yielded only 3-hydroxy-2-methylbutanoic acid and 2-methylbutanoic acid with no evidence of either tiglic acid or methylpropanoic acid. Furthermore, all compounds from these samples seemed to have the same basic core structure, **1**, although it cannot be absolutely ruled out that one or more of the very minor components from the two samples might have different monosaccharide units and (or) other short-chain fatty acids. However, based on the HPLC traces, there appear to be at least eight major components in the two samples that must have the basic core structure and with one or more molecules of 3-hydroxy-2-methylbutanoic acid and (or) 2-methylbutanoic acids ester-linked to the core. One of these could possibly be the compound of Miyahara and co-workers containing only 2-methylbutanoic acid ester-linked to C-2 of R in structure **1** (16). However, the others must be new compounds. Further investigations are being undertaken to isolate and characterize these additional compounds.



Experimental

Isolation

Plant material was obtained through a local market in Mexico City and identified as *Ipomea stans* by Dr. Miguel Martinez (Instituto de Biologia (UNAM)). Dried roots (1 kg) were defatted with hexane by maceration at room temperature. The material was then macerated three times with three litres of ethyl acetate. About 70 g of a white resinous powder was obtained as the overall residue from the latter treatment. Preliminary inspection of the residue by TLC showed two major spots on SiO_2 eluted with $CHCl_3$:CH_3OH (86:14) with R_f about 0.35 and 0.37. The less polar spot was ca. ten times as abundant as the more polar one. Preparative column chromatography of the crude residue afforded 9.2 g

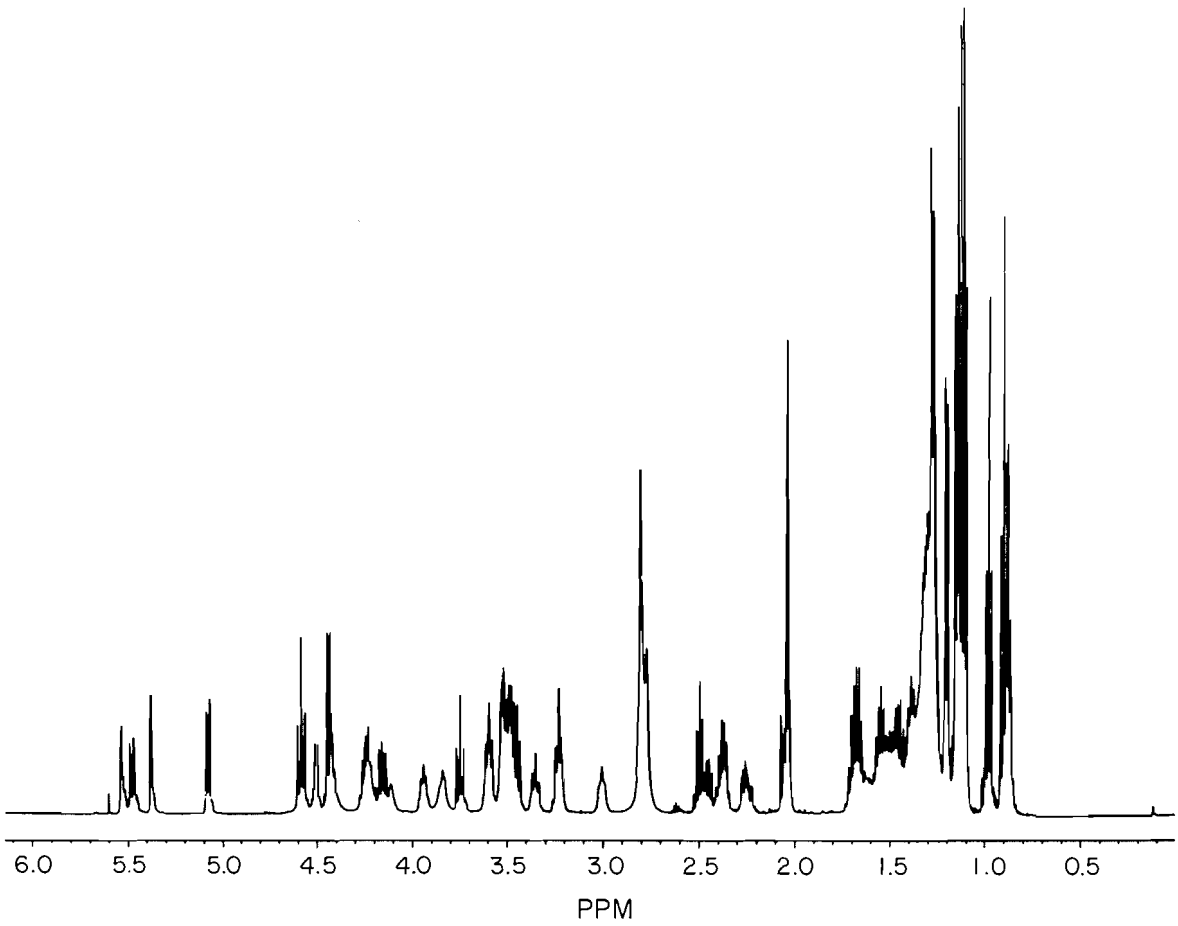

FIG. 4. The 500 MHz ^1H spectrum of **2** in $(CD_3)_2CO$.

of the less polar compound (A) and 0.8 g of the more polar compound (B). Their IR and 90 MHz ^1H NMR spectra indicated that both possessed glycolipid structures. However, more detailed characterization by 400 MHz ^1H NMR and 100 MHz ^{13}C NMR spectra indicated that each product was a mixture of isomers. Neither product would crystallize.

Basic hydrolysis

A (300 mg) was refluxed with 50 mL of ethanolic 0.1 N NaOH for 30 min. The solution was neutralized with dilute acid and extracted with ether. Evaporation of the ether layer yielded an oily liquid, which, on the basis of 90 MHz ^1H NMR, GC–FTIR, and GC–MS was identified as a ca. 60:40 mixture of 2-methylbutanoic acid ethyl ester and 3-hydroxy-2-methylbutanoic acid ethyl ester. The aqueous layer was lyophilized, the residue was extracted with ethanol, and a white crystalline solid, **1**, was isolated.

Treatment of B gave the same fatty acid products in roughly similar proportions.

Acid hydrolysis

A (200 mg) was refluxed for 2 h in 3 N HCl. After neutralization with 0.1 N NaOH the solution was alternatively extracted with $(CH_3CH_2)_2O$ and $CHCl_3$. The organic layers were dried and combined. After evaporation of the solvent, the residue was derivatized with $CH_3OH:BF_3$ prior to GC–MS analysis. The derivative was identified as the methyl ester of 11-hydroxypalmitic acid by comparison with previously reported mass spectral fragmentation patterns for this compound (20). The observed rotation ($[\alpha]_D^{25}$ = +0.42) is very similar to that previously reported for the *S* enantioner of this ester ($[\alpha]_D^{25}$ = +0.45 (16)). As a further confirmation, this compound was converted to its trimethylsilyl ether. Three major fragment ions with *m/z* (relative intensity) of 173(100), 287(70), and 327(13) were observed, respectively consistent with fragments $[CH_3(CH_2)_4CHOSi(CH_3)_3]^+$, $[(CH_3)_3SiOCH(CH_2)_9CO_2CH_3]^+$, and $CH_3(CH_2)_4CH(OSi(CH_3)_3)(CH_2)_9CO]^+$, as expected for the derivatized 11-hydroxypalmitic acid.

Peracetylation of the tetrasaccharide glycoside isolated from basic hydrolysis

1 (40 mg) was repeatedly dissolved in pyridine (3 mL, 5 times) and evaporated to dryness on a rotoevaporator in order to remove traces of water from the sample. After further drying of the sample *in vacuo* over P_2O_5 overnight, 200 μL each of pyridine and acetic acid was added and the mixture heated with stirring at 100°C for 30 min. After 0.5 mL of water was added to the sample, the resultant cloudy mixture was stirred at room temperature for 15 min and then evaporated to dryness. The dried sample was taken up in 4 mL of $CHCl_3$, then washed with 0.1 M sodium carbonate followed by 0.01 M HCl. The organic solution was evaporated to dryness, first with a rotoevaporator, then a vacuum pump, yielding 42 mg of a slightly yellow solid (mp 119–120°C).

HPLC purification

HPLC separation of sample A was carried out on a Varian liquid chromatograph model 8500 equipped with a reverse-phase, cyano-bonded analytical column (Econosphere 250 × 4.6 mm, particle diameter = 5 μm) with an Altex refractive index detector and a Varian integrator model 4270. The eluent was a gradient of CH_3CN/H_2O going from 80:20 to 50:50 respectively, flow at 1.0 mL/min at a pressure of 100 atm (1 atm = 101.3 kPa). The initial chromatogram revealed at least six fractions of which the major (slowest moving) fraction was collected. By repeated injections about 60 mg of the major component was obtained at ca. 90% purity. Further purification by the same procedure gave about

25 mg of product at ca. 97% purity. When the NMR spectrum indicated that the sample was actually a mixture of diastereomers, the whole process was repeated with a new sample of A, but only sampling the leading edge of the major peak. After repeated runs, ca. 30 mg of compound was isolated containing an approximately 85:15 ratio of the two diastereomers. The isolated material was an amorphous white solid, mp = 103°C.

NMR spectra

Preliminary NMR spectra were obtained on a Varian EM-390 spectrometer. All subsequent spectra (including 2D spectra) were obtained on a Varian XL-400 spectrometer. Typically, COSY spectra were obtained using f_1 and f_2 spectral windows of 2000 Hz, 512 time increments (zero-filled to 1024), 16 transients per time increment, 1024 data points for each f.i.d., and a 1 s relaxation delay. Spectra were processed using pseudo-echo weighting in both domains followed by symmetrization by triangular folding. Relay spectra were similar except that they used 64 transients per time increment and a relay delay of 0.5 s. Relay spectra were obtained using the sequence described by Bain and co-workers (21). $^{1}H-^{13}C$ shift correlation spectra were obtained using the Bax modification (10*b*) of the standard shift correlation sequence (10*a*). Typical parameters involved a $^{13}C(f_2)$ spectral window of 10 000 Hz with 2048 data points (zero-filled to 4096), an ^{1}H (f_1) spectral window of 2000 Hz with 192 time increments (zero-filled to 512), 128 transients per time increment, and a relaxation delay of 0.6 s. Modified pseudo-echo processing (similar to shifted-sine-bell processing) was used in both domains.

The XCORFE spectrum was obtained using an f_2 spectral window of 10 000 Hz with 2048 data points zero-filled to 4096. The f_1 spectral window was 2000 Hz and 360 time increments (zero-filled to 1024) were collected with 128 transients per increment. The fixed time prior to polarization transfer was 0.090 s with a refocussing delay of 0.032 s after polarization transfer and a relaxation delay of 0.6 s. Delays in the BIRD pulses were optimized for J_{CH} = 155 Hz. The FLOCK parameters were generally similar except that 160 time increments were used with 256 transients per time increment and a delay prior to polarization transfer of 0.064 s. A separate FLOCK spectrum was run for the ^{13}C carbonyl region with an f_2 spectral width of 600 Hz and 256 data points (zero-filled to 1024).

JUN YANO, KOTARO OGURA, AKIRA KITANI, and KAZUO SASAKI. Can. J. Chem. **70**, 1009 (1992).

Electrode reactions of dissolved inorganic redox species on a polyaniline (PAN) film did not take place when the film was in media of low acidity (pH >3.5 (pK_a of PNA)) and (or) was held at the potential region where PAN itself was not redox active. Redox waves of several dissolved organic species, however, were clearly observed on such an electroinactive PAN film. Further, the organic species transformed the electroinactive PAN film into electrically conducting film.

Key words: electroinactive polyaniline, electrode reaction, organic species.

JUN YANO, KOTARO OGURA, AKIRA KITANI et KAZUO SASAKI. Can. J. Chem. **70**, 1009 (1992).

Aucune réaction d'électrode des espèces redox inorganiques dissoutes n'a eu lieu sur le film polyaniline (PAN), lorsque celui-ci était dans un milieu peu acide (pH > 3.5 (pK_a de PAN)) et (ou) était maintenu dans la région potentielle où le PAN n'était pas redox. Par contre, les ondes redox de plusieurs espèces organiques dissoutes étaient constatées sur le même film PAN électro-inactif. En plus, on a pu voir les espèces organiques transformer le film électro-inactif en film électriquement conductible.

Mots clés : polyaniline électro-inactif, réaction d'électrode, espèces organiques.

Although many studies of the properties of polyaniline (PAN) have been driven by the wide variety of possible applications, little attention has been paid to the electrochemical response of the PAN film to dissolved species. Papers dealing with the response to dissolved *organic* species are especially limited. The PAN film does not respond to any dissolved inorganic species over the potential region where PAN itself is not redox active (1) and (or) in less acidic media (pH >3.5 (pK_a of PAN)) (2). In this communication, we wish to focus our attention on such electroinactive PAN films and examine whether or not the films respond to certain organic species.

Even in the electroinactive potential region (Fig. 1(*b*)), the redox wave of *p*-dimethoxybenzene is evident (Fig. 1(*a*)). Those of *p*-dihydroxydiphenyl and *p*-methoxyphenol were also observed. On the other hand, the PAN film does respond to hydroquinone (Fig. 1(*c*)), although the film itself is electroinactive (Fig. 1(*d*)). It also responded to other quinones such as *o*-benzoquinone, duroquinone, and chloranil. Moreover, it is interesting to find that the film also responded to I^-, in spite of it being one of the inorganic species.

Electroinactive PAN films do not catalyze the electrode reactions of *p*-dimethoxybenzene and hydroquinone (Fig. 1(*a*) and (*c*)). The reason is that the films have few redox-active sites near the film/solution interface and do not work as electron-transfer-mediating catalysts. Two mechanisms of the charge transport are, therefore, proposed for the electrochemical response: (*i*) dissolved species pass through the film smoothly and then reach the electrode substrate; and (*ii*) the film is transformed into an electron conductor by the contact with the species. Ohnuki *et al.* found that the PAN film was hardly permeable to species having a Stokes radii (γ_S) of more than 2 Å (3). This explains the fact that the film responds not to $Fe(CN)_6^{3-}$ (γ_S = 2.7 Å), etc., but to I^- (γ_S = 1.2 Å) in the pH 5 solution. Such permeability also suggests that the film blocks the passage of bulky organic species such as hydroquinone, whose size is roughly equal to that of $Fe(CN)_6^{3-}$. To confirm this, a PAN pellet electrode was employed. The electrode was prepared by compressing PAN powder obtained by potentiostatic electrolysis, as described previously (4). The geometric area of the PAN pellet was 0.32 cm^2 and that of the platinum wire inside the pellet was 0.025 cm^2. The steady-state current–potential (*i*–*E*) curves for the oxidation of 10 mM *p*-dimethoxybenzene in 0.1 M H_2SO_4 and of 10 mM hydroquinone in the pH 5 solution were measured by using both the pellet electrode and a platinum wire electrode having an area of 0.025 cm^2. The limiting oxidative currents of *p*-dimethoxybenzene and hydroquinone were 0.34 and 0.28 mA, respectively. These values were at least 10 times greater than those obtained with the platinum wire electrode. This result strongly supports mechanism (*ii*) as reasonable for the charge transport of the film.

On the PAN film coated electrode experiencing the response of hydroquinone, the redox current of $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ was observed, although it was about one tenth smaller than that measured with a bare platinum electrode. This also leads to mechanism (*ii*). To obtain direct evi-

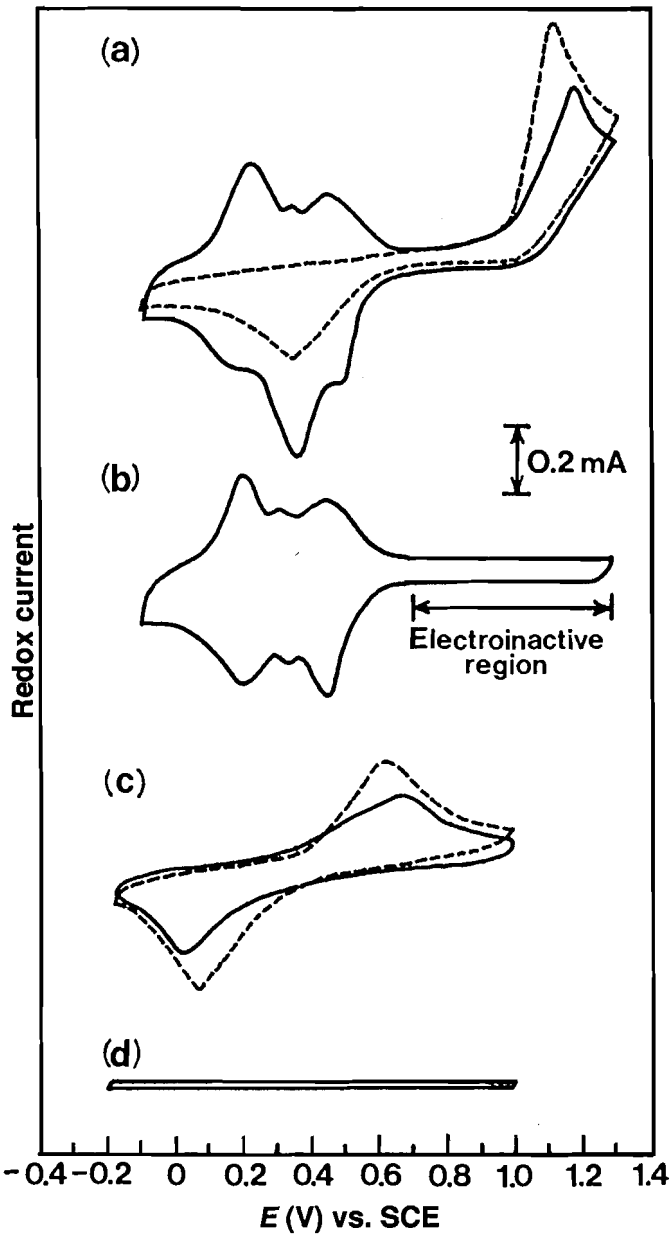

FIG. 1. (*a*) Cyclic voltammograms of *p*-dimethoxybenzene on a bare platinum electrode (broken line) and on the PAN film coated electrode (solid line). Solution: 5 mM *p*-dimethoxybenzene + 0.1 M H_2SO_4. (*b*) Voltammogram showing the redox wave of the PAN film itself on the platinum electrode. Solution: 0.1 M H_2SO_4. (*c*) Voltammograms of hydroquinone on the platinum electrode (broken line) and the PAN film coated electrode (solid line). Solution: McIlvaine buffer solution containing 10 mM hydroquinone (pH 5). (*d*) Voltammogram showing the electroactivity of the PAN film in a McIlvaine buffer solution of pH 5.

dence, the conductivity of the PAN pellet was measured before and after measurements of the steady-state *i*–*E* curves described previously. The conductivity of the pellets equilibrated with 0.1 M H_2SO_4 and the pH 5 solution were 0.87 S cm^{-1} and 8.2×10^{-9} S cm^{-1}, respectively: that of the latter pellet was almost recovered when the pellet was returned to a 0.1 M H_2SO_4 solution. After the measurements, the values became 1.8 S cm^{-1} and 3.5×10^{-6} S cm^{-1}, respectively. The increase is probably caused by interactions between PAN and the species. PAN releases dopant anions over the electroinactive potential region because of the deprotonation of the PAN nitrogens that accompanies oxidation to the imine form (5). The release also occurs in less acidic media (pH >3.5) due to deprotonation of amine and (or) imine forms (6). In both cases, the limited dopant anions that exist near the film/solution interface are expected to be released from the films due to their small diffusion coefficient of about 10^{-13} cm^2 s^{-1} (7), and the redox-active sites still remain inside the film. The organic species used probably have affinities for the films and permeate through the films to reach the oxidized sites. They are oxidized to give the films their oxidized products, quinones. The quinones are incorporated into the parts containing the deprotonated nitrogens within the films. They play the role of the dopant anions and promote electron hopping between the redox-active sites within the films, since they are π-electron-rich species.

La réaction du ferrocène et de l'hexafluorophosphate de tropylium conduit au PF_6 de ferrocényltropylium qui cristallise dans le groupe d'espace monoclinique $P2_1/C$ (a = 9,7858(10), b = 16,3692(24) et c = 10,901(4) Å, β = 113,030(18)°, Z = 4, T = 27°C, V = 1607,0(7) Å^3, R_f = 0,091 et R_w = 0,040) pour 102 paramètres et 929 réflexions observées ($I > 2{,}5\ \sigma(I)$) tirées de 2087 réflexions totales mesurées. La réaction du nickelocène et du tétrafluoroborate de triphénylméthyle fournit tétrafluoroborate de triphénylméthylcyclopentényl cyclopentadiényl nickel qui cristallise dans le groupe d'espace monocyclique $P2_1/n$ (a = 11,0306(19), b = 14,078(4) et c = 17,117(4) Å, β = 101,134(18)°, Z = 4, T = 27°C, V = 2608,0(11) Å^3, R_f = 0,091 et R_w = 0,035) pour 147 paramètres et 1334 réflexions d'un ensemble de 3361 mesurées.

[Traduit par la rédaction]

Introduction

In the first characterization of the structure of ferrocene, its aromatic character was shown by acylation under Friedel–Crafts conditions (1). However, the reaction with triphenylmethylchloride was reported to yield ferriciniuim tetrachloroferrate (2). Therefore, it appeared of interest to study the reaction of ferrocene with stable carbonium ions. The ferrocenylcarbenium ion has been isolated in a few cases (3, 4). A second type of reaction frequently observed with metallocenes under acylation or alkylation conditions is the addition of the organic group to one of the cyclopentadienyl rings (5). Another reaction of metallocenes is as electron donors in charge transfer complexes (6, 7). The stable carbonium ion tropylium acts as an electron acceptor in charge transfer complexes with aromatic hydrocarbons (8). The reactions of tropylium hexafluorophosphate and triphenylmethyl tetrafluoroborate with ferrocene and nickelocene were investigated to determine to which of the three preceding categories they might belong.

Experimental section

Ferrocene, $Fe(C_5H_5)_2$, was recrystallized from hexane. Nickelocene, triphenylmethyl tetrafluoroborate, and tropylium hexafluorophosphate were used as supplied (Aldrich). Acetonitrile was shaken with P_2O_5 and transferred under vacuum to a container on the preparative vacuum line. Methylene chloride was successively shaken with H_2SO_4, $AlCl_3$, and H_2O, then dried successively with $CaCl_2$ and P_2O_5 and transferred under vacuum to the preparative apparatus. Benzene was dried over 5Å molecular sieve and similarly transferred. Sulfur dioxide was stored as a liquid, over P_2O_5, in a container closed with a pressure/vacuum stopcock on the preparative vacuum line. All manipulations of solids were performed in a vacuum glove box under a dry nitrogen atmosphere.

$Fe(C_5H_5)(C_5H_4\text{-}C_7H_6)PF_6$ was prepared from 107.3 mg (0.577 mmol) ferrocene and 49.8 mg (0.211 mmol) $C_7H_7PF_6$ dissolved in 2.4 g acetonitrile. During 48 h at room temperature the colour of the solution changed from orange to a very deep blue-green and some brown solid precipitated. The supernatant liquid was decanted into a second container and the solvent removed under vacuum. The solid residue was washed three times with benzene to remove unreacted ferrocene. It was extracted with CH_2Cl_2 to give a blue solution and a dark residue. The CH_2Cl_2 was evaporated to give 39.3 mg (0.094 mmol) of a deep blue microcrystalline solid whose identity was established by UV, IR, ^{1}H NMR, and a single crystal X-ray structure determination. IR (cm^{-1}) (KBr pellet): 1494 s, 1270 s, 836 vs. UV (CH_2Cl_2 soln.) (λ_{max} Å, log ε): 2600, 4.26; 2640, 4.27; 3300, 3.64; 4010, 4.35; 7000, 3.73. The ^{1}H NMR spectrum in CD_3CN showed multiple resonances at 8.29 (2H), 5.37 (2H), and single lines at 4.30 (2H) and 2.50 (broad, 9H). Single crystals were grown from $CHCl_3$ solution. The dark CH_2Cl_2 insoluble residue was recrystallized from acetonitrile to give, in part, crystals of unreacted tropylium hexafluorophosphate.

$Ni(C_5H_5)(C_5H_5\text{-}C(C_6H_5)_3)BF_4$ was prepared from 17.0 mg nickelocene (0.090 mmol) and 29.0 mg (0.118 mmol) triphenylmethyl tetrafluoroborate dissolved in sulfur dioxide in one arm of an H-shaped reactor. The clear, very dark solution was carefully decanted from some solid into the other arm of the reactor and an equal volume of CH_2Cl_2 condensed with it. At room temperature, solvent was slowly distilled back into the original reactor arm by a slight temperature differential. When some blue-black crystals had formed from the solution the remaining liquid was also decanted back. All volatiles were removed under vacuum and the blue-black crystals were characterized by a single crystal structure determination.

Proton magnetic resonance spectra were obtained at 400 MHz on a Bruker AM 400 spectrometer. Infrared spectra were obtained for KBr pellets on a Nicolet 520 FT-IR spectrometer and UV–visible spectra on CH_2Cl_2 solutions with a Cary 210 spectrophotometer. X-ray diffraction intensities were collected at room temperature on an Enraf–Nonius CAD-4 diffractometer controlled by NRCCAD (9) software, with graphite monochromatized MoK_α radiation, λ = 0.70932 Å, using the θ/2θ scan technique with profile analysis (10). The crystal data are listed in Table 1. The structures were solved by direct methods and refined by full-matrix least-squares calculations. Scattering factors were taken from the *International tables* (11).

$$S = \frac{\sqrt{\Sigma w(F_o - F_c)^2}}{n - 1}$$

All computing was performed using the NRCVAX program system (12). Three reference reflections were collected every 100 reflections and their fluctuation was insignificant. No absorption correction was made.

The cation of the tropylium ferrocene compound appeared well defined, but the PF_6 anion was disordered. It was modelled as two rigid groups with fluorine occupancies of 0.7 and 0.3. The major component was fitted as a regular octahedron wtih central phosphorus, P—F = 1.58 Å. The minor component was fitted as an octahedron with no central atom and fluorines 1.58 Å from the centre. Rigid groups were refined anisotropically, as was the iron atom (carbons left isotropic). Hydrogen atoms were included in calculated positions. A weighting scheme based on counting statistics was used.

Results

In the reaction of ferrocene and tropylium hexafluorophosphate, the tropyplium ring bonds to one of the cyclopentadienyl (Cp) rings with the loss of two hydrogen atoms. The structure of the cation is shown in Fig. 1. The reaction proceeds slowly and is significantly incomplete after two days at room temperature. This is shown by the recovery of tropylium hexafluorophosphate even though ferrocene was present in excess. The structure of tropylium hexafluorophosphate was found to be isomorphous with that reported for the perchlorate (13). Key parameters are listed in Table 1.

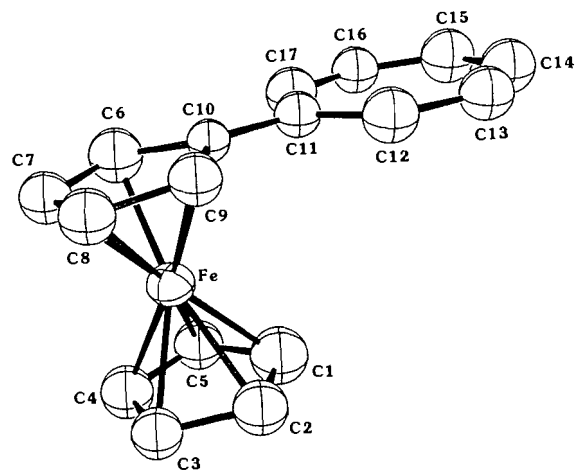

FIG. 1. ORTEP plot of tropylferrocene cation.

The structure of the tropylium ferrocene cation has a planar 7-membered ring bonded to one Cp ring of ferrocene. The ferrocene moiety has almost parallel Cp rings (dihedral angle

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

of 3°), with Fe—C distances ranging from 2.018(10) to 2.054(12) Å. The 7-membered ring is not quite coplanar with the bonded Cp ring (dihedral angle of 8°). The C—C inter-ring bond is 1.459(16) Å, slightly short for a single C—C bond, implying some delocalization throughout both rings. The Fe is equidistant from the two Cp rings at 1.646(2) Å. The Fe—C and Fe—Cp ring distances are in excellent agreement with those for ferrocene itself (14, 15), and shorter than those for the ferricenium ion (16). The packing arrangement is illustrated in Fig. S1.[3] The atomic coordinates are listed in Table 2. Tables of bond lengths and angles, least-squares planes, atomic positions for phosphorus, fluorine, and hydrogen atoms, thermal parameters, and structure factors are found in Table S1–S5 respectively (supplementary material).[3]

There was no evidence for reaction between ferrocene and triphenylmethyl tetrafluoroborate.

Triphenylmethyl tetrafluoroborate adds to one of the cyclopentadienyl rings of nickelocene to give a compound for which the structure of the cation is shown in Fig. 2, and its key X-ray parameters are listed in Table 1. The atom positions for those atoms which were independently refined are listed in Table 3, and the positions of the phenyl carbon atoms, which were refined as rigid groups, are listed in Table S6.[3]

The unsubstituted cyclopentadienyl ring of the nickelocene moiety is planar with a maximum deviation for C10 of 0.039 Å from the best plane. C1 of the substituted cyclo-

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

pentadienyl ring is tetrahedrally surrounded by four substituents and is 0.426 Å from the plane of the other four ring atoms. The two cyclopentadienyl rings are nearly coplanar (dihedral angle of 4.7°) with nickel–ring distances of 1.656 and 1.697 Å. Tables of selected bond lengths and angles, least-squares planes, hydrogen atom positions, thermal pa-

rameters and structure factors for $NiC_{29}H_{25}BF_4SO_2$ are found in Tables S7–S11 respectively (supplementary material).[3] A stereo depiction of the packing is shown in Fig. S2.[3]

There was no evidence for reaction between nickelocene and tropylium hexafluorophosphate, nor was their any reaction of either cation with cobaltocene or bis(benzene) chromium.

Discussion

No charge transfer complex formation was observed between the stable cations triphenylmethyl or tropylium and ferrocene or nickelocene, nor was a normal acylation reaction observed. Addition of the triphenylmethyl cation to nickelocene, but not ferrocene, was observed and is consistent with results reported under normal alkylating conditions (3). The reaction of tropylium and ferrocene is not a normal alkylation with respect to tropylium although it is for ferrocene. The loss of a hydrogen from one of the carbon atoms of the tropylium ring is rather unusual but unfortunately we could not isolate other reaction products to elucidate the overall reaction.

The synthesis of diaceperylene (**1**) from 5,6-dilithioacenaphthene via nickel or cobalt catalysed couplings proceeded in better yield than a multistep synthesis involving formation of 5,5′-diacenaphthene first. Dehydrogenation of **1** to dicyclopenta[1,2,3-*cd*:1′,2′,3′-*lm*]perylene (**2**) proved a better route than coupling of 5,6-disubstituted acenaphthylene derivatives. Ultraviolet, proton, and carbon nuclear magnetic resonance spectra and electrode reduction potential data of **1** and **2** are discussed with respect to molecular mechanics calculations of strain in these and related bridged naphthalenes. Both **1** and **2** were found to be weakly mutagenic in an Ames microsome test, in contrast to cyclopenta[*cd*]pyrene.

REGINALD H. MITCHELL, MAHIMA CHAUDHARY, RICHARD VAUGHAN WILLIAMS, ROBERT FYLES, JACK GIBSON, MICHAEL J. ASHWOOD-SMITH et ALBERT J. FRY. Can. J. Chem. **70**, 1015 (1992)

La synthèse du diacéperylène (**1**), utilisant le 5,6-dilithioacénaphtène comme produit de départ et des couplages catalysés par le nickel ou le cobalt, donne de meilleurs rendements qu'une synthèse en plusieurs étapes impliquant une formation préliminaire du 5,5′-diacénaphtène. La déshydrogénation du composé **1** en dicyclopenta[1,2,3-*cd*:1′,2′,3′-*lm*]pérylène (**2**) est une meilleure voie d'accès à cet hydrocarbure que le couplage d'acénaphtylènes substitués en positions 5 et 6. On discute des spectres UV et RMN du proton et du carbone et des données relatives aux potentiels de réduction à l'électrode des composés **1** et **2** en fonction de calculs de mécanique moléculaire de la tension dans ces composés et dans des dérivés naphtaléniques pontés apparentés. On a trouvé que, contrairement au cyclopenta[*cd*]pyrène, les composés **1** et **2** sont légèrement mutagènes dans un essai microsomique d'Ames.

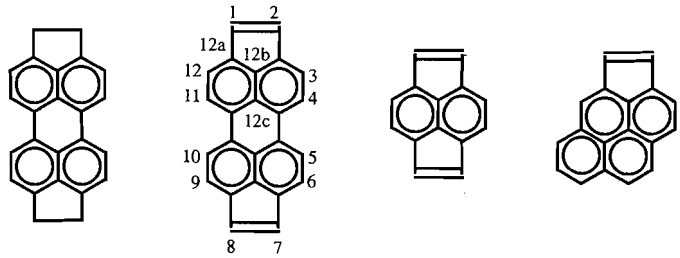
[Traduit par la rédaction]

Introduction

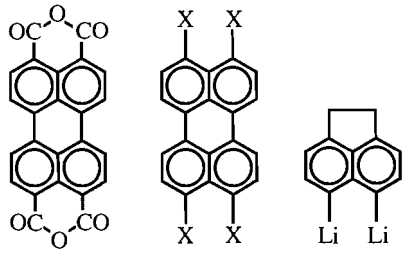
In the previous paper (1), we discussed strain in acenaphthenes and how further substitution of acenaphthene in the peri positions increases the overall strain of the substituted system. In this paper we investigate straining the perylene nucleus by synthesis and study of diaceperylene (**1**), and dicyclopenta[1,2,3-*cd*:1′,2′,3′-*lm*]perylene ("diaceperylylene")[6] (**2**). The latter is of especial interest in that in the same way that pyracylene (**3**) is a perturbed [12]annulene (2), **2** is formally a perturbed [20]annulene. Moreover, synthesis of cyclopenta aromatics has been attracting unusual interest (3–9) in recent years with the discovery that cyclopenta[*cd*]pyrene ("acepyrylene") **4** is a widespread mutagen (10), despite the fact that pyrene itself is not.

Syntheses

The most logical approach to **1** and **2** is from the commercially available dianhydride **5**. We envisioned reduction of **5** to a tetra-alcohol, followed by conversion to 3,4,9,10-tetrakis(bromomethyl)perylene, and then ring closure using either PhLi (2) or Ph_3P (11). However, we were not able to reduce **5** to the tetra-ol **6** using either $LiAlH_4$/THF or *i*-Bu_2AlH/PhH with conditions that work well for naphthalic anhydride. Conversion of **5** to the tetra-ester **7** proved equally frustrating; MeOH/*p*-TsOH, $(MeO)_3P{=}O$/NaOH (12), MeI/HMPA (13), and diazomethane each yielded only traces of **7**. Dimethyl sulphate/NaOH/dioxane (14) did yield some **7**, but again reduction to **6** failed.



1 **2** **3** **4**



5 **6** X = CH_2OH **8**
7 X = CO_2Me

Coupling of 5,6-dilithioacenaphthene (**8**) (1) was thus attempted next. Numerous coupling procedures (for an extensive list, see ref. 15) are suitable for biaryl preparation, and indeed $Ni(Ph_3P)_2$, $CuCl_2$, TlBr, $Ni(acac)_2$, and $CoCl_2$ all produced pale yellow **1** from **8**. However, the best yields (20–

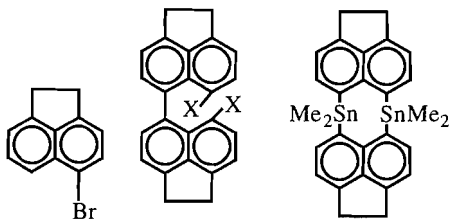
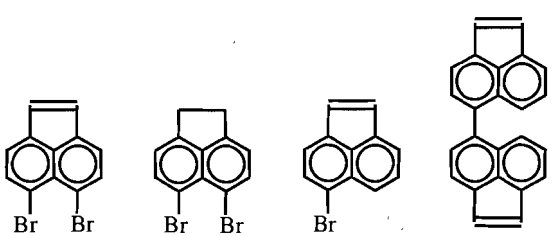
35%) were obtained with the last two catalysts. Tanaka and Kasai (16) also reported the formation of **1**, but as a red by-product, obtained from the TMEDA complex of **8** on reaction with quinones. Indeed, as obtained from the coupling reactions, **1** is always accompanied by some **2**, which is red, and is extremely difficult to separate from **1**. However, using HPLC, pure **1** can be obtained as yellow crystals, mp 333–335°C (dec.). Very recently, Jaworek and Vögtle (17) reported a different synthesis of **1**. We also investigated stepwise coupling to **1**, by first coupling 5-bromoacenaphthene (**9**) with *n*-BuLi/$CoCl_2$ to give the bi-acenaphthenyl **10**, bromination with NBS/DMF (18) to give dibromide **11**, and coupling of this with *n*-BuLi/$CoCl_2$ to give **1**, but the overall yield was not better, and the product was harder to purify.



9 **10** X = H, **11** X = Br **12**

Reaction of the dilithio compound **8** with Me_2SnCl_2 gave 26% of the stannocin **12**, mp 277–279°C, which on irradiation in benzene gave less than 5% of **1**. The analogous case in which 1,8-dilithionaphthalene was used to prepare perylene went in 60% yield (19). Dehydrogenation of **1** with DDQ in refluxing benzene yielded 60% of **2** as a dark red compound, mp >350°C (argon). This proved in our hands to be the only useful route to **2** (see also ref. 17), since coupling (*n*-BuLi/$CoCl_2$) of both 5,6-dibromoacenaphthylene (**13**) (obtained by DDQ dehydrogenation of 5,6-dibromacenaphthene (**14**)), and 5-bromoacenaphthylene (15) (obtained from **9** both by DDQ dehydrogenation and NBS-bromination/KI-debromination(2)) proceed to be extremely dirty, producing more than a dozen products each. These coupling reactions were monitored by HPLC for authentic **2** and 5,5′-diacenaphthylene (**16**) (prepared by DDQ dehydrogenation of **10**), and in each case, although some product was observed, it was only in minor amount, and not isolable by us. Clearly, the additional unsaturation of the ace bridge had a dramatic effect on the coupling reactions.

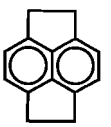


13 **14** **15** **16**

Results and discussion

Ultraviolet spectra

We have discussed the effects of strain on the ultraviolet spectra of aromatic hydrocarbons in our previous paper (1). Introduction of a strained bridge usually results in a bathochromic shift of the *p*-band (the intense, log ε 3–4, long wavelength bands associated with the HOMO–LUMO transition), which is somewhat greater than the effect of the corresponding dimethyl derivative (20). For example the *p*-band of naphthalene (275 nm) is shifted by 1762 cm^{-1} in acenaphthene (289 nm), but only by 1276 cm^{-1} in 1,8-dimethylnaphthalene (285 nm). These are not directly proportional to strain, however, since molecular mechanics calculations (21) indicate that acenaphthene has about 12 kcal/mol more strain than naphthalene, while for 1,8-dimethylnaphthalene the value is only about 3 kcal/mol. Addition of the second bridge to acenaphthene to form pyracene (**17**) (295 nm) substantially increases the strain in the mole-



17

cule, some 36 kcal/mol more than in naphthalene, yet causes a considerably smaller bathochromic shift of 704 cm^{-1} than addition of two more methyl groups to 1,8-dimethylnaphthalene to give 1,4,5,8-tetramethylnaphthalene (296 nm), 1304 cm^{-1}. From naphthalene, the total shift for the latter is 2580 cm^{-1}, which is then very similar to that for pyracene at 2466 cm^{-1}, despite the rather different calculated strains of 12 and 36 kcal/mol, respectively, relative to naphthalene. The recent synthesis (17) of 3,4,9,10-tetramethylperylene now permits comparison with **1**. From perylene (434 nm) (22), the tetramethyl compound (451 nm) is shifted 869 cm^{-1}, while the diace compound **1** (455 nm) is shifted 1015 cm^{-1}, which thus suggests that **1** is more similar (in strain) to acenaphthene than to pyracene. This is borne out by molecular mechanics calculations (21), which indicate that addition of two ace bridges to perylene only increases the strain energy by about 19 kcal/mol. As well, it is interesting to note that when two acenaphthenes are joined to form **1**, the calculated increase in strain is only about 5 kcal/mol, while when two naphthalenes are joined to perylene, strain increases by about 9 kcal/mol. This suggests that the pinching caused by the ace bridge is counteracted somewhat by the union to form the perylene nucleus. Unfortunately calculations are not at a stage where λ_{max} values of sufficient accuracy to be of use here can be predicted (23).

Addition of unsaturated bridges to both naphthalene and perylene has, as would be expected, a considerably greater effect on $\Delta E_{HOMO-LUMO}$, and thus λ for the *p*-band is strongly bathochromically shifted. However, since the resultant molecules (**2** and **3**) are non-alternate hydrocarbons, the Streitwieser (24) correlations between ν and Δm (the HMO energy difference between the highest occupied and lowest unoccupied orbitals) do not hold well. For example λ_{max} predicted for acenaphthylene and pyracylene are 357 and 544 nm, respectively, whereas those found are 323 and 385 nm. The perturbation on naphthalene (275 nm) to form pyracylene (385 nm) at 10 390 cm^{-1} is, however, considerably greater than that, 2989 cm^{-1}, on perylene (435 nm) to form diaceperylylene (**2**) (500 nm). Again strain calculations (21) indicate that pyracylene is about 40 kcal/mol more strained than naphthalene, while diaceperylylene is about 30 kcal/mol more strained than perylene.

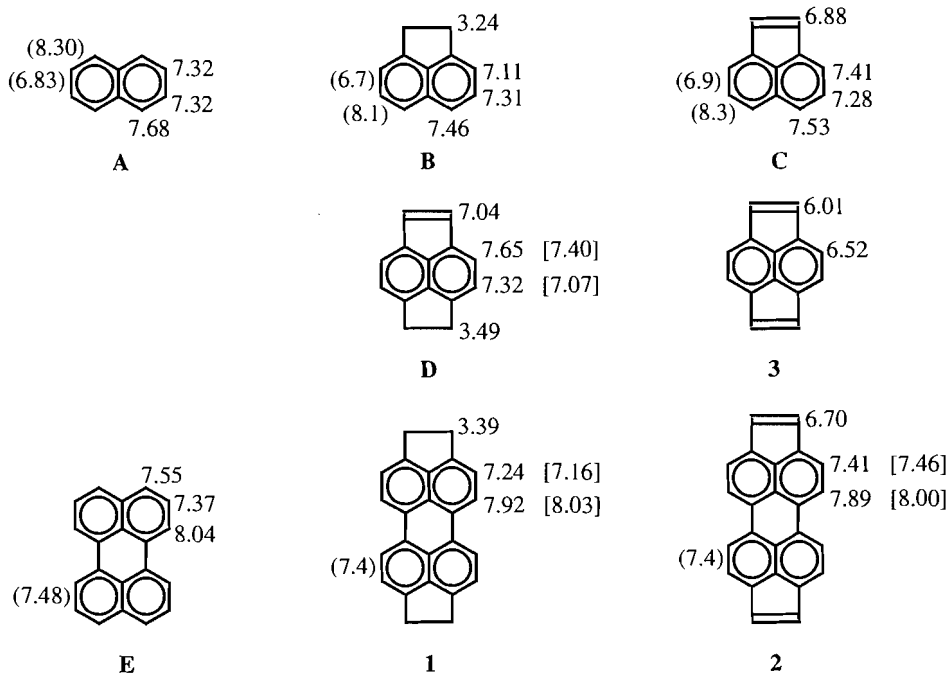

CHART 1. ^{1}H NMR chemical shifts, δ, and (coupling constants) for napthalene (25), acenapthene (26), acenaphthylene (26), pyracylene (2), dihydropyracylene (2), perylene (25), and **1** and **2** [with calculated shifts].

Proton magnetic resonance spectra

The chemical shifts and coupling constants (in parentheses) for compounds **1**, **2**, and several reference compounds are given in Chart 1. The ^{1}H NMR spectrum quoted (17) for **2** must have been misprinted, since it is not consistent with the proposed structure or our data. Comparison of naphthalene, **A**, and acenaphthene, **B**, in Chart 1, indicates that introduction of the saturated bridge shields the adjacent β-H (H-3,8) by ca. 0.2 ppm while leaving the distant β-H (H-4,7) almost unchanged. Introduction of the unsaturated bridge as in acenaphthylene, **C**, however, deshields the adjacent β-H by ca. 0.1 ppm. In perylene, **E**, the bay protons (H-1,6,7,12) are deshielded by 0.7 ppm from those of naphthalene. Summation of these effects would lead to predicted (27–30) chemical shifts of 8.03 and 7.16 for the aryl protons of **1**, very close to those found. Unfortunately the ^{1}H NMR spectrum of pyracene, **17**, does not appear to have been reported, and thus the direct effect of the second five-membered ring is not known; however, fusion of the second five-membered ring to acenaphthylene as in **D** yields chemical shifts of 7.32 and 7.65 ppm, whereas 7.07 and 7.40 might have been expected. The differences could be attributed to the additional strain, but they are rather small. The closer agreement in the case of **1** might indicate that it is less strained than **D**, which is reasonable. Introduction of a double bond into the second bridge of **D** to give **3** markedly shields both the aryl (1.13 ppm) and bridge (1.03 ppm) protons. This has been ascribed (2) to a paramagnetic ring current in the [12]annulene perimeter. The chemical shifts predicted (on the basis of **A**, **C**, **E**) for H-3 (δ 7.46) and for H-4 (δ 8.00) of **2** agree closely with those found, δ 7.41 and 7.89, respectively. They are, however, both marginally shielded (0.05–0.09 ppm), as is the bridge proton by 0.18 ppm, and collectively this may indicate a very weak paramagnetic ring current due to the [20]annulene perimeter of **2**. However, the effect is certainly much weaker than for pyracylene **3**.

Carbon magnetic resonance spectra

The well-known additivity (30, 31) of carbon chemical shifts is used in Chart 2 to predict the chemical shifts of **1** and **2** based on the reference compounds shown. Thus data for **1** are derived by combining the shift data for naphthalene-acenaphthene and naphthalene-perylene and those for **2** are derived from naphthalene-acenaphthylene and naphthalene-perylene. The experimental results are surprisingly close to those calculated, the largest difference occurring for carbons of type 12d, and this may reflect the additional strain of the double pinching of the five-membered rings, which is known (32) to manifest itself most at the 5,6 positions of acenaphthene by a scissoring effect. In pyracylene **3**, the paratropism of the molecule manifests itself mostly in a difference of about 8 ppm, in the downfield shift for the internal carbons C-8a,b, from that calculated (30). Unfortunately, due to the low solubility of **2**, we were not able to see these carbons; however, Jaworek and Vögtle (17) recently reported them at δ 124.5, 130.5, 131.4, and 140.8 in excellent agreement with our calculations, thus indicating very little paratropism. Similar calculations were made to assign the other carbon spectra reported in the experimental section.

Electrode reduction potentials

The hydrocarbons **1** and **2** can be reduced at the dropping mercury electrode and give reproducible (±0.003 V) half-wave potentials. Compound **2** also gives a second wave, corresponding to addition of two electrons to the compound. The measurements were recorded in 85 and 95% aqueous dioxane relative to the standard calomel electrode and are shown, together with those for reference compounds, in Table 1.

*See ref. 17

CHART 2. ^{13}C NMR chemical shifts, δ, [additivity constants from naphthalene], and (calculated shifts). Data for **A**, **B**, **C**, and **E** are from ref. 37.

TABLE 1. Half-wave electrode reduction potentials (in aqueous dioxane (D)) and molecular orbital energies

	$-\epsilon_{1/2}$ vs. SCE (V)						
	75% D (ref. 33)	85% D	95% D	$-m_{m+1}$	ν, p-band (cm^{-1})	Δm	m_m
A	2.50			0.666	36 364	1.359	0.693
B	2.61	2.58		0.712	34 602	1.266	0.554
E	1.67	1.63	1.70	0.315	23 042	0.658	0.343
1	—	1.76	1.825	0.353	22 026	0.605	0.252
C	1.65	1.62	1.68	0.307	30 960	1.075	0.768
2	—	0.88	0.86	−0.019	20 000	0.498	0.517
2	—	1.19	1.19	(Second wave)			

The literature values and the 85% dioxane values were then used to calculate the experimental values of the LUMO, $\epsilon_{m+1} = \alpha + m_{m+1}\beta$, and the HOMO, $\epsilon_m = \alpha + m_m\beta$, using the previously (1) derived relationships. The values of m_{m+1} and m_m obtained should be equal and of opposite sign (e.g., for naphthalene (**A**) and perylene (**E**)), and give an indication of the accuracy of the method, when compared to the normal Hückel values of 0.618 and 0.347, respectively. Similarly the value obtained (−0.307) for m_{m+1} of acenaphthylene can be compared with the calculated value of −0.285. Fry and Fox (33) have recently shown that an improved correlation between $\epsilon_{1/2}$ and LUMO energies can be obtained using a modified (OMEGAMO) HMO calculation. In the case of **2**, the Hückel value for m_{m+1} is changed from 0 to 0.119, which changes the calculated values of $\epsilon_{1/2}$ from −0.868 to −0.918 V. The observed value of 0.88[2] falls between these. Clearly, however, for **2** the LUMO is close to α in value. Addition of an ace bridge to naphthalene makes reduction more difficult by 0.11 V. However, addition of the two ace bridges to perylene to give **1** makes reduction more difficult by only 0.13 V, somewhat smaller than might be expected. This is consistent with our previous results (1) in the acenaphth[1,2-*a*]acenaphthylene series where each ace bridge added 0.06 V rather than the 0.11 V expected, and thus may give some indication of strain in the system.

Mutagenicity results

The method for detecting mutagenicity was the Salmonella/mammalian microsome test described by Ames *et al.* (34). The *Salmonella typhimurium* strain used was TA 98 (1538 plus an R factor plasmid), kindly provided by Professor B. N. Ames (Berkeley). The microsomal fractions were obtained from rat liver homogenates as described by us previously (35). Without microsomes neither **1** or **2** produced any revertant colonies with TA 98. With microsomes, however, at 100 μg/plate both **1** and **2** gave 20 revertant colonies per plate, while the positive control at 2 μg/plate (2-aminoanthracene) gave 105 revertant colonies/plate after subtraction for negative control. Even at 10 μg/plate, **1** and **2** showed 4 and 16 revertant colonies/plate respectively. Thus both **1** and **2** are very weakly mutagenic, with **2** probably stronger than **1**. They are, however, totally different from **4**,

which is a strong mutagen (10). This should be of interest to theoreticians concerned with models of chemical carcinogenicity.

Conclusions

This synthesis of **1** and **2** has made available important members of the cyclopenta-fused aromatics. We have documented their UV, ^{1}H, and ^{13}C NMR spectra, and $\epsilon_{1/2}$ values, and have discussed these relative to strain calculations of structurally similar molecules, to provide data suitable for more detailed study by competent theoreticians.

Experimental

Melting points were determined on a Kofler hot stage and are uncorrected. ^{1}H NMR spectra were determined in $CDCl_3$ (unless otherwise stated) on a Perkin–Elmer R12B (60 MHZ), R32 (90 MHz), or Bruker WM-250 (250 MHz) spectrometer. ^{13}C NMR spectra were recorded either on a Nicolet TT-14 (15.1 MHz) or Bruker WM-250 (62.9 MHz) spectrometer. All chemical shifts are reported in ppm downfield from tetramethylsilane as internal standard. Mass spectra were determined on a Finnigan 3300 mass spectrometer at 70 eV (EI) or using methane chemical ionization (CI). UV spectra were recorded on a Beckman DU-8 spectrometer using cyclohexane as solvent. Microanalyses were carried out by this department or by Canadian Microanalytical Services Ltd. (Vancouver, B.C.). All evaporations were carried out under reduced pressure on a rotary evaporator at about 40°C, and all organic layers were washed with water (unless otherwise stated) and dried with anhydrous $MgSO_4$. The samples for which spectroscopic data are reported were checked for purity by HPLC.

3,4,9,10-Tetrakis(carbomethoxy)perylene **7**

Dimethyl sulphate (20 g, 150 mmol) was added to a stirred solution of the dianhydride **5** (5.6 g, 14 mmol) in aqueous NaOH (25%, 80 mL) and dioxane (400 mL). The mixture was heated under reflux for 24 h, and then was neutralized with aqueous HCl and extracted with dichloromethane–ether (70:30). The extract was washed, dried, and evaporated to give crude **7** (340 mg, 5%). Chromatography over silica gel using dichloromethane–ether (1:1) as eluant gave pure **7** as a pale orange powder, mp 272–275°C. ^{1}H NMR, δ (90 MHz): 8.31, 8.06 (d, J = 7 Hz, 4H each, ArH), 3.95 (s, 12H, -OMe); ^{13}C NMR, δ: 167.8, 140.9, 129.8, 128.1, 124.1, 120.9, 108.2, and 51.1; MS (CI) m/e: 485 (MH^+, 19%), 453 (M − OMe), 100%). Anal. calcd. for $C_{28}H_{20}O_8$: C 69.42, H 4.16; found: C 69.35, H 4.05.

Diaceperylene (1,2,7,8-tetrahydrodicyclopenta[1,2,3-cd:1′,2′,3′-lm]perylene) **1**

n-BuLi (65 mmol in 35 mL hexane) was injected into a stirred solution of 5,6-dibromoacenaphthene (1) (10 g, 32 mmol) in anhydrous ether (1 L) at −10 to −30°C. After 30 min the reaction mixture was cooled to −78°C and $Ni(acac)_2$ (14.4 g, 60 mmol) or anhydrous $CoCl_2$ (dried under vacuum at 110°C for 4 h) (7.8 g, 60 mmol) was added. The mixture was stirred at −78°C for 1 h, then at room temperature for 1 h, and then was heated under reflux for 1 h. The suspended solids were filtered. The ether was washed with water and was evaporated. The residue was combined with the filtered solids and was washed with water, and then thoroughly extracted with hot benzene. The benzene extract was evaporated and chromatographed over basic alumina (activity 2–3) using benzene as eluant. The vividly fluorescent eluant gave a red-orange product on evaporation, crude **1** (>95% pure by NMR) (0.9–1.7 g, 20–35%). Recrystallization from benzene (charcoal) gave a yellow-orange product, mp 333–335°C, with extensive previous darkening even under argon (lit. (16) mp 345–346°C (dec. argon); lit. (17) mp 332–334°C). Preparative HPLC was required to produce a pale yellow sample. UV (cyclohexane) λ_{max} (log ϵ_{max}): 455 nm (4.76), 450sh (4.62), 444sh (4.39), 426 (4.58), 402 (4.22), 380 (3.75), 259 (4.46), 252 (4.41), 246 (4.39), 229 (4.49), and 222 (4.63); ^{1}H NMR, δ (250 MHz) (CD_2Cl_2–CS_2): 7.92, 7.24 (AB, J = 7.4 Hz, 4H each, ArH) and 3.39 (s, 8H, -CH_2-); ^{13}C NMR, δ (63 MHz) (CD_2Cl_2–CS_2): 145.1(C-12a), 141.3(C-12b), 129.0(C-12d), 128.3(C-12c), 121.1(C-3(4)), 121.0(C-4(3)), and 31.7(C-1,2); MS m/e: 304 ($M^{+\cdot}$, 100%). Anal. calcd. for $C_{24}H_{16}$: C 94.70, H 5.30; found: C 95.03, H 5.05.

Diaceperylylene, (dicyclopenta[1,2,3-cd:1′,2′,3′-lm]perylene) **2**

DDQ (2,3-dichloro-5,6-dicyanoquinone) (317 mg, 1.4 mmol) was added to a solution of diaceperylene **1** (170 mg, 0.56 mmol) in dry, argon-degassed benzene (250 mL), and the mixture was heated under reflux for 3 h under argon. After cooling, the mixture was filtered, and the benzene evaporated to give crude product. This was chromatographed over water (4%) deactivated silica gel using benzene–pentane (3:7) as eluant to give the product **2** (102 mg, 60%), which on recrystallization from benzene gave dark red crystals, mp >350°C (argon). UV (cyclohexane) λ_{max} (log ϵ_{max}): 500 nm (4.62), 466 max (4.40), 437 (4.00), 412 (3.55), 336 (3.87), 322 (3.66), 246 (4.50), and 220 (4.67); ^{1}H NMR, δ (250 MHz): 7.89, 7.41 (AB, J = 7.4 Hz, 4H each, ArH) and 6.70 (s, 4H, -CH=CH-); ^{13}C NMR, δ (63 MHz) (CS_2): 130.0(C-1,2,7,8), 125.0(C-3,6,9,12), and 122.2(C-4,5,10,11) (only =CH carbons could be observed, see text); MS m/e 300: ($M^{+\cdot}$, 100%), 150 (100%). Anal. calcd. for $C_{24}H_{12}$: C 95.97, H 4.03; found: C 95.99, H 4.01.

5,5′-Diacenaphthene **10**

n-BuLi (43 mmol) in hexane (27 mL) was injected under argon into a stirred solution of 5-bromoacenaphthene **9** (1) (10.0 g, 43 mmol) in dry ether (100 mL) at 0°C. After 2 h, anhydrous (see **1** above) $CoCl_2$ (13 g, 100 mmol) was added, and the mixture was heated under reflux for 12 h. After cooling, the mixture was poured onto ice, acidified with aqueous 2 M HCl, and the organic layer was washed with water, dried, and evaporated. The crude product was then chromatographed on alumina (activity 2–3) using pentane as eluant and gave, after elution of unchanged **9** and some acenaphthene, 5,5′-diacenaphthene **10** (4.86 g, 74%), which in recrystallization from dichloromethane–hexane gave very pale yellow crystals of **10**, mp 179–180°C (lit. (36) mp 176–178°C). ^{1}H NMR (250 MHz), δ: 7.51 (AB, J = 7.2 Hz, 2H, H-4,4′), 7.41 (AB, J = 7.2 Hz, 2H, H-3,3′), 7.39–7.31 (m, 6H, H-6,6′,7,7′,8,8′), and 3.50 (s, 8H, -CH_2-); ^{13}C NMR (15 MHz), δ: 146.0(C-8a), 145.4(C-2a), 139.4(C-8b), 133.5(C-5), 131.0(C-8c), 129.5(C-4), 127.7(C-7), 121.5(C-6), 119.2(C-3), 119.0(C-8), 30.6(C-2), and 30.1(C-1).

6,6′-Dibromo-5,5′-diacenpahthene **11**

N-Bromosuccinimide (9.75 g, 55 mmol) in DMF (50 mL) was added to a stirred solution of the diacenaphthene **10** (8.4 g, 27 mmol) in DMF (170 mL) at 70–80°C. After 12 h, the reaction mixture was cooled, poured into water, and extracted with dichloromethane. The extract was washed well with water, saturated aqueous NaCl, dried, and evaporated. The residue was chromatographed over silica gel using dichloromethane–pentane (3:7) as eluant to give 7.9 g (62%) of yellow dibromide **11**, mp 180–188°C, which was used directly in the next reaction. ^{1}H NMR (90 MHz), δ: 7.61 (d, J = 8 Hz, 2H, H-4,4′ or 7,7′), 7.5–7.0 (m, 6H, ArH), 3.45 and 3.41 (s, 4H each, -CH_2-); MS (CI) m/e: 463,465,467 (MH, 1:2:1 ratio).

Coupling of **11**

n-BuLi (8.6 mmol) in hexane (3.6 mL) was injected under argon to a stirred solution of the crude dibromide **11** (2.0 g, 4.3 mmol) in dry ether (120 mL) at −10 to 0°C. After 2 h, anhydrous $CoCl_2$ (2.2 g, 17 mmol) was added, and the mixture was heated under reflux for 12 h. The reaction was then worked up as described for **1** above. HPLC indicated that **1** was present, but that the reaction was much dirtier than the direct coupling to **1** described above; moreover, the isolation of **1** was only achieved with difficulty using HPLC (reverse phase C18 with methanol).

5,5,12,12-Tetramethyldiacenaphtho[5,6-bc:5′,6′-fg]-(1,5)distannocin **12**

n-BuLi (6.4 mmol) in hexane (4.3 mL) was injected into a stirred solution of 5,6-dibromoacenaphthene (1) (1.0 g, 3.2 mmol) in dry ether (50 mL) at 20°C. After stirring for 1 h, dimethyltindichloride (0.705 g, 3.21 mmol) was added, and the mixture was then stirred for a further hour before collecting the white precipitate. This was extracted with boiling benzene, and the extract was evaporated and recrystallized from benzene–hexane to yield pale yellow needles of **12** (500 mg, 26%), mp 277–279°C. ^{1}H NMR (90 MHz), δ: 7.72, 7.27 (d, J = 7 Hz, 4H each, ArH), 3.32 (s, 8H, -CH_2-), and 0.54 (s, 12H, -CH_3); MS (CI) m/e: 6.05 (MH^+ for Sn^{120}, correct isotope pattern), intense M − CH_3 peaks. Anal. calcd. for $C_{28}H_{28}Sn_2$: C 55.87, H 4.69; found: C 56.03, H 4.85.

Photolysis of **12** *to give* **1**

A solution of the stannocin **12** (0.4 g) in dry benzene (200 mL) was irradiated in a quartz Hanovia reactor (medium pressure) for 48 h. After filtration, the filtrate was evaporated and chromatographed over basic alumina (activity 2–3) using benzene–hexane (1:5) as eluant. The eluate contained a 3–5% yield of **1** (confirmed by HPLC and UV). However, this sample was difficult to crystallize.

5,6-Dibromoacenaphthylene **13**

DDQ (1.09 g, 4.8 mmol) was added to a stirred solution of 5,6-dibromoacenaphthene (1) (1.0 g, 3.2 mmol) in dry benzene (35 mL), and the mixture was heated under reflux for 30 h. After cooling, pentane (175 mL) was added and the mixture was filtered. The filtrate was passed through a short column of basic alumina (activity 2–3), and the eluate on evaporation yielded 740 mg (75%) of product, which on recrystallization from hexane gave deep yellow crystals of 5,6-dibromoacenaphthylene, mp 132–133°C. ^{1}H NMR (250 MHz), δ: 7.86, (AB, J = 7.35 Hz, 2H, H-4,7), 7.40 (AB, J = 7.35 Hz, 2H, H-3,8), and 6.85 (s, 2H, -CH=CH-); ^{13}C NMR (15 MHz) δ: 140.3(C-2a,8a), 135.8(C-8c), 135.4(C-4), 129.1(C-1,2), 125.7(C-8b), 125.1(C-3,8), and 121.0(C-5,6); MS m/e (CI): 309, 311, 313 (MH^+, 1:2:1 ratio, 100%). Anal. calcd. for $C_{12}H_6Br_2$: C 46.50, H 1.95; found: C 46.87, H 2.03.

Attempted coupling of 5,6-dibromoacenaphthylene

n-BuLi (0.6 mmol) was added to a solution of 5,6-dibromoacenaphthylene (100 mg, 0.3 mmol) in dry THF (30 mL) at 0°C (also at −78°C) under nitrogen. After 30 min, anhydrous $CoCl_2$ (167 mg, 1.3 mmol) was added, and the mixture was then heated under reflux for 14 h. After addition of water and extraction into ether, HPLC indicated that 13 products had formed. No **2** could be isolated.

5-Bromoacenaphthylene **15**

(i) By dehydrogenation

DDQ (1.16 g, 5.1 mmol) was added to a stirred solution of 5-bromoacenaphthene (1) (1.0 g, 4.3 mmol) in dry benzene (25 mL) and the mixture was heated under reflux for 14 h. After cooling, pentane (125 mL) was added and the mixture was filtered. The filtrate was passed through a short column of basic alumina (activity 2–3) to yield 600 mg (60%) of the product, which on recrystallization from ethanol gave yellow crystals, mp 53–55°C. ^{1}H NMR (60 MHz), δ: 7.9–7.0 (m, 5H, ArH) and 6.78 (s, 2H, -CH=CH-); ^{13}C NMR (15 MHz), δ: 140.0(C-2a), 139.4(C-8a), 130.8(C-4), 129.5(C-1), 129.1(C-2), 128.7(C-6), 128.3(C-8b or 8c), 126.4(C-7), 124.9(C-3), 124.7(C-8), and 122.9(C-5); MS m/e (CI): 231, 233 (MH^+, 100%). Anal. calcd. for $C_{12}H_7Br$: C 62.37, H 3.05; found: C 62.09, H 3.22.

(ii) By bromination/dehydrobromination

N-bromosuccinimide (30 g, 0.172 mol) was divided into six portions, and one was added to a stirred solution of 5-bromoacenaphthene (20 g, 0.086 mol) in dry CCl_4 (500 mL), which was then heated to reflux under a bright incandescent light, at which point benzoyl peroxide (100 mg) was added. At approximately 15 min intervals, the remaining portions of NBS were added, and reflux continued with irradiation until nearly all the succinimide product floated. The reaction mixture was then cooled, and the succinimide removed by filtration. The filtrate was evaporated, and the residue recrystallized from ethanol to give 1,2,5-tribromoacenaphthene (24 g, 72%), mp 88–90°C. ^{1}H NMR (90 MHz), δ: 8.0–7.1 (m, 5H, ArH) and 5.95 (bs, 2H, -CHBr-). This tribromide (22 g, 56 mmol) was dissolved in acetone (400 mL), and KI (93 g, 0.56 mmol) and $Na_2S_2O_3.5H_2O$ (112 g, 0.45 mol) were added with stirring. The reaction mixture was stirred under reflux for 14 h, cooled, and filtered. The filtrate was evaporated, and the residue extracted into ether, washed, dried, and evaporated and then chromatographed over silica gel using pentane as eluant to give, after recrystallization from ethanol, yellow crystals of 5-bromoacenaphthylene (7.0 g, 35% overall), identical to the sample obtained in (*i*).

5,5′-Diacenaphthylene **16**

DDQ (185 mg, 0.81 mmol) was added to a stirred solution of 5,5′-diacenaphthene **10** (100 mg, 0.33 mmol) in dry benzene (30 mL) and the mixture was heated under reflux for 14 h. After cooling, pentane (150 mL) was added and the mixture was filtered. The filtrate was passed through a short column of alumina (activity 2–3) to yield the yellow product, which was further purified by HPLC (MCH-10, reverse phase, methanol) to a yellow waxy product. ^{1}H NMR (90 MHz), δ: 7.9–7.1 (m, 10H, ArH) and 7.03 (s, 4H, -CH=CH-); ^{13}C NMR (15 MHz), δ: 139.6(C-8a), 139.3(C-2a), 138.1(C-8b), 130.3(C-2), 129.7(C-1), 129.1(C-4), 128.3(C-5), 128.2(C-8c), 127.7(C-7), 126.8(C-6), 124.1(C-3), and 123.6(C-8); MS m/e (CI): 303 (MH^+, 100%).

Attempted coupling of 5-bromoacenaphthylene

n-BuLi (13 mmol) in hexane (5.4 mL) was added to a stirred solution of 5-bromoacenaphthylene (**15**) (3.0 g, 13 mmol) in dry ether (75 mL) under nitrogen at 0°C. After 3 h, anhydrous $CoCl_2$ (3.4 g, 26 mmol) was added, and then the reaction was heated under reflux for 14 h. After coolling, the ether was washed, dried, and evaporated. The residue consisted of 18 products by HPLC (MCH-10, reverse phase, methanol), one of which was 5,5′-diacenaphthylene (**16**) as about 7% of the mixture.

Measurement of electrode reduction potentials

The values quoted in Table 1 were measured on a Metrohm–Polarecord 626 as 0.0005 M solutions of hydrocarbon in 90% aqueous dioxane, which was 0.175 M in tetra-*n*-butylammonium iodide using a dropping mercury electrode relative to a standard calomel electrode.

Mutagenicity tests

These were carried out using DMSO solutions of **1** and **2** (0.1 mg/mL) on *Salmonella typhimurium* TA 98 (with and without microsomes) as described by us previously (35).

Curve crossing analysis of LFER data in Michael addition reactions[1]

ZEEV GROSS AND SHMARYAHU HOZ[2]
Department of Chemistry, Bar-Ilan University, Ramat-Gan, Israel 52900

Received July 5, 1991

ZEEV GROSS and SHMARYAHU HOZ. Can. J. Chem. **70**, 1022 (1992).

Rate constants for the Michael addition of CN^- in water, aqueous sulfolane, and DMSO, and MeO^- in MeOH to eight mono- and disubstituted 1,1-diaryl-2,2-dinitroethylenes were measured. The ρ values are in the range 0.7 (CN^-/H_2O) – 1.6 (MeO^-/MeOH). For each of the four systems a correlation was found between log *k* and the ^{13}C chemical shift of the carbon that undergoes the nucleophilic attack. However, the quality of the correlation as well as the slope decreases with decreasing ρ values. Analysis of the electronic configuration of the transition state using the curve crossing model shows that the traditional interpretation of the location of the transition state should be reversed. This analysis provides a rationale for the observed dependence of the chemical shift – rate correlation on the ρ value.

ZEEV GROSS et SHMARYAHU HOZ. Can. J. Chem. **70**, 1022 (1992).

On a mesuré les constantes de vitesse pour l'addition de Michael du CN^- (dans l'eau, en solutions aqueuses de sulfolane et dans le DMSO) et du MeO^- (dans le méthanol) sur huit 1,1-diaryl-2,2-dinitroéthylènes mono- et disubstitués. Les valeurs de ρ varient de 0,7 (CN^-/H_2O) à 1,6 (MeO^-/MeOH). Pour chacun des quatre systèmes, on a pu établir une corrélation entre le log *k* et le déplacement chimique (en RMN du ^{13}C) du carbone qui subit l'attaque nucléophile. Toutefois, la qualité de la corrélation ainsi que la pente diminuent avec une diminution des valeurs de ρ. Une analyse de la configuration électronique de l'état de transition à l'aide du modèle du croisement des courbes montre que l'interprétation traditionnelle de la position de l'état de transition doit être renversée. Cette analyse fournit une explication rationnelle pour la relation qui a été observée entre la corrélation déplacement chimique/vitesse et la valeur de ρ.

[Traduit par la rédaction]

Introduction

Although the Ritchie equation was originally designed for anion–cation combination reactions (1), we have shown that after inclusion of a selectivity parameter (eq. [1]), it can also accommodate nucleophilic additions to some activated olefins (2).

[1] $\log k/k_0 = S_+N_+$

The equation was found to be valid for systems having the framework of 9-methylenefluorene (eq. [2]) with various activating groups on the α carbon.

To examine the effect of substitution on the β carbon in these reactions, we have studied the analogous diphenyl system where the aromatic rings can be relatively easily substituted. Since the 9-dinitromethylenefluorene system (eq. [2], X=Y=NO_2, FDN) gave an excellent fit (2) to the Ritchie equation, the diaryl system chosen for the present study was also activated by two nitro groups on the α carbon (DArDN).

As will be shown later, the results of this study seem to imply a contradiction between basic principles and postulates in the field of reaction mechanism. A resolution of this apparent contradiction is advanced using the curve crossing model for nucleophilic attacks on Low LUMO compounds.

[2] 
Results

Rate constants for the reactions of various nucleophilic systems (nucleophile/solvent) with a series of substituted 1,1-diaryl-2,2-dinitroethylenes (DArDN, eq. [3]) were determined at 25°C.

[3]

A	OMe	OMe	Me	H	F	Cl	Cl	NO_2
B	OME	H	Me	H	F	H	Cl	H

The reactions were followed spectroscopically by monitoring the disappearance of the absorption of the olefin at its λ_{max}. Occasionally the reactions were also monitored by following the formation of the products. Identical rate constants were obtained by both methods. The concentrations of the substrate were in the range 10^{-5}–10^{-4} M. Concentrations lower than 10^{-5} M were used only for the reactions in water to avoid zero-order kinetics due to aggregation (3). In

all cases the nucleophile concentration was at least ten times higher than that of the substrate. In protic solvents the cyanide anion is partly protonated. The concentration of the free CN^- was calculated from its pK_a and the dissociation constant of the solvent (see experimental section). Usually the free [CN^-] was in the range 0.002–0.01 M. All reactions went to completion. In aqueous solutions, hydrolysis due to the presence of OH^- was observed for the two most reactive derivatives. For these substrates, the reactions were conducted in borax buffered solutions at pH 9.2, thereby minimizing the competing hydrolytic reaction.

Second-order rate constants and λ_{max} for the various derivatives are given in Table 1.

The ^{13}C NMR chemical shifts of C_α and C_β were measured for each of the substrates. The data are given in Table 1.

Discussion

Hammett vs. Ritchie equations

Variation of the nucleophilic system (nucleophile/solvent) in combination with a variation of substituents on the aromatic ring enables a simultaneous analysis of two LFER's: the Ritchie and the Hammett equations. Both equations contradict the reactivity–selectivity principle and cannot coexist unless the ρ values remain constant for all nucleophilic systems. Thus, in the present case the ρ in DMSO, for example, must be equal to that in water.

The question at hand is therefore whether the two LFER's do coexist for DArDN at the price of the severe restriction of having ρ constant for all nucleophilic systems and, in case they do not, which LFER will supersede the other. It should be pointed out that in spite of the severe requirement, cases of simultaneous coexistence of the two equations are known (4).

The reactions of the four nucleophilic systems with the various substituted substrates were found to obey the Hammett equation (Table 2 and Fig. 1). In aqueous solutions the data are best correlated with σ, whereas in nonaqueous media a slightly better correlation is obtained with σ^0 (5). However, as shown in Table 2, the use of one type of σ or the other does not affect the actual ρ values. It should also be pointed out that the σ values of the disubstituted substrates are additive with no apparent deviation (see, however, ref. 6). On the other hand, the Ritchie equation is

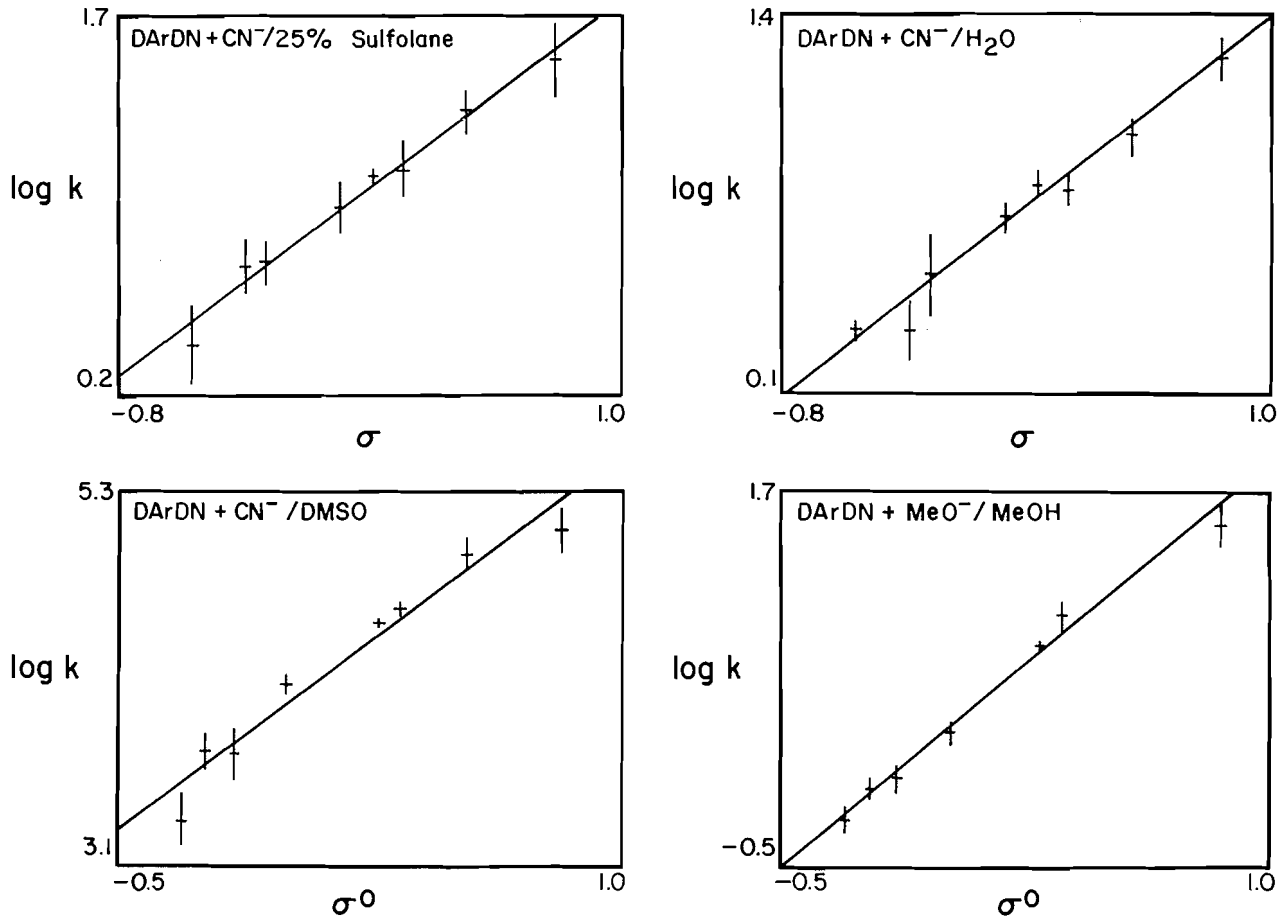

FIG. 1. Hammett plots for nucleophilic additions to 1,1-diaryl-2,2-dinitroethylenes.

not obeyed (Fig. 2). Most probably the requirements of the latter are more stringent, leading thus to a limited range of applicability.

In light of the difference between the Ritchie (N_+) (1) and the Swain–Scott (7) (n) nucleophilicity scales, we have suggested that substrates participating in nucleophilic reactions should be classified according to their LUMO energies (2*a*, 8–10). High LUMO (HL) substrates will obey the Swain–Scott equation (7), whereas low LUMO (LL) substrates will obey the Ritchie N_+ equation (1). The question, in terms of LUMO energy, is: where is the border line between these two classes of substrates? If LUMO energies are the only major factor affecting the behavior of a substrate, then the border line lies (at least within the activated double bond series) between FDN and DArDN derivatives. In a more quantitative way, using half-wave reduction potentials as a measure for the energy of the LUMO, the aforementioned border line lies between −0.2 and −0.94 V, which are the half-wave reduction potentials of DPDN and FDN respectively.[3] Substrates with LUMO energies close to that of FDN are expected to obey both the Hammett and the Ritchie equations, whereas those nearing DPDN will probably obey only the Hammett equation.

[3]The half-wave potentials of the first cathodic wave were determined in methylene chloride with tetrabutylamonium perchlorate as the supporting electrolyte and a platinum rotating disk electrode. We are grateful to Dr. Y. Liftman for the electrochemical measurements.

General description of TS structure in Michael addition reaction (MAR)

Let us first briefly discuss our model for nucleophilic attacks on low-lying LUMO (LL) substrates (8–10). Phenomenologically, substrates of low electrophilicity, i.e., high LUMO substrates, form covalent bonds in their reactions with nucleophiles. On the other hand, increasing the electrophilicity of a substrate will eventually lead to an electron transfer reaction. The radical pair formed may either collapse to the covalent bond or dissociate to the free radicals. Our model assumes continuity between these two extreme cases. That is, in any TS there is a partial covalent bonding as well as a partial diradical character. The relative contributions of these features vary with the LUMO height. Hence, nucleophilic attacks on low LUMO substrates are characterized by a transition state (TS) in which both the nucleophile and the substrate acquire a relatively large radical character. A similar conclusion was reached by Fukuzumi and Kochi for electrophilic aromatic substitution (11). Shaik and Pross have rigorously developed, with a similar outcome, a valence bond model for a large variety of reactions (12, 13). The model is best demonstrated by using the curve crossing method for the construction of the MAR profile (14) (Fig. 3). The profile is constructed by overlaying potential energy curves of the reactants and the products (I and II, Fig. 3). The two curves differ from each other by a transfer of a single electron from N^- to the substrate. Thus, motion from the ionic state of the reactants at the right to form the covalent bond at the left *must involve a partial electron transfer*. The TS

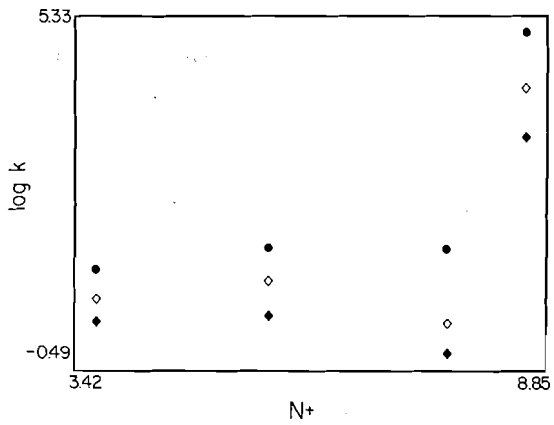

FIG 2. A Ritchie type diagram for selected substrates: MNDN ●; DPDN ◇; DADN ◆.

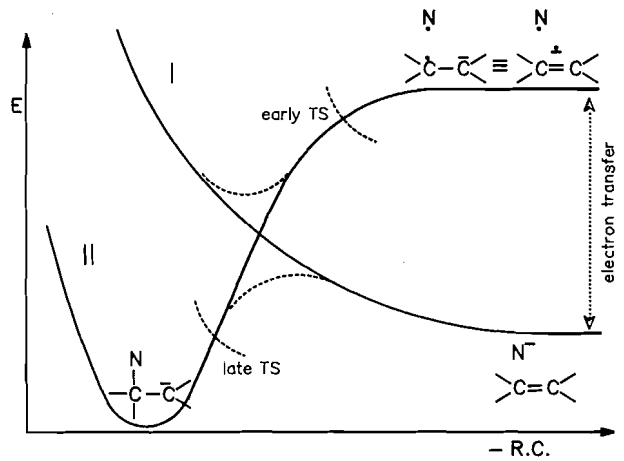

FIG. 3. Construction of a reaction profile for the Michael addition reaction.

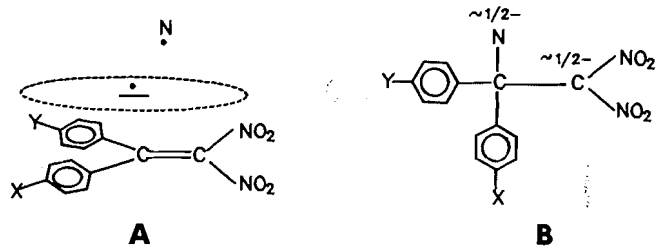
is achieved in the region of the avoided crossing. At this point the two configurations are of equal energy and hence the state function at this point has *equal contributions* from the two configurations. Therefore, as was already pointed out (12), about *half an electron* has been transferred from the nucleophile to the substrate at the TS.[4] It should be emphasized that this process does not lead to the formation of two distinct radicals since the TS decays to the covalent product.

Another important feature of this system is that the balance between the diradical and the covalent character varies as one progresses along the Morse type curve. An early TS, that is, an early crossing of the two curves, will result in a larger contribution from the diradical character, whereas a late TS will cause covalent bonding to be highly advanced at the expense of the diradicaloid character.

Thus, although the same amount of charge is transferred from the nucleophile to the substrate regardless of the position of the TS, the actual charge sensed by substituents on the aromatic rings (the probe) depends on the extent to which covalent bond formation has progressed, i.e., on the location of the TS. In a very early TS, the negative charge (the odd electron at the LUMO of the substrate) can be almost freely delocalized onto the aromatic rings and their substituents, leading to a relatively high ρ value (structure **A**). In a very late TS, covalent bond formation becomes dominant, disrupting the probe – negative charge interaction with the latter being now confined mainly to the remote location of the activating group region (structure **B**). Such a separation of the charge from the substituent will lower the ρ value. Thus, contrary to the traditional interpretation, *there is an inverse relationship between the* ρ *and the location of the TS. A relatively small* ρ *corresponds to a late TS and vice versa.*



In a previous paper we showed how this model accommodates various observations made in the analogous 1,1-diaryl-2-nitroethylene system (10). In the present paper we will show how this model is further supported by the ^{13}C chemical shift – rate correlation observed in the present system.

^{13}C chemical shift – rate correlation

Variations in reaction rate constants can be correlated with variations in a property of the substrate that is related to the equilibrium energy of the reaction. Assuming a monotonic variation of this property between the reactants and the products, one would expect a linear correlation (LFER) between the rate and that property (both given in energy-related units). The effect on the rate, expressed as a fraction of the equilibrium-related effect, can be used as a measure for the location of the TS along the reaction coordinate (15). However, if the given property is not an equilibrium-related property but is rather an intrinsic property of the reactants, then one would expect to observe such a correlation only for an early TS where the reactants retain this property to a given extent. Thus, for example, the LUMO energy of a substrate does not necessarily have any relation to the equilibrium of the reaction. It becomes energetically meaningful only when interacting with the HOMO of the nucleophile. Thus, in a very early TS, a rate – LUMO energy correlation can be observed. However, in a late TS, since the substrate has undergone significant geometric and electronic changes, the relevancy of the interaction between the HOMO and the original substrate's LUMO to the activation energy is diminished (the relevant LUMO in this case would be that of the deformed substrate).

As can be seen from Fig. 4, log *k* for each of the four reaction sets can be correlated with the ^{13}C NMR chemical shift of the carbon atom that undergoes the nucleophilic attack. The chemical shift of $^{13}C_\alpha$ (where the charge will eventually reside) is insensitive to variation of substituents on the aryl groups. The ^{13}C NMR chemical shift is another property of the reactants that is not related to the reaction equilibrium energy. It may be related to the rate effect through a possible connection with the LUMO energy. In a similar manner, since ^{13}C chemical shift is related to the charge on the

[4]This approximation is valid at the two-configuration approximation level. In reality, the mixing of higher energy configurations as well as the skewing effect may somewhat shift the actual amount of the transferred charge from 0.5 e^-.

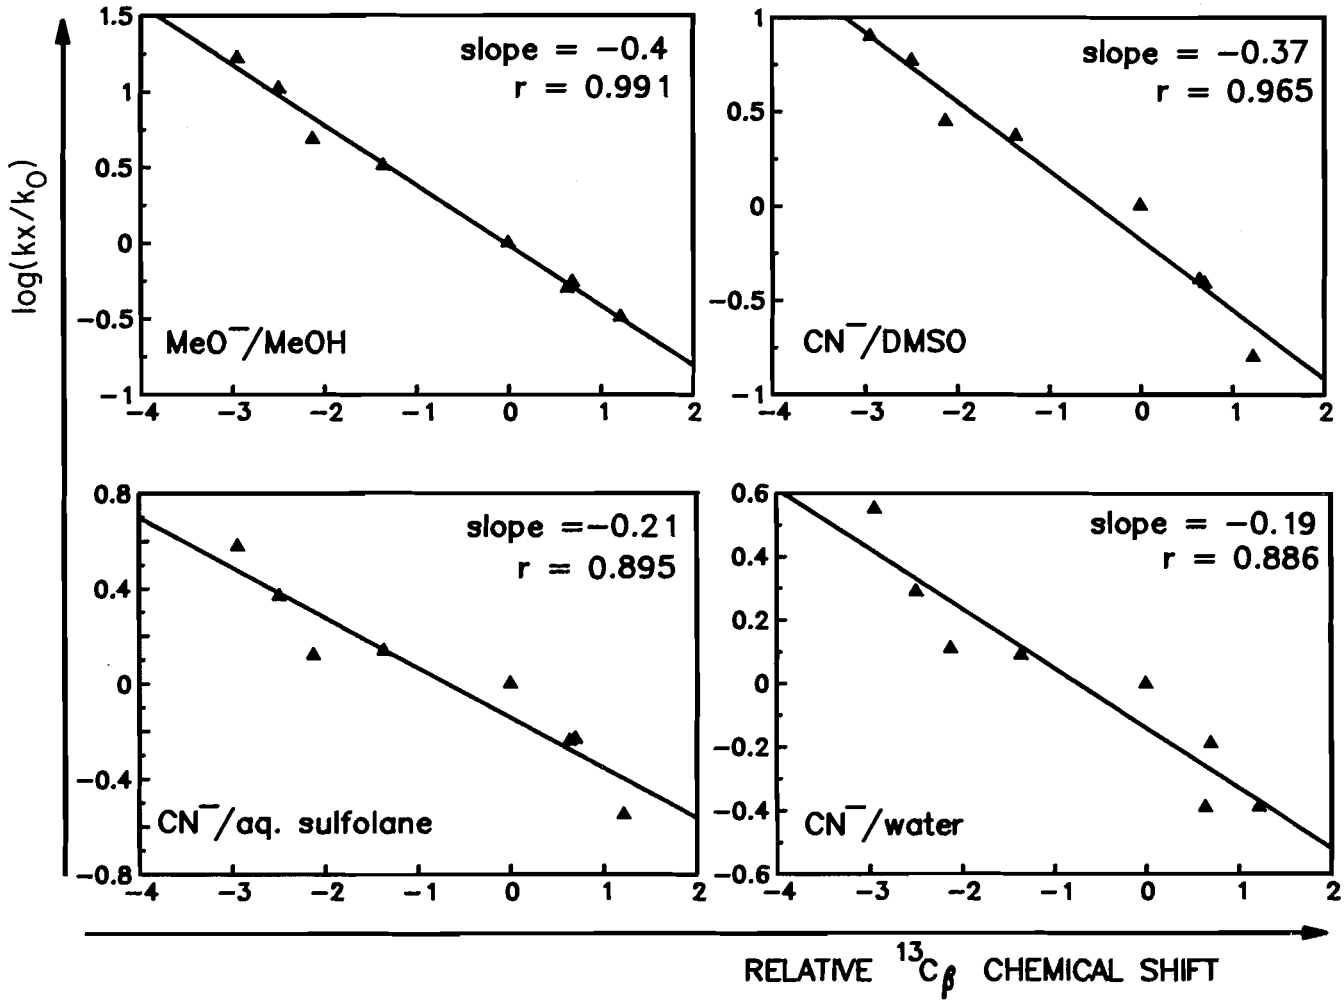

FIG. 4. Log k vs. relative $^{13}C_\beta$ chemical shift.

nucleus (16), it may reflect the electrostatic interaction at the TS. In both cases, it is clear that the later the TS, the less relevant this property is to the rate. Thus, both the quality of the correlation and the slope are expected to decrease as the TS becomes later. Examination of the data in Table 2 and Fig. 4 suggest therefore that the earliness of the TS increases in the order $MeO^-/MeOH > CN^-/DMSO > CN^-/$ aqueous sulfolane $> CN^-/H_2O$. This result is in excellent agreement with our model since the reactions with $MeO^-/$ MeOH and with $CN^-/DMSO$ have larger ρ values and are therefore indeed predicted to have a TS earlier than the reactions with CN^-/aqueous sulfolane and CN^-/H_2O, whose ρ values are smaller. It should be noted that this conclusion also concurs with the Hammond postulate (17), which predicts that the more reactive system has an earlier TS.

Summary and conclusions

The major conclusions of this study, in which the reactivities of four nucleophilic systems (nucleophile/solvent) towards a series of dinitro activated olefins (DArDN) were determined, are (*a*) unlike the analogous fluorenyl system, the DArDN system does not obey the Ritchie N_+ equation. It is suggested that, at least within the realm of activated olefins, the border line between the N_+ and the n (Swain–Scott) behavior lies with substrates having LUMO's with energy between that of DArDN and FDN. In terms of half-wave reduction potentials of substrates, the border line lies between −0.2 and −0.9 V; (*b*) the TS has a structure (radical anionic) that is not an intermediate one between that of reactants and products; (*c*) in the present case, a large ρ value is indicative of an early TS and vice versa; (*d*) the above conclusion provides a rationale for the unexpected behavior of rate – ^{13}C chemical shift correlation as a function of ρ values.

Experimental section

Instrumentation

Kinetic measurements were performed on Uvikon 810-820, Gilford 2400, and Durrum 110 stopped-flow spectrophotometers that were equipped with an Apple II microcomputer for data acquisition. pH measurements were taken with a Radiometer PHM-52 digital pH-meter. ^1H and ^{13}C NMR spectra were recorded on a Bruker AM 300 spectrometer.

Substrates and products

1,1-Diphenyl-2,2-dinitroethylene (DPDN) and 1,1-di(4-methoxyphenyl)-2,2-dinitroethylene (DADN) are known compounds (18). In general, the preparation of the DArDN substrates involved dinitration of the parent 1,1-diarylethylenes according to the following procedure. To a stirred solution of 20 mL glacial acetic acid containing 20 mmol of 1,1-diarylethylene, 3.5 mL red fuming nitric acid in 16.5 mL AcOH was added. The reaction mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 79.173.37.17 on 09/08/12
For personal use only.

was refluxed for 1 h. After cooling, chloroform and ice water were added and the aqueous phase was washed three times with chloroform. The combined chloroform solution was rapidly washed with a 5% $NaHCO_3$ solution, dried over $MgSO_4$, and evaporated. The residue was chromatographed on a silica column (CH_2Cl_2:hexane 2:1). The dinitration products were collected and recrystallized from hexane. The structure of the products was verified by NMR spectroscopy (data will be reported in a separate paper) and elemental analyses (satisfactory elemental analysis was obtained for all elements; oxygen was not analyzed). In this procedure no ring nitrations were observed. The preparation of 1-(4-nitrophenyl)-1-phenyl-2,2-dinitroethylene (MNDN) involved ring nitration of 1,1-diphenyl-2,2-dinitroethylene (DPDN) using the following procedure. To an ice-cold stirred mixture of DPDN (0.27 g, 1 mmol), 15 mL CF_3COOH, and 0.2 g H_2SO_4, 0.11 g red fuming nitric acid in 1 mL CF_3COOH was added over 1 min. After stirring for 15 min at 0–5°C and an additional 20 min at room temperature, the reaction mixture was treated with water and ether. The aqueous phase was washed with three portions of ether, and the combined ethereal solution was treated similarly to the above chloroform solution. No attempt was made to optimize yields. Yields obtained (mp, °C): MADN 37% (107); DTDN 25% (122); MClDN 20% (135); DClDN 21% (132); DFDN 14% (97); MNDN 57% (109). 2,2-Diaryl-3,3-dinitropropionitrile, the adduct of DPDN, is known (18). The general procedure for the preparation of the adducts was as follows: to a mixture of 0.065 g KCN (1 mmol) and 1 mmol DArDN, dry DMSO (10 mL) was added all at once with vigorous stirring. After a few minutes all the solids dissolved and the mixture was poured into a mixture of crushed ice and 50 mL 5% HCl solution. The solids were filtered, and the filtrate was extracted three times with $CHCl_3$, which was dried over $MgSO_4$ and evaporated. Up to this stage the yield was quantitative (NMR and TLC). Attempts were made to crystallize these compounds from hexane, ether, ethanol, acetic acid, trifluoroacetic acid, 5% aqueous HCl, and various mixtures of these solvents, without success. The oils decomposed on standing for several days. Only with 2,2-di-(4-chlorophenyl)-3,3-dinitropropionitrile was a solid product obtained (crystallized from ethanol, acidified with trifluoroacetic acid, mp 127°C; satisfactory C, H, N, Cl elemental analysis was obtained).

Kinetic measurements

The solvents for the kinetic measurements were prepared as follows: double distilled water was boiled prior to use; sulfolane was vacuum-distilled three times, twice over NaOH and once from CaH_2. The middle fraction boiling at 130°C (6.5 Torr; 1 Torr = 133.3 Pa) was collected (19). MeOH was refluxed over Mg + I_2 for 1 h and distilled (20); DMSO, stored for a week over NaOH, was distilled from BaO (21). The concentrations of free CN^- were calculated from the pK_a value of HCN (9.2 (22) and 9.13) (23)) and pK_w (14 and 14.47) (24) of water and a solution of 25% sulfolane in water (v/v). The pK_a of HCN in the aqueous sulfolane was determined by measuring the hydroxide concentration of several KCN solutions using a calibrated pH–KOH profile. Prior to each set of kinetic runs the pH of the freshly prepared cyanide stock solution was determined. The pH measurements were in excellent agreement with the calculated hydroxide concentration. For the relatively slow reactions, the nucleophilic solutions were incubated in the thermostated spectrophotometer until the temperature of 25 ± 0.2°C was reached. The substrate was then injected into the cells (ca. 2.5 μL into 2.5 mL ethanolic solution for the reaction in water). The concentration of the substrate was usually in the range of 10^{-4}–10^{-5} M. The nucleophile concentration was always at least 10 times larger than that of the substrate. In each case first-order rate constants were determined for 3–5 different concentrations of nucleophile. The reactions were usually followed by monitoring the disappearance of the substrate's absorption at its λ_{max}.

The mass spectral fragmentation pathways of a series of phenylazoxypyridine-*N*-oxides have been studied under electron impact conditions using tandem mass spectrometry. Besides simple C—N cleavages, the azoxypyridine-*N*-oxides undergo deep-seated rearrangements directly from the molecular ion. In addition, the spectra are complicated by a purely chemical reduction of the N—O functionalities that occurs in the ion source prior to ionization.

NIGEL J. BUNCE, H. STEWART MCKINNON, RANDY J. SCHNURR, SAM B. KEUM et ERWIN BUNCEL. Can. J. Chem. **70**, 1028 (1992).

Faisant appel à la spectrométrie de masse en tandem, dans des conditions d'impact électronique, on a déterminé les spectres de masse d'une série de *N*-oxydes de phénylazoxypyridines et on a examiné leurs modes de fragmentation. En plus des simples clivages C—N, les *N*-oxydes d'azoxypyridines subissent des transpositions profondes directement de l'ion moléculaire. De plus, les spectres sont compliqués par une réduction purement chimique des fonctions N—O qui se trouve dans la source ionique avant le processus d'ionisation.

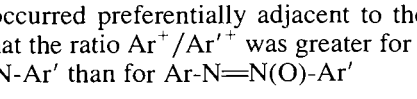
Introduction

The mass spectra of aromatic azoxy compounds have received relatively little study. In the 1960s, Bowie *et al.* (1) examined the electron impact (EI) spectra of a wide variety of azoxybenzene derivatives and established the major fragmentation pathways. In addition, they noted that the ratio of the ions Ar^+/Ar'^+ offered a method of distinction between the isomers Ar-N(O)=N-Ar′ and Ar-N=N(O)-Ar′; fragmentation occurred preferentially adjacent to the Ar-N(O) group, so that the ratio Ar^+/Ar'^+ was greater for the isomer Ar-N(O)=N-Ar′ than for Ar-N=N(O)-Ar′



1 **2**

This finding had analytical potential, because the distinction between these isomers has been a difficult problem in the chemistry of aromatic azoxy compounds (2), even with modern spectroscopic techniques.

A more recent study by Waddell *et al.* (3) confirmed most of the conclusions of Bowie *et al.*, but with two important extensions. First, the ratio of the ions Ar^+/Ar'^+ was found to depend upon the sample size introduced into the ion source; the relationship between this ratio and the structure of the azoxy compound was more reliable at high sample sizes as, for example, under direct insertion conditions. Second, it was found that the ion appearing at m/z 182 in the EI spectrum of azoxybenzene, i.e., $(M - 16)^+$, does not originate by loss of an oxygen atom from the molecular ion, as presumed by Bowie *et al.*, but rather arises through a chemical reduction of azoxybenzene in the ion source. This observation is significant in that $(M - O)^+$ is commonly found in the EI spectra of aromatic azoxy compounds, sometimes at high intensities. If a substantial proportion of the substrate undergoes this pre-ionization reaction, then the observed EI spectrum is not simply that of the original azoxy compound, but is the superimposed spectra of two different substances, the azoxy compound and the corresponding azo compound. This could undermine the conclusion of Bowie *et al.* that the ratio of the ions Ar^+/Ar'^+ provides a method of distinguishing between positional isomers of aromatic azoxy compounds, because Ar^+ and Ar'^+ are prominent fragments in the mass spectra of both aromatic azo compounds and aromatic azoxy compounds.

Waddell *et al.* noted that pre-ionization chemical reduction could be expected for any aromatic compounds containing oxygen bonded to nitrogen. We previously described the preparation (4) and acid-catalyzed rearrangements (5) of a series of phenylazoxypyridine-*N*-oxides. These compounds contain two *N*-oxide functionalities: the azoxy bridge and the pyridine-*N*-oxide. Thus one or both N—O functions may undergo pre-ionization chemical reduction in the ion source. In this paper, we report the mass spectra of four isomeric phenylazoxypyridine-*N*-oxides, and show that they do indeed undergo pre-ionization chemical reduction. This study has been greatly aided by the use of tandem mass spectrometry, which allows one to determine unambiguously the parent–daughter relationships between pairs of ions.

Methodology

The azoxy compounds were available from previous studies in our laboratories (6). The mass spectrometer was a Kratos model MS 890, which is a double-focussing mass spectrometer of conventional geometry, i.e., with the electric sector preceding the magnetic sector. Samples were introduced into the mass spectrometer by direct insertion, with an ion source temperature in the neighbourhood of 200°C. The electron beam in the ion source had an energy of 70 eV. The composition of each ion was obtained by

comparing the observed mass at high resolution with the calculated mass. In cases where more than one ion of the same nominal mass was detected, peak matching (a scan between two reference peaks of a perfluorokerosene standard) was used to obtain the composition of each of the ions. Spectra were obtained either as conventional electron impact (EI) scans at 70 eV or as linked scans with B/E constant, a scan which identifies all the daughter ions from a given parent.

Results and discussion

Tandem mass spectrometry

The conventional EI spectrum records low-energy ions that survive to the detector without undergoing any fragmentation (molecular ions), and ions initially having much higher energies that undergo single or multiple unimolecular decompositions within the ion source (fragment ions). Tandem mass spectrometry takes advantage of the additional information that can be gleaned from a study of ions of intermediate energy when they fragment in the field-free regions of the spectrometer. The following possibilities exist: (*i*) detect all the daughter ions of a given parent, whether the parent is the molecular ion or is itself a fragment ion; (*ii*) detect all the parents that give rise to a given daughter; (*iii*) detect all the parent ions that cleave to give a particular neutral fragment.

In the present experiments we were interested in detecting all the daughter ions of a given parent ion. For an instrument of conventional geometry, the following scan laws all detect daughter ions arising from parent ions that fragment in the first field-free region (7):

1. V, fixed; Scan B and E, keeping the ratio B/E constant
2. E, fixed; Scan B and V, keeping the ratio B^2/V constant
3. B, fixed; Scan E and V, keeping the ratio E^2/V constant

Scan 1 is the most convenient, because the ion optics in the ion source are inevitably defocussed whenever the accelerating voltage is changed. The Kratos model 890 allows scan 1 to be performed under computer control, i.e., B and E are automatically scanned from low to high values such that their ratio is held constant.

Azoxybenzene

Azoxybenzene had been thoroughly studied by Waddell *et al.* and was included in this work as a standard for comparison. The compositions of all major ions in the EI spectrum were confirmed: see Table 1. Peak matching on the ion at m/z 170 showed this peak to be somewhat asymmetrical. While the chief contributor to this ion is clearly $(M - CO)^+$: m/z 170.0794, there was also a small contribution from an ion having mass ca. m/z 170.06–170.07, possibly $(M - CH_2N)^+$: see Fig. 1.

Tandem mass spectrometry provided evidence in support of the fragmentation scheme previously proposed (Scheme 1). The significant omission from Scheme 1 is m/z 182, $C_{12}H_{10}N_2$. This ion is formed by chemical reduction prior to ionization, and hence represents the molecular ion of azobenzene. Thus m/z is absent from the EI spectrum of azoxybenzene, showing that loss of an oxygen atom is not a reaction of the azoxybenzene cation radical.

The daughter ion scan of m/z 182 is very similar to the EI spectrum of azobenzene.

m/z 182 → 170; 142; 105; 77

TABLE 1. Major ions in the EI spectrum of azoxybenzene

m/z (%)	Composition
198.0795 (28.7)	$C_{12}H_{10}N_2O$
197.0714 (2.8)	$C_{12}H_9N_2O$
182.0839 (3.2)	$C_{12}H_{10}N_2$
170.0825 (6.6)	$C_{11}H_{10}N_2$
169.0748 (9.2)	$C_{11}H_9N_2$
142.0772 (3.1)	$C_{11}H_{10}$
141.0711 (6.7)	$C_{11}H_9$
115.0548 (3.2)	C_9H_7
105.0462 (19.9)	$C_6H_5N_2$
93.0442 (6.4)	C_6H_5O (major)
91.0410 (28.2)	C_6H_5N
78.0436 (8.1)	C_6H_6
77.0403 (100)	C_6H_5

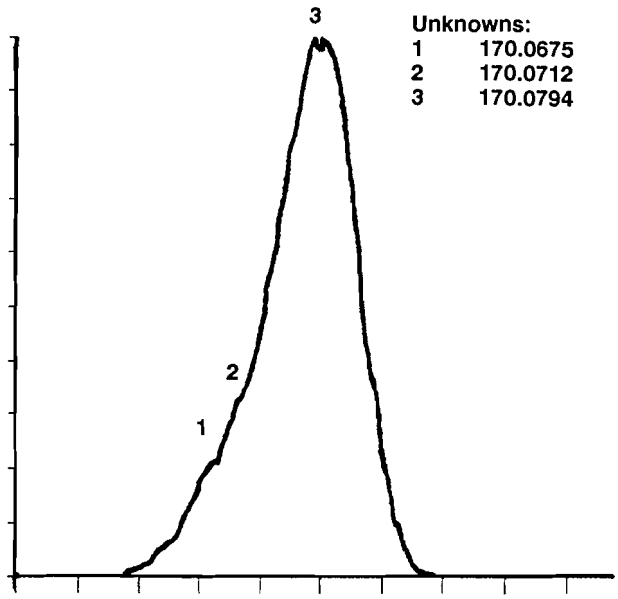

FIG. 1. High resolution peak matching scan of m/z 170 in azoxybenzene.

m/z 198 → 170; 142; 105; 77
169; 142; 141; 115; 93; 91; 77
142; 141; 115; 93; 91; 77

SCHEME 1

Thus m/z 170, 142, 105, and 77 are prominent ions in the mass spectra of both azoxybenzene and azobenzene, as shown by the daughter ion fragment scans on both m/z 198 and 182. By contrast, m/z 91, C_6H_5N, appears to be truly characteristic of azoxybenzene, since it is absent from the spectrum of azobenzene.

Phenylazoxypyridine-N-oxides

The four isomers studied were Ph-N=N(O)-3-PyO, **3**; Ph-N(O)=N-3-PyO, **4**; Ph-N=N(O)-4-PyO, **5**; and Ph-N(O)=N-4-PyO, **6**. Their EI spectra are summarized in Table 2, and a representative EI spectrum is shown in Fig. 2.

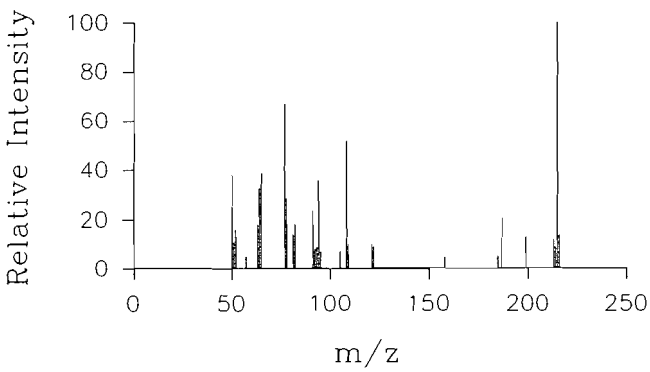

FIG. 2. EI spectrum of compound **5**.

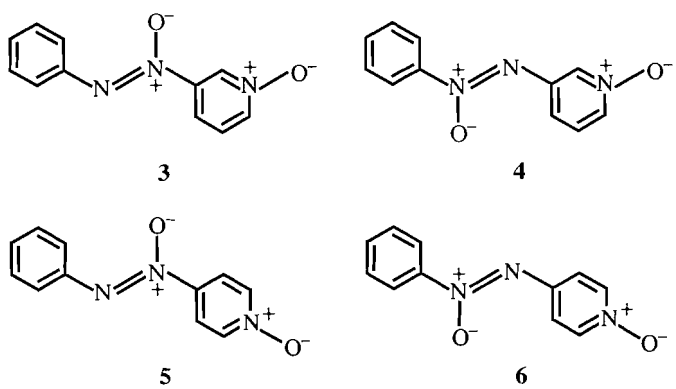

3 **4**

5 **6**

All four isomers show strong molecular ions and significant $[M - O]^+$ peaks, leading us to anticipate the occurrence of pre-ionization chemical reduction. In addition to $[M - O]^+$ peaks (*m/z* 199), $[M - O_2]^+$ peaks were observed at lower intensity at *m/z* 183. Linked scans showed that *m/z* 199 and 183 were both, in all cases, chemical reduction products, since they were absent from the daughter ion spectrum of *m/z* 215; likewise *m/z* 183 did not appear in the daughter ion spectrum of *m/z* 199. Thus both the pyridine-*N*-oxide function and the azoxy bridge *N*-oxide are subject to chemical reduction in the ion source. Tandem mass spectrometry showed that by contrast the appearance of *m/z* 198 $[M - OH]^+$ does result from direct fragmentation of the molecular ion, and is not loss of H from *m/z* 199.

As for azoxybenzene and its derivatives, strong Ar^+ and Ar'^+ ions were observed for the phenylazoxypyridine-*N*-oxides, with *m/z* 77 frequently the base peak of the EI spectrum. The ratio Ar^+/Ar'^+ was obtained for all isomers.

Isomer	Intensity ratio, *m/z* 77: 94
3	4.2
4	14.
5	2.0
6	10.

Although all isomers had much greater intensity at *m/z* 77 ($C_6H_5^+$) than 94 ($C_5H_4NO^+$), these four phenylazoxypyridine-*N*-oxides conform to the rule proposed by Bowie *et al.* that fragmentation tends to be favoured, in a relative sense, at the Ar—N bond closer to the azoxy N—O function. Thus compounds **3** and **5** showed a relatively greater extent of fragmentation to give $C_5H_4NO^+$ than their positional isomers **4** and **6**. However, it would be necessary to have both isomers available to distinguish them on this basis. The Bowie *et al.* "rule of thumb" holds true for these azoxy compounds despite the incursion of pre-ionization chemical reduction.

An ion at nominal mass *m/z* 171 was observed as a direct fragmentation product of the molecular ions of all four phenylazoxypyridine-*N*-oxides, but in no case was there a good match between the experimental mass and the calculated mass of any likely fragment. Peak matching indicated that these ions were actually composites of $C_{10}H_9N_3^+$ and $C_{10}H_7N_2O^+$, although in very different ratios. $C_{10}H_9N_3^+$ is clearly a product of deep-seated rearrangement of the molecular ion, since its composition implies $[M - CO_2]^+$; $C_{10}H_7N_2O^+$ requires the loss of CH_2NO from the molecular ion.

	Composition of *m/z* 171
Isomer	Intensity ratio $C_{10}H_9N_3^+/C_{10}H_7N_2O^+$
3	0.6
4	0.1
6	12

Isomer **5** gave too weak a signal at *m/z* 171 to allow the peak matching experiment to be done. Another difference in the mass spectral behaviour of **5** compared with the other isomers was that **5** was the only one to show evidence of the secondary fragment $[M - CHN_2O]$ at *m/z* 158, corresponding to *m/z* 141 in azoxybenzene.

In the case of the *m/z* 171 ion observed from isomer **4**, the $[M - CH_2NO]$ pathway was the predominant one. In

addition, the EI spectrum of isomer **4** showed a distinctive ion at *m/z* 172, which was identified as the related species $(C_{10}H_8N_2O)^+$, i.e., $[M - HCNO]^+$. It is tempting to ascribe this ion to extrusion of HCNO from the pyridine-*N*-oxide ring, but there is no experimental evidence to support this speculation.

In some respects there were differences in the mass spectroscopic behaviour of the pair of pyridine-3-*N*-oxides compared with the 4-*N*-oxide isomers. For example, both **5** and **6**, the pyridine-4-*N*-oxides, had prominent fragment ions at *m/z* 108 $(C_5H_4N_2O)^+$, i.e., $[M - C_6H_5N]$, which were absent in the EI spectra of the pyridine-3-*N*-oxide isomers. Isomer **5** was the only phenylazoxypyridine-*N*-oxide to show an ion at *m/z* 187 (M − CO), corresponding to *m/z* 170 in the spectrum of azoxybenzene. The daughter ion scan on the molecular ion of the azoxy compound **5** afforded *m/z* 187 (M − CO), 131, and 122, although in the presence of helium as collision gas *m/z* 187 and 108 $(C_5H_4N_2O)$ were the most intense fragments. Similarly, *m/z* 187 yielded *m/z* 170, 158, 109, and 108 (Fig. 3). Fragmentation of the molecular ion $\mathbf{6}^+$ also gave chiefly *m/z* 187 and 108, even though *m/z* 187 was of very low intensity in the EI spectrum.

The daughter ion mass spectrum of the molecular ion $\mathbf{3}^+$ afforded *m/z* 198 $(M - OH)^+$, 171, and 121. The ions at *m/z* 105 and 93, which are prominent in the EI spectrum of **3**, were absent from the daughter ion mass spectrum of the molecular ion $\mathbf{3}^+$. Instead, they are fragmentation products of *m/z* 199, thus explaining their presence in the EI spectrum of **3** as due to the chemical reduction product [M − O]. However, it is not possible to tell which *N*-oxide function of the parent ion had been reduced to afford *m/z* 199. A fragment ion scan of *m/z* 171 also failed to produce ions at *m/z* 105; instead, *m/z* 143 and 115 were the most abundant products.

The fragment ion spectrum of $\mathbf{4}^+$ (*m/z* 215) included *m/z* 198 (M − OH), 186 (M − CHO), 172 (M − HCNO), 147, 143, 105, 91, and 77. In turn, *m/z* 172 afforded *m/z* 143 and 117, while the chemical reduction product at *m/z* 199 gave rise to *m/z* 182, 170, 147, and 105. Once again, some of these ions could therefore be associated fairly unambiguously with either the azoxy compound or its chemical reduction product, but others were common to both spectra.

In the case of **5**, the most abundant fragment from *m/z* 199 appeared at *m/z* 121, while *m/z* 183 fragmented into several species (*m/z* 168, 142, 140, 130, 109, 105, and 92), many of which were of extremely low intensity in the original EI spectrum. The behaviour of the chemical reduction products of compound **6** was more like that of **3**: the most abundant fragment from *m/z* 199 appeared at *m/z* 105, with less intense peaks at m+/z 171 and 122, while *m/z* 183 fragmented rather cleanly into *m/z* 105.

Conclusions

The present results represent the first mass spectrometric study of azoxypyridine derivatives. They show that phenylazoxypyridine-*N*-oxides undergo pre-ionization chemical reduction in the ion source of the mass spectrometer, and hence that their EI spectra are a superposition of the spectra of the substrate and its singly and doubly deoxygenated products. Tandem mass spectrometry is currently the preeminent method for establishing which mass spectral peaks belong to the substrate and which to impurities including, as in this study, impurities introduced through chemical reduction in the ion source of the mass spectrometer.

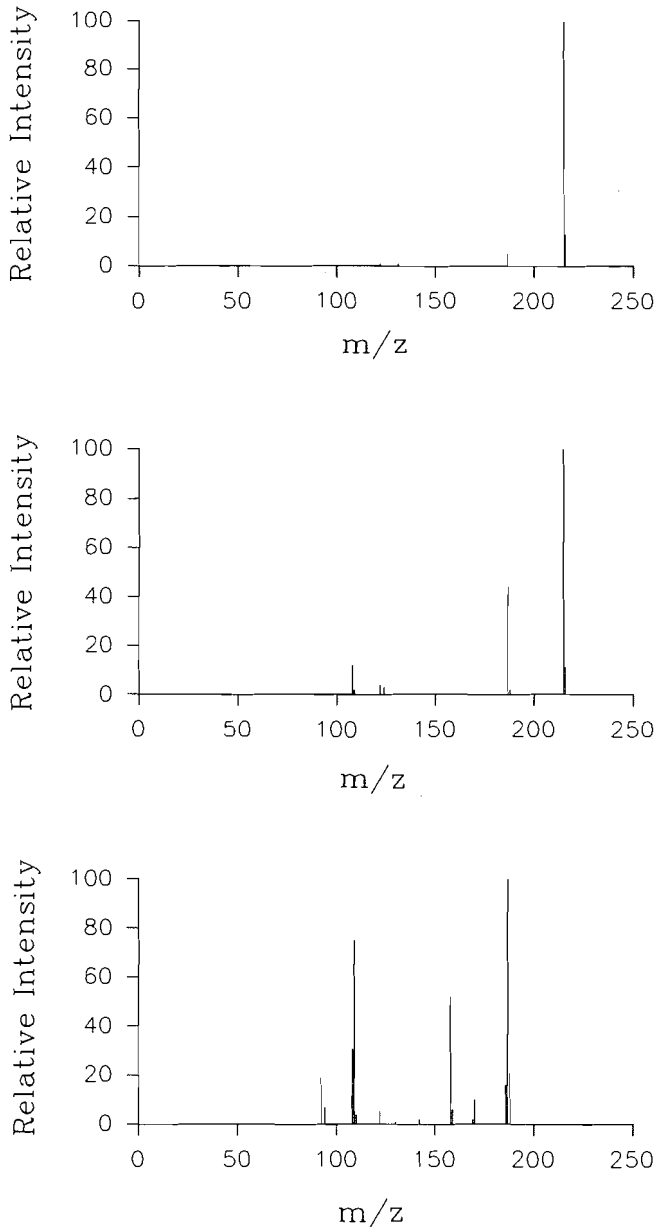

FIG. 3. Daughter ion (B/E) spectra of compound **5**; (top) from the molecular ion without collision gas; (middle) from the molecular ion with helium collision gas; (bottom) from *m/z* 187.

From the analytical perspective, the incursion of pre-ionization chemical reduction implies that the relative intensities of ions in the EI spectra of aromatic azoxy compounds and other *N*-oxides will depend on the conditions in the ion source, and hence upon the operating parameters and also on the instrument used. This would be important in library searching of the spectra of aromatic azoxy compounds and other *N*-oxides, where the exactness of the match between the experimental and the library spectra depends upon relative peak intensities. However, despite this caveat, the dominant fragmentation pathway into Ar^+ ions still permits some distinction of the position of the azoxy oxygen atom on the azo bridge in this series of compounds.

The structure of one of these compounds was previously

For personal use only.

unambiguously determined by X-ray crystallography (6). However, it is not possible to draw structural inferences for several reasons. Comparative X-ray analyses are not available for the complete series of compounds. Even if they were, it would not be profitable to compare the structures of high-energy gas-phase cations based on information obtained from their crystalline neutral counterparts. Despite differences in the detailed pathways and the presence or absence of specific ions in the spectra of the individual phenylazoxypyridine-*N*-oxides, the picture that emerges from the EI spectra as reported in Table 2 is that the mass spectra of these isomers are broadly similar. Differences are more easily visualized in the fragment ion spectra, as shown by the summary scheme below:

Ions formed directly from the molecular ions (m/z 215) of phenylazoxypyridine-*N*-oxides

G. W. BUCHANAN, A. RODRIGUE, C. BENSIMON, and C. I. RATCLIFFE. Can. J. Chem. **70**, 1033 (1992).

The title complex has two distinct 18-crown-6 moieties of approximate D_{3d} symmetry in the unit cell. The 45.3 MHz ^{13}C CPMAS spectra have two regions of broadening for the crown ether carbons. At high temperatures a dipolar washout mechanism is operative, leading to broadening when molecular motion has a correlation time approximately equal to the inverse of the decoupling field. At lower temperatures broadening occurs when the motional correlation time is equal to the inverse of the chemical shift difference. The activation energy for 18-crown-6 reorientation in this solid is calculated to be ca. 48 kJ/mol. For the chloroacetonitrile, the CH_2 carbon also shows dipolar washout, but at a temperature much lower than the 18-crown-6. The activation energy for reorientation for this "guest species" is ca. 42 kJ/mol.

G. W. BUCHANAN, A. RODRIGUE, C. BENSIMON et C. I. RATCLIFFE. Can. J. Chem. **70**, 1033 (1992).

L'unité asymétrique du complexe mentionné dans le titre comprend deux portions distinctes d'éthers 18-couronnes-6 de symétrie se rapprochant de D_{3d}. Les spectres RMN du ^{13}C, à 45,3 MHz, par la technique de la polarisation croisée avec rotation à l'angle technique, présentent deux régions d'élargissement pour les carbones de l'éther couronne. À température élevée, il existe un mécanisme de déplacement dipolaire qui conduit à un élargissement lorsque le temps de corrélation d'un mouvement moléculaire est approximativement égal à l'inverse du champ de découplage. À des températures plus faibles, l'élargissement se produit lorsque le temps de corrélation du mouvement est égal à l'inverse de la différence du déplacement chimique. On a calculé que l'énergie d'activation de la réorientation de l'éther 18-couronne-6 est d'environ 48 kJ/mol. Pour le chloroacétonitrile, le carbone du CH_2 présente aussi un déplacement dipolaire; on l'observe à une température beaucoup plus faible que pour l'éther 18-couronne-6. L'énergie d'activation pour la réorientation de cette «espèce invitée» est d'environ 42 kJ/mol.

Introduction

Dynamic stereochemical phenomena in solid 18-crown-6 ether and several complexes were observed previously via variable temperature ^{13}C CPMAS NMR spectroscopy in these laboratories (1–4). In the case of the 1:1 complex of 18-crown-6 with benzenesulfonamide, independent motions for guest and host species can be detected (3). Recently, we became interested in the ability of 18-crown-6 to complex small neutral halogenated molecules, and isolated and characterized via X-ray crystallography the 2:1 fluoroacetonitrile–18-crown-6 complex (5). In the present work, we report the X-ray structure and the ^{13}C solid phase NMR spectra as a function of temperature for the 2:1 complex of chloroacetonitrile with 18-crown-6 ether, a material whose preparation was previously reported (6) but for which no detailed structural data are available. Evidence is presented for independent reorientational motion in the 18-crown-6 and the chloroacetonitrile moieties. At 230 K, the observed ^{13}C chemical shift pattern for the crown ether carbons is rationalized in terms of torsional angle influences on ^{13}C shieldings.

Results and discussion

NMR spectra

Figure 1 contains the complete 45.3 MHz ^{13}C CPMAS spectra of the 2:1 chloroacetonitrile–18-crown-6 complex **1**, over the temperature range of 335–270 K. In Fig. 2 are presented the spectra of the crown ether carbon region for temperatures ranging from 260 to 230 K.

At 290 K, the ^{13}C solid phase spectrum of **1** shows three resonances at 119.1, 70.0, and 27.2 ppm respectively. In $CDCl_3$ solution at the same temperature there are also three resonances in the ^{13}C NMR spectrum with shifts of 116.7, 70.7, and 25.8 ppm, corresponding to the CN, CH_2O, and CH_2CN carbons respectively. Hence there appear to be no major chemical shift differences between the solution and solid phase spectra for this material at ambient temperature. In CD_2Cl_2, the ^{13}C NMR spectrum of **1** is essentially independent of temperature over the range of 300–173 K.

By contrast, the solid phase spectra show substantial temperature dependence (Figs. 1 and 2). As one proceeds up in temperature from 290 K, the resonance for the CH_2O carbon of the crown ether moiety essentially disappears at 310 K, to reappear with increasing intensity and sharpness as the high-temperature limit of 335 K is reached. This behaviour is reminiscent of that found in the 18-crown-6 moiety of the 1:1 benzenesulfonamide complex (3) and can be attributed to a "dipolar washout" phenomenon (7). When molecular motion has a rate such that the correlation time for the C–H vector, τ_C, is the inverse of the ^1H decoupling field amplitude, then the decoupler is rendered ineffective because of destructive interference between the incoherent spatial modulation due to motion and the coherent spin-space modulation provided by the rf of the ^1H decoupler. This results in a very broad dipolar coupled ^{13}C spectrum.

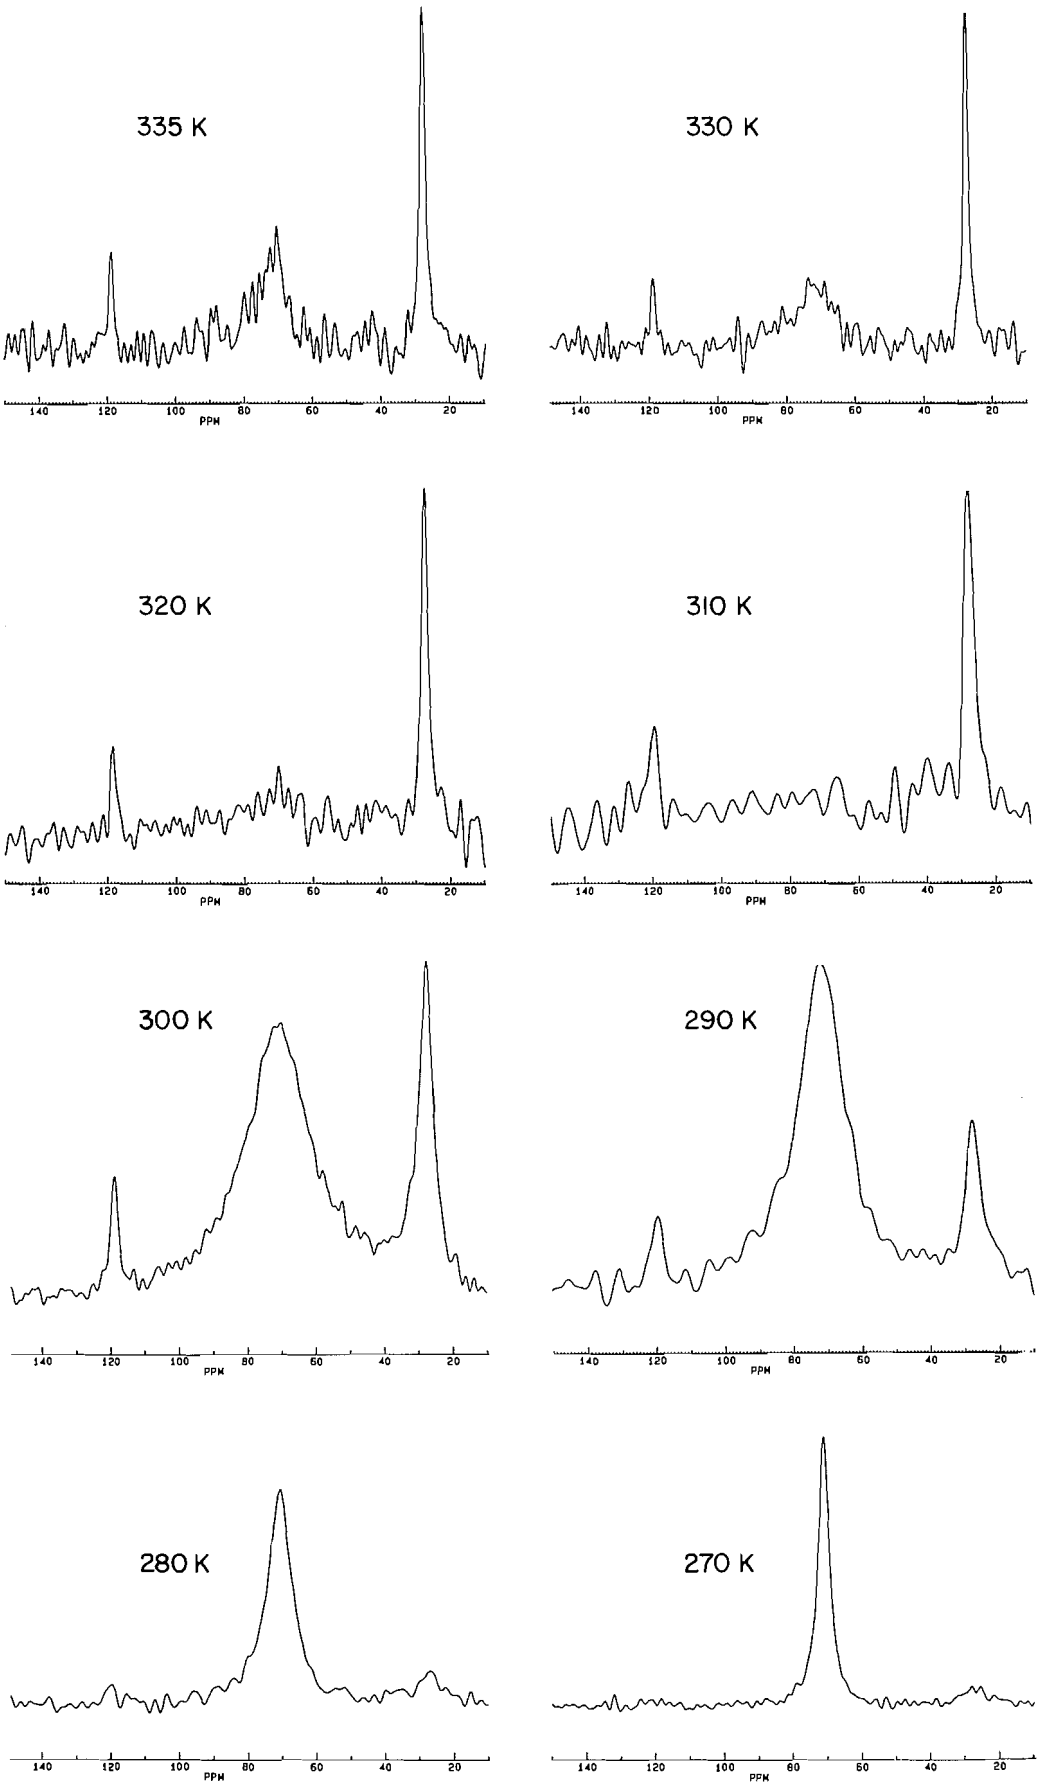

FIG. 1. Complete 45.3 MHz ^{13}C CPMAS NMR spectrum of **1** as a function of temperature.

