[c]All the non-hydrogen atoms were refined anisotropically. For **1** all the methylene hydrogens were fixed in calculated positions with idealized angles (d_{C-H} = 1.08 Å) and hydrogen atoms on the hetero atoms were located from the difference map and fixed. For **2** all hydrogen atom positions were calculated (d_{C-H} = 1.08 Å).

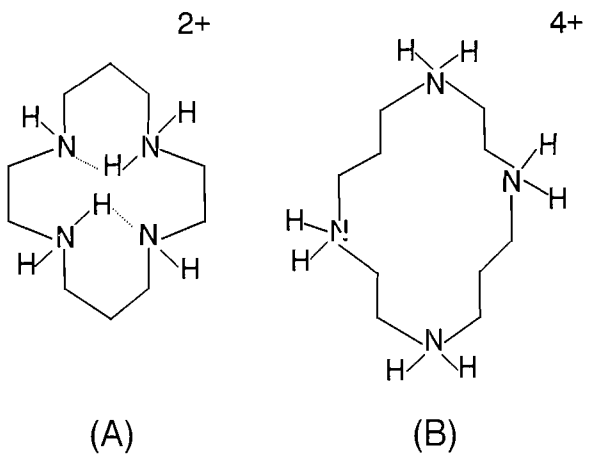

FIG. 1. Conformation of di (A) and tetra (B) cations of cyclam and intramolecular hydrogen bonding in the dication.

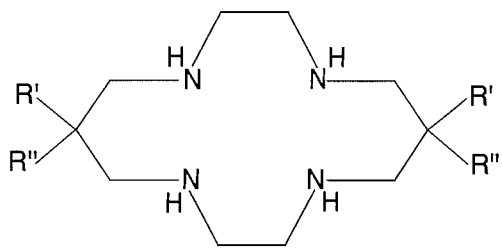

capable of promoting network hydrogen bonding and therefore of potential relevance in crystal engineering.

Experimental

$FeCl_3 \cdot 6H_2O$, $FeCl_2 \cdot 4H_2O$, and concentrated HCl were purchased from Fisher Scientific Co., cyclam was purchased from

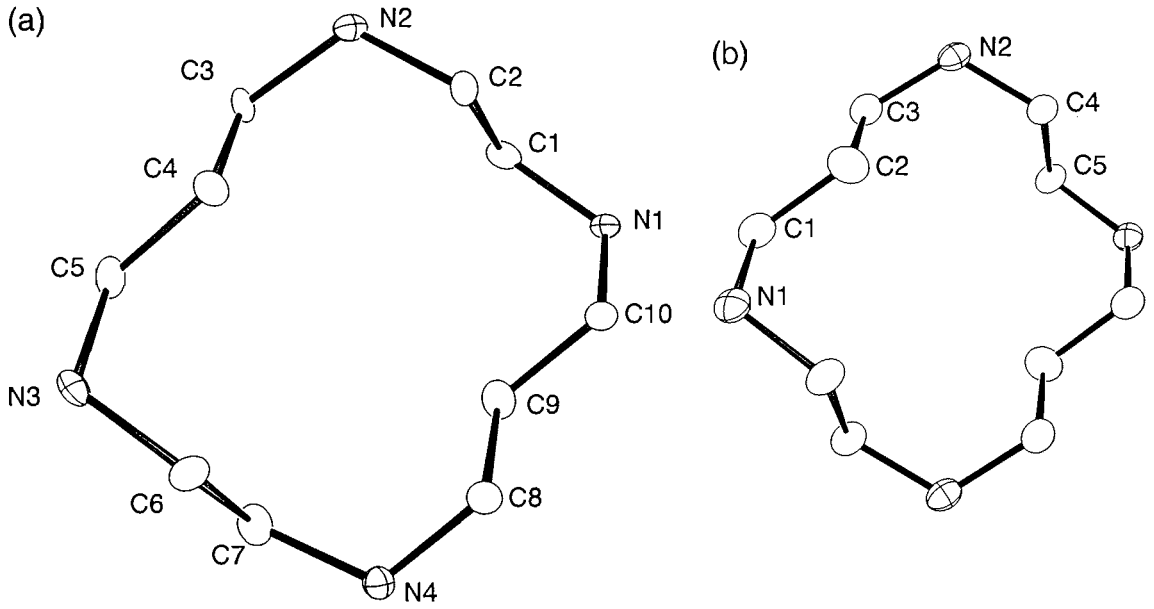

FIG. 2. ORTEP perspective views of the $[H_4(cyclam)]^{4+}$ cations in (*a*) **1** and (*b*) **2**.

Strem Chemicals, Inc., and trifluoroacetic acid was purchased from Aldrich Chemical Co. All reagents were used as received. Microanalysis was performed by Canadian Microanalytical Services Ltd., B.C. IR spectra were recorded on a Perkin–Elmer 1600 Series FTIR using the solid reflectance technique (KBr crystals). Melting points were recorded on a Fisher–John apparatus and were not corrected.

*Preparation of [H_4(cyclam)][$FeCl_5(OH_2)$][$Cl)_2$ (**1**)*

To a solution of 0.20 g (1.0 mmol) of $FeCl_2 \cdot 4H_2O$ in 20 mL of water, 0.20 g (1.0 mmol) of cyclam in 20 mL of aqueous ethanol (1:1) was added. Initially, a dark green precipitate was formed. However, within minutes it turned brown in the presence of air. Concentrated HCl was added dropwise under stirring to dissolve this precipitate and the resulting bright yellow solution, approximately 4 M in HCl, was allowed to evaporate and afforded large orange-red crystals (0.42 g, 0.80 mmol, 80%) of **1**. Melting point: slowly darkens above 195°C and decomposes at 250°C. IR, cm^{-1}: 3125 (O-H, broad), 3024 (C-H, broad), 2674 (-NH_2-$^+$ cation), sharp peaks at 1634 (N-H), 1570, 1469, 1373, 1298, 1199, 1155, 1128, 1078, 1030, 1007, 952, 910, 850, 816, and 742. Anal. calcd. for $FeCl_7ON_4C_{10}H_{30}$: C 22.81, H 5.70, N 10.64; found: C 22.95, H 5.59, N 10.61.

1 can also be obtained following an identical procedure except that $FeCl_2 \cdot 4H_2O$ is replaced with $FeCl_3 \cdot 6H_2O$.

*Preparation of [H_4(cyclam)][$CF_3COO]_4$ (**2**)*

Cyclam (0.100 g, 0.499 mmol) was dissolved in 15 mL of trifluoroacetic acid. The resulting solution was allowed to slowly evaporate at room temperature and afforded large colourless crystals of **2**. Yield: 0.310 g (0.472 mmol, 94.6%). **2** melts sharply at 147°C into a clear liquid with decomposition. IR, cm^{-1}: 3307, 3146 (N-H, sharp), 2936 (C-H), 2534 (NH_2^+ cation), 1795, 1734 (C=O), 1654 (N-H), 1580, 1453, 1355, 1307, 1258, 1202, 1147, 1052, 940, 851, 750.

X-ray structure determinations

Single crystals suitable for X-ray crystallography were obtained directly from the reaction mixtures. Suitable crystals were mounted and sealed in thin-walled glass capillaries and diffraction data were collected on an Enraf–Nonius CAD4 diffractometer. The experimental parameters used for the data collection and structure refinement are presented in Table 1. The function $R = \Sigma(F_o - F_c)/(F_o)$, was minimized and values of $Rw = [(\Sigma w(F_o - F_c)^2/\Sigma wF_o^2]^{1/2}$ and GOF = $[\Sigma w(F_o - F_c)^2/$(no. of reflns. − no. of parameters)$]^{1/2}$ are also presented. Weights based on counting statistics were used, the weight modifier, k, being determined experimentally via statistical analysis of the variation in intensity of the standard reflections. Final fractional coordinates and selected interatomic distances and angles are presented in Tables 2–5.[3] The only unusual aspects of structure refinement concern **2**. The CF_3 groups were found to be disordered. It was possible to refine two independent CF_3 moieties for each anion (sets A and B, each with site occupancy factors of 0.5 and identified as such in Table 4). The fluorine atoms exhibited high thermal motion, presumably accounting for the relatively high R values obtained, although thermal motion was observed to be low elsewhere, particularly within the cation. The $[H_4(cyclam)]^{4+}$ in **2** was found to lie around a crystallographic inversion center (1, 1/2, 0) whereas the CF_3COO^- anions were located in general positions. All crystallographic calculations were effected using the PC version of the NRCVAX suite of programs (23). Neutral atom scattering factors and corrections for anomalous dispersion were taken from ref. 24. To determine the enantiomorph for **1**, data were collected from −12, to 12 in h, −2 to 15 in k, and −17 to 17 in l, the merging R value of equivalent intensities being 0.014. The enantiomorph was determined using the Rogers method (25).

Results and discussion

Cyclam forms stable complexes with both the common and the uncommon oxidation states of 3*d*, 4*d*, and 5*d* transition metal ions (9–12, 26) and Fe(II) and Fe(III) complexes of cyclam are known (27, 28). However, solvent and acid concentration of the reaction media play very important roles and, under the conditions we employed, formation

[3]Listings of complete atom positional parameters and anisotropic thermal parameters for **1** and **2** (4 pages) and observed and calculated structure factors for **1** and **2** (19 pages) may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of atom positional parameters have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

of $[H_4(cyclam)]^{4+}$ and $[FeCl_5(OH_2)]^{2-}$ is favoured over Fe(cyclam) moieties. Indeed, **1** is not the only product that can be recrystallized from the crude reaction mixture.[4] Under other reaction conditions oxidative dehydrogenation of the ligand can occur and both monomeric and dimeric Fe(II) complexes containing unsaturated ligands have been isolated (29, 30). A reasonable mechanism under the conditions we employed is that cyclam, being a strong base (31), converts hydrolyzed $FeCl_2$ to ferrous hydroxide, which in turn undergoes aerial oxidation to form ferric hydroxide. Subsequent addition to acid results in the formation of the tetracation, $[H_4(cyclam)]^{4+}$, and the complex dianion, aquapentachloroferrate(III), $[FeCl_5(OH_2)]^{2-}$. Salts of both the di- and tetracations of cyclam and its derivatives have been reported (20, 31, 32); However, only the perchlorate salt of the dication, $[H_2(cyclam)]^{+2}$, has been characterized by X-ray crystallography (31). Another relevant macrocyclic cation that has been characterized by X-ray crystallography is the hexacyanoferrate(III) salt of the tetracation $[H_4(\mathbf{3})]^{+4}$ (**3** = 6,13-dimethyl-1,4,8,11-tetraazacyclotetradecane-6,13-diamine) (20). In both $[H_2(cyclam)]^{2+}$ and $[H_4(\mathbf{3})]^{4+}$ only two of the four nitrogen atoms of the macrocyclic rings (*trans* to each other) are protonated, with the two primary amino groups being protonated in the latter. The ethylene bridges adopt a *gauche* and the propylene bridges adopt a *syn* conformation. Hence, the 14-membered macrocyclic rings in both these cations adopt a conformation in which the nitrogen atoms are endodentate. Such a conformation is also enhanced by strong intramolecular hydrogen bonding (Fig. 1).

An ORTEP (33) diagram of $[H_4(cyclam)]^{4+}$ is presented in Fig. 2*a* and a portion of the polymeric chain in Fig. 3. The atomic coordinates and important lengths and angles are

[4] If the ratio of water and ethanol used for recrystallization is different, a hydrate of **1**, $[H_4(cyclam)][FeCl_5(OH_2)]Cl_2 \cdot H_2O$, is obtained. The structure of this compound has also been solved: space group triclinic, $P\bar{1}$, a = 7.8092(11), b = 10.1643(18), c = 15.001(4) Å, α = 102.30(3)°, β = 94.21(4)°, γ = 106.08(2)°, V = 1106.7(4) Å^3, Z = 2, R = 0.033, Rw = 0.040 for 2505 independent observed reflections. Full details will be published elsewhere.

presented in Tables 2 and 3, respectively. The salient feature of the structure concerns the conformation adopted by $[H_4(cyclam)]^{4+}$, which is dramatically different from that adopted by cyclam and $[H_2(cyclam)]^{2+}$. $[H_4(cyclam)]^{+4}$ adapts a conformation such that the ammonium centers are positioned as far away as possible from each other (presumably to minimize electrostatic repulsions). As a result, the ethylene bridges adopt a *transoid* conformation and the propylene bridges, adapt a "W" ($^{N}\backslash_{C}/^{C}\backslash_{C}/^{N}$) conformation. Thus, the endodentate orientation (31) of the nitrogens observed in the dication, $[H_2(cyclam)]^{+2}$, is lost in the tetracation, $[H_4(cyclam)]^{+4}$. The consequence of this geometry is that the nitrogen hydrogen atoms are now predisposed towards network interionic hydrogen bonding. In the case of **1** this facilitates the formation of a one-dimensional polymer with the counterions, two chlorides and an aquapentachloro-ferrate(III).

The network hydrogen bonding is illustrated in Fig. 3. This view was generated by assuming that significant hydrogen bonding occurs when Cl....X (X = O,N) distances are <3.2 Å when corresponding Cl....H distances are <2.3 Å. There are numerous weak interionic interactions that were considered to be insignificant in the context of determining the nature of the networking. Figure 3 illustrates how the $[FeCl_5(OH_2)]^{2-}$ anion and one chloride anion are involved in hydrogen bonding such that they bridge adjacent cations. The remaining chloride ion, Cl7, is terminally hydrogen bonded to the cation through H31. The closest interionic contacts (Cl....O and Cl....N) vary in the range 3.044(6)–3.190(6) Å and are at the short end of the range found in other amine hydrochloride salts (34–36). Hydrogen bonds between $[FeCl_5(OH_2)]^{2-}$ ions, with an average O....Cl distance of 3.20(4) Å, were observed in the crystal structures of $M_2[FeCl_5(OH_2)]$ (M = Cs^+, NH_4^+, and OH_3^+) (37–39);

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

however, these hydrogen bonds are interanionic. The N-H...Cl and O-H...Cl distances in $(NH_4)_2[FeCl_5(OH_2)]$ and $(OH_3)_2[FeCl_5(OH_2)]$ are 3.53(4) and 3.306(8) Å, respectively. The nature of the network hydrogen bonding, which is a direct consequence of the ability of $H_4(cyclam)^{4+}$ to hydrogen bond, makes the two directional senses of the polymeric network geometrically and physically different. This direction of the crystal is therefore polar and hence **1** crystallizes in a polar space group.

The aquapentachloroferrate(III) anion is well known (40). This study agrees well with the earlier X-ray crystallographic reports (36–39). The Fe atom exists in a distorted octahedral environment (Fig. 4). The distortion presumably results from repulsive interactions between the chlorines, which would be expected to be greater than those between the chlorine atoms and water. This is reflected in the Cl—Fe—Cl and O—Fe—Cl angles (see Table 3). The Fe—Cl distances are not equivalent. Specifically, the Fe—Cl

a: $2 - x$, $1 - y$, $-z$
b: $1 + x$, y, z
c: $1 - x$, $0.5 + y$, $0.5 - z$
d: $1 - x$, $-0.5 + y$, $0.5 - z$

bond that is *trans* to the water molecule is consistently shorter than the other four Fe—Cl distances, presumably a manifestation of *trans* influence.

Compound **2** was crystallized directly from a solution of cyclam in trifluoroacetic acid. An ORTEP (33) diagram of the $[H_4(cyclam)]^{4+}$ cation is presented in Fig. 2*b* and a portion of the polymeric chain in Fig. 5. The atomic coordinates and important bond lengths and angles are presented in Tables 4 and 5, respectively. The geometry of the cation is almost identical to that of the cation in **1** and network hydrogen bonding is once again observed. As was observed in **1**, not all of the anions are involved in the network but the networking is less complex. There are two pairs of crystallographically equivalent anions. One pair of CF_3COO^- anions forms terminal hydrogen bonds through one oxygen atom to the cation (O12....N2, 2.681(4) Å). The other pair of CF_3COO^- moieties bridges three separate cations through both oxygen atoms (O1....N2, 2.797(4) Å; O1....N1 of a second cation, 2.830(4) Å; and O2....N1 of a third cation, 2.742(4) Å). The net result is a two-dimensional network that contains inversion centers. **2** therefore crystallizes in a centrosymmetric space group.

To conclude, under the highly acidic conditions employed in this study, formation of $[H_4(cyclam)]^{4+}$ is facilitated. $[H_4(cyclam)]^{4+}$ adopts an exodentate conformation that favours network hydrogen bonding and, in the case of **1**, a polar one-dimensional network of hydrogen bonds. Materials that are polar in their crystalline state have been shown to possess a number of useful and interesting physical properties, particularly as SHG-active materials. $[H_4(cyclam)]^{4+}$ therefore has potential relevance as a bridging group in crystal engineering of SHG-active materials.

Stereoisomerism of oxotrichlorobis(triphenylphosphine)rhenium(V), $ReOCl_3(PPh_3)_2$: a reinvestigation

ANNE-MARIE LEBUIS AND ANDRÉ L. BEAUCHAMP[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Québec), Canada H3C 3J7

Received August 26, 1992

ANNE-MARIE LEBUIS and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **71**, 441 (1993).

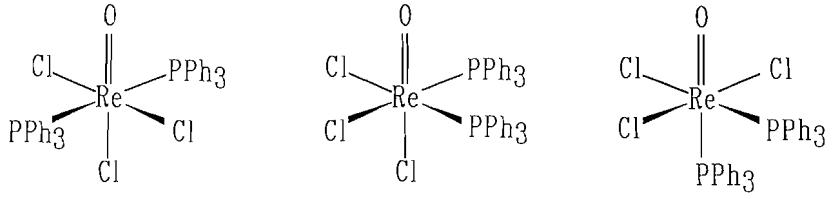
The various preparative procedures described in the literature for $ReOCl_3(PPh_3)_2$ were repeated. The standard methods were found to yield a yellow triclinic material ($P\bar{1}$, a = 11.793, b = 14.300, c = 16.422 Å, α = 64.04°, β = 84.31°, γ = 87.32°, R = 0.064). The unit cell contains three discrete monomeric molecules with the *trans*-bis(phosphine) configuration, one of which has its Cl-Re=O unit disordered over two opposite directions. Recrystallization in CH_2Cl_2 yielded crystals of the bright green monoclinic polymorph ($C2/c$, a = 24.347, b = 9.604, c = 15.666 Å, β = 116.77°, R = 0.025) containing the same monomeric molecule, but with a different conformation of the PPh_3 ligands and a different packing pattern. These two polymorphs actually correspond to "isomers" 1 and 2 described by Johnson, Lock, and Wilkinson in 1964. Attempts to prepare their third "isomer" yielded powders containing $ReOCl_3(PPh_3)_2$ (green polymorph) and $ReNCl_2(PPh_3)_2$. The IR and ^{31}P NMR spectra of these samples are discussed.

ANNE-MARIE LEBUIS et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **71**, 441 (1993).

Les différentes méthodes de préparation décrites dans la litterature pour $ReOCl_3(PPh_3)_2$ ont été répétées. Les méthodes courantes conduisent à un produit triclinique jaune ($P\bar{1}$, a = 11,793, b = 14,300, c = 16,422 Å, α = 64,04°, β = 84,31°, γ = 87,32°, R = 0,064). La maille élémentaire renferme trois molécules individuelles ayant une configuration *trans*-bis(phosphine), dont l'une possède un motif Cl-Re=O désordonné selon deux directions opposées. La recristallisation dans CH_2Cl_2 donne des cristaux du polymorphe monoclinique vert brillant ($C2/c$, a = 24,347, b = 9,604, c = 15,666 Å, β = 116,77°, R = 0,025) renfermant la même molécule monomère, mais la conformation des ligands PPh_3 et l'empilement cristallin sont différents. Ces deux polymorphes correspondent aux «isomères» 1 et 2 décrits par Johnson, Lock et Wilkinson en 1964. Des tentatives pour préparer leur troisième «isomère» ont conduit à des poudres contenant $ReOCl_3(PPh_3)_2$ (polymorphe vert) et $ReNCl_2(PPh_3)_2$. Les spectres IR et RMN ^{31}P de ces échantillons sont discutés.

Introduction

$ReOCl_3(PPh_3)_2$ is extensively used as a starting compound in the coordination chemistry of rhenium (1). It was first identified as a yellow material in a short paper by Lock and Wilkinson in 1962 (2). Shortly after, Chatt and Rowe (3, 4) proposed the *mer-trans* structure **A** for this compound on the basis of the dipole moment. In a more detailed report, Johnson, Lock, and Wilkinson (5) described three varieties of $ReOCl_3(PPh_3)_2$, which they labelled "isomers" 1, 2, and 3.[2] They could be differentiated by their color and Re=O stretching band in infrared, but no structure was assigned to any of these materials. More recently, tested procedures were proposed to prepare the yellow complex (6, 7). The products obtained by these methods correspond to the compound studied by Chatt and Rowe (4) and to "isomer" 1 of Johnson *et al.* (5), but its stereochemistry is not explicitly identified. Hence, although the existence of stereoisomers for $ReOCl_3(PPh_3)_2$ has been mentioned (5, 6, 8), this question has apparently not yet received a satisfactory answer.



The present paper reports X-ray diffraction and ^{31}P NMR results showing that two distinct varieties of $ReOCl_3(PPh_3)_2$ indeed exist in the solid state, but that they are polymorphs of the same compound with configuration **A**. No evidence could be found for configurations **B** and **C**.

Experimental section

Reactants and methods

$KReO_4$ and PPh_3 were used as received from Aldrich. Samples of $ReOCl_3(PPh_3)_2$ were prepared by the various methods available in the literature (4–7). $ReNCl_2(PPh_3)_2$ and $ReOCl_3(PPh_3)(OPPh_3)$ were synthesized by published methods (9, 10) and checked by IR and ^1H and ^{31}P NMR spectroscopies.

IR spectra (4000–250 cm^{-1}) were recorded as CsI pellets on a Perkin–Elmer 783 spectrophotometer. UV–visible spectra (220–750 nm) were obtained on a Varian Instruments DMS 100S spec-

$^aR = \Sigma| |F_o| - |F_c| |/\Sigma|F_o|$; $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$; $S = [\Sigma w(|F_o| - |F_c|)^2/(n - v)]^{1/2}$.

trophotometer. ^{1}H NMR spectra (in CD_2Cl_2) were recorded at 300 MHz on a Varian VXR-300 spectrometer. The residual solvent signal (δ 5.320 ppm) served as internal standard. The ^{31}P solution and solid-state spectra were recorded at 121.42 MHz with the same instrument. For the solids, the relaxation delays and spin rates were respectively 10 s and 2.5 kHz for $ReNCl_2(PPh_3)_2$, 4s and 4 kHz for the other samples. The spectra were referenced to external D_3PO_4 85% in D_2O (δ 0 ppm). X-ray powder patterns were taken with a Debye–Scherrer camera (radius 57.3 mm) using Ni-filtered CuKα̃ radiation (1.54178 Å).

X-ray work — monoclinic polymorph

Bright green, roughly hexagonal, platelets were obtained by recrystallization of the yellow powder in CH_2Cl_2. The crystallographic work was done at room temperature on an Enraf–Nonius CAD-4 diffractometer using graphite monochromatized MoKα̃ radiation. The reduced cell (a_r = 9.63, b_r = 13.10, c_r = 15.71 Å, α_r = 63.44°, β_r = 71.95°, γ_r = 68.48°) was determined from 15 centered reflections located from a preliminary polaroid photograph and checked with long-exposure axial photographs about the three axes. A Laue mirror plane perpendicular to the a_r axis and the Niggli parameters suggested a non-primitive monoclinic lattice. The reduced cell was first transformed to an I-monoclinic cell with matrix 27 (11), and then the usual transformation to a conventional C-centered cell ($\boldsymbol{a}_C = \boldsymbol{a}_I + \boldsymbol{c}_I$, $\boldsymbol{b}_C = \boldsymbol{b}_I$, $\boldsymbol{c}_C = -\boldsymbol{a}_I$) was applied. As expected, the a_r axis, for which a Laue mirror had been observed, has now become the unique b axis of the monoclinic cell. The accurate cell parameters given in Table 1 were obtained by refinement on a new set of 25 centered high-angle reflections ($20° < 2\theta < 22°$).

Intensity data ($2\theta \leq 50°$) were collected by the ω scan technique over a range $\Delta\omega = (1.00 + 0.35 \tan\theta)°$. Option FLAT was used to adjust the ψ angle so that absorption is minimized for the plate-shaped crystal. Orientation was monitored every 200 measurements and intensity was checked every hour with seven standard reflections. Intensity fluctuations remained within ±1.2%. A total of 5704 reflections with $h + k = 2n$ were measured in octants hkl, $h\bar{k}l$, $hk\bar{l}$, and $h\bar{k}\bar{l}$. The data were corrected for absorption (Gaussian integration, 10 × 10 × 10 grid). Averaging of the equivalent $+k/-k$ pairs (R_{av} = 0.037) yielded a set of 2881 unique reflections, of which 2109 with $I \geq 3.0\ \sigma(I)$ were retained for structure determination and refinement. The usual corrections for the effects of Lorentz and polarization were finally applied.

Monoclinic Laue symmetry and systematic absences (hkl, $h + k \neq 2n$; $h0l$, $l \neq 2n$) were consistent with space groups Cc and $C2/c$. The structure was solved in the centric $C2/c$ space group by the heavy-atom method. The Re atom was located from a Patterson map and all other non-hydrogen atoms were found from successive difference Fourier (ΔF) maps. Refinement was done by full-matrix least-squares procedures. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with weights w based on counting statistics ($w = 1/\sigma^2(F) + 0.001\ F^2$). The non-hydrogen atoms were refined anisotropically. Hydrogens were fixed at idealized positions (C—H = 0.95 Å, U = 0.065 Å^2). Their parameters were not refined, but the coordinates were recalculated after each cycle. There

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

were no indications, such as high thermal motion or large residuals in the final ΔF map, to suggest that the space group could be *Cc* instead of $C2/c$.

X-ray work — triclinic polymorph

Suitable crystals of this yellow polymorph were not readily obtained. Conversion of the raw material to the monoclinic polymorph occurred in polar solvents (acetone, CH_2Cl_2, THF). Benzene reproducibly yielded the yellow polymorph, but the crystals obtained were very small and often twinned. Slow vapour diffusion of light petroleum ether into a saturated benzene solution gave the best results. The specimen used for X-ray work was the largest available that was not twinned. A set of precession and cone-axis photographs indicated a triclinic unit cell and provided starting cell parameters. The rest of the X-ray work was carried out on a Syntex $P\bar{1}$ diffractometer using graphite monochromatized MoK$\bar{\alpha}$ radiation. The reduced cell obtained as above from 15 reflections was identical to the one deduced from precession work. Lattices of symmetry higher than triclinic were ruled out by the Niggli parameters. The final cell parameters given in Table 1 were obtained by refinement on a new set of 15 centered reflections in the range $18° < 2\theta < 24°$.

Intensity data ($2\theta \leq 45°$) were collected at room temperature by the $\omega/2\theta$ scan technique over a range $\Delta\omega = (0.90 + 0.35 \tan\theta)°$. Three standard reflections checked every 75 measurements showed fluctuations within ±3.0% during data collection. A total of 6498 *hkl*, $h\bar{k}l$, $hk\bar{l}$, and $h\bar{k}\bar{l}$ reflections was measured, of which 2021 with $I \geq 3.0\,\sigma(I)$ were retained for structure determination and refinement. The data were corrected as above for the effects of absorption, Lorentz, and polarization.

The structure was solved in the centric space group $P\bar{1}$ by the heavy-atom method. Structure resolution was not straightforward, since the Re positions introduced pseudosymmetry that could be removed only at a late stage in the refinement. Since the unit cell contained three formula units, at least two independent types of Re atoms had to be present. The Patterson map readily revealed the positions of a Re(1) atom in special position (0, 0, 0) and a pair of Re(2) atoms in general positions near (1/3, 1/3, 1/3) and 2/3, 2/3, 2/3). The Cl and P atoms could be located from a ΔF map, but they did not remove pseudosymmetry. The nine independent phenyl rings were laboriously extracted from the overlapping images in a series of ΔF maps. It is only after this model was isotropically refined that Re could be refined anisotropically and clear features emerged for the oxygens.

Re(1) being situated on an inversion center, the necessarily noncentric $ReOCl_3(PPh_3)_2$ molecule had to be disordered. However, no evidence of disorder was found in the phosphine and the Cl(12) atom *cis* to oxygen. When full occupancy was assumed for the *trans* Cl(11) position extracted from the ΔF map, an abnormally high temperature factor was obtained and a new peak, closer to Re(1), appeared in the map. Thus, this region (and its centrosymmetry-related counterpart) had to be statistically occupied by oxygen and chlorine atoms, leading to two opposite orientations of the Cl(11)-Re(1)=O(1) bonds. However, there were no indications of disorder at Re(1) itself, which was kept at the origin. Since coalescence occurred when the O(1) and Cl(11) half-atoms were simultaneously refined, O(1) was fixed on the Re(1)-Cl(11) line at 1.66 Å from Re (the distance found in the monoclinic polymorph), and only Cl(11) was refined. In the other molecule, geometric constraints were not applied. The structure was refined by least-squares procedures as above: Re, Cl, and P anisotropically, remaining non-hydrogen atoms isotropically, hydrogens fixed. Although disorder was not detected for the molecule sitting in general position, the presence of a small amount of disorder in the $ReOCl_3$ plane cannot be totally ruled out, considering the limitations imposed by poor crystal quality.

The scattering factors used were those of Cromer and Liberman (12), except for hydrogen (13). Anomalous dispersion was included in structure factor calculations for Re, Cl, and P (14). The computer programs used are listed elsewhere (15). The refined coordinates for the non-hydrogen atoms are listed in Tables 2 and 3.[3]

Results and discussion

Wilkinson's "isomers" 1 and 2

Samples of $ReOCl_3(PPh_3)_2$ were prepared following the two tested methods described in Inorganic Synthesis (6, 7). The earlier procedures reported by Johnson *et al.* (5) and by Chatt and Rowe (4) were also repeated. These various runs allowed us to isolate in pure form a yellow triclinic and a bright green monoclinic material.

The product obtained by the standard methods consists of a yellow powder or microcrystalline solid. The approach used by Parshall *et al.* (7), which was adapted from Chatt and Rowe (4), consists of reacting Re_2O_7 or $KReO_4$ with excess PPh_3 in a HCl–ethanol mixture. Although some KCl is present if $KReO_4$ is used, it can be removed by washing with small amounts of water. In the method proposed by Johnson *et al.* (6), which corresponds to one of the approaches they

[3]The supplementary material includes a view of the unit cell of $ReNCl_2(PPh_3)_2$, *d*-spacings from powder patterns of $ReNCl_2(PPh_3)_2$, $ReOCl_3(PPh_3)_2$, and "isomer" 3, crystallographic results (lists of observed and calculated structure factor amplitudes, anisotropic thermal parameters, hydrogen coordinates, torsion angles, distances and angles in phosphine, and atom-to-plane distances for both structures) (59 pages). Complete set of data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Calculated powder patterns, stereoview of the unit cell, and tables of hydrogen atom coordinates and distances and angles in PPh_3 ligands have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[a]Fixed (see experimental section).

used to obtain their "isomer" 1 (5), $HReO_4$ is the source of rhenium and the reaction is carried out in acetic acid. The same product is also obtained by these authors by reacting $ReO(OEt)Cl_2(PPh_3)_2$ with HCl. All these methods were found to give good yields of the same yellow powder, identified by the strong Re=O stretching band at 969 cm^{-1} in infrared.

Yellow triclinic crystals were obtained when this material was recrystallized from benzene – petroleum ether. The X-ray work described hereafter shows that it contains monomeric molecules with the *mer-trans* configuration **A**. The yellow crystals and the powder have superimposable infrared spectra. As a further check that they are the same phase, the idealized X-ray powder pattern was calculated (16) from the refined coordinates of Table 3. The *d*-spacings (Table S-11, supplementary material) were found to be in excellent agreement with those observed in the Debye–Scherrer pattern recorded with the powder.

In the papers describing the tested preparation methods, the authors do not mention which stereoisomer is obtained, but they apparently take for granted that the yellow material corresponds to configuration **A**. This is the stereochemistry preferred by Chatt and Rowe (4), who based their conclusion on preliminary single-crystal X-ray film work and a dipole moment. It should be noted, however, that the X-ray results are found here *not* to correspond to the yellow material (see below). Therefore, the only evidence for structure **A** was the comparison of the dipole moment with those of stereoisomers **A** and **B** of $ReOCl_3(PPhEt_2)_2$ (4), whose structures are known from X-ray diffraction studies (17, 18). The dipole moment of 2.5 D for the PPh_3 complex was regarded as more consistent with the *mer-trans* molecule **A** (1.7 D) than with the *cis* species **B** (10.8 D). This interpretation is now found to be correct from the complete single-crystal X-ray diffraction work described hereafter.

Upon refluxing the yellow material in acetone or CH_2Cl_2, Johnson *et al.* (5) obtained a green crystalline solid (their "isomer" 2), whose Re=O band is shifted to 981 cm^{-1} (our value 978 cm^{-1}). The X-ray diffraction work below shows that it contains the same stereoisomer **A** as the yellow form, but with a different arrangement of phenyl rings in the phosphine and a completely different packing. The X-ray powder pattern (Table S-11) calculated from the data of Table 2 differs markedly from that of the yellow material, and corresponds with the Debye–Scherrer diagram obtained on the green material. Thus, the green monoclinic phase ("isomer" 2 of Johnson *et al.*) (5) and the yellow triclinic phase ("isomer" 1) are polymorphs of the same compound of structure **A**.

The X-ray diffraction results briefly mentioned by Chatt and Rowe (4) as evidence for the presence of structure **A** call for some comments. These authors obtained a set of X-ray Weissenberg films indicating a *C*-monoclinic cell with the following parameters: a = 24.55(5), b = 9.56(2), c =

15.80(4) Å, β = 117.2(1)°. Even though the crystals used are claimed to be those of the yellow phase, they actually correspond to the bright green polymorph, as can be seen from the crystal data in Table 1. In addition, as pointed out by Lock and Turner (19), the proposed interpretion was not completely rigorous. The systematic absences revealed by the films were considered to identify space group *C*2/*c*, but it was not mentioned that space group *Cc* was equally possible. With the density indicating the presence of four molecules per unit cell, no useful conclusions concerning stereochemistry could be drawn for space group *Cc*, since the molecule would sit in general position. It is only if the space group is *C*2/*c* that a special position on a crystallographic twofold axis is available to accommodate a molecule with the *trans*-phosphine structure **A**. Fortunately, the *C*2/*c* space group retained by the authors is now found to be correct and the molecule in the *green* polymorph does lie on a crystallographic twofold axis.

The IR spectra of both $ReOCl_3(PPh_3)_2$ polymorphs show the series of bands expected for triphenylphosphine (20). Besides the ν(Re=O) vibration discussed earlier, the spectra include bands at 310 (broad) and 265 cm^{-1}. On the basis of assignments proposed by Fergusson and Heveldt (21) for analogous compounds with other phosphines, the former band is believed to include the two stretching modes for the Re—Cl bonds *cis* to Re=O, whereas the low-frequency band should correspond to Re—P stretching. The Re—Cl_{trans} band is expected to show below 250 cm^{-1}.

The yellow and the green polymorphs, when dissolved in CH_2Cl_2, give identical UV–visible spectra, consisting of bands at 420 nm (ε = 7.5 × 10^2), 319 nm (ε = 3.2 × 10^3), and 271 nm (ε = 2.2 × 10^4). Similarly, the ^{31}P NMR spectra in CD_2Cl_2 both show a single resonance at −15.8 ppm (Table 4), shifted upfield from free PPh_3 (−2.3 ppm). This is consistent with structure **A**, although structure **B** is not ruled out, since it also contains two equivalent phosphines. However, structure **C** is excluded, since inequivalent phosphines should yield distinct signals (unless a fast exchange process takes place). The solids are indefinitely stable and CD_2Cl_2 solutions in closed NMR tubes show no appreciable decomposition after 24 h, even when they had not been degassed. When air is freely admitted in the tube, a pair of doublets at 52.5 and −30.8 ppm, with 4.7 Hz coupling, is visible after 60 h: these signals correspond with those of an authentic sample of $ReOCl_3(PPh_3)(OPPh_3)$. Under similar conditions, a solution of this new species also decomposes slowly to yield two signals of the same intensity at 60.4 and 49.3 ppm, which are most probably due to $ReOCl_3(OPPh_3)_2$. The structures of these two molecules are not known but, in the related complex $ReOCl_3(PPhEt_2)(OPPhEt_2)$, the OPR_3 ligand is *trans* to the Re=O bond (18). As to the $ReOCl_3(OPPh_3)_2$ species, it must adopt the *mer-cis* structure of type **C**, since the two other structures would give a single ^{31}P signal.

Crystal structures

ORTEP drawings of the $ReOCl_3(PPh_3)_2$ molecules in the two polymorphs are given in Fig. 1. In both cases, the *trans*-bis(phosphine) stereoisomer **A** is present. Structure refinement for the bright green monoclinic crystals grown from CH_2Cl_2 raised no particular problems. On the other hand, the crystals of the yellow phase were small and of poor quality, so that relatively few observed reflections were accessible. Structure resolution was further complicated by disorder and pseudo-symmetry problems. Although the overall structure can be regarded as well established despite these problems, distances and angles are much less reliable. Only the values derived from the monoclinic structure will be discussed.

The principal distances and angles are given in Table 5. In the monoclinic compound, the perfectly linear Cl(2)-Re=O(1) unit lies on a crystallographic twofold axis. Angular deformation about the metal is small: the *cis* angles deviate from 90° by <3.4°, the *cis* Cl and P atoms being displaced away from O(1), but less than in $ReO(OEt)Cl_2(PPh_3)_2$ (22).

The Re—P distance of 2.519(1) Å is on the short side of the range (2.519–2.553 Å) found for the three ethoxo-halogen derivatives $ReO(OEt)X_2(PPh_3)_2$ (22–24). In the nitride $ReNCl_2(PPh_3)_2$ (25), the shorter distance (2.448(2) Å) can be ascribed to the coordination number being reduced from six to five. The much shorter distances (2.444–2.478 Å) observed for a series of related compounds with the less bulky $PPhEt_2$ ligand (17, 18) point to the primary role of steric effect.

The Re—Cl distances lie in the range (2.37–2.44 Å) found for a series of $ReOCl_3(PR_3)_2$ compounds (17). The presence of chlorine, instead of an ethoxo group, *trans* to Re=O renders the *cis* Re—Cl bonds (2.397(1) Å) somewhat shorter than in $ReO(OEt)Cl_2(PPh_3)_2$ (2.422 Å) (22). The Re—Cl bond *trans* to the oxo group (2.383(2) Å) is identical with the one recently found for the mixed-halide compound *trans*-*trans*-$ReOClI_2(PPh_3)_2$ (26). It is roughly equal to or slightly shorter than Re—Cl_{cis},[4] even though the oxo group has been reported to lengthen the opposite Re—Cl bond in related compounds. For instance, in *trans*-$ReOCl_3(PPhEt_2)_2$ (17), the Re—Cl_{trans} distance (2.445(3) Å) is greater than the *cis* distances (2.380(3), 2.420(4) Å). Phosphine displacement from the axial directions toward the Cl_{trans} side (P—Re—P = 161°) perhaps contributes to increasing the Re—Cl_{trans} bond length. For $ReOCl_3$(diphos) (18), the extent of distortion cannot be evaluated, since the structure is reported very briefly without crystallographic coordinates. On the other hand, the possibility has to be considered that the Re—Cl_{trans} distance observed here is artificially short because of a replacement of some of the Re—Cl by Re=O bonds in the crystal. A

[4]X-ray data were collected altogether on three specimens, for which refinement converged to *R* = 0.025 (reported here), 0.031, and 0.051, respectively. The individual and mean Re—Cl distances found are: Re—Cl_{trans}: 2.383(2), 2.394(3), 2.387(4), mean 2.388 Å; Re—Cl_{cis}: 2.397(1), 2.395(4), 2.390(3), mean 2.394 Å. Hence, Re—Cl_{trans} is not longer than Re—Cl_{cis}.

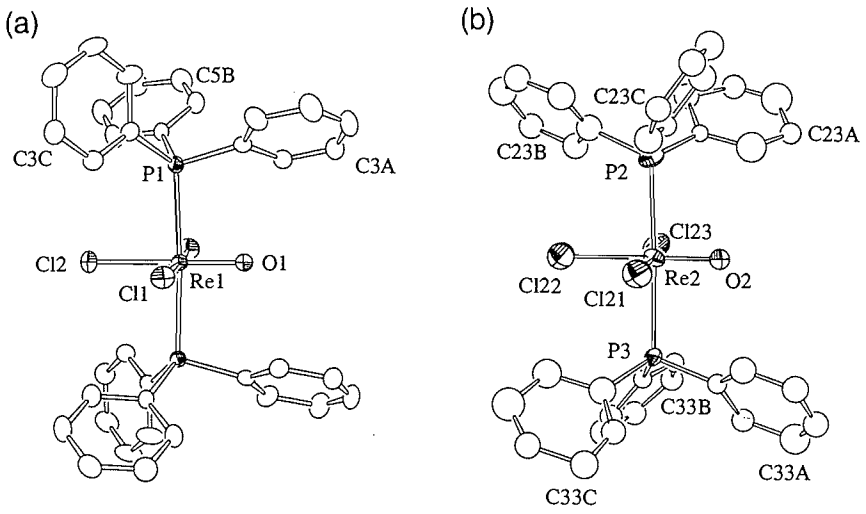

FIG. 1. ORTEP drawings of the $ReOCl_3(PPh_3)_2$ molecules found in the two polymorphs: (*a*) monoclinic form, crystallographic twofold axis along O(1)=Re-Cl(2); (*b*) triclinic form, molecule 2 in general position. Conformation is similar for the disordered molecule 1 in the triclinic polymorph. Hydrogens are omitted for simplicity. Ellipsoids correspond to 50% probability. In the symbols used for the carbon atoms, the letter identifies the ring, the first digit identifies the ligand, and the second digit corresponds to the position around the ring starting with 1 for the P-bonded atom. For the monoclinic compound containing only one type of ligand, the first digit is omitted.

[a]Oxygen position fixed, see text.

related case of Mo complexes forming solid solutions has been discussed recently (27): when part of the *fac*-$MoCl_3(PR_3)_3$ molecules are replaced by isostructural Mo-$OCl_2(PR_3)_3$ molecules, resolved positions are not detected for the two types of atoms in the electron density map, but the apparent Mo—(Cl/O) distance based on the refined Cl/O position significantly decreases. One way to make our Re—Cl_{trans} bond artificially short would be a small amount of orientation disorder interchanging the direction of the Cl(2)-Re=O(1) unit. However, the Re=O(1) bond would then be simultaneously stretched, which is not the case: our Re=O(1) distance of 1.663(5) Å, comparable with those of the related Re-oxo compounds mentioned earlier, lies just below the range reported by Mayer (28) for a series of mono-oxo compounds of Re(V). The normal Re=O(1) and the short Re—Cl_{trans} distances could be explained by a substitution disorder involving a species like *trans-trans*-Re-$O_2Cl_2(PPh_3)_2$. However, judging from the "distance vs. composition" curve reported for the Mo systems (27), ~40% substitution by Re=O would be required to decrease the

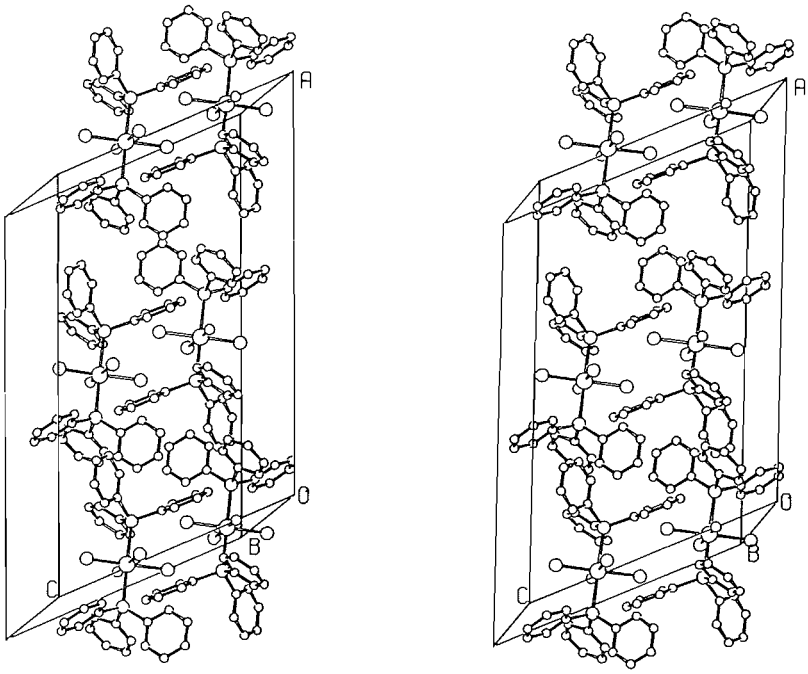

FIG. 2. Stereoview of the unit cell of the monoclinic polymorph. Atoms are represented by spheres of arbitrary size: Re > Cl ~ P > O ~ C. Hydrogens are omitted.

Re—Cl_{trans} distance by ~0.05 Å. There are no warnings to this end from either the X-ray or the spectroscopic results. Nevertheless, in such systems, where the metal can access oxidation states one unit greater or lower and the shape of the molecule is controlled by bulky phosphines, substitution disorder of the type observed with the Mo compounds remains a definite possibility. Studies underway on $ReOCl_3(PR_3)_2$ compounds with related phosphines should cast more light on this problem.

Details on the geometry of the coordinated phosphine are provided in the supplementary material. The P—C distances are normal (mean 1.823(5) Å). As usual, coordination increases the C—P—C angles (mean 105.1°) above the value found in uncoordinated phosphine (mean 102.6°) (29).

Each PPh_3 ligand introduces four conformational degrees of freedom in the complex, that is, three rotations about P—C bonds and one about the Re—P bond. The corresponding torsion angles are listed in the supplementary material. As can be seen from Fig. 1*a*, phenyl ring C is almost coplanar with the Re—P(1) bond (Re—P(1)—C(1C)—C(2C) = −4.3(5)°) and an *ortho* hydrogen is near the $ReOCl_3$ plane. Its projection in the plane is roughly the bisector of Cl(1)—Re—Cl(2), to minimize steric hindrance, but short intramolecular contacts remain between H(2C) and Cl(1) (2.60 Å) and Cl(2) (2.87 Å). An extra intermolecular contact of 2.94 Å is found between Cl(2) and H(4B). Steric effect is also revealed by the pattern of Re—P—C angles: the Re—P(1)—C(1B) (116.5(2)°) and Re—P(1)—C(1C) angles (119.8(2)°), on the side of these interactions, are greater than Re—P(1)—C(1A) (104.5(2)°). Ring A is above O(1), making the Re=O(1) and P(1)—C(1A) bonds nearly eclipsed. The crystallographic twofold axis repeats the same pattern on the other side of the plane, so that O(1) is nearly coplanar with two Re—P(1)—C(1A) units in a *cisoid* arrangement.

The distances and angles in the triclinic polymorph (Table 5) are much less accurate, but consistent with those of the above green material. The two independent $ReOCl_3(PPh_3)_2$ molecules have similar, although not superimposable, conformations, which differ strikingly from that observed in the monoclinic compound. The coordinated phosphine adopts a more classic 60°/60°/40° pattern of Re—P—C_P—C_{ortho} torsion angles (30) (see supplementary material), in contrast with the previous case, where one of these angles was near 0°. There are no short contacts of *ortho* hydrogens with the $ReOCl_3$ plane. In molecule 2, the conformation is such that the P(2)—C(21B) and P(2)—C(21C) bonds are nearly eclipsed with the Re—Cl(22) and Re—Cl(21) bonds, respectively, whereas similar orientations are found, on the other side of the $ReOCl_3$ plane, for the P(3)—C(31A) and P(3)—C(31B) bonds with respect to Re—O(2) and Re—Cl(23), respectively. In this case, the arrangement is close to being centrosymmetric, but this is not imposed by crystallographic symmetry. For molecule 1, disordered on the origin, the P(1)—C(11A) bond of one ligand is eclipsed with the Re=O(1) bond, whereas the same bond in the other phosphine is eclipsed with the Re—Cl(11) bond: the disorder results from atoms O(1) and Cl(11) exchanging their role and leading to statistical distribution over two centrosymmetry-related orientations of the O(1)=Re(1)—C(11) unit.

Views of the unit cells are given in Figs. 2 and 3. In both cases, all molecules have their P—Re—P bonds oriented along the same direction, roughly parallel to the *a* axis. However, the different van der Waals envelopes resulting from phosphine conformation generate distinct packing patterns. In the monoclinic polymorph, the *trans* Cl—Re=O bonds all lie on the crystallographic twofold axes along *b* but, for any molecule, the nearest neighbours have their Cl—Re=O direction inverted. In the triclinic polymorph, for the two molecules in general position inside the unit cell, the Cl—Re=O directions are parallel (along the bisector of *c* and −*b*) and opposite. As to the molecule sitting on the

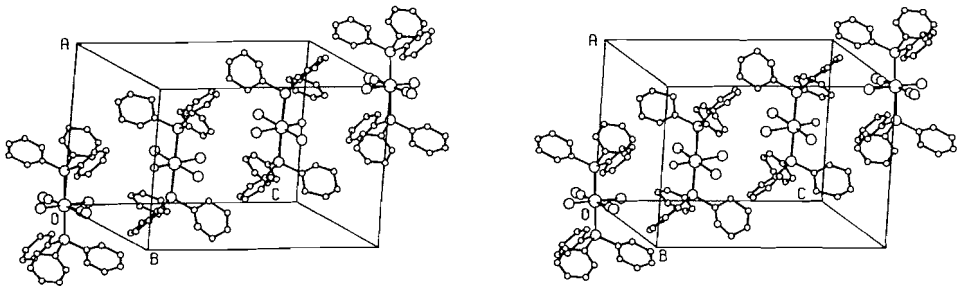

FIG. 3. Stereoview of the unit cell of the triclinic polymorph. Atoms are represented by spheres as in Fig. 2. Molecules of type 2, inside the unit cell, are not disordered. In molecules of type 1, sitting on the origin, both disordered sets of positions for O(1) and Cl(11) are shown.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

inversion center at the origin, the Cl—Re=O bonds are aligned differently, roughly parallel to the *b* axis, and they are statistically disordered over the two opposite orientations.

Judging from the relatively large size of the phosphine and overall shape of the molecule, it can be anticipated that phosphine conformation should have considerable influence on packing. In this respect, it is interesting to note that our monoclinic polymorph and the nitride complex $ReNCl_2(PPh_3)_2$ have very similar structures, even though they are chemically different. The crystallographic work on the nitride complex was done by Doedens and Ibers (25), who solved the structure in space group $I2/a$, an alternative definition of $C2/c$. When this cell is redefined in a C-centered monoclinic lattice, its dimensions (a = 24.01, b = 9.53, c = 15.71 Å, β = 116.1°) are almost equal to those of $ReOCl_3(PPh_3)_2$ (Table 1). Furthermore, the van der Waals envelopes of the molecules are very similar and the P—Re—P directions are also oriented along the *a* axis (stereoview and torsion angles in supplementary material). Therefore, because of their small volume, the $ReNCl_2$ or $ReOCl_3$ planes seem to have relatively little effect on packing, which is largely guided by nonbonded interactions of the bulky phenyl rings. This point will be further discussed below in connection with "isomer" 3.

Wilkinson's "isomer" 3

The third "isomer" of $ReOCl_3(PPh_3)_2$ described by Johnson *et al.* (5) is puzzling. It was obtained when hydrazinium dihydrochloride was reacted with $HReO_4$ in dry ethanol – HCl, thorough drying being achieved by distilling out H_2O via the benzene–ethanol–water azeotrope. This same material was later obtained when Chatt *et al.* (8) reacted yellow $ReOCl_3(PPh_3)_2$ or $ReO(OEt)Cl_2(PPh_3)_2$ with hydrazinium hydrochloride in dry ethanol or THF. Exclusion of moisture in the ethanol solution was identified as a necessary condition to isolate a $ReOCl_3(PPh_3)_2$ complex, since the nitride $ReNCl_2(PPh_3)_2$ was obtained when the ethanol was wet. In fact, these methods are very similar to those leading to the nitride (8, 9).

We were unable to obtain the yellow plates described by Johnson *et al.* (5). In all cases, the material was an orange-brown powder. The ^{31}P NMR spectrum in CD_2Cl_2 showed only two roughly equal singlets, whose chemical shifts were identical with those of authentic samples of $ReNCl_2(PPh_3)_2$ and $ReOCl_3(PPh_3)_2$, respectively (Table 4). The IR spectrum was also a superposition of the spectra of both compounds, with the Re=O band at 978 cm^{-1} identical in shape and position with that of our monoclinic form. It should be pointed out that in contrast with most other $ReNCl_2(PR_3)_2$ complexes, the PPh_3 compound does not exhibit a strong characteristic Re≡N stretching vibration near 1050 cm^{-1} (8). This may explain that the nitride went unnoticed as a component of "isomer" 3. In the low-frequency region, Chatt *et al.* (8) reported bands at 343 (s), 322 (m), and 308 (m) for $ReNCl_2(PPh_3)_2$. In our spectrum, only two bands were observed in the 250–400 cm^{-1} region, at 332 (s) and 311 cm^{-1} (w), respectively. For our samples of "isomer" 3, the low-frequency region is a superposition of those we observed for $ReNCl_2(PPh_3)_2$ and $ReOCl_3(PPh_3)_2$. The ^{31}P CP/MAS NMR spectra were also recorded for $ReNCl_2(PPh_3)_2$, our green polymorph of $ReOCl_3(PPh_3)_2$, and "isomer 3". Although the signals were broad, the spectrum of "isomer" 3 does correspond to a simple summation of those of both pure compounds. Finally, the powder pattern observed for "isomer" 3 was compared with those of pure $ReNCl_2(PPh_3)_2$ and both polymorphs $ReOCl_3(PPh_3)_2$ (supplementary material, Table S-11): it was found to be similar to those calculated for the nitride and the monoclinic polymorph.

Although $ReNCl_2(PPh_3)_2$ and $ReOCl_3(PPh_3)_2$ are identified as the two components of the bulk sample, the above methods cannot distinguish between simple mixtures and solid solutions of the type reported for the $MoOCl_2(PMe_2Ph)_3$–$MoCl_3(PMe_2Ph)_3$ pair (27). A related example of solid solution in Re chemistry is the deep violet material originally formulated as $Re(OH)Cl_3(PPhEt_2)_2$ and subsequently shown to contain *mer-trans*-$ReOCl_3(PPhEt_2)_2$ and *trans*-$ReCl_4(PPhEt_2)_2$ (31). In the present case, with such similar molecular geometries and packing patterns, it is conceivable that co-crystallization of $ReNCl_2(PPh_3)_2$ and $ReOCl_3(PPh_3)_2$ under suitable conditions could lead to a mixed phase. However, from the results available, no definitive conclusion can be drawn as to the intimate structure of our orange-brown material.

Conclusion

Of the three "isomers" of $ReOCl_3(PPh_3)_2$ described in the literature, the present work shows that two are actually polymorphs of the *mer*-trichloro-*trans*-bis(phosphine) molecule **A**. The two phases differ mainly by molecular packing, which is largely controlled by nonbonded interactions of phenyl rings. As to "isomer" 3, our results are consistent with the presence of the monoclinic polymorph of $ReOCl_3(PPh_3)_2$ and of $ReNCl_2(PPh_3)_2$ in the sample. Therefore, there is no evidence whatsoever for the presence of structures **B** and **C** in this case, even though one of the *cis* isomers has been shown to exist for $ReOCl_3(PPhEt_2)_2$. The

greater cone angle (32) of PPh_3 probably makes either *cis* molecule more difficult to isolate because of steric hindrance.

Acknowledgments

We wish to thank M. Simard for assistance in collecting data for the green polymorph, and F. D. Rochon who kindly collected the data for the yellow polymorph. We would also like to thank S. Boisvenue, C. Roux, and C. Pearson for preparing some of the samples.

The photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction (Part 4): methanol–olefins, methyl 4-cyanobenzoate[1]

KEVIN MCMAHON AND DONALD R. ARNOLD[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received August 13, 1992

KEVIN MCMAHON and DONALD R. ARNOLD. Can. J. Chem. **71**, 450 (1993).

Dicyanobenzene-1,4 (**1**) and -1,2 are known to undergo substitution upon irradiation, in the presence of an olefin, in acetonitrile–methanol (3:1) solution. The products are 1:1:1 (methanol:olefin:aromatic) adducts, substituted on the aromatic ring with loss of a cyano group. This reaction, referred to as the photo-NOCAS (nucleophile–olefin combination, aromatic substitution) reaction, has been shown to be fairly general with regard to the olefin and the nucleophile that can be incorporated. Less is known about the scope of the reaction incorporating other electron-withdrawing substituted aromatic molecules. The purpose of this study was to determine if methyl 4-cyanobenzoate (**10**) would also take part in this reaction, to form 4-substituted aromatic esters. Irradiation of acetonitrile–methanol solutions of **10** and olefins 2,3-dimethyl-2-butene (**2**) and 1-methylcyclohexene (**5**) gave cyclic imine esters, **11** and **13**, respectively, instead of photo-NOCAS products. The photo-NOCAS products were obtained when the codonor biphenyl (**4**) was added to the irradiation mixture. Formation of the cyclic imine ester is attributed to excitation of the charge-transfer complex formed between **10** and the olefin. The addition of biphenyl (**4**) serves to generate the contact radical ion pair (CRIP) upon irradiation of the charge-transfer complex between **10** and **4**. This CRIP can dissociate to the solvent-separated radical ions, the radical cation of **4** can accept an electron from the olefin, and the olefin radical cation can go on to give the photo-NOCAS products. Irradiation of a solution of **10** and **2** in nonpolar solvent (benzene) gave the oxetane, believed to arise from the exciplex. In addition to photo-NOCAS products from **10**, 4-cyanophenylketones **17** and **23** are also formed by attack of the β-alkoxyalkyl radical at the carboxyl carbonyl. The differences in behaviour between 1,4-dicyanobenzene (**1**) and methyl 4-cyanobenzoate (**10**) under these reaction conditions are described and explained.

KEVIN MCMAHON et DONALD R. ARNOLD. Can. J. Chem. **71**, 450 (1993).

Il est connu que les 1,4-(**1**)- et 1,2-dicyanobenzènes subissent une réaction de substitution lors de leur irradiation, en solution dans un mélange 3 : 1 d'acétonitrile–méthanol, en présence d'une oléfine. Les produits sont des adduits 1 : 1 : 1 (méthanol : oléfine : produit aromatique) dans lesquels le noyau aromatique a subit une substitution avec perte du groupe cyano. Cette réaction, connue comme une photo-SACON (substitution aromatique avec combinaison d'une oléfine et d'un nucléophile) est reconnue comme une réaction assez générale par rapport aux oléfines et aux nucléophiles potentiels. On connaît moins de choses concernant l'étendue de la réaction avec d'autres molécules aromatiques portant des groupes électroaffinitaires. Le but du présent travail était de déterminer si le 4-cyanobenzoate de méthyle (**10**) donnerait cette réaction pour former des esters aromatiques substitués en position 4. Irradiation du produit **10**, en solution dans un mélange d'acétonitrile–méthanol avec des oléfines 2,3-diméthylbut-2-ène (**2**) ou 1-méthylcyclohexène (**5**), conduit, suivant le cas, aux esters imines cycliques **11** ou **13**, plutôt qu'aux produits de photo-SACON. On n'a obtenu les produits de photo-SACON que lorsqu'on a ajouté du biphényle (**4**) comme codonneur au mélange réactionnel. On attribue la formation des esters imines cycliques à l'excitation du complexe de transfert de charge que se forme entre le produit **10** et l'oléfine. L'addition du biphényle (**4**) sert à générer la paire ion-radical de contact (PIRC) lors de l'irradiation du complexe de charge des composés **10** et **4**. Cette PIRC peut se dissocier en ions radicaux séparés par le solvant, le cation radical de **4** peut accepter un électron de l'oléfine et le cation radical de l'oléfine peut alors donner les produits de photo-SACON. L'irradiation d'une solution des produits **2** et **10** dans un solvant non polaire (benzène) a donné l'oxétanne qui doit être formé à partir de l'exciplex. En plus des produits de photo-SACON du produit **10**, il y a aussi formation des 4-cyanophénylcétones **17** et **23** par attaque du radical β-alkoxyalkyle sur le carbonyle du carboxyle. On décrit les différences de comportement entre le 1,4-dicyanobenzène (**1**) et le 4-cyanobenzoate de méthyle (**10**) dans ces conditions réactionnelles et on les explique.

[Traduit par la rédaction]

Introduction

The photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction is a potentially useful synthetic procedure. Readily available starting materials (a nucleophile, an olefin, and an aromatic molecule) are combined to make a more complex bifunctional product in one simple step; two new bonds are made during the process. The utility of this procedure for the synthesis of *para*-cyanophenyl β-alkyl ethers has been amply demonstrated (e.g., reactions [1] and [2]) and a mechanism has been proposed that is consistent with all of the observations (Scheme 1) (2). Reaction occurs when an acetonitrile–methanol solution of 1,4-dicyanobenzene (**1**) and the olefin is irradiated through Pyrex; the efficiency and yield of photo-NOCAS product may be significantly increased when a codonor, e.g., biphenyl (**4**), is added to the reaction mixture.[3]

Nucleophiles that have been incorporated include methanol, water, and cyanide ion. The reaction has been shown to be fairly general with respect to the olefin; both acyclic

[3]Yields are based upon the aromatic molecule; the olefin is generally present in excess. Side products include the following: 1:1 (olefin:aromatic) adducts formally resulting from substitution by the allylic radical, formed upon deprotonation of the olefin radical cation, on the aromatic ring; dimers of the olefin resulting from coupling of the allylic radicals; and ethers resulting from the addition of methanol to the olefin radical cation.

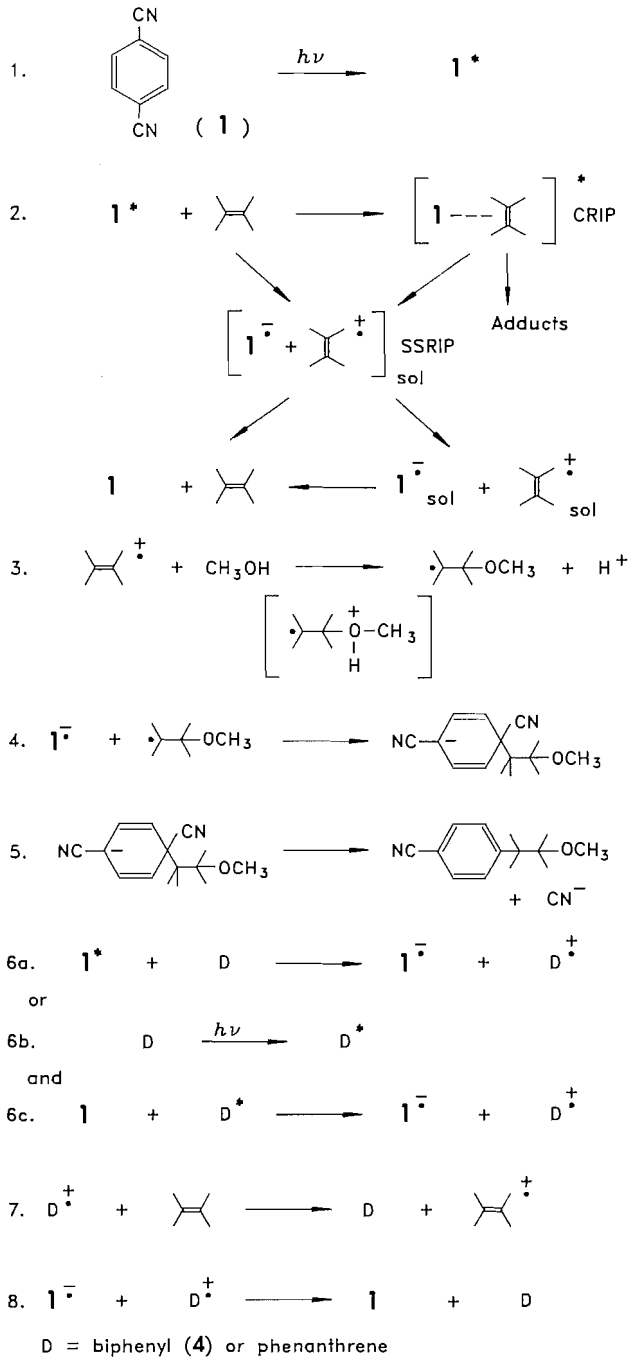
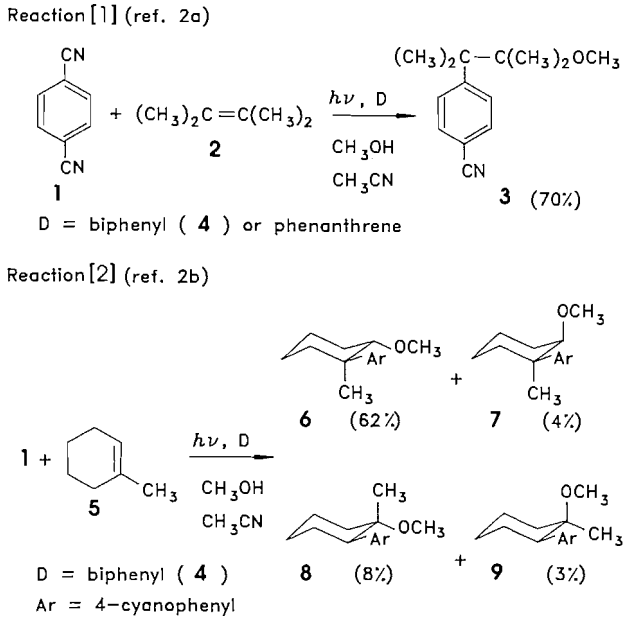


SCHEME 1

and cyclic olefins react regio- and stereoselectively to give predominately *anti*-Markovnikov products.[4] Previous work has emphasized 1,4- and 1,2-dicyanobenzene as the electron-accepting aromatic reactant (1*a*, 2). While the *para*- or *ortho*-cyano group incorporated in the product is useful functionality for further synthetic modification, for many applications it will be desirable to have some other functional group. Consideration of the mechanism leads to the

[4]The designation of regiochemistry as *anti*-Markovnikov is in keeping with the original definition. The methanol (anion) is attached at the less-substituted ethenoid carbon atom. The designation *cis* or *trans* refers to the relative orientation of the aryl and methoxyl groups.



suggestion that the reaction may incorporate other electron-withdrawing substituted aromatic molecules. The main objective of this study was to determine the reactivity of such an alternative, methyl 4-cyanobenzoate (**10**), under these conditions. While there are some obvious similarities between 1,4-dicyanobenzene (**1**) and methyl 4-cyanobenzoate (**10**), there are also important differences (Table 1) (3). Comparison of the behaviour of the two (**1** and **10**) under these reaction conditions has led to a more complete understanding of the mechanism.

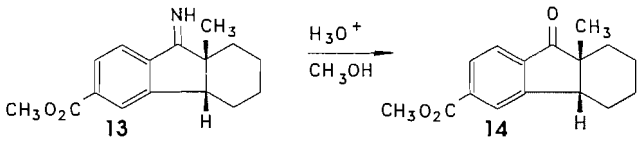
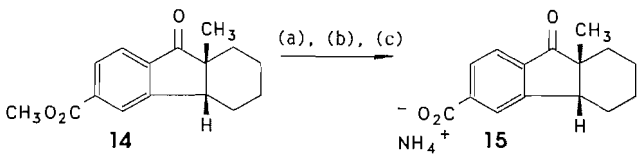
gave the cyclic imine (**11**) as the only significant volatile product (83% yield based upon **10**, reaction [3]). There was no evidence (capillary column gas chromatography with mass selective detection, gc/ms) for formation of the photo-NOCAS product. Imine **11** was readily hydrolysed to ketone **12**, under mild conditions, by treatment with aqueous acidic methanol (reaction [4]). Reactions [3] and [4] were repeated using *tert*-butyl 4-cyanobenzoate (**10***a*) instead of the methyl ester. The resulting *tert*-butyl ester imine (**11***a*) and *tert*-butyl ester ketone (**12***a*) were fully characterized; **12***a* was converted to **12** upon transesterification.

When an acetonitrile–methanol solution of methyl 4-cyanobenzoate (**10**) and 1-methylcyclohexene (5) was irradiated, the analogous imine (**13**) was obtained (30%, reaction [5]). Analysis (gc/ms) of the crude photolysate indicates that **13** was the only isomer formed in appreciable amounts; less than 1% of any regio- or stereoisomer was detected, and there were no photo-NOCAS products. Imine **13** gave ketone **14** under mild hydrolysis conditions (reaction [6]). More rigorous hydrolysis of ketone **14** gave the keto acid, isolated as a crystalline ammonium salt **15** (reaction [7]).

Reaction [6]



Reaction [7]



(a) NaOH, H_2O
(b) H_3O^+
(c) NH_3, ether

The addition of biphenyl (4) to these reaction mixtures has a profound effect. Irradiation of an acetonitrile–methanol solution of methyl 4-cyanobenzoate (**10**), 2,3-dimethyl-2-butene (**2**), and biphenyl (**4**) gave photo-NOCAS

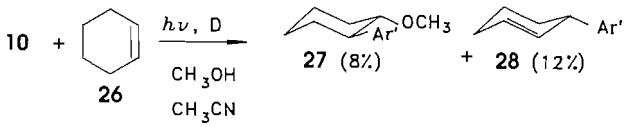
product **16** (15%) along with alcohol **18** (17%, reaction [8]). When this irradiation was carried out to low conversion, ketone **17** was also obtained in low yield. This ketone was not detected in the photolysate when the irradiation was carried out to high conversion. Only trace amounts of imine **11** and amine **19** were formed under these conditions.

Photo-NOCAS products were also obtained upon irradiation of acetonitrile–methanol solutions of methyl 4-cyanobenzoate (**10**) and 1-methylcyclohexene (**5**) when biphenyl (**4**) was added to the reaction mixture (reaction [9]). Three isomeric esters (**20–22**) (combined yield, 37%) were isolated and characterized. The major product (**20**) has the *trans* configuration of the *anti*-Markovnikov regiochemistry. Also isolated from the reaction mixture was the 4-cyanophenyl ketone (**23**) with the *trans anti*-Markovnikov structure. Substantial amounts of ethers: 2-methoxy-1-methylcyclohexane (**24** *cis* and *trans*) and 1-methoxy-1-methylcyclohexane (**25**), were formed. This reaction was repeated using acetonitrile–methanol-*O*-*d* as solvent. Ethers *cis*- and *trans*-**24** and **25** were analyzed (gc/ms) for deuterium incorporation. These results are summarized in Table 2.

Cyclohexene (**26**) was incorporated into a photo-NOCAS product; irradiation of an acetonitrile–methanol solution of **10**, **4**, and **26** gave the *trans* 1:1:1 adduct **27** (8%, reaction [10]). The major product was the 1:1 (olefin:aromatic) adduct, 3-(methyl 4-benzoate)cyclohexene (**28**, 12%).

Reaction [10]

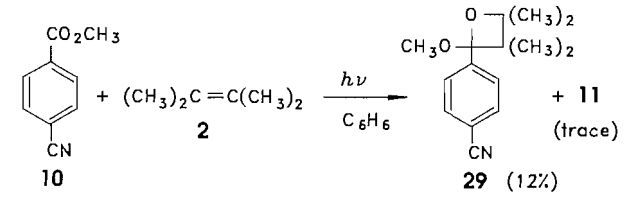


D = biphenyl (**4**)
Ar' = methyl 4–benzoate

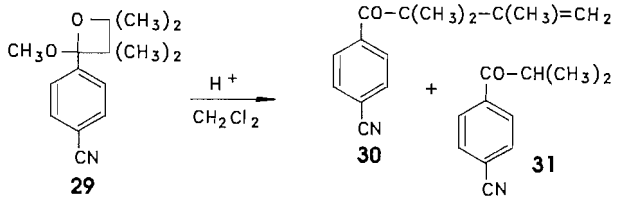
All of the photochemical reactions described so far were carried out using acetonitrile–methanol (3:1) as solvent; irradiations were also performed in benzene solution in order to assess the importance of solvent polarity. Irradiation of a benzene solution of methyl 4-cyanobenzoate (**10**) and 2,3-dimethyl-2-butene (**2**) gave oxetane **29** (12%) along with a trace of imine **11** (reaction [11]). Similar irradiation of the *tert*-butyl ester (**10***a*) gave only the imine (**11***a*); there was no evidence for formation of an oxetane in this case. Acid-catalyzed cleavage of oxetane **29** gave ketones **30** and **31** (reaction [12]).

When a benzene solution of **10** and 2-methylpropene (**32**) was irradiated, the expected oxetane analogous to **29** was not detected. The only volatile product was oxetane **33**, isolated in low yield (reaction [13]).

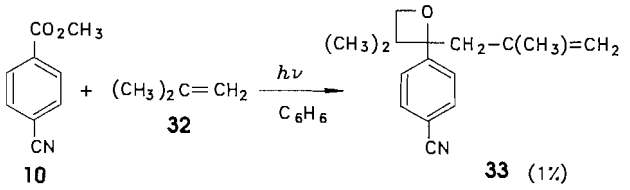
Reaction [11]



Reaction [12]



Reaction [13]



Reactions of methyl 4-cyanobenzoate (**10**) and 1,4-dicyanobenzene (**1**) with methyl and *tert*-butyl Grignard and lithium reagents were studied in order to gain a better understanding of the addition step (Scheme 1, step 4) in the proposed mechanism. That is, should this step be viewed as an alkyl radical adding to an aromatic radical anion, or as an alkyl anion adding to the neutral aromatic? Products obtained with the Grignard reagent are shown in reactions [14]–[17]. Imines **39** and **41** obtained in reactions [16] and [17] were hydrolysed to ketones, **35** and 4-cyanoacetophenone (**42**), respectively, during work-up. These results are summarized in Table 3.

Ultraviolet absorption spectra of 1,4-dicyanobenzene (**1**), methyl 4-cyanobenzoate (**10**), and biphenyl (**4**) are shown in Fig. 1. The long-wavelength ultraviolet absorption of

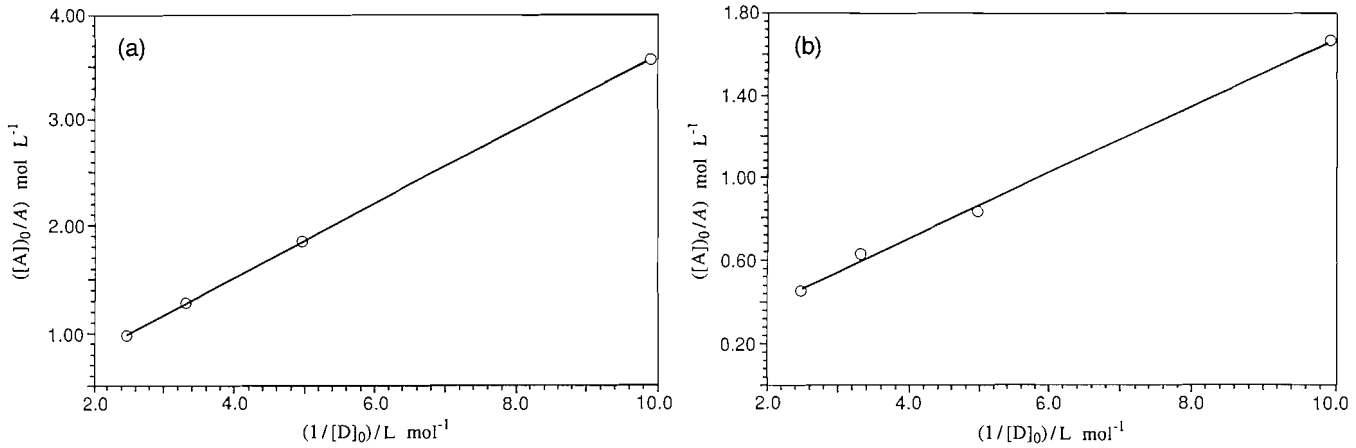

FIG. 3. Benesi–Hildebrand plots of $[A]_0/A$ against $1/[D]_0$ for a series of acetonitrile–methanol (3:1) solutions of methyl 4-cyanobenzoate (**10**) with varying concentrations of (*a*) 2,3-dimethyl-2-butene (**2**); (*b*) 1-methylcyclohexene (**5**).

Spin and charge distributions on the radical anions of 1,4-dicyanobenzene (**1**) and methyl 4-cyanobenzoate (**10**) were calculated. *Ab initio* molecular orbital calculations were carried out with the Gaussian 90 series of programmes (5). Carbon atoms of the aromatic ring and the atoms directly attached were constrained to a plane, and the methyl group of the ester was not allowed to rotate; the remaining structural features were fully optimized at the UHF/STO-3G level. Spin density were taken as the square of the coefficient at the atomic p_z-orbital in the singly occupied molecular orbital (SOMO) and the charge distribution was calculated by Mulliken population analysis (6). The limitations of this method have been discussed (7). These data are summarized in Figs. 4 and 5.

Structural determination

Imine **11** (reaction [3]) was labile towards hydrolysis, but could be isolated and characterized. A broad band was observed in the infrared spectrum at 3400 cm^{-1} attributed to the N–H stretching frequency. There was a strong absorption band at 1645 cm^{-1} due to carboxyl carbonyl, but no absorption in the region of the nitrile stretching frequency. An exchangeable (D_2O) proton was observed at 8.6 ppm in the ^1H nmr spectrum. Signals due to three hydrogens were clearly resolved in the aromatic region of the ^1H nmr spectrum, with three corresponding doublets in the aromatic region of the coupled ^{13}C nmr spectrum. The two pairs of equivalent methyl groups were evident in the ^1H nmr spectrum as sharp singlets at 1.19 and 1.10 ppm.

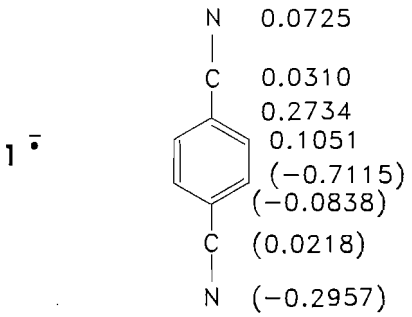

FIG. 4. Calculated (STO-3G) (spin) and charge densities on the radical anion of 1,4-dicyanobenzene (**1**).

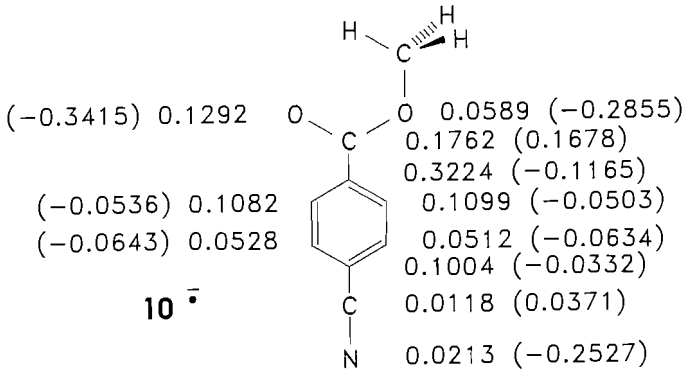

FIG. 5. Calculated (STO-3G) (spin) and charge densities on the radical anion of methyl 4-cyanobenzoate (**10**).

After hydrolysis (reaction [4]), the spectra of ketone **12** were similar to those of imine **11**, with some important differences. The band due to the N–H stretching frequency, observed in the infrared, and the signal attributed to the exchangeable proton in the ^{1}H nmr spectra of the imine were no longer present. Two sharp singlets at 1.26 ppm and 1.10 ppm were attributed to the two pairs of equivalent methyl groups. The singlet resonance observed at 188.23 ppm in the ^{13}C nmr spectrum of **11**, attributed to the carbon of the imine group, was shifted to 210.59 ppm, indicative of a ketone carbonyl carbon. The mass spectrum of **12** also showed the expected increase by one mass unit in the molecular ion and in the base peak (loss of CH_3.).

Structures assigned to the *tert*-butyl ester imine **11***a* and ketone **12***a*, similar to those of the analogous methyl ester, were consistent with the observed spectra.

The assignment of the regio- and stereochemistry of structures **13** and **14** (reaction [5] and [6]), from the ^{1}H and ^{13}C nmr spectra, was not as straightforward and was ultimately achieved by X-ray analysis of a single crystal of the ammonium salt of the carboxylic acid derivative **15**. Trisubstitution of the aromatic ring in **14** was apparent from the three distinct signals due to aromatic hydrogens (8.13, 8.04, and 7.80 ppm) in the ^{1}H nmr spectrum, and three doublets in the aromatic region of the ^{13}C nmr spectrum (128.60, 124.25, and 125.59 ppm). An apparent triplet (J = 5.24 Hz) due to a single hydrogen was observed at low field (3.08 ppm). Acid- and base-catalyzed deuterium exchange experiments were carried out to determine if this hydrogen was exchangeable and therefore adjacent to the carbonyl at the junction between the 5- and 6-membered rings. An attempt was also made to alkylate the enolate anion. These reactions were carried out using conditions found to be effective for the exchange and alkylation at the carbon α to the carbonyl of 1-indanone. However, there was no evidence (^{1}H nmr and gc/ms, with single ion monitoring) for deuterium exchange or alkylation of **14**. These results provided the first indication that the low-field signal (3.08 ppm) was due to a benzylic hydrogen (not a hydrogen α to a carbonyl group) and thus established the regiochemistry of the cycloaddition.

The ^{1}H nmr spectrum of ester **14** was recorded in benzene-d_6 and in chloroform-*d*; the variation in chemical shift for the signals due to the methyl and the benzylic hydrogens was compared. Benzene is known to interact with electron-deficient sites on the solute molecule (8). Orientation of the solute–solvent complex is governed by local dipolar interactions and the benzene will be remote from the negative end of the solute molecule. This distortion causes a change in the total screening constant (σ), which has a contribution from the solute–solvent interaction. The "carbonyl plane rule" has been proposed as a method for assigning the position of a hydrogen (or a group of hydrogens) relative to a plane drawn through the carbonyl carbon perpendicular to the C—O bond (9). Hydrogens that lie on the oxygen side of this plane will have a negative difference in chemical shift ($\Delta = \delta_{CDCl_3} - \delta_{C_6D_6}$), while those on the other side of the plane will be shifted positively. Hydrogens in the reference plane will be relatively unaffected. In the case of **14** a much larger difference in chemical shifts was observed for the single hydrogen (+0.55 ppm) than for the methyl group (+0.19 ppm). This suggests that the methyl group is nearer the reference plane, and therefore α to the carbonyl group. Again, this is indicative of the regiochemistry of the ring juncture; however, the stereochemistry of the ring juncture was still uncertain. Therefore, **14** (an oil) was converted into a crystalline derivative for X-ray analysis.

Ester **14** was hydrolysed to the acid under basic conditions. The acid was readily converted to the crystalline ammonium salt (**15**) (reaction [7]), which was used for X-ray analysis. The results clearly show that the methyl group is α to the carbonyl group, and the 5- and 6-membered rings are fused in a *cis* juncture (Fig. 6). Interatomic distances, bond angles, and torsional angles are listed in the appendix (Depository of Unpublished Data).[5]

Identification of the products from reaction [8]: the peak characteristic of the nitrile stretching frequency was not observed in the infrared spectrum of photo-NOCAS product **16**. The ^{1}H nmr spectrum of **16** is indicative of a symmetric structure: an A_2X_2 pattern in the aromatic region confirms the 1,4 ring substitution. Two low-field peaks assigned to the methyl groups on oxygen, as well as two peaks due to six equivalent hydrogens of the two pairs of methyl groups, are observed.

Ketone **17** was easily identified. The ^{1}H nmr spectrum showed the methyl groups as two singlets indicative of the symmetric structure. The carbonyl group was detected in the infrared spectrum (the carbonyl stretching frequency at 1680 cm^{-1}) and in the ^{13}C nmr spectrum (a singlet due to the carbonyl carbon at 210.65 ppm). The nitrile stretching frequency (2240 cm^{-1}) in the infrared spectrum and the symmetric pattern in the aromatic region of the ^{1}H nmr spectrum confirm the 4-cyano substitution on the aromatic ring.

For compound **18**, the presence of the hydroxyl group was indicated by a broad, exchangeable (D_2O), low-field (5.72 ppm), absorption due to the hydroxyl proton in the ^{1}H nmr spectrum, and a peak due to the O–H stretching frequency observed at 3450 cm^{-1} in the infrared spectrum. The presence of a chiral centre renders the geminal methyl groups

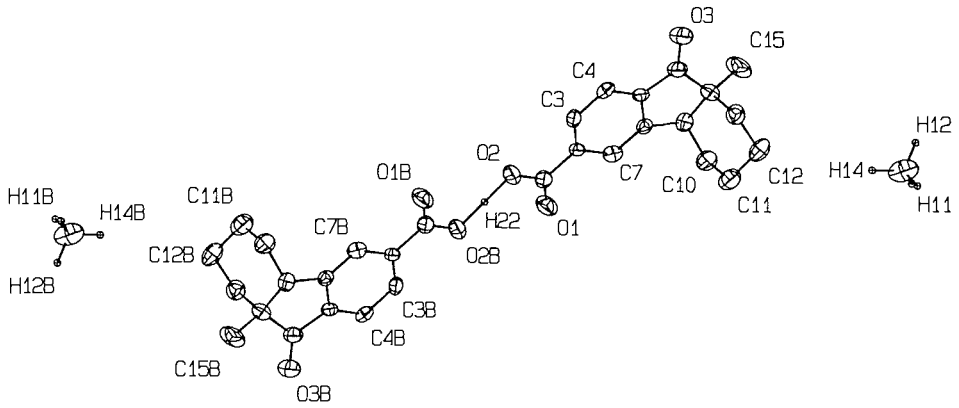

FIG. 6. X-ray crystal structure (Chemgraf) of ammonium salt **15**.

heterotopic; four distinct singlets are observed in the ^{1}H nmr spectrum. The signal due to the benzylic hydrogen geminal to a hydroxyl group occurs as a singlet at 4.98 ppm (compare with the signal due to the benzylic hydrogen of benzyl alcohol, which occurs at 4.58 ppm). The nitrile stretching frequency (2260 cm^{-1}) is observed in the infrared spectrum and an AA′XX′ pattern in the aromatic region of the ^{1}H nmr spectrum confirms the 1,4 disubstitution.

The four methyl groups in the spectrum of the product assigned to amine **19** appear as distinct singlets in the ^{1}H nmr spectrum, indicative of a chiral molecule. The benzylic hydrogen shows up as a singlet at low field (4.10 ppm). The primary amine function is indicated by a broad exchangeable (D_2O) singlet equivalent to two hydrogens at 1.46 ppm in the ^{1}H nmr spectrum, attributed to the protons on nitrogen, and by a broad band centred at 3400 cm^{-1} in the infrared spectrum due to the N–H stretching frequency. The mass spectrum gives a molecular ion with an odd mass (m/z = 247) and a major fragment (72%) resulting from loss of one mass unit, indicative of a molecular ion of an amine that loses the α-hydrogen (C*H*-NH_2) to give the nitrogen-stabilized cation. The aromatic region of the ^{1}H nmr spectrum is consistent with a trisubstituted aromatic ring — three distinct resonances with the expected couplings.

Structure proof of the photo-NOCAS products from methyl 4-cyanobenzoate (**10**) and 1-methylcyclohexene (**5**) (reaction [9]) was aided by comparison of spectra with those from the analogous cyano compounds **6**–**9** reported earlier (2*b*). The distinction between Markovnikov and *anti*-Markovnikov adducts was made on the basis of the chemical shift due to the single proton multiplet at low field, geminal to either the phenyl ring or the methoxy group. On this basis, adduct **20** (low-field dd at 3.48 ppm, hydrogen α to oxygen) and ketone **23** (dd at 3.58 ppm) were assigned the *anti*-Markovnikov structure, while **21** (higher field dd at 2.86 ppm, therefore a benzylic hydrogen) and **22** (dd at 2.47 ppm) are Markovnikov adducts. Additional evidence for these assignments comes from the ^{13}C nmr spectrum where signals due to carbon adjacent to the ether oxygen also appear at lower field than benzylic carbons. Low-field doublets at 84.12 (J = 139.3 Hz) and 81.92 (J = 143.1 Hz) ppm are consistent with the assigned structures, **20** and **23**, respectively. The signal due to the carbon of the methoxy group in these spectra is observed as a quartet of doublets, showing long-range coupling (J^3_{C-H} = 4.3 Hz for **20** and 4.2 Hz for **23**) to the hydrogen geminal to the methoxy group. Signals due to the carbon of the methoxy group in **21** and **22** were simply quartets; there was no evidence of long-range coupling.

Having established the regiochemistry of these products (**20**–**23**), the stereochemistry was determined on the basis of vicinal proton–proton and proton–carbon coupling; axial–axial coupling is relatively large (10). The ^{1}H nmr spectrum of isomer **20** shows a large vicinal coupling in the signal due to the proton geminal to the methoxy group (J^3_{H-H} = 9.6 and 3.6 Hz) indicative of axial–axial and axial–equatorial coupling. The methoxy group is therefore in the equatorial position. A similar coupling is observed in the signal due to the proton geminal to the methoxy group in the spectrum of ketone **23** (J^3_{H-H} = 10.1 and 3.9 Hz); in this case also, the methoxy group is assigned to the equatorial position. For isomer **20** and ketone **23**, the relative position of the methyl and aryl groups was determined by examining the long-range coupling between the methyl carbon and the vicinal hydrogens in the coupled ^{13}C nmr spectra. One of the central lines of the quartet due to the carbon of the methyl group was expanded, and a measure of the width at half-height gave an indication of the magnitude of the coupling. This long-range hydrogen–carbon coupling generally can be related to the vicinal proton–proton coupling by the empirical relationship shown in eq. [18].

$$[18] \quad \text{(ref. 11)} \qquad J^3_{C-H} = 1.2 \times J^3_{H-H} - 3.5 \text{ Hz}$$

Central lines of the quartet due to the methyl group in the ^{13}C nmr spectrum of isomer **20** are broad (13.5 Hz). Similar broad lines (14.4 Hz) are observed in the spectrum of ketone **23**. The methyl groups in **30** and **23** are therefore in the axial position. Signals in the ^{1}H nmr spectrum due to the benzylic hydrogens of isomers **21** and **22** are broad; large coupling constants (**21**, 11.7 and 4.0 Hz; **22**, 12.8 and 3.3 Hz) indicate that these protons are in the axial position. The coupled ^{13}C nmr spectrum of isomer **21** also showed a large J^3_{C-H} coupling (12.9 Hz) indicative of an axial methyl group. The structure of isomer **22**, with an axial benzylic hydrogen, was therefore assigned with an equatorial methyl group and an axial methoxy group.

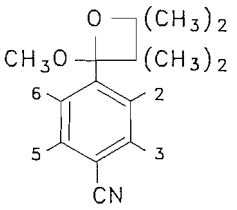
The ethers **24** *cis* and *trans*, and **25** are known compounds, positively identified by direct comparison (gc/ms, retention times, and mass spectra) with authentic samples.

The structure of the photo-NOCAS product (**27**), formed in reaction [10], was determined in much the same manner as that for **20**. In the ^{1}H nmr spectrum of **27**, the signal for the hydrogen adjacent to the methoxy group appears at low

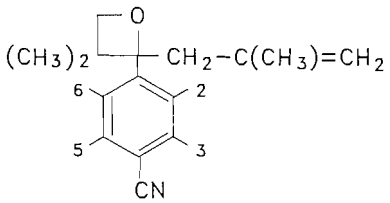
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

field (3.27 ppm) as an apparent triplet of doublets (J = 10.2 and 4.2 Hz). This corresponds to two coincidentally equivalent large axial–axial and one smaller axial–equatorial couplings. The methoxy group is therefore in the equatorial position, adjacent to the equatorial aryl group. Substitution product **28** is clearly a 1:1 (olefin:aromatic) adduct. Only one signal (3.90 ppm) for a methoxy group was observed in the ^{1}H nmr spectrum, and this is associated with the carbonyl group; hence, there was no incorporation of methanol. Two olefinic hydrogens were evident from signals in the vinyl region (5.69 and 5.92 ppm). The high-field signal is clearly coupled to two other hydrogens with one large geminal coupling (9.9 Hz) to the other vinyl hydrogen and one smaller coupling (2.0 Hz) to the benzylic proton. Hence, the aryl group is attached at the allylic position of the olefin.

Strong absorption in the infrared spectra, at 1020 cm^{-1} for **29** and 955 cm^{-1} for **33**, is characteristic of the C–O stretching frequency of the oxetanes formed in reactions [11]



29



33

and [13] (12). The ^{1}H nmr spectra of these oxetanes are particularly interesting (Figs. 7 and 8). There is clear evidence, from the multiplicity of peaks in the aromatic region, that there is a significant barrier to rotation of the 4-cyanophenyl group. In the spectrum of **29**, at −70°C, the signals assigned to H5 and H6 are coincidentally equivalent (7.79 ppm) while H2 and H3 appear as an AB quartet (7.34 ppm, J = 8.2 Hz, and 7.73 ppm, J = 8.1 Hz). As the temperature is increased, H3 and H5 coalesce at −20°C and H2 and H6 coalesce at +10°C. Analysis of this data indicates that the barrier to rotation of the 4-cyanophenyl group is 54.4 ± 0.9 kJ mol^{-1} (13.0 ± 0.2 kcal mol^{-1}) (13). Results for **33** are similar: at −70°C, the signals due to H5 and H6 overlap at 7.71 ppm and H2 and H3 appear as an AB quartet (6.97 ppm, J = 8.3 Hz, and 7.60 ppm, J = 8.3 Hz). Signals due to H3 and H5 coalesce at −20°C while the signals due to H2 and H6 coalesce at +10°C. The barrier to rotation of the 4-cyanophenyl group in **33** is 53.18 ± 0.97 kJ mol^{-1} (12.7 ± 0:2 kcal mol^{-1}).

Structures for the products from reactions [14]–[17] were established by analysis of ^{1}H and ^{13}C nmr spectra. Imines **39** and **41** were hydrolysed to ketones, *tert*-butyl (4-cyanophenyl) ketone (**35**) and 4-cyanoacetophenone (**42**), which were fully characterized. The structure of the product that results from addition of the *tert*-butyl Grignard reagent to the ring of **1** (**40**, reaction [16]) was evident from the ^{1}H nmr spectrum; signals due to the vinyl hydrogens on C2 and C5 (3.03 and 2.95 ppm) are not coupled to each other.

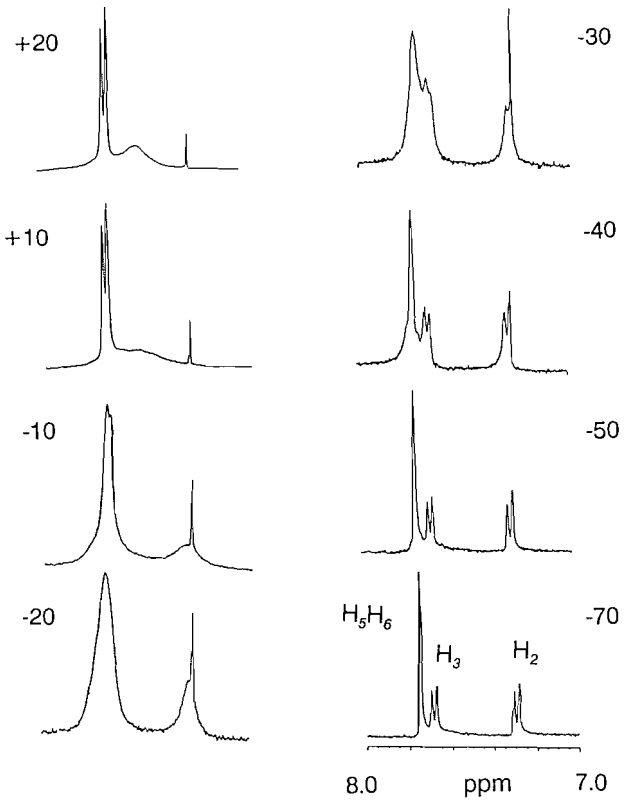


FIG. 7. Variable temperature ^{1}H NMR (360 MHz) study of oxetane **29**.

Discussion

Like 1,4-dicyanobenzoate (**1**), methyl 4-cyanobenzoate (**10**) can be an effective electron-accepting aromatic component in the photo-NOCAS reaction, **but only when the irradiation is carried out in the presence of a codonor, e.g., biphenyl (4)**. This reaction can be used for the synthesis of 4-substituted benzoate esters (reactions [8]–[10]). However, there are major differences in the behaviour of 1,4-dicyanobenzene (**1**) and methyl 4-cyanobenzoate (**10**):

(*i*) While irradiation of acetonitrile–methanol solutions of **1** and an olefin leads to formation of photo-NOCAS products, cyclic imines are obtained from **10** under these conditions. Addition of biphenyl (**4**) to the irradiation mixture of **1** and an olefin increases the efficiency of the formation of photo-NOCAS products; in marked contrast, no photo-NOCAS products are formed upon irradiation of acetonitrile–methanol solutions of **10** and an olefin unless **4** has been added to the solution.

(*ii*) In these reactions involving 1,4-dicyanobenzene (**1**), attack of the intermediate β-alkoxyalkyl radical occurs exclusively at the *ipso* position of **1**$^{\cdot-}$; there is no evidence for attack directly on the cyano group. With methyl 4-cyanobenzoate (**10**) the photo-NOCAS products, which result from attack of the β-alkoxyalkyl radical on the position *ipso* to the cyano group, are accompanied by products resulting from attack directly on the carboxyl carbonyl.

The mechanism (Scheme 1), which is consistent with all of the results for 1,4-dicyanobenzene (**1**), obviously is in-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

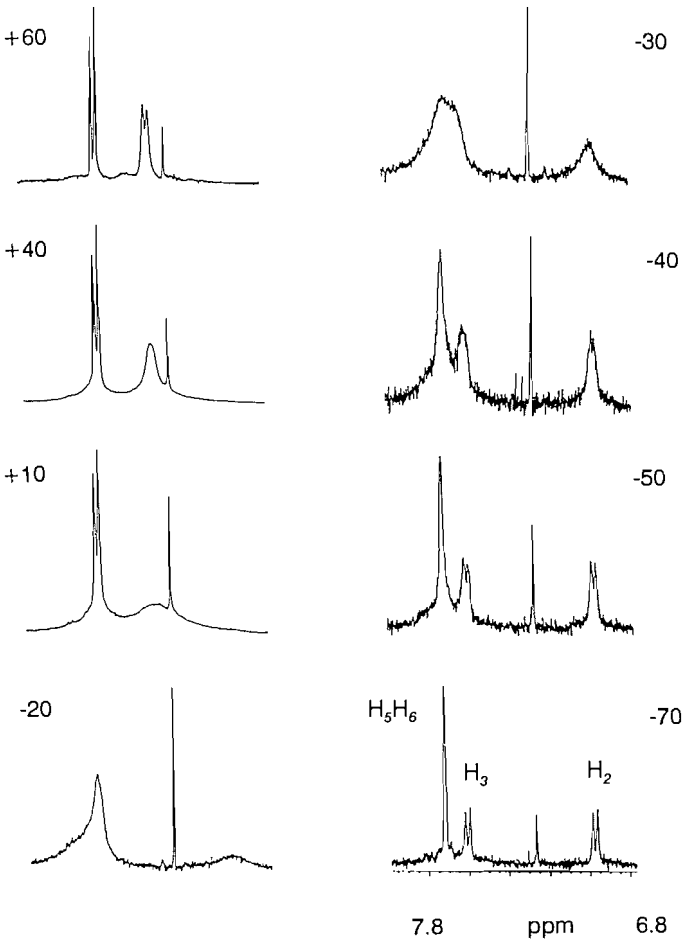

FIG. 8. Variable temperature ^{1}H NMR (360 MHz) study of oxetane **33**.

adequate for reactions of methyl 4-cyanobenzoate (**10**); deficiencies arise within the first two steps.

Step 1: Excitation of 1,4-dicyanobenzene (**1**), in the long-wavelength ultraviolet region (>280 nm), leads to the lowest excited singlet state (^1L_b) (14). In this excited state **1** is a powerful oxidant; based upon the Weller equation (eq. [19] (ref. 15)), this state will accept an electron at the rate of formation of the collision encounter complex (ca. 1.7×10^{10} M^{-1} s^{-1} in acetonitrile (2*a*)) from any prospective donor having an oxidation potential less than ca. 2.4 V (vs. sce) when $\Delta G_{et} = -20$ kJ mol^{-1} (2*a*).

[19] (ref. 15) $\Delta G_{et} = F[E^{ox}_{1/2}(D) - E^{red}_{1/2}(A) - e/\epsilon\alpha] - E_{0,0}(A)$

Step 2: The measured lifetime of the ^1L_b state of **1** is 9.7 ns (Table 1). Stern–Volmer studies show that fluorescence from **1** is indeed quenched by olefin **2** ($E^{ox}_{1/2}$ = 1.62 V, vs. sce) at the diffusion-controlled rate ($k_q = 1.5 \times 10^{10}$ M^{-1} s^{-1} (2*a*)). Therefore, under the usual conditions for the photo-NOCAS reaction, i.e., 0.1 M concentration of olefin, electron transfer leading directly to formation of the solvent-separated radical ion pair (SSRIP) is competitive with unimolecular deactivation (intersystem crossing and internal conversion) of the singlet excited state of **1**. Formation of the solvent-separated radical ion pair is necessary for reaction; the SSRIP may proceed subsequently to the individually solvated radical ions, and the mechanism continues.

The long-wavelength absorption band of methyl 4-cyanobenzoate (**10**) also involves excitation of the ^1L_b transition. The first contrast in the behaviour of **1** and **10** lies in the singlet excited state lifetime. Attempts to measure the singlet lifetime of **10** have so far failed. We, and others (3*d*), have been unable to detect fluorescence emission from **10**. The singlet excited state lifetime of **10** must be significantly less than 1 ns, the limit of our detection system. Even though the singlet of **10** should undergo electron transfer at the diffusion-controlled rate with olefins **2** and **5**, ΔG_{et} = −78.0 kJ mol^{-1} for **2** and −48.1 kJ mol^{-1} for **5**, this bimolecular reaction cannot compete with unimolecular deactivation. Involvement of a triplet state also seems unlikely. The triplet of **10** (301.2 kJ mol^{-1}) will be quenched (energy transfer) by olefins. Deactivation of the olefin π,π^* triplet is rapid (the "free-rotor") effect).

We propose that formation of the cyclic imines, **11** and **13** in reactions [3] and [5], can be accounted for by excitation of the ground state charge-transfer complex formed between **10** and olefins **2** and **5**.[6] The increased absorption on the long-wavelength tail of the ^1L_b band of **10**, as a function of olefin concentration (Fig. 2), is indicative of ground state charge-transfer complex formation. Excitation of this charge-transfer complex in polar solvent leads directly to the excited state of the charge-transfer complex which can accurately be described as a contact radical ion pair (CRIP); electron transfer is exergonic. In terms of the Mulliken description of the excited charge-transfer complex, the contribution of the "no bond" wavefunction involving locally excited states is small relative to that of the "dative bond" wavefunction (4*d*). Reaction of the contact radical ion pair leads to cyclic imine formation. The sequence of bond-forming events leading to the imine is not known; however, the regiochemistry of **13** (reaction [5]) is indicative of initial bonding between the carbon *ortho* to the cyano group and the olefin.

When the irradiation of **10** and **2** is carried out in non-polar solvent (benzene), the dative bond wavefunction contributes less to the nature of the excited state of the charge-transfer complex and the oxetane **29** is formed instead (reaction [11]).

There is a veritable plethora of reactions that are known to occur upon irradiation of cyanoaromatics in the presence of an olefin (17–27).[7] In addition to the photo-NOCAS reaction (1*a*, 2, 17), other reactions that may occur include (*a*) formation of 1:1:1 (nucleophile:olefin:aromatic) adducts without loss of cyanide ion (18); (*b*) formation of 1:1 (olefin:aromatic) adducts by addition of the allylic radical to the ring (19); (*c*) cycloaddition of the olefin to the cyanoaromatic, across the nitrile bond (20) or (*d*) across the ring (either *ortho* or *meta*) (21). Furthermore, the cyanoaromatic may act as a photosensitizer leading to (*a*) *anti*-Markovnikov addition of nucleophilic solvent to the olefin (22); (*b*) cyclic dimers, [2e + 1e] and [4e + 1e], of the olefin (23); (*c*) *cis–trans* isomerization of the olefin (24); (*d*) rearrangement of the olefin (25); or (*e*) tautomerization of the olefin (26).

[6]There are several reports of bimolecular reactions of similar benzoate esters attributed to the singlet excited state (16). This interpretation seems improbable in view of the short singlet excited state lifetime of these compounds. Excitation of ground state charge-transfer complexes may be involved in these cases as well.

[7]Many of these references (17–27) discuss more than one type of reaction.

Despite this considerable effort to define the reactivity of cyanoaromatics irradiated in the presence of olefins, there are few reported examples of cyclic imine formation analogous to that observed here (reactions [3] and [5]). This type of product has not been observed previously with either **1** or with **10**. Irradiation of acetonitrile solutions of 1,3,5-tricyanobenzene and 2,3-dimethyl-2-butene (**2**), and of 2-cyanopyridine and 2-methyl-2-butene, leads to cyclic imine formation (27). Electron transfer, from the olefin to the singlet excited state of these cyanoaromatics, is exergonic in both these cases. Ground state charge-transfer complex formation is also likely; the mechanism for imine formation has not been defined in either case.

1,4-Dicyanobenzene (**1**) also forms a ground state charge-transfer complex with olefins; for example, with **2**, $K_x^{AD} = 0.15 \pm 0.01$. Nevertheless, cyclic imines have never been detected (gc/ms) following irradiation of acetonitrile–methanol solutions of **1** and olefins; with **2**, only photo-NOCAS products are formed (reaction [1]). The implication is that following formation of the CRIP obtained upon irradiation of the ground state charge-transfer complex between **1** and **2** (and other olefins), the rate of reaction leading to cyclic imine is slow relative to solvent separation of the radical ions. Irradiation of the charge-transfer complex between **10** and **2** leads to a CRIP which reacts to give the cyclic imine more rapidly than solvent separation.

Photo-NOCAS products are observed from methyl 4-cyanobenzoate (**10**) when biphenyl (**4**) has been added to the reaction mixture (reactions [8]–[10]). Photo-NOCAS adduct **16** is a major product, formed upon irradiation of an acetonitrile–methanol solution of methyl 4-cyanobenzoate (**10**), 2,3-dimethyl-2-butene (**2**), and biphenyl (**4**); imine **11** and amine **19** are minor products under these conditions (reaction [8]). Ketone **17** and alcohol **18** are also major products. Products **18** and **19** may result from secondary photolysis, reduction of the primary products **17** and **11**. We believe this reduction involves electron transfer from the initially formed radical anion $\mathbf{10}^{-\cdot}$ to the ketone **17** and imine **11**, followed by protonation of the radical anion and disproportionation. The reduction potential of ketone **17** will be significantly less negative than that of **10** (compare, for example, 4-cyanoacetophenone, $E_{1/2}^{red} = -0.65$ V (28)). Direct photochemical reduction of ketone **17** involving intermolecular hydrogen abstraction by the carbonyl n,π^* triplet state seems unlikely; intramolecular hydrogen abstraction should be more favourable. Alternatively, the imine may be reduced by chemical sensitization, i.e., hydrogen atom transfer (29).

Reaction involving the unsymmetric olefin 1-methylcyclohexene (**5**) provides more insight into the mechanism; the regio- and stereochemistry are diagnostic. The three isomeric photo-NOCAS products **20**, **21**, and **22**, formed from methanol, 1-methylcyclohexene (**5**), and methyl 4-cyanobenzoate (**10**), when biphenyl (**4**) is present (reaction [9]), are produced in the expected ratio; the *trans-anti*-Markovnikov adduct **20** is the major product. In this case also, the 4-cyanophenyl ketone (**23**) is a major product.

The photo-NOCAS adduct **27** is also formed upon irradiation of an acetonitrile–methanol solution of **10**, **4**, and cyclohexene (**26**) (reaction [10]). Only the *trans* isomer was isolated. The major product from this reaction is the 1:1 (olefin:aromatic) adduct 3-(methyl 4-benzoate)cyclohexene (**28**). This product results from attack of the 3-cyclohexenyl radical, which is formed upon deprotonation of the radical cation of cyclohexene, at the *ipso* position of the methyl 4-cyanobenzoate radical anion. Similar results were observed from 1,4-dicyanobenzene (**1**) and cyclohexene (**26**) upon irradiation under these conditions (2*b*). The radical cation of cyclohexene is particularly prone to deprotonation.

The role of biphenyl (4)

The singlet energy of biphenyl (**4**) ($E_{0,0}$ = 399.6 kJ mol^{-1} (30)) is higher than that of methyl 4-cyanobenzoate (**10**). The long-wavelength absorption tail of this transition does not extend much beyond 280 nm; therefore, most of the initial excitation must involve either methyl 4-cyanobenzoate (**10**) or the methyl 4-cyanobenzoate (**10**) – biphenyl (**4**) charge-transfer complex. Excitation of the charge-transfer complex of **10** and **4** will generate the CRIP, which can subsequently separate. The oxidation potential of biphenyl (**4**) ($E_{1/2}^{ox}$ = 1.9 V (31)) is similar to that of the olefins, and the effectiveness of the biphenyl radical cation ($\mathbf{4}^{+\cdot}$), serving as a codonor for reactions of olefins (Scheme 1, step 7), is well documented (2, 32). The olefin radical cation generated in this way is then free to react with nucleophile (methanol) (Scheme 1, step 3) and the mechanism continues. The fact that photo-NOCAS products are produced under these conditions is additional evidence that irradiation in the absence of added biphenyl (**4**) does not generate the solvated olefin radical cation.

Step 4 in the proposed mechanism (Scheme 1) is depicted as an attack of an alkyl radical at the *ipso* position, bearing the cyano group, of the radical anion. This process is related to the mechanism involving attack of a carbanion on the neutral molecule by single electron transfer (SET). A related duality of mechanism has received considerable attention in connection with reactions of Grignard and alkyl lithium reagents (33). The observation of ketonic products in reactions [8] and [9] now takes on additional significance. Should attack of the β-alkoxyalkyl moiety on the aromatic be considered as a radical attack on the radical anion or as an attack of a carbanion on the neutral molecule? Reactions of **1** and **10** with Grignard and alkyl lithium reagents are shown in reactions [14]–[17] and the results are summarized in Table 3. Differences observed can be correlated with the oxidation potentials of the Grignard and alkyl lithium reagents and the reduction potentials of **1** and **10** (33*d*).

Consider first the reactions of 1,4-dicyanobenzene (**1**). Reaction of **1** with the methyl Grignard (reaction [17]) or methyllithium reagents gives imine **41**, the product expected from nucleophilic attack of the methyl carbanion directly on the nitrile. No *ipso* attack, substitution of methyl for cyano on the aromatic ring, was observed. A major product from the analogous *tert*-butyl reagents, on the other hand, results from attack at the *ipso* position and displacement of cyanide ion, to give 4-*tert*-butylbenzonitrile (**38**). The product resulting from attack at the *ortho* position (**40**), was also formed in significant amounts. Attack of the *tert*-butyl reagent directly on the nitrile is a relatively minor pathway.

This difference in reactivity can be explained in terms of the relative oxidation potentials of the methyl and *tert*-butyl reagents. The oxidation potentials of Grignard and alkyl lithium reagents have been measured (34). There are complications involved in making and interpreting these measurements in terms of the redox couple $R^-/R^\cdot$: structures of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

these reagents are complex, they are known aggregates, involvement of the counter cation is difficult to assess, values are usually reported in ethereal solution and these reagents form complexes with this solvent, and the electrochemical process is not reversible. Nevertheless, the results do provide a reasonably good relative scale of potentials even though the absolute values have no thermodynamic significance and they should only be used in a qualitative sense.

Oxidation potentials for the methyl reagents (CH_3MgBr, $E^{ox}_{1/2} = -0.25$ V; CH_3Li, $E^{ox}_{1/2} = -0.5$ V) are relatively low. The significantly more negative reduction potential of 1,4-dicyanobenzene (**1**) ($E^{red}_{1/2} = -1.66$ V ensures that the methyl reagents exhibit anionic reactivity. Carbanion nucleophilic attack occurs directly on the nitrile group forming the imine (**41**). The oxidation potentials of the *tert*-butyl analogues are much more negative (*tert*-BuMgBr, $E^{ox}_{1/2} = -1.07$ V; *tert*-BuLi, $E^{ox}_{1/2} = -2.30$ V); SET from the alkyl reagent to **1** is now possible, and reaction involving alkyl radical attack on the radical anion ($\mathbf{1}^{-\bullet}$) can now compete with carbanion attack directly on the nitrile.

Ab initio calculations on $\mathbf{1}^{-\bullet}$, at the STO-3G level (Fig. 4), show that spin density is highest at the *ipso* positions, with significant spin also at the *ortho* positions, and very little spin density on the carbons of the nitriles. Coupling of the *tert*-butyl radical at positions of high spin density can account for formation of the major products (**38** and **40**). The minor product, imine **39**, may result from competitive attack of the *tert*-butyl anionic reagent on the nitrile.

The 1,4-diene (**40**) resembles products normally obtained upon Birch reduction of the aromatic (35). Addition of *tert*-butyl radical to the *ortho* position of $\mathbf{1}^{-\bullet}$ gives the carbanion intermediate, which may be stabilized by interaction with the metal counterion. Protonation during work-up gives **40**.

Reactions of methyl 4-cyanobenzoate (**10**) with the Grignard and alkyl lithium reagents are somewhat more complex. The methyl reagents again show exclusive nucleophilic attack at the carboxyl carbonyl expected of anionic species.[8] The methyl Grignard reagent gives a good yield of alcohol **37**, formed by further reaction of the initial product, 4-cyanoacetophenone (**42**). Methyllithium gives a mixture of **37** and ketone **42**. The reduction potential of **10** ($E^{red}_{1/2} = -1.76$ V) is even more negative than that of **1**; the methyl reagents react as anions. Nucleophilic attack occurs exclusively at the carboxyl carbonyl.

The *tert*-butyl reagents attack at both the carbonyl group and at the *ipso* position. The disubstituted product **36** is formed as a secondary product from **34**. Reactions of the *tert*-butyl reagents are again dominated by single electron transfer, followed by *tert*-butyl radical attack at the *ipso* position of the radical anion $\mathbf{10}^{-\bullet}$.

Ab initio calculations on $\mathbf{10}^{-\bullet}$ (Fig. 5) show that spin density is high at the *ipso* positions. Single electron transfer from the *tert*-butyl reagents to **10**, followed by attack of the *tert*-butyl radical at the *ipso* position bearing the cyano group of $\mathbf{10}^{-\bullet}$ can account for the formation of the major products **34** and **36**. The spin density is also high on the carboxyl carbonyl carbon; therefore formation of ketone **42** may involve either (or both) radical–radical anion coupling or anionic attack at the carboxyl carbonyl. Complexation by the metal ion at the carbonyl oxygen may further increase spin density at the carbonyl carbon.

Step 3 (Scheme 1) yields the β-alkoxyalkyl radical; step 4 begins with the radical attacking the radical anion. Electrochemical measurements of the reduction potential of alkyl radicals have been reported (37). Standard potentials of the $R^{\bullet}/R^{-}$ couple are bracketed by (V vs sce, DMF): *tert*-butyl, −1.48, −1.60; *sec*-butyl, −1.38, −1.50; *n*-butyl, < −1.30, −1.42. These values are (perhaps surprisingly) not very different from the values determined for the oxidation of the Grignard and alkyl lithium reagents. Clearly, equilibrium SET involving the β-alkoxy *sec*- or *tert*-alkyl radicals and the radical anions $\mathbf{1}^{-\bullet}$ and $\mathbf{10}^{-\bullet}$ is thermochemically feasible; step 4 can be viewed as a radical attack on the radical anion. Spin density is high (0.27) on the *ipso* positions of the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\bullet}$) and there is very little spin density on the cyano group (Fig. 4). In marked contrast, the spin density on the carbon *ipso* to the cyano group in the radical anion of methyl 4-cyanobenzoate ($\mathbf{10}^{-\bullet}$) is relatively small (0.10) and a larger fraction of the spin density is associated with the carbonyl group (Fig. 5). It is reasonable to suggest that coupling of the β-alkoxylalkyl radical and $\mathbf{10}^{-\bullet}$ will occur at both the *ipso* position and at the carbonyl carbon. While the results can be explained in terms of a reaction of the equilibrium concentration of β-alkoxyalkyl radical and carbanion, it is also possible that SET from the anion radical to the radical may, in fact, be slow relative to attack of the radical on the radical anion. Solvent reorganization and configurational change, associated with conversion from a planar alkyl radical to a tetrahedral carbocation, contribute to an intrinsic barrier for SET as high as 0.58 eV (37, 38). Therefore, product mixtures may be controlled either by kinetics or by the equilibrium of SET.

Deuterium incorporation in the ethers *cis*- and *trans*-**24** and **25**, isolated from reaction [9] when the irradiation is carried out in acetonitrile–methanol-*O*-*d* (Table 2), provides good evidence that SET does occur. Photosensitized (electron transfer) *anti*-Markovnikov addition of alcohols to alkenes is a well-known reaction (22). Two mechanisms have been recognized. After the alkene radical cation reacts with alcohol: the resulting β-alkoxyalkyl radical may be reduced by SET, followed by protonation of the carbanion, or the radical may abstract a hydrogen atom, either by disproportionation or from the allylic position of the starting alkene. Deuterium incorporated in the product ether when the irradiation is carried out in methanol-*O*-*d* is evidence for the SET, protonation (deuteration) of the β-alkoxy carbanion. The fact that deuterium is incorporated in *cis*- and *trans*-**24** and **25** provides strong support for the SET, deuteration sequence. The fact that the percentage of deuterium incorporation is not high indicates that the radical mechanism is also occurring. An alternative mechanism for formation of **25**, addition of methanol to *trans*-1-methylcyclohexene, may contribute. But this mechanism also requires deuterium incorporation and it is, therefore, not a major process.

Conclusions

1. In contrast with 1,4-dicyanobenzene, the singlet excited state (^1L_b) of methyl 4-cyanobenzoate is too short-lived for diffusion-controlled bimolecular reactions.

2. Irradiation of the ground state charge-transfer complex between methyl 4-cyanobenzoate and olefins, in polar solvent, leads to cyclic imine formation. The intermediate

[8]The carboxyl carbonyl is more susceptible to nucleophilic attack than is the nitrile (36).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

excited state of the charge-transfer complex can be described as a contact radical ion pair (CRIP).

3. Irradiation of methyl 4-cyanobenzene and an olefin in nonpolar solvent (e.g., benzene) leads to oxetane formation. In nonpolar solvent the excited state of the charge-transfer complex is dominated by the "no-bond" wavefunction involving locally excited states.

4. When irradiation of methyl 4-cyanobenzoate and an olefin is carried out in acetonitrile–methanol and in the presence of a codonor (e.g., biphenyl) the solvent-separated methyl 4-cyanobenzoate radical anion and olefin radical cation can be obtained and photo-NOCAS products result. This reaction is a useful synthetic procedure for the synthesis of benzoate esters.[9]

5. Attack of an alkyl radical on a radical anion and the attack of a carbanion on a neutral molecule are complimentary/competitive processes, related by single electron transfer (SET). A key step in the photo-NOCAS reaction of methyl 4-cyanobenzoate is depicted as a β-alkoxyalkyl radical attack on the radical anion. Attack may occur at both the *ipso* position, bearing the cyano group, and at the carboxyl carbonyl; both are positions of high spin density.

6. Attack of a carbanion (e.g., the methyl Grignard or methyllithium reagent) on methyl 4-cyanobenzoate occurs exclusively at the carboxyl carbonyl. The *tert*-butyl carbanion (e.g., *tert*-BuMgBr and *tert*-BuLi) is relatively easy to oxidize, SET gives the *tert*-butyl radical and methyl 4-cyanobenzoate radical anion, and alkyl radical attack on the radical anion occurs at the *ipso* position.

Experimental

General information

^{1}H and ^{13}C nmr spectra were recorded on a Nicolet 360 NB, a Varian EM-360L, or a Bruker 300 MSL spectrometer. Chemical shifts are reported in parts per million (ppm) downfield relative to tetramethylsilane. Infrared spectra (ir) were recorded on an air-purged Perkin–Elmer 180 grating spectrometer and are reported in wavenumbers (cm^{-1}). The spectra were calibrated against the 1601.4 cm^{-1} absorption band of polystyrene film. Mass spectra were recorded on a Hewlett–Packard 5970 series mass selective detector and are reported as m/z with the relative intensities in parentheses. Exact mass determinations were carried out using a ZAB-E spectrometer. Elemental analyses were carried out by Canadian Microanalytical Service Ltd., B.C. Melting points were determined using a Cybron Corporation Thermolyne apparatus linked to a digital thermocouple, and are corrected. Ultraviolet absorption spectra were recorded on a Cary Varian 219 spectrometer and are reported in nm. Product analyses were determined by gas chromatography (gc) using either a Hewlett–Packard 5890 gc, fitted with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33 μm film thickness), coupled to a H–P mass selective detector (gc/ms), or a H–P 5890 gc, fitted with a DB 1701 fused silica WCOT column (30 m × 0.25 mm, 0.25 μm film thickness), with a flame ionization detector (gc/fid). Preparative gc was carried out using Varian Aerograph models A-700 and 920, fitted with either a 10% FFAP SW 60/80 or 10% QF-1 Chromasorb P 60/80 column. Preparative medium-pressure liquid chromatography (mplc) was carried out using a 2.5 cm × 1 m column packed with tlc grade silica gel (without binder) (Merck, Kieselgel 60 PF_{254}) at 15 psi helium (1 psi = 6.9 kPa). The chromatograms were generally developed with a hexanes–dichloromethane linear solvent gradient and the eluent was monitored and collected by a uv spectrometer – fraction collector. Dry column flash (dcfc) and flash chromatography (fc) were performed using tlc grade silica gel (Merck) and silica gel (Aldrich, 230–400 mesh 60A) respectively (39).

Irradiations were carried out at 10°C using either a CGE 1-kW or an Hanovia 450-W medium-pressure mercury vapour lamp contained in a quartz immersion well. Solutions were degassed by nitrogen ebullition prior to irradiation.

Materials

Solvents were fractionally distilled immediately before use. Acetonitrile was purified by the reported method (40). Anhydrous diethyl ether (Mallinckrodt) was used without further purification. Tetrahydrofuran (Anachemia, ACS grade) was refluxed for 24 h over lithium aluminum hydride, then fractionally distilled directly into reaction vessels under nitrogen. Thiophene-free benzene was distilled from sodium/benzophenone under nitrogen. Hexane used for uv studies was stirred with sulphuric acid (conc.) to remove alkenes, washed with water, dried over magnesium sulphate, and fractionally distilled from sodium hydride. The olefins 2,3-dimethyl-2-butene (**2**), 1-methylcyclohexene (**5**), and cyclohexene (**26**) were obtained from Aldrich and were fractionally distilled from calcium hydride prior to use. Methyl 4-cyanobenzoate (**10**) (Aldrich) was sublimed and recrystallized twice from methanol. 1,4-Dicyanobenzene (**1**) (Aldrich) was purified by the previously reported method (40). Biphenyl (**4**), 1-methylcyclohexanol, 2-methylcyclohexanol (*cis* and *trans*), and the Grignard and lithium reagents were obtained from Aldrich, and were used as received. 2-Methylpropene was obtained from Matheson.

*Irradiation of methyl 4-cyanobenzoate (**10**) and 2,3-dimethyl-2-butene (**2**) in acetonitrile–methanol (reaction [3])*

A solution of methyl 4-cyanobenzoate (**10**) (0.65 g, 4 × 10^{-3} mol) and 2,3-dimethyl-2-butene (**2**) (1 mL, 8.4 × 10^{-3} mol) in acetonitrile–methanol (3:1, 40 mL) was terminated through quartz using the 450-W lamp. The irradiation was irradiated after 70 h (35.6% conversion, based on unrecovered **10**). Volatile components were removed from the photolysate by distillation at reduced pressure, leaving a yellow oil, which was separated (fc, silica gel, dichloromethane – ethyl acetate). Imine **11** (0.20 g, 83%) was characterized immediately; ir (liq. film) ν: 3400(m, broad), 3240(m), 2960(s), 2870(m), 1720(s), 1645(s), 1590(m), 1380(s); ^{1}H nmr (60 MHz, $CDCl_3$) δ: 8.6(b, 1H, exch.), 8.2–7.7(m, 3H), 3.9(s, 3H), 1.2(s, 6H), 1.1(s, 6H); ^{1}H nmr (361.027 MHz, $CDCl_3$) δ: 8.03(s, 1H), 8.01(m, 1H), 7.78(m, 1H), 3.94(s, 3H), 1.19(s, 6H), 1.10(s, 6H); ^{13}C nmr (90.79 MHz, $CDCl_3$) δ: 188.23(s), 166.75(s), 156.84(s), 139.12(s), 133.34(d, J = 5.0 Hz), 128.62(d, J = 163.3 Hz), 124.29(d, J = 167.2 Hz), 122.42(d, J = 165.9 Hz), 52.28(q, J = 147.1 Hz), 52.01(s), 46.35(s), 25.68(q, J = 127.4 Hz), 25.40(q, J = 126.6 Hz); m/z: 246(3), 245($M^{+\cdot}$, 18), 244(3), 231(39), 230(100), 215(24), 171(23), 128(10), 115(10), 77(5).

*Hydrolysis of imine **11** to ketone **12** (reaction [4])*

Hydrolysis of **11** (0.29 g) was carried out in aqueous methanol (50 mL) and HCl (1 mL, 6 M). The solvent was removed by distillation at reduced pressure, and the residue was diluted with water (50 mL) and extracted with dichloromethane (3 × 25 mL). The combined organic layers were washed with aqueous sodium bicarbonate and water, dried over magnesium sulphate, and evaporated to give a yellow oil. Ketone **12** was isolated (fc, silica gel, dichloromethane) as a colourless solid (0.20 g, 69%). Recrystallization of **12** from 95% ethanol afforded fine needles; mp 69.4–70.4°C; ir (KBr) ν: 2980(m), 2940(m), 2880(w), 1730(vs), 1625(w), 1595(w), 1450(m), 1340(m), 1290(s), 1250(s), 1200(s), 985(s), 760(s); ^{1}H nmr (361.03 MHz, $CDCl_3$) δ: 8.15(s, 1H), 8.03(d, 1H, J = 8.1 Hz), 7.76(d, 1H, J = 8.1 Hz), 3.97(s, 3H), 1.26(s, 6H),

[9]Our study of the scope of the photo-NOCAS reaction has been extended to include 4-(methylsulphonyl)benzonitrile, 4-(trifluoromethyl)benzonitrile, 4-fluorobenzonitrile, (4-cyanophenyl)trimethylammonium iodide, 4-cyanobenzaldehyde, and 4-cyanobenzophenone. Only with 1,4-dicyanobenzene and methyl 4-cyanobenzoate were photo-NOCAS products formed (D. R. Arnold and K. McMahon, unpublished results).

1.10(s, 6H); ^{13}C nmr (90.79 MHz, $CDCl_3$) δ: 210.59(s), 166.47(s), 161.45(s), 136.73(s), 135.47(s), 128.69(d, J = 164.0 Hz), 124.68(d, J = 163.5 Hz), 123.88(d, J 164.1 Hz), 54.15(s), 52.49(q, J = 147.4 Hz), 44.95(s), 26.22(q, J = 127.0 Hz), 21.57(q, J = 127.5 Hz); ms m/z: 247(5), 246($M^{+\cdot}$, 25), 232(19), 231(100), 215(5), 172(6), 128(11), 155(11), 91(5). Anal. calcd. for $C_{15}H_{18}O_3$: C 73.15, H 7.35; found: C 73.14, H 7.37.

Irradiation of tert*-butyl 4-cyanobenzoate (**10**a) and 2,3-dimethyl-2-butene (**2**) in acetonitrile–methanol*

A solution of **10***a* (1.8 g, 8×10^{-3} mol) and **2** (2.14 mL, 1.8×10^{-2} mol) in acetonitrile–methanol (3:1, 90 mL) was irradiated through Pyrex (450 W) for 120 h. The photolysate was concentrated at reduced pressure to give a residual red solid mixture that was separated using dcfc. Elution using 20% ethyl acetate – dichloromethane solvent gave the starting ester (1.7 g, 7.7% conversion) and the cyclic imine **11***a* (0.07 g, 2.4×10^{-4} mol, 36%). **11***a*: ir (liq. film, NaCl) ν: 3240(w, broad), 2980(m), 2980(m), 1720(vs), 1700(m), 1370(m), 1300(s), 1250(s), 1165(vs), 1115(m), 835(w); ^{1}H nmr (361.01 MHz, $CDCl_3$) δ: 7.98(m, 2H, Ar-H and N-H), 7.84(d, 1H, J = 7.80 Hz), 7.77–7.76(m, 1H), 1.63(s, 9h), 1.20(s, 6H), 1.13(s, 6H); ^{13}C nmr (75.47 MHz, DEPT, $CDCl_3$) δ: 188.96(s), 165.39(s), 157.19(s), 138.11(s), 135.70(s), 128.52(d), 124.06(d), 122.70(d), 81.49(s), 52.15(s), 46.49(s), 28.15(s), 28.15(q, *t*-Bu), 25.42(q), 22.58(q); ms m/z: 288(4), 287($M^{+\cdot}$, 18), 272(28), 231(10), 217(39), 216(100), 214(24), 171(20), 57(24).

Imine **11***a* (0.03 g, 1.08×10^{-4} mol) was stirred at room temperature in acetone (5 mL) with a trace of hydrochloric acid (1 M) for 15 m. The sample was evaporated at reduced pressure, dissolved in dichloromethane (2 mL), and passed down a short silica column (Sep-pak). Further elution with dichloromethane (5 mL) gave ketone **12***a* (0.015 g, 5.20×10^{-5} mol, 50%).

12*a*, colourless oil: ir (liq. film, NaCl) ν: 2980(m), 2940(w), 1720(vs), 1370(m), 1310(m), 1285(m), 1255(m), 1165(s), 960(w); ^{1}H nmr (361.01 MHz, $CDCl_3$) δ: 8.09(s, br, 1H), 7.97(dd, 1H, J = 8.00 Hz, J = 1.04 Hz), 7.73(d, 1H, J = 8.00 Hz), 1.62(s, 9H), 1.25(s, 6H), 1.09(s, 6H); ^{13}C nmr (90.78 MHz, $CDCl_3$) δ: 210.82(s), 165.18(s), 161.39(s), 137.42(s), 136.32(s), 128.53(d, J = 165.30 Hz), 124.42(d, J = 161.43 Hz), 123.70(d, J = 165.30 Hz), 81.87(s), 54.16(s), 44.93(s), 28.15(q, J = 127.31 Hz), 26.22(q, J = 129.15 Hz), 21.61(q, J = 128.06 Hz); ms m/z: 289(5), 288($M^{+\cdot}$, 24), 232(36), 218(24), 217(100), 215(24), 172(16), 129(18), 128(24), 115(21), 57(40).

The *tert*-butyl ester (**12***a*) was converted to the methyl ester (**12**) by heating in methanolic hydrochloric acid (1 M) at 70°C for 24 h. The product was identical (gc/ms, retention time, and mass spectrum) with an authentic sample of **12**.

*Irradiation of methyl 4-cyanobenzoate (**10**) and 1-methylcyclohexene (**5**) in acetonitrile–methanol (reaction [5])*

An acetonitrile–methanol (3:1, 250 mL) solution of **10** (3.2 g, 0.02 mol) and **5** (4.7 mL, 0.04 mol) was degassed and irradiated through quartz at 10°C using the 450-W lamp for 17 h. Dilute aqueous HCl (10 mL) was added and the solution was stirred at room temperature for 7 h until the imine (**13**) hydrolysed (gc/ms). The solution was then concentrated under reduced pressure and the residual oil was chromatographed (mplc, silica gel, 90% hexanes – ethyl acetate eluent). Ketone **14** was isolated as a colourless oil (0.45 g, 17.5%, at 50% conversion of the ester **10**).

14: ir (liq. film) ν: 2955(s), 2800(m), 1735(vs), 1630(w), 1600(w), 1500(s), 1455(s), 1210(s), 1100(m), 980(w), 765(m); ^{1}H nmr (361.01 MHz, $CDCl_3$) δ: 8.13(s, 1H), 8.04(d, 1H, J = 7.94 Hz), 7.80(d, 1H, J = 7.79 Hz), 3.97(s, 3H), 3.08(t, 1H, J = 5.24 Hz), 2.03–1.94(m, 2H), 1.58–1.20(m, 6H), 1.28(s, 3H); ^{13}C nmr (90.78 MHz, $CDCl_3$) δ: 209.93(s), 166.43(s), 155.36(s), 138.62(s), 135.09(s), 128.60(d, J = 167.04 Hz), 124.25(d, J = 165.91 Hz), 125.59(d, J = 163.43 Hz), 52.43(q, J = 147.34 Hz), 50.22(s), 45.60(d, J = 132.10), 31.52(t, J = 127.40 Hz), 26.14(t, J = 127.31 Hz), 21.14(tm), 21.01(tm), 21.66(q, J = 127.34 Hz); ms m/z: 260(2), 259(13), 258($M^{+\cdot}$, 84), 244(17), 243(100), 240(21), 229(41), 227(19), 225(13), 217(41), 216(21), 203(21), 181(50), 171(16), 143(15), 142(12), 141(21), 129(25), 128(43), 127(19), 115(48), 77(19), 75(12), 59(24). Exact Mass calcd. for $C_{16}H_{18}O_3$: 258.1256; found: 258.1256.

*Preparation of ammonium salt **15** from keto ester **14** (reaction [7])*

An aqueous sodium hydroxide solution (0.5 mL, 6.2 M) of the keto ester **14** (0.10 g, 3.9×10^{-4} mol) was heated under reflux for 20 min, after which time the ester had dissolved. The solution was cooled in an ice-bath, and water (0.5 mL) was added. This solution was then acidified using hydrochloric acid (conc.). A pale yellow solid was collected by filtration and washed with water. This solid was dissolved in dichloromethane and dried over magnesium sulphate. Evaporation of the solvent gave the acid, 0.08 g (88%), as a colourless solid. The ^{1}H nmr spectrum showed the presence of an exchangeable hydrogen and the absence of the ester methoxy group; ^{1}H nmr (361.01 MHz, $CDCl_3$) δ: 8.214(s, 1H), 8.136(d, 1H, J = 7.95 Hz), 7.856(d, 1H, J = 7.95 Hz), 3.115(t, 1H, J = 5.32 Hz), 2.060–1.930(m, 2H), 1.298(s, 3H), 1.628–1.204(m, 6H). An exchangeable proton was detected (EM-360L) at 8.6 ppm (this peak was not evident in the high-field spectrum (Nicolet)); ^{13}C nmr (90.784 MHz, acetone-d_6) δ: 170.42, 155.47, 139.40, 134.09, 129.28, 126.25, 124.49, 50.38, 45.65, 31.56, 26.24, 21.72, 21.21.

Ammonium salt **15** was formed by bubbling ammonia through a diethyl solution of the acid at room temperature. The salt immediately precipitated from solution. The mixture was filtered; the solid was washed with diethyl ether to remove traces of unreacted acid, and dried under vacuum. The resulting colourless solid was then recrystallized from methanol, to give a sample (mp 183.4–184.8°C) from which a crystal was chosen for X-ray analysis.

*The photo-NOCAS reaction: methanol, 2,3-dimethyl-2-butene (**2**), methyl 4-cyanobenzoate (**10**), and biphenyl (**4**) (reaction [8])*

An acetonitrile–methanol (3:1, 20 mL) solution of ester **10** (0.32 g, 2.0×10^{-3} mol), biphenyl (**4**) (0.31 g, 2.0×10^{-3} mol), and olefin **2** (0.5 mL, 4.2×10^{-3} mol) was degassed and irradiated through quartz using the 450-W lamp. The reaction was stopped after 35 h, at 91.5% conversion of the ester. After the volatile components of the reaction mixture were removed under vacuum, the crude yellow oil was chromatographed using dcfc. Biphenyl (**4**) was recovered (84%) using hexane as the eluent. The photo-NOCAS product (**16**) eluted with 5% diethyl ether – hexane as a colourless solid, 0.068 g (15%). Alcohol **18** was also isolated as a solid, 0.077 g (17%), using 10% acetone–dichloromethane eluent.

16: recrystallized from methanol to give fine needles, mp 66.8–67.4°C; ir (KBr) ν: 3000(m), 2970(w), 1720(s), 1600(w), 1445(m), 1280(s), 1200(m), 1120(m), 1105(s), 1060(m), 1015(m), 770(m), 705(m); ^{1}H nmr (361.11 MHz, $CDCl_3$) δ: 7.92(d, 2H, J = 8.49 Hz), 7.52(d, 2H, J = 8.51 Hz), 3.89(s, 3H), 3.10(s, 3H), 1.39(s, 6H), 1.00(s, 6H); ^{13}C nmr (90.78 MHz, $CDCl_3$) δ: 167.28(s), 153.06(s), 128.62(d, J = 159.46 Hz), 128.10(d, J = 128.12 Hz), 127.20(s), 78.82(s), 51.90(q, J = 146.56 Hz), 49.46(q, J = 140.40 Hz), 45.79(s), 24.35(q, J = 126.65 Hz), 19.88(q, J = 125.31 Hz); ms m/z: no mol, ion, 235(1.5), 219(0.7), 178(2.1), 163(3.2), 118(2.5), 117(2.5), 115(2.7), 103(1.5), 102(1.6), 91(2.5), 74(5.0), 73(100), 51(1.4). *The photo-NOCAS reaction: methanol, 1-methylcyclohexene (**5**), methyl 4-cyanobenzoate (**10**), and biphenyl (**4**) (reaction [9])*

A solution of **10** (0.65 g, 4.03 × 10^{-3} mol), **4** (0.62 g, 4.02 × 10^{-3} mol), and **5** (1 mL, 8.45 × 10^{-3} mol) in acetonitrile–methanol (3:1, 40 mL) was degassed and irradiated through quartz (1 kW). Progress of the reaction was followed by gc/fid and when conversion of the ester was essentially complete (12 h) the reaction was stopped. Removal of the volatile components of the mixture by distillation under reduced pressure gave a yellow oil (2.10 g). This mixture was separated using mplc. When necessary, combined fractions were further purified using dcfc. The isomeric photo-NOCAS products **20**–**22** and the ketone **23** were obtained.

Isomer **20**, 31%: ir (liq. film, NaCl) ν: 2970(m), 2930(s), 2860(m), 2810(w), 1725(vs), 1610(s), 1440(s), 1280(vs), 1190(s), 1105(vs), 760(s), 700(s); ^{1}H nmr (300.13 MHz, $CDCl_3$) δ: 7.99(d, 2H, J = 8.5 H z), 7.49(d, 2H, J = 8.5 Hz), 3.88(s, 3H), 3.48(dd, 1H, J = 9.6 Hz, 3.6 Hz), 3.14(s, 3H), 1.88–1.46(m, 8H), 1.31(s, 3H); ^{13}C (75.47 MHz, $CDCl_3$) δ: 167.12(s). 154.89(s), 129.37 (dd, J = 161.8 Hz, J = 6.0 Hz), 127.49(s), 126.22(dd, J = 157.2 Hz, J = 6.8 Hz), 84.12(d, J = 139.3 Hz), 57.02 (qd, J = 140.6 Hz, J = 4.3 Hz), 51.88(q, J = 147.0 Hz), 43.37(s), 37.88(t, J = 126.8 Hz), 25.90(t, J = 127.4 Hz), 23.73(t, J = 125.4 Hz), 21.78(t, J = 125.4 Hz), 19.54(qm, J = 127.1 Hz); ms m/z: 263(11), 262($M^{+\cdot}$, 71), 231(36), 230(100), 176(43), 145(42), 143(87), 115(33), 91(22), 71(76), 59(22). Ethers *cis*- and *trans*-**24** and **25** were isolated from the volatile components of the photolysate and were identified by direct comparison (ir, gc/ms) with authentic samples.

Reaction [9] was repeated using acetonitrile–methanol-*O*-*d* (3:1) as solvent. The ethers (*cis*- and *trans*-**24**, and **25**) were analyzed by gc/ms, using selective ion monitoring, to determine the percent of deuterium incorporation. The results are shown in Table 2.

Preparation of ethers: cis- *and* trans-*1-methoxy-2-methylcyclohexane (**24**) and 1-methoxy-1-methylcyclohexane (**25**)*

Ethers *cis*- and *trans*-**24** and **25** were made from commercially available alcohols using published procedures (41). The alcohol was treated with sodium hydride in tetrahydrofuran, and then with an excess of methyl iodide. After work-up, the ethers were purified using prep-gc (QF1 column).

1-Methoxy-1-methylcyclohexane (**25**); ^{1}H nmr (361.01 MHz, $CDCl_3$) δ: 3.18(s, 3H, OCH_3), 1.69–1.21(m, 10H), 1.11(s, 3H, CH_3).

cis-1-Methoxy-2-methylcyclohexane (*cis*-**24**); ^{1}H nmr (361.01 MHz, $CDCl_3$) δ: 3.31(s, 3H, OCH_3), 3.21(m, 1H), 1.79–1.25(m, 9H), 0.92(d, 1H, J = 7.19 Hz).

trans-1-Methoxy-2-methylcyclohexane (*trans*-**24**); ^{1}H nmr (361.01 MHz, $CDCl_3$) δ: 3.35(s, 3H, OCH_3), 2.65(td, 1H, J_{aa} = 9.75, 9.75 Hz, J_{ae}= 4.02 Hz), 2.11–2.06(m, 1H), 1.78–1.03(m, 8H), 0.98(d, 3H, CH_3, J = 6.48 Hz).

*The photo-NOCAS reaction: methanol, cyclohexene (**26**), methyl-4-cyanobenzoate (**10**), and biphenyl (**4**) (reaction [10])*

A solution of **10** (1.61 g, 1.0 × 10^{-2} mol), **4** (1.55 g, 1.0 × 10^{-2} mol), and **26** (2.1 mL, 1.8 × 10^{-3} mol) in acetonitrile–

The irradiation of tert*-butyl 4-cyanobenzoate (**10**a) and 2,3-dimethyl-2-butene (**2**) in benzene*

A solution of **10***a* (1.6 g, 0.008 mol) and **2** (0.016 mol) in dry benzene (80 mL) was irradiated (1-kW lamp) through Pyrex for 105 h (9.6% conversion of the ester). Analysis (gc/ms) of the reaction mixture showed only the presence of cyclic imine **11***a* and ketone **12***a*.

*Irradiation of methyl-4-cyanobenzoate (**10**) and 2-methylpropene (**32**) in benzene (reaction [13])*

A solution of **10** (1.45 g, 9.02×10^{-3} mol) and **32** (2.0×10^{-2} mol) in benzene (90 mL) was irradiated through Pyrex. Analysis of the photolysate indicated that an inefficient reaction had occurred. The product, isolated in low yield (1%) as a colourless oil by dcfc, has been assigned structure **33**; ir (liq. film, NaCl) ν: 2980(s), 28880(m), 2240(s, sharp), 1605(m), 955(s), 820(m); ^{1}H nmr (361.01 MHz, $CDCl_3$) δ: 7.64(d, 2H, J = 7.76 Hz) (variable temperature studies are described in the results section), 7.35(broad signal, 2H), 4.56(s, 1H), 4.42(s, 1H), 4.46(d, 1H, J = 5.51 Hz), 4.12(d, 1H, J = 5.51 Hz), 3.16(d, 1H, J = 13.95 Hz), 2.56(d, 1H, J = 14.01 Hz), 1.45(s, 3H), 1.34(s, 3H), 0.78(s, 3H); ^{13}C nmr (75.47 MHz, DEPT, $CDCl_3$) δ: 148.74(s), 141.21(s), 131.55(d), 126.00(d), 119.07(s), 114.95(t), 110.25(s), 92.94(t), 44.44(t), 42.88(s), 25.94(q), 23.75(q), 21.85(q); ms m/z: 241($M^{+\cdot}$, 0.1), 211(5), 196(22), 186(86), 168(20), 131(19), 130(100), 116(24), 102(83), 75(16), 56(49), 55(20), 51(19).

Alkyl Grignard and lithium study

Typical reaction

The electron acceptor (1,4-dicyanobenzene (**1**) or methyl 4-cyanobenzoate (**10**)) was dissolved in freshly distilled tetrahydrofuran and cooled to −84°C (ETOAc – liquid nitrogen slush bath). The Grignard or alkyl lithium reagent was added dropwise under a nitrogen atmosphere. The resulting solution was stirred at low temperature for 1 h and then at room temperature for 1 h. The reaction was quenched by the addition of saturated aqueous ammonium chloride solution. The mixture was stirred for 15 min and extracted with CH_2Cl_2. The combined extracts were washed with H_2O and dried over $MgSO_4$. The solution was filtered and concentrated by rotary evaporation, and the crude mixture was made up to 250 mL with CH_2Cl_2. A 25-mL aliquot, with a known amount of cyclododecane (ca. 0.013 g), was made up to 50 mL with CH_2Cl_2. This solution was then analyzed (gc/fid).

The following samples, isolated from the reaction mixtures, were prepared for calibration of the gc/fid. 1-(4-Cyanophenyl)-2,2-dimethyl-1-propanone (**35**): ir (liq. film, NaCl) ν: 2980(m), 2245(m), 1685(s), 1480(m), 1280(m), 1195(m), 1175(w), 950(m), 840(m); ^{1}H nmr ($CDCl_3$, 361.03 MHz) δ: 7.72(s, 4H), 1.34(s, 9H); ms m/z: 187($M^{+\cdot}$, 5), 131(19), 130(28), 103(22), 130(28), 103(22), 102(24), 75(12), 57(100).

40: recrystallization from methanol affords needles, mp 86.6–87.3°C; ir (KBr) ν: 2940(m), 2840(m), 2200(s), 1605(s), 1460(s), 1405(m), 1355(m), 1275(m), 1200(s), 1015(m), 995(m), 950(s), 900(s), 815(s); ^{1}H nmr ($CDCl_3$, 300.13 MHz) δ: 6.83(m, 1H), 6.75–6.74(m, 1H, J = 4.7 Hz), 3.05–3.00(m, 2H), 2.97–2.92(m, 1H), 1.06(s, 9H); ^{13}C nmr ($CDCl_3$, 90.785 MHz) δ: 143.94(d, J = 165.1 Hz), 142.38(d, J = 166.4 Hz), 119.16(s), 117.73(s), 113.13(s), 110.20(s), 48.61(d, J = 129.2 Hz), 39.20(s), 29.12(t, J = 132.6 Hz), 27.50(q, J = 125.2 Hz); ms m/z: no $M^{+\cdot}$, 184(0.2, loss of H_2), 169(1.5), 130(5), 129(16), 128(10), 102(11), 76(5), 75(6), 57(100), 51(8). The multiplets due to olefinic hydrogens collapse to two singlets upon irradiation of the alkyl hydrogens. This observation, along with the uv spectrum, which showed no long-wavelength absorption, is indicative of a 1,4-diene. Anal. calcd. for $C_{12}H_{14}N_2$: C 77.38, H 7.58, N 15.04; found: C 76.98, H 7.48, N 14.87.

Methyl 4-*tert*-butylbenzoate (**34**): ^{1}H nmr ($CDCl_3$, 361.03 MHz) δ: 7.97(d, 2H, J = 8.7 Hz), 7.43(d, 2H, J = 8.7 Hz), 3.88(s, 3H), 1.32(s, 9H); ms m/z: 193($M^{+\cdot}$, 4), 192(32), 178(24), 177(100),

161(21), 149(44), 145(10), 118(12), 117(16), 115(18), 105(24), 93(12), 91(25), 77(13), 59(21), 51(10).

*Preparation of 1-[4-(1,1-dimethylethyl)phenyl]-2,2-dimethyl-1-propanone (**36**)*

The procedure followed was that used by Pearson (43). Dry magnesium (2.43 g, 0.1 mol) and 1-bromo-4-*tert*-butylbenzene (21.7 g, 0.1 mol) in diethyl ether (75 mL) were placed in an ultrasonic bath for 1 h until all the metal had dissolved. Trimethylacetonitrile (8.3 g, 0.1 mol) in diethyl ether (10 mL) was added dropwise to the solution. The mixture was refluxed for 2 h; an off-white precipitate formed. The mixture was poured onto ice/HCl (6 M, 200 mL) and allowed to stand overnight. The organic layer was separated and the aqueous layer was extracted with ether (3 × 100 mL). The combined organic layers were washed with dilute HCl (2 × 100 mL), saturated sodium bicarbonate (2 × 100 mL), and H_2O (2 × 100 mL). The solution was dried and concentrated at reduced pressure to give a yellow liquid. Fractional distillation at reduced pressure gave the desired ketone in 34% yield; bp 90–95°C, 0.1 Torr (1 Torr = 133.3 Pa) (lit. (43) mp 103–106°C, 1 Torr) ir (liq. film, NaCl) ν: 2980(m), 2880(m), 1660(s), 1600(m), 1460(s), 1390(m), 1355(s), 1270(s), 1200(m), 1170(s), 1100(m), 945(s), 830(s); ^{1}H nmr ($CDCl_3$, 361.027 MHz) δ: 7.40(d, 2H, J = 8.5 Hz), 7.73(d, 2H, J = 8.5 Hz), 1.36(s, 9H), 1.31(s, 9H), ms m/z: 218($M^{+\cdot}$, 3), 162(48), 161(100), 146(25), 118(24), 117(12), 115(12), 105(11), 91(24), 77(12), 57(21).

2-(4-Cyanophenyl)-2-propanol (**37**): ir (liq. film) ν: 3450(s, broad), 2990(m), 2250(s), 1600(m), 1170(m), 1090(m), 945(m), 823(s); ^{1}H nmr ($CDCl_3$, 60 MHz) δ: 7.6(s, 4H), 2.9(s, 1H, exch.), 1.6(s, 6H); ms m/z: 161($M^{+\cdot}$, 2), 147(11), 146(100), 102(11), 75(11), 59(14), 51(11).

Ultraviolet absorption studies

Ultraviolet absorption spectra were recorded in acetonitrile–methanol (3:1) solution, the solvent system used in the photo-NOCAS reaction, to determine if there were charge-transfer (CT) complexes present under the irradiation conditions. A stock solution of acceptor (0.1 M) was used for this study. The absorptions were studied at 310 nm, where **1**, **10**, and **10*a*** show no absorbance at this concentration. The absorbance was studied as a function of increasing olefin concentration (0.0 M–2.0 M).

To carry out the determination of the association constant, the concentration of the acceptor was made 0.010 M while the concentration of the olefin was varied over the range 0.101–0.404 M in keeping with the assumption used in the derivation of the Benesi–Hildebrand equation (4). To maintain constant solvent characteristics, the total number of moles added to the stock solutions was kept constant by the coaddition of *n*-hexane. The total concentration of added alkene and hexane was 0.404 M.

Acknowledgements

This work was supported by a grant from the Natural Sciences and Engineering Research Council of Canada. We thank Dr. D. L. Hooper at the Atlantic Regional Magnetic Resonance Centre at Dalhousie University for the high-field NMR spectra and for help in the preparation of the manuscript. Exact mass measurements were carried out by Mr. D. Embree at the Institute for Marine Biosciences, Halifax. We also thank Dr. T. S. Cameron at Dalhousie for the X-ray analysis of **15**.

Solvation and metal ion effects on structure and reactivity of phosphoryl compounds. Part 2.[1] Alkali metal ion catalysis in the demethylation of methyl di(3-nitrophenyl)phosphinate by iodide ion

AGNES M. MODRO AND TOMASZ A. MODRO[2]

Centre for Heteroatom Chemistry, Department of Chemistry, University of Pretoria, Pretoria 0002, South Africa

Received September 18, 1992

AGNES M. MODRO and TOMASZ A. MODRO. Can. J. Chem. **71**, 469 (1993).

Second-order rate constants for the demethylation of methyl di(3-nitrophenyl)phosphinate by iodide in acetone-d_6 at 25°C have been measured. For a series of iodide salts the rate increased in the order: $NBu_4I < KI \leq NaI < LiI$. The addition of crown ethers or D_2O has a retarding effect on the reaction rate. The results are discussed in terms of the increase of the nucleofugality of the phosphinate group via the complexation of metal ions with the phosphoryl function.

AGNES M. MODRO et TOMASZ A. MODRO. Can. J. Chem. **71**, 469 (1993).

On a mesuré les constantes de vitesse du deuxième ordre de la réaction de déméthylation du di(3-nitrophényl)-phosphinate de méthyle par l'iodure dans l'acétone-d_6, à 25°C. Pour une série d'iodures, la vitesse augmente dans l'ordre $NBu_4I < KI \leq NaI < LiI$. L'addition d'éthers couronnes ou de D_2O diminue la vitesse de la réaction. On discute des résultats en fonction de l'augmentation du caractère nucléofuge du groupe phosphinate via une complexation des ions métalliques par la fonction phosphoryle.

Methyl phosphotriester analogues of polynucleotides attract increasing attention (2), while nucleophilic removal of the methyl group from the POMe function (see, for example, ref. 3) represents the final step in the "phosphotriester" method of oligonucleotide synthesis. Various nucleophiles can be employed in the dealkylation, and the utility of halide ions as reagents for selective removal of alkyl groups in phosphate esters was recognised 40 years ago by Zervas and Dilaris (4), as well as by Todd in his classic studies on phosphorylation (5). Although the effect of the counterion of the halide salt on the reaction rate was never the subject of an investigation, it was reported in one of Todd's papers (6) that the yield of debenzylation of benzyl diphenylphosphate by M^+I^- increases in the order: $M^+ = C_6H_{11}NH_3^+ < Na^+ < Li^+$. The participation of the Li^+ ion in the demethylation of phosphoric esters was postulated by van Lier and co-workers (7), followed by their nmr spectroscopic study of the interactions between Li^+ and phosphoryl substrates (8). On the other hand, Winstein (9) and others (10) demonstrated that the rate of dealkylation of alkyl arenesulfonates by halide ions in acetone or HMPTA is independent of the cation used.

In a recent series of papers on the nucleophilic displacement at phosphorus and sulfur centers, Buncel and co-workers demonstrated for the first time, and quantitatively assessed, alkali metal ion catalysis in the displacement at the phosphoryl centre by oxygen nucleophiles (11). The catalysis, increasing in the order: $K^+ < Na^+ < Li^+$, was interpreted in terms of the association of the metal ion and the transition state. Our own studies on the effect of metal ions (K^+, Na^+, Li^+, Mg^{2+}) on nmr spectroscopic parameters and the conformational preferences of phosphonic esters (1) gave evidence for strong interactions between the metal ion and the PO_3R_2 group. In this work we report our results on the O-demethylation of methyl di(3-nitrophenyl)phosphinate **1** by iodide salts in acetone (Scheme 1), which show, to our knowledge for the first time, metal ion catalysis in an S_N2 process with the phosphate-derived ion, $X_2PO_2^-$, as a leaving group.

Results and discussion

Methyl di(3-nitrophenyl)phosphinate (**1**) was prepared by nitration of methyl diphenylphosphinate and the pure bis-*meta* isomer was isolated by column chromatography. The rate of reaction of **1** with iodide salts in acetone-d_6 at 25°C was studied by ^{31}P nmr spectroscopy, following the disappearance of the signal due to the substrate (δ_P 28.8) and the appearance of the signal due to the di(3-nitrophenyl)phosphinate ion (δ_P 7–14). The observed second-order rate constants (k_{obs}) were calculated in the usual way from the conversion values and the initial concentrations of **1** and the (total) iodide salt. The values obtained for the alkali metal (K^+, Na^+, Li^+) and the ammonium (NH_4^+, NBu_4^+) iodides are listed in Table 1. For the kinetic runs with [**1**]/[MI] = 1, some curvature of the second-order rate plots was obtained due to the change in concentration of the free ions with the degree of conversion. The k_{obs} values determined for low conversions (given in parentheses in the fourth column of Table 1) were not, however, significantly different from the average values obtained from the whole runs. As in all cases involving ion-pairing nucleophiles in S_N2 reactions (12), the observed rate constants decrease with increase in salt concentration due to the supression of the dissociation of the ion pairs into free ions. Using the available (13) dissociation constants for the iodides studied, the specific second-order rate constants for the free iodide ion, k_{I^-}, were calculated and are given in the last column of Table 1. It is clear that the rate of the demethylation depends on the counterion introduced with the nucleophile, the reactivity of the salts increasing in the order: $NBu_4I \approx NH_4I < KI \leq NaI < LiI$. Taking for each cation the average value of k_{I^-}, the catalytic effect of the alkali metal ions relative to the rate obtained with NBu_4^+ as a counterion (no catalysis, $k_{rel} = 1.0$) is approximately $k_{rel} = 3.9$, 4.5, and 30.7, for K^+, Na^+, and Li^+, respectively. The order and the magnitude of the rate acceleration obtained for these three

alkali metal ions parallel the results reported by Buncel and co-workers (11) for nucleophilic displacement at the phosphinyl centre by ethoxide salts.

Catalysis by the alkali metal ions in the nucleophilic displacement of the phosphinate ester was confirmed by the effect of complexing agents on the reaction rate (Table 2). When the reaction was carried out in the presence of 5–7.5 mol-equivalent of crown ethers, a decrease in the rate was observed; again, the effect increased in the order: $K^+ < Na^+ < Li^+$. Under those conditions the rate constants reached approximately the same value for all three metal ions (10^4 $k_2 = 1.80 \pm 0.63$), and are in reasonable agreement with the value of k_{I^-} obtained for the ammonium salts (Table 1, 10^4 $k_{I^-} = 2.55 \pm 0.52$), for which no cation catalysis should be expected.

The addition of protic solvents often has a decelerating effect in S_N2 reactions (14); for example, exchange of the halide ions between benzyl iodide and NaI in acetone is decelerated by the addition of water, by a factor of ca. 0.4 at a [water]/[acetone] ratio of 0.1 (15). The retarding effect is attributed to the hydrogen bonding of the halide ion, decreasing the latter's nucleophilic activity. We have measured the effect of water (D_2O) on the demethylation of **1** and the results are given in Table 3. As expected, the addition of D_2O decreased the rate of the reaction, with the retarding effect increasing in the order: $NBu_4^+ < K^+ < Na^+ < Li^+$. In the medium containing 10% (v/v) of D_2O all salts react with approximately the same rate (10^4 $k_{obs} = 0.20 \pm 0.03$). This result is consistent with an assumption that under those conditions (molar ratio D_2O/MI $\approx 10^2$) the ions of the iodide salts are fully hydrated, and any catalytic effects of the metal ions are therefore absent. The observed rate constant is ca. 10 times smaller than k_{I^-} obtained for ammonium iodides in acetone (Table 1), reflecting the decelerating effect of the hydrogen bonding of the iodide ion to the molecules of water.

In their interpretation of catalysis in the nucleophilic displacement at phosphorus, Buncel and co-workers (11) proposed a model according to which ". . . bond formation between the alkoxide oxygen and the phosphorus atom . . . occurs concomitantly with association of the phosphinyl oxygen with M^+ . . ." We would like to extend this model to the nucleophilic displacement at the α-carbon atom of a phosphinyl center by introducing the mechanism (Fig. 1) in which the departure of the leaving group is enhanced by coordination of the metal ion to the phosphinyl oxygen atoms that develop negative charge in the transition state. The metal-ion-assisted pathway can involve free ions (Fig. 1*a*), as well as the ion pair (Fig. 1*b*); in the latter case the delivery of the iodide ion to the methyl carbon should be facilitated by coordination to the phosphoryl oxygen.

In acetone solution the reaction product, diarylphosphinate ion, interacts strongly with the counterion and probably exists as a tight ion pair. ^{31}P nmr chemical shift of the phosphinate salt varied significantly with the counterion, and

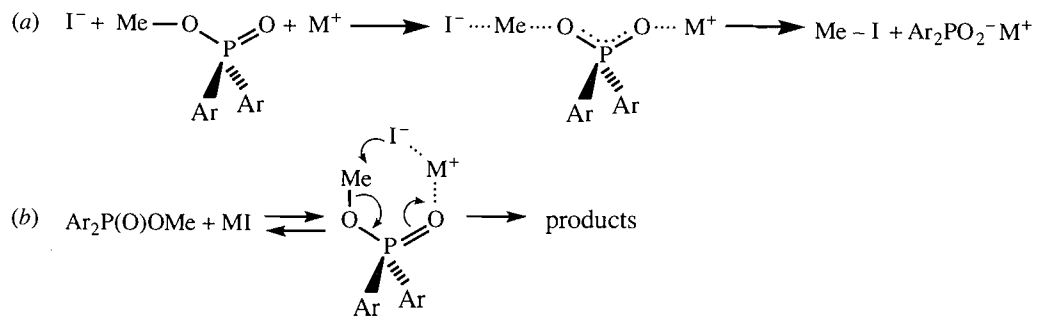

FIG. 1. Proposed models for the metal-ion catalysis in the nucleophilic displacement of phosphinate ester.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

decreased in the order: δ_P = 13.7, 11.5, 11.4, 10.7, and 7.1, for Li^+, Na^+, K^+, NH_4^+, and NBu_4^+, respectively. In the case of the Li^+ salt, the ^{31}P nmr signal was very broad, indicating strong association that eventually led to the precipitation of lithium phosphinate from the acetone solution. In the medium consisting of 90% of acetone-d_6 and 10% of D_2O (v/v), on the other hand, all phosphinate salts gave rise to the ^{31}P nmr signal at the same field (δ_P 12.3 ± 0.7) irrespective of the nature of the cation.

We believe that we have demonstrated that alkali metal ions can play a role in the nucleophilic displacement at carbon of a phosphoric ester via the complexation of the phosphoryl group in a similar way to their effects on the phosphorylation (11), or on the conformational equilibria (1). Our further investigations are aimed at the evaluation of such catalytic effects in systems containing a larger number of oxygen atoms at the phosphoryl center, i.e., the phosphonic and the, biologically more related, phosphoric esters.

Experimental section

Solvents and commercially available reagents were purified by standard methods immediately before use. Acetone-d_6 (Aldrich, 99.5 at.% D) was dried over molecular sieves. The salts were dried in an oven at 120°C and stored in a desiccator over P_4O_{10}. The nmr spectra were recorded on a Bruker AC 300 MHz spectrometer at a probe temperature of 30°C. Chemical shifts are given relative to $SiMe_4$ (^1H) or 85% H_3PO_4 (^{31}P). Coupling constants are given in Hz. The mass spectrum was recorded on a Varian MAT-212 double-focusing direct-inlet spectrometer at an ionization potential of 70 eV. Only the molecular ion data are included.

Methyl diphenylphosphinate was prepared from diphenylphosphinic chloride and methanol in the presence of triethylamine (16) and purified by bulb-to-bulb distillation (oven temp. 250°C/0.2 Torr; 1 Torr = 133.3 Pa). δ_H ($CDCl_3$): 3.77 (3 H, d, J_{HP} 11.1, OMe), 7.42–7.52 (6 H, m, *meta* and *para* H's of Ph), 7.78–7.82 (4 H, m, *ortho* H's of Ph). δ_P: 33.7.

Methyl di(3-nitrophenyl)phosphinate **1** was prepared by nitration of methyl diphenylphosphinate according to the following procedure, reported (17) for a similar synthesis.

To a solution of the substrate (2.50 g, 10.77 mmol) in glacial acetic acid (15 mL) a solution of nitric acid (100%, freshly distilled from conc. H_2SO_4, 30 mL) in glacial acetic acid (7.5 mL) was added dropwise with stirring and cooling in an ice bath. The solution was left at room temperature for 70 h and poured on ice (750 g). The first fraction of a crude product (1.54 g, 44.5%) was collected by filtration and dissolved in chloroform. The aqueous filtrate was extracted with chloroform (3 × 30 mL), the combined chloroform solutions were dried ($MgSO_4$), and the solvent was removed under reduced pressure. Crude **1** was obtained as a pale yellow solid, 3.46 g (98%), and was purified by column chromatography (silica gel, $CHCl_3$), followed by crystallization from benzene – ethyl acetate – acetone. Colorless crystals, mp 127–128°C; δ_H ($CDCl_3$): 3.87 (3 H, d, J_{HP} 11.3, OMe), 7.71 (1 H, dt, J_{ortho} 9.0, J_{HP} 5.0, H-5), 8.16 (1 H, dddd, J_{HP} 11.7, J_{ortho} 7.6, J_{meta} 1.8, 1.1, H-6), 8.41 (1 H, ddd, J_{ortho} 9.1, J_{meta} 2.0, 1.8, H-4), 8.64 (1 H, ddd, J_{HP} 12.9, J_{meta} 1.8, 0.5, H-2); δ_P: 27.3; ms, m/z: 332 (M^+, 2%).

Sodium di(3-nitrophenyl)phosphinate

A sample of **1** was incubated at room temperature in aqueous methanolic solution containing 1 mol-equivalent of NaOH, and the progress of the hydrolysis was followed by TLC. After all **1** was consumed, the solution was evaporated to dryness under reduced pressure, the residue was washed several times with ether, and dried. Yield: quantitative; white powder, δ_P (D_2O) 18.7.

Kinetic measurements

Solutions of substrates in acetone-d_6 (or in acetone-d_6/D_2O) were transferred to an nmr tube and incubated in a thermostatted water bath at 25 ± 0.2°C. Tubes were withdrawn at selected time intervals and the ^{31}P nmr spectra of the reaction mixtures were recorded immediately. The concentration changes of the reaction product, measured from the integrated peak areas of **1** and of the reaction product, followed second-order kinetics. In cases when the ^{31}P nmr signal of the product was broad (lithium salts), the internal standard (benzyltriphenylphosphonium tetrafluoroborate, δ_P = 25.0) was used. The runs were carried out to at least 80% conversion. Good second-order linear plots were obtained, with values of r^2 = 0.9945–0.9999.

RENÉ T. BOERÉ, KLAUS H. MOOCK, SEAN DERRICK, WILLIAM HOOGERDIJK, KATHRYN PREUSS, JUDY YIP, and MASOOD PARVEZ. Can. J. Chem. **71**, 473 (1993).

New preparative routes to the title compounds are reported in which the yields are substantially improved over previous methods. In one method, reaction of O_2 with a mixture of $XC_6H_4CN_2S_2^+Cl^-$ and Ph_3Sb leads to the products in 40–60% yield. In another, the reaction of the same salts with silylated amidines $XC_6H_4C\{NSiMe_3\}N(SiMe_3)_2$ in a 1:1 mol ratio leads to the same compounds in 18–65% yield. The syntheses of 3,7-$(XC_6H_4)_2\{CN_2S_2N_2C\}$, X = H, 4-$CH_3$, 4-$CH_3O$, 4-Cl, 4-$CF_3$, and 3-$CF_3$, are reported. Mixed derivatives were also prepared, but not isolated as pure compounds. The crystal structure of the 4-CF_3 compound has been determined by X-ray diffraction; triclinic, $P\bar{1}$ with Z = 1; cell dimensions: a = 6.835(2), b = 9.936(3), c = 6.320(2) Å, α = 96.44(3)°, β = 102.88(3)°, γ = 88.42(3)°. R = 3.4%, R_w = 3.5% for 1100 data. The eight-membered ring is flat with equivalent bond lengths between any two types of atoms, indicative of a delocalized electron distribution. The 10π central aromatic rings have been oxidized and reduced in CH_2Cl_2 using voltammetric methods. The reversible one-electron reduction step gives stable 11π species. The resistance to oxidation of the title compounds is contrasted to the ease of oxidizing 3,7-$[(CH_3)_2N]_2\{CN_2S_2N_2C\}$, in accordance with earlier chemical studies.

RENÉ T. BOERÉ, KLAUS H. MOOCK, SEAN DERRICK, WILLIAM HOOGERDIJK, KATHRYN PREUSS, JUDY YIP et MASOOD PARVEZ. Can. J. Chem. **71**, 473 (1993).

On a développé de nouvelles voies de synthèse des composés mentionnés dans le titre qui donnent des rendements de beaucoup supérieurs à ceux rapportés antérieurement. Dans une méthode, la réaction du O_2 avec un mélange de $HC_6H_4CN_2S_2^+Cl^-$ et de Ph_3Sb conduit aux produits avec des rendements allant de 40 à 60%. Dans une autre méthode, la réaction des mêmes sels avec les amidines silylées $XC_6H_4C\{NSiMe_3\}N(SiMe_3)_2$, dans un rapport molaire de 1 : 1, conduit aux mêmes produits avec des rendements allant de 18 à 65%. Donc on rapporte la synthèse des 3,7-$(XC_6H_4)_2\{CN_2S_2N_2C\}$, X = H, 4-$CH_3$, 4-$CH_3O$, 4-Cl, 4-$CF_3$ et 3-CF_3. On a aussi préparé des dérivés mixtes; toutefois, il n'a pas été possible de les isoler à l'état pur. On a déterminé la structure cristalline du composé 4-CF_3 par diffraction des rayons X; triclinique, $P\bar{1}$, avec a = 8,835(2), b = 9,936(3) et c = 6,320(2) Å, α = 96,44(3)°, β = 102,88(3)° et γ = 88,42(3)°, Z = 1. R = 3,4% et R_w = 3.5% pour 1100 données. Le cycle à huit chaînons est plat alors que les longueurs des liaisons sont équivalentes entre tous les atomes pris deux à deux; ce résultat indique que la distribution électronique est délocalisée. Utilisant des méthodes voltampérométriques et opérant dans le CH_2Cl_2, on a oxydé et réduit les cycles aromatiques à 10 électrons π. La réduction réversible par un électron conduit à des espèces stables à 11 électrons π. En accord avec les études chimiques antérieures, les composés mentionnés dans le titre sont beaucoup plus difficiles à oxyger que le 3,7-$[(CH_3)_2N]_2\{CN_2S_2N_2C\}$.

[Traduit par la rédaction]

Introduction

1,5-Dithia-2,4,6,8-tetrazocine heterocycles **4** are structurally and theoretically interesting molecules that may exist either in the planar, 10π aromatic structure I or in the folded structure II, in which the two halves are planar. Since their discovery in 1981 (1), there have been numerous studies on the synthesis (2–4), UV photoelectron spectra (5, 6), magnetic circular dichroism (7), and MO electronic structure of these compounds (6, 8, 9). This class of compound has been placed in context in a recent comprehensive review (10).

The type II compounds have interesting chemical reactivity in oxidation reactions, and as ligands to low-valent metal complexes (11–13). However, the chemistry of the type I compounds is less developed. We have reported the complete resistance of these compounds towards both polar and radical oxidants (12), while Amin and Rees were able to degrade the eight-membered ring by reaction with ozone (3). A major limitation towards further chemical studies has been the lack of a synthetic method for the preparation of reasonable quantities of the type I compounds. Amin and Rees investigated more than 10 methods and variations for the preparation of **4***a* (see Scheme 1), without managing to increase the yield above 10%.

Recently we discovered a higher yield route to type I derivatives through the reaction of 4-aryl-1,2,3,5-dithiadiazolyl dimers **3** with dioxygen (14). This is a novel and unexpected reaction, and in this paper we provide the full details of this investigation. Starting from here we have developed a much higher yield synthetic method with a simple work-up for the preparation of **4***a–f*. Both existing and new compounds have been prepared by this route, and the products have been fully characterized. The ^1H and ^{13}C NMR spectra have been recorded and shown to be quite diagnostic. The single-crystal X-ray structure of **4***e* is also reported.

For personal use only.

There is a claim in the literature that **4***a,b,e,g* can be prepared in high yield by the reaction of **1***a,b,e,g* with 1.5 equivalents of SCl_2 in toluene (4). However, the physical properties of the products reported do not agree with those we have determined, and we believe that the yields in this report are in error.[3] Amin and Rees demonstrated that both benzamidine and its persilylated analogue *N,N,N'*-tris(trimethylsilyl)benzamidine react with sulfur dichloride or sulfur monochloride in CH_2Cl_2 to give a large amount of **2***a* and simultaneously a small amount of **4***a* (less than 10%) (2, 3). We were intrigued by these conflicting reports and speculated about the origin of two products from such a simple condensation reaction. In this paper we also demonstrate a second viable synthetic route to aryl dithiatetrazocines by the reaction of purified salt **2** with another equivalent of amidine **1**.

We have probed the previously noted difference in the reactivity of the type I and II compounds through a detailed electrochemical study. Cyclic voltammetry and phase-sensitive alternating-current voltammetry measurements of **4***a–f* are reported and discussed in the light of molecular orbital calculations. Our results improve the understanding of the electronic structure of these interesting compounds. These results are contrasted to the voltammetric behaviour of the type II compound with R = Me, i.e., $Me_2N\text{-}CN_2S_2N_2C\text{-}NMe_2$, **9**.

Experimental section

Starting materials and general procedures

Silylated amidines **1***a–g* were prepared by the literature methods (15), as were the known dithiatetrazocines $^tBu\text{-}CN_2S_2N_2C\text{-}^tBu$, **5**, and **9** (1, 6). **5** was purified by sublimation at 10^{-2} Torr (1 Torr = 133.3 Pa) at ambient temperature (7). Chlorine (Matheson), triphenylantimony, *p*-nitrobenzonitrile, and magnesium (Aldrich) were obtained commercially and used as received. NBu_4PF_6 (Aldrich) was vacuum dried before use and handled in a glove box. Sulfur dichloride (Aldrich) was distilled from PCl_3 immediately before use. Solvents were Fisher reagent grade, or better, and were distilled from P_2O_5 (CCl_4, $CHCl_3$, CH_3Cl_2) and Na wire (diethyl ether). CH_3CN was double-distilled from P_2O_5 and CaH_2. O_2 gas was passed through a 30-cm Drierite column before use. Unless otherwise indicated, all procedures were performed under an atmosphere of purified N_2 using a dry-box, Schlenk-ware, and vacuum-line techniques. Infrared spectra were recorded on a Bomem MB102 Fourier transform spectrometer as Nujol mulls between CsI plates and are reported in the 1700–200 cm^{-1} region only, unless otherwise indicated. NMR spectra were recorded on a Bruker AC-F 250 MHz FT spectrometer. NMR data are collected in Table 1. Electronic absorption spectra were obtained in 1.00-cm quartz cuvettes on a Varian DMS 100S spectrophotometer. Data are collected in Table 2. Mass spectra were recorded by the Mass Spectrometry Centre, University of Alberta. Elemental analyses were performed by MHW Laboratories, Phoenix Ariz.

Preparation of **2**a–g

2*a* was prepared by the published procedure (16, 17). The IR spectrum agreed with that reported previously (18).

2*b*: From 2.1 g (6.1 mmol) of **1***b* and 2.5 mL SCl_2 (excess) in 100 mL CH_3CN; yield 0.93 g, 64% as deep orange needles. An analytical sample was obtained by recrystallizing from acetonitrile, mp 160°C. IR: 1604(m), 1413(w), 1296(w), 1259(w), 1211(w), 1198(w), 1155(w), 1041(w), 1026(w), 924(m), 901(m), 847(m), 825(w), 725(m), 686(w), 547(w), 493(w), 289(w). Mass spectrum (EI, 70 eV), high resolution: 195.0052 (calcd.: 195.0051); *m/z*: 195 ($RCN_2S_2^+$, R = $CH_3C_6H_4$, 98%), 149 ($RCNS^+$, 38%), 117 (RCN^+, 30%), 116 (RCN − H^+, 38%), 78 (S_2N^+, 100%). Anal. calcd. for $C_8H_7ClN_2S_2$: C 41.64, H 3.06%, N 12.14%; found: C 41.79, H 3.20, N 12.28%.

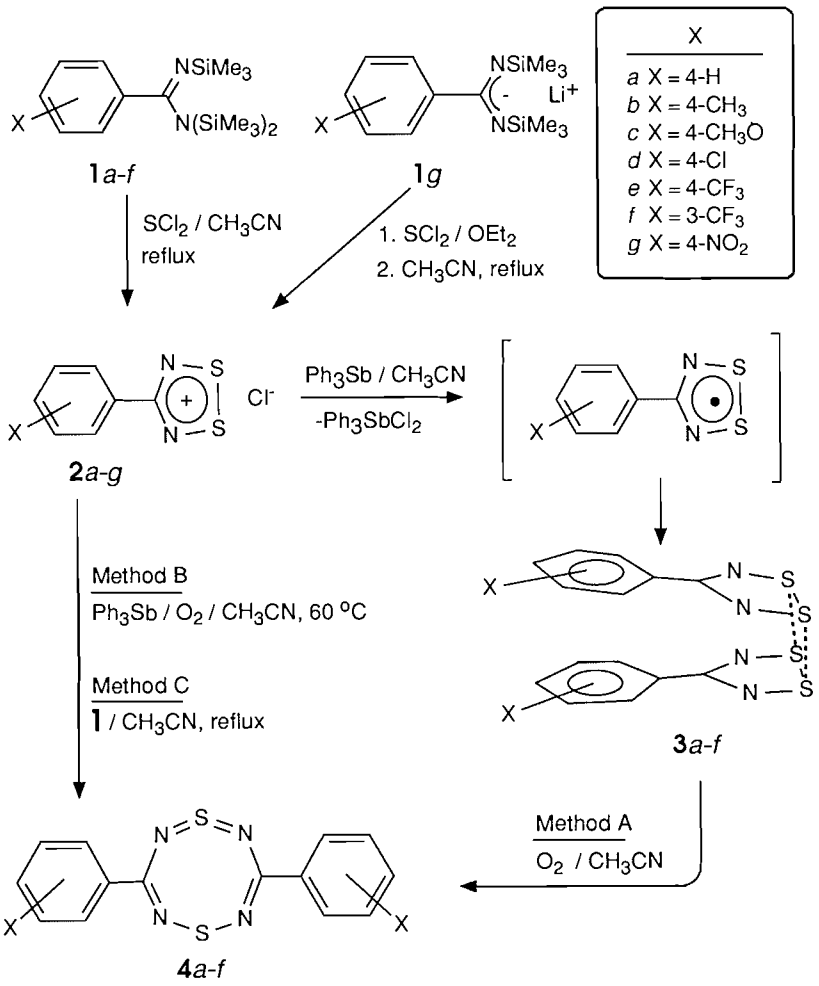
2*c*: From 3.5 g of (9.5 mmol) of **1***c* and 1.5 mL SCl_2 (excess) in 20 mL CH_3CN; yield 1.8 g, 76% as a dark solid. An analytical sample was obtained by recrystallizing from acetonitrile, mp 218°C. IR: 1674(s), 1601(s), 1574(m), 1520(w), 1427(m), 1393(vs), 1323(m), 1306(w), 1269(s), 1198(w), 1173(vs), 1121(w), 1015(s), 919(m), 891(s), 859(s), 848(m), 820(m), 793(w), 743(m), 723(w), 691(m), 631(w), 600(m), 550(m), 532(w), 484(w), 407(w), 286(w), 228(w). Mass spectrum (EI, 70 eV) *m/z*: 211 ($RCN_2S_2^+$, R = $CH_3OC_6H_4$, 100%), 165 ($RCNS^+$, 48%), 133 (RCN^+, 71%), 78 (S_2N^+, 100%). Anal. calcd. for $C_8H_7ClN_2OS_2$: C 38.94, H 2.90, N 11.53%; found: C 39.15, H 2.90, N 11.53%.

2*d*: From 5.0 g of (13.5 mmol) of **1***d* and 2.0 mL SCl_2 (excess) in 50 mL CH_3CN; yield 2.7 g, 80% as orange needles. The infrared spectrum matched that reported in the literature (18).

2*e*: From 5.0 g (12.4 mmol) of **1***e* and 2.0 mL SCl_2 (excess) in 40 mL CH_3CN; yield 2.84 g, 81% as orange plates. An analytical sample was obtained by recrystallizing from acetonitrile, mp 208–210°C. IR: 1680(w), 1518(w), 1414(vs), 1404(s), 1329(vs), 1321(s), 1260(m), 1221(m), 1171(vs), 1155(s), 1124(vs), 1067(vs), 1015(m), 927(w), 891(m), 858(s), 845(s), 801(w), 752(w), 698(m), 691(m), 596(w), 547(m), 384(w), 278(w), 224(m). Mass spectrum (EI, 70 eV) *m/z*: 249 ($RCN_2S_2^+$, R = $CF_3C_6H_4$, 100%), 230 (*M* − F^+, 6%), 203 ($RCNS^+$, 30%), 171 (RCN^+, 33%), 152 (RCN − F^+, 25%), 121 ($FC_6H_4CN^+$, 24%), 78 (S_2N^+, 98%). Anal. calcd. for $C_8H_4ClF_3N_2S_2$: C 33.75, H 1.42, N 9.84%; found: C 29.07, H 1.59, N 8.36%.

2*f*: From 5.0 g (12.4 mmol) of **1***f* and 2.0 mL SCl_2 (excess) in 40 mL CH_3CN; yield 3.0 g, 85% as yellow crystals. An analytical sample was obtained by recrystallizing from acetonitrile, mp 195–197°C. IR: 1613(w), 1391(vs), 1292(s), 1217(w), 1157(m), 1123(s), 1092(m), 1074(m), 949(m), 918(w), 891(w), 851(w), 826(w), 725(m), 696(m), 552(w), 385(w), 265(w). Mass spectrum (EI, 70 eV) *m/z*: 249 ($RCN_2S_2^+$, R = $CF_3C_6H_4$, 64%), 230 (*M* − F^+, 7%), 203 ($RCNS^+$, 40%), 171 (RCN^+, 23%), 152

[3]We find that the IR spectrum and the mp point of **4***b*, as well as the mp and NMR data of **4***e* reported in ref. 4 differ greatly from our own results (see Experimental and Table 1). Although we have not found a reliable method for the preparation of **4***g*, the samples we obtained with a mass spectrum fitting **4***g* had quite different NMR parameters from those reported in ref. 4.



SCHEME 1

(RCN − F$^+$, 24%), 121 ($FC_6H_4CN^+$, 21%), 78 (S_2N^+, 100%). Anal. calcd. for $C_8H_4ClF_3N_2OS_2$: C 38.94, H 2.90, N 11.53%; found: C 42.12, H 1.65, N 12.01%.

2*g*: To a solution prepared by stirring *p*-$NO_2C_6H_4CN$ (10.0 g, 67.5 mmol) and $LiN(SiMe_3)_2 \cdot Et_2O$ (16.30 g, 67.5 mmol) in 250 mL diethyl ether for 12 h was added dropwise 15.4 mL of SCl_2 in 20 mL ether while cooling the solution with an ice bath. After a further 30 min, 100 mL of CH_3CN was added, the ether was distilled off, and the resulting solution refluxed for 30 min, cooled, and filtered. Yield 16.1 g of impure **2***g* (containing LiCl). An analytical sample was obtained by dissolving a small sample in hot PhCN, filtering off the LiCl, and cooling. The resulting crystalline solid lost crystallinity on vacuum drying. It was therefore rinsed exhaustively with CH_3CN, and vacuum dried to a yellow powder, mp 213–217°C. IR: 1603(w), 1521(s), 1514(s), 1489(w), 1348(vs), 1330(vs), 1259(w), 1138(w), 1117(s), 1107(s), 1010(s), 926(w), 898(w), 866(m), 851(m), 785(s), 727(s), 714(vs), 698(m), 664(m), 565(m), 534(m), 507(m), 496(w), 453(w), 438(m). Mass spectrum (EI, 70 eV) *m/z*: 249 ($RCN_2S_2^+$, R = $NO_2C_6H_4$, 100%), 180 ($RCNS^+$, 36%), 148 (RCN^+, 11%), 134 (RC^+, 15%), 102 ($C_6H_4CN^+$, 30%), 78 (S_2N^+, 72%). Anal. calcd. for $C_7H_4ClN_2O_2S_2$: C 32.13, H 1.5, N 16.06%; found; C 32.23, H 1.72, N 16.02%.

Preparation of **3**a–g

3*a* was prepared as described in the literature (16, 17). Its physical and spectroscopic properties agreed with those reported previously (18). A similar approach was used to prepare the rest.

3*b*: From 0.58 g of **2***b* (2.5 mmol) and 1.16 g Ph_3Sb (2.5 mmol) in 25 mL of CH_3CN. The solution had to be filtered hot to remove a yellow precipitate, then cooled to room temperature. Dark crystals were collected. These were sublimed for 48 h at 80°C under high vacuum. Yield 0.12 g of **3***b* (0.61 mmol *as the monomer*, 24%), mp 140°C. IR: 1608(w), 1456(s), 1416(w), 1314(w), 1260(m), 1238(w), 1182(w), 1173(w), 1132(m), 1109(m), 1022(m), 822(s), 806(s), 775(s), 729(w), 674(w), 652(m), 509(m), 482(w). Mass spectrum (EI, 70 eV), high resolution: 195.0050 (calcd.: 195.0051); *m/z*: 195 ($RCN_2S_2^+$, R = $CH_3C_6H_4$, 100%), 149 ($RCNS^+$, 20%), 117 (RCN^+, 15%), 116 (RCN − H^+, 13%), 78 (S_2N^+, 90%). Anal. calcd. for $C_8H_7N_2S_2$: C 49.20, H 3.61, N 14.34, S 32.84%; found: C 49.46, H 3.65, N 14.23, S 32.89%.

3*c*: From 3.38 g of **2***c* (13.7 mmol) and 2.55 g Ph_3Sb (7.20 mmol) in 50 mL of CH_3CN. A copious, fibrous crystalline product formed in the hot solvent, was cooled at room temperature, and filtered. Yield 2.44 g of **3***c* (11.6 mmol *as the monomer*, 84%), mp 131°C. IR: 1602(w), 1514(w), 1508(w), 1302(w), 1256(s), 1192(w), 1185(w), 1171(m), 1128(w), 1105(w), 1020(w), 833(w), 802(w), 791(w), 775(w), 727(w), 654(w), 596(w), 519(w), 280(w). Mass spectrum (EI, 70 eV) *m/z*: 211 ($RCN_2S_2^+$, R = $CH_3OC_6H_4$, 100%), 165 ($RCNS^+$, 38%), 133 (RCN^+, 85%), 90 (CNS_2^+, 41%), 78 (S_2N^+, 87%), 64 (S_2^+, 47%). Anal. calcd. for $C_8H_7N_2OS_2$: C 45.48, H 3.34, N 13.26, S 30.35%; found: C 44.05, H 4.60, N 12.62, S 17.85%.

3*d*: From 2.97 g **2***d* (11.2 mmol) in 80 mL and 3.95 g Ph_3Sb (11.2 mmol) in 20 mL. Hot filtered to remove yellow precipi-

TABLE 3. Experimental details

A. Crystal data	
Empirical formula	$C_{16}H_8F_6N_4S_2$
Formula weight	434.38
Crystal color, habit	Yellow, plate
Crystal dimensions	0.230 × 0.360 × 0.070
Crystal system	Triclinic
No. of reflections used for unit cell determination (2θ range)	14 (20.1–33.4°)
Omega scan peak width at half-height	0.36°
Lattice parameters	a = 6.835(2) Å b = 9.936(3) Å c = 6.320(2) Å α = 96.44(3)° β = 102.88(3)° γ = 88.42(3)° V = 415.8(2) Å^3
Space group	$P\bar{1}$ (No. 2)
Z value	1
D_{calc}	1.735 g/cm^3
F_{000}	218.00
$\mu_{(MoK\alpha)}$	3.79 cm^{-1}
B. Intensity measurements	
Diffractometer	Rigaku AFC6S
Radiation	MoKα (λ = 0.71069 Å) graphite monochromated
Take-off angle	6.0°
Detector aperture	6.0 mm horizontal 6.0 mm vertical
Crystal to detector distance	40 mm
Temperature	−103.0°C
Scan type	ω–2θ
Scan rate	2.0°/min (in omega) (3 rescans)
Scan width	(1.52 + 0.35 tan θ)°
$2\theta_{max}$	50.2°
No. of reflections measured	Total: 1616 Unique: 1481 (R_{int} = 4.54)
Corrections	Lorentz–polarization Absorption (trans. factors: 0.8978–1.0000) Decay (−4.36% decline)
C. Structure solution and refinement	
Structure solution	Direct methods (SAPI91)
Refinement	Full-matrix least-squares
Least-squares weights	$1/\sigma^2F + 0.000134F^2$)
Anomalous dispersion	All non-hydrogen atoms
No. observations ($I > 3.00\sigma(I)$)	1100
No. variables	173
Reflection/parameter ratio	6.4
Residuals: R; Rw	0.034; 0.035
Max shift/effor in final cycle	0.13
Maximum peak in final diff. map	0.22 e/Å^3
Minimum peak in final diff. map	−0.20 e/Å^3

(7.0 mmol) in 10 mL CH_3CN. Cooled to −30°C, and filtered crude product. Sublimed at 60–70°C onto a water-cooled finger. Yield 0.90 g of purple solid (3.6 mmol, 51%), mp 142–145°C. IR: 1559(w), 1335(m), 1260(s), 1231(w), 1171(m), 1134(s), 1072(m), 932(w), 910(w), 835(w), 804(m), 787(w), 772(w), 733(w), 691(m), 648(w), 600(w), 509(w), 383(w), 204(s). Mass spectrum (EI, 70 eV) m/z: 249 ($RCN_2S_2^+$, R = $CF_3C_6H_4$, 82%), 230 ($M - F^+$, 10%), 203 ($RCNS^+$, 34%), 171 (RCN^+, 13%), 152 ($RCN - F^+$, 20%), 121 ($FC_6H_4CN^+$, 17%), 78 (S_2N^+, 100%).

Preparation of **4**a–f

Three routes, A, B, and C, to these compounds have been developed, as outlined below for **4***a*. Purity was established in all cases

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

by ^{1}H NMR (Table 1). The other compounds were prepared in an analogous manner.

Method A: Dry O_2 was bubbled through a suspension of 0.12 g (0.66 mmol) of **3***a* in 25 mL of dry CH_3CN warmed to 60°C for 3 h. The initially black solution slowly turned dark brown, then orange and dark yellow. The solvent was removed (Rotovap), and the residue extracted with hot toluene to give a bright yellow solution. After removal of the solvent, the residue was shown by ^{1}H NMR to be a mixture containing some **4***a*. The residue was purified by column chromatography (20 × 2 cm dimensions, 200–400 mesh, Terrochem). A bright yellow band was elluted with 1:1 toluene:ethyl acetate. After removal of solvent, the bright yellow solid was shown by ^{1}H NMR to be pure **4***a*. Yield 9%. The identity of **4***a* was confirmed by comparing the IR spectrum (KBr disk) of a pure sample with that reported in the literature (1), and by comparing the ^{1}H NMR parameters with those reported in the literature (3).

Method B: To a suspension of 0.50 g **2***a* (3.4 mmol) in 15 mL of CH_3CN saturated with O_2 was added dropwise 1.20 g (3.4 mmol) of Ph_3Sb in 5 mL CH_3CN. The solution was then heated in an O_2 atmosphere to 60°C for 1.5 h, cooled to room temperature, and the precipitate that formed was filtered off and shown by ^{1}H NMR to be pure **4***a*. Yield 0.22 g of yellow powder (0.74 mmol, 43%).

Method C: To a suspension of 0.090 g of **2***a* in 10 mL of CH_3CN was added 0.139 g of **1***a*. The orange suspension was heated to reflux for 3 h, then cooled to room temperature. The resulting yellow crystals were filtered, and the filtrate reduced to dryness. Analysis by ^{1}H NMR showed the precipitate to be pure **4***a*, while the residue was a mixture of several components.

4*b*: Method A: 20% yield after chromatography on silica gel. Method B: From 0.50 g of **2***b* in 15 mL CH_3CN and 0.77 g Ph_3Sb in 5 mL CH_3CN. The precipitate was pure **4***b*, 0.16 g (0.48 mmol, 45% yield). Method C: From 0.25 g **2***b* and 0.38 g **1***b* in 15 mL CH_3CN. The precipitate was pure **4***b*, 0.80 g, 23% yield. An analytical sample was prepared by recrystallizing from hot CH_3CN, mp 267°C. IR (KBr disk): 1369(s), 1340(w), 1319(w), 1261(w), 1229(w), 1173(m), 1128(w), 1111(w), 1067(w), 1018(w), 943(w), 826(m), 720(w), 650(s), 617(w), 592(w), 526(w), 488(w), 369(s), 319(w). Mass spectrum (EI, 70eV) *m/z*: 326 ($RCN_2S_2N_2CR^+$, R = $CH_3C_6H_4$, 36%), 281 (RCN_2SNCRH^+, 7%), 163 (RCN_2S^+, 12%), 149 ($RCNS^+$, 100%), 117 (RCN^+, 39%), 46 (SN^+, 32%), 28 (N_2, 89%). Anal. calcd: for $C_{16}H_{14}N_4S_2$: C 58.87, H 4.32, N 17.16, S 19.64%; found: C 58.51, H 4.76, N 17.07, S 19.39%.

4*c*: Method A: 10% yield after chromatography on silica gel. Method B: From 0.50 g of **2***c* in 15 mL CH_3CN and 0.72 g Ph_3Sb in 5 mL CH_3CN. The precipitate was almost pure **4***c*, 0.14 g (0.40 mmol, 39% yield). A pure sample, as judged by ^{1}H NMR, was prepared by recrystallizing from hot CH_3CN. The IR spectrum (KBr disk) of the recrystallized material matched that reported in the literature (1).

4*d*: Method A: 7% yield after chromatography on silica gel. Method B: From 0.50 g of **2***d* in 15 mL CH_3CN and 0.67 g Ph_3Sb in 5 mL CH_3CN. The precipitate was pure **4***d*, 0.19 g (0.52 mmol, 55% yield). Method C: From 0.25 g **2***d* and 0.37 g **1***d* in 30 mL CH_3CN. The precipitate was pure **4***d*, 0.10 g, 40% yield. An analytical sample was prepared by recrystallizing from hot CH_3CN, mp 238–239°C. IR (KBr disk): 1593(m), 1487(m), 1404(w), 1373(s), 1281(w), 1225(w), 1173(w), 1105(w), 1098(s), 1013(m), 941(w), 833(s), 826(m), 729(w), 719(m), 650(s), 637(m), 525(w), 501(w), 482(w). Mass spectrum (EI, 16eV) *m/z* (reported on ^{35}Cl): 366 ($RCN_2S_2N_2CR^+$, R = ClC_6H_4, 49%), 169 ($RCNS^+$, 82%), 92 ($S_2N_2^+$, 100%). Anal. calcd. for $C_{14}H_8Cl_2N_4S_2$: C 45.78, H 2.20, N 15.25, S 17.46%; found: C 45.52, H 2.73, N 14.90, S 17.21%.

4*e*: Method A: product hydrolyzed under chromatographic workup. Method B: From 0.50 g of **2***e* in 15 mL CH_3CN and 0.62 g Ph_3Sb in 5 mL CH_3CN. The precipitate was pure **4***e*, 0.12 g (0.28 mmol, 32% yield). Method C: From 0.25 g **2***e* and 0.36 g **1***e* in 30 mL CH_3CN. The precipitate was pure **4***e*, 0.069 g, 18% yield. An analytical sample was prepared by recrystallizing from hot CH_3CN, mp 226–228°C. IR (KBr disk): 1412(w), 1369(m), 1315(vs), 1262(w), 1240(w), 1181(m), 1171(m), 1135(m), 1109(m), 1065(s), 1015(m), 942(w), 851(m), 685(w), 655(m), 644(m), 590(W), 528(w), 448(w). Mass spectrum (EI, 70 eV) *m/z*: 434 ($RCN_2S_2N_2CR^+$, R = $CF_3C_6H_4$, 17%), 415 ($RCN_2S_2N_2CR - F^+$, 7%), 263 ($RCN_3S_2^+$, 4%), 249 ($RCN_2S_2^+$, 1%), 203 ($RCNS^+$, 100%), 46 (SN^+, 31%), 28 (N_2, 77%). Anal. calcd. for $C_{16}H_8F_6N_4S_2$: C 44.24, H 1.86, N 12.90, S 14.76%; found: C 44.40, H 1.69, N 13.05, S 14.58%.

4*f*: Method B: From 0.50 g of **2***f* in 15 mL CH_3CN and 0.62 g Ph_3Sb in 5 mL CH_3CN. The precipitate was pure **4***f*, 0.23 g (0.53 mmol, 60% yield). Method C: From 0.25 g **2***f* and 0.36 g **1***f* in 30 mL CH_3CN. The precipitate was pure **4***f*, 0.25 g, 66% yield. An analytical sample was prepared by recrystallizing from hot CH_3CN, mp 201–203°C. IR (KBr disk): 1638(m), 1616(m), 1489(m), 1445(m), 1371(s), 1325(vs), 1290(s), 1240(m), 1206(s), 1173(s), 1128(vs), 1094(m), 1072(s), 972(m), 930(w), 910(m), 808(s), 787(w), 696(s), 689(s), 640(s), 598(m), 530(m), 364(w). Mass spectrum (EI, 70 eV) *m/z*: 434 ($RCN_2S_2N_2CR^+$, R = $CF_3C_6H_4$, 9%), 415 ($RCN_2S_2N_2CR - F^+$, 4%), 263 ($RCN_3S_2^+$, 3%), 249 ($RCN_2S_2^+$, 1%), 203 $RCNS^+$, 100%), 171 (RCN^+, 15%), 152 ($RCN - F^+$, 19%), 46 (SN^+, 56%), 28 (N_2, 13%). Anal. calcd. for $C_{16}H_8F_6N_4S_2$: C 44.24, H 1.86, N 12.90, S 14.76%; found: C 44.38, H 1.79, N 13.07, S 14.61%.

Crystal structure determination

Accurate cell dimensions and a crystal orientation matrix were determined on a Rigaku AFC6S diffractometer by a least-squares fit of the setting angles of 14 reflections. Experimental details are provided in Table 3. Data were corrected for Lorentz, polarization, and empirical absorption effects (20), transmission factors being in the range 0.8978–1.0000.

The structure was solved by direct methods using SAPI91 (21). Refinement of the structure was by full-matrix least-squares calculations, initially with isotropic and finally with anisotropic temperature factors for the non-hydrogen atoms using SHELX-76 (22). Fluorine atoms of the CF_3 group were found to be disordered; F-atoms were allowed to refine with anisotropic temperature factors along with their site occupancy factors. At an intermediate stage in the refinement, a difference map revealed maxima consistent with the positions of the hydrogen atoms, which were included in the subsequent cycles of refinement with fixed isotropic temperature factors. Refinement converged at $R = 0.034$ and $Rw = 0.035$. In the refinement cycles, weights were derived from the counting statistics. Scattering factors were those of Cromer and Mann (23) and Stewart, Davidson, and Simpson (24), and allowance was made for anomalous dispersion (25). A difference map calculated at the conclusion of the refinement had no chemically significant features. The computer programs used for data reduction were part of TEXSAN (26) installed on a Silicon Graphics Personal Iris 4D/35 computer, and Fig. 1 was plotted using ORTEP II (27). Experimental details are summarized in Table 3, fractional coordinates and U_{eq} in Table 4, and important interatomic distances in Table 5.[5]

Electrochemistry

Cyclic voltammetric studies (scan rates ν = 20–1000 mV s^{-1}) and phase-sensitive alternating current (a.c.) measurements (ω = 615 Hz, ν = 10 mV s^{-1}) were made with a PAR 173 potentiostat

[5]Tables of bond lengths and angles (S1), anisotropic thermal parameters (S2), and observed and calculated structure factors (S3) for the crystal structure may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2.

Tables of bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre. University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

in combination with a PAR 175 programmer and EGG 9209 lock-in amplifier and recorded on a Houston Graphics 2000 XY plotter. Electrochemical experiments were performed on a platinum three-electrode system with the platinum working electrode either a Pt wire or a 0.5 mm diameter Pt micro-tip. The vacuum-tight all-glass cell has an integrated cooling finger for studies at low temperatures. The cell was charged with electrolyte (0.4 M NBu_4PF_6), and the solvent, dry degassed CH_2Cl_2, transferred on a vacuum line. Samples and ferrocene as an internal reference were added to the cell using break-seal techniques. The ferricenium/ferrocene couple appeared in this system at 0.48 V vs. SCE at 25°C in CH_2Cl_2.

Results and discussion

Synthetic method

The preparation of salts **2** and radicals **3** follows a well-established route (16, 17). We found that the best solvent for the preparation of the rather insoluble chloride salts **2** is indeed acetonitrile. Amin and Rees used methylene chloride, and reported a 60% yield of **2***a* from the reaction of **1***a* and SCl_2 in this solvent (3). They also obtained about 6% of **4***a* in this reaction. To see if the switch to the even less polar solvent toluene might change these relative yields dramatically, we repeated the reaction of **1***a* with freshly distilled SCl_2 according to the exact stoichiometry reported in ref. 4. A copious yellow precipitate is indeed obtained, but ^{1}H NMR analysis failed to detect any appreciable amount of **4***a*, and the IR spectrum of the bulk material matched that of **2***a*. Since **2** are readily hydrolysed (for example, this occurs by preparing an NMR sample with $CDCl_3$ from a freshly opened bottle), it is not surprising that these workers detected **4** by mass spectroscopy, or that, by extensive washing, materials with approximately the correct chemical analysis were obtained. Based on our experience and the results of ref. 3, it seems clear that the reaction of SCl_2 with silylated amidines in low-polarity solvents consistently leads to **2** as the major product and **4** as the minor product (reaction [1]). We recommended the use of hot acetonitrile and excess SCl_2 for the preparation of **2**.

*Reaction of **3** with dioxygen*

Method A

Our entry into this chemistry was the serendipitous discovery that **4***b* was formed as a by-product in the synthesis of **3***b* from **2***b* by reduction with Ph_3Sb (14). The hypersensitivity of **3***b* towards O_2 may well be caused by its much greater solubility compared to that of **3***a*. We had to go to quite extraordinary lengths in degassing our solvent to suppress this side reaction. After realizing what was occurring, we deliberately exposed solutions of **3** to dry O_2 in warm acetonitrile. We observed in all cases the slow disappear-

ance of the dark black or purple colour of solutions of **3** and the corresponding monomers over the space of 1–3 h. The final solutions were usually pale orange. After removal of the solvent, ^{1}H NMR analysis showed that the residues in all cases were complex mixtures, with as few as four and as many as eight or 10 different constituents containing the aromatic ring from **3**. Nonetheless, column chromatography using a 1:1 toluene:ethyl acetate eluant produced samples of pure **4** in yields at least as good as the best previously reported (9% for **4***a*), and in some cases substantially higher (e.g., **4***b*, 20%).

A similar reaction occurs for **3***a,e* in the melt. A small quantity of pure **3** (consisting of black or purple flakes) was placed in a porcelain boat (1 × 10 cm) inside a Pyrex tube, and heated either with a hot-air blower or with a tube furnace. Dry O_2 was passed through the tube for 2–3 h. Upon cooling, the melt solidified to a yellow solid, which had a honeycomb appearance under the microscope, with bright yellow regions interspersed with other, lighter coloured regions. Chromatographic work-up and NMR analysis showed that yields of **4***a,e* similar to those from the solution-phase reactions with O_2 were obtained.

[1] 
Method B

Since many of the by-products were colourless, somewhat water-soluble, solids, we reasoned that they represented over-oxidation at sulfur, and speculated that if the reaction could be slowed down, higher yields of **4** might be obtained. We thus developed Method B (see experimental), in which we added the reducing agent Ph_3Sb dropwise to a solution of salts **2** in warm CH_3CN that had been saturated in O_2. This method indeed led to substantially higher yields of **4**, and of course avoided the difficult preparation of pure samples of the dimers **3**. Moreover, the work-up is greatly simplified, and the yields reported in the Experimental section (40–60%) refer to the amount of pure **4** that precipitated from CH_3CN on cooling to room temperature. In several instances there was ^{1}H NMR evidence for more product in the filtrate, but we judged the recovery of this contaminated product to be more effort than it was worth.

Amidine coupling reactions

Method C

We were intrigued by the fact that both **2** and **4** seemed to be formed in the reaction of **1** with SCl_2 in less polar solvents, as discussed above. We reasoned that this could simply be a kinetically controlled phenomenon: the reaction of SCl_2 with **1** could be much faster than the further reaction of already formed **2** with **1**. We therefore attempted the reaction of purified **2** (i.e., filtered and rinsed with fresh CH_3CN) with a further equivalent of **1** (Method C, Scheme 1). Indeed we discovered that this is also a viable route to **4**. Yields of precipitated **4** range from 18 to 66%, and have not been optimized. We believe that this methodology could be developed into large-scale, "one-pot" syntheses, by which crude **2**, made from **1**, is filtered, rinsed back into the same flask, and converted to **4**.

Characterization of dithiatetrazocine ring compounds

The new compounds **4***b,d–f* have been fully characterized by elemental analysis and all have consistent mass spectra. **4***a,c* are well-characterized known compounds (1). However, apart from the ^{1}H NMR spectrum of **4***a* (2), little is known about their NMR spectra. Since we found that NMR was an essential tool in monitoring the progress of the reactions and the purity of the products from the various preparative routes, we present the full ^{1}H, ^{13}C, and, where relevant, ^{19}F NMR parameters for **4** in Table 1. The compounds were insufficiently soluble, in any solvent tried, to enable measurement of the ^{14}N spectra. In a few specific cases, an almost complete assignment of the ^{13}C resonances was possible (e.g., for **4***a,e,f*). In our opinion the endocyclic ^{13}C resonance should be assigned to the signals found in the range 136–141 ppm. While complete certainty is not possible, we note that in ^{t}BuCN$_2$S$_2$N$_2$C^{t}Bu, **5**, the endocyclic resonance can be indisputably assigned as 144.8 ppm (6). This resonance is also the least intense, either due to a long relaxation time or to line broadening from the adjacent nitrogen atoms.

We note that the ^{1}H resonances of $H_{2,6}$ (see Table 1) are found in the range 8.4–8.8 ppm, i.e., very far downfield. For comparison, the *ortho* protons in biphenyl occur at 7.4 ppm. Only in the bay region of polyaromatics such as phenanthrene are such shifts surpassed, e.g., 8.93 ppm (28). In the related heterocycle **6**, the *ortho* protons are at 7.966 ppm, while in **7** they are found at 8.08 and 8.61 ppm. Presumably there are two contributors to this deshielding: inductive or through-space effects from the neighbouring N—C—N functional group, and the ring current of the dithiatetrazocine ring. An excellent probe for these effects is found in the NMR spectrum of a mixed substituent 3-dimethylamino-7-phenyl-1,5-dithia-2,4,6,8-tetrazocine, **8**, which has a type II structure according to its electronic absorption spectrum (3). The $H_{2,6}$ resonance in this compound is found at 8.17 ppm (dd, J = 1.5 and 8.5 Hz), i.e., 0.38 ppm further upfield than in **4***a*. While these protons in **8** should experience a very similar inductive influence from the N—C—N group to that in **4***a*, they will not be subject to a ring current, since the aromaticity of the type II structures has been quenched (10). Thus the downfield shift of about 1.4 ppm from the position in benzene of the *ortho* protons in **4***a* caused by the dithiatetrazocine "substituent" is about two thirds due to inductive effects, and one third due to ring current.

The $H_{3,4,5}$ chemical shifts are found in the correct relative positions expected for being *ortho* to the X substituent in XC_6H_4- (28). However, all the resonances are shifted 0.3–0.4 ppm downfield. We attribute this shift to the dithiatetrazocine ring. By comparing the shifts in **4***a* with that in **8** (m, 7.35–7.5 ppm), we see that the downfield shift effect on these protons by the 10π ring current is only about one

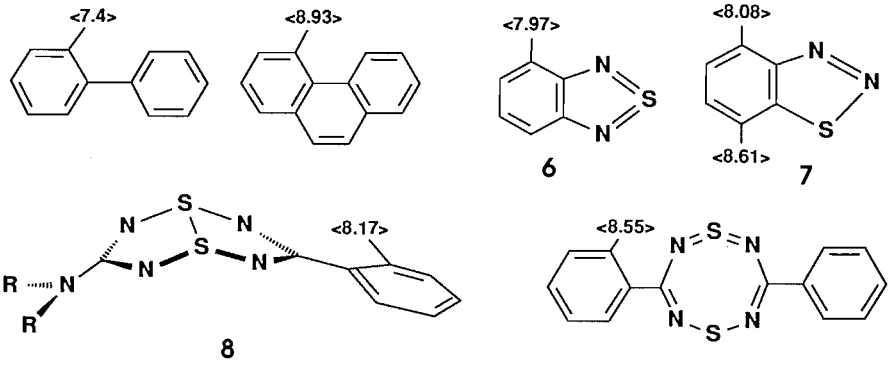
Structures II



quarter of the total. In conclusion, we suggest that the chemical shift of protons on aryl rings *ortho* to a planar dithiatetrazocine ring will characteristically be found in the range 8.4–8.8 ppm, and that such shifts are diagnostic of the type I structure.

Structure

The electronic absorption spectra of **4***a* and the type II dithiatetrazocine **9** are quite distinct and, as has already been mentioned, this fact can be used with confidence to assign structure (1, 3, 10). The spectral data are summarized in Table 2, and it is clear that **4***a–f* have very similar spectra, and can thus be assigned a common type I structure.

Since there is some dispute about the spectral and physical properties of **4***e* (4), we have also determined its structure by X-ray crystallography. An ORTEP illustration of the structure is given in Fig. 1, and the crystallographic parameters are found in Tables 3–5. **4***e* does indeed have the planar structure first noted for **4***a,c*. The appearance of disorder in the CF_3 atom positions is not unexpected for such a rod-like molecule, whose twofold symmetry axis is at odds with the threefold axis in the CF_3 group. A simple disorder model accounts for this quite effectively, although the C—F bond distances are somewhat unrealistic as a result. In Table 5, the metric parameters relevant to the eight-membered ring are collected for the three crystallographically characterized compounds of this type. **4***e,a,c* represent aryl dithiatetrazocines with electron-withdrawing, neutral, and electron-donating substituents, respectively. The influence of these remote substituents is not apparent in the structural parameters. A statistical treatment of the three structures shows that while the bonds should not be averaged, they are not definitely different either. In general there is as much variation in similar bond lengths within any of these structures as there is between them (29).

The rod-like molecules of **4***e* stack side-by-side and end-to-end in long ribbons, approximately along the (111) plane of the crystal, as shown in Fig. 2. Since there is only one molecule per unit cell, this stacking is completely ordered. It is interesting to note that although the crystals of **4***a,c,e* each belong to a different space group, the molecules are all located at sites with inversion symmetry.

In conclusion, the similarity in the electronic spectra of **4***a–f*, the consistent crystal structures of **4***a,c,e*, as well as the similarity in mass-spectral fragments suggest that all these aryl-1,5,3,4,6,8-dithiatetrazocines have a similar geometry

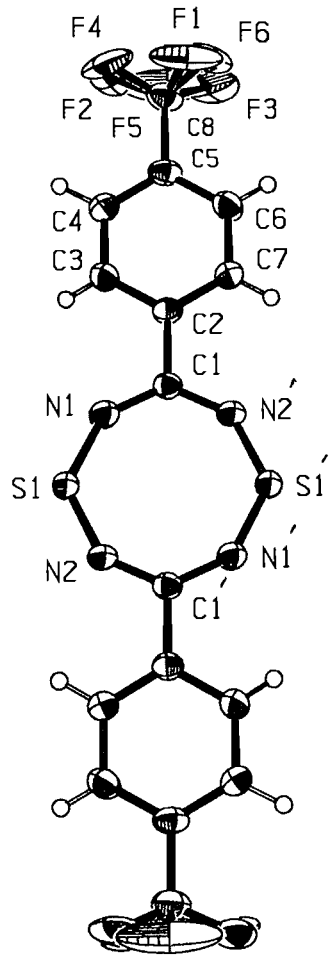


FIG. 1. ORTEP illustration of **4***e*, showing the atom numbering scheme. The hydrogen atoms are shown with artificially small temperature factors for clarity.

and are type I structures. We have not characterized any material corresponding to the 1,3,2,4,6,8 isomer (30).

Electrochemistry and electronic structure

4 are sufficiently soluble in the noncoordinating solvent CH_2Cl_2 to be studied by d.c. and a.c. voltammetric methods. Figure 3 contrasts the cyclic voltammetry of the 10π aromatic type I heterocycle **4***a* with the folded, nonaromatic

type II compound **9** at room temperature. All the type I and type II compounds that we have studied were found to undergo a fully reversible one-electron reduction, except for **5** where quasi-reversible conditions were observed. The type I aryl-substituted systems **4***a–f* are reduced over the narrow potential range of −0.90 to −1.02 V vs. SCE, while the 'Bu derivative **5** at $\mathscr{E}_{1/2} = -1.14$ V has the lowest reduction potential of the type I compounds, distinct from the aryl compounds. The type II compound **9** has a much lower reduction potential than the others (−1.36 V).

None of the oxidation processes studied is reversible at ambient temperature and slower scan rates. The anodic peak potentials of type I structures **4***a–f* and **5** are strongly substituent dependent, varying from +1.54 for **4***c* to + 2.05 for **4***e*. Irreversible oxidation of **9** occurs at $\mathscr{E}_a = +1.28$ V, making it far easier to oxidize than the type I compounds. A quasi-reversible response of the oxidation step of **4***a,b,c,e* could be obtained using fast-scan techniques and by working at lower temperatures. Scheme 2 illustrates the principle electrode processes of the 10π ring system. All electrode potentials measured in this study, together with the conditions chosen to achieve Nernstian behaviour, are listed in Table 6.

The electrochemical results for **4** are in agreement with simple MO arguments. The HOMO (b_{1u}) and LUMO (b_{2g}) of the model compound $HCN_2S_2N_2CH$ are both π orbitals. (Fig. 4). The LUMO, to which electrons are added in the reduction of **4**, posseses a node at the C atoms, so that the effect of substituents on the energy of this orbital is negligible. This result is unchanged for the diaryl-substituted ring (8). Consistently, the reduction potentials for all these compounds are highly similar, and even that of **5**, in which the aryl group is completely replaced by *tert*-butyl, is only slightly more negative. The HOMO has a large coefficient at the C atoms, and should be much more greatly influenced by substituents bearing p–π orbitals. Thus the lower oxidation potential of **4***a* versus **5** can be explained by extension of conjugation in the former.

A more dramatic effect on the oxidation $\mathscr{E}_a$ occurs upon substitution of the aryl ring. This shows that π-donating substituents, in particular, have a large influence on the oxidation step, leading to lowering of the redox potential, while inductively withdrawing substituents have a smaller effect in raising the potential. A very similar trend is observed in the position of λ_1 in the electronic absorption spectrum (Table 2). This transition has been identified as the HOMO–LUMO transition by magnetic circular dichroism (7). The latter study also concluded that "the extension of conjugation due to the presence of the two phenyl rings (in **4***a*) can hardly be viewed as a minor perturbation." Our voltammetric study strongly substantiates this comment.

The remarkably large thermodynamic stability "window" within which the type I compounds resist oxidation or reduction is fully consistent with their description as aromatic species. The width of this window ranges from 2.49 to 2.96 V, depending on substituents. Although the folded compound **9** has a similar window width (2.63 V), the whole is shifted towards negative potentials. Thus it is by far the most easily oxidized of the series, and the most difficult to reduce. These results are fully consistent with our previous chemical studies, in which we observed **4***a* to be completely resistant to chemical oxidation by chlorine, SO_2Cl_2, and the powerful radical oxidant $(CF_3)_2NO$. On the other hand, **9** reacted readily with these reagents (11, 12).

Attempts to prepare other compounds

We have attempted to extend methods B and C to the preparation of some non-aryl dithiatetrazocines. For many of these, silylated amidines analogous to **1** are not available. This restricts us to method B. We have accordingly reacted X-$CN_2S_2^+Cl^-$ **10** (**10***a* X = CH_3 (18), **10***b* ^{t}Bu (31), **10***c* Cl (32), and **10***d* Me_2N (33)) with Ph_3Sb/O_2 in warm acetonitrile. However, no precipitates formed in these reactions, as might be expected for the much greater solubility anticipated for the corresponding dithiatetrazocines. In fact it proved impossible to separate the product(s) of these reactions from Ph_3SbCl_2. The latter compound was impossible to separate by column chromatography, being found in *every* fraction collected. We were able to prepare the type II dithiatetrazocine **9** in an atmosphere of O_2 from **10***d* using fine Mg powder as the reducing agent. However, the yield was only 5%. Our attempts to prepare **5** by this route from **10***b* also failed, only S_8 being isolated.

We also applied method C in an attempt to prepare mixed aryl-substituted derivatives of **4**. For example, the chloride salt **2***d* was refluxed in a minimum volume of CH_3CN with one equivalent of **1***e*. We were quite surprised to see clear evidence in the NMR spectra for the appearance of all three products resulting from a scrambling process, i.e., **4***d*, **4***e*, as well as {4-$CF_3C_6H_4$}$CN_2S_2N_2C${4-C_6H_4Cl}. Allowing for differences in solubility both in the reaction solvent and in the NMR solvent, we judge these products to be formed in about equal quantity, and the overall yield is at least 50%. We also investigated the residues that did not precipitate on cooling the reaction mixture. ^{1}H NMR analysis after removal of the solvent indicated the presence of many different compounds, including the three products identified in the precipitate.

Since the mixed product **8** had been prepared by others, albeit in very low yield (3), we reacted **1***a* with **10***b*. Again, the three possible products were formed, as judged by the known NMR parameters of these compounds. These reactions do not fall within the scope of this paper as simple preparative routes, and we have not attempted the separation of these mixtures. However, we consider these results to be mechanistically significant.

Mechanistic considerations

The mechanism for the reactions of methods A and B are not clear. Since radicals are involved, NMR monitoring of the reaction is not feasible. And since the reaction mixture is saturated with dioxygen, following the course of the reaction by ESR is also not feasible. The rate and product distribution for method A does not seem to be greatly affected by concentration; e.g., much the same yields and times are found for the melt reactions as for reactions in acetonitrile or toluene. Presumably this means that the presence of dimers **3** is not a requirement for this reaction. One conceivable reaction of O_2 with a radical momomer is the formation of SO_2, leaving a four-membered ring radical $RCN_2S^{\cdot}$. Dimerization of this latter species would lead directly to **4**. Such four-membered ring species have been implicated in solution in equilibrium with the type II heterocycles $R_2PN_2Se_2N_2PR_2$ (34).

Method C starts with sulfur in the +II oxidation state. As Amin and Rees have already noted, this reaction requires a change in oxidation state to S(III) (i.e., the average oxidation state of the two sulfur atoms in one canonical structure of **4**).

It is possible to imagine a simple condensation reaction of **11** with **2**, leading to chain intermediate **12** (Scheme 3). Ring closure leads to the reduced ring **13**, which can undergo elimination of disilane to produce **4**. A precedent is again known in selenium chemistry where, even in the absence of aromatization of the eight-membered ring, elimination of alkyl groups from $Ph_2PN_2(SeR)_2N_2PPh_2$ (R = Me, Et) occurs to give the type II compound $Ph_2PN_2Se_2N_2PPh_2$ (35).

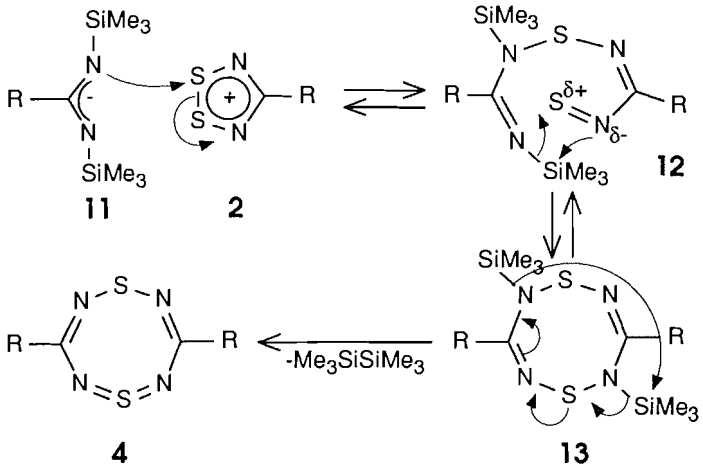
For personal use only.



SCHEME 3

This elimination could be preceded by a variety of possible silyl-migration steps. The result of using mixed substituents in this reaction gives credence to such a migration process. Indeed, if the initial condensation reaction leading to **12** as well as the formation of **13** is reversible, then the observed scrambling reaction is certainly feasible. According to this model, the silane elimination must be a slow step. Once elimination occurs, the process is no longer reversible. To test this we heated **4***d* and **4***e* together under reflux in acetonitrile as well as in the presence of 10 equivalents of $ClSiMe_3$. There was no evidence of the mixed-substituent species being formed. In an attempt to see if the elimination step could be enhanced by external conditions, we performed the mixed-substituent reactions in an atmosphere of both O_2 and Cl_2, but found no enhancement or retardation of the process.

Conclusions

We have developed two higher yield synthetic routes to 1,5-dithiatetrazocines with greatly simplified work-up. These methods further illustrate the utility of silylated amidines as an entry into sulfur nitrogen heterocyles. We have properly characterized **4***b,e*, for which the previously reported physical and spectroscopic properties are partly in error. We have prepared and characterized three previously unknown dithiatetrazocines. However, for reasons that remain unclear, but may be related to solubility, the method appears to work only for aryl derivatives. Thus the route described in the literature for *tert*-butyl remains the only viable way to prepare this ring. Finally, for the bent type II rings, the method originally reported is far superior to those reported here.

Our voltammetric studies have confirmed the stability of the aromatic 10π electronic structure of **4**. The width of the redox stability window is directly comparable to the wavelength of the lowest energy (HOMO–LUMO) transition in the electronic spectrum. Thus we have confirmed electrochemically the extension of conjugation in aryl-1,5-dithiatetrazocines first noted in electronic and magnetic circular dichroism spectroscopic studies (7).

We are currently investigating the feasibility of preparing novel mixed-substituent dithiatetrazocines by the reactions described here. It seems likely that such species will be more reactive than the symmetrical compounds. The preparation of benzene rings disubstituted with dithiatetrazocines is also being investigated.

Secondary metabolites of the aspen fungus *Stachybotrys cylindrospora*

WILLIAM A. AYER[1] AND SHICHANG MIAO
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 24, 1992

WILLIAM A. AYER and SHICHANG MIAO. Can. J. Chem. **71**, 487 (1993).

The secondary metabolites produced by the fungus *Stachybotrys cylindrospora*, which is known to be strongly antagonistic to the blue-stain fungus *Ceratocystiopsis crassivaginata*, have been examined. The compounds responsible for the antifungal activity are trichodermin (**5**) and trichodermol (**6**), two previously known mycotoxins belonging to the trichothecene family. The other metabolites, stachybotrydial (**1**), stachybotramide (**8**), and 6,8-dihydroxy-3,5,7-trimethylisochroman (**7**), although not active against *C. crassivaginata*, are new natural products. The structures of the new compounds were established by spectroscopic techniques.

WILLIAM A. AYER et SHICHANG MIAO. Can. J. Chem. **71**, 487 (1993).

On a étudié les métabolites secondaires produits par le champignon *Stachybotrys cylindrospora* qui est connu pour être un antagoniste puissant du champignon à teinte bleue *Ceratocystiopsis crassivaginata*. Les composés responsables de l'activité antifongique sont la trichodermine (**5**) et le trichodermol (**6**), deux mycotoxines isolées antérieurement appartenant à la famille du trichothécène. Les autres métabolites, les stachybotrydial (**1**), stachybotramide (**8**) et 6,8-dihydroxy-3,5,7-triméthylisochromane (**7**) qui ne sont pas actifs contre le *C. crassivaginata* sont de nouveaux produits naturels. On a déterminé les structures des nouveaux composés à l'aide de techniques spectroscopiques.

[Traduit par la rédaction]

Introduction

The decay and staining of aspen (*Populus tremuloides* Michaux) caused by fungi is a serious problem associated with aspen utilization in Canada (1, 2). For aspen lumber and wood products such as chipboard and chopsticks, even small amounts of rot or stain can drastically reduce product quality and make it unmarketable (1). Two of the most important staining fungi are the so-called blue-stain fungi *Ceratocystiopsis crassivaginata* (H. D. Griffin) Upadhyay (NOF1509)[2] and *Ophiostoma piliferum* (Fr.: Fr.) Syd. and Syd. (1). Another fungal pathogen of aspen, *Stachybotrys cylindrospora* C. N. Jensen (NOF1828) (3), isolated from aspen has been found to be strongly antagonistic to the blue-stain fungus *C. crassivaginata* when grown on malt extract agar plates.[3] In this paper, we report several secondary metabolites produced when *S. cylindrospora* is grown in malt extract liquid culture. Two of these compounds, trichodermin (**5**) and trichodermol (**6**), which have been previously reported as mycotoxins, are responsible for the above-mentioned antagonistic activity. The other compounds, stachybotrydial (**1**), stachybotramide (**8**), and 6,8-dihydroxy-3,5,7-trimethylisochroman (**7**), albeit not active against *C. crassivaginata*, are new natural products.

Results and discussion

Stachybotrys cylindrospora was grown in malt extract/yeast extract liquid culture. The culture broth of the first and fourth fermentations was extracted with ethyl acetate to provide a large quantity of metabolites that did not exhibit antagonistic activity against *C. crassivaginata*. The major compound present is a new natural product (**1**), which we have named stachybotrydial. A portion of the crude extract was acetylated to produce the corresponding diacetate (**2**) of **1**. The remaining portion of the extract decomposed to produce an artifact (**3**) that was inseparable from the original compound (**1**). Since the original compound was an aldehyde, it could be reduced by sodium borohydride to the corresponding alcohol (**4**), which could then be separated from the artifact (**3**). All other fermentations have produced metabolites that show antifungal activity against *C. crassivaginata*. It was found that still cultures produce more of the bioactive metabolites than do shake cultures. The active extract was fractionated on Sephadex LH20. The bioactivity was located in the early fraction, which after repeated chromatography on silica gel yielded two pure compounds, **5** and **6**. The remaining fractions were subjected to repeated silica gel chromatography to give pure compounds: compound **7** from the second fraction, compound **3** from the third fraction, orsellinic acid from the fourth fraction, compound **8** (as its acetylated derivative **9**) from the fifth fraction.

Stachybotrydial diacetate (2)

Compound **2** was obtained as a pale yellow solid. The molecular formula $C_{27}H_{34}O_7$ was determined by HREIMS and indicates 11 unsaturations. A literature search based on the spectroscopic data of compound **2** revealed that its unacetylated parent compound, **1**, for which we propose the name stachybotrydial, is the 2-deoxy analog of a previously reported fungal metabolite, K-76 (**10**) (4, 5). The IR spectrum of compound **2** displays a strong band at 1690 cm^{-1} corresponding to the phthalaldehyde functionality as well as two bands at 1773 and 1728 cm^{-1} corresponding to the two acetoxy groups. The aldehyde absorption is similar to that reported for K-76 (4). The ^1H NMR spectrum (Table 1) of compound **2** displays very characteristic signals at 10.55 (s) and 10.61 (s) ppm for the phthalaldehyde moiety. The ^{13}C NMR chemical shifts for compound **2** (Table 3) are very similar to those reported for K-76 (5*b*) except for C2 (22.15 ppm) and for the carbons of the two acetoxy groups (3-OAc: 21.10. 170.45; 2′-OAc: 20.76, 167.25 ppm). A COSY experiment, assisted by a HETCOR experiment, clearly identified the two spin systems in ring A and ring B of the

drimane moiety. For example, in ring A, the signal for H3β (4.62, br s) is coupled to a methylene pair at 1.82 and 1.62 ppm, and these in turn are coupled to another methylene pair at 1.12 and 1.65 ppm. In a long-range COSY experiment, H3′ (7.14 ppm) was found to couple with one (10.55 ppm) of the aldehyde protons. This long-range benzylic coupling accounts for the fact that the aldehyde peak at 10.55 ppm is broader than the aldehyde proton at 10.61 ppm. All of the observed nuclear Overhauser enhancements (Fig. 1) are consistent with the proposed structure for compound **1**. The HREIMS fragmentation pattern (Fig. 2) is also in good agreement with the proposed structure. For example, the base peak at 190.1716 is attributed to the drimane fragment arising from cleavage a. Another cleavage, a′, produces the phthalaldehyde fragment that accounts for the peak at 220.0371. The strong peaks at 272.0681 ($C_{15}H_{12}O_5$) and 230.0579 ($C_{13}H_{10}O_4$) are attributed to cleavage b across ring B.

Compound 3

Compound **3**, believed to be an artifact formed from stachybotrydial (**1**), was separated from **1** as a white crystalline solid after **1** was reduced to the corresponding diol (**4**). Examination of its NMR data suggested that its structure is **3**; the dialdehyde moiety in stachybotrydial (**1**) is transformed into a lactone. The spectroscopic evidence supporting this proposal is as follows. The HREIMS revealed that the molecular formula is $C_{23}H_{30}O_5$, identical with that of the dialdehyde, **1**. In the IR spectrum, the aromatic aldehyde absorption is replaced by a band at 1742 cm^{-1}, appropriate for an α,β-unsaturated γ-lactone. The ^1H (Table 1) and ^{13}C NMR (Table 3) signals corresponding to the dialdehyde functionality are replaced by methylene signals at 5.23 and 5.17 ppm (J = 14.7) in the ^1H NMR and at δ 67.84 (t) and 171.29 in the ^{13}C NMR. A COSY experiment (Table 1) together with an HMQC (6) experiment identified the two spin systems in the drimane nucleus. An HMBC experiment (Table 1) was employed to establish the regiochemistry of the lactone system. Thus a three-bond correlation from H3′ (6.76 ppm) to the carbonyl at 171.29 ppm unambiguously indicates that the lactone carbonyl is located at C7′ rather than C8′. The correlations from the lactone methylene protons (5.23 and 5.17 ppm) to C5′ (128.07 ppm), C4′ (119.22 ppm), and C6′ (155.47 ppm) indicate that the methylene is located at C8′, while the correlation from the same methylene protons to the lactone carbonyl confirmed the presence of a γ-lactone. All of the observed HMBC correlations are consistent with structure **3** for this compound.

The spontaneous transformation of stachybotrydial (**1**) in

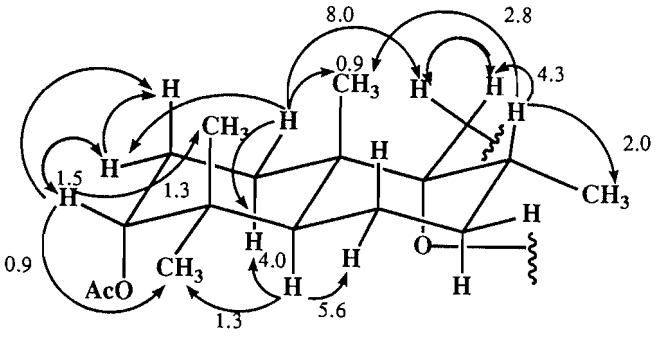

FIG. 1. Selected nOes for stachybotrydial diacetate (**2**).

organic solvents into the corresponding lactone (**3**) results from an intramolecular Cannizzaro reaction, which normally requires alkaline conditions. However, no alkali was used during the isolation. Stachybotrydial diacetate (**2**) underwent the same transformation in $CDCl_3$ when kept in the fridge for several weeks. This transformation has not been reported for K-76 (**10**) (4, 5*a*, 5*b*).

Stachybotramide (8)

Another new compound, **8**, for which we propose the name stachybotramide, was isolated in its acetylated form (**9**) as a white amorphous solid. Stachybotramide triacetate (**9**) has the molecular formula $C_{31}H_{41}NO_8$ according to HREIMS. The similarity between the NMR data of stachybotramide triacetate (**9**) and those of the lactone diacetate (**11**) (Table 2) suggests that **9** possesses the same phenylspirodrimane skeleton. The COSY and TOCSY (7) spectra of compound **9** clearly identified the three spin systems in the drimane moiety, i.e., C1-C2-C3 in ring A, C5-C6-C7-C8-C12 in ring B, and the C11 methylene. Long-range H/C correlations provided by an HMBC experiment are fully consistent with the proposed structure (see Table 2). A proton spin system that is not present in **11**, $>NCH_2CH_2O$- (^{1}H δ: 3.85, 4.32 ppm; ^{13}C δ: 41.86, 62.25 ppm), was also identified by COSY and TOCSY. Both the proton and carbon signals of the C8′ methylene were shifted significantly upfield to 4.46 and 4.34 ppm and 48.18 ppm, respectively. This is accounted for by the replacement of the oxygen atom on C8′ of **11** by the nitrogen in **9**. Both the IR absorption at 1696 cm^{-1} and ^{13}C NMR signal at δ 167.99 ppm are consistent with the presence of a γ-lactam. An HMBC experiment (Table 2) optimized for J = 4 Hz provided unambiguous evidence for the attachment of the $>NCH_2CH_2O$- fragment to C7′ and C8′. For example, the C9′ methylene protons (3.85 ppm) showed long-range correlations to both C7′ and C8′ as well as to C10′ (62.25 ppm); the C10′ methylene

[a]H11a is defined as the proton on the side of C10, while H11b is on the side of C8.

protons showed long-range correlations to C9′ (41.86 ppm) and an acetoxy carbonyl carbon (170.69 ppm), indicating that the oxygen in the $>NCH_2CH_2O$- fragment is acetylated. Thus stachybotramide possesses structure **8**.

Trichothecenes (5, 6)

Compound **5** was obtained as a colorless oil, $[\alpha]_D$ −9.3, IR ν_{max}: 1735, 1374, 1244, 1081 cm^{-1}. The molecular formula $C_{17}H_{24}O_4$ was determined by HREIMS. Extensive NMR studies including ^{1}H, ^{13}C, COSY, HMQC, and HMBC revealed that compound **5** is identical with trichodermin, a known mycotoxin belonging to the trichothecene family.[4] The spectroscopic data are consistent with those reported for trichodermin (8). Compound **6**, slightly more polar than com-

[4]For reviews on the chemistry and biological activities of trichothecenes, see ref. 8.

*These assignments may be interchanged.

pound **5**, was obtained as an amorphous white solid, $[\alpha]_D$ −22, IR ν_{max}: 3458, 1625, 1070 cm^{-1}. The molecular formula is $C_{15}H_{22}O_3$ according to HREIMS, C_2H_2O less than that of compound **5**. NMR studies established that compound **6** is the desacetyl form of compound **5**, known as trichodermol, a well-known mycotoxin in the trichothecene family (8).

Bioassays against the blue-stain fungus *C. crassivaginata* indicate that trichodermin (**5**) and trichodermol (**6**) are responsible for the antifungal activity.[5] Trichothecenes have been isolated from various species of *Fusarium, Myrothecium, Trichothecium, Cephalosporium, Verticimonosporium, Stachybotrys, Trichoderma*, and *Cylindrocarpon*. Many trichothecenes possess a variety of significant biological activities such as toxicity, antifungal activity, enzyme inhibition, and immunosuppresion (8). This is the first report of the isolation of trichothecenes from *S. cylindrospora*.

6,8-Dihydroxy-3,5,7-trimethylisochroman (7)

Compound **7** was isolated as an amorphous yellow solid. HREIMS revealed the molecular formula $C_{12}H_{16}O_3$. The IR spectrum displayed a broad band at 3412 cm^{-1}, suggesting the presence of hydroxy groups. The ^1H NMR spectrum of compound **7** (Table 4) displays singlets at 7.00 and 6.94 ppm, a methylene AB system at 4.83 and 4.52 ppm (J = 14.7), methyl singlets at 2.13 and 2.06 ppm, and a $(Ar)CH_2CH(O)CH_3$ fragment. The proton signals at 7.00 and 6.94 ppm are replaced by aromatic acetyl methyl signals (2.34, 2.30 ppm) upon acetylation (compound **12**), indicating the presence of two phenolic hydroxyls in **7**. The carbon spectrum (Table 4) of compound **7** contains six aromatic singlets between 152.44 and 109.63 ppm, indicating that four of the five unsaturations of the molecule may be accounted for by a fully substituted benzene ring. The substituents are two hydroxyls, two methyls, one methylene, and the $CH_2CH(O)CH_3$ fragment. The latter two fragments must be *ortho* related and connected through the oxygen atom to create a ring which accounts for the fifth unsaturation. The substitution pattern of the methyls and hydroxyls on the benzene ring was determined by a series of nOe irradiations (Fig. 3). Thus the structure of compound **7** is established as 6,8-dihydroxy-3,5,7-trimethylisochroman. Long-range H/C correlations (Table 4) provided by an HMBC experiment are fully consistent with the proposed structure **7**. For example, the correlations from both the C1 methylene and the C4 methylene protons to C9 (131.08 ppm) and C10 (115.25 ppm) established the *ortho* relationship between these two groups. The correlation between the C1 methylene protons and C3 (71.23 ppm) confirmed the ether linkage between C1 and C3.

In conclusion, the investigation of the metabolites of the aspen fungus *Stachybotrys cylindrospora* has led to the isolation and identification of three types of compounds, namely, the phenylspirodrimanes (stachybotrydial (**1**) and stachybotramide (**8**)), the trichothecenes (trichodermin (**5**) and trichodermol (**6**)), and 6,8-dihydroxy-3,5,7-trimethylisochroman (**7**). Trichodermin (**5**) and trichodermol (**6**) are responsible for the antifungal activity of *S. cylindrospora*

against the blue-stain fungus *Ceratocystiopsis crassivaginata*. Compounds **1**, **7**, and **8** are new natural products.

Experimental

General

All solvents used were distilled prior to use. ^{1}H NMR spectra were recorded on either a Bruker AM400 or Varian Unity-500 spectrometer. All ^{13}C NMR spectra were recorded on a Bruker AM400 spectrometer. All COSY and LR-COSY experiments were performed by using standard Bruker or Varian Unity programs. All HMQC and HMBC experiments were performed on a Varian Unity-500 spectrometer, with 2K data points in the F2 domain and 256 increments, and optimized for $^1J_{H/C}$ = 140 Hz and $^{2-3}J_{H/C}$ = 7 Hz unless otherwise stated in the text.

Culture conditions for S. Cylindrospora

Stachybotrys cylindrospora was cultured in 5 or 10 L malt extract/yeast extract liquid medium (20 g malt extract/1 g yeast extract in 1 L double-distilled water) for 3 weeks. The early batches were shake cultures (100 rpm) while the later batches were still cultures, which were found to produce larger amounts of the active compounds (**5** and **6**). Details of culturing techniques have been described previously (9).

Work-up and isolation procedures

1. Procedures for batches 1 and 4. The mycelium was removed by filtration through cheese cloth to give 5 L yellow broth, which was then concentrated to 1/10 volume under reduced pressure. The concentrate was extracted with ethyl acetate three times. The organic extract was dried over sodium sulfate and concentrated under reduced pressure to yield an orange solid (1.2 g), which contained mainly one compound, **1**. A portion (120 mg) of the extract was acetylated with Ac_2O/pyridine to yield 30 mg of compound **2** as a white amorphous solid after purification on a silica gel column (solvent: 10–20% acetone/hexanes). The remaining portion of the extract partially decomposed to give compound **3**, which was inseparable from compound **1**; 119 mg of this mixture was treated with 250 mg $NaBH_4$ (in 20 mL CH_3CH/H_2O, 30 min at 0°C, 3 h at room temperature). The reaction mixture was acidified with AcOH, diluted with water, and extracted with EtOAc. The organic extract was chromatographed on silica gel (25–50% acetone/hexanes) to yield 16 mg compound **3** and 40 mg compound **4**.

2. Procedures for the other culture batches. The broth (10 L) was separated from the mycelium by filtration through cheese cloth and either extracted with EtOAc or passed through an XAD-16 column, which was then eluted with acetone. The crude extract was partitioned over Sephadex LH20 (acetone) to give five fractions. Fraction 1 was biologically active and repeatedly chromatographed on silica gel (step 1: preparative TLC: 1:1 acetone/hexanes; step 2: 3% acetone/CH_2Cl_2 for the first active TLC fraction and 5% MeOH/CH_2Cl_2 for the second active TLC fraction) to yield two pure compounds, **5** (6.5 mg) and **6** (2.1 mg). Fraction 2 was purified by silica gel chromatography (15–100% acetone/hexanes) to yield 25 mg compound **7**. Fraction 3 was chromatographed on silica gel (preparative TLC: 1:1 acetone/hexanes) to give 2.0 mg compound **3** and a small amount of compound **7**. Fraction 4 was fractionated on a silica gel column (0.5% AcOH–5% MeOH/CH_2Cl_2) to yield 25 mg orsellinic acid. Fraction 5 was acetylated with Ac_2O/pyridine to give 4 mg stachybotramide triacetate (**9**) after chromatography over silica gel (15–40% acetone/hexanes).

Stachybotrydial diacetate (2): obtained as a white amorphous solid; $[\alpha]_D$ −69 (*c* 0.063, $CHCl_3$); IR ($CHCl_3$) ν_{max}: 2930, 1773, 1728, 1690, 1595, 1403, 1257, 1247, 1190, 1093 cm^{-1}; UV (MeOH) λ_{max}: 230 (14 000), 252 (sh, 9400), 282 (4300), 357 (4300) nm; HREIMS *m/z*: 470.2306 ($C_{27}H_{34}O_7$, Δmmu = 0.2, 2%), 410.2117 ($C_{25}H_{30}O_5$, 40%), 368.1976 ($C_{23}H_{28}O_4$, 10%), 272.0681 ($C_{15}H_{12}O_5$, 10%), 230.0579 ($C_{13}H_{10}O_4$, 56%), 190.1716 ($C_{14}H_{22}$, 100%), 178.0263 ($C_9H_6O_4$, 29%); ^{1}H NMR (400 MHz, $CDCl_3$), see Table 1; ^{13}C NMR (100 MHz, $CDCl_3$), see Table 3.

Compound 3: obtained as a white or pale yellow crystalline solid; mp 280°C (dec.); $[\alpha]_D$ −6.4 (*c* 0.09, acetone); IR ($CHCl_3$) ν_{max}: 3600–3100, 2939, 1742, 1623, 1469, 1389, 1356, 1332, 1079, 954, 943, 772, 737 cm^{-1}; UV (MeOH) λ_{max}: 218 (28 000), 268 (5300), 309 (2600) nm; HREIMS *m/z*: 386.2095 ($C_{23}H_{30}O_5$, Δmmu = 0.1, 53%), 368.1977 ($C_{23}H_{28}O_4$, 11%), 353.1753 ($C_{22}H_{25}O_4$, 9%), 244.0730 ($C_{14}H_{12}O_4$, 9%), 230.0579 ($C_{13}H_{10}O_4$, 100%), 217.0499 ($C_{12}H_9O_4$, 18%), 207.1747 ($C_{14}H_{23}O$, 38%),

Squaraine chemistry. A new approach to symmetrical and unsymmetrical photoconductive squaraines. Characterization and solid state properties of these materials

KOCK-YEE LAW[1] AND F. COURT BAILEY

Xerox Webster Research Center, 800 Phillips Road, 0114-39D, Webster, NY 14580, U.S.A.

Received September 15, 1992

KOCK-YEE LAW and F. COURT BAILEY. Can. J. Chem. **71**, 494 (1993).

A new approach to 1-(*p*-dimethylaminophenyl)-2-hydroxycyclobutene-3,4-dione (**4**), a precursor for the synthesis of symmetrical and unsymmetrical photoconductive squaraines, is described. *In situ* generation of *p*-nitrophenyl ketene, by the reaction of *p*-nitrophenylacetyl chloride and triethylamine in the presence of tetraethoxyethylene in anhydrous ether, results in a (2+2) cycloaddition between the ketene and the electron-rich olefin. The cycloadduct generated, **6**, was hydrolyzed to give 1-(*p*-nitrophenyl)-2-hydroxycyclobutene-3,4-dione (**5**) in 51% yield. Reductive alkylation of **5** by hydrogen in the presence of formaldehyde in DMF at 50–60°C affords **4** in 81% yield. The overall yield of **4** is 41% from tetraethoxyethylene and is significantly better than other preparative procedures of **4** based on a partial Friedel–Crafts reaction or an arylation reaction of a squaric acid derivative with an aniline, where yields ranging from 8.5% to 24% were reported. Condensations of **4** with 2 equivalents of *N*,*N*-dimethylaniline and its derivatives in refluxing 2-propanol in the presence of 6 equivalents of tributyl orthoformate yield symmetrical squaraine **1***a* and unsymmetrical squaraines **1***b*–**1***e*. The synthesis is accomplished by a (2+2) cycloaddition – reductive alkylation – condensation reaction sequence and represents a new, cost-effective synthesis for photoconductive squaraines where the expensive squaric acid reactant is bypassed. The spectroscopic and the solid state properties of **1***a*–**1***e* have been studied. Results show that the properties exhibited by **1***a*–**1***e* are essentially identical to those exhibited by other photoconductive, symmetrical squaraines that are synthesized by other known processes. From the resemblance in solid state properties, **1***a*–**1***e* are expected to be photoconductive. This has indeed been observed in preliminary experiments.

KOCK-YEE LAW et F. COURT BAILEY. Can. J. Chem. **71**, 494 (1993).

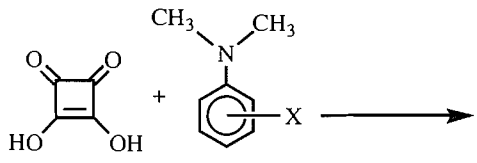
On décrit une nouvelle approche pour la préparation de la 1-(*p*-diméthylaminophényl)-2-hydroxycyclobutène-3,4-dione (**4**), un précurseur dans la synthèse de squaraïnes photoconductrices symétriques et non-symétriques. La génération *in situ* du *p*-nitrophényl cétène, par la réaction du chlorure de *p*-nitrophénylacétyle avec la triéthylamine en présence de tétraéthoxyéthylène dans l'éther anhydre, conduit à une cycloaddition (2+2) du cétène et de l'oléfine riche en électrons. L'hydrolyse du cycloadduit, **6**, ainsi généré conduit à la 1-(*p*-nitrophényl)-2-hydroxycyclobutène-3,4-dione (**5**) avec un rendement de 51%. L'alkylation réductrice de **5** par de l'hydrogène en présence de formaldéhyde dans de DMF, à 50–60°C, fournit le composé **4** avec un rendement de 81%. Le rendement global de **4** est de 41% à partir du tétraéthoxyéthylène et ce rendement est supérieur à ceux obtenus lors de préparations impliquant une réaction de Friedel–Crafts partielle ou une réaction d'arylation d'un dérivé de l'acide squarique avec de l'aniline alors que les rendements rapportés sont de l'ordre de 8,5 à 24%. Les condensations de **4** avec deux équivalents de *N*,*N*-diméthylaniline et de ses dérivés, dans du propan-2-ol, en présence de 6 équivalents d'orthoformate de tributyle conduisent à la squaraïne symétrique **1***a* et aux squaraïnes non-symétriques **1***b*–**1***e*. La synthèse est réalisée par une séquence de réactions de cycloaddition (2+2) – alkylation réductrice – condensation et elle représente une nouvelle synthèse efficace du point de vue du prix de squaraïnes photoconductrices dans laquelle l'acide squarique qui est très chère n'est pas impliquée. On a étudié les propriétés spectroscopiques et les propriétés à l'état solide des composés **1***a*–**1***e*. Les résultats montrent que les propriétés de ces composés sont essentiellement identiques à celles d'autres squaraïnes symétriques photoconductrices qui ont été synthétisées par d'autres procédés connus. En se basant sur la ressemblance des propriétés à l'état solide des produits **1***a*–**1***e*, on peut s'attendre à ce qu'ils soient photoconducteurs. C'est ce qui a été observé dans des expériences préliminaires.

[Traduit par la rédaction]

Introduction

Bis(4-dimethylaminophenyl)squaraine (**1***a*) and many of its derivatives are photoconductive pigments known to be useful for xerographic diode laser printers (1). The traditional synthesis, which involves the condensation of one equivalent of squaric acid, and two equivalents of an *N*,*N*-dimethylaniline derivative in an azeotropic solvent, is very straightforward and versatile (2); a large number of squaraine derivatives have been synthesized by this procedure (2–8).

Squaraines synthesized by this procedure are, however, often found to exhibit low charge-accepting properties and high dark-conductivity in bilayer xerographic devices (1). Because of their low solubility in organic solvents, a conventional purification procedure to improve their xerographic properties has yet to be developed. Two modified procedures, using the mono- and the dialkyl esters of squaric acid as precursors for the squaraine synthesis, have been



squaric acid

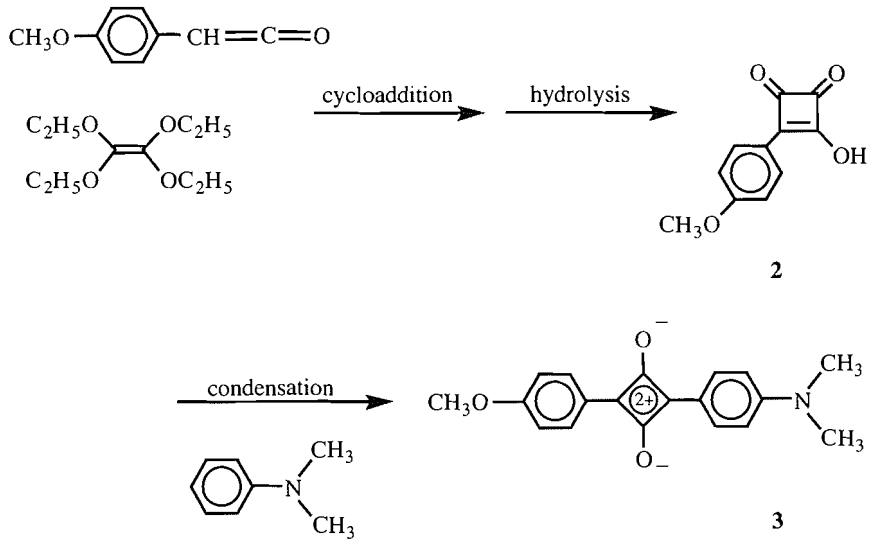
developed to circumvent the performance problem (9, 10). The common starting material for these procedures is squaric acid, a relatively expensive chemical. It is thus advantageous from the viewpoint of cost reduction to develop new procedures for squaraines, so that low-cost starting materials can be used.

With this research direction in mind, a new approach to photoconductive unsymmetrical squaraines, based on a (2+2) cycloaddition – condensation reaction sequence, has been developed (11, 12). The essence of this approach involves the preparation of intermediate **2** by a (2+2) cycloaddition reaction between *p*-methoxyphenyl ketene and tetraethoxyethylene, followed by an acid hydrolysis reaction, and the condensation of **2** and an *N*,*N*-dimethylaniline derivative to form unsymmetrical squaraine **3** or its derivatives.



Since no squaric acid is used and since both cycloaddition and condensation reactions appear to be efficient, the goals of developing a new procedure for squaraines with cost reduction and synthetic simplification are accomplished.

The aim of this report is to describe our investigation of the extension of the above concept to synthesize squaraines, such as **1***a* and its derivatives, that are known to be photoconductive in device applications.[2] Here, the synthesis of **1***a* and its unsymmetrical analogs **1***b*–**1***e* by a (2+2) cycloaddition – reductive alkylation – condensation reaction sequence is reported. The merit and the limitations of the synthesis will be discussed. The spectroscopic and the solid state properties of **1***a*–**1***e* are presented and are found to be similar to those exhibited by squaraines that are photoconductive.

Experimental

Materials

p-Nitrophenylacetic acid (97%), phosphorus pentachloride, triethylamine (99+%), palladium (10%) on activated carbon, formaldehyde (37% solution in water), and *N*,*N*-dimethylaniline were purchased from Aldrich. Tributyl orthoformate was bought from Pfaltz & Bauer. Acetone, ether (anhydrous), toluene, methanol, *N*,*N*-dimethylformamide, tetrahydrofuran, 2-propanol, and *n*-heptane were certified grade from Fisher; concentrated hydrochloric acid was reagent grade, also from Fisher. All these materials were used as received. Substituted *N*,*N*-dimethylanilines were synthesized by methylating the corresponding aniline with trimethyl phosphate (14).

General techniques

Melting points were taken on a capillary melting point apparatus (Thomas Hoover) and were uncorrected. Infrared spectra were determined on a Perkin–Elmer model 1750 FTIR. Proton NMR spectra were recorded either on a Bruker WP-80 spectrometer or a Bruker AM360 spectrometer. Absorption spectra were taken on a Cary 17 spectrophotometer or on a Hewlett Packard 8451 diode array spectrophotometer. Mass spectra were recorded on a Varian VG 7035 mass spectrometer at the University of Rochester. Elemental analyses were performed by Galbraith Laboratories. X-ray powder diffraction patterns were performed in-house on a Scintag PAD V X-ray diffractometer.

Synthesis of p*-nitrophenylacetyl chloride*

p-Nitrophenylacetic acid (60.6 g) and phosphorus pentachloride (74.4 g) were placed in a 1-necked 1-L flask. The two solid compounds were mixed gently with a glass rod and an exothermic reaction was observed, which was accompanied by the formation of phosphorus oxychloride. As soon as the exotherm subsided, the mixture was brought to reflux at an oil-bath temperature of ~120°C for ~2 h. The mixture was cooled to ~60°C and phosphorus oxychloride was removed under reduced pressure. The crude product was then recrystallized from *n*-heptane (~1.5 L), yield pure *p*-nitrophenylacetyl chloride (white solid), 53.6 g (83%); mp 47.5–49°C (lit. (15) mp 46–47°C). IR (KBr): ~1800 cm^{-1} (C=O).

*Synthesis of 1-(*p*-nitrophenyl)-2-hydroxycyclobutene-3,4-dione*

Tetraethoxyethylene (51.3 g), which was freshly prepared according to procedures described by Bellus *et al.* (16), triethylamine (54.8 g), and diethyl ether (1.6 L) were placed in a 3-necked 3-L flask, which was equipped with a nitrogen inlet and a mechanical stirrer. An ethereal solution containing 105.2 g of *p*-nitrophenylacetyl chloride in 800 mL of ether was slowly added to the tetraethoxyethylene solution at room temperature over a 2-h period. A light brown precipitate was formed during the addition. The product mixture was then kept at 25–30°C by a warm water

[2]A preliminary account of this work has appeared in ref. 13.

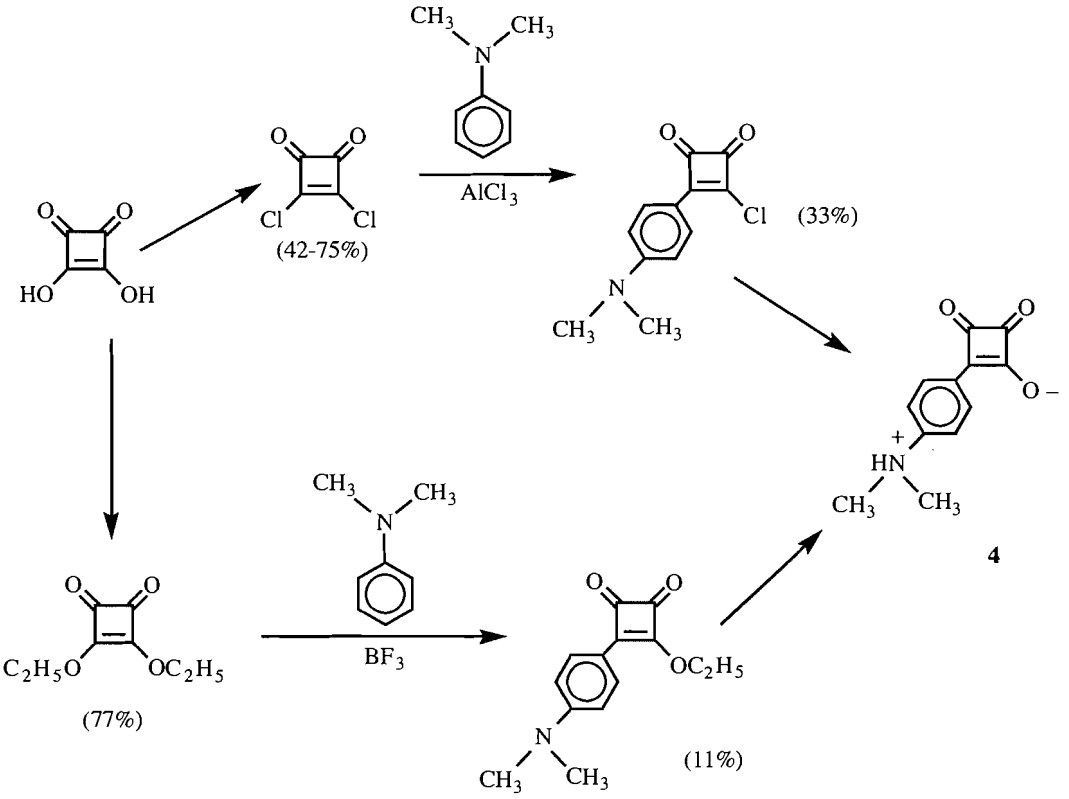
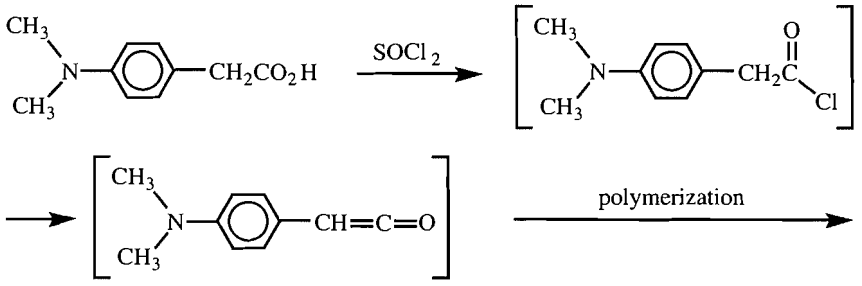


SCHEME 1



SCHEME 2

bath for a further 4 h. The product, which was soluble in diethyl ether, was isolated by filtration. The insoluble precipitate was washed with another litre of ether. The filtrate was combined. After solvent evaporation, 83.2 g of yellow residue was obtained. The yellow residue was then hydrolyzed by 150 mL of 18% hydrochloric acid at reflux for 4.5 h. Hydrochloric acid was evaporated under reduced pressure, yield 46.5 g crude product (a tan-colored gum). The crude product was then digested with boiling *n*-hexane and was recrystallized from a mixture of acetone and toluene. A light yellow solid, 1-(*p*-nitrophenyl)-2-hydroxycyclobutene-3,4-dione (**5**) was obtained, yield 28.2 g (51%); mp 162–163°C (dec.) (lit. (17) mp 187°C, (18) mp 160°C (dec.), (19) mp 188°C). IR (KBr): 1822, 1790, and 1724 cm^{-1}. ^1H NMR (DMSO-d_6) δ: 8.05–8.40 (AB quartet). MS (*m/z*): 219 (M^+). Anal. calcd. for $C_{10}H_5NO_5$: C 54.81, H 2.30, N 6.39; found: C 54.91, H 2.86, N 6.57.

*Synthesis of 1-*p*-dimethylaminophenyl-2-hydroxycyclobutene-3,4-dione*

A solution containing 8.77 g of 1-(*p*-nitrophenyl)-2-hydroxycyclobutene-3,4-dione in 160 mL of DMF was placed in a 500-mL Parr bottle. Formaldehyde (8.8 mL, 37% in water) and 2.4 g catalyst (10% palladium on carbon) were added. The bottle was then placed on a Parr apparatus and the mixture was hydrogenated at a pressure of ~60 psi (1 psi = 6.89 kPa) at ~50°C for ~1.5 h. The catalyst was removed by filtration and the solvent was evaporated under reduced pressure. The resulting orange-brown residue was then digested with acetone. After vacuum drying, 7.02 g (80.8%) of orange solid, 1-(*p*-dimethylaminophenyl)-2-hydroxycyclobutene-3,4-dione (**4**), was obtained; mp >300°C. IR (KBr): 1766, 1756, and 1707 cm^{-1}. ^1H NMR (DMSO-d_6) δ: 3.04 (s, 6H, NCH_3), 6.86 (d, J = 9.6 Hz, 2H), and 7.87 (d, J = 9.6 Hz, 2H). MS (*m/z*): 217 (M^+). Anal. calcd. for $C_{12}H_{11}NO_3$: C 66.35, H 5.10, N 6.45; found: C 64.61, H 5.17, N 6.95.

Synthesis of symmetrical and unsymmetrical squaraines

N,N-Dimethylaniline (0.35 mL, 2.76 mmol), 2-propanol (25 mL), and tributyl orthoformate (2 mL) were placed in a 3-necked 100-mL flask, which was equipped with a magnetic stirbar and a nitrogen inlet. The mixture was stirred and was brought to reflux. A solution containing 1-(*p*-dimethylaminophenyl)-2-hydroxycyclobutene-3,4-dione (0.3 g, 1.38 mmol) in ~4 mL of DMF was added slowly through a pressure-equalizing funnel over a 3-h period. After the addition was completed, the product mixture was

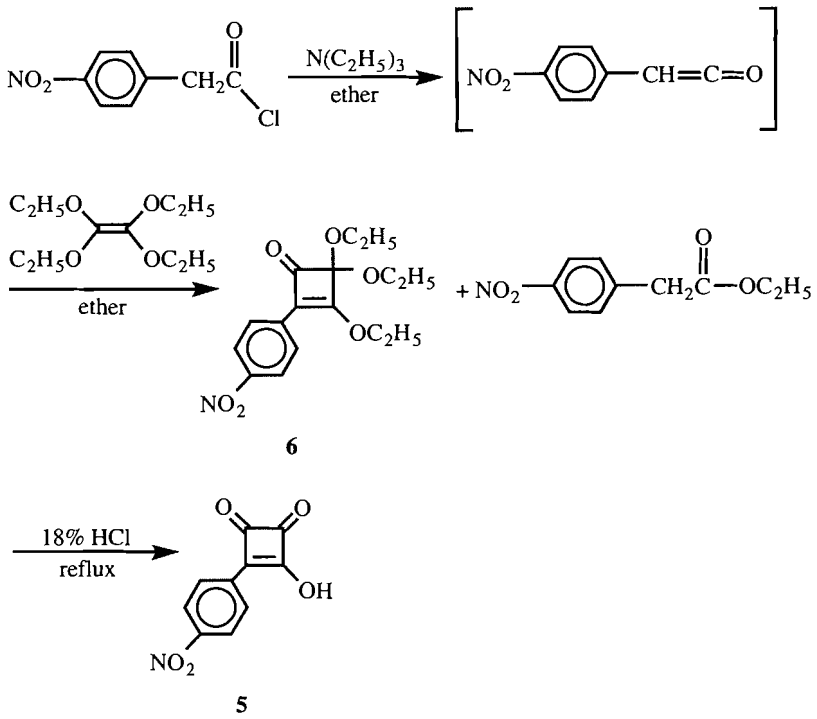
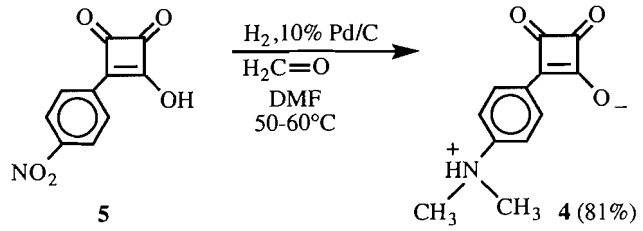


SCHEME 3



SCHEME 4

kept at reflux for a further 3 h. A blue precipitate was formed and was isolated by filtration. After washing with methanol and ether and vacuum drying, 0.20 g of a blue solid, which was subsequently identified as bis(4-dimethylaminophenyl)squaraine (**1***a*), was obtained (46%).

Unsymmetrical squaraines were analogously synthesized by condensing 1-(*p*-dimethylaminophenyl)-2-hydroxycyclobutene-3,4-dione and an appropriate aniline. The yields, the physical properties, and the spectral data of these materials are summarized in Tables 1–3.

Results and discussion

*Precursor, 1-(*p*-dimethylaminophenyl)-2-hydroxycyclobutene-3,4-dione (**4**)*

Strategy and synthesis

As noted earlier, squaraines can be synthesized from squaric acid, and the mono- as well as the dialkyl ester of squaric acid. Regardless of the precursors in these syntheses, the final squaraine formation step involves the condensation of **4** and an *N*,*N*-dialkylaniline (9). It becomes obvious that if one can develop an independent synthesis of **4**, one would not only be able to optimize the reaction condition for the squaraine formation step, but also have access to unsymmetrical squaraines when an appropriate aniline reactant is chosen. Kazmaier *et al.* (20) proposed that **4** could either be synthesized by a partial Friedel–Crafts reaction between the acid dichloride of squaric acid and *N*,*N*-dimethylaniline, followed by hydrolysis of the resulting mono-acid chloride to **4**, or by mono-arylation of the diethyl ester of squaric acid with *N*,*N*-dimethylanine, followed by hydrolysis of the subsequent monoethyl ester to **4**. These reaction schemes are summarized in Scheme 1.

The synthetic yields for the acid dichloride and the diethyl ester were reported to be 42–75% (21, 22) and 77% (23), respectively, from squaric acid. Assuming that both hydrolysis reactions in Scheme 1 are quantitative, the overall yield of **4** (from squaric acid) would be in the range of 8.5–24%, due to the low yields obtained in the Friedel–Crafts reaction (33%) and the arylation reaction (11%). The low synthetic yield of **4** and the need of using squaric acid as a precursor are major obstacles to the further development of the synthetic concepts in Scheme 1.

We recently reported the synthesis of **2**, an analog of **4**, using a (2+2) cycloaddition reaction (11, 12). The intention here is to extend the cycloaddition approach to synthesize **4**. Initial attempts to synthesize *p*-dimethylaminophenylacetyl chloride, a precursor for the (2+2) cycloaddition to synthesize **4**, consistently produced a brown polymeric material. Since *p*-dimethylaminophenylacetyl chloride consists of an acid chloride group and a dimethylamino group, the formation of a polymeric product is then attributable to the polymerization reaction of *p*-dimethylaminophenyl ketene, which is generated as soon as the acid chloride is formed owing to its self-reaction (Scheme 2).

The strategy in this work is to use a nitro group as a masking group and then regenerate the dimethylamino group by a reductive-alkylation process. The acid chloride for the (2+2) cycloaddition process is *p*-nitrophenylacetyl chloride, which can be synthesized by a direct reaction between *p*-nitrophenylacetic acid and phosphorus pentachloride.

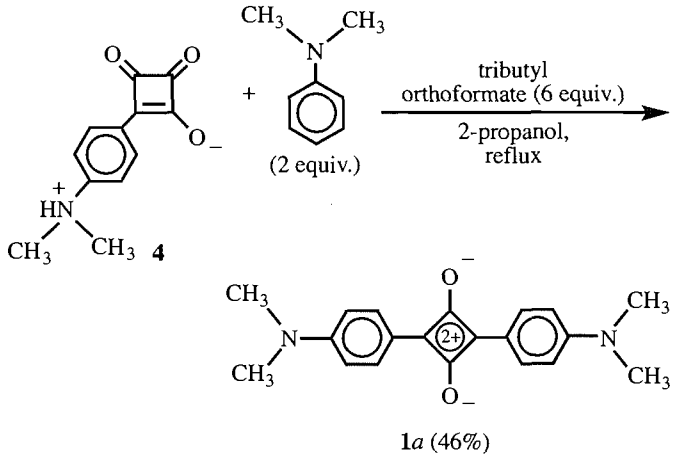

SCHEME 5

Addition of an ethereal suspension of *p*-nitrophenylacetyl chloride to an ethereal solution of tetraethoxyethylene in the presence of triethylamine leads to a (2+2) cycloaddition reaction between *p*-nitrophenyl ketene and the electron-rich olefin. The product mixture exhibits strong vibrational bands at 1735, 1748, and 1764 cm^{-1} in the IR spectrum. By comparing with the frequency of the C=O stretch of ethyl *p*-nitrophenylacetate, which is at 1735 cm^{-1}, and the C=O stretches of products of similar cycloaddition reactions (12), the bands at 1748 and 1764 cm^{-1} can be assigned to cycloadduct **6**. This assignment is confirmed by proton NMR spectral data of the product mixture. For instance, after subtracting proton signals corresponding to ethyl *p*-nitrophenylacetate, proton signals at δ 1.27 (t, J = 8.7 Hz), 1.55 (t, J = 8.7 Hz), 3.5–4.1 (two overlapped quartets), 7.93 (d, J = 11.2 Hz), and 8.25 (d, J = 11.2 Hz) of approximate ratio of 6:3:6:2:2 are observed. Since proton signals of **6** dom-

inate the NMR spectrum, our data indicate that **6** is the major cycloadduct for the cycloaddition reaction. The side product is ethyl *p*-nitrophenylacetate. Hydrolysis of the crude cycloaddition mixture in refluxing 18% HCl results in the formation of 1-*p*-nitrophenyl-2-hydroxycyclobutene-3,4-dione (**5**), which is isolated and purified in 51% yield after recrystallization from a mixture of acetone and toluene. The reaction sequence is summarized in Scheme 3.

The use of the cycloaddition between *p*-nitrophenyl ketene and tetraethoxyethylene for **5** was advanced by Bellus (18). The reported yield was 25%. The yield improvement obtained in this work is attributable to the use of ether rather than hexane as a reaction solvent for the cycloaddition. Compound **5** was also reported to be synthesized in an overall yield of 44% by a (2+2) cycloaddition reaction between *p*-nitrophenylacetylene and trifluorochloroethylene, followed by acid hydrolysis with sulfuric acid and an oxidation reaction (17). More recently, **5** was reported to be synthesized in 58% yield by reacting semisquaric acid with 4-nitrobenzene-1-diazonium chloride (19). The procedure reported here appears to be more attractive for practical use, because of the simplicity of the synthesis and the use of low-cost starting materials.

The dimethylamino group in **4** is regenerated by reductive alkylation of **5** under an atmospheric pressure of hydrogen in the presence of >2 equivalents of formaldehyde and a catalyst (10% Pd on charcoal). Initial attempts were carried out using the reductive-alkylation condition of *p*-nitrophenylacetic acid, where ethanol was used as the reaction solvent (24). By comparing the hydrogen consumption of the model reaction, only 10% of the expected hydrogen was consumed in the reductive-alkylation reaction of **5**. It is worth pointing out that the hydrogen uptake was stopped after the initial small exotherm. TLC analysis of the reaction mixture (after removing the catalysts) revealed that the major component is **5**. A minute amount of insoluble brown solid was isolated by concentrating the product solution. This brown solid was identified as **7** by mass spectrometry, where an intense peak at *m/z* 189 attributed to the molecular ion of **7** was observed.

The fact that there was no further uptake of hydrogen after the initial reaction and that most of **5** could be recovered from the reaction mixture suggests that the catalyst used in the hydrogenation process was poisoned as soon as the reduction occurred. Since it is known from the literature that hydroxy groups of squaric acid derivatives are highly acidic (pK_a ranges from +0.2 to −1.1) (18), the reduced product **7** and the reductive-alkylation product **4** are therefore expected to

7

exist as zwitterions due to the protonation of the -NH_2 and -$N(CH_3)_2$ groups. We believe that the catalyst poisoning is the result of the precipitation of **7** and **4** onto the surface of the catalyst, because of their low solubility in ethanol. To circumvent the solubility problems and to minimize the effect of catalyst poisoning, we modify the reductive-alkylation condition in this work by using (*a*) DMF as the reaction solvent, (*b*) a large excess of catalyst (×6 of the model reaction), and (*c*) an elevated reaction temperature (50–60°C). This modification has resulted in a tremendous improvement in the reductive alkylation of **5**, and an isolated yield of 81% has been obtained for **4**. The overall yield of **4** is 41% from tetraethoxyethylene and is significantly higher than the processes shown in Scheme 1. More importantly, **4** is synthesized without using squaric acid, indicating a definite cost saving and a probable synthetic simplification for the squaraine synthesis developed in this work.

Structural characterization

Compound **4** is a high-melting orange solid. Unlike its methoxy analogs, which are soluble in slightly polar (acetone, THF) and polar (DMF, DMSO) solvents, **4** is only slightly soluble in DMSO and DMF. Since the hydroxy groups in squaric acid derivatives are known to be highly acidic (18), **4** should exist as a zwitterion; its insolubility in THF and acetone is therefore reasonable. This structural assignment is further supported by the IR spectrum of **4**. For instance, **4** exhibits broad C=O bands consisting of a doublet at 1756 and 1766 cm^{-1} and a band at 1707 cm^{-1}. The fre-

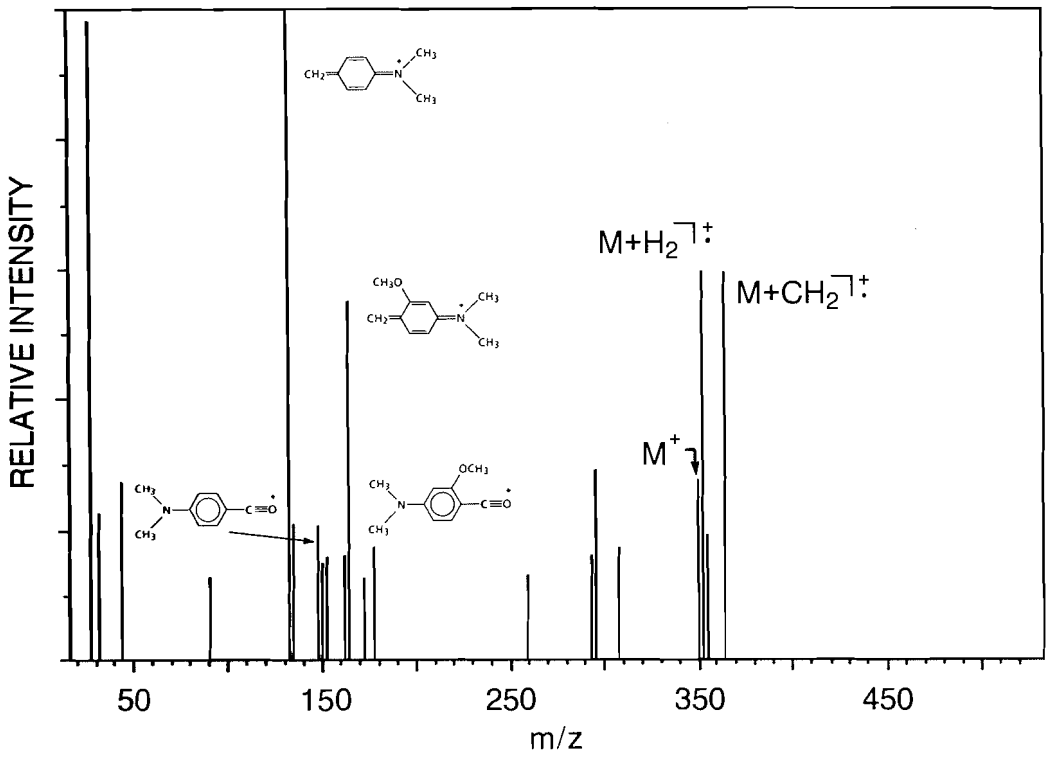

FIG. 2. Electron impact mass spectrum of **1***d*.

quency and the pattern are very similar to the deprotonated form of **2** (12).

In DMSO solution, **4** exhibits a singlet at 3.04 ppm for the six *N*-methyl protons and two doublets at 6.86 and 7.87 ppm for the four aromatic protons in the proton NMR spectrum. Due to the low solubility, acquisition of a good solution ^{13}C NMR spectrum for **4** requires at least an overnight scan, even on a Bruker AM360 instrument. The long scan time improves the signal-to-noise ratio of the spectrum, but **4** was found to decompose slowly during the overnight scan. The appearance of peaks from the decomposition product makes detailed chemical shift assignment of the solution ^{13}C NMR spectrum of **4** not probable. However, in a short (20 min) scan, ^{13}C signals at 44.3, 45.0, 112.3, 127.5, 151.3, 173.8, 194.8, and 194.9 ppm are clearly observable. From the ^{13}C NMR spectral data of **2**[3] and of *N*,*N*-dimethylaniline,[4] these signals can be assigned to *N*-methyl, *N*-methyl, C7 and C9, C6 and C10, C8, C1, and C2 and C4 of **4**, respectively (see inset of Fig. 1 for labelling). The observation of two peaks for the two *N*-methyl groups and two peaks for C2 and C4 suggests that the C—N bond in **4** is not freely rotated in DMSO solution. However, ^{13}C signals for C3 and C5 are within the noise level and could not be positively identified.

In this work, we further characterize **4** by solid state CP MAS ^{13}C NMR spectroscopy.[5] Figure 1*a* shows the full ^{13}C NMR spectrum of **4** and Fig. 1*b* shows the ^{13}C spectrum of the nonprotiated carbons of **4**. Six nonprotiated carbons are observed. The spectral result is consistent with the structure of **4** and also indicates that C2 and C4 are also not equivalent in the solid. The three downfield ketonic protons at 210.8, 200.3, and 195.8 ppm are assigned to C3, C4, and C2, respectively, based on their ketonic character in the resonance structure (27). It is worth pointing out that while the chemical shift difference between C2 and C4 is only 0.1 ppm in DMSO, the difference becomes 4.5 ppm in the solid state. The increase in nonequivalency between C2 and C4 is presumably due to rigidity of the entire carbon skeleton of **4** in the solid state. The nonprotiated carbons at 172.2, 144.4, and 133.2 ppm are assigned to C1, C8, and C5, respectively, based on the solution ^{13}C data of **2**, **4**, and *N*,*N*-dimethylaniline.

Two protiated carbon peaks at 129.0 and ~122.9 ppm with a ratio of ~1:3 are observed by subtracting Fig. 1*b* from Fig. 1*a*. From the solution data, C7 and C9 would be at ~122.9 ppm. C6 and C10 become magnetically nonequivalent in the solid state. We tentatively assign C10 at ~122.9 ppm because of its proximity to the negative charge. The chemical shift data are summarized in the inset of Fig. 1.

Squaraine synthesis

Squaraines can be synthesized by directly condensing **4** with an *N*,*N*-dimethylaniline derivative. The condition for the condensation reaction is investigated using **4** and *N*,*N*-dimethylaniline as reactants. The squaraine product is **1***a*; the quality of the product obtained can be compared with other **1***a* samples (9). Results showed that, when **4** and *N*,*N*-dimethylaniline were condensed in refluxing 1-butanol (2), 1-heptanol (under reduced pressure) (4), or 2-propanol (in the presence of tributyl orthoformate) (11, 12), a greenish-blue

[3]Using the labelling system of **4** (Fig. 1), the ^{13}C chemical-shift assignments of **2** are (in ppm, in DMSO-d_6) 55.4 (OCH_3), 114.7 (C7 and C9), 122.2 (C5), 127.9 (C6 and C10), 161.4 (C8), 172.6 (C1), 195.3 (C2 and C4), and 199.5 (C3).

[4]The chemical shifts of the carbons in *N*,*N*-dimethylaniline are 150 (C1), 113 (C2 and C6), 128.9 (C3 and C5), and 117 (C4); data taken from ref. 25.

[5]For details of the procedure for acquiring the CP MAS ^{13}C spectrum, see ref. 26.

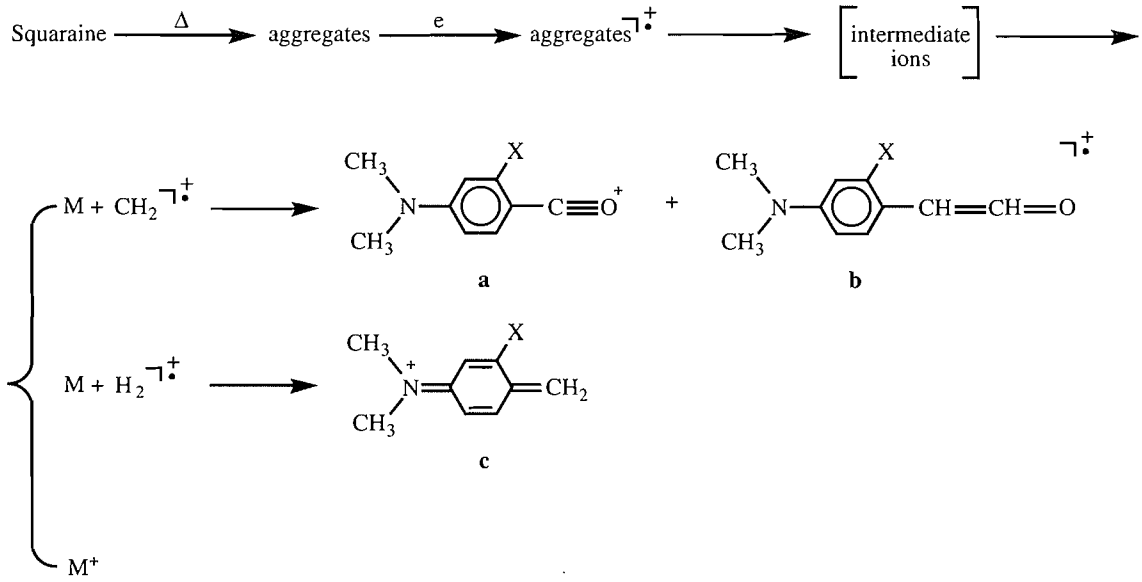

SCHEME 7

solid was obtained. VIS-absorption, TLC, and IR analysis indicated that the greenish-blue solid is a mixture of **1***a* and **4**. The incomplete consumption of **4** is somewhat surprising because the major side reaction in these condensation media is the esterification reaction of **4** to form an alkyl ester (4, 9, 12). We attribute the incomplete reaction to the low solubility of **4** in alcoholic solvents.

To circumvent the low solubility, we introduce **4** into the condensation media as a saturated DMF solution. According to the mechanism of the squaraine synthesis, **4** is the key reaction intermediate and is usually present at a very low concentration (9). In this work, we attempt to stimulate this condition by adding the DMF solution of **4** very slowly (over a period of 3 h) into the condensing medium. Our data show that the optimal condition for the synthesis of **1***a* is to add a saturated DMF solution of **4** into a refluxing 2-propanol solution containing 6 equivalents of tributyl orthoformate. The isolated yield of pure **1***a* was ~46% and is comparable to the yields obtained from other processes (9) (Scheme 5). The significance here is that, since **4** is synthesized by a cycloaddition – reductive alkylation process, the squaraine synthesis described thus represents a new and general approach to squaraine in which the use of squaric acid as a precursor is bypassed.

Using the above optimal conditions, several unsymmetrical squaraines (**1***b*–**1***e*) were synthesized. The yields and the physical properties of these materials are summarized in Table 1. The isolated yields of **1***b*–**1***e* are in the range of 3.8–52%, depending on the reactivity of the aniline reactant. In comparison with the yields of similar reactions (9), the yields reported in Table 1 appear to be relatively low. Thus, even though novel unsymmetrical squaraines have been synthesized by the present process, work is still needed to improve the efficiency of the condensation reactions.

The major difference between the condensation of **4** and *N*,*N*-dimethylaniline and that reported earlier between **2** and *N*,*N*-dimethylaniline is the use, in this work, of DMF in introducing **4**. Thus we also examined the effect of DMF on the condensation of **2** and *N*,*N*-dimethylaniline. The results are given in Scheme 6. Our results confirm that DMF exhibits a strong, adverse effect on the condensation reaction. The relatively low yields of **1***a*–**1***e* in Table 1 are attributable to the adverse effect exhibited by DMF in the condensation reaction. Future direction for yield improvement should thus be focussed on identifying a solvent for **4** that would at least be neutral to the condensation reaction.

Finally, condensations of 1-aryl-2-hydroxycyclobutene-3,4-diones with primary and secondary amines are known to form the corresponding 1,3-disubstituted unsymmetrical squaraine products (28–30). A similar reaction has also been reported for a pyrrole derivative (31). However, none of these squaraines is known to possess useful photoconductivity. The present study, as well as our previous work (11, 12), represents an extension of these condensation reactions to teritary aromatic amines. The resulting compounds are intensely absorbing in the visible region and are found to be photoconductive in xerographic devices.

Spectroscopic properties

IR spectra

Results in Table 2 show that all squaraines synthesized exhibit intense bands at ~1600 cm^{-1}. The absence of any C=O stretchings at ~1700 cm^{-1} is very characteristic for squaraine (3, 4, 12). The spectral results here suggest that, even though there is asymmetrical charge distribution in the two phenyl rings as revealed by proton NMR spectroscopy, the electrons in the central C_4O_2 unit are fully delocalized.

VIS spectra

The visible absorption spectrum of **1***a* synthesized in this work was found to be identical to the **1***a* sample that was synthesized by other processes (32). In the case of unsymmetrical squaraines **1***b*–**1***e*, all exhibit intense and sharp absorption bands in dilute chloroform solutions with λ_{max} ranging from 625 to 633 nm. Their molar extinction coefficients are typical of squaraines, in the order of 10^5 cm^{-1} M^{-1} (32, 33). Substituents are known to have an effect on the λ_{max}. In the case of **1***b*–**1***e*, it is interesting to point out that the substituent effect on their λ_{max} is smaller than on the λ_{max} of their symmetrical, disubstituted analogs (33). For instance, when the squaraine is substituted with two hydroxy groups

For personal use only.

in the positions adjacent to the central C_4O_2 unit, the λ_{max} is at 635.9 nm (33). The λ_{max} of **1***b* is at 626.1 nm and is midway between those of **1***a* and the dihydroxy compound.

^1H NMR spectra

Despite the low solubility, most of the squaraines synthesized in this work (except **1***b*) can be examined in $CDCl_3$ on a 360 MHz spectrometer. The results in Table 2 show that **1***a* exhibits a singlet at δ 3.20 and two doublets at δ 6.77 and 8.41 in a ratio of 3:1:1. They can be assigned to the *N*-methyl protons, the aromatic protons adjacent to the *N*,*N*-dimethylamino group, and the aromatic proton adjacent to the C_4O_2 unit, respectively (4, 34).

In the cases of unsymmetrical squaraines **1***c*–**1***e*, there are five magnetically nonequivalent aromatic protons. All five of them are identifiable by their chemical shifts, their coupling pattern, and their relative intensity.

Electron-impact mass spectra

Squaraines have been reported to exhibit anomalous electron-impact mass spectrometric behavior (3). For instance, owing to strong intermolecular donor–acceptor charge-transfer interactions in the solid state, squaraines vaporize thermally as molecular aggregates in the mass spectrometer. Ionization of these aggregates by electron impact results predominantly in intermediate fragment ions of formula

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

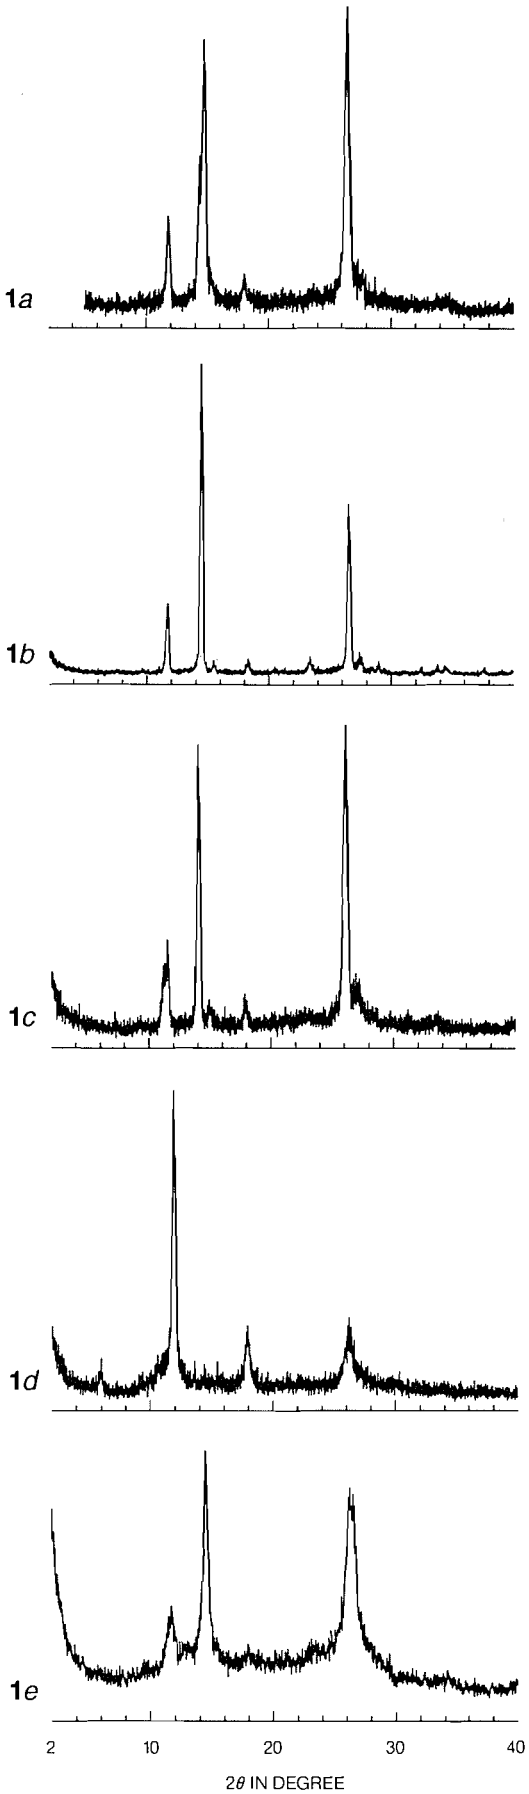

FIG. 4. X-ray powder diffraction patterns of squaraines **1***a*–**1***e*.

weight higher than the molecular weight of squaraine. In the case of **1***a*, fragmentation of the intermediate fragment ion leads to an alkylated ion M + $CH_2^{\square+}$, a dihydrogenated ion M + $H_2^{\square+}$, and the molecular ion M^+. Further fragmentation of these ions in the mass spectrometer results in the formation of characteristic rearranged ions, types **a**, **b**, and **c** (Scheme 7). Mechanistic details of their formation have been described previously (3). The mass spectral data of **1***a* are tabulated in Table 3 and are found to be identical to previous spectral data of **1***a* (3), for which a different synthetic route was used.

In the cases of **1***b*–**1***e*, more fragment ions are anticipated due to the unsymmetrical structure. The mass spectral data are listed in Table 3. A typical mass spectrum of an unsymmetrical squaraine (**1***d*) is depicted in Fig. 2. Comparing the spectral data of **1***b*–**1***e* with those of **1***a* indicates that all unsymmetrical squaraines have a similar set of mass spectral reactions (Scheme 7).

Solid state properties

The photoconductivity and the spectral response of squaraines are shown to be governed by the state of aggregation of squaraine molecules in their microcrystalline state (35). The photoactive aggregates are characterized by the broad and panchromatic solid state absorption, which typically consists of two bands, one in the visible (500–650 nm) and the other in the near IR (~700 nm) (36), and by the characteristic powder pattern with diffraction lines at 2θ 11.5°, 14.5°, and 26° (1). The solid state absorption spectra and X-ray powder diffraction patterns of **1***a*–**1***e* are given in Figs. 3 and 4, respectively. The solid state absorption spectrum and the X-ray powder pattern of **1***a* are found to be identical to those of the **1***a* samples synthesized by other processes (1, 36), suggesting that the **1***a* synthesized in this work exhibits solid state properties identical to previous **1***a* samples. Thus, the **1***a* sample prepared here should be photoconductive in xerographic photoreceptor devices and this has indeed been verified experimentally (37).

The data in Figs. 3 and 4 also suggest that the solid state properties of **1***b*–**1***e* are similar to those of **1***a*, despite their unsymmetrical structures. These results are not unexpected in view of similar results obtained from other symmetrical and unsymmetrical squaraines and in view of the small substituent effect on the solid state properties (1, 12, 38). Studies of the photoconductivities of these compounds are underway.

Concluding remarks

This work reports a new, general approach to the synthesis of squaraines based on a (2+2) cycloaddition – reductive alkylation – condensation reaction sequence. The goal of synthesizing squaraines at a lower cost, e.g., without using squaric acid, was accomplished. Due to the low solubility of the precursor compound (**4**) in alcoholic solvents, DMF, which was shown to have a detrimental effect on the yield of the condensation reaction, had to be used. Future investigation to improve the efficiency of the condensation reaction, such as identifying a substitute for DMF, is needed to enhance the practical value of the new synthetic approach described here.

One symmetrical and four unsymmetrical squaraines were synthesized. These compounds are shown to exhibit spectroscopic and solid state properties very similar to those of

their symmetrical analogs. Their solid state properties indicate that these squaraines should be photoconductive in xerographic devices. Very encouraging results have been obtained.

CLAUDIO ROSSI, ALESSANDRO DONATI, SERGIO ULGIATI, and MARIA ROSARIA SANSONI. Can. J. Chem. **71**, 506 (1993).

In view of the important biological functions of oxidized glutathione (GSSG), we investigated the correlation between dynamic and conformational properties and biological activity. Anisotropic molecular motion characterizes different GSSG molecular districts. This information, obtained by NMR carbon relaxation investigations, suggests that the peptide does not independently assume any stable structure in solution. Analysis of the effects of the addition of a stable spin label to the solution confirmed the absence of conformation of GSSG in D_2O. Moreover, the paramagnetic effects observed on proton and carbon nuclei of oxidized glutathione suggest that the dipolar term is the main source of paramagnetic relaxation.

CLAUDIO ROSSI, ALESSANDRO DONATI SERGIO, ULGIATI et MARIA ROSARIA SANSONI. Can. J. Chem. **71**, 506 (1993).

Considérant les fonctions biologiques importantes du glutathion oxydé (GSSG), on a examiné la corrélation entre les propriétés dynamiques et conformationnelles et l'activité biologique. Un mouvement moléculaire anisotropique caractérise les différentes portions moléculaires du GSSG. Cette information, obtenue par des études de relaxation en RMN du carbone, suggère que, d'une façon indépendante, le peptide n'assume aucune structure stable en solution. L'analyse des effets de l'addition d'un marqueur de spin à la solution a confirmé l'absence de conformation dans le GSSG dans le D_2O. De plus, les effets paramagnétiques observés sur le proton et les noyaux de carbone du glutathion oxydé suggèrent que le terme dipolaire est la principale source de relaxation paramagnétique.

Introduction

Glutathione (GSH), *N*(*N*-γ-L-glutamyl-L-cysteinyl-glycine), is the most abundant intracellular non-protein thiol. Under normal circumstances its oxidized form (GSSG) accounts for 1% of GSH concentrations. It is mainly formed in cells as a consequence of the protective activity of GSH against hydroperoxides (1). Oxidized glutathione is not solely the result of the reductive activity of GSH; in fact several metal ion – GSSG complexes seem to be involved in biological reactions. The copper and zinc complexes of GSSG in particular are believed to play an important role in promoting GSSG reduction (2) and the Cu(II)–GSSG complex acts as an inhibitor of the opiate receptor site (3). GSH and GSSG peptides are important in the vital functions of cells and biological fluids (4), and several papers have been published on their conformations (5, 6) and those of their metal complexes (7–13). Cyclic peptides frequently assume a definite conformation in solution (14–19). This does not occur in linear peptides since the intramolecular non-covalent interactions necessary for stabilizing any conformation are less probable. In oxidized glutathione, a disulphide bridge between the cisteine residues could promote specific structure in solution. This makes oxidized glutathione an interesting semilinear peptide molecule for evaluating the conformational effects induced by structural constraints.

In this paper proton and carbon NMR spin-lattice relaxation rate measurements were used to study the dynamic motion conditions of the peptide. The soluble spin label, TEMPOL, was used for further inspection of conformational properties. Soluble spin labels have been used (20–24) to investigate the solvent-exposed vs. solvent-shielded protons of biopolymers. Here we report: (*a*) the effects of the addition of a spin label on the proton spin-lattice relaxation rates of the peptides; (*b*) the extension of these measurements to carbon nuclei for a more accurate description of the interaction between spin label and oxidized glutathione; (*c*) the use of nitroxide-enhanced spin-lattice relaxation rates as quantitative criteria of the exposure of the peptide backbone and side-chain hydrogens and carbons.

Experimental

Oxidized glutathione, GSSG (Fig. 1), *N*,*N*′-[dithiobis[1-[(carboxymethyl) carbamoyl]ethylene]]diglutamine, and TEMPOL (ethyl-4-hydroxy-piperidin-1-oxyl) were purchased from Sigma Chemical Co. and used without any further purification. $Mg(ClO_4)_2 \cdot 6H_2O$ was obtained from Aldrich.

The measurements performed on the GSSG diamagnetic system were obtained using a 0.15 mol dm^{-3} D_2O (99.9%) solution at pH 5.5. The final TEMPOL concentration was in the range $5 \times 10^{-3} - 4 \times 10^{-2}$ mol dm^{-3}. All the experiments, when not otherwise indicated, were run at 25°C.

NMR spectra were recorded on a Varian XL-200 spectrometer with an "ADVANCE" computer system, operating at 200.058 and 50.03 MHz for ^1H and ^{13}C respectively. Proton and carbon spin-lattice relaxation rates were obtained using the $(180°–\tau–90°–t)_n$ pulse sequence and subsequent three-parameters exponential regression analysis of the longitudinal magnetization recovery curves. In general, the recovery of proton longitudinal magnetization after a 180° pulse is not a single exponential, due to the sum of different relaxation terms. To account for this, proton spin-lattice relaxations were calculated using the initial slope approximation, considering only the first part of the recovery curves (25, 26). A maximum experimental error of ±6% was calculated for the relaxation measurements. The paramagnetic contributions R_{1p} were obtained from the expression:

$$R_{1p} = R_{1\,\mathrm{exp}} - R_{1\,\mathrm{blank}}$$

where $R_{1\,\mathrm{blank}}$ is the relaxation rate measured in the absence, and $R_{1\,\mathrm{exp}}$ that measured in the presence of nitroxide.

The EPR spectra were recorded with a Bruker ER 200-tt spectrometer operating in the X-band (ω_0 = 9.78 GHz).

Results and discussion

The conformational and dynamic properties of oxidized glutathione were analyzed by proton and carbon NMR relaxation studies, as well the effects induced on proton and carbon R_1, by the addition of water-soluble spin label TEMPOL to the GSSG solution.

Dynamic analysis

The dynamic properties of oxidized glutathione were investigated by analyzing the proton and carbon spin-lattice relaxation rates of GSSG. It is well known that the relaxation rates of carbon nuclei are dominated by the proton–carbon dipolar interactions. For protonated carbons the short proton–carbon internuclear distance makes this process extremely efficient. Since the C*i*—H*i* distance is constant, the correlation time modulating the dipolar interaction can be determined from the equation (27):

$$[1]\quad R_1^{DD} = \frac{1}{10}\frac{N\gamma_H^2\gamma_C^2\hbar^2}{r_{Ci-Hi}^6}\left[\frac{3\tau_c}{1+\omega_C^2\tau_c^2} + \frac{6\tau_c}{1+(\omega_H+\omega_C)^2\tau_c^2} + \frac{\tau_c}{1+(\omega_H-\omega_C)^2\tau_c^2}\right]$$

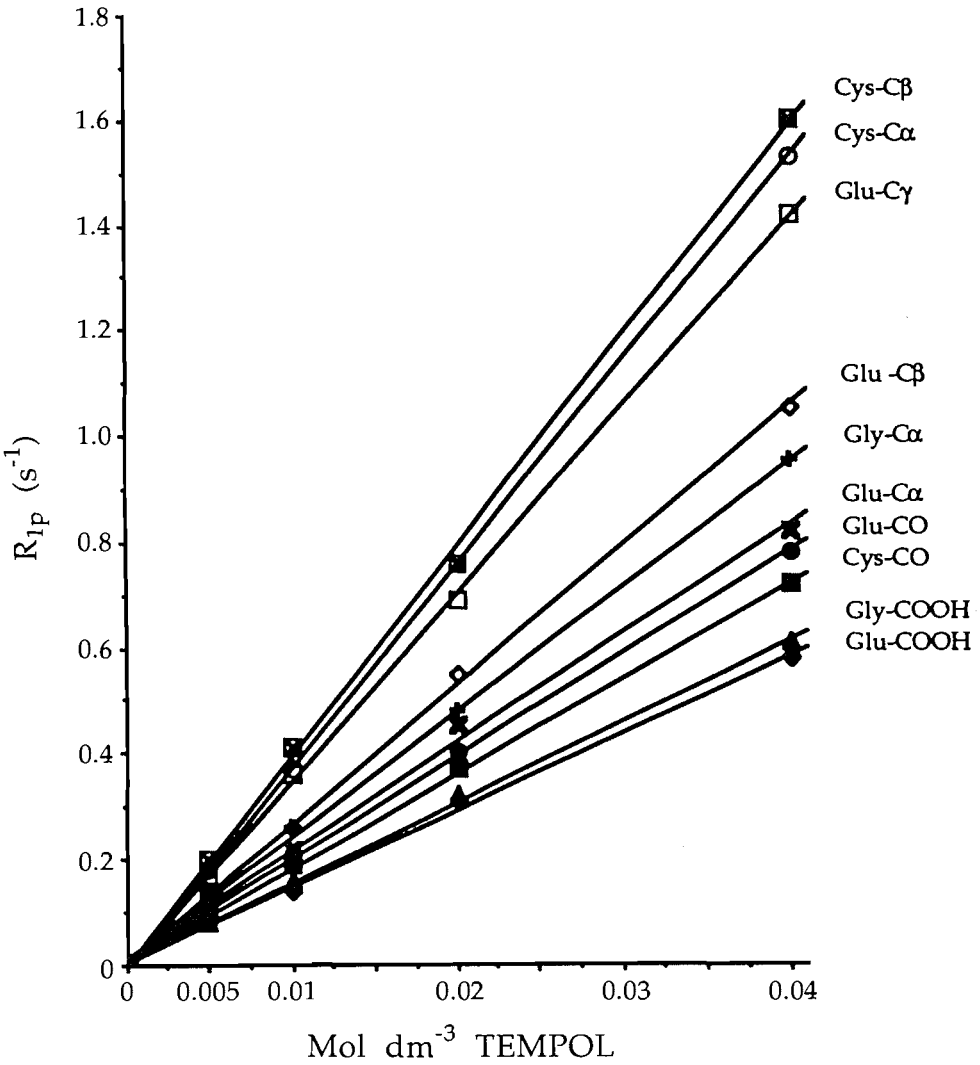

FIG. 3. Dependence of carbon R_{1p} on TEMPOL concentration for 0.15 mol dm^{-3} oxidized glutathione in D_2O at 25°C.

the region subject to the most restricted molecular motion in GSSG is the cysteine moiety, whereas the glycine region is characterized by faster motion. In the glutamic side chain, Glu Cγ is subject to faster motion than Glu Cα, but to slower motion than Glu C_β. The presence of a correlation time distribution along the molecule also suggests that GSSG does not assume any specific stable conformation in solution but rather that the amino acid side chains are subject to random motion around specific allowed spatial positions. For structured peptides, a more uniform correlation time is expected due to constraints determined by non-covalent interaction between amino acid moieties.

In contrast, whenever a molecule consists of unstructured rigid and mobile moieties, the degree of the segmental motion is greatest at the end of the side chains, decreasing steadily towards the centre, as previously shown in phospholipids (28).

The correlation time values calculated by carbon relaxation analysis can be confirmed by the proton relaxation data reported in Table 1. In particular, confirmation of the effective correlation time $\tau_{c_{eff}}$ calculated from carbon relaxation can be obtained from the analysis of proton relaxation rates of Gly Hα, Cys $H\beta_{1,2}$, Glu Hγ, and Glu H_β methylene groups. The calculated values were 7.4×10^{-11}, 2.42×10^{-10}, 2.30×10^{-10}, 1.26×10^{-10}, and 1.29×10^{-10}, respectively. These values, calculated taking into account the dominant geminal methylene H—H interaction, confirm the presence in the molecule of regions with different dynamic properties. Nevertheless the values obtained from proton spin-lattice relaxation rates appear to be overestimated. This is presumably due to contributions (which were not considered) of vicinal protons to the proton R_1 of the methylene groups.

GSSG – spin label interaction

The analysis of the correlation time values obtained from carbon, R_1, suggests that oxidized glutathione does not assume specific structure in solution.

To have more information on the dynamic and structural properties of oxidized glutathione in solution and on the interaction process between GSSG and nitroxide free radicals, the relaxation effect of TEMPOL on GSSG was analyzed. As previously shown, nitroxides may be used to induce paramagnetic perturbation on R_1 and R_2 relaxation rates of peptide protons in solution (20–22). These results were used to delineate the inner and outer protons, i.e., those exposed to, and shielded from, the solvent.

Oxidized glutathione is an interesting molecule for studying the induction of proton and carbon relaxation enhance-

ments by the addition of soluble spin-label reagents. In fact, using this peptide it is possible to compare the paramagnetic effects on the proton and carbon nuclei, to investigate the paramagnetic relaxation mechanisms, and to derive conformational information. Tables 2 and 3 show the proton and carbon spin-lattice relaxation rates of GSSG in D_2O at different TEMPOL concentrations. The dependence of R_{1p} on TEMPOL concentration for GSSG protons and carbons is shown in Figs. 2 and 3, respectively. The temperature dependence of proton R_{1p} was also investigated. Figure 4 shows the plot of proton R_{1p} vs. $1000/T(K)$. The positive slope shown for all the GSSG protons indicates a condition of fast chemical exchange between the peptide and the spin label. Moreover, the linearity of these plots shows that nuclear relaxation is mainly a diffusion-limited process, proportional to the mean diffusion coefficient of the radical and the peptide and consistent with Hubbard's "outer sphere" mechanism (29, 30). Besides the collisional mechanism, other contributions, such as the one arising from peptide–nitroxide transient complexes, could be of some importance in determining the relaxation of proton and carbon peptide nuclei (31).

To have more evidence of the nature of the GSSG–nitroxide interaction, the EPR spectra of the nitroxide and GSSG–nitroxide systems were recorded. The typical three-line EPR spectrum of TEMPOL in D_2O was indistinguishable from that of the GSSG–TEMPOL system, indicating a nitroxide isotropic rotational correlation time of $\tau_c < 1 \times 10^{-11}$ s (30, 32). The absence of linewidth broadening and a small reduction in the intensity of the EPR spectrum suggested that the presence of the peptide did not significantly affect the solution behaviour of the nitroxide molecules.

A different experiment was then performed. The paramagnetic contribution to carbon spin-lattice relaxation induced by TEMPOL on the Mg(II)–GSSG system was analyzed. As shown in Table 4, the presence of the Mg(II) ion did not significantly change the experimental R_{1p} values. Nevertheless, an increase in R_{1p} values with respect to solutions without Mg(II) ions was observed for all proton and carbon nuclei of oxidized glutathion. This could be the result of two effects: (*i*) the change in the diffusion coefficient of GSSG on complexation and (*ii*) the neutralization of the carboxylic negative charge by the magnesium ion, facilitating the approach of the nitroxide to the peptide molecule. Our results suggest that: (*i*) in both GSSG – nitroxide and GSSG – Mg(II) nitroxide systems, the main source of paramagnetic relaxation is related to the formation of collisional complexes ("outer-sphere"); and (*ii*) the spread of R_{1p} among proton and carbon nuclei of GSSG excludes the presence of completely shielded nuclei. However, the presence of different paramagnetic terms suggests some specificity in GSSG–nitroxide interaction.

An *ab initio* study on the reaction of $CH(X^2\pi)$ with CH_4

ZHONGHUA YU, CONGXIANG CHEN, AND MINGBAO HUANG[1]

Department of Modern Chemistry, University of Science and Technology of China, Hefei, Anhui 230026, China

Received October 5, 1992

ZHONGHUA YU, CONGXIANG CHEN, and MINGBAO HUANG. Can. J. Chem. **71**, 512 (1993).

The mechanism of the reaction $CH(X^2\pi) + CH_4$ has been investigated by *ab initio* molecular orbital calculations. Addition, insertion, and abstraction–addition reaction paths have been examined by, in total, five methods of approach. The addition reaction path has a rather high energy barrier. Our calculations have implied that the assumed insertion reaction path does not seem to exist for the reaction $CH + CH_4$, and a two-step mechanism (abstraction–addition reaction path) was then proposed. For the abstraction–addition reaction, the reactants, transition state, intermediates, and products were optimized at the HF/3-21G and HF/6-31G* levels, and vibrational frequencies were calculated at the HF/3-21G level. Electronic correlation energy was estimated by means of the Møller–Plesset perturbation theory and configuration interaction method. The excited-state abstraction reaction was also studied in some detail.

ZHONGHUA YU, CONGXIANG CHEN et MINGBAO HUANG. Can. J. Chem. **71**, 512 (1993).

Faisant appel à des calculs d'orbitales moléculaires *ab initio*, on a étudié le mécanisme de la réaction $CH(X^2\pi) + CH_4$. On a examiné cinq voies réactionnelles différentes, dont l'addition, l'insertion et l'arrachement–addition. La réaction d'addition implique une énergie relativement élevée. Nos calculs impliquent que la réaction d'insertion ne semble pas exister pour la réaction $CH + CH_4$; on propose donc un mécanisme en deux étapes (voie d'arrachement–addition). Pour cette voie d'arrachement–addition, on a optimisé les réactifs, l'état de transition, les intermédiaires et les produits aux niveaux HF/3-21G et HF/6-31G* et on a calculé les fréquences vibrationnelles au niveau HF/3-21G. On a évalué l'énergie de corrélation électronique à l'aide de la théorie perturbationelle de Møller–Plesset et par la méthode des interactions de configuration. On a aussi étudié la voie d'arrachement du état excité en détail.

[Traduit par la rédaction]

Introduction

Carbynes are presently attracting the attention of experimentalists and theoreticians, and methylidine (CH), the simplest member of this family of monovalent carbon radicals, is known to be one of the most reactive of all free radicals (1). For the CH radical, many reactions with such small molecules as H_2, O_2, N_2, H_2O, NH_3, CH_2O, oxides of carbon and nitrogen, and a number of saturated and unsaturated hydrocarbons, have been studied in kinetic experiments (1). However, very few theoretical studies of CH reactions have been reported. In 1977, Brooks and Schaefer (2) carried out CI calculations for the simple $CH + H_2$ reaction. For the insertion reaction with the $CH_3(^2A_2)$ radical as the product, the least-motion path, where the CH radical is perpendicular to the H_2 molecule, was found to have an energy barrier of about 75 kcal/mol. However, for the "non-least-motion" path, where the CH radical is parallel to the H—H bond, there was little or no energy barrier.

In 1986, Dunning *et al.* (3) presented a comprehensive theoretical description of the $CH + H_2$ reaction based on their GVB and CI calculations and pointed out a new reaction pathway. Strausz and co-workers (4) carried out *ab initio* calculations for the $CH(X^2\pi) + C_2H_4(X^1A_g)$ addition and insertion reactions using the ROHF SCF method with configuration interaction, and their results indicated that, in agreement with experiment, the energy barrier for the addition reaction was zero if an asymmetric non-least-motion path was followed. On the other hand, their computed barrier for the insertion reaction path was very high (15 kcal/mol). These important studies somehow imply that in theoretical studies for the CH reactions unexpected situations and complexities may occur. In 1990, Vegiri and Farantos (5) calculated potential energy surfaces for the reaction $CH(A^2\Delta) + H_2$ using the MRDCI method.

[1]Author to whom correspondence may be addressed.

Because of their importance in combustion and planetary atmospheric chemistry, the reactions of CH with a number of saturated and unsaturated hydrocarbons have been studied experimentally (1). For the reaction of $CH(X^2\pi)$ with CH_4, detailed kinetic experiments have been performed (6–9). Using the laser-photolysis/LIF technique, Berman and Lin (9) found that, in the temperature range 167–652 K and at a fixed total pressure of 100 Torr (1 Torr = 133.3 Pa), the measured activation energy was −0.4 kcal/mol, and that at 297 K the measured rate constants were independent of the total pressure. On the basis of the above facts and thermochemistry data, they proposed the following reaction mechanism (1, 9):

$$[1]\quad CH(X^2\pi) + CH_4 \xrightarrow{(a)} C_2H_5 \xrightarrow{(b)} C_2H_4 + H$$

(0.0 kcal/mol) (−94.5 kcal/mol) (−59.0 kcal/mol)

$$[2]\quad CH(X^2\pi) + CH_4 \rightarrow CH_2 + CH_3$$

(0.0 kcal/mol) (2.6 kcal/mol)

According to their proposed mechanism, in the first reaction a vibrationally hot ethyl radical is the product of the insertion of the CH radical into a methane C—H bond and is a long-lived intermediate complex. Reaction [1] was considered (1) as the dominant channel since it is strongly exothermic. On the other hand, reaction [2] is slightly endothermic and therefore could not compete with the first reaction because of its weak endothermicity (1).

We have noticed that no theoretical studies for the CH reaction with CH_4 have been reported. We believe that a detailed theoretical study of this reaction may be of very fundamental significance for CH reactions with organic molecules (at least, with paraffinic molecules). We therefore directed our attention to the first reaction (a) above and performed *ab initio* calculations. In this paper we report our theoretical results and draw some conclusions about the

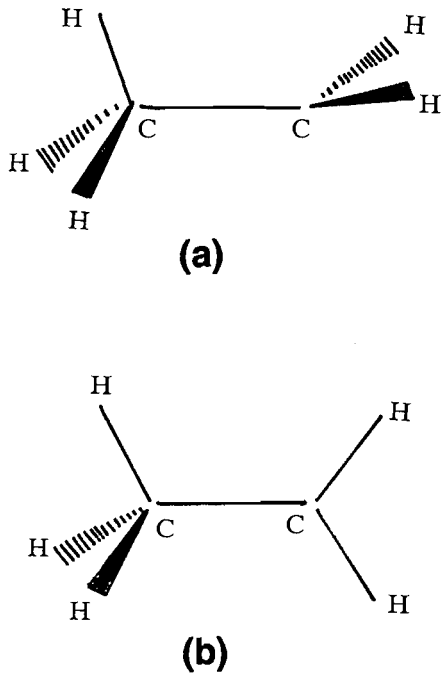

FIG. 1. The two conformations of the ethyl radical: (*a*) staggered; (*b*) eclipsed.

mechanism of the CH + CH_4 reaction. Step (b) of reaction [1] has already been studied by Schlegel (10).

Calculation methods and details

We performed *ab initio* calculations[2] with the GAUSSIAN82 program (12), using extended 3-21G and polarized 6-31G* basis sets. All equilibrium geometries and transition-state structures were fully optimized with the analytical gradient method at the Hartree–Fock level and, in some cases, at the MP2 level. Electronic correlation energy was estimated by using Møller–Plesset perturbation theory up to fourth order (MP4SDTQ, full) and using configuration interaction theory (CISD, full). Vibrational frequencies were obtained from analytical second derivatives calculated at the HF/3-21G level.

For the reaction CH + CH_4, we examined addition, insertion, and abstraction–addition reaction paths in turn. The 3-21G basis was employed in the overall scans of the reaction paths, and the total energies as functions of the reaction coordinates were calculated by optimizing all the rest of the geometric parameters of the reaction system. The polarized 6-31G* basis was also used in calculations for the critical points of the reaction paths. For the ethyl radical C_2H_5, previous experimental and theoretical studies (13) indicated that the potential energy curve for internal rotation about the C—C bond is very flat and the staggered conformer (see Fig. 1(*a*)) corresponds to the energy minimum. The eclipsed conformer (see Fig. 1(*b*)) is only 0.14 kcal/mol (MP2/6-31G*//HF/6-31G*) less stable than the staggered one. In the three reaction paths we examined, the reaction system was assumed to have a symmetry plane. Thus, the expected product C_2H_5 would be in the eclipsed conformation ($^2A''$) in the addition and insertion paths, while it would be in the staggered conformation ($^2A'$) in the abstraction–addition path, as will be described clearly below.

[2]A general description of the calculation methods and basis sets is given in ref. 11.

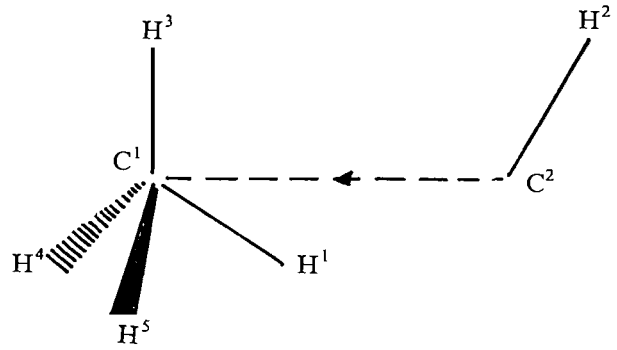

FIG. 2. Addition reaction path.

Results

To study the mechanism of the reaction CH + CH_4, we considered three reaction paths by, in total, five methods of approach.

1. Addition reaction path

For the addition reaction path (see Fig. 2), we assumed that methylidyne, with its carbon atom C^2, attacks methane directly at the carbon C^1, and the C^1—C^2 distance was taken as the reaction coordinate *Z*. We further assumed that the CH radical approached between the C^1H^1 and C^1H^3 bonds of methane and within the plane $H^1C^1H^3$, so the system had only C_s symmetry. Such a reaction path was proposed in imitation of the route considered for insertion of the CH radical into C_2H_4, adopted by Strausz and co-workers (4), and of the C atom reaction with CH_4, adopted by Lebrilla and Maier (14). We hoped that, as the *Z*-value decreased, the changes in geometric parameters would show migration of one methane hydrogen (H^1 or H^3) to the methylidyne carbon C^2, finally leading to the eclipsed conformation ($^2A''$) of the C_2H_5 radical. The HF/3-21G potential energy curve for the addition path was calculated starting at $Z = 4.0$ Å, but we stopped the calculations at $Z = 1.80$ Å. At $Z = 1.80$ Å, the values of the C^2H^1, C^2H^3, C^1H^1, and C^1H^3 distances were 2.04, 1.38, 1.07, and 1.15 Å, respectively, indicating that significant hydrogen migration in that geometry had not yet taken place. However, the energy value was already 46 kcal/mol higher than the sum of the HF/3-21G energies of the reactants, which implies that the addition reaction path is not energetically favourable.

2. Insertion reaction paths

For the insertion reaction, we considered two paths (a) and (b), which are shown in Fig. 3(*a*) and (*b*), respectively. In both cases, the CH radical was assumed to approach within the $H^1C^1H^3$ plane (an assumed symmetry plane of the system) at the center, denoted as X, of the C^1H^1 bond of methane, and the C^2X distance (*Z*) was taken as the reaction coordinate. In path (a), the $H^2C^2XH^1$ part was in a *trans* form. Such an insertion reaction path was proposed in imitation of the method adopted by Gordon and Gano (15) in their *ab initio* study of the insertion of singlet methylene into the C—H bond of methane, and we hoped that, as the *Z*-value decreased, the H^1 atom would migrate to C^2 and the optimized C^1–C^2 distance would become shorter, finally lead-

ing to the eclipsed conformation ($^2A''$) of C_2H_5. The HF/3-21G energy curve $E(Z)$ for the insertion reaction path (a) is shown in Fig. 4. This curve appears discontinuous and seems to consist of three sections: A ($Z = \infty$, the reactants) – B (Z = 1.605 Å), B–C (Z = 1.600 Å), and C–D (Z = 0.66 Å, the product). However, it should be emphasized that the electronic state ($^2A''$) and electronic configuration (α,β-electron occupation numbers in the MOs of A' and A'' symmetries) were kept unchanged throughout the curve from A to D.

The geometry evolution along the AB part of the curve seemed quite optimistic, H^1 migrating and the C–C distance being shortened. In the geometry corresponding to point B, shown in Fig. 3(*c*), the decreased C–C distance has a value of 2.083 Å and both the C^1H^1 and C^2H^1 distances are longer than 1.2 Å, which indicates that at Z = 1.605 Å the C^1H^1 bond has broken and the C^2H^1 bond has not yet formed. This geometry should be close to the transition-state geometry, which was not located exactly. The HF/3-21G energy at point B is 23.3 kcal/mol higher than the energy sum of the reactants (point A).

It was unexpected that the C–C distance would be much elongated as the system went along the curve from B to C in Fig. 4. The geometry corresponding to point C (shown in Fig. 3(*d*)) indicates that, at Z = 1.600 Å, H^1 has completed its migration and the system can be viewed as two separate fragments, $H^1C^2H^2$ and $C^1H^3H^4H^5$, due to the long C–C distance of 3.976 Å. The bent geometry of the $H^1C^2H^2$ fragment is very close to the HF/3-21G geometry of the triplet ground state ($^3B_1$) of CH_2 (d_{C-H} = 1 .071 Å and ∠HCH = 131.3°), while the flat geometry of the $C^1H^3H^4H^5$ fragment is close to the HF/3-21G geometry of CH_3 ($^2A_2$) (d_{C-H} = 1.072 Å and ∠HCH = 120.0°). The sums of the calculated atomic spin densities on the atoms of the $H^1C^2H^2$ and $C^1H^3H^4H^5$ fragments are 2.16 and −1.12, respectively. The energy of the system at the point C, −78.0524 au, is approximately equal to the sum of the HF/3-21G energies of CH_2 ($^3B_1$) and CH_3 ($^2A_2$), −78.0518 au. The above analyses of the geometries, atomic spin densities, and energies suggest that the ABC part of the energy curve for the insertion reaction path (a) represents the following reaction step,

$$CH(X^2\pi) + CH_4 \rightarrow CH_2(^3B_1) + CH_3(^2A_2)$$

From C to D along the curve in Fig. 4, the energy decreases monotonically and without any energy barrier. Point D represents the product C_2H_5 in its eclipsed conformation ($^2A''$). At the HF/3-21G level, the energy difference between the eclipsed and staggered conformations of C_2H_5 is only 2.1 kcal/mol, which is almost negligible compared with the energy difference of about 70 kcal/mol between E(C) and E(D). Actually the CD part of the energy curve for the insertion reaction path (a) represents the following reaction step.

$$CH_2(^3B_1) + CH_3(^2A_2) \rightarrow C_2H_5(^2A'')$$

We also performed HF/6-31G* calculations around the critical points A, B (Z = 1.605 Å), C (Z = 1.600 Å), and D, and the skeleton of the HF/6-31G* potential energy curve is similar to the HF/3-21G curve shown in Fig. 4. The HF/6-31G* energy difference between E(B) and E(A) is 21.4 kcal/mol, which is slightly smaller than the HF/3-21G difference (23.3 kcal/mol).

In the insertion reaction path (b), shown in Fig. 3(*b*), the $H^2C^2XH^1$ part was in a *cis* form, which was proposed in imitation of the non-least-motion paths of the insertion reaction $CH(X^2\pi) + H_2 \rightarrow CH_3$, adopted by Brooks and Schaefer (2), and of the reaction $CH_2(^1A_1) + H_2 \rightarrow CH_4$, adopted by Sosa and Schlegel (16). Our calculated HF/3-21G energies at Z = 2.40 Å and 2.00 Å were both about 3 kcal/mol higher than the corresponding energies in path (a), which implies that path (b) is less favourable than path (a). We then stopped the calculations for path (b).

3. Abstraction–addition reaction path

Based on analyses of the results described above, we propose an abstraction–addition reaction path, explicitly considering a two-step mechanism as implied by the curve in Fig. 4. The first step is an abstraction reaction $CH + CH_4 \rightarrow CH_2(^3B_1) + CH_3$ (see Fig. 5(*a*)), and the second step is an addition reaction $CH_2(^3B_1) + CH_3(^2A_2'') \rightarrow C_2H_5$ (staggered) (see Fig. 1(*a*)).

In the study of the first step of the abstraction–addition reaction path, we first optimized the geometry of the transition state (identified by performing frequency analysis calculations), then we calculated the potential energy curve ABC. This is shown in Fig. 6, the points A, B, and C representing the reactants, transition state, and products of this step, respectively. We took the distance C^2H^1 as the reaction coordinate Z in the B–A part of the curve, and the distance C^1H^1 as Z in the B–C part. The system along the curve A–B–C is in the $^2A''$ electronic state and we denote the transition state as $^2A''$TS. The optimized geometry of $^2A''$TS is shown in Fig. 5(*c*), the unique imaginary frequency being 2507i cm^{-1}. At the HF/3-21G level, the predicted energy barrier (E(B)–E(A)) is 15.5 kcal/mol, which is the lowest of all the paths we considered. Our energetic results therefore imply that the abstraction reaction path is the most favourable, which is unexpected.

The second step of the abstraction–addition reaction path is an addition reaction to form the final product C_2H_5 in its staggered conformation ($^2A'$). The reaction system was assumed to have a staggered geometry (see Fig. 1(*a*)) and the C–C distance was taken as the reaction coordinate Z. The HF/3-21G potential energy curve (D–F) is shown in Fig. 6, the electronic state being $^2A'$. Both points D and C in Fig. 6 denote $CH_2(^3B_1) + CH_3$ ($Z = \infty$), and the point F the final product. No energy barrier was found along the curve D–F, and this step was predicted to be strongly exothermic.

For the critical points along the abstraction–addition path, we also carried out higher level calculations rather than the HF/3-21G level. The HF/6-31G* transition-state optimization calculations predicted an $^2A''$TS geometry, which is similar to the HF/3-21G geometry, both sets of the optimized geometric parameters being given in Fig. 5(*c*). Table 1 gives total energies for the critical points along the abstraction–addition reaction path. Relative energies are collected in Table 2. At the HF/3-21G and HF/6-31G* levels, the first reaction step was predicted to be exothermic by 14.4 and 12.8 kcal/mol (E(C)–E(A)), respectively, while, based on thermochemistry data, it should be weakly endothermic. As shown in Table 2, inclusion of correlation energies is important for narrowing the energy gap between A and C. At the MP4SDTQ/6-31G*//HF/6-31G* level, the first reaction step was predicted to be endothermic by 2.8 kcal/mol, which is in agreement with experiment (1). At this level, the

energy barrier (E(B)–E(A)) for the first step was predicted to be 13.7 kcal/mol. The experimental value for the heat of the (whole) reaction is −94.5 kcal/mol, and our calculations at all the levels gave large values (−84.6 and −103.6 kcal/mol) for the energy difference (E(F) − E(A)) (see Table 2).

For the first step, we also tested another pathway, shown in Fig. 5(*b*). However, the calculated energies (HF/3-21G)

at several large *Z* values were higher than those for the approach shown in Fig. 5(*a*); we then stopped the calculations.

4. The excited-state abstraction reaction

We also studied the excited-state abstraction reaction $CH(X^2\pi)$ + $CH_4 \rightarrow CH_2(^1A_1)$ + $CH_3(^2A_2)$ in the $^2A'$ electronic state, and the corresponding HF/3-21G potential energy curve A–B′–C′ is shown in Fig. 6(*b*). The optimized geometry of the transition state (B), denoted as $^2A'$TS, is shown in Fig. 5(*d*). This transition state was characterized by an imaginary frequency of 2535i cm^{-1} at the HF/3-21G level. In Fig. 5(*d*), it is seen that calculations of the three different levels predicted very similar geometries for $^2A'$TS. The geometries of $^2A''$TS and $^2A'$TS are quite different. The $\angle H^1C^2H^2$ angle in the $^2A''$TS geometry is about 12° larger than that in the $^2A'$TS geometry, which is consistent with the fact that the ground-state abstraction reaction ($^2A''$) leads to the triplet $CH_2(^3B_1)$ ($\angle HCH$ = 131.2°) while the excited-state reaction leads to the singlet $CH_2(^1A_1)$ ($\angle HCH$ = 102.4°) product. The $\angle C^2H^1C^1$ angle in the $^2A'$TS geometry is about 20° larger than that in the $^2A''$TS geometry.

At the HF/3-21G level, this excited-state reaction was predicted to be endothermic by 21.5 kcal/mol, and all the energetic results for this reaction are given in Table 3. The effect of inclusion of *d*-functions on carbon atoms is very small. Correlation energy corrections with Møller–Plesset perturbation theory decrease the energy barrier by 5–6 kcal/mol. At the MP2/6-31G* level, the energy barrier for this reaction was predicted to be 34.3 kcal/ mol. At this level, the reaction was predicted to be endothermic by 20.3 kcal/mol, which is in agreement with the experimental value, 22.1 kcal/mol. The latter value is the sum of the $^3B_1$–$^1A_1$ energy separation of CH_2, 19.5 kcal/mol (17), and the heat of the ground-state abstraction reaction, 2.6 kcal/mol (1).

Discussion

Because the assumed insertion reaction CH + $CH_4 \rightarrow C_2H_5$ is strongly exothermic and the measured activation energy for the reaction CH + CH_4 is negative, −0.4 kcal/mol, Berman and Lin (9) suggested that the insertion reaction path was the dominant channel for the reaction $CH(X^2\pi)$ + CH_4. We examined addition, insertion, and abstraction–addition reaction paths using, in total, five methods of approach. Our calculations indicated that the addition path has a very high energy barrier. Our calculation results for the assumed insertion path implied just a two-step mechanism — the abstraction–addition reaction path, for which we performed detailed calculations. Based on our calculations, we would conclude that the abstraction–addition reaction path is the most favourable channel for the reaction CH + CH_4, which is not in line with Lin's proposal. How to rationalize the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

discrepancy between theoretical indications and experimental results seems to be a difficult problem.

Our predicted energy barrier for the first step, 13.7 kcal/mol, is relatively high compared with the experimental activation energy of −0.4 kcal/mol. We expect that inclusion of *p*-functions on the hydrogen atoms and geometry optimizations at the MP levels will considerably lower the calculated energy barrier, but the calculated energy barrier will not disappear due to the weak endothermicity of the abstraction reaction step.

Our study indicates that the reaction $CH(X^2\pi) + CH_4$ cannot be a synchronous or concerted reaction. This is also supported by Dewar's opinion (18) that multibond reaction cannot normally be synchronous.

Summary

Our detailed theoretical studies for the reaction $CH(X^2\pi) + CH_4$ indicate that the insertion reaction path does not seem to be feasible, and we have proposed a two-step mechanism (abstraction–addition path) for this reaction. However, our predicted energy barrier for the first step is relatively high compared with the experimental value. More sophisticated experimental *and* theoretical studies are both required.

An ^{1}H NMR conformational analysis of 3-phenylpentane in solution

TED SCHAEFER[1] AND LINA B.-L. LEE
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received October 20, 1992

TED SCHAEFER and LINA B.-L. LEE. Can. J. Chem. **71**, 520 (1993).

Some 30 proton chemical shifts and proton–proton coupling constants are reported for a 4.7 mol% solution of 3-phenylpentane in a CS_2/C_6D_{12}/TMS solvent mixture at 300 K. The long-range coupling constant over six formal bonds between the methine and *para* protons is used to deduce an apparent twofold barrier of 15.0 ± 0.3 kJ/mol to rotation about the Csp^2—Csp^3 bond, at least twice as large as that for isopropylbenzene in solution. AM1 computations agree with experiment in finding the conformation of lowest energy as that in which the methine C—H bond is situated in the phenyl plane, but predict a barrier height of only 13.9 kJ/mol. The vicinal coupling constants are consistent with a fractional population, 0.38(2), of the TT conformer, that in which all the carbon atoms of the alkyl chain lie in a plane. A doubly degenerate conformer, $TG^+(G^-T)$, in which one methyl group is twisted away from the phenyl substituent, then has a fractional population of 0.62(2). The assumption that only these three conformers are present is tested with the signs and magnitudes of the four different coupling constants over four bonds. These coupling constants are consistent with the absence of significant proportions of the other six all-staggered conformers. These six are characterized by a close approach of the methyl groups (1,5 interactions) or by proximity of the methyl and phenyl moieties.

TED SCHAEFER et LINA B.-L. LEE. Can. J. Chem. **71**, 520 (1993).

Opérant à 300 K, on a déterminé quelques 30 déplacements chimiques et constantes de couplage proton–proton du 3-phénylpentane en solution à 4,7 mol% dans un mélange des solvants CS_2/C_6H_{12}/TMS. On utilise la constante de couplage à longue distance à travers six liaisons entre les protons méthine et *para* pour déduire une barrière binaire apparente de 15,0 ± 0,3 kJ/mol pour la rotation autour de la liaison Csp^2—Csp^3; cette valeur est deux fois plus grande que celle observée pour l'isopropylbenzène en solution. Des calculs AM1 sont en accord avec le fait que la conformation de plus basse énergie est celle dans laquelle la liaison C—H du méthine se trouve dans le plan du phényle; toutefois, ces calculs prédisent une barrière de seulement 13,9 kJ/mol. Les constantes de couplage vicinales sont en accord avec une population fractionnaire de 0,38(2) pour le conformère TT, celui dans lequel tous les atomes de carbone de la chaîne alkyle sont dans un plan. Un conformère doublement dégénéré, $TG^+(G^-T)$, dans lequel un méthyle est éloigné du substituant phényle, possède donc une population fractionnaire de 0,62(2). On a évalué l'hypothèse selon laquelle ces trois conformères sont présents en faisant appel aux signes et aux amplitudes des quatre constantes de couplage différentes à travers quatre liaisons. Ces constantes de couplage sont en accord avec l'absence des six autres conformères complètement décalés. Ces six conformères sont caractérisés par un rapprochement des groupes méthyles (interactions 1,5) ou par une proximité des portions méthyle et phényle.

Introduction

Of the nine all-staggered conformers of 3-phenylpentane shown in Scheme 1, only the TT and the $TG^+(G^-T)$ are thought to exist in the liquid or in solution. Two bands in the infrared spectrum of the liquid are assigned to these conformers (1). The temperature dependence of the intensities of these bands indicates an enthalpy difference of 1.7 kJ/mol between these conformers. In the solid form, one of the bands is absent. The remaining band is assigned to the less stable $TG^+(G^-T)$ conformers. An early ^{1}H nmr investigation (1) employs an approximate analysis of the spectrum of the methylene protons at two temperatures of liquid 3-phenylpentane to deduce an enthalpy of 1.5 kJ/mol favoring the TT form over the $TG^+(G^-T)$ forms. The assumption underlying this deduction, that only these three conformers are present, is supported by some molecular mechanics calculations reported in that investigation (1). Presumably the other conformers are energetically unfavorable because of close approaches of phenyl and methyl groups (G^+T), of the two methyl groups (G^-G^+), or because of the presence of both of these repulsive interactions (G^+G^-).

With modern nmr instrumentation, higher dispersion and resolution are possible. A proper analysis of a current ^{1}H nmr spectrum will yield additional spectral parameters helpful in the conformational characterization of this molecule. Thus, the long-range coupling constants between the methine and ring protons can provide an estimate of the barrier to rotation about the Csp^2—Csp^3 bond as well as the preferred conformation of the phenyl group relative to the alkyl backbone. Again, the coupling constants over four bonds, three of them between the protons in the two methylene groups, and one between the methine and methyl protons, are very likely sensitive in sign and magnitude to the presence of the various conformers.

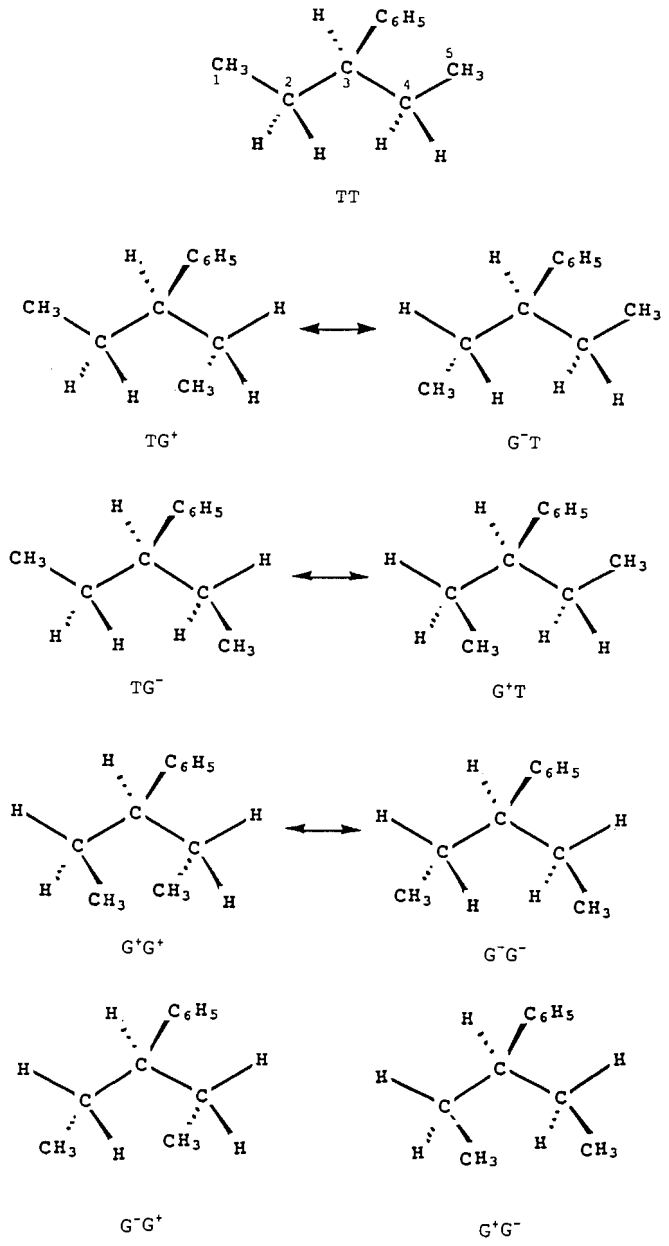
Accordingly, the precise analysis of the ^{1}H nmr spectrum of 3-phenylpentane is reported here. The ensuing spectral parameters allow the indicated, more detailed, characterization of the conformational behaviour of 3-phenylpentane.

Experimental

A 4.7 mol% solution of 3-phenylpentane (K & K Laboratories) in a CS_2/C_6D_{12}/TMS solvent mixture (see Table 1 for details) was filtered through cotton wool into a 5 mm o.d. nmr sample tube. The tube was degassed by five cycles of the freeze–pump–thaw procedure and was then flame-sealed under vacuum to produce a reasonably symmetric top.

The ^{1}H nmr spectra were acquired in the way described before (2). A typical acquisition time for a free induction decay was 41 s, of which as many as 64 were accumulated on a Bruker AM300 spectrometer. A digital resolution of not less than about 0.025 Hz/point was used and the induction decays were zero-filled twice or four times before Fourier transformation. Moderate amounts of resolution enhancement were also applied.

[1]Author to whom correspondence may be addressed.



SCHEME 1

AM1 computations (3) used the algorithms in GAUSSIAN 86 (4). During rotation about the Csp^2—Csp^3 bond at fixed intervals of the torsion angle, all bond angles and lengths were allowed to relax, with the constraint, however, that the atoms of the phenyl group remain in a plane.

Results and discussion

Spectral analyses

The complete ^1H nmr spectrum of 3-phenylpentane corresponds to a 16-spin system. The program NUMARIT (5), as extensively modified by R. Sebastian in this laboratory, accommodates 12 spins only. Accordingly, the spectrum of the alkyl protons was analyzed as an $A_3A'_3BB'CC'D$ system, the methylene protons being magnetically nonequivalent. The spectrum of the aromatic protons, which couple to the methine and methyl protons, yielded to an analysis based on the spin system $A_6BCC'DD'E$. The peaks in the methine proton region of the spectrum were not assigned; the methine proton couples significantly to 15 protons. Table 1 presents the spectral parameters obtained from the composite analyses. As a simple example of how the complexity of the total spectrum yielded the signs of coupling constants, Fig.

1 displays the sensitivity of the relatively simple methyl proton region to the sign of $^4J(H,CH_3)$.

The motion about the Csp^2—Csp^3 *bond*

^6J(H-4, C-H) = ^6J in toluene derivatives is given by $^6J = {}^6J_{90} \sin^2\theta$, in which θ is the angle by which the α C—H bond twists out of the plane of the phenyl group (6). In toluene, $^6J_{90}$ is −1.204(4) Hz, that is, when the C—H bond lies in a plane perpendicular to the phenyl plane (2). An electronegative substituent on the side chain polarizes the α C—H bond and thereby decreases the hyperconjugative overlap between the C—H and π orbitals. It has been shown, for example, that $^6J_{90}$ is −0.95 Hz in benzyl fluoride (7). From previous work on the ethyl and isopropyl derivatives of benzene (8, 9) it follows that $-1.12 \geq J_{90} \geq -1.16$ Hz holds for 3-phenylpentane, where ^6J is −0.107(1) Hz (Table 1). Therefore the expectation value of $\sin^2\theta$ obeys $0.094(1) \leq \langle\sin^2\theta\rangle \leq 0.096(1)$ at 300 K. A hindered rotor model or a classical average then yields an apparent twofold barrier of $15.0_5(2_5)$ kJ/mol for rotation about the sp^2—sp^3 bond. The conformation of lowest energy is characterized by θ = 0, as previously assumed (1).

The barrier magnitude is more than twice as large as that in isopropylbenzene, 6.6(7) kJ/mol (9). The relatively large magnitude in 3-phenylpentane very likely arises from the close approach of the methyl groups to the *ortho* C—H bonds as rotation occurs in the TT and $TG^+(G^-T)$ conformers. In the all-staggered arrangements the hydrogen atoms of the alkyl and aromatic C—H bonds would move to within about 0.8 Å of each other for a θ of 90°, whereas in isopropylbenzene this distance would be about 2 Å.

The proximity of the hydrogen atoms of the *ortho* and methyl C—H bonds during some part of the torsional motions is also consistent with the relatively large through-space coupling between their protons, formally over six bonds, its magnitude being 0.054 Hz (Table 1). This coupling magnitude is an average over the potential surface for two *ortho* protons and six methyl protons. The coupling constant is large when the hydrogen atoms come within the sums of their van der Waals radii.

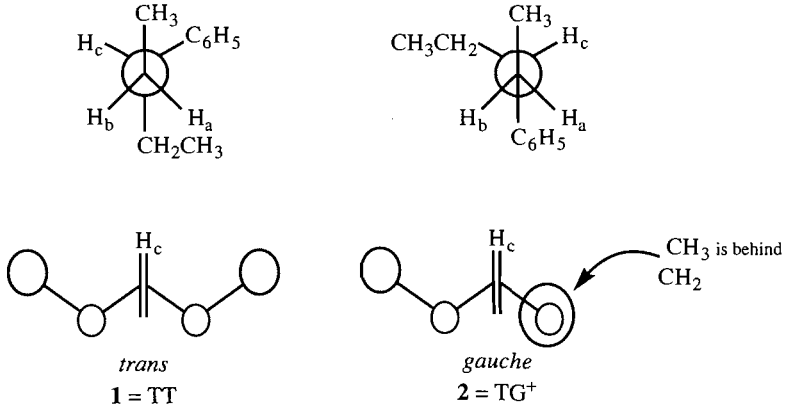
Of course, the severe repulsive interactions will be relieved somewhat by compensatory twisting about the Csp^3—Csp^3 bonds in the side chain, which, however, is also hindered because, for example, the internal barrier in ethane is 12.1 kJ/mol. It appears that a compromise is reached in which the torsion about the Csp^2—Csp^3 bond is considerably more hindered than in isopropylbenzene. The measured ^6J represents an average over all occupied conformers in Scheme 1 and hence cannot yield a barrier for the individual conformers.

The geometry-optimized AM1 computations give a barrier height of 13.9 kJ/mol for rotation about the Csp^2—Csp^3 bond in 3-phenylpentane and 6.6 kJ/mol for isopropylbenzene. The relatively good agreement with the apparent twofold barriers in solution may be accidental because the AM1 value for the internal barrier in ethane, 5.2 kJ/mol, is much too low, so that the twist energy about the C—C bonds in the side chain of 3-phenylpentane, necessary to relieve steric strain, is presumably underestimated.

It may be noted that an analysis of Raman line-shapes for *meso* 2,4-diphenylpentane in chloroform solution indicates the sp^2—sp^3 barrier as 13.8 ± 1.3 kJ/mol in magnitude (10). A precise analysis of the ^{1}H nmr spectrum of this compound would be of interest; it would also be difficult.

The populations of the TT and $TG^+(G^-T)$ *conformers*

If only the cited conformers are present then (see **1** and **2**) the following analysis is possible. Because of symmetry,



one need discuss the protons in only one methylene group.

$$[^3J_{ac} = P(TT)J_t + P(TG^+)J_g + P(G^-T)J_t]$$

$$[^3J_{bc} = P(TT)J_g + P(TG^+)J_t + P(G^-T)J_g]$$

These equations assume that J_t and J_g do not vary between conformers. Because $P(TG^+) = P(G^-T)$, $P(TT) + 2P(TG^+) = 1$. It follows that $^3J_{ac} + {}^3J_{bc} = J_t + J_g = 14.457(5)$ Hz and that $^3J_{ac} - {}^3J_{bc} = [1-2P(TG^+)](J_t - J_g) = 3.957(5)$ Hz. The fractional populations depend on $J_t - J_g$. A recent discussion of ^3J in ethane-like fragments shows the unlikelihood that J_g is larger than 2 Hz (11). If J_g is taken as 2.0 Hz, then $2P(TG^+)$ is 0.62. Hence the free energy difference is 1.22 kJ/mol at 300 K, favoring the *gauche* conformers.

The double degeneracy of the *gauche* conformer implies an enthalpy difference of 0.5 kJ/mol between the conformers, the TT conformer having the greater stability. The error in ΔH^0, in this treatment, depends on the error in J_g, which, if it amounts to 10%, implies that ΔH^0 is 0.5(1) kJ/mol. This value is 1 kJ/mol less than that obtained from the differences between J_{ac} and J_{bc} at 293 and 453 K for the liquid (1). The disagreement can be traced to 3.2 Hz (error not stated) given for $J_{ac} - J_{bc}$ at 293 K (1). Judging by the difference of more than 0.3 Hz between the ^2J(H,H) values in the two

TABLE 2. Computed ^4J(H, H) for the conformers of 2-phenylpentane[a]

Conformer	^4J(aa')[b]	^4J(bb')[b]	^4J(ab)	^4J(H, CH_3)
TT	−0.49	−0.49	−0.16	−0.22
TG^+, G^-T	−0.16	−0.02	−0.26	−0.22
TG^-, G^+T	−0.02	−0.16	−0.26	−0.13
G^+G^+, G^-G^-	−0.02	−0.02	−0.68	−0.13
G^-G^+	−0.49	1.52	−0.02	−0.22
G^+G^-	1.52	−0.49	−0.02	0.49
Experimental	−0.233(3)	−0.228(2)	−0.23(0)	−0.273(2)
Predicted[c]	−0.28	−0.20	−0.22	−0.22

[a]Using columns D in Tables 2 and 3 of ref. 16.

[b]^4J(aa') and ^4J(bb') are interchangeable. Attempts at identification of a and b protons on the basis of shifts induced by the diamagnetic anisotropy of the phenyl group proved unsuccessful.

[c]P(TT) = 0.38, $P(TG^+) = P(G^-T) = 0.31$.

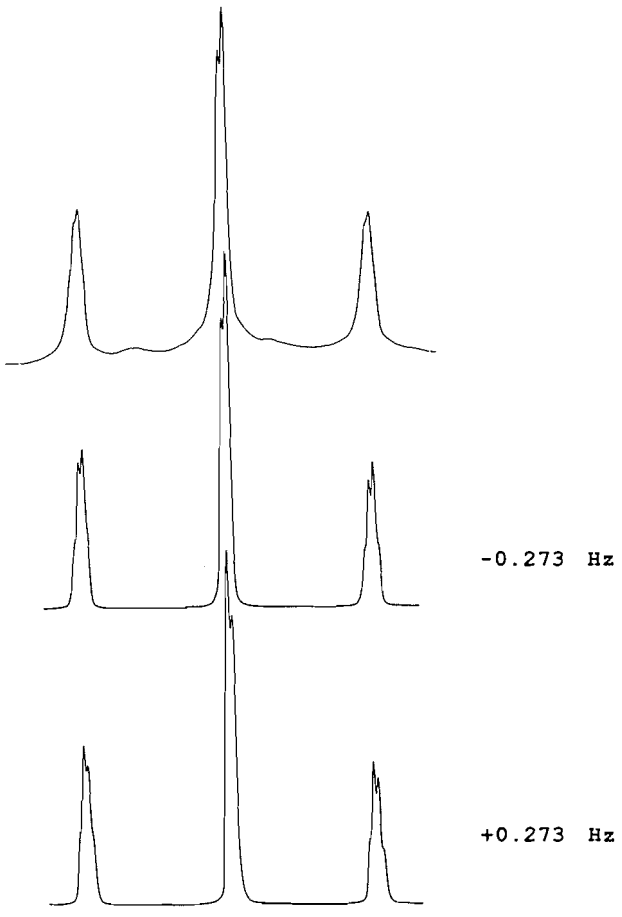


FIG. 1. The ^{1}H nmr spectrum of the methyl protons is displayed for a 4.7 mol% solution of 3-phenylpentane in CS_2/C_6D_{12} at 300 K and 300 MHz. The calculated spectra take $^4J(H,CH_3)$ as −0.273 and +0.273 Hz. There occur many transitions within the components of the "triplet" because the vicinal coupling constants to the neighbouring methylene protons are not identical and also because (Table 1) there occurs additional coupling to the *ortho* protons of the phenyl group. In consequence, the width of the components is substantial. The computed spectra are given somewhat narrow peaks to emphasize the asymmetry introduced by $^4J(H,CH_3)$.

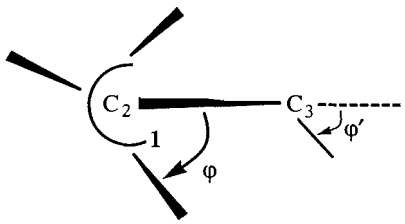
analyses, the uncertainty in $J_{ac} - J_{bc}$ in the previous analysis might be as large as 0.6 Hz. It is unlikely (8, 9, 12, 13) that the conformational equilibrium is markedly solvent dependent.

The *gauche* form of the parent, pentane, is 3.5 kJ/mol less stable than the *trans* conformer (14). Comparison with present results for 3-phenylpentane suggests that, in the TT conformer, there occurs a repulsive interaction between the methyl and phenyl groups; one C—H bond of the methyl group approaches the ipso carbon atom to within 2 Å. The large barrier to rotation about the Csp^2—Csp^3 bond, relative to that in isopropylbenzene, must surely arise, in part at least, from methyl–phenyl repulsions. At least for 3-phenylpentane there appears to be no evidence for so-called attractive CH/π forces (15).

Conformational information from ^{4}J(H,H)

In the propanic fragment, ^4J(H,H) depends on two dihedral angles, φ and φ', indicated in **3** (16).



3

The reasonably successful theory (16) of ^4J(H,H), particularly of $^4J(H,CH_3)$, is here used to calculate the four ^4J(H,H) values for the alkyl chain in 3-phenylpentane. Table 2 presents the theoretical numbers for the various conformers, appropriate averages of ^4J(H,H) for the various dihedral angles being employed. These angles were taken as ideal or regular angles for the staggered conformations in Scheme 1, that is, values such as 60°, 120°, and 180°.

Comparison between the calculated ^4J(H,H) and the experimental values, also given in Table 2, suggests that the assumption of a predominance of the TT and TG^+,G^-T conformers at 300 K is essentially correct. For example, the absence of G^-G^+ is indicated by the three ^4J(H,H) values for the methylene protons, whereas that of G^+G^- is consistent

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

with $^4J(H,CH_3)$. Furthermore, the theoretical value of $^4J(H,CH_3)$ for the predominant TT and TG^+,G^-T forms becomes fully consistent with experiment when it is noted (Fig. 4 of ref. 16) that the theoretical values of $^4J(H,CH_3)$ for the appropriate dihedral angles are about 0.05 Hz too small in magnitude compared to the available experimental data. Again, significant amounts of G^+G^-,G^-G^+ can be excluded on the basis of all four coupling constants, while three of the coupling constants strongly suggest that TT is not the most populated conformer in the sense that the sum of the fractional populations of the isoenergetic TG^+ and G^-T conformers is 0.62.

Exact agreement between predicted and measured coupling constants is not to be expected, of course, for a number of reasons. Among them are the likely deviations from pure all-staggered bond arrangements and the neglect of intermediate rotational states of the methyl group. Nevertheless, the present results illustrate that precise analyses of good spectra can be important in conformational analysis.

CHENGRUI WANG, YUXIANG MO, MEEHAE JANG, and ALEXANDER F. JANZEN. Can. J. Chem. **71**, 525 (1993).

^{13}C nuclear magnetic resonance data for a variety of phenyl derivatives of boron, silicon, tin, phosphorus, and tellurium fluorides are presented. Neutral, anionic, and cationic complexes are included and the coordination number of the central element varies from 3 to 6. Empirical equations of the ^{13}C chemical shifts of the benzene ring have been deduced by taking into consideration the charge density, dipole moment, and binding energy, and the ^{13}C chemical shifts calculated from these equations deviate from the experimental values by up to 1.4 ppm, but mostly less than 0.7 ppm.

CHENGRUI WANG, YUXIANG MO, MEEHAE JANG et ALEXANDER F. JANZEN. Can. J. Chem. **71**, 525 (1993).

On présente de données de résonance magnétique nucléaire du ^{13}C pour une variété de dérivés phénylés de fluorures de bore, de silicium, d'étain, de phosphore et de tellure comprenant des complexes neutres, anioniques et cationiques pour lesquels le nombre de coordination de l'élément central varie de 3 à 6. On a déduit les équations empiriques des déplacements chimiques du ^{13}C du benzène en prenant en considération la densité de charge, le moment dipolaire et l'énergie de liaison, et les déplacements chimiques du ^{13}C calculés diffèrent des valeurs expérimentales par des valeurs allant jusqu'à 1,4 ppm; toutefois, ces différences sont généralement inférieures à 0,7 ppm.

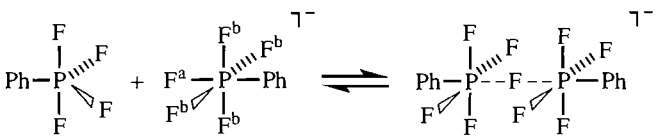
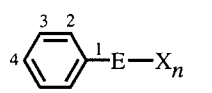
Halogen exchange occurs rapidly in systems such as $PhPF_4$–$PhPF_5^-$ (*1*, *2*)



9 **10**

or $PhPCl_4$–$PhPCl_5^-$ (3), and related systems (4), and this intermolecular exchange, sometimes initiated by common impurities, as well as axial–equatorial ligand exchange in trigonal bipyramidal molecules, may complicate spectral identification if ^{19}F nmr is used to monitor fluorine site exchange. It was therefore decided to record the ^{13}C nmr spectra of the non-labile phenyl substituent of a variety of B, Si, Sn, P, and Te fluorides in which the coordination number of the central element varies from 3 to 6 in neutral, anionic, or cationic complexes.

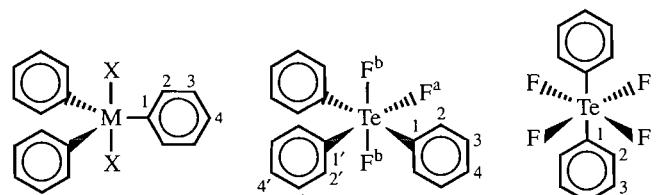
The ^{13}C nmr data for phenyl-element fluorides **1**–**15** are given in Table 1. All the compounds contain the structural unit



E = B, C, Si, Sn, P, Te
X = F, Cl
n = 2-5

However, *mer*-Ph_3TeF_3 **12** has nonequivalent phenyl rings, as expected for the *mer* structure, which has been established by X-ray crystallography (5), and the carbons C1′–C4′ are assigned to the phenyl ring *trans* to F^a.

The ^{13}C nmr spectra of $Ph_3TeF_2^+$ **11**, Ph_3TeFCl^+ **13**, and $Ph_3SnF_2^-$ **15** show equivalent phenyl groups, as expected for



11 $Ph_3TeF_2^+$
13 Ph_3TeFCl^+
15 $Ph_3SnF_2^-$

12 *mer*-Ph_3TeF_3

14 *trans*-Ph_2TeF_4

a trigonal bipyramidal geometry with three phenyls in the equatorial plane, and the two phenyl substituents in *trans*-Ph_2TeF_4 **14** are also equivalent. For $PhSiF_4^-$ **8** and $PhPF_4$ **9**, which undergo rapid axial–equatorial exchange, carbons are coupled equally to four fluorines, but different couplings from carbon to nonequivalent fluorines F^a and F^b can be observed in "rigid" $PhPF_5^-$ **10** and *mer*-Ph_3TeF_3 **12**. The assignments of C1–C4 peaks in the ^{13}C spectra of phenyl-element fluorides are based on relative intensities, carbon–fluorine couplings, and related nmr spectra reported in the literature (6).

We have included for comparison purposes the published data for $PhCF_2^+$ **5** (7) and $PhCF_3$ **6** (8); the other ^{13}C nmr spectra were recorded for this study although the spectra of $PhBF_2$ and $PhBF_3^-$ have been reported previously (9).

The distribution of the chemical shifts of compounds **1**–**12** is shown in Fig. 1 and it can be seen that the chemical shift of C1 moves consistently downfield by 15.6 to 25.7 ppm as F^- is added to various phenyl-element fluorides. There is an opposite effect on carbons C2–C4, which move upfield as F^- is added, with the exception of C2 of $PhSiF_3$ **7**. In the case of $Ph_3TeF_2^+$ **11**, the addition of F^- produces a larger shift in phenyl carbons C1–C4, which are *cis* to F^a, than on carbons C1′–C4′, which are *trans* to F^a.

Figure 1 shows that chloride ion has an effect similar to

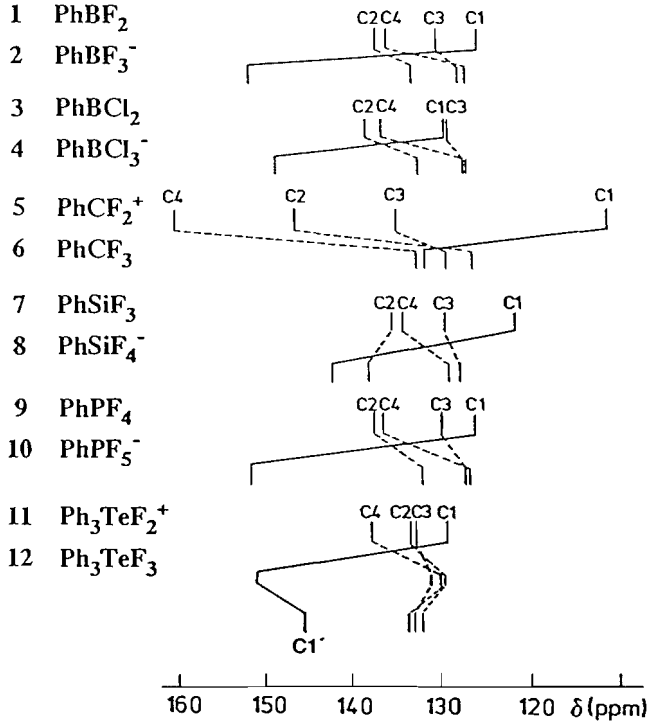

FIG. 1. Distribution of ^{13}C chemical shifts of compounds **1**–**12**. Data are taken from Table 1.

that of fluoride, and addition of Cl^- to $PhBCl_2$ results in a downfield shift of C1 of 19.5 ppm as $PhBCl_3^-$ is formed. Similar changes have been observed on addition of Cl^- to triphenyltin chloride (10), i.e., Ph_3SnCl (δC1 137.1 ppm) versus $Ph_3SnCl_2^-$ (δC1 147.5 ppm), or on addition of $C_6H_5^-$ to triphenylboron (11), i.e., Ph_3B (δC1 144.9 ppm) versus Ph_4B^- (δC1 164.8 ppm).

3 $PhBCl_2$	−0.6	−0.5	+0.7	0
6 $PhCF_3$[b]	+1.1	+0.1	−0.5	−0.3
9 $PhPF_4$	+0.1	−0.2	−0.4	0
10 $PhPF_5^-$	+1.0	+0.2	+0.2	−0.3

[a]$\Delta\delta^{13}C = \delta^{13}C(\text{calcd.}) - \delta^{13}C(\text{expt.})$
[b]Experimental value from ref. 8.

A similar result might be expected with donor solvents, although a dynamic equilibrium may give only a weighted average value for δC1, and this effect has been observed by other workers (12) who found a downfield shift in δC1 of only 3.7 ppm as acetonitrile was added to $PhSnCl_3$. Any competition between donor solvents and halide ions could mask differences between δC1 of various species in solution, as illustrated by the very similar chemical shifts in p-$PhC_6H_4TeCl_3$ (δC1 145.5 ppm) and p-$PhOC_6H_4TeCl_4^-$ (δC1 146.7 ppm) if both are dissolved in DMSO solution (13).

These changes in δC1 are thus a useful indicator of changes in coordination number and electron count of the central element E as ligands such as F^-, Cl^-, or $C_6H_5^-$ are added, and the ^{13}C nmr of the non-labile phenyl substituent may complement nmr studies of systems undergoing rapid ligand exchange.

TABLE 3. CNDO/2 calculated valence charge density, VCD, binding energy, BE (au), and dipole moments, DM (debye) of some phenyl-element fluorides

Compound	VCD					BE	DM
	C1	C2	C3	C4	E		
1	4.1300	3.9253	4.0189	3.9500	2.5173	−7.2831	3.27534
2	4.0893	3.9819	4.0146	4.0181	2.5465	−7.5322	7.06203
3	4.0560	3.9347	4.0169	3.9505	2.7959	−7.2901	3.00721
6	4.0436	3.9716	3.9959	3.9974	3.4145	−7.7812	2.69120
9	4.0352	3.9503	3.9934	3.9976	4.1689	−6.9349	3.52916
10	4.0782	3.9682	4.0148	4.0039	4.1688	−7.1408	8.76378

The coupling constants J(C,F) are given in Table 1 and in each case there is an increase in ^2J(C1,F) of 9.9 to 46.1 Hz as F^- is added; furthermore, J(C,F) depends significantly on stereochemical changes in these "rigid" complexes, but rapid intermolecular fluorine exchange would result in loss of coupling between carbon and fluorine.

Calculated chemical shifts

The phenyl-element fluorides discussed above show significant differences in their structure, coordination number, and electron count and these differences will influence the chemical environment of the central atom, which in turn will affect the carbon atoms of the benzene ring.

The relationship between the ^{13}C chemical shifts of the benzene ring and the characteristics of the substituted group has been studied for a long time, but often the chemical shift of the *para* carbon (δC4) is related to a single parameter such as total charge density, Hammett σ constant, or dual substituent parameter, and the empirical equations for the chemical shifts of the *ortho* (δC2) and *meta* (δC3) carbons often do not show a good correlation (6). We therefore derived empirical equations of chemical shifts and compared the calculated and measured ^{13}C chemical shifts.

The chemical shift of a nucleus is determined by its chemical environment and the atom in a molecule can be distinguished from the same atom in the free state by the partial shift of its valence electrons, which means the change of the valence charge density. Hence the valence charge density will definitely be one of the major factors affecting the chemical shift. Moreover, since the applied magnetic field in nmr affects all the atoms of the molecule, the chemical shift should be related to the charge distribution of the whole molecule, and the dipole moment of the molecule, $\boldsymbol{\mu} = e \int\psi^*\gamma\psi \, d\tau$, where ψ is the wave function of the system, the physical property that describes the charge distribution of the whole molecule. Thus, there should be a dipole moment term in the empirical equation of chemical shifts. Since the nucleus will be shielded not only by its own electrons but also by the other electrons in the molecular system, then, considered from the view of energy, it may be stated that chemical shifts will also be related to the binding energy.

For these reasons we used the three parameters of valence charge density (ρ) (where ρ_E = ρ of atom E in the molecule), dipole moments (μ), and binding energy (BE), and carried out a multivariable, step-by-step regression analysis to get the empirical equations [1]–[4] for the ^{13}C chemical shifts of the monosubstituted benzene ring.

$$[1]\quad \delta C1 = -4.871866 * \rho^2 + 4.912487 * \mu - 12.43392 * BE + 101.8069$$

$$[2]\quad \delta C2 = -3.98671 * \rho_E - 0.4117336 * \mu + 18.01284 * BE + 280.1893$$

$$[3]\quad \delta C3 = 1.522819 * BE - 0.03860589 * \mu^2 + 140.476$$

$$[4]\quad \delta C4 = 7.141028 * BE - 15.3116\rho - 1.599473 * \mu + 252.6104$$

The correlation coefficients of the regression equations [1]–[4] are 0.9955, 0.9956, 0.961, and 0.9993, respectively. We used these four equations to calculate the ^{13}C chemical shifts for the molecules and anions **1**–**3**, **6**, **9**, **10**, and the differences between calculated and experimental values of ^{13}C chemical shifts are listed in Table 2.

As seen in Table 2, the maximum absolute deviation is 1.4 ppm, but the relative deviation is 1% and the data in most cases deviate by less than 0.7 ppm or 0.5%. We have used eqs. [1]–[4] to calculate the ^{13}C chemical shifts for the molecule $PhCF_3$ **6**, and compared the results with experimental results from the literature (8); as seen in Table 2, the deviations for $PhCF_3$ **6** are also within the range established for the other compounds.

A CNDO/2 program was used to calculate the charge density, dipole moments, and binding energy, and these data (Table 3) were used for the calculation of ^{13}C chemical shifts. Molecular configurations were obtained from standard sources (14).

Experimental

$PhBCl_2$ **3** (Alfa) and *n*-Bu_4NF in THF (Aldrich) were obtained commercially. A solution of *n*-Pr_4NF in acetonitrile was made by diluting *n*-Pr_4NOH (30 mL of 10% aq. sol.) to 3% and neutralizing the solution to pH 7 with dilute hydrofluoric acid; the resulting solution was reduced to a thick oil on a rotary evaporator and 80 mL of CH_3CN was added.

$PhBF_2$ **1** (15), $PhSiF_3$ **7** (16), *n*-$Pr_4N^+PhSiF_4^-$ **8** (17), $PhPF_4$ (18), *n*-$Pr_4N^+PhPF_5^-$ **10** (1), $Ph_3TeF_2^+PF_6^-$ **11** (5), *mer*-Ph_3TeF_3 **12** (5), $Ph_3TeFCl^+PF_6^-$ **13** (4), *trans*-Ph_2TeF_4 **14** (19), and *n*-$Bu_4N^+Ph_3SnF_2^-$ **15** (20) were prepared according to literature methods.

n-$Bu_4N^+PhBF_3^-$ **2** was prepared by slowly adding $PhBF_2$ (1.33 g, 10.6 mmol) to a solution of *n*-Bu_4NF (2.16 g of 1 M THF solution) with stirring, followed by removal of solvent with rotary evaporator and filtration under vacuum to give white crystals identified as *n*-$Bu_4N^+PhBF_3^-$ (3.4 g, 83% yield, mp 193–195°C) by ^{19}F, ^{11}B, and ^{13}C nmr. $Et_4N^+PhBCl_3^-$ **4** (21) was prepared by slowly adding $PhBCl_2$ (5 g, 31 mmol), with stirring, to a cooled (−78°C) solution of Et_4NCl (5 g, 30 mmol) in CH_2ClCH_2Cl (150 mL); removal of solvent by rotary evaporator and filtration gave white crystals, which were dried under vacuum and identified as $Et_4N^+PhBCl_3^-$ **4** (1.27 g, 13%) by ^{11}B and ^{13}C nmr.

All ^{13}C (proton-decoupled) nmr spectra were recorded at ambient temperature on a Bruker WH90 spectrometer at 22.63 MHz, except for tellurium and tin compounds **11**–**15**, which were recorded on a Bruker AM300 spectrometer at 75.4 MHz. The samples were dissolved in $CDCl_3$ or CD_2Cl_2 (30%, w/w) in 10-mm tubes (internal reference: $CDCl_3$ δC 79.73 ppm, CD_2Cl_2 δC 53.90 ppm) and degassed and sealed.

Received December 7, 1992

KIYOSHI MATSUMOTO, YUKIO IKEMI, MOTOO SHIRO, TAKANE UCHIDA, and JAMES WILLIAM LOWN. Can. J. Chem. **71**, 529 (1993).

Reactions of 5-cyano-1,4-diphenylpyridazino[4,5-*a*]indolizines with dimethyl acetylenedicarboxylate afforded the 1:2 adducts regioselectively and, unexpectedly, in a Michael fashion rather than in a 1,3-dipolar manner. The structure of the products was established by X-ray crystallography. Regiospecific formation of the observed product **3** can be explained by the higher nucleophilicity of the nitrogen at the 2 position than at the 3 position of the 5-cyano-1,4-diphenylpyridazino[4,5-*a*]indolizine **1** owing to the contribution of a resonance structure **5** to the hybrid. This favors two successive Michael additions to two equivalents of dimethyl acetylenedicarboxylate affording the observed 1:2 adducts **3**.

KIYOSHI MATSUMOTO, YUKIO IKEMI, MOTOO SHIRO, TAKANE UCHIDA et JAMES WILLIAM LOWN. Can. J. Chem. **71**, 529 (1993).

Les réactions des 5-cyano-1,4-diphénylpyridazino[4,5-*a*]indolizines avec l'acétylènedicarboxylate de diméthyle fournit d'une façon inattendue et régiosélective les adduits 1 : 2 d'une réaction de Michael plutôt ceux d'une réaction 1,3-dipolaire. On a déterminé la structure de produits par diffraction des rayons X. On peut expliquer la formation régiospécifique observée des produits **3** en faisant appel au caractère nucléophile plus grand de l'azote en position 2 (par rapport à celui en position 3) du 5-cyano-1,4-diphénylpyridazino[4,5-*a*]indolizine **1** qui est dû à la contribution d'une structure de résonance de **5** à l'hybride. Cette orientation favorise deux additions successives de Michael à deux équivalents de l'acétylènedicarboxylate de diméthyle conduisant aux adduits-1,2 observés, **3**.

[Traduit par la rédaction]

Introduction

Bicyclic bridgehead nitrogen-containing heterocycles such as indolizines (1) and azapentalenes (2), the resonance hybrids of which involve an ylide structure, could serve as a bicycloimmonium or masked azomethine ylide (Scheme 1). Indeed, several indolizines (3–5) undergo [8+2]π cycloaddition with electron-deficient alkynes to afford the cycl[2.2.3]azines (6). Furthermore, investigations of addition reactions of acetylenic esters to nitrogen-containing heterocycles have been stimulated because of the problems involved in unraveling the novel types of reactions and structures sometimes observed (7, 8). Annulation of the benzene ring at the 1,2 position proved to activate 3-cyanoindolizines as 1,3-dipolar species, probably because of aromatic stabilization in favor of the azomethine ylide structure (Scheme 1). Thus, 6-cyanobenz[*a*]indolizines undergo 1,3-dipolar cycloaddition smoothly with activated alkynes such as dibenzoylacetylene (4) and dialkyl acetylenedicarboxylate (9). Therefore, we expected that annulation of a heteroaromatic ring at the 1,2 position of 3-cyanoindolizine would also favor the azomethine ylide structure by means of aromatic stabilization. Since 1,2-pyridazine-fused 3-cyanoindolizines are readily available by 1,3-dipolar cycloaddition reactions of dicyanomethylides with dibenzoylacetylene, followed by treatment with hydrazine (Scheme 2) (4), we have examined the reactions of 1,4-diphenylpyridazino[4,5-*a*]indolizines with dimethyl acetylenedicarboxylate (DMAD).

Results and discussion

Reaction of 5-cyano-1,4-diphenylpyridazino[4,5-*a*]indolizine (**1***a*) with four equimolar amounts of DMAD in refluxing toluene for 14 h gave yellow crystals, mp 282–283°C. The mass spectral and microanalytical analysis established that the compound had a 1:2 adduct structure. Similarly, the corresponding 1:2 adducts were obtained in low to moderate yields from **1***b*–**1***f* with excess DMAD. The results are presented in Table 1. Initially, we expected that the compounds would have the structure **2**, and could be formed by successive Michael-type additions and subsequent cyclization (Scheme 3). There are precedents for this type of 1:2 structure being formed from nitrogen heterocycles such as azapentalenes (10) and azaazulenes (11).

However, the ^{13}C value (6) of δ 116 does not appear to be at high enough field for an sp^3 secondary carbon. Furthermore, all attempts to convert the compounds to the corresponding [2.2.4]cyclazines failed. Fortunately, the 1:2 adduct obtained from the 1,4,8-triphenylpyridazino[4,5-*a*]indolizine (**1***d*) formed crystals suitable for an X-ray

analysis. An analysis of this adduct established that the compound had structure **3***d* as shown in Fig. 1 (7). No regioisomers of type **4** could be isolated in our hands.

Regiospecific formation of **3** could be explained by the higher nucleophilicity of the nitrogen at the 2 position than at the 3 position owing to the contribution of resonance hybrid **5**, since the adducts probably arise from successive Michael additions as shown in Scheme 4. In agreement with this interpretation, neither 3-chloro-6-phenylpyridazine nor 3-chloro-6-methoxypyridazine reacted with DMAD under comparable conditions. Neither were Diels–Alder adducts across the pyridazine ring observed. This latter observation is in agreement with the previous result that the reaction of the dihydropyridazine **6** with DMAD showed no tendency to add in a Diels–Alder fashion to give **7** but instead added the ester in a Michael manner, affording **8** (Scheme 5) (12).

Finally, reaction of 7-azaindolizine **9** with DMAD took place in a similar fashion to give the 1:2 adduct **10** (Scheme 6). This type of structure is well documented in the reactions of pyridines with DMAD (7). Thus, **9** behaved as a nucleophile rather than as a 1,3-dipole. In contrast, 2-phenyl-1-azaindolizine (13) and 7-methyl-2-phenyl-6-azaindolizine (14) with DMAD were reported to give the corresponding azacycl[2.2.3]azines.

Experimental

General

Melting points were taken on a Yanagimoto micro melting point apparatus and are uncorrected. The ^{1}H NMR spectra were measured on one of the following: a Hitachi R40 (90 MHz), a Jeol JNM FX90Q (90 MHz), a Varian VX200 (200 MHz), or a Jeol JNE-EX270 (270 MHz) instrument. ^{13}C NMR spectra were recorded either on a Jeol JNJ-FX90Q or a JNM-EX270 pulsed Fourier transform spectrometer operating at 22.49 MHz and 67.80 Hz, respectively. Chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. Partial proton decoupling was used to distinguish between individual carbon atoms. Preparative medium-pressure liquid chromatography was carried out using a column (25 × 310 mm) prepacked with silica gel (Lobar, LiChroprep Si60, Merck).

Reaction of 5-cyano-1,4-diphenylpyridazino[4,5-a]indolizine (1) with DMAD: general procedure

A solution of **1** (9) (0.85 mmol) and DMAD (3.39 mmol) in toluene (30 mL) was heated under reflux for 40 h. After evaporation of the solvent, the residue was chromatographed on silica (Wako Gel C-200) using benzene – ethyl acetate as eluent (from 39:1 to 17:3 in a gradient fashion) giving the 1:2 adducts **3**. The analytical samples were obtained by recrystallization from ethanol–dichloromethane.

*8-Cyano-7,13c-diphenyl-1,2,3,4-tetramethoxycarbonyl-13c*H*-pyrido[1′,2′:2,3]pyridazino[4,5-a]indolizine (3a; R^1 = R^2 = R^3 = H)*

^{1}H NMR (90 MHz) δ: 3.45, 3.65, 3.86, 3.88 (s each, 3H each), 6.80–6.96 (m, 2H), 7.15–7.35 (m, 5H), 7.50–7.65 (m, 4H), 7.66–7.77 (m, 2H), 8.19–8.24 (m, 1H). ^{13}C NMR (22.49 MHz) δ: 54.2, 53.3, 54.1, 54.2 (q each), 65.3, 91.6, 103.5, 109.5, 115.8, 118.1, 128.5, 133.0, 134.4, 141.8, 141.8, 144.5, 145.7 (s each), 116.1, 119.9, 126.0, 126.5, 128.7, 128.8, 129.5, 131.2, 132.6 (d each), 165.0, 165.1, 166.2, 168.5 (s each). *Reaction of 7-azaindolizine **9** with DMAD*

To a solution of 7-azaindolizine **9** (14) (1 g, 8.5 mmol) in acetonitrile (30 cm^3) was added dropwise DMAD (3 g, 21 cm^3) at room temperature. After 15 min, **9** was no longer detected by TLC. The solvent and excess of DMAD were removed *in vacuo* and the residue was chromatographed on silica (benzene – ethyl acetate) and further purified by recrystallization from ethanol to give 8,9,10,11-tetramethoxycarbonyl-11a*H*-pyrazino[1,2-*a*]pyrro[2,1-*c*]pyrazine **10** (440 mg, 13%) as orange crystals, mp 171–175°C. IR: 1720, 1697 and 1612 (C=O) cm^{-1}; ^{1}H NMR (90 MHz) δ: 3.66, 3.71 (3H × 2, each s, OCH_3), 3.88 (s, 6H, OCH_3), 5.77–5.87 (m, 1H, H-1), 5.95–6.07 (m, 1H, H-2), 6.18 (br t, 1H, J = 4 Hz, H-3), 6.64–6.80 (m, 2H, 5, H-11a), 7.31 (d, 1H, J = 9 Hz, H-6). ^{13}C NMR (22.49 Hz; $CDCl_3$) δ: 52.1, 52.2, 52.5, 53.3 (q each, OCH_3), 5.49 (d, C-11a), 96.3 (s, C-9), 110.9 (s, C-10), 125.6 (s, C-11), 138.6 (s, C-8), 148.0 (s, C-121b), 107.2 (d, C-1), 109.7 (d, C-2), 112.3 (d, C-6), 117.1 (d, C-5), 119.8 (d, C-3), 162.7, 163.5, 164.3, 167.2 (s each, C=O). Anal. calcd. for $C_{19}H_{18}N_2O_8$: C 56.71, H 4.51, N 6.96; found: C 56.96, H 4.59, N 6.72.

Crystal structure determination

The 1:2 adduct **3*d*** was recrystallized from hexane–dichloromethane giving yellow, prismatic crystals that proved to be crystalline complexes with dichloromethane. A summary of the crystal data and structure refinement details are given in Table 2.[2] The structure was solved by a direct method (15), and refined by full-matrix least squares. The atoms other than hydrogen were refined anisotropically. The atomic scattering factors for all atoms and the anomalous dispersion correction factors for atoms other than hydrogen were taken from the literature (16–18). All calculations were performed using the TEXSAN (19) crystallographic software package of the Molecular Structure Corporation.

Acknowledgments

This work was supported in part by a Grant-in-Aid (to K. M.) for Scientific Research from the Ministry of Education, Science, and Culture, Japan (No. 04453023) and a grant (to J. W. L.) from the Natural Sciences and Engineering Research Council of Canada (No. A-2305). We thank Dr. M. Toda (Kyoto University) and Professor A. Kakehi (Shinshu University) for helpful assistance in the preliminary stage of this work.

Application of thioglycoside chemistry to the synthesis of trisaccharides and deoxy-trisaccharides related to the *Shigella flexneri* Y polysaccharide[1]

FRANCE-ISABELLE AUZANNEAU AND DAVID R. BUNDLE[2]
Institute for Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A OR6

Received November 30, 1992

FRANCE-ISABELLE AUZANNEAU and DAVID R. BUNDLE. Can. J. Chem. **71**, 534 (1993).

The *Shigella flexneri* lipopolysaccharide has a biological repeating unit, →2)α-L-Rha*p*(1→2)α-L-Rha*p*(1→3)α-L-Rha*p*(1→3)β-D-GlcNAc*p*(1→ ABCD, but the residue segment BCD suffices to fill the binding site of an O-antigen specific monoclonal antibody, SYA/J6. Synthetic modifications to this trisaccharide have been designed to investigate the involvement in binding of the acetamido moiety, the 4- and 6-OH groups of the GlcNAc residue D, the 4′-OH group of the Rha residue C, and the 3″- and 4″-OH groups of the Rha residue B. Sequential chain extension provided the protected trisaccharides **18**, **24**, **26**, **28**, **30**, **32**, and **35** using thioglycoside glycosyl donors activated by iodonium ions generated *in situ* from *N*-iodosuccinimide and triflic acid. Trisaccharides each monodeoxygenated in either ring B **25** and **27** or ring C **29** were accessed by the use of 3,6-dideoxy or 4,6-dideoxy glycosyl donors **14** and **17** and when these were used in sequential steps trisaccharides **31** and **33**, each deoxygenated at double sites in adjacent residues, were obtained. Selective protection of the glucosamine residue as its *N*-benzyloxycarbonyl derivative provided a facile route to the trisaccharide amino compound **20**, from which *N*-acetyl **21**, *N*-propionyl **22**, and *N*-trifluoroacetyl **23** derivatives were directly prepared. Orthoester intermediates were detected in several glycosylation reactions and culminated in an orthoacetate **34** as a major product rather than the target trisaccharide **35**. When triflic acid concentration was increased these products were avoided but acid-catalyzed migration of a 2-*O*-acetyl group led to both 1→2 and 1→3 linked trisaccharides **35** and **37**. To avoid similar undesirable 1,2-linked products, a block synthetic strategy using the 2-*O*-benzoylated disaccharide glycosyl donor **40** was chosen so that the propensity for orthoester formation was minimized in reactions leading to the trisaccharide analogue deoxygenated at C-6 of the glucosamine unit D.

FRANCE ISABELLE AUZANNEAU et DAVID R. BUNDLE. Can. J. Chem. **71**, 534 (1993).

Le tétrasaccharide →2)-α-L-Rha*p*(1→2) α-L-Rha*p*(1→3) α-L-Rha*p*(1→3)β-D-GlcNAc*p*, ABCD constitue l'unité biologique répétitrice du lipopolysaccharide de *Shigella flexneri*, mais le segment BCD suffit à remplir le site de reconnaissance de l'anticorps monoclonal SYA/J6 spécifique de cet antigène-O. La préparation de trisaccharides modifiés a été effectuée afin d'évaluer l'importance pour la reconnaissance des groupes acétamido, 4- et 6-OH du résidu GlcNAc ainsi que des groupes 4′-, 3″- et 4″-OH des résidus rhamnosyles C et B. Les trisaccharides protégés **18**, **24**, **26**, **28**, **30**, **32** et **35** ont été obtenus en suivant une stratégie d'élongation de chaîne séquentielle utilisant comme donneurs de glycosyles des thioglycosides activés par des ions iodonium générés *in situ* depuis la *N*-iodosuccinimide et l'acide triflique. Les trisaccharides monodésoxygénés sur les résidus B **25**, **27** ou C **29** furent obtenus en utilisant les thioglycosides 3,6- ou 4,6-didésoxy **14** et **17**, dont l'emploi séquentiel combiné permit également l'accès aux trisaccharides **31** et **33** chacun didésoxygénés sur les résidus adjacents B et C. La protection sélective de la glucosamine par un groupe *N*-benzyloxycarbonyle permit d'obtenir facilement le trisaccharide amino **20**, précurseur des composés *N*-acétyl **21**, *N*-propionyl **22** et *N*-trifluoroacétyl **23**. La formation intermédiaire d'orthoesters, détectée au cours de plusieurs glycosylations, fut culminante durant la synthèse du trisaccharide **35** à l'issue de laquelle l'orthoacétate **34** fut isolé majoritairement. Sa formation fut évitée en augmentant la concentration d'acide triflique, mais la migration acido-catalysée du groupe 2-*O*-acétyl conduisit, dans ces conditions, à la formation des trisaccharides **37** et **35** respectivement 1→2 et 1→3 liés. Pour éviter la formation indésirable de composés similaires 1,2 liés, l'analogue **46**, désoxygéné en C-6 de l'unité de glucosamine D, fut préparé en suivant une stratégie de synthèse par bloc, utilisant un disaccharide 2-*O*-benzoylé comme donneur de glycosyle afin de minimiser sa tendance à former un orthoester.

Introduction

In our studies of the antibody combining sites that are generated by immunization of mice with killed vaccines of variant Y *Shigella flexneri*, we have concentrated on two antibodies that are typical of the majority that bind to the Y polysaccharide antigen, an IgM GC-4 and an IgG SYA/J6 (1–3). In their binding patterns with native antigen and glycoconjugates both exhibit a specificity that is directed toward an epitope occurring at the junction of the biological repeating unit (1). Preliminary investigations were based on enzyme immunoassay (EIA) screening with synthetic ligands coupled to BSA and a limited set of modified oligosaccharides (1). These results identified the probable extent of the oligosaccharide–protein contacts and, of the four residues that make up the biological repeating unit of the bacterial *O*-antigen:

[→2)-α-L-Rha*p*(1→2)-α-L-Rha*p*(1→3)-α-L-Rha*p*(1→3)-β-D-GlcNAc*p*(1−]
A B C D

it seemed most probable that the residue sequence BCDA represented the extent of the oligosaccharide epitope. Although the contribution to the binding by the A residue was estimated to be very small (1), we did not properly consider the possibility that the trisaccharide BCD rather than the tetrasaccharide BCDA filled the binding site. Conclusions that the acetamido group of residue D was exposed to

solvent were based on the use as inhibitor of partially *N*-deacetylated trisaccharide BCD. The residual activity of the trisaccharide α-L-Rha*p*(1→3)-α-L-Rha*p*(1→3)-β-D-GlcNAc*p*-1→*O*Me, which was a 40% contaminant of the intended α-L-Rha*p*(1→3)-α-L-Rha*p*(1→3)-β-D-GlcNH$_2$*p*-1→*O*Me inhibitor, led to an erroneous conclusion that the acetamido group was not a contact residue in the site. To complete the mapping of the SYA/J6 binding site a reliable synthesis of these two trisaccharides as well as various *N*-acylated derivatives was required, together with a complete investigation via monodeoxy derivatives of the hydroxyl groups that form hydrogen bonds to the antibody. The results of this study will provide an important comparison with the detailed oligosaccharide–antibody interactions that should be available now that the crystal structures have been solved for antibody SYA/J6 Fab cocrystallized with penta- and trisaccharide ligands (4).

In this report, we describe the use of the *N*-benzyloxycarbonyl protecting group to provide the amino congener of the naturally occurring trisaccharide Rha→Rha→GlcNAc, as well as other acylamido analogues. Early work (1) had suggested that the B residue contributed some 1.5–2.0 kcal/mol of binding energy but its attribution to hydrogen bonding involving the 3- or 4-hydroxyl groups was not investigated. It was also suggested that a hydrogen bond involving the 4-hydroxyl group of the glucosamine unit was crucial to the binding of the antigen to SYA/J6 but that neither the 6-OH group of unit D, or the 4-OH group of residue C were involved in important polar contacts ($\Delta(\Delta G) < 0.5$ kcal/mol). However, the latter results were measured using monodeoxydisaccharide analogues (1) of CD and therefore had to be confirmed using analogues of the trisaccharide BCD that represents the smallest antigen epitope that could fill the SYA/J6 IgG binding site.

To identify the trisaccharide hydroxyl groups that form the most important polar contacts with the protein, five monodeoxy analogues involving various positions within units B, C, or D were synthesized. Two dideoxygenated trisaccharides were also prepared to evaluate the additivity effects to binding energy when changes were made in both the units B and C.

The 11 trisaccharide target compounds were synthesized from thioglycosides. These are flexible and stable intermediates that are well suited for oligosaccharide chemistry since the thioalkyl group can be easily converted to glycosyl halide under mild conditions or activated, *in situ*, by thiophilic reagents (5). Sequential chain extension strategies involving activation of thioglycosides with iodonium ions generated, *in situ*, from *N*-iodosuccinimide and triflic acid (6, 7) were employed for most of these oligosaccharide syntheses.

Results

The known (8) disaccharides **1**, **4**, **7**, and **9** were employed as precursors of the glycosyl acceptors needed to prepare the protected trisaccharides **18**, **24**, **26**, **28**, **30**, **32**, and **35**. The triacetates **1** and **4** were transesterified to the triol derivatives **2** and **5**. Regioselective acetylations of **2**, **4**, and **9** to give respectively the acceptors **3**, **6**, and **10** were then accomplished in three steps. Reaction of the triols with trimethylorthoacetate gave 2′,3′-orthoesters that were acetylated at OH-4 prior to acid-catalyzed regioselective opening

to O-2 by treatment in aqueous acetic acid. The diol **7** was converted into the acceptor **8** analogously by formation of a 2′,3′-orthoacetate and regioselective opening to the axial position with mild acidic treatment.

The thioethylrhamnopyranoside **11**, and the thioethyldideoxyhexopyranosides **14** and **17** were used as glycosyl donors. Preparation of a rhamnosyl donor deoxygenated at C-3 was accomplished from methyl 2-*O*-benzoyl-3,6-dideoxy-α-L-*arabino*-hexopyranoside (9) **12**. The glycoside was converted by acetolysis to a mixture of anomeric acetates **13** (α) and **15** (β) from which the α anomer crystallized from hexanes. Reaction of **13** with ethanethiol in the presence of BF_3–etherate gave the α-L and β-L thioglycosides **14** (75%) and **16** (11%), which were separated by chromatography.

Ethyl tri-*O*-acetyl-1-thio-α-L-rhamnopyranoside (10–12) **11** activated by iodonium ions (6) generated *in situ* from *N*-iodosuccinimide and triflic acid (0.13 equivalent) reacted

with the disaccharide acceptor **3** to give the protected trisaccharide **18** (84%). Using identical reaction conditions glycosylation of the *N*-acetylated disaccharide **6** with the 3,6-dideoxythiohexoside **14** required further addition of both glycosyl donor and triflic acid to afford the trisaccharide **24** in only 57% yield. Consequently, glycosylation of disaccharide **6** with the thioglycoside **17** was started using more triflic acid (0.26 equivalent) than for the preparation of **18** and gave trisaccharide **26** (86%) without further addition of acid. In view of this result, the same glycosylation conditions were employed to condense the acceptor deoxydisaccharide **8** with the thioglycosides **11**, **14**, and **17**. When **14** and **17** were reacted with **8**, trisaccharides **30** and **32** were isolated in good yields (respectively 82% and 89%). Surprisingly, glycosylation of **8** with the triacetate **11** gave the trisaccharide **28** in only 55% yield. In this case TLC monitoring of the reaction showed complete disappearance of the glycosyl acceptor with simultaneous consumption of the

rhamnosyl donor but formation of two UV-absorbent compounds. Upon further addition of triflic acid the less polar product was converted into the more polar compound, which was isolated and identified as the desired trisaccharide **28**. These observations suggested the formation of an orthoester intermediate that rearranged to give **28**. Similarly, when disaccharide **10** was glycosylated with the triacetate **11**, the formation of two products was observed. Work-up and chromatography of the reaction mixture afforded the orthoester **34** (54%) and the target trisaccharide **35** (11%). Their structures were assigned on the basis of ^1H and ^{13}C NMR spectra (Tables 6 and 7). The orthoester **34** showed signals at 26.4 ppm (^{13}C) and 1.63 ppm (^1H) characteristic of an orthoacetate C-CH_3 group (13). As well, the typical signal of a quaternary carbon at 124.7 ppm was evident, while only five signals corresponding to quaternary carbons of carbonyl groups were observed. Since only one stereoisomer was observed, and as the nucleophilic attack of an alcohol on an intermediate 1,2-cyclic acyloxonium ion is sterically favored from the side *trans* (*exo*) to the pyranose ring (14), it is most likely that compound **34** has the *exo* configuration. As expected, the formation of this orthoester could be avoided by adding twice as much triflic acid (0.56 equivalent) when starting the glycosylation. Under these conditions a TLC homogenous mixture (75:25) of the isomeric trisaccharides **35** (53%) and **37** (18%) was obtained. The formation of trisaccharide **37** can be explained by the acid-catalyzed (2′→3′) migration of the 2′-*O*-acetyl group in disaccharide **10** leading to a glycosyl acceptor with a 2-hydroxy group on the rhamnose unit, which can be easily glycosylated by the

activated donor **11**. The results described above showed that the success of the iodonium-catalyzed glycosylation of analogous disaccharides such as **3**, **6**, **8**, or **10** was dependent on the structure of both acceptors and donors. Ethyl thiorhamnopyranosides with a 2-*O*-acetyl group react with the acceptor alcohols to form the glycosidic linkage via an orthoacetate, which may be stable in the weakly acidic reaction medium. This observation led us to investigate a block synthetic strategy to prepare trisaccharide **42**, the precursor of the 6-deoxy trisaccharide **46**. The alcohol **39** (12) was glycosylated with acetobromorhamnose (15) (AgOTf) to give disaccharide **40**, which was condensed with monosaccharide **41** (16) under iodonium ion catalysis. As no acetyl group migration was likely to occur when using **41** as glycosyl acceptor, the glycosylation was performed with 0.5 equivalent of triflic acid to avoid orthoester formation and trisaccharide **42** was isolated in 71% yield. The disaccharide donor **40** avoids troublesome orthoester products (17) and thus provides a more convenient route to trisaccharides that are modified in the Glc*N*Ac residue D.

The *N*-benzyloxycarbonyl derivative **19** was obtained as an analytically pure white powder after acetal hydrolysis and transesterification of the protected trisaccharide **18**. Removal of the benzyloxycarbonyl group was accomplished by hydrogenolysis of a methanolic solution of **19** and the amine **20** was precipitated as its hydrochloride salt. Each of the trisaccharides **21**–**23** was prepared from **19** by hydrogenolysis of the *N*-protecting group and *N*-acylation of the crude amine **20**. A methanolic solution of **20** was treated with acetic or propionic anhydride to give **21** (85%) and **22** (73%). The acetylation proceeded much faster than the propionylation, which required the addition of triethylamine to reach completion. Trifluoroacetylation was achieved by treating a solution of **20** in anhydrous pyridine with an excess of trifluoroacetic anhydride, followed by the *in situ* hydrolysis of the *O*-trifluoroacetyl groups, by adding water to the crude reaction mixture. The *N*-trifluoroacetate **23** (50%) was pu-

rified by chromatography and obtained free of salt by gel permeation chromatography on a Biogel P2 column eluted with water.

The 3″-, 4″-, and 4′-monodeoxygenated trisaccharides **25**, **27**, and **29** as well as the dideoxy analogues **31** and **33** were obtained by a two-step procedure from the protected trisaccharides **24**, **26**, **28**, **30**, and **32**. The transesterification of the *O*-acyl groups in methanol was followed by the hydrogenolysis of the benzylidene acetal. The latter reaction was preferred to an acid hydrolysis in order to preserve the acid-labile dideoxyhexopyranoside linkages. An analogous sequence of reactions was applied to the mixture of **35** and **37** to obtain the deprotected trisaccharides **36** and **38** that were separated by reversed-phase HPLC.

Deoxygenation at C-6 of the glucosamine unit was achieved in four steps from the protected trisaccharide **42**. Hydrolysis of the benzylidene acetal gave the diol **43**, which was selectively brominated at C-6 using conditions analogous to those described by Garegg *et al.* for the selective chlorination of sugar (18). The brominated trisaccharide **44** (55%) was then reduced to give the 6-deoxy derivative **45**, which, upon transesterification of the acyl groups, led to the deprotected analogue **46** (84%, from **44**).

New compounds and intermediates were fully characterized by ^{1}H NMR spectroscopy (Tables 1 and 3–6). Glycosylation and bromination products as well as final compounds were also characterized by ^{13}C NMR spectroscopy (Tables 2 and 7) and the configurations of the anomeric linkages were assigned according to the heteronuclear coupling constants measured between anomeric carbons and protons (19). The spectroscopic data were in full accord with the proposed structures.

Discussion

The synthesis of 11 trisaccharides reported here underscores the convenience and efficacy of thioglycosides in both block and sequential oligosaccharide synthesis, especially when the glycosyl donors are activated by *N*-iodosuccimide/triflic acid (6). The acidic conditions of activation are sufficiently mild that intermediate orthoesters are observed under typical glycosylation conditions, e.g., synthesis of **34** from reaction of the donor **11** with the acceptor disaccharide **10**. In several reactions TLC monitoring suggested the formation of intermediate orthoesters that rearranged during the normal reaction period, 4–7 h. The formation of orthoester was minimized by increasing the acidity of the reaction mixture; however, in general this is potentially hazardous because of the likelihood of acyl group migration, especially when acetate esters are employed for selective protection. The simplest explanation for the formation of both the 1,2- and 1,3-linked trisaccharide products **35** and **37** was the acid-catalyzed migration of an acetate from *O*-2 to *O*-3 of the terminal rhamnose residue of disaccharide **10**.

Orthoester formation in the *manno* series is well documented (13) and it could be anticipated that the formation of acetoxonium ions following activation of the acylated thioglycoside would lead to orthoester formation under appropriate circumstances of donor and acceptor reactivity (17, 20).

The use of functional group replacement, particularly monodeoxy analogues to map protein binding sites and to draw conclusions about three-dimensional features of the carbohydrate–protein binding sites (21), assumes that only minor perturbations of the conformational equilibria about glycosidic linkages result from these synthetic changes. An initial indication of the validity of this assumption may be drawn from an examination of the ^{1}H NMR and ^{13}C NMR chemical shift changes that accompany the modifications. Carbon-13 chemical shifts of anomeric and aglyconic carbon atoms have been shown to be sensitive to torsional and valence angle changes (22–24). Proton NMR shifts are also diagnostic of predominant conformations (24, 25).

Examination of the ^{1}H NMR chemical shifts for D_2O solutions of the modified and deprotected trisaccharides relative to the native trisaccharide **21** shows a consistent pattern of chemical shifts. Both α-L-rhamnopyranose residues B and C adopt the typical $^1C_4$(L) chair conformation as judged by the ^3J values, and in similar fashion the β-D-GlcNAc residue D has ^1J coupling constants consistent with the $^4C_1$(D) chair conformation (Table 1). The ^{13}C NMR chemical shifts also show closely related values and a consistent pattern for the native trisaccharide and its cogeners. Together, the chemical shift similarities suggest that the conformational equilibria of each trisaccharide are closely related. This is in agreement with calculations that predict closely related potential energy surfaces for each glycosidic linkage of the series of monodeoxy derivatives and, furthermore, shows no indication of substantially shifted conformational equilibria. This conclusion then provides a sound basis for direct comparison of the inhibitory power of each structure and its correlation with a three-dimensional model for the epitope bound to its antibody.

Experimental

General methods

The methods employed were described in an earlier publication (8). NMR data are presented in tables, ^{1}H NMR in Tables 1 and 3–6, ^{13}C NMR in Tables 2 and 7.

*Methyl 2-amino-4,6-*O*-benzylidene-2-*N*-benzyloxycarbonyl-2-deoxy-3-*O*-(α-L-rhamnopyranosyl)-β-D-glucopyranoside (2)*

A solution of the protected disaccharide **1** (8) (2.02 g, 2.94 mmol) in methanolic NaOMe (0.1 M, 200 mL) was stirred for 1 h at room temperature and deionized with Amberlite IR-120 (H^+) resin. The solution was filtered and concentrated to give the triol **2** (1.61 g, 98%) as a white powder that was isolated by filtration from Et_2O: mp 222–224°C (dec.); $[\alpha]_D^{25}$ −99.2 (*c* 0.6, MeOH). Anal. calcd. for $C_{28}H_{35}NO_{11}$: C 59.9, H 6.3, N 2.5; found: C 59.6, H 6.3, N 2.3.

*Methyl 2-amino-3-*O*-(2′,4′-di-*O*-acetyl-α-L-rhamnopyranosyl)-4,6-*O*-benzylidene-2-*N*-benzyloxycarbonyl-2-deoxy-β-D-glucopyranoside (3)*

Trimethylorthoacetate (520 μL, 1.5 mol-equiv.) was added to a suspension of the triol **2** (1.53 g, 2.72 mmol) in anhydrous CH_3CN (60 mL) containing *p*-toluenesulfonic acid (87 mg), and the mixture was stirred for 1 h under N_2 at room temperature. NEt_3 (5 mL) was added, the solution was concentrated to dryness, and residual traces of MeOH were coevaporated with a mixture of anhydrous pyridine–NEt_3 (4:1, 25 mL). *N*,*N*-Dimethylaminopyridine (40 mg) and acetic anhydride (520 μL, 2 mol-equiv.) were then added to a stirred solution of the residue in anhydrous pyridine (60 mL). After 1 h at room temperature more anhydride (100 μL) was added and stirring was continued for another hour. MeOH (200 μL) was added to destroy excess reagent, solvents were evaporated, and the residue, dissolved in EtOAc (200 mL), was washed successively with 1 M HCl (50 mL), saturated aqueous $NaHCO_3$ (50 mL), saturated aqueous NaCl (50 mL), and dried. The solid obtained after concentration was dissolved in aqueous 80% acetic acid (100 mL), stirred 30 min at room temperature, and solvents were evaporated at 25°C under high vacuum. Residual traces of acid were coevaporated with toluene (3 × 20 mL), and flash chromatography ($CHCl_3$–acetone, 10:1.5) of the residue gave the alcohol **3** (1.3 g, 73%), which crystallized on standing: mp 221.6°C; $[\alpha]_D^{25}$ −45.3 (*c* 0.7, $CHCl_3$). Anal. calcd. for $C_{32}H_{39}NO_{13}$: C 59.5, H 6.1, N 2.2; found: C 59.1, H 6.2, N 2.2.

*Methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-3-*O*-(α-L-rhamnopyranosyl)-β-D-glucopyranoside (5)*

Deacetylation of disaccharide **4** (8) (1.25 g, 2.1 mmol), as well as work-up of the reaction, was performed in the same manner as the preparation of disaccharide **2**. Triol **5** was obtained as a pure white powder (951 mg, 96%) by crystallization from Et_2O: mp 232.5–234.2°C; $[\alpha]_D^{25}$ −112.5 (*c* 1.0, MeOH). Anal. calcd. for $C_{22}H_{31}NO_{10}$: C 56.3, H 6.7, N 3.0; found: C 55.8, H 6.7, N 3.3.

*Methyl 2-acetamido-3-*O*-(2′,4′-di-*O*-acetyl-α-L-rhamnopyranosyl)-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside (6)*

Selective acetylation of triol **5** (860 mg, 1.83 mmol) was performed in three steps, using conditions similar to those used to prepare the alcohol **3**. The alcohol **6** was crystallized from MeOH–Et_2O and obtained as a white powder (904 mg, 89%): mp 255–257°C (dec.); $[\alpha]_D^{25}$ −46.2 (*c* 0.55, $CHCl_3$). Anal. calcd. for $C_{26}H_{35}NO_{12}$: C 56.4; H 6.4, N 2.5; found: C 56.2, H 6.4, N 2.3.

*Methyl 2-acetamido-3-*O*-(2′-*O*-acetyl-4′-deoxy-α-L-*lyxo*-hexopyranosyl)-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside (8)*

Treatment of the diol **7** (8) (763 mg, 1.68 mmol) with trimethylorthoacetate and acid opening of the intermediate 2′,3′-orthoacetate using identical conditions to those used to prepare the alcohol **3** gave the alcohol **8** as an amorphous white solid isolated by filtration from EtOAc (687 mg, 82%); $[\alpha]_D^{25}$ −76.0 (*c* 0.7, DMSO). Anal. calcd. for $C_{24}H_{33}NO_{10}$: C 58.2, H 6.7, N 2.8; found: C 58.3, H 6.7, N 2.8.

*Methyl 2-acetamido-3-*O*-(2′,4′-di-*O*-acetyl-α-L-rhamnopyranosyl)-6-*O*-benzyl-2,4-dideoxy-β-D-*xylo*-hexopyranoside (10)*

Triol **9** (8) (444 mg, 0.97 mmol) was selectively acetylated in the conditions used to prepare alcohol **3**. The alcohol **10** was isolated as a white solid (290 mg, 55%) from MeOH–Et_2O. Chromatography of the mother liquors ($CHCl_3$–MeOH; 40:1, 150 mL; 30:1, 90 mL; 20:1, 80 mL) gave more alcohol (101 mg, 19%), which was also filtered off in MeOH–Et_2O: mp 212.3–212.9°C (dec.); $[\alpha]_D^{25}$ −23.2 (*c* 0.6, $CHCl_3$). Anal. calcd. for $C_{26}H_{37}NO_{11}$: C 57.9, H 6.9, N 2.6; found: C 57.5, H 6.8, N 2.6.