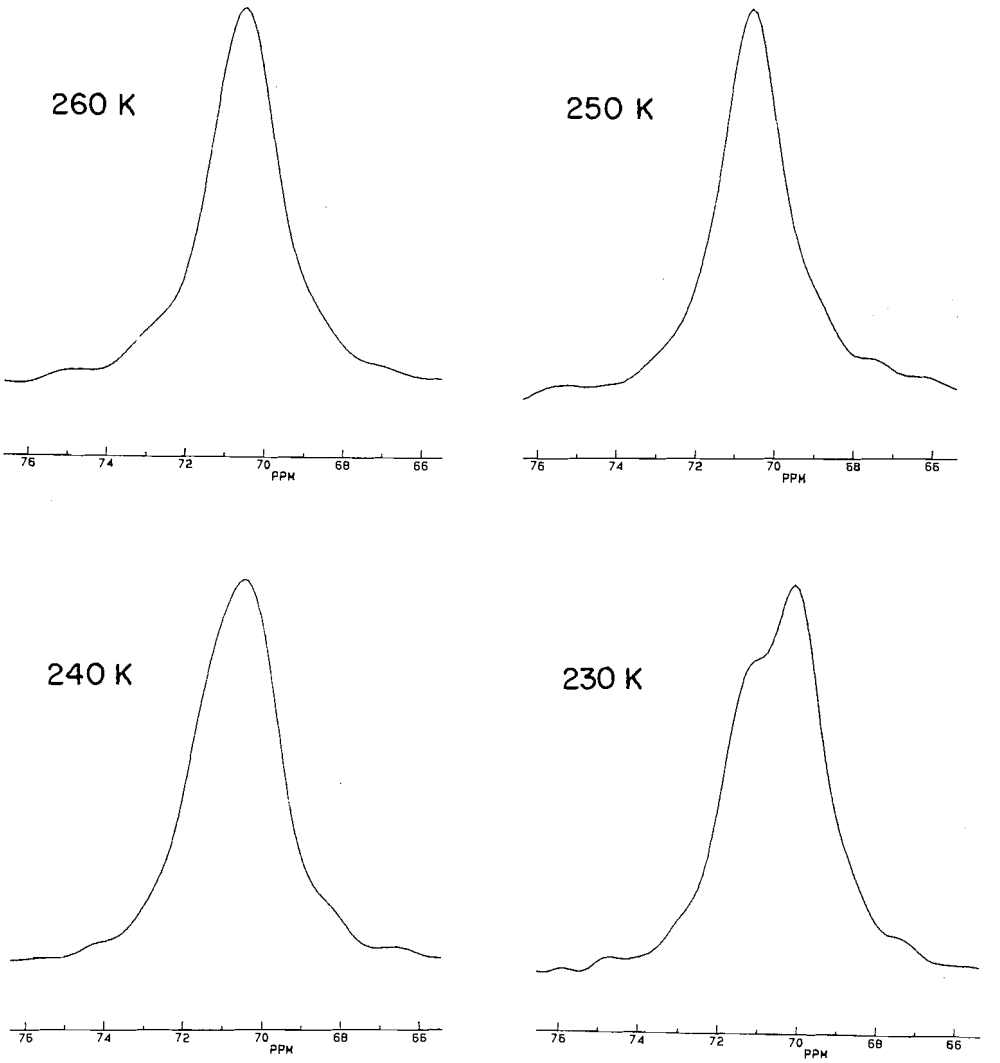

FIG. 2. Expanded crown ether carbon region of ^{13}C CPMAS NMR of **1**.

In the present experiment, the decoupling field amplitude is 60 kHz, so that $\tau_C = \frac{1}{2}\pi\gamma H_1 = \frac{1}{2}\pi \times 60$ kHz $= 2.7 \times 10^{-6}$ s. An estimate of the barrier for this process can be obtained by application of the Waugh–Fedin approximation (8). Employing a temperature of 310 K, the value obtained is ca. 48 kJ/mol.

Below 240 K, a more subtle broadening of the 18-crown-6 carbon resonance occurs (Fig. 2), until two discernible resonances are observed with shifts of 70.0 and 71.1 ppm, at the low-temperature limit of 230 K. Below this temperature, the rate of interconversion between conformations of the solid 18-crown-6 is slow relative to the chemical shift difference (in Hz) between conformationally nonequivalent carbons.

From Fig. 1 it is evident that the CH_2 carbon of the chloroacetonitrile moiety undergoes a dipolar washout near 270 K. Application of the Waugh–Fedin approximation in this case leads to a barrier for reorientation of the $ClCH_2CN$ part of the complex of ca. 42 kJ/mol.

X-ray crystallographic structure

The ORTEP plot and numbering scheme for the unit cell of **1** are depicted in Fig. 3. Table 1 contains the atomic parameters, while bond distances and bond angles are collected in Tables 2 and 3 respectively. There are two different 2:1 complexes present in this unit, both of which possess effectively D_{3d} symmetry in the 18-crown-6 ether ring. The torsion angles for the asymmetric units of the upper and lower complexes (as depicted in Fig. 3) are listed in Table 4. From these data it is evident that all the C—O—C—C networks are within 5° of a pure *transoid* geometry with the exception of C8—O5—C9—C10 where the dihedral angle contracts to 164.2°. All the O—C—C—O networks are *gauchoid*, with angles ranging from 64.0° to 76.5°.

It is of interest to compare the intermolecular C—H---O distances found in **1** to those for related complexes. With the exception (5) of the fluoroacetonitrile complex where these distances are very long (2.89 Å) relative to the sum of the van der Waals radii (2.6 Å) (9), the usual range is from 2.2 to 2.7 Å. For the 2:1 malononitrile–18-crown-6 complex (10), the distances are 2.23 and 2.69 Å respectively, while for the 2:1 acetonitrile–18-crown-6 case (11), the values are 2.43, 2.53, and 2.67 Å. For **1** the intermolecular C—H---O distances are listed in Table 5. The strongest interaction in **1** is between H15B and O6 where the distance is only

2.288 Å. By contrast, the weakest interaction is between H13A and O2 where the distance is found to be 2.787 Å.

To discuss the limiting low-temperature ^{13}C NMR spectrum of the crown ether carbons, it is instructive to examine the torsional environments for each carbon on an individual basis. Each carbon will be present in four networks (ignoring hydrogens), which can be denoted as O—C*—C—O, C*—O—C—C, C—O—C*—C, and C—O—C—C*. Table 6 lists the torsional environments for the individual carbons described via this procedure.

In Figs. 4 and 5 are presented results of GIAO (12–14) calculations of the dihedral angle dependence of ^{13}C NMR shieldings for the above four structural units using ethylene glycol as a model for the O—C*—C—O network and ethylmethyl ether as a model for the other three structural entities. In these calculations, the absolute scale is used wherein chemical shifts increase with increased shielding. On this scale, methane occurs at 221.0 ppm, whereas on the usual TMS scale it appears at −2.1 ppm.

Examination of these figures indicates that expansion of the O—C*—C—O angle above 60° leads to deshielding until an angle of ca. 90° is reached. Also contraction of the C—O—C—C angle below 180° leads to deshielding at all three carbons until an angle of ca. 120° is obtained. Thus by examining the relative deviations from 60° and 180° for each carbon and the calculated shielding change, one can obtain an order of anticipated deshielding for the crown ether carbons in the limiting low-temperature ^{13}C spectrum of solid **1**. Using this method, one concludes that C8, C9, C10, C11, and C12 should be slightly (1–2 ppm) deshielded relative to the other seven carbons. Hence the appearance of the broad doublet of relative component intensity (from peak heights)

of 5:7, at 71.2 and 70.0 ppm respectively at 230 K, is in accord with expectations. The observed chemical shift difference of 1.2 ppm in **1** is similar to that found in other 18-crown-6 complexes that possess D_{3d} or pseudo D_{3d} symmetry (1). The relative intensities differ in each case, however, depending on the number of carbons in each type of environment.

Clearly, the relatively broad resonances in the ^{13}C CPMAS spectrum preclude a more detailed analysis of the data. Although we have analysed the shielding trends in terms of torsion angle influences, it is possible that steric and electronic effects of the chloroacetonitrile may also play a role in determining the observed ^{13}C chemical shift differences of the crown ether carbons.

The activation parameters obtained for the $ClCH_2CN$ and 18-crown-6 motions must of course represent averages of the values for the two different components of the unit cell of the crystal. Based on the geometries of the structures obtained, however, it is reasonable to suggest that the motional parameters do not vary substantially for the two different molecules of the complex present in the unit cell.

Experimental

Spectra

The ^{13}C CPMAS solid phase spectra were recorded at 45.3 MHz on a Bruker CXP-180 instrument. Cross polarization (CP) times were typically 3 ms with the radio frequency field amplitude being 60 kHz. Normally 400 accumulations were collected. The sweep width was 20 kHz with a recycle time of 4–8 s. 2K data points were collected with zero filling to 8K before Fourier transformation. Magic angle spinning (MAS) rates of ca. 3 kHz were obtained using Kel-F spinners of the Andrew–Beams type. Chemical shifts were measured relative to external solid hexamethylbenzene (HMB) and converted to the TMS scale via the factor of 16.9 ppm, which is the chemical shift for the CH_3 group of HMB.

Crystallographic measurements and structure solutions

A summary of the crystal data is given in Table 7. Diffraction intensities were collected on a Rikagu diffractometer using MoKα

radiation at room temperature. The $\Theta/2\Theta$ scan technique with profile analysis (15) was employed at a speed of $4°/\Omega$. The space group was determined by systematic absences. Unit cell parameters were obtained by refinement of the setting angles of 24 reflections with 2Θ angles in the range of 30–47°. Lorentz and polarization factors were applied but no correction for absorption was made.

Structures were solved by direct methods plus Fourier maps and were refined by full-matrix least-squares analysis with weights based on counting statistics. The last least-squares cycle was calculated with 54 atoms, 236 parameters, and 856 out of 2007 reflections. Non-H atoms were refined anisotropically. H atoms were calculated. All calculations were performed using the NRC VAX Crystal Structure programs (16). Anisotropic thermal parameters are available as supplementary data.[2]

Materials

The 2:1 chloroacetonitrile–18-crown-6 complex **1** was prepared via the following procedure. To 18-crown-6 (1.06 g, 4.0 mmol) dissolved in 15 mL of ethyl acetate was added 1.0 mL of chloroacetonitrile followed by 40 mL of 30–60°C petroleum

A group equivalents scheme for free energies of formation of organic compounds in aqueous solution

J. PETER GUTHRIE
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received February 13, 1991[1]

J. PETER GUTHRIE. Can. J. Chem. **70**, 1042 (1992).

Group contributions have been determined allowing the calculation of free energies of formation in aqueous solution for organic compounds containing carbon, hydrogen, and oxygen. The system works well for monofunctional compounds. The available literature data for 198 compounds can be accommodated using 79 parameters with an rms deviation of 0.74 kcal/mol.

J. PETER GUTHRIE. Can. J. Chem. **70**, 1042 (1992).

On a déterminé les contributions de groupes permettant de calculer les énergies libres de formation, en solution aqueuse, de composés organiques contenant du carbone, de l'hydrogène et de l'oxygène. Le système fonctionne bien avec les composés monofonctionnels. Utilisant 79 paramètres, on peut accommoder les données disponibles dans la littérature pour 198 composés avec un écart tmr de 0,74 kcal/mol.

Introduction

We have made frequent use of thermodynamics calculations as a tool in investigating organic reaction mechanisms (1–13). The traditional way of carrying out these calculations is to determine, experimentally or by estimation, $\Delta H_f^0(g)$, $S^0(g)$, and ΔG_t, and then from these to calculate $\Delta G_f^0(aq)$. ΔG_t is the free energy of transfer of a compound from the gas at 1 atm (101.3 kPa) to 1 M aqueous solution. We will use as standard states the ideal gas at 1 atm and 1 M aqueous solution with an infinitely dilute reference state. Estimation by Benson's group additivity scheme (14) is generally reliable for $\Delta H_f^0(g)$ and $S^0(g)$ of simple compounds, and parameters reported by Hine and Mookerjee (15) allow calculation of ΔG_t. We have found it extremely convenient to generate group contribution parameters allowing direct estimation of $\Delta G_f^0(aq)$. Such parameters would allow direct calculation of equilibrium constants in solution. The present paper reports a set of these parameters for compounds of carbon, hydrogen, and oxygen, tested against the available data base of monofunctional compounds for which experimental values are available. An advantage of parameterizing for $\Delta G_f(aq)$ directly is that equilibrium constants in solution can be used as additional sources of information permitting calculation of new parameters (16). This approach will be employed in a few cases in this work, although exploiting its full potential will be a major undertaking.

At present this treatment is restricted to monofunctional compounds, because in polyfunctional compounds there are important distant polar interactions (15) that require more elaborate treatment.

Results

We began by calculating contributions to $\Delta G_f^0(aq)$ for all groups for which contributions to $\Delta H_f^0(g)$, $S^0(g)$, and ΔG_t were available from the literature. These lead to the values found in Table 1. In a number of cases we could fill in missing group equivalents by use of recent thermochemical data for compounds containing groups for which contributions have not been reported; these group equivalents are also found in Table 1, and the thermodynamic data upon which they are based are found in Table 2. Table 2 is a compilation of free energies of formation in aqueous solution for monofunctional compounds. In several cases we could, by measuring ΔG_t values or calculating them from data in the literature, fill in missing terms and calculate contributions to $\Delta G_f^0(aq)$; such values are also found in Table 1. The ΔG_t values used are found in Table 2. Then we estimated entropy contributions where this was the only thing missing, and where standard estimation procedures looked reasonable, and so filled in more missing terms; these values as well are in Table 1, with suitable cautionary indications. Still more terms could be added by making use of equilibrium constant data. The equilibrium constants are found in Table 3, and led to free energies of formation in aqueous solution, which are found in Table 2. Table 2 also includes values calculated using the parameters in Table 1.

We now turn to a detailed description of the calculations required to complete these tables.

We assume that the heat of vaporization of 3-hexanol will be very similar to that of 2-hexanol, based on their very similar boiling points, 134.5–135.5 and 136 respectively, and the known relationship between boiling point and heat of vaporization (17, 18), and use the value for 2-hexanol (19) as an approximation.

Entropy estimations

The standard entropy of gaseous trans-*2-heptene* was estimated from the value reported for *trans*-2-pentene (20) by adding twice the contribution for $[CH_2(C)_2]$. For *1,5-hexadiene, 2,3-dimethyl-1,3-butadiene, 1-methylcyclohexene, 2-methyl-1-propanol, 2-methyl-1-butanol, 3-methyl-1-butanol, 4-methyl-2-pentanol, 4-methyl-3-pentanol, cyclopentanol,* and *cycloheptanol* values were estimated using Benson's additivity scheme (14). Entropies for *propanoic, butanoic, pentanoic, hexanoic,* and *heptanoic acids* were estimated from the value for acetic acid, by adding increments of $[CH_2(C)(CO)]$ and $[CH_2(C)_2]$. It is distressing that the one literature value, that for pentanoic acid, deviates seriously from expectation, being 105.12 (21) where the estimated value is 95.9 cal deg^{-1} mol^{-1}. The literature value is calorimetric. We feel that it is more likely that the additivity derived value is correct, but clearly there is a need for

[1]Revision received October 10, 1991.

"All at 25°C; enthalpies and free energies are in kcal mol^{-1}, entropies are in cal deg^{-1} mol^{-1}, standard states are the ideal gas at 1 atm and 1 M aqueous solution with an infinitely dilute reference state. Unless otherwise noted, group contributions to $\Delta H_f^0(g)$ and $S^0(g)$ are from ref. 14, group contributions to ΔG_t are calculated from the contributions to log(γ) in ref. 15, and group contributions to $\Delta G_f^0(g)$ and $\Delta G_f^0(aq)$ are calculated from other values in this table. Symbols identifying the groups are as used by Benson (14). C_d is a doubly bonded carbon, C_t is a triply bonded carbon, C_B is a carbon that is part of one aromatic ring, C_{BF} is a carbon that is at the ring fusion of a fused ring aromatic system.

[b] Based on ΔG_t for 3-methyl-1-butene (22).

[c] Provisionally taken as equal to $[C(C)_3(C_B)]$.

[d] Based on ΔG_t for styrene (8).

[e] Based on ΔG_t for diphenyl (22).

[f] Based on $\Delta H_f^0(g)$ for diphenymethane (24).

[g] Based on $S^0(g)$ for diphenylmethane, Table 2.

[h] Based on ΔG_t for diphenylmethane (22).

[i] Based on ΔH_f^0 for triphenylmethane (24).

[j] Based on $S^0(g)$ for triphenylmethane, Table 2.

[k] Based on ΔG_t for triphenylmethane, this work.

[l] Based on ΔH_f^0 for tetraphenylmethane (24).

[m] Based on $S^0(g)$ for tetraphenylmethane, Table 2.

[n] Based on ΔG_t for tetraphenylmethane, Table 2.

[o] Assigned, as $[C_dH(C_B) \equiv [C_dH(C_d)]$, after Benson (55).

[p] Based on ΔG_t for α-methylstyrene (8).

[q] Based on ΔG_t for butenyne (22).

[r] Assigned, as $[C_dH(C_t)] \equiv [C_dH(C_d)]$, after Benson (55).

[s] This value (55) differs from that in Benson's book (14), but it is not clear what the origin of the more recent value is. The older value seems to give better agreement with experiment and is used here.

[t] Based on S^0 for dimethoxymethane (20).

[u] Based on equilibrium constants for acetal formation, Table 3.

[v] Based on equilibrium constants for ketal formation, Table 3.

[w] Based on ΔG_t for 2,2-dimethoxypropane, evaluated in this work.

[x] Based on ΔH_f^0 for trimethyl orthoformate (24).

[y] Provisionally assumed to be equal to $[CH(C)_3]$. No entropy data could be found to allow evaluation.

[z] Based on ΔG_t for trimethyl orthoformate (1).

[aa] Based on ΔH_f^0 for trimethyl orthoacetate (24), including allowance for two *gauche* interactions (14).

[ab] Provisionally assumed to be equal to $[C(C)_4]$. No entropy data could be found to allow evaluation.

[ac] Based on ΔG_t for trimethyl orthoacetate (1).

[ad] Based on $S^0(g)$ for benzyl alcohol, calculated from S^0 (l) (20), ΔH_{vap} (24), and the vapor pressure, estimated as described in the text.

[ae] Based on ΔG_t for benzyl alcohol (62).

[af] Based on the equilibrium constant for benzaldehyde dimethyl acetal, Table 3.

[ag] Based on the equilibrium constant for acetophenone dimethyl ketal, Table 3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 79.173.37.17 on 09/08/12

TABLE 1 (*concluded*)

[ah] Based on ΔH_f^0(g) for trimethyl orthobenzoate (5).
[ai] Provisionally assumed to be equal to $[C(C_B(C)_3]$. No entropy data could be found to allow evaluation.
[aj] Based on ΔG_t for trimethyl orthobenzoate (5).
[ak] Based on S^0(g) for allyl alcohol (20).
[al] Revised value: the value in ref. 16 is incorrect as a result of a computer programming error.
[am] Based on fitting ΔG_f^0(aq) for enols (16).
[an] Based on the equilibrium constant for 1-phenyl-1-ethenol formation, Table 3.
[ao] Assigned, as $[OH(C_d)] \equiv [OH(C_B)] \equiv [OH(C)]$, after Benson (55, 63). As previously discussed (16), Benson's treatment of enols and enol ethers is not internally consistent. We have based our contributions to ΔG_f^0(aq) on the assignment of $[OH(C_d)]$, and have calculated $[C_dH(O)]$ and $[C_d(C)(O)]$ from experimental data (16).
[ap] Based on the equilibrium constant for formation of α-methoxystyrene (64).
[aq] Based on S^0(g) for anisole, Table 2.
[ar] Based on ΔG_t for anisole (22) and phenetole (62).
[as] Based on S^0 (l) (20) and a vapor pressure for diphenyl ether extrapolated from data in ref. 26.
[at] Based on ΔG_t for diphenyl ether, calculated from the solubility (65) and the vapor pressure (26).
[au] Based on ΔG_t values for isobutyraldehyde (62), corrected for hydration (66), for methyl isopropyl ketone (22), and for diisopropyl ketone (22).
[av] Based on S^0(g) of pivaldehyde (S^0 (l) (32), ΔH_v estimated (18) from the boiling point (26), and the vapor pressure estimated (18) from the vapor pressure, ΔH_v, and ΔC_p (27)) and pinacolone (S^0 (l) (67), ΔH_v estimated (18) from the boiling point (26), and the vapor pressure estimated (18) from the vapor pressure, ΔH_v, and ΔC_p (27, 68)).
[aw] Based on ΔG_t for pinacolone (67).
[ax] Based on ΔG_t for acetaldehyde, propanal, butanal, and methylpropanal, corrected for hydration as described in the text.
[ay] Assigned, as $[CHO(C_d)] \equiv [CHO(C_B)] \equiv [CHO(C)]$ after Benson (55, 63).
[az] Based on S^0(g) for acrolein.
[ba] Based on S^0(g) for methyl methacrylate, Table 2.
[bb] Based on ΔG_t for methyl methacrylate, evaluated in this work.
[bc] Based on S^0(g) for benzaldehyde (69).
[bd] Based on S^0(g) for methyl vinyl ketone.
[be] Based on ΔG_t for methyl vinyl ketone, 3-penten-2-one, mesityl oxide, and benzalacetone (8). Higher weights were given to the values for 3-penten-2-one and mesityl oxide.
[bf] Based on S^0(g) for acetophenone (20).
[bg] Assigned, as $[CHO(O)] \equiv [CHO(C)]$ after Benson (55, 63).
[bh] Based on S^0(g) for acrylic acid (20).
[bi] Based on ΔG_t for acrylic acid, crotonic acid, and cinnamic acid (8).
[bj] Based on S^0(g) for benzoic acid (20).
[bk] Based on ΔG_t for benzoic acid (5) and methyl benzoate (5).
[bl] Based on ΔG_t for isopropenyl acetate, this work; until a more precise value of ΔG_t for an enol is available it is not practical to separate $[O(C_d)(CO)] + [C_d(C)(CO)]$.
[bm] Based on the equilibrium constant for formation of phenyl acetate in solution (70).
[bn] Based on S^0(g) for acetic anhydride (20).
[bo] Calculated from the group contributions to ΔG_f^0(g) and ΔG_f^0(aq).
[bp] Based on the equilibrium constant for formation of acetic anhydride in solution (71).

more experimental values for carboxylic acids. The entropies of *2-pentanol* and *3-hexanol* were estimated from that for 2-butanol (20) by adding increments for $[CH_2(C)_2]$. The entropy of *3-pentanol* was estimated from that for 2-propanol (20) by adding twice the increment for $[CH_2(C)_2]$. The entropies of *2-methyl-2-butanol* and *2-methyl-2-pentanol* were estimated from that for 2-methyl-2-propanol (20) by adding increments for $[CH_2(C)_2]$ and correcting for the loss of symmetry. The entropy for *1-ethoxypropane* was estimated from that for diethyl ether (20) by adding the increment for $[CH_2(C)_2]$ and correcting for the loss of symmetry. The entropy for *ethyl vinyl* ether was calculated from the value for methyl vinyl ether (this work, *vide infra*) by adding the increment for $[CH_2(C)(O)]$. Similarly the entropy for *phenetole* was calculated from that of anisole.

The directly measured free energy of transfer for aliphatic aldehydes refers to the process: gas to equilibrium mixture of aldehyde and covalent hydrate. Since aliphatic aldehydres are appreciably hydrated this means that the observed values are significantly different from those for the free aldehyde, which are generally the quantities of interest. We have revised the literature contributions to refer to the process: free aldehyde in the gas phase to free aldehyde in aqueous solution. To so do we used the observed free energies of transfer (22) for acetaldehyde, propanal, butanal, and 2-methylpropanal, −1.60, −1.54, −1.28, and −0.97 kcal mol^{-1} respectively, and the equilibrium constants for covalent hydration (23), K_h = [hydrate]/[free aldehyde], 1.06, 0.85, 0.65, and 0.62 respectively. ΔG_t(free) = ΔG_t(obs) + RT ln(1 + K_h), so we calculate ΔG_t(free) values of −1.23, −1.18, −0.98, −0.68 respectively. From these values we deduce $[CHO(C)_{free}] = -4.08 \pm 0.09$.

Entropy data in some cases had not been reported for the gas but had been reported for the liquid or solid. In such cases: *benzyl alcohol, diphenyl ether, tetrahydrofuran, anthracene, phenanthrene, pyrene, methacrylic acid, methyl methacrylate, methyl acrylate, diphenylmethane, triphenylmethane,* and *tetraphenylmethane,* we used the heat of vaporization at 25°C, the vapor pressure at 25°C, and the entropy of the liquid to calculate the entropy of the gas. For *benzyl alcohol,* we used the heat of vaporization (24), and a vapor pressure calculated from the Antoine parameters (25). For *diphenyl ether,* we used the entropy of the liquid (20) and

[a]All at 25°C; enthalpies and free energies are in kcal mol^{-1}, entropies are in cal deg^{-1} mol^{-1}, standard states are the ideal gas at 1 atm and 1 M aqueous solution with an infinitely dilute reference state. Unless otherwise noted, enthalpies of formation are from ref. 24, entropies are from ref. 20, and free energies of transfer are from ref. 22.

[b]Calculated from the values of ΔH_f^0 (l) (24) and ΔH_{vap} (72).

[c]Reference 62.

[d]Calculated from the values of ΔH_f^0 (l) (24) and ΔH_{vap} (73).

[e]Estimated as described in the text.

[f]Reference 20.

[g]Reference 74.

[h]Estimated value.

[i]Reference 8.

[j]Calculated from the values of ΔH_f^0 (l) (24) and ΔH_{vap} (75).

[k]Reference 76.

[l]Calculated from S^0 (l) (20), ΔH_v (24), and vp (25).

[m]This work.

[n]Calculated from the solubility (77) and the vapor pressure (25).

[o]Reference 78.

[p]Estimated as described in the text.

[q]Reference 79.

[r]Calculated from S^0 (l) (20), ΔH_v (24), and vp (25).

[s]Reference 16.

[t]Calculated from the uncertainty in ΔG_f^0(aq) for the keto tautomer (16), assuming an uncertainty of 0.1 kcal mol^{-1} in $\Delta G^0_{enol'n}$.

[u]Calculated from S^0 (l) (29), ΔH_v (24), and vp (30).

[v]Calculated from spectroscopic data as described in the text.

[w]Reference 12; these values must be regarded as provisional, because they are based on an assumed value of [C_d(C)(O)], and a similar assumption for [C_dH(O)] was inconsistent with the spectroscopic entropy of methyl vinyl ether.

[x]Calculated from the value for methyl vinyl ether by adding [CH_2(C)(O)].

[y]Calculated from S^0 (l) (67), ΔH_v (19), and vp estimated (18) from the vp (26), ΔH_v, and ΔC_p (27, 68).

[z]Calculated from structural and spectroscopic parameters as described in the text.

[aa]Calculated from S^0 (l) (20), ΔH_v (24), and vp (26).

[ab]Calculated from the solubility (65) and vp (26).

[ac]Calculated from S^0 (l) (67), ΔH_v (19), and vp (26).

[ad]Reference 69.

[ae]Calculated from the measured equilibrium constant (59).

TABLE 2 (*concluded*)

[af] Based on the equilibrium constant for cinnamaldehyde formation (60), Table 3.
[ag] Calculated for the free aldehyde as described in the text.
[ah] Reference 80.
[ai] Reference 1.
[aj] Calculated from S^0 (l) (20), an estimated ΔH_v, and vp (26).
[ak] Reference 5.
[al] Calculated from the equilibrium constants in Table 3.
[am] Calculated from S^0 (l) (20), ΔH_v (24), and vp (25).
[an] The entropy value given is based on spectroscopic data as described by the text, but leads to a free energy of formation that is not in good agreement with the prediction of our group additivity scheme, nor in good agreement with expectation based on the equilibrium free energy (86) and free energies of formation of benzoic acid and methanol. The group additivity parameters for entropy give a value of 100.28 cal deg^{-1} mol^{-1}. MM3 calculations (81) gave a value of 107.26 cal deg^{-1} mol^{-1}; MM3 gives values in good agreement with experiment for methyl acetate, benzaldehyde, and acetophenone. Using the MM3 entropy gives ΔG_f^0(aq) = −43.65 kcal mol^{-1} in satisfactory agreement with our group contribution prediction. A reinvestigation of the experimental bases for the entropy of methyl benzoate appears to be in order.

TABLE 3. Equilibrium constants leading to group contributions to free energy of formation[a]

Reaction	log K	ΔG^0
C_6H_5-CO-CH_3 + $CH_3OH \leftrightharpoons C_6H_5$-C($OCH_3$)=$CH_2$ (+H_2O)	−8.17	11.16[b]

extrapolated the vapor pressure from that at 1 Torr[2] (26), using the heat of vaporization of the liquid (24), an estimated heat capacity of vaporization (27), and a method based on that of Prausnitz (18, 28). For *tetrahydrofuran* we used the entropy of the liquid (29), the heat of vaporization (24), and a vapor pressure calculated from Antoine parameters (30). For *anthracene, phenanthrene,* and *pyrene* we used entropies for the solid (20), heats of sublimation (31), and vapor pressures calculated from Antoine parameters (25). For *methacrylic acid* and *methyl methacrylate* we used the entropies of the liquids (32), heats of vaporization estimated from the boiling points (18), and vapor pressures extrapolated from literature data (26). For *diphenylmethane* we used the entropy of the liquid (20), the heat of vaporization (33), and a vapor pressure calculated from Antoine parameters (25). For *triphenylmethane* we used the entropy of the solid (20), the heat of sublimation (24), and a vapor pressure calculated from Antoine parameters (25). For *tetraphenylmethane* we used the entropy of the solid (20), the heat of sublimation (24), and a vapor pressure calculated from Antoine parameters (25). In this case the Antoine parameters were derived for higher temperatures, so there will be an additional error from extrapolating beyond the range where they apply.

In a number of cases, no entropy value had been reported, but sufficient data were available in the literature to allow a calculation of the entropy from statistical mechanics, using structural and spectroscopic information (14, 34, 35). This was done for *acrolein, methyl vinyl ketone, anisole, methyl benzoate, methyl acrylate,* and *methyl vinyl*

ether. For *acrolein* we calculated the moments of inertia using MM2 (36) and then used vibrational frequencies (37), and the potential barrier for internal rotation (38), and calculated the reduced moments of inertia for this rotation following Benson (14) using the geometries calculated by MM2. These data lead to $S_{tr} = 37.99$, $S_{rot} = 23.19$, $S_{vib} = 2.90$, $S_{hr} = 4.03$, and $S^0(g) = 68.12$ cal deg^{-1} mol^{-1}. S_{hr} was calculated using tables for a symmetric rotor (14), but the rotor in acrolein is asymmetric, so $R \ln(n)$ must be added to the entropy (39). This correction is needed for all compounds discussed here except anisole. For *methyl vinyl ketone* we used moments of inertia based on microwave spectroscopy (40), vibrational frequencies (38), and the potential barrier for internal rotation (38) and calculated the reduced moments of inertia for this rotation following Benson (14) using the geometries calculated by MM2. These data lead to $S_{tr} = 38.66$, $S_{rot} = 25.47$, $S_{vib} = 4.81$, $S_{hr} = 8.01$, and $S^0(g) = 76.94$ cal deg^{-1} mol^{-1}. For *anisole* we used overall moments of inertia from microwave spectroscopy (41), and reduced moments of inertia for methyl and methoxyl rotation calculated from the MM2 structure. A literature value was used for the barrier to methyl rotation, 4.59 kcal mol^{-1} (42) (theoretical calculation, in good agreement with the observed frequency), and that for methoxyl rotation was derived from microwave spectroscopy, 3.26 kcal mol^{-1} (41). Vibrational frequencies were taken from Owen and Hester (43). These data lead to $S_{tr} = 39.95$, $S_{rot} = 27.92$, $S_{vib} = 9.94$, $S_{hr} = 5.68$, and $S^0(g) = 83.50$ cal deg^{-1} mol^{-1}. For *methyl vinyl ether* we used overall moments of inertia from microwave spectroscopy (44) and reduced moments of inertia for molecular fragments from the literature (methyl (45)) or calculated from the MM2 structure (methoxyl). Literature values were used for the barrier to methyl rotation, 4.07 kcal mol^{-1} (45), and methoxyl rotation, 5.24 kcal mol^{-1} (46). Longer wavelength frequencies were taken from Owen and Sheppard (47). These data lead to $S_{tr} = 38.10$, $S_{rot} = 23.86$, $S_{vib} = 2.77$, $S_{hr} = 5.96$, and $S^0(g) = 70.69$ cal deg^{-1} mol^{-1}. For *methyl acrylate* we used moments of inertia for the whole molecule and the methyl group from microwave spectroscopy (48) and moments of inertia for methoxyl and carbomethoxyl calculated from the MM2 structure. The literature value was used for the barrier to methyl rotation, 1.22 kcal mol^{-1} (48). Barriers for methoxyl and carbomethoxyl rotation were calculated (49) from the torsional vibration frequencies, 175 cm^{-1} (not reported for methyl acrylate; this value is an average for similar compounds (48)) and 160 cm^{-1} (value for methyl crotonate; not observed for methyl acrylate (50)) respectively, as 13.73 kcal mol^{-1} and 10.16 kcal mol^{-1} respectively. Vibrational frequencies were taken from several studies (50–52). These data lead to $S_{tr} = 38.66$, $S_{rot} = 26.35$, $S_{vib} = 6.12$, $S_{hr} = 11.15$, and $S^0(g) = 82.28$ cal deg^{-1} mol^{-1}. For *methyl benzoate* we used moments of inertia for the whole molecule and fragments subject to hindered internal rotation calculated from the MM2 structure. Barriers for methyl, methoxyl, and carbomethoxyl rotation were calculated (49) from the torsional vibration frequencies, 170 cm^{-1}, 100 cm^{-1}, and 58 cm^{-1} (53) respectively, as 2.03, 6.58, and 4.97 kcal mol^{-1} respectively. These frequencies were assigned as mixtures of torsion and skeletal vibration, so they are not an ideal basis for evaluating the potential barriers. The barrier for methyl rotation is in fair agreement with that for CH_3-OCHO, 1.2 kcal mol^{-1} (48). The barrier for methoxyl rotation is quite different from that for CH_3-$COOCH_3$, 13 kcal mol^{-1} (14), but the difference would amount to only 0.7 cal deg^{-1} mol^{-1} in overall entropy. Vibrational frequencies were taken from several studies (53, 54). These data lead to $S_{tr} = 40.64$, $S_{rot} = 29.28$, $S_{vib} = 13.50$, $S_{hr} = 12.20$, and $S^0(g) = 95.14$ cal deg^{-1} mol^{-1}.

We have a particular interest in acetals and ortho esters (13), and therefore have tried to estimate values for the group contributions to entropies, which are the only missing quantities for thermodynamic calculations. The problem is the shortage of entropy values for these types of compounds. Benson has suggested (14) that contributions to entropy would be approximately the same for groups differing only in the attached non-hydrogen atoms so that $[C(C)_4]$ would be a reasonable approximation for $[C(C)_2(O)_2]$ or $[C(C)(O)_3]$. We can examine the quality of this approximation for three series: $[CH_2(C)_2] = 9.42$ (55), $[CH_2(O)_2] = 10.30$ (55), $[CH_2(O)_2] = 7.81$ (this work); $[CH(C)_3] = -12.07$ (55), $[CH(C)_2(O)] = -11.0$ (55), $[CH(C)(O)_2] = -14.1$ (this work); and $[C(C)_4] = -35.10$ (55), $[C(C)_3(O)] = -33.56$ (55), $[C(C)_2(O)_2] = -38.3$ (this work). There is clearly variation, suggesting that the approximation is imperfect. There may be a pattern; one oxygen replacement gives a more positive value than all carbons, two oxygen replacements gives a more negative value. When one notes that only the hydrocarbon groups and $[CH_2(C)(O)]$ are based on more than one experimental entropy, and both $[CH(C)(O)_2]$ and $[C(C)_2(O)_2]$ are based on equilibrium constants in solution, it seems clear that for the moment the best approximation for the groups that must be estimated is to use the corresponding hydrocarbon group, i.e., $[CH(O)_3] \approx [CH(C)_3] = -12.07$, and $[C(O)_4] \approx [C(C)(O)_3] \approx [C(C)_4] = -35.10$.

It was necessary to derive the appropriate enthalpy and entropy ring corrections for cyclohexanone in Benson's scheme (14); these are for an exocyclic double bond to a six-membered ring. We assume that these will be the same as for methylenecyclohexane. The equilibrium constant for isomerization of methylenecyclohexane to 1-methylcyclohexene (56), and the enthalpies of formation of methylenecyclohexane (57) and 1-methylcyclohexene (24) are available. From the equilibrium constant, [1-methylcyclohexene]/[methylenecyclohexane] = 43.2, gas, 180°C (56), we obtain $\Delta G^0 = -3.40$ at 180°C. From the heats of formation of gaseous 1-methylcyclohexene (24) and methylenecyclohexane (57), $\Delta H^0 = -4.28$, and thus $\Delta S^0 = -1.95$ for the conversion of methylenecyclohexane to 1-methylcyclohexene. Since the entropy of 1-methylcyclohexene is available by well-established estimation procedures, Table 2, we can calculate the entropy of methylenecyclohexane as 85.38. We can now evaluate the ring compound corrections as 3.49 kcal mol^{-1} for ΔH and 23.99 cal deg^{-1} mol^{-1} for S^0. For comparison the corrections for cyclohexene are 1.4 kcal mol^{-1} and 21.5 cal deg^{-1} mol^{-1} (14). These corrections were used to calculate ΔG_f^0 for cyclohexanone.

We wished to calculate uncertainties in the $\Delta G_f^0(aq)$ values based on the uncertainties in the data from which they were derived. Although it is common to give uncertainty limits for $\Delta H_f^0(g)$, it is less common to report uncertainties for $S^0(g)$ or ΔG_t. Uncertainties in $\Delta H_f^0(g)$ are the major contributions to uncertainties in $\Delta G_f^0(aq)$, so it seemed acceptable to make rather arbitrary assignments of uncertainties as follows. Experimentally derived entropy values were assigned uncertainties of 0.3 cal deg^{-1} mol^{-1}; estimated values (using group contributions) were assigned uncertainties

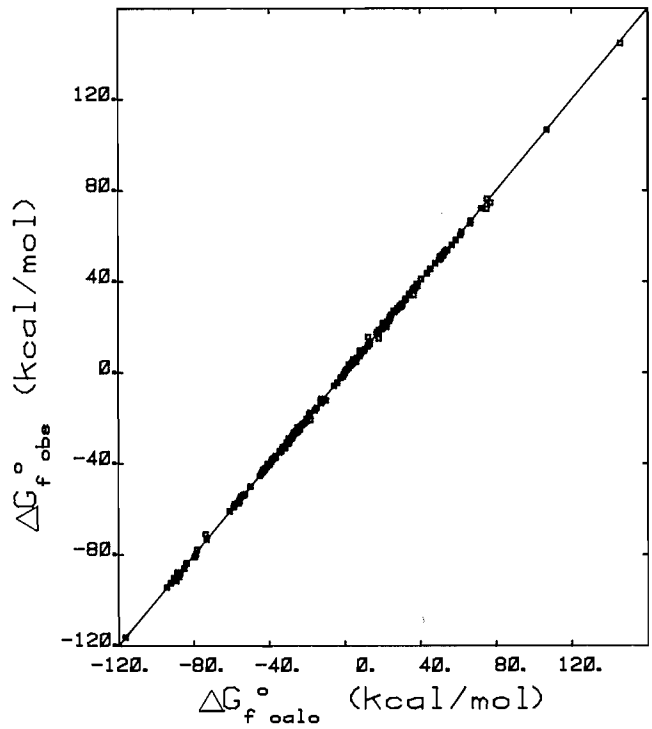

FIG. 1. Free energy of formation in aqueous solution: calculated vs. experimental values.

of 1.5 cal deg^{-1} mol^{-1}. Values of ΔG_t were assigned errors of 0.1 kcal mol^{-1}, as were ΔG^0 values based on equilibria. Uncertainties in ΔG_f^0(aq) values calculated from the ΔG^0 were then derived from the uncertainties in ΔG^0 and in ΔG_f^0(aq) values for the reactants and products.

Discussion

The available body of free energy of formation data for monofunctional organic compounds in aqueous solution is found in Table 2. This table does not include some multifunctional biochemical molecules, for which the simple approach given here is unlikely to give useful estimates, nor various polyfunctional compounds for which ΔG_f^0(aq) has been reported. Monofunctional has been loosely interpreted to mean the absence of strongly interacting polar groups, where the interactions fall outside the group equivalents scheme. Thus ortho esters are included because the interactions of the three oxygens are allowed for by the new groups [$CH(O)_3$], $C(C)(O)_3$], and [$C_B(C)(O)_3$]. Similarly for benzyl or allyl alcohols the groups [$CH_2(C_B)(O)$] and [$CH_3(C_d)(O)$] incorporate the interaction. We exclude compounds such as $CH_3OCH_2CH_2OCH_3$, where there is an important interaction (15) that is not recognized in the group contributions scheme. We also excluded compounds that would otherwise qualify but where there was no experimentally based entropy if the entropy could not be estimated by well-tested procedures. We do not claim to have done an exhaustive literature search, but believe that this is a relatively complete set of data as of this moment. Figure 1 shows a plot of calculated vs. experimental values of ΔG_f^0(aq) for all compounds in Table 2. The rms deviation of calculated from experimental values is 0.74 kcal mol^{-1} for 198 compounds.

Cyclic compounds require additional corrections to both ΔH_f^0(g) and S^0(g), which are listed in Benson's book (14). We have used these corrections unchanged, except for cycloheptatriene, as noted in Table 2, and do not reproduce them here.

We encountered particular problems in picking the best values for the entropies of the polyphenylmethanes. Although there is a recent paper devoted to this topic (58) the situation is still unsettled. Marcus and Loewenschuss estimated entropies for di-, tri-, and tetraphenylmethanes based on estimated frequencies. Frequencies for torsional modes were treated as vibrations and not as hindered rotations. Since the vibrational contribution is dominated by the low-frequency torsional modes, for which there is the least information, it is not clear how reliable these estimates can be. We used the literature values for condensed phase entropies (20), heats of vaporization (33), or sublimation (24), and vapor pressures calculated from Antoine equations (25). Our values differ appreciably from the calorimetric values of Marcus and Loewenschuss (58), in part because of different vapor pressure values, and partly because of a sign error in the calculations which they report. Our values appear to be internally consistent and lead to group contributions that fall into reasonable patterns relative to related groups; attempts to use the entropies reported by Marcus and Lowenschuss did not give such consistent values.

We have examined the data for those compounds where the difference between experimental and calculated values is more than 1 kcal mol^{-1}. In some cases we can see that the problem is probably the simple way in which corrections for crowding have been made: clearly more elaborate steric effects calculations are needed once these corrections become appreciable. This appears to be the situation for 3,3-diethylpentane, and possibly 2,2,5-trimethylhexane. For a number of compounds the discrepancy arises in ΔH_f^0(g) for which we can calculate a value from the parameters in Table 1, even though there is not a large steric correction. It is not clear whether this indicates a defect in the parameterization or a problem with the experimental data. This situation arises for 2,2-dimethylbutane, 1-methylcyclohexene, butenyne, 2-methyl-1-pentene, anthracene, pyrene, anisole, acrylic acid, and perhaps 2,2,5-trimethylhexane. For 2,4-dimethyl-3-pentanone the discrepancy appears to arise in the entropy, since the estimated value is 3.5 cal deg^{-1} mol^{-1} larger than the experimental value. This might imply reduced freedom for internal rotation because of gearing of the two isopropyl groups. For benzalacetone and cinnamaldehyde, where the experimental values are based on equilibrium constants for the aldol condensations (59, 60), we find that the calculated values are in error by 2 kcal mol^{-1}, the compounds being less stable than predicted. This suggests an interaction across the double bond of the conjugated phenyl and carbonyl groups, which is contrary to standard intuition.

For aldehydes we have revised the parameter reported by Hine and Mookerjee (15) to refer only to the free aldehyde in aqueous solution, i.e., we have corrected for covalent hydration. Since Hine and Mookerjee assumed the same value for all [CHO(X)] contributions, and had very few data for unsaturated aldehydes, ketones, and carboxylic acid derivatives, this has serious implications for a number of other groups. For aliphatic ketones the problem is not important because the standard assumption of the same value for all [CH_3(X)] groups leads to a well-defined value for [$CO(C)_2$]. We have calculated new values for the contribu-

For personal use only.

tions [$C_dH(CO)$], [$C_d(C)(O)$], [$C_B(CO)$], [$CO(C)(C_d)$], [$CO(C)(C_B)$], [$CO(C_d)(O)$], and [$CO(C_B)(O)$]. The first three values change in the opposite sense to [CHO(X)], and the last four in the same sense. The net effect of these changes should be zero for the unsaturated carbonyl compounds, since all that has been changed is the way certain combinations of contributions have been split up.

In attempting to devise a predictive scheme such as that described here, the major problem encountered is the shortage of data. This is particularly severe for entropies. Although entropy is the most readily estimated thermodynamic quantity, largely because it is, for small molecules, largely determined by molecular weight and size through the translational and rotational contributions, and although relatively satisfactory estimates can be made by a variety of methods (14), a fully satisfactory parameterization scheme should be based on solid experimental values, with each parameter derived from several independent data values. This happy state has not yet been achieved.

It must be recognized that in the long run and broad perspective any hope of a general group additivity scheme is doomed by the combinatorial explosion of possible groups. This has been recognized, and attempts are being made to derive more efficient schemes (61). In the short run, group additivity schemes can be enormously useful and practical in providing estimates for a limited range of compounds while we wait for better methods. It must also be observed that it is still very rare for quantum mechanical calculations to be carried out to a level permitting usefully accurate absolute enthalpies or entropies of gaseous molecules, and that until such calculations become routinely practical, there will be a need for additivity schemes.

Our conclusion, based upon the results shown in Fig. 1 and Table 2, is that direct estimation of $\Delta G_f^0(aq)$ is a useful procedure, and that further elaboration to accommodate polyfunctional compounds would be a worthwhile endeavor.

Experimental

Materials

2,2-Dimethoxypropane, methyl methacrylate (BDH), and isopropenyl acetate (Eastman) were commercial samples redistilled before use. Triphenylmethane (Aldrich) was used without further purification.

Methods

Samples of the organic compounds were added to portions of suitable aqueous buffers (0.1 N NaOH for 2,2-dimethoxypropane; pH 7 phosphate buffer, ionic strength 0.1 M, for methyl methacrylate and isopropenyl acetate, and distilled water for triphenylmethane) and agitated vigorously at intervals during equilibration in a water bath at 25°C. After a suitable equilibration period (at least 1 h for 2,2-dimethoxypropane, methyl methacrylate, or isopropenyl acetate, 10 days for triphenylmethane) samples of the aqueous solutions were removed after centrifuging, if necessary, to obtain phase separation. Precautions were taken to avoid including any undissolved organic compound, and the samples were analyzed by ^1H nmr (2,2-dimethoxypropane, methyl methacrylate, and isopropenyl acetate) or uv spectroscopy (triphenylmethane). For nmr spectroscopic analysis a suitable amount of *tert*-butyl alcohol was added to a known volume of aqueous solution to act as an internal concentration standard.

The aldol condensation of acetone with acetophenone

J. PETER GUTHRIE[1] AND XIAO-PING WANG
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received March 8, 1991[2]

J. PETER GUTHRIE and XIAO-PING WANG. Can. J. Chem. **70**, 1055 (1992).

The kinetics and equilibria involved in the aldol condensation of acetone, acting as carbon acid, and acetophenone have been studied in aqueous alkaline solution. The enone isolated is the *E* isomer. The reactions are all first order in hydroxide, with rate and equilibrium constants (defined for *E*-enone as initial compound) of: $k_{12} = (5.55 \pm 0.17) \times 10^{-6}$ M^{-1} s^{-1}, $k_{21} = (8.00 \pm 0.40) \times 10^{-6}$ M^{-1} s^{-1}, $K_{21} = (1.44 \pm 0.55)$ (ketol to *E*-enone), $K_{24} = 0.160 \pm 0.033$ (ketol to *Z*-enone), $K_{32} = (1.89 \pm 0.26) \times 10^{-3}$ M^{-1} (acetone plus acetophenone to ketol), $k_{23} = 0.180 \pm 0.005$ M^{-1} s^{-1}, $k_{32} = (3.41 \pm 0.49) \times 10^{-4}$ M^{-2} s^{-1}. There is an equilibration of the two enones in base that is faster than hydration to the ketol: $k_{14} = (3.14 \pm 0.84) \times 10^{-5}$ M^{-1} s^{-1}; $k_{41} = (2.81 \pm 0.61) \times 10^{-4}$ M^{-1} s^{-1}; $K_{14} = 0.112 \pm 0.019$. To analyze the behavior of the enone:ketol equililbrium system in acid we simultaneously fitted analytical data for all three species (*E*-enone, *Z*-enone, and ketol) to a kinetic model, so that the rate constants were determined by the best fit to all of the data for an experiment.

J. PETER GUTHRIE et XIAO-PING WANG. Can. J. Chem. **70**, 1055 (1992).

Opérant en solution aqueuse alcaline, on a étudié les cinétiques et les équilibres impliqués dans la condensation aldolique de l'acétone, agissant comme acide carboné, et l'acétophénone. L'énone isolée est l'isomère *E*. Les réactions sont toutes du premier ordre en ion hydroxyde alors que les constantes de vitesse et d'équilibre (définies pour l'énone *E* comme produit initial) sont : $k_{12} = (5{,}55 \pm 0{,}17) \times 10^{-6}$ M^{-1} s^{-1}, $k_{21} = (8{,}00 \pm 0{,}40) \times 10^{-6}$ M^{-1} s^{-1}; $K_{21} = 1{,}44 \pm 0{,}55$ (cétol de l'énone *E*), $K_{24} = 0{,}160 \pm 0{,}033$ (cétol de l'énone *Z*), $K_{32} = (1{,}89 \pm 0{,}26) \times 10^{-3}$ M^{-1} (acétone plus acétophénone conduisant au cétol), $k_{23} = 0{,}180 \pm 0{,}005$ M^{-1} s^{-1} et $k_{32} = (3{,}41 \pm 0{,}49) \times 10^{-4}$ M^{-2} s^{-1}. En milieu basique, il existe un équilibre qui est plus rapide que l'hydratation en cétol : $k_{14} = (3{,}14 \pm 0{,}84) \times 10^{-5}$ M^{-1} s^{-1}, $k_{41} = (2{,}81 \pm 0{,}61) \times 10^{-4}$ M^{-1} s^{-1}; $K_{14} = 0{,}112 \pm 0{,}019$. Dans le but d'analyser le comportement de l'équilibre céto–énolique en milieu acide, on a ajusté les données analytiques obtenues pour les trois espèces (énones *E* et *Z* et cétol) à un modèle cinétique; on a ainsi pu déterminer les constantes de vitesse qui correspondent le mieux avec l'ensemble des données pour une expérience.

Introduction

We recently reported on the aldol condensation of acetophenone, acting as carbon nucleophile, with acetone (1). This was, in part, background information for ongoing studies of elimination reactions catalyzed by steroidal imidazoles (2, 3). In the course of this investigation we became aware that there was a concurrent condensation in the opposite sense, with acetone, acting as carbon nucleophile, attacking acetophenone. The reactions involved are described in Scheme 1. The kinetic analysis is from the perspective of the retroaldol reaction, since this is the direction that gives the more accurate rate constants. This reaction turned out to be somewhat more difficult to sort out, but we have now completed the kinetic analysis, and wish to report it in turn. This provides another example of a fully analyzed aldol condensation, to add to those we (1, 4–10) and others (11–14) have previously reported. To complete the analysis we had to develop computer programs allowing us to fit simultaneously multiple sets of data described by equations with common parameters.

Results

Preparation

When we set out to make 3-hydroxy-3-methyl-1-phenyl-1-butanone we found that directed aldol condensation using the preformed lithium enolate of acetophenone gave mixtures consisting mainly of the desired product with small amounts of 4-hydroxy-4-phenyl-2-pentanone. These were essentially impossible to separate on a preparative scale, and we had to use an alternative synthesis (1). 4-Hydroxy-4-phenyl-2-pentanone could be prepared in pure form by reaction of phenyl magnesium bromide with 2,4-pentanedione (15), and 4-phenyl-3-penten-2-one could be obtained by dehydration of the ketol. The enone so obtained was the *E* isomer, based on comparison of its ^1H NMR spectrum with literature values for the two isomers. The diagnostic signals are those for the CH_3-C=C signal, which appears at 2.09δ (16*a*), *Z* isomer, or 2.35δ (16*a*), 2.47δ (16*b*), *E* isomer, and the vinyl hydrogen, for which the signals are at 6.94δ (16*a*), *Z* isomer, or 6.21δ (16*a*), 6.34δ (16*b*), *E* isomer, all in CCl_4. We observed signals at 2.45δ and 6.35δ in CCl_4.

Overall kinetics

We studied the retroaldol kinetics of both *E*-enone and ketol in dilute alkaline solution, and discovered that the two compounds reacted on markedly different time scales, with apparent second-order rate constants of 0.180 ± 0.005 M^{-1} s^{-1} for disappearance of the ketol and $(9.99 \pm 0.25) \times 10^{-6}$ M^{-1} s^{-1} for disappearance of the *E*-enone; see Figs. 1 and 2. The data for the *E*-enone also showed a small amplitude kinetic phase with an apparent second-order rate constant of $(3.12 \pm 0.68) \times 10^{-4}$ M^{-1} s^{-1}; because of the small amplitude of this phase it is not well defined by the data, but appears to be real. We attribute this behavior to isomerization of the enones prior to conversion to the ketol and retroaldol cleavage. This isomerization will be considered in more detail later. The experimental results are found in Table 1. The observed behavior is interpreted in terms of rapid, essentially complete, breakdown of ketol to acetone and

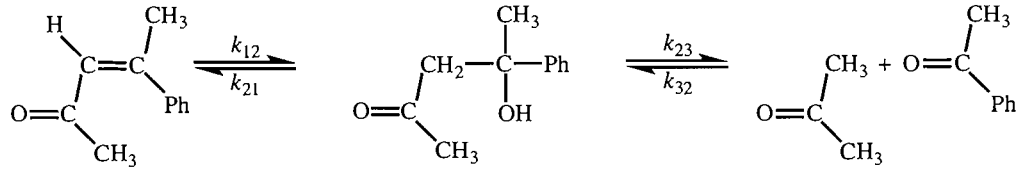

SCHEME 1

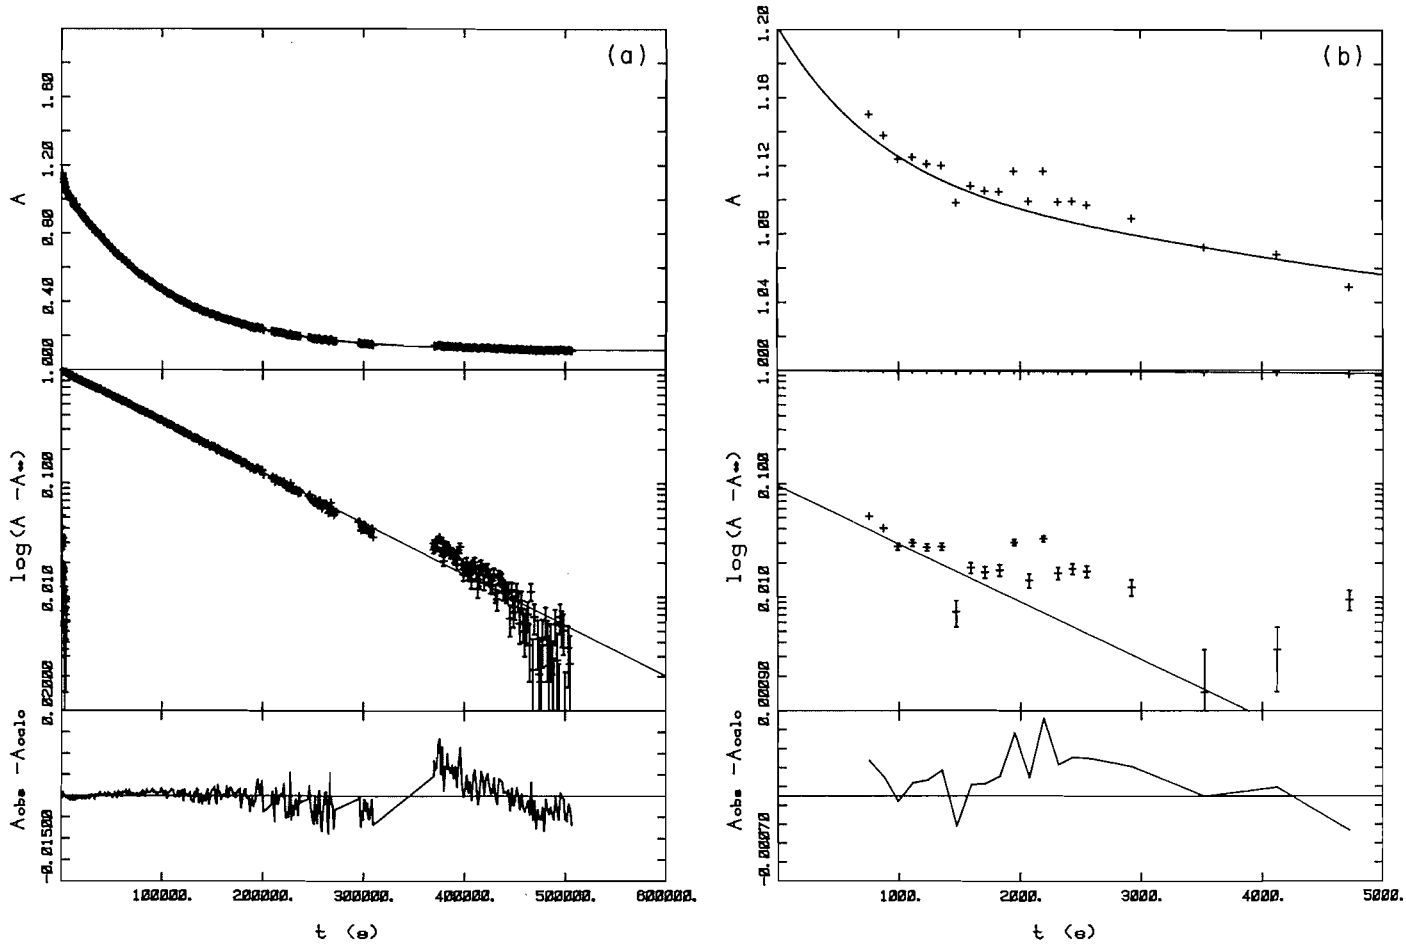

FIG. 1. Kinetics of retroaldol reaction of *E*-enone; 8.89×10^{-6} M enone in 1.0 M aqueous NaOH at 25°C. The lines are calculated using the parameters evaluated by least squares.

acetophenone, with hydration of the enone as rate-determining step for reaction starting with the enone. Had dehydration of the ketol occurred at a rate competitive with breakdown, one would have observed buildup of enone, followed by slow decay. Although some enone doubtless forms, the amounts are very small, as shown by the essential absence of a second exponential decay term in the rate law. This suggests that the apparent rate constants may be simply interpreted since, in terms of Scheme 1, the apparent rate constant for disappearance of enone is k_{12}, and the apparent rate constant for disappearance of ketol is k_{23}. The attractive simplicity of this analysis is marred by the clear signs of deviations from simple first-order behavior for the retroaldol cleavage of the *E*-enone at short reaction times mentioned above. We would like to evaluate all four rate constants in Scheme 1. To carry out a complete analysis of the kinetics it is necessary to measure the equilibrium constants for hydration and the overall aldol condensation. Then with two rate constants from the overall kinetics and two equilibrium constants it should be possible to extract the four rate constants we want.

Rate and equilibrium constants for hydration in acid

To measure K_{12}, the equilibrium constant for covalent hydration of the *E*-enone, we studied equilibration in acid solution, where we expect, based on analogy with other systems (17–19), that hydration–dehydration can be studied without interference by retroaldol cleavage. This proved to be the case, but a complicating factor intervened. Whether one started with *E*-enone or ketol, HPLC analysis of equilibrating solutions in acid showed the presence of three species: the ketol, the *E*-enone, and a third species which we

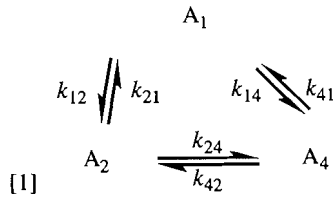
believe is the geometrical isomer of the enone, i.e., *Z*-4-phenyl-3-penten-2-one. The results of these experiments are found in Table 2. The actual experimental data are given in Table S1.[3] The final proportions of these three species are independent of the starting conditions. A striking feature of the kinetics was that when reaction started with the *E*-enone, the concentration of the *Z*-enone first rose and then fell. This requires that the ketol not be an intermediate on the reaction path from *E*-enone to *Z*-enone, but rather that the *Z*-enone be in a sense an intermediate species that can be formed by a more rapid path and accumulate to levels higher than for the equilibrium state, to which it will relax by a slower path. Thus the reaction system cannot be:

$$E\text{-enone} \leftrightharpoons \text{ketol} \leftrightharpoons Z\text{-enone}$$

Two mechanisms were considered to account for this behavior. In the first we assume that the enol intermediate in hydration–dehydration undergoes loss of water faster than protonation at carbon. This mechanism is shown in Scheme 2; the corresponding reaction coordinate diagram is shown in Fig. 3. If, as seems highly reasonable, the enol were a steady-state intermediate, then this scheme would be equivalent to a simple triangular reaction system:



[1]

$A_1 = E$–enone
A_2 = ketol
$A_4 = Z$–enone

For this system, starting with *E*-enone, we can derive, following Ikai and Tanford (20),[4] the equations

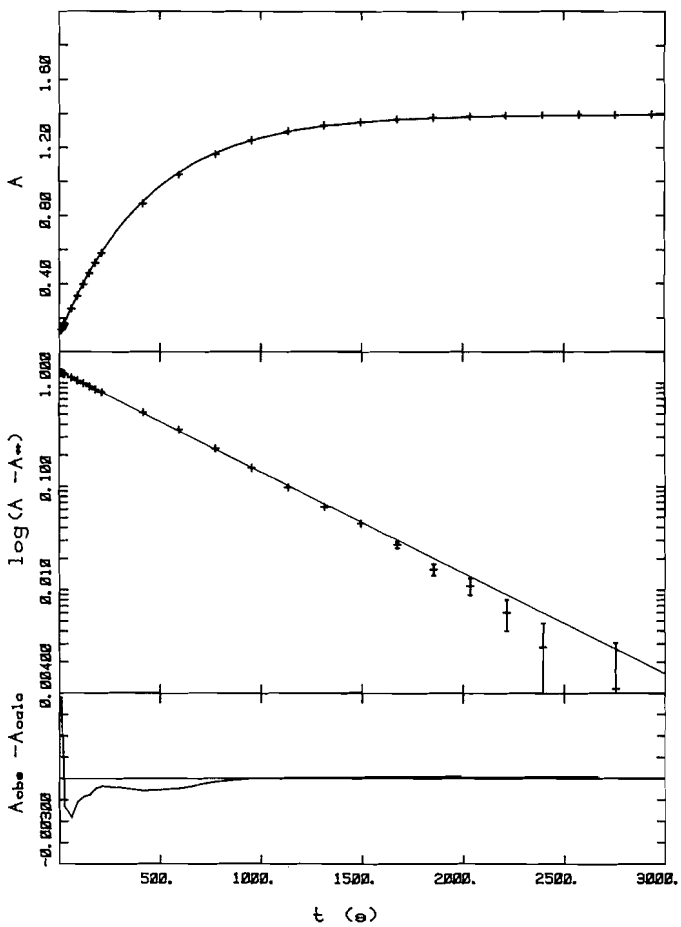


FIG. 2. Kinetics of retroaldol reaction of ketol; 1.64×10^{-5} M ketol in 0.0097 M aqueous NaOH at 25°C. The lines are calculated using the parameters evaluated by least squares.

[3]Copies of the Supplementary Tables may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

[4]There is an error on page 161 of Ikai and Tanford (20): $C_1(0) = 0$ should be $C_1(0) = C_0$.

$$[E\text{-Enone}] = C_0k_{21}k_{41}/(k_{21}k_{41} + k_{12}k_{41} + k_{14}k_{21}) + \{C_0(\lambda_2(k_{12} + k_{14}) - (\gamma_2 + \gamma_3))/\lambda_2(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t) - \{C_0(\lambda_3(k_{12} + k_{14}) - (\gamma_2 + \gamma_3))/\lambda_3(\lambda_2 + \lambda_3)\} \exp(-\lambda_3 t)$$

[2] $$[\text{Ketol}] = C_0k_{12}k_{42}/(k_{21}k_{42} + k_{12}k_{42} + k_{12}k_{24}) + \{C_0(\gamma_2 - k_{12}\lambda_2)/\lambda_2(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t) - \{C_0(\gamma_2 - k_{12}\lambda_3)/\lambda_3(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t)$$

$$[Z\text{-Enone}] = C_0k_{14}k_{24}/(k_{24}k_{41} + k_{14}k_{42} + k_{14}k_{24}) + \{C_0(\gamma_3 - k_{14}\lambda_2)/\lambda_2(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t) - \{C_0(\gamma_2 - k_{12}\lambda_3)/\lambda_3(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t)$$

and for the case of starting with ketol:

$$[E\text{-Enone}] = C_0k_{21}k_{41}/(k_{12}k_{41} + k_{21}k_{41} + k_{21}k_{14}) + \{C_0(\gamma_2 - k_{21}\lambda_2)/\lambda_2(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t) - \{C_0(\gamma_2 - k_{21}\lambda_3)/\lambda_3(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t)$$

[3] $$[\text{Ketol}] = C_0k_{12}k_{42}/(k_{12}k_{42} + k_{21}k_{42} + k_{12}k_{24}) + \{C_0(\lambda_2(k_{21} + k_{24}) - (\gamma_2 + \gamma_3))/\lambda_2(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t) - \{C_0(\lambda_3(k_{21} + k_{24}) - (\gamma_2 + \gamma_3))/\lambda_3(\lambda_2 + \lambda_3)\} \exp(-\lambda_3 t)$$

$$[Z\text{-Enone}] = C_0k_{14}k_{24}/(k_{24}k_{41} + k_{14}k_{42} + k_{14}k_{24}) + \{C_0(\gamma_3 - k_{24}\lambda_2)/\lambda_2(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t) - \{C_0(\gamma_3 - k_{24}\lambda_3)/\lambda_3(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t)$$

where

$$p = k_{12} + k_{21} + k_{14} + k_{41} + k_{24} + k_{42} \qquad q = (p^2 - 4)(\gamma_1 + \gamma_2 + \gamma_3))^{1/2}$$

$$\gamma_1 = k_{21}k_{41} + k_{21}k_{42} + k_{24}k_{41} \qquad \lambda_2 = (p + q)/2;$$

$$\gamma_2 = k_{12}k_{41} + k_{12}k_{42} + k_{14}k_{42} \qquad \lambda_3 = (p - q)/2$$

$$\gamma_3 = k_{12}k_{24} + k_{14}k_{21} + k_{14}k_{24}$$

When we attempted to fit the data to the integrated rate law derived for this mechanism, we found that two of the rate constants, describing the interconversion of ketol and the *Z*-enone, were only marginally defined by the data, with uncertainties large relative to the values assigned by least squares. At the 95% confidence level, neither k_{24} nor k_{42} is distinguishable from zero. Thus the first mechanism was rejected.

Since the facts require that the enones interconvert, but that the *Z*-enone *not* be directly converted to ketol, we had to consider possibilities that at first glance seemed implausible. The mechanism that worked is that shown in Scheme 3, which assumes that only the *E*-enone can undergo hydration, so that the *Z*-enone must first isomerize before it can hydrate. We will here show that this mechanism is consistent with the facts. In the discussion we will attempt to justify it in structural terms. The mechanism in Scheme 3, making the plausible steady-state assumption for all intermediates, is equivalent to the simple reaction system:

[4] $$Z\text{-enone} \underset{k_{14}}{\overset{k_{41}}{\leftrightharpoons}} E\text{-enone} \underset{k_{21}}{\overset{k_{12}}{\leftrightharpoons}} \text{ketol}$$

This system is described by the reaction coordinate diagram shown in Fig. 4, and we may derive an integrated rate law, for the case of starting with *E*-enone,

$$[Z\text{-Enone}] = [E\text{-enone}]^0\{k_{14}k_{21}/\lambda_2\lambda_3 + [k_{14}(k_{21} - \lambda_2)/\lambda_2(\lambda_2 - \lambda_3)] \exp(-\lambda_2 t) + [k_{14}(\lambda_3 - k_{21})/\lambda_3(\lambda_2 - \lambda_3)] \exp(-\lambda_3 t)\}$$

[5] $$[E\text{-Enone}] = [E\text{-enone}]^0\{k_{41}k_{21}/\lambda_2\lambda_3 + [(k_{21} - \lambda_2)(k_{41} - \lambda_2)/\lambda_2(\lambda_2 - \lambda_3)] \exp(-\lambda_2 t) - [(k_{21} - \lambda_3)(k_{41} - \lambda_3)/\lambda_3(\lambda_2 - \lambda_3)] \exp(-\lambda_3 t)\}$$

$$[\text{Ketol}] = [E\text{-enone}]^0\{k_{41}k_{12}/\lambda_2\lambda_3 + [k_{12}(k_{41} - \lambda_2)/\lambda_2(\lambda_2 - \lambda_3)] \exp(-\lambda_2 t) - [k_{12}(k_{41} - \lambda_3)/\lambda_3(\lambda_2 - \lambda_3)] \exp(-\lambda_3 t)\}$$

and for the case of starting with ketol,

$$[Z\text{-Enone}] = [\text{ketol}]^0\{k_{41}k_{12}/\lambda_2\lambda_3 + [k_{12}k_{41}/\lambda_2(\lambda_2 - \lambda_3)] \exp(-\lambda_2 t) - [k_{41}k_{12}/\lambda_3(\lambda_2 - \lambda_3)] \exp(-\lambda_3 t)$$

[6] $$[E\text{-Enone}] = [\text{ketol}]^0\{k_{41}k_{21}/\lambda_2\lambda_3 + k_{41}(k_{21} - \lambda_2)/\lambda_2(\lambda_2 - \lambda_3)] \exp(-\lambda_2 t) + k_{41}(\lambda_3 - k_{21})/\lambda_3(\lambda_2 - \lambda_3)] \exp(-\lambda_3 t)\}$$

$$[\text{Ketol}] = [\text{ketol}]^0\{k_{14}k_{21}/\lambda_2\lambda_3 + [k_{41}(\lambda_2 - k_{12} - k_{21})/\lambda_2(\lambda_2 - \lambda_3)] \exp(-\lambda_2 t) + k_{41}(k_{12} + k_{21} - \lambda_3)/\lambda_3(\lambda_2 - \lambda_3)] \exp(-\lambda_3 t)\}$$

Equilibrium constants:

K_{21} = [*E*-enone]/[Ketol] = 1.44 ± 0.55
K_{24} = [*Z*-enone]/[Ketol] = 0.160 ± 0.033
K_{14} = [*Z*-enone]/[*E*-enone] = 0.112 ± 0.019

A_1 is the ketol, A_2 is the *E*-enone, and A_4 is the *Z*-enone.

[a]In aqueous solution at 25°C; $[H^+]$ = 1.0 M. Reaction was followed by HPLC, monitoring at 220 nm. Data were fitted to the kinetic models of Schemes 2 or 3, fitting six sets of peak height vs. time data at once as described in the text. Values in parentheses are standard deviations estimated by the least-squares program. Values of "extinction coefficient" = peak height/concentration and initial concentration were treated as parameters in the fitting process but constrained to be close to the observed values. These observed values are given in the table to allow comparison of fitted and measured values.

where

$$\lambda_2 = (p + q)/2$$

$$\lambda_3 = (p - q)/2$$

$$p = k_{41} + k_{14} + k_{12} + k_{21}$$

$$q = (p^2 - 4(k_{41}k_{12} + k_{14}k_{21} + k_{41}k_{21}))^{1/2}$$

When we attempted to fit the data to the integrated rate law derived for this mechanism, we found that a satisfactory set of rate constants could be obtained, and that the uncertainties for each rate constant were less than for the corresponding rate constants when we fitted to the mechanism of Scheme 2.

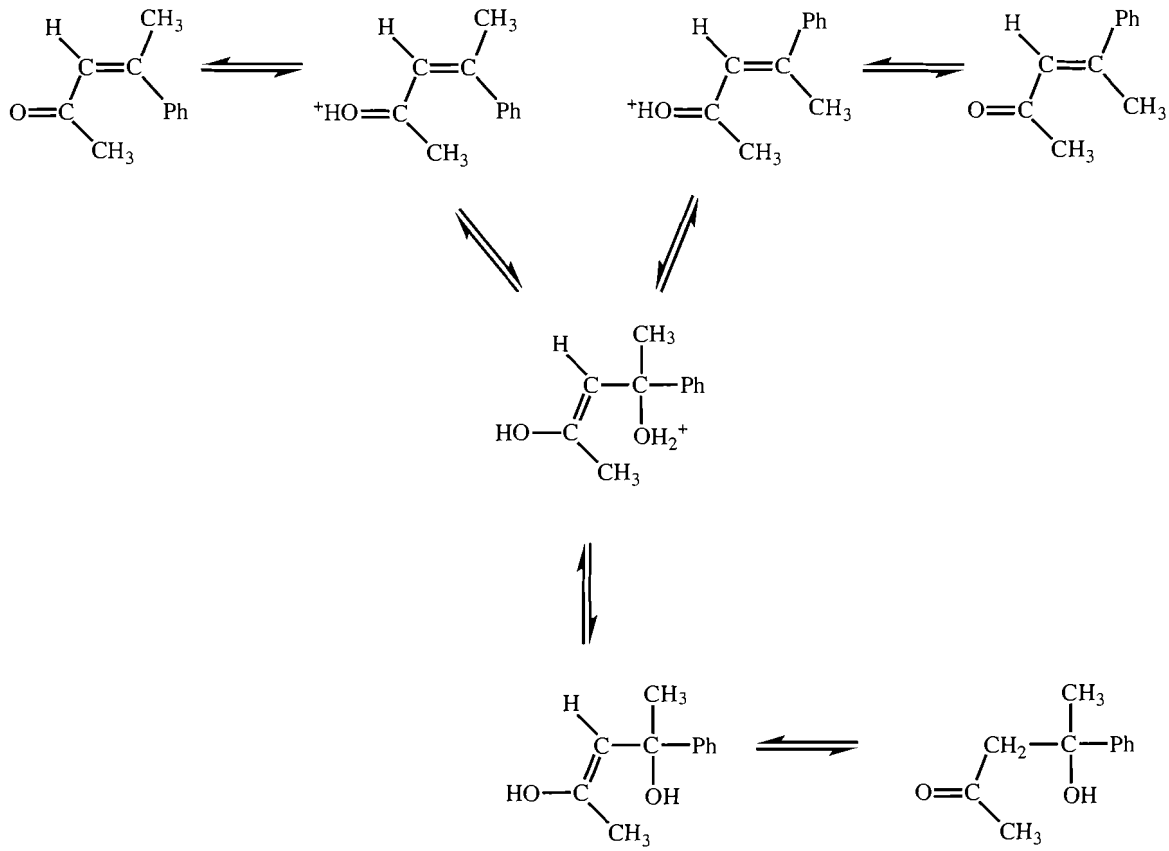
For both models we fitted all the data at once, including HPLC peak heights for three species as a function of time for experiments beginning with enone and with ketol. We used the initial concentrations in the two experiments, and the "extinction coefficients" derived from calibrations as adjustable parameters, but imposed constraints upon the values of these concentrations and the extinction coefficients for enone and ketol by adding extra conditions to the program, minimizing the deviations between the adjusted parameters and the measured values. This allows some variation in these values to optimize the fit, but constrains them to remain close to the directly measured value. Since measurement is subject to error, it would be improper to treat the measured values as absolute. The quality of the final fit is shown in Fig. 5.

At this stage we have a mechanism that is consistent with the data and requires only rate constants that were defined by the data. With this we can fit the experimental points and be confident that we have parameters defining the thermodynamic equilibrium, which we have approached but not quite attained in our experiments.

From the analysis of the equilibrations in acid, we derive K_{24} = [*Z*-enone]/[ketol] = 0.160 ± 0.033; K_{21} = [*E*-enone]/[ketol] = 1.44 ± 0.55; K_{14} = [*Z*-enone]/[*E*-enone] = 0.112 ± 0.019. These equilibrium constants are weighted averages of the values from fits to two pairs of experiments, for each of which the uncertainties were calculated using the full covariance matrix calculated by the least-squares procedure (21).

Equilibrium constant for aldol condensation

To determine the overall equilibrium constant for the aldol condensation, K_{31}, we studied the rate of approach to equilibrium in base, for solutions containing 1.1 M acetone and 0.01 M acetophenone, with or without *E*-enone. The results of least-squares fitting to these data are found in Table 3, and the quality of the fit is shown in Fig. 6. The actual experimental data are found in Table S2.[3] We also examined the initial stages of retroaldol reactions of both *E*-enone and ketol using HPLC analysis. To obtain maximum sensitivity, in



SCHEME 2

these experiments a wavelength optimized for *E*-enone was chosen that meant low sensitivity for ketol, which in any case would have been difficult to see because it eluted close to the acetophenone peak. In these experiments equilibration of the isomeric enones could be seen accompanying the approach to aldol equilibrium. Detailed interpretation of this behavior is not possible because of an unexpected problem in the analysis. Samples taken from the reaction were quenched with phosphoric acid to give near neutral solutions, which were stored for some days before HPLC analysis. Later we realized that isomerization continued even in these quenched solutions, so that relative proportions of the two enones are not meaningful. This unexpected reaction was discovered during the study of acid-catalyzed equilibration, and the experiments reported there are based on analyses carried out immediately after withdrawing and quenching samples of the reaction solution. The experiments in base are sufficient to give the information we require, and so were not repeated, but cannot be analyzed to give rates of isomerization. The data were fitted to a double exponential rate law, which allows us to determine infinity points for use in calculating the equilibrium constant. All four data sets, starting with or without *E*-enone present, and following both *E*- and *Z*-enone, were fitted simultaneously with the same apparent rate constants for all four, but with individual preexponential and constant terms. This allows all available information to be used to obtain the apparent rate constants and the infinity values needed to calculate equilibrium constants.

Analysis of the results of equilibration experiments in basic solutions containing acetone and acetophenone shows that $K_{overall}$ = [*E*-enone]/[acetone] [acetophenone] = K_{32}/K_{12} $(2.73 \pm 0.37) \times 10^{-3}$ M^{-1}, and consequently $K_{32} = (1.89 \pm 0.26) \times 10^{-3}$, and $k_{32} = (3.41 \pm 0.49) \times 10^{-4}$ M^{-2} s^{-1}.

Partitioning of the ketol in base

When the ketol is injected into 1 M NaOH, it is essentially completely converted into acetophenone (observed) and acetone (presumed), with only very small amounts of enones. The proportions, by HPLC analysis, were [acetophenone]/[*E*-enone] = $6.8 \times 10^{-3}/6.4 \times 10^{-7} = 1.1 \times 10^{4}$. This qualitatively confirms the simple interpretation of the UV kinetics presented above, namely that the ketol is converted essentially exclusively to acetone and acetophenone, whereas the *E*-enone reacts with rate-limiting hydration followed by rapid retroaldol cleavage. Since a peak of comparable size is seen for the *Z*-enone, and an unknown amount of equilibration has occurred after quenching, further analysis is pointless. When the *E*-enone is injected into 1 M NaOH, no ketol is seen at any time, but acetophenone is slowly formed, and *Z*-enone is formed by a more rapid equilibration process.

Detailed analysis of the kinetics of retroaldol reactions

For retroaldol reactions starting with the *E*-enone in base we now know that breakdown of the ketol to acetone and acetophenone is much faster than dehydration, by a factor of around 10 000. When the retroaldol reaction is followed by UV spectroscopy, a process is observed with a small amplitude, about 100 times faster than the major reaction

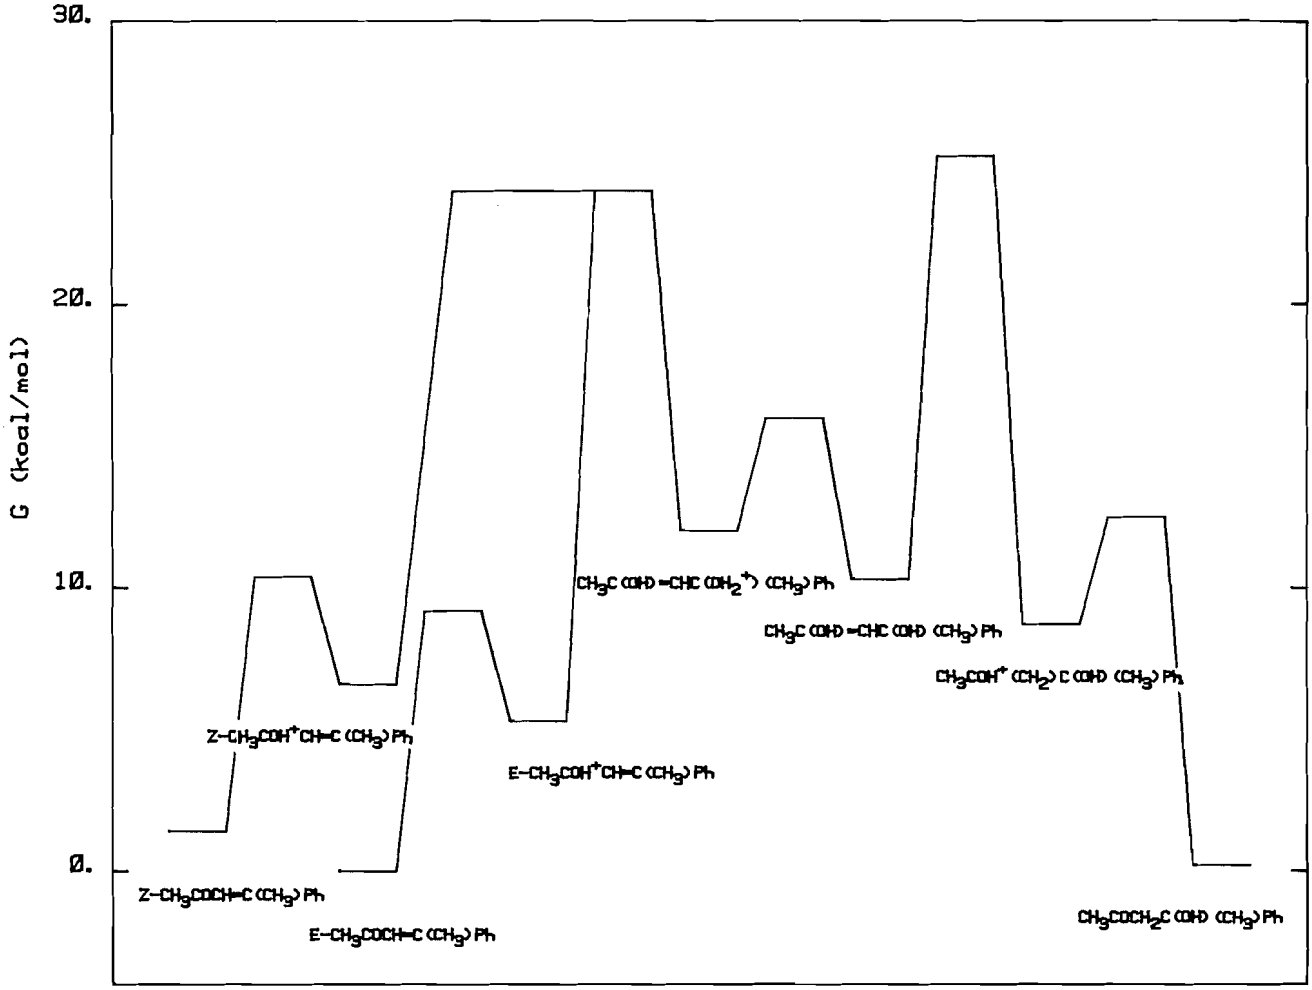

FIG. 3. Reaction coordinate diagram for equilibration of ketol and enones, using the mechanism of Scheme 2. There is an ambiguity since we do not know which of the activation barriers to dehydration from the enol of the ketol by way of the O-protonated form to *E*- or *Z*-enone is higher or if they are coincidentally the same. We have shown them both at the same level. There should be two different rotamers of the protonated enol, since deprotonation is almost certainly faster than rotation of this species, but this could clutter the diagram without there being any additional facts to add. We have assumed that proton transfers are diffusion controlled in the thermodynamically favored direction, and used estimated pK_a values of -4 for the carbonyl protonated enones (assumed to act like vinylogous acetophenone), -6.2 for the carbonyl protonated ketol (assumed to act like acetone), and -1.3 for the protonated enol; the enol content was assumed to be the same as for acetone.

process. This is now attributed to isomerization of the *E*-enone to the *Z*-enone. This must occur without intervention of the ketol. One possibility is that addition of hydroxide ion to the *E*-enone to give the enolate ion corresponding to ketol is most often followed by reversal, expulsion of hydroxide ion to give one or the other enone, and only at a lower rate followed by protonation at carbon to give the ketol. Formation of ketol constitutes essentially irrevocable commitment to cleavage. Thus the system of reactions, shown in Scheme 4, corresponds to a simplified version of the triangular reaction system discussed above for the equilibration in acid, but now $k_{21} = k_{24} = 0$, and species 2 is not the ketol but acetophenone (plus acetone). A kinetically equivalent alternative would be base-catalyzed removal of a γ-proton to give a dienolate, which could then isomerize.[5] Furthermore, since the two phases of the reaction differ by a factor of 100 in rate, we may make the further approximation: k_{14}, $k_{41} >> k_{12}$, k_{42}. Making these substitutions in the equations derived above we now obtain:

$$p = k_{12} + k_{14} + k_{41} + k_{42} \approx k_{14} + k_{41}$$

$$\gamma_1 = 0$$

$$\gamma_2 = k_{12}k_{41} + k_{12}k_{42} + k_{14}k_{42} \approx k_{12}k_{41} + k_{14}k_{42}$$

$$\gamma_3 = 0$$

$$q = (p^2 - 4\gamma_2)^{1/2}$$

$$\lambda_2 = (p + q)/2 \approx p \approx k_{14} + k_{41}$$

$$\lambda_3 = (p - q)/2 \approx \gamma_2/p \approx (k_{12}k_{41} + k_{14}k_{42})/(k_{14} + k_{41})$$

$$\lambda_2\lambda_3 = \gamma_2$$

[5]We thank a referee for suggesting this alternative mechanism.

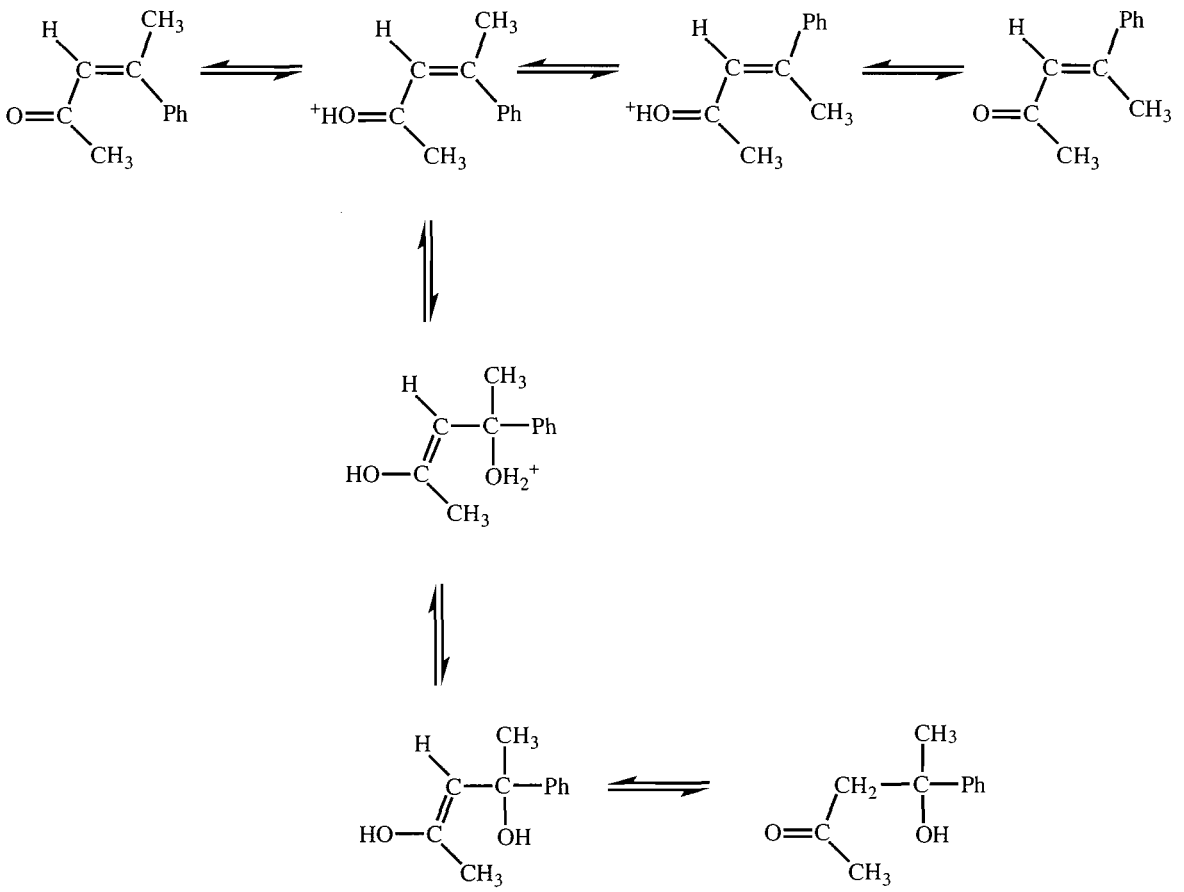

SCHEME 3

$$[E\text{-enone}] = \{C_0(k_{14} - \lambda_3)/(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t) - \{C_0(k_{14} - \lambda_2)/(\lambda_2 + \lambda_3)\} \exp(-\lambda_3 t)$$
$$\approx \{C_0 k_{14}/(k_{14} + k_{41})\} \exp(-\lambda_2 t) + \{C_0 k_{41}/(k_{14} + k_{41})\} \exp(-\lambda_3 t)$$

[7] $$[\text{Acetophenone}] = C_0 + \{C_0(\lambda_3 - k_{12})/(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t) - \{C_0(\lambda_2 - k_{12})/(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t)$$
$$\approx C_0 + \{C_0 k_{14}(k_{42} - k_{12})/(k_{14} + k_{41})^2\} \exp(-\lambda_2 t) - \{C_0\} \exp(-\lambda_2 t)$$

$$[Z\text{-Enone}] = -\{C_0 k_{14}/(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t) + \{C_0 k_{14}/(\lambda_2 - \lambda_3)\} \exp(-\lambda_2 t)$$
$$\approx -\{C_0 k_{14}/(k_{14} + k_{41})\} \exp(-\lambda_2 t) + \{C_0 k_{14}/(k_{14} + k_{41})\} \exp(-\lambda_2 t)$$

Then the absorbance at any time is given by:

$$\text{Absorbance} = \epsilon_1[E\text{-enone}] + \epsilon_2[\text{acetophenone}] + \epsilon_4[Z\text{-enone}]$$
$$= C_0\epsilon_2 + \{C_0 k_{14}/(k_{14} + k_{41})\}\{\epsilon_1 + \epsilon_2(k_{42} - k_{12})/(k_{14} + k_{41}) - \epsilon_4\} \exp(-\lambda_2 t)$$
$$+ \{C_0/(k_{14} + k_{41})\}\{\epsilon_1 k_{41} - \epsilon_2(k_{14} - k_{41}) + \epsilon_4 k_{14}\} \exp(-\lambda_3 t) = C_0\epsilon_2 + \alpha \exp(-\lambda_2 t) + \beta \exp(-\lambda_3 t)$$

Since $\epsilon_2 \approx \epsilon_1/10$, and $k_{42} \approx 10k_{12}$, and $k_{12} \approx k_{14}/100$, and $\alpha \approx \beta/10$, we may conclude that $\alpha \approx \{C_0 k_{14}/(k_{14} + k_{41})\}(\epsilon_1 - \epsilon_4)$, which means that the two geometrical isomers have rather similar extinction coefficients, that for the *E*-enone being somewhat larger.

The analysis so far leads to the reaction coordinate diagram shown in Fig. 7. This figure is drawn for the addition–elimination mechanism for isomerization. If isomerization occurs by a deprotonation–reprotonation mechanism, then an additional pair of dienolate intermediates, and three transition states, all *lower* than G_{45}* or G_{15}* would have to be added to the diagram. There would be no change to the analysis that follows. It is possible to derive a relationship between k_{42} and k_{12}; this is most readily done using free energies, and referring to Fig. 7. If species 5 is the enolate of the ketol, then

$$\Delta G^{\ddagger}_{12} = G_{52} - G_1$$
$$\Delta G^{\ddagger}_{42} = G_{52} - G_4$$
$$\Delta G^{0}_{14} = G_4 - G_1$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 79.173.37.17 on 09/08/12
For personal use only.

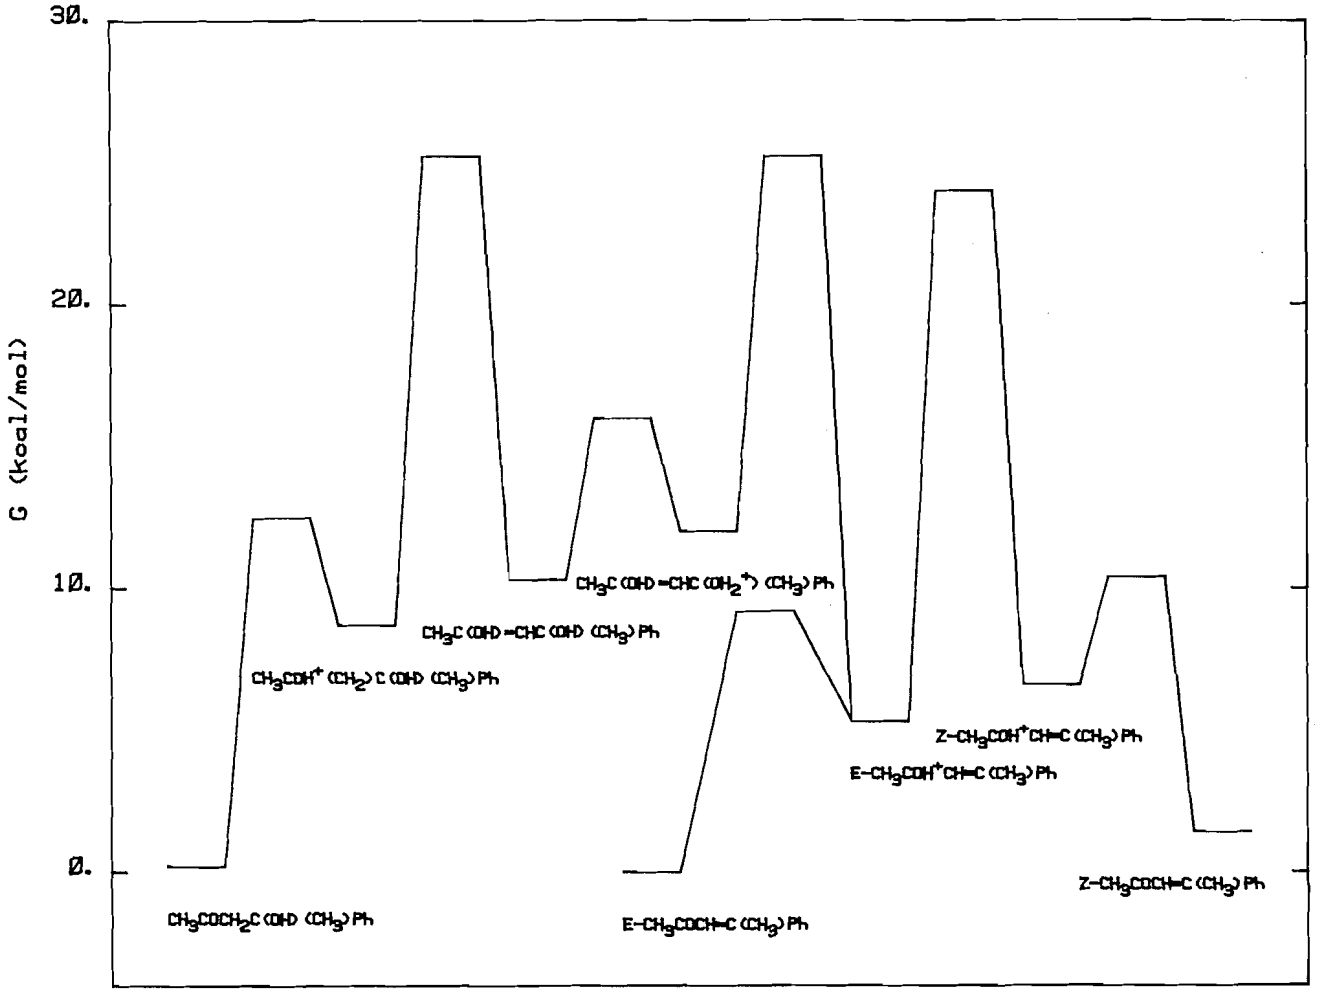

FIG. 4. Reaction coordinate diagram for equilibration of ketol and enones, using the mechanism of Scheme 3. There is an ambiguity because we do not know whether conversion of carbonyl protonated *E*-enone to the enolized ketol or ketonization of the ketol is rate limiting; we have drawn both transition states at the same level. The same assumptions were made concerning basicity of reactants as for Fig. 3.

$$\Delta G^{\ddagger}_{12} - \Delta G^{\ddagger}_{42} = G_4 - G_1 = \Delta G^{0}_{14}$$

$$k_{12}/k_{42} = K_{14}$$

$$k_{42} = k_{12}/K_{14}$$

Now we can simplify the expression for λ_3:

$$\lambda_3 \approx (k_{12}k_{41} + k_{14}k_{42})/(k_{14} + k_{41})$$

$$= k_{12}/(1 + k_{14}/k_{41}) + k_{42}(k_{14}/k_{41})/(1 + k_{14}/k_{41})$$

$$= k_{12}/(1 + K_{14}) + k_{12}(1/K_{14})K_{14}/(1 + K_{14})$$

$$= 2k_{12}/(1 + K_{14})$$

This result is at first surprising, but simply means that if two rapidly interconverting species can both go to product, there are in effect two reaction channels, and reaction is twice as fast as if there were only one. Since the observed value for $\lambda_3 = (9.99 \pm 0.25) \times 10^{-6}\ M^{-1}\ s^{-1}$, and $K_{14} = 0.112 \pm 0.019$, we may now calculate $k_{12} = (9.99 \pm 0.25) \times 10^{-6}\ M^{-1}\ s^{-1}\ (1 + 0.112 \pm 0.019)/2 = (5.55 \pm 0.17) \times 10^{-6}\ M^{-1}\ s^{-1}$. It follows that $k_{42} = k_{12}/K_{14} = (4.96 \pm 0.93) \times 10^{-5}\ M^{-1}\ s^{-1}$.

With k_{12} and k_{42} now determined, and K_{12} and K_{42} known from the analysis of the kinetics of equilibration in acid, we may calculate k_{21} and k_{24}, as $(8.00 \pm 0.40) \times 10^{-6}\ M^{-1}\ s^{-1}$ and $(7.93 \pm 2.22) \times 10^{-6}\ M^{-1}\ s^{-1}$ respectively.

We have now completed the kinetic analysis to the point of having all of the rate and equilibrium constants for the rate-limiting processes for the two principal stages of the aldol condensations leading to the *E*- and *Z*-enones.

The accuracy of the λ_2 values is low, because these parameters are determined by a small amplitude process at short times, but we can extract approximate estimates of k_{14} or k_{41}. $\lambda_2/[OH^-]$ has a weighted average value of $(3.12 \pm 0.68) \times 10^{-4}\ M^{-1}\ s^{-1}$. Since K_{14} is known from both kinetics in base, $K_{14} = 0.159 \pm 0.033$, and kinetics in acid, $K_{14} = 0.112 \pm 0.019$ (values which agree within their estimated standard deviations, we will use the more accurate value from kinetics in acid, and can calculate that $k_{14} = (3.14 \pm 0.84) \times 10^{-5}\ M^{-1}\ s^{-1}$ and $k_{41} = (2.81 \pm 0.61) \times 10^{-4}\ M^{-1}\ s^{-1}$.

Discussion

In the course of the work described in this paper we have developed computer programs written in FORTRAN that

[a]In aqueous solution at 25°C, followed by HPLC analysis monitoring absorbance at 280 nm. To obtain convenient peak heights the volume injected and the absorbance scales were adjusted; for ease of comparison the peak heights have been corrected to a common basis, even though this corresponds to peaks over a meter high in some cases. Peak heights vs. time data were fitted to peak height = $a_1 + a_2(\exp(-a_3 t) + a_4 \exp(-a_5 t)$, with a_1, a_2, a_4 specific to the particular data set, while a_3 and a_5 were the same for all data sets, and all four data sets were fitted simultaneously.

allow us to fit several sets of data simultaneously with some parameters common to all sets and some specific to a particular set. Two variations on this theme were used. In the first we fitted the exact integrated rate law, using theoretical expressions for both the exponential terms (apparent rate constants) and the preexponential terms. In favorable cases, including the present example of fitting equilibration data for the two isomeric enones and the ketol in acidic solution, this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 79.173.37.17 on 09/08/12

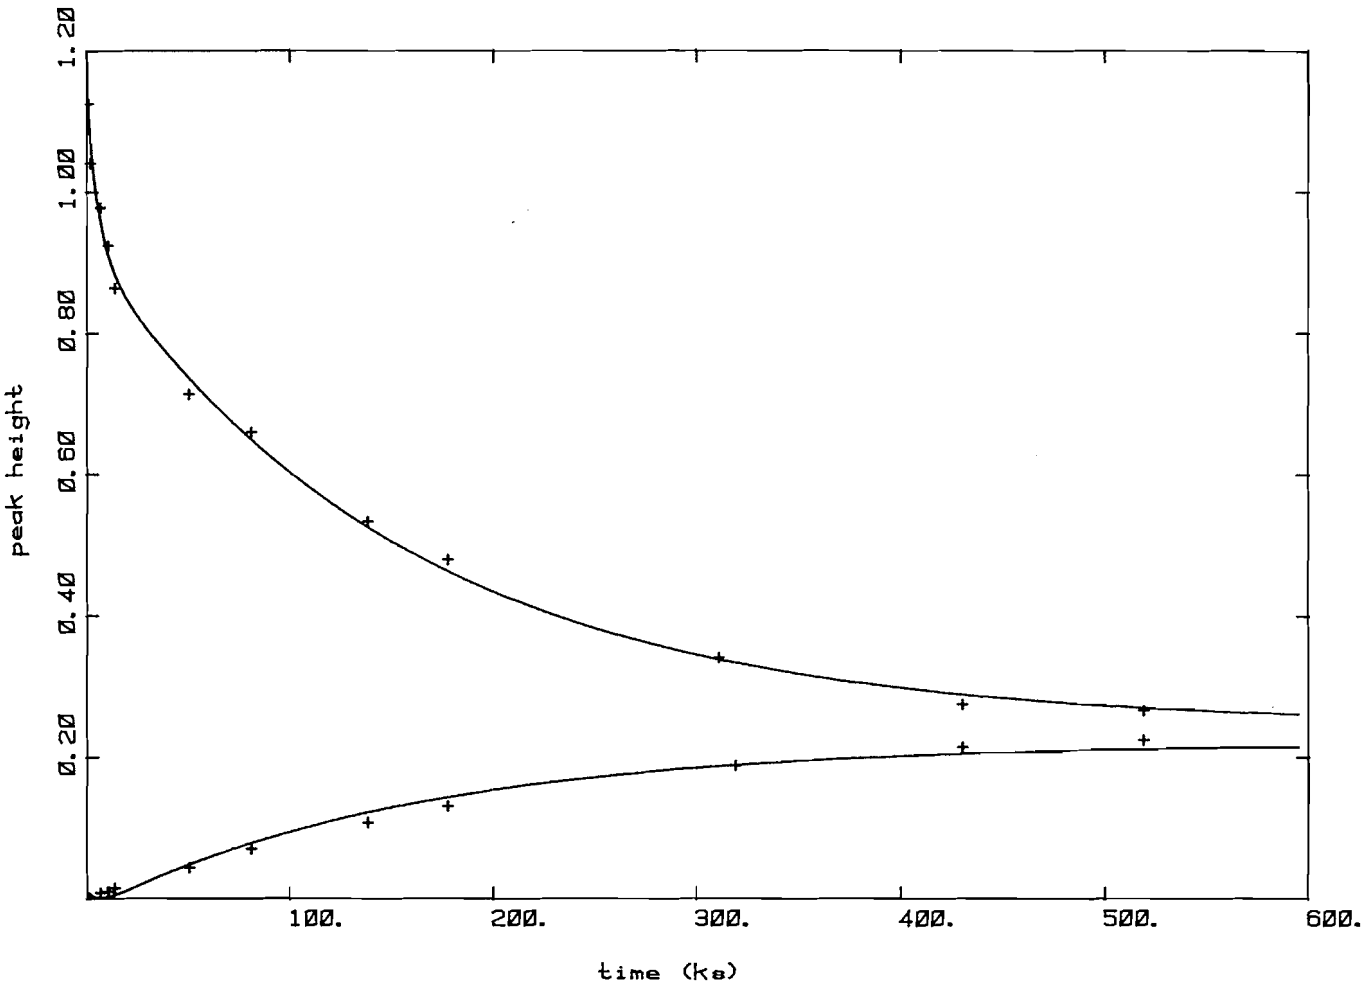

FIG. 6. Equilibration in base: the concentration of *E*-enone as a function of time (as measured by HPLC analysis), starting with either no enone present or 1.0×10^{-4} M enone present. In both cases the solution contained 1.086 M acetone and 0.010 M acetophenone, and 0.887 M NaOH.

allows direct calculation of the relevant rate constants. In the second, used where the data were less precise and we knew there were experimental problems precluding detailed interpretation, we simply fitted all sets of peak heights vs. time data to the same form of integrated rate law, with common apparent rate constants and individual preexponential terms. This allows satisfactory fitting to all the data, even when an individual data set would not give a satisfactory fit because the least-squares program could not converge. It is of course essential to be sure that all data sets used do in fact belong to a single reaction system, so that it is legitimate to apply this procedure. If this precondition is not met, then fitting in this way will provide a new way to mislead oneself.

With the ready availability of HPLC apparatus, it will become increasingly common to use this technique for reaction kinetics. The advantage is that one follows individual species (assuming satisfactory analytical conditions with good resolution); the disadvantage is that the precision is less than can be obtained by UV spectrophotometric kinetics. By treating data for all species involved in a reaction, and for sets of reaction that must have the same values for pseudo first-order rate constants, we can obtain the best possible precision, as well as having the greater accuracy inherent in having a more specific analytical technique.

The second mechanism, shown in Scheme 3, assumes that only the original isomer of the enone undergoes hydration to ketol, while the second isomer does not. This seems peculiar at first glance, but can be rationalized in terms of the conformations of the cations obtained by protonation at the carbonyl oxygen. The *E* isomer can be planar, as is required for maximum conjugative stabilization of the positive charge, although this incurs some destabilizing steric interactions. The *Z* isomer cannot be planar, and may plausibly be assumed to have the phenyl ring nearly orthogonal to the plane of the protonated enone. This avoids steric interactions of the *ortho* hydrogens with the *cis* acetyl group, but imposes interference by these *ortho* hydrogens to the attack of water on the C=C double bond. Thus acid-catalyzed interconversion of the geometrical isomers by way of the protonated enone can lead to addition of water only to the protonated *E* enone.

Further logical implications of the above mechanisms are that acid-catalyzed rotation about the C_3—C_4 bond occurs because the bond order is decreased in the cation, even though the phenyl group can provide little or no conjugative stabilization for the *Z* isomer of the cation. This seems to require that rotation from the *Z* cation to the *E* cation entails only a modest energy barrier because loss of conjugation to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 79.173.37.17 on 09/08/12

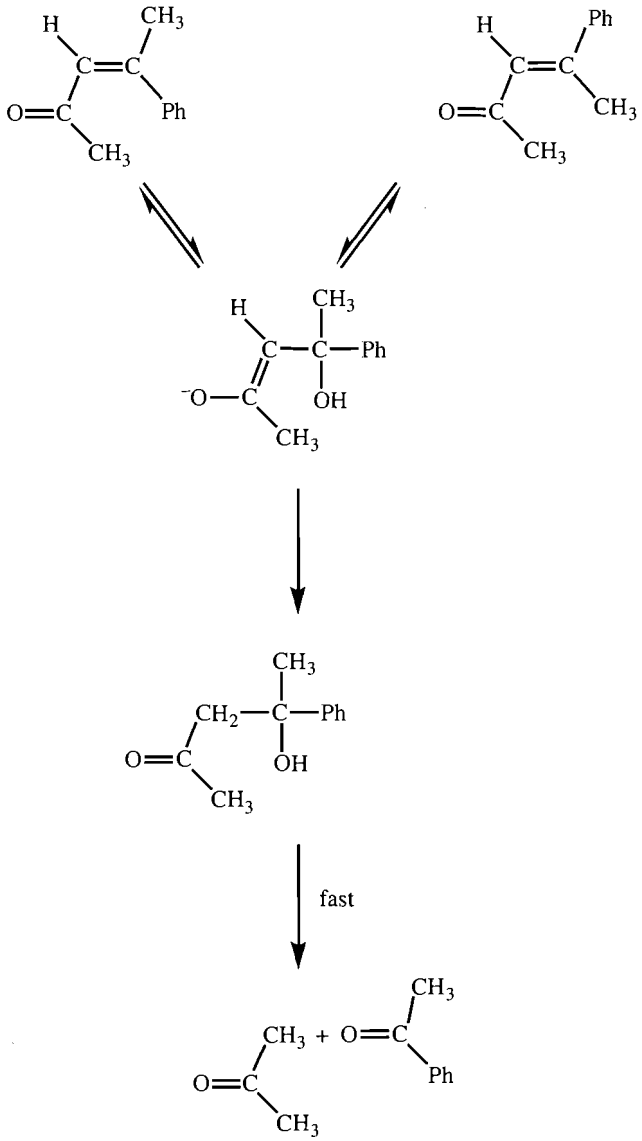

SCHEME 4

the OH can be compensated by gain of conjugation to the phenyl, which rotates as C_3—C_4 rotation occurs.

It is striking that in base, where the form of the overall kinetics followed by UV demands that the ketol undergo retroaldol much faster than dehydration to enone, equilibration of the two enones nonetheless occurs at rates competitive with retroaldol cleavage. Since our principal interest was in determining rate constants for the aldol condensation, we have not settled the mechanism of this isomerization. If it occurs by addition–elimination, then it must follow that the enolate, which is the immediate product of hydroxide addition to either enone, can rotate and expel hydroxide faster than it undergoes reprotonation. If isomerization occurs by deprotonation–reprotonation, then this must be fast relative to ketol formation.

The kinetics of equilibration were fitted to a double exponential integrated rate law. In the present case, since we did not have a sample of the *Z*-enone, and could not apply mass balance constraints, we could not determine a calibration constant for the *Z*-enone. Instead of the more elaborate procedure used for the equilibrations in acid, we simply imposed the requirement that the same apparent rate constants, for both exponentials, apply to all of the species whose reaction could be followed for a given hydroxide concentration. We could then fit four sets of peak height vs. time data (for the two isomeric enones, starting from solutions with identical hydroxide, acetone, and acetophenone concentrations, but initially zero or finite *E*-enone content) and fit simultaneously to obtain the best values of the apparent rate constants. The values so obtained are found in Table 3. Naturally, in these experiments we also observed the formation of the alternative aldol condensation product, 3-methyl-1-phenyl-2-buten-1-one.

The data in Table 4 show that there is a linear free energy relationship between the equilibrium constant for aldol addition reactions with acetone as carbon nucleophile and the equilibrium constant for the addition of water. This is illustrated in Fig. 8. Although the correlation is not exact, it is enough to suggest that there is a useful way to obtain approximate predictions.

Perhaps unsurprisingly there is much less pattern discernible in the equilibrium constants for the dehydration step. Clearly a phenyl group on the β-position of the enone favors dehydration relative to a hydrogen, as does a methyl group, and a phenyl is much more effective ($\delta \log K = +2.75$ for phenyl, +0.52 for methyl). A methyl forced to be *cis* to the acetyl group in the enone is detrimental, although the effect on $\log K_{21}$ is not uniform, $\delta \log K$ being −1.22 when the first β substituent is phenyl, and −0.35 when the first β substituent is methyl. As significant steric effects develop, the magnitude of the effect becomes specific to the particular compound, and is not susceptible to back-of-the-envelope calculations. Molecular mechanics calculations may in time be the best way to predict these effects.

When we compare the two modes of reaction possible for the crossed aldol of acetone and acetophenone we find that the reaction studied in the present work is considerably more favorable than might have been expected. As we have just shown, there is generally a correlation between the equilibrium constant for an aldol addition and that for the addition of water. The two nucleophiles, acetone and acetophenone, have very similar inherent tendencies to add to carbonyls, as measured by their γ values (4, 22), and the equilibrium constants for hydration differ by a factor of 208, favoring acetone. Thus it is disconcerting to find that the equilibrium constants for the two alternative modes of crossed aldol addition differ only by a factor of 2, favoring addition of acetophenone to acetone. Because we had expected a factor more like 200 to disfavor addition of acetone to acetophenone, we were surprised when the synthetic experiments showed that the two reactions were competitive. After the encouraging signs of predictable behavior that we had found, it is perhaps salutary to be reminded that the aldol reaction still has surprises.

Experimental

Materials

4-Hydroxy-4-phenyl-2-pentanone

Bromobenzene (11.8 g, 75 mmol) in 30 mL dry THF was dropped into magnesium turnings (1.8 g, 75 mmol) in 20 mL dry THF under nitrogen in a 100 mL round-bottomed flask with a reflux condenser over a period of 1 h and left to react at room temperature for an additional 0.5 h. A solution of 2.5 g (25 mmol) of

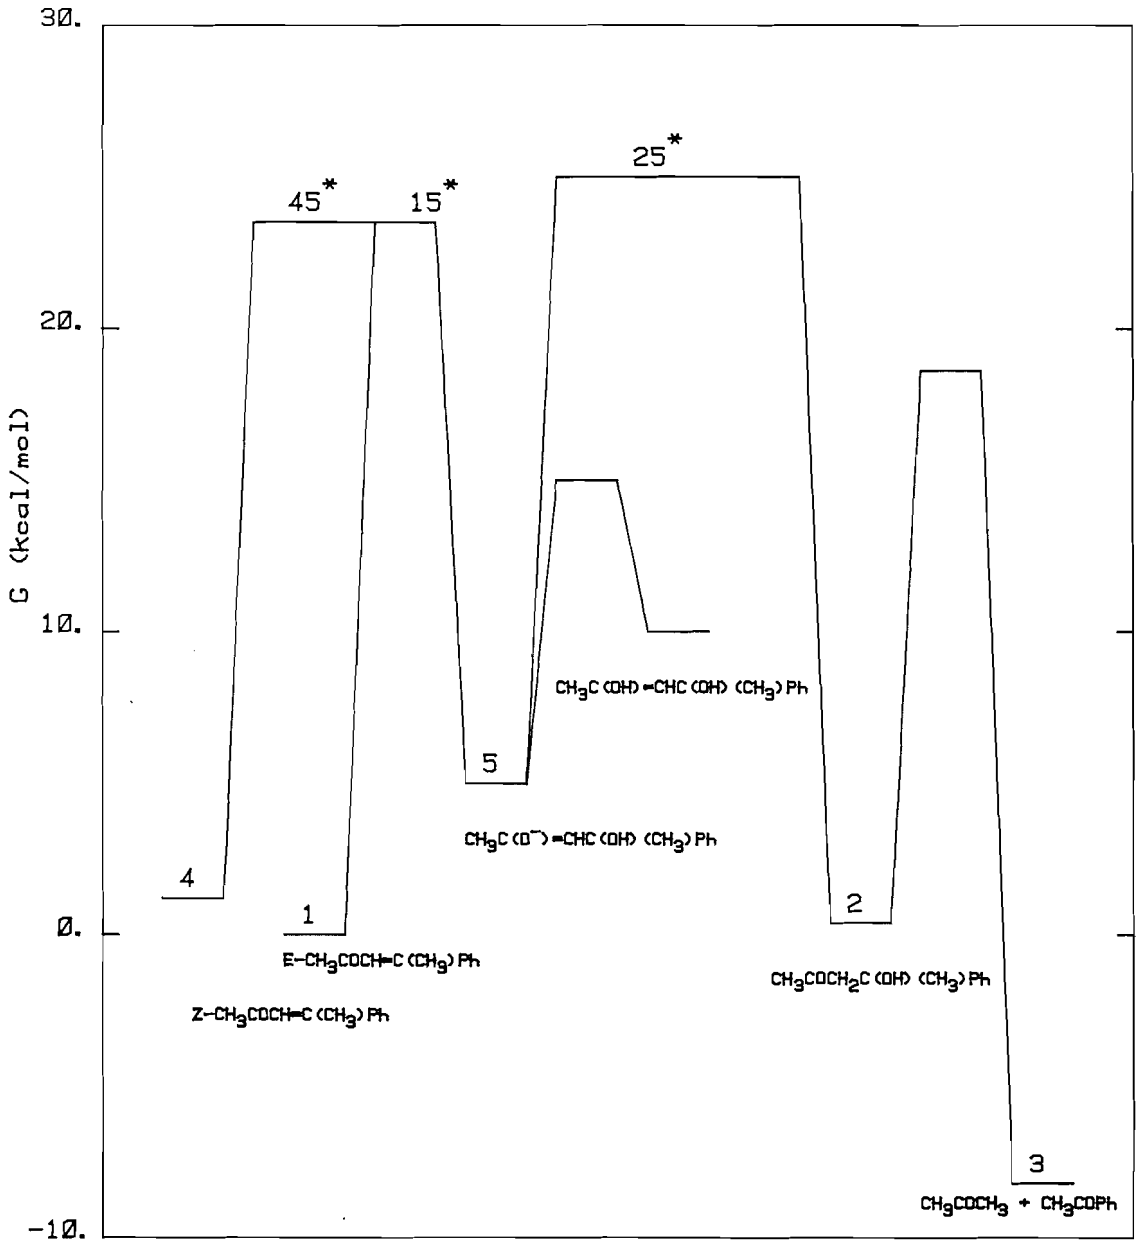

FIG. 7. Reaction coordinate diagram for equilibration of ketol and enones, using the mechanism of Scheme 4. There is an ambiguity because we do not know whether the activation barrier for conversion of the enolate of the ketol to the *E*- or *Z*-enone is higher; consequently we have drawn them both the same, equal to the observed value. As before the enol content of the ketol was assumed the same as for acetone, and a pK_a of 10 was assumed for this enol. Proton transfers to and from oxygen were assumed to be diffusion controlled in the thermodynamically favored direction.

2,4-pentanedione in 20 mL dry THF was added dropwise to the stirred solution of the Grignard reagent. After all the diketone solution was added, the reaction mixture was stirred overnight (13 h), and poured gradually into 100 mL of a stirred, ice-cold, saturated solution of ammonium chloride in water. The organic layer was separated, dried over anhydrous magnesium sulfate, filtered, and evaporated to dryness, yielding 14 g. The crude product, 1 g, from above, was chromatographed on a column of silica G, 40 g, eluted with a linear gradient (0–30%) of ethyl acetate in hexane. The eluates were pooled according to TLC analysis and evaporated separately to dryness. The fraction that had the same retention time as authentic $PhC(OH)(CH_3)CH_2COCH_3$ was pumped for a half hour to remove residual solvents, yielding 0.7 g. The proton NMR indicated that it was mainly $PhC(OH)(CH_3)CH_2COCH_3$, with some $PhC(CH_3)=CHCOCH_3$ and other impurities.

Pure 4-hydroxy-4-phenyl-2-pentanone was obtained by crystallizing relatively purified ketol at 0°C from 1:1 diethyl ether/hexane and washing with cold hexane. UV (MeOH), λ_{max}:258 nm, ϵ_{max} 187, ϵ_{280} 51. NMR ($CDCl_3$, 200 MHz), δ: 1.51 (s, 3H), 2.06 (s, 3H), 2.83, 3.19 (dd, J = 17.1 Hz, 2H), 4.54 (s, 1H), 7.22–7.45 (m, 5H); lit. (23) ($CDCl_3$, 60 MHz) δ: 8.66–7.30 (m, C_6H_5), 4.73 (s, OH), 3.43, 2.43 (dd, J = 18 Hz, 2H), 2.16 (s, CH_3-C-O), 1.60 (s, CH_3). Exact Mass calcd.: 178.0994; found: 178.0993 ± 0.00009.

4-Phenyl-3-penten-2-one

The crude product (mainly $PhC(OH)(CH_3)CH_2COCH_3$), 0.5 g, from above was added to a crucible containing a small amount of silica gel G. Three drops of 6 N HCl and a small amount of methanol were added. The entire mixture of solid and liquid was mixed

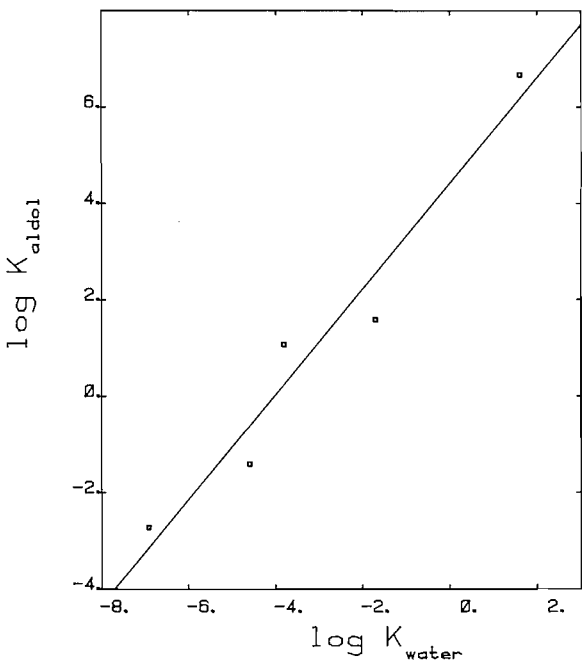

FIG. 8. Correlation between log K_{aldol} for the aldol addition of acetone as nucleophile reacting with formaldehyde, acetaldehyde, benzaldehyde, acetone, and acetophenone, and log K_{H_2O} for the addition of water. Both equilibrium constants are expressed with units of M^{-1}. The correlation line, fitted by least squares, is log K_{aldol} = 4.42 ± 0.94 + 1.09 ± 0.15 log K_{H_2O}.

completely and heated on a steam bath for 1 h. The reaction mixture was washed through filter paper, using solvent ethyl acetate. The filtrate was evaporated to dryness and loaded on a column of silica G, 40 g, eluted with a linear gradient (0–30%) of ethyl acetate in hexane. The eluates were evaporated separately to dryness according to TLC analysis.

Pure 4-phenyl-3-penten-2-one was obtained by crystallizing relatively purified enone at 0°C from 1:1 diethyl ether/hexane and washing with cold hexane. UV(MeOH), λ_{max}:280 nm, ϵ_{max} 18 300; lit. (24) (EtOH), λ_{max}: 280 nm, ϵ_{max} 19 000. NMR ($CDCl_3$, 200 MHz), δ: 2.30 (s, 3H), 2.54 (d, J = 1.3 Hz, 3H), 6.51 (m, J = 1.2 Hz, 1H), 7.26–7.50 (m, 5H); lit. (16) (CCl_4, 60 MHz), δ: 2.06 (s, 3H), 2.35 (d, J = 1 Hz, 3H), 6.21 (m, 1H), 7.10 (br s, 5H). Exact Mass calcd.: 160.0888; found: 160.0911 ± 0.0030.

Methods

Kinetics

The procedure for kinetics was as described (16). Reactions followed by UV spectroscopy were carried out in 10-cm cells holding 25 mL of solution at 25°C. Reactions that were followed by HPLC analysis were carried out in suitable vessels, thermostatted in a water bath, and samples were taken at intervals. For reactions in base, the samples were quenched with 1 M H_3PO_4; for reactions in acid the samples were quenched with 1 M Na_2HPO_4. At first quenched samples were stored and analyzed together, but it was discovered that slow equilibration of the enones was occurring in the quenched samples. For the experiments in Table 2, analysis was carried out immediately after quenching. For the experiments in Table 3, analysis was delayed, and thus no detailed interpretation of enone concentrations can be meaningful except at the end of the equilibration. The solvents used were different mixtures of methanol and water flowing at 2.0 mL/min through a C18 Radial Pak column.

Stock solutions were prepared by weighing purified compounds into volumetric flasks and diluting with solvents (spectrophotometric grade methanol or acetonitrile) to the mark. Sodium hydroxide solutions were titrated against standardized hydrochloride solution using two indicators (phenolphthalein and methyl red) and correcting for carbonate. The extinction coefficients of various compounds were measured by adding measured amounts (Hamilton syringe) of a stock solution in methanol to 25 mL of a solvent (either methanol, ethanol, water, or aqueous potassium chloride solution).

Silicon cation and anion chemistry in a fuel-rich, methane–oxygen flame

J. Hugh Horton and John M. Goodings[1]

Department of Chemistry, York University, 4700 Keele Street, North York, Ont., Canada M3J 1P3

Received July 26, 1991

J. Hugh Horton and John M. Goodings. Can. J. Chem. **70**, 1069 (1992).

Silicon cations and anions in a fuel-rich, premixed, methane–oxygen flame at atmospheric pressure doped with 0.01 mol% of trimethylsilane were observed by sampling the flame through a nozzle into a mass spectrometer. Twelve cations were observed which can be grouped into five series: $SiOH^+.nH_2O$ (n = 0–2); $SiOCH_3^+.nH_2O$ (n = 0–2); $Si(OH)_3^+.nH_2O$ (n = 0–2); cations by nucleophilic substitution (e.g., $Si(OH)(CH_3)_2(H_2O)^+$); and carbonaceous aromatic cations (c-$HSiCH{=}CH^+$ and c-$HSiCH{=}CCH_3^+$). Similarly, five anions were observed as members of two series: $H_xSiO_3^-$ (x = 0, 1) and $H_xSiO_4^-$ (x = 1–3). The chemical ionization reactions for the formation of these ions are discussed in detail, including proton transfer and also methyl cation transfer, three-body addition, nucleophilic substitution (S_N2) of both the ions themselves and also their neutral silicon precursors, and H-atom abstraction reactions. The neutral silicon chemistry in the flame is dominated by SiO, but evidence was obtained from both the cation and the anion chemistry for the presence of HSiO(OH), silanoic acid; $SiO(OH)_2$, metasilicic acid; and $Si(OH)_4$, orthosilicic acid. The silicon ion chemistry differs markedly from the normal carbon ion chemistry that occurs naturally in the undoped methane–oxygen flame; the silicon ions show a strong tendency towards Si—O bond formation. Consideration is given to the probable structures of the various silicon cations and anions observed.

J. Hugh Horton et John M. Goodings. Can. J. Chem. **70**, 1069 (1992).

On a observé des anions et des cations siliciés dans la flamme de prémélange d'un mélange de méthane–oxygène riche en méthane à la pression atmosphérique et dopé avec 0,1% de triméthylsilane, en injectant, à l'aide d'une buse, des échantillons de flamme dans un spectromètre de masse. On a observé 12 cations que l'on peut regrouper en cinq catégories : $SiOH^+.nH_2O$ (n = 0–2); $SiOCH_3^+.nH_2O$ (n = 0–2); $Si(OH)_3^+.nH_2O$ (n = 0–2); des cations obtenus par substitution nucléophile (par exemple : $Si(OH)(CH_3)_2(H_2O)^+$); et des cations carbonés aromatiques (c-$HSiCH{=}CH^+$ et c-$HSiCH{=}CCH_3^+$). D'une façon analogue, on a observé cinq anions appartenant à deux séries : $H_xSiO_3^-$(x = 0, 1); et $H_xSiO_4^-$ (x = 1–3). On discute en détail des réactions d'ionisation chimique conduisant à ces ions. Ces réactions comprennent : le transfert de proton et de cation méthyle, l'addition a trois espèces, la substitution nucléophile (S_N2) des deux anions eux-mêmes et de leur précurseur silicié et les réactions d'abstraction d'hydrogène. La chimie du silicium neutre, dans la flamme, est dominée par le SiO, mais on a obtenu des preuves de la présence de l'acide silanoique, HSiO(OH), de l'acide métasilicique, $SiO(OH)_2$, et de l'acide orthosilicique, $Si(OH)_4$, à partir de la chimie des cations et des anions. La chimie du silicium diffère nettement de la chimie d l'ion carbone normal qui se forme naturellement dans la flamme du mélange méthane–oxygène non dopé; les ions silicium exhibent une forte tendance vers la formation de liaison Si—O. On formule des hypothèses sur les structures probables des différents cations et anions siliciés observés.