*1,4-Di-*O*-acetyl-2-*O*-benzoyl-3-deoxy-α-L-*arabino*-hexopyranoside (13) and 1,4-di-*O*-acetyl-2-*O*-benzoyl-3-deoxy-β-L-*arabino*-hexopyranoside (15)*

A solution of sulfuric acid in glacial acetic acid (0.47 M, 5 mL) was added dropwise to a stirred solution of the glycoside **12** (9) (2.21 g, 8.7 mmol) in a mixture of glacial acetic acid and acetic anhydride (2:5, 185 mL). After 1 h at 20°C (water bath) NaOAc (5 g) was added and the reaction mixture was poured slowly into an ice-cold saturated solution of $NaHCO_3$ (250 mL). The product was extracted in EtOAc (2 × 250 mL), washed with saturated aqueous NaCl (200 mL), dried, and concentrated. Chromatography (hexanes–EtOAc, 7:3) of the oily residue gave a mixture (2.5 g) of the α-(**13**) and β-(**15**) anomers (94:6). Monosaccharide **13** crystallized from hexanes (2.0 g, 71%): mp 90.2–90.8°C; $[\alpha]_D^{25}$ −31.7 (*c* 0.95, $CHCl_3$). Anal. calcd. for $C_{17}H_{20}O_7$: C 60.7, H 6.0; found: C 60.7, H 6.0.

*Ethyl 4-*O*-acetyl-2-*O*-benzoyl-3-deoxy-1-thio-α-L-*arabino*-hexopyranoside (14) and ethyl 4-*O*-acetyl-2-*O*-benzoyl-3-deoxy-1-thio-β-L-*arabino*-hexopyranoside (16)*

The di-*O*-acetate **13** (1.80 g, 5.35 mmol) dissolved in dry CH_2Cl_2 (100 mL) was reacted for 30 min at room temperature with EtSH

(700 μL, 1.8 mol-equiv.) and BF_3–etherate (800 μL, 1.2 mol-equiv.). NEt_3 (1.1 mL) was added slowly and the solution was concentrated to dryness. The residue dissolved in EtOAc (200 mL) was washed successively with saturated aqueous $NaHCO_3$ (2 × 100 mL), saturated aqueous NaCl (100 mL), and dried. Concentration and flash chromatography (hexanes–EtOAc; 9:1, 400 mL; 8:2, 400 mL) gave the α-L-thioglycoside **14** (1.36 g, 75%), which crystallized on standing: mp 84.3–84.8°C; $[\alpha]_D^{25}$ −103.9 (*c* 0.9, $CHCl_3$). Anal. calcd. for $C_{17}H_{22}O_5S$: C 60.3, H 6.6; found: C 60.1, H 6.7.

For personal use only.

Further elution of the column gave the β-anomer **16** (200 mg, 11%) as a colourless oil: $[\alpha]_D^{25}$ +36.6 (*c* 1.0, $CHCl_3$). Anal. found: C 60.1, H 6.6.

Methyl 2-amino-3-O-[2',4'-di-O-acetyl-3'-O-(2",3",4"-tri O-acetyl-α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-4,6-O-benzylidene-2-N-benzyloxycarbonyl-2-deoxy-β-D-glucopyranoside (18)

A mixture of the alcohol **3** (585 mg, 0.91 mmol) and the glycosyl donor **11** (350 mg, 1.2 mol-equiv.) in anhydrous CH_2Cl_2 (30 mL) containing powdered activated molecular sieves 4Å (2 g) was stirred under N_2 for 18 h at room temperature. *N*-Iodosuccinimide (262 mg, 1.3 mol-equiv.) and a saturated solution of triflic acid in CH_2Cl_2 (0.15 M, 785 μL, 0.13 mol-equiv.) were added to the mixture, which was protected from light, and stirred 30 min at room temperature. NEt_3 (800 μL) was added to the reaction mixture, and solids were removed by filtration and rinsed with EtOAc (75 mL). The combined organic solutions were washed successively with a 5% solution of sodium thiosulfate in aqueous 0.5 M NaOH (3 × 50 mL), 1 M HCl (50 mL), saturated aqueous $NaHCO_3$ (50 mL), saturated aqueous NaCl (50 mL), and then dried. Concentration and flash chromatography (toluene–EtOAc, 7:3) gave the trisaccharide **18** (697 mg, 84%) as a white powder: mp 119–123°C (dec.); $[\alpha]_D^{25}$ −40.6 (*c* 0.9, $CHCl_3$). Anal. calcd. for $C_{44}H_{55}NO_{20}$: C 57.6, H 6.0, N 1.5; found: C 57.4, H 6.1, N 1.8.

Methyl 2-amino-2-N-benzyloxycarbonyl-2-deoxy-3-O-[3'-O-(α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-β-D-glucopyranoside (19)

A solution of the trisaccharide **18** (647 mg, 0.7 mmol) in 60% acetic acid (35 mL) was stirred for 45 min at 100°C and concentrated to a syrup. Residual acid was removed by evaporating a mixture of toluene–MeOH (1:1, 2 × 20 mL). The dry residue was dissolved in a 0.06 M methanolic solution of NaOMe (30 mL) and was stirred for 18 h at room temperature. The reaction mixture was deionized with Amberlite IR-120 (H^+) resin, filtered, and the filtrate was concentrated. The deprotected trisaccharide **18** was obtained as a white powder from EtOH–acetone (397 mg; 91%); mp 210–213°C (dec.); $[\alpha]_D^{25}$ −55.1 (*c* 0.5, H_2O). Anal. calcd. for $C_{27}H_{41}NO_{15}$: C 52.3, H 6.7, N 2.3; found: C 51.9, H 6.5, N 2.2.

Methyl 2-amino-2-deoxy-3-O-[3'-O-(α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-β-D-glucopyranoside (20)

A solution of the trisaccharide **19** (56 mg, 0.09 mmol) in MeOH (5.5 mL) containing Pd–C catalyst (10%, 19 mg) was stirred for 2 h at room temperature under a hydrogen atmosphere. The catalyst was removed by filtration, rinsed with MeOH (10 mL), and the combined filtrates were concentrated to dryness. The residue was dissolved in H_2O (2 mL), the pH lowered to 4 by addition of 0.1 M HCl, and the solution was concentrated. The pure trisaccharide **20** was then precipitated (EtOH–acetone) as the hydrochloride salt, centrifuged, washed (acetone 2 × 1 mL), and dried (38 mg, 82%); $[\alpha]_D^{25}$ −56.4 (*c* 0.4 MeOH). Anal. calcd. for $C_{19}H_{36}ClNO_{13}$: C 43.7, H 6.9, N 2.7; found: C 43.6, H 6.8, N 2.5.

Methyl 2-acetamido-2-deoxy-3-O-[3'-O-(α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-β-D-glucopyranoside (21)

Hydrogenolysis of the trisaccharide **19** (34 mg, 0.05 mmol) was performed as described for the preparation of **20**. Acetic anhydride (200 μL) was added to the crude reaction mixture, which was stirred for 1 h at room temperature, then filtered and concentrated. The trisaccharide **21** was purified by elution from a Biogel P-2 column (H_2O) and it was obtained as a white powder by freeze-drying (24.6 mg, 85%); $[\alpha]_D^{25}$ −74.9 (*c* 0.4, MeOH). Anal. calcd. for $C_{21}H_{37}NO_{14}$: C 47.8, H 7.1, N 2.6; found: C 47.6, H 7.0, N 2.8.

Methyl 2-deoxy-2-methylacetamido-3-O-[3'-O-(α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-β-D-glucopyranoside (22)

The amine obtained from **19** (53.9 mg, 0.09 mmol) by hydrogenolysis was dissolved in MeOH (4 mL) and treated with propionic anhydride (200 μL). After 1 h at room temperature, more

[a]In $(CD_3)_2SO$.
[b]In 1:1 CD_3OD–D_2O at 310 K.
[c]In 9:1 $CDCl_3$–CD_3OD.
[d]In $CDCl_3$.

anhydride (100 μL) was added and the reaction mixture was stirred for an additional hour. As a TLC (EtOAC–MeOH–H_2O, 6:3:1, R_f (product) 0.6) showed that the reaction was not proceeding further, NEt_3 (600 μL) and propionic anhydride (200 μL) were added to the solution stirred at 18°C (water bath). The acylation was completed within 1 h. Solvents were evaporated and the residual NEt_3 was coevaporated with MeOH (2 × 2 mL). The residue dissolved in MeOH (1 mL) was deionized on a mixed bed column (20 × 1.5) (top half Rexyn 201 (OH^-) and bottom half Amberlite IR-120 (H^+)). Elution with MeOH and concentration of the effluent gave the trisaccharide **22** as a white powder (35 mg, 73%) that was centrifuged from an acetone suspension (2 mL) and dried; $[\alpha]_D^{25}$ −76.9 (*c* 0.4, MeOH). Anal. calcd. for $C_{22}H_{39}NO_{14}$: C 48.8, H 7.3, N 2.6; found: C 48.6, H 7.3, N 2.4.

*Methyl 2-deoxy-3-*O*-[3′-*O*-(α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-2-trifluoroacetamido-β-D-glucopyranoside (**23**)*

The amine obtained by hydrogenolysis of the trisaccharide **19** (21 mg, 0.03 mmol) was filtered, concentrated, evaporated with anhydrous pyridine (2 × 2 mL), and a solution of the dry residue in anhydrous pyridine (1.5 mL) containing trifluoroacetic anhydride (60 μL) was stirred 48 h at 40°C. Water (100 μL) was added to the reaction mixture, which was concentrated, and residual pyridine was coevaporated with H_2O (2 × 1 mL). Flash chromatography (EtOAc–MeOH–H_2O, 8:1.2:1) of the oily residue gave the trisaccharide **23**, subsequently obtained free of salts by chromatography on a Biogel P2 column (H_2O). Freeze-drying of the appropriate fractions gave **23** as an amorphous white powder (9.6 mg, 50%); $[\alpha]_D^{25}$ −79.2 (*c* 0.4, MeOH). Anal. calcd. for $C_{21}H_{34}F_3NO_{14}$: C 43.4, H 5.9, N 2.4; found: C 43.3, H 5.8, N 2.3.

*Methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-3-*O*-[2′,4′-di-*O*-acetyl-3′-*O*-(4″-*O*-acetyl-2″-*O*-benzoyl-3″-deoxy-α-L-arabino-hexopyranosyl)-α-L-rhamnopyranosyl]-β-D-glucopyranoside (**24**)*

A mixture of the alcohol **6** (216 mg, 0.4 mmol), the thioglycoside **14** (153 mg, 1.3 mol-equiv.), and activated powdered molecular sieves 4Å (1.1 g) in anhydrous CH_2Cl_2 (15 mL) was stirred for 2 h under N_2 at room temperature. *N*-Iodosuccinimide (120 mg,

For personal use only.

1.3 mol-equiv.) and a saturated solution of triflic acid in CH_2Cl_2 (0.15 M, 400 μL, 0.15 mol-equiv.) were added to the reaction mixture, which was stirred for 30 min in the dark at room temperature. More glycosyl donor (10.8 mg, 0.2 mol-equiv.) in CH_2Cl_2 (120 μL), and more acid (3 × 200 μL) were added during the following 2 h. NEt_3 (900 μL) was then added to the reaction mixture and work-up was carried out as described for the preparation of **18**. Flash chromatography ($CHCl_3$–MeOH, 30:1) gave the pure trisaccharide **24** (148 mg, 46%) as a colourless glass. Preparative TLC (Silica Gel 60 F254, Merck, 2-mm plate, $CHCl_3$–MeOH, 20:1) of impure fractions gave another 37 mg (11%) of pure **24**; $[\alpha]_D^{25}$ −40.7 (*c* 0.7, $CHCl_3$). Anal. calcd. for $C_{41}H_{51}NO_{17}$: C 59.3, H 6.2, N 1.7; found: C 59.1, H 6.4, N 1.9.

*Methyl 2-acetamido-2-deoxy-3-*O*-[3′-*O*-(3″-deoxy-α-*L*-*arabino*-hexopyranosyl)-α-*L*-rhamnopyranosyl]-β-*D*-glucopyranoside (25)*

A solution of the protected trisaccharide **24** (46 mg, 0.055 mmol) in methanolic NaOMe (3.2 mL, 0.07 M) was stirred 18 h at room temperature, deionized with Amberlite IR-120 (H^+) resin, and filtered. The resin was rinsed with MeOH (5 mL) and the combined filtrates were concentrated to dryness. A solution of the residue in aqueous acetic acid (90%, 3 mL) was hydrogenated 18 h at 60 psi (1 psi = 6.89 kPa) in the presence of 10% Pd–C catalyst (54 mg). The reaction mixture was filtered, the catalyst rinsed with MeOH, and the combined filtrates concentrated. Chromatography (EtOAc–MeOH–H_2O, 7:2:1) of the residue gave the trisaccharide **25**, finally purified on a Biogel P2 column (H_2O) and obtained as a white amorphous powder by freeze-drying (19 mg, 68%); $[\alpha]_D^{25}$ −92.8 (*c* 0.4, H_2O). Anal. calcd. for $C_{21}H_{37}NO_{13}$: C 49.3, H 7.3, N 2.7; found: C 49.1, H 7.4, N 2.8.

*Methyl 2-acetamido-3-*O*-[2′,4′-di-*O*-acetyl-3′-*O*-(2″,3″-di-*O*-acetyl-4″-deoxy-α-*L*-*lyxo*-hexopyranosyl)-α-*L*-rhamnopyranosyl]-4,6-*O*-benzylidene-2-deoxy-β-*D*-glucopyranoside (26)*

A mixture of the alcohol **6** (100.4 mg, 0.18 mmol), the thioglycoside **17** (8) (62.5 mg, 1.3 mol-equiv.), and activated powdered molecular sieve 4Å (550 mg) in anhydrous CH_2Cl_2 (7 mL) was stirred 18 h under N_2 at room temperature. *N*-Iodosuccinimide (56 mg, 1.4 mol-equiv.) and a saturated solution of triflic acid in CH_2Cl_2 (320 μL, 0.26 mol-equiv.) were added to the reaction mixture, which was protected from light and stirred 3.5 h at room temperature. NEt_3 was added and work-up was carried out as described for the preparation of **18**. The trisaccharide **26** was purified by flash chromatography ($CHCl_3$–MeOH, 30:1) and obtained as a colourless glass (119 mg, 86%); $[\alpha]_D^{25}$ −49.5 (*c* 0.8, $CHCl_3$). Anal. calcd. for $C_{36}H_{49}NO_{17}$: C 56.3, H 6.4, N 1.8; found: C 56.1, H 6.4, N 1.5.

*Methyl 2-acetamido-2-deoxy-3-*O*-[3′-*O*-(4″-deoxy-α-*L*-*lyxo*-hexopyranosyl)-α-*L*-rhamnopyranosyl]-β-*D*-glucopyranoside (27)*

The trisaccharide **26** (96 mg, 0.125 mmol) was deprotected using the conditions employed to prepare trisaccharide **25**. Flash chromatography (EtOAc–MeOH–H_2O; 7:1.5:1, 150 mL; 7:2:1, 50 mL) gave trisaccharide **26**, finally purified on a Biogel P2 column (H_2O) and obtained as a white amorphous powder by freeze-drying (47 mg, 73%); $[\alpha]_D^{25}$ −86.4 (*c* 0.8, H_2O). Anal. calcd. for $C_{21}H_{37}NO_{13}$: C 49.3, H 7.3, N 2.7; found: C 49.0, H 7.3, N 2.6.

*Methyl 2-acetamido-3-*O*-[2′-*O*-acetyl-4′-deoxy-3′-*O*-(2″,3″,4″-tri-*O*-acetyl-α-*L*-rhamnopyranosyl)-α-*L*-*lyxo*-hexopyranosyl]-4,6-*O*-benzylidene-2-deoxy-β-*D*-glycopyranoside (28)*

Glycosylation of the disaccharide **8** (102 mg, 0.2 mmol) with the glycosyl donor **11** (85 mg, 1.22 mol-equiv.) was started in the same conditions as those used to prepare the trisaccharide **26**. After 4 h at room temperature more acid (150 μL, 0.11 mol-equiv.) was added, and the reaction was allowed to proceed during an additional 3 h at room temperature and quenched by addition of NEt_3 (50 μL). Work-up was carried out as described for the preparation of **18** and the trisaccharide **28** was purified by flash chromatography ($CHCl_3$–MeOH, 50:1) to yield a colourless glass (87 mg, 55%); $[\alpha]_D^{25}$ −62.6 (*c* 0.5, $CHCl_3$). Anal. calcd. for $C_{36}H_{49}NO_{17}$: C 56.3, H 6.4, N 1.8; found: C 56.5, H 6.5, N 2.0.

*Methyl 2-acetamido-2-deoxy-3-*O*-[4′-deoxy-3′-*O*-(α-*L*-rhamnopyranosyl)-α-*L*-*lyxo*-hexopyranosyl]-β-*D*-glucopyranoside (29)*

The trisaccharide **28** (70 mg, 0.1 mmol) was deprotected as described for **25**. Flash chromatography (EtOAc–MeOH–H_2O, 7:1.5:1) gave trisaccharide **29**, finally purified on a Biogel P2 column (H_2O) and isolated as a white powder by freeze-drying (34 mg, 72%); $[\alpha]_D^{25}$ −92.9 (*c* 0.4, H_2O). Anal. calcd. for $C_{21}H_{37}NO_{13}$: C 49.3, H 7.3, N 2.7; found: C 49.2, H 7.4, N 2.7.

reaction, followed the procedure described for the synthesis of trisaccharide **26**. The trisaccharide **32** was purified by flash chromatography ($CHCl_3$–MeOH, 50:1) and isolated as a colourless glass (129 mg, 89%); $[\alpha]_D^{25}$ −65.2 (*c* 0.65, $CHCl_3$). Anal. calcd. for $C_{34}H_{47}NO_{15}$: C 57.5, H 6.7, N 2.0; found: C 57.2, H 6.5, N 1.8.

*Methyl 2-acetamido-2-deoxy-3-*O*-[4'-deoxy-3'-*O*-(4"-deoxy-α-L-*lyxo*-hexopyranosyl)-α-L-*lyxo*-hexopyranosyl)-β-D-glucopyranoside (**33**)*

The trisaccharide **32** (107 mg, 0.15 mmol) was deprotected in similar fashion to trisaccharide **24**. Flash chromatography (EtOAc–MeOH–H_2O, 7:1.5:1) and gel permeation chromatography (Biogel P2, H_2O) gave pure trisaccharide **33** (58 mg, 77%) isolated as a white lyophilized powder; $[\alpha]_D^{25}$ −99.8 (*c* 0.5, H_2O). Anal. calcd. for $C_{21}H_{37}NO_{12}$: C 50.9, H 7.5, N 2.8; found: C 51.0, H 7.5, N 2.7.

*3,4-Di-*O*-acetyl-1,2-*O*-[2',4'-di-*O*-acetyl-1'-*O*-(2"-acetamido-6"-*O*-benzyl-2",4"-dideoxy-1"-*O*-methyl-β-D-*xylo*-hexopyranos-3"-yl)-α-L-rhamnopyranos-3'-yl orthoacetyl)-α-L-rhamnopyranose (**34**), methyl 2-acetamido-3-*O*-[2',4'-di-*O*-acetyl-3'-*O*-(2",3",4"-tri-*O*-acetyl-α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-6-*O*-benzyl-2,4-dideoxy-β-D-*xylo*-hexopyranoside (**35**), and methyl 2-acetamido-3-*O*-[3',4'-di-*O*-acetyl-2'-*O*-(2",3",4"-tri-*O*-acetyl-α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-6-*O*-benzyl-2,4-dideoxy-β-D-*xylo*-hexopyranoside (**37**)*

Method A

Glycosylation of the disaccharide **9** (109 mg, 0.2 mmol) by the glycosyl donor **11** (82 mg, 1.2 mol-equiv.) initially used conditions similar to the synthesis of trisaccharide **26**. After 1.5 h at room temperature more acid (175 μL, 0.13 mol-equiv.) was added and the reaction proceeded for 2 h at room temperature, after which it was quenched by addition of NEt_3 (100 μL). Work-up followed the procedure described for **18**. Flash chromatography (EtOAc–hexanes; 7:3, 100 mL; 8:2, 100 mL) gave the orthoester **34** (87 mg, 54%). Further elution of the column gave the trisaccharide **35** as a colourless glass (18 mg, 11%). Both compounds were characterized by NMR spectroscopy (Tables 6 and 7).

Method B

A mixture of the disaccharide **10** (103 mg, 0.3 mmol), the donor **11** (71 mg, 1.12 mol-equiv.), and activated powdered 4Å molecular sieves (400 mg) in anhydrous CH_2Cl_2 (7 mL) was stirred 18 h under N_2 at room temperature. *N*-Iodosuccinimide (59 mg, 1.4 mol equiv.) and a saturated solution of triflic acid (0.15 M, 740 μL, 0.56 mol-equiv.) were added to the mixture, which was protected from light, and stirred 6 h at room temperature. NEt_3 (100 μL) was added to the mixture and work-up was carried out as described for the preparation of **18**. Flash chromatography ($CHCl_3$–MeOH, 50:1) gave a mixture (75:25, 110 mg, 71%) of trisaccharides **35** and **37** that could not be separated. They were characterized by NMR spectroscopy (Tables 6 and 7).

*Methyl 2-acetamido-2,4-dideoxy-3-*O*-[3'-*O*-(α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-β-D-*xylo*-hexopyranoside (**36**) and methyl 2-acetamido-2,4-dideoxy-3-*O*-[2'-*O*-(α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-β-D-*xylo*-hexopyranoside (**38**)*

The mixture of trisaccharides **35** and **37** (75:25, 110 mg) was dissolved in anhydrous MeOH (9 mL) and a solution of NaOMe (1 M, 200 μL) in MeOH was added. The mixture was stirred 18 h at room temperature, deionized with amberlite IR-120 (H+) resin, and filtered. The resin was rinsed with MeOH (3 mL) and the combined filtrates were concentrated. Pd–C catalyst (10%, 50 mg) was added to a solution of the residue in MeOH (9 mL) and the mixture was hydrogenated for 18 h at 60 psi. The catalyst was fil-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

tered off, rinsed with MeOH (3 mL), and the combined filtrates were concentrated. Reversed-phase HPLC (C-18 column, H_2O) gave the pure trisaccharide **36** (43 mg, 84%), isolated as a white powder upon freeze-drying; $[\alpha]_D^{25}$ −73.1 (*c* 0.45, MeOH). Anal. calcd. for $C_{21}H_{37}NO_{13}$: C 49.3, H 7.3, N 2.7; found: C 49.0, H 7.3, N 2.8.

Further elution of the column gave the pure trisaccharide **38** (13 mg, 75%) isolated as a white powder upon freeze-drying; $[\alpha]_D^{25}$ −71.6 (*c* 0.5, MeOH). Anal. found: C 49.0, H 7.4, N 2.9.

*Ethyl 3-O-(2',3',4'-tri-O-acetyl-α-L-rhamnopyranosyl)-2,4-di-O-benzoyl-1-thio-α-L-rhamnopyranoside (**40**)*

A solution of the alcohol **39** (12) (522 mg, 1.25 mmol) in anhydrous CH_2Cl_2 (50 mL) containing powdered activated molecular sieve 4Å (2 g) and silver trifluoromethanesulfonate (651 mg, 2 mol-equiv.) was stirred 2 h in the dark under N_2 and cooled to −75°C. A solution of tri-*O*-acetyl-α-L-rhamnopyranosyl bromide (15) (598 mg, 1.35 mol-equiv.) in anhydrous CH_2Cl_2 (5 mL) was added dropwise and the mixture was allowed to reach −50°C over 2 h, at which temperature it was left for an additional 0.5 h. NEt_3 (270 μL) was added to the reaction mixture and solids were filtered off on Celite. The solids were rinsed with CH_2Cl_2 (150 mL), and the combined filtrates washed with saturated aqueous $NaHCO_3$ (50 mL), H_2O (50 mL), and dried. Concentration and chromatography (hexanes–EtOAc; 6:2, 200 mL; 6:3, 400 mL) gave the disaccharide **40** (620 mg, 72%) as a colourless glass; $[\alpha]_D^{25}$ −1.09 (*c* 1.1, $CHCl_3$). Anal. calcd. for $C_{34}H_{40}O_{13}S$: C 59.3, H 5.8; found: C 59.4, H 6.0.

*Methyl 2-acetamido-3-O-[2',4'-di-O-benzoyl-3'-O-(2",3",4"-tri-O-acetyl-α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-4,6-O-benzylidene-2-deoxy-β-D-glucopyranoside (**42**)*

A mixture of the acceptor **41** (274 mg, 0.85 mmol) (16), the disaccharide thioglycoside **40** (698 mg, 1.2 mol-equiv.), and powdered activated molecular sieves 4Å (1.6 g) in anhydrous CH_2Cl_2 (40 mL) was stirred 18 h under N_2 at room temperature. *N*-Iodosuccinimide (259 mg, 1.35 mol-equiv.) and a saturated solution of triflic acid (0.15 M, 2.6 mL, 0.5 mol-equiv.) in CH_2Cl_2 were added to the mixture, which was protected from light and stirred 2 h under N_2 at room temperature. NEt_3 (200 μL) was then added and work-up was carried out as described for the preparation of **18**. Flash chromatography (EtOAc–hexanes, 65:35) gave the pure trisaccharide **42** (544 mg, 67%) as a colourless glass. Combined impure fractions containing mostly **42** were subjected to reversed-phase HPLC (C-18 column, CH_3CN–H_2O 6:4) and gave additional pure trisaccharide **42** (31 mg, 4%); $[\alpha]_D^{25}$ −6.1 (*c* 0.8, $CHCl_3$). Anal. calcd. for $C_{48}H_{55}NO_{19}$: C 60.7, H 5.8, N 1.5; found: C 60.6, H 5.7, N 1.42.

*Methyl 2-acetamido-3-O-[2',4'-di-O-benzoyl-3'-O-(2",3",4"-tri-O-acetyl-α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-2-deoxy-β-D-glucopyranoside (**43**)*

A solution of the acetal **42** (895 mg, 0.94 mmol) in 60% acetic acid (30 mL) was stirred 1 h at 100°C, cooled to room temperature, and concentrated. Residual acid was coevaporated with a mixture of toluene–MeOH (10:1, 3 × 10 mL) and flash chromatography ($CHCl_3$–MeOH, 30:1) of the dry residue gave the pure diol **43** (637 mg, 78%) as a white powder; $[\alpha]_D^{25}$ +31.0 (*c* 0.3, $CHCl_3$). Anal. calcd. for $C_{41}H_{51}NO_{19}$: C 57.1, H 6.0, N 1.6; found: C 57.3, H 6.0, N 1.8.

*Methyl 2-acetamido-6-bromo-3-O-[2',4'-di-O-benzoyl-3'-O-(2",3",4"-tri-O-acetyl-α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-2,6-dideoxy-β-D-glucopyranoside (**44**)*

Imidazole (125 mg, 8 mol-equiv.), triphenylphosphine (238 mg, 4 mol-equiv.), and carbon tetrabromide (757 mg, 10 mol-equiv.) were added to a stirred solution of the diol **43** (196 mg, 0.22 mmol) in a mixture of anhydrous CH_3CN and anhydrous pyridine (1:1, 6 mL). After 22 h at room temperature MeOH (400 μL) was added, solvents were evaporated, and the residue dissolved in EtOAc (100 mL) was washed successively with 1 M aqueous HCl (2 × 50 mL), saturated aqueous $NaHCO_3$ (50 mL), and H_2O (50 mL). The washings were reextracted with EtOAc (2 × 50 mL) and the combined organic phases were dried and concentrated. Chromatography ($CHCl_3$–MeOH, 60:1) of the residue gave the trisaccharide **44** contaminated with triphenylphosphine oxide (124 mg) and the pure trisaccharide **44** (58 mg, 27%). Rechromatography (solvent as above) of the impure trisaccharide again yielded a contaminated fraction (80 mg) and the pure trisaccharide **44** (36 mg, 17%). The remaining contaminated trisaccharide was finally isolated pure (21 mg, 11%) by preparative TLC (solvent as above). The trisaccharide **44** was isolated as a colourless glass, $[\alpha]_D^{25}$ +35.0 (*c* 0.83, $CHCl_3$). Anal. calcd. for $C_{41}H_{50}BrNO_{18}$: C 53.2, H 5.4, N 1.5; found: C 53.1, H 5.6, N 1.3.

*Methyl 2-acetamido-2,6-dideoxy-3-O-[3'-O-(α-L-rhamnopyranosyl)-α-L-rhamnopyranosyl]-β-D-glucopyranoside (**46**)*

A solution of the brominated trisaccharide **44** (115 mg, 0.14 mmol) in EtOH (9 mL) containing NEt_3 (50 μL, 2.6 mol-equiv.) was hydrogenated 18 h at 60 psi in the presence of Pd–C catalyst (10%, 100 mg). More catalyst (20 mg) was added and hydrogenolysis was continued during another 8 h at 60 psi. The catalyst was filtered off, rinsed with dichloromethane (20 mL), and the combined filtrates were concentrated. A solution of the residue in CH_2Cl_2 (30 mL) was washed successively with 1 M HCl (25 mL), saturated aqueous $NaHCO_3$ (20 mL), and H_2O (20 mL). The washings were reextracted with CH_2Cl_2 (2 × 20 mL) and the combined organic phases were dried and concentrated to give the pure trisaccharide **45**, characterized by ^1H NMR spectroscopy (Table 6). Compound **45** was used directly in the next step. It was concentrated from anhydrous MeOH (2 × 3 mL), dissolved in anhydrous MeOH (6 mL), and a solution of NaOMe, 1 M in MeOH (600 μL), was added. The mixture was stirred 18 h at room temperature, more NaOMe was added portionwise over 3 h (2 × 200 μL), and stirring was continued during 2 h. The solution was deionized with Amberlite IR-120 (H^+) resin, diluted with MeOH (8 mL), filtered and the resin was washed with MeOH (10 mL). The combined filtrates were concentrated to dryness and chromatography (EtOAc–MeOH–H_2O, 7.5:1.5:1) gave **46**, which was finally purified on a Biogel P-2 column (H_2O). The trisaccharide **46** was obtained pure (53 mg, 84%) as a white solid by evaporation from MeOH; $[\alpha]_D^{25}$ −74.9 (*c* 0.6, MeOH). Anal. calcd. for $C_{21}H_{37}NO_{13}$: C 49.3, H 7.3, N, 2.7; found: C 48.9, H 7.5, N 2.8.

Preparation and structure of 7-azaindolium salts containing unusual chloro-copper(II) anionic units

JACQUES POITRAS, MARTIN LEDUC, AND ANDRÉ L. BEAUCHAMP[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Québec), Canada H3C 3J7

Received June 23, 1992[2]

JACQUES POITRAS, MARTIN LEDUC, and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **71**, 549 (1993).

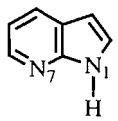
Dark-red crystals of $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$ were obtained by addition of HCl to equimolar amounts of 7-azaindole (Haza) and $CuCl_2 \cdot 2H_2O$ in methanol. They were shown by X-ray diffraction (triclinic, $P\bar{1}$, a = 9.396(1), b = 9.894(1), c = 15.958(1), Å, α = 106.10(1)°, β = 98.25(1)°, γ = 105.56(1)°, Z = 1, R = 0.031) to contain infinite chains in which the basic $[Cu_5Cl_{14}(H_2O)_4]^{4-}$ pattern is built up from *trans*-$CuCl_2(H_2O)_2$, $[CuCl_3(H_2O)]^-$, and dichloro-bridged $[Cu_2Cl_6]^{2-}$ species. In the idealized chain, these units occur in the 1:2:1 ratio, but disorder is present and some of the $CuCl_2(H_2O)_2$ units are randomly replaced by $[CuCl_3(H_2O)]^-$. The Cu atoms have a roughly square-planar primary coordination, and connection along the chain is achieved by weaker apical Cu–Cl bridging interactions. All azaindole molecules are present as uncoordinated N7-protonated monocations. A related $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$ salt was obtained as a side-product of the reaction of 7-azaindole with excess $CuCl_2 \cdot 2H_2O$ in methanol without acid. In these brown crystals (triclinic, $P\bar{1}$, a = 9.308(1), b = 9.964(1), c = 19.212(4) Å, α = 76.67(1)°, β = 79.35(1)°, γ = 75.27(1)°, Z = 2, R = 0.046), the $[Cu_6Cl_{16}(H_2O)_6]^{4-}$ pattern of the chain contains the same three building units as above, but in the 2:2:1 ratio. In both salts, the polymeric chloro-copper chains are parallel and separated by azaindolium cations stacked along the same direction. The structures are stabilized by networks of hydrogen bonds involving the azaindolium cations, the chlorine atoms, and water molecules in the chloro-copper chain, and a noncoordinated Cl^- ion. Most of the azaindolium cations are disordered. The influence of N7-protonation on the infrared spectrum of azaindole is discussed.

JACQUES POITRAS, MARTIN LEDUC et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **71**, 549 (1993).

Les cristaux rouge sombre de $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$ ont été obtenus par addition de HCl à des quantités équimolaires de 7-azaindole (Haza) et de $CuCl_2 \cdot 2H_2O$ dans le méthanol. La diffraction des rayons X (triclinique, $P\bar{1}$, a = 9.396(1), b = 9.894(1), c = 15.958(1) Å, α = 106.10(1)°, β = 98.25(1)°, γ = 105.56(1)°, Z = 1, R = 0.031) démontre la présence de chaînes infinies dans lesquelles le motif de base $[Cu_5Cl_{14}(H_2O)_4]^{4-}$ est constitué d'espèces *trans*-$CuCl_2(H_2O)_2$, $[CuCl_3(H_2O)]^-$ et $[Cu_2Cl_6]^{2-}$ à double pont chlore. La chaîne idéalisée renferme ces motifs selon un rapport 1 : 2 : 1, mais la présence de désordre entraîne le remplacement aléatoire de quelques segments $CuCl_2(H_2O)_2$ par $[CuCl_3(H_2O)]^-$. Les atomes de Cu possèdent une coordination primaire à peu près plan carré et la connexion le long de la chaîne est assurée par des interactions axiales Cu–Cl pontantes. Toutes les molécules d'azaindole sont sous forme de monocations protonés en N7 et non coordonnés. Un sel analogue $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$ a été obtenu comme produit secondaire de la réaction du 7-azaindole avec un excès de $CuCl_2 \cdot 2H_2O$ dans le méthanol sans acide. Ces cristaux bruns (triclinique, $P\bar{1}$, a = 9.308(1), b = 9.964(1), c = 19.212(4) Å, α = 76.67(1)°, β = 79.35(1)°, γ = 75.27(1)°, Z = 2, R = 0.046) contiennent des chaînes dont le motif $[Cu_6Cl_{16}(H_2O)_6]^{4-}$ renferme les trois mêmes espèces que ci-haut, mais selon un rapport 2 : 2 : 1. Dans les deux sels, les chaînes polymères chloro-cuivriques sont parallèles et séparées par des cations azaindolium empilés selon la même direction. Les structures sont stabilisées par un réseau de liaisons hydrogène impliquant les cations azaindolium, les chlores et l'eau de la chaîne chloro-cuivrique, et un anion Cl^- non coordonné. La plupart des cations azaindolium sont désordonnés. L'influence de la protonation en N7 sur le spectre infrarouge de l'azaindole est discutée.

Introduction

In many of the complexes of 7-azaindole (Haza, Scheme 1) reported so far, the ligand monoanion plays a bridging role similar to that of carboxylates in stabilizing dinuclear units. For instance, copper(II) azaindolate has been found to contain discrete $Cu_2(aza)_4$ dimeric units with the "windmill" tetra(azaindolate)dimetal structure of copper(II) acetate (1). A similar bridging role has been observed in compounds with several other metals (2–4). As yet, unidentate binding of the anionic form has been observed only in the $[CH_3Hg(aza)]$ molecule, which was recently shown to exist as an N1-bonded monomer (4–6). Because azaindole is a much weaker acid, adduct formation with the neutral molecule is anticipated to occur more commonly than with carboxylic acids. Nevertheless, when this work was undertaken, only a few simple adducts had been structurally characterized, e.g., those with CH_3Hg^+ (4, 6), $ZnCl_2$ (7), and $Rh_2(carboxylate)_4$ (8, 9). In a previous paper (10), we reported on the reactions of



SCHEME 1

azaindole with copper(II) chloride in methanol, under conditions that favored ligand binding in the neutral form. To complete our survey of the $CuCl_2$–azaindole system, some experiments were run in slightly acidic solution, conditions that were known to lead to N7-protonated azaindolium salts with $ZnCl_2$ (7). This was intended to yield salts of simple chloro-copper anions that would provide routine infrared diagnostics to distinguish between coordinated and protonated azaindole. However, the composition of the material obtained did not correspond to any known type of halo-copper(II) anions (11). We also isolated another salt of unusual composition as a by-product of reactions in neutral solution. The crystallographic work below provides the first examples of chlorine-bridged chains built from *three* types of chloro-copper(II) units with different compositions.

Experimental section

$CuCl_2 \cdot 2H_2O$ (BDH) and 7-azaindole (Aldrich) were used as received. The methanol used was of reagent grade. Infrared spectra (4000–250 cm^{-1}) were recorded as KBr pellets with a Perkin–Elmer 783 spectrophotometer.

Reactions

$(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$

To a solution of 1.16 g (10 mmol) of 7-azaindole in 30 mL of methanol was added a solution of 1.71 g (10 mmol) of $CuCl_2 \cdot 2H_2O$ in 30 mL of methanol. A light brown mixture of $CuCl_2(Haza)_2$ and $Cu_4OCl_6(Haza)_4$ precipitated immediately, and redissolved instantly on addition of concentrated HCl (1 mL) to give a lime-green solution. Dark-red prismatic crystals appeared over 2 days, as the solvent slowly evaporated. Yield: 2.06 g (69%).

$(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$

To 3.41 g (20 mmol) of $CuCl_2 \cdot 2H_2O$ in 30 mL of methanol was added 0.59 g (5 mmol) of 7-azaindole in 20 mL of the same solvent. The mixture was stirred for several minutes and filtered to remove 0.58 g of the light-green precipitate of $CuCl_2(Haza)_2$. The filtrate was left at room temperature for slow evaporation, and after 10 days a small amount of dark-brown crystals of $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$ mixed with a brown powder of $Cu_4OCl_6(Haza)_4$ was obtained.

Crystallographic measurements and structure determination

The crystallographic work was carried out with an Enraf–Nonius CAD-4 diffractometer following similar methods for both compounds. The reduced triclinic cell was determined from a set of 25 randomly distributed reflections, generated by the automatic search routine of the CAD-4 software and centred in the counter aperture. The Niggli coefficients unambiguously ruled out all lattices of symmetry higher than triclinic, leaving $P\bar{1}$ and $P1$ as possible space groups.

The crystal data are collected in Table 1. The intensities were measured as described earlier (12). Six standard reflections were monitored for crystal decay every hour and for misorientation every 200 reflections. In the case of $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$, a half-sphere of data (hkl, $h\bar{k}l$, $\bar{h}kl$, $\bar{h}\bar{k}\bar{l}$) was collected (6300 reflections). The data were corrected for absorption (Gaussian integration, transmission range = 0.26–0.54). For $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$, the whole sphere was measured (9368 reflections) and averaging (R_{av} = 0.016) yielded a set of 4684 independent hkl, $\bar{h}kl$, $h\bar{k}l$, and $hk\bar{l}$ data. An absorption correction was not deemed necessary, considering the low absorption coefficient and small size of the crystal. The intensities were corrected for the effects of Lorentz and polarization.

Similar strategies were applied to refine both structures. The centric $P\bar{1}$ space group was clearly favored in both cases by the slightly hypercentric distribution of the normalized structure factors. Full-matrix least squares were used to refine all non-hydrogen atoms isotropically. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with individual weights w based on counting statistics. The Cl and Cu atoms were then allowed to refine anisotropically, while the remaining non-hydrogen atoms were kept isotropic. At this stage, occupancy factors were determined for the disordered azaindole rings. Hydrogens were introduced at idealized positions (C(N)—H = 0.95 Å, U_{iso} = 0.05 Å^2). Their parameters were not refined, but their coordinates were recalculated after each least-squares cycle. Anisotropic temperature factors were finally refined for the non-hydrogen atoms. The scattering curves were taken

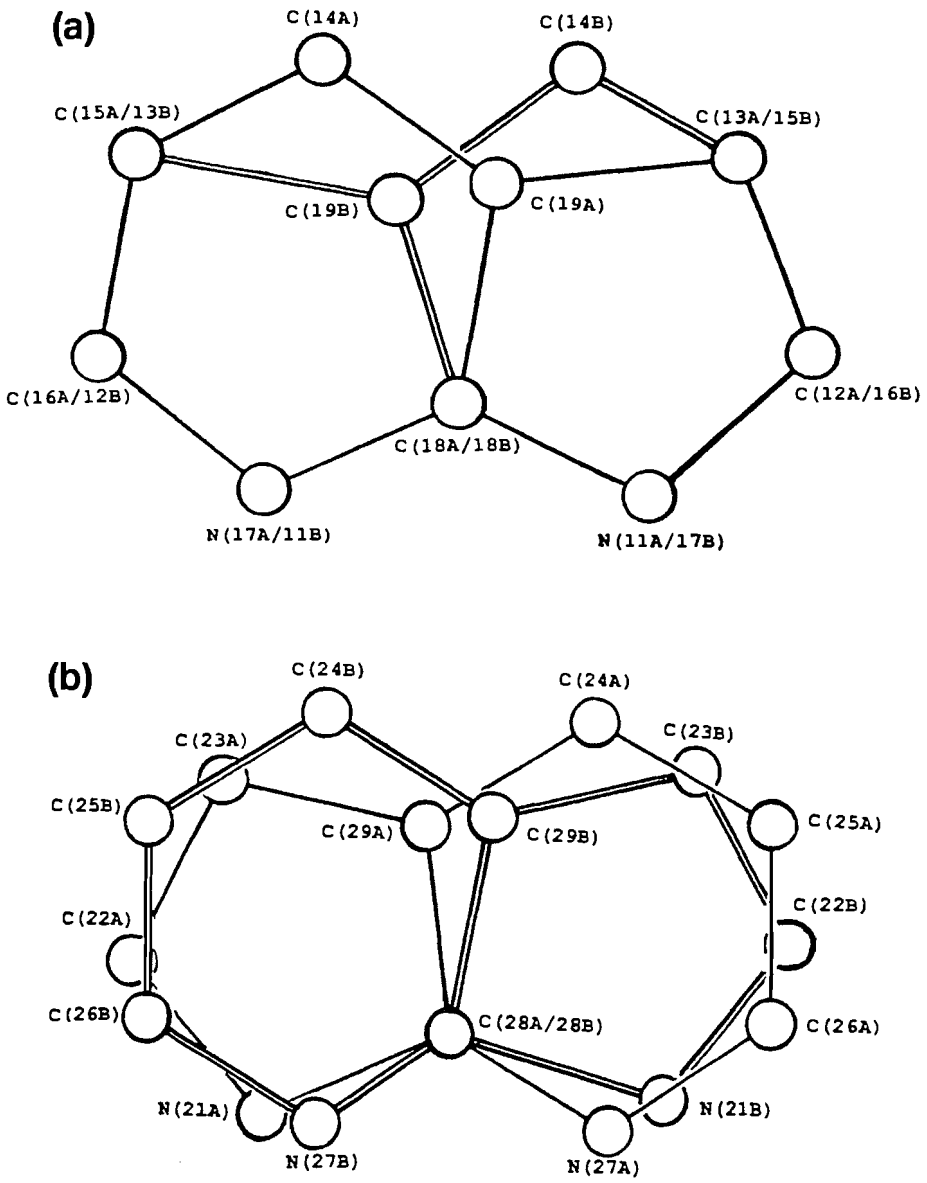

FIG. 1. Disorder of the azaindolium cations in $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$. (*a*) Cation 1 (occupancies = 0.80(A)/0.20(B)). (*b*) Cations 2 (0.50/0.50) and 3 (0.70(A)/0.30(B)). Pattern *a* (0.80(A)/0.20(B)) is also found for cation 1 in $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$.

from standard sources (13). The contributions of Cu and Cl to anomalous dispersion were those of Cromer (14).

Structure resolution of $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$

The three independent Cu atoms were located by the direct methods of SHELX-86 (15). Interpretation was continued with the SHELX-76 package (16). From a difference Fourier (ΔF) map, the atoms attached to Cu, an uncoordinated Cl^- ion, and non-hydrogen atoms for three independent azaindolium cations could be identified. They were all refined by full-matrix least-squares procedures. When convergence was reached with this model (R = 0.166), abnormally high thermal parameters indicated that the azaindolium ions were all disordered. Inspection of the ΔF map revealed that most of the strongest residual peaks were partners of azaindolium atoms already located. For ion 1 (Fig. 1*a*), the five-membered ring of one individual was roughly superimposed with the six-membered ring of the other, and vice versa. This pattern was encountered with free azaindole (4) and $Mo_2(acetate)_2(azaindolate)_2 \cdot 2DMF$ (2). The nitrogen atoms were identified from the positions and distances to hydrogen-bond acceptors. The unresolved atoms were assigned full occupancies, whereas the resolved C(14A), C(14B), C(19A), and C(19B) positions were temporarily assigned half-occupancies. The coordinates and isotropic temperature factors were refined. The temperature factors of the resolved components were then fixed at 0.07 Å^2 (~mean of unresolved atoms). The occupancy factors were refined, but those of fractional atoms belonging to the same disordered individual were constrained to be equal. The refined occupancies of 1.25 for C(14A) and C(19A) and 0.29 for C(14B) and C(19B) were scaled down to 0.80 and 0.20, respectively, and fixed for the rest of the refinement. The coordinates and temperature factors of these fractional atoms were finally refined individually, together with those of the remaining non-hydrogen atoms. Disorder for azaindolium 2 followed a different pattern (Fig. 1*b*). All atoms were disordered over two resolved sites, except C(28A/28B), which was assigned full occupancy. By applying constraints as above, the normalized occupancies were found to be 0.50/0.50. The same pattern was observed for cation 3 with occupancy factors of 0.70/0.30.

For the final least-squares cycles, hydrogen atoms with appropriate occupancies were fixed at idealized positions, which were recalculated after each cycle. The water hydrogens were not located. The final residuals were R = 0.046 and R_w = 0.061. The

background in the final ΔF map was within ±0.6 e Å^{-3}. The refined coordinates are listed in Table 2.[3]

Attempts were made to refine the structure in the non-centric group, but the regions disordered in $P\bar{1}$ remained disordered in $P1$, and refinement was extremely unstable and erratic because of very high correlations. The $P\bar{1}$ model was retained.

Structure resolution of $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$

The SHELX-86 package (15) revealed the presence of three independent Cu atoms, one of which occupied the inversion centre at the cell origin. A ΔF map (16) provided positions for all chlorine and oxygen atoms. Three independent azaindolium cations could also be recognized in the map, two of them showing extensive peak doubling due to disorder. One set of peaks defining a reasonable geometry was first introduced with full occupancy. Isotropic refinement by full-matrix least squares converged to R = 0.067. Strong residual peaks were found in the ΔF map near azaindolium cations. Disorder for ion 1 followed the pattern encountered for ion 1 in the previous compound (Fig. 1*a*). Cation 2 was not disordered, but ion 3 showed a new type of disorder with all atomic positions resolved (Fig. 2). No site could be assigned to nitrogen exclusively, since the N(37/C34)–N(31/C33) and the C(34/N37)–C(33/N31) pairs could participate equally well in hydrogen bonding and no indications were provided by ΔF peaks or temperature factors. Thus, the cation had to be statistically distributed over two orientations with the N1–N7 and C3–C4 sides interchanged by 180° rotation about an axis through C(32/C32) and the inversion center. Average "half-C half-N" scattering curves were used for mixed positions. This cation was further disordered by the crystallographic inversion centre over two equally populated orientations, in which the six- and the five-membered rings were interchanged. Thus, any cation can adopt altogether four possible arrangements. The refined coordinates likely represent averages of unresolved, but not exactly coincident, atomic positions. For any given cation, the N1-H group is probably slightly closer to its hydrogen-bond acceptor, thereby lengthening the intermolecular contacts involving C3-H.

All non-hydrogen atoms were refined anisotropically. Hydrogens were introduced at idealized positions with appropriate occupancy factors. The coordinates were recalculated after each least-squares cycle. Water hydrogens were not located. The final residuals were R = 0.031 and R_w = 0.036. The final ΔF map had a background below ±0.4 e Å^{-3}. The refined coordinates are listed in Table 3. As above, attempts to refine a non-centric $P1$ model failed.

Although agreement with the X-ray data is excellent, the distance obtained for Cu(1)—O(11) is unusually long (2.19 Å): the apparent "stretch" corresponds to ~70% of the difference between the normal Cu—OH_2 and Cu—Cl bond lengths (~1.99 and ~2.27 Å, respectively). This large distance and the O(11) thermal ellipsoid elongated along the Cu—O bond suggest that the O(11) site is partly occupied by chlorine, so that some of the $CuCl_2(H_2O)_2$ units around Cu(1) would actually be $[CuCl_3(H_2O)]^-$ (disordered over two orientations across the inversion centre). However, any chlorine transferred near Cu(1) has to be removed from somewhere else in the structure to keep the charge balanced. Since the Cu—Cl bonds are all normal, the source of chlorine is probably the free anion site Cl(0), where the Cl^- ion is presumably replaced by water. Thus, the overall effect is a balanced transfer of water and chlorine to the Cl(0) and O(11) sites, respectively.

Various attempts were made to estimate the extent of exchange. First, the final cycles of refinement were rerun assuming full transfer (that is, Cl(0) occupied by oxygen, O(11) by chlorine). The rest of the structure remained essentially unchanged, but the temperature factor became negative for Cl(0) and extremely large for the O(11) site. Therefore, the description with these sites as initially populated was close to reality. Similarly, assuming no exchange and keeping U_{iso} of O(11) and Cl(0) fixed at 0.07 Å^2, refinement of occupancies yielded values close to unity for these atoms, again indicating that the extent of exchange was relatively small. At first glance, a small amount of substitution seems to be inconsistent with the large Cu—(O/Cl) distance observed, but the results reported recently for a related substitution disorder in $MoCl_3(PR_3)_3$/$MoOCl_2(PR_3)_3$ solid solutions (17) indicate that there is no contradiction. As for the present structure, resolved peaks did not appear in the Fourier map for the two types of atoms. The "apparent" Mo—(O/Cl) distance was found to increase, as expected, when the Mo=O bond of $MoOCl_2(PR_3)_3$ was replaced by the Mo—Cl bond of the isostructural $MoCl_3(PR_3)_3$ molecule. Because of the higher atomic number of chlorine, the Mo—(O/Cl) distance increased rapidly as a function of substitution at low substitution levels. The "distance vs. composition" curve (Fig. 10 of ref. 17) reveals that ~25% substitution of O by Cl is enough to "stretch" the Mo=O bond by 70% of the difference between the Mo=O and Mo—Cl bond lengths. Since extensive disorder in other parts of the present Cu structure precludes any reliable evaluation of the extent of exchange from X-ray data alone, it will be assumed that the observed 70% "stretch" of our Cu—O(11) distance is also produced by ~25% substitutions of Cu—OH_2 by Cu—Cl bonds. A final check was done by refining the structure with occupancies adjusted to fit the average number of electrons (1.14 for O(11), 0.87 for Cl(0)). Refinement converged to the same R and R_w factors, the rest of the structure remained unaffected, and the coordinates of O(11) and Cl(0) did not shift significantly. The changes were picked up by the temperature factors: U_{eq} = 0.088 Å^2 for O(11) and 0.047 Å^2 for Cl(0). Thermal motion for O(11) is slightly high, but not unreasonable considering that O(11) spans two unresolved positions ~0.28 Å apart.

Results and discussion

In a previous paper (10), we reported on the green *trans*-$CuCl_2(Haza)_2$ and $[CuCl_2(Haza)_2][Cu(Haza)_4]Cl_2$ compounds obtained from methanol solutions containing $CuCl_2 \cdot 2H_2O$ and excess azaindole. Under appropriate conditions, equimolar mixtures led to the tetranuclear μ_4-oxide cluster $Cu_4OCl_6(Haza)_4$ in pure form. When no special precautions were taken, some $CuCl_2(Haza)_2$ precipitated first and was difficult to remove from the brown compound.

This part of our study on $CuCl_2 \cdot 2H_2O$ reactions with azaindole was intended to provide azaindolium salts from which infrared features characteristic of this cation could be identified. A 1:1 methanol solution was prepared and concentrated HCl was added. The light-brown mixture of $CuCl_2(Haza)_2$ and $Cu_4OCl_6(Haza)_4$ redissolved instantly and a lime-green solution resulted. By evaporation, dark-red prismatic crystals of $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$ were isolated in good yield.

A small amount of crystals, first believed to be of the same material, was obtained from a reaction with excess $CuCl_2 \cdot 2H_2O$ without added acid. After the initially formed

[3]The supplementary material includes a table of infrared frequencies for azaindolium salts and crystallographic results (refined temperature factors, hydrogen coordinates, distances and angles in the azaindole rings, distances and angles for hydrogen bonds, least-squares plane calculations and structure factor amplitudes) for both structures (68 pages). Complete set of data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen coordinates, distances and angles in the azaindole rings, and distances and angles for hydrogen bonds have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

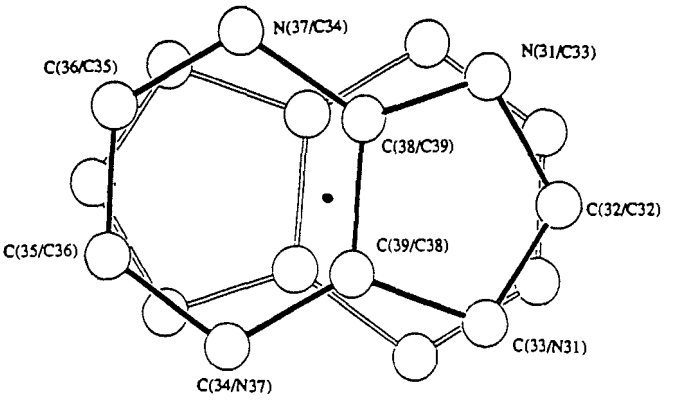

FIG. 2. Disorder of azaindolium cation 3 in $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$ (occupancies = 0.50/0.50). The crystallographic inversion centre is indicated by a black dot.

$CuCl_2(Haza)_2$ complex was filtered, the green solution was allowed to evaporate in open air, whereupon a brown powder shown to be $Cu_4OCl_6(Haza)_4$ appeared, mixed with brown crystals. The latter crystals were expected to contain the azaindolium cation, since two H^+ ions were liberated for each $Cu_4OCl_6(Haza)_4$ molecule formed. Preliminary X-ray work showed cell parameters different from those of the above dark-red compound. The composition of this material was shown by X-ray diffraction to be $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$.

Crystal structures of $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$ and $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$

Although the formulas look very different, these compounds are actually closely related. In both cases, azaindole is present only as the uncoordinated N7-protonated cation and the unit cell includes free Cl^- anions. Infinite chains of chlorine-bridged copper atoms are generated from *three* kinds of square-planar units, namely *trans*-$CuCl_2(H_2O)_2$ about Cu(1), $[CuCl_3(H_2O)]^-$ about Cu(2), and chlorine-bridged $[Cu_2Cl_6]^{2-}$ dimers containing Cu(3). The preference of copper(II) for square-planar primary coordination is well established, as well as its ability to form one or two weaker bridging axial bonds with halogens of adjacent units, resulting in square-pyramidal [4+1] or elongated octahedral [4+2] overall coordinations (11). In the case of $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$, the tris-copper asymmetric unit is repeated by crystallographic inversion centres at both the Cu(1) and the Cu(3) ends, generating the infinite chain of Fig. 3, in which the basic repetition pattern (within braces) is ···Cu(3)-{Cu(3)-Cu(2)-Cu(1)-Cu(1)-Cu(2)-Cu(3)}Cu(3)···. In the case of $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$ (Fig. 4), the basic pattern is ···Cu(3){Cu(3)-Cu(2)-Cu(1)-Cu(2)-Cu(3)}Cu(3)···, with only one Cu(1) centre instead of two. This compound shows evidence for a small amount of disorder about Cu(1), on which we will comment below. The present discussion deals with the pattern of Fig. 4 representing the major part of the structure.

Polymeric arrangements are often observed for chloro-Cu(II) species in the solid state. For instance, chain or layer structures are found for salts of the $[CuCl_4]^{2-}$ ion (18, 19). Various salts of composition A^ICuCl_3 consist of $[CuCl_3]^-$ units or chlorine-bridged $[Cu_2Cl_6]^{2-}$ dimers connected into a linear chain (20–24). Salts of $[CuCl_3(H_2O)]^-$ are also known (25). A number of infinite one-dimensional structures resulting from stacking of higher chloro-Cu(II) oligomers have also been described (20, 26, 27). Chains are known for $CuCl_2L_2$ compounds with ligands L such as imidazoles (28) and pyridines (29). In most of these materials, the chains are constructed from a single square-planar Cu(II) monomer. Only a few examples of arrangements created from two copper units alternating along the chain are known (30–32). To our knowledge, periodic chains of the types observed here, based on *three* different ligand compositions, are unprecedented. The distances and angles around copper for the two structures are listed in Table 4.

(a) Cu(1): trans-*$CuCl_2(H_2O)_2$*

The Cu—OH_2 (mean 2.006 Å) and the short Cu—Cl bonds (2.267(1)Å) in $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$ are similar to those found for the same unit in other compounds (18, 31, 33). In $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$, the same distance is obtained for the short Cu—Cl bonds, but the observed Cu—OH_2 distance is ~0.18 Å longer. This value is artificially high because some $CuCl_2(H_2O)_2$ units are statistically replaced by $[CuCl_3(H_2O)]^-$ along the chain (see experimental part and (*f*) below). Cu(1) occupies an inversion centre, so that all *trans* angles are exactly 180° and the square plane is rigorously planar, whereas departure from 90° in the *cis* angles is small (< 2.2°). In $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$, Cu(1) has no local symmetry. The *cis* angles between the four strong bonds (89.2°–92.3°) are close to 90°. The atom-to-plane distances (Table S-5, supplementary material) indicate a small, but significant, tetrahedral distortion, which is also reflected by the *trans* angles being appreciably different from 180°.

(b) Cu(2): $[CuCl_3(H_2O)]^-$

The structures observed for this ion in the two compounds are very similar, although distortion is a little greater in $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$. The Cu—Cl bonds in the square plane (mean 2.284 Å) are comparable to those found earlier (25), as are the Cu—OH_2 bonds (mean 1.992 Å). The *cis* angles range from 87.1° to 92.2°. The water molecule is displaced from the $CuCl_3$ plane by 0.2–0.3 Å on the Cl(32) side (supplementary material), distorting the Cl(23)—Cu(2)—O(21) angle to 173.1(1)° in $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$ and to 169.8(1)° in $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$. A normal bridging bond of ~2.8 Å is formed with Cl(11), but the sixth neighbour Cl(32), completing the elongated octahedron, is much more distant (~3.2 Å). Weaker interaction in the latter case is also reflected by the greater departure from 90° or 180° for the bonds involving this atom. It is not clear whether the Cu(2)–Cl(32) interaction should be described as a weak bond to a [4+2]-coordinated metal or an extra intermolecular contact with a [4+1] square-pyramidal entity. In any event, Cl(32) efficiently blocks the region of the sixth apex of a distorted octahedron around Cu(2).

(c) Cu(3): $[Cu_2Cl_6]^{2-}$

Two centrosymmetry related Cu(3) atoms define a dichloro-bridged dimer of the type found in various A^ICuCl_3 salts (20–23). The four short Cu—Cl bonds around Cu(3) (2.249(1)–2.309(1) Å) are comparable with those found in related salts (21, 22, 24). Within the bridge, the angles at Cu(3) and Cl(31) (mean values 82.8° and 97.2°, respectively) are typical of this type of bridging. A [4+1] square-pyramidal overall coordination around each Cu(3) centre is completed by an axial Cu(3)—Cl(21) bond of ~2.66 Å. Cu(3) is displaced by ~0.12 Å from the plane of the four strongly bonded Cl atoms, toward the apical Cl(21) atom, which is a common feature in square pyramids. This results

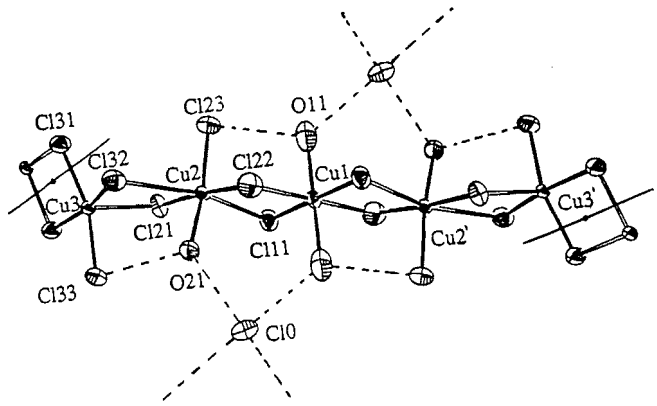

FIG. 4. ORTEP drawing of the $[Cu_5Cl_{14}(H_2O)_4]^{4-}$ unit. The asymmetric tris-copper segment is repeated by crystallographic inversion centres on Cu(1) and near Cu(3), generating the five-copper basic pattern of the infinite chain. Cl(0) is the uncoordinated Cl^- ion. Thermal ellipsoids correspond to 50% probability. Dashed lines represent hydrogen bonds.

in the angles between *trans* ligands being decreased to 163° and 170°.

(d) Azaindolium cations

The unit cell of $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$ includes three symmetry-independent azaindolium cations, all disordered over two orientations. This flat molecule is prone to disorder, because its van der Waals envelope does not change drastically if the five- and six-membered rings are interchanged by a 180° rotation about C8—C9. In both orientations, N1 and N7 remain properly oriented toward their hydrogen-bond acceptors. The kind of disorder found for cations of type 1 (Fig. 1*a*) has been observed in other structures where the N1–N7 side is firmly anchored to metal atoms (1, 2) or to hydrogen-bond acceptors (4). For cations of types 2 and 3 (Fig. 1*b*), the relative orientation of the two individuals is less constrained and only the C8 atoms remain unresolved. In $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$, one of the three independent cations (type 2) shows no evidence of disorder. Ion 1 shows the disorder pattern of Fig. 1*a*. Ion 3 is involved in a new, more complex, type of disorder (Fig. 2), in which four equally probable atomic distributions are obtained by interchanging the five- and six-membered rings, and the N1–N7 and C3–C4 sides.

The distances and angles in the azaindolium ions are listed in the supplementary material. Considering that apparent distortion results from the refined unresolved positions describing not exactly coincident atoms, the geometry is in reasonable agreement with those observed for free azaindole (4) or the azaindolium ion (7). The cations are planar within experimental error.

(e) Packing

A stereoview of the unit cell of $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$ is shown in Fig. 5. It includes the six-copper basic pattern of Fig. 3 for two adjacent chains. These parallel chains, translated along the *a* axis, define infinite layers, which also contain the uncoordinated Cl^- ions, near the $CuCl_2(H_2O)_2$ units. Between the layers, oriented in the same direction as the chloro-copper chains and just above the region occupied by the Cl^- ions, are found slanted stacks of azaindolium cations, separated by ~3.45 Å.

Cohesion between these components is provided to a large extent by hydrogen bonding. Within the chains (Fig. 3), both hydrogens of each water molecule form O—H···Cl bonds of 3.05–3.20 Å (normal range: 2.86–3.21 Å) (34) with favourably oriented Cl^- ions or coordinated chlorines (Table 5). Two adjacent chains provide each of the two nearby Cl^- ions in the middle of the cell with four roughly coplanar and orthogonal hydrogen bonds. Above this plane, a type 2 azaindolium cation forms an extra N—H···Cl bond of 3.20 Å (normal range: 2.91–3.52 Å) (34). A number of other hydrogen bonds are formed by other azaindolium ions with coordinated chlorines (Table S-4, supplementary material).

In the case of $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$ (Fig. 6), the infinite chloro-copper chains, represented by the five-copper pattern of Fig. 4, similarly form infinite layers with Cl^- ions inserted between $CuCl_2(H_2O)_2$ units of adjacent chains. The slanted stacks of azaindolium cations are also positioned between the layers, above the region of the Cl^- ions.

This structure can be regarded as derived from $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$ by removing one of the central $CuCl_2(H_2O)_2$ units, a Cl^- anion, and an imidazolium cation. This can be done without loss of the local stabilizing interactions along the chains. For instance, inside the chain, all water molecules form the same number of O—H···Cl bonds, the two symmetry-equivalent O—H···Cl(23) bonds being provided now by the same, instead of two distinct, $CuCl_2(H_2O)_2$ units (Fig. 4 and Table 6). Cutting one $CuCl_2(H_2O)_2$ unit removes two water molecules making hydrogen bonds with the Cl^- ions in the previous compound, but these are no longer needed, since a Cl^- ion has also been removed. The five-copper chain is ~3.45 Å shorter than the six-copper one, but since the imidazolium rings are roughly 3.45 Å thick, removing one cation shortens the stack by the same amount. Hence, each remaining azaindolium ion is facing the same pattern of hydrogen-bond acceptors as before and maintains similar interactions with the chain, without sacrificing inter-ring stacking stabilization.

(f) Substitution disorder in $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$

In this compound, some of the central $CuCl_2(H_2O)_2$ units (Fig. 4) are replaced by $[CuCl_3(H_2O)]^-$ groups, as a result of a partial interchange of Cl^- ions and water molecules between the O(11) and Cl(0) sites. Substitution does not appreciably affect the geometry about Cu(1), except for the "apparent" Cu—O(11) distance of 2.187(4) Å (Table 4), which is greater than for a normal Cu—OH_2 bond (~1.99 Å), although less than that of a Cu—Cl bond (~2.27 Å). By comparing with a related case of substitution disorder (17), the extent of interchange was estimated to be ~25% (see experimental section). As revealed by careful inspection of molecular packing (Fig. 6), mutual O(11)/Cl(0) substitution can take place without greatly affecting the overall structure, because water and chloride ions can play the same roles as ligands to Cu(1) and hydrogen-bond acceptors, whereas the O—H···Cl(0) bonds they form to one another are always retained. It is not clear, however, why no such substitution disorder is detected in $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$.

Infrared spectra of the azaindolium salts

A list of frequencies and tentative assignments for 7-azaindole and its protonated Cl^-, ClO_4^-, and $[Cu_5Cl_{14}(H_2O)_4]^{4-}$ salts are provided in the supplementary material. The infrared spectrum of azaindole has been discussed elsewhere (2, 6, 10). Protonation can be detected from new bands and significant shifts in the spectra. The N–H vibrations in

[c] $1 - x, -y, 1 - z$.
[d] $-x, -y, -z$.

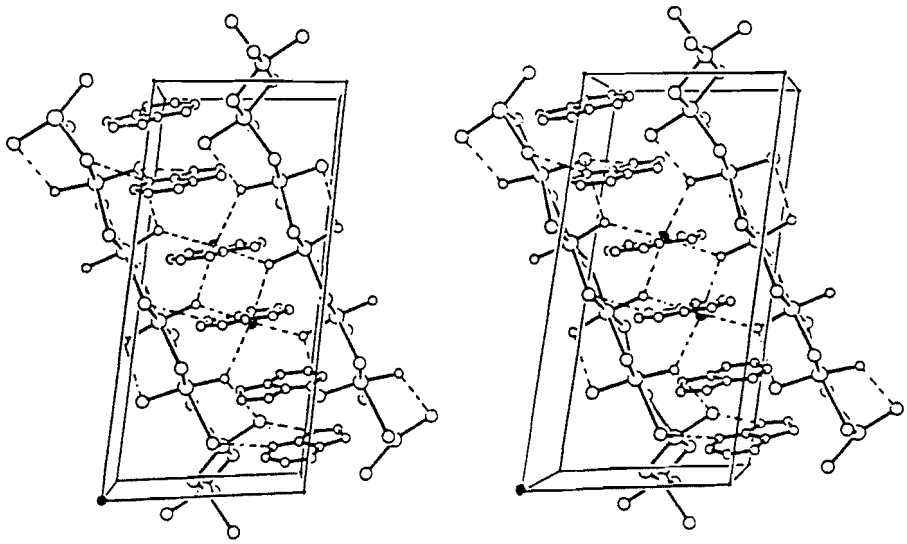

FIG. 5. Stereoview of the unit cell of $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$. Axes *a* (horizontal, right) and *c* (vertical, up) are in the plane of the figure, whereas *b* points away from the reader. Atoms are represented by spheres of arbitrary size: C ~ N ~ O < Cl < Cu. The uncoordinated Cl^- ion is shown as a black sphere and hydrogen bonds as dashed lines. The atoms in the chain can be identified from Fig. 3. Only the most abundant orientations of the disordered azaindolium cations are shown.

the salts introduce a broad feature at 3300–3600 cm^{-1}, whereas the maximum of the azaindole massif at 2900 cm^{-1} is displaced to 3100 cm^{-1} in the Cl^- and ClO_4^- salts, and to 3280 cm^{-1} in $(H_2aza)_5[Cu_5Cl_{14}(H_2O)_4]Cl$. A general shift to higher frequency is also noted in the 1650–1470 cm^{-1} range containing ring stretching modes. The ligand bands at 1600, 1583, and 1498/1480 cm^{-1} are displaced to 1634, 1613, and 1505/1492 cm^{-1}, respectively, in the salts, whereas a new weak band appears at 1524 cm^{-1}. Bands at 878 and 762 cm^{-1} lose intensity and shift to 884 and 749 cm^{-1}, respectively, in the salts. In the low-frequency region, the ligand out-of-plane ring mode at 559 cm^{-1} is displaced to 546 cm^{-1}, whereas the doublet at 428/419 cm^{-1} moves to 410/400 cm^{-1}. These spectral changes are different from those found for complexes containing N7-coordinated neutral (6, 10) or N1–N7-bridged anionic azaindole (2). Hence, they provide good diagnostics to identify the N7-protonated cation.

The ligand shows no vibrations in the 250–400 cm^{-1} range. This spectral region for $(H_2aza)_2[Cu_5Cl_{14}(H_2O)_4]Cl$ exhibits bands at 280, 250, and 235 cm^{-1}, which are probably due to Cu–Cl stretching modes (35).

Concluding remarks

In the two structures described here, 7-azaindole cannot act as a ligand, since both of its nitrogen donors are protonated. However, as the counter-cation, it plays a determining role in stabilizing an unusual type of chloro-copper(II) chains based on a square-planar building block of three different compositions. Two varieties of periodic chains, respectively based on five- and six-copper patterns, have been found. Both contain the -Cu(2)-Cu(3)-Cu(3)-C(2)- sequence, that is, a dichloro-bridged $[Cu_2Cl_6]^{2-}$ dimer in the middle and $[CuCl_3(H_2O)]^-$ units at each end. Such segments are connected by a single *trans*-$CuCl_2(H_2O)_2$ unit in $(H_2aza)_2[Cu_5Cl_{14}(H_2O)_4]Cl$, but by two such units in $(H_2aza)_3[Cu_3Cl_8(H_2O)_3]Cl$. The extra $CuCl_2(H_2O)_2$ unit in the latter case extends the chain by ~3.45 Å, but this does not lead to disruption of the structure. An extra Cl^- ion is simultaneously added, filling the space in the layer between the new $CuCl_2(H_2O)_2$ in adjacent chains and acting as hydrogen-bonding acceptor for the coordinated water molecules. Also, introducing an extra azaindolium ion extends the cationic stack by the same amount, while providing contributions to stabilization via extra hydrogen bonding and inter-

For personal use only.

ring stacking interactions. Features that likely contribute to the azaindolium ion playing this specific role are the relatively large aromatic system that favours stacking and the orientation of N—H bonds on the same side of the molecule. Judging from the structures observed here, it can be anticipated that increased water content at crystallization time could lead to chains based on a longer basic pattern, in which more than two consecutive $CuCl_2(H_2O)_2$ units could be inserted between the -Cu(2)-Cu(3)-Cu(3)-C(2)- sequences. However, a $CuCl_2(H_2O)_2$–$CuCl_3(H_2O)$ substitution disorder of the type representing ~25% of the structure of the $[Cu_5Cl_{14}(H_2O)_4]^{4-}$ chain is a definite possibility in such systems, because of the similar roles of water and Cl^- as ligands to Cu(II) and hydrogen-bond acceptors.

Acknowledgments

We wish to thank M. Simard and F. Bélanger-Gariépy for their assistance in solving the X-ray structures, and one of the reviewers for helpful suggestions concerning disorder in the $[Cu_5Cl_{14}(H_2O)_4]^{4-}$ chain. The support of the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged.

2-Acylidene-3,5-diaryl-2,3-dihydro-1,3,4-thiadiazoles and related compounds: a question of hypervalent S...O interactions

NARESH PANDYA, ANTHONY J. BASILE, AJAY K. GUPTA, PATRICK HAND, CINDY L. MACLAURIN, TAJ MOHAMMAD, ELAREF S. RATEMI, MARTIN S. GIBSON,[1] AND MARY FRANCES RICHARDSON[1]

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received July 28, 1992

NARESH PANDYA, ANTHONY J. BASILE, AJAY K. GUPTA, PATRICK HAND, CINDY L. MACLAURIN, TAJ MOHAMMAD, ELAREF S. RATEMI, MARTIN S. GIBSON, and MARY FRANCES RICHARDSON. Can J. Chem. **71**, 561 (1993).

A new synthesis of **1** by selective deacetylation of **2** is reported. The acylation step implied in earlier syntheses of **1** and related compounds is exemplified by direct acylations of **3** to give **4***a* and **4***b*. Several new 2-acylidene-3-(2,4-dibromophenyl)-5-phenyl-2,3-dihydro-1,3,4-thiadiazoles (**11**) and thioacylidene analogues (**12**) are described. The crystal structures of **11***a*, **11***b*, **11***c*, and **11***d* reveal a hypervalent interaction, ca. 2.45–2.7 Å long, between the sulfur and carbonyl oxygen atoms. The dibromophenyl ring is nearly perpendicular to the thiadiazole ring plane in the crystal structures, and NMR data suggest that this conformation is maintained in solution. Molecular mechanics calculations show that the S...O interaction need only be a few kilocalories in order to stabilize the observed acylidene side chain configuration over other possible isomers. Crystals of **11***a* are triclinic, $P\bar{1}$, with cell dimensions a = 12.937(2), b = 13.429(2), c = 13.489(2) Å, α = 60.14(1)°, β = 74.59(1)°, γ = 58.70(1)°, Z = 4, and R = 0.044 for 3287 observed reflections. Crystals of **11***b* are monoclinic, $P2_1/c$, with cell dimensions a = 10.512(1), b = 12.084(2), c = 16.268(4) Å, β = 96.91(1)°, Z = 4, R = 0.050 for 1938 observed reflections. Crystals of **11***c* are monoclinic, $P2_1/c$, with cell dimensions a = 17.492(4), b = 16.979(1), c = 14.962(1) Å, β = 106.46(1)°, Z = 8, R = 0.057 for 3112 observed reflections. Crystals of **11***d* are monoclinic, $P2_1/c$, with cell dimensions a = 11.749(1), b = 8.533(1), c = 22.670(4) Å, β = 100.17(1)°, Z = 4, and R = 0.059 for 2265 observed reflections.

NARESH PANDYA, ANTHONY J. BASILE, AJAY K. GUPTA, PATRICK HAND, CINDY L. MACLAURIN, TAJ MOHAMMAD, ELAREF S. RATEMI, MARTIN S. GIBSON et MARY FRANCES RICHARDSON. Can. J. Chem. **71**, 561 (1993).

On décrit une nouvelle synthèse du composé **1** réalisée par une désacétylation sélective du composé **2**. L'étape d'acylation impliquée dans les synthèses antérieures du composé **1** et de ses composés apparentés est démontrée par des acylations directes de **3** qui donnent **4***a* et **4***b*. On décrit plusieurs nouveaux 2-acylidène-3-(2,4-dibromophényl)-5-phényl-2,3-dihydro-1,3,4-thiadiazoles (**11**) et leurs analogues thioacylidènes (**12**). Les structures cristallines des composés **11***a*, **11***b*, **11***c* et **11***d* révèlent l'existence d'une interaction hypervalente, d'une longueur d'environ 2,45–2,7 Å, entre le soufre et l'oxygène du carbonyle. Dans les structures cristallines, le noyau dibromophényle est pratiquement perpendiculaire au plan du noyau thiadiazole et les données de la RMN suggèrent que cette conformation est maintenue en solution. Des calculs de mécanique moléculaire montrent qu'il suffit d'une interaction S···O de quelques kilocalories pour stabiliser la configuration observée pour la chaîne latérale par rapport aux autres isomères possibles. Les cristaux du produit **11***a* sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 12,937(2), b = 13,429(2) et c = 13,489(2) Å, α = 60,14(1)°, β = 74,59(1)° et γ = 58,70(1)°, Z = 4 et R = 0,044 pour 3287 réflexions observées. Les cristaux du produit **11***b* sont monocliniques, groupe d'espace $P1_1/c$, avec a = 10,512(1), b = 12,084(2) et c = 16,268(4) Å, β = 96,91(1)°, Z = 4 et R = 0,050 pour 1938 réflexions observées. Les cristaux du produit **11***c* sont monocliniques, groupe d'espace $P1_1/c$, avec a = 17,492(4), b = 16,979(1) et c = 14,962(1) Å, β = 106,46(1)°, Z = 8 et R = 0,057 pour 3112 réflexions observées. Les cristaux du produit **11***d* sont monocliniques, groupe d'espace $P1_2/c$, avec a = 11,749(1), b = 8,533(1) et c = 22,670(4) Å, β = 100,17(1)°, Z = 4 et R = 0,059 pour 2265 réflexions observées.

[Traduit par la rédaction]

Introduction

We previously described syntheses of a number of 2-acylidene-3,5-diaryl-2,3-dihydro-1,3,4-thiadiazoles such as **1** from a variety of substituted thiohydrazides (1) and 1,3,4-thiadiazolium salts (2). We now report a further synthesis of **1** by acidic hydrolysis of the acetylacetonylidene derivative **2**.

Compounds such as **1** can be regarded as acyl derivatives of methine bases, and, in our view, a reactive methine base is generated *in situ* in the earlier syntheses (1, 2) and then intercepted by the acylating agent present. We have now demonstrated the acylation step for a representative methine base **3** by reaction with two aroyl chlorides to give **4***a* and **4***b*. The enaminic character of **3** is further indicated by its reaction with iodomethane and with trichloroacetic acid to give **5** and **6**, respectively, so providing a parallel with the benzothiazole series (3). We noted, however, that attempted acetylation of **7** gave dimer **8** although the parent thiadiazolium salt reacted normally to give **9**. This behavior recalls that of methine bases in the 1,3,4-oxadiazole series, which form rearranged dimers on attempted acetylation (4). We tried to trap one such methine base, generated *in situ*, but obtained the rearranged dimer **10** (4).

2-Acylidene-3,5-diaryl-2,3-dihydro-1,3,4-thiadiazoles (**11**) and the thioacylidene analogs (**12**) (5) are of interest from a number of points of view. Formally, geometrical isomerism is possible, yet in all syntheses to date only one isomer has

been isolated (6). We early suspected that these compounds possessed (*Z*) geometry and might be bicyclic as in **13** (5). We have since prepared a number of acyl compounds **11** (and thioacyl analogues **12**) in which the methine proton is replaced by alkyl in order to determine the overall geometry and the effect of alkyl size on the interatomic S—X (X = O,S) distance and hence the extent of S...X interaction. This paper reports the crystal structures of four acyl compounds **11***a*–**11***d* and interprets the short S...O distance as a hypervalent interaction that stabilizes the (*Z*) configuration.

Experimental section

Instrumentation

The following instruments were used: Analect FX-6220 FT IR spectrophotometer for IR spectra; Bruker WP-60 FT and WP-80 CW spectrometers for ^{1}H NMR spectra (tetramethylsilane was used as an internal standard); DMS 100 UV–visible spectrophotometer for UV spectra (log ε values given in parentheses); AEI MS30 double-beam instrument for mass spectra. Melting points are uncorrected.

Hydrolysis of **2** *(7)*

Compound **2** (1) (50 mg, 0.15 mmol) was refluxed in concentrated HCl (5 mL) for 50 min. When cool, the mixture was neutralized with 1 M NaOH solution, and the solid was collected. Crystallization from absolute EtOH gave **1** (20 mg, 45%), mp 147–149°C, identified by mp and spectral correlation with a reference sample (1).

Reactions of 2-benzylidene-2,3-dihydro-3,5-diphenyl-1,3,4-thiadiazole (3) (8)

(a) Acylation

A solution of the methine base **3** (0.33 g, 1 mmol) in dry benzene (10 mL) containing triethylamine (0.1 g, 1 mmol) and freshly distilled benzoyl chloride (0.14 g, 1 mmol) was refluxed under nitrogen for 2.5 h. The triethylamine hydrochloride was filtered off and the filtrate was evaporated to give a brown solid (0.42 g). Purified by chromatography on silica, the benzoyl derivative **4***a* crystallized from 95% ethanol as yellow prisms (0.39 g, 90%), mp 171–173 °C; UV (MeCN): 242 (4.28) and 387 (4.26) nm; IR (KBr): 1585 (C=O) cm^{-1}; mass spectrum *m/z*: 432 (M^+, base peak). Anal. calcd. for $C_{28}H_{20}N_2OS$: C 77.77, H 4.62, N 6.48; found: C 77.54, H 4.51, N 6.33.

Similarly prepared (2 mmol scale), the *p*-nitrobenzoyl derivative **4***b* crystallized from chloroform–methanol as deep orange needles (0.74 g, 77%), mp 237–240°C; UV (MeCN): 248 (4.31) and 398 (4.16) nm; IR (KBr): 1595 (C=O) cm^{-1}; mass spectrum *m/z*: 477 (M^+, base peak). Anal. calcd. for $C_{28}H_{19}N_3O_3S$: C 70.44, H 3.98, N 8.81; found: C 70.28, H 4.07, N 9.01.

(b) Methylation

A solution of **3** (0.5 g, 1.5 mmol) in MeI (8 mL) was refluxed for 72 h, and excess MeI was then evaporated *in vacuo*. Crystallization from MeCN gave 2-(1-phenethyl)-3,5-diphenyl-1,3,4-thiadiazolium iodide (**5**) as a yellow crystalline solid (0.4 g, 56%), mp 233–235°C; UV (MeCN): 247 (4.32) and 285 (4.00) nm; ^1H NMR (CD_3CN) δ: 1.98 (d, *J* 7 Hz, 3H, CH_3), 4.80 (q, *J* 7 Hz, 1H, CH), and 7.26–8.06 (m, 15H, arom H); mass spectrum *m/z*: 342 (M^+ − HI). Anal. calcd. for $C_{22}H_{19}IN_2S$: C 56.17, H 4.04, I 27.02, N 5.96; found: C 55.99, H 4.11, I 27.31, N 6.02.

(c) Reaction with trichloroacetic acid

A solution of **3** (0.5 g, 1.5 mmol) in dry benzene (10 mL) containing freshly distilled trichloroacetic acid (0.25 g, 1.5 mmol) was refluxed under nitrogen for 1.5 h. The solvent was evaporated *in vacuo* and the residual gum was crystallized from 95% EtOH to give 2-benzyl-2,3-dihydro-3,5-diphenyl-2-trichloromethyl-1,3,4-thiadiazole (**6**) as a yellow crystalline solid (0.55 g, 81%), mp 45–50°C; UV (MeCH): 232 (4.22) and 342 (3.92) nm; ^1H NMR ($CDCl_3$) δ: 3.70 (d, *J* 16 Hz, 1H), 4.10 (d, *J* 16 Hz, 1H), and 7.10–7.75 (m, 15H, arom H); mass spectrum *m/z*: 328 (M^+ − $CHCl_3$). Anal. calcd. for $C_{22}H_{17}Cl_3N_2S$: C 58.86, H 3.79, N 6.24; found: C 59.15, H 3.88, N 6.26.

Attempted acetylation of 7

Compound **7** (8) (0.2 g, 0.7 mmol) was added in portions to a stirred mixture of acetyl chloride (0.1 mL, ca. 1.4 mmol) and dry pyridine (3 mL) at 0°C. The solution was stirred at 0°C for 1 h, and then at room temperature for 4 h. The reaction mixture was poured into water and was extracted with chloroform. The combined organic extracts were washed with water and dried (Na_2SO_4). Evaporation *in vacuo* gave a red solid (0.18 g), which was identified as **8** (8) by comparison with an authentic specimen (mp and mixture mp; ^1H NMR spectrum).

2-(1-Chloroacetonylidene)-2,3-dihydro-3,5-diphenyl-1,3,4-thiadiazole (9)

2-Chloromethyl-3,5-diphenyl-1,3,4-thiadiazolium perchlorate (8) (0.5 g, 1.3 mmol) was added in portions to a stirred mixture of acetyl chloride (0.15 mL, ca. 2.1 mmol) and dry pyridine (5 mL) at 0°C. The resulting dark red mixture was stirred at 0°C for 1 h, and then at room temperature for 30 min. The reaction mixture was poured into water (50 mL) and left overnight. The separated solid was filtered off, washed with water, and dried. Two crystallizations from absolute EtOH gave **9** as a pale yellow crystalline solid (0.20 g, 47%), mp 142–146°C; UV (MeCN): 237 (4.31) and 369 (4.25) nm; IR (KBr): 1600 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.43 (s, 3H, CH_3) and 7.38–8.13 (m, 10H, arom H); mass spectrum (rel. int.) *m/z*: 328 (M^+, 14%), and 103 (base peak). Anal. calcd. for $C_{17}H_{13}ClN_2OS$: C 62.19, H 3.96, N 8.53; found: C 62.34, H 4.09, N 8.50.

3,5-Diphenyl-2-methyl-1,3,4-oxadiazolium perchlorate and 10

A mixture of *N*-phenylbenzohydrazide (1.0 g, 44 mmol) and acetonitrile (0.3 mL, ca. 53 mmol) in acetic acid (2 mL) and 70% perchloric acid (1 mL) was refluxed for 5 min. When cool, water (20 mL) was added with stirring; the suspension cleared, and the oxadiazolium salt slowly separated as a white crystalline solid (1.5 g, 99%), mp 188–190°C (lit. (4) mp 191–192.5°C).

Treatment of this salt in acetonitrile with triethylamine, alone or in conjunction with acetic or benzoic anhydride, gave 3-(*N'*,*N'*-dibenzoyl-*N*-phenylhydrazino)-5-methyl-1-phenylpyrazole (**10**), identified by correlation of mp and spectral data with published values (4).

2-Acylidene-3,5-diaryl-2,3-dihydro-1,3,4-thiadiazoles (11)

*(a) 11*c

A stirred mixture of *N'*-(2,4-dibromophenyl)-*N'*-propionylbenzothiohydrazide (1) (2.20 g, 5.0 mmol) and benzoic anhydride (6.0 g, 26.5 mmol) in MeCN (15 mL) was refluxed for 3 h. After cooling, 10% aqueous NaOH (75 mL) was added, and the mixture was stirred for 2 h. The separated solid was filtered off, washed with water, and dried. Crystallization from chloroform – light petroleum gave **11**c as a light brown crystalline solid (2.0 g, 76%), mp 199–201°C; UV (MeCN): 237 and 380 nm; IR (KBr): 1595 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.60 (s, 3H, CH_3) and 7.30–8.00 (m, 13H, arom H); mass spectrum (rel. int.) *m/z*: 526 (M^+, 4%) and 105 (base peak). Anal. calcd. for $C_{23}H_{16}Br_2N_2OS$: C 52.27, H 3.03, N 5.30; found: C 51.96, H 3.04, N 5.05. Crystals were grown from ethyl acetate.

*(b) 11*d

Similarly prepared (1.1 mmol scale), **11***d* crystallized from MeCN as light brown prisms (0.425 g, 72%), mp 153–155°C; UV (MeCN): 238 (4.34) and 375 (4.21) nm; IR (KBr): 1595 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.57 (t, *J* 7 Hz, 3H, CH_3), 1.94–2.33 (m, 2H, CH_2), and 7.39–7.92 (m, 13H, arom H); mass spectrum (rel. int.) *m/z*: 540 (M^+, 9%) and 105 (base peak). Anal. calcd. for $C_{24}H_{18}Br_2N_2OS$: C 53.14, H 3.32, N 5.17; found: C 53.09, H 3.32, N 4.99. Crystals were grown from acetonitrile.

3,5-Diaryl-2,3-dihydro-2-thioacylidene-1,3,4-thiadiazoles (12)

*(a) 12*b

To a stirred solution of 3-(2,4-dibromophenyl)-2-ethyl-5-phenyl-1,3,4-thiadiazolium perchlorate (2) (0.5 g, 1.5 mmol) and thiobenzoylthioglycollic acid (1.0 g, 4.7 mmol) in absolute EtOH (15 mL) was added triethylamine (0.3 mL). The resulting mixture was refluxed for 20 h. The solvent was evaporated *in vacuo* and the residue was dissolved in chloroform (75mL). The chloroform solution was washed with 5% aqueous NaOH (2 × 25 mL) and water (2 × 25 mL), then dried over Na_2SO_4. Evaporation of chloroform and chromatography on silica gave **12***b*, which crystallized from chloroform–hexane as a brick-red crystalline solid (0.25 g, 48%), mp 303–304°C (dec. after changing colour to yellow-green at 185°C); UV (MeCN): 235 (4.40) and 447 (4.16) nm; ^1H NMR ($CDCl_3$) δ: 1.70 (s, 3H, CH_3) and 7.28–7.91 (m, 13H, arom H); mass spectrum (rel. int.) *m/z*: 542 (M^+, 2%) and 103 (base peak). Anal. calcd. for $C_{23}H_{16}Br_2N_2S_2$: C 50.73, H 2.94, N 5.14; found: C 50.44, H 3.27, N 4.93. Crystals were grown from chloroform.

*(b) 12*c

A stirred suspension of **11***d* (0.75 g, 1.4 mmol) and phosphorus pentasulfide (0.8 g, 3.6 mmol) in dry benzene (25 mL) was refluxed for 30 min. The product was isolated as described for **12***b*.

Crystallization from absolute EtOH gave **12***c* as an orange-red crystalline solid (0.45 g, 58%), mp 265–268°C (dec. after darkening at 150°C); UV (MeCN): 232 (4.45) and 444 (4.09) nm; ^{1}H NMR ($CDCl_3$) δ: 0.63 (t, J 7 Hz, 3H, CH_3), 1.99–2.40 (m, 2H, CH_2), and 7.30–7.94 (m, 13H, arom H); mass spectrum (rel. int.) m/z: 556 (M^+, 6%) and 103 (base peak). Anal. calcd. for $C_{24}H_{18}Br_2N_2S_2$: C 51.61, H 3.22, N 5.01; found; C 50.83, H 3.21, N 4.76. Crystals were grown from acetonitrile.

Crystal structure determinations

Crystals of **11***c* and **11***d* were obtained as described above; **11***a* and **11***b* were prepared in previous work (1). Unit cell dimensions were determined from the angular setting of 25 reflections measured with graphite-monochromatized MoKα radiation (λ = 0.71069 Å). Intensities were measured by the ω–2θ technique at room temperature (293–298 K) with an Enraf–Nonius CAD4 single-crystal diffractometer and corrected for Lorentz and polarization effects but not for absorption. The structures were solved by Patterson methods and refined by full-matrix least-squares techniques (**11***b* and **11***d*) or by block-diagonal least squares (**11***a* and **11***c*) with each block containing all of the atoms in one independent molecule plus the sulfur and bromine atoms in the second. Hydrogen atom positions were calculated. Anisotropic displacement parameters were assigned to all atoms except hydrogen in **11***a*, **11***b*, and **11***d*. The phenyl carbons and the hydrogens in **11***c* were refined with isotropic displacement parameters; the remaining atoms were refined with anisotropic displacement parameters. Scattering factors, including the real and imaginary parts of the anomalous scattering, were taken from the *International tables for X-ray crystallography* (9). The weighting scheme was $w = [\sigma^2(F) + p\,F^2]^{-1}$ with a value of p assigned to minimize the variance as a function of reflection intensity. Programs used included SHELX-76 (10) and ORTEP (11). The largest peaks and holes on the final difference maps (ca. ±1 e Å^{-3}) were located near the bromines, and are due to the lack of an absorption correction. The crystal data and experimental details are listed in Table 1. The final parameters are given in Tables 2–5.[2]

Molecular mechanics

Molecular mechanics calculations were carried out with Chem3D Plus (Cambridge Scientific Computing, Cambridge, Mass.), which implements Allinger's MM2 force field (12) with automatic π-calculation. A few new parameters were introduced and standard parameters were modified slightly to reproduce the structure of **11***a*; the full parameter set is given in the Supplementary Material.

Results and discussion

Syntheses and characterization

Syntheses of **11***a* and **11***b* were described previously (1); compounds **11***c* and **11***d* were prepared from the corresponding *N'*-acyl-*N'*-(2,4-dibromophenyl)benzothiohydra-

[2]Packing diagrams, anisotropic displacement parameters, hydrogen atom positions, short contact distances, bond distances and angles in the phenyl rings and side chains, least-squares planes, and structure factor tables for **11***a*–**11***d*, as well as molecular mechanics parameters and the results of the Cambridge Crystallographic Database Search, may be purchased from: The Depository of Unpublished Data, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Packing diagrams and tables of hydrogen atom positions, short contact distances, and bond distances and angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

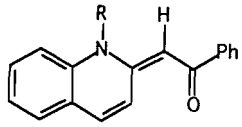
zide and benzoic anhydride. Of the corresponding thioacyl derivatives, **12***a* was prepared from thiobenzoylthioglycollic acid and the required thiadiazolium salt by the literature method (2). This method was successfully extended to the preparation of **12***b*, although a small amount of PhCSOEt was also apparently formed. However, PhCSOEt emerged as the main product (IR, NMR, and mass spectral identification) recovered from the complex mixture obtained when a similar synthesis of **12***c* was attempted. This compound was therefore prepared, though not in analytically pure condition, from **11***d* and phosphorus pentasulfide (5); Lawesson's reagent (13), as an alternative reagent to phosphorus pentasulfide, proved unsuitable for this purpose. We did not obtain crystals suitable for X-ray structure determinations for any of the thioacyl compounds.

As noted, we early suspected that compounds such as **1** and their thioacyl analogues possessed (*Z*) geometry and might even be bicyclic structures such as **13** (5). For compounds like **1**, our suspicions were aroused by the somewhat low frequency (ca. 1600 cm^{-1}) observed for carbonyl absorption in the IR spectra (for similar quinoline derivatives **14** with R = Me or Et, the carbonyl absorption band is at 1635 cm^{-1} (14)). For the thioacyl compounds, our suspicions were based on mass spectra; for example, **11***b* shows *m/z* 105 (PhCO) as base peak, whereas **12***a* shows *m/z* 103 (PhCN) as base peak, with a peak at *m/z* 425 (12%) (M − PhCN) that suggests S–S interaction. Similar features are exhibited by compounds **11***c* and **11***d*, and by **12***b* and **12***c*, though the last does not show a detectable (M − PhCN) fragment.



14

Molecular structures

The structures of **11***a*–**11**d are shown in Figs. 1–4, and important distances and angles are listed in Table 6. Bond distances lie within the range of values established for similar structural fragments (15). The six independent mole-

[a] $U_{eq} = 1/3\ \Sigma\Sigma U_{ij} a_i^* a_j^* \mathbf{a}_i \cdot \mathbf{a}_j$.

cules exhibit several common features: a short S...O contact (2.463–2.691 Å), essentially planar thiadiazole rings with the C(15)—C(16)—O side chain deviating only slightly from the plane of the thiadiazole ring, and the dibromophenyl ring nearly perpendicular to the thiadiazole ring (N(1)—N(2)—C(8)—C(9) torsion angles of 63.1–97.0°). The C(14)—C(15) and C(15)—C(16) distances, intermediate between single and double bond lengths, show that there is delocalization in the C(14)—C(15)—C(16)—O moiety. However, the C(16)—O distances are not significantly longer than the expected distance for a C=O bond (15).

The S...O contacts in all six independent molecules in **11***a*–**11***d* adhere closely to the geometry observed by Rosenfield, Parthasarathy, and Dunitz (16) for the approach of nucleophiles to divalent sulfur: the C(7)—S...O and S...O—C(16) angles of ≈165° and 100°, respectively, are consistent with a hypervalent interaction in which a pair of electrons from the carbonyl donates to a C—S σ* orbital (16), or with σ-bond coupling between a filled oxygen *p*-orbital with an empty sulfur $d_{x^2-y^2}$ orbital (17). Both bonding models explain the shift of the carbonyl stretching frequency to ≈1600 cm^{-1}, and both are consistent with a structure lying along the reaction coordinate that connects the monocyclic **11** and the bicyclic **13** (18). The S...O distance varies with the substituents, and is longest when R^1 = H (**11***a*, **11***b*). Replacement of the methine proton by methyl (**11***c*) or ethyl (**11***d*) shortens the S...O distance by ca. 0.20 Å. The shortening can be interpreted in terms of steric crowding, as the N(2)—C(14)—C(15) and C(15)—C(16)—C(17) angles increase to accommodate the bulkier alkyl groups.

There are also trends in the C(15)—C(16) distance and C(14)—C(15)—C(16) angle with substituent: when R^2 =

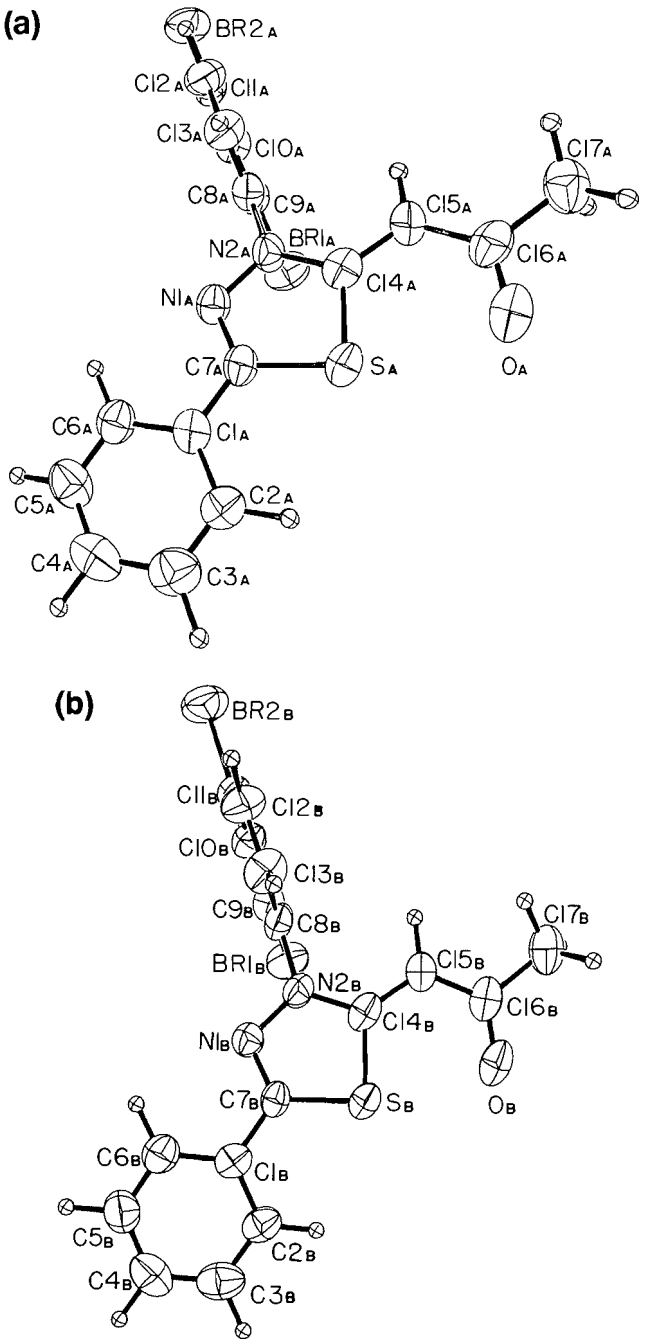

FIG. 1. Independent molecules (*a*) A and (*b*) B in the structure of **11***a*.

methyl (**11**a), C(15)—C(16) is ca. 0.05 Å shorter and C(14)—C(15)—C(16) is ca. 3° larger than when R^2 = phenyl (**11***b*, **11***c*, **11***d*). These changes, which are due to electronic effects, also affect the S...O distance so that it is nearly the same in **11***a* and **11***b*.

The orientation of the dibromophenyl ring nearly perpendicular to the thiadiazole plane was unexpected since phenyl rings do not normally twist greatly out of the plane of another delocalized ring system (e.g., note the N(1)—C(7)—C(1)—C(2) torsion angles in the present structures; Table 6). A search of the Cambridge Crystallographic Database (ref. 19; see supplementary information) yielded eight structures having 2-bromophenyl rings attached to planar atoms in 5- or 6-membered rings. Of the eight, only one had a dihedral angle less than 50°. That such a large dihedral angle is maintained across a spectrum of different compounds is an indication that it reflects the most favorable conformation of a 2-bromophenyl ring. This is an important point since below we shall interpret NMR spectra in terms of the differing phenyl and dibromophenyl ring conformations in **7**, **11**, and **12** and their corresponding nonbrominated analogues.

Two of the structures (**11***a* and **11***c*) have two independent molecules in the asymmetric unit. This phenomenon occurs with reasonable frequency in lower-symmetry space groups (20), and sometimes the independent molecules have essentially identical conformations (21). The conformations of molecules A and B in **11***c* are quite different (note the N(1)—N(2)—C(8)—C(9), N(1)—C(7)—C(1)—C(2), and C(15)—C(16)—C(17)—C(18) torsion angles in Table 6), whereas molecules A and B in **11***a* are essentially identical. We checked carefully for higher symmetry in **11***a*, especially since there is a pseudo-monoclinic C-centred cell that can be derived from the triclinic cell. However, nominally equivalent reflections in the monoclinic cell did not have the same intensity, and the final structure showed that molecules A and B are not related by a monoclinic symmetry element.

In every structure, the C(12)—H and (or) C(13)—H groups in the dibromophenyl ring make short contacts with carbonyl oxygens in adjacent molecules. Some of these contacts are short enough to be regarded as C—H...O hydrogen bonds (22).

Molecular mechanics, isomerism, and conformations

Molecular mechanics allows a semiquantitative estimate of the relative energies of isomers and conformers of a given molecule. The accuracy of the calculated structure and the steric energy depend on the quality of the parameters, which are less well established for molecules such as **11***a*–**11***d* than for simpler compounds. For example, the MM2 minimization of **11***a* gave structures with the dibromophenyl ring included at an angle of ≈32° with respect to the thiadiazole plane, and a corresponding energy of 1–5 kcal less than the observed conformation with the dibromophenyl ring perpendicular to the plane. The final torsion angle of the dibromophenyl ring depended on the parameters associated with the lone pair on N(1). The S...O and other distances varied with the orientation of the dibromophenyl ring and, in order to produce consistent results, minimizations were carried out with the N(1)—N(2)—C(8)—C(9) torsion angles fixed at the values observed in the crystal structures.

Scheme 1 shows the possible isomers/conformers of **11**, designated as if there were no delocalization in the side chain. In **11***a* (R^1 = H, R^2 = CH_3), the two (*Z*) conformers in Scheme 1 both have lower steric energies (21.7 and 21.8 kcal) than the two (*E*) conformers (23.7 and 27.2 kcal). The steric energies of (*Z*) conformers 1 and 2 remain similar as R^2 is changed to phenyl, but the steric energy of (*E*) conformer 2 increases sharply unless the R^2CO group is rotated out of the thiadiazole plane. The similar steric energies of both of the (*Z*) conformers is an additional argument for a hypervalent S...O interaction, whose energy need be no more than a few kilocalories to account for the overwhelming predominance of conformer 1. These results are consistent with quantum chemical calculations that show the

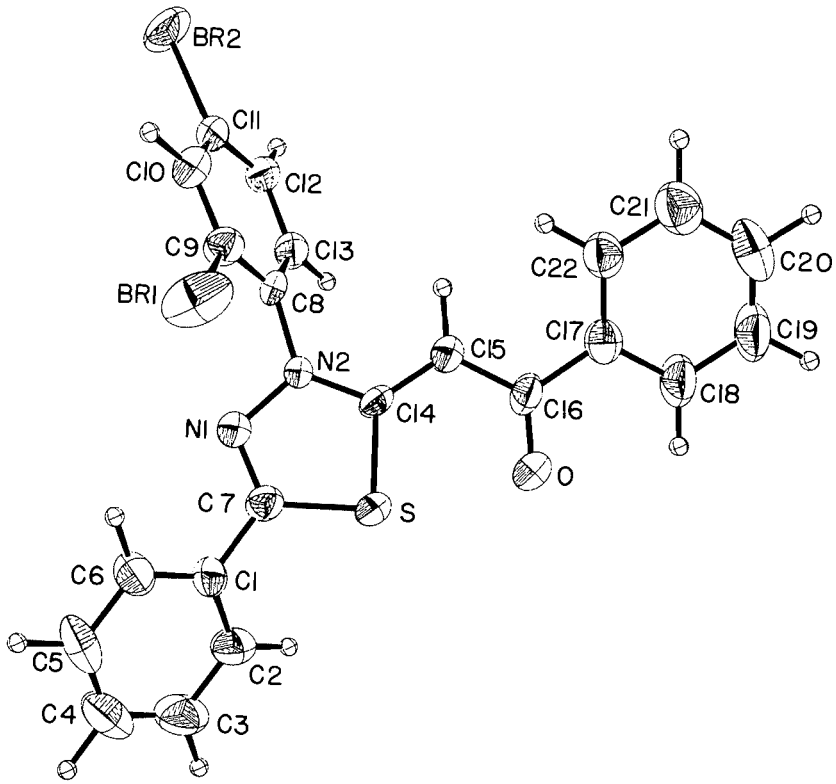

FIG. 2. The structure of **11***b*.

S...O interaction in $CH_3SCH{=}CHCHO$ to be equivalent to about 10% of a usual single bond (23).

The minimized "single-ring" structures shown as (*Z*) conformer 1 in Scheme 1 had S...O distances ≈0.2 Å longer than observed in the crystal structures. Decreasing the S—O distance (by changing the angles at C(14), C(15), and C(16)) resulted in increased van der Waals repulsions of several kilocalories. When the MM2 parameter set was changed to allow for an additional bond between S and O, the minimized structures more closely resembled the observed structures. The MM2 calculations reproduced the bond angle changes in bond angles and S...O distances that occurred as R^1 and R^2 were varied, thus substantiating the proposal that substituent effects in the series **11***a*–**11***d* are steric rather than electronic in nature.

Calculations for **11***d* show that the ethyl group is tightly sandwiched between the phenyl and dibromophenyl rings. Rotation of the ethyl group results in severe high-energy strain in the rest of the molecule. Hindered rotation is thus very likely the cause of the complex ^{1}H NMR spectrum for the CH_2 group in **11***d* and **12***c*, as well as for the apparent disorder of the ethyl group in the crystal structure of **11***d*. (The large displacement parameters and the uncertainty in the positions suggest disorder; unfortunately the difference map did not clearly reveal a second position for the methyl carbon C(24).)

NMR spectra and conformations in solution

It is interesting to recall that the ^{1}H NMR spectra of compounds such as **11***a* and **11***b*, which contain an *ortho* substituent in the N-aryl group, display the methine proton signal ca. 0.6 ppm upfield from that for analogous compounds containing no such *ortho* substituent (8). This is compatible with (*Z*) geometry and a conformation in solution in which the N-aryl group is twisted out of the plane of the thiadiazole ring. This implies that the conformation in solution is similar to the structure in the crystal, and that it is not simply a crystal packing effect that holds the dibromophenyl rings nearly perpendicular to the thiadiazole ring plane. Similar shifts have been noted for thioacyl derivatives **12**, from which (*Z*) geometry and a perpendicular dibromophenyl ring may also be inferred, as well as for chloromethylene derivatives like **7**. Indeed the close similarity in ^{1}H NMR spectra of **11***b*–*d* and **12***a*–*c*, respectively, implies similar conformations and thus a significant hypervalent S...S interaction in the thioacylidene series of compounds **12**. A hypervalent S...Cl interaction may additionally stabilize compounds such as **7**.

The ^{1}H NMR spectrum of **2**, run at ambient temperature, is also of interest in that the methyl protons appear as a singlet (1). This suggests appreciable single bond character for the carbon–carbon "double bond", analogous to the C(14)—C(15) bonds in **11***a*–**11***d*, with a low barrier to rotation. This is borne out by a low-temperature study. The ^{1}H NMR spectrum of **2** (in CD_2Cl_2) at 183 K shows two distinct singlets at δ 1.85 and 2.23 for the protons of the two methyl groups. As the temperature is raised, the intensities of these two signals decrease and the signals broaden. By 213 K, the two signals have collapsed to a broad hump that continues to sharpen, and by 303 K only one sharp signal is observed for the two methyl groups, at δ 2.04. Lowering of this rotational barrier is thus associated with (electrophilic) acetylation of **1** to give 2 (1). This is relevant to electrophilic substitution in the 1,6,6a-trithiapentalene series where ring opening – rotation – alternative ring closure reactions have been observed during nitrosation (24) and treatment with aryl diazonium ions (25); 1-oxa-6,6a-dithiapentalenes behave similarly in the latter reaction (25).

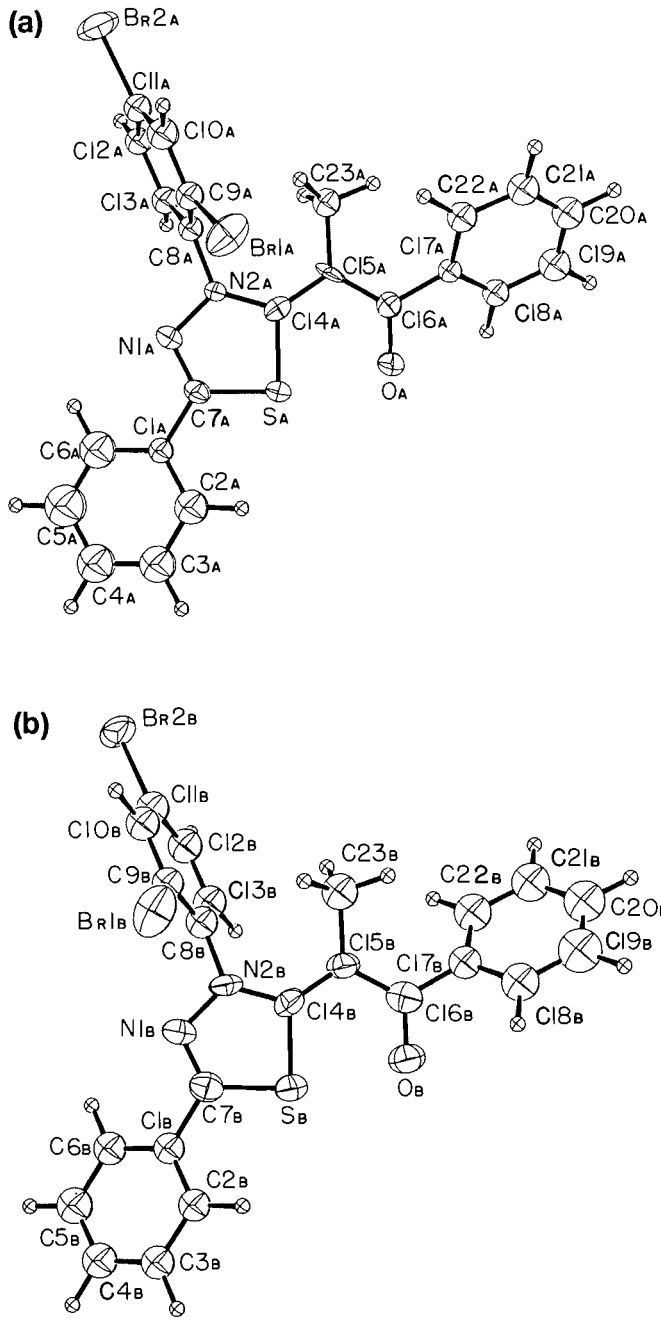

FIG. 3. Independent molecules (*a*) A and (*b*) B in the structure of **11***c*.

aryl diazonium ions (25); 1-oxa-6,6a-dithiapentalenes behave similarly in the latter reaction (25).

The ^{1}H NMR spectrum of **11***d* is interesting in that the signal due to the CH_2 protons appeared as a multiplet rather than a quartet, suggesting that these protons might be diastereotopic with respect to the dibromophenyl ring because of restricted rotation. No simplification was observed when the spectrum was run at 56.5°C, nor was there clear evidence of simplification when the CH_3 triplet was irradiated at ambient temperature. Similar data were obtained from the spectrum run in pyridine-d_5, even at temperatures of 57, 69, and 82°C.

Finally we wish to comment further on the ^{1}H NMR spectra of **15***a* and **15***b*. The spectrum of **15***a*, originally

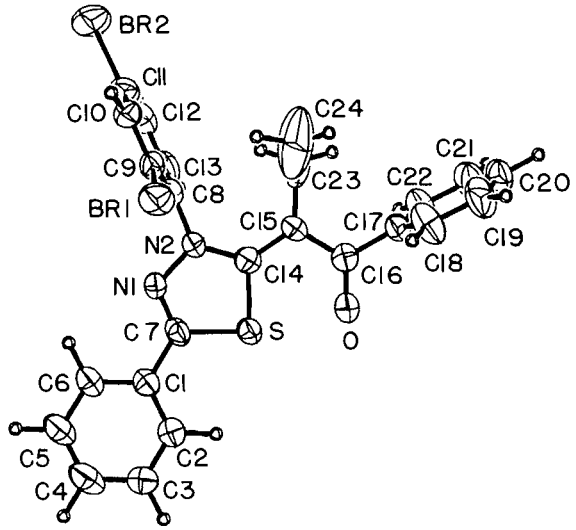

FIG. 4. The structure of **11***d*.

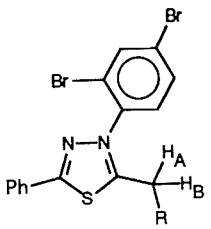
measured at 60 MHz, was reported to exhibit the CH_2 proton signal as a multiplet, suggestive of restricted rotation



15*a*: R = Me
15*b*: R = Ph

about the N-aryl bond (2). We have rerun this spectrum several times (at 80 and 200 MHz in CD_3CN, CD_3COCD_3, and in $(CD_3)_2SO$) on more modern instruments and can confirm that this signal appears at ambient temperatures as a quartet; typically, the compound shows δ (CD_3CN): 1.38 (t, *J* 7 Hz, 3H, CH_3) and 3.25 (q, *J* 7 Hz, 2H, CH_2), and saturation of the CH_3 protons causes the quartet to collapse to a singlet. To determine whether N-aryl rotation might become restricted at lower temperatures, we scanned the ^{1}H NMR spectrum (200 MHz) of **15***a* in CD_3COCD_3 over the temperature range 303–213 K. At 253 K, the CH_2 quartet shows signs of splitting as a result of differentiation of A and B protons as an AB system. This becomes clearer as the temperature is lowered, and from the spectrum at 233 K we calculate J_{AB} 7.3 Hz. By 213 K the methylene proton signal is a multiplet (ABX_3 system). By this temperature, interconversion of enantiomeric conformers through N-aryl rotation has become very slow.

We have also noted that the CH_2 signal in the ^{1}H NMR spectrum (80 MHz) of **15***b* in CD_3CN at ambient temperatures is a slightly broadened singlet (8). However, the spectrum at 200 MHz of this salt in $(CD_3)_2SO$ (with perchloric acid added to suppress dissociation to the methine base) shows the methylene protons clearly discriminated as an AB system with signals at δ: 4.13 (d, *J* 18 Hz, 1H) and 4.76 (d, *J* 18 Hz, 1H). Evidently there is restricted N-aryl rotation in **15***b* under these conditions.

Generalization of an empirical model for bond dissociation energies

YU-RAN LUO AND PHILIP D. PACEY[1]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received July 16, 1991[2]

YU-RAN LUO and PHILIP D. PACEY. Can. J. Chem. **71**, 572 (1993).

A relationship between homolytic bond dissociation energies (BDEs) of C—X bonds and the electronegativity of X and the degree of methyl substitution of C has been extended. The range of leaving groups, X, now includes SiH_3, GeH_3, and PH_2 and a variety of C-, N-, and O-centred radicals. Alkyl groups with ethyl and propyl chains attached to the radical centre have been incorporated. Steric effects, including those in bulky silanes, have been treated. The method is believed to be generally applicable where resonance and ring strain are not significant. BDEs for 73 bonds have been calculated; in the 42 cases where experimental data are available, the average deviation is 0.7 kcal/mol.

YU-RAN LUO et PHILIP D. PACEY. Can. J. Chem. **71**, 572 (1993).

On a étendu une relation entre les énergies de dissociation homolytique des liaisons (EDL) C—X, l'électronégativité de X et le degré de substitution méthyle du C. Les groupes qui partent comprennent maintenant le SiH_3, le GeH_3 et le PH_2 ainsi qu'une variété de radicaux centrés sur les atomes de C, N et O. On a incorporé des groupes alkyles dans lesquels des chaînes éthyles et propyles sont attachées au centre radicalaire. On a traité des effets stériques, y compris ceux des silanes volumineux. On croit que la méthode est générale et applicable dans tous les cas où la résonance et les tensions de cycle ne sont pas importantes. On a calculé les EDL de 73 liaisons; dans les 42 cas où des données expérimentales sont disponibles, la déviation moyenne est de 0,7 kcal/mol.

[Traduit par la rédaction]

1. Introduction

Knowledge of bond dissociation energies (BDEs) is fundamental to our understanding of chemical reactions. Most available BDEs have been obtained from gas kinetic measurements, which are restricted to volatile compounds. There is a need to develop dependable methods for estimating BDEs for larger molecules.

Recently Luo and Benson (1) were able to correlate BDEs of simple alkyl substituents, RX, with the degree of methyl substitution, m, of the radical, R, and the electronegativity, V_X, of the substituent, X. In this article we shall attempt to generalize these findings to a wider range of fragments, R and X. In the next section we will establish a hierarchy of interactions. In Sect. 3, the range of substituents, X, will be extended to include C_2H_5, CN, CH_3CO, ONO, i-C_3H_7O, ON, O_2N, SiH_3, GeH_3, and PH_2. In Sects. 4 and 5 the range of radicals R will be extended to include longer linear and branched alkyl radicals, respectively.

Most heats of formation of organic molecules used in this work have been taken from ref. 2. The heats of formation of methyl, ethyl, isopropyl, and *tert*-butyl radicals are the same as those used in ref. 1. Heats of formation of *n*-propyl and *sec*-butyl radicals have been taken from ref. 3, but have been adjusted upward by 0.6 kcal/mol to conform to the revised (1) heat of formation of methyl, which was used as a standard in ref. 3. The BDEs of CH_3—SiH_3, CH_3—GeH_3, and CH_3—PH_2 are from refs. 4, 5, and 6. Heats of formation of leaving groups X are from refs. 7–9.

2. Hierarchy of forces

The strong correlation between BDEs of R—X bonds and electronegativity was demonstrated in ref. 1. This suggests the presence of electrostatic forces that are propagated either though bonds by the inductive effect or through space as the field effect. We consider each of these effects separately elsewhere (10, 11). For now we will merely note that electrical effects decline with increasing distance, as illustrated in Fig. 1.

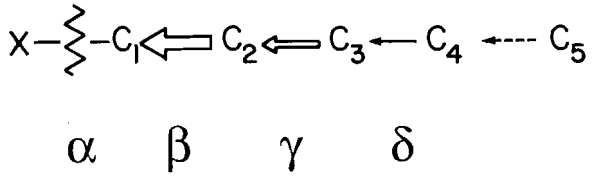

FIG. 1. Hierarchy of interactions. Replacement of H by CH_3 at position C_2 gives rise to the β effect, and a similar replacement at position C_3 to the γ effect.

Among the hierarchy of forces in the figure, the strongest interaction is the direct bond between X and atom C_1 (10, 11). The non-bonding interaction between the next-nearest neighbours X and C_2 is still strong (1–5 kcal/mol). This interaction, which will be called the β-effect, was the subject of ref. 1. The next-next-nearest neighbouring interaction between C_3 and X is predicted to be weaker, and will be called the γ-effect. Longer range electrical forces would be weaker still.

Some molecules involve other types of forces, such as resonance and steric effects. We have limited the effect of resonance in this article by considering only singly bonded alkyl groups, R. Steric effects will be considered in Sect. 5.

3. The effect of methyl substitution at the β position

Recently, Luo and Benson (1) described the methyl substituent effect on bond dissociation energies, DH.

$$[1]\quad DH^0(X—C(CH_3)H_{3-m}) = DH^0(X—CH_3) - m\frac{6.33 + 0.36\,m - V_x}{0.67 + 0.21\,m}$$

Here $C(CH_3)_mH_{3-m}$ is an ethyl, isopropyl, or *tert*-butyl group when m = 1, 2, or 3, respectively. In eq. [1], V_X is the co-

[1]Author to whom correspondence may be addressed.

TABLE 1. Estimated BDEs of Si—C, Ge—C, and P—C bonds, in kcal/mol

X	V_X	CH_3	C_2H_5	i-C_3H_7	t-C_4H_9
SiH_3	3.41	88.5 ± 1.5[a]	84.8	81.8	79.1
GeH_3	3.27	82.6[b]	78.7	75.7	73.1
PH_2	4.55	73.0 ± 2.5[b]	70.6	68.4	66.4

[a]Observed value from refs. 4 and 5.
[b]Observed values based on ref. 6.

valent potential, a new scale of electronegativity. The covalent potential is defined as

[2] $V_X = n_X/r_X$

Here n_X is the number of valence electrons in the bonding atom in X and r_X is its covalent radius. Equation [1] provides a convenient manner of estimating the homolytic BDEs of X—R bonds.

Luo and Benson did not estimate BDEs for cases in which X is SiH_3, GeH_3, or PH_2, because data for heats of formation of these compounds were not available. Nevertheless, eq. [1] should be valid for these cases. Therefore, we may estimate the BDEs for these bonds from those for X—CH_3, as shown in Table 1. Values of V_X were reported in ref. 5.

In the particular case that X is CH_3, eq. [1] reduces to a simple form:

[3] $DH^0(CH_3—C(CH_3)_mH_{3-m}) = DH^0(CH_3—CH_3) - 1.7\,m$

Each extra methyl group attached to one end of a C—C bond weakens the bond by 1.7 kcal/mol. Since both ends of the C—C bond in ethane are identical, the same reduction must apply, irrespective of which end of the molecule has the methyl group added. Thus the C—C bonds in propane have an experimental BDE of 88.5 kcal/mol, 1.7 kcal/mol less than that in ethane, as listed in Table 2. Furthermore, the central C—C bond in butane, with an experimental BDE of 86.8 kcal/mol, is observed to be 1.7 kcal/mol weaker than the C—C bonds in propane. In the case of butane the substituent X is the same as the radical R.

Estimation of the effect of substitution at the β position in the substituent X is not possible using eq. [1] when X is not an alkyl group. Table 2 lists BDEs for several other substituents for which the central atom is C, O, or N. Replacement of three β hydrogen atoms in CH_3 by an N atom in CN gives a much stronger bond to another CH_3. In all the other cases, replacement of β hydrogen atoms by other elements leads to much weaker bonds. In several of these cases the radical formed would be stabilized by resonance, a phenomenon not explicitly considered in the present approach. We will leave the effect of β substitution in X, except for alkyl groups, to future work.

We note that the present approach uses experimental values of the BDEs in CH_3X as reference values, eliminating any need to estimate them.

The effect of substitution of a hydrogen atom by a methyl group at the β position in R is shown in the third full column (headed C_2H_5) in Table 2. The numbers in the first row for each X are experimental. The numbers in parentheses below these were calculated using eq. [1], taking V_x as the electronegativity of the central atom in group X in each case. There is good agreement between experiment and eq. [1]. The average absolute error in this column is 0.2 kcal/mol, with a maximum error of 0.9 kcal/mol for aminoethane. Replacement of CH_3 by C_2H_5 weakens C—C bonds by 1.7 kcal/mol, strengthens C—O bonds by 1.6 kcal/mol, and makes no difference to C—N bonds.

The last two columns in this table will be discussed in Sect. 5.

4. The effect of methyl substitution at the γ position and beyond in derivatives of normal alkanes

The effect of a methyl group at the β position on the BDE lies between −4.5 kcal/mol for C—H bonds and +1.6 kcal/mol for C—O bonds. According to the hierarchy in Sect. 2, we expect that methyl groups farther from the breaking bond would have lesser effects.

The experimental thermochemistry has been established for very few radicals with a methyl group at the γ position. In Table 3 we can see a comparison between experimental BDEs for C_2H_5—X and n-C_3H_7—X. The extra γ-methyl group leaves BDEs unchanged within a standard deviation of ±0.2 kcal/mol, a negligible amount compared to the average experimental uncertainty of 1.3 kcal/mol. For s-C_4H_9—X compared to i-C_3H_7—X, the extra methyl group weakens the C—X bonds by an average of 0.8 ± 0.7 kcal/mol.

We conclude that there is insufficient experimental evidence to support assignment of a γ-effect at present and we will assume that electrostatic effects at the γ position and beyond are negligible.

5. Steric effects

The hierarchy in Fig. 1 assumes that interactions become weaker as one proceeds farther along a chain of carbon atoms. This is probably valid for normal alkanes and their derivatives. However, for ring compounds or highly branched alkanes, atoms farther along the chain may be forced to a position a short distance from atoms on the other side of the breaking bond. In this case, one would expect van der Waals forces between the nearby atoms.

van der Waals forces exist even between next-nearest neighbouring atoms and in molecules like CH_3X. Such forces are automatically subtracted out in $DH^0(CH_3X)$ or incorporated into the β-effect in eq. [1]. We seek an expression for the van der Waals interaction between groups separated by three or more bonds. This could correspond to an interaction between two β-methyl groups in X and R or interactions between groups separated further still. The same problem arose when the group additivity scheme was being established (12). Next-nearest neighbouring interactions were automatically incorporated in the group parameters, but less direct interactions were counted separately as steric effects. The magnitudes of these interactions were determined empirically by comparing the heats of formation of molecules with and without groups in close proximity, but separated by three or more bonds. The approach was not extended to radicals or bond dissociation energies. In the present article we have adopted the steric terms for molecules from the group additivity scheme and have extended the approach to radicals.

For noncyclic saturated hydrocarbons, the group additivity method identified two types of steric repulsive interactions: the 1,4-*gauche* interaction and the 1,5-H repulsion (12).

[a]Difference between numbers in previous two columns, the γ effect. Heats of formation of n-C_3H_7 and s-C_4H_9 are from ref. 3, adjusted as described in Sect. 1.

The 1,4-*gauche* interaction occurs when there are two methyl groups at positions 1 and 4, separated by three C—C bonds, oriented in the *gauche* conformation about the bond joining C_2 to C_3. This conformation forces two H atoms (at positions 0 and 5) very close. Benson (12) found such an interaction raised the heats of formation of hydrocarbons by 0.8 kcal/mol on average. Since the effect is repulsive, such conformations are avoided by internal rotation, if possible. The number of unavoidable 1,4-*gauche* interactions about bond C_2—C_3 is

$$[4] \quad g_{2,3} = (n_2 - 1)(n_3 - 2)$$

where n_2 is the number (1–4) of alkyl groups attached to the less substituted carbon and n_3 is the number attached to the more substituted carbon. Note that $n = 2$ for a secondary carbon, 3 for tertiary, and 4 for quaternary and is equal to m (from eq. [1]) plus one.

In ethers, where either atom 2 or 3 is oxygen, we follow Benson (12) in assigning 0.5 kcal/mol for each *gauche* interaction between methyl groups.

In radicals and ketones, the bond angles about one carbon atom increase to 120°, allowing the repelling hydrogen atoms to separate and reducing any interaction. Accordingly we have taken 1,4-methyl interactions involving sp^2 centres as 0.5 kcal/mol, as Benson did for alkene centres (12).

Where there are five carbon atoms in a chain and both atoms 2 and 4 are quaternary, two pairs of hydrogen atoms on carbons 1 and 5 are forced to a short internuclear separation. This results in two 1,5-H repulsions, estimated (12) at 1.5 kcal/mol each. We have adopted the same value here.

[a]Based on eq. [5].
[b]The observed values are based on experimental heats of formation of free alkyls and hydrocarbons. The data on free radicals are from refs. 1 and 3; those on hydrocarbons are from ref. 2.
[c]These are the differences between the observed and estimated BDEs.

We can now obtain a more general expression for the BDE of an X—R bond

$$[5]\quad DH^0(X—R) = DH^0(X—CH_3) - m\frac{6.33 + 0.36\,m - V_x}{0.67 + 0.21\,m} + \Delta V_s$$

Here ΔV_s is the change in the steric interaction. Where this includes only 1,4-*gauche* interactions in alkanes,

$$[6]\quad \Delta V_s = (0.8\,\Delta g)\ \text{kcal/mol}$$

Here Δg is the change in the total number of *gauche* interactions from R—X to R and X. This includes the sum of *gauche* interactions across all bonds, not just the dissociating bond. Where other types of steric interactions are involved, ΔV_s is the sum of the steric interactions in R and X minus the sum of the steric interactions in RX. It is generally negative.

We will first apply this principle to C—C bonds in alkanes. With no 1,5-H repulsions, eq. [5] can be simplified as follows:

$$[7]\quad DH^0(R_1—R_2) = (90.2 - 1.7\beta + 0.8\,\Delta g)\ \text{kcal/mol}$$

Here 90.2 is the BDE of the C—C bond in ethane and β is the total number of alkyl groups attached to the two ends of the breaking bond.

Three examples of estimations of the BDEs of C—C bonds are given below:

1. DH^0 (C(C)(C)—C(C)(C)—C)$_{est}$ = 90.2 − (1.7 × 5) − (0.8 × 4)
= 78.5 kcal/mol

The experimental value is 78.8 ± 1.0 kcal/mol, as in Table 4.

2. An example, in which 1,5-H repulsion energy is significant, is the BDE of a C_2—C_3 bond in 2,2,4,4-tetramethyl pentane. There are four carbon atoms at the β positions in the radicals, and four *gauche* conformations and two 1,5-H repulsions in the parent molecule. The BDE of the C—C bond is predicted to be

DH^0 (C(C)(C)—C(C)(C)—C)$_{est}$
= 90.2 − (1.7 × 4) − (0.8 × 4) − (1.5 × 2)
= 77.2 kcal/mol

This bond strength has not been determined experimentally.

3. The estimated BDEs of four C—C bonds in 2,2,4-trimethyl pentane are as follows:

C_1----C_2(C)----C_3----C_4----C_5

$DH^0(C_1—C_2)_{est}$ = 90.2 − (1.7 × 3) − (0.8 × 2) − 1.5 + 0.5 = 82.5 kcal/mol

$DH^0(C_2 - C_3)_{est}$ = 90.2 − (1.7 × 4) − (0.8 × 3) − 1.5 = 79.5 kcal/mol

$DH^0(C_3 - C_4)_{est}$ = 90.2 − (1.7 × 3) − (0.8 × 3) − 1.5 = 81.2 kcal/mol

$DH^0(C_4—C_5)_{est}$ = 90.2 − (1.7 × 2) − 0.8 − 1.5 = 84.5 kcal/mol

There are no observed values available for comparison.

The predictions of eq. [5] are compared with experimental results in Table 4. For 11 cases where a comparison is possible, the difference between prediction and experiment, listed in the last column, has an average value of ±0.7 kcal/mol, with a maximum value of −1.5 kcal/mol for tetramethylbutane, which is the only case where the difference exceeds the experimental uncertainty.

Positive deviations occur in Table 4 for small values of Δg; the three negative values occur in cases where Δg is −4 to −6. Where there are few *gauche* interactions, the bond angles can adjust to weaken the van der Waals repulsion. Where there are many interactions, as in tetramethylbutane, the *gauche* repulsions are difficult to escape.

The table continues with predictions of BDEs for bonds involving the i-C_4H_9 and n-C_4H_9 radicals, for which accurate experimental heats of formation are not available.

Equation [5] has been applied to C-, O-, and N-centred leaving groups, X, bonded to isopropyl and *tert*-butyl groups

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 88.255.202.194 on 09/08/12
For personal use only.

in the last two columns in Table 2. The average absolute deviation between experimental values and the predictions of eq. [5] is 0.5 kcal/mol. The greatest deviation is 1.9 kcal/mol for *tert*-butyl cyanide.

The steric correction can be extended to H—Si bonds. Griller and co-workers (13, 14) found anomalously low values for highly substituted silanes. In two molecules, $HSiEt_3$ and $HSi(Me)_2Si(Me)_3$, the distances between the hydrogen atoms involved in either 1,4-*gauche* or 1,5-H interactions are larger than 2.6 Å. That means there is no steric repulsion of these types in these two molecules. But in the staggered structure of $HSi(SiMe_3)_3$, the distance between hydrogen atoms involved in the 1,5-H interaction is about 1.8 Å. This is about equal to the distances between hydrogens involved in the 1,4-*gauche* interactions in tetramethylbutane. Therefore we suggest that the contribution to steric repulsion from each 1,5-H pair in $HSi(SiMe_3)_3$ is about 0.8 kcal/mol. The total steric compression release due to cleaving of the H—Si bond is about 4.8 kcal/mol for six pairs of 1,5-H repulsions. Combining this with the results of our previous work (15), we obtain

$$DH^0(H—SiEt_3)_{est} \approx DH^0(H—SiH_3) = 90.3 \pm 1.2 \text{ kcal/mol}$$

$$DH^0(H—Si(Me)_2SiMe_3)_{est} \approx DH^0(H—Si_2H_5) = 86.3 \pm 2 \text{ kcal/mol}$$

$$DH^0(H—Si(SiMe_3)_3)_{est} \approx DH^0(H—Si_2H_5) - 4.8 = 81.5 \pm 2 \text{ kcal/mol}$$

The values of the BDEs of H—Si bonds in SiH_4 and Si_2H_6 were taken from refs. 4 and 16. The observed values (13, 14) were 90.1 ± 2.0, 85.3 ± 2.0, and 79.0 ± 2.0 kcal/mol, respectively. This explains the fact that BDEs of H—Si bonds are not sensitive to alkyl substitution, unlike H—C bonds in hydrocarbons, but that H—Si bonds are sensitive to substitution by $SiMe_3$ groups.

6. Discussion

Equation [5], the central result in this work, is empirically based but has considerable predictive power. It contains four numerical constants, which were found in the earlier work (1) by examining data on eight leaving groups, X, and four alkyl groups, methyl, ethyl, isopropyl, and *tert*-butyl. Five parameters are contained in the steric term, ΔV_s, for five different types of steric interaction. The steric parameters, except those for radicals, ketones, and silanes, are taken from the work of Benson (12). To calculate the BDEs given in this paper, 12 values of $DH^0(X—CH_3)$ and six values of the covalent potential, V_X, are also needed. Since V_X is calculated from covalent bond lengths, not BDEs, it is really a semi-empirical, as opposed to empirical, parameter. In total, 21 empirical parameters and six semi-empirical parameters were used to estimate 73 BDEs in the tables in this article. For comparison, in the group additivity method (12), it would be necessary to supply 54 parameters to calculate these BDEs.

The key to this approach is the covalent potential, V_X. Of all available electronegativity scales, V_X gives the best correlation for the effect of methyl substitution on heats of formation and BDEs of organic molecules (17). It has also been shown to correlate well with group parameters (18), atomic ionization potentials (19), Lewis acid strengths (20), divalent state stabilization energies (21), heterolytic bond dissociation energies (22), and heats of formation of organic cations (23). It is also linearly related to theoretical electronegativity scales, such as the Mulliken electronegativity of the valence state, the electronic chemical potential, and the central electrostatic potential (24).

The method is based on the BDEs of methyl derivatives, for which most values have been determined with high precision. In this way, calculation of the direct interaction in C—X bonds has been avoided, and we have been able to focus on the weaker interactions in Fig. 1.

The numerical constants appearing in eq. [5] are derived from the heats of formation of the prototypical alkyl radicals. There has, recently, been some controversy (25–30) surrounding these values. The basic features of eq. [5] and the main conclusions of this work would be valid even if these input parameters were adjusted. If we had taken the values from Gutman's (27), Tsang's (29), or Griller's (30) groups, the estimated γ-effect and higher order interactions would still be small quantities, less than the current experimental uncertainty. If Gutman's (27) negative activation energies and the resulting thermochemistry had been accepted, eq. [5] would have changed a little:

$$[8] \quad DH^0(X—R) = DH^0(X—CH_3) - (3.8 + 3.9\,m) + \frac{mV_X}{0.67 + 0.21\,m} + \Delta V_s$$

This equation would behave very much like eq. [5].

Equation [1] was originally developed to correlate the BDEs of 24 bonds involving eight substituents, X, and three alkyl groups, R. The present work has extended the applicability of this equation in several ways. The range of substituents, X, has been enlarged to include SiH_3, GeH_3, and PH_2 in Table 1, seven new C-, O-, and N-centred groups in Table 2, and four new alkyl groups with methyl groups at the γ or δ positions relative to the radical centre in Tables 3 and 4. Section 5 also discusses three cases where R contains silicon atoms. Equation [5] and Table 4 incorporate steric effects. For the 42 cases where a comparison is possible between predicted and observed BDEs, the average absolute error is 0.7 kcal/mol, less than the average uncertainty of 1.1 kcal/mol in the experimental values. Of these 42 cases, 33 are discussed for the first time. Equation [5] may be used to predict other organic BDEs where resonance effects and ring strain are not important. It may also provide a step toward a better theoretical understanding of bond strengths.

Received July 31, 1992

THOMAS EGGIMANN, NAN IBRAHIM, R. ANTHONY SHAW, and HAL WIESER. Can. J. Chem. **71**, 578 (1993).

The infrared absorption (vapor phase and solution) and Raman (liquid phase) spectra of bicyclo[3.2.1]octane, 8-oxabicyclo[3.2.1]octane, 6-oxabicyclo[3.2.1]octane, 6,8-dioxabicyclo[3.2.1]octane, and the 7,7-dideutero-substituted derivatives of the last two compounds are reported in the region 100–1500 cm^{-1} for the first time. The vibrational spectra are assigned almost completely with the guidance of *ab initio* 3-21G geometries and scaled force fields. A total of 14 force-field scale facors are transferred from smaller molecules, predicting the frequencies with an average error of 7.6 cm^{-1} (1.2%) for 196 assigned transitions. After optimizing the factors in an overlay refinement involving all six molecules, the frequencies are within 5.7 cm^{-1} (0.75%) of experiment. The *ab initio* absorption and Raman intensities are calculated with the 3-21G basis set and are demonstrated to be of such accuracy as to be useful for the spectral assignments. These intensities are calculated with uniformly and nonuniformly scaled force fields and compared to the experimental spectra. The intensities derived from the latter force fields are superior, meaning that nonuniform scaling is preferable at this level of theory for both vibrational frequencies and normal mode descriptions.

THOMAS EGGIMANN, NAN IBRAHIM, R. ANTHONY SHAW et HAL WIESER. Can. J. Chem. **71**, 578 (1993).

On a déterminé pour la première fois les spectres d'absorption (100–1500 cm^{-1}) infrarouge (phase vapeur et solution) et Raman (phase liquide) des bicyclo[3.2.1]octane, 8-oxabicyclo[3.2.1]octane, 6-oxabicyclo[3.2.1]octane, 6,8-dioxabicyclo[3.2.1]octane et des dérivés 7,7-dideutérés des deux derniers composés. On a attribué les bandes des spectres de vibration en faisant appel presqu'uniquement aux géométries *ab initio* 3-21G et aux champs de force. Utilisant des molécules plus petites, on a transféré un total de 14 facteurs d'échelle de champs de force et on a ainsi pu prédire les fréquences avec une erreur moyenne de 7,6 cm^{-1} (1,2%) pour les 196 transitions attribuées. Après avoir optimisé les facteurs à l'aide d'un affinement impliquant les six molécules, les fréquences calculées sont à 5,7 cm^{-1} (0,75%) des valeurs expérimentales. On a calculé l'absorption et les intensités Raman *ab initio* à l'aide de l'ensemble 3-21G et on a démontré que les valeurs calculées sont d'une telle exactitude qu'elles peuvent être utiles pour attribuer des spectres. On a calculé ces intensités à l'aide de champs de force à échelles uniformes et non uniformes et on les a comparées à celles des spectres expérimentaux. Les intensités obtenues à l'aide des derniers champs de force sont supérieurs, c'est-à-dire que, pour les fréquences vibrationnelles ainsi que pour les descriptions des modes normaux, les échelles non uniformes sont préférables à ce niveau de la théorie.

[Traduit par la rédaction]

Introduction

In recent years the assignment of the vibrational spectra of small molecules by means of *ab initio* calculated geometries and harmonic force fields has become almost a routine procedure. The *ab initio* calculations can be performed at various levels of theory with a choice of many different basis sets. The accuracy of the results is largely limited by the size of the molecule and the available computing power. In attempting to reproduce experimental frequencies as accurately as possible, more or less severe corrections are applied to the *ab initio* geometries and force fields, depending on the level of approximation.

We are interested in the vibrational dynamics of monocyclic and bicyclic molecules with low symmetry and seek conceptually simple ways to interpret the experimental infrared absorption, Raman, and vibrational circular dichroism (VCD) spectra (1–6). Our approach is to calculate harmonic *ab initio* force fields (3-21G, or higher if possible) from the uncorrected geometries optimized with the same basis set. The force constants are transformed to appropriate local symmetry coordinates, then scaled with a small set of factors for particular types of modes. These procedures are basically equivalent to the standard scaled quantum mechanical (SQM) force field, originally developed and recommended by Pulay *et al.* (7), with the difference that we prefer not to correct the *ab initio* geometries. Such scale factors, in our experience, when judiciously selected and transferred from similar moieties, lead to frequency predictions with errors well below 2% on average. Even quite complex spectra can then be assigned with high confidence. Simultaneously, the scale factors can be refined in a least-squares fit of the frequencies in overlay refinements involving series of molecules. Finely tuned factors are thus obtained that are again suitable for transfer to the corresponding local symmetry modes of other classes of molecules with similar structural elements. Such refinements of scale factors are significant, as a dependence on the chemical or structural environment has been noted for the factors of certain modes. For the C—O stretching mode, for example, values of 0.903 (dimethyl ether) (1), 0.851 (2-methyloxetane) (2*a*), and 0.845 (7-oxanorbornane) (5) were found, indicating unequal overestimations of the *ab initio* C—O stretching force constants for different molecules, possibly depending on the C—O—C bond angle. It is essential therefore to explore scale factors for local symmetry modes in a variety of different environments, thereby rendering them more suitable for a transfer to new structures.

A good fit of the frequencies by nonuniform scaling and refining does not guarantee that the normal mode descriptions are correctly calculated. Moreover, the solutions of the refinements need not be unique. It is therefore even more

important to start out with a set of scale factors that are already close to the optimized values and to perform the refining procedure very carefully. To judge the quality of scaling it is essential to investigate both the frequencies and the normal mode descriptions of the vibrations. The latter cannot be observed directly, but their accuracy appears with great sensitivity in the calculated intensities of the absorption, Raman, and even more in the VCD spectra. We demonstrate in this work that nonuniform scaling of force fields does not deteriorate the *ab initio* eigenvectors if enough care is taken in the process of transferring and refining the factors. It is also shown that in spite of using the primitive 3-21G basis set, the *ab initio* absorption and Raman intensities reflect the experimental spectra sufficiently accurately that, at the very least, the intensities can assist in the assignments. This aspect is of particular importance for this series of molecules, two of which have C_s symmetry and the remaining four are asymmetric, as the most useful and unambiguous experimental data, namely vapor phase band shapes and Raman polarization ratios, are helpful only for very few bands. The properties that are available to guide the spectral assignments other than the frequencies are then the calculated absorption and Raman intensities. In addition, the method of scaling and simultaneously optimizing several force fields with the same set of factors is indispensable for this series of sufficiently similar molecules, since the wealth of combined experimental data that can be fitted with just a few parameters helps to resolve a number of ambiguities that otherwise would be intractable.

We report below the vibrational spectra from 100 to 1500 cm^{-1} and corresponding assignments based on *ab initio* 3-21G harmonic force fields for bicyclo[3.2.1]octane (BCO), and the 8-oxa (8OXA), 6-oxa (6OXA), 7,7-d_2-6-oxa (6OXA-d_2), 6,8-dioxa (DIOXA), and 7,7-d_2-6,8-dioxa (DIOXA-d_2) analogues (Figs. 1, 2). The investigation of the VCD spectrum of DIOXA described earlier (6) was based on these assignments. Of interest for further VCD studies are the vibrational spectra and assignments of several mono- and dimethyl substituted analogues of DIOXA, to be reported in a subsequent publication.

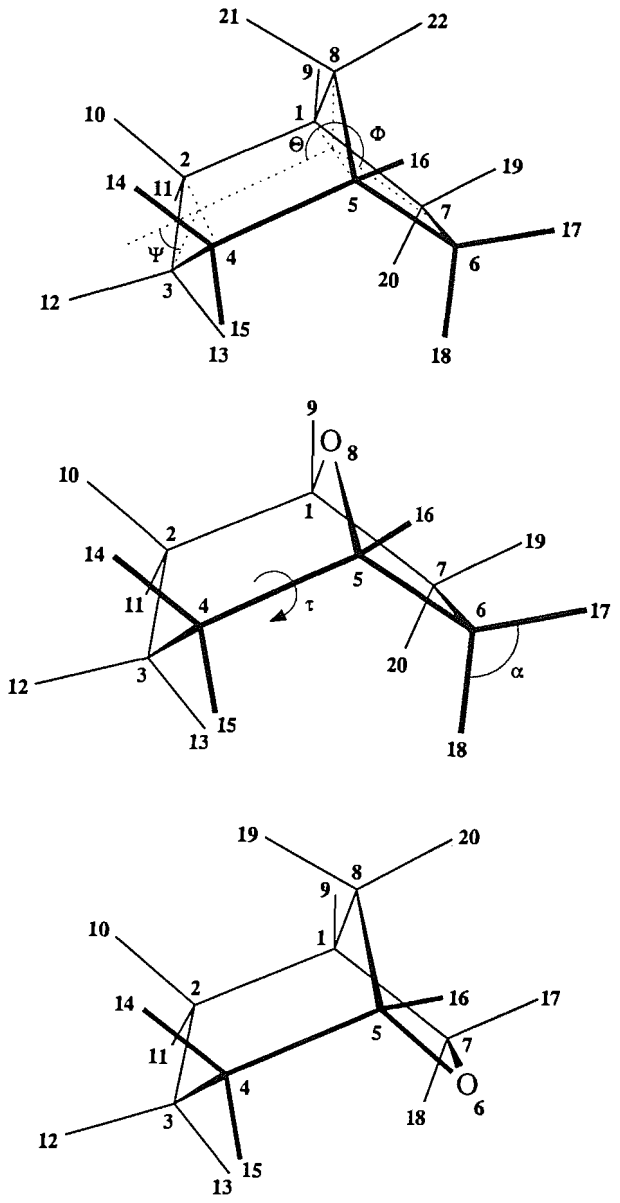

FIG. 1. Structures of bicyclo[3.2.1]octane (BCO), (top); 8-oxabicyclo[3.2.1]octane (8OXA), (middle); and 6-oxabicyclo-[3.2.1]octane (6OXA), (bottom). Numbers correspond to atom numbering used in Tables 7 and 8–10.

Syntheses

The synthesis of DIOXA has been described elsewhere (8). All the compounds were further purified to >98% by vacuum sublimation before recording their spectra. The purities were confirmed by gas chromatography.

Bicyclo[3.2.1]octane (BCO)

Following a known procedure (9), dichlorocarbene was added to norbornene to form *exo*-3,3-dichlorotricyclo[3.2.1.$0^{2,4}$]octane, which upon heating rearranged to *exo*-3,4-dichlorobicyclo[3.2.1]-oct-2-ene with an overall yield of 19%. This dichloride was dechlorinated using a method recommended for a similar compound (10). A mixture of dry THF (400 mL), sodium metal (1.6 mol, cut into small pieces), and *tert*-butanol (0.57 mol) was stirred vigorously and heated under a nitrogen atmosphere. When reflux of the solvent started, 3,4-dichlorobicyclo[3.2.1]oct-2-ene (0.17 mol) was added dropwise. After stirring and refluxing for 40 h, the product was separated and purified as recommended (10). Bicyclo-[3.2.1]oct-2-ene was obtained in 44% yield.

In a hydrogenation flask were placed bicyclo[3.2.1]oct-2-ene (37 mmol), absolute ethanol (30 mL), and 5% Pd/C (100 mg). The addition was carried out in a Parr hydrogenator applying an initial pressure of 70 psi (1 psi = 6.9 kPa) of hydrogen. The pressure dropped quickly and the reaction was stopped after 4 h. The mixture was filtered through Celite and the BCO precipitated by adding a large volume of water. The yield of crude product after filtration was 2.4 g (59%). The structures of the products in every step were confirmed by ^1H nmr.

8-Oxabicyclo[3.2.1]octane (8OXA)

This synthesis has been reported by other workers and is therefore given in short form only. From cyclopentanone and pyrrolidine the enamine (1-(*N*-pyrrolidinyl)cyclopentene was prepared, which was reacted with acrolein to form 2-(*N*-pyrrolidinyl)-bicyclo[3.2.1]octan-8-one (11, 12). The methyl iodide of this amine was converted to 4-cycloheptenecarboxylic acid by base-induced ring opening (11–13). Lead tetraacetate decarboxylation of the acid, followed by the reduction of the acetate with $LiAlH_4$, gave 4-cycloheptenol (14). Ring closure to 8-oxabicyclo[3.2.1]octane-2-mercurial iodide was achieved by treatment with mercury acetate (15). Treatment with iodine gave 2-iodo-8-oxabicyclo[3.2.1]octane, which, upon reduction with $LiAlH_4$, afforded the desired

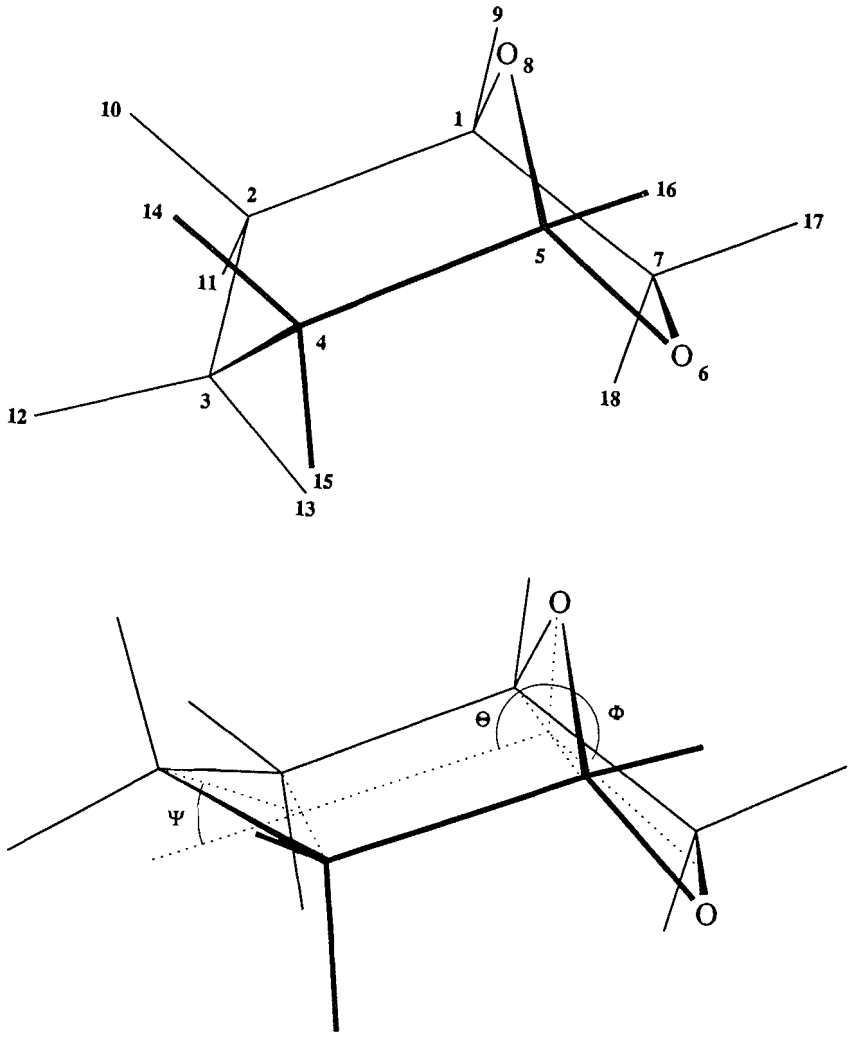

FIG. 2. Structures of the chair (upper) and boat (lower) conformers of 6,8-dioxabicyclo[3.2.1]octane (DIOXA). Numbers correspond to atom numbering used in Tables 7 and 11.

8OXA (15). In all steps the yields were comparable to values reported in the stated references. The products were always checked by their ^{1}H nmr spectra.

6-Oxabicyclo[3.2.1]octane (6OXA)

The precursor, 4-hydroxymethylcyclohexene, was obtained from cyclohexene-4-carboxaldehyde (Aldrich) by reduction with sodium borohydride in methanol, following a published procedure for a similar compound (16). The yield after work-up was 84%.

Ring closure of the alcohol to the bicyclic structure was achieved analogously to 8OXA (15). A solution of mercury acetate (40 mmol) and sodium acetate (40 mmol) in 50 mL of water was stirred. The alcohol (40 mmol) was added within 5 min and stirring was maintained at ambient temperature for 15 min. A solution of potassium iodide (52 mmol) and sodium hydroxide (40 mmol) in 50 mL water was added dropwise, causing the product to precipitate. After stirring for another 15 min, the supernatant liquid was decanted and the solid 6-oxabicyclo[3.2.1]octane-2-mercurial iodide was dried under vacuum at room temperature and used as such for the following step.

The mercury was eliminated by stirring the mercurial iodide (40 mmol) with an equimolar amount of iodine in 250 mL of carbon tetrachloride for 28 h. The work-up was carried out as described (15), yielding 6.8 g of crude iodide (71% relative to 4-hydroxymethylcyclohexene).

The iodide was reduced with $LiAlH_4$ in ether (15). After the usual work-up, 6OXA was distilled at aspirator vacuum and obtained with 50% yield. Its ^{1}H nmr spectrum was identical to the reported spectrum (17).

7,7-d_2-6-Oxabicyclo[3.2.1]octane (6OXA-d_2)

Following a published procedure (18), *m*-hydroxybenzoic acid was hydrogenated with sodium in boiling absolute ethanol. When all the sodium had reacted, water was added and the mixture was neutralized with hydrochloric acid. The alcohol was evaporated and after adding an excess of hydrochloric acid the solution was extracted continuously with ether for 8 h. The extract was dried with $MgSO_4$ and the ether was evaporated to give a residue containing *cis*- and *trans*-3-hydroxycyclohexanecarboxylic acid. The mixture was heated at 170°C for 40 min to convert the *cis* isomer to 6-oxabicyclo[3.2.1]octan-7-one (25% yield after distillation).

6OXA-d_2 was prepared by a modification of a published procedure (17). A solution of the lactone (24 mmol) in ether (50 mL) was added dropwise to a stirred slurry of $LiAlD_4$ (38 mmol) in ether (90 mL). The mixture was refluxed for 2.5 h. After work-up an oil was recovered containing the *cis*-3-hydroxycyclohexyl-1,1-dideuteromethanol, which was used without further purification. The crude diol and *p*-toluenesulfonic acid were mixed and heated to 150°C (oil bath temperature) in a distillation apparatus at aspirator vacuum. The fraction boiling at 50–80°C was collected and redistilled. The 6OXA-d_2 was obtained in 20% overall yield; ^{1}H nmr

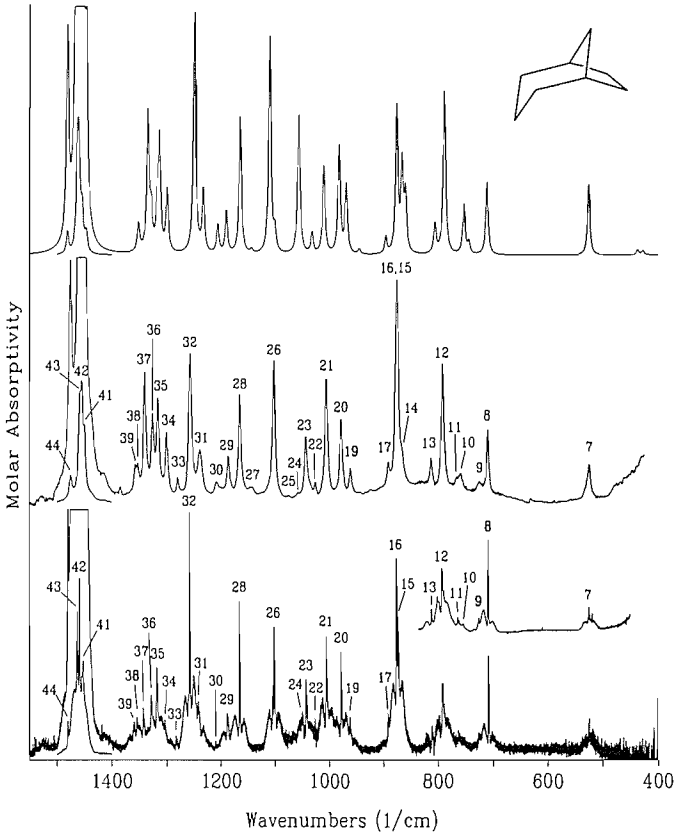

FIG. 3. Calculated (top) and observed solution (middle) and vapor phase (bottom) absorption spectra of bicyclo[3.2.1]octane (BCO). The solution and theoretical spectra are on the same scale. For experimental conditions see text. The insert vapor phase spectrum (450–830 cm^{-1}) was recorded with 0.5 cm^{-1} resolution (500 scans). Numbers correspond to "Band nos." in Tables 1 and 13.

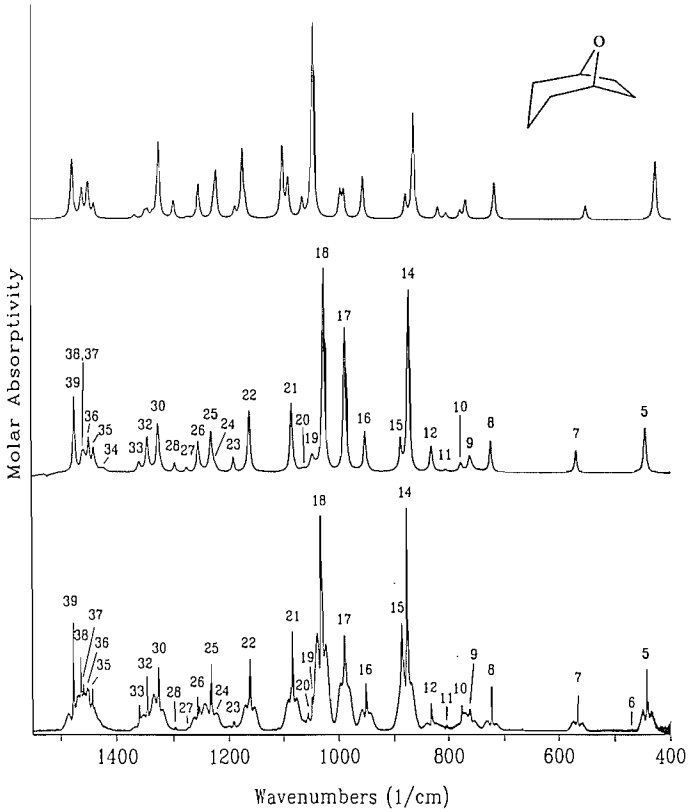

FIG. 4. Calculated (top) and observed solution (middle) and vapor phase (bottom) absorption spectra of 8-oxabicyclo[3.2.1]-octane (8OXA). The solution and theoretical spectra are on the same scale. For experimental conditions see text. Numbers correspond to "Band nos." in Tables 2 and 14.

(Bruker AC 200, 200 MHz, $CDCl_3$) δ: 1.5–1.9 (m, 8H), 2.36 (s, br, 1H, C1-H), 4.31 (t, 1H, C5-H).

7,7-d_2-6,8-Dioxabicyclo[3.2.1]octane (DIOXA-d_2)

3,4-Dihydro-2*H*-pyran-2-carboxylate ethyl ester (8) was reduced with an equimolar amount of $LiAlD_4$ by stirring for 2 h to yield 3,4-dihydro-2*H*-pyran-2-(1,1-dideutero)-methanol after decomposition (88% after distillation, F = 85–87°C, asp. vacuum). For cyclization, the alcohol (26 mmol) was refluxed for 1 h in *p*-toluenesulfonic acid (30 mg) and benzene (30 mL). The mixture was neutralized with sodium methanolate, filtered, and distilled. DIOXA-d_2 was collected at 68–74°C (asp. vacuum) in 79% yield; ^1H nmr (Bruker AC 200, 200 MHz, $CDCl_3$) δ: 1.5–2.0 (m, 6H), 4.49 (s, 1H, C1-H), 5.51 (s, 1H, C5-H).

Experimental

The absorption spectra were measured with a Nicolet 8000 FT-IR interferometer using a MCT detector with a cutoff at 400 cm^{-1}. The condensed phase spectra (400–1500 cm^{-1}) were recorded from solutions in CS_2 (700–840 cm^{-1}) and CCl_4 (remaining parts of the spectra) with typical concentrations of 0.5 mol/L (0.8 mol/L for BCO) and with 0.1 mm path length. To obtain adequate signal-to-noise for Fourier self-deconvolution, 2000 scans were coadded at 1 cm^{-1} resolution. For the mid-infrared vapor phase spectra (400–1500 cm^{-1}), the compounds were evaporated into a Wilks variable-path gas cell adjusted to approximately 5 m path length using pressures of typically 1.4 Torr (1 Torr = 133.2 Pa), except for BCO for which 12 Torr were required. In all cases 500 scans were collected with 0.12 cm^{-1} resolution (unapodized). The water lines in the spectrum of BCO were diminished by subtracting a spectrum of water recorded with identical instrumental settings. The spectra are displayed in Figs. 3–8.

The far-infrared vapor phase spectra (80–400 cm^{-1}) were recorded for BCO, 8OXA, 6OXA, 6OXA-d_2, and DIOXA with 0.12 cm^{-1} resolution. The spectra exhibit well-resolved sequences of *Q*-branches for many fundamentals resulting from skeletal anharmonicities. While the details are published elsewhere (19), peak positions of the fundamentals are included here for the sake of completeness. For BCO, the absence of significant transition dipole moments results in very weak absorptions, obscured in addition by water lines. Nonetheless, two bands located at 262.5 and 358.1 cm^{-1} could be identified and assigned to A' fundamentals.

The Raman spectra of the neat melted compounds (Figs. 9–14) were measured between 100 cm^{-1} and 1500 cm^{-1} with a Jarrell–Ash model 25-100 double grating monochromator, utilizing for excitation the 514.5-nm line of an argon ion laser (Coherent Radiation) with 300 mW power at the sample. The photomultiplier detector was interfaced to a microcomputer, which allowed coaddition of 8 scans for each spectrum with a scanning step size of 2 cm^{-1} and a time constant of 1 s. The slits were adjusted to an effective spectral width of 5 cm^{-1} at 1000 cm^{-1}. Since the samples have relatively high vapor pressures, they were sealed into capillary tubes and melted with a stream of hot air (50–150°C) in a specially designed apparatus. The laser beam was focused into the samples from the bottom of the capillary tubes. The frequencies were calibrated against the CCl_4 peaks. The measured intensities were not corrected for the frequency-dependent response of the photomultiplier tube. The resulting errors are estimated to be within 15% maximally over the whole reported spectral region, and

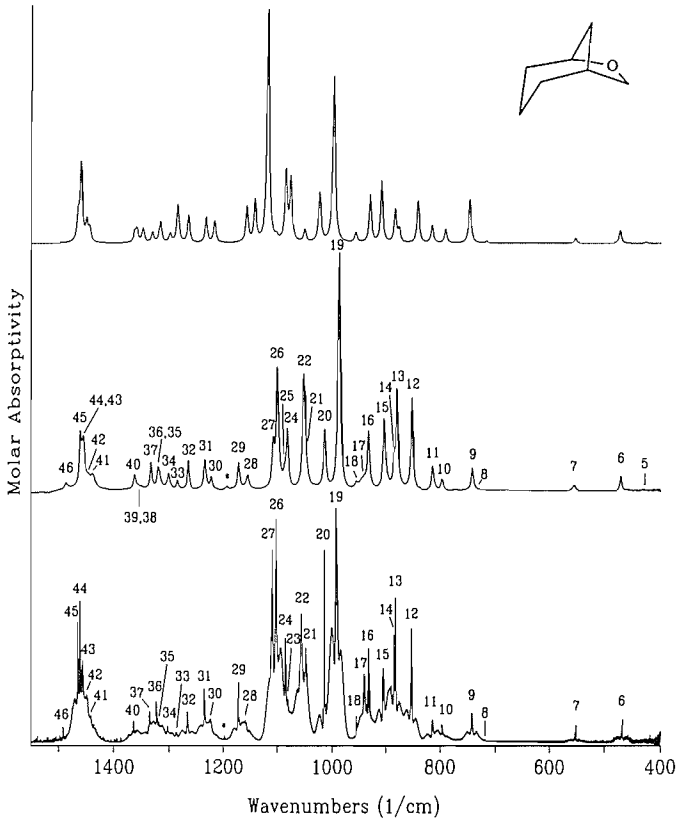

FIG. 5. Calculated (top) and observed solution (middle) and vapor phase (bottom) absorption spectra of 6-oxabicyclo[3.2.1]-octane (6OXA). The solution and theoretical spectra are on the same scale. For experimental conditions see text. Numbers correspond to "Band nos." in Tables 3 and 15. Asterisks indicate bands that are believed to arise from impurities.

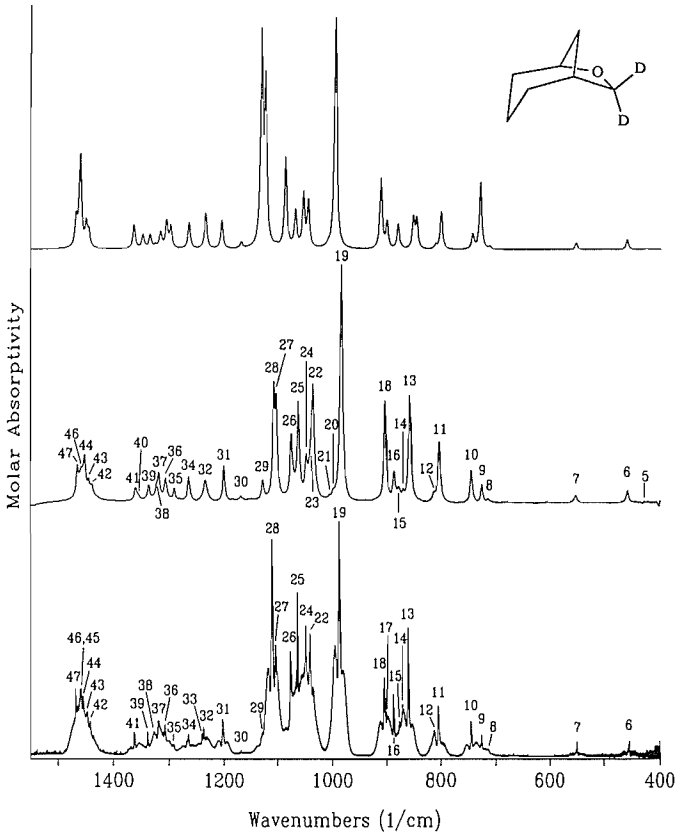

FIG. 6. Calculated (top) and observed solution (middle) and vapor phase (bottom) absorption spectra of 7,7-d_2-6-oxabicyclo[3.2.1]octane (6OXA-d_2). appreciably less in narrower regions of specific group frequencies within which intensity comparisons are invariably made in the following text for the purpose of assisting with assignments.

Observed vibrational frequencies and absorption intensities (expressed as dipole strengths) are listed in Tables 1–6. Selected portions of the condensed phase absorption spectra were subjected to Fourier self-deconvolution (20) in order to resolve partially overlapped bands and to check for transitions that might be completely hidden by other bands. Accurate frequencies were thus measured for a number of bands that otherwise would have been uncertain or left unnoticed. Such bands are marked with the label "dcn" in Tables 1–6. Absorption intensities were determined from the solution spectra by fitting Lorentzian band-shape functions and measuring band heights and widths at half height. The results obtained by visual and least-squares methods and for different solutions usually varied between 2 and 10%. The errors in the experimental intensities are thus estimated to lie in this range for most bands, while for a few of the very weak and overlapped lines the errors may be above 20%.

Calculations

Ab initio *calculations*

The geometries of BCO, 8OXA, 6OXA, and DIOXA were fully optimized and their harmonic force fields calculated by analytical second differentiation of the energies at the equilibrium geometries. The computations were carried out at the SCF-RHF level of theory using the programs GAUSSIAN 82 implemented on a CDC Cyber 205 (STO-3G basis set), and GAUSSIAN 86 (21) running on a Convex C120 (3-21G basis set). The atomic polar tensors and the polarizability derivatives were computed using the 3-21G basis set. BCO and 8OXA were restricted C_S symmetry. The existence of a true minimum in the potential hypersurface at the stationary point was ensured in every instance by confirming that all diagonal force constants were positive. Proof of good convergence was supplied by the fact that the lowest vibrational frequencies, which would be most affected by insufficient convergence of the energy, are calculated with an average error of 10.8 cm^{-1} (5.7%), which is within the expected error for the unscaled force fields. Contrary to Pulay's advocated standard procedure (7, 22), according to which corrected geometries afford more accurate force fields, we prefer to obtain the force fields at the uncorrected *ab initio* geometries. The practice of calculating Cartesian force fields at distorted theoretical geometries would require nonlinear transformations to other coordinate systems in order to account for the non-vanishing forces. For the bicyclic structures investigated, any correctional variations of the bond lengths and angles would unavoidably lead to distortions in the ring segments, and these distortions would be dependent on the choice of the valence coordinates in which the corrections are carried out.

The calculations utilizing STO-3G force fields are not presented here since they are clearly inferior to the 3-21G results. Information, however, can be obtained from the authors. Selected structural parameters and the RHF energies of all four parent molecules are given in Table 7 for the two

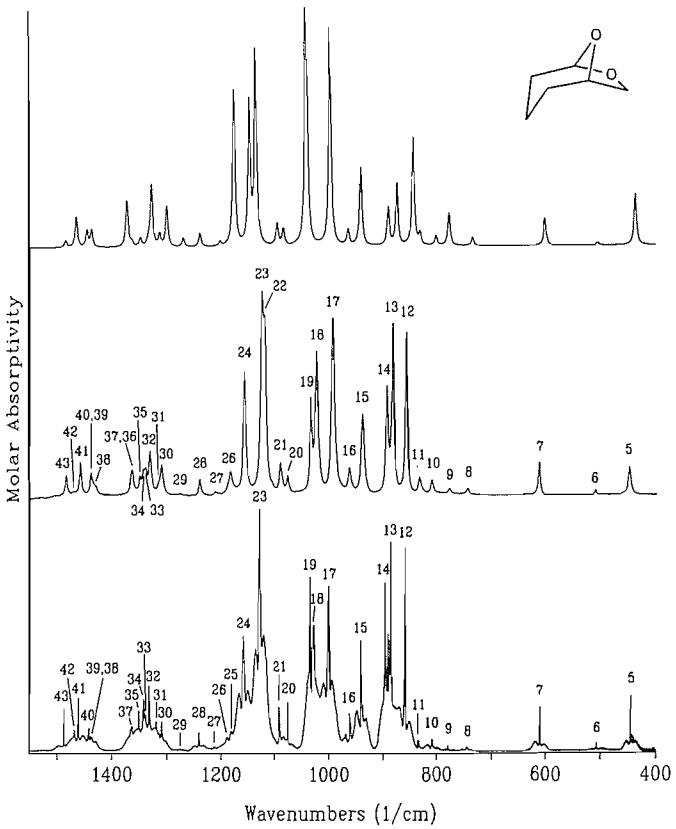

FIG. 7. Calculated (top) and observed solution (middle) and vapor phase (bottom) absorption spectra of 6,8-dioxabicyclo-[3.2.1]octane (DIOXA). The solution and theoretical spectra are on the same scale. For experimental conditions see text. Numbers correspond to "Band nos." in Tables 5 and 17.

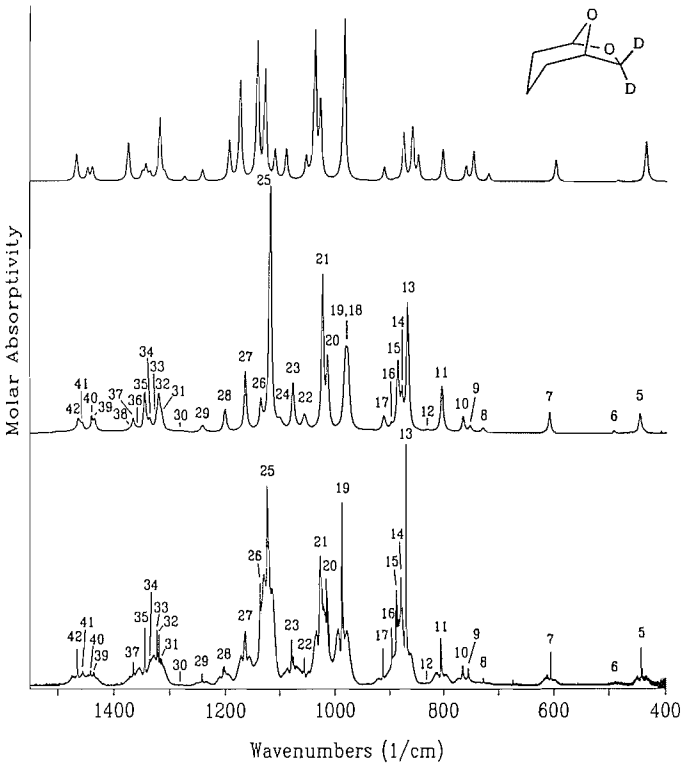

FIG. 8. Calculated (top) and observed solution (middle) and vapor phase (bottom) absorption spectra of 7,7-d_2-6,8-dioxabicyclo[3.2.1]octane (DIOXA-d_2). The solution and theoretical spectra are on the same scale. For experimental conditions see text. Numbers correspond to "Band nos." in Tables 6 and 18.

basis sets. For each of these bicyclics, two stable conformers may be expected to exist, which may be described by the chair and boat forms of the six-membered ring segment. All four structures converged to the chair conformation (Figs. 1, 2) in the geometry optimizations. To better characterize the potential surface of the ring inversion, the boat conformer of DIOXA was relaxed, converging at the 3-21G level in a local minimum higher in energy by 1577 cm^{-1} (18.9 kJ/mol) compared to the chair (Fig. 2). The chair to boat inversion is accompanied by other changes, involving considerable lengthening of the bonds C1—C2 and C4—C5, as well as an increase of the twist in the seven-membered ring segment, as expressed by the dihedral angle δ(1-7-6-5) in Table 7. The STO-3G calculation in addition proposes a remarkable expansion of the O6—C7 bond. Although no similar calculations for the other compounds were carried out, we suspect that they all possess similar highly asymmetric double minimum potentials for the inversion of the six-membered ring. The vibrational analysis of the boat conformers of the two DIOXA isotopomers revealed a number of transitions that should be observable distinctively among those of the chairs, but none were detected in the experimental spectra. This is in accord with the calculated population (0.04%, neglecting the zero-point vibrational energy) of the boat at the experimental conditions. Experimental structures have been published for 8OXA from a microwave study (23) and for BCO from electron diffraction (24). In both cases the agreement with the calculated geometries is reasonably good. These experimental studies confirm for both molecules the strong preponderance of the chair form at ambient temperatures.

Scaling and refining of ab initio *force fields*

These procedures, which were also described in previous publications (1, 2*a*, 4, 5), were carried out with a program developed by Shaw (25). The harmonic *ab initio* Cartesian force constants were transformed to a nonredundant set of local symmetry coordinates (LSCs), defined as linear combinations of internal coordinates following Pulay *et al.* (22) and listed in Tables 8–11 for the four parent molecules. The transformed force constants K_{ij} were then scaled with factors c_i and c_j associated with the local symmetry modes i and j, respectively, according to $F_{ij} = (c_i c_j)^{1/2} K_{ij}$, where the F_{ij} are the scaled force constants (26). The scale factors for the individual LSCs were transferred from similar molecules (see Table 12) and subsequently optimized stepwise in overlay refinements including all six compounds by least-squares fitting of the calculated frequency parameters, $\lambda_k = (2\pi c\bar{\nu}_k)^2$, to the observed values after weighting by $(1/\lambda_k^{obs})^2$.

Three vibrational calculations are presented here which differ in the way the *ab initio* force fields were scaled. The three scaling techniques were analyzed for the resulting accuracy in reproducing the experimental spectra in an attempt to find the most favorable force-field correction method. The simplest scheme, namely uniform scaling, consists of multiplying all diagonal and off-diagonal force constants by the same factor, which is subsequently refined. These results are found in column 1 under "Calculated wavenumbers" in Tables 13–18. The other two

Numbers correspond to "Band nos." in Tables 2 and 14. Asterisks indicate bands that are believed to arise from impurities.

calculations adopt the method of nonuniform scaling, applying and adjusting several factors, separately scaling the force constants for different types of LSCs as outlined above. Tables 13–18 contain the resulting wavenumbers using 14 factors directly transferred from other molecules (column 2, see discussion below), and fully refined (column 3). The factors applied to the three scaling schemes are listed in Table 12.

Intensity calculations

The absorption and Raman intensities listed in Tables 13–18 were derived from the refined nonuniformly scaled force fields. The dependence of the intensities on the scaling method is analysed below in the Discussion. The theoretical absorption intensities were computed by the standard expression for the dipole strength D_i (in units of esu^2 cm^2) of the ith fundamental (27, 28):

$$[1]\quad D_i = \frac{h}{8\pi^2\nu_i}\left|\sum_a \left(\frac{\partial \underline{\mu}}{\partial \underline{x}_a}\right)_0 \left(\frac{\partial \underline{x}_a}{\partial q_i}\right)\right|^2 = \frac{3(2303)hc}{8\pi^3 N_0}\int_{\text{band}} \frac{\epsilon(\nu)\,d\nu}{\nu}$$

where the symbols, h, c, N_0, and ν_i refer, respectively, to Planck's constant, the speed of light, Avogadro's number, and the vibrational frequency of normal mode i, in cgs units. The atomic polar tensor $(\partial \underline{\mu}/\partial \underline{x}_a)_0$ is the *ab initio* molecular dipole moment derivative with respect to the Cartesian position vector $\underline{x}_a$ of atom a, evaluated at the equilibrium geometry, and $(\partial \underline{x}_a/\partial q_i)$ is the Cartesian eigenvector for atom a in normal coordinate q_i as obtained from the Wilson GF formalism (29). The right-hand side of the equation defines the connection to the experimentally available molar absorptivity $\epsilon(\nu)$ if used in units of M^{-1} cm^{-1}.

The Raman scattering activities may be obtained to a good approximation from the derivatives of the molecular polarizability with respect to the normal coordinates $\partial \underline{\underline{\alpha}}/\partial q_i)$ if the electronic ground state is nondegenerate, and if the Raman frequency shifts ν_i are small compared to the frequency ν_0 of the incident light and compared to $\nu_E - \nu_0$, where ν_E is the lowest electronic absorption frequency (28*a*, 29). All these conditions are satisfied for the title compounds. The desired quantities can be calculated using:

$$[2]\quad \left(\frac{\partial \underline{\underline{\alpha}}}{\partial q_i}\right) = \sum_a \left(\frac{\partial \underline{\underline{\alpha}}}{\partial \underline{x}_a}\right)_0 \left(\frac{\partial \underline{x}_a}{\partial q_i}\right)$$

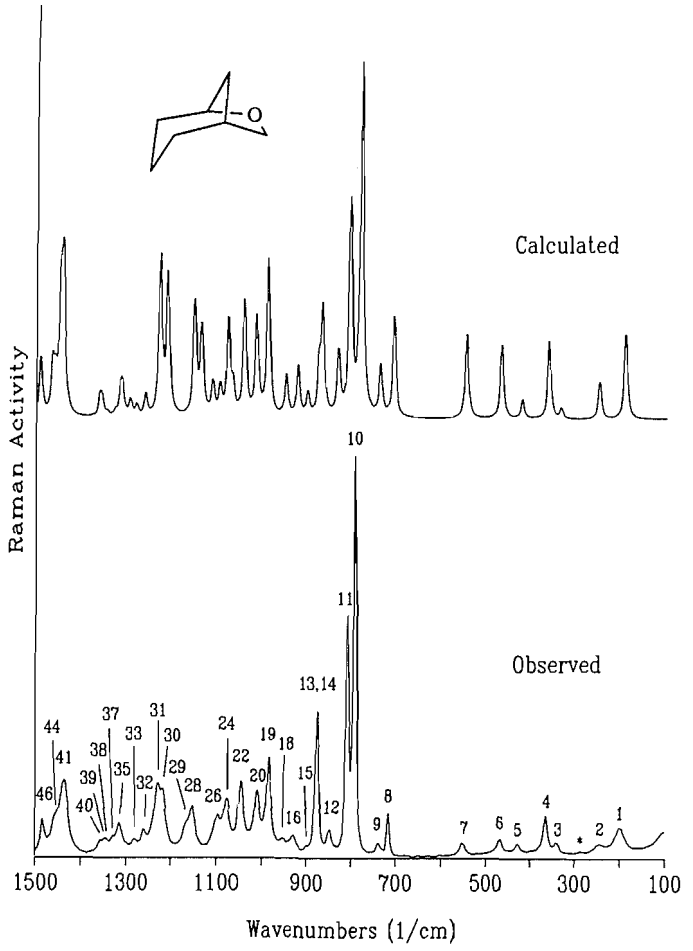

FIG. 11. Observed and calculated total Raman intensities (I^T) of liquid 6-oxabicyclo[3.2.1]octane (6OXA). For experimental conditions see text. Numbers correspond to "Band nos." in Tables 3 and 15. Asterisks indicate bands that are believed to arise from impurities.

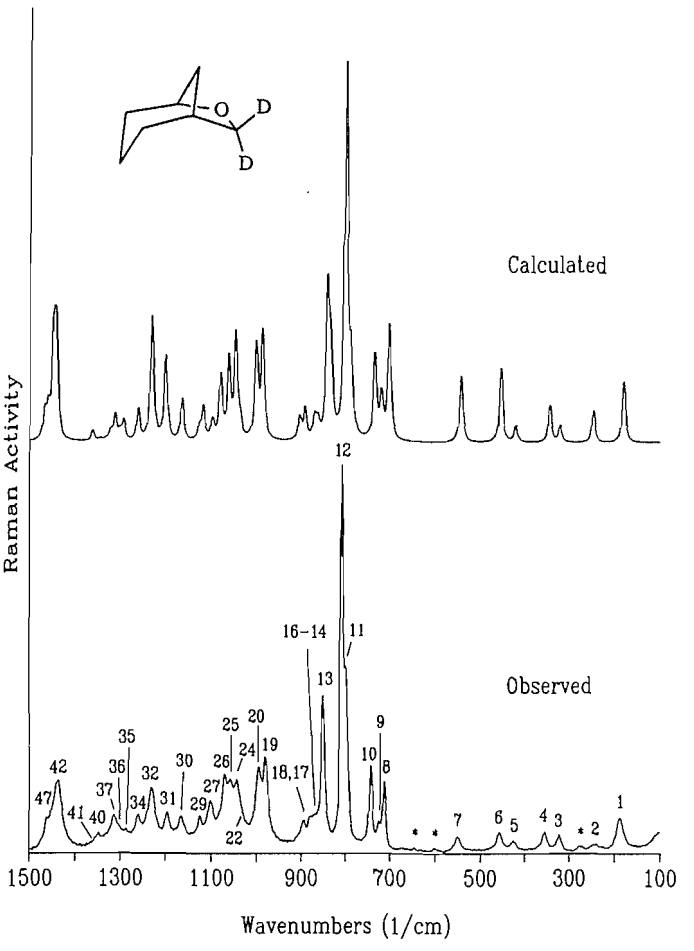

FIG. 12. Observed and calculated total Raman intensities (I^T) of liquid 7,7-d_2-6-oxabicyclo[3.2.1]octane (6OXA-d_2). For experimental conditions see text. Numbers correspond to "Band nos." in Tables 4 and 16. Asterisks indicate bands that are believed to arise from impurities.

where the polarizability derivatives with respect to Cartesian atomic coordinates $(\partial\underline{\alpha}/\partial x_a)_0$ are generated *ab initio* in the GAUSSIAN86 program. The mean value $\bar{\alpha}_i$ and the anisotropy γ_i^2 of the polarizability derivative tensors are then substituted into the standard classical equations for the Raman intensity of fundamentals (28*a*, 29, 30). For our experimental setup, which is collecting the scattered light at 90° from the progagation direction and perpendicularly to the electric field vector of the incident plane-polarized laser beam, these expressions are

$$[3] \quad S^T_i = 45\bar{\alpha}_i^2 + 7\,\gamma_i^2$$

$$[4] \quad S^{\parallel}_i = 45\bar{\alpha}_i^2 + 4\,\gamma_i^2$$

$$[5] \quad S^{\perp}_i = 3\,\gamma_i^2$$

$$[6] \quad \rho_i = 3\,\gamma_i^2/(45\bar{\alpha}_i^2 + 4\,\gamma_i^2)$$

where S^T_i designates the total intensity of the scattered light in the stated direction, $S^{\parallel}_i$ and $S^{\perp}_i$ are the parallel and perpendicular polarized components, respectively, and ρ_i is the depolarization ratio of normal mode *i*. The Raman data listed in Tables 13–18 were calculated using eqs. [3] and [6]. These quantities, although commonly reported, are not proportional to the experimental Raman activities. To allow direct comparison to observed intensities, the pertinent theoretical equations [3]–[5] must be multiplied with the factor $(\nu_0 - \nu_i)^4/\nu_i$ and another term correcting for the relative populations of the vibrational levels as derived from the Boltzmann distribution law (30, 31):

$$[7] \quad I_i = C\,\frac{(\nu_0 - \nu_i)^4}{\nu_i}\,[1 - \exp(-h\nu_i/kT)]^{-1}\,S_i$$

Here, C is a constant, k is Boltzmann's constant, and T is the absolute temperature. The expression in square brackets implicitly includes a summation over the population-weighted fundamental and hot band transitions, which is significant for the lowest vibrations. Equation [7] was utilized for the theoretical Raman spectra plotted in Figs. 9–14. The constant C is irrelevant here because the Raman spectra were not measured on an absolute scale, and only the relative Raman band strengths could be compared.

Basis set tests

After the assignments and force field refinements described below had been completed, the *ab initio* geometries, force fields, and intensity parameters were also

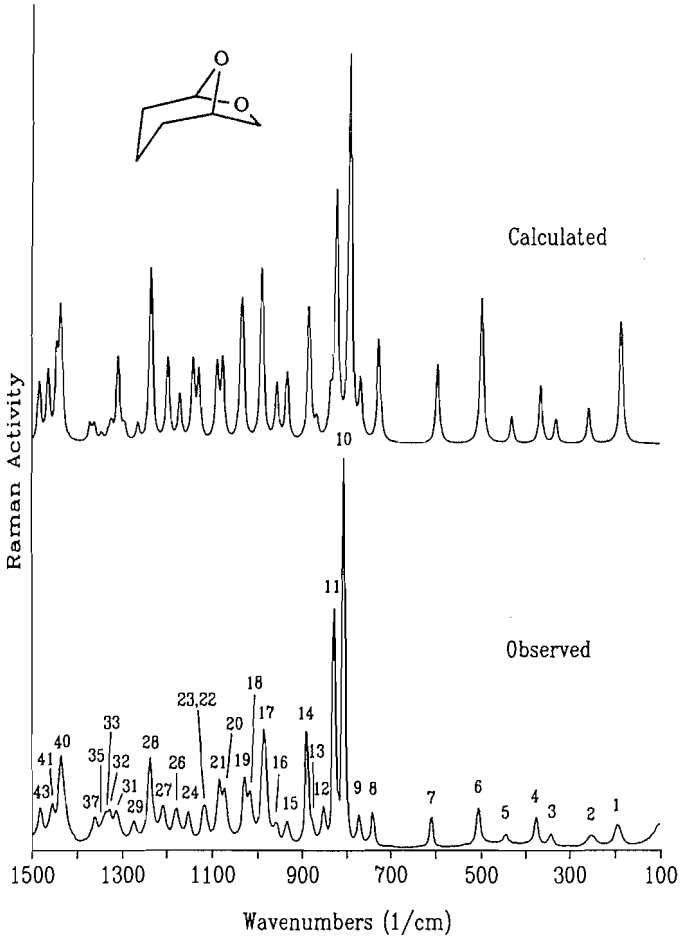

FIG. 13. Observed and calculated total Raman intensities (I^T) of liquid 6,8-dioxabicyclo[3.2.1]octane (DIOXA). For experimental conditions see text. Numbers correspond to "Band nos." in Tables 5 and 17.

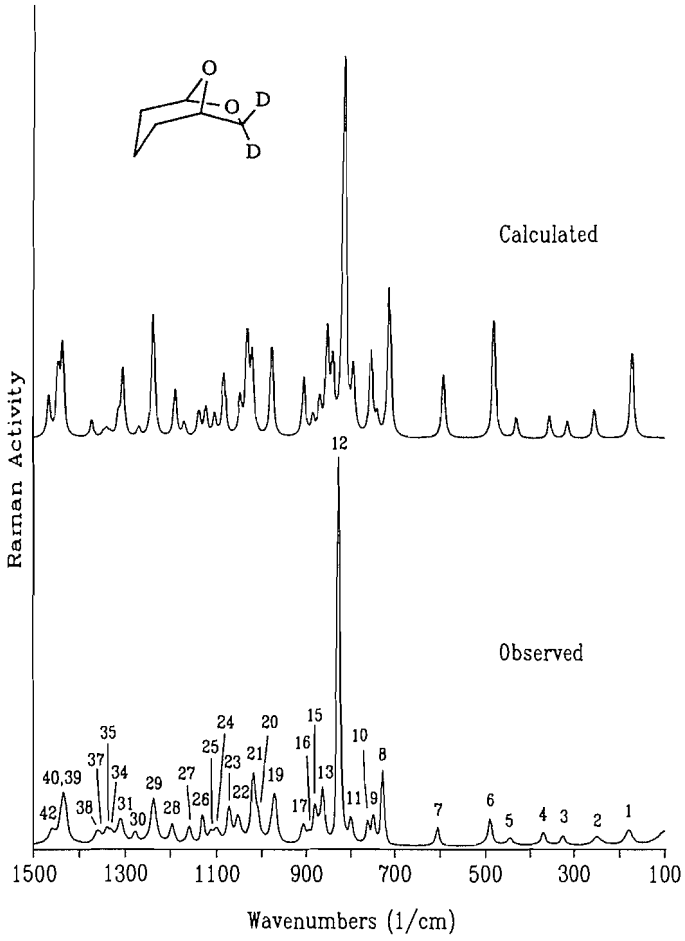

FIG. 14. Observed and calculated total Raman intensities (I^T) of liquid 7,7-d_2-6,8-dioxabicyclo[3.2.1]octane (DIOXA-d_2). For experimental conditions see text. Numbers correspond to "Band nos." in Tables 6 and 18.

computed for DIOXA with the basis sets 6-31G, 6-31G*, 6-31*$^{(0.3)}$, and 6-31G**. The 6-31G*$^{(0.3)}$ basis set (32) derives from the standard 6-31G* by reducing the exponents for the *d* functions from 0.8 to 0.3, thus rendering the polarization functions considerably more diffuse. This or very similar modifications have been recommended by several authors for calculating dipole moments and polarizabilities and their derivatives (7*a*, 32, 33). These force fields were scaled with the refined 3-21G factors (Table 12), which were then optimized again for each force field, based on the 72 assigned band positions of DIOXA and DIOXA-d_2. The band assignments for the two molecules suggested by the 3-21G results (Tables 17, 18) were confirmed by the higher level calculations. To allow proper comparison, the 3-21G scale factors were also refined once more using the data of the two DIOXA isotopomers only, changing the factors by small amounts. The average error in the frequency predictions reduced to 0.52% with the 6-31G calculation as compared to 0.70% for 3-21G. The improvement of the eigenvectors was also reflected in the better agreement of the absorption and Raman intensities. However, addition of polarization functions with the 6-31G* and 6-31G** basis sets did not give rise to any further improvements in the frequencies or intensities. In fact, the last two basis sets yielded virtually identical results after the scale factor refinements (wavenumbers agreed within 0.025%, absorption intensities within 6%, and Raman within 5%). Even the 6-31G*$^{(0.3)}$ basis set, although designed for absorption and Raman intensities, did not provide significantly improved results.

It was found that, when employing the same eigenvectors in combination with the APTs and polarizability derivatives from the various basis sets, the theoretical absorption and Raman intensities were the same throughout. That is, the *ab initio* calculated intensity parameters were insensitive to the basis set applied, except for small changes in the absolute intensities (6-31G* intensities were largest). The distribution of the relative intensities among the vibrational modes was completely governed by the eigenvectors. The basis set dependence of the eigenvector was further traced back to the force fields. While there was also a small dependence on the geometry, the accuracy of the vibrational intensities attainable by the split-valence and the polarized basis sets was thus primarily determined by the quality of the force field. The tests also suggest that the quality of the scaled 3-21G force field closely approaches the scaled 6-31G force field, which is as accurate as the scaled 6-31G* and 6-31** force fields. Among the basis sets tested, the 6-31G calculation appeared to have the best performance-to-cost ratio. Compar-

ing these results to similar studies on smaller molecules (*7a*, *7b*, 34), it appears that the basis set dependencies of the vibrational intensities encountered here are less severe, particularly for the polarized basis sets. The conclusions derived from these tests apply strictly only to the DIOXA isotopomers. Similar results may be found for other large molecules with related structures.

Assignments and scaling of force fields

General procedure

In general, the complexity of the spectra prevented straightforward assignments based only on observed features. The majority of the bands had to be assigned on the basis of the theoretical frequencies. In the cases where such assignments were ambiguous, the calculated absorption in-

tensities, and Raman activities and polarization ratios turned out to be very helpful guides, assuming that at least the order of magnitude of the calculated intensities was correct. The validity of this assumption will be demonstrated in the Discussion. In general, therefore, band assignments were initially based on the mode symmetries as deduced from Raman polarization ratios and gas phase absorption band shapes where applicable, and on the frequencies, which are the most reliable theoretical predictions with the 3-21G basis set. The intensities usually were consulted only for transitions that were observed or calculated less than 10 cm^{-1} apart (which is in the same range as the uncertainly in the predicted band positions) and only on a semi-quantitative basis, that is, if the absorption or Raman intensities of the involved bands were sufficiently different, to provide a safe criterion to differentiate between them. A few bands were assigned despite remaining uncertainties, if the predicted frequencies were in good agreement with the frequencies of observed bands that appeared to correspond to the normal modes in question. This was done to ensure that there were sufficient data to guarantee stability in the refinement of the force field. Even if a few of these assignments were incorrect, the ef-

fect on the optimized scale factors was negligible because the frequency errors were always small.

Initially, the force fields were scaled with 11 factors, 10 of which (factors 1, 2, and 4–11 in Table 12) were transferred from the norbornane series (4) (from refinement "A" in that reference, where the ring out-of-plane deformation factor of norbornane was used) and applied to the corresponding local symmetry modes of the bicyclo[3.2.1]-octanes. The C—O stretching factor (3 in Table 12) was taken from 7-oxanorbornane (5). Previous experience from the assignment of the vibrational spectrum of 2-methyloxetane (2*a*) suggests that different scale factors may be required for certain methylene deformation modes if the CH_2 group is located next to an oxygen atom, and for methyne

deformations if an adjacent C—O bond is located approximately in the plane of the CH bend. Two special factors for the CH_2 wag and twist (12 and 13 in Table 12) were therefore transferred from 2-methyloxetane (2*a*) and used for the corresponding modes on C7 of 6OXA, DIOXA, and their isotopomers. Factor 14 was taken from the same source and used for all "in-plane" (i/p) and "out-of-plane" (o/p) methyne CH bends for which an adjacent oxygen atom lies approximately in the plane of the motion of the hydrogen atom (C1 and C5 o/p in 8OXA, C5 i/p in 6OXA and

6OXA-d_2, C1 o/p, C5 i/p and o/p in DIOXA and DIOXA-d_2).

The frequency predictions that resulted from this first correction of the force field with the 14 factors led to the unambiguous assignment of 55 bands for the six molecules in the methylene scissoring (1400–1500 cm^{-1}) and the low frequency (100–600 cm^{-1}) regions. The assignments in the latter were straightforward. Except for BCO, the seven lowest modes for each molecule were identified in either or both the absorption and Raman spectra simply by consulting the frequencies. Additional confirmation was obtained for BCO and 8OXA from the Raman polarization ratios, clearly establishing A′ symmetry for a number of vibrations. The factors for the dominant local symmetry modes (factors 4, 10, and 11) were then refined. Next, bands from 600 to about 1050 cm^{-1} were included and the factors 1, 3, and 5 were floated together with 4, 10, and 11, fitting a total of 123 frequencies. The assignment of the rest of the spectra turned

out to be more difficult because of congested bands. However, it was possible to assign with relatively high confidence a number of bands in the remaining parts of the spectra, followed by the third refinement cycle including the factors 6–9 and 12–14. With a total of 196 assigned transitions, all the factors except the one for the C—H stretch were finally optimized simultaneously, converging to the set listed in Table 12 as "Refined factors" with an average error of 5.7 cm^{-1} (0.75%).

Tables 13–18 list in bold lettering the assignments included in the refinements, and the frequencies calculated with the three scaling methods. Also listed are dipole strengths, Raman intensities and depolarization ratios, and the strongest contributors to the potential energy distribution (PED) of the normal modes, all of which have been calculated with the fully refined, nonuniformly scaled force fields. The following paragraphs contain an outline of the rationales used for the most problematic band assignments, as well as discussions about spectral details that are interesting for other reasons. In some instances, plausible assignments are suggested for bands that were not included in the refinement cycles; they are listed in Tables 13–18 in italic lettering.

Bicyclo[3.2.1]octane (BCO)

There are only four CH_2 scissoring modes apparent in the spectrum of BCO. Band 44 is separated from the rest and exhibits strong polarization in the Raman spectrum (Figs. 3 and 9). It clearly corresponds to ν_{10} (Table 13). The remaining three observed bands (41–43) can be assigned to ν_{39}, ν_{12}, and ν_{11} by noting that the last two scissoring modes, ν_{13} and ν_{40}, are predicted with much smaller absorption intensities by comparison. The latter two transitions, not included in the refinement, are predicted to give rise to the strongest Raman lines of all scissoring modes, and are therefore likely to be the principal if not the only significant contributors to band 40 in Fig. 9.

The region between 1050 and 1400 cm^{-1} is quite congested. The modes ν_{46} and ν_{50} cannot be found in the spectrum. They are both predicted with very low infrared intensities near prominent fundamentals (32 and 26, respectively) and are therefore likely to be completely hidden. There is one unassigned band (25 in Fig. 3) that could be identified with ν_{50}, but the large discrepancy in frequency makes this assignment problematic. Some of the bands in the wagging region (1280–1350 cm^{-1}) were assigned, although not with absolute confidence. Band 34 with the lowest frequency and band 37 with the highest intensity were ascribed to ν_{44} and ν_{42}, respectively. For the three fundamentals predicted between these two, namely ν_{15}, ν_{16}, and ν_{43}, there are only two observed absorptions (bands 35 and 36). One plausible assignment is suggested in Table 13. The remaining two bands at the highest frequencies in this region (38 and 39) were included in the refinement by virtue of their

predicted positions and infrared intensities as corresponding to ν_{41} and ν_{14}, respectively, although their ordering may be reversed.

Many assignments in the 600–1050 cm^{-1} region were guided by the Raman spectrum, which exhibits intense, strongly polarized lines. The two fundamentals ν_{28} (A′) and ν_{57} (A″) were not assigned as there are three observed bands (9–11) in the vicinity. The predicted frequencies would suggest bands 10 and 11 as the fundamentals. This is contradicted by the Raman spectrum, which shows both as strongly polarized. Accordingly, band 9 should be assigned to the A″ fundamental ν_{57}, while the bands 10 and 11 may possibly result from Fermi resonance involving ν_{28} (A′). Although the three bands near 870 cm^{-1} (14–16) were not included in the refinement, a plausible assignment may be suggested. Of the three fundamentals ν_{25}, ν_{26}, and ν_{55}, the second is predicted to give rise to a polarized Raman line with much greater intensity than the other two, while the first should have the highest infrared intensity. Accordingly, ν_{26} most likely corresponds to band 15, and bands 16 and 14 to ν_{25} and ν_{55}, respectively.

8-Oxabicyclo[3.2.1]octane (8OXA)

The highest and the lowest frequency CH_2 scissoring bands 39 and 35 (Figs. 4, 10) are assigned to ν_8 (A′) and ν_{36} (A″), respectively (Table 14). Besides the clear separation from others, band 39 is readily distinguished by the relatively high infrared intensity, and the low Raman depolarization ratio, as predicted for ν_8. The assignment of band 35 is supported mainly by the pronounced observed and calculated Raman intensities. The remaining three scissoring modes cannot be clearly assigned, but must correspond to bands 36–38. They have therefore not been included in the refinements.

Also left unassigned was ν_{17}, as it may correspond either to band 20, in which case the calculated frequency and intensity would be completely wrong, or it may coincide with ν_{45} (band 21). The second alternative is consistent with the

Raman spectrum where band 20 has no analog. A similar situation holds for ν_{16} (left unassigned) and ν_{44}, both of which likely contribute to band 22 in the infrared and Raman spectra. The ordering of ν_{15} and ν_{42} (bands 25 and 24, respectively) was reversed based on the absorption intensities and the apparent B-type contour of band 24 (not visible in Fig. 4). In the wagging region, band 30 can be assigned confidently to ν_{13} based on the observed and calculated infrared intensities, while band 33 must correspond to ν_{11} by virtue of the observed and calculated positions. Mode ν_{39} is absent in the absorption spectra, but is observed in the Raman (band 29). The last remaining A′ wagging mode, ν_{12}, must correspond to the partially polarized Raman line 32, while the remaining two A″ frundamentals, ν_{38} and ν_{37}, cannot be assigned unambiguously. The former may give rise to band 31 (in the Raman only), while the latter may be hidden under band 32.

Although ν_{24} and ν_{51} are predicted in the wrong order, their assignment is unambiguous based on the apparent B-type contour of the latter (band 9 in gas phase infrared) and the clearly polarized Raman line 10 corresponding to the former. The location of ν_{48} remains uncertain as evidently it is too weak to be observed in the absorption spectra. The slight asymmetry of Raman band 16 may indicate the presence of ν_{48} there. Band 17 probably contains ν_{19} (A′) and ν_{47} (A″), both of which are calculated with equally strong absorption intensities. Moreover, ν_{19} is predicted to give rise to a dominant polarized Raman line, which is consistent with the observed spectrum, justifying inclusion of ν_{19} in the refinement, while ν_{47} was not added to the certain assignments.

6-Oxabicyclo[3.2.1]octane (6OXA) and 7,7-d_2-6-oxabicyclo[3.2.1]octane (6OXA-d_2)

The spectra of these two isotopically related molecules are similar in several respects and are therefore discussed

together. Of the methylene scissoring modes of 6OXA, ν_{13} is separated from the rest and must correspond to band 46 (Figs. 5, 11, Table 15). It clearly disappears on deuteration (Figs. 6, 12, Table 16), confirming the assignment to C7 scissoring. Another prominent feature in the congested region is the strong Raman line labelled as 41 and 42 for the two compounds, respectively (Figs. 11 and 12). For 6OXA a connection between this band and ν_{17} is readily made with confidence. For the isotopomer, the infrared band is not as neatly separated and therefore was not included in the refinement, although the assignment to ν_{16} is nonetheless reasonable by comparison. Since ν_{16} and ν_{15} in the two compounds, respectively, also are predicted to exhibit relatively strong Raman lines, they probably contribute significantly to lines 41 and 42, respectively, while being clearly resolved in the absorption spectra and labelled as band 42 in Fig. 5 and band 43 in Fig. 6. The last relatively certain assignment in this region is band 47 in the infrared spectrum of 6OXA-d_2 (Fig. 6) that we believe must correspond to ν_{13} in this compound. By comparison, the same mode in 6OXA, ν_{14}, can probably be associated with band 45 in Fig. 5. For the last scissoring mode in both compounds, several choices of observed bands are possible and the fundamental cannot be located unambiguously.

The abundance of bands with undistinguished intensities in the region of 1280–1380 cm^{-1} seemingly confuses their assignment. The region contains the CH_2 wagging and CH bending modes variously coupled. Their predicted intensities are not expected to be very reliable, since small differences in force constants may subtly alter the eigenvectors. Nonetheless, a one-to-one correspondence between predicted and observed band positions exists for both derivatives. The assignment, therefore, of ν_{18}–ν_{25} to bands 40–33, respectively, in 6OXA, and ν_{17}–ν_{23} to bands 41–35 in 6OXA-d_2, can be made with little hesitation, although for the sake of refining the scale factors only ν_{18}, ν_{24}, and ν_{25} in 6OXA, and ν_{17} and ν_{21}–ν_{23} in 6OXA-d_2, were included as firm.

For ν_{35} of 6OXA, the predicted position and intensities provided reasonable grounds for association with band 22. The predicted intensities for ν_{31}–ν_{34} appeared unreasonably different from those of bands 24–27 to which presumably these modes should correspond. They were therefore not

Average error of calculations			*22.2 (2.6%)*	*7.5 (1.3%)*	*7.0 (1.0%)*				

[a]Measured from vapour phase absorption unless designated R (Raman).
[b]As listed in Table 2 and Figs. 4 and 10.
[c]Calculated with uniformly scaled force field (1), transferred scale factors (2), and fully refined scale factors (3); see text.
[d]In units of 10^{-40} esu^2 cm^2, from fully refined force field.
[e]S^T_i (eq. [3] in text) in units of Å^4 amu^{-1}, from fully refined force field.
[f]Depolarization ratios ρ_i (eq. [6] in text), from fully refined force field.
[g]Most important contributors to potential energy distribution (PED) of the normal modes. Numbers in parentheses refer to coordinate definitions in Table 9.

Average error of calculations			*15.1 (1.6%)*	*6.6 (1.1%)*	*4.0 (0.56%)*				

[a]Measured from vapour phase absorption unless designated sol (absorption of solution) or R (Raman).
[b]As listed in Table 4 and Figs. 6 and 12.
[c]Calculated with uniformly scaled force field (1), transferred scale factors (2), and fully refined scale factors (3); see text.
[d]In units of 10^{-40} esu^2 cm^2, from fully refined force field.
[e]S^T_i (eq. [3] in text) in units of Å^4 amu^{-1}, from fully refined force field.
[f]Depolarization ratios ρ_i (eq. [6] in text), from fully refined force field.
[g]Most important contributors to potential energy distribution (PED) of the normal modes. Numbers in parentheses refer to coordinate definitions in Table 10.

included in the refinement. Bands 24, 27, and 26 may be ascribed to ν_{33}, ν_{32}, and ν_{31}, respectively, based on approximately matching intensities. The location of ν_{34} is left uncertain unless it gives rise to band 22, in which case ν_{35} could be reassigned to band 21; however, the calculated frequency of ν_{34} appears unreasonably high. Evidently, band 23 and possibly band 25 are not fundamental transitions. The corresponding normal modes ν_{29}–ν_{34} in 6OXA-d_2 are readily assignable to bands 28–22, respectively, from the point of view of the frequencies, but appreciable differences in the absorption intensities emerge. A similar competition between position and intensity is found also for ν_{28} in the same compound (band 29 in Fig. 6). From the point of view of the former, the assignment given in Table 16 seems the most reasonable and was adopted as firm only in the very last refinement cycle on that basis. The scale factors as a result changed very little. From the point of view of the intensities, however, it would seem better if ν_{28}, ν_{29}, and ν_{30} were assigned to bands 28, 27, and 30, respectively, thereby clearly introducing major discrepancies in the frequencies. This dilemma remains unresolved.

Bands 13 and 14 in 6OXA, which must correspond to one or the other of ν_{41} and ν_{42}, were originally not assigned and hence not included in the refinement. In retrospect, ν_{41} is predicted to be the stronger of the two in absorption, while ν_{42} should be stronger in the Raman (Figs. 5 and 11). The assignment suggested in Table 15 is based on the relative intensities in the infrared spectra. The corresponding fundamentals in 6OXA-d_2 are thought to be nearly coincident, together giving rise to band 13 (Fig. 6). The last remaining ambiguity concerns bands 17 and 18 for both compounds. Only one normal mode (ν_{38}) is at disposal for assigning the two bands for 6OXA. While band 17 appears prevalent in the infrared, the Raman experiment suggests band 18 as the fundamental. Bands 17 and 18 in the isotopomer may be ascribed to ν_{37} and ν_{38} as a nearly coincident pair.

6,8-Dioxabicyclo[3.2.1]octane (DIOXA) and 7,7-d_2*-6,8-dioxabicyclo[3.2.1]octane (DIOXA-*d_2*)*

The methylene scissoring bands 43, 41, and 40 of DIOXA (Figs. 7, 13) were readily assigned to ν_{11}, ν_{12}, and ν_{13}, respectively (Table 17). Near the predicted position of ν_{14}, the two bands 38 and 39 are observed with about equal intensities, preventing firm identification of the fundamental. One of the bands 38 or 39 and also 42, therefore, are likely to arise from higher order transitions. The normal mode descriptions for the three methylene scissors ν_{11}–ν_{13} of DIOXA-d_2 (Table 18) are essentially the same as for the corresponding modes (ν_{12}–ν_{14}) in DIOXA. The vibrations are identified for DIOXA-d_2 as bands 39, 40, and 42 (Figs. 8, 14) by comparison with the spectrum of DIOXA, and confirmed by the predictions of the frequencies and intensities.

The methylene wagging and methyne bending regions for both molecules were completely assigned on the basis of the good agreement of predicted frequencies and intensities with the observed absorption spectra, although some ambiguities remain. The band ordering may be wrong for the modes ν_{20} and ν_{21} and for ν_{17} and ν_{18} for DIOXA, and for ν_{15} and ν_{16} for the isotopomer. The C5 C—H bending vibration of DIOXA (ν_{15}) is observed to be split into the two bands 36 and 37, while the corresponding mode of DIOXA-d_2 (ν_{14}) has shoulders on either side (bands 36, 38) that are not fundamentals. The Raman spectra confirm the assignments to a satisfactory degree.

Presuming that bands 22 and 23 are both fundamental transitions, the calculations suggest bands 22–24 of DIOXA to correspond to ν_{27}–ν_{25} despite large errors in the frequencies, but leave uncertain the correct ordering of ν_{27} and ν_{26}. Bands 25 and 27 cannot be fundamentals. Bands 25 and 26 of DIOXA-d_2 must be attributed to ν_{25} and ν_{24} even though their calculated intensities are in error in absorption and Raman scattering. Similar discrepancies were encountered in the same region for DIOXA (bands 23 and 22, Fig. 7), 6OXA-d_2 (bands 28 and 29, Fig. 6), and 6OXA (bands 26 and 27, Fig. 5). None of these bands was assigned firmly.

The region 600–1050 cm^{-1} is reproduced unambiguously by the theory for both molecules except for a few congested lines. For DIOXA, the pair of bands 18 and 19 (ν_{30}, ν_{31}), which are calculated only 1.6 cm^{-1} apart, are tentatively assigned in the reverse order using the Raman intensities as a criterion. The correct ordering of ν_{36}, ν_{35}, and ν_{34} for the deuterated isotopomer cannot be resolved due to the differences between experiment and the predictions of frequencies and intensities in both the absorption and Raman spectra, preventing any firm interpretation of bands 13–15. The transition ν_{31} of DIOXA-d_2 involving C—O stretching is split into a doublet (bands 18 and 19) with about equal inensities in the solution absorption spectrum, while the splitting is not evident in the gas phase and Raman.

Discussion

The detailed analysis of the absorption spectra described above revealed the presence of a number of transitions that cannot be fundamentals, many of them with considerable intensities, likely due to mixing with fundamentals by Fermi resonance. Such bands have repeatedly confused definitive identifications of fundamentals in this study. Recurring examples are the lines in the CH_2 scissoring region at approximately 1440 and 1465 cm^{-1} and a mode around 1080 cm^{-1}. While an investigation of the origin of these transitions would be of great interest, such endeavor is beyond the scope of this work as it would require anharmonic force fields. Some vapor phase bands exhibit series of Q-branches that probably arise from coupling to excited vibrational states of low energy vibrations of anharmonic skeletal deformations. This observation and the occurrence of Fermi resonances are evidence for high anharmonicity in the potentials of certain vibrations, in particular the ones involving skeletal deformations.

Force-field scaling and refining

The average errors of the frequency predictions for all six bicyclo[3.2.1]octanes after uniform scaling is 20.4 cm^{-1} (2.2%), which is lowered to 7.6 cm^{-1} (1.2%) and 5.7 cm^{-1} (0.75%), respectively, upon nonuniform scaling with the transferred and refined sets of factors (see Table 12). Tables 13–18 contain the corresponding errors for the six individual molecules, among which 8OXA has the largest deviation in the frequency predictions after refinement (1.0%), and also has the worst fit after uniform scaling (2.6%). The excellent fit of the frequencies in general and the qualitative agreement of the intensities strongly support the assignments listed in Tables 13–18 in bold letters as firm, except for a small number of bands that are discussed in the previous section. Difficulties were encountered especially for clusters of closely spaced bands with similar intensities. In some cases, such modes were tentatively assigned to cal-

culated transitions despite uncertainties and may therefore be incorrect. Nevertheless, the success of the spectral assignments is also reflected in the refined scale parameters, which deviate only slightly from the transferred values, demonstrating as well the validity of transferring the parameters. The comparatively large changes for the ring bend (+9.1%) and ring torsion (−13.8%) factors may be rationalized by the smaller ring strain of the bicyclo[3.2.1]octane system compared to the bicyclo[2.2.1]octane (norbornane) system from which these parameters were taken, and also by the presence of one or two oxygen atoms in the rings, since the C—O—C and the C—C—C bending force constants were not scaled differently. Vibrational anharmonicities may also account in part for the differences as they influence the magnitudes of the scale factors.

The necessity of special scale factors for deformations of methylene groups adjacent to oxygen atoms is confirmed for the wagging mode, but not for the twisting mode. The "normal" CH_2 wagging and twisting factors converge to similar values as observed previously for norbornane (2*a*). The "special" factor for wagging does not change upon refinement and is found still considerably higher than the normal value. However, the "special" twist factor converges back to its original value. Whether this trend is real or not is not clear at this stage as the uncertainty of the refined value is relatively large. The most ambiguous scale factors in this work are the ones used for the methyne deformations. The problem apparently lies in their strong dependence on neighboring substituents and bonding, necessitating three separate factors that are then supported only by a relatively small number of experimental data. This naturally leads to large uncertainties in the refinement process. Removal of any one of the CH bending factors leads to appreciably worse frequency fits.

Intensities

In general, the calculated absorption intensities and, perhaps even more surprisingly, the Raman activities and depolarization ratios of the title compounds are predicted very satisfactorily using the 3-21G basis set. All intensity data are certainly accurate enough to be useful in a qualitative manner for spectral interpretations. Other workers have reported before that simple split-valence basis sets afford absorption intensities that are correct in the order of magnitude (7*b*, 22, 26, 35). The calculated absorption intensities in this study appear to surpass this order of magnitude accuracy as will be demonstrated below with a statistical analysis of the data. Raman activities have been reported to be even more susceptible to basis set truncation (7*b*, 22, 36). Large *ab initio* basis sets extended by polarization functions were deemed necessary for reasonable predictions (37). In this study, the relative intensities agree in the order of magnitude or better (Figs. 9–14). The calculated relative Raman intensities and depolarization ratios appear to be about as accurate as the absorption intensities. With theoretical predictions of such quality at hand, it would be worthwhile now for the purpose of spectral assignments to measure Raman depolarization ratios even for asymmetric molecules, as these properties can be calculated with reasonable accuracy. Furthermore, our results for DIOXA and DIOXA-d_2 from various *ab initio* calculations indicate that the APTs and polarizability derivatives are only slightly basis-set dependent in the domain of the split-valence and the 6-31G*, 6-31G*$^{(0.3)}$, and 6-31G** basis sets. The relative absorption and Raman intensities were found to be governed only by the accuracy of the normal mode descriptions.

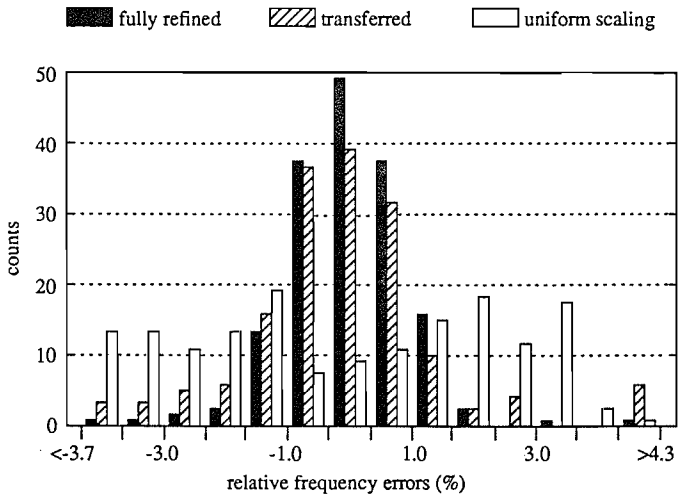

FIG. 15. Error distributions of the calculated frequencies for all six molecules using the three different force fields (fully refined nonuniform, transferred nonuniform, and uniform scaling).

Accuracy of eigenvectors

Some recently reported analyses of vibrational spectra have adopted uniform scaling methods, multiplying the entire force field by only one parameter. In the same studies, the nonuniform correction procedures used for SQM force fields were found to deteriorate the *ab initio* vibrational eigenvectors (38). Uniform scaling was preferred by these authors because it does not change the composition of the *ab initio* normal modes. These observations conflict with the findings by other workers that different local symmetry coordinates need different scale factors to obtain good frequency fits, which originally led to the idea of nonuniform scaling (39). The abundance of data for the series of molecules in this work permits a statistical analysis of the errors in the calculated intensities which rely partly on the underlying eigenvectors. This should allow some conclusions to be drawn about the preferable approach to scale force fields. To reexamine the validity of our approach and to gauge the accuracy of the scaled force fields, tests were carried out based on the assignments of the bicyclo[3.2.1]octanes as outlined above, probing the quality of our scaling method against uniform scaling. Figure 15 displays histograms that compare the distributions of the relative errors in the calculated frequencies for the force fields obtained by scaling with the fully refined and transferred multiple set of factors, and with the uniform parameter, respectively. The standard deviations of the errors of the 196 firmly assigned transitions are found at 1.1%, 2.0%, and 2.6%, respectively, assuming Gaussian distributions. The apparent superiority of the nonuniformly scaled force field in predicting the vibrational frequencies does not guarantee that the eigenvectors also are calculated more accurately. To judge the effect of nonuniform vs. uniform scaling on the normal mode compositions, the accuracy of the calculated absorption intensities was also investigated. Due to the large error margins on the intensities, distributions using relative errors for the abscissa of the histograms are not symmetric. The error in absorption intensity for every assigned transition is therefore mea-

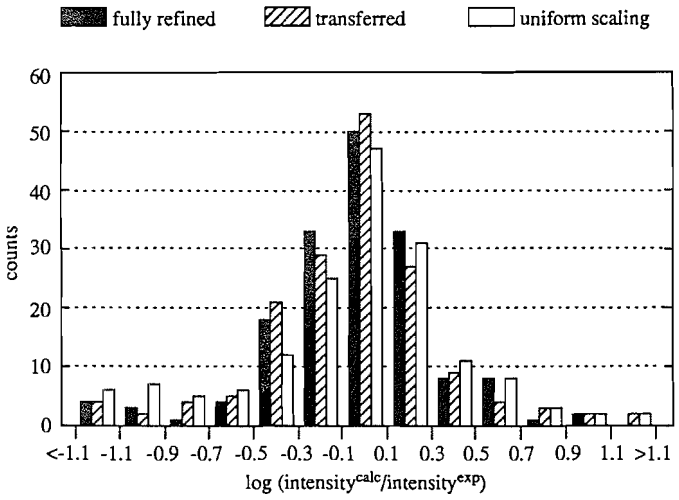

FIG. 16. Error distributions of the calculated absorption intensities for all six molecules using the three different force fields (fully refined nonuniform, transferred nonuniform, and uniform scaling).

sured here by the ratio of the calculated and the experimental intensity of the band ($f_k = I_k^{calc}/I_k^{exp}$). A histogram using $\log(f_k)$ for the abscissa is approximately symmetric and does reflect a Gaussian distribution (Fig. 16). The standard deviations calculated in this fashion are then found at $f_k = 2.5$, 2.7, and 3.2, respectively, for refined nonuniform, transferred nonuniform, and uniform scaling. The error distributions demonstrate clearly that nonuniform scaling certainly does not deteriorate but rather slightly improves the intensities. The Raman spectra did not allow a similar test as the experimental absolute intensities were not measured. However, a qualitative comparison of the relative calculated Raman intensities with the spectra leads to the same conclusion.

Conclusions

It appears that for these compounds and probably also for a large set of other moieties the *ab initio* eigenvectors are generally not deteriorated by nonuniform scaling if the factors are transferred from appropriate molecules and then carefully refined. This statement holds for the 3-21G basis set that was utilized here and can probably be extended to all split-valence basis sets. Even the intensities predicted by the transferred, unrefined set of scale parameters are notably superior to the calculations based on the uniformly scaled force field. It is known that similar calculations closer to the Hartree–Fock limit utilizing large basis sets require fewer scale factors. Consequently, if more sophisticated basis sets are used, uniform scaling will give more favorable results compared to this study, or may even be superior to nonuniform scaling (40). Some very recent theoretical work suggests that the Hartree–Fock-limit force field for a given molecule can be corrected with one factor only (41). However, due to basis set truncation, calculations at the 3-21G level are significantly less accurate and require nonuniform scaling as demonstrated theoretically (41) and confirmed here.

In principle, the errors in the intensities originate from two possible sources, firstly from deficiencies in the eigenvectors and secondly from inaccurate atomic polar tensors and polarizability derivatives. If a principal part of these intensity deviations originates from poor eigenvectors, some degree of correlation between the frequency errors and the intensity errors would be expected. However, linear regression of the errors from the above analysis shows no correlation at all, meaning that the intensity errors encountered here are basically independent of the remaining inaccuracies of the force field. When properly scaled force fields are utilized, the deviations from the observed values of the intensities must therefore originate from deficiencies in the APTs and polarizability derivatives, and cannot be substantially improved with more accurate force fields. Deficiencies in the force fields would obviously become more evident if the APTs and polarizability derivatives were obtained with sophisticated basis sets. However, the scaled force fields developed here are probably almost as accurate as any other harmonic *ab initio* force field, except if very large basis sets or electron correlation methods were used, which in any case are not yet feasible or are very expensive for molecules of this size. The basis set tests carried out with the DIOXA isotopomers not only demonstrate that the intensity parameters remain largely unchanged up to the 6-31G** basis set, but also that, after scaling, the 3-21G force field is only slightly inferior to the force fields from the considerably larger basis sets. This study fully justifies using the 3-21G basis set for the vibrational calculations for the title compounds. Application of the 6-31G basis set may be recommended, which appears to produce improved force constants without much increase of computational costs.

In connection with reports that favor uniformly scaled harmonic *ab initio* force fields, the following comments seem appropriate. It is crucial to realize that the fine tuning of several scale factors is important for large molecules with low symmetry, as even very small frequency shifts of normal modes will cause considerable remixing among modes of similar energies and hence subtle redistributions of intensities, more so than for small and highly symmetric molecules where the modes perturb each other to a lesser degree. For the latter, scaling with a very small set of independent factors may be preferable for the sake of simplicity or because of lack of sufficient experimental data, but the eigenvectors will almost certainly be less accurate than they could be using a full set of scale factors. Such inaccuracies in the predicted normal modes, if present for large molecules, will likely prevent or confuse numerous band assignments in the congested regions of the spectra. A judicious nonuniform scaling with a full set of factors, as demonstrated above, will yield more reliable predictions, allowing for firmer band assignments.

Finally, according to the standard deviation of the intensity errors, 95.5% of the calculated absorption intensities lie within a factor of 5 of the measured values. This validates the approach to utilize theoretical intensities from 3-21G *ab initio* calculations as an aid for spectral assignments, especially if only orders of magnitude are required. The theoretical relative Raman intensities are judged qualitatively to be comparably accurate. The 3-21G intensities are particularly gratifying when compared to the calculations carried out with the polarized and diffuse basis sets, all of which are only marginally more accurate. The successful performance of the 3-21G basis set for the absorption and Raman intensities may be connected to the large size of these molecules. Despite the small number of basis functions per atom, the overall sum of the functions applied in these molecules is considerable

For personal use only.

and may permit a sufficiently detailed description of the electron densities and the connected properties. In terms of the accuracy of the theoretical predictions, applying a simple split-valence basis set to large molecules may therefore be equivalent to utilizing more sophisticated basis sets for small molecules.

Summary

We have assigned 196 observed bands as fundamental transitions in the vibrational spectra (100–1500 cm^{-1}) of six bicyclo[3.2.1]octane analogs. More assignments are suggested that could not be unambiguously confirmed by the available data. All assignments were based on the theoretical *ab initio* RHF geometries, harmonic force fields, and absorption and Raman intensities calculated with the 3-21G basis set. To correct for the deficiencies in the predicted frequencies, three methods for scaling force constants were tested, namely, multiplication by a uniform optimized factor, scaling with a set of parameters originally transferred from other molecules, and, finally, optimization by least-squares fitting of the frequency parameters. The three procedures produced frequency predictions with average errors of 2.2%, 1.2%, and 0.75%, respectively. To assess the accuracy of the vibrational eigenvectors resulting from the differently scaled force fields, the errors in the theoretical absorption intensities were analyzed in detail. The error distributions demonstrate that the absorption intensities are reproduced most accurately with nonuniformly corrected force fields and after refining the scale factors. A qualitative inspection of the theoretical Raman spectra indicates a similar trend. We conclude that for the most accurate predictions of frequencies and normal mode descriptions, scaling with multiple factors followed by refinement is preferable provided that the scale parameters are judiciously selected and transferred from other molecules and then refined with great care. We believe that this applies to all *ab initio* RHF force fields derived from split-valence basis sets. Accurate predictions of vibrational frequencies and intensities are crucial, particularly for large molecules, since the spectra become considerably more congested, which aggravates the problem of identifying the vibrations. In addition, the mixing of the modes is more pronounced such that even small deviations of the frequencies may result in erroneous normal mode descriptions and intensities.

The 3-21G calculated absorption intensities and the Raman data agree very satisfactorily with the experiments. The observed intensities are reproduced by the theory considerably better than just in order of magnitude. The intensity predictions are therefore extremely valuable in guiding the spectral assignments. The theoretical Raman depolarization ratios are particularly useful for this purpose since they can be applied to molecules with no symmetry. While a better force field for DIOXA was obtained by applying the 6-31G basis set, the intensity parameters remained essentially unchanged. Calculations using the 6-31G* and 6-31G** basis sets did not further improve the 6-31G frequencies and intensities.

Diastereoselective intramolecular Diels–Alder reactions of the furan diene: the synthesis of (±)-1,4-epoxycadinane

CHRISTINE ROGERS AND BRIAN A. KEAY[1]

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received October 9, 1992

CHRISTINE ROGERS and BRIAN A. KEAY. Can. J. Chem. **71**, 611 (1993).

The diastereoselective intramolecular Diels–Alder reactions of the furan diene (IMDAF), in which the side arm comprises four carbon atoms and is substituted by a methyl group adjacent to, or one carbon removed from, the furan ring, are described. Adducts are formed in moderate to excellent yields when treated with either Florisil in methylene chloride at room temperature or methylaluminum dichloride in methylene chloride at −78°C. Florisil is most effective for substrates containing unsubstituted dienophiles. An equimolar quantity (1.1 equivalents) of methylaluminum dichloride is most effective for precursors having methacrolein-type dienophiles, while a catalytic quantity (0.1 equivalent) is effective for crotonaldehyde-type dienophiles. Only the adducts with the side arm orientated *syn* with respect to the oxygen bridge are detected and isolated. The major diastereomer is the one in which the methyl group (initially on the side arm) is situated equatorially on the newly formed six-membered ring. An application of the diastereoselective IMDAF reaction to the synthesis of (±)-1,4-epoxycadinane is described, beginning with 2-methylfuran.

CHRISTINE ROGERS et BRIAN A. KEAY. Can. J. Chem. **71**, 611 (1993).

On décrit les réactions diastéréosélectives de Diels–Alder intramoléculaires du furane (DAIMF) agissant comme diène et dans lequel la chaîne latérale comporte quatre atomes de carbone et est substituée par un groupe méthyle sur le carbone en α ou en β par rapport au noyau furanique. Les adduits se forment avec des rendements allant de moyens à excellents lorsqu'on les traite soit avec du Florisil dans le chlorure de méthylène à la température ambiante soit avec du dichlorure de méthylaluminium dans le chlorure de méthylène à −78°C. Le Florisil est le plus efficace pour les substrats contenant des diénophiles qui ne sont pas substitués. Une quantité équimolaire (1,1 équivalents) de dichlorure de méthylaluminium est le plus efficace pour des diénophiles précurseurs du type méthacroléine alors qu'une quantité catalytique (0,1 équivalent) est efficace pour les diénophiles du type crotonaldéhyde. On n'a détecté et isolé que les adduits dont la chaîne latérale est orientée en *syn* par rapport au pont oxygéné. Le diastéréoisomère principal est celui dans lequel le groupe méthyle (initialement dans la chaîne latérale) est en position équatoriale dans le cycle à six chaînons nouvellement formé. On décrit une application de la réaction diastéréosélective Diels–Alder intramoléculaire du furane pour la synthèse du (±)-1,4-époxycadinane à partir du 2-méthylfurane.

[Traduit par la rédaction]

The intramolecular Diels–Alder reaction of the furan diene (IMDAF) has been studied by many groups since it was first reported in 1978 (1). These investigations have attempted to define the scope and limitations of the IMDAF reaction with respect to (*i*) the effect of varying the length of the tether linking the diene and dienophile,[2,3] (*ii*) the effect of substituting heteroatoms for carbon on the tether,[2,3] (*iii*) the effect of varying the type and placement of substituents on both the furan ring and dienophile,[2,3] (*iv*) the development of methods to overcome the unfavourable equilibrium towards product,[2,3] and, lastly, (*v*) utilization of the adducts in the synthesis of natural products (7).

Our efforts have concentrated on defining the scope and limitations of the IMDAF reaction of systems containing a four-carbon-atom side arm (8–10). Precursors containing substituted dienophiles have an equilibrium favouring starting material, and therefore we examined methods to shift the equilibrium toward adduct formation. We recently showed (9) that the IMDAF reaction of precursors having a four-carbon-atom side arm was accelerated by methylaluminum dichloride in methylene chloride at −78°C (Scheme 1). The oxatricyclo adducts were obtained in good to excellent yield after only 2–8 h. In addition, the reaction was shown to be 100% stereoselective; only the adducts in which the side arm was orientated *syn* with respect to the oxygen bridge were isolated. Thus, adducts were prepared containing up to four asymmetric centres of known stereochemistry depending on the substituent pattern of the dienophile (i.e., Scheme 1: R^1 = Me, R^2 = H, R^3 = H or Me).

Placement of a single substituent on the side arm of the IMDAF precursor could lead to two diastereomers. The major isomer was expected to be that with the substituent in the equatorial position of the newly formed six-membered ring (Scheme 1: R^1 = H, R^2 = R^3 = Me), since the above IMDAF reactions were shown to be under thermodynamic control. This modification would result in adducts having up to five asymmetric centres of known relative stereochemistry (i.e., Scheme 1: R^1 = R^2 = R^3 = Me), which would be useful as intermediates for the synthesis of natural products, such as 1,4-epoxycadinane **1**.

We recently reported (11) that stirring various IMDAF precursors possessing a methyl-substituted four-carbon-atom tether with Florisil in methylene chloride for 0.5–19 days provided oxatricyclo adducts in which the major diastereomer had the methyl group situated in the equatorial position on the newly formed six-membered ring.[4] The adducts with the side arm *syn* to the oxygen bridge were the only isomers detected (by ^{1}H NMR) and isolated (i.e., Scheme 1: R^1 = H, R^2 = R^3 = Me). Since methylaluminum dichloride is an effective Lewis acid for accelerating the IMDAF reaction, we studied the effect of methylaluminum dichloride on the diastereomeric ratios of a number of IMDAF precursors having monosubstituted tethers. We herein provide (*i*) a full

account of both the effect of Florisil and methylaluminum dichloride on the IMDAF reaction of precursors containing a single substituent on the tether, and (*ii*) the application of this methodology to the synthesis of (±)-1,4-epoxycadinane **1** (Scheme 1).[5]

Preparation of monosubstituted IMDAF precursors

The synthesis of the precursors with monosubstituted tethers was accomplished as outlined in Scheme 2. Friedel–Crafts alkylation (13) of 2-methylfuran **2** with either methacrolein or crotonaldehyde, in the presence of a trace of concentrated sulfuric acid, provided aldehydes **3** (53%) and **4** (36%), respectively. Although the yields were low, the starting materials are inexpensive, the reactions could be run on large scale, and the products were easily purified by distillation. The aldehydes **3** and **4** were converted into their respective iodides **5** and **6** by (*i*) reduction of the aldehydes with sodium borohydride in ethanol to the corresponding alcohols, (*ii*) conversion of the alcohols into tosylates, and (*iii*) displacement of the tosylate moiety by iodide in refluxing acetone. Treatment of iodides **5** and **6** with 2.2 equivalents of *tert*-butyllithium at −78°C (14), followed by trapping of the resulting carbanion with either acrolein, methacrolein, or crotonaldehyde, provided the allylic alcohols **7**–**12** in good yield. Alcohols **7**, **8**, **10**, and **11** were isolated as mixtures of diastereomers that were not separated, but were oxidized under Swern conditions (15) to provide enones **13**, **14**, **16**, and **17**, respectively. Alcohols **9** and **12** were oxidized to enones **15** and **18**, respectively, with Fétizon's reagent (16), since the Swern conditions provided low yields of the desired enones and a mixture of unidentified by-products.

IMDAF reactions with Florisil in methylene chloride

A study was performed to determine the optimum quantity of Florisil necessary for accelerating the IMDAF reaction. Compound **13** was studied as a model since previous work had shown (8, 9*c*) that the IMDAF reaction of precursors with unsubstituted dienophiles and side chains was accelerated by Florisil. Thus, furan **13** (100 mg) was treated with various quantities of Florisil (100–200 mesh) at room temperature, and aliquots were removed at various intervals to determine the ratio of starting material to adduct (SM : A) by integration of the ^1H NMR spectrum of the mixture. Gas chromatography was not used since some of the adducts cyclo-reversed on the column. The results of this study are summarized in Table 1 and several points are noteworthy. First, the presence of Florisil was required for the IMDAF reaction to occur. Secondly, two isomeric products **19**e and **19**a were formed, with the proportion of **19**e increasing over time. Both isomers had the side chain orientated *syn* with respect to the oxygen bridge (at C-6)[6] due to an *exo* mode of attack; however, the methyl group at C-2 was positioned equatorially (*syn* to the oxygen bridge) in the major isomer (**19**e) and axially (*anti* to the oxygen bridge) in the minor isomer (**19**a) (*vide infra*). Thirdly, equilibrium was attained more rapidly as the quantity of Florisil was increased; however, the use of greater than 10 weight equivalents led to low recoveries. Finally, the equilibrium was shifted completely toward adduct formation when 10 weight equivalents of Florisil were employed, and the reaction was stirred for 19 days.

Precursors **14**–**18** were therefore treated under the optimized conditions in methylene chloride at room temperature. The results are summarized in Table 2. The IMDAF

[5]The numbering of all oxatricyclo adducts in this paper will follow the IUPAC nomenclature rules. The natural product 1,4-epoxycadinane was originally numbered as a decahydronaphthalene system and thus the "1,4" numbering in the name does not follow the IUPAC numbering.

[6]See ref. 9*c* for details regarding the assignment of the stereochemistry of the side arm relative to the oxygen bridge in oxatricyclo adducts.

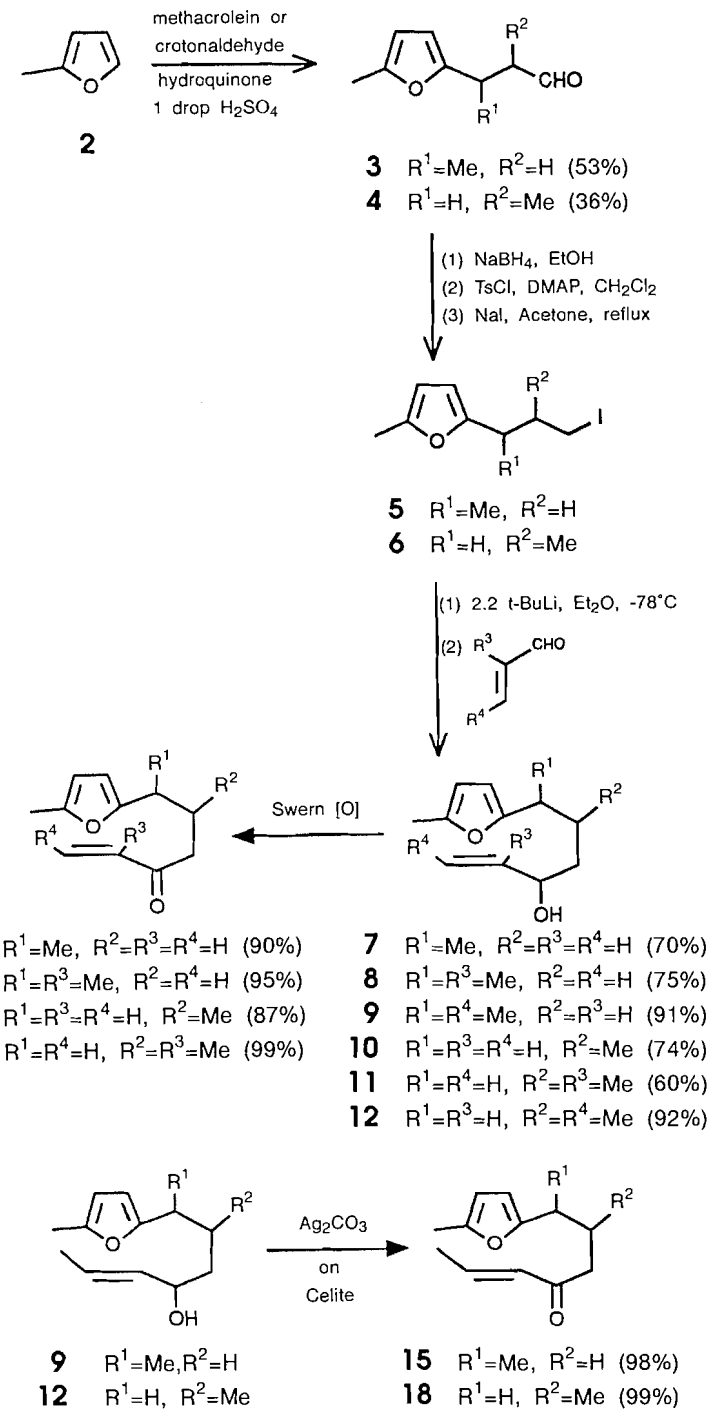

SCHEME 2

reactions of precursors **13–15** were less diastereoselective than those of the corresponding precursors **16–18** (diastereoselectivity will refer to the stereocenter on the side chain (i.e., C-2 or C-3)). Only the adducts in which the side chain was orientated *syn* to the oxygen bridge (at C-6) were detected (by ^{1}H NMR) and isolated.

Precursors **13–15** always provided a mixture of two diastereomers with the major isomer having the side-chain methyl equatorially positioned (*syn* to the oxygen bridge). The stereochemistry of the C-2 methyl group was determined as follows, using adducts **19**e and **19**a as representative examples. Irradiation of the C-2 methyl doublet resulted in the collapse of the C-2 hydrogen signal to a doublet of doublets and a triplet for compounds **19**e and **19**a, respectively. The measured coupling constants of 4.5 Hz (axial–equatorial) and 13.0 Hz (axial–axial) for the C-2 proton in compound **19**e indicated that it was axial. The coupling constant of 4.6 Hz (equatorial–equatorial and equatorial–axial) for the triplet indicated that the C-2 hydrogen was equatorial in compound **19**a.

Compounds **16–18** yielded only one isomer in which the methyl on the side chain was equatorially positioned (*anti* to the oxygen bridge). The stereochemistry of the C-3 methyl group was determined as follows using adduct **22**e as an ex-

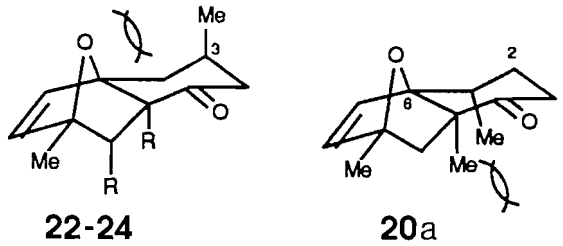
ample. Since the C-3 hydrogen was "buried" in the 300 MHz ^{1}H NMR spectrum, the stereochemistry of the C-3 hydrogen atom was assigned by measuring the vicinal coupling constants of the adjacent C-2 and C-4 protons. For example, the doublet of doublets (12.0 Hz to H-3 and 14.5 Hz (germinal)) at δ 1.92 was assigned to H-2α by a combination of one- and two-dimensional NMR techniques. The large vicinal coupling constant of 12.0 Hz indicated that the C-3 hydrogen was axial, thus placing the methyl group equatorial.

A possible reason for the increased diastereoselectivity observed with compounds **16**–**18** may be due to an unfavourable 1,3-diaxial interaction, which would exist between the C-3 side-chain methyl group and the oxygen atom of the ether bridge if the methyl group were axial in adducts **22**–**24** (Fig. 1); this 1,3-diaxial interaction is absent in adducts **19**–**21**. This unfavourable interaction may promote the retro-Diels–Alder reaction, and thus equilibration occurs to provide the thermodynamically more stable equatorially substituted adduct.

The IMDAF reactions of precursors **14** and **17** also resulted in the formation of the desired adducts, although the SM:A ratios were in favour of starting material. The lower SM:A ratios relative to those of **13** and **16** may be a result of either unfavourable steric interactions in the transition state due to substitution of the dienophile, or decreased reactivity of the dienophile, which would be more electron rich than the unsubstituted dienophile due to the electron-donating methyl group (17). Substitution of the tether with a single methyl group accelerated the IMDAF reaction relative to that of the corresponding unsubstituted precursors, which showed no reaction in the presence of Florisil (8, 9*c*). Again, the IMDAF reaction of precursor **17** was more diastereoselective than that of compound **14** (*vide supra*). A higher proportion of equatorial to axial isomers was obtained for product **20** relative to adduct **19** (12:1 for compound **20** versus 7:1 for compound **19**). A very strong 1,3-diaxial interaction exists in adduct **20**a between the C-2 and C-6 methyl groups (Fig. 1), which could promote the retro-Diels–Alder reaction and thus favour equilibration to the equatorial isomer **20**e.



22-24 20a

FIG. 1. 1,3-Diaxial interaction in compounds **22**–**24** and **20**a.

Compounds **15** and **18** showed even less propensity to undergo the IMDAF reaction than the methacrolein precursors **14** and **17**. The reduced reactivity is likely due to steric interaction between the methyl groups on the terminus of the dienophile and on the 5-position of the furan ring in the transition state. Again, the major adducts produced (**21**e and **24**e, respectively) had the methyl group oriented equatorially on the newly formed six-membered ring.

It is interesting to note that heating precursors **13**, **17**, and **18** to 40°C resulted in acceleration of the rate at which the IMDAF equilibrium was attained. This result is in contrast to the behaviour of the adducts derived from precursors with unsubstituted side arms, which revert to starting material upon heating (8, 9*c*). This method provided equilibrium ratios within 1 day similar to those obtained at room temperature after 19 days and is therefore more synthetically useful.

IMDAF reactions with methylaluminum dichloride in methylene chloride

We have reported that methylaluminum dichloride accelerates the IMDAF reaction of precursors having unsubstituted side chains (9). Both 1.1 and 0.1 equivalents of methylaluminum dichloride were shown to be effective; precursors with a substituted dienophile provided a higher ratio of adduct when the catalytic quantity of methylaluminum dichloride was employed. Precursors **13**–**15**, **17**, and **18** were therefore treated with methylaluminum dichloride, and the results are summarized in Table 2. The use of 1.1 equivalents of methylaluminum dichloride was found to be very effective for accelerating the IMDAF reaction of compounds **13**, **14**, and **17**. The products were formed stereoselectively in favour of the adduct with the methyl group situated equatorially on the newly formed cyclohexanone ring. In all cases the side chain was orientated *syn* with respect to the oxygen bridge due to an *exo* mode of attack. The reaction was complete within 15 min at −78°C compared to the 4–14 days required for equilibrium to be achieved with Florisil (Table 2), and provided the adducts in excellent yields (81–88%). Thus methylaluminum dichloride is much superior to Florisil in accelerating the IMDAF reaction.

Precursors **15** and **18**, having a terminally substituted dienophile, provided SM:A ratios of 79:21 and 42:58, respectively, with 1.1 equivalents of methylaluminum dichloride. The ratios were improved to 17:79 and 11:89 by treating precursors **15** and **18** with 0.1 equivalent of

[a]Isolated yield of the major adduct.

methylaluminum dichloride at −65°C for 2 h.[7,8] The major adducts (**21**e and **24**e) were those with the methyl group on the side arm in the equatorial position on the newly formed six-membered ring. The major adducts were formed in excellent yield (73% and 85%, respectively) and were easily separated from the minor adduct and starting material by flash chromatography.

Conclusions

The Florisil-mediated diastereoselective IMDAF reaction was optimized with 10 weight equivalents of Florisil in methylene chloride. Optimized results with methylaluminum dichloride were obtained at −78°C when 1.1 equivalents were employed with either unsubstituted or α-substituted dienophiles; β-substituted dienophiles gave the best results with 0.1 equivalent of methylaluminum dichloride. The IMDAF reactions with Florisil and methylaluminum dichloride were highly diastereoselective. Only the adducts with the side arm orientated *syn* with respect to the oxygen bridge were detected and isolated. In addition, the major adduct had the methyl substituent in the equatorial position of the newly formed six-membered ring, and reactions that resulted in the substituent in the C-3 position were more diastereoselective than those with the substituent in the C-2 position. Finally, the use of methylaluminum dichloride was superior to that of Florisil since the reaction time was reduced from up to 19 days with Florisil to a couple of hours with methylaluminum dichloride. In addition, higher yields of the adducts were obtained and lower temperatures were required when methylaluminum dichloride was employed. The reaction time with

[7]Catalytic quantities of $MeAlCl_2$ were not used on compounds **14** and **17** since the results with 1.1 equivalents provided the adducts in excellent yield.

[8]A paper describing competitive complexation NMR studies with $MeAlCl_2$ has recently been submitted, which provides evidence to support our hypothesis (ref. 9) on why catalytic quantities of $MeAlCl_2$ provide higher ratios of adduct to starting material than when 1.1 equivalents of $MeAlCl_2$ are used.

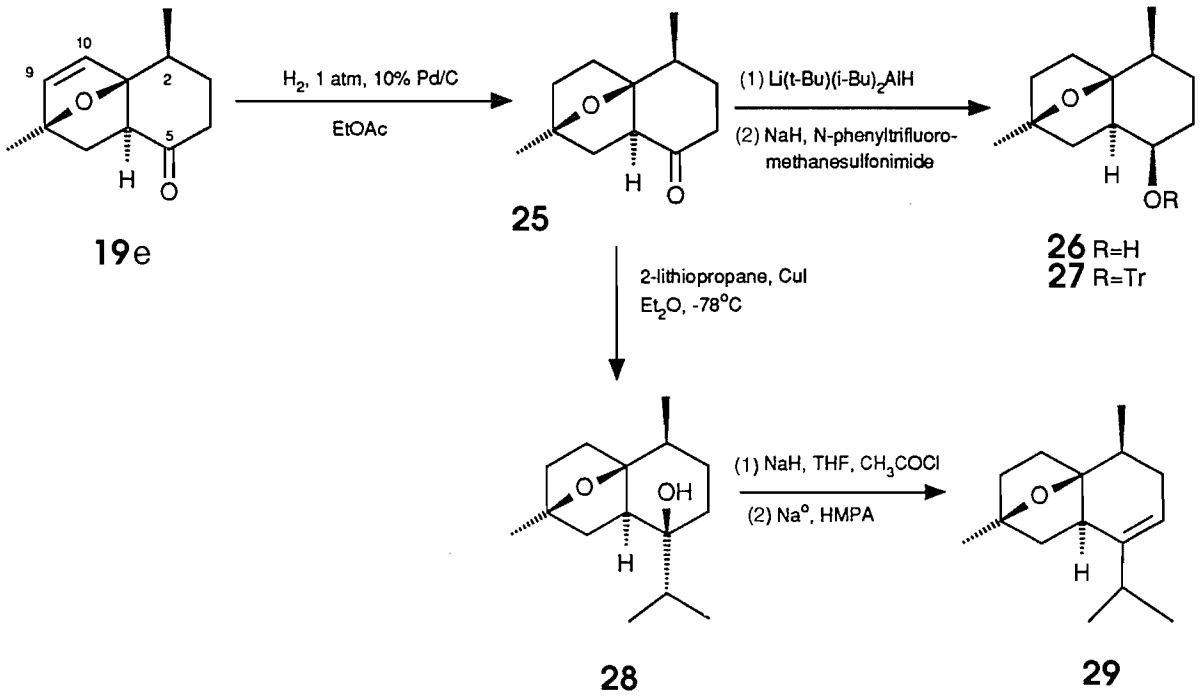

SCHEME 3

Florisil, however, could be reduced from 19 days to 1 day by refluxing the mixture at 40°C in methylene chloride.

Thus, these reactions constitute the first examples of diastereoselective IMDAF reactions with the diene and dienophile connected by a four-carbon-atom tether. In addition, adducts containing up to five asymmetric centers, all of known relative stereochemistry, were formed in one step from an acyclic precursor. The accompanying synthesis of 1,4-epoxycadinane illustrates the synthetic usefulness of the above IMDAF reactions.

The synthesis of (±)-1,4-epoxycadinane

The natural product 1,4-epoxycadinane **1** (Scheme 1) was isolated as a crystalline, optically active, solid from the brown alga *Dilophus fasciola* in 1979 (18*a*). 1,4-Epoxycadinane **1** is a sesquiterpene containing the cadinane ring (18*b*, 18*c*) system with five asymmetric centres and an oxygen ether linkage between carbons 1 and 8 (IUPAC numbering). While there have been many reported syntheses of natural products containing the cadinane ring system, 1,4-epoxycadinane has not been synthesized (19).

The methyl group at C-2 and the isopropyl group at C-5 are both equatorially positioned on ring C of 1,4-epoxycadinane. In addition, the C-2 methyl group and C-6 hydrogen are *syn* and *anti*, respectively, to the oxygen bridge. Since the IMDAF reaction of precursor **13** provided adduct **19**e, which contains four of the five asymmetric centres present in 1,4-epoxycadinane, as the major product (Table 2), we investigated the conversion of adduct **19**e into 1,4-epoxycadinane. The synthesis of 1,4-epoxycadinane would therefore entail (1) reduction of the C9—C10 double bond and (2) stereoselective conversion of the C-5 ketone into the equatorially positioned isopropyl group.

The first step in the synthesis of 1,4-epoxycadinane was routine. Compound **19**e was hydrogenated using 10% palladium on carbon in ethyl acetate to provide compound **25** in 95% yield (Scheme 3) (20). The absence of the vinyl protons at δ 6.08 and 6.18 in the ^{1}H NMR spectrum indicated the carbon–carbon double bond had been reduced, while the presence of the absorption at 1713 cm^{-1} in the IR spectrum confirmed that the ketone had not been reduced to the alcohol.

The conversion of the carbonyl moiety into the equatorially positioned isopropyl group proved to be more troublesome than initially expected. Our first approach involved (1) a stereoselective reduction of the ketone to an axial alcohol, (2) conversion of the alcohol into a good leaving group, and (3) an S_N2 displacement of the leaving group with an isopropyl moiety. Reduction of ketone **25** with lithium *tert*-butyldiisobutylaluminum hydride in THF at −78°C provided a single compound **26** in which the alcohol group was axial (Scheme 3). The attempted conversion of alcohol **26** into the triflate **27**, employing a variety of conditions (21), provided only starting material upon work-up, although TLC indicated that the alcohol had reacted. Since it was possible that the triflate was being hydrolyzed during work-up, the above reaction was repeated and the mixture added directly to an ethereal solution of isopropylmagnesium chloride in the presence of copper(I) iodide to attempt an *in situ* displacement of the triflate. Again, only starting material was recovered. Attempts to prepare the tosylate of alcohol **26** were equally unsuccessful under a variety of conditions (22). An alternative approach was therefore required.

Since the bulky reducing agent lithium *tert*-butyldiisobutylaluminum hydride reduced the ketone in compound **25** exclusively from the α face, attack by isopropyl nucleophile should provide alcohol **28** having the isopropyl group in the equatorial position (Scheme 3). Removal of the tertiary hydroxyl group with retention of stereochemistry would then complete the synthesis. Although compound **25** did not react with isopropylmagnesium chloride (quantitative recovery of starting material) it did react smoothly with the less basic, higher order, cuprate (23) of 2-lithiopropane (24)

(prepared by adding 2-lithiopropane (8 equivalents) to copper(I) iodide (3 equivalents)) in ether at 0°C to provide a single alcohol **28**. Treatment of compound **28** under a variety of conditions reported for the deoxygenation of tertiary alcohols (25) did not provide 1,4-epoxycadinane. Either starting material **28** was recovered or eliminated product **29** was isolated and was inert to catalytic hydrogenation (H_2, PtO_2, or 10% Pd/C) (Scheme 3).

Since the shorter synthetic routes for the conversion of the ketone carbonyl into an isopropyl group failed, a longer sequence was utilized (Scheme 4). This synthetic strategy takes advantage of the fact that the presence of the oxygen bridge in compound **25** does not allow the adjacent cyclohexanone ring to undergo chair interconversions. Thus, elaboration of the ketone in compound **25** to an aldehyde group via Wittig chemistry should provide an equatorially disposed aldehyde under thermodynamic conditions (see compound **31**, Scheme 4). The aldehyde (at C-5) would therefore be *trans* to the methyl group at C-2, thus providing the correct relative stereochemistry at C-5.

Wittig reaction of ketone **25** with the ylid of (methoxymethyl)triphenylphosphonium chloride provided compound **30** (82%) as a 2:3 mixture of double bond isomers. No attempt was made to separate these isomers. The mixture was treated immediately with dilute HCl in THF to provide aldehyde **31** (63%) as a single isomer (26). The stereochemistry of the aldehyde was determined by decoupling experiments. Irradiation of the aldehyde signal resulted in a collapse of the signal centered at δ 2.18 to a doublet (3.3 Hz) of triplets (10.9 Hz). These coupling constants are indicative of a vicinal axial–equatorial and two axial–axial couplings, respectively. Therefore the C-5 hydrogen was axial, establishing the aldehyde in the desired equatorial position.

The aldehyde **31** was converted into the methyl ketone **33** in two steps. Treatment of **31** with excess methyllithium at −78°C for 1.5 h provided compound **32** (97%) as a 7:3 mixture of diastereomers. The mixture was smoothly oxidized to the methyl ketone **33** (90%) under Swern conditions (15). The stereochemistry at C-5 was again confirmed by measuring the coupling constants of the C-5 hydrogen (δ 2.3, doublet of triplets). The single coupling constant of 3.1 Hz (doublet, axial–equatorial) and two 10.4 Hz couplings (triplet, axial–axial) established that the C-5 hydrogen in compound **33** was axial.

Wittig reaction of ketone **33** with a 20-fold excess of the ylid of methylenetriphenylphosphorane (27) provided compound **34** (74%) and some unreacted starting material (20%). The mixture was easily separated and the unreacted starting material was recycled. Finally, vinyl compound **34** was hydrogenated (H_2, PtO_2, 1 atm (1 atm = 101.3 kPa)) to provide 1,4-epoxycadinane in 93% yield. Although the ^{13}C and ^1H NMR spectra of synthetic 1,4-epoxycadinane agreed very well with the data reported for the authentic sample (Table 3), irradiation of the proton at δ 1.81 did not result in a collapse of the methyl doublets at δ 0.73 and δ 0.89 as reported by Fattorusso *et al.* (i.e., the isopropyl methine hydrogen) (18*a*). Through 2D-NMR techniques the isopropyl methine hydrogen was assigned to the signal at δ 1.58. Fattorusso informed us that the reported irradiation of the peak at δ 1.81 was a typographical error and should have been δ 1.58.

Thus, (±)-1,4-epoxycadinane was synthesized in 14 steps from 2-methylfuran in 9% overall yield. The relative stereochemistry of four of the five stereocentres was controlled by the IMDAF reaction, while the rigidity of the oxatricyclo adduct was used effectively to control the stereochemistry of the fifth stereocentre. This synthesis clearly illustrates the synthetic usefulness of the IMDAF reaction for the preparation and control of remote stereocentres.

Experimental

General methods

Melting points were determined using an Electrothermal melting point apparatus and are uncorrected. Boiling points refer to the air-bath temperature using Kugelrohr distillation apparatus, and are also uncorrected. Infrared spectra were obtained as thin films (oils) on either NaCl or KBr plates or as KBr pellets (solids). The infrared spectra were recorded on either a Nicolet 5-DX FT-IR spectrophotometer or a Mattson model 4030 FT-IR.

Nuclear magnetic resonance spectra were obtained on one of three instruments: Bruker AC-300 (^1H 300 MHz, ^{13}C 75 MHz), Bruker ACE-200 (^1H 200 MHz, ^{13}C 50 MHz), or a Bruker AM-400 spectrometer (^1H 400 MHz). Deuterochloroform was used both as the solvent, and as the internal standard (^1H, δ 7.27, ^{13}C, δ 77.0), unless otherwise stated. All ^1H NMR spectra listed will have the following format: chemical shift (in ppm), (multiplicity, number of protons, coupling constants (Hz), assignment). The abbreviations used to describe the multiplicities are as follows: br = broadened, s = singlet, d = doublet, t = triplet, q = quartet, and ABq refers to a quartet due to an AB spin system. The ^{13}C NMR spectra listed will have the following format: chemical shift (in ppm), (number of attached protons as determined by DEPT experiments).

Low-resolution mass spectra were recorded using either a Varian CH5 spectrometer or a VG 7070 instrument. The data are listed as mass (*m/e*), (relative intensity, assignment). The spectra were obtained either by the electron-impact (EI) method or field ionization (FI), and the method will only be listed if FI was used. High-resolution mass spectra were recorded on a Kratos MS80. Microanalyses were performed either by Guelph Chemical Laboratories Limited, Guelph, Ontario, or by Mrs. D. Fox, Department of Chemistry, University of Calgary.

Solvents were either dried by standard methods (28), then distilled prior to use, or were purchased as anhydrous solvents in Sure-Seal® bottles from the Aldrich Chemical Company. THF was dried over sodium and benzophenone, as was diethyl ether. Methylene chloride, diisopropyl amine, and triethylamine were dried over CaH_2. Methanol was refluxed with Mg^0 metal for 12 h, then distilled. DMSO was dried over NaOH. Acetonitrile, DMF, and diethyl ether were purchased as anhydrous solvents, and HPLC-grade acetone was used.

All glassware and syringes were dried in a 120°C oven for at least 4 h, then cooled under a stream of argon, or in a desiccator containing Drierite. Reactions that were sensitive to moisture or atmospheric conditions were performed under an argon atmosphere. Compounds were purified by flash chromatography using various ratios of petroleum ether and ethyl acetate.

The experimental procedures for the preparation of compounds **3–17** have been deposited as Supplementary Material.[9]

General procedure 1: IMDAF reactions in Florisil

The freshly distilled enone (1 mmol) was dissolved in dry CH_2Cl_2 (15 mL) and placed in an argon-purged round-bottom flask. To this was added Florisil (100–200 mesh, 10 weight equivalents to the enone). The reaction was wrapped in foil and stirred at the appropriate temperature for the required length of time. The reaction was then filtered, the Florisil washed well with EtOAc (20 mL), and the

solvent removed *in vacuo* without external heating to provide the crude product, which could be purified by flash chromatography (pet. ether: EtOAc).

General procedure 2: IMDAF reactions using Lewis acid

The freshly distilled enone (0.2 mmol) was dissolved in dry CH_2Cl_2 (10 mL), placed in an argon-purged 3-necked flask, and cooled to the appropriate temperature. Methylaluminum dichloride (1.0 M in hexane) was added to the cooled enone solution, and the reaction was stirred for the appropriate length of time. The reaction was quenched with 10% $NaHCO_3$ (10 mL), and warmed until no frozen material remained. The aqueous layer was extracted with CH_2Cl_2 (4 × 10 mL), then the organic layer was washed with H_2O (15 mL), dried over Na_2SO_4, filtered, and the solvent removed *in vacuo* without external heating to provide the crude product, which was purified by flash chromatography (pet. ether: EtOAc).

*(6αH)-2β,8β-Dimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (**19e**) and (6αH)-2α,8β-dimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (**19a**)*

Enone **13** (380.1 mg) was stirred with Florisil (4.0 g) according to general procedure 1 for 13 days at room temperature under argon to provide a mixture of **13**:**19e**:**19a** in a ratio of 0:87:13. The isolated yields were **19e**: 70% (239 mg) and **19a**: 71% (29 mg).

Enone **13** (48.8 mg, 0.254 mmol) was treated with excess $MeAlCl_2$ (280 μL, 0.280 mmol) according to general procedure 2 at −78°C for 15 min to provide a mixture of **13**:**19e**:**19a** in a ratio of 0:90:10 with quantitative recovery (**19e**: 88% (40 mg); **19a**: 90% (4.2 mg)). The above mixtures were separated using flash chromatography (9:1, pet. ether: EtOAc).

*Compound **19e** (colourless oil)*: IR (neat): 1709, 1108 cm^{-1}; ^{1}H NMR (300 MHz) δ: 1.06(d, 3H, J = 7.0 Hz, C-2-CH_3), 1.52(s, 3H, C-8-CH_3), 1.55(dd, 1H, $J_{7\alpha,6\alpha}$ = 8.3 Hz, J_{gem} = 11.8 Hz, H-7α), 1.73(dq, 1H, $J_{3\beta,4\beta}$ = 5.6 Hz, $J_{3\beta,2\alpha}$ = 13.0 Hz, $J_{3\beta,4\beta}$ = 13.0 Hz, J_{gem} = 13.0 Hz, H-3β), 1.88(ddd, 1H, $J_{3\alpha,2\alpha}$ = 4.5 Hz, J_{gem} = 13.0 Hz, H-3α), 2.10(dd, 1H, $J_{7\beta,6\alpha}$ = 3.4 Hz, J_{gem} = 11.8 Hz, H-7β), 2.28(dd, 1H, $J_{6\alpha,7\beta}$ = 3.4 Hz, $J_{6\alpha,7\alpha}$ = 8.3 Hz, H-6α), 2.35(ddq, 1H, $J_{2\alpha,3\alpha}$ = 4.5 Hz, $J_{2\alpha,12}$ = 7.0 Hz, $J_{2\alpha,3\beta}$ = 13.0 Hz, H-2α), 2.28–2.45(overlapping m, 2H, H-4α and H-4β), 6.07 and 6.17(ABq, 2H, J = 5.5 Hz, H-9 and H-10); ^{13}C NMR (75 MHz) δ: 16.32(q), 18.68(q), 29.68(t), 33.58(d), 35.65(t), 41.61(t), 53.46(d), 85.61(s), 93.62(s), 137.17(d), 140.89(d), 209.70(s); mass spectrum, *m/e*: 192(4, M^+), 122(100, $M-C_4H_6O$, retro IMDAF–McLafferty rearrangement); HRMS (EI) calcd. for $C_{12}H_{16}O_2$: 192.1151; found: 192.1154.

*2β,6α,8β-Trimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (**20e**)*

Enone **14** (108.0 mg) was stirred with Florisil (1.1 g) according to general procedure 1 for 13 days at room temperature under argon to provide a mixture of **14**:**20**e:**20**a in a ratio of 48:47:4 in quantitative yield. The starting material **14** could be separated from the adducts by flash chromatography (9:1); however, the minor isomer **20**a could not be completely separated from the major isomer **20**e. Only the major isomer could therefore be characterized.

Enone **14** (79.5 mg, 0.385 mmol) was treated with excess $MeAlCl_2$ (424 μL, 0.424 mmol) according to general procedure 2 at −78°C for 5 min to provide a mixture of **14**:**20**e:**20**a in a ratio of 9:88:3 with quantitative recovery. IR (KBr): 1707 cm^{-1}; ^{1}H NMR (400 MHz) δ: 1.07(s, 3H, C-6-CH_3), 1.07(d, 3H, J = 6.8 Hz, C-2-CH_3), 1.12(d, 1H, J_{gem} = 11.7 Hz, H-7α), 1.52(s, 3H, C-8-CH_3), 1.76(m, 1H, $J_{3\beta,4\beta}$ = 3.0 Hz, $J_{3\beta,2\alpha}$ = 11.7 Hz, $J_{3\beta,4\alpha}$ = 13.1 Hz, J_{gem} = 13.1 Hz, H-3β), 1.82–1.89(m, 1H, H-3α), 2.38(ddq, 1H, $J_{2\alpha,3\alpha}$ = 4.2 Hz, J = 6.8 Hz, $J_{2\alpha,3\beta}$ = 11.7 Hz, H-2α), 2.40(dt, 1H, $J_{4\beta,3\alpha}$ = 4.1 Hz, $J_{4\beta,3\beta}$ = 4.1 Hz, J_{gem} = 14.6 Hz, H-4β), 2.54(d, 1H, J_{gem} = 11.7 Hz, H-7β), 2.65(dt, 1H, $J_{4\alpha,3\alpha}$ = 6.0 Hz, $J_{4\alpha,3\beta}$ = 14.3 Hz, J_{gem} = 14.3 Hz, H-4α), 6.13 and 6.26(ABq, 2H, J = 5.6 Hz, H-9 and H-10); ^{13}C NMR (50 MHz) δ: 16.59(q), 18.95(q), 22.40(q), 29.19(t), 38.31(t), 30.39(d), 44.03(t), 57.17(s), 85.55(s), 95.29(s), 135.37(d), 141.30(d), 213.72(s); mass spectrum, *m/e*: 206(5, $M^{+\cdot}$), 122(100, M−C_5H_8O, retro IMDAF–McLafferty rearrangement); HRMS (EI) calcd. for $C_{13}H_{18}O_2$: 206.1307; found: 206.1306.

*(6αH)-2β,7α,8α-Trimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (**21e**) and (6αH)-2α,7α,8α-trimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (**21a**)*

Enone **15** (95.4 mg) was stirred with Florisil® (0.95 g) according to general procedure 1 for 13 days at room temperature under argon to provide a mixture of **15**:**21**e:**21**a in a ratio of 73:19:8 in quantitative yield.

Enone **15** (145.2 mg, 0.704 mmol) was treated with excess $MeAlCl_2$ (774 μL, 0.774 mmol) according to general procedure 2 at −78°C for 5 min to provide a mixture of **15**:**21**e:**21**a in a ratio of 79:16:5 with quantitative recovery.

Enone **15** (350.1 mg, 1.70 mmol) was treated with catalytic $MeAlCl_2$ (170 μL, 0.17 mmol) at −65°C for 2 h to provide a mixture of **15**:**21**e:**21**a in a ratio of 17:75:4 with 98% recovery. Flash chromatography (9:1) provided the compounds **15** (4.0 mg), and **21**e (250 mg) and **21**a (2.0 mg).

*Major isomer **21e**:* mp 55–56°C; IR (neat): 1709 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.94(d, 3H, J = 7.0 Hz, C-7-CH_3), 1.10(d, 3H, J = 6.9 Hz, C-2-CH_3), 1.52(s, 3H, C-8-CH_3), 1.73(dq, 1H, $J_{3\beta,4\beta}$ = 3.9 Hz, $J_{3\beta,2\alpha}$ = 13.6 Hz, $J_{3\beta,4\alpha}$ = 13.6 Hz, J_{gem} = 13.6 Hz, H-3β), 1.83(d, 1H, $J_{6\alpha,7\beta}$ = 4.2 Hz, H-6α), 1.89(m, 1H, $J_{3\alpha,4\beta}$ = 3.3 Hz, $J_{3\alpha,2\alpha}$ = 5.0 Hz, $J_{3\alpha,4\alpha}$ = 5.0 Hz, J_{gem} = 13.6 Hz, H-3α), 2.33(m, 1H, $J_{2\alpha,3\alpha}$ = 4.2 Hz, J = 6.9 Hz, $J_{2\alpha,3\beta}$ = 13.6 Hz, H-2α), 2.41(dq, 1H, $J_{7\beta,6\alpha}$ = 4.2 Hz, J = 7.0 Hz, H-7β), 2.30–2.42(m, 1H, H-4α), 2.49(dt, 1H, $J_{4\beta,3\alpha}$ = 3.6 Hz, $J_{4\beta,3\beta}$ = 3.6 Hz, J_{gem} = 14.4 Hz, H-4β), 6.17 and 6.23 (ABq, 2H, J = 5.6 Hz, H-9 and H-10); ^{13}C NMR(50 MHz) δ: 16.21(q), 17.07(q), 17.15(q), 29.42(t), 33.66(d), 41.60(t), 43.47(d), 61.36(d), 88.41(s), 93.07(s), 138.38(d), 138.66(d), 210.28(s); mass spectrum, *m/e*: 206(14, $M^{+\cdot}$), 122(100, M−C_5H_7O, retro IMDAF–McLafferty rearrangement); HRMS (EI) calcd. for $C_{13}H_{18}O_2$: 206.1307; found: 206.1315.

*(6αH)-3α,8α-Dimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (**22e**)*

Enone **16** (372.8 mg) was stirred with Florisil (3.79 g) according to general procedure 1 for 6 days at room temperature under argon to provide a mixture of **16**:**22**e in a ratio of 0:100 in 75% yield after purification by flash chromatography (3:1). The product was obtained as a white crystalline solid (280.0 mg), mp 62–64.5°C; IR (KBr): 1700 cm^{-1}; ^{1}H NMR (300 MHz) δ: 1.05(d, 3H, J = 6.1 Hz, C-3-CH_3), 1.56(s, 3H, C-8-CH_3), 1.59(dd, 1H, $J_{7\alpha,6\alpha}$ = 8.2 Hz, J_{gem} = 11.8 Hz, H-7α), 1.92(dd, 1H, $J_{2\alpha,3\beta}$ = 12.0 Hz, J_{gem} = 14.5 Hz, H-2α), 2.12–2.20(m, 2H, H-3β and H-4α), 2.18(dd, 1H, $J_{7\beta,6\alpha}$ = 3.4 Hz, J_{gem} = 11.8 Hz, H-7β), 2.30(dd, 1H, $J_{6\alpha,7\beta}$ = 3.4 Hz, $J_{6\alpha,7\alpha}$ = 8.2 Hz, H-6α) 2.38(dt, 1H, $J_{2\beta,3\beta}$ = 3.2 Hz, $J_{2\beta,4\beta}$ = 3.2 Hz, J_{gem} = 14.5 Hz, H-2β), 2.45(ddd, 1H, $J_{4\beta,2\beta}$ = 2.2 Hz, $J_{4\beta,3\beta}$ = 3.2 Hz, J_{gem} = 10.2 Hz, H-4β), 6.15 and 6.21(ABq, 2H, J = 7.9 Hz, H-9 and H-10); ^{13}C NMR (75 MHz) δ: 18.67(q), 21.94(q), 29.08(d), 35.42(t), 37.15(t), 50.02(t), 52.87(d), 85.99(s), 90.36(s), 137.61(d), 141.15(d), 209.19(s); mass spectrum, *m/e*: 192(4, $M^{+\cdot}$), 122(100 M−C_4H_6O, retro IMDAF–McLafferty rearrangement); HRMS (EI) calcd. for $C_{12}H_{16}O_2$: 192.1151; found: 192.1148.

*3α,6α,8α-Trimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (**23e**)*

Enone **17** (75.7 mg) was stirred with Florisil (760 mg) according to general procedure 1 for 19 days at room temperature under argon to provide a mixture of **17**:**23**e in a ratio of 50:50 in quantitative recovery.

Enone **17** (79.5 mg, 0.385 mmol) was treated with excess $MeAlCl_2$ (424 μL, 0.424 mmol) according to general procedure 2 at −78°C for 5 min to provide a mixture of **17**:**23**e in a ratio of 11:89 with quantitative recovery. Flash chromatography (9:1) provided the compounds **17** (4.5 mg), and **23**e (84.7 mg) as a white crystalline solid, mp 45–49°C; IR (KBr): 1705 cm^{-1}; ^{1}H NMR (400 MHz) δ: 1.04(d, 3H, J = 6.2 Hz, C-3-CH_3), 1.08(s, 3H, C-6-CH_3), 1.14(d, 1H, J_{gem} = 11.8 Hz, H-7α), 1.51(s, 3H, C-8-CH_3), 1.89(dd, 1H, $J_{2\alpha,3\beta}$ = 12.0 Hz, J_{gem} = 14.1 Hz, H-2α), 2.18(m, 1H, $J_{3\beta,2\beta}$ = 4.2 Hz, $J_{3\beta,4\beta}$ = 4.2 Hz, J = 6.2 Hz, $J_{3\beta,2\alpha}$ = 12.0 Hz, $J_{3\beta,4\alpha}$ = 12.0 Hz, H-3β), 2.23(dt, 1H, $J_{2\beta,4\beta}$ = 2.1 Hz, $J_{2\beta,3\beta}$ = 4.2 Hz, J_{gem} = 14.1 Hz, H-2β), 2.32(t, 1H, $J_{4\alpha,3\beta}$ = 12.3 Hz, J_{gem} = 12.3 Hz, H-4α), 2.38(ddd, 1H, $J_{4\beta,2\beta}$ = 2.1 Hz, $J_{4\beta,3\beta}$ = 4.2 Hz, J_{gem} = 13.6 Hz, H-4β), 2.57(d, 1H, J_{gem} = 11.7 Hz, H-7β), 6.14 and 6.29(ABq, 2H, J = 5.6 Hz, H-9 and H-10); ^{13}C NMR (50 MHz) δ: 18.78(q), 21.87(q), 22.12(q), 28.02(d), 34.43(t), 43.40(t), 46.52(t), 85.68(s), 91.79(s), 135.74(d), 141.53(d), 212.89(s); mass spectrum, *m/e*: 206(3, $M^{+\cdot}$), 122(100, M−C_5H_8O, retro IMDAF–McLafferty rearrangement); HRMS (EI) calcd. for $C_{13}H_{18}O_2$: 206.1307; found: 206.1316.

*(6αH)-3α,7α,8α-Trimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undec-9-en-5-one (**24e**)*

Enone **18** (233.8 mg) was stirred with Florisil (2.4 g) according to general procedure 1 for 8 days at room temperature under argon to provide a mixture of **18**:**24**e in a ratio of 80:20 in 68% yield.

Enone **18** (103.6 mg, 0.500 mmol) was treated with excess $MeAlCl_2$ (552 μL, 0.552 mmol) according to general procedure 2

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

at −65°C for 5 min to provide a **18**:**24**e ratio of 42:58 with 96% recovery. Flash chromatography (9:1) provided the compounds **18** (32.8 mg), and **24**e (37.8 mg) as oils.

Enone **17** (60.5 mg, 0.293 mmol) was treated with catalytic $MeAlCl_2$ (30 μL, 0.03 mmol) at −65°C for 9 min to provide, after flash chromatography (9:1), **17** (41.6 mg), **24**e (12.5 mg), and **24**a (2.5 mg) with 93% recovery. Compound **24**a was always contaminated with compound **24**e and therefore could not be characterized. Compound **24**e: IR (neat): 1710 cm^{-1}; ^1H NMR (400 MHz) δ: 0.94(d, 3H, J = 7.1 Hz, C-7-CH_3), 1.05(d, 3H, J = 6.2 Hz, C-3-CH_3), 1.50(s, 3H, C-8-CH_3), 1.82(d, 1H, $J_{6\alpha,7\beta}$ = 4.1 Hz, H-6α), 1.85(dd, 1H, $J_{2\alpha,3\beta}$ = 11.9 Hz, J_{gem} = 14.6 Hz, H-2α), 2.07(dd, 1H,$J_{4\alpha,3\beta}$ = 13.0 Hz, J_{gem} = 13.0 Hz, H-4α), 1.90–2.16(m, 1H, H-3β), 2.33(dt, 1H, $J_{2\beta,3\beta}$ = 3.1 Hz, $J_{2\beta,4\beta}$ = 3.1 Hz, J_{gem} = 14.6 Hz, H-2β), 2.45(dt, 1H, $J_{4\beta,2\beta}$ = 3.1 Hz, $J_{4\beta,3\beta}$ = 3.1 Hz, J_{gem} = 13.0 Hz, H-4β), 2.46(dq, 1H, $J_{7\beta,6\alpha}$ = 4.1 Hz, J = 7.1 Hz, H-7β), 6.20 and 6.23(ABq, 2H, J = 5.6 Hz, H-9 and H-10); ^{13}C NMR (50 MHz) δ: 16.96(q), 17.02(q), 21.91(q), 28.77(d), 37.30(t), 43.17(d), 49.94(t), 60.65(d), 88.69(s), 89.87(s), 138.72(d), 138.84(d), 209.48(s); mass spectrum, *m/e*: 206(2, $M^{\cdot+}$), 122(100, $M-C_5H_8O$, retro IMDAF–McLafferty rearrangement); HRMS (EI) calcd. for $C_{13}H_{18}O_2$: 206.1307; found: 206.1307.

(6αH)-2β,8α-Dimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undecan-5-one (25)

Ketone **19**e (0.13 g, 0.65 mmol) was dissolved in EtOAc (10 mL) and a small spatula tip of 10% palladium on carbon was added. The flask was evacuated, then filled with hydrogen gas three times via a hydrogen-filled balloon attached to a three-way stopcock. The reaction was stirred at room temperature for 1 h, filtered through Celite®, and the solvent removed *in vacuo* to produce the hydrogenated ketone **25** (0.12 g, 0.62 mmol) as a colourless oil in 95% yield, bp 58–62°C/0.025 Torr (1 Torr = 133.3 Pa), IR (neat): 1713, 1088 cm^{-1}; ^1H NMR (300 MHz) δ: 1.10(d, 3H, J = 6.9 Hz, C-2-CH_3), 1.42(s, 3H, C-8-CH_3), 1.45–2.00(overlapping m, 7H), 2.11(ddq, 1H, $J_{2\alpha,3\alpha}$ = 4.4 Hz, J = 6.9 Hz, $J_{2\alpha,3\beta}$ = 12.4 Hz, H-2α irradiation of methyl doublet at δ 1.10 resulted in collapse of signal to dd), 2.00–2.20(m, 1H), 2.30–2.50(overlapping m, 3H); ^{13}C NMR (75 MHz) δ: 15.21(q), 20.94(q), 30.93(t), 33.94(t), 37.24(t), 37.62(t), 41.42(t), 33.94(d), 57.04(d), 83.26(s) 89.87(s), 210.61(s); mass spectrum, *m/e*: 194(73, $M^{\cdot+}$); Anal. calcd. for $C_{12}H_{18}O_2$: C 74.19, H 9.34; found: C 74.29, H 9.51.

(E)- and (Z)-(6αH)-2β,8α-Dimethyl-5-(methoxymethylene)-11-oxatricyclo[6.2.1.0^{1,6}]undecane (30)

(Methoxymethyl)triphenylphosphonium chloride (0.82 g, 2.38 mmol) was suspended in dry THF (30 mL) and cooled to −78°C. To this was added LDA (1.59 mL, 2.38 mmol), and the reaction was stirred for 10 min at −78°C, then warmed to 0°C for 30 min and subsequently to room temperature for 30 min before being cooled to 0°C once more. Ketone **25** (0.11 g, 0.54 mmol) was dissolved in THF (6 mL), added dropwise to the anion, and stirred overnight. The reaction was quenched with wet Et_2O (10 mL), and the solvent was removed *in vacuo* to yield a crude brown oil. The product was purified by a filter column (5:1), then flash chromatography (9:1), then distillation to yield compound **30** as a clear, colourless oil (98.4 mg, 0.44 mmol) in 82% yield as a mixture of isomers, bp 56–60°C/0.06 Torr; IR (neat): 1676, 1102 cm^{-1}; ^1H NMR (300 MHz) δ: 1.02 and 1.03(d, 3H each, J = 6.9 Hz, C-2-CH_3), 1.41 and 1.44(s, 3H each, C-8-CH_3), 1.20–2.80(overlapping multiplets, 24H), 3.47 and 3.51(s, 3H each, vinyl methoxy CH_3), 5.65 and 5.58(m, 1H each, vinyl-H); ^{13}C NMR (75 MHz) δ: 16.06(q), 16.22(q), 21.35(q), 21.46(q), 24.20(t), 25.85(t), 30.21(t), 30.29(t), 30.87(t), 32.12(t), 36.21(t), 37.01(t), 42.06(t), 43.81(t), 34.23(d), 34.40(d), 46.08(d), 46.33(d), 59.28(q), 59.40(q), 82.56(s), 82.89(s), 88.00(s), 88.20(s), 125.49(s), 119.57(s), 140.37(d), 141.37(d); mass spectrum, *m/e*: 222(1, $M^{\cdot+}$); HRMS calcd. for $C_{14}H_{22}O_2$: 222.1621; found: 222.1624.

(6αH)-2β,8α-Dimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undecane-5-carboxaldehyde (31)

The mixture of methyl enol ethers **30** (98.4 mg, 0.44 mmol) was dissolved in THF (4 mL) and 10% HCl (3 mL) and stirred at room temperature for 1 h. The solution was neutralized to pH 7 (monitored with universal pH paper) with saturated Na_2CO_3, then the aqueous layer was extracted with Et_2O (3 × 10 mL). The organic layer was dried (over Na_2SO_4), filtered, and the solvent was removed *in vacuo* to yield a crude yellow oil. Distillation yielded compound **31** (57.8 mg, 0.28 mmol) as a clear, colourless oil (62%), bp 60°C/0.03 Torr; IR (neat): 2706, 1722, 1094 cm^{-1}; ^1H NMR (300 MHz) δ: 1.05(d, 3H, J = 6.6 Hz, C-2-CH_3), 1.17(dt, 1H, J = 3.0 Hz, J = 3.0 Hz, J = 12.4 Hz), 1.30–1.50(overlapping m, 4H), 1.43(s, 3H, C-8-CH_3), 1.52–1.78(overlapping m, 3H), 1.80–2.05(overlapping m, 3H), 2.18(dddd, 1H, $J_{5\beta,11}$ = 1.6 Hz, $J_{5\beta,4\beta}$ = 3.4 Hz, $J_{5\beta,6\alpha}$ = 10.5 Hz, $J_{5\beta,4\alpha}$ = 12.4 Hz, H-5β, assignment confirmed since irradiation of H-11 at δ 9.57 caused collapse to ddd with 1.6 Hz coupling removed), 9.57(d, 1H, J = 1.6 Hz, H-11); ^{13}C NMR (75 MHz) δ: 15.76(q), 21.32(q), 25.26(t), 30.58(t), 33.91(t), 37.67(t), 44.19(t), 34.06(d), 44.07(d), 56.62(d), 83.93(s), 85.90(s), 204.31(d); mass spectrum, *m/e*: 208(9, $M^{\cdot+}$), 179(100, M−CHO); Anal. calcd. for $C_{13}H_{20}O_2$: C 74.96, H 9.68; found: C 74.81, H 9.73.

(6αH)-5α-(1-Hydroxyethyl)-2β,8α-dimethyl-11-oxatricyclo[6.2.1.0^{1,6}]undecane (32)

Freshly distilled aldehyde **31** (49.2 mg, 0.24 mmol) was dissolved in THF (5 mL) and the solution was cooled to −78°C. Methyllithium (1.00 mL, 1.40 mmol) was added; the reaction was stirred for 1.5 h at −78°C, then was allowed to warm to room temperature and was quenched with saturated NH_4Cl (5 mL). The aqueous layer was extracted with EtOAc (3 × 10 mL), the organic layer was dried over Na_2SO_4, filtered, and the solvent was removed *in vacuo*. The resulting crude oil was purified by flash chromatography (5:1) to produce compound **32** (51.6 mg, 0.23 mmol) as a mixture of two isomers in 97% yield, bp 80°C/0.024 Torr (data listed for 1 isomer only); IR (neat): 3422, 1092 cm^{-1}; ^1H NMR (300 MHz) δ: 1.02(d, 3H, J = 6.6 Hz, C-2-CH_3), 1.15(d, 3H, J = 6.5 Hz), 1.41(s, 3H, C-8-CH_3), 3.68(dq, 1H, J = 1.2 Hz, J = 6.5 Hz), 1.10–1.40(overlapping m, 6H), 1.41–1.75(overlapping m, 6H), 1.80–1.92(overlapping m, 2H); ^{13}C NMR (75 MHz) δ: 16.03(q), 21.69(q), 21.88(q), 23.31(t), 31.32(t), 34.50(t), 37.64(t), 44.66(t), 34.61(d), 46.71(d), 49.42(d), 67.66(d), 83.55(s), 87.05(s); mass spectrum, *m/e*: 224 ($M^{\cdot+}$); HRMS (EI) calcd. for $C_{14}H_{24}O_2$: 224.1777; found: 224.1780.

(6αH)-2β,8α-Dimethyl-5α-(1-oxoethyl)-11-oxatricyclo[6.2.1.0^{1,6}]undecane (33)

Oxalyl chloride (11 mmol) was dissolved in dry CH_2Cl_2 (25 mL) and cooled to −60°C (Dry Ice/chloroform) in an argon-purged 3-neck round-bottom flask equipped with a dropping funnel. Freshly distilled alcohol **32** (21.6 mg, 10 mmol) was dissolved in dry CH_2Cl_2 (10 mL) and placed in the dropping funnel. DMSO (22 mmol) was added neat (by syringe) to the oxalyl chloride solution, the reaction was stirred for 2 min, and then the alcohol solution was added within 5 min. The mixture was stirred an additional 15 min; then Et_3N (50 mmol) was added and stirring was continued for another 5 min before warming the reaction to room temperature. Water (50 mL) was added, and the aqueous layer was extracted with CH_2Cl_2 (5 × 25 mL). The combined organic layers were washed with 5% HCl (15 mL), 5% Na_2CO_3 (15 mL), and water (15 mL), dried over Na_2SO_4, filtered, and the solvent removed *in vacuo* to provide the crude product. This was purified by flash chromatography, then distilled to provide compound **33** (19.2 mg, 0.086 mmol) as a clear, colourless oil in 90% yield after purification by flash chromatography (5:1), bp 58–60°C/0.03 Torr; mp 63.5–64.5°C; IR (neat): 1702, 1087 cm^{-1}; ^1H NMR (300 MHz) δ: 0.97(dt, 1H, $J_{7\beta,6\alpha}$ = 2.9 Hz, $J_{7\beta,9\beta}$ = 2.9 Hz, J_{gem} = 11.8 Hz, H-7β), 1.04(d, 3H, J = 6.6 Hz, C-2-CH_3), 1.21(dq, 3H, J = 2.6 Hz, J = 12.8 Hz, J = 12.8 Hz), 1.30–

1.49(overlapping m, 3H), 1.41(s, 3H, C-8-CH_3), 1.50–1.72(overlapping m, 3H), 1.80–1.95(overlapping m, 3H), 2.00(ddd, 1H, $J_{6\alpha,7\beta}$ = 2.9 Hz, $J_{6\alpha,7\alpha}$ = 8.1 Hz, $J_{6\alpha,5\beta}$ = 10.6 Hz, H-6α), 2.10(s, 3H, $COCH_3$), 2.31(ddd, 1H, $J_{5\beta,4\beta}$ = 3.1 Hz, $J_{5\beta,6\alpha}$ = 10.2 Hz, $J_{5\beta,4\alpha}$ = 13.1 Hz, H-5β); ^{13}C NMR (75 MHz) δ: 15.76(q), 21.42(q), 29.31(q), 28.61(t), 31.39(t), 34.00(t), 37.70(t), 44.74(t), 34.00(d), 45.57(d), 57.75(d), 83.73(s), 86.09(s), 211.83(s); mass spectrum, *m/e*: 222(28, $M^{\cdot+}$), 179(38, M−MeCO); HRMS (EI) calcd. for $C_{14}H_{22}O_2$: 222.1621; found: 222.1625.

(6αH)-2β,8α-Dimethyl-5α-(1-methylethenyl)-11-oxatricyclo[6.2.1.0^{1,6}]undecane (34)

Methyltriphenylphosphonium bromide (Aldrich Chemical Co.) was purified by washing with hot toluene, then dried under high vacuum for 8 h. The purified phosphonium salt (0.88 g, 2.45 mmol) was suspended in dry THF (10 mL), and cooled to 0°C. Butyllithium (0.98 mL, 2.48 mmol) was added dropwise by syringe, and the reaction was warmed to room temperature and stirred for 20 min. A solution of ketone **33** (27.6 mg, 0.124 mmol) in THF (3 mL) was added to the orange anion solution, and the reaction was refluxed overnight. The reaction was cooled, quenched with wet Et_2O (10 mL), and the solvent was removed *in vacuo*. The crude compound was purified by flash chromatography (5:1) to yield starting material (9.0 mg) and product **34** (30.9 mg) as a mixture with an aromatic-containing impurity. The mixture was further purified by flash chromatography (20:1) to yield compound **34** (20.8 mg, 71%), bp 50–60°C/0.04 Torr; IR (KBr): 1088 cm^{-1}; ^{1}H NMR (300 MHz) δ: 0.90–1.4(overlapping m, 6H), 1.04(d, 3H, J = 6.6 Hz, C-2-CH_3), 1.42(s, 3H, C-8-CH_3), 1.48–1.82 (overlapping m, 5H), 1.85–1.96(m, 1H), 1.62(m, 3H, J = 1.0 Hz, vinyl-CH_3), 4.63 and 4.67(m, 2H, J_{gem} = 1.4 Hz, J = 2.5 Hz); mass spectrum, *m/e*: 220(15, $M^{\cdot+}$); HRMS (EI) calcd. for $C_{15}H_{24}O$: 220.1828; found: 220.1827.

(6αH)-2β,8α-Dimethyl-5α-(1-methylethyl)-11-oxatricyclo[6.2.1.0^{1,6}]undecane (epoxycadinane) (1)

Compound **34** (8.8 mg, 0.04 mmol) was dissolved in absolute ethanol (5 mL). Platinum(IV) oxide (28.5 mg, 0.126 mmol) was added, then the flask was evacuated and filled with hydrogen gas three times by way of a hydrogen-filled balloon attached to a three-way stopcock. The reaction was stirred at room temperature for 1 h; then the catalyst was removed by filtration and the solvent was removed *in vacuo* to yield compound **1** (6.0 mg, 0.027 mmol) as a colourless oil in 93% yield, bp 42–50°C/0.06 Torr; IR (neat): 2964–2869, 1376, 1367, 1094 cm^{-1}; ^{1}H NMR (300 MHz), see Table 4; ^{13}C NMR (75 MHz), see Table 4; mass spectrum, *m/e*: 222(3, $M^{\cdot+}$), 179(100, M−$CHMe_2$); HRMS (EI) calcd. for $C_{15}H_{26}O$: 222.1984; found: 222.1986.

Reçu le 6 août 1992

BOUALEM OUSSAID, CATHY HUBERT, LEILA MOEINI, BERNARD GARRIGUES et JEAN-PIERRE FAYET. Can. J. Chem. **71**, 623 (1993).

La conformation de dérivés pyrroliques (**1**, **2**, **3***a*,*b*, **4***a*,*b*, **5**, **6** et **7**) a été étudiée à partir de calculs théoriques de mesures de moments dipolaires, de l'utilisation du couplage stéréospécifique à travers cinq liaisons et des expériences d'effets Overhauser (**6**).

BOUALEM OUSSAID, CATHY HUBERT, LEILA MOEINI, BERNARD GARRIGUES, and JEAN-PIERRE FAYET. Can. J. Chem. **71**, 623 (1993).

The conformations of pyrrole derivatives (**1**, **2**, **3***a*,*b*, **4***a*,*b*, **5**, **6**, and **7**) have been elucidated from theoretical investigations, dipole moment measurements, use of stereospecific coupling through five bonds, as well as Overhauser experiments (**6**).

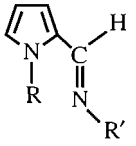
Introduction

De nombreux travaux ont été effectués afin de déterminer en solution la conformation des dérivés pyrroliques. Ces études (1) ont été menées à partir de mesures de moments dipolaires, par infrarouge, micro-ondes, par calculs théoriques et surtout par RMN ^{1}H, grâce à la stéréospécificité (2) d'un couplage entre cinq liaisons qui impose une disposition en zigzag et la planéité de la molécule.

Le 2-formyl pyrrole a été particulièrement étudié par différentes techniques. Les premiers travaux remontent à 1954 (3) où une étude par mesure de moment dipolaire conclut à la stabilisation du conformère 2*c* (NH, O *cis*), stabilisé par liaison hydrogène. Ce résultat a éte confirmé par infrarouge (4, 5) et par des études de RMN ^{1}H : à partir des constantes de couplages, il a été établi qu'il y avait 95% de la forme 2*c* (6). À −70°C, ces mêmes auteurs ont pu mettre en évidence la présence des deux conformères (6). De nombreux calculs théoriques ont confirmé la prépondérance de la forme (2*c*) chelatée (7, 8), avec une barrière à la rotation de 39,2 kJ mol^{-1} (9). Pour une série de *N*-alkyl 2-formyl pyrroles (alkyl : méthyle, éthyle, isopropyle, tertiobutyle), la valeur de la constante de couplage $^5J_{CHO-H(5)}$ de l'ordre de 1,2 Hz permet de conclure à la prépondérance de la forme 2*c* (NR, O *cis*) (10).

L'étude de la conformation du 3-formylpyrrole fait apparaître une absence de convergence. Les travaux effectués à partir de la RMN (6, 11) et des mesures de moments dipolaires (7, 12) sont en bon accord : la forme 3*t* (NH, O *trans*) est prépondérante 95–100%. À partir de calculs théoriques, certains auteurs ont montré que la structure 3*c* (NH, O *cis*) était favorisée (8, 9).

Il n'existe qu'une seule étude concernant les imines pyrroliques (13). L'étude des quatre imines : la 2-méthyliminométhyl pyrrole (R = H, R′ = CH_3), la 2-*n*-butyliminométhyl pyrrole (R = H, R′ = *n*-C_4H_9), la 2-méthyliminométhyl *N*-méthyl pyrrole (R = CH_3, R′ = CH_3) et la 2-*n*-butyliminométhyl *N*-méthyl pyrrole (R = CH_3, R′ = *n*-C_4H_9) a été effectuée par RMN à température variable. Ces études excluent la présence d'une isomérie rotationnelle. Les valeurs des couplages stéréospécifiques à travers cinq liaisons prouvent que la conformation *s-trans* est la seule qui existe.



Des études théoriques de la conformation de 2-vinyl pyrroles ont abouti à des conclusions divergentes (8, 14). Enfin, le 2-pyrrole carboxylate de méthyle existe de façon préférentielle, en solution, majoritairement sous la conformation plane 2*c* (NH, O *cis*) (12).

La conformation de *N*-alkyl 2 ou 3 carboxylate ou des 2,4 ou 2,5 *N*-alkyl dicarboxylate a été étudiée par infrarouge (15); par exemple : les *N*-alkyl 2-carboxylate existent majoritairement sous un seul rotamère probablement *syn–s-trans* (15).

Nous nous proposons dans ce travail d'étudier à partir de calculs théoriques MNDO (16), de mesures de moments dipolaires et par RMN la conformation d'aldéhydes, d'imines, d'éthyléniques et d'esters pyrroliques non encore abordée dans la littérature.

Partie expérimentale

Généralités

Points de fusion, non corrigés, en capillaires (appareil Tottoli, Büchi). Spectres IR : entre lames CaF_2, enregistrés sur un spectromètre Perkin–Elmer 257. Spectres de RMN ^{1}H : déplacements chimiques en ppm par rapport au TMS; constantes de couplage en Hz : appareil Bruker AC 250.

Les spectres ^{1}H ont été enregistrés avec une résolution digitale de 0,15 Hz/point. Celle des spectres ^{13}C est de 0,46 Hz/point.

TABLEAU 1. Grandeurs intermédiaires pour la détermination des moments dipolaires expérimentaux

	α	β	R_{MD}	$P_{2\infty}$	μ_D
1	17,53	~0	31,89	448,05	4,51
2	9,39	−0,20	42,46	350,56	3,95
3*a*	1,46	−0,10	42,67	73,83	1,23
3*b*	6,40	−0,22	48,39	234,33	3,01
4*a*	11,90	−0,30	28,73	233,18	3,16
4*b*	2,50	~0	37,58	110,48	1,88
5	4,31	~0	39,58	147,81	2,55
6	4,13	−0,50	52,71	178,30	2,48
7	11,39	~0	49,39	524,55	4,82

Les expériences 2D-NOESY ont été réalisées dans des conditions tout à fait classiques, avec un temps de mélange $t_m \sim T_1$. D'autre part, pour permettre une relaxation optimum, nous avons choisi dans tous les cas un délai entre deux accumulations légèrement supérieur à $5\times T_1$.

Les analyses élémentaires ont été effectuées par le service de microanalyse de l'École nationale supérieure de chimie de Toulouse.

Synthèse des dérivés

Les composés **1**, **2**, **3***a*, **6** et **7** ont été préparés, respectivement, à partir des références 17, 18, 19, 20 et 21.

Synthèse des dérivés **3**b, **4**a,b *et* **5**

On mélange à température ambiante soit 0,01 mol de 2-formyl *N*-phényl pyrrole (**3***b*) préparé d'après la référence 18, soit 0,01 mol de 3-formyl pyrrole (**4***a*,*b*), soit 0,01 mol de 2,5-diformyl pyrrole préparé d'après la référence 20 avec 0,05 mol d'amine, en solution dans 30 mL d'acétonitrile anhydre, sous argon. L'évolution de la réaction est suivie par RMN ^{1}H. Lorsque la réaction est terminée, le mélange réactionnel est évaporé à sec. On obtient un produit analytiquement pur sour forme d'huile pour **3***b* et **5**, solide pour **4***a* (F = 158°C), **4***b* (F = 90°C). Ces imines, peu stables, se décomposent par purification sur colonne de silice.

2-Méthyliminométhyl N*-phényl pyrrole :* **3**b. Rdt = 89%. IR (entre lames) : 1638 (C=N) cm^{-1}. 3-Isopropyliminométhyl pyrrole : **4**b. Rdt = 91%. IR (entre lames) : 3126 (NH); 1639 (C=N) cm^{-1}. RMN ^{1}H (C_6D_6) : 9,75 (s, 1H, NH); 8,25 (s, 1H, CH=N); 7,26 (dd, 1H, $^4J_{24}$ = 1,5, $^4J_{25}$ = 2,0, H2); 6,76 (dd, 1H, $^4J_{25}$ = 2,0, $^3J_{45}$ = 2,8, H5); 6,56 (dd, 1H, $^3J_{45}$ = 2,8 $^4J_{24}$ = 1,5, H4); 3,44 (hept, 1H, ^3J = 6,3, CH); 1,24 (d, 6H, ^3J = 6,3, CH_3). RMN ^{13}C {^{1}H} (C_6D_6) : 153,9 (s, C=N); 122,9 (s, C3 pyr.); 121,2 (s, pyr.); 119.5 (s, pyr.); 107,2 (s, pyr.); 81,6 (s, CH-C); 24,4 (s, CH_3). Anal. calc. pour $C_8H_{12}N_2$ (MM = 136,2) : C 70,54; H 8,89; N 20,57; tr. : C 70,24; H 8,75; N 20,27.

2,5-Bis[(méthylimino)methyl]pyrrole : **5**. Rdt = 88%. IR (entre lames) : 1642 (C=N) cm^{-1}. RMN ^{1}H ($CDCl_3$) : 8,02 (q, 2H, ^4J = 1,5, HC=N); 6,42 (s, 2H, HC=C); 3,40 (d, 6H, ^4J = 1,5, CH_3). RMN ^{13}C {^{1}H} ($CDCl_3$) 152,5 (s, C=N); 132,7 (s, C-NH); 113,7 (s, C=C); 47,7 (s, CH_3). Anal. calc. pour $C_8H_{11}N_3$ (MM = 149,19) : C 64,40; H 7,43; N 28,16; tr. : C 63,95; H 7,66; N 28,40.

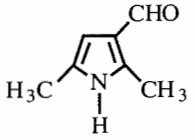
Les moments dipolaires des composés étudiés sont mesurés dans le dioxanne à 25°C (tableau 1). La formule de Debye est utilisée ainsi que la méthode d'extrapolation d'Halverstadt et Kumler (22) pour calculer la polarisation totale avec $\alpha = (d\varepsilon/d\omega_2)\omega_2 \rightarrow 0$, $\beta = (dv/d\omega_2)\omega_2 \rightarrow 0$ et $0{,}001 < \omega_2 < 0{,}05$. ε est la constante diélectrique, ω_2 la fraction massique de l'échantillon et v le volume massique. Les polarisations électroniques sont assimilées aux refractions moléculaires R_{MD}.

Les calculs théoriques ont été effectués pour l'ensemble des conformations des 11 dérivés pyrroliques. Les approximations de base dans la méthode MNDO inclue un modèle semi-empirique pour les intégrales à deux centres (16).

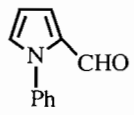
Pour juger de la fiabilité de cette méthode on peut comparer les valeurs calculées en MNDO aux valeurs expérimentales (23) pour les chaleurs de formation, les géométries moléculaires, les potentiels d'ionisation et les moments dipolaires; on constate le bon accord ce qui justifie l'utilisation de la méthode.

Résultats et discussion

Nous nous sommes tout d'abord intéressés à l'étude conformationnelle en solution des aldéhydes **1** et **2**.

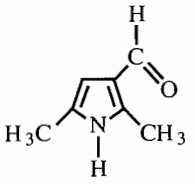


1

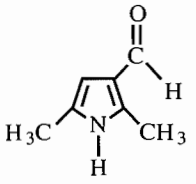


2

Le 2,5-diméthyl 3-formyl pyrrole **1** peut exister en solution soit sous la conformation 3*c* (NH, O *cis*) soit sous la conformation 3*t* (NH, O, *trans*).



3*c*

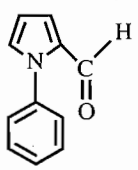


3*t*

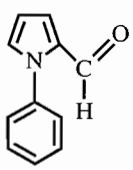
Les calculs MNDO montrent que les énergies des formes 3*c* (−1551, 40 eV) et 3*t* (−1551, 46 eV) sont très proches.

La valeur expérimentale du moment dipolaire mesuré dans le benzène à 25°C (μ_{ex} = 4,51 D) indique la prépondérance de la forme 3*c* qui a un moment théorique de 4,65 D alors que la forme 3*t* a un moment de 3,49 D. Ceci peut s'expliquer par la formation d'une liaison hydrogène possible entre un hydrogène du groupe méthyle et l'oxygène du carbonyle. Cette structure est analogue à celle obtenue pour la forme céto-énolique, majoritaire des β dicétones.

Nous avons étudié la conformation du 2-formyl *N*-phenyl pyrrole **2**, qui peut exister soit sous la conformation 2*c* (N, O *cis*) soit 2*t* (N, O *trans*).



2*c*



2*t*

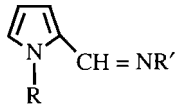
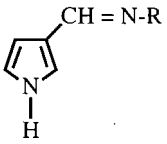
Nous avons par calcul optimisé la position du phényle en le faisant tourner autour de la liaison phényle–azote. Dans le cas où la molécule serait plane, nous avons obtenu pour une valeur de $\phi = 0°$ (ϕ = angle entre le plan du phényle et du pyrrole) des valeurs de l'énergie pour 2*c* (−2051,03 eV) et pour 2*t* (−2056,06 eV). L'énergie a été optimisée à $\phi = 90°$ avec des valeurs très proches respectivement de −2058,02 eV pour 2*c* et −2058,08 eV pour 2*t*. Les mesures de moments dipolaires nous ont permis de préciser le pourcentage respectif de chacun des conformères. La valeur théorique, avec le phényle perpendiculaire au plan du pyrrole, des conformations 2*c* (1,26 D) et 2*t* (4,55 D), comparée à la valeur expérimentale mesurée dans le benzène à 20°C (μ = 3,95 D) permet de préciser qu'il existe un équilibre conformationnel entre ces deux structures déplacé vers la forme 2*t* (73%). La structure 2*t* est favorisée, car dans la zone des électrons π du noyau benzénique il est préférable d'avoir un hydrogène positivé que l'oxygène du carbonyle chargé négativement.

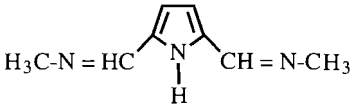
Nous avons étudié par calcul, mesure de moments dipolaires et RMN les imines pyrroliques **3***a*,*b*, **4***a*,*b* et **5**.



3*a* R = H, R′ = *t*Bu
3*b* R = C_6H_5, R′ = CH_3

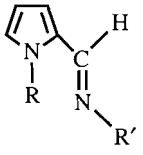


4*a* R = CH_3
4*b* R = iPr



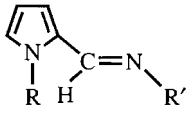
5

Les composés **3***a*,*b* peuvent se présenter sous l'une des quatre conformations possibles : 2*c trans*, 2*c cis*, 2*t trans* et 2*t cis*.

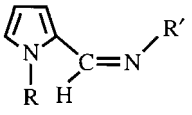


2*c trans*

2*c cis*

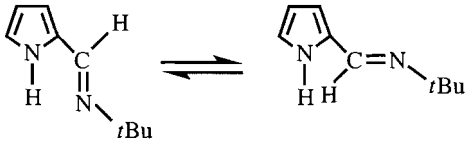


2*t trans*



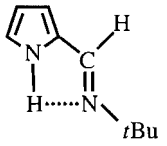
2*t cis*

L'examen des énergies dans le cas de **3***a* montre que les conformations 2*c trans* (−1756,64 eV) et 2*t trans* (−1756,58 eV) sont les plus basses en énergie (tableau 2). Pour la conformation 2*c cis*, l'encombrement stérique ne permet pas de calculer l'énergie et la valeur théorique du moment dipolaire. La valeur expérimentale du moment dipolaire (μ = 1,23 D), mesurée à 25°C dans le dioxanne, permet de préciser l'existence d'un équilibre entre ces deux conformations 2*c trans* et 2*t trans* dans un rapport 80 : 20 (tableau 2).



80% 20%

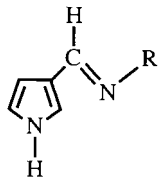
La molécule étant plane, il doit exister un couplage stéréospécifique entre protons séparés par cinq liaisons, dans une disposition zigzag (proton de la fonction imine et H5). Dans le spectre de RMN ^{1}H, il existe un tel couplage $^5J_{HCN-H(5)}$ = 0,75 Hz ce qui confirme bien la prépondérance de la conformation 2*c trans*, stabilisée par une liaison hydrogène intramoléculaire, comme cela avait déjà été montré pour des molécules appartenant à cette famille (14).



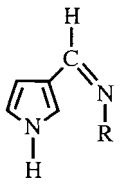
Nous avons étudié la conformation du 2-méthyliminométhyl *N*-phényl pyrrole **3***b*. Les différentes conformations ont été calculées dans le cas où la molécule est coplanaire ($\phi = 0°$) et optimisées en faisant tourner le plan du phényl. Nous avons obtenu une énergie minimale à $\phi = 90°$ correspondant aux formes 2*c trans* (−2113,22 eV) et 2*t trans* (−2113,25 eV) très proches en énergie (tableau 2).

La valeur expérimentale du moment dipolaire mesurée dans le dioxanne (3,01 D) permet de conclure à l'existence en solution d'un équilibre entre les deux conformations 2*c trans* et 2*t trans* (le phényle étant perpendiculaire au pyrrole) avec un pourcentage respectif de 39% et 61% (tableau 2).

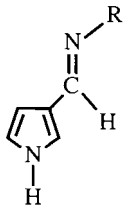
Nous nous sommes intéressés à la conformation du 3-méthyliminométhyl pyrrole **4***a* (R=CH_3) et du 3-isopropyliminométhyl pyrrole **4***b* (R=iPr). Ces molécules peuvent exister sous l'une des quatre conformations 3*c trans*, 3*c cis*, 3*t trans* et 3*t cis*.



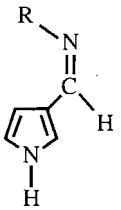
3*c trans*



3*c cis*



3*t trans*



3*t cis*

Les quatre conformations ont été calculées. Comme on peut le voir dans le tableau 3, il existe pour ces deux dé-

TABLEAU 2. Valeur des énergies (eV) et des moments dipolaires (D) des conformations **3***a* et **3***b*

	R	R′	N°	2*c trans*	2*t trans*	2*t cis*	2*c cis*
E	H	*t*Bu	**3***a*	−1756,64	−1756,58	−1748,12	[a]
μ_{th}	H	*t*Bu	**3***a*	1,12	1,61	2,33	[a]
E (θ = 0)	C_6H_5	CH_3	**3***b*	−2105,34	−2111,22	−2108,22	[a]
E (θ = 90)	C_6H_5	CH_3	**3***b*	−2113,22	−2113,25	−2110,22	−2093,83
μ_{th} (θ = 90)	C_6H_5	CH_3	**3***b*	0,90	3,79	3,38	2,17

[a]Incompatibilité stérique.

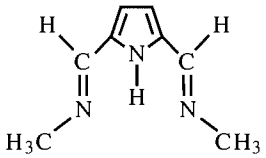
TABLEAU 3. Valeur des énergies (eV) et des moments dipolaires (D) pour les quatre conformations des composés **4***a* et *b*

	R	N°	3c *trans*	3c *cis*	3t *trans*	3t *cis*	μ_{exp}
E	Me	**4***a*	−1293,42	−1289,67	−1293,37	−1289,66	
μ_{th}	Me	**4***a*	1,79	4,07	3,16	4,38	3,16
E	iPr	**4***b*	−1606,06	−1602,27	−1606,01	−1602,27	
μ_{th}	iPr	**4***b*	1,84	3,92	3,11	4,54	1,88

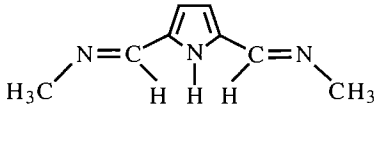
rivés deux conformations qui sont les plus basses en énergie et très proches : respectivement les conformations 3*c trans* (−1293,42 eV pour **4***a* et −1606,06 eV pour **4***b*) et 3*t trans* (−1293,37 eV pour **4***a* et −1606,01 eV pour **4***b*). La valeur expérimentale du moment dipolaire, mesurée dans le dioxanne à 25°C pour **4***a* (μ = 3,16 D) et dans le benzène à 25°C pour **4***b* (μ = 1,88 D) a permis de préciser que dans le cas de **4***a* la conformation 3*t trans* est prépondérante (μ_{th} = 3,16) et que dans le cas de **4***b* c'est au contraire la conformation 3*c trans* qui est majoritaire (μ_{th} 1,84) (tableau 3).

Ces conclusions ont pu être confirmées par le spectre de RMN ^{1}H. Dans le case de **4***a*, la conformation majoritaire étant 3*t trans*, on doit observer dans le spectre un couplage stéréospécifique, à cause de la disposition zigzag, entre les protons de la fonction imine et le proton H5. En effet, un tel couplage $^5J_{HCN-H(5)}$ = 0,6 Hz est observé. Dans le cas de **4***b*, la conformation priviligiée étant 3*c trans*, l'absence d'un tel couplage confirme les conclusions précédentes. Il est à noter que l'on n'observe pas de modifications des spectres de RMN lorsqu'on refroidit à −60°C.

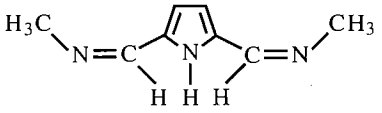
Nous avons étudié la conformation du 2,5-bis(méthyliminométhyl) pyrrole **5**. La simplicité du spectre de RMN ^{1}H de ce composé, dans un domaine de température de −60°C à +60°C ne peut s'expliquer que par la présence d'un plan de symétrie passant par l'atome d'azote. Cela entraîne qu'il n'existe que quatre conformations planes possibles 2*c* 5*c trans*, 2*t* 5*t trans*, 2*t* 5*t cis* et 2*c* 5*c cis*; cette dernière pour des raisons d'encombrement stérique n'a pas pu être calculée.



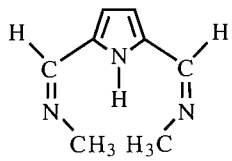
2*c* 5*c trans*



2*t* 5*t trans*



2*t* 5*t cis*



2*c* 5*c cis*

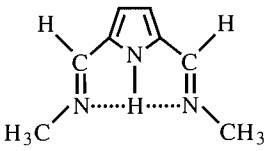
TABLEAU 4. Valeurs des énergies (eV) et du moment dipolaire (D) pour les trois conformations de **5**

	2*c* 5*c trans*	2*t* 5*t trans*	2*t* 5*t cis*
E	−1793,44	−1791,66	−1789,96
μ_{th}	2,58	2,52	0.02

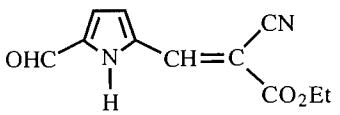
Un calcul théorique MNDO, effectué pour les trois conformations, montre (tableau 4), que la conformation 2*c* 5*c trans* est la plus basse en énergie (−1793,44 eV). La mesure du moment dipolaire expérimental, effectuée dans le dioxanne à 25°C (2,55 D) est compatible avec la valeur théorique de la conformation 2*c* 5*c trans* (2,58 D).

Le spectre de RMN ^{1}H, confirme que le 2,5-bis(méthyliminométhyl) pyrrole **5** existe de façon prépondérante sous la conformation 2*c* 5*c trans*. En effet, dans cette conformation, on n'a pas de disposition zigzag entre le proton de la fonction imine et le proton du cycle pyrrolique, donc pas de couplage ^5J stéréospécifique entre protons séparés par cinq liaisons. Ceci exclut donc les conformations 2*t* 5*t trans* et 2*t* 5*t cis*.

La conformation privilégiée 2*c* 5*c trans* peut s'expliquer facilement si l'on admet une stabilisation par liaison hydrogène intramoléculaire.



Nous avons étudié la conformation du composé **6**



6

Dans le spectre de RMN ^{1}H on n'observe pas de couplage stéréospécifique ^5J entre le proton aldéhydique et le proton H3 du cycle ce qui est en faveur d'une conforma-

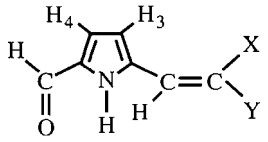
TABLEAU 5. Valeur des énergies (eV) et du moment dipolaire (D) des conformations de **6** et **7**

	N°	*a*	*b*	*c*	*d*	*e*
E	**6**	−2913,17	−2904,90	−2920,85	−2920,80	
μ_{th}	**6**	2,76	4,18	0.53	3,71	
E	**7**	−2955,52	−2935,07	−2940,10	−2893,84	−2942,39
μ_{th}	**7**	4,92	10,88	1,72	9,58	8,03

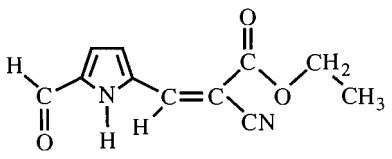
tion (O, NH, *cis*). Il existe un couplage stéréospécifique $^5J_{HC=C-H(4)}$ = 0,7 Hz compatible avec une conformation dans laquelle la fonction éthylénique est en *trans* par rapport au NH.



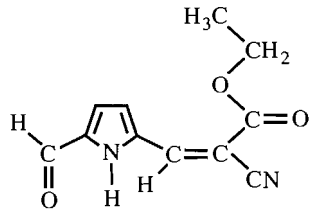
Cette géométrie a été confirmée dans le spectre de RMN ^{2}D NOESY par une très forte tache de correlation entre les protons H4 et aldéhydique et une absence de tache de correlation entre H3 et le proton éthylénique.

Nous avons effectué des calculs théoriques MNDO pour les quatre conformations ci-dessous **6***a*, **6***b*, **6***c*, **6***d* en choisissant une conformation *s-trans* pour la fonction ester comme cela a été clairement établi dans la littérature (16).

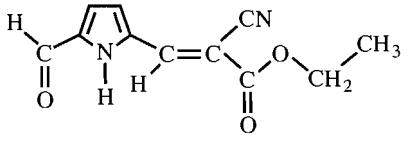
L'examen des énergies (tableau 5) montre que les conformations **6***c* et **6***d* sont les plus basses en énergies et ont



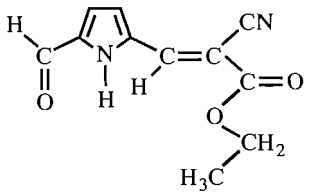
6*a*



6*b*



6*c*



6*d*

des valeurs très proches, respectivement −2920,85 eV et −2920,80 eV. Les formes **6***a* (−2913,17 eV) et **6***b* (−2904,90 eV) peuvent être éliminées. La valeur expérimentale du moment dipolaire, mesurée dans le dioxanne à 25°C (2,48 D), est en faveur de la prépondérance de la conformation **6***d*. Cette structure est favorisée, car elle permet de former deux liaisons hydrogènes : l'une entre le NH et le carbonyle aldéhydique, l'autre entre le proton éthylénique et l'oxygène de l'éthoxy du groupe ester.

Enfin, nous avons étudié la conformation du 3,4-carbethoxy pyrrole **7**. La simplicité du spectre de RMN ^{1}H ne s'explique que par l'existence d'un plan de symétrie passant par l'atome d'azote. Nous n'avons pas observé de modification du spectre lorsque la solution est refroidie à −60°C. Si l'on compare la valeur des énergies du tableau 5, il est clair que l'énergie la plus basse correspond à la conformation **7***a* (−2955,52 eV) dans laquelle les deux carboxyles sont en *trans* de l'azote, les deux fonctions esters sont *s-trans*. En faisant tourner le CH_3 autour de la liaison O—C, l'énergie minimale correspond à une disposition *s-trans*. Le moment dipolaire expérimental mesuré dans le benzène à 25°C (4,82 D) est en parfait accord avec la valeur théorique calculée pour **7***a* (4,92 D) (tableau 5). Dans ce dernier cas il n'y a pas de liaison hydrogène possible ni d'encombrement stérique. Il est alors normal que les deux doubles liaisons conjugées soient *s-trans*.

Conclusion

Alors que la conformation du 3-formyl pyrrole a fait l'objet de controverses, les études que nous avons effectuées à partir de calculs théoriques, de mesures de moments dipolaires, de l'utilisation du couplage stéréospécifique à travers cinq liaisons et des expériences de NOESY, montrent une convergence des résultats.

Le 2,5-diméthyl 3-formyl pyrrole (**1**) existe en solution de façon prépondérante sous la conformation 3*c* (NH, O *cis*). Le 2-formyl *N*-phényl pyrrole (**2**) présente une énergie mi-

nimale avec le phényle perpendicularie au plan du cycle. Dans le cas du 2-*tert*-butyliminométhyl pyrrole (**3***a*) et du 2-méthyliminométhyl *N*-phényl pyrrole (**3***b*), il existe un équilibre conformationnel entre les formes 2*c trans* et 2*t trans*. Le 3-méthyliminométhyl pyrrole (**4***a*) et le 3-isopropyliminométhyl pyrrole (**4***b*) existent majoritairement, respectivement sous les conformations 3*t trans* et 3*c trans*. Le 2,5-bis(méthyliminométhyl) pyrrole **5** est présent sous la conformation 2*c* 5*c trans*. Enfin, pour les composés **6** et **7** les conformations **6***d* et **7***a* sont privilégiées.

Il est à noter, qu'en aucun cas, en refroidissant les solutions jusqu'à −60°C, nous n'avons pu, par RMN ^{1}H, mettre en évidence une barrière à la rotation.

Remerciements

Nous remercions A. Colomer et G. Pelletier pour l'enregistrement respectifs des spectres IR et de RMN à 250 MHz.

MOHAMMAD S. IQBAL, SYED J. KHURSHID, and MOHAMMAD Z. IQBAL. Can. J. Chem. **71**, 629 (1993).

Cu(II) – Schiff base complexes containing anthranilic acid and aldoses (sugars) as part of the base were prepared and characterized by microanalytical, thermogravimetric, magnetic, and spectroscopic data. The complexes are four-coordinate, anhydrous, and ML_2 type. The electron paramagnetic resonance spectral lines exhibited rhombic distortion from axial symmetry in the square-planar Cu(II) complexes with $g_{\parallel} > g_{\perp} > g_e$. The complexes were found to be active against kaolin paw oedema and standard strains of *Escherichia coli*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*.

MOHAMMAD S. IQBAL, SYED J. KHURSHID et MOHAMMAD Z. IQBAL. Can. J. Chem. **71**, 629 (1993).

On a préparé des complexes du Cu(II)/bases de Schiff contenant de l'acide anthranilique et des aldoses (sucres) dans la base et on les a caractérisés par des méthodes microanalytique, thermogravimétrique, magnétique et spectroscopique. Les complexes sont tétracoordinés, anhydre et du type ML_2. Les raies des spectres de résonance paramagnétique électronique des complexes Cu(II) plan carrés présentent une distorsion rhombique par rapport à la symétrie axiale avec $g_{\parallel} > g_{\perp} > g_e$. On a trouvé que les complexes sont actifs contre l'oedème et certaines souches d'*Escherichia coli*, *Staphylococcus aureus* et *Pseudomonas aeruginosa*.

[Traduit par la rédaction]

Introduction

Schiff bases and transition metal – Schiff base complexes are important intermediates in certain biologic processes, such as non-enzymatically controlled transamination reactions (1). In these reactions amino acids lend their amino group for Schiff base formation whereas the carbonyl group can be provided by a host of carbonyl compounds, such as pyridoxal compounds, aldoses, and certain hormones, occurring naturally in biological systems. The chemistry and the biochemistry of Schiff bases and transition metal – Schiff base complexes derived from amino acids and pyridoxal compounds, and some other carbonyl compounds that do not occur in biological systems, have been extensively studied (2, 3). Although they occur abundantly in biological systems, no attempt has been made to study the possibility of Schiff base formation in vitro utilizing the carbonyl group of aldoses. However, Horecker *et al.* (see refs. 4–6 in ref. 4) suggest Schiff base formation, in vivo, between an aldose and a terminal amino group associated with an amino acid of an enzyme. In the present work we prepared and characterized some copper(II) – Schiff base complexes in which the Schiff bases were derived from anthranilic acid and naturally occurring sugars.

Since the claim (5) of enhanced anti-inflammatory (AI) activity of Cu(II) complexes of AI drugs, a variety of Cu(II) complexes of both non-AI and AI drugs have been prepared and studied for their AI activity (6–10). The present work includes a study of the effect of the complexes under investigation on kaolin paw oedema in rat. Taking into consideration the possible role of pathogens in rheumatic diseases (11, 12), the antibacterial activity of these complexes is also presented. The combination of the sugar components in these complexes is of significance because sugar containing substances have been used since ancient time for wound treatment (13–15) and in antimicrobial effects (16).

Experimental

Materials

L-Arabinose, D-xylose, D-glucose, and D-galactose were obtained from Sigma Chemical Co. and anthranilic acid and copper acetate dihydrate from E. Merck. The standard strains used for antibacterial activity were *Escherichia coli* (ATCC 25922), *Staphylococcus aureus* (ATCC 25923), and *Pseudomonas aeruginosa* (ATCC 27853).

Preparation of complexes

Anthralinic acid (0.1 mol) and the appropriate sugar (0.1 mol) were mixed together in ethanol (200 mL), and potassium hydroxide (0.1 mol) was added. The mixture was refluxed for 15 min. To the lemon-yellow solution thus obtained a solution of copper acetate dihydrate (0.05 mol in 50 mL ethanol) was added slowly and the reaction mixture was refluxed for a further 15 min. The resulting green precipitate was isolated by filtration, washed with ethanol and ether, and dried under vacuum. The complexes thus obtained are listed in Table 1.

Characterization

Microanalysis was carried out by the usual techniques. Copper was estimated by the Hitachi Z-8000 atomic absorption spectrophotometer. Molecular weights were determined mass spectrometrically. Thermal analysis was carried out on a Netzsch simultaneous thermal analyzer on TGA and DTA modes. Conductivity measurements were carried out using a Wescan 212 conductivity meter in *N*,*N*-dimethylformamide (DMF) at room temperature. Magnetic moments were determined by Gouy's

4. (gal anth)$_2$Cu	3405	1618	1540	1325	720	550	420	340

technique and diamagnetic corrections were calculated from Pascal's constants (17). Infrared spectra were recorded on a Perkin–Elmer 882 IR spectrophotometer using KBr disc and Nujol mull techniques. Electronic absorption spectra were obtained with a Hitachi 220S spectrophotometer using DMF as solvent. Electron paramagnetic resonance (EPR) spectra were recorded in powder and solution (in DMF) form, both at room temperature, on a Jeol JES-FE 1XG machine, in the X-band, operating at a microwave frequency of 9.44 GHz. The g values were determined by use of the Kneubühl approximation (18). The spectra were calibrated using α,α-diphenyl-β-picrylhydrazyl radical (dpph, g = 2.0036) as a field marker.

Anti-inflammatory activity

Kaolin paw oedema was induced, according to a reported method (19), in male Wistar rats (90–100 g) in groups of five. The Cu(II) complexes under investigation were administered orally in 5% Mulgophen (GAF Co. Manchester) in distilled water (0.2 mL/100 g body weight) 1 h before the kaolin. The rats were dosed on a weight of drug (mg) per body weight (kg) of animal basis. Oedema was evaluated 4 h after the subplantar administration of kaolin in 0.9% w/v sodium chloride solution. Inhibition of oedema was evaluated by comparing the swelling obtained in treated animals with the controls, and was expressed as percentage inhibition. The statistical significance was evaluated by using the Student t-test.

Antibacterial activity

The antibacterial activity against the standard strains of *E. coli*, *S. aureus*, and *P. aeruginosa* of the complexes was determined using the plate method (20). The inhibitory zones were measured in mm.

Results and discussion

Characterization

Microanalytical data (Table 1) agree with a ML_2 composition of the complexes, where M = Cu(II) and L = the Schiff base ligand. Thermal analysis indicated the absence of any lattice or coordinated water. The molecular weights as determined mass spectrometrically also confirm the ML_2 composition. The infrared (IR) spectra of the complexes contained all the bands due to the ligands with additional bands indicative of the coordination of the ligands with copper through N and O. Some important bands along with their assignments are listed in Table 2. The assignments were made by comparison with related Schiff base complexes (21). It is seen that ν(C=N) frequencies are slightly higher due to coordination and lie in the 1610–1620 cm^{-1} range, which is in agreement with the literature values for such compounds (22). The C=N coordination was confirmed by the appearance of a new ν(M—N) mode around 420 cm^{-1}. In the complexes the ν(CO_2) were observed to be on the lower side as a result of coordination of the carboxylate ion.

Imine formation occurred when a sugar and anthranilic acid were mixed, and was indicated by a yellowing of the solution and development of an absorption band with a maximum at about 400 nm (23). The Schiff base ligands could not be isolated due to their instability. It is known that, normally, the Schiff bases obtained from aliphatic carbonyl compounds hydrolyze readily and are, therefore, not very stable; however, they can be isolated as metal chelates. On addition of the metal salt the yellow color was replaced by

a green color and complexation occurred. The electronic absorption maxima of the complexes under investigation are listed in Table 3. The representative spectrum of (arab anth)$_2$Cu is reproduced in Fig. 1. The intense band at 280 nm was assigned to a phenyl ring π–π* transition (24). The bands in the 329–370 nm range, by analogy with (Sal)(−)pn–Zn (25), were attributed to a π–π* transition originating in the -CH=N- chromophore, while the lower energy bands were due to *d–d* transitions. The electronic spectra of Cu(II) complexes are generally poor indicators of geometry. However, the values of extinction coefficient and position of the absorption bands of the Cu(II) complexes under investigation are consistent with a distorted square-planar environment (26).

The magnetic moments of the complexes (Table 4) are normal values as expected for mononuclear Cu(II) complexes. From the microanalytical and the spectroscopic data all the complexes reported in this work appear to be four-coordinate. The coordinating groups as indicated by the IR spectra are C=N and -COO^- present in the Schiff base ligands. Lower molar concentration values (15.23–17.19 ohm^{-1} mol^{-1} cm^2) were indicative of the nonelectrolytic nature of the complexes. Neutral four-coordinate Cu(II) complexes with chelating agents are usually planar.

The polycrystalline and solution EPR spectra of the (arab anth)$_2$Cu are shown in Fig. 2. The spectra produced by other complexes were similar and hence are not shown. There was general correspondence between the powder and solution spectra, however; the $g_\parallel$ region was well resolved in solution. The spectra exhibited rhombic distortion from axial symmetry in the square-planar geometry because of two different kinds of atoms (O and N) coordinating directly to the metal ion. The spectra were characteristic of magnetically dilute systems with Cu(II) ions in the $d_{x^2-y^2}$ ground state ($g_\parallel > g_\perp > g_e$ (Table 5)). Hyperfines due to nitrogen ($I = 1$)

are visible on the main absorption line, $g_\perp$ (Fig. 2), confirming the coordination through N.

Sugars usually exhibit hemiacetal structure in solution, which results from cyclization of the carbonyl group. Apparently there is no free carbonyl group available. From the results obtained it appears that the hemiacetal linkage of the reducing sugars is labile and the carbonyl group becomes available for formation of the Schiff base. This phenomenon is not unusual as the reactivity of the carbonyl group in cyclic or acyclic form (which are in equilibrium) has been demonstrated in some other reactions as well (27). We have included two hexsoses and two pentoses in the preparation of the ligands because the hexsoses are by far the most abundant, while the pentoses are important components of nucleic acids and various polysaccharides.

The present study clearly indicates that the ligands form stable coordinate complexes with Cu(II) as evidenced by microanalytical, magnetic, and spectroscopic data. Unsuccessful attempts to isolate crystals suitable for X-ray studies prevented further structure elucidation. The structures of the complexes under investigation, proposed on the basis of the above experimental evidence, are shown in Fig. 3.

Anti-inflammatory activity

All of the complexes inhibited kaolin paw oedema (Table 6). They were found to be equipotent at the dose tested. The toxicity data (LD_{50}, Table 6) indicate that these compounds can become potential AI drugs because they possess comparable AI activity to that of Cu(II)-aspirinate and far less toxicity (ca. $LD_{50} = 760 \pm 100$ for Cu(II)-aspirinate (5). The low toxicity of these complexes can be attributed to greater biocompatibility of the Schiff base ligands and also to the presence of sugar as one of the components in the complexes.

Antibacterial activity

All the complexes under investigation were found to be active against the strains tested. The observed antibacterial activity of the complexes is of interest and supports the speculated role of pathogens in inflammatory processes, as previously indicated by the antibacterial activity of a variety of AI drugs including Cu(II) complexes (12).

Ryanoids and related compounds. A total synthesis of 3-epiryanodine

LUC RUEST[1] AND PIERRE DESLONGCHAMPS

Laboratoire de synthèse organique, Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Received November 24, 1992

LUC RUEST and PIERRE DESLONGCHAMPS. Can. J. Chem. **71**, 634 (1993).

In the course of a preliminary investigation on the relationships between chemical structure of ryanoids and their affinity to the ryanodine (**1**) binding site, we have synthesized 3-epiryanodine (**13**) from anhydroryanodol (**4**), a key intermediate in our total synthesis of (+)-ryanodol (**2**).

LUC RUEST et PIERRE DESLONGCHAMPS. Can. J. Chem. **71**, 634 (1993).

Dans le cadre d'une étude préliminaire des relations structures chimiques – activité biologique des ryanoïdes et de leur affinité au site récepteur de la ryanodine (**1**), nous avons synthétisé la 3-épiryanodine (**13**) à partir de l'anhydroryanodol (**4**), un intermédiaire-clé de la synthèse totale du (+)-ryanodol (**2**).

Introduction

Ryanodine (**1**), a natural product isolated from *Ryania speciosa Vahl* (1), is the ester of α-pyrrole carboxylic acid and the complex diterpene (+)-ryanodol (**2**). It is an interesting and important calcium release channel modulator in mammalian muscle (2). Its chemical structure was elucidated several decades ago by Wiesner and co-workers (3). We completed a total synthesis of (+)-ryanodol (**2**) in 1979 (4) and have published a detailed report on that work (5–8).

Recently, we began to investigate the influence of chemical modifications of the ryanodine substituents on the biological activity (affinity to the [^{3}H]-ryanodine binding site) in a search to identify the structural features that are necessary to maintain biological activity. Several natural ryanoids isolated from the plant by us (9, 10) and others (11–16) have thus been examined (10, 17), as well as some of their derivatives (10, 12). In the course of this work we also carried out some chemical modifications on anhydroryanodine (**3**) and anhydroryanodol (**4**) obtained from natural source (3), which led to the synthesis of 3-epiryanodine (**13**). We wish now to report this work.

Results and discussion

It was shown earlier (12) that anhydroryanodine (**3**), easily obtained by dehydration of ryanodine (**1**) (3) (see Scheme 1) has a low affinity to the ryanodine binding site. To measure the importance of the hemiketalic hydroxyl at C15 for the affinity, we thought that the simple reduction of the lactone moiety of anhydroryanodine (**3**) to a hemiketal (see **5**) could afford an answer to the problem, especially if this modification results in a retrieved affinity.

Unfortunately, using the usual reducing agents, we were not successful in reducing the lactone moiety specifically. We noted, nevertheless, that treatment of either anhydroryanodine (**3**) (Scheme 1) or anhydroryanodol (**4**) with lithium in ammonia led to olefin **7** in moderate yields. A similar reductive cyclization had been previously used to synthesize ryanodol from 1,2-epoxyanhydroryanodol (**8**) (8) (Scheme 1). Formation of olefin **7** can formally be explained as follows: under treatment with lithium in ammonia, the lactone carbonyl group of either **3** or **4** would be reduced to the dianion **6** (X = OPyr or OH) (or a radical anion) making C15 nucleophilic enough to perform a transannular S_N2' displacement of the allylic substituent X at position 3, i.e., α-pyrrole carboxylate for anhydroryanodine (**3**) or simple hydroxyl group for anhydroryanodol (**4**). Analogous intramolecular cyclization by S_N' cleavage of allylic ether by enolate anion has recently been reported by Paquette and Schreiber (18, 19).

Introducing a double bond in ring A provided a possible entry to chemical modifications in that ring. Epoxidation of the C2—C3 double bond of olefin **7** (Scheme 2) with an excess of reagent led directly to epoxylactone **11** formed successively through the acid-catalyzed opening of unstable β-epoxide **9** to give, first, 3-epianhydroryanodol (**10**), followed by epoxidation of the newly formed 1,2-double bond to yield epoxide **11** bearing a β-hydroxyl group at position 3.

The reducing conditions previously discussed (Li/NH_3) (*vide supra*) were then applied to epoxide **11** and 3-epiryanodol (**12**) was obtained in good yield. This compound showed significant differences in its NMR data compared to ryanodol (**2**), especially noticeable upfield shifts for the HC3 (+0.34 ppm) and the H_AC14 (+0.53 ppm) signals, in concordance with their new magnetic environment. In addition, the structure of compound **12** was confirmed by monocrystal X-ray diffraction analysis (20) (Fig. 1).

Esterification of 3-epiryanodol (**12**) with α-pyrrole carboxylic acid following a known procedure (21) led to 3-epiryanodine (**13**) in good yield. This new 3-epimer of ryanodine was shown to have ~0.01 the affinity of ryanodine.[2] We reported earlier (8) our fruitless efforts to esterify ryanodol (**2**) to ryanodine (**1**): in the conditions just described, ryanodol (**2**) gave a modest yield of 10-O-α-pyrrolecarbonylryanodol (**14**). This compound, surprisingly, showed an interesting affinity to the binding site of ryanodine. The details of this preliminary observation will soon appear elsewhere.[2]

Conclusion

We have achieved a total synthesis of 3-epiryanodine (**13**) starting from anhydroryanodol (**4**). The global "epimerization" at position 3 was performed through transannular reactions typical of the ryanoid skeleton.

SCHEME 1

Experimental

Apparatus, materials, and methods

Melting points were determined on a Reichert hot stage apparatus and are uncorrected. Tetrahydrofuran was dried by distilling over sodium benzophenone ketyl. Dichloromethane, ethylene dichloride, and acetonitrile used for reactions were distilled over calcium hydride. All reactions were performed under nitrogen atmosphere. Analytical and preparative thin-layer chromatography were carried out on glass plates precoated with silica gel 60F-250 (Merck). Column chromatography was performed with Merck (200–400 mesh) silica gel. The infrared spectra (ir) were taken on a Perkin–Elmer 681 spectrophotometer. The ^1H nmr spectra were recorded on a Bruker WM-250 instrument (with CHD_2OD as internal standard centered at 3.30 ppm). The following abbreviations have been used: s, singlet; d, doublet; dd, doublet of doublets; t, triplet; m, multiplet; br, broad. Mass spectra and peak matching (Exact Mass) were recorded on a VG Micromass ZAB-2F spectrometer.

2,3-Dideoxy-2,3-didehydroryanodol (7)

(a) From anhydroryanodol (4) (Method A)

A solution of anhydroryanodol (**4**) (77 mg, 0.202 mmol) in anhydrous tetrahydrofuran (THF) (3 mL) was transferred to a cold (−78°C) blue mixture of lithium (~8 mg, 2.67 mmol) in ammonia (10 mL). The mixture was stirred for 1.5 h, then treated with solid ammonium chloride (~100 mg). The cold bath was removed and ammonia was allowed to escape with a nitrogen stream while raising the temperature to ~25°C. The mixture was then dissolved in water, neutralized (HCl, 1 N), and extracted with ethyl acetate. The crude product was purified by flash chromatography ($CHCl_3$:CH_3OH; 2–10%) to give olefin **7** (55 mg, 75%) together

with some starting material **4** (10 mg, 13%); mp 220–223°C (ether); ir (KBr, ν cm^{-1}): 3600–3350 (br); ^1H nmr (CD_3OD, δ ppm): 5.18 (1H, d, 1.3 Hz, HC3), 3.77 (1H, d, 10.2 Hz, HC10), 2.28 (1H, m, HC13), 2.20 (1H, m, HC9), 1.82 (1H, m), 1.80 (1H, d, 12.8 Hz, H_AC14), 1.70 (1H, d, 12.8 Hz, H_BC14), 1.50 (1H, m), 1.27 (2H, m), 1.15 (3H, s, CH_3C1), 1.09 (3H, d, 6.8 Hz, CH_3C9), 1.06 (3H, d, 6.8 Hz, CH_3C13), 1.00 (3H, d, 6.5 Hz, CH_3C13), 0.88 (3H, s, CH_3C5). Exact Mass calcd. for $C_{20}H_{30}O_6$: 366.2042 (M^+); found: 366.2035.

(b) From anhydroryanodine (3)

A solution of anhydroryanodine (**3**) (25 mg, 0.053 mmol) in dry THF (3 mL) was transferred into a cold (−78°C), blue mixture of lithium (~20 mg, large excess) in ammonia (~10 mL). The reaction mixture was quenched after 20 min by the addition of ammonium chloride. Extraction was performed as described above to furnish a colored crude product that was chromatographed to give olefin (**7**) (6 mg, 31%) and anhydroryanodol (**4**) (9 mg, 45%).

Epoxydation of olefin 7

A freshly prepared solution of trifluoroperacetic acid (0.9 M in $(CH_2Cl)_2$, 400 μL, 0.360 mM) was added to a cold solution (0°C) of olefin **7** (40 mg, 0.109 mmol) in a mixture of 1,2-dichloroethane (8 mL) and acetonitrile (2 mL) containing a suspension of $NaHCO_3$(120 mg). After 6 h of stirring at room temperature, the mixture was poured into a dilute solution of sodium thiosulfate (0.5 M) and extracted with ethyl acetate. Flash chromatography of the crude product ($CHCl_3$:CH_3OH; 2–10%) yielded crystalline 1,2-epoxy-3-epianhydroryanodol (**11**) (28 mg, 65%); mp 230–232°C (ether); ir ($CHCl_3$, ν cm^{-1}): 3600, 3420 (br), 1744, 1252; ^1H nmr (CD_3OD, δ ppm): 4.41 (1H, s, HC3), 4.04 (1H, d, 10.3 Hz, HC10), 2.74 (1H, d, 20.2 Hz, H_AC14), 2.63 (1H, d, 20.2 Hz, H_BC14), 1.68 (2H, m, HC9 and HC13), 1.55 (3H, s, CH_3C1), 1.6–1.45 (4H, m), 1.16 (3H, d, 7.0 Hz), 1.06 (3H, d, 6.3 Hz), 1.04 (3H, d, 7.0 Hz), 0.92 (3H, s, CH_3C5). Exact Mass calcd. for $C_{20}H_{30}O_8$ (M^+): 398.1941; found: 398.1936.

3-Epiryanodol (12) from epoxide 11

A solution of 1,2-epoxy-3-epianhydroryanodol (**11**) (33 mg, 0.083 mmol) in THF (2 mL) was transferred to a cold (−78°C), stirred, blue solution of lithium (15 mg) in ammonia (~10 mL). After 20 min, work-up procedure was done as described previously for the preparation of olefin **7** (Method A) (*vide supra*). Flash chromatography of the crude product (28 mg) ($CHCl_3$:CH_3OH, 9:1) gave crystalline material (27 mg, 81%) that was recrystallized (CH_2Cl_2–CH_3OH) to beautiful tetrahedral crystals suitable for monocrystal X-ray diffraction analysis; mp 310°C (dec.); ^1H nmr (CD_3OD, δ ppm): 3.80 (1H, d, 10.2 Hz, HC10), 3.74 (1H, s, HC3), 2.10 (1H, m, HC9), 2.05 (1H, m, HC13), 1.87 (1H, d, 14.0 Hz, H_AC14), 1.85 (1H, m), 1.66 (1H, d, 14.0 Hz, H_BC14), 1.52 (2H, m), 1.33 (3H, s, CH_3C1), 1.27 (1H, m), 1.04 (3H, d, 6.6 Hz, CH_3C13), 1.00 (3H, d, 6.4 Hz, CH_3C9), 0.97 (3H, d, 6.8 Hz, CH_3C13), 0.89 (3H, s, CH_3C5). Exact Mass calcd. for $C_{20}H_{32}O_8$ (M^+): 400.2097; found: 400.2102.

3-Epiryanodine (13)

To a solution of 3-epiryanodol (**12**) (18 mg, 0.045 mmol) in THF (3 mL) and dichloromethane (2 mL) was successively added α-pyrrole carboxylic acid (10 mg, 0.090 mmol), dimethylaminopyridine (DMAP) (2 mg), and a solution of dicyclohexylcarbodiimide (DCC) (18 mg, 0.09 mmol) in dichloromethane (1 mL). The mixture was stirred at room temperature for 60 h, then poured into aqueous sodium bicarbonate and extracted with ethyl acetate. The crude product was purified by thin-layer chromatography ($CHCl_3$:CH_3OH, 9:1) to yield 3-epiryanodine (**13**) (14 mg, 63%) together with unreacted starting material **12** (6 mg, 33%): mp 228–230°C (CH_2Cl_2–CH_3OH); ^1H nmr (CD_3OD, δ ppm): 6.98 (2H, m) and 6.21 (1H, dd, 3.6 and 2.6 Hz) (pyrrole ring hydrogens), 5.25 (1H, s, HC3), 3.78 (1H, d, 10.2 Hz, HC10), 2.05 (2H, m, HC9 and HC13), 1.96 (1H, d, 14.2 Hz, H_AC14), 1.82 (1H, d, 14.2 Hz, H_BC14), 1.81 (1H, m), 1.52 (2H, m), 1.40 (3H, s, CH_3C1), 1.27 (1H, m), 1.05 (3H, d, 6.6 Hz, CH_3C13), 1.03 (3H, s, CH_3C5), 1.00 (3H, d, 6.5 Hz, CH_3C9), 0.84 (3H, d, 6.8 Hz, CH_3C13). Exact Mass calcd. for $C_{25}H_{35}O_9N$ (M^+): 493.2312; found: 493.2297.

10-O-α-Pyrrolecarbonylryanodol (14)

In similar conditions just described (*vide supra*) for the esterification of 3-epiryanodol (**12**), a solution of ryanodol (**2**) (157 mg, 0.392 mmol) in THF (15 mL) and dichloromethane (5 mL) was treated with α-pyrrole carboxylic acid (157 mg, 1.414 mmol), dicyclohexylcarbodiimide (300 mg, 1.46 mmol), and DMAP (3 mg). After 24 h, the mixture was extracted and the crude product was purified by flash chromatography to give 10-*O*-α-pyrrolecarbonyl ryanodol (**14**) (36 mg, 18%) together with unreacted ryanodol (**2**) (110 mg, 70%); mp 187–189°C (CH_2Cl_2–CH_3OH); ^1H nmr (CD_3OD, δ ppm): 6.95, 6.90, and 6.18 (3 dd of 1H each for pyrrole hydrogens), 5.41 (1H, d, 10.4 Hz, HC10), 4.06 (1H, s, HC3), 2.56 (1H, d, 13.2 Hz, H_AC14), 2.15 (2H, m, HC13 and HC9), 1.78 (1H, d, 13.2 Hz, H_BC14), 1.62 (1H, m), 1.35 (2H, m), 1.24 (3H, s, CH_3C1), 1.13 (3H, s, CH_3C5), 1.08 (1H, m), 1.04 (3H, d, 6.8 Hz, CH_3C9), 0.95 (3H, d, 6.4 Hz, CH_3C13), 0.85 (3H, d, 6.5 Hz, CH_3C13). Exact Mass calcd. for $C_{25}H_{33}O_8N$ ($M^+ - H_2O$): 475.2206; found: 475.2201.

^{1}H nuclear magnetic resonance and molecular orbital studies of the internal rotational potential and electron delocalization in triphenylphosphine

TED SCHAEFER,[1] RUDY SEBASTIAN, AND FRANK E. HRUSKA
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received September 15, 1992

TED SCHAEFER, RUDY SEBASTIAN, and FRANK E. HRUSKA. Can. J. Chem. **71**, 639 (1993).

The ^{1}H nuclear magnetic resonance spectral parameters are reported for triphenylphosphine as solutions in CS_2/C_6D_{12} and acetone-d_6 at 300 K. The internal rotational potential opposing torsion about the P—C bond is computed by AM1 and STO-3G MO methods. The computed potentials are used to calculate the average shielding of the *para* protons caused by the diamagnetic anisotropies of the neighbouring phenyl groups. The results are used to estimate the degree of electron delocalization from the lone pair on phosphorus. The extent of delocalization depends on the internal motions and comparisons are made with phenylphosphine. The maximum possible screening of the *para* protons in phenylphosphine is calculated as 0.19 ppm for a conformation in which the lone pair on phosphorus is oriented perpendicular to the aromatic plane. The intramolecular rotational potentials then yield 0.02_9 ppm as the shielding of the *para* protons in triphenylphosphine due to electron delocalization, just as found for the CS_2/C_6D_{12} solution after correction for diamagnetic anisotropy fields.

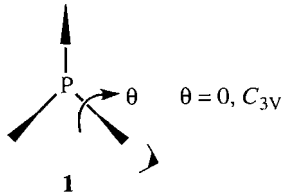
TED SCHAEFER, RUDY SEBASTIAN et FRANK E. HRUSKA. Can. J. Chem. **71**, 639 (1993).

On a déterminé les paramètres des spectres de résonance magnétique nucléaire du ^{1}H déterminés à 300 K pour des solutions de triphénylphosphine dans du CS_2/C_6D_{12} ou de l'acétone-d_6. Faisant appel à des méthodes AM1 et STO-3G, on a calculé le potentiel de la rotation interne qui s'oppose à la torsion autour de la liaison P—C. On a utilisé les potentiels ainsi évalués pour calculer le blindage moyen des protons en *para* provoqué par les anisotropies diamagnétiques des groupes phényles avoisinants. On utilise les résultats pour évaluer le degré de délocalisation électronique de la paire libre du phosphore. Le degré de délocalisation dépend des mouvements internes et on fait des comparaisons avec la phénylphosphine. On a évalué que le maximum de blindage des protons *para* de la phénylphosphine est égal à 0,19 ppm pour une conformation dans laquelle la paire d'électrons libres sur le phosphore est orientée perpendiculairement par rapport au plan du noyau aromatique. À cause de la délocalisation électronique, les potentiels de la rotation intramoléculaire ajoutent alors $0,02_9$ ppm au blindage des protons *para* de la triphénylphosphine, comme on l'a observé pour la solution dans le CS_2/C_6D_{12}, après correction pour les champs d'anisotropie diamagnétique.

[Traduit par la rédaction]

Introduction

Although triphenylphosphine (TPP) has been studied by a variety of physical techniques, the torsion about the P—C bonds has not been characterized. The dipole moment is insensitive to this torsion and also, apparently, to a large variation in the CPC angle (1). In the crystal the torsion angles about the three P—C bonds are unequal (2), probably best discussed as follows. With reference to **1**, it is convenient



1

to define the torsion angle, θ, as zero for this conformation in which the C_3 axis lies in the phenyl planes. The other conformation of C_{3V} symmetry has θ as 90°. Intermediate chiral conformers with three equal θ values have C_3 symmetry. The conformer present in the crystal displays torsion angles of about 22°, 25°, and 54°, deviation from C_3 symmetry perhaps attributable to intermolecular forces (2).

However, the ^{31}P chemical shift tensor is axially symmetric in the solid, consistent with a large amplitude of motion of the phenyl groups about the P—C bonds (3); the inversion barrier is computed as 147 kJ/mol (4) and so inversional motions can be neglected at ambient temperatures. A large torsional amplitude implies a low barrier to rotation about the P—C bonds, consistent with ease of distortion of the molecular symmetry by packing forces in the crystal. Also implied is slight conjugation of the lone pair on phosphorus with the π electron system of the phenyl groups, consistent with P—C bond lengths of 1.83 Å, differing by only about 0.01 Å from the slightly longer P—C lengths in $P(CH_3)_3$ (2). A low degree of p...π conjugation in TPP is also indicated by its photoelectron spectrum (5), there being little apparent perturbation by the phosphorus atom of the π orbital energies of the phenyl groups.

The chemical shift of the *para* ^{13}C nucleus (C-4) is essentially the same as that in benzene (6), again consistent (7) with the absence of p–π conjugation in TPP. By way of contrast, the *para* proton (H-4) is relatively strongly shielded for solutions of TPP in benzene-d_6. δ_4 is 7.042 for a 55% w/w solution (8) and 6.926 for a 12% w/v solution (9), both at 305 K, whereas we measure δ_H as 7.153 for a 3 mol% solution of benzene in benzene-d_6 at 300 K. Of course, the benzene molecule is diamagnetically highly anisotropic and, on average, will pack about the phenyl groups of TPP so as to shield H-4; for example, a global minimum energy of −10 kJ/mol is computed for a T-arrangement of two benzene molecules, a C—H bond of one molecule lying along the C_6 axis of the other (10–12). Hence the intrinsic chemical shift of H-4 is unknown. Indeed, benzene solutions of TPP were used in the ^{1}H nmr studies because the solvent molecules, via their magnetic anisotropy, dispersed the proton shifts sufficiently to allow an analysis of the nmr spectrum.

Returning to the conformational properties of TPP, both C_{3v} conformations are unstable because they entail large repulsions between the *ortho* hydrogen atoms of neighboring rings, which approach each other to within less than 1 Å in such conformations. Neither conformation will represent a global minimum in the torsional potential, written as a function of θ, even though a θ of 90° allows the maximum p...π interaction (the lone-pair orbital is roughly sp^2 hybridized, there being no direct relationship between the CPC bond angle and the hybridization state in such a description (13, 14)). Hence a collection of TPP molecules will represent, at a given instant, a mixture of nonchiral (C_{3v}) and chiral conformations, only some of the latter being characterized by three equal θ values (finite temperature). On average, however, as measured in solution by most physical methods, the conformation of TPP can be described in terms of a potential function hindering rotation about the P—C bond, having a minimum at $0° < \theta < 90°$. An approximation to this minimum is available from birefringence measurements on TPP in a benzene solution at 298 K, giving a value of 59 ± 4° (15). This number is at best a value of arc sin $\sqrt{\sin^2\theta}$ and, of course, does not define the depth of the minimum. It does raise the question as to which of the angles in the crystal are distorted by packing forces. The need for a potential was noted in a discussion of ^{13}C and ^{31}P spin-lattice relaxation times measured as a function of temperature for TPP in $CDCl_3$ solution (16). In its absence it could only be concluded that internal rotation was rather faster than rotation of the whole molecule. The latter rotation, treated as an activated process, was hindered by some 15 kJ/mol (16). While molecular mechanics calculations of the molecular geometry and the dipole moment of TPP agree well with experiment, the internal barrier has not been calculated, although such calculations yield good results for alkylphosphines (17).

The aim of the present work is threefold: first, to find the chemical shifts of the ring protons of TPP in nonpolar and polar solvents; second, to compute the potential hindering torsion of the phenyl groups; and, third, to use this potential to calculate the average shift of H-4 due to the magnetic anisotropies of the neighbouring rings. The chemical shift of H-4, corrected for the anisotropic fields and compared to the ^1H shielding of benzene in the same solvents, provides a measure of electron density at the *para* site or, at least, of p...π conjugation, in the manner usually employed (7, 18, 19) in such discussions.

Experimental

Dilute solutions of triphenylphosphine in CS_2/C_6D_{12}/TMS and acetone-d_6TMS solvent mixtures (see Table 1 for details) were filtered into 5-mm o.d. nmr sample tubes. The tubes were degassed by five cycles of the freeze–pump–thaw procedure and then flame-sealed to give symmetrical tops. The ^1H nmr free induction decays were acquired at a probe temperature of 300 K on a Bruker AM 300 spectrometer. Shimming of the magnetic field utilized the TMS response signal. Our standard procedures (20) yielded spectra in which line widths at half height were approximately 0.06 Hz, allowing the resolution of many peaks for this tightly coupled spin system.

Molecular orbital computations with the GAUSSIAN 86 algorithms (21) utilized geometry optimization procedures in the sense that the phenyl groups were constrained to be planar while all other bond angles and lengths were allowed to vary. With reference to **1**, the angle θ was increased in steps of 15° between 0 and 90° and, during the SCF cycles, the other phenyl groups were allowed to rotate. Because of the size of TPP, the computations included only the semiempirical AM1 procedure (22) and the ab initio STO-3G basis (23).

TABLE 1. The ^1H nmr spectral parameters for triphenylphosphine in CS_2/C_6D_{12} and $(CD_3)_2C{=}O$ solutions at 300 K

[d]Numbers in parentheses are standard deviations in the NUMARIT analyses.

Results and discussion

Spectral analyses

The analyses of the ^1H nmr spectra of TPP were aided by the knowledge of reasonably precise coupling constants for the spectra in benzene solutions (8, 9). The program NUMARIT (24), greatly modified by R. Sebastian, yielded the spectral parameters in Table 1. The relatively large standard deviations of some of the coupling constants, as large as 0.007 Hz for $^4J_{26}$ in CS_2/C_6D_{12}, are a consequence of the very small dispersion of the chemical shifts; the shift range is only 1.7 Hz for the nonpolar solution. The analyses are reliable, in our opinion. Thus, the iterated spectrum in acetone-d_6 solution has 156 transitions, some of which overlap, giving rise to 112 peaks; some are of very low intensity. The experimental spectrum has 94 "non-noise" peaks (significant intensities); of these, 91 were assigned, some to multiple transitions, giving rise to 120 assignments. If the total calculated intensity of the spectrum is 160.0, then the assigned intensity is 146.4, that is, over 91% of the intensity is assigned. The experimental and simulated spectra are congruent. Similar remarks apply to the analysis for the CS_2/C_6D_{12} solution.

The torsional potential

The θ dependence of the computed energies of TPP is presented in Table 2. The relative energies can be fitted to a series in $\sin^2(n\theta)$, resulting in eqs. [1] and [2] for the STO-3G

$$[1]\quad V(\theta)/\text{kJ mol}^{-1} = 1.18\sin^2\theta - 2.71\sin^2 2\theta + 0.18\sin^2 3\theta - 0.58\sin^2 4\theta$$

TABLE 2. Relative AM1 and STO-3G MO energies for P—C rotation in triphenylphosphine

Torsion angle/deg	Relative Energy/kJ mol^{-1}					
	AM1	φ_1	φ_2	STO-3G	φ_1	φ_2
0	0.00	54.8	35.1	0.00	63.7	43.6
15	−1.85	33.5	31.6	−1.13	57.1	45.6
28.3_6[a]	−2.58	28.3_6	28.3_6	—	—	—
30	−2.56	28.3	28.3	−1.87	48.6	46.6
42.5_0[a]	—	—	—	−2.06[b]	42.5_0	42.5_0
45	−1.81	26.8	24.6	−2.05	42.0	40.9
60	−0.79	26.0	23.0	−1.64	35.5	33.5
75	−0.42	27.2	24.2	0.19_5	27.4	15.9
90	0.25	22.3	25.5	1.22	4.5	−16.1

[a]At these values of θ, the other two torsion angles also have this value in the respective calculation. At other θ values, the torsion angles for the other phenyl groups, φ_1 and φ_2, are not equal to θ, naturally.
[b]The total energy is −1018.903 601 au.

[2] $V(\theta)/\text{kJ mol}^{-1} = 1.46 \sin^2\theta - 1.68 \sin^2 2\theta - 1.12 \sin^2 3\theta - 0.77 \sin^2 4\theta - 0.31 \sin^2 6\theta$

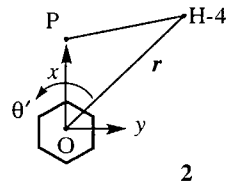
and AM1 data, respectively; the standard error of fit is 0.08 and 0.05 kJ/mol, respectively. The dominant term is the fourfold component[2] in $\sin^2 2\theta$.

The minima occur at 42.5° (STO-3G) and 28.4° (AM1) where all three torsion angles are equal (C_3 symmetry) but, at 300 K, the average values of θ are 42.0° (STO-3G) and 40.3° (AM1), suggesting perhaps that all of the angles in the crystal (see above) are significantly affected by the packing forces. The computed potentials indicate the ease with which the torsion angles can change. The AM1 energy for the conformation in the crystal is about 1.5 kJ/mol higher than that at the minimum.

Which of the two potentials is more realistic is difficult to assess. The STO-3G geometry near phosphorus for the conformation of lowest energy (Table 2) has the P—C length as 1.839 (1.828 ± 0.005) Å, the CPC angle as 101.2°(103.0 ± 0.2), and the two PCC angles as 124.9°(124.0 ± 0.4) and 117.3°(116.1 ± 0.4), the crystal (2) values being given in parentheses. The AM1 geometry is characterized by 1.751 Å, 103.2°, 124.7°, and 115.4° for these parameters. The rather short P—C length found by the semiempirical algorithm is its only apparent drawback. However, both potentials yield very similar averages in the computations below, no doubt because of their relatively shallow nature compared to thermal energies. Only if the intermolecular forces in solution were to alter the potentials dramatically, would these averages be altered significantly.

The magnetic anisotropy model

Computation of the anisotropic magnetic fields at H-2 or H-3 as a function of the internal rotational potentials is difficult because it depends on the torsional motion of the phenyl group carrying H-2 and H-3 as well as on the torsion of the group giving rise to the magnetic field. We have not solved this problem. However, the distance from H-4 to the centre of a neighbouring phenyl group is independent of the torsions about the P—c bonds. The average anisotropic field at H-4 from another phenyl group, given an internal rotational potential, is easily calculated as follows. It is convenient to define a coordinate system indicated by **2**. The origin, O, lies at the centre of the neighbouring phenyl group. The *z*-axis, the principal axis in the treatment of the neighbour anisotropic effect (25–27), is perpendicular to the page in **2** and the vector *r* lies in the plane of this phenyl group when θ′ is zero. Given that the diamagnetic anisotropy of the



P-O, 3.2_2 Å
P-H4, 5.6_9 Å
∠CPC, 103°

2

phenyl group, $\Delta\chi = \chi_{11} - \chi_1$, is negative, and that the δ scale increases as the shielding decreases, one has eq. [3].

[3] $\Delta\delta_4 = -\Delta\chi(1 - 3\cos^2\phi)/3r^3$

Here φ is the angle between ***r*** and the *z* axis. A straightforward analysis then yields eq. [4],

[4] $\cos\phi = 0.77_6 \sin\theta'$

the coefficient depending on the angles and lengths given for **1**, as obtained from the crystal structure (2).

The calibration of eq. [3] depends on the anisotropic shift of the protons in benzene, most often taken as 1.50 ppm (27). For TPP it follows that $\Delta\delta_4 = 0.043\ \langle 1 - 3\cos^2\phi\rangle$, angular brackets indicating the expectation value determined by the torsional potential and the temperature.

The computations of the torsional potential, however, employed a different origin of the rotation angle, θ (see **1** and **2**). A simple projection into a plane perpendicular to the P—C bond demonstrates that the phase shift between θ in **1** and θ′ in **2** is very nearly 60°. Hence, write $\langle\sin^2\theta'\rangle = \langle\sin^2(\theta \pm 60)\rangle$, which, from eqs. [1] and [2], is 0.536 (AM1) and 0.521 (STO-3G) at 300 K. Consequently, eqs. [3] and [4] yield $\Delta\delta_4$ as 0.00_4 (AM1) and 0.00_7 (STO-3G) as the contributions from the magnetic anisotropy of the two neighbouring phenyl groups to the shielding of the *para* proton. The very small

[2]At first sight, the C_3 symmetry at phosphorus (ignoring the phenyl moieties) would suggest a significant threefold component, absent in eqs. [1] and [2]. While it is true that the energies for $0° \le \theta \le 60°$ are fit well by a potential containing threefold and sixfold components, the actual potential repeats at intervals of 180°.

magnitudes are a consequence of geometry and of the theoretical potentials.

Now, we measure δ_H for benzene in CS_2/C_6D_{12} as 7.218 at 300 K, to be compared with the δ_4 in TPP of 7.186. It appears that H-4 is shielded by 0.02_8 ppm due to electron delocalization from phosphorus. By way of comparison, δ_4 of phenylphosphine in C_6D_{12} is 7.078 (28) and δ_H of C_6H_6 in C_6D_{12} is 7.211, implying a $\Delta\delta_4$ of −0.133, presumably again due to p...π conjugation. The degree of conjugation depends on $\langle\sin^2\theta\rangle$, θ being the angle between the lone-pair direction and the phenyl plane.

Geometry-optimized computations give the internal barrier to rotation in phenylphosphine as eqs. [5] and [6].

[5] $V/\text{kJ mol}^{-1} = -4.72\sin^2\theta - 0.56\sin^2 2\theta + 0.04\sin^3 3\theta$ (STO-3G, standard error of 0.01 kJ/mol)

[6] $V/\text{kJ mol}^{-1} = -0.61\sin^2\theta - 0.42\sin^2 2\theta - 0.06\sin^2 3\theta$ (AM1, standard error <<0.01kJ/mol/mol)

It seems that, if the barrier is dominated by the p...π conjugation, then eq. [5] is the more reasonable, possibly because the P—C length is given satisfactorily by the STO-3G basis (see above for TPP), while the AM1 parameterization has this length rather too small.

At 300 K, the potential in eq. [5] yields $\langle\sin^2\theta\rangle$ as 0.70_3, so that the maximum $\Delta\delta_4$ is predicted[3] as $-0.133/0.70_3$ or −0.189. If this $\Delta\delta_4$ is apportioned equally among the three phenyl groups in TPP, then, for the *same* torsion potential as in phenylphosphine, $\Delta\delta_4$ is -0.06_3. But $\langle\sin^2\theta\rangle$ for TPP is 0.46 from eq. [1]. Therefore $\Delta\delta_4$ due to p...π conjugation for TPP is -0.02_9 ($\langle\sin^2\theta\rangle$ from the AM1 potential is 0.43).

This number agrees exactly with the corrected experimental value of -0.02_8 above. The small amount of shielding of H-4 in TPP due to p...π conjugation is therefore a consequence of two factors: the delocalization is shared by three phenyl groups that, due to geometry, are not oriented for optimal conjugation with the lone pair on phosphorus.

Turning to the δ_4 of 7.346 for the acetone-d_6 solution, compare it to the δ_H of 7.352 for benzene in acetone-d_6. The decreased screening of the benzene protons in acetone, relative to CS_2 solution, is understandable as a result of C^-—H^+ ... O=C interactions, the C—H bonds in benzene being polarized in the indicated manner (10–12, 30). The application of the small anisotropy shift computed for TPP above to δ_4 of TPP yields δ_4 equal to δ_H of benzene. In view of the other possible mechanisms possible in a polar solvent it is perhaps surprising at the near equivalence of these shifts. The present discussion ignores electric dipolar fields originating at phosphorus. Although the dipole moment of TPP is 1.40(3) D (1), the electronegativity of phosphorus is close to that of hydrogen. It may be that the dipole components are such that electric dipolar fields are small at the *para* position.

The coupling constants

The coupling parameters in Table 1 agree reasonably well with the earlier values (8, 9), which were necessarily of lower precision. The solvent dependences of ^nJ(H,H) are not peculiar to TPP, being similar to those found in this laboratory for a variety of benzene derivatives. For example, $^4J_{26}$ increases in the polar solvent, whereas $^4J_{24}$ decreases and $^4J_{35}$ is relatively unchanged, a generally applicable statement for monosubstituted benzene derivatives. The solvent dependences of ^nJ(H,P) in Table 1 are reminiscent of those for ^nJ(H,F) in fluorobenzene and its derivatives. For example, ^5J(H,F), while negative in 2-fluorobenzaldehyde (31), increases algebraically in passing from CS_2/C_6D_{12} to acetone-d_6 solution. Parenthetically, we find ^5J(H,P) in a TPP derivative to be negative for the benzene ring carrying the substituent. It is thought (8) that ^nJ(H,P) depends on the orientation of the lone pair relative to the phenyl plane. Hence the numbers in Table 1 imply that the internal motion about the P—C bonds is much the same in the two solvents, in line with the above discussion of the chemical shifts of H-4.

[3] $\Delta\delta_4$ is -0.62_5 for aniline in cyclohexane (19). The internal barrier to rotation about the C—N bond is relatively large, about 21 kJ/mol (29); hence this value of $\Delta\delta_4$ can be compared to the -0.18_9 for phenylphosphine. In other words if, for steric or other reasons, the lone pair on phosphorus is situated in a plane perpendicular to the benzene plane, then the degree of delocalization is about 30% effective relative to the amino group.

High-resolution NMR spectroscopic analysis of the C-polysaccharide of *Streptococcus pneumoniae*[1]

MALGORZATA KULAKOWSKA, JEAN-ROBERT BRISSON, DOUGLAS W. GRIFFITH, N. MARTIN YOUNG, AND HAROLD J. JENNINGS[2]

Institute for Biological Sciences, National Research Council of Canada, Ottawa, Ont. Canada K1A 0R6

Received October 27, 1992

MALGORZATA KULAKOWSKA, JEAN-ROBERT BRISSON, DOUGLAS W. GRIFFITH, N. MARTIN YOUNG, and HAROLD J. JENNINGS. Can. J. Chem. **71**, 644 (1993).

The complete structure of the complex cell-wall C-polysaccharide from *Streptococcus pneumoniae* R36A was elucidated using a combination of high-resolution NMR spectroscopy and theoretical calculations. The C-polysaccharide is composed of the following repeating unit β-D-Glc*p*1→3-α-D-AAT*p*1→4-α-D-Gal*p*NAc1→3-β-D-Gal*p*NAc1→1-ribitol-5-phosphate where AAT is 2-acetamido-4-amino-2,4,6-trideoxygalactopyranoside. The C-polysaccharide contains two phosphorylcholine substituents per repeating unit, which are situated on O-6 of each of the two 2-acetamido-2-deoxygalactopyranose residues. The repeating units are linked through a diphosphate ester from ribitol to O-6 of the β-D-glucopyranosyl residue.

MALGORZATA KULAKOWSKA, JEAN-ROBERT BRISSON, DOUGLAS W. GRIFFITH, N. MARTIN YOUNG et HAROLD J. JENNINGS. Can. J. Chem. **71**, 644 (1993).

Faisant appel à une combinaison de RMN à haute résolution et de calculs théoriques, on a résolu la structure complète du C-polysaccharide complexe de la cellule de la paroi du *Streptococcus pneumoniae* R36A. Le C-polysaccharide est composé de l'unité répétitive suivante : β-D-Glc*p*1-β→3-α-D-AAT*p*1→4-α-D-Gal*p*NAc1→3-β-D-Gal*p*NAc1→1-ribitol-5-phosphate dans laquelle ATT est le 2-acétamido-4-amino-2,4,6-tridésoxygalactopyranoside. Le C-polysaccharide porte deux substituants phosphorylcholines par unité répétitive et elles sont situées sur le O-6 de chacun des deux résidus 2-acétamido-2-désoxygalactopyranose. Les unités répétitives sont liées par un ester diphosphate du ribitol au O-6 du résidu β-D-glucopyranosyle.

Introduction

Streptococcus pneumoniae produce a complex species-specific antigenic polysaccharide (PnC), which was first described by Tillett and Francis (1). It is of interest as a common antigen of the various strains of pneumococci because, as a common antigen, it has the potential to be a simpler vaccine than the currently used complex mixture of type-specific polysaccharide (3). PnC contains phosphorylcholine (2) and this component is responsible for several properties of the polysaccharide. It is a major antigenic determinant (4), and the interactions of PnC with acute phase serum C-reactive protein (1) and with certain mouse myeloma proteins (5) are both due to phosphorylcholine (6, 7). PnC is attached to the cell-wall mucopeptide in the organism and mucopeptide fragments are often present in PnC preparations.

We previously published a structure for the C-polysaccharide based on methylation analysis and ^{13}C NMR spectroscopic studies (8); however, the more recent application of high-resolution NMR spectroscopic studies on PnC has revealed some minor discrepancies in the previously reported structure. Therefore, we wish now to report the revised structure of PnC based on these studies.

Experimental procedures

Growth of the organism and isolation of PnC

A frozen stock of *S. pneumoniae* R36A was used to inoculate 25 mL of sterile medium and the culture was incubated overnight at 37°C without shaking. The basal medium was Bacto Todd-Hewitt Broth (Difco No. 0492-01), which was supplemented with 0.1% (v/v) sodium bicarbonate and 1% D-glucose (50 mL of a sterile 20% (w/v) aqueous D-glucose solution added asceptically to the basal medium following autoclaving). The basal medium plus sodium bicarbonate was adjusted to pH 7.3 prior to autoclaving. The first culture was then used to inoculate 125 mL of medium and, following an additional overnight incubation, this was added to 600 mL of medium. Finally after overnight incubation, the 600 mL was used to inoculate the production flask (2500 mL of medium in a 4.0 L Erlenmeyer flask). The cultures were killed with formalin of a final concentration of 0.75% (v/v) and the cells were obtained by centrifugation.

The cells of *S. pneumoniae* R36A were extracted with trichloroacetic acid and the extract was fractionated as previously described (8). PnC was then purified from the above crude fraction by column chromatography by the method of Brundish and Baddiley (2), also as previously described by us (8). *N*-Acetylated PnC (PnCNAc) was produced by treating PnC with acetic anhydride in aqueous solution buffered with $NaHCO_3$. Oligosaccharide fragment III was obtained by periodate oxidation of PnCNAc as previously described (8) and was designated oligosaccharide III in this latter publication.

Nuclear magnetic resonance

All experiments were performed as described before by Baumann *et al.* (9) on a Bruker AMX spectrometer at 300 K using a 5-mm broadband probe with ^1H coil nearest the sample. The NMR samples consisted of 10–20 mg of each substance dissolved in 0.5 mL D_2O, at pH 7 using Na^+ counterions. Phosphoric acid (25%) was used as an external chemical shift reference for ^{31}P NMR (δ 0.00 ppm) and acetone was used as an internal chemical shift reference for ^1H NMR (δ 2.225 ppm) and for ^{13}C NMR (δ 31.07 ppm).

Calculations

The starting geometry for AAT*p* NAc (*N*-acetylated AAT*p*) and Gal*p*NAc was generated from the crystallographic data for the methyl glycoside of galactose (10). The coordinates of the methyl glycosides obtained by potential energy minimizations, using the molecular mechanics program MM2 (87) (QCPE) of Burket and Allinger (11), were then used in all calculations.

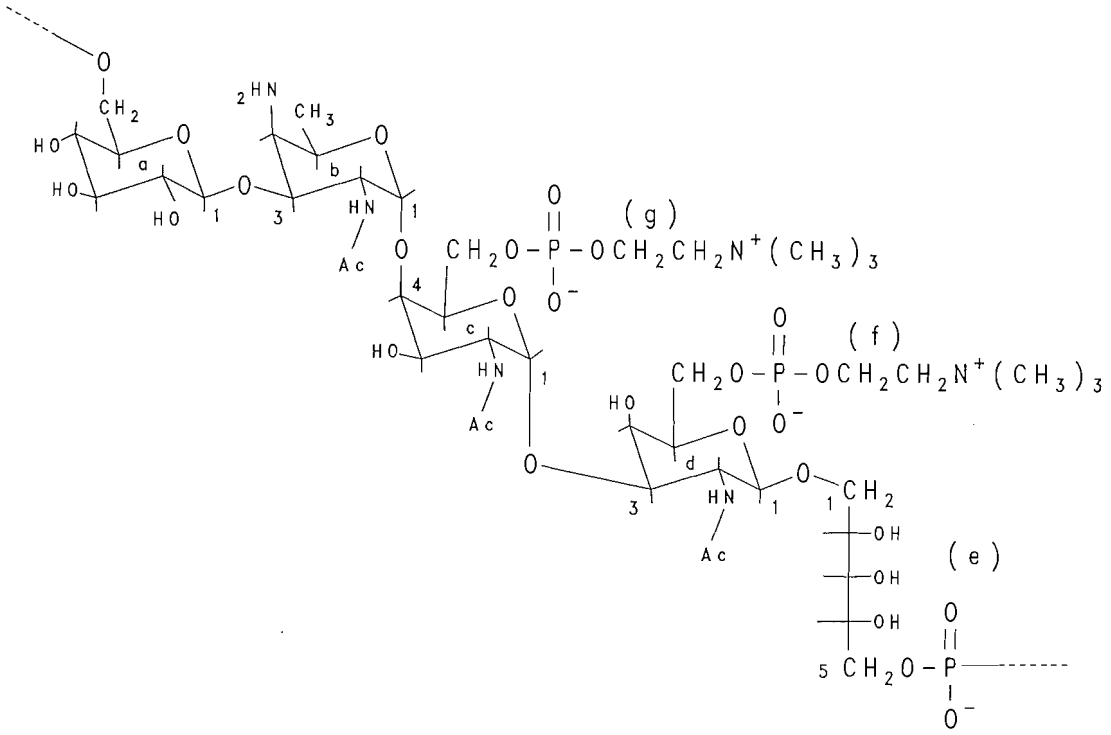

FIG. 1. Structure of the repeating unit of PnC.

The conformational analysis was evaluated using the PFOS potential designed by Tvaroska and Perez (12). Rotational barriers of 1.0 and 0.5 kcal/mol were used for ϕ and ψ, respectively. The linkage conformation for α-AAT*p*NAc-(1→4)-α-Gal*p*NAc (**b**–**c**) was defined by ϕ = (H1**b**—C1**b**—O1**b**—C4**c**) and ψ = (C1**b**—O1**b**—C4**c**—H4**c**). The glycosidic bridge angle C1**b**—O1**b**—C4**c** was set at 117°. Potential energy maps were calculated at 5° intervals for ϕ and ψ.

The truncated driven NOE was calculated using the complete relaxation matrix with the assumption of isotropic tumbling (13). The (ϕ,ψ) ensemble $\langle r^{-6}\rangle$ averaged NOE was calculated as described by Cumming and Carver (14). The rotational correlation time of 2 ns used in the NOE calculations was determined from a best fit of the experimental data to the calculated values for the intraresidue NOE's.

Results and discussion

Structure of PnC

The revised structure of PnC as determined by high-resolution NMR spectroscopy and theoretical calculations is shown in Fig. 1. The complete assignment of proton and carbon signals was carried out as described by Baumann *et al.* (9) and each spin system could be combined with one of the five sugar residues or one of two phosphorylcholine substituents in the repeating unit of PnC. The ^{1}H and ^{13}C NMR chemical shifts for the individual components of PnC together with their corresponding monosaccharides are given in Tables 1 and 2. The residues are labeled **a**–**e** in order of sequence, **g** and **f** being phosphorylcholine substituents. The high-resolution ^{1}H and ^{13}C NMR spectra are consistent with the same five sugar residues identified earlier (8) in the repeating unit of PnC, e.g., β-D-glucopyranose (a), 2-acetamido-4-amino-2,4,6-trideoxy-D-galactopyranose (b), 2-acetamido-2-deoxy-α-D-galactopyranose (c), 2-acetamido-β-D-galactopyranose (d), and ribitol-5-phosphate (e), except that both residues **c** and **d** were found to be *N*-acetylated. Previous studies (8) had identified two free amino functions on residues **b** and **d**, whereas in the revised structure of PnC only residue **b** was found to have a free amino group. This observation is also consistent with the identification of three distinct *N*-acetyl signals at 2.092, 2.083, and 2.050 ppm in the ^{1}H NMR spectrum of PnC (Table 1) and an additional *N*-acetyl signal in the ^{1}H NMR spectrum of PnCNAc and the oligosaccharide fragment (III) of PnCNAc (8) containing residues **b**, **c**, **d**, **g**, and **f** (Table 1).

After determination of all the residues and substituents of PnC, the revised structure was established with the help of other NMR methods. Although the sequence of sugars in the repeating unit of PnC had been well established by fragmentation techniques (8), it was further confirmed in 2D NOE studies. Interresidue NOE's were found for all linkages in PnC, and cross sections from the 2D NOE spectrum showing enhancements from the anomeric protons are shown in Fig. 2. The pattern of enhanced signals is entirely consistent with the sequence proposed for the repeating unit of PnC (Fig. 1), the only complexity being due to the overlap of the 1**d** and 5**b** signals.

The identification of two different phosphorylcholine substituents in PnC was not previously detected (8) in earlier ^{13}C NMR spectroscopic studies, where only one (**f**) was identified situated on O6 of **d**. The additional phosphorylcholine substituent was also identified in a ^{1}H–^{31}P correlated spectrum (HMQC) of PnC (Fig. 3), which showed the presence of three different diphosphate esters (^{31}P chemical shifts listed in Table 3) and their connectivities. Consistent with previous assignments (8) the phosphate diester linkage in PnC has connectivities to C5 of **e** and C6 of **a**, indicating linkages to O5 of **e** and O6 of **a**, and the phosphodiester group of one of the phosphorylcholine substituents (f) has connectivities to C6 of **d**, indicating a linkage to O6 of **d**. For the newly identified phosphorylcholine substituent the phos-

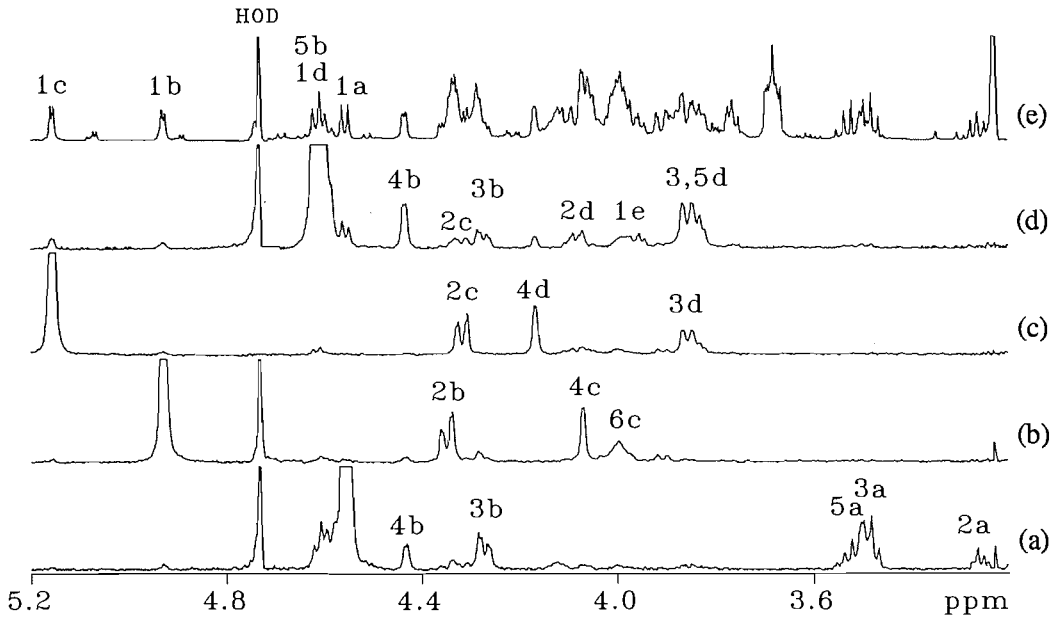

FIG. 2. Truncated driven NOE difference spectra for 400 ms irradiation of H1**a** (*a*), H1**b** (*b*), H1**c** (*c*), H1**d** and H5**b** (*d*) and the resolution enhanced partial ^{1}H spectrum (*e*) at 600 MHz for PnCNAc in D_2O at 300 K.

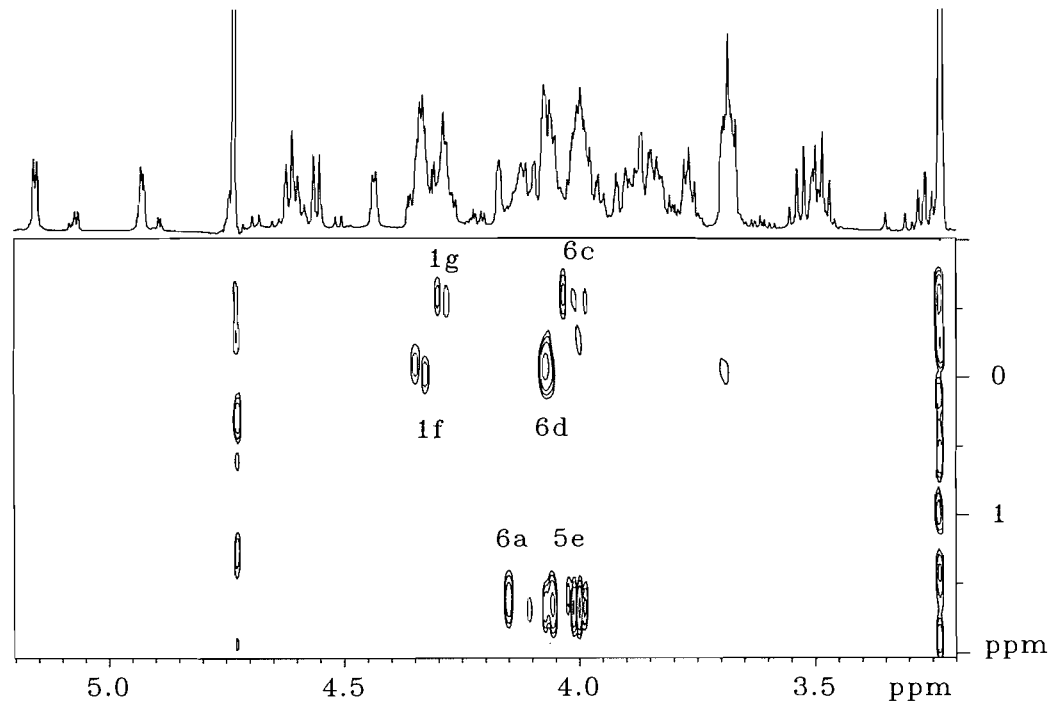

FIG. 3. Proton detected $^1H-^{31}P$ correlated spectrum (HMQC) of PnCNAc indicating the presence of three phosphorus atoms and the linkage sites.

are still components of the polysaccharide chain (9). The NOE, due to its sensitivity to interatomic proton distances, was also used to determine the absolute configuration of AAT (b) in PnCNAc. The (ϕ,ψ) potential energy contour map for α-D-AAT$_p$NAc-(1–4)-α-D-Gal$_p$NAc and α-L-AAT$_p$NAc-(1–4)-α-D-Gal$_p$NAc (Fig. 4) showed that the conformational space of each disaccharide was quite different. The calculated ensemble average NOE's for both disaccharides were also quite different (Table 4) and clearly indicated that AAT had the D configuration. Especially, the H1**b**–H6**c** and H5**b**–H2**c** NOE's were quite sensitive to the absolute configuration of AAT. In contrast, the calculated inter-residue NOE's for β-D-Glc$_p$-(1–3)-α-D-AAT$_p$NAc and β-D-Glc$_p$-(1–3)-α-L-AAT$_p$NAc where not very sensitive to the relative configuration of both sugars, since the potential energy surfaces for both disaccharides were similar (data not shown).

In a recent publication using mass spectrometric studies (15), Behr *et al.* proposed an identical structure to the one

A kinetic study on the reactivity of chromium(IV)

JOAQUIN F. PEREZ-BENITO AND CONCHITA ARIAS
Departamento de Quimica Fisica, Facultad de Quimica, Universidad de Barcelona, Marti i Franques, 1, 08028 Barcelona, Spain

Received November 24, 1992

JOAQUIN F. PEREZ-BENITO and CONCHITA ARIAS. Can. J. Chem. **71**, 649 (1993).

The inhibition effect of Mn^{2+} on the rates of the Cr(VI) oxidations of 13 different organic reductants (RH) in aqueous perchloric acid has been studied. The reductants were formaldehyde, formic acid, maleic acid, and 10 alcohols (8 primary and 2 secondary). The second-order rate constants decrease with increasing $[Mn^{2+}]$ according to the law

$$k_2 = a/(1 + b'\,[Mn^{2+}]/[RH]) + c$$

Parameter b' is interpreted as the ratio between the rate constants for the Cr(IV)–Mn^{2+} and Cr(IV)–RH reactions. Cr(IV) is reduced by Mn^{2+} (and also by Ce^{3+}) much faster than by organic reductants RH. The Cr(IV) oxidations of primary alcohols follow Taft's equation with a negative reaction constant ($\rho^* = -0.80 \pm 0.06$). The Cr(IV) present in aqueous perchloric acid is postulated as an oxo species (CrO^{2+}) capable of reacting by one-electron transfer with both Mn^{2+} and Ce^{3+}, and by hydride-ion transfer with organic reductants. Relevance of these results to the general mechanism for the Cr(VI) oxidations of organic substrates is discussed.

JOAQUIN F. PEREZ-BENITO et CONCHITA ARIAS. Can. J. Chem. **71**, 649 (1993).

On a étudié l'effet inhibiteur du Mn^{2+} sur les vitesses d'oxydations chromiques de 13 agents réducteurs organiques différents (RH), dans de l'acide perchlorique aqueux. Les agents réducteurs étudiés sont : le formaldéhyde, l'acide formique, l'acide maléique et 10 alcools (dont 8 primaires et 2 secondaires). Les constantes de vitesse du deuxième ordre diminuent avec une augmentation de $[Mn^{2+}]$ en suivant la loi suivante :

$$k_2 = a/(1 + b'[Mn^{2+}]/[RH]) + c.$$

On interprète le paramètre b' comme le rapport entre les constantes de vitesse des réactions avec Cr(IV)–Mn^{2+} et Cr(IV)–RH. Le Cr(IV) est réduit par le Mn^{2+} (ainsi que par Ce^{3+}) à une vitesse beaucoup plus grande que celle observée avec les agents réducteurs RH. Les oxydations des alcools primaires par le Cr(IV) suivent l'équation de Taft et la constante de la réaction est négative ($\rho^* = -0{,}80 \pm 0{,}06$). On fait l'hypothèse que le Cr(IV) présent dans l'acide perchlorique aqueux est sous la forme d'une espèce oxo (CrO^{2+}) capable de réagir par un transfert monoélectronique avec le Mn^{2+} ainsi qu'avec le Ce^{3+} et par un transfert d'hydrure avec les agents réducteurs organiques. On discute de l'importance de ces résultats pour le mécanisme général des oxydations des substrats organiques par le Cr(VI).

[Traduit par la rédaction]

Introduction

In a pioneering work, Westheimer (1) proposed two possible mechanisms for the chromium(VI) oxidations of organic substrates (RH). In one of them chromium(V) and chromium(IV) are involved as the only chromium intermediates (Mechanism I).

Mechanism I

$$\mathrm{Cr(VI)} \xrightarrow{\mathrm{RH}} \mathrm{Cr(IV)} \xrightarrow{\mathrm{Cr(VI)}} 2\mathrm{Cr(V)} \xrightarrow{\mathrm{RH}} 2\mathrm{Cr(III)}$$

Alternatively, the second mechanism also involves chromium(II) as an intermediate (Mechanism II).

Mechanism II

$$\mathrm{Cr(VI)} \xrightarrow{\mathrm{RH}} \mathrm{Cr(IV)} \xrightarrow{\mathrm{RH}} \mathrm{Cr(II)} \xrightarrow{\mathrm{Cr(VI)}} \mathrm{Cr(III)}$$

$$+\ \mathrm{Cr(V)} \xrightarrow{\mathrm{RH}} \mathrm{Cr(III)}$$

We can see that in both Westheimer's mechanisms the organic substrate behaves as a two-equivalent reducing agent throughout the reaction sequence. However, Rocek and coworkers (2) have proposed a third mechanism in which the organic substrate behaves as a two-equivalent reducing agent toward both chromium(VI) and chromium(V), and as a one-equivalent reducing agent toward chromium(IV) (Mechanism III).

Mechanism III

$$\mathrm{Cr(VI)} \xrightarrow{\mathrm{RH}} \mathrm{Cr(IV)} \xrightarrow{\mathrm{RH}} \mathrm{Cr(III)} + \mathrm{R}\cdot$$

$$\mathrm{Cr(VI)} \xrightarrow{\mathrm{R}\cdot} \mathrm{Cr(V)} \xrightarrow{\mathrm{RH}} \mathrm{Cr(III)}$$

Although Mechanism I has been preferred in the past, in recent years Mechanism III has been widely accepted as the correct mechanism for the chromium(VI) oxidations of many organic compounds (3*a*).

On the other hand, Mechanism II has been dismissed by most authors, largely because chromium(II) is such a powerful reducing agent that it is not considered a likely species in the system (4). Although Beattie and Haight (5) pointed out that Mechanism II had not been ruled out by any valid experiment or theoretical argument, neither was there evidence to support it.

However, in recent work Scott, Bakac, and Espenson have clearly demonstrated that chromium(IV) is actually reduced by methanol (6*a*) and other organic compounds (6*b*) to chromium(II) and not to chromium(III). Therefore, Mechanism II has to be considered as correct.

We now wish to report some experiments which, by an independent method, confirm the results found by those authors. Whereas they trapped chromium(II) with oxygen to form superoxochromium(III) ion (CrO_2^{2+}) and followed formation of the latter at 245 and 290 nm (6*b*), we have used the inhibitory effect that manganese(II) ion is known to exert

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

on the rates of the chromium(VI) oxidations of many organic compounds (7, 8). Mn(II) behaves as a trap for chromium(IV) (9),

[1] $Cr(IV) + Mn(II) \rightarrow Cr(III) + Mn(III)$

whereas the direct oxidation of manganese(II) ion by chromium(VI) is thermodynamically unfavorable (5). In this way, we have been able to study the reactivity of Cr(IV), which (as can be seen in Mechanisms I–III) is the key intermediate for selecting the correct mechanism.

Experimental section

The solvent water was purified by deionization followed by double distillation (the first time from a potassium permanganate solution). The acidity of the solutions was controlled with perchloric acid. The ionic strength of the solutions was kept constant with appropriate additions of sodium perchlorate.

The oxidant was chromium(VI) from commercially available potassium dichromate. The organic substrates acting as reductants were formaldehyde, formic acid, maleic acid, methanol, ethanol, 2-chloroethanol, 2-methoxyethanol, 2-ethoxyethanol, 1-propanol, 2-propanol, 1-butanol, benzyl alcohol, and 2,5-hexanediol. The reductants were in all cases in large excess with respect to chromium(VI).

The inhibitors were manganese(II) ion from commercial manganese(II) sulfate, and cerium(III) ion from commercial cerium(III) nitrate. They always were in very low concentration, so that the ionic strength of the solution was controlled by the total perchlorate concentration ($HClO_4$ + $NaClO_4$).

All of the reagents were used as purchased (analytical grade), except 2-propanol (reagent grade), which was used after distillation.

The reactions were followed by monitoring the chromium(VI) decay at 352 nm with a Varian Cary 219 UV–vis spectrophotometer. This instrument was equipped with a cell holder with capacity for five cuvettes (quartz, lightpath 1 cm) that was connected to an externally thermostated bath at 25.0°C.

The kinetic data were obtained by means of the initial-rates method. Since initial rates were found to be rather sensitive toward the room temperature (at which some manipulations at the beginning of the kinetic runs had to be necessarily done), the temperature of the laboratory was kept as close as possible to that of the runs (external temperature 25.0 ± 0.8°C). The kinetic data given in this work are the averages of two independent determinations for each rate constant. Reproducibility of those duplicate determinations was excellent (average standard deviation ±0.6% for 1700 kinetic runs).

Results

Although the reductants always were in large excess with respect to chromium(VI), the first-order rate plots (ln [Cr(VI)] vs. time) failed, in some of the cases, to yield straight lines. Actually, for four of the reductants (methanol, 2-chloroethanol, 2-methoxyethanol, and maleic acid) the reaction rate decreased more slowly than expected from the corresponding chromium(VI) decay. This behavior, typical of autocatalytic processes (10, 11), is probably due to overoxidation of the organic reaction products by chromium(VI) (2*b*). For the other nine reductants, however, the first-order rate plots were fairly linear.

As a consequence, the kinetic data were obtained by means of the initial-rates method. The initial reaction rate was directly proportional to the concentrations of both oxidant (initial) and reductant in all of the cases. The second-order rate constants were obtained from the initial rates (r_0) as indicated in eq. [2],

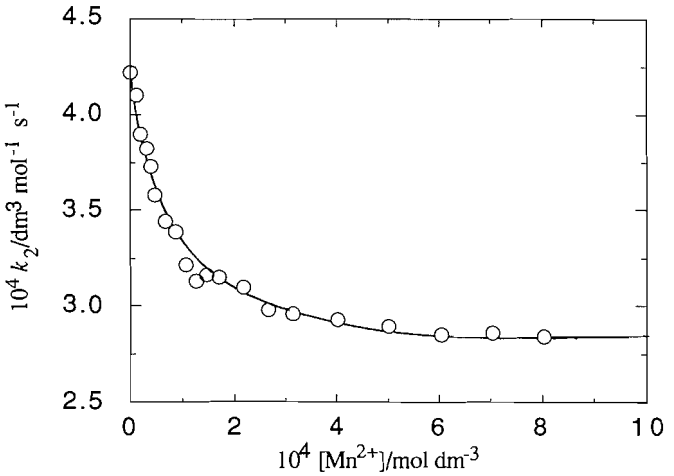

FIG. 1. Decrease of the second-order rate constant with the manganese(II) ion concentration for the oxidation of 2-ethoxyethanol (0.206 mol dm^{-3}) by chromium(VI) (8.74×10^{-4} mol dm^{-3}) in aqueous perchloric acid (0.366 mol dm^{-3}) at 25.0°C.

[2] $k_2 = r_0/[Cr(VI)]_0\,[RH]$

where [RH] denotes the concentration of organic substrate. For the nine reductants with linear first-order rate plots the rate constants obtained from those plots were in good agreement with those obtained from the initial rates (typical difference, ±2%).

In all of the cases studied by us, the reaction rate decreased when manganese(II) ion was added in low concentration to the solutions (Fig. 1). The decrease of the second-order rate constant with increasing manganese(II) ion concentration could always be fitted to functions of the type given in eq. [3] (12).

[3] $k_2 = a/(1 + b[Mn^{2+}]) + c$

Parameters *a*, *b*, and *c* were obtained in each case by a nonlinear least-squares fit.

The second-order rate constants corresponding to the noninhibited reactions were obtained from the sums $a + c$, and are given in Table 1. The ratios $(a + c)/c$ gave the values of the maximum inhibition attained in each case. Those ratios always were in the range 1–2, and they were fairly independent of the concentrations of both chromium(VI) and organic substrate, but decreased markedly as the perchloric acid concentration increased (Table 2).

The slopes of both the log *b* vs. log $[Cr(VI)]_0$ and log *b* vs. log. [RH] plots were obtained for nine different organic substrates and are given in Table 3. We can see that the slope of the log *b* vs. log $[Cr(VI)]_0$ plots ranged between −0.15 and +0.17, the average value being 0.00 ± 0.10, whereas the slope of the log *b* vs. log [RH] plots ranged between −1.19 and −0.88, the average value being −1.00 ± 0.10. Therefore, we can conclude that parameter *b* was in all cases roughly independent of the initial concentration oxidant, whereas it was inversely proportional to the reductant concentration. Hence, eq. [3] can be rewritten as

[4] $k_2 = a/(1 + b'\,[Mn^{2+}]/[RH]) + c$

[a]Ratios between the values of parameter b' for 2-propanol and RH.
[b]Ratios between the values of the rate constants for the reactions of Cr(IV) with RH and 2-propanol given in ref. 6*b*.
[c][$HClO_4$] = 1.83 mol dm^{-3}.

where b' is a new, dimensionless parameter defined as $b' = b[RH]$.

The values of b' obtained for the organic substrates studied in this work are listed in Table 4. All these values are given for the same perchloric acid concentration (0.366 mol dm^{-3}) except for the case of maleic acid (1.83 mol dm^{-3}), since the latter was very unreactive toward chromium(VI) unless a high concentration of perchloric acid was used. It is interesting to notice that all the values given in Table 4 are much larger than unity (the lowest is around 10^3). Also, the value obtained for oxidation of formic acid was much higher than those obtained for the other organic substrates. In particular, b' for formic acid was around 70 times higher than the value for formaldehyde, which means that manganese(II) ion was a much more efficient inhibitor for the Cr(VI)–HCO_2H reaction than for the Cr(VI)–HCHO reaction.

It can be seen in Fig. 2 for inhibition by manganese(II) ion in the chromium(VI) oxidations of primary alcohols that, except for the case of benzyl alcohol, the logarithm of parameter b' gave a good linear correlation with Taft's polar substituent constant σ^* (13), and the associated slope was $\rho^* = -0.80 \pm 0.06$.

Parameter b' has also been represented against the second-order rate constant corresponding to the non-inhibited oxidation of each organic substrate by chromium(VI) in a double-logarithmic plot (Fig. 3). For six of the eight primary alcohols studied a good linear correlation was obtained, the only primary alcohols falling outside of the linear correlation being methanol and benzyl alcohol. It is interesting to notice that the point corresponding to the latter correlated well with those corresponding to the two secondary alcohols studied (2-propanol and 2,5-hexanediol).

Finally, since the cerium(III) ion is known to exert an inhibitory effect on the chromium(VI) oxidations of many organic compounds similar to that exerted by the manganese(II) ion (14), given that both ions reduce chromium(IV) to chromium(III), we performed some experiments in order to compare the inhibitory effects caused by the two ions on the

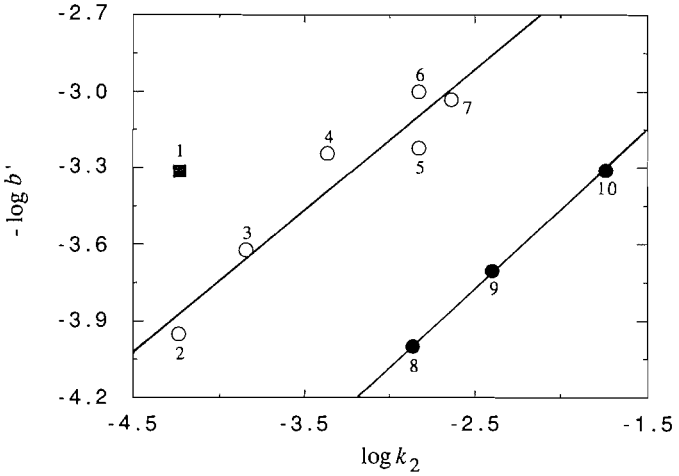

FIG. 2. Logarithm of parameter b' against Taft's polar substituent constant for inhibition by manganese(II) ion in the oxidations of primary alcohols by chromium(VI) (8.74×10^{-4} mol dm^{-3}) in aqueous perchloric acid (0.366 mol dm^{-3}) at 25.0°C. Alcohols: 2-chloroethanol (1), 2-methoxyethanol (2), methanol (3), ethanol (4), 1-propanol (5), 1-butanol (6), and benzyl alcohol (7). The value for methanol has been corrected with the statistical factor 3/2. The value for benzyl alcohol has been excluded from the fit. Reaction constant: $\rho^* = -0.80 \pm 0.06$.

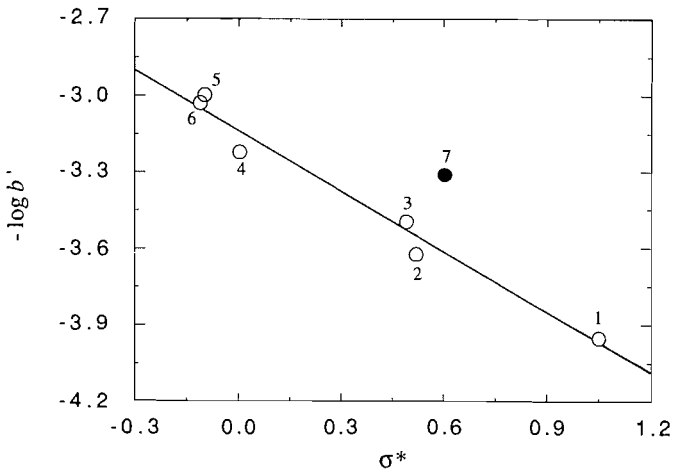

FIG. 3. Double-logarithmic plot of parameter b' for inhibition by manganese(II) ion against the second-order rate constant in the absence of inhibitor for the oxidations of both primary and secondary alcohols by chromium(VI) (8.74×10^{-4} mol dm^{-3}) in aqueous perchloric acid (0.366 mol dm^{-3}) at 25.0°C. Alcohols: methanol (1), 2-chloroethanol (2), 2-methoxyethanol (3), 2-ethoxyethanol (4), ethanol (5), 1-propanol (6), 1-butanol (7), 2-propanol (8), 2,5-hexanediol (9), and benzyl alcohol (10). Slopes: 0.56 ± 0.08 (points 2–7) and 0.61 ± 0.01 (points 8–10).

chromium(VI) oxidation of formic acid. The results indicated that the maximum inhibition attained by the manganese(II) ion was notably inferior to that attained by the cerium(III) ion, as shown by the corresponding $(a + c)/c$ ratios (1.64 for Mn^{2+} and 1.92 for Ce^{3+}). However, the asymptotic value of the second-order rate constant was reached earlier when the manganese(II) ion was the inhibitor, as reflected by the corresponding values of parameter b' (9.62×10^4 for Mn^{2+} and 6.47×10^4 for Ce^{3+}).