[Traduit par la rédaction]

Introduction

The ion chemistry of carbon in flames has been studied for many years by sampling a flame into a mass spectrometer. A general review article is available (1), and detailed statements of both the carbon cation (2) and anion (3) chemistry have been given for the same flame employed in the present work. However, there have been very few studies of silicon ion chemistry in flames. Silicon is of interest for several reasons. One objective is a comparison with the flame-ion chemistry of carbon; that is, the extent to which the chemistry of carbon and silicon are parallel or different from one another, as well as the extent to which the two elements compete. Since silicon is found as an impurity in coal, silicon compounds are released into the atmosphere when coal is burnt. These compounds have also been observed in the Arctic haze (4). A study of the flame-ion chemistry of silicon can provide information about what silicon compounds are formed during combustion and might suggest mechanisms for their formation. Finally, several silicon compounds, especially SiO, have been implicated in the chemistry of interstellar gas clouds (5, 6).

The few studies of silicon ion chemistry in a flame which have been performed (7, 8) were primarily intended to survey the effects of various Group IV elements on flame ionization detectors. Here, we describe a more detailed study of the silicon ion chemistry taking place in a premixed hydrocarbon flame of fuel-rich composition, using trimethylsilane (TrMS) as the silicon source. Complete profiles of the ion concentrations as a function of distance along the flame axis are presented, rather than isolated measurements at a fixed point in a flame. Also, silicon anions as well as cations have been observed in this work.

Reactions of a large number of silicon ions, especially cations, have been studied using flowing afterglow and selected ion flow tube (SIFT) techniques at room temperature (9–11). These experiments encompass measurements of the kinetics of silicon ion reactions, as well as attempts to formulate mechanisms. In addition, a number of structural calculations have been carried out (5, 12). Of greatest applicability to silicon flame-ion chemistry are the studies of the structure and reactions of $SiOH^+$, and the formation and structure of $SiOCH_3^+$ (13, 14). In many ways, the flame work is complementary to the SIFT studies; our observations of ions that were also seen in the SIFT demonstrate that these ions exist in real systems such as flames. The observed flame ions also suggest that some unexplored mechanisms of silicon ion formation such as methyl cation transfer are possible.

TABLE 1. Bulk characteristics of the fuel-rich flame

Flame parameter	Value
Equivalence ratio ϕ	2.15
Unburnt gas flow rates (mL s^{-1})	
CH_4	13.0
O_2	12.1
Adiabatic flame temperature (K)	2456
Measured flame temperature (K)	2200
Burnt-gas rise velocity (m s^{-1})	2.0
Equilibrium burnt-gas composition at 2200 K (mol fractions):	
H_2O	0.25144
H_2	0.41195
O_2	0.00000049
CO	0.29781
CO_2	0.034872
H	0.0036255
OH	0.00030488
O	0.00000191

When silicon compounds burn, silicon oxides are produced that are deposited on the sampling orifice of the flame-ion mass spectrometer and interfere with the sampling of the flame ions. This effect limited our experiments to low concentrations of TrMS additive in fuel-rich flames. The observation of ions in fuel-lean (i.e., oxygen-rich) flames, in which even more silicon oxides are formed, was ruled out.

Experimental

The flame used in these experiments was a premixed, laminar, fuel-rich, methane–oxygen flame at atmospheric pressure. Bulk characteristics are given in Table 1. The flame was conical in shape, ca. 3.5 mm in base diameter and 5 mm in height with a rounded tip. It was stabilized on a quartz capillary burner of inner diameter 2.3 mm, and was surrounded by a Pyrex tube of diameter 25 mm through which cold Ar flowed to minimize entrainment of ambient air. Gases used were Matheson CP-grade (CH_4 > 99.0%, Ar > 99.9%, and O_2 > 99.6%). All were added directly from high-pressure cylinders without further purification. The flame had a distinct bluish colour, and a bright blue reaction zone of thickness ca. 0.3 mm. Upon adding TrMS, the flame appeared to become slightly more purple in colour.

Silicon was added to the flame as trimethylsilane, $HSi(CH_3)_3$ (TrMS), to give a silicon concentration in the burnt gas of 0.01 mol%. The TrMS (Petrarch, 97%) was added directly from its cylinder into the oxygen gas flow feeding the burner without further purification. Since TrMS has a boiling point of about 7°C, the vapour pressure inside the cylinder (>1 atm; 1 atm = 101.3 kPa) could be readily controlled by immersion in a cooled water bath. The very small and uniform flow rate of TrMS required (0.0024 mL s^{-1}) was achieved by use of a variable leak valve (Granville–Phillips, type C).

The addition of silicon produced SiO_2 in the flame. It caused a buildup of a quartz-like deposit around the sampling orifice of the mass spectrometer, which eventually became blocked. The very small concentration level of 0.01 mol% was chosen to minimize this problem. Silicon ions could only be studied in a fuel-rich flame since a fuel-lean flame would have led to even greater SiO_2 formation. Also, a large sampling orifice of diameter ca. 0.18 mm was used. Even so, experiments could be run for only 3 h at a time before the orifice became clogged with quartz. After each run, the quartz had to be mechanically removed using a steel needle ground to a very fine point.

The burner was mounted on a motorized carriage with the flame in a vertical position to avoid distortion of axial symmetry due to buoyancy effects. The burner drive was calibrated to provide spatial resolution of ±0.02 mm when sampling ion concentrations along the flame axis, z. The burner could be positioned to provide accurate alignment of the conical flame axis with the sampling nozzle of a mass spectrometer. The nozzle itself was made by modifying a platinum electron microscope lens in the form of a "top hat" (J.B. EM Services Inc.), which was swaged into a water-cooled plate in a manner previously described (15). The lens was initially supplied with an orifice diameter of 0.15 mm that was subsequently opened up to 0.18 mm.

The flame-ion mass spectrometer has been described elsewhere in detail (2). Briefly, the sampled ions pass through two stages of differential pumping into a quadrupole mass filter. The mass-analyzed ions are detected with a parallel-plate Faraday collector connected to a vibrating reed electrometer having a grid-leak resistance of 10^{10} Ω. The data are presented below as profiles of ion signal measured in volts versus distance z along the flame axis. Cations or anions can be sampled by reversing the polarity on all electrodes. Also, total cations or total anions can be measured by switching off the dc electric voltages supplied to the quadrupole rods. However, the sensitivity for total ion signals is not the same as that for the individual ion signals, so the profile magnitudes are not directly comparable.

A method has been described (2) for locating a reproducible origin (z = 0) in the flame. It corresponds to the downstream tip of the luminous reaction zone. Thus, negative z refers to the reaction zone of the flame and positive z to the downstream region. The ion signal magnitudes given in the data below have been corrected for mass discrimination present in the filter against ions of high mass number by a method previously described (16). One problem encountered when calibrating peak magnitudes was that signal strengths would slowly decrease as the orifice became clogged by quartz deposits. Thus, peak heights were measured in the first half hour of run-time over a period of several days, and gave reproducible results.

The flame gas is cooled in passing through the thermal boundary layer surrounding the sampling orifice, and also during the expansion to supersonic velocity that proceeds inside the nozzle downstream of the orifice throat. Some ion signals can be subject to distortion during sampling by the mass spectrometer since an ion–molecule reaction having a high kinetic rate can shift in the exothermic direction (17). An example might be the formation of an ion hydrate. However, the enhancement of ion hydrates in the cold boundary layer around the sampling orifice has been minimized in the present experiments by the use of a relatively large orifice 0.18 mm in diameter.

Neutral silicon species

Before proceeding with the silicon ion chemistry, it is first necessary to consider the neutral silicon species likely to be present in the flame. Although silicon is added as trimethylsilane (TrMS), it will decompose and oxidize to give a variety of neutral species whose final equilibrium concentrations are determined by the composition of the burnt gas at 2200 K given in Table 1; at equilibrium, the chemical nature of the original additive is irrelevant. Using ΔG_f^0 values at 2200 K taken from the JANAF tables (18), a series of bimolecular reactions was chosen to encompass all of the silicon species listed in the JANAF tables of any importance, and the major neutral species present in the equilibrium burnt gas of the fuel-rich flame; the burnt-gas composition was also determined using data from JANAF tables (18). Unfortunately, thermochemical data are not available for several silicon species of interest such as silanoic acid, HSiO(OH):

TABLE 2. Equilibrium concentrations of neutral silicon species in the fuel-rich flame

Species	ΔG_f^{0a} 2200 K (kJ mol^{-1})	Reaction	ΔG_{rxn}^0 2200 K (kJ mol^{-1})	Equilibrium concentration[b] (mol fraction)
Si	144.382	$SiO + H_2 \rightarrow Si + H_2O$	286.385	5.16×10^{-10}
Si_2	219.682	$2SiH \rightarrow Si_2 + H_2$	98.788	1.16×10^{-17}
Si_3	249.366	$Si_2 + SiH \rightarrow Si_3 + H$	−34.839	3.14×10^{-24}
SiC	316.922	$SiH + CO \rightarrow SiC + OH$	466.821	1.18×10^{-18}
SiC_2	187.219	$2SiC \rightarrow SiC_2 + Si$	−302.243	4.06×10^{-20}
Si_2C	155.136	$SiC + SiH \rightarrow Si_2C + H$	−226.309	1.13×10^{-20}
SiO	−265.908	$SiO_2(g) + H_2 \rightarrow SiO + H_2O$	−97.663	1.98×10^{-3}
$SiO_2(g)$	−292.150	$SiO_2(l) \rightarrow SiO_2(g)$	220.522	5.81×10^{-6}
SiH	159.235	$Si + H_2 \rightarrow SiH + H$	109.565	1.47×10^{-10}

[a]All values of ΔG_f^0 are taken from JANAF tables (18).
[b]Equilibrium pressures of H_2, H_2O, H, CO, and OH used to calculate the partial pressures of the silicon species are given in Table 1.

metasilicic acid, $SiO(OH)_2$; and orthosilicic acid $Si(OH)_4$. The former two species have been observed using infrared spectroscopy by reacting O atoms with SiH_4 in a frozen Ar matrix (19, 20), and their presence in the flame is implied by the ions observed there. For the common silicon species, however, equilibrium constants K for the above-mentioned reactions were calculated and, ultimately, the concentration of the neutral silicon species could be determined. The calculated equilibrium concentrations are given in Table 2.

There is an interesting and important consideration for these silicon calculations in the flame context. For silicon dioxide, $SiO_2(l)$ is in equilibrium with its vapour, $SiO_2(g)$. Since the activity, a, for any liquid is essentially unity, this sets the concentration of $SiO_2(g)$ and hence the concentration of all other silicon species in a given flame (see, for example, ref. 21). Thus, no matter how much silicon is added, so long as the total concentration exceeds the maximum allowed in the gas phase given by the sum of the concentrations of all silicon gas-phase species, the rest of the silicon should exist as $SiO_2(l)$. Here, the total amount in the gas phase is approximately 0.002 mol fraction, little more than the concentration of the one dominant neutral species, SiO(g). This gives the interesting conclusion that, above a lower limit, the amount of gas-phase silicon is independent of the amount added. If less than 0.002 mol fraction were to be added, as was the case in this experiment (0.0001 mol fraction), then presumably no $SiO_2(l)$ will form. All this assumes that a normal liquid–vapour equilibrium exists for SiO_2 in the flame. If the liquid were to form as tiny droplets in the flame, there might well be surface-energy effects that were not explored in this model.

At *equilibrium*, it can be seen that SiO is by far the dominant gaseous silicon species present in the flame. This agrees well with observations of a silicon/oxygen system in a graphite furnace (22) in which SiO was found to form in the range of 1800–2200 K independent of the partial pressure of oxygen, and to dominate in this temperature region at high oxygen partial pressures. Calculations on a fuel-rich, acetylene–oxygen flame doped with silicon (8) also show SiO(g) as the dominant neutral species, with a concentration of 0.0013 mol fraction. Also, it is clear that adding massive amounts of silicon has only detrimental effects; the ion signals will not be enhanced, and the orifice will clog up with quartz more rapidly. Virtually all of the SiO_2, liquid or vapour, will eventually be deposited as quartz on the much cooler surfaces of the sampling plate.

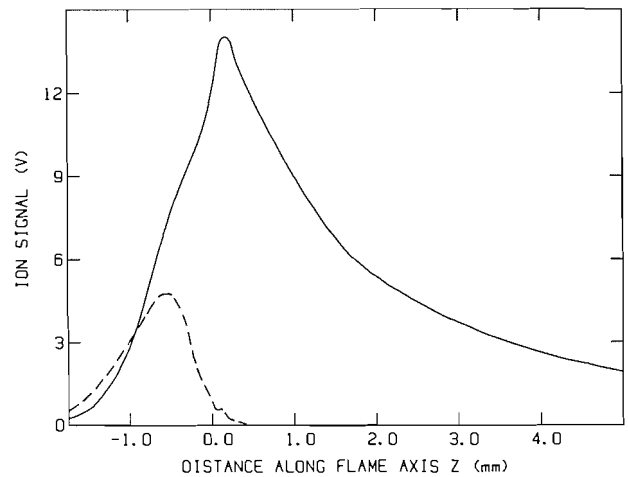

FIG. 1. Concentration profiles for the total positive ion signal (solid line) and total negative ion signal (broken line). The flame reaction zone is located upstream of $z = 0$ (negative z).

Results

All of the results presented refer to measurements made in the fuel-rich, methane–oxygen flame doped with 0.01 mol% of TrMS in the burnt gas. Total positive ion (TPI) and total negative ion (TNI) profiles are presented in Fig. 1, measured with the dc voltages to the quadrupole rods switched off. Within experimental error, these total ion profiles were unchanged when the additive was not present. Profiles for all of the individual cations containing Si observed below 160 u are given in Fig. 2. The 12 measured profiles are listed by increasing mass number and can be divided into five series on the basis of chemical similarity. These series consist of cations of the form $SiOH^+.nH_2O$ (n = 0–2); $Si(OH)_3^+.nH_2O$ (n = 0–2); $SiOCH_3^+.nH_2O$ (n = 0–2); $SiC_xH_y^+$ (x,y = 2,3 and 3,5); and the methylated cation $Si(OH)_2(CH_3)_2^+$.

Profiles for all anions containing Si observed below 160 u are presented in Fig. 3. The five measured anion profiles are similarily grouped into two series of the form $H_xSiO_3^-$ (x = 0, 1) and $H_xSiO_4^-$ (x = 1–3). In addition to

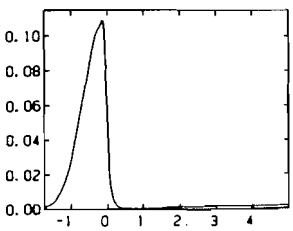

FIG. 2. Mass numbers, chemical assignments, and concentration profiles of silicon cations observed in the fuel-rich flame below 160 u. The mass number of each cation is given first, then an empirical formula that identifies it as a member of a particular series, followed by its probable structural formula(e). All profile magnitudes (see Table 3) are given in volts, plotted against distance z along the flame axis in mm. The reaction zone is located upstream of $z = 0$ (negative z).

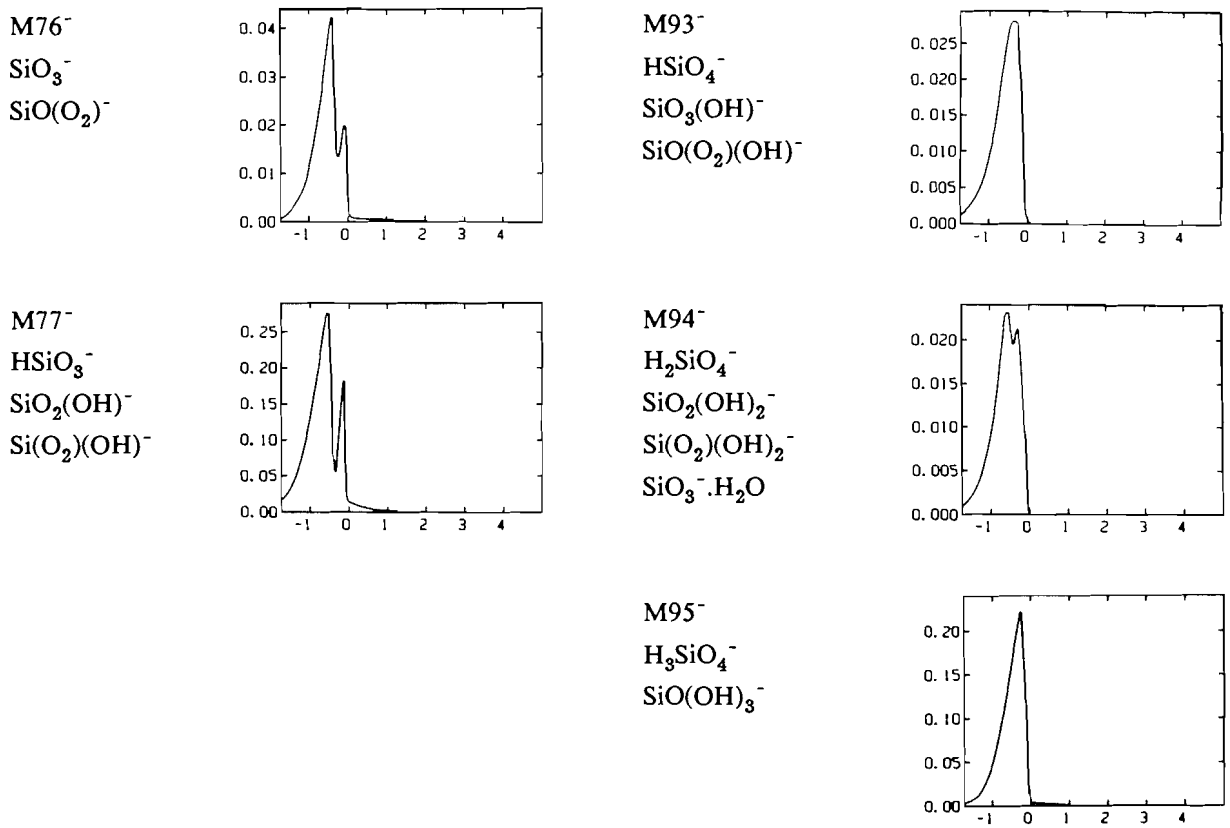

FIG. 3. Mass numbers, chemical assignments, and concentration profiles of silicon anions observed in the fuel-rich flame below 160 u. The mass number of each cation is given first, then an empirical formula that identifies it as a member of a particular series, followed by its probable structural formula(e). All profile magnitudes (see Table 3) are given in volts, plotted against distance z along the flame axis in mm. The reaction zone is located upstream of $z = 0$ (negative z).

these data, which represent profiles of ^{28}Si ions (natural abundance 92.23%), several much smaller peaks were found corresponding to the isotopes ^{29}Si (4.67%) and ^{30}Si (3.10%).

The profile labels give the mass number M of the ion and the sign of its charge, followed by an "empirical" formula and then by possible structural formulae. The empirical formula emphasizes the relationship between various families of ions, and provides an easy reference to the ion in question. Except for $M55^+$ and $M69^+$, which will be discussed later, all of the ionic structures are assumed to have Si as the central atom with hydrogen (H), hydroxy (OH), methoxy (OCH_3), and (or) methyl (CH_3) groups attached directly. The designation (H_2O) indicates a water molecule that is coordinated onto the Si atom, while $.H_2O$ indicates a hydrate formed by hydrogen bonding to the molecule's outer coordination sphere. The designation (O_2) represents an oxygen molecule coordinated onto Si, while O_x indicates x O atoms bonded individually to the Si atom.

All of the profile data are summarized in Table 3 in which the various ions are listed by empirical formula. The profiles exhibit, at most, three maxima; one or two relatively sharp peaks associated with the reaction zone near $z = 0$ (designated Reaction zone (1) and Reaction zone (2) in Table 3) and a broader peak further downstream with $z > 0$. The peak heights are measured in volts, referring to the collected ion current passing through a grid-leak resistor of 10^{10} Ω in the electrometer input circuit. Those peaks attributed to naturally occurring flame ions are noted. These were identified by comparison with profiles of the same mass number without any additive present, as well as by comparing profiles of the same chemical identity but of a different Si isotope.

Discussion

Total ion profiles

The profiles for the total positive and negative ions in the silicon-doped flame shown in Fig. 1 did not differ from those observed in the undoped flame (23). This suggests that the addition of silicon does not introduce new source or sink reactions for ions of any significance involving chemi-ionization or enhanced electron-ion recombination. Also, the very small amount (0.01 mol%) of silicon added would not be sufficient for the silicon chemistry to compete significantly with the normal hydrocarbon chemistry of the flame. For both reasons, the total ion profiles were unaffected.

The silicon additive did have an interesting effect on the *relative* peak heights of the total positive ion (TPI) and total negative ion (TNI) signals, although it was not a chemical effect. During any experimental run, the sampling orifice would clog with silicon oxides over the course of several hours. The TPI signal was affected in the expected manner; it fell from 14 to 11 V over about 3 h as the orifice clogged with SiO_2, thereby allowing less flame gas to be sampled. The TNI signal, however, became larger as time passed, climbing from 4–5 V to about 8 V over the 3-h period. Presumably this was due to the fact that three-body electron attachment, initially to O_2 molecules, is promoted in the cool boundary layer surrounding the orifice. As the orifice di-

ameter shrinks, the effect of the boundary layer is enhanced, so that the TNI signal increases.

Positive ion chemistry

It is logical to begin discussion of the cation chemistry with those ions which are derived from the major neutral silicon species in the flame, SiO. These are ions of the $SiOH^+.nH_2O$ series and possibly also the $SiOCH_3^+.nH_2O$ series.

$SiOH^+.nH_2O$ series (n = 0–2)

The ion found at $M45^+$ is protonated SiO, formed mainly by proton transfer from H_3O^+ downstream

[1] $$SiO + H_3O^+ \rightleftarrows SiOH^+ + H_2O$$

The SiO molecule could protonate on either the O or Si site giving rise to the ions $SiOH^+$ or $HSiO^+$, respectively. *Ab initio* calculations (24) give the proton affinity (PA) at the Si site as 131.8 kcal mol^{-1} and at the O site as 192.4 kcal mol^{-1}, while an experimental value of 189.3 kcal mol^{-1} has been obtained (24). This strongly suggests that $SiOH^+$ is predominant. Either structure places a positive charge density on Si, an effect that seems to be common to many Si cations (12). In contrast, the carbon analogue, CO, protonates mainly on C instead of on O.

The $SiOH^+$ ion has been seen in a premixed acetylene–oxygen flame (8) but not in hydrogen diffusion flames (7). The profile shape shown in Fig. 2 is significant since it closely resembles that of H_3O^+ (2), although it is only about one third as high. This suggests that $SiOH^+$ is maintained primarily by the equilibrium in reaction [1]. The lack of any significant signal in the reaction zone (negative z) does not mean that SiO is not present in that region; it is more likely that other species with higher PA's compete more effectively for protons than SiO in this region.

The next two ions in this series at $M63^+$ and $M81^+$ may be thought of as the first and second hydrates of $SiOH^+$. To the best of our knowledge, neither has been observed previously in a flame. Both exist primarily in the downstream region; the peaks in the reaction zone seen in Fig. 2 are due to naturally occurring $C_xH_yO_z^+$ flame ions. The relative peak heights decrease on going from parent ion to first to second hydrate, and the peak maxima move progressively further downstream. These features suggest that three-body collisions could be responsible for their formation

[2] $$SiOH^+ + H_2O + M \rightleftarrows SiOH^+.H_2O + M$$

[3] $$SiOH^+.H_2O + H_2O + M \rightleftarrows SiOH^+.2H_2O + M$$

where M is a third body. The first hydrate at $M63^+$ has been observed in a selected ion flow tube (SIFT) experiment (13). The pseudo-second-order rate constant k for reaction [2] has been found to be 1×10^{-11} cm^3 $molecule^{-1}$ s^{-1} at 296 K and a helium pressure of 0.35 Torr (1 Torr = 133.3 Pa). The reactions of $SiOH^+$ with ethanol, formic acid, and acetic acid were also found to form $M63^+$ with a rate constant about 10 times larger. However, the concentrations of these neutral species are extremely low in the downstream region of the flame, so that such reactions are not expected to be a significant source of $M63^+$. The ion at $M63^+$ can be formed by S

insertion of $SiOH^+$ into the O—H bond of water (13). This would result in the structure $HSi(OH)_2^+$, which is simply protonated silanoic acid. Alternatively, if silanoic acid itself exists in the flame, $M63^+$ could be formed by proton transfer.

The second hydrate at $M81^+$ has been seen to form by reaction [3] (13) but no rate constant has been measured. There are two possibilities for this structure. The first is a true hydrate of $M63^+$, $HSi(OH)_2^+.H_2O$, in which the water is hydrogen-bonded to the oxygen atoms of the OH groups. The other is one in which water coordinates directly onto the silicon site, represented by $HSi(OH)_2(H_2O)^+$. This second structure is favoured because it maximizes the number of strong Si—O bonds. All of this ion chemistry is summarized in Fig. 4.

$SiOCH_3^+.nH_2O$ series (n = 0–2)

The next series involving $SiOCH_3^+.nH_2O$ can again be derived from SiO. Methyl cation transfer from protonated ketene, CH_3CO^+, the main ion seen in the reaction zone of fuel-rich flames (2), is one possible source for the $SiOCH_3^+$ ion at $M59^+$

$$[4] \quad SiO + CH_3CO^+ \rightleftarrows SiOCH_3^+ + CO$$

Extensive *ab initio* calculations have been carried out in order to determine the structure of this ion (14). These indicate that the structure in which SiO is methylated at the O site has the lowest energy. It is 25.8 kcal mol^{-1} lower in energy than H_3SiCO^+, the second most stable isomer, and 30.3 kcal mol^{-1} lower than the Si-methylated CH_3SiO^+ ion.

While $SiOCH_3^+$ has not, to the best of our knowledge, been observed in a flame, it has been studied in a SIFT experiment where it was seen to form by two mechanisms (13). The first was the reaction of methanol with Si^+

$$[5a] \quad Si^+ + CH_3OH \rightarrow SiOCH_3^+ + H_2O$$

$$[5b] \quad \rightarrow SiOH^+ + CH_3$$

which has a global rate constant k of 2.2×10^{-9} cm^3 $molecule^{-1}$ s^{-1} at 296 K, and a product distribution of 0.25 $SiOCH_3^+$ and 0.75 $SiOH^+$. This seems an unlikely mechanism in our case, as no Si^+ was observed in the flame. A more likely reaction might be

$$[6a] \quad SiOH^+ + CH_3OH \rightarrow SiOCH_3^+ + H_2O$$

$$[6b] \quad \xrightarrow{M} SiOH^+.CH_3OH$$

where the global rate constant k is 1.15×10^{-9} cm^3 $molecule^{-1}$ s^{-1} at 296 K and a helium pressure of 0.35 Torr, giving a product distribution of 0.9 $SiOCH_3^+$ and 0.1 $SiOH^+.CH_3OH$. However, it can be seen from Fig. 2 that $SiOCH_3^+$ exists mainly in the flame reaction zone where $SiOH^+$ is absent; conversely, $SiOH^+$ is prominent downstream where $SiOCH_3^+$ is disappearing. Methanol has been

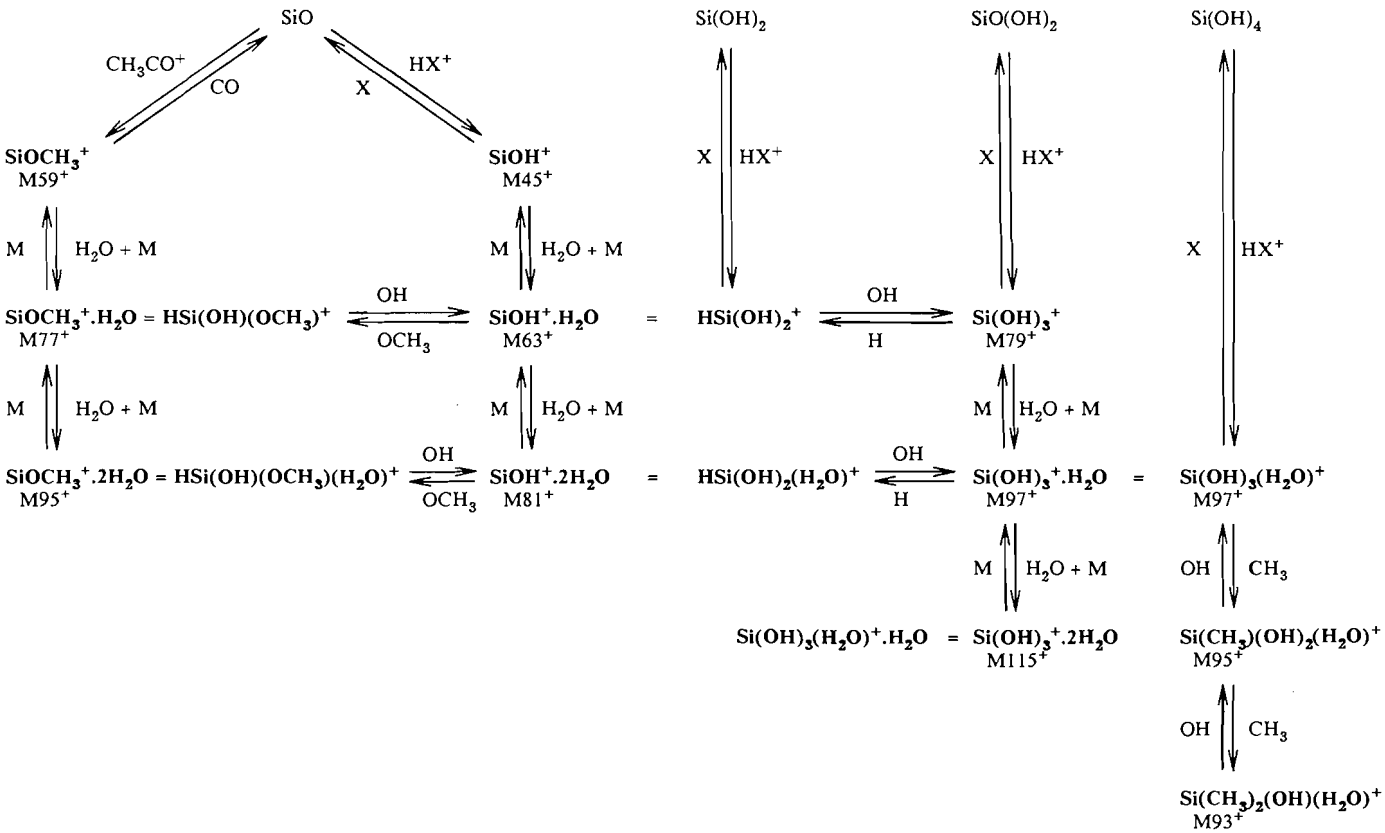

FIG. 4. Reaction flow diagram that summarizes the silicon cation chemistry leading to the ionic series $SiOH^+.nH_2O$, $SiOCH_3^+.nH_2O$, $Si(OH)_3^+.nH_2O$, and some cations formed by nucleophilic substitution. Empirical formulae and probable structural formulae for the cations are given in bold, with their mass numbers written underneath. Equivalent empirical and structural formulae are indicated with an equals sign (=). The symbols HX^+ and X represent other flame species, which are proton donors or proton receptors, respectively. Relevant silicon neutral species in the flame appear across the top of the figure.

observed in the reaction zone but not downstream in fuel-lean and stoichiometric methane–oxygen flames at 40 Torr (25). It must be present in the reaction zone of the fuel-rich flame but was not detected at a concentration level above 10^{-5} mol fraction (26). This means that the two reagents used to produce $SiOCH_3^+$ in reaction [6*a*] both exist in the flame, but in the wrong places. Thus, this mechanism, although initially attractive, appears to be a poor one in the flame context.

Ruling out the two mechanisms observed in the SIFT experiments leaves the methyl cation transfer of reaction [4]. In analogy with proton transfer reactions, methyl cation transfer has an associated methyl cation affinity (MCA) defined as the negative ΔH^0 of

$$[7] \quad B + CH_3^+ \rightarrow BCH_3^+$$

Neither the rate constant for reaction [4] nor the MCA of SiO has yet been measured. However, using empirical rules developed by McMahon *et al.* (27), one can say that for a base B of high PA (PA > 170 kcal mol^{-1}), PA(B) − MCA(B) ≈ 100 kcal mol^{-1}, giving a rough value of about 89 kcal mol^{-1} for MCA(SiO). The MCA of CO is calculated to be 80 kcal mol^{-1} (28–30). Using these numbers, reaction [4] should be exothermic by approximately 9 kcal mol^{-1}. A rate constant for reaction [4] is not easy to estimate; methyl cation transfer reactions have very variable rate coefficients that are dependent on both the nature of the methyl cation receptor B and the exoergicity of the reaction (27). The results of McMahon *et al.* suggest that if reaction [4] has a ΔG^0 value of about −27 kcal mol^{-1} or less (a reasonable expectation if ΔH^0 is approximately −9 kcal mol^{-1}), the rate constant should be in the range of $(0.5–1) \times 10^{-9}$ cm^3 $molecule^{-1}$ s^{-1}. This value is typical of many bimolecular ion–molecule reactions in the flame (31, 32).

Further evidence that reaction [4] is the source of $SiOCH_3^+$ comes from a comparison of the profile of $SiOCH_3^+$ in Fig. 2 with that of the protonated ketene ion, CH_3CO^+, at $M43^+$ (2). The shapes are very similar with a fairly sharp peak in the reaction zone and a small downstream maximum, which slowly tails off. This similarity suggests a relationship between the two ions.

The remaining two ions in this series at $M77^+$ and $M95^+$ seen in Fig. 2 can again be formed by successive hydration of the parent ion, $SiOCH_3^+$. The resultant structures should be analogous to those discussed for $SiOH^+.nH_2O$ (n = 1, 2) except that a methoxy group replaces one of the hydroxy groups. Thus, $M77^+$ is the silicon equivalent of protonated methyl formate; i.e., protonated methyl silanoate. Unlike the $SiOH^+.nH_2O$ hydrate series, however, the peak heights increase with increasing n for $SiOCH_3^+.nH_2O$. This suggests that more than simple hydration reactions are occurring.

One possibility is that ions in the $SiOCH_3^+.nH_2O$ series undergo nucleophilic substitution (S_N2) by OH radicals to yield ions of the $SiOH^+$ series; for example

$$[8] \quad HSi(OH)(OCH_3)^+ + OH \rightleftarrows HSi(OH)_2^+ + OCH_3$$

Since [OH] is much greater than [OCH_3] in the flame, such reactions would favour the production of ions of the $SiOH^+.nH_2O$ series. All of this ion chemistry is summarized in Fig. 4.

Nucleophilic substitution (S_N2) reactions

Another possible explanation for the large signals seen for the ions at $M77^+$ and $M95^+$ involves contributions by different isomers to the ion signal. This follows from the fact that there is another source of methylated silicon ions in the flame; namely, the additive TrMS. Figure 5 shows a series of neutral silicon species that may be formed by one or more nucleophilic displacements (S_N2) of CH_3 or H by OH or OCH_3 on TrMS. For example, the first neutral species in the figure, $HSi(CH_3)_2(OH)$, may be formed by the reaction

$$[9] \quad HSi(CH_3)_3 + OH \rightleftarrows HSi(CH_3)_2(OH) + CH_3$$

From Fig. 5, it is evident that there are a number of other possibilities for ions at $M59^+$, $M77^+$, and $M95^+$. A second possible isomer of $M59^+$, protonated $Si(CH_3)_2$ having the formula $HSi(CH_3)_2^+$, can be formed by protonation of $HSi(CH_3)_2(OH)$ to give $HSi(CH_3)_2(H_2O)^+$ at $M77^+$, which can then form $HSi(CH_3)_2^+$ by loss of water. In another series of reactions, $M95^+$ is formed by protonation of $Si(CH_3)(OH)_3$ to yield $Si(CH_3)(OH)_2(H_2O)^+$. Dehydration of this species then yields $Si(CH_3)(OH)_2^+$ at $M77^+$. Since all of these ions are derived by neutral nucleophilic substitution of the additive TrMS, they would be expected to contribute to the ion signal mainly in the reaction zone. Finally, if some of the $M59^+$ signal is present as the higher energy isomer $SiO(CH_3)^+$, hydration of this species would yield a further possible form of $M77^+$, $SiO(CH_3)(H_2O)^+$.

Protonation of additive products formed by nucleophilic substitution could also be responsible for the ion observed at $M93^+$. There are several possible structures at this mass number. One form is $Si(OH)_2(OCH_3)^+$, which would seem the most likely amongst the three listed in Fig. 2, since this structure maximizes the number of strong Si—O bonds. Other possibilities are $HSi(CH_3)(OCH_3)(H_2O)^+$, and $Si(CH_3)_2(OH)(H_2O)^+$. This last ion is very interesting, since it can undergo two successive nucleophilic substitutions with OH as shown in Fig. 4

$$[10] \quad Si(CH_3)_2(OH)(H_2O)^+ + OH \rightleftarrows Si(CH_3)(OH)_2(H_2O)^+ + CH_3$$

$$[11] \quad Si(CH_3)(OH)_2(H_2O)^+ + OH \rightleftarrows Si(OH)_3(H_2O)^+ + CH_3$$

to yield ions at $M95^+$ and $M97^+$. The latter ion is the second member of the $Si(OH)_3^+.nH_2O$ series discussed in the next section. All of the ion chemistry stemming from nucleophilic substitution (S_N2) reactions is summarized in Fig. 5.

$Si(OH)_3^+.nH_2O$ series (n = 0–2)

Profiles of a third series of ions involving $Si(OH)_3^+.nH_2O$ are given in Fig. 2 and their ion chemistry is summarized in Fig. 4. Members of this series have been observed, both in hydrogen diffusion flames doped with tetramethylsilane (TMS) (7), and in a premixed oxygen–acetylene flame (8). In the diffusion flame, all three ions in the series were found; $Si(OH)_3^+.H_2O$ had the largest signal, while in the premixed flame only the first two ions in the series were observed. These experiments provide data at only one fixed point downstream in the flame. The continuous ion profiles measured along the flame axis presented in Fig. 2 give a much more complete picture.

Unlike the $SiOH^+$ series, this cation series has peaks in both the reaction zone and downstream regions. The peaks *in the reaction zone* in Fig. 2 decrease in height with increasing n; in all cases where there is more than one peak in

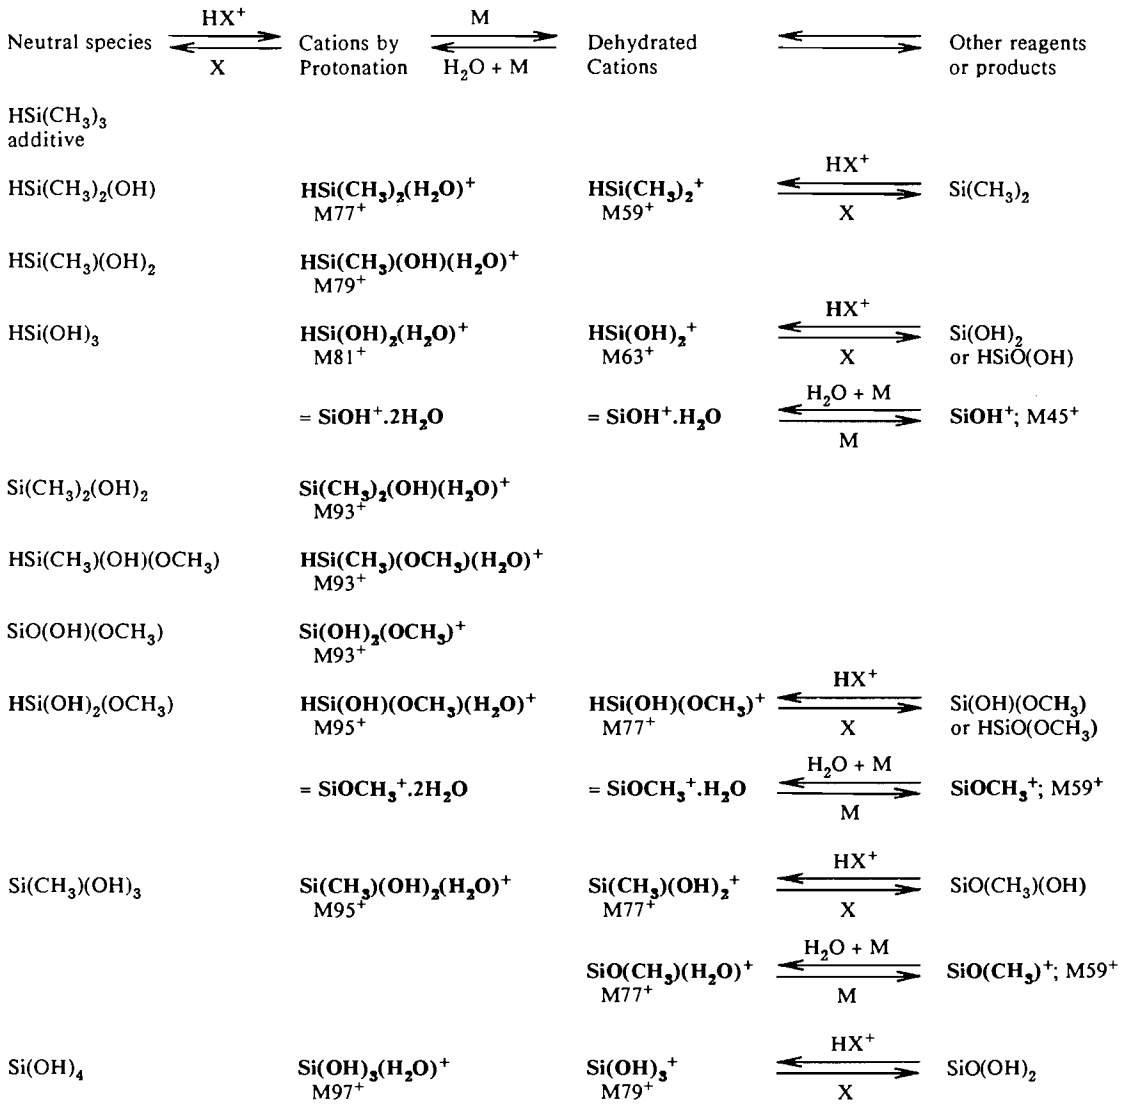

FIG. 5. Reaction flow diagram that summarizes the silicon cation chemistry initiated by neutral products arising from nucleophilic substitution (S_N2) of the trimethylsilane additive. Probable structural formulae and, in some cases, empirical formulae of the cations are given in bold with their associated mass numbers. Equivalent structural and empirical formulae are indicated with an equals sign (=). The figure indicates the formation of the primary cations by proton transfer to the substitution products, then secondary cations formed by dehydration, followed by possible tertiary steps in the reaction sequences. The symbols HX^+ and X represent other flame species, which are proton donors or proton receptors, respectively.

the reaction zone, the one associated with Si ions is closer to $z = 0$. The downstream maxima follow a different pattern; first hydrate ($M97^+$) > nude ion ($M79^+$) >> second hydrate ($M115^+$).

This difference in behaviour suggests that there are different routes to formation of the ions in the downstream region and reaction zone. In the downstream region, $M97^+$ is probably the parent ion, formed by proton transfer to neutral orthosilicic acid, $Si(OH)_4$

$$[12] \quad Si(OH)_4 + H_3O^+ \rightleftarrows Si(OH)_3(H_2O)^+ + H_2O$$

Further evidence for the presence of $Si(OH)_4$ in the flame is provided by deprotonated $Si(OH)_4$ observed in the anion chemistry discussed below. Once formed, the ion at $M97^+$ can then either gain or lose a water molecule to form $M115^+$ or $M79^+$, respectively

$$[13] \quad Si(OH)_3(H_2O)^+ + M + H_2O \rightleftarrows Si(OH)_3(H_2O)^+.H_2O + M$$

$$[14] \quad Si(OH)_3(H_2O)^+ + M \rightleftarrows Si(OH)_3^+ + H_2O + M$$

Since $Si(OH)_3^+$ is dominant in the reaction zone where $Si(OH)_4$ is presumably less abundant, another formation pathway must be found. Protonation of metasilicic acid is a possible source for this ion as indicated in Fig. 4

$$[15] \quad SiO(OH)_2 + HX^+ \rightleftarrows Si(OH)_3^+ + X$$

where the proton donor is written as HX^+ since there are a number of proton sources in the reaction zone. Once $M79^+$ is formed, it can undergo successive hydrations to form $M97^+$ and $M115^+$. Although the proton affinity of metasilicic acid is not known, the reaction is probable since protonation would remove the Si=O double bond to form a highly symmetric molecule. This mechanism is also attractive since deprotonated metasilicic acid is observed in the anion chemistry in the flame reaction zone discussed below. It might also be noted that $M79^+$ could be written as $SiO_2H^+.H_2O$, or the first hy-

For personal use only.

drate of protonated SiO_2. However, SiO_2H^+ at $M61^+$ was not observed.

Another possible formation mechanism for ions of this series involves nucleophilic substitution of other ions already discussed

[16] $SiOH^+.H_2O$ or $HSi(OH)_2^+ + OH \rightleftarrows H + Si(OH)_3^+$

[17] $SiOH^+.2H_2O$ or $HSi(OH)_2(H_2O)^+ + OH \rightleftarrows H + Si(OH)_3(H_2O)^+$ or $Si(OH)_3^+.H_2O$

This mechanism is attractive since it links ions of the $SiOH^+$ and the $Si(OH)_3^+$ hydrate series in the downstream region, as shown in Fig. 4. The profiles of these ions given in Fig. 2 tend to suggest this link; all six profiles have similar shapes for their downstream maxima.

The structures of these ions are fairly straightforward. The $Si(OH)_3^+$ ion amounts to protonated metasilicic acid H_2SiO_3, the silicon analogue of carbonic acid. There is no known carbon analogue for this species in the flame, nor is carbonic acid itself thought to be an important flame species. The $Si(OH)_3^+.H_2O$ ion has two possible structures. First, the water molecule might be hydrogen-bonded to O atoms in the outer coordination sphere of the parent ion. However, the second possibility in which the water molecule is coordinated directly to the central silicon atom to give $Si(OH)_3(H_2O)^+$ is preferable; it is a highly symmetric tetrahedral structure that maximizes the number of Si—O bonds. In the final member of the series at $M115^+$, one water molecule must be hydrogen-bonded to give a structure represented by $Si(OH)_3(H_2O)^+.H_2O$. It is probably not a true flame ion, and arises due to cooling of the flame gas during sampling.

Carbonaceous silicon cations

The last two cations at $M55^+$ and $M69^+$ assigned to $SiC_2H_3^+$ and $SiC_3H_5^+$, respectively, are unlike the other cations previously discussed. Significantly, empirical formulae that include oxygen do not appear to be possible. The formation of numerous carbonaceous silicon ions by reaction of Si^+ with various hydrocarbons has been studied using the SIFT technique (11), and $M55^+$ is one of them. The SIFT experiments indicate that carbonaceous silicon ions are reasonably stable and many are well known. In the flame context, $M55^+$ and $M69^+$ might be expected to have rather special structures.

In our fuel-rich flame, the largest ion signal occurs at $M39^+$(2), and is attributed to $C_3H_3^+$ in which all three carbon atoms are equivalent. A similar structure involving a three-membered ring is proposed for the silicon ion observed at $M55^+$; namely, the silacyclopropenyl cation or *c*-$HSiCH{=}CH^+$, which would be aromatic with two π electrons. Writing the structure with a C=C double bond places the positive charge predominantly on the silicon atom. The ion at $M69^+$ would have a similar structure with one carbon methylated; this is the 2-methylsilacyclopropenyl cation or *c*-$HSiCH{=}CCH_3^+$.

Ab initio calculations are not available for either of these two structures although the *c*-$HSiCH{=}CH^+$ structure has been proposed (11). However, the neutral cyclic SiC_2H_4 species in which two hydrogens are attached to the Si site has been modelled (33) and found to be the second most stable structure, 15.4 kcal mol^{-1} higher in energy than the linear $H_3SiC{\equiv}CH$ isomer, the global minimum. This demonstrates that a cyclic structure for the cation, especially if it is stabilized by π delocalization, is not unreasonable.

A mechanism for the formation of these ions can be suggested, based on a possible mechanism for the formation of the naturally occurring flame ion $C_3H_3^+$ in the undoped flame (34)

[18] $CH_3CO^+ + C_2H_2 \rightarrow C_3H_3^+ + H_2CO$

Although it may take place in more than one step, the mechanism involves the reaction of protonated ketene, the major ion in the flame reaction zone, with acetylene, an important neutral intermediate in fuel-rich combustion.

By analogy, using $SiOCH_3^+$ at $M59^+$ as a precursor

[19] $SiOCH_3^+ + C_2H_2 \rightarrow SiC_2H_3^+ + H_2CO$

[20] $SiOCH_3^+ + C_3H_4 \rightarrow SiC_3H_5^+ + H_2CO$

where C_3H_4 is methylacetylene. Such a reaction would explain why $M59^+$ is such a weak signal compared with its hydrates if much of it is consumed in the formation of these carbonaceous silicon species. Clearly, however, the detailed mechanisms of reactions [18] and [19] are different from the $C_3H_3^+$ case since CH_3 is predominantly attached to the O atom in $SiOCH_3^+$ but not in the case of CH_3CO^+. While the carbonaceous silicon ions exhibit large signals in the flame reaction zone, they also survive downstream, indicating that they are stable against chemical attack in the burnt-gas region.

Anion chemistry

$H_xSiO_3^-$ series (x = 0, 1)

Profiles of the two ions of the $H_xSiO_3^-$ anion series at $M76^-$ and $M77^-$ are shown in Fig. 3. They are interesting because they are the silicon analogues of two major carbon anions, CO_3^- and HCO_3^-, seen previously in this fuel-rich flame (3). To the best of our knowledge, neither SiO_3^- nor $HSiO_3^-$ has been observed previously in a flame. However, they have been studied in a SIFT experiment (9), formed by reaction of $HSiO^-$ with various neutral reagents. For both these species, the silicon ion signal is identified with the peak closer to $z = 0$ in the profiles of Fig. 3. In each case, the larger peak further upstream arises from a naturally occurring flame ion at the same mass number.

The most likely structure for $M77^-$ is that of deprotonated metasilicic acid involving a hydroxy group attached to the Si, with the negative charge delocalized over the two individually bonded O atoms. The ion at $M76^-$ is a free radical. The first possible structure is one in which there are three individually bonded O atoms with the negative charge and unpaired electron delocalized over all three, giving SiO_3^-. The other structure is one in which O_2 is coordinated directly onto the silicon to give $SiO(O_2)^-$.

The SiO_3^- and $HSiO_3^-$ anions may be formed by a mechanism analogous to that proposed for the formation of CO_3^- and HCO_3^- in the undoped flame with CO replaced by SiO (3)

[21] $O_2^- + SiO + M \rightleftarrows SiO_3^- + M$

[22] $SiO_3^- + HY \rightleftarrows HSiO_3^- + Y$

where HY could be such flame species as H_2, OH, or H_2O.

This mechanism requires the radical anion SiO_3^- to form first. The corresponding carbon anions have peak heights that are relatively the same size, with CO_3^- always somewhat larger than HCO_3^-. In the silicon case the signal for the radical SiO_3^- is one tenth the magnitude of the $HSiO_3^-$ signal. However, it is also possible that $HSiO_3^-$ is the source of SiO_3^- and not the other way around.

An alternative mechanism is one in which $HSiO_3^-$ is formed directly from neutral metasilicic acid. The fact that protonated metasilicic acid $Si(OH)_3^+$ was also seen in the flame is good evidence that the neutral exists, and could be deprotonated by a strong base such as OH^-

[23] $OH^- + SiO(OH)_2 \rightleftarrows SiO_2(OH)^- + H_2O$

Indeed, delocalization of the Si=O double bond in metasilicic acid by formation of the negative ion might be quite favourable. Then, SiO_3^- anions could be formed by an H-atom stripping reaction in the flame

[24] $SiO_2(OH)^- + H,OH \rightleftarrows SiO_3^- + H_2, H_2O$

which is the reverse of reaction [22]. All of this ion chemistry is summarized in the reaction flow diagram given in Fig. 6.

$H_xSiO_4^-$ series (x = 1–3)

Profiles of the members of the final ion series, $H_xSiO_4^-$, at $M93^-$, $M94^-$, and $M95^-$ are given in Fig. 3. These ions have not, to the best of our knowledge, been previously observed in a flame. Again, there is an analogy to the carbon chemistry in that the ions HCO_4^- and CO_4^- have been observed in the undoped fuel-rich flame (3). These carbon ions are formed by the addition of O_2^- to CO_2, a mechanism analogous to that proposed for CO_3^- and HCO_3^- formation with CO replaced by CO_2 (3). In the silicon case with CO_2 replaced by SiO_2, the addition of SiO_2 to O_2^- could result in the analogous silicon anions. The silicon anion chemistry probably has a very different origin, however, since SiO_4^- was not observed at all, although $H_2SiO_4^-$ and $H_3SiO_4^-$ were present in the flame.

The structure of $H_3SiO_4^-$ at $M95^-$ is fairly straightforward. It is almost certainly a deprotonated $Si(OH)_4$ molecule, $SiO(OH)_3^-$, with a negative charge residing on the O atom. The $H_2SiO_4^-$ ion at $M94^-$ is more difficult to specify, and is a free radical. It is possible that the unpaired electron and negative charge are delocalized over two individually bonded O atoms with two hydroxy groups attached to Si, to give $SiO_2(OH)_2^-$. Another possible structure is one in which an oxygen molecule is coordinated to the Si centre as are the hydroxy groups, giving $Si(O_2)(OH)^-$. Also, $M94^-$ might be a hydrate of $M76^-$, $SiO_3^-.H_2O$.

The final $HSiO_4^-$ ion at $M93^-$ has two possible structures. The first is one in which three O atoms are individually bonded to Si along with one hydroxy group, $SiO_3(OH)^-$. A more reasonable structure would be an oxygen molecule coordinated to the Si centre along with an O atom and hydroxy group, giving $SiO(OH)(O_2)^-$.

The fact that neutral orthosilicic acid, $Si(OH)_4$, has already been proposed as a logical source for a flame cation, $Si(OH)_3(H_2O)^+$ at $M97^+$, and that the major ion in this series at $M95^-$ amounts to deprotonated $Si(OH)_4$, strongly suggests that orthosilicic acid must be present in the flame. It can then function as the primary source of $H_3SiO_4^-$, which can go on to produce the other series members by H-atom stripping

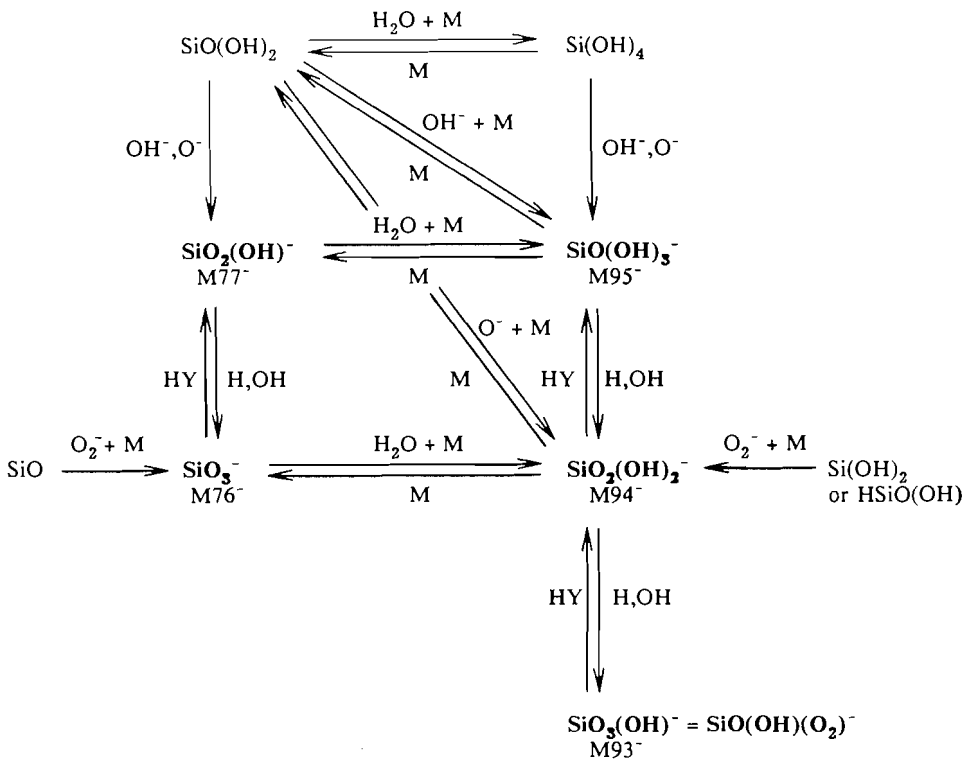

FIG. 6. Reaction flow diagram that summarizes the silicon anion chemistry leading to the ionic series $H_xSiO_3^-$ (x= 0, 1) and $H_xSiO_4^-$ (x = 1–3). Structural formulae for the anions are given in bold, with their mass numbers written underneath. The symbol HY represents an H-atom donor such as H_2 or H_2O. Relevant silicon neutral species in the flame appear around the periphery of the figure.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

[25] $OH^- + Si(OH)_4 \rightleftarrows H_3SiO_4^- + H_2O$

[26] $H_3SiO_4^- + H,OH \rightleftarrows H_2SiO_4^- + H_2,H_2O$

[27] $H_2SiO_4^- + H,OH \rightleftarrows HSiO_4^- + H_2,H_2O$

This is essentially the same mechanism as that proposed in reactions [23] and [24] based on metasilicic acid for the formation of SiO_3^- and $HSiO_3^-$ in the previous section.

Hydrogen-atom abstraction from $M95^-$ is not the only possible source for $M94^-$, however. This ion could be formed by the addition of O_2^- to metasilicic acid

[28] $O_2^- + HSiO(OH) + M \rightleftarrows SiO_2(OH)_2^- + M$

or by the addition of O^- to metasilicic acid

[29] $O^- + SiO(OH)_2 + M \rightleftarrows SiO_2(OH)_2^- + M$

Metasilicic acid could also be the source of $M95^-$ by the addition of OH^-

[30] $OH^- + SiO(OH)_2 + M \rightleftarrows SiO(OH)_3^- + M$

Finally, it is also possible that $M94^-$ and $M95^-$ can be formed by three-body hydrations of $M76^-$ and $M77^-$ since the former two ions can be written as hydrates of the latter two

[31] $SiO_3^- + H_2O + M \rightleftarrows M + H_2SiO_4^-$ or $SiO_3^-.H_2O$

[32] $HSiO_3^- + H_2O + M \rightleftarrows M + H_3SiO_4^-$ or $HSiO_3^-.H_2O$

All of this ion chemistry is summarized in Fig. 6. Clearly, the anion chemistry is very interlinked. Also, it reinforces the cation chemistry with regard to the presence in the flame of the neutral silicon species SiO, $HSiO(OH)$, $SiO(OH)_2$, and $Si(OH)_4$.

Summary and conclusions

The silicon ion chemistry of a fuel-rich methane–oxygen flame doped with 0.01 mol% trimethylsilane has been studied using a flame-ion mass spectrometer. Addition of silicon to the flame did not have any observable effect on the total ion profiles, either positive or negative.

A total of 12 silicon cations was observed in the flame below 160 u. For organizational purposes, they can be grouped into five series: $SiOH^+.nH_2O$ (n = 0–2); $SiOCH_3^+.nH_2O$ (n = 0–2); $Si(OH)_3^+.nH_2O$ (n = 0–2); cations formed by nucleophilic substitution (e.g., $Si(OH)(CH_3)_2(H_2O)^+$); and carbonaceous cations, $SiC_2H_3^+$ and $SiC_3H_5^+$. The various groups overlap to some extent, particularly the cations formed by nucleophilic substitution. Similarily, five anions were observed, which are members of two series: $H_xSiO_3^-$ (x = 0, 1) and $H_xSiO_4^-$ (x = 1–3). The anions are strongly interlinked, chemically.

A number of fairly general conclusions can be drawn as a result of this work.

1. The ion chemistry of silicon differs markedly from the carbon ion chemistry that occurs naturally in the flame.

2. Silicon shows a strong preference towards Si—O bonding as opposed to Si—C bonding. Practically every ion observed contains at least one Si—O bond. The exceptions to this rule are c-$HSiCH{=}CH^+$ and c-$HSiCH{=}CCH_3^+$.

3. As has been well documented (35), silicon tends to avoid the formation of multiple bonds.

4. The silicon flame ions observed favour the coordination number 4 where possible. However, major signals were obtained for species with lower coordination numbers such as $SiOH^+$ and $Si(OH)_3^+$.

5. While most silicon cations gave signals in the flame reaction zone, every cation persisted into the burnt gas region downstream to some degree, in particular, the carbonaceous ions $SiC_2H_3^+$ and $SiC_3H_5^+$. This downstream trend is much less noticeable for the naturally occurring carbon cations in the undoped flame. Also, the downstream persistence is much less pronounced with the silicon anions, which are probably destroyed by associative electron detachment reactions with H atoms.

6. Relatively few reaction mechanisms are required to explain the silicon ion chemistry observed. These include: proton transfer to (cation formation) or from (anion formation) silicon neutral species present in the flame, and also methyl cation transfer; three-body addition reactions involving H_2O (cation chemistry) and O_2^- or O^- (anion chemistry); nucleophilic substitution (S_N2) reactions involving OH, OCH_3, H, and CH_3 on the ions themselves, but principally on the TrMS additive, which provides a variety of species as neutral reagents for chemical ionization processes; and also H-atom abstraction reactions in the anion chemistry.

7. In addition to the dominant neutral species SiO, evidence was obtained from both the cation and the anion chemistry for the presence in the flame of $HSiO(OH)$ (silanoic acid), $SiO(OH)_2$ (metasilicic acid), and $Si(OH)_4$ (orthosilicic acid). However, no direct evidence was obtained for $SiO_2(g)$.

Synthesis of non-enolizable α- and β-peltatins

TONY DURST[1] AND LESLIE DONALD BEHNIA
Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received August 28, 1991

TONY DURST and LESLIE DONALD BEHNIA. Can. J. Chem. **70**, 1082 (1992).

The preparation of non-enolizable derivatives of both α- and β-peltatins via reaction of the lactone enolates of the corresponding TBDMS derivatives with CH_3I and hexachloroethane is described. These derivatives are considerably less toxic than the precursor peltatins but show, at best, only marginal activity in in vivo tests against P 388 leukemia.

TONY DURST et LESLIE DONALD BEHNIA. Can. J. Chem. **70**, 1082 (1992).

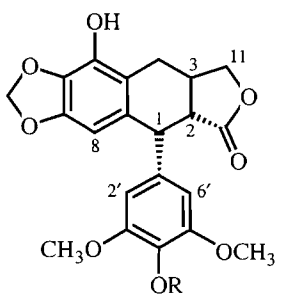
On décrit la préparation de dérivés non-énolisables des α- ainsi que β-peltatines par l'intermédiaire d'une réaction des énolates de la lactone des dérivés TBDMS correspondants avec le CH_3I et l'hexachloroéthane. Ces dérivés sont beaucoup moins toxiques que les peltatines qui leur donnent naissance; lors d'essais in vivo, ils ne présentent toutefois qu'une activité marginale contre la leucémie P388.

[Traduit par la rédaction]

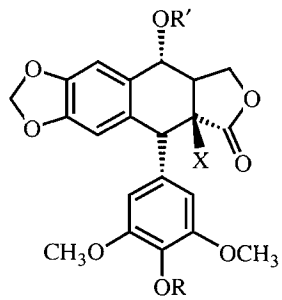
Introduction

α- and β-Peltatin **1** and **2** are members of the lignan family of compounds (1). These compounds were first isolated and characterized by Hartwell in 1956 from North American podophyllin (*podophyllum peltatum L*) (2). Like the closely related podophyllotoxin, **3**, both peltatins show considerable antineoplastic activity. Clinical use of these compounds was briefly investigated in the 1950's by Greenspan but abandoned due to their high toxicity, unfavourable therapeutic ratios, and their inability to effect more than short-term tumor remissions (3).

In the case of podophyllotoxin it was eventually possible to obtain clinically important derivatives such as Etoposide and Teniposide. No therapeutically useful derivatives have been prepared from either **1** or **2** (1).



1 R = H
2 R = CH_3



3 R = CH_3, R′ = H
X = H

In 1986 we reported the preparation of several non-enolizable podophyllotoxin derivatives, that is, compounds in which the hydrogen α to the lactone carbonyl group had been replaced by substituents such as CH_3, Cl, Br, and SCH_3 (4). In general, those compounds in which the podophyllotoxin geometry (*trans*-fused lactone, structure **3**) had been retained showed comparable or better in vivo activity against P 388 (T/C = 167 for the chloro derivative (X = Cl) at 40 mg/kg vs. 110 for podophyllotoxin) compared to podophyllotoxin itself. In addition, these derivatives were considerably less toxic. Not surprisingly, those compounds that had the picropodophyllotoxin geometry (*cis*-fused lactone) were inactive and nontoxic at the levels tested. We therefore decided to prepare the analogous derivatives of both α- and β-peltatins to see if a reduction in toxicity might allow one to observe useful anticancer activity.

Results and discussion

The peltatins were isolated from commercially available podophyllin resin. We found that further separation of the crude chromatography fractions containing both peltatins was facilitated by conversion of the phenolic hydroxyl groups to TBDMS ethers. Using this approach, we were able to isolate the TBDMS derivatives **4** and **5**. The amounts obtained are equivalent to a recovery of 8.9 and 7.6% of **1** and **2** from the commercial resin. These compare favourably with the 6.4 and 6.0% yield of these compounds obtained by Hartwell and Detty (2*b*). Further details of the isolation procedure are given in the experimental section.

The protection of the phenolic groups in **1** and **2** was also useful for the subsequent enolate formation. This proceeded smoothly for both **4** and **5** with LDA in THF at −78°C. Protonation of the enolates of **4** and **5** with H_2O at −78°C resulted in their regeneration accompanied by the *cis*-fused isomers **6** and **7**, respectively, in roughly 1:3 ratios. These ratios can be compared with the 45:55 podo- to picropodophyllotoxin ratio obtained upon protonation of the enolate of the THP of podophyllotoxin with acetic acid (5).

Reaction of the enolate of **4** with CH_3I afforded the 2-methyl *trans*-lactone **8** and the isomeric *cis*-fused lactone **9** in 38 and 56% isolated yields, respectively. Similar reaction of the enolate derived from **5** gave the methylated products **10** and **11** in 52 and 46% yields. Chlorination of these enolates with hexachloroethane was considerably more selective. Thus, the enolate of **4** gave 92% of the *trans*-lactone **12** and only 4% of the *cis*-lactone **13**, while 83% of **14** and 6% of **15** were obtained from the enolate of **5**. Similar trends in the ratios of *cis*- to *trans*-fused lactone products were observed in the podophyllotoxin series (4).

The structure and stereochemistry of the 2-substituted products were readily assigned on the basis of their ^1H NMR spectra. The relevant data are summarized in Table 1 and compared with the unsubstituted and isomerized peltatins.

Substitution at C-2 was clearly indicated by the presence of a sharp singlet due to the remaining doubly benzylic hydrogen at C-1. This signal was found in the δ = 4.2 range

TABLE 1. Key chemical shifts and coupling constants in the TBDMS protected α- and β-peltatins

Compound	γ-Lactone fusion	Chemical shifts (δ) H-1	H-8	C-2′,6′	Coupling constant H3–H11 (Hz)
4	*trans*	4.57	6.27	108.4	10.1
6	*cis*	4.35	6.32	105.0	3.4
5	*trans*	4.59	6.26	108.2	10.2
7	*cis*	4.36	6.31	104.9	3.4
8	*trans*	4.22	6.23	109.1	11.0
9	*cis*	4.18	6.35	106.9	2.9
10	*trans*	4.24	6.23	108.8	11.3
11	*cis*	4.20	6.34	106.8	3.1
12	*trans*	4.73	6.26	109.1	9.7
13	*cis*	4.48	6.36	—	0
14	*trans*	4.75	6.25	108.9	9.7
15	*cis*	4.51	6.34	—	0

for the methylated compounds **8–11** and δ 4.5–4.7 for the chlorinated derivatives **12–15**.

The *cis*- or *trans*-fusion of the lactone ring was assigned on the basis of J_{H3-11}. As has been noted for the corresponding podophyllotoxins (4), *trans* ring fusion results in >9 Hz coupling constants while the *cis*-fused isomers have J_{H3-11} < 3. Several other consistent trends can be noted from Table 1. The C-1 proton of the isomer having the *trans*-fused lactone is always shifted further downfield than that of the corresponding *cis* isomer. The opposite effect is observed for H-8. In the latter case the aromatic ring at C-1 is essentially perpendicular to the other rings when the lactone fusion is *trans* and thus should have little anisotropy effect on H-8. In the case of the *cis*-fused lactones the half-chair conformation places H-8 in an aromatic ring deshielding zone. Finally, the ^{13}C chemical shifts for C-2′, C-6′ in the *trans*-fused isomers were typically found in the δ = 108–109 ppm range; these were consistently deshielded relative to the corresponding *cis* isomer by at least 2 ppm.

Desilylation of the compounds **8–15** was carried out with either 4 equivalents of tetrabutylammonium fluoride (TBAF) in THF at 0°C for 1 min followed by quenching with saturated NH_4Cl solution or, in the case of the more sensitive chloro compounds, with the same reagents in acetic acid. The proton spectra of the desilylated products were consistent with the structure assignments. See Table 1 and experimental section. Again the size of the J_{H3-11} was crucial in confirming the stereochemistry of the lactone ring junction.

Biological screening results

Testing against leukemia P 388 was performed on the peltatins, all four methylated isomers, and the two *trans*-fused chloro isomers at the Anti-Tumor Division of Bristol Laboratories using the following protocol (6). Ascitic fluid containing 10^6 cancer cells was implanted interperitoneally in female CDF1 mice (4 mice per test group). Treatment began 24 h after implant. The results are given in Table 2.

Under these conditions, α- and β-peltatins are toxic (the majority of the test animals died within 5 days of the administration of the compounds, compared to the 9-day life expectancy of the control group) at levels of 4 and 16 mg/kg. The *cis*-2-methyl derivatives of both α- and β-peltatins were inactive at dosages up to 64 mg/kg. All of the *trans*-fused derivatives were considerably less toxic than the parent peltatins, but only the *trans*-2-methyl-β-peltatin showed any marginal anti-cancer activity (T/C = 133 at 64 mg/kg) at the levels tested. The possibility that some of these com-

[b]Determined at Bristol Laboratories using the standard procedure (6).

pounds might show improved biological activity after glycosylation remains to be investigated.

Experimental section

General comments

^1H and ^{13}C NMR spectra were recorded on Varian XL200 and Varian FT-80 spectrometers, respectively, using $CDCl_3$ as solvent and TMS as internal standard. Melting points were determined on a Gallenkamp apparatus and are uncorrected. Optical rotations were recorded as $CHCl_3$ solution (c = 1.0) unless otherwise indicated, using a Perkin Elmer 241 polarimeter. Preparative thin-layer chromatography (PTLC) was carried out on glass plates coated with a 1.0 mm layer of Kieselgel 60GF 254. High-performance liquid chromatography was carried out using PrePak-500 silica gel cartridges on a Waters 500 instrument. Typical work-up refers to quenching the reaction mixture with saturated NH_4Cl solution, several extractions with either ethyl acetate or CH_2Cl_2, drying, and evaporating the organic solvents on a rotatory evaporator. All yields refer to isolated, chromatographically homogeneous products.

Preparation of the TBDMS derivatives of α- and β-peltatin from crude podophyllin resin

Podophyllin resin (10.2 g, U.S. Biochemicals) was stirred overnight with 50 mL of $CHCl_3$. The solution was filtered and the residue was similarly treated two more times. Evaporation of the $CHCl_3$ afforded 5.86 g of yellow-brown foam.

The chloroform soluble material (6.0 g) was further fractionated by placing it on 30 g of silica and eluting with 200 mL each of (1) hexanes; (2) 20% CH_2Cl_2 – 80% hexanes; (3) 40% CH_2Cl_2 – 60% hexanes; (4) 60% CH_2Cl_2 – 40% hexanes; (5) 80% CH_2Cl_2 – 20% hexanes; (6) CH_2Cl_2; (7)–(10) fractions contain 2, 4, 6, and 8% ethyl acetate in CH_2Cl_2. The last 5 fractions were combined and evaporated to yield 3.5 g of crude peltatin mixture.

The above mixture (2.38 g), imidazole (16.1 g), and *tert*-butyldimethylsilyl chloride (1.71 g) were combined in 11 mL of DMF, heated overnight at 50°C, and then worked up in the usual manner to yield 3.30 g of a yellow-brown foam. Purification by HPLC (1:9 ethyl acetate – hexanes) afforded 987 mg (14%) of the bis-TBDMS of α-peltatin and 630 mg (9%) of the TBDMS derivative of β-peltatin after recrystallization from hexanes.

*Preparation of the lactone enolates derived from **4** and **5** and subsequent reaction with electrophiles*

Representative procedure

TBDMS derivative **4** (510 mg, 0.81 mmol) was dissolved in 5 mL of dry THF and added slowly to a −78°C solution of 0.85 mmol of LDA in 10 mL of dry THF. The solution (bluish color) was stirred for 15 min at −78°C and 0.5 mL of CH_3I was added. The reaction mixture was allowed to warm to room temperature and stirred for a further 10–20 h. Usual work-up afforded a crude product that was separated via preparative TLC (1:7 ethyl acetate – hexane) to afford 200 mg (38%) of the *trans*-fused, less polar isomer **8** and 292 mg (56%) of the methylated *cis*-fused lactone **9**.

*Isomer **8**:* mp 78–83°C; $[\alpha]_D = -102$; ^1H NMR, δ (ppm): 0.10 (s, 6H), 0.24 (s, 3H), 0.27 (s, 3H), 0.98 (s, 9H), 1.03 (s, 9H), 1.22 (s, 3H), 2.36 (dd, J = 12.6, 16.2 Hz, 1H), 2.69–2.92 (m, 1H), 3.01 (dd, J = 5.3, 16.3 Hz, 1H), 3.68 (s, 6H), 3.98 (dd, J = 8.4, 11.0 Hz, 1H), 4.22 (s, 1H), 4.28–4.40 (m, 1H), 5.90 (s, 2H), 6.23 (s, 1H), 6.30 (s, 2H); ^{13}C NMR, δ (ppm): −4.55 (q), −4.06 (q), 16.4 (q), 18.7 (s), 23.1 (t), 25.8 (q), 25.9 (q), 34.3 (d), 46.1 (s), 52.3 (d), 56.0 (q), 70.1 (t), 100.8 (t), 105.2 (d), 109.1 (d), 120.9 (s), 131.3 (s), 133.4 (s), 135.4 (s), 136.3 (s), 147.8 (s), 150.6 (s), 178.6 (s). Hz, 1H), 4.24 (s, 1H), 4.37 (dd, J = 7.4, 8.2 Hz, 1H), 5.90 (s, 2H), 6.23 (s, 1H), 6.35 (s, 2H); ^{13}C NMR, δ (ppm): −4.1 (q), 16.4 (q), 18.6 (s), 23.1 (t), 25.9 (q), 34.4 (d), 45.9 (s), 52.4 (d), 56.6 (q), 60.7 (q), 70.1 (t), 100.9 (t), 105.1 (d), 108.8 (d), 120.9 (s), 130.9 (s), 135.5 (s), 136.4 (s), 136.5 (s), 136.9 (s), 147.8 (s), 152.2 (s), 178.5 (s). Anal. calcd. for $C_{25}H_{38}O_8Si$: C 64.18, H 7.06; found: C 59.19, H 6.47. The low carbon and hydrogen values appear to be due to occluded halocarbons, which were difficult to remove from the foamy solid even under high vacuum.

Compound 11: foam, mp 71–75°C; $[\alpha]_D$ = −107; ^{1}H NMR, δ (ppm): 0.21 (s, 3H), 0.24 (s, 3H), 1.03 (s, 9H), 1.23 (s, 3H), 2.64–2.77 (m, 1H), 3.02 (d, J = 5.4 Hz, 2H), 3.79 (s, 6H), 3.81 (s, 3H), 4.01 (dd, J = 3.1, 9.3 Hz, 4.21 (s, 1H), 4.51 (dd, J = 6.9, 9.3 Hz, 1H), 5.85 (s, 2H), 6.35 (s, 3H); ^{13}C NMR, δ (ppm): −4.17 (q), 18.5 (s), 22.8 (q), 25.9 (q), 26.9 (t), 39.6 (d), 47.0 (s), 51.4 (d), 56.1 (q), 60.8 (q), 73.4 (t), 100.7 (t), 103.4 (d), 106.8 (d), 119.6 (s), 132.2 (s), 135.5 (s), 135.8 (s), 136.3 (s), 137.0 (s), 147.4 (s), 152.9 (s), 181.2 (s). Anal. calcd. for $C_{29}H_{38}O_8Si$: C 64.18, H 7.06; found: C 61.19, H 6.57. The low C and H values appear to be due to occluded halocarbon solvents, which could not be removed from the foamy solid even after prolonged high vacuum.

*Reaction of the enolates of **4** and **5** with hexachloroethane*

The enolate prepared as above from 426 mg (0.68 mmol) of **4** was allowed to react with 1.29 (5.5 mmol) of hexachloroethane, first at −78°C, then at room temperature for 22 h. Usual work-up and purification by PTLC (1:6 ethyl acetate – hexanes) afforded the 2-chloro-*trans* derivative **12** (414 mg, 92%) and 2-chloro-*cis* product **13** (19 mg, 4%).

*2-Chloro-*trans *isomer **12**:* mp 79–86°C; ^{1}H NMR, δ (ppm): 0.10 (s, 6H), 0.26 (s, 3H), 0.29 (s, 3H), 0.98 (s, 9H), 1.04 (s, 9H), 2.65 (dd, J = 10.9, 15.7 Hz, 1H), 2.82–3.00 (m, 1H), 3.08 (dd, J = 5.6, 15.6 Hz, 1H), 3.68 (s, 6H), 4.16 (dd, J = 8.5, 9.7 Hz, 1H), 4.40 (dd, J = 6.7, 8.5 Hz, 1H), 4.73 (s, 1H), 5.90 (d, J = 1.4 Hz, 1H), 5.93 (d, J = 1.4 Hz, 1H), 6.26 (s, 1H), 6.34 (s, 2H); ^{13}C NMR, δ (ppm): −4.54 (q), −4.02 (q), 18.7 (s), 23.5 (t), 25.8 (q), 25.9 (q), 36.7 (d), 53.3 (d), 56.0 (q), 70.6 (t), 71.5 (s), 101.0 (t), 104.6 (d), 109.1 (d), 120.3 (s), 129.5 (s), 131.0 (s), 134.2 (s), 135.8 (s), 136.3 (s), 148.0 (s), 150.9 (s), 170.9 (s). Anal. calcd. for $C_{33}H_{47}O_8Si_2Cl$: C 59.75, H 7.14; found: C 59.21, H 7.38.

*2-Chloro-*cis *isomer **13**:* foam; ^{1}H NMR, δ (ppm): 0.115 (s, 6H), 0.207 (s, 3H), 0.235 (s, 3H), 0.994 (s, 9H), 1.014 (s, 9H), 2.95–3.40 (m, 3H), 3.725 (s, 6H), 4.171 (d, J = 9.0 Hz, 1H), 4.475 (s, 1H), 4.738 (dd, J = 4.9, 8.9 Hz, 1H), 5.881 (s, 2H), 6.358 (s, 1H), 6.421 (s, 2H). This material was not characterized further.

Preparation of the 2-chloro derivatives of TBDMS-protected β-peltatin

The lactone enolate derived from 465 mg (0.88 mmol) of **5** was reacted with excess (1.63 g) of hexachloroethane as above. Work-up and purification (PTLC, 1:5 ethyl acetate – hexanes) afforded 409 mg (83%) of the *trans*-2-chloro isomer **14** and 27 mg (60%) of the *cis* isomer **15**.

trans-*2-Chloro isomer **14**:* mp 212–215°C; $[\alpha]_D$ (c = 1.0) = −133; ^{1}H NMR, δ (ppm): 0.26 (s, 3H), 0.29 (s, 3H), 1.04 (s, 9H), 2.67 (dd, J = 11.0, 15.6 Hz, 1H), 2.80–3.04 (m, 1H), 3.10 (dd, J = 5.5, 15.7 Hz, 1H), 3.75 (s, 6H), 3.80 (s, 3H), 4.19 (dd, J = 8.7, 9.7 Hz, 1H), 4.43 (dd, J = 6.6, 8.4 Hz, 1H), 4.75 (s, 1H), 5.91 (d, J = 1.4 Hz, 1H), 5.93 (d, J = 1.4 Hz, 1H), 6.25 (s, 1H), 6.39 (s, 2H); ^{13}C NMR, δ (ppm): −4.03 (q), 18.6 (s), 23.4 (t), 25.9 (q), 36.8 (d), 53.4 (d), 56.3 (q), 60.7 (q), 70.6 (t), 71.2 (s), 101.0 (t), 104.5 (d), 108.9 (d), 120.3 (s), 129.1 (s), 134.1 (s), 135.9 (s), 136.3 (s), 137.6 (s), 148.0 (s), 152.6 (s), 163.9 (s), 170.9 (s). Anal. calcd. for $C_{28}H_{35}O_8SiCl$: C 59.72, H 6.26; found: C 59.78, H 6.36.

cis-*2-Chloro derivative **15**:* foam; ^{1}H NMR, δ (ppm): 0.21 (s, 3H), 0.24 (s, 3H), 1.02 (s, 9H), 2.97–3.36 (m, 3H), 3.80 (s, 6H), 3.83 (s, 3H), 4.18 (d, J = 9.0 Hz, 1H), 4.51 (s, 1H), 4.75 (dd, J = 5.2, 9.0 Hz, 1H), 4.86 (d, J = 1.4 Hz, 1H), 5.88 (d, J = 1.4 Hz, 1H), 6.35 (s, 1H), 6.47 (s, 2H); M^+ = 562 (calcd. for $C_{28}H_{35}O_8Si$; ^{35}Cl 562. This material was not further characterized.

Desilylation experiments. Method A. Typical procedure

To a solution of 575 mg (0.90 mmol) of **9** in 5 mL of dry THF at 0°C was added 4 equivalents of TBAF (3.6 mL, 1.0 M in THF). The solution was stirred for 1 min and then quenched with saturated NH_3Cl solution. Usual work-up followed by PTLC separation (2:1 ethyl acetate – hexane) afforded 319 mg (86%) of 2-methyl-α-peltatin (*cis*) as fine beige needles, mp 108–111°C; $[\alpha]_D$ (CH_3OH, c = 1.0) = −104; ^{1}H NMR, δ (ppm): 1.20 (s, 3H), 2.81–3.25 (m, 3H), 3.79 (s, 6H), 4.09 (dd, J = 2.2, 9.4 Hz, 1H), 4.14 (s, 1H), 4.58 (dd, J = 6.2, 9.2 Hz, 1H), 5.62 (s, 2H), 5.84 (d, J = 1.0 Hz, 1H), 5.85 (d, J = 1.2 Hz, 1H), 6.29 (s, 1H), 6.54 (s, 2H). Anal. calcd. for $C_{22}H_{22}O_8$: C 63.76, H 5.35; found: C 64.08, H 4.92.

*2-Methyl-α-peltatin (*trans*)*

Treatment of 220 mg (0.34 mmol) of **8** with equivalents of TBAF according to method A above afforded 100 mg (71%) of 2-methyl-α-peltanin (*trans*) after PTLC (2:1 ethyl acetate – hexanes), mp 228–233°C; $[\alpha]_D$ (CH_3OH, c = 0.97) = −123; ^{1}H NMR, δ (ppm): 1.25 (s, 3H), 2.46 (dd, J = 12.4, 16.2 Hz, 1H), 2.70–2.96 (m, 1H), 3.08 (dd, J = 5.4, 16.2 Hz, 1H), 4.25 (s, 1H), 4.30–4.40 (m, 1H), 5.37 (s, 1H), 5.44 (s, 1H), 5.94 (s, 2H), 6.36 (s, 2H). Anal. calcd. for $C_{22}H_{22}O_8$: C 63.76, H 5.35; found: C 63.48, H 5.28.

*2-Methyl-β-peltatin (*trans*)*

Prepared in 75% yield from 169 mg (0.31 mmol) of **10** and 2 equivalents of TBAF following procedure A, mp 242–244°C; ^{1}H NMR, δ (ppm): 1.26 (s, 3H), 2.48 (dd, J = 12.4, 16.4 Hz, 1H), 2.75–2.98 (m, 1H), 3.08 (dd, J = 5.3, 16.1 Hz, 1H), 3.75 (s, 6H), 3.801 (s, 3H), 4.02 (dd, J = 8.7, 11.3 Hz, 1H), 4.26 (s, 1H), 4.31–4.45 (m, 1H), 5.48 (bs, 1H), 5.92 (s, 1H), 6.19 (s, 1H), 6.36 (s, 1H). Anal. calcd. for $C_{23}H_{24}O_8$: C 64.48, H 5.65; found: C 64.59, H 5.82.

*2-Methyl-β-peltatin (*cis*)*

This compound was obtained in 67% yield as yellowish prisms, mp 127–130°C (from CH_2Cl_2–hexanes) from **11** following the desilylation procedure A; $[\alpha]_D$ ($CHCl_3$) = −113; ^{1}H NMR, δ (ppm): 1.24 (s, 3H), 2.67–3.11 (m, 3H), 3.79 (s, 6H), 3.82 (s, 3H), 4.08 (dd, J = 2.8, 9.4 Hz, 1H), 4.20 (s, 1H), 4.52 (dd, J = 6.7, 9.1 Hz, 1H), 5.30 (s, 1H), 5.85 (dd, J = 1.4 Hz, 1H), 5.87 (d, J = 1.4 Hz, 1H), 6.31 (s, 1H), 6.36 (s, 2H). Anal. calcd. for $C_{23}H_{24}O_8$: C 64.48, H 5.65; found: C 64.01, H 5.57.

*2-Chloro-α-peltatin (*trans*)*

A solution of 60 mg (0.091 mmol) of **12** was dissolved in 5 mL of dry THF at 0°C. Acetic acid (0.1 mL) was added followed by 4 equivalents of TBAF (0.35 mL, 1.0 M in THF). After several minutes the reaction mixture was quenched with saturated NH_4Cl solution and then washed with sodium bicarbonate. Further work-up followed by PTLC (3:2 ethyl acetate – hexanes) afforded 38 mg (96%) of 2-chloro-α-peltatin (*trans*) as pale yellow prisms, mp 208–210°C; $[\alpha]_D$ (CH_3OH, c = 0.97) = −136; ^{1}H NMR, δ (ppm): 2.74 (dd, J = 11.0, 15.4 Hz, 1H), 2.84–3.06 (m, 1H), 3.157 (dd, J = 5.4, 15.6 Hz, 1H), 3.784 (s, 6H), 4.19 (dd, J = 8.5, 9.7 Hz, 1H), 4.41 (dd, J = 6.8, 8.4 Hz, 1H), 4.75 (s, 1H), 5.93 (d, J = 1.4 Hz, 1H), 5.96 (d, J = 1.4 Hz, 1H), 6.22 (s, 1H), 6.41 (s, 2H). Anal. calcd. for $C_{21}H_{19}O_8Cl$: C 58.01, H 4.40; found: C 57.70, H 4.41.

*2-Chloro-β-peltatin (*trans*)*

This compound was prepared from the monosilylated chloro derivative **14** using 2 equivalents of TBAF in THF/acetic acid, as above. The yield of product was 91%; mp 182–184°C (pale yellow flakes); $[\alpha]_D$ (CH_3OH, c = 1.01) = −129; ^{1}H NMR, δ (ppm): 2.76 (dd, J = 11.1, 15.7 Hz, 1H), 2.85–3.05 (m, 1H), 3.16 (dd, J = 5.3, 15.7 Hz, 1H), 3.76 (s, 6H), 3.81 (s, 3H), 4.20 (dd, J = 8.7, 9.5 Hz, 1H), 4.43 (dd, J = 6.7, 8.5 Hz, 1H), 4.77 (s, 1H), 5.97 (d, J = 1.4 Hz, 1H), 5.95 (d, J = 1.4 Hz, 1H), 6.22 (s, 1H), 6.40 (s, 2H). Anal. calcd. for $C_{22}H_{21}O_8Cl$: C 58.87, H 4.72; found: C 58.85, H 4.67.

*Reaction of the enolate of **4** with saturated NH_4Cl solution*

The enolate prepared from 202 mg of **4** was prepared as usual at −78°C and then quenched with saturated NH_4Cl solution. Work-up followed by PTLC chromatography (1:6 ethyl acetate – hexanes) afforded 39 mg (19%) of α-peltatin-bis-TBDMS and 158 mg (78%) of the less mobile *cis*-fused isomer **6** as a pale yellow foam, mp 140–142°C; ^{1}H NMR, δ: 0.11 (s, 6H), 0.18 (s, 3H), 0.21 (s, 3H), 0.99 (s, 9H), 1.00 (s, 9H), 2.63–2.71 (m, 2H), 2.92–3.05 (m, 1H), 3.33 (dd, J = 2.8, 9.6 Hz, 1H), 3.69 (s, 6H), 3.89 (dd, J = 3.4, 9.0 Hz, 1H), 4.35 (d, J = 2.6 Hz, 1H), 4.42 (dd, J = 7.6, 9.2 Hz, 1H), 5.86 (d, J = 1.4 Hz, 1H), 5.90 (d, J = 1.4 Hz, 1H), 6.27 (s, 2H), 6.33 (s, 1H); ^{13}C NMR, δ (ppm): −4.6 (q), −4.2 (q), 1.85 (s), 18.7 (s), 24.8 (t), 25.8 (q), 32.6 (d), 45.4 (d), 46.3 (d), 55.9 (q), 73.1 (t), 100.7 (t), 103.9 (d), 105.0 (d), 121.0 (s), 131.6 (s), 133.1 (s), 134.9 (s), 136.0 (s), 136.7 (s), 147.3 (s), 151.6 (s), 178.6 (s). Anal. calcd. for $C_{33}H_{48}O_8Si_2$: C 63.02, H 7.69; found: C 63.06, H 7.49.

*Reaction of the enolate of **5** with saturated NH_4Cl solution. Preparation of **7***

The enolate of **5** was quenched at −78°C with NH_4Cl solution as above. Work-up and PTLC (1:6 ethyl acetate – hexanes) afforded 40 mg (20%) of β-peltatin and 130 mg (64%) of the slightly less polar *cis* isomer **7**; mp 55–60°C; ^{1}H NMR, δ (ppm): 0.21 (s, 3H), 0.27 (s, 3H), 1.01 (s, 9H), 2.71 (dd, J = 1.5, 5.9 Hz, 2H), 2.92–3.10 (m, 1H), 3.32 (dd, J = 2.8, 9.6 Hz, 1H), 3.78 (s, 6H), 3.83 (s, 3H), 3.93 (dd, J = 3.4, 9.0 Hz, 1H), 4.36 (d, J = 3.0, 1H), 4.43 (dd, J = 7.3, 9.3 Hz, 1H), 5.87 (d, J = 1.4 Hz, 1H), 5.92 (d, J = 1.4 Hz, 1H), 6.31 (s, 1H), 6.34 (s, 2H); ^{13}C NMR, δ (ppm): 4.24 (q), 18.5 (s), 24.8 (t), 25.8 (q), 32.6 (d), 45.5 (d), 46.4 (d), 56.2 (d), 60.9 (d), 73.0 (t), 100.7 (t), 103.8 (d), 104.9 (d), 121.0 (s), 131.1 (s), 136.1 (s), 136.7 (s), 136.8 (s), 138.4 (s), 153.3 (s), 178.4 (s). Anal. calcd. for $C_{28}H_{36}O_8Si$: C 63.61, H 6.86; found: 63.89, H 6.69.

A microcolumn method for hexazinone and metabolite residues in soil and vegetation

JOSEPH C. FENG

Forestry Canada, Northern Forestry Centre, 5320-122 Street, Edmonton, Alta., Canada T6H 3S5

Received July 17, 1991

JOSEPH C. FENG. Can. J. Chem. **70**, 1087 (1992).

A soil cleanup method using a disposable microcolumn and a modified capillary gas chromatographic method is described for the analysis of hexazinone (3-cyclohexyl-6-(dimethylamino)-1-methyl-1,3,5-triazine-2,4(1*H*,3*H*)-dione) and two primary metabolites, 3-(4-hydroxycyclohexyl)-6-(dimethylamino)-1-methyl-1,3,5-triazine-2,4(1*H*,3*H*)-dione (metabolite A) and 3-cyclohexyl-6-(methylamino)-1-methyl-1,3,5-triazine-2,4(1*H*,3*H*)-dione (metabolite B). The limits of detection (LOD) were 7, 18, and 36 ng g^{-1} for hexazinone, metabolite B, and metabolite A, respectively; limits of quantitation (LOQ) were 22, 52, and 99 ng g^{-1}, respectively. The mean recoveries were 94 ± 3% and 94 ± 5% for hexazinone and the phytotoxic metabolite B fortified above LOQ and ranging from 0.03 to 6.25 and 0.06 to 12.5 μg g^{-1}, respectively. The recoveries from the non-phytotoxic metabolite A above LOQ increased with concentrations from 0.125 to 25 μg g^{-1}, but were consistent at each level. The final product of cleanup was stable for at least 6 months, and no derivatization was needed before gas chromatography. The use of toluene as the final solvent and the modification of the injection system of the gas chromatograph improved the stability of peak responses. The method is three times more efficient than conventional methods. The cleanup method for soils was modified for the analysis of vegetation samples. Efficient removal of chlorophyll enabled quantitation of hexazinone by gas chromatography. Recoveries of hexazinone ranged from 73 to 96% for forest litter and four different plant species.

JOSEPH C. FENG. Can. J. Chem. **70**, 1087 (1992).

On décrit une méthode de nettoyage du sol qui utilise une microcolonne jetable et une méthode modifiée de chromatographie gazeuse capillaire et qui permet d'analyser l'hexazinone (3-cyclohexyl-6-(diméthylamino)-1-méthyl-1,3,5-triazine-2,4-(1*H*,3*H*)-dione) et deux de ses métabolites primaires, la 3-(4-hydroxycyclohexyl)-6-(diméthylamino)-1-méthyl-1,3,5-triazine-2,4(1*H*,3*H*)-dione (métabolite A) et la 3-cyclohexyl-6-(méthylamino)-1-méthyl-1,3,5-triazine-2,4(1*H*,3*H*)-dione (métabolite B). Les limites de détection (LDD) sont respectivement 7, 18 et 36 ng g^{-1} pour l'hexazinone, le métabolite B et le métabolite A; les limites de quantification (LDQ) sont respectivement 22, 52 et 99 ng g^{-1}. Les récupérations moyennes sont respectivement de 94 ± 3% et de 94 ± 5% pour l'hexazinone et le métabolite phytotoxique B fortifié au-dessus de la LDQ et elles varient respectivement de 0,03 à 6,25 et de 0,06 à 12,5 μg g^{-1}. Les récupérations du métabolite non-toxique A au-dessus de la LDQ augmentent avec les concentrations de 0,125 à 25 μg g^{-1}, mais elles sont cohérentes à chaque niveau. Le produit final du nettoyage est stable pour au moins 6 mois et il n'est pas nécessaire de préparer des dérivés avant d'effectuer la chromatographie gazeuse. L'utilisation de toluène comme solvant final et la modification du système d'injection du chromatographe en phase gazeuse augmentent la stabilité des réponses des pics. La méthode est trois fois plus efficace que les méthodes conventionnelles. La méthode de nettoyage a été modifiée pour l'analyse d'échantillons de végétation. L'élimination efficace de la chlorophylle a permis de quantifier l'hexazinone par chromatographie gazeuse. Les récupérations d'hexazinone s'établissent entre 73 et 96% pour la litière de la forêt et pour quatre espèces différentes de plantes.

[Traduit par la rédaction]

Introduction

Hexazinone is a triazine herbicide registered for forestry use in Canada. Two of its formulations, Pronone 10G (granular) and Velpar L (liquid), have been used in forest site preparation and conifer release (1–5), and are being tested in strip thinning of aspen in mixedwoods (ref. 6, and Sidders[1]).

Because of environmental concerns and pesticide regulations, sensitive analytical methods are required for monitoring this chemical in treated forest areas. Holt's method (7) provides a basic analytical approach for the determination of residues of hexazinone and two primary and two minor metabolites (moderately polar compounds) named as metabolites A, B, D,[2] and E,[3] respectively. Another minor metabolite (metabolite C[4]) is treated as a separate compound and requires a different method in residue analysis, i.e., isolation and gas chromatography, due to its highly polar nature (7). Among these metabolites, only metabolite B is phytotoxic and is about 1% as potent as the parent compound in inhibiting photosynthesis of loblolly pine (*Pinus taeda* L.) (8). A liquid/liquid partitioning procedure followed by derivatization with trifluoroacetic anhydride is employed in Holt's method (7), which is sensitive to a detection limit of 40 ng g^{-1} for hexazinone and metabolites A and B in soils, when analyzed with a packed column gas chromatograph (GC) equipped with a nitrogen–phosphorus detector (NPD). However, the derivatized final product is unstable and has a shelf life of less than 8 h. Feng (9) modified Holt's (7) method by eliminating the derivatization process to increase the shelf life and by using direct[5] gas chromatography to simplify the sample handling. The mod-

ified method has a detection limit similar to the latter and has been adopted by researchers in several major forestry studies on the environmental fate of hexazinone (5, 10, 11). The method was further modified by using capillary GC to improve peak resolution (12). The capillary GC method has been adopted in the evaluation of an applicator (13), a soil sampling method (14), the chemical release rate (12), and the chemical movement in soil leachate (15). During the course of development of the analytical method for hexazinone and metabolite residues, the basic concept of extraction and isolation developed by Holt (7) has not changed.

The difficulties experienced in the application of the conventional methods lie in the lack of compatibility of their final products of cleanup with the current available GC–NPD systems. Stringent control of peak fluctuation must be included by analyzing a standard solution alternately with each field sample (5, 9–14). Their isolation processes are labour intensive, time consuming, and costly. Furthermore, the conventional methods are not effective in removing the chlorophyll of vegetation samples. This paper describes a simple, effective isolation method using a disposable microcolumn and a modified GC analysis for hexazinone and metabolite residues in soils, and a further modified isolation method for vegetation.

Experimental

Soil preparation and fortification

Bulk quantity of uncontaminated soil was obtained from a northern Alberta forest and air-dried in an insulated dark room with a portable dehumidifier running at high speed for several days until soil moisture contents stabilized at about 3% oven-dry weight. The air-dried soil was then homogenized, sifted through a 2-mm mesh sieve, and mixed thoroughly (16). Soil was loamy clay containing 10% organic matter. Sixty 20-g aliquots of soil were weighed into separate 250-mL Nalgene polymethylpentene centrifuge bottles (Nalge 2107). Twenty aliquots were extracted and cleaned using the microcolumn method and analyzed separately by GC–NPD to determine the limit of detection (LOD) and limit of quantitation (LOQ) (17, 18). The sensitivity and analyte recovery of the method were determined using fortified soil samples as follows. Three aliquots of soil were reserved as controls. Thirty-six aliquots were fortified as triplicates or sextets with 10 different concentrations of mixture solutions (in toluene) of analytical grade[6] hexazinone, metabolite B, and metabolite A at a weight-ratio of 1:2:4 ranging from 0.001 to 1.25, 0.002 to 2.5, and 0.004 to 5.0 $\mu g\ g^{-1}$, respectively; the last sample was fortified at the highest concentrations of 6.25, 12.5, and 25.0 $\mu g\ g^{-1}$, respectively, without replication, because large amounts of analytical standards were needed. All treated samples were shaken horizontally for 15 min on an Eberbach reciprocating shaker at 280 excursions per minute and allowed to stand in a refrigerator (−5°C) for 40 h.

Crude soil extracts and precolumn sample preparation

Each bottle of soil (20 g) was wetted with 4 mL HPLC grade water and shaken horizontally for 5 min on an Eberbach shaker as described above. The sample was then treated with 200 mL accurately measured methanol, shaken horizontally for 15 min, and allowed to stand overnight in a refrigerator. The next morning, the sample was shaken for another 15 min and was centrifuged at 800 × *g* for 10 min to separate soil and the supernatant, which was designated as "crude extracts." About 170 mL of crude extracts were carefully poured, without disturbing the soil precipitate, through a Millipore Assembly consisting of a 47-mm Teflon-faced glass filter holder assembly, a 0.45-μm HVLP Durapore membrane filter, and a layer of anhydrous sodium sulfate (to remove moisture). A 150-mL aliquot of filtrate (equivalent to 15 g soil) was accurately measured with a 250-mL graduated cylinder and quantitatively transferred with triplicated 5-mL methanol rinse of the cylinder into a 500-mL round bottom flask. The neck of the flask was rinsed with small amounts of methanol. The volume of filtrate was reduced to about 3 mL by using a rotary evaporator at 45°C under reduced pressure. The concentrated filtrate was transferred quantitatively with triplicated 3-mL methanol rinse (or more, if necessary) into a 15-mL graduated conical tube with Teflon-lined cap (17 mL max. capacity). The sample volume was again reduced to 5 mL under a stream of nitrogen by using a 45°C N-Evap (Organomation Assoc. Inc., South Berlin, Mass).

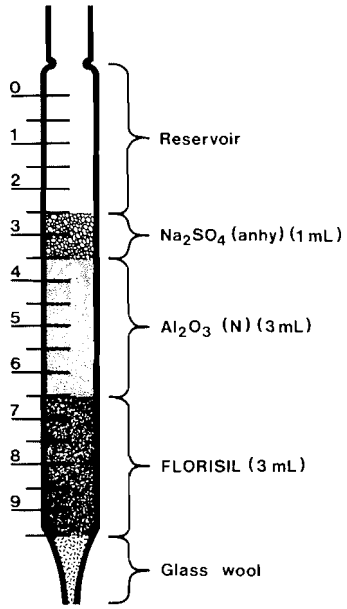

FIG. 1. Schematic illustrating the packing components of a microcolumn made of a 10-mL disposable volumetric pipet for the cleanup of hexazinone and metabolite residues in soil and vegetation.

Disposable microcolumn and cleanup for soil

Isolation of hexazinone and metabolites A and B from the filtered "crude extracts" of soils was accomplished using a homemade disposable microcolumn (Fig. 1).

(i) Preparation of disposable microcolumn

The bottom end of a 10-mL disposable glass volumetric pipet was plugged with glasswool prewashed by Soxhlet extraction in methanol (Fig. 1). A 3-mL bedding of anhydrous Florisil was packed into the glass pipet by lightly tapping on the pipet wall. A second 3-mL bedding of anhydrous, neutral aluminum oxide (Al_2O_3) was added on top by tapping and was followed with a 1-mL layer of anhydrous sodium sulfate (Na_2SO_4) prewashed by Soxhlet extraction in methanol. A dry-packing technique was used and no prewashing of the microcolumn was required before sample loading. The liquid-retaining capacity of the column packing was about 3 mL. An identical microcolumn was also prepared for the vegetation samples.

(ii) Microcolumn cleanup

The concentrated crude extract (5 mL) was loaded on the dry-packed microcolumn followed with triplicated 1-mL methanol rinse of the sample tube. The microcolumn was eluted with 12 mL of methanol (the eluent was the same solvent as in crude extracts). All eluates were collected into a fresh 15-mL graduated conical tube and evaporated to dryness with a stream of nitrogen in a 45°C N-Evap. Toluene (2.5 mL or predetermined volume between 1 and

[6]Analytical grade (100% pure) hexazinone and metabolites A, B, D, and E were supplied by E.I. Du Pont de Nemours, Wilmington, Del. via Du Pont Canada Inc., Mississauga, Ont.

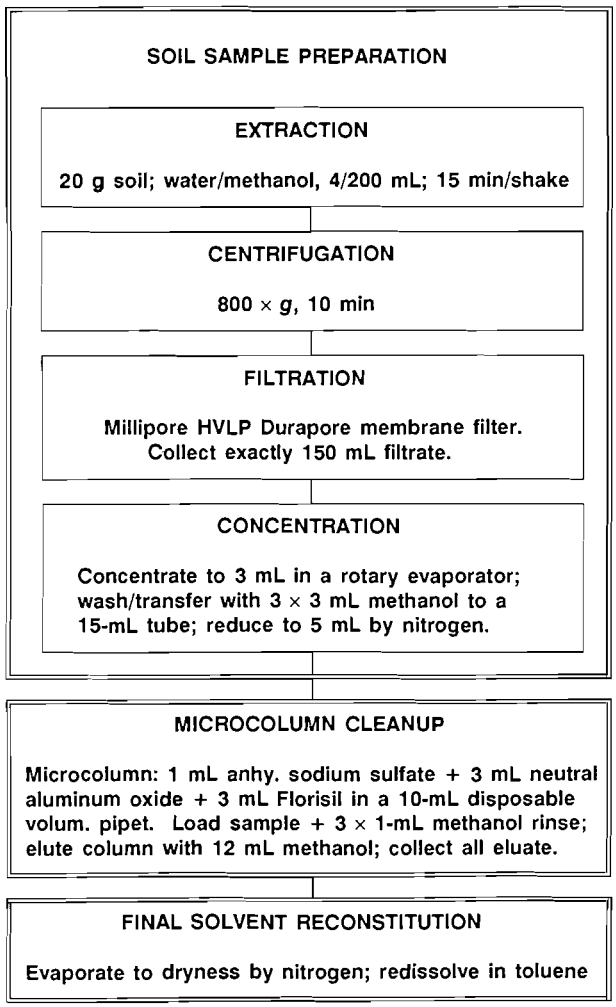

FIG. 2. Flow chart of the sample preparation and the microcolumn cleanup method for determination of hexazinone and metabolite residues in soils.

10 mL depending on the predicted residue concentration in a field sample) was added to the sample tube to redissolve residues before GC analysis. For the calculation of residue concentrations, the total weight of soil sample was 15 g. A flow chart of the foregoing procedure is presented in Fig. 2.

Vegetation sample preparation and fortification

Representative dominant species of tree, shrub, herbaceous, and grass plants or foliage with fine twigs as well as fresh forest litter were collected from the uncontaminated area of a northern Alberta forest. These vegetation species were trembling aspen (*Populus tremuloides* Michx.), willow (*Salix* spp.), showy aster (*Aster conspicuus* Lindl.), and reed grass (*Calamagrostis canadensis* Nutt.). Fresh-frozen vegetation samples were used in this method for better extraction efficiency. Broadleaf foliage and grasses were cut with scissors into 1-cm strips; twigs and fine stems were cut into 0.5-cm lengths. Dry weight and moisture content were determined from 10-g aliquots of samples oven-dried at 105°C for 48 h (16). Duplicate 15-g aliquots of vegetation samples were weighed into 250-mL Nalgene polymethylpentene centrifuge bottles and fortified with 1 μg g^{-1} hexazinone on a dry weight basis. Duplicates of non-spiked samples of each species were analyzed as controls.

Extraction and precolumn cleanup for vegetation

Each bottle of vegetation sample (15 g fresh weight) was treated with 60 mL methanol (accurately measured) and homogenized for 2 min using a Polytron PT-10 homogenizer. The entire bottle contents were filtered as described for soils. The filtrate was collected into a 50-mL graduated conical centrifuge tube with Teflon-lined cap (60 mL total capacity). A 30-mL aliquot of the filtrate (equivalent to extracts of 7.5-g samples) was kept in the tube by removing the excess amounts with a Pasteur pipet or by aspiration. The chlorophyll contents of the filtrate were reduced by partitioning five times with 25 mL hexane and shaking each time for 30 s. The upper phase of the hexane wash was discarded by aspiration. Twenty-five mL of the lower methanol phase (extracts of a 6.25-g sample) were retained by removing the excess amounts with a Pasteur pipet or by aspiration. The volume of sample was reduced to 5 mL with a stream of nitrogen in a 45°C N-Evap.

Microcolumn cleanup for vegetation

A disposable microcolumn identical to that described for soil was used in the isolation of hexazinone and metabolites A and B from the partially cleaned vegetation extracts. The concentrated sample (5 mL) was loaded into the dry-packed microcolumn followed with triplicated 1-mL methanol rinse of the sample tube. Methanol (14 mL) was also used as the eluent to elute hexazinone and metabolites from the adsorbents of the microcolumn. All eluates were collected into a 15-mL graduated conical tube and concentrated to exactly 5 mL with a stream of nitrogen in a 45°C N-Evap. The sample was then partitioned four times, with 10-mL hexane each time. The hexane upper phase of each partitioning and the excess amounts of the lower methanol phase of the last partitioning were removed with a Pasteur pipet or by aspiration and were discarded. Exactly 4 mL of the lower methanol phase was retained in the tube and evaporated to dryness with a stream of nitrogen in a 45°C N-Evap (small amounts of oily residue may remain in the tube). Toluene (2.5 mL or predetermined volume between 1 and 10 mL depending on the predicted concentration of residues in a field sample) was added to the sample tube to redissolve residues of hexazinone and metabolites before GC analysis. For calculating the recovery rate of residues, the total sample fresh weight was 5 g, and the moisture content was used to obtain the oven-dry weight of each sample. A flow chart of this method is presented in Fig. 3. To report the residue level of a field sample, the concentration of herbicide on a dry weight basis should be used.

Capillary gas chromatography

A modified capillary GC was used to determine concentrations of residues of hexazinone and the two primary metabolites A and B. The specific GC conditions were as follows.

(i) Gas chromatograph

A Varian model 3500 Capillary GC was equipped with a specially fitted megabore injector, a Thermionic Specific Detector (NPD), a model 8035 autosampler, a Varian DS 654 data system, and a NEC Pinwriter P6 printer-plotter.

(ii) Chromatographic column

A 15-m J&W fused silica DB-17 capillary column; 0.325 mm i.d.; 0.25 μm film thickness. A 1-m fused silica guard column (phenylmethyl siloxane deactivated, uncoated, megabore tubing of 0.53 mm i.d.) was installed between the megabore injector and the analytical column.

(iii) Temperatures

Injector, 250°C; detector, 300°C; oven temperature program, 80°C (held for 2 min) to 250°C (at 30°C min^{-1}; held for 7.3 min); total run time, 15 min.

(iv) Gases

All gases were supplied by Alberta Oxygen, Edmonton, Alberta. Carrier gas, helium (ultra pure grade) 4.3 mL min^{-1} at 80°C; linear velocity, 57 cm s^{-1} at 80°C; head pressure, 110 kPa; make-up gas, nitrogen (ultra pure grade) 30 mL min^{-1}; plasma gases, air (zero gas grade) 175 mL min^{-1} and hydrogen (ultra pure grade) 4.5 mL min^{-1}.

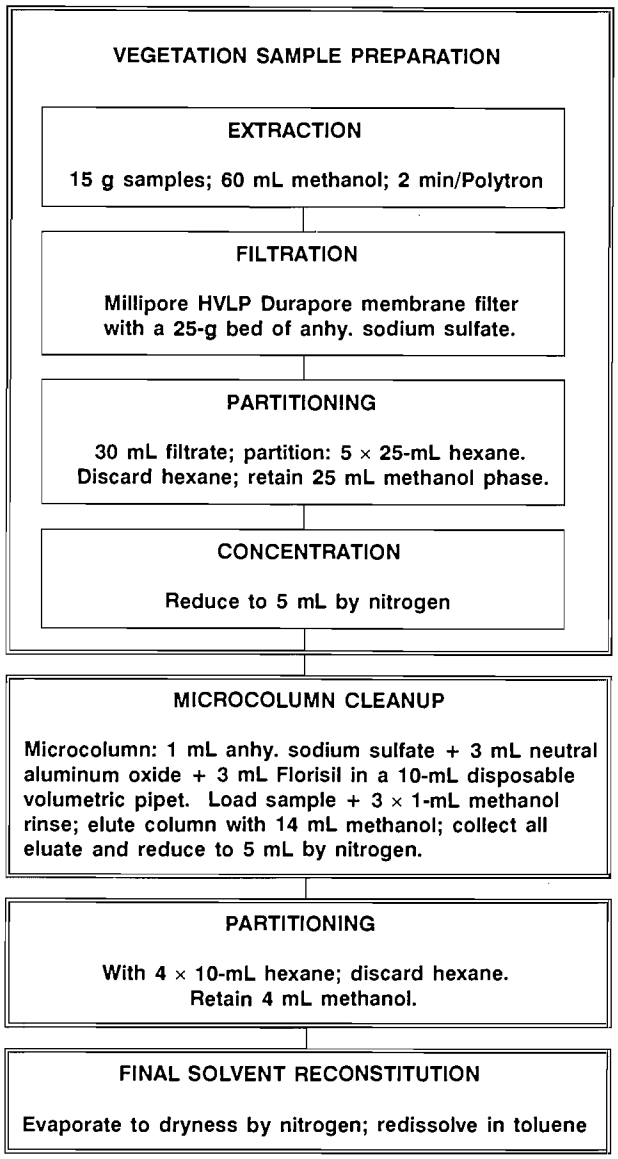

FIG. 3. Flow chart of the sample preparation and the microcolumn cleanup method for determination of hexazinone and metabolite residues in vegetation.

(v) Residue peak quantitation

Use of reference standards[5] in peak height quantitation was reported earlier (9) and can be summarized as follows. A mixture standard solution containing 2.5, 5.0, and 10.0 μg g^{-1} of hexazinone, metabolites B and A, respectively, was analyzed immediately before and after each sample analysis. When a sample showed twice or more the concentration of standard solution, the sample was diluted to near the concentration of standard solution and reanalysed. The average height of two corresponding peaks of the mixture standard solution, analyzed before and after a sample was measured, was used proportionally in calculating the residue concentration of the sample.

Results and discussion

Microcolumn cleanup for soils

The LOD and LOQ were calculated from the gross signals of the analytes (the slope of calibration curve ranging from 0.025 to 2.5 μg mL^{-1}), the mean signal value of field blanks (N = 20) at the retention time of the analyte, and three (LOD) or 10 (LOQ) times the standard deviation of the field blank signals (17, 18). The LOD's were 0.044, 0.110, and 0.218 μg mL^{-1} for hexazinone and metabolites B and A, respectively; LOQ's were 0.132, 0.312, and 0.594 μg mL^{-1}, respectively. The theoretical LODs of three analytes in soils, respectively, were 0.007, 0.018, and 0.036 μg g^{-1}; LOQ's were 0.022, 0.052, and 0.099 μg g^{-1}, respectively, when calculated at full recovery rate (100%) of each analyte using the described analytical method.

The actual recoveries of hexazinone and metabolites A and B from the microcolumn cleanup were tested at 11 concentration levels with a 1:6250 ratio between the lowest and the highest levels of each compound (Table 1). The recoveries of the two phytotoxic compounds, hexazinone and metabolite B, immediately above LOQ at 0.0313 and 0.0625 μg g^{-1}, respectively, were reliable at 94 ± 4 and 89 ± 7%, respectively. Recoveries of both analytes at higher levels were similar to that at 0.0313 and 0.0625 μg g^{-1}, respectively. The overall mean recovery for hexazinone ranging from 0.0313 to 6.25 μg g^{-1} (six levels of concentration) was 94 ± 3%. For metabolite B ranging from 0.0625 to 12.5 μg g^{-1} (six concentration levels), the mean recovery was 94 ± 5%.

Recoveries of the non-phytotoxic metabolite A increased steadily with the increase of concentrations (Table 1). Although the overall recovery for metabolite A above LOQ was relatively lower at 77 ± 21% between 0.125 and 25 μg g^{-1} (six concentration levels), the recovery rates were greater than 50% and were reasonably consistent at each concentration level. Correction factors may be established for several concentration ranges above 0.125 μg g^{-1} and used in calculating the concentration of metabolite A in a field sample.

Total amount of solvents used for the extraction and cleanup of each soil sample in this method was 225 mL. This was less than 30% of the amount required in conventional methods (765 mL) (7, 9). Although rewetting the air-dried sample with 10–20% water (w/w) is necessary in desorbing residues,[7] the initial air-drying of soil is essential in preparing a homogenous sample for subsampling (10). The use of methanol as the extracting solvent made possible the complete desorption of hexazinone and metabolite A and B residues from the soil particles. An aliquot of the crude extract can be taken, with a volume correction, to represent the product of an exhaustive extraction as in the conventional method. The extraction process was further simplified using methanol rather than an acetone–water solution (7, 9), where acetone must be completely evaporated from the aqueous solution followed by separate triplicate partitions with hexane, acetonitrile, and chloroform. Hexazinone and its metabolites A and B are not adsorbed strongly on the microcolumn packing compared with most of coextractives. Therefore, the same solvent, methanol, can be used as the eluent of the microcolumn. Because the fully activated Florisil and aluminum oxide are used in this method, loss of hexazinone and its metabolites to the absorbents would occur if the mixture solution of pure standards[5] is used alone, causing a lack of coextractives to occupy the active sites of the absorbents. Because there was no need to change the solvent phase, the column eluting time was greatly reduced. The final sample dissolved in toluene was stable for

Reed grass (*Calamagrostis canadensis* Nutt.)	92.3
Fresh litter	81.5

at least 6 months at 5°C. Due to the simplicity of this method, 20 soil samples can be cleaned up as one batch by one person in 1 day and that is three times or more efficient than the conventional methods. The cost for waste disposal and the risk in environmental and health hazards are also reduced.

Microcolumn cleanup for vegetation

The original method of Holt (7) and its modification (9) were tested using fresh aspen foliage. The end product of sample cleanup showed a dense, dark-green color and high viscosity and was impossible to analyze by either the packed column GC or the capillary GC. Neither was the microcolumn method for soil sample cleanup described above capable of removing chlorophyll from the foliage extracts. The microcolumn method for soils was modified for the cleanup of vegetation samples by using hexane partitioning both before and after microcolumn cleanup to remove chlorophyll from the methanol extracts. Further cleanup was achieved in the final step of the method by changing the solvent from methanol to toluene (final solvent reconstitution) (Fig. 3). The end product was clear or a pale amber color and produced a clean chromatogram. Mean recoveries of hexazinone were the highest for understory species (92–96% for grass and aster), followed by fresh litter (82%) and tree species (73–76% for willow and aspen) (Table 2). The lower limit of detectability for hexazinone using this cleanup method was determined in a separate study and was similar to the soil method described above (19). Total amount of solvents needed for the cleanup of a 15-g vegetation sample was 245 mL. Twelve samples could be processed as one batch by one person in 2.5 days.

Gas chromatography

Earlier reports indicated that both methanol and ethyl acetate seemed to cause fluctuations in peak responses in the Varian GC and that stringent control of peak fluctuation using alternated analyses of reference standard and samples was required for quantifying hexazinone and its metabolites (5, 9–13, 15). The stability of the Varian model 3500 GC was improved by replacing the split/splitless capillary GC injector with a megabore injector fitted with a 1-m-long megabore fused silica guard column and using toluene[8] (20) as the sample solvent. The frequency of analysis of the standard solution may be reduced to once for every 10 field samples for the purpose of "good laboratory practice (GLP)."

In analyzing the toluene solution of reference standards of hexazinone and four metabolites, i.e., metabolites A, B, D, and E, the responses of all peaks were consistent and sensitive. When using toluene in the analysis of both soil and vegetation samples, however, the responses of metabolites A, D, and E were reduced. These losses occurred during the final solvent reconstitution after the microcolumn cleanup when the sample in methanol was evaporated to dryness and redissolved in toluene. Some of these residues tended to adsorb on the coextractive, which adhered on the glass and became less soluble in toluene. Although recoveries of hexazinone and its demethylated derivative, metabolite B, were good when the sample was redissolved in toluene, the recovery of its hydroxylated derivative, metabolite A, was relatively low at lower concentration levels (Table 1). The

[8]Use of toluene for better stability in GC was recommended and supported by the analysis of hexazinone (analytical grade[5]) by C. Jennison, Varian Canada Inc., Georgetown, Ont.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 79.173.37.17 on 09/08/12
For personal use only.

recoveries of both minor trione metabolites D and E were the lowest among the five tested compounds and were unreliable (data are not shown). When analyzing for metabolites D and E, the final solvent reconstitution should be omitted and the method of residue peak quantitation described above should be followed.

The GC analysis time was shortened by 25% per sample, when the shorter (15 m) than conventional (30 m) DB-17 fused silica capillary column was used. Peaks of hexazinone and four metabolites were well resolved. Retention times were 6.7, 7.7, 9.0, 9.5, and 11.5 min for metabolites D and E, hexazinone, and metabolites B and A, respectively; peak widths at half-height were 3.5, 3.3, 2.9, 6.2, and 8.3 s, respectively. The introduction and frequent replacement of a 1-m fused silica guard column extended the lifetime of the analytical column by about a factor of five for the analyses of foliage samples.

The combined use of the modified capillary GC method and the microcolumn cleanup technique is recommended as an efficient, reliable, and less labour-intensive substitute for conventional methods in analyzing residues of hexazinone and two primary metabolites, A and B, in soil and vegetation.

Received August 29, 1991

STEFANO CHIMICHI, BARBARA COSIMELLI, FABRIZIO BRUNI, and SILVIA SELLERI. Can. J. Chem. **70**, 1093 (1992).

The ^{13}C and ^1H NMR spectra of some pyrazolo[1,5-*a*]pyrimidine derivatives are discussed. All ^{13}C resonances were unambiguously assigned by means of both 2D experiments and gated decoupled spectra from which one-bond and long-range ^{13}C–^1H coupling constants were determined. The literature assignments for H-5 and H-7 in the parent system have been revised and a simple method for distinguishing between 5-methyl and 7-methyl compounds is suggested, based on the carbon chemical shift of the methyl group or on its fine structure in the ^1H NMR spectrum. Regioselective syntheses for all the reported methyl derivatives are also described.

STEFANO CHIMICHI, BARBARA COSIMELLI, FABRIZIO BRUNI et SILVIA SELLERI. Can J. Chem. **70**, 1093 (1992).

On discute des spectres RMN du ^1H et du ^{13}C de quelques dérivés pyrazolo[1,5-*a*]pyrimidine. On a attribué toutes les raies de spectres ^{13}C d'une façon non-ambiguë à l'aide d'expériences en 2D et de spectres découplés à connexion intermittente à partir desquels on a déterminé les constantes de couplage ^{13}C–^1H à travers une et plusieurs liaisons. On a révisé les attributions faites dans la littérature pour les H-5 et H-7 et on suggère une méthode simple pour distinguer les composés portant des méthyles en 5 ou en 7; elle est basée sur le déplacement chimique du carbone des groupes méthyles ou sur la structure fine dans les spectres RMN du ^1H. On décrit aussi des synthèses régiospécifiques pour tous les dérivés méthyles examinés.

[Traduit par la rédaction]

Introduction

As part of our continuing interest in hetero-condensed five-membered heterocycles (1–3), we recently reported a new synthetic pathway to pyrazolo[1,5-*a*]pyrimidines (4). During this work, we noticed the lack of carbon-13 NMR data for this class of compound, some members of which show interesting biological properties (5–7).

We report here a detailed ^{13}C and ^1H NMR study of some pyrazolo[1,5-*a*]pyrimidines, including the parent ring system, carried out by means of gated decoupled, hetero- and homonuclear correlation spectroscopy techniques. We also demonstrate that NMR spectroscopy can be valuable for distinguishing the isomeric 7-methyl and 5-methyl derivatives, this not being easily achieved by other common spectroscopic techniques.

Experimental

Chemicals

3(5)-Aminopyrazole and 4,4-dimethoxybutan-2-one (acetylacetaldehyde dimethyl acetal) are commercially available (Aldrich); 5-amino-3-phenylpyrazole and compounds **1**, **4**, **5**, and **8** were synthesized according to published procedures (8–12, respectively).

5-Methylpyrazolo[1,5-a]pyrimidine (2)

The procedure reported by Bajwa and Sykes (13) was modified by adding 4,4-dimethoxybutan-2-one (1.00 g, 7.6 mmol) to a solution of 3(5)-aminopyrazole (0.57 g, 6.9 mmol) in EtOH (3.5 mL). The solution was then refluxed for 30 min; removal of the solvent left a yellow solid (0.86 g, 94%) mainly consisting (90%, TLC and ^1H NMR spectrum) of compound **2**, together with a very small quantity of the 7-methyl isomer. An analytical sample (colorless plates) obtained by recrystallization from petroleum ether melted at 122–123°C (lit. (13) mp 122–124°C).

7-Methylpyrazolo[1,5-a]pyrimidine (3)

A solution of 3(5)-aminopyrazole (0.57 g, 6.9 mmol) in EtOH (3.5 mL) was added to a solution of the β-keto-acetal (1.00 g, 7.6 mmol) in concentrated HCl (0.3 mL). The solution was refluxed for 30 min and then poured into water (20 mL) and extracted exhaustively with diethyl ether. The ethereal extracts were washed with water (50 mL) and dried on Na_2SO_4. Evaporation to dryness left a yellow solid (0.66 g, 80%) containing the isomeric 7- and 5-methyl derivatives in the ratio 87:13. The mixture was resolved by flash chromatography with ethyl acetate/petroleum ether (bp 40–70°C) (1:1 v/v) as eluent; the faster band gave compound **3** (77%), mp 58–59°C (from petroleum ether) (lit. (13) mp 59–60°C). The second compound was easily recognized (TLC, ^1H NMR spectrum) as 5-methylpyrazolo[1,5-*a*]pyrimidine (**2**) (10%).

5-Methyl-1-phenylpyrazolo[1,5-a]pyrimidine (6)

Operating as for compound **2** employing 5-amino-3-phenylpyrazole, a pink solid (0.62 g, 95%) consisting mainly (96%, TLC and ^1H NMR spectrum) of compound **6** was obtained. An analytical sample (colorless plates) melted at 177–178°C (from ethyl acetate). Anal. calcd. for $C_{13}H_{11}N_3$: C 74.62, H 5.3, N 20.08; found: C 74.26, H 5.21, N 20.27.

7-Methyl-2-phenylpyrazolo[1,5-a]pyrimidine (7)

Operating as for compound **3** starting from 5-amino-3-phenylpyrazole, a yellow solid (0.61 g, 94%) containing the two isomeric 7- and 5-methyl derivatives (93:7) was obtained. Recrystallization from ethanol/water (1:1 v/v) afforded compound **7** as yellow needles, mp 93–94°C (lit. (14) mp 95–96°C).

Instruments

All melting points were determined on a Gallenkamp melting point apparatus and are uncorrected. Carbon-13 and proton NMR spectra were recorded on a Varian VXR-300 instrument in the Fourier transform mode. All carbon spectra were recorded in 10-mm o.d. tubes at 25 ± 0.5°C for 0.5 M solutions in $CDCl_3$, proton coupled spectra were obtained in the "gated decoupling" mode; proton spectra were recorded in 5-mm o.d. tubes at the same temperature. Chemical shifts are reported in ppm high frequency from

TMS as secondary reference standard and coupling constants in Hz. Silica gel plates (Merck F_{254}) and silica gel 60 (Merck 230–400 mesh) were used for analytical TLC and for flash chromatographies, respectively. Solvents were removed under reduced pressure.

Results and discussion

The carbon chemical shifts of the examined compounds **1**–**8** (Scheme 1) are given in Table 1; spectra were analyzed on a first-order basis, the necessary assumptions being fulfilled. Coupling constants are assembled in Table 2; the assignments of carbon resonances (see below) are based on chemical shift arguments, on ^1J(CH) values, and on the fine splitting pattern caused by long-range couplings as well as on HETCOR spectra.

Chemical shift considerations did not always allow an unambiguous assignment; as regards compound **1**, apart from the singlet attributable to the quaternary carbon atom C-3a, the five methine ring carbons appear as doublets with further long-range couplings. The signals at lower frequencies (δ 96.86 and 107.66) are easily attributed to C-3 and C-6, respectively, because the former appears as a doublet of doublets ($^2J_{C3-H2}$ = 9.7 Hz) whereas the latter is a doublet of doublets of doublets due to the long-range couplings both to H-5 and H-7 ($^2J_{C6-H5}$ = 9.9 Hz and $^2J_{C6-H7}$ = 3.0 Hz). Assignment of C-2, C-5, and C-7 resonances is more difficult, their chemical shifts being very close, and was achieved on the following basis.