Discussion

Interpretation of parameter b'

By application of the steady-state approximation to the intermediate Cr(IV) in the case of Mechanism I, to both Cr(IV) and Cr(II) for Mechanism II, and to both Cr(IV) and R· for Mechanism III, it is easy to demonstrate that the expression obtained for parameter b in the case of Mechanism I is

$$[5] \quad b = k_{inh}/k_{ox}\,[Cr(VI)]_0$$

whereas for both Mechanisms II and III we obtain

$$[6] \quad b = k_{inh}/k_{red}\,[RH]$$

where k_{inh}, k_{ox}, and k_{red} are the rate constants for the reactions of the intermediate chromium(IV) with manganese(II) ion (inhibitor), chromium(VI) (oxidant), and the organic substrate (reductant), respectively (12).

We can see in Table 3 that parameter b is independent of the chromium(VI) initial concentration, but is inversely proportional to the concentration of organic substrate. Thus, we can conclude that the reduction of chromium(VI) by organic substrate does not take place via Mechanism I, since the intermediate chromium(IV) does not react with chromium(VI) but with the organic substrate instead, either in a two-equivalent reduction (Mechanism II) or in a one-equivalent reduction (Mechanism III).

Although the fact that chromium(IV) is not oxidized by chromium(VI) is consistent with considerations based on reduction potentials, as reported by Rahman and Rocek (2*d*), Ghosh and Gould (15) have reported that a complex of chromium(IV) with 2-ethyl-2-hydroxybutanoic acid is actually oxidized by chromium(VI). However, the reactivity of that complex might presumably be very different from that of the chromium(IV) species present in aqueous perchloric acid solution.

Since $b' = b[RH]$, from eq. [6], this yields the following expression for parameter b':

$$[7] \quad b' = k_{inh}/k_{red}$$

It can be seen in Fig. 2 that the negative logarithm of parameter b' for inhibition by manganese(II) ion in the chromium(VI) oxidations of primary alcohols decreases linearly with Taft's polar substituent constant σ^*. According to eq. [7], we can conclude that the logarithm of rate constant k_{red} decreases linearly with increasing σ^*, given that the logarithm of rate constant k_{inh} for the Cr(IV)–Mn^{2+} reaction affects the intercept but not the slope since it is a constant in the plot. Therefore, Fig. 2 must be interpreted as a Taft-like plot for the reactions between the intermediate chromium(IV) and primary alcohols. It can also be seen that the data for the chromium(IV) oxidation of benzyl alcohol do not correlate well with those for the other primary alcohols, which is possibly due to the fact that Taft's polar substituent constant σ^* does not take into account resonance effects.

Rahman and Rocek (2*c*) also studied the chromium(IV) – primary alcohols reactions; after Espenson's work (16), they proposed chromium(IV) as an intermediate in the reduction of chromium(VI) by vanadium(IV). The value of Taft's reaction constant determined in our work for the reactions between chromium(IV) and primary alcohols ($\rho^* = -0.80 \pm 0.06$, Fig. 2) agrees well with the one determined by Rahman

and Rocek (2*c*) for the same reactions ($\rho^* = -0.85$). This concordance is notable because the two values of the reaction constant were determined by two very different, indirect, methods. In both studies, what was determined was not the rate constant for each Cr(IV)–RH reaction but the value of its ratio with another rate constant.

In Table 4 the values of parameter b' obtained in this work for different reductants RH are compared with the rate constants obtained by Scott *et al.* (6*b*) for the Cr(IV)–RH reactions using a different method. To that end, both the b' and rate constant values are referred to a standard (2-propanol). We can see that, among the seven reductants common to both studies, the two sets of data are in good agreement in all but two cases, formic acid and 1-butanol (especially the latter). The values found in the two studies for the other five reductants (formaldehyde, ethanol, benzyl alcohol, methanol, and 2-propanol) have been combined to obtain the rate constant corresponding to the reaction between the intermediate chromium(IV) and manganese(II) ions (eq. [1]), yielding the value $k_{inh} = (1.19 \pm 0.15) \times 10^5$ dm^3 mol^{-1} s^{-1}.

Hydrogen-atom versus hydride-ion transfer

It can be seen in Table 4 that the values of parameter b' for inhibition by manganese(II) ion in the chromium(VI) oxidations of organic substrates are always much higher than unity (10^3 or higher). The value of b' determined for inhibition by cerium(III) ion in the chromium(VI) oxidation of formic acid was also of the same order of magnitude. We can then conclude that the reactions of the intermediate chromium(IV) with the inorganic ions acting as inhibitors (Mn^{2+} and Ce^{3+}) have rate constants at least 10^3-fold higher than the reactions of the same intermediate with organic substrates. This finding clearly suggests that the Cr(IV)–RH reactions involve cleavage of a C—H bond in the organic molecule by transfer of either a hydrogen atom (Mechanism III) or a hydride ion (Mechanism II) from the organic molecule to chromium(IV). Therefore, they are much slower than both the Cr(VI)–Mn^{2+} and Cr(IV)–Ce^{3+} one-electron transfer reactions, which do not involve bond cleavage (eq. [1]).

If hydrogen-atom transfer is accepted for the Cr(IV)–RH reactions, there would be a competition between bimolecular destruction (recombination or dismutation) of the free radicals R· and their oxidation by chromium(VI) (see Mechanism III). Since the oxidizing power of chromium(VI) is dramatically reduced by a decrease in the acidity of the medium (5), it follows that bimolecular destruction of free radicals should predominate at low perchloric acid concentrations.

In Mechanism III the free radicals are formed from the Cr(IV)–RH reaction, but the Cr(IV)–Mn(II) reaction (eq. [1]) does not yield free radicals. Hence, given that when enough Mn(II) is added free radicals are not formed, according to that mechanism it is precisely the elimination of the Cr(VI)–R· reaction by addition of manganese(II) ion to the reaction mixture that explains the inhibitory effect of the latter. As a result, in a situation where the free radicals were not consumed by chromium(VI) oxidation but instead by recombination of dismutation (at $[H^+] \cong 0$), no inhibition by manganese(II) ion would be expected, for recombination and dismutation of free radicals do not affect the rate of disappearance of chromium(VI). Therefore, if Mechanism III holds, the maximum inhibition ratio $(a + c)/c$ should decrease with decreasing acidity. However, we have seen in Table 2 that a decrease of the acidity of the medium actually led to an increase of that ratio.

Furthermore, Rahman and Rocek (2*c*,*d*), pointed out that an increase in the concentration of organic substrate would lead to an increase in the concentration of free radicals R·, and so also to an increase of the bimolecular destruction of free radicals relative to their oxidation by chromium(VI), since the rates of the R·–R· and Cr(VI)–R· reactions increase with the second and first powers of [R·], respectively. Therefore, if Mechanism III holds, a decrease of the maximum inhibition ratio with increasing concentration of organic substrate would be expected. However, we have found that $(a + c)/c$ is essentially independent of the RH concentration.

According to eq. [7], Fig. 3 is actually a representation of the Cr(IV)–RH reactivity against the corresponding Cr(VI)–RH reactivity, since the rate constant k_{inh} for the Cr(IV)–Mn(II) reaction is a constant in the plot, and the abscissa is the logarithm of the second-order rate constant for each Cr(VI)–RH reaction in the absence of inhibitor. We can see that in the case of primary alcohols the rate constants for the Cr(IV)–RH reactions correlate well with those corresponding to the Cr(VI)–RH reactions. Since it is widely accepted that the rate-determining redox step for the chromium(VI) oxidation of alcohols involves a two-equivalent reduction of the oxidizing agent (1, 2*d*), this finding seems to support that the redox step of the Cr(IV)–RH reactions also involves a two-equivalent reduction of chromium(IV).

However, the oxidations of both methanol and benzyl alcohol by chromium(IV) do not correlate well with those by chromium(VI), in contrast to the other primary alcohols. In the case of methanol, it should be noted that its reactivity toward chromium(VI) is known to be much lower than expected from polar substituent considerations (2*b*), but we can see in Fig. 2 that methanol correlates well with the other primary alcohols for their oxidation by chromium(IV), which explains the position of the point corresponding to methanol in Fig. 3 above the linear correlation observed for the other primary alcohols. Hence, the position of that point seems to be due to some specific effect in the Cr(VI)–CH_3OH reaction that is not present in the Cr(IV)–CH_3OH reaction.

We can also see in Fig. 3 that the point corresponding to benzyl alcohol is below the linear correlation found for primary alcohols, and that it seems to correlate well with the two secondary alcohols studied by us (2-propanol and 2,5-hexanediol). This fact is relevant to the hydrogen-atom versus hydride-ion transfer argument. If the redox step of the Cr(IV)–RH reactions takes place by hydrogen-atom transfer, one would expect the organic free radical formed by oxidation of benzyl alcohol to be highly stabilized by resonance. Moreover, the free radicals formed in the chromium(IV) oxidations of secondary alcohols should be more stable than those formed from primary alcohols (3*b*). Hence, in a representation of the reactivity toward chromium(IV) against the reactivity toward chromium(VI), the points corresponding to benzyl alcohol and secondary alcohols would all be expected to be above the linear correlation observed for primary alcohols, which is in open disagreement with the situation shown in Fig. 3.

Nevertheless, the positions of the points corresponding to both benzyl alcohol and the secondary alcohols in Fig. 3 require consideration. Actually, we believe that steric hindrance caused by the phenyl or alkyl groups might be a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

plausible explanation for that low reactivity of chromium(IV) toward benzyl alcohol and secondary alcohols, respectively.

Since the first step in the oxidation of alcohols by chromium(VI) is the formation of the corresponding chromate(VI) esters (17, 18), and the esterification equilibrium constants can be assumed to be roughly independent of the molecular structure of the alcohol (19), steric hindrance caused by the structure of the alcohol is not expected to play an important role in the case of oxidation by chromium(VI). This is corroborated by the fact that we have found that the reactivity of 1-propanol toward chromium(VI) is only 1.10 times greater than that of 2-propanol (Table 1).

However, alcohols do not seem to form esters with chromium(IV). This hypothesis is based on the finding that chromium(VI) is 2400 times more reactive toward ethanol than toward diethyl ether (2*c*), whereas chromium(IV) is only 30 times more reactive toward the alcohol than toward the ether (2*c*) (20 times according to results of Scott *et al.* (6*b*)). Thus it seems that the presence of a hydroxyl group in the organic substrate to allow the formation of a chromate ester is essential in the case of chromium(VI) oxidation, but it is not so important in the case of chromium(IV) oxidation. In fact, steric hindrance might be a plausible explanation for the low Cr(IV)–$C_2H_5OC_2H_5$ reactivity as compared with that of Cr(IV)–C_2H_5OH.

Therefore, steric hindrance caused by the phenyl or alkyl groups might play an important role in the redox step of the oxidation of both benzyl alcohol and secondary alcohols by chromium(IV). Actually, we can see in Table 4 that parameter b' for 1-propanol is ca. 10 times lower than that for 2-propanol, which means that the reactivity of 1-propanol toward chromium(IV) is 10 times higher than that of 2-propanol, since the reactivity of RH toward Cr(IV) is inversely proportional to the corresponding value of parameter b' (eq. [7]). That big difference in reactivity contrasts with the small difference for the reactions of those substrates with chromium(VI).

The fact that the value of parameter b' corresponding to formic acid is ca. 70 times higher than that corresponding to formaldehyde (Table 4) can be taken as another proof supporting hydride-ion transfer. Effectively, the finding that the reactivity of formic acid toward chromium(IV) is much lower than the reactivities of the other 12 organic substrates studied by us (70 times lower than that of formaldehyde, for instance) might be due to the fact that, among the organic substrates given in Table 4, formic acid is the only one for which there would be two oxygen atoms attached to the carbon atom bearing the positive charge in the carbocation formed by hydride-ion transfer from the organic substrate to chromium(IV). As indicated in eq. [8], due to the lower electronegativity of the carbon atom with respect to that of oxygen, transfer of a C-H hydride ion is preferred to that of an O-H hydride ion.

$$[8] \quad Cr(IV) + HCO_2H \rightarrow Cr(II) + {}^{+}CO_2H$$

Formation of the stable oxidation product (carbon dioxide) would occur by proton transfer from the carbocation formed in eq. [8] to the solvent (3*c*). However, since the high electronegativity of the two oxygen atoms attached to the carbon atom bearing the positive charge will render that carbocation very unstable, the reactivity of formic acid toward chromium(IV) would be much lower than those of other organic substrates (Table 4).

It should be pointed out that carbocations are also formed in hydride-ion transfer from other organic compounds (such as alcohols) to chromium(IV). Since carbocations are known to initiate polymerization reactions (20), they might be responsible for the polymerization of acrylamide and acrylonitrile detected in the reaction of chromium(IV) with 2-propanol (2*d*), because, according to Scott's (6) results and our own, it seems that free radicals are not formed in that reaction. In the absence of easily polymerizable substrates, those carbocations would instead be stabilized by proton transfer to the solvent (3*c*).

Nature of the chromium(IV) species

There are some clues leading to elucidation of the nature of the chromium(IV) species present in aqueous perchloric acid. These are the following:

1. It cannot be chromium(IV) oxide, because, due to the high polarity of the Cr—O double bonds, the neutral CrO_2 molecules would have a high tendency to coagulate (as happens in the case of the MnO_2 molecule (21)), so that chromium(IV) would then be an insoluble, stable product instead of a soluble, unstable intermediate.

2. The tendency of chromium(VI) ($HCrO_4^-$ or H_2CrO_4) to form esters with alcohols and other organic compounds (17, 18), and also ester-like species with inorganic compounds (22), is well known. However, chromium(IV) does not seem to form esters with alcohols. This suggests that the chromium(IV) molecule does not contain any hydroxyl group. Hence, possible formulas corresponding to neutral molecules containing OH groups (such as H_2CrO_3) can be discarded. Therefore, the two arguments considered so far suggest that the chromium(IV) species is not a neutral molecule. It cannot be a hydroxyl-containing oxyanion (such as $HCrO_3^-$) either.

3. It is well known that protonation increases the oxidizing power of oxyanions dramatically. Thus permanganic acid is a much stronger oxidant than permanganate ion (23), and the oxidizing power of chromium(VI) is known to be enhanced by an increase of the acidity of the medium (5). However the oxidizing power of chromium(IV) does not seem to be much influenced by the acidity of the medium (2*c*), except when the reductant is a carboxylic acid (6*b*). This suggests that the chromium(IV) species does not show any tendency to take protons from the solution under acidic conditions and, therefore, is not an oxyanion. Hence, species such as CrO_3^{2-} (even if they do not contain any hydroxyl group) can also be discarded. Thus, the arguments considered so far lead to the conclusion that the chromium(IV) species is either Cr^{4+} or CrO^{2+}.

4. We have seen that the chromium(IV) species seems to present a strong tendency to withdraw a hydride ion from organic substrates RH. This is more consistent with an oxo species such as CrO^{2+} than with Cr^{4+}, since the high electronegativity of the oxygen atom of the former can easily explain the hydride-ion transfer process via the transition state $[Cr{=}O \cdots H \cdots R]^{2+}$.

Thus the results found in this work support the hypothesis that the chromium(IV) species present in aqueous perchloric acid solutions is actually CrO^{2+}, in agreement with the proposal of Scott *et al.* (6). This conclusion also agrees with the structure proposed by Ghosh and Gould (15) for the

bischelated complex formed in the stabilization of chromium(IV) by 2-ethyl-2-hydroxybutanoic acid (LigH), since it was assumed to be an oxo species featuring a $Cr^{IV}=O$ linkage. In fact, that complex would be easily formed as the neutral molecule resulting from the association of CrO^{2+} with two Lig^- (2-ethyl-2-hydroxybutanoate) ions, as indicated in eq. [9].

[9] $CrO^{2+} + 2LigH \rightarrow (Lig)_2Cr^{IV}=O + 2H^+$

Conclusions

These results suggest that the chromium(IV) present in aqueous perchloric acid solution is an oxo species (CrO^{2+}). It does not react with chromium(VI) (at least under the conditions of this work), but it reacts with reducing organic substrates by hydride-ion transfer, yielding chromium(II) and a carbocation that is stabilized by proton transfer to the solvent. It also reacts with the inorganic reductants, manganese(II) and cerium(III) ions, by one-electron transfer.

The geometrical parameters of acryloyl fluoride were optimized completely at the MP2/6-31G* computational level for 17 points on the internal rotation potential energy (IRPE) curve for rotation around the formal single carbon–carbon bond. The expansion coefficients of the reduced rotational constant function $F(\varphi)$ and the four, five, and six-term expansions of the IRPE function,

$$V(\varphi) = \sum_n 1/2\, V_n (1 - \cos n\varphi), \qquad \text{where } n = 1, 2, 3\ldots,$$

were obtained from these data. The theoretical IRPE functions were then refined using only the experimental torsional transition frequencies in both the *s-trans* and *s-cis* wells. The IRPE functions obtained are compared with those in the literature, calculated at lower levels of theory in both the rigid and nonrigid rotation approximations. The best representation of the refined IRPE function is given by the six-term expansion with $V_1 = 71.7$, $V_2 = 1944.8$, $V_3 = 113.0$, $V_4 = -122.8$, $V_5 = -8.7$, and $V_6 = 12.5$ cm^{-1}, respectively. From this IRPE function, one correctly predicts the *s-trans* conformer to be more stable with $\Delta H_0 = 168$ cm^{-1}. The barrier to rotation from the *s-trans* to the *s-cis* positions, $\Delta H^{\#}$, is 2048 cm^{-1} at 88° from the *s-trans* well. The advantages of using the nonrigid rotation approximation, based on high-quality quantum mechanical calculations that include correlation effects, to construct the effective IRPE function for molecules are emphasized.

GEORGE R. DE MARÉ, YURII N. PANCHENKO, ALEXANDER V. ABRAMENKOV et CHARLES W. BOCK. Can. J. Chem. **71**, 656 (1993).

On a optimisé complètement les paramètres géométriques du fluorure d'acryloyle au niveau de calcul MP2/6-31G* pour 17 points de la courbe d'énergie potentielle de rotation interne (EPRI) pour la rotation autour de la liaison carbone–carbone formellement simple. À l'aide de ces données, on a déduit les coefficients d'expansion de la fonction de la constante de rotation réduite, $F(\phi)$, ainsi que les expansions à quatre, cinq et six termes de la fonction d'EPRI,

$$V(\phi) = \sum_n 1/2\, V_n (1 - \cos n\phi), \qquad \text{où } n = 1, 2, 3\ldots,$$

On a alors affiné les fonctions théoriques de l'EPRI en utilisant seulement les fréquences experimentales des transitions de torsion des puits d'énergie des conformères *s-trans* et *s-cis*. On a comparé les fonctions théoriques de l'EPRI avec celles rapportées dans la littérature et calculées à des niveaux inférieurs de la théorie dans les approximations de rotation tant rigides que non rigides. La meilleure représentation de la fonction EPRI affinée est donnée par une expansion à six termes dans laquelle $V_1 = 71{,}7$, $V_2 = 1944{,}8$, $V_3 = 113{,}0$, $V_4 = -122{,}8$, $V_5 = -8{,}7$ et $V_6 = 12{,}5$ cm^{-1}. À partir de cette fonction d'EPRI, on peut prédire correctement que le conformère *s-trans* est le plus stable. $\Delta H_0 = 168$ cm^{-1}. La barrière à la rotation des positions *s-trans* à *s-cis*, $\Delta H^{\#}$, située à 88° du puits d'énergie du conformère *s-trans*, est égale à 2048 cm^{-1}. On met en évidence les avantages qu'il y a d'utiliser l'approximation non rigide de la rotation, basée sur des calculs de mécanique quantique d'excellent qualité qui incluent les effets de corrélation, pour construire une fonction d'EPRI efficace des molécules.

[Traduit par la rédaction]

Introduction

It is well established that the curve for internal rotation about the formal C—C single bond in acryloyl fluoride, CH_2=CH-CF=O (Fig. 1), has minima at the planar *s-trans* and *s-cis* structural points (see refs. 1–3, and references therein). This rotational curve was studied recently (1) using a technique that combines quantum mechanical calculations of the geometrical parameters (non-rigid rotation) with experimental data on the torsional transition frequencies and their overtones in both wells. This approach (4, 5), which is based on a one-dimensional model of internal rotation (6),

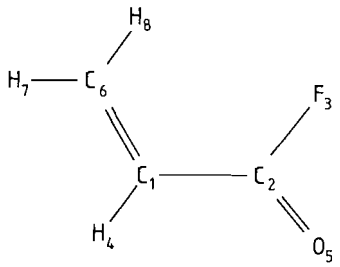

FIG. 1. Atom numbering used throughout the text.

makes it possible to obtain a physically meaningful picture of the nonrigid rotation, but still guarantees the necessary accuracy. It is important to note that this approach does *not* use the enthalpy difference (ΔH_0) between the rotational isomers in the refinement procedure for the theoretical curve since the experimental enthalpy differences are often determined with relatively low accuracy.

The difference in enthalpy between the two conformers of acryloyl fluoride is rather small and the populations of molecules in the two wells are quite similar (1–3). This is an unusual feature for structures with conjugated double bonds, for which the relative populations of molecules in the *cis* and *gauche* wells are usually low (see, for example, refs. 2, 4, 7–27, and references therein). Thus, in typical refinement procedures for conjugated molecules, one often has available only the frequencies of a few of the lowest torsional transitions. Recently it was demonstrated that in such a case (for example for glyoxal (26, 27)) the calculated energy difference between the minima depends on the computational level used to account for the molecular relaxation during the rotation. A marked improvement was obtained (26) in going from the Hartree–Fock model to a model based on second-order Møller–Plesset perturbation theory, which recovers a significant portion of the correlation energy for a given basis set. It is therefore desirable to update the effective curve for internal rotation of acryloyl fluoride using completely relaxed geometries at the MP2/6-31G* level. The ΔH_0 between the two stable rotamers, calculated from the final refined potential curve, should provide a better estimate of the "true experimental" value than previously obtained (1). We also consider the effects of truncating the internal rotational potential energy (IRPE) function expansion on the values of the coefficients and the values of ΔH_0. The *s-trans* and *s-cis* acryloyl fluoride rotamers provide an excellent opportunity for such an investigation, since a relatively large number of torsional transition frequencies are known for both potential wells (3).

Method

The theoretical IRPE function for rotation about the formal C—C single bond of acryloyl fluoride was obtained from MP2/6-31G* level optimizations at the *s-cis*, *s-trans*, and *transition state* (TS) critical points and at 14 additional points along the curve for which only the rotational angle (φ) was kept fixed ($\varphi = \phi - 180°$; where ϕ = the C=C—C=O dihedral angle). The optimizations were carried out using GAUSSIAN 90 (28) on the Cray Y-MP2E/116 computer of the ULB/VUB Computing Centre. The optimized geometrical parameters for the *s-trans* and *s-cis* planar forms are juxtaposed to the experimental microwave data (29, 30) and other theoretical structures (2, 3) in Table 1. The geometrical parameters from the 17 MP2/6-31G* points were used to calculate the reduced moments of inertia for constructing the reduced rotational constant function, $F(\varphi)$ (5) (see Table 2), and its Fourier expansion coefficients up to the ninth term. Including higher terms in this function does not affect the final results. Literature results (1, 3) are included in Table 2 for comparison purposes.

A least-squares procedure was used to fit the MP2/6-31G* IRPE curve of acryloyl fluoride to the function

$$V(\varphi) = \sum_n 1/2\, V_n\,(1 - \cos n\varphi), \qquad \text{where } n = 1, 2, 3\ldots,$$

truncated after the first four, five, six, seven, and eight terms, respectively. As observed previously for other conjugated molecules, and notably for the isoelectronic series butadiene, acrolein, and glyoxal (4, 7, 10, 13, 14, 16, 26, 27), truncation of the above series after six terms reproduces the theoretical IRPE curve satisfactorily; i.e., the standard deviation of the energies for the 17 theoretical points is only about 3 cm^{-1}. In contrast, the standard deviations for the four and five-term expansions are almost an order of magnitude larger, approximately 15 cm^{-1}.

The four, five, and six-term expansions of the theoretical IRPE function were refined by a least-squares method to obtain the best agreement between predicted torsional transition frequencies for both the *s-trans* and the *s-cis* conformers and the corresponding experimental values (3) (see Table 3). This procedure, implemented in the program of ref. 31, may cause some difficulties inherent in most inverse problems. Special measures, such as the SVD algorithm (32), were taken to avoid possible ill-conditioned sets of equations. The refined coefficients of the IRPE functions, as well as other results from the literature, are given in Table 4.

Discussion

The optimized MP2/6-31G* geometrical parameters for the *s-trans* and *s-cis* acryloyl fluoride conformers coincide reasonably well with the results of ref. 2 (obtained with an earlier version of the GAUSSIAN programs (see Table 1)). Small deviations in the extreme right digits of some parameter values are the result of rounding off or of small differences in the cutoff criteria for the optimizations.

The major variations observed in the geometrical parameters on going from the *s-trans* to the *s-cis* conformations of acryloyl fluoride are (1) the single C—C bond length at first increases up to $\varphi \cong 90°$, and then decreases, becoming essentially constant for $\varphi \geq 165°$ (see Fig. 2); (2) the O=C—C and C—C—H bond angles increase regularly; and (3) the C=C—C, F—C—C, and C=C—H_8 bond angles decrease regularly. The predicted variation of the single C—C bond length as a function of φ for optimizations at the RHF/6-31G* level (1) is also shown in Fig. 2. Including electron correlation markedly affects the slope of the curve, which is much less sharply peaked for the MP2/6-31G* optimizations. The shape of these curves is similar to that for many conjugated hydrocarbon compounds (for examples see refs. 10, 14, and 16) and also for substituted cyclopropanes, where the three-membered ring may be assimilated to a double bond (for example vinylcylopropane (35), isopropenylcyclopropane (36), and cyclopropanecarboxaldehyde (37). Note that the character of the slopes and of the variations of the analogous curves is different than that observed in the case of glyoxal (26). It is precisely these differences in the parameter dependencies that require one to take into account the relaxation of the geometry in such investigations. Note also that the presence of substituents and the asymmetrical structure of acryloyl fluoride (in comparison with such related compounds as buta-1,3-diene and oxalyl fluoride) result in some unexpected structural changes. For example, the C=C—C bond angle in acryloyl fluoride decreases on going

[a]The authors state (*i*) that *ab initio* structural parameters were used (either 3-21G or 6-31G*, this is not specified) and (*ii*) "The effects of structural relaxation were included in the calculation of $F(\alpha)$." How these effects were included is apparently not mentioned in the paper.
[b]Refined potential, nonrigid rotation.

from the *s-trans* to the *s-cis* conformer whereas in buta-1,3-diene it is larger for the *gauche* than for the *s-trans* rotamer and is predicted to be even larger for the *s-cis* transition state (10, 14). An "inverse" behaviour is also observed for the F—C—C and C—C—H bond angles (see Table 1). Indeed, the central C—C—H bond angles in buta-1,3-diene are predicted to be smaller in the *gauche* than in the *s-trans* conformation (10, 14), whereas the C—C—F bond angle in the O=CF-CF=O molecule increases on going from the *s-trans* to *s-cis* conformer (2). It should be emphasized that all the predicted changes in the geometrical parameters on going from the planar *s-trans* to the planar *s-cis* acryloyl fluoride conformations are in good agreement with the observed experimental differences (29) (see Table 1). This gives weight to the predicted changes at intermediate angles. These peculiarities demonstrate the rough character of the rigid rotor approximation and emphasize again the importance of involving the dependence of the geometrical parameters on the rotational angle when constructing the effective IRPE function for a molecule. It is worth mentioning here that the values of the O=C—C and F—C—C bond angles, calculated from the moments of inertia reported in ref. 30, deviate considerably, from the present calculations and results of refs. 1, 2, and 29.

Including correlation effects in the optimizations at the MP2/6-31G* level produced marked differences in the Fourier expansion coefficients of the reduced rotational constant function, $F(\varphi)$, when compared with the corresponding coefficients calculated from theoretical geometrical parameters optimized at the RHF/6-31G* level (see Table 2). In fact, some higher coefficients are changed by an order of magnitude. The plots of the two functions are shown in Fig. 3.

The purely theoretical six-term MP2/6-31G* IRPE curve and the four-term and six-term experimentally refined IRPE curves are shown in Fig. 4. Comparison of these three curves reveals that the rotational barrier height computed at the MP2/6-31G* level is somewhat overestimated. This is most likely connected with the truncation of the basis set and the failure to pick up all the correlation energy at the MP2 level. However, comparing the theoretical and the six-term refined IRPE curves shows that the difference in ΔE is much less than the difference in the heights of the corresponding barriers to internal rotation ($\Delta H^{\#}$). This suggests that the possible errors in estimating ΔE (or ΔH_0) are apparently less than those incurred in estimating $\Delta H^{\#}$ when using this approach. In the case of the four-term refined IRPE function the deviation of ΔE from the theoretical curve is approximately the same as that between the corresponding barrier heights. Note, however, that, considering experimental accuracy, the standard deviations of the calculated torsional transition frequencies from the experimental values are

[a]Calculated using the above coefficients, i.e., ΔE (*cis-trans*) = $V_1 + V_3 + V_5$ = 164 cm^{-1} and $\Delta H_0 = \Delta E + 0.5\ (\omega_{cis} - \omega_{trans})$ = 156 cm^{-1}. The value of 79 ± 50 given in Table I of ref. 3 does not correspond to these coefficients.

[b]Calculated using the above coefficients.

[c]In degrees from the *s-trans* conformation, calculated using the appropriate coefficients; rounding off of the coefficients may affect the barrier position.

practically the same for both the four-term and the six-term IRPE functions (see Table 3). The same is true in the case of the five-term IRPE function. This implies that successfully fitting the calculated torsional transition frequencies to the experimental ones, while necessary, is not a sufficient condition to assume the accuracy of the IRPE function obtained.

It is important to stress that the value of ΔH_0 obtained from the six-term refined function is much lower than in the case of the analogous calculation starting from the RHF/6-31G* level calculation in ref. 1 (see Table 4). (Note that a value of ΔH_0 = 156 cm^{-1} can be deduced from the RHF/6-31G* torsional potential energy curve reported by Durig *et al.* (3).) The present value, 168 cm^{-1}, seems quite realistic when one considers the experimental data on the intensities of the IR bands of both conformers reported in refs. 3 and 38. It follows from these considerations that using only the first four terms in the potential energy expansion is insufficient to describe adequately the corresponding IRPE function. The effect of the quality of the quantum mechanical potential energy surface calculation was also demonstrated in the case of glyoxal (26), where starting with the theoretical MP2/6-31G* IRPE curve instead of the RHF/6-31G* curve significantly improved the agreement between the calculated and experimental values of ΔH_0. It should be mentioned that the measured value of ΔH_0 for glyoxal (39) is a relatively rare example of a high-quality experimental determination of an enthalpy change between rotational conformers of conjugated molecules.

Let us consider the problem of the number of terms used in the IRPE function expansion and the value of ΔH_0 from another point of view: the rigid rotor (RR) approximation method.

The RR approximation arises quite naturally from the purely empirical approach to constructing the IRPE curve in the framework of the one-dimensional model since there are

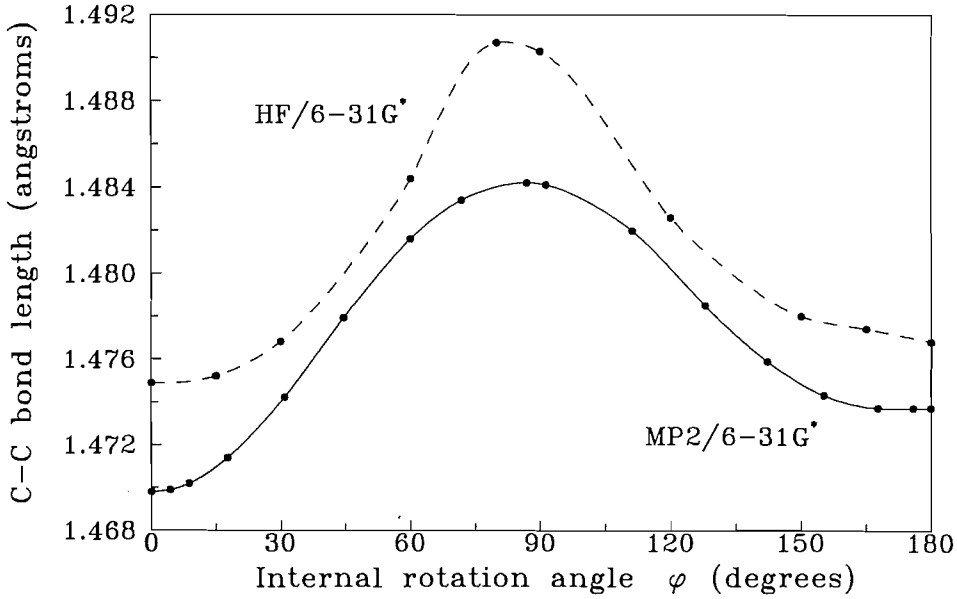

FIG. 2. The optimized single C—C bond length as a function of the internal rotation angle, φ, in acryloyl fluoride (*s-trans* corresponds to φ = zero degrees).

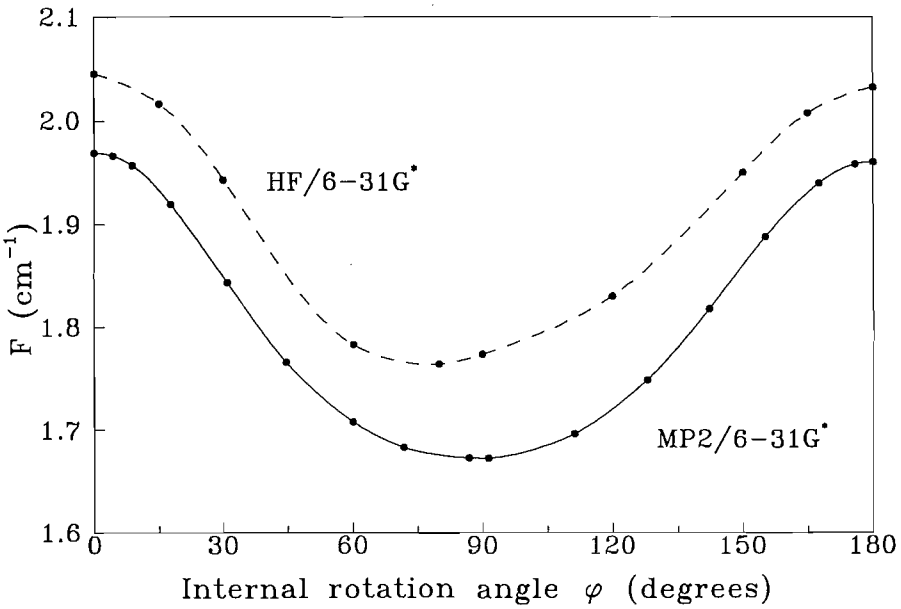

FIG. 3. Plots of the reduced rotational constant function F versus the internal rotational angle in acryloyl fluoride (*s-trans* corresponds to φ = zero degrees).

no experimental methods giving the necessary information about the change of the molecular geometrical parameters in the course of internal rotation. The rather rough character of the RR approximation does not prevent one from properly reproducing the torsional transition frequencies at the last step of iterative fitting of the initial IRPE curve to the experimental data. This may be explained by the fact that the potential function used in the one-dimensional model is, in reality, an effective potential including some terms from the kinetic energy operator (6). In the case of the RR approximation, neglecting the changes in the molecular moiety geometries means that the corresponding contributions are excluded from the kinetic energy and transferred into potential. In this case the solution of the inverse problem results in the correct description of the spectrum although the actual shape of the IRPE curve is, of course, disturbed. This brings about incorrect estimations of the ΔH_0 and $\Delta H^{\#}$ magnitudes and may even result in absolutely unrealistic values. Similar disturbances are especially noticeable when a small number of terms are used in the expansion of the IRPE function. Such a function cannot provide sufficient flexibility for adequate representation of the kinetic component of this pseudo-potential. To try to overcome these difficulties when using the RR approximation one involves the experimental value of ΔH_0 (and sometimes even $\Delta H^{\#}$) together with the torsional transition frequencies in the set of the experimental data from which the refinement of the initial theoretical IRPE curve is performed by the least-squares method.

Raman (3)[b]	−93 ± 33		

[a]In the harmonic approximation $\Delta H_0 = \Delta E + 1/2(\omega_{cis} - \omega_{trans})$.
[b]From temperature studies of the Raman spectra of the gas the *cis* conformer was calculated to be more stable.
[c]The difference between the present result and that of ref. 2 is partially due to rounding off of the last digits.

Concerning the accuracy of experimental ΔH_0 values, acryloyl fluoride is a very instructive example. Indeed, the dispersion of the values measured using various experimental methods is large (see Table 5). There is even a negative experimental ΔH_0 value: measurements of the Raman band intensities as a function of temperature indicated that *s-cis* acryloyl fluoride is more stable than the *s-trans* conformer (3). Nevertheless, the authors of ref. 44 suggested using a mean value of the experimental ΔH_0 data in determining a IRPE function by the RR approximation method. Because of the negative value of ΔH_0 mentioned above, this approach seems to be especially unrealistic in the case of the CH_2=CH-CF=O molecule.

As mentioned above, using different numbers of terms in the IRPE function expansion showed that it is possible to approximate the theoretical potential curve satisfactorily only with a minimum of six terms. Also, discussion of the results of Table 4 revealed that use of the four-term IRPE function leads to an overestimated value of ΔH_0. The use of the experimental value of ΔH_0 in the least-squares fitting with the RR approximation probably alters the actual slope of the IRPE curve approximated by the four-term expansion which results in a loss of the physical meaning of the final IRPE function obtained. Therefore, in the case of more complicated molecular systems of low symmetry, such as the α,β-unsaturated carbonyl compounds, all the four-term IRPE functions that have been reported to date need to be recalculated without using the experimental value of ΔH_0, using a six-term IRPE expansion, and including data on molecular relaxation during rotation.

Nevertheless, it is necessary to mention the special role of the number of the available experimental torsional transition frequencies used in the inverse problem of refining the initial IRPE function. It is desirable that their number be sufficient to allow refinement of *all* the coefficients of the six-term IRPE function expansion. Otherwise only a certain number of these coefficients may be varied during the IRPE function refinement.

Conclusions

The considerations given above for the acryloyl fluoride molecule reveal that the use of a high quality theoretical *ab initio* IRPE curve (which necessarily implies accounting for molecular relaxation during rotation) as the initial IRPE function provides very important advantages in the course of determination of an effective IRPE function. They are the following:

1. Accurate prediction of the number of wells and barriers and their positions.
2. Construction of a correct reduced rotational constant function $F(\varphi)$.
3. Use of the six-term starting IRPE function.
4. The possibility of avoiding using the experimental ΔH_0 value in the corresponding inverse problem. This is very desirable because the accuracy of ΔH_0 measurements is usually quite low.
5. It permits one to obtain a *physically meaningful* effective IRPE function that not only reproduces the frequencies of the torsional transitions in all the wells, but also predicts the values of ΔH_0 and $\Delta H^{\#}$ with a certain degree of accuracy. The accuracy of such predictions is increased as the theoretical level of the initial *ab initio* curve is enhanced.

As pointed out by a referee, $\Delta H_0 = 168$ cm^{-1}, obtained using the refined six-term MP2/6-31G* IRPE and the zero-point energies for torsional transitions of the acryloyl fluoride rotamers, is "more than a factor of 2 larger than either the mean or the median experimental values." It is nevertheless smaller than the NMR result (42) (where solvent or aggregation effects may, however, be important). We feel that $\Delta H_0 = 168$ cm^{-1} for the acryloyl rotamers is credible. The overall picture points out the necessity for further experimental studies on the rotational isomerism of this molecule, preferably with very accurate far-IR intensity measurements by a method such as that recently reported by Hurtmans *et al.* (45).

Hydrogen isotopic exchange between D_2 and H_2O has been investigated on alumina prepared by sputtering at 803 K and at low pressures. The alumina is amorphous, consisting of aluminum with coordination numbers four, five, and six in the ratio 1:2:1 as determined by NMR. A kinetic model is proposed on the basis of the pressure dependence of the exchange rate and the heats of adsorption at adsorbed sites, evaluating by molecular orbital calculations. The adsorbed sites are assumed to be Lewis acid–base pairs composed of a coordinatively unsaturated aluminum and the adjacent unsaturated oxygen site. The site relating to the rate-determining step contains threefold aluminum, which is formed by unsaturation of fourfold aluminum at the surface. As a consequence, the exchange rate depends on the amount of fourfold aluminum when the alumina is heat treated and changes its phase.

FUMIO IOKA, TETSUO SAKKA, YUKIO OGATA et MATAE IWASAKI. Can. J. Chem. **71**, 663 (1993).

On a étudié l'échange isotopique d'hydrogène entre le D_2 et le H_2O, qui se produit sur de l'alumine préparée par bombardement à 803 K et à de basses pressions. L'alumine est amorphe et elle comporte de l'aluminium avec des indices de coordination de quatre, cinq et six dans un rapport de 1 : 2 : 1, tel que déterminé par RMN. On propose un modèle cinétique qui permet d'expliquer la relation entre la vitesse d'échange et les chaleurs d'adsorption évaluées par des calculs d'orbitales moléculaires. On fait l'hypothèse que les sites d'adsorption sont des paires d'acide et de base de Lewis formées d'un aluminium insaturé pentacoordiné et du site oxygéné insaturé adjacent. La site impliqué dans l'étape cinétiquement limitante contient trois fois plus d'aluminium et cette situation est le résultat d'une insaturation dans une quantité quatre fois plus grande d'aluminium à la surface. En conséquence, la vitesse d'échange dépend de la quantité d'aluminium présent en quantité quatre fois plus grande quand l'alumine est traitée par chauffage et qu'elle change de phase.

Introduction

Catalytic behavior of supported platinum catalysts for hydrogen isotopic exchange has been extensively investigated in relation to the separation of deuterium and tritium (1). In practical processes operated in a gas–liquid system, the use of waterproofed platinum catalysts (2) is considered promising; otherwise the exchange rate becomes sluggish by the retardation of hydrogen transfer across condensed water over platinum (3, 4). Both platinum alone and mixtures of other components are used as catalytic particles. The second component promotes the dispersion of platinum and prevents sintering during heat treatment, realizing a large effective surface area. In addition, it often enhances the catalytic activity (5–7). Thus, the apparent catalytic activity of supported catalysts varies in both the physical and the chemical sense.

For the design of effective catalysts it is of importance to comprehend the catalytic activity of each single element. Along this line, some researchers have investigated the hydrogen isotopic exchange reaction between hydrogen and water vapor on unsupported platinum powder and plate (8, 9). The results showed that the reaction mechanism was equivalent to the mechanism proposed by Rolston and Goodale (3) for an alumina-supported platinum catalyst: the rate was controlled by an exchange step between hydrogen chemisorbed on the platinum and water physically adsorbed on the alumina. A pure platinum catalyst provides the two kinds of sites mentioned above (9). Such support materials as silica and graphite (8) do not exhibit any appreciable catalytic activity for hydrogen exchange, but some materials exhibit this activity, if used by themselves as catalyst. Of the latter, alumina shows activity at high temperatures (10, 11), and also shows catalytic activity for isomerization of alkenes, dehydration of alcohols, and other organic reactions (12).

We have studied the actual catalytic activity of platinum at low pressures of reactants where hindrance of the transport of gaseous reactants due to condensation of water at the surface could be avoided, and have obtained reasonable kinetic relationships for the isotopic exchange between D_2 and H_2O (9). In this paper, hydrogen isotopic exchange kinetics is investigated on a pure alumina surface at low pressures and high temperature. Alumina has been extensively employed not only as a catalyst support but also as an active catalyst. The activity is closely connected with the surface structure. Catalytic alumina has a γ or η form in the polymorphs and is generally prepared from amorphous alumina made by thermal decomposition of aluminum hydroxide or aluminum nitrate, or by anodization of aluminum. Sputtering offers another possibility for preparing amorphous alumina. The sputtering technique permits formation of an alumina layer with a large area. This study employs alumina prepared by sputtering. The kinetics is related to the surface states of alumina, particularly to the coordination states of the aluminum. A model for the hydrogen exchange, stressing the reaction sites, is proposed.

Experimental procedure

Preparation of alumina

For the isotopic exchange experiments and the X-ray diffraction, alumina was sputtered onto a silica glass substrate by an rf-diode glow discharge magnetron sputtering instrument (Shimadzu HSR-322S). An aluminum foil substrate was also employed when a considerable amount of the alumina sample was required for the characterization. An α-alumina target of purity 99.9999% was set

under the substrate. Pressure and flow rate of argon discharge gas were adjusted to 0.01 Torr (1 Torr = 133.3 Pa) and 5 cm^3 min^{-1}, respectively. Temperature control of the substrate was not carried out. An rf power of 200 W was utilized and the average deposition rate was then 0.58 nm s^{-1}, measured by a quartz crystal microbalance, Inficon XTC.

Characteristics of the deposited alumina were evaluated by an X-ray diffractometer (XRD), Rigaku RAD-2C, equipped with an attachment for measurement of thin films where Cu-K_α was used and the θ angle was fixed at 2°, and by a thermal analysis unit, Rigaku SN 82151, with a temperature increase of 10 K min^{-1} for the DTA and TG measurements.

The coordination numbers of aluminum in powdered alumina samples were measured by a JEOL JNM-X400 NMR spectrometer. ^{27}Al NMR spectra were obtained at a resonance frequency of 104.17 MHz at 9.4 T with the magic angle spinning (MAS) technique at 7.0 kHz with a zirconia rotor. $\pi/18$ pulses of 0.5 μs were applied and the repetition time was 1 s. This short excitation pulse assures that the error is less than 5% in the central transition (13). Chemical shifts of ^{27}Al were recorded with respect to $AlCl_3 \cdot 6H_2O$. ^{27}Al CP/MAS NMR spectra were also measured by using alumina samples without heat treatment and with heat treatment at 1073 K under conditions satisfying the Hartman–Hahn condition (14). A contact time of 0.5 ms was employed and the repetition time was 3 s.

Kinetic measurements

Hydrogen exchange rates between D_2 and H_2O were measured at 803 K on alumina of surface area 35 cm^2, prepared by sputtering and positioned in a silica glass. The operating temperature was selected as a compromise between the sluggish exchange rate at low temperatures and avoidance of the phase transition of alumina during the kinetic runs at high temperatures. The progress of the exchange reaction was followed by monitoring the variation of the quantities of D_2, HD, and H_2 with a quadrupole mass spectrometer, Nichiden Anelva AQA-100MPX. The isotope effects on introducing the sample gas to the mass analyzing chamber and the ionic reactions in the chamber were taken into account and the readings were corrected. The other details of the experimental setup and procedures were as described previously (9).

Results

Characterization of sputtering alumina

Alumina prepared by sputtering was transparent and the surface was smooth. The weight loss of about 1% caused by dehydration was completed below 600 K in the TG curve measured under atmospheric conditions, as Peri and Hannan (15) observed that heating at 673 K removed all water molecules though surface hydroxyl groups still remained, and any significant weight changes were not observed above that temperature. This implies that the sputtered alumina satisfied its stoichiometry: there was no significant oxygen deficiency. In the DTA curve, two exothermic peaks appeared at 1170 K and 1460 K. The phase transition was followed by XRD using alumina samples treated at various temperatures. The alumina treated at lower than 1073 K was amorphous; γ-type appeared at 1173 K, then α-type coexisted at 1273 K, and finally the alumina was composed of only α-type at 1373 K. As a result, two peaks in the DTA curve are attributed to the transitions from amorphous to γ-type and from γ-type to α-type, respectively. It is to be noted that the transition temperature of amorphous to γ-type, 1170 K, is 200–400 K higher than other alumina obtained by conventional techniques such as thermal decomposition of aluminum hydroxide (970 K) (16) and anodization of aluminum (770 K) (17).

Figure 1 shows typical ^{27}Al MAS NMR spectra of heat-

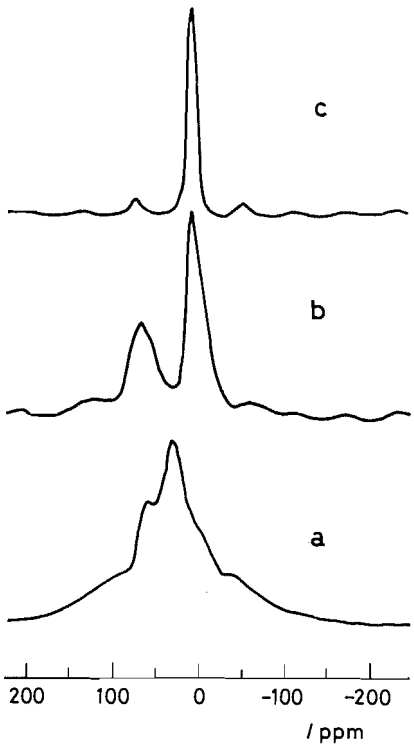

FIG. 1. Variation of ^{27}Al MAS NMR spectrum with heat treatment of alumina: (*a*) as prepared, (*b*) 1173 K, and (*c*) 1473 K. Resonance frequency = 104.17 MHz, excitation pulse = 0.5 μs, repetition time = 1 s, and number of scans = 256.

treated alumina. Three peaks were found in the spectra and the chemical shifts were about 5, 35, and 70 ppm, respectively. The chemical shifts of octahedrally (sixfold) and tetrahedrally (fourfold) coordinated aluminum are well established, appearing in the regions 0–20 ppm and 50–80 ppm (18), respectively. The other chemical shift around 30 ppm has been assigned to the fivefold coordination and it exists only in disordered materials (19). The observed spectra were resolved into three Gaussians to separate the coordinations, where the line width and intensity were adjusted to minimize the root-mean-square errors between the observed and the calculated spectra. The amounts of the different coordinations were evaluated from the area of each Gaussian. This procedure made a quantitative evaluation of the coordination states possible. Variations of the coordinations are shown in Fig. 2 as a function of the temperature of heat treatment. The ratio of the coordinations varied with the temperature. At temperatures lower than 1100 K, four-, five-, and sixfold coordinated aluminum existed in a ratio about 1:2:1. The fivefold coordination disappeared above 1150 K and the four and sixfold coordinations increased in the fractions, 35 and 65%, respectively. When the temperature was raised over 1400 K, the alumina consisted solely of the sixfold coordination. The transition temperatures correspond to the peak temperatures observed in the DTA curves. The structures tell us that α-alumina is composed of only sixfold coordinated aluminum and the coordination numbers of γ-alumina are four and six in the ratio 1:2, while the ratio of the coordinations in the amorphous alumina prepared by sputtering has been determined to be 1:2:1 in the present measurements.

^{27}Al CP/MAS NMR spectra with different heat treatments are shown in Fig. 3. The surface environment of alu-

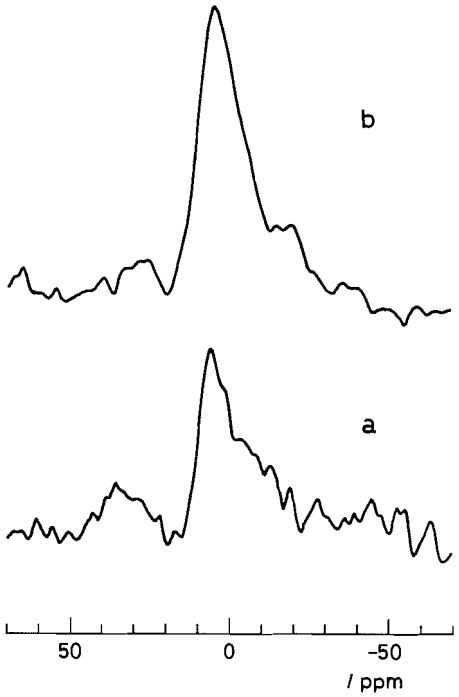

FIG. 3. ^{27}Al CP/MAS NMR spectra of alumina (*a*) without and (*b*) with heat treatment at 1073 K. Contact time = 0.5 ms, repetition time = 3 s, and number of scans > 21 000.

minum can be obtained by the cross polarization technique between ^{27}Al and ^{1}H (20) because the surface of alumina is covered with hydroxyl groups. Quantitative analysis of the peak strength is, however, difficult because the peak intensity depends on the separation between aluminum and proton and on the symmetry. Both samples should belong to the amorphous type according to the results from the bulk measurements, i.e., DTA and ^{27}Al MAS NMR, but the local environment of the surface exhibited different features. Two peaks, six- and fivefold coordinated aluminum, were observed at ca. 5 and 35 ppm, respectively, for the sample without heat treatment. However, the intensity of the fivefold was very weak relative to the sixfold coordination, in

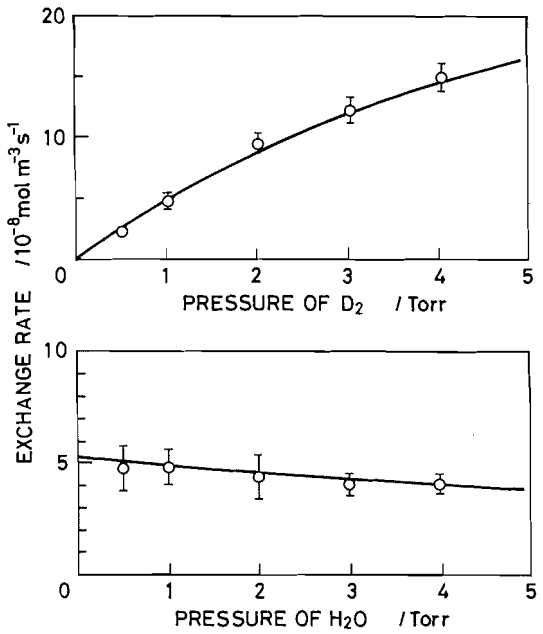

FIG. 4. Pressure dependence of hydrogen exchange rate with variation of deuterium and water pressures. Fixed gas pressure is 1 Torr in each case. Solid lines are regression curves according to eq. [7].

contrast to the bulk measurements where the ratio was ca. 2:1. Furthermore, the fourfold coordination was hardly observable in the spectrum. This low sensitivity is attributed to the unfavorable CP parameters caused by the geometry of the tetrahedral site and adsorbed hydroxyl groups on the site. It has been observed that substances composed of completely fourfold coordinated aluminum, such as lithium aluminum hydride and sodium magnesium aluminosilicate, give no significant signals in the CP/MAS NMR spectrum (20). Fivefold coordinated aluminum at the surface is formed by unsaturation of the sixfold coordination (12). Hydroxyl groups easily occupy the unsaturated sites exposed at the surface, resulting in the formation of the sixfold coordination and hence a decrease in the ratio of the fivefold coordination at the surface. Fivefold coordinated aluminum disappeared in the CP/MAS NMR spectrum when alumina was heat treated at 1073 K. This indicates that the transition from amorphous to γ starts at lower temperatures at the surface than in the bulk (see Fig. 2). Removal of water or hydroxyl from alumina might facilitate the transition since the desorption would be accompanied by some reorganization. This interpretation is in accordance with the fact that sputtered alumina has a higher transition temperature than alumina prepared by other techniques, as mentioned above, in which some amount of residual water or hydroxyl would exist.

Hydrogen isotopic exchange on alumina

Initial exchange reaction rates were determined by the decrease in D_2 in a reaction cell heated at 803 K by an electric furnace. The temperature fluctuation was within ±5 K. Variations of the exchange rates as a function of the pressures of D_2 and H_2O are shown in Fig. 4 where alumina as prepared was employed. The fixed gas pressure was set to 1 Torr. The D_2 pressure dependence was evaluated preliminarily by curve fitting with three types of functions (Fig.

For personal use only.

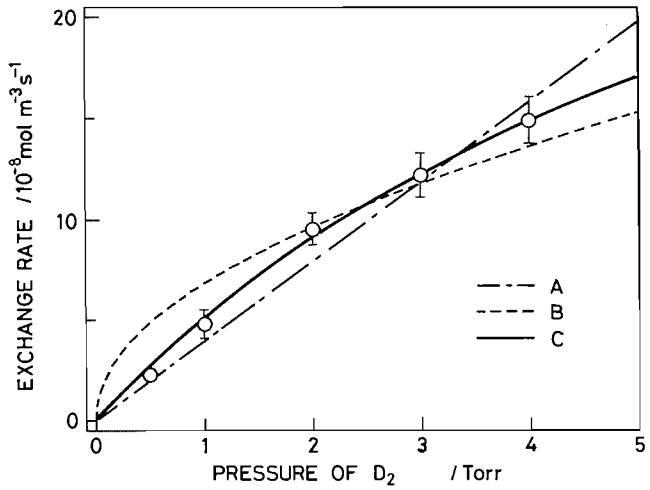

FIG. 5. Curve fitting for D_2 pressure dependence of the exchange rate. (*a*) $r = 4.0 \times 10^{-8} C_{D_2}$, (*b*) $r = 6.8 \times 10^{-8} C_{D_2}^{1/2}$, (*c*) $r = 5.8 \times 10^{-8} C_{D_2}/(1 + 0.14C_{D_2})$.

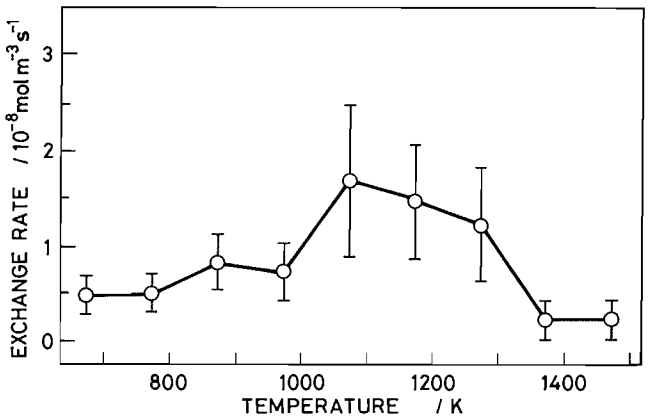

FIG. 6. Change of hydrogen exchange rate on alumina heat treated at various temperatures. Pressures of deuterium and water were 1 Torr. Vertical lines indicate the errors.

5). The exchange rate increased with increasing pressure of D_2 depending on the D_2 concentration rather than on the square root, and the fitting curve (*c*) satisfied the relation. It seems that the adsorption took place without dissociation. H_2O slightly inhibited the exchange rates, where it was not plausible to assume that condensation of water on the catalyst hindered transport of reactants or caused the inhibition because the experiments were performed under such low-pressure conditions. The possible reaction mechanism will be discussed later.

The exchange rate varied with temperature of heat treatment, as shown in Fig. 6. The quantitative reproducibility was poor in specimens separately prepared; however, each specimen showed a similar variation with the temperature and the results obtained by repeated measurements using a given specimen agreed satisfactorily. The error bars in the figure, which are large, indicate that the fluctuation originated from different specimens measured. The catalytic activity increased at 1073 K, then alumina lost its activity at the temperatures over 1373 K. The catalytic change is attributed to the phase transition of alumina: γ-alumina has the highest activity but the α surface does not exhibit an appreciable catalytic activity. It seems that the catalytic activity is responsible for the amount of fourfold coordinated aluminum, although the transition temperature shifted to somewhat low temperature compared to the NMR spectra because the surface could transform at low temperatures and the exchange rate depended on the surface state but not on the bulk state. The BET surface area of alumina as prepared and treated at 1273 K did not cause any significant difference, and it was ca. 2 $m^2 g^{-1}$ for both samples, which were prepared by collecting the deposit on aluminum foil and weighed 0.2–0.3 mg. Therefore, the difference in the exchange rates could not be caused by that of the actual surface area; Abbatista *et al.* reported that amorphous alumina prepared by the conventional method decreased the surface area and increased the catalytic activity by a factor of three in the dehydration reaction of methanol after the transition to γ-alumina by thermal treatment (21). It is to be noted that the surface area of γ-alumina thus prepared by sputtering and heat treatment is extraordinarily small compared to that of the usual active transition alumina, which has a surface area up to several hundred $m^2 g^{-1}$.

Discussion

The surface adsorptive states of hydrogen and water on alumina were investigated by molecular orbital (MO) calculations to clarify the states in the course of the exchange process. Aluminum at an alumina surface is bonded to unsaturated oxygen or hydroxyl groups, or is exposed as its bare state. Under ambient conditions, almost all of the bare and oxygen sites are covered by hydroxyl groups due to adsorption of water (22). The adsorption forms a bond and occupies the unsaturated sites, so that only a small amount of fivefold aluminum with unsaturated coordination was detected at the alumina surface in the CP/MAS NMR results. However, the hydroxyl groups are removed at high temperatures, e.g., evacuation at 800 K decreases the coverage of hydroxyl groups to 0.3 (23). Thus unsaturated oxygen and bare aluminum exist at the alumina surface at 803 K, which is the temperature at which the present kinetic experiments were conducted, and these sites function as Lewis acid and base providing adsorptive sites or catalytically active sites (12, 24). Adsorption of hydrogen on alumina has been considered to take place at the acid–base sites composed of coordinatively unsaturated aluminum and oxygen, on the basis of results of IR measurements (11) and quantum chemical calculations (24). So, *ab initio* MO calculations were conducted using small clusters, modeling alumina with three- and fivefold coordinated aluminum formed by unsaturation of the four- and sixfold coordinations, respectively; the Al—O network was terminated by hydrogen as $Al(OH)_3$ and $Al(OH)_5$. The model clusters employed are shown in Fig. 7 together with the optimized parameters. The calculations were carried out using the GAUSSIAN-82 program (26). The structures were optimized by using the 3-21G basis set with the gradient method. The angles of Al—O—H and O—Al—O were fixed and the separations of Al—O and O—H were optimized for the coordinatively unsaturated sites. In the case of the adsorbed states of hydrogen and water, the structures of the adsorbents kept their original coordinatively unsaturated structures, and separations between adsorbates and adsorbents and the related angles were optimized. No stable structure was obtained in hydrogen adsorption on alumina with fivefold coordinated aluminum.

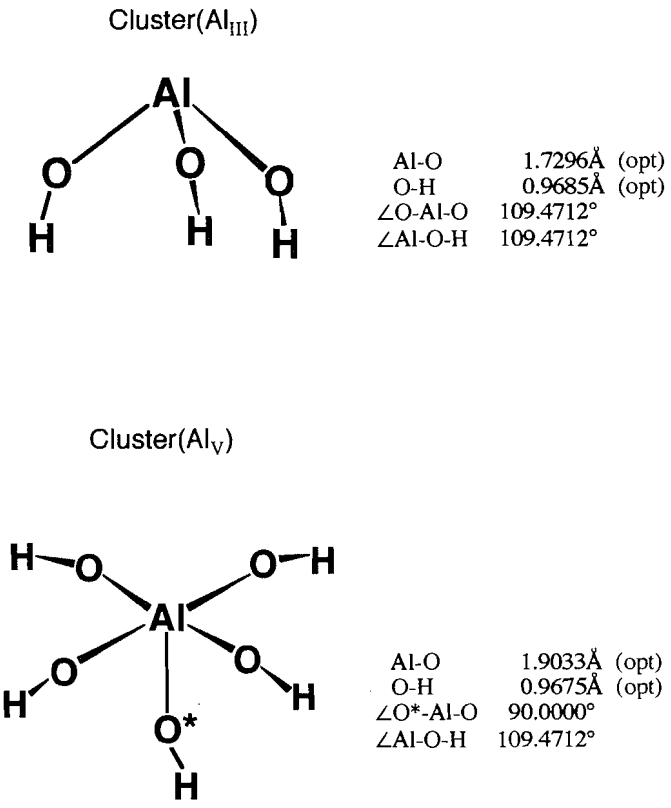

FIG. 7. Model clusters for alumina with coordinatively unsaturated aluminum.

TABLE 1. Calculated energy of clusters and heat of adsorption

Cluster	Energy (hartree)	Heat of adsorption (kJ mol^{-1}) Adsorbed site	Adsorbate D_2	Adsorbate H_2O
D_2	−75.5860	$Al(OH)_3$	127.3	302.7
H_2O	−1.1230	$Al(OH)_5$	—	83.2
$Al(OH)_3$	−465.7731			
$Al(OH)_5$	−615.6596			
D_2 on $Al(OH)_3$	−466.9446			
D_2 on $Al(OH)_5$[a]	—			
H_2O on $Al(OH)_3$	−541.4744			
H_2O on $Al(OH)_5$	−691.2773			

[a]Stable structure is not obtained.

These optimized geometries were used for single point calculations with the 3-21G basis set in order to obtain the total energy. The results and the resulting heats of adsorption are given in Table 1 for the respective cases. The heats of adsorption thus obtained may not be *quantitative* but the order of the values is plausible: H_2O at $Al(OH)_3$, D_2 at $Al(OH)_3$, and H_2O at $Al(OH)_5$. The experimental results of the exchange kinetics were strongly dependent on D_2 pressure as shown in Fig. 4, and the active site should be related to the fourfold coordinated aluminum judging from the results in Fig. 6. The adsorption site for D_2 must be the threefold coordinated site from the MO calculations because the adsorptive state at the fivefold coordination is unstable and a large portion of the fourfold coordinated

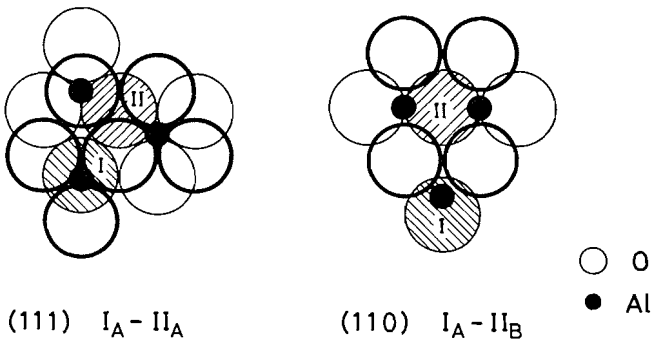

FIG. 8. Examples of the Lewis acid–base pair produced from adjacent aluminum sites. Circle with thin line denotes oxygen existing at the upper layer. OH is desorbed from the hatched I site and H is desorbed from the hatched II site; they becomes the acid and base sites, respectively.

TABLE 2. Net charge of adsorption for different adsorptive states

State X	X-OH	X-O	X-
I_A	−0.25	−1.25	+0.75
I_B	−0.5	−1.5	+0.5
II_A	+0.25	−0.75	+1.25 (+0.5 + 0.75)[a]
II_B	0.0	−1.0	+1.0 (+0.5 × 2)[a]
III	+0.5	−0.5	+1.5 (+0.5 × 3)[a]

[a]The values in parentheses are the net charges for the fragments.

aluminum would be unsaturated at a high temperature such as 803 K and would have the threefold coordination. Competitive adsorption of H_2O is also possible at the site and the heat of adsorption is greater than that of the D_2 adsorption, and hence the threefold aluminum site is in favor of the H_2O adsorption. H_2O can be adsorbed also at the fivefold site but the heat is small, i.e., the desorption is easy there.

Now we consider the adsorptive states. The (111), (110), and (100) planes are preferentially exposed at the surface of active transition alumina such as the γ- and η-types. Almost the whole surface was covered by adsorbed hydroxyl groups at room temperature and the states have been classified into five types (12, 27): I_A, I_B, II_A, II_B, and III, where the number denotes the number of aluminum atoms participating in the adsorption and subscripts A and B mean tetrahedral and octahedral aluminum atoms, respectively, with the exception of II_A, which is composed of a tetrahedral and an octahedral aluminum atom, and III, which contains three octahedral aluminum atoms, and each type has different vibrations of the O—H stretching. We assume that such sites exist also in amorphous alumina. As shown in the experimental results and the MO calculation, D_2 can be adsorbed only at the fourfold aluminum. The layers containing fourfold aluminum have sites where the different types adjoin each other as nearest neighbors: I_A–II_A on the (111) plane, and I_A–II_B on the (110) plane (Fig. 8). The other possible combination is II_B–III but it consists only of sixfold aluminum. The I_B site also exists due to the removal of aluminum ion from II_A or II_B. Since a large fraction of hydroxyl groups are removed as water from the surface at 803 K as mentioned before (23), OH is desorbed from I_A and H is desorbed from II_A or II_B on considering the values of the net electronic charge (12) given in Table 2, which can be a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

measure for stability. The sites where the desorption occurs are indicated by hatching in Fig. 8. In consequence, Lewis acid–base pairs consisting of coordinatively unsaturated threefold aluminum and oxygen are produced (Fig. 8). It is expected that analogous pairs would exist also in the case of the amorphous state. These sites denoting A–B, where A means the Lewis acid site and consists of the threefold aluminum and B means the base site, can be an adsorption site for D_2. The exchange of hydrogen and the desorption should be rate-determining steps because of the D_2 dependence of the exchange kinetics.

A possible scheme for the exchange process is proposed as below.

$$[1]\quad \text{A–B} + \text{D}_2 \overset{K_1}{\rightleftarrows} \begin{matrix} \text{D} & \text{D} \\ | & | \\ \text{A–B} \end{matrix}$$

$$[2]\quad \begin{matrix} \text{D} & \text{D} \\ | & | \\ \text{A–B} \end{matrix} + \text{S–H} \overset{k}{\rightarrow} \text{DH} + \begin{matrix} \text{D} \\ | \\ \text{A–B} \end{matrix} + \text{S}$$

$$[3]\quad \text{S} + \text{H}_2\text{O} \overset{K_3}{\rightleftarrows} \text{S–H}_2\text{O}$$

$$[4]\quad \begin{matrix} \text{D} \\ | \\ \text{A–B} \end{matrix} + \text{S–H}_2\text{O} \overset{K_4}{\rightleftarrows} \text{DHO} + \text{A–B} + \text{S–H}$$

$$[5]\quad \text{A–B} + \text{H}_2\text{O} \overset{K_5}{\rightleftarrows} \begin{matrix} \text{OH} & \text{H} \\ | & | \\ \text{A–B} \end{matrix}$$

where k and K are rate constant and equilibrium constant, respectively. Although step [2] might be separated into a surface reaction and a desorption process of DH, both processes were combined above because the rate of desorption is usually not known separately (28); in step [4] this is also the case. D_2 is adsorbed at the Lewis acid–base site A–B containing unsaturated threefold aluminum and the adsorption would be dissociative because of its high heat of adsorption at the threefold aluminum, as can be seen in Table 1 (eq. [1]). At the A–B site, H_2O adsorption is also possible (eq. [5]); the adsorption competes with the adsorption of D_2 and the adsorptive state is stable because of the high value of the heat of adsorption. Then the adsorbed D_2 at A–B exchanges with H from S–H, producing DH and leaving D adsorbed at A–B and site S (eq. [3]). Here, the source supplying H denoted as S–H must be present at the start of the exchange process because sources formed by adsorption of H_2O should not participate in this rate-determining step; otherwise we should have observed a strong dependence of H_2O pressure on the exchange rate, but we could not. The S–H probably consists of the remaining hydroxyl groups on the alumina surface because a significant percentage of the surface would be still covered by hydroxyl groups under the present experimental conditions (23). The dehydrogenated site S adsorbs H_2O (eq. [3]). Although the site is simply denoted by S because we could not know the structural state, it is probable that the site is also composed of the Lewis acid–base pair consisting of fivefold aluminum sites, which is favorable for the adsorption of polar molecules such as water and the heat of adsorption is low. The two types of adsorption sites are regenerated by producing DHO and they recover their original states, A–B and S–H (eq. [4]).

On assuming that amounts of DH, H_2, DHO, and D_2O are small because the exchange rates were measured in the early stage, the rate equation becomes

$$[6]\quad r = \frac{kS_1^T S_2 K_1 C_{D_2}}{1 + K_1 C_{D_2} + K_5 C_{H_2O}}$$

where r is the hydrogen exchange rate, C denotes concentration, and S_1^T and S_2 are the total number of A–B sites and the number of S–H sites, respectively. S_2 may be constant at the initial stage of the exchange process because the S–H "site" is considered to include those sites adsorbing OH remaining at the surface. This equation was applied for the least-squares fitting of the experimental results, resulting in a satisfactory agreement with the experimental values as shown by the solid lines in Fig. 4, and the regression gave a relation:

$$[7]\quad r = \frac{6.09 \times 10^{-8} C_{D_2}}{1 + 0.150 C_{D_2} + 0.086 C_{H_2O}}$$

where the units of r and C are given by mol m^{-3} s^{-1} and Torr, respectively. Coefficients in the denominator are equivalent to the adsorption equilibrium constants for reactions [1] and [5]. The equilibrium equation can be expressed as follows (29),

$$[8]\quad K = \frac{C_a}{C_g C_s} = \frac{f_a}{f_g f_s} \exp\left(\frac{H_{ad}}{RT}\right)$$

where f is a partition function, subscripts a, g, s denote adsorbed species, reactant gas, and site, respectively, and H_{ad} is equal to the heat of adsorption where the sign is positive when the adsorptive process is exothermic. The partition function for the site may be taken as unity because it has little freedom of motion. The partition function for adsorbed species may also be negligible in terms of the translation and the rotation. On denoting translational, rotational, and vibrational terms by subscripts t, r, and v, respectively, the above equation is represented by

$$[9]\quad K = \frac{f_{a,v}}{f_{g,t} f_{g,r} f_{g,v}} \exp\left(\frac{H_{ad}}{RT}\right)$$

If the change in the fundamental vibrations due to adsorption is small and (or) the new modes to be created by adsorption have relatively high wavenumbers, say, higher than 1500 cm^{-1}, the ratio of the vibrational partition functions of gas and the adsorbed species can be taken as unity. Equation [9] is then reduced to an equation composed solely of the partition functions of translational and rotational contributions for gas. Using the values of the mass and the moment of inertia for D_2 and H_2O (30), and the values obtained for K_1 and K_5, the heats of adsorption can be estimated as 145 ± 3 kJ mol^{-1} for the adsorption of D_2 and 177 ± 7 kJ mol^{-1} for H_2O. The order of magnitude corresponds to the result obtained by MO calculations in the case of adsorption at the threefold aluminum site. The value for the water adsorption is equivalent to the result for a γ-alumina sample outgassed at 800 K, measured by means of a differential microcalorimeter by Hendriksen *et al.* (31). In the case of hydrogen adsorption on alumina, Senchenya and Kazanskii have given a value, 110 kJ mol^{-1}, which is close to the

For personal use only.

present result, for the heat of adsorption at the threefold coordinatively unsaturated aluminum site (25).

Thus the proposed model can explain the experimental results: the strong dependence of the exchange rate on D_2 pressure, the inhibition caused by the presence of H_2O, and the function of the fourfold aluminum as the active site. The concentration dependence of the exchange rate appeared to be physisorptive as described in the results section, but the adsorption must be dissociative from the viewpoint of the heat of adsorption. The reason becomes clear on considering the model: a D_2 molecule is adsorbed dissociatively at a Lewis acid–base pair but the adsorbed D atoms do not work equally in the hydrogen exchange due to their different environments, and hence only a D atom adsorbed at the threefold aluminum is effective for the exchange in the rate-determining step (eq. [2]); accordingly, the exchange rate depends on D_2 concentration rather than on its square root. Phase transition by heat treatment affected the exchange rate at the alumina surface together with the change in the coordinated states. A threefold coordinatively unsaturated site, which represents a Lewis acid–base site for the rate-determining step, plays an important role in the hydrogen exchange process at high temperatures. Since unsaturated threefold aluminum is produced from the saturated fourfold state at the surface, the amount of fourfold aluminum in the bulk can be a measure of the amount of the threefold state at the surface, and the state enhances the exchange rate; consequently, the amount of fourfold aluminum was closely related to the exchange rate, as can be seen in Figs. 2 and 6.

In conclusion, the active site in the hydrogen exchange process on alumina between D_2 and H_2O is a Lewis acid–base pair containing coordinatively unsaturated threefold aluminum. A possible model for the exchange is proposed, based on the pressure dependence of the rate and the estimation of heats of adsorption. Although the model must be verified by further detailed energy calculations and others, at least it is assumed to be true that the active site is composed of the acid–base pair at which D_2 can be adsorbed since otherwise we cannot explain that the exchange rate depends on D_2 pressure rather than the square root of the pressure, which dependence has been observed for pure platinum (8, 9) and platinum–alumina catalysts (3).

Received October 13, 1992

TREVOR J. BROXTON and ROBIN A. COX. Can. J. Chem. **71**, 670 (1993).

The hydrolysis of 5-nitro-2-(trifluoroacetylamino)benzoic acid (**1**) has been studied at pH 7 in water and in the presence of micelles of cetyltrimethylammonium bromide (ctab) and of copper-containing micelles formed from the reaction of *N,N,N'*-trimethyl-*N'*-hexadecylethylenediamine and cupric chloride. It has been found that the hydrolysis of **1** is inhibited by micelles of ctab but strongly catalysed by the copper-containing micelle at this pH. At a higher pH where the hydroxide ion reaction becomes important the reaction is catalysed by micelles of ctab as well, but the catalysis is stronger by the copper-containing micelle. The effect of added sodium chloride on the rate of reaction is shown to be larger for reaction in the presence of ctab than for reaction in the presence of the copper micelles. Also reported are the effects of the buffer concentration on the rate of reaction at various pH for both micelles. It is concluded that the mechanism of reaction in the copper-containing micelle involves a metal-bound hydroxyl rather than a free hydroxide ion loosely associated with the cationic micelle surface. It is interesting that the catalysis of this reaction by the copper-containing micelle is large enough to allow amide hydrolysis at a reasonable rate at neutral pH at ambient temperature.

TREVOR J. BROXTON et ROBIN A. COX. Can. J. Chem. **71**, 670 (1993).

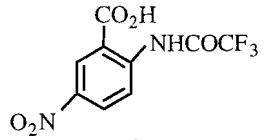
On a étudié l'hydrolyse de l'acide 5-nitro-2-(trifluoroacétylamino)benzoïque (**1**) dans l'eau à un pH de 7 et en présence de micelles de bromure de cétyltriméthylammonium (bcta) ou de micelles contenant du cuivre formées par la réaction de la *N,N,N'*-triméthyl-*N'*-hexadécyléthylènediamine et le chlorure cuivrique. On a trouvé que l'hydrolyse de **1** est inhibée par la présence de micelles de bcta, mais que, à ce pH, elle est fortement catalysée par la micelle contenant le cuivre. À un pH plus élevé, quand la réaction de l'ion hydroxyde devient importante, la réaction est aussi catalysée par les micelles de bcta; toutefois, la catalyse est plus forte avec la micelle contenant le cuivre. On montre que l'addition de chlorure de sodium provoque un effet plus grand sur la réaction réalisée en présence de bcta que sur celle réalisée en présence de micelles de cuivre. On rapporte aussi les effets de la variation de la concentration du tampon sur les vitesses des réactions à divers pH, en présence des deux micelles. On en conclut que la mécanisme de la réaction avec la micelle contenant du cuivre implique un groupe hydroxyle lié au métal plutôt qu'un ion hydroxyde libre faiblement associé avec la surface micellaire cationique. Il est intéressant de réaliser que la catalyse de cette réaction par les micelles contenant le cuivre est suffisamment importante pour permettre l'hydrolyse de l'amide à une vitesse raisonnable, à un pH neutre, à la température ambiante.

[Traduit par la rédaction]

Introduction

The preparation and the catalytic activity of metallomicelles on various organic reactions is currently of interest. Menger *et al.* (1) have reported the preparation of the copper(II) complex of *N,N,N'*-trimethyl-*N'*-tetradecylethylenediamine and have studied its effect on the hydrolysis of phosphate esters. Tonellato and co-workers (2) have reported the preparation of metal chelating micelles containing copper(II) or zinc(II) and have studied their effect on the hydrolysis of *p*-nitrophenylpicolinate. Tonellato and co-workers (3) also reported the preparation of bolaform metallomicelles and studied their effect on the same reaction. Nolte and co-workers (4) have reported the preparation of vesicles containing metal ions including copper(II) and zinc(II). Engbersen and co-workers (5) have also reported the preparation of copper(II)- and zinc(II)-containing metallosurfactants and studied their effect on both carboxylic and phosphate ester hydrolysis.

Because of our interest in the kinetic and mechanistic effects of micelles on amide hydrolysis (6) and because of the reported (7) cleavage of *N*-terminal peptides by the complex $Co(trien)H_2O(OH)^{2+}$ we have studied the effect of the C_{16} analogue of the Menger metallomicelle on the hydrolysis of 5-nitro-(2-trifluoroacetylamino)benzoic acid (**1**).



1

We have compared the effect of micelles of cetyltrimethylammonium bromide (ctab) and the copper-containing micelle on the hydrolysis of this amide. We report the effects of detergent concentration (Table 1), the pH (Table 2), the concentration of added salt (Table 3), and the buffer concentration (Table 4) on the rate of this amide hydrolysis in both micelles.

Results and discussion

N,N,N'-Trimethyl-*N'*-hexadecylethylenediamine was prepared from the reaction of *N,N,N'*-trimethylethylenediamine with 1-bromohexadecane in absolute ethanol. This

amine was then treated with anhydrous cupric chloride to give the copper-containing metallomicelle.

From Table 1 we see that at pH 7 the hydrolysis of **1** is inhibited by micelles of ctab but strongly catalysed (×50) by the copper-containing micelle. As the pH is increased (Table 2) the observed rate of hydrolysis increased in all systems. The reaction in ctab was actually catalysed at a pH of 7.5 or above and the magnitude of this catalysis increased as the pH was increased. We thus conclude that the water reaction at pH 7 is inhibited by micelles of ctab but that the hydroxide ion reaction at higher pH is catalysed. This effect was previously observed (8) for the hydrolysis of aspirin. In that case, however, the water reaction involved intramolecular general base catalysis by the ionized carboxylate group. Previous studies (9) of the hydrolysis of **1** in water provided no evidence of such intramolecular catalysis of this reaction. As is typical of amide hydrolysis, the reaction in water is slow at a neutral pH and a pH of at least 9 is required before hydrolysis is observed at a rate similar to that found in the copper micelle at a pH of 7. The magnitude of the catalysis of this hydrolysis by the copper-containing micelle at pH 7 is interesting in that it results in amide hydrolysis at a reasonable rate in neutral solution at ambient temperature. The

half-life of this hydrolysis is 20–66 min, depending on the concentration of the copper-containing micelle. While the cleavage of N-terminal peptide bonds with the complex $Co(trien)H_2O(OH)^{2+}$ was also achieved at pH 7.5, a temperature of 65°C was necessary for that reaction (7).

Salt effects

The effect of added sodium chloride on the rate of hydrolysis of **1** (Table 3) is instructive. In ctab at pH 7.5 or 8, approximately 20% reduction in rate is seen on the addition of NaCl. This is consistent with a hydroxide ion reaction. The added chloride ions compete with hydroxide ions for sites on the micelle surface, as required by the pseudophase ion exchange (PPIE) kinetic model (10), resulting in a decrease in the observed rate. In the copper-containing micelle the effect of added chloride ions is much smaller (5–8%) and this indicates that ion exchange at the surface of this micelle is less important than in ctab. According to Menger *et al.* (1), either a hydroxyl chelated to the copper or a hydroxide ion loosely associated with the cationic micelle surface could be the catalytically active nucleophile in this type of micelle. The small effect of added chloride ions argues strongly in favour of the metal-bound hydroxyl. This metal-bound hydroxyl is most likely formed by the loss of a proton from a metal-bound water molecule. The pK_a of a copper-bound water molecule has been variously estimated (11) to be as high as 9 or to be as low as 6.8 (12) depending on the ligand attached to the copper ion and on the geometry of the complex. Menger *et al.* (1) found that in the presence of the copper-containing cationic micelle the hydrolysis rate of their phosphate ester was insensitive to pH between 6.0 and 8.3. They thus concluded that the copper-bound water molecule was completely ionized at pH = 6.0. We observe some variation in the rate of hydrolysis of **1** in the copper-containing micelle between pH 7 and pH 7.5, possibly due to the deprotonation of the metal-bound water molecule as the pH is increased within this range, and this indicates that the pK_a of a copper-bound water molecule in the presence of a

cationic micelle is somewhat higher than Menger suggests. Above a pH of 7.5 in the copper-containing micelle, precipitation of a pale blue material, presumably copper hydroxide, was observed.

Buffer effects

The effect on the rate of hydrolysis of **1**, of increasing the tris buffer concentration 2.5-fold in both ctab and in the copper-containing micelle, is given in Table 4. In ctab at both pH 7.5 and 8.5 such an increase in buffer concentration resulted in a decrease in rate of about 50% at either pH. This is probably due to the inhibitory effect of the added chloride ion component of the buffer on a reaction of hydroxide ion at the surface of the ctab micelle. In the presence of the copper-containing micelle the buffer effect was dependent on the pH, increasing at higher pH. At a higher pH the concentration of free Tris is higher than at a lower pH and it is possible that this is responsible for the inhibitory effect rather than the chloride ion. At pH 7 the rate decreased by about 30% as the buffer concentration was increased 2.5-fold while at pH 7.5 the decrease was 79%. It seems likely that this inhibition could be due to complexation of the free Tris buffer by the metal ion thus excluding water and, ultimately, the metal-bound hydroxyl group, which is the catalytically active species.

The optimum rate of hydrolysis of the amide in the presence of the copper-containing micelle was at 0.27 mM. Menger *et al.* (1) found that the critical micelle concentration (cmc) of their tetradecyl micelle was 0.18 mM. From conductance measurements as a function of detergent concentration we conclude that the cmc of the hexadecyl micelle in the absence of any additives is about 0.8 mM. An interesting observation in this case, however, was that whereas, for ctab solutions, the slope of the graph of conductance versus detergent concentration decreased above the cmc, for solutions of the copper-containing micelle, the slope increased above the cmc.

Further studies showed that the pH of the solution decreased as the detergent concentration was increased. The slope of the plot of pH versus the detergent concentration showed two linear sections with a clear break at 0.8 mM that we attribute to the cmc of this micelle. The pH at this concentration was 5.6. A probable reason for this break in the pH – detergent concentration plot is the increased acidity of the water bound to the copper atom once micelles are formed (1). This results in an increase in the amount of free protons in solution and, as a consequence, an increase in the conductivity above the cmc.

The optimum rate of amide hydrolysis in the copper micelle at 0.27 mM is not unreasonable because it has previously been shown that the cmc of ctab is reduced by additives. Although the normally accepted cmc of ctab in the absence of additives is 0.9 mM (13), previous kinetic studies (14) have indicated that the cmc of ctab in the presence of hydroxide ions and chlorodinitrobenzoate ions may be as low as 0.3 mM. Thus it is not unreasonable that the cmc of the copper micelle may also be reduced in the presence of substrate **1** and tris buffers. We find little difference in the rate of hydrolysis between 0.5 and 5.0 mM ctab. It therefore seems that the substrate is very efficiently solubilized by micelles. Furthermore, the rate in the absence of chloride ions at 0.51 mM ctab (Table 3) was 70% faster than that in water at pH 7.5 (Table 2) while at pH 8 the rate of hydrolysis was more than five times faster in ctab than in water (Tables 2 and 3). This also indicates the presence of micelles even at this low ctab concentration.

Experimental section

Materials

Compound **1** was available from previous work (9); ctab was commercially available (BDH) and was purified by the method of Mukerjee and Mysels (15). Distilled water was further purified by a Millipore system to achieve a resistivity of at least 10 MΩ cm^{-1}.

N,N,N'-Trimethyl-*N'*-hexadecylethylene diamine was prepared by the alkylation of *N,N,N'*-trimethylethylene diamine (6.0 g) with 1-bromohexadecane (7.0 g) in absolute ethanol (35 mL) at reflux for 10 min. The mixture was then cooled and NaOH (2.0 g) in water (2 mL) was added to neutralize the HCl produced. The resulting solution was then heated to reflux for 16 h. The product was cooled to room temperature, added to a mixture of 1-butanol (10 mL), benzene (10 mL), and water (50 mL), shaken, and allowed to separate. The organic layer was washed with a saturated salt solution, separated, dried ($MgSO_4$), and concentrated under vacuum. The product, a yellow semisolid, was distilled under reduced pressure (160°C at 0.05 Torr (1 Torr = 133.3 Pa)) to produce a light yellow solid, mp 30–35°C. The electrospray mass spectrum of this compound was recorded on a VG Bio-Q triple quadrupole mass spectrometer (VG Bio Tech, Altringham, Cheshire, U.K.) using a mobile phase of 50:50 aqueous methanol also containing 1% acetic acid, and had a principal ion at m/z 327 corresponding to the protonated amine.

The copper(II) complex of this amine was prepared by dissolving the amine (1.0 g) in absolute ethanol (10 mL) and adding the solution slowly to a solution of anhydrous $CuCl_2$ in absolute ethanol (15 mL) with stirring. The anhydrous $CuCl_2$ was prepared from the hydrated material by heating at 120°C for 16 h. After addition of the amine the mixture was stirred for 30 min at 0°C. The dark blue-

green precipitate was filtered at the pump, washed with ice-cold ethanol, and recrystallized from ethanol. Further purification was achieved by a second recrystallization, this time from acetonitrile, giving blue crystals, mp 99–101°C. Anal. calcd. for $C_{21}H_{46}N_2Cl_2Cu$: C 54.7, H 10.0, N 6.1%; found: C 54.7, H 9.8, N 6.2. The electrospray mass spectrum of this complex obtained under the above conditions had a principal ion at m/z corresponding to $Cu(L)OAc^+$ where L represents the diamine ligand. This m/z value was for the most intense peak in the isotopic mass cluster and the experimental distribution (100:29:53:15) agreed well with the calculated one (100:25:47:10).

Kinetics

A stock solution (0.01 M) of **1** was prepared in HPLC-grade acetonitrile. Stock solutions of ctab (20 mM) and the copper micelle (1.6 mM, 3 mM, and 10 mM) were prepared in purified water. Tris buffer solutions of pH 7, 7.5, 8, 8.5, and 9 were prepared as described in the Handbook of chemistry and physics (16). Kinetic solutions (6 mL) were made up by taking appropriate amounts of these stock solutions and water as required. Kinetic runs were initiated by the addition of substrate (20 μL) to the kinetic solutions that had been temperature equilibrated (to 31°C) in 1-cm cuvettes in the jacketed cell compartment of a Varian Associates 635 UV–VIS spectrophotometer. Reactions were followed by monitoring product formation at 375 nm. The UV–visible spectrum of the hydrolysis product from this reaction was identical to that of 2-amino-5-nitrobenzoic acid under these conditions.

Critical micelle concentration

The cmc was determined in neutral solution at 30.0°C, using a jacketed beaker containing purified water (30 mL) and a platinum electrode attached to an Activon PT1-10 conductivity meter. Aliquots (0.5 mL) of detergent solution (0.01 M) were added and the conductivity was measured as a function of detergent concentration.

pH

The pH of the detergent solutions as a function of detergent concentration was measured by a similar technique using a glass electrode and a Radiometer PHM 80 portable pH meter.

Chemical and electrochemical oxidation of phenothiazine

ALEXEI N. PANKRATOV,[1] INNA M. UCHAEVA, AND ALEXANDER N. STEPANOV
Department of Chemistry, N.G. Chernyshevskii Saratov State University, Saratov 410026, Russia

Received September 21, 1992

ALEXEI N. PANKRATOV, INNA M. UCHAEVA, and ALEXANDER N. STEPANOV. Can. J. Chem. **71**, 674 (1993)

The oxidation of phenothiazine in dilute solutions of sulphuric acid leads to the corresponding cation radical. Using a potentiometric technique, a pK_a value of 5.72 ± 0.05 was determined for phenothiazine. The kinetics has been studied and participation of both protonated and unprotonated oxidant in the oxidation reaction has been confirmed. Using a voltammetric technique with a rotating disk electrode, the anodic oxidation of phenothiazine was shown to be a one-electron diffusion-controlled process. A quantum chemical explanation was found for the direction of phenothiazine protonation and the absence of a dimerization stage of oxidation.

ALEXEI N. PANKRATOV, INNA M. UCHAEVA et ALEXANDER N. STEPANOV. Can. J. Chem. **71**, 674 (1993)

L'oxydation de la phénothiazine, en solutions diluées d'acide sulfurique, conduit au cation radical. Faisant appel à une technique potentiométrique, on a déterminé un pK_a de 5,72 ± 0,05 pour la phénothiazine. On a étudié la cinétique de la réaction et on a démontré que l'oxydant protoné aussi bien que le non protoné participent à la réaction d'oxydation. Faisant appel à la technique de voltampérométrie avec une électrode à disque tournant, on a démontré que l'oxydation anodique est une réaction impliquant un électron dans un processus contrôlé par la diffusion. On a expliqué la direction de la protonation de la phénothiazine et l'absence d'étape de dimérisation durant l'oxydation.

Introduction

To contribute to the understanding of the mechanisms of oxidation of aromatic amino compounds, investigation of the oxidation reactions of substances containing the fragment Ar-N-Ar′ is of interest. Phenothiazine is representative of such compounds, derivatives of which have found application as photometric redox indicators in dilute solutions of acids (1).

Chemical (2–6) and electrochemical (7, 8) oxidation of phenothiazine has been studied in acidic media. Oxidation of phenothiazine in concentrated sulphuric acid leads via cation radical states to 3,10′-diphenothiazinyl and small quantities of 1,10′-diphenothiazinyl (2). 10-Acyl- and 10-alkylphenothiazines oxidized by HNO_3 and H_2O_2 yield the corresponding sulphoxides and sulphones (3). The reaction of phenothiazine with HNO_3 in the presence of $HClO_4$ results in the formation of 3-nitrophenothiazine-*S*-oxide (4–6). Electrooxidation of some phenothiazines in the chronopotentiometric mode has been studied using a tubular graphite electrode in sulphuric acid media; formation of cation radicals that are stable in acidic medium and unstable in neutral and weakly acidic solutions occurs (7). Some phenothiazine derivatives have been oxidized to sulphoxides in dilute sulphuric acid on a gold anode (8). Thus an investigation of the reactions of different oxidants with phenothiazine and a kinetic study of the homogeneous oxidation process of the substrate seem appropriate. Some additional information about anodic oxidation of phenothiazine may be obtained using a rotating disk electrode.

The aim of the present communication was spectrophotometric, voltammetric, and quantum chemical investigation of the reaction of phenothiazine oxidation in acidic media.

Experimental

Electronic spectra were obtained using a Specord M40 spectrophotometer. Kinetic measurements were carried out with a KFK-2 photoelectric colorimeter using a colour filter No. 5 (λ_{max} = 490 nm). For mixing the solutions, a Budarin vessel (9) was used. The time was measured with a chronometer, from the moment of mixing the solutions, which were thermostatted at 298 K and 315 K using a UT-10 thermostat. The reaction orders for the oxidation reaction of phenothiazine were established using the method of Neues and Ostwald (10). Reaction rate $V = dC_{PO_x}/dt$ (where C_{PO_x} is the concentration of coloured oxidation product of phenothiazine) was measured for reaction mixtures of phenothiazine and ammonium vanadate (concentrations of both substances varying between 2×10^{-5} and 1.4×10^{-4} M) and of phenothiazine (2×10^{-5}–1.4×10^{-4} M) and potassium dichromate (3.3×10^{-6}–2.3×10^{-5} M) in sulphuric acid (2.1×10^{-1}–3×10^{-1}M for vanadate, and 4.4×10^{-6}–8.8×10^{-2} M for dichromate oxidations). Linear dependence of V on concentrations of substrate and oxidant indicated a second-order reaction, first in phenothiazine and first in oxidant.

The value of pK_a for phenothiazine conjugate acid was determined by potentiometric titration using a pH-673.M pH-meter with a glass electrode and a saturated silver, silver chloride reference electrode (26.47 wt.% KCl) at 298 K. The ionic strength of the solution was maintained equal to 0.1 using potassium chloride.

A glassy-carbon rotating disk electrode with a surface area of 0.035 cm^2 was used together with a spiral platinum wire as an auxiliary electrode and a saturated silver, silver chloride electrode (26.47% KCl) as a reference electrode. The circular rotation rates (w) were 81.7; 117.3; 167.6; 209.4; 303.7 rps. Current–potential curves were recorded using a P-5848 potentiostat; the current was registered using an LKD-4 pen recorder. The potential sweep rate was 4 mV/s. To determine the number of electrons involved in the redox process, the method of Hitchman and Albery (11) was applied.

Quantum chemical calculations by the SCF MO LCAO method with CNDO/2, INDO approximations were carried out using the programs of the VIKING complex on a BESM-6 electronic computer (12), and by the Hückel MO method using the program (13) on a personal computer Elektronika D3-28.

Results and discussion

We have stated that a stable, coloured, oxidation product is formed during interaction of phenothiazine with various oxidants: $Ce(SO_4)_2$, NH_4VO_3, $K_2Cr_2O_7$, $KMnO_4$, $(NH_4)_2S_2O_8$, KIO_3, KIO_4, H_2O_2 in the medium of 6.55×10^{-4}–5.4 M sulphuric acid. Spectral curves in the electronic absorption

spectra of oxidized forms of the substrate feature bands with λ_{max} = 436.0 and 516.5 nm. This allows one to conclude, in accordance with literature references (14–16), that the corresponding cation radical is the final product of oxidation in all the aforementioned cases.

At pH about 1–3 in the sulfuric acid solutions studied, phenothiazine is present in the solution prodominantly in the protonated form. This follows from the reported (17) pK_a values of between 4.5 and 7.8 for substituted phenothiazines. At ionic strength 0.1 we found, by potentiometric titration, the value of $pK_a = 5.72 \pm 0.05$. Using the Hückel MO LCAO method and parameters for thiazine (18), a pK_a value of 5.99 was obtained, in acceptable agreement with experimental results. The pK_a value found provides evidence for the protonation of the phenothiazine molecule at the nitrogen atom, which is given a quantum chemical explanation below.

The reaction kinetics of phenothiazine oxidation by ammonium vanadate and potassium dichromate was studied in the sulphuric acid medium. The reaction with both oxidizing agents was shown to be first order in substrate (phenothiazine) and first order in oxidant. Furthermore, the reaction rate depends upon the concentration of the acidic component.

For explanation of the latter, let us consider the following two reaction schemes of substrate with oxidant, assuming the participation of protonated phenothiazine PH^+ in the redox process.

1. The conjugate acid PH^+ reacts with unprotonated oxidant (VO_3^- or $Cr_2O_7^{2-}$):

[1] $PH^+ + Ox \rightarrow POx + Red$

where Ox is the oxidant, Red its reduced form, and POx the product of phenothiazine oxidation. Then the dependence of second-order rate constant k' on acidity would be as follows:

$$k' = \frac{k[H^+]}{K_a + [H^+]}$$

and at $[H^+] >> K_a$ (fulfilled at $pH < (pK_a - 2)$) this leads to the constant value $k' = k$.

2. The species PH^+ interacts with protonated oxidant. Since PH^+ predominates in solution at pH 1–3, no proton transfer occurs before reaction with Ox. If $V \sim [H^+]$ at pH 1–3, it means that another proton transfer occurs before the electron transfers. This may be protonation of the anions of the oxidants: pK_a values for HVO_3 and $HCr_2O_7^-$ are 3.8 and 0.7, respectively (19), and hence the sequence is

[2] $PH^+ \rightleftarrows P + H^+$

[3] $OxH^+ \rightleftarrows Ox + H^+$

[4] $PH^+ + OxH^+ \rightarrow POx + RedH^+$

Since $pH < (pK_a - 2)$, the role of equilibrium [2] is negligible and

$$k' = \frac{k[H^+]}{K_{OxH^+} + [H^+]}$$

where K_{OxH^+} is the equilibrium constant of process [3]. For potassium dichromate at $pH > 2$, $K_{OxH^+} >> [H^+]$ and, approximately,

[5] $k' = K[H^+]/K_{OxH^+}$

The values of $[H^+]$ for H_2SO_4 solutions were estimated assuming a complete first dissociation step and that, with regard to the second step, sulphuric acid is an electrolyte of middle strength: $K_2 = 1.15 \times 10^{-2}$ (20). If the molar concentration of sulphuric acid is C, then, considering the dissociation equilibrium of the HSO_4^- ion, one can obtain

$$[H^+] = 0.5\,(-K_2 + C + \sqrt{(K_2 + C)^2 + 4K_2C})$$

Our experiments have shown that the dependence k' vs. $[H^+]$ for dichromate oxidations within the range of H_2SO_4 concentrations 4.4×10^{-3}–2.2×10^{-2} M is linear, but the line does not pass through the origin and gives a positive intercept at the ordinate axis (Fig. 1). Under the conditions considered, obviously both processes [1] and [4] proceed in parallel. This is related to the existence of the oxidant in solutions at pH 1–3 in the two forms, Ox and OxH^+: at pH 1 the degree of protonation of dichromate anion is 0.334 and at pH 3 it is 0.005.

Additional evidence that the acid–base equilibrium affecting k' at pH 1–3 does not reflect biprotonation of P is the independence of $E_{1/2}$ from pH in the range studied (see below). The electrochemical process does not involve oxidant and hence is not affected by $[H^+]$.

On the basis of the dependence k' vs. $[H^+]$:

$$k' = k + \frac{k}{K_{OxH^+}}[H^+]$$

using the least-squares method, we have evaluated the rate constants k of reaction [1]: $(4.61 \pm 0.71) \times 10^4$ L mol^{-1} min^{-1} at 298 K and $(7.83 \pm 1.08) \times 10^4$ L mol^{-1} min^{-1} at 315 K (confidence intervals have been found for confidence probability 0.95 for three parallel measurements of each k value). An estimation of the activation energy for reaction [1] gives the value of 24.3 kJ mol^{-1}, which confirms the homolytic character of the process.

At H_2SO_4 concentrations exceeding 2.2×10^{-2} M the dependence k' vs. $[H^+]$ is no longer linear, since relationship [5] becomes inadequate. At $C_{H_2SO_4} < 4.4 \times 10^{-3}$ M, linearity of the function $k' = f([H^+])$ is also not observed; this may be related to deprotonation of the species PH^+ and $HCr_2O_7^-$.

To compare with the homogeneous oxidation, electrooxidation of 1 mM phenothiazine was investigated in sulphuric acid solutions containing 50% ethanol and using 0.3 M LiCl as supporting electrolyte. Using a glassy-carbon rotating disk electrode, an anodic wave was obtained with limiting current controlled by diffusion. This was proved by linear dependence of i_{lim} on $w^{1/2}$. The half-wave potential ($E_{1/2}$ = 0.51 V vs. saturated silver, silver chloride electrode in 26.47% KCl solution) is independent of the sulphuric acid concentration between 0.65 and 6.8 mM acid. Independence of $E_{1/2}$ from pH indicates that the species predominating in the bulk of solution undergoes electrooxidation. Because in all instances the conjugate base of a substrate is oxidized more readily than the acid, the observed independence also means that the dissociation of PH^+ under the conditions used is slow when compared with rate of oxidation. The number of oxidations on rotating disk electrodes accompanied by acid–base equilibria reported in the litera-

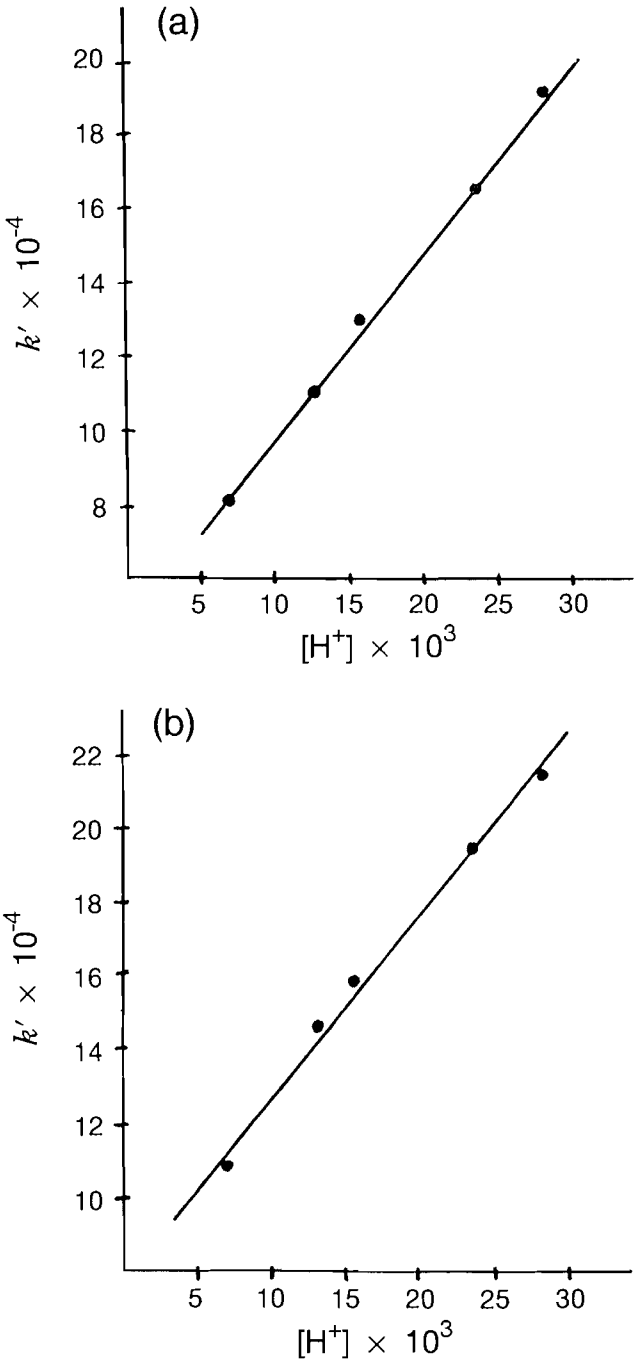

FIG. 1. Dependence of second-order rate constant k' (L mol^{-1} min^{-1}) of phenothiazine oxidation by potassium dichromate upon the hydronium ion concentration (mol L^{-1}) at temperatures (*a*) 298 K and (*b*) 315 K.

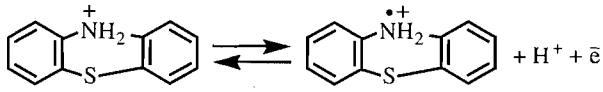
ture (21) is limited and hence no estimate of the rate of dissociation of PH^+ can be offered.

Decay curves of the limiting current with time at the potential 0.80 V vs. saturated silver, silver chloride electrode (26.47% KCl) were measured. A linear dependence of i_{lim} on $t^{1/2}$ (t is time) at the end part of the decay curve provides evidence for mixed control conditions of the anodic reaction in the corresponding time interval (22).

Using the method of Hitchman and Albery, we have found the diffusion coefficient of depolarizer to be 1.00×10^{-5} cm^2 s^{-1} in the medium 1.31×10^{-3} M H_2SO_4. Determination of the number of electrons (n) involved in the redox process gave the value $n = 0.91$, and the phenothiazine cation radical is formed.

A scheme of the both chemical (from the viewpoint of substrate behaviour) and electrochemical oxidation of phenothiazine may be represented as follows:



We have calculated the electronic structure of phenothiazine molecule and cation radical using the methods SCF MO LCAO, CNDO/2, and INDO. One should note the existence of negative charges at the nitrogen and sulphur atoms, as well as at carbon atoms in positions 1 and 3 of the molecule. According to the data of the CNDO/2 method, in the *sp* basis the aforementioned charge values are −0.184, −0.064, −0.040, and −0.014, respectively. Reactions of polar molecules with charged particles are known to be charge controlled (23). On the basis of charge control, electrophilic attack of the hydronium ion at the nitrogen atom during protonation of the phenothiazine molecule can be readily explained.

As has already been mentioned, the phenothiazine cation radical under certain conditions may undergo dimerization leading to the formation of 3,10′-diphenothiazinyl and a small amount of 1,10′-diphenothiazinyl (2). In the present work, the formation of diphenothiazinyls was not detected. At the same time, oxidational dimerization via the cation radical step under identical or similar conditions (oxidation by vanadate or dichromate in sulphuric acid medium) is characteristic for structurally similar diarylamines (24–26). Using the INDO method, we found spin density distribution in the cation radical. An excess of this spin density value features the following atoms: nitrogen (−0.468), sulphur (−0.323), carbon in positions 1 (−0.029) and 3 (−0.071) of the cycle. The most probable centre of recombination is the nitrogen atom. However, N,N-coupling is hindered by the lability of the N—N bond in acidic media (27, 28).

Also, S,S-coupling is impossible, since it would lead to the formation of an S—S bond between positively charged sulphur atoms. Dimerization of the C,S-type cannot be realized either: the formation of sulphonium salts is known to occur only in heterolytic alkylation (but not arylation) reactions of sulphides (29).

Coupling involving the C-3 and C-1 carbon atoms may occur, the latter to a lesser degree owing to both a lesser density of the uncoupled electron and the steric factor (which has been proved for diphenylamine derivatives (25)). From the viewpoint of spin density, the formation of 3,10′- and 1,10′-diphenothiazinyls as well as their relative quantities is explained.

At the same time, following from the present work and the previous data (7), oxidational dimerization for phenothiazine is characteristic to a lesser degree than for diarylamines, the reason being a smaller value of spin density at the nitrogen and C-3 atoms in the phenothiazine cation radical, as compared to the cation radicals of diphenylamines (30).

CONCEPCION LOPEZ, ROSA MA. CLARAMUNT, SWIATOSLAW TROFIMENKO, and JOSÉ ELGUERO. Can. J. Chem. **71**, 678 (1993).

The ^{13}C chemical shifts and some $^{1}H-^{13}C$ coupling constants of 23 pyrazoles and indazoles are reported and discussed. The spectra were recorded in $CDCl_3$ and in DMSO-d_6 solutions and, in several cases, also in the solid state (CP/MAS technique). These data allow us to determine the tautomerism of these compounds in the solid state (usually only one tautomer) and in solution. The position of the tautomeric equilibrium is related to the Hammett σ_m value of the 3(5)-substituent.

CONCEPCION LOPEZ, ROSA MA. CLARAMUNT, SWIATOSLAW TROFIMENKO et JOSÉ ELGUERO. Can. J. Chem. **71**, 678 (1993).

Les déplacements chimiques du carbone-13 et quelques constantes de couplage $^{1}H-^{13}C$ de 23 pyrazoles sont rapportées et discutées. Les spectres de RMN ont été déterminées en solution dans du $CDCl_3$ et DMSO-d_6 et, dans plusieurs cas, à l'état solide (technique CP/MAS). Ces données ont permis de determiner la position de l'équilibre tautomère à l'état solide (en général, un seul tautomère) et en solution. D'une façon qualitative, cette position est reliée au coefficient σ_m d'Hammett.

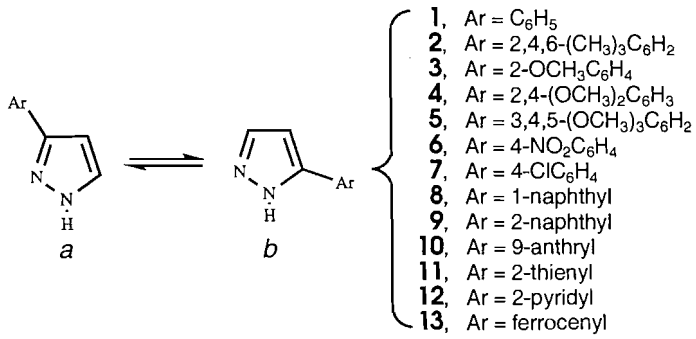
Introduction

The aim of this work is twofold: first, to report accurate and properly assigned ^{13}C chemical shifts and $^{1}H-^{13}C$ coupling constants of a set of N-H pyrazoles; second, to use these data to discuss the tautomeric structure of pyrazoles in solution and, in some cases, in the solid state.

Pyrazoles unsubstituted on nitrogen are important ligands in metallo-organic chemistry, either by themselves or as pyrazolate anions (1–3). Moreover, they can be transformed into tris-pyrazolylborates, one of the most used anionic ligand classes (4). In earlier work, only commercial or readily accessible pyrazoles were used but, lately, more complex pyrazoles have been introduced. This is a consequence of the search for more specific ligand properties towards the metal and, in particular, has led to a series of pyrazolylborates with substituents at positions 3 and 5 of different size and geometry (5–28).

Since NMR, and particularly ^{13}C NMR, is the method of choice to establish the structure of the resulting complexes in solution, a careful characterization of the pyrazolyl ligands is useful (in a subsequent work the corresponding borates will be reported[2]). With this purpose in mind, we report the study of the NMR spectroscopy of 32 N-H pyrazoles (including some indazoles), of which 23 have not been previously described and 9 are already known but are necessary for comparisons.

The formulae of these pyrazoles are represented in Scheme 1 (3(5)-aryl derivatives), Scheme 2 (3(5)-alkyl, 3(5)-alkyl-4-bromo, and 3,5-disubstituted derivatives), and Scheme 3 (bicyclic pyrazoles and indazoles).



SCHEME 1

Results and discussion

Thanks to experience (29–31, 33–39), the assignment of pyrazole and indazole carbon chemical shifts has become routine. For this reason, the ^{1}H NMR study and the NOESY and HETCOR experiments used in some cases will not be reported. Also, most $^{1}H-^{13}C$ coupling constants of the substituents will be omitted for the sake of brevity. The data corresponding to compounds depicted in Schemes 1, 2, and 3 are given in Tables 1, 2, and 3, respectively.

The numbering of pyrazole carbons depends on the chosen tautomer, since the N-H is always N1. For instance, in tautomer **1***a*, C3 is the carbon bearing the phenyl substituent while in **1***b* it is a C-H. In the tables, when there is a letter, *a* or *b*, after the number, the chemical shifts refer to a particular tautomer and the numbering of carbons corre-

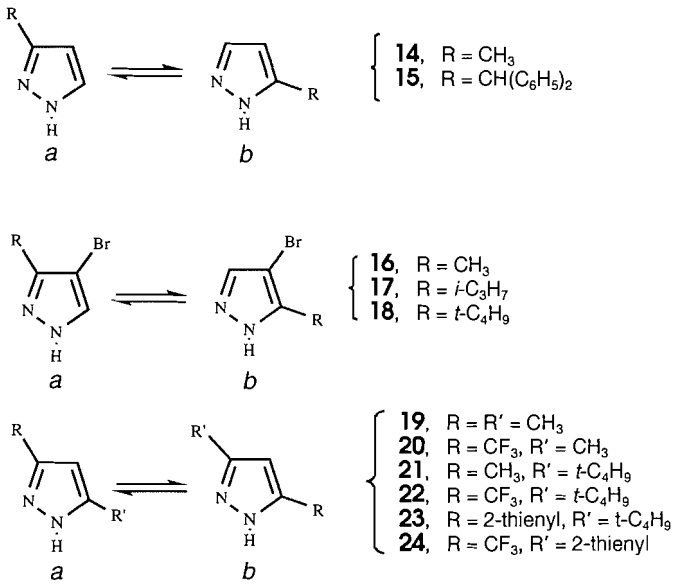

SCHEME 2

sponds to that tautomer. When there is no letter, the chemical shifts are those of the tautomeric mixture; in that case, the numbering *always* corresponds to tautomer *a*, without any implication concerning tautomerism. For instance, C3 in compounds **20**, **22**, and **24** (Table 2) is the carbon bearing a CF_3 substituent.

This problem does not arise for indazoles (Scheme 3) where the atom numbering is independent of tautomerism. In this case, *a* and *b* tautomers (compounds **30–32**) are called 1*H*- and 2*H*-indazoles, respectively.

Chemical shifts and coupling constants of pyrazole and indazole carbons

The chemical shifts of carbons C3 and C5 of Table 1 depend too much on the $a \rightleftharpoons b$ tautomerism and will be discussed later on. On the other hand, the chemical shift of C4 is, in a first approximation, the same for both tautomers but depends on the conformation of the 3-aryl residue. In "planar" compounds it appears at 102–103 ppm while in "twisted" ones the signal appears at 105.6 (**2**), 106.8 (**8**) (compare with 102.2 ppm for **9**), and 108.0 ppm in the "orthogonal" anthryl derivative **10**. Note that compounds **3**, **4**, and **12** behave like "planar" compounds, a fact that is related to their tautomerism. When X-ray diffraction data are available (30), the conformation of the aryl group deduced from ^{13}C CP/MAS is consistent with those found in the monocrystals.

The most remarkable observation in the bicyclic pyrazoles of Table 3 is the ring strain effect, common to pyrazoles **25** and **27**, that deshields C3 and C5. The chemical shifts of indazole **30** and benzo[*g*]indazole **31** show similar relationships as those in naphthalene/phenanthrene (40), except for carbon C7, which in the first case is deshielded by 2.4 ppm, and in the second by 9.1 ppm.

Since this paper concerns pyrazoles, only the ^1H-^{13}C coupling constants of annular carbons (C3, C4, and C5) are reported in Tables 1–3; they are consistent with previous values (35) and with those of the already known compounds, which we have included in the tables. There is much less information about ^{13}C–^{19}F coupling constants in pyrazoles (35); for this reason all of them have been included in the tables.

Chemical shifts and coupling constants of the substituents

The chemical shifts of the substituents and, especially, the carbon atom linked to the pyrazole ring depend on their position on the ring; they are more deshielded when they are at position 3 than when they are at position 5: CH_3 (13–14 vs. 10–10.5 ppm) (35), CF_3(121.5–122 vs. 119.5–120 ppm) (41, 42), C_6H_5, C_{ipso}(134.5–135 vs. 130–130.5 ppm) (35), and thienyl C2′ (136.5–137 vs. 130 ppm).

The methylene signals of the CH_2CH_2 bridge (compounds **28** and **29**, carbon atoms C7′ and C8′, Scheme 3) have chemical shifts consistent with the shielding effect of the pyrazole ring compared with the phenyl ring in *C*-methyl derivatives, 4-methylpyrazole (35) vs. toluene (40).

The $^1J(^{13}C–^{19}F) \sim 268$ Hz measured in the CF_3 substituents of compounds **20**, **22**, and **24** is reported here for the first time.

The use of ^{13}C NMR spectroscopy to study the annular tautomerism of pyrazoles and indazoles

In the solid state, only one pyrazole tautomer is observed (33). Exceptions are compound **26**[3] and compound **13** (Table 1, tautomers **13***a* and **13***b*). Compound **19** being symmetrical, tautomers **19***a* and **19***b* are identical.

The determination of the tautomer present in the solid state requires either the knowledge of "blocked" pyrazoles, i.e., those in which the N-H is replaced by an N-R (35), or the slowing down of prototropic exchange in order to observe the signals of both tautomers in solution (29, 30, 32, 43). Several examples of this last case are reported in the tables.

To illustrate the determination of the structure of the tautomer consider, for instance, the 3(5)-aryl derivatives of Table 1. The carbon bearing the aryl group appears at 149.7 ppm (C3) in tautomer **1***a* and at 141.1 (C5) in tautomer **1***b* (150.2 and 142.1 ppm in the case of tautomers **5***a* and **5***b*). Clearly the tautomer present in the solid state for pyrazole **4** is the **4***b* (C5 at 141.0 ppm) whereas for pyrazole **11** it is the **11***a* (C3 at 151.4 ppm). In Table 2, the pyrazoles whose methyl substituent resonates at 10 ppm are 5-methyl pyrazoles (**16***b*, **19**, **20***a*) whereas those with a methyl signal at 13 ppm are 3-methyl pyrazoles (**19**, **21***a*).

The knowledge of the chemical shifts of the tautomer present in the solid state allows us to determine, at least qualitatively, the tautomeric composition in solution. The results are collected in Table 4. More quantitative information is not available at this moment except for a few compounds.

The main conclusions of the Table 4 results are as follows:

1. Clearly, the tautomer present in the solid is also the major tautomer in solution. A possible exception is 3(5)-phenylpyrazole, which in solution is mainly (72%, Table 1) in the 3-phenyl form **1***a* whereas in the solid state it seems to be the 5-phenyl tautomer **1***b* (to be confirmed by crystallography[4]).

2. In the case of pyrazoles **3**, **4**, and **12**, the most abundant tautomers are **3***b*, **4***b*, and **12***a*. Only these tautomers can be "planar" as we have deduced above from the chemical shifts of C4.

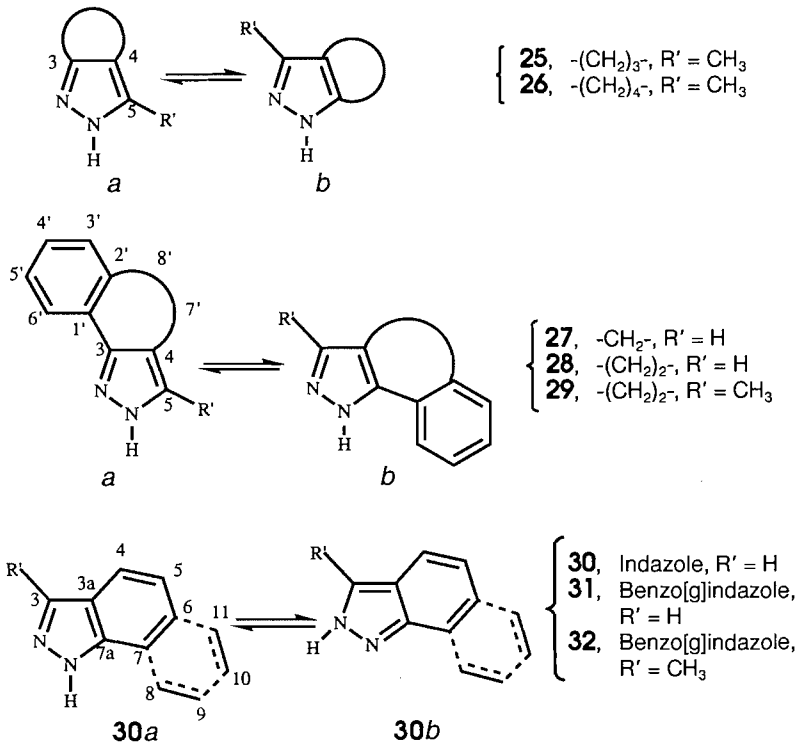
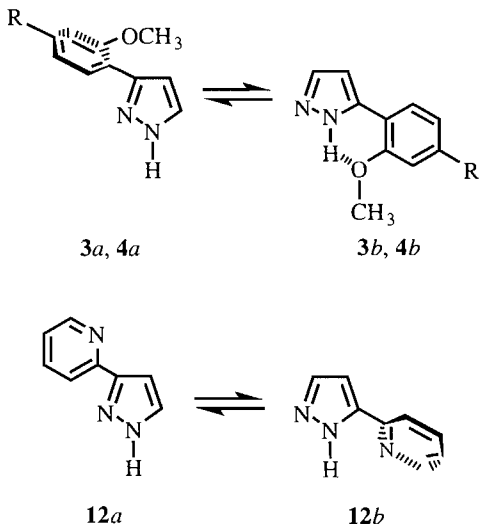


SCHEME 3



3. The ferrocenyl derivative **13** appears to be a mixture of both tautomers in the solid state. This was unexpected for a 3(5)-monosubstituted pyrazole (the only other example, **26**, is a 3,4,5-trisubstituted derivative). All attempts to obtain convenient crystals to determine the structure of pyrazole **13** by crystallography proved unsuccessful.

4. Together with the results reported earlier (33), we now have a large collection of data of the predominant (solution) or the only observed tautomer (solid state): (*i*) Substituents that prefer the position 3: CF_3 > Br > Ar(Het) (exception: *ortho*-methoxyphenyl). (*ii*) Substituents that prefer the position 5: *tert*-butyl > isopropyl > methyl. (*iii*) No preference: ferrocenyl.

Since the pK_a's of pyrazoles (44) follow a linear relationship with the σ_m of the substituent, and since tautomerism and pK_a are related (1), we find it interesting to report the literature values of σ_m for the above substituents (45): CF_3 (0.46) > Br (0.37) > 2-thienyl (0.09) > phenyl (0.05) > ferrocenyl (0.00) > $CHPh_2$ (−0.03) > Me (−0.06) > iPr (−0.08) > *t*Bu (−0.09). It can be observed that there is a clear relationship between σ_m and the tautomerism of pyrazoles: when σ_m is positive the substituent prefers the 3-position, when it is null (ferrocenyl) both tautomers have the same energy, and when σ_m is negative the substituent prefers the 5-position. The qualitative order is followed even in the two extreme groups.

In the gas phase (46) the phenyl substituent stabilizes the 3-substituted tautomer while the *tert*-butyl substituent stabilizes the 5-tautomer, in agreement with the findings in solution and in the solid state. However, since the intrinsic differences in the gas phase are quite small (46), formation of hydrogen bonds with the solvent in solution or with other molecules in the crystal could modify the tendency observed in the isolated molecule.

Conclusion

For a variety of substituents (alkyl, aryl, heteroaryl, trifluoromethyl) the possible isomers are characterized as tautomers *a* and *b*. A knowledge of the preferred tautomers has been gathered which can be relevant for the reactivity of these systems. Even in the case where no suitable crystals for X-ray crystallography can be obtained, high-resolution ^{13}C NMR spectroscopy provides a method for determining the structure of pyrazoles in the solid state.

Experimental

Synthesis

Of the 23 pyrazoles whose NMR spectroscopy is described here for the first time, some are new compounds[5] and the remaining ones

Spectroscopy. In solution

Proton noise-decoupled ^{13}C NMR spectra and gated decoupled ^{13}C NMR spectra were recorded at 50.32 MHz on a Bruker AC-200 instrument; all chemical shifts are expressed in ppm relative to tetramethyl-silane (TMS) and are given with a precision of ±0.01 ppm; the coupling constants are given with a precision of ±0.1 Hz.

Spectroscopy. Solid state NMR

The high-resolution solid state ^{13}C NMR spectra were obtained at room temperature on a Bruker AC-200 spectrometer working at 50.32 MHz under conditions of cross polarization (CP) and magic angle spinning (MAS) using a 7-mm Bruker DAB 7 probehead that achieves rotation frequencies of about 3.5–4.5 kHz. Samples were carefully packed in ZrO_2 rotors (approximately 200 mg of material). The standard CP/MAS pulse sequence was applied with a 7 μs $^{1}H-90°$ pulse width, 3–5 ms contact pulses, and 5 s repeti-

An X-ray and conformational study of 5,7-dihydro-1,11-dimethyl-6*H*-dibenzo[*a*,*c*]cyclohepten-6-one and its methyl derivatives

ROBERT R. FRASER,[1] CORINNE BENSIMON, FANZUO KONG,[2] AND XINFU WU
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received July 15, 1992[3]

ROBERT R. FRASER, CORINNE BENSIMON, FANZUO KONG, and XINFU WU. Can. J. Chem. **71**, 685 (1993).

The crystal structures for the title compound **1** and its α-methyl derivatives **2–4** have been determined. Molecular mechanics calculations of the conformation of minimum energy for **1**, **3**, and **4** correspond closely to the symmetric structures observed in the crystal. For **2**, rotation at the CO—CH_2 bond by 24° produced an asymmetric conformation matching that seen in the solid state. The calculated changes in energy as a function of the torsional angle for **1** and **2** were compared with those for cyclohexanone and the axial conformer of the α-methyl derivative. The energy requirements for conformational change in the seven-membered ring were significantly greater than for the cyclohexane analogue. The calculated energy differences between diastereomeric methyl derivatives **2–4**, **6**, and **7** were in agreement with epimerization experiments. The distance of closest approach observed between a proton of the axial methyls of **2** and **3** and the distal benzene ring is smaller than expected on the basis of van der Waals' radii.

ROBERT R. FRASER, CORINNE BENSIMON, FANZUO KONG et XINFU WU. Can. J. Chem. **71**, 685 (1993).

On a déterminé les structures cristallines du composé **1** mentionné dans le titre et de ses dérivés α-méthylés, **2–4**. Des calculs de mécanique moléculaire de la conformation d'énergie minimale des composés **1**, **3** et **4** correspondent bien aux structures symétriques observées dans les cristaux. Pour le composé **2**, la rotation de 24° autour de la liaison CO—CH_2 provoque une conformation asymétrique qui correspond à celle observée à l'état solide. On a comparé les changements d'énergie en fonction de l'angle de torsion qui ont été calculés pour les composés **1** et **2** avec ceux de la cyclohexanone et du conformère axial de son dérivé α-méthylé. L'énergie requise pour effectuer le changement conformationnel dans le cycle à sept chaînons est beaucoup plus grand que celui nécessaire avec l'analogue de la série cyclohexanique. Les différences d'énergie calculées entre les dérivés méthylés diastéréoisomères **2–4**, **6** et **7** sont en accord avec ceux de données d'épimérisation. La distance la plus courte observée entre un proton des groupes méthyles axiaux des composés **2** et **3** et le noyau benzénique distal est plus courte que celle attendue sur la base des rayons de van der Waals.

[Traduit par la rédaction]

The bridged biaryl ketone, 5,7-dihydro-1,11-dimethyl-6*H*-dibenzo[*a*,*c*]cyclohepten-6-one, **1**, is a chiral derivative of biphenyl whose barrier to racemization was found to be 39 kcal/mol (1, 2). A C_2 axis passes through the central ring of **1** and along the C—O bond of the carbonyl group. As a consequence there are two possible orientations α to the carbonyl, either "axial" or "equatorial" on the basis of their similarity to the geometry at the α positions of cyclohexanone (see Fig. 1). The ring possesses a single rigid conformation, as indicated by molecular models and supported by its proton nmr spectra (2). We previously made use of **1** and its α-methyl derivatives in three separate studies of stereoselective reactions of the carbonyl group (3–5). In each case, **1** appeared to provide advantages over the more frequently used cyclohexanone and its derivatives. It is the aim of this paper to assess the relative merits of these two ketones as models for stereochemical studies.

Since the recognition of the fundamental effect of its chair conformation on reactivity (6), cyclohexane has played a central role in the development of the field of conformational analysis (7). The rigid[4] nature of its six-membered ring provided a skeleton on which the reactivity of pendant groups could be studied. The degree of rigidity of the ring was found to be high in mono- and disubstituted derivatives whose barriers to conformational change (8) were normally around 10 kcal/mol. Conformational homogeneity was achievable using a *tert*-butyl substituent whose energetic preference for the equatorial position was over 5 kcal/mol. Unfortunately the "rigidity" of the ketone derivative, cyclohexanone, is much less pronounced. The chair conformation of this ketone is only 3 kcal/mol more stable than its boat forms (8, 9). Consequently, the involvement of such less stable species in reaction pathways is of concern, though difficult to assess. This is one of several weaknesses that have been recognized in the use of cyclohexanone derivatives for conformational studies. Also of concern is the fact that a large anchoring group such as *tert*-butyl (10) or phenyl (11) changes the geometry of the ring significantly from that of cyclohexanone itself.

The relative lack of rigidity of cycloheptanes is well known. As discussed by Dunitz and Waser (12), a seven-membered ring has seven fixed bonds and seven fixed internal angles, leaving one torsional degree of freedom to permit flexibility. If one or more torsional constraints appear, the ring will become rigid. This has been proposed to be the case for ketone **1**. The only quantitative information regarding its rigidity is the very high barrier of 39 kcal/mol reported for the racemization of **1**. The major contribution to this barrier comes from the two *ortho* methyls, in whose absence the barrier falls to below 10 kcal/mol (13). Since the double bonds of the central ring are also fixed, the only possible mobile portions of the ring are the C—C single bonds that bridge the biphenyl moiety. We initially sought to probe the resistance of **1** to conformational change in a qualitative manner. We obtained X-ray data for crystalline samples of

[3]Revision received January 21, 1993.
[4]The term "rigid" is vague, implying that the molecule resides at the minimum of a potential energy well of unspecified depth or shape.

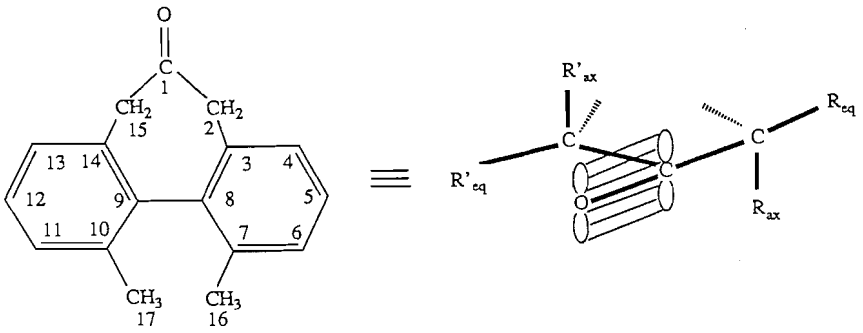

FIG. 1. The structure and three-dimensional representation for **1** and its derivatives **2–6**.

1 and three of its methyl derivatives, **2**, **3**, and **4**. Some variation in their conformations was observed. Molecular mechanics calculations were then carried out to assess the energy requirements of these conformational changes and, where possible, were compared with the available experimental data. The results provide evidence that **1** is of significantly greater rigidity than cyclohexanone.

[a]The relative sign is important with respect to the data for an individual structure.
[b]Standard deviations appear in parentheses.

from the torsional or dihedral angles given in Table 2. It is noteworthy that two crystallographically independent molecules were found in one unit cell for both **1** and **2**. The ORTEP plots for **1** appear in Fig. 2. Only one of these, **1***b*, was exactly symmetric about its C_2 axis as shown by the equal values for the torsional angles O—C1—C15—C14 and O—C1—C2—C3. The second structure, **1***a*, differs from the symmetric form primarily through rotation of about 15° about C1—C2 and C1—C15.[5] As seen in the representation in Fig. 3, the unit cell of **1** contains an aggregate of three antipodes. In this arrangement the central molecule would be expected to be symmetric, as in **1***b*, while the terminal members of the cell could adopt a structure reflecting their asymmetric environment. Since the cocrystallization of **1***a* with **1***b* suggests that their energies are similar, the observed distortion in **1***a* is an indication of some flexibility in **1**. In contrast, each of the structures **2***a* and **2***b* was distinctly asymmetric, possessing a further distortion relative to **1***a* of 8° rotation at each of the single bonds at C1. This undoubtedly occurs to lessen the repulsive interaction (vide infra) between the axial methyl and the π cloud of the distal benzene ring. These differences in rotation about the C1—C2 bond in **1***b*, **1***a* and the C1—C15 bond in **2***b* are illustrated by the stereochemical formulae in Fig. 4.

For **3** and **4**, the axis of symmetry is again in evidence, as indicated by the torsional angles about C1—C2 and C1—C15. Bond displacement from C_2 symmetry cannot relieve the strain in the diaxial dimethyl derivative **3**, as any rotation that diminishes one of the two axial methyl inter-

[5]These rotations are accompanied by smaller changes at the C2—C3 and C15—C14 bonds.

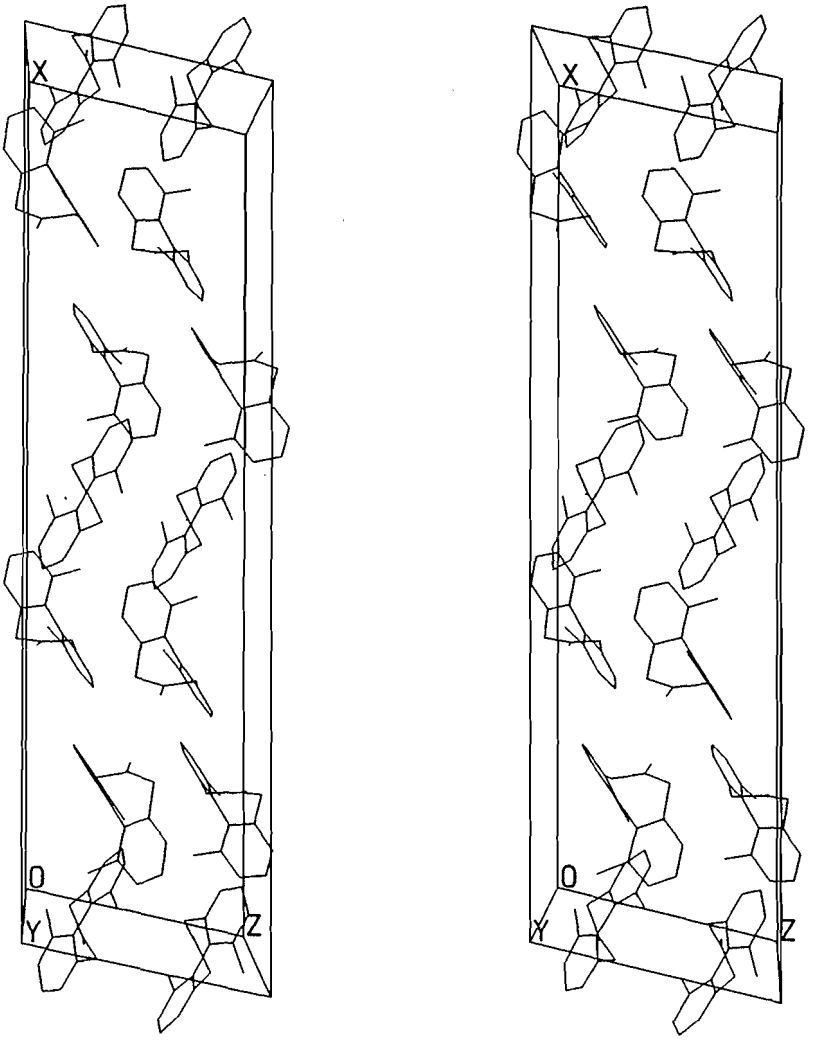

FIG. 3. A stereoview of the unit cell for **1**.

actions will increase the other. Partial relief appears to be achieved by angular distortion, i.e., an increase in the C3—C2—Me and C14—C15—Me bond angles. These angles are 117.4° and 115.2°, respectively, in **3** compared to the value of 111.3° found for C3—C2—Me in **2**. In the diequatorial dimethyl compound, both methyl groups are almost eclipsed with the adjacent carbonyl, each dihedral angle being 6°. This type of eclipsed conformation is energetically favored over the *anti*(axial-like) conformation in 2-butanone (9).

A feature common to all six structures for **1–4** is the value of 60° ± 4 for the dihedral angle between the two benzene rings. This increase in angle of about 8° over that reported (14) for the unsubstituted biaryl ketone **5** is clearly due to a repulsion between the two *ortho* methyls of **1**. Since this increase is limited by the three-carbon bridge, the two methyl groups are only 3.23 Å apart (average found for **1–4**), at which distance sufficient repulsion remains to produce a measurable distortion of each aromatic ring. These deviations from the planarity of the aromatic ring are listed in Table 3.

There is an additional important contribution available from the above data for **1** and its methyl derivatives. The axial methyl substituents in **2** and **3** are all periplanar with respect to the adjacent π orbital of the carbonyl group, as previously claimed (3–5). The methyl substituents in **4** are equatorial.

Conformational properties of **1** *and its derivatives as calculated by* MMX

Recently a new molecular mechanics program, MMX, has been developed (15).[6] It calculates strain energies using the MM2 method (16) and includes π-VESCF routines taken from MMPI (15). In view of the potential utility of this program for compounds containing aromatic rings, we wished to use the results of the crystallographic analyses as a test of the ability of MMX to calculate the conformational properties of **1–4**. Energy minimization provided the most stable conformation for **1**, having a C_2 axis of symmetry and corresponding closely to that of **1***b*, found in the crystal. For **2–4** we also calculated the most stable conformation as well as that most closely corresponding to each of the crystal forms. Table 4 lists the energies and torsional angles for all the

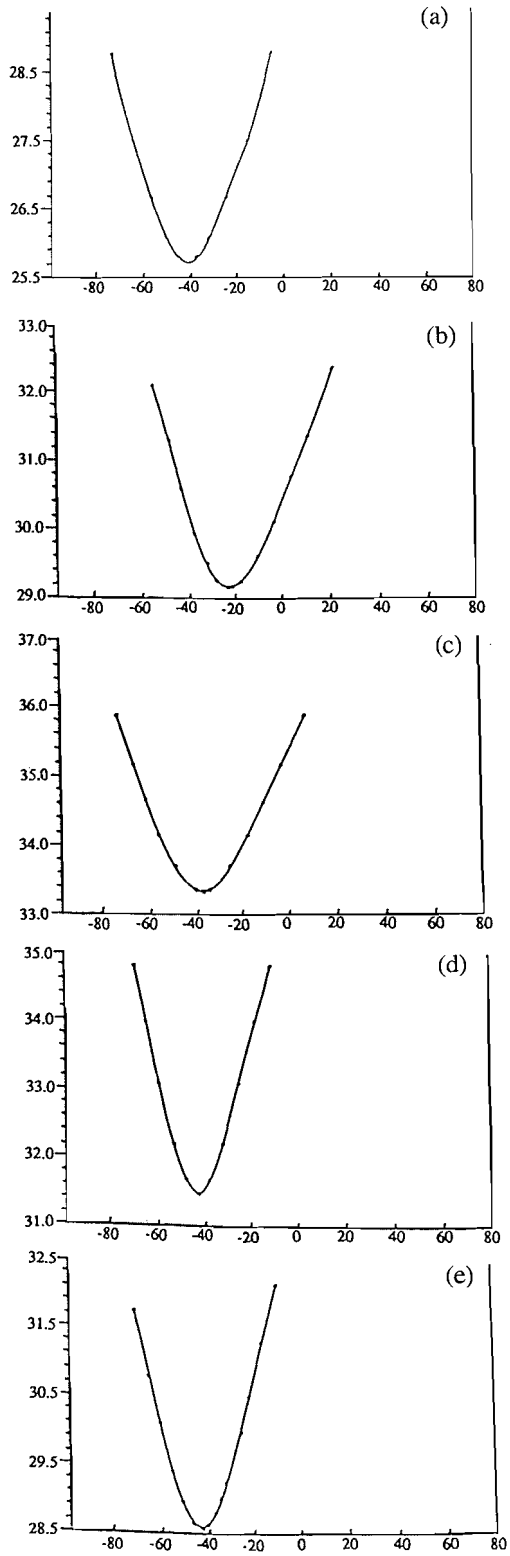

FIG. 5. A plot of energy (kcal/mol) versus the torsional angle (deg) at C15—C1—C2—C3 for **1**, **2**, **3**, **4**, and **6**(*a*–*e*).

minimum energy conformations as calculated by MMX. The difference between the calculated angles and the experimental angles in Table 1*a* appear in parentheses.

For **1**–**4** we calculated the variation in energy over a 40° range in the dihedral angle at C1—C2. For **1** the results are plotted in Fig. 5*a*. The curve shows the calculated energy difference between **1***a* and **1***b* to be 0.9 kcal/mol.[7] The calculated energy well is relatively shallow, thereby allowing some change in the conformation of **1** with a change in its position in the unit cell.

The two distinct structures found in the unit cell of **2** are both asymmetric. They have similar conformations in which the C15—C1—C2—C—3 torsional angle is increased 21° and 23° from that in **1***b*. The most stable conformation for **2** as calculated by MMX is similar to each of those found in the solid state. The energy dependence of **2** versus dihedral angle is plotted in Fig. 5*b*. The calculated energy change for conversion of the minimum energy form to either observed crystal conformation is only 0.1 kcal/mol, which accounts for the occurrence of two forms for **2** in the solid state.

The plots of energy versus dihedral angle for **3**, **4**, and **6** appear in Figs. 5*c*, 5*d*, and 5*e*. It is evident that the strain in **3** has caused it to be more flexible than either **4** or **6**.

In Table 4, agreement between the calculated and experimental dihedral angles about C1—C2 is within 1° for **1**, **2**, and **4** and within 3° for **1***a* and **3**. Larger differences are found for the angles involving a proton, presumably due to the less accurate experimental data. There are differences of over 5° in several of the angles involving carbons of the aromatic ring. The MMX calculations are apparently less accurate in this area, though the reason for this is not clear.

The van der Waals' radius of a benzene ring

In **2** and **3** the distance between the aromatic ring and the hydrogens of the axial methyl group could be determined from the crystallographic data. One of the methyl protons (H18A) of **2** was found to be very close to the distal ring, as indicated by the following spatial relations. The distances from H18A to C9, C10, and C14 were 2.56, 2.86, and 2.93 Å, respectively. Such proximity even after rotation by 24° is surprising. In **3** the distance between either of the axial methyl protons H18A and the carbons C9, C10, and C14 or H19A and C8, C7, and C3 of the distal benzene showed similar values. All these distances are summarized in Table 5 along with the data provided from the MMX calculations. For any of the axial methyls the distance of closest approach[8] is between 2.54 and 2.73 Å, which is significantly less than the estimated sum of the van der Waals' distances (3.05 Å) for a hydrogen and an aromatic ring (17). It appears that some strain has been relieved in **3** as reflected in a slightly larger internal angle for C3—C2—Me (vide supra). The data to be presented later for epimerization of **2** and **3** to the more stable equatorial isomers reveal much greater residual strain in **3**. Since the repulsive portion of a van der Waals' curve is steep, the above observed distance of approach (2.6 Å) very likely represents its min-

[7]This calculated difference does not include any effects of entropy. It is noteworthy that **1***a* is statistically favoured over **1***b* by the factor R ln 2, which reduces the free energy difference to 0.5 kcal/mol.

[8]This distance is normally considered to be the most reliable estimate for the sum of the van der Waals' radii for two contiguous atoms. Any example of distance less than the accepted minimum is then considered as evidence for the presence of a bonding interaction (16). In certain situations this distance may require a modification to include the effects of attractive intramolecular interactions (ref. 16, p. 41).

imum. Consequently, the presently accepted value for one half of the thickness of a benzene ring of 1.85 Å (17) appears to be too large when the approaching atom is hydrogen.[9] There are some recent data in support of this proposal. Ab initio calculations regarding the interaction of a proton of a water molecule in a vertical approach to the center of the benzene ring found the energy minimum at 2.5 Å. For the vertical approach of one benzene towards another the minimum occurred at 2.4 Å (18) although more recent theoretical estimates report this distance to be larger (19, 20). A recent X-ray study of an inclusion complex, in which an aromatic guest is oriented perpendicular to one aromatic ring of the host, measures the distance between the guest proton and the plane of the host ring to be 2.7 Å (21).

Comparison of conformational properties; MMX versus experiment

Although we were unable to obtain a crystalline sample of **6**, the monoequatorial epimer of **2**, we investigated its conformational properties by MMX. These are described through its torsional angles and energy profile given in Table 4 and Fig. 5*e*. The calculations indicate that the equatorial conformer is more stable than its epimer **2** by 0.6 kcal/mol. This energy difference, which is for the vapor phase, is in reasonable agreement with the experimental value of 1.2 kcal/mol measured in methanol (see Table 6).

Calculations have also been carried out for the α-axial, α-equatorial dimethyl derivative **7**. Table 5 reports its energy relative to **3** and **4** along with the experimental values obtained from the proportions measured at equilibrium in tetrahydrofuran. The close correspondence between the calculated energy differences and the experimental values provides support for the reliability of the energy data obtained from MMX.

Finally, calculation of the minimum energy structure for the ketone **5** yielded a value of 49° for the dihedral angle between the rings, similar to that calculated earlier by Mislow and co-workers (14).

*Comparison of **1** with cyclohexanone **8** for use as stereochemical models*

The most important property of a hydrocarbon skeleton when used to test stereoelectronic effects is its ability to provide derivatives of known fixed stereochemistry. This follows from the fact that the maximum observable magnitude of any identifiable effect is limited by the energy requirement for skeletal distortion. Figures 6*a* and *b* describe the energies required for ring distortion in **1** and **8**.[10] These show a significant difference. A 40° change in dihedral angle from its ground state requires 1.3 and 0.85 kcal/mol of energy for **1** and **8**, respectively. The curve for the methyl derivative **9** can be seen in Fig. 6*c* and indicates still greater flexibility. Thus all of these curves indicate the ring skeleton in **1** to be more rigid than that of cyclohexanone, yet possessing some degree of flexibility. In addition, **1** offers simpler spectral properties while **8** provides more easily accessible derivatives. The differing symmetry characteristics of the two cyclic ketones complement one another.

Conclusion

The crystal structures for **1–4** establish their ground state conformational properties. The axial methyl groups in **2** and **3** are oriented antiperiplanar to the distal lobe of the carbonyl, as was earlier claimed (3). MMX calculations provide a quantitative measure of the rigidity of the central ring. The calculated energy difference between epimers is supported by equilibration experiments. A comparison of the data for

[9]Errors in determining the position of the hydrogen preclude any quantitative estimate of this thickness.

[10]The barrier to ring inversion by MMX is seen to be 3.8 kcal/mol, in agreement with earlier calculations (9) and nmr measurements (22).

1 and **8** indicates that the former possesses greater rigidity for use as a stereochemical model. Observations of the distance between protons of an axial methyl and the π cloud of the neighbouring aromatic ring suggest the currently accepted thickness of a benzene ring (17) is too large.

Experimental

Compound **1** was synthesized according to the literature (1). Recrystallization from ether–hexanes gave a suitable single crystal. Compounds **2**, **3**, and **4** were synthesized according to the reported method (4), and recrystallization from hexanes afforded suitable crystals for X-ray determination.

A summary of the crystal data for compounds **1–4** is given in Table 1.[11] Selected bond lengths and bond angles are given in

[11]Tables of all bond lengths, bond angles, atomic coordinates, mean plane data, anisotropic parameters, and structure factors for **1**, **2**, **3**, and **4** may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of bond lengths, bond angles, and atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Tables 7 and 8, respectively. The diffraction intensities were collected on a Rigaku diffractometer at 295 K with MoKα radiation (λ = 0.7093 Å) using the θ/2θ scan technique with profile analysis (23). The standards were measured after every 150 reflections; no crystal decay was noticed. The space group was determined by systematic absence. Unit cell parameters were obtained by least-squares refinement of the setting angle for 25 reflections ($40° < 2\theta < 47°$ for **2**, **3**, **4** and $40° < 2\theta < 50°$ for **1**). Lorentz and polarization factors were applied but no corrections were made for absorption.

For compounds **1** and **4** all the hydrogens were found by difference Fourier map. For compounds **2** and **3**, most of the hydrogens were found by difference Fourier map and the rest were calculated. All the calculations were performed with the NRCVAX Crystal Structure Package (24).

Molecular mechanics calculations were performed using the MMX program embedded in the PCMODEL 4.1 (footnote 6) on an IBM-386. The dielectric constant used throughout the calculations was 1.50. Each calculated total energy consisted of stretching, bending, stretching–bending, torsional, van der Waals, and dipole–dipole contributions.

Equilibration of **2** and **6** was carried out by treating a 3 mg sample of either compound in THF (4 mL) with 3 mg of sodium methoxide at room temperature for 24 h. The mixture of **2** and **6** after neutralization and isolation was analysed by 300 MHz ^{1}H NMR. The integral ratio for the two well-resolved methyl doublets for **2** and **6** at δ 0.80 and 1.34, respectively, gave the value of 2.0 ± 0.1 for the equilibrium constant. The equilibrium distribution between **3**, **4**, and **7** was similarly determined. The results appear in Table 5.

ALEXIS NDIBWAMI, SERGE LAMOTHE, DANIEL GUAY, RAYMOND PLANTE, PIERRE SOUCY, SOLO GOLDSTEIN, and PIERRE DESLONGCHAMPS. Can. J. Chem. **71**, 695 (1993).

Transannular Diels–Alder reactions on 14-membered macrocycles containing properly located diene and methyl-substituted dienophile units lead to A.B.C.[6.6.6] tricycles related to steroids. To study the influence of the olefin and diene geometry on the stereochemical outcome of the Diels–Alder reaction it was necessary to prepare macrocyclic trienes of well-defined stereochemistry. Eight different types of macrocyclic trienes might be obtained by the coupling of appropriate dienophiles and dienes, namely, TTC, TTT, TCC, TCT, CTC, CTT, CCC, and CCT. In this paper (first in a series of two), the synthesis of appropriately functionalized dienophile and diene synthons, as well as their coupling reaction affording macrocyclic triene precursors, is described.

ALEXIS NDIBWAMI, SERGE LAMOTHE, DANIEL GUAY, RAYMOND PLANTE, PIERRE SOUCY, SOLO GOLDSTEIN et PIERRE DESLONGCHAMPS. Can. J. Chem. **71**, 695 (1993).

Les macrocycles à 14 chaînons contenant en positions appropriées un diène et un diénophile portant un substituant méthyle, fournissent par une réaction de Diels–Alder transannulaire des tricycles A.B.C.[6.6.6] apparentés aux stéroïdes. Afin d'étudier l'influence de la géométrie du diène et du diénophile, il était nécessaire de préparer des triènes macrocycliques de stéréochimie bien définie. Huit types de ces triènes peuvent être obtenus par le couplage de différents diènes et diénophiles, à savoir TTC, TTT, TCC, TCT, CTC, CTT, CCC et CCT. Dans cet article (le premier dans une série de deux) on décrit la synthèse des synthons diène et diénophile fonctionnalisés de manière adéquate ainsi que leur réaction de couplage générant les précurseurs de triènes macrocycliques.

Among the various synthetic methods available for the construction of complex carbocyclic skeletons (1) the transannular Diels–Alder reaction on macrocycles developed in our laboratory shows enormous synthetic potential. As recently pointed out, this novel methodology allows a particularly easy, convergent, and predictable stereoselective entry to polycyclic structures related to steroids and terpenes (2).

The case of 14-membered macrocyclic trienes containing various geometrical isomers of the diene and methyl-substituted dienophile moieties was illustrated in our recent papers (3). As outlined below in a general manner (Scheme 1), these macrocycles leading to A.B.C.[6.6.6] tricycles related to steroids were obtained by the cyclization of appropriate acyclic trienes, which in turn were assembled from the different geometrical isomers of the diene and dienophile synthons using dimethyl malonate connectors.

To study the influence of olefin and diene geometry on the stereochemical outcome of the transannular Diels–Alder reaction, it was necessary to prepare the macrocyclic trienes from stereochemically well-defined acyclic precursors.

The geometry of the dienophile might be either *cis* (C) or *trans* (T), while the diene moiety might possess a *trans-trans* (TT), *trans-cis* (TC), *cis-trans* (CT), or *cis-cis* (CC) arrangement; coupling of the diene and dienophile synthons will therefore lead to eight possible macrocyclic trienes, namely, *trans-trans-cis* (TTC), TTT, TCC, TCT, CTC, CTT, CCC, and CCT, the three letters referring to unsaturations at C5, C3, and C11, respectively (cf. Scheme 1).

The synthesis of the appropriately functionalized dienophile and diene synthons as well as their coupling reaction leading to the corresponding macrocyclic triene precursors is described in the present paper.

[1]Author to whom correspondence may be addressed.

Synthesis of dienes

The preparation of the requisite dienes (all geometrical isomers) is outlined in Scheme 2. Syntheses were planned to place, at appropriate positions, a leaving group or precursors thereof to be used later in the coupling with the dienophile synthon.

Diene ester **2** (*trans-trans*) was prepared as previously described (4) starting with commercially available *cis*-2-butene-1,4-diol, which was monoprotected (5) and then oxidized with pyridinium chlorochromate to the corresponding *trans* aldehyde (6), which was further reacted with the anion derived from ethyl diisopropyl phosphonoacetate. The *trans-trans* geometry could be easily established by virtue of the coupling constant (J = 15.3 Hz) observed for the vinylic protons in the ^{1}H nmr spectrum of the compound (4). Reduction of the ester function using two equivalents of diisobutyl aluminium hydride (8) gave the corresponding alcohol **3**, in 96% yield, which was quantitatively[2] transformed into the *trans-trans* allylic chloride **4** (LiCl, CH_3SO_2Cl, *s*-collidine, DMF) (9). The above allylic chloride was employed as such for the subsequent steps.

The remaining dienes were also prepared from the same starting material (Scheme 2). Thus, Swern oxidation (10) of alcohol **1** at −78°C afforded *cis* aldehyde **5**, which was reacted in tetrahydrofuran (THF) at low temperature with the carbanion (NaH) derived from methyl bis(trifluoroethyl)-phosphonoacetate, a reagent known to produce selectively *Z*-unsaturated esters (11). In our case the reaction products, *cis-cis* diene ester **6** and *trans-cis* diene ester **7**, were obtained in a 85:15 ratio (68% overall yield from alcohol **1**). This selectivity did not change when either sodium hydride and a crown ether or potassium hexamethyldisilazide were

[2]Lower yields of **4** were obtained after attempted purification by chromatography due to decomposition.

SCHEME 3. Preparation of *trans* dienophiles.

used to form the phosphonate anion (11). The above compounds were readily separated by column chromatography on silica gel and their ^1H nmr spectra were found to be consistent with the indicated structures. Diene ester **6** was transformed into alcohol **8** (76% crude) and then into allylic chloride **9** in the same manner as described for **3** and **4**.

On the other hand, an Emmons–Horner reaction performed on crude *cis* aldehyde **5** using the anion derived from ethyl diisopropylphosphonoacetate (12) led to protected *trans-cis* diene ester **10** in 68% overall yield from alcohol **1**, after flash chromatography on silica gel. The stereochemistry of the double bonds could be again secured via ^1H nmr spectra, which show coupling constants of 11.7 Hz and 15.3 Hz for the corresponding *cis* and *trans* vinylic protons. As before, reduction of the ester function led to allylic alcohol **11** in 91% yield after flash chromatography. This compound was then transformed, using the Collington Meyers protocol (9), into chlorodiene **12** (~100% crude yield).

Furthermore, protection of alcohol **11** (*tert*-butyldiphenyl silyl chloride, imidazole, dimethylformamide) (13) followed by selective cleavage of the tetrahydropyranyl ether (80% acetic acid) (14) afforded, after purification by flash chromatography, *cis-trans* diene alcohol **14** in 48% overall yield. The corresponding allylic chloride was obtained by the usual procedure, in 82% yield, after flash chromatography.

Thus all the desired diene isomers could be obtained from a common starting material using appropriate reagents and reaction conditions.

Synthesis of dienophiles

The synthesis of the *trans* dienophile building block **21** (Scheme 3) started with the preparation of the known vinyl iodide **16**, which was obtained in 92% crude yield by a zirconium-catalyzed carboalumination of homopropargyl alcohol followed by iodinolysis (15). The alcohol function was protected (16) to afford the silyl derivative **17** in 90% yield after flash chromatography. Palladium-catalyzed cross coupling (17*a*, *b*) with 3-carbomethoxypropylzinc iodide obtained from iodoester **18**[3] then afforded *trans* olefin **19**[4] in 75% yield after flash chromatography. Cleavage of the silyl ether (Bu_4NF, THF) afforded alcohol **20**, which was transformed into its mesylate (CH_3SO_2Cl, Et_3N, CH_2Cl_2), followed by displacement, in the presence of potassium iodide, with the anion derived from dimethyl malonate to afford triester **21** in 85% yield after flash chromatography.

The synthesis of the *cis*-dienophile building block **27** is outlined in Scheme 4. Thus, reduction of 3-methylanisole (Li/NH_3, EtOH) (18), at −78°C, led to **22** in 92% yield. Ozonolysis of **22** followed by reduction (O_3, $(CH_3)_2S$, CH_2Cl_2/CH_3OH; $NaBH_4$, EtOH) (19) afforded hydroxy ester **23** in about 50% yield. Protection of the alcohol function (20) gave silyl derivative **24** (96% after flash chromatography) whose ester function was then reduced to afford alcohol **25** ($LiAlH_4$, Et_2O, 97%). Crude alcohol **25** was transformed into its mesylate (99% yield), which was reacted without further purification with the anion derived from

[3]Iodo-ester **18** could be obtained on a large scale from the reaction of γ-butyrolactone with thionyl chloride in the presence of zinc chloride to afford 4-chlorobutyryl chloride, which was transformed into the corresponding methyl ester (pyridine, MeOH) (17*c*) and then to **18** (NaI, acetone, reflux) in 46% overall yield.

[4]About 5% of the corresponding *cis* isomer was detected by gas chromatography.

SCHEME 4. Preparation of *cis* dienophile.

dimethyl malonate (*vide supra*) to afford *cis* dienophile **27** in 81% yield. Consistent with the olefin geometry, the methyl protons were observed in the ^1H nmr spectra as a singlet at 1.69 ppm in the case of **27** and as a doublet (J = 1.2 Hz) at 1.58 ppm in the case of **21**. The patterns observed for the vinylic proton in the two compounds are also in accord with the respective *cis* and *trans* stereochemistry (see experimental). Next, the assembling of acyclic trienes via coupling of the different diene and dienophile building blocks was undertaken.

Synthesis of acyclic trienes

TTC, CTC, TCC, and CCC trienes (Scheme 5)

Reaction of allylic chloride **4** with the anion derived from **27** (NaH, THF/DMF) occurred at room temperature to afford acyclic triene **28** in 80% yield. Selective cleavage of the silyl ether (Bu_4NF, THF) (20) led to alcohol **29** in 87% yield after chromatography. The introduction of a second malonate unit was performed starting with alcohol **29**, in the same manner as described for **27**, to obtain, after flash chromatography, tetraester **30** in 79% yield. Finally, cleavage of the tetrahydropyranyl ether (PPTS, CH_3OH) (21) at room temperature afforded the TTC triene **31** in 77% yield after chromatography.

Preparation of CTC trienes required the coupling of a *cis* olefin with a *cis-trans* diene. Thus, coupling of **27** with diene **15** by the above-mentioned procedure led to disilylated triene **32** (88% yield). Selective cleavage of the *tert*-butyldimethylsilyl ether (PPTS, iPrOH, 70°C) (22)[5] afforded the corresponding alcohol **33** in 90% yield. CTC triene **36** could then be obtained using our standard procedure involving mesylation, displacement with the anion derived from dimethyl malonate, and cleavage of the remaining silyl ether (~68% yield for the three steps). TCC triene **40** and CCC triene **44** were obtained in a similar manner, by first coupling olefin **27** with either diene **12** or diene **9**, respectively.

[5]Also, L. Ruest, unpublished results.

CTT, TCT, CCT, and TTT trienes (Scheme 6)

For this series of trienes, *trans* olefin **21** was employed in the coupling step. Thus, displacement of the allylic chloride in **15** by the usual method furnished triester **45** in 84% yield. The lithium-diisopropylamide-generated enolate of **45** (23) was then trapped with methyl chloroformate, giving **46** in 74% yield, which, following the usual deprotection procedure, afforded CTT triene **47** (72% yield).

TCT triene **48** was obtained in 77% yield by alkylation of the malonate anion derived from **21** with allylic chloride **12**. Generation of the second malonate unit as described above afforded **49** (42% yield), which led to TCT triene **50** by deprotection of the alcohol function. CCT triene **53** and TTT triene **56** were obtained in an analogous manner by first coupling **21** with either CC diene **9** or TT diene **4**, respectively.

To examine the influence of steric interactions due to one of the esters in position 8 (cf. Scheme 1) on the course of the Diels–Alder reaction of TCC and TCT macrocyclic trienes (see following paper in this series), it was necessary to prepare such compounds bearing only one ester in this position. Therefore, the corresponding acyclic triene precursors were synthesized along the lines depicted in Scheme 7.

Thus, diester **38** was decarbalkoxylated (NaCN, DMSO) (24), giving triene **57** in 81% yield after purification. Introduction of the malonate unit and deprotection of the alcohol were performed in the usual manner to afford TCC triester **59** in 67% overall yield (Scheme 7A).

TCT triene **62** was obtained by two alternative sequences, as follows. Decarbalkoxylation of **48** under the conditions described above provided **60** in 69% yield. Treatment of the enolate derived from this compound with methyl chloroformate provided triester **61** (44% yield) and tetraester **49** (53% yield). Separation of **61** by chromatography followed by removal of the alcohol protecting group afforded TCT triene **62** in 92% yield (Scheme 7B).

A more efficient way for the preparation of **61** (Scheme 7C) started from *trans* olefin **63***a* (prepared as outlined in

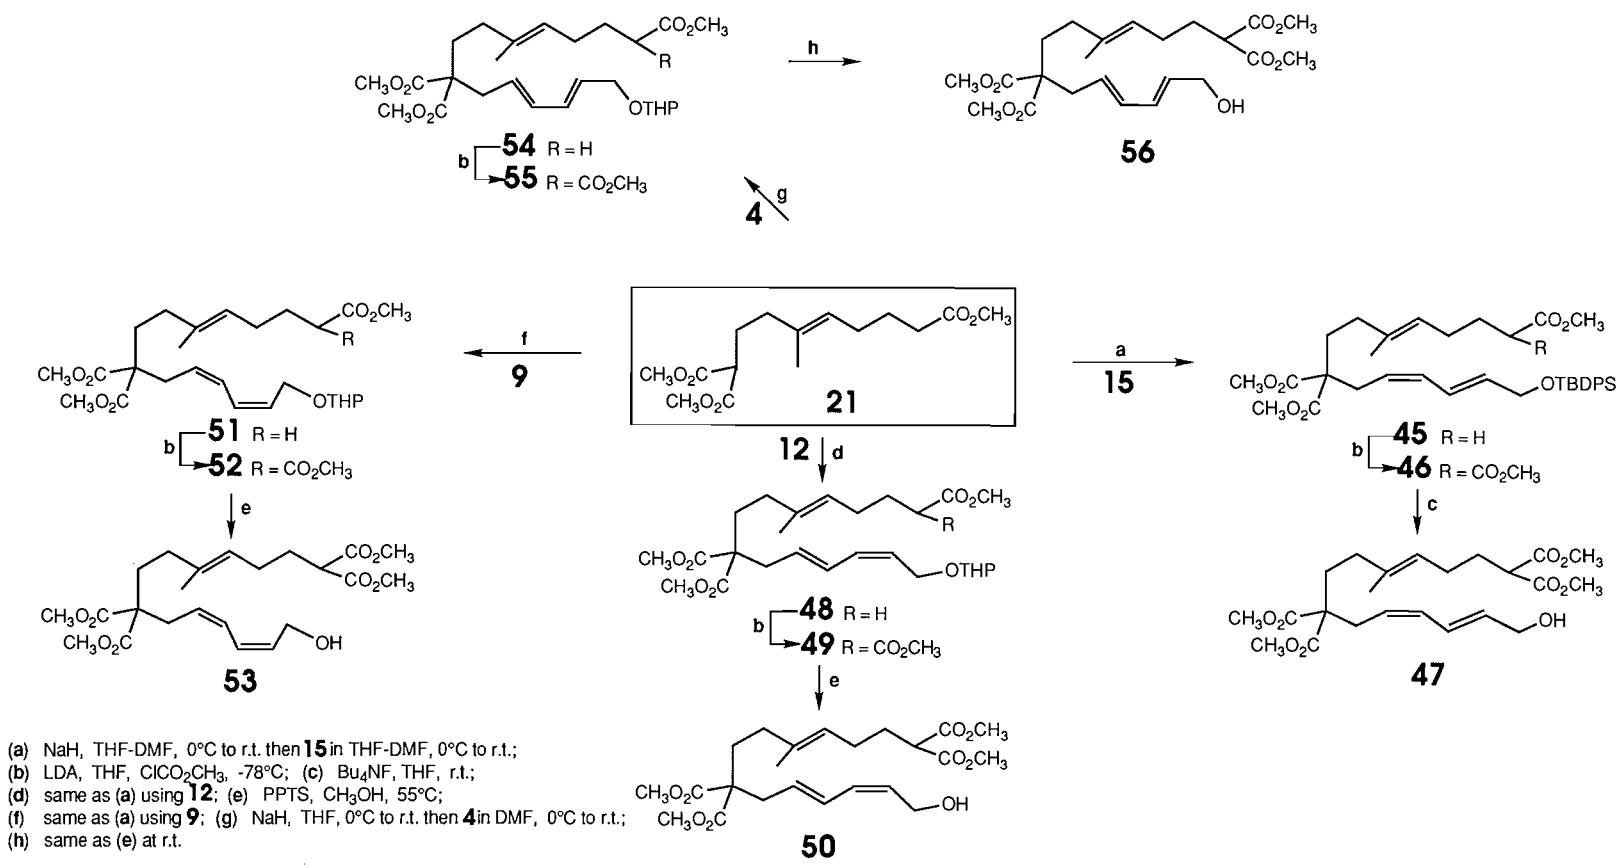
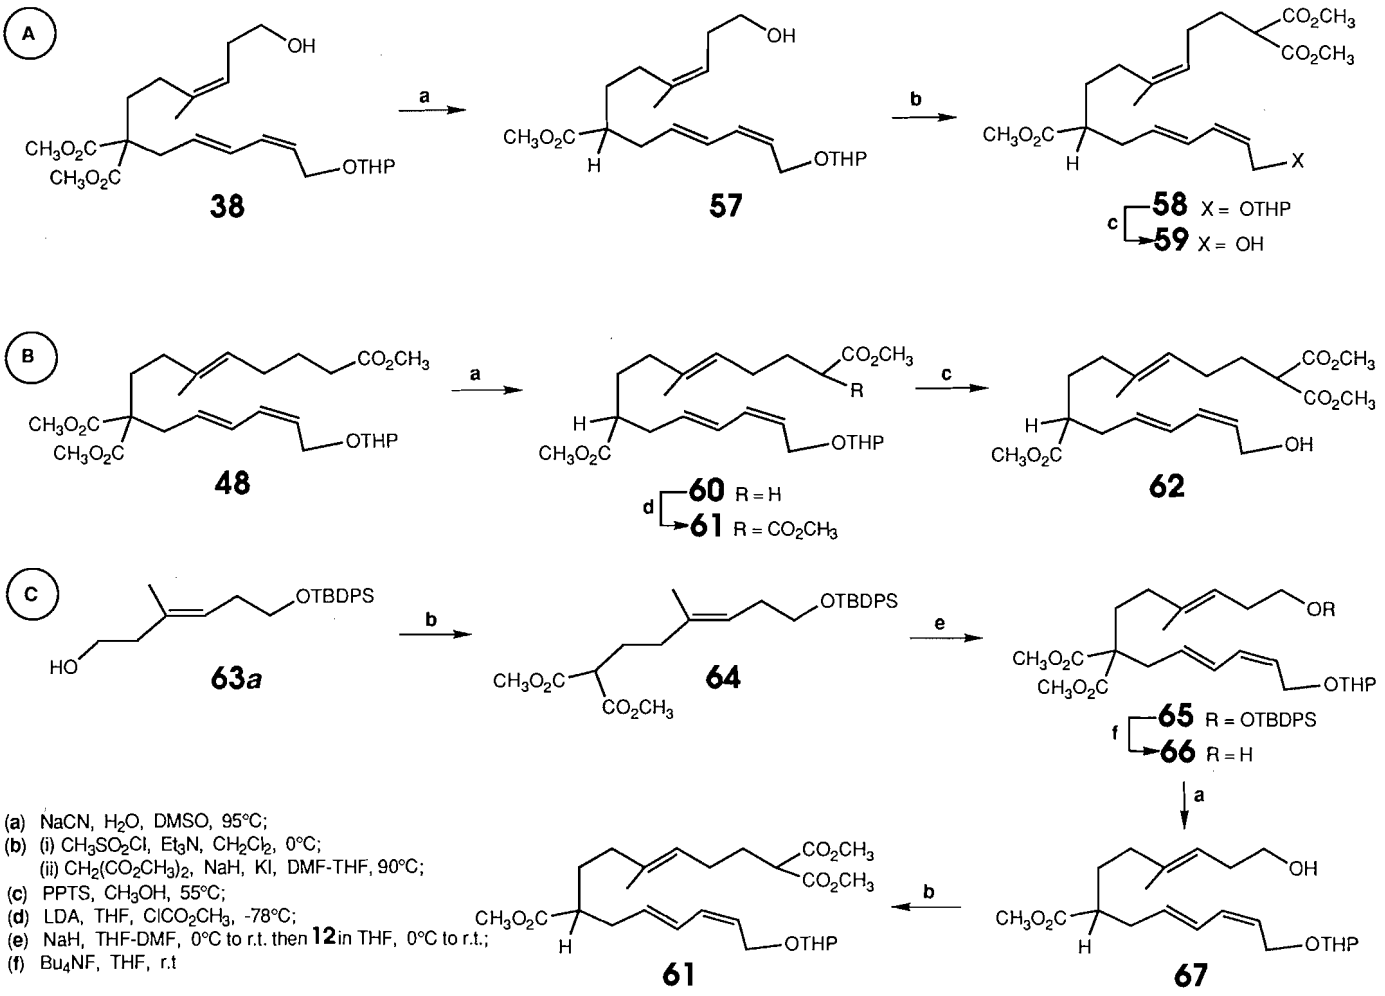


SCHEME 6. CTT, TCT, CCT, and TTT sequences.



SCHEME 7. Decarboxylative TCC and TCT sequences.

Scheme 8). Mesylation followed by displacement with sodiomalonate furnished **64** in 85% yield after purification. Usual coupling with allylic chloride **12** (62% yield) followed by removal of the silyl group (92% yield) afforded diester **66**. Decarbalkoxylation led to monoester **67** (85% yield), which was then transformed into TCT triene **61** (77% yield) by the before-mentioned procedure.

In conclusion, this work outlines a highly convergent approach for the preparation of acyclic trienes containing a diene and a methyl-substituted dienophile moiety. All possible geometrical isomers could be easily obtained by the coupling of readily prepared and stereochemically defined olefins and dienes. Further elaboration of these compounds into A.B.C.[6.6.6] tricycles via the 14-membered macrocyclic trienes is described in the following paper of this issue.

Experimental

General

The ir spectra were taken on a Perkin–Elmer 681 spectrophotometer using chloroform ($CHCl_3$) or dichloromethane (CH_2Cl_2), or run as neat films on sodium chloride cells. Proton nmr spectra were recorded on a Bruker WP-80 or Bruker WM-250 instrument. The following abbreviations have been used: s, singlet; d, doublet; dd, doublet of doublets; dt, doublet of triplets; ddd, doublet of doublets of doublets; dddd, doublet of doublets of doublets of doublets; ddt, doublet of doublets of triplets; ddq: doublet of doublets of quartets; t, triplet; td: triplet of doublets; q, quartet; and m, multiplet. Chemical shifts are reported in δ values relative to chloroform as internal standard. Carbon nuclear magnetic resonance spectra were recorded on a Bruker WP-80 or Bruker WM-250 instrument (chloroform as internal standard). Mass spectra were obtained on a Micromass ZAB-2F instrument. Melting points were determined on a Büchi M-50 or on a Reichert apparatus and are uncorrected.

Unless otherwise specified all reactions were performed under an argon atmosphere and were monitored by thin-layer chromatography. For flash chromatography, silica gel Merck Kieselgel 60 (230–400 mesh, ASTM) was used. All solvents used in chromatography were distilled. Anhydrous solvents were obtained by standard means.

Dienes syntheses

trans,trans *Hydroxy diene 3*

DIBAL-H (30 mmol from a 1 M solution in cyclohexane) was slowly added at −78°C to a solution of hexadienoate **2** (see ref. 4) (3.34 g, 13.9 mmol) in dichloromethane. The mixture was stirred for 1.5 h at this temperature followed by addition of a saturated ammonium chloride solution (50 mL). Ether (25 mL) was added and the reaction mixture was allowed to reach room temperature. The aqueous layer was separated, extracted with ether, and then was acidified and reextracted with ether (2 × 40 mL). The organic phases were dried on magnesium sulfate, filtered, and evaporated. The crude product was purified by flash chromatography (40–

60% EtOAc in hexane) affording 2.63 g (96%) of hydroxy diene **3**; ir ($CHCl_3$): 3400, 1100–1000 cm^{-1}; ^1H nmr (δ): 6.47–5.60 (4H, olefinic protons), 4.64 (1H, s, O-C*H*-O), 4.41–3.4 (6H, m, 3 × -CH_2-O), 2.0–1.4 (7H, m, O*H* and -$(CH_2)_3$-); ms *m/e*: 198 (M^+), 180 ($M^+ - H_2O$).

trans,trans *Allylic chloride 4*

To a solution of allylic alcohol **3** (360 mg, 1.8 mmol) in 5 mL of dimethylformamide, cooled to −10°C, were added lithium chloride (110 mg, 2.6 mmol), collidine (385 mL, 2.9 mmol), and methanesulfonyl chloride (210 mL, 2.7 mmol). The reaction mixture was stirred for 16 h while temperature changed from −10°C to 25°C. Ether (10 mL) and hexane (20 mL) were added followed by a 2% sodium bicarbonate solution (20 mL). The aqueous phase was extracted with a 1:1 mixture of ether and hexane (2 × 20 mL), and the combined organic layers were washed with water, dried ($MgSO_4$), and evaporated. The residue was rapidly purified by flash chromatography (10% EtOAc in hexane, containing 2% of triethylamine) giving 183 mg (46%) of **4**; ir ($CHCl_3$): 1100–1000 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.5–5.5 (4H, m, olefinic protons), 4.64 (1H, s, O-C*H*-O), 4.5–3.3 (6H, m, -CH_2Cl and 2 × -CH_2-O), 2.0–1.3 (6H, m, -$(CH_2)_3$-).

(2Z,4Z)-Methyl 6-tetrahydropyranyloxy-2,4-hexadienoate (6)

A solution of anhydrous dimethyl sulfoxide (1 mL, 14 mmol) in dichloromethane (5 mL) was added dropwise, with stirring, to a solution of oxalyl chloride (1 mL, 11 mmol) in dichloromethane (20 mL) at −78°C. The mixture was stirred for an additional 10 min, then alcohol **1** (1.72 mg, 10 mmol) in dichloromethane (10 mL) was added over a period of 15 min using a syringe pump. The stirring was continued at −78°C, for 45 min. Diisopropylethylamine (8.7 mL, 50 mmol) was added and the mixture was warmed to −10°C. After addition of water (50 mL), the reaction mixture was extracted with ether. The organic layer was washed with brine, dried, and the solvent was evaporated. The resulting crude aldehyde **5** was used as such for the next step.

For personal use only.

To a suspension of sodium hydride (60% in oil, 48 mg, 1.2 mmol) in tetrahydrofuran (5 mL) at 0°C was added a solution of methylbis(trifluoroethyl)phosphonoacetate (see ref. 11) (477 mg, 1.5 mmol) in tetrahydrofuran (2 mL). The mixture was stirred at 0°C for 30 min, then the temperature was lowered to −78°C and aldehyde **5** (about 1 mmol) in tetrahydrofuran (1 mL) was added dropwise. The reaction mixture was stirred for an additional 30 min. Saturated aqueous ammonium chloride solution was added and the resulting solution was extracted with ether. The organic layer was dried and the solvent evaporated. Chromatography on silica gel (0.5% acetone in dichloromethane) afforded *cis,cis* isomer **6** (124 mg) and *cis,trans* isomer **7** (21 mg) in 68% combined overall yield, from alcohol **1**; ir ($CHCl_3$):3010–2860, 1715, 1640, 1600, 1220, and 1030 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.39 (1H, tq, J = 11.4 Hz, 1.3 Hz, -OCH_2CH=C*H*CH=CH-), 6.94 (1H, td, J = 11.7 Hz, 1.2 Hz, -OCH_2CH=CHC*H*=CH-), 5.99 (1H, dddd, J = 11.2 Hz, 7.2 Hz, 6.7 Hz, 1.4 Hz, -OCH_2CH=CHCH=CH-), 5.74 (1H, dd, J = 11.5 Hz, 1.2 Hz, -OCH_2CH=CHCH=C*H*-), 4.64 (1H, t, J = 3.9 Hz, -OCHO-), 4.43 (1H, ddd, J = 13.1 Hz, 6.2 Hz, 1.8 Hz, -OC*H*HCH=), 4.28 (1H, ddd, J = 13.6 Hz, 7.2 Hz, 1.6 Hz, -OCH*H*CH=), 3.86 (1H, m, -OCHO-C*H*H-), 3.73 (3H, s, -OCH_3), 3.52 (1H, m, -OCHO-CH*H*-), 1.87–1.47 (6H, m, -OCHO-CH_2-(CH_2)$_3$-).

(2Z,4Z)-6-Tetrahydropyranyloxy-2,4-hexadien-1-ol (8)

To a solution of ester **6** (124 mg, 0.55 mmol) in dichloromethane (3 mL) was added dropwise, at −78°C, a solution of DIBAL-H (1 M in cyclohexane, 1.4 mL, 1.4 mmol). The reaction mixture was stirred at −78°C for 3 h. Sodium sulfate decahydrate (500 mg) was added and the mixture was allowed to reach room temperature, then diluted with anhydrous acetone (5 mL). The solid was filtered off and washed several times with acetone. The solvents were evaporated, leaving alcohol **8** (82.4 mg, 76%); ir ($CHCl_3$): 3600, 3450, 3000–2850, and 1020 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.38 (2H, m, -OCH_2CH=C*H*C*H*=C*H*CH_2OH), 5.70 (2H, m, -OCH_2CH=CHCH=C*H*CH_2OH), 4.64 (1H, t, J = 2.9 Hz, -OC*H*O-), 4.32 (3H, m, -OC*H*HCH=CHCH=CHCH_2OH), 4.21 (1H, ddd, J = 13.1 Hz, 7.2 Hz, 1.3 Hz, -OCH*H*CH=), 3.87 (1H, m, -OCHO-C*H*H-), 3.52 (1H, m, -OCHO-CH*H*-), 2.75 (1H, br, -CH_2OH), 1.86–1.47 (6H, m, -OCHO-CH_2-(CH_2)$_3$-); ^{13}C nmr ($CDCl_3$) δ: 131.44, 129.18, 125.48, 124.96 (C=C), 97.99 (-OCHO), 62.51, 62.21, 58.46 (-OCH_2-), 30.55, 25.37, 19.36 (-OCHO-CH_2-(CH_2)$_3$-); ms *m/e*: 113 (M^+ −C_5H_9O), 101 (M^+ −97), 95 (M^+ −$C_5H_{11}O_2$), 85 (M^+ −113). Exact Mass calcd. for M^+ −C_5H_9O: 113.0602; found: 113.0601 ± 0.0003.

Allylic chloride 9

To a solution of alcohol **8** (247 mg, 1.25 mmol) in dimethylformamide (5 mL) was rapidly added 212 mg (5 mmol) of lithium chloride. After complete dissolution, *s*-collidine (330 mL, 2.5 mmol) was added and the reaction mixture was stirred at room temperature for 5 min. The temperature was lowered to 0°C and methanesulfonyl chloride (194 mL, 2.5 mmol) was added dropwise. The reaction mixture was stirred at 0°C for 1 h, at room temperature for an additional hour, and was then poured in an ice–water mixture. Extraction with a 1:2 mixture of hexane and ether (3 × 50 mL) was followed by washing the combined organic layers with a saturated copper nitrate solution and drying over magnesium sulfate. The solvent was evaporated leaving 271 mg (~100%) crude chloride, which was used as such for the next step; ir ($CHCl_3$): 3000–2850, 1120, 1030 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.43 (2H, m, (CH_2CH=C*H*C*H*=CHCH_2Cl), 5.75 (2H, m, -OCH_2CH=CHCH=C*H*CH_2Cl), 4.71 (1H, m, -OC*H*O-), 4.55–4.05 (4H, m, -OCH_2CH=CHCH=CHCH_2Cl), 4.00–3.72 (1H, m, -OCHO-C*H*H-), 3.65–3.35 (1H, m, O-CHO-CH*H*), 1.65 (6H, m, -OCHO-CH_2-(CH_2)$_3$-).

(2E,4Z)-Ethyl 6-tetrahydropyranyloxy-2,4 hexadienoate (10)

Ethyl diisopropylphosphonoacetate (3.78 g, 15 mmol; see ref. 12) in tetrahydrofuran (10 mL) was added at 0°C to a suspension of sodium hydride (60% in oil, 500 mg, 12 mmol) in tetrahydrofuran (50 mL). The solution was stirred for 20 min, then the temperature was lowered to −78°C. Aldehyde **5** (~10 mmol) in tetrahydrofuran (20 mL) was added over a period of 30 min using a syringe pump. The stirring was continued for an additional 30 min, then a saturated aqueous ammonium chloride solution (20 mL) was added, the mixture was extracted with ether, the organic layer dried, and the solvent was evaporated. Flash chromatography (30% EtOAc in hexane) gave diene **10** (1.64 g, 68% overall yield from alcohol **3**); ir ($CHCl_3$): 3000–2850, 1710, 1640, 1620, 1270, 1180, 1120, and 1030 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.61 (1H, ddd, J = 15.3 Hz, 11.6 Hz, 1.0 Hz, -OCH_2CH=CHC*H*=CH-), 6.23 (1H, tm, J = 11.7 Hz, -OCH_2CH=C*H*CH=CH-), 5.96 (1H, m, -OCH_2CH=CHCH=CH-), 5.90 (1H, d, J = 15.3 Hz, -OCH_2CH=CHCH=C*H*-), 4.47 (1H, ddd, J = 15.2 Hz, 6.1 Hz, 1.6 Hz, =CHC*H*HOCHO-), 4.29 (1H, ddd, J = 15.0 Hz, 7.0 Hz, 1.6 Hz, =CHCH*H*OCHO-), 4.20 (2H, q, J = 7.1 Hz, -OCH_2CH_3), 3.87 (1H, m, -OCHO-C*H*H-), 3.65 (1H, m, -OCHO-CH*H*-), 1.90–1.50 (6H, m, -OCHO-CH_2-(CH_2)$_3$-), 1.29 (3H, t, J = 7.2 Hz, -OCH_2CH_3).

(2E,4Z)-6-Tetrahydropyranyloxy-2,4-hexadien-1-ol (11)

Diisobutylaluminium hydride (1 M in cyclohexane, 15 mL, 15 mmol) was added dropwise, at −78°C, to a solution of ester **10** (1.64 g, 6.8 mmol) in dichloromethane (50 mL). The solution was stirred for 2 h, then saturated aqueous ammonium chloride (30 mL) was added and the mixture was allowed to warm to room temperature. Ether (100 mL) was added and the solution was filtered on Celite. The aqueous layer was separated and extracted with ether (2 × 100 mL). The combined organic layers were washed with water, then dried, and the solvent was evaporated. Flash chromatography (40% ether in hexane) afforded allylic alcohol **11** (1.23 g, 91%); ir ($CHCl_3$): 3610, 3440, 3010–2850, and 1025 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.56 (1H, ddq, J = 15.4 Hz, 11.4 Hz, 1.2 Hz, -OCH_2CH=CHC*H*=CHCH_2OH), 6.16 (1H, t, J = 11.0 Hz, -OCH_2CH=C*H*CH=CHCH_2OH), 5.85 (1H, dt, J = 15.2 Hz, 5.5 Hz, -OCH_2CH=CHCH=C*H*CH_2OH), 5.59 (1H, dt, J = 10.9 Hz, -OCH_2CH=CHCH=CHCH_2OH), 4.64 (1H, t, J = 2.9 Hz, -OC*H*O-), 4.36 (1H, ddd, J = 12.7 Hz, 6.3 Hz, 1.5 Hz, =CHC*H*H-OCHO), 4.23 (1H, ddd, J = 12.7 Hz, 6.53 Hz, 1.3 Hz, =CHCH*H*-OCHO), 4.21 (2H, dd, J = 5.2 Hz, 1.3 Hz, -CHCH_2OH), 3.88 (1H, m, -OCHO-C*H*H-), 3.53 (1H, m, OCHO-C*H*H-), 1.88–1.48 (6H, m, -OCHO-CH_2-(CH_2)$_3$-); ^{13}C nmr ($CDCl_3$) δ: 134.27, 130.77, 127.32, 125.65 (-*C*H=*C*H-), 97.74 (-O*C*HO-), 63.01, 62.69, 62.15 (-O*C*H_2-), 30.54, 25.38, 19.32 (-OCHO-CH_2-(*C*H_2)$_3$-); ms *m/e*: 183 (M^+ −15), 113 (M^+ −C_5H_9O), 101 (M^+ −97), 95 (M^+ −$C_5H_{11}O_2$), 85 (M^+ −113). Exact Mass calcd. for M^+ −C_5H_9O: 113.0602; found: 113.0604 ± 0.0003.

Allylic chloride 12

The same procedure as that used for the preparation of **9** was employed, starting with alcohol **11** (297 mg, 1.5 mmol). As before, the crude chloride (216 mg, ~100%) was used as such for the next step; ir ($CHCl_3$): 3010–2860, 1025 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.80–5.10 (4H, m, olefinic protons), 4.65 (1H, m, -OCHO-), 4.40–4.05 (4H, m, -OCH_2CH=CHCH=CHCH_2Cl), 4.00–3.30 (2H, m, -OCHO-CH_2-), 1.90–1.40 (6H, m, -OCHOCH_2-(CH_2)$_3$-).

*(2Z,4E)-1-Tetrahydropyranyloxy-6-*tert*-butyldiphenylsilyloxy-2,4-hexadiene (13)*

tert-Butyldiphenylsilyl chloride (75.6 mg, 0.27 mmol) was added to a solution of alcohol **11** (49 mg, 0.25 mmol) and imidazole (37 mg, 0.55 mmol) in dimethylformamide (4 mL). The reaction mixture was stirred at room temperature for 9 h. Saturated aqueous ammonium chloride (5 mL) was added and the solution was extracted with a 1:1 mixture of ether and hexane. The organic layer was dried over magnesium sulfate and the solvent was evaporated. The crude product was used, as such for the next step; ir ($CHCl_3$): 2080, 3050, 3000–2860, and 1580 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.85–7.30 (10 H, m, 2 × -C_6H_5), 7.10–5.40 (4H, m, olefinic protons), 4.70 (1H, m, -OC*H*O-), 4.40–4.10 (4H, m, -OCH_2CH=

For personal use only.

CHCH=CHCH_2O-), 3.90–3.35 (2H, m, -OCHO-CH_2-), 1.80–1.40 (6H, m, -OCHO-CH$_2$-(CH_2)$_3$-), 1.10 (9H, s, *t*-Bu).

*(2Z,4E)-6-*tert*-Butyldiphenylsilyloxy-2,4-hexadien-1-ol (**14**)*

A solution of the diene **13** in 80% acetic acid (2.5 mL) was stirred at room temperature for 3 h, then was heated at 30°C–40°C for an additional 3 h. Saturated aqueous sodium bicarbonate was added and the solution was extracted with ether. The organic layer was dried and the ether was evaporated to give, after purification on silica gel (50% EtOAc in hexane), alcohol **14** (42 mg, 48% overall from alcohol **11**); ir ($CHCl_3$): 3610, 3440, 3080, 3050, 3010–2860, 1580, and 1110 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.76–7.36 (10H, m, 2 × -C$_6$H$_5$), 6.77–5.44 (4H, m, olefinic protons), 4.30 (4H, m, -OCH_2CH=CHCH=CHCH_2O-), 1.44 (1H, br, -CH$_2$O*H*), 1.10 (9H, s, *t*-Bu).

*Allylic chloride **15***

Methanesulfonyl chloride (324 mg, 2.84 mmol) was added dropwise over a period of 5 min to a solution of alcohol **14** (950 mg, 2.70 mmol), lithium chloride (180 mg, 4.29 mmol), and *s*-collidine (359 mg, 2.97 mmol) in 30 mL of dimethylformamide at 0°C. The mixture was stirred at room temperature for 8 h, then was quenched with 300 mL of ice-water and extracted with a 2:1 mixture of ether and hexane (4 × 125 mL). The combined organic layers were washed with water (2 × 50 mL), then with a saturated aqueous copper nitrate solution (2 × 50 mL), and finally again with water (50 mL). Drying over magnesium sulfate followed by evaporation of the solvents and purification by column chromatography on silica gel (5% EtOAc in hexane), afforded pure chloride **15** (815 mg, 82%); ir ($CHCl_3$): 3015, 2960, 2935, and 2860 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.68 and 7.40 (10H, 2m, -C$_6H_5$), 6.62 (1H, br dd, J = 14.8 and 11.4 Hz, -C*H*=CH-CH$_2$-O-), 6.18 (1H, t, J = 11.0 Hz, -C*H*=CH-CH$_2$-Cl), 5.89 (1H, dt, J = 15.0 and 4.6 Hz, =C*H*-CH$_2$-O-), 5.60 (1H, bq, J = 10.4 Hz, =C*H*-CH$_2$Cl), 4.30 (2H, d, J = 4.4 Hz, -CH_2-O-), 4.20 (2H, d, J = 8.1 Hz, -CH_2-Cl), 1.09 (9H, s, *t*-Bu).

Dienophile syntheses

*(3E)-4-Iodo-3-methyl-3-butene-1-ol (**16**)*

To a solution of trimethylaluminium (20.6 mL, 214.2 mmol) and bis(cyclopentadienyl)zirconium dichloride (5.21 g, 17.85 mmol; see ref. 15) in 1,2-dichloroethane (150 mL) at 0°C was added dropwise, over a period of 90 min, a solution of 3-butyn-1-ol (5.43 mL, 71.4 mmol) in 1,2-dichloroethane (36 mL). The mixture was stirred at room temperature for 14 h. The solution temperature was lowered to −40°C, and then a solution of iodine (22 g, 86 mmol) in tetrahydrofuran (70 mL) was added at a rate such as to maintain the mixture at a constant temperature of −30°C. The resulting solution was warmed to 0°C and saturated aqueous potassium carbonate (15 mL) was added over a period of 2 h. The product was extracted with a 2:1 mixture of hexane and ether (5 × 200 mL). The combined organic layers were dried on magnesium sulfate, and the solvent was evaporated to give iodo-alcohol **16** (13.98 g, 92%); ^{1}H nmr ($CDCl_3$) δ: 6.20 (1H, q, J = 0.8 Hz, -C=C(I)-*H*), 3.74 (2H, m, HOCH_2-), 2.48 (2H, td, J = 6.4 Hz, 0.8 Hz, -CH_2C=), 1.88 (3H, d, J = 0.8 Hz, CH_3-C=), 1.44 (1H, m, -CH$_2$O*H*).

*(3E)-4-Iodo-3-methyl-1-*tert*-butyldimethylsilyloxy-3-butene (**17**)*

To a solution of alcohol **16** (13.98 g, 66 mmol) in dichloromethane (300 mL) were added triethylamine (23 mL, 165 mmol), *tert*-butyldimethyl silyl chloride (12.06 g, 80 mmol), and 4-dimethylaminopyridine (1.2 g, 9.9 mmol). The resulting solution was stirred at room temperature for 3.5 h. Saturated aqueous ammonium chloride solution (100 mL) was added and the mixture was extracted with ether. The organic layer was dried and the solvent was evaporated. Flash chromatography on silica gel (hexane) afforded silyl ether **17** (21 g, 90% from 3-butyn-1-ol); ir ($CHCl_3$): 3000–2860, 1620, and 1100 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 5.93 (1H, q, J = 1.1 Hz, C=C(I)-*H*), 3.68 (2H, t, J = 6.6 Hz, -OCH_2-), 2.41 (2H, td, J = 6.6 Hz, 0.9 Hz, -CH_2C=), 1.85 (3H, d, J = 1.1 Hz, CH$_3$-C=), 0.88 (9H, s, *t*-Bu), 0.00 (6H, s, -Si-(CH_3)$_2$).

*(5E)-Methyl 6-methyl-8-*tert*-butyldimethylsilyloxy-5-octenoate (**19**)*

To a suspension of Zn–Cu couple (5.13 g) in a 100:7 mixture of benzene and dimethylacetamide (100:7) (107 mL) was added methyl 4-iodobutyrate **18** (11.7 g, 51.3 mmol), and the mixture was stirred at room temperature for 1 h, then at 60°C for 3.5 h. A suspension of tetrakis(triphenylphosphine) palladium(0) (5 g, 4.34 mmol) in anhydrous benzene (35 mL) was added. The stirring was continued for 5 min, and vinylic iodide **17** (11.18 g, 34.3 mmol) in benzene (13 mL) was added. The reaction mixture was stirred at 60°C for 90 min, and was cooled to room temperature. The resulting suspension was diluted with ethyl acetate (185 mL), then filtered, and the solid washed with ethyl acetate. The solvent was evaporated, the residue was diluted again with ether, filtered, and the ether was evaporated. Flash chromatography on silica gel (4% EtOAc in hexane) gave alkene **19** (7.7 g, 75%); ir ($CHCl_3$): 2960–2860, 1735, 1250, and 1090 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 5.13 (1H, tq, J = 7.2 Hz, 1.2 Hz, =C*H*-), 3.66 (3H, s, -OCH_3), 3.65 (2H, t, J = 7.0 Hz, -OCH_2-), 2.30 (2H, t, J = 7.4 Hz, -CH_2CO$_2$CH$_3$), 2.19 (2H, t, J = 7.1 Hz, -CH_2C-(CH$_3$)=CH-), 2.02 (2H, q, J = 7.3 Hz, -C=CHCH_2CH$_2$-), 1.69 (2H, dt, J = 7.3 Hz, 7.2 Hz, -C=CHCH$_2$CH_2CH$_2$-), 1.60 (3H, d, J = 1.0 Hz, CH_3-C=CH-), 0.88 (9H, s, *t*-Bu), 0.04 (6H, s, Si-(CH$_3$)$_2$).

*(5E)-Methyl 6-methyl-8-hydroxy-5-octenoate (**20**)*

Tetrabutylammonium fluoride (1 M in tetrahydrofuran, 5.8 mL, 5.8 mmol) was added to a solution of silyl ether **19** (864.7 mg, 2.88 mmol) in tetrahydrofuran (10 mL) at 0°C. The solution was stirred at room temperature for 4 h, and the solvent was evaporated. The residue was purified by chromatography on silica gel (40% EtOAc in hexane) to afford alcohol **20** (535 mg, 99%); ir ($CHCl_3$): 3500, 3000–2870, 1730, 1240, and 1050 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 5.25 (1H, m, -C=C*H*-), 3.75 (3H, s, -OCH_3), 3.73 (2H, t, J = 6.5 Hz, HOCH_2-), 2.70–1.85 (9H, m, *H*OCH$_2$CH$_2$C-(CH$_3$)=CH(CH_2)$_3$-), 1.90 (3H, m, CH_3-C=CH-).

*(4E)-4-Methyl-1,1,8-trimethoxycarbonyl-4-octene (**21**)*

Methanesulfonyl chloride (268 μL, 3.45 mmol) was added dropwise to a solution of alcohol **20** (535 mg, 2.87 mmol) and triethylamine (0.6 mL, 4.3 mmol) in dichloromethane (10 mL). The reaction mixture was stirred at 0°C for 1 h, then the solution was poured into ice-cold water and extracted with dichloromethane. The organic layer was separated and dried. The solvent was evaporated and the residue (776.5 mg) (homogenous on thin-layer chromatography) was used as such for the next step.

Methyl malonate (1.64 mL, 14.35 mmol) was added dropwise to a suspension of sodium hydride (517.7 mg, 12.9 mmol) in a 1:1 mixture of dimethylformamide and tetrahydrofuran (30 mL) at 0°C. The mixture was stirred at 0°C for 30 min, then at room temperature for an additional 30 min. The above mesylate dissolved in tetrahydrofuran (5 mL) was then added, followed by a catalytic amount of potassium iodide (249 mg, 1.44 mmol). The reaction mixture was heated at 95°C (oil bath temperature) for 6 h, then was cooled to room temperature. Saturated aqueous ammonium chloride solution (15 mL) was added and the resulting solution was extracted with a 1:2 mixture of hexane and ether (3 × 100 mL). The combined organic layers were dried and the solvent was evaporated. The product was purified by chromatography on silica gel (25% EtOAc in hexane) yielding 742 mg (86%) of triester **21**; ir ($CHCl_3$): 3020–2840, 1740, and 1150 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 5.10 (1H, tq, J = 7.2 Hz, 1.1 Hz, -C=C*H*-), 3.73 (6H, s, -CH(CO$_2$CH_3)$_2$), 3.66 (3H, s, CH$_2$CO$_2$CH_3), 3.33 (1H, m, -C*H*-(CO$_2$CH$_3$)$_2$), 2.29 (2H, t, J = 7.4 Hz, -CH_2CO$_2$CH$_3$), 2.00 (6H, m, -CH_2CH_2C(CH$_3$=CHCH$_2$-), 1.66 (2H, dt, J = 7.3 Hz, 7.2 Hz, -CH$_2$CH_2CH$_2$CO$_2$CH$_3$), 1.58 (3H, d, J = 1.2 Hz, CH_3-C=CH-); ^{13}C nmr ($CDCl_3$) δ: 174.06 (*C*O$_2$CH$_3$), 169.86 (-CH(*C*O$_2$-CH$_3$)$_2$), 134.38 (-*C*(CH$_3$)=CH-), 124.99 (-C(CH$_3$)=*C*H-), 52.31,

51.31, 50.92 (-CO_2CH_3, -$CH(CO_2CH_3)_2$), 37.06, 33.38 (-CH_2-$C(CH_3)$=$CHCH_2$-), 27.17, 26.97 ($(CH_3O_2C)_2CHCH_2$-, -CH_2CO_2-CH_3), 24.83 (-$CH_2CH_2CH_2CO_2CH_3$), 15.60 (CH_3-C=CH-); ms *m/e*: 300 (M^+). Exact Mass calcd: 300.1573; found: 300.1566 ± 0.0009.

Cyclohexadiene 22

Lithium (450 mg, 64 mmol) was added in small portions to a solution of *meta*-methylanisole (2.0 g, 16.3 mmol) and ethanol (12 mL) in liquid ammonia (60 mL) at −78°C. The mixture was stirred for 30 min and ammonium chloride (1.5 g) was then added in portions. The resulting mixture was warmed to room temperature and the ammonia was allowed to evaporate overnight. Water (10 mL) was added to the residue and the product was extracted with ether (3 × 20 mL). The combined organic layers were washed with water (5 mL), dried over potassium carbonate, and the solvent was evaporated. The crude material (1.86 g, 92%) was used without further purification; ir (CH_2Cl_2); 3000, 2825, 1695, 1665, and 1220 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.43 (1H, m, CH_3-C=C*H*-), 4.64 (1H, m, CH_3-O-C=C*H*-), 3.56 (3H, s, CH_3-O-), 3.00–2.40 (4H, m, -CH_2-), 1.72 (3H, m, CH_3-CH=).

Hydroxy ester 23

Ozone was bubbled into a solution of cyclohexadiene **22** (6.10 g, 49.2 mmol) in 40 mL of methanol and 20 mL of dichloromethane at −78°C, until 95% of the starting material had disappeared (the reaction was monitored by gas chromatography). Excess ozone was removed by bubbling argon through the solution, followed by addition of dimethyl sulfide (3.97 g, 64 mmol). The mixture was stirred for 1 h at −78°C and was then slowly warmed up to room temperature. The solvents were evaporated, ethanol (60 mL) was added to the residue, and the solution was cooled to −78°C. Sodium borohydride (700 mg, 18.4 mmol) was added portionwise over a period of 30 min, the resulting mixture was stirred for an additional 15 min at −78°C, and was then allowed to warm up to room temperature. The solvent was evaporated, the residue was treated with 200 mL of a 10% hydrochloric acid solution, and the mixture was extracted with ether (4 × 200 mL). The combined organic layers were washed with a saturated sodium bicarbonate solution (2 × 50 mL) and dried over magnesium sulfate. The residue obtained after evaporation of the solvent was purified by column chromatography on silica gel (hexane: EtOAc: ether, 7:2:1) to afford 900 mg (12%) of pure **23** along with 3.4 g (44%) of the same material, which was analysed to be 90% pure; ir ($CHCl_3$): 3615, 3480, 3010, 2950, and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.39 (1H, br t, *J* = 7.7 Hz, -C*H*=), 3.69 (3H, s, -CO_2CH_3), 3.64 (2H, m, -CH_2-OH), 3.10 (2H, s, -CH_2-CO_2CH_3), 2.29 (2H, br q, *J* = 6.7 Hz, -CH_2-CH_2-OH), 2.07 (1H, m, -O*H*), 1.78 (3H, q, *J* = 1.2 Hz, =C-CH_3).

Ester 24

To a solution of alcohol **23** (680 mg, 4.30 mmol) in 20 mL of dichloromethane at room temperature were added *tert*-butyldimethylsilyl chloride (805 mg, 5.37 mmol), triethylamine (868 mg, 8.59 mmol), and dimethylaminopyridine (10 mg, 0.08 mmol). The resulting mixture was stirred at room temperature overnight, after which time 30 mL of ether were added. The resulting precipitate was filtered off and the solvents were evaporated. Purification of the crude material by column chromatography on silica gel (3% acetone in hexane) afforded 1.12 g (96%) of ester **24**; ir ($CHCl_3$): 2950, 2930, 2860, 1730, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.36 (1H, br t, *J* = 7.3 Hz, =C*H*-), 3.67 (3H, s, -CO_2CH_3), 3.59 (2H, t, *J* = 7.0 Hz, -CH_2-O-Si-), 3.06 (2H, s, -CH_2-CO_2CH_3), 2.24 (2H, br q, *J* = 7.1 Hz, -CH_2-CH_2-O-), 1.77 (3H, q, *J* = 1.3 Hz, CH_3-C=), 0.88 (9H, s, *t*-Bu), 0.04 (6H, s, -Si(CH_3)$_2$).

Alcohol 25

The ester **24** (5.30 g, 19.5 mmol) dissolved in 50 mL of ether was added dropwise, over a period of 10–15 min, to a suspension of lithium aluminum hydride (405 mg, 10.7 mmol) in ether (75 mL) at room temperature. The rate of addition was controlled in order to maintain gentle reflux of the solvent. The mixture was stirred for 1.5 h at room temperature and then sodium sulfate decahydrate (1.47 g, 4.57 mmol) was added portionwise. The resulting mixture was stirred for 1.5 h, the solid was decanted, and the solution was filtered through a pad of Celite covered with magnesium sulfate. The crude alcohol **25** (4.60 g, 97%) obtained after evaporation of the solvent was used for the next step without further purification; ir (neat): 3610, 3440, 2950, 2930, 2860, and 835 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.30 (1H, br t, *J* = 7.0 Hz, =C*H*-), 3.65 (2H, q, *J* = 6.5 Hz, -CH_2-OH), 3.63 (2H, t, *J* = 7.0 Hz, -CH_2-O-Si-), 2.32 (2H, t, *J* = 6.5 Hz, -CH_2-CH_2-OH), 2.28 (2H, q, *J* = 7.0 Hz, -CH_2-CH_2-O-Si-), 2.08 (1H, t, *J* = 6.5 Hz, -O*H*), 1.74 (3H, q, *J* = 1.2 Hz, CH_3-C=), 0.88 (9H, s, *t*-Bu) 0.04 (6H, s, -Si(CH_3)$_2$).

Mesylate 26

To a solution of alcohol **25** (7.70 g, 31.5 mmol) and triethyl amine (4.77 g, 47.3 mmol) in 200 mL of dichloromethane was added dropwise, at 0°C, methanesulfonyl chloride (3.79 g, 33.1 mmol). The reaction mixture was stirred for 5 min and was then poured into ice-water (100 mL). The water layer was separated and extracted with dichloromethane (3 × 100 mL). The combined organic layers were washed with water (3 × 50 mL) and dried over magnesium sulfate. The crude mesylate **26** obtained after evaporation of solvent (10.1 g, 99%) was used as such for the next step; ir ($CHCl_3$): 2960, 2930, 2860, 1360, 1175, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.34 (1H, t, *J* = 7.1 Hz, =C*H*-), 4.24 (2H, t, *J* = 7.2 Hz, -CH_2-O-S-), 3.60 (2H, t, *J* = 6.8 Hz, -CH_2-O-Si-), 2.98 (3H, s, CH_3-S-), 2.50 (2H, br t, *J* = 7.2 Hz, -CH_2-CH_2-O-S-), 2.23 (2H, br q, *J* = 6.8 Hz, -CH_2-CH_2-O-Si-), 1.75 (3H, q, *J* = 1.3 Hz, CH_3-C=), 0.89 (9H, s, *t*-Bu), 0.05 (6H, s, -Si(CH_3)$_2$).

Malonate 27

Dimethylmalonate (11.9 g, 90.1 mmol) was added dropwise to a suspension of sodium hydride (1.95 g, 81.2 mmol) in 300 mL of a 1:1 tetrahydrofuran and dimethylformamide mixture at 0°C. The mixture was warmed to room temperature and stirred until hydrogen evolution ceased. The crude mesylate **26** (5.80 g, 18.0 mmol) dissolved in 20 mL of the above solvent mixture was then added, followed by potassium iodide (149 mg, 0.9 mmol). The resulting reaction mixture was refluxed (oil bath temperature at 80–85°C) for 12 h. After cooling to room temperature, 50 mL of a saturated aqueous solution of ammonium chloride were slowly added, and the water layer was separated and extracted with a 2:1 ether and hexane mixture (3 × 150 mL). The combined organic layers were washed with water (2 × 50 mL) and dried over magnesium sulfate. Column chromatography on silica gel (5–20% EtOAc in hexane) afforded 5.20 g (81%) of **27**; ir ($CHCl_3$): 2950, 2930, 2860, 1730, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.19 (1H, br t, *J* = 7.2 Hz, =C*H*-), 3.74 (6H, s, -(CO_2CH_3)$_2$), 3.56 (2H, t, *J* = 7.0 Hz, -CH_2-O-), 3.33 (1H, t, *J* = 7.0 Hz, -CH(CO_2CH_3)$_2$), 2.17 (2H, q, *J* = 7.2 Hz, =CH-CH_2-), 2.10–1.90 (4H, m, -(CH_2)-$CH(CO_2CH_3)_2$), 1.68 (3H, s, CH_3-C=), 0.88 (9H, s, *t*-Bu), 0.04 (6H, s, -Si(CH_3)$_2$); ms *m/e*: 301 (M^+ − $C(CH_3)_3$).

Alcohol 29

To a suspension of sodium hydride (121 mg, 5.05 mmol) in 5 mL of tetrahydrofuran and 5 mL of dimethylformamide at 0°C was added malonate **27** (1.50 g, 4.21 mmol) dissolved in 10 mL of tetrahydrofuran and 10 mL of dimethylformamide. The mixture was stirred for 15 min at 0°C and was then warmed to room temperature and stirred for another 15 min. Chloride **4** (1.00 g, 4.63 mmol) dissolved in 40 mL of tetrahydrofuran and 5 mL of dimethylformamide was added and the resulting mixture was stirred at room temperature for 22 h. A saturated aqueous solution of ammonium chloride (5 mL) was added, followed by 150 mL of water. The water layer was extracted with a 2:1 ether and hexane mixture (3 × 100 mL), and the combined organic layers were washed with water (50 mL) and with a saturated bicarbonate solution after which they were dried over magnesium sulfate. Evaporation of the solvents gave a crude oil that was purified by column chromatography on silica gel (10% EtOAc in hexane) to afford 1.24 g (80% based on 30% recovered malonate **27**) of silyl ether **28**.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

The silyl ether **28** (1.12 g, 2.08 mmol) was dissolved in 35 mL of tetrahydrofuran at room temperature. To this solution was added tetrabutylammonium fluoride (1 M in tetrahydrofuran, 3.1 mL, 3.1 mmol) and the resulting mixture was stirred for 3 h, after which the solvent was evaporated. The crude product was purified by column chromatography on silica gel (25 to 50% EtOAc in hexane), to afford alcohol **29** (768 mg, 87%); ir ($CHCl_3$): 3610, 3005, 2950, 2870, and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.17 (2H, m=C*H*-C*H*=), 5.72 (1H, dt, *J* = 14.6 and 6.2 Hz, =C*H*-CH_2-O-), 5.49 (1H, dt, *J* = 14.2 and 7.7 Hz, =C*H*-CH_2-$C(CO_2CH_3)_2$-), 5.12 (1H, tl, *J* = 7.3 Hz, =C*H*-CH_2-CH_2-O-), 4.63 (1H, t, *J* = 3.5 Hz, -O-C*H*-O-), 4.25 (1H, dd, *J* = 13.2 and 6.1 Hz, =CH-C*H*H-O-), 3.97 (1H, dd, *J* = 13.0 and 7.0 Hz, =CH-CH*H*-O-), 3.86 (1H, m, -O-C*H*H-CH_2-CH_2-), 3.73 (6H, s, -$(CO_2CH_3)_2$), 3.58 (2H, t, *J* = 6.5 Hz, -CH_2-OH), 3.54 (1H, m, -O-CH*H*-CH_2-CH_2-), 2.71 (2H, d, *J* = 7.7 Hz, -$(CO_2CH_3)_2$C-CH_2-CH=), 2.20 (2H, q, *J* = 6.5 Hz, -CH_2-CH_2-OH), 1.90 (4H, s, -CH_2-CH_2-$C(CH_3)$=), 1.69 (3H, d, *J* = 1.1 Hz, CH_3-C=), 1.95–1.45 (7H, m, -$(CH_2)_3$-CH_2-O- and -O*H*); ms *m/e*: 425 (M^+ +H), 407 (M^+ −OH). Exact Mass calcd. for $M^+ - C_5H_{10}O_2$: 322.1780; found: 322.1780 ± 0.009.

Tetraester 30

Using the procedure employed for the preparation of **26**, alcohol **29** (160 mg, 0.38 mmol) and triethylamine (58 mg, 0.57 mmol) in 5 mL of dichloromethane were treated with methanesulfonyl chloride (47 mg, 0.42 mmol) for 1.5 h. The crude mesylate was reacted according to the procedure employed for the synthesis of **27** using sodium hydride (41 mg, 1.71 mmol), dimethyl malonate (251 mg, 1.90 mmol), and potassium iodide (6.1 mg, 0.037 mmol) in 10 mL of a 1:1 tetrahydrofuran and dimethylformamide mixture for 20 h. The crude product was purified by column chromatography on silica gel (25% EtOAc in hexane) affording tetraester **30** (160 mg, 79% overall); ir ($CHCl_3$): 3025, 2955, and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.17 (2H, m, =C*H*-C*H*=), 5.71 (1H, dt, *J* = 14.3 and 6.2 Hz, =C*H*-CH_2-O-), 5.49 (1H, dt, *J* = 14.3 and 7.2 Hz, -$(CO_2CH_3)_2$C-CH_2-C*H*=), 5.07 (1H, m, =C*H*-CH_2CH_2-), 4.63 (1H, t, *J* = 3.5 Hz, -O-C*H*-O-), 4.25 (1H, dd, *J* = 13.2 and 6.3 Hz, =CH-C*H*H-O-), 3.98 (1H, dd, *J* = 13.5 and 6.5 Hz, =CH-CH*H*-O-), 3.86 (1H, m, -O-C*H*H-CH_2-CH_2), 3.73 and 3.72 (12H, 2s, -CO_2CH_3), 3.52 (1H, m, -O-CH*H*-CH_2-CH_2-), 3.35 (1H, t, *J* = 7.1 Hz, -C*H*$(CO_2CH_3)_2$), 2.69 (2H, d, *J* = 7.9 Hz, -$(CO_2CH_3)_2$C-CH_2-CH=), 1.85 (4H, br s, -CH_2-CH_2-$C(CH_3)$=), 1.66 (3H, d, *J* = 1.1 Hz, CH_3-C=), 2.0–1.45 (10H, m, =CH-CH_2-CH_2 and -$(CH_2)_3$-CH_2-O-); ms *m/e*: 528 (M), 507 (M−OCH_3). Exact Mass calcd. for $M^+ - C_5H_{10}O_2$: 436.2097; found: 436.2095.

Alcohol 31

To a solution of tetraester **30** (150 mg, 0.28 mmol) in methanol (1.5 mL) was added pyridinium *p*-toluenesulfonate (17 mg, 0.068 mmol). The mixture was stirred at room temperature for 22 h. The solvent was evaporated and the residue was purified by column chromatography on silica gel (30% EtOAc in hexane) to yield 97 mg (77%) of alcohol **31**; ir ($CHCl_3$): 3610, 3020, 2955, and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.17 (2H, m, =C*H*-C*H*=), 5.77 (1H, app. dt, *J* = 14.7 and 5.8 Hz, =C*H*-CH_2-O-), 5.49 (1H, app dt, *J* = 14.6 and 7.3 Hz, -$(CO_2CH_3)_2$C-CH_2-C*H*=), 5.06 (1H, m, =C*H*-CH_2-CH_2-), 4.16 (2H, br t, *J* = 4.8 Hz, -CH_2-OH), 3.72 (12H, s, -CO_2CH_3), 3.34 (1H, t, *J* = 7.3 Hz, -$CH(CO_2CH_3)_2$), 2.70 (2H, d, *J* = 7.7 Hz, -$(CO_2CH_3)_2$C-CH_2-CH=), 2.00–1.80 (4H, m, =CH-CH_2-CH_2-), 1.83 (4H, br s, -CH_2-CH_2-$C(CH_3)$=), 1.68 (1H, m, -O*H*), 1.65 (3H, d, *J* = 0.9 Hz, CH_3-C=); ms *m/e*: 454 (M^+), 436 (M^+ −H_2O). Exact Mass calcd: 454.2203; found: 454.2203 ± 0.0017.

Triene 32

To a suspension of sodium hydride (45 mg, 1.9 mmol) in 10 mL of tetrahydrofuran at 0°C was added malonate **27** (644 mg, 1.80 mmol) dissolved in 10 mL of tetrahydrofuran. The mixture was warmed to room temperature, stirred for 1 h, and then heated to 35–40°C for one more hour (or until hydrogen gas evolution ceased). Allylic chloride **15** (825 mg, 2.23 mmol) dissolved in 20 mL of dimethylformamide was added and the resulting mixture was stirred at room temperature for 15 h. The work-up of the reaction is identical with that used for **28**. After chromatography (5% EtOAc in hexane), 1.09 g (88%) of triene **32** was obtained; ir ($CHCl_3$): 2955, 2930, 2860, 1730, and 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.68 and 7.40 (10H, 2m,-C_6H_5), 6.59 (1H, m, -C*H*=CH-CH_2-O-), 6.13 (1H, br t, *J* = 11.0 Hz, -$(CO_2CH_3)_2$C-CH_2-CH=C*H*-), 5.78 (1H, dt, *J* = 15.1 and 5.0 Hz, =C*H*-CH_2-O), 5.26 (1H, m, -$(CO_2CH_3)_2$C-CH_2-C*H*=), 5.13 (1H, m, =C*H*-CH_2-CH_2-O-), 4.26 (2H, br d, *J* = 4.9 Hz, =CH-CH_2-O-), 3.70 (6H, s, -$(CO_2CH_3)_2$), 3.54 (2H, t, *J* = 7.0 Hz, -CH_2-CH_2-O-), 2.82 (2H, d, *J* = 8.0 Hz, -$(CO_2CH_3)_2$C-CH_2-CH=), 2.14 (2H, br q, *J* = 7.1 Hz,-CH_2-CH_2-O-), 1.90 (4H, m, -CH_2-CH_2-$C(CH_3)$=), 1.66 (3H, d, *J* = 1.2 Hz, CH_3-C=), 1.07 (9H, s, t-*Bu*-Si$(C_6H_5)_2$), 0.88 (9H, s, t-*Bu*-Si$(CH_3)_2$), 0.03 (6H, s, -Si$(CH_3)_2$).

Alcohol 33

To a solution of disilyl ether **32** (1.05 g, 1.52 mmol) in 20 mL of isopropanol was added pyridinium *p*-toluenesulfonate (38 mg, 0.15 mmol). The mixture was stirred at 70°C for 17 h; then 50 mg of solid sodium carbonate was added and the solvent was evaporated under vacuum at 35°C. The residue was purified by column chromatography on silica gel (25% EtOAc in hexane) affording alcohol **33** (790 mg, 90%); ir ($CHCl_3$): 3620–3300, 3005, 2955, 2930, 2860, and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.68 and 7.40 (10H, 2m, -C_6H_5), 6.61 (1H, ddq, *J* = 15.0, 11.2, and 1.1 Hz, -C*H*=CH-CH_2-O-), 6.14 (1H, br t, *J* = 11.1 Hz, -$(CO_2CH_3)_2$C-CH_2-CH=C*H*-), 5.80 (1H, dt, *J* = 15.0 and 4.9 Hz, =C*H*-CH_2-O-), 5.24 (1H, dt, *J* = 10.9 and 7.9 Hz, -$(CO_2CH_3)_2$C-CH_2-C*H*=), 5.14 (1H, tq, *J* = 7.4 and 1.4 Hz, -C*H*-CH_2-CH_2-O-), 4.27 (2H, dd, *J* = 4.9 and 1.3 Hz, =CH-CH_2-O-), 3.71 (6H, s, -$(CO_2CH_3)_2$), 3.57 (2H, br t, *J* = 6.4 Hz, -CH_2-CH_2-OH), 2.83 (2H, dd, *J* = 7.9 and 1.2 Hz, -$(CO_2CH_3)_2$C-CH_2-CH=), 2.19 (2H, qd, *J* = 6.6 and 1.1 Hz, -CH_2-CH_2-OH), 1.92 (4H, s, -CH_2-CH_2-$C(CH_3)$=), 1.69 (3H, q, *J* = 1.2 Hz, CH_3-C—), 1.48 (1H, m, -O*H*), 1.07 (9H, s, *t*-Bu); ms *m/e*: 578 (M^+), 521 (M^+ − *t*-Bu).

Mesylate 34

Using the procedure employed for the preparation of **26**, alcohol **33** (775 mg, 1.34 mmol) and triethylamine (202 mg, 2.00 mmol) in 25 mL of dichloromethane were treated with methanesulfonyl chloride (169 mg, 1.47 mmol) affording mesylate **34** (890 mg, > 100% crude); ir ($CHCl_3$): 2955, 2930, 2860, and 1730 cm^{-1}: ^1H nmr ($CDCl_3$) δ: 7.68 and 7.40 (10H, 2m, -C_6H_5), 6.61 (1H, br dd, *J* = 15.0 and 11.2 Hz, -C*H*=CH-CH_2-O-), 6.15 (1H, br t, *J* = 11.1 Hz, -$(CO_2CH_3)_2$C-CH_2-CH-C*H*-), 5.81 (1H, dt, *J* = 15.0 and 4.8 Hz, =C*H*-CH_2-O-), 5.24 (1H, m, -$(CO_2CH_3)_2$C-CH_2-C*H*=), 5.11 (1H, br t, *J* = 7.3 Hz, =C*H*-CH_2-CH_2-O-), 4.27 (2H, br d, *J* = 4.7 Hz, =CH-CH_2-O-), 4.14 (2H, t, *J* = 6.9 Hz, -CH_2-CH_2-O-), 3.72 (6H, s, -$(CO_2CH_3)_2$), 2.97 (3H, s, CH_3-S-), 2.82 (2H, dd, *J* = 7.9 and 1.2 Hz, -$(CO_2CH_3)_2$C-CH_2-CH=), 2.37 (2H, br q, *J* = 7.0 Hz, -CH_2-CH_2-O-), 1.90 (4H, s, -CH_2-CH_2-$C(CH_3)$=), 1.68 (3H, q, *J* = 1.2 Hz, CH_3-C=), 1.07 (9H, s, *t*-Bu).

Tetraester 35

Using the procedure employed for the preparation of **27**, sodium hydride (144 mg, 6.00 mmol) and dimethyl malonate (884 mg, 6.70 mmol) were reacted in 15 mL of tetrahydrofuran to which were then added mesylate **34** (880 mg, 1.34 mmol) and potassium iodide (22 mg, 0.13 mmol) dissolved in 15 mL of dimethylformamide. The mixture was heated for 16 h at 80°C affording tetraester **35** (761 mg, 82%); ir ($CHCl_3$): 3025, 2955, 2930, 2860, and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.68 and 7.40 (10H, 2m, -C_6H_5), 6.60 (1H, m, -C*H*=CH-CH_2-O-), 6.13 (1H, br t, *J* = 11.1 Hz, -$(CO_2CH_3)_2$C-CH_2-CH=C*H*-), 5.26 (1H, m, -$(CO_2CH_3)_2$C-CH_2-C*H*=), 5.07 (1H, m, =C*H*-CH_2-CH_2-), 4.26 (2H, br d, *J* = 4.9 Hz, -CH_2-O-), 3.71 (12H, 2s, -$(CO_2CH_3)_2$-), 3.34 (1H, m, -C*H*$(CO_2CH_3)_2$), 2.81 (2H, br d, *J* = 7.9 Hz,

-(CO_2CH_3)$_2$C-CH_2-C*H*=), 3.02–2.78 (8H, m, -(CH_2)$_2$-C(CH_3)=CH(CH_2)$_2$-), 1.65 (3H, d, J = 1.2 Hz, CH_3-C=), 1.07 (9H, s, *t*-Bu).

Alcohol ***36***

Using the procedure employed for the preparation of **29**, silyl ether **35** (750 mg, 1.08 mmol) was treated with tetrabutylammonium fluoride (1 M in tetrahydrofuran, 1.18 mL, 1.18 mmol) in 25 mL of tetrahydrofuran to afford alcohol **36** (409 mg, 83%); ir ($CHCl_3$): 3600, 3520, 3020, 2950, and 1730 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.56 (1H, ddq, J = 15.1, 11.1, and 1.2 Hz, -C*H*=CH-CH_2-O-), 6.13 (1H, br t, J = 11.1 Hz, -(CO_2CH_3)$_2$C-CH_2-CH=C*H*-), 5.87 (1H, dt, J = 15.1 and 5.5 Hz, =C*H*-CH_2-OH), 5.25 (1H, dt, J = 10.9 and 7.8 Hz, -(CO_2CH_3)$_2$C-CH_2-C*H*=), 5.06 (1H, m, =C*H*-CH_2-CH_2-), 4.22 (2H, br d, J = 5.1 Hz, -CH_2-OH), 3.73 and 3.72 (12H, 2s, -(CO_2CH_3)$_2$-), 3.34 (1H, t, J = 7.3 Hz, -C*H*(CO_2CH_3)$_2$), 2.82 (2H, dd, J = 7.9 and 1.5 Hz, -(CO_2CH_3)$_2$C-CH_2-CH=), 2.03–1.70 (9H, m, -(CH_2)$_2$-C(CH_3)=CH-(CH_2)$_2$- and -O*H*), 1.65 (3H, d, J = 1.2 Hz, CH_3-C=).

Triene ***37***

Malonate **27** (300 mg, 0.84 mmol) in tetrahydrofuran (3 mL) was added dropwise to a suspension of sodium hydride (24 mg, 1 mmol) in a 2:1 tetrahydrofuran and dimethylformamide mixture (15 mL) at 0°C. The suspension was stirred at 0°C for 20 min and then at room temperature for an additional 10 min. The temperature was again lowered to 0°C and allylic chloride **12** (216 mg, 1 mmol) in tetrahydrofuran (3 mL) was added. The reaction mixture was stirred at room temperature for 17 h. A saturated aqueous ammonium chloride solution (10 mL) was added and the product was extracted with a 3:2 ether and hexane mixture (3 × 100 mL). The combined organic layers were dried and the solvents were evaporated. Purification by chromatography on silica gel (10% EtOAc in hexane) gave triene **37** (402 mg, 89%); ir ($CHCl_3$): 3030–3010, 2960–2860, 1730, and 1075 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.60–5.30 (4H, m, olefinic protons), 5.15 (1H, m, -C(CH_3)=C*H*-), 4.65 (1H, m, -OC*H*O-), 4.40–3.00 (6H, m, 3 × -CH_2O-), 3.73 (6H, s, 2 × -OCH_3), 2.72 (2H, d, J = 8.0 Hz, (CH_3O_2C)$_2$C-CH_2CH=), 2.15 (2H, q, J = 8.0 Hz, -C(CH_3)=CH-CH_2CH_2O-), 1.88 (4H, s, (CH_3O_2C)$_2$-CH_2-CH_2-C(CH_3)=), 1.65 (6H, m, -OCHO-CH_2-(CH_2)$_3$-), 0.88 (9H, s, *t*-Bu), 0.04 (6H, s, -Si(CH_3)$_2$).

Alcohol ***38***

To the silyl ether **37** (363 mg, 0.675 mmol) in tetrahydrofuran (5 mL) at 0°C, was added tetrabutylammonium fluoride (1 M in tetrahydrofuran, 1.25 mL, 1.25 mmol). The reaction mixture was stirred at room temperature for 4 h. The solvent was evaporated and the resulting residue was purified by chromatography on silica gel (30% EtOAc in hexane) to give alcohol **38** (277 mg, 97%); ir ($CHCl_3$): 3620, 3480, 3000–2870, 1730, and 1030 cm^{-1}; ^{1}H nmr ($CDCl_3$); δ: 6.44 (1H, ddd, J = 15.0 Hz, 11.7 Hz, 1.1 Hz, -OCH_2CH=CHC*H*=CH-), 6.09 (1H, tm, J = 11.8 Hz, -OCH_2-CH=C*H*CH=CH-), 5.54 (2H, m, -OCH_2C*H*=CHCH=C*H*-CH_2-), 5.13 (1H, td, J = 7.5 Hz, 1.4 Hz, -C(CH_3)=C*H*-), 4.63 (1H, t, J = 3.8 Hz, -OC*H*O-), 4.36 (1H, ddd, J = 13.8 Hz, 6.0 Hz, 1.6 Hz, -OCHO-C*H*HCH=), 4.15 (1H, ddd, J = 13.8 Hz, 7.3 Hz, 1.4 Hz, -OCHO-CH*H*CH=), 3.74 (1H, m, -C*H*H-OCHO-), 3.73 (6H, s, 2 × -OCH_3), 3.57 (3H, m, -CH*H*-OCHO, -CH_2OH), 2.74 (2H, d, J = 6.6 Hz, (CH_3O_2C)$_2$C-CH_2CH=), 2.21 (2H, qd, J = 6.3 Hz, 1.1 Hz, -C(CH_3)=CH-CH_2CH_2OH), 1.90 (4H, s, (CH_3O_2C)$_2$C-CH_2CH_2-C(CH_3)=CH-), 1.69 (3H, d, J = 1.3 Hz, -C(CH_3)=CH-), 1.75–1.50 (6H, m, -(CH_2)$_3$-CH_2-OCHO-).

Tetraester ***39***

Methanesulfonyl chloride (61 μL, 0.78 mmol) was added, dropwise, to a solution of alcohol **38** (277 mg, 0.653 mmol) and triethylamine (136 μL, 0.98 mmol) in dichloromethane (5 mL) at 0°C. The mixture was stirred at 0°C for 1 h and was then poured into ice-cold water. The product was extracted with dichloromethane (3 × 50 mL). The combined organic layers were washed with water, dried, and the solvent was evaporated. The resulting crude mesylate (310 mg) was used as such for the next step.

Methyl malonate (354 μL, 3.1 mmol) was added, dropwise, to a suspension of sodium hydride (67 mg, 2.79 mmol) in a 1:1 dimethylformamide and tetrahydrofuran mixture (8 mL) at 0°C. The mixture was stirred at 0°C for 20 min, and at room temperature for 10 min. The above mesylate in tetrahydrofuran (3 mL) was added, followed by a catalytic amount of potassium iodide (52 mg, 0.31 mmol). The reaction mixture was heated at 95°C for 4 h and was then cooled to room temperature. Saturated aqueous ammonium chloride solution was added and the product was extracted with a 2:1 ether and hexane mixture (3 × 50 mL). The combined organic layers were dried and the solvent was evaporated. Chromatography on silica gel (25% EtOAc in hexane) gave tetraester **39** (268 mg, 76% overall from the alcohol **38**); ir ($CHCl_3$): 3000–2850 and 1730 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.60–5.30 (4H, m, olefinic protons), 5.10 (1H, m, -C(CH_3)=C*H*-), 4.65 (1H, m, -OC*H*O-), 4.40–3.25 (5H, m, -C*H*(CO_2CH_3)$_2$, -CH=CH-CH_2-OCHO-CH_2-), 2.70 (2H, d, J = 8.0 Hz, (CH_3O_2C)$_2$C-CH_2-CH=CH-), 2.10–1.30 (17H, m, -CH_2-CH_2-C(CH_3)=CH-CH_2-CH_2-, -OCHO-CH_2-(CH_2)$_3$-).

Alcohol ***40***

A catalytic amount of pyridinium *p*-toluenesulfonate (25 mg, 0.1 mmol) was added to the tetrahydropyranyloxy derivative **39** (268 mg, 0.5 mmol) in methanol (5 mL). The mixture was heated at 55°C for 3 h. The solvent was evaporated and the resulting residue was purified by chromatography on silica gel (40% EtOAc in hexane) to give alcohol **40** (216 mg, 96%)); ir ($CHCl_3$): 3600, 3500, 3020–2870, and 1730 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.65–5.30 (4H, m, olefinic protons), 5.10 (1H, m, -C(CH_3)=C*H*-), 4.30 (2H, apparent d, J = 6.9 Hz, -CH=CH-CH_2OH), 3.75 (12H, s, 4 × -OCH_3), 3.45 (1H, t, J = 8.0 Hz, -C*H*(CO_2CH_3)$_2$), 2.72 (2H, d, J = 7.0 Hz, (CH_3O_2C)$_2$C-CH_2CH=CH-), 2.15–1.80 (8H, m, -CH_2-CH_2-C(CH_3)=CH-CH_2-CH_2-), 1.65 (3H, d, -C(CH_3)=CH-).

Triene ***41***

The procedure employed was identical with that described for the preparation of triene **37** except for using allylic chloride **9**; yield: 80%; ir ($CHCl_3$): 3010–2860, 1730, 1100, and 1030 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.39 (2H, m, -OCH_2CH=C*HCH*=CH-), 5.66 (1H, m, -OCH_2C*H*=CHCH=CH-), 5.35 (1H, m, -OCH_2CH=CH-CH=C*H*-), 5.12 (1H, td, J = 7.2 Hz, 1.5 Hz, -C(CH_3)=C*H*-), 4.62 (1H, dd, J = 4.8 Hz, 3.0 Hz, -OC*H*O-), 4.34 (1H, ddd, J = 12.9 Hz, 6.2 Hz, 1.3 Hz, -OC*H*HCH=CH-), 4.19 (1H, ddd, J = 12.7 Hz, 7.0 Hz, 1.1 Hz, -OCH*H*CH=CH-), 3.86 (1H, m, -OCHO-C*H*H-), 3.71 (6H, s, 2 × -OCH_3), 3.55 (1H, t, J = 7.0 Hz, -CH_2-CH_2O-), 3.52 (1H, m, -OCHO-CH*H*-), 2.81 (2H, d, J = 7.3 Hz, (CH_3O_2C)$_2$C-CH_2CH=), 2.13 (2H, qd, J = 7.1 Hz, 1.2 Hz, -C(CH_3)=CH-CH_2CH_2O-), 1.89 (4H, m, (CH_3O_2C)$_2$C-C*H*CH_2-C(CH_3)=CH-), 1.85–1.48 (6H, m, -OCHO-CH_2-(CH_2)$_3$-), 1.66 (3H, d, J = 1.3 Hz, -C(CH_3)=CH-), 0.88 (9H, s, *t*-Bu), 0.03 (6H, s, -Si(CH_3)$_2$).

Alcohol ***42***

The same procedure as that described for the preparation of alcohol **38** was employed; yield: 92%; ir ($CHCl_3$): 3620, 3480, 3000–2860, 1730, 1220, and 1030 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.40 (2H, m, -OCH_2CH=C*HCH*=CH-), 5.80–4.90 (3H, m, -OCH_2C*H*=CHCH=C*H*-, -C(CH_3)=C*H*-), 4.60 (1H, m, -OC*H*O-), 4.50–3.30 (6H, m, -CH_2OH, =CHCH_2OCHOCH_2-), 3.70 (6H, s, 2 × -OCH_3), 2.80 (2H, d, J = 8.0 Hz, (CH_3O_2C)$_2$C-CH_2-CH=), 2.15 (2H, m, =CHCH_2CH_2OH), 1.88 (4H, s, (CH_3O_2C)$_2$C-CH_2-CH_2C(CH_3)=CH-), 1.80 (1H, s, -CH_2O*H*), 1.70–1.40 (9H, m, -C(CH_3)=CH-, -OCHO-CH_2-(CH_2)$_3$-).

Tetraester ***43***

The procedure was identical with that described for the preparation of **39**; yield: 90% (overall from alcohol **42**); ir ($CHCl_3$): 3000–2840, 1730, 1230, 1200, and 1020 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.40 (2H, m, -OCH_2CH=C*HCH*=CH-), 5.80–5.25 (2H, m, -OCH_2-

Alcohol ***44***

The procedure described for the preparation of alcohol **40** was employed; yield: 92%; ir ($CHCl_3$): 3610, 3520, 3020–2840, 1730, 1440, 1200, and 1020 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.38 (2H, m, HOCH$_2$CH=CHCH=CH-), 5.71 (1H, m, HOCH$_2$CH=CHCH=CH-), 5.36 (1H, m, HOCH$_2$CH=CHCH=CH-), 5.31 (1H, m, -C(CH$_3$)=CH-), 4.32 (2H, d, J = 6.7 Hz, HOCH$_2$CH=), 3.73 (12H, 2 × s, 4 × -OCH$_3$), 3.34 (1H, t, J = 7.2 Hz, -CH(CO$_2$CH$_3$)$_2$), 2.82 (2H, d, J = 7.5 Hz, (CO$_2$CH$_3$)$_2$C-CH$_2$-CH=), 1.99–1.67 (9H, m, -CH$_2$CH$_2$-C(CH$_3$)=CH-CH$_2$CH$_2$-, -CH$_2$OH), 1.65 (3H, s, -C(CH$_3$)=CH-).

Triester ***45***

Using previously described procedures (see the preparation of **28** for example), sodium hydride (46 mg, 1.92 mmol) was reacted with malonate **21** (520 mg, 1.73 mmol) followed by reaction with allylic chloride **15** (700 mg, 1.89 mmol), in 50 mL of a 1:1 tetrahydrofuran and dimethylformamide mixture, at room temperature for 8 h. The crude triester was purified by chromatography on silica gel (20% ether in hexane) yielding pure triester **45** (930 mg, 84%); ir (CH_2Cl_2): 2955, 2930, 2860, and 1730 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.68 and 7.40 (10H, 2m, -C$_6$H$_5$), 6.59 (1H, br dd, J = 15.0 and 11.3 Hz, -CH=CH-CH$_2$-O-), 6.13 (1H, br t, J = 11.1 Hz, -(CO$_2$CH$_3$)$_2$C-CH$_2$-CH=CH-), 5.80 (1H, dt, J = 15.0 and 4.8 Hz, =CH-CH$_2$-O-), 5.24 (1H, dt, J = 10.9 and 8.0 Hz, -(CO$_2$CH$_3$)$_2$C-CH$_2$-CH=), 5.10 (1H, br t, J = 7.3 Hz, =CH-CH$_2$-CH$_2$-), 4.26 (2H, br d, J = 4.8 Hz, -CH$_2$-O-), 3.70 (6H, s, -(CO$_2$CH$_3$)$_2$-), 3.65 (3H, s, -CO$_2$CH$_3$), 2.80 (2H, br d, J = 8.0 Hz, -(CO$_2$CH$_3$)$_2$C-CH$_2$-CH=), 2.28 (2H, t, J = 7.5 Hz, -CH$_2$-CO$_2$-CH$_3$), 2.07–1.77 (6H, m, -(CH$_2$)$_2$-C(CH$_3$)=CH-CH$_2$-), 1.64 (2H, qn, J = 7.3 Hz, -CH$_2$-CH$_2$-CO$_2$CH$_3$), 1.56 (3H, d, J = 1.0 Hz, CH$_3$-C=), 1.07 (9H, s, *t*-Bu).

Tetraester ***46***

Stock solution of LDA. *n*-Butyllithium (1.55 M in hexane, 1.72 mL, 2.67 mmol) was added dropwise to a solution of diisopropylamine (289 mg, 2.86 mmol) in 4 mL of tetrahydrofuran at 0°C. The mixture was stirred at 0°C for 15 min.

Carbomethoxylation. To a solution of triester **45** (455 mg, 0.72 mmol) in 7 mL of tetrahydrofuran at −78°C was added 1.63 mL of the LDA stock solution (0.72 mmol). The mixture was stirred for 30 min and then methyl chloroformate (34 mg, 0.36 mmol) was added. After 20 min, a second aliquot of 815 μL (0.36 mmol) of the stock solution was added; the resulting mixture was stirred for 20 min after which time methyl chloroformate (20.4 mg, 0.22 mmol) was again added. The process was repeated twice, reducing the quantities by a twofold factor each time. After the last addition of methyl chloroformate the mixture was stirred for 5 min at −78°C and then 15 mL of a saturated aqueous ammonium chloride solution was added. The mixture was extracted with ether (3 × 20 mL), and the combined organic layers were washed with water (10 mL) and dried over magnesium sulfate. The solvent was evaporated, giving an oil that was purified by chromatography on silica gel (10–20% EtOAc in hexane) to afford tetraester **46** (365 mg, 74%); ir ($CHCl_3$): 3020, 2960, 2930, 2860, and 1730 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.68 and 7.40 (10H, 2m, -C$_6$H$_5$), 6.59 (1H, br dd, J = 14.9 and 11.2 Hz, -CH=CH-CH$_2$-O-), 6.12 (1H, br t, J = 11.1 Hz, -(CO$_2$CH$_3$)$_2$C-CH$_2$-CH=CH-), 5.79 (1H, dt, J = 15.0 and 5.0 Hz, =CH-CH$_2$-O-), 5.23 (1H, dt, J = 10.9 and 8.9 Hz, -(CO$_2$CH$_3$)$_2$C-CH$_2$-CH=), 5.08 (1H, br t, J = 6.5 Hz, =CH-CH$_2$-CH$_2$-), 4.26 (2H, br d, J = 4.8 Hz, -CH$_2$-O), 3.72 and 3.69 (12H, 2s, -(CO$_2$CH$_3$)$_2$-), 3.35 (1H, t, J = 7.2 Hz, -CH(CO$_2$CH$_3$)$_2$), 2.79 (2H, br d, J = 7.9 Hz, -(CO$_2$CH$_3$)$_2$C-CH$_2$-CH=), 2.05–1.75 (8H, m, (-CH$_2$)$_2$-C(CH$_3$)=CH-(CH$_2$)$_2$-), 1.55 (3H, d, J = 1.1 Hz, CH$_3$-C=), 1.07 (9H, s, *t*-Bu).

Alcohol ***47***

Using the procedure employed for the preparation of **29**, silyl ether **46** (360 mg, 0.52 mmol) was treated with tetrabutylammonium fluoride (1 M in THF, 572 μL, 0.572 mmol) in 8 mL of tetrahydrofuran to afford alcohol **47** (170 mg, 72%); ir ($CHCl_3$): 3600, 3520, 3020, 2950, and 1730 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.53 (1H, ddq, J = 15.1, 11.1, and 1.2 Hz, -CH=CH-CH$_2$-O-), 6.12 (1H, br t, J = 11.1 Hz, -(CO$_2$CH$_3$)$_2$C-CH$_2$-CH=CH-), 5.86 (1H, dt, J = 15.1 and 5.6 Hz, =CH-CH$_2$-O-), 5.26 (1H, dt, J = 10.9 and 7.9 Hz, -(CO$_2$CH$_3$)$_2$C-CH$_2$-CH=), 5.07 (1H, br t, J = 6.0 Hz, =CH-CH$_2$-CH$_2$-), 4.21 (2H, br d, J = 5.3 Hz, -CH$_2$-OH), 3.73 and 3.70 (12H, 2s, -(CO$_2$CH$_3$)$_2$-), 3.34 (1H, t, J = 7.2 Hz, -CH(CO$_2$CH$_3$)$_2$), 2.80 (2H, dd, J = 7.9 and 1.3 Hz, -(CO$_2$CH$_3$)$_2$C-CH$_2$-CH=), 2.05–1.75 (8H, m, -(CH$_2$)$_2$-C(CH$_3$)=CH-(CH$_2$)$_2$), 1.64 (1H, m, -OH), 1.55 (3H, d, J = 1.1 Hz, CH$_3$-C=).

Triester ***48***

Malonate **21** (1.205 g, 4 mmol) in tetrahydrofuran (5 mL) was added, dropwise, to a suspension of sodium hydride (125 mg, 5.2 mmol) in a 1:2 dimethylformamide and tetrahydrofuran mixture (90 mL) at 0°C. The reaction mixture was stirred at 0°C for 30 min and then at room temperature for an additional 30 min. The temperature was lowered to 0°C and the allylic chloride **12** (954 mg, 4.4 mmol) in tetrahydrofuran (5 mL) was added, followed by stirring at room temperature for 21 h. A saturated aqueous ammonium chloride solution (50 mL) was added and the resulting solution was extracted with a 3:2 ether and hexane mixture (5 × 100 mL). The combined organic layers were dried and the solvent was evaporated. Purification by chromatography on silica gel (15% EtOAc in hexane) gave the triene **48** (1.476 g, 77%); ir ($CHCl_3$): 3030–2860, 1730, 1440, 1230, 1200, and 1020 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.37 (1H, ddd, J = 15.0 Hz, 11.8 Hz, 0.9 Hz, -OCH$_2$CH=CHCH=CH-), 6.08 (1H, t, J = 11.1 Hz, -OCH$_2$CH=CHCH=CH-), 5.51 (2H, m, -OCH$_2$CH=CHCH=CH-), 5.09 (1H, td, J = 6.7 Hz, 1.1 Hz, -C(CH$_3$)=CH-), 4.62 (1H, t, J = 2.9 Hz, -OCHO-), 4.32 (1H, ddd, J = 12.8 Hz, 6.2 Hz, 1.4 Hz, =CH-CHHO-), 4.16 (1H, ddd, J = 12.3 Hz, 7.4 Hz, 1.3 Hz, =CH-CHHO-), 3.87 (1H, m, -OCHO-CHH-), 3.71 (6H, s, -C(CO$_2$CH$_3$)$_2$), 3.66 (3H, s, -CH$_2$CO$_2$CH$_3$), 3.51 (1H, m, -OCHO-CHH-), 2.69 (2H, d, J = 6.7 Hz, (CH$_3$O$_2$C)$_2$C-CH$_2$CH=), 2.28 (2H, t, J = 7.5 Hz, -CH$_2$CO$_2$CH$_3$), 2.04–1.48 (17H, m, -CH$_2$CH$_2$C(CH$_3$)=CHCH$_2$CH$_2$-, -OCHO-CH$_2$-(CH$_2$)$_3$-).

Tetraester ***49***

Triester **48** (529 mg, 1.1 mmol) was reacted in tetrahydrofuran at −78°C with a total of 2.2 mmol lithium diisopropylamide (from a 0.635 M stock solution in tetrahydrofuran) and with a total of 1.1 mmol methyl chloroformate, using the same procedure as described for the preparation of **46**. Tetraester **49** (250 mg) was obtained in 42% yield after chromatography on silica gel (25% EtOAc in hexane); ir ($CHCl_3$): 3010–2840, 1730, 1440, 1220, and 1020 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.38 (1H, ddd, J = 15.1 Hz, 11.1 Hz, 1.0 Hz, -OCH$_2$CH=CHCH=CH-), 6.08 (1H, t, J = 11.0 Hz, -OCH$_2$CH=CHCH=CH-), 5.51 (2H, m, -OCH$_2$CH=CHCH=CH-), 5.09 (1H, m, -C(CH$_3$=CH-), 4.63 (1H, m, -OCHO-), 4.25 (1H, ddd, J = 12.5 Hz, 6.2 Hz, 1.3 Hz, -OCHHCH=), 4.16 (1H, ddd, J = 12.8 Hz, 7.5 Hz, 1.3 Hz, -OCHHCH=), 3.84 (1H, m, -OCHO-CHH-), 3.73 (6H, s, 2 × -OCH$_3$), 3.71 (6H, s, 2 × -OCH$_3$), 3.51 (1H, m, -OCHO-CHH-), 3.36 (1H, t, J = 7.4 Hz, -CH(CO$_2$CH$_3$)$_2$), 2.70 (2H, d, J = 7.6 Hz, (CH$_3$O$_2$C)$_2$CCH$_2$CH=), 2.02–1.45 (17H, m, -CH$_2$CH$_2$C-(CH$_3$)=CH-CH$_2$CH$_2$-, -OCHO-CH$_2$-(CH$_2$)$_3$-); ms *m/e*: 538 (M$^+$).

Alcohol ***50***

To a solution of tetrahydropyranyloxy derivative **49** (242 mg, 0.45 mmol) in methanol (5 mL) was added pyridinium *p*-toluenesulfonate (22.5 mg, 0.1 mmol). The mixture was stirred at 55°C for 2 h. The methanol was evaporated, and the residue was purified by chromatography on silica gel (5% acetone in dichloromethane) to give alcohol **50** (197 mg, 97%); ir ($CHCl_3$): 3600, 3500, 3020–2840, 1730, 1440, and 1230 cm^{-1}; ^{1}H nmr ($CDCl_3$)

δ: 6.36 (1H, ddd, J = 15.0 Hz, 11.2 Hz, 1.2 Hz, $HOCH_2CH$=$CHCH$=CH-), 6.03 (1H, t, J = 11.3 Hz, $HOCH_2CH$=$CHCH$=CH-), 5.54 (2H, m, $HOCH_2CH$=$CHCH$=CH-), 5.08 (1H, td, J = 6.2 Hz, 1.2 Hz, -$C(CH_3)$=CH-), 4.28 (2H, d, J = 7.1 Hz, $HOCH_2$-), 3.73 (6H, s, 2 × -OCH_3), 3.72 (6H, s, 2 × -OCH_3), 3.35 (1H, t, J = 7.2 Hz, -$CH(CO_2CH_3)$), 2.70 (2H, d, J = 7.5 Hz, $(CH_3O_2C)_2C$-CH_2CH=), 2.04–1.81 (9H, m, -$CH_2CH_2C(CH_3)$=CH-CH_2CH_2-, -CH_2OH), 1.56 (3H, d, J = 1.1 Hz, -$C(CH_3)$=CH-).

Triester 51

The procedure described for the preparation of **48**, except for using allylic chloride **9**, led to triene **51** in 78% yield; ir ($CHCl_3$): 3000–2840, 1730, 1440, 1220, and 1020 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.39 (2H, m, -OCH_2CH=$CHCH$=CH-), 5.66 (1H, m, -OCH_2-CH=$CHCH$-CH-), 5.36 (1H, m, -OCH_2CH=$CHCH$=CH-), 5.09 (1H, td, J = 7.1 Hz, 1.2 Hz, -$C(CH_3)$=CH-), 4.62 (1H, dd, J = 4.3 Hz, 4.1 Hz, -OCHO-), 4.38 (1H, ddd, J = 12.5 Hz, 5.3 Hz, 1.2 Hz, -OCHHCH=CH-), 4.21 (1H, ddd, J = 12.9 Hz, 6.5 Hz, 1.0 Hz, -OCHHCH=CH-), 3.86 (1H, m, -OCHO-CHH-), 3.70 (6H, s, 2 × -OCH_3), 3.66 (3H, s, -$CH_2CO_2CH_3$), 3.50 (1H, m, -OCHO-CHH-), 2.80 (2H, d, J = 7.4 Hz $(CH_3O_2C)_2C$-CH_2CH=), 2.28 (2H, t, J = 7.5 Hz, -$CH_2CH_2CO_2CH_3$), 2.04–1.42 (17H, m, -$CH_2CH_2C(CH_3)$=$CHCH_2CH_2$-, -OCHO-CH_2-$(CH_2)_3$-); ms m/e: 480 (M^+), 462 (M^+ − 18), 396 (M^+ − C_5H_9O), 378 (M^+ − $C_5H_{10}O_2$). Exact Mass calcd. for M^+ − $C_5H_{10}O_2$: 378.2042; found: 378.2042 ± 0.0011.

Tetraester 52

The same procedure as described for the preparation of **46** was employed, affording **52** in 44% yield; ir ($CHCl_3$): 3020–2840, 1730, 1435, 1200, and 1020 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.39 (2H, m, -OCH_2CH=$CHCH$=CH-), 5.63 (1H, m, -OCH_2CH=$CHCH$=CH-), 5.35 (1H, m, -OCH_2CH=$CHCH$=CH-), 5.08 (1H, td, J = 7.5 Hz, 1.1 Hz, -$C(CH_3)$=CH-), 4.62 (1H, t, J = 3.0 Hz, -OCHO-), 4.35 (1H, dd, J = 13.9 Hz, 5.6 Hz, -OCHH-CH=), 4.19 (1H, dd, J = 12.9 Hz, 7.0 Hz, -OCHH-CH=), 3.86 (1H, m, -OCHO-CHH-), 3.73 (6H, s, 2 × -OCH_3), 3.70 (6H, s, 3 × -OCH_3), 3.49 (1H, m, -OCHO-CHH-), 3.35 (1H, t, J = 7.2 Hz, -$CH(CO_2CH_3)_2$), 2.80 (2H, d, J = 7.5 Hz, $(CH_3O_2C)_2C$-CH_2-CH=), 2.04–1.48 (14H, m, -CH_2CH_2-$C(CH_3)$=CH-CH_2CH_2-, -OCHO-$CH_2(CH_2)_3$-), 1.55 (3H, d, J = 0.9 Hz, $C(CH_3)$=CH-).

Alcohol 53

The procedure described for the preparation of **50** was employed, affording alcohol **53** in 93% yield; ir ($CHCl_3$): 3600, 3500, 3020–2840, 1730, 1440, and 1220 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.35 (2H, m, $HOCH_2CH$=$CHCH$=CH-), 5.70 (1H, m, $HOCH_2CH$=$CHCH$=CH-), 5.35 (1H, m, $HOCH_2CH$=$CHCH$=CH-), 5.07 (1H, t, J = 7.5 Hz, -$C(CH_3)$=CH-), 4.32 (2H, d, J = 6.6 Hz, HOH_2CH=), 3.73 (6H, s, 2 × -OCH_3), 3.71 (6H, s, 2 × -OCH_3), 3.35 (1H, t, J = 7.2 Hz, -$CH(CO_2CH_3)_2$), 2.80 (2H, d, J = 7.6 Hz, $(CH_3O_2C)_2C$-CH_2CH=), 2.02–1.80 (8H, m, -CH_2CH_2-$C(CH_3)$=CH-CH_2CH_2-), 1.60 (1H, br s, $HOCH_2$-), 1.55 (3H, s, -$C(CH_3)$=CH-).

Triester 54

Using the procedure described for the preparation of **28**, sodium hydride (164 mg, 6.83 mmol) was reacted with malonate **21** (1.96 g, 6.53 mmol) in 75 mL of tetrahydrofuran to give the corresponding sodiomalonate, which was treated at room temperature for 11 h with allylic chloride **4** (1.90 g, 8.77 mmol) dissolved in 75 mL of dimethylformamide. The crude product was purified by column chromatography on silica gel (10% acetone in hexane) to give triester **54** (2.51 g, 80%); ir ($CHCl_3$): 3030, 3010, 2955, and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.14 (2H, m, =CH-CH=), 5.70 (1H, dt, J = 14.3 and 6.4 Hz, =CH-CH_2-O-), 5.48 (1H, dt, J = 14.3 and 7.5 Hz, -$(CO_2CH_3)_2C$-CH_2CH=), 5.10 (1H, m, =CH-CH_2-CH_2-), 4.63 (1H, m, -O-CH-O-), 4.25 (1H, dd, J = 13.2 and 6.3 Hz, =CH-CHH-O-), 3.98 (1H, m, -CH-CHH-O-), 3.86 (1H, m, -O-CHH-CH_2-CH_2-), 3.71 and 3.66 (12H, 2s, -$(CO_2CH_3)_2$-), 3.51 (1H, m, -O-CHH-CH_2-CH_2-), 2.68 (2H, d, J = 7.7 Hz, -$(CO_2CH_3)_2C$-CH_2-CH=), 2.28 (2H, t, J = 7.5 Hz, -CH_2-CO_2CH_3), 2.07–1.45 (14H, m, -$(CH_2)_2$-$C(CH_3)$=CH-$(CH_2)_2$- and -$(CH_2)_3$-CH_2-O-), 1.56 (3H, d, J = 1.2 Hz, CH_3-C=).

Tetraester 55

To a solution of *n*-butyllithium (1.6 M in hexane, 1.77 mL, 2.84 mmol) in 7 mL of tetrahydrofuran at 0°C was added diisopropylamine (300 mg, 2.97 mmol) dissolved in 2 mL of tetrahydrofuran. The mixture was stirred at 0°C for 30 min and was then cooled to −78°C. Triester **54** (680 mg, 1.42 mmol) dissolved in 7 mL of tetrahydrofuran was added dropwise over a period of 10 min. The dark-red mixture was stirred at −78°C for 40 min and was transferred via canula to a solution of methyl chloroformate (1.34 g, 14.2 mmol) dissolved in 5 mL of tetrahydrofuran at −78°C. The solution was kept at −78°C for 35 min and was then quenched with a saturated aqueous solution of ammonium chloride (50 mL). The phases were separated and the aqueous layer was extracted with ether (3 × 30 mL). The combined organic layers were washed with water (20 mL) and brine (20 mL), and were dried over magnesium sulfate. The crude material obtained after evaporation of the solvents was purified by chromatography on silica gel (10% acetone in hexane) to afford tetraester **55** (454 mg, 60%); ir ($CHCl_3$): 3020, 2955, and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.16 (2H, m, =CH-CH=), 5.70 (1H, dt, J = 14.5 and 6.2 Hz, =CH-CH_2-O-), 5.48 (1H, dt, J = 14.5 and 7.1 Hz, -$(CO_2CH_3)_2C$-CH_2-CH=), 5.08 (1H, m, =CH-CH_2-CH_2-), 4.63 (1H, m, -O-CH-O-), 4.25 (1H, dd, J = 12.9 and 5.5 Hz, -CH-CHH-O-), 3.98 (1H, dd, J = 12.9 and 6.7 Hz, =CH-CHH-O-), 3.86 (1H, m, -O-CHH-CH_2-CH_2-), 3.73 and 3.71 (12H, 2s, -$(CO_2CH_3)_2$-), 3.51 (1H, m, -O-CHH-CH_2-CH_2-), 3.36 (1H, t, J = 7.2 Hz, -$CH(CO_2CH_3)_2$), 2.68 (2H, d, J = 7.6 Hz, -$(CO_2CH_3)_2C$-CH_2-CH=), 2.09–1.45 (14H, m, -$(CH_2)_2$-$C(CH_3)$=CH-$(CH_2)_2$- and -$(CH_2)_3$-CH_2-O-), 1.55 (3H, d, J = 1.1 Hz, CH_3-C=).

Alcohol 56

Using the procedure described for the preparation of **31**, tetraester **55** (450 mg, 0.84 mmol) was treated with pyridinium *p*-toluenesulfonate (21 mg, 0.084 mmol) in 6 mL of methanol to afford alcohol **56** (288 mg, 76%); ir ($CHCl_3$): 3610, 3020, 2950, and 1728 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.15 (2H, m, =CH-CH=), 5.76 (1H, dt, J = 14.9 and 5.7 Hz, =CH-CH_2-O-), 5.49 (1H, dt, J = 14.4 and 7.0 Hz, -$(CO_2CH_3)_2C$-CH_2-CH=), 5.08 (1H, m, =CH-CH_2-CH_2-), 4.16 (1H, br d, J = 5.8 Hz, -CH_2-O-), 3.73 and 3.71 (12H, 2s, -$(CO_2CH_3)_2$-), 3.35 (1H, t, J = 7.2 Hz, -CH-$(CO_2CH_3)_2$), 2.68 (2H, d, J = 7.6 Hz, -$(CO_2CH_3)_2C$-CH_2-CH=), 2.08–1.75 (8H, m, -$(CH_2)_2$-$C(CH_3)$=CH-$(CH_2)_2$-), 1.61 (1H, m, -OH), 1.55 (3H, d, J = 1.1 Hz, CH_3-C=).

Monoester 57

Sodium cyanide (49.7 mg, 1.01 mmol) and water (28 μL, 1.5 mmol) were added to a solution of the diester **38** (214 mg, 0.5 mmol) in dimethyl sulfoxide (8 mL). The mixture was heated at 95°C for 30 h and was then cooled to room temperature. The resulting solution was poured into ice-cold water, which was then saturated with sodium chloride and extracted with hexane (4 × 50 mL). The combined organic layers were dried and the solvent was evaporated. Purification by chromatography on silica gel (40% EtOAc in hexane) gave monoester **57** (149.8 mg, 81%); ir ($CHCl_3$): 3500, 3000–2840, 1730, 1440, and 1220 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.36 (1H, ddq, J = 14.9 Hz, 11.1 Hz, 1.0 Hz, -OCH_2CH=$CHCH$=CH-), 6.09 (1H, tm, J = 11.2 Hz, -OCH_2CH=$CHCH$=CH-), 5.63 (1H, dt, J = 15.0 Hz, 7.2 Hz, -OCH_2CH=$CHCH$=CH-CH_2-), 5.49 (1H, dt, J = 10.9 Hz, 6.9 Hz, -OCH_2-CH=$CHCH$=CH-), 5.15 (1H, tq, J = 7.3 Hz, 0.9 Hz, -$C(CH_3)$=CH-), 4.64 (1H, apparent t, J = 3.1 Hz, -OCHO-), 4.34 (1H, dddd, J = 12.6 Hz, 4.9 Hz, 3.2 Hz, 1.3 Hz, -OCHO-CHH-CH=CH-), 4.17 (1H, dddd, J = 12.7 Hz, 7.5 Hz, 2.7 Hz, 1.3 Hz, -OCHO-CHH-CH=CH-), 3.88 (1H, m, -CHH-OCHO-), 3.67 (3H, s, -CO_2CH_3), 3.60 (2H, m, -CH_2OH), 3.51 (1H, m, -CHH-OCHO-), 2.45–2.19 (7H, m, =CH-CH_2CH-$(CO_2CH_3)CH_2CH_2C(CH_3)$=$CHCH_2$-), 2.03 (3H, m, -CH($CO_2$-

For personal use only.

$CH_3)CH_2$-, -CH_2OH), 1.88–1.48 (6H, m, -$(CH_2)_3CH_2$-OCHO-), 1.69 (3H, d, J = 1.3 Hz, -C(CH_3)=CH-).

Triester ***58***

Methanesulfonyl chloride (40 μL, 0.51 mmol) was added, dropwise, to a solution of alcohol **57** (155 mg, 0.42 mmol) and triethylamine (89 μL, 0.64 mmol) in dichloromethane (5 mL). The reaction mixture was stirred at 0°C for 1 h, then was poured into ice-cold water and extracted with dichloromethane. The combined organic layers were dried and the solvent was evaporated to give a crude mesylate, which was used as such for the next step.

Methyl malonate (242 μL, 2.1 mmol) was added to a suspension of sodium hydride (45.7 mg, 1.9 mmol) in a 1:1 mixture of tetrahydrofuran and dimethylformamide at 0°C. The mixture was stirred at 0°C for 30 min, then at room temperature for 10 min. The above mesylate in tetrahydrofuran (2 mL), followed by a catalytic amount of potassium iodide (35.1 mg, 0.21 mmol), was then added. The reaction mixture was heated at 95°C for 4 h. The solution was cooled to room temperature, saturated aqueous ammonium chloride solution was added, and the resulting solution was extracted with a 2:1 ether and hexane mixture. The combined organic layers were dried and the solvent was evaporated to afford crude triester **58** (234 mg), which was used without purification for the next step.

Alcohol ***59***

Pyridinium *p*-toluenesulfonate (23 mg, 0.09 mmol) was added to a solution of the tetrahydropyranyloxy derivative **58** (233.6 mg, crude product of the preceding reaction) in methanol (5 mL). The mixture was heated at 95°C for 1.5 h, was then cooled to room temperature, and the solvent was evaporated. Purification by chromatography on silica gel (40% EtOAc in hexane) gave alcohol **59** (112 mg, 67% overall from **57**); ir ($CHCl_3$): 3600, 3480, 3020–2840, 1730, 1435, and 1220 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.35 (1H, ddq, J = 15.0 Hz, 11.2 Hz, 1.1 Hz, -OCH_2CH=CHC*H*=$CHCH_2$-), 6.04 (1H, tm, J = 11.2 Hz, -OCH_2CH=C*H*CH=CH-), 5.65 (1H, dt, J = 15.0 Hz, 7.2 Hz, -OCH_2CH=CHCH=C*H*-CH_2-), 5.52 (1H, dt, J = 10.9 Hz, 6.9 Hz, -OCH_2C*H*=CHCH=CH-), 5.09 (1H, tm, J = 7.1 Hz, -C(CH_3)=C*H*-CH_2-), 4.29 (2H, dd, J = 6.6 Hz, 2.7 Hz, -O*C*H_2CH=), 3.73 (6H, s, -$CH(CO_2CH_3)_2$), 3.67 (3H, s, -$CH(CO_2CH_3)$-), 3.56 (1H, t, J = 7.2 Hz, -C*H*$(CO_2CH_3)_2$), 2.45–2.26 (5H, m, -$CHCH_2CH(CO_2CH_3)CH_2CH_2C(CH_3)$=$CHCH_2$-), 2.04–1.81 (7H, m, -$CH_2CH_2C(CH_3)$=$CHCH_2$-$CH_2$-, -CH=CH-$CH_2OH$), 1.65 (3H, d, J = 1.2 Hz, -C(CH_3)=CH-).

Diester ***60***

Sodium cyanide (22.5 mg, 0.46 mmol) and water (12 μL, 0.69 mmol) were added to a solution of triester **48** (110 mg, 0.23 mmol) in dimethyl sulfoxide (3 mL). The reaction mixture was heated at 95°C for 35 h and was then cooled to room temperature and poured into ice-cold water. The resulting solution was saturated with sodium chloride and extracted with hexane (3 × 100 mL). The organic layers were dried and the solvent was evaporated. Purification by chromatography on silica gel (15% EtOAc in hexane) gave diester **60** (67 mg, 69%); ir ($CHCl_3$): 3020–2850, 1730, 1440, 1210, and 1020 (cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.34 (1H, dd, J = 14.8 Hz, 11.1 Hz, OCH_2CH=CHC*H*=$CHCH_2$-), 6.08 (1H, t, J = 11.1 Hz, -OCH_2CH=C*H*CH=CH-CH_2-), 5.63 (1H, dt, J = 14.9 Hz, 7.0 Hz, -OCH_2CH=CHCH=C*H*CH_2-), 5.49 (1H, dt, J = 10.8 Hz, 6.8 Hz, -OCH_2C*H*=CHCH=$CHCH_2$-), 5.08 (1H, apparent t, J = 6.8 Hz, -C(CH_3)=C*H*CH_2-), 4.63 (1H, apparent t, J = 3.0 Hz, -OCHO-), 4.33 (1H, dd, J = 12.6 Hz, 6.6 Hz, -OCHO-C*H*HCH=), 4.17 (1H, dd, J = 12.6 Hz, 7.2 Hz, OCHO-CH*H*CH=), 3.88 (1H, m, -C*H*HOCHOCH_2-CH=), 3.66 (6H, s, 2 × -CO_2CH_3), 3.54 (1H, m, -CH*H*OCHO-CH_2CH=), 2.50–2.20 (3H, m, =$CHCH_2CH(CO_2CH_3)$-), 2.30 (2H, t, J = 7.5 Hz, -$CH_2CO_2CH_3$), 2.10–1.90 (4H, m, -CH_2C-(CH_3)=CHCH_2-), 1.88–1.40 (13H, m, -$CH_2CH_2C(CH_3)$=$CHCH_2$-$CH_2CH_2CO_2CH_3$, -$(CH_2)_3CH_2OCHO$-).

Triester ***61***

Method A. To a solution of diisopropylamine (20 μL, 0.146 mmol) in tetrahydrofuran (1 mL) at 0°C was added a solution of butyllithium (1.6 M in hexane, 87 μL, 0.14 mmol). The mixture was stirred at 0°C for 1 h, the temperature was lowered to −78°C, and then ester **60** (31 mg, 0.073 mmol) in tetrahydrofuran (0.5 mL) was added. The resulting solution was stirred at −78°C for 30 min, then excess methyl chloroformate (102 μL, 1.46 mmol) was added and stirring was continued for another 15 min. A saturated aqueous ammonium chloride solution (1 mL) was added and the solution was extracted with ether (3 × 10 mL). The organic layer was dried and the solvent was evaporated. Separation by chromatography on silica gel (25% EtOAc in hexane) gave triester **61** (15.6 mg, 44%) and tetraester **49** (21.8 mg, 53%).

Method B. Methyl malonate (285 μL, 2.5 mmol) was added to a suspension of sodium hydride (54 mg, 2.25 mmol) in a 1:1 dimethylformamide and tetrahydrofuran mixture (15 mL) at 0°C. The reaction mixture was stirred at 0°C for 20 min, then at room temperature for 30 min. The crude mesylate prepared from alcohol **67** (see below) (184 mg, 0.5 mmol, Et_3N, MsCl, 0°C) in tetrahydrofuran (5 mL) was added, followed by a catalytic amount of potassium iodide (42 mg, 0.25 mmol). The reaction mixture was heated at 95°C for 4 h. After cooling to room temperature, a saturated aqueous ammonium chloride solution was added and the product was extracted with a 2:1 ether and hexane mixture. The organic layer was dried and the solvent was evaporated. Purification by chromatography on silica gel (25% EtOAc in hexane) gave triester **61** (185 mg, 77% overall from alcohol **67**); ir ($CHCl_3$): 3040–2850, 1730, 1440, 1220, and 1020 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.34 (1H, ddd, J = 15.0 Hz, 10.7 Hz, 1.0 Hz, -OCH_2CH=CHC*H*=$CHCH_2$-), 6.08 (1H, apparent t, J = 11.0 Hz, -OCH_2CH=C*H*CH=CH-), 5.63 (1H, dt, J = 14.9 Hz, 7.4 Hz, -OCH_2CH=CHCH=C*H*CH_2-), 5.48 (1H, dt, J = 10.7 Hz, 7.5 Hz, -OCH_2C*H*=CHCH=$CHCH_2$-), 5.07 (1H, tm, J = 7.5 Hz, 1.2 Hz, -C(CH_3)=C*H*-CH_2-), 4.64 (1H, apparent t, J = 3.1 Hz, -OCHO-), 4.35 (1H, dd, J = 12.5 Hz, 7.5 Hz, -OC*H*HCH=CH-), 4.18 (1H, dd, J = 12.5 Hz, 7.5 Hz, -OCH*H*CH=CH-), 3.90 (1H, m, -OCHO-C*H*H-), 3.73 (6H, s, -$CH(CO_2CH_3)_2$), 3.66 (3H, s, -$CH(CO_2CH_3)$-), 3.54 (1H, m, -OCHO-CH*H*-), 3.37 (1H, t, J = 7.5 Hz, -$CH_2CH(CO_2CH_3)_2$), 2.39 (5H, m, -CH=CH-$CH_2CH(CO_2CH_3)$-$(CH_2)_2C(CH_3)$=$CHCH_2$-), 1.94 (6H, m, -CH_2-$CH_2C(CH_3)$=$CHCH_2$-CH_2-), 1.90–1.45 (9H, m, -C(CH_3)=CH-, -OCHO-$CH_2(CH_2)_3$-); ms m/e: 480 (M^+).

Alcohol ***62***

Pyridinium *p*-toluenesulfonate (20 mg, 0.08 mmol) was added to a solution of tetrahydropyranyloxy derivative **61** (178 mg, 0.37 mmol) in methanol (5 mL). The mixture was heated at 55°C for 3 h and then the solvent was evaporated. Purification by chromatography on silica gel (10% acetone in dichloromethane) gave alcohol **62** (134 mg, 92%); ir ($CHCl_3$): 3600, 3500, 3020–2850, 1730, 1440, 1220, and 1170 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.34 (1H, apparent ddd, J = 15.0 Hz, 11.3 Hz, 1.1 Hz, $HOCH_2CH$=CHC*H*=$CHCH_2$-), 6.04 (1H, apparent t, J = 10.9 Hz, $HOCH_2$-CH=C*H*CH=$CHCH_2$-), 5.63 (1H, dt, J = 15.1 Hz, 7.5 Hz, $HOCH_2CH$=CHCH=C*H*CH_2-), 5.53 (1H, dt, J = 10.8 Hz, 6.9 Hz, $HOCH_2$C*H*=CHCH=$CHCH_2$-), 5.07 (1H, tq, J = 7.5 Hz, 1.2 Hz, -C(CH_3)=C*H*-), 4.29 (2H, m, HOC*H*$_2$CH=), 3.73 (6H, s, -$CH(CO_2CH_3)_2$), 3.66 (3H, s, -$CH(CO_2CH_3)$-), 3.37 (1H, t, J = 7.3 Hz, -C*H*$(CO_2CH_3)_2$), 2.50–2.20 (3H, m, =$CHCH_2CH(CO_2CH_3)$-), 2.10–1.50 (9H, m, -$CH_2CH_2C(CH_3)$=$CHCH_2CH_2$-, -CH_2OH), 1.55 (3H, d, J = 0.9 Hz. -C(CH_3)=CH-).

Malonate ***64***

To a solution of alcohol ***63a*** (1.258 g, 3.145 mmol; see below) and triethylamine (658 mL, 4.72 mmol) in dichloromethane (40 mL) at 0°C was added, dropwise, methanesulfonyl chloride (294 μL, 3.8 mmol). The mixture was stirred at 0°C for 1 h and was then poured into ice-cold water and extracted with dichloromethane. The organic layer was washed with water and dried. Evaporation of the solvent gave a crude mesylate (1.5 g, ~99%), which was used as such for the next step.

Methyl malonate (1.8 mL, 15.7 mmol) was added, at 0°C, to a suspension of sodium hydride (341 mg, 14.2 mmol) in a 1:1 tet-

For personal use only.

rahydrofuran and dimethylformamide mixture (40 mL). The mixture was stirred at 0°C for 30 min and then at room temperature for an additional 30 min. The above mesylate in tetrahydrofuran (5 mL) was added, followed by a catalytic amount of potassium iodide (269 mg, 1.6 mmol). The reaction mixture was heated at 95°C for 4 h. The resulting solution was cooled to room temperature, and saturated aqueous ammonium chloride solution (15 mL) was added. The solution was extracted with a 2:1 ether and hexane mixture (4 × 100 mL). The combined organic layers were dried and the solvent was evaporated. Purification by chromatography on silica gel (15% EtOAc in hexane) gave malonate **64** (1.42 g, 86% from alcohol **63**); ir ($CHCl_3$): 3080–3020, 3000–2860, 1730, and 1120 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.67 and 7.39 (10 H, m, 2 × -C_6H_5), 5.13 (1H, t, J = 7.0 Hz, -C=CH-), 3.71 (6H, s, 2 × -OCH_3), 3.62 (2H, t, J = 7.0 Hz, -CH_2O-), 3.33 (1H, m, -C*H*(CO_2CH_3)$_2$), 2.25 (2H, q, J = 7.0 Hz, =CH-C*H*$_2$-CH_2O-), 1.99 (4H, m, -CH-C*H*$_2$C*H*$_2$-C=CH-), 1.55 (3H, s, CH_3-C-CH-), 1.04 (9H, s, *t*-Bu); ^{13}C nmr ($CDCl_3$) δ: 169.88 (C=O), 135.60 (C_3, aromatic ring), 135.26 (C_1, aromatic ring), 134.11 (-*C*(CH_3)=CH-), 129.52 (C_4, aromatic ring), 127.58 (C_2, aromatic ring), 122.10 (C=*C*H-), 63.64 (*C*H(CO_2CH_3)$_2$), 52.34 (-OCH_3), 51.03 (-CH_2O-), 37.15 (-*C*H$_2$-C(CH_3)=CH-), 31.58 (-C=CH-*C*H$_2$-), 27.03 ((CH_3O_2C)$_2$CH-*C*H$_2$-), 26.84 (-CH_3, *t*-Bu), 19.16 (-*C*(CH_3)$_3$), 15.82 (*C*H$_3$-C=CH-); ms *m/e*: 425 ($M^+ - C_4H_9$). Exact Mass calcd. for $M^+ - C_4H_9$: 425.1784; found; 425.1789 ± 0.0012.

Diester 65

The *trans* olefin **64** (1.36 g, 2.94 mmol) in tetrahydrofuran (5 mL) was added, dropwise, to a suspension of sodium hydride (82 mg, 3.4 mmol) in a 1:2 dimethylformamide and tetrahydrofuran mixture (100 mL) at 0°C. The reaction mixture was stirred at 0°C for 30 min, then at room temperature for an additional 30 min. The temperature was lowered to 0°C and allylic chloride **12** (760 mg) in tetrahydrofuran (5 mL) was added. The reaction mixture was stirred at room temperature for 24 h. A saturated aqueous ammonium chloride solution (40 mL) was added and the resulting solution was extracted with a 3:2 ether and hexane mixture. The organic layer was dried and the solvent was evaporated. Purification by chromatography on silica gel (10% EtOAc in hexane) gave triene **65** (1.2 g, 62%); ir ($CHCl_3$): 3080–3010, 2960, 2860, 1730, 1430, and 1110 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.66 and 7.40 (10H, m, 2 × -C_6H_5), 6.37 (1H, dd, J = 15.0 Hz, 11.3 Hz, -OCH_2CH=CHC*H*=CH-), 6.06 (1H, t, J = 11.3 Hz, -OCH_2CH=C*H*CH=CH-), 5.50 (2H, m, -OCH_2C*H*=CHCH=C*H*-), 5.11 (1H, td, J = 7.5 Hz, 1.3 Hz, -C(CH_3)=C*H*-), 4.61 (1H, t, J = 3.8 Hz, -OCHO-), 4.30 (1H, ddd, J = 12.5 Hz, 5.0 Hz, 1.3 Hz, -OC*H*H-CH=), 4.13 (1H, ddd, J = 12.5 Hz, 6.5 Hz, 1.4 Hz, -OCH*H*-CH=), 3.86 (1H, m, -OCHO-C*H*H-), 3.69 (6H, s, 2 × -OCH_3), 3.61 (2H, t, J = 7.1 Hz, -C*H*$_2$OSi-), 3.50 (1H, m, -OCHO-CH*H*-), 2.69 (2H, d, J = 7.3 Hz, (CH_3O_2C)$_2$C-C*H*$_2$CH=), 2.24 (2H, q, J = 7.0 Hz, -CH-C*H*$_2$$CH_2O$;-), 1.97–1.41 (10H, m, -C*H*$_2$C*H*$_2$C(CH_3)=CH-, -OCHO-CH_2-(C*H*$_2$)$_3$-), 1.56 (3H, s, -C(C*H*$_3$)=CH-), 1.04 (9H, s, *t*-Bu).

Alcohol 66

Tetrabutylammonium fluoride (1 M in tetrahydrofuran, 3 mL, 3 mmol) was added to a solution of silyl ether **65** (990 mg, 1.5 mmol) in tetrahydrofuran (5 mL) at 0°C. The reaction mixture was stirred at room temperature for 4 h. Tetrahydrofuran was evaporated and the residue was purified by chromatography on silica gel (40% EtOAc in hexane) to give alcohol **66** (583 mg, 92%); ir ($CHCl_3$): 3620, 3460, 3040–2840, 1730, 1440, 1200, and 1040 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.39 (1H, dd, J = 15.0 Hz, 11.4 Hz, -OCH_2CH=CHC*H*=CH-), 6.08 (1H, t, J = 11.3 Hz, -OCH_2CH=C*H*CH=CH-), 5.50 (2H, m, -OCH_2C*H*=CHCH=C*H*-), 5.15 (1H, t, J = 7.1 Hz, -C(CH_3)=C*H*-), 4.63 (1H, t, J = 3.2 Hz, -OCHO-), 4.35 (1H, ddd, J = 12.8 Hz, 6.4 Hz, 1.3 Hz, -OC*H*HCH=), 4.16 (1H, ddd, J = 12.2 Hz, 7.4 Hz, 1.2 Hz, -OCH*H*CH-), 3.87 (1H, m, -OCHO-C*H*H-), 3.71 (6H, s, 2 × -OCH_3), 3.62 (2H, m, -C*H*$_2$OH), 3.50 (1H, m, -OCHO-CH*H*-), 2.71 (2H, d, J = 7.4 Hz, (CH_3O_2C)C-C*H*$_2$CH=), 2.26 (2H, q, J = 6.8 Hz, =CH-C*H*$_2$$CH_2$OH), 2.02–1.80 (4H, m, -C*H*$_2$C*H*$_2$-C(CH_3)=CH-), 1.79–1.37 (7H, m, -OCHO-CH_2-(C*H*$_2$)$_3$-, -CH_2-OH), 1.61 (3H, s, -C(CH_3)=CH-).

Ester 67

Sodium cyanide (59 mg, 1.2 mmol) and water (33 μL, 1.8 mmol) were added to a solution of the diester **66** (257.5 mg, 0.6 mmol) in dimethyl sulfoxide (5 mL). The reaction mixture was heated at 95°C for 39 h, then cooled to room temperature. The solution was poured into ice-cold water, saturated with sodium chloride, and then extracted with hexane. The organic layer was dried and the solvent was evaporated. Purification by chromatography on silica gel (40% EtOAc in hexane) gave monoester **67** (187 mg, 85%); ir ($CHCl_3$): 3620, 3500, 3030–2850, 1730, 1450, and 1020 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.34 (1H, ddd, J = 15.9 Hz, 11.0 Hz, 1.0 Hz, -OCH_2CH=CHC*H*=CH-), 6.08 (1H, t, J = 11.1 Hz, -OCH_2CH=C*H*CH=CH-), 5.62 (1H, dt, J = 15.0 Hz, 7.1 Hz, -OCH_2-CH=CHCH=C*H*-), 5.48 (1H, dt, J = 11.2 Hz, 7.2 Hz, -OCH_2C*H*=CHCH=CH-), 5.12 (1H, tq, J = 7.2 Hz, 1.2 Hz, -C(CH_3)=C*H*-), 4.63 (1H, t, J = 3.4 Hz, -OCHO-), 4.35 (1H, ddt, J = 12.6 Hz, 8.3 Hz, 2.3 Hz, =CH-C*H*H-OCHO-), 4.15 (1H, ddt, J = 12.5 Hz, 7.4 Hz, 2.3 Hz, -CHCH*H*-OCHO-), 3.88 (1H, m, -OCHO-C*H*H-), 3.66 (3H, s, -OCH_3), 3.62 (2H, m, -C*H*$_2$OH), 3.51 (1H, m, -OCHO-CH*H*-), 2.43–2.23 (5H, m, =CHC*H*$_2$-C*H*(CO_2CH_3)-CH_2CH_2C(CH_3)=CH-C*H*$_2$-), 2.00 (2H, t, J = 7.2 Hz, -C*H*$_2$C(CH_3)=CH-), 1.86–1.49 (9H, m, -CH(CO_2CH_3)-C*H*$_2$$CH_2$-, -$CH_2$O*H*, -OCHO-$CH_2$-(C*H*$_2$)$_3$-), 1.61 (3H, d, J = 0.8 Hz, -C(C*H*$_3$)=CH-).

2-(2-Bromoethoxy)tetrahydropyran (68)

To a solution of 2-bromoethanol (19.2 g, 154 mmol) in CH_2Cl_2 (200 mL) at 0°C under argon was added over 10 min, with stirring, pyridinium *p*-toluenesulfonate (387 mg, 1.5 mmol) followed by 3,4-dihydro-2*H*-pyran (210 mL, 230 mmol). The mixture was allowed to warm to room temperature, becoming increasingly dark purple in colour. After 2.3 h of total reaction time, a saturated sodium bicarbonate solution (120 mL) was added to produce a light brown-yellow coloured solution. The organic phase was separated and concentrated to an orange-brown crude oil (38.1 g) that was purified by distillation at 1.4 Torr (1 Torr = 133.3 Pa) (63–64°C) to afford 25.7 g (81%) of **68**, as a colourless oil; ir ($CHCl_3$): 2945–2850, 1125, and 1030 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.67 (1H, t, J = 3.3 Hz, O-C*H*-O), 4.06–3.97 and 3.81–3.72 (2H, 2 dt, J = 11.2 Hz and 6.2 Hz, -CH_2-C*H*$_2$-OTHP), 3.93–3.84 and 3.56–3.48 (2H, 2m, -O-CHO-C*H*$_2$-), 3.53–3.48 (2H, m, Br-C*H*$_2$-CH_2-), 1.85–1.49 (6H, m, -O-CHO-CH_2-(C*H*$_2$)$_3$-).

4-Tetrahydropyranyloxybutyl-2-triphenylphosphonium bromide (69)

(Ethyl)triphenylphosphonium bromide (32.3 g, 87 mmol) was dried under high vacuum overnight at 115°C and was then suspended in THF (200 ml) at 0°C under argon with stirring. Potassium hexamethyldisilazane (174 mL, 87 mmol, 0.5 M in toluene) was added dropwise at 0°C over 50 min, producing a cherry-orange-coloured suspension that was stirred for an additional 0.5 h at 0°C. A solution of protected bromoethanol **68** (25.8 g, 125 mmol) in THF (70 mL) was then added dropwise at 0°C over 0.5 h. The red-orange mixture was warmed to room temperature and stirred for a total of 50 h, becoming successively orange, peach, orange-pink, and pink in colour. The thick, pink mixture was filtered on a Buchner funnel, leaving a white solid, and a rose-coloured filtrate that contained only impurities. The solid was repeatedly washed with tetrahydrofuran. The filtrate collection flask was changed and the solid was washed with dichloromethane until only solid, grey, KBr (10.1 g) remained in the funnel. The dichloromethane filtrate was concentrated to yield an off-white crude salt (40.8 g) that was recrystallized from a minimum volume of hot dichloromethane in hot hexane, to afford 38 g (88%) of **69** as fine clear snowflake crystals; yield: 38.0 g (88%); ir ($CHCl_3$): 3060–3010, 2950–2860, 1442, 1115, and 1038 cm^{-1}; ^1H nmr (250 MHz) ($CDCl_3$) δ: 8.01–7.62 (15H, 2m, P*Ph*$_3$), 5.27–5.13 and 5.08–4.87 (1H, 2m from diastereoisomers, -P-C*H*-CH_2), 4.63–4.61 and 4.59–

For personal use only.

4.57 (1H, 2m from diastereoisomers, -O-C*H*-O-), 4.17–3.87 (2H, large m, -CH_2-CH_2-OTHP), 3.85–3.79 and 3.54–3.45 (2H, 2m, -CH-O-CH_2), 2.30–2.19 and 1.87–1.69 (2H, 2m, -CH-CH_2-CH_2-OTHP), 1.63–1.31 (6H, large m, -CH-O-CH_2-$(CH_2)_3$-), 1.43 (3H, dd, J_{HCCP} = 19.8 Hz and 7.1 Hz, -CH(CH_3)-).

1-tert-*Butyldiphenylsilyloxy propanol (**70**)*

A solution of 1,3-propanediol (20.0 g, 263 mmol) and imidazole (3.58 g, 52.6 mmol) in tetrahydrofuran (180 mL) was stirred under argon at room temperature. *tert*-Butylchlorodiphenylsilane (13.7 mL, 52.6 mmol) was added by syringe and the cloudy, white mixture was stirred for 25 h before being poured into a separatory funnel containing water (100 mL). The products were extracted into hexane (5 × 100 mL) and the combined organic layers were washed once with water (200 mL), then dried, filtered, and concentrated to give a crude, brown-tinged oil (17.41 g) that was purified by flash chromatography (10% EtOAc in hexane) to afford 15.86 g (96%) of a colourless oil; yield: 15.86 g; ir ($CHCl_3$): 3620, 3080–3020, 2960–2860, 1430, 1115, and 1068 cm^{-1}; ^1H nmr (80 MHz) ($CDCl_3$) δ (ppm): 7.66 and 7.46 (10H, m, Ph_2Si-), 3.88 (2H, t, J = 5.7 Hz, -CH_2-$OSiPh_2$), 3.86 (2H, q, J = 5.7 Hz, -CH_2-OH), 2.35 (1H, t, J = 5.4 Hz, -CH_2-O*H*), 1.98–1.52 (2H, m, -CH_2-CH_2-CH_2OH), 1.05 (9H, s, $(CH_3)_3$CSi-).

3-tert-*Butyldiphenylsilyloxy propanal (**71**)*

To a solution of oxalyl chloride (4.8 mL, 55.3 mmol) in dichloromethane (115 mL) at −78°C under argon was added with stirring over a period of 20 min freshly distilled dimethyl sulfoxide (7.9 mL, 110.6 mmol) in dichloromethane (25 mL). The mixture was stirred for 20 min before adding a solution of alcohol **70** (15.8 g, 50.3 mmol) in dichloromethane (50 mL) over a period of 25 min. The cloudy mixture was stirred for another 45 min at −78°C before triethylamine (35 mL) was added. The thick white mixture was then allowed to warm to room temperature over 1 h. Water (100 mL) was added to the yellow paste and the mixture was extracted with dichloromethane (3 × 100 mL). The combined organic layers were washed with water (2 × 50 mL) and brine (100 mL) before being dried, filtered, and concentrated to give a crude yellow oil (15.3 g) that was purified by flash chromatography (10% EtOAc in hexane) to afford 13.6 g (86%) of **71** as an off-white solid oil; ir ($CHCl_3$): 3080–3010, 2960–2860, 2740, 1728, 1430, 1115 cm^{-1}; ^1H nmr (80 MHz) ($CDCl_3$) δ: 9.83 (1H, t, J = 2.4 Hz, -CH_2-C*H*O), 7.81–7.35 (10H, m, Ph_2Si-), 4.03 (2H, t, J = 6.1 Hz, -CH_2-OSi), 2.61 (2H, dt, J = 5.6 and 2.8 Hz, -CH_2-CHO), 1.05 (9H, s, $(CH_3)_3$CSi-).

*(3*E *and 3*Z*)-3-Methyl-6-*tert-*butyldiphenylsilyloxy-1-tetrahydropyrannyloxy-3-hexene (**72**)*

The phosphorane salt **69** (25.9 g, 51.9 mmol), previously dried overnight under high vacuum at 110°C, was suspended in tetrahydrofuran (200 mL) at 0°C under argon with stirring. *n*-Butyllithium (29.7 mL, 47.6 mmol, 1.6 M in hexane) was added dropwise over 17 min, creating a deep-burgundy colour, and stirring was continued for an additional 40 min at 0°C. A solution of the aldehyde **71** (13.5 g, 43.3 mmol) in tetrahydrofuran (70 mL) was added dropwise over 35 min to the above ylide solution. With syringe washings, the total tetrahydrofuran volume was increased to approximately 350 mL. The mixture was stirred at 0°C for 3 h and then evaporated to a rust-coloured solid–oil combination. A 1:1 petroleum ether and hexane mixture was introduced to the flask and the contents were filtered over a Celite plug. Concentration of the filtrate yielded a crude yellow-coloured oil (15.2 g). The solid remaining in the funnel was dissolved in water, which was then extracted with ethyl ether (5 × 100 mL). The combined organic layers were dried, filtered, and concentrated to give a solid–oil (~8 g), which was washed carefully while filtering with ethyl ether. Concentration of the filtrate yielded a yellow-coloured solid–oil (~5 g), which was combined with the original crude material. Flash chromatography (4% EtOAc in hexane) gave 1.2 g (61%) of purified products as a mixture of *cis* and *trans* isomers (43:57 ratio by ^1H nmr); ir (neat): 3075, 2940 and 2860, 1430, 1115, 1036 cm^{-1}; ^1H nmr (250 MHz) ($CDCl_3$) δ (ppm): 7.70–7.62 and 7.48–7.33 (10H, 2m, Ph_2Si-), 5.23–5.15 (1H, m (2 tq), -CH_2-C*H*=C(CH_3)-), 4.58–4.53 (1H, m (2t), -O-C*H*-O-), 3.88–3.70 and 3.52–3.32 (4H, 2m, -O-CH-O-CH_2- and -CH_2-CH_2-OTHP), 3.63 and 3.62 (2H, 2t, J = 7.1, -CH_2-CH_2-OSi-), 2.34–2.19 (4H, m, -CH_2-CH=C(CH_3)-CH_2-), 1.89–1.30 (6H, large m, -O-CH-O-CH_2-$(CH_2)_3$-), 1.71 (3H, d, $J_{allylic}$ = 1.3 Hz, -HC=C(CH_3)-*cis*), 1.58 (3H, s, -HC=C(CH_3)-*trans*), 1.04 (9H, s, *t*-Bu).

*(3*E *and 3*Z*)-3-Methyl-6-*tert-*butyldiphenylsilyloxy-3-hexen-1-ol (**63**a) and (**63**b)*

A solution of the *cis* and *trans* isomers **72** (8.0 g, 17.7 mmol) in isopropanol (370 mL) was stirred under argon at room temperature. Pyridinium *p*-toluenesulfonate (800 mg, 3.2 mmol, 10% by weight of dienophile) was added and the mixture was heated to between 75°C and 80°C for 4 h. The mixture was cooled to room temperature and then partitioned between water and ethyl ether. The separated aqueous phase was extracted with additional aliquots of ethyl ether. The combined organic phases were dried, filtered, and concentrated to yield a yellow-coloured crude oil (6.7 g, 100% crude). The *cis–trans* mixture was separated by medium pressure chromatography (29–31 psi (1 psi = 6.89 kPa), 5% EtOAc in hexane) affording 355 mg of pure **63***b*, 522 mg of **63***a*, and 80 mg of a *cis–trans* mixture (1 g, loading).

cis *Isomer **63**b:* ir ($CHCl_3$): 3618, 3460, 3075–3055, 2960–2860, 1430, 1385, 1110, and 1055 cm^{-1}; ^1H nmr (250 MHz) ($CDCl_3$) δ: 7.72–7.63 and 7.46–7.34 (10H, 2m, Ph_2Si-), 5.30 (1H, br t, J = 7.0 Hz, $J_{allylic}$ = variable, -CH_2-C*H*=C(CH_3)-), 3.63 (2H, t, J = 6.7 Hz, -Si-O-CH_2-), 3.61 (2H, t, J = 6.4 Hz, -CH_2-CH_2-OH), 2.31 (2H, qd, ^3J = 6.8 Hz, J = 0.7, SiO-CH_2-CH_2-), 2.264 (2H, t, J = 6.4 Hz, =C(CH_3)-CH_2-), 1.723 (3H, d, J = 1.3 Hz, =C(CH_3)-CH_2-), 1.043 (9H, s, *t*-Bu).

Transannular Diels–Alder reactions on 14-membered macrocyclic trienes. Part II: formation of macrocycles and thermal conversion into tricyclic systems

ALEXIS NDIBWAMI, SERGE LAMOTHE, PIERRE SOUCY, SOLO GOLDSTEIN, AND PIERRE DESLONGCHAMPS[1]

Laboratoire de synthèse organique, Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Received November 16, 1992

ALEXIS NDIBWAMI, SERGE LAMOTHE, PIERRE SOUCY, SOLO GOLDSTEIN, and PIERRE DESLONGCHAMPS. Can. J. Chem. **71**, 714 (1993).

In the preceding paper (Part I) we described the synthesis of eight isomeric acyclic trienes. These compounds could be transformed into the corresponding macrocyclic trienes, which were further converted into tricyclic A.B.C.[6.6.6] products by a thermal transannular Diels–Alder reaction. The experimental results of this study and their analysis are reported in the present paper. The comparison with theoretical predictions is also discussed.

ALEXIS NDIBWAMI, SERGE LAMOTHE, PIERRE SOUCY, SOLO GOLDSTEIN et PIERRE DESLONGCHAMPS. Can J. Chem. **71**, 714 (1993).

Dans l'article précédent (Partie I), nous avons décrit la synthèse de huit trièns acycliques isomères. Ces produits ont été transformés en trièns macrocycliques correspondants qui à leur tour fournissent des produits tricycliques A.B.C.[6.6.6] par une réaction de Diels–Alder transannulaire. Les résultats expérimentaux de ces travaux ainsi que leur analyse sont décrits dans l'article qui suit (Partie II). La comparaison avec les prédictions théoriques est également discutée.

We recently reported, in preliminary form (1, 2), a general study on the transannular Diels–Alder reaction[2] of 14-membered macrocyclic trienes having a methyl-substituted dienophile. In the preceding paper (4) (Part I) we reported in detail the synthesis of the eight isomeric acyclic triene precursors **1***a–h* (Scheme 1) that were necessary for this study. In this paper (Part II) we wish to report on the formation of the corresponding eight isomeric macrocycles **3***a–h* as well as their thermal conversion into tricyclic products **4***a–f* via the transannular Diels–Alder reaction.

Theoretical predictions on the outcome of transannular Diels–Alder reaction as a function of olefin geometry are first disclosed. The macrocyclization of the eight different acyclic trienes is then presented, followed by a report on the thermal transformation of the eight macrocyclic trienes to tricyclic products. A discussion of the results follows.

Predictions for the transannular Diels–Alder reaction (1)

We first examine the relationship between geometrical isomerism of the macrocyclic triene and stereochemistry in the resulting tricycle.

A diene can have four different configurations (TT (*trans-trans*), TC, CT, and CC) and the dienophile two (C or T). The corresponding macrocyclic trienes **3** can therefore have eight different configurations: *cis-trans-trans* **3***a* (CTT), **3***b* (TCT), **3***c* (CCT), **3***d* (TTT), **3***e* (CTC), **3***f* (TCC), **3***g* (CCC), and **3***h* (TTC). For example, a TC diene with a T dienophile corresponds to a TCT configuration, where the three letters refer to the unsaturations at C5, C3, and C11 respectively. Tricycles **4**, which have four chiral centers (C5 and C8–10, steroid numbering), can exist in eight different racemic diastereoisomeric configurations i.e., *cis-anti-cis* (CAC), *trans-syn-trans* (TST), etc. (Scheme 1).

On first analysis, each triene configuration can theoretically lead to two different tricyclic diastereoisomers (and their respective enantiomer). For example, triene **3***a* (CTT) can give either TAT or CAC tricycles. However, as indicated in Table 1, it can be predicted that several transannular Diels–Alder reactions cannot take place. This is because the Diels–Alder reaction must take place via a boat-like transition state, producing an A.B.C.[6.6.6] tricycle in which the middle ring must be in a boat conformation. Indeed, molecular models show that because of this restriction, which is stereoelectronic in nature, it is sterically impossible in some cases to reach the required transition state. For instance, due to steric reasons, a TAT tricycle cannot take a conformation with ring B in a boat form, and as a result it becomes impossible to produce this compound from **3***a* (CTT) and **3***b* (TCT) macrocyclic trienes.

On the other hand, there are tricycles that can take two such conformations and can thus be produced from two different trienes. This is the case for the CAC tricycle that can be formed from either a **3***a* (CTT) or a **3***b* (TCT) macrocyclic triene. There are other situations where the tricycle can take only one conformation with ring B in a boat form and, therefore, these tricycles can be produced from only one macrocyclic triene. For instance, a TSC tricycle can be produced from the **3***f* (TCC) but not from the **3***e* (CTC) macrocycle. Also, if the triene cannot take a conformation leading to a boat-like transition state as required for the transannular Diels–Alder reaction, then this reaction should not take place. This is the case for the **3***c* (CCT) macrocyclic triene.

In summary, the predictions for the eight triene configurations are the following: one triene, **3***c* (CCT), cannot undergo the transannular Diels–Alder, five trienes, **3***a* (CTT), **3***b* (TCT), **3***c* (CTC), **3***f* (TCC), and **3***g* (CCC), can give only one racemic diastereoisomer, and two trienes, **3***d* (TTT) and **3***h* (TTC), can theoretically lead to two racemic diastereoisomers. Only one (TAT) of the eight diastereoisomeric tricycles cannot be produced directly by a transannular Diels–Alder reaction. It is also interesting to mention that *syn* and *anti* tricyclic compounds are derived from *cis* and *trans* dienophiles, respectively.

The next stage in our investigation was to submit these predictions to experimental verification (2). The required four dienes and two dienophiles were synthesized and assembled

using dimethyl malonate to produce the eight acyclic triene precursors as described in Part I.

Macrocyclization and transannular Diels–Alder reaction

The allylic alcohol triene precursors **1***a–h* were first converted into their corresponding allylic chlorides **2***a–h* using the method described by Collington and Meyers (5) (CH_3SO_2Cl, LiCl, collidine, DMF). Macrocyclization of allylic chlorides **2***a–h* was carried out (6) by slow addition under medium dilution conditions ((1–5) × 10^{-3} M) to a solution of cesium carbonate in tetrahydrofuran–dimethylformamide (1:1) at 80–85°C. The results obtained at the macrocyclization step and at the Diels–Alder stage are summarized in Table 2. The expected macrocycles were isolated in six cases (entries 1–3 and 5–7). These macrocycles, namely, **3***a* (CTT), **3***b* (TCT), **3***c* (CCT), **3***e* (CTC), **3***f* (TCC), and **3***g* (CCC), were found to be crystalline and the structures of three of them, **3***e* (CTC),[3] **3***a* (CTT),[3] and **3***b* (TCT),[4] were rigorously confirmed by X-ray diffraction analysis. In the remaining cases, **3***d* (TTT) and **3***h* (TTC), which have a TT diene, tricyclic compounds rather than the expected macrocycles were directly isolated, indicating that the Diels–Alder reactions took place at the macrocyclization temperature (~80°C). More precisely, the **3***d* (TTT) acyclic triene gave a 2:1 mixture of **4***b* (TAC) and **4***c* (CAT) tricycles in 65% yield, whereas the **3***h* (TTC) macrocylic triene gave the **4***f* (TST) tricycle (53%) along with a side product **5** (23%) (Scheme 2) having a 12-membered ring. Compound **5**, whose structure was established by X-ray analysis (7), is the result of an S_N2' macrocyclization of the TTC allylic chloride **2**.

The mild reaction conditions for the cycloaddition of the **3***d* (TTT) and **3***h* (TTC) macrocycles are explained by the fact that the TT diene can easily adopt the required *cisoid* conformation, which is devoid of steric repulsion. The other macrocycles had to be heated at high temperature (>300°C) in order to observe a complete thermal conversion, indicating that, as expected, there is severe steric hindrance that prevents the formation of the *cisoid* conformation when the diene has a CT or CC geometry.

The macrocyclization experiment on the TTC allylic chloride **2***h* was repeated at lower temperature (45°C), where it was found possible to isolate the corresponding **3***h* (TTC) macrocycle (26%) along with compound **5** as well as cyclic dimer **6** (11%). The TTC macrocycle was shown to undergo

a cycloaddition at 80°C, giving the TST tricycle in quantitative yield. On the other hand, the TTT allylic chloride **2***d* does not undergo macrocyclization at a temperature lower than 60°C, and at this temperature it leads directly to the same 2:1 mixture of TAC and CAT tricycles. Thus, macrocyclization of **2***d* (TTT) is more difficult than that of TTC macrocycles **3***h*, but it was not possible to verify the minimum temperature required for the cycloaddition reaction as it takes place readily at 60°C.

Macrocycles **3***a* (CTT), **3***e* (CTC), and **3***f* (TCC) (entries 1, 5, and 6), upon heating at 300°C, gave the predicted tricycles **4***a* (CAC), **4***d* (CST), and **4***e* (TSC), respectively. Upon heating at 350°C, the **3***b* (TCT) macrocycle (entry 2) gave, in addition to the predicted **4***a* (CAC) tricycle, two other products having structures **13** and **15** (Scheme 3) (see also footnote 8). As mentioned above, the **3***d* (TTT) macrocycle (entry 4) could not be isolated, since the result obtained indicates that it led to the predicted **4***b* (TAC) and **4***c* (CAT) tricycles. Also, the **3***h* (TTC) macrocycle (entry 8) gave the predicted **4***f* (TST) tricycle; however, none of the other predicted diastereoisomer, i.e., the CSC tricycle, was observed. Upon heating at 365°C, the **3***g* (CCC) macrocycle (entry 7) did not lead to the predicted CSC tricycle, but rather gave a 1:1 mixture of the **4***d* (CST) and **4***e* (TSC) tricycles. Finally, the **3***c* (CCT) macrocycle (entry 3), which was predicted not to produce a Diels–Alder adduct, upon heating at 365°C gave a mixture of four isomeric products. The major isomer was shown to have the bicyclic structure **17** (Scheme 4) by X-ray diffraction analysis.[5] The other three products were found to be identical to those obtained from the **3***b* (TCT) macrocycles, i.e., CAC tricycle **4***a* plus compounds **13** and **15** (see footnote 8). All thermal processes took place in high yield. The lower overall yield observed in the **3***d* (TTT) and **3***h* (TTC) series (entries 4 and 8) is mainly the result of a low yield at the macrocyclization step. The structures of the **4***e* (TSC)[4] and **4***f* (TST) (7) tricycles were established by X-ray analyses. The structure of the **4***a* (CAC) tricycle was rigorously established in a closely related series.[6] The structure of CAT tricycle **4***c* was elucidated by a chemical correlation. In another study,[7] a mixture of TAC and CAT tricycles **7***a* and **7***b* (Scheme 2), which contain only three ester functions, was obtained from the corresponding TTT macrocycle. The structure of TAC tricycle **7***a* was established by X-ray analysis[7] and the other isomer, CAT tricycle **7***b*, was converted (LDA, $ClCOOCH_3$) into CAT tricycle **4***c*.

Discussion

The **3***a* (CTT) and **3***b* (TCT) macrocycles, which are predicted to give the same **4***a* (CAC) tricycle, can be analyzed together (Scheme 3). Assuming that the Diels–Alder reaction takes place via a chair–boat–chair-like transition state, molecular models clearly indicate that the methyl group of the dienophile creates more steric hindrance in the CAC transition state resulting from TCT (cf. **10** → **11**) than in that resulting from CTT (cf. **8** → **9**). As a consequence, the reaction TCT → CAC, i.e., **10** → **11**, is not quantitative and the formation of side products **13** and **15** is observed. The formation of the a priori unexpected tricycle **15** from the TCT macrocycle **3***b* can be explained by the competing transannular ene reaction **12** → **13** producing a bicyclic intermediate that undergoes another transannular ene reaction to give the new CTT macrocyclic triene **14**. Compound **14** is then easily transformed into CAC tricycle **15**, because the Diels–Alder reaction is no longer sterically hindered by the presence of the methyl group. Interestingly, the sequence **12** → **13** → **14** is an oxido-reduction process in which the dienophile and the diene have been mutually interconverted.[8]

The results obtained from the CCT macrocycle **3***c*, which cannot undergo a direct Diels–Alder reaction, are examined next. The formation of the major product, bicyclo[8.4.0] system **17**, is readily rationalized via a transannular ene reaction as shown (**16**→ **17**) in Scheme 4. On the other hand, since we know that the TCT macrocycle **3***b* gives CAC tricycle **4***a* as well as **13** and **15** whereas the CTT macrocycle **3***a* gives only the CAC tricycle **4***a*, it is reasonable to as-

[5]A. Ndibwami, M. Drouin, and A. Michel. Unpublished results.

[6]In another study, it was shown that CTT macrocycle **3** having three ester functions gave the corresponding CAC tricycle whose structure was confirmed by X-ray analysis (8).

[7]M. Drouin, A. G. Michel, P. Soucy, and P. Deslongchamps. Unpublished results.

[8]The structure of CAC tricycle **15** was secured by X-ray analysis (9*b*). In another study,[9] it was observed that when TCT macrocycle contains an additional methyl group on the diene, i.e., **12** (H1 = CH_3), the formation of a CAC tricycle corresponding to **4** with an additional CH_3 at C8 is not observed because there are too many severe steric interactions in the corresponding transition state. Instead, the exclusive formation of CAC tricycle **15** (H1 = CH_3) occurs via the intermediate **13** (H1 = CH_3), which was characterized spectroscopically. The structure of CAC tricycle **15** (H1 = CH_3) was also firmly established by X-ray analysis (9*a*).

[9]A. Roughton and P. Deslongchamps. Unpublished results.

(E = $COOCH_3$)

SCHEME 3

sume that the CCT macrocycle **3***c* must have partly isomerized into a mixture of CTT and TCT macrocycles **3***a* and **3***b* in order to produce a mixture of CAC tricycle **4***a*, **13**, and **15** (but in a different ratio than that from TCT macrocycle **3***b*). The thermal isomerization of the CCT macrocycle **3***c* can be explained by two series of [1,5] hydride shifts. First, CCT macrocycle **3***c* can either produce CTT macrocycle **19** (cf. **18** → **19**) or TCT macrocycle **20** (cf. **18** → **20**). Then, the new CTT and TCT macrocycles **19** and **20** can be transformed into the known TCT and CTT macrocycles **3***b* and **3***a* by another [1,5] sigmatropic hydrogen migration. The mixture obtained, of TCT and CTT macrocycles **3***b* and **3***a*, is finally converted into a mixture of **4***a* (CAC), **13**, and **15** in a ratio different than that obtained from the TCT macrocycle **3***b*. It is interesting to note that intermediates **19** and **20** do not undergo a Diels–Alder reaction, probably because they would produce tricycles having an A.B.C.[5.6.7] ring structure. Such processes must be sterically disfavored due to the formation of the seven-membered ring.

The Diels–Alder reactions of the **3***e* (CTC) and **3***f* (TCC)

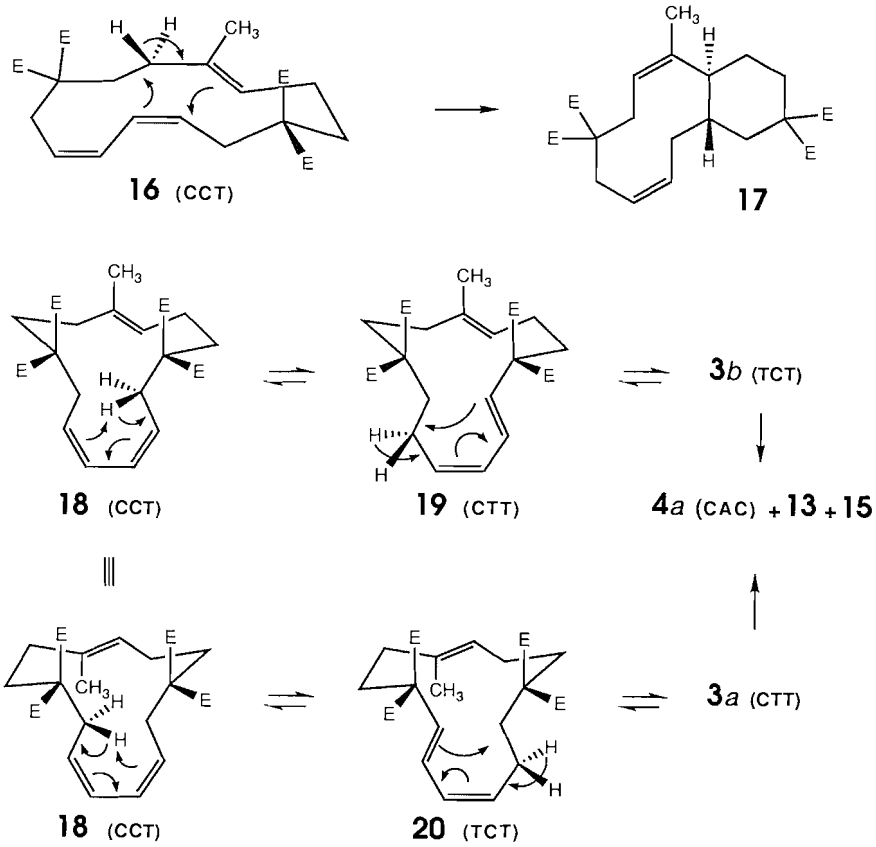
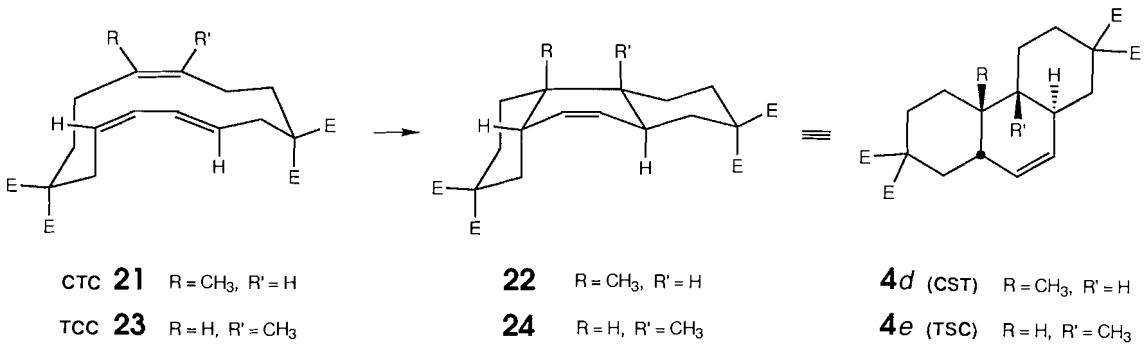


SCHEME 4



SCHEME 5

macrocycles yielding **4***d* (CST) and **4***f* (TSC) tricycles, respectively, are readily explained. Indeed, both processes (**21** → **22** and **23** → **24**) can take place via a chair–boat–chair-like transition state essentially devoid of severe steric repulsions, as indicated in Scheme 5.

The predicted formation of the CSC tricycle from the CCC macrocycle **3***g* did not occur because this process would have to take place via a very severely crowded transition state (cf. **25** → **26**, Scheme 6). This situation results from the fact that the *cis-cis* diene becomes sterically congested when it must take the *cisoid* geometry required for the Diels–Alder reaction. The formation of a 1:1 mixture of CST and TSC tricycles **4***d* and **4***e* suggests that rather than yielding the CSC tricycle, which is too costly energetically (cf. conformation **26**), CCC macrocycle **3***g* undergoes a thermal isomerization through sequential hydride shift (**27** → **28** → **21** or **29** → **30** → **23**) to give a mixture of CTC and TCC macrocycles **21** and **23**, which are then respectively converted into CST and TSC tricycles **4***d* and **4***e* as described in Scheme 5.

The selective formation of TST tricycle **4***d* from TTC

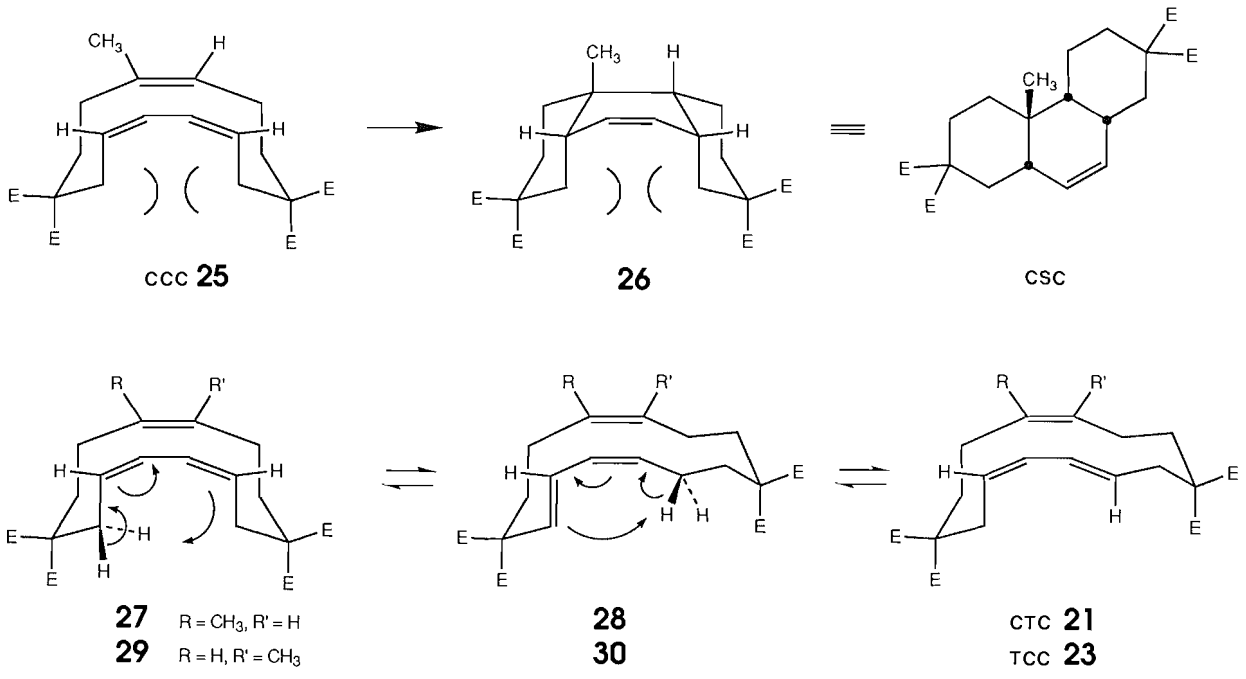
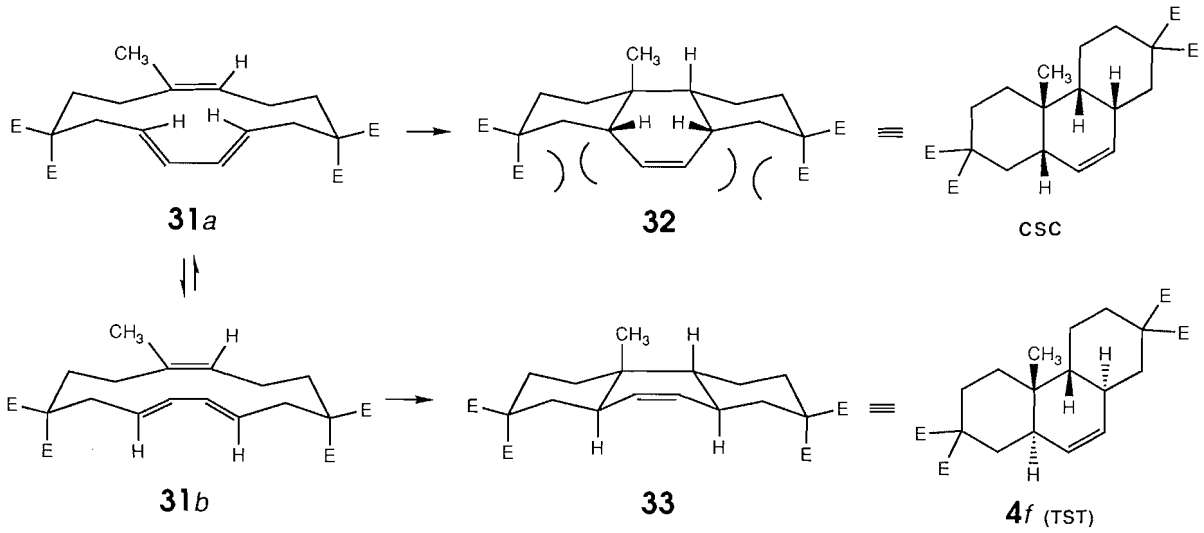


SCHEME 6



SCHEME 7

macrocycle **3***h* can be readily explained by considering the relative steric effect played by the ester function at the transition state level. TTC macrocycle **3***h* can either react via conformations **31***a* or **31***b* (Scheme 7) producing CSC and **4***f* (TST) tricycles in conformations **32** and **33**, respectively. Analysis of molecular models reveals that, in the chair–boat–chair transition state which leads to the CSC tricycle (**31***a* → **32**), there are two 1,3-diaxial-type steric interactions between each pseudo-axial ester function and a CH group of the olefin. There are no equivalent interactions in the competing transition state (**31***b* → **33**). This steric effect would therefore be the main discriminating factor favoring formation of a **4***f* (TST) tricycle.

It remains to explain the formation of TAC and CAT tricycles **4***b* and **4***c* from TTT macrocycle **3***d*. Assuming chair–boat–chair-like transition states, TTT macrocycle **3***d* was expected to react via conformations **34***a* and **34***b* (Scheme 8) to yield **4***c* (CAT) and **4***b* (TAC) tricycles, respectively. The two competing pathways can be best compared by examining their respective transition states (**34***a* → **35** and **34***b* → **36**). Examination of molecular models shows that structures **35** and **36** have identical conformations. Indeed if rings

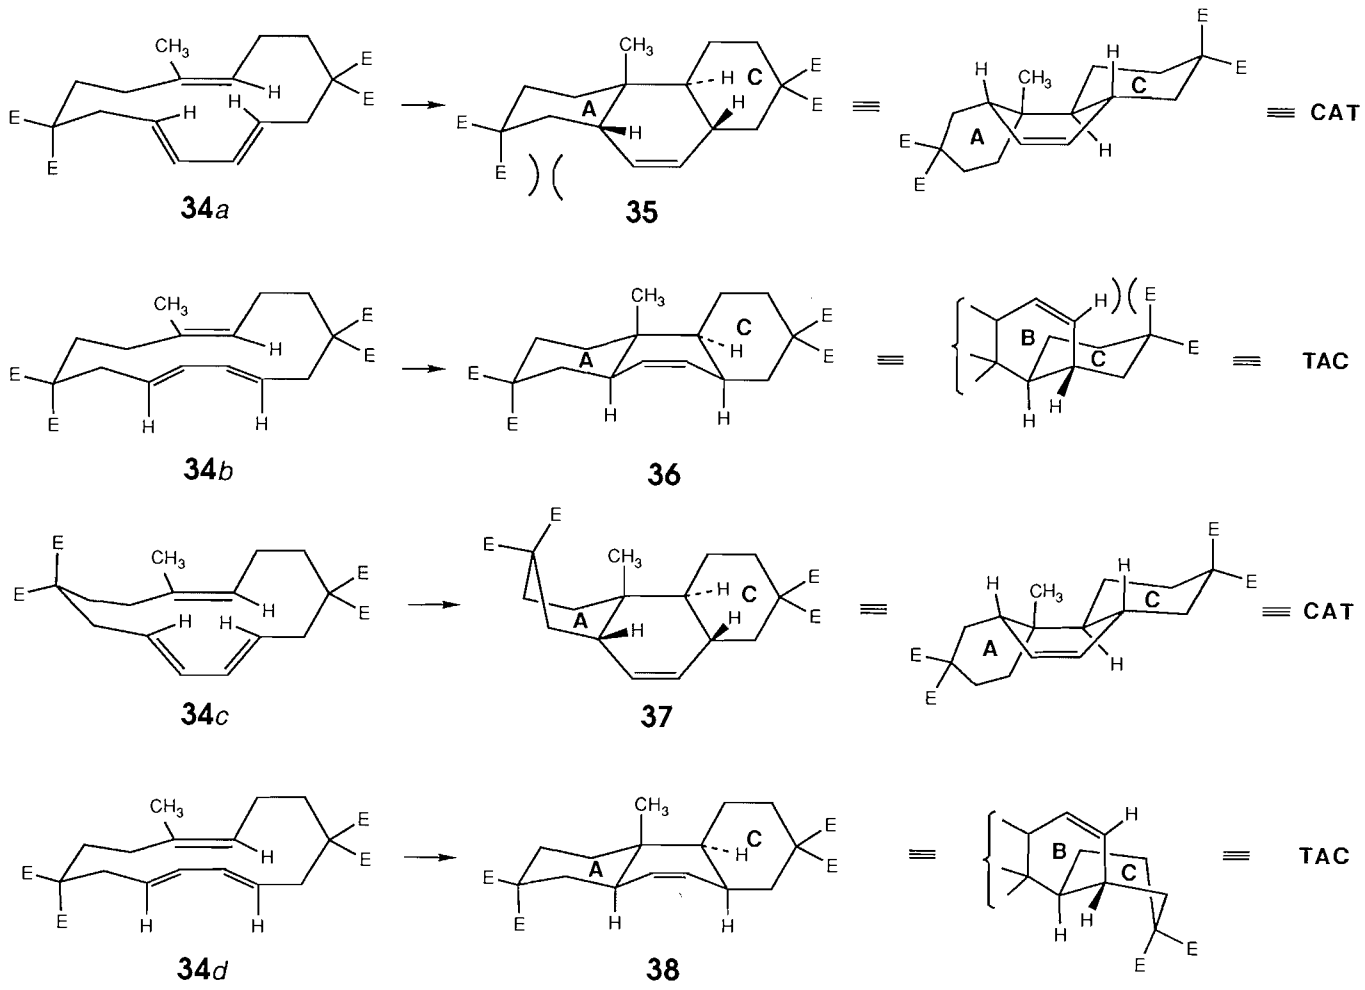

SCHEME 8

CBA of **36** are superposed on rings ABC of **35** the only difference resides in the location of the methyl group. The models also indicate that this group is sterically more crowded in **36** than in **35**. The difference does not appear to be very large, and a mixture is therefore expected; surprisingly, however, this analysis predicts a ratio with the CAT tricycle (**34***a* → **35**) predominating, in contradiction of the experimental ratio observed!

Since it does not appear possible to involve the influence of a stereoelectronic effect because the only substituent is a methyl group, this led us to assume that the formation of the **4***c* (CAT) and **4***b* (TAC) tricycles might take place via a boat–boat–chair rather than the normally more appealing chair–boat–chair transition state. In transition states **34***a* → **35** and **34***b* → **36**, there is a severe pseudo 1,3 diaxial steric interaction between one ester function and the olefinic CH group; this interaction occurs in ring A for CAT (cf. **35**) and in ring C for TAC (cf. **36**). These steric interactions can be eliminated if the formation of the **4***c* (CAT) and **4***b* (TAC) tricycles takes place, respectively, from boat–boat–chair or chair–boat–boat transition states **34***c* → **37** and **34***d* → **38** (Scheme 8). These two new transition states are quite appealing because the relative ratio of the **4***b* (TAC) and **4***c* (CAT) tricycles can be readily explained. Indeed, in **34***c* → **37**, the methyl group is in a boat-like conformation (cf. ring A in **37**), creating more steric hindrance than in **34***d* → **38** where the methyl group is in a chair-like conformation (cf. ring A in **38**). On that basis, transition state **34***d* → **38** is of lower energy than **34***c* → **37**, and this explains why the TAC tricycle is obtained as the major isomer. As bond formation is not yet completed at the transition state level, boat–boat–chair can easily compete on a steric basis with chair–boat–chair in order to avoid additional steric interactions occurring in the latter.[10]

In general, the results summarized in Table 2 confirm the predictions made in Table 1. The anomalous results observed (entries, 2, 7, and 8) are readily rationalized on the basis of a simple analysis at the transition state level. The global results demonstrate the power of the transannular Diels–Alder reaction on macrocyclic trienes for the construction of tricyclic compounds. Indeed, so far, six of the eight possible diastereoisomers can be obtained and the degree of stereochemical control is remarkable.

[10]An experimental demonstration that boat–boat–chair can compete with chair–boat–chair was later obtained in another study (C. Ouellet and P. Deslongchamps, unpublished results). This work has been summarized (cf. p. 53 and Scheme 17 in ref. 3).

These assumptions were also examined using Sybyl molecular modeling software. Thus the TTT macrocycle (*transoid* diene) was constructed by standard functions within Sybyl; a dynamic trajectory was then simulated (1 fs time step) at 500 K (temperature coupling factor 25 fs) during 10 ps. Conformers at each 100 fs were saved and minimized by Maximin. The assembly of 100 conformers thus generated was checked to remove duplicata and locate lowest energy conformers. Besides conformers with a *transoid* diene moiety (lowest in energy), four other minima (*cisoid* diene) were found within a 3 kcal range (Fig. 1).

The planes of the diene and dienophile moieties are perpendicular to the plane of the macrocycle, thus minimizing transannular nonbonded interactions (10) and placing the π systems in the plane of the ring. The distances between the extremities of the diene and dienophile are only 3–3.5 Å, with the olefin slightly twisted relative to the diene.

To mimic the situation in the transition state more closely, the torsion angle between the forming bonds and the torsion angle in the butadiene moiety were set at 0° as found by *ab initio* calculations for the transition state of butadiene and ethylene (11).

The distances between the termini of the dienophile and the diene were set to 3 Å and the structures obtained were minimized using these constraints,[11] leading to the geometries depicted in Fig. 2. Structures like A′ (chair–boat–chair) (cf. **34***b* → **36**) and B′ (chair–boat–boat) (cf. **34***d* → **38**) would generate the **4***b* (TAC) product while C′ (chair–boat–chair) (cf. **34***a* → **35**) and D′ (chair–boat–boat) (not shown) would produce the **4***c* (CAT) isomer.

Taking into account the early nature of the Diels–Alder transition state and the close similarity of the structures, one might expect to get a fair estimation of the product ratio from the relative energies of A′–D′. Indeed a Boltzmann distribution among the above four states indicated that the TTT macrocycle should lead to a product ratio **4***b* (TAC):**4***c* (CAT) of 2:1, in complete agreement with the experimental result (A′:B′:C′:D′ = 0.58:0.1:0.3:0). To investigate further possible transition states a structure with a boat–boat–chair arrangement (cf. **34***c* → **37**, Scheme 8) leading to CAT isomer **4***c* has been constructed:[13] the energy of the minimized structure was found to be 4 kcal higher than that of C′ (chair–boat–chair arrangement) thus indicating that this kind of transition state should be eliminated. Even if the boat–boat–chair state is considered instead of D′ (chair–boat–boat), which is about 2 kcal higher in energy, the Boltzmann distribution of the four states is still that indicated previously. Thus, the above calculations suggest that the TAC tricycle **4***b* would be obtained mainly via a chair–boat–boat transition state while the **4***c* (CAT) isomer would be obtained from a chair–boat–chair transition state, and this explains nicely the ratio of the obtained products.

[11]An accurate description of the transition state requires a higher level of theory. Very recently empirical force-field models for the transition states of intramolecular Diels–Alder reactions based upon *ab initio* transition structures have been described (12). Available software that uses the MMX[12] force field and allows a choice of bond orders between two atoms in the transition state did not lead in our case to results in agreement with experiment. This has been observed also for other examples (12).

[12]PC MODELS. Serena Software, P.O. Box 3076, Bloomington, IN 47402-3076, U.S.A.

[13]The corresponding conformers have not been detected by our short dynamic simulation; the structure was constructed from structure B′ by removing the methyl group and placing it at the other end of the olefin.

Conclusion

The work reported in the present paper further extends the scope of the transannular Diels–Alder reaction as a powerful synthetic strategy for the stereoselective preparation of A.B.C.[6.6.6] tricycles. It also answers questions about the factors governing the stereochemical outcome of the cycloaddition reaction and factors leading to competing chemical processes.

The knowledge of such factors stemming from a high degree of conformational restriction of macrocyclic trienes leads to predictable results in terms of stereochemistry, and therefore such an approach should be more advantageous than conventional intramolecular reactions. Moreover, transannular Diels–Alder reactions may be performed with nonactivated dienophiles and with *cis,trans* dienes, processes that are very rare in classical inter- and intramolecular cycloadditions. Also, all eight stereoisomers of the tricyclic products might be obtained by such a strategy whereas conventional cycloadditions usually afford one or two such stereoisomers.

Optimization of the developed schemes as well as applications of the described results to syntheses of natural products is underway in our laboratory.

Experimental

General

The ir spectra were taken on a Perkin–Elmer 681 spectrophotometer using chloroform ($CHCl_3$), dichloromethane (CH_2Cl_2), or run as neat films on sodium chloride cells. Proton nmr spectra were recorded on a Bruker WP-80 or Bruker WM-250 instrument. The following abbreviations have been used: s, singlet; d, doublet; dd, doublet of doublets; dt, doublet of triplets; ddd, doublet of doublets of doublets; dddd, doublet of doublets of doublets of doublets; ddt, doublet of doublets of triplets; ddq: doublet of doublets of quartets; t, triplet; td: triplet of doublets; q, quartet; and m, multiplet. Chemical shifts are reported in δ values relative to chloroform as internal standard. Carbon nuclear magnetic resonance spectra were recorded on a Bruker WP-80 or Bruker WM-250 instrument (chloroform as internal standard). Mass spectra were obtained on a Micromass ZAB-2F instrument. Melting points were determined on a Büchi M-50 or on a Reichert apparatus and are uncorrected.

Unless otherwise specified, all reactions were performed under an argon atmosphere and were monitered by thin-layer chromatography. For flash chromatography, silica gel Merck Kieselgel 60 (230–400 mesh, ASTM) was used. All solvents used in chromatography were distilled. Anhydrous solvents were obtained by standard means.

Macrocyclization

Allylic chloride **2**a *(CTT)*

To a solution of CTT alcohol **1***a* (160 mg, 0.35 mmol), lithium chloride (59 mg, 1.40 mmol), and *s*-collidine (68 mg, 0.56 mmol) in 5 mL of dimethylformamide at 0°C was added, dropwise, methanesulfonyl chloride (60 mg, 0.53 mmol). The mixture was then warmed up to room temperature and stirred for 3 h, and was then poured onto 25 mL of ice-water. After extraction with a 2:1 mixture of ether and hexane (3 × 20 mL) the combined organic layers were washed with water (10 mL), then with a saturated aqueous solution of copper nitrate (10 mL), again with water (10 mL), and were dried over magnesium sulfate. The crude product obtained after evaporation of the solvent was purified by column

chromatography on silica gel with 10% ethyl acetate in hexane to afford CTT chloride **2***a* (147 mg, 89%); ir ($CHCl_3$): 3015, 2950, and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.57 (1H, ddq, J = 14.9, 11.1, and 1.1 Hz, -C*H*=CH-CH_2-Cl), 6.11 (1H, br t, J = 11.1 Hz, -$(CO_2CH_3)_2$C-CH_2CH=C*H*-), 5.83 (1H, dt, J = 14.9 and 7.3 Hz, =C*H*-CH_2-Cl), 5.36 (1H, dt, J = 11.0 and 7.8 Hz, -$(CO_2CH_3)_2$C-CH_2-C*H*=), 5.08 (1H, br t, J = 6.8 Hz, =C*H*-CH_2-CH_2-), 4.13 (2H, dd, J = 7.2 and 1.0 Hz, -CH_2-Cl), 3.73 and 3.71 (12H, 2s, -$(CO_2CH_3)_2$-), 3.35 (1H, t, J = 7.3 Hz, -C*H*$(CO_2CH_3)_2$), 2.80 (2H, dd, J = 8.0 and 1.4 Hz, -$(CO_2CH_3)_2$C-C*H*$_2$-CH=), 2.07–1.75 (8H, m, -$(CH_2)_2$-C(CH_3)=CH-$(CH_2)_2$-), 1.55 (3H, d, J = 1.2 Hz, C*H*$_3$-C=).

Allylic chloride **2**d *(TTT)*

To a solution of TTT alcohol **1***d* (101 mg, 0.22 mmol), lithium chloride (19 mg, 0.44 mmol), and *s*-collidine (40 mg, 0.33 mmol) in dimethylformamide (1 mL) at 0°C was added methanesulfonyl chloride (35 mg, 0.31 mmol). The mixture was warmed up to room temperature and stirred for 3 h. It was then poured into water (10 mL) and extracted with a mixture of ether and hexane (2:1) (3 × 10 mL). The combined organic layers were washed with water (5 mL), a saturated aqueous solution of copper nitrate (5 mL), and finally with brine (5 mL). The crude oil obtained after evaporation of the solvent was purified by column chromatography on silica gel using 20% ethyl acetate in hexane to give TTT chloride **2***a* (71 mg, 68%); ir ($CHCl_3$): 3020, 2955, 1740, and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.23 (1H, dd, J = 14.8 and 10.5 Hz, =C*H*-CH=), 6.07 (1H, dd, J = 14.8 and 10.5 Hz, =CH-C*H*=), 5.71 (1H, dt, J = 14.7 and 7.2 Hz, =C*H*-CH_2-Cl), 5.56 (1H, dt, J = 14.8 and 7.4 Hz, -$(CO_2CH_3)_2$C-CH_2-C*H*=), 5.08 (1H, m, =C*H*-C*H*$_2$-CH_2), 4.07 (2H, d, J = 7.3 Hz, -C*H*$_2$-Cl), 3.72 and 3.71 (12H, 2s, -$(CO_2CH_3)_2$-), 3.35 (1H, t, J = 7.2 Hz, -C*H*$(CO_2CH_3)_2$), 2.68 (2H, d, J = 7.6 Hz -$(CO_2CH_3)_2$C-C*H*$_2$-CH=), 2.10–1.77 (8H, m, -$(CH_2)_2$-C(CH_3)=CH$(CH_2)_2$), 1.55 (3H, s, C*H*$_3$-C=); ms *m/e*: 441 ($M^+ - OCH_3$), 436 ($M^+ - HCl$). Exact Mass calcd.: 441.1680 ($M^+ - OCH_3$); found: 441.1674 ± 0.0013.

Macrocycle **3**a *(CTT)*

To a solution of cesium carbonate (103 mg, 0.32 mmol) in 4.5 mL of tetrahydrofuran and 3.5 mL of dimethylformamide at 85°C was added, over a period of 5 h, CTT chloride **2***a* (30 mg, 0.063 mmol) dissolved in 9 mL of a mixture of tetrahydrofuran and dimethylformamide (4:5). After the addition was completed, the mixture was stirred for an additional hour and, after cooling to room temperature, the carbonate was filtered off. The solvents were evaporated (0.5 Torr (1 Torr = 133.3 Pa), 45°C) and the residue was subjected to column chromatography purification using 10% ethyl acetate in hexane to afford CTT macrocycle **3***a* (24 mg, 87%), which could be recrystallized from ether (mp 143–153°C); ir ($CHCl_3$): 2955 and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.13 (2H, m, =C*H*-C*H*=), 5.36–5.16 (2H, m, =C*H*-CH_2-CH_2- and -C*H*=CH-CH_2-), 5.01 (1H, br, q, J = 9.1 Hz, -CH_2=C*H*-), 3.74 and 3.73 (12H, 2s, -CO_2CH_3), 2.77 (2H, br, d, J = 6.8 Hz, -CH=CH-C*H*$_2$), 2.74 (2H, br, d, J = 8.4 Hz, -C*H*$_2$-CH=CH-), 2.05–1.74 (8H, m, -$(CH_2)_2$-C(CH_3)=CH-$(CH_2)_2$), 1.58 (3H, d, J = 1.1 Hz, C*H*$_3$-C=); ms *m/e*: 436 (M^+), 421 ($M^+ - CH_3$), 405 ($M^+ - OCH_3$). Exact Mass calcd.: 436.2097; found: 436.2095 ± 0.015.

Macrocycle **3**e *(CTC)*

CTC Allylic chloride **2***e* was obtained in 76% yield after chromatography (based on 10% recovered starting material), following the procedure described above; ir ($CHCl_3$): 3020, 2950, 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.58 (1H, ddm, J = 14.9 and 11.1 Hz, -C*H*=CH-CH_2-Cl), 6.12 (1H, bt, J = 11.3 Hz, -$(CO_2CH_3)_2$C-CH_2-CH=C*H*-), 5.83 (1H, dt, J = 14.9 and 7.2 C*H*, =C*H*-CH_2-Cl), 5.37 (1H, dt, J = 10.9 and 8.0 Hz, $(CO_2CH_3)_2$C-CH_2-C*H*=), 5.02 (1H, m, =C*H*-CH_2-CH_2), 4.13 (2H, dd, J = 7.2 and 1.0 Hz, -C*H*$_2$Cl), 3.73 and 3.72 (12H, 2s, 4 × -CO_2CH_3), 3.34 (1H, t, J = 7.2 Hz, -C*H*$(CO_2CH_3)_2$), 2.81 (2H, dd, J = 8.0 and 1.4 Hz, -$(CO_2CH_3)_2$C-C*H*$_2$-CH=), 2.03–1.75 (8H, m, -$(CH_2)_2$), 1.65 (3H, d, J = 1.2 Hz, C*H*$_3$-C=).

The above chloride (16 mg, 0.034 mmol) dissolved in 2 mL of a 1:1 tetrahydrofuran–dimethylformamide mixture was added, over 11 h, to a solution of cesium carbonate (55 mg, 0.17 mmol) in 5 mL of the same solvent mixture kept at 75°C. The reaction mixture was stirred for an additional 2 h at this temperature. After cooling to room temperature, the carbonate was filtered off and the solvents evaporated (0.5 Torr) to afford a crude oil that was subjected to purification by column chromatography on silica gel with 10–25% ethyl acetate in hexane, yielding CTC macrocycle **3***e* (12 mg, 81%), which could be recrystallized from dichloromethane–hexane (mp 210–220°C); ir ($CHCl_3$): 3020, 2950, and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.57 (1H, br dd, J = 14.9 and 11.1 Hz, -C*H*=CH-CH_2-), 6.16 (1H, t, J = 11.1 Hz, -C*H*=CH-CH_2-), 5.43 (1H, dt, J = 15.0 and 8.0 Hz, -CH=C*H*-CH_2-), 5.13 (1H, m, =C*H*-CH_2-CH_2-), 4.98 (1H, dt, J = 10.8 and 8.8 Hz, -CH_2-C*H*=CH-), 3.75 and 3.74 (12H, 2s, -CO_2CH_3), 2.83 (2H, br d, J = 8.6 Hz, -C*H*$_2$-CH=CH-), 2.78 (2H, br d, J = 8.0 Hz, -C*H*$_2$-CH=CH-), 2.00–1.65 (8H, m, -$(CH_2)_2$-C(CH_3)=CH-$(CH_2)_2$), 1.75 (3H, d, J = 0.7 Hz, C*H*$_3$-C=); ms *m/e*: 436 (M^+), 421 ($M^+ - CH_3$), 405 ($M^+ - OCH_3$). Exact Mass calcd.: 436.2097; found: 436.2097 ± 0.0017.

Macrocycle **3**f *(TCC)*

Methanesulfonyl chloride (21 μL, 0.264 mmol) was added, dropwise, to a solution of TCC alcohol **1***f* (59.5 mg, 0.132 mmol), lithium chloride (22.3 mg, 0.530 mmol), and collidine (35 μL, 0.265 mmol) in dimethylformamide (1 mL) at 0°C. The mixture was stirred at 0°C for 1 h, then at room temperature for 2.5 h. The solution was poured into ice-cold water and extracted with ether–hexane (2:1). The organic layer was washed with saturated aqueous copper(II) nitrate solution, then with water. This organic layer was dried and the solvent was evaporated to give the TCC allylic chloride **2***f*, which was used as such for the macrocyclization step.

TCC chloride **2***f* in 5 mL of a 1:1 tetrahydrofuran–dimethylformamide mixture was added, over 15 h, using a syringe pump, to a suspension of cesium carbonate (215 mg, 0.66 mmol) in 21.4 mL of a 1:1 tetrahydrofuran–dimethylformamide mixture at 70°C. After the addition was finished, the stirring was continued at 70°C for 5 h. The resulting solution was cooled down to room temperature and excess cesium carbonate was removed by filtration.

Tetrahydrofuran was evaporated and dimethylformamide was distilled off under reduced pressure. The TCC macrocyclic triene **3***f* was purified by chromatography on silica gel using a 1:2:7 mixture of ethyl acetate – dichloromethane–hexane yielding 49 mg (86% overall yield). The product was recrystallized from dichloromethane–hexane (3:4) (mp 224–225°C); ir ($CHCl_3$): 3020–2840, 1730, 1450, and 1220 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.57 (1H, ddd, J = 15.0, 11.3, 0.8 Hz, -CH_2CH=C*H*CH=CHCH_2-), 6.19 (1H, t, J = 11.1 Hz, -CH_2CH=CHC*H*=CHCH_2-), 5.37 (1H, dt, J = 14.8, 7.5 Hz, -CH_2C*H*=CHCH=CHCH_2-), 5.02 (2H, m, CH_2CH=CHCH=C*H*CH_2-, -C(CH_3)=CH-), 3.75, 3.73 (12H, 2 singlets, 4 × -CO_2CH_3), 2.81 (4H, m, J = 7.6 Hz, -C*H*$_2$-CH=CHCH=CHC*H*$_2$-), 1.90–1.70 (8H, m, -C*H*$_2$C*H*$_2$C(CH_3)=CH-C*H*$_2$C*H*$_2$-), 1.65 (3H, d, J = 1.0 Hz, -C(C*H*$_3$)=CH-); ms *m/e*: 436 (M^+). Exact Mass calcd.: 436.2097; found: 436.2095 ± 0.0013.

Macrocycle **3**b *(TCT)*

Following the previous procedure, 243 mg (0.535 mmol) of alcohol **2***b* (TCT) afforded 106.5 mg (46% yield; 1 × 10^{-3} M dilution conditions). The product could be recrystallized from methanol (mp 154–156°C); ir ($CHCl_3$): 3020–2850, 1730, 1435, and 1220 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.26 (1H, ddd, J = 14.6, 11.1, 0.8 Hz, -CH_2CH=C*H*CH=CHCH_2-), 6.08 (1H, tm, J = 11.0 Hz, -CH_2CH=CHC*H*=CHCH_2-), 5.40 (1H, dt, J = 15.0, 7.9 Hz, -CH_2C*H*=CHCH=CHCH_2-), 5.18 (1H, tm, J = 6.5, 1.1 Hz, -C(CH_3)=C*H*-), 4.94 (1H, dt, J = 10.7, 7.8 Hz, -CH_2CH=CHCH=C*H*CH_2-), 3.74, 3.73 (12H, 2s, 4 × -CO_2CH_3), 2.85 (2H, dd, J = 7.4, 1.5 Hz, -CH=CHC*H*$_2$-), 2.74 (2H, d, J = 7.9 Hz,

-CH_2CH=CH-), 2.03–1.80 (8H, m, -CH_2CH_2C(CH_3)=CHCH_2-CH_2-), 1.58 (3H, br s, -C(CH_3)=CH-); ^{13}C nmr ($CDCl_3$) δ: 171.77, 171.70 (C=O), 133.84 (-C(CH_3)=CH-), 131.66, 131.16, 127.93, 124.66, 124.43 (=CH-), 58.43, 56.99 (-*C*(CO_2CH_3)$_2$), 52.42 (-OCH_3), 35.06, 31.32, 30.35, 30.23, 28.75, 23.23 (-CH_2-), 17.14 (-CH_3); ms *m/e*: 436 (M^+). Exact Mass calcd.: 436.2097; found: 436.2095 ± 0.0013.

Macrocycle **3**c *(CCT)*

Following the previous procedure starting with 58 mg (0.128 mmol) alcohol **2***c* (CCT), this macrocycle was obtained in 45% yield (1×10^{-3} M dilution conditions) and it was recrystallized from methanol (mp 158–159°C); ir ($CHCl_3$): 3020–2850, 1730, 1435, and 1200 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.24 (2H, m, CH_2CH=*CHCH*=CHCH_2-), 5.25, 5.22 (2H, 2 × m, -CH_2*CH*=CH-CH=*CH*CH_2-), 5.09 (1H, tq, *J* = 6.6, 1.3 Hz, -C(CH_3)=CH-), 3.73 (12H, s, 4 × -CO_2CH_3), 2.77 (2H, dd, *J* = 7.4, 1.5 Hz, -CH_2CH=CHCH=CHCH_2-), 2.71 (2H, d, *J* = 8.0 Hz, -CH_2-CH=CHCH=CHCH_2-), 2.11–1.65 (8H, m, -CH_2CH_2C(CH_3)=CHCH_2CH_2-), 1.51(3H, bs, -C(*C*H_3)=CH-); ^{13}C nmr ($CDCl_3$) δ: 171.94, 171.82 (C=O), 134.37 (-*C*(CH_3)=CH-), 128.33, 127.20, 127.00, 125.83, 124.98 (=CH-), 58.04, 56.97 (-*C*(CO_2CH_3)$_2$), 52.51, 52.43 (-OCH_3), 32.59, 31.74, 31.35, 30.54, 28.90, 22.22 (-CH_2-), 16.13 (-CH_3); ms *m/e*: 436 (M^+). Exact Mass calcd.: 436.2097; found: 436.2095 ± 0.0013.

Macrocycle **3**g *(CCC)*

This macrocycle was obtained in 78% yield starting with 139 mg (0.306 mmol) of alcohol **2***g* (CCC) and using 1×10^{-3} M dilution conditions, as described above. The compound was recrystallized from methanol (mp 179–182°C); ir ($CHCl_3$): 3020–2840, 1730, 1450, and 1200 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.48 (2H, m, -CH_2-CH=*CHCH*=CHCH_2-), 5.35 (2H, m, -CH_2*CH*=CHCH=*CH*-CH_2-), 5.12 (1H, m, -C(CH_3)=C*H*-), 3.76, 3.74 (12H, 2s, 4 × CO_2CH_3), 3.04 (1H, dd, *J* = 12.9, 6.5 Hz, -*CH*HCH=CH-CH=CHCH_2-), 2.99 (1H, dd, *J* = 12.9, 6.5 Hz, -CH*H*CH=CHCH=CHCH_2-), 2.64 (2H, dm, *J* = 15.3 Hz, -CH_2CH=CHCH=CHCH_2-), 2.20–1.50 (11H, m, -CH_2CH_2C(CH_3)=CH-CH_2CH_2-); ^{13}C nmr ($CDCl_3$) δ: 171.70, 171.55, 171.46 (C=O), 135.57 (-*C*(CH_3)=CH-), 127.76, 126.50, 126.33, 123.82 (-CH=), 56.97, 56.54 (-*C*(CO_2CH_3)$_2$), 52.58 (-OCH_3), 32.19, 30.53, 30.01 (-CH_2CH=), 26.06, 22.97 (-CH_2-), 22.07 (-CH_3); ms *m/e*: 436 (M^+). Exact Mass calcd.: 436.2097; found: 436.2095 ± 0.0013.

Tricycle **15**

This compound was obtained from the transannular Diels–Alder reaction of TCT macrocycle **3***b* (see Table 2) (mp 151–153°C) (recrystallized from methanol); ir ($CHCl_3$): 3030–2860, 1730, 1460, 1440, 1230 cm^{-1}; ^{1}H nmr (C_6D_6) δ: 5.22 (1H, dd, *J* = 4.5 Hz, -C(CH_3)=C*H*-), 3.41, 3.28, 3.27 (12H, 3s, 4 × CO_2CH_3), 2.67 (1H, dq, *J* = 13.6, 2.3 Hz), 2.48 (1H, dm, *J* = 13.6, 2.2 Hz), 2.31 (3H, m), 2.13 (1H, dt, *J* = 12.5, 4.0 Hz), 1.90–1.50 (8H, m), 1.63 (3H, app t, *J* = 1.3 Hz, -C(*C*H_3)=CH-), 1.33 (2H, m).

Transannular Diels–Alder reactions

Tricycle **4**a *(CAC)*

CTT Macrocycle **3***a* (8.2 mg, 0.019 mmol) dissolved in toluene (0.5 mL) was heated to 300°C in a quartz tube (sealed under vacuum) for 1 h 45 min. The crude mixture obtained after evaporation of the solvent was purified by column chromatography on silica gel with 30% ethyl acetate in hexane to yield CAC tricycle **4***a* (7.5 mg, 91%), which could be recrystallized from methanol (mp 161–162°C); ir ($CHCl_3$): 3030, 2960, and 1730 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 5.26 (2H, br s, -*CH*=*CH*-), 3.68, 3.66, 3.65 (12H, 3s, -CO_2CH_3), 2.72–0.90 (15H, m, -C*H*- and -CH_2-), 1.00 (3H, s, CH_3-C); ms *m/e*: 436 (M^+), 421 ($M^+ - CH_3$), 405 ($M^+ - OCH_3$). Exact Mass calcd.: 436.2097; found: 436.2091 ± 0.0013.

Bicyclic compound **17**

This compound was obtained in 64% yield after chromatography by the transannular Diels–Alder reaction performed on CCT macrocycle **3***c* (see Table 2 for conditions) (mp 175–176°C) (recrystallized from methanol); ir ($CHCl_3$): 3020–2840, 1730, 1450, 1435, 1240, and 1200 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 5.63 (1H, dddd, *J* = 13.7, 9.6, 4.3, 0.9 Hz, -CH_2*CH*=CHCH_2C(CO_2CH_3)$_2$-). 5.13 (1H, dddd, *J* = 12.9, 11.5, 7.4, 1.0 Hz, -CH_2CH=*CH*CH_2C-(CO_2CH_3)$_2$-), 4.83 (1H, dm, *J* = 9.3 Hz, -C(CH_3)=C*H*-), 3.77, 3.76, 3.71 (12H, 3s, 4 × -CO_2CH_3), 2.77 (2H, dd and ddd, *J* = 13.0, 7.2, 1.1 Hz, -C(CH_3)=CH*CH*HC(CO_2CH_3)$_2$*CH*HCH=CH-), 2.35 (5H, m, -*CH*C(CH_3)=CHCH*H*C(CO_2CH_3)$_2$-CH*H*CH=CH*CH*HCH-), 1.90–1.30 (7H, m, =CHCH*H*CH-CH_2C(CO_2CH_3)$_2$-CH_2CH_2-), 1.56 (3H, d, *J* = 1.1 Hz, -C(*C*H_3)=CH-); ^{13}C nmr ($CDCl_3$) δ: 172.75, 171.66, 171.54 (C=O), 141.32 (-*C*(CH_3)=CH-), 129.59, 125.74, 120.40 (-CH=), 57.22, 55.45 (*C*(CO_2-CH_3)$_2$), 52.55, 52.43 (-OCH_3), 40.57, 34.73 (-CH-), 35.19, 30.84, 29.98, 29.91, 29.85, 26.69 (-CH_2-), 18.89 (-CH_3); ms *m/e*: 436 (M^+). Exact Mass calcd.: 436.2097; found: 436.2095 ± 0.0013.

Tricycle **4**d *(CST)*

The transannular Diels–Alder reaction was performed as described before (see Table 2 for conditions) on CTC macrocycle **3***e* (7.0 mg, 0.016 mmol) affording 6.2 mg (89%) of CST tricycle **4***d* after chromatography on silica gel (25% ethyl acetate in hexane); ir $CHCl_3$): 3025, 2960, and 1732 cm^{-1}; ^{1}H nmr (C_6D_6) δ: 5.36 (2H, m, -*CH*=*CH*-), 3.33, 3.30, 3.27, and 3.26 (12H, 4s, -CO_2CH_3), 2.75–2.65 (2H, m, H_{eq}C12 and H_{eq}C14), 2.58 (1H, dd, *J* = 14.5 and 6.0 Hz, H_{ax}C4), 2.47 (1H, m, H_{eq}C2), 2.40 (1H, dt, *J* = 14.2 and 3.0 Hz, H_{eq}C4), 2.12 (1H, tm, *J* = 12.0 Hz, HC8), 1.98 (1H, tdd, *J* = 13.7, 4.0, and 0.5 Hz, H_{ax}C1), 1.92 (1H, m, HC5), 1.70 (1H, t, *J* = 12.9 Hz, H_{ax}C14), 1.64 (1H, dt, *J* = 13.2 and 4.1 Hz, H_{ax}C12), 1.57 (1H, td, *J* = 13.5 and 3.4 Hz, H_{ax} C2), 1.52 (1H, m, H_{eq}C11), 0.97 (1H, dt, *J* = 14.1 and 2.4 Hz, H_{eq}C2), 0.87 (1H, tm, *J* = 12.0 Hz, HC9), 0.76 (3H, s, -*CH*$_3$); ms *m/e*: 436 (M^+), 421 ($M^+ - CH_3$), 405 ($M^+ - 0CH_3$). Exact Mass calcd.: 436.2097; found: 436.2095 ± 0.0013.

Tricycle **4**e *(TSC)*

Using the previously described procedure (see Table 2 for conditions), TCC macrocyclic triene **3***f* (39 mg) in toluene (2.5 mL) afforded 39.5 mg (~100%) of TSC tricycle **4***e*, homogeneous by tlc and gc. The product was recrystallized from dichloromethane–hexane (mp 123–124°C); ir ($CHCl_3$): 3020–2860, 1725, 1450, 1435, and 1250 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 5.33 (1H, ddd, *J* = 9.7, 3.4, 3.6 Hz, HC6), 5.21 (1H, ddd, *J* = 9.7, 2.6 Hz, HC7), 3.76, 3.69, 3.68, 3.67 (12H, 4s, 4 × -CO_2CH_3), 2.71 (1H, m, HC8), 2.49 (1H, dt, *J* = 13.5, 2.6 Hz, H_{eq}C14), 2.39 (1H, dt, *J* = 9.5, 3.2 Hz, H_{eq}C12), 2.30 (1H, m, *J* = 14.4 Hz, H_{eq}C2), 2.12 (1H, dd, *J* = 10.2, 2.3 Hz, H_{eq}C4), 2.06 (1H, dd, *J* = 14.4, 5.9 Hz, H_{ax}C14), 1.98 (1H, ddd, *J* = 13.6, 13.4, 4.7 Hz, H_{ax}C2), 1.85 (2H, m, HC5 and H_{ax}C4), 1.74 (1H, dddq, *J* = 13.1, 12.9, 4.6, 1.1 Hz, H_{ax}C1), 1.58 (1H, app dd, *J* = 11.9, 4.2 Hz, H_{eq}C11), 1.44 (2H, m, H_{ax}C11 and H_{ax}C12), 1.27 (1H, m, HC9), 1.07 (1H, dm, *J* = 13.7 Hz, H_{eq}C1), 0.87 (3H, s, -CH_3); ^{13}C nmr ($CDCl_3$) δ: 173.11, 172.72, 171.72, 171.29 (C=O), 129.70 (-*CH*=*CH*-), 55.53 (C10), 52.60 (-OCH_3), 51.95 (C3, C13), 44.16, 35.50, 35.19, 35.05, 32.63, 30.91, 26.70, 19.16 (-CH- and -CH_2), 17,72 (-CH_3); ms *m/e*: 436 (M^+). Exact Mass calcd.: 436.2097; found: 436.2095 ± 0.0013.

Tricycles **4**b *(TAC) and* **4**c *(CAT)*

To a solution of cesium carbonate (93 mg, 0.29 mmol) in 20 mL of tetrahydrofuran and 28 mL of dimethylformamide at 85°C was added, over a period of 16 h, TTT chloride **2***d* (27 mg, 0.057 mmol) dissolved in 8 mL of tetrahydrofuran. After the end of the addition, the mixture was stirred for an hour at 85°C and was then cooled down to room temperature. The carbonate was filtered and the solvents distilled off (45°C, 0.5 Torr). The residue was purified by column chromatography on silica gel using 15% ethyl acetate in hexane to yield a 2:1 unseparable mixture of tricycles **4***b* (TAC) and **4***c* (CAT) (16.1 mg, 65%); ir (CH_2Cl_2): 3055, 2955, and 1730 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 5.62–5.52 (1H, m, -*CH*= (CAT)), 5.54 (1H, dm, *J* = 9.8 Hz, -*CH*= (TAC)), 5.38–5.30 (1H, m, -*CH*= (CAT)), 5.32 (1H, dm, *J* = 10.2 Hz, -*CH*= (TAC)), 3.73,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

3.72, and 3.70 (12H, 3s, -CO_2CH_3 (TAC)), 3.74, 3.70, and 3.69 (12H, 3s, -CO_2CH_3 (CAT)), 2.65–0.80 (15H, m, -CH_2 and -CH- for both compounds), 0.83 (3H, s, CH_3-C (TAC)), 0.75 (3H, s, CH_3-C (CAT)).

Tricycle **4**c *(CAT) (from* 7b*)*

To a solution of diisopropylamine (30 mg, 41.7 μL, 0.297 mmol) in freshly distilled anhydrous tetrahydrofuran (0.5 mL) at 0°C was added *n*-butyllithium (1.6 M solution, 148.5 μL, 0.238 mmol). The mixture was stirred for 20 min at 0°C, and then was cooled to −78°C. A solution of triester **7***b* (30 mg, 0.0793 mmol) in anhydrous tetrahydrofuran (0.3 mL) was then added. The resulting mixture was allowed to warm to 0°C for 45 min, then cooled again to −78°C and dry methylchloroformate was added. The mixture was allowed to warm to 0°C and stirred for 2 h. The reaction mixture was diluted with dichloromethane and was washed successively with a dilute hydrochloric acid solution and water. Drying and removal of the solvent left a crude product that was purified by preparative chromatography on silica gel using 20% ethyl acetate in hexane as eluant to provide 13.3 mg (45%) of CAT tetraester **4***c* (mp 122–125°C); ir (CH_2Cl_2): 3055, 2950, 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.63–5.52 (2dd, 1H, J = 2.5, 10 Hz, HC6), 5.40–5.31 (br d, 1H, J = 9.8, 0.5 Hz, HC7), 3.75, 3.70, and 3.69 (3s, 12H, 4 × H_3COOC), 2.56–2.37 (m, 2H, H_{eq}C11 and H_{eq}C2), 2.36–2.23 (m, 1H, H_{eq}C14), 2.12–1.96 (m, 1H, HC5), 1.96–0.95 (m, 11H), 0.75 (s, 3H, H_3C); ms *m/e*: 436 (M^+).

Tricycle **4f** *(TST) and macrocycle* **5**

To a solution of TTC alcohol **1***h* (435 mg, 0.96 mmol), lithium chloride (84 mg, 2.0 mmol), and *s*-collidine (161 mg, 1.3 mmol) in 8 mL of dimethylformamide at 0°C was added methanesulfonyl chloride (140 mg, 1.2 mmol). The mixture was stirred at room temperature for 18 h and was poured into ice-water (40 mL). The water layer was extracted with a mixture of ether and hexane (2:1, 4 × 40 mL) and the combined organic layers were washed with water (20 mL) and with saturated copper nitrate solution (20 mL), and were dried over magnesium sulfate. The crude chloride **2***h* obtained after evaporation (435 mg, 0.92 mmol) was dissolved in 15 mL of tetrahydrofuran and was added over a period of 15 h with the help of a syringe pump to a suspension of cesium carbonate (1.63 g, 5.0 mmol) in 255 mL of tetrahydrofuran and 250 mL of dimethylformamide at 80°C. After the addition was completed, the mixture was stirred for 3 h and was cooled down to room temperature. The carbonate was filtered off and the solvents were evaporated (0.5 Torr). The crude material was purified by column chromatography on silica gel using 25% ethyl acetate in hexane to yield TST tricyle **4***e* (220 mg, 53% overall), which could be recrystallized from methanol (mp 116–118°C); ir (CH_2Cl_2): 3055, 2985, 2955, 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 5.59 (2H, m, -CH=CH-), 3.74, 3.73, 3.68, and 3.67 (12H, 4s, -CO_2CH_3), 2.60–0.75 (15H, m, -CH_2- and -CH-), 0.78(3H, s, -CH_3); ms *m/e*: 436 (M^+), 405 ($M^+ - OCH_3$). Exact Mass calcd.: 436.2097; found: 436.2095 ± 0.0013; and macrocycle **5** (93 mg, 23% overall), which could be recrystallized from ether (mp 143–144°C); ir (CH_2Cl_2): 3060, 2960, 1735 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.01 (1H, br dd, J = 15.5 and 7.2 Hz, -CH_2-CH=CH-), 5.89 (1H, ddd, J = 18.2, 10.4, and 7.9 Hz, -CH=CH_2), 5.47 (1H, dt, J = 15.5 and 6.8 Hz, -CH_2-CH=CH-), 5.16 (1H, m, =CH-CH_2-CH_2-), 5.04 (1H, br d, J = 10.4 Hz, CH=CH_{cis}H), 5.00 (1H, br d, J = 18.1 Hz, -CH=CHH_{trans}), 3.74, 3.73, 3.72, and 3.64 (12H, s, 4 × -CO_2CH_3), 3.52 (1H, br t, J = 7.4 Hz, -CH-CH=CH_2), 2.94 (1H, ddd, J = 14.9, 6.4, and 1.5 Hz, -CHH-CH=CH-), 2.65 (1H, br dd, J = 14.9 and 7.7 Hz, CHH-CH=CH-), 2.25–1.90 and 1.80–1.50 (8H, 2 m, $(CH_2)_2$-C(CH_3)=CH-$(CH_2)_2$), 1.67 (3H, d, J = 1.2 Hz, CH_3-C=C). Exact Mass calcd.: 436.2097; found: 436.2095 ± 0.0013.

Macrocycle **3**h *(TTC) and dimer* **6**

Crude TTC allylic chloride **2***h* (47 mg, 0.09 mmol) (prepared as above) afforded, using the previous procedure (45°C, addition time 16 h) and after chromatography on silica gel (10–20% in hexane), TTC macrocycle **3***h* (11.5 mg, 26% contaminated with 15% **5**); ir ($CHCl_3$): 3025, 2955, and 1730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.30–6.10 (2H, m, =CH-CH=), 5.85–5.57 (2H, m, -CH=CH-CH=CH-), 4.99 (1H, m, =CH-CH_2-CH_2-), 3.74 and 3.72 (12H, 2s, -CO_2-CH_3), 2.69 and 2.65 (4H, 2d, J = 7.4 Hz, -CH_2CH-CH-CH=CH-CH_2-), 1.90–1.60 (8H, m, -CH_2-CH_2-C(CH_3)-CH-CH_2CH_2), 1.62 (3H, d, J = 1.3 Hz, CH_3-C=); and dimer **6** (4.7 mg, 11%) (mp 130–138°C); ir (CH_2Cl_2): 3055, 2955, and 1735 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.15–5.95 (4H, m, =CH-CH=), 5.58–5.32 (4H, m, -CH=CH-CH=CH-), 5.02 (2H, m, =CH-CH_2-CH_2-), 3.72 and 3.68 (24H, 2s, -CO_2CH_3), 2.69 and 2.61 (8H, 2d, J = 7.5 and 7.7 Hz, -CH_2-CH=CH-), 2.00–1.60 (16H, m, -CH_2-CH_2-), 1.62 (6H, d, J = 1.0 Hz, CH_3-C=); ms *m/e*: 872 (M^+), 841 ($M^+ - OCH_3$). Exact Mass calcd.: 872.4194; found: 872.4200 ± 0.0026.

Received November 27, 1992

JIANLIANG XIAO and MARTIN COWIE. Can. J. Chem. **71**, 726 (1993).

Reaction of the tetracarbonyl species $[M(CO)_2(\mu\text{-mtz})]_2$ (M = Rh, Ir; mtz = 2-mercaptothiazolinate) with 1 equivalent of the diphosphines $(Ph_2P(CH_2)_nPPh_2$; n = 1 (dppm), 2 (dppe)) yields the compounds $[M_2(CO)_2(\mu\text{-L})(\mu\text{-mtz})_2]$ (M = Rh, L = dppm (**1**), dppe (**3**); M = Ir, L = dppm (**2**)), which readily undergo oxidative addition of iodine to give $[M_2I_2(CO)_2(\mu\text{-L})(\mu\text{-mtz})_2]$ (M = Rh, L = dppm (**4**), dppe (**6**); M = Ir, L = dppm (**5**)). When 2 equivalents of dppm are used, the A-frame compounds $[M_2(CO)_2(\eta^1\text{-mtz})(\mu\text{-mtz})(dppm)_2]$ (M = Rh (**7**), Ir (**8**)) are afforded. In solution the dangling mtz group of **7** undergoes exchange with both the free mtz anion and the bridging mtz ligand. Compounds **7** and **8** are also produced by treatment of *trans*-$[MCl(CO)(dppm)]_2$ (M = Rh, Ir) with 2 equivalents of the mtz anion. Reaction of these dppm-bridged dichloro species with 1 equivalent of the mtz anion yields $[M_2Cl(CO)_2(\mu\text{-mtz})(dppm)_2]$ (M = Rh (**9***a*), Ir (**10**)). Compound **9***a* undergoes reversible Cl^- dissociation to give $[Rh_2(CO)_2(\mu\text{-mtz})(dppm)_2][Cl]$ (**9***b*), which is also the stable form in the solid. Reaction of **9** with CO gives the carbonyl-bridged species $[Rh_2(CO)_2(\mu\text{-CO})(\mu\text{-mtz})(dppm)_2][Cl]$. The structures of **6** and **9***b* have been determined by X-ray crystallography. Compound **6** crystallizes in the triclinic space group $P\bar{1}$ with one-half equivalent of THF per asymmetric unit in a cell having a = 9.856(3) Å, b = 14.078(6) Å, c = 16.245(5) Å, α = 103.66(3)°, β = 93.21(3)°, γ = 92.91(3)°, V = 2182(1) Å^3, and Z = 2, and has refined to R = 0.045 and R_w = 0.057 on the basis of 433 parameters varied. Compound **9***b* crystallizes with one equivalent of CH_2Cl_2 in the monoclinic space group $P2_1/n$ with a = 11.400(1) Å, b = 21.944(2) Å, c = 22.134(1) Å, β = 92.494(7)°, V = 5532(1) Å^3, and Z = 4, and has refined to R = 0.062 and R_w = 0.082 on the basis of 613 parameters varied.

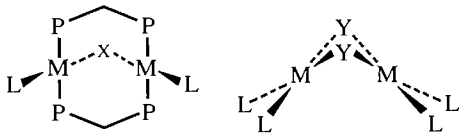
JIANLIANG XIAO et MARTIN COWIE. Can. J. Chem. **71**, 726 (1993).

La réaction des espèces tétracarbonylées $[M(CO)_2(\mu\text{-mtz})]_2$ (M = Rh, Ir; mtz = 2-mercaptothiazolinate) avec un équivalent de diphosphines $(Ph_2P(CH_2)_aPPh_2$; n = 1 (dppm), 2 (dppe)) fournit les composés $[M(CO)_2(\mu\text{-L})(\mu\text{-mtz})_2]$ (M = Rh, L = dppm (**1**), dppe (**3**); M = Ir, L = dppm (**2**)), qui subissent l'addition oxydative d'iode pour donner les $[M_2I_2(CO)_2(\mu\text{-L})(\mu\text{-mtz})_2]$ (M = RH, L = dppm (**4**), dppe (**6**); M = Ir, L = dppm (**5**)). Lorsqu'on utilise deux équivalents de dppm, on obtient les composés en forme de A, $[M_2(CO)_2(\eta^1\text{-mtz})(\mu\text{-mtz})_2(dppm)_2]$ (M = Rh (**7**) et Ir (**8**)). En solution, le groupe mtz pendant du produit **7** subit un échange avec l'anion mtz libre ainsi qu'avec le coordinat mtz agissant comme pont. On obtient aussi les composés **7** et **8** par traitement du *trans*-$[MCl(CO)dppm)]_2$ (M = Rh ou Ir) avec deux équivalents de l'anion mtz. Le réaction de ces espèces dichlorées comportant un pont dppm avec un équivalent de l'anion mtz fournit les espèces $M_2Cl(CO)_2(\mu\text{-mtz})(dppm)_2]$ (M = Rh (**9***a*), Ir (**10**)). Le composé **9***a* subit une dissociation réversible du Cl^- pour donner le $[Rh_2(CO)_2(\mu\text{-mtz})(dppm)_2][Cl]$ (**9***b*) qui est aussi la forme stable à l'état solide. La réaction du produit **9** avec du CO fournit des espèces comportant un pont carbonyle $[Rh_2(CO)_2(\mu\text{-CO}(\mu\text{-mtz})(dppm)_2][Cl]$. Les structures des composés **6** et **9***b* one été déterminées par diffractions des rayons X. Le composé **6** cristallise dans le groupe d'espace triclinique $P\bar{1}$, avec un demi équivalent de THF par unité asymétrique, avec a = 9,856(3), b = 14,078(6) et c = 16,245(5) Å, α = 103,66(3)°, β = 93,21(3)° et γ = 92,91(3)°, V = 2182(1) Å^3 et Z = 2; on a affiné sa structure jusqu'à des valeurs de R = 0,045 et R_w = 0,057 pour 433 paramètres. Le composé **9***b* cristallise avec un équivalent de CH_2Cl_2 dans le groupe d'espace monoclinique $P2_1/n$ avec a = 11,400(1), b = 21,944(2) et c = 22,134(1) Å, β = 92,494(7)°, V = 5532(1) Å^3 et Z = 4; on a affiné sa structure jusqu'à des valeurs de R = 0,062 et R_w = 0,082 pour 613 paramètres.

[Traduit par la rédaction]

Introduction

Binuclear complexes, in which the metals are held in close proximity, are of interest because of the possibility that the two metals may interact in a cooperative manner and in so doing may display chemistry unique from that displayed at a single metal (1). Two common classes of binuclear complexes involving Rh and Ir are those of the "A-frame" and related compounds (2) or of the "open-book" (3) complexes. In the former class the metals are bridged by two neutral diphosphine or related groups (most often dppm $(Ph_2PCH_2PPh_2)$), occupying a *trans* orientation at each metal, whereas in the latter class the only bridging groups are anionic and occupy *cis* positions at both metals, as shown below for **A** and **B**, respectively.



A **B**

In an effort to combine some of the features of both classes of binuclear species we set out to prepare open-book complexes that also contained bridging dppm groups. As a starting point we chose species related to the 2-mercaptothiazolinate-bridged complexes, $[M(CO)L(\mu\text{-mtz})]_2$ (M = Rh, Ir), since the dirhodium species, in which L = PMe_3, was shown to have a short metal–metal separation of ca. 3.05 Å (3*m*), comparable to the bite of dppm, suggesting that this group could be incorporated as an additional bridge in these complexes. Previous work had also shown that the mtz-

bridged binuclear frameworks readily undergo fragmentation in reactions involving molecules such as H_2S and H_2.[2] It seemed likely that the incorporation of a bridging diphosphine group into these complexes would offer greater stability and may allow the isolation of open-book complexes in which one, or even both, bridging mercaptothiazolinate groups were terminally bound. Such "bridge-opened" species had been proposed as key intermediates in the activation of substrates by open-book binuclear complexes (4). We were also interested in the possibility of incorporating dppe ($Ph_2PCH_2CH_2PPh_2$) as a bridging group by utilizing an open-book complex in which the metals are constrained to be in close proximity. Complexes having this diphosphine as a bridging group are extremely rare (5) owing to the well-established propensity of this group to chelate (6). These and related studies are reported herein.

Experimental

All solvents were dried and distilled before use and were stored under dinitrogen. Reactions were carried out at room temperature by using standard Schlenk procedures. 2-Mercaptothiazoline (Hmtz) and bis(diphenylphosphino)methane (dppm) were purchased from Aldrich, bis(diphenylphosphino)ethane (dppe) was obtained from Strem Chemicals, hydrated iridium(III) chloride was obtained from Johnson–Matthey, and ^{13}CO (99%) was supplied by Isotec Inc. These and all other reagents were used as received. The compounds *trans*-$[MCl(CO)(dppm)]_2$ (M = Rh (7), Ir (8)), $[M(COD)(\mu\text{-mtz})]_2$ (M = Rh, Ir)(3*n*), and $[Rh(CO)_2(\mu\text{-mtz})]_2$ (3*m*) were prepared by the previously reported procedures.

The NMR spectra were recorded on a Bruker AM400 spectrometer at 400.1 MHz for ^1H, at 161.9 MHz for $^{31}P\{^1H\}$, and at 100.6 MHz for $^{13}C\{^1H\}$ spectra. The $^{13}C\{^1H, ^{31}P\}$ NMR spectra were obtained on a Bruker WH200 spectrometer operating at 50.32 MHz. Infrared spectra were performed on Nicolet 7199 or Mattson Polaris Fourier transform interferometers with use of Nujol mulls on KBr plates, or in solution in KCl cells with 0.5-mm window path lengths. Spectral data for all compounds are given in Table 1. Elemental analyses were performed by the microanalytical service within the department. Conductivity measurements were made on 1.0×10^{-3} M solutions with use of a Yellow Springs Instrument Co., model 31 conductivity bridge.

Preparation of compounds

(a) $[Rh_2(CO)_2(\mu\text{-mtz})_2(dppm)]$ (1)

To a THF solution of $[Rh(CO)_2(\mu\text{-mtz})]_2$, prepared by the addition of CO to a THF solution of $[Rh(COD)(\mu\text{-mtz})]_2$ (66.0 mg, 0.10 mmol, in 10 mL), was added 38.4 mg (0.10 mmol) of dppm in 5 mL of THF, causing an immediate colour change from wine red to dark purple. After stirring for 1 h, the volume was reduced to ca. 5 mL and 10 mL of hexane was slowly added to the solution, affording the compound as dark purple microcrystals (75% yield). Anal. calcd. for $Rh_2S_4P_2O_2N_2C_{33}H_{28}$: C 44.90, H 3.43, N 3.17; found: C 44.91, H 3.98, N 3.03.

(b) $[Ir_2(CO)_2(\mu\text{-mtz})_2(dppm)]$ (2)

The procedure was the same as for **1**, except that $[Ir(COD)(\mu\text{-mtz})]_2$ was used to prepare the tetracarbonyl precursor. The dark purple compound was only spectroscopically characterized due to its extreme air sensitivity.

(c) $[Rh_2(CO)_2(\mu\text{-mtz})_2(\mu\text{-dppe})]$ (3)

To a THF solution of $[Rh(CO)_2(\mu\text{-mtz})]_2$ (prepared from $[Rh(COD)(\mu\text{-mtz})]_2$ (66.0 mg, 0.10 mmol, in 10 mL of THF)) was slowly added 38.5 mg (0.097 mmol) of dppe in 5 mL of THF, causing an immediate colour change to deep red. The mixture was stirred for ca. 0.5 h and the volume was then reduced to ca. 2 mL followed by addition of hexane to give a red precipitate. This compound was extremely air sensitive, the solid instantly changing colour to brown upon exposure to air.

(d) $[Rh_2I_2(CO)_2(\mu\text{-mtz})_2(dppm)]\cdot 0.5$ THF (4)

To a THF solution of **1** (prepared from 66.0 mg (0.10 mmol) of $[Rh(COD)(\mu\text{-mtz})]_2$ (in 10 mL of THF)) was added 24.5 mg (0.097 mmol) of I_2 in 4 mL of THF, causing an immediate colour change from intense purple to dark red. After stirring for 1 h, the volume was reduced to ca. 2 mL, and addition of hexane precipitated a dark red solid (70% yield). Anal. calcd. for $Rh_2I_2S_4P_2O_{2.5}N_2C_{35}H_{32}$: C 35.84, H 2.93, N 2.39, I 21.65; found: C 35.61, H 2.85, N 2.31, I 21.80.

(e) $[Ir_2I_2(CO)_2(\mu\text{-mtz})_2(dppm)]$ (5)

To a THF solution of **2** (prepared by using $[Ir(COD)(\mu\text{-mtz})]_2$ (84.0 mg, 0.10 mmol, in 10 mL of THF)) was added 24.5 mg (0.097 mmol) of I_2 in 4 mL of THF, causing an immediate colour change to orange. The mixture was stirred for 0.5 h, after which reduction of the volume followed by addition of hexane precipitated an orange solid.

(f) $[Rh_2I_2(CO)_2(\mu\text{-mtz})_2(\mu\text{-dppe})]\cdot 0.5$ THF (6)

To a THF solution of **3** (prepared from 134.0 mg (0.20 mmol) of $[Rh(COD)(\mu\text{-mtz})]_2$) was added 51.0 mg of I_2 in 5 mL of THF; a deep purple solution was immediately formed. Reduction of the volume followed by addition of hexane yielded a dark red solid (70–75% yield). The solid was stored overnight under vacuum. Anal. calcd. for $Rh_2I_2S_4P_2O_{2.5}N_2C_{36}H_{36}$: C 36.44, H 3.06, N 2.36, I 21.39; found: C 36.80, H 3.18, N 2.29, I 22.66. The presence of THF was verified by NMR and the X-ray study (*vide infra*).

(g) $[Rh_2(mtz)(CO)_2(\mu\text{-mtz})(dppm)_2]\cdot CH_2Cl_2$ (7)

Method A. To a THF solution of $[Rh(CO)_2(\mu\text{-mtz})]_2$ (prepared from $[Rh(COD)(\mu\text{-mtz})]_2$ (132.0 mg, 0.2 mmol, in 20 mL)) was added 153.0 mg (0.40 mmol) of dppm, resulting in an immediate colour change to deep red. After stirring for 0.5 h, the volume was reduced to ca. 5 mL followed by precipitation with hexane. Compound **7** was crystallized from CH_2Cl_2–hexane. Anal. calcd. for $Rh_2Cl_2S_4P_4O_2N_2C_{59}H_{54}$: C 52.41, H 4.03, N 2.07, S 9.49; found: C 52.85, H 3.95, N 2.20, S 9.70.

Method B. A 110.0 mg (0.10 mmol) sample of *trans*-$[RhCl(CO)(dppm)]_2$ was suspended in 10 mL of THF, to which was added 28.4 mg (0.20 mmol) of sodium-2-mercaptothiazolinate in 5 mL of THF, causing a colour change to red within several min. After stirring for 5 h, the solvent was removed under vacuum. The red solid was redissolved in 10 mL of CH_2Cl_2. The solution was then filtered and concentrated to ca. 3 mL. Microcrystals were obtained upon addition of hexane (90% yield).

(h) $[Ir_2(mtz)(CO)_2(\mu\text{-mtz})(dppm)_2]$ (8)

To a slurry of *trans*-$[IrCl(CO)(dppm)]_2$ (220.0 mg, 0.17 mmol) in 10 mL of THF was added 49.0 mg (0.34 mmol) of sodium-2-mercaptothiazolinate in 5 mL of THF. The mixture was stirred overnight, during which time a red-orange solution was formed. Filtration followed by reduction in the volume of the solution and addition of hexane gave an orange solid (85–90% yield). Anal. calcd. for $Ir_2S_4P_4O_2N_2C_{58}H_{52}$: C 48.18, H 3.63, N 1.94; found: C 47.83, H 3.70, N 2.03.

(i) $[Rh_2(CO)_2(\mu\text{-mtz})(dppm)_2][Cl]\cdot CH_2Cl_2$ (9b)

The procedure was the same as for **7** in method B, except that 1 equivalent of sodium-2-mercaptothiazolinate was used. Red crystals of **9*b*** were obtained from CH_2Cl_2-hexame (87% yield). Conductivity measurements: $\Lambda = 29.8\ \Omega^{-1}\ cm^2\ mol^{-1}$ in CH_2Cl_2; $\Lambda = 71.6\ \Omega^{-1}\ cm^2\ mol^{-1}$ in CH_3NO_2. Anal. calcd. for $Rh_2Cl_3S_2P_4O_2NC_{56}H_{50}$: C 52.99, H 3.99, N 1.10; found: C 52.97, H 3.95, N 1.01.

(j) $[Rh_2(CO)_2(\mu\text{-mtz})(dppm)_2][PF_6]$ (9c)

To a CH_2Cl_2 solution of **9*b*** (118.0 mg, 0.10 mmol, in 10 mL) was added 1 equivalent of $AgPF_6$ (25.0 mg, 0.10 mmol, in 5 mL of CH_2Cl_2). After stirring for 0.5 h, the solution was filtered and the volume was then reduced to ca. 3 mL. Microcrystals were obtained upon addition of hexane (90% yield). Anal. calcd. for

$Rh_2ClS_2P_5F_6O_2NC_{55}H_{48}$: C 49.69, H 3.65, N 1.05; found: C 49.56, H 3.64, N 1.14.

*(k) [$Ir_2Cl(CO)_2(\mu\text{-}mtz)(dppm)_2$] (**10**)*

The procedure was the same as for **8**, except that 1 equivalent of sodium-2-mercaptothiazolinate was used. Compound **10** was crystallized from THF–hexane. Anal. calcd. for $Ir_2ClS_2P_4O_2NC_{55}H_{48}$: C 48.47, H 3.56, N 1.03; found: C 48.63, H 3.90, N 0.91.

*(l) [$Rh_2(CO)_2(\mu\text{-}CO)(\mu\text{-}mtz)(dppm)_2$][Cl] (**11**a)*

A stream of CO was passed through a CH_2Cl_2 solution of **9**, causing an immediate colour change to orange accompanied by formation of an orange precipitate. Carbonyl loss from **11***a* occurred very rapidly under dinitrogen. Compound **11***a* was determined to be a 1:1 electrolyte in CH_3NO_2 (Λ = 74.0 Ω^{-1} cm^2 mol^{-1}).

*(m) [$Rh_2(CO)_2(\mu\text{-}CO)(\mu\text{-}mtz)(dppm)_2$][$PF_6$] (**11**b)*

The procedure was the same as for **11***a*, except that **9***c* was used. Carbonyl loss from **11***b* also occurred very readily.

X-ray data collection

*(a) [$Rh_2I_2(CO)_2(\mu\text{-}mtz)_2(dppe)$]·0.5 THF (**6**)*

Dark red crystals of **6** were grown by diffusion of hexane into a THF solution of the complex. Suitable crystals were mounted on glass fibres with use of epoxy cement. Data were collected on an Enraf–Nonius CAD4 diffractometer using MoKα radiation. Unit-cell parameters were obtained from a least-squares refinement of the setting angles of 25 reflections in the range $12.6 \leq 2\theta \leq 33.6°$. The automatic peak search and reflection indexing programs[3] generated a triclinic cell with the possible space groups of $P1$ or $P\bar{1}$. The space group $P\bar{1}$ was chosen, and later verified by the successful refinement of the structure.

Intensity data were collected at 22°C by using the $\theta/2\theta$ scan technique to a maximum $2\theta = 50°$. Backgrounds were scanned for 25% of the peak width on either side of the peak scan. Three reflections were chosen as intensity standards, being remeasured after every 120 min of X-ray exposure; no unusual variation in their intensities was evident. The data were processed in the usual manner with a value of 0.04 for p to downweigh intense reflections (9). Corrections for Lorenz and polarization effects and for absorption by using the method of Walker and Stuart were applied (10).

*(b) [$Rh_2(CO)_2(\mu\text{-}mtz)(dppm)_2$][Cl]·$CH_2Cl_2$ (**9**b)*

Red crystals of **9***b* were obtained by diffusion of hexane into a CH_2Cl_2 solution of the complex. Crystals were mounted and flame-sealed in glass capillaries under solvent vapour to minimize solvent loss. Data collection and derivation of unit-cell parameters proceeded in a manner similar to that above (the setting angles of 25 reflections were in the range $22.0° \leq 2\theta \leq 25.7°$). The monoclinic diffraction symmetry and systematic absences ($h0l$, $h + l$ = odd; $0k0$, k = odd) were consistent with the space group $P2_1/n$.

Intensity data were collected at 22°C with use of the $\theta/2\theta$ scan technique to a maximum $2\theta = 50.0°$. No unusual variation was found for the intensity standards. See Table 2 for pertinent crystal data and details of intensity collection for both **6** and **9***b*.

Structure solution and refinement

Both structures were solved in the respective space groups ($P\bar{1}$ for **6** and $P2_1/n$ for **9***b*) with use of standard Patterson and Fourier techniques. Full-matrix least-squares refinements proceeded so as to minimize the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2/\sigma^2(F_o^2)$. Atomic scattering factors and anomalous dispersion terms were taken from the usual tabulations, refs. 11–13. The positions of all hydrogen atoms in the complex were generated on the basis of the geometry of their attached carbon atom with C—H distances of 0.95 Å. Thermal parameters for the hydrogens were fixed at 1.2 times that of their attached carbon atom. The hydrogen atoms were included as fixed contributions in the least-squares calculations. The solvent atoms of complex **6** were input as a rigid half-occupancy five-carbon ring that most appropriately described the ring of poorly resolved, smeared-out electron density that appeared on Fourier maps. The occupancy of $\frac{1}{2}$ was established by ^1H NMR of the crystals and the thermal parameters of 12 $Å^2$ were arbitrarily selected since these atoms were not well behaved in refinement attempts; they were not refined in subsequent least-squares cycles, and their hydrogen atoms were not included. Due to the bad disorder of the THF molecule the carbon and oxygen atoms could not be distinguished so were all input as carbon atoms.

The final model for complex **6**, with 433 parameters varied, refined to $R = 0.045$ and $R_w = 0.057$. In the final difference Fourier map the 10 highest residuals had intensities of 0.8–1.1 e $Å^{-3}$ and were primarily located near the disordered solvent molecule. For compound **9***b* the final model, with 613 parameters varied, converged to $R = 0.062$ and $R_w = 0.082$. The 10 highest peaks (0.6–2.5 e $Å^{-3}$) were again located near the solvent molecule. There is apparently some slight disorder of the mtz^- ligand as seen by the larger thermal parameters of S(2) and C(7); however, this was not resolvable. The positional and thermal parameters for the non-hydrogen atoms, excluding the phenyl groups, of **6** are given in Table 3, and selected bond lengths and angles are given in Tables 5 and 6, respectively. For complex **9***b* the pertinent data are found in Tables 4, 7, and 8. Anisotropic thermal parameters, idealized hydrogen parameters, and bond lengths and angles within the phenyl

[3]Programs used were those of the Enraf–Nonius Structure Determination Package, in addition to local programs by R. G. Ball.

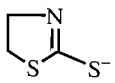
rings and solvent molecules for **6** and **9***b* are available as supplementary data.[4]

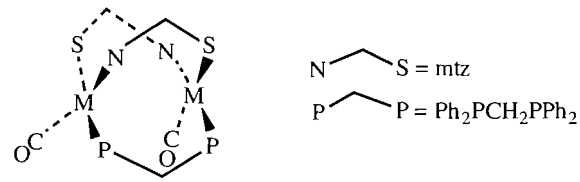
Discussion

Previous studies (3*m*,*n*) have shown that the 2-mercaptothiazolinate ion (mtz$^-$), diagrammed below, coordinates to two metal centres through the mercapto sulfur and the nitrogen atom. The complexes of Rh and Ir so-formed have



typical open-book structures. Although the tetracarbonyl species $[Rh(CO)_2(\mu\text{-mtz})]_2$ has been described (3*m*), the diiridium analogue $[Ir(CO)_2(\mu\text{-mtz})]_2$ was not previously reported. Both are prepared by the reaction of their cyclooctadiene precursors, $[M(COD)(\mu\text{-mtz})]_2$ (3*n*) with CO in THF. Neither species was isolated but each was reacted *in situ* with the appropriate phosphine to obtain the desired product. The IR spectrum of the diiridium tetracarbonyl precursor displays the expected carbonyl bands (2075, 2040, 2005, and 1990 cm^{-1}) typical of these open-book complexes (3*j*,*l*,*m*).

A series of mtz-bridged complexes of rhodium, containing monodentate tertiary phosphines such as PPh_3, has been described (3*m*); however, no complex involving this anionic bridging group and diphosphine ligands such as $Ph_2PCH_2PPh_2$ (dppm) has been reported. As was the case for monodentate phosphines, these tetracarbonyl species react readily with the diphosphine, dppm, yielding the dppm-bridged products, $[M_2(CO)_2(dppm)(\mu\text{-mtz})_2]$ (M = Rh(**1**), Ir(**2**)), as shown below. For the rhodium species **1** the two carbonyl stretches in the IR spectrum (1995, 1948 cm^{-1}) display a significantly larger separation than those of the PPh_3 analogue (1974, 1966 cm^{-1}). This is probably a consequence of the geometrical difference in these two species. In the PPh_3 adduct the phosphines have a *trans* disposition at the two metals and both carbonyl groups are opposite the nitrogen ends of the bridging mtz ligands (3*m*). In **1**



M = Rh (**1**); Ir (**2**)

and **2**, however, the bridging dppm group demands that the ends of the diphosphine group be mutually *cis*, so assuming a head-to-tail arrangement of mtz ligands, one carbonyl will be *trans* to nitrogen while the other is opposite sulfur. A head-to-tail arrangement, in which different ends of the two ligands are bound to each metal, is most often seen in binuclear complexes containing these anionic three-atom bridges (3*b*,*g*,*h*,*k*,*l*), although the head-to-head arrangement has also been reported (3*j*). The bifunctional nature of the mtz ligands in **1** gives rise to two chemically inequivalent phosphorus nuclei (also opposite either N or S) as shown in the $^{31}P\{^1H\}$ NMR spectrum, which displays two doublets of doublets at δ 30.8 ($^1J_{RhP}$ = 153.4 Hz, $^2J_{PP}$ = 58.2 Hz) and δ 45.9 ($^1J_{RhP}$ = 142.8 Hz). The geometry observed leads to the inequivalence of all 10 methylene protons associated with the dppm and mtz groups, although owing to overlap of two of these resonances in the ^1H NMR spectrum only nine are

[4]A complete set of data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen atom parameters and bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University of Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

resolved (Table 1). The methylene resonances for the dppm group (δ 4.20, 3.70) were identified by the appropriate ^{31}P-decoupling experiments. The spectroscopic parameters for **2** are comparable to those of **1**, suggesting similar structures.

Although these species have been identified as open-book species having a bridging dppm group, they can also be viewed as A-frame complexes having the dppm and one of the mtz groups in mutually *trans* bridging positions and the other mtz group in the apical position opposite the carbon-

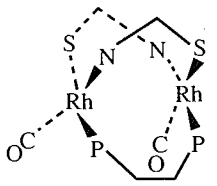
yls. In these compounds, with three similar bridging groups, the A-frame and open-book formulations are clearly two equivalent ways of categorizing the same structure.

Reaction of $[Rh(CO)_2(\mu\text{-mtz})]_2$ with 1 equivalent of dppe ($Ph_2PCH_2CH_2PPh_2$) yields $[Rh_2(CO)_2(\mu\text{-dppe})(\mu\text{-mtz})_2]$ (**3**), an unusual example of a dppe-bridged species, analogous to compounds **1** and **2**. This species is extremely air sensitive and was only characterized spectroscopically. Its IR spectrum shows two carbonyl stretches like those of the dppm analogue **1**, and its $^{31}P\{^1H\}$ NMR spectrum shows two resonances, at δ 39.1 ($^1J_{RhP}$ = 157.8 Hz, $^3J_{PP}$ = 2.6 Hz) and δ 40.2 ($^1J_{RhP}$ = 147.6 Hz). Although the 3-bond P–P coupling is much smaller than that observed in other dppe-bridged complexes such as $[WM(CO)_{10}(dppe)]$ (M = Cr, Mo, W), for which values of ca. 35 Hz are observed (14), it is comparable to the results obtained for $[Ru_4H_4(CO)_{10}(\mu\text{-dppe})]$, for which no P–P coupling was observed (15).

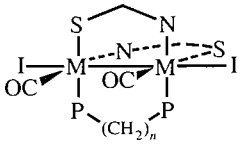
The ^1H NMR spectrum of **3** resembles those of **1** and **2**, suggesting a structure similar to the dppm analogues, as shown. The four resonances (δ 4.20, 3.73, 2.37, 1.80) assigned to the dppe methylene groups were identified by



3

broad-band ^{31}P decoupling.

One of the unique reactivity patterns of binuclear compounds is the transannular oxidative-addition reaction, which results in a formal one-electron oxidation of each metal, often accompanied by metal–metal bond forming or breaking (*3a,e,i,l*). Although each of the monophosphine complexes $[M(CO)(PR_3)(\mu\text{-mtz})]_2$ (M = Rh; Ir; R = Ph, Me) gives mixtures of several species in the reactions with halogens (footnote 2), all three diphosphine-bridged species **1–3** readily undergo transannular oxidative addition of I_2 to cleanly yield the respective products **4–6**, diagrammed below. These three oxidized products are more stable than their M(+1) precursors, permitting the isolation of the dppe-bridged **6**, and allowing unambiguous confirmation of the bridging dppe group. In these three products the IR spectra show two carbonyl stretches, the frequencies of which have increased by ca. 70 cm^{-1} from those of the precursors, as expected for the oxidation of the metals from the +1 to the +2 oxidation state. The $^{31}P\{^1H\}$ NMR spectra for all three compounds are consis-



M = Rh, *n* = 1 (**4**); *n* = 2 (**6**)
= Ir, *n* = 1 (**5**)

tent with two chemically different phosphorous environments, one opposite sulfur and the other opposite nitrogen. For **4** the Rh–P and P–P couplings are not immediately obvious owing to the complexity of the spectrum; however, for **5** and **6** the $^{31}P\{^1H\}$ spectra are simple, both appearing as two sets of doublets, resulting from two-bond phosphorus–phosphorus coupling in **5** and one-bond rhodium–phosphorus coupling in **6**. No P–P coupling is resolved in the spectrum of **6**. Other spectral parameters, shown in Table 1, are in agreement with these structural formulations, which have been verified by the X-ray structure determination of **6**.

The structure of $[Rh_2I_2(CO)_2(\mu\text{-mtz})_2(\mu\text{-dppe})]$ (**6**) is shown in Fig. 1, and the associated structural parameters are summarized in Tables 5 and 6. This determination clearly confirms the binuclear, dppe-bridged structure, in which the two mtz ligands bridge in a head-to-tail arrangement. In this geometry the complex can again be viewed as an open-book complex bridged by dppe or it can be thought of as resembling an A-frame complex, except with rather substantial distortions resulting from the small bite of the mtz ligands combined with the wide bite of the dppe group. In this latter

formulation the dppe and mtz groups, which are mutually *trans*, take the positions occupied by dppm groups in the majority of A-frames, while the other mtz ligand occupies the apical site opposite the carbonyls. Both iodo ligands occupy the positions on each metal opposite the Rh—Rh bond, giving the metals octahedral geometries. The Rh—Rh separation of 2.748(1) Å is consistent with a single bond, as expected between the two Rh(II) centres. The octahedra are offset from each other in two ways. First they are inclined about the axial directions (parallel to the Rh–P vectors) by a dihedral angle of 16.4° owing to the differing bites of the mtz and dppe groups, as noted. These different bites are clearly seen in the N(2)–S(3) and P(1)–P(2) non-bonded separations of 2.685(6) and 3.841(3) Å, respectively. Second, the octahedra are staggered about the Rh—Rh bond by an average torsion angle of ca. 33°. Although this skewing may be required to minimize nonbonded contacts between the carbonyl groups, it is more likely necessary in order to accommodate the bridging dppe ligand. A similar twisting of the metal framework has been observed in dppe-bridged complexes of rhenium in which torsion angles up to 50° have been noted (16).

Most parameters within the complex are normal, therefore the Rh—P distances (2.317(2), 2.333(2) Å) are in good agreement, and resemble the analogous distances in dppm-bridged complexes. The Rh—S and Rh—N distances are also normal, except that the distances for atoms opposite dppe are longer than those opposite the carbonyls (Rh—S = 2.418(2), 2.382(2) Å; Rh—N = 2.132(5), 2.099(5) Å). This is the opposite of that observed in the related species $[Rh(CO)(PPh_3)(\mu\text{-SPh})]_2$, in which the Rh—S bonds opposite phosphorus were found to be shorter than those opposite CO (17).

Unlike diphosphine bridges, which are generally rather inert, the mercaptothiazolinate bridges are quite labile and are readily broken (footnote 2). It was therefore of interest to determine whether both mtz bridges would remain intact upon reaction with two equivalents of dppm. Given the overwhelming preference of dppm to bridge metals, and the unlikelihood that both dppm *and* both mtz ligands would simultaneously bridge, it was anticipated that one or both mtz ligands might move from their bridging sites. Treatment of $[M(CO)_2(\mu\text{-mtz})]_2$ (M = Rh, Ir) with two equivalents of dppm yields $[M_2(CO)_2(\eta^1\text{-mtz})(\mu\text{-mtz})(dppm)_2]$ (M = Rh(**7**), Ir(**8**)) as diagrammed below. The diiridium species **8** displays two signals in the $^{31}P\{^1H\}$ NMR spectrum, characteristic of an AA′BB′ spin system, and shows four resonances in the ^1H NMR spectrum for the mtz methylene hydrogens at δ 4.41, 3.30, 2.68, and 1.67, in addition to the dppm resonances. Based on a comparison with the resonances for the free mtz anion, at δ 4.0 and 3.6, the low-field resonances above are attributed to the dangling group, while the high-field pair are identified as those of the bridging group. The dangling mtz ligand, as shown, is proposed to coordinate through sulfur as has been suggested for closely related ligands in other complexes (*3h*, 18). In the IR spectrum of **8** the two carbonyl bands (1946, 1896 cm^{-1}) are consistent with terminally bound carbonyls, although the lower frequency stretch suggests that this may result from a weak semi-bridging interaction with the second metal, as is demonstrated for **7** (*vide infra*). The $^{13}C\{^1H\}$ NMR spectrum

M = Rh(7)
= Ir(**8**)

displays two sharp triplets for the carbonyls at −70°C, the high-field one of which becomes broad and featureless at room temperature, without changing significantly in position. The reason for the broadening is not obvious.

In contrast to **8**, the NMR spectra of **7** show strong temperature dependence, and its solution IR spectrum is more complicated than expected for a dicarbonyl. In the solid the IR spectrum of **7** displays the two carbonyl bands expected at 1926 and 1825 cm^{-1}; again the low-frequency band is suggestive of a semibridging mode as shown for structure **7***a* in Scheme 1. However, in solution, four carbonyl stretches are observed. The lower frequency pair (1936, 1820 cm^{-1}), which are close to those of the solid, appear to correspond to **7***a* while those at 2000 and 1973 cm^{-1} appear to arise from the cationic species **7***b*, which results from mercaptothiazolinate ion dissociation. Addition of excess mtz^- (as the sodium salt) supports this proposed equilibrium, causing a decrease in the intensity of the two high-frequency bands and an increase in those ascribed to **7***a*. This equilibrium is also apparent in the NMR spectra. At ambient temperature the mtz protons appear in the ^1H NMR spectrum at δ 4.32, 3.15, 2.70, and 1.83. As excess mtz^- is added to a solution of **7**, the two low-field resonances increase in intensity and shift towards the resonances for free mtz^- (δ 4.0, 3.6). Not only does this behaviour support the previous assignment for the mtz proton resonances in **8**, it also supports the equilibrium between **7***a* and **7***b*. At −80°C resonances due to both **7***a* (δ 32.5, 26.5) and **7***b* (δ 29.5, 20.8) are observed in the $^{31}P\{^1H\}$ NMR spectrum, in an approximate 4:1 intensity ratio, respectively. This assignment is based on the close resemblance of the spectral parameters of the minor species (**7***b*) with those of the cationic species, $[Rh_2(CO)_2(\mu\text{-mtz})(dppm)_2][X]$ (X = Cl(**9***b*), PF_6(**9***c*)) (*vide infra*). In the $^{13}C\{^1H\}$ NMR spectrum of **7** at −80°C the resonance at δ 193.3 ($^1J_{RhC}$ = 74.6 Hz, $^2J_{PC}$ = 16 Hz) is assigned to the terminal carbonyl of **7***a* and the broad doublet at δ 211.8 is ascribed to the semibridging carbonyl of this species. Broadband ^{31}P decoupling experiments clearly show this semibridging interaction, as the ^{13}C resonance transforms from a broad doublet to a doublet of doublets with 67 Hz coupling to one rhodium and 13 Hz coupling to the other. The signals arising from the carbonyls of the minor species (**7***b*) are apparently obscured by the high-field ^{13}C resonance of **7***a*, as indicated by the broadness of the bottom part of the latter as well as by its integration. In the ^1H NMR spectrum at −80°C the appearance of a major and minor species in the appropriate ratio is also apparent, although a couple of the resonances for the major species shift substantially, and some of those for the minor species are obscured by other resonances. Selective homonuclear decoupling experiments at ambient temperature point to an additional fluxionality that occurs slowly on the NMR time scale. Irradiation of one of the methylene proton resonances of the bridging mtz group causes the other methylene resonance of this group to collapse to a singlet, as expected. However, unexpectedly this results in a significant decrease in the intensity of the corresponding methylene resonance of the dangling group. This observation of spin saturation transfer indicates a slow exchange of terminal and bridging mtz groups as diagrammed vertically in Scheme I. Attempts to increase the rate of terminal-bridging mtz exchange to achieve rapid interconversion, by raising the temperature, were unsuccessful since the compound decomposed at temperatures above ca. 45°C.

Complexes containing two bridging dppm groups and a bridging mtz ligand can also be obtained by the reactions of *trans*-$[MCl(CO)(dppm)]_2$ (M = Rh, Ir) with sodium mercaptothiazolinate. When two equivalents of mtz^- are used, compounds **7** and **8** are obtained, as seen in the reactions of $[M(CO)_2(\mu\text{-mtz})]_2$ with two equivalents of dppm. When the above dppm-bridged dichloro complexes are reacted with only one equivalent of mtz^-, replacement of only one chloride ligand occurs, yielding $[M_2Cl(CO)_2(\mu\text{-mtz})(dppm)_2]$ (M = Rh(**9**), Ir(**10**)). The spectral parameters for **10** are closely comparable to those of **8**, apart from the absence of resonances for the dangling mtz group in the ^1H NMR spectrum, so this compound is assigned an analogous structure in which the dangling mtz group in **8** is replaced by a terminal chloro ligand in **10**.

Although **9** is shown above as having a coordinated chloro ligand, in solution it, like compound **7**, is better represented as an equilibrium mix of the neutral species **9***a* together with the cationic species **9***b*, resulting from chloride dissociation as shown in eq. [1]. This is clearly seen in the IR spectrum

[1] $[Rh_2Cl(CO)_2(\mu\text{-mtz})(dppm)_2]$ (**9***a*)

$$\rightleftharpoons [Rh_2(CO)_2(\mu\text{-mtz})(dppm)_2][Cl] \text{ (9}b\text{)}$$

in solution, which displays three carbonyl stretches at 2001, 1970, and 1933 cm^{-1}. The middle band is broad and apparently results from two overlapping bands, so the stretches due to **9***a* appear at 1970 and 1933 cm^{-1} whereas those of **9***b* appear at 2001 and 1970 cm^{-1}. Addition of $AgBF_4$ to solutions of **9** results in the disappearance of the 1933 cm^{-1} band and sharpening of the central band, and addition of sodium chloride causes these bands to reappear. In the solid state the two carbonyl bands observed (1988, 1953 cm^{-1}) are consistent with the ionic structure **9***b*, and this is confirmed by an X-ray structure determination of this species (*vide infra*).