First, we attempted to assign all the proton resonances of compound **1** (Table 3) by a COSY-90 experiment, which would then be useful in rationalizing the heteronuclear correlation (HETCOR) spectrum. Unfortunately, the COSY spectrum, besides confirming the assignment of H-3 and H-6, allowed us only to attribute the signal at δ 8.166 to H-2; as regards H-7 and H-5 an unambiguous assignment was not attained. Moreover, the HETCOR spectrum shows that the most deshielded carbon atom is not connected with the most deshielded proton but with the signal at δ 8.461; this finding, together with chemical shifts considerations and the fine splitting pattern, suggested that the highest frequency signal in the ^{1}H NMR spectrum should be attributed to H-7 instead of H-5, contrary to the report of Lynch *et al.* (9). To reach a definitive assignment, we synthesized the methyl derivatives **2**, **6** and **3**, **7**. As for the preparation of these compounds, a synthetic pathway leading to a mixture of compounds **2** and **3** was reported in the literature (13) starting from 4,4-dimethoxybutan-2-one. A simple change in the experimental procedure (see Experimental) allowed us to make the synthesis highly regioselective also employing 3-

TABLE 4. Substituent coupling constants (CH_3-SCC) for the pyrazolo[1,5-*a*]pyrimidines (Hz)

Compound	(5,6)[a]	(5,7)	(7,5)	(7,6)
2	−1.9	−0.8	—	—
3	—	—	−1.9	−2.7
6	−2.0	−0.7	—	—
7	—	—	−1.9	−2.6

[a]The numbering system (*m*,*n*) is referred to the pyrazolo[1,5-*a*]pyrimidine ring.

phenyl-5-aminopyrazole as starting material, thus obtaining the requisite 5- (compounds **2** and **6**) and 7-methyl derivatives (**3** and **7**). The regioisomers can be easily distinguished on the basis of the carbon chemical shift of the methyl group without a detailed analysis of the other spectral data. This substituent exhibits a diagnostic low-frequency shift (δ 24.8–24.6 vs. 17.2–17.0 ppm, respectively) on going from position 5 to 7. Moreover, as regards the proton spectrum, the methyl group in position 5 does not show coupling to H-6; on the contrary, a small coupling of 0.9 Hz between 7-CH_3 and H-6 is always present in the spectra of derivatives **3**, **4** and **7**, **8** (see Table 3). Because the C-5 and C-7 resonances are easily recognizable in the model compounds **3**, **4** and **7**, **8**, the attribution of signals for the corresponding atoms in compound **1** becomes straightforward. Once the carbon resonances have been established, the HETCOR spectrum allows an unambiguous assignment of H-5 and H-7 signals, thus showing that the previously reported one (9) must be reversed.

Comparison of ^1J(CH) values for pyrazolo[1,5-*a*]pyrimidines and pyrimidine (15) shows that the pyrazole ring fusion is responsible for an increase in all one-bond coupling constants with respect to pyrimidine, thus confirming the electron-withdrawing effect of the fused five-membered ring (1, 2). The methyl-substituted pyrazolo[1,5-*a*]pyrimidines show, as recently reported for other heterocycles (15, 16), additivity of substituent effects upon ^1J(CH). The substituent coupling constant (SCC) for the methyl group in the pyrazolo[1,5-*a*]pyrimidines (Table 4) is defined as the change that occurs in the value of ^1J(CH) at C-*n* upon substitution at a pyrimidine ring carbon, C-*m*($m \neq n$), by a methyl group. The ^1J(CH) values observed for the dimethyl derivatives **4** and **8** agree well with those calculated by using the CH_3-SCC values (166.5 vs. 166.6 Hz and 166.5 vs. 166.5 Hz, respectively).

Finally, it is interesting to note that the general rules outlined for other heterocyclic compounds (1, 17) hold for this ring system too. For example, ^2J(C-β,H-α), in which the coupled proton is geminal to an sp^2 nitrogen atom, and ^3J(CH) through an heteroatom are larger in comparison with other geminal or vicinal couplings, respectively, as well as ^3J(C, CH_3) being smaller than ^2J(C, CH_3) (15).

Comportement photoélectrochimique de $ZnIn_2S_4$(n) dans l'obscurité et sous éclairement en solution électrolytique aqueuse

O. SAVADOGO

Département de métallurgie et de génie des matériaux, École polytechnique de Montréal, C.P. 6079, succ. A, Montréal (Québec), Canada H3C 3A7

Reçu le 9 février 1990[1]

O. SAVADOGO. Can. J. Chem. **70**, 1098 (1992).

Les caractéristiques photoélectrochimiques du $ZnIn_2S_4$(n) ont été étudiées à l'aide de techniques potentiodynamiques et de mesures de capacité d'interface. La variation de la densité de courant anodique (i_a) en fonction de $[OH^-]$ et $[H_3O^+]$ a été étudiée dans l'obscurité. Le courant dans l'obscurité est faible (~ 1 μA cm^{-2}) et il a été attribué à la dissolution anodique du matériau. Les résultats expérimentaux montrent que le processus n'est pas limité par la diffusion en surface des espèces en solution. Ce comportement a été interprété par un transfert d'électrons par effet tunnel à travers des états de surface localisés. La dissolution du matériau a été déterminée sous éclairement. Cette dissolution utilise huit porteurs minoritaires p. La variation du coefficient de stabilisation S (i_{ox}/i_t) en fonction du potentiel redox (V_{redox}) et de la concentration en S^{2-} a été déterminée. L'influence de $[S^{2-}]$ et de l'éclairement sur la valeur du potentiel de bandes plates a été déterminée.

O. SAVADOGO. Can. J. Chem. **70**, 1098 (1992).

Photoelectrochemical characteristics of $ZnIn_2S_4$(n) have been studied by potentiodynamic methods and capacity measurements. The variation of the anodic current density (i_a) as a function of $[OH^-]$ and $[H_3O^+]$ has been studied under darkness. This darkness current is small (~ 1 μA cm^{-2}) and it has been attributed to the anodic dissolution of the material. This process is not diffusion controlled. This behaviour was attributed to electron transfer by tunnel effect via localized interface states. The dissolution of the material under illumination has been determined. Its dissolution requires eight holes. The variation of the stabilisation coefficient S (i_{ox}/i_t) with the redox potential (V_{redox}) and the S^{2-} species concentration (C_t) has been studied. The effects of $[S^{2-}]$ and illumination on the flat band potential of the electrode have been determined.

1. Introduction

Les réactions de transfert de charge à l'interface semiconducteur/électrolyte peuvent être effectuées par les électrons de la bande de conduction ou par les trous de la bande de valence (1–4). Les deux types de porteurs ne sont pas tous situés près du niveau de Fermi mais ils sont séparés par la largeur de la bande interdite du semiconducteur. Comme, de plus, la concentration de ces porteurs dans les semiconducteurs est relativement faible, chaque type de porteurs peut être traité comme étant un réactif individuel lors de la réaction interfaciale. Ainsi, selon la nature du composé semiconducteur utilisé, la composition de l'électrolyte, les conditions de polarisation et la présence ou l'absence de l'éclairement, il est possible de mettre en évidence le type de proteurs qui est impliqué dans la réaction de transfert de charge. Ceci n'est pas le cas pour l'électrode métallique où la densité des états au voisinage du niveau de l'énergie de Fermi est très éleveé et où la concentration des électrons y est très importante. En conséquence, contrairement au métal, il semble intéressant et peut-être important de déterminer le type de porteurs (électrons ou trous) qui sont impliqués dans les réactions de transfer de charge à l'interface semiconducteur/électrolyte. Pour mieux comprendre cette différence, il est important d'étudier les réactions de transfert de charge à l'interface semiconducteur/électrolyte pour de nouveaux composés afin de déterminer le rôle exact du matériau sur ces réactions.

Ce travail porte sur l'étude du transfert de charge à l'interface $ZnIn_2S_4$ (n)/solution électrolytique aqueuse dans l'obscurité et sous éclairement. L'effet de $[OH^-]$ sur la densité de courant anodique est étudié à l'aide de l'électrode à disque tournant. Il a été déterminé le nombre de porteurs mis en jeu lors du processus de dissolution anodique de $ZnIn_2S_4$(n) et la variation du courant dû à l'oxydation de l'espèce réductrice (S) en solution en fonction du couple oxydoréducteur. La variation de S en fonction de la composition de l'électrolyte redox et de la densité de courant totale (i_t) est aussi étudiée. Une étude du mécanisme de transfert de charge à l'interface, par l'intermédiaire des états de surface est proposée.

2. Techniques expérimentales

Les cristaux de $ZnIn_2S_4$(n) ont été obtenus par sublimation sous vide ou par transport à l'iode (5, 6). Le taux de porteurs n a été déduit des mesures de capacité d'interface : $n \approx 10^{18}$ cm^{-3}. Les échantillons utilisés ont été préparés suivant une méthode analogue à celle utilisée pour $CdIn_2Se_4$ (7). Une face plane est obtenue par polissage mécanique à la pâte diamant puis à l'alumine «12 heures». Il est procédé ensuite à un décapage chimique par un mélange HNO_3–HCl (1:4) pendant 10 s puis KCN 10% pendant 1 min. Ce traitement est complété par un décapage photoélectrochimique de 15 min ($V_E = 1$ V/E.C.S.; $i = 10^{-3}$ A cm^{-2}). Une surface polie est ainsi obtenue. Une cellule à trois compartiments a été utilisée.

Le montage classique à trois électrodes a été utilisé. L'électrode de référence est une électrode au calomel saturé (E.C.S.), la contre-électrode est une feuille de platine de grande surface (12 cm^2) et l'électrode de travail est $ZnIn_2S_4$(n). Les caractéristiques courant-potentiel de l'interface $ZnIn_2S_4$/solution électrolytique ont été déterminées à l'aide d'un potentiostat PAR 273 et une interface électrolytique (modèle 176). Le capacité de l'interface a été mesurée à l'aide de l'analyseur de réponse en fréquence type PAR 5208 conecté au potentiostat 273 et piloté par le programme PAR 378.

3. Résultats

3.1 Mesure de capacités d'interface

La détermination de la disposition relative des bandes de valence et de conduction à la surface du matériau est possi-

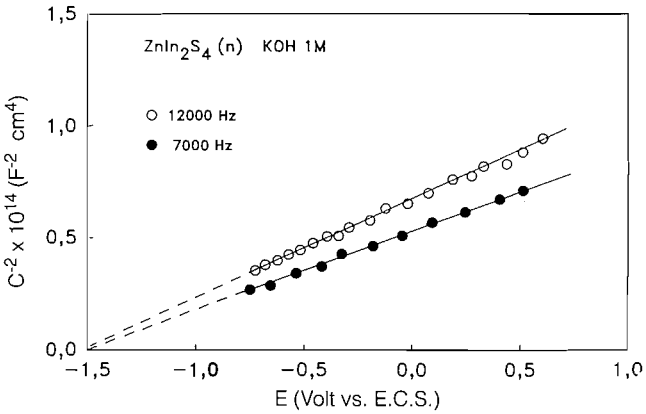

FIG. 1. $C^{-2} = f(V)$ de $ZnIn_2S_4$/KOH 1 M.

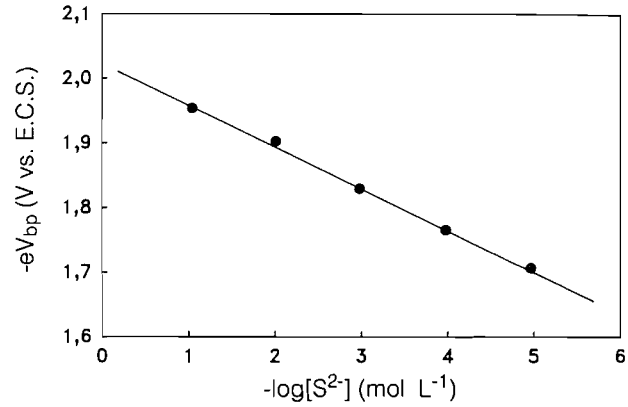

FIG. 2. Variation du potentiel de bandes plates de $ZnIn_2S_4$ en fonction de$[S^{2-}]$ dans KOH 1M.

ble grâce à la connaissance de son potentiel de bandes plates (V_{bp}). V_{bp} peut être obtenu (figure 1) à partir des courbes $C^{-2} = f(V_E)$ qui sont linéaires dans un domaine étendu de potentiel (~1 V) pour les deux fréquences de mesures. Alors, l'équation suivante est vérifiée pour cette interface pour chaque fréquence de mesure :

$$\frac{1}{C^2} = \frac{2}{e\epsilon_0\epsilon n}\left(V_{bp} - V_E - \frac{kT}{e}\right)$$

C est la capacité d'interface par unité de surface, e la charge de l'électron (1.6×10^{-19} C), ϵ la constante diélectrique du semi-conducteur, ϵ_0 la permittivité du vide et n, la densité du nombre de donneurs. V_{bp} a été déterminé à ± 0,100 V près. Les pentes des deux droites sont différentes pour les deux fréquences (figure 1). La pente est plus élevée pour la fréquence la plus importante. Les sens de variation des pentes correspond à un matériau de type n. La valeur de n est de $n \sim 10^{18}$ cm^{-3}. L'extrapolation des droites $C^{-2} = f(V)$ jusqu'à la valeur $C^{-2} = 0$ conduit à la même valeur du potentiel de bandes plates pour les deux fréquences de mesures utilisées :

$$V^{(n)}_{bp} = -1.50 \text{ V/E.C.S.}$$

L'influence des ions sulfures sur les caractéristiques d'impédance a été étudiée dans KOH 1 M parce que dans ce milieu l'addition de quantités variables des ions sulfures $[S^{2-}]$ ne modifient pas le pH du milieu. Les caractéristiques des courbes $C^{-2} = f(V)$ ne sont pas modifiées par $[S^{2-}]$ sauf pour le potentiel de bandes plates dont la variation avec $p[S^{-2}]$ est linéaire avec une pente de 0.057 V (figure 2). Cette variation est identique à celle observée sur $CdIn_2S_4$ (5, 6) et CdS (7, 8) et est attribuée à l'adsorption de HS^- à la surface du matériau. Sous éclairement, l'allure des caractéristiques $C^{2-} = f(V)$ n'est pas modifiée : variation linéaire des courbes avec des pentes identiques à celles obtenues à l'obscurité.

3.2. Courbes courant–potentiel

La figure 3 représente les caractéristiques courant–potentiel dans l'obscurité et sous éclairement. La solution électrolytique d'étude est KOH 1 M. Cette figure présente deux parties distinctes. La région I est caractérisée par une forte variation de courant en fonction de V. Sous éclairement ($I_{h\nu}$), elle est voisine d'un régime de Tafel entre 2 mA cm^{-2} et 5×10^{-1} mA cm^{-2}. Elle s'étend du potentiel de transition V_{tr} à une tension voisine de 0,2 V. Elle est très peu

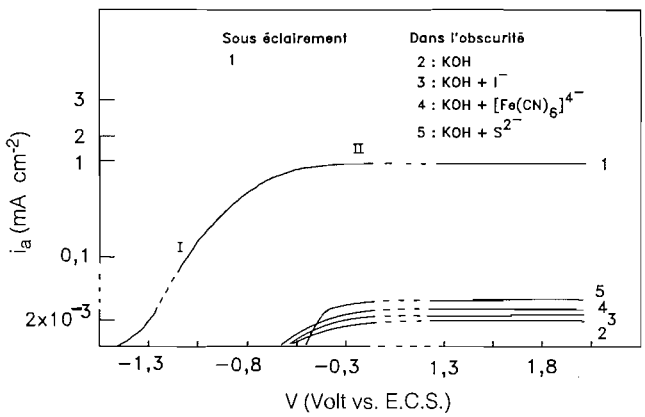

FIG. 3. Caractéristiques V vs. log i de $ZnIn_2S_4$ dans l'obscurité et sous éclairement en présence de plusieurs couples oxydo-réducteurs dans KOH 1M.

étendue dans l'obscurité. Dans la région II, le courant varie peu en fonction du potentiel. Il varie linéairement en fonction de l'intensité lumineuse incidente lorsqu'il est supérieur au courant d'obscurité qui est très faible (10^{-6} A cm^{-2}). Dans l'obscurité, les courbes sont parfaitement reproductibles, le courant de saturation a été étudié en fonction du pH et de la nature des ions. La variation du courant de saturation peut être représentée par les deux lois suivantes :

[2] en milieu acide : $i_a = k_a[H_3O^+]^1$

[3] en milieu basique : $i_a = k_b[OH^-]^{1/2}$ (fig. 4)

Les attaques observées pour un même pH (~14) dans les milieux RbOH, KOH, NaOH et LiOH montrent que le courant de saturation varie en fonction de la nature du cation. Il est d'autant plus faible que le cation est plus petit. La variation de i_a avec la mobilité du cation est linéaire (fig. 5) Pour un milieu donné (RbOH, KOH, NaOH ou LiOH), le courant de saturation varie linéairement avec la concentration du cation. De plus le courant de saturation dû à la réaction dans un milieu contenant plusieurs cations est égal à la somme des densités de courant dûes aux réactions dans les milieux contenant respectivement chacun des cations. Le potentiel de transition anodique–cathodique ne varie pratiquement pas avec la taille du cation. En présence des ions I^-, $[Fe(CN)_6]^{4-}$ ou S^{2-} dans KOH 1 M, une densité de

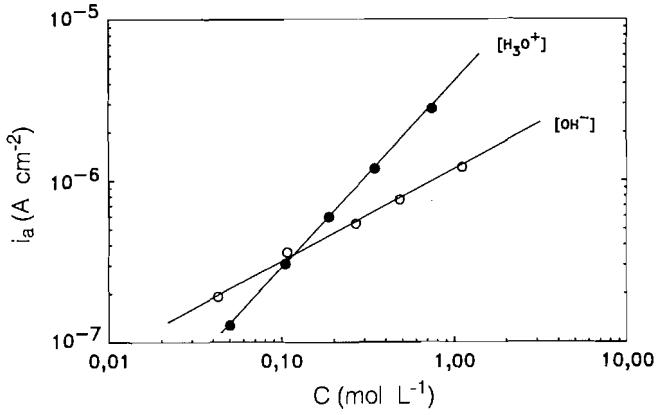

FIG. 4. Cinétique de dissolution anodique de $ZnIn_2S_4$ dans l'obscurité en milieu acide et basique.

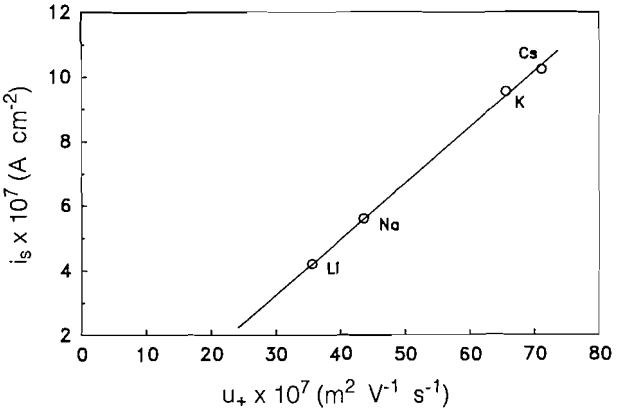

FIG. 5. Variation de i_a en fonction de la mobilité du cation dans l'obscurité pour V = 1 V/ECS en milieu basique.

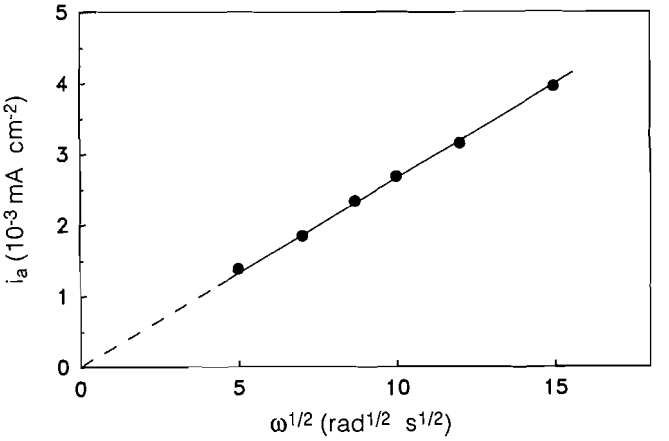

FIG. 6. $i_a = f(\omega^{1/2})$ dans l'obscurité pour $V_E \geq 1{,}8$ V/ECS. ω : vitesse de rotation de l'électrode dans KOH 1 M.

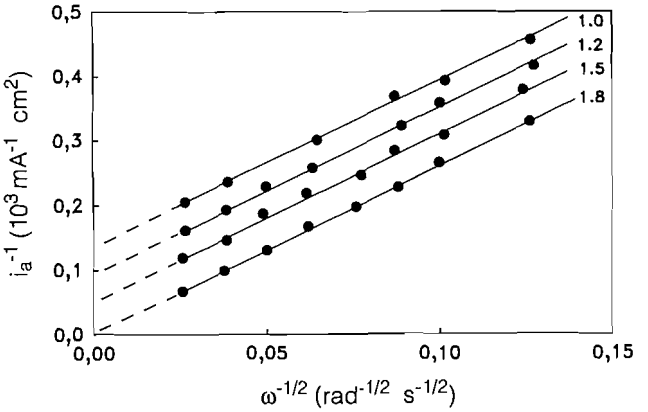

FIG. 7. $i_a^{-1} = f(\omega^{-1/2})$ dans KOH 1 M.

courant de saturation supplémentaire apparaît par rapport à KOH seul. Le courant le plus élevé est observé en présence des ions S^{2-}. Le potentiel de transition anodique–cathodique (V_{tr}) se déplace de 0,1 V/E.C.S. et +0,15 V/E.C.S. vers les valeurs anodiques, en présence de 5×10^{-3} M I^- et $[Fe(CN)_6]^{4-}$ respectivement. Par contre, en présence de 5×10^{-3} M S^{2-}, V_{tr} diminue de 0,1 V. Dans le domaine I, lorsque l'on passe de I^- à $[Fe(CN)_6]^{4-}$ et à S^{2-}, la variation du courant en fonction de V est de plus en plus rapide. Pour une concentration donnée en ions OH^-, la valeur de la vitesse de rotation de l'électrode (ω) influe sur le régime de saturation. La variation de la densité de courant limite (i_a) dans KOH 1 M en fonction de la vitesse de rotation montre que la courbe $i_a = f(\omega^{1/2})$ (fig. 6) est une droite passant par l'origine pour $V_E \geq 1{,}8$ V/E.C.S. Le critère de Levich (9–11) est donc vérifié pour cette électrode, donc le courant serait limité par la diffusion. La variation de la densité de courant (i_a) en fonction de ω permet de séparer le courant qui serait dû à la diffusion et le courant qui serait dû à l'influence de la réaction d'activation pure (i_a^*) :

$$[4] \qquad \frac{1}{i_a} = \frac{1}{i_a^*} + \frac{1}{i_d}$$

i_d est de la forme

$$[5] \qquad \frac{1}{i_d} = A\,\omega^{-1/2}$$

d'où

$$[6] \qquad \frac{1}{i_a} = \frac{1}{i_a^*} + A\,\omega^{-1/2}$$

A est une constante. Les courbes $1/i_a = f(\omega^{-1/2})$ sont des droites parallèles pour différents potentiels du régime de saturation. Seule la droite obtenue pour $V_E \geq 1{,}8$ V passe par l'origine des axes. Pour ces potentiels, la réaction qui proviendrait de la diffusion masque l'influence de la réaction qui serait due à l'activation. Pour les potentiels inférieurs, l'ordonnée à l'origine notée $1/i_a^*$ n'est pas nulle. Par exemple si V_E = 1,5 V/E.C.S., $i_a^* = 12{,}5 \times 10^{-3}$ mA cm^{-2}. i_a^* augmente avec le potentiel (fig. 7). On vérifie ainsi que plus le potentiel est élevé, plus le courant qui proviendrait de l'activation pure est élevé. La variation de i_a en fonction de la température nous a permis de déterminer l'énergie d'activation de la réaction; E_a = 2,2 kcal/mol.

Sous éclairement et pour un pH donné en milieu basique, le potentiel de transition anodique–cathodique se déplace vers les valeurs négatives lorsque l'intensité lumineuse augmente. La variation de V_{tr} en fonction de log $i_{h\nu}$ est linéaire. De même V_{tr} varie linéairement en fonction du pH de 60 mV/

TABLEAU 1. Valeurs du nombre de charges élémentaires par unité formulaire $ZnIn_2S_4$ pour différents temps de dissolution dans KOH 1 M.

Temps (min)	60	100	140	180	400	420
Nombre de charge	8,0	7,9	8,1	7,9	7,8	7,9

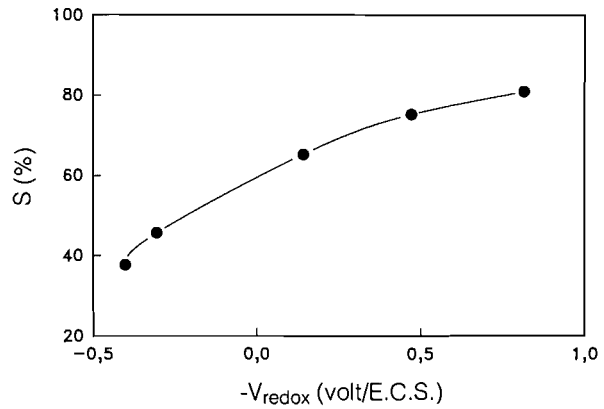

FIG. 8. Variation de S (i_{ox}/i_t) en fonction du potentiel d'oxydo-réduction (V_{redox}) dans KOH 1 M.

unité pH. En présence des ions sulfures, V_{tr} a une variation opposée en fonction de l'intensité lumineuse : il augmente de 60 mV/décade en courant. En plus, il est indépendant de $[S^{2-}]$ pour des concentrations supérieures à 0,25 M. La densité de courant anodique (i_t) est indépendente de la concentration (OH^-). La présence des ions I^-, $[Fe(cn)_6]^{4-}$ ou S^{2-} ne modifie pratiquement pas la valeur de i_t. La dissolution du matériau est étudiée dans KOH 1 M par la mesure de la perte de masse de l'électrode sous éclairement permanent. Le courant a été maintenu pendant un temps à une valeur constante $i_t = 10^{-3}$ A cm^{-2} correspondant au palier de saturation. Avant et après chaque cycle d'attaque, l'électrode est pesée après avoir été rincée et séchée sous un courant d'air chaud. Le tableau 1 montre les résultats obtenus. La dissolution anodique met en jeu huit charges élémentaires par unité formulaire $ZnIn_2S_4$. Dans les conditions de travail utilisées, $V \sim 1$ V, les charges arrivant sur l'interface sont essentiellement constituées par les porteurs p crées dans le région de charge d'espace, draînés par le champ électrique, et le courant i_{ox} est négligeable. La dissolution d'une unité formulaire consomme huit porteurs p. Le bilan des réactions chimiques et électrochimiques à l'électrode a été également établi en présence d'espèces réductrices en solution. Pour ce faire, la mesure de la perte de masse a été réalisée pendant 4 h environ. Pour la même polarisation anodique (~ 1 V), le courant d'oxydo-réduction est indiquée sur la figure 8. D'autre part, pour le même potentiel de polarisation, i_{ox}/i_t varie en fonction de la concentration des ions sulfures (fig. 9). Il a été vérifié expérimentalement que i_{ox}/i_t varie très peu avec i_t pour des concentrations élevées en S^{2-} alors que i_{ox}/i_t diminue avec i_t pour de faibles concentrations en S^{2-} (fig. 10).

Le déplacement de V_{tr} vers les valeurs négatives avec l'augmentation de l'intensité lumineuse indique une dégradation du matériau sous éclairement due aux porteurs p. En présence de fortes concentrations d'ions sulfures, le déplacement de V_{tr} vers les valeurs positives indique une

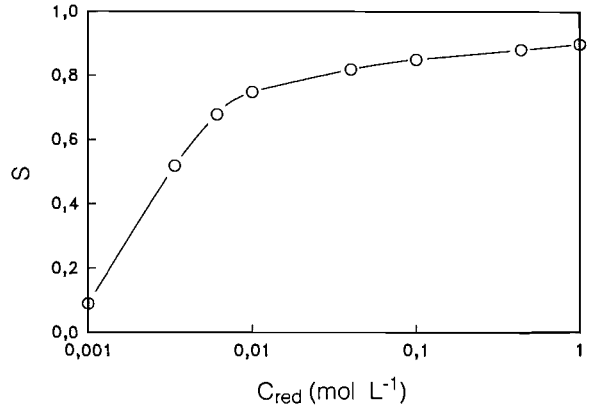

FIG. 9. Variation de S (i_{ox}/i_t) en fonction de la concentration en ions sulfures dans KOH 1 M.

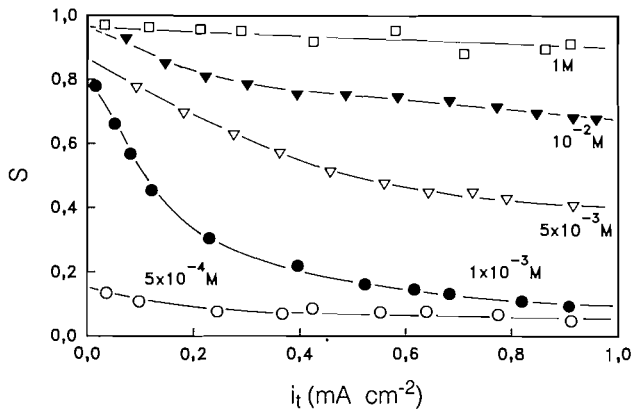

FIG. 10. Variation de S (i_{ox}/i_t) en fonction de i_t dans KOH 1 M.

stabilisation de l'interface, les porteurs étant essentiellement utilisés pour l'oxydation des ions sulfures et non pour la décomposition du matériau.

4. Discussion

L'interprétation des résultats porte sur l'ensemble de ceux obtenus en milieu basique. En milieu acide, à part la cinétique de dissolution, l'ensemble des autres résultats ne sont pas intéressants et ne sont pas indiqués dans ce travail.

4.1 Dans l'obscurité

Les mesures de capacité d'interface ont permis de déterminer la densité de porteurs du matériau $n \sim 10^{18}$ cm^{-3}. La largeur de la bande interdite est de 2,6 eV (12–14) et dans l'obscurité la densité de porteurs p dans la masse est négligeable. Ainsi, le mécanisme de transfert de charge qui utiliserait les porteurs p ne peut donc se produire. L'effet des espèces en solution sur la pseudo-saturation observée aux potentiels élevés pourrait être attribué à un phénomène de diffusion décrit par le modèle de Levich. C'est à dire que la variation linéaire observée entre i_a et $\omega^{1/2}$. Un palier de saturation est interprété de façon classique par la diffusion des ions qui est considérée comme étape lente de la réaction. Un certain nombre de faits seraient favorables à cette interprétation : en effet, la variation du courant de saturation (i_a) en fonction de $\omega^{1/2}$ est linéaire et passe par l'origine des axes pour $V_E \geq 1{,}8$ V/E.C.S. L'établissement des courbes classiques $i_a^{-1} = f(\omega^{-1/2})$ pour différents potentiels a per-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 79.173.37.17 on 09/08/12

For personal use only.

mis la séparation des composantes dues à la réaction en surface et à la diffusion et a montré que la composante qui serait due à la diffusion, qui est l'étape la plus lente de la réaction, joue un rôle d'autant plus important que le potentiel est plus élevé. D'autres résultats expérimentaux seraient également en faveur avec cette interprétation : (*i*) l'énergie d'activation E_a est compatible avec une cinétique limitée par la diffusion; (*ii*) l'influence de la mobilité des cations sur i_a est également favorable à cette interprétation.

Cependant, plusieurs faits expérimentaux montrent l'insuffisance d'interpréter les résultats obtenus ici par des phénomènes de diffusion dans l'électrolyte : (*i*) la valeur de la densité de courant de pseudo-saturation obtenue dans ce travail ($\sim 10^{-6}$A cm^{-2}) est bien inférieure à celle requise pour une densité de courant due à la diffusion des ions. Par exemple, la détermination de la densité de courant de pseudo-saturation correspondant à l'électrode de platine dans les mêmes conditions expérimentales effectuées dans ce travail donne une valeur de i_a de l'ordre de 10^{-2}A cm^{-2}; (*ii*) la proportionnalité de i_a avec $(OH^-)^{1/2}$ et non avec $(OH^-)^1$. Dans le cas d'une électrode de platine, les résultats obtenus dans ce travail montrent que i_a est proportionnel à $(OH^-)^1$ et non à $(OH^-)^{1/2}$.

Ces considérations montrent qu'une interprétation cohérente des résultats dans l'obscurité n'est pas possible pour l'instant. D'autres hypothèses d'interprétation sont présentement étudiées. En particulier, l'hypothèse selon laquelle i_a serait dû à la formation des sites superficiels nécessaires à l'attaque du matériau est considérée et l'établissement d'un modèle mathématique lié à cette hypothèse est actuellement étudié.

La variation de i_a avec la mobilité du cation peut être attribuée à la contribution de chaque espèce ionique j à la densité de courant selon la relation classique (15, 16) :

$$[7] \quad i_{aj} = Z_j F C_j U_{+j} E$$

où Z_jF est la charge du cation, C_j sa concentration, U_{+j} sa mobilité et E le champ électrique unitaire exercé sur le cation. Nous avons aussi verifié que la densité de courant totale due à la contribution de l'ensemble des cations se trouvant dans un électrolyte est la somme des contributions partielles des courants dûs aux différents cations. En plus pour un cation donné, la variation linéaire de la densité de courant avec la concentration de l'espèce dans l'électrolyte est favorable à cette interprétation.

Les variations de i_a en fonction de $[OH^-]^{1/2}$ et de $[H_3O^+]^1$ sont linéaires. Elles sont différentes de celles observées sur GaAs (6) où i_a varie comme $[OH^-]$ et $[H_3O^+]^{1/2}$. Dans le cas du germanium, Beck *et al.* (17) ont montré que sa dissolution anodique est une réaction du premier ordre en $[OH^-]$ et en porteurs p^+. Selon le mécanisme proposé, l'étape qui détermine la vitesse de la réaction est la rupture d'une des deux liaisons covalentes du germanium après capture d'un porteur p. Les résultats expérimentaux obtenus dans ce travail favorisent l'idée que l'apparition du courant dans l'obscurité est liée à un transfert d'électrons à travers la charge d'espace par effet tunnel. Ainsi, des électrons qui proviennent d'états superficiels quittent la surface laissant derrière eux des trous dont les niveaux d'énergie sont situés à l'intérieur de la bande interdite du matériau. Le transfert d'électrons à travers la charge d'espace par effet tunnel est possible parce que, dans le régime de pseudo-saturation, la différence de potentiel de charge d'espace (ΔV_{ce}) est comprise entre 2,8 et 3,4 V, la largeur de la bande interdite étant de 2,6 V, les électrons situés à la surface dans la bande de valence ont une énergie supérieure à l'énergie E_{bc} du bas de la bande de conduction du matériau dans le volume. Ainsi ces électrons doivent traverser une barrière dont l'épaisseur est de 1000 Å et qui est pratiquement opaque. Il a été montré que (18, 19) pour les barrières métal/semiconducteur, qui constituent des dispositifs semblables, en première approximation, à l'interface semiconducteur/électrolyte, le transfert d'électrons par effet tunnel devient le mécanisme dominant lorsque le champs électrique devient supérieur à 10^7 V/m. Si $\Delta V_{ce} = 3$ V, $n \geq 10^{24}$ m^{-3}, le champ à la surface est supérieur à 10^8 V/m, et un transfert par effet tunnel peut être envisagé. Si nous appelons S_m un site «potentiel» de fixation de OH^- à la surface du matériau, les réactions de formation, de dissociation et de réaction par oxydation du site pourraient s'écrire :

$$[8a] \quad S_m + OH^- \rightleftharpoons S_m + e^- \text{ (lente)}$$

$$[8b] \quad «e» \qquad S_m + OH^- + p^+ \rightleftharpoons S_m - OH \text{ (lente)}$$

$$[8c] \quad S_m - OH \Rightarrow \text{produits d'oxydation (rapide)}$$

En présence d'une espèces comme Br^-, $[Fe(CN)_6]^{4-}$, I^-, ..., et dans le cas où cette espèce n'est pas encore oxydée, il y a empêchement de la réaction des sites avec OH^- par réaction de ces sites avec cette espèce. Il y a donc compétition entre cette espèce et OH^- pour réagir avec les sites. Dans le cas où cette espèce est Br^- la réaction pourraît être :

$$[9a] \quad S_m + Br^- \rightleftharpoons S_m - Br + e^- \text{ (lente)}$$

$$[9b] \quad «e» \qquad S_m + Br^- + p^+ \rightleftharpoons S_m - Br \text{ (lente)}$$

$$[9c] \quad S_m - Br \rightleftharpoons \text{produits de réaction (rapide)}$$

En plus, la valeur trouvée de l'énergie d'activation thermique de la dissolution anodique du matériau (E_a = 2,2 kcal/mol) favorise l'interprétation selon laquelle les réactions d'interface dans l'obscurité procèdent par des états de surface intermédiaires. Cette interprétation est également en accord avec celle obtenue sur $GaAs_{1-x}P_x$ (x = 0,39) en contact avec KOH 1 M (20).

4.2 Sous éclairement

Sous éclairement, l'absence de variation de i_a avec $[H_3O^+]$ et $[OH^-]$ montre que les phénomènes des réactions sont différents par rapport à celles observées dans l'obscurité. C'est donc l'arrivée des porteurs p à l'interface qui limite la réaction anodique. Ceci est confirmé par le fait que le courant est proportionnel à l'intensité lumineuse lorsque la différence de potentiel de charge d'espace est notable. Les porteurs p^+ générés par les photons sont alors drainés vers la surface et les courants dus à leurs réactions d'interface constituent l'essentiel du courant anodique. La réaction de dissolution met en jeu huit charges élémentaires. En milieu basique, elle peut s'écrire :

$$[10] \quad ZnIn_2S_4 + 11OH^- + 8\,p^+ \rightarrow HZnO_2^- + 2\,InO_2^- + 4\,S(surf) + 5\,H_2O$$

Un dépôt de soufre a été effectivement observé sur la surface de l'électrode. Un résultat analogue a été obtenu pour CdS (18–21, 22). Comme dans les cas de CdS (22) et GaAs (23), la dissolution sous éclairement a lieu par l'arrivée des porteurs p^+ au sommet de la bande de valence. Les dispositions relatives des niveaux d'énergie des bandes de va-

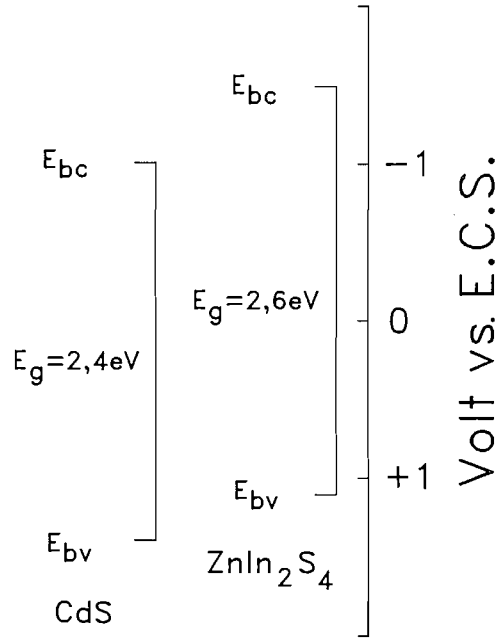

FIG. 11. Dispositions relatives des niveaux d'énergies aux interfaces $ZnIn_2S_4$/KOH 1 M et CdS/KOH 1 M.

lence et de conduction sont représentées sur la figure 11. Elles ont été déterminées à partir du potentiel de bandes plates et de la largeur de la bande interdite. En comparaison, il a été également porté la position des niveaux dans CdS selon les données des références 24 et 25. La bande de valence est profonde dans l'échelle des énergies et les échanges isoénergétiques avec la solution sont peu probables. Il est donc possible d'admettre que la dissolution de ces matériaux s'effectuent par l'intermédiaire d'états de surface ou sites superficiels ayant des niveaux énergétiques situés dans la bande interdite.

Les étapes suivantes peuvent être impliquées dans le mécanisme de dégradation.

[11] $Zn{:}In_2S_4 + p^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Zn.In_2S_4$

[12] $Zn.In_2S_4 + p^+ \xrightarrow{k_d}$ produits de décomposition

[13] $Red + p^+ \xrightarrow{k_{ox}} Ox^+$

[14] $Red + Zn.In_2S_4 \xrightarrow{k_1'} Ox^+ + Zn{:}In_2S_4$

Il est également possible de considérer que si l'intermédiaire de surface $Zn.In_2S_4$ est mobile, alors des réactions d'oxydation irréversibles avec les espèces $Zn.In_2S_4$ peuvent apparaître

[15] $2\ Zn.In_2S_4 \xrightarrow{k_2} A_2$

[16] $A_2 + Zn.In_2S_4 \xrightarrow{k_3} A_3$

---

[17] $A_{n-1} + Zn.In_2S_4 \xrightarrow{k_n}$ produits de réactions

Les courants liés aux différentes réactions peuvent être déterminées : Pour la réaction [11]

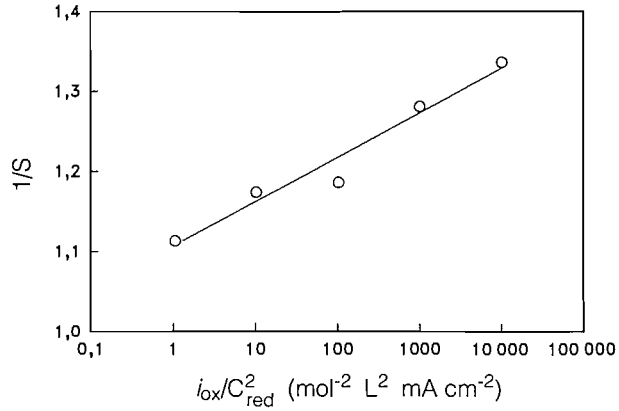

FIG. 12. Variation de S (i_{ox}/i_t) en fonction de $1/C^2_{red}$ dans KOH 1 M.

[18] $i_1 = k_1 p^+$

[19] $i_{-1} = k_{-1}\,[Zn.In_2S_4]$

Pour la réaction [12]

[20] $i_d = k_d\, p^+\, [Zn.In_2S_4]$

Pour la réaction [13]

[21] $i_{ox} = k_{ox}\, C_r\, p^+$

Pour la réaction [14]

[22] $i_1' = k_1'\, C_r\, [Zn.In_2S_4]$

Pour la réaction [17]

[23] $i_n = k_2[Zn.In_2S_4]^2 = k_3[Zn.In_2S_4][A_1] = k_n[A_{n-1}][Zn.In_2S_4]$

Le densité de courant i_d peut être mise sous la forme (26)

[24] $$i_d = \frac{k_1\, k_d\, p^{2+}}{k_{-1} + k_{ox}\, p^+}$$

si $k_{ox}p^+ << k_{-1}$, l'utilisation de l'équation [21] permet de mettre l'équation [24] sous la forme

[25] $$i_d = \frac{k_1\, k_d\, i_{ox}^2}{k_{-1}\, k_{ox}^2\, C_r^2}$$

Comme : $i_t = i_d + i_{ox}$ et $S = i_{ox}/i_t$, alors avec $\alpha = k_1\, k_d/k_{-1}\, k_{ox}$

[26] $$1/S = 1 + \frac{\alpha i_{ox}}{C_r^2}$$

L'utilisation des relations [23] et [24] en tenant compte des équations [21] et [22] permettent également d'avoir une expression identique à la relation [26].

Ainsi la variation linéaire de $1/S$ en fonction de i_{ox}/C_r^2 observée sur la figure 12 est bien expliquée par l'équation [26]. Ainsi S dépend de C_r^2 et de la densité de courant, ce qui est en accord avec l'interprétation selon laquelle que les réactions à l'interface $ZnIn_2S_4$/électrolyte sous éclairement sont limitées essentiellement par la quantité des porteurs p qui arrivent à l'interface. Ainsi, l'interprétation des résultats expérimentaux de ce travail peut être réalisée en utilisant les réactions [12] et [13] ou les réactions [14] et [17].

For personal use only.

La variation de $1/S$ avec i_{ox}/C_r^2 est analogue avec les résultats expérimentaux obtenus sur les systèmes GaAs/Fe(II)–EDTA, GaP/Fe(II)–EDTA, InP/Fe(II)–EDTA et GaP/Fe $(CN)_6^{4-}$ (27–30) pour lesquels une variation linéaire de $S^2/(1 - S)$ en fonction de C_r^2/i_{ox} a été obtenue. Par contre le résultat est différent de celui obtenu sur n-GaP/Fe^{2+} (31) pour lequel une variation linéaire de S en fonction de C_r/i_{ox} a été obtenue.

L'influence du pH et de la température sur la valeur de S sera déterminée ultérieurement et comparée à celle de ZnS et In_2S_3 afin d'étudier l'effet de la transition de ZnS à $ZnIn_2S_4$ et à In_2S_3 sur la valeur de S.

Conclusion

Les réactions à l'interface $ZnIn_2S_4$/electrolyte aqueux ont été étudiées dans l'obscurité et sous éclairement. Dans l'obscurité, le passage du courant serait donc dû à un transfert d'électrons par effet tunnel à travers la barrière de charge d'espace; les électrons issus d'un état superficiel dû à l'interaction entre la solution et la surface laissant derrière eux des trous qui contribuent à la dissolution anodique du matériau. Sous éclairement, le coefficient de stabilisation (S) varie avec la concentration de l'espèce réductrice en solution [C_r] suivant la relation $1/S$ en fonction de i_{ox}/C_r^2. Ces réactions procèdent par l'intermédiaire d'états de surface situés à l'intérieur de la bande interdite et elles sont limitées par l'arrivée des porteurs p en surface.

Phosphoranes et thio-oxazaphospholidines d'aldohexoses protégés. Synthèses et études stéréochimiques

ZOUHAIR BOUNJA, DOURAID HOUALLA,[1] MONIQUE REVEL ET ROBERT WOLF

Unité de recherche associée au Centre national de la recherche scientifique n° 454, Université Paul Sabatier, 118 Route de Narbonne, 31062 Toulouse CEDEX, France

Reçu le 4 juillet 1991

ZOUHAIR BOUNJA, DOURAID HOUALLA, MONIQUE REVEL et ROBERT WOLF. Can. J. Chem. **70**, 1105 (1992).

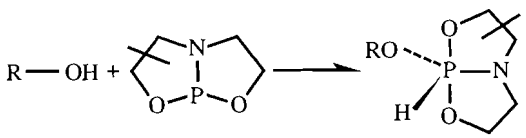
Les alcoxybicyclophosphoranes **1**–**5** ont été obtenus par l'action du bicyclophosphane **6** sur les cinq alcools suivants : 1,2,3,4-di-*O*-isopropylidène α-D-galactopyranose **7**, 1,2,5,6-di-*O*-isopropylidène α-D-glucofuranose **8**, méthanol, isopropanol et tertio-butanol. La sulfuration de **1**–**5** fournit les thio-oxazaphospholidines correspondantes : **1**(P═S)–**5**(P═S). Les formes tautomères phosphocines intermédiaires: **1**(P═S)*–**5**(P═S)* sont observées dans tous les cas. Une étude stéréochimique détaillée, basée sur les résultats de RMN de ^{1}H, ^{13}C et ^{31}P est présentée pour les huit composés **1**–**4** et **1**(P═S)–**4**(P═S). En solution, on observe le passage quantitatif du thio-oxazaphospholidine **4**(P═S) au dérivé oxo correspondant **4**(P═O) par la méthode à l'anhydride trifluoroacétique.

ZOUHAIR BOUNJA, DOURAID HOUALLA, MONIQUE REVEL, and ROBERT WOLF. Can. J. Chem. **70**, 1105 (1992).

The alkoxyphosphoranes **1**–**5** have been obtained by the reaction between the bicyclophosphane **6** and the five following alcohols: 1,2,3,4-di-*O*-isopropylidene-α-D-galactopyranose **7**, 1,2,5,6-di-*O*-isopropylidene-α-D-glucofuranose **8**, methanol, isopropanol, and tertiobutanol. The sulfuration of **1**–**5** yields to the corresponding thio-oxazaphospholidines: **1**(P═S)–**5**(P═S). In each case the intermediate tautomeric form **1**(P═S)*–**5**(P═S)*, with an eight-membered ring, is observed. A detailed stereochemical study, based on ^{1}H, ^{13}C, and ^{31}P NMR results is presented for eight compounds: **1**–**4** and **1**(P═S)–**4**(P═S). In solution we observed the quantitative transformation of **4**(P═S) into the corresponding oxo derivative **4**(P═O) by the trifluoroacetic anhydride method.

1. Introduction

L'addition oxydante des alcools et polyols sur les bicyclophosphanes[2] **I** conduit facilement aux alcoxybicyclophosphoranes[2] **II** (1)

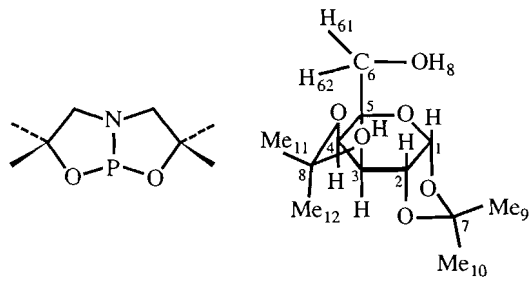


I **II**

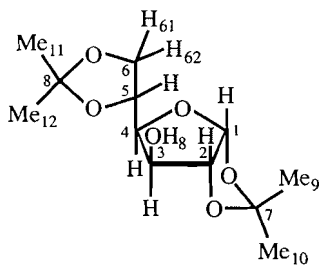
Nous avons récemment utilisé cette réaction avec le myo-inositol. L'oxydation des polybicyclophosphoranes qui en dérivent suivie de l'hydrolyse des produits obtenus nous a permis d'accéder, d'une façon simple et rapide, à quelques myo-inositol phosphates biologiquement intéressants (2, 3).

Poursuivant l'étude de la phosphoranylation comme moyen d'accéder à des produits d'intérêt biologique, nous avons préparé cinq bicyclophosphoranes du type **II**, **1**–**5**. Deux dérivent d'aldohexoses protégés : le galactopyranose **7** et le glucofuranose **8**, les trois autres sont issus respectivement du méthanol, de l'isopropanol et du tertio-butanol. C'est le bicyclophosphane **6** qui est utilisé dans tous les cas.

Dans ce travail, nous nous sommes attachés à l'obtention de dérivés soufrés. En effet, parmi les réactions explorées sur **II**, nous avons montré que la sulfuration conduit à un



6 **7**



8

mélange de thio-oxazaphospholidine **II** (P═S) et de thiodioxaphosphocine **II** (P═S)*.

Le premier est l'isomère stable et il est pratiquement seul présent après un délai de 24 h. Le fait qu'il comporte une fonction alcool permet d'envisager, par une répétition du schéma réactionnel, de fixer plusieurs restes thio-oxazaphospholidines sur le même substrat hydroxylé.

Le même comportement est observé avec les polybicyclophosphoranes de polyols : partant du glycol (4), du

[1]Auteur à qui adresser toute correspondance.

[2]Nomenclature correcte : (1) pour les bicyclophosphanes (**I**) : 2,8-dioxa 5-aza 1-phospha^{III}bicyclo[3,3,0]octane; (2) pour les bicyclophosphoranes (**II**) : 1-alcoxy 2,8-dioxa 5-aza 1-phospha^{V}-bicyclo[3,3,0]octane.

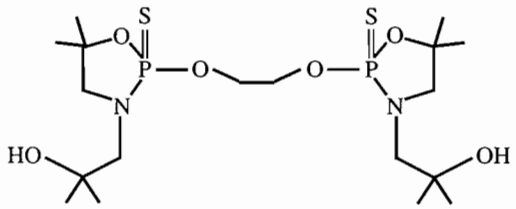
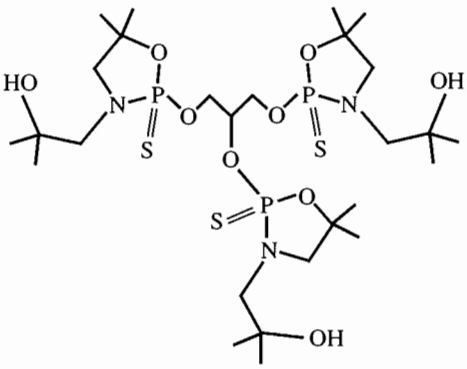
II II (PS) II (PS)*

glycerol[3] ou encore du myo-inositol (2) nous avons pu observer le même déroulement dans les réactions de perphosphoranylation et de sulfuration. Dans les cas du glycol (4), et du glycérol,[3] nous avons pu caractériser, toujours en utilisant le bicyclophosphane tétraméthylé **6**, les deux polythio-oxazaphospholidines **9** et **10** :

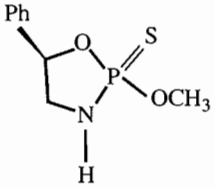


9

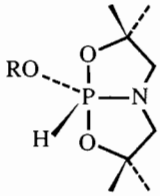


10

Dans les nouveaux dérivés présentés dans ce travail la présence des cycles pyranose ou furanose pourrait conférer aux produits obtenus des propriétés utiles, les sucres jouant le rôle de vecteur du fragment thio-oxazaphospholidine. On sait que des insecticides très actifs appartiennent à cette famille de composés, en particulier l'énantiomère $(R)_C(R)_P$5-phényl thio-oxazaphospholidine **11** (5):



11



1-5

1 R = galactopyranosyl
2 R = glucofuranosyl
3 R = methyl
4 R = isopropyl
5 R = *tert*-butyl

C'est pour mettre en évidence un éventuel effet dû aux restes aldohexoses que nous avons jumelé à cette étude celle de trois alcoxybicyclophosphoranes **3**, **4**, **5** et des trois dérivés soufrés correspondants **3**(P=S), **4**(P=S), **5**(P=S).

2. Résultats et discussion

2.1. Synthèses

La préparation des cinq bicyclophosphoranes de départ **1**–**5** à partir des cinq alcools choisis et du bicyclophosphane **6** ne présente pas de difficultés particulières (voir partie expérimentale). Elle nous a permis d'établir le tableau qui suit :

Phosphoranes obtenus	ROH	^{31}P	$^{1}J_{H-P}$
1	Galactopyranose **7**	−36,9	804,4
2	Glucofuranose **8**	−41,3	812
3	CH_3OH	−33,8	791,5
4	$(CH_3)_2CHOH$	−36,9	798
5	$(CH_3)_3COH$	−34,7	779

Pour chacune de ces préparations, suivie par RMN de ^{31}P la disparition rapide du signal à δ = 163 ppm correspondant au bicyclophosphane **6** est accompagnée par l'apparition concomitante d'un doublet à champ fort entre −34 et −42 ppm, le couplage $^{1}J_{H-P}$ étant de l'ordre de 800 Hz. Après enlèvement du solvant les phosphoranes **1** et **2** se présentent comme des liquides très visqueux alors que **3** est distillable.

La sulfuration est réalisée par action du soufre élémentaire S_8 en proportion stoechiométrique. À la température ambiante la solubilisation totale de ce dernier dans la solution toluènique utilisée marque la fin de la réaction. Elle nécessite quelques heures dans les cas défavorables de **1** et **2**, mais elle est beaucoup plus rapide avec **3**–**5**. Dans le tableau qui suit nous avons sélectionné un certain nombre de données expérimentales concernant la sulfuration.

Phosphoranes soumis à sulfuration	Temps après l'addition du soufre (h)	Phosphorane restant (%)	**1**–**5**(P=S) (%)	**1**–**5**(P=S)* (%)
1	2	43	48	9
	20	0	97	3
	100	0	98	2
2	1	65	29	6
	4	22	75	3
	100	0	98	2
3	1	0	75	25
	24	0	ca. 100	Traces
4	1	0	70	30
	24	0	ca. 100	Traces
5	1	0	55	45
	24	0	ca. 100	Traces

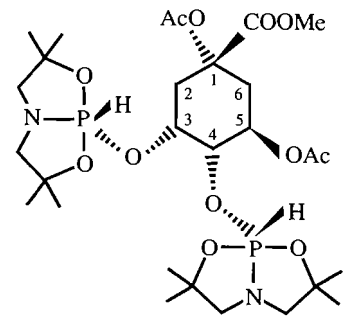
Les résultats obtenus montrent que l'équilibre étant atteint, les thio-oxazaphospholidines **1**(P=S)–**5**(P=S) sont très largement majoritaires sinon les produits uniques de la réaction. Dans **1**(P=S) et **2**(P=S), l'atome de phosphore étant chiral il y a formation de deux diastéréoisomères. L'induction asymétrique est pratiquement nulle dans **1**(P=S) : les deux pics de RMN ^{31}P à 85,0 ppm et 84,7 ppm ont quasiment la même intensité alors qu'elle est significative dans **2**(P=S), les deux pics à 84,7 et 83,5 ppm sont sensiblement inégaux, respectivement comme 65 et 35%. Ce résultat doit être relié au fait que dans **1**(P=S) le premier atome de carbone chiral est en position γ par rapport au phosphore alors que dans **2**(P=S) il est en position β.

Le tableau qui suit regroupe les valeurs de δ ^{31}P des dix composés soufrés caractérisés :

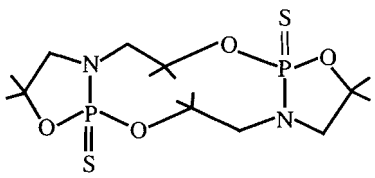
1(P=S)	**2**(P=S)	**3**(P=S)	**4**(P=S)	**5**(P=S)
85 et 84,7	84,7 et 83,5	86,8	83,5	86,8
1(P=S)*	**2**(P=S)*	**3**(P=S)*	**4**(P=S)*	**5**(P=S)*
52,5	50	54,1	51,0	42,4

2.2. Stéréochimie

Aucun des produits étudiés au cours de ce travail n'a été obtenu à l'état cristallin. Aussi aucune détermination de structure par diffraction des rayons X n'a pu être réalisée. L'étude stéréochimique des ces composés repose donc sur l'analyse de leurs paramètres de RMN. Cependant les résultats conformationnels que nous présentons sont fortement étayés par la connaissance des structures moléculaires de composés analogues **12** (7) et **13** (8).



12



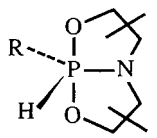
13

*2.2.1. Les bicyclophosphoranes **1–4***

Comme nous venons de le dire nous disposons depuis peu de la structure moléculaire établie par diffraction des rayons X du même reste bicyclophosphoranique dans le dérivé **12** issu de l'acide quinique (7). Comme il s'agit précisement du même fragment, nous pouvons admettre que dans les quatre dérivés **1–4** la géométrie du squelette bicyclophosphoranique est la même. Il s'agit d'une bipyramide trigonale avec une annelation axiale-équatoriale-axiale : les deux atomes d'oxygène occupent les positions axiales et l'atome d'azote une position équatoriale. Afin de compléter cette donnée stéréochimique il nous reste à préciser la conformation des cycles pentagonaux, les modifications qu'ils subissent quand les composés sont en solution, et déterminer l'influence de la phosphoranylation sur la conformation des ensembles galactopyranose de **1** et glucofuranose de **2**.

2.2.1.1. Conformation des cycles pentagonaux. Dans les bicyclophosphoranes présentés, la double substitution sur l'atome de carbone en α de l'oxygène (deux groupements méthyles) nous prive des constantes de couplage $^3J_{H-C-O-P}$, qui suivent une loi de Karplus (9) et apportent des informations sur les angles dièdres correspondants. Cet handicap est en partie levé par la connaissance de la conformation des cycles pentagonaux qui nous est fournie par les rayons X de **12** : c'est une forme enveloppe avec l'atome de carbone en α de l'oxygène à la pointe du rabat (7). Nous conviendrons, avec peu de risques, que cette conformation reste privilègiée en solution pour les composés **1–4**. Les constantes de couplage $^3J_{H-C-N-P}$ (tableau 1) constituent également une sonde intéressante pour l'étude conformationnelle de ces cycles à cinq chainons. L'examen du tableau 1 montre qu'il existe quelques différences entre les quatre composés étudiés.

Dans les dérivés **3** et **4** les constantes de couplage $^3J_{H-C-N-P}$ sont très voisines : 16,2 et 11,2 Hz pour **3**, 15 et 12,8 Hz pour **4**. Nous en concluons que la libration des cycles pentagonaux peut se faire librement. Il est intéressant de noter à ce propos que les mêmes cycles pentagonaux des bicyclophosphoranes (**III**) (R=alkyl ou aryl)



III

sont bloqués en solution : les deux constantes de couplage $^3J_{H-C-N-P}$ ont des valeurs très contrastées comme 24 et 3 Hz (10). Dans **1** et **2** la chiralité des groupements galactopyranose et glucofuranose discrimine tous les sites protoniques des restes bicyclophosphoranes : ainsi aux quatre substituants CH_3 et aux quatre hydrogènes des deux groupements N-CH_2 correspondent des signaux distincts. Dans **1** les couples de constantes de couplage observées pour les deux groupements N-CH_2 sont peu différentes : 12,6 et 14,3 Hz d'une part, 13–14,1 Hz d'autre part. Dans **2** ces paires de constantes de couplage deviennent 19 et 11,3 Hz d'un coté, 21,4 et 11 Hz de l'autre. L'examen d'un modèle moléculaire montre que cette dernière discrimination est interprêtable. En effet, dans **1** l'attachement du groupe bicyclophosphorane à la fonction alcool primaire exocyclique l'éloigne de toute gêne stérique et la libration des cycles pentagonaux peut s'effectuer librement. Il n'en est plus de même dans **2**. Cette fois le bicyclophosphorane est porté par une fonction alcool secondaire directement liée au cycle, ce qui le place à proximité du groupement glucofuranose, lui même encombré par les substituants protecteurs isopropylidènes. On conçoit que la position d'équilibre puisse être telle que l'un des cycles pentagonaux est loin du groupement furanose permettant la libration du cycle alors que l'autre est stériquement gêné et conserve des valeurs contrastées des constantes de couplage $^3J_{H-C-N-P}$.

[a] Valeurs extraites de la référence 4.

[b] H(141) et H(142) sont respectivement équivalents à H(151) et H(152). Ils constituent la partie AB d'un système ABX (X = P).

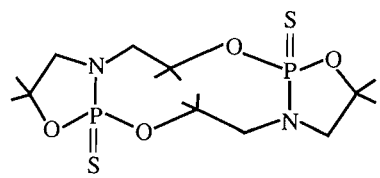
2.2.1.2. Influence de la phosphoranylation sur les cycles galactopyranose et glucofuranose. L'examen du tableau 2 qui rassemble les paramètres de RMN ^1H des protons cycliques et des groupements CH_3 protecteurs permet de faire les remarques suivantes :

1. En passant du galactopyranose **7** à son dérivé phosphoranylé **1** les déplacements chimiques des protons H(1), H(2) et H(3) et les constantes de couplage entre eux n'ont pratiquement pas changé. Les seules modifications observées concernent les protons H(5), H(61), H(62) et H(4). Dans **7** les trois premiers donnent naissance à un multiplet ABC entre 3,80 et 3,89 ppm nettement séparé du signal de H(4) à 4,07 ppm. La phosphoranylation se traduit par un déblindage de tous ces protons qui donne naissance à un multiplet ABCD entre 4,18 et 4,36 ppm. Les signaux dus aux groupements CH_3 ne présentent que des variations mineures. En bref la conformation de l'ensemble galactopyranose s'est maintenue lors de la phosphoranylation.

2. La phosphoranylation du glucofuranose **8** a des effets nettement plus marqués. Dans **8** les protons H(2), H(3), H(4) et H(5) forment un multiplet complexe de type ABCD entre 4,35 et 4,45 ppm. Les mêmes protons du dérivé phosphoranylé **2** conduisent à des signaux bien séparés en raison des déblindages qu'ils subissent. Compte tenu du fait que les protons deviennent distinguables à partir d'un système ABCD, nous pouvons estimer les déblindages minima qui interviennent : 0,12 ppm pour H(4), 0.29 ppm pour H(5), 0,36 ppm pour H(2), enfin 0,93 ppm pour H(3). Il en est de même des groupements CH_3 des cycles protecteurs. Ceux qui sont en position *exo*, notés 9 et 11, sur les dessins des molécules **1**, **2**, **7**, **8** subissent des déplacements sensiblement plus importants (0,11 et 0,19 ppm) que les méthyles *endo*, notés 10 et 12 (déblindages respectifs : 0,04 et 0 ppm). Toutes ces observations convergent. Elles permettent de constater que le groupement bicyclophosphorane induit dans son environnement proche un effet de déblindage marqué.

2.2.2. Les thio-oxazaphospholidines **1**(P=S)–**4**(P=S)

Comme nous l'avons dit plut haut, nous connaissons l structure moléculaire du dérivé tricyclique **13** (8) qui com porte deux fois le motif thio-oxazaphospholidine que nou étudions ici : le cycle pentagonal adopte une forme enve loppe avec l'atome de carbone en α de l'oxygène à la point du rabat.[4]



13

Nous admettrons qu'il en sera de même pour les com posés **1**(P=S)–**4**(P=S). L'analyse des paramètres de RMI ^1H des protons diastéréotopes NCH_2, seuls sites commun aux quatre dérivés qui permettent une étude comparative fournira l'essentiel de l'information stéréochimique. Le ta bleau 3 rassemble ces paramètres ainsi que ceux de l'oxo oxazaphospholidine **4** (P=O). Ce dernier a été spécialemen prépare pour cette étude. Il dérive du composé **4** (P=S) dan lequel l'atome de soufre a été remplacé par un atom d'oxygène.

(*a*) Les deux constantes de couplage $^3J_{P-N-C-H}$ des deu groupes de protons diastéréotopes N-CH_2 présentent de

[4] En fait la maille cristalline de ce composé comporte deux en tités, une centrosymétrique et une dépourvue de toute symétrie Dans cette dernière les cycles pentagonaux adoptent tous les deu une forme enveloppe mais se différencient par la position du rabat Dans l'un c'est l'atome de carbone en α de l'oxygène qui occup cette position; dans l'autre c'est celui en α de l'azote (8).

C(18)	s 29,1		s 29,3		s 29,0		s 29,1	
C(19)	s 29,6		s 29,5		d 29,6	^3J 5,5	d 29,7	^3J 4,9
C(20)	s 28,9		s 28,8		s 29,0		s 29,1	

[a]Ces valeurs sont, en fait, les moyennes des constantes de couplage $^2J_{C\text{-}O\text{-}P}$ et $^3J_{C\text{-}C\text{-}N\text{-}P}$.
[b]De même ces valeurs sont les moyennes de $^2J_{C\text{-}N\text{-}P}$ et de $^3J_{C\text{-}C\text{-}O\text{-}P}$.

différences significatives d'un composé à l'autre. Pour les protons N-CH_2 cycliques elles sont identiques dans **4** (P=O), voisines dans les deux diastéréosiomères de **2** (P=S) ainsi que dans **3** (P=S) et **4** (P=S) (de l'ordre de 11–12 Hz) mais sensiblement différentes dans les deux diastéréoisomères de **1** (P=S) (de l'ordre de 7 et 12 Hz). En utilisant pour les constantes de couplage $^3J_{P\text{-}N\text{-}C\text{-}H}$ et les angles dièdres que font les quatre atomes correspondants une relation de Karplus (9), ces observations peuvent refléter une vitesse de basculement du rabat des cycles pentagonaux différente selon le composé. Rapide jusqu'à moyenner les angles dièdres P—N—C—H dans **4** (P=O) elle est quelque peu ralentie dans **2** (P=S), **3** (P=S) et **4** (P=S), et suffisamment faible dans **5** (P=S) pour qu'une forme enveloppe du cycle pentagonal puisse être observée en solution.

(*b*) La comparaison des paramètres de **4** (P=S) et de **4** (P=O) montre que le remplacement du groupement thiophosphoryle P=S par le groupe phosphoryle P=O a des effets significatifs sur les déplacements chimiques des protons N-CH_2 cycliques et acycliques. Pour les premiers nous assistons à un déblindage de 0,39 ppm de l'un (passage de 2,69 à 3,08 ppm) et un blindage de 0,05 ppm pour l'autre (de 3,25 à 3,20 ppm). Quant aux protons N-CH_2 acycliques il sont tous deux déblindés mais avec des amplitudes différentes : 0,28 ppm pour l'un (de 2,88 à 3,16 ppm) et 0,12 ppm pour l'autre (de 3,16 à 3,04). Ces observations sont à rapprocher de celles que nous avons présentées pour le composé **14** et son dérivé soufré **13** (8).

2.3. RNM ^{13}C

Nous terminerons cette étude par quelques commentaires sur les paramètres de RMN ^{13}C de ces composés, en nous limitant à la partie organo-phosphorée de nos molécules. Le tableau 4 rassemble les données concernant les groupements bicyclophosphoranes, le tableau 5 concerne les hétérocycles thio-oxazaphospholidines.

(*a*) L'examen du tableau 4 montre comme attendu, que la chiralité des ensembles galactopyranose et glucofuranose, dans **1** et **2**, conduit à la discrimination de tous les noyaux de carbones des restes bicyclophosphoraniques. Quatre signaux correspondant aux quatre groupements méthyles, deux pour N-CH_2 et deux pour les carbones O-C. Notons qu'aucun carbone méthylique de **1** et **2** n'est couplé avec l'atome de phosphore alors qu'un tel couplage existe

C(20)	s 27,6		s 27,5		s 27,5		s 27,6	
	s 27,7		s 27,5					

[a]Ces valeurs sont, en fait, les moyennes des constantes de couplage $^2J_{C-O-P}$ et $^3J_{C-C-N-P}$.
[b]Diastéréoisomère majoritaire.
[c]Ces valeurs sont les moyennes de $^2J_{C-N-P}$ et de $^3J_{C-C-O-P}$.

pour un groupement CH_3 dans **3** et **4**. Comme il est admis que les constantes de couplages $^3J_{C-C-O-P}$ suivent une relation du type Karplus (9) cette observation traduit, à notre sens, une différence de conformation des cycles pentagonaux dans **1** et **2** d'une part, **3** et **4** d'autre part.

(*b*) Le passage des bicyclophosphoranes **1**, **2**, **3**, **4** aux thio-oxazaphospholidines **1** (P=S), **2** (P=S), **3** (P=S) et **4** (P=S) conduit à un dédoublement de tous les signaux des atomes de carbone. En effet le fragment -O-C$(CH_3)_2$-CH_2-N-CH_2-C$(CH_3)_2$-O, symétrique au départ, se trouve en fin de compte partagé entre un hétérocycle et une chaine linéaire. Les attributions qui figurent dans le tableau 5 résultent de la comparaison des paramètres obtenus avec ceux de composés proches étudiés au laboratoire : **13** (8) et **15**.[5]

3. Conclusion

Au cours de ce travail, nous avons montré que la phosphoranylation d'aldohexoses monohydroxylés constitue un excellent moyen d'accès aux thio-oxazaphospholidines correspondantes. L'analyse des paramètres de RMN ^1H et ^{13}C de ces deux types de composés a permis de mettre en évidence plusieurs particularités stéréochimiques.

[5]Résultats non publiés.

4. Partie expérimentale

4.1. Résonance magnétique nucléaire

Les spectres de RMN ^{31}P, ^1H et ^{13}C ont été enregistrés avec différents spectromètres Bruker : AC 80, AC 200, AC 250 et WM 250. Les déplacements chimiques, exprimés en parties par millions (ppm), sont mesurés avec une précision de ±0,005 ppm pour ^1H et ±0,03 ppm pour ^{31}P et ^{13}C (références tétraméthylsilane, TMS, pour ^1H et ^{13}C, H_3PO_4 pour ^{31}P). Les constantes de couplages, exprimées en Hz, sont mesurées avec une précision de 0,2 Hz pour ^1H et 0,5 Hz pour ^{13}C et ^{31}P. La résolution complète des spectres a été parachevée par des expériences de découplage homonucléaire proton–proton et hétéronucléaire proton–phosphore et carbone–phosphore. Les données expérimentales citées dans le texte ou les tableaux ne sont pas reprises dans ce qui suit.

4.2. Préparations

*4.2.1. Les bicyclophosphoranes : **1–4***

4.2.1.1. Le 3,3,7,7-tétraméthyl 1-[1,2,3,4-di-O-*isopropylidène* α-D-*galactopyranosyloxyl*]*2,8-dioxa 5-aza 1-phospha*^{V} *bicyclo[3.3.0]octane*, ***1***. Quantités utilisées : galactopyranose **7** 541 mg (2,08 × 10^{-3} mol), bicyclophosphane **6** 393 mg (2,08 × 10^{-3} mol), toluène 3 mL. L'enlèvement du solvant après la fin de la réaction conduit à un liquide incolore très visqueux que nous avons caractérisé à l'aide des spectres de RMN de trois noyaux ^1H, ^{31}P et ^{13}C et analyse élémentaire. Parmi les données expérimentales qui n'apparaissent pas dans l'article ajoutons celles concernant la RMN de $^{13}C\{H\}$ (62,89 MHz benzène-d_6) : 24,4 ppm

(s, C(10), *endo*), 25,0 ppm (s, C(12), *endo*), 26,3 ppm (s, C(9), *exo*), 64,9 ppm (d, C(6), $^2J_{C-P}$ = 6,1 Hz), 67,7 ppm (d, C(5), $^3J_{C-P}$ = 10 Hz), 71,1–71,2 et 71,3 (3s, C(2), C(3), C(4)), 96,8 ppm (s, C(1)); 108,4 et 109,2 ppm (2s, C(7), C(8)). Anal. calc. pour $C_{20}H_{36}NO_8P$: C 53,44; H 8.07; N 3,11; trouvé C 52,34; H 7,9; N 3,22.

*4.2.1.2. Le 3,3,7,7-tétraméthyl 1-[1,2,5,6-di-*O*-isopropylidène-α-D-glucofuranosyloxy] 2,8-dioxa 5-aza 1-phospha^V bicyclo[3.3.0]octane,* **2**. Quantités utilisées : glucofuranose **8** 463 mg (1,78 × 10^{-3} mol), bicyclophosphane **6** 336 mg (1,78 × 10^{-3} mol) toluène 3 mL. Le composé **2** est un liquide incolore très visqueux. RMN $^{13}C\{H\}$(62,89 MHz benzène-d_6) : 25,7 ppm (s, C(9), *exo*), 26,4 ppm (s, C(10), *endo*), 27,2 ppm (s, C(11), *exo* et C(12) *endo*), 67,9 ppm (s, C(6)), 73,4 ppm (s, C(5)), 79,1 ppm (d, C(3), $^2J_{C-P}$ = 7,9 Hz), 85,3 ppm (d, C(2), $^3J_{C-P}$ = 2,3 Hz), 105,8 ppm (s, C(1)), 109,1 et 111,6 (2s, C(7) et C(8)). Anal. calc. pour $C_{20}H_{36}NO_8P$: C 53,44; H 8,07; N 3,11; trouvé : C 52,23; H 7,9; N 2,97.

4.2.1.3. Le 3,3,7,7-tétraméthyl 1-méthoxy 2,8-dioxa 5-aza 1-phospha^V bicyclo[3.3.0]octane, **3**. Quantités utilisées : méthanol fraichement redistillé 169,5 mg (5,29 × 10^{-3} mol), bicyclophosphane **6** 1000 mg (5,29 × 10^{-3} mol), toluène 3 mL. Après enlèvement du solvant le phosphorane a été purifié par distillation sous pression réduite. Eb.$_{0,05}$: 40°C. Le composé **3** a été caractérisé par RMN et analyse élémentaire. RMN ^1H (250 MHz, benzène-d_6) : 3,45 ppm (d, 3H, CH_3O, $^3J_{H-P}$ = 14,9 Hz), 7,04 ppm (d, 1H, H(8), $^1J_{H-P}$ = 794,9 Hz). RMN $^{13}C\{^1H\}$ (62,89 MHz, benzène-d_6) : 53,3 ppm (d, C(21), $^2J_{C-P}$ = 6 Hz). Anal. calc. pour $C_9H_{20}NO_3P$: C 48,87; H 9,12; N 6,33; trouvé : C 48,67; H 9,3; N 6.75. La synthèse et les caractéristiques du composé **4** ont été publiées par ailleurs (4).

4.3. Les thio-oxazaphospholidines : ***1****(P═S)–****4****(P═S)*

Ces composés ont été obtenus par action du soufre élémentaire sur les bicyclophosphoranes **1**–**4**.

*4.3.1. Le 5,5-diméthyl 3-[(2-méthyl 2-hydroxypropyl] 2-[1,2,3,4-di-*O*-isopropylidéne α-D-galactopyranosyloxy] 2-thio 1,3,2- oxazaphospholidine* ***1*** *(P═S)*

Quantités utilisées : bicyclophosphorane **1**, 330 mg (0,73 × 10^{-3} mol) benzène 4 mL, soufre élémentaire 23,3 mg (0,72 × 10^{-3} atome). Quelques particularités sur l'évolution de la réaction sont dans le texte. Le mélange des deux diastéréoisomères est caractérisé par RMN et analyse élémentaire. RMN ^1H (250 MHz, benzène-d_6) : entre 1,03 et 1,55 ppm (14 s, 48 H, correspondant aux 16 groupements CH_3 attendus, chaque diastéréoisomère comportant 8 groupements méthyles), entre 3,7 et 3,9 ppm (multiplet complexe, 2H, correspondant aux protons H(61) et H(62) des 2 diastéréoisomères; ces protons forment avec H(5) et P un système du type ABXY), 4,23 ppm (dd, 1H, H(2), $^3J_{H(2)-H(1)}$ = 5 Hz, $^3J_{H(2)-H(3)}$ = 2,4 Hz), 4,24 ppm (dd, 1H, H(2) second diastéréoisomère, $^3J_{H(2)-H(1)}$ = 5 Hz, $^3J_{H(2)-H(3)}$ = 2,4 Hz), entre 4,3 et 4,5 ppm (multiplet complexe, 3H, H(3), H(4), et H(5) des deux diastéréoisomères), 5,44 ppm (d, 1H, H(1) des deux diastéréoisomères). Quant aux protons N-CH_2, leurs paramètres se trouvent dans le tableau 3. RMN $^{13}C\{^1H\}$ (62,89 MHz, benzène-d_6) : entre 23 et 28 ppm (15 s correspondant aux 16 carbones méthyliques attendus), 67,2 ppm (d, C(6), premier diastéréoisomère, $^2J_{C-P}$ = 5,4 Hz), 67,4 ppm (d, C(6), 2ième diastéréoisomère, $^2J_{C-P}$ = 5,4 Hz), 67,4 ppm (d, C(5), 1er diastéréoisomère, $^3J_{C-P}$ = 6,9 Hz), 67,8 ppm (d, C(5), 2ième diastéréoisomère, $^3J_{C-P}$ = 6,9 Hz), entre 70,8 et 71,3 ppm (5s correspondant aux 6 carbones C(2), C(3) et C(4) attendus), 96,7 ppm (s, C(1), premier diastéréoisomère), 96,8 ppm (s, C(1), 2ième diastéréoisomère), 108,7 et 109,5 ppm (2s, correspondant aux 2 carbones C(7) et 2 carbones C(8) attendus). Quant aux paramètres des noyaux de carbone C(13), C(14), C(15) et C(16) ils sont rassemblés dans le tableau **5**. Anal. calc. pour $C_{20}H_{36}NO_8PS$: C 49,88; H 7,54; N 2,9; trouvé : C 48,1; H 7,6; N 2,9.

*4.3.2. Le 5,5-diméthyl 3-(2-méthyl 2-hydroxypropyl) 2-[1,2,5,6-di-*O*-isopropylidène α-D-glucofuranosyloxy] 2-thio 1,3,2-oxazaphospholidine,* ***2****(P═S)*

Quantités utilisées : bicyclophosphorane **2** 654,6 mg (1,34 × 10^{-3} mol), benzène 4 mL, soufre élémentaire 43,1 mg (1,3(10^{-3} atome). À la différence du cas précédent la forme thiophosphate **2** (P═S)* à δ ^{31}P = 50 ppm est pratiquement indétectable au bout de 4 jours. Les deux diastéréoisomères de **2** (P═S) ont été caractérisés par RMN et analyse élémentaire. RMN ^1H (250 MHz benzène-d_6) : entre 0,99 et 1,39 ppm (12 s 48H, correspondant aux 16 groupements CH_3), entre 3,97 et 4,17 ppm (multiplet, 2H H(61), H(62), ou H(4), H(5) des deux diastéréoisomères), entre 4,39 et 4,48 ppm (multiplet, 2H, H(4), H(5) ou H(61), H(62) des deux diastéréoisomères), 5,03 ppm (d, 0,35H, H(2) minoritaire $^3J_{H(2)-H(1)}$ = 3,7 Hz), 5,14 ppm (d, 0,65H, H(2) majoritaire $^3J_{H(2)-H(1)}$ = 3,7 Hz), 5,2 ppm (dd, 0,35H, H(3) minoritaire $^3J_{H(3)-H(4)}$ = 2,4 Hz, $^3J_{H-P}$ = 9 Hz), 5,37 ppm (dd, 0,65H, H(3) majoritaire $^3J_{H(3)-H(4)}$ = 2,4 Hz, $^3J_{H-P}$ = 9 Hz), 5,89 ppm (d, 0,35H H(1) minoritaire), 5,85 ppm (d, 065H, H(1) majoritaire). RMN $^{13}C\{^1H\}$ (62,89 MHz benzène-d_6) : entre 25,5 et 27,5 ppm (6s correspondant aux 16 carbones méthyliques attendus), 67,4 ppm (s C(6) minoritaire), 67,8 ppm (s, C(6) majoritaire), 72,6 ppm (s, C(5) minoritaire), 72,9 ppm (s, C(5) majoritaire), 80,8 ppm (d, C(4) majoritaire et minoritaire, $^3J_{C-P}$ = 5,4 Hz), 81 ppm (d, C(3) majoritaire et minoritaire $^2J_{C-P}$ = 10 Hz), 84,5 ppm (s, C(2) minoritaire), 84,6 ppm (s, C(2) majoritaire), 105,4 ppm (s, C(1 majoritaire), 105,5 ppm (s, C(1), minoritaire), 109,5 ppm (s, C(7 ou C(8) minoritaire), 109,6 ppm (s, C(7) ou C(8) majoritaire) 112,1 ppm (s, C(8) ou C(7) minoritaire), 112,3 ppm (s, C(8) ou C(7) majoritaire). Anal. calc. pour $C_{20}H_{36}NO_8PS$: C49,88; H 7,54 N 2,9; trouvé : C 50,5; H 7,6; N 2,9.

4.3.3. Le 5,5-diméthyl 3-[2-méthyl 2-hydroxypropyl] 2-méthoxy 2-thio 1,3,2-oxazaphospholidine, ***3*** *(P═S)*

Quantités utilisées : bicyclophosphorane **3** 279 mg (1,26 × 10^{-3} mol) toluène 3 mL, soufre élémentaire 40,4 mg (1,28 × 10^{-3} atome). Le solvant est enlevé 48 h après la fin de la réaction après avoir vérifié l'absence de **3** (P═S)* tautomère. **3** (P═S) est un liquide jaunâtre et visqueux caractérisé par RMN et analyse élémentaire. RMN ^1H (200 MHz, benzène-d_6) : 1,09; 1,10; 1,1 et 1,18 ppm (4s, 12H, CH_3(17), CH_3(18), CH_3(19) et CH_3(20)) 3,47 ppm (d, 3H, CH_3-O, $^3J_{H-P}$ = 14,4 Hz). RMN $^{13}C\{^1H$ (50,32 MHz, benzène-d_6) : 54,6 ppm (d, C(21), $^2J_{C-P}$ = 5,6 Hz Anal. calc. pour $C_9H_{20}NO_3PS$: C 42,67; H 7,96; N 5,72; trouvé C 41,4; H 8,1; N 5,7.

4.3.4. Le 5,5-diméthyl 3-[2-méthyl 2-hydroxypropyl] 2-isopropyloxy 2-thio 1,3,2-oxazaphospholidine, ***4*** *(P═S)*

Quantités utilisées : bicyclophosphorane **4** 305 mg (1,22 × 10^{-3} mol), toluène 2,5 mL, soufre élémentaire 39,2 mg (1,22 × 10^{-3} atome). Le composé **4** (P═S) est une huile jaunâtre très visqueuse que nous n'avons pas réussi à cristalliser. Il a été caractérisé par RMN et analyse élémentaire. RMN ^1H (200 MHz benzène-d_6) : entre 1,10 et 1,17 ppm (3s, 18H, CH_3(17), CH_3(18) CH_3(19), CH_3(20), CH_3(22) et CH_3(23)), 4,9 ppm (heptuple dédoublé, 1H, H(21), $^3J_{H-H}$ = 6,2 Hz, $^3J_{H-P}$ = 10,6 Hz). RMN $^{13}C\{^1H\}$ (50,3 MHz, benzène-d_6) : 23,2 ppm (d, C(22), $^3J_{C-P}$ = 8,2 Hz), 23,4 ppm (d, C(23), $^3J_{C-P}$ = 2,5 Hz, 72,8 ppm (d, C(21) $^2J_{C-P}$ = 5,6 Hz). Anal. calc. pour $C_{11}H_{24}NO_3PS$: C 46,95; H 8,59 N 4,98; trouvé : C 46,6; H 8,63; N 5,69.

4.4. Le 5,5-diméthyl 3-[2-méthyl 2-hydroxypropyl] 2-isopropyloxy 2-oxo 1,3,2-oxazaphospholidine, ***4*** *(P═O)*

Nous avons suivi la méthode récemment décrite par Helinski *et al.* (13). À une solution de 359 mg (1,28 × 10^{-3} mol) de **4** dans 2 mL de dichlorométhane on ajoute 1 mL de pyridine, puis, en une fois, 321 mg (1,53 × 10^{-3} mol) d'anhydride trifluoroacétique. Le mélange, agité à la température ambiante, est suivi dans sa composition par RMN de ^{31}P. Le remplacement du soufre par l'oxygène c'est à dire la disparition du pic à δ = 83,1 ppm au profit d'un nouveau pic de résonance se trouvant à δ = 18,6 ppm, est terminé

en 2 h. Une évaporation sous pression réduite des produits volatils permet d'isoler un liquide sirupeux qui est extrait plusieurs fois au pentane. L'enlèvement de ce dernier conduit à un liquide visqueux jaunâtre, caractérisé par RMN. RMN ^{31}P (32,44 MHz, $CDCl_3$) : 19,9 ppm (s). RMN ^1H (250 MHz, $CDCl_3$) : 1,23 ppm (d, 3H, CH_3(22), $^3J_{H-H}$ = 6,3 Hz), 1,26 ppm (d, 3H, CH_3(23), $^3J_{H-H}$ = 6,3 Hz), 1,39 ppm (s, 3H, CH_3(17)), 1,41 ppm (s, 3H, CH_3(18)), 1,56 ppm (s, 6H, CH_3(19), CH_3(20)), 4,58 ppm (heptuplet dédoublé, 1H, H(21), $^3J_{H-P}$ = 7,3 Hz). RMN $^{13}C\{^1H\}$ (62,89 MHz, $CDCl_3$) : 22,9 ppm (s, C(22), C(23)), 23,5 ppm (s, C(19), C(20)), 27,3 ppm (s, C(17)), 27,8 ppm (s, C(18)), 54,8 ppm (d, C(15), $^2J_{C-P}$ = 4,5 Hz), 61,1 ppm (d, C(14), 1/2 ($^2J_{C-P}$ + $^3J_{C-P}$ = 13,9 Hz), 72,5 ppm (d, C(21), $^2J_{C-P}$ = 6,4 Hz), 81,1 ppm (s, C(16)), 89,4 ppm (d, C(13), 1/2 ($^2J_{C-P}$ + $^3J_{C-P}$ = 4,2 Hz).

Eight new diorganotin complexes formulated as $R_2Sn(OArCR''{=}NCHR'COO)$ were prepared and characterized by ^1H and ^{13}C NMR, IR, and elemental analysis. A single crystal X-ray diffraction study of the dibutyltin *N*-salicylidenevaline complex, $Bu_2Sn(OC_6H_4CH{=}NCH(i\text{-}Pr)COO)$, determines the molecular structure. The crystals are orthorhombic, space group $P2_12_12_1$ with a = 9.187(2) Å, b = 10.003(2) Å, c = 23.482(4) Å, V = 2157.8(6) Å^3, Z = 4, and D_c = 1.392 g cm^{-3}. The final discrepancy factors are R_F = 0.040, and R_W = 0.021 for 1131 significant reflections. The tin atom has a distorted trigonal bipyramidal coordination, with no short intermolecular contacts. The two axial Sn—O bonds of 2.078(10) and 2.151(8) Å and the equatorial Sn—N bond of 2.158(8) Å are among the shortest found in related complexes. The fact that the closest intermolecular Sn—O distance is 4.511(8) Å indicates a nonbridging carbonyl group.

F. E. SMITH, ROSEMARY C. HYNES, T. T. ANG, L. E. KHOO et G. ENG. Can. J. Chem. **70**, 1114 (1992).

On a préparé huit nouveaux complexes diorganostanniques de formule $R_2Sn(OArCR''{=}NCHR'COO)$ et on les a caractérisés par RMN du ^1H et du ^{13}C, par IR et par analyses élémentaires. Une étude par diffraction des rayons X réalisée sur un cristal unique du complexe dibutylétain de la *N*-salicylidènevaline, $Bu_2Sn(OC_6H_4CH{=}NCH(i\text{-}Pr)COO)$, a permis de déterminer sa structure. Les cristaux sont orthorhombiques, groupe d'espace $P2_12_12_1$, avec a = 9,187(2), b = 10,003(2) et c = 23,482(4) Å, V = 2157,8(6) Å^3, Z = 4, D_c = 1,392 g cm^{-3}, R_F = 0,040 et R_W = 0,021 pour 1131 réflexions significatives. La coordination de l'atome d'étain correspond à une bipyramide trigonale déformée qui ne comporte pas de contacts intermoléculaires courts. Les longueurs des deux liaisons Sn—O axiales, 2,078(10) et 2,151(8) Å, et de la liaison Sn—N équatoriale, 2,158(8) Å, sont les plus courtes du genre pour des complexes apparentés. Le fait que la distance Sn—O intermoléculaire la plus courte soit égale à 4,511(8) Å indique que le groupe carbonyle n'agit pas comme pont.

[Traduit par la rédaction]

Introduction

A variety of organotin complexes structurally related to *cis*-platin and its derivatives (1, 2) have been investigated for antitumour properties (3–5). Recent reports of the activity of certain diorganotin derivatives of pyridine 2,6-dicarboxylic acid and some related compounds (6, 7) against the P388 lymphocytic leukemia tumour, both in vitro and in vivo, led us to report the synthesis and characterization of a series of diorganotin iminodiacetates (8). As a continuation of these studies we now wish to report the results of an investigation into the synthesis and characterization of a series of diorganotin(IV)–*N*-arylidene-α-amino acid complexes. In this study, eight diorganotin complexes were prepared by condensing diorganotin oxides R_2SnO with the ligands **1**–**4**:

the results are reported along with a variety of spectroscopic data for both the dimethyltin and dibutyltin derivatives of these ligands.

Experimental

Chemicals and reagents

Dimethyltin and dibutyltin oxides were purchased from Alfa Inorganics and other chemicals were purchased from the Aldrich Chemical Company. All were used without further purification except for salicylaldehyde, which was distilled before use.

IR spectra

These were obtained on a Nicolet instrument with the samples as Nujol mulls or in KBr discs. Results are summarized in Table 1.

NMR spectra

The ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ on a CFT-20 or Bruker AC-P300 spectrometer. NMR results are summarized in Tables 2 and 3.

*Preparation of ligands **1** and **2** (refs. 9–11)* (Note: ligands **3** and **4** could not be isolated, and so were prepared *in situ*)

A mixture of free (*dl*) α-amino acid (0.1 mol) and the corresponding aldehyde (0.15 mmol) in 300 mL of absolute ethanol and 30 mL of methanol was stirred overnight before refluxing for 3–4 h. After cooling in the refrigerator, a crystalline precipitate formed, which was filtered, washed with petroleum ether (60–80°C), dried, and recrystallized from methanol to give the pure product in 50–60% yield. Microanalyses were carried out at the School of Chemical Sciences, Universiti Sains Malaysia, using an elemental analyzer (model 240-XA). Analytical data for ligands:

N-2-Hydroxynaphthalidieneglycine (**1**), mp 206–208°C (dec.). Anal. calcd. for $C_{13}H_{11}NO_3$: C 68.10, H 4.85; N, 6.11; found: C 68.34, H 4.87; N 6.24.

N-Salicylidenevaline (**2**), mp 160–162°C. Anal. calcd. for $C_{12}H_{15}NO_3$: C 65.15, H 6.85, N 6.33; found: C 64.72, H 6.87, N 6.59.

Preparation of diorganotin–N-2-hydroxyarylidene-α-amino acid complexes

Method A

The diorganotin–*N*-2-hydroxyarylidene-α-amino acid carboxylates can be prepared via the condensation reaction of R_2SnO with either **1** or **2**. An equimolar amount (10 mmol) of either **1** or **2** and R_2SnO (R = CH_3 or *n*-Bu) was mixed with 100 mL of toluene. The mixture was refluxed and the water formed removed azeotropically using a Dean–Stark apparatus. After all the water had been removed from the reaction mixture (about 4 h) the solvent was evaporated with a rotary evaporator and the solid recrystallized from toluene to give the diorganotin carboxylate in high yield. Melting point and analytical data are summarized in Table. 1.

Method B

As ligands **3** and **4** could not be isolated (10, 11), the diorganotin complexes were synthesized by refluxing a mixture of glycine (in excess), R_2SnO, and either salicylaldehyde or 2-hydroxyacetophenone in absolute ethanol.

[a] B_{eq} is the mean of the principal axes of the thermal ellipsoid.

cine was filtered off after cooling and the filtrate concentrated to dryness. The solid was recrystallized from toluene.

The dimethyltin derivative of **4** is insoluble in absolute ethanol so the excess glycine was removed during recrystallization. The yield of these complexes is 60–80% and is comparable to the yield using Method A. Melting points, yields, and analytical and IR data are summarized in Table 1.

X-ray data

Space group and cell dimensions

Empirical formula: $SnC_{20}H_{31}O_3N$ FW = 452.16

Orthorhombic $P2_12_12_1$, a = 9.187(2) Å, b = 10.003(2) Å, c = 23.482(4) Å, volume = 2157.8(6) Å^3. Cell dimensions were obtained from 24 reflections with 2θ in the range 28.00°–33.00°. Crystal dimensions: 0.20 × 0.30 × 0.10 mm, Z = 4, $F(000)$ = 924.86, D_{calc} = 1.392 Mg m^{-3}, μ = 1.20 mm^{-1}, λ = 0.70930 Å (Mo Kα), $2\theta_{max}$ = 44.7°.

Data collection, structure solution and refinement

The intensity data were collected at 295 K on a Nonius diffractometer run by the NRCCAD diffractometer control program (12), using the θ/2θ scan mode and profile analysis (13); 1759 reflec-

tions were measured, of which 1632 were unique. Of these, 1131 had $I_{net} > 2.5\sigma(I_{net})$. No correction was made for absorption. The structure was solved by direct methods, followed by a difference Fourier. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions. Secondary extinction was refined as in Larson (14) as 0.0558(22). The refined parameter is the average length of a mosaic block in microns. The final least-squares cycle was calculated with 228 parameters and 1131 out of 1632 reflections. Weights based on counting statistics were used. Final residuals are $R_F = 0.040$, $R_W = 0.021$ for data with $I_{net} > 2.5\sigma(I_{net})$, $R_F = 0.006$, $R_W = 0.023$ for all data. The goodness of fit was 1.87. Maximum shift/error was 0.012. In the last *D*-map, the top peak was 0.54 e/Å^3, and the deepest hold was -0.55 e/Å^3. The absolute configuration refined to an η value of 0.82. Scattering factors were taken from the International tables for X-ray crystallography, Vol. IV (15). All computation was performed using the NRCVAX system of crystal structure solving programs (16).

Results and discussion

Organotin carboxylates frequently have di- or polymeric structures resulting from intermolecular bridging by carbonyl oxygen atoms (8, 17). It was anticipated that this series of complexes would exhibit this characteristic, and be six-coordinate. However, the X-ray structural investigation of $Bu_2Sn(OC_6H_4CH{=}NCH(i\text{-}Pr)COO)$ shows that this compound has a five-coordinate monomeric structure. An ORTEP (18) plot of the organotin complex is given in Fig. 1. A stereo pair showing the packing arrangement of the molecules in the unit cell is shown in Fig. 2. The final fractional coordinates of non-hydrogen atoms with equivalent isotropic thermal parameters are listed in Table 4 while the bond lengths and bond angles for the complex are in Tables 5 and 6 respectively. Calculated and observed structure factors, calculated hydrogen atom parameters, and anisotropic thermal parameters have been deposited as Tables S-1, S-2, and S-3, respectively.[2]

The ligand behaves as a tridentate chelating agent via the phenolic oxygen, the imino nitrogen, and a carboxylate oxygen. The two butyl groups and the imino nitrogen take up the equatorial positions and the two oxygens the axial sites in a distorted trigonal bipyramidal arrangement around the tin. The tin atom lies in the ligand plane and forms a five-membered and a six-membered chelate ring with the ligand. There are no close contacts beween the complex entities, and thus no intermolecular tin–oxygen bridging. The closest Sn—O distance between the complexes is 4.511(8) Å (i.e., O(2) at $-x, \frac{1}{2} + y, \frac{1}{2} - z$). Further evidence for the fact that the free carbonyl group on the ligand is not involved in coordination with another tin atom can be deduced from the short C—O distance of 1.213(16) Å. A similar C—O bond length of 1.179(13) Å was reported for a corresponding nonbridging carbonyl group in the compound $Ph_3SnCl{:}2HOC_6H_4CH{=}NCH_2CO_2Et$ (19). The similarities of the spectroscopic data indicate that five-coordinate structures should be proposed for all the organotin compounds studied in this series.

The IR carbonyl stretching vibrations for these diorganotin derivatives are normal and range from 1650 to 1580 cm^{-1} (Table 1). However, the almost equal intensity observed for the asymmetric and symmetric Sn—Me stretching vibrations indicates a bent C—Sn—C moiety for the dimethyltin complexes. This would be consistent with a trigonal bipyramidal configuration for the tin atom, with the methyl groups taking up two of the equatorial positions. The ^{1}H and ^{13}C NMR data are shown in Tables 2 and 3 respectively. Very little shift for the proton and ^{13}C signals was observed for the ligands upon complex formation. However spin–spin coupling between the azomethine proton and the tin nucleus, ^3J(SnN=CH), was detected in all the complexes. This type of spin–spin coupling where the tin nuclei are located in a *trans* position to the azomethine proton has previously been reported (20, 21). It thus confirms the presence of nitrogen–tin coordination in all the complexes. In addition the values of the coupling constant for the diorganotin derivatives, 36–58 Hz for ^3J(SnN=CH) and 78–84 Hz for $^2J(SnCH_3)$ (Table 2), are in agreement with the values reported for the dimethyltin dichloride complexes of a range of Schiff bases (20) obtained from substituted salicylaldehydes and *ortho*-aminophenols (^3J(SnN=CH) = 46–70 Hz; $^2J(SnCH_3)$ = 77–81 Hz). Furthermore the $^2J(SnCH_3)$ values for the dimethyltin derivatives were found to correspond (22) to a C—Sn—C angle range of 120–143°. Similarly the ^1J(SnC) of 774 Hz for **5** is calculated to correspond (22) to a C—Sn—C angle of 145°. This would indicate that the bent C—Sn—C moiety forms part of the trigonal plane of these pentacoordinate complexes. In Tables 2 and 3, it will be noticed that two Sn—Me signals are detected for compound **9** ($Me_2Sn(OC_6H_4CH{=}NCH(i\text{-}Pr)COO)$). This occurs because the underlined proton is enantiotropic and causes the methyl groups bound to the tin, and the *i*-Pr group, to be diastereotopic. These groups thus give two NMR peaks (23).

Some of the Sn—N, Sn—O, and Sn—C bond distances found in this and related complexes are listed in Table 7. It is noteworthy that the Sn—N bond of 2.158(8) Å observed in the present study is the second shortest of the Sn—N bonds listed in Table 7. In addition, the Sn—O and Sn—C bonds

Metal pyrazolate polymers. Part 3. Synthesis and study of Cu(I) and Cu(II) complexes of 4-Xdmpz (where X = H, Cl, Br, I, and CH_3 for Cu(I) and X = H, Cl, Br, and CH_3 for Cu(II); dmpz = 3,5-dimethylpyrazolate)

MARTIN K. EHLERT, ALAN STORR,[1] AND ROBERT C. THOMPSON[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Z1

Received October 11, 1991

MARTIN K. EHLERT, ALAN STORR,[1] and ROBERT C. THOMPSON. Can. J. Chem. **70**, 1121 (1992).

The copper(I) complexes $[Cu(4\text{-}Xdmpz)]_3$ (where X = H, Cl, Br, I and CH_3; dmpz = 3,5-dimethylpyrazolate) and the copper(II) complexes $[Cu(4\text{-}Xdmpz)_2]_x$ have been synthesized and characterized. Qualitative solubility, infrared spectroscopic, and differential scanning calorimetric studies are reported for all complexes. Mass spectra support trimeric formulations for the copper(I) complexes. Scanning electron micrographs and powder X-ray diffractograms have been recorded for the copper(II) compounds. Electronic and EPR spectroscopic studies as well as magnetic susceptibility studies from 2 to 300 K are also reported for the copper(II) compounds, which are proposed to have polymeric chain structures. The magnetic data reveal strong antiferromagnetic interactions in all four of the copper(II) compounds. The data have been analysed employing an isotropic Heisenberg model for antiferromagnetic coupling in extended chain polymers. Values of the exchange coupling constant, J, are determined as -58, -61, -66, and -66 cm^{-1} for the X = H, CH_3, Cl, and Br complexes respectively. The X = Cl compound exhibits an abrupt decrease in magnetic susceptibility below 40 K and possible causes of this anomalous behaviour are discussed.

MARTIN K. EHLERT, ALAN STORR et ROBERT C. THOMPSON. Can. J. Chem. **70**, 1121 (1992).

On a synthétisé et caractérisé les complexes de cuivre(I) $[Cu(Xdmpz\text{-}4)]_3$ (ou X = H, Cl, Br, I et CH_3; dmpz = pyrazolate de diméthyl-3,5) et les complexes de cuivre(II) $[Cu(Xdmpz\text{-}4)_2]_x$. Pour tous ces complexes, on rapporte des études relatives á la solubilité qualitative, à la spectroscopie infrarouge et à la colorimétrie par balayage différentiel. Les spectres de masse confirment les structures trimères proposées pour les complexes de cuivre(I). On a enregistré les micrographiques obtenus par balayage électronique, et les diffractogrammes obtenus par diffraction de rayons X sur les poudres des complexes de cuivre(II). On rapporte également les études spectrospiques et de RPE ainsi que les succeptibilités magnétiques réalisées à des températures allant de 2 à 300 K sur les complexes de cuivre(II) pour lesquels on propose une structure sous forme de chaînes polymérisées. Les données magnétiques révèlent de fortes interactions antiferromagnétiques dans tous les composés de cuivre(II). On a analysé les données obtenues en utilisant un modèle d'Heisenberg isotropique pour le couplage antiferromagnétique dans les longues chaines de polymères. On a déterminé les valeurs de la constante de couplage d'échange, J. Elles sont respectivement de -58, -61, -66 et -66 cm^{-1} pour les complexes où X = H, CH_3, Cl et Br. Le composé où X = Cl montre une brusque diminution de la succeptibilité magnétique en-dessous de 40 K et on discute des causes possibles de ce comportement anormal.

[Traduit par la rédaction]

Introduction

Previous papers in this series have described the synthesis and study of the binary copper(II) pyrazolates $[Cu(4\text{-}Xpz)_2]_x$ (where X = H, Cl, Br, and CH_3; pz = pyrazolate) (1, 2). Two forms of the X = Cl compound (green and brown) were characterized. These compounds all appear to have polymeric chain structures in which adjacent copper ions, with distorted tetrahedral CuN_4 chromophores, are doubly bridged by pyrazolate ligands. This structure was confirmed by single crystal X-ray diffraction studies on the X = H, CH_3, and Cl (green form) materials. Magnetic susceptibility studies over the temperature range 2–300 K revealed relatively strong antiferromagnetic exchange in all the compounds. The magnetic data were successfully analyzed employing an anisotropic Heisenberg model for antiferromagnetic exchange in extended chain polymers, yielding values of the exchange coupling constant, J, in the range -81 to -105 cm^{-1}. A consideration of the relationship between the observed magnitude of exchange and structural considerations led to the suggestion that an important factor in determining the magnitude of exchange in these complexes is the overlap between the pyrazolate π-orbital systems and the metal's magnetic orbital (2). To further investigate the effects of structural change on magnetic exchange in these systems we have synthesized and characterized the four new binary copper(II) pyrazolates, $[Cu(4\text{-}Xdmpz)_2]_x$, where X = H, Cl, Br, and CH_3 and dmpz = 3,5-dimethylpyrazolate. As a group these compounds differ from those previously studied in that they have bulky methyl substituents in the more sterically sensitive 3,5-positions. Otherwise they form an analogous series with H, Cl, Br, and CH_3 substituents in the 4-position.

The syntheses of the $[Cu(4\text{-}Xdmpz)_2]_x$ complexes presented some technical problems. While the 4-X = H compound could be obtained from the molten ligand–metal reaction employed earlier in the preparation of $[Cu(4\text{-}Hpz)_2]_x$ (1), this reaction led to impure products for the other 4-X complexes. This led to the development of a successful route to the required compounds via the copper(I) derivatives, $[Cu(4\text{-}Xdmpz)]_3$. Some characterization of these latter complexes is included in this report. Repeated attempts to obtain samples of the $[Cu(4\text{-}Xdmpz)_2]_x$ compounds in crystalline form suitable for single crystal X-ray diffraction studies were unsuccessful; consequently, it was necessary to resort to indirect methods to obtain structural information on these compounds.

Experimental

3,5-Dimethylpyrazole was purchased from Aldrich and used without further purification.

Syntheses

3,4,5-Trimethylpyrazole

The procedure of Chambers *et al.* was employed (3). ^{1}H NMR ($CDCl_3$ solution), δ: 1.85 (s, 3, CH_3), 2.15 (s, 6, CH_3), 10.45 (br s, 1, NH). Anal. calcd. for $C_6H_{10}N_2$: C 65.4, H 9.2, N 25.5; found: C 65.2, H 9.0, N 25.5.

4-Chloro-3,5-dimethylpyrazole

The method of Hüttel, Schäfer, and Welzel (4) for the synthesis of 4-chloropyrazole was adopted for use here. 3,5-Dimethylpyrazole (9.23 g, 0.0960 mol) was dissolved in 100 mL of water and glacial acetic acid (15 mL, 0.26 mol) was added to the solution. NaOCl (aq) (200 mL of 0.482 M, 0.0964 mol) was added to the solution and it was stirred at room temperature for 2 h. The mixture was then neutralized with Na_2CO_3 and made slightly basic with a few drops of concentrated ammonia (aq). The resulting mixture was cooled to 5°C and suction filtered. The collected solid was washed with cold water and dried under vacuum at room temperature for 4 h, yielding 10.9 g (87%) of 4-chloro-3,5-dimethylpyrazole. ^{1}H NMR ($CDCl_3$ solution), δ: 2.26 (s, 6, CH_3), 9.93 (br s, 1, NH). Anal. calcd. for $C_5H_7ClN_2$: C 46.0, H 5.4, N 21.4; found: C 45.8, H 5.3, N 21.5.

4-Bromo-3,5-dimethylpyrazole

3,5-Dimethylpyrazole (9.6 g, 0.10 mol) was dissolved in 300 mL of water. Bromine (5.2 mL, 0.10 mol) was added to the solution dropwise, with stirring; the bromine decolourized almost immediately and a small amount of pale yellow oil separated. The resulting mixture was neutralized with concentrated NaOH (aq) and then allowed to settle. The aqueous supernatant was cooled to 5°C overnight and a white solid that precipitated was collected by suction filtration, washed with cold water, and air-dried. The oily component was dried under vacuum, yielding a tan coloured solid. Both solid fractions were combined, recrystallized from toluene, suction filtered, washed with ice-cold petroleum ether, and dried under vacuum at room temperature, yielding 11.2 g (64%) of 4-bromo-3,5-dimethylpyrazole as a white solid. ^{1}H NMR ($CDCl_3$ solution), δ: 2.21 (s, 6, CH_3), 11.2 (br s, 1, NH). Anal. calcd. for $C_5H_7BrN_2$: C 34.3, H 4.0, N 16.0; found: C 34.6, H 4.1, N 16.3.

4-Iodo-3,5-dimethylpyrazole

A variation of the method of Morgan and Ackerman was employed (5). 3,5-Dimethylpyrazole (9.0 g, 0.094 mol) and Na_2CO_3 (0.53 g, 0.050 mol) were dissolved in 500 mL of water and the solution was heated to reflux with stirring. To this solution was added dropwise a solution of KI (31.0 g, 0.186 mol) and I_2 (23.0 g, 0.0905 mol) dissolved in 80 mL of water. When addition of the KI_3 solution was complete, the reaction was cooled to 5°C and left overnight. The precipitate was suction filtered and washed with 300 mL of ice-cold water. The filtercake was dissolved in 200 mL of CH_2Cl_2 and extracted with an equal volume of a dilute aqueous solution of Na_2CO_3 to remove any remaining HI. The CH_2Cl_2 phase was collected, flash evaporated, and dried at room temperature under vacuum for 5 h, yielding 19.0 g (94%) of 4-iodo-3,5-dimethylpyrazole as a white solid. ^{1}H NMR ($CDCl_3$ solution), δ: 2.23 (s, 6, CH_3), 11.65 (br s, 1, NH). Anal. calcd. for $C_5H_7IN_2$: C 27.0, H 3.2, N 12.6; found: C 27.1, H 3.2, N 12.6.

[(Cu(tmpz)]$_3$

This was the first of the Cu(I) pyrazolates prepared in this study and, at the time, it was not recognised that these compounds are air-sensitive when in contact with solvents. $[Cu(tmpz)]_3$, unlike the other compounds in this series, was prepared in air, so the yield of this compound is lower than those for the other copper(I) pyrazolates described here. A variation of the method of Ardizzoia *et al.* was employed (6). Cuprous iodide (1.90 g, 10.0 mmol) was dissolved in 70 mL of acetonitrile. To this was added a solution of 3,4,5-trimethylpyrazole (2.20 g, 20.0 mmol) dissolved in 60 mL of acetone. Within a few minutes the solution had turned brown. Triethylamine (2.8 mL, 20 mmol) was added to the solution and a white solid immediately precipitated. The mixture was allowed to stir for 1 h and then suction filtered, resulting in a white filtercake and green filtrate. The filtercake was washed with acetone and petroleum ether and dried in air at 110°C for 15 min, yielding 1.13 g (66%) of $[Cu(tmpz)]_3$ as a white powder. Anal. calcd. for $C_{18}H_{27}Cu_3N_6$: C 41.7, H 5.2, N 16.2; found: C 41.3, H 5.2, N 16.0.

The preparation of X-ray diffraction quality single crystals of $[Cu(tmpz)]_3$ is described elsewhere (7).

[Cu(4-Xdmpz)]$_3$(where X = H, Cl, Br, I)

These compounds were prepared as white solids in high yields by similar routes. The method is given in detail for the X = Cl compound. Cuprous iodide (1.90 g, 10.0 mmol) was dissolved in 80 mL of deoxygenated acetonitrile under a dinitrogen atmosphere. 4-Chloro-3,5-dimethylpyrazole (1.30 g, 10.0 mmol) was added to the solution and a flocculent white precipitate formed immediately. More white precipitate formed upon addition of triethylamine (1.6 mL, 11 mmol). The mixture was stirred for 2 h, suction filtered, and the filtercake washed with acetonitrile and acetone. The filtercake was dried for 30 min at 110°C in air, yielding 1.81 g (94%) of $[Cu(4\text{-}Cldmpz)]_3$ as a white solid. Anal. calcd. for $C_{15}H_{18}Cl_3Cu_3N_6$: C 31.1, H 3.1, N 14.5; found: C 31.1, H 3.2, N 14.4. Anal. calcd. for $C_{15}H_{18}Br_3Cu_3N_6$: C 25.3, H 2.5, N 11.8; found: C 25.1, H 2.5, N 11.8. Anal. calcd. for $C_{15}H_{18}Cu_3I_3N_6$: C 21.1, H 2.1, N 9.8; found: C 21.3, H 2.2, N 9.7. Anal. calcd. for $C_{15}H_{21}Cu_3N_6$: C 37.8, H 4.4, N 17.6; found: C 38.0, H 4.4, N 17.8.

[Cu(4-Hdmpz)$_2$]$_x$

$[Cu(4\text{-}Hdmpz)_2]_x$ was synthesized via two different routes. The first employed the molten ligand–metal reaction described previously (1). Copper metal shot (3.15 g, 49.6 mmol), washed with 12 M HCl, water, acetone, and dried, and 3,5-dimethylpyrazole (11.0 g, 114 mmol) were combined in a small reaction vessel and heated in air at 115°C, with stirring, for 4 days. The mixture was then cooled to room temperature and extracted from the flask with CH_2Cl_2. The mixture was then suction filtered and the filtercake was washed with petroleum ether, and dried in air at 110°C for 4 h. This yielded approximately 0.5 g of $[Cu(4\text{-}Hdmpz)_2]_x$ as a reddish-brown powder. Anal. calcd. for $C_{10}H_{14}CuN_4$: Cu 25.0, C 47.3, H 5.6, N 22.1; found: Cu 25.2, C 47.1, H 5.4, N 22.3.

In the second method $[Cu(4\text{-}Hdmpz)]_3$ (0.319 g, 2.01 mmol Cu(I)) and 3,5-dimethylpyrazole (1.92 g, 20.0 mmol) were combined in a small vessel and heated under a dioxygen atmosphere at 124°C for 3 h (reaction was probably complete after 1 h). The mixture was then cooled to room temperature and extracted with dry tetrahydrofuran (THF) and suction filtered. The filtercake was washed with more THF and dried in a desiccator at room temperature. This yielded 0.509 g (99%) of $[Cu(4\text{-}Hdmpz)_2]_x$. Anal. calcd. for $C_{10}H_{14}CuN_4$: C 47.3, H 5.6, N 22.1; found: C 47.3, H 5.6, N 22.2.

[Cu(tmpz)$_2$]$_x$ and [Cu(4-Xdmpz)$_2$]$_x$ (where X = Cl, Br)

These compounds were prepared as brown solids (dark brown for X = Br) by similar routes. The method, which gave high yields in all cases, is described in detail for $[Cu(tmpz)_2]_x$. $[Cu(tmpz)]_3$ (0.345 g, 2.00 mmol) and 3,4,5-trimethylpyrazole (1.76 g, 16.0 mmol) were combined in a small vessel and the mixture was heated to 140°C, with stirring, under a dioxygen atmosphere for 2 h and then cooled to room temperature and dried under vacuum for 10 h. The mixture was extracted from the flask under dinitrogen with dry, deoxygenated, THF and then suction filtered under dinitrogen, the filtercake washed with THF, and dried at room temperature under vacuum for 5 h. This yielded 0.540 g (96%) of $[Cu(tmpz)_2]_x$ as a brown powder. Anal. calcd. for $C_{12}H_{18}CuN_4$: Cu 22.5, C 51.1, H 6.4, N 19.9; found: Cu 22.5, C 51.0, H 6.4, N 20.1. Anal. calcd. for $C_{10}H_{12}Cl_2CuN_4$: Cu 19.7, C 37.2, H 3.8, N 17.4; found: Cu 19.7, C 37.2, H 3.7, N 17.4. Anal. calcd. for $C_{10}H_{12}Br_2CuN_4$: Cu 15.4, C 29.2, H 2.9, N 13.6; found: Cu 15.5, C 29.3, H 3.0, N 13.7.

Attempted preparation of $[Cu(4\text{-}Idmpz)_2]_x$

Attempts to prepare $[Cu(4\text{-}Idmpz)_2]_x$ from the corresponding copper(I) complex were unsuccessful. The temperature and prolonged reaction time required caused significant decomposition of the molten ligand, liberating I_2 (this was visible as purple vapour above the reaction mixture). Presumably, liberated iodide caused partial reduction of the copper(II) formed, preventing the formation of pure product.

Physical characterization

^1H NMR spectra were recorded using a Bruker AC-200 FT-NMR spectrometer equipped with a Bruker B-ACS 120 sample exchanger. Residual $CHCl_3$ in the $CDCl_3$ solvent was used as the internal standard for calibration.

Differential scanning calorimetry (DSC) measurements were made with a Mettler DSC 20 standard cell and TC 10 TA processor as described previously (8).

X-Ray powder diffractograms were collected with a Rigaku Rotaflex RU-200BH rotating anode X-ray powder diffractometer (nickel-filtered or graphite monochromated Cu-K_α radiation). Diffractograms for the copper(II) pyrazolates have been deposited.[2]

Scanning electron micrographs of samples were recorded with a Hitachi S-570 scanning electron microscope. Samples were prepared by applying a thin suspension of the sample in ethanol or petroleum ether to a stainless steel stub, allowing the suspension to dry, and then sputter coating the stub with a thin layer of gold.

Mass spectra were recorded using a Kratos MS 50 mass spectrometer employing the electron impact ionization technique.

Infrared spectra (250–4000 cm^{-1}) were obtained using a Perkin–Elmer model 598 spectrometer. The samples were mulled in hexachlorobutadiene and sandwiched between KRS-5 plates (Harshaw Chemical Co.) and (or) mulled in Nujol and sandwiched between KBr plates.

Electronic spectra (200–2500 nm) were recorded using a Cary 5 UV/visible/NIR spectrophotometer. Samples were mulled in Nujol and pressed between quartz plates.

EPR spectra were recorded using an X-band homodyne spectrometer, which was described previously (2). Samples were measured as polycrystalline powders placed in sealed quartz tubes and measurements were performed at ~90 K.

Magnetic susceptibilities were measured over the temperature range 2–300 K using a Quantum Design (MPMS) SQUID magnetometer (field = 10 kOe). Temperature measurement with this instrument was achieved using a combination of Ge and Pt resistance thermometers. Susceptibility calibration was performed using high purity Ni and Bi standards. The samples were packed as powders into a specially constructed sample holder made from polyvinylchloride (PVC). The sample holder possessed a constant cross-sectional area, thus minimizing its contribution to the SQUID signal. Magnetic susceptibilities were corrected for diamagnetism: copper, −11; $C_5H_7N_2$, −62; $C_6H_9N_2$, −74; $C_5H_6ClN_2$, −76; $C_5H_6BrN_2$, −87 (values in 10^{-6} cm^3 mol^{-1}). A correction of 60×10^{-6} cm^3 mol^{-1} was applied for temperature-independent paramagnetism of the copper(II) ion.

C, H, and N analyses were performed by P. Borda of this department. Cu analyses were performed using iodometric titration.

Results and discussion

Copper(I) complexes, $[Cu(4\text{-}Xdmpz)]_3$

The failure of the molten ligand–metal reaction to yield pure copper(II) complexes of the type $[Cu(4\text{-}Xdmpz)_2]_x$, where X = Cl, Br, and CH_3, led to the development of a clean route to these compounds employing the corresponding copper(I) analogues. These latter complexes may be obtained by the reaction of CuI with the appropriate pyrazole in acetonitrile. The method follows that described by Ardizzoia *et al.* for the synthesis of $[Cu(4\text{-}Hdmpz)]_3$ (6). These compounds are insoluble (or at best, sparingly soluble) in common organic solvents. They are colourless solids and are stable towards O_2 when dry; however, in water-containing solvents they are oxidized to yellow-green soluble species. Ardizzoia *et al.* characterized a cyclic, octameric, copper(II) complex bridged by 4-Hdmpz and hydroxide as the aerial oxidation product of $[Cu(4\text{-}Hdmpz)]_3$ in wet CH_2Cl_2, pyridine, or nitrobenzene (9).

Prior to our recent X-ray diffraction study of $[Cu(4\text{-}Hdmpz)]_3$, which showed a trimeric ring structure (10), the copper(I) pyrazolates were thought to be polymeric (11). We more recently determined by single crystal X-ray diffraction methods that $[Cu(4\text{-}CH_3dmpz)]_3$ also has a trimeric ring structure (7). We conclude that all of the copper(I) pyrazolates prepared in this study have a trimeric structure similar to those mentioned above. In support of this, all of the copper(I) compounds studied here exhibit electron impact mass spectra in which the most intense peak is that due to the molecular ion expected for the trimer. The isotopic patterns are in excellent agreement with those predicted. Further support for the conclusion that the compounds are trimeric comes from the observation that, with the exception of the compound hexakis(μ-3,5-diphenylpyrazolato-*N*,*N*′)hexagold(I) (12), all other structurally characterized univalent coinage metal pyrazolates are trimers (12–14). The copper(I) compounds are all thermally robust. The X = CH_3 compound melts at 308°C and thermally decomposes at 365°C. The X = Cl, Br, and I compounds decompose, without melting, at 350°C, 300°C, and 300°C respectively.

Copper(II) compounds, $[Cu(4\text{-}Xdmpz)_2]_x$: structural studies

Powder X-ray diffractograms of the copper(II) 4-Xdmpz derivatives have been deposited.[2] They indicate that the compounds are crystalline; however, attempts to obtain single crystals were unsuccessful. Nonetheless, based on indirect evidence and comparisons with the structurally characterized $[Cu(4\text{-}Xpz)_2]_x$ complexes (1, 2) we conclude that the compounds are polymeric. The empirical formulae of the 4-Xdmpz compounds do not support monomeric species, unless one assumes either the unlikely coordination number of two for copper(II) or the equally unlikely formation of three-membered chelate rings. Polymeric structures for the compounds are supported by their lack of solubility in a wide range of polar and nonpolar common organic solvents. The X = CH_3, Cl, and Br compounds dissolve with decomposition in water and wet solvents, yielding green soluble species and small amounts of greyish-green insoluble species. The soluble hydrolysis products do not crystallize, but form amorphous films upon drying. These films have not been characterized further. The X = H compound is stable towards water and water-containing organic solvents. Structurally characterized binary copper(II) pyrazolates have extended chain structures and scanning electron micrographs of the 4-Xdmpz complexes studied here show their microcrystals to be long fibres, consistent with such a structure. A scanning electron micrograph of $[Cu(4\text{-}Hdmpz)_2]_x$ is shown in Fig. 1. Furthermore, the similarity in the thermal properties of the compounds studied here and those of the structurally characterized analogues is consis-

tent with similar structures. DSC studies show the 4-Xdmpz complexes decompose without melting at 245°C, 233°C, 245°C, and 245°C for the X = H, CH_3, Cl, and Br derivatives. The 4-Xpz compounds also decompose without melting, albeit at 25–45°C higher in temperature. Finally, as discussed in the next section, the magnetic properties of the 4-Xdmpz complexes have been successfully analysed, employing models for magnetically coupled linear chains as reported previously for the 4-Xpz analogues. We conclude that the complexes under investigation here most likely have structures involving extended chains of copper ions linked by double pyrazolate bridges as seen in the single crystal X-ray determined structures of the complexes $[Cu(4\text{-}Xpz)_2]_x$, where X = H, CH_3, and Cl (1, 2). While the presence of sterically hindering methyl groups in the $[Cu(4\text{-}Xdmpz)_2]_x$ complexes does not appear to prevent the formation of extended chain polymers, spectroscopic evidence to be presented next indicates they do have an effect on the geometry of the CuN_4 chromophore.

The 4-Xdmpz complexes are reddish-brown to dark brown in colour; their UV–visible–NIR spectra are shown in Fig. 2. In the visible region, two band maxima are observed for each of the compounds as follows: X = H, 19 000 and 23 100 cm^{-1} (sh); X = CH_3, 18 300 and 21 700 cm^{-1} (sh); X = Cl, 17 800 (sh) and 20 700 cm^{-1}; X = Br, 19 000 (sh) and 21 700 cm^{-1}. In addition, all four compounds show the presence of strong bands in the UV region, presumably charge transfer in origin (Fig. 2), as well as a weak band in the NIR region at 10 500 cm^{-1}. The bands in the visible region, which likely arise from *d–d* transitions, are at significantly higher energies than the corresponding bands reported previously for the analogous $[Cu(4\text{-}Xpz)_2]_x$ compounds. These latter compounds have compressed tetrahedral CuN_4 chromophores and *d–d* bands centred around 15 500 cm^{-1} (2). According to Hathaway (15), complexes with CuN_4

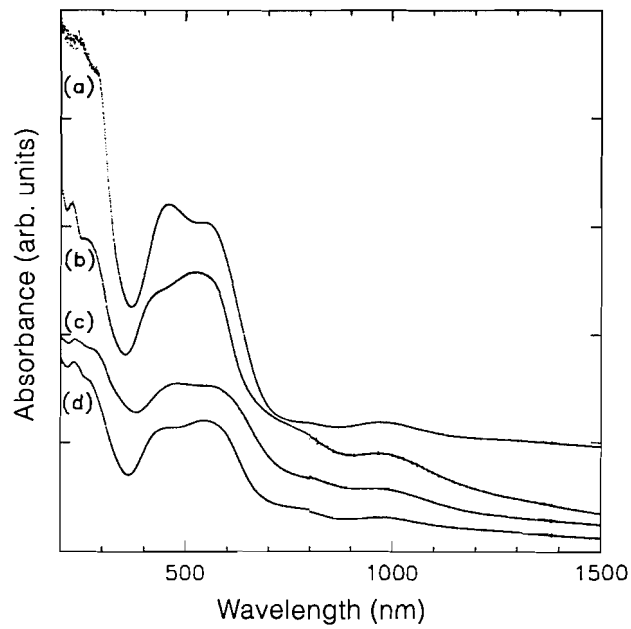

FIG. 2. Electronic spectra for the $[Cu(4\text{-}Xdmpz)_2]_x$ compounds: (*a*) X = Br, (*b*) X = H, (*c*) X = Cl, (*d*) X = CH_3.

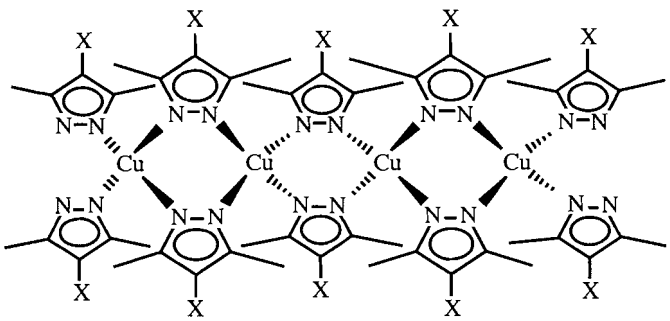
chromophores that exhibit *d–d* bands in the 18 000–20 000 cm^{-1} region, as observed in the present study, are likely to have square-coplanar stereochemistries. This spectroscopic criterion of stereochemistry has previously been successfully applied to pyrazolate complexes (16). The mononuclear complexes $[Me_2Ga(4\text{-}Hdmpz)_2]_2Cu$ and $[Me_2Ga(4\text{-}Hpz)_2]_2Cu$ have CuN_4 chromophores with compressed tetrahedral coordination in the former and square-coplanar coordination in the latter (17). The former complex exhibits *d–d* bands at 9 400 cm^{-1} and 12 000 cm^{-1} (sh) while the

corresponding bands in the latter complex are in the 17 000–20 000 cm^{-1} region (16).

Steric crowding involving the methyl substituents in the 3- and 5-positions of the pyrazolate ring may be alleviated in the chain polymer either by a distortion of the $[Cu(4\text{-}Hpz)_2]_x$ structure (1) towards a more regular tetrahedral CuN_4 chromophore or, alternatively, by adopting a polymeric structure like that shown in **1**, which is based on the structures of $[(ON)Ni(4\text{-}Hdmpz)_2]_2Ni$ and $[(C_3H_5)Ni(4\text{-}Hdmpz)_2]_2Ni$ (18, 19) in which the central Ni ions possess square-planar coordination. The spectroscopic evidence presented above supports a structure of the type shown in **1** for the $[Cu(4\text{-}Xdmpz)_2]_x$ compounds.



1

To further study the geometries of the CuN_4 chromophores in these complexes we examined their powder EPR spectra at 90 K. As reported previously (2), all of the $[Cu(4\text{-}Xpz)_2]_x$ complexes, except one, exhibit two g-value spectra at ~90 K with $g_\parallel$ values in the range 2.22–2.24 and $g_\perp$ values of ~2.08. The brown form of the X = Cl compound exhibited an isotropic spectrum with $g_0 = 2.084$. The $[Cu(4\text{-}Xdmpz)_2]_x$ complexes, on the other hand, give broad, asymmetric, single resonance lines that lack the features necessary for the determination of g-values directly from the spectra. There appears to be less exchange narrowing here, in comparison to the $[Cu(4\text{-}Xpz)_2]_x$ analogues, due to weaker antiferromagnetic coupling (discussed below). Although these powder EPR spectra do not permit an unequivocal assignment of the CuN_4 chromophore geometry, the fact that they are significantly different from those of the $[Cu(4\text{-}Xpz)_2]_x$ compounds (2) is not inconsistent with a change in chromophore geometry.