As was noted for **7***a* and **7***b*, the exchange between **9***a* and **9***b* is fast on the NMR time scale. Thus at ambient temperature both the $^{31}P\{^1H\}$ and the $^{13}C\{^1H\}$ NMR spectra of the equilibrium mixture display two broad resonances, while the ^1H NMR spectrum shows only two triplets (δ 2.43, 1.85) for the mtz methylene protons. Lowering the temperature sharpens the signals in the $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR spectra. However, in contrast to the equilibrium involving **7***a* and **7***b*, only one species is revealed at −80°C, the spectroscopic parameters of which closely resemble those of $[Rh_2(CO)_2(\mu\text{-mtz})(dppm)_2][PF_6]$ (**9***c*) obtained by reaction of **9** with $AgPF_6$. Therefore it is clear that lowering the temperature shifts the equilibrium in favor of **9***b*. At −80°C, the $^{31}P\{^1H\}$ NMR spectrum of **9***b* is as expected for an unsymmetric structure, and the $^{13}C\{^1H\}$ NMR spectrum reveals two doublets of triplets at δ 194.4 and 193.4, reminiscent of those of **7***b*. The mtz methylene hydrogens appear as triplets at δ 2.39 and 1.46.

Among the dppm-bridged binuclear compounds of group VIII metals, complexes **7–10** represent a new type of A-frames, in which the anionic capping ligand is bifunctional, binding to the two metals by different atom types, and because of this the two metal centres in these A-frames are electronically different, which could give rise to interesting reactivity patterns. The bifunctional feature of the apical mtz ligand also provides an easy access to coordinative unsaturation through cleavage from a metal of one of its ends, which is shown to be feasible by the dynamic behavior of **7**. Coordinative unsaturation induced by bridge opening has been proposed to be crucial in substrate activation by open-book compounds (4), as noted earlier. Related A-frame complexes of group VIII metals, in which the anionic apical ligands are those typically used as bridges in open-book compounds, have been reported recently (2*e*,*f*,*i*,*j*). However, these ligands, such as pyrazolyl groups, have the same atom type binding to each metal.

The structure of **9***b*, as the methylene chloride solvate, has been determined and a representation of the cation is shown in Fig. 2. This compound much more resembles conventional "A-frames" than does **6**, in that the *trans*-bridging groups are dppm with the anionic group (mtz^-) at the apex opposite the carbonyls. In fact the structure quite closely resembles that of $[Rh_2(CO)_2(\mu\text{-dmpz})(dppm)_2]^+$ (2*j*), (dmpz = 3,5-dimethylpyrazolate). The structure determination clearly shows that the chloride ion is not associated with the complex, and the closest contact between rhodium and this anion is 6.842(2) Å. Similarly the CH_2Cl_2 molecule is isolated from both the anion and the cation. Although the geometries about the Rh centres are essentially square planar, there are significant distortions from the idealized geometry. Therefore the N(1)—Rh(1)—C(1) angle is 172.9(2)° and the S(1)—Rh(2)—C(2) angle is 151.9(2)°, resulting from an apparent movement of C(1)O(1) towards Rh(2) and C(2)O(2) away from Rh(1). This distortion is accompanied by a Rh(1)—Rh(2) separation of 2.9957(7) Å, which is compressed slightly compared with the intraligand P–P nonbonded contacts of 3.056(2) and

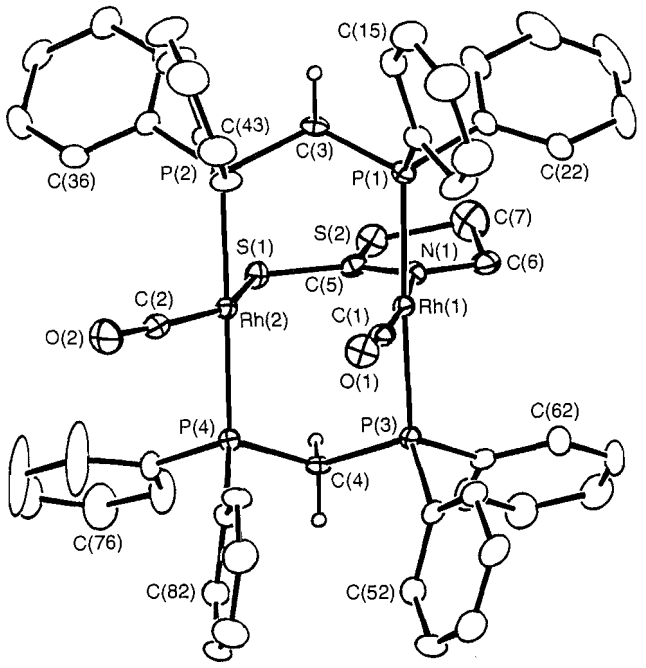

FIG. 2. A representation of the $[Rh_2(CO)_2(\mu\text{-mtz})(dppm)_2]^+$ cation of **9***a*. Thermal ellipsoids are as in Fig. 1.

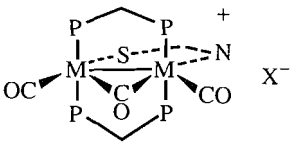
3.068(2) Å, suggesting a possible weak interaction between the metals. We believe, however, that these distortions result from the packing. As can be seen in Fig. 2, phenyl rings 4 and 8 are aimed between the carbonyls and the short C(2)—H(42) and C(2)—H(86) contacts of 2.72 and 2.62 Å appear to distort this carbonyl from its idealized position. Similarly rings 1 and 5 appear to force C(1)O(1) towards Rh(2), giving a C(1)—H(12) contact of 2.56 Å. The contact between Rh(2) and C(1) (3.158(6) Å) appears to be too long to suggest even a weak semi-bridging interaction, and the IR spectra also do not argue in favor of such an interaction.

In conventional A-frames (2*a*–*c*) the capping ligand binds to both metals through a common atom, resulting in a substantial tilt of the two metal square planes by about 83°. In **9***b* (and in **6**) the capping mtz ligand binds through two well-separated donor atoms, opening up the A-frame and resulting in more closely parallel coordination planes at the metals (the dihedral angle is only 16(2)°). As such, the structure of **9***b* takes on a geometry similar to the face-to-face dimers such as *trans*-$[Rh_2Cl_2(CO)_2(dppm)_2]$ (19) and $[Rh_2(CNR)_4(dppm)_2]^{2+}$ (20, 21).

All other parameters within the complex are essentially as expected, comparing well with the appropriate parameters in **6**, so deserve no further comment.

The equilibrium mix of **9***a* and **9***b* reacts with CO to give $[Rh_2(CO)_2(\mu\text{-mtz})(\mu\text{-CO})(dppm)_2][Cl]$ (**11***a*), whereas **11***b*, having PF_6^- as the counterion, is obtained by the analogous reaction of **9***c*. Carbonyl loss from both species to give the starting complexes is very facile, occurring simply under an N_2 purge. The $^{31}P\{^1H\}$ NMR spectra of the two compounds are similar and appear as sharp AA'BB'XY spin patterns, consistent with the structure as shown. The infrared spectrum of **11***a* displays two terminal carbonyl stretches (1981, 1958 cm^{-1}), whereas for **11***b* only one stretch (1976 cm^{-1}) is revealed for the terminal carbonyls. However, the broadness of this stretch suggests that another band is beneath it. Both compounds display bridging carbonyl stretches at ca. 1797 cm^{-1} in the IR spectra. The CO stretches of **11***a*, *b* appear at significantly lower frequencies than those (2005–1860 cm^{-1}) observed for the closely related compounds, $[Rh_2(CO)_2(\mu\text{-X})(\mu\text{-CO})(dppm)_2][X]$ (X = Cl, Br, I) (19), suggesting that the mtz ligand is more electron releasing than the halides.



X = Cl(**11***a*); PF_6(**11***b*)

Summary

A series of binuclear complexes of Rh and Ir has been synthesized, in which the metals are bridged by both neutral diphosphine ligands (dppm and dppe) and anionic mercaptothiazolinate (mtz) groups. In the first class, $[M_2(CO)_2(\mu\text{-mtz})_2(\mu\text{-L})]$ (L = diphosphine), containing two anionic bridging groups, the complexes can be classified as having either "open-book" or "A-frame" geometries, and both descriptions appear to be equally valid. Two of these species, $[Rh_2(CO)_2(\mu\text{-mtz})_2(\mu\text{-dppe})]$ and $[Rh_2I_2(CO)_2(\mu\text{-mtz})_2(\mu\text{-dppe})]$, are unusual examples in which dppe functions as a *bridging* group. In the second class of compounds, $[M_2X(CO)_2(\mu\text{-mtz})(dppm)_2]$ (M = Rh, Ir; X = Cl, mtz), containing two bridging dppm groups, the ease of displacement of the anionic groups from a bridging site has been demonstrated. These species have only one mtz group bridging the metals and are best viewed as classical A-frame complexes. The additional anionic ligand (Cl^- or mtz^-) is terminally bound to one metal, and for M = Rh these terminal groups readily dissociate, yielding cationic complexes.

Although numerous open-book complexes containing phosphine ligands are known, the complexes $[M_2(CO)_2(\mu\text{-mtz})_2(\mu\text{-L})]$ are the first examples in which diphosphines have been incorporated as ligands together with a bifunctional ligand, binding through different atom types (S,N). It will be of interest to further explore the chemistry of these species. The complexes of the second class are interesting in that they contain a bifunctional apical ligand, the possible effects of which have been noted. It may be the bifunctionality of the mtz ligand that gives rise to the unusual dynamic behavior for the complex $[Rh_2(\eta^1\text{-mtz})(CO)_2(\mu\text{-mtz})(dppm)_2]$, as shown in Scheme 1.

^{13}C and ^{1}H NMR investigation of pilocarpine hydrochloride in water solution

ELENA GAGGELLI, NICOLA GAGGELLI, GIANNI VALENSIN,[1] AND ANTONIO VIVI
Department of Chemistry, University of Siena, Pian dei Mantellini 44, Sienna 53100, Italy

Received April 27, 1992[2]

ELENA GAGGELLI, NICOLA GAGGELLI, GIANNI VALENSIN, and ANTONIO VIVI. Can. J. Chem. **71**, 738 (1993).

Dynamic and geometric features of pilocarpine in water solution were delineated by interpreting ^{13}C and ^{1}H NMR spin-lattice relaxation rates and nuclear Overhauser effects. The motional correlation time was evaluated at 53 ± 5 ps at 298 K. $^{1}H—^{1}H$ distances, as calculated from double-selective ^{1}H spin-lattice relaxation rates, and $^{13}C—^{1}H$ distances, as calculated from selective $^{13}C–\{^{1}H\}$ Overhauser effects, gave evidence of a *C*7 puckered conformation of the furanone ring and of an angle of ca. 50° between the two rings.

ELENA GAGGELLI, NICOLA GAGGELLI, GIANNI VALENSIN et ANTONIO VIVI. Can. J. Chem. **71**, 738 (1993).

En se basant sur les vitesses de relaxation spin-réseau et sur les effets nucléaires Overhauser des spectres RMN du ^{1}H et du ^{13}C de ses solutions aqueuses, on a pu déterminer les caractéristiques dynamiques et géométriques de la pilocarpine. On a évalué que, à 298 K, le temps de corrélation des mouvements est égal à 53 ± 3 ps. On a calculé les distances $^{1}H—^{1}H$ à partir des temps de relaxation spin-réseau du ^{1}H doublement sélectifs et les distances $^{13}C—^{1}H$ à partir d'effets Overhauser $^{13}C–\{^{1}H\}$ sélectifs; ces données suggèrent que le cycle furanone existe dans une conformation plissée et que l'angle entre les deux cycles est d'environ 50°.

[Traduit par la rédaction]

Introduction

Pilocarpine ((3*S*-*cis*)-3-ethyldihydro-4-[(1-methyl-1*H*-imidazol-5-yl)methyl]-2(3*H*)-furanone) (PLC) (Fig. 1) is the chief alkaloid obtained from the leaves of South American shrubs of the genus *Pilocarpus* (1). It is a cholinomimetic agent that acts mainly at muscarinic acetyl-choline receptors (mAChR) of autonomic effector cells, mediating a large diversity of neurophysiological actions in the central and peripheral nervous systems (2).

As a drug, PLC is valued as a topical miotic, in ophthalmic solution, in the treatment of glaucoma (3), although it has been shown that aqueous solutions are poorly stable at pH > 7, at elevated temperature (4), and in the presence of phosphate and carbonate buffers (5). Chemical, pharmaceutical, and spectroscopic properties of PLC have been summarized elsewhere (6).

An understanding of mechanisms responsible for binding of agonists and antagonists to mAChR is quite important for rational drug design. Since effector molecules are usually highly flexible, the basis for such drug design has to be sought in determining the conformation in the bound rather than in the free state. From this point of view NMR is the technique of choice as it has the potential of determining dynamic and geometric features in both states, provided the ligand exchanges between the two at a relatively fast rate. Another aspect is, moreover, relevant. In the free state flexible molecules are characterized by several conformations separated by relatively low energy barriers, whereas in the bound state it is commonly accepted that the same molecules exist in unique conformations. Consequently, binding interactions imply a process of conformational selection, the role of which has been neglected so far.

As a first step, NMR data are herein presented for pilocarpine in water solution at pH 5–6; conformational features are discussed in the light of reorientational dynamics, and the "preferred" structure in solution is determined. The structure detected by NMR is not, of course, a minimum energy conformation but, rather, a geometric arrangement arising by motional averaging of many low-energy conformations. The ^{1}H NMR data for PLC in water solution have been previously published (7).

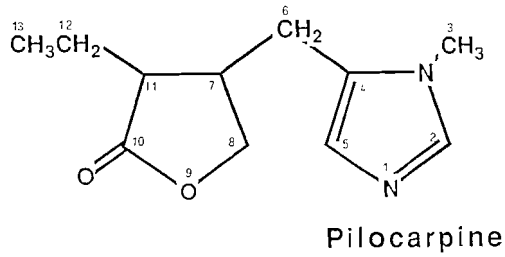

FIG. 1. Molecular formula of pilocarpine.

Experimental

Pilocarpine hydrochloride was purchased from Sigma Chemical Co. and used without further purification. Solutions were made in deuterium oxide 99.95% (Merck), adjusted in pH with either DCl or NaOD, and carefully deoxygenated by bubbling nitrogen gas.

NMR spectra were obtained on a Varian VXR 200 spectrometer operating at the controlled temperature of 300 ± 1 K. Spin-lattice relaxation rates were measured with inversion–recovery pulse sequences and calculated in the initial rate approximation. Selective and double-selective ^{1}H NMR spin-lattice relaxation rates were measured with inversion–recovery pulse sequences where the 180° inverting pulse was provided by a DANTE (8) or a double-DANTE pulse train (9). In either case the relaxation rate values were calculated from the initial slope of longitudinal magnetization recovery (10).

$^{13}C–\{^{1}H\}$ nuclear Overhauser effects (nOe) were measured with gated decoupling methods either in the noise-modulated or in the long-pulse mode to provide nonselective or selective presaturation, respectively (11).

Molecular modelling was achieved by using the molecular graphics package ChemX implemented on a Vax 750 computer connected to a digital VT 240 terminal (19).

Results and discussion

Geometric features can be obtained by relaxation rates or nuclear Overhauser effects. In both cases the relevant pa-

rameter is the dipolar interaction energy between spin pairs, which depends upon the inverse of the sixth power of the internuclear distance and the correlation time of the reorientational motion undergone by the internuclear vector. Since the ^{13}C NMR spin-lattice relaxation rate or protonated carbons is mainly determined by the one-bond $^{13}C-^1H$ dipolar interaction, the usual approach consists of interpreting ^{13}C NMR rates in terms of reorientational dynamics and, thereafter, in interpreting single $^1H-^1H$ or $^{13}C-^1H$ dipolar interaction energies in terms of geometric parameters.

^{13}C NMR data are summarized in Table 1. The $^{13}C-\{^1H\}$ nuclear Overhauser effects (nOe) measured upon noise-modulated gated decoupling of all ^1H resonances were found, within the limits of experimental error, at the maximum value (η_{max} = 1.98) for all protonated carbons. The $^{13}C-^1H$ dipolar interaction was therefore considered as the dominant relaxation mechanism and spin-lattice relaxation rates (R_1) were interpreted by the dipolar interaction with the n_H protons attached at the distance r = 1.09 Å (12). The reorientational motional correlation times could consequently be evaluated by using the usual approach from the literature (13). It may be noticed that all protonated carbons, except the *N*-methyl and the ethyl, experience nearly the same dipolar relaxation energies, yielding a mean value of 53 ± 5 ps at 298 K for the correlation time. The ethyl chain carbons relax with features typical of segmental motion with shorter effective correlation times. As for the *N*-methyl, the fact that its normalized relaxation rate (R_1/n_H) is much slower than that

[a]Calculated from eq. [3] by taking r_{C7H6} = 2.17 Å as the reference distance.

of the ring carbons suggests that it is likely to behave as a free rotor.

An independent check of the value of the correlation time was obtained by measuring dipolar interaction energies between protons at fixed distance. This can be achieved either by detecting $^1H-\{^1H\}$ nuclear Overhauser effects (14) (which measure, for a proton pair, the ratio, σ/ρ, between the cross-dipolar and the direct dipolar spin-lattice relaxation rates) or, better, by measuring absolute values of σ from double-selective and single-selective proton spin-lattice relaxation rates ($\sigma_{ik} = R_i^{i,k} - R_i^{sel}$, where $R_i^{i,k}$ is the rate obtained upon double-selective excitation of Hi and Hk and R_i^{sel} is that obtained upon single-selective excitation of Hi) (15–18). In this last case problems arising from cross-saturation effects are avoided. When this method is applied to the two geminal H8 protons (Table 2) a mean value of 0.46 s^{-1} is obtained for the cross-relaxation rate, which is consistent with a motional correlation time of 50 ± 10 ps at 298 K.

As for the total ^1H NMR data, reported in Table 2, it is apparent that the relaxation mechanism is dominated by the $^1H-^1H$ dipole–dipole interactions, as verified by the fact that the ratio, F, between nonselective and single-selective spin-lattice relaxation rates ($F = R_i^{nsel}/R_i^{sel}$) is found at $F \sim 1.5$ for most protons (10). Lower F values for H2 and H5 are accounted for by dipolar interactions with nitrogens and those for H12a and H12b by imperfect selectivity of the excitation pulse. The cross-relaxation rate is the structure-sensitive parameter (15):

$$[1] \quad \sigma_{ik} = \frac{1}{10}\frac{\gamma^4 h^2}{r_{ik}^6}\left\{\frac{6\tau_c}{1+4\omega^2\tau_c^2} - \tau_c\right\}$$

where γ is the magnetogyric ratio, h is the reduced Planck constant ($= h/2\pi$), r_{ik} is the Hi—Hk internuclear distance, and τ_c is the motional correlation time for reorientational modulation of the Hi–Hk internuclear vector. Substitution of τ_c values from ^{13}C NMR relaxation analysis and application of eq. [1] allowed the calculation of some relevant distances, as reported in Table 3. The distances obtained gave evidence of a *C*7 puckered conformation of the furanone ring and of an angle of ca. 50° between the two rings.

Occurrence of such a "preferred" conformation was ratified by a second set of geometric information obtained by measuring $^{13}C-\{^1H\}$ nOe's upon selective presaturation of single proton resonances. Such an nOe is interpreted (11) by the equation:

$$[2] \quad \eta_i = f_{Ci}\{Hk\} = \frac{0.1}{R_{Ci}}\frac{\gamma_H^3\gamma_C h^2}{r_{CiHk}^6} f(\omega C, \omega H, \tau_c)$$

where R_{Ci} is the ^{13}C spin-lattice relaxation rate and f is a function of Larmor frequencies and motional correlation time. The simplest way of evaluating distances is to assume the same correlation time functions for nOe's generated on two different carbons, Ci and Cj, by presaturation of a given proton resonance, Hk, such that eq. [2] can be reduced to:

$$[3] \quad \frac{f_{Ci}\{Hk\}R_{Ci}}{f_{Cj}\{Hk\}R_{Cj}} = \left(\frac{r_{CjHk}}{r_{CiHk}}\right)^6$$

If one of the two distances is fixed and known or it can be measured in molecular models, the other can be evaluated. The measured nOe's and the evaluated proton–carbon distances are summarized in Table 4. Although the assumption of the same correlation time function may be not justified and, therefore, the calculated distances may not be very precise, what was observed upon selective saturation of one or the other of the two H6 methylene protons satisfactorily fits the conformation shown by ^1H NMR and also adds new information, such as some folding back of the ethyl chain. This last result was quite unexpected for a small flexible mole-

For personal use only.

cule, but we believe that sufficient evidence was provided; the distance measured between the low-field methylene proton and the methyl carbon may be not very accurate, but no nOe would have been measured in the absence of chain folding.

All conformational features, as obtained by NMR, were used to build up the Dreiding model of the "preferred" structure of protonated pilocarpine in water solution. Such a structure is shown in Fig. 2 as stereo projections obtained with the ChemX software implemented on a graphics terminal. The conformation in solution proves different from that of pilocarpine-trichlorogermanate(II) hemihydrate in the solid state (20). In this last case an angle of 87.6° was evaluated between the two rings and the ethyl chain was not folded towards the imidazole ring.

The spectral and electrochemical properties of tetrabenzo[5,10,15]triazaporphine (TBTAP) and its magnesium derivatives having a long alkyl chain attached to the *meso* carbon have been studied. Both metal-free and metallated species show typical metal-free phthalocyanine-like spectra. Two reduction and two oxidation redox couples have been observed. The cation, anion, and dianion species of these porphyrin derivatives have been electrochemically generated and their electronic spectra are recorded.

YU-HONG TSE, ALOK GOEL, MOUGANG HU, A. B. P. LEVER, C. C. LEZNOFF et JOHAN E. VAN LIER. Can. J. Chem. **71**, 742 (1993).

On a étudié les propriétés spectrales et électrochimiques de la tétrabenzo[5,10,15]triazaporphine (TBTAP) portant une longue chaîne alkyle attaché au carbone *méso* et de ses dérivés contenant du magnésium. Les espèces tant métalliques que non métalliques présentent les spectres caractéristiques des composés ressemblant aux phtalocyanines non-métallisées. On a observé deux couples rédox de réduction et deux d'oxydation. Faisant appel à des méthodes électrochimiques, on a généré les espèces cationiques, anioniques et dianioniques de ces dérivés de la porphyrine et on a enregistré leurs spectres électroniques.

[Traduit par la rédaction]

Introduction

Tetrabenzo[5,10,15]triazaporphine (TBTAP) differs from phthalocyanine (Pc) by a methine group, instead of a nitrogen, at a *meso* position. These unsymmetrical porphyrin derivatives have received relatively less attention than related macrocyclic compounds. During the early development of phthalocyanine chemistry (1, 2) it was shown that reaction of methylmagnesium halide with phthalonitrile yields magnesium tetrabenzotriazaporphine (TBTAPMg). Recently, a variety of TBTAP derivatives (3), substituted at both benzo and *meso* positions, were prepared using a similar procedure. When substituted phthalonitriles are used, inseparable mixtures of regioisomers are obtained. However tetrabenzotriazaporphines derived from unsubstituted phthalonitrile and long-chain alkylmagnesium halide gave only one isomer, which was usually readily soluble in organic solvents. Variations in the alkyl chain length of the Grignard reagent can provide an interesting series of new TBTAP(C_n)M derivatives substituted at the *meso* position. ((C_n) designates the length of the alkyl chain at the *meso* position.) Unsymmetrical porphyrins have also been used in cancer photodynamic therapy (4). The TBTAP derivatives may provide higher stability and efficiency, in this application, than the generally less stable porphyrin nuclei.

This work reports the syntheses of a series of metal-free, TBTAP(C_n)H_2, and metallated, TBTAP(C_n)M, species with an alkyl chain at the *meso* position. The electrochemical and spectroelectrochemical properties of some of these derivatives will also be reported.

Experimental

Materials

Tetrabutylammonium perchlorate (TBAP; Kodak) was recrystallized from absolute ethanol and dried in a vacuum oven at 50°C for 2 days. 1,2-Dichlorobenzene (DCB, Aldrich) and *N*,*N*-dimethylformamide (DMF; Aldrich) were used as supplied. Argon gas (Linde) was purified by passage through heated copper filings for electrochemical measurement. Matheson high-purity argon was used to maintain inert atmosphere conditions for syntheses.

Methods

Differential pulse voltammetry was performed with a Princeton Applied Research (PAR) model 174A polarographic analyzer. Cyclic voltammetry was performed with a Pine Instruments RDE-3 potentiostat, and rotating disk electrode studies with a Pine Instruments PIR rotator.

A conventional three-electrode cell was used in electrochemical experiments. A platinum (Pt) disk described by the cross-sectional area of a 27-gauge wire, sealed in glass, was used as the working electrode, a Pt wire as the counter electrode, and a AgCl/Ag wire as the quasi-reference electrode. Potentials were referenced internally to the ferricenium/ferrocene (Fc^+/Fc) couple. For the rotating disc study, a Pt disk with an area of 0.44 cm^2 was used as working electrode.

Electronic spectra were recorded with a Guided Wave Inc. model 100-20 optical waveguide spectrum analyser or a Cary model 2400 spectrometer. Spectroelectrochemical data were collected following a published design (5). Note that we used an internal AgCl/Ag electrode and that, in the thin-layer cell, the actual potential of the AgCl/Ag electrode may deviate slightly from its true thermodynamic value. Infrared (ir) spectra were recorded on a Pye Unicam SP1000 infrared spectrophotometer using KBr discs. Nuclear magnetic resonance (nmr) spectra were recorded on a Bruker AM300 nmr spectrometer. The observed splittings of the nmr signals are described as singlets(s), doublets(d), triplets(t), or multiplets(m). Mass spectra (ms) were recorded at 70 eV on a VG Micromass 16F mass spectrometer in the EI mode.

(*b*) Rotating disc electrode (RDE) study for *t*-NTNTAP(C_{15})H_2 (**14**) in DCB (0.15 M TBAP, Pt disc working electrode, scan rate 10 mV/s, 400 rpm, [*t*-NTNTAP(C_{15})H_2] = 2×10^{-4} M).

Thin-layer chromatography (tlc) was performed using silica gel G as the adsorbent. Flash chromatography was performed using silica gel of particle size 20–45 μm. All reactions were stirred with a magnetic stirrer. Sublimations were generally carried out at 300°C and 0.005 Torr pressure (1 Torr = 133.3 Pa). Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario.

Syntheses

*(27-Pentyl-29*H*,31*H*-tetrabenzo[*b,g,l,q*][5,10,15]-triazaporphine) magnesium (**1**)*

Hexylmagnesium chloride (8.0 mL of 2 M solution in diethyl ether, 16 mmol) was added dropwise to a stirred suspension of phthalonitrile (2 g, 15.6 mmol) in dry diethyl ether (10 mL), under an argon atmosphere. The reaction mixture was stirred for 2 h at room temperature. During this time the reaction underwent a colour change from purple to reddish-brown. Ether was removed by passing a stream of argon through the reaction flask for 15 min to obtain a brown residue. This residue was dissolved in distilled quinoline (5 mL) and stirred at 185°C, under argon. After 2 h the reaction mixture underwent a colour change from reddish-brown to green, and tlc analysis (THF–hexane (1:4) as eluant) of this mixture showed the presence of a blue compound, a green compound, and a very mobile purple intermediate. After 24 h the purple intermediate had disappeared and the reaction mixture comprised mainly a blue and a green pigment. The reaction mixture was cooled to room temperature, passed through a silica gel column, and eluted with THF–hexane (1:9). This procedure removed an insoluble blue-black impurity and gave a green fraction. Evaporation of the solvent gave a green semisolid. A solution of this solid was loaded on a silica gel column (flash) and eluted with THF-hexane (1:9) to obtain a green and then a blue fraction. The blue fraction proved to be the magnesium phthalocyanine (by comparison of the uv/vis spectrum with that of an authentic sample). The green fraction was evaporated to obtain a green solid. A solution of this solid was loaded on a gel permeation column (Bio-beads, SX-2, 200–400 mesh) and eluted with THF. This procedure removed a residual trace of yellow impurity. Crystallization from ether–hexane (1:9) gave green needles. After sublimation, under reduced pressure, the sublimate was found to be pure **1** (TBTAP(C_5)Mg) (182 mg, 8% yield); uv/vis (THF) peak λ_{max} (nm) (log ε): 668(5.20), 647(5.00), 615(4,10), 593(4.21), 445(4.43), 400(4.70); ir (cm^{-1}): 2920, 2860, 1490, 1330, 1290, 1170, 1130, 1120, 1090, 720; ^1H nmr (pyridine-d_5) δ: 10.14(m, 2H), 9.80(m, 4H), 9.36(m, 2H), 8.20(m, 8H), 5.40(m, 2H),

27-Pentyl-29H,31H-tetrabenzo[b,g,l,q][5,10,15]-triazaporphine (2)

Species **1** (61 mg, 0.1 mmol) was dissolved in glacial acetic acid (10 mL), refluxed for 2 h, cooled to room temperature, and centrifuged to obtain a bluish-green precipitate. The precipitate was washed with water and then with methanol. Reprecipitation from a concentrated solution of toluene by methanol gave a bluish-green solid. Crystallization from toluene gave bluish-green needles (44 mg, 75% yield). Residual traces of impurities were sublimed off, under reduced pressure, to obtain a pure sample of **2** (TBTAP(C_5)H_2); uv/vis (THF) peak λ_{max} (nm) (log ε): 682(5.10), 642(4.89), 616(4.41), 589(3.79), 385(4.33); ir (cm^{-1}): 3440 (br, NH), 2920, 2860, 1500, 1470, 1440, 1340, 1320, 1130, 1120, 1100, 1030, 760, 720; ms *m/z*: 583(M^+, 100), 526(16). Anal. calcd. for $C_{38}H_{29}N_7$: C 78.19, H 5.01, N 16.80; found: C 78.00, H 4.77, N 16.60.

(27-Pentyl-29H,31H-tetrabenzo[b,g,l,q][5,10,15]-triazaporphine) zinc (3)

To a solution of **2** (29 mg, 0.05 mmol) in 5 mL of dry dimethylformamide(DMF)–toluene (1:1) was added anhydrous zinc acetate (92 mg, 0.5 mmol), and the mixture was refluxed for 20 h (under argon). The reaction mixture was cooled to room temperature and the solvent was evaporated to obtain a green solid. After washing with water and methanol, crystallization from ether gave crystals with a purple reflex. Impurities were removed by sublimation under reduced pressure, affording a residue of pure **3** (TBTAP(C_5)Zn) (26 mg, 80% yield) as microcrystals with a purple reflex; uv/vis (THF) peak λ_{max} (nm) (log ε): 668(5.13), 645(4.98), 615(4.22), 591(4.21), 443(4.01), 385(4.50); ir (cm^{-1}): 2920, 2860, 1490, 1410, 1330, 1290, 1170, 1130, 1120, 1100, 780, 720; ms *m/z*: 645 (M^+, 100), 588(39), 294(23). Anal. calcd. for $C_{38}H_{27}N_7Zn$: C 70.54, H 4.18, N 15.15; found: C 70.28, H 4.00, N 15.00.

(27-Nonyl-29H,31H-tetrabenzo[b,g,l,q][5,10,15]-triazaporphine) magnesium (4)

Decylmagnesium bromide (7.8 mL of 1 M solution in diethyl ether, 7.8 mmol) was added dropwise to a stirred suspension of phthalonitrile (1 g, 7.8 mmol) in dry diethyl ether (5 mL), under an argon atmosphere. The reaction mixture was stirred for 2 h at room temperature. During this time, the reaction underwent a colour change from purple to reddish-brown. Ether was removed by passing a stream of argon through the reaction flask for 15 min to obtain a brown residue that was dissolved in distilled quinoline (5 mL) and stirred at 120°C, under argon. After 2 h the reaction

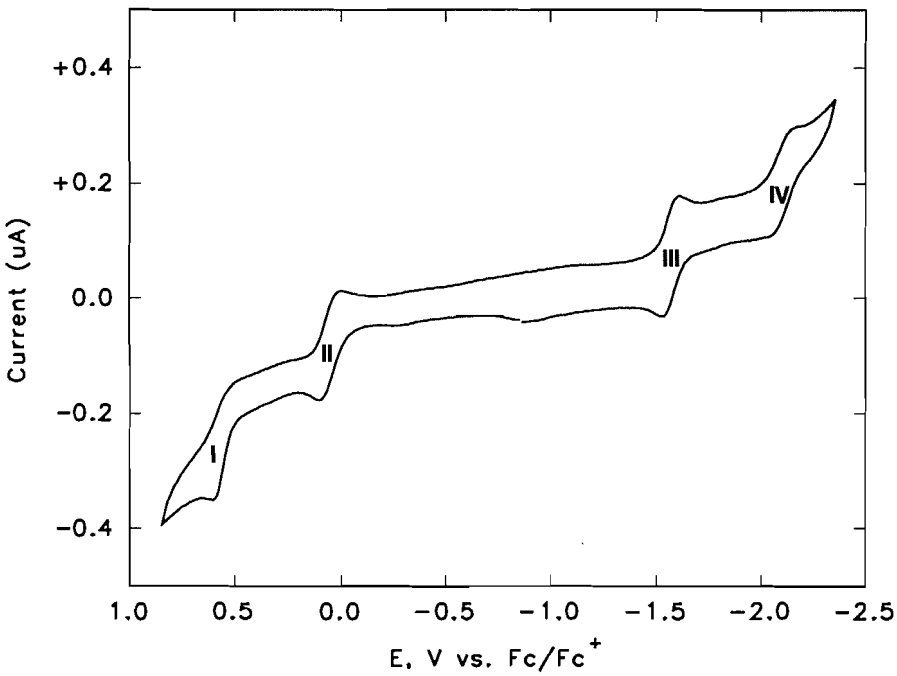

FIG. 3. Cyclic voltammogram for TBTAP(C_9)Mg in DMF (0.15 M TBAP, Pt working electrode, scan rate 100 mV/s).

mixture underwent a colour change from reddish-brown to green, and tlc analysis (pyridine–hexane (1:4) as eluant) of this mixture showed the presence of a blue compound, a green compound, and a very mobile purple intermediate. After 18 h the purple intermediate had disappeared and the reaction mixture comprised mainly a blue and a green pigment. The reaction mixture was cooled to room temperature, passed through a silica gel column, and eluted with ether–hexane (1:1). This procedure removed an insoluble blue-black impurity and gave a green fraction. Evaporation of the solvent gave a green semisolid. A solution of this solid was loaded on a silica gel column (flash) and eluted with pyridine–hexane (1:4) to obtain a green and then a blue fraction. The green fraction was evaporated to obtain a green solid. Crystallization from ether–hexane (1:9) gave pure **4** (TBTAP(C_9)Mg) as green needles (100 mg, 8% yield); uv/vis (THF) peak λ_{max} (nm) (log ε): 668(5.22), 647(5.06), 615(4.18), 593(4.25), 445(4.48), 400(4.74); ir (cm^{-1}): 2920, 2860, 1490, 1330, 1290, 1170, 1130, 1120, 1090, 720; ^{1}H nmr (pyridine-d_5) δ: 10.14 (m, 2H), 9.80 (m, 4H), 9.42 (d, J = 7.5 Hz, 2H), 8.22 (m, 8H), 5.46 (m, 2H), 2.92 (m, 2H), 2.22 (m, 2H), 1.62 (m, 2H), 1.60–1.20 (m, 8H), 0.91 (t, J = 7.0 Hz, 3H) ppm; ms *m/z*: 661 (M^+, 100), 548(41), 535(9).

*27-Nonyl-29*H,*31*H-*tetrabenzo*[b,g,l,q][*5,10,15*]-*triazaporphine (5)*

Species **4** (75 mg, 0.11 mmol) was dissolved in glacial acetic acid (10 mL), refluxed for 2 h, cooled to room temperature, and centrifuged to obtain a bluish-green precipitate. The precipitate was washed with water and then with methanol. Reprecipitation from a concentrated solution of toluene by methanol gave a bluish-green solid. Crystallization from toluene gave bluish-green needles (55 mg, 78% yield). Residual trace impurities were sublimed off, under reduced pressure, to obtain pure **5** (TBTAP(C_9)H_2); uv/vis (THF) peak λ_{max} (nm) (log ε): 682(5.13), 642(4.93), 616(4.40), 589(3.80), 385(4.38); ir (cm^{-1}): 3440 (br, NH), 2920, 2860, 1500, 1470, 1440, 1340, 1320, 1130, 1120, 1100, 1030, 760, 720; ms *m/z*: 639 (M^+, 80), 473 (38). Anal. calcd. for $C_{42}H_{37}N_7$: C 78.85, H 5.83, N 15.32; found: C 78.50, H 6.23, N 14.95.

*(27-Nonyl-29*H,*31*H-*tetrabenzo*[b,g,l,q][*5,10,15*]-*triazaporphine) zinc (6)*

To a solution of **5** (25.5 mg, 0.04 mmol) in 5 mL of dry dimethylformamide (DMF)–toluene (1:1) was added anhydrous zinc acetate (73.6 mg, 0.4 mmol), and the mixture was refluxed for 20 h (under argon). The reaction mixture was cooled to room temperature and the solvent was evaporated to obtain a green solid. After washing with water and methanol, crystallization from ether gave crystals with a purple reflex. Sublimation under reduced pressure afforded a sublimate of pure **6** (TBTAP(C_9)Zn) (24 mg, 85% yield) as microcrystals with a purple reflex; uv/vis (THF) peak λ_{max} (nm) (log ε): 668(5.15), 645(4.98), 615(4.23), 591(4.20), 443(3.98), 385(4.58); ir (cm^{-1}): 2920, 2860, 1490, 1410, 1330, 1290, 1170, 1130, 1120, 1100, 780, 720; ms *m/z*: 703(M^+, 71), 576(100), 471(34), 288(33).

*(27-Tridecyl-29*H,*31*H-*tetrabenzo*[b,g,l,q][*5,10,15*]-*triazaporphine) magnesium (7)*

Tetradecylmagnesium chloride (7.8 mL of 1 M solution in THF, 7.8 mmol) was added dropwise to a stirred suspension of phthalonitrile (1 g, 7.8 mmol) in freshly distilled THF (5 mL), under an argon atmosphere. The reaction mixture turned purple immediately. The reaction mixture was stirred for a further 2 h at room temperature. During this time, the reaction underwent a colour change from purple to reddish-brown. Tetrahydrofuran was removed by passing a stream of argon through the reaction flask for 15 min to obtain a dark brown residue, which was dissolved in distilled quinoline (3 mL) and the mixture stirred at 120°C, under an argon atmosphere. After 0.5 h the reaction mixture underwent a colour change from reddish-brown to dark green, and tlc analysis (pyridine–hexane (1:4) as eluant) of this mixture showed the presence of a blue compound, a green compound, and a purple intermediate. After 18 h the purple intermediate was still present. Hence, the temperature was raised to 180°C and the mixture was refluxed for a further 24 h. The reaction mixture was cooled to room temperature and loaded on a short silica gel column (flash). The column was eluted with pyridine–hexane (1:4) and a green fraction was collected. The solvent was evaporated to obtain a green oil. This oil was loaded on another silica gel column (flash) and again eluted with pyridine–hexane (1:4). This chromatographic procedure afforded separation of the required product from the phthalocyanine by-product. Reprecipitation from a concentrated solution of THF (1 mL) by methanol (9 mL) gave crude **7** (TBTAP(C_{13})Mg) (47 mg, 3% yield). After sublimation, under

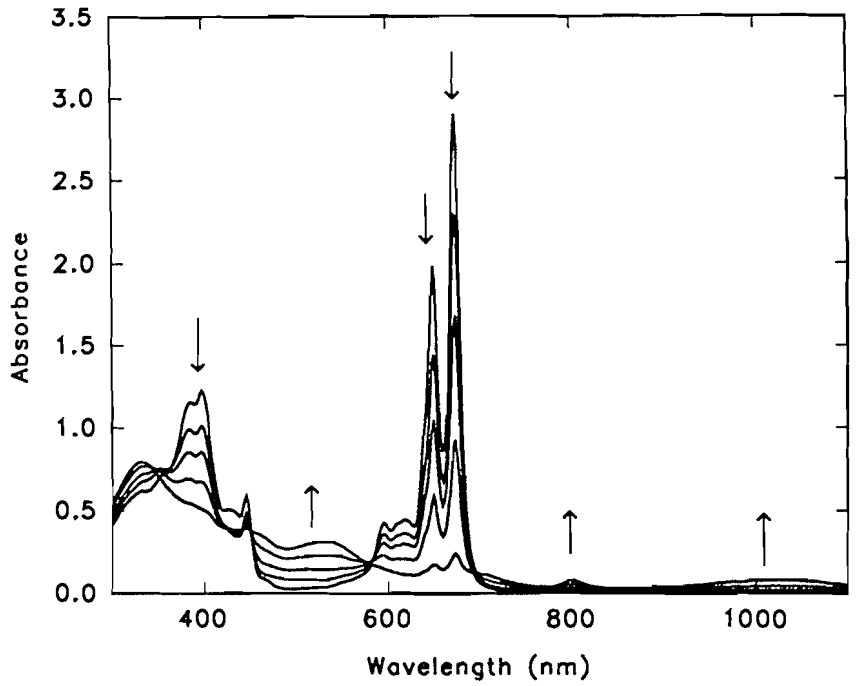

FIG. 6. Spectroscopic changes accompanying the controlled potential oxidation of TBTAP(-2)(C_9)Mg (**4**) (8.6×10^{-4} M) in DMF (0.15 M TBAP). The first (top) spectrum is the starting material, unpolarized. Successive spectra are equilibrium spectra obtained with the electrode polarized at 0.45, 0.50, 0.55, and 0.575 V vs. AgCl/Ag.

the pure **8** (TBTAP(C_{13})H_2); uv/vis (THF) peak λ_{max} (nm) (log ε): 682(5.15), 642(4.94), 616(4.45), 589(3.82), 385(4.47); ir (cm^{-1}): 3440 (bd, NH), 2920, 2860, 1500, 1470, 1440, 1340, 1320, 1130, 1120, 1100, 1030, 760, 720; ms *m/z*: 695 (M^+, 100), 526 (10). Anal. calcd. for $C_{46}H_{45}N_7$: C 79.39, H 6.52, N 14.09; found: C 79.42, H 6.34, N 14.39.

*(27-Tridecyl-29*H,*31*H-*tetrabenzo*[b,g,l,q]*[5,10,15]-triazaporphine) zinc (9)*

Anhydrous zinc acetate (73.6 mg, 0.4 mmol) was added to a solution of **8** (17.35 mg, 0.025 mmol) in 5 mL of dry DMF–toluene (1:1) and the mixture refluxed for 24 h (under argon). The reaction mixture was cooled to room temperature and the solvent evaporated to obtain a green solid. After washing with water and methanol, crystallization from ether gave dark blue crystals. After sublimation under reduced pressure, the residue was found to be the pure **9** (TBTAP(C_{13})Zn), (12 mg, 63% yield); uv/vis (THF) peak λ_{max} (nm) (log ε): 668(5.13), 645(5.00), 615(4.28), 591(4.25), 443(4.21), 385(4.63); ir (cm^{-1}): 2920, 2860, 1490, 1410, 1330, 1290, 1170, 1130, 1120, 1100, 780, 720; ms *m/z*: 758(M^+, 100), 588(41), 575(14), 294(14).

*(27-Heptadecyl-29*H,*31*H-*tetrabenzo*[b,g,l,q]*[5,10,15]-triazaporphine) magnesium (10)*

Octadecylmagnesium chloride (7.8 mL of 1 M solution in THF, 7.8 mmol) was added dropwise to a stirred suspension of phthalonitrile (1 g, 7.8 mmol) in freshly distilled THF (5 mL), under an argon atmosphere. The reaction mixture was stirred for 2 h at room temperature. Tetrahydrofuran was removed by passing a stream of argon through the reaction flask. Distilled quinoline (5 mL) was added and the mixture was stirred at 140°C, under argon, for 18 h. A tlc analysis (THF–hexane (1:1) as eluant) showed a very mobile green spot for the required product along with some brown impurities. The reaction mixture was cooled to room temperature, passed through a silica gel column, and eluted with THF–hexane (1:1). This procedure removed an insoluble blue-black impurity and gave a green fraction. A tlc analysis (pyridine–hexane (1:4) as eluant) of this fraction showed a green spot (R_f 0.9) for the required magnesium tetrabenzotriazaporphine and a blue spot (R_f 0.25) for the magnesium phthalocyanine by-product. The solvent was evaporated and the residue loaded onto a silica gel column (flash) and eluted with pyridine–hexane (1:9). This chro-

matographic procedure afforded separation of the required **10** (TBTAP(C_{17})Mg) from the phthalocyanine by-product. Crystallization from THF–methanol (1:1) gave **10** as needles with a purple reflex (86 mg, 6% yield); uv/vis(THF) peak λ_{max} (nm) (log ε): 668(5.24), 647(5.06), 615(4.09), 593(4.20), 445(4.60), 400(4.71); ir (cm^{-1}): 2920, 2860, 1490, 1330, 1290, 1170, 1130, 1120, 1090, 720; ^{1}H nmr (pyridine-d_5) δ: 10.14(m, 2H), 9.8(m, 4H), 9.42(d, J = 7.9 Hz, 2H), 8.22(m, 2H), 5.46(m, 2H), 2.92(m, 2H), 2.21(m, 2H), 1.62(m, 2H), 1.42–1.23(m, 24H), 0.84(t, J = 7.0 Hz, 3H) ppm; ms m/z: 774(M^+, 100), 548(56), 535(20).

*27-Heptadecyl-29*H,*31*H-*tetrabenzo*[b,g,l,q][*5,10,15*]-*triazaporphine (**11**)*

Compound **10** (86 mg, 0.11 mmol) was dissolved in glacial acetic acid (5 mL), refluxed for 2 h, cooled to room temperature, and centrifuged to obtain a bluish-green precipitate. The precipitate was washed with water and then with methanol until the washings were colourless. Reprecipitation from a concentrated solution of toluene by methanol gave a bluish-green solid. Crystallization from toluene gave plates with a purple reflex (60 mg, 70% yield). After sublimation under reduced pressure, the residue was found to be the pure **11** (TBTAP(C_{17})H_2); uv/vis (THF) peak λ_{max} (nm) (log ε): 682(5.28), 642(5.09), 616(4.61), 589(3.71), 385(4.46); ir (cm^{-1}): 3260 (br, NH), 2920, 2860, 1500, 1470, 1440, 1340, 1320, 1130, 1120, 1100, 1030, 760, 720; ms m/z: 751(M^+, 100), 526(9).

*(27-Heptadecyl-29*H,*31*H-*tetrabenzo*[b,g,l,q][*5,10,15*]-*triazaporphine) zinc (**12**)*

To a solution of **11** (30 mg, 0.04 mmol) in 5 mL of dry DMF–toluene (1:1) was added anhydrous zinc acetate (73.6 mg, 0.4 mmol), and the mixture was refluxed for 24 h (under argon). The reaction mixture was cooled to room temperature and the solvent evaporated to obtain a green solid. After washing with water and methanol, crystallization from ether gave a bluish-green solid. Further purification by flash chromatography, using a solvent system of pyridine–hexane (1:9), and sublimation under reduced pressure gave a residue with a purple reflex. It was found to be the pure **12** (TBTAP(C_{17})Zn) (20 mg, 61% yield); uv/vis (THF) peak λ_{max} (nm) (log ε): 668(5.23), 645(5.05), 615(4.34), 591(4.29), 443(4.16), 385(4.66); ir (cm^{-1}): 2920, 2860, 1490, 1410, 1330, 1290, 1170, 1130, 1120, 1100, 780, 720; ms m/z: 814(M^+, 100),

Results and discussion

A. Syntheses

Reaction of phthalonitrile with a variety of Grignard reagents led to the formation of magnesium tetrabenzotriazaporphines, TBTAP(C_n)Mg, along with some magnesium phthalocyanine (MgPc) by-product. Magnesium tetrabenzotriazaporphines could be separated from the magnesium phthalocyanine by using flash chromatography. Sometimes

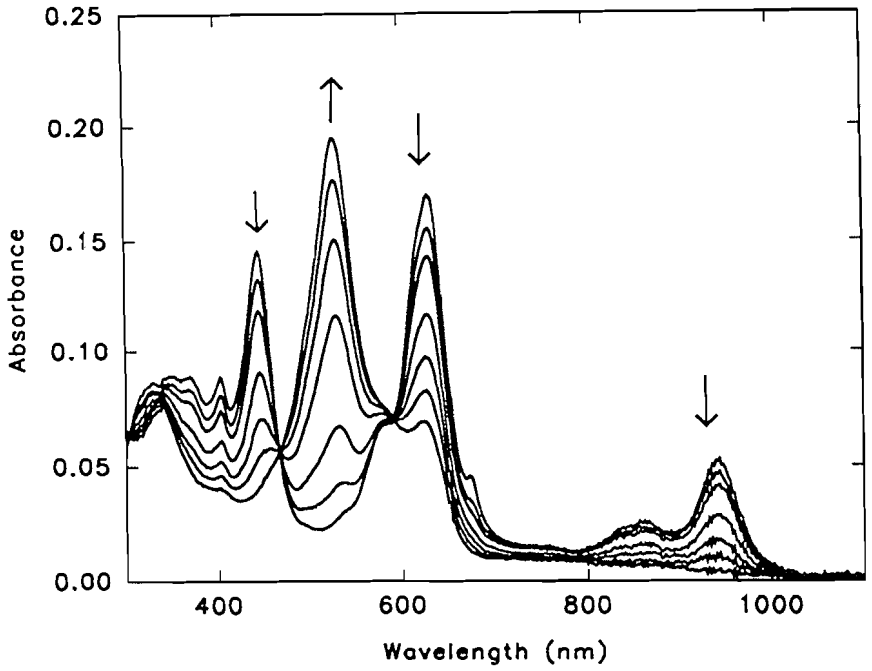

FIG. 9. Spectroscopic changes accompanying the controlled potential reduction of $[TBTAP(-3)(C_9)H_2]^-$ (5^-) (8.8×10^{-5} M) in DCB (0.15 M TBAP). These spectra were obtained as a series by polarizing the electrode from −1.30 to −1.45 V vs. AgCl/Ag in 0.025 V steps (see experimental section for further comment).

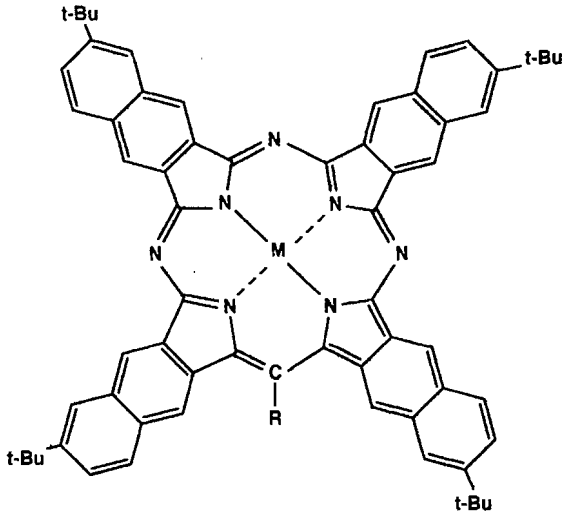

14 **M = H_2, R = $(CH_2)_{14}CH_3$**

it was necessary to filter the product mixture through a normal silica gel column to remove insoluble impurities, before performing the flash chromatography. Magnesium TBTAP species were further purified by crystallization from ether–hexane or tetrahydrofuran (THF)–methanol, and sublimation under reduced pressure. The sublimate was usually a brown impurity and the residue the required pure $TBTAP(C_n)Mg$.

Magnesium tetrabenzotriazaporphines could be demetallated by refluxing in glacial acetic acid. Metal-free tetrabenzotriazaporphines ($TBTAP(C_n)H_2$) were generally less soluble than the corresponding magnesium tetrabenzotriazaporphines. Metal-free tetrabenzotriazaporphines were purified by crystallization from toluene, followed by removal of impurities by sublimation, the residue after sublimation being the required $TBTAP(C_n)H_2$. Zinc tetrabenzotriazaporphines could be obtained from reaction of the corrresponding metal-free tetrabenzotriazaporphines and anhydrous zinc acetate.

B. Electronic structure of the TBTAP system

Simple PcM species have D_{4h} symmetry, while demetallation leads to the PcH_2 species of D_{2h} symmetry. However, in contrast, in the TBTAP species, the metallated complexes at best have twofold symmetry, while the free base species cannot exceed C_s; thus all orbital degeneracies are lifted, for both metallated and free base. The electronic structure of $TBTAPC_1Mg$ has been discussed by Solovev *et al.* (6) using Gouterman's four-orbital model. For the metal-free and main-group metal derivatives, the HOMO-1, HOMO, LUMO, and LUMO + 1 orbitals of the $TBTAP(C_n)$ system are $[b_1(\pi)]^2$, $[a_2(\pi)]^2$, $[b_2(\pi^*)]^0$, and $[b_1(\pi^*)]^0$, respectively (with electron occupations noted). Thus the overall electronic structure parallels that of metal-free phthalocyanine.

C. Electrochemistry

The electrochemical properties of phthalocyanine species are well known (7). The electrochemistry of these triazabenzporphine species was briefly studied to investigate how the replacement of one aza bridgehead by a long-chain-linked CH methine bridgehead influences these properties.

(i) $TBTAP(C_n)H_2$

Species **5**, $n = 9$, and **11**, $n = 17$, were chosen to study the effect of the length of the alkyl group in the *meso* position on the electrochemical properties of the unsubstituted benzo TBTAP derivatives. The electrochemistry of species **13** and **14**, $n = 15$, were investigated to monitor the effect of changing the substituents on the benzo position.

Oxidation and reduction of these compounds directly involve the triazaporphine ring system, since the metal centres

For personal use only.

are not redox active. Cyclic voltammograms generally show (e.g., Fig. 1*a*) (Table 1) three waves (two reduction (**III,IV**), one oxidation (**I**); **III,IV** are reversible or quasi-reversible, **I** is usually irreversible) diffusion controlled with $i_c = i_a$, and $i \propto v^{1/2}$ (v = scan rate in cyclic voltammogram) and, in addition, two less well-defined and overlapping oxidation waves, **II** and **II′**. The rest potential lies between processes **II′** and **III**.

A rotating disc (RDE) analysis shows that the sum of the limiting current for waves **II** and **II′** corresponds to a one-electron transfer process (Fig. 1*b*) and is equal to the current for process **I**. Thus processes **II** and **II′** (combined) correspond with ring oxidation to the cation radical, $[TBTAP(-1)H_2]^+$/TBTAP(-2)H_2 (using previously defined nomenclature (8)). A differential pulse voltammetry study shows that the redox potentials for waves **II** and **II′** are concentration dependent. At very low concentration, only one differential pulse signal was observed at a potential close to that of wave **II′** (Table 1, Fig. 2). The concentration limit for observing one peak for species **5** and **13** is below 10^{-5} M, and is below 10^{-6} M for species **14**.

The dual wave arises from aggregation, a well-known phenomenon in phthalocyanine derivative chemistry (9). However Beer–Lambert plots for the parent **5** from 8.2×10^{-5} M to 6.6×10^{-7} M at 687 and 647 nm do not show any deviation from linearity, indicating that the parent unoxidized species is not aggregated. Therefore the oxidized species, $[TBTAP(-1)H_2]^+$, must aggregate according to:

$$[1] \quad [TBTAP(-1)H_2]^+ + TBTAP(-2)H_2 \; <= = => \{[TBTAP(-1)H_2]TBTAP(-2)H_2\}^+$$

Since it is apparently wave **II′** and not wave **II** which survives in very dilute solution, wave **II′** must correspond to oxidation of the mononuclear species, which then combines, as in eq. [1], to form a mixed valence species that then oxidizes at wave **II** to 2 $[TBTAP(-1)H_2]^+$ (but see below that this species is in equilibrium with a dipositively charged dimeric species). The equilibrium [1] becomes much less important at very low concentrations, as shown in Fig. 2, when only direct oxidation of TBTAP(-2)H_2 to $[TBTAP(-1)H_2]^+$ is observed. The formation of binuclear mixed-valence single-ring oxidized species such as that shown in eq. [1] is becoming fairly well known in phthalocyanine chemistry, especially with binuclear linked species (10–12), but is also purported to occur (13) during the oxidation of MgPc(-2), via $[MgPc(-1).MgPc(-2)]^+$, to $2[MgPc(-1)]^+$.

Wave **I** is assigned to oxidation to the dication radical, namely, process $[TBTAP(0)H_2]^{2+}/[TBTAP(-1)H_2]^+$. This redox couple is irreversible except for species **14**. Waves **III** and **IV** are quasi-reversible diffusion-controlled one-electron transfer processes assigned to the reduction processes TBTAP(-2)H_2/$[TBTAP(-3)H_2]^-$ and $[TBTAP(-3)H_2]^-$/$[TBTAP(-4)H_2]^{2-}$, respectively.

Increasing the alkyl chain from 9 to 17 carbon atoms in the *meso* position provides no significant change in the redox potential.

*(ii) TBTAP(C_n)Mg (species **4**, **10**)*

These magnesium species show voltammograms typical for MPc-like species with oxidation processes **II** and **I** to the ring-oxidized mono- and di-cation radical, respectively, and two reduction processes (**III**, **IV**) to the ring-reduced mono- and di-anion radical, respectively (Figs. 3, 4; Table 1). The forward and reverse differential pulse polarograms are especially well behaved (Fig. 4), showing the electrochemical reversibility of all the observed processes, with the exception of **I** (and possibly **IV**, see below).

(iii) Comparison with regular phthalocyanine species

Although the overall features in the electrochemical behaviour of the TBTAP species parallel those of the phthalocyanines very closely, the first and second reductions for TBTAP(C_n)H_2 are about 300 mV negative of those for regular metal-free phthalocyanine species such as metal-free tetraneopentoxyphthalocyanine (6, 14). This is due to the replacement of one electron-withdrawing bridgehead nitrogen link by the less-withdrawing methine link. Porphyrins are more difficult to reduce than the corresponding phthalocyanines and these TBTAP species obviously lie, in character, between the porphyrins and phthalocyanines.

The naphthalene-substituted species, **14**, is easier to oxidize and more difficult to reduce than the corresponding benzotriazaporphin, an observation consistent with previous phthalocyanine experience (7).

D. Electronic absorption

(i) TBTAP(C_n)H_2 and TBTAP(C_n)M

In the electronic spectroscopy of fourfold symmetry, D_{4h}, MPc(-2) species, π–π^* transitions from the two upper filled π orbitals (HOMO and HOMO-1) to the π^* LUMO orbital provide a strong band, usually in the range 620–720 nm, called the *Q* band, and a second band, in the range 320–420 nm, called the *B* band (or Soret). The *Q* band is usually associated with a weaker vibrational satellite to higher energy (near 600–620 nm) (15). In the metal-free species, of twofold symmetry, the *Q* band is split into two strong features, usually with at least two weaker vibrational satellites. Such a doubled *Q* band is expected, and observed, in these lower symmetry TBTAP(-2)(C_n)H_2 and TBTAP(-2)-(C_n)M species (Fig. 5). The data reported here (Table 2) correspond closely with those previously published for TBTAP(-2)H_2, TBTAP(-2)Mg, and TBTAP(-2)Zn (3, 5).

The *Q*-band splitting in the spectra of the TBTAP(-2)(C_n)M species is about 500 cm^{-1}, whereas it is about 900 cm^{-1} in the spectra of metal-free TBTAP(-2)(C_n)H_2, perhaps because of the lower symmetry of the latter. This *Q*-band splitting is substantially larger than that imposed on mixed benzo, naphthophthalocyanines where one or three benzene rings is replaced by a napthalene ring; such systems show splittings (16) of 225–250 cm^{-1}. Changing the length of the alkyl chain causes no significant shift or change in the relative intensities of either the *Q* or *B* bands, in the spectrum recorded in THF.

(ii) Spectroelectrochemistry

(a) Cation radicals, $(a_2)^1$, $^2A_2$: The spectroscopic changes accompanying the oxidation of TBTAP(C_9)Mg (**4**) and *t*-BuTBTAP(C_{15})H_2 (**13**) to their corresponding cation radicals are shown in Figs. 6 and 7. The resulting loss of *Q*-band intensity between 600 and 700 nm, and the growth of weaker and broader absorption near 550 and 850 nm, is typical of the formation of a phthalocyanine cation radical, Pc(-1), species (13, 17, 18) (Table 3). Indeed the spectra (13, 18) of ZnPc(-1) and MgPc(-1) species are dramatically similar to those spectra reported here, leaving no doubt that these species are cation radicals. The principal difference is that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

the band near 850 nm, reputed to be the *Q* band for the monomeric cation radical (13), is relatively less strong, and is broader, than in the MPc(-1) species. The broadness may reflect incipient splitting in the lower symmetry of these species. The peak at 530–570 nm is a $\pi-\pi$ transition in the mononuclear species, similar to previous assignments of related species (13, 14, 18, 20, 21).

These species show isosbestic points upon reduction and may be oxidized back to the starting species with recovery of the initial spectrum; thus the spectroelectrochemistry is reversible with no significant decomposition.

The presence of a hole in the HOMO orbital frequently leads, in phthalocyanine chemistry, to some stabilization of a dimeric species (8, 10–12, 18, 19), which may be written for the TBTAP species as:

[2] $2[\text{TBTAP(-1)H}_2]^+ <= = => [\text{TBTAP(-1)H}_2]_2^{2+}$

Comparison of the electronic spectra of phthalocyanine and TBTAP cation radical spectra leads to the presumption that the peak at 1010–1080 nm arises from dimeric TBTAP radical cation species. Support for this conclusion arises from concentration-dependent studies that show, for TBTAP-$(C_{15})H_2$, that the intensity ratio for the peak at 1070 nm relative to that at 860 nm increases with increasing concentration, e.g., the ratio 1070/860 is 0.4 at 2.5×10^{-4} M, and 1.1 at 1×10^{-3} M TBTAP(-2)H_2.

(*b*) *Mono-anion radicals* $(a_2)^2(b_2)^1$, $^2B_2$: Figure 8 shows the spectroscopic changes during the reduction of **13** to its anion radical with related data for other species in Table 4. Isosbestic points again attest to good behaviour with no significant decomposition. The spectroscopic features are characteristic of Pc(-3) anion radicals (14, 16, 22–24). While MPc(-2) species yield a single *Q* band, $[\text{MPc(-3)}]^-$ species usually have a doubled band in the *Q* region. Conversely, these low-symmetry $[\text{TBTAP(-3)}(C_n)]^-$ species only exhibit a single band in the *Q* region (Fig. 8). A magnetic circular dichroism study of these and related systems provides an explanation of this apparent anomaly and will be published elsewhere.[2] Otherwise the spectra are characteristic of the mono-anion radical, especially with respect to the band near 440 nm and the double system (assigned as $\pi^*-\pi^*$) near 860 and 950 nm, which, however, is red shifted from the corresponding bands in the phthalocyanine series (14, 22–24).

(*c*) *Di-anion radicals* $(a_2)^2(b_2)^2$ $^1A_1$: The spectroscopic changes during the reduction of the mono-anion radical of **5** to its di-anion radical are shown in Fig. 9, with data for other di-anion radicals summarized in Table 4. The metal-free di-anion radical spectra show clean complete reduction with isosbestic points. However, some decomposition is noted during the reduction of the Mg species to the di-anion state. These spectroscopic data are characteristic for Pc(-4) species, especially the strong band near 530 nm (14); in this case, the number of strong features in the Pc(-4) and TBTAP(-4)(C_n) spectra and the overall shape of the band envelope are similar.

Summary

The spectroscopic and electrochemical properties of the triazaporphine species parallel very closely those for two-fold symmetry metallophthalocyanines. The presence of one methine linkage replacing an aza bridgehead does not, it appears, have a major effect upon the electronic properties of these phthalocyanine-like species save for removing all orbital degeneracies. Thus the wealth of understanding that has grown in the phthalocyanine field can be transferred with some confidence to the triazaporphines, subject only to the change in symmetry. These species do have some important properties, however, which make them very useful in the pursuit of molecular electronic applications, namely: (*i*) organic solvent soluble, single isomer, species can readily be synthesized; (*ii*) Langmuir–Blodgett films may readily be made from amphiphilic species constructed with long alkyl chains (25–27); (*iii*) the facile ability to modify the functional group attached to the methine linkage should provide for the synthesis of a wide range of strategically designed molecules.

MICHELINE GRIGNON-DUBOIS, MICHELLE FIALEIX et JEAN-MICHEL LEGER. Can. J. Chem. **71**, 754 (1993).

La silylation de l'isoquinoléine par les réactifs $Me_3SiCl/Li/THF$ ou $Me_3SiCl/Mg/THF$ a été étudié en détail. L'influence de la nature du métal utilisé et des conditions opératoires a été mise en évidence. Ces paramètres conditionnent l'orientation de la réaction et permettent l'accès à des produits de silylation originaux.

MICHELINE GRIGNON-DUBOIS, MICHELLE FIALEIX, and JEAN-MICHEL LEGER. Can. J. Chem. **71**, 754 (1993).

Silylation of isoquinoline with $Me_3SiCl/Li/THF$ or $Me_3SiCl/Mg/THF$ reagents has been studied. The choice of the metal and the experimental conditions govern the course of the silylation reaction and lead to new trimethylsilyl heterocyclic compounds.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

Nous avons précédemment montré (1) que la silylation réductrice de la quinoléine par le système $Me_3SiCl/Li/THF$ permettait d'accéder à des hydroquinoléines polysiliciées originales. L'intérêt de ces composés pour des fonctionnalisations ultérieures justifiait d'étudier d'autres hétérocycles aromatiques. La première étape de ces réactions étant la silylation de l'atome d'azote, sa position dans le squelette devrait jouer un rôle important dans la réactivité. L'étude de l'isoquinoléine paraissait donc particulièrement intéressante; en particulier, la disilylation réductrice qui intervenait essentiellement en position 1,4 avec la quinoléine (1) ne pourra ici s'effectuer qu'en 1,2 ou, éventuellement, en 2,6.

Le seul dérivé silicié d'hydroisoquinoléine connu était le 2,2′-bis-triméthylsilyl-1,1′,2,2′-tétrahydro-1,1′biisoquinoléine isolé par Becker et Neumann (2) par silylation de l'isoquinoléine au moyen du bis-triméthylsilyl-mercure. Nous avons pour notre part utilisé les réactifs $Me_3SiCl/Li/THF$ et $Me_3SiCl/Mg/THF$. L'étude de la quinoléine (1) ayant montré l'importance des conditions expérimentales sur l'orientation de la réaction, nous avons examiné en détail le rôle de ces paramètres et plus particulièrement l'influence de la nature du métal, de la concentration des réactifs et de leur ordre d'introduction dans le milieu réactionnel.

Résultats et discussion

Silylation par $Me_3SiCl/Li/THF$

La réaction est effectuée à 0°C avec 2, 4 ou 6 équivalents d'agent silylant et poursuivie jusqu'à disparition du métal ou de l'isoquinoléine. Elle conduit à des produits siliciés différents, selon que Me_3SiCl ou l'hétérocycle sont additionnés au mélange des autres réactifs.

(a) Addition de Me_3SiCl

Ce procédé permet d'être toujours en défaut de Me_3SiCl. L'utilisation de 2 équivalents de lithium et 2 équivalents de Me_3SiCl conduit au mélange de deux composés originaux, **2** et **3** (schéma 1; tableau 1)) obtenus avec des rendements respectifs de 30 et 50%. Il n'y a pas formation de dérivés disiliciés. Quatre équivalents d'agent de silylation conduisent au même résultat; par contre, avec 6 équivalents, les composés **2** et **3** ne sont isolés qu'avec respectivement 13 et 33% de rendement à côté de résidu abondant provenant de la polymérisation de l'isoquinoléine.

Le *cis,cis-ortho,ortho*-(*N,N′*-bis-triméthylsilyl-2-aminoéthényl)-stilbène, **2**, qui résulte de l'ouverture du cycle azoté n'avait pas été précédemment décrit. Il est isolé du mélange par précipitation dans le cyclohexane. Les analyses physicochimiques habituelles (RMN, spectrométries de vibration et de masse) ne permettant pas d'élucider totalement sa structure, nous avons effectué une étude radiocristallographique (tableau 2). La figure **1** montre une vue spatiale de la molécule, qui est centrosymétrique. On constate que la gêne stérique introduite par les groupes silyles provoque une torsion de 5° au niveau de la double liaison énamine et une déformation plus importante (45°) entre le plan de cette double liaison et celui du noyau aromatique adjacent.

Le deuxième produit de la réaction est isolé par évaporation du filtrat et a été identifié au 2,2′-bis-triméthylsilyl-1,1′,2,2′-tétrahydro-1,1′-biisoquinoléine, **3**. Son état physique (huile jaune pâle) montre que nous n'avons pas obtenu le même stéréoisomère que Becker et Neumann, qui par action du bis-triméthylsilyl-mercure (2) isolait un solide (*F* 162–164°C) mais sans préciser sa stéréochimie. Afin d'élucider totalement la structure du composé **3**, nous l'avons mis à réagir avec le chlorure d'acétyle à 0°C; nous avons ainsi isolé le dimère *N*-acétylé correspondant **4**, sous la forme d'un solide blanc (rdt. 80%; *F* 196°C). Par action d'un mélange zinc – anhydride acétique sur l'isoquinoléine, A.T. Nielsen (3) avait obtenu le 2,2′-diacétyl-1,1′,2,2′-tétrahydro-1,1′-biisoquinoléine sous la forme d'un mélange des deux diastéréoisomères (rdt. 58%; *thréo/méso* 50 : 50). Le produit que nous isolons présente les mêmes caractéristiques que l'isomère *thréo* obtenu par Nielsen, qui attribue cette stéréochimie par corrélation chimique (3). Cependant les réactions mises en jeu s'effectuant à 118°C et ayant constaté pour notre part que cette température peut être suffisante pour en-

traîner une isomérisation partielle de ces dimères, nous avons effectué une analyse cristalline du dérivé **4** (fig. 2, tableau 2). Nous avons ainsi mis en évidence la géométrie *thréo* de l'enchaînement 1–1′, ce qui confirme les résultats de Nielsen et permet d'attribuer la même stéréochimie au composé **3**. Signalons que Kurkutova et al. (4) avaient rapporté une étude radiocristallographique d'un des deux isomères de **4**, mais sans préciser lequel et de manière très succincte. Le dimère *N*-silicié *thréo* **3** n'était pas connu. Par chauffage à 150°C sous atmosphère inerte, il conduit à l'isomère *méso*, **3*a*** (rdt. 85%), qui est cristallisé (*F* 160°C) et identique au dérivé isolé par Becker et Neumann (2) dont nous établissons ainsi la stéréochimie. La stéréosélectivité de la dimérisation, différente selon le réactif utilisé, est remarquable. Elle montre que le mécanisme intervenant avec le système $Me_3SiCl/Li/THF$ doit être plus complexe qu'une simple duplication radicalaire : les phénomènes de solvatation associés à des effets de sel pourraient jouer ici un rôle dans le déroulement de la réaction. L'isomérisation thermique de **3** en **3*a*** implique une scission homolytique de la liaison 4,4′ conduisant au radical correspondant ce qui est en accord avec les résultats décrits par Mitchell dans la série des 1,1′,2,2′-tétrahydrobipyridines (5). L'examen de modèles moléculaires montre que la forme *méso* est moins encombrée que la forme *thréo*; la facilité de cette isomérisation pourrait s'expliquer par la décompression stérique qui en résulte. Lorsque la thermolyse est conduite en présence d'air, on isole l'isoquinoléine (rdt. 80%) à côté d'un résidu noir.

(b) Addition de l'isoquinoléine

La réaction est conduite à 0°C pendant 3 h, temps nécessaire à la disparition du lithium engagé. Afin d'être toujours en excès d'agent silylant, l'isoquinoléine a été additionnée lentement au mélange $Me_3SiCl/Li/THF$ dont nous avons fait varier la concentration (2–6 équivalents par mole

d'isoquinoléine; tableau 1). Dans ces conditions, nous n'observons pas la formation du composé **2**. Avec 2 équivalents de réactif, la réaction est incomplète : 55% de l'isoquinoléine engagée est récupérée en fin de réaction et le composé **3** n'est isolé qu'avec 15% de rendement. Par contre, avec 4 ou 6 équivalents, la réaction est totale mais conduit à des mélanges réactionnels très instables qui se désilylent rapidement lorsqu'on les manipule. Leurs spectres de RMN ^{1}H montrent l'absence de protons aromatiques et un massif large et intense, constitué de plusieurs singulets indiscernables centrés vers 0,1 ppm. Ceci semble indiquer la présence de produits persiliciés, hypothèse en accord avec le fait qu'aucune trace de produits disiliciés n'est isolé lors des tentatives de distillation et que la masse du mélange réactionnel augmente avec la quantité de réactif (pour 1 g de substrat elle est respectivement de 1,8,3 ou 4,3 g pour 2, 4 ou 6 équiv.). L'addition de cyclohexane aux mélanges réactionnels isolés à partir de 4 ou 6 équivalents conduit à la précipitation d'un solide jaune pâle montrant cinq groupes $SiMe_3$ en RMN (^{1}H, ^{13}C). Une analyse radiocristallographique (fig. 3, tableau 2) a permis de l'identifier au diastéréoisomère *méso* du 2,2′,3,3′,5,5′,6,6′,7,7′-déca-triméthylsilyl-1,1′, 2,2′, 3,3′, 5,5′, 6,6′,7,7′-dodécahydro-1,1′-biisoquinoléine, **5**, qui doit résulter de la persilylation du dimère *N*-silicié **3***a* dans le milieu réactionnel. Les rendements sont respectivement de 4% (4 équiv.) et 8% (6 équiv.). La figure 3 montre que la molécule est centrosymétrique, chaque motif renfermant une structure diénique *transoïde* comparable à celle obtenue par persilylation de la quinoléine (1). Les calculs effectués à partir des coordonnées atomiques montrent que les doubles liaisons forment un angle de 19,6° et que tous les groupes silyles sont en *trans* les uns par rapport aux autres (positions équatoriales sur les sommets 3, 5 et 6 et axiales sur les sommets 2 et 7. Les liaisons

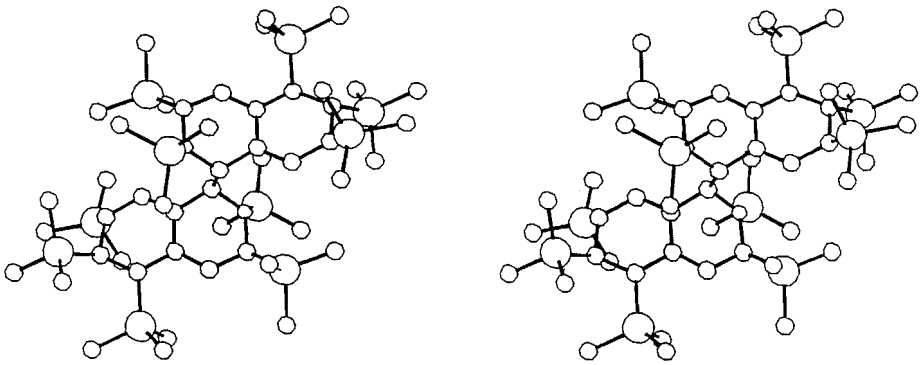

FIG. 3. Vue stéréoscopique du composé **5**.

C_6—Si et C_7—H sont pratiquement en position éclipsée (3°) de même que les liaisons C_7—Si et C_6—H (3°). À l'exception de l'angle dièdre entre les protons H_5 et H_6 qui est de 133°, tous les autres sont compris entre 44° et 109° ce qui rend compte des faibles couplages observés dans le spectre de RMN ^{1}H. Le composé **5** de stéréochimie *thréo* n'est pas observé. L'encombrement stérique, plus important dans le dimère monosilicié *thréo* **3** que dans le *méso* **3***a*, pourrait empêcher ici la polysilylation du cycle. Cependant, nous ne pouvons rejeter l'hypothèse de sa formation. En effet, nous avons constaté que le composé **3**, beaucoup moins stable que son isomère **3***a*, se désilyle en présence d'air pour conduire à l'isoquinoléine par scission de la liaison 1–1′. Il n'est donc pas exclu que le dimère pentasilicié *thréo* se forme également et évolue vers un monomère par aromatisation et perte partielle de silicium.

Les autres produits de la silylation n'ont pu être isolés par suite de leur fragilité. Toute tentative de purification par distillation ou par chromatographie liquide–liquide aboutit à leur désilylation partielle et à la formation de résidu. Le même phénomène intervient en solution, ce qui empêche leur analyse par RMN. Les mélanges réactionnels ont donc été abandonnés à l'air pendant 1 nuit puis chromatographiés sur silice afin d'isoler les produits d'aromatisation; ils ont été identifés aux composés **6–9** (fig. 4), obtenus avec des rendements variables selon la quantité d'agent de silylation mis en jeu (tableau 1) : avec 4 équiv., on isole le mélange suivant : **6** (rdt. 6%), **7** (rdt. 10%), **8** (rdt. 25%), **9** (rdt. 9%); avec 6 équiv., on isole : **6** (rdt. 63%), **7** (rdt. 5%), **8** (rdt. 10%), **9** (rdt. 5%). Dans ce dernier cas nous avons également séparé les constituants par distillation et obtenu : **6** (rdt. 70%), **7** (rdt. 5%), **9** (rdt. 11%).

Ces résultats montrent que **6** est toujours le produit majoritaire lorsqu'on travaille avec 6 équivalents de réactif. Les composés **6** et **8** présentent en RMN ^{1}H les signaux caractéristiques d'une 5,6,7,8-tétrahydroisoquinoléine : on note en particulier en RMN ^{1}H le couplage $^3J_{3,4}$ voisin de 5 Hz et un singulet attribuable au proton H-1 vers 8 ppm. Nous les avons identifié au 5,6,7-tris-triméthylsilyl-5,6,7,8-tétrahydroisoquinoléine, **6**, et au 6,7-bis-triméthylsilyl-5,6,7,8-tétrahydroisoquinoléine, **8**. Le composé **6** est constitué de deux isomères **6***a* et **6***b* dans les proportions 50 : 50. Les constantes de couplage $^3J(^1H,^1H)$ du cycle carboné ont été comparées à celles mesurées pour le 5,6,7-tris-triméthylsilyl-5,6,7,8-tétrahydroquinoléine, obtenu dans les mêmes conditions par aromatisation du 1,2,3,5,6,7-hexakis-triméthylsilyl-1,2,3,5,6,7-hexahydroquinoléine (1). Ces valeurs sont rassemblées dans le tableau 3. Nous y avons également inclus celles rapportées par Birkofer et Ramadan pour le 1,2,3,7-tétrakis-triméthylsilyl-1,2,3,7-tétrahydronaphtalène provenant de la silylation du naphthalène (6) ainsi que celles que nous avons mesurées pour le 1,1,3,5,6,7-hexakis-triméthylsilyl-1,4,5,6,7,8-hexahydronaphtalène, dont nous avons déterminé la géométrie par radiocristallographie (7*a*). La comparaison de ces valeurs montre que tous les composés, à l'exception de **6***a*, ont la même géométrie. Ceci permet d'attribuer sans ambiguïté à l'isomère **6***b*, la structure où les siliciums sont *trans*-diaxiaux sur les sommets 5 et 6 et *trans*-équatorial sur le sommet 7 avec un cycle en conformation bateau (fig. 5). Ces résultats confirment les structures que nous avions précédemment proposées dans le cas de la quinoléine (1) mais remettent en cause celle que Birkofer et Ramadan avaient avancée dans le cas du trisilyl-tétrahydronaphtalène (6). En ce qui concerne l'isomère **6***a*, la similitude des couplages $J_{7,8}$ et $J_{7,8}$, montre que le proton H-7 est sur la bissectrice de l'angle formé par les protons H-8 et H-8′ ce qui impose à Si-7 d'être axial. Les couplages $J_{5,6}$ et $J_{6,7}$, voisins de 3,5 Hz, sont compatibles avec des siliciums *trans*-diaxiaux sur un cycle demi-chaise (fig. 5). Ces conclusions sont en accord avec les études radiocristallines effectuées sur les produits polysiliciés obtenus par silylation réductrice du naphtalène (7*a*) et de benzènes monoalkylés (7*b*) : elles ont montré que la polysilylation des cycles aromatiques conduit à des composés tout-*trans* et la structure du dimère pentasilicié **5** que nous rapportons ici en est une nouvelle confirmation. De plus, des calculs MM2 effectués par Cartledge et coll. (8) dans la série des 1,2-bis-triméthylsilyl-cyclohexane et cyclohexène ont permis de montrer la plus grande stabilité des isomères *trans*-diaxiaux par rapport aux *trans*-diéquatoriaux.

Les composés **7** et **9** sont des isoquinoléines disiliciées. La présence dans les deux spectres de RMN ^{1}H d'un singulet vers 9 ppm montre que le carbone 1 n'est pas substitué. L'analyse des autres signaux nous a conduit à les identifier respectivement au 3,6-bis-triméthylsilyl-isoquinoléine, **7** et au 6,7-bis-triméthylsilyl-isoquinoléine, **9**. Cette attribution a été confirmée sur la base des déplacements chimiques du ^{13}C, qui ont été comparés aux valeurs calculés selon Ewing (9) pour tous les isomères théoriquement possibles. Notons que le composé **9** est toujours présent, quel que soit la quantité de réactif et la méthode de purification. Par contre, le composé **8**, auquel il s'apparente, n'est obtenu que lorsqu'on effectue une chromatographie sur silice. La forma-

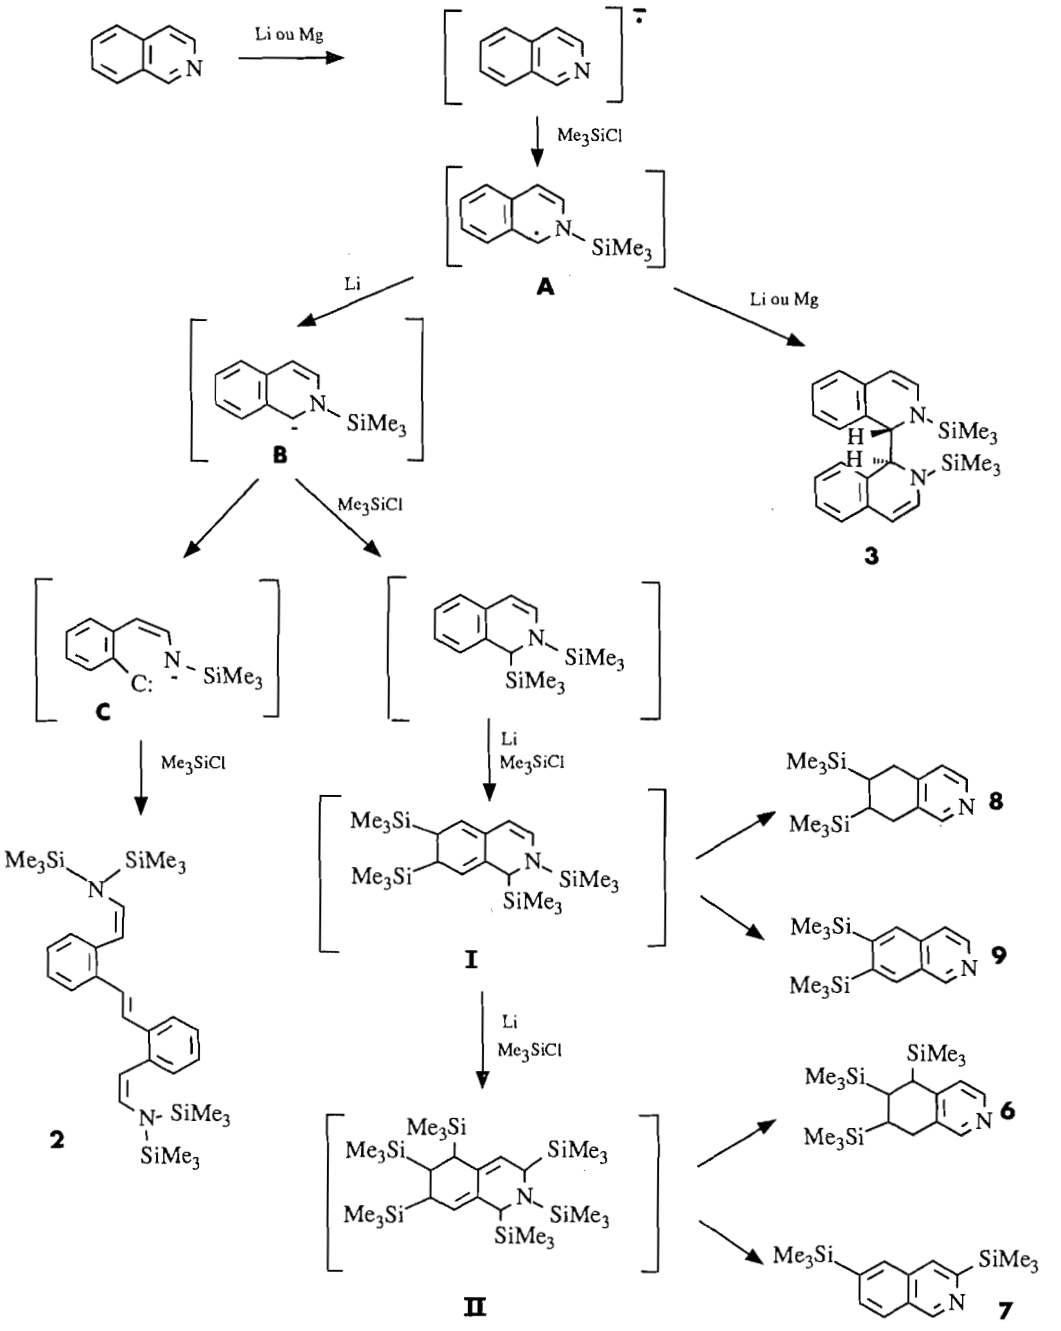

FIG. 4. Influence des conditions opératoires sur l'évolution de la silylation.

tion de ce dernier implique la fixation de deux atomes d'hydrogène, processus qui pourrait s'effectuer lors de la purification sur silice. Ceci est à rapprocher des résultats de Laguerre et al. (10) qui avaient obtenu le 6,7-bis(triméthylsilyl)-5,6,7,8-tétrahydronaphtalène à partir du 1,2,6,7-tétrakis(triméthylsilyl)-1,2,6,7-tétrahydronaphtalène.

Compte tenu de la structure de ces composés et des résultats précédemment observés à partir de la quinoléine, nous pensons que la polysilylation de l'isoquinoléine conduit au mélange des composés tétra- et hexasiliciés **I** et **II** (fig. 4), à côté du dimère pentasilicié **5**. Notons que certaines tentatives d'analyse RMN ^{1}H, effectuées sur les mélanges réactionnels débarrassés du dimère pentasilicié, ont montré la présence de quatre doublets d'égale intensité à 5,15 (1,7 Hz), 5,20 (1,7 Hz), 5,42 (1,5 Hz) et 5,51 ppm (1,5 Hz) compatibles avec un mélange de deux isomères hexasiliciés, ce qui confirmerait la filiation de **6** à **II**. Le composé **6** est toujours accompagné de 3,6-bis-triméthylsilyl-isoquinoléine, **7**, ce qui suggère qu'ils proviennent du même précurseur. Les composés **8** et **9** se formeraient à partir de **I**.

Silylation par $Me_3SiCl/Mg/THF$

Les premiers essais ont été conduits à température ambiante avec 1 équivalent de magnésium et 1,1 équivalent de Me_3SiCl. Après 48 h, la réaction étant toujours incomplète, nous avons opéré au reflux du THF. Dans ces conditions, l'isoquinoléine est entièrement consommée en 4 h pour conduire au mélange des deux dimères *N*-siliciés **3** et ***3a*** (rdt. : 97%; ***3/3a*** 80 : 20) (schéma 1). La prolongation du reflux à 20 h conduit au même rendement global, mais le rapport ***3/3a*** passe à 70 : 30. L'utilisation d'un excès de

réactif (4–6 équiv.) ne modifie pas ces résultats. Le magnésium n'est donc pas suffisamment réducteur pour permettre la polysilylation du squelette. L'adjonction de petite quantité de zinc (10% en poids par rapport au magnésium utilisé) ne modifie pas le cour de la réaction mais permet de diminuer le temps de chauffage (2,5 h au lieu de 4 h) conduisant ainsi à une meilleure stéréosélectivité puisque le rapport **3**/**3***a* atteint 85 : 15. Cette réaction constitue donc une bonne voie d'accès au dimère *thréo* qui n'était pas précédemment accessible. La stéréosélectivité de la réaction est remarquable et on peut raisonnablement penser que la formation de **3***a* résulte d'un début d'isomérisation au reflux du THF.

L'ensemble de ces résultats, associés à ceux précédemment obtenus à partir de la quinoléine (1) et ceux décrits dans le cas du naphtalène (10) montre l'importance de l'azote et de la position qu'il occupe dans la réactivité de ces squelettes. Ils mettent en outre en évidence le rôle du métal et des conditions opératoires. De plus, la position de l'atome d'azote, conditionnant le site de la première silylation, joue en rôle important tant au niveau de la structure des produits formés que de leur stabilité. Ainsi, avec l'isoquinoléine la réaction débute par le sommet 2 conduisant à un radical essentiellement localisé sur le sommet 1, position très favorable à une dimérisation ou à une ouverture du cycle azoté. Ceci explique que les conditions opératoires aient ici une influence beaucoup plus importante qu'avec la quinoléine et que nous n'ayons jamais observé la formation de dérivés résultant de la simple disilylation réductrice de l'isoquinoléine (fig. 4). Ainsi, avec le magnésium, métal faiblement réducteur comparé au lithium (11), la dimérisation à partir de **A**, beaucoup plus rapide que la capture d'un deuxième électron, s'effectue quantitativement. Le lithium, plus réducteur que le magnésium, permet un deuxième transfert d'électron conduisant à l'anion **B**. Cependant, lorsqu'on se trouve en défaut de Me_3SiCl (addition de Me_3SiCl au mélange des autres réactifs), la dimérisation intervient encore pour 50%. Elle est concurrencée par l'ouverture du cycle de **B** qui est plus rapide que la silylation du sommet 1; elle conduit à l'intermédiaire **C** de type ⟨⟨anio-carbénique⟩⟩ dont la duplication accompagnée de la silylation de l'atome d'azote rendent compte de l'obtention du composé **2**. Par contre, lorsqu'on est en excès de réactif (addition de l'isoquinoléine au mélange des autres réactifs), la polysilylation devient la réaction principale; l'utilisation de 6 équivalents d'agent de silylation permet alors de fixer six groupes triméthylsilyles sur le cycle azoté et la dimérisation n'intervient plus que pour 8% du substrat. L'influence de la position de l'atome d'azote se traduit par la facilité manifestée par l'isoquinoléine à conduire à des dimérisations par le sommet 1 et sa plus grande réactivité : ainsi le magnésium permet le silylation de l'isoquinoléine avec un rendement quantitatif, alors que, dans les mêmes conditions, le naphtalène ne réagit pas et la quinoléine conduit à un mélange inexploitable renfermant beaucoup de polymères.

Partie expérimentale

Caractéristiques physico-chimiques des produits siliciés obtenus

Les points de fusion ont été mesurés sur un appareil Mettler FP 61. Les analyses centésimales ont été effectuées au service central d'analyse du CNRS (F-69390 Vernaison). Les spectres de masse (SM) ont été enregistrés sur un appareil VG micromass 16 F (70 eV) et les spectres IR sur un spectromètre Perkin–Elmer 1420 ; tous les dérivés siliciès isolés présentent en IR des bandes de très forte intensité à 1250 et 850 cm^{-1} caractéristiques des groupes $SiMe_3$ et qui peuvent masquer le reste du spectre.[2] Les spectres de RMN du ^{13}C ont été enregistrés sur un appareil Bruker AC 250 fonctionnant à 62,9 MHz (C_6H_{12} réf. int. à 27,08 ppm) et ceux du ^{29}Si sur un appareil Bruker WH 500 fonctionnant à 99,32 MHz (TMS réf. int. à 0,0 ppm). Les spectres RMN ^1H ont été enregistrés sur les spectromètres Bruker AC 250 et Bruker WH 500 fonctionnant respectivement à 250 et 500 MHz (C_6H_{12} ref. int. à 1,4 ppm).

*Études radiocristallographiques des composés **2**, **4**, **5***

L'enregistrement des réflexions a été effectué sur un diffractomètre automatique CAD-4 Enraf–Nonuis en balayage $\omega/2\theta$ avec la radiation CuKα. Les détails expérimentaux sont rassemblés dans le tableau 2. Les mesures ont été corrigées des facteurs de Lorentz et polarisation. Les structures ont été résolues avec le programme MULTAN 80 (12). Les positions atomiques et les paramètres ther-

[2]Les caractéristiques physico-chimiques suivantes : spectres IR des composés **2** et **3**; spectre Raman du composé **2**; paramètres atomiques et écarts types des composés **2**, **4** et **5**, peuvent être achetés de : Dépôt des données non publiées, Service de fourniture de documents, ICIST, Conseil national de recherches Canada, Ottawa Canada K1A 0S2.

Les paramètres atomiques des composés **2**, **4** et **5** sont également disponibles au Cambridge Crystallographic Data Centre. On peut les obtenir en s'adressant au directeur, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, Royaume-Uni.

miques ont été affinés par moindres carrés avec la matrice diagonale.[2] Pour le dérivé **2**, le groupe d'espace centrosymétrique P_1 est nettement établi à partir des tests de centrosymétrie sur les facteurs de structure normalisés et conduit à $Z = 1$. La molécule est en position particulière sur le centre de symétrie. Pour le dérivé **5**, une variation significative et régulière des intensités de référence (environ 50% entre début et fin des mesures) a conduit à effectuer des corrections sur les mesures enregistrées. Le groupe spatial est $P2_1/n$ avec $Z = 2$; la molécule est en position particulière sur le centre de symétrie.

Le THF est distillé sur sodium et benzophénone afin d'enlever les traces d'eau et le Me_3SiCl sur Mg en poudre. Le lithium est préalablement granulé par fusion dans l'huile de vaseline puis lavé au THF. Le magnésium est utilisé en poudre. Les réactions sont conduites à la rampe à vide sous atmosphère d'argon.

Silylation par le système $Me_3SiCl/Li/THF$

Addition de MeSiCl

À une suspension de lithium finement granulé (0,28 g; 0,04 at.g) dans 150 mL de THF et 0,02 mol d'isoquinoléine (2,58 g) fraîchement distillée, on ajoute goutte à goutte 0,044 mol (4,75 g) de Me_3SiCl tout en maintenant la température entre 0 et 5°C. L'avancement de la réaction est suivi par CCM (SiO_2, hexane–EtOH 80 : 20). Au bout de 3 h, on note la disparition du produit de départ. Le THF est alors évaporé à la rampe à vide puis on ajoute 120 mL de cyclohexane, solvant dans lequel LiCl précipite, ce qui permet de l'éliminer par filtration. Le filtrat est ensuite évaporé et redissout dans 120 mL de cyclohexane afin d'éliminer les sels qui pourraient subsister. On obtient ainsi une huile jaune qui est redissoute dans 50 mL de cyclohexane et laissée au repos pendant 1 nuit. Dans ces conditions, le composé **2** précipite et est isolé par filtration à la rampe à vide (1,65 g; rdt. 30%). L'évaporation du filtrat conduit au composé **3**, isolé sous forme d'huile. Il est purifié par chromatographie sur silice (éluant : hexane–ether 80 : 20) (2 g; rdt. 50%). Il peut également être distillé, à condition toutefois d'opérer sous un vide inférieur à 0,01 Torr (1 Torr = 133.3 Pa). Dans le cas contraire, le chauffage entraîne l'isomérisation partielle de **3** en **3***a*.

cis,cis-ortho,ortho-(N,N'-*Bis-triméthylsilyl-2-aminoéthényl)-stilbène* (**2**) : rdt. 30%; *F* 158°C; IR (KBr cm^{-1}) : 1625, 1600, 1565; Raman (cm^{-1}) : 1629 (FFP), 1599 (FdP). RMN ^1H (500 MHz, $CDCl_3$) δ ppm : 0,09 (s, 18H, 4 $SiMe_3$), 6,03 (d, 1H, *J* 8,4 Hz), 6,17 (d, 1H, *J* 8,4 Hz), 7.18–7,21 (m, 2H), 7,20 (s, 1H), 7,56 (dd, 1H, *J* 6,9 et 1,9 Hz), 7,82 (dd, 1H, *J* 6,7 et 1.6 Hz). RMN ^{13}C ($CDCl_3$; 99,32 MHz) δ ppm : $SiMe_3$ à 2,0; 7 CH à 119,9, 126,4, 126,9, 127,1, 129,1, 130,3, 135,8; 2 C à 136,05 et 136,6. RMN ^{29}Si (C_6D_6, 200,132 MHz) δ ppm : 5,5. SM *m/e* (%) : 550 (26),478 (7), 477 (10), 390 (6), 202 (5), 176 (5), 175 (12), 174 (60), 172 (6), 130 (6), 74 (9), 73 (100), 59 (6), 45 (6), 28 (19). Anal. calc. pour $C_{30}H_{50}N_2Si_4$: C 65,38, H 9,15, N 5,08; trouvée : C 64,98, H 9,10, N 4,94.

2,2'- Bis-triméthylsilyl-1,1',2,2'- tétrahydro-1,1'- biisoquinoléine (**3**) : Eb 70°C/0,003 Torr; rdt. 50% par action du système $Me_3SiCl/Li/THF$ et 82% par action du système $Me_3SiCl/Mg/THF$. IR (NaCl, cm^{-1}) : 1610, 1560, 1490. RMN ^1H ($CDCl_3$, 250 MHz) δ ppm : 0,2(s, 9H), 4,4(s, 1H, H-1), 5,8(d, 1H, *J* 7,4 Hz), 5,9(d, 1H, *J* 7,4 Hz), 6,6–7,3(m, 4H). RMN ^{13}C ($CDCl_3$; 50,3 MHz) δ ppm : $SiMe_3$ à −0,27; 7 CH à 54,5, 105,5, 121,6, 123,9, 126,4, 127,4, 133,9; 2 C à 127,6 et 132,2. RMN ^{29}Si (C_6D_6, 99,32 MHz) δ ppm : 7,1.

2,2'- Bis- triméthylsilyl-1,1',2, 2'- tétrahydro-1,1'- biisoquinoléine (**3***a*) : il est obtenu par chauffage de l'isomère **3** (4,0 g; 0,02 mol) à 150°C pendant 3 h. La réaction est effectuée sans solvant sous atmosphère d'argon. Puis les cristaux obtenus sont rincés au cyclohexane afin d'éliminer les traces de l'isomère **3**.

3*a* : 3,5 g; rdt. 85%; *F* 163°C (hexane); IR (KBr, cm^{-1}) : 1608, 1560. RMN ^1H ($CDCl_3$, 500 MHz) δ ppm : −0,35 (s, 9H), 4,3 (s, 1H, H-1), 5,9 (d, 1H, H-4, $J_{4,3}$ 7,0 Hz), 6,4 (d, 1H, H-3, $J_{3,4}$ 7 Hz), 6,9 (d, 1H, *J* 7,3 Hz), 7,0 (dd, 1H, *J* 7,5 et 1,1 Hz), 7,1 (dt, 1H, *J* 7,3 et 1,3 Hz), 7,2 (dt, 1H, *J* 7,5 et 1,3 Hz). RMN ^{13}C (CD_2Cl_2 ; 50,3 MHz) δ ppm : $SiMe_3$ à −2,3; 7 CH à 53,6, 105,2, 121,9, 124,1, 126,6, 128,2, 128,9; 2 C à 128,4 et 132,7. RMN ^{29}Si (C_6D_6, 99,32 MHz) δ ppm : 9,9. SM *m/e* (%) : 203 (19), 202 (100, M/2), 129 (11), 73 (51). Anal. calc. pour $C_{24}H_{32}N_2Si_2$: C 71,23, H 7,97, N 6,92; trouvée : C 70,31, H 7,95, N 6,87.

Addition de l'isoquinoléine

À une suspension de lithium finement granulé (0,84 g; 0,12 at.g) dans 350 mL de THF et 0,12 mol (13 g) de Me_3SiCl fraîchement distillé, on ajoute goutte à goutte 0,02 mol (2,58 g) d'isoquinoléine de telle sorte que le température du milieu réactionnel soit maintenue entre 0 et 5°C. Les réactifs sont laissés en contact pendant 6 h puis le THF est évaporé à la rampe à vide et on effectue le traitement précédemment décrit. On isole ainsi une gomme orange (11,1 g) qui est redissoute dans 60 mL de cyclohexane afin de faire précipiter le composé **5**. Il est isolé, après 2 h de repos, par filtration (0,79 g; rdt. 8%). L'évaporation du filtrat conduit à une huile orangée très épaisse montrant plusieurs singulets indiscernables vers 0 ppm et l'absence de protons aromatiques en RMN ^1H. Elle est abandonnée à l'air pendant 1 nuit; une nouvelle analyse en RMN ^1H montre un éclatement des signaux centrés vers 0 ppm ainsi que l'apparition de plusieurs signaux entre 7 et 9,5 ppm. Le mélange est chromatographié sur silice (éluant : C_6H_{12}–Et_2O 70 : 30). On isole ainsi successivement les composés **7** (0,28 g; rdt. 5%), **6***a* (2,18 g; rdt. 31%), **6***b* (2,24 g; rdt. 32%), **9** (0,28 g; rdt. 5%) et **8** (0,57 g; rdt. 10%). Le mélange réactionnel a également été distillé à l'aide d'un four à boules. Dans ces conditions on isole les composés **7** (0,27 g; rdt. 5%), **6***a* (2,54 g; rdt. 36%), **6***b* (2,37 g; rdt. 34%) et **9** (0,28 g; rdt. 5%).

méso*2,2',3,3',5,5',6,6',7,7'-Décatriméthylsilyl-1,1',2,2',3,3', 5,5',6,6',7,7'-dodécahydro-1,1'-biisoquinoléine* (**5**) : rdt. 8%; *F* 198°C (Et_2O). RMN ^1H ($CDCl_3$, 500 MHz) δ ppm : −0,04(s, 9H), −0,01(s, 9H), 0,07(s, 9H), 0,14(s, 9H), 0,18(s, 9H), 1,3(dd, 1H, H-6, *J* 7,9 et 3,0 Hz), 1,8(signal large, 1H, H-7), 2,0(signal large, 1H, H-5), 3,3(dd, 1H, *J* 4,0 et 4,2 Hz), 5,4(d, 1*H*, *J* 5,3 Hz), 5,5(signal large, 1H). 6,7-Bis-triméthylsilyl-isoquinoléine (9) : R_f 0,30 (SiO_2; C_6H_{12}–Et_2O 50 : 50). RMN ^1H ($CDCl_3$, 250 MHz) δ ppm : 0,41(s, 9H, $SiMe_3$), 0,43(s, 9H, $SiMe_3$), 7,5(d, 1H, H-4, *J* 5,8 Hz), 8,1(s, 1H, H-5 ou H-8), 8,2(s, 1H, H-8 ou H-5), 8,5(d, 1H, H-3, *J* 5,8 Hz), 9,2(s, 1H, H-1). RMN ^{13}C ($CDCl_3$, 62,9 MHz) δ ppm : 2 $SiMe_3$ à 1,85 et 1,94; 5 CH à 120,1, 133,8, 134,7, 143,7 et 152,4; 4 C à 127,5, 134,5, 144,5 et 148,4. Anal. calc. pour $C_{15}H_{23}NSi_2$: C 65,86, H 8,48, N 5,12; trouvée : C 65,77, H 8,43, N 5,19.

Silylation par le système $Me_3SiCl/Mg/THF$

À une suspension de magnésium (0,84 g; 0,035 at.g) dans 120 mL de THF et 0,035 mol d'isoquinoléine (4,5 g) on additionne rapidement 0,038 mol de Me_3SiCl (4,1 g). Le mélange est ensuite porté au reflux pendant 4 h. Après évaporation du THF, on additionne 150 mL de cyclohexane et les sels de magnésium sont éliminés par filtration. Cette opération est répétée à nouveau puis le filtrat est évaporé. L'addition d'éthanol permet, en quelques minutes, de faire chuter le composé **3***a* qui est isolé par filtration (1,37 g; rdt. 19%). L'évaporation du filtrat conduit à **3** isolé sous forme d'huile (5,48 g; rdt. 77%). Ils sont identiques aux échantillons isolés par action du système $Me_3SiCl/Li/THF$ (addition de Me_3SiCl). L'addition de zinc en poudre (0,08 g) lors de la silylation permet de limiter la durée du chauffage à 2,5 h. Les rendements sont alors de 83% pour **3** et 14% pour **3***a*.

Acétylation

Le chlorure d'acétyle (0,044 mol; 3,45 g) préalablement distillé sur magnésium est additionné à 0,02 mol de **3** (8,08 g). Le mélange est agité à 0°C pendant 6 h, puis le solvant et l'excès de chlorure d'acétyle sont éliminés à l'évaporateur rotatif conduisant à un solide orangé (6,1 g) qui est recristallisé dans l'acétone. On isole ainsi **4** (5,5 g) qui présente les mêmes caractéristiques IR et RMN ^1H que le composé décrit par Nielsen (3).

2,2′-Diacétyl-1,1′,2,2′-tétrahydro-1,1′-biisoquinoléine (4) : rdt. 80%; *F* 195°C (acétone) (litt. (3) *F* 194–195°C). RMN ^{13}C ($CDCl_3$, 62,9 MHz) δ ppm : 1 CH_3 à 21,5; 6 CH à 52,5, 111,0, 124,2, 125,8, 128,0, 128,85; 2 C à 128,7 et 130,85; C=O à 169,1. SM *m/e* (%) : 172 (31), 130 (100), 73 (15), 43 (16), 28 (15). Anal. calc. pour $C_{22}H_{20}N_2O_2$: C 76,73, H 5,85, N 8,13, O 9,29; trouvée : C 76,80, H 5,87, N 8,09, O 9,19.

Remerciements

Ce travail a bénéficié d'une subvention des Laboratoires SARGET (Avenue J.F. Kennedy, BP 100, 33701 Mérignac Cédex) que nous remercions vivement en la personne de Monsieur C. Feniou.

Solution speciation in the aqueous Na(I)–EDTA and K(I)–EDTA systems

MIN CHEN and R. STEPHEN REID[1]
Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received October 28, 1992

MIN CHEN and R. STEPHEN REID. Can. J. Chem. **71**, 763 (1993).

Speciation in the aqueous sodium(I) – ethylenediaminetetraacetic acid and potassium(I) – ethylenediaminetetraacetic acid equilibrium systems was investigated by automated gravimetric potentiometric titration. It was found that in both cases, particularly below neutral pH values, speciation includes a previously uncharacterized diprotonated complex. All formation and acid dissociation constants were measured for the full systems. The validity of previous literature equilibrium constants, which are based on incomplete equilibrium models, is discussed.

MIN CHEN et R. STEPHEN REID. Can. J. Chem. **71**, 763 (1993).

Faisant appel à des titrages gravimétriques potentiométriques automatisés, on a étudié la spéciation des systèmes aqueux à l'équilibre des sels de sodium (ou de potassium) avec l'acide éthylènediaminetétraacétique. On a trouvé que, dans les deux cas, particulièrement à des pH inférieurs à ceux de la neutralité, la spéciation inclut un complexe diprotoné qui n'avait pas été caractérisé antérieurement. On a mesuré, pour tous les systèmes, toutes les constantes de formation et de dissociation. On discute de la validité des constantes d'équilibre rapportées antérieurement dans la littérature et basées sur des modèles d'équilibre incomplets.

Introduction

Ethylenediaminetetraacetic acid (EDTA) is a widely used metal-ion complexing agent. It finds considerable use in complexation titrations (1), and as a metal-sequestering agent in many different applications — for instance, in the sequential extraction of metal ions from soil and sediment samples (2). The complexation of EDTA with a large variety of metal ions has been investigated, and the relevant complex formation constants measured. These data have been compiled and reviewed on several occasions (3–5).

While the EDTA complexes with sodium and potassium ions are weak compared to those formed with many other metal ions, the complexation of EDTA by these two metal ions may be important in certain situations. Firstly, many environmental water samples contain these ions at high concentration, especially estuarine (brackish) or marine samples. So also do many biological fluids. Secondly, these ions (as "inert salts") are often used to adjust ionic strength and maintain it at a more or less constant value during equilibrium studies.

The Na(I)–EDTA and K(I)–EDTA systems have been studied a number of times (6–10). Literature formation constant values for complexes of 1:1 stoichiometry are given in Tables 1 and 2. However, this does not completely characterize the speciation in these mixtures. Neutral EDTA can lose four hydrated protons in a series of "acid dissociations."[2] In addition, since the coordination number of the alkali metal ions is generally 4–6 (11), there is the possibility that some EDTA coordinating groups are not in fact coordinated to the metal ion, or coordinated only weakly, in the complex. If so, the complex could also display one or more acid dissociations. A few of the literature studies (7, 10) have recognized the possibility of one protonation; none, to our knowledge, of two. A reaction scheme, using our established convention of representing metal complexation horizontally and protonation vertically (12), is given in Fig. 1.

If all species existing in any multiequilibrium system are not accounted for in modelling that system, it is axiomatic that the apparent equilibrium constants resulting, and any prediction of speciation made from them, will be to some extent in error. The observed poor agreement between values from different laboratories for the same constants (Tables 1 and 2) underlines this possible complication. Further, while studying the Gd(III)–EDTA system in the presence of Na(I) and K(I) in this laboratory (13), it became obvious that corrections for complexation by these ions based on literature constants were in error.

We therefore decided to investigate the complexation of EDTA by Na(I) and K(I) in more detail, using potentiometric titrations implemented on our previously developed gravimetric equilibrium autotitrator (14). Following the recommendation of Anderegg (4), tetramethylammonium hydroxide (TMA-OH) was employed as a strong base for titrations. (Because of the low charge density of the TMA^+ ion, it was assumed that its strength of complexation to EDTA is negligible. We evaluate this assumption below.) Ionic strength was maintained close to 0.15 M, using tetramethylammonium chloride (TMA-Cl). In addition to being close to a physiological value, this value of ionic strength has the advantage that ionic activity coefficients vary only slightly with variations in ionic strength in this region.

Experimental

Reagents

All chemicals used were of analytical grade and were used without further purification except as noted below. All solutions were prepared using distilled, deionized water (Millipore). Where applicable, materials were dried for about 2 h at 110°C before use to remove surface moisture.

Titration apparatus and conditions

Titrations were performed using a microcomputer-controlled gravimetric autotitrator, which is described elsewhere (14). Five replicate titrations were normally performed, of the "combination" type, with a constant potential increment (typically 4 mV) between successive additions of titrant, defaulting to a minimum

[1]Author to whom correspondence may be addressed.

[2]Neutral EDTA can also gain two additional protons, but only under extremely acidic conditions.

TABLE 1. Literature formation constants of 1:1 Na(I)–EDTA complexes

Medium/ionic strength	Temperature, °C	$\log(K_f)^a$	Reference

$$K_{fl} = \frac{[MY^{3-}]}{[M^+]\cdot[Y^{4-}]}\ ;\ K_{a1} = \frac{[H^+]\cdot[H_3Y^-]}{[H_4Y]}\ ;\ K'_{a1} = \frac{[H^+]\cdot[MYH^{2-}]}{[MYH_2^-]}$$

FIG. 1. Equilibrium scheme for the M(I)–EDTA system (M = K, Na), and definition of some typical equilibrium constants. Y^{4-} refers to fully deprotonated EDTA.

titrant addition of typically 0.0010 g in the region of the titration endpoint. Titrant solutions were degassed by the slow bubbling of argon gas through the solution for 10 min prior to titration. Titrant solutions were prepared under argon, using freshly boiled and cooled water, and dispensed from bottles equipped with soda-lime tubes, to prevent any carbonate contamination. Titrations were performed under an argon atmosphere at a temperature of 25 ± 1°C. A standard glass electrode/saturated calomel electrode setup was calibrated routinely using secondary standard buffers (BDH, nominal pH values 4.00, 7.00, and 10.00 ± 0.01), the exact pH values of which were established periodically by standardization against pH standard solutions prepared to NBS specifications (15).

Solutions for titrations

The ionic strength of all solutions was adjusted to approximately 0.15 M using TMA-Cl. A solution of TMA-OH of approximate concentration 0.02 M was standardized by titration against potassium hydrogen phthalate (KHP). An HCl solution of approximate concentration 0.006 M was standardized by titration against TMA-OH. Solutions of EDTA alone, and of approximate NaCl:EDTA ratios 4:1 and 20:1 and of KCl:EDTA 5:1 and 20:1, were prepared with an approximate concentration of EDTA of 0.001 M. This is close to the solubility of EDTA; in order to avoid any further dilution, 0.001 M EDTA was also added to the titrant (see above).

Data analysis

This was performed on a Dell System 310 80386 PC-standard microcomputer. A utility contained within SASKWATCH (the autotitrator software) automatically sets up titration data in suitable form for data analysis by the routine SUPERQUAD (16). Preliminary analysis and graphing was accomplished using Quattro Pro, Version 4.0 (Borland International).

Titrations performed

The exact shape of a potentiometric titration curve depends upon a large number of variables. These include the relative stoichiometry of the reactants (the concentrations initially added), the equilibrium constants, fundamental solution parameters (activity coefficients, the autolysis constant of water), and electrode parameters (slope and standard potential). Although in principle all these parameters could be determined in a single experiment, in practise this is not feasible. The optimal values for many of the parameters are strongly dependent upon each other, so large uncertainties result. A "divide and conquer" approach, involving sequential determination of parameters in systems of gradually increasing complexity, is preferable.

A summary of the titrations performed in the present study is given in Table 3. In the first set of titrations, the acidimetric standard KHP was titrated. The gravimetrically determined moles of KHP (T_{KHP}) and a literature value of the apparent molar ionic product of water (pK^c_w) were input to SUPERQUAD as constants. SUPERQUAD then refined estimates of the total moles of titratable proton (T_{H^+}), the concentration of the TMA-OH titrant (C_{OH^-}), $\log(K_a)$ for KHP, and (as for all titrations) the apparent electrode standard potential ($E^{0\prime}$). T_{H^+} was within experimental error of the value predicted from the mass of KHP used, confirming its purity. The value of pK^c_w was refined using a second set of titrations with an aqueous solution of HCl as titrand, determining also T_{H^+} for this solution. The third set of titrations assumed the values (determined in the first two sets) for pK^c_w and C_{OH^-}, and a gravimetrically derived value for the total moles of EDTA (T_{EDTA}). The values of the acid dissociation constants of free EDTA were refined, together with T_{H^+} (which again, on comparison with T_{EDTA}, confirmed the purity of the EDTA). Finally, in titrations of metal ion – EDTA mixtures, all values from previous titrations were assumed. T_{H^+}, T_M, and the log complex formation constants and the acid dissociation constants for metal-complexed EDTA were refined.

Results and discussion

Apparent molar ionic product of water (K^c_w)

This is defined as:

$$[1]\quad K^c_w = [H^+].[OH^-] = (a_H + .a_{OH^-})/(\gamma_M\cdot\gamma_{OH}) = K_W/(\gamma_M\cdot\gamma_{OH})$$

where K_w is the "true" or thermodynamic molar ionic product, a refers to activity, and γ to activity coefficient. The pK^c_w value yielded in this study is compared with literature values in Table 4. Agreement with the value of Anderegg in 0.1 M TMA-Cl is excellent (corrected using the Davies equation (19) to an ionic strength of 0.15 M, Anderegg's value is 13.92 ± 0.03). Furthermore, the value of mean activity coefficient obtained here (0.88) is in excellent agreement with the value estimated from electrode calibra-

TABLE 3. Summary of titrations performed, and refined (variable) and constant parameters. T refers to total moles of a substance, C to formal (added) concentration. See text for further definitions

Titrand	Variable parameters	Constant parameters
KHP	T_{H^+}, C_{OH^-}, $E^{0\prime}$, $\log(K_a)$	pK_w^c, T_{KHP}
HCl	T_{H^+}, $E^{0\prime}$, pK_w^c	C_{OH^-}
EDTA	T_{H^+}, $E^{0\prime}$, $\log(K_a)$	pK_w^c, T_{EDTA}, C_{OH^-}
EDTA + M[a]	T_{H^+}, T_M, $E^{0\prime}$, $\log(K_f)$, $\log(K_a')$	pK_w^c, T_{EDTA}, C_{OH^-}, $\log(K_a)$

[a]M = Na or K.

TABLE 4. Values of pK_w^c under various conditions

Medium/ionic strength	Temperature, °C	pK_w^c	Reference
0.1 M TMA-Cl	20	13.96(2)[a]	17
1 M TMA-Cl	20	14.11(2)	17
1 M KCl	20	13.96(2)	17
0.14 M KNO_3	25	13.753(2)	18
0.15 M TMA-Cl	25	13.89(1)	This work
0.15 M KNO_3	25	13.86(1)	This work

[a]Standard deviation (in terms of least-significant digit) in parentheses.

tion. (The standard potential of the electrode, E_0, obtained from calibration, and the apparent standard potential, E_0', obtained from the titration, are related by the expression:

$$[2] \quad E_0' = E_0 - S.\log\gamma$$

where S is the experimental "slope" of the electrode response, obtained from calibration. A value of $\gamma = 0.87 \pm 0.02$ was otained by this method.)

However, the present value of pK_w^c in TMA-Cl seems to compare only indifferently with that of Jameson and Wilson (18). The measurement was repeated in 0.1 M KNO_3 (see Table 3) to demonstrate that the identity of the electrolyte did not account for the discrepancy. Jameson and Wilson calculated pK_w^c based upon only 10 points on the titration curve, 5 each side of the titration endpoint. Simulation of this approach with our data showed that choice of the particular points used could significantly affect the value of pK_w^c obtained from the experimental data. The present value, based on the entire titration curve (60 or more points) was therefore considered more trustworthy and is used in further calculations below.

Acid dissociation constants of EDTA

These are shown in Table 5, together with some literature values. The fairly small differences observed can again be ascribed to variations in ionic strength, temperature, and possibly sophistication of data analysis.

Complex formation constants

A typical titration curve, for a titrand 0.001 M in EDTA and 0.004408 M in KCl, is shown in Fig. 2. Points represent experimental data; every second point is omitted for clarity. The line is calculated from the model of Fig. 1 using the mean equilibrium constants yielded by separately fitting the data from five replicate titrations to the model. Using SUPERQUAD, the experimental data were fitted to a series of multi-equilibrium models involving the successive addition of species MY^{3-}, MHY^{2-}, MH_2Y^-, and MH_3Y. SUPERQUAD has the ability to "reject" a species from a model if its inclusion seems unwarranted on statistical grounds. This occurred with the species MH_3Y. However, the other species were "retained" by SUPERQUAD and values of the relevant equilibrium constants with acceptable uncertainties were returned. Residuals decreased steadily as the first three species were added into the model. Residuals for the final model appeared randomly distributed and were well within those expected from experimental uncertainties. Results are given in Table 6.

The values of both formation constants are significantly larger than those previously reported, particularly in the potassium case (see Tables 1 and 2). This is because previous studies neglected the presence of the diprotonated complex MYH_2^-. To demonstrate this further, the portion of the present data in the pH range 7.5–11 was fitted to a model involving no diprotonated complex. The "$\log(K_f)$" values thus obtained were 0.57(2) and 1.75(1) for the K(I) and Na(I) cases, respectively, close to the corresponding values in Tables 1 and 2. However, even in this restricted pH region, there was some evidence (indifferent fit, trends in residuals) that the equilibrium model was incorrect. The importance of including the diprotonated complexes in an equilibrium model of these systems is therefore confirmed.

The pK_a' values are similar for the Na(I) and K(I) complexes, and similar also to pK_{a3} and pK_{a4} for free EDTA itself. Since these equilbria can be plausibly assumed to involve EDTA functional groups not involved in complexation, this is scarcely surprising. Which specific groups are involved cannot, of course, be determined by potentiometry, which can measure the overall status of protonation of a species, but gives no indication as to the site of protonation. We are currently studying the sites of protonation and metal-ion complexation in EDTA complexes by nuclear magnetic resonance spectroscopy.

Speciation in the Na(I)–EDTA and K(I)–EDTA equilibrium systems

The speciation in a 0.001 M EDTA/0.004 M Na^+ solution was calculated as a function of pH using a simple Turbo Pascal (Borland International) program, and is shown in Fig. 3. Figure 4 shows a similar plot for a 0.001 M EDTA/0.005 M K^+ solution. In both cases, maximal amounts of MH_2Y^- are observed in the pH range 4–5, and significant amounts up to and beyond neutrality. Obviously, any speciation calculations outside the fairly alkaline region

will be in error if they neglect the diprotonated complexes.

In viewing a titration curve such as Fig. 2, the temptation to attempt to analyze the curve intuitively may prove irresistible. However, use of Fig. 4 to determine the species present at each stage in the titration shows the pitfalls in such an approach. Although Fig. 2 shows two apparent "breaks" and two "buffer regions," these are due to multiple changes in the solution speciation, not to the titration of any one species. In fact, the gross shape of the titration curve is determined mainly by the titration of free EDTA species, the more interesting chemistry described here being "hidden" in the exact shape of the curve.

Complexation of TMA^+ with EDTA?

No effects of changing TMA concentrations not readily ascribable to simple activity coefficient effects were observed. It can be concluded that if TMA–EDTA complex(es) form, it is to an extent negligible even by the standards of K^+ and Na^+.

Conclusions

This study has reexamined the Na(I)–EDTA and K(I)–EDTA equilibrium systems. It has been shown that a full description of speciation, particularly below pH 7, must include the presence of a diprotonated complex. All relevant formation and acid dissociation constants have been measured.

More generally, the study provides a cautionary tale. It suggests that other literature equilibrium studies, especially

Determination of Al, P, and Si in fruit juices stored in glass and aluminized containers

K. SOLIMAN, L. ZIKOVSKY,[1] AND C. DALLAIRE[2]

Institut de génie énergétique, École polytechnique de Montréal, C.P. 6079, Succursale "A", Montréal (Québec), Canada H3C 3A7

Received April 10, 1992

K. SOLIMAN, L. ZIKOVSKY, and C. DALLAIRE. Can. J. Chem. **71**, 769 (1993).

The concentration of Al, P, and Si in 142 samples of five fruit juices, measured with neutron activation analysis and atomic absorption spectroscopy, varies from 0 to 1.44, 31 to 201, and 1.5 to 35 μg/mL, respectively. The mean concentration of Al in apple, grape, grapefruit, orange, and pineapple juices is 0.54, 0.94, 0.24, 0.29, and 0.62 μg/mL, respectively. The mean concentration of P in the same juices is 102, 115, 124, 127, and 76 μg/mL. The storage of juice in aluminized containers with internal plastic coating does not increase the concentration of Al in the juice.

K. SOLIMAN, L. ZIKOVSKY et C. DALLAIRE. Can. J. Chem. **71**, 769 (1993).

Les concentrations d'Al, de P et de Si, mesurées par activation neutronique et par absorption atomique, dans 142 échantillons de cinq types de jus de fruits varient de 0 à 1,44, 31 à 201 et 1.5 à 35 μg/mL respectivement. Les concentrations moyennes d'Al mesurées dans les jus de pomme, de raisin, de pamplemousse, d'orange et d'ananas sont égales à 0,54, 0,94, 0,24, 0,29 et 0,62 μg/mL respectivement. Les concentrations moyennes de P dans les mêmes jus sont égales à 102, 115, 124, 127 et 76 μg/mL respectivement. L'utilisation de récipients en carton aluminisé avec un revêtement interne en plastique n'augmente pas les teneurs en Al de ces jus.

Introduction

Aluminum is the third most common element and the most abundant metal. It has historically been regarded as nonessential and nontoxic. Recently there has been an increase in reports of aluminum toxicity from environmental exposure. Aluminum has been implicated in the pathogenesis of a number of clinical disorders ranging from cancer and renal osteodystrophy to Alzheimer's disease (1). Its toxicity towards the central nervous system has been demonstrated in several mammalian species (2). Despite all this, there are many researchers who believe that aluminum can safely be used with food, and that the correlation between Alzheimer's disease and Al is purely coincidental (3). Thus the question concerning the toxicity of aluminum remains quite controversial. The food industry is using aluminum-coated paper with internal plastic coating for some juice containers. This implies that aluminum could be leached out of the packing material by the juice. For this reason, neutron activation analysis and atomic absorption spectroscopy were used to measure the concentration of aluminum in juice stored in glass and aluminized containers, to see if there is any difference in the leaching behaviour of these containers.

Experimental procedure

The juices were bought from stores in Montreal while the fresh juices were prepared by hand extraction from fruits. Because aluminum is ubiquitous in our environment, all handling of samples was done in a clean room. No metal tools were used and, of course, no aluminum. The juice was transferred directly from its container to a plastic irradiation vial. Each sample was irradiated in a Slowpoke reactor for 200 s, at a flux of 10^{12} n cm^{-2} s^{-1}. The juice was then transferred into a new vial (in 60 s or less) and counted for 600 s. The γ-ray spectra were analyzed and the concentrations were calculated using the semi-absolute method (4). Phosphorus and silicon can interfere with the determination of aluminum and these elements were also measured in some samples. To determine phosphorus, the juices were irradiated for 15 min at a flux of 10^{12} n cm^{-2} s^{-1}, left to decay for 28 days, mixed with a liquid scintillator (Aquasol), and β-counted for 10 min with a Packard Tricarb analyzer. The silicon content was determined by atomic absorption spectroscopy.

Results and discussion

The aluminum concentration was determined using the following nuclear reaction: Al-27 (n, γ)Al-28. Unfortunately, Al-28 can also be produced from P or Si via the reactions: P-31(n,α)Al-28 and Si-28(n,p)Al-28. The results obtained for Al must be corrected for these nuclear interferences. In our case, the interference factor (5) for the first reaction is 690 and for the second 207. This means that 690 μg/mL of P or 209 μg/mL of Si would produce an apparent concentration of 1 μg/mL of aluminum. For this reason, some of the juices studied were also analyzed for P and Si. The concentrations found (Table 1) vary from 31 to 201 μg/mL for P and from 1.5 to 35 for Si. These data can be compared with values cited by Quaranta et al. (6) for fresh strawberries (P: 180 μg/mL; Si: 21 μg/mL). The mean concentration of P found in the juice was then divided by the interference factor for P (690), and subtracted from the apparent Al concentration.

For Si, the mean concentration is 11.5 μg/mL. Considering its interference factor of 207, its concentration to the activity of 28-Al is less than 0.06 μg/mL and was neglected.

The mean concentration of Al (corrected values) determined in the fruit juices studied is listed in Table 1. It varies from 0.17 to 1.3 μg/mL. These concentrations are low when compared with other elements.

To decide whether the difference of mean concentrations of juices packaged in different containers is statistically significant, the Student's *t*-test for small samples was used (7). The hypothesis that there is essentially no difference between the mean concentrations was tested at a 0.01 level of significance (t_{995}). The results obtained are listed in Table 2. There are five cases (out of 11 possibilities) where the difference between the aluminized and glass containers is sig-

nificant. But there are also four cases (from seven) where juices prepared by two different companies and packaged in aluminized containers have significantly different concentrations. There are also concentration differences between the fresh juice and the juice sold in a glass container (two cases out of five possibilities) or in an aluminized container (two cases out of five). Consequently, we conclude that the observed differences are due to the processing or the natural variation rather than to the effect of the container. The higher concentrations of Al in juices may be caused by contamination during preparation.

Finally, it is useful to estimate the potential intake of Al from juices with the amount ingested from all other sources. This amount has been estimated (8) to be 30–50 mg of aluminum per day. We have calculated the overall mean concentrations (and their standard deviations) of Al in the juices studied. They are equal to 0.55(0.32), 0.94(0.33), 0.24(0.13), 0.29(0.18), 0.62(0.39) for apple, grape, grapefruit, orange, and pineapple juice, respectively. If we assume the consumption of 1 litre of juice per day, based on our data, the daily intake of Al would vary from 0.24 to 0.94 mg. This amounts to 0.1–3% of the total intake. Consequently, the contribution of fruit juices to the total aluminum intake seems to be minor.

Conclusions

The concentration of aluminum in commercial fruit juices is low when compared with other elements (Ca,K,Na). The use of aluminized containers for the packaging of juices does not seem to increase the concentration of Al in the packaged juice. The concentration of Al in juice varies considerably, probably as a result of contamination during processing. Finally, aluminum from juice constitutes a minor contribution to the total daily intake of aluminum.

LUIS GARCÍA RODENAS, PEDRO J. MORANDO, MIGUEL A. BLESA, STELLA DUHALDE, and CELIA SARAGOVI. Can. J. Chem. **71**, 771 (1993).

A mixed Fe,Cr oxide formed of maghemite and chromium hydrous oxide was prepared by oxidative precipitation at 90°C. Mineral acids dissolve the chromium phase very quickly, whereas iron dissolves slowly and independently; there is little mutual influence in the dissolution behaviour. Calcination of this oxide at 600°C yields a mixture of α-Fe_2O_3 and $Cr_{1.3}Fe_{0.7}O_3$ that leaches iron slowly upon acid attack. The reactivity of the oxide towards H^+ is largely determined by the degree of crosslinking of the Cr-containing phase. Oxidative attack (by $KBrO_3$) increases the rate of dissolution of both Cr and Fe, against simple expectations that Fe dissolution rates might be reduced. This effect is of importance in chemical cleaning and decontamination of stainless steels. This influence of acidity and $[BrO_3^-]$ are interpreted in terms of the formation of surface $\equiv$Cr(III)-O-Br(V) species that evolve to produce $Cr(VI)_{aq}$. These surface complexes form more readily than analogous solution species, making surface Cr(III) more readily oxidizable than aqueous (Cr(III).

LUIS GARCÍA RODENAS, PEDRO J. MORANDO, MIGUEL A. BLESA, STELLA DUHALDE et CELIA SARAGOVI. Can. J. Chem. **71**, 771 (1993).

On a préparé un oxyde mixte de Fe et de Cr par précipitation oxydante, à 90°C, de maghemite et d'oxyde de chrome hydraté. Les acides minéraux dissolvent la phase chromée très rapidement alors que le fer ne se dissout que lentement et d'une façon indépendante; il n'y a que peu d'interaction mutuelle sur le comportement de dissolution. La calcination de cet oxyde à 600°C fournit un mélange d'oxydes formé de α-Fe_2O_3 et de $Cr_{1.3}Fe_{0.7}O_3$ qui, sous l'influence d'acide, ne relargue le fer que lentement. La réactivité de l'oxyde vis-à-vis des H^+ est grandement déterminée par le degré de réticulation de la phase contenant du chrome. Alors qu'on s'attendait à ce que les vitesses de dissolution du Fe pourraient être réduites, une attaque oxydante (par du $KBrO_3$) augment la vitesse de dissolution du Cr ainsi que celle du Fe. Cet effet est important lors du nettoyage chimique et la décontamination des aciers inoxydables. On interprète l'influence de l'acidité et de la $[BrO_3^-]$ en fonction de la formation à la surface d'espèces $\equiv$Cr(III)-O-Br(V) qui évoluent pour conduire à des espèces $Cr(VI)_{aq}$. Ces complexes de surface se forment plus facilement que les espèces analogues en solution et rendent les espèces Cr(III) de surface plus susceptibles à l'oxydation que les espèces aqueuses correspondants.

[Traduit par la rédaction]

Introduction

Chemical dissolution of metal oxides is important in a wide variety of fields, ranging from materials science (1–3) to environmental science (4–6), and even including aspects of biochemistry such as the mobilization of iron in living organisms (7, 8). Two very important metal oxides are those of chromium(III) and iron(III); their dissolution behaviour has been amply studied by us and by others (9–16). Both oxides may dissolved by acid attack, although very drastic conditions are required in the case of α-Cr_2O_3 (G. B. Reartes, P. J. Morando, M. A. Blesa, P. Hewlett and E. Matijević, unpublished results). More importantly, both oxides are prone to redox dissolution; the chemical conditions conducive to fast dissolution of iron(III) oxides include the presence of reductants capable of reducing surface $\equiv$Fe(III) complexes, usually via inner sphere mechanisms (12). On the other hand, chromium(III) oxides are better dissolved by strong oxidants (17). Inspection of the corresponding Pourbaix diagrams are especially illustrative of these drastically differing behaviours (12).

Examples of cases in which dissolution of these oxides is important include the chemical cleaning of metal surfaces, microbiological corrosion, hydrometallurgy, corrosion of Fe- and Cr-based ceramic oxides, environmental fate, and availability of both metals in natural media, etc.

One important point that has not yet been addressed is the cross effects appearing in the dissolution behaviour when both oxides are present. This is a matter of importance both in the case of single-phase mixed oxides such as $FeCr_2O_4$ and in the case of complex mixtures of two or more phases containing either or both metal ions.

The first case, the dissolution of well-defined binary oxidic phases, has been conceptually analyzed by Valverde (18), who suggested that the overall behaviour may be determined either by the fast-dissolving metal oxide or by the more passive one. Current work in our laboratory is directed to the experimental study of the important iron chromite $FeCr_2O_4$ (L. García Rodenas, P. J. Morando, and M. A. Blesa, unpublished results).

The second case is of widespread occurrence in practice. Preferential leaching of minerals, behaviour of multiphase ceramic oxides, and the chemical cleaning of stainless steel surfaces are examples. Thus, oxide films grown or deposited onto stainless steels are complex mixtures of Cr(III) and Fe(III) oxides, as evidenced, e.g., by in-depth profiling studies using X-ray photoemission spectroscopy (XPS)

techniques (19, 20). It is therefore not surprising that the most efficient processes developed to clean stainless steel surfaces are composed of two stages, an oxidative one to attack chromium(III) (hydrous) oxides, and a reductive one to remove iron(III) (hydrous) oxides (21). In principle, the efficiency of the two-stage cleaning procedures may be interpreted simply in terms of noninteracting processes, the oxidative stage leaving the iron oxides practically unaffected, and the chromium oxide behaving as impervious to the reductive attack.

By contrast, in all analyses of the leaching of minerals, the importance of the evolution of surface area is stressed, and many types of complex behaviour are found in practice.

The purpose of this paper is to determine experimentally the degree of mutual influence evidenced in the dissolution behaviour of multiphase Cr,Fe oxides by studying the acid and the oxidative attack of coprecipitated Cr/Fe (hydrous) oxides. The acid attack is used here as an alternative to reductant attack; both procedures are efficient in dissolving iron oxides and ineffective in dissolving chromium from crystalline α-Cr_2O_3. The aggressiveness of acid toward chromium oxides is a sensitive measure of the degree of crosslinking, as demonstrated in this and a related paper (17). The degree of crosslinking is measured by the average coordination number of oxygen atoms; in a highly crystalline material such as α-Cr_2O_3 this number is four, and it decreases as the hydration/hydroxylation of the material increases (42). The study of the dissolution of mixed oxides by acids therefore provides a tool to explore the changes in their reactivity patterns as the chromium-containing phase becomes more crystalline.

Experimental

Materials

Two types of synthetic mixed oxides were used.

Oxide A was prepared by oxidative precipitation of 600 cm^3 of 0.155 M $FeSO_4$ and 0.065 M $Cr(NO_3)_3$ upon addition of 30 cm^3 NH_3 27 wt.%, in the presence of 0.2 M $NaNO_3$. The atomic ratio Fe/Cr = 2.6 in solution was chosen to adjust the ratio in the resulting solids; both ratios were similar. Precipitation was carried out at 90°C. This procedure differs in several aspects from that reported by Schwertmann and Cornell (22) to synthesize Cr-substituted goethites. The most important differences in our preparation are the stronger oxidizing conditions and the lower alkalinity that lead to a fast total oxidation of Fe(II), and to total precipitation of Cr(III). The scanning electron micrograph (SEM) observed in Fig. 1 was obtained using a Philips SEM 500 electron microscope and showed the presence of irregularly shaped polydisperse particles, without evidence for gel-like amorphous material. The oxidative procedure used here is known to yield crystalline product in short reaction times (23). X-ray diffraction (XRD) showed that the resulting solids were mixtures of maghemite (γ-Fe_2O_3) and chromium(III) (hydrous) oxide ($Cr(OH)_3 \cdot 3.3\ H_2O$). Using elementary analysis data for Fe and Cr (38.0 and 14.8 wt.% respectively), the solid is found to be composed of 54 wt.% γ-Fe_2O_3 and 46 wt.% $Cr(OH)_3 \cdot 3.3\ H_2O$. According to Schwertmann and Cornell (22), crystalline goethite particles incorporate up to 12% Cr (referred to total metal content, on an atomic basis) when synthesized from solutions containing Cr(III). If Cr-substitution in γ-Fe_2O_3 was also operative in our case, the actual composition of the mixture was somewhat different. For example, for a 12% substitution, the composition would be 61 wt.% $Fe_{1.8}Cr_{0.2}O_3$ and 39 wt.% $Cr(OH)_3 \cdot 3.3\ H_2O$. Our structural characterization and the results of the kinetic experiments are not sensitive enough to derive an experimental value for the degree of Cr-substitution in γ-Fe_2O_3. The BET specific surface area was 54 $m^2\ g^{-1}$.

Oxide B was obtained by calcining oxide A at 600°C during 45 min in a N_2 atmosphere. It was characterized by X-ray diffraction using a Philips X-ray generator PW 1130 and by Mössbauer spectroscopy. Mössbauer spectra were obtained in a transmission geometry with a source of ^{57}Co in Rh matrix and the measurements were carried out with the source at room temperature and the absorber, in powder form, at room temperature and liquid N_2 temperature. Mössbauer spectra were least-squares fitted employing pure Lorentzian shapes and constraining the peak intensities to

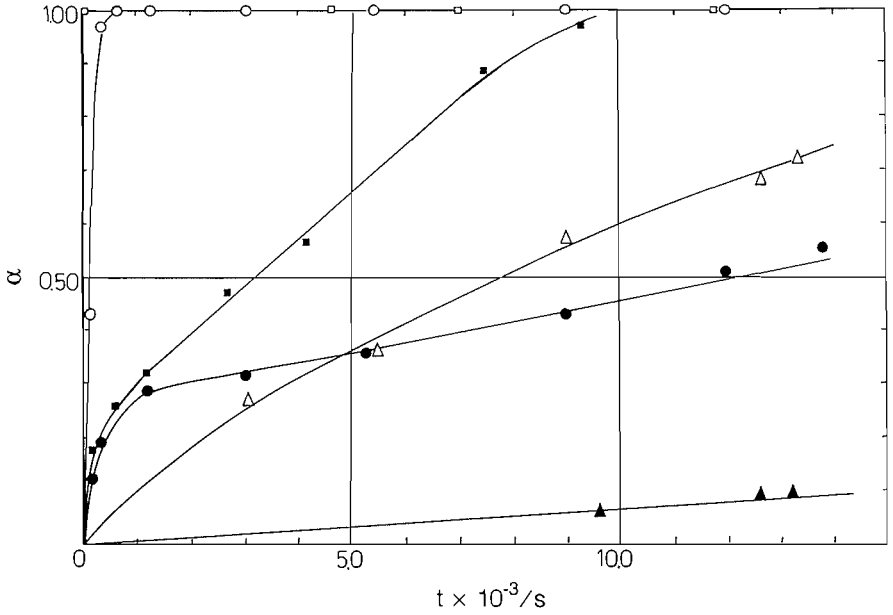

FIG. 2. Fraction (α) of dissolved Fe (full symbols) and Cr(III) (empty symbols) from oxide A vs. time at 65°C: ▲, △: 10^{-2}; ●, ○: 0.5; and ■, □: 2.5 mol dm^{-3} H_2SO_4.

satisfy the 3:2:1 ratio in the case of sextets; the quality of each computer fit was checked by a χ^2 test. The results of the structural characterization are given below. The BET area decreased to 15 m^2 g^{-1} in the calcination procedure, and the assay of Cr (19.0 wt.%) and Fe (50.8 wt.%) indicated total dehydration while maintaining the same Fe:Cr ratio.

All reagents were analytical grade; water was bidistilled.

Procedure

Dissolution experiments of oxides A and B were performed in a magnetically stirred cylindrical beaker provided with a jacket connected to a thermostat. Temperature was controlled to 65.0 ± 0.1°C. In a typical experiment, oxide A or B (ca. 12 mg) was poured over 100 cm^3 of solution containing the appropriate oxidant and acid concentrations. Samples of 1 cm^3 were taken periodically with a syringe and filtered through a 0.45 μm cellulose acetate membrane. Care was taken to withdraw the samples under strong stirring to avoid changes in the surface area/volume ratio.

Cr(VI) and total Fe were measured spectrophotometrically using diphenylcarbazide (24) and thioglycolic acid (25), respectively. In the acid dissolution experiments, total Cr was measured by atomic absorption spectrometry (AAS) using a Varian AAR 5 spectrophotometer, to explore the possible presence of Cr(III).

Results and discussion

Oxide A dissolution

Figure 2 shows the fraction of dissolved iron and chromium α ($\alpha = w_0 - w/w_0$, where w is the mass of solid at time t and w_0 is the initial mass) as a function of time in 0.01, 0.5, and 2.5 M H_2SO_4 at 65°C. Chromium dissolves very quickly as chromium(III), whereas the dissolution of maghemite is slower. Table 1 shows the initial rates, $R_0 = (d\alpha/dt)_{t=0}$, for both metals. The iron dissolution rate can be compared with literature data. Sidhu *et al.* (26) reported an initial dissolution rate of maghemite in 0.5 M HCl of 4.98×10^{-10} mol Fe m^{-2} s^{-1} at 25°C and an activation energy of 84.9 kJ mol^{-1}. Extrapolation to 65°C yields $R_0 = 2.79 \times 10^{-8}$ mol Fe m^{-2} s^{-1}, i.e., a factor 5.5 lower than our result in 0.5 M H_2SO_4. Although a contribution to this difference produced by the change in acid (H_2SO_4 vs. HCl) cannot be totally ruled out, the most important factor is certainly the influence of the different preparative methods on the extent of defects associated to imperfect coordination polyhedra: Sidhu *et al.* (26) heated magnetite at 220°C for 3 h whereas our samples were precipitated at 90°C and not subjected to further heat treatment. As shown previously (27), important changes in reactivity are caused by annealing of coordination polyhedra defects.

Figure 3 shows the fraction of dissolved iron and chromium in an experiment with 2.5 M H_2SO_4 in the presence of 0.1 M $KBrO_3$ at 65°C. As expected, bromate does not noticeably influence the iron dissolution rates. Chromium dissolution rates are also not affected by bromate (cf. Figs. 2 and 3). The inset of Fig. 3 shows the data from two different experiments. In the first one, the evolution of Cr(III) and Cr(VI) concentration in the dissolution of oxide A in $KBrO_3$ (0.1 mol dm^{-3}) and H_2SO_4 (2.5 mol dm^{-3}) at 65°C was measured. In the second one, the oxidation of a solution of $Cr(NO_3)_3 \cdot 9H_2O$ was monitored. This solution contained an initial concentration of Cr(III) equal to the final concentration of total chromium in the first experiment. The curve obtained shows that the appearance rate of Cr(VI) coincides in both experiments and therefore demonstrates that chromium is dissolved essentially as Cr(III).

In the strong acidic medium chosen for this study, the hydrous chromium(III) oxide is highly reactive to acids, and each metal oxide behaves nearly independently.

Oxide B characterization

To interpret the dissolution experiments, it was necessary to know in detail the nature of the phases present in oxide B. This was essentially achieved by using Mössbauer spectroscopy. Chemical analyses and XRD data could be interpreted as indicative of mixtures of $(Fe_xCr_{1-x})_2O_3$ and α-Fe_2O_3, but independent values of x and of the chromite:hematite ratio could not be derived from this information. Available ASTM diffraction pattern cards (28) suggested $Cr_{1.3}Fe_{0.7}O_3$ and α-Fe_2O_3. The relative amounts of these phases would be 43 and 57 wt.%, respectively, from the elementary Cr and Fe analysis data, but this interpretation required better substantiation.

Figure 4 shows a typical Mössbauer spectrum of oxide B. The fitting of the spectrum requires the inclusion of at least two sextets, and better fitting results are obtained if a third one is included.

Table 2 shows the parameters that best fit the observed three sextets. The H sextet parameters indicate the existence of hematite and the c_1 and c_2 sextet parameters correspond to those of the $(Fe_xCr_{1-x})_2O_3$ system (29). The linewidths of these two sextets are broad (0.6 mm s^{-1}) pointing to a distribution of similar Fe-ion environments, which is characteristic of Fe_2O_3–Cr_2O_3 solid solutions. It is possible to find the relative concentration of chromite and hematite using the corresponding area ratio (30). Using the fitted values, this ratio is 1:1.27 assuming equal f values for the hematite and chromite and the formula $Cr_{1.3}Fe_{0.7}O_3$ for this last component. This result is in reasonable agreement with those obtained from the stoichiometry 1:1.33. Moreover, the low values obtained for the c_1 and c_2 magnetic fields support the assigned x value for the iron content in the chromite. In addition to the magnetic signals, a significant contribution of a central doublet is apparent in Fig. 4; this disappears when the temperature is lowered, the associated Mössbauer signal probably merging with the magnetic signals.

Oxide B dissolution

At 65°C, 2.5 M H_2SO_4 does not attack chromium and dissolves iron only very slowly (α = 0.08 in 120 min). Assuming that the chromite is not attacked, the initial rate of dissolution of the purely ferric phase α-Fe_2O_3 is calculated to be R_0 = 7.66 × 10^{-8} mol Fe m^{-2} s^{-1}, i.e., ca. 2 times slower than that of γ-Fe_2O_3 in oxide A. Because of the lower reactivity of α-Fe_2O_3 compared to γ-Fe_2O_3 (31) and the decrease in surface area, the results do not indicate any special decrease in reactivity in iron oxides, although the initial rates measured in this work may reflect the contribution of the nonmagnetic phase responsible for the doublet in the Mössbauer spectrum. On the other hand, extensive cross-linking and dehydration of the Cr-containing phase brings about the drastic decrease observed in the rate of Cr dissolution. Over long periods, this effect should produce a passivation of iron, which can only be leached through the passive $Cr_{1.3}Fe_{0.7}O_3$ phase.

Figure 5 shows a typical α/t profile using 0.05 M $KBrO_3$

and the same acid concentration and temperature as above. In this case, iron is released from both phases, $Cr_{1.3}Fe_{0.7}O_3$ and α-Fe_2O_3. Assuming congruent dissolution for the first phase, Fig. 5 can be replotted showing the iron fraction released from each phase separately. The results are shown in Fig. 6 for different oxidant concentrations. Table 3 shows the R_0 values calculated for each phase from Fig. 6, on the assumption that the specific surface areas of both phases were equal.

Dependence of $R_0(Cr_{1.3}Fe_{0.7}O_3)$ *on oxidant concentration*

The $Cr_{1.3}Fe_{0.7}O_3$ phase dissolution rates are first order with respect to the oxidant concentration. The data in Table 3 yield

$$[1] \quad R_0(Cr_{1.3}Fe_{0.7}O_3) = k\,[BrO_3^-]$$

where $k = 1.28 \times 10^{-5}$ mol Cr m^{-2} s^{-1} M^{-1}.

The oxidative dissolution of α-Cr_2O_3 with $KBrO_3$ was studied recently (17). In agreement with the present results, it was found that α-Cr_2O_3 dissolution rates increase with increasing oxidant concentration. Small deviations from linearity, together with evidence from related Cr_2O_3 dissolution by other oxidants, lead us to postulate a Langmuir–Hinshelwood equation to describe the rate (17):

$$[2] \quad R_0 = \frac{R_{0\max}\,[BrO_3^-]}{1/K_s + [BrO_3^-]}$$

where K_s is the adsorption constant of BrO_3^- on the surface Cr(III) sites. K_s and $R_{0\max}$ values were 1.3 dm^3 mol^{-1} and 2.0×10^{-5} mol Cr m^{-2} s^{-1}, respectively. Our present data can be described by the same K_s value and can be fitted with a slightly lower $R_{0\max}$ value of 1.35×10^{-5} mol Cr m^{-2} s^{-1}.

Dependence of R_0 *(α-*Fe_2O_3*) on oxidant concentration*

In principle, it could be expected that the α-Fe_2O_3 dissolution would not be affected by the oxidant concentration.[2] However, the α-Fe_2O_3 dissolution rate increases with increasing BrO_3^- concentration. The data in Table 3 fitted by linear least squares yield

$$[3] \quad R_0(\alpha\text{-}Fe_2O_3) = k_1 + k_2\,[BrO_3^-]$$

where $k_1 = 1.11 \times 10^{-7}$ mol Fe m^{-2} s^{-1} and $k_2 = 4.80 \times 10^{-6}$ mol Fe m^{-2} s^{-1} M^{-1}. The influence of BrO_3^- on the rate of dissolution of α-Fe_2O_3 disappears when all $Cr_{1.3}Fe_{0.7}O_3$ has dissolved (see Fig. 6). It is concluded that eq. [3] represents the effective increase in the specific surface area of α-Fe_2O_3 brought about by the oxidative dissolution of the chromite. Thus, the presence of chromium phase makes the hematite also less reactive, passivation is only broken by oxidative attack, and iron oxide dissolution rates increase with increasing oxidant concentration. As an example of a practical consequence of this behaviour, it should be expected that the first stage of two-stage procedures to dissolve oxide films grown onto stainless steels (oxidative attack) may produce an important release of iron, especially in cases where acidic oxidants are used (32). Iron release is not necessarily restricted to the second, reducing/complexing, stage.

Dependence of R_0 *on acid concentration*

The dependences of the initial dissolution rates R_0 on the concentration of H_2SO_4, HNO_3, and $HClO_4$, at constant oxidant concentration ($[BrO_3^-]$ = 0.1 M) and temperature (65°C) are shown in Fig. 7 for both phases. A linear dependence is observed:

$$[4] \quad R = k_3[\text{acid}]$$

Table 4 shows the k_3 values for each phase in different

[2]As mentioned, these rates may include a contribution from the nonmagnetic phases that should also be insensitive to bromate concentration.

mineral acids. Hematite dissolution is accelerated by a factor of ca. 3.6 when sulfuric acid is substituted for $HClO_4$ or HNO_3 of the same molar concentration. The main factor seems to be that HSO_4^- is as effective as H_3O^+ as an acid; in addition, these results are in line with the known influence of sulfate on acid dissolution, through the formation of surface ≡Fe(III)-SO_4^{2-} complexes (33). The possibility of dissociative chemisorption of HSO_4^- (M. A. Blesa, unpublished) is a related phenomenon with the same consequences. In the case of $Cr_{1.3}Fe_{0.7}O_3$ the increase of ca. 50% in the rate of dissolution when sulphuric is substituted for perchloric acid can again be attributed to the increased acidity of the medium. This conclusion is supported by complementary rate measurements in HNO_3 in the presence of

K_2SO_4: the rate of Cr dissolution is unaffected by the substitution of HSO_4^- for HNO_3, whereas the overall Fe dissolution rate is increased, probably due to the complexing effect on hematite.

Reactivity of chromium in the oxide B

The kinetics of Cr(III) surface oxidation by BrO_3^- were compared with those of the hydrated dissolved species $Cr(H_2O)_6^{3+}$. The amount of aqueous Cr(VI) formed by reaction with 0.1 M $KBrO_3$ from dissolved $Cr(NO_3)_3 \cdot 9\ H_2O$ and from an oxide B suspension, both with the same initial Cr(III) content, are plotted in Fig. 8. To compare R_{homog}/[Cr(III)] and R_{heter}/[active sites], the active sites concentration was calculated using eq. [5]:

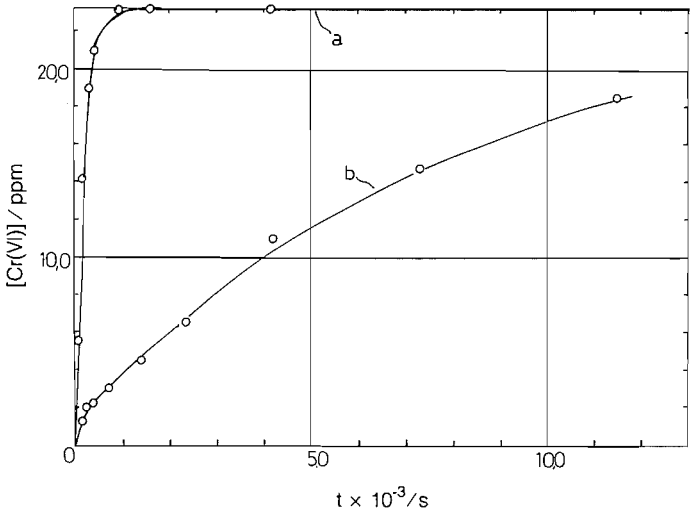

FIG. 8. (*a*) [Cr(VI)] from an oxide B suspension and (*b*) from $Cr(NO_3)_3 \cdot 9\ H_2O$ solution by reaction with 0.1 mol dm^{-3} $KBrO_3$, both with the same initial Cr(III) content (23.2 ppm).

$$[5] \quad [\text{active sites}] = N_s S_e w / V$$

where S_e = specific surface area. w = weight of chromite, and V = volume of solution. N_s, the number of active sites per unit area, was estimated to be ~5 sites nm^{-2}, or 8.30 μmol m^{-2} (the literature value for KF absorption on α-Fe_2O_3 (34) is 10 sites nm^{-2} and for EDTA adsorption on magnetite varies between 1.2 and 2.4 sites nm^{-2} depending on pH (35)).

The resulting ratios are (R_{heter}/[active sites]) = 3.6×10^2 dm^3 mol^{-1} s^{-1} and (R_{homog}/[Cr(III)]) = 1.7 dm^3 mol^{-1} s^{-1}. Surface Cr(III) in oxide B is oxidized ca. 2×10^2 times faster than the hydrated species $Cr(H_2O)_6^{3+}$. A probable rationale for this finding is provided by the surface complexation approach to describe dissolution kinetics (42). If the rate of substitution on BrO_3^- to form the precursor complex determines the rate, as found in homogeneous oxidations by BrO_3^- (36, 37), rate enhancement may be related to a higher rate of formation of interfacial ≡Cr(III)-O-BrO species as compared to aqueous Cr(III)-O-BrO. Whereas it is reasonable to assume that substitution on BrO_3^- controls the rate of homogeneous oxidation, a very substantial increase in this rate on the surface of the oxide may lead to a shift in rate control to subsequent steps involving the redox evolution of the surface complex and (or) phase transfer of Cr in higher oxidation states.

Metal oxide dissolution is in essence an electrochemical phenomenon. The kinetics of dissolution must therefore comply with the standard electrochemical formalisms, and the importance of the potential drop profile across the interface must be taken into account. Electrochemical descriptions of the dissolution of iron oxides and chromium oxides are available both from our previous work (17, 33) and from the work of other authors (38, 39). Two effects are incorporated in the influence of surface potential: (*a*) the influ-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

ence on ionic adsorption; and (*b*) the influence on the kinetics of ionic phase transfer (Butler–Volmer kinetics). The surface complexation model in the simplest version used above neglects the second effect; this approximation is justified in cases in which the rate-determining step precedes the phase transfer step (for further discussion of this point see ref. 42). For oxides grown or deposited onto metals the electrochemical nature of the dissolution reaction results in further complications that obviously must be taken into account, especially in chemical cleaning applications. For instance, the underlying metal is not indifferent in the course of Fe_3O_4 dissolution from carbon steel films (40, 41).

Thermal organosolv glycol lignins and their fractions have been characterized by means of elemental composition, molecular weight distribution, and ^1H and ^{13}C NMR spectroscopy. Fractionation of each lignin by sequential solvent extraction produced fractions of increasing molecular weight and polydispersity. Structures in the highest molecular weight fractions were found to be linked by a high proportion of β-*O*-4 type bonds, whilst the lowest molecular weight fractions consisted of a high content of saturated aliphatic side-chain structures. A noticeable difference in the content of carbohydrate contaminants in both starting lignins indicated the formation of relatively stable lignin–carbohydrate complexes, especially in the lignin recovered from pretreated wood. In addition, depolymerization of the lignins and their fractions to monomeric compounds was explored using alkaline hydrolytic and nitrobenzene oxidative routes. The highest molecular weight fractions from each lignin were identified as the best candidates for production of useful monomeric phenolic compounds.

RONALD W. THRING, ESTEBAN CHORNET et RALPH P. OVEREND. Can. J. Chem. **71**, 779 (1993).

En se basant sur la composition élémentaire, la distribution des poids moléculaires et la RMN du ^1H et du ^{13}C, on a caractérisé les lignines thermiques de l'organosolv glycol et leurs fractions. Le fractionnement de chaque lignine par extraction séquentielle par les solvants a fourni des fractions de poids moléculaires et de polydispersités croissants. On a trouvé que les structures des fractions de poids moléculaires les plus élevés sont liées en grande partie par des liaisons de type β-*O*-4 alors que celles des fractions de poids moléculaires plus faibles comportent de grandes quantités de chaînes latérales aliphatiques saturées. On a noté une différence notable dans le contenu en hydrates de carbone des deux lignines; elle indique qu'il y a formation de complexes lignine – hydrate de carbone relativement stables, particulièrement dans la lignine récupérée du bois prétraité. On a de plus examiné la dépolymérisation des lignines et de leurs fractions en composés monomères par hydrolyse alcaline et par oxydation avec du nitrobenzène. Pour la production de composés phénoliques monomères utiles, on a identifié que les fractions de poids moléculaires les plus élevés de chacune des lignines seraient les plus appropriées.

[Traduit par la rédaction]

Introduction

New developments in lignocellulosic fractionation technologies by aqueous-steam (1) and solvolytic treatments (2, 3) have demonstrated that clean, uncontaminated lignins with a low degree of polymerization can be obtained in significant yields.

Our laboratory has recently carried out a number of studies of the fractionation of lignocellulosics and succeeded in isolating one or more of the three constituent polymers in high yields by aqueous-steam (4, 5) and solvolysis treatments (6–9). To achieve the last objective, we have studied two strategies: (*a*) direct solvolysis using ethylene glycol, whereby the lignin and hemicelluloses are preferentially solubilized, leaving the cellulose virtually intact as a residue (6–9); (*b*) a sequential aqueous-steam and solvolytic treatment in which all three fractions are isolated in high yields from the same initial substrate (10, 11). The two strategies were applied to the prototype hardwood aspen poplar (*Populus deltoides*).

One of our goals is to deduce the structural changes induced in each polymer as a function of the conditions of fractionation of the wood. This information will provide the basis for further upgrading studies on each wood constituent to valuable products. In one study, using the direct solvolysis approach, we found a similarly produced lignin to be a potential source of monomeric compounds (7, 12). Fractionation of this lignin by sequential extraction with organic solvents demonstrated that it consisted of fractions of distinct molecular weight also showing structural differences (13).

The objectives of this paper then are twofold. The first objective is to elaborate on an earlier comparative study by us (9) on the properties of lignins (subsequently designated as thermal organosolv lignin (TOL) and thermal organosolv lignin from pretreated wood (PTOL), respectively) isolated by strategies (*a*) and (*b*) above. A detailed characterization study on the lignins and their fractions by elemental composition, molecular weight distribution, and ^1H and ^{13}C NMR spectroscopy is reported here. An assessment of the potential of the lignins and their fractions as a source for production of monomeric phenolic compounds is also presented. Alkaline hydrolysis and nitrobenzene oxidation were selected as the two modes of depolymerization due to their simplicity in experimental technique as well as the relatively small number of monomers produced in rather significant yields (i.e., high selectivity) when compared to other methods of lignin degradation (14).

Experimental

Apparatus

Reactor

A 500-mL stainless steel autoclave equipped with a magnetic stirrer was used for the depolymerization experiments. Heating and cooling were provided by a preheated salt bath (for hydrolysis) or an oil bath (for oxidation) and a cold water bath, respectively, such that heating and quenching periods did not exceed 6 min each.

Gas chromatographs

A Hewlett–Packard 5890A gas chromatograph equipped with a DB-5 capillary column (0.25 mm i.d. and 60 m column length) was used for analyses of the ether solubles from the hydrolysis runs. The carrier gas was helium at 1.2 mL/min. A DB-1 wide-bore column (0.53 mm i.d. and 30 m length) was used for analyses of the ether solubles from the alkaline nitrobenzene oxidation runs.

Chemicals and reagents used were of pure or analytical grade. Samples for preparing standards for quantifying the monomers identified were purchased from Aldrich Chemicals Co. and Alfa Chemicals Co. (U.S.A.).

Materials and methods

Sample preparation

The isolated thermal organosolv lignins were fractionated into three fractions by successive extraction on 125-g dry samples with ethyl acetate followed by methanol (13). The detailed method of fractionation employed has already been presented (15). All samples were kept in a desiccator over Drierite until further use.

Analytical techniques

1. *Elemental composition*: Analyses were conducted in-house using a Perkin Elmer 240C instrument. Oxygen was determined by difference as (100 − C% − H% − N%).

2. *Sugar analyses*: The carbohydrate content was estimated from determination of the total amount of identifiable monosaccharides present according to the acid hydrolysis procedure (16).

3. *High-pressure solvent elution chromatography (HPSEC)*: Analyses by HPSEC were carried out by using a Varian model 5000 liquid chromatograph connected to an on-line computer via a Waters Maxima 820 data system. Two sets of two stainless steel columns connected in series were used; the columns (300 × 7.5 mm) were packed with PLgel spherical particles from Polymer Laboratories (UK). The first set consisted of 5-μm particles of 50 Å (column 1) and 500 Å (column 2) porosity. The second set consisted of 10-μm particles of 10^4 Å (column 1) and 10^5Å (column 2) porosity. Detection was made with a UV monitor at 254 nm. A constant flow rate through the system was maintained by a single piston, reciprocating pump. The following operating conditions were employed: eluent, degassed tetrahydrofuran (purged with N_2); flow rate, 1 mL/min; pressure, 7.0 MPa; temperature, 25°C; injection volume, 10 μL; sample concentration, 1 mg/mL.

4. *^1H and ^{13}C NMR*: Both NMR spectra were recorded on samples (ca. 800 mg/2 g of solvent) dissolved in DMSO-d_6. The instrument used was a Brüker 250 WM spectrometer. The carbon-13 spectra were recorded at a frequency of 62.9 MHz with broad band decoupling, in the Fourier transform mode, and without nuclear Overhauser effect (NOE). A pulse tip angle of 45° and a time delay of 16 s were used, and the transients were accumulated at a sweep width of 20 kHz with 6800 data points. The solvent was used as the reference.

5. *Acetylation*: Analyses by both HSPSEC and NMR methods were conducted on lignin samples that were acetylated using a previously described procedure (13).

Depolymerization

1. *Alkaline hydrolysis*: Lignins and fractions were each subjected to hydrolytic treatment in alkali media using a 500-mL top-stirred batch autoclave. Reaction conditions selected were those previously reported for producing the highest amount of identifiable monomeric compounds from a similarly produced lignin (7).

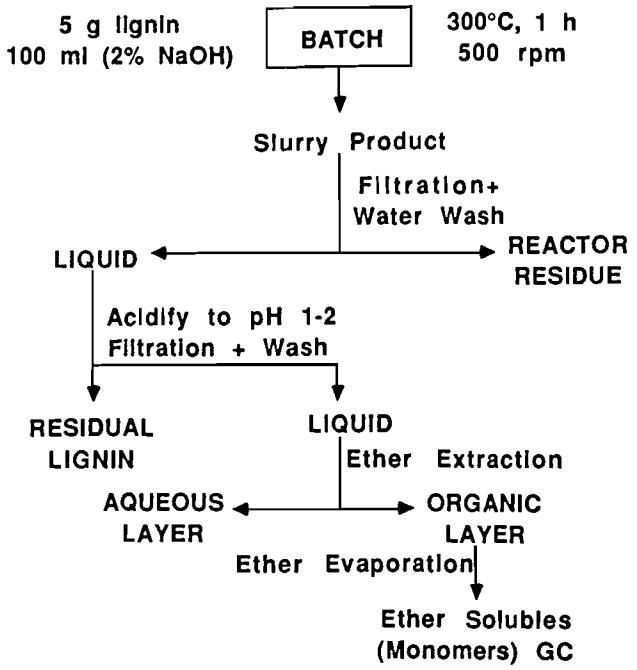

FIG. 1. Procedure for product work-up after alkaline hydrolysis of TOL and PTOL lignins and their fractions.

These conditions were 100 mL of 2% (w/w) sodium hydroxide solution, 5 g of sample, temperature of reaction 300°C (held for 1 h). Throughout the reaction period, the reactor contents were agitated at 500 rpm.

After the desired treatment, the reaction was quenched by immersing the reactor in a cold-water bath maintained with running water. The products were decanted and the reactor washed with water. The combined washings and product liquids were stored in 250-mL bottles at −18°C for subsequent analysis.

The procedure employed for product work-up is presented in Fig. 1.

2. *Nitrobenzene oxidation*: The experiments were conducted in the same autoclave as above. Amounts of initial sample and reactants used per run were as follows: 5 g of dry sample, 120 mL of 2 N sodium hydroxide solution, and 16 mL nitrobenzene. Reaction conditions were 180°C held for 1.5 h, 500 rpm agitation. The amounts of reactants used and the product separation methodology were based on the work of Pepper et al. (17).

After reaction, the combined washings and product liquids were stored in 250-mL bottles at −18°C prior to work-up by the following procedure. The solution was initially extracted (5×) with 100 mL of ether to remove the excess nitrobenzene. The aqueous layer was then acidified with 10% (v/v) hydrochloric acid to a pH of 1–1.5, filtered, and the filtrate extracted with ether until the last ether extract was judged to be colourless. The combined ether extracts were evaporated to constant weight under reduced pressure at room temperature, leaving an oily yellowish fraction as residue.

Product identification: A portion of the ether-soluble fraction was derivatized by the acetic anhydride – pyridine procedure and directly analysed by gas chromatography (18). Compounds were identified by comparing their peak retention times to those of authentic samples. Response factors were determined for each compound to be quantified and tests on a standard blend showed the deviation to be within 5% of the true value for the majority of compounds. Both GC columns were found to give similar response factors and errors, using 4-ethylresorcinol as the internal standard. The following oven program was found to produce good product separation for both columns: initial temperature, 65°C; rate,

Results and discussion

It should be pointed out here that a first characterization of the starting lignins via elemental composition, solvent fractionation, molecular weight distribution, and ^{13}C NMR has already been made in a related article (9). The data are only included here for ease of comparison with the corresponding fractions.

Elemental composition

The values of the carbon, hydrogen, nitrogen, and oxygen content listed in Table 1 are average values from duplicate analyses of the same sample. Both starting lignins have a comparable carbon content whose magnitude provides a first indication of their low degree of condensation and high purity (i.e., low in carbohydrate contaminants). The fractions (Fr) from both starting lignins each show a small increase in C content (and a decrease in O) with increase in fraction number. This trend has been attributed to differences in the proportions of syringyl to guaiacyl units in fractions from a similarly isolated lignin (13) (also see complementary data below). The same behaviour has also been reported for organosolv lignins extracted from cooking spruce chips at increasing times by the Organocell process (19). These authors attributed this trend to the presence of organic nonlignin substances, namely, extractives and sugar degradation products. Chua and Wayman (20), in their work on the characterization of autohydrolysis lignins, also reported the presence of nonlignin portions, and postulated that incorporation of hemicelluloses into the lignin may occur during autohydrolysis.

Carbohydrate content

The total amount of monosaccharides (five sugars) from the starting lignins TOL and PTOL was estimated to be 0.6 wt.% and 4.1 wt.%, respectively.

HPSEC

As seen in Figs. 2 and 3, both solvolysis lignins yield three fractions of increasing molecular weight when subjected to sequential solvent fractionation. The yields of these fractions have been presented and interpreted in a related article (9). Other important observations in the chromatograms of the two lignins and corresponding fractions are as follows. Both starting lignins exhibit multimodal distribution patterns, with TOL showing a larger low molecular weight peak, whose maximum corresponds to 300 g/gmol (polystyrene equivalent), than PTOL. This implies that TOL contains a high proportion of low molecular weight material. This is to be expected since it has been found that, under optimal conditions of operation of the aqueous-steam unit for recovery of the sugars from *Populus deltoides*, almost 20 wt.% of the protolignin in the wood is invariably removed with the hemicelluloses (4, 6). This lignin was extractable from the filtrate using ethyl acetate, suggesting that it is of low molecular weight. Fr-1 from PTOL exhibits more high molecular weight material than the corresponding fraction isolated from TOL.

Table 2 shows the weight and number average molecular weight values (polystyrene weight equivalent) M_w and M_n, respectively, and polydispersity M_w/M_n. The M_w and M_n values are slightly higher for TOL and PTOL lignin, suggesting that PTOL is more depolymerized to lower molec-

[a]Acetylated samples, M_w and M_n, are polystyrene weight equivalent values.

ular weight material during its isolation. The values for Fr-1 and Fr-2 from TOL are lower than the corresponding ones from PTOL, indicating that the latter contains more material of higher molecular weight in the low and medium molecular weight fractions than the former.

A steady increase is observed in both polydispersity and molecular weight for fractions from Fr-1 to Fr-3 from both lignins. This shows that Fr-1 contains materials of essentially similar molecular weight whereas Fr-3 comprises more of a mixture of medium and high molecular weight materials.

Alkaline hydrolysis

Among the advantages found in utilizing this method for depolymerizing lignin are that the yields of monomeric products can be significant and the spectrum of products as a whole is not extensive. The technique has been applied by a number of other workers (21–23). Depolymerization patterns of a glycol lignin similarly produced by alkaline hydrolysis have also been mapped by us (7) via the reaction ordinate, a severity parameter that combines the effects of temperature and time into a single variable. Optimum reaction conditions were determined for the production of important identifiable monomers, namely, catechol and its methyl and ethyl derivatives, which made up 9 wt.% of the initial lignin added to the reactor.

The same reaction conditions (see experimental section) were employed here. Table 3 shows the results for both lignins and their fractions. The low content of reactor residue from all the samples suggests that little or no recondensation of the lignin occurred due to cross-linking reactions between the lignin fragments during the alkaline treatment. The highest values were from the lowest molecular weight fraction, particularly Fr-1 from PTOL. This agrees with results from nitrobenzene oxidation (see below), which indicated that this fraction contains the highest amount of condensed structures, which are rather resistant to degradation. Also, the presence of nonlignin components or a stable lignin–carbohydrate complex (LCC) in this fraction, which are not only resistant to degradation by alkaline hydrolysis but are insoluble in the alkaline medium, may account for the high amount of reactor residue.

The total yield of catechols from each sample is approximately 7.5 wt.% of the initial sample, except from Fr-3 (PTOL). For the experimental conditions employed, this fraction produced the highest yield of catechols, namely, 9.06 wt.% of the initial sample, further revealing that it contains the highest amounts of guaiacyl and syringyl units, which would give rise to catechols upon demethoxylation and (or) demethylation during alkaline hydrolysis. Nitrobenzene oxidation and ^{13}C NMR (see below) have all demonstrated that indeed this particular fraction has the highest content of guaiacyl and, especially, syringyl units.

Alkaline nitrobenzene oxidation

This depolymerization technique has been widely used for characterizing protolignin in order to deduce its structural features as well as any changes in extracted lignins caused by the method of isolation (24–26). As has been demonstrated by Leopold (27) in studies on lignin model compounds, lower yields of aromatic aldehydes are obtained upon the alkaline nitrobenzene oxidation of condensed lignin structures (i.e., carbon-carbon linked). The method has been applied to isolated lignins to deduce their degree of condensation (25) and to compare the structural features of wood lignins in different wood species (17). We applied the method here to elucidate if significant structural differences exist between TOL and PTOL lignins as well as between their respective fractions.

The results are shown in Table 4. The yields of identifiable monomers suggest that moderate structural differences do exist between TOL and PTOL lignins. In particular, the lower yield of the total aromatic aldehydes in PTOL indicates that it is more condensed than TOL. The lower value of the syringaldehyde/vanillin (S/V) ratio in PTOL than in TOL strongly suggests that the lignin extracted during the aqueous-steam treatment was richer in syringyl than guaiacyl units. The same observation was reported by Wayman and Chua (25) in their work on the characterization of extracted autohydrolysis lignin from aspen wood.

Yields of 4-hydroxybenzaldehyde are seen to be the same from both starting lignins; they are highest in the lowest molecular weight fractions, particularly in Fr-1 from TOL, and decrease with increasing fraction number. On the other hand, the yield of 4-hydroxybenzoic acid from PTOL lignin is somewhat higher than that found in TOL lignin. For both lignins, the yield of this acid generally increases with increasing fraction number, and is lowest in Fr-1 from TOL lignin. The presence of 4-hydroxybenzoic acid structures in different tissues and lignins isolated from hardwoods was previously demonstrated by Venverloo (28). That work showed that higher yields of this acid are obtained during the alkaline hydrolysis of native lignin than for lignin isolated from the same wood species. Thus, in our work, the low yields of both aldehyde and acid obtained upon alkaline nitrobenzene oxidation of both TOL and PTOL lignins indicate that some of these compounds are split off during the isolation of the lignins. The loss is almost identical in both lignins.

The yields of aromatic aldehydes were lowest in Fr-1 from both lignins, and highest in Fr-3, suggesting that the latter contains the highest amount of uncondensed syringyl units. Fr-1 (PTOL), in particular, produced the lowest amount of aromatic aldehydes, indicating that it contains the highest amount of condensed structures, which makes it the least amenable to oxidative degradation to phenolic aldehydes.

By virtue of the high aromatic aldehyde content, which reflects their uncondensed nature, Fr-2 and Fr-3 in particular may be valuable as prepolymers in phenolic resin applications or as a source of chemicals via specific catalytic bond cleavage. Fr-1, on the other hand, due to its low molecular weight and high hydroxyl content (especially phenolic) (see ^{13}C NMR below) may prove useful in the adhesives area.

Ether solubles	53.33	44.13	60.76	60.85	51.37	42.36	58.69	54.13

Also, it was postulated by Wayman and Chua (25) that the obtention of low yields of aromatic aldehydes is due to the incorporation, by physical or chemical means during autohydrolysis, of nonlignin materials such as carbohydrate degradation products. As suggested by Klemola and Nyman (26), furfural and its precursors might react with lignin to form new carbon–carbon bonds, thus giving rise to a more condensed, stable material.

The data reported so far show that moderate differences exist between the monomers, isolated with slightly higher yields, produced from TOL than PTOL. The higher yields of 4-hydroxybenzaldehyde from the Fr-1 fractions than from the corresponding initial lignins suggest a higher content of 4-hydroxybenzoic acid residues in this fraction. Further evidence for this is the presence of a higher amount of aromatic hydroxyl groups in this fraction (see ^{13}C NMR below). In fact this fraction was previously reported to have the highest content of total hydroxyl (aromatic + aliphatic) groups (13). The syringyl/guaiacyl (S/V) ratio has been reported to be an important criterion for assessing the degree of condensation of a lignin (25). Syringol is excluded in the S/V calculation because it is not an aromatic aldehyde, and is produced only in trace quantities (unlike syringaldehyde and vanillin) during the alkaline nitrobenzene oxidation of lignin. From Table 4, no significant differences can be observed in the S/V ratios for Fr-2 and Fr-3 except that the values for TOL are slightly higher than those from PTOL. However, a clear distinction is seen when comparing the S/V values of the Fr-1 fractions to the others. The low values obtained in Fr-1 again confirm the high guaiacyl content, as was previously reported (13). The lowest value of Fr-1 (PTOL) suggests that pretreatment by autohydrolysis of the initial wood removed more syringyl than guaiacyl moieties from the lignin.

Nuclear magnetic resonance

^1H NMR

The proton NMR spectra of TOL and PTOL lignins and their fractions are shown in Figs. 4 and 5, respectively. The assignments of peaks recorded in Table 5 are in accordance with those of other workers (29–32).

From Fig. 4, the intensity of the signal of acetates due to aromatic hydroxyl protons decreases steadily from Fr-1 to Fr-3, suggesting a decrease in aromatic hydroxyl bearing units (e.g., catecholic) with increase in fraction number. The same trend is seen in the spectra of the PTOL fractions, as shown

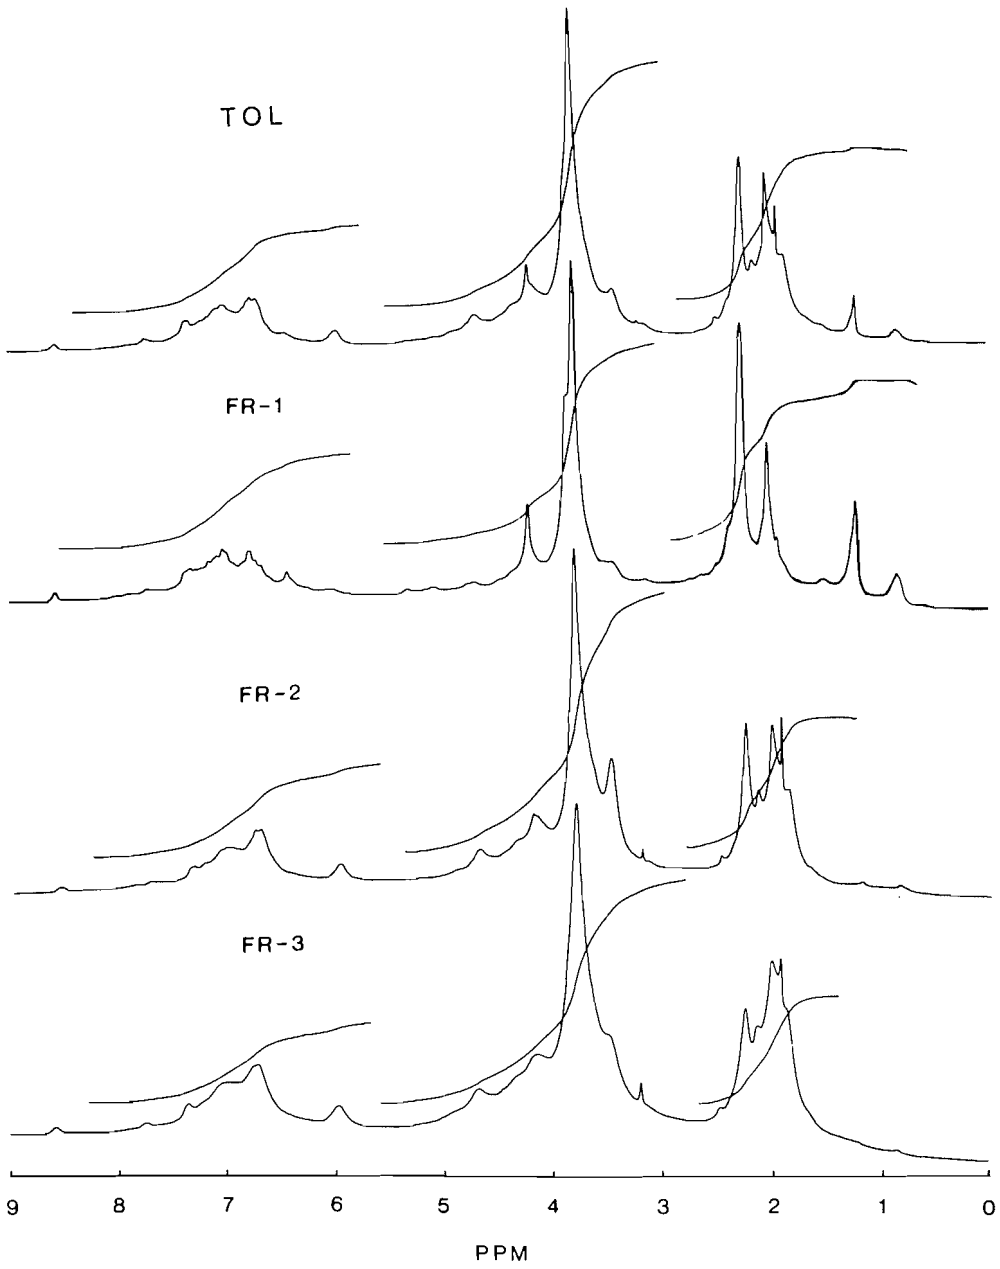

FIG. 4. ^{1}H NMR spectra of acetylated TOL lignin and its fractions; solvent, DMSO-d_6.

in Fig. 5. For both lignins, Fr-1 exhibits the highest intensity of signals at 4.2 ppm (H-α in β-*O*-4) and 0.9–1.3 ppm (methyl, methylene protons), which suggests that these fractions contain the most β-*O*-4 interlinkages and aliphatic saturated structures. The strong sharp signals at about 2 ppm and at 3.3 ppm are significant in the fractions from PTOL, and may also arise from carbohydrate contaminants (29, 33). As seen, the intensity of the sharp signal at 3.3 ppm increases steadily from Fr-1 to Fr-3 in PTOL, indicative of a possible increase in carbohydrate contamination from Fr-1 to Fr-3.

The signals in the 1.9–2.2 ppm region have also been attributed to protons on saturated or reduced side chains (34). The high intensity of these signals in this case would indicate that fractions from PTOL contain more structures whose side chains are saturated than the corresponding fractions from TOL. The intensity of signals between 4.2 and 6.4 ppm (due to protons attached to carbons involved in aryl ether bonds) in Fr-2 and Fr-3 from PTOL are lower in intensity than in the spectra of the corresponding fractions from TOL. This strongly supports the interpretation that more β-*O*-4 linkages have been cleaved during the isolation of PTOL than TOL. In particular, the intensity of the signal at 6.03 ppm (H-α in β-aryl ether bonds) is higher in Fr-2 and Fr-3, but is almost absent in Fr-1 of both lignins, suggesting that the former fractions contain more structures linked by β-aryl ether linkages than the latter. This is confirmed by the results from ^{13}C NMR below and nitrobenzene oxidation.

The spectra of Fr-1 from each lignin display a marked difference in the 6.4–8.0 ppm region (protons attached to aromatic carbons). This implies that the aromatic character of this fraction is distinct from that of the starting lignin and its higher fractions, whose spectra are more similar in appearance.

TABLE 5. Assignments of signals in the ^{1}H NMR spectra of acetylated TOL and PTOL lignins and their fractions; solvent DMSO-d_6

Chemical shift (ppm)	Assignment
0–1.6	Hydrocarbon protons
1.6–2.2	H of aliphatic acetates/acetylated carbohydrates
2.2–3.0	H of aromatic acetates
3.0–4.2	H of methoxyl groups
4.2–6.4	Hα, Hβ, Hγ in β-*O*-4 structures
6.4–6.8	Aromatic protons in syringyl units
6.8–8.0	Aromatic protons in guaiacyl units
8.0–10.0	H of carboxylic acid groups

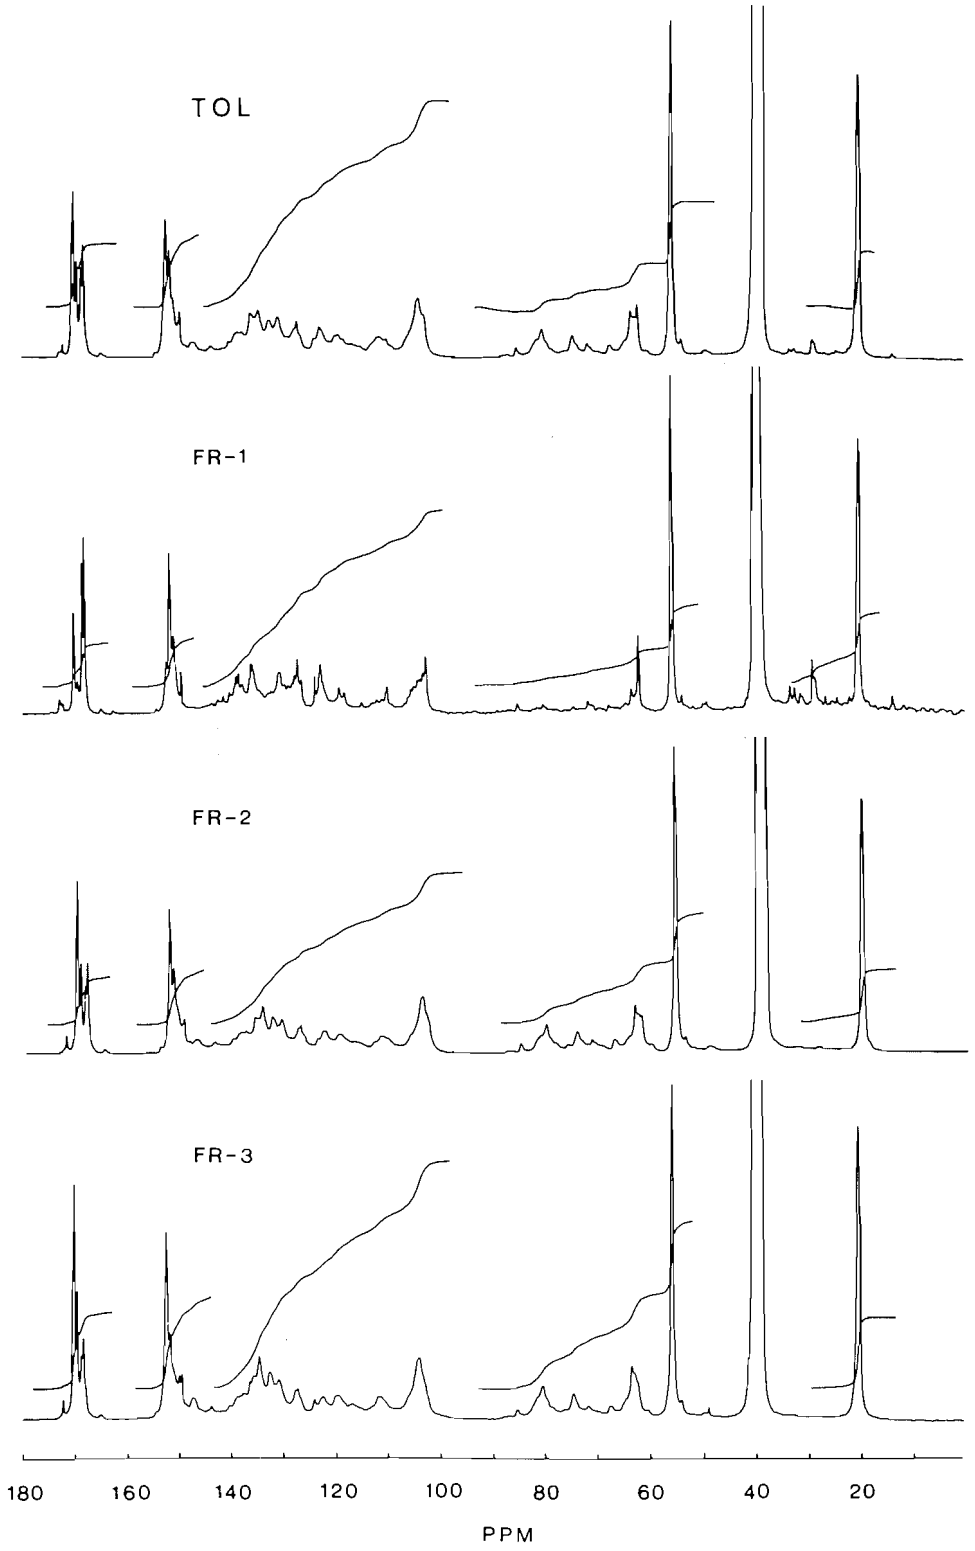

FIG. 6. ^{13}C NMR spectra of acetylated TOL lignin and its fractions; solvent, DMSO-d_6.

The signals between 8 and 9 ppm, assigned to protons of carboxylic acid groups, are more intense in PTOL and its fractions but are very weak in TOL and its corresponding fractions. This suggests that these groups are formed during the aqueous-steam pretreatment (also confirmed by ^{13}C NMR below).

^{13}C NMR

The ^{13}C NMR spectra of TOL and PTOL lignins and their corresponding fractions are shown in Figs. 6 and 7, respectively. The assignment of peaks can be found in other related work and in one of our articles (13).

As we shall see below, the major differences between

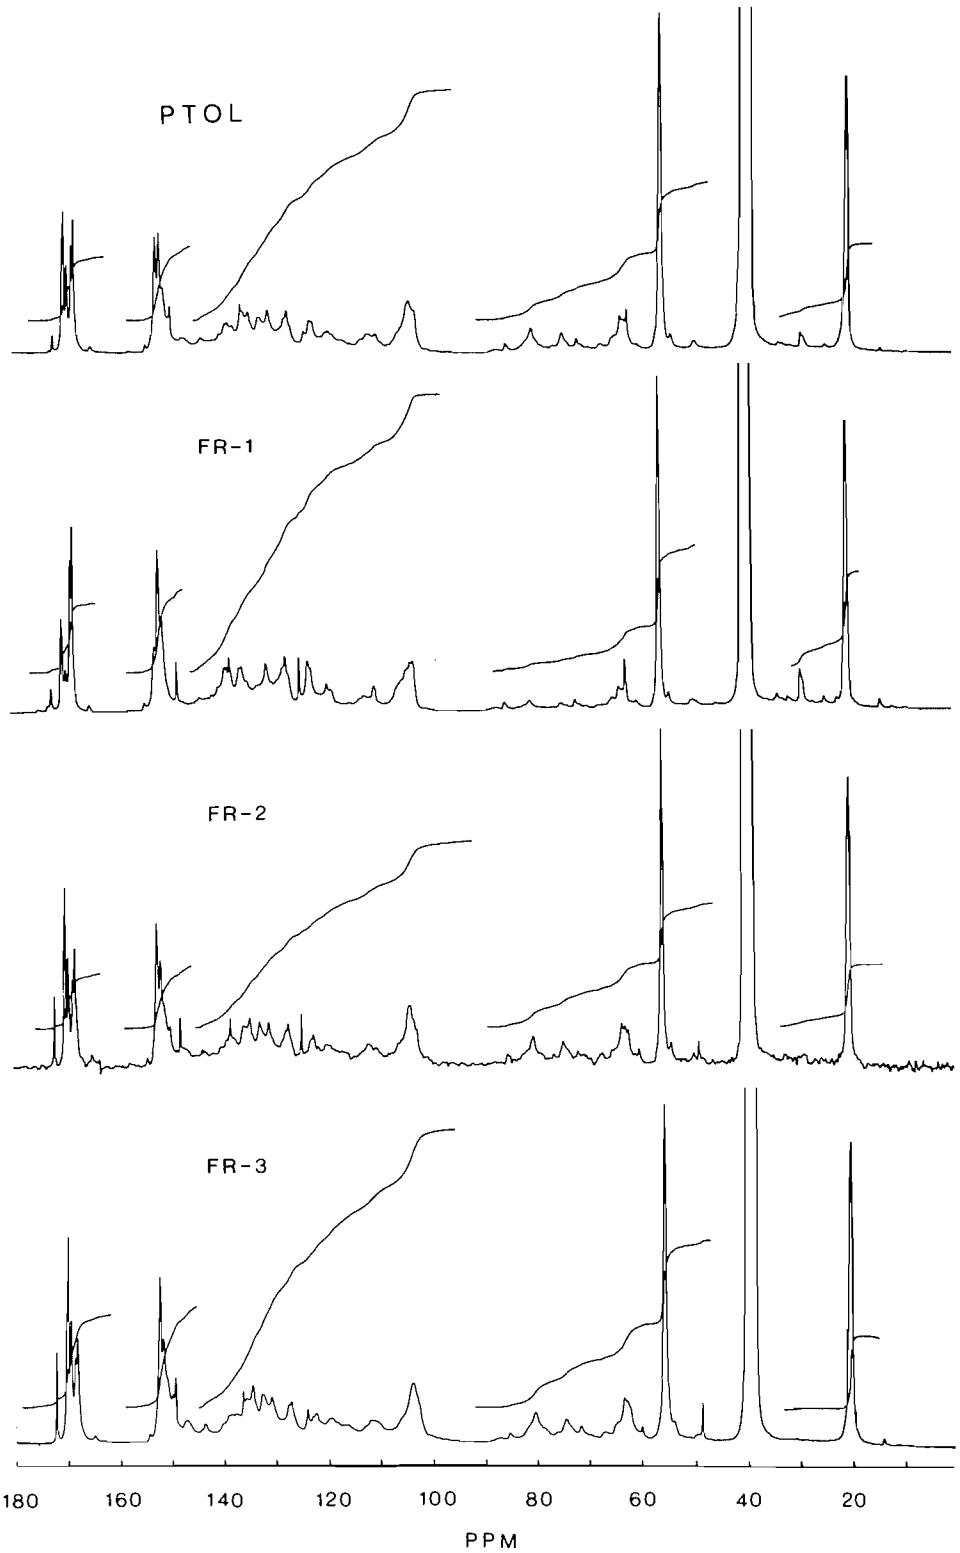

FIG. 7. ^{13}C NMR spectra of acetylated PTOL lignin and its fractions; solvent, DMSO-d_6.

spectra of the same fraction number may be related primarily to the method of isolation and the presence of contaminants in the starting lignins. The discussion will only focus on signals that reflect important structural differences between the two sets of spectra.

The carboxylic signal at 172 ppm increased in intensity with increasing fraction number for fractions in both sets of spectra, and was much more significant in the fractions from PTOL. This signal may be due to aliphatic esters, like the acetate or uronic esters in carbohydrate components (27). The data from sugar analysis also showed a higher content of carbohydrates in PTOL than in TOL. However, the results suggest that for practical purposes, the carbohydrate contamination in both starting lignins is negligibly low.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

From the spectrum of TOL lignin, the intensity of the signal at 170 ppm (aliphatic hydroxyl groups) is higher than the one at 168 ppm (phenolic hydroxyl groups), suggesting that this lignin contains a higher content of aliphatic than phenolic hydroxyl groups. However, the intensity of these signals in the spectrum of PTOL lignin shows this lignin to have a higher phenolic than aliphatic hydroxyl content. As seen from the spectra of both starting lignins, PTOL lignin has a higher content of phenolic hydroxyl groups than TOL lignin. The variation of the signals due to hydroxyl groups in the fractions is similar in both sets of spectra. As seen, the intensity of the signals strongly suggests that the content of aliphatic hydroxyl groups increases whilst that of the aromatic hydroxyl groups decreases with increase in fraction number.

In the portion of the spectra attributed to aromatic carbons, signals at approximately 119 and 149 ppm (due to guaiacyl units) were more intense in Fr-1 from both lignins than in the other fractions. In particular, these signals had the highest intensity in Fr-1 (PTOL), indicating the guaiacyl moiety to be the most important in this fraction. In both lignins, the intensity of the signals around 85 and 65 ppm, attributed to β-*O*-4 structures, is much lower in Fr-1 than in the higher molecular weight fractions, where each signal has virtually the same intensity.

Thus, as demonstrated in this work, lignins can be recovered as a "clean" fraction from the lignocellulosic raw material. Subsequently, their conversion into basic oxychemicals can be readily accomplished via thermo-catalysis.

Conclusions

In this work, a detailed comparison was carried out on thermal organosolv lignins from untreated and aqueous-steam pretreated wood.

The data from alkaline hydrolysis showed that, under optimal conditions for production of catechols from a similarly produced thermal organosolv lignin, both lignins and their fractions produced approximately 7.5% catechols, except Fr-3 from TOL, from which 9% of the initial sample formed catechols.

Nitrobenzene oxidation revealed an increase in the ratio of syringyl to guaiacyl units from Fr-1 to Fr-3 in both lignins. This ratio was found to be generally higher in TOL and its fractions than in PTOL and its corresponding fractions. This finding was confirmed by NMR studies. The highest and lowest yields of total aromatic aldehydes were obtained from Fr-3 (TOL) and Fr-1 (PTOL), respectively. This is directly related to the amounts of uncondensed structures in these fractions. Proton and ^{13}C NMR revealed that these structures are linked by a high proportion of β-*O*-4 type bonds in Fr-3, but Fr-1 consists of a high content of structures with saturated aliphatic linkages. The potential of the former fraction as a source of phenolic monomeric compounds, when compared to its respective starting lignin and other fractions, has been demonstrated in this study.

Carbohydrate contamination of the lignins and isolated fractions was evident from ^{1}H and ^{13}C NMR, and from sugar analyses. Analysis by acid hydrolysis for monosaccharides in both starting lignins revealed 0.6 wt.% to be present in TOL and 4.1 wt.% in PTOL.

The evidence presented has unequivocally demonstrated that the differences in heterogeneity between TOL and PTOL lignins are primarily a consequence of the different routes employed in their isolation from the wood.

This work shows conclusively that isolated lignins obtained from the hardwood *Populus deltoides* via direct solvolysis using ethylene glycol and a sequential aqueous-steam followed by solvolysis treatment do not differ significantly in terms of their structural characteristics. However, noticeable differences in their content of carbohydrate contaminants suggest the formation of relatively stable lignin–carbohydrate complexes via possible covalent bonding in the lignin isolated from pretreated wood. Complementary evidence has been provided by spectral and lignin depolymerization methods.

Acknowledgements

We would like to thank the following members of our research group for their invaluable assistance: J. Bouchard and P.F. Vidal for helpful discussions; A. Roireau for recording the HPSEC spectra; M. Trottier for the elemental analyses; J. Lapointe for calibrating the DB-1 column for GC analyses. Thanks are also expressed to S. Bérubé (Department of Chemistry, University of Sherbrooke) for recording the NMR spectra. Financial assistance by the Natural Sciences and Engineering Research Council of Canada; Energy, Mines and Resources (Bioenergy Division) (Ottawa, Canada); and the Ministry of Education of Quebec (FCAR) is deeply appreciated.

Excess molar volumes and viscosities for the *n*-decane + 1-chlorodecane system at different temperatures

MERCEDES E. F. DE RUIZ HOLGADO, CECILIA R. DE SCHAEFER, FRANCO DAVOLIO, AND MIGUEL KATZ[1]

Cátedra de Fisicoquímica, Instituto de Ingeniería Química, Facultad de Ciencias Exactas y Tecnología, U.N. de Tucumán, Avda. Independencia 1800, S.M. de Tucumán (4000), R. Argentina

Received August 12, 1992

MERCEDES E. F. DE RUIZ HOLGADO, CECILIA R. DE SCHAEFER, FRANCO DAVOLIO, and MIGUEL KATZ. Can. J. Chem. **71**, 790 (1993).

Excess molar volumes, excess viscosities, and excess energies of activation for viscous flow have been determined for the *n*-decane + 1-chlorodecane system at different temperatures, over the whole concentration range. The Prigogine–Flory–Patterson model for solution thermodynamics has been used to calculate the excess molar volumes. Grunberg and Nissan, McAllister, Teja and Rice, and Schrodt and Akel models have been used to calculate viscosity coefficients and these were compared with experimental data for the mixtures.

MERCEDES E. F. DE RUIZ HOLGADO, CECILIA R. DE SCHAEFER, FRANCO DAVOLIO et MIGUEL KATZ. Can. J. Chem. **71**, 790 (1993).

Opérant à diverses températures et faisant varier la concentration sur l'ensemble des concentrations possibles, on a déterminé les excés de volumes molaires, de viscosités et d'énergies d'activation de l'écoulement visqueux du système *n*-décane + 1-chlorodécane. On a utilisé la modèle de Prigogine–Flory–Patterson de la thermodynamique des solutions pour calculer les excès de volume molaires. On a utilisé les modèles de Grunberg et Nissan, de McAllister, de Teja et Rice et de Schrodt et Akel pour calculer les coefficients de viscosité et on a comparé ces valeurs aux données expérimentales obtenues pour les mélanges.

Introduction

Excess molar volumes (V^E) and excess viscosities (η^E) of binary mixtures have been extensively studied from both theoretical and experimental points of view (1, 2). This work reports V^E, η^E, and excess energies of activation for viscous flow (ΔG^{*E}) for *n*-decane + 1-chlorodecane mixtures at 293.15, 298.15, 303.15, and 308.15 K. An equation that reproduces the viscosity as a function of temperature and composition has been established for this system.

Information could be obtained concerning the interaction between the mixed chemical species. The V^E values were analyzed in terms of the Prigogine–Flory–Patterson model. The analysis shows the importance of the three contributions, ΔV_{int}, ΔV_{P*}, and ΔV_F, to V^E.

Excess viscosities and energies of activation for viscous flow were used to calculate some thermodynamic parameters of activation. Some existing equations that calculate viscosities, viz., those of Grunberg and Nissan (3), McAllister (4), Teja and Rice (5), and Schrodt and Akel (6), have been compared, and this last equation showed the best agreement with experimental data.

Experimental

The methods used in our laboratory have been described previously (1, 2). Densities were determined with an AP digital densimeter, model DMA 45. A thermostatically controlled bath (constant to ±0.01 K) was used. Calibration was carried out with air and doubly distilled water with an error of ±0.1 kg m^{-3}. All weighings were made on a Mettler H315 balance. Temperatures were read from calibrated thermometers.

Viscosities of the pure components and of the mixtures were determined with a Schott-Geräte AVS 300 viscosimeter. The Ubbelohde viscosimeter tubes were calibrated and the temperature were maintained to ±0.02 K with a Schott-Geräte CT 1450 temperature controller. The estimated error was ±0.005 mPa s.

n-Decane Fluka (puriss.) and 1-chlorodecane Schuchardt (puriss.) were distilled and only the middle fractions were collected. The binary mixtures were prepared by mixing weighed amounts of the pure liquids. Caution was taken to prevent evaporation.

Results and discussion

The experimental results for the pure components are reported in Table 1 together with literature values for comparison.

The excess molar volumes were calculated with the following equation:

$$[1] \quad V^E = x_1M_1(\rho^{-1} - \rho_1^{-1}) + x_2M_2(\rho^{-1} - \rho_2^{-1})$$

where x_1 and x_2 are the mole fractions of the components, M_1 and M_2 are the molecular weights of the components 1 and 2, and ρ, ρ_1, and ρ_2 are the densities of the solution and of the pure components.

Excess viscosities were calculated from:

$$[2] \quad \eta^E = \eta - \exp(x_1 \ln \eta_1 + x_2 \ln \eta_2)$$

where the additivity law in a logarithm form has been considered for the ideal mixture.

The excess free energies of activation for viscous flow were obtained from the following equation:

$$[3] \quad \Delta G^{*E} = RT(\ln \eta V - x_1 \ln \eta_1 V_1 - x_2 \ln \eta_2 V_2)$$

where V_1 and V_2 are the molar volumes of the components and V is the molar volume of the solution: $V = (x_1M_1 + x_2M_2)/\rho$.