Infrared spectra were recorded for all the complexes, primarily as a preliminary test of product purity. In the 4-H, 4-CH_3, 4-Cl, and 4-Brdimethylpyrazolates, a sharp band observed between 700 and 800 cm^{-1} in the copper(I) compounds shifts 10–15 cm^{-1} lower in energy in the corresponding copper(II) compounds. This band was used as a check of whether conversion of the copper(I) to copper(II) compound was complete in the synthesis of the latter. No other particularly useful structural information was obtainable from the infrared spectra. Tabulated band frequencies have been deposited.[2]

$[Cu(4\text{-}Xdmpz)_2]_x$ compounds: magnetic susceptibilities

Magnetic susceptibilities of the four $[Cu(4\text{-}Xdmpz)_2]_x$ compounds were measured from 2.0 to 300 K employing a SQUID magnetometer. Tabulated magnetic susceptibility data for the $[Cu(4\text{-}Xdmpz)_2]_x$ compounds are deposited[2] and plots of χ_M versus temperature are shown in Fig. 3 for $[Cu(4\text{-}Hdmpz)_2]_x$ and $[Cu(4\text{-}Cldmpz)_2]_x$. All four compounds exhibit maxima in their susceptibility versus temperature plots (in the range 105–120 K) indicative of antiferromagnetic exchange coupling. In all cases an increase in susceptibility is observed as the temperature decreases at the lowest temperatures studied. This is not uncommon in strongly antiferromagnetically coupled copper(II) systems and was observed previously for the $[Cu(4\text{-}Xpz)_2]_x$ compounds where it was ascribed to the presence of small amounts of paramagnetic impurities (1, 2). In analysing the magnetic data we employed the isotropic Heisenberg model for exchange coupled linear chains developed by Hall and Estes *et al.* (20, 21). In addition, as in our previous work (1, 2), allowance was made for the paramagnetic impurity by modelling it as a Curie paramagnet with a g-value equal to that of the bulk sample. The expressions used in the fitting procedure are presented below and the symbols have their usual meanings (22). Reasonable fits between experimental data and theory were obtained for the X = H, CH_3, and Br compounds and best-fit

$$\chi_{chain} = \frac{Ng^2\mu_B^2}{kT} \times \left[\frac{0.25 + 0.14995\,x^{-1} + 0.30094\,x^{-2}}{1 + 1.9862\,x^{-1} + 0.68854\,x^{-2} + 6.0626\,x^{-3}}\right]$$

where

$$x = kT/|J|$$

$$\chi_{para} = \frac{Ng^2\mu_B^2 S(S+1)}{3kT}$$

$$\chi = [1 - P]\chi_{chain} + P\chi_{para}$$

values of the J, g, and percent paramagnetic impurity parameters are given for these in Table 1. Better agreement between experiment and theory, particularly in the region of the susceptibility maximum, is obtained when only data at and above 40 K are used in the fitting procedure. Values of J and g obtained from these high-temperature data fits are also given in Table 1. The paramagnetic impurity contributes more to the low-temperature data and the improvement in fit on using the high-temperature data probably reflects inadequacies in modelling the paramagnetic component as was discussed previously (1, 2). Pursuing this further, we examined fits of the experimental susceptibilities for the X = H, CH_3, and Br compounds to theory over the whole temperature range, modelling the paramagnetic component as a Curie–Weiss paramagnet. This adds a fourth parameter, θ,

$$\chi_{para} = \frac{Ng^2\mu_B^2 S(S+1)}{3k(T-\theta)}$$

to the fitting procedure and produces an excellent fit over the entire temperature range studied. The J and g-values obtained with this model agree well with those obtained using fits to the high temperature data only (Table 1).

$[Cu(4\text{-}Cldmpz)_2]_x$ exhibits somewhat unique magnetic properties. Above 40 K it behaves much like the other complexes studied here, exhibiting a broad maximum in its susceptibility versus temperature plot at 120 K. The magnetic data above 40 K are reasonably well modelled according to the isotropic Heisenberg model for exchange coupled linear chains and the best-fit values of J and g obtained using this

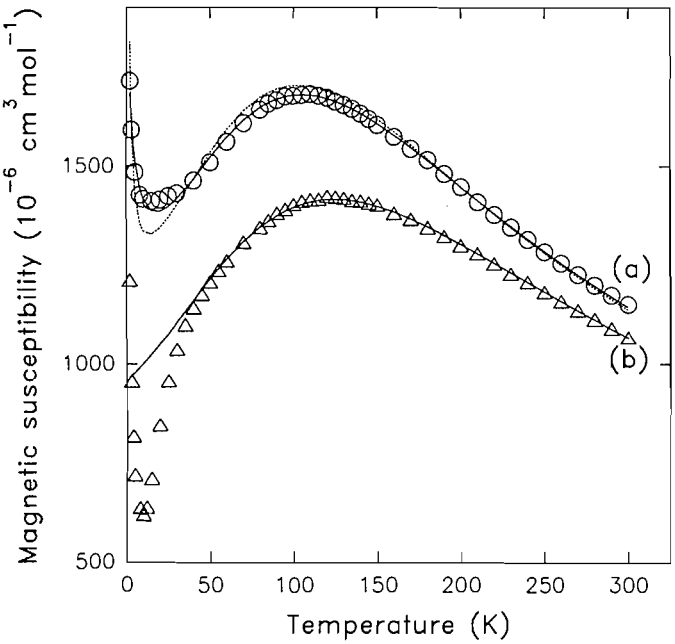

FIG. 3. Plot of magnetic susceptibility versus temperature for (*a*) $[Cu(4\text{-}Hdmpz)_2]_x$ and (*b*) $[Cu(4\text{-}Cldmpz)_2]_x$. The broken curve for (*a*) represents the best fit to theory with a Curie paramagnetic component and the solid curve represents the best fit to theory with a Curie–Weiss paramagnetic component. The solid curve in (*b*) represents the best fit of the data to theory from 40 to 300 K.

model and ignoring paramagnetic impurity are comparable to the values obtained for the other 4-Xdmpz compounds (Table 1). Below 40 K, however, the susceptibility drops abruptly until about 8 K, below which the effects of paramagnetic impurity are seen. The magnetic properties for this compound cannot be modelled well below 40 K using the linear chain model with or without paramagnetic impurity. The abrupt decrease in susceptibility below 40 K is behaviour similar to that observed for $CuSb_2O_6$ (23), which possesses the trirutile structure and behaves magnetically as a linear chain antiferromagnet above 9 K. Nakua *et al.* attributed the rapid decrease in susceptibility below 9 K in $CuSb_2O_6$ as a transition to long-range antiferromagnetic order. One of the pieces of evidence they used to support this conclusion was an examination of the field dependence of $CuSb_2O_6$. Nakua *et al.* found that the magnetization of the compound at 2 K (below T_c) over the applied field range 0–30 kOe exhibited two linear regimes with a transition region between. This behaviour is characteristic of a spin flop transition in polycrystalline antiferromagnets. At 11 K (above T_c) they found the magnetization to be completely linear over the same field range, which is characteristic of the paramagnetic state.

Noting the similarity between the temperature dependence of the susceptibility of $CuSb_2O_6$ and $[Cu(4\text{-}Cldpmz)_2]_x$, we undertook a study of the magnetic field dependence of $[Cu(4\text{-}Cldmpz)_2]_x$. The compound's applied field dependence was examined in the range 0–55 kOe at 5, 10, 15, and 20 K. The results of this study are depicted in Fig. 4. It is apparent that the magnetization data for $[Cu(4\text{-}Cldmpz)_2]_x$ do not exhibit the spin flop transition evident in the data for $CuSb_2O_6$. The magnetization plots at 10 K and especially 5 K for $[Cu(4\text{-}Cldmpz)_2]_x$ show some deviation from linearity at the highest fields. This is most likely due to magnetic saturation effects as the Brillouin function η value at 5 K and 55 kOe is 1.65 for this compound. Even though $[Cu(4\text{-}Cldmpz)_2]_x$ does not exhibit field dependence indicative of a spin flop transition in the range studied, this does not rule out the possibility of such a transition occurring in the compound. The molecular field theory (24) description of spin flop in antiferromagnets predicts that the transition field, H_{SF}, at $T = 0$ K is dependent on both the anisotropy field and the antiferromagnetic exchange energy. If the anisotropy fields for $CuSb_2O_6$ and $[Cu(4\text{-}Cldmpz)_2]_x$ are similar, then the H_{SF} would be expected to be greater for the compound with the larger antiferromagnetic exchange. $[Cu(4\text{-}Cldmpz)_2]_x$ ex-

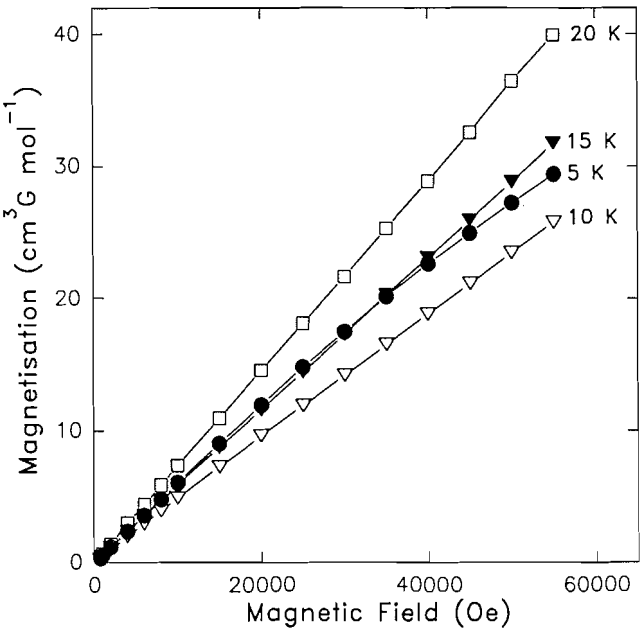

FIG. 4. Magnetization vs. applied magnetic field plot at various temperatures for $[Cu(4\text{-}Cldmpz)_2]_x$. The solid lines are merely a guide to the eye.

hibits its anomalous decrease in susceptibility for an antiferromagnetically coupled linear chain in the range 30–40 K, whereas $CuSb_2O_6$ exhibits this feature between 8 and 9 K. This would imply that if long-range antiferromagnetic ordering is occurring in $[Cu(4\text{-}Cldmpz)_2]_x$, then the magnitude of the interaction is much larger in this compound than in $CuSb_2O_6$ and, as discussed above, one would expect H_{SF} to be higher in the former compound than in the latter, perhaps beyond our experimentally accessible field range.

Our field-dependence studies do not preclude the possibility of long-range order accounting for the unusual susceptibility data for $[Cu(4\text{-}Cldmpz)_2]_x$, but neither do they support such a conclusion. Other possibilities that might account for the behaviour of this compound are a transition to two-dimensional ordering or a structural phase transition that facilitates much stronger one-dimensional antiferromagnetic exchange.

Turning now to a consideration of the magnitude of the exchange coupling in these $[Cu(4\text{-}Xdmpz)_2]_x$ complexes, some interesting comparisons can be made with the $[Cu(4\text{-}Xpz)_2]_x$ analogues. We note that in both sets of compounds the $|J|$ values for the 4-Cl and 4-Br derivatives are the same within experimental uncertainty and are slightly, but significantly, greater than the values for the 4-H and 4-CH_3 derivatives. This variation does not correlate with simple ideas based on relative ligand basicities since the halo-substituted pyrazolates should be expected to be the least basic, form the weakest bonds to copper, and therefore provide the poorest, rather than the most efficient, pathways for exchange. As discussed previously (2), the exchange in these systems appears to be affected more by detailed structural differences between compounds that affect the overlap between the pyrazolate π-orbital system and the metal's magnetic orbital. The effects of structural differences on the magnitude of exchange can be seen by comparing the $|J|$ values of the $[Cu(4\text{-}Xpz)_2]_x$ compounds as a group with the $|J|$ values of the $[Cu(4\text{-}Xdmpz)_2]_x$ compounds. Although all of the compounds under consideration are considered to have extended chain structures, the geometry of the CuN_4 chromophore in the former group is compressed tetrahedral while, as discussed above, the geometry of the chromophore in the latter group is almost certainly different and likely square planar. This basic structural difference probably accounts for the fact that the $[Cu(4\text{-}Xpz)_2]_x$ complexes exhibit $|J|$ values (range 81–105 cm^{-1}) that are consistently higher than those of the $[Cu(4\text{-}Xdmpz)_2]_x$ complexes (range 58–67 cm^{-1}).

Clearly, a better understanding of magneto-structural correlations in the $[Cu(4\text{-}Xdmpz)_2]_x$ complexes will require more detailed structural information. Thus far, we have been unable to obtain crystals large enough for single crystal X-ray diffraction studies. Their lack of solubility and the fact that the compounds decompose without melting have ruled out crystallization approaches. We have had some success in the past in obtaining suitable single crystals of $[Cu(4\text{-}Xpz)_2]_x$ complexes by altering the conditions of synthesis so as to obtain a very slow rate of polymer formation. Unfortunately, we have found that applying such conditions to the synthesis of 4-Xdmpz complexes leads to the decomposition of the pyrazolate ligand, specifically oxidation of the methyl substituents. Investigations of some of these reactions has led to the isolation and structural characterization of some new carboxyl-substituted pyrazolate complexes. These studies will be presented in a subsequent communication.

After gas-chromatographic separation as volatile organometallics, some transition elements were found to respond with analytically relevant sensitivities in the flame photometric detector. Their minimum detectable amounts, in mole of metal per second at an $S/N_{p\text{-}t\text{-}p}$ ratio of 2, were 1×10^{-14} for nickel and 6×10^{-13} for rhenium, as well as a less sensitive 2×10^{-12} for molybdenum and 3×10^{-12} for cobalt. (When divided by 3.7, these values yield the $S/\sigma = 3$ limit of detection as recommended by IUPAC.) Calibration curves were established for these elements in comparison with transition metals already known to respond in the flame photometric detector. Their chemiluminescent spectra, together with that of chromium, were measured in the detector at analytically (as opposed to spectroscopically) optimized conditions. Atomic lines, molecular bands, and continua were all present. Also, the spectra produced by several types of carbon compounds were recorded for a definition of potential spectral interferences from hydrocarbonaceous sample matrices. The atomic lines and the massive continua displayed by certain metals are discussed in some detail. Atomic lines appear up to a limiting energy level of 3.6 eV above ground state. It is suggested that continua could arise from small, perhaps catalytically active particles. Also discussed, in accordance with a reviewer's request, are the analytical performance of the FPD compared to ICP and MIP sources, and the definition and influence of noise on measured performance criteria.

XUN-YUN SUN, BRIAN MILLIER et WALTER A. AUE. Can. J. Chem. **70**, 1129 (1992).

On a trouvé que certains éléments de transition, séparés par chromatographie gazeuse sous le forme d'organométalliques volatils, peuvent répondre avec des sensibilités analytiquement acceptables dans un détecteur photométrique à flamme. Les quantités minimales détectables, en mole de métal par seconde, à un rapport de $S/N_{p\text{-}t\text{-}p}$ de 2, sont de 1×10^{-14} pour le nickel et de 6×10^{-13} pour le rhénium alors que des sensibilités plus faibles de 2×10^{-12} et 3×10^{-12} ont été déterminées respectivement pour le molybdène et le cobalt. (Lorsqu'on divise ces valeurs par 7, on obtient la limite de détection $S/\sigma = 3$ recommandée par l'UICPA.) On a établi des courbes de calibration de ces éléments et on les a comparé avec celles de métaux de transitions déjà connus pour donner une réponse dans le détecteur photométrique à flamme. Opérant dans des conditions analytiquement (par opposition à spectroscopiquement) optimisées, on a mesuré leur spectre de chimiluminescence ainsi que celui du chrome dans le détecteur. Des raies atomiques, des bandes moléculaires et des continua sont présents dans tous les cas. De plus, dans le but de définir les interférences spectrales potentielles dues à des matrices d'échantillons contenant des hydrocarbures, on a aussi enregistré les spectres de plusieurs types de composés carbonés. On discute en détail des raies atomiques et des continua importants observés avec certains métaux. Les raies atomiques apparaissent jusqu'à un niveau limite d'énergie de 3,6 eV au-dessus de l'état fondamental. On suggère que les continua sont dûs à des petites particules qui seraient peut-être catalytiquement actives. On discute aussi, à la suggestion d'un arbitre, de la performance de la DPF par comparaison avec les sources ICP et MIP ainsi que la définition et l'influence du bruit sur les critères de la performance mesurée.

[Traduit par la rédaction]

Introduction

The flame photometric detector (FPD) is extensively used in the gas chromatography (GC) of phosphorus and (or) sulfur containing biocides and pollutants (1). In its GC version (and only this version will be considered here) it is a rather simple and comparatively inexpensive device that, beyond P and S, can also detect compounds of B, Ge, Sn, Pb, N, As, Sb, Bi, Se, Te, Cl, Br, and I (the latter three indirectly, e.g., as indium halides). All of these analytes are, of course, *main group* elements.

In contrast, transition elements are rarely determined in the FPD. This is not surprising. The device has a long history (2) and, in its conjunction with GC, was originally developed for organic compounds such as nerve gases (3). Typical applications occur in such related areas as sulfur-containing air pollutants, phosphorus-containing insecticides, and tin-containing antifouling paints. The best-known chemiluminescent emissions from the FPD (from S_2, HPO, and SnH) are molecular in nature. The flame is hydrogen-rich and cool (typically 300–600°C). It is monitored by a combination of interference filter and photomultiplier tube.

In contrast, the typical determination of transition metals by emission spectrometry involves thermal excitation of atomic lines, starting from aqueous solutions of inorganic ions. The high-temperature sources are monitored by monochromators or polychromators. In many instances, such sources, e.g., oxyhydrogen flames, have also been used with gas chromatographic effluents. High-energy sources are well suited for the atomic emission and absorption spectrometry of transition metals.

In the FPD, the situation seems reversed. The only transition metal for which, over the years, the FPD has provided analytical trace methodology is chromium (as the trifluoroacetylacetonate (4, 5)). Recently, we reported on the use of the FPD for metallocenes of the iron group (6–8) and for the determination of manganese (as methylcyclopentadienylmanganesetricarbonyl) in gasolines (9). Unexpectedly, some of the pertinent chemiluminescent emissions turned out to be not molecular but atomic in nature.

The fact that a "cool" source produces strong emission from a very few, highly selective atomic lines, is obviously

of fundamental interest. But it may also prove analytically important. Transition metals occur in a wide variety of biochemical, industrial, and environmental key compounds. While few of these are amenable to gas chromatography, some can be converted into volatile derivatives. More importantly, the flame photometric detector is no longer restricted to conventional gas chromatographic effluents, but is increasingly being used with capillary liquid chromatography and supercritical fluid chromatography. Both techniques are capable of dealing with analytes of low volatility.

It would seem profitable, therefore, to find further transition elements that respond in the FPD with analytically interesting sensitivities. Given the low temperature of the FPD flame, chemical (as opposed to thermal) excitation is a virtual precondition. This brings up some salient points. For one, there exists so far no logical basis on which to predict (*a*) whether a particular element will or will not emit light and (*b*) whether the emission, if any, will be atomic or molecular in nature. However, chemiluminescent emitters can be expected to be much fewer in number and their spectra hence much cleaner in appearance. Also, the presence or absence of spectra, as well as their intensity, should be strongly dependent on detector conditions.

This can be of paramount importance for the FPD's analytical performance. For instance, iron compounds produce mainly atomic lines at low temperature (less oxygen) but mostly molecular bands at high temperature (more oxygen) (6). This is, in a formal sense, contrary to their behavior in high-energy flames or plasmas. Furthermore, the Fe lines occur in the UV, the bands in the visible, making the choice of a monitoring wavelength highly condition-dependent. A related problem is detector cleanliness. Particularly the spectra of weak emitters depend to an inordinate degree on other compounds present in the detector environment. For example, response from different carbon compounds (matrix components, column bleed, the organic part of the analyte) appears to vary over time in overall intensity, wavelength dependence, and even direction (regular vs. inverted peaks). If, say, an FPD has a persistent background of residual sulfur, carbon compounds will produce inverted peaks and the "carbon" spectrum will roughly conform to the (inverted) S_2 bands. Similar effects can be observed from other elements of low FPD response.

All this mandates that spectra can be obtained *at the analytical operating conditions* of the detector. While many of the flame colors (blue S_2, violet Se_2, greenish HPO, red SnH, green BO and BO_2, etc.) are strong enough to be discerned by the dark-adapted eye, the absolute light output is still so weak that only the most prominent of spectra can be measured by a grating monochromator, and then only with wide slits and the most sensitive of phototubes. In many cases, and this study is no exception, the spectra of the FPD's diffuse luminescence phenomena can be picked up only by a variable interference filter ("filter monochromator") that, while allowing much more of the faint light to be collected, is of very low resolution and hence inadequate for most spectral assignments (e.g., the question of whether a particular emission is a molecular band or an atomic line). This is the reason why the spectra of certain elements are often not measured in the FPD, or, worse, why measurements from flames of higher energy are substituted. Occasionally, the luminescent features from low vs. high temperature, and hydrogen-rich vs. air-rich flames do coincide; more often they do not. The FPD is particularly prone to strong changes in the relative intensity of different spectra with just minor changes in operating conditions, much more so than typical high-energy sources. Also, analytically relevant emissions in the FPD cover an enormous range of intensity. On a molar, elemental basis, tin will for instance produce radiation more than eight orders of magnitude stronger than carbon/hydrogen (carbon compounds are common FPD interferents) and more than six orders of magnitude stronger than boron (boron compounds are common FPD analytes).

Yet, without knowledge of the actual spectral mix under particular analytical circumstances, a rational choice of detector conditions, especially for increasing the selectivity of one species over another, is difficult and time-consuming to make. This applies not only to the organometallic analytes, but also to the carbonaceous materials that provide the bulk of many a biological or environmental sample. In this report we shall therefore concentrate on the spectra and calibration curves of some transition elements, and shall add some speculations regarding excited states. In a subsequent report (10) we shall demonstrate how such information can be used to improve the selectivity of the FPD.

Experimental

This study used a basic gas chromatograph with a dual-channel flame photometric detector (Shimadzu GC-4BMPF). Unless otherwise indicated, a packed column (100 × 0.3 cm i.d. glass, 5% OV-101 on Chromosorb W, 100/120 mesh) was kept under a nitrogen flow of between 13 and 27 mL/min. Injection port and detector base temperatures were set at least 30° higher (between 160 and 200°C) than that of the column. The detector, with its quartz chimney removed, was run with 300 mL/min hydrogen and 55–60 mL/min air (depending on the analyte), and an additional 18–24 mL/min of nitrogen was added to the air supply. An efficient exhaust duct was positioned directly above the FPD flue. The photomultipliers were Hamamatsu tubes R 268 (bialkali, 300–650 nm, maximum response at 420 nm) and R 1104 (multialkali, 180–850 nm, maximum response at 420 nm) as indicated in the legends. Their output was amplified by two electrometers and displayed on a dual-channel strip chart recorder (all Shimadzu).

To obtain spectra from the detector, its flow conditions were first optimized for each element in the open (= no interference filter) mode. Then one of the FPD photomultiplier tubes was replaced by a Jarrell–Ash model 82-415 quarter-meter monochromator with a 1180 grooves/mm grating blazed for 500 nm, a pair of (usually) 2.1-mm slits, and the Hamamatsu R 1104 photomultiplier tube. When called for, a 500-nm cut-on filter was inserted into the optical path (at wavelength settings above 600 nm) in order to prevent second-order spectral interference. If the emission was too weak to be detected by the grating monochromator, a variable interference filter (Oriel model 7155 filter monochromator, range 400–700 nm) was used behind an infrared absorbing filter (Oriel 7165). Analytes in amounts corresponding to the upper end of their linear range were repeatedly injected while the wavelength drive was being manually advanced. The measurement of some weak spectra, particularly those of three different types of carbon compounds, was repeated a couple of months after the initial experiment, and again some time after that, to assess and assure adequate reproducibility.

Results and discussion

The responses of some easily available and sufficiently volatile and stable transition metal compounds were measured in the FPD. Several produced luminescence that was substantially more intense than could be expected from the analytes' carbon content. These analytes were the simple

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

bis(cyclopentadienyl) derivatives of nickel and cobalt, and carbonyls of rhenium and molybdenum. The metals are thus joining the roster of chromium (4), manganese (9), iron (6), ruthenium (7), and osmium (8), whose responses in the FPD had been previously described.

A variety of other transition metals produced only negligible response. (For this study, "negligible response" is roughly defined as less than ten times the expected carbon response.) We consider such negative results, obtained from compounds of Y, V, W, Zn, Cd, Hg, and Zr, much less conclusive than the positive results on which this study focusses. Conditions in the FPD may not have been suitable for these elements. Or some of the organometallics may have decomposed before reaching the detector. While the latter is immediately obvious when the expected peak *fails* to appear, the opposite effect, i.e., the presence of a peak commensurate with the carbon portion of the molecule, is ambiguous. Such a peak could have been caused by the formation of a non-metallic product from the decomposing analyte. Note that the lack of response from certain transition elements, as mentioned here, refers only to their behaviour in the cool and hydrogen-rich flame of the typical FPD. By no means does it imply that these metals would also fail to respond in, say, a conventional oxyhydrogen flame (which has occasionally been reviewed together with the FPD proper (1)).

Calibration curves

The most sensitive of the new analytes is nickel. This fact commands interest since nickel is an element of economic, environmental, and medical importance. Industrially as well as analytically, it is easily transformed into its highly volatile (and highly toxic) tetracarbonyl (11, 12). Figure 1 shows the calibration curve of bis(cyclopentadienyl)nickel, a compound that is less stable but safer to handle under exploratory circumstances.

Figure 1 also includes the calibration curves of the other new transition metal analytes. Each is the result of an individual, coarse optimization of flow conditions. All measurements are made in the non-dispersive mode. (Data on *dispersive* modes will be given in the companion manuscript (10)). In most cases, and particularly when the spectrum consists of broad bands of low intensity that stretch over an extended wavelength region, the open mode produces higher signal/noise ratios than the use of an interference filter.

(Note that an important criterion here seems to be the amount of light that reaches the phototube. This flux is obviously larger in the non-dispersive than in any dispersive mode, with the implication that types of noise other than that caused by the flame do play a role. To our knowledge, a thorough study of the origins and characteristics of noise in the FPD has never been done, despite the basic interest and potential benefit it would seem to offer.)

Minimum detectable limits can be read directly from this graph: at an ordinate value of 2 for the conventional measurement, at an ordinate value of 0.54 for the IUPAC definition, $S/\sigma = 3$. (The ordinate term "noise" refers here to the short-term peak-to-peak fluctuation of the baseline. For a more precise definition of noise and the detection limit, as well as for a discussion of the pros and cons of using "signal/noise" as the ordinate, refer to the later Note Added in Revision.) Since the GC column temperature was so chosen that each analyte eluted at about 2 min with a $2\sigma_{peak}$ close to 10 sec, these minimum detectable amounts (really: flows), at the more conservative $S/N = 2$ definition, vary from 1×10^{-14} mol/s for nickel to 3×10^{-12} mol/s for cobalt. Table 1 lists these values together with column temperatures and detector conditions. Included in Table 1 are also data for typical carbon compounds, as well as literature references to other transition elements. The assumption inherent in accepting as *elemental* detection limits numbers that were determined using only one compound of a thermally and (or) chemically labile nature, is that no significant decomposition occurred during gas chromatography. A further assumption is that the non-metal part of the analyte molecule did not significantly detract from, or contribute to, the response of the metal.

To allow a visual comparison without repeating information already in the literature, as well as to avoid cluttering up Fig. 1, the relative positions of Ru (7), Mn (9), Fe (6), and Os (8) responses are indicated at the bottom of the graph. The calibration curve for $Cr(CO)_6$ is shown in dashed form, since the flame photometric detection of chromium, as $Cr(tfa)_3$, was described in the literature many years ago. Our measurements are somewhat more sensitive than those found in the seminal work of Ross and Shafik (2.5 ng Cr at $S/N = 6.0$ (4)). However, they fall short by about a factor of two when compared with the minimum detectable amount reported by Burgett and Green (79 pg Cr at $S/N = 12.6$ (5)): in the units used by these authors, our minimum detectable amount is 24 pg Cr at $S/N = 2$.

The calibration curves for $Mo(CO)_6$ and $Co(C_5H_5)_2$ are barely beyond our working definition of significant metal response in the FPD, i.e., that of ten times the response expected from the molecule-sans-metal. Analytically, they are thus of only marginal interest. Here they are shown in dotted lines, for reasons that will become obvious during the later discussion of their spectra.

Spectra

The spectra will be considered in the order of overall intensity (innate sensitivity), i.e., following the calibration curves of Fig. 1 from left to right.

Nickel

One of the definitely interesting transition metal spectra is that of nickel (nickelocene). It is shown in Fig. 2. Unfortunately, most of its features must remain unassigned at this stage. This is due, in part, to the limited resolution available from an FPD emitter of only moderate strength. For reasons discussed earlier, the use of flame conditions optimized for spectral (as opposed to analytical) purposes, was considered inappropriate to this study.

The spectral feature centered at 345 nm, which appears to be slightly broader than the optical bandpath (6.7 nm), is, in our opinion, due to an accumulation of atomic lines. Many prominent Ni lines occur between, say, 335 and 355 nm (13), among them the strongest ones known from emission, absorption, and fluorescence spectrophotometry (14). If preference is given to strong transitions from/to the *ground* state, including states that exceed the ground state by no more than the ambient thermal (kinetic) energy, then the roster includes such lines as 341.476 nm (205–29481 cm^{-1}), 352.454 nm (205–28569 cm^{-1}), 346.165 nm (205–29084 cm^{-1}), 336.957 nm (0–29669 cm^{-1}), 339.105 nm (0–29481 cm^{-1}), and 343.728 nm (0–29084 cm^{-1}). The upper

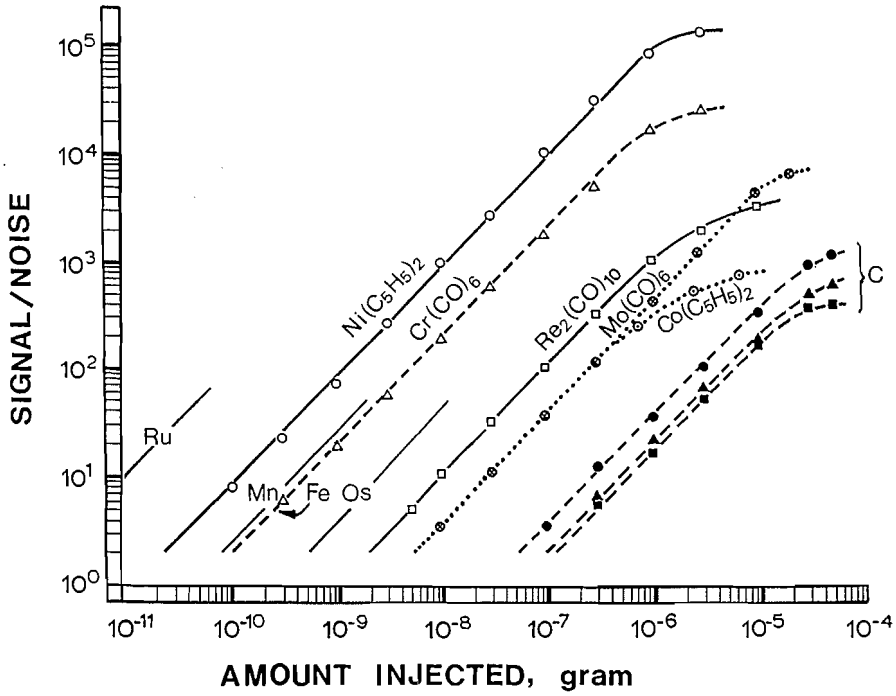

FIG. 1. Calibration curves of compounds containing transition elements, as well as carbon compounds without metals. The position in this graph of earlier reported curves is indicated only by a short section of their lower range: Ru = dicyclopentadienylruthenium (7); Mn = methylcyclopentadienylmanganesetricarbonyl (9); Fe = dicyclopentadienyliron (6) (coincident here with chromiumhexacarbonyl); Os = dicyclopentadienylosmium (8). Other organometallics are indicated by formula. C = carbon compound standards. From left to right: naphthalene, dodecane, di-*n*-hexyl ether. All spectra non-dispersive (no interference filter). Hamamatsu R 268 photomultiplier. Flow conditions as given in the experimental section and in Table 1.

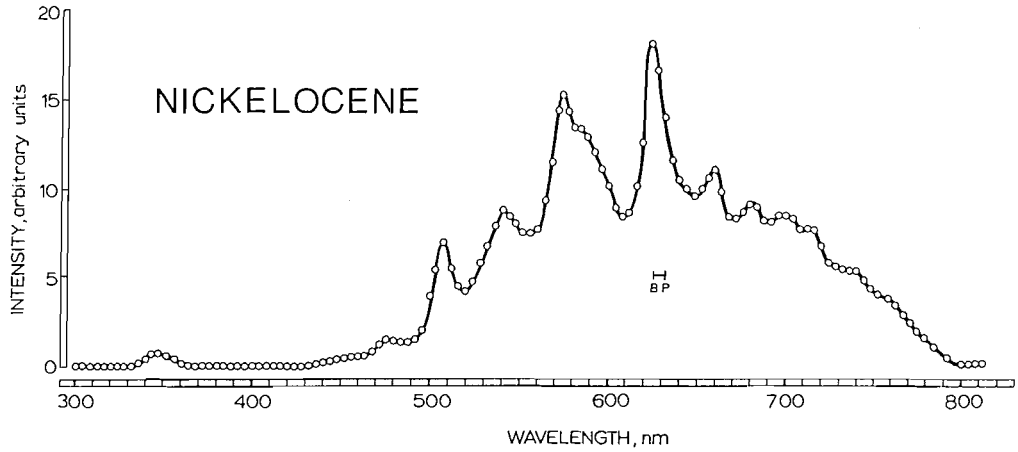

FIG. 2. Spectrum obtained by repeatedly injecting 500 ng of nickelocene under *analytically* optimized gas flows (300 mL/min H_2 and 55 mL/min air). Grating monochromator bandpass: 6.7 nm; photomultiplier tube: R 1104.

state energies are 3.66 and 3.54 eV for the two first-cited lines, as well as 3.68 eV for the line of highest energy whose presence could not be reasonably excluded. (Chemical exitation, for which these numbers are of interest, will be discussed later.)

The much more intense emission(s) between about 450 and 800 nm are puzzling. The literature lists several systems of NiO that occur in that region. The 0,0 transitions of NiO systems V and VI are given as 509.83 and 473.0 nm (15), i.e., at values that appear close to two of the maxima shown in Fig. 2. Judged from the spectrum, the 0,1 transition of System IV at 540.77 nm may be present (but then why not the 0,0 transition at 517.45 nm ?). Similarly, other bands representing these systems fail to appear in the low-resolution spectrum. Also, the overall appearance is quite different from, for instance, the NiO spectrum produced by the chemiluminescent reaction of $Ni(CO)_4$ with O_3 (12).

A quite plausible emitter for some of the sharper bands is NiH. Pearse and Gaydon list several systems. One of these, the "6257 Å system" (NiH $^2\Delta_{2\,1/2} \rightarrow {}^2\Delta_{2\,1/2}$), has strong 0,0 and 1,0 transitions that are close to the maxima of Fig. 2 at 626 and 574 nm (15). And the band shown at 507 nm may correspond to a NiH band mentioned by R. E. Smith (16). While no definitive assignment can be made under the circumstances, we believe that NiH and (with less justification) NiO should be considered as candidates for producing much of the emission in the visible.

Chromium

The spectrum from chromium (chromium hexacarbonyl) was checked because, even though the FPD response of chromium compounds had been known for quite some time and had been claimed to be "specific" with the use of a 425.4-nm interference filter (4), the corresponding FPD spectrum has, to our knowledge, never been reported. Even if it had, the fact that earlier studies were carried out on a Melpar FPD, while this study used a Shimadzu FPD, would have mandated a re-measurement of the chromium spectrum to serve the envisioned experiments on selectivity. The choice of the 425.4-nm interference filter in the seminal FPD paper (4) was obviously based on chromium's strongest emission line at 425.435 nm (actually, on the triplet at 425.435, 427.480, and 428.972 nm, given the bandpass typical of interference filters). This wavelength had been used previously for monitoring Cr emission from an oxyhydrogen torch (i.e., from a hot, oxygen-rich flame of 5.7 L/min H_2 and 39 L/min O_2) connected to a gas chromatograph (17). The choice of a 520-nm filter in the most sensitive FPD determination of Cr reported to date (5) may have been aimed at the strongest emission line in an air–hydrogen flame (520.604 nm (14)). Note, however, that this atomic transition (7593–26796 cm^{-1}), together with its triplet companions, does *not* involve the ground state and that, based on arguments made in this report, it is therefore unlikely to produce strong response in the FPD. (It is interesting to note, nevertheless, that its upper-level energy of 26796 cm^{-1} is *lower* than that of the most energetic line seen, i.e., 27935 cm^{-1} for the 357.869-nm line.)

The upper half of Fig. 3 displays the spectrum obtained under regular operating conditions of our FPD. As expected, it does *not* show the 520-nm line, but it does indeed include a distinct maximum centered at about 427 nm. This peak represents the earlier mentioned triplet, which is also easily observed in the conventional air–hydrogen flame (14). Another combination of three strong emission lines occurs at 357.869, 359.349, and 360.533 nm, with the resulting peak centered in our spectrum at 359 nm (the CrH bands around 368 do not seem to show up). There are no clearly assignable lines at higher energy.

Aside from these atomic emissions, the spectrum is dominated by some broad features of unknown origin. Not surprisingly, then, the minimum detectable limit of chromium hexacarbonyl is considerably better when using the "open" (non-dispersive) mode than when using an interference filter at 427 nm. Indeed, the most prominent spectral feature is located far away, i.e., between 670 and 750 nm (as seen by the red-extended phototube).

Aware of the case of iron (6), we became interested in possible spectral changes resulting from shifts in flame conditions. If such changes occur, the *individual* optimization of disparate emission features can serve purposes both analytical (e.g., increase selectivity) and spectral (e.g., yield information on the identity of the emitters).

In the case of chromium, however, the overall distribu-

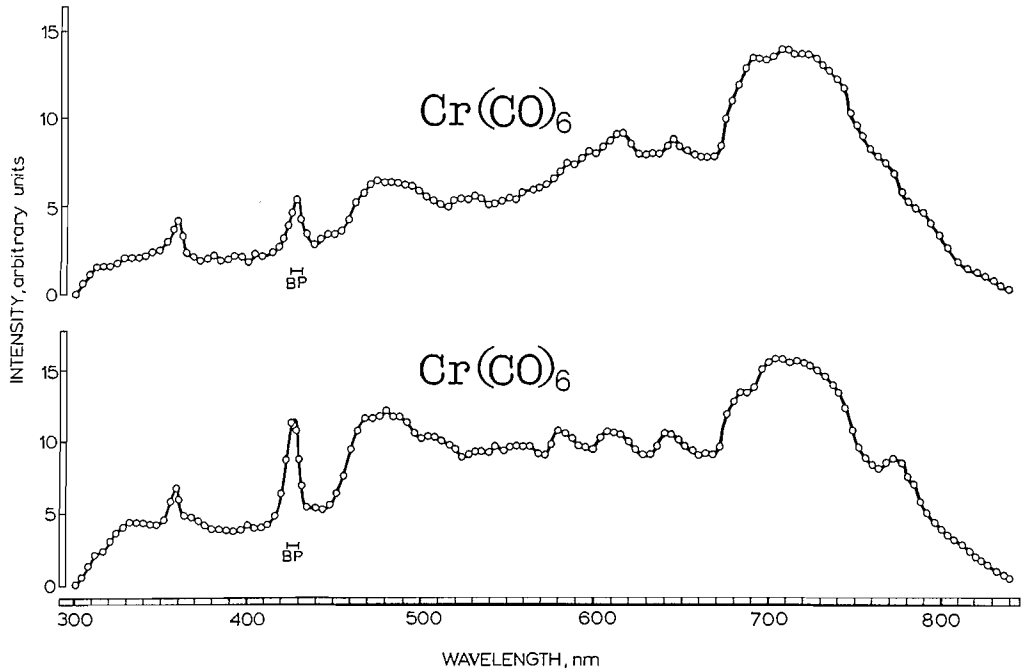

FIG. 3. Spectra obtained from chromium hexacarbonyl with R 1104 PMT and 2.1-mm slits (6.7 nm bandpass). A 500-nm cut-on filter was placed in front of the grating monochromator from 600 nm on to exclude the second order. Upper half: spectrum at regular flame condition (300 mL/min H_2 and 55 mL/min air); lower half: spectrum at stoichiometric flame conditions (50 mL/min H_2 and 125 mL/min air).

tion of the spectrum changes but little, and that within a very wide range of flame conditions. To document this with one out of several runs, the spectrum shown in the lower part of Fig. 3 was obtained from a stoichiometric flame. Not shown here, but in agreement with the conclusion given above, were runs with (*a*) a flame much hotter than usual, though still hydrogen-rich, and (*b*) a flame much cooler and so starved of oxygen as to hover near extinction. (The latter spectrum, because of its very low light level, had to be obtained within the much shorter range and lower dispersion of a filter monochromator.)

It may be mentioned that some of the smaller features, particularly in the hotter and more oxygen-rich flame, could possibly be attributed to CrO. The relevant heads are 579.44 (1,0), 605.16 (0,0), and 639.43 (0,1) nm (15).

The benefits of having available an FPD spectrum valid at *analytically* relevant conditions (top of Fig. 3) are obvious. It alone allows a reasonable choice of wavelength for optimization of response and, much more importantly, for optimization of selectivity vis-a-vis other FPD-active species (10). In this context, the initial literature choice of 425.4 nm as the central wavelength of an interference filter for chromium (with a presumed bandpass around 10 nm) is interesting in light of the fact that the largest response of carbon compounds also occurs in that spectral window (*vide infra*). The "specific" response for chromium at 425.4 nm (4) against the background, presumably mainly carbon compounds, relies therefore on the innate difference in luminescence intensity rather than on the wavelength at which the two emissions are compared. In fact, in our system — and different FPD's can differ greatly in this regard — the open mode produces a higher selectivity for chromium against aliphatic carbon than if that analysis had been carried out with the 425-nm interference filter in place. The reason is obvious from the two spectra obtained at analytical operating conditions.

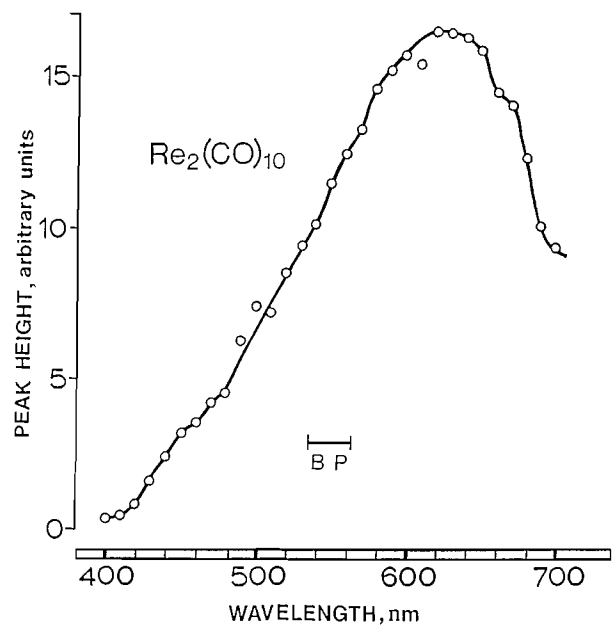

FIG. 4. Spectrum obtained from dirheniumdecacarbonyl at regular flame conditions. Filter monochromator with 4-mm slit and R 1104 PMT. Bandpass (specification) = 28 nm at 550 nm.

Rhenium

The spectrum of rhenium (dirheniumdecacarbonyl) under regular operating conditions is shown in Fig. 4. Rhenium is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

not a particularly strong emitter in the FPD and, furthermore, its spectrum is essentially continuous: two characteristics that necessitate use of the more sensitive but less versatile filter monochromator. The spectrum differs from rhenium spectra found in the literature. It is known, for instance, that Re is a "flame-greening" element (2) (whereas Fig. 4 suggests red). There is also little similarity between it and the continuum seen in a low-temperature hydrogen diffusion flame (18).

For reasons discussed in the cases of chromium and iron, and for the chance to use the higher resolution and wider wavelength range of the grating monochromator, a variety of hotter flames were tried that, while still hydrogen-rich, contained less hydrogen and more oxygen than the analytically optimized setting. Figure 5 shows the case for Re. Not surprisingly for such a heavy atom (cf. Os (8)), identifying features tend to be submerged in the broad continuum.

The resonant line of Re at 346.047 nm (3.58 eV) is not seen in the spectrum. (Note that the region from 300 to 400 nm was included in the measurement but proved blank.) Either there are too few free atoms present in the first place, or they fail to undergo chemical excitation, or excited atoms are not formed in chemiluminescent processes from di- or triatomic species, or molecular excitation pathways are energetically favored. The only known atomic transitions from *less* than 3.58 eV to/from the ground state, are located at 488.914 nm (2.54 eV) and 527.556 nm. Both are characterized as "cw" (complex and wide) in an arc (13), but are the strongest lines seen in emission from an oxyhydrogen flame (14). Both are absent from this spectrum; however, yet another spectrum from a still hotter flame (not shown here) contained, superimposed on the continuum, some very minor features at these two wavelengths.

The spectrum shown in Fig. 5 for Re is similar in general appearance to that shown in Fig. 3 for Cr, and to those reported earlier for Os (8) and perhaps also for Fe (6). Similar to these other elements, the case can be made here as well that oxides may be involved (for instance, a series of ReO bands is known to occur between 606 and 609 nm (15)). However, the main contribution to response originates from the unassigned continuum.

Molybdenum

Figures 6 and 7 show the spectra obtained from repeatedly injecting $Mo(CO)_6$ and $Co(C_5H_5)_2$. In the calibration curves presented in Fig. 1, response from these two analytes is displayed by dotted lines. The reason for that visual caveat is that we question whether the recorded spectra are, in fact, due to emission from species containing these metals. Our scepticism is based not only on the weakness of response, which is relatively close to the response of carbon compounds, but also on certain spectral features.

The most prominent feature of the molybdenum spectrum shown in Fig. 6 is the relatively sharp peak around 420 nm. There are two prominent atomic lines for Mo in the vicinity, i.e., at 414.355 and 418.832 nm. However, the energy levels for these transitions are apparently in question (13), and it is thus unlikely that they represent transitions to/from the ground state. Also, MoO is very refractory. Owing to the prevailing low light level, we did not separately check for the possible presence of, for instance, the prominent lines 386.411 nm (0–25872 cm^{-1}, 3.21 eV) and 390.296 nm (0–25614 cm^{-1}).

A look at the calibration curves shows that, on a weight basis, the molybdenum compound is only about one order of magnitude larger in response than a typical aromatic carbon compound. However, the spectral measurements demonstrate that the luminescence from molybdenum hexacarbonyl at 420 nm is about ten times stronger than the luminescence obtained from a commensurate amount of naphthalene. Thus it appears that the spectrum shown does indeed contain most of the luminescence that established the calibration curve (note the difference in wavelength range between the calibration curve and the spectrum!). Our own preference is that response is indeed provided by a Mo-containing emitter. However, the formal possibility of carbonaceous emission being enhanced (catalyzed) by the presence of molybdenum is not precluded by the experiment.

Cobalt

Similar arguments can be made in the case of Co (here in the form of dicyclopentadienylcobalt) whose spectrum is shown in Fig. 7. It is even more suggestive of an aromatic

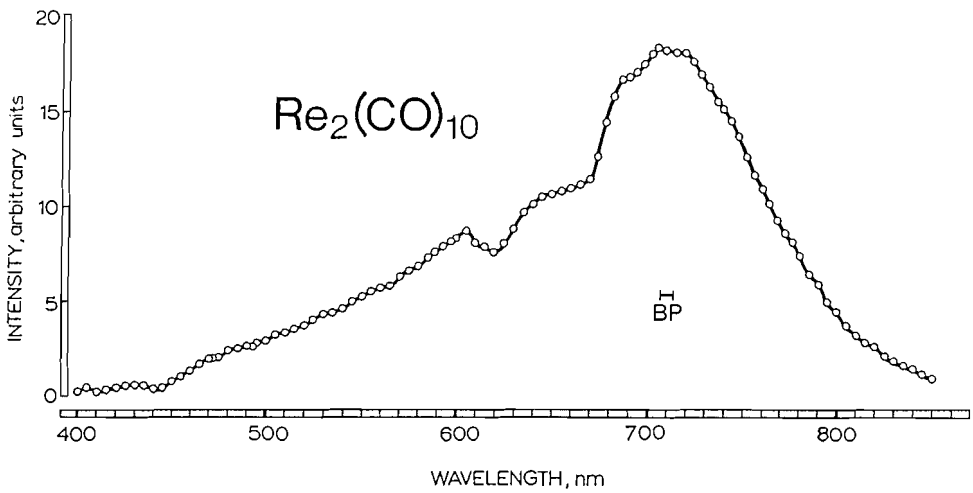

FIG. 5. Spectrum obtained from dirheniumdecacarbonyl in a hotter but still hydrogen-rich flame. Hydrogen: 120 mL/min; air: 125 mL/min. Grating monochromator bandpass: 6.7 nm; PMT: R 1104.

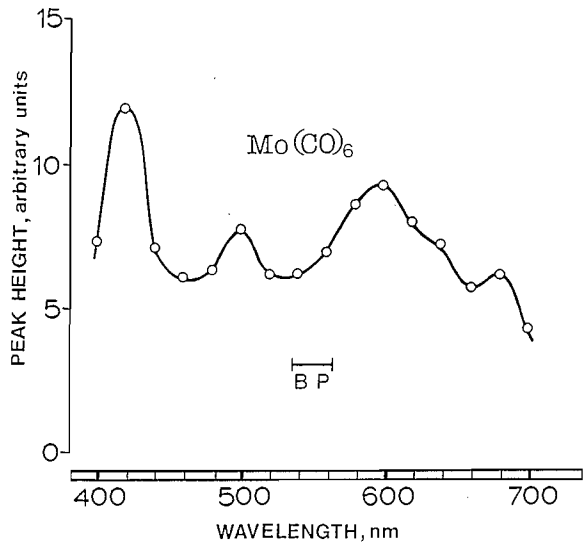

FIG. 6. Spectrum obtained from molybdenum hexacarbonyl at regular flame conditions through a filter monochromator equipped with 4-mm slit and R 1104 photomultiplier.

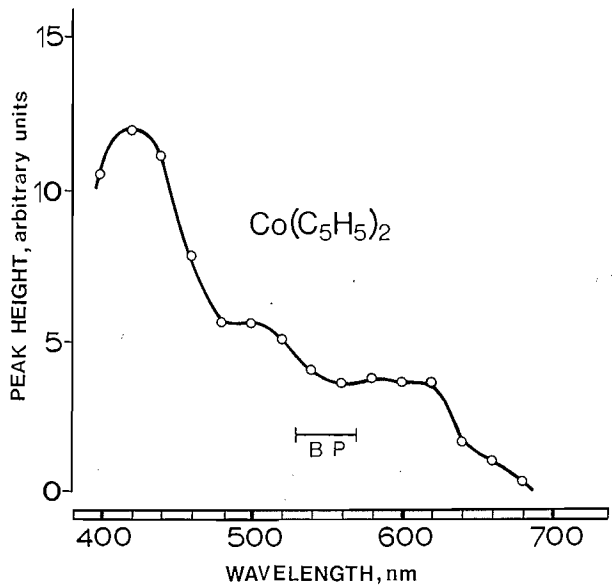

FIG. 7. Spectrum obtained from dicyclopentadienylcobalt under regular flame conditions. Filter monochromator with R 1104 PMT and 6-mm slit.

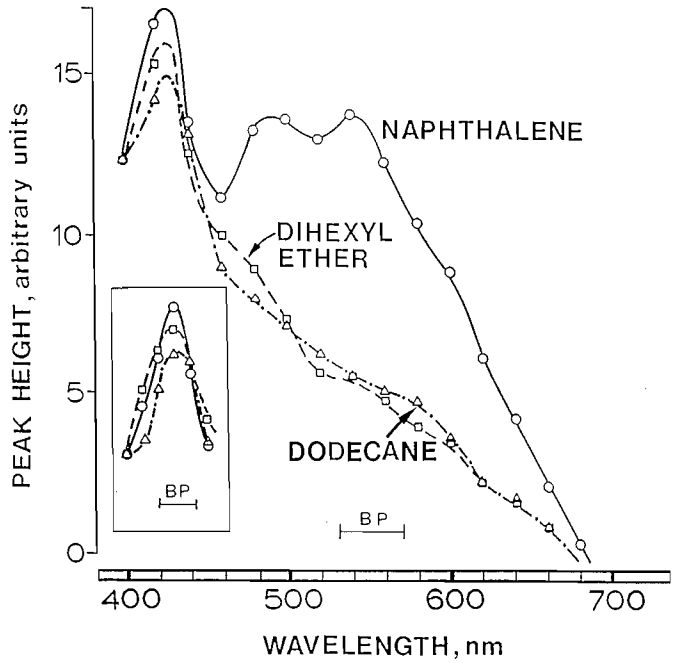

FIG. 8. Spectra obtained from naphthalene (solid line), di-*n*-hexyl ether (dashes), and dodecane (dashes and dots) with a filter monochromator using a 6-mm slit and an R 1104 photomultiplier. Flame conditions: 300 mL/min H_2 and 60 mL/min air. Bandpass: 30 nm at 550 nm. Rectangular insert: Same conditions but 4-mm slit.

hydrocarbon (see below) than that of molybdenum. In the region of the blue maximum there are two cobalt lines involving the ground state, namely 419.071 nm (0–23856 cm^{-1}) and 423.400 nm (0–23612 cm^{-1}) (13). However, these lines are very weak in other systems and, furthermore, one would have expected that, if atomic excitation were occurring, the very strong lines around 350 nm (13, 14) should have been observed in the form of a stronger overall response for Co (the lines are outside the range of the filter monochromator but are included in the open mode of the FPD calibration curve). It may also be mentioned that one of the R heads of CoH is situated at 419.45 nm (but the other, for the 0,0 transition, is located at 448.19 nm!) (16). More reasonable than invoking such spectral features may be to assume that the emission observed within the 400–700 nm range of the filter monochromator is dominated by carbon-based response. If so, this would suggest either that there occurs significant luminescence from cobalt-containing species outside this range, or that the presence of cobalt somehow stimulates carbonaceous emission(s). A comparison of the absolute magnitude of suitable spectra suggests, but does not prove, the former alternative, i.e., that there may indeed exist further uncharted Co emissions.

Both cobalt- and molybdenum-derived emissions could be further investigated. However, because of their low sensitivity and hence minor analytical importance in the FPD, the matter was dropped.

Carbon compounds

Of greater interest are the spectra obtained from carbon compounds themselves, since the latter constitute the major components of many samples wherein trace amounts of organometallics need to be determined. To our knowledge, no literature source describes such spectra as obtained from an FPD at conventional operating conditions. (Spectra from carbon-containing emitters in much hotter and oxygen-rich H_2/O_2 and H_2/air flames are, however, discussed in various papers (e.g., refs. 20–25).) Besides, weak FPD responses are particularly likely to vary with differences in detector construction, condition, and contamination. And, until the *analytically* relevant spectra are known, it is difficult to establish conditions for optimal selectivity (other than by a rather time-consuming trial-and-error approach).

Figure 8 shows the luminescence spectra obtained from three standard carbon compounds (an alkane, an aliphatic ether, and an aromatic) at regular FPD operating conditions. The three compounds were injected *as a mixture* in order to keep the relative amounts precisely the same. Sim-

ilar spectra were obtained from experiments repeated over the course of several months.

It is well-known that aromatics respond stronger in the FPD than aliphatics. The data shown in Fig. 8 demonstrate that this is due to a partly different (not just a proportionally enhanced) spectrum. There is little agreement between these spectra and the carbon-based emissions from oxyhydrogen flames (20–25), except for the seemingly common peak at 430 nm. In the oxyhydrogen flames this peak clearly represents CH, with the 0,0 transition of $CH(A^2\Delta–X^2\pi)$ located at 431.42 nm (15). As shown in Fig. 8, the peak apex was rescanned, at the highest resolution obtainable at this low light level. Within the considerable error limits of such a measurement, the maximum is indeed located at that wavelength. Our motivation for rechecking the region was related not only to its obvious analytical importance, but also to our suspicion that some or all of the FPD luminescence found there may originate from excited formaldehyde ("Emeleus's cool flame spectrum," occurring "in the cool flame of ether, acetaldehyde, hexane and other organic substances" (15)). However, the very low light level characteristic of typical FPD settings prevents an experimental assessment of the relevant contributions from CH and CH_2O.

In oxyhydrogen flames, the second most common spectral feature is C_2 ($A^3\pi_g–X'^3\pi_u$), i.e., the Swan bands (15). Prominently visible is usually the 0,0 transition (head at 516.52 nm), accompanied by the 0,1 (563.55 nm) and 1,0 (473.71 nm) transitions. Aside from the measurement shown in Fig. 8, a larger number of spectra were obtained at different times and with different compounds. In none of these did the Swan bands show up unambiguously, although they could, of course, be present. The low light levels involved, and the differences between different carbon structures at wavelengths longer than, say, 460 nm, make this a difficult question to investigate. Aside from CH, and perhaps CH_2O and C_2, the luminescence does not appear to fit any other known carbonaceous emitters. While thus not overly revealing in a spectroscopic context, knowledge of the carbon-related spectra is of considerable value for improving analytical selectivity (10).

Speculations

Some response patterns do appear to show up among the well-responding transition metals. We shall speculate on two of these: the apparent energy limitation of atomic lines, and the ostensible similarity of spectral continua.

Atomic lines

Of the elements covered in this study, only chromium shows clear evidence of atomic lines. For nickel the evidence is, literally, much weaker, and there is no experimental basis for assuming lines to be present in the spectrum from rhenium (or in the ambiguous spectra from molybdenum and cobalt). Table 2 lists the relevant wavelengths of Cr and Ni, together with data of Mn, Fe, and Ru from earlier studies. The atomic lines are particularly pronounced in the cases of Mn and Fe, where they even represent the spectral feature preferred for analysis.

Unfortunately, the extremely low light levels from an FPD run at conventional conditions prevent conclusive high-resolution measurements to be made. Therefore, the case for atomic lines must rest primarily on the agreement of experimental wavelengths with literature values. Given (*a*) the typical condition of a low-temperature FPD flame; (*b*) the experimental evidence that most of the presumedly atomic emissions increase but little in intensity with large increases in flame temperature; and (*c*) the fact that, in contrast to high-temperature AES sources, some metals emit very strongly while others emit only very weakly (if indeed at all), it follows that the excitation cannot simply be ascribed to a thermal process. Furthermore, the reasonable alternative, i.e., the occurrence of chemiluminescence, is consistent with the presence of very *few* lines and, more revealingly, with the detector's preference for those lines that represent transitions from/to the ground state (perhaps including easily accessible levels within the prevailing thermal (kinetic) energy of about 0.1 eV).

TABLE 2. Evidence for atomic lines in FPD spectra

Element	Wavelength (nm)	Reference
Ni	340–355	This paper
Cr	357–360, 425–430	This paper
Mn	403, (540)	9
Fe	344, 373, 387	6
Ru	350, 373, 380	7

If so, then the question arises as to the amount of energy that is being provided by the chemiluminescent process. Just for reference, the (in the context of luminescence) often invoked recombination of hydrogen atoms yields 4.5 eV, while the formation of water from H and OH produces 5.1 eV.

The following comparison will list the shortest wavelengths at which emission from atomic lines is still manifest in the spectra, together with "reasonable" lines of slightly higher energy where it is not. Our criteria for calling a line "reasonable" are strong response in other systems (arc, oxyhydrogen flame, etc.) and the involvement of the ground state. Individually, any one of the deductions resulting from such vague criteria is highly questionable. Cumulatively, however, their similarities enhance one another and thus confer some credibility on the results.

The better responding metals that do display atomic response are Mn (9), Fe (6), Cr, Ru (7), and Ni; the ones that do not are Re and Os (8). Although the FPD-active metals are too few to be definitively classified in terms of their excitation/emission processes and the associated intensity of luminescence, it appears that the strongest responding metals display dominant molecular bands (Ru, Ni), followed by those that show prevailing atomic lines (Mn, Fe, and to a lesser extent Cr), followed by those that produce massive continua (Re, Os, and again, Cr).

Which are the lines of highest energy that do show up, and which are the (reasonable) ones of still higher energy that do not? Manganese emits at 403 nm (3.1 eV), but the next prominent line at 280 nm (4.4 eV) is not seen (and neither is a weak ground-state transition at 322 nm, i.e., at 3.9 eV) (9). Iron emits strongly at 344 nm (3.6 eV), but a weak line at 319 nm (3.9 eV) and a much stronger one at 302 nm (4.1 eV) are not present (6). The most energetic chromium line in the FPD spectrum occurs at 358 nm (3.5 eV), with no reasonably strong lines expected in its vicinity. In ruthenium, the 350-nm line is in evidence but the 343-nm line is not (7). Given that resolution and calibration in that particular experiment were of sufficient quality, this means that 3.55 eV shows up but 3.61 eV does not (there are no

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

prominent ground-state transitions close by at higher energies). The most energetic line of nickel that cannot be excluded on spectral evidence is at 355 nm (3.7 eV), but it occurs close to the edge of a broader spectral feature that is preferably assigned to the 341- and 352-nm lines (3.6 and 3.5 eV). The closest reasonable line that clearly fails to appear is that at 323 nm (3.8 eV).

It thus seems that, where atomic lines do show up, *3.6 eV is the approximate energy limit*. Several cases of metals mentioned above argue for that limit and none clearly contradicts it. However, to assume the same upper limit for all metals is tantamount to suggesting that a single particular reaction may drive the various atomic excitation processes (or that some very efficient reaction quenches all emissions above it). No prominent flame gas reaction yielding 3.6 eV comes immediately to mind. The recombination of hydrogen atoms, a prime candidate considering the type of flame and the evidence of the literature on a variety of flame systems, produces 4.5 eV. But why, then, is none of the possible lines in evidence between 340 and 300 nm, a region that was scanned for all strongly responding elements? Of course this could be happenstance: too little is known about excitation process(es) to predict whether or not a particular line could or should show up. Also, the formation of refractory species may have depleted the free atom concentration of certain metals. Or, the recombination of hydrogen atoms may have occurred not via the most straightforward route

$$H + H + Me \rightarrow H_2 + Me^*$$

but via such routes as

$$MeH + H \rightarrow H_2 + Me^*$$

(but note the differing MeH bond energies!). Other high-energy radical recombinations could be involved. Obviously, though, these are not the only scenarios possible.

Continua

Apparent similarities among elements show up not only in atomic emissions but also in the extended continua that figure prominently in the spectra obtained from Re, Cr, Os (8), and, perhaps, Fe (6) compounds. To illustrate this similarity, Fig. 9 repeats and compares spectra involving three elements monitored by the same, red-extended phototube (though at slightly different flame conditions).

In the earlier discussion of these spectra, we mentioned cases that possibly involved oxide bands. However, MeO emissions alone could hardly explain these commanding continua that peak in the red and near infrared (and may reach beyond the photomultiplier's upper wavelength limit).

The process by which these spectra were procured (i.e., by measuring the peak height of compounds injected into the gas chromatograph) circumvents any influence of the solvent or the flame itself, unless, of course, the analyte were so massive in amount or so catalytic in nature that it could seriously alter the general chemistry of the flame.

Hence, if one is to speculate on the origin of these continua, metal-containing species are prime suspects. Although, and because, there is no hard evidence available on this question, we would like to mention the possible presence of small aggregates of metal atoms (with or without other atoms such as O and H). Continua involving various elements in the flame have been repeatedly ascribed to hot oxide particles (27). It is true that blackbody radiation, at temperatures typical of the FPD, is very weak and that its maximum occurs at considerably longer wavelengths. Yet very *small* particles can reportedly shift that spectrum toward the blue. Furthermore, the luminescence of solid bodies can be driven or enhanced by flame radicals. A well-known example of this is the Welsbach mantle, which involves (additional) heating of a solid surface by the recombination of hydrogen atoms (19).

It would thus be conceivable that *small, analyte-derived aggregates,* perhaps acting as catalysts for flame processes and hence offering higher temperatures for excitation, could produce the observed continua. A possible argument against this scenario is the linearity of the calibration curve: considering the low concentration and the short residence time of the analyte in the flame, the size of (and hence the light yield per metal atom from) the very small particles should vary considerably within the wide concentration range covered by the calibration curves. (Obviously, this argument ignores the influence that parameters other than concentration could exert on particle size. As well, it neglects the possible recycling of particles by eddies in the detector chamber, the conceivable temporary coating of detector walls, and a host of other easily imaginable processes.) Consequently, any significant role for the emission of light from small particles must remain an object of speculation: a more conventional interpretation of the obtained spectra is certainly possible.

NOTE ADDED IN REVISION:

One reviewer of this manuscript requested (*a*) that "a perspective of the current usage of ICP's and MIP's as detectors for GC should be presented and briefly compared to the FPD capability presented here," and (*b*) that the term "noise" be closer defined and the use of the "signal/noise" ordinate in Fig. 1 be justified. Both requests touch on topics that range more widely and are of a more basic nature than the current manuscript. We are therefore pleased to comply.

(a) A comparison of the FPD with ICP's and MIP's as GC detectors

This comparison juxtaposes instruments not only of a very different level of complexity, but also of a very different nature. In attempting to correlate that nature to their analytical utility (a correlation necessary because practical experience is incomplete on both sides) we shall consider only transition elements, particularly those mentioned in this paper and its companion (10). Also, since the referee's request was limited to the ICP and MIP, we will not compare atomic absorption (cf. ref. 28), mass spectrometry, or any other type of detection device.

The combination of gas chromatography with various instruments of atomic spectroscopy has been reviewed in considerable detail (28). Both the microwave-induced plasma (MIP) and the inductively coupled plasma (ICP) are high-energy sources in which excitation temperatures exceed the already high kinetic temperatures. Consequently they are very bright — capable, it seems safe to predict, of exciting atomic lines from *all* the transition elements. In the ICP, the detection limits of most transition metals are contained within only two orders of magnitude [cf. ref. 29]. In contrast, FPD response to transition metals varies over at least five orders of magnitude ("at least" because the chromatographically necessary presence of carbon limits the experimental determination of that number). In practice that means that the FPD can be considered *un*responsive to many of the transitior

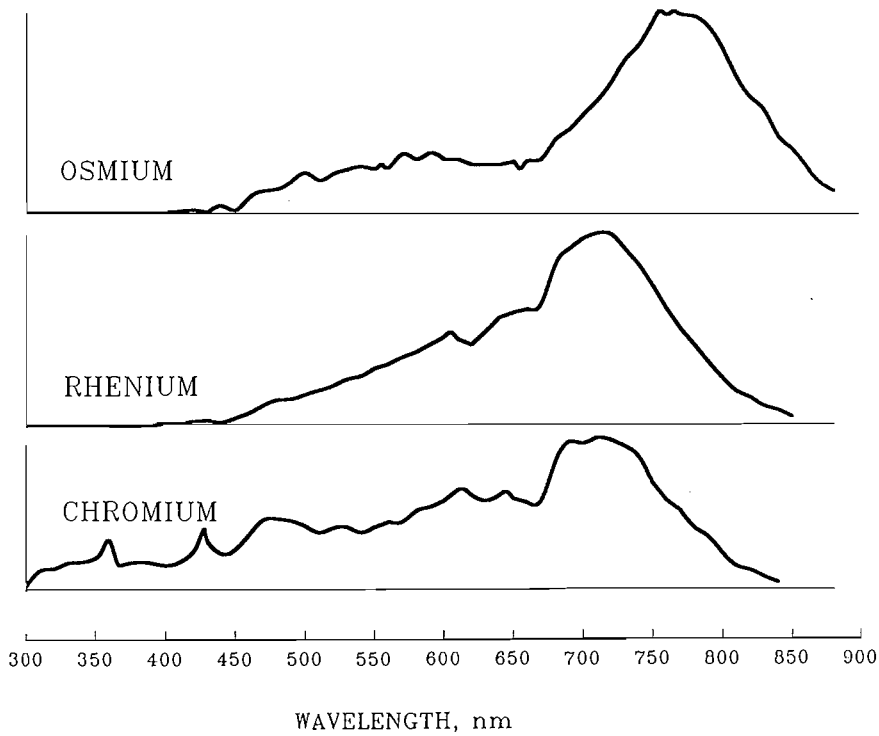

FIG. 9. Similarity of three continua: vertically offset spectra from compounds of osmium (8), rhenium (Fig. 5), and chromium (upper part of Fig. 3).

For personal use only.

elements. This is not surprising: for response in the low-temperature FPD, a suitable chemiluminescent excitation mechanism has to exist. The FPD is hence far more limited (selective) in the choice of suitable analytes.

The transition elements to which the FPD has been shown to respond reasonably well are Ru (7), Ni, Mn (9), Fe (6), Cr (4, 5), Os (8), and Re. Their detection limits still vary (under the same analytical conditions) by three orders of magnitude (see Fig. 1). The priority of performance criteria must depend on the task and training of the analyst, but it can be argued that in this area "sensitivity may rightly be seen as the major problem" (28).

The most popular and, it seems, overall most sensitive of the plasma techniques is the MIP. This is also the one technique by which transition metal analytes similar to ours have been tested (30), and where a commercial instrument has recently become available (31).

Ruthenium, the best responding transition element in the FPD, has an S/N = 2 detection limit of 7.8 pg/s in the MIP (30). In comparison, the FPD detection limit is 0.1 pg/s at the optimized conditions of the original study (7), and 0.4 pg/s at the generalized conditions of the present work (10). Among the transition elements first described as FPD-active in this manuscript, the best responding and probably most important one is nickel. Its detection limit in the FPD is 0.4 pg/s (10), as compared to 2.6 pg/s in the MIP (30). In similar comparisons, chromium appears to respond more strongly in the FPD, manganese response is comparable, and iron responds clearly more weakly than in the MIP (30). The plasma techniques would also be decidedly more sensitive to osmium (30) and, we presume, rhenium (no GC–MIP data available). That ends the current list of reasonable analytes in the FPD. There do exist more transition elements that have been shown to respond well in the GC–MIP but apparently fail to do so in the GC–FPD, such as Co, Cu, and Zn (28). Many more would obviously respond if suitable test compounds were to be injected into a GC–MIP.

In other words, the elements that respond best in the FPD also display greater sensitivity there than in the MIP (as well as in the ICP and DCP); a few more elements are comparable in sensitivity in the two instruments, and for the rest the FPD response is either clearly inferior, or practically non-existent, or unexplored. This typically "selective" behaviour of the FPD vis-a-vis the "general" behaviour of MIP and ICP concurs with our perception of their respective excitation modes.

For the group of elements where the FPD can reasonably compete (Ru, Ni, Mn, Cr, Fe), the selectivity ratios against carbon vary in the MIP form from 6.47×10^3 for Ni to 2.80×10^5 for Fe (30). Note that the newer commercial MIP system claims a general improvement in selectivities "by more than an order of magnitude (through) the use of appropriate reagent gases, the water-cooled thin-walled discharge tube and, most importantly, real-time multipoint background correction..." (31). While the experiments of that particular study are restricted to main-group elements, the quoted conclusion may as well be valid for transition metals. In the FPD, single-channel selectivity ratios against carbon (as in dodecane) vary from 4×10^4 for Mn and Fe to 7×10^5 for Ru in non-dispersive, and from 5×10^4 for Cr to 4×10^6 for Ru in dispersive (interference filter) mode (10). *Dual*-channel FPD modes generally increase these selectivity ratios further by one to two orders of magnitude (10). Hence, for those metals to which it responds well, the FPD appears superior in selectivity to the plasma detectors.

Yet, this statement requires the addition of an important caveat. "Selectivity" in hyphenated GC detector systems is traditionally understood to mean the selectivity of a hetero-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

element versus *carbon*; this is the only specification generally accepted and commonly determined for the GC–MIP, GC–ICP, etc. (refs. 30, 31, etc.). However, selectivity in the FPD arises from different causes than in the MIP, ICP, DCP, etc. Selectivity in the FPD is primarily a function of relative photon yields from different elements, while in the MIP *et al.* it is primarily a function of spectral resolution and background correction. Hence, metal/carbon selectivity ratios are very high in the FPD simply because its response to a typical hydrocarbonaceous test compound such as dodecane happens to be very low. However, metal/metal selectivities could be a different matter altogether because plasma instruments (*a*) monitor line emission exclusively and with superior spectral resolution, and (*b*) use sources in which most elements radiate well and with comparable intensity. Some metal/metal selectivities in the FPD are given in the companion paper (10): many of these fall between one and two orders of magnitude in single-channel mode, with another one to three orders added by dual-channel operation. In our opinion (and we know of no relevant experiments concerning this point) the high-energy, high-resolution sources should be able to do better.

A further detector criterion is the linear range. Typical values in the MIP are three orders of magnitude (30), while in the FPD they span four orders or more (see refs. 7 and 9, and Fig. 1). Although the FPD's performance is clearly better here, we do not consider linear range an overly important criterion.

On still other analytical criteria, little information exists about transition metals in the two types of detectors. We are therefore forced to speculate on the basis of general principles.

The detector speed (resistance to peak broadening) should be somewhat better in the FPD than in the MIP or ICP due to the short residence time (less than 1 ms) in the very small FPD flame. However, capillary peaks of very low chromatographic dispersion have been reported from the two high-power sources. The quartz tube used in the MIP may lead to some sample hold-up (plus other problems), but this can usually be ameliorated by changing the chemical composition of the plasma. Thus speed is not likely to become a decisive criterion for choosing one or the other type of instrument.

A similar statement can be made about quantitation and long-term reproducibility. These are better in the FPD as judged by its much better track record over many years. However, the high-power sources should still be capable of adequate performance, particularly when used with internal standards.

As already mentioned, the range of applicability to different elements must be far wider in the high-energy sources. The FPD is valuable for some metals and worthless for others. The ICP (sans GC) can be easily used for aqueous samples; this is not practicable with commercial MIP or FPD models. If equipped with polychromatic readouts, both the ICP and the MIP are capable of producing several selective chromatograms from one separation. A dual-channel FPD with data acquisition by computer is capable of similar results (though by electronic, not spectral, means — and with a certain time delay for each chromatogram (10, 32)).

The FPD is, in the best sense of the word, a workhorse. In regard to the important analytical criteria of simplicity and ruggedness, it is patently preferable to the plasma systems. Its "prestige" is lower but so is its price: a simple, single-channel GC–FPD model can be had for under $10K, and it can be operated much more cheaply than the plasma systems, particularly the ICP.

In summary then, and with the understanding that all scores on this issue are by no means in, the FPD is cheaper, simpler, faster, and more reliable than the plasma sources. For a selected, small number of transition elements (Ru, Ni, Cr, Mn) it is of comparable or better sensitivity, selectivity (against carbon), and linear range. It may be marginally suited for a few more metals (Fe, Os, Re), but it is unsuited for several other transition elements for which the high-energy sources should provide good response.

(b) Noise and signal/noise

In accordance with its chromatographic origin, "noise" is defined in this manuscript as the short-term peak-to-peak fluctuation of the baseline. The critical problem here is whether ostensible outliers (signal spikes that are considered non-random, as caused for instance by a diatomaceous particle entering the flame) are to be included; and how short "short-term" should be (note that the result of peak-to-peak measurements of white noise increases with the time period covered). Most chromatographers will liberally exclude outliers; and they will measure over a time/distance that, to them, would include "flicker" but exclude "drift." Usually, that will involve one to ten base widths of an analyte peak. This graphic assessment is simpler to learn and use than to describe; but it is second nature to every chromatographer. It is also surprisingly reproducible in intra- (and, we presume, inter-) laboratory practice, despite being an overtly "subjective" measurement.

Various presumedly "objective" measurements have been described in the literature. They usually consider noise to be random and hence employ the normal (Gaussian) distribution to quantify it. Since the standard deviation (sigma, σ) can be easily and precisely calculated, once data points are stored in a computer and agreement exists on how many and (or) which ones to use, this approach seems preferable. If computer storage (or a suitable RMS meter) is not available, statistical methods based on recorder traces can be used (33). IUPAC recommends a detection limit of $S/\sigma = 3$ (ref. 34, cf. ref. 35), and nowadays its use is often requested by reviewers and editors.

In anticipation of such requests, our in-house computer program CHROM (10) offers a routine called SIGMA. It calculates the standard deviation, σ, of the baseline noise within user-defined time limits (and after removing drift from the baseline, if necessary). It is also capable, though with less accuracy, to calculate σ for fast noise superimposed on a considerably slower peak. We will be using it here to address the important points made by the reviewer.

Since the value of σ appears almost instantaneously on the CRT, it was easy for us to compare many baseline segments of varying duration. They were taken from several isothermal chromatograms (typical length: 20–25 min) that display from 10 to 20 peaks each or, as especially produced for the occasion, show only noise of different intensity. In the CHROM program, data points are taken every tenth of a second. For this additional study, the SIGMA routine was used on baseline segments 10–200 s long (i.e., 100–2000 data points were considered per calculation). Each original chromatogram was sent to a strip-chart recorder (with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

damping off) and the peak-to-peak noise (with disregard for outliers) was graphically determined for the same time segments as examined by the computer.

Isothermal chromatograms are assumed to display constant noise levels throughout. Hence, in an ideal case, the σ values should remain constant while the peak-to-peak distances should increase slightly with the length of the chosen time span. In the experiments, six measurements of 10–60 s duration were taken of the peak-containing chromatograms and seven measurements of 10–200 s duration were taken of the noise-only chromatograms. The objective was to determine the variability of (*a*) the σ values and (*b*) the peak-to-peak noise values; to compare these variabilities; and then to determine the mutual conversion factor, and its variability, within and among the chromatograms. It should be noted that neither the computer-derived σ value nor the graphically determined peak-to-peak noise is a wholly objective measurement, but the latter does admittedly contain more subjective components than the former.

The experiment brought very clear results. The variability of the σ data within each chromatogram was somewhat less than that of the peak-to-peak data; the former ranging from 7 to 14% and the latter from 13 to 16% relative standard deviation. This means that the FPD's short-term noise was fairly constant and that the measurements were well reproducible. The conversion factor, i.e., the ratio of the graphically derived peak-to-peak distance to the computer-determined standard deviation, was calculated for each pair of measurements. It showed similar variability within and among chromatograms: the latter number, based on 27 data pairs, was 5.5 ± 0.4. This variability of only 7% RSD means that the two types of noise measurement can be reliably correlated (though formally only for *our* particular measurement techniques and circumstances).

If "our" noise did indeed conform to a normal distribution, a range of 5.5 standard deviations would include 99.4% of all data points. (If presumed outliers had been included, the number would have been somewhat higher and more dependent on the chosen time span.) This is close to the estimate, commonly employed in spectrophotometry, that σ (the root-mean-square noise) equals one-fifth of the peak-to-peak noise (ref. 36, cf. refs. 37, 38).

In this manuscript we used the ASTM definition commonly agreed upon in chromatography, namely that the minimum detectable amount has a signal/noise ratio of 2, with noise being defined as the short-term peak-to-peak fluctuation of the baseline (outliers disregarded). If we followed IUPAC (ref. 34, cf. ref. 35) recommendations, the limit of detection would be defined as three times the standard deviation of the blank. (Note, however, that IUPAC's LOD concept was developed based on spectroscopic, as opposed to chromatographic, precepts; and that it was designed to evaluate whole analytical procedures, not mere detector performance.) Its use for chromatographic measurements is not a trivial matter and has therefore been questioned (39). If our $N_{p\text{-}t\text{-}p}/\sigma$ ratio equals 5.5, then our minimum detectable amount determined at $S/N_{p\text{-}t\text{-}p} = 2$ involves 11 σ units and is therefore 3.7 times higher than the IUPAC $S/\sigma = 3$ limit of detection. In other words, the IUPAC recommended LOD values could be read from the (linearly extrapolated) calibration curves of Fig. 1 at an ordinate value of $S/N = 0.54$. While this number applies rigorously only to our own particular instruments and procedures, it should not be far from typical.

Thus we could reliably convert the $S/N_{p\text{-}t\text{-}p} = 2$ minimum detectable amounts determined in this paper to the IUPAC $S/\sigma = 3$ limits of detection based on random noise. (That this noise was truly random has not, however, been established!) For practical purposes, though, it still seems reasonable to stick with the initial data. First, the $S/N_{p\text{-}t\text{-}p} = 2$ definition is almost universally accepted among chromatographers, and its use therefore allows the widest comparison with literature data. Second, it is easily carried out on a recorder chart and does not require the services of an appropriately programmed computer. Third, its reproducibility, at least in our experience, is very good, close to that of the computer calculation. This is as far as this manuscript can go: for a more general comparison, such aspects as noise distributions resulting from different types of detectors, effects of ancillary electronic instruments (electrometer, recorder), effects of chromatographic parameters, etc., would all have to be considered.

Figure 1 uses the unconventional ordinate unit "signal/noise." Our reviewer pointed out, and correctly so, that plain "signal" is the *y*-axis most frequently used in spectrophotometry, and that confusion should be avoided between the true S/N ratio of, say, an atomic absorption signal, where N refers to noise measured on the *signal*, and the S/N ratio conventionally given for gas chromatographic peaks, where N refers to noise measured (usually of necessity) on the *baseline*.

First, where is noise best measured? Chromatographic peaks, in contrast to AA signals, do not lend themselves well to the measurement of superimposed noise. The SIGMA routine mentioned above was used to estimate noise on peaks that were close to the $S/N_{p\text{-}t\text{-}p} = 2$ detectability limit. Although the results were approximate, it was obvious that little difference existed between noise measured on the baseline and noise measured on the peak. This is as expected. (Note that FPD noise appearing on a *tall* peak should be larger than the noise appearing on the baseline, but that is of no consequence to a problem involving the detection limit.)

Second, why was "signal/noise," rather than "signal," used for the ordinate of Fig. 1? The experiments that produced these curves were each carried out under *individually S/N-optimized* conditions. If "signal" only had been used for the plot, and the reader were to compare one calibration curve to another in an effort to assess relative signal intensities or comparative detectabilities in planning an analysis, the results could be gravely in error. "Signal/noise", besides alerting the analyst to the potential problem, tends to reduce that error.

Also, just about every element reacts differently to the variation of H_2 and air supply rates in the FPD: some increase with increasing air flow, some decrease, some stay about constant, some show maxima. If, tempted by the signal-only ordinate, we had maximized the signal intensity, the resulting curves would have turned out very different from those produced by maximizing the signal/noise ratio. While signal-only curves have definite value for spectral assignments, and while they make general sense in the context of typical high-energy AES sources, they would have little analytical relevance for the FPD. The "signal-noise" ordinate allows the reader an immediate grasp of the important de-

tection limits. It seems far better suited to comparing a greater number of elements, each of which was determined under its own optimized set of conditions. (These sets also include individually optimized photomultiplier tube voltages that, in turn, introduce further large variations of *absolute* signal strength among the different elements.) Signal/noise measurements are also, of course, recommended for general analytical purposes (38).

Flame photometric detection of some transition metals. II. Enhancement of selectivity[1]

WALTER A. AUE,[2] BRIAN MILLIER, AND XUN-YUN SUN
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received May 10, 1991[3]

WALTER A. AUE, BRIAN MILLIER, and XUN-YUN SUN. Can. J. Chem. **70**, 1143 (1992).

A flame photometric detector was used in single-channel and in differential dual-channel modes to characterize and control its selectivity for various transition elements against a hydrocarbon background. The experiments included gas-chromatographable compounds of Cr, Mn, Fe, Co, Ni, Ru, Re, and Os. Single-channel dispersive modes brought only modest gains in selectivity vis-a-vis the non-dispersive (no optical filter) mode. In dual-channel differential modes, however, metal–carbon selectivities could be improved by factors of one to two orders of magnitude. The highest still measurable selectivity ratios are now in excess of 10^7. The differential dual-channel operation of the detector also made it possible to increase the selectivity of one hetero-element vis-a-vis another; and to distinguish between two hetero-elements, by oppositely directed peaks, in a (spectrally suppressed) matrix of carbon compounds. Metal–metal selectivities could be improved by factors of one to three orders of magnitude over the best dispersive single-channel modes.

WALTER A. AUE, BRIAN MILLIER et XUN-YUN SUN. Can. J. Chem. **70**, 1143 (1992).

On a utilisé un détecteur photométrique à flamme opérant dans un mode à canal unique ou dans un mode différentiel à double canal pour caractériser et pour contrôler sa sélectivité vis-à-vis de divers éléments de transition comportant un fond hydrocarboné. Les expériences comportaient des composés du Cr, du Mn, du Fe, du Co, du Ni, du Ru, du Re et du Os pouvant être chromatographiés en phase gazeuse. Par rapport au mode sans dispersion (sans filtre optique), les modes de dispersion à canal unique n'ont apporté qu'une modeste amélioration à la sélectivité. Toutefois, dans les modes différentiels à double-canaux, on a pu améliorer les sélectivités métal–carbone par des facteurs de un à deux ordres de grandeur. Les rapports les plus élevés de sélectivité encore mesurables sont maintenant plus grands que 10^7. L'opération du détecteur dans le mode différentiel à double canal a permis d'augmenter la sélectivité d'un hétéro-élément par rapport à un autre et de distinguer entre deux hétéro-éléments; pour ce faire, on fait appel à des raies directement opposées dans une matrice (supprimée d'une point de vue spectral) de composés carbonés. Par rapport aux meilleurs modes de dispersion en canal unique, on peut améliorer les sélectivités métal–métal par des facteurs de un à trois ordres de grandeur.

[Traduit par la rédaction]

Introduction

Selectivity in the flame photometric detector (FPD) is usually understood to mean the ratio of response from a particular hetero-atom vs. the response from carbon. This is in accordance with the most common use of the FPD: to determine gas-chromatographic analytes containing one particular hetero-element, e.g., sulfur or phosphorus or tin, in sample matrices of a mostly hydrocarbonaceous nature.

As the knowledge of further FPD-active elements has increased, so has the awareness that one element could possibly be mistaken for another. The danger is particularly acute in highly complex, environmental samples of largely unknown composition. This is but one of several reasons why improved understanding and control of selectivity ratios is needed, not just for each element against carbon, but for each element against all the others.

While the conventional interference filter – photomultiplier tube combination makes the FPD a very sensitive device (for elements that do produce strong chemiluminescence), its inherently low spectral resolution and the fact that it often monitors broad molecular bands raise the question of selectivity. Indeed, one of the FPD's teething problems happened to be the spectral interference of the S_2 bands of sulfur with the HPO signal of phosphorus at 526 nm (1). Furthermore, the highest sensitivity is often obtained by operating the FPD in the absence of optical dispersion (i.e., without interference filter). This "open" mode is particularly suited for monitoring *all* kinds of FPD-active elements, and for detecting analytes that produce expansive band systems. But it is also the one mode where selectivities are, in general, at their lowest.

While transition metals are most often determined by those methodologies that employ high-energy, high-resolution atomic spectrometry, several elements have shown analytically useful responses in the low-energy, low-resolution FPD (2). And although the vast majority of the industrially, environmentally, and biochemically important transition metal compounds are not volatile enough to make it through a *gas* chromatograph, they can be processed by capillary liquid chromatography and (or) supercritical fluid chromatography, two techniques that make increasing use of typical GC detectors (including the FPD).

Hence it would appear timely to explore the selectivity of various transition metals against each other. And it would appear challenging to improve such selectivities in the low-resolution FPD to the point where they could compete with those obtained in the high-resolution instruments of atomic spectroscopy.

Selectivity ratios in the FPD vary in accordance with the geometric, chemical, and spectral conditions of the detector. In this study we shall vary only spectral conditions, while imposing the same detector geometry and chemistry on all

analytes. The latter is reasonable because the optimum detector gas flows do not change much from one transition element to the other. In return for this possible minor decrease in sensitivity, the results acquire both general applicability and comparability. The obvious starting point is to define selectivity ratios in the non-dispersive (open) mode. At the next stage, interference filters are chosen for each element, and the measurements are repeated. While this approach defines neither the best possible sensitivity for each element, nor its best possible selectivity against others, it does provide the most general and useful way of dealing with the multitude of potential analytes and chromatographic conditions.

How can selectivity against carbon/hydrogen — or, for that matter, against other transition metals — be further improved? Conventionally, single chromatograms are produced by only one optical channel. Yet, many FPD's have available two channels (a design intended to allow the simultaneous detection of phosphorus and sulfur), and one channel can be subtracted from the other with relative ease to produce a *differential* single output. We have used such an approach recently in the determination of methylcyclopentadienylmanganesetricarbonyl (MMT) in gasolines (3). Briefly: one channel monitored the wavelength at which the metal responded best but at which some response from carbon compounds was also seen; the other monitored a wavelength where carbon responded well but response from the metal was weak (or, preferably, absent). One of the amplified outputs was then attenuated such that the carbon responses in the two channels became equal, and hence vanished when one channel was subtracted from the other.

For this approach to be successful, the relevant emission spectra have to be known *at the analytical operating conditions* of the detector. For some FPD-active transition elements, as well as for different types of carbon compounds, such spectra have recently been determined (2).

The simple subtraction circuit we described earlier (3) would be too cumbersome and time-consuming to use for the measurement and manipulation of a larger number of transition-element selectivities. It requires multiple runs for establishing an acceptably precise intensity ratio of the two channels, or for subjecting the same sample to different modes of discrimination. On the other hand, such a circuit accepts a wide range of signal levels and, because of its simplicity and on-line operation, does appear preferable for routine analyses.

Two types of signal-processing devices were therefore developed. The first device is a more sophisticated version of the earlier circuit (3). This "Analog Interface" is designed to serve in simple tasks where the signals from the two electrometers, after scaling by a given factor, are used to produce a subtraction chromatogram on the recorder chart.

The second device is a computer-based system capable of performing a much wider variety of measurements and manipulations. This "Computer System" can store high-quality two-channel detector signals, filter digital data, correct baselines, scale channels with high precision, measure basic selectivity ratios and minimum detectable quantities, establish best analytical conditions, and subject single data sets to sequential algorithms that represent disparate selectivity regimes.

Such data-processing capabilities should be of interest beyond the confines of this study. For instance, they lend themselves to conventional analytical development and are helpful in the analysis of those environmental samples that are severely limited in supply and highly complex in composition: data from a single injection can generate several chromatograms of different selectivity and information content.

What effects can prevent the differential FPD mode from reaching infinite selectivity (= specificity) for the chosen metal vis-a-vis carbon? First, very large amounts of *any* compound disturb the extremely weak flame and lead to the kind of baseline fluctuation (involving, one assumes, changes in flame chemistry and hence both background and analyte spectra) that even the best differential circuitry cannot cancel. Second, it is well known that the FPD signal for carbon compounds depends to some degree on their structure: for instance, aliphatics respond more weakly than aromatics. The spectral profiles, while similar in one wavelength region, differ strongly in another (2). Consequently, the choice of a carbon standard with which to match the two channels can be crucial. Third, the position (retention) of a particular compound in a complex, temperature-programmed chromatogram can influence its response. The gas flow, the temperature, the column bleed, and the detector memory (e.g., from contamination by residual and (or) decomposed analyte) are all subject to change during the run. Fourth, there always exists the possibility that a co-eluting species may influence the response of the analyte, or that it may, by itself, produce response on one or both of the two channels. Fifth, the luminescence phenomena may not be of perfect spatial symmetry in regard to the two observation channels. Sixth, conventional GC electrometers are unlikely to meet the unusual, severe linearity requirements posed by the differential mode when it attempts to cancel a peak that is orders of magnitude larger than the operating scale. Peak distortions induced by two different R-C output circuits, for instance, are unlikely to match one another within the precision required for complete peak cancellation under overload conditions.

A truly comprehensive survey of *inter-metal* selectivity would be a time-consuming task. More to the point, its practical value could be questioned in light of disparate commercial FPD designs and the myriad of possible analytical circumstances under which these are used. We shall therefore rely on typical chromatograms as opposed to numerical tables to characterize the situation. In several simplified examples we shall illustrate what selectivity can be expected from a typical FPD, and how it can be manipulated.

The conventional way to improve FPD selectivity is to use a single channel with the best overall choice of interference filter for one element against another. A second way is to use a differential mode in which two channels are deducted from each other such that response from one element is maintained and response from the other element cancelled. Yet a third way is to use a differential mode in which the two channels are deducted such that both elements produce strong responses, but in opposite directions. (This "qualitative" form of selectivity makes sense only when compounds containing the two elements are chromatographically resolved, and when a multicomponent sample is to be scanned for the presence of particular elements.) A variant of the latter mode matches channels with the additional purpose of annulling carbon response. We shall examine all these types of selec-

tivity adjustments, while keeping in mind the continued integrity of calibration curves and other analytical performance criteria.

A word should be added here about the method used to measure various selectivity ratios. Selectivity ratios, to restate the conventional definition, are the ratios of response produced by equal amounts of analytes or, alternatively, the ratios of analyte amounts that produce the same response. These alternative definitions represent the horizontal (amount) and vertical (response) distances between conventional calibration curves.

Thus, a complete picture of selectivity among two or more compounds can be given only by a comparison of their fully extended calibration curves. If a *single number* is to suffice for describing a two-compound (and, by inference, a two-element) selectivity, it needs to be determined with *both* compounds well within their respective linear ranges. For a metal/carbon ratio, for instance, much higher "selectivity ratios" can be recorded if the interferent hydrocarbon is used in amounts beyond its linear range. In this study, all calibration curves are linear at low concentrations, and the choice was therefore made to determine the selectivity ratios from minimum detectable analyte flow rates. This approach, while somewhat more time-consuming, assures the applicability of results within respective linear ranges, and carries with it the additional benefit of defining the analytically important detection limits under a variety of optical (but a common set of chromatographic) conditions.

Experimental

A short description of the conventional gas chromatographic system and simple spectroscopic accessories can be found in the companion manuscript (2). The only major difference is that, in this study, the flame gas supplies were kept constant throughout at 300 mL/min hydrogen and 60 mL/min air.

The potentiometer, which regulates the photomultiplier tube voltage and is normally located inside the Shimadzu electrometer, was replaced by an external one for optimizing the dynode voltage to give a close-to-maximum S/N ratio (re the definition of N see the Note added in Revision to the companion manuscript (2)). A typical setting for our R-268 tube in open-mode runs was 550 V. Prior to data processing, large-step signal attenuations were carried out as usual at the electrometer level.

The analog interface

The interface was set up not only to display on-line differential (subtraction) chromatograms on a strip-chart recorder, but also to transmit unmodified signals to the data acquisition system of the computer. This circuit, a "2-channel low-pass filter," is shown in Fig. 1. It consists of an input attenuator (a ten-turn potentiometer with vernier dial) and a three-pole active filter. This circuit is duplicated for the second channel, and a simple switch selects either the intact two channels or their difference for output to the recorder. The potentiometers offer calibrated attenuation for each channel, and a choice of nominal cut-off frequencies is available via independent switches.

An advantage of this analog approach over the computer acquisition method is its dynamic range. Signals entering this circuit are typically on the order of 10 mV for a full-scale recorder output. Yet, large signals approaching 10 V can be accommodated, since the circuit is built for *passively* subtracting one signal from the other (see S4 in Fig. 1) before any filter action or amplification takes place. The CMRR (common mode rejection ratio) in this passive circuit is, in theory, infinite. When operated in the independent two-channel mode, signal overloads will make the two recorder pens go off scale. But, in the differential mode, the circuit has the ability to subtract signals much greater in amplitude than the chosen recorder scale. This contrasts with the developed computer acquisition system, which offers signal extension (data storage capacity) to two full scales, but which cannot approach the wide dynamic range of the analog interface. (A wider-ranging computer system, should it be needed for a particular purpose, appears entirely feasible.)

The computer system

For digital data processing, the "integrator" outputs of the two Shimadzu electrometers are connected to the computer through an interface. This interface is built around an IBM PC Prototype card, the schematic for which is available in the IBM PC Technical Reference Manual, publication 6025005. The schematic for the custom part of the circuit ("2-channel chromatographic interface") is given in Fig. 2.

The circuit consists of two identical channels. A simple R–C filter at the input blocks high-frequency noise. This is necessary as any noise with frequencies above 1/2 the sampling rate (10 Hz) must be removed prior to sampling and converting the analog detector output signal to a digital value; otherwise aliasing noise will be present in the digital data. A voltage-to-frequency converter is used to transform the signal to a digital pulse train, and a counter accumulates these pulses over 0.1 s intervals. A full-scale input signal will produce a digital count value of 16 000, providing resolution about equal to that of a 14-bit analog-to-digital converter. The input voltage to this circuit, required to produce the full-scale digital output, is about 200 mV. The Shimadzu electrometers' "integrator" outputs are slightly modified to provide the computer with a signal 10 times the amplitude of that sent to the recorder. Therefore the computer offers a 2:1 over-ranging capability compared to the recorder, assuming the latter is operated on its 10 mV scale.

An Analog Devices AD567 digital-to-analog converter generates an analog signal that is fed to a dedicated strip chart recorder for hard-copy output of computer-processed chromatograms. Since the DAC output is 0–10 V, that strip-chart recorder operates on its 10-V range.

To provide for a data display of satisfactory appearance and reasonable operating speed, the hardware configuration includes a 12 MHz AT-compatible computer with one megabyte memory, 40 meg hard disk, 80287 math coprocessor, VGA display adapter, and Multi-Sync monitor.

The program, named "CHROM," is written in compiled Quick Basic, which generates reasonably fast code. All data acquisition is performed by assembly language routines using interrupts for timing accuracy. However, due to the large amounts of data collected per run, a math coprocessor is needed to allow data manipulation such as filtering and scaling at a speed acceptable to the user.

The program samples the two channels every 0.1 s and provides up to 1600 seconds (26′40″) readout on the screen. The sample injection is marked and two horizontal and two vertical cursors appear for manipulation of the two chromatograms. The vertical cursors define the time section to be worked on; the horizontal cursors set the baselines and allow the approximate measurement of peak heights in subsequent routines.

In typical operation, a time window is selected and the peak(s) it contains are horizontally expanded to fill the screen. At this, as well as at later stages, several routines are available that offer convenient data processing such as cubic-spline baseline correction, digital filtering, and numerical definition of the baseline noise in Gaussian parameters. One peak is selected as a tuning standard for cancellation of its cogeners; e.g., dodecane may be selected for cancelling aliphatics. In both channels, the height of this standard peak is vertically defined by two horizontal cursors for a rough first measurement. The algorithm then scale-expands one of the channels in order to equalize the two peak heights, deduct one channel from the other, and display the result. It also lists on the screen the "magnification factor" (scaling factor) of one channel over the other, and keeps track of any changes in that number during further manipulations. For fine-tuning, the program then proceeds through

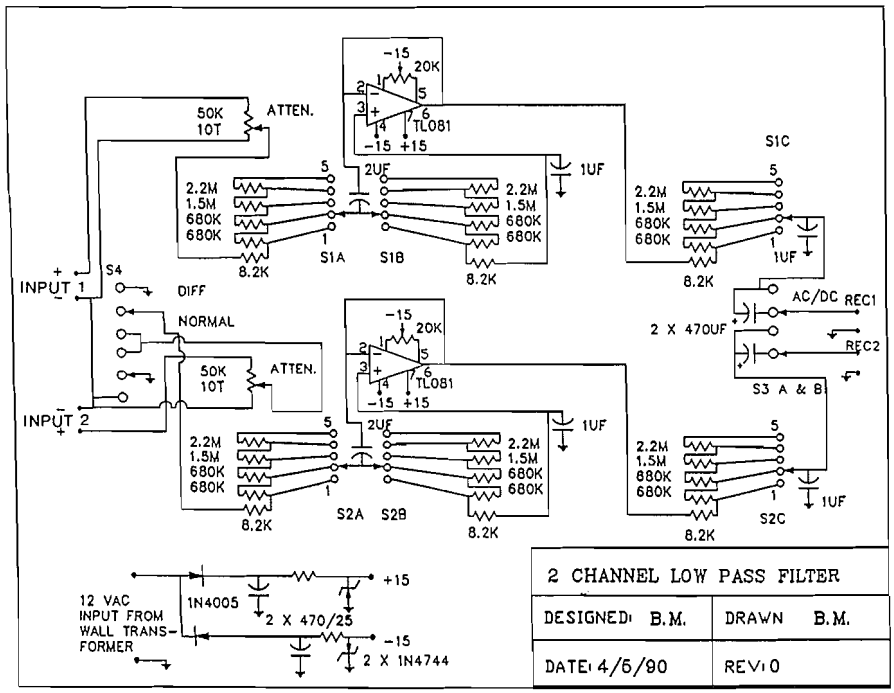

FIG. 1. Analog Interface for manipulation and recording of independent or dual-channel differential chromatograms.

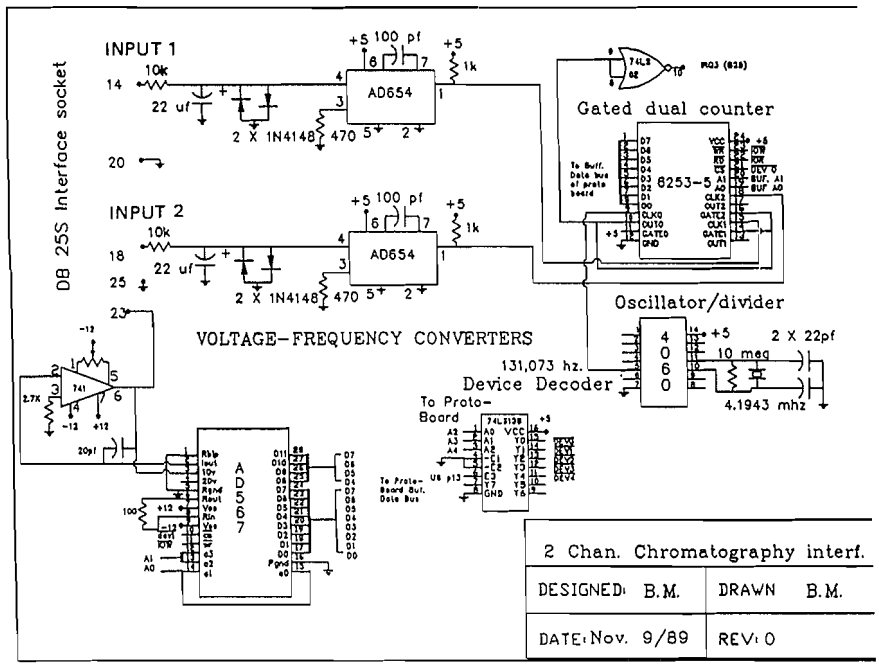

FIG. 2. Computer System interface for computer input and output of dual-channel chromatograms.

several user-prompted iterations in which the two-channel intensity ratio is changed by small increments. The visually "best" iteration is selected by the user to scale *all* of the data. This final magnification factor can be employed directly in further computer runs and (or) it can be manually transferred to the "Analog Interface." For analytes contained in complex matrices, this routine works well for obtaining the best overall discrimination against the background. The resulting differential chromatogram (plus magnification factor) can be stored on hard disc like any conventional chromatogram. It can also be processed using the routines described above (digital filtering, etc.) and can be sent, with or without time indicators, to its dedicated strip-chart recorder.

Results and discussion

The molar detection limits of metals (in organometallics), as well as carbon (in three selectivity probes) and nitrogen (in indole), are listed in Table 1 for the same, standard conditions in non-dispersive, single-channel FPD mode. These numbers can be used to calculate "innate" molar se-

lectivities for atoms of one element against atoms of another. Such selectivities are listed in Table 1 for transition elements versus carbon. Inter-metal selectivities can be calculated in the same manner.

The response of a standard compound containing one metal atom (the usual case) could serve to construct a molar calibration curve valid for all analytes containing one atom of that metal. Or, nearer the current context, the selectivity of a particular metal vis-a-vis others could be used to define the molar selectivity behavior for all compounds containing these metals. However, that approach requires caution. It cannot be automatically assumed that every response observed is a strictly linear function of the amount of hetero-atom injected (although most of the time this is likely to be the case). For one, different compounds containing the same hetero-atom may be subject to different degrees of on-column decomposition. Also, response may to some extent depend on compound structure.

In those cases where a few compounds of the same metal have actually been tested, i.e., in the studies of iron (4) and manganese (3), response was roughly proportional to metal content. Other transition elements were not examined in that context (owing mainly to the limited commercial availability of suitable test compounds) but they should prove equally well behaved.

In the case of different types of carbon compounds, however, response is not proportional to carbon content. For instance, aromatics respond more strongly than aliphatics. There also exists considerable literature on the response of sulfur compounds depending — or, for other authors, not depending — on the type of functional sulfur group present. And, when a particular hetero-element responds but weakly in the FPD, special caution is called for. In the case of the nitrogen compound indole, for instance, the response will obviously contain some contribution from indole's aromatic carbons. Since this contribution is relatively small compared to that of nitrogen, it is disregarded in our calculation. The only reason why we have included indole here at all is to draw attention to the fact that nitrogen compounds, which often occur in complex sample matrices, do respond more strongly than carbon compounds and that they, because of their different spectrum, demand a different magnification ratio prior to subtraction. Having duly mentioned these caveats, we feel that FPD sensitivities and selectivities, which are reported in a general manner based on moles of atoms, are of wider analytical significance than those which are based on grams of compounds actually measured; hence the former are used in the tables. In any case, such data can be easily reconverted, i.e., recalculated to give the weights of the initial test compounds, within the precision allowed by one significant digit.

The reason that data in Table 1 (as in all other tables) are reported in this manner is that they are derived from minimum detectable amounts (which, to the purist, admit to only one significant figure). Also, one-digit data are used in awareness of the changes in detector sensitivity that occur with the passage of time, the variation of temperature, the severity of contamination, and the switching of individual photomultiplier tubes. Still, measurements were always taken, and calculations always carried out, on the basis of two or more significant digits.

Minimum detectable amounts and selectivity ratios are recorded here for the two most common types of photomultiplier tubes used with the FPD. These are, in Hamamatsu codes, the R-268 (bialkali, 300–650 nm) and the red-extended R-1104 (multi-alkali, 180–850 nm). Differences between the two sets of results conform to expectations based on analyte spectra. The important fact, however, is that these differences are comparatively small: they do not exceed a factor of five.

[a]Molar detection limit, mol metal per second, at S/N = 2.
[b]Minimum detectable mol carbon per second in dodecane (RH), naphthalene (ArH), or di-*n*-hexyl ether (R_2O); or mol nitrogen per second in indole (ArN); divided by minimum detectable mol metal per second.

The "innate" metal–carbon (carbon as in dodecane) selectivities for the clearly responding metals Ru, Ni, Cr, Os, Fe, Mn, and Re fall between 7×10^5 and 4×10^3 in non-dispersive mode, i.e., roughly between three and six orders of magnitude. These numbers could be expected to rise in the dispersive mode.

Results from dispersive, single-channel detection using a variety of filters are listed in Table 2 for the R-268 tube, and in Table 3 for the R-1104 tube. "Best" selectivities for each metal against carbon (again as in dodecane) now range from 4×10^6 to 1×10^4. This very small extent of improvement may come as a surprise to the reader who is accustomed to responses in the FPD being called "specific" and that behaviour being attributed to the choice of a particular interference filter. However, the numbers listed in Tables 2 and 3 for various transition metals are consistent with their respective spectra, i.e., with the location of the chosen metal wavelength in relation to the broad emissions of carbon

compounds (2), as well as with the extent to which the metal spectra are dominated by lines or sharp bands as opposed to broad bands and continua. The factors that describe the improvement (or, occasionally, impairment) in selectivity, from the better suited of the two photomultipliers in the open mode, to the best filter/photomultiplier tube combination in the dispersive mode, never exceed one order of magnitude. Atomic selectivities vis-a-vis carbon (carbon as in dodecane) are thus bettered by a factor of 6 for Ru, 8 for Ni, 5 for Fe, and 3 for Mn, and worsened by a factor of 0.7 for Cr, 0.2 for Os, and 0.5 for Re.

Similarly, enhancement of selectivities among the various transition metals themselves depends on their spectra: how far and in what complexity they cover, in relation to each other, the accessed wavelength range. Some selectivity ratios are listed in Table 4; they were chosen for general importance as well as for later reference. These results suggest that the improvement in inter-metal selectivity from non-dispersive to single-channel dispersive mode, i.e., the improvement obtained from the judicious choice of an interference filter, is rather limited. If the numbers in Table 4 are compared with the open-mode metal–metal selectivities easily extracted from Table 1, most improvements of selectivity amount to no more than one order of magnitude. For instance, the improvement in selectivity from the best non-dispersive to the best dispersive mode involves a factor of 2 for Ru/Ni, Ru/Cr, Ru/Fe, Cr/Ru, Cr/Fe, and Cr/Re; a factor of 3 for Cr/Mn; and a factor of 4 for Cr/Fe, Cr/Os, and Ru/Mn (in these analyte/interferent pairs, the first-named element is considered the analyte and hence determines the choice of the interference filter). There are other cases where no improvement, or even some impairment, is noticed in progressing from a non-dispersive to a dispersive mode: this happens in the pairs Ru/Os, Ru/Re, Fe/Ru, and Fe/Cr. The *significant* improvements occur mainly in cases involving iron, Fe/Mn, Fe/Os, Fe/Re, where factors can exceed two orders of magnitude. This is due to the fact that Fe is monitored at 340 nm, where only a few of the other metals luminesce.

As mentioned earlier, a frequently held perception equates the use of an interference filter in the FPD with "specific" response for the monitored element. Within the confines of this study, such was definitely not the case. In fact, we doubt that true specificity (= infinite selectivity) can ever be associated with the use of a particular wavelength. To obtain more significant improvements than single-channel dispersive operation can offer, *dual*-channel differential modes must be used.

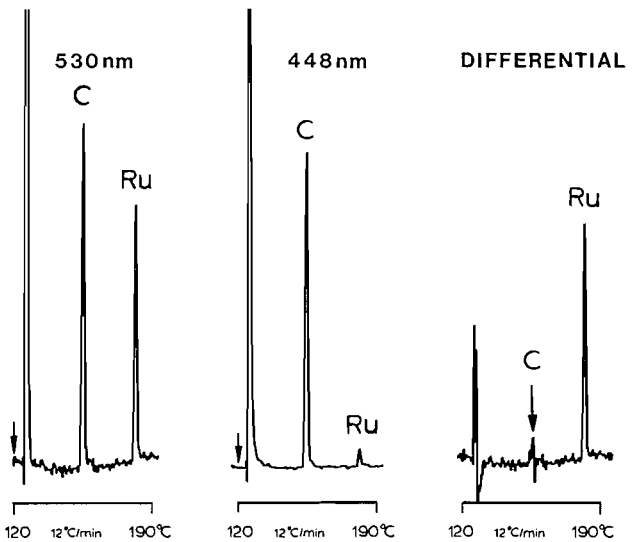

FIG. 3. Single-channel and dual-channel differential chromatograms of a sample containing 30 μg dodecane (C) and 300 pg $Ru(C_5H_5)_2$ (Ru) in acetone. Analog Interface.

A simple example is presented in Figure 3, which shows the separation of 30 μg of dodecane and 0.3 ng of ruthenocene. The chromatogram on the left was acquired from a single channel at 530 nm. This monitors a major wavelength of Ru that yields the best discrimination against carbon. The peaks are almost of the same height, suggesting a compound-to-compound selectivity of 7.4×10^4 (corresponding to an atomic Ru/C selectivity of 1.2×10^6). The chromatogram shown in the middle was taken from a single channel at 448 nm, where the ruthenium emission is fairly weak. The chromatogram captioned "Differential" was obtained from the 530/448 nm dual-channel differential mode tuned for quantitative discrimination against carbon. The amount of dodecane had been deliberately chosen from the upper end of its linear range, where its concentration just becomes large enough to start distorting the Gaussian peak shape. A vacillating, clearly non-Gaussian, signal appears in place of the dodecane peak. Even counting the full vertical pen displacement caused by this perturbation, the compound-to-compound selectivity is now in excess of 10^6, the atomic ruthenium-to-carbon selectivity in excess of 10^7.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

For any reasonable analytical purpose, this seems more than adequate.

If still larger amounts of dodecane are injected, the peak distortion in single-channel mode becomes clearly visible and the characteristic flip-flop pattern of the differential mode intensifies. But does this flip-flop arise from the peak asymmetry (which, after all, is seen by both photomultipliers)?

As will be demonstrated later, purely electronic distortion is likely present in such peak remnants. But limitations of an other than electronic nature can contribute as well. This is not surprising, taking into account the puny and feeble FPD flame. Note for instance that, at the apex of the carbon peak shown in Fig. 3, the combustion of dodecane already requires more than 3% of the detector's oxygen supply, and significant changes in flame size, temperature, chemistry, and flicker behaviour could be expected under such severe overload.

Beyond electronic artifacts and flame perturbations, carbon compounds pose special difficulties that stem from the infinite variety of their structures. In particular, the spectra of aromatics are more intense than those of aliphatics in the 480–660 nm region (2). This is chromatographically illustrated in Fig. 4 with a mixture of three carbon compounds. The differential mode, when using two channels at 448 and 530 nm via the computer system, can cancel either the aromatic or the two aliphatics, but it cannot cancel all three at the same time. For producing the right-hand chromatogram in Fig. 4, the two channels are so tuned that the result distinguishes between aromatics and aliphatics in a qualitative sense, i.e., by the direction of response. While this would seem interesting in a general analytical context, it should be noted that the FPD's sensitivity to carbon is very low, and that ambiguous results can be expected from molecules combining different sites/degrees of saturation.

Still, it is possible to cancel all three carbon compound types if other wavelengths are used. The relevant spectra (2) suggest that wavelengths up to about 440 nm should be suitable. A chromatogram of the same three carbon compounds shown in Fig. 4, together with compounds of chromium and nitrogen (plus an impurity of unknown composition), is shown in Fig. 5. The differential mode, tuned to forestall the appearance of carbon compounds, achieves that objective quite well, despite the fact that the latter are of very different structure and overall spectrum. Thus, if no other circumstances militate against it, 430 nm (or a wavelength close to it) is the preferred choice for the channel used to neutralize the response of carbon compounds. (Obviously, the analyte channel wavelength also has to be lower than 440 nm.)

The eradication of carbon response can also be achieved while, at the same time, the two metals are being qualitatively differentiated by the direction of their peaks. This is shown for manganese and chromium in Fig. 6. Clearly, this detector mode can be easily extended to most if not all FPD-active elements, and should be of particular help in screening-type analyses.

Note that in Fig. 6 the solvent peak is not completely cancelled in the differential mode. This particular tuning and subtraction process, similar to the one whose results are shown in Fig. 5, was carried out by the Computer System. In contrast to the Analog Interface, the Computer System is not capable of subtracting a very large peak from its second-channel counterpart. What is shown in Fig. 6 as a clipped solvent peak merely represents the ratio of the upper limits of the two channels. Similarly, this ratio just happened to coincide with the baseline in Fig. 5, perhaps falsely suggesting there that the solvent acetone had been entirely suppressed. Obviously, this limitation in range of the Computer System does not affect peaks that are smaller than two full scales.

The next series of simplified chromatograms is designed to explore and illustrate the degree of control and the improvement of measured selectivity ratios that can be typi-

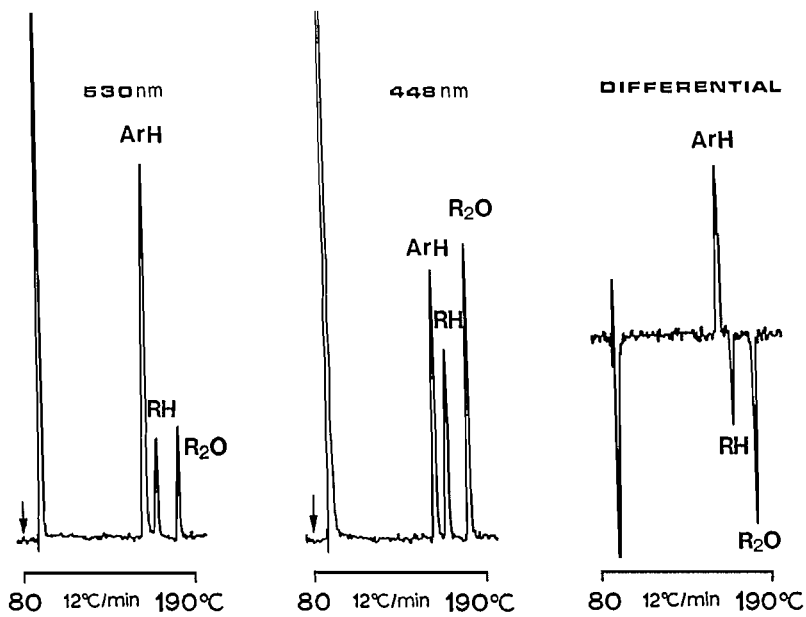

FIG. 4. Single-channel and dual-channel differential chromatograms of a sample containing 10 μg naphthalene (ArH), 10 μg dodecane (RH), and 15 μg di-*n*-hexyl ether (R_2O) in acetone. Computer System.

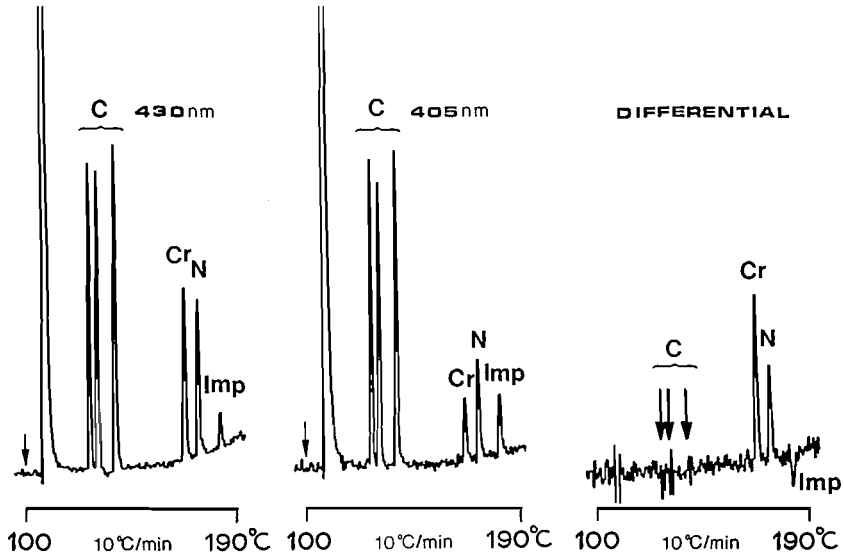

FIG. 5. Single-channel and dual-channel differential chromatograms of a sample containing 8 μg naphthalene, 8 μg dodecane, and 12 μg di-*n*-hexyl ether (C), together with 4 ng $C_6H_6Cr(CO)_3$ (Cr) and 600 ng indole (N) in acetone. Imp = impurity of unknown composition. Computer System.

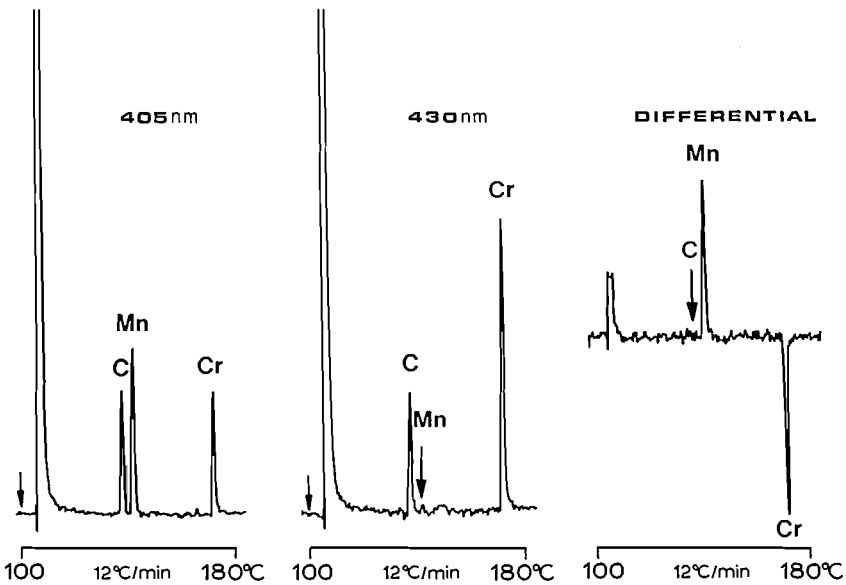

FIG. 6. Single-channel and dual-channel (carbon-suppressed) differential chromatograms of a sample containing 5 μg dodecane (C), 500 pg $C_5H_4CH_3Mn(CO)_3$ (Mn), and 4 ng $C_6H_6Cr(CO)_3$ (Cr) in acetone. Computer System.

cally expected for two transition metals. This example uses ruthenium and chromium. To set the scene, the series starts with single-channel chromatograms. The left side and the middle of Fig. 7 show these channels, at preferred wavelengths for the analysis of Ru (480 nm) and Cr (430 nm). Note that the single-channel operation provides only a modest enhancement of selectivity vis-a-vis the open mode and that, in a complex "real-life" situation, it might even fail to distinguish between the two metals. The *dual*-channel operation, in its qualitative mode, achieves that distinction quite readily (right side of Fig. 7). For the more important quantitative mode, the same channels are tuned (scaled) to different ratios, with the result that either Ru or Cr are annulled (Fig. 8). This absence of any visible trace of interferent begs the question: how large an amount of either of these two species can the system cancel? In other words, how large an improvement in selectivity can the differential modes provide?

The original demonstration sample for Figs. 7 and 8 had been mixed so that it would furnish comparably sized peaks in non-dispersive mode, and thence easily observable peaks for both species in the two single-channel modes. Both of these peaks, by having been obliterated in the differential mode, established lower limits to the respective selectivity ratios. For extending the measurement further, however, *two* mixtures must be made in which either one or the other compound is heavily fortified. But how heavy?

As pointed out earlier, amounts of interferents from be-

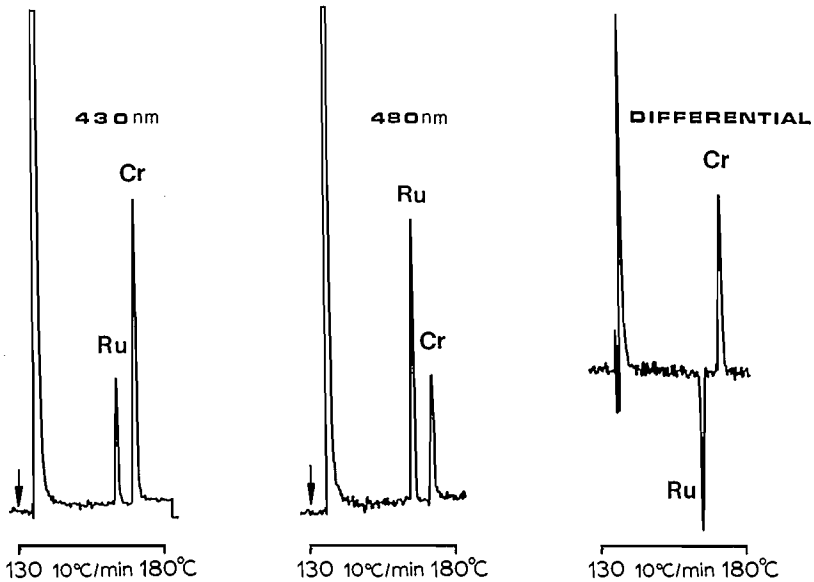

FIG. 7. Single-channel and dual-channel differential chromatography of a sample containing 500 pg $Ru(C_5H_5)_2$ (Ru) and 4 ng $C_6H_6Cr(CO)_3$ (Cr) in acetone. Computer System.

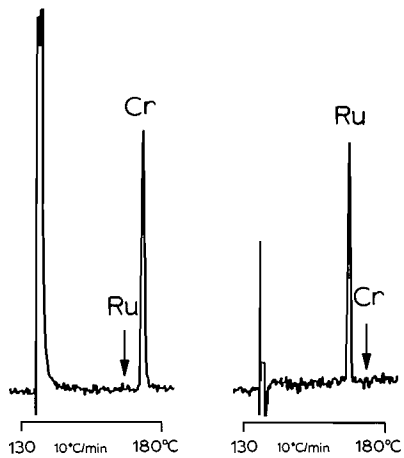

FIG. 8. Suppression of ruthenium and chromium by dual-channel differential chromatography in the same sample as shown in Fig. 7. Computer System.

yond their linear range are inappropriate candidates for determining selectivity ratios (even though they can produce much larger numbers). The amounts chosen for cancellation in this experiment were therefore taken from the upper ends of the single-channel linear calibration of the designated interferents (as seen by the channel chosen to elicit the best response of the *analyte*).

To put the results of this experiment in their proper perspective, it is reasonable to speculate first on the theoretically largest improvement in analyte/interferent selectivity that could be measured in moving from single-channel to dual-channel differential operation. Ideal circumstances imply that the analyte does not respond at all, while the interferent responds very strongly, on the particular channel that is used to cancel the interferent. Further, it is implied that the noise of the interferent channel would be significantly smaller than the noise of the analyte channel: only then could the analyte peak rise to full height above a baseline free of additional noise. And, of course, that there should be no perturbations present of an electronic, chemical, or physical nature. If we assume that the interferent (taken from the upper end of its linear range) fails to respond (more precisely: that it fails to respond above the S/N = 2 limit), then the largest improvement in selectivity ratio obtainable by switching from single to dual-channel differential operation *cannot exceed the linear range of the interferent*.

Note that this implies formal dependency, though to a numerically minor degree, on where the linear range is defined to start and to end. Note further that it is experimentally feasible to measure selectivity ratios that are larger than the "true" ones (by working outside the linear range of the interferent). And, when working inside the linear range but with the interferent peak completely cancelled (i.e., submerged in the baseline noise), only a lower limit to the true selectivity can be given. (A "true" selectivity ratio, following the conventional definition, is represented by the vertical (response) or the horizontal (amount) difference between two linear, or linearly extrapolated, calibration curves.)

To summarize: at ideal conditions and within respective linear ranges, the maximum observable improvement for dual-channel differential as opposed to single-channel operation is given by the linear range of the interferent (on the analyte channel). Thus, no greater a selectivity improvement than two to four orders of magnitude (with the number depending on the elemental nature of the interferent) can be measured by experiments in which the peak resulting from an amount of interferent close to its upper limit of linearity is successfully diminished to an amplitude smaller than the baseline noise of the differential chromatogram.

This theoretical extent of improvement could not be reached here. The reason is twofold: some of the "ideal" conditions mentioned above could not be realizd and, as is obvious from the fairly typical chromatograms of Figs. 9 and 10, very small remnants of the initially very large interferent peaks tended to persist as non-Gaussian artifacts. Still, in these figures the gain in selectivity is quite impressive. For a visual comparison, the respective mixtures are also portrayed in their best *single*-channel appearance on the left side of Figs. 9 and 10. The numerical improvement of selectiv-

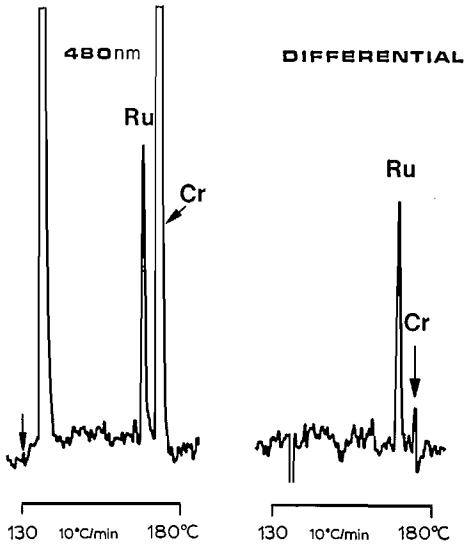

FIG. 9. Suppression of large amounts of chromium in a sample containing 250 ng $C_6H_6Cr(CO)_3$ and 200 pg Ru $(C_5H_5)_2$ in acetone. Other conditions as in Fig. 8. Analog Interface.

ity from single- to dual-channel differential operation is 3×10^2 for Ru/Cr and 2×10^1 for Cr/Ru (these numbers are based on peak heights; if peak areas are used they become much larger).

Figure 10 also contains, on the right-hand side and marked "Differential B," a chromatogram taken under the same chromatographic conditions and overall electronic amplification as the one marked "Differential A." (Note that the Cr peak remains at the same height.) However, different settings were used for the combination of input amplification and output attenuation of the two electrometers (which perform rough scaling on the signals before they reach the Analog Interface). The comparison of the two chromatograms demonstrates that the vacillating signal, which represents the difference between two very large off-scale peaks, is likely to contain electronic perturbations (in addition to other types of perturbations as have been discussed earlier). The chromatogram labelled "Differential A" is the best, the chromatogram labelled "Differential B" the worse, of a series of matches with the same overall electronic simplification. It is reasonable to expect that more attention to this problem (which, of course, never arises in "regular" chromatography) could reduce the size of the artifacts.

Improvements in selectivity similar to those shown in Figs. 7–10 can be realized for other pairs of transition elements as well. How large a number is obtained in each case depends strongly on the relative nature of the two spectra (and on the corresponding wavelengths chosen for the two channels), on the extent of the linear ranges, and on other considerations as discussed above. In our opinion, a visual record of performance, such as given in Figs. 7 through 10 for the fairly typical behaviour of ruthenium and chromium, is often preferable to a tabular one.

The dual-channel differential modes described in this manuscript work well on systems of two and possibly three different elements, particularly if the latter need to be differentiated with a very high degree of reliability. However, the methodology obviously runs into difficulties if more than two or three luminescing elements participate in the chromatogram. Although real-life samples of this type may be rare, it should be instructive to cast at least a cursory look at a mixture made up of several transition metals, in amounts that produce comparable peak heights in the open mode. The particular standard mixture shown here was also given a compound of sulfur, in recognition of the role that this main-group element plays in many natural samples.

Chromatograms of the mixture are shown in Fig. 11, first in single-channel, then in dual-channel differential mode. The first channel is open (no interference filter). The second channel at 530 nm was originally chosen for ruthenium. However, it also shows all the other peaks (though with different intensities). This reinforces the point made earlier that spectral discrimination in a single channel, as compared with the open mode, rarely affords the analyst the desired big increase in selectivity.

The differential-mode chromatogram shown on the right side of Fig. 11 is obtained by tuning the two channels such that the ruthenium responses cancel. This purpose is well

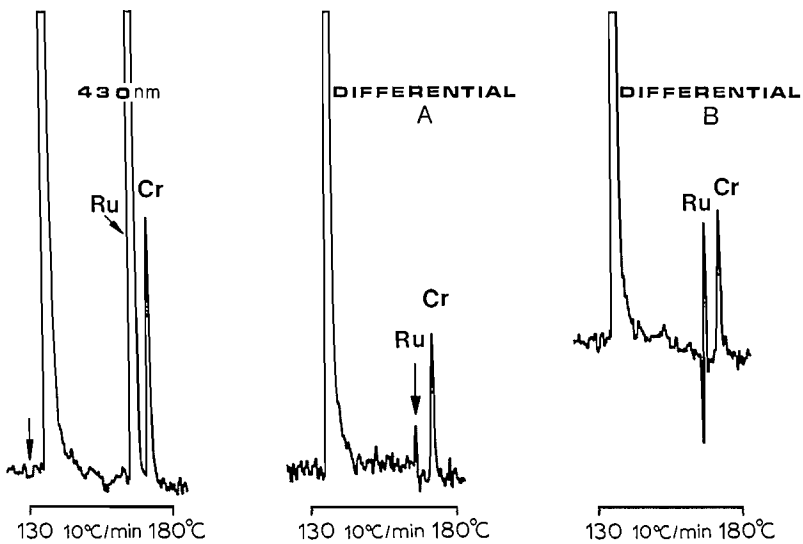

FIG. 10. Suppression of large amounts of ruthenium in a sample containing 10 ng $Ru(C_5H_5)_2$ (Ru) and 4 ng $C_6H_6Cr(CO)_3$ (Cr) in acetone. Other conditions as in Fig. 8. Analog Interface.

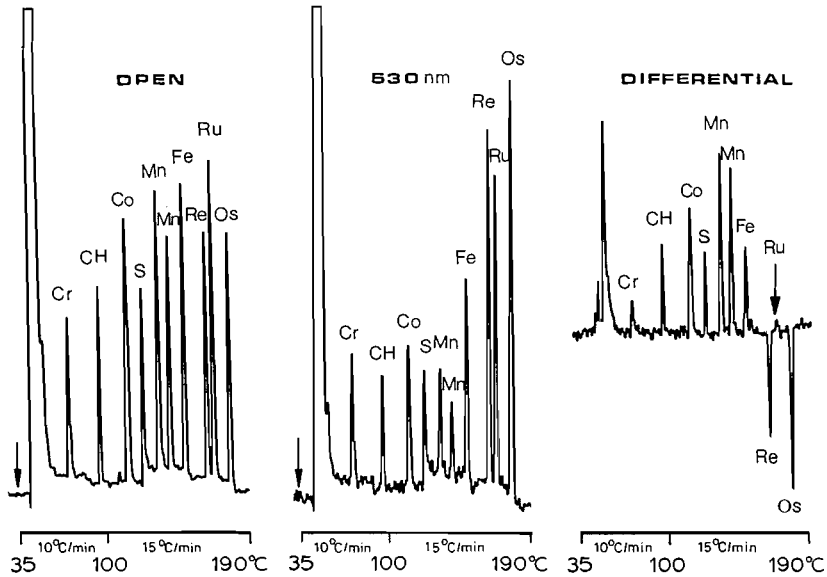

FIG. 11. Single-channel and dual-channel differential (ruthenium-suppressed) chromatograms of a mixture containing 1.3 ng $Cr(CO)_6$, 1.6 μg nonane (CH), 200 ng $Co(C_5H_5)_2$ (Co), 17 ng $[(CH_3)_3CS]_2$ (S), 3.2 ng $C_5H_5Mn(CO)_3$ and 4 ng $C_5H_4CH_3Mn(CO)_3$ (both Mn), 3.2 ng $Fe(C_5H_5)_2$ (Fe), 24 ng $Re_2(CO)_{10}$ (Re), 0.16 ng $Ru(C_5H_5)_2$ (Ru), and 4 ng $Os(C_5H_5)_2$ (Os) in acetone. Computer System.

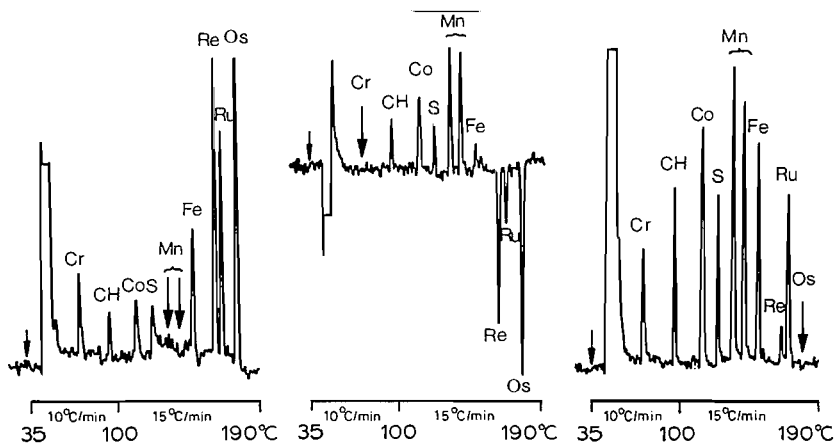

FIG. 12. Dual-channel differential chromatograms of the same mixture (and the same chromatographic run) as shown in Fig. 11, with suppression of, from left to right, manganese, chromium, and osmium. Computer System.

achieved. Thus, a peak vanishing from the chromatogram under this particular selectivity regime would alert the analyst to the possible presence of a ruthenium compound. And, other channel combinations (wavelengths) could be used to confirm that finding. In addition, clear *qualitative* discrimination is obtained between Cr, C, Co, S, Mn, and Fe on one hand, and Re and Os on the other.

Still, the situation is less than totally satisfying. What if the analyst wants to see *only* peaks of ruthenium, with compounds of all other elements vanishing from the chromatogram? While this is possible to achieve, the necessary algorithms are substantially different from the ones covered here and do display limitations of their own (6). They will be the subject of a separate manuscript. Within the present context, however, two further comments are relevant for the analysis of a multicomponent mixture as shown in Fig. 11.

First, different wavelength combinations could be used to achieve the disappearance of *any* element. At the same time, the choice of particular wavelengths can easily take into consideration the qualitative discrimination resulting among the other elements, and how it can best suit particular analytical needs. For instance, carbon compounds could have been eliminated in a manner similar to the process illustrated earlier in Fig. 6, with wavelengths particularly suited to the detection and qualitative distinction of interesting organometallic analytes.

Second, the two single channels of data stored in the computer could be used to impose, sequentially, a series of different selectivity regimes on the same chromatographic run. This makes little sense for a routine sample of qualitatively known composition, but it can be quite helpful for a complex sample that contains many components of a chemically disparate nature. For instance, the hypothetical question could be posed whether there were present in our test mixture any manganese compounds beyond the one "known" to contain Mn. To find the answer, the channels can be tuned

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

for the disappearance of the "known" manganese peak (or of a separately injected manganese standard if the contents of the mixture are *truly* unknown). If this is carried out, the second, pretendedly "unknown" manganese peak vanishes as well. A demonstration of this is shown on the left-hand side of Fig. 12.

The middle and right-hand sides of Fig. 12 display two further chromatograms in which the selfsame computer-stored data are used to cancel peaks of chromium and osmium, respectively, while leaving other peaks largely intact. Further elements can be so tested. This is interesting because it demonstrates that several new selectivity criteria can be meaningfully imposed on already existing data. The inter-metal differences in dual-channel response ratios are obviously large enough to allow such approaches, even though the original choice of wavelength had not been made with these additional combinations in mind.

In the high-resolution chromatography of complex samples that include a larger number of compounds containing the *same* hetero-element, procedures like the one mentioned above can lead to fast and facile early indications of which peaks are likely to represent the hetero-element of interest, which represent other hetero-elements, etc. Clearly, the underlying assumption, that the spectral response of the metal is independent of analyte amount and organic structure, may need to be ascertained for particular combinations of element and wavelength(s). Where such an assumption could be checked in our study of transition elements, as in the case of the two manganese compounds discussed above, it did indeed hold true.

NOTE ADDED IN PROOF: For lack of a better expression, this manuscript and its companion (2) use the term "dispersive" in its derivative meaning of "wavelength-selective". Thus, a "dispersive" FPD channel uses an interference (or other type of) filter, while a "non-dispersive" channel is doing without. It goes without saying, however, that filters "disperse" light neither in the etymological nor the original spectroscopic sense of the word (with the possible exception of the tilting effect in interference filters).

The ^1H and ^{13}C NMR spectra of the amnesic shellfish poison, domoic acid, in H_2O and D_2O solutions have been studied as a function of pH or pD. The results yielded the NMR spectral parameters for each of the five protonation stages of domoic acid, provided accurate pK_a values, and enabled each pK_a to be associated with a particular protonation site.

JOHN A. WALTER, DONALD M. LEEK et MICHAEL FALK. Can. J. Chem. **70**, 1156 (1992).

On a étudié les changements observés dans les spectres RMN ^1H et ^{13}C de solutions d'acide domoïque, une toxine amnésique, dans H_2O et D_2O en fonction du pH ou du pD. Les résultats nous ont permis de calculer les paramètres spectraux pour les cinq étapes de la protonation de l'acide domoïque, d'obtenir des valeurs de pK_a plus précises et d'associer chaque pK_a avec un site de protonation particulier.

Introduction

Domoic acid (DA, Fig. 1) was recently identified as the toxin responsible for an episode of shellfish poisoning involving mussels from an area of eastern Canada (1). This compound had been known for some 30 years to have anthelmintic properties in humans, as well as to act as an insecticide (2, 3). Subsequently, it was found to have profound neurological effects when ingested by humans, and to be the agent binding most strongly to the kainate receptors of the central nervous system (4–6). This has prompted renewed interest in the spectroscopy of this compound both as a means of its identification and as a source of information regarding its physical properties, particularly those that may have some bearing on the physiological and neurological characteristics.

DA possesses one imino group, >NH, and three carboxylate groups, $-COO^-$ (Fig. 1), all capable of protonation. Therefore, DA molecules in solution are a mixture of five distinct protonation states (Table 1), their proportions in solution being determined by the four pK_a values, and varying with pH (7). A different NMR, IR, UV, etc. spectrum will correspond to each protonation state, and the solution spectra will therefore be pH dependent. We have recently reported the results of our studies of the UV spectrum (7) and solubility (8) of DA, and now present our investigation of ^1H NMR and ^{13}C NMR spectra as a function of pH and pD. The NMR spectra have the advantage of yielding more precise pK_a values and permitting the identification of the sites of protonation corresponding to each pK_a (9–12).

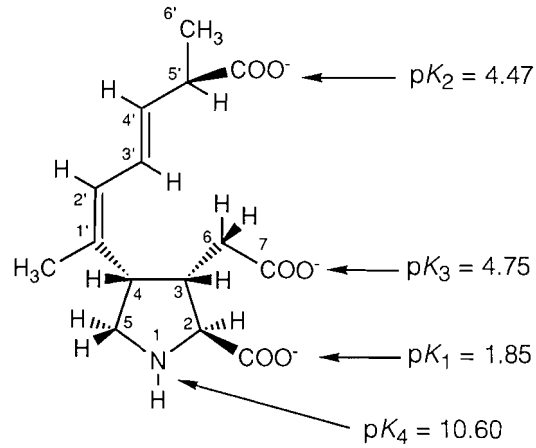

FIG. 1. Molecular structure of domoic acid in its fully deprotonated form.

Experimental

All NMR spectra were recorded using a Bruker MSL300 spectrometer at 300 MHz (^1H) or 75.5 MHz (^{13}C), at 20°C. DA from the stock used in previous studies (7, 8) was dissolved in H_2O or D_2O and placed in 5-mm sample tubes with a concentric 2-mm tube (Wilmad 520-1) containing TSP in D_2O for a reference. Acquisition times were 3.4 s (^1H) or 0.49 s (^{13}C), and chemical shifts were measurable to a precision of ca. 0.003 ppm or 0.02 ppm respectively, except where precluded by strong coupling, linewidth, or overlap. Adjustment of pH was by addition of minute amounts of 1 N NaOH (NaOD for solutions in D_2O) or 1 N HCl (DCl), starting with pH 3.4, which corresponds to the isoelectric point. Back titration was avoided to minimize the formation of salt. The concentration of DA was low enough (20 mM) to avoid precipitation at any pH (8), and dilution of the solution due to the addition of acid or base was negligible. All pH and pD measurements were made within the NMR tubes using a Fisher Accumet model 610A pH meter and an Ingold 6030 combination electrode calibrated for each measurement with Anachemia standard buffer solutions. Values of pD reported here are direct pH meter readings without correction for changes in electrode characteristics in D_2O (13), unless otherwise stated. Chemical shifts of strongly coupled protons were determined where necessary by simulation, using the Bruker PANIC program.

Titration curves for each ^1H and ^{13}C resonance were fitted to eq. [1], which is analogous to eq. [1] in ref. 11:

$$[1] \quad \delta = \delta_L + \Sigma\{\Delta_i.10^x/(10^x + 1)\}$$

where $x = pH - pK_{ai}$, Δ_i is the chemical shift variation at a given nucleus corresponding to a change from complete protonation to deprotonation at the ith site, δ_L is the shift for complete protonation, and $i = 1$–4 corresponding to each of the protonation sites. Equation [1] is based on the assumption that the different protonation states have equal activity coefficients, and that the proton

exchange proceeds quickly compared to the time scale of the NMR experiment. Optimization to minimize the sum of squares of the residuals was performed with a SIMPLEX routine (14) written in Pascal for use with up to nine variable parameters and run on a PC/AT-compatible computer, which also generated the plots shown (Figs. 2–5).[3] Initial values of pK_a were estimated from logarithmic plots of the chemical shift titration curves of nuclei close to each of the four protonation sites. Resonance assignments were known previously (1). Thus, at pH < 6, the shifts of resonances of C-2, C-2 carboxyl, and H-2 were principally affected by protonation at the C-2 carboxylate; those of C-6, C-7, and H-6 by protonation at carboxylate C-7; and those of C-5′, C-5′ carboxyl, C-6′, H-5′, and H_3-6′ by protonation at the C-5′ carboxylate. Pronounced effects due to protonation of NH at pH > 7 occurred at C-1′, C-2 carboxyl, H-2, H-3, H-5α, and H-5β; lesser effects occurred at other nuclei. Within each of the above groups of nuclei, separate values of pK_a obtained by curve fitting agreed closely, confirming the dominant effect of the nearby protonation site and permitting each

[a]Typical errors in δ_L resulting from independent fits to the same data are 0.005 ppm (^1H) or 0.03 ppm (^{13}C).

[b]pH and pK_a measurements used in generating Table 2 are **uncorrected** for changes in glass electrode characteristics when obtained in D_2O solution. Corrected values may be obtained by adding 0.40 to pH meter readings in D_2O and to the corresponding pK_a values derived from curve fitting (13) (see Table 3).

of the four pK_a's to be assigned to specific groups. Where nuclei were influenced by two or more protonation sites at pH < 6, fitted curves were generated by varying Δ_i's only, the pK_a's being held to the above values obtained from resonances of nuclei near protonation sites. It should be emphasized that, although the pK_a determinations are highly accurate, the values of the Δ_i parameters in Table 2 should be regarded as no more than indicators of the amount of influence that protonation at a particular site has on a given nucleus. When a nucleus is remote from the protonation site and Δ_i is small, and the site is one of the two with closely similar pK_a's, the quality of the curve fitting is insensitive to Δ_i and it is difficult to distinguish the contribution of a particular protonation site. Nevertheless, the parameters in Table 2 should yield predicted shifts for any pH with an accuracy close to that of the measurement.

Results and discussion

Titration curves for ^1H and ^{13}C resonances of DA at constant concentration in D_2O are shown in Figs. 2 and 3, together with curves generated by least-squares fitting of eq. [1], which yielded the parameters in Table 2. Similar plots for DA at the same concentration in H_2O (Figs. 4 and 5) are available in the depository, as are tables of the original chemical shift data on which these figures are based.[3] Comparison with preliminary results in H_2O, where the concentration was varied, showed slight concentration dependence of both ^1H and ^{13}C shifts: at 70 mM concentration, pH 7.1, ^1H resonances shifted upfield by 0.005–0.020 ppm, whereas ^{13}C peaks moved downfield by 0.04–0.24 ppm (excepting the C-4′ resonance, which moved upfield), relative to those observed at a concentration of 20 mM.

The results show that the pK_a's in ascending order are associated with deprotonation of carboxylate groups at positions 2 and 5′, carboxylate C-7, and the NH group at position 1, respectively. The pK_a values obtained are gathered in Table 3; we have adopted the mean H_2O values (underlined). The previously reported pK_a's (2) were obtained by an unstated

[b]Error ±0.5 Hz.

method and are of unknown accuracy; our own UV study (7) could only confirm the pK_a values roughly and without assigning them to specific protonation sites. These rough pK_a values were used to calculate the proportions of the five protonation states of DA as a function of pH (7). The pH variation of the proportions determined from the NMR-derived pK_a's is similar, and is readily visualized with the aid of Fig. 5 of ref. 7.

In a strongly acid environment, at pH below 1, DA molecules exist largely as the fully protonated cations A (Table 1). As pH increases towards pK_{a1} = 1.85, the nominally neutral DA molecules B appear, in which the C-2 carboxyl group is deprotonated and negatively charged. The C-2 carboxyl group is nearest to the positively charged imino group, and the proximity of the two oppositely charged groups apparently makes this form of the zwitterion more stable than the ones involving the more remote C-5′ carboxyl group or carboxyl C-7. As pH increases further towards pK_{a2} = 4.47, the C-5′ carboxyl also becomes deprotonated, giving rise to the singly charged anion, C. The relative stability of the isomer with positive charge on the imino group and negative charges on C-5′ and C-2 carboxyls appears to be due to the large separation between the two negatively charged groups. As pH increases further towards pK_{a3} = 4.75, the carboxyl C-7 also becomes deprotonated, giving rise to the doubly charged anion D. At still higher pH values, approaching pK_{a4} = 10.60, the imino group loses its extra proton to yield the triply charged anion E.

It has been reported (12) that protonation of either a carboxylate or an amino group leads to upfield shifts of ^{13}C resonances and downfield shifts of ^1H resonances, the observed shifts decreasing monotonically with the number of bonds separating the nucleus from the field source. However, upon the titration of the amino group of an amino acid, larger ^{13}C shifts are observed (12) for the C_β and the carboxyl carbons than for C_α. This pattern is exactly what is observed in the case of DA. Table 4 shows the general similarity of the ^{13}C titration shifts for the corresponding carbon atoms in DA and glutamic acid (GA).

Proton coupling constants of DA (Table 5) are relatively little affected by protonation. The largest changes (up to 2.8 Hz) occur with protonation of the imino group, to J(2,3), J(4,5β), J(5α,5β), J(3,6a), and J(3,6b). Lesser changes to J(2,3), J(4,5α), J(3,6a), J(3,6b), and J(6a,6b) are associated with protonation at other sites.

Synthesis of cyclopentane analogs of 5-fluorouracil nucleosides

LUCJAN J. J. HRONOWSKI AND WALTER A. SZAREK[1]
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received August 29, 1990[2]

LUCJAN J. J. HRONOWSKI and WALTER A. SZAREK. Can. J. Chem. **70**, 1162 (1992).

New carbocyclic analogs (**12**, **14**, and **15**) of 5-fluorouracil nucleosides have been prepared by fluorination, using elemental fluorine, of the acetylated analogs (**8**, **10**, and **11**, respectively) of 1-(2′,3′-dideoxy-*glycero*-pentofuranosyl)- and 1-(2′- and 3′-deoxy-β-*threo*-pentofuranosyl)-uracil nucleosides. The carbocyclic analog (**14**) of 1-(2′-deoxy-β-*threo*-pentofuranosyl)-5-fluorouracil was then utilized for the preparation of various new carbocyclic analogs of 1-(3′-substituted-2′,3′-dideoxy-β-*erythro*-pentofuranosyl)-5-fluorouracil nucleosides by S_N2 displacement of the 3′-mesyloxy group in the protected derivative **17**. In this way analogs having the chloro (see **23**), bromo (see **24**), and azido (see **25**) groups at the 3′-position were obtained; the analog **29** having a 3′-amino group was obtained by reduction of the azido group. In addition (±)-5-fluoro-1-{3-(hydroxymethyl)-3-cyclopenten-1-yl}-2,4(1*H*,3*H*)-pyrimidinedione (**26**) was obtained as an elimination side-reaction product in the preparation of the 3′-chloro and 3′-bromo analogs. Compounds **8**, **9**, **12**, **14**, **15**, **25**, and **29** were tested against the herpes simplex viruses and were found to be inactive. Compound **26** inhibited the growth of K-562 cells with an ID_{50} (10^{-4}–10^{-3}), which was about 100-fold greater than that of 5-fluorouracil in this test system. Analogs **12**, **25**, and **29** were slightly cytotoxic.

LUCJAN J. J. HRONOWSKI et WALTER A. SZAREK. Can. J. Chem. **70**, 1162 (1992).

On a préparé de nouveaux analogues carbocycliques (**12**, **14** et **15**) de nucléosides du 5-fluoro-uracile en effectuant la fluoration, à l'aide de fluor élémentaire, des analogues acétylés (respectivement **8**, **10** et **11**) des nucléosides des 1-(2′,3′-didésoxy-*glycéro*-pentofuranosyl)- et 1-(2′- et 3′-désoxy-β-*thréo*-pentofuranosyl)-uraciles. Faisant appel à une réaction de substitution S_N2 du groupe 3′-mésyloxy du dérivé protégé **17**, on a alors utilisé l'analogue carbocyclique (**14**) du 1-(2′-désoxy-β-*thréo*-pentofuranosyl)-5-fluoro-uracile pour préparer divers nouveaux analogues des nucléosides du 1-(2′,3′-didésoxy-β-*érythro*-pentofuranosyl)-5-fluoro-uracile substitués en position 3′. De cette façon, on a obtenu des analogues portant des groupes chloro (*voir* **23**), bromo (*voir* **24**) et azido (*voir* **25**) en position 3′; on a obtenu l'analogue **29** portant un groupe amino en position 3′ par réduction du groupe azido. De plus, on a obtenue la (±)-5-fluoro-1-[3-(hydroxyméthyl)-cyclopent-3-en-1-yl]-2,4-(1*H*,3*H*)-pyrimidinedione (**26**) comme sous-produit de la réaction d'élimination dans la préparation des analogues 3′-chloro et 3′-bromo. On a évalué l'activité des composés **8**, **9**, **12**, **14**, **15**, **25** et **29** contre les virus de l'herpes simplex et on a trouvé qu'ils sont inactifs. Le composé **26** inhibe la croissance des cellules du K-562 avec un ID_{50} de (10^{-4}–10^{-3}) qui, dans le système d'évaluation, est environ 100 fois plus grand que celui du 5-fluoro-uracile. Les analogues **12**, **25** et **29** sont légèrement cytotoxiques.

[*Traduit par la rédaction*]

Introduction

5-Fluorouracil (5-FUra) and its deoxynucleoside, 5-fluoro-2′-deoxyuridine (5-FdUrd), are widely used as anticancer drugs (1, 2). Both of these drugs are extensively metabolized in vivo such that the 5-fluorouracil base becomes incorporated into the ribo- and 2′-deoxyribo-nucleosides and nucleotides as well as the nucleic acids (1–5). In the case of 5-FdUrd, it may be converted first by the pyrimidine nucleoside phosphorylases into 5-FUra, which then is utilized for the synthesis of ribo- and 2′-deoxyribo-nucleotides (3). However, there is considerable evidence that the therapeutic effects of these compounds are due to the metabolite, 5-fluoro-2′-deoxyuridine 5′-phosphate, which is a potent inhibitor of thymidylate synthetase, an essential enzyme for DNA synthesis (6–9). As a result of these observations, there has been an interest in recent years in the development of 5-fluorouracil-containing nucleosides that are resistant to the pyrimidine nucleoside phosphorylases, in order to maximize the amount of the therapeutically active metabolite within the tumor cells.

Two approaches have provided 5-fluorouracil-containing nucleosides that did not function as substrates for the pyrimidine nucleoside phosphorylases. In the first approach fluorine was introduced into the sugar ring to provide 1-(2′-deoxy-2′-fluoro-β-D-arabinofuranosyl)-5-fluorouracil (10) and 5-fluoro-2′,3′-dideoxy-3′-fluorouridine (11). The 5′-monophosphates of these nucleosides were shown to be noncompetitive inhibitors of the thymidylate synthetase enzyme. In the second approach, described by Shealy *et al.* (12), the furanose-ring oxygen was replaced by a methylene group to provide carbocyclic analogs of 5-fluorouracil nucleosides. As expected, the carbocyclic analog of 5-fluoro-2′-deoxyuridine did not undergo phosphorolysis to 5-fluorouracil but was phosphorylated enzymatically to the analog of 5-FdUrd 5′-phosphate (12). The carbocyclic analog of 5-FdUrd was cytotoxic to L1210 cells in culture and showed slight activity against leukemia P-388 in vivo.

In the present work, elemental fluorine was used for the synthesis of carbocyclic analogs of 1-(2′- and 3′-deoxy-β-*threo*-pentofuranosyl)-5-fluorouracil nucleosides, and a series of carbocyclic analogs of 1-(3′-substituted-2′,3′-dideoxy-β-*erythro*-pentofuranosyl)-5-fluorouracil nucleosides. In addition, preliminary results of tests on these compounds for the inhibition of the growth of K-562 cells are discussed.

Results and discussion

The synthesis of the carbocyclic analogs (**4**–**7**)[3] that were utilized for the preparation of 5-fluorouracil analogs was described previously (13, 14). Briefly, the syntheses

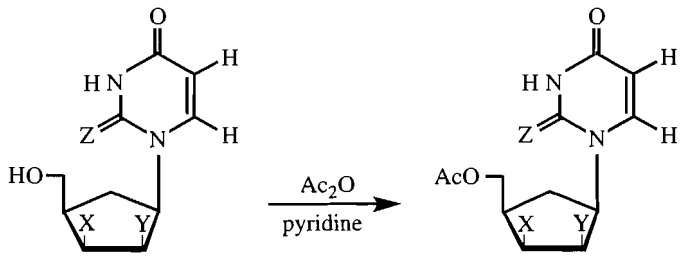
SCHEME 1

involved the coupling of an appropriate *cis*-3-aminocyclopentanemethanol with 3-ethoxypropenoyl isocyanate or 3-ethoxypropenoyl isothiocyanate to give the corresponding propenoylureas or propenoylthiourea. The propenoylureas were cyclized in 2 N H_2SO_4 and the propenoylthiourea was cyclized in 15 N aqueous ammonia to give the required carbocyclic nucleoside analogs.

Fluorination of the uracil and 2-thiouracil nucleoside analogs using elemental fluorine

Fluorination of carbocyclic analogs of uracil nucleosides using elemental fluorine was performed previously by Shealy *et al.* (12) using the unprotected nucleoside analogs. However, the yields reported by this approach were generally below 50%. The fluorination of the uracil base was also accomplished using a variety of other fluorinating reagents (15), including trifluoromethyl hypofluorite (16), xenon difluoride (17), cesium fluoroxysulfate (18), and acetyl hypofluorite (19). Moderate to high yields of fluorinated compounds were obtained using all except the xenon difluoride reagent (10% yield of 5-fluorouracil). The fluorination, using trifluoromethyl hypofluorite, elemental fluorine, or cesium fluoroxysulfate, was shown to proceed by way of an addition–elimination mechanism (see Scheme 1). Thus, treatment of uracil derivatives (**1**) dissolved in methanol with a solution of trifluoromethyl hypofluorite in fluorotrichloromethane gave adducts **2** having a methoxyl group at the 6-position (R^2 = OMe). In addition, ^1H and ^{19}F nmr spectroscopy and a single-crystal X-ray analysis of compound **2** (R^1 = Me, R^2 = OMe) established conclusively a *cis* stereochemistry of the adducts (16*f*). Barton *et al.* (16*b*) fluorinated uracil (**1**, R^1 = H) using the trifluoromethyl hypofluorite reagent in an aqueous solvent and obtained adduct **2** (R^1 = H, R^2 = OH) having a hydroxyl at the 6-position. The desired 5-fluorouracil (**3**) was obtained by heating, or by treatment of the adduct **2** with a base such as triethylamine or ammonium hydroxide. Similar adducts were obtained in fluorinations using elemental fluorine (12, 20) or cesium fluoroxysulfate (18); however, fluorinations using the latter reagent in methanol gave a mixture of *cis*- and *trans*-5-fluoro-6-methoxy adducts. However, all of the above fluorinations are regiospecific, so that only the 5-position of the uracil ring becomes fluorinated. There seems to be no advantage in using one of the three reagents in preference over the other two, since all were shown to give moderate to high yields of the fluorinated products. The elemental fluorine reagent has been shown to give higher yields and fewer decomposition products if the acetic acid solvent is saturated first with fluorine, and this solution is used then for fluorination, rather than if there is direct addition of fluorine to a solution of the uracil derivative in acetic acid (20).



4 X = Y = H, Z = O
5 X = Y = H, Z = S

14 X = OH, Y = R = H
15 X = R = H, Y = OH

SCHEME 2

Also, both elemental fluorine and trifluoromethyl hypofluorite are extremely toxic, and violent decompositions have been observed (21) in the case of the cesium fluoroxysulfate reagent.

In fluorinations of unprotected 2′-deoxyuridine nucleosides using elemental fluorine, Cech and Holý (20*b*) had obtained low yields (~50%), similar to those obtained by Shealy *et al.* (12) with the carbocyclic analogs; however, considerably higher yields (69–82%) were obtained when the sugar hydroxyl groups were protected with benzoyl groups. Protection of the hydroxyl groups with acetyl groups also improved considerably the yields in this type of fluorination (20*a*). Thus, in the present work, as shown in Scheme 2, the carbocyclic analogs (**4**–**7**) of uracil and 2-thiouracil nucleosides were acetylated using acetic anhydride in pyridine to give compounds **8**–**11**, respectively. The protected nucleoside analogs were fluorinated then by passing a fluorine–nitrogen mixture (5:95) through solutions of the analogs in acetic acid. Treatment of the products with a solution of

triethylamine–methanol–water {2:9:9 (v/v/v)} gave the corresponding, unprotected 5-fluorouracil derivatives (**12**, **14**, and **15**); in the case of the 2-thiouracil derivative (**9**), only the 5-fluorouracil analogs **12** (40%) and **13** (10%) were obtained. The yields of the deprotected 5-fluorouracil derivatives (**12**, **14**, and **15**) from the protected uracil derivatives (**8**, **10**, and **11**, respectively) were 60–80%.

The ^{1}H nmr spectra of the protons in the cyclopentyl moieties of the 5-fluorouracil derivatives (**12**, **14**, and **15**) are nearly identical with those for the corresponding uracil derivatives (**4**, **6**, and **7**, respectively) (13, 14). However, the protons on the pyrimidine ring resonate 0.3–0.6 ppm further downfield in the case of the 5-fluorouracil derivatives than the corresponding protons in the case of the uracil derivatives.

Synthesis of cyclopentane analogs of 3′-substituted-2′,3′-dideoxy-5-fluorouridines

As shown in Scheme 3, the carbocyclic analog (**14**) of 1-(2′-deoxy-β-*threo*-pentofuranosyl)-5-fluorouracil was utilized for the synthesis of a variety of 3′-substituted-2′,3′-dideoxy-5-fluorouridine analogs. The primary hydroxyl group of compound **14** was protected by a trityl group using trityl chloride in pyridine at 100°C (22) to give **16**. Treatment of compound **16** with methanesulfonyl chloride in pyridine at room temperature afforded the 3′-mesylate (**17**) in 75% yield from **14**. Nucleophilic displacement of the 3′-mesyloxy group using tetra-*n*-butylammonium chloride (TBACl) in *N*,*N*-dimethylformamide gave the 3′-chloro derivative (**18**). The 3′-bromo derivative (**19**) was prepared analogously using tetra-*n*-butylammonium bromide (TBABr). The 3′-azido derivative (**20**) was prepared by displacement of the 3′-mesyloxy group using sodium azide in *N*,*N*-dimethylformamide. The elimination products, compounds **21** and **22**, were obtained also in the reactions with TBACl (in 29% yield) and TBABr (in 33% yield); the structures of these compounds were assigned on the basis of ^{1}H nmr spectral data. In the reaction with TBACl, **21** and **22** were obtained in a 3:1 ratio, respectively, whereas, with TBABr, compound **21** was formed preponderantly and only a trace of **22** was produced. Detritylation of compounds **18–22** in methylene chloride using diethylaluminum chloride at room temperature (23) afforded compounds **23–27**, respectively; in the cases of compounds **23–25**, the yields were 84–93%. The azido group in compound **25** was converted into the amino group as shown in Scheme 4. Treatment of the azide **25** with triphenylphosphine in pyridine (24) gave the triphenylphosphinimine intermediate (**28**), which, on hydrolysis using concentrated ammonium hydroxide (25), afforded the amino derivative **29** in 90% yield.

The assignments of the chemical shifts of the resonances of the protons in the compounds shown in Schemes 3 and 4 were made with the aid of spin–spin decoupling experiments. In the cases of compounds **18–20** and **23–25**, the signals of the 2′, 2″, 4′, and 5″ protons consist of complex overlapping multiplets (at 200 MHz) such that, in most instances, only a range of chemical shifts is given for these signals. The ^{1}H nmr spectra (at 200 MHz) of compounds **18** and **19** show similar multiplet patterns, and the chemical shifts of the resonances of corresponding protons in the two compounds are nearly identical, with the largest difference occurring for the resonance of the proton at C-3′. In the case of the bromine-containing analog (**19**), this proton resonates 0.05 ppm further downfield than does the proton in the chlorine-containing analog (**18**). The chemical shifts of the resonances of corresponding protons in the deprotected compounds **23** and **24** are also similar, and a similar trend was observed for the resonance of the proton at C-3′ in these compounds as was seen for the tritylated compounds. Also, the chemical shifts of the H-3′ signal are almost identical in the corresponding cases of the protected (**18**, **19**, and **20**) and deprotected (**23**, **24**, and **25**, respectively) compounds. Finally, the chemical shifts of the resonances of H-3 and H-6 on the pyrimidine base are almost identical in compounds **18–20** and **23–25**.

Ultraviolet spectra of the nucleoside analogs

The ultraviolet spectra of the acetylated, uracil- (**8**, **10**, and **11**) and 2-thiouracil- (**9**) nucleoside analogs resemble very closely those of the corresponding unprotected nucleoside analogs (**4–7**) (13, 14) and the spectra of 1-methyluracil and 1-methyl-2-thiouracil (26), respectively, at the corresponding pH's. However, in the cases of the acetylated, uracil-nucleoside analogs (**8**, **10**, and **11**), the absorption maxima are shifted slightly (1–3 nm) to shorter wavelengths compared to the cases of the corresponding unprotected compounds. In the case of the acetylated, 2-thiouracil-nucleoside analog (**9**), the absorption maxima occur at the same wavelengths as in the case of the unprotected analog (**5**). The absorption spectra of the 5-fluorouracil analogs (**12–15**, **25**, **26**, and **29**) have maxima at 208–210 nm and 273–275 nm in both neutral and acidic solvents, and at 218–221 nm and 272–274 nm in basic solvent. The positions of the absorption maxima at the short wavelengths (208–210 and 218–221 nm) differ little between the spectra of the uracil and 5-fluorouracil analogs; however, the long-wavelength maxima occur at significantly shorter wavelengths (265–268 nm) in the spectra of the uracil analogs (**4**, **6**, and **7**). Similar patterns have been observed for the cases of uracil and 5-fluorouracil (27), and their 1-methyl and 1-glycosyl derivatives (26–28).

Biological evaluation

Compounds **12**, **14**, **15**, **23–26**, and **29** were tested for cell-growth inhibition using cultured K-562 cells by methods described previously (29). Compounds **12**, **14**, **15**, **23**, **24**, and **29** showed no cell-growth inhibition at concentrations as high as 10^{-3} M. Compound **25** showed some cell-growth inhibition at 10^{-3} M, and compound **26** had an ID_{50} (dose which inhibits cell-number increase to 50% of the control) in the range 10^{-4}–10^{-3} M and was about 100-fold less active than 5-fluorouracil in this test system. Compounds **12**, **14**, **15**, and **29** were evaluated also for inhibition of leukemia L1210 cell growth in vitro. The ID_{50}'s of compounds **14** and **15** were greater than 10^{-4}, and those of **12** and **29** were 6.4×10^{-4} M and 7.3×10^{-4} M, respectively. In this test system the ID_{50} of 5-fluorouracil was $\sim 10^{-6}$ M. Compound **29** was evaluated also for cytotoxicity using B16-F10-murine melanoma, C26-murine colon, HCT-116-human colon, KB-human nasopharyngyl, Moser-human colon, and M109-murine lung cell lines, and showed no activity at 160 μg/mL. Compounds **8**, **9**, **12**, **14**, **15**, **25**, and **29** were tested also for antiviral activity against herpes simplex viruses 1 and 2, and were found to be inactive.

Conclusions

Three new carbocyclic analogs of 5-fluorouracil nucleosides have been synthesized by fluorination using elemental fluorine of acetylated uracil analogs that were synthesized

as described previously (13, 14). The carbocyclic analog (**14**) of 1-(2′-deoxy-β-*threo*-pentofuranosyl)-5-fluorouracil was utilized for the synthesis of novel carbocyclic analogs of 1-(3′-substituted-2′,3′-dideoxy-β-*erythro*-pentofuranosyl)-5-fluorouracil nucleosides by S_N2 displacement of the 3′-mesyloxy group in the protected derivative **17**. The novel nucleoside analogs produced in this way contained a chloro, bromo, or an azido group at the 3′-position; reduction of the azido group gave the 3′-amino analog. The ^{1}H nmr spectra (at 200 MHz) of all of the new analogs of nucleosides have been determined and discussed. In addition, the new analogs were evaluated for tumor-cell growth inhibition, and for antiviral activity against the herpes simplex viruses.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Infrared spectra were determined in potassium bromide on a Perkin–Elmer 598 spectrophotometer. The ^{1}H nmr spectra were recorded on a Bruker CXP-200 spectrometer at 200 MHz. The proton chemical shifts (δ) are given relative to Me_4Si (δ = 0). Assignments of chemical shifts and coupling constants were made with the aid of spin-decoupling experiments. The following abbreviations are used in describing ^{1}H nmr signals: singlet (s), doublet (d), triplet (t), quartet (q), quintuplet (qu), multiplet (m), and broadened (br). Ultraviolet spectra were recorded on a Perkin–Elmer 552 spectrophotometer without any precautions having been taken to exclude oxygen. Thin-layer chromatography (tlc) was performed using silica gel 60 F-254 plates and column chromatography on silica gel 60. The plates and silica gel 60 were purchased from BDH Chemicals. The developed plates were dried and sprayed with a solution of ceric sulfate (1%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid, and heated at ~150°C. Unless otherwise indicated, the same solvent was used for both tlc and column chromatography.

*(±)-1-{*cis*-3-(Acetoxymethyl)cyclopentyl}-2,4(1*H*,3*H*)-pyrimidinedione (**8**)*

A solution of **4** (0.685 g, 3.26 mmol) and acetic anhydride (2.0 mL, 21.2 mmol) in pyridine (20 mL) was kept at room temperature for 13 h. The reaction solution was treated with ethanol (5 mL) and the solvent was evaporated under vacuum. The residue was evaporated then with ethanol–water {2 × 10 mL, 1:1 (v/v)} to give a crystalline solid, which was purified further by silica gel column chromatography to give **8** (0.641 g, 78%) as a white solid, R_f 0.45 {4:4:1 (v/v/v) ethyl acetate – toluene–2-propanol}. An analytical sample was prepared by recrystallization from ethyl acetate – hexanes, mp 140–141°C; uv λ_{max} (C_2H_5OH): 209 (ε 9000), 267 (10 200) nm; λ_{max} (0.01 M HCl in C_2H_5OH): 209 (ε 9100), 267 (10 200) nm; λ_{max} (0.01 M NaOH in C_2H_5OH): 219 (ε 9300), 266 (7400) nm; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.33–2.34 (7H, m, H-2′, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 2.01 (3H, s, OAc), 3.98 (2H, m, AcOCH_2), 4.74 (1H, m, H-1′), 5.58 (1H, d of d, $^2J_{5,6}$ = 8.2, $^4J_{5,3}$ = 1.8 Hz, H-5), 7.74 (1H, d, $^3J_{6,5}$ = 8.2 Hz, H-6), 11.24 (1H, br s, H-3). Anal. calcd. for $C_{12}H_{16}O_4N_2$: C 57.13, H 6.39, N 11.10; found: C 57.07, H 6.03, N 11.10.

*(±)-2,3-Dihydro-1-{*cis*-3-(acetoxymethyl)cyclopentyl}-2-thioxo-4(1*H*)-pyrimidinone (**9**)*

A solution of **5** (0.492 g, 2.17 mmol) and acetic anhydride (2.0 mL, 21.2 mmol) in pyridine (20 mL) was kept at room temperature for 19 h. The reaction solution was treated then as described for the preparation of **8**, and, after fractionation by silica gel chromatography, compound **9** (0.466 g, 80%) was obtained as a white solid, mp 152–155°C; R_f 0.50 {8:8:1 (v/v/v) ethyl acetate – toluene–2-propanol}. Recrystallization from ethyl acetate – hexanes gave material having mp 152–154°C; uv λ_{max} (C_2H_5OH): 219 (ε 17 600), 273 (13 700) nm; λ_{max} (0.01 M HCl in C_2H_5OH): 219 (ε 17 700), 273 (13 600) nm; λ_{max} (0.01 M NaOH in C_2H_5OH): 240 (ε 19 700), 257 (14 600), 273 (16 300) nm; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.29–2.37 (7H, m, H-2′, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 2.02 (3H, s, OAc), 4.02 (2H, m, AcOCH_2), 5.76 (1H, m, H-1′), 6.00 (1H, br d, $^3J_{5,6}$ = 8.2 Hz, H-5), 7.91 (1H, d, $^3J_{6,5}$ = 8.2 Hz, H-6), 12.61 (1H, br s, H-3). Anal. calcd. for $C_{12}H_{16}O_3N_2S$: C 53.71, H 6.01, N 10.44, S 11.95; found: C 53.96, H 6.04, N 10.39, S 12.45.

*(±)-1-{(1*β*,3*β*,4*β*)-3-Acetoxy-4-(acetoxymethyl)cyclopentyl}-2,4(1*H*,3*H*)-pyrimidinedione (**10**)*

A solution of **6** (0.500 g, 2.21 mmol) and acetic anhydride (2.0 mL, 21.2 mmol) in pyridine (20 mL) was kept at room temperature for 18 h. It was treated then as described for the preparation of **8**, and, after fractionation by silica gel column chromatography, **10** (0.525 g, 77%) was obtained as a solid, R_f 0.45 {3:3:1 (v/v/v) ethyl acetate – toluene–2-propanol}. An analytical sample was prepared by recrystallization from ethanol to give **10** as a white crystalline solid, mp 157–158°C; uv λ_{max} (C_2H_5OH): 208 (ε 10 100), 267 (10 600) nm; λ_{max} (0.01 M HCl in C_2H_5OH): 208 (ε 10 200), 267 (10 600) nm; λ_{max} (0.01 M NaOH in C_2H_5OH): 218 (ε 9800), 265 (7900) nm; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.63 (1H, m, J_{gem} = 12.2, ^3J = 10.6 Hz, H-5′), 1.71 (1H, m, J_{gem} = 15.1, $^3J_{2',1'}$ = 6.6, $^3J_{2',3'}$ = 2.5 Hz, H-2′), 1.99 (3H, s, OAc), 2.05 (3H, s, OAc), 2.14 (1H, m, J_{gem} = 12.2, ^3J = 7.2 Hz, H-5″), 2.27–2.57 (2H, m, H-2″ and H-4′), 4.02 (1H, d of d, J_{gem} = 11.0, $^3J_{toH\text{-}4'}$ = 6.5 Hz, OCH_2), 4.12 (1H, d of d, J_{gem} = 11.0, $^3J_{toH\text{-}4'}$ = 8.2 Hz, OCH_2), 4.98 (1H, m, H-1′), 5.15 (1H, t of d, ^3J = 5.2, $^3J_{3',2'}$ = 2.2 Hz, H-3′), 5.66 (1H, d, $^3J_{5,6}$ = 8.1 Hz, H-5), 7.59 (1H, d, $^3J_{6,5}$ = 8.1 Hz, H-6), 11.27 (1H, br s, H-3). Spin–spin decoupling was performed at δ 2.14, 4.98, and 5.15. Anal. calcd. for $C_{14}H_{18}O_6N_2$: C 54.19, H 5.85, N 9.03; found: C 53.88, H 5.88, N 9.03.

*(±)-1-{(1*β*,2*β*,4*β*)-2-Acetoxy-4-(acetoxymethyl)cyclopentyl}-2,4(1*H*,3*H*)-pyrimidinedione (**11**)*

A solution containing **7** (0.705 g, 3.12 mmol) and acetic anhydride (2.5 mL, 26.5 mmol) in pyridine (25 mL) was kept at room temperature for 25 h. It was treated then as described for the preparation of **8**, and, after fractionation by silica gel column chromatography, **11** (0.83 g, 86%) was obtained as a solid, R_f 0.41 {4:4:1 (v/v/v) ethyl acetate – toluene–2-propanol}. An analytical sample was obtained by recrystallization from ethyl acetate – hexanes to give **11** as a white crystalline solid, mp 126–127°C; uv λ_{max} (C_2H_5OH): 208 (ε 9700), 265 (10 900) nm; λ_{max} (0.01 M HCl in C_2H_5OH): 208 (ε 9900), 265 (11 000) nm; λ_{max} (0.01 M NaOH in C_2H_5OH): 219 (ε 9500), 265 (8300) nm; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.46 (1H, m, J_{gem} = 13.8, $^3J_{3',4'}$ = 5.9, $^3J_{3',2'}$ = 2.0 Hz, H-3′), 1.82–2.46 (4H, m, H-3″, H-4′, H-5′, and H-5″), 1.92 (3H, s, OAc), 2.03 (3H, s, OAc), 4.02 (2H, m, OCH_2), 4.78 (1H, m, $^3J_{1',5'}$ = 12.4, $^3J_{1',5''}$ = 7.4, $^3J_{1',2'}$ = 5.2 Hz, H-1′), 5.14 (1H, m, $^3J_{2',1'}$ = 5.2, $^3J_{2',3''}$ = 4.8, $^3J_{2',3'}$ = 2.0 Hz, H-2′), 5.51 (1H, d, $^3J_{5,6}$ = 8.1 Hz, H-5), 7.71 (1H, d, $^3J_{6,5}$ = 8.1 Hz, H-6), 11.28 (1H, br s, H-3). Spin–spin decoupling was performed at δ 1.46, 4.02, 4.78, and 5.14. Anal. calcd. for $C_{14}H_{18}O_6N_2$: C 54.19, H 5.85, N 9.03; found: C 53.92, H 5.98, N 9.03.

*(±)-5-Fluoro-1-{*cis*-3-(hydroxymethyl)cyclopentyl}-2,4(1*H*,3*H*)-pyrimidinedione (**12**)*

A fluorine–nitrogen mixture containing 5.1% fluorine was bubbled through a solution of acetic acid (150 mL) and compound **8** (0.505 g, 2.00 mmol) for 30 min. The reaction solution was flushed with N_2 for 10 min and the solvent was evaporated. The residue was dissolved in a solution of triethylamine–methanol–water {50 mL, 2:9:9 (v/v/v)}, and the solution was kept at room temperature for 15 h. The solvent was evaporated with 10 mL of ethanol. The residue was diluted with methanol and fractionated by silica gel column chromatography to give **12** (0.308 g, 67%) as a white solid, R_f 0.67 {1:1:1 (v/v/v) toluene – ethyl acetate – 2-propanol}. An analytical sample was prepared by recrystallization from ethanol–hexanes, mp 152–153°C; uv λ_{max} (C_2H_5OH): 209 (ε 9700), 275 (9100) nm; λ_{max} (0.01 M HCl in C_2H_5OH): 209 (ε 9500), 275 (9100) nm; λ_{max} (0.01 M NaOH in C_2H_5OH): 218 (ε 8700), 273

(6900) nm; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.28–2.13 (7H, m, H-2′, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 3.38 (2H, t, ^3J = 5.4 Hz, OCH_2), 4.58 (1H, t, ^3J = 5.2 Hz, OH), 4.72 (1H, m, H-1′), 8.11 (1H, d, ^3J = 7.3 Hz, H-6), 11.74 (1H, br d, J = 4.7 Hz, H-3). Anal. calcd. for $C_{10}H_{13}O_3N_2F$: C 52.63, H 5.74, N 12.27, F 8.32; found: C 52.57, H 5.82, N 12.36, F 8.49.

Fluorination of compound ***9***

Compound **9** (0.361 g, 1.34 mmol) was treated as described for the preparation of compound **12**. After fractionation by silica gel column chromatography two components were isolated having R_f's 0.82 and 0.67 {1:1:1 (v/v/v) toluene – ethyl acetate – 2-propanol}. The component having R_f 0.67 (0.123 g, 40%) was shown by its mp, ^{1}H nmr and uv spectra, and elemental analysis to be identical with compound **12**. The component having R_f 0.82 (0.035 g, 10%) was compound **13**. An analytical sample of compound **13** was prepared by recrystallization from ethyl acetate – hexanes, mp 136–137°C; uv λ_{max} (C_2H_5OH): 208 (ε 10 400), 275 (9000) nm; λ_{max} (0.01 M HCl in C_2H_5OH): 209 (ε 10 000), 275 (9000) nm; λ_{max} (0.01 M NaOH in C_2H_5OH): 218 (ε 10 000), 273 (6900) nm; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.34–2.08 (6H, m, H-2′, H-2″, H-4′, H-4″, H-5′, and H-5″), 2.01 (3H, s, OAc), 2.25 (1H, m, H-3′), 3.99 (2H, m, OCH_2), 4.75 (1H, m, H-1′), 8.15 (1H, d, ^3J = 7.7 Hz, H-6), 11.76 (1H, br d, J = 4.7 Hz, H-3). Spin–spin decoupling was performed at δ 2.25 and 4.75. Anal. calcd. for $C_{12}H_{15}O_4N_2F$: C 53.33, H 5.59, N 10.37, F 7.03; found: C 53.02, H 5.70, N 9.94, F 7.00.

*(±)-5-Fluoro-1-{(1β,3β,4β)-3-hydroxy-4-(hydroxymethyl) cyclopentyl}-2,4(1H,3H)-pyrimidinedione (**14**)*

An acetic acid solution (400 mL) of compound **10** (1.467 g, 4.72 mmol) was treated as described for the preparation of compound **12**. After fractionation by silica gel chromatography, **14** (0.698 g, 60%) was obtained as a solid, R_f 0.55 {1:1:1 (v/v/v) toluene – ethyl acetate – 2-propanol}. An analytical sample was prepared by recrystallization from ethanol, mp 213°C; uv λ_{max} (C_2H_5OH): 208 (ε 9900), 275 (9000) nm; λ_{max} (0.01 M HCl in C_2H_5OH): 209 (ε 9600), 275 (9000) nm; λ_{max} (0.01 M NaOH in C_2H_5OH): 221 (ε 7400), 273 (6900) nm; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.37 (1H, t of d, J_{gem} = 12.1, ^3J = 8.6 Hz, H-5′), 1.56 (1H, br d of d, J_{gem} = 15.1, $^3J_{2',1'}$ = 3.4 Hz, H-2′), 1.88 (1H, m, H-4′), 2.08 (1H, m, H-5″), 2.27 (1H, m, J_{gem} = 15.1, $^3J_{2'',1'}$ = 11.0, $J_{2'',3'}$ = 4.5 Hz, H-2″), 3.42 (1H, m, J_{gem} = 10.6, ^3J = 5.3 Hz, OCH_2), 3.59 (1H, m, J_{gem} = 10.6, $^3J_{to\,OH}$ = 5.3, $^3J_{to\,H\text{-}4'}$ = 7.7 Hz, OCH_2), 4.11 (1H, m, H-3′), 4.39 (1H, t, ^3J = 5.3 Hz, $HOCH_2$), 5.04 (1H, m, H-1′), 5.12 (1H, d, $^3J_{to\,H\text{-}3'}$ = 3.6 Hz, OH), 8.19 (1H, d, ^3J = 7.3 Hz, H-6), 11.72 (1H, br d, J = 5.2 Hz, H-3). Spin–spin decoupling was performed at δ 4.11 and 5.04. Anal. calcd. for $C_{10}H_{13}O_4N_2F$: C 49.18, H 5.37, N 11.47, F 7.78; found: C 49.18, H 5.03, N 11.05, F 7.45.

*(±)-5-Fluoro-1-{(1β,2β,4β)-2-hydroxy-4-(hydroxymethyl) cyclopentyl}-2,4(1H,3H)-pyrimidinedione (**15**)*

An acetic acid solution (200 mL) of compound **11** (0.715 g, 2.30 mmol) was treated as described for the preparation of compound **12**. After fractionation by silica gel column chromatography, **15** (0.451 g, 80%) was obtained as a white solid, R_f 0.57 {1:1:1 (v/v/v) toluene – ethyl acetate – 2-propanol}. An analytical sample was obtained by recrystallization from ethanol–hexanes, mp 160–161°C; uv λ_{max} (C_2H_5OH): 208 (ε 10 000), 275 (9800) nm; λ_{max} (0.01 M HCl in C_2H_5OH): 209 (ε 9800), 275 (9800) nm; λ_{max} (0.01 M NaOH in C_2H_5OH): 219 (ε 9100), 273 (7500) nm; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.30 (1H, m, H-3′), 1.66–2.15 (4H, m, H-3″, H-4′, H-5′, and H-5″), 3.39 (2H, m, OCH_2), 4.04 (1H, m, H-2′), 4.48 (1H, m, $^3J_{1',5'}$ = 11.6, $^3J_{1',5''}$ = 7.2 Hz, H-1′), 4.62 (1H, t, ^3J = 5.0 Hz, $HOCH_2$), 4.93 (1H, d, ^3J = 4.5 Hz, OH at 2′), 7.92 (1H, d, ^3J = 7.7 Hz, H-6), 11.74 (1H, br s, H-3). Spin–spin decoupling was performed at δ 4.04 and 4.48. Anal. calcd. for $C_{10}H_{13}O_4N_2F$: C 49.18, H 5.37, N 11.47, F 7.78; found: C 49.31, H 5.10, N 11.30, F 7.69.

*(±)-5-Fluoro-1-{(1β,3β,4β)-3-hydroxy-4-(triphenylmethoxy-methyl)cyclopentyl}-2,4(1H,3H)-pyrimidinedione (**16**)*

A solution of **14** (0.698 g, 2.86 mmol) and chlorotriphenylmethane (1.252 g, 4.49 mmol) in pyridine (30 mL) was heated at 100°C in an oil bath for 1 h. Additional chlorotriphenylmethane (0.292 g, 1.05 mmol) was added and the heating was continued for 0.5 h. The reaction solution was cooled to room temperature and poured into ice–water (150 mL), and the mixture was stirred until a solid was obtained. The solid was collected by filtration, washed with water (50 mL), dried, dissolved in methylene chloride – ethanol, and fractionated by silica gel column chromatography to give **16** (1.255 g, 90%) as a white solid, mp 223–224°C, R_f 0.59 {10:10:1 (v/v/v) toluene – ethyl acetate – 2-propanol}. A second purification by silica gel column chromatography gave a white powdery solid after dilution of the concentrated eluate with toluene, mp 226–228°C; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.39 (1H, m, J_{gem} = 12.0 Hz, H-5′), 1.55 (1H, d of d, J_{gem} = 15.4 ^3J = 3.3 Hz, H-2′), 1.9–2.3 (2H, m, H-4′ and H-5″), 2.32 (1H, m, J_{gem} = 15.4, ^3J = 11.0, $^3J_{2'',3'}$ = 4.4 Hz, H-2″), 2.99 (1H, m, OCH_2), 3.24 (1H, d of d, J_{gem} = 8.3, ^3J = 6.8 Hz, OCH_2), 4.16 (1H, m, H-3′), 5.07 (1H, m, H-1′), 5.18 (1H, d, $^3J_{to\,H\text{-}3'}$ = 3.7 Hz, OH), 7.15–7.42 (15H, m, Ph), 8.08 (1H, d, ^3J = 7.3 Hz, H-6), 11.73 (1H, br d, J = 5.2 Hz, H-3). Spin–spin decoupling was performed at δ 4.16.

*(±)-5-Fluoro-1-{(1β,3β,4β)-3-(methylsulfonyloxy)-4-(triphenylmethoxymethyl)cyclopentyl}-2,4(1H,3H)-pyrimidinedione (**17**)*

A solution of **16** (1.184 g, 2.43 mmol) in pyridine (20 mL) was cooled in an ice bath and methanesulfonyl chloride (1.0 mL, 12.9 mmol) was added. The reaction solution was then stirred at room temperature for 16 h. The reaction solution was poured into ice–water (150 mL) and the mixture was stirred until the ice melted. The solid was collected by filtration, washed with water (100 mL), dried, dissolved in pyridine, and fractionated by silica gel column chromatography to give **17** (1.142 g, 83%) as a faintly yellow solid, mp 160–165°C (dec.), R_f 0.54 {12:12:1 (v/v/v) toluene – ethyl acetate – 2-propanol}; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.56 (1H, m, H-5′), 1.98 (1H, br d of d, J_{gem} = 15.6, $^3J_{2',1}$ = 5.5 Hz, H-2′), 2.18 (1H, m, J_{gem} = 12.4, ^3J = 7.1 Hz, H-5″), 2.4–2.6 (1H, m, H-4′), 2.63 (1H, m, J_{gem} = 15.6, $^3J_{2'',1'}$ = 10.1, $^3J_{2'',3'}$ = 5.2 Hz, H-2″), 2.98 (3H, s, Me), 3.02–3.22 (2H, m, OCH_2), 5.03 (1H, m, H-1′), 5.21 (1H, m, H-3′), 7.14–7.43 (15H, m, Ph), 7.73 (1H, d, ^3J = 7.1 Hz, H-6), 11.81 (1H, br d, J = 5.2 Hz, H-3). Spin–spin decoupling was performed at δ 1.56 and 5.21.

*(±)-5-Fluoro-1-{(1β,3α,4β)-3-chloro-4-(triphenylmethoxy-methyl)cyclopentyl}-2,4(1H,3H)-pyrimidinedione (**18**),(±)-5-fluoro-1-{3-(triphenylmethoxymethyl)-3-cyclo-penten-1-yl}-2,4(1H,3H)-pyrimidinedione (**21**), and (±)-5-fluoro-1-{cis-4-(triphenylmethoxymethyl)-2-cyclopenten-1-yl}-2,4(1H,3H)-pyrimidinedione (**22**)*

A solution of **17** (0.191 g, 0.338 mmol) and tetra-*n*-butylammonium chloride (0.47 g, 1.70 mmol) (dried over 4 Å sieves) in *N*,*N*-dimethylformamide (10 mL) was heated in an oil bath at 85°C for 1 h and then kept at room temperature overnight. The volume of the solution was reduced by evaporation under reduced pressure and the residue was fractionated by silica gel column chromatography. Two components were isolated having R_f's 0.41 (**18**) and 0.29 (**21** and **22**) {3:1 (v/v) toluene – ethyl acetate}. Compound **18** (0.106 g, 62%) was recrystallized from ethanol–water to give a white crystalline solid (0.082 g), mp 231–233°C; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.65 (1H, m, H-5′), 2.09–2.49 (4H, m, H-2′, H-2″, H-4′, and H-5″), 3.07 (1H, d of d, J_{gem} = 9.0, ^3J = 6.1 Hz, OCH_2), 3.18 (1H, d of d, J_{gem} = 9.0, ^3J = 5.2 Hz, OCH_2), 4.44 (1H, q, ^3J = 7.2 Hz, H-3′), 4.96 (1H, m, H-1′), 7.22–7.43 (15H, m, Ph), 8.09 (1H, d, ^3J = 7.3 Hz, H-6), 11.79 (1H, br d, J = 5.2 Hz, H-3). Spin–spin decoupling was performed at δ 4.44 and 4.96. The component having R_f 0.29 (0.046 g, 29%) was a colorless glassy solid and consisted of a mixture of compounds **21**

For personal use only.

and **22** in a 3:1 ratio, respectively. This ratio was calculated from the integrals of the ^{1}H nmr signals of the 1′, 2′, 3′, and 4′ protons. Compound **22**: ^{1}H nmr (400 MHz, Me_2SO-d_6) δ: 1.29 (1H, m, H-5′), 2.41–2.50 (1H, m, H-5″), 2.94 (1H, m, H-4′), 3.05–3.07 (2H, m, OCH_2), 5.41 (1H, m, H-1′), 5.75 (1H, m, H-2′ or H-3′), 6.17 (1H, m, H-2′ or H-3′), 7.1–7.4 (15H, m, Ph), 7.44 (1H, d, ^3J = 6.8 Hz, H-6), 11.77 (1H, d, J = 5.3 Hz, H-3). The remaining signals in the ^{1}H nmr spectrum correspond to those in the spectrum of the compound, assigned the structure of **21**, obtained in the following experiment.

*(±)-5-Fluoro-1-{(1β,3α,4β)-3-bromo-4-(triphenylmethoxymethyl)cyclopentyl}-2,4(1H,3H)-pyrimidinedione (**19**), **21**, and **22***

A solution of **17** (0.160 g, 0.283 mmol) and tetra-*n*-butylammonium bromide (0.517 g, 1.60 mmol) (dried over 4 Å sieves) in *N*,*N*-dimethylformamide (10 mL) was heated in an oil bath at 85°C for 1 h and then kept at room temperature overnight. The volume of the solution was reduced by evaporation under reduced pressure and the residue was fractionated by silica gel column chromatography. Two components were isolated having R_f's 0.41 (**19**) and 0.29 (**21** and a trace of **22**) {3:1 (v/v) toluene – ethyl acetate}. Compound **19** (0.065 g, 42%) was recrystallized from ethanol–water to give a white crystalline solid (0.054 g), mp 205–208°C (dec.); ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.66 (1H, m, H-5′), 2.13–2.60 (4H, m, H-2′, H-2″, H-4′, and H-5″), 3.06 (1H, d of d, J_{gem} = 9.2, ^3J = 6.2 Hz, OCH_2), 3.19 (1H, d of d, J_{gem} = 9.2, ^3J = 5.2 Hz, OCH_2), 4.49 (1H, q, ^3J = 7.8 Hz, H-3′), 4.97 (1H, m, H-1′), 7.22–7.44 (15H, m, Ph), 8.10 (1H, d, ^3J = 7.5 Hz, H-6), 11.79 (1 H, br d, J = 5.2 Hz, H-3). Compound **21** (0.043 g, 33%) was obtained as a solid after drying under vacuum; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 2.38–2.87 (4H, m, H-2′, H-2″, H-5′, and H-5″), 3.58 (2H, m, OCH_2), 5.12 (1H, m, H-1′), 5.78 (1H, m, H-4′), 7.14–7.46 (15H, m, Ph), 7.77 (1H, d, ^3J = 7.2 Hz, H-6), 11.78 (1H, br d, J = 5.2 Hz, H-3).

*(±)-5-Fluoro-1-{(1β,3α,4β)-3-azido-4-(triphenylmethoxymethyl)cyclopentyl}-2,4(1H,3H)-pyrimidinedione (**20**)*

A mixture of **17** (0.50 g, 0.88 mmol) and sodium azide (0.291 g, 4.48 mmol) in *N*,*N*-dimethylformamide (11 mL) was stirred in an oil bath at 85°C for 30 min. The reaction mixture was cooled and poured into ice–water (80 mL). The white solid was collected by filtration, washed with water (40 mL), and dried, to afford **20** (0.418 g, 93%) as a solid, R_f 0.34 {3:1 (v/v) toluene – ethyl acetate}; ir ν_{max}(KBr): 2110 (azide) cm^{-1}; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.56 (1H, m, H-5′), 1.95 (1H, m, J_{gem} = 14.1, $^3J_{2',1'}$ = 8.8, $^3J_{2',3'}$ = 5.6 Hz, H-2′), 2.1–2.3 (3H, m, H-2″, H-4′, and H-5″), 3.03–3.19 (2H, m, OCH_2), 4.04 (1H, m, H-3′), 4.84 (1H, m, H-1′), 7.23–7.44 (15H, m, Ph), 8.12 (1H, d, ^3J = 7.4 Hz, H-6), 11.8 (1H, br s, H-3). Spin–spin decoupling was performed at δ 4.04 and 4.84.

*(±)-5-Fluoro-1-{(1β,3α,4β)-3-chloro-4-(hydroxymethyl)cyclopentyl}-2,4(1H,3H)-pyrimidinedione (**23**)*

To a solution of compound **18** (65.5 mg, 0.130 mmol) in dry methylene chloride (20 mL) was added diethylaluminum chloride (1.08 mmol) in toluene (0.6 mL) and the reaction solution was stirred at room temperature for 45 min. The solution was then treated with a saturated aqueous solution of sodium hydrogen carbonate (6 mL). The mixture was extracted with methylene chloride – acetonitrile solution {6 × 30 mL, 2:1 (v/v)}, the solvent was evaporated, and the residue was fractionated by silica gel column chromatography to give **23** (30.5 mg, 90%); R_f 0.46 {5:5:1 (v/v/v) toluene – ethyl acetate – 2-propanol}. An analytical sample was prepared by recrystallization from ethanol–hexanes, mp 150–152°C; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.54 (1H, m, H-5′), 2.08–2.49 (4H, m, H-2′, H-2″, H-4′, and H-5″), 3.40–3.58 (2H, m, OCH_2), 4.43 (1H, d of t, ^3J = 6.8, ^3J = 5.1 Hz, H-3′), 4.90 (1H, t, ^3J = 5.3 Hz, OH), 5.02 (1H, qu, ^3J = 8.7 Hz, H-1′), 8.11 (1H, d, ^3J = 7.3 Hz, H-6), 11.80 (1H, br d, J = 5.2 Hz, H-3). Anal. calcd. for $C_{10}H_{12}N_2O_3ClF$: C 45.73, H 4.60, N 10.66, Cl 13.50, F 7.23; found: C 45.80, H 4.66, N 10.62, Cl 13.50, F 6.99.

*(±)-5-Fluoro-1-{(1β,3α,4β)-3-bromo-4-(hydroxymethyl)cyclopentyl}-2,4(1H,3H)-pyrimidinedione (**24**)*

Compound **19** (45.5 mg, 0.083 mmol) was treated with a solution of diethylaluminum chloride (0.54 mmol) in toluene (0.3 mL) as described for the preparation of compound **23**. After fractionation of the reaction product by silica gel column chromatography, **24** (21.5 mg, 84%) was obtained as a solid, R_f 0.47 {5:5:1 (v/v/v) toluene – ethyl acetate – 2-propanol}. An analytical sample of **24** was obtained by recrystallization from ethanol–hexanes, mp 162–165°C (dec.); ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.54 (1H, d, of t, J_{gem} = 12.7, ^3J = 9.4 Hz, H-5′), 2.10–2.64 (4H, m, H-2′, H-2″, H-4′, and H-5″), 3.3–3.8 (2H, m, OCH_2), 4.49 (1H, m, H-3′), 5.05 (1H, qu, ^3J = 8.6 Hz, H-1′), 8.12 (1H, d, ^3J = 7.1 Hz, H-6), 11.8 (1H, br d, J = 5.3 Hz, H-3). Anal. calcd. for $C_{10}H_{12}N_2O_3BrF$: C 39.11, H 3.94, N 9.12, Br 26.02, F 6.19; found: C 38.98, H 3.96, N 8.91, Br 26.32, F 5.96.

*(±)-5-Fluoro-1-{(1β,3α,4β)-3-azido-4-(hydroxymethyl)cyclopentyl}-2,4(1H,3H)-pyrimidinedione (**25**)*

Compound **20** (0.362 g, 0.71 mmol) was treated with a solution of diethylaluminum chloride (3.6 mmol) in toluene (2.0 mL) as described for the preparation of compound **23**. After fractionation of the reaction product by silica gel column chromatography, **25** (0.177 g, 93%) was obtained as a colorless oil, R_f 0.48 {4:4:1 (v/v/v) toluene – ethyl acetate – 2-propanol}; ir ν_{max} (KBr): 3480 (hydroxyl), 2120 (azide) cm^{-1}; uv λ_{max} (C_2H_5OH): 210 (ε 8600), 274 (8900) nm; λ_{max} (0.01 M HCl in C_2H_5OH): 211 (ε 8200), 274 (8900) nm; λ_{max} (0.01 M NaOH in C_2H_5OH): 220 (ε 8100), 272 (6800) nm; ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 1.49 (1H, m, H-5′), 1.91 (1H, m, J_{gem} = 13.3, $^3J_{2',1'}$ = 8.5, $^3J_{2',3'}$ = 4.6 Hz, H-2′), 1.97–2.23 (3H, m, H-2″, H-4′, and H-5″), 3.42–3.53 (2H, m, OCH_2), 4.04 (1H, d of t, ^3J = 7.8, ^3J = 4.7 Hz, H-3′), 4.83 (1H, m, H-1′), 4.89 (1H, t, ^3J = 5.0 Hz, OH), 8.12 (1H, d, ^3J = 7.3 Hz, H-6), 11.79 (1H, br d, J = 3.9 Hz, H-3).

*(±)-5-Fluoro-1-{3-(hydroxymethyl)-3-cyclopenten-1-yl}-2,4(1H,3H)-pyrimidinedione (**26**) and (±)-5-fluoro-1-{cis-4-(hydroxymethyl)-2-cyclopenten-1-yl}-2,4(1H,3H)-pyrimidinedione (**27**)*

A sample of compounds **21** and **22** (56.5 mg, 0.120 mmol), which were obtained as side-products in the preparation of compounds **18** and **19**, was treated with a solution of diethylaluminum chloride (0.72 mmol) in toluene (0.4 mL) as described for the preparation of compound **23**. After fractionation of the reaction product by silica gel column chromatography, a product (15 mg, 56%) was obtained as a white solid, R_f 0.29 {4:4:1 (v/v/v) toluene – ethyl acetate – 2-propanol}. The ^{1}H nmr spectrum showed that this material consisted of compound **26** and a small amount of compound **27**; the latter was identified by the chemical shifts for the signals of H-2′ and H-3′, namely, δ 5.68 and 6.09. The uv (of the mixture) λ_{max} (C_2H_5OH): 209 (ε 8500), 274 (8200) nm; λ_{max} (0.01 M HCl in C_2H_5OH): 210 (ε 7900), 275 (8200) nm; λ_{max} (0.01 M NaOH in C_2H_5OH): 219 (ε 8200), 274 (6300) nm. Compound **26**: ^{1}H nmr (200 MHz, Me_2SO-d_6) δ: 2.31–2.87 (4H, m, H-2′, H-2″, H-5′, and H-5″), 4.0 (2H, m, OCH_2), 5.10 (1H, m, H-1′), 5.55 (1H, m, H-4′), 7.71 (1H, d, ^3J = 7.3 Hz, H-6), 11.78 (1H, br d, J = 5.2 Hz, H;-3).

*(±)-5-Fluoro-1-{(1β,3α,4β)-3-amino-4-(hydroxymethyl)cyclopentyl}-2,4(1H,3H)-pyrimidinedione (**29**)*

A solution of **25** (0.132 g, 0.49 mmol) and triphenylphosphine (0.265 g, 1.01 mmol) in pyridine (15 mL) was kept at room temperature for 6 h; 15 M ammonia in water (2.0 mL) was added and the reaction solution was kept at room temperature for an additional 3 h. The volume of the solution was reduced to 2.0 mL and the residue was fractionated by silica gel column chromatography {3:3:1 (v/v/v) acetonitrile–2-propanol – 15 M ammonia in water} to give **29** (0.107 g, 90%) as a white solid. An analytical sample

was prepared by recrystallization from water–ethanol, mp 176–178°C (dec.); uv λ_{max} (C_2H_5OH): 210 (ε 7800), 275 (8500) nm; λ_{max} (0.01 M HCl in C_2H_5OH): 210 (ε 7700), 273 (8500) nm; λ_{max} (0.01 M NaOH in C_2H_5OH): 219 (ε 7600), 273 (6500) nm; ^1H nmr (200 MHz, Me_2SO-d_6) δ: 1.41 (1H, m, H-5′), 1.58–1.76 (2H, m, H-2′ and H-4′), 1.92 (1H, d of t, J_{gem} = 13.2, ^3J = 7.9 Hz, H-2″), 2.04 (1H, d of t, J_{gem} = 12.6, ^3J = 7.2 Hz, H-5″), 3.17 (1H, m, H-3′), 3.39–3.55 (2H, m, OCH_2), 4.94 (1H, m, H-1′), 8.06 (1H, d, ^3J = 7.3 Hz, H-6). Spin–spin decoupling was performed at δ 3.17 and 4.94. Anal. calcd. for $C_{10}H_{14}N_3O_3F \cdot H_2O$: C 45.98, H 6.17, N 16.08, F 7.27; found: C 46.26, H 5.90, N 16.14, F 7.11.

Acknowledgements

The authors are grateful to the Natural Sciences and Engineering Research Council of Canada for its support of this work in the form of a grant (to W. A. S.). They also thank Dr. K. Rosenthal of McMaster University for permitting the cell-growth inhibition studies using K-562 cells to be performed in his laboratory. Testing for cytotoxicity and antiviral activities was performed by the Bristol–Myers Company. The authors also thank D. R. J. Bernacki of the Grace Cancer Drug Center in Buffalo, New York, for cytotoxicity testing.

Received July 26, 1991

This paper is dedicated to the memory of Dr. Julius A. Rippel, 1901–1990

GEORGE R. PETTIT, JEREMIAH C. COLLINS, DELBERT L. HERALD, DENNIS L. DOUBEK, MICHAEL R. BOYD, JEAN M. SCHMIDT, JOHN N. A. HOOPER, and LARRY P. TACKETT. Can. J. Chem. **70**, 1170 (1992).

The blue marine sponge cribrostatins 1 (**1**, 8.8×10^{-6}% yield) and 2 (**2**, 3.1×10^{-6}% yield) active against the P388 lymphocytic leukemia cell line (ED_{50} 1.58 and 2.73 μg/mL respectively) have been isolated. The previously known isoquinolinequinones mimosamycin (**3**), renierone (**4**), and *O*-demethylrenierone (**5**) were also isolated and shown to display activity against the P388 cell line (ED_{50} 0.73, 2.75, and 8.36 μg/mL, respectively). Importantly, both cribrostatin 1 and mimosamycin showed selective activity against all of the nine human melanoma cell lines employed by the U.S. National Cancer Institute. Structural determinations were accomplished utilizing high field nuclear magnetic resonance (400 MHz) and mass spectral studies. Confirmation of the cribrostatin 1 structure was achieved by X-ray crystallographic techniques.

GEORGE R. PETTIT, JEREMIAH C. COLLINS, DELBERT L. HERALD, DENNIS L. DOUBEK, MICHAEL R. BOYD, JEAN M. SCHMIDT, JOHN N. A. HOOPER et LARRY P. TACKETT. Can. J. Chem. **70**, 1170 (1992).

On a isolé les cribrostatines 1 (**1**, rendement de $8{,}8 \times 10^{-6}$%) et 2 (**2**, rendement de $3{,}1 \times 10^{-1}$%) de l'éponge marine bleue; elles sont actives contre la lignée de cellules P388 de la leucémie lymphocytaire (ED_{50} respectives de 1,58 et 2,73 μg/mL). On a aussi isolé les isoquinoléinequinones suivantes qui sont déjà connues, mimosamycine (**3**), réniérone (**4**) et *O*-déméthylréniérone (**5**), et qui ont montré une activité contre la lignée de cellules P388 (ED_{50} respectives de 0,73, 2,75 et 8,36 μg/mL). Plus important encore, la cribrostatine 1 ainsi que la mimosamycine ont démontré une activité sélective contre les neuf lignées de cellules mélanomes humaines employées par l'Institut National du Cancer des États Unis. On a déterminé les structures à l'aide des spectres en résonance magnétique nucléaire à 400 MHz et par spectrométrie de masse. On a confirmé la structure de la cribrostatine 1 par les techniques de la diffraction des rayons X.
[Traduit par la rédaction]

Introduction

The phylum Porifera rapidly became of increasing importance in our early research devoted to the first systematic investigation of marine animals as new sources of potential anticancer drugs (2). Subsequent detection of antineoplastic activity in some of these sponge species led us to the isolation of such cell growth inhibitory compounds as macrocyclic lactones (3), pyrroles (4), peptides (5), and proteins (6). Meanwhile the isolation of heterocyclic marine sponge constituents such as pyrroles (7), imidazoles (8), oxazoles (9), indoles (10), pyridines (11), quinolizidines (12), pteridines (13), acridines (14), other nitrogen systems (15), and quinones (16) has been rapidly accelerating. So far ten isoquinolinequinones have been isolated from blue species of the sponge genera *Reniera* and *Xestospongia* (17).

In 1986 we conducted an exploratory survey of marine Porifera off remote islands in the Republic of the Maldives and located a deep-blue colored specimen of *Cribrochalina sp.* (Haplosclerida order) that afforded an orange ethanol extract. The encrusting sponge was found in areas of strong (and dangerous) currents to −45 m in the south side of east reef passages and yielded an ethanol extract that provided 40% life extension (at 50 mg/kg) against the U.S. National Cancer Institute's in vivo murine P388 lymphocytic leukemia (PS system). Bioassay-directed isolation using the in vitro PS leukemia led to the discovery of new cytostatic isoquinolinequinones designated cribrostatin 1 (**1**) and cribrostatin 2 (**2**), as well as several previously known pigments that were also found to possess PS cell growth inhibitory activity. Only one other species of the genus, *Cribrochalina dura* (from the Bahamas), appears to have received prior chemical study, and a cytotoxic acetylenic carbinol (duryne) was isolated (18).

A 1989 recollection (about 350 kg wet weight) of the Maldive *Cribrochalina sp.* was subjected to successive ethanol and 1:1 methanol – methylene chloride extractions, and an array of solvent partition separations, to provide a PS active methylene chloride extract, which upon evaporation yielded a black semisolid (PS ED_{50} 6.7 μg/mL). The PS active fraction was further separated by a series of size exclusion and partition chromatographic steps utilizing Sephadex LH-20 (Scheme 1) to afford the new isoquinolinequinones, cribrostatin 1 (**1**) as red-orange crystals (31 mg, 8.8×10^{-6}% yield) and the golden-yellow cribrostatin 2 (**2**, 11 mg, 3.1×10^{-6}% yield). The structure of the cytostatic metabolite cribrostatin 1 (**1**) was determined by hreims, a variety of high-field nmr techniques, and confirmed by single-crystal X-ray diffraction analysis. We also report here isolation of the previously known mimosamycin (**3**, 124 mg, ref. 21), renierone (**4**, 174 mg, ref. 19), and *O*-demethylrenierone (**5**, 94 mg, ref. 20), identical with authentic samples.[5]

Mass spectral (by hreims) analysis of cribrostatin 1 revealed the molecular formula $C_{11}H_{10}N_2O_2$. The mass spectral fragmentation pattern of cribrostatin 1 exhibited the loss of HCN (27) and CO (28), indicating the possibility of a nitrogen-containing quinone. The results of uv/vis (232, 265, and 272 nm) and infrared spectra (1681 and 1635 cm^{-1}) suggested a quinone while further infrared absorptions (3405 and 3300 cm^{-1}) hinted at the presence of a primary amine. The 400 MHz ^1H nmr spectrum (Table 1) of cribrostatin 1 displayed a set of doublets at δ 7.86 and 8.83 (J = 4.9 Hz). The downfield signal at δ 8.83 suggested a proton adjacent to nitrogen in a heteroaromatic system. The spectrum also exhibited two methyl group resonances at δ 2.01 and 2.98 and a broad two-proton singlet at δ 5.20. The latter signal disappeared on deuterium exchange, again suggesting a primary amino group. The ^{13}C nmr spectrum of cribrostatin 1 revealed two carbonyl carbon signals at δ 180.9 and 181.85 suggestive of a quinone. Five other quaternary aromatic carbons were evident as well as two aromatic methine carbons and two methyl carbons. The substitution pattern was established by application of a heteronuclear multiple bond correlation (hmbc) (22) nmr experiment in conjunction with ^1H–^{13}C couplings (23). Most of the two- and three-bond ^1H–^{13}C coupling signals were evident and supported structure **1** for cribrostatin 1. An X-ray crystallographic analysis (cf. Fig. 1) was used to confirm the structure (**1**) of cribrostatin 1.

Mimosamycin (**3**), renierone (**4**), and *O*-demethylrenierone (**5**) were isolated employing chromatographic techniques on Sephadex LH-20 as summarized in Scheme 1. Mimosamycin was identified by hreims and ^{13}C and ^1H nmr techniques and was identical with an authentic sample isolated from the marine sponge *Reniera sp.* (20; see also footnote 5). The quinone was first isolated from *Streptomyces lavendulae* No. 314 (21) and subsequently from the sponge *Xestospongia caycedoi* (24). The first fully assigned ^{13}C nmr signals for mimosamycin are recorded in Table 2. Unambiguous assignment was made possible by employing hmbc nmr experiments. The long-range two- and three-bond ^1H–^{13}C coupling confirmed the structure of mimosamycin and provided a means for differentiating between the quinone carbonyl carbon signals and identifying the remaining carbon signals. Mimosamycin was earlier evaluated against the L1210 murine lymphocytic leukemia cell line (21) and found inactive. However, we found significant activity against the P388 leukemia cell line (ED_{50} 0.73 μg/mL) and this potentially important observation was pursued as noted in the sequel.

Cribrostatin 2 (**2**) was isolated (Scheme 1) from the same parent fraction as mimosamycin. The structure of this quinone (mp 194–195°C, 11 mg) was identified by analyzing the ^{13}C and ^1H nmr spectra. The ethoxy group was evident from the presence of a quartet and a triplet at δ 4.48 and 1.39 (J = 7.0 Hz) respectively, with the corresponding carbon signals at δ 69.78 and 16.07. The remaining proton and carbon nmr data were very similar to those of mimosamycin except for the distinct lack of any signals due to a methoxy group (Table 2). Further structural support for cribrostatin 2 was obtained from the mass spectral fragmentation pattern. Losses of HCN (27), CH_3 (15), and CO (28) were consistent with the structure. A fragmentation ion at m/z 218 was indicative of ethyl group removal from the molecular ion.

Renierone (**4**) and its *O*-demethyl derivative (**5**) were isolated from *Cribrochalina sp.* as outlined in Scheme 1. The sponge *Reniera sp.* (19) earlier yielded renierone (**4**), *O*-demethylrenierone (**5**) (20), and mimocin (**6**) (also isolated from *Streptomyces lavendulae* No. 314, ref. 25) and these represented the first examples of isoquinolinequinones found in nature. Cribrostatins 1 (**1**) and 2 (**2**) herewith join this relatively rare group of sponge and microorganism biosynthetic products. Indeed the sponge isoquinolinequinones may in turn be derived from commensal marine microorganisms.

Presently the *Cribrochalina sp.* constituents are undergoing detailed antineoplastic evaluation. Initial investigations of cribrostatin 1 (**1**) and mimosamycin (**3**) in the U.S. National Cancer Institute's new in vitro disease-oriented antitumor screen (26) revealed melanoma cell line subpanel specificity; the statistical criteria currently used to define subpanel specificity are defined elsewhere (27). The human tumor cell line panel currently used for these studies consists of a diverse array of 60 different cell lines representing eight major cancer subtypes (26). All nine of the melanoma cancer lines (LOX-1MVI; MALME-3M; M14: M19-MEL; SK-MEL-2; SK-MEL-28; SK-MEL-5; UACC-257; UACC-62) currently included in the panel showed sensitivity greater than the panel mean; LC_{50} values (27) ranged between 10^{-5} and 10^{-6} molar, with the greatest sensitivity shown by the M19-MEL and the SK-MEL-5 lines. Further biological studies are underway.

Experimental

General methods

Solvents used for chromatographic procedures were redistilled. The Sephadex LH-20 (25–100 μm) employed for gel permeation and partition chromatography was obtained from Pharmacia Fine Chemicals AB, Uppsala, Sweden. Gilson FC-220 and FC-202 fraction collectors were used for chromatographic fractionation experiments. Silica gel GF Uniplates for tlc and silica gel Si 60 Lobar columns were used for chromatographic separation. All tlc plates were viewed with uv light and (or) developed with a ceric sulfate – sulfuric acid spray (heating to approximately 150°C for 10 min).

The uncorrected melting points were observed with a Reichert type 7905 melting point apparatus. The ir spectral data were obtained using a Nicolet MX-1 FTIR spectrophotometer. Mass spectra were obtained using a Kratos MS-50 spectrometer (70 eV). The

nmr experiments were conducted with Bruker WH-400 and Varian VXR-500 instruments using deuteriochloroform as solvent (TMS internal standard). The X-ray crystallographic experiments were conducted with an Enraf–Nonius CAD-4 diffractometer. Elemental analyses were performed by Spang Microanalytical Laboratories. Authentic samples of previously known compounds were compared with the isolated products by means of tlc, ir (KBr), and nmr techniques to establish mutual identities.

Animal collection and preliminary experiments

In June 1986, approximately 2 kg (wet wt.) of the sponge *Cribrochalina sp.* (Niphatidae family, Haplosclerida order, Demospongiae class) was collected by SCUBA in the channel between Guradu and Madu Islands of South Malé Atoll, Republic of the Maldives, at depths of −15 to −33 m and then preserved in ethanol. The combined ethanol and subsequent 2:1 methanol – methylene chloride extracts gave a confirmed level of activity against the murine P388 lymphocytic leukemia (PS system) with 40% life extension at 50 mg/kg.

Animal extraction and solvent partitioning

In 1988–1989 some 350 kg (wet wt.) of *Cribrochalina sp.* was collected at various locations on North and South Malé Atolls (on

the south side of east coast passes), Republic of the Maldives, at depths of −5 to −45 m and were preserved in ethanol. The ethanol solution was decanted and the sponge reextracted twice with 1:1 methanol – methylene chloride over a period of 5–19 days. The ethanol solution was partitioned with methylene chloride in a counter-current manner, with each portion being partitioned five times. The methylene chloride was removed (evaporation *in vacuo*) to provide a 1.3 kg residue (PS ED_{50} 1.25 μg/mL). The chlorocarbon residue was partitioned between hexane and 9:1 methanol–water; the methanol–water phase was diluted to 3:2 methanol–water and partitioned against methylene chloride (the active fraction 127 g, PS ED_{50} 2.6 μg/mL). Meanwhile the two methanol – methylene chloride extracts of the sponge were processed by adding water (15%) to separate a methylene chloride phase, which was evaporated (*in vacuo*) to dryness (521 g, 323 g; PS ED_{50} 12.5, 0.2 μg/mL). These fractions were combined and partitioned as just summarized for the ethanol extract, yielding an additional active methylene chloride fraction (68 g, PS ED_{50} 6.7 μg/mL).

Isolation of cribrostatin 1 (1)

A 195 g sample of the PS active methylene chloride fraction was chromatographed on a column of Sephadex LH-20 (15 × 150 cm) in methanol, employing the same solvent as eluent. Twelve distinct fractions were separated; two fractions were combined and designated B (elution volume 3.0 L, 3.8 g, PS ED_{50} 4.0 μg/mL). Fraction B was separated by partition chromatography on a Sephadex LH-20 column (5 × 105 cm) with 3:2 methylene chloride – methanol as eluent to furnish active fraction D (elution volume 300 mL, 1.091 g, PS ED_{50} 3.4 μg/mL). Further partition chromatography on Sephadex LH-20 (3 × 90 cm column) and elution with 3:1:1 hexane–toluene–methanol gave active fraction F (elution volume 300 mL, 634 mg, PS ED_{50} 1.6 μg/mL). Final partition chromatography on a Sephadex LH-20 column (3 × 90 cm) employing 8:1:1 hexane–2-propanol–methanol as eluent resulted in six distinct composite fractions, of which the fraction labeled I (67 mg, PS ED_{50} 2.8 μg/mL) at elution volume 100 mL gave, on fractional recrystallization from methylene chloride – methanol, cribrostatin 1 as red-orange crystals (31 mg, 8.8×10^{-6}% yield): mp 220–235°C (dec.); tlc (on silica gel) R_f 0.48 (20:1 methylene chloride – methanol); uv/vis (CH_3OH) λ_{max}: 207 (ε 8730), 232(4700), 265(4170), 272(4160), 324(537) nm; ir ν_{max} (NaCl): 3405, 3300, 1681, 1635, 1602, 1558 cm^{-1}; ^{1}H nmr and ^{13}C nmr (see Table 1); hreims (*m/z*): 202.0737 (M^+ calcd. for $C_{11}H_{10}N_2O_2$ 202.0742). Anal. calcd. for $C_{11}H_{10}N_2O_2$: C 65.33, H 4.98, N 13.77; found: C 65.09, H 5.22, N 13.77.

Crystal structure of cribrostatin (1)

Dark-red crystals of cribrostatin 1 separated from a deuteriochloroform – dimethyl sulfoxide solution (in an nmr tube) of the quinone upon standing. A crystal of dimension ≈ 0.04 × 0.40 × 0.18 mm was obtained by cleavage from a larger crystal. Data were collected (Enraf–Nonius CAD-4 diffractometer) to a maximum of 2Θ = 140° at 26 ± 1°C. A quadrant of data was collected for the orthorhombic crystal, space group $Pna2_1$, with a = 16.792(3), b = 14.124(1), c = 3.912(1) Å, α = β = γ = 90°, V = 927.8 Å^3, ρ_0 = 1.431 g cm^{-3}, ρ_c = 1.447 g cm^{-3} for Z = 4. The ω/2Θ scan technique was used with graphite monochromated Cu Kα radiation (λ 1.54178 Å). After Lorentz and polarization corrections, merging of equivalent reflections, and rejection of systematic absences, a total of 720 reflections ($I > 3\sigma(I)$) were used in the structure determination. No absorption correction was made. Direct methods were used in the structure determination. All non-hydrogen atom coordinates were revealed in the initial run of SHELXS-86 (28). Refinement was performed with MOLEN (29). A non-Poisson contribution weighting scheme (scheme number 1 in MOLEN) was used with Dunitz–Seiler modified weight (30). The hydrogen atom coordinates were calculated at optimum positions and were included in a subsequent final stage of refinement, but were restrained to ride on the atom to which they were bonded. Full-matrix least-squares anisotropic refinement on all non-hydrogen atoms, and isotropic temperature factors for hydrogens, yielded standard crystallographic residuals of R = 0.084, Rw = 0.051. A computer-generated perspective view of cribrostatin 1, showing 50% probability ellipsoids, is shown in Fig. 1.

Isolation of cribrostatin 2 (2)

Separation of the active methylene chloride extract (195 g) on a Sephadex LH-20 column (15 × 150 cm) in methanol yielded 12 fractions of which the fraction designated B was further separated on a Sephadex LH-20 column (5 × 105 cm) in 3:2 methylene chloride – methanol to yield active fraction C (elution volume 300 mL, 1.12 g, PS ED_{50} 2.6 μg/mL). Additional chromatographic separations on Sephadex LH-20 employing the solvents recorded in Scheme 1 resulted in active fraction G (50 mg, PS ED_{50} 0.9 μg/mL). Final separation was performed on a Lobar column (silica gel) employing a gradient eluent (1:9 → 3:7 ethyl acetate – methylene chloride) with a flow rate of 1.5 mL/min to furnish the title compound as a golden-yellow solid (11 mg, 3.1×10^{-6}% yield): mp 194–195°C; tlc (on silica gel) R_f 0.58 (20:1 methylene chloride – methanol); uv/vis (CH_3OH) λ_{max}: 209 (ε 5829), 328 (4126) nm; ir ν_{max} (KBr): 2953, 2854, 1682, 1643, 1609, 1548 cm^{-1}; ^{1}H nmr and ^{11}C nmr (see Table 2); eims *m/z*: 247, 232, 218, 203, 191, 175, 163, 149, 135.

Isolation of mimosamycin (3)

Fraction B (3.8 g, PS ED_{50} μg/mL, see Scheme 1) derived from the 195 g active methylene chloride fraction was chromatographed on Sephadex LH-20 employing the three successive solvents as displayed in Scheme 1 to provide fraction H (135 mg, PS ED_{50} 2.5 μg/mL). Subsequent fractional recrystallization from methylene chloride – methanol furnished mimosamycin (**3**) as golden-yellow crystals (124 mg, 3.5×10^{-5}% yield): mp 223–227°C; tlc (on silica gel) R_f 0.51 (20:1 methylene chloride – methanol); ir ν_{max} (KBr): 1678, 1644, 1633, 1582 cm^{-1}; ^1H nmr and ^{13}C nmr (see Table 2); hreims (*m/z*): 233.0680 (M^+ calcd. for $C_{12}H_{11}NO_4$ 233.0688). Anal. calcd. for $C_{12}H_{11}NO_4$: C 61.80, H 4.75, N 6.01; found: C 61.74, H 4.89, N 5.71.

Isolation of renierone (4)

Scheme 1, fraction A (29.9 g, PS ED_{50} 2.2 μg/mL) was further separated by chromatography on a Sephadex LH-20 column (10 × 135 cm) with 3:2 methylene chloride – methanol as eluent to give fraction J (elution volume 640 mL, 6.2 g, PS ED_{50} 2.3 μg/mL). Further chromatographic separation of fraction I on a Sephadex LH-20 column (5 × 105 cm) with 3:1:1 hexane–toluene–methanol as solvent furnished fraction K (elution volume 900 mL, 1.13 g, PS ED_{50} 1.2 μg/mL). Final chromatography on Sephadex LH-20 with 8:1:1 hexane–isopropanol–methanol resulted in the isolation of renierone (**4**, 174 mg, 5.0×10^{-5}% yield, PS ED_{50} 2.8 μg/mL), which recrystallized from methylene chloride – methanol as amber colored crystals: mp 92.5–93.5°C; tlc (on silica gel) R_f 0.74 (20:1 methylene chloride – methanol); ir ν_{max} (KBr): 2957, 2924, 1718, 1669, 1653, 1570, cm^{-1}; ^1H nmr (400 MHz) δ: 1.97 (3H, dq, J = 1.5, 1.5 Hz) 2.01 (3H, dq, J = 7.2, 1.5 Hz), 2.08 (3H, s), 4.14 (3H, s), 5.77 (2H, s), 6.10 (1H, qq, J = 7.2, 1.5 Hz), 7.86 (1H, d, J = 4.9 Hz), 8.90 (1H, d, J = 4.9 Hz); ^{13}C nmr (100 MHz) δ: 9.07, 15.75, 20.62, 61.23, 65.34, 118.34, 122.66, 127.84, 130.49, 138.00, 138.87, 153.99, 156.88, 158.49, 167.93, 181.75, 184.56; eims *m/z*: 315, 216, 83, 82, 55.

Isolation of O-demethylrenierone (5)

The title compound was isolated from the same fraction K that furnished renierone by employing chromatography on Sephadex LH-20 with 8:1:1 hexane–isopropanol–methanol as eluent. *O*-Demethylrenierone crystallized from methylene chloride – hexane as yellow-lime micro-needles (94 mg, 2.7×10^{-5} yield, PS ED_{50} 8.4 μg/mL): mp 137–138°C; ir ν_{max} (KBr): 3280, 2950, 2920, 1700, 1660, 1650, 1640, 1570 cm^{-1}; ^1H nmr (400 MHz) δ: 1.97 (3H, dd, J = 1.5, 1.5 Hz), 2.01 (3H, dq, J = 7.1, 1.5 Hz), 2.11 (3H, s), 5.79 (2H, s), 6.11 (1H, qq, J = 7.1, 1.5 Hz), 7.51 (1H, br s), 7.94 (1H, d, J = 5.0 Hz), 8.96 (1H, d, J = 5.0 Hz); ^{13}C nmr (100 MHz) δ: 8.56, 15.76, 20.60, 65.18, 119.05, 120.36, 120.59, 127.69, 138.31, 139.96, 153.72, 155.29, 157.09, 167.84, 181.26, 183.57; eims *m/z*: 301, 273, 244, 202, 162, 146, 117, 83, 82, 55.

Acknowledgments

With appreciation we acknowledge the very necessary financial assistance provided by Outstanding Investigator Grant CA 44344-01A1 and PHS Grants CA-16049-07-12 awarded by the Division of Cancer Treatment, NCI, DHHS, the Fannie E. Rippel Foundation, the Arizona Disease Control Research Commission, the Robert B. Dalton Endowment Fund, Virginia Piper Ladies' Auxiliary, V. F. W., Dept. of Arizona, and the Eagles Art Ehrmann Cancer Fund.

For other very useful assistance we are pleased to thank the Government of the Republic of the Maldives (Maizan H. Maniku, A. Naseer, and M. Shiham), Drs. Ronald A. Nieman and Michael D. Williams, and Mrs. Denise K. Tackett, Mr. Lee Williams, Mr. Willie G. Schulz, and Mrs. Laura E. Galbreath, the U.S. National Science Foundation (Grant CHE-8409644), and the NSF Regional Instrumentation Facility in Nebraska (Grant CHE-8620177).

WOLFGANG KLIEGEL, LUTZ PREU, UTE SCHUMACHER, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **70,** 1176 (1992).

The preparation of the organoboron compounds 4-(2-hydroxy-2,2-diphenylacetyl)-6,6-pentamethylene-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane, **6**, 4-(2,2-difluoro-5,5-diphenyl-1,3-dioxa-2-borata-4-cyclopentylidene)-6,6-pentamethylene-2-phenyl-1,3-dioxa-4-azonia-2-boracyclohexane, **14***a*, and 4-[2,2-difluoro-5,5-bis(4-methoxyphenyl)-1,3-dioxa-2-borata-4-cyclopentylidene]-6,6-pentamethylene-2-phenyl-1,3-dioxa-4-azonia-2-boracyclohexane, **14***b*, are reported. Crystals of **6** are triclinic, $P\bar{1}$, a = 8.7348(5), b = 11.0529(6), c = 14.104(1) Å, α = 65.781(5)°, β = 72.147(6)°, γ = 79.928(6)°, Z = 2, ρ_c = 1.130 g cm^{-3}, and crystals of **14***b* · 1/2 CH_2Cl_2 are also triclinic, $P\bar{1}$, a = 11.799(1), b = 13.464(2), c = 10.047(2) Å, α = 103.28(2)°, β = 92.60(2)°, γ = 79.752(8)°, Z = 2, ρ_c = 1.285 g cm^{-3}. The structures were solved by direct methods and were refined by full-matrix least-squares procedures to final R values of 0.040 and 0.060 for 3881 and 3221 reflections with $I \geq 3\sigma(I)$, respectively. Compound **6** has a six-membered cycloboronate structure, bond distances involving the trigonal planar boron atom being (N)O—B = 1.390(2), (C)O—B = 1.345(2), and B—C(phenyl) = 1.557(2) Å. Compound **14***b* represents a derivative of **6** in which an intramolecularly hydrogen-bonded hydrogen atom has been replaced by a difluoroboron moiety and represents the first structurally characterized compound containing both a phenylboronate and a difluoroboron chelate ring within the same molecule. Bond lengths in **14***b* involving the trigonal planar boron atom are (N)O—B = 1.403(5), (C)O—B = 1.326(5), and B—C(phenyl) = 1.550(5) Å and those involving the tetrahedral boron atom are O—B = 1.427(5) and 1.547(5), F—B = 1.353(5) and 1.382(5) Å.

WOLFGANG KLIEGEL, LUTZ PREU, UTE SCHUMACHER, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **70,** 1176 (1992).

On rapporte la préparation des composés organiques du bore suivants : 4-(2-hydroxy-2,2-diphénylacétyl)-6,6-pentaméthylène-2-phényl-1,3-dioxa-4-aza-2-boracyclohexane, **6**, 4-(2,2-difluoro-5,5-diphényl-1,3-dioxa-2-borata-4-cyclopentylidène)-6,6-pentaméthylène-2-phényl-1,3-dioxa-4-azonia-2-boracyclohexane, **14***a*, et 4-[2,2-difluoro-5,5-bis(4-méthoxyphényl)-1,3-dioxa-2-borata-4-cyclopentylidène]-6,6-pentaméthylène-2-phényl-1,3-dioxa-4-azonia-2-boracyclohexane, **14***b*. Les cristaux du produit **6** sont tricliniques, $P\bar{1}$, a = 8,7348(5), b = 11,0529(6), c = 14,104(1) Å, α = 65,781(5)°, β = 72,147(6)° et γ = 79,928(6)°, Z = 2, ρ_c = 1,130 g cm^{-3} alors que les cristaux du composé **14***b* · 1/2 CH_2Cl_2 sont tricliniques, $P\bar{1}$, a = 11,799(1), b = 13,464(2), c = 10,047(2) Å, α = 103,28(2)°, β = 92,60(2)° et γ = 79,752(8)°, Z = 2, ρ_c = 1,285 g cm^{-3}. On a résolu les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de R de 0,040 et 0,060 respectivement pour 3881 et 3221 réflexions avec $I \geq 3\sigma(I)$. Le composé **6** comprend une structure cycloboronate à six chaînons dans laquelle les distances impliquant l'atome de bore plan trigonal sont (N)O—B = 1,390(2), (C)O—B = 1,345(2) et B—C(phényle) = 1,557(2) Å. Le composé **14***b* représente un dérivé du composé **6** dans lequel on a remplacé un atome d'hydrogène impliqué dans une liaison intramoléculaire par une entité difluorobore et il représente la premier composé de structure caractérisée comportant dans la même molécule un phénylboronate ainsi qu'un cycle chélate difluorobore. Les longeurs de liaisons du composé **14***b* impliquant l'atome de bore plan trigonal sont (N)O—B = 1,403(4), (C)O—B = 1,326(5) et B—C(phényle) = 1,550(5) Å alors que celle impliquant l'atome de bore tétraédrique sont O—B = 1.427(5) et 1,547(5) et F—B = 1,353(5) et 1,382(5) Å.

[Traduit par la rédaction]

Introduction

Hydroxamic acids have long been known to be important biologically active compounds (1), possessing numerous pharmacological, toxicological, and pathological properties in addition to potential therapeutic applications (2). In medicinal chemistry these compounds are of special interest in their capacity as sequestering agents (3). Thus the physical characteristics of the hydroxamate function, the changes therein upon complexation, and especially the site of chelation in polyfunctional hydroxamic acids are of great significance with respect to the biological and medicinal chemistry of these compounds. General data on the reactivity and structure of open-chain or cyclic hydroxamic acids and their chelating properties, particularly information on electron delocalization and (or) tautomeric phenomena, can be obtained by the synthesis and structure analysis of the

boron derivatives that form part of this series (4). In these compounds a borenium cation (R_2B^+) functions as a "pseudometal" cation (5) and replaces a hydrogen-bonded proton of the hydroxamic acid group. Borate complexes of this kind also play a role in drug synthesis via hydroxamates or in the blocking of hydroxamic enzyme inhibitors (6). Structures deviating from the "normal" type of hydroxamate complexes have been established for the reaction products of some polyfunctional hydroxamic acids with boron compounds (7, 8).

The reaction of the bis(hydroxyalkyl)-substituted hydroxamic acid **1** with BF_3 leads to the formation of the difluoroboron chelate **2** via intramolecular ring closure to an oxazoline-*N*-oxide and the subsequent[3] formation of the BF_2 chelate. The structure of **2** has been established by an X-ray crystallographic analysis (8). To assess the capability of the polyfunctional ligand **1** for similar reactions with organoboron compounds we reacted it with phenylboronic acid, which, like BF_3, is both a Lewis acid and bears suitable leaving groups (the hydroxyl residues). The crystalline substance that was isolated after the reaction of **1** with phenylboronic acid in ethanol had the elemental composition expected for the *B*-hydroxy-*B*-phenylboron chelate **3**, analogous to **2**. The infrared spectrum of the product displayed a sharp O—H absorption band at 3390 cm^{-1}, and the ^1H nmr spectrum showed two exchangeable signals with a total peak area consistent with one OH proton. These data could support the desired product **3** or an isomeric chelate **4** with the "normal" boron hydroxamate moiety that has been established for several diphenyl- and difluoroboron chelates (4) and postulated for boron chelates derived from phenylboronic acid and various aryl-substituted hydroxamic acids (9). The ^{11}B nmr spectrum, however, displays a broad resonance at $\delta(Et_2OBF_3) = 33.4$ ppm, which usually indicates the presence of a trivalent (sp^2)-boron atom (10). Considering this information, the structures **3** and **4** seemed less probable than the alternative isomeric structures like **5–9**, which all contain sp^2-hybridized boron atoms incorporated into boronate ester functions. Compounds of type **5** having simple *N*-alkyl or -aryl residues (**10**, R = alkyl, aryl) are easily available by cyclocondensation of *N*-substituted glycolohydroxamic acids with arylboronic acids.[4] Six-membered cycloboronates like **6** can be obtained from *N*-(2-hydroxyalkyl) hydroxamic acids (eliminating the α-hydroxyl function of the carbonic acid moiety) and phenylboronic acid,[5] like compound **11** described in this work. The seven-membered cyclic *N*-oxide **7** could be the result of a cyclic anhydride formation between phenylboronic acid and a hydrogen-bond stabilized hydroximate form of **1** involving the carbonyl oxygen atom and the *N*-(2-hydroxyalkyl) substituent. Another case involving incorporation of the carbonyl function is exemplified by the isomeric five-membered phenylboronate **8** having the hydroximic *N*-oxide function in an exocyclic position. However, the fact that the carbonyl oxygen atom of hydroxamic acids generally is not the preferred site of attack for acylating agents (11) disclaims both of the *N*-oxide structures, **7** and **8**. The eight-membered isomer **9**, resulting from cycloboronate formation via esterification of both alcohol functions, also does not seem very likely, even though cyclic aryl- and alkylboronates of this ring size are reported to be quite stable compounds (12). In hypothetical compounds like **7–9** strong intramolecular hydrogen bonds should be present and result in broadened O—H stretching bands at lower wavenumbers in the infrared spectra. For the same reason the ^1H nmr signals of the OH protons should appear at lower fields in the spectra of these compounds. Thus, the spectroscopic data tend to support the six-membered cycloboronate structures **5** and **6**. Nevertheless the structural assignment remains uncertain, especially in view of the two separate signals observed for the OH proton as well as for some CH protons in the ^1H nmr spectra and double signals in the ^{13}C nmr spectrum that could indicate the presence of two isomers, at least in solution.

An X-ray crystallographic analysis (see below) confirms the structure **6** possessing an (*E*)-configuration about the hydroxamic C⋯N moiety and an intramolecular hydrogen bridge from the α-hydroxy group to the hydroxamic carbonyl oxygen atom (cf. **6*B***). The splitting of the OH signal in the ^1H nmr spectra of **6** into two differently shaped part signals (each about 50% of the total peak area) indicates the presence of nearly equimolar amounts of two different molecular species in solution. The upfield signal (between δ = 2.83 and 2.90 ppm in $CDCl_3$, or at 2.91 ppm in C_6D_6) could be assigned to the free cyclohexanol moiety of compound **5** by analogy to similar compounds containing the same alkanol moiety, like **12** which shows a signal at 2.68 ppm in $CDCl_3$ (4*e*) or 2.37 ppm in C_6D_6 (this work). The downfield signal (between 5.33 and 5.41 ppm in $CDCl_3$, or at 5.86 ppm in C_6D_6) should arise from the α-hydroxycarbonyl function of **6**; the corresponding OH signal for the model compound **13** (ref. 13 and footnote 4) appears at δ = 6.12 ppm in $CDCl_3$ solution. In full agreement with the splitting of the OH signal is the doubling of the NCH_2 singlet in the ^1H nmr spectra of **6**. Two separate peaks[6] indicate nearly equimolar amounts of two different species like **5** and **6**. Additional evidence is found in the region of aromatic proton resonance: the doublet arising from the *ortho* protons of the *B*-phenyl group of **5/6** is split into two different doublets (each about 50% of the total peak area). These findings from the ^1H nmr data are consistent with the ^{13}C nmr spectra, which show all of the carbons signals doubled, with varying differences in shift between the corresponding pairs of peaks. The ^{13}C signal of the NCH_2 group appears at δ = 52.51 and 59.36 ppm and can be assigned to the species **6** and **5**, respectively, by comparison with the corresponding NCH_2 signals for the reference compounds **11** and **12** (51.26 and 59.57 ppm, respectively).

In addition to the assignments made on the basis of the ^1H and ^{13}C nmr spectra of **6/5**, and the comparisons with the spectra of the reference compounds, a 2D heteronuclear nmr experiment yielded a $^{13}C,^1H$-COSY spectrum of **6** (in C_6D_6

[3]The mechanism of this reaction is not fully understood, and simultaneous or preliminary chelation of BF_2 is also possible.

[4]W. Kliegel and U. Schumacher. Unpublished results.

[5]W. Kliegel, U. Schumacher, and M. Tajerbashi. Unpublished results.

[6]The small difference between the δ values of the two NCH_2 singlets for **6** in $CDCl_3$ solution (Δ = 0.01 ppm, detectable at 400 MHz, but not at 90 MHz) is somewhat more distinct in aromatic solvents such as chlorobenzene or hexadeuterobenzene (Δ = 0.05 and 0.16 ppm, respectively). The signal at 3.56 ppm (in C_6D_6) is the same as that observed for the NCH_2 grouping within the six-membered ring of the cycloboronate **11**, indicating a comparable ring system for **6**.

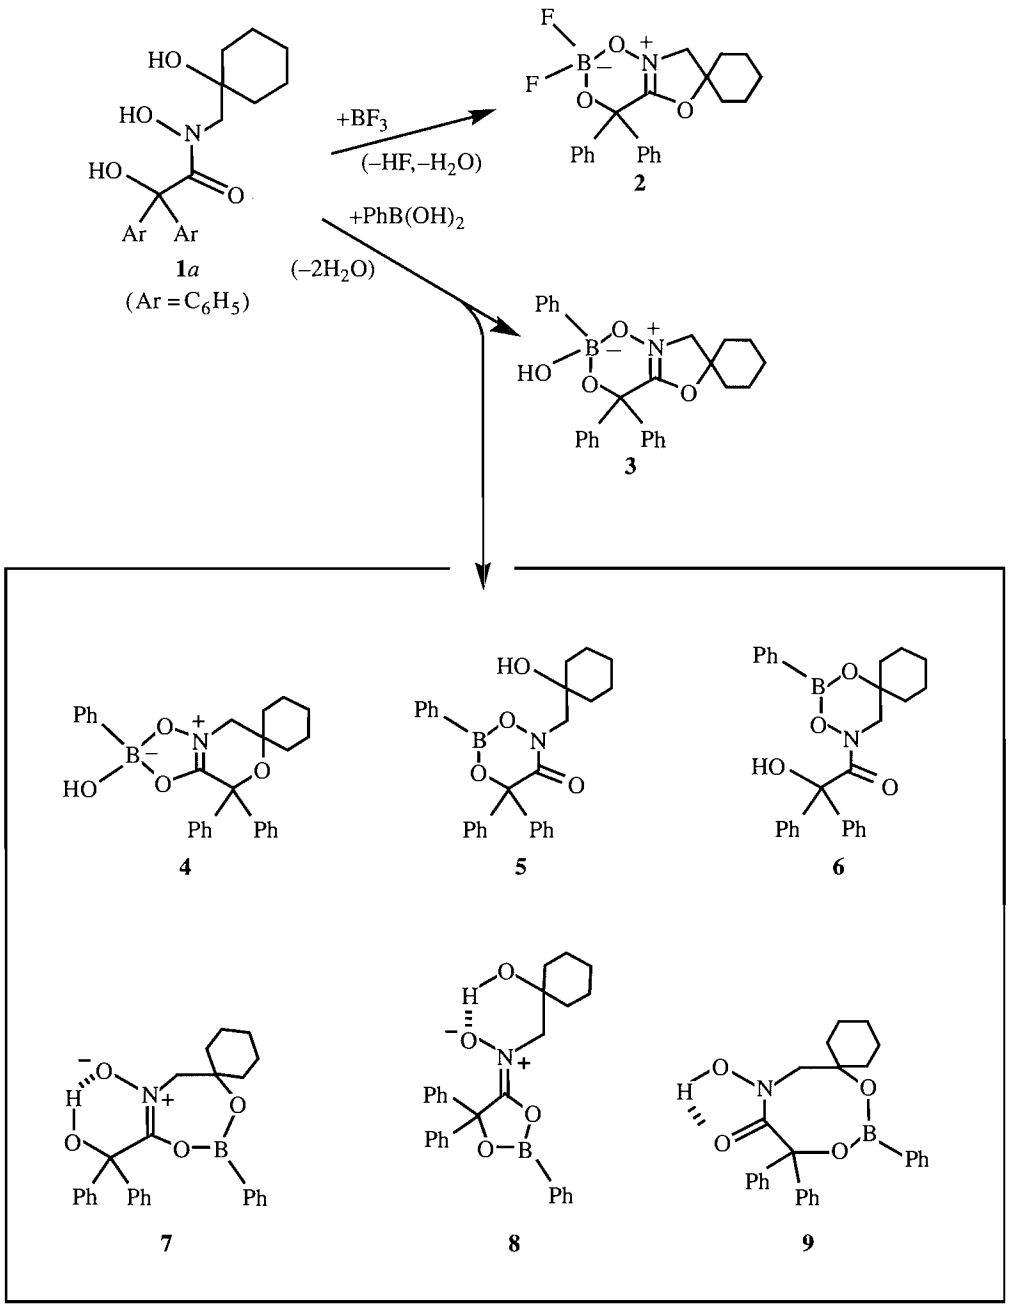
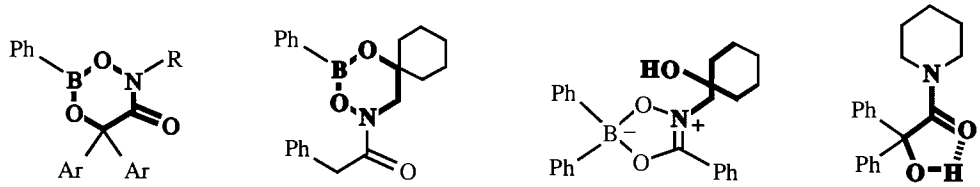
For personal use only.



solution) that links the ^1H resonances at δ = 3.56 and 3.72 ppm to the ^{13}C resonances at δ = 52.51 and 59.36 ppm, respectively.

The presence of two different structural species in the solutions of **6** suggests an equilibrium reaction, obviously an intra- (or perhaps inter-) molecular reesterification process, running from the cycloboronate **5** through a (hypothetical) primary reesterification product to the isomeric cycloboronate **6A**, which could turn (by a 180° rotation about the (HO)C-C(=O) bond, C(8)—C(9) in Fig. 1) into the conformer **6B**, and vice versa. This chemical exchange process between **5** and **6** is further evidenced by a ^1H nmr saturation transfer experiment (14). Saturation of the NCH_2 signal at δ = 3.56 ppm (assigned to **6**) causes a distinct reduction of the intensity of the signal at 3.72 ppm (assigned to **5**), and vice versa. Likewise, an irradiation at the resonance frequency



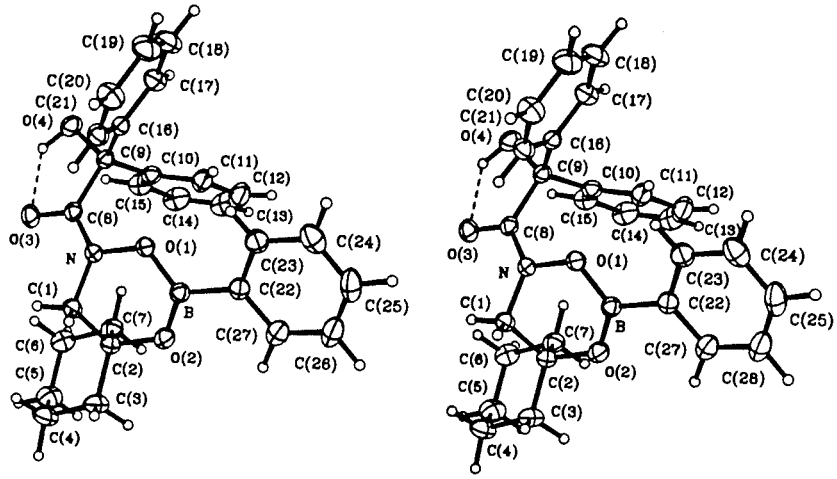


FIG. 1. Stereoview of **6**; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

of the *ortho* protons of the *B*-phenyl group at $\delta = 7.42$ ppm leads to a marked decrease in the intensity of the corresponding signal at 7.96 ppm, and vice versa.

Preliminary variable-temperature ^{1}H nmr experiments between −35° and +100°C indicate a temperature dependence of the equilibrium between **5** and **6**. At 313 K (40°C) the spectrum of **6** (in chlorobenzene) reveals two singlets of nearly equal intensity at $\delta = 3.78$ and 3.83 ppm, indicating the NCH_2 groups of **5** and **6** in a 1:1 ratio. Lowering the temperature leads to a decrease in the intensity of the singlet at 3.83 ppm, whereas raising the temperature causes a reduction in the intensity of the singlet at 3.78 ppm. In addition, the chemical shifts of the two signals are temperature dependent. With increasing temperature the two singlets are both shifted downfield, to different extents, and form a virtual singlet at 3.87 ppm at a temperature of 373 K (100°C). Lowering the temperature results in an upfield shift of both signals, again differing in magnitude for the two components, which form a broad singlet at 3.67 ppm at a temperature of 238 K (−35°C).

It appears that **6** is the kinetically favored product predominating at lower temperatures and that **5** (which could not be isolated) is the thermodynamically favored product predominating at higher temperatures in the equilibrium in solution. Thus only **6** could be crystallized by cooling the solution.

Evidence for the intramolecular hydrogen bridge found in the solid state structure of **6** and depicted in formula **6B** is given by the reaction of compound **6** with BF_3 yielding nearly 70% of a difluoroboron chelate with the postulated structure

14*a*. Unfortunately we could not produce single crystals suitable for an X-ray analysis to establish this structure.[7] To this end we prepared the hydroxamic acid **1***b*, another example of a type **1** compound having a dianisyl instead of a diphenyl substitution at the α-carbon atom. The condensation of **1***b* with phenylboronic acid gave an oily product that could not be recrystallized and was reacted, without further purification, with BF_3. The resulting crystalline, high-melting product indeed showed the analytical data expected for **14***b*. Infrared and ^{1}H nmr spectra, however, were not sufficient to exclude the isomeric structures **15–19**. Two signals in the ^{11}B nmr spectrum at $\delta(Et_2OBF_3)$ = 12.2 and 32.5 ppm demonstrate the presence of two types of boron, presumably in tetracoordinate (sp^3) and tricoordinate (sp^2) environments (10). Formula **15** represents the BF_2 chelate of the ligand **8**. The "normal" difluoroboron hydroxamate **16** would require the formation of an eight-membered, probably less favorable, boronate ring **9**. Similarly the eight-membered BF_2 chelate **17** does not seem to be a very likely structure, even though the fused five-membered boronate ring is a stable moiety observed with *N*-unsubstituted hydroxamic acids.[8] The six-membered BF_2 chelate ring, as in **18**, is already well known.[9] The corresponding ligand for the chelate **18** would have the structure **7** (see above). Compound **19** would represent the BF_2 chelate of the ligand **5** and contains a six-membered phenylboronate ring system (c.f. **10**) that could be synthesized as such from *N*-substituted glycolohydroxamic acids.[4] Single crystals were available in this case, thus an X-ray crystallographic analysis was carried out.

Experimental

*4-(2-Hydroxy-2,2-diphenylacetyl)-6,6-pentamethylene-2-phenyl-1,3-dioxa-4-aza-2-boracyclohexane, **6***

N,2-Dihydroxy-*N*-(1-hydroxycyclohexyl)methyl-2,2-diphenylacetamide (8) (0.71 g, 2 mmol) and phenylboronic acid (0.24 g, 2 mmol) are dissolved under slight heating in a small amount of absolute ethanol. After partial evaporation a small amount of petroleum ether is added and crystallization starts upon cooling. Yield: 0.86 g (98%) colorless crystals, mp 136–138°C (from toluene/petroleum ether). Infrared (KBr): 3390 (O—H), 1635 (C=O) cm^{-1}; ^{1}H nmr (90 MHz, $CDCl_3$/TMS), δ (ppm): 1.17–1.95 (m, $(CH_2)_5$), 2.83 (s, 1/2 OH, exchangeable), 3.98 (s, NCH_2), 5.33 (s, 1/2 OH, exchangeable), 7.07–7.60 (m, 13 aromatic H), 7.75–7.95 (m, 2 aromatic H); ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$); δ (ppm): 33.4 (broad); ^{1}H nmr (400 MHz, $CDCl_3$/TMS), δ (ppm): 1.33–1.68 (m, $(CH_2)_5$), 2.90 (s, 1/2 OH, exchangeable), 4.00 (s, 1/2 NCH_2), 4.01 (s, 1/2 NCH_2), 5.41 (s, 1/2 OH, exchangeable), 7.17–7.54 (m, 14 aromatic H), 7.89 (d, 1 aromatic H). ^{1}H nmr (400 MHz, C_6D_6/TMS), δ (ppm): 0.93–1.72 (m, $(CH_2)_5$), 2.91 (s, 1/2 OH), 3.56 (s, 1/2 NCH_2), 3.72 (s, 1/2 NCH_2), 5.86 (s, 1/2 OH), 7.01–7.27 (m, 9 aromatic H), 7.42 (d, 1 aromatic H), 7.74 (d, 4 aromatic H), 7.96 (d, 1 aromatic H); ^{13}C nmr (100.6 MHz, C_6D_6/TMS), δ (ppm): 21.72 (t, C(4) and C(6)[10]), 22.23 (t, C(4) and C(6)), 25.52 (t, C(5)), 26.08 (t, C(5)), 35.32 (t, C(3) and C(7)), 36.11 (t, C(3) and C(7)), 52.51 (t, C(1)), 59.36 (t, C(1)), 72.18 (s, C(2)), 74.27 (s, C(2)), 82.02 (s, C(9)), 83.04 (s, C(9)), 127.95 (d, aromatic C), 131.79 (d, aromatic C), 141.74 (s, aromatic C), 142.72 (s, aromatic C), 165.86 (s, C(8)), 171.37 (s, C(8)); ^{13}C,^{1}H nmr COSY spectrum (400 MHz/100.6 MHz, C_6D_6/TMS): cross peaks at $\delta(^1H)$ = 3.56/$\delta(^{13}C)$ = 52.51 ppm, and $\delta(^1H)$ = 3.72/$\delta(^{13}C)$ = 59.36 ppm; ^{1}H nmr (60 MHz, C_6H_5Cl/TMS, variable temperature): 313 K (40°C), δ (ppm): 3.78 (s, 1/2 NCH_2), 3.83 (s, 1/2 NCH_2); 238 K (−35°C), δ (ppm): 3.67 (s, broad, NCH_2); 373 K (100°C), δ (ppm): 3.87 (s, NCH_2). Anal. calcd. for $C_{27}H_{28}BNO_4$: C 73.48, H 6.40, B 2.45, N 3.17; found: C 73.48, H 6.51, B 2.43, N 3.15. Crystals suitable for X-ray analysis were obtained by recrystallization from benzene/petroleum ether.

*6,6-Pentamethylene-2-phenyl-4-phenylacetyl-1,3-dioxa-4-aza-2-boracyclohexane, **11***

N-Hydroxy-*N*-[(1-hydroxycyclohexyl)methyl]phenylacetamide[11] (0.26 g, 1 mmol) and phenylboronic acid (0.12 g, 1 mmol) are dissolved in 30 mL of benzene and refluxed for 30 min using a Dean–Stark trap for continuous removal of water. The solution is evaporated *in vacuo* to a volume of 1–2 mL. After addition of

[7]Analysis of a data set collected using a twinned crystal did not produce a publishable crystal structure but did confirm the proposed structure **14***a* (R = 0.12) (W. Kliegel, U. Schumacher, S. J. Rettig, and J. Trotter, unpublished results.

[a] $B_{eq} = (8\pi^2/3)\Sigma\Sigma U_{ij} a_i^* a_j^* (\mathbf{a}_i \cdot \mathbf{a}_j)$. Site occupancy factors for the solvent molecule in **14***b* are Cl(1) 0.5, Cl(2) 0.36, Cl(2A) 0.14, and C(30) 0.5.

After partial evaporation of the solvent *in vacuo* the remaining solution (2–3 mL) is cooled until colorless crystals begin to form. Yield: 0.74 g (76%); mp 196–197°C (dec.) (from dichloromethane/petroleum ether). Infrared (KBr): 1665 (C=O/C=N$^+$) cm^{-1}; ^{1}H nmr (90 MHz, $CDCl_3$/TMS), δ (ppm): 1.15–1.77 (m, $(CH_2)_5$), 4.10 (s, N-CH_2), 7.07–7.62 (m, 15 aromatic H). Anal. calcd. for $C_{27}H_{27}B_2F_2NO_4$: C 66.30, H 5.56, N 2.86; found: C 65.87, H 5.50, N 2.78. The crystals obtained by recrystallization from dichloromethane/petroleum ether were found to be twinned, and did not allow for a satisfactory crystal structure analysis.[7]

N,2-Dihydroxy-N-(1-hydroxycyclohexyl)methyl-2,2-bis(4-methoxyphenyl)acetamide, ***1***b

1-(Hydroxyaminomethyl)cyclohexanol (15) (30 mmol) is reacted with ethyl oxalyl chloride (30 mmol) and 4-methoxyphenylmagnesium bromide (225 mmol) according to literature methods (16). The product crystallizes from tetrachloromethane. Yield: 7.15 g (57%) of a colorless powdery material; mp 115–117°C (from CCl_4). Infrared (KBr): 3570, 3350, 3130 (O—H), 1640 (C=O) cm^{-1}; ^{1}H nmr (90 MHz, $CDCl_3$/TMS), δ (ppm): 1.40 (s, $(CH_2)_5$), 3.55 (s, N-CH_2), 3.70 (s, 2 OCH_3), 4.17 (s, broad, exchangeable, C-OH), 5.85 (s, broad, exchangeable, C-OH), 6.67–6.92 (m, 4 aromatic H), 7.03–7.27 (m, 4 aromatic H), 9.18 (s, broad, exchangeable, N-OH). Anal. calcd. for $C_{23}H_{29}NO_6$: C 66.49, H 7.04, N 3.37; found: C 66.82, H 6.96, N 3.38.

4-[2,2-Difluoro-5,5-bis(4-methoxyphenyl)-1,3-dioxa-2-borata-4-cyclopentylidene]-6,6-pentamethylene-2-phenyl-1,3-dioxa-4-azonia-2-boracyclohexane, ***14***b

1*b* (1.25 g, 3 mmol) and phenylboronic acid (0.37 g, 3 mmol) are dissolved in 30 mL of toluene and refluxed for 30 min using a Dean–Stark trap for the continuous removal of water. The solvent is distilled off *in vacuo*, and the oily residue dissolved in 10 mL of dichloromethane. After addition of dimethyl ether – boron trifluoride (0.34 g, 3 mmol) and freshly regenerated molecular sieve (type 4 Å, 2 g) the solution is kept at room temperature for 12 h. The molecular sieve is then filtered off, and the solution evaporated to a volume of 2 mL. Addition of petroleum ether initiates crystallization. Yield: 1.05 g (64%) colorless crystals; mp 159–161°C (dec.) (from CH_2Cl_2/petroleum ether). Infrared (KBr): 1655 (C=O/C=N$^+$) cm^{-1}; ^{1}H nmr (90 MHz, $CDCl_3$/TMS), δ (ppm): 1.20–1.80 (m, $(CH_2)_5$), 3.71 (s, 2 OCH_3), 4.10 (s, N-CH_2), 6.62–6.92 (m, 4 aromatic H), 7.17–7.55 (m, 9 aromatic H); ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$), δ (ppm): 12.2 (broad), 32.5 (very

broad). Anal. calcd. for $C_{29}H_{31}B_2F_2NO_6$: C 63.42, H 5.69, B 3.93, N 2.55; found: C 63.41, H 5.70, B 3.78, N 2.38. Crystals suitable for X-ray analysis were obtained by recrystallization from dichloromethane and contain 1/2 mol CH_2Cl_2 as solvate; mp 154°C (dec.).

X-ray crystallographic analyses of ***6*** *and* ***14****b* · *1/2* CH_2Cl_2

Crystallographic data for the two complexes appear in Table 1. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 40.0–48.4° for **6** and 50.8–85.2° for **14***b* · 1/2 CH_2Cl_2. The intensities of three standard reflections, measured every hour of X-ray exposure time for **6** and every 250 reflections for **14***b* · 1/2 CH_2Cl_2 throughout the data collections, remained essentially constant for the former and showed a linear decay of 6.5% for the latter. The data were processed[13] and corrected for Lorentz and polarization effects. Decay and absorption (empirical, based on azimuthal scans for four reflections) corrections were applied for **14***b* · 1/2 CH_2Cl_2.

Both structure analyses were initiated in the centrosymmetric space group $P\bar{1}$ on the basis of *E*-statistics, these choices being confirmed by subsequent calculations. The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. The non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were refined with isotropic thermal parameters for **6** and were fixed in idealized positions (C—H = 0.98 Å, B_H = 1.2 $B_{bonded\ atom}$) for **14***b* · 1/2 CH_2Cl_2. The dichloromethane solvate molecule in the structure of **14***b* · 1/2 CH_2Cl_2 was found to be disordered about a centre of symmetry and, in addition, was orientationally disordered (via a rotation about the C(30)—Cl(1) bond). Site occupancy factors for the two components of the disordered Cl atom were initially estimated from relative Fourier peak heights and were subsequently adjusted to yield approximately equal thermal parameters. Neutral atom scattering factors and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (17). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, bond angles, and intra-annular torsion angles appear in Tables 2–5, respectively. Hydrogen atom parameters, anisotropic thermal parameters, general torsion angles, intermolecular contacts, and least-squares planes (for **14***b* · 1/2 CH_2Cl_2 only), and measured and calculated structure factor amplitudes for the both structures are included as supplementary material.[14]

Results and discussion

As mentioned in the introduction, the reaction of **1** with phenylboronic acid results in a product (Fig. 1) having the structure **6** which features a six-membered cycloboronate ring derived from the *N*-(2-hydroxyalkyl)hydroxylamine residue. At least in the solid state, the compound has an (*E*)-configuration about the hydroxamic C=N grouping, formulated by **6A**. The relatively short C(8)—N, 1.333(2) Å, and long C(8)—O(3) bonds, 1.229(1) Å, are typical for acyclic amide groups (18). From plots of π-bond order vs. bond length (19), the C(8)—N bond has about 50–60% double bond character and the C(8)—O(3) bond retains about 80% of its double bond character. The O(1)—N-C(8)—O(3) torsion angle of −179.8(1)° attests to the planarity of the amide function. There is an intramolecular O—H···O hydrogen bond between the α-hydroxyl group and the carboxamide carbonyl oxygen atom (O(4)—H(O4)···O(3), O—H = 0.95(2), O···H = 1.85(2), O···O = 2.539(1) Å,

O—H···O = 127(2)°). The ring formed by the intramolecular hydrogen bond (O(3)—C(8)—C(9)—O(4)—H(O4)) is planar to within 0.04(2) Å, and is oriented approximately coplanar with the amide group (torsion angles O(4)—C(9)—C(8)—N = −176.3(1)° and O(1)—N-C(8)—C(9) = 3.2(2)°).

The six-membered BONCCO phenylboronate ring in **6** has a "semi-planar" C(1)-sofa conformation (see Table 5) similar to those observed for other six-membered cycloboronates (ref. 20 and references therein). As noted for other boronic acid esters, O—B *pp*(π) back-donation results in partial double bond character for the O—B bonds and is responsible for the near planarity (to within ~0.1 Å) of the N-O(1)-B-O(2)-C(2) portion of the phenylboronate ring. The two O—B bonds differ in length by 0.045(3) Å, that involving the alcoholate oxygen atom O(2) being shorter (1.345(2) Å), presumably as a result of the better *p*(π) donor ability of this oxygen atom relative to that of the hydroxamate oxygen atom O(1) (O(1)—B = 1.390(2) Å). The B—C(aryl) bond between the phenyl ring and the cycloboronate ring, 1.557(2) Å, is similar to those reported for other cyclic phenylboronates (ref. 20 and references therein). The *B*-phenyl ring and the boron coordination group are approximately coplanar, the dihedral angle between normals to the respective mean planes being 4.1°. The cyclohexane ring, spiro-fused to the cycloboronate ring at C(2), has a nearly ideal chair conformation (see Table 5) with the substituents C(1) and O(1) occupying axial and equatorial positions respectively.

The X-ray analysis establishes structure **14***b* (Fig. 2) for the compound obtained from the consecutive reaction of the hydroxamic acid **1***b* with phenylboronic acid and boron trifluoride and provides indirect evidence that compound **14***a* results from the same reaction sequence starting with the hydroxamic acid **1**. This demonstrates the replacement of the "chelated proton", as observed in the structure of **6** (see above), by a difluoroborenium ion (F_2B^+) to give **14***a* and the analogous derivative **14***b*. The structure is consistent with the fact that no exchange reactions take place between the difluoroboron and phenylboron moieties at the polyfunctional ligand that could lead to one of the alternative constitutions **15**–**19**. To the best of our knowledge this is the first structurally characterized compound containing both a phenylboronate and a difluoroboron chelate ring within the same molecule.

The general ring assembly of **14***b* is very similar to that of **6** and has an (*E*)-configuration about the hydroxamate

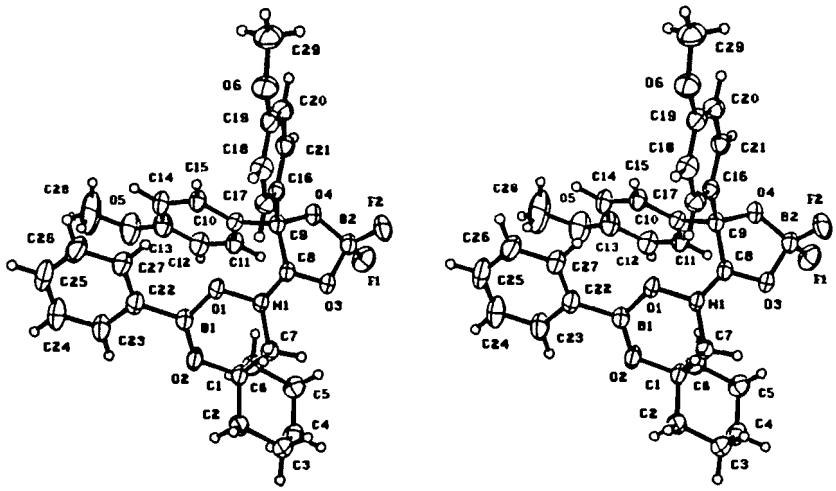

FIG. 2. Stereoview of **14***b*; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

C⋯N bond that connects the six-membered cycloboronate ring to the five-membered difluoroboron chelate ring. Compared to **6** the double bond character of the hydroxamic C⋯N bond in **14***b* is enhanced: C(8)—N(1) = 1.300(4) Å is consistent with an estimated bond order of 1.75 from a plot of π-bond order vs. bond length (19). Correspondingly, the C(8)—O(3) bond is longer (1.293(4) Å) than the comparable C=O bond in **6** (1.229(1) Å), indicating a decreased double bond character for the carbonyl function in **14***b*. A 50% double-bond character for the carbonyl C—O bond in **14***b* is estimated from a plot of C—O bond length vs. π-bond order (19). The electron delocalization leads to a distinct iminium salt character (with the intramolecular borate counteranion) for **14***b*, which represents a new type of *B*,*N*-betaine (21). The torsion angles O(1)—N(1)—C(8)—O(3) = −179.5(3)°, O(1)—N(1)—C(8)—C(9) = −2.5(5)°, and O(3)—C(8)—N(1)—C(7) = −6.3(5)° show an approximately planar arrangement of the substituents about the hydroxamate C⋯N group, confirming the distinct double bond character and justifying the nomenclature employed that describes this compound as a zwitterionic species.

The are no dramatic changes in the other geometric parameters of **14***b* compared to those of **6**. The cyclohexane moiety of **14***b* has a chair conformation (see Table 5) and bears the oxygen atom O(2) of the spiro-connected boronate ring in an equatorial position and C(7) in an axial position, exactly as observed for **6**. The cycloboronate ring of **14***b* has a distorted C(7)-envelope (sofa) conformation and, like **6**, has significantly different O—B bond lengths. The difference between the two O—B bond lengths, 0.077(7) Å, is significantly larger than the value of 0.045(3) Å observed for **6**. This could be a consequence of an electron-withdrawing effect of the difluoroboron chelate formation, further reducing the already weaker donor properties of the hydroxamate oxygen atom O(1) (a Lewis acid effect on this atom).

The five-membered BOCCO chelate ring in **14***b* has a flattened B-envelope conformation (see Table 5), the ring being planar to within 0.129(4) Å. The B—F bond lengths in **14***b* (mean 1.368 Å) are in the range normally observed for B—F bonds in five-membered difluoroboron chelates: mean B—F = 1.358 (4*f*), 1.378 (4*a*), 1.404 (22), 1.405 Å (23). In contrast to other five-membered difluoroboron chelates (4*a*, 4*f*, 22, 23), the O—B bonds of the chelate moiety show a considerable (0.120(7) Å) difference in length: O(3)—B(2) = 1.547(5) and O(4)—B(2) = 1.427(5) Å. Once again, the alcoholate ligand C(9)—O(4) is the stronger donor compared to the hydroxamate ligand C(8)—O(3), analogous to the situation at the cycloboronate site in the same molecule where the difference in donor strength between the two oxygen atoms is very similar. The mean B—F/mean B—O bond length ratio of 0.920 lies in the range of 0.900–0.962 reported for other five-membered difluoroboron chelates (4*a*, 4*f*, 22, 23), consistent with intermediate overall binding strength of the *O*,*O*-chelating ligand with respect to the F_2B^+ moiety. The O(3)—B(2)—O(4) angle of 102.9(3)° is similar to those in other five-membered difluoroboron chelates that range from 101.8° to 108° with an average value of 104.4° (4*a*, 4*f*, 22, 23). Bond angles at B(2) range from 102.9(3)° to 114.0(3)°, corresponding to an irregular tetrahedral coordination geometry. The relatively small O—B—O angle in **14***b* is associated with an O(3)⋯O(4) "bite" of 2.326(4) Å.

Structural studies of organoboron compounds LI.[1] *N*-Methylhydroxylamine(*O-B*)2,5-diphenyl-1,3,2-dioxaborolan-4-one[2]

WOLFGANG KLIEGEL AND UTE SCHUMACHER
Institut für Pharmazeutische Chemie der Technischen Universität Braunschweig, Beethovenstrasse 55, 3300 Braunschweig, Germany

AND

STEVEN J. RETTIG AND JAMES TROTTER
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Z1

Received January 21, 1991[3]

WOLFGANG KLIEGEL, UTE SCHUMACHER, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **70,** 1188 (1992).

Three synthetic methods for the preparation of *N*-methylhydroxylamine(*O-B*)2,5-diphenyl-1,3,2-dioxaborolan-4-one (2-(1-oxa-2-azoniapropyl)-2,5-diphenyl-1,3-dioxa-2-boratacyclopentan-4-one), **9**, in good yield are described. Crystals of this material are triclinic, a = 10.1073(7), b = 12.159(2), c = 14.116(2) Å, α = 65.079(8)°, β = 99.255(9)°, γ = 92.69(1)°, Z = 4, space group $P\bar{1}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.039 and R_w = 0.045 for 2603 reflections with $I \geq 3\sigma(I)$. Compound **9** is the first structurally characterized example of an *N*-alkylhydroxylamine(*O-B*)boron complex having an open-chain *B,N*-betaine structure. Average bond lengths involving the tetrahedrally coordinated boron atoms in the two crystallographically independent molecules (corrected for thermal libration) are (N)O—B = 1.494, (carboxylate)O—B = 1.524, (alcoholic)O—B = 1.486, and (aryl)C—B = 1.594 Å.

WOLFGANG KLIEGEL, UTE SCHUMACHER, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **70,** 1188 (1992).

On décrit trois méthodes de synthèse de la *N*-méthylhydroxylamine(*O-B*)2,5-diphényl-1,3,2-dioxaborolan-4-one (2-(1-oxa-2-azoniapropyl)-2,5-diphényl-1,3-dioxa-2-boratacyclopentan-4-one), **9**, avec un bon rendement. Les cristaux de cette substance sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 10,1073(7), b = 12,159(2) et c = 14,116(2) Å, α = 65,079(8)°, β = 99,255(9)° et γ = 92,69(1)° et Z = 4. On a résolu la structure par des méthodes directes et on l'affinée par la méthode des moindres carrés jusqu'à des valeurs de R = 0,039 et R_w = 0,045 pour 2603 réflexions avec $I \geq 3\sigma(I)$. Le composé **9** correspond au premier exemple d'un complexe de *N*-alkylhydroxylamine(*O-B*)bore possédant une structure de bétaïne-*B,N* en chaîne ouverte. Les longeurs moyennes des liaisons impliquant les atomes de bore cordonnés d'une façon tétraédrique dans les deux molécules indépendantes d'un point de vue cristallographique (corrigées pour la libration thermique) sont : (N)O—B = 1,494, (carboxylate)O—B = 1,524, (alcoolique)O—B = 1,486 et (aryl)C—B = 1,594 Å.

[Traduit par la rédaction]

Introduction

N-Methylmandelohydroxamic acid **1** was reacted with phenylboronic acid in ethanolic solution in an attempt to synthesize the six-membered cyclic phenylboronate **2**. Similar condensations leading to cycloboronates of type **2** were successful with various *N*-alkyl- and *N*-aryl-substituted diarylglycolohydroxamic acids using absolute ethanol as solvent.[4] The use of the monoarylglycolohydroxamic acid **1** as an educt, however, resulted in a crystalline compound having the elemental composition of **2** containing one mole of water. In addition to the ordinary hydrate structure **2** · H_2O, an intermediate "half-condensate" structure **3** (which could be stabilized by intramolecular O→B coordination) had to be considered, but the C=O stretching frequency at 1710 cm^{-1} in the infrared spectrum seemed contradictory since cyclic boronates of type **2** typically absorb at frequencies between 1640 and 1670 cm^{-1}.[4] The ^1H nmr spectrum would also be consistent with the isomeric structure **4**, the hypothetical rearrangement product of an N→O acyl shift, also stabilized by intramolecular coordination (N→B in this case). N→O acylotropy has been observed in thermally induced rearrangements of *N*-methyl benzohydroxamic acids (1) as well as in pentanoylation reactions of *N*-methyl hydroxylamine (2), and N→O transacylation products of *N*-aryl

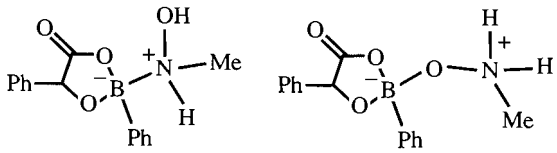
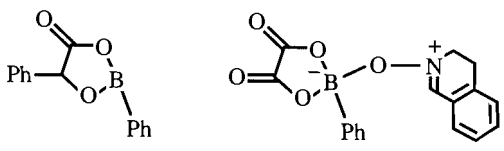
α-aminohydroxamic acids have been trapped *in situ* during amine-catalyzed N→O acyl transfer (3). *N*-Carbamoylated hydroxylamines are reported to undergo an N→O acyl migration if there is an *N-tert*-alkyl substituent (4).

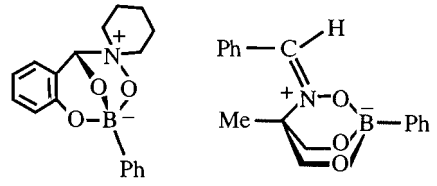
The fact that certain hydroxamic acids can serve as ligands for phenylboronic acid (5) led to the consideration of the five-membered chelate structure **5**. Hydroxamate complexes of this type, however, show C=O/C=N$^+$ absorptions between 1610 and 1640 cm^{-1} in their infrared spectra (5). A similar C=O/C=N$^+$ stretching frequency can be expected for the isomeric five-membered chelate **6** having an exocyclic hydroxamic N-OH group. A comparable six-membered O—B—O chelate of *N*-methoxy-*N*-methylsalicylamide has a C=O/C=N$^+$ band at 1615 cm^{-1} (6). Thus the C=O/C=N$^+$ bands expected in the infrared spectra of **5** and **6** are quite different from the observed band at 1710 cm^{-1}. The tautomeric structure **7** can be ruled out by the ^{1}H nmr spectrum, which displays a one-proton singlet at 5.30 ppm, characteristic of a methine proton. In addition, the absence of a color reaction with $FeCl_3$ in ethanolic solution suggests that the molecule contains no hydroxamate moiety at all, these being detected by the formation of tris(hydroxamato)iron(III) complexes. An exchange (formal) of the *N*-methylhydroxylamino and *B*-hydroxy groups leads to the isomeric structures **8** or **9**, adducts of *N*-methylhydroxylamine and the phenylboronate **10** by N→B or O→B coordination, respectively. This is strongly supported by the synthesis via addition of *N*-methylhydroxylamine to the preformed[5] 1,3,2-dioxaborolan-4-one **10** or by the one-pot synthesis via three-component condensation of mandelic acid, *N*-methylhydroxylamine, and phenylboronic acid. Both of these procedures lead to products identical to that resulting from the reaction of **1** with phenylboronic acid. Yet, the C=O stretching frequency of 1710 cm^{-1} observed for "**2** + H_2O" is significantly different from the value of 1800 cm^{-1} reported for **10** (7).



8 **9**



10 **11**



12 **13**

The formation of one of the isomers **3**–**6** could not be ruled out by the spectroscopic data nor by the independent synthetic routes studied. In addition, an unambiguous decision between the isomeric structures **8** and **9** could not be made on the basis of the infrared and ^{1}H nmr data. Complexes of hydroxylamine or *N*-monosubstituted derivatives thereof with Lewis acid boron compounds are traditionally formulated as N→B adducts (8), but there is also evidence for O→B coordination in BF_3 complexes of hydroxylamine (9). In the transition metal coordination chemistry of hydroxylamine (10) it is known that the neutral ligand can bind to the metal via nitrogen, as H_2N—OH, as well as via oxygen in the tautomeric aminoxide form H_3N^+—O^-. This has been established by X-ray and neutron diffraction studies, e.g., for Ni(II)—NH_2OH (11) and for U(VI)—ON^+H_3 (12). To resolve the ambiguities surrounding the structure of "**2** + H_2O" and the course of the reaction between **1** and phenylboronic acid, an X-ray crystallographic analysis has been carried out.

Experimental

N-*Methylhydroxylamine*(O-B)*2,5-diphenyl-1,3,2-dioxaborolan-4-one*, **9**

Method A

2-Hydroxy-*N*-methyl-2-phenylacetohydroxamic acid **1** (13) (0.18 g, 1 mmol) and phenylboronic acid (0.12 g, 1 mmol) are dissolved in a small amount of absolute ethanol with slight heating. Upon cooling and addition of petroleum ether colorless crystals of high purity are formed.

Method B

Mandelic acid (7.61 g, 50 mmol) and phenylboronic acid (6.10 g, 50 mmol) are suspended in 60 mL of benzene and refluxed for 1 h with continuous removal of water in a Dean–Stark trap. The hot solution is filtered and the solvent evaporated off *in vacuo* to a volume of 15 mL, at which time crystallization of **10** commences (yield: 10.85 g, 91%); mp 123°C (from benzene) (lit. (7) mp 124°C (from benzene/petroleum ether)). **10** (1.19 g, 5 mmol) is dissolved in 20 mL of dichloromethane and is mixed with a solution of *N*-methylhydroxylamine (5 mmol)[6] in absolute ethanol. Crystallization eventually starts at room temperature, after evaporation of the solvents.

Method C

Mandelic acid (1.52 g, 10 mmol), phenylboronic acid (1.22 g, 10 mmol), and *N*-methylhydroxylamine (10 mmol)[6] are each dissolved, separately, in the minimum amount of ethanol (necessary for solution). The three solutions are mixed and kept at room temperature. After partial evaporation of the solvent *in vacuo*, crystallization begins.

Yields: 0.20 g (70%, method A), 0.86 g (60%, method B), 2.37 g (83%, method C); mp 145–146°C (from ethanol/petroleum ether). Infrared (KBr): 3130, 2770, 2540 (N—H), 1710 (C=O) cm^{-1}. ^{1}H nmr (90 MHz, d_6-DMSO/TMS), δ (ppm): 2.78 (s, CH_3), 5.30 (s, O-CH), 6.97–7.63 (m, B-C_6H_5, C-C_6H_5), 9.45–10.75 (s, broad, exchangeable, NH_2). Anal. calcd. for $C_{15}H_{16}BNO_4$: C 63.19, H 5.66, N 4.91; found: C 63.24, H 5.68, N 4.90. Crystals suitable for X-ray analysis were obtained by recrystallization from absolute ethanol/petroleum ether.

X-ray crystallographic analysis of **9**

A crystal ca. 0.11 × 0.24 × 0.35 mm in size was mounted on a glass fiber. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 24.0–35.2°) measured on a diffractometer with Mo-K_α radiation ($\lambda_{K\alpha1}$ = 0.70930, $\lambda_{K\alpha2}$ = 0.71359 Å). Crystal data at 21°C are:

$C_{15}H_{16}BNO_4$ fw = 285.11

[5]In a modification of the literature method (7), mandelic acid was condensed with phenylboronic acid.

[6]*N*-Methylhydroxylamine hydrochloride is added to the solution of an equimolar amount of KOH in absolute ethanol. After stirring for 10 min the precipitated KCl is filtered off, and the solution is used for the reaction.

For personal use only.

Triclinic, a = 10.1073(7), b = 12.159(2), c = 14.116(2) Å, α = 65.079(8)°, β = 99.255(9)°, γ = 92.69(1)°, V = 1552.4(3) Å^3, Z = 4 (two molecules per asymmetric unit), ρ_c = 1.220 Mg m^{-3}, $F(000)$ = 600, μ(Mo-K_α) = 0.82 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (No. 2) from structure analysis.

Intensities were measured with graphite-monochromated Mo-K_α radiation on an Enraf–Nonius CAD4-F diffractometer. An ω-2θ scan at 1.0–10.0° min^{-1} over a range of (0.65 + 0.35 tan θ)° in ω (scan extended by 25% on each side for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every hour of X-ray exposure time throughout the data collection, showed only small random variations. The data were processed[7] and corrected for Lorentz and polarization effects. Of the 7089 independent reflections measured, 2603 (36.7%) had intensities greater than or equal to 3$\sigma(I)$ above background where $\sigma^2(I) = [C + 2B + (0.040(C-B))^2]$ with C = scan count, B = normalized total background count.

The structure analysis was initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the E-statistics, this choice being confirmed by the subsequent successful solution and refinement of the structure. The structure was solved by direct methods, the coordinates of all non-hydrogen atoms of two crystallographically independent molecules being determined from an E-map. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (N—H = 0.92, C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å, U_H = 1.2 $U_{\text{bonded atom}}$). Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 14. The weighting scheme $w = 1/\sigma^2(F)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix least-squares refinement of 379 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.039 and R_w = 0.045 for 2603 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$. On the final cycle of refinement the maximum parameter shift corresponded to 0.14σ. The mean error in an observation of unit weight was 1.36. The final difference map showed maximum fluctuations of ±0.16 e Å^{-3}.

The thermal motion has been analyzed in terms of the TLS model (15). The rms error in the temperature factors U_{ij} (derived from the least-squares analysis) is 0.0022 Å^2. Three structural subunits of each of the two independent molecules were separately analyzed (rms ΔU_{ij} = 0.0028–0.0045 Å^2). The bond lengths have been corrected for libration (15, 16) using shape parameters q^2 of 0.08 for all atoms. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths (corrected and uncorrected) and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, general torsion angles, and structure factors have been deposited.[8]

Results and discussion

The X-ray analysis establishes the structure **9** for the reaction product. The two crystallographically independent molecules of **9** (Fig. 1) have bond lengths that agree to within experimental error, the most obvious difference between the two being in the orientation of the phenyl rings. There are two chiral centres in the molecule, at C(2) and B. The two independent molecules have the same relative configurations at the chiral centres (Fig. 1 shows the 2*S*,5*R* enantiomer (chemical numbering; B and C(2) in Fig. 1)) and equal numbers of both enantiomers are present in the centrosymmetric crystals. The crystal structure (Fig. 2) consists of infinite chains of molecules, double-linked by N—H···O hydrogen bonds. The asymmetric unit comprises two independent molecules that form a pseudo-centrosymmetric dimer linked by N—H···O hydrogen bonds involving the carbonyl oxygen atom (N—H(N1)···O(3′) and N′—H(N′2)···O(3), H···O = 1.86 and 1.96 Å, N···O =

2.751(3) and 2.817(3) Å, N—H···O = 163° and 155°). Each of the two independent molecules is also hydrogen-bonded about a crystallographic centre of symmetry (at 1,1/2,1 and 1/2,1/2,1/2 for the unprimed and primed molecules, respectively) by interactions involving a ring oxygen atom (N—H(N2)···O(2)(2-*x*,1-*y*,2-*z*) and N′—H(N′1)···O(2′)(1-*x*,1-*y*,1-*z*), H···O = 1.96 and 1.86 Å, N···O = 2.838(3) and 2.751(3) Å, N—H···O = 159° and 161°), thus forming the infinite chain.

The reaction of **1** with phenylboronic acid in ethanol appears to involve a solvolytic scission of the hydroxamic acid releasing *N*-methylhydroxylamine which then adds to the Lewis acid cyclic phenylboronate **10**, a condensation product easily formed in ethanolic solution.[9] *N*-Methylhydroxylamine coordinates through the oxygen atom to the electron-deficient boron atom of the 1,3,2-dioxaborolan-4-one ring of **10**, resulting in the zwitterionic addition compound **9** having a (rehybridized) tetravalent borate anion and an ammonium cation. These findings confirm the assumption that *N*-methylhydroxylamine coordinates to Lewis acid boron compounds via the oxygen atom of the tautomeric *N*-oxide form rather than via the nitrogen atom of the hydroxylamine form, supporting the formulations postulated for boron complexes of unsubstituted hydroxylamine (9). To the best of our knowledge, compound **9** is the first structurally characterized example of an *N*-alkylhydroxylamine(*O*-*B*)boron complex having an open-chain *B*,*N*-betaine structure (17).

The geometry about the boron atom in **9** is very similar to that reported for compound **11**, an addition product between a 1,3,2-dioxaborolan-4,5-dione and a cyclic nitrone (7). The mean (N)O—B, (C)O—B, and B—C(phenyl) distances[10] of 1.494, 1.505, and 1.594 Å for **9** can be compared to corresponding values of 1.502, 1.503, and 1.576 Å for **11** (7). The mean bond angles about the distorted tetrahedral boron atom in **9**: O(1)—B—O(2) (within the five-membered chelate ring) = 102.1°, (phenyl)C—B—O(*N*-oxide) = 106.1°, O(1)—B—O(4) = 109.2°, O(2)—B—O(4) = 111.5°, C(10)—B—O(1) = 112.5°, and C(10)—B—O(2) = 116.0° are similar to the corresponding values of 102.9°, 105.6°, 109.5°, 109.5°, 113.7°, and 115.6° reported for **11**. The molecular structures of two other phenylboronate *N*-oxide complexes with Ph-B$^-$(O-C)$_2$(O-N)$^+$ 1,3-betaine moieties have been determined. Both of these compounds, **12** (18) and **13** (19), are cyclic *B*,*N*-betaines and represent examples of the intramolecular coordination of *N*-oxides to the phenylboronate function. The sums of bond lengths about the boron atom (one B—C(phenyl), one B—O(N), and two B—O(C)) are 6.099 (corrected) for **12**, 6.101 (corrected) for **13**, 6.100 for **9**, and 6.083 Å for **11**. The B—O(N) bonds in the acyclic compounds **9** and **11** (mean 1.494(2) and 1.502(8) Å, respectively) are distinctly shorter than the corresponding bonds in the cyclic derivatives **12** and **13** (1.539(2) and 1.604(7) Å, respectively),

[9]We have subsequently been able to obtain the six-membered cycloboronate **2** by carrying out the condensation reaction of **1** and phenylboronic acid in benzene solvent under water-eliminating conditions (see footnote 4).

[10]Libration-corrected bond lengths for **9** are employed throughout the discussion. Values reported for other compounds are uncorrected unless otherwise indicated.

which are subject to some steric strain in the bicyclic ring systems formed by the intramolecular coordination.

The N—O bond length in the adduct **9** (mean 1.424(2) Å) is considerably shorter than the value of 1.477(2) Å reported for an electron diffraction study of free *N*-methylhydroxylamine (20) as a result of the influence of the Lewis acid. This effect appears to be more pronounced than that induced by protonation of *N*-methylhydroxylamine: N—O in $MeNH_2OH^+Cl^-$ = 1.447 Å (21), 1.45 Å (22). Similar differences have been reported for the N—O bonds of unsubstituted hydroxylamine where the N—O bond length in the free base is 1.476(30) Å in the solid state (23) and 1.453(2) Å in the vapor phase (by microwave spectroscopy) (24), while the N—O distance is 1.411(2) Å in the protonated form $NH_3OH^+Cl^-$ (25) and 1.42(1) Å in the H_3N^+–O–U(IV) moiety of a uranium complex (12). The N—C bond of *N*-methylhydroxylamine shows the opposite tendency, that in the free base (1.420(2) Å by electron diffraction) (20) being shorter than those in the protonated form $MeNH_2OH^+Cl^-$ (1.455 Å (21) and 1.46 Å (22)) and the Lewis acid adduct **9** (mean 1.478(2) Å). This shortening of the N—O bond and lengthening of the N—C bond may be indicative of a respective decrease/increase of repulsion between the nitrogen and the oxygen/methyl carbon atom as the electron-withdrawing proton or Lewis acid interacts with the free base. Steric crowding is not involved in this case.

The difference between the O(2)—B bond involving the alcoholate ligand in **9** (mean 1.486(3) Å) and the O(1)—B bond involving the carboxylate ligand (mean 1.524(2) Å) probably arises from the higher binding strength of the alcoholate oxygen atom O(2). The reduced donor quality of the carboxylate ligand through involvement of O(1) in the mesomeric carboxylate system is also obvious from the short O(1)—C(1) bond (mean 1.314(4) Å). In comparable γ-lactone ring systems the average (O=)C—O bond is known to be 1.350(12) Å in length (26). Correspondingly, the C=O bond in **9** (mean 1.219(5) Å) is slightly longer than those in the γ-lactones (mean 1.201(9) Å) (26). The enormous shift of the C=O frequency in the infrared spectrum going from **10** to **9** (1800 → 1710 cm^{-1}) can now be interpreted as a consequence of the rehybridization of the boron atom, which can interact with O(2) by pp(π) back-donation in **10**. This interaction is inhibited by tetracoordination of the boron atom in **9**. The high frequency of the C=O stretching vibration in **10** is similar to that reported for β,γ-unsaturated five-membered cyclic lactones, showing C=O absorptions around 1800 cm^{-1} that are shifted to lower frequencies if no π-bond is present in the β,γ-position of the lactone (27). The five-membered BOCCO chelate rings in **9** are planar to within 0.025(3) and 0.044(4) Å for the unprimed and primed molecules, respectively, and have flattened C(2)- and B′-envelope conformations (see Table 4).

Kinetics and mechanism of the formation of *N*-vinyl pyridinium cations in elimination reactions in aqueous base

JOHN W. BUNTING,[1] ANDREA TOTH, AND JAMES P. KANTER
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 28, 1991

JOHN W. BUNTING, ANDREA TOTH, and JAMES P. KANTER. Can. J. Chem. **70**, 1195 (1992).

The rates of the elimination reactions of *N*-(2-bromoethyl) pyridinium cations (**1**) and *N*,*N*′-ethylene bispyridinium dications (**3**) to give the corresponding *N*-vinyl pyridinium cations (**2**) have been measured spectrophotometrically in basic aqueous solutions (ionic strength 0.1, 25°C) for a variety of substituents in the pyridine rings of each of these classes of pyridinium cation. The reaction kinetics are first order in **1** or **3** and first order in hydroxide ion. Brønsted-type plots of the second-order rate constants (k_{OH}) as a function of the basicity (as pK_{BH}) of the corresponding substituted pyridine are nonlinear for each of **1** and **3** and can be interpreted in terms of E1cb reaction mechanisms. For **1**, the Brønsted-type plot displays two distinct "concave down" linear regions; rate-determining deprotonation for $pK_{BH} < 5.16$ (slope = −0.30), and a change in rate-determining step to bromide ion departure for $pK_{BH} > 5.16$ (slope −0.58). For **3**, the Brønsted-type plot appears to be smoothly curved for symmetrically disubstituted bispyridinium dications, as a consequence of the multiple substituent effects upon each step of the E1cb reactions of these dications. However, log k_{OH} for **3** is a smooth linear function of the previously reported log k_{OH} for the E1cb reactions of *N*-(2-cyanoethyl) pyridinium cations over a range in which a change in rate-determining step has been directly demonstrated for these latter cations. Thus a change in rate-determining step as a function of pyridine basicity is also required within the E1cb mechanism for **3**. The E1cb reactions of **1** are approximately 10^4-fold faster than the corresponding hydroxide ion catalyzed E2 eliminations from 2-phenylethyl bromides that are isoelectronic with **1**.

JOHN W. BUNTING, ANDREA TOTH et JAMES P. KANTER. Can. J. Chem. **70**, 1195 (1992).

Opérant en solutions aqueuses basiques (force ionique de 0,1, à 25°C) et faisant appel à des méthodes spectrophotométriques, on a mesuré les vitesses des réactions d'élimination des cations *N*-(2-bromoéthyl)pyridinium (**1**) et des dications *N*,*N*′-éthylène bispyridinium (**3**) qui portent une variété de substituants sur les pyridines de chacune des classes de cations pyridinium et qui conduisent à la formation des cations *N*-vinylpyridinium correspondants (**2**). Les cinétiques des réactions sont du premier ordre en composés **1** (ou **3**) et du premier ordre en ion hydroxyde. Pour chacun des produits **1** et **3**, les courbes de type Brønsted des constantes de vitesse du deuxième ordre (k_{OH}) en fonction de la basicité (exprimé en pK_{BH}) de la pyridine substituée correspondante ne sont pas linéaires; on peut interpréter ces résultats en fonction de mécanismes réactionnels E1cb. Pour les composés **1**, la courbe de type Brønsted présente deux régions linéaires «concaves vers le bas» distinctes; une déprotonation qui détermine la vitesse se produit à un $pK_{BH} < 5{,}15$ (pente = −0,30) et un changement dans l'étape qui détermine la vitesse de départ de l'ion bromure à un $pK_{BH} > 5{,}16$ (pente = −0,58). Pour les composés **3** impliquant des dications bispyridinium symétriquement disubstitués, la courbe de type Brønsted semble bien aplanie; cette situation résulte des multiples effets de substituants sur chacune des étapes des réactions E1bc de ces dications. Toutefois, dans les cas des composés **3**, le log k_{OH} est une fonction régulière de log k_{OH} rapportée antérieurement pour les réactions E1cb des cations *N*-(2-cyanoéthyl)pyridinium pour une plage de valeur impliquant, pour ces derniers cations, un changement dans l'étape qui détermine la vitesse. Pour le mécanisme E1cb des composés **3**, il est donc nécessaire de faire intervenir un changement, relié à la basicité de la pyridine, dans l'étape qui détermine la vitesse. Les réactions E1cb des composés **1** se font approximativement 10^4 fois plus rapidement que les réactions E2 correspondantes, catalysées par l'ion hydroxyde, réalisés sur le bromure de 2-phényléthle qui est isoélectronique avec les composés **1**.

[Traduit par la rédaction]

Katritzky and co-workers (1, 2) have reported synthetic procedures for the preparation of *N*-vinyl pyridinium cations (**2**) via base-catalyzed elimination reactions from the corresponding *N*-(2-bromoethyl) pyridinium cations (**1**) (eq. [1]). The *N*,*N*′-ethylene bispyridinium dications (**3**), which are usually obtained as by-products in the synthesis of **1** from the substituted pyridine and 1,2-dibromoethane, are also potential sources of **2** via elimination reactions (eq. [2]) although we can find no previous report of this reaction in the literature. In the current work we have found that both the elimination reactions of eqs. [1] and [2] proceed readily in dilute aqueous base at rates that are readily measured for most X-substituents.

The reactions of eqs. [1] and [2] would be expected to most probably proceed via either the E1cb or E2 mechanisms, although we have been unable to locate any mechanistic investigation of either of these two types of reaction. The elimination reactions of the *N*-(2-bromoethyl) pyridinium cations (**1**) are of particular mechanistic interest since they are clearly related to the analogous base-catalyzed eliminations from 2-phenylethyl bromides (**4**) (eq. [3]) (3–6). Base-catalyzed eliminations from **4** have been found to be E2 (6). However, for the related eliminations (eq. [4]) from *N*-(2-phenylethyl) quinuclidinium cations, changes between the E2 and E1cb reaction mechanisms, as well as changes in rate-determining step within the E1cb mechanism, can occur upon variation of the substituent X in the phenyl ring or upon variation of the reaction conditions (base concentration, solvent, etc.) (5–7).

In the current study, we have measured the rates of elimination from **1** and **3** for a variety of X-substituents over the range pH 11–13 in aqueous solution. Brønsted plots give nonlinear correlations between the second-order rate con-

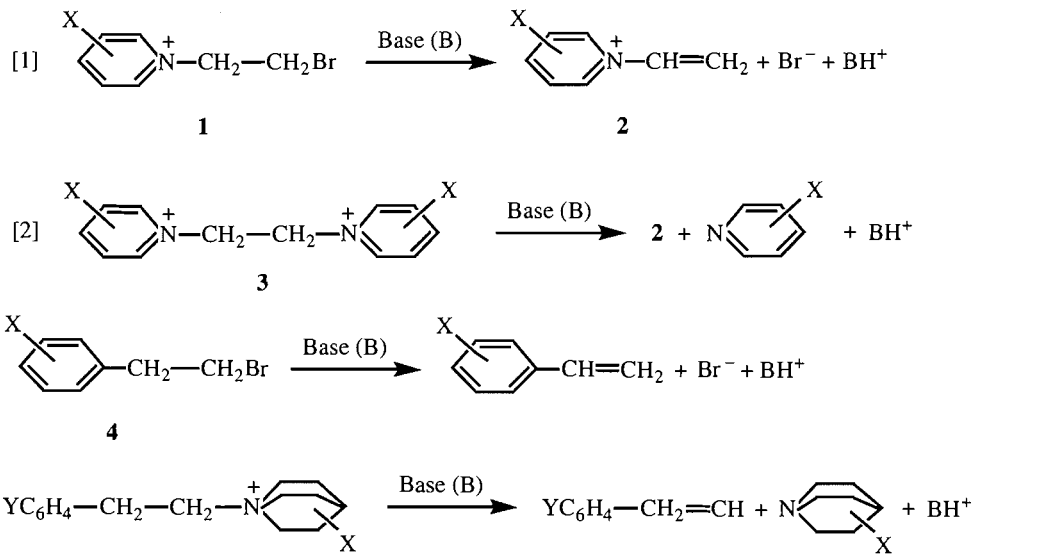
stants for the hydroxide ion catalyzed eliminations and the basicities of the corresponding substituted pyridines over the range pK_{BH} = 2–10. These data now allow detailed comparisons of the reactivities of **1**, **3**, and **4** in base-catalyzed eliminations in aqueous solution, and also demonstrate that the reactions of eqs. [1] and [2] are consistent with E1cb processes. Quantitative comparisons can also be made of the reactivities in these systems and in related elimination reactions in which substituted pyridines are the nucleofugic leaving groups (8, 9).



Experimental

Syntheses

A mixture of the bromide salts of **1** and **3** was usually obtained upon refluxing equimolar ethanolic solutions (≈ 0.04 M) of the substituted pyridine and 1,2-dibromoethane for periods ranging from 5 to 30 h. The bispyridinium dibromides (**3** · $(Br^-)_2$) precipitated from these solutions, and were recrystallized from ethanol. The filtrate contained predominantly the *N*-(2-bromoethyl) pyridinium bromide salt (**1** · Br^-), which was usually contaminated with a small amount of the corresponding **3** · $(Br^-)_2$. These crude **1** · Br^- salts were purified by several recrystallizations from appropriate solvent mixtures (usually 2-propanol–ethanol – ethyl acetate). Occasionally, a preparation using a threefold molar excess of either the substituted pyridine or 1,2-dibromoethane was used to maximize the yield of either **1** or **3** as desired.

The purified bromide salts were characterized by ^1H NMR spectroscopy (Table 1). The methylene signals at δ ≈ 5.5 in the spectra of **3** are useful indicators of the absence of **3** as a contaminant in purified samples of **1**. Vollhard titrations of the bromide ion content of purified samples of **1** · Br^- and **3** · $(Br^-)_2$ indicated purities of 100(±1)%.

Kinetic studies

All kinetic data were obtained spectrophotometrically in aqueous solutions of ionic strength 0.1 (KOH + KCl) at 25°C, on either a Durrum–Gibson stopped-flow spectrophotometer or a Cary 210 spectrophotometer. All data collection and analysis closely followed the methods that we have previously described (8). In most cases, analytical wavelengths were in the vicinity of 250 nm, although wavelengths in the vicinity of 300 nm were more appropriate for the 3- and 4-aminopyridinium cations. Substrate concentrations were in the range 0.05–0.1 mM.

Results

The time-dependence of the electronic absorption spectrum of **1***a* (X = H) in an aqueous solution of pH 11.9 is shown in Fig. 1. The spectrum of the product from **1***a* (λ_{max} = 253 nm, ε = 8100) is similar to that reported (2) for the unsubstituted *N*-vinyl pyridinium cation (**2**: X = H).[2] The time-dependence of the absorption spectrum of **1***m* (X = 4-$N(CH_3)_2$) at pH 13.0 is shown in Fig. 2. The spectrum of the product λ_{max} = 308 nm, ε = 27 300) is consistent with that reported (2) for **2**: X = 4-$N(CH_3)_2$. The tight isosbestic point that is indicated in Fig. 2 is consistent with the clean conversion of **1***m* to **2***m* without the formation of any significant concentration of intermediate species, and also indicates that there are no significant competing reactions of the *N*-vinyl pyridinium cation product on the time scale of the current elimination reaction.

Similar spectral observations, consistent with the formation of the various ring-substituted *N*-vinyl pyridinium cations (**2**), were made for the reactions of **1***a*–**1***m* and **3***a*–**3***k* in aqueous base. The spectral changes for the conversion of **3** to **2** were smaller than for the corresponding elimination reactions of **1** due to the presence of two pyridinium chromophores per dication in **3**. However, the products from **3** displayed spectra that were identical to those of 1:1 mole ratios of the appropriate X-substituted **2** and X-substituted pyridine. The 4,4′-diamino and 4,4′-bis-(dimethylamino) dications (**3***l* and **3***m*) appeared to be stable at pH 13 over several hours, so that we were unable to observe the elimination reactions for these two dications (see below).

We were unable to observe the elimination reaction from **1***d* (X = 3-CN), because of a competing reaction that generated a species having λ_{max} = 360 nm. We have not investigated this reaction in detail; similar reactions resulting from hydroxide ion addition to the pyridinium ring carbon atoms have been reported for the *N*-methyl 3-cyanopyridinium

[2]All absorption maxima in the current study are at 2–4 nm shorter wavelength than those previously reported (2). The wavelength scale of our instrument was recently calibrated against the absorption spectrum of benzene vapour.

cation and related species (10–13). The 3-chloropyridinium cation, **1***b*, underwent a clean elimination to the *N*-vinyl cation; however, prolonged incubation in these basic solutions led to a subsequent unidentified slower reaction.

We have observed the elimination reaction of **1***m* (0.046 M) by ^{1}H NMR spectroscopy in basic D_2O (pD ≈ 12.5). The decrease in the intensity of the signals from **1***m* is concerted with the appearance of the spectrum of the corresponding *N*-vinyl pyridinium cation (**2***m*) (δ 3.32 (s, 6H), 5.36 (dd, 1H), 5.71 (dd, 1H), 7.00 (d, 2H), 7.06 (dd, 1H), 8.23 (d, 2H)). It should be noted that under these conditions the formation of **2***m* occurs without significant exchange of the vinylic proton (δ 7.06) adjacent to the ring-nitrogen atom. Consistent with this observation, there is no exchange of the corresponding methylene protons in unreacted **1***m* during the course of the elimination reaction.

The elimination reactions of both **1** and **3** proved to be strictly first order in pyridinium cation concentration for >95% of the reaction in all cases. Pseudo-first-order rate constants (k_{obs}) were evaluated as a function of pH, usually over the pH range 11–13. Some examples of the pH-dependences of k_{obs} are given in Figs. 3 and 4 for **1** and **3**, respectively. In most cases, log k_{obs} shows a linear dependence upon pH with unit slope (Table 2), although slight variations from unit slope were found in some cases. While the most reactive **1** and **3** cations in Table 2 appear to display accurate unit slopes within experimental error, there appears to be a trend towards increasing slope as the reactivity decreases. Similar deviations from unit slope in related elimination reactions from pyridinium and quinuclidinium cations have been attributed (5, 6, 9) to specific ion effects upon replacement of chloride ions by hydroxide ions in these constant ionic strength solutions. Second-order rate constants (k_{OH}) for the hydroxide ion catalyzed elimination reactions were evaluated by interpolation at pH 12 on the least-squares correlation lines, and are collected in Table 2.

In one case, **3***b* (X = 3-Cl), a nonlinear pH–rate profile is apparent in Fig. 4. In this case, k_{obs} was found to be consistent with eq. [5]. Fitting of the data to this equation gave: k_{OH} = 12 (±1) M^{-1} s^{-1} and pK_a = 12.77 (±0.07). We assume that pK_a = 12.77 for **3***b* represents pK_{R^+} for hydroxide ion addition to one of the ring-carbon atoms.

$$[5] \quad k_{obs} = k_{OH}[^-OH]/(1 + K_a/[H^+])$$

Discussion

The best available synthetic route to an *N*-vinyl pyridinium cation (**2**) involves the treatment of the corresponding *N*-(2-bromoethyl) pyridinium cation (**1**) with one equivalent of base in alcoholic solution at −10°C (1, 2). Higher temperatures lead to the loss of **2** to polymerization. In the current work, we found that the rates of elimination by **1** to give

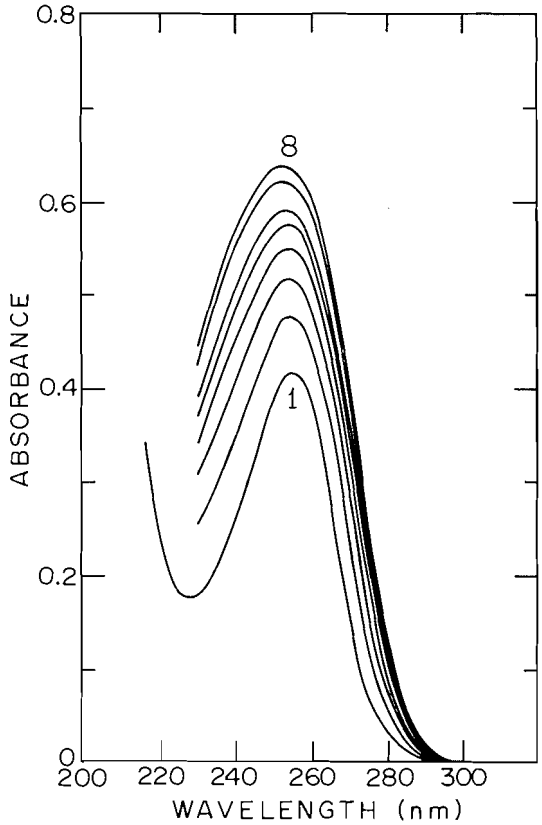

FIG. 1. Time dependence of the electronic absorption spectrum of the *N*-(2-bromoethyl) pyridinium cation (**1***a*) (0.08 mM) in aqueous solution of pH 11.9 at 25°C. Successive scans (1–8) are at 1, 4, 7, 9, 11, 14, 23, and 60 min, respectively.

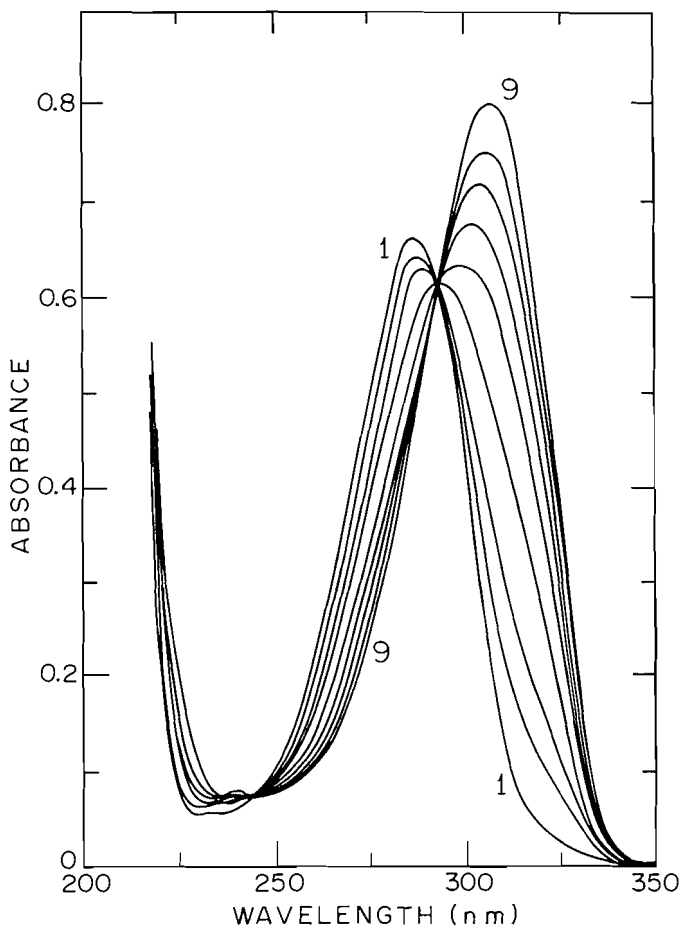

FIG. 2. Time dependence of the electronic absorption spectrum of the *N*-(2-bromoethyl) 4-dimethylaminopyridinium cation (**1***n*) (0.03 mM) in aqueous solution of pH 13.0 at 25°C. Successive scans (1–9) are at 0, 30, 60, 120, 180, 240, 300, 360, and 600 min, respectively.

2 can be studied spectrophotometrically in dilute aqueous base (pH 11–13) at 25°C. We did not observe any complications from polymerization processes at the low concentrations (0.05–0.1 mM) of *N*-vinyl pyridinium cations that are produced in these kinetic studies. We also found that the *N*,*N*′-ethylene bispyridinium dications (**3**) undergo a clean elimination reaction to give **2** in dilute aqueous base, although this reaction becomes extremely slow for the dications that are derived from the most basic pyridines.

The elimination reactions of eqs. [1] and [2] are kinetically first order in each of the pyridinium cation (**1** or **3**) and hydroxide ion. Although this observation is formally consistent with either an E2 or an E1cb reaction mechanism, we will argue below that all of the available data are only readily reconciled in terms of the E1cb mechanism for both **1** and **3**.

A Brønsted-type plot of k_{OH} for **1** as a function of the basicity of the corresponding substituted pyridine is shown in Fig. 5. This plot is nonlinear; the data can be represented by two distinct linear relationships (eqs. [6] and [7]) having Brønsted $\alpha = 0.30$ (for $pK_{BH} \leq 5.16$) and $\alpha = 0.58$ (for $pK_{BH} \geq 5.16$).

$$[6] \quad \log k_{OH} = -0.30(\pm 0.03)pK_{BH} + 1.13\ (\pm 0.05) \qquad (r = 0.991)$$

$$[7] \quad \log k_{OH} = -0.58(\pm 0.01)pK_{BH} + 2.54(\pm 0.05) \qquad (r = 0.999)$$

The data in Fig. 5 represent a classic case of a "concave-down" linear free energy relationship, which is only readily interpretable in terms of a change in rate-determining step. For base-catalyzed elimination reactions, this is an indication of an E1cb reaction mechanism (Scheme 1) rather than an E2 mechanism. We interpret eqs. [6] and [7] in terms of rate-determining deprotonation (k_1) for the more reactive **1** (eq. [6]), and rate-determining expulsion of the bromide ion from the zwitterionic conjugate base (k_2) for the less reactive **1** (eq. [7]).

For a steady-state zwitterionic intermediate (**5**), $k_{OH} = k_1$ and $\alpha = 0.30$ from eq. [6], and $k_{OH} = k_1k_2/k_{-1}$ and $\alpha = 0.58$ from eq. [7]. Irrespective of reaction mechanism, X-substituent effects upon the elimination reaction of **1** are predominantly expressed via their influence upon the acidity (kinetic or thermodynamic) of the methylene group adjacent to the ring-nitrogen atom. For the E1cb mechanism of Scheme 1, $\alpha = 0.30$ (eq. [6]) is a measure of the substituent effect upon the kinetic acidity of the methylene group adjacent to the ring-nitrogen atom. The broken line in Fig. 5 represents the extrapolation of eq. [6] to substituents for which k_1 is no longer rate determining. In eq. [7], $\alpha = 0.58$ is a combination of the equilibrium substituent effect upon the thermodynamic acidity of this methylene group ($k_1/k_{-1} = K_a/K_w$), and the

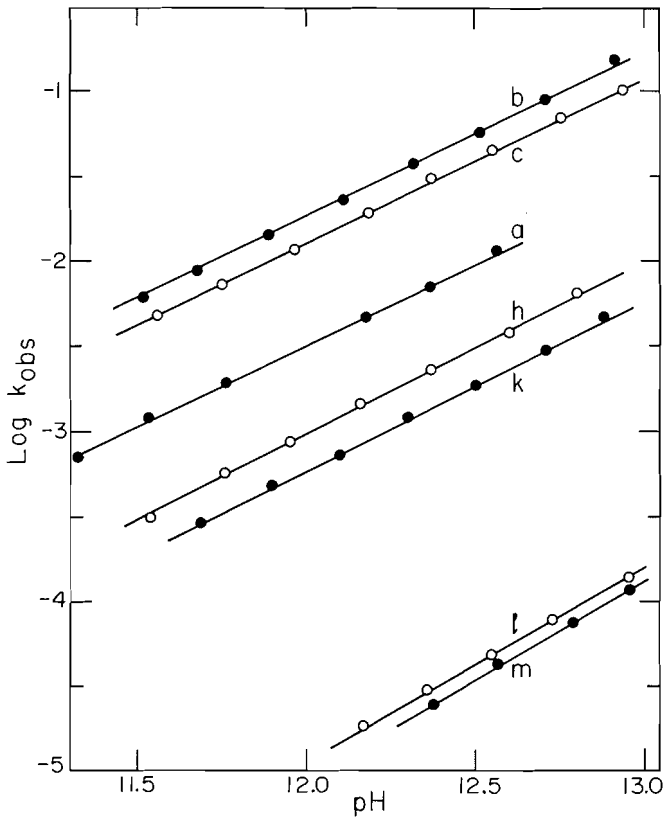

FIG. 3. The pH dependence of the pseudo-first-order rate constants (k_{obs}) for the elimination reactions of selected **1** in aqueous solution at ionic strength 0.1 and 25°C.

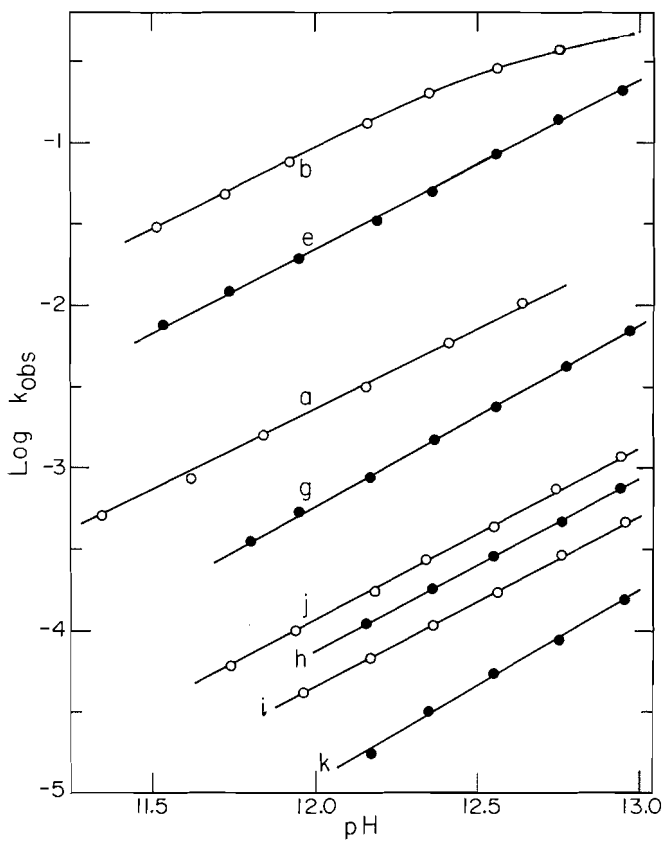

FIG 4. The pH dependence of the pseudo-first-order rate constants (k_{obs}) for the elimination reactions of selected **3** in aqueous solution at ionic strength 0.1 and 25°C.

substituent effect upon the k_2 step. Since substituent effects upon k_2 should oppose those upon K_a, the observed $\alpha = 0.58$ then represents a minimum value for the equilibrium substituent effect upon pK_a vs. pK_{BH}. This then sets a maximum value of $\alpha < (0.30/0.58 = 0.52)$ for substituent effects upon the kinetic acidity of **1** when this latter Brønsted α is defined in terms of log k_{OH} vs. pK_a for the deprotonation of **1**.

The equilibrium $\alpha > 0.58$ that is deduced above for the pK_a of **1** relative to pK_{BH} can be compared with the correspondingly defined[3] equilibrium $\alpha = 0.67$ for the deprotonation of *N*-hydroxy pyridinium cations (**6**) (eq. [8]) and $\alpha = 0.33$ for the deprotonation of *N*-di(ethoxycarbonyl)methyl pyridinium cations (**7**) (eq. [9]). These α values are consistent with the expectation that the delocalization of the negative charge in the conjugate base of **7** into the carbonyl substituents will result in the thermodynamic acidity of **7** being less sensitive to X-substituents than are the acidities of **1** (conjugate base = **5**) and **6**, for which the negative charge in each conjugate base is essentially localized on the atom adjacent to the ring nitrogen atom.

The observation that **1***m* undergoes elimination without exchange of the protons of the activated methylene group for deuterium in basic D_2O must be considered within the con-

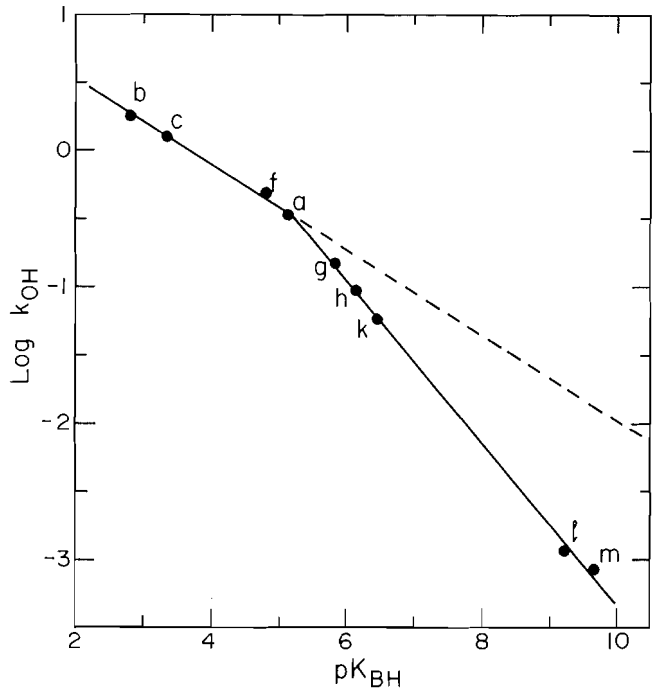

FIG. 5. Brønsted-type plot for k_{OH} as a function of pyridine basicity for the elimination reactions of **1**.

[3]Literature data (13, 14) for the pK_a values defined by eqs. [8] and [9] in aqueous solution are linearly correlated with pK_{BH} for the corresponding substituted pyridinium cations:

$pK_a(\mathbf{6}) = 0.67(\pm0.02)\ pK_{BH} + 2.6(\pm0.2)$ ($n = 11$; $r = 0.994$)

$pK_a(\mathbf{7}) = 0.33(\pm0.01)\ pK_{BH} + 3.41(\pm0.06)$ ($n = 7$; $r = 0.997$)

7

text of the rate-determining bromide ion departure from the carbanionic intermediate that is deduced above from the concave-down Brønsted plot. This result requires that elimination occurs within a solvated (hydrogen-bonded) intermediate in which bromide ion departure occurs more rapidly than exchange of the HOD molecule with bulk D_2O (i.e., $k_2 >> k_s$ in Scheme 2). A similar observation has been reported for rate-determining nucleofuge departure in the elimination reactions of **10**: X = 4-$N(CH_3)_2$ in aqueous base (9) and also for the analogous eliminations from 2-cyanoethyl sulfides (16). Such a process indicates that the elimination from **1***m* corresponds to an $(E1cb)_{ion\ pair}$ (i.e., $A_{xh}D_H{}^*D_N$) mechanism (17, 18).

The Brønsted plot for the elimination reactions of **3** (eq. [2]) is shown in Fig. 6. This plot appears to have pronounced curvature and cannot be as readily separated into two linear regions as can the plot in Fig. 5. The influence of X-substituents upon k_{OH} for **3** will be quite complex. In addition to the direct effect of X upon the acidity of the methylene group, analogous to that in **1** ⇌ **5**, there will also be a smaller indirect effect from the X-substituent in the other pyridinium ring upon this acidity. This latter effect cannot be ignored; a Brønsted $\alpha = 0.30$ has been found (8) upon the kinetic acidities for the analogous substituent effect in **8**. Another pronounced X-substituent effect will be derived from the pyridine leaving group when its departure is rate determining. Furthermore, superimposed upon all of these effects is the expected change in rate-determining step from deprotonation to nucleofuge departure, analogous to that which is observed for **1** and **8**.

The most reactive **3** (X = 3-Cl) undergoes hydroxide ion catalyzed elimination 3.3-fold faster (after allowing for the statistical factor in **3**) than the similarly substituted **1**. This result is only interpretable in terms of rate-determining deprotonation within an E1cb mechanism for both **1** (Scheme 1) and **3** (Scheme 4) since the 3-chloropyridine leaving group is a far poorer nucleofuge than is bromide ion. The best demonstration of this latter assertion is probably the fact that S_N2 reactions are essentially unknown for *N*-alkyl pyridinium cations under conditions in which such displacement reactions occur readily on simple alkyl bromides.

The limiting slopes are −0.5 at low pK_{BH} and −2.5 at high pK_{BH} for the curve that is sketched as a reasonable visual fit to the data in Fig. 6. The former value is about what is expected for the combined substituent effects from the two X-substituents upon the rate-determining deprotonation of **3** to give **9** in Scheme 4. The higher slope of approximately −2.5 must be interpreted in terms of rate-determining k_2 (i.e., k_{OH}

[d]Nonlinear (eq. [4]: $pK_a = 12.77(\pm0.07)$).

$= k_1k_2/k_{-1}$); the reinforcing effects of both X-substituents are expressed upon $K_a/K_w = k_1/k_{-1}$, and are combined with a significant substituent effect upon k_2 from both X-substituents.

A simple linear extrapolation of log k_{OH} over the range pK_{BH} 5.82–6.45 to $pK_{BH} = 9.68$, allows an estimate of $k_{OH} \approx 8 \times 10^{-12}$ M^{-1} s^{-1} for **3***m* (X = 4-$N(CH_3)_2$). Alternatively, an estimate of the reactivity of **3***m* can be made from the observation that log k_{OH} for **3** is a simple linear function of log k_{OH} for **8** (Fig. 7; eq. [10]). Extrapolation of eq. [10] to $k_{OH} = 4.17 \times 10^{-3}$ M^{-1} s^{-1} for **8**: X = 4-$N(CH_3)_2$, gives $k_{OH} = 3 \times 10^{-11}$ M^{-1} s^{-1} for **3***m*, which is in reasonable

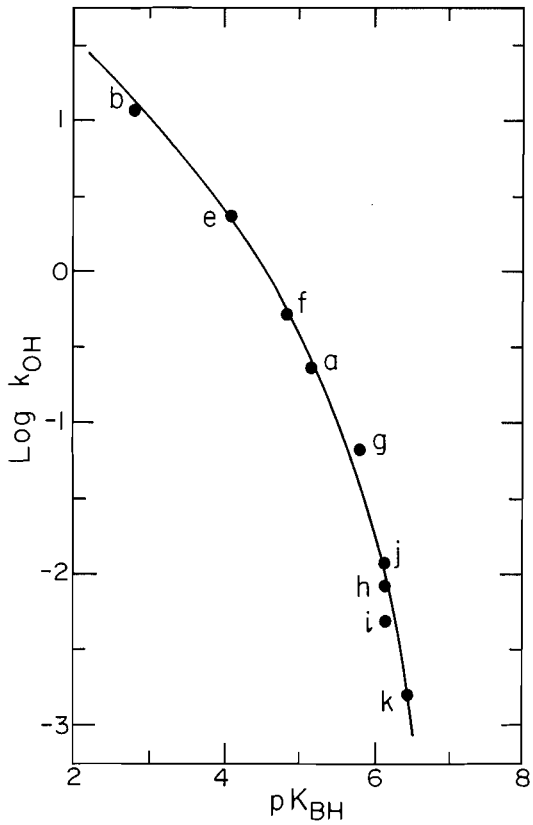

FIG. 6. Brønsted-type plot for k_{OH} as a function of pyridine basicity for the elimination reactions of **3**. The curve is sketched as a best visual fit to the data points.

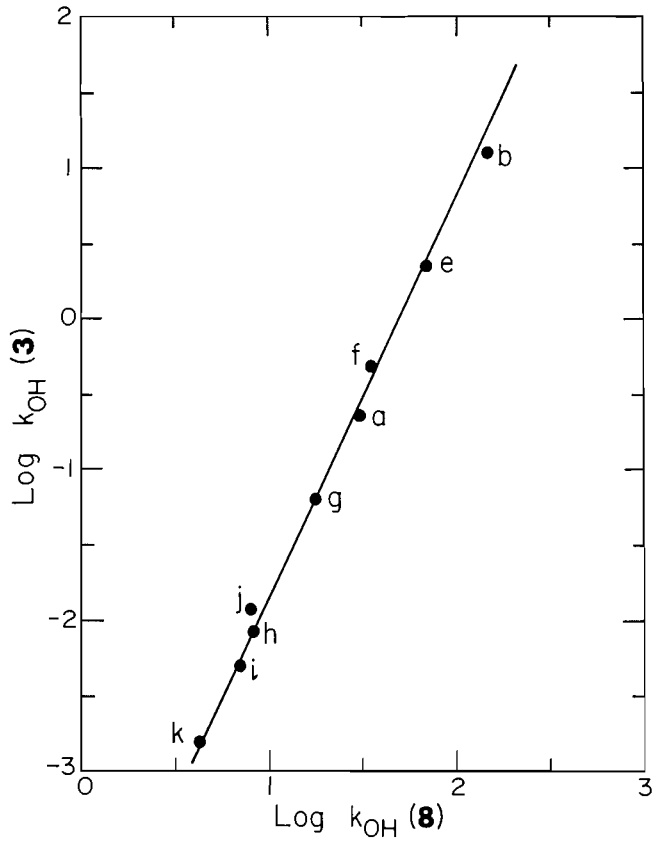

FIG. 7. The relationship between k_{OH} for the elimination reactions of **3** and **8**. The data for **8** are taken from ref. 8.

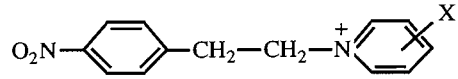
agreement with the estimate that is given above. This second-order rate constant ($k_{OH} \approx 10^{-11}$ M^{-1} s^{-1}) is 10^{12}-fold smaller than k_{OH} for the most reactive bispyridinium dication in Table 2 (**3***b*: X = 3-Cl), and corresponds to a reaction half-time of about 10^4 years for elimination from **3***m* at pH 13 and 25°C! This should be compared with a half-time of 0.6 s for **3***b* under the same reaction conditions, and a half-time of 2.2 h for **1***m* under these conditions.

[10] $\log k_{OH}(\mathbf{3}) = 2.55(\pm 0.07) \log k_{OH}(\mathbf{8}) - 4.4(\pm 0.1)$

$(r = 0.997)$

There is an additional implication in the linearity displayed in Fig. 7. The Brønsted plot for the hydroxide ion catalyzed elimination reaction of various ring-substituted **8** is concave-down, consistent with a change in rate-determining step from deprotonation (k_1) to nucleofuge departure (k_2) at pK_{BH} = 5.8 (8). The data in Fig. 7 cover a range pK_{BH} = 2.84–6.45, and can only display linearity over this range if the E1cb eliminations of **3** also undergo a similar change in rate-determining step near pK_{BH} = 5.8. We thus have direct evidence that the curvature in the Brønsted plot in Fig. 6 does combine dual substituent effects from the two X-substituents with a change in rate-determining step. The slope of 2.55 in Fig. 7 primarily reflects the difference in the influence of substituent effects upon carbanion stabilization from a pyridinium ring directly upon the carbanionic centre, with one that is a further methylene group removed. The magnitude of this slope is similar to that (1/0.36 = 2.8) associated with the transmission of polar effects through a saturated carbon atom (19).

The elimination reactions of 2-phenylethyl bromides (**4**) in aqueous base have been shown to occur via the concerted E2 reaction mechanism (6), whereas we have concluded above that the corresponding eliminations from **1** and **3** occur via the two-step E1cb mechanism. Table 3 summarizes the relative reactivities of **1**, **3**, **4**, and some related species in hydroxide ion catalyzed eliminations, and the mechanistic assignments (using Bordwell's convention (17)) that have been made for these reactions. Both **1***a* and **3***a* are clearly much more reactive than either 2-phenylethyl bromide (**4**: X = H) or even its 4-nitro derivative (**4**: X = 4-NO$_2$). However, the latter species is 3-fold more reactive than **1***m*, which is the least reactive *N*-(2-bromoethyl) pyridinium cation in the current study. The E1cb reaction of **1***a* (X = H) occurs over 10^4-fold faster than the E2 reaction of **4**: X = H. This comparison is of particular interest since these latter two species are isoelectronic.



10

The reactants, **8** (X = H), **3***a*, and **10**, in Table 3, all have the same leaving group and have all been established as involving rate-determining deprotonation (i.e., (E1cb)$_{irrev}$), so that the relative reactivities of these species indicate the rel-

[b]Current work.
[c]Calculated from data in refs. 5 and 6, by assuming that the relative reactivities of **4**: X = H and **4**: X = 4-NO_2 are the same in aqueoous solution as they are in 40% dimethyl sulfoxide – 60% water.
[d]After correction by a statistical factor of 2.

ative influence of cyano, pyridinio, and 4-nitrophenyl substituents upon the kinetic acidities of adjacent methylene groups. If we tentatively assume that the 224-fold difference in the reactivities of **3***a* and **10** is also a reasonable estimate of the relative kinetic acidities of **1***a* and **4** (X = 4-NO_2), then a second-order rate constant, $k_{OH} = 1.4 \times 10^{-3}$ M^{-1} s^{-1}, is obtained for the deprotonation of this latter species. This value, which represents the upper limit to the second-order rate constant for an E1cb process for this molecule, is somewhat smaller than the experimentally observed k_{OH} for the hydroxide ion catalyzed elimination. This result is consistent with the mechanistic assignment of the hydroxide ion catalyzed elimination from 2-(4-nitrophenyl)ethyl bromide as an E2 process that does not involve an intermediate conjugate base species.

We previously demonstrated a change in rate-determining step within the E1cb reaction mechanism by variation of the substituents in the pyridine nucleofuge for two series of constant activating groups (cyano (**8**) (8) and 4-nitrophenyl (**10**) (9)). In the current work, we show a change in rate-determining step in an E1cb reaction for a constant leaving group (bromide ion) but with a systematic variation in reactivity via substitution in the pyridinio activating group (**1**). The *N*,*N*′-ethylene bispyridinium dications (**3**) combine these two effects via substitution in both the activating and leaving groups. Such double substitution results in an enormous range of reactivities in the elimination reactions from these dications.

Annulations leading to diene systems. Total syntheses of the dolastane-type diterpenoids (±)-(5*S*,12*R*,14*S*)-dolasta-1(15),7,9-trien-14-ol and (±)-amijitrienol

EDWARD PIERS[1] AND RICHARD W. FRIESEN

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Z1

Received October 15, 1991

EDWARD PIERS and RICHARD W. FRIESEN. Can. J. Chem. **70**, 1204 (1992).

Alkylation of the substituted cycloalkanones **14***a–d* and **30** with (*Z*)-1-bromo-4-methyl-3-trimethylstannyl-2-pentene (**13**) produced compounds **15***a–d* and **33**, which were readily converted into the corresponding enol trifluoromethanesulfonates (triflates) **16***a–d* and **34**. Intramolecular Pd(O)-catalyzed coupling of the vinylstannane and enol triflate functions in **16***a–d* and **34** provided the dienes **17***a–d* and **35**. The annulation product **35** served as a suitable starting material for the total syntheses of the dolastane diterpenoids (±)-(5*S*,12*R*,14*S*)-dolasta-1(15),7,9-trien-14-ol (**2**) and (±)-amijitrienol (**3**). The key steps of the synthesis of (±)-**2** involved the stereoselective methylation of the ketone **44** (readily derived from **35**) to provide **46** and the Barbier type ring closure of **47** to provide the target compound. For the synthesis of (±)-**3**, the notable conversions included the reductive transformation of the diene **35** into the alkene **53**, the aldol condensation of the ketone **54** with 4-trimethylstannyl-4-pentenal (**55**), the chemo- and stereoselective reduction of the dione **58**, and the one-pot conversion of the keto vinylstannane **63** into the triene **65**, via the intermediate **64**.

EDWARD PIERS et RICHARD W. FRIESEN. Can. J. Chem. **70**, 1204 (1992).

L'alkylation des cycloalcanones substituées **14***a–d* et **30** avec le (*Z*)-bromo-1-méthyl-4-triméthylstannyl-2-pentène (**13**) conduit aux composés **15***a–d* et **33** que l'on transforme facilement en les trifluorométhanesulfonates d'énol correspondants (triflates) **16***a–d* et **34**. Le couplage intramoléculaire, catalysé par le Pd(O), des fonctions stannane de vinyle et triflate d'énol des composés **16***a–d* et **34** donne les diènes **17***a–d* et **35**. Le produit d'annellation **35** sert parfaitement de produit de départ pour la synthèse totale des diterpènes dolastane (±)-(5*S*,12*R*,14*S*)-dolastatriène-1(15),7,9-ol-14 (**2**) et du (±)-amijitriénol (**3**). L'étape clé de la synthèse du composé (±)-**2** implique la méthylation stéréosélective de la cétone **44** (obtenue facilement à partir du composé **35**) qui conduit au composé **46** et la fermeture de cycle du type Barbier du composé **47** qui permet d'accéder au produit attendu. Dans le cas de la synthèse du composé (±)-**3** les transformations particulières comprennent la transformation réductrice du diène **35** en alcène **53**, la condensation aldolique de la cétone **54** sur le triméthylstannyl-4-pentenal-4 (**55**), la reduction chimique et stéréosélective de la dione **58** et la transformation *in situ* de la céto vinylstannane **63** en triène **65** par l'intermédiaire du composé **64**.

[Traduit par la rédaction]

Introduction

The dolastane family of diterpenoids share the structurally interesting carbon skeleton **1**.[2] Members of this class of natural products have been isolated from a variety of marine organisms (1–12). Collectively, they exhibit varying degrees of unsaturation and oxygen functionalization and their absolute configuration has been determined (8, 9). Furthermore, many of the dolastanes display useful and potentially important biological properties, including antimicrobial activity and cytotoxicity. A number of dolastanes contain, as part of their structures, conjugated diene units. For example, the structurally interesting trienol **2**,[3] which was isolated from an intertwined mixture of algae (*Dictyota linearis* (C. Ag.) and *D. divaricata* (lamour)) collected from the coral reefs of the Honduras Bay Islands, contains a heteroannular 1,3-butadiene moiety involving carbons 7–10. On the other hand, amijitrienol ((4*R*,5*S*,12*R*)-dolasta-1(15),8,13-trien-4-ol) (**3**), a dolastane derived from *D. linearis* collected in the

[1]Author to whom correspondence may be addressed.

[2]In the two original reports (1, 2) regarding natural products possessing the carbon skeleton **1**, it was proposed that the names dolastane and clavularane be used to designate the carbon skeletons **i** and **ii**, respectively. Under these proposals, the dolastanes and clavularanes share a common skeletal framework and differ only in configuration at a number of stereogenic centers. In our opinion, this convention is unnecessarily complicated and confusing and its continuation should be discouraged. We propose that the name clavularane be dropped and that all diterpenoids that display the general skeleton **1**, devoid of configurational designations, be referred to as dolastanes.

[3]Substance **2** was originally named (14*S*)-14-hydroxydolasta-1(15),7,9-triene (7). However, on the basis of our proposal that the term dolastane should no longer include configurational implications (see footnote 2), we suggest that **2** should be designated (5*S*,12*R*,14*S*)-dolasta-1(15),7,9-trien-14-ol.

Bay of Tosa (11), embodies a conjugated diene system connecting carbons 13, 14, 1, and 15. The natural product **3** exhibits moderate antimicrobial activity against *Staphylococcus aureas* and *Mucor mucedo* (11).

Recent reports (13) from this laboratory have described a new annulation method represented in general terms by **4** → **5** → **6**. The key step of this sequence involved the intramolecular, palladium(O)-catalyzed coupling of the vinylstannane and enol trifluoromethanesulfonate (triflate) functions of the intermediate **5** to provide the annulation product **6**. If one compares the structure of **6** (n = 2) with that of amijitrienol (**3**), it is immediately evident that the AB ring portion of the natural product should be amenable to preparation via application of the new method. Furthermore, it was envisaged that an appropriate variant of the method, involving formation of products in which both double bonds of the diene unit are endocyclic (e.g., **4** → **7** → **8**) could serve effectively as a route for the synthesis of the BC ring segment of the dolastatrienol **2**. We report herein model studies that show that transformations represented in general terms by **4** → **7** → **8** are readily accomplished. Furthermore, we describe total syntheses of the dolastanes (±)-**2** and (±)-**3** via routes in which our new annulation methods play a key role.[4] It is important to note that other research groups have published work that culminated in the total syntheses of a number of dolastanes (16–18) or have described synthetic approaches to the preparation of members of this interesting family of diterpenoids (19–22).

Results and discussion

(a) Preparation of (Z)-1-bromo-4-methyl-3-trimethylstannyl-2-pentene (13) and its use in diene-producing annulation sequences

One of the bifunctional reagents required for this study, (*Z*)-1-bromo-4-methyl-3-trimethylstannyl-2-pentene (**13**), was prepared by use of (trimethylstannyl)cuprate chemistry developed earlier in our laboratory (see Scheme 1). Thus, treatment of methyl 4-methyl-2-pentynoate (**9**) with lithium (phenylthio)(trimethylstannyl)cuprate (**10**) (23) under appropriate reaction conditions (24) provided the *Z* enoate **11**. Reduction of this material with diisobutylaluminum hydride, followed by reaction of the resultant allylic alcohol **12** with triphenylphosphine dibromide in the presence of triethylamine, produced the required bromide **13** in 69% overall yield from **9**. Although it proved to be a viable reagent for our purposes (*vide infra*), compound **13** is quite unstable and could not be distilled without considerable decomposition. Even upon storage in the dark at −4°C, **13** slowly decomposed. Consequently, this substance was employed in subsequent reactions immediately after its preparation and was not distilled prior to use.

In spite of the "handling difficulties" associated with its instability and even though the CH_2Br function in **13** is *cis* to the sterically bulky Me_3Sn group, this substance served effectively as an alkylating agent. For example, reaction of the potassium enolate of 2-methoxycarbonylcyclopentanone (**14***a*) with the bromide **13** in refluxing tetrahydrofuran (THF) afforded the expected product **15***a* in 78% yield (Scheme 2). In similar fashion, the β-keto esters **14***b* and **14***c*

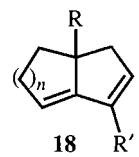
For personal use only.

could be transformed cleanly and efficiently into the corresponding alkylation products **15***b* and **15***c*. Furthermore, alkylation of 2-methylcycloheptanone (**14***d*) (25) with **13** under conditions (*t*-BuOK, *t*-BuOH, THF) that would cause rapid enolate anion equilibration produced **15***d* as the major product, albeit in mediocre isolated yield (42%).

To determine whether or not **15***a–d* would serve as effective substrates for the synthesis of dienes of general structure **17** (Scheme 2), the former substances were allowed to react sequentially with lithium diisopropylamide (LDA) and *N*-phenyltrifluoromethanesulfonimide (Tf_2NPh) (26). The resultant enol trifluoromethanesulfonates (triflates) **16***a–d* were obtained in excellent yields (82–87%). Treatment of each of these intermediates with 0.05 equivalents of $(Ph_3P)_4Pd$ in THF or MeCN resulted in the smooth, efficient (>80%) formation of the dienes **17***a–d*.[5] Thus, this brief study showed clearly that the originally desired annulation sequence (**4** → **8**) is readily accomplished. The generality of the method was demonstrated to some degree by the formation of dienes possessing bicyclo[3.3.0]octane (**17***a*), bicyclo[4.3.0]nonane (**17***b*), and bicyclo[5.3.0]decane (**17***c*, *d*) carbon frameworks. It is highly likely that replacement of the isopropyl moiety in **13** by a different alkyl group or by a functionalized alkyl group would permit the extension of this chemistry to the facile preparation of a wide variety of bicyclic dienes represented in general terms by structural formula **18**. It should also be mentioned that the conversion of 2-methylcycloheptanone (**14***d*) into the diene **17***d* represented an excellent model for the preparation of the BC ring system present in the dolastatrienol **2**. The total synthesis of (±)-**2** via a route that utilizes this method is described in the next section of this paper.



18 R′

An interesting observation was made in comparing the Pd(O)-catalyzed cyclizations of the vinylstannane-enol triflates **16***c* and **16***d*. These substrates, which differ only with respect to the nature of the substituent adjacent to the enol triflate moiety (CO_2Me vs. Me), undergo cyclization at significantly different rates. Thus, completion of the ring closure of **16***c* required ~30 min at 82°C (refluxing MeCN), while **16***d* was converted completely into **17***d* in 5 min at room temperature (THF solution).[6]

Presumably, the overall coupling processes involving **16***c* and **16***d* take place via a sequence of steps that, in broad terms, may be represented as shown in Scheme 3. In *inter*molecular reactions of this type, the rate-limiting step is proposed (27) to be the transmetalation reaction, corresponding to step B in Scheme 3. However, in *intra*molecular couplings, it is possible that the monomolecular transmetalation reaction (**19** → **20**, step B) is faster than the bimolecular oxidative addition (**16***c*, *d* → **19**, step A). In this case, the initial conversion in Scheme 3 would be rate limiting. It is likely that, in either case, the fact that **16***c* cyclizes at a rate significantly slower than **16***d* is due to the electron-withdrawing inductive effect of the CO_2Me function. Thus, if step A is rate determining, one would have to conclude that the adjacent CO_2Me group has a deleterious effect on the rate of oxidative addition of the Pd(O) catalyst to the C—O bond of the enol triflate moiety in **16***c*. On the other hand, if B is the slow step, one would postulate that intramolecular transmetalation of an "electron deficient" vinylpalladium(II) species (**19**, R = CO_2Me) is slower than the corresponding process involving an "electron rich" vinylpalladium(II) intermediate (**19**, R = Me).

(b) Total synthesis of (±)-(5S,12R,14S)-dolasta-1(15),7,9-trien-14-ol (2)

The starting material that was chosen for the total synthesis of the dolastatrienol (±)-**2** was the commercially available keto ketal **21** (see Scheme 4). Since the six-membered carbocyclic ring of this material was to become ring B of the target molecule **2**, it was necessary to convert **21** into the substituted cycloheptanone **30**. This overall transformation, requiring a methylation and a one-carbon ring expansion, was accomplished as summarized in Scheme 4.

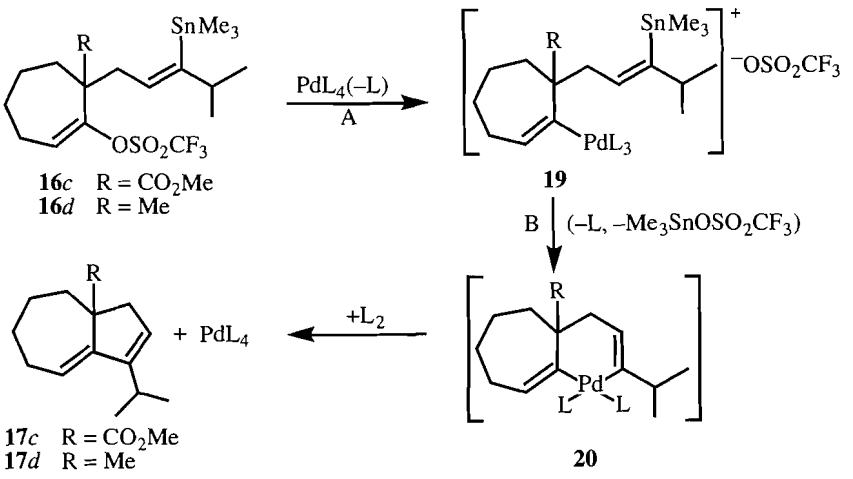
Methylation of **21** was achieved by use of the method developed by Corey and Enders (29). Monoalkylation of the *N*,*N*-dimethylhydrazone **22** occurred cleanly and efficiently and, after cleavage of the hydrazone linkage in **23**, the keto ketal **24** was obtained in excellent yield. The required ring expansion of **24** was conveniently performed via the method reported by Saegusa *et al.* (30). Thus, cyclopropanation (31) of the enol silyl ether **25**, derived (32) from the ketone **24**, produced a mixture of the cyclopropanes **26** and **27**, in a ratio of approximately 2:1.[7] Treatment of this mixture with anhydrous ferric chloride in *N*,*N*-dimethylformamide containing one equivalent of pyridine (30) gave the rather unstable β-chloro ketone **28**. Dehydrochlorination (NaOAc in hot methanol) of this crude material produced, in 62% yield from the mixture of **26** and **27**, the enone ketal **29**. Hydrogenation (H_2, Pd–C) of **29** in hexane removed the unwanted carbon–carbon double bond and provided the required cycloheptanone **30**.

The stage was now set for subjection of the intermediate **30** to the diene-producing annulation sequence developed earlier (*vide supra*). To that end, the ketone **30** was alkylated with the allylic bromide **13** under reaction conditions (*t*-BuOK, *t*-BuOH, 1,2-dimethoxyethane (DME)) that would promote enolate anion equilibration (see Scheme 5). Analysis (tlc) of the crude product indicated the presence of a small amount of starting material, one major product, and two additional (minor) components. Column chromatogra-

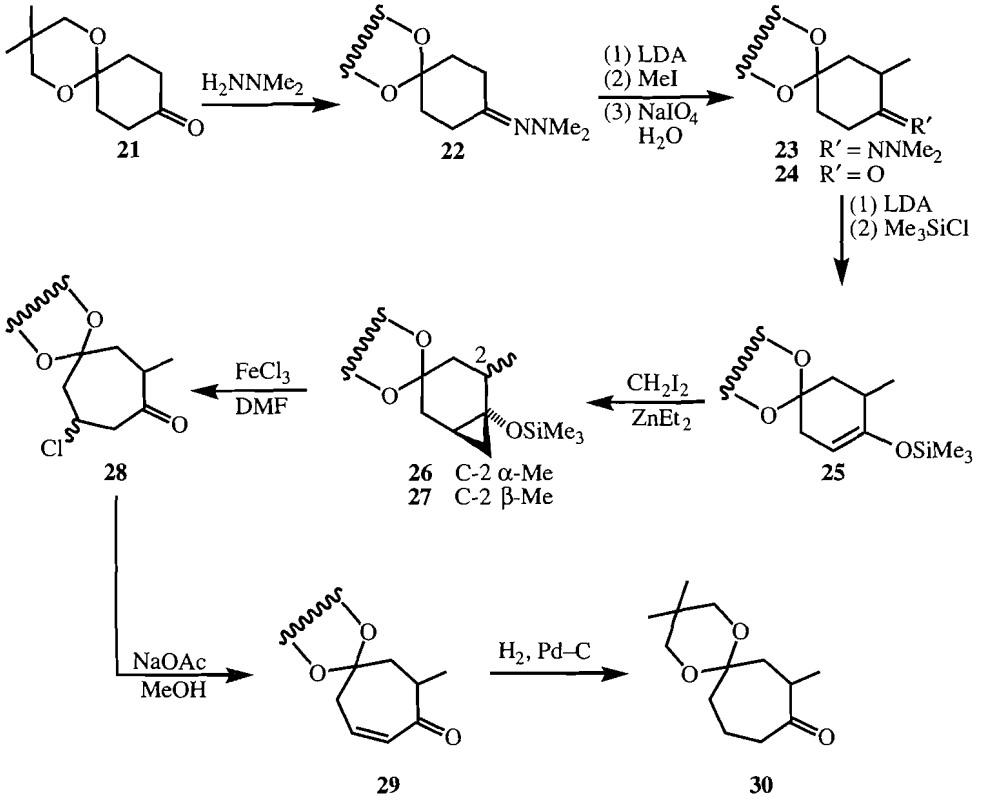
[5]These Pd(O)-catalyzed cyclization reactions are intramolecular versions of the Stille coupling of vinylstannane and enol triflate functions. Stille and co-workers (27, 28) have studied in detail the intermolecular variants of this synthetically useful process.

[6]These reactions could be monitored conveniently by removal, work-up, and analysis (glc, tlc) of small aliquots of the reaction mixtures. In our studies, we have found that MeCN is generally a *better* solvent (faster reaction rates, higher product yields) than THF for cyclizations of this type. Therefore, the observations with respect to the rate of ring closures of **16***c* and **16***d* cannot be due to a solvent effect.

[7]Although no firm evidence was obtained for the configurations of **26** and **27**, it seems reasonable to propose that, for steric reasons, the major product should be **26**, resulting from preferential cyclopropanation of **25** from the side opposite the secondary methyl group. In any case, the fact that a mixture was obtained was of no consequence, since both **26** and **27** were subsequently converted into the same desired product **30**.



SCHEME 3



SCHEME 4

phy of this mixture on silica gel provided, in order of elution, the dialkylation product **31** (11%, a mixture of two diastereomers), the monoalkyl product **32** (2%, a single diastereomer of undetermined configuration), and the desired substance **33** (59%). The structural assignments were based on spectral data. Although the yield of **33** was not high, the procedure employed was straightforward and amenable to reasonably large scales. Furthermore, the overall process was faciliated by the fact that **33** was cleanly separated from the side products by chromatography.

Conversion of the ketone **33** into the corresponding enol triflate **34** was achieved in the normal manner (26) (Scheme 5). However, unlike the enol triflates **16***a–d* (*vide supra*), **34** was not isolated. Instead, a catalytic amount of $(Ph_3P)_4Pd$ was added directly to the reaction mixture derived from sequential treatment of **33** with LDA and Tf_2NPh in THF. Warming of the resultant solution to 30°C for 5 min, followed by work-up and product purification, provided the bicyclic ketal diene **35** in 81% yield.[8] Mild acid hydrolysis

[8]This one-pot procedure was significantly superior to that in which the enol triflate **34** was isolated and then cyclized in a separate operation. The two-pot process converted **33** into **35** in an overall yield of about 55%. The advantage of using a one-pot protocol for conversion of keto vinylstannanes into dienes has been noted previously (13).

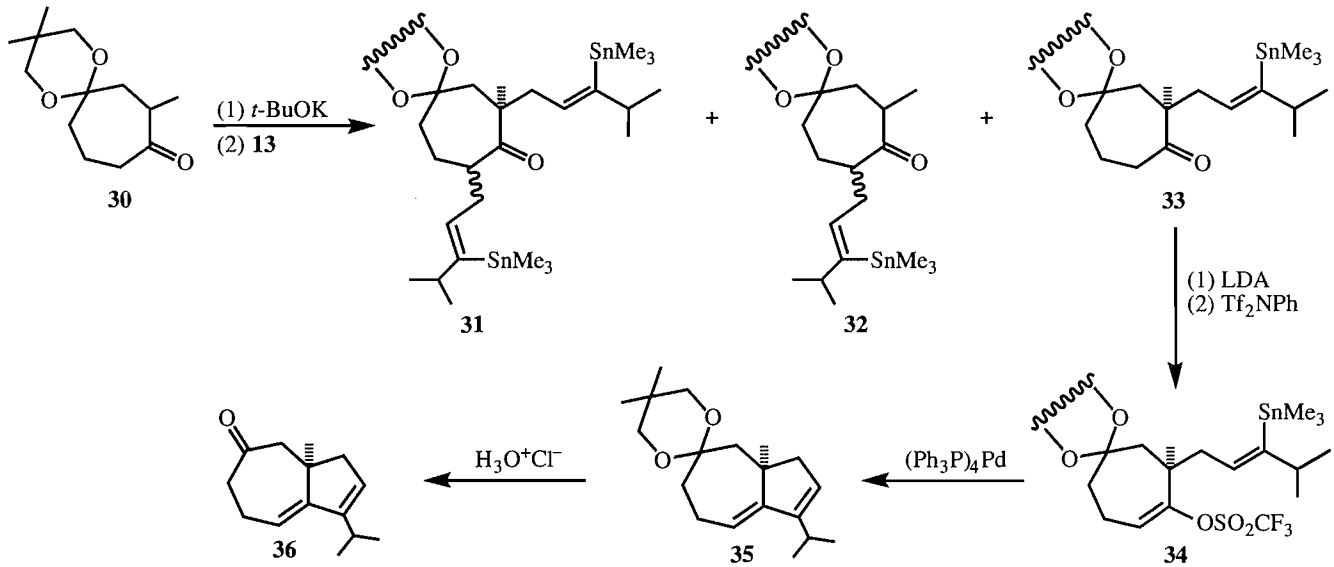


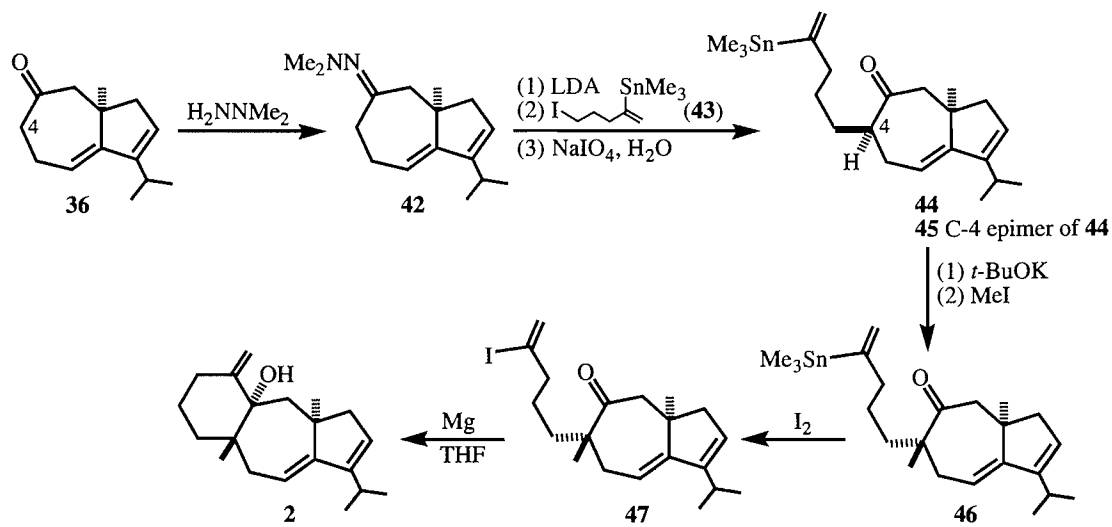
SCHEME 5

of **35** provided, in nearly quantitative yield, the keto diene **36**. Thus, the BC ring portion of the dolastatrienol (±)-**2** was in hand.

The final phase of the total synthesis of (±)-**2** required initially the stereocontrolled introduction of two substituents at C-4 of the ketone **36** (see Scheme 6). One of these appendages was a simple methyl group, while the other had to be a functionalized five-carbon unit that would permit a subsequent ring closure to give the allylic alcohol entity associated with ring A of the target compound.

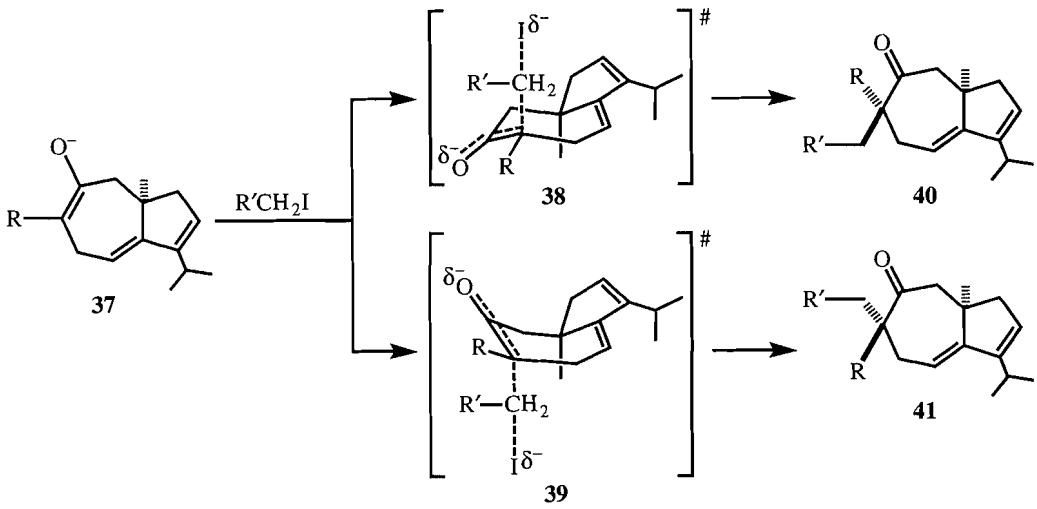
With respect to stereochemistry, it was concluded that the order of introduction of the two substituents was crucial. It is obvious that, theoretically, alkylation of the enolate anion **37** (Scheme 7) with $R'CH_2I$ could provide one (or both) of the stereoisomeric products **40** or (and) **41**. However, if one assumes that, conformationally, the transition state(s) for alkylation has (have) product-like characteristics and that the reaction is subject to stereoelectronic control, then two possible transition states must be considered. These may be represented, in general terms, as shown in **38** and **39**. In transition state **38**, the stereoelectronic requirement is satisfied via a geometric arrangement in which the seven-membered ring is in a chair-like conformation. However, in transition state **39**, the stereoelectronically engendered axial attack of the alkylating agent requires that the (forming) cycloheptenone ring adopt a boat-like geometry. Clearly, one would reasonably conclude that, of these two possibilities, **38** should be energetically favored over **39**. Furthermore, molecular models show that, in **39**, there could well be some steric repulsion between the incoming alkylating agent and the angular methyl group. The fact that no comparable steric interaction destabilizes **38** provides additional weight to the proposal that the major product of alkylation of **37** should be **40**, formed via the lower energy transition state **38**.

If this reasoning has validity, the first alkylation at C-4 of **36** (see Scheme 6) would have to be done with a suitable five-carbon alkylating agent. A subsequent alkylation at C-4 with MeI would (presumably) provide a (major) product with the correct relative configuration at the newly introduced chiral center.



SCHEME 6

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.



SCHEME 7

The bifunctional reagent 5-iodo-2-trimethylstannyl-1-pentene (**43**) (13) (Scheme 6) was chosen as the alkylating agent for incorporation of the necessary five-carbon side chain. Unfortunately, direct alkylation of **36** with **43**, employing a number of different bases (LDA, lithium 2,2,6,6-tetramethylpiperidide, *t*-BuOK) under a variety of experimental conditions, failed to produce the desired products **44** and (or) **45** cleanly. Although, in some of the reactions, **44** and **45** were formed as the major products, small amounts of other substances were also generated and these proved to be very difficult to separate from the desired material(s).

In view of these difficulties, the previously employed protocol of ketone alkylation via the corresponding dimethylhydrazone derivative (29) (see **21** → **24**, Scheme 4) was followed. Thus, conversion of **36** into **42**, followed by alkylation of the latter substance with **43** and subsequent hydrolysis of the hydrazone linkage, provided, in 68% overall yield, a single ketone. Anions of dimethylhydrazones of substituted cyclohexanones are known to show high preference for axial alkylation (29, 33, and references cited therein) and, therefore, on the basis of theoretical considerations similar to those presented earlier (*vide supra*, Scheme 7), the configuration of the alkylation product was assigned as shown in **44**. Unfortunately, the ^{1}H nmr spectrum of **44** failed to provide conclusive evidence to support this assignment.[9] However, during the next step of the synthesis, the chirality of C-4 in **44** would be destroyed (enolate anion formation) and, therefore, from a synthetic viewpoint, designation of the relative stereochemistry of this substance was not particularly important.

Methylation of the ketone **44** under conditions (*t*-BuOK, THF–HMPA) that would cause rapid enolate anion equilibration provided, in 63% yield, the keto triene **46**. The fact that alkylation had taken place at the desired site (C-4) was shown clearly by the ^{1}H nmr spectrum of the product **46**, which exhibited two three-proton singlets (δ 1.03, 1.11) due to the tertiary methyl groups. Since the spectral data derived from **46** did not provide unequivocal evidence for the stereochemistry of this substance, the assignment was based primarily on the previously discussed predictions regarding the (expected) preferred pathway for alkylation of the enolate anion **37** (Scheme 7).[10]

Reaction of the keto vinylstannane **46** with iodine in dichloromethane produced, cleanly and efficiently (84%), the keto vinyl iodide **47**.

On the basis of literature reports, it appeared that the required ring closure of **47** to the target compound (±)-**2** could be effected by use of a variety of synthetic methods. After a number of unsuccessful attempts, it was gratifying to find that the desired conversion could be achieved via a straightforward procedure that involved treatment of **47** with small pieces of freshly ground magnesium metal in refluxing THF. Chromatography of the crude product provided (±)-(5*S*,12*R*,14*S*)-dolasta-1(15),7,9-trien-14-ol (**2**) as the only tricyclic product (49% yield).[11] Recrystallization of this material from heptane gave material that exhibited mp 105–106°C and produced spectra in good agreement with those derived from the natural product.[12]

The stereochemical outcome of the transformation of **47** into **2** requires brief comment. Although the mechanistic details of this Barbier-type reaction are uncertain (34, 35), it is evident from an examination of molecular models that the conversion in question should occur in the desired stereochemical sense. Thus, the ring closure **47** to give **48**, the C-14 epimer of **2**, could take place via one (or both) of two transition states that may be represented, in somewhat simplistic terms, by **49** and **50**. In **49**, both the seven-membered ring and the forming six-membered ring are in chair-shaped conformations and the alkenyl moiety approaches the

[9]Treatment of **44** with NaOMe in MeOH provided a 1:1.4 mixture of the epimers **44** and **45**, from which a pure sample of **45** could be obtained by column chromatography. Again the ^{1}H nmr spectrum of **45** did not furnish unambiguous corroboration for the stereochemical assignment.

[10]It should be noted that, in their total synthesis of (±)-isoamijiol, Pattenden and co-workers carried out a comparable methylation on a substrate structurally similar to **44** (16).

[11]The crude product contained a small amount of a second component that, on the basis of its chromatographic and spectral properties, was considered to be the uncyclized keto triene (**47**, H in place of I). This material was not isolated or characterized further.

[12]We are grateful to Professor P. Crews for copies of the ^{1}H nmr, ^{13}C nmr, and mass spectra of natural **2**.

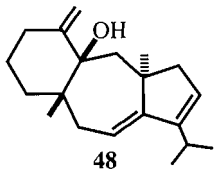
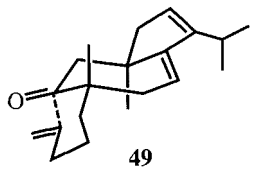
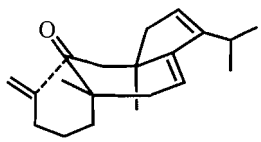
carbonyl group from an axial direction. However, this geometric arrangement is destabilized by steric interactions, the most notable of which is a severe repulsion between the angular methyl group (C-16, dolastane numbering) and the terminal methylene unit of the (approaching) vinyl group. This interaction is relieved in the alternative transition state **50**, in which the substituted alkenyl function approaches the carbonyl from an equatorial direction. However, this transition state is destabilized by a number of steric repulsions and by the torsional strain inherently present in the boat-like conformation of the cycloheptenone ring. On the other hand, the pathway leading from **47** to racemic **2** can proceed via a transition state (see **51**) that is devoid of serious steric interactions and in which both the seven-membered ring and the forming six-membered ring possess chairlike geometries.



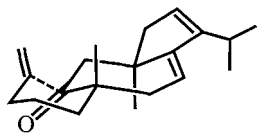
48



49

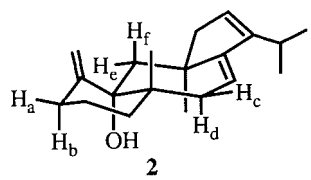


50



51

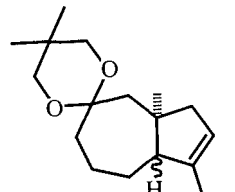
A few comments regarding the ^{1}H nmr spectrum of **2** are in order. The resonance at δ 2.60 (ddd, J = 6, 12.5, 12.5 Hz) was assigned by Crews *et al.* (7) to H_b. In a decoupling experiment, irradiation at δ 2.60 changed the broad doublet (J = 12.5 Hz) at 1.97 to a broad singlet, and therefore, the latter signal may be assigned to H_a. Crews *et al.* (7) had assigned the δ 1.97 resonance to one of the protons at C-13 (H_e or H_f). Actually, the signals due to H_e and H_f can be observed as a pair of doublets (J = 14.5 Hz) at δ 2.03 and 1.48. The doublet of doublets (J = 4.5, 15 Hz) at δ 3.22 had been ascribed by Crews *et al.* (7) to one of the C-6 protons (H_c or H_d). However, the other C-6 proton had not been assigned to a particular signal. Irradiation at δ 3.22 resulted in simplification of the doublet of doublets (J = 9.5, 15 Hz) at 1.51 and, consequently, the resonances at 1.51 and 3.22 may be assigned to protons H_c and H_d.



2

(c) Total synthesis of (±)-amijitrienol (3)

It was envisaged that the ketal diene **35** would serve as a suitable starting material for the synthesis of (±)-amijitrienol (**3**). The use of **35** in this context required, initially, the reductive conversion of this material into the ketal alkene **53** (see Scheme 8). To that end, **35** was treated with lithium in ammonia – diethyl ether. This reaction produced, in high yield, a mixture of two products in a ratio of ~4:1 (glc). Analysis of this mixture by glc – mass spectrometry and ^{1}H nmr spectroscopy showed that the two components were isomeric (M^+ = 292 for each substance) and that the major product was the desired alkene **53**. Furthermore, the ^{1}H nmr spectrum indicated that the minor product was the ketal alkene **52**.[13] Thus, the spectrum exhibited a single olefinic proton signal at δ 5.41, with a width at half-height of ~16 Hz. Had the minor product been the isomeric alkene **60**, one would probably have observed a signal in the alkene region of the spectrum with $w_{1/2} \approx$ 6 Hz. For example, in the ^{1}H nmr spectra of **35** and **36**, the signals due to the cyclopentene olefinic protons have $w_{1/2}$ = 6.5 Hz.

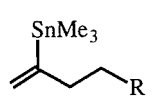


60

Unfortunately, compounds **52** and **53** proved to be very difficult to separate by chromatography on silica gel. However, it was gratifying to find that treatment of the mixture of these substances with a catalytic amount of iodine in refluxing hexane for 3 h caused quantitative isomerization of **52** into **53** (Scheme 8). Mild acid hydrolysis of the crude product[14] derived from this reaction provided the desired keto alkene **54** in 88% yield from the ketal diene **35**. Compound **54** had been prepared previously by Pattenden and co-workers (16), via a route very different from that described in this paper. The ^{1}H nmr spectra of the two synthetic samples were found to be identical.[15]

The final portion of the overall synthesis of (±)-amijitrienol (**3**) required two crucial operations, the stereoselective introduction of the secondary hydroxyl group at what would eventually become C-4 of **3**, and the construction, with concomitant ring closure, of the diene unit associated with carbons 13, 14, 1, and 15 of the target compound. The bifunctional reagent chosen for these purposes was 4-trimethylstannyl-4-pentenal (**55**). Clearly, condensation of this substance with the C-4 enolate anion of **54** (see Scheme 8) would place an oxygen function at the required position of the introduced side chain (see **56**). Furthermore, the vinylic trimethylstannyl function would, presumably, permit the subsequent desired ring closure via the method developed earlier in our laboratory (13) (see **4** → **6**).

The aldehyde **55** was produced conveniently by Swern oxidation (37) of the alcohol **61**, which, in turn, was prepared by reaction of 4-pentyn-1-ol with $Me_3SnCu \cdot SMe_2$ under conditions modified somewhat from those reported (38) earlier. The aldehyde **55** proved to be quite unstable and decomposed slowly even when stored under argon at low tem-

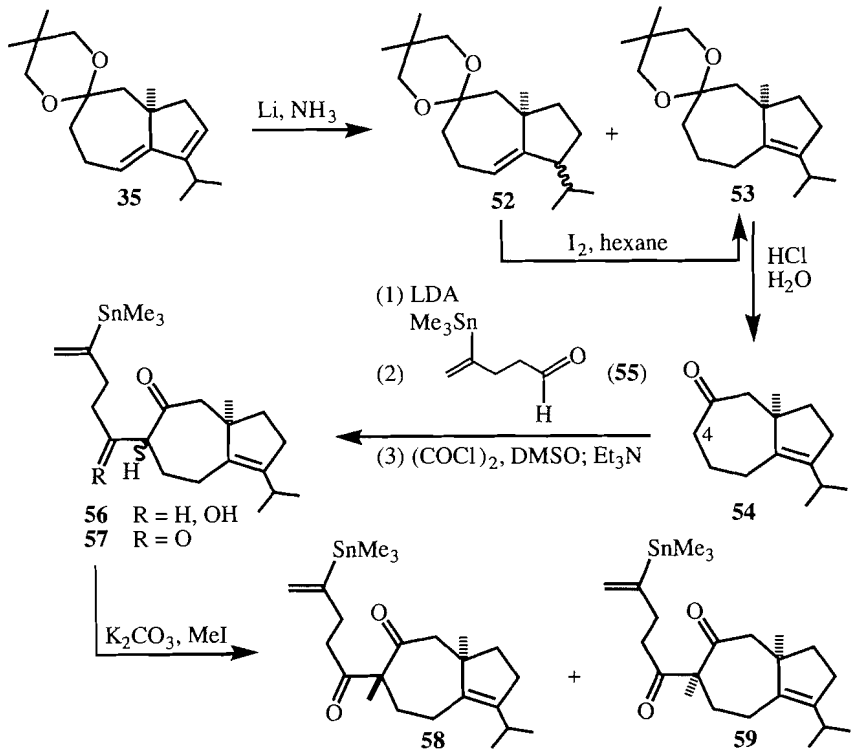


61 R = CH_2OH
55 R = CHO

[13]The stereochemical orientation of the isopropyl group in this substance was not determined.

[14]Distilled **53** exhibited spectra that agreed well with those reported (36) for this compound.

[15]We are very grateful to Professor Pattenden for a copy of the ^{1}H nmr spectrum of synthetic **54** prepared in his laboratory.



SCHEME 8

peratures (freezer). Consequently, it was generally used immediately after its preparation.

Deprotonation of **54** with LDA in THF at −78°C, followed by reaction of the resultant enolate anion with the aldehyde **55**, provided, in 62% yield, a mixture of three ketols of general structure **56**. Immediate subjection of this material to Swern oxidation (37) gave the diketone **57**, which, like the ketol mixture **56**, was quite unstable toward chromatography on silica gel. Therefore, **57** was directly methylated with K_2CO_3–MeI in acetone. This reaction gave a chromatographically separable mixture (~2:1 by ^1H nmr analysis) of the epimeric products **58** and **59**. The overall isolated yields of these two substances from the mixture of ketols **56** were 41 and 16%, respectively. Unambiguous spectroscopic evidence that would permit designation of the relative stereochemistry of **58** and **59** could not be obtained. Therefore, at this stage of the work, the configuration of the major alkylation product was assigned as shown in **58**. This assignment, which was made primarily on the basis of analogy with the stereochemical outcome of the methylation

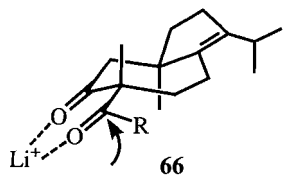
performed earlier (**44** → **46**, Scheme 6), was subsequently shown to be correct by acquisition of the target compound, (±)-**3**.

At this juncture of our synthesis, it was necessary to chemically differentiate between the two carbonyl groups of **58**. After a number of unsuccessful attempts to accomplish this objective, it was found that treatment of a THF solution of **58** with excess LiCl, followed by cooling of the mixture to −78°C and addition of excess *i*-Bu_2AlH, provided a *single* ketol **62** (see Scheme 9).[16] The latter material was immediately converted (*t*-$BuMe_2SiOTf$, 4-(*N*,*N*-dimethylamino)pyridine, Et_3N, CH_2Cl_2) into the corresponding silyl ether **63**, which was obtained in 79% yield from the diketone **58**.

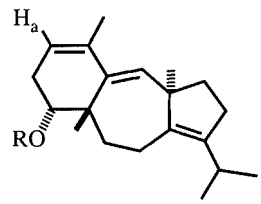
Since compound **63** served as a precursor for the synthesis of (±)-**3** (*vide infra*) it was subsequently determined that the reduction of **58** with *i*-Bu_2AlH in the presence of LiCl had produced a product **62** with the correct relative configuration at the newly introduced chiral center. The chemo- and stereoselectivity of this interesting, synthetically pleasing reaction may be rationalized by proposing initially that coordination of the lithium cation with the 1,3-diketone system of **58** provides a "frozen" conformation as depicted in **66**. Approach of the reducing agent from the top face of either of the carbonyl groups in **66** would be hindered by adjacent, axially oriented methyl group. Furthermore, reduction of the ring carbonyl from the bottom face would involve steric repulsion between the approaching reagent and the axial, angular methyl group. Thus, the only mode of attack that is relatively free of steric repulsions is that involving delivery of hydride to the bottom face of the side-chain carbonyl function, as shown by the arrow in **66**. The result of such a chemo- and stereoselective pathway would be the production of the ketol **62**, the observed product.



66

To complete the synthesis of (±)-amijitrienol (**3**), the keto vinylstannane **63** had to be subjected to the diene-producing annulation method developed earlier in our laboratory (13). This required, initially, the conversion of **63** into the corresponding enol triflate **64**. However, it was found that the lithium enolate of **63**, formed by treatment of **63** with LDA in THF, did not react with Tf_2NPh. Presumably, the failure of this (proposed) reaction was due primarily to the hindered nature of the enolate anion moiety. Fortunately, the use of the more reactive potassium enolate proved to be successful. Thus, sequential treatment of **63** with potassium hexamethyldisilazide and Tf_2NPh in THF provided the required enol triflate **64** (Scheme 9). Palladium(O)-catalyzed ring closure of this material in refluxing acetonitrile containing a small amount of triethylamine gave the tricyclic triene **65** in 74% yield from **63**. Cleavage of the silyl ether linkage with tetra-*n*-butylammonium fluoride provided, in 78% yield, crystalline (±)-amijitrienol (**3**), which exhibited mp 119–119.5°C (from hexane) and produced spectra identical with those of natural (+)-amijitrienol.[17]

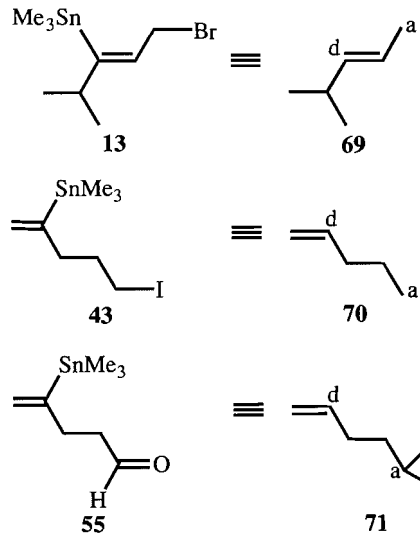
One point regarding the cyclization reaction (**64** → **65**) deserves explicit mention. Triethylamine was added to the reaction mixture because it was found that the exocyclic double bond present in each of the substances **65** and **3** was quite prone to acid-catalyzed rearrangement. In fact, the $CDCl_3$ that was used to record the ^1H nmr spectra of **65** and **3** had to be shaken with solid Na_2CO_3–$MgSO_4$ and then filtered through basic alumina just prior to use. If "untreated" $CDCl_3$ was employed, the ^1H nmr spectra of (initially) pure samples of **65** and **3** showed that the major components present were the isomeric substances **67** and **68**, respectively. In these spectra, the H_a protons of **67** and **68** appear as multiplets at δ 5.26 and 5.37, while the vinyl methyl groups give rise to broad singlets at δ 1.80 and 1.84, respectively.



67 R = *t*-$BuMe_2Si$
68 R = H

Conclusion

The work reported in this paper includes (a) the development of a new annulation sequence that can be described in general terms by **4** → **7** → **8**, and (b) the application of this and a related, previously reported (13) annulation process to the total syntheses of the dolastane diterpenoids (±)-(5*S*,12*R*,14*S*)-dolasta-1(15),7,9-trien-14-ol (**2**) and (±)-amijitrienol (**3**). In this study, the bifunctional reagents **13**, **43**, and **55** served effectively as synthetic equivalents of the donor–acceptor synthons **69**–**71**, respectively. The fact that these reagents played such a central role in the work reported herein illustrates the value and versatility of organotin compounds in organic synthesis.



13 **69**
43 **70**
55 **71**

[16]Interestingly, reduction of **58** with *i*-Bu_2AlH (~1 equivalent) in various solvents (THF, Et_2O, PhMe) at −78°C in the *absence* of LiCl produced complex mixtures that contained **58**, ketols, and diols.

[17]We are indebted to Professor M. Ochi for copies of the ^1H nmr, ^{13}C nmr, and mass spectra of (+)-**3**.

Experimental

General information

Distillation temperatures, which refer to bulb-to-bulb (Kugelrohr) distillations, and melting points are uncorrected. Proton (^{1}H) and carbon (^{13}C) nuclear magnetic resonance (nmr) spectra were, unless otherwise noted, recorded on $CDCl_3$ solutions. Carbon chemical shifts are given relative to that of $CDCl_3$ (δ 77.0). Proton signal positions for compounds containing the Me_3Sn group are given relative to the signal for $CHCl_3$ (δ 7.25). Tin–proton coupling constants (J_{Sn-H}) are given as the average of the ^{117}Sn and ^{119}Sn values. For substances that contain the Me_3Sn function, high-resolution molecular mass determinations were determined on the (M^+ − Me) fragment (39) and are based on ^{120}Sn. Gas–liquid chromatography (glc) was performed using instruments equipped with 25 m × 0.21 mm fused silica columns coated with cross-linked SE-54. Thin-layer chromatography (tlc) was carried out with commercial aluminum-backed silica gel plates (E. Merck, Type 5554). Conventional (drip) column chromatography as well as medium pressure and flash chromatography (40) were performed with 230–400 mesh silica gel (E. Merck). Reagents and solvents were purified and dried using standard methods. Aqueous NH_4Cl–NH_4OH (pH 8) refers to a solution prepared by adding ~50 mL of aqueous ammonium hydroxide (58%) to ~1 L of saturated aqueous ammonium chloride.

NOTE: Unless otherwise noted, all reactions were carried out under an atmosphere of argon in flame- or oven-dried glassware.

NOTE: All compounds for which high resolution mass measurements are given exhibited, unless otherwise noted, clean ^{1}H nmr spectra and one spot on tlc analyses. Furthermore, the purity of these substances was judged to be ≥95% by glc analyses.

Methyl 4-methyl-2-pentynoate (9)

To a cold (−78°C), stirred solution of 3-methyl-1-butyne (3.4 g, 50 mmol) in 100 mL of dry THF was added a solution of MeLi in Et_2O (34 mL, 55 mmol). The solution was stirred at −78°C for 10 min and then at −20°C for 1 h. Methyl chloroformate (4.64 mL, 60 mmol) was added and the mixture was stirred at −20°C for 30 min and at room temperature for 30 min. Saturated aqueous $NaHCO_3$ (50 mL) and Et_2O (50 mL) were added. The organic phase was separated and the aqueous phase was extracted with 1:1 Et_2O–hexane. The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. Distillation (60–70°C/0.15 Torr (1 Torr = 133.3 Pa)) of the crude product gave 5.92 g (94%) of the ester **9**, a colorless oil that displayed ir (neat): 2220, 1715, 1390, 1370, 1260 cm^{-1}; ^{1}H nmr (80 MHz) δ: 1.18 (d, 6H, J = 7 Hz), 2.63 (septet, 1H, J = 7 Hz), 3.70 (s, 3H). Exact Mass calcd. for $C_7H_{10}O_2$: 126.0681; found: 126.0686.

Methyl (Z)-4-methyl-3-trimethylstannyl-2-pentenoate (11)

To a cold (−78°C), stirred solution of lithium (phenylthio)(trimethylstannyl)cuprate (**10**) (23) (45.4 mmol) in dry THF (400 mL) was added a solution of the acetylenic ester **9** (4.4 g, 34.9 mmol) in 50 mL of dry THF. The mixture was stirred at −78°C for 15 min and then at −48°C for 4 h. Methanol (50 mL) and petroleum ether (200 mL) were added and the vigorously stirred mixture was allowed to warm to room temperature. The yellow slurry was filtered through a plug of Celite and the collected material was washed thoroughly with petroleum ether (200 mL). The combined filtrate was concentrated and the residue was subjected to flash chromatography (240 g silica gel, 100:1 petroleum ether – Et_2O). Distillation (110–115°C/15 Torr) of the oil thus obtained afforded 8.43 g (83%) of the (*Z*)-2-pentenoate **11**, a colorless oil that exhibited ir (neat): 1700, 1599, 1210, 780 cm^{-1}; ^{1}H nmr (80 MHz) δ: 0.14 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.02 (d, 6H, J = 7 Hz), 2.71 (br septet, 1H, J = 7 Hz), 3.70 (s, 3H), 6.35 (d, 1H, J = 1 Hz, $^3J_{Sn-H}$ = 126 Hz). Exact Mass calcd. for $C_9H_{17}O_2Sn$ (M^+ − Me): 277.0250; found: 277.0252.

(Z)-4-Methyl-3-trimethylstannyl-2-penten-1-ol (12)

To a cold (−78°C), stirred solution of the α,β-unsaturated ester **11** (6.3 g, 21.7 mmol) in dry Et_2O (120 mL) was added slowly a solution of diisobutylaluminum hydride (54 mmol) in hexane. The mixture was stirred at −78°C for 1 h and then at 0°C for 2 h. Saturated aqueous NH_4Cl (20 mL) was added and the mixture was allowed to warm to room temperature. Anhydrous $MgSO_4$ was added to the slurry and the mixture was filtered through a plug of Celite. The collected material was washed thoroughly with Et_2O (150 mL). The combined filtrate was washed with brine, dried ($MgSO_4$), and concentrated. Distillation (110–115°C/15 Torr) of the residual material yielded 5.5 g (97%) of the allylic alcohol **12**, a colorless oil that showed ir (neat): 3300, 1380, 1360, 1025, 770 cm^{-1}; ^{1}H nmr (80 MHz) δ: 0.19 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 1.01 (d, 6H, J = 7 Hz), 1.30 (m, 1H, exchanges with D_2O), 2.46 (br septet, 1H, J = 7 Hz), 4.08 (br t, 2H, J = 6.5 Hz, $^4J_{Sn-H}$ = 110 Hz), 6.18 (dt, 1H, J = 1, 6.5 Hz, $^3J_{Sn-H}$ = 144 Hz). Exact Mass calcd. for $C_8H_{17}OSn$ (M^+ − Me): 249.0301; found: 249.0294.

(Z)-1-Bromo-4-methyl-3-trimethylstannyl-2-pentene (13)

To a cold (0°C), stirred solution of Ph_3P (7.07 g, 27.0 mmol) in dry CH_2Cl_2 (120 mL) was added, dropwise, Br_2 (1.38 mL, ~27 mmol) until the colorless solution became pale yellow. One crystal of solid Ph_3P was added, followed by Et_3N (3.76 mL, 27.0 mmol). The resulting white, cloudy mixture was cooled to −10°C and then a solution of the allylic alcohol **12** (5.90 g, 22.5 mmol) in 15 mL of dry CH_2Cl_2 was added dropwise. The mixture was stirred for 15 min and most of the solvent was removed under reduced pressure. The remaining slurry was diluted with petroleum ether (100 mL) and the mixture was filtered through a plug of Celite. The collected material was washed with petroleum ether (20 mL). The colorless solution was concentrated under reduced pressure and the petroleum ether washing–filtration procedure was repeated twice. The allylic bromide **13** (6.3 g, 86%) obtained after concentration of the final filtrate proved to be quite unstable, even when stored at −4°C in the dark, and, therefore, this material was used immediately in subsequent reactions. The bromide **13** was judged to be >90% pure (glc, ^{1}H nmr) and exhibited ir (neat): 1200, 775 cm^{-1}; ^{1}H nmr (80 MHz) δ: 0.25 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 1.01 (d, 6H, J = 7 Hz), 2.50 (septet, 1H, J = 7 Hz), 3.95 (d, 2H, J = 8 Hz), 6.23 (t, 1H, J = 8 Hz). Exact Mass calcd. for $C_8H_{16}{}^{79}BrSn$ (M^+ − Me): 310.9457; found: 310.9442.

2-Methoxycarbonyl-2-((Z)-4-methyl-3-trimethylstannyl-2-pentenyl)cyclopentanone (15a)

To a well-stirred suspension of KH (39 mg, 0.97 mmol) in dry THF (3 mL) at room temperature was added, dropwise, a solution of 2-methoxycarbonylcyclopentanone (**14***a*) (125 mg, 0.88 mmol) in 0.75 mL of dry THF. After the mixture had been stirred for 45 min, a solution of the allylic bromide **13** (316 mg, 0.97 mmol) in 1 mL of dry THF was added and the solution was heated under reflux for 1 h. The solution was cooled and most of the solvent was removed under reduced pressure. Column chromatography (27 g silica gel, 25:1 petroleum ether – ethyl acetate) of the residual oil–salt mixture, followed by distillation (145–149°C/0.6 Torr) of the oil thus obtained, provided 258 mg (78%) of the β-keto ester **15***a*, a colorless oil that displayed ir (neat): 1740, 1720, 1225, 773 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.19 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.97 (two d separated by 9 Hz, 3H each, J = 7 Hz in each case), 1.85–2.05 (m, 3H), 2.20 (m, 1H), 2.36–2.50 (m, 4H), 2.63 (dd, 1H, J = 8, 14.5 Hz), 3.69 (s, 3H), 5.75 (dt, 1H, J = 1, 8 Hz, $^3J_{Sn-H}$ = 144 Hz). In a decoupling experiment, irradiation at δ 5.75 simplified the signal at 2.63 to a d (J = 14.5 Hz) and sharpened the multiplet at 2.36–2.50. Exact Mass calcd. for $C_{15}H_{25}O_3Sn$ (M^+ − Me): 373.0825; found: 373.0821.

2-Methoxycarbonyl-2-((Z)-4-methyl-3-trimethylstannyl-2-pentenyl)cyclohexanone (15b)

Alkylation of 2-methoxycarbonylcyclohexanone (**14***b*) (140 mg, 0.90 mmol) with the allylic bromide **13** (321 mg, 0.99 mmol) was carried out via a procedure similar to that outlined above, except that the reaction was carried out at room temperature for 2 h. Column chromatography (30 g silica gel, 25:1 petroleum ether – ethyl acetate) of the crude product mixture and distillation (158–161°C/

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

0.6 Torr) of the resultant liquid produced 302 mg (85%) of the β-keto ester **15***b*, a colorless oil that showed ir (neat): 1710, 1203, 772 cm^{-1}; ^1H nmr (400 MHz) δ: 0.19 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.96 (d, 6H, *J* = 7 Hz), 1.33 (ddd, 1H, *J* = 4.5, 13, 14 Hz), 1.55–1.78 (m, 3H), 2.00 (m, 1H), 2.30 (dd, 1H, *J* = 7, 14 Hz), 2.35–2.53 (m, 4H), 2.63 (dd, 1H, *J* = 7, 14 Hz), 3.67 (s, 3H), 5.86 (dt, 1H, *J* = 1, 7 Hz, $^3J_{Sn-H}$ = 145 Hz); decoupling experiment: irradiation at δ 5.86 changed the signals at 2.30 and 2.63 to doublets (*J* = 14 Hz in each case). Exact Mass calcd. for $C_{16}H_{27}O_3Sn$ (M^+ − Me): 387.0982; found: 387.0983.

*2-Methoxycarbonyl-2-((Z)-4-methyl-3-trimethylstannyl-2-pentenyl)cycloheptanone (**15**c)*

Using a procedure similar to that outlined above, 190 mg (1.12 mmol) of 2-methoxycarbonylcycloheptanone (**14***c*) was alkylated with 400 mg (1.23 mmol) of the allylic bromide **13**. The reaction was carried out at room temperature for 1 h. Column chromatography (60 g silica gel, 25:1 petroleum ether – ethyl acetate) of the crude product, followed by distillation (160–163°C/0.6 Torr) of the liquid thus obtained, yielded 367 mg (80%) of the β-keto ester **15***c*, a colorless oil that displayed ir (neat): 1700, 1205, 770 cm^{-1}; ^1H nmr (400 MHz) δ: 0.19 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.96 (d, 6H, *J* = 7 Hz), 1.41 (m, 1H), 1.50–1.80 (m, 6H), 2.10 (dd, 1H, *J* = 9.5, 14 Hz), 2.33 (dd, 1H, *J* = 7, 14 Hz), 2.39–2.49 (m, 2H), 2.61 (m, 1H), 2.74 (dd, 1H, *J* = 7, 14 Hz), 3.68 (s, 3H), 5.81 (dt, 1H, *J* = 1, 7 Hz, $^3J_{Sn-H}$ = 145 Hz). In a decoupling experiment, irradiation at δ 5.81 simplified the signals at 2.33 and 2.74 to doublets (*J* = 14 Hz in each case). Exact Mass calcd. for $C_{17}H_{29}O_3Sn$ (M^+ − Me): 401.1139; found: 401.1139.

*2-Methyl-2-((Z)-4-methyl-3-trimethylstannyl-2-pentenyl)cycloheptanone (**15**d)*

To a well-stirred solution of *t*-BuOK (140 mg, 1.25 mmol) in a mixture of dry THF (4 mL) and dry *t*-BuOH (1 mL) at room temperature was added a solution of 2-methylcycloheptanone (**14***d*) (25) (166 mg, 1.32 mmol) in dry THF (2 mL). The mixture was stirred for 0.5 h and then a solution of the allylic bromide **13** (430 mg, 1.32 mmol) in dry THF (2 mL) was added. After the solution had been stirred at room temperature for 2 h, the mixture was concentrated under reduced pressure. Water (50 ml) was added to the residual material and the mixture was extracted with Et_2O (3 × 25 mL). The combined extracts were dried ($MgSO_4$) and concentrated. Column chromatography (120 g silica gel, 40:1 petroleum ether – Et_2O) of the remaining material, followed by distillation (116–119°C/0.1 Torr) of the acquired liquid, provided 205 mg (42%) of the ketone **15***d*, a colorless oil that displayed ir (neat): 1700, 760 cm^{-1}; ^1H nmr (400 MHz) δ: 0.20 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.99 (d, 6H, *J* = 7 Hz), 1.04 (s, 3H), 1.28–1.80 (m, 8H), 2.18 (dd, 1H, *J* = 7, 14 Hz), 2.22 (dd, 1H, *J* = 7, 14 Hz), 2.37–2.49 (m, 2H), 2.62 (dt, 1H, *J* = 2.5, 11.5 Hz), 5.89 (dt, 1H, *J* = 1, 7 Hz, $^3J_{Sn-H}$ = 147 Hz). In a decoupling experiment, irradiation at δ 5.89 simplified the signals at 2.18 and 2.22 to doublets (*J* = 14 Hz in each case). Exact Mass calcd. for $C_{16}H_{29}OSn$ (M^+ − Me): 357.1241; found: 357.1267.

*8-Isopropyl-5-methoxycarbonylbicyclo[3.3.0]octa-1,7-diene (**17**a)*

To a cold (−48°C), well-stirred solution of lithium diisopropylamide (LDA) (0.43 mmol) in dry THF (2.8 mL) was added, dropwise, a solution of the β-keto ester **15***a* (110 mg, 0.284 mmol) in 1.0 mL of dry THF. The solution was stirred at −48°C for 1 h. Finely ground, solid *N*-phenyltrifluoromethanesulfonimide (Tf_2NPh) (0.45 mmol) was added and the yellow solution was warmed to room temperature over a period of 30 min. Most of the solvent was removed under reduced pressure. Flash chromatography (18 g silica gel, 20:1 petroleum ether – ethyl acetate) of the residual material provided, upon concentration of the appropriate fractions and removal of last traces of solvent (vacuum pump), 117 mg (87%) of the enol triflate **16***a*, a colorless oil that showed ir (neat): 1732, 1422, 1207, 1142, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.18 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 0.94 (d, 6H, *J* = 7 Hz), 1.75–2.75 (m, 7H), 3.71 (s, 3H), 5.65–5.85 (m, 2H). Exact Mass calcd. for $C_{16}H_{24}F_3O_5SSn$ (M^+ − Me): 505.0318; found: 505.0318.

To a stirred solution of the enol triflate **16***a* (90 mg, 0.174 mmol) in dry CH_3CN (8 mL) was added solid $(Ph_3P)_4Pd$ (0.009 mmol). The mixture was refluxed for 45 min, was cooled to room temperature, and then was concentrated under reduced pressure. Flash chromatography (15 g silica gel, 20:1 petroleum ether – ethyl acetate) of the remaining material, followed by distillation (52–55°C/0.1 Torr) of the acquired liquid, produced 30 mg (84%) of the diene **17***a*, a colorless oil that displayed ir (neat): 1735, 1390, 1370, 805 cm^{-1}; ^1H nmr (400 MHz) δ: 1.10 (d, 3H, *J* = 7 Hz), 1.14 (d, 3H, *J* = 7 Hz), 1.85 (ddd, 1H, *J* = 8.0, 10, 12.5 Hz), 2.19 (br d, 1H, *J* = 16 Hz), 2.39 (dd, 1H, *J* = 6, 12.5 Hz), 2.54 (m, 1H), 2.60 (ddd, 1H, *J* = 3.5, 8.0, 16 Hz), 2.83 (ddd, 1H, *J* = 1.0, 2.5, 16 Hz), 2.93 (m, 1H), 3.63 (s, 3H), 5.50 (br s, 1H, $w_{1/2}$ = 7 Hz), 5.76 (br s, 1H, $w_{1/2}$ = 6 Hz). The following decoupling experiments were carried out: irradiation at δ 1.85 simplified the signals at 2.39 and 2.60 to a d (*J* = 6 Hz) and a dd (*J* = 3.5, 16 Hz), respectively, and sharpened the m at 2.93; irradiation at δ 2.19 changed the m at 2.54 to a br septet (*J* = 7 Hz) and the ddd at 2.83 to a dd (*J* = 1.0, 2.5 Hz); irradiation at δ 2.39 simplified the signals at 1.85 and 2.93 to a dd (*J* = 8.0, 10 Hz), and a br dd (*J* = 10, 16 Hz); irradiation at δ 2.83 sharpened the resonances at 2.19 (to a br s) and 5.76; irradiation at δ 2.93 simplified the signals at 1.85, 2.39, 2.60, and 5.50 to a dd (*J* = 8.0, 12.5 Hz), a d (*J* = 12.5 Hz), a dd (*J* = 3.5, 8.0 Hz) and a br d (*J* = 3.5 Hz); irradiation at δ 5.50 changed the signals at 2.60 and 2.93 to a dd (*J* = 8.0, 16 Hz) and a br ddd (*J* = 6, 10, 16 Hz); irradiation at δ 5.76 sharpened the signal at 2.19 and changed the resonance at 2.83 to a br d (*J* = 16 Hz). Exact Mass calcd. for $C_{13}H_{18}O_2$: 206.1307; found: 206.1306.

*9-Isopropyl-6-methoxycarbonylbicyclo[4.3.0]nona-1,8-diene (**17**b)*

The β-keto ester **15***b* was transformed into the diene **17***b* via procedures similar to those outlined above. From 263 mg (0.656 mmol) of **15***b* there was obtained, after flash chromatography (40 g silica gel, 25:1 petroleum ether – ethyl acetate) of the crude product, 294 mg (84%) of the enol triflate **16***b*, a colorless oil that showed ir (neat): 1732, 1416, 1215, 1145, 733 cm^{-1}; ^1H nmr (80 MHz) δ: 0.20 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 0.95 (d, 6H, *J* = 7 Hz), 1.45–1.80 (m, 3H), 2.00–2.65 (m, 6H), 3.73 (s, 3H), 5.75–5.95 (m, 2H). Exact Mass calcd. for $C_{17}H_{26}F_3O_5SSn$ (M^+ − Me): 519.0475; found: 519.0475.

The reaction time for the Pd-catalyzed ring closure of the vinylstannane-enol triflate **16***b* was 3 h. Flash chromatography (30 g silica gel, 25:1 petroleum ether – ethyl acetate) of the crude product derived from 269 mg (0.504 mmol) of **16***b*, followed by distillation (69–73°C/0.6 Torr) of the resultant oil, provided 92 mg (83%) of the diene **17***b*, a colorless oil that exhibited ir (neat): 1722, 1385, 810 cm^{-1}; ^1H nmr (400 MHz) δ: 1.09 (d, 3H, *J* = 7 Hz), 1.14 (d, 3H, *J* = 7 Hz), 1.43–1.55 (m, 2H), 1.75 (m, 1H), 2.10 (m, 1H), 2.24 (m, 1H), 2.34 (br d, 1H, *J* = 16 Hz), 2.42 (m, 1H), 2.52 (br septet, 1H, *J* = 7 Hz), 2.73 (dd, 1H, *J* = 2.5, 16 Hz), 3.63 (s, 3H), 5.48 (br s, 1H, $w_{1/2}$ = 6 Hz), 5.56 (t, 1H, *J* = 4 Hz). Decoupling experiments: irradiation at δ 5.48 changed the signals at 2.34, 2.52, and 2.73 to a dd (*J* = 2, 16 Hz), a d of septets (*J* = 2, 7 Hz), and a d (*J* = 16 Hz); irradiation at δ 5.56 simplified the resonances at 2.10 and 2.24 to a br dt (*J* = 18 8 Hz) and a br dd (*J* = 5, 18 Hz). Exact Mass calcd. for $C_{14}H_{20}O_2$ 220.1464; found: 220.1456.

*10-Isopropyl-7-methoxycarbonylbicyclo[5.3.0]deca-1,9-diene (**17**c)*

Procedures similar to those described above were employed to convert the β-keto ester **15***c* into the bicyclic diene **17***c*. Flash chromatography (50 g silica gel, 25:1 petroleum ether – ethyl acetate) of the crude product obtained from 323 mg (0.779 mmol) of **15***c* provided 352 mg (82%) of the enol triflate **16***c*, a colorless oil that displayed ir (neat): 1735, 1418, 1220, 776 cm^{-1}; ^1H nmr

For personal use only.

(80 MHz) δ: 0.21 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 0.96 (d, 6H, J = 7 Hz), 1.10–2.85 (m, 11H), 3.74 (s, 3H), 5.89 (br t, 1H, J = 7 Hz, $^3J_{Sn-H}$ = 132 Hz), 6.03 (t, 1H, J = 6 Hz). Exact Mass calcd. for $C_{18}H_{28}F_3O_5SSn$ (M^+ − Me): 533.0631; found: 533.0647.

From 243 mg (0.444 mmol) of the enol triflate **16***c* there was obtained, after flash chromatography (30 g silica gel, 25:1 petroleum ether – ethyl acetate) of the crude product and distillation (65–69°C/0.1 Torr) of the acquired liquid, 84 mg (81%) of the diene **17***c*. The reaction time for the cyclization reaction was 30 min. The product **17***c*, a colorless oil, displayed ir (neat): 1723, 1385, 832 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.08 (d, 3H, J = 7 Hz), 1.10 (d, 3H, J = 7 Hz), 1.34 (br q, 1H, J = 12 Hz), 1.54 (dt, 1H, J = 3, 13 Hz), 1.60–1.79 (m, 2H), 1.89 (m, 1H), 2.05–2.26 (m, 3H), 2.36–2.50 (m, 2H), 2.76 (dd, 1H, J = 2.5, 17.5 Hz), 3.69 (s, 3H), 5.53 (br s, 1H, $w_{1/2}$ = 6 Hz), 5.79 (dd, 1H, J = 5, 8.5 Hz). Decoupling experiments: irradiation at δ 2.76 simplified the m at 2.36–2.50; irradiation at δ 5.53 sharpened the m at 2.36–2.50 and changed the signal at 2.76 to a d (J = 17.5 Hz); irradiation at δ 5.79 simplified the m at 2.05–2.26. Exact Mass calcd. for $C_{15}H_{22}O_2$: 234.1621; found: 234.1617.

*10-Isopropyl-7-methylbicyclo[5.3.0]deca-1,9-diene (**17**d)*

The ketone **15***d* was converted into the diene **17***d* by means of procedures similar to those described above. Flash chromatography (15 g silica gel, 30:1 petroleum ether – Et_2O) of the crude product obtained from 50 mg (0.13 mmol) of the ketone **15***d*, followed by concentration of the appropriate fractions, gave 57 mg (84%) of the enol triflate **16***d*, a colorless oil that exhibited ir (neat): 1405, 1205, 1140, 768 cm^{-1}. Exact Mass calcd. for $C_{17}H_{28}F_3O_3SSn$ (M^+ − Me): 489.0733; found: 489.0720.

The palladium-catalyzed cyclization of the vinylstannane-enol triflate **16***d* was accomplished in THF at room temperature for 5 min. Flash chromatography (5 g silica gel, 30:1 petroleum ether – Et_2O) of the crude product obtained from 50 mg (0.10 mmol) of **16***d*, followed by distillation (142–144°C/30 Torr) of the acquired liquid, yielded 16 mg (85%) of the diene **17***d*, a colorless oil that showed ir (neat): 2890, 830 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.03 (d, 3H, J = 7 Hz), 1.10 (d, 3H, J = 7 Hz), 1.13 (s, 3H), 1.32 (br q, 1H, J = 12 Hz), 1.48–1.90 (m, 5H), 2.12 (dd, 1H, J = 2.5, 17 Hz), 2.15–2.42 (m, 4H), 5.54 (dd, 1H, J = 3.5, 8.5 Hz), 5.57 (d, 1H, J = 2.5 Hz). Exact Mass calcd. for $C_{14}H_{22}$: 190.1721; found: 190.1721.

Preparation of the N, N*-dimethylhydrazone **22***

A stirred solution of the commercially available ketone **21** (19.5 g, 98.3 mmol) and 1,1-dimethylhydrazine (9.0 mL, 117.6 mmol) in dry benzene (200 mL) was refluxed under a Dean–Stark water trap for 2 h. The solution was dried ($MgSO_4$) and concentrated. Distillation (105–120°C/0.03 Torr) of the residual oil gave 23.5 g (99%) of the hydrazone **22** as a white, crystalline material that exhibited mp 45–46°C; ir (KBr): 2773, 1640 cm^{-1}; ^{1}H nmr (80 MHz) δ: 0.99, 1.05 (s, s, 3H each), 1.83–2.15 (m, 4H), 2.20–2.75 (m, 4H), 2.49 (s, 6H), 3.56 (s, 4H). Exact Mass calcd. for $C_{13}H_{24}O_2N_2$: 240.1837; found: 240.1835.

*Preparation of the keto ketal **24***

To a cold (0°C), stirred solution of LDA (118 mmol) in dry THF (100 mL) was added a solution of the ketal *N*,*N*-dimethylhydrazone **22** (23.5 g, 97.8 mmol) in dry THF (50 mL) and the solution was stirred at 0°C for 1.5 h. Methyl iodide (12.2 mL, 196 mmol) was added; the mixture was allowed to warm to room temperature and then was stirred for 2 h. Water (100 mL) was added and most of the organic solvent was removed under reduced pressure. The residual mixture was extracted with ethyl acetate (3 × 250 mL) and with CH_2Cl_2 (3 × 100 mL). The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. A mixture of the remaining crude *N*,*N*-dimethylhydrazone **23**, sodium metaperiodate (46.0 g, 215 mmol), THF (350 mL), water (100 mL), and aqueous phosphate buffer (100 mL, pH 7) was stirred (mechanical stirrer) at room temperature for 24 h. The THF was removed under reduced pressure and the residual mixture was extracted with CH_2Cl_2 (6 × 150 mL). The combined organic extracts were dried ($MgSO_4$) and concentrated. Recrystallization of the remaining brownish solid from petroleum ether provided 20.5 g (99%) of the keto ketal **24** as colorless needles that displayed mp 66–66.5°C; ir ($CHCl_3$): 1711, 1115 cm^{-1}; ^{1}H nmr (80 MHz) δ: 1.01, 1.05 (s, s, 3H each), 1.06 (d, 3H, J = 7 Hz), 1.45–2.00 (m, 2H), 2.20–2.80 (m, 5H), 3.55, 3.58 (s, s, 2H each). Exact Mass calcd. for $C_{12}H_{20}O_3$: 212.1412; found: 212.1413.

*Preparation of the cyclopropane silyl ethers **26** and **27***

To a cold (0°C), stirred solution of LDA (222 mmol) in dry 1,2-dimethoxyethane (DME) (200 mL) was added, dropwise, a solution of the keto ketal **24** (31.4 g, 148 mmol) in dry DME (75 mL). The solution was stirred for 45 min and then Me_3SiCl (56.3 mL, 444 mmol) and Et_3N (68.1 mL, 444 mmol) were added sequentially. The mixture was stirred for 30 min at 0°C, was warmed to room temperature, and then was diluted with Et_2O (100 mL). The solution was washed with cold (0°C) aqueous $NaHCO_3$ (2%, 3 × 50 mL), dried ($MgSO_4$), and concentrated. The crude enol silyl ether **25** was dissolved in dry toluene (200 mL) and to the resultant stirred solution was added sequentially a solution of diethylzinc in toluene (166 mL, 15% solution, 200 mmol) and CH_2I_2 (16.2 mL, 200 mmol). The reaction mixture, under an air atmosphere and protected with a drying tube, was stirred at 55°C for 15 h. The mixture was cooled and Et_2O (100 mL) and saturated aqueous NH_4Cl (100 mL) were added. The phases were separated and the aqueous layer was extracted with Et_2O (3 × 150 mL). The combined organic extracts were washed with aqueous $NaHCO_3$ (2%, 100 mL), dried ($MgSO_4$), and concentrated. Distillation (110–115°C/0.1 Torr) of the residual liquid gave 37.9 g (86%) of a 2:1 mixture of the cyclopropane silyl ethers **26** and **27**, a colorless oil that showed ir (neat): 3073, 842, 765 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.09, 0.10 (s, s, ratio ~2:1, 9H), 0.22, 0.55 (t, dd, ratio ~1:2, 1H, J = 6 Hz, J = 5.0, 5.5 Hz), 0.70, 0.73 (t, dt, ratio ~2:1, 1H, J = 8 Hz, J = 1, 4.5 Hz), 0.88, 0.93, 0.935, 0.94 (s, s, s, s, ratio ~2:1:1:2, 6H), 1.04, 1.12 (d, d, ratio ~1:2, 3H, J = 6.5, 7 Hz), 1.10–2.68 (m, 6H), 3.34–3.52 (m, 4H). Exact Mass calcd. for $C_{16}H_{30}O_3Si$: 298.1965; found: 298.1963.

*Preparation of the enone ketal **29***

To a cold (0°C), stirred solution of dry ferric chloride (11.3 g, 69.6 mmol) in dry *N*,*N*-dimethylformamide (DMF) (75 mL) was added, over a period of 2 h (syringe pump), a solution of dry pyridine (1.87 mL, 23.2 mmol) and a 2:1 mixture of the silyl ethers **26** and **27** (6.89 g, 23.2 mmol) in dry DMF (30 mL). The cooling bath was removed and the mixture was stirred at room temperature for 2 h. Hydrochloric acid (2%, 100 mL) was added and the mixture was extracted with Et_2O (5 × 200 mL). The combined extracts were washed with brine (150 mL), dried ($MgSO_4$), and concentrated. The crude β-chloro ketone **28** was dissolved in MeOH (100 mL), NaOAc (13.3 g, 162 mmol) was added, and the resultant mixture was refluxed, with stirring, for 15 h. The cooled mixture was poured into water (50 mL) and the mixture was extracted with Et_2O (5 × 100 mL). The combined organic extracts were washed with saturated aqueous $NaHCO_3$ (100 mL), dried ($MgSO_4$), and concentrated. Flash chromatography (360 g silica gel, 4:1 to 1:1 petroleum ether – ethyl acetate) of the crude product, followed by distillation (126–130°C/0.1 Torr) of the acquired liquid, produced 3.22 g (62%) of the enone ketal **29**, a colorless oil that displayed ir (neat): 1672, 1109 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.93, 1.02 (s, s, 3H each), 1.17 (d, 3H, J = 7 Hz), 1.83 (dd, 1H, J = 11.5, 14.5 Hz), 2.33 (dd, 1H, J = 3.5, 14.5 Hz), 2.63–2.77 (m, 2H), 2.88 (dd, 1H, J = 7.5, 16.5 Hz), 3.40–3.56 (m, 4H), 6.08 (dd, 1H, J = 2.5, 12 Hz), 6.40 (ddd, 1H, J = 5, 7.5, 12 Hz). Decoupling experiments: irradiation at δ 2.33 collapsed the signal at 1.83 to a d (J = 14.5 Hz), and simplified the m at 2.63–2.77; irradiation at δ 2.88 simplified the m at 2.63–2.77 and changed the ddd at 6.40 to a dd (J = 5, 12 Hz); irradiation at δ 6.40 sharpened the m at 2.63–2.77 and changed the signals at 2.88 and 6.08 to a d (J = 16.5 Hz) and a br s. ^{13}C nmr

(75.3 MHz) δ: 16.7, 22.4 (two carbons), 29.9, 36.8, 38.4, 41.6, 70.1, 70.6, 100.2, 133.0, 138.4, 204.3. Exact Mass calcd. for $C_{13}H_{20}O_3$: 224.1412; found: 224.1410.

Preparation of the keto ketal ***30***

A solution-suspension of the enone ketal **29** (6.2 g, 27.7 mmol) and 10% palladium-on-carbon (200 mg) in dry hexane (100 mL) was stirred under an atmosphere of hydrogen (atmospheric pressure) for 2 h. The mixture was filtered through a plug of Celite and the collected material was washed with Et_2O (100 mL). Concentration of the filtrate, followed by distillation (110–114°C/0.1 Torr) of the residual liquid, afforded 6.2 g (99%) of the keto ketal **30**, a colorless oil that displayed ir (neat): 1703, 1104 cm^{-1}; ^1H nmr (400 MHz) δ: 0.99 (s, 6H), 1.10 (d, 3H, J = 7 Hz), 1.14 (ddd, 1H, J = 2.5, 12, 14.5 Hz), 1.56 (dd, 1H, J = 11.5, 15 Hz), 1.69–1.93 (m, 2H), 2.25 (dt, 1H, J = 15, 2.5 Hz), 2.42 (ddt, 1H, J = 14.5, 6, 2 Hz), 2.49 (dd, 2H, J = 4.5, 8 Hz), 2.78 (m, 1H), 3.40–3.57 (m, 4H); ^{13}C nmr (75.3 MHz) δ: 17.4, 17.9, 22.5, 22.6, 30.0, 35.6, 39.08, 39.14, 42.3, 69.9, 70.0, 98.3, 215.3. Exact Mass calcd. for $C_{13}H_{22}O_3$: 226.1570; found: 226.1565.

Preparation of the keto vinylstannane ***33***

To a stirred solution of *t*-BuOK (6.8 g, 60.4 mmol) in a mixture of dry *t*-BuOH (5 mL) and dry DME (150 mL) was added a solution of the keto ketal **30** (5.06 g, 22.36 mmol) in dry DME (50 mL). After the mixture had been stirred for 45 min at room temperature, a solution of the allylic bromide **13** (9.8 g, 29.1 mmol) in dry DME (50 mL) was added. The solution was stirred for 15 min and then water (100 mL) was added. The resultant mixture was extracted with ethyl acetate (3 × 150 mL). The combined extracts were washed with brine, dried ($MgSO_4$), and concentrated. Analysis (tlc) of the residual liquid indicated the presence of a small amount of the starting material **30** and three additional components. Medium pressure column chromatography (360 g silica gel, 6:1 petroleum ether – Et_2O) of this mixture provided three product fractions.

The first material to be eluted was a mixture of two diastereomeric, dialkylated ketones **31** (1.76 g, 11%). This colorless oil (not distilled) exhibited ir (neat): 1703, 1611, 770 cm^{-1}; ^1H nmr (270 MHz) δ: 0.164, 0.167, 0.179, 0.186, (s, s, s, s, 18H), 0.80–1.15 (21H), 1.15–2.55 (13H), 3.30–3.60 (4H), 5.75–5.95 (2H). Exact Mass calcd. for $C_{30}H_{55}O_3Sn_2$ (M^+ − Me): 703.2195; found: 703.2218.

The second fraction to be eluted consisted of a single monoalkylated ketone **32** of undetermined stereochemistry (210 mg, 2%). This colorless oil (not distilled) showed ir (neat): 1707, 1613, 1107, 770 cm^{-1}; ^1H nmr (270 MHz) δ: 0.16 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.90, 0.92 (s, s, 3H each), 0.94, 1.01 (d, d, 6H, 3H, J = 7 Hz in each case), 1.20–1.70 (m, 4H), 1.94–2.05 (m, 2H), 2.18–2.50 (m, 4H), 2.60–2.75 (m, 1H), 3.34–3.47 (m, 4H), 5.82 (t, 1H, J = 7 Hz, $^3J_{Sn-H}$ = 145 Hz). Exact Mass calcd. for $C_{21}H_{37}O_3Sn$ (M^+ − Me): 457.1765; found: 457.1769.

Distillation (188–193°C/0.1 Torr) of the liquid obtained from the third chromatography fraction yielded 6.17 g (59%) of the desired ketone **33**, a colorless oil that exhibited ir (neat): 1706, 1611, 1100, 770 cm^{-1}; ^1H nmr (400 MHz) δ: 0.20 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 0.99 (d, 6H, J = 7 Hz), 0.82, 1.05, 1.15 (s, s, s, 3H each), 1.58–1.84 (m, 3H), 2.06 (s, 2H), 2.13–2.27 (m, 3H), 2.38–2.50 (m, 2H), 2.65 (m, 1H), 3.32–3.58 (m, 4H), 5.92 (t, 1H, J = 7 Hz, $^3J_{Sn-H}$ = 146 Hz); ^{13}C nmr (75.3 MHz) δ: −6.9, 20.4, 22.3, 22.9, 22.95, 23.0, 23.1, 30.0, 31.8, 38.1, 39.5, 44.6, 46.0, 48.2, 69.8, 70.0, 100.0, 131.1, 154.5, 215.2. Exact Mass calcd. for $C_{21}H_{37}O_3Sn$ (M^+ − Me): 457.1765; found: 457.1772.

Preparation of the ketal diene ***35***

To a cold (−78°C), stirred solution of LDA (11.15 mmol) in dry THF (70 mL) was added dry $(Me_2N)_3PO$ (2.59 mL, 14.87 mmol) and the solution was stirred at −78°C for 10 min and at 0°C for 10 min. After the solution had been recooled to −78°C, a solution of the keto vinylstannane **33** (3.5 g, 7.436 mmol) in dry THF (30 mL) was added. After the mixture had been stirred at −78°C for 5 min and at 0°C for 1 h, Tf_2NPh (4.14 g, 11.67 mmol) was added as a powdery solid and the resultant mixture was stirred at room temperature for 2 h. Tetrakis(triphenylphosphine)palladium(0) (429 mg, 0.37 mmol) was added and the mixture was warmed to 30°C for 5 min. Most of the solvent was removed under reduced pressure and the residual material was subjected to flash chromatography (240 g silica gel, 20:1 petroleum ether – Et_2O). Distillation (142–146°C/0.1 Torr) of the acquired liquid gave 1.748 g (81%) of the ketal diene **35**, a colorless oil that displayed ir (neat): 1647, 1111, 832 cm^{-1}; ^1H nmr (400 MHz) δ: 0.93, 1.02, 1.20 (s, s, s, 3H each), 1.03, 1.10 (d, d, 3H each, J = 7 Hz in each case), 1.53 (d, 1H, J = 14 Hz), 1.59 (br d, 1H, J = 14 Hz), 2.03–2.48 (m, 6H), 2.51 (dd, 1H, J = 2.5, 14 Hz), 3.40–3.60 (m, 4H), 5.54 (br s, 1H, $w_{1/2}$ = 6.5 Hz), 5.60 (dd, 1H, J = 5, 8 Hz); ^{13}C nmr (75.3 MHz) δ: 20.7, 21.8, 22.2, 22.7, 22.9, 25.4, 25.6, 30.1, 36.5, 42.5, 43.7, 50.0, 69.8, 69.9, 100.4, 116.9, 124.6, 149.9, 154.9. Exact Mass calcd. for $C_{19}H_{30}O_2$: 290.2246; found: 290.2248.

Preparation of the keto diene ***36***

A solution of the ketal diene **35** (1.137 g, 3.915 mmol) and 5 drops of hydrochloric acid (1 N) in acetone (50 mL) was stirred at room temperature for 3 h. The solvent was removed under reduced pressure and the residual material was treated with 50 mL of water. The mixture was extracted with Et_2O (3 × 50 mL). The combined extracts were washed with brine, dried ($MgSO_4$), and concentrated. Flash chromatography (70 g silica gel, 7:1 petroleum ether – Et_2O) of the residual liquid and distillation (82–85°C/0.1 Torr) of the acquired material provided 796 mg (99%) of the keto diene **36**, a colorless oil that exhibited ir (neat): 1704, 1640, 831 cm^{-1}; ^1H nmr (400 MHz) δ: 1.10 (s, 3H), 1.07, 1.14 (d, d, 3H each, J = 7 Hz in each case), 2.22 (dd, 1H, J = 2.5, 17 Hz), 2.33–2.60 (m, 7H), 2.72 (d, 1H, J = 12 Hz), 5.64 (br s, 1H, $w_{1/2}$ = 6.5 Hz), 5.71 (t, 1H, J = 6 Hz). Decoupling experiments: irradiation at δ 2.22 sharpened the br s at 5.64 ($w_{1/2}$ = 4.5 Hz) and simplified the m at 2.33–2.60; irradiation at δ 5.64 changed the signal at 2.22 to a d (J = 17 Hz); irradiation at δ 5.71 simplified the m at 2.33–2.60. ^{13}C nmr (75.3 MHz) δ: 21.7, 22.0, 23.2, 25.4, 25.6, 43.3, 45.0, 48.1, 55.2, 115.5, 125.8, 149.8, 155.3, 211.8. Exact Mass calcd. for $C_{14}H_{20}O$: 204.1515; found: 204.1518.

Preparation of the N,N*-dimethylhydrazone* ***42***

A stirred solution of the keto diene **36** (200 mg, 0.98 mmol) and 1,1-dimethylhydrazine (0.74 mL, 9.8 mmol) in spectral grade MeOH (20 mL) was refluxed in the presence of 3 Å molecular sieves (~20 g) for 4.5 h. The mixture was cooled to room temperature and filtered. The collected material was washed with Et_2O (20 mL). Concentration of the filtrate, followed by distillation (95–105°C/0.1 Torr) of the remaining liquid, produced 238 mg (98%) of the hydrazone **42**, a colorless oil that consisted of a 2:1 mixture of geometric isomers. This material displayed ir (neat): 2769, 1626, 1447, 828 cm^{-1}; ^1H nmr (400 MHz) δ: 1.07 (s, 3H), 1.04, 1.11 (d, d, 3H each, J = 7 Hz in each case), 1.95–2.65 (m, 8H), 2.41, 2.49 (s, s, ratio ~1:2, 6H total), 3.31, 3.59 (m, dd, ratio ~2:1, 1H total, J = 2, 12.5 Hz), 5.58–5.67 (m, 2H). Exact Mass calcd. for $C_{16}H_{26}N_2$: 246.2096; found: 246.2095.

Preparation of the keto trienes ***44*** *and* ***45***

To a cold (0°C), stirred solution of LDA (1.68 mmol) in dry THF (10 mL) was added, dropwise, a solution of the *N*,*N*-dimethylhydrazone **42** (345 mg, 1.4 mmol) in dry THF (10 mL). The solution was stirred at −78°C for 1 h and at 0°C for 1 h. To the deep red solution was added a solution of 5-iodo-2-trimethylstannyl-1-pentene (**43**) (13) (502 mg, 1.68 mmol) in dry THF (6 mL). This mixture was warmed to room temperature and then was stirred for 1 h. Saturated aqueous ammonium chloride (25 mL) was added and the two phases were separated. The aqueous layer was extracted with Et_2O (3 × 100 mL). The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. The remaining oil was dissolved in THF (30 mL) and water (8 mL), aqueous phosphate buffer (pH 7, 9 mL), and sodium metaperiodate (1.2 g, 5.6 mmol) were added. The vigorously stirred mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

was heated at 40°C for 48 h. Aqueous NH_4Cl–NH_4OH (pH 8) (10 mL) was added and the phases were separated. The aqueous layer was extracted with Et_2O (3 × 100 mL). The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. Flash chromatography (50 g silica gel, 10:1 petroleum ether – Et_2O) of the crude product and distillation (190–200°C/0.1 Torr) of the acquired liquid gave 420 mg (69%) of the keto triene **44**, a colorless oil that displayed ir (neat): 1699, 1641, 915, 841, 768 cm^{-1}; ^1H nmr (400 MHz) δ: 0.13 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 1.08 (s, 3H), 1.07, 1.13 (d, d, 3H each, J = 7 Hz in each case), 1.22–1.50 (m, 3H), 1.66 (m, 1H), 2.15–2.65 (m, 8H), 2.40 (br d, 1H, J = 12 Hz), 2.79 (d, 1H, J = 12 Hz), 5.13 (m, 1H, $^3J_{Sn-H}$ = 71 Hz), 5.22 (dd, 1H, J = 5, 8.5 Hz), 5.63 (m, 2H); ^{13}C nmr (75.3 MHz) δ: −9.5, 21.9, 22.0, 24.9, 25.5, 27.2, 27.7, 30.0, 40.5, 43.4, 48.4, 51.3, 54.6, 112.6, 124.8, 126.1, 149.6, 155.0, 155.2, 213.7. Exact Mass calcd. for $C_{21}H_{33}OSn$ (M^+ − Me): 421.1554; found: 421.1545.

A 10 mg sample of the ketone **44** was dissolved in dry MeOH (1 mL) and NaOMe (~1 mg) was added. The solution was stirred at room temperature for 22 h and the solvent was removed under reduced pressure. Water (2 mL) was added and the mixture was extracted with Et_2O (3 × 3 mL). The combined organic extracts were dried ($MgSO_4$) and concentrated. Analysis (glc) of the crude product indicated that it was composed of a 1:1.4 mixture of the ketones **44** and **45**. Column chromatography (5 g silica gel, 10:1 petroleum ether – Et_2O) of this material and distillation (190–200°C/0.1 Torr) of the acquired liquid provided a small sample of the keto triene **45**, a colorless oil that showed ir (neat): 1705, 1642, 914, 833, 768 cm^{-1}; ^1H nmr (400 MHz) δ: 0.13 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.04 (s, 3H), 1.05, 1.13, (d, d, 3H each, J = 7 Hz in each case), 1.19–1.43 (m, 3H), 1.77 (m, 1H), 2.05–2.52 (m, 8H), 2.55, 2.61 (d, d, 1H each, J = 11 Hz in each case), 5.13 (m, 1H, $^3J_{Sn-H}$ = 71 Hz), 5.63 (m, 2H), 5.67 (dd, 1H, J = 4.5, 9 Hz); ^{13}C nmr (75.3 MHz) δ: −10.0, 21.7, 22.0, 25.36, 25.38, 27.4, 30.5, 30.6, 40.8, 43.5, 48.0, 54.0, 55.1, 114.7, 124.5, 125.9, 149.7, 155.2, 155.4, 212.1. Exact Mass calcd. for $C_{21}H_{33}OSn$ (M^+ − Me): 421.1554; found: 421.1557.

*Preparation of the keto triene **46***

A stirred solution of the ketone **44** (150 mg, 0.345 mmol) and *t*-BuOK (155 mg, 1.725 mmol) in a mixture of dry THF (11 mL) and dry $(Me_2N)_3PO$ (3 mL) was heated at 60°C for 1 h. To the resultant dark red solution was added MeI (0.129 mL, 2.07 mmol) and the mixture was stirred at 60°C for 15 min. The solution was poured into cold water (25 mL). The mixture was extracted with Et_2O (3 × 50 mL). The combined extracts were washed with brine, dried ($MgSO_4$), and concentrated. Flash chromatography (40 g silica gel, 20:1 petroleum ether – Et_2O) of the crude product, followed by distillation (220–230°C/0.1 Torr)[18] of the acquired liquid, afforded 97 mg (63%) of the ketone **46**, a pale yellow oil that exhibited ir (neat): 1706, 1621, 915, 768 cm^{-1}; ^1H nmr (300 MHz) δ: 0.13 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.03, 1.11 (s, s, 3H each), 1.01, 1.08 (d, d, 3H each, J = 7 Hz in each case), 1.20–1.70 (m, 4H), 2.00 (dd, 1H, J = 8, 14 Hz), 2.10 (dd, 1H, J = 3, 16 Hz), 2.22 (br t, 2H, J = 7 Hz), 2.30–2.50 (m, 3H), 2.43 (d, 1H, J = 12 Hz), 2.83 (d, 1H, J = 12 Hz), 5.12 (m, 1H, $^2J_{Sn-H}$ = 72 Hz), 5.51–5.58 (m, 2H), 5.63 (m, 1H, $^3J_{Sn-H}$ = 154 Hz). Exact Mass calcd. for $C_{22}H_{35}OSn$ (M^+ − Me): 435.1710; found: 435.1704.

*Preparation of the keto vinyl iodide **47***

To a stirred solution of the vinylstannane ketone **46** (65 mg, 0.145 mmol) in dry CH_2Cl_2 (10 mL) was added, dropwise, a solution of iodine in dry CH_2Cl_2 (~3.6 mL of a 0.04 M solution, ~0.145 mmol) until the pale violet color of excess iodine persisted. The solution was stirred for a further 15 min and then water (10 mL) and Et_2O (100 mL) were added. The organic phase was separated and then was washed with saturated aqueous sodium thiosulfate until the organic solution was colorless. The solution was dried ($MgSO_4$) and concentrated. Flash chromatography (40 g silica gel, 20:1 petroleum ether – Et_2O) of the remaining material and distillation (210–220°C/0.1 Torr)[18] of the resultant liquid afforded 50 mg (84%) of the vinyl iodide **47**, a pale yellow oil that showed ir (neat): 1704, 1617, 893 cm^{-1}; ^1H nmr (400 MHz) δ: 1.09, 1.13 (s, s, 3H each), 1.03, 1.10 (d, d, 3H each, J = 7 Hz in each case), 1.25–1.65 (m, 4H), 2.04 (dd, 1H, J = 8.5, 15 Hz), 2.14 (dd, 1H, J = 2, 16 Hz), 2.33–2.44 (m, 3H), 2.44–2.52 (m, 2H), 2.54 (d, 1H, J = 12 Hz), 2.81 (d, 1H, J = 12 Hz), 5.55 (dd, 1H, J = 6, 8.5 Hz), 5.60 (br s, 1H, $w_{1/2}$ = 6 Hz), 5.71 (d, 1H, J = 1.5 Hz), 6.03 (m, 1H). Exact Mass calcd. for $C_{20}H_{29}IO$: 412.1265; found: 412.1261.

*(±)-(5S,12R,14S)-Dolasta-1(15),7,9-trien-14-ol (**2**)*

To a stirred solution of the vinyl iodide **47** (28 mg, 0.068 mmol) in dry THF (10 mL) was added metallic magnesium (small, finely ground pieces, ~20 mg, ~12 equiv.). The mixture was heated to reflux temperature and then one drop of 1,2-dibromoethane (passed through a plug of basic alumina immediately prior to use) was added. The mixture was refluxed for 2.5 h and then was cooled to room temperature. Saturated aqueous NH_4Cl (5 mL) was added and the phases were separated. The aqueous phase was extracted with Et_2O (3 × 10 mL). The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. Drip column chromatography (7 g silica gel, 20:1 petroleum ether – Et_2O) of the remaining material provided 9.5 mg (49%) of the dolastatrienol **2** as a white, crystalline solid. Recrystallization of this material from heptane produced needle-shaped crystals that exhibited mp 105–106°C; ir ($CHCl_3$): 3604, 3500, 1639, 1002, 906 cm^{-1}; ^1H nmr (400 MHz, C_6D_6) δ: 0.92 (s, 3H), 1.11, 1.14 (d, d, 3H each, J = 7 Hz in each case), 1.25–1.35 (m, 1H), 1.39 (s, 3H), 1.43–1.66 (m, 2H), 1.48 (d, 1H, J = 14.5 Hz), 1.51 (dd, 1H, J = 9.5, 15 Hz), 1.97 (br d, 1H, J = 12.5 Hz), 2.03 (d, 1H, J = 14.5 Hz), 2.05–2.15 (m, 2H), 2.22 (br d, 1H, J = 17 Hz), 2.42 (septet, 1H, J = 7 Hz), 2.60 (ddd, 1H, J = 6, 12.5, 12.5 Hz), 3.22 (dd, 1H, J = 4.5, 15 Hz), 4.61 (br s, 1H, $w_{1/2}$ = 4 Hz), 4.78 (br s, 1H, $w_{1/2}$ = 4 Hz), 5.46 (dd, 1H, J = 4.5, 9.5 Hz), 5.54 (br s, 1H, $w_{1/2}$ = 6.5 Hz). Decoupling experiments: irradiation at δ 2.60 sharpened the multiplet at 1.43–1.66 and collapsed the br d at 1.97 to a br s; irradiation at δ 3.22 changed the resonances at 1.51 and 5.46 to doublets (J = 9.5 Hz in each case); irradiation at δ 5.46 altered the signals at 1.51 and 3.22 to doublets (J = 15 Hz in each case). ^{13}C nmr (100.4 MHz) δ: 19.8, 22.1, 22.2, 23.2, 25.6, 27.4. 32.0, 35.1, 37.2, 41.5, 43.4, 45.4, 50.9, 79.5, 108.4, 114.4, 124.7, 149.8, 153.9, 154.1. Exact Mass calcd. for $C_{20}H_{30}O$: 286.2297; found: 286.2297.

*Preparation of the ketal alkene **53** and the keto alkene **54***

To cold (−48°C), stirred liquid ammonia (~100 mL) was added lithium metal (535 mg, 77.1 mmol) and the resultant mixture was stirred at −48°C for 30 min. A solution of the ketal diene **35** (2.239 g, 7.71 mmol) in 50 mL of dry Et_2O was added and the dark blue mixture was stirred at −48°C for 1.75 h. Saturated aqueous NH_4Cl (50 mL) was added carefully (vigorous stirring). The cooling bath was replaced with a warm water bath (~50°C) and the ammonia was allowed to evaporate over a period of a 2 h. The remaining mixture was extracted with Et_2O (3 × 200 mL). The combined extracts were washed with brine, dried ($MgSO_4$), and concentrated. Distillation (125–135°C/0.1 Torr) of the remaining liquid provided 2.15 g (95%) of a colorless oil that, on the basis of analysis by glc, consisted of a mixture of the ketal alkenes **52** and **53**, in a ratio of ~1:4, respectively. A glc – mass spectrometry experiment showed that both components of this mixture possessed a molecular mass of 292.

The 1:4 mixture of **52** and **53** (2.12 g, 7.25 mmol) was dissolved in spectral grade hexane (100 mL) and iodine (185 mg,

[18]Due to some decomposition at the elevated distillation temperatures, this material was generally not distilled.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

0.72 mmol) was added. The stirred, pale red solution was refluxed for 3 h. Saturated aqueous sodium thiosulfate was added to the cooled solution until the organic phase became colorless. The phases were separated and the aqueous layer was extracted with Et_2O (2 × 25 mL). The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. Analysis (glc) of the residual material indicated that it consisted of a single component, the ketal alkene **53**. This liquid was dissolved in acetone (100 mL) and 1 mL of 1 N hydrochloric acid was added. The mixture was stirred at room temperature for 1 h and then saturated aqueous $NaHCO_3$ (50 mL) was added. The organic phase was separated and the aqueous phase was extracted with Et_2O (3 × 25 mL). The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. Distillation (80–85°C/0.1 Torr) of the crude product gave 1.39 g (93%) of the keto alkene **54** (16), a colorless oil that showed ir (neat): 1703, 1456, 1185 cm^{-1}; ^1H nmr (400 MHz) δ: 0.95, 0.98 (d, d, 3H each, J = 7 Hz in each case), 1.04 (s, 3H), 1.52–1.74 (m, 3H), 1.88–2.00 (m, 2H), 2.18–2.25 (m, 2H), 2.37–2.44 (m, 2H), 2.55 (s, 2H), 2.61–2.71 (m, 2H); ^{13}C nmr (75.3 MHz) δ: 21.0, 21.5, 24.0, 24.2, 24.8, 26.6, 27.3, 38.1, 43.9, 47.6, 54.9, 138.6, 141.9, 213.1. Exact Mass calcd. for $C_{14}H_{22}O$: 206.1671; found: 206.1671.

In another experiment, distillation (126–134°C/0.1 Torr) of a small sample of the liquid derived from the iodine-induced isomerization reaction (see above) provided the ketal alkene **53** (36) as a colorless oil that displayed ir (neat): 2954, 1110 cm^{-1}; ^1H nmr (400 MHz) δ: 0.92, 0.97, 1.04 (s, s, s, 3H each), 0.93, 0.94 (d, d, 3H each, J = 7 Hz in each case), 1.40–1.51 (m, 2H), 1.70–1.97 (m, 7H), 2.10–2.23 (m, 2H), 2.46 (dt, 1H, J = 7, 14 Hz), 2.63 (septet, 1H, J = 7 Hz), 3.39–3.54 (m, 4H); ^{13}C nmr (75.3 MHz) δ: 20.2, 21.2, 21.4, 22.76, 22.81, 23.6, 25.6, 26.7, 27.1, 30.0, 33.2, 39.5, 45.3, 47.7, 69.8, 69.9. 101.1, 139.2, 140.2. Exact Mass calcd. for $C_{19}H_{32}O_2$: 292.2404; found: 292.2402.

*4-Trimethylstannyl-4-penten-1-ol (**61**)*

To a cold (−78°C), stirred solution of $Me_3SnCu \cdot Me_2S$ (23) (43.8 mmol) in dry THF (300 mL) was added, dropwise, a solution of 4-pentyn-1-ol (2.45 g, 29.2 mmol) in dry THF (15 mL). Dry MeOH (59 mL) was added and the resulting solution was stirred at −78°C for 2 h and at 0°C for 1 h. Aqueous NH_4Cl–NH_4OH (pH 8) (150 mL) and petroleum ether (200 mL) was added. The resultant mixture was opened to the atmosphere and was stirred vigorously at room temperature until the aqueous phase was deep blue. The phases were separated and the aqueous layer was extracted with 4:1 pentane–Et_2O (200 mL). The combined organic extracts were washed with aqueous NH_4Cl–NH_4OH (pH 8) (3 × 100 mL), dried ($MgSO_4$), and concentrated. Flash chromatography (180 g silica gel, 2:1 petroleum ether – Et_2O) of the remaining liquid and distillation (95–100°C/20 Torr) of the acquired oil provided 3.9 g (54%) of the alcohol **61**, a colorless oil that exhibited spectra identical with those reported earlier (38).

*4-Trimethylstannyl-4-pentenal (**55**)*

To a cold (−78°C), stirred solution of oxalyl chloride (1.58 mL, 18.1 mmol) in dry CH_2Cl_2 (100 mL) was added dry Me_2SO (1.29 mL, 18.1 mmol). The solution was stirred for 5 min and then a solution of the alcohol **61** (3.47 g, 13.9 mmol) in dry CH_2Cl_2 (50 mL) was added. The mixture was stirred for 20 min and then dry Et_3N (7.78 mL, 55.6 mmol) was added. The mixture was stirred at −78°C for 5 min, was warmed to room temperature, and then was stirred for an additional 30 min. Water (100 mL) was added and the phases were separated. The aqueous phase was extracted with CH_2Cl_2 (3 × 50 mL) and the combined organic extracts were dried ($MgSO_4$) and concentrated. Distillation (80–90°C/15 Torr) of the crude product produced 2.20 g (64%) of the aldehyde **55**, a colorless oil. This material, which was somewhat unstable and slowly decomposed even when stored under argon in a freezer, exhibited ir (neat): 2719, 1728, 1601, 919, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.18 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 2.29–2.68 (m, 4H), 5.21 (m, 1H, $^3J_{Sn-H}$ = 71 Hz), 5.68 (m, 1H, $^3J_{Sn-H}$ = 146 Hz), 9.78 (br s, 1H, $w_{1/2}$ = 3 Hz). Exact Mass calcd. for $C_7H_{13}OSn$ (M^+ − Me): 232.9988; found: 232.9987.

*Preparation of the diketones **58** and **59***

To a cold (−78°C), stirred solution of LDA (3.15 mmol) in dry THF (20 mL) was added, dropwise, a solution of the keto alkene **54** (500 mg, 2.42 mmol) in dry THF (6 mL). The solution was stirred at −78°C for 15 min and at 0°C for 15 min, and then was recooled to −78°C. A solution of the aldehyde **55** (717 mg, 2.90 mmol) in dry THF (5 mL) was added and the resultant mixture was stirred at −78°C for 15 min and at room temperature for 30 min. Water (50 mL) was added and the phases were separated. The aqueous layer was extracted with Et_2O (3 × 30 mL). The combined extracts were washed with brine, dried ($MgSO_4$), and concentrated. Flash chromatography (100 g silica gel, 10:1 to 5:1 petroleum ether – Et_2O) afforded 126 mg of the starting material **54** and 508 mg (62% based on recovered starting material) of a colorless oil that, based on ^1H nmr spectroscopy, consisted of a mixture of three keto alcohols of general structure **56**. This material was not characterized further.

To a cold (−78°C), stirred solution of oxalyl chloride (0.27 mL, 2.15 mmol) in dry CH_2Cl_2 (40 mL) was added dry Me_2SO (0.15 mL, 2.15 mmol). After the mixture had been stirred for 5 min, a solution of a mixture of the keto alcohols **56** (750 mg, 1.655 mmol) in dry CH_2Cl_2 (10 mL) was added. The mixture was stirred for 20 min and then dry Et_3N (0.92 mL, 6.6 mmol) was added. The solution was stirred at −78°C for 5 min, was warmed to room temperature, and then was stirred for an additional 30 min. Water (50 mL) was added, the phases were separated, and the aqueous phase was extracted with CH_2Cl_2 (3 × 75 mL). The combined organic extracts were dried ($MgSO_4$) and concentrated. The remaining oil was dissolved in spectral grade acetone (50 mL) and to the resulting stirred solution was added MeI (0.21 mL, 3.3 mmol) and dry K_2CO_3 (343 mg, 2.48 mmol). The mixture was refluxed for 15 h and then most of the solvent was removed under reduced pressure. Water (40 mL) was added and the mixture was extracted with Et_2O (3 × 50 mL). The combined organic extracts were dried ($MgSO_4$) and concentrated. Analysis (tlc, ^1H nmr) of the remaining liquid indicated that it consisted of two epimeric products in a ratio of ~2:1. Drip column chromatography (120 g silica gel, 30:1 petroleum ether – Et_2O) of this material provided three fractions. Distillation (180–190°C/0.1 Torr) of the initially eluted oil gave 315 mg (41%) of the diketone **58**, a colorless oil that displayed ir (neat): 1713, 1695, 1600, 918, 770 cm^{-1}; ^1H nmr (400 MHz) δ: 0.14 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 0.90, 0.94 (d, d, 3H each, J = 6 Hz in each case), 1.06, 1.23 (s, s, 3H each), 1.40 (ddd, 1H, J = 4, 7, 14 Hz), 1.60 (ddd, 1H, J = 3, 6.5, 9 Hz), 1.85 (dt, 1H, J = 12, 9 Hz), 2.06–2.23 (m, 3H), 2.32 (d, 1H, J = 11.5 Hz), 2.36–2.68 (m, 7H), 2.77 (d, 1H, J = 11.5 Hz), 5.16 (m, 1H, $^2J_{Sn-H}$ = 70 Hz), 5.63 (m, 1H, $^3J_{Sn-H}$ = 149 Hz); ^{13}C nmr (75.3 Hz) δ: −9.5, 19.7, 20.8, 21.1, 21.2, 25.7, 26.8, 27.7, 33.2, 33.9, 36.6, 38.2, 47.9, 52.4, 65.6, 125.0, 136.2, 143.4, 153.7, 208.8, 208.9. Exact Mass calcd. for $C_{22}H_{35}O_2Sn$ (M^+ − Me): 451.1659; found: 451.1652.

The second fraction to be eluted (76 mg, 10%) contained a mixture of the diketones **58** and **59**.

Distillation (180–190°C/0.1 Torr) of the liquid obtained from the third fraction produced 120 mg (16%) of the diketone **59**, a colorless oil that showed ir (neat): 1714, 1694, 917, 770 cm^{-1}; ^1H nmr (400 MHz) δ: 0.15 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.93, 1.00 (d, d, 3H each, J = 6.5 Hz in each case), 0.91, 1.37 (s, s, 3H each), 1.51–1.73 (m, 3H), 1.83 (ddd, 1H, J = 1.5, 8.5, 14 Hz), 2.13–2.28 (m, 3H), 2.40 (d, 1H, J = 11 Hz), 2.40–2.70 (m, 6H), 2.68 (d, 1H, J = 11 Hz), 5.15 (m, 1H, $^3J_{Sn-H}$ = 70 Hz), 5.62 (m, 1H, $^3J_{Sn-H}$ = 150 Hz); ^{13}C nmr (75.3 Hz) δ: −9.5, 19.7, 20.1, 21.1, 21.6, 23.3, 26.5, 27.7, 33.7, 33.8, 37.8, 38.7, 48.7, 53.8, 66.6, 124.9, 139.0, 140.7, 153.7, 208.6, 209.7. Exact Mass calcd. for $C_{22}H_{35}O_2Sn$ (M^+ − Me): 451.1659; found: 451.1656.

Preparation of the keto silyl ether ***63***

To a cold (−78°C), stirred solution of the diketone **58** (43.5 mg, 0.094 mmol) and LiCl (80 mg, 1.88 mmol) in dry THF (10 mL) was added, dropwise, a solution of diisobutylaluminum hydride in toluene (0.37 mL of a 1 M solution, 0.37 mmol). The mixture was stirred for 10 min and then saturated aqueous NH_4Cl (2 mL) was added. The cooling bath was removed and the mixture was stirred for 30 min as it was warmed to room temperature. Magnesium sulfate was added and the mixture was filtered. The collected material was washed with Et_2O (100 mL). The combined filtrate was concentrated. The residual material, which, on the basis of tlc analysis consisted of a single keto alcohol (**62**), was dissolved in dry CH_2Cl_2 (20 mL). To the resultant stirred solution at room temperature was added sequentially, 4-*N*,*N*-dimethylaminopyridine (2 mg), Et_3N (0.08 mL), and *t*-$BuMe_2SiOSO_2CF_3$ (0.11 mL, 0.47 mmol). The solution was stirred for 30 min and then water (20 mL) was added. The phases were separated and the aqueous phase was extracted with CH_2Cl_2 (3 × 20 mL). The combined organic solution was dried ($MgSO_4$) and concentrated. Flash chromatography (27 g silica gel, 60:1 petroleum ether – Et_2O) of the residual liquid gave 43 mg (79%) of the keto silyl ether **63**, a colorless oil that exhibited ir (neat): 1698, 915, 836, 774 cm^{-1}; ^1H nmr (400 MHz) δ: 0.08, 0.09, (s, s, 3H each), 0.13 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.89, 0.94 (d, d, 3H each, J = 7 Hz in each case), 0.91 (s, 9H), 0.94, 1.09 (s, s, 3H each), 1.35–1.60 (m, 4H), 1.82 (dt, 1H, J = 12.5, 10 Hz), 2.04–2.27 (m, 4H), 2.24 (d, 1H, J = 11.5 Hz), 2.38–2.58 (m, 3H), 2.60 (septet, 1H, J = 7 Hz), 3.07 (d, 1H, J = 11.5 Hz), 3.53 (dd, 1H, J = 3, 7.5 Hz), 5.11 (m, 1H, $^3J_{Sn-H}$ = 71 Hz), 5.62 (m, 1H, $^3J_{Sn-H}$ = 153 Hz). Exact Mass calcd. for $C_{29}H_{54}O_2SiSn$: 582.2916; found: 582.2917.

(±)-Amijitrienol (3)

To a cold (0°C), stirred solution of $(Me_3Si)_2NK$ (1.07 mL of a 0.5 M solution in toluene) in dry THF (15 mL) was added, dropwise, a solution of the ketone **63** (62 mg, 0.107 mmol) in dry THF (5 mL). The solution was stirred at room temperature for 30 min and then solid Tf_2NPh (190 mg, 0.54 mmol) was added. The pale yellow solution was stirred for 30 min and then the solvent was removed under reduced pressure. The residual material, containing the enol triflate **64**, was dissolved in dry acetonitrile (25 mL) containing 10 drops of dry Et_3N, and to the resulting stirred solution was added $(Ph_3P)_4Pd$ (7 mg, 0.006 mmol). The solution was refluxed for 30 min and then the solvent was removed under reduced pressure. Drip column chromatography (10 g silica gel, hexane) of the remaining material provided 32 mg (74%) of the silyl ether triene **65**, a colorless oil that was used directly for the next reaction.

A stirred solution of the ether **65** (12.5 mg, 0.031 mmol) and *n*-Bu_4NF (0.062 mL of a 1 M solution in THF) in dry THF (10 mL) was refluxed for 3.5 h. The reaction mixture was concentrated (reduced pressure) and the residual material was subjected to drip column chromatography (5 g silica gel, 3:1 hexane–Et_2O). Recrystallization (hexane) of the white solid thus obtained provided 7.0 mg (78%) of (±)-amijitrienol (**3**) as fine, white needles that exhibited mp 119–119.5°C; ir ($CHCl_3$): 3626, 1631, 1626, 1455, 900 cm^{-1}; ^1H nmr (400 MHz) δ: 0.87, 1.29 (s, s, 3H each), 0.92, 0.93 (d, d, 3H each, J = 7 Hz in each case), 1.34 (ddd, 1H, J = 5, 5, 12 Hz), 1.64 (ddd, 1H, J = 7, 8.5, 12 Hz), 1.72–1.83 (m, 2H), 1.94 (dddd, 1H, J = 2.5, 5, 14, 14 Hz), 2.08, (m, 2H), 2.16 (ddd, 1H, J = 2.5, 5, 13 Hz), 2.30 (m, 1H), 2.47 (ddddd, 1H, J = 2.3, 2.3, 5, 14, 14 Hz), 2.53–2.65 (m, 2H), 2.63 (septet, 1H, J = 7 Hz), 3.37 (br s, 1H, $w_{1/2}$ = 10 Hz), 4.63 (dd, 1H, J = 2.5, 2.5 Hz), 4.74 (dd, 1H, J = 2.5, 2.5 Hz), 5.81 (s, 1H). Decoupling experiments: irradiation at δ 3.37 simplified the m at 1.72–1.83 and changed the dddd at 1.94 to a ddd (J = 5, 14, 14 Hz). ^{13}C nmr (75.3 MHz) δ: 20.5, 20.8, 21.3, 21.9, 26.9, 27.1, 27.2, 28.5, 29.1, 33.3, 42.4, 44.7, 52.2, 78.2, 110.9, 136.6, 138.7, 139.5, 142.5, 150.3. The $CDCl_3$ used for the ^1H nmr and ^{13}C nmr measurements was shaken with Na_2CO_3–$MgSO_4$ and then was filtered through basic alumina immediately prior to use. Exact Mass calcd. for $C_{20}H_{30}O$: 286.2297; found: 286.2296.

Received July 30, 1991

G. ANGELINI, G. LILLA, C. SPARAPANI, O. URSINI, E. ROSSI, A. L. SEGRE, M. A. MCALLISTER, and T. T. TIDWELL. Can. J. Chem. **70**, 1221 (1992).

The title compound **3** has been prepared by reaction of $CF_3C{\equiv}CCF_3$ with tritium gas on Lindlar catalyst poisoned with quinoline. The qualitative and quantitative analyses of the products ($CF_3CH{=}CHCF_3$, $CF_3CH{=}C^3HCF_3$, $CF_3C^3H{=}C^3HCF_3$) have been carried out using GC/MS and ^1H, ^3H, and ^{19}F NMR techniques. A strong isotope-induced shift has been detected in the ^{19}F spectra of **3**.

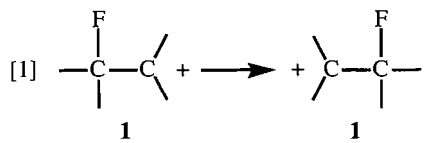
G. ANGELINI, G. LILLA, C. SPARAPANI, O. URSINI, E. ROSSI, A. L. SEGRE, M. A. MCALLISTER et T. T. TIDWELL. Can. J. Chem. **70**, 1221 (1992).

On a préparé le composé **3**, mentionné dans le titre, en faisant réagir du CF_3-C≡C-CF_3 avec du tritium gazeux sur un catalyseur de Lindlar empoisonné avec de la quinoléine. On a effectué les analyses qualitative et quantitative des produits (CF_3-CH=CH-CF_3, CF_3-CH=C^3H-CF_3 et CF_3-C_3H=C^3H-CF_3) à l'aide de techniques de CPG/SM et RMN du ^1H, du ^3H et du ^{19}F. Dans le spectre RMN du ^{19}F du produit **3**, on a détecté un déplacement chimique induit par l'isotope important.

[Traduit par la rédaction]

Introduction

The stability and reactivity of trifluoromethyl-substituted carbocations have recently received considerable attention (1). Theoretical studies have elucidated the potential energy surfaces for the $CF_3CH_2^+$(2*a*), $CH_3FCH_2^+$ (2*b*),[2] and $CF_3C{=}CH_2$ (3) ions and suggested that intramolecular fluoride transfers (eq. [1]) via bridged fluoronium ions may be viable processes for these ions. Several gas-phase investigations (4) have provided evidence for fluorine isomerization (eq. [1]), although some of these results have instead been interpreted (4*b*) by an elimination–readdition pathway

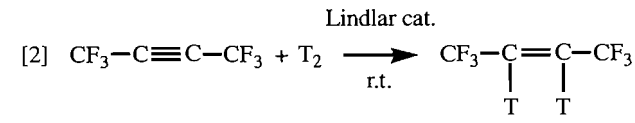


[1]

1 **1**

A further test of the occurrence of this process in both gas and liquid phases at atmospheric or higher pressure would be the "tritium nuclear decay technique." As described previously (5), tritium nuclear decay of a doubly tritiated molecule with the tritium atoms in chemically equivalent positions forms, at least initially, a well-characterized carbocation, whose stability and reactivity can be studied under different experimental conditions.

In this paper is reported the synthesis of no-carrier-added 1,1,1,4,4,4-hexafluoro-2,3-ditritio-2-butene **3** by partial tritium addition to hexafluoro-2-butyne **2** (eq. [2]). Compound **3** displays a strong isotope-induced shift in the ^{19}F NMR spectrum.



[2]

2 **3**

Experimental

Materials

Pure tritium gas was purchased from the Radiochemical Centre, Amersham, England and was used after a vacuum line distillation, trapping the impurities with a cold bath at −77 K.[3] Hexafluoro-2-butyne **2** was obtained from Strem Chemical Inc., analyzed by GC/MS, and used without further purification.

[1]Author to whom correspondence may be addressed.

[2]M. A. McAllister and T. T. Tidwell, unpublished results.

[3]To obtain the best radiochemical yield of product **3**, a tritium purification step was very important. One run using a directly purchased tritium sample without further purification produced a very low yield of **3** together with a considerable amount of oxygen containing compounds as indicated by ^3H NMR analysis.

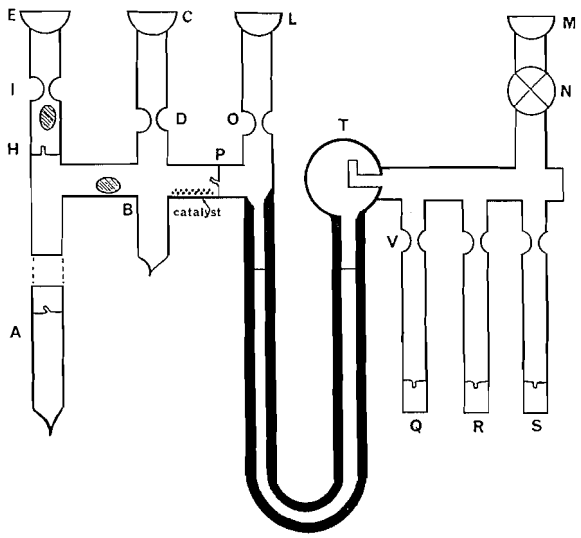

FIG. 1. Glass apparatus for the radiochemical synthesis.

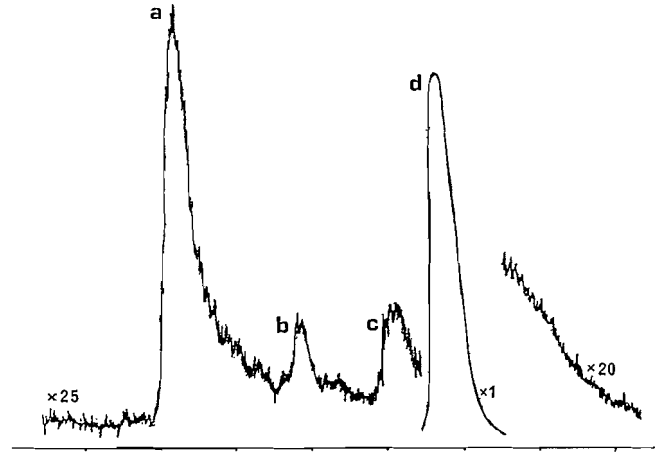

FIG. 2. Radio-gas chromatographic analysis of tritiated 1,1,1,4,4,4-hexafluoro-2 butenes **3** and **4** (peak d), decomposition products (peaks a,b), 1,1,1,4,4,4-hexafluorobutane (peak c).

Pure deuterium gas was obtained from Matheson and Lindlar catalyst from Aldrich.

Methods

Radio-gas chromatographic analyses of the radioactive products were performed using a Carlo Erba model 4200 instrument equipped with a 80/100 mesh Carbopack B with 1% SP-1000 column (2 m × 3 mm. stainless steel) and a TCD detector. A gaseous proportional counter (Berthold AG) was connected to the GC system, for radiochemical analyses.

Isotopic abundances (for deuteriated and tritiated products) were determined by capillary GC/MS analysis using a Hewlett Packard 5988A instrument equipped with a 50 m HP-FFAP quartz column (0.32 mm i.d.).

The isotopic distribution in the recovered tritiated products was also measured by ^{3}H and ^{19}F NMR analyses, in which about 0.55 GBq samples were examined on a Bruker AM 200 NMR spectrometer operating at 213.47 MHz according to spectroscopic procedures reported elsewhere (5).

Static determinations of the radioactivity during the steps of the synthetic procedure were obtained by liquid scintillation counting with a Packard Tri-Carb 2260 XL spectrometer. All the operations involving radioactive products were carried out using a greaseless high-vacuum line.

Preparation of 1,1,1,4,4,4-hexafluoro-2,3-ditritio-2-butene 3

The glass apparatus is shown in Fig. 1. The Pyrex vial A (7 mL), containing purified tritium gas (about 37 BqG at 46 Torr; 1 Torr = 133.3 Pa), was joined to the main part of the device and the central part of the apparatus was carefully outgassed under high vacuum for approximately 3 h at 150°C. Then 15 mg of fresh Lindlar catalyst was placed in B and carefully poisoned with 15 μL of quinoline. The apparatus was connected to the vacuum line with the ground joint C and outgassed. Then ca. 1.6×10^{-5} mol of **2** was transferred by the vacuum line into B, frozen in the cold finger, and the apparatus was sealed off at D. The break seal of ampoule A was broken with a magnetic hammer embedded in glass, and the tritium was allowed to react at room temperature for 4 h.

Unreacted tritium was then removed by connecting the apparatus through the ground joint E to the vacuum line. The cold finger was cooled in a liquid nitrogen bath and the system was carefully outgassed after breaking the seal H. Residual tritium gas (about 80 ± 10% of the starting amount) was recovered by cyclic Töpler pumpings, keeping the cold finger at −196°C.

The apparatus was sealed in I, and mercury (25 mL) was carefully put in the "U" shaped section of the system, which was then simultaneously connected by the ground joints L and M to the vacuum line. After short alternate pumpings through the ground joints L and M, the mercury balanced and the rest of the apparatus was completely outgassed. The stopcock N was closed and the system was sealed off at O.

The last break-seal P was broken using the corresponding magnetic hammer and the crude reaction product was allowed to expand in the "U" shaped section, unbalancing the mercury contained in it.

A slow polymerization process, probably induced by the ionic species formed by tritium nuclear decay, determined the minimum decrease of the pressure. Apart from this, the differential reading of the mercury levels substantially reflected the initial amount of the starting butyne **2**.

The apparatus permitted the consecutive sharing of the crude reaction products into the three collecting vials (Q, R, and S). By allowing the mercury to flow into the spherical head T, the gaseous mixture expanded throughout the apparatus. The return of the mercury into the "U" shaped section divided the gaseous mixture in a ratio that was approximately determined by the volume of the parts connected to the arms of the "U". The gas was condensed, with liquid nitrogen, in vial Q, which was then sealed off at V. The above operations were repeated exactly for the vial R.

The pressures of no-carrier-added products present in vials Q and R were 160 and 53 Torr respectively.

Then 1,1,1,4,4,4-hexafluoro-2,3-dideutero-2-butene was introduced from the stopcock M into the apparatus to wash out and recover any tritiated products absorbed on the walls or catalyst. This last fraction was collected in vial S, frozen at −196°C, keeping the mercury in the spherical head T.

Vial R was used to carry out the following radioanalytical and spectroscopic analyses. A measured sample was diluted in neopentane ($1:10^{4}$) and then a known volume was condensed in a vial containing scintillation liquid. This vial was sealed off and its radioactivity determined by a beta scintillation counter. This measurement permitted the evaluation of the activity of vial R (about 1.1 GBq) and of vials Q and S (about 3.7 and 0.6 GBq respectively) with a radiochemical total yield of 5.4 GBq (15%).

A second small sample (about 0.37 MBq) was analyzed by radio-GC to assay the purity of the product (Fig. 2). The results indicated that more than 94% of the total activity was localized in the ditritiated butene **3** and eventually in the 1,1,1,4,4,4-hexafluoro-2-tritio-2-butene **4**, as confirmed by the comparison of the retention time with an authentic inactive sample. Less than 5% was present in very volatile compounds (probably residual T_2 and HT) and only 1% as tritiated 1,1,1,4,4,4-hexafluorobutane.

Subsequently, a complete analysis of the mass region of interest was carried out using a GC/MS instrument HP 5988 A. This

TABLE 1. NMR parameters of $CF_3—C\equiv C—CF_3$ measured on ^{19}F NMR spectrum

$^{12}CF_3—^{12}C\equiv^{12}C—^{12}CF_3$	$\delta_{\nu^*_F}$ = 22.878 ppm
$^{13}CF_3\cdot—^{12}C\equiv^{12}C—^{12}CF_3$	$\Delta\delta_{\nu_F}$ = 0.280 ppm upfield from $\delta\nu^*_F$
$^{12}CF_3\cdot—^{13}C\equiv^{12}C—^{12}CF_3$	$\Delta\delta_{\nu_F}$ = 0.031 ppm from $\delta_{\nu^*_F}$

$J_{^{13}CF}$ geminal = |260.7| Hz
$J_{^{12}CF_3-^{13}C}$ vicinal = |56.2| Hz
$J_{CF_3\text{-}CF_3}$ = |2.6| Hz

analysis confirmed the tritiated butenes **3** and **4** as the only radioactive products, together with the inactive starting compound **2**.

The GC/MS analysis showed clearly fragments at *m/e* 149, 147, and 145, corresponding to the loss of one fluorine atom from butenes **3**, **4**, and 1,1,1,4,4,4-hexafluoro-2-butene **5**, in relative percentages of 20, 40, and 40, respectively, based on their corresponding ionic intensities.

Finally, about 0.55 GBq of crude products was transferred through the vacuum line into a 5-mm NMR tube containing 0.5 mL of acetone-d_6 (isotopic purity 99.996%). The tube, frozen at 77 K, was sealed, and gave ^3H and ^{19}F NMR data discussed below that fully agreed with the GC/MS product distribution.

Based on the above isotopic distribution, a very high specific activity (about 1000 TBq/mol) for butenes **3** and **4** is expected. Considering that the radioactive products are diluted by residual starting compound **2** at the end of the reaction, a significant amount (about 144 TBq/mol) of specific activity was obtained. To avoid collateral self-radiolytic decomposition, the contents of vial Q (about 3.7 GBq) were diluted with neopentane (1:200) in the presence of O_2 and trimethylamine as radical and ionic scavengers, respectively. The new specific activity was 0.72 TBq/mol. The radioactive mixture was then purified by several distillation and condensation processes through the vacuum line to eliminate any trace of radioactive impurities. The radioactive product was then stored in the dark prior to use in tritium nuclear decay experiments.

NMR analysis

The ^{19}F NMR spectrum of butyne **2** gave a chemical shift of 22.878 ppm (from 1% v/v of CF_3COOD in acetone-d_6); since **2** was not previously NMR characterized, its NMR parameters, measured on the ^{19}F NMR spectrum, are given in Table 1.

CF_3-CH=CH-CF_3 **5** (entry d of Table 2), was characterized in acetone-d_6 by ^1H NMR (Fig. 3). This spectrum shows the *cis/trans* isomers at 6.65 and 6.95 ppm, respectively, having an intensity ratio larger than 95:5. The only previous synthesis of **5** (6) reports the preparation of the *cis* isomer, with no acceptable proof of its structure, so complete analysis of ^1H and ^{19}F spectra of the major component was performed.

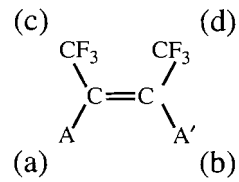
The spectrum of *cis* **5** is a strongly coupled $A_3A_3'XX'$ system with the following parameters: δ_{1_H} = 6.65 ppm; δ_{19_F} = 15.88 ppm; $J_{CF_3\text{-}CH}$ = 8.69 Hz; $J_{CF_3C=CH}$ = −0.4 Hz; J_{H-H} = 12.83 Hz; J_{CF_3,CF_3} = 9.96 Hz with a R.M.S.D. = 0.07 Hz.

The low value of J_{H-H} (7) supports the *cis* geometry, as does the high value of $J_{CF_3\text{-}CF_3}$ (8), especially if compared with the much lower value for butyne **2**, which has the two CF_3 groups nearly at the same distance as the *trans* isomer. A small amount of another compound (<1%) was also found, whose chemical shift suggests the presence of the $CF_3CH_2CH_2CF_3$ **6**.

Due to the strongly coupled $A_3A_3'XX'$ system the proton spectrum is extremely complex and a poor sensitivity in the corresponding ^3H spectrum is expected. The ^3H NMR spectrum of butenes **3** and **4** gave a broad main multiplet (see Fig. 4), and a barely observable ^3H multiplet attributable to the *trans* isomers. Since the ^3H NMR spectra were not useful as a measure of the ratio between mono- and ditritiated compounds, a ^{19}F NMR spectrum was measured (Fig. 5).

The ^{19}F singlet at 22.878 ppm is due to CF_3-C≡C-CF_3 and nearby there is a very small signal possibly due to a small amount (≈0.5%) of another perfluoroalkyne.

The main multiplet at about 15.8 ppm is shown enlarged in Fig. 6. This complex multiplet arises from the partial superimposition of the ^{19}F spectra due to CF_3-CH=CH-CF_3 **5**, CF_3-CH=C^3H-CF_3 **4**, and CF_3-C^3H=C^3H-CF_3 **3**. A strong isotope-induced shift must be invoked to rationalize the experimental spectra, which were simulated (see insert of Fig. 6) in order to perform a quantitative analysis. The following labelling:



was used for compounds **5**, **4**, and **3**.

NMR data relative to light **5**, monotritiated **4**, and ditritiated 1,4-hexafluorobutenes **3** are summarized in Table 3.

As evinced by the values reported in Table 3, the ^3H induced shift on the ^{19}F NMR can be quantified as follows: $\Delta\delta_c$ = 0.06 ppm upfield and $\Delta\delta_d$ = 0.04 ppm upfield for monotritiated butene **4** with respect to the light one **5**; $\Delta\delta_c = \Delta\delta_d$ = 0.1 ppm upfield for bitritiated butene **3** with respect to light **5**.

TABLE 2. Relative distribution of the products in the deuterium addition to perfluoro-2-butyne **s**[a]

	Deuterium (mmol)	Perfluoro-2-butyne **2** (mmol)	Pressure (Torr)	Time (h)	Products (%)		
					2	**5**	**6**
(a)	0.18	0.16	300	1	95	5	—
(b)	0.017	0.016	50	4	85	15	—
(c)	0.18[b]	0.16	300	4	85	15	—
(d)	8.0	7.0	450	6	80	17	3
(e)	0.18	0.16	300	12	60	30	10
(f)	0.017	0.016	50	19	40	30	30
(g)	3.2	2.8	500	24	—	40	60

[a]All the experiments were carried out in the gas phase in the presence of Lindlar catalyst (0.5 mg for 1 Torr of starting compound **2**) poisoned with quinoline (1 μL/mg of catalyst). Different glass vessels with different internal volume were used for the reported blank runs.

[b]Similar conditions were used for radiochemical synthesis.

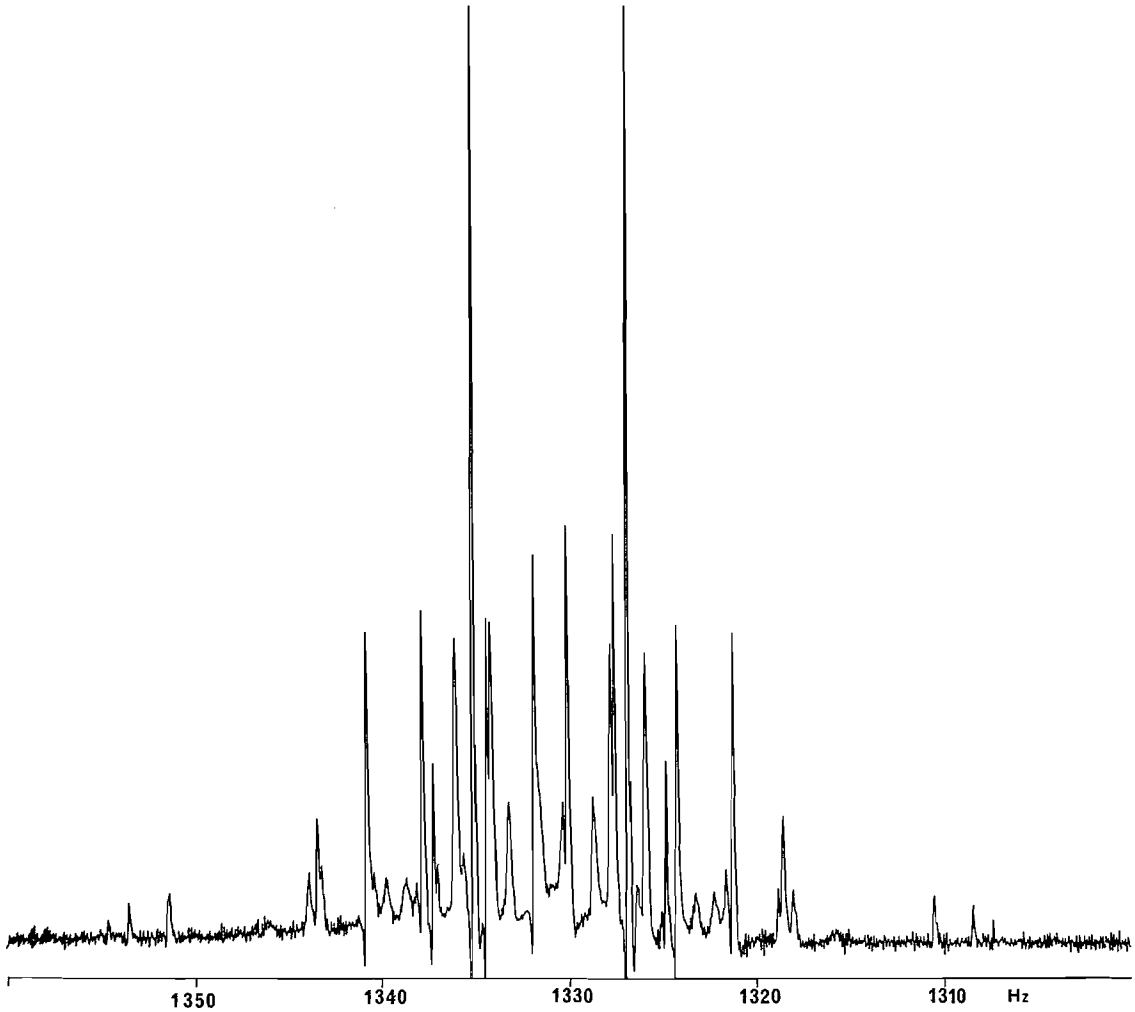

FIG. 3. ^{1}H NMR spectrum of CF_3-CH=CH-CF_3 **5**.

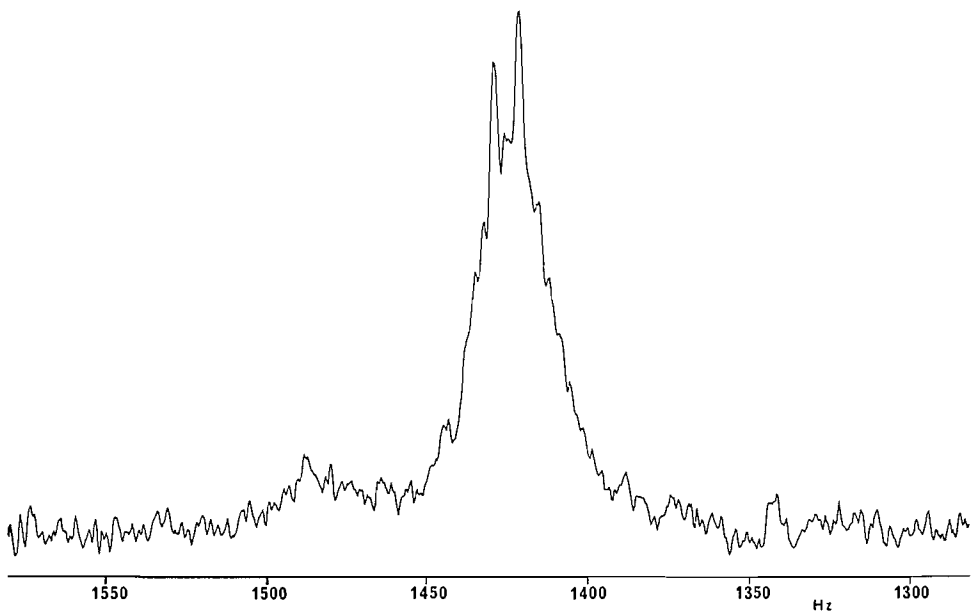

FIG. 4. ^{3}H NMR spectrum of tritiated 1,1,1,4,4,4-hexafluoro-2-butenes **3** and **4**.

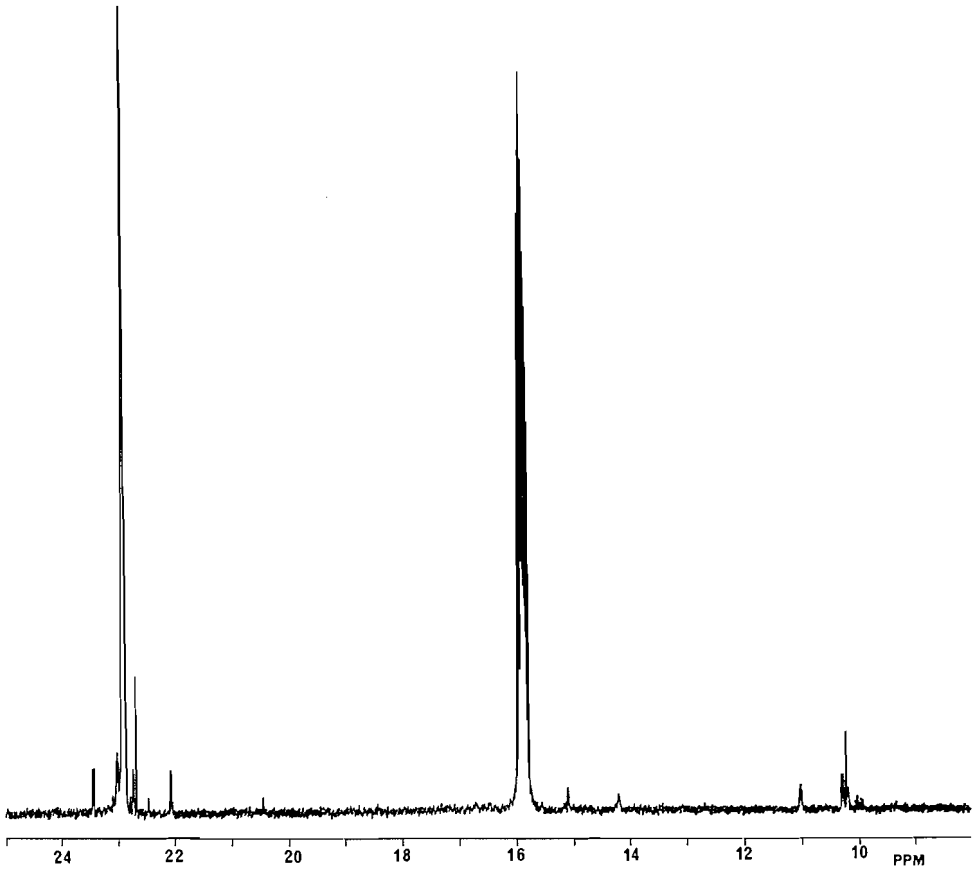

FIG. 5. ^{19}F NMR spectrum of butene mixture of **3**, **4**, and **5**.

To confirm the above interpretation an ^{1}H decoupled ^{19}F spectrum was run (Fig. 7). Here the spectrum of **5** becomes a singlet, the spectrum of **3** is unaffected (note the similarity of the dashed lines due to **3** with the calculated spectrum shown in the insert of Fig. 6), while the two CF_3 groups of the monotritiated moiety **4** are nonequivalent due to the different isotope chemical shifts induced by ^{3}H, respectively 3 of 5 bonds apart (note the different multiplicity of the two broad doublets at 15.83 and at 15.85 ppm, which confirms the previous assignment). However, due to the presence of the nuclear Overhauser effect (NOE), different in compounds **5** and **4** and absent in **3**, the quantitative analysis was performed on the undecoupled spectrum (Fig. 6); here the first peak on right is due only to the ditritiated moiety, the central broad resonance is due only to the monotritiated moiety, while the lowest field peak is due to the inactive butene; all these peaks have a known weight as shown by the simulated spectra. Quantitative analysis gave relative amounts of 40% **5**, 35% **4**, and 25% **3**.

Other extremely weak peaks in the ^{19}F spectrum are due to the *trans* impurity already detected in the ^{3}H spectrum and possibly to the saturated compound.

Results and discussion

The high-pressure hydrogenation of $CF_3C{\equiv}CCF_3$ butyne **2** is reported (6) to give 1,1,1,4,4,4-hexafluoro-2-butene **5** as the main product, plus hexafluorobutane **6** (eq. [3]).

$$[3]\quad \underset{\mathbf{2}}{CF_3C{\equiv}CCF_3} \xrightarrow{H_2} \underset{\mathbf{5}}{CF_3CH{=}CHCF_3} \xrightarrow{H_2} \underset{\mathbf{6}}{CF_3CH_2CH_2CF_3}$$

Three substantial changes were introduced to adapt this procedure to radiochemical requirements. First the synthesis was carried out in the gas phase in the presence of the catalyst with the initial total pressure in the range 150–500 Torr. These pressures were easily reached using standard glassware apparatus and reasonable amounts of radioactive tritium gas (37–110 GBq).

The second change was the use of poisoned Lindlar catalyst (9) instead of Raney nickel. The former catalyst was less reactive and so minimized further hydrogenation of the initial butene. However the ratio [quinoline]/[Lindlar catalyst] was important and numerous blank runs revealed that 1 μL/mg was best.

The last change was the use of a short reaction time (4 h or less) to limit formation of butane **6**.

Several blank runs were carried out using deuterium gas (>99 mol%) and perfluoro-2-butyne **2** at constant molar ratio ($[D_2]/[\mathbf{2}] = 1.15$) as reported in Table 2. The relative yields and isotopic distributions were determined by GC/MS. Whenever the reaction was stopped before 6 h no butane **6** was observed. For entries (a), (b), (c), and (d) of Table 2, the averaged relative abundances of d_2, d_1, and d_0 products were 60%, 30%, and 10% respectively. The butene **3** in the radiochemical synthesis was formed in smaller amount than butenes **4** and **5**. This different isotopic distribution is ascribed both to a low level of the radioisotopic purity of the tritium gas employed and some hydrogenated impurity present in the reaction medium during the radiochemical run.

The isotopic distribution values obtained for the radioactive butenes **3** and **4** by GC/MS analyses were quite reproducible, despite the limited amounts of the radioactive material employed in the investigation and the different iso-

[a]Obtained by multiplying the values of **5** by γ^3H/γ^1H.

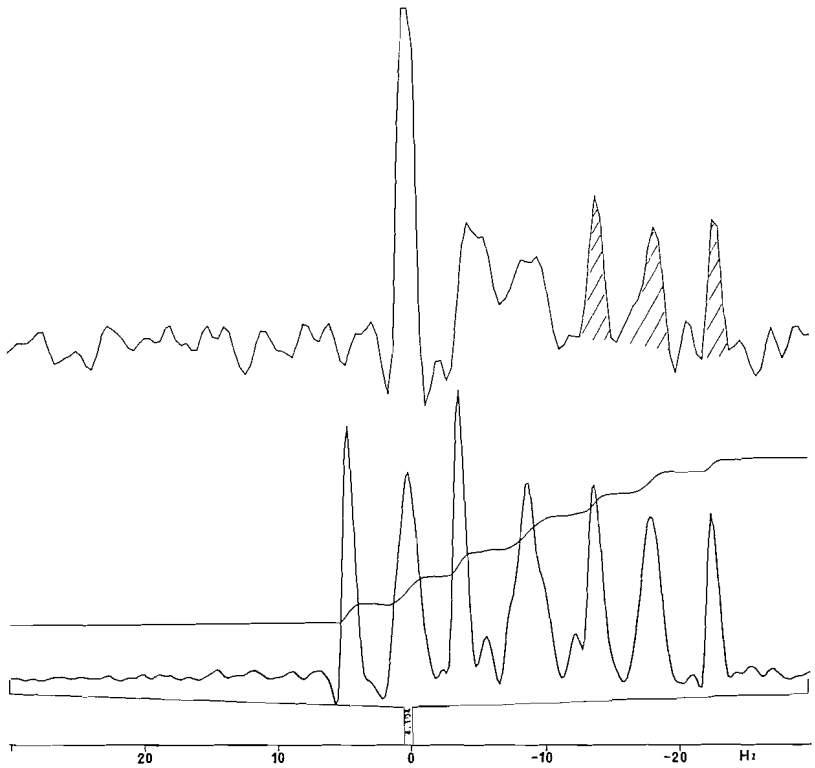

FIG. 7. Enlarged experimental ^{1}H decoupled ^{19}F spectrum (above) in comparison to the spectrum described in Fig. 6 (bottom) of the tritiated butenes **3** and **4** and the light **5**.

topic (tritium) contents present in the three butenes. The quantitative evaluation was done using the characteristic fragmentation peak, $[M^+ - F]$, for every butene of the mixture, avoiding in this way any possible uncertainties due to different isotopic fragmentation pathways, which a choice of other characteristic peaks could have induced.

Confirmation of the results came from the ^{3}H and ^{19}F NMR analyses of the butenes **3**, **4**, and **5**. Previously, ^{3}H NMR was shown (10) to be an important technique for the qualitative and quantitative analyses of products formed by radiochemical procedures. In the present study, this technique also provided some indications about the nature of the desired products and some other collateral substances (see footnote 2) formed during the synthesis.

However, due to the complex spectral multiplicity of the ^{3}H NMR signals for the butenes **3** and **4**, the quantitative evaluation of the isotopic (tritium) distribution between the two possible tritiated products was impossible. Fortunately, however, the tritium isotope-induced shift on the ^{19}F NMR spectra allowed the quantitative identification of the butenes **3**, **4**, and **5**, confirming the results obtained by the GC/MS technique.

While tritium isotope effects on ^{13}C spectra were reported previously (11), our results give the first evidence of a strong tritium isotope-induced shift shown in ^{19}F NMR (12), thus allowing a good quantitative analysis. This should be a generally useful way for the structural investigation of fluorinated molecules including those labeled also with stable isotopes, such as deuterium.

Received June 17, 1991

GANG WU, RODERICK E. WASYLISHEN, WILLIAM P. POWER, and GRAZIANO BACCOLINI. Can. J. Chem. **70**, 1229 (1992).

Phosphorus-31 NMR static powder spectra and high-resolution magic angle spinning spectra have been obtained for a new heterocyclic compound, *cis*-2,10-dimethyl[1,2,3]benzothiadiphospholo[2,3*b*][1,2,3]benzothiadiphosphole (**1**), which contains a P(III)—P(III) single bond. The homonuclear $^{31}P-^{31}P$ dipolar interaction manifests itself in both the magic angle spinning spectra and the non-spinning line shape. Under the AX spin pair approximation, analysis of the spinning sidebands in the MAS experiment yields a full characterization of the two ^{31}P chemical shielding tensors. This approximation is confirmed by the exact powder line shape simulation for a homonuclear spin pair. Analysis of the dipolar subspectra also yields the absolute sign of $^1J(P,P)$, which is found to be negative.

Key words: phosphorus–phosphorus single bond, chemical shielding tensors, dipolar NMR, MAS, static line shape.

GANG WU, RODERICK E. WASYLISHEN, WILLIAM P. POWER et GRAZIANO BACCOLINI. Can. J. Chem. **70**, 1229 (1992).

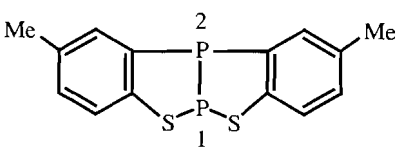
On a déterminé le spectre RMN du ^{31}P, de la poudre statique ainsi qu'à l'aide de la technique de rotation à l'angle magique, d'un nouveau composé hétérocyclique, le *cis*-2-,10-diméthyl[1.2.3]benzothiadiphospholo[2,3*b*][1,2,3]benzothiadiphosphole (**1**), qui contient une liaison simple P(III)—P(III). L'interaction dipolarie $^{31}P-^{31}P$ homonucléaire se manifeste tant dans le spectre détermine à l'aide de la technique de rotation à l'angle magique que dans la forme de la raie du spectre statique. En utilisant l'approximation AX pour la paire de spin, l'analyse des bandes latérales de rotation obtenues lors des expériences réalisées à l'aide de la technique de rotation à l'angle magique, on obtient une caractérisation complète des deux tenseurs de blindage chimique du ^{31}P. Cette approximation est confirmée par la simulation exacte de la forme de la raie du spectre statique pour une paire de spin homonucléaires. L'analyse des sous-spectres dipolaires fournit aussi le signe absolu de la constante $^1J(P,P)$, qui est négative.

Mots clés : liaison simple phosphore–phosphore, tenseurs de blindage chimique, RMN dipolaire, technique de rotation à l'angle magique, forme de la raie du spectre statique.

[Traduit par la rédaction]

Introduction

A new heterocyclic system containing a P(III)—P(III) single bond, *cis*-2,10-dimethyl[1,2,3]benzothiadiphospholo[2,3*b*][1,2,3]benzothiadiphosphole (**1**), has recently been synthesized by the reaction of methyl *p*-tolyl sulphide with PCl_3 and $AlCl_3$ (1, 2). Based upon **1**, a highly stereospecific phosphorus–carbon exchange process has been developed (3, 4). The "butterfly" arrangement of **1** forces the phosphorus electron lone pairs to adopt an eclipsed



1

conformation. Because this conformation is unusual for a molecule containing a P(III)—P(III) single bond, we thought that it would be of interest to characterize the magnetic shielding tensor of each of the two phosphorus centres in **1**, where P6 and P12 (the IUPAC nomenclature) are renumbered as P1 and P2 for convenience. The technique used in this study is dipolar/chemical shift NMR spectroscopy and in the case of **1** it involves a study of the ^{31}P NMR spectrum of a solid powder sample with and without magic angle spinning (MAS). Although this technique has been widely used to study isolated spin pairs (5), there have been few reports dealing with $^{31}P-^{31}P$ spin pairs (6–9) and, to our knowledge, a full characterization of the ^{31}P chemical shielding (CS) tensor in a compound containing a P(III)—P(III) single bond has not appeared. In addition to obtaining information about the ^{31}P shielding tensors of **1**, we were interested in determining whether or not the solid-state ^{31}P NMR spectrum of **1** could be successfully analyzed as an AX spin system. Here we discuss the criterion that permits a homonuclear two-spin solid-state spectrum to be analyzed as an AX spectrum.

Theory

In the solid state the NMR spectrum of an isolated spin-$\frac{1}{2}$ nucleus is dominated by the orientation dependence of the chemical shift. The NMR spectrum of such a powder sample permits one to directly determine the three principal components of the shielding tensor. However, in general, information concerning the orientation of the shielding tensor is unavailable from the powder spectrum. If the isolated spin is adjacent to another spin-$\frac{1}{2}$ nucleus, then the spectrum is modified by the direct dipolar coupling and the indirect spin–spin "*J*" coupling interactions. The direct dipolar interaction is also dependent upon the orientation of the internuclear dipolar vector in the magnetic field and, in principle, provides a reference frame for fixing the orientation of the shielding tensor. Because the dipolar interaction is axially

symmetric, the orientation of the shielding tensor cannot in general be completely determined from a dipolar/chemical shift NMR powder spectrum. In the discussion which follows we present a general discussion of the dipolar/chemical shift NMR spectrum of an isolated homonuclear spin pair. In particular, we will begin by describing the general NMR spectrum of a spin pair where the chemical shift difference between the two nuclei, A and X, is always much greater than both the J and the dipolar coupling between them at all orientations. In general, the static dipolar/chemical shift NMR spectrum of the homonuclear AX system consists of two dipolar subspectra for each nucleus. Each dipolar subspectrum has the same line shape as that well known for an isolated nucleus with anisotropic chemical shift, and can be characterized by three principal components of an effective dipolar/chemical shift tensor.

It is quite common that one principal axis of the chemical shift tensor is perpendicular to the dipolar vector (internuclear vector) in a dipolar coupled spin pair (10–16). If we assume that one principal component, ν_{ii}, of the CS tensor at one nucleus is perpendicular to the dipolar vector, matrix elements of the effective dipolar/chemical shift tensor **T** at this nucleus in the AX spin system are given by eq. [1] (10, 11):

$$[1a] \quad T_{ii} = \nu_{jj} + m\,(R_{\text{eff}} + J_{\text{iso}})$$

$$[1b] \quad T_{jj} = \nu_{jj} + m\,[R_{\text{eff}}(1 - 3\cos^2\theta) + J_{\text{iso}}]$$

$$[1c] \quad T_{kk} = \nu_{kk} + m\,[R_{\text{eff}}(1 - 3\sin^2\theta) + J_{\text{iso}}]$$

$$[1d] \quad T_{jk} = T_{kj} = -(3/2)m\,R_{\text{eff}}\sin 2\theta$$

$$[1e] \quad T_{ij} = T_{ji} = T_{ik} = T_{ki} = 0$$

where $i, j, k = 1, 2, 3$, and cyclic permutations, θ is the angle between ν_{jj} of the CS tensor and the dipolar vector, while $m = +\frac{1}{2}$ and $-\frac{1}{2}$ correspond to the two dipolar subspectra. R_{eff} is the effective dipolar coupling constant and J_{iso} is the isotropic indirect spin–spin coupling constant. The effective dipolar coupling constant can be written:

$$[2] \quad R_{\text{eff}} = \langle R_{\text{DD}}\rangle - \langle \Delta J\rangle/3$$

where $\langle R_{\text{DD}}\rangle = (\mu_0/4\pi)\gamma_{\text{P}}^2(\hbar/2\pi)\langle r_{\text{PP}}^{-3}\rangle$ is the dipolar coupling constant in frequency units, and $\Delta J = J_{\parallel} - J_{\perp}$ is the anisotropy in the indirect spin–spin interaction; $J_{\parallel}$ and $J_{\perp}$ refer to components parallel and perpendicular to the internuclear vector, respectively. Equation [2] is based upon the assumption that the indirect spin–spin interaction **J** tensor is axially symmetric with the unique axis along the internuclear dipolar vector. The angular brackets in eq. [2] indicate that both R_{DD} and ΔJ are subject to motional averaging (11, 17).

The matrix of eq. [1] can be diagonalized and the three principal values of each subspectra are given by eq. [3],

$$[3a] \quad T_i = \nu_{ii} + m\,(R_{\text{eff}} + J_{\text{iso}})$$

$$[3b] \quad T_j = \frac{1}{2}[\nu_{jj} + \nu_{kk} + m\,(2J_{\text{iso}} - R_{\text{eff}}) + \alpha]$$

$$[3c] \quad T_k = \frac{1}{2}[\nu_{jj} + \nu_{kk} + m\,(2J_{\text{iso}} - R_{\text{eff}}) - \alpha]$$

where

$$\alpha = [(\nu_{jj} - \nu_{kk})^2 - 6m(\nu_{jj} - \nu_{kk})R_{\text{eff}}\cos 2\theta + 9m^2R_{\text{eff}}^2]^{1/2}$$

When $|\nu_{jj} - \nu_{kk}| \gg R_{\text{eff}}$, one can neglect the off-diagonal elements in eq. [1] and obtain the three principal values of the effective dipolar/chemical shift tensor **T** to a zeroth order approximation

$$[4a] \quad T_i = \nu_{ii} + m\,(R_{\text{eff}} + J_{\text{iso}})$$

$$[4b] \quad T_j = \nu_{jj} + m\,[R_{\text{eff}}(1 - 3\cos^2\theta) + J_{\text{iso}}]$$

$$[4c] \quad T_k = \nu_{kk} + m\,[R_{\text{eff}}(1 - 3\sin^2\theta) + J_{\text{iso}}]$$

It is readily seen from eqs. [3] and [4] that the isotropic positions of the two effective dipolar/chemical shift tensors at each nucleus occur at $\nu_{\text{iso}} \pm \frac{1}{2}J_{\text{iso}}$, respectively. Therefore, two J-coupled doublets will be observed for a homonuclear AX spin pair under the MAS condition. From the intensity distribution of the spinning sidebands, effective dipolar/chemical shift tensors can be recovered (18, 19) and the effective dipolar coupling constant and the relative orientation of the chemical shift tensors in the molecular frame can be deduced. One important general feature of the dipolar subspectra is that the difference between effective tensor components at the direction perpendicular to the dipolar vector gives direct information on the effective dipolar coupling constant, since $\Delta T_i = T_i^+ - T_i^- = R_{\text{eff}} + J_{\text{iso}}$. The positive and negative superscripts refer to the sign of the spin quantum number m.

Experimental

Synthesis of the new heterocyclic compound **1** was reported previously (1, 2). Phosphorus-31 NMR spectra were obtained on a Bruker MSL-200 NMR spectrometer ($B_0 = 4.70$ T) operating at 81.033 MHz. A fine white powder sample of **1** was packed into a aluminum oxide rotor. All spectra were recorded at 21°C with high-power ^{1}H decoupling during data acquisition. Cross-polarization was fulfilled under the Hartmann–Hahn match. The 90° pulse width was 4.0 μs. Typical values of the contact time were 2–5 ms and the recycle time was 10 s. MAS spinning speeds ranged from 2 to 4 kHz. The magic angle was adjusted by examining the ^{79}Br NMR signal of a KBr sample (20).

All ^{31}P chemical shifts were referenced to 85% H_3PO_4(aq) by using solid $NH_4H_2PO_4$, which has a resonance at +0.81 ppm relative to 85% H_3PO_3(aq).

Spinning sideband analysis was performed using a simplex program based upon the method of Herzfeld and Berger (19). Typically, the relative intensities of six or seven spinning sidebands were used and three best-fit tensorial elements were obtained after a few iterations.

The static powder line shape for a homonuclear spin pair was simulated with a program written in FORTRAN-77 incorporated with the POWDER routine (21). The simulations were based upon the exact analytical expression for a homonuclear spin pair (10). Both the direct dipolar and indirect spin–spin interactions were taken into account. The calculated line shape was convoluted with a Gaussian line-broadening function.

Results and discussion

Analysis of MAS spectra

The slow MAS ^{31}P NMR spectrum of compound **1** with spinning speed 4.0 kHz is shown in Fig. 1. Two isotropic doublets were found centred at 75.8 and 52.0 ppm, and were assigned to P1 and P2, respectively. The assignment of the low-field doublet to P1, the phosphorus atom attached to two sulphur atoms, was based on the ^{1}H coupled solution ^{31}P

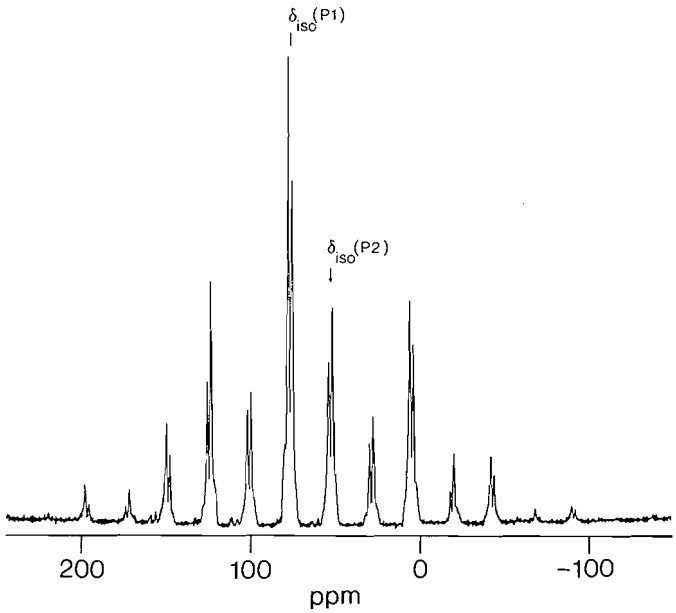

FIG. 1. ^{31}P CP/MAS NMR spectrum of **1**. The sample spinning rate is 4.0 kHz. Isotropic peaks are indicated by the arrows.

NMR spectrum, which shows a doublet for P1 arising from ^1J(P1,P2) = 211.5 Hz, and a doublet of triplets for P2 due to ^1J(P1,P2) and ^3J(P2, H) = 7.8 Hz, respectively. This assignment of P1 and P2 differs from that reported in ref. 1 and ref. 2. The observation of doublets arising from ^1J(P,P) coupling at each phosphorus site in the solid state ^{31}P NMR spectrum of **1** is consistent with the X-ray structure, which indicates that the triclinic unit cell contains two crystallographically equivalent molecules (1). Both of these isotropic chemical shifts are at low frequency (upfield shift) compared with those observed in solution state, i.e., 88.3 and 65.4 ppm for P1 and P2, respectively (1). The large number of spinning sidebands associated with each doublet in the MAS spectrum shown in Fig. 1 indicates that the chemical shift anisotropy at both phosphorus sites is large (*vide infra*).

The splitting of each doublet was 160 ± 5 Hz, arising from the homonuclear ^{31}P–^{31}P J interaction, and was confirmed by the MAS spectra at a higher field strength (B_0 = 7.04 T). This splitting was independent of spinning speed at 4.70 and 7.04 T. Although the homonuclear dipolar interaction between the two adjacent phosphorus nuclei is large in this compound (ca. R_{DD} = 1770 Hz based upon the P—P bond length, r_{PP} = 2.234 Å, determined by X-ray diffraction), we did not observe any spinning-frequency-dependent splitting as previously reported in the ^{31}P NMR spectra of dipolar coupled phosphorus spin pairs in some inorganic phosphates (9, 22) that contain ^{31}P nuclei with identical isotropic chemical shifts. It seems that such a spinning-rate-dependent splitting can only be observed easily in systems where the dipolar coupled spins have the same principal components of the chemical shielding tensor but different orientations with respect to the dipolar vector.

The magnitude of the one-bond J coupling constant in **1** was substantially smaller than the typical values reported for ^1J(P,P) in compounds containing two directly bonded tricoordinate phosphorus atoms, but significantly larger than those involving two five-coordinate phosphorus atoms (23, 24). Interestingly, the J coupling constant for **1** in the solid state was significantly smaller than the value observed in solution, 211.5 Hz (1). Since ^1J(P,P) is very dependent on the local geometry at the P—P unit (24), our observation of a smaller J in the solid state may indicate a slightly different geometric structure due to crystal packing effects. Such a change in conformation may also explain the rather large difference in solution and solid-state isotropic chemical shifts (≈12 ppm). It is worth noting that a correlation between the value of $|^1J$(P,P)| and the ^{31}P chemical shift was reported for various tetraalkyldiphosphanes, $(R_2P)_2$, with different substituents R in solution (25). Our observation on the changes of the ^1J(P,P) and $\delta(^{31}P)$ in compound **1** from solution state to solid state follows the same trend, which may indicate that crystal packing effects force the two "wings" of the butterfly molecule **1** to open slightly wider in the solid state.

P2(−)	178	33	−58	+29	−16	−8

[a]The tensor components are in ppm and errors are estimated ±2 ppm.
[b]The plus and minus signs describe the high- and low-frequency peaks in each J-coupled doublet, respectively.

As stated in the theory section, the dipolar interaction manifests itself in the intensity distribution of each individual J-coupled sideband pattern. In Fig. 1 spinning sidebands associated with two isotropic doublets correspond to four different powder patterns, which are the four subspectra in the dipolar spectrum of a homonuclear spin pair. From the relative intensities of these spinning sidebands, all 12 principal components of the four effective dipolar/chemical shift tensors are readily calculated using the procedure of Herzfeld and Berger (19). Results are summarized in Table 1. Differences between corresponding principal components due to two relevant subspectra at each ^{31}P nucleus, $\Delta T_i = T_i^+ - T_i^-$ (i = 1,2,3), are also given in Table 1.

From the results shown in Table 1, the anisotropy of the dipolar subspectrum, defined as $|T_1 - T_3|$, is larger for the low-frequency peak of the P1 doublet than for the high-frequency one. This indicates that the absolute sign of the J coupling constant is negative (11). The anisotropies of the dipolar subspectra for the P2 doublet are in an opposite order, since the anisotropy is *negative* at P2, i.e., $|T_1 - T_{iso}| > |T_3 - T_{iso}|$, again confirming a negative ^1J(P,P). This is in agreement with the general observations and theoretical calculations of the sign of ^{31}P–^{31}P one-bond J couplings (23, 24).

The crystal structure of compound **1** indicates that, to a good approximation, the molecule has a mirror plane containing the P—P bond. As shown later, the excellent agreement between the observed powder line shape and the calculated spectrum supports this assumption. This element of molecular pseudo-symmetry requires that one of the principal axes for each of the ^{31}P shielding tensors be perpendicular to the mirror plane, and therefore perpendicular to the dipolar vector. In this case, only one angle is then required to specify the other two principal axes in the approximate mirror plane.

Given that the four subspectra contain a total of 12 effec-

TABLE 2. Principal components[a] and orientations of ^{31}P chemical shift tensors in **1**

Phosphorus	δ_{iso}	δ_{11}	δ_{22}	δ_{33}	$\Delta\delta$[b]	η[c]	θ[d]
P1	75.8	129	122	−25	154	0.07	10°
P2	52.0	190	25	−54	244	0.58	80°

[a] All principal components are in ppm and estimated errors are ±2 ppm.
[b] $\Delta\delta = |\delta_{11} - \delta_{33}|$.
[c] $\eta = (\delta_{11} - \delta_{22})/(\delta_{iso} - \delta_{33})$ for P1 and $\eta = (\delta_{22} - \delta_{33})/(\delta_{11} - \delta_{iso})$ for P2.
[d] θ is the angle between δ_{33} and the dipolar vector and the estimated error is less than ±5°.

tive principal components, we then have enough information to solve all ten remaining unknowns in this system: they are the six shielding tensorial elements for the two ^{31}P nuclei, one isotropic J coupling constant, one effective dipolar coupling constant, and two angles that specify the orientation of the dipolar vector in the principal axis system of the two ^{31}P shielding tensors.

We indicated in the theory section that the difference between effective tensor components of two subspectra along the principal direction perpendicular to the dipolar vector gives directly the sum of the effective dipolar coupling constant and the isotropic J coupling constant. From the data given in Table 1 we readily deduced that δ_{11} of P1 and δ_{22} of P2 are perpendicular to the molecular mirror plane respectively and that the effective dipolar coupling constant is $R_{eff} = 1459 \pm 162$ Hz. Substituting T_i ($i = 1,2,3$) listed in Table 1 and the above R_{eff} into eq. [3], the chemical shift tensor components and their orientations were obtained. Our calculations yield the following principal components for the chemical shift tensors: at P1, $\delta_{11} = 127$ ppm, $\delta_{22} = 124$ ppm, $\delta_{33} = -24$ ppm, and at P2, $\delta_{11} = 192$ ppm, $\delta_{22} = 25$ ppm, $\delta_{33} = -62$ ppm. The standard errors in these values were estimated to be ±2 ppm. Also, the calculations indicate that the angle between δ_{22} of P1 and the dipolar vector is 72° ± 10° while the angle between δ_{33} of P2 and the dipolar vector is 67° ± 10°. Equation [4] was also used for the above calculation and almost identical results were obtained within experimental error, indicating that the condition of $|\nu_{jj} - \nu_{kk}| \gg R_{eff}$ is valid in the present case where ν_{jj} and ν_{kk} describe the two principal components in the pseudo-mirror plane.

Analysis of the static spectrum

To examine the validity of the above calculations, i.e., to test the assumption that the ^{31}P spin pair in **1** can be treated as a homonuclear AX spin system, we performed computer simulation of the static powder line shape for a homonuclear AB spin pair, based upon the exact solution of four transitions in such a spin system (10). Although it is difficult to infer second-order (AB) character from magic angle spinning sidebands it should be readily apparent from static powder line shapes (10). Data calculated from the slow MAS spectrum were used as initial input for the simulation and they were further refined by comparing the observed powder line shape with the simulated spectrum. The final best-fit parameters for two ^{31}P chemical shift tensors are given in Table 2. The effective dipolar coupling constant was adjusted to be $R_{eff} = 1600 \pm 162$ Hz. This observed dipolar coupling constant is somewhat smaller than expected from the X-ray bond length considerations, $R_{DD} = 1770$ Hz. There are two possible reasons for such a decrease in the effective dipolar coupling constant. First, motional averaging may reduce the dipolar coupling constant. Second, there may be anisotropy in the indirect spin–spin interaction, ΔJ (see eq. [2]). If no motional correction is taken into account, the anisotropy in J is 510 ± 486 Hz assuming that R_{eff} is of the same sign as R_{DD}. Theoretical *ab initio* calculations of the $^1J(P,P)$ coupling constant in P_2H_4 indicated that the Fermi contact mechanism is dominant for the *cis* conformation (26, 27). Since the Fermi contact mechanism is isotropic, ΔJ is expected to be small in **1**. Therefore, the deviation of R_{eff} from R_{DD} is probably due to motional averaging.

It was found that the powder line-shape simulations were more sensitive to the orientation of the CS tensors than to the magnitude of the principal components. Therefore, in Table 2 all principal components are essentially the same as those obtained from the analysis of the slow MAS spectrum (except for δ_{33} of P2) while the orientations of the two CS tensors are modified by approximately 10°.

In a general heteronuclear AX spin system, any rotation of the CS tensor about the dipolar vector will give invariant powder line shapes in the static experiment, or intensity distribution of spinning sidebands in the slow MAS experiment. However, for a homonuclear spin pair, one has to be cautious about such a statement, since the relative orientation of the two CS tensors with respect to one another may become important. Obviously, two CS tensors are fixed in an AB spin pair to give a unique powder line shape. Even in the homonuclear AX approximation, it is still possible that changing the relative orientation between two CS tensors may break down the validity of the AX approximation, at least in some directions.

Within the constraints of the molecular symmetry, we have reduced the number of possible orientations to two for each ^{31}P CS tensor. Given that the angles between δ_{33} of the two CS tensors and the dipolar vector are known (θ in Table 2), there are still four possible ways to orient two CS tensors in the molecule, since both angles could be either positive or negative. All four possible orientations were put into our line-shape simulation program and a best fit is portrayed in Fig. 2. A schematic diagram illustrating the orientations of two ^{31}P CS tensors determined through this work is presented in Fig. 3. It places δ_{33} of P1 10° away from the internuclear vector towards the electron lone pair at P1, with δ_{22} lying almost in the S—P1—S plane. The determination of the CS tensor at P2 requires that δ_{11} lies in the mirror plane, being rotated by 10° from the P—P bond as indicated in Fig. 3. Similarly, δ_{33} of P2 is nearly in the plane containing the C—P2—C fragment. Simulated dipolar subspectra at each ^{31}P nucleus are also shown in Fig. 2 using the same parameters given in Table 2. The sum of the subspectra for P1 and P2 gives the powder line shape shown in Fig. 2(*b*). One does not observe any AB character in these calculated dipolar subspectra indicating that two ^{31}P nuclei in **1** could be treated as an AX system at $B_0 = 4.70$ T. One might at first expect some AB character for the homonuclear ^{31}P–^{31}P spin pair in **1**, since the difference between the isotropic chemical shifts of P1 and P2, $\Delta\delta_{iso} = 24$ ppm (ca. 1944 Hz at $B_0 = 4.70$ T), is comparable to the dipolar coupling constant between them, $R_{DD} = 1770$ Hz. However, one should realize that the ratio between $\Delta\delta_{iso}$ and R_{DD} is not the correct criterion for judg-

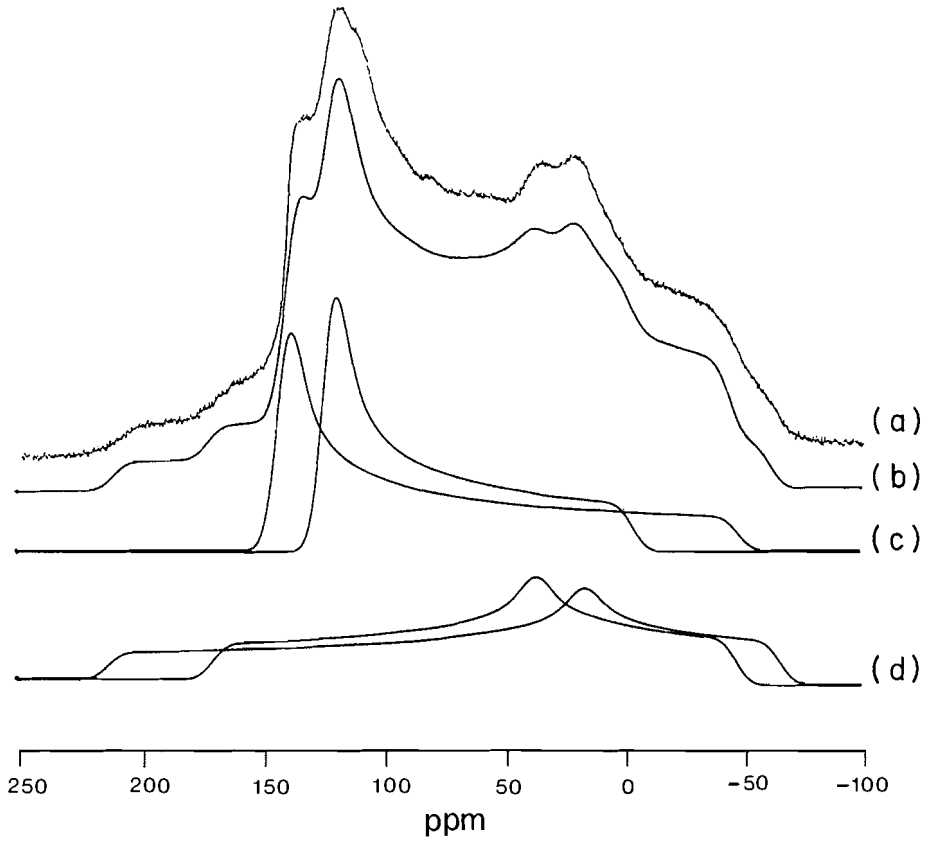

FIG. 2. (*a*) Experimental ^{31}P CP NMR spectrum of a static sample of **1**; (*b*) calculated ^{31}P NMR spectrum of **1** using the parameters in Table 2; (*c*) and (*d*) calculated dipolar subspectra for P1 and P2, respectively, using the same parameters as in (*b*).

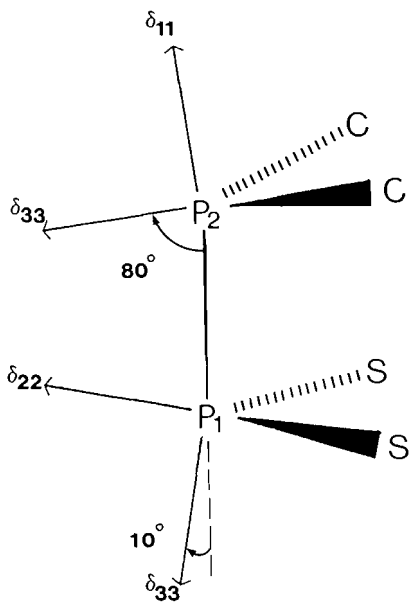

FIG. 3. A schematic diagram of the orientation of the two ^{31}P CS tensors in **1** obtained from an analysis of the ^{31}P NMR spectrum of a static powder sample. δ_{11}(P1) and δ_{22}(P2) are perpendicular to the approximate mirror plane of the molecule.

ing whether a dipolar coupled spin pair should be analyzed as an A_2, AB, or AX spin system. Because of the tensorial nature of chemical shifts in solids, one has to consider the relative orientation of the two CS tensors that make up the two-spin system. Although there is extensive overlap of the four dipolar subspectra in **1**, we found that at almost all orientations of $\boldsymbol{r}_{PP}$ in the applied magnetic field, $\boldsymbol{B}_0$, the AX approximation is valid. For example, if the magnetic field lies perpendicular to the molecular mirror plane, an orientation in which δ_{11} of P1 and δ_{22} of P2 are coincident, the chemical shift difference is about 100 ppm (ca. 8100 Hz at B_0 = 4.70 T). This is much greater than the dipolar coupling at this orientation, 800 Hz. A similar discussion also applies for the two orthogonal orientations. Extensive computer calculations of the ratio, $R/[\nu(P1) - \nu(P2)]$, as a function of orientation indicate that this ratio is less than 0.1 except when the polar angle is approximately 50° and the azimuthal angles are 50°–60° and 300°–310°. The actual contributions that these latter orientations make to the overall line shape are negligible.

We have ruled out the possible orientations of δ_{33} where two θ's have different signs, since it results in a similar, though inferior, fit. An alternative assignment occurs if both CS tensors are rotated simultaneously by 180° about the dipolar vector, giving two negative θ's. Although this gives an identical powder line shape, it will be argued below that the assignment shown in Fig. 3 is more reasonable.

The CS tensor of P1 shows near-axial symmetry ($\delta_{11} \approx \delta_{22}$), although there is no apparent local symmetry in the

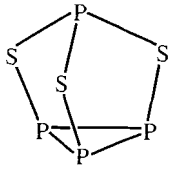
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 92.62.229.171 on 09/08/12
For personal use only.

molecular structure that would imply axial symmetry in the CS tensor. Since we have determined that δ_{11} of P1 is perpendicular to the molecular mirror plane, it is also perpendicular to the electron lone pair at P1. If we place δ_{33} of P1 10° away from the dipolar vector in the opposite direction to that shown in Fig. 3 (i.e., $\theta = -10°$), the direction of δ_{22} would lie nearly along the electron lone pair. Since it is unlikely that the chemical shielding would be the same along the lone pair (δ_{22} component) as in the direction perpendicular to the lone pair (δ_{11} component), this alternative assignment is discounted.

The results in Table 2 indicate that the ^{31}P shielding anisotropy of P2, $\Delta\delta = 244$ ppm, is much larger than the values reported in two related compounds containing a phosphorus–phosphorus single bond (8, 9) and by a theoretical calculation on P_2H_4 (28). The ^{31}P chemical shielding anisotropy in tetraphenyldiphosphine was also found to be relatively small ($\Delta\delta = 46$ ppm).[2] Another class of related compounds containing P(III) atoms are phosphines. Still, $\Delta\delta$ of P2 in **1** appears noticeably large compared with most of the reported values for the phosphines (ca. $\Delta\delta = 6$–85 ppm) (29). Additionally, the isotropic chemical shift of P2 in compound **1** is at a much lower field than the above-mentioned phospines and diphosphines. Although a large $\Delta\delta$ has been reported in a strained phosphirane (30), the shielding anisotropy at P2 shows an opposite trend and our data also deviate from the straight line in ref. 30. The large shielding anisotropy, $\Delta\delta$, and large isotropic shift at P2 in **1** result primarily from the significant deshielding in the δ_{11} direction, which is approximately perpendicular to the C—P—C plane. Probably, the unusual *cis* conformation of the adjacent electron lone pairs in **1** is responsible for the relatively large chemical shift anisotropy at P2. However, given the complicated nature of the anisotropic chemical shift and lack of reliable theoretical calculations, ^{31}P chemical shielding tensors are far from being fully understood.

The ^{31}P CS tensors of several inorganic phosphorus–sulphur systems were investigated recently by high-resolution solid state NMR (31–35). In these systems, $\Delta\delta$ of the $PS_{3/2}$ unit varies from 110 to 340 ppm. An attempt has been made to correlate the ^{31}P chemical shift anisotropy with the distortion from local C_{3v} symmetry (33). However, using additional data from a more recent study (34), the previous simple correlation was found to be invalid (35). With P1 bonded to two sulphur atoms and one phosphorus atom, its chemical shift anisotropy, $\Delta\delta = 154$ ppm, is smaller than the value, $\Delta\delta = 257$ ppm, found for the apical ^{31}P in P_4S_3, **2**; the two P—S bonds in **1** are much longer than the P—S bonds in P_4S_3.

It would be more informative if we were able to compare the orientation of the ^{31}P CS tensor in **1** with related compounds containing P—S single bonds. Unfortunately, only in P_4S_3 have the orientations of the CS tensor been determined by a single crystal study (36). In this case the least shielded component of the apical ^{31}P and the most shielded component of the basal ^{31}P are nearly parallel to the C_3 axis of the molecule. In the other systems, local symmetry was used to tentatively assign the unique axis in the CS tensors. Comparison of the principal values and their orientations of the ^{31}P CS tensor between the apical phosphorus atom in P_4S_3 and P1 in **1** reveals significant difference between these two ^{31}P CS tensors, although the difference in their isotropic chemical shift is relatively small. The unique component in the apical phosphorus atom in P_4S_3 corresponds to the least shielded direction while it is the most shielded in **1**. We are not in a position to give a complete explanation of the ^{31}P shielding anisotropies measured in this study, because of the limited data available and their complexity.



2

Conclusions

We have demonstrated that ^{31}P dipolar NMR spectroscopy is an invaluable alternative to single crystal NMR in providing a full characterization of the ^{31}P chemical shielding tensor in **1**. It is advantageous to combine the MAS experiment with the static (non-spinning) experiment in dealing with a dipolar coupled homonuclear ^{31}P spin pair, especially when there is *J* coupling between the two nuclei. This is because (*a*) resolved *J*-coupled sideband patterns in the MAS spectrum make it possible to separate different dipolar subspectra and to provide a good starting point for interpreting the static powder line shape, and (*b*) the static powder line shape contains all the information on the dipolar interaction and the shielding tensors, and thus serves as a test for the AX approximation that is usually used for analyzing the dipolar subspectra in the MAS experiment.

The CS tensor at P1 in **1** is nearly axially symmetric with the most shielded component δ_{33} as the unique direction. Significant deshielding is observed at P2 along the δ_{11} direction, which describes a direction perpendicular to the C—P—C plane. This deshielding effect results in a large anisotropy at P2, $\Delta\delta = 244$ ppm, compared with related compounds. The shielding anisotropy at P1 is 154 ppm and falls in the normal range reported for related compounds containing the P—S single bonds. Clearly, a complete understanding of the ^{31}P chemical shielding anisotropy still needs far more work from both experimentalists and theoreticians.

Acknowledgements

This research was supported by operating and equipment grants (R.E.W.) and a scholarship (W.P.P.) provided by the Natural Sciences and Engineering Research Council of Canada. We thank Dr. A. Berger and Dr. Kentgens for providing software to aid in the fitting of slow-spinning MAS spectra. Also, G.B. acknowledges financial support by the C.N.R. of Italy.

This paper is dedicated to Dr. Zdenek (Denny) Valenta on the occasion of his 65th birthday

O. Boyé, A. Brossi, H. J. C. Yeh, E. Hamel, B. Wegrzynski, and V. Toome. Can. J. Chem. **70**, 1237 (1992).

Trimethoxy-substituted dihydrodibenzocycloheptenes **4–7**, required for a structure–activity study measuring the inhibition of tubulin polymerization in vitro, were synthesized by four different routes: (1) Synthesis of **4** was achieved from 2,3-dimethoxybenzaldehyde via biphenyl aldehyde **17**, chain lengthening to propionic acid **20**, acid-catalyzed cyclization toward ketone **21**, and removal of the carbonyl group. (2) Compound **5** was obtained by eliminating the sterically most hindered methoxy group in **25** or **26** by metal reduction in alcohol. (3) Compound **6** was prepared from biphenyl aldehyde **34** obtained by Grignard reaction on oxazoline **32**. (4) Compound **7** was obtained by reductive deoxygenation of the tetrazolyl ether derivative of *N*-acetylcolchinol **41**. The key role of the aromatic oxygen atoms in colchicine and allo congeners as points of interaction with the colchicine binding site on tubulin was demonstrated by the lack of inhibitory activity of compounds **4–7**. Optically active 5-acetamide **8***a*,*b* isomers of *N*-acetylcolchinyl methyl ether **2** were obtained after chemical resolution of amine **47**. The absolute configuration of the optical isomers **47***a*,*b* and **8***a*,*b* was determined by ^{1}H NMR and CD measurements. These compounds were found inactive as inhibitors of tubulin polymerization.