Tables 2 and 3 show the experimental values of densities and viscosities at four different temperatures.

Each set of results was fitted with a Redlich–Kister equation of the type:

$$[4] \quad X^E = x_1(1 - x_1) \sum_{j=1}^{n} a_j(1 - 2x_1)^{j-1}$$

where X^E is V^E or η^E or ΔG^{*E}; a_j are the parameters obtained by a least-squares fitting procedure. In each case, the optimum number of coefficients are ascertained from an examination of the variation of the standard error σ estimated with n (calculated with a VAX 11/780 computer):

$$[5] \quad \sigma = [\Sigma (X^E_{obs} - X^E_{calc})^2/(n_{obs} - n)]^{1/2}$$

The values adopted for the coefficients a_j and the standard error estimates associated with the use of eq. [5] are summarized in Table 4.

The viscosity of liquids varies with temperature according to the classical Andrade equation:

$$[6] \quad \eta = A \exp(B/T)$$

where A and B are constants that depend on the nature of the liquids. The viscosity of liquid mixtures varies also with composition as:

$$[7] \quad \eta = f(T,x)$$

By using a multiple linear regression, an equation has been obtained which correlates T and x. For this system, the equation is

$$[8] \quad \ln \eta = -4.626 - 0.79\, x_1 + \frac{1549}{T} + 0.09\, x_1^3$$

with $\sigma = 0.02$, where x_1 is the mole fraction of *n*-decane. The standard deviation of the logarithm of the viscosity coefficients has the form of eq. [5].

Figures 1, 2, and 3 show the experimental values of V^E, η^E, and ΔG^{*E}, respectively. The continuous curves were calculated from eq. [4] using the adopted values for the coefficients.

This system shows positive values of V^E and negative values of η^E. Several effects may contribute to the values of V^E, such as breaking of liquid order on mixing, contribution due to the difference in size and shape of the components, difference in free volumes, and dipole–dipole interactions. The observed V^E is a resultant contribution of the above effects. The positive values of V^E indicate that the two former effects are dominant over the latter effects in this system (10, 11), implying that dispersion forces are dominant. The variation in the magnitude of V^E with increasing temperature is found to be small.

Generally, positive V^E corresponds to negative η^E, as in this case. The free energy ΔG^{*E} is considered a reliable means of detecting the interaction between molecules (12, 13). Positive values of ΔG^{*E} can be seen in binary systems where specific interactions between molecules take place. In this system, ΔG^{*E} is negative; thus we conclude again that dispersion forces are dominant.

Molar excess volume can be calculated from the Prigogine–Flory–Patterson (PFP) theory (14). The original Prigogine–Flory theory includes three contributions in order

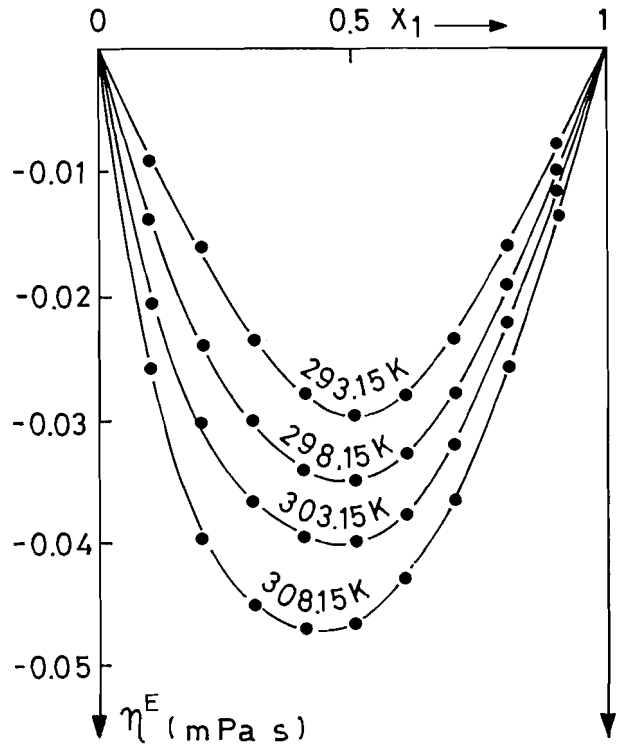

FIG. 2. Excess viscosities for the *n*-decane (1) + 1-chlorodecane (2) system. Continuous curves were calculated from eq. [4].

to explain the thermodynamic behavior of the liquid mixtures: an interactional contribution (ΔV_{int}), which is proportional to the interactional parameter X_{12}; the free volume contribution, which arises from the dependence of the reduced volume upon the reduced temperature as a result of the difference between the degree of expansion of the two components (ΔV_F); and the internal pressure contribution (ΔV_{P*}), which depends on both the difference of characteristic pressures and on the reduced volumes of the components.

Some new effects not treated in this theory have been discussed for molecules of different shape (15). The equation is

$$[9]\quad \frac{V^E}{x_1V_1^* + x_2V_2^*} = \frac{(\tilde{V}^{1/3} - 1)\tilde{V}^{2/3}}{(4/3)\tilde{V}^{-1/3} - 1}\psi_1\theta_2\frac{X_{12}}{P_1^*} - \frac{(\tilde{V}_1 - \tilde{V}_2)^2\left(\frac{14}{9}\tilde{V}^{-1/3} - 1\right)}{[(4/3)\tilde{V}^{-1/3} - 1\ \tilde{V}]}\psi_1\psi_2 + \frac{(\tilde{V}_1 - \tilde{V}_2)\,(P_1^* - P_2^*)}{\psi_1P_2^* + \psi_2P_1^*}\psi_1\psi_2$$
$$= \Delta V_{int} - \Delta V_F + \Delta V_{P^*}$$

where $\tilde{V}$ is the reduced volume, V^* is the characteristic volume, P^* is the characteristic pressure, ψ is the contact energy fraction, ϕ is the hard core volume fraction, and θ is the surface site fraction.

Heintz (16) introduced the so-called ERAS model, which combines the linear chain association model with Flory's equation of state theory. In this case, both components are not associated in the pure state and the chemical contribution is not taken into account.

The various parameters involved in eq. [9] for the pure components (with subscript) and the mixture (without subscripts) are obtained from Flory's theory (17) and are shown in Table 5.

The interactional contribution to V^E contains the interaction parameter X_{12}, which is usually calculated using experimental values of the excess enthalpy H^E. As no values of H^E are available for this system, X_{12} values were derived by fitting the theory to experimental values of V^E for this system.

The value of X_{12} obtained at 298.15 K is -0.316×10^{-6} J m^{-3} and, for equimolecular values, the three contributions are $\Delta V_{int} = -6.56 \times 10^{-5}$, $\Delta V_F = 4.26 \times 10^{-4}$, and $\Delta V_{P^*} = 1.40 \times 10^{-3}$ with a calculated $V^E = 0.143 \times 10^{-6}$ m^3 mol^{-1}.

An analysis of each of the three contributions to V^E shows that the interaction contribution is negative and small compared with the other two. The free volume contributions are positive and smaller than the internal pressure contribution. The total theoretical values are found to be in agreement with the experimental data, as shown in Fig. 4, with more error observed between x_1 0.4 and 0.6.

Different equations exist in the literature that can calculate viscosity coefficients for mixtures. Grunberg and Nissan (3) proposed an empirical equation to describe real mixtures:

$$[10]\quad \ln\eta = x_1\ln\eta_1 + x_2\ln\eta_2 + x_1x_2\delta$$

where δ reflects the nonideality of the system. The parameter δ has usually been regarded as an approximate measure of the strength of the interaction between the components. However, it has been shown that in certain cases it can also be correlated with the difference in molecular volumes of the components and with the entropy of mixing (10). The values obtained for δ at 298.15 K for the system are summarized in Table 6 together with the percent error.

The McAllister correlation (4) is based on a model proposed by Eyring *et al.* (18), which considers that interaction occurs between three bodies:

$$[11]\quad \ln\nu = x_1^3\ln\nu_1 + x_2^3\ln\nu_2 + x_1^3\ln M_1 + x_2^3\ln M_2 - \ln(x_1M_1 + x_2M_2) + 3x_1^2x_2\ln\left(2M_1 + \frac{M_2}{3}\right)$$
$$+ 3x_1x_2^2\ln\left(M_1 + \frac{2M_2}{3}\right) + 3x_1^2x_2\ln\nu_{12} + 3x_1x_2^2\ln\nu_{21}$$

where ν represents the kinematic viscosity (η/ρ) and ν_{12} and ν_{21} are the interaction parameters obtained by a least-squares method. Table 6 gives these values with their percent error.

We applied the corrresponding states method of Teja and Rice (5) to calculate viscosities of the mixtures. These authors proposed the relation:

$$[12]\quad \ln(\eta\xi) = \ln(\eta\xi)^{(r_1)} + \frac{\omega - \omega^{(r_1)}}{\omega^{(r_2)} - \omega^{(r_1)}}[\ln(\eta\xi)^{(r_2)} - \ln(\eta\xi)^{(r_1)}]$$

where (r_1) and (r_2) refer to the properties of two reference fluids (in this case, the pure components) and ω is the acentric factor.

The values of ξ from eq. [12] were obtained from:

$$[13]\quad \xi = V_c^{2/3}/(T_cM)^{1/2}$$

where V_c and T_c are the critical volume and temperature, respectively. For mixtures, the pseudo-critical properties V_{cm}, T_{cm}, and ω_m of hypothetical substances that replace the pure fluids are defined (22). Values of $(\eta\xi)^{(r_1)}$ and $(\eta\xi)^{(r_2)}$ at the same reduced temperature have been calculated with ψ values, indicated in Table 6.

Table 7 shows the parameters used for this application.

Following the model of Schrodt and Akel (6), which is based upon Eyring's concept of fluid viscosity, the equation applying to mixtures (22), is

$$[14]\quad \ln\eta = \ln\frac{hN_A}{V} + \Sigma\, x_i\ln\eta_i^0 + \Sigma\, x_i\ln\gamma_i^v$$

where $\eta_0^0 = \eta_iV_i/hN_A$, γ_i^v is the viscosity activity coefficient, and N_A is Avogadro's number.

Using a set of binary viscosity data, we found ΔG^{*E} values, and the viscosity activity coefficients were determined in this

[a]Reference 21.

case from equations like non-random two liquids' theory (NRTL) and related to $\Delta G^{*E}/RT$. The parameters of the NRTL equations are also given in Table 6 together with the percent error defined as:

$$[15] \quad AD = [\Sigma(\eta_{exp} - \eta_{calc})^2/n]^{1/2} \times 100$$

Various thermodynamic properties of activation for viscous flow have been determined using Eyring's equation (ref. 18); for example:

$$[16] \quad \ln \frac{vM}{hN_A} = -\frac{\Delta S^*}{R} + \frac{\Delta H^*}{RT}$$

Over a short range of temperatures, the molar enthalpy of activation ΔH^* and the molar entropy of activation ΔS^* are approximately constant. Using a least-squares method, the activation parameters ΔH^* and ΔS^* were obtained and ΔG^* was determined from the following equation:

$$[17] \quad \Delta G^* = \Delta H^* - T\Delta S^*$$

The values obtained for ΔG^* vary between 26 000 and 29 000 J mol^{-1}. They decrease with mole fraction of *n*-decane and increase with temperature. The values of ΔH^* at 298.15 K vary from 10 000 to 14 000 J mol^{-1} and ΔS^* varies from -49 to -55 J K^{-1} mol^{-1}.

Only 1-chlorodecane is a polar molecule and η^E is very small. This does not necessarily mean absence of interaction, but could imply that there is an interaction of the dipole–dipole induced type. Fort and Moore (11) and Nigam and Mahl (23) have reported that specific interactions are stronger in binary mixtures where η^E and δ are large and positive. In this system, both are negative and that means weak interactions. In regard to the values of ΔG^*, the sign and magnitude are governed by the corresponding values of ΔH^* and ΔS^* according eq. [17]. A negative ΔS^* indicates that the formation of an activated complex requires comparatively increased molecular order for an increase in its viscous flow.

From the different equations that calculate viscosities of mixtures, the Schrodt and Akel model shows the best agreement with experimental data, since it presents the smallest deviation when compared with the other relations.

Received July 13, 1992[2]

LING-LING TIEN, SHAW-TAO LIN, HSIEN-JU TIEN, and GWO-MING FANG. Can. J. Chem. **71**, 796 (1993).

In the presence of a Lewis acid, 4-hydroxymethylsydnones undergo reaction with alcohols and benzene to form 4-alkoxysydnones **1***a*, bis(4-sydnonylmethyl) ethers **1***b*, or 4-benzylsydnones **1***d* depending upon the reaction conditions. At 0°C, compounds **1***a* and **1***b* are formed from compound **1** in benzene and alkyl alcohol, respectively. Compound **1***b* is converted to compound **1***d* at 40°C. When the reactions are carried out in a cosolvent of benzene and methyl alcohol at 40°C, compound **1***a* is obtained preferentially and followed by conversion to compound **1***d*. The α-sydnonylmethylene cation derived from either compound **1** or **1***a* is responsible for the formation of compound **1***d*.

LING-LING TIEN, SHAW-TAO LIN, HSIEN-JU TIEN et GWO-MING FANG. Can. J. Chem. **71**, 796 (1993).

Les 4-hydroxyméthylsydnones mises en présence d'un acide de Lewis réagissent avec les alcools et le benzène pour former, suivant les conditions de la réaction, les 4-alkoxysydnones (**1***a*), les éthers bis(4-sydnonylméthyle) (**1***b*) ou les 4-benzylsydnones (**1***d*). À 0°C, le composé **1** conduit aux composés **1***a* ou **1***b* suivant qu'il mis en présence d'alcool aliphatique ou de benzène. À 40°C, les composés **1***b* se transforment en produits **1***d*. Lorsqu'on réalise les réactions en présence d'un cosolvant de benzène et de méthanol, à 40°C, les composés **1***a* sont obtenus d'une façon préférentielle avant d'être transformés en composés **1***d*. Le cation α-sydnonylméthylène qui dérivé soit du composé **1** ou des composés **1***a* est responsable de la formation des composés **1***d*.

[Traduit par la rédaction]

The nature of the sydnone ring demonstrates the electron-withdrawing character on N(3) and electron-donating properties on C(4) (1). This dual character of the ring has been observed in the nitration of 3-(4′-alkylphenyl)sydnones and 3-benzylsydnone, resulting in the formation of 3-(4′-alkyl-3′-nitrophenyl)sydnone and 3-(3′-nitrobenzyl)sydnone, respectively (2). Electrophilic substitution, i.e., formylation and acetylation, takes place at the C(4) position (3). In the gas phase, the sydnonylmethylene cation has been generated from sydnonylmethanols and their derivatives (4). This fact suggested that the C(4) is also able to stabilize the methylene group (4). If the sydnonyl ring is able to stabilize the C(4)-methylene cation as in the benzylic system, the sydnonylmethanol will then be able to act as an electrophile in the presence of Lewis acid. In this work we study the reaction of sydnonylmethanol with benzene and (or) alcohol in the presence of either sulfuric acid or boron trifluoride to ascertain the properties of C(4) of the sydnonyl ring.

Results and discussion

The sydnone carbinols are highly soluble in chlorinated solvents. In chloroform or in the presence of strong acid, these compounds are less stable and tend to give highly colored solutions. The condensations between sydnonylmethanol and alkyl alcohol were carried out in methylene chloride solution because of these considerations of solubility and stability. At 40°C, using Lewis acids such as sulfuric acid, boron trifluoride, and trifluoroacetic acid, this leads to condensation products as shown in Table 1. The darkening of color reflects product yields, sulfuric acid being better than BF_3 and CF_3COOH. When CF_3COOH is used as a catalyst, longer reaction times (24 h) are required to obtain comparable yields (entry 3).

The steric factor of alkyl groups plays an insignificant role in the yields of **1***g*. Clean products obtained from the reaction

of compound **1** and *n*-propanol in the presence of either H_2SO_4 or BF_3 indicate that there is no isomerization of the *n*-propyl group during the reaction (entries 6, 7). The formation of the ether product can occur by either an S_N1 or an S_N2 mechanism (5). However, the absence of rearranged product implies either that no carbocation is derived from *n*-propanol or that the Lewis acid reacts preferentially with sydnonylmethanol rather than with the alkyl alcohol.

Further inspection of the yields of the products obtained from different sydnones reflects the important role of substituents: electron-withdrawing groups destabilize the reaction center through the sydnonyl ring resulting in lower yields of products (entry 16).

The kinetic study on the rate of conversion to the corre-

24	**5**	0.78	0.034	−0.131

[a]The rates were measured by ^{1}H NMR spectroscopy monitoring the decrease of the methylene signal for the first 30% conversion.

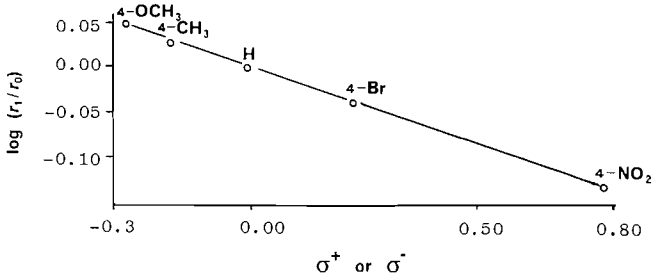

FIG. 1. The correlation between log (r_0/r_1) and the Hammett substituent constant (σ) for aryl-substituted 4-hydroxymethylsydnones.

sponding ethers was carried out at 40°C and monitored by ^{1}H NMR to the first 30% conversion (Table 2). The correlation between the substituent constant σ of the specific substituents on the phenyl ring and the conversion rate gives $\rho = -0.02$ with a correlation coefficiency of 0.956 (Fig. 1). The small and negative ρ value implies that the reaction center bearing the positive charge is influenced by the remote substituent. This ability of the sydnonyl ring to transmit the inductive effect has also been observed in the gas phase (4).

Boron trifluoride has been shown to be an effective catalyst for the reaction of benzyl alcohol and benzene to form diphenylmethane via a typical Friedel–Crafts reaction (5). However, BF_3 is not an ideal catalyst for the sydnone system. This might be due to the formation of a complex as is observed for γ-diketones (6), i.e., the BF_3 interacts with the oxygen atoms of hydroxyl groups as well as with the carbonyl of the sydnonyl ring.

To undergo electrophilic substitution, the sydnonylmethanol must be converted to its corresponding carbocation. In the presence of H_2SO_4, the reaction of the sydnonyl methanols and benzene at 40°C, either without solvent or in CH_3CN, CH_2Cl_2, leads to 3-aryl-4-benzylsydnones in good yields (Table 3). The variation of the yield as a function of the substituent on the phenyl ring reflects the reactivity of the corresponding cation. Bis-sydnonylmethyl ethers *b* are obtained from the same reactions at 0°C when H_2SO_4 or BF_3 is used. Also, the same results are obtained in the presence of BF_3 at 40°C (Scheme 1). The inability of BF_3 to catalyze the formation of compounds *d* may be due either to insufficient reactivity to form the carbocation or to the formation of stable complexes with boron fluoride as described above.

During the reaction, the sydnonylmethanol can be converted to either a carbocation or a protonated state. The carbocation reacts either with benzene or with methanol yielding a Friedel–Crafts product *d* or ether *a*, respectively. However, the protonated sydnonylmethanol may react only with alcohol, yielding an ether *a* rather than *d* as a final product. To differentiate whether carbocation or protonated sydnone is involved in this reaction system, compound **1** was dissolved in a mixture of equal amounts of benzene and methanol (1.0 mL: 1.0 mL) in the presence of H_2SO_4 as a catalyst. At 0°C, after a 3 h reaction period, only ether **1***a* was isolated. On the other hand, when the same reaction was carried out at 40°C, 4-benzylsydnone **1***d* was obtained as a major product (Table 4). We interpret these results as follows. At a lower temperature, the ether is produced via an S_N2 process, i.e., the methylene group of protonated sydnonylmethanol is attacked by methanol. At a higher temperature, the carbocation derived from sydnonylmethanol or ether **1***a* undergoes electrophilic substitution. The formation of carbocation could be caused by cleavage of ether *b*, methyl ether *a*, or derived from the precursor itself. To ascertain which of these three possible sources is involved in this system, the following experiments were carried out. The benzene-d_6 solution of methyl-d_3 ether in the presence of H_2SO_4 was monitored by ^{1}H NMR at 40°C by comparing the methylene signal of ether **1***a* (4.35 ppm) with that of the methylene of the benzyl ether **1***d* (3.85 ppm). The signal at 4.35 ppm completely disappeared within 2 h, suggesting that the methyl ether *a* is readily cleaved to generate cation *c* for further reaction. The same experiment was carried out with ether **1***b* instead of methyl ether **1***a*. The signal of the methylene group of ether **1***b* at 3.95 ppm completely disappeared after 5 h. Therefore, the formation of 4-benzylsydnone from ether *b* can be an alternative pathway. Even so, the above pathway is unlikely because of the insignificant amount of ether *b* that is formed in the presence of methanol.

Conclusion

In the presence of Lewis acids, sydnonylmethanols readily react with alcohols to produce the corresponding ether derivatives. Below room temperature, no Friedel–Crafts reaction is observed due to insufficient energy for the formation of the sydnonylmethyl cation intermediate. However, its formation at 40°C has been established from either sydnonylmethanols or methoxymethylsydnones. For aryl-substituted sydnones, the rate of electrophilic substitution is a function of the substituent; this fact implies the ability of the sydnonyl ring to transmit electron density from the aryl ring and the ability of the aryl substituent to stabilize the methylene cation in a manner similar to effects observed for the benzyl system. This observation is consistent with results obtained from mass spectroscopic studies (4).

Experimental

Melting points were measured on a Yanaco MP-J3 micro melting apparatus and are uncorrected. Infrared spectra were determined with a Perkin–Elmer model 457n grating infrared spectrophotometer using a potassium bromide pellet. Mass spectra were measured on a Jeol JMS DX-300 mass spectrometer using 70 eV ionization energy. NMR spectra were determined with a Bruker AC-250 FT-NMR by using $CDCl_3$ as a solvent and Si_4Me as an internal standard.

3-Aryl-4-hydroxymethylsydnones were prepared according to literature procedures (7, 8).

[a]Arylsydnonylmethanol (0.01 mol) in a mixture of benzene and methanol (10 mL: 10 mL). Reaction time was 3 h.
[b]Ether: arylsydnonylmethyl methyl ether; benzyl: 3-aryl-4-benzylsydnone.
[c]The purity of the products isolated was determined by ^{1}H NMR. The ratio of two products was also obtained by NMR calculated from the areas of the methylene groups at 4.20 and 3.80 ppm, respectively.

Preparation of 3-aryl-4-alkoxylsydnones. Typical procedure

(*a*) To an ice-cooled and stirred solution of 4-(hydroxymethyl)-3-phenylsydnone (0.2 g, 1.04 mmol) in CH_2Cl_2 (5 mL) containing methanol (1 mL) was added concentrated H_2SO_4 (0.2 mL). After being stirred for 0.5 h, the solution was allowed to warm to 30°C, and was stirred for an additional 3 h. The resultant solution was poured into ice-cold sodium bicarbonate aqueous solution. Following filtration, the crude product was recrystallized from 95% ethanol yielding **1***a* as colorless needle crystals: 0.18 g (82% yield); mp 56°C.

The following compounds were obtained according to this procedure.

*3-(4-Methoxyphenyl)-4-methoxymethylsydnone(***2**a*):* mp 181–182°C; IR(KBr) $\nu_{C=O}$: 1744 cm^{-1}; NMR(DMSO-d_6) δ: 3.40(s, 3H, OCH_3), 3.98(s, 3H, OCH_3), 4.24(s, 2H, CH_2), 7.24(d, 2H, J = 9.1 Hz, aromatic), 7.91(d, 2H, J = 9.1 Hz, aromatic); MS, m/z(relative intensity): 236(M^+, 16), 178(100). Anal. calcd. for $C_{11}H_{12}N_2O_4$: C 55.93, H 5.08, N 11.86; found: C 55.82, H 5.09, N 11.83).

*3-(4-Nitrophenyl)-4-methoxymethylsydnone(***5**a*):* mp 116–117°C; IR(KBr) $\nu_{C=O}$: 1775 cm^{-1}; NMR (DMSO-d_6) δ: 3.45(s, 3H, OCH_3), 4.29(s, 2H, CH_2), 8.08(d, 2H, J = 9.0 Hz, aromatic), 8.83(d, 2H, J = 9.0 Hz, aromatic); MS, m/z(relative intensity): 251(M^+, 3), 45(100). Anal. calcd. for $C_{10}H_9N_3O_5$: C 47.81, H 3.59, N 16.73; found: C 47.77, H 3.68, N 16.78.

*3-(Cyclohexyl)-4-methoxymethylsydnone(***6**a*):* mp 95–96°C; IR(KBr) $\nu_{C=O}$: 1734 cm^{-1}; NMR (DMSO-d_6) δ: 1.37–1.62(m, 11H, C_6H_{11}), 3.94(s, 3H, OCH_3), 4.32(s, 2H, CH_2); MS, m/z(relative intensity): 212(M^+, 33), 83(100). Anal. calcd. for $C_{10}H_{16}N_2O_3$: C 56.60, H 7.55, N 13.20; found: C 56.39, H 7.51, N 13.21.

(*b*) This reaction was carried out by the same procedure as above, except that CH_2Cl_2 (5 mL) containing methanol (1 mL) and benzene (1 mL) was used instead of methanol and CH_2Cl_2 solution. After work-up, colorless needles of **1***a* were obtained; yield: 0.17 g (78%).

Preparation of 3-aryl-4-benzylsydnones. Typical procedure

(*a*) To an ice-cooled and stirred solution of 4-(hydroxymethyl)-3-(4-tolyl)sydnone (0.09 g, 0.44 mmol) in CH_2Cl_2 (5 mL) containing benzene (1 mL), was added concentrated H_2SO_4 (0.1 mL). After being stirred for 5 min, the solution was allowed to warm to 40°C, and stirred for an additional 3 h. During the reaction, the color of solution changed from light brown to deep green. This resultant solution was poured into ice-water yielding a glue-like precipitate. The crude solid product obtained upon treating with sodium bicarbonate solution was recrystallized from 95% ethanol, yielding **3***d* as colorless crystals (0.09 g, 72% yield); mp 97–98°C; IR(KBr) $\nu_{C=O}$: 1748 cm^{-1}; NMR(DMSO-d_6) δ: 2.42(s, 3H, CH_3), 3.79(s, 2H, CH_2), 6.99–7.60(m, 9H, aromatic); MS, *m/z* (relative intensity): 266(M^+, 16), 91(100). Anal. calcd. for $C_{16}H_{14}N_2O_2$: C 72.18, H 5.26, N 10.53; found: C 72.19, H 5.16, N 10.46.

The followwing compounds were obtained by this procedure:

*3-(Phenyl)-4-benzylsydnone(**1**d):* mp 99–100°C; IR(KBr) $\nu_{C=O}$: 1734 cm^{-1}; NMR(DMSO-d_6) δ: 3.80(s, 2H, CH_2), 6.94–7.25(m, 5H, aromatic), 7.74–7.83(m, 5H, aromatic); MS, *m/z*(relative intensity): 252(M^+, 11), 91(100) Anal. calcd. for $C_{15}H_{12}N_2O_2$: C 71.43, H 4.76, N 11.11; found: C 71.22, H 4.65, N 10.99.

*3-(4-Methoxyphenyl)-4-benzylsydnone(**2**d):* mp 175–176°C; IR-(KBr) $\nu_{C=O}$: 1744 cm^{-1}; NMR (DMSO-d_6) δ: 3.80(s, 2H, CH_2), 3.98(s, 3H, OCH_3), 6.95–7.59(m, 9H, aromatic); MS, *m/z*(relative intensity): 282(M^+, 21), 91(100). Anal. calcd. for $C_{16}H_{14}N_2O_2$: C 68.09, H 4.96, N 9.93; found: C 67.79, H 4.96, N 9.91.

*3-(4-Bromophenyl)-4-benzylsydnone(**4**d):* mp 197–199°C; IR-(KBr) $\nu_{C=O}$: 1740 cm^{-1}; NMR(DMSO-d_6) δ: 3.73(s, 2H, CH_2), 6.90–7.24(m, 5H, aromatic), 7.57–7.92(m, 5H, aromatic); MS, *m/z*(relative intensity): 330(M^+, 5), 91(100). Anal. calcd. for $C_{15}H_{11}N_2O_2Br$: C 54.50, H 3.32, N 8.46; found: C 54.21, H 3.25, N 8.34.

*3-(4-Nitrophenyl)-4-benzylsydnone(**5**d):* mp 110–112°C; IR(KBr) $\nu_{C=O}$: 1762 cm^{-1}; NMR(DMSO-d_6) δ: 3.83(s, 2H, CH_2), 6.98–7.36(m, 5H, aromatic), 8.08(d, 2H, J = 9.0 Hz, aromatic), 8.83(d, 2H, J = 9.0 Hz, aromatic); MS, *m/z*(relative intensity): 297(M^+, 4), 91(100). Anal. calcd. for $C_{15}H_{11}N_3O_4$: C 60.61, H 3.70, N 14.14; found: C 60.43, H 3.69, N 14.10.

*3-(Cyclohexyl)-4-benzylsydnone(**6**a):* mp 106–107°C; IR(KBr) $\nu_{C=O}$: 1722 cm^{-1}; NMR(DMSO-d_6) δ: 1.30–1.75(m, 11H, C_6H_{11}), 3.94(s, 2H, CH_2), 6.95–7.33(m, 5H, aromatic); MS, *m/z*(relative intensity): 258(M^+, 50), 83(100). Anal. calcd. for $C_{15}H_{18}N_2O_2$: C 69.74, H 6.98, N 10.84; found: C 69.52, H 6.90, N 10.79.

(*b*) The reaction was also carried out by the same procedure as above, except for the use of benzene instead of CH_2Cl_2 as solvent. After work-up, colorless crystals of **2***d* were obtained (0.10 g, 81% yield).

Competitive reaction between benzene and methanol with 3-phenyl-4-hydroxymethylsydnone in the presence of H_2SO_4

To an ice-cooled stirred solution of 4-(hydroxymethyl)-3-phenylsydnone (0.2 g, 1.04 mmol) in CH_2Cl_2 (5 mL) containing methanol (1 mL) and benzene (1 mL) was added concentrated H_2SO_4 (0.2 mL). After being stirred for 10 min, the solution was allowed to warm to 40°C, and was stirred for an additional 3 h. The reaction mixture was poured into ice-cold aqueous sodium bicarbonate solution; the precipitate was then collected and dried to give 0.19 g of product. The ratio of *a* to *d* was determined from the ^1H NMR spectra by measuring the areas of the methylene groups at 4.30 and 3.85 ppm, respectively.

Reaction between 3-phenyl-4-trideuteriomethoxymethylsydnone and deuteriobenzene in the presence of H_2SO_4

To an ice-cold solution of 3-phenyl-4-trideuteriomethoxymethylsydnone (0.005 g) in 0.5 mL C_6D_6 in a 5-mm NMR tube was added concentrated H_2SO_4 (ca. 1 μL). The mixture was monitored using NMR regularly at 40°C until the signal at 4.20 ppm disappeared (ca. 2 h).

Reaction of bis(3-phenylsydnonylmethyl) ether and benzene in the presence of H_2SO_4

To an ice-cold solution of bis(3-phenylsydnonylmethyl) ether (0.005 g) in 0.5 mL of C_6D_6 in a 5-mm NMR tube was added concentrated H_2SO_4 (ca. 1 μL). The mixture was monitored by using NMR regularly at 40°C to observe the changes of the proton signals at 3.95 and 3.80 ppm. No proton signal at 3.95 ppm was observed after 5 h.

Kinetic study of the reaction between 3-arylsydnonylmethanols and methanol in methylene chloride in the presence of H_2SO_4

To an ice-cold solution of 3-arylsydnonylmethanol (0.01 mmol) and methanol (2 μL, 0.05 mmol) in CD_2Cl_2 (0.3 mmol) was added concentrated H_2SO_4 (1 μL). The rate of conversion was determined by monitoring the relative intensities of the methylene absorption at 4.50 and 4.35 ppm, respectively, in the ^1H NMR spectra. The spectra were recorded at 10 min intervals. Rates were calculated on the basis of monitoring the reaction to 30% conversion.

Received January 12, 1991[2]

M.S. PRASADA RAO, A. RAMA MOHAN RAO, KARRI V. RAMANA, and S.R. SAGI. Can. J. Chem. **71**, 801 (1993).

Titrimetric and spectrophotometric methods are developed for the estimation of hypophosphite (PO_2^{3-}) at mmol and micromol ranges, respectively. In these methods thallium(III) is used as an oxidant and the reduced thallium(I) is determined either oxidimetrically by potassium bromate in the titrimetric method or by measurement of the optical density of thallium(III) at 260 nm in the presence of 0.1 M NaCl and 1 M $HClO_4$ in the spectrophotometric method. Convenient methods are described for the determination of ternary mixtures of hypophosphite (PO_2^{3-}), phosphite (PO_3^{3-}), and oxalate ($C_2O_4^{2-}$). A method is also described for the estimation of thallium(III) using hypophosphite as reductant, and the method is applied to the determination of mixtures of thallium(I) and thallium(III).

M.S. PRASADA RAO, A. RAMA MOHAN RAO, KARRI V. RAMANA et S.R. SAGI. Can. J. Chem. **71**, 801 (1993).

On a mis au point méthodes titrimétriques et spectrophotométriques pour évaluer les concentrations d'hypophosphite (PO_2^{3-}) aux niveaux respectivement des mmol et de micromol. Dans ces méthodes, on utilise du thallium(III) comme oxydant et on détermine la concentration du thallium(I) produit soit d'une façon oxydimétrique, par le bromate de potassium dans la méthode titrimétrique, soit par la mesure de la densité optique du thallium(III), à 260 nm, en présence de NaCl 0,1 M et de $HClO_4$ 1 M, dans la méthode spectrophotométrique. On décrit des méthodes faciles pour la détermination d'ions hypophosphite (PO_2^{3-}), phosphite (PO_3^{3-}) et oxalate ($C_2O_4^{2-}$) dans des mélanges tertiaires. On décrit aussi une méthode de détermination de la concentration du thallium(III) qui fait appel à l'hypophosphite comme réducteur; on a appliqué la méthode à des mélanges de thallium(I) et de thallium(III).

[Traduit par la rédaction]

Introduction

Hypophosphite (PO_2^{3-}) is a powerful reducing agent. Hypophosphites act as inorganic anti-oxidants and are used as such, specifically for the prevention of oxidation of iodides and iron(II) compounds. Hypophosphite has been used in medicine as a source of phosphorus in tonics. It is used as an anti-oxidant in hydroiodic acid and ferrous iodide syrups and also as a pharmaceutical aid. In all these preparations there is a need to maintain specific concentrations of hypophosphite. A survey of the literature reveals that few redox methods are available for the estimation of hypophosphite. Komarowsky et al. (1) determined hypophosphite by oxidizing hypophosphite to phosphite by treating with excess chloramine-T in a sulphuric acid medium for 24 h at room temperature, followed by iodometric titration of its excess. Rupp and Kroll (2) determined hypophosphite by treatment with excess potassium bromate for 1 h at room temperature or by heating at 60°C for 30 min in a sulphuric acid medium, followed by iodometric titration of its excess. Bernhart (3) described a method in which hypophosphite is oxidized quantitatively to phosphate by cerium(IV) in sulphuric acid solution at room temperature within 2 h. The excess of cerium(IV) is determined by titration with iron(II) solution using ferroin as indicator. Boyer and Bauzil (4) described a method in which an excess of iodine slowly oxidizes hypophosphite to phosphate in bicarbonate solution. The excess iodine is then back-titrated with standard 0.1 N arsenite. Rao and Gowda (5) reported that hypophosphite is oxidized by vanadate in the presence of silver sulphate as catalyst after heating for 20 min in a boiling water bath. After cooling, the mixture is titrated with 0.05 N Mohr's salt in the presence of *N*-phenylanthranilic acid as indicator.

In all of these indirect methods, after a prolonged treatment with an excess of an oxidant, the unreacted excess oxidant is determined with a suitable reductant. Because there are virtually no methods available for the estimation of hypophosphite in the micromol range, there is a need for simple and direct methods for its estimation in this range. Thus, we examined the photochemical and thermal reaction between thallium(III) and hypophosphite in the presence of various catalysts. Based on this reaction, convenient photochemical and thermal methods were developed for the determination of hypophosphite in the mmol and micromol ranges.

It was suggested in the literature (6) that phosphite and oxalate are likely to occur along with hypophosphite and, whenever the purity of these samples have to be tested, tests for phosphite and oxalate should be carried out. Keeping this point in view, an attempt was made to analyse the hypophosphite, phosphite, and oxalate present in a mixture. Based on work done earlier on the thallium(III)–oxalate system (7) and the thallium(III)–phosphite system (8), and on the results of the present study, a convenient method is described for the analysis of ternary mixtures of hypophosphite, phosphite, and oxalate.

Experimental

Thallium(III) solutions in perchloric and sulphuric acids were prepared and standardized as reported earlier (9,10) and verified by other methods. An aqueous solution of sodium hypophosphite (May and Baker) was prepared and determined by cerimetry (3). All other reagents were of analytical reagent grade. Although the photochemical reactions described take place at a much faster rate under direct sunlight, all the work was done using a Phillips high-pressure mercury vapour lamp (200/250 V, 125 W) as the light source, as the direct sunlight is of variable intensity. The photochemical reactions were performed by exposing the solutions, in

colourless uncovered glass containers, directly from the top at a constant distance of 15 cm from the light source.

A Shimadzu UV-260 recording spectrophotometer with silica cells of 1-cm path length was used for the absorbance measurements.

Recommended procedures for the estimation of hypophosphite

A. Titrimetric procedure (mmol range)

Thermal method. To an aliquot containing 0.01–0.1 mmol of hypophosphite in a 250-mL round-bottom flask add 20 mL of 5 M $HClO_4$ and 0.40 mmol of thallium(III), and dilute the mixture with water to 100 mL. Reflux for 60 min. Add 15 mL of concentrated hydrochloric acid and cool to 60°C. Add 0.1 mL of 0.1% methyl orange indicator and titrate the thallium(I) formed with 0.05 N potassium bromate (1.392 g/L) until the indicator becomes colourless. This method is also applicable in sulphuric acid medium.

Photochemical method. To an aliquot containing 0.01–0.1 mmol of hypophosphite in a 150-mL beaker add 20 mL of 5 M $HClO_4$, 0.20 mmol of bromide, and 0.40 mmol of thallium(III), and dilute the mixture with water to 100 mL. Stir the solution and expose it to the radiation from a high-pressure mercury vapour lamp for 5 h. Add 15 mL of concentrated hydrochloric acid, 0.1 mL of 0.1% methyl orange indicator, heat to 60°C, and titrate with 0.05 N potassium bromate (1.392 g/L) until the indicator becomes colourless. This method is also applicable in sulphuric acid medium. Although the method requires prolonged exposure to the mercury vapour lamp, it will be highly useful for the estimation of hypophosphite under conditions where heating has to be avoided.

The results (recovery data) presented in Table 1 show that both methods are quite satisfactory and accurate.

B. Spectrophotometric method (μmol range)

Preparation of Beer's Law calibration curve. Prepare six sample solutions by taking different amounts of hypophosphite (0.25, 0.50, 0.75, 1.00, 1.25, and 1.50 μmol) along with 6 mL of 1×10^{-3} M thallium(III) and 1.0 mL of 5 M perchloric acid. Reflux each solution for 60 min. For the photochemical method, instead of refluxing, expose a similar set of solutions to the radiation from a high-pressure mercury vapour lamp for 5 h in the presence of 3 μmol of sodium bromide as catalyst. Transfer the solutions to 25-mL volumetric flasks and add 2.00 mL of 11.6 M perchloric acid and 2.5 mL of 1.0 M sodium chloride. Dilute with water to produce standards 1A, 1B, 1C, 1D, 1E, and 1F. Prepare another solution in a 25-mL volumetric flask by mixing all the above solutions except hypophosphite. This provides solution II. Mix well and wait for 60 min. Measure the optical density of solution II six times, adjusting the spectrophotometer each time to read the optical density of each of the standards to read zero. A calibration curve is drawn by taking the hypophosphite concentration on the *x*-axis and the absorbance of the corresponding solution on the *y*-axis.

Thermal method. To an aliquot containing 0.5–1.25 μmol of hypophosphite add 1 mL of 5 M perchloric acid and 5 mL of 1×10^{-3} M thallium(III). Reflux for 60 min. Transfer the solution to a 25-mL volumetric flask, add 2.00 mL of 11.6 M perchloric acid and 2.5 mL of 1 M sodium chloride, and dilute with water to produce solution I. Prepare another solution in a 25-mL volumetric flask by mixing all the above solutions except hypophosphite. This provides solution II. Mix well and wait for 60 min, then adjust the spectrophotometer to read the optical density of solution I to zero and measure the optical density of solution II (which corresponds to the thallium(III) reacted). The concentration of thallium(III) thus reacted corresponds to the hypophosphite concentration, which can be read from the Beer's Law calibration curve.

Photochemical method. To an aliquot containing 0.5–1.25 μmol of hypophosphite add 1 mL of 5 M perchloric acid, 2.5 μmol of sodium bromide, and 5 mL of 1×10^{-3} M thallium(III), and expose the solution to the radiation from a high-pressure mercury vapour lamp for 5 h. Transfer the solution to a 25-mL volumetric flask, add 2.00 mL of 11.6 M perchloric acid and 2.5 mL of 1 M sodium chloride, and dilute with water to produce solution I. Adopting the same procedure, in the absence of hypophosphite prepare another solution and dilute with water to solution II. The amount of hypophosphite is computed as described before.

The results (recovery data) are presented in Table 2.

Recommended procedure for the titrimetric estimation of thallium(III) (mmol range)

Photochemical method

To an aliquot containing 0.05–0.20 mmol of thallium(III) in a 150-mL beaker add 20 mL of 5 M perchloric acid, 0.8 mmol of hypophosphite, and 0.05 mmol of bromide, and dilute the mixture with water to 100 mL. Stir the solution and expose it to the light from a high-pressure mercury vapour lamp for 10 min or add 0.4 mmol of chloride instead of 0.05 mmol of bromide and dilute the mixture with water to 100 mL. Stir the solution and expose it to the light from a high-pressure mercury vapour lamp for 30 min. Add 15 mL of concentrated hydrochloric acid and 0.1 mL of 0.1% methyl orange indicator, heat to 60°C and titrate the thallium(I) formed with 0.05 N potassium bromate until the indicator becomes colourless.

Thermal method

To an aliquot containing 0.05–0.20 mmol of thallium(III) in a 150-mL beaker add 20 mL of 5 M perchloric acid (to maintain 1 M) and 0.8 mmol of hypophosphite, dilute the mixture to 100 mL, and heat on a boiling water bath for 5 min. The reduced thallium(I) is titrated with potassium bromate under the conditions already described.

Recommended procedure for the estimation of mixtures of thallium(I) and thallium(III)

Using the differential method, mixtures of thallium(I) and thallium(III) are also estimated. Take two identical aliquots of mixtures of thallium(I) (0.1–0.5 mmol) and thallium(III) (0.1–0.5 mmol). First estimate the thallium(I) directly by titrating the first sample bromatometrically using methyl orange as indicator. Reduce the second sample either thermally or photochemically as described earlier and titrate to find the total thallium. The difference between the two titres corresponds to the thallium(III) present in the mixture. The results (Table 3) show that thallium(III) can be determined satisfactorily either alone or in such mixtures. This method is also applicable in sulphuric acid medium.

Recommended procedure for the analysis of ternary mixtures of hypophosphite, phosphite, and oxalate

To an aliquot containing 0.01–0.05 mmol each of hypophosphite, phosphite, and oxalate in a 150-mL beaker, add 20 mL of 5 M perchloric acid and 0.4 mmol of thallium(III). Then add 0.2 mmol of sodium bromide and dilute the mixture with water to 100 mL. Stir the solution and expose to light from a high-pressure mercury vapour lamp for 5 h or, in the absence of sodium bromide, reflux for 60 min. Add 15 mL of concentrated hydrochloric acid and 0.1 mL of 0.1% methyl orange indicator, heat to 60°C, and titrate with 0.05 N potassium bromate (1.392 g/L) until the indicator becomes colourless. The titre corresponds to the amount of thallium(I) formed (*a* mmol) equivalent to the conversion of both hypophosphite and phosphite to phosphate and of oxalate to carbon dioxide.

To a second aliquot of the mixture in a 150-mL beaker add 0.4 mmol of thallium(III) and 4.0 mmol of chloride instead of bromide. Then add 20 mL of 5 M perchloric acid and dilute the mixture with water to 100 mL. Stir the solution and expose to light from a high-pressure mercury vapour lamp for 10 min. Repeat the same procedure; this titre corresponds to the thallium(I) formed (*b* mmol), which is equivalent to the oxalate present in the mixture.

To the third aliquot of the mixture in a 150-mL beaker add 0.1 mmol of chloramine-T and 10 mL of 5 M sulphuric acid. Keep the solution for 24 h at room temperature. The unreacted chloramine-T is determined iodometrically. The chloramine-T reacted (*c* mmol) corresponds to the amount of hypophosphite present in the mixture. The amount of phosphite corresponds to $a-(b + 2c)$ mmol.[3]

The conditions for analysis of the ternary mixtures are summarized in Table 4 and the results (recovery data) are presented in Table 5.

Interferences

Cd(II), Zn(II), Ru(III), Co(II), Ni(II), Hg(II), Al(III), Pb(II), NH_4^+, Na^+, K^+, Ca^{2+}, Ba^{2+}, SO_4^{2-}, CH_3COO^-, PO_4^{3-}, 2,2′-bipyridyl, and 1,10-phenanthraline do not interfere even if they are present in 100-fold excess over hypophosphite. Traces of oxalate and phosphite interfere by reducing thallium(III) to thallium(I). Arsenite interferes with the bromatometric titration method; Cu(II) up to 0.05 M does not interfere, but at high concentrations its colour interferes with detection of the end point in the bromatometric titration. Traces of chloride and higher concentrations of bromide retard the photochemical oxidation of hypophosphite. Optimum concentrations of chloride and bromide catalyse the photochemical reduction of thallium(III) with hypophosphite.

Results and discussion

Titrimetric procedure for the estimation of hypophosphite

Oxidation of hypophosphite with thallium(III) is slow but the reaction is catalysed in the presence of light. In addi-

[3]Twice the equivalent of thallium(I) will be formed during the conversion of hypophosphite to phosphate.

Note: The subscript is not a significant figure.

tion, the reaction is considerably faster at elevated temperatures. Separate studies have shown that hypophosphite does not interfere in the titration of thallium(I) with bromate, using methyl orange as indicator. This reaction was therefore used to monitor the progress of all the reactions described in the investigation. The reactions were carried out in sulphuric and perchloric acid media.

As per the stoichiometry of the reaction, eq. [1], a minimum of two moles of thallium(III) per mole of hypophosphite is required for a quantitative oxidation.

$$[1] \quad PO_2^{3-} + 2Tl(III) + 2H_2O \rightarrow PO_4^{3-} + 2Tl(I) + 4H^+$$

The rate of the reaction is found to increase with an excess of thallium(III) up to a concentration four times that of hypophosphite. Any concentration ratio of thallium(III) to hypophosphite above 4:1 does not appear to further increase the rate of the reaction. In the case of the above reaction a positive acid effect was observed up to an acid concentration of 1.0 mol/L with respect to perchloric acid for both the photochemical and thermal reactions. During the kinetic investigations a negative hydrogen ion effect was reported for this reaction by Gupta and Gupta (12). However, they attributed this observation to medium effects. In the presence of chloride ion, a hydrogen ion effect similar to that observed in the present investigation was noticed by these workers (13). The acid effect can be explained by assuming Tl^{3+} rather than $Tl(OH)^{2+}$ to be the reactive species. At low acid concentrations both these species will be present in solution. However, because of the small hydrolysis constant of thallium(III), the concentration of $Tl(OH)^{2+}$ gradually decreases with an increase in acid concentration. At a particular acid concentration (about 1 M) all the thallium exists as Tl^{3+} and a further increase in acid concentration has no effect on the nature of the species, which explains initial catalysis and then the levelling effect observed at higher acid concentrations.

The hydrogen ion effect can also be linked with hypo-

For personal use only.

phosphite. In aqueous solutions it will be present as $H_2PO_2^-$ and H_3PO_2. Increasing the hydrogen ion concentration will increase the concentration of H_3PO_2. Thus the hydrogen ion effect can be explained by assuming H_3PO_2 as the reactive species and limiting rates can be ascribed to the complete conversion of $H_2PO_2^-$ to H_3PO_2. Jenkins and Yost (14) studied the exchange of radioactive hydrogen between hypophosphorous acid and water. The rate law obtained by these investigators for the exchange reaction is identical with the rate law derived for the oxidation of hypophosphorous acid by a variety of oxidizing agents. Hence they suggested that the exchange and oxidation reactions take place by similar mechanisms and also that these mechanisms involve two tautomeric forms of hypophosphorous acid in aqueous solution. Further, the non-exchangeability of hypophosphite hydrogens in neutral solutions was established by Erlenmeyer et al. (15) and verified by Jenkins and Yost (14). The existence of a tautomeric equilibrium was confirmed (14) and the exchange reaction is represented as:

[2] 
Active form

[3] 
The formation of the active form of the tautomer (shown in eq. [2]) due to the exchange reaction is the active species in the reduction reaction. The exchange reaction is catalysed in the presence of mineral acid, the rate reaching a maximum at a certain acid concentration but showing a leveling effect at still higher values of acid. This might also be one of the reasons for the trend in acid effect observed in the present investigation.

The use of halides to catalyse thallimetric oxidations has been reported (7, 8, 10, 16–21). Hence the effect of bromide and chloride ions on the rate of this reaction was examined. The reaction between thallium(III) and bromide in different acid concentrations at high temperatures confirmed that bromide itself reduces thallium(III) to thallium(I) (22). Thus the effect of bromide ion on the thermal reaction between thallium(III) and hypophosphite could not be studied. The effect of bromide ion on the photochemical oxidation of hypophosphite by thallium(III) in varying concentration of perchloric acid was investigated and the results are shown in Fig. 1. From the data presented in the figure it is clear that photochemical oxidation is fastest when the ratio of thallium(III) to bromide is in the range 4:1–1:1. From the above data it is also clear that the acid effect follows the trend; that is, there is an initial increase in rate as acid concentration is increased, and after reaching a particular acid concentration the rate remains steady at all bromide ion concentrations.

So far, our studies have shown that the photochemical oxidation of hypophosphite to phosphate is complete in 10 h. Further, the effect of chloride on the photochemical and thermal oxidation of hypophosphite was investigated. In the presence of chloride ion the reaction is not complete in 10 h, and these investigations indicated a two-stage process for the oxidation of hypophosphite to phosphate via phosphite that can be represented by the following equations.

[1*a*] $PO_2^{3-} + Tl(III) + H_2O \rightarrow PO_3^{3-} + Tl(I) + 2H^+$

[1*b*] $PO_3^{3-} + Tl(III) + H_2O \rightarrow PO_4^{3-} + Tl(I) + 2H^+$

The first stage of the reaction, that is, the oxidation of hypophosphite to phosphite (eq. [1*a*]) is catalysed by chloride ions with a concentration of up to 50 times that of thallium(III). But the second stage of the reaction (eq. [1*b*]) is retarded in the presence of chloride ions. In the presence of still higher concentrations of chloride, more than 50 times that of thallium(III) (14), both stages of the reaction are retarded. For the reduction of thallium(III) in the presence of excess hypophosphite, only reaction [1*a*] occurs and hence the chloride catalyses throughout the progress of the reaction. The results of these investigations on the thermal oxidations show a trend similar to the results observed in photochemical reactions except for the fact that the thermal reaction is fast compared to the photochemical reaction (Tables 6 and 7).

Unlike chloride, however, which catalyses only the first stages of the photochemical and thermal reactions, bromide in low concentrations catalyses both stages of the photochemical oxidation. As already reported (23), the phosphorus nucleophiles are known to attack the halogen when the latter is bonded to an electron-withdrawing group. Hence, in this case, Cl^- or Br^- attached to Tl^{3+}, a highly positively charged metal ion, can be assumed to be attacked by the phosphorus nucleopile. Under these conditions the lower halo complexes (24) with high formation constants (13, 25) are likely to occur and probably can be active. Hence, these complexes can be considered attached to the active form of the hypophosphite, as proposed by Jenkins and Yost (14), through chloro or bromo bridges that facilitate the electron transfer. Hence, the probable structure of the activated complex may be represented as

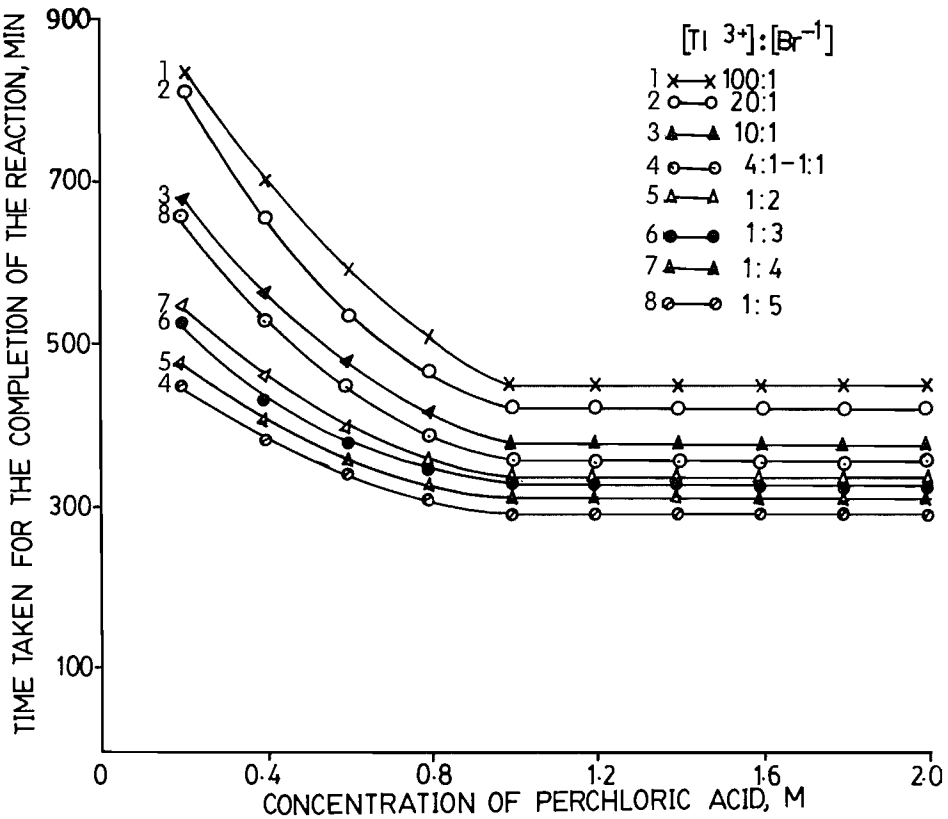

FIG. 1. Effect of $[H^+]$ and $[Br^-]$ on the rate of photochemical oxidation of hypophosphite by thallium(III). Volume of the reaction mixture = 100 mL; amount of thallium(III) = 0.1 mmol; amount of hypophosphite = 0.025 mmol.

However, in the case of Cl^-, the general mechanism proposed here holds good for the first stage of the reaction only.

Spectrophotometric method for the estimation of microquantities of hypophosphite

The absorption spectra (26) of thallium(I) and thallium(III) alone in a medium containing 1 M perchloric acid and 0.1 M hydrochloric acid show that thallium(III) absorbs at 260 nm (molar absorptivity $\epsilon = 9150$ L M^{-1} cm^{-1}) while thallium(I) has no absorbance at this wavelength. In this method an excess of thallium(III) is allowed to react with hypophosphite either photochemically (using bromide as a catalyst) or thermally. The optical density of thallium(III) at 260 nm in the presence of 0.1 M NaCl and 1 M $HClO_4$ is measured to determine the concentration of thallium(III) before and after reaction with hypophosphite. Thallium(I), hypophosphite, and the other reagents employed in this reaction have no absorbance at this wavelength and the thallium(III) chloro species obey Beer's Law. The amount of hypophosphite corresponds to the amount of thallium(III) reduced to thallium(I), which can be computed from the standard curve.

Estimation of thallium(III)

Further investigation of this reaction (eq. [1*a*]) led to the development of a procedure for estimation of thallium(III) that can be applied to the determination of mixtures of thallium(I) and thallium(III). Reduction of thallium(III) with hypophosphite is normally a slow reaction. At room temperature, reduction of thallium(III) with hypophosphite requires 72 h for completion of the reaction. However, in the presence of light the reaction is complete within 3 h. A minimum of one mole of hypophosphite is required per one mole of thallium(III) for a quantitative reduction as per eq. [1*a*].

It was found that four times the amount of hypophosphite to that of thallium(III) was necessary for a rapid reaction and that any ratio of hypophosphite to thallium(III) above 4:1 will not further alter the rate of the reaction. With the concentration of hypophosphite four times that of thallium(III), the effect of acid, chloride, and bromide concentrations on the speed of the reaction was studied in perchloric acid medium and the conditions optimized. Chloride catalyses the photochemical reduction of thallium(III) in the presence of excess hypophosphite as the oxidation of hypophosphite to phosphite is sufficient to bring about the quantitative reduction of thallium(III) to thallium(I). As already pointed out, this stage of the reaction is catalysed by chloride.

Analysis of ternary mixtures of PO_2^{3-}, PO_3^{3-}, and $C_2O_4^{2-}$

Based on the fact that the thallimetric oxidations of hypophosphite, phosphite, and oxalate proceed selectively, convenient methods can be developed for the determination of ternary mixtures of these anions. Chloride and bromide in small concentrations catalyse the photochemical oxidation of oxalate by thallium(III) (7). Bromide in small concentrations catalyses the photochemical oxidation of hypophosphite and phosphite (8) by thallium(III), while chloride in small concentrations inhibits the overall oxidations of hypophosphite and phosphite to phosphate.

TABLE 6. Effect of chloride ion concentration on the photochemical oxidation of hypophosphite by thallium(III)[a]

Amount of chloride taken (mmol)	Percentage of photochemical oxidation of hypophosphite				
	In 2 h	In 4 h	In 6 h	In 8 h	In 10 h

7.00	19	24	33	40	52	61.0
8.00	16	19	25	34	45	54.0
10.0	11	17	22	27	36	50.0

[a]Amount of hypophosphite = 0.025 mmol. Amount of thallium(III) = 0.10 mmol. Perchloric acid = 1 M. Total volume of the reaction mixture = 100 mL.

Thallium(III) oxidizes oxalate, hypophosphite, and phosphite photochemically in the presence of sufficient bromide or at elevated temperatures. In the presence of a suitable concentration of chloride, oxalate is photochemically oxidized, leaving hypophosphite and phosphite unaltered. As reported earlier in this paper, even though the first phase of the reaction, that is, the oxidation of hypophosphite to phosphite by thallium(III), is catalysed by chloride, no noticeable change in the concentration of hypophosphite was observed during the exposure time of 10 min prescribed for the determination of the oxalate in the reaction mixture, under the experimental conditions (Tables 4 and 6). Therefore, if the reaction is carried out in the presence of chloride the result is the quantitative photochemical oxidation of oxalate only under the prescribed time of exposure. In both cases, the thallium(I) formed is determined bromatometrically. The first titre value corresponds to the total thallium(I) formed, corresponding to the conversion of hypophosphite and phosphite to phosphate and oxalate to carbon dioxide and water. The second titre value corresponds to the concentration of oxalate.

Hypophosphite alone can be determined by oxidizing it to phosphite (1) by treating with a known excess of chloramine-T in a sulphuric acid medium for 24 h at room temperature, leaving the original phosphite and oxalate unaltered. Excess chloramine-T is determined iodometrically. The amount of chloramine-T consumed corresponds to the hypophosphite present in the mixture. The concentration of phosphite can be computed from the above two titre values and the chloramine-T consumed.

Electron paramagnetic resonance study of radicals derived from 2- and 3-fluoropropene

PETER SMITH,[1] CYNTHIA ANN HOUGUM, AND ART ARESH HOSSEINIAN
Paul M. Gross Chemical Laboratory, Duke University, Box 90346, Durham, NC 27708-0346, U.S.A.

Received November 25, 1992

PETER SMITH, CYNTHIA ANN HOUGUM, and ART ARESH HOSSEINIAN. Can. J. Chem. **71**, 809 (1993).

Using the $TiCl_3$–H_2O_2, –NH_2OH, –$Na_2S_2O_8$, and –H_2O_2/Na_2SO_3, continuous-flow, radical-generating methods at 25°C, we have successfully characterized by electron paramagnetic resonance spectroscopy radicals formed by the reaction of each of the substrates 2- and 3-fluoropropene with the radicals •OH, $•NH_3^+$, $•OSO_3^-$, and $•SO_3^-$, respectively. With 2- and 3-fluoropropene, respectively, the radicals identified were of general formula $CH_3(X)\dot{C}FCH_3$ and $CH_2(X)\dot{C}HCH_2F$ where -X is the added group, except that treatment of 3-fluoropropene with the $TiCl_3$–H_2O_2 reaction system also yielded $•CH_2CH(X)CH_2F$. The results obtained are discussed in terms of the effect of the presence of the fluorine substituent on both the apparent reactivity of the substrate molecules towards the radical-generating systems and the spectroscopic properties of the radicals observed.

PETER SMITH, CYNTHIA ANN HOUGUM et ART ARESH HOSSEINIAN. Can. J. Chem. **71**, 809 (1993).

Opérant à 25°C, utilisant des méthodes d'écoulement continue pour générer des radicaux à l'aide de $TiCl_3$–H_2O_2, –NH_2OH, –$Na_2S_2O_8$ et –H_2O_2/Na_2SO_3, et faisant appel à la résonance paramagnétique électronique, on a caractérisé les radicaux qui résultent de la réaction des 2- et 3-fluoropropènes avec respectivement les radicaux •OH, $•NH_3^+$, $•SO_3^-$ et $•SO_3^-$. Avec respectivement les 2- et 3-fluoropropènes, les radicaux identifiés étaient de la formule générale $CH_2(X)\dot{C}FCH_3$ et $CH_2(X)\dot{C}HCH_2F$ dans lesquels X est le groupe ajouté; toutefois, dans le cas du traitement du 3-fluoropropène avec le système réactionnel $TiCl_3$–H_2O_2, il y a aussi formation de $•CH_2CH(X)CH_2F$. On discute des résultats obtenus en fonction de l'effet de la présence du fluor sur la réactivité apparente du substrat pour les systèmes générant des radicaux ainsi que sur les propriétés spectrales des radicaux observés.

[Traduit par la rédaction]

Introduction

In our laboratory, there have been a number of electron paramagnetic resonance (epr) investigations of radicals formed from allyl alcohol, CH_2=$CHCH_2OH$, methallyl alcohol, CH_2=$C(CH_3)CH_2OH$, and related compounds using $TiCl_3$-based, continuous-flow, radical-generating methods (1–6). These previous investigations deal mainly with the addition of •OH and $•NH_3^+$ radicals to these compounds. The present study extends this earlier work to include the reactions of two fluorinated isomers, 3-fluoropropene, CH_2=$CHCH_2F$ (**1**), and 2-fluoropropene, CH_2=$CFCH_3$ (**2**), with not only •OH and $•NH_3^+$ radicals, but also the radical anions $•SO_3^-$ and $•OSO_3^-$. The species identified were addition radicals that, to our knowledge, have not been characterized before by epr.

Fluoropropenes are of interest because the fluorine substituent would be expected to affect the reactivity of these monomers towards attack by electrophilic radicals such as those generated by the $TiCl_3$-based reaction systems employed in our work (7–11). Moreover, the geometry and consequently the spectroscopic properties of the radical adduct formed would tend to be affected by the presence of the highly electronegative fluorine substituent (7–13). The results of this investigation are discussed in the light of these factors.

Experimental

The experimental arrangements and procedures were essentially as before (14) except that all measurements were taken using a Varian E-231 multipurpose single cavity. The field and *g*-value standard was potassium peroxylamine disulfonate (Alpha, 95%) (15, 16) in an aqueous solution saturated at room temperature with potassium carbonate (Fisher, anhydrous, ACS reagent), the temperature of the standard as used being 25.0 ± 1.0°C. Spectrum simulation was carried out on a VAX 8350 utilizing a program by Oehler and Janzen (17) and assuming the lineshape to be primarily Lorentzian (90%). Previous work in our laboratory has shown that variation of the lineshape made little difference in the appearance of simulated spectra (1). All spectra were recorded at 25.0 ± 1.0°C as the first derivative of the signal at a 100-kHz field-modulation frequency. The field-modulation amplitude was normally 0.050–1.0 G and all results refer to that range. Relative radical concentrations were estimated using the peak-height method and non-overlapping lines of equal peak-to-peak linewidth (ΔH_{pp}) (18, 19).

All radicals were observed using either a two- or a three-stream, rapid-mixing, continuous-flow epr system (14, 20, 21). The epr sample flow cells employed were of the aqueous, mix-and-flow type and were either of the Borg design (22), as before (14), or as supplied by Wilmad Glass Company, Inc. (Cat. no. WG-804-Q), both cells yielding indistinguishable results. The total flow rate was maintained at 2.9–4.7 mL s^{-1}, this being equally divided between the individual reaction streams, and the results obtained being independent of flow rate over this range. Where necessary, pH measurements on reaction mixtures were taken using a DigiSense pH meter and a Fisher electrode (Cat. no. 13-620-104).

The substrates, 3-fluoropropene, **1**, and 2-fluoropropene, **2**, both from PCR, were mixed in turn with titanous chloride (Fisher, 20%) and each of the following oxidizing agents: hydrogen peroxide (Fisher 30%, ACS reagent), hydroxylamine hydrochloride (Aldrich, 99%), and sodium persulfate (Aldrich, 98+%). In addition, as an extension of the $TiCl_3$–H_2O_2 radical-generating method, **1** and **2** were each examined using this method modified to include sodium sulfite (Fisher, ACS reagent, anhydrous, 98+%) by way of a third reaction stream. The remaining reagents employed were H_2SO_4 (Mallinckrodt, analytical reagent, 96.0%), NH_4OH (Mallinckrodt, analytical reagent, 29.8%), and disodium ethylenediamine tetraacetate (EDTA, Fisher, 95%).

When employing the $TiCl_3$–H_2O_2 radical-generating method (14), the reducing stream was 0.004–0.005 M in $TiCl_3$, the oxidizing

TABLE 1. Electron paramagnetic resonance data[a] for radicals derived from CH_2=$CHCH_2F$

Radical	Coupling constants (G)[b,c] α-CH	β-CH_2X[d]	β-CH_2F	Other[e]	Δg[f]
3 $CH_2(OH)\dot{C}HCH_2F$	21.45(7)	23.86(5)	15.72(3)	86.91(4)	41(5)
4 $\cdot CH_2CH(OH)CH_2F$	22.09(4)[g]	24.47(4)[h]	—	4.94(3)	54(5)
5 $CH_2(NH_3^+)\dot{C}HCH_2F$	22.02(4)	21.92(5)	19.25(4)	69.01(5), 5.58(5)[i]	44(2)
6 $CH_2(OSO_3^-)\dot{C}HCH_2F$[j]	21.68(6)	20.22(2)	18.45(6)	73.17(7)	37(3)
7 $CH_2(SO_3^-)\dot{C}HCH_2F$[j]	21.57(4)	15.64(4)	19.48(6)	69.42(3)	59(4)

[a]At 25.0 ± 1.0°C and, unless stated otherwise, pH ca. 1.
[b]Unless indicated otherwise, all *a* values are for protons. All protons at a given designation are magnetically equivalent. Each number in parentheses is the standard deviation of the mean, σ_{n-1}, times 10^2 and the maximum error limit is approximately $\pm 2\sigma_{n-1}$, based on the reported error limits for the field standard (15).
[c]The ΔH_{pp} values were 0.4–0.5 G for **3**, **4**, **5**, and **7** and 0.5–1.0 G for **6**.
[d]-X is equal to -OH, $-NH_3^+$, $-OSO_3^-$, or $-SO_3^-$, respectively, for **3**, **5**, **6**, and **7**.
[e]a_F, unless stated otherwise.
[f]Δg value = (g − 2.00200) times 10^5, and each number in parentheses is σ_{n-1} times 10^5. The maximum error limits are $\pm(\sigma_{n-1} + 0.00005)$ based on the reported error limits of the field and g-value standard (15, 16).
[g]α-CH_2.
[h]β-CH(OH).
[i]a_N.
[j]pH 9.0 ± 0.1.

stream 0.10 M in H_2O_2, and both streams 0.10 M in H_2SO_4 and of equal concentration, within the range 0.015–0.020 M, in **1** or **2**, unless stated otherwise. When using the $TiCl_3$–NH_2OH method (14), the reaction conditions were as for the $TiCl_3$–H_2O_2 work except that the H_2O_2 in the oxidizing stream was replaced with 1.0 M NH_2OH•HCl. When employing the $TiCl_2$–$Na_2S_2O_8$ system, the reaction conditions employed first were as for the $TiCl_3$–H_2O_2 work, i.e., with the reaction mixture at pH ca. 1, except that the H_2O_2 in the oxidizing stream was replaced with 0.20 M $Na_2S_2O_8$. However, to improve the signal-to-noise (S/N) ratio of the spectra obtained using the $TiCl_3$–$Na_2S_2O_8$ system, data were also taken with the pH of the reaction mixture varied over the range 7–9 (23, 24). This was achieved by making the reducing stream 0.016 M in EDTA, and eliminating H_2SO_4 from and adding NH_4OH to both streams, the results being qualitatively indistinguishable over that pH range. All results quoted for use of this system refer to pH 9.0 ± 0.1. Moreover, to further improve the S/N ratio when examining **1**, the concentration of substrate was increased to 0.060–0.080 M.

When utilizing the $TiCl_3$–H_2O_2/Na_2SO_3 reaction system, the conditions when the reaction mixture was of pH ca. 1 were as for the $TiCl_3$–H_2O_2 work except that the concentration of H_2O_2 in the oxidizing stream was lowered to 0.050 M and a third reaction stream containing 0.20 M Na_2SO_3 was added, all three streams being of equal concentration, within the range 0.015–0.045 M, in **1** or *2*. The Na_2SO_3 stream joined the reducing stream by way of a Y-piece located about 10 cm upstream from the mixing chamber of the epr sample flow cell where the mixture encountered the H_2O_2 stream. As was the case for the $TiCl_3$–$Na_2S_2O_8$ work, this system was run with the pH of the reaction mixture ca. 1 and 7–9. The data over the pH range 7–9 were taken with the $TiCl_3$ stream 0.016 M in EDTA and with H_2SO_4 omitted from the $TiCl_3$ and H_2O_2 streams and replaced, in the case of the $TiCl_3$ stream, with NH_4OH, the results obtained when the pH was 7–9 being essentially the same and of higher S/N than when the pH was ca. 1. All the data referred to for this system are for pH 9.0 ± 0.1. In the reactions with both **1** and **2** there was a residual signal from the unreacted $\cdot SO_3^-$, g-value = 2.0030 (21), that was evident in all spectra.

Results and discussion

Tables 1 and 2, respectively, summarize the epr spectroscopic data obtained from the reaction of monomers **1** and **2** within the $TiCl_3$–H_2O_2, –NH_2OH, –$Na_2S_2O_8$, and –H_2O_2/Na_2SO_3 systems. In all cases the concentration of monomer was low enough that polymeric radicals were not observed (5, 6).

In general, our results are consistent with simple expectations based on the electronic and steric character of both the fluorinated monomers and the attacking radicals. However, it should be noted that the kinetic complexity of the radical-generating systems used (6, 23–27) prevents a detailed analysis of these factors here. Nevertheless, while bearing in mind these factors, it seems that the $TiCl_3$–H_2O_2 radical-generating system is more reactive towards **1** and **2** than the other systems.

3-Fluoropropene, 1

When examined using the $TiCl_3$–H_2O_2 system, **1** underwent head and tail hydroxyl-radical addition to yield $CH_2(OH)\dot{C}HCH_2F$, **3**, and $\cdot CH_2CH(OH)CH_2F$, **4**, respectively. The major product, **3**, corresponded to radical addition to the unhindered end of the double bond, which is also the site of highest electron density (11, 28), the value of the ratio [**3**]/[**4**] in the steady state being equal to 4, in qualitative agreement with the corresponding data from analogous studies of other allyl compounds (5, 6). Not surprisingly, in view of the electrophilicity of •OH (5, 6, 28) and the high electron-withdrawing ability, *-I*, of fluorine (11, 29), there was no evidence for the formation of the allylic radical, CH_2=$CH\dot{C}HF$. This result contrasts with the observation of the CH_2=$CH\dot{C}HOH$ radical in analogous $TiCl_3$–H_2O_2 studies of allyl alcohol, consistent with the lower inductive ability of -OH in comparison with -F (5, 6, 28).

When reacting **1** with $\cdot NH_3^+$, $\cdot SO_3^-$, and $\cdot OSO_3^-$, only the head-addition radical product was observed. The result when using the $TiCl_3$–NH_2OH system is consistent with the electrophilicity of $\cdot NH_3^+$ (28) and the well-known lower apparent reactivity of this radical-generating system, in comparison to that of the $TiCl_3$–H_2O_2 method (5, 14, 30).

TABLE 2. Electron paramagnetic resonance data[a] for radicals derived from CH_2—$CFCH_3$

Radical	Coupling constants (G)[b,c]			Δg[f]
	β-CH_3	β-CH_2X[d]	Other[e]	
8 $CH_2(OH)\dot{C}FCH_3$	22.53(7)	10.51(6)	58.18(5)	147(3)
9 $CH_2(NH_3^+)\dot{C}FCH_3$	22.81(7)	13.52(5)	59.17(7), 8.02(9)[g]	139(6)
10 $CH_2(OSO_3^-)\dot{C}FCH_3$[h]	22.97(5)	7.96(8)	56.92(5)	150(4)
11 $CH_2(SO_3^-)\dot{C}FCH_3$[h]	22.82(2)	11.46(2)	55.43(7)	159(3)

[a]See Table 1, footnote *a*.
[b]See Table 1, footnote *b*.
[c]The ΔH_{pp} values were 0.3–0.6 G for each of **8**–**11**.
[d]-X is -OH, $-NH_3^+$, $-OSO_3^-$, or $-SO_3^-$, respectively, for **8**, **9**, **10**, and **11**.
[e]See Table 1, footnote *e*.
[f]See Table 1, footnote *f*.
[g]See Table 1, footnote *i*.
[h]See Table 1, footnote *j*.

The apparent reactivity of the $TiCl_3$–H_2O_2/Na_2SO_3 and $-Na_2S_2O_8$ systems in comparison with the $TiCl_3$–H_2O_2 system does not appear to have been reported in the literature. Consequently, it should be noted that although evidence for a signal was obtained when employing the $TiCl_3$–$Na_2S_2O_8$ system with **1** at the same concentration as that used with the other systems, i.e., 0.015–0.020 M, it was only with a quadrupled concentration of **1** that an acceptable S/N ratio was obtained.

The presence of only head-addition radical products in the reactions of **1** with $\cdot OSO_3^-$ and $\cdot SO_3^-$ provides evidence for the electrophilicity of these two attacking radicals, which is consistent with the literature (28). Previous experimental work indicated that $\cdot OSO_3^-$ is more reactive than SO_3^- in regard to hydrogen-atom abstraction from alkanes, this difference in reactivity being plausibly explained as arising because the unpaired electron is centered on the oxygen in $\cdot OSO_3^-$ and on the sulfur in $\cdot SO_3^-$ (31–33). However, $\cdot OSO_3^-$ and $\cdot SO_3^-$ are found to show variable differences in apparent reactivity in regard to addition to monosubstituted ethylenes that can be attributed to steric and electrostatic effects arising from the nature of the substituent (23, 24, 31, 32). Thus, the strong electronegativity of the fluorine substituent in **1** could account for the apparent low reactivity of $\cdot OSO_3^-$ with **1** in comparison with that of $\cdot SO_3^-$.

In analyzing the spectroscopic data obtained for the various radical adducts of **1**, Table 1, with the general structure $CH_2(X)\dot{C}HCH_2F$ and X being the added group, the following observations should be drawn. The coupling constant for the α-CH protons, $a_{\alpha\text{-H}}$, is relatively constant, 21.7 ± 0.3 G. This is in keeping with previous findings in our laboratory (5, 6) for radicals of general structure $CH_2(X)\dot{C}HCH_2Z$, where X and Z are various substituents, and is to be expected as ρ_α^π, the π-electron unpaired spin density at the α-C, and the value of Q_α in the McConnell equation (34)

$$[1] \qquad a_{\alpha\text{-H}} = Q_{\alpha\text{-H}}\rho_\alpha^\pi$$

should be relatively insensitive to the identity of X or Z (35). Therefore, it follows that, for a given radical, any observed differences in the two β-CH_2 proton coupling constants may be largely attributed to conformational differences in the -CH_2X and the -CH_2F groups, as may the variation of these two β-CH_2 proton coupling constants and of the β-CH_2F fluorine coupling constant for the radicals **3** and **5**–**7**. Thus, the data in Table 1 suggest that for each $CH_2(X)\dot{C}HCH_2F$ radical, the -CH_2 (1:2:1)-proton coupling may be assigned by utilizing the reasonable assumption that $a_{\beta\text{-H}}(CH_2F)$ should depend on $a_{\beta\text{-F}}(CH_2F)$ in an inverse fashion, while $a_{\beta\text{-H}}(CH_2X)$ should vary with the identity of X, but not depend to any large extent on the value of $a_{\beta\text{-F}}(CH_2F)$. This approach is in accord with the McConnell equation (34), which, for the case of the β-CH_2F protons, has the form

$$[2] \qquad a_{\beta\text{-H}}(CH_2F) = 2\,Q_{\beta\text{-H}}(CCH_2F)\rho_\alpha^\pi\langle\cos^2\theta\rangle$$

where θ is the dihedral angle between the C_β—F bond and the $2p_z$-orbital at C_α and $\langle\cos^2\theta\rangle$ is the time-averaged value, analogous relationships holding for $a_{\beta\text{-F}}(CH_2F)$ and $a_{\beta\text{-H}}(CH_2X)$.

Hence, for a -CH_2F group, when θ is small, the resulting dihedral angles between the C_β—H bonds and the $2p_z$-orbital at C_α are large, causing the β-CH_2F proton and fluorine coupling constants to be inversely related. The assignment of the remaining β-CH_2 proton coupling to the β-CH_2X group is further confirmed by comparisons with data for analogous radicals (5, 6, 23, 24). The *g*-values found for **3** and **5**–**7** are also in good agreement with those seen previously in radicals of this type (5, 6, 23).

Only in the case of •OH addition to **1** was a tail-addition radical $\cdot CH_2CH(OH)CH_2F$, **4**, produced. The resulting couplings and *g*-value of **4** are in accord with those seen for other radicals of general structure $\cdot CH_2CH(OH)CH_2Y$ (5, 6).

2-Fluoropropene, 2

In the reaction of **2** within each of the $TiCl_3$-based radical-generating systems, only one radical adduct was observed, corresponding to addition to the sterically unhindered end or head end of the double bond, where the electron density is a maximum (11, 36). The presence of the fluorine substituent on the hindered end of the double bond deactivates that carbon, the *-I* effect predominating over the *+M* effect as evidenced by head addition of electrophilic radicals, such as •OH, $\cdot NH_3^+$, $\cdot SO_3^-$, and $\cdot OSO_3^-$. That **1** yielded **3** and **4** when treated in the $TiCl_3$–H_2O_2 system and **2** produced only $CH_2(OH)\dot{C}FCH_3$, **8**, suggests this differ-

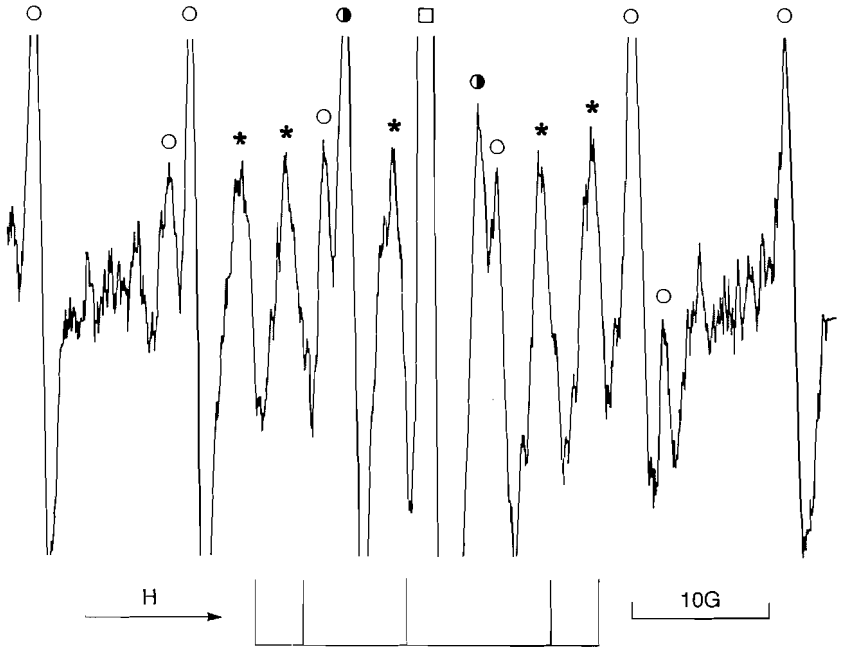

FIG. 1. The center of the epr absorption observed using the $TiCl_3$–H_2O_2/Na_2SO_3 system with **2**: [$TiCl_3$], 0.004 M, and [EDTA], 0.016 M, in the reducing stream, this containing enough NH_4OH so that the mixed reaction-mixture stream was of pH 9.0 ± 0.1; [H_2O_2], 0.050 M in the oxidizing stream; [Na_2SO_3], 0.20 M in the Na_2SO_3 stream; [**2**], 0.045 M in all three streams; total flow rate 2.9 mL s^{-1} equally divided between the three streams; modulation amplitude, 1.0 G; fieldscan rate, 12.5 G min^{-1}; time constant, 1.0 s; receiver gain, 4.0×10^4; microwave power, 20 mW. All the peaks expected in the first-order spectrum of **11** are identified by ○ or ◑, each of the latter representing two overlapping lines; the five peaks assigned to **12** are denoted by asterisks and the stick diagram; □ indicates the signal from $\cdot SO_3^-$. Apart from the uncertainty of the line structure for **12** about the spectrum center cited in the text, there is the possibility of the presence of low-intensity lines between the two outermost peaks of **11** in both the high- and the low-field regions shown in this figure.

ence in apparent monomer reactivity arises from electronic rather than steric interactions at the C-2 position in **1** and **2**, as we would expect the latter to be comparable in the two cases (36). This follows because -H and -F are roughly the same size and are clearly smaller than the similarly sized groups $-CH_3$ and $-CH_2F$ (36). Preferential head addition is seen in analogous studies of isopropenyl monomers that are deactivated or sterically hindered at one of the ethylene carbons (1, 2, 4–6, 37).

Most of the epr absorption produced by the reaction of **2** with $\cdot SO_3^-$ was readily assignable to the addition radical $CH_2(SO_3^-)\dot{C}FCH_3$, **11**. However, apart from this major component, the rest of the absorption, ca. 10% of the total signal, consisted of five lines, namely, a (1:1)-doublet of (1:1)-doublets with couplings of 3.6 G and 22.2 G and a *g*-value of ca. 2.0032, which, for the sake of discussion, we denote as arising from radical **12**. Close to the center of the four-line spectrum of **12** was one extra line 11.1 G upfield from the low-field wing peak with an intensity approximately equal to one of the other four; however, the observed intensity of this extra line and the apparent absence of any neighboring lines may be a result of overlap with those from **1** and $\cdot SO_3^-$. Figure 1 shows that part of the observed epr absorption is relevant to the discussion here. The two most plausible products would be the tail addition radical, $\cdot CH_2CF(SO_3^-)CH_3$, **13**, or the allylic hydrogen-abstraction product, $CH_2{=}CFCH_2\cdot$, **14**. The epr absorption found is inconsistent with that expected for **13**, which, for example, should have an α-CH_2 proton coupling similar in size to that in **4** and a β-CF fluorine coupling possibly as large as those present in **3** and **5–7**. Also, the isotropic epr spectrum of **14** has already been reported and is very different from the absorption we observed (8–10). It should also be noted the $TiCl_3$–H_2O_2/Na_2SO_3 radical-generating system is more complicated than the others used in this study because of the number of reactants present in the two-step method for $\cdot SO_3^-$ production.

In analyzing the spectroscopic data for **8–11** the following items should be noted. The *g*-values observed are in reasonable agreement with the literature for radicals of structure similar to **8–11** (13, 38). The β-CH_3 proton couplings are relatively constant, 22.8 ± 0.2 G, as are the α-CF fluorine couplings. Therefore, any differences in the β-CH_2X proton couplings must be largely the result of conformational preferences about the C_α—$C_\beta H_2X$ bond induced by the -X group. Moreover, the presence of the strongly electronegative fluorine on C_α may cause a lack of planarity about C_α compared to that expected in **3** and **5–7**, for example (9, 12). We would expect this lack of planarity to tend to hinder the rotation of the β-CH_2X group about the C_α—C_β bond in **8–1** relative to that occurring in **3** and **5–7**, respectively, this giving rise to smaller $a_{\beta\text{-H}}(CH_2X)$ values (9, 38, 39). This comparison of **8–11** with **3** and **5–7** rests on the previously mentioned assumption that -H and -F are roughly the same size and much less bulky than the similarly sized groups $-CH_2F$ and $-CH_3$ (37). This assumption implies quite reasonably that the non-planarity at C_α favors increased steric and polar interactions between the β-CH_2X and the α-$C(F)CH_3$ groups.

1,2-Nucleophilic additions of organolithium reagents to chiral oxime ethers

R. KARL DIETER[1] AND RAVINDRA DATAR
Department of Chemistry, Clemson University, Clemson, SC 29634-1905, U.S.A.

Received January 3, 1993

R. KARL DIETER and RAVINDRA DATAR. Can. J. Chem. **71**, 814 (1993).

Chiral oxime ethers are readily prepared from chiral alkoxyamines derived from ephedrine and norephedrine. These chiral oxime ethers of isobutyraldehyde and benzaldehyde undergo 1,2-nucleophilic addition reactions with alkyllithium reagents (*n*-BuLi, PhLi and *n*-BuLi, *tert*-butyllithium, respectively) to afford the chiral alkoxyamines with a diastereomeric excess of 64–88%. Reduction of the alkoxyamines with $LiAlH_4$ gave the corresponding chiral amines. The diastereoselectivity of the reaction appears to directly mirror the *E*:*Z* ratio of the starting oxime ethers.

R. KARL DIETER et RAVINDRA DATAR. Can. J. Chem. **71**, 814 (1993).

On peut facilement préparer des éthers d'oxines chirales à partir des aldoximes chirales dérivées de l'éphédrine ou de la norephédrine. Ces éthers d'oximes chirales de l'isobutyraldéhyde ou du benzaldéhyde peuvent subir des réactions d'addition nucléophiles-1,2 avec des réactifs d'alkyllithium (respectivement *n*-BuLi, PhLi et *n*-BuLi, *tert*-butyllithium) pour conduire aux alkoxyamines chirales avec un excès diastéréoisomériques de 64–88%. La réduction des alkoxyamines avec du $LiAlH_4$ conduit aux amines chirales correspondantes. La diastéréosélectivité de la réaction semble être le reflet direct du rapport *E*:*Z* des éthers des oximes de départ.

Although the enantioselective addition of organometallic reagents to aldehydes is a well-studied reaction (1), the corresponding 1,2-nucleophilic addition to imines (2) and their analogs (e.g., hydrazones and oximes) has only recently begun to receive comparable attention. This synthetic approach to chiral amines must contend both with the reduced electrophilicity of imines and their analogs and with the problem of C=N double bond geometry, which generally produces mixtures of *E* and *Z* stereoisomers. Enantioselective addition of organometallic reagents to chiral imines (3), hydrazones (4), oximes (5, 6), nitrones (7), and iminium ions (8) has been reported and promising studies involving addition of organometallic reagents to imines (9), oximes (10), and mixed benzotrazole aminals (11) in the presence of chiral catalysts have recently appeared. Some of these procedures, however, appear limited to aryl imines. The RAMP and SAMP hydrazones give good asymmetric induction upon reaction with organolithium (4*d*, *e*) and organocerium (4*a*–*c*) reagents. Reduction of the hydrazine N—N bond, however, requires strong reducing agents that may not be compatible with a wide range of functional groups, although improved procedures (4*f*) have been developed.

The N—O bond of alkoxy amines is much easier to reduce, but activated chiral oxime ethers are reported (5*b*, *c*) to give relatively modest optical yields upon reaction with organolithium reagents. Addition of organolithium reagents to unactivated oxime ethers has only recently been achieved (12) with the aid of $BF_3 \cdot Et_2O$. Utilization of chiral unactivated oxime ethers has been limited to reduction reactions with metal hydrides (6) and addition of allyl Grignard, lithium, and cerium reagents (5*a*) to chiral α-alkoxyoximes. Our recently reported procedure (13) for effecting regio- and stereoselective substitution of the benzylic hydroxyl group in ephedrine derivatives provides a facile synthetic route to chiral alkoxyamines. We have examined the reaction of chiral oxime ethers (prepared from the ephedrine-derived alkoxyamines) with organometallic reagents as a potentially viable route to chiral amines. Some qualitative insight into the relative reactivity of oxime ether *E* and *Z* geometrical isomers and their role in determining the diastereoselectivity of the reaction has been obtained.

Results

The chiral alkoxyamines **3** and **4** can be readily prepared from *N*-methylephedrine **1***a* and the known (14) norephedrine derivative **1***b*, respectively, in a stereo- and regiospecific manner (Scheme 1) (13). Treatment of **1***a*,*b* with methanesulfonyl chloride – triethylamine followed by addition of *N*-hydroxyphthalimide affords alkoxyimides **2***a*,*b*. Cleavage of the phthalimide with hydrazine gave the alkoxyamines **3** and **4** in excellent overall yield from ephedrine and norephedrine, respectively. Reaction of **3** and **4** with aldehydes in ethanol (eq. [1]) afforded the corresponding oxime ethers **5***a*–*c* and **6**, respectively, as mixtures of *E*:*Z* stereoisomers (Table 1, 94:6 to 63:37 ratios). The ratio of *E*:*Z* isomers was determined from ^1H NMR (15) integration ratios or ^{13}C NMR (16) peak height ratios. Comparison of *E*:*Z* ratios determined by both ^1H and ^{13}C NMR measurements provides an independent verification since values de-

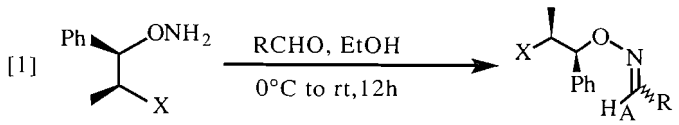
[a]The crude reaction mixture was >90% homogeneous for oxime and addition product by ^{1}H NMR.
[b]Product to starting material mole ratios were determined by ^{1}H NMR integration ratios.
[c]In this experiment, the E:Z ratio of **5***a* was 38:62.
[d]In this experiment, the E:Z ratio of **5***a* was 63:37.
[e]THF was added as a cosolvent to facilitate solubility.

termined from ^{13}C NMR measurements may be inaccurate due to differential T_1 and nuclear Overhauser effects (16*a*). Formation of oxime ether **5***a* in pyridine gave predominantly the Z stereoisomer.



3 X = NMe_2

4 X = 
5 X = NMe_2 *a* R = Me; *b* R = ^{i}Pr; *c* R = Ph

6 X =  , R = ^{i}Pr

Oxime ethers **5***a* and **5***b* were treated with several organometallic reagents in an initial probe of oxime ether reactivity and reagent efficacy. The reagents PhMgCl ($PhCH_3$), PhMgBr–$ZnBr_2$ (THF), and PhLi (THF–$PhCH_3$) gave only recovered starting material while n-BuLi–$CeCl_3$ (THF) (4*a*–*c*) and PhMgBr–$LiClO_4$ (Et_2O) (17) gave a mixture of starting material and N-methylephedrine resulting from cleavage of the N—O bond. The cuprate reagent, n-Bu_2CuLi (THF), gave a complex mixture consisting chiefly of N-methylephedrine. Reaction of oxime ether **5***a* (63:37 E:Z mixture) with n-BuLi (THF, −78°C, 30 min) gave the addition product **7***a* (40%, 60:40 mixture of diastereomers), recovered Z-oxime ether **5***aZ* (22%), and N-methylephedrine (37%).

Examination of $BF_3 \cdot Et_2O$ as an additive (12) in the addition reactions of n-BuLi to oxime ethers **5***a*–*c* revealed that 3.0 equivalents of n-BuLi–$BF_3 \cdot Et_2O$ were required for complete disappearance of the starting oxime ethers (Table 2). In these experiments, the n-BuLi reagent was added dropwise to the toluene solution of the oxime and $BF_3 \cdot Et_2O$. The reactions of oxime ether **5***a* provided several interesting observations. First, oxime ether **5***a* rich in the Z isomer gave greater conversion to the addition product (Table 2, entry 1) with 1.2 equivalents of the reagents than the sample of **5***a* rich in the E isomer (Table 2, entry 2) gave with 2 equivalents of the reagents. Second, unreacted oxime ether **5***a* originally rich in the Z isomer displayed a 1:1 E:Z ratio

2	2	63:37	60:40	55:45	50:50
3	3	63:37	—	100:0	60:40

[a]Ratios were determined by ^{1}H NMR integration ratios.
[b]Obtained by preparation of oxime ether in pyridine.

after treatment with *n*-BuLi–$BF_3 \cdot Et_2O$ whereas unreacted oxime ether **5***a* originally rich in the *E* isomer displayed the same *E*:*Z* ratio after treatment with *n*-BuLi–$BF_3 \cdot Et_2O$ as it did before treatment (Table 3, entries 1, 2). Third, in the reactions of oxime ether **5***a* with *n*-BuLi–$BF_3 \cdot Et_2O$, the addition product diastereomeric ratios closely mirrored the original *E*:*Z* ratios of the starting oxime ether sample (Table 3, entries 1 and 3).

The yield of addition product **7***a* derived from **5***a* could be increased to 70% (Table 4, entry 1) by using 3 equivalents of an *n*-BuLi–$BF_3 \cdot Et_2O$ mixture (12) in toluene at −78 to −30°C. At higher reaction temperatures complex mixtures of products were obtained. Oxime ethers **5***b*,*c* similarly required 3.0 equivalents of *n*-BuLi–$BF_3 \cdot Et_2O$ for complete disappearance of starting oxime ether (Table 2) to give the addition products in yields of 90% and 72%, respectively (Table 4, entries 3 and 5).

The chiral oxime ether of acetaldehyde (**5***a*) gave a 20% diastereomeric excess (d.e.) with *n*-BuLi and 61% d.e. with the more sterically bulky *t*-BuLi (Table 4, entries 1 and 2). The addition of *tert*-butyllithium to **5***a* also afforded *N*-methylephedrine (19%) and unreacted oxime ether **5***a* recovered as the *Z* isomer. Similarly, good diastereoselectivities (64–88% d.e.) were obtained upon reaction of the isobutyraldehyde oxime ether **5***b* with PhLi or *n*-BuLi and the benzaldehyde oxime ether **5***c* with *n*-BuLi or *t*-BuLi (Table 4, entries 3–6). Chiral isobutyraldehyde oxime ether **6**, containing a piperidine ring in the chiral auxiliary, afforded a diminution in the enantioselectivity by approximately 25% (Table 4, entries 3, 4 vs. 7, 8). When these alkyllithium addition reactions were run on a large scale (>1.0 g) a precipitate was obtained upon warming the solution to −45 to −50°C, causing difficulty with the magnetic stirring bars. Running the reaction at −78°C, using a greater volume of $PhCH_3$ as solvent or dropwise addition of THF (approx. 1 mL THF/15 mL $PhCH_3$), resulted in dissolution of the precipitate and none of these modifications affected the observed diastereoselectivity.

The diastereomeric excess was determined directly by analysis of the ^{1}H or ^{13}C NMR spectra. The d.e. could be determined from both the ^{1}H and ^{13}C NMR spectra for alkoxyamines **7***b*, **8***a*,*b*, and **9***a* and only from the ^{13}C NMR spectra for **7***a* and **9***b*. The values determined from the ^{1}H and ^{13}C NMR spectra were generally in close agreement, differing by ±4.8%. To confirm the diastereoselectivity of these reactions and to assign the absolute configuration at the newly formed stereogenic center, alkoxyamines **8***a*,*b* and **9***a*,*b* were reduced to the amines **11***a*,*b* and **12***a*,*b* with $LiAlH_4$ (eq. [2]). In all cases, except the conversion of **8***b* to **11***b*, the enantiomeric excess determined by optical rotation on the free amine corresponded very closely to the highest value determined for the diastereomeric excess determined from the ^{1}H or ^{13}C NMR spectra (Table 4) of alkoxyamines **8** and **9**. Racemization appears to have occurred during the reduction of **8***b* to amine **11***b*.

Several organolithium reagents did not undergo 1,2-addition reactions to these chiral oxime ethers. Reaction of methyllithium with oxime ethers **5***b*,*c* gave only starting oxime ether while oxime ether **5***b* failed to react with 2-thienyllithium or 1-hexynyllithium (recovered oxime ether had the same *E*:*Z* ratio). Similarly, oxime ether **5***c* failed to react with the lithium derivative of methyldiphenylphosphine oxide

and gave recovered oxime ether with an unchanged *E*:*Z* ratio. Treatment of oxime ether **5***a*, however, with 1-hexynyllithium (eq. [3]) afforded the addition product **13** (37%) along with recovered oxime ether (63%) present as the *E* isomer. The addition product displayed a single set of adsorptions characteristic of a single diastereomer. In a second experiment, addition of 4 equivalents of 1-lithiohexyne–$BF_3 \cdot Et_2O$ to **5***a* (−78 to −60°C) existing as a 47:53 *E*:*Z* ratio yielded recovered oxime ether (47:23, *E*:*Z*) and addition product **13** (30%) as determined by ^{1}H NMR analysis.

Discussion

The alkoxyamines **8** and **9** could be reduced with lithium aluminium hydride in Et_2O at room temperature to afford the chiral amines **11** and **12**. Measurement of the optical rotations for the free amines and comparison with reported literature values (18) provided the enantiomeric excess for the method, which could be directly compared with the diastereomeric excess for the initial addition reaction as measured by ^{1}H and ^{13}C NMR spectroscopy. In all cases the two values were within ±5% except for the addition of phenyllithium to isobutyraldehyde oxime ether **5***b*, which gave 64% d.e. for the alkoxyamine and only 12% e.e. for the amine, indicative of racemization occurring during the $LiAlH_4$ reduction step. For this benzylic alkoxyamine, racemization may occur by initial β-elimination of a metal alkoxide followed by reduction of the achiral imine.

Although the diastereomeric excess appears, in general, to parallel the *E*:*Z* ratio of starting oxime ether (Table 4), the oxime ether of acetaldehyde (**5***a*, 63:37 *E*:*Z* ratio) gave a significantly better diastereoselectivity of 64% d.e. upon reaction with *tert*-butylithium–$BF_3 \cdot Et_2O$. This reaction, however, gave ephedrine (19%) from N—O bond cleavage and 6% recovered *Z*-oxime ether. If, for the sake of argument, it is assumed that the ephedrine arises from cleavage of the *Z* isomer, then the *E*:*Z* diastereomer ratio would be 84:16 (68% d.e.), which correlates nicely with the 64% d.e. observed in the addition reaction. However, reaction of **5***a* (63:37 *E*:*Z* ratio) with *n*-BuLi in THF in the absence of $BF_3 \cdot Et_2O$ gave addition product **7***a* (40% yield, 60:40 diastereomer ratio), ephedrine from N—O bond cleavage (37%), and recovered oxime ether (22%) existing as the *Z* isomer (i.e., **5***aZ*). These numbers suggest that the recovered *Z* isomer derives from the original *Z* isomer of the starting material, and the ephedrine now derives solely from the *E* isomer! The achievement of 40% addition in this reaction is in contrast to the general reluctance of alkyllithium reagents to add to oxime ethers in the absence of $BF_3 \cdot Et_2O$ (12), and the failure of alkyllithiums to add to oxime ethers in THF even in the presence of $BF_3 \cdot Et_2O$ as reported by Brooks and co-workers (12*b*). These data and the literature reports are internally consistent if it is assumed that complexes **14** and **15** are formed in THF in the absence of $BF_3 \cdot Et_2O$ and complexes **16** and **17** are formed with $BF_3 \cdot Et_2O$ in toluene. Complex **14** can fragment via a *syn* elimination to afford acetonitrile and ephedrine and complex **15** can undergo enolization to afford the *Z* enolate. In the presence of $BF_3 \cdot Et_2O$, complex **17** is expected to undergo both enolization and elimination (*anti* elimination) at a faster rate then complex **16**. Formation of complexes **14** and **15** followed by deprotonation is consistent with the formation of dipole-stabilized carbanions via complex-induced proximity effects (19) (CIPE). This interpretation is also consistent with the observation that deprotonation of oxime ethers occurs exclusively *syn* to the oxime ether oxygen atom (20). There are, however, other routes for cleavage of the N—O bond in these reactions. Addition of alkyllithium reagents to oxime ethers generates alkoxyamine nitrogen anions, which

17

are known to undergo substitution reactions with alkyllithium reagents with displacement of the alkoxy group (21). Mechanisms involving a nitreneoid intermediate (12*a*) and direct S_N2 displacement of the alkoxy group by the alkyllithium reagent (21) have been proposed and evidence for both mechanistic pathways has been obtained. If N—O bond cleavage occurs from the nitrogen anion obtained upon addition of RLi to these chiral oxime ethers, the yield of ephedrine should not reflect the stereoelectronic and complex-induced proximity effects described above. Efforts to detect acetonitrile in the reaction of *t*-BuLi–$BF_3 \cdot Et_2O$ with **5***a* were unsuccessful and we are unable to draw a conclusion as to the probable reaction mechanism for the cleavage pathway.

From these observations, it appears that the addition reaction of organolithium reagents with these chiral oxime ethers is highly stereospecific with the diastereoselectivity largely reflecting the ratio of *E*:*Z* isomers undergoing the addition reaction. Direct experimental confirmation was provided by reaction of oxime ether **5***a* with *n*-butyllithium. Reaction of **5***a* existing as a 63:37 *E*:*Z* mixture gave a 60:40 mixture of two diastereomers, which was exactly reversed to a 40:60 ratio of the same two diastereomers when a 38:62 *E*:*Z* mixture of **5***a* was used (Table 3). The *E*:*Z* ratio of recovered unreacted oxime ether **5***a* (Table 3) appears to be a reflection of the relative reaction rates of the *E* and *Z* geometrical isomers and not a result of *E*/*Z* isomerization occurring under the reaction conditions. This view is consistent with the observation that oxime ethers **5***b*,*c* recovered after treatment with lithiomethyldiphenylphosphine oxide – $BF_3 \cdot Et_2O$ or 1-lithiohexyne–$BF_3 \cdot Et_2O$ (no reaction) displayed the same *E*:*Z* ratio as the starting oxime ethers.

The relative reactivity of the oxime ether *E* and *Z* isomers is indicated by several experimental results. Treatment of oxime ether **5***a*, rich in the *Z* isomer, with *n*-butyllithium gave a higher ratio of product to starting material (78:22) than **5***a* rich in the *E* isomer (55:45) even though a smaller quantity of *n*-BuLi–$BF_3 \cdot Et_2O$ was employed (1.2 vs. 2 equivalents). Since most of the oxime ethers that we examined existed largely in the *E* configuration, the failure of lithium acetylides and 2-thienyllithium to undergo reaction with these chiral oxime ethers may be a reflection of the relative reactivity of the oxime ether stereoisomers. This was confirmed by the successful addition of 1-lithiohexyne to **5***a* (63:37 *E*:*Z* ratio) to afford addition product **13** and unreacted recovered *E* oxime in a 37:63 ratio. Similarly, in a second experiment the *E*:*Z* ratio of recovered unreacted oxime ether **5***a* (47:23, *E*:*Z* ratio) and addition product **13** (30%) mirrored exactly the *E*:*Z* ratio (47:53) of the starting oxime ether sample. This observation also suggests that *E*:*Z* isomerization does not occur under these reaction conditions. Although the addition product could not be separated from the *E* oxime, a single diastereomer was observed for the addition product, providing additional evidence for the stereospecificity of the reaction.

Although the nature of the reagent in these reactions is unclear, the results are consistent with literature suggestions that alkyllithiums are stable and react slowly with $BF_3 \cdot Et_2O$ at low temperatures (e.g., −78°C) (22). From this perspective, the Lewis acid activates the oxime ether by complexation[2] to form **16** and **17**, which then undergo addition by the alkyllithium reagent. Three equivalents of RLi–$BF_3 \cdot Et_2O$ are required to compensate for competitive destruction of the alkyllithium reagent, which can occur by reaction with $BF_3 \cdot Et_2O$ to afford alkylidifluoroboranes, alkylfluoroborates, and tetralkylborates or by reaction with the aminoboron trifluoride salt formed in the addition reaction. The work of Ganem and co-workers (22*a*) suggests that the aminoboron trifluoride salts formed in the addition reaction may be more reactive with alkyllithium reagents then $BF_3 \cdot Et_2O$. The use of 3 equivalents of RLi/$BF_3 \cdot Et_2O$ ensures that addition of the alkyllithium reagent to the oxime ether will proceed to completion even in the presence of the competitive destruction of the alkyllithium reagent.

It appears, therefore, that very basic strongly nucleophilic reagents such as *n*-BuLi, PhLi, and *t*-BuLi add very readily to both the *E* and *Z* oxime ether geometrical isomers in the presence of $BF_3 \cdot Et_2O$, although the failure of MeLi to add seems surprising. Weaker bases and less nucleophilic species such as lithium acetylides appear to react only with the more reactive *Z* isomers. Recovery of the oxime ether *Z* stereoisomer in the reaction of **5***a* with *tert*-butyllithium suggests that α-deprotonation of the *Z* isomer forms an oxime ether enolate that is protected from further reaction and that affords the starting *Z* oxime ether upon workup. A similar result is obtained when **5***a* is reacted with *n*-BuLi in the absence of $BF_3 \cdot Et_2O$; the addition product reflects the ratio of *E* isomer, and unreacted oxime ether of *Z* configuration is recovered. This is consistent with the known regioselective deprotonation *syn* to the oxime hydroxyl or oxime ether oxygen (20).

The absolute configuration of the stereogenic center created in these reactions can be understood in terms of complexes **16** and **17**, which can exist in a chair-like conformation. The absolute configurations for the major enantiomers of amines **11***a*,*b* all arise from addition of the alkyllithium reagent to the bottom face of the chair conformation (i.e., **18**) of complex **16** formed from the *E* oxime (see eq. [4]). The *R* configuration observed for amine **11***b* is an artifact of the Cahn–Ingold–Prelog convention for determination of absolute configuration and not a result of the direction of attack. Attack from the bottom face of complex **17** arising from the *Z*

[2]In an NMR study of oxime hydrochlorides, the authors argue that protonation occurs on the nitrogen atom (23).

oxime affords the minor enantiomer. Molecular models suggest that the axial methyl substituent of the *N,N*-dimethyl group provides much of the steric hindrance required for the observed facial selectivity.

[4] 
18

In summary, ephedrine or norephedrine can be readily converted into chiral alkoxyamines, which give chiral oxime ethers upon reaction with aldehydes. These chiral oxime ethers undergo 1,2-nucleophilic addition reactions with organolithium reagents in the presence of $BF_3 \cdot Et_2O$ to afford alkoxyamines, which can be reduced to chiral amines. The reaction appears to be highly stereospecific, with the diastereoselectivity of the addition reaction mirroring the initial *E*:*Z* geometry of the starting oxime ether.

Experimental

NMR spectra were recorded as $CDCl_3$ solutions on a Bruker AC-300 instrument. ^1H NMR chemical shifts are reported as δ values in parts per million (ppm) relative to tetramethylsilane (δ_{TMS} = 0.00 ppm) as an internal standard. The ^{13}C NMR chemical shifts are reported in ppm downfield from TMS and referenced with respect to internal $CDCl_3$ (δ_{CDCl_3} = 77.04 for the center line). Infrared spectra (IR) were recorded on a Nicolet 5 DX FT-IR spectrometer as neat samples (sodium chloride plates) unless otherwise noted. Mass spectral measurements were performed on a Hewelett–Packard 5840 or 5890 gas chromatography/mass spectrometer at 70 eV; mass data are tabulated as *m/z* and intensity is expressed as a percent of the base peak. Melting points were determined on a Haake Buchler melting point apparatus and are uncorrected. Elemental analyses were determined by Atlanta Microlab Inc., Atlanta, Ga. The optical rotation measurements were performed on a Horiba Sepa-200 polarimeter.

Tetrahydrofuran and diethyl ether were distilled from sodium benzophenone ketyl. Toluene was distilled from sodium. Commercially available ethanol, methanol, hexane, and methylene chloride were used without further purification. $BF_3 \cdot Et_2O$ was purified by distillation. Alkyllithium reagents were purchased from Aldrich Chemical Company. All the reactions were carried out under a nitrogen atmosphere.

(1R,2S)-O-(2-Dimethylamino-1-phenylethyl) hydroxylamine (3)

To a suspension of *N*-alkoxyphthalimide derivative (13) **2***a* (13.0 g, 40 mmol) in ethanol (120 mL), anhydrous hydrazine (2.0 mL, 63 mmol) was added. The mixture was heated under reflux for 12 h and then cooled to room temperature; the precipitate was filtered and the solvent from the filtrate was evaporated under vacuum. The filter cake from the filtration and the residue from the evaporation were mixed together and water (20 mL) and concentrated HCl (20 mL) were added to it. The resulting mixture was heated under reflux for 3 h. The resulting solid was filtered off. The pH of the filtrate was adjusted to 5 by adding solid NaOH. The resulting aqueous solution of the alkoxyaminehydrochloride was then washed with methylene chloride (20 mL) and the organic layer was discarded. The aqueous layer was diluted if necessary and solid Na_2CO_3 was added to it to adjust the pH to between 8 and 9. The alkaline aqueous layer was extracted with CH_2Cl_2 (4 × 20 mL), and the organic layer was washed with water, brine, and dried over $MgSO_4$. Evaporation of the solvent under reduced pressure provided crude alkoxyamine **3** (6.4 g, 82% yield) as a pale-yellow solid. A spectroscopically pure sample was obtained by crystallization from hexane; mp 81–83°C; IR (KBr): 3296 (w), 3233 (w), 3149 (w) cm^{-1}; ^1H NMR δ: 1.01 (d, *J* = 6.6 Hz, 3H), 2.32 (s, 6H), 2.64 (dq, *J* = 4.2 Hz, *J* = 6.9 Hz, 1H), 4.73 (d, *J* = 4.2 Hz, 1H), 5.22 (br s, 2H), 7.24–7.38 (m, 5H); ^{13}C NMR δ: 8.8, 41.9 (2C), 64.2, 87.7, 126.7 (2C), 127.3, 128.3 (2C), 141.1; mass spectrum *m/z* (intensity) CI: 195 (M + 1, 100); EI: 162 (M − ONH_2, 3.8), 72 ($CH_3CH{=}N^+Me_2$, 100).

*(1R,2S)-2-(1-Piperdino)-1-phenyl-1-*N*-phthalimidohydroxypropane (2b)*

The procedure reported by Dieter et al. (13) was used. To a CH_2Cl_2 solution of (1*R*,2*S*)-1-phenyl-2-piperidinopropanol **1***a* (4.38 g, 20 mmol) and triethyl amine (2.22 g, 22 mmol), cooled to −78°C, methanesulfonyl chloride (1.7 mL, 22 mmol) was added in a dropwise manner. The reaction was allowed to warm to room temperature and stirred at room temperature for 6 h. Additional triethyl amine (2.22 g, 22 mmol) and *N*-hydroxyphthalimide (6.525 g, 40 mmol was added as a solid) were added to the reaction mixture, which was heated under vigorous reflux for 16 h. The solvent was evaporated under reduced pressure and benzene (100 mL) and aqueous $NaHCO_3$ solution were added to the residue. The mixture was stirred until no solid remained and two clear phases were formed. The organic layer was washed with saturated aqueous $NaHCO_3$ solution until the red color of the organic phase disappeared. Further washing of the organic phase with water and brine followed by drying ($MgSO_4$) provided the crude product **2***b* (6.7 g, 92% yield), which was >95% homogenous by ^1H NMR and ^{13}C NMR and was used without further purification; ^1H NMR δ: 1.35 (d, *J* = 6.6 Hz, 3H), 1.34–1.40 (m, 6H), 2.53–2.59 (m, 4H), 2.98–3.06 (m, 1H), 5.52 (d, *J* = 6.3 Hz, 1H), 7.23–7.69 (m, 9H); ^{13}C NMR δ: 10.3, 24.7, 26.5 (2C), 50.2 (2C), 64.1, 89.6, 123.2 (2C), 127.7 (2C), 128.2 (2C), 128.3 (2C), 128.9, 134.1 (2C), 138.1, 163.6 (2C).

(1R,2S)-O-(1-(2-Piperidino)-1-phenylethyl)hydroxylamine (4)

The same procedure employed for the synthesis of **3** was used except for the change of substrate. *N*-Hydroxyphthalimide derivative **2***b* (6.7 g, 18.4 mmol) was treated with hydrazine (1.0 mL, 31.5 mmol). The crude alkoxyamine **4** (3.60 g, 84% yield) was >95% pure by ^1H and ^{13}C NMR. It was used in the subsequent reactions without further purification; ^1H NMR δ: 1.03 (d, *J* = 6.9 Hz, 3H), 1.39–1.50 (m, 6H), 2.54–2.67 (m, 5H), 4.74 (d, *J* = 4.2 Hz, 1H), 5.22 (s, 2H), 7.25–7.37 (m, 5H); ^{13}C NMR δ: 9.5, 24.7, 26.5 (2C), 50.7 (2C), 65.1, 87.7, 126.6 (2C), 127.1, 128.1 (2C), 141.4.

General procedure A: Synthesis of oxime ethers

To a round-bottom flask fitted with a nitrogen inlet were added alkoxyamine (**3** or **4**) (1 mmol) and absolute ethanol (10 mL). The resulting solution was cooled to 0°C and aldehyde (2 mmol, neat) was added to it in a dropwise manner. The reaction mixture was allowed to warm to room temperature while stirring was continued for 12 h. After evaporating ethanol in vacuo, CH_2Cl_2 (20 mL) was added to the residue. The organic layer was washed successively with water (2 × 20 mL), saturated $NaHCO_3$ solution (20 mL), water (2 × 20 mL), and brine (20 mL) and was then dried over $MgSO_4$. Evaporation of the solvent in vacuo afforded prod-

uct oxime ethers that were analyzed by ^1H and ^{13}C NMR spectroscopy.

*(1R,2S)-2-Dimethylamino-1-phenyl-1-[[ethylideneamino]oxy]propane (**5**a)*

General procedure A was followed. To an ethanol solution of alkoxyamine **3** (1.00 g, 5.15 mmol), cooled to 0°C, acetaldehyde (0.60 mL, 10.7 mmol) was added. The crude product **5***a* (1.06 g, 93% yield, *E*:*Z*/60:40) was >95% homogeneous by ^1H and ^{13}NMR. An analytically pure sample was obtained by column chromatography on silica gel (MeOH); IR: 3085 (w), 3064 (m), 3029 (m), 1679 (w), 899 (s) cm^{-1}; ^1H NMR (*E* isomer) δ: 1.03 (d, J = 6.9 Hz, 3H), 1.78 (d, J = 6.0 Hz, 3H), 2.36 (s, 6H), 2.74 (dq, J = 6.9 Hz, J = 3.3 Hz, 1H), 5.31 (d, J = 3.9 Hz, 1H), 7.19–7.34 (m, 5H), 7.52 (q, J = 6 Hz, 1H); ^1H NMR (*Z* isomer) δ: 1.07 (d, J = 6.9 Hz, 3H), 1.92 (d, J = 5.4 Hz, 3H), 2.37 (s, 6H), 2.83 (dq, J = 6.9 Hz, J = 3.3 Hz, 1H), 5.38 (d, J = 3.6 Hz, 1H), 6.76 (q, J = 5.4 Hz, 1H); ^{13}C NMR (*E* isomer) δ: 9.1, 15.2, 41.7, 64.4, 84.0, 126.6 (2C), 127.0, 128.0 (2C), 142.0, 147.3; ^{13}C NMR (*Z* isomer) δ: 8.9, 12.2, 41.4, 84.3, 126.3 (2C), 126.9; mass spectrum *m/z* (intensity) EI: 162 (M − ON=CHCH$_3$, 1.4), 72 ($CH_3CH{=}N^+Me_2$, 100). Anal. calcd. for $C_{13}H_{20}N_2O$: C 70.88, H 9.14; found: C 70.70, H 9.11.

*(1R,2S)-2-Dimethylamino-1-phenyl-1-[[[2-methylpropylidene]amino]oxy]propane (**5**b)*

General procedure A was followed. To an ethanol solution of alkoxyamine **3** (1.00 g, 5.15 mmol), cooled to 0°C, isobutyraldehyde (0.94 mL, 10.3 mmol) was added. The crude product **5***b* (1.22 g, 96% yield, *E*:*Z*/92.8) was >95% homogeneous by ^1H and ^{13}C NMR. An analytically pure sample was obtained by column chromatography on silica gel (MeOH); IR: 3085 (w), 3064 (w), 3029 (w), 1644 (w), 1454 (s), 913 (s) cm^{-1}; ^1H NMR (*E* isomer) δ: 0.92–0.97 (apparent t, m, 9H), 2.31 (s, 6H), 2.35 (oct, J = 6.9 Hz, 1H), 2.70 (dq, J = 6.9 Hz, J = 3.3 Hz, 1H), 5.24 (d, J = 3.6 Hz, 1H), 7.14–7.27 (m, 5H), 7.31 (d, J = 6.9 Hz, 1H); ^1H NMR (*Z* isomer) δ: 0.99–1.03 (apparent t, m, 9H), 2.32 (s, 6H), 2.80 (dq, J = 6.9 Hz, J = 3.3 Hz, 1H), 3.17 (oct, J = 6.9 Hz, 1H), 5.27 (d, J = 3.6 Hz, 1H), 6.40 (d, J = 6.9 Hz, 1H); ^{13}C NMR (*E* isomer) δ: 9.19, 20.16, 29.15, 41.75, 64.31, 83.76, 126.55 (2C), 126.67, 127.85 (2C), 141.85, 156.44; ^{13}C NMR (*Z* isomer) δ: 9.01, 19.69, 29.20, 41.45, 64.37, 84.49, 157.51; mass spectrum *m/z* (intensity) EI: 162 (M − ON=CH(i-Pr), 5.6), 72 ($CH_3CH{=}N^+Me_2$, 100). Anal. calcd. for $C_{15}H_{24}N_2O$: C 72.55, H 9.73; found: C 72.32, H 9.68.

*(1R,2S)-2-Dimethylamino-1-phenyl-1-[[[1-phenylmethylidene]amino]oxy]propane (**5**c)*

General procedure A was followed. To an ethanol solution of alkoxyamine **3** (2.04 g, 10.5 mmol), cooled to 0°C, benzaldehyde (1.60 mL, 15.8 mmol) was added. The crude product **5***c* (2.81 g, 95% yield, *E*:*Z*/90:10) was >95% homogeneous by ^1H and ^{13}C NMR. An analytically pure sample was obtained by column chromatography on silica gel (MeOH); IR: 3064 (m), 3029 (m), 1686 (w), 941 (s), cm^{-1}; ^1H NMR (*E* isomer) δ: 1.09 (d, J = 6.6 Hz, 3H), 2.40 (s, 6H), 2.80 (dq, J = 6.9 Hz, J = 3.3 Hz, 1H), 5.50 (d, J = 3.6 Hz, 1H), 7.22–7.53 (m, 10H), 8.21 (s, 1H); ^1H NMR (*Z* isomer) δ: 1.17 (d, J = 6.9 Hz, 3H), 5.54 (d, J = 3.6 Hz, 1H); ^{13}C NMR (*E* isomer) δ: 9.3, 41.8, 64.2, 85.2, 126.6 (2C), 126.9, 127.1 (2C), 128.0 (2C), 128.5 (2C), 129.7, 132.2, 141.9, 149.1; ^{13}C NMR (*Z* isomer) δ: 41.5, 86.5, 146.4; mass spectrum *m/z* (intensity) EI: 162 (M − ON=CHPh, 1.4), 77 (Ph^+, 12.9), 72 ($CH_3CH{=}N^+Me_2$, 100). Anal. calcd. for $C_{18}H_{22}N_2O$: C 76.57, H 7.85; found: C 76.37, H 7.86.

*(1R,2S)-2-(1-Piperidino)-1-phenyl-1-[[[2-methylpropylidene]amino]oxy]propane (**6**)*

General procedure A was used. The alkoxyamine **4** (2.3 g, 10.0 mmol) was treated with isobutylaldehyde (1.080 g, 15.0 mmol) in ethanol. The crude oxime ether **6** (2.88 g, 100% yield) was >95% homogeneous by ^1H and ^{13}C NMR and was used without purification; ^1H NMR (*E* isomer) δ: 0.98–1.10 (m, 9H), 1.39–1.53 (m, 6H), 2.44 (sept, J = 6.9 Hz, 1H), 2.57–2.81 (m, 5H), 5.31 (d, J = 3.6 Hz, 1H), 7.19–7.31 (m, 5H), 7.35 (d, J = 7 Hz, 1H); ^1H NMR (*Z* isomer) δ: 5.32 (d, J = 3.0 Hz, 1H), 6.50 (d, J = 7 Hz, 1H); ^{13}C NMR (*E* isomer) δ: 9.7, 20.2 (2C), 24.7, 26.4 (2C), 29.2, 50.5 (2C), 65.2, 83.8, 126.3, 126.4 (2C), 127.7 (2C), 142.4, 156.3; ^{13}C NMR (*Z* isomer) δ: 19.8, 157.5.

General procedure B: Addition of organolithium reagents to chiral oxime ethers

To a round-bottom flask fitted with a nitrogen inlet were added oxime ether (0.5 mmol) and toluene (5 mL). The resulting solution was cooled to −78°C and $BF_3 \cdot Et_2O$ (1.5 mmol, neat) was added to it. The alkyllithium reagent (1.5 mmol) was then added dropwise to the solution via syringe over 10 min. After the addition was complete the resulting clear, pale-yellow solution was stirred at −78°C for 1 h. The reaction was quenched by addition of water (0.5 mL). After evaporation of the solvent, the residue was taken up in CH_2Cl_2 (40 mL), washed successively with 15% NaOH (2 × 20 mL), water (2 × 20 mL), brine (20 mL), and then dried over $MgSO_4$. After filtration and solvent removal in vacuo, the resulting crude material was dissolved in hexane (20 mL), filtered through Celite, and concentrated in vacuo to afford product alkoxyamines that were analyzed by ^1H and ^{13}C NMR. Spectroscopically pure samples were obtained by column chromatography on silica gel (MeOH).

*(1R,2S)-N-[1-Phenyl-2-(dimethylamino)propyl]oxy]hexane-2-amine (**7**a)*

General procedure B was followed. To acetaldehyde oxime derivative **5***a* (0.110 g, 0.5 mmol), dissolved in toluene, $BF_3 \cdot Et_2O$ (0.18 mL, 1.5 mmol) and *n*-BuLi (0.63 mL, 2.4 M, 1.5 mmol) were added. Evaporation of the solvent gave product **7***a* (0.097 g, 70%), which was >95% homogeneous by ^1H and ^{13}C NMR spectroscopy; IR: 3296 (w, br) cm^{-1}; ^1H NMR (major diastereomer) δ: 0.83–0.96 (m, 3H), 0.97–1.16 (m, 6H), 1.18–1.30 (m, 6H), 2.30 (s, 6H), 2.70–2.74 (m, 1H), 2.97 (m, 1H), 4.73 (d, J = 5.1 Hz, 1H), 5.10 (s, 1H) 7.22–7.36 (m, 5H); ^1H NMR (minor diastereomer) δ: 4.74 (d, J = 4.8 Hz, 1H); ^{13}C NMR (major diastereoisomer) δ: 8.84, 14.04, 18.19, 22.85, 28.11, 33.88, 41.46 (2C), 55.92, 64.16, 85.67, 126.80 (2C), 127.02, 128.11 (2C), 142.17; ^{13}C NMR (minor diastereomer) δ: 14.00, 18.64, 22.78, 33.66, 64.06; mass spectrum (GC–MS): 162 (M − ONHCH(*n*-Bu)CH$_3$), 72 ($CH_3CH{=}N^+Me_2$).

*(1R,2S)-N-[1-Phenyl-2-(dimethylamino)propyl]oxy]-3-dimethyl-2-aminobutane (**7**b)*

General procedure B was followed. To acetaldehyde oxime derivative **5***a* (0.770 g, 3.5 mmol) dissolved in toluene were added $BF_3 \cdot Et_2O$ (1.28 mL, 10.5 mmol) and *t*-BuLi (7.0 mL, 1.5 M, 10.5 mmol). The crude material obtained (0.800 g) was purified by column chromatography on silica gel (MeOH) to obtain pure **7***b* (0.590 g, 61% yield); IR: 3212 (br) cm^{-1}; ^1H NMR (major diastereomer) δ: 0.84 (s, 9H), 1.04 (d, J = 7.0 Hz, 3H), 1.09 (d, J = 7.0 Hz, 3H), 2.30 (s, 6H), 2.69–2.75 (m, 2H), 4.73 (d, J = 4.8 Hz, 1H), 5.10 (br s, 1H), 7.23–7.34 (m, 5H); ^1H NMR (minor diastereomer) δ: 0.77 (s, 9H), 2.29 (s, 6H); ^{13}C NMR (major diastereomer) δ: 8.67, 14.14, 26.76 (3C), 33.34, 41.44 (2C), 63.81, 63.89, 84.86, 126.78 (2C), 126.89, 128.02 (2C), 142.33; ^{13}C NMR (minor diastereomer) δ: 8.96, 26.57, 33.15, 85.16, 126.33 (2C); mass spectrum *m/z* (intensity) EI: 162 (M − ONHCH(*t*-Bu)CH$_3$, 31), 72 ($CH_3CH{=}N^+Me_2$, 100).

*(1R,2S)-3-Amino-2-methyl-N-[1-phenyl-2-(dimethylamino)propyl]oxy]heptane (**8**a)*

General procedure B was followed. To isobutyraldehyde oxime derivative **5***b* (0.500 g, 2.0 mmol) dissolved in toluene, $BF_3 \cdot Et_2O$ (0.77 mL, 6.0 mmol) and *n*-BuLi (2.40 mL, 2.5 M, 6.0 mmol) were added. Evaporation of the solvent gave product **8***a* (0.541 g, 90% yield), which was >95% homogeneous by ^1H and ^{13}C NMR spectroscopy; IR: 3346 (br) cm^{-1}; ^1H NMR (major diastereomer) δ: 0.80 (d, J = 6.9 Hz, 2H), 0.86–0.88 (m, 6H), 1.05 (d, J = 6.8 Hz, 3H), 1.12–1.49 (m, 6H), 1.92 (oct, J = 7.5 Hz, 1H), 2.29

(s, 6H), 2.54–2.63 (m, 1H), 2.72 (pent, J = 7.8 Hz, 1H), 4.71 (d, J = 5.1 Hz, 1H), 5.30 (vbr s, 1H), 7.22–7.36 (m, 5H); ^{13}C NMR (major diastereomer) δ: 8.88, 14.10, 18.09, 19.16, 22.95, 27.95, 28.81, 29.01, 41.44 (2C), 64.00, 65.68, 85.33, 126.90 (2C), 127.03, 128.08 (2C), 142.37; ^{13}C NMR (minor diastereomer) δ: 85.53; mass spectrum (GC–MS): 162 (M − ONHCH(*n*-Bu)i-Pr), 72 ($CH_3CH{=}N^+Me_2$).

(1R,2S)-α-(1-Methylethyl)-N-*[1-phenyl-2-(dimethylamino)propyl]oxy]benzenemethanamine (**8**b)*

General procedure B was followed. To isobutyraldehyde oxime derivative **5***b* (0.500 g, 2.0 mmol) dissolved in toluene, $BF_3 \cdot Et_2O$ (0.73 mL, 6.0 mmol) and PhLi (3.35 mL, 1.8 M, 6.04 mmol) were added. The crude material obtained (0.690 g) was purified by column chromatography on silica gel (MeOH) to obtain spectroscopically pure **8***b* (0.46 g, 70% yield); IR: 3198 (br) cm^{-1}; ^{1}H NMR (major diastereomer) δ: 0.65 (d, J = 6.6 Hz, 3H), 0.73 (d, J = 6.6 Hz, 3H), 0.88 (d, J = 6.6 Hz, 3H), 1.80 (oct, J = 6.6 Hz, 1H), 1.95 (s, 6H), 2.49–2.58 (m, 1H), 3.71 (dd, J = 7.2 Hz, J = 3.6 Hz, 1H), 4.54 (d, J = 5.1 Hz, 1H), 5.57 (d, J = 3.6 Hz, 1H), 7.14–7.43 (m, 10H); ^{1}H NMR (minor diastereomer) δ: 2.23 (s, 6H), 4.74 (d, J = 5.6 Hz, 1H), 5.45 (d, J = 3.6 Hz, 1H); ^{13}C NMR (major diastereomer) δ: 8.64, 19.27, 20.13, 31.15, 40.80 (2C), 63.71, 71.59, 85.59, 126.80, 126.88, 126.94, 127.70, 128.07, 128.46, 141.88, 142.31; ^{13}C NMR (minor diastereomer) δ: 18.52, 30.50, 41.42, 70.85, 85.46; mass spectrum m/z (intensity) CI: 328 (M + 2, 20), 327 (M + 1, 100); EI: 162 (M − ONHCH(i-Pr)Ph, 20), 72 ($CH_3CH{=}N^+Me_2$, 100).

(1R,2S)-α-Butyl-N-*[1-phenyl-2-(dimethylamino)propyl]oxy]benzenemethanamine (**9**a)*

General procedure B was followed. To benzaldehyde oxime derivative **5***c* (1.00 g, 3.54 mmol) dissolved in toluene, $BF_3 \cdot Et_2O$ (1.30 mL, 10.6 mmol) and *n*-BuLi (4.24 mL, 2.5 M, 10.6 mmol) were added. The crude material obtained (1.010 g) was purified by column chromatography on silica gel (MeOH) to obtain spectroscopically pure **9***a* (0.870 g, 72% yield); IR: 3212 (br) cm^{-1}; ^{1}H NMR (major diastereomer) δ: 0.83 (t, J = 7.0 Hz, 3H), 0.98 (d, J = 6.8 Hz, 3H), 1.00–1.35 (m, 4H), 1.50–1.65 (m, 1H), 1.84–1.96 (m, 1H), 2.26 (s, 6H), 2.69 (dq, J = 6.4 Hz, J = 3.3 Hz, 1H), 3.94 (s, br, 1H), 4.76 (d, J = 5.2 Hz, 1H), 5.35 (s, br, 1H), 7.16–7.34 (m, 10H); ^{1}H NMR (minor diastereomer) δ: 1.97 (s, 6H), 4.54 (d, J = 5.2 Hz, 1H), ^{13}C NMR (major diastereomer) δ: 8.82, 13.96, 22.71, 28.27, 33.42, 41.49 (2C), 63.95, 65.59, 85.71, 126.87, 127.00, 127.23, 127.64, 128.04, 128.19, 141.78, 141.89; ^{13}C NMR (minor diastereomer) δ: 33.90, 40.87; mass spectrum m/z (intensity) CI: 342 (M + 2, 18.7), 341 (M + 1, 100), 162 (M − ONHCH(*n*-Bu)Ph, 55); EI: 341.3 (M + 1, 1.7), 162 (M − ONHCH(*n*-Bu)Ph, 6.7), 72 ($CH_3CH{=}N^+Me_2$, 100).

(1R,2S)-α-(1-Dimethylethyl)-N-*[1-phenyl-2-(dimethylamino)propyl]oxy]benzenemethanamine (**9**b)*

General procedure B was followed. To benzaldehyde oxime derivative **5***c* (1.00 g, 3.54 mmol) dissolved in toluene, $BF_3 \cdot Et_2O$ (1.30 mL, 10.6 mmol) and *t*-BuLi (7.0 mL, 1.5 M, 10.6 mmol) were added. The crude material obtained (1.220 g) was purified by column chromatography on silica gel (MeOH) to obtain spectroscopically homogeneous **9***b* (0.842 g, 71% yield); IR: 3219 (br) cm^{-1}; ^{1}H NMR (major diastereomer) δ: 0.81 (d, J = 6.0 Hz, 3H), 0.82 (s, 9H), 2.18 (s, 6H), 2.65 (dq, J = 6.4 Hz, J = 3.3 Hz, 1H), 3.80 (d, J = 7.5 Hz, 1H), 4.75 (d, J = 5.1 Hz, 1H), 5.70 (d, J = 9.0 Hz, 1H), 7.16–7.30 (m, 10H); ^{1}H NMR (minor diastereomer) δ: 0.80 (s, 9H), 2.22 (s, 6H); ^{13}C NMR (major diastereomer) δ: 8.41, 27.38 (3C), 34.05, 41.39 (2C), 63.57, 73.17, 84.61, 126.67, 127.04, 127.41, 128.00, 128.55, 140.82, 141.71; ^{13}C NMR (minor diastereomer) δ: 28.36; mass spectrum m/z (intensity) CI: 342 (M + 2, 16.6), 341 (M + 1, 100); EI: 162 (M − ONHCH(*t*-Bu)Ph, 48), 72 ($CH_3CH{=}N^+Me_2$, 100).

(1R,2S)-3-Amino-2-methyl-N-*[1-phenyl-2-(1-piperidino)propyl]oxy]heptane (**10**a)*

General procedure B was followed. To isobutyraldehyde oxime derivative **6** (0.144 g, 0.5 mmol) dissolved in toluene, $BF_3 \cdot Et_2O$ (0.183 mL, 1.5 mmol) and *n*-BuLi (0.6 mL, 2.5 M, 1.5 mmol) were added. The crude product **10***a* (0.187 g) was analyzed by ^{1}H and ^{13}C NMR. No attempts to purify the product were made; ^{1}H NMR δ: 0.80–0.95 (m, 9H), 1.06 (d, J = 6.6 Hz, 3H), 1.17–1.55 (m, 12H), 1.87–1.94 (m, 1H), 2.50–2.69 (m, 6H), 4.75 (d, J = 4.2 Hz, 1H), 5.31 (s, br, 1H), 7.14–7.33 (m, 5H); ^{13}C NMR (major diastereomer) δ: 9.74, 14.08, 18.19, 19.17, 22.94, 24.82, 26.54, 28.04, 28.85, 28.93, 50.58 (2C), 65.12, 65.63, 85.13, 126.73 (2C), 126.82, 127.83 (2C), 142.61; ^{13}C NMR (minor diastereomer) δ: 13.86, 19.01, 25.81, 85.71.

(1R,2S)-α-(1-Methylethyl)-N-*[1-phenyl-2-(1-piperidino)propyl]oxy]benzenemethanamine (**10**b)*

General procedure B was followed. To isobutyaldehyde oxime derivative **6** (0.144 g, 0.5 mmol) dissolved in toluene, $BF_3 \cdot Et_2O$ (0.183 mL, 1.5 mmol) and PhLi (0.83 mL, 1.8 M, 1.5 mmol) were added. The crude product **10***b* (0.173 g, 94% yield) was analyzed by ^{1}H and ^{13}C NMR. No attempt to purify the product was made; ^{1}H NMR (major diastereomer) δ: 0.65 (d, J = 6.9 Hz, 3H), 0.81 (d, J = 6.9 Hz, 3H), 0.88 (d, J = 6.9 Hz, 3H), 1.08–1.44 (m, 6H), 1.77 (oct, J = 6.9 Hz, 1H), 2.15–2.54 (m, 5H), 3.73 (d, J = 7.5 Hz, 1H), 4.70 (d, J = 4.2 Hz, 1H), 5.63 (s, br, 1H), 7.17–7.43 (m, 10H); ^{1}H NMR (minor diastereomer) δ: 0.74 (d, J = 6.9 Hz, 3H), 0.91 (d, J = 6.9 Hz, 3H), 0.96 (d, J = 6.9 Hz, 3H), 3.77 (d, J = 7.5 Hz, 1H), 4.84 (d, J = 4.2 Hz, 1H); ^{13}C NMR (major diastereomer) δ: 9.18, 19.28, 20.00, 24.23, 26.12, 26.41, 31.29, 49.33 (2C), 65.13, 71.53, 84.65, 126.56 (2C), 126.81 (2C), 127.75 (3C), 128.03 (2C), 128.19 (2C), 128.44, 141.97, 142.25; ^{13}C NMR (minor diastereomer) δ: 18.45, 30.47, 50.57, 64.97, 70.66, 85.03.

General procedure C: Reduction of alkoxyamines to amines

To the alkoxyamine **8**(*a*,*b*) and **9**(*a*,*b*) (2 mmol) dissolved in dry ether at room temperature, $LiAlH_4$ (3 mmol) was added in a portionwise manner. The reaction was allowed to stir at room temperature for 12 h. The reaction was then quenched by successive dropwise addition of water (0.1 mL), 15% NaOH (0.1 mL), and water (0.3 mL). The granular precipitate formed after stirring for 15 min was filtered off and the filtrate was dried over K_2CO_3. Ether was evaporated by warming the flask on a water bath. The amines **11**(*a*,*b*) and **12**(*a*,*b*) thus obtained were volatile. Careful distillation using a Kugelrohr apparatus provided the pure amines (yields were low because of the losses due to evaporation) as a distillate and *N*-methylephedrine **1***a* (quantitative yield) as a pot residue. The optical rotations of the amines were recorded immediately. All the amines gave satisfactory spectral data.

*(3S)-2-Methyl-3-heptanamine (**11**a)*

General procedure C was followed using **8***a* (1.00 g, 3.3 mmol) as the starting compound. The product amine **11***a* was purified by Kugelrohr distillation (80% yield, determined by ^{1}H NMR): bp 40°C (40 Torr; 1 Torr = 133.3 Pa); $[\alpha]_D^{24}$ − 17.18 (*c* 3.2, C_2H_5OH), *S*, 85% ee (lit. (18*a*) $[\alpha]_D^{24}$ +17.4 (*c* 3.3, C_2H_5OH), *R*, 86% ee); ^{1}H NMR δ: 0.86 (d, J = 6.9 Hz, 3H), 0.90 (d, J = 6.6 Hz, 3H), 0.84–0.93 (overlapping t, 3H), 1.14–1.20 (m, 8H), 1.58–1.60 (m, 1H), 2.48–2.49 (m, 1H); ^{13}C NMR δ: 14.10, 17.07, 19.27, 22.90, 28.87, 33.23, 34.45, 56.51.

*(1-R)-α-(1-Methylethyl)benzenemethanamine (**11**b)*

General procedure C was followed using **8***b* (0.624 g, 1.91 mmol) as the starting compound. The product amine **11***b* was purified by Kugelrohr distillation (0.156 g, 56% yield): bp 40–50°C (0.1 Torr); $[\alpha]_D^{24}$ +2.11 (*c* 2.0, C_2H_5OH), *R*, 12% ee (lit. (18*b*) $[\alpha]_D^{24}$ +13.0 (*c* 2.5, C_2H_5OH), *R*); ^{1}H NMR δ: 0.76 (d, J = 6.6 Hz, 3H), 0.97 (d, J = 6.6 Hz, 3 H), 1.52 (s, 2H), 1.82–1.86 (m, 1H), 3.59 (d, J = 7.2 Hz, 1H), 7.22–7.33 (m, 5H); ^{13}C NMR δ: 18.90, 19.80, 35.44, 62.47, 126.74, 127.00 (2C), 128.12 (2C), 145.49.

*(1-S)-α-Butyl benzenemethanamine (**12**a)*

General procedure C was followed using **9***a* (0.450 g, 1.32 mmol) as the starting compound. The product amine **12***a* was

purified by Kugelrohr distillation (0.100 g, 46% yield): bp 45°C (0.25 Torr); $[\alpha]_D^{24}$ −10.31 (*c* 3.2, $CHCl_3$), *S*, 81% ee (lit. (18*c*) $[\alpha]_D^{24}$ +11.7 (*c* 1.0, $CHCl_3$), *R*, 92% ee); ^{1}H NMR δ: 0.84–0.88 (m, 3H), 1.10–1.32 (m, 4H), 1.50–1.68 (m, 4H), 3.86 (t, *J* = 6.9 Hz, 1H), 7.25–7.32 (m, 5H); ^{13}C NMR δ: 14.00, 22.67, 28.77, 39.38, 56.29, 126.30 (2C), 126.83, 128.40 (2C), 146.84.

*(1S)-α-(1,1-Dimethylethyl)benzenemethanamine (**12**b)*

General procedure C was followed using **9***b* (0.700 g, 2.05 mmol) as the starting compound. The product amine **12***b* was purified by Kugelrohr distillation (0.165 g, 49% yield): bp 45°C (0.25 Torr); $[\alpha]_D^{24}$ −2.26 (*c* 5.3, CH_3OH), *S*, 90% ee (lit. (18*d*) $[\alpha]_D^{24}$ +2.5 (*c* 4.0, CH_3OH), *R*); ^{1}H NMR δ: 0.90 (s, 9H), 1.51 (s, 2H), 3.69 (s, 1H), 7.22–7.31 (m, 5H); ^{13}C NMR δ: 26.51 (3C), 35.00, 65.31, 126.71, 127.48 (2C), 128.23 (2C), 143.76.

*(1R,2S)-2-Amino-*N*-[1-phenyl-2-(dimethylamino)propyl]oxy]-3-octyne (**13**)*

To a solution of 1-hexyne (0.164 g, 2.0 mmol) in THF (2 mL) cooled to −30°C was added *n*-BuLi (0.83 mL, 2.4 M, 2.0 mmol) and the resulting solution was stirred for 45 min. In another flask, to a solution of acetaldehyde oxime ether derivative **5***a* (0.110 g, 0.5 mmol) in toluene (15 mL) cooled to −78°C was added boron trifluoride etherate (0.244 mL, 2.0 mmol, neat). The anion of 1-hexyne was then added to this flask in a dropwise manner via cannula over a period of 10 min. The reaction was allowed to warm to room temperature over 8 h before quenching with aqueous 15% NaOH solution. Toluene was then evaporated under vacuum and methylene chloride was added to the residue. The organic layer was washed with 15% NaOH, water, and brine. Drying the organic layer over $MgSO_4$ and filtration of the drying agent, followed by evaporation of the solvent, gave crude material (0.117 g) that was analyzed by ^{1}H and ^{13}C NMR. It was identified as a 60:40 mixture of *E* isomer of the starting oxime ether **5***a* and the product alkoxyamine in quantitative yield. Attempted purification of the crude material by column chromatography on silica gel (MeOH) did not result in separation of the product from starting oxime. Data from the crude sample for **13**: IR: 3310 (w, br), 3085 (w), 3064 (w), 2235 (w) cm^{-1}; ^{1}H NMR δ: 0.88 (t, *J* = 7.0 Hz, 3H), 1.06 (d, *J* = 6.6 Hz, 3H), 1.29 (d, *J* = 6.9 Hz, 3H), 1.36–1.46 (m, 4H), 2.11–2.16 (m, 2H), 2.32 (s, 6H), 2.69–2.76 (m, overlapping with starting oxime, 1H), 3.81–3.83 (m, 1H), 4.80 (d, *J* = 4.8 Hz, 1H), 5.19 (br s, 1H), 7.19–7.55 (m, overlapping with starting oxime 5H); ^{13}C NMR δ: 8.57, 13.53, 18.31, 19.83, 21.81, 30.73, 41.43 (2C), 48.02, 64.08, 80.24, 83.58, 85.55, 126.71 (2C), 126.99, 128.04 (2C), 141.85.

Received November 25, 1992

KEITH E. JOHNSON and RONALD G. TREBLE. Can. J. Chem. **71**, 824 (1993).

Aluminum present in pooled samples of cerebrospinal fluid is essentially uncomplexed since it may be determined by differential pulse polarography of the Al: Solochrome Violet RS (SVRS) complex. The aluminum may also be determined spectrophotometrically through its depression of the SVRS absorbance at 600 nm at pH 8.4. The Al:SVRS ratio in the complex is 1:2.

KEITH E. JOHNSON et RONALD G. TREBLE. Can. J. Chem. **71**, 824 (1993).

L'aluminium présent dans des échantillons regroupés de fluide cérébrospinal est essentiellement non complexé puisqu'il peut être déterminé par polarographie impulsionnelle différentielle du complexe Al : Solochrome Violet RS (SVRS). On peut aussi déterminer l'aluminium d'une façon spectrophotométrique par le biais de la diminution de l'absorption du SVRS à 600 nm, à un pH de 8,4. Le rapport de Al : SVRS dans le complexe est de 1 : 2.

The role, if any, of aluminum in Alzheimer's disease has not been unequivocally settled. We reasoned that it would be useful to be able to determine low levels (<10 μg L^{-1}) of aluminum in cerebrospinal fluid (CSF), the medium that bathes the surfaces of the central nervous system. We have shown (1) that graphite furnace atomic absorption spectrophotometry (GFAAS) is a reliable and accurate method for determining total aluminum in this, and other, biological fluids from the level of μg L^{-1} up to hundreds of micrograms per litre. It is generally believed (2) that aluminum is toxic to plant and animal life when it is present as free aquo ionic complexes in solution; hence, the concern exists for the effect of acid rain on aluminum-containing rocks, sediments, and soils. Various methods seem feasible for the differentiation of free ionic from complexed aluminum, but we chose electroactivity as a measure of the ionic Al in water (2). This was accomplished by determining aluminum as its complex at pH 4.6 with the azo-dye Solochrome Violet RS (sodium 4-hydroxy-3-[(2-hydroxy-1-naphthalenyl)azo] benzene-sulfonate) by differential pulse polarography (DPP).

Normal CSF samples have a pH of ~7.4 but a variety of infectious samples obtained from the Regina General Hospital had pH values of 8 or more. The use of the above electrochemical method, therefore, implied its evaluation under alkaline conditions. This paper reports the results of this action and a spectrophotometric study of the Al^{3+} : SVRS system in both a simple bicarbonate buffer and in actual CSF media.

Experimental

(a) Differential pulse polarography

A Metrohm Polarecord 626 was employed with an E354 Metrohm Polarography stand utilizing a mercury electrode with an electronically controlled drop knocker. The auxiliary electrodes were platinum. The reference electrode was AgCl/Ag for the small cell (~3 mL working volume) used for CSF solutions. Deaeration of the surfactant CSF's required the use of a Nupro model "M" fine metering valve and a Varian 0–60 mL gas flow meter no. 29-000086-00. Operating conditions were: peak height, 2 nA mm^{-1}; scan rate, 5 mV s^{-1}; pulse amplitude, 50 mV; Hg drop rate, 1 drop s^{-1}; chart printout, 100 mV cm^{-1}; CSF deaeration rate, 43 mL min^{-1}.

SMI, Oxford, and Eppendorf pipets (10–200 μL) were used for the addition of SVRS and aluminum standards to CSF aliquots.

pH was measured with a Fisher ACUMET pH Meter, model 805 MP. All containers were of polypropylene or were plastic vacutainers. All vessels were rinsed thoroughly with deionized water prior to use.

(b) Spectrophotometry

A Hewlett Packard diode array UV–visible spectrometer, model no. 8452A, was employed. Solutions were prepared in new plastic vacutainers accommodating plastic stoppers.

(c) Reagents

UHP argon for deaeration was from Canadian Oxygen Limited. Aluminum stock solutions were prepared from $AlK(SO_4)_2 \cdot 12H_2O$ (BDH) and water was purified by reverse osmosis and ion exchange. Acetate (0.1 M) and bicarbonate (0.1 M) solutions were used for pH 4.6 and 8.4 buffers, respectively. Solochrome Violet RS (Lot no. KJ101187, INC Pharmaceuticals Inc.) was recrystallized twice from 50% aqueous ethanol and dried at 70–80°C for 8 h.

(d) Total aluminum analysis

Total aluminum in samples and reagents was determined by GFAAS (1).

Results and discussion

Differential pulse polarography

The CSF obtained was in the form of pooled samples (potentially infectious) and each pooled sample was first analyzed for total aluminum by GFAAS. The remainder of the sample was then analyzed by DPP using the method of standard additions. For each sample point the specimen was first decanted. SVRS and standard aluminum solution were

[1]Author to whom correspondence may be addressed.

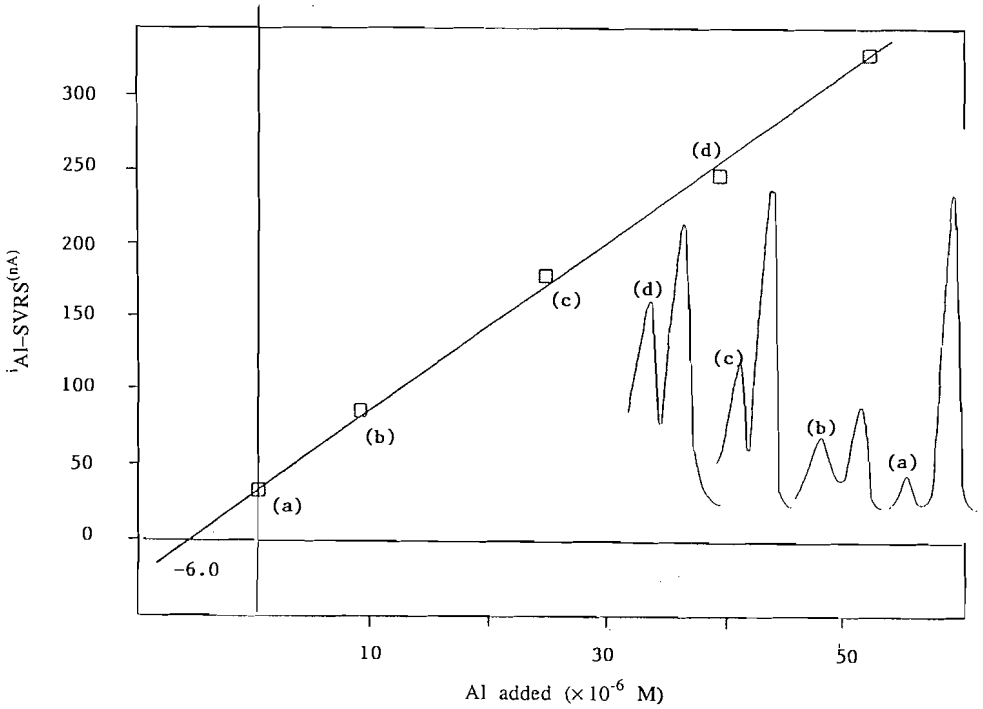

FIG. 1. Standard addition calibration curve for $i_{Al-SVRS}$(nA) vs. added Al concentration. Inset: form of differential pulse polarogram. Lettered peaks and points are corresponding $i_{Al-SVRS}$ values. Large unlettered peaks correspond to excess SVRS reduction.

TABLE 1. DPP analysis of unbuffered CSF pools for Al using standard additions

Parameter	Pool A	Pool B
Initial volume	6.5 mL	3.0 mL
Volume used for DPP	5.0 mL	1.9 mL
Initial pH	8.1	8.1
Final pH	9.1	8.8
SVRS potential	−0.56 V	−0.54 → − 0.55 V
Al-complex potential	−0.72 V	−0.72 → −0.79 V
Number of additions	3	4
Al found by GFAAS (10^6 × M)	3.76 ± 0.2	5.74 ± 0.3
Al found by DPP (10^6 × M)	3.8 ± 0.5	6.0 ± 0.6

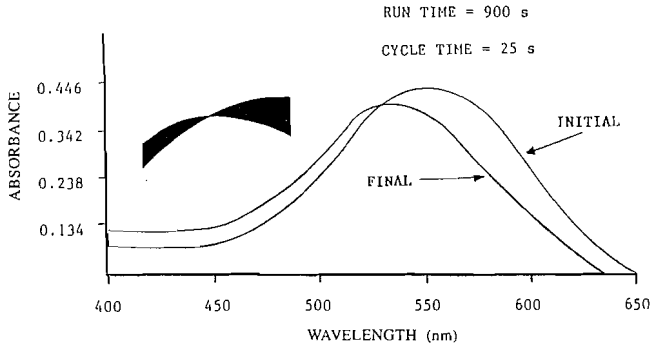

FIG. 2. The effect of additions of Al on the UV–visible spectrum of 2.0×10^{-5} M SVRS. pH = 8.4, temperature = 22°C. Inset: Isosbestic point region.

then added and the mixture heated to 70°C for 10 min, cooled, and then subjected to DPP. The results for two pools are summarized in Table 1. Figure 1 shows the standard addition calibration curve for determining Al in pool B with an indication of the form of the polarogram.

Thus, it appears that differential pulse polarography is applicable to the Al:SVRS system in alkaline media; indeed, attempts to acidify the CSF samples caused much frothing. Further, since the aluminum concentrations found by GFAAS and DPP are the same, we infer that any complexes formed between aluminum and the constituents of CSF are sufficiently weak that conversion to the Al:SVRS complex is complete; this conversion is complete for aluminum in some but not all natural water samples brought to a pH of 4.6.

UV–visible spectophotometry

The purified free SVRS dye showed an absorption maximum at 500 nm at pH = 4.6; Beer's law is obeyed over the range $(1.0–8.0) \times 10^{-5}$ M with $\varepsilon_{max} = 2.1 \times 10^4$ L mol^{-1} cm^{-1}, in agreement with the value of 2.2×10^4 L mol^{-1} cm^{-1} obtained by Coates and Rigg (3). λ_{max} was shifted to 554 nm at pH = 8.4 and ε_{max} had the value of 2.2×10^4 L mol^{-1} cm^{-1} for the range $(2.0–9.0) \times 10^{-5}$ M. Using pH = 8.4 data, the purity of the crude dye was found to be 54%.

The addition of aluminum solution to SVRS at pH 8.4 and a temperature of 22°C gives rise to the spectral changes shown in Fig. 2. After 900 s the spectrum is stable. Although we have an isosbestic point at 530 nm, there is no λ_{max} corresponding to the formation of the aluminum complex; instead, the most significant absorbance change is the decrease in intensity at 600 nm with the addition of aluminum. This decrease in absorbance was used to determine the stoichi-

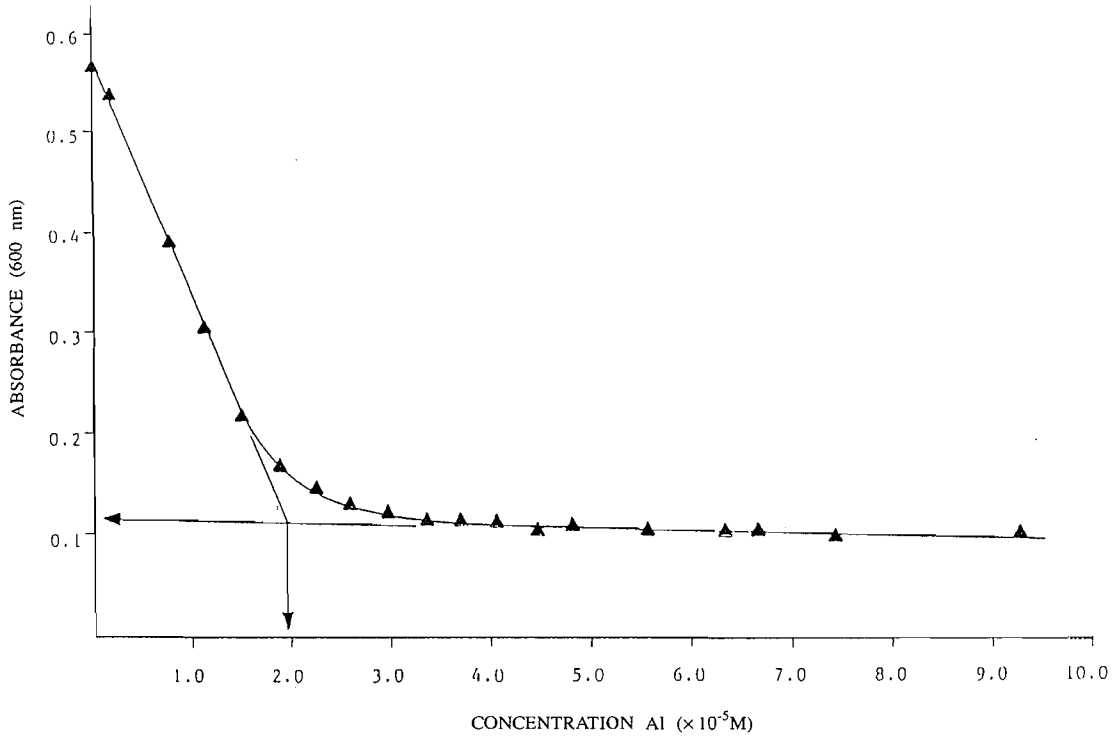

FIG. 3. Absorbance at 600 nm vs. concentration of Al added to 4.0×10^{-5} M SVRS. pH = 8.5, temperature = 22°C. Reaction time 17 h for each of the 19 separate sample solutions.

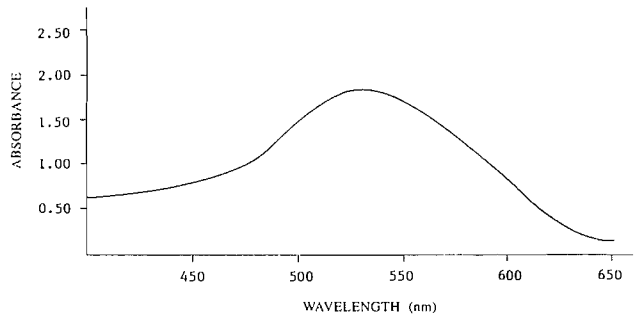

FIG. 4. UV–visible spectrum of a human CSF pool sample containing 7.40 μM Al and 90.9 μM SVRS.

TABLE 2. Spectrophotometry of human CSF containing Al

Solution	CSF vol. (mL)	Aqueous Al vol (μL)	10^5 Al in CSF (M)	$Abs_{600\,nm}$
1	0.50	0	0.74	0.787
2	0.48	20	2.06	0.639
3	0.47	30	2.72	0.550
4	0.46	40	3.38	0.486

SVRS concentration throughout = 9.09×10^{-5} M.
Reaction time = 15 min. Temperature ≈ 22°C. pH = 8.4.

ometry of the complex as depicted in Fig. 3: the formation of $Al(SVRS)_2$ is quite clear. ε_{600} was found to be 1.4×10^4 L mol^{-1} cm^{-1} for SVRS and 6.0×10^3 L mol^{-1} cm^{-1} for $Al(SVRS)_2$.

The spectrum of a CSF pool containing 7.40 μM aluminum (as determined by GFAAS) and 90.9 μM SVRS is shown in Fig. 4. It has essentially the same shape as that of the Al:SVRS system in a bicarbonate buffer (Fig. 3). To verify that the spectrophotometric determination of Al in CSF is possible using SVRS, several additions of standard Al and SVRS solutions were made to this solution (Table 2). A linear decrease of absorbance at 600 nm occurred. The change in predominant medium from $NaHCO_3$ solution to CSF led to ε_{600} values for SVRS and $Al(SVRS)_2$ of 9.6×10^3 and 7.6×10^3 L mol^{-1} cm^{-1}, respectively. Thus, in any actual Al determination it is more appropriate to make separate small additions of both the standard Al solution and CSF to the dye:buffer mixture.

Conclusions

The determination of aluminum in human cerebrospinal fluid is possible by both an electrochemical and a spectrophotometric method, certainly at the 50–100 μg L^{-1} level, although probably with greater sensitivity. Both methods employed the dye Solochrome Violet RS with measurement of (*a*) the differential pulse current of the aluminum complex and (*b*) the decrease in absorbance at 600 nm of the dye upon complexation. It appears that CSF does not contain strong complexing agents and any aluminum present therein would be potentially toxic if transferred to other parts of the body. It is planned to miniaturize the electrochemical operation and thus be able to measure aluminum in vitro or in vivo and correlate the results with clinical diagnoses on an individual basis.

The mechanism of stereoselectivity in the cycloaddition reactions of α-hydroxy-*ortho*-quinodimethanes with the fumarate of methyl lactate and mandelate

JAMES L. CHARLTON[1] AND SHAWN MADDAFORD
Department of Chemistry, University of Manitoba, Winnipeg, Man. Canada R3T 2N2

Received November 17, 1992

JAMES L. CHARLTON and SHAWN MADDAFORD. Can. J. Chem. **71**, 827 (1993).

The Diels–Alder cycloaddition reaction of the fumarate of methyl lactate or methyl mandelate with α-hydroxy-*ortho*-quinodimethane produces an unexpected *exo* product with very high asymmetric induction. Experiments and calculations have been carried out that show that the origin of the stereoselectivity in these reactions is related to hydrogen bonding between the α-hydroxy-*o*-quinodimethane and the lactate or mandelate group in the dienophile.

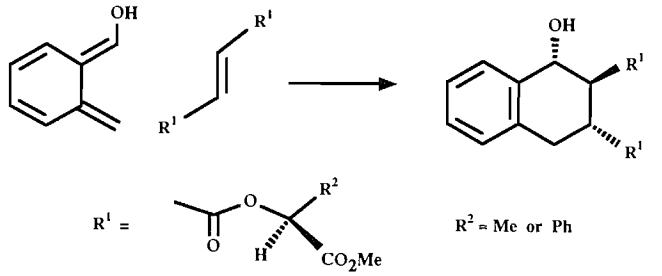
JAMES L. CHARLTON et SHAWN MADDAFORD. Can. J. Chem. **71**, 827 (1993).

La réaction de cycloaddition de Diels–Alder du fumarate du lactate de méthyle ou du mandélate de méthyle avec l'α-hydroxy-*ortho*-quinodiméthane conduit à un produit *exo* inattendu, avec une induction asymétrique très élevée. On a effectué des expériences et des calculs qui montrent que l'origine de la stéréosélectivité de ces réactions est reliée à la liaison hydrogène entre l'α-hydroxy-*ortho*-quinodiméthane et le groupe lactate ou mandélate du diénophile.

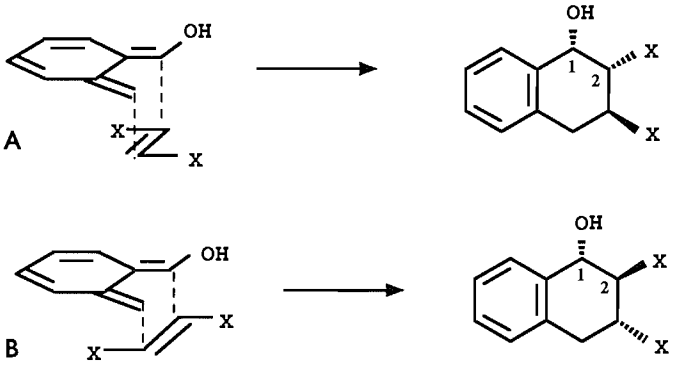
[Traduit par la rédaction]

Introduction

We recently published several accounts of the stereoselective and asymmetric Diels–Alder reactions of α-hydroxy-*ortho*-quinodimethanes (α-hydroxy-*o*-QDMs) with the fumarate of methyl lactate or methyl mandelate (1–5).



While these reactions are proving useful in asymmetric synthesis (1, 3, 6), a satisfactory explanation of the stereoselectivity observed has not yet been proposed. Such an explanation would have to account for both the absolute stereoselectivity and the unusual relative stereoselectivity observed. The relative stereoselectivity is unusual in that all previous accounts of Diels–Alder reactions of α-hydroxy or α-alkoxy-*o*-QDMs with dienophiles have shown that the reactions produce *cis*-1,2 adducts via *endo* transition states (**A**) (7–11). This is in contrast to the reactions of α-hydroxy-*o*-QDMs with the fumarates of lactate or mandelate, where predominantly *trans*-1,2 adducts are formed via *exo* transition states (**B**).



[1]Author to whom correspondence may be addressed.

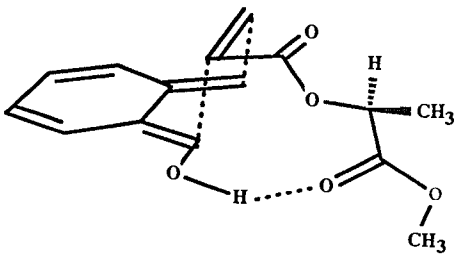


FIG. 1. Possible transition state for the Diels–Alder reaction of α-hydroxy-*o*-QDM with the acrylate of methyl (*S*)-lactate.

The *absolute* stereochemistry of the products is that produced from *exo* addition of the *o*-QDM to the *re* face of the fumarate of methyl (*S*)-lactate **1** (as in transition state **B**, see also Fig. 1). The observed addition to the *re* face of the dienophile is similar to results of previous Diels–Alder studies on this dienophile by Helmchem and co-workers (12, 13), who attributed this absolute stereoselectivity to steric blocking of the *si* face of the dienophile. While steric factors could be used to explain facial selectivity with respect to the dienophile when reaction occurs with an α-hydroxy-*o*-QDM, it would not explain the unusual preference for the *exo* transition state geometry **B**. It seemed possible, given the position of the hydroxyl group on the *o*-QDM, that hydrogen bonding between the hydroxyl group and the lactyl carbonyl might be responsible for this preferred *exo* reaction geometry as illustrated in Fig. 1.

Models show that a similar hydrogen-bonded transition state is sterically unlikely for the *endo* transition state. Although controlling stereoselectivity by such a long-range hydrogen bond may seem implausible, a similar type of nine-membered ring hydrogen bond has been found to be responsible for facial selectivity in the Diels–Alder reaction shown in Fig. 2 (14).

Even if one accepts the hypothesis of a hydrogen-bonded *exo* transition state for the reaction of the fumarate of methyl (*S*)-lactate with an α-hydroxy-*o*-QDM, it is not immediately obvious how the *S* chiral auxiliary directs addition to the *re* face of the dienophile (as is shown in Fig. 1). The steric crowding appears to be similar for both the *S* and *R* chiral

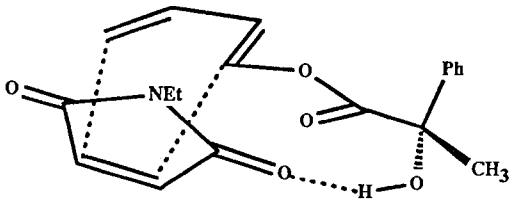

FIG. 2. Hydrogen bonding control of facial selectivity in Diels–Alder reaction (14).

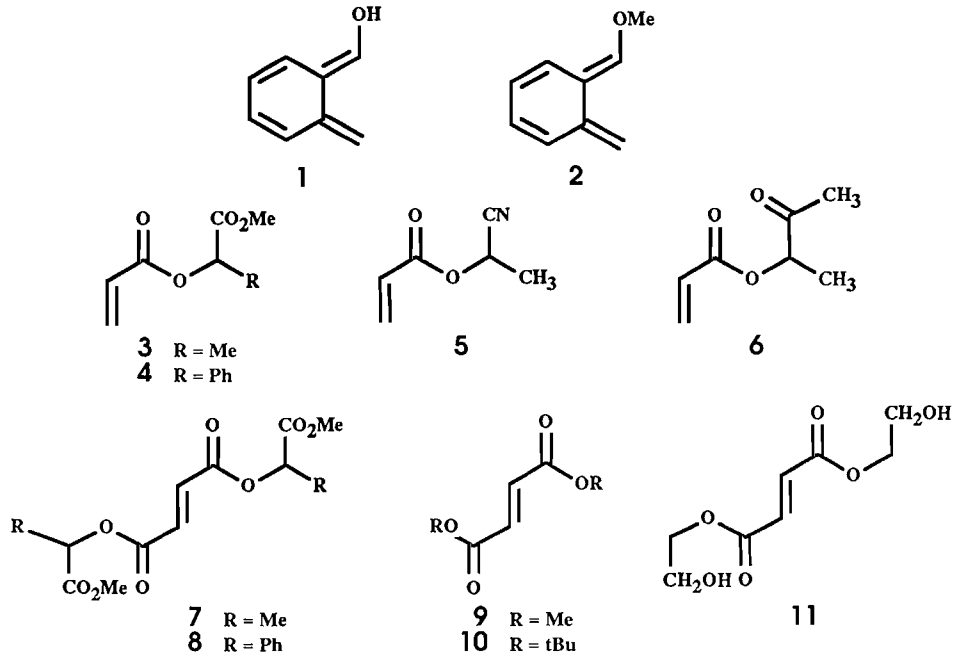
auxiliaries when reaction occurs at the *re* face of the dienophile.

In an attempt to determine the mechanism of the stereoselectivity in the title reactions, we have studied the effect of variation in *o*-QDM structure, solvent, and dienophile structure. We have also carried out molecular orbital calculations (GAUSSIAN-86 AM1) on possible transition states for the reaction of the acrylate of methyl (*S*)-lactate with α-hydroxy-*o*-QDM.

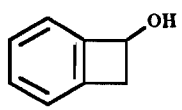
Results and discussion

As a probe of structural effects on stereoselectivity we have studied the reactions of α-hydroxy-*o*-QDM **1** with several new dienophiles, **5**, **6**, **10**, and **11**, and the reactions of α-methoxy-*o*-QDM **2** with **7** and **10**. The stereoselectivity of these reactions was compared to the stereoselectivity of reactions previously reported.[2]

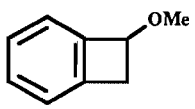


Dienophiles **5**, **6**, **10**, and **11** were all synthesized by an uncatalysed reaction of the acid chloride with an excess of the appropriate alcohol, followed by chromatography on silica gel.

o-QDMs **1** and **2** were generated by heating either benzocyclobutenol **12** (16) or 1-methoxybenzocyclobutene **13** (16) in toluene containing the dienophile and 4Å molecular sieves.



12



13

Cycloadducts were separated by flash chromatography on silica gel using ethyl acetate – hexanes as solvent. In some cases separation and characterization of all of the individual isomers was not possible. Determination of isomer ratios was carried out using either ^{1}H nmr (300 or 500 MHz) or hplc (ODS-2, methanol–water as eluent). The assignment of relative stereochemistry within the tetralin ring of the cycloadducts (*endo* vs. *exo*) was made using ^{1}H nmr. For all cycloadducts H1 appear between 4.6 and 5.2 ppm (in $CDCl_3$) and *endo* (*cis*-1,2) coupling constants, $J_{1,2}$, are 2–5 Hz, while *exo* (*trans*-1,2) coupling constants are 7–12 Hz (for previous examples see refs. 2–6, 17). The results of the product study are shown in Table 1.

In the case of cycloadducts from dienophiles **3–8**, there are four possible diastereomeric products (two *endo* and two *exo*) for each absolute configuration of the chiral center in the dienophile. These four possible diastereomers are illustrated in Fig. 3 for **1** reacting with the acrylate of methyl (*S*)-lactate, **3**.

As mentioned above, it has been shown that the major product from the reaction of **1** with **3** is the *exo-re* cycloadduct (4). The *exo-re* cycloadduct is also the major cycloadduct from the reaction of **1** with (*S*)-**4**, (*S*)-**7**, and (*S*)-**8** (2, 4). Racemic material was studied in the case of dienophiles **5** and **6** and, although the *endo* isomers could be distinguished from the *exo* isomers by ^{1}H nmr, no attempt was

[2]The preparation of dienophiles **3** and **7** is given in ref. 4 while that of **8** is given in ref. 1. The preparation of dienophile **4** is described by K.K.S. Koh (15).

[a]Ratio of *exo* and (or) *endo* diastereomers for cases in which the dienophile carries a chiral auxiliary.

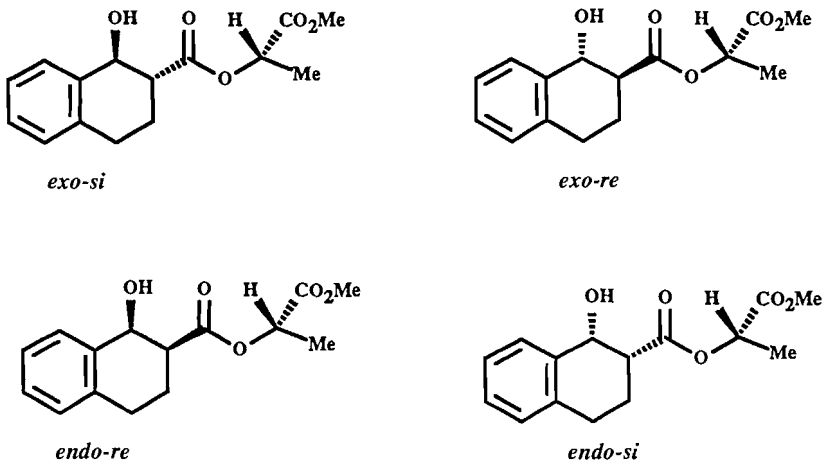

FIG. 3. Possible products from the reaction of α-hydroxy-*o*-QDM, **1**, with the acrylate of methyl (*S*)-lactate.

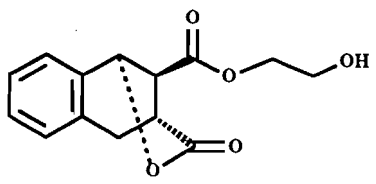
made to determine the configuration of the tetralin ring carbons relative to the center in the chiral auxiliary.

Reaction of **1** with dienophile **5** gave a mixture of four diastereomers as evidenced by the number of doublets in the H1 region of the ^{1}H spectrum. Correct elemental composition was confirmed by elemental analysis of the mixture. The ^{1}H nmr at 500 MHz in 20% $CDCl_3$ in deuterobenzene allowed integration of the four H1 signals of isomers *exo*-1, *exo*-2, *endo*-1, and *endo*-2, giving the ratio of 34:16:33:17, respectively (J = 9.1, 8.9, 3.25, and 3.45, respectively). The hplc separation of the mixture on ODS-2 using a methanol–water mixture as eluent resulted in the isolation of three of the four isomers (in order of elution, *exo*-1, *endo*-1, *endo*-2) and their individual ^{1}H nmr spectra are reported in the experimental.

Reaction of **1** with dienophile **6** gave only a single *exo* cycloadduct in 45% yield after chromatography. No signals consistent with other diastereomers could be observed in the nmr of the crude product.

The product mixture from dienophile **11** was more complicated. An ^{1}H nmr spectrum of the crude product mixture showed doublets at 5.43 (J = 5.17), 5.12 (J = 3.65), and 4.86 (J = 9.53) ppm ($CDCl_3$). Chromatography on silica gel resulted in the isolation and characterization of only one of the three compounds. Based on its ir spectrum (1788 cm^{-1}) and comparison of its ^{1}H nmr spectrum to that of a similar compound (4), it was assigned structure **14**.



14

The doublet appearing at 5.43 ppm in the nmr spectrum of the crude product comes from compound **14** and the remaining two doublets at 5.13 and 4.86 ppm were tentatively assigned to the *endo* and *exo* cycloadducts, respectively, on the basis of the coupling constants. Presumably the *exo* cycloadduct readily closes to the lactone **14** as has been noted in similar cycloadducts (4). The *endo*/*exo* ratio given in Table 1 for dienophile **11** is calculated using the ratio of the nmr integration for the presumed *endo* doublet at 5.13 ppm to the sum of the other two doublets.

Dienophile **9** has been reported to give a mixture of *endo* (major) and *exo* (minor) isomers in good yield on reaction with *o*-QDM **1**, produced by irradiation of *o*-methylbenzaldehyde (18).

The reaction of di-*tert*-butyl fumarate, **10**, with **1** gave a mixture of the *endo* (major) and *exo* (minor) cycloadducts, which were separated by chromatography and characterized.

In the case of α-methoxy-*o*-QDM **2**, primarily *endo* prod-

ucts were formed with dienophiles **7**, **9**, and **10**. Reaction with **7** gave two diastereometric *endo* adducts, which were both isolated and characterized. Reaction with **9** was reported previously to give only an *endo* cycloadduct (32%) with no indication of the presence of other isomeric cycloadducts (18). Reaction of *o*-QDM **2** with di-*tert*-butyl fumarate **10** gave primarily an *endo* cycloadduct, which was isolated by chromatography and characterized. The ^{1}H nmr spectrum of the crude reaction mixture also exhibited a doublet at 4.74 ppm (J = 8.1), which was assumed to be the *exo* cycloadduct. The integration of this peak relative to that assigned to H1 of the *endo* cycloadduct (4.53 ppm, J = 3.39) gave the *endo/exo* ratio of 88:12 reported in Table 1.

From the above results a pattern of reactivity can be seen. Only *o*-QDM **1**, with an α-hydroxyl group, gives *exo* cycloadducts with high stereoselectivity. *o*-QDM **2**, with an α-methoxy group, gives primarily *endo* adducts. Steric bulk of the ester group in the dienophile makes little difference to the *endo/exo* ratio as evidenced by the comparison of dimethyl and di-*tert*-butyl fumarate, **9** and **11**. Only dienophiles with a strong hydrogen-bonding acceptor group give *exo* cycloadducts, with the exception of **5**.

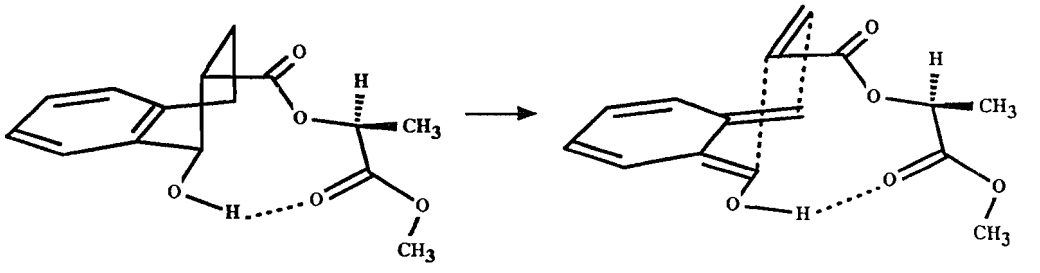
All of the above facts suggest that a hydrogen-bonded transition state, perhaps similar to that depicted in Fig. 1, directs the *endo/exo* stereoselectivity of the cycloaddition reaction of **1** with dienophiles **3**, **4**, **6**, **7**, **8**, and **11**. In the case of dienophile **5**, it appears that the linear geometry of the nitrile function makes it sterically impossible for it to form a hydrogen bond to the hydroxyl group of the *o*-QDM. For dienophiles **9** and **10** and (or) reactions involving *o*-QDM **2**, the expected *endo* products are predominantly formed.

If the proposed hydrogen bonding theory is correct, it should be easily disrupted by solvent effects. Just such an effect was found for the reaction of *o*-QDM **1** with the fumarate of methyl (*S*)-lactate **7**. When **1** (from **12** at 100°C) was reacted with **7** in toluene containing 30% dimethyl sulfoxide (DMSO) by volume, a mixture of four products was formed. Their ratios, measured by hplc, were 9:15:34:42 (presumed *exo-si*, *exo-re*, *endo*-1, and *endo*-2 respectively. The *exo-re* isomer was identified by comparison to an authentic sample (4, 5). The two *endo* adducts were both separated and characterized, although it could not be determined which was the *endo-re* and which was the *endo-si* isomer. The remaining minor product could not be isolated in sufficient quantity for characterization but was assumed to be the remaining *exo-si* diastereomer. As expected, DMSO appears to interfere with the normal diastereoselectivity by hydrogen bonding to the hydroxyl group of the *o*-QDM, thereby preventing the formation of a hydrogen-bonded transition state similar to that illustrated in Fig. 1. This results in the formation of more *endo* products and a loss in asymmetric induction for both *endo* and *exo* products.

Molecular orbital calculations

If the hydrogen-bonded transition state shown in Fig. 1 is correct it must also be able to account for the high facial selectivity observed with respect to the dienophile. For example, the reaction of α-hydroxy-*o*-QDM **1** with the acrylate of methyl (*S*)-lactate **3** gives the *exo-re* cycloadduct with higher than 90% de. To test the validity of the model, molecular orbital calculations have been carried out on the *exo-re* transition state for the acrylate of both methyl (*S*)-lactate and methyl (*R*)-lactate. Such a calculation is equivalent to comparing the *exo-re*-(*S*) transition state to the *exo-si*-(*S*) transition state since *exo-si*-(*S*) is the mirror image of *exo-re*-(*R*). If the model is correct, the energy of the *exo-re*-(*S*) transition state should be lower than that of the *exo-re*-(*R*) (*exo-si*-(*S*)). By using geometry optimization it should also be possible to confirm that a hydrogen bond, similar to that depicted in Fig. 1, is possible for a conformationally relaxed transition state.

Molecular orbital calculations were carried out at the semiempirical level (AM1) with geometry optimization using the program GAUSSIAN-86 (19). To model the transition state the calculations were started at the cycloadduct stage with the saturated tetralin ring in a boat conformation, typical of the final state of Diels–Alder reactions. The lactyl side chain was twisted into a conformation for which hydrogen bonding to the OH group was possible. The initial atom coordinates for the starting structure were obtained from a model constructed, and conformationally relaxed (molecular mechanics minimization), using the computer program PC-MODEL (20).[3] The dienophile and diene were then iteratively separated by elongation of the 1,2 and 3,4 bonds until a separation (diene–dienophile) of 2.0 Å was reached, a distance close to the Diels–Alder reaction transition state (21). At each stage of the iterative dissociation of the adduct, the 1,2 and 3,4 bond lengths were fixed and the rest of the geometry optimized.



The calculations confirmed that it is possible to have a conformationally relaxed transition state with hydrogen bonding between the OH group and the lactyl carbonyl (2.14–2.31 Å). The calculations also showed that there are two low-energy conformations of the lactyl side chain that allow for hydrogen bonding and that these two conformations roughly correspond to the *s-cis* and the *s-trans* dienophile conformations. The *s-cis* conformation is shown in the diagram

[3]Calculations carried out on a Silicon Graphics IRIS 4D70/GT workstation.

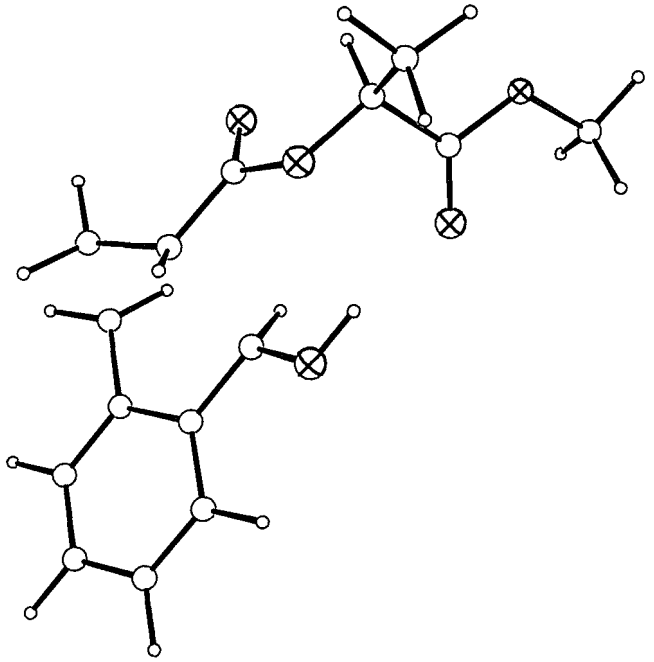


FIG. 4. An ORTEP diagram of the *exo-re-s-cis-S* transition state.

although calculations were carried out for both the *s-cis* and the *s-trans* conformations (for both the *R* and *S* dienophile). The relative energies of the *exo-re* transition state with the *s-cis-S*, *s-cis-R*, *s-trans-S*, and *s-trans-R* dienophile were found to be 0.0 (reference), 8.51, 10.6, and 5.79 kJ/mol, respectively. An ORTEP (22) plot of the conformationally minimized *exo-re-s-cis-S* transition state is shown in Fig. 4.

The calculations are consistent with the experimental results since the calculated lowest energy transition state, *exo-re-S*, leads to the observed product. It is interesting to note that the correct prediction of asymmetric induction can be achieved only if the dienophile is in the *s-cis* conformation.

It was hoped that the calculated optimized geometries of the *exo-re-S* and *exo-re-R* transition states would give some hint as to the mechanism of the asymmetric control exerted by the chiral auxiliary. However, there was very little difference in the geometries of the two diastereotopic transition states, indicating that the effect of the auxiliary on reaction diastereoselectivity is very subtle and not simply due to sterically induced changes in reaction geometry.

The calculations do confirm that a hydrogen-bonded transition state leading to the preferred product is structurally and energetically feasible. Large rate enhancements have been observed as a result of hydrogen bonding in other Diels–Alder reactions involving dienolic substrates such as 9-hydroxyanthracene (23). A similar rate enhancement in the reactions described here may explain the preference for the hydrogen-bonded transition state leading to the *exo* cycloadducts.

Experimental

The ^{1}H nmr spectra were recorded on a Bruker AM-300 or AMX-500 instrument using tetramethylsilane as internal standard. The ir spectra were recorded on a Perkin–Elmer 881 spectrometer. Aldrich silica gel (28,859-4) was used for all chromatography. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario. Exact Mass/mass spectra were obtained on an Analytical VG 7070E-HF instrument. Melting points were measured on a hot stage instrument and are uncorrected.

Acrylate of rac-*lactonitrile*, ***5***

Acryloyl chloride (5.9 g, 5.3 mL, 65 mmol) and lactonitrile (2.95 g, 3 mL, 37.8 mmol) were refluxed in methylene chloride (50 mL) over dry molecular sieves (6.7 g, 4 Å) for 68 h. The solution was filtered and the solvent evaporated, leaving a light yellow liquid. The liquid was fractionally distilled (bp 160°C, 1 atm (1 atm = 101.3 kPa)) to remove the lower boiling acryloyl chloride and methylene chloride. The distillate was chromatographed on silica gel (5% ethyl acetate/hexanes) to give a colourless liquid (1.4 g, 11.3 mmol, 30%): ir (CH_2Cl_2): 1739 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.52 (dd, 1H, J = 1.29, 17.21), 6.15 (dd, 1H, J = 10.44, 17.14), 5.98 (dd, 1H, J = 1.29, 10.5), 5.47 (q, 1H, J = 6.9), 1.69 (d, 3H, J = 6.97); ^{13}C nmr ($CDCl_3$) δ: 164.06, 133.29, 126.64, 117.46, 57.39, 18.79; mass spectrum, ammonia ionization *m/e* (rel. %): 143 (M + NH_4^+, 11), 126 (M + H^+, 1.1), 99 (2.2), 72 (12), 70 (5), 55 (100), 46 (4). Exact Mass (EI) calcd. for $C_6H_7O_2N$: 125.0477; found: 125.0484.

Acrylate of rac-*3-hydroxy-2-butanone*, ***6***

Acryloyl chloride (5 mL, 61.5 mmol) and 3-hydroxy-2-butanone (5.46 g, 61.9 mmol) were refluxed in CH_2Cl_2 (5 mL) over dry molecular sieves (4 Å, 8 g) for 4 days. The solution was filtered and the solvent evaporated to leave an oil. The crude oil was chromatographed on silica (10% ethyl acetate/hexanes) to give a colourless oil (5.7 g, 66%): ir (CH_2Cl_2): 1730 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.41 (dd, 1H, J = 1.35, 17.34), 6.13 (dd, 1H, J = 10.40, 17.33), 5.85 (dd, 1H, J = 1.36, 10.40), 5.09 (q, 1H, J = 7.05), 2.12 (s, 3H), 1.38 (d, 3H, J = 7.06); ^{13}C nmr ($CDCl_3$) δ: 205.61, 165.37, 131.90, 127.67, 75.07, 25.58, 16.02; mass spectrum *m/e* (rel. %): 142 (M^+, 0.4), 100 (1.8), 99 (7.7), 98 (13), 87 (2.4), 55 (100), 43 (36). Exact Mass calcd. for $C_7H_{10}O_3$: 142.0630; found: 142.0646.

*Di-*tert*-butyl fumarate*, ***10***

Fumaryl chloride (5.1 g, 0.033 mol) was dissolved in benzene (50 mL) and *tert*-butyl alcohol (15 mL, 4.8 mol-equiv.) was added at room temperature. Molecular sieves (5.01 g, 4 Å, flame-dried under nitrogen) were added and the solution refluxed for 38 h. The resulting solution was filtered through a short column of silica (EtOAc) and the filtrate washed with aqueous $NaHCO_3$ solution (5%, 3 × 20 mL). The solution was dried ($MgSO_4$) and evaporated, giving a yellow oil (2.99 g, 42%) that crystallized on standing. Flash chromatography on silica (eluent 20% ethyl acetate/hexanes) yielded a colourless solid (1.74 g, 24%) a sample of which was crystallized from ethyl acetate/hexanes; mp 62–63°C; ir (CH_2Cl_2): 1709 cm^{-1}; ^{1}H nmr (60 MHz, $CDCl_3$) δ: 6.73 (s, 2H), 1.53 (s, 18H); ^{13}C nmr (75.47 MHz, $CDCl_3$) δ: 164.38, 134.53, 81.64, 27.99; mass spectrum *m/e* (rel. %): 155 (15), 99 (53), 57 (100), 56 (30). Anal. calcd. for $C_{12}H_{20}O_4$: C 63.14, H 8.83; found: C 63.41, H 8.91.

Di-(2-hydroxyethyl) fumarate, ***11***

Fumaryl chloride (1 mL, 1.40 g, 9.16 mmol) and ethylene glycol (5.2 mL, 10 mol-equiv.) were stirred at 27°C for 24 h. The solution was diluted with water (25 mL) and extracted with EtOAc (3 × 25 mL). The organic phase was dried (Na_2SO_4) and the solvent evaporated, leaving a viscous oil (1.51 g). The oil was chromatographed on silica (80% ethyl acetate/hexanes) to give a semicrystalline product (1.01 g, 54%); mp 52–53°C; ir (CH_2Cl_2): 1728 cm^{-1}; ^{1}H nmr (300 MHz, $CDCl_3$) δ: 6.92 (s, 2H), 4.33 (m, 4H), 3.87 (m, 4H), 2.79 (bs, 2H); ^{13}C nmr (75.47 MHz, $CDCl_3$) δ: 165.06, 133.64, 66.87, 60.67; mass spectrum *m/e* (rel. %): 144 (15), 143 (100), 117 (12.5), 99 (65.9), 85 (23), 82 (26). 57 (29). Anal. calcd. for $C_8H_{12}O_6$: C 47.06, H 5.92; found: C 46.99, H 5.77.

Reactions of benzocyclobutenol ***12*** *with dienophiles* ***5***, ***6***, ***10***, *and* ***11***

Reaction of ***1*** *with* ***5***

Benzocyclobutenol (0.125 g, 1.04 mmol) and acrylate **5** (0.439 g, 3.51 mmol, 3.36 mol-equiv.) were refluxed in toluene

Reaction of ***1*** *with* ***11***

The fumarate of ethylene glycol (330 mg, 1.62 mmol) and benzocyclobutenol (214 mg, 1.78 mmol, 1.1 mol-equiv.) were refluxed in toluene (10 mL) in the presence of molecular sieves (4Å) for 18 h. The solution was filtered through a short column of sicila (eluent, ethyl acetate) and the solvent evaporated in vacuo. The ^{1}H nmr spectrum of the crude product revealed the presence of three doublets at δ 5.43 (J = 5.18), 5.12 (J = 3.65), and 4.86 (J = 9.53). The crude oil was chromatographed on silica (eluant 70% ethyl acetate/hexanes) to give only one pure fraction (93 mg, 22%); mp 114–115°C; ir (CH_2Cl_2): 3600, 1788, 1745 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.35 (dd, 1H, J = 1.71, 7.3), 7.29–7.16 (m, 3H), 5.46 (d, 1H, J = 5.18), 4.18 (ddd, 1H, J = 3.08, 6.04, 9.13), 3.94 (m, 1H), 3.84 (t, 1H, J = 5.19), 3.51 (dd, 1H, J = 17.9, 5.28), 3.46 (bm, 2H), 3.35 (m, 1H, J = 1.14, 5.34), 3.09 (d, 1H, J = 17.9); ^{13}C nmr ($CDCl_3$) δ: 176.52, 167.37, 133.84, 126.80, 78.06, 66.38, 60.72, 47.64, 39.04, 27.32; mass spectrum m/e (rel. %): 262 (M^+, 7.0), 200 (12), 173 (5.7), 172 (8.2), 156 (5.9), 129 (100), 128 (77), 127 (16). Reactions of 1-methoxybenzocyclobutene ***13*** *with dienophiles* ***7*** *and* ***10***

Reaction of ***2*** *with* ***7***

The fumarate of methyl (*S*)-lactate, **7** (115 mg, 0.397 mmol), and 1-methoxybenzocyclobutene (66.6 mg, 0.496 mmol) were refluxed together in toluene (10 mL) for 3 days. The solution was filtered through a short column of silica gel (eluent EtOAc) and evaporated to leave a yellow oil (185 mg). The ^{1}H nmr spectrum exhibited two doublets at δ 4.75 (J = 2.96) and 4.56 (J = 3.33) in a ratio of 1.57:1; hplc (ODS-2, acetonitrile–water–methanol) exhibited two peaks in a ratio of 1.56:1. Chromatography of the crude oil on silica gel (eluent 5% EtOAC–benzene) gave adduct *endo*-**1** (62.6 mg) and adduct *endo*-**2** (27.1 mg) (combined yield 62%).

endo-**1**: ir (CH_2Cl_2): 1746 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.18–7.32 (m, 4H), 5.24 (q, 1H, J = 7.04), 5.16 (q, 1H, J = 7.10), 4.68 (d, 1H, J = 3.00), 3.77 (s, 3H), 3.75 (s, 3H), 3.65 (m, 1H), 3.44 (dd, 1H, J = 7.04, 17.16), 3.34 (s, 3H), 3.17 (dd, 1H, J = 11.62, 3.00), 2.94 (dd, 1H, J = 10.94, 17.16), 1.54 (d, 3H, J = 7.11), 1.53 (d, 3H, J = 7.04); ^{13}C nmr ($CDCl_3$) δ: 174.85, 171.34, 171.24, 134.49, 133.13, 129.63, 129.14, 128.87, 125.66, 77.19, 68.65, 56.67, 52.24, 47.12, 36.24, 31.17, 17.20, 16.87; mass spectrum m/e (rel. %): 422 (M^+, 1.1), 359 (21), 258 (25), 187 (42), 186 (33), 185 (34), 159 (86), 155 (100), 128 (46). Reaction of benzocyclobutenol **12** *with the fumarate of methyl (S-lactate* **7** *in DMSO/toluene*

Benzocyclobutenol (42 mg, 0.35 mmol) and fumarate **7** (83 mg, 0.29 mmol) were heated at 100°C in 30% DMSO–toluene (by volume, 10 mL), over molecular sieves (4Å, 300 mg), for 21 h. The solution was filtered through a short silica gel column (eluant EtOAc), diluted with benzene, and extracted with water. The organic fraction was dried ($MgSO_4$) and the solvent evaporated. Residual solvent was removed at high vacuum (0.5 Torr, 30°C) to leave an oil (109 mg, 72%). The major isomers were separated using reverse phase hplc (ODS-2, 53% water- 41% methanol: 6% acetonitrile increasing to 100% methanol). The identity of the fourth eluted peak was established as the *exo-re* adduct by comparison to an authentic sample (4,5). The two major adducts, eluting second and third, were isolated and characterized.

A new and simple spectrophotometric method for the determination of selenium in the presence of copper and tellurium

GÜLER SOMER[1] AND NURAY KUTAY
Department of Chemistry, Faculty of Science, Gazi University, 06500 Ankara, Turkey

Received February 22, 1991[2]

GÜLER SOMER and NURAY KUTAY. Can. J. Chem. **71**, 834 (1993).

Selenium in anodic slime is determined by using an indirect method. Selenite is reduced by ferrous iron, the ferric iron formed is complexed with KSCN, and the absorbance at 480 nm is measured. In this way selenium (10^{-3}–10^{-2} M) can be determined in the presence of copper and tellurium without any separation.

GÜLER SOMER et NURAY KUTAY. Can. J. Chem. **71**, 834 (1993).

Faisant appel à des méthodes indirectes, on peut déterminer la quantité de sélénium présente dans les boues anodiques. Le sélénite est réduit par l'ion ferreux; l'ion ferrique qui se forme est complexé par du KSCN et on mesure alors l'absorption à 480 nm. De cette façon, on peut déterminer des quantités de sélénium de l'ordre de 10^{-3}–10^{-2} M en présence de cuivre et de tellure sans séparation préalable.

[Traduit par la rédaction]

For personal use only.

The most important source for selenium production is the anodic slime that is obtained during the electrolytic purification of copper. It is therefore important to determine the amount of selenium present in the anodic slime with a method that is simple and rapid. Anodic slime contains Se, Te, Cu, Au, Ag, Pb, As, and Sb. The level of selenium is between 8 and 20%, copper is between 20 and 40%, and tellurium is between 0.3 and 3%. In most selenium determination methods, copper seems to be the most serious interfering element due to its very similar redox properties. The aim of this work is to determine selenium in the presence of copper and tellurium without any separation. The quantity of selenium can be determined by titrimetric (1–3), spectrophotometric (4, 5), and gravimetric (6, 7) methods. Selenium in trace quantities is determined by Atomic Absorption Spectroscopy (AAS) (8), by polarography (9, 10), and by Anodic Stripping Voltammetry (ASV) (11, 12). In most of these methods separation of selenium is required.

We propose here a spectrophotometric method, in which selenium can be determined without any separation. Selenite is reduced by FeII. FeIII, the reaction product, is complexed by the addition of KSCN. The absorption of this complex is measured and the FeIII concentration is calculated. Since a stoichiometric amount of selenite has reacted, the amount of selenium is readily calculated.

Experimental

Reagents

All reagents used were analytical reagent grade. Triply distilled water was used for the preparation of all solutions and at all other stages of analysis.

FeII solution (0.1 M): Approximately 2.0 g $Fe(NH_4)_2SO_4$ is diluted to 100 mL with water that contains 40 mL of concentrated hydrochloric acid. Since this solution contains FeIII, it is reduced with $SnCl_2$ and the excess $SnCl_2$ is oxidized with $HgCl_2$. This solution is standardized with $K_2Cr_2O_7$ and stored under a nitrogen atmosphere to protect it from air oxidation.

Selenite solution (0.1 M): 0.547 g of SeO_2 is dissolved in 500 mL water.

FeIII solution (1.5×10^{-2} M): Approximately 0.32 g $FeCl_3 \cdot 6H_2O$ is diluted to 100.0 mL with water that contains 4.0 mL of HCl. This solution is standardized both with $KMnO_4$ and $K_2Cr_2O_7$ solutions.

Calibration curve

The molecular absorption spectrum of FeIII–thiocyanate has a maximum at 480 nm. FeIII solutions ($(0.67–1.40) \times 10^{-4}$ M) mixed with 100 times excess of KSCN show a linear relationship between concentration and absorbance.

In all absorption measurements, FeII solutions with KSCN were used as the blank.

Procedure

FeII solution, which is about 80–10 times more concentrated than that of the selenite, is added to the selenite solution. (For 1 mL of approximately 10^{-2} M SeO_3^{2-}, 8–10 mL of 0.1 M FeII solution is added.) The same volume of FeII solution is used as the reference. Both solutions are left to stand at room temperature for 15–20 min. Then measured volumes are taken, 2 M KSCN is added (the volumes are taken so that FeII/SCN concentration ratios are about 200), and absorbance is measured at 480 nm. Using the calibration curve for the FeIII–thiocyanate complex the amount of selenium in the sample can be calculated.

Solutions resembling anodic slime solutions were prepared (e.g., 10^{-2} M SeO_3^{2-}, 3×10^{-2} M Cu, and 5×10^{-3} M Te) and the recovery of selenite was determined. The results are given in Table 1. While the recovery for 10^{-2} M selenite solution was nearly 100%, it was reduced to 95% for 10^{-3} M solutions.

The same procedure has been applied for anodic slime after digestion. (This anodic slime contains 37% copper, 2% tellurium, and 4% lead.) For this purpose about 0.6 g of anodic slime was dissolved in an HCl + HNO_3 mixture (1).

The nitrous oxides were destroyed by adding urea. The solution was boiled and the reaction mixture was diluted to 100 mL with water. This solution did not show any absorbance at 480 nm after the addition of KSCN. For selenite determination, the above procedure was applied. The results obtained are in agreement with the results using different methods (Table 2) for the same anodic slime.

Results and discussion

When anodic slime is dissolved in a mixture of HCl + HNO_3, selenium and tellerium are present in the solution as selenite and tellurite. In this solution only selenite reacts with FeII, forming FeIII. Tellurite does not react. This reaction therefore can be used as a specific reaction for selenite determination. The FeIII concentration can be determined by the addition of KSCN and then by measuring the absorbance of the FeIII–SCN complex. The reaction between selenite and ferrous ion is an equilibrium reaction as given below:

[1] $SeO_3^{2-} + 4Fe^{2+} + 6H_3O^+ \rightleftharpoons Se + 4Fe^{3+} + 9H_2O$

[1]Author to whom correspondence may be addressed.

TABLE 1. Recovery of selenium from different solutions

Se_3^{2-} concentration (mol/L)	Concentration ratios $FeII/SeO_3^{2-}$	Concentration ratios $SCN^-/FeII$	Number of experiments	% Recovery of selenium[c]
10^{-2} [a]	80	200	6	101 ± 2
10^{-3} [b]	80	200	7	94 ± 0.7
10^{-3} [b]	160	200	3	95 ± 0,9

[a]FeII(8.0 mL 0.1 M) + SeO_3^{2-} (1.0 mL 10^{-2} M).
[b]FeII(1.0 mL 0.1 M) + SeO_3^{2-}(1.0 mL 10^{-3} M).
[c]90% confidence interval.

TABLE 2. Percentage of selenium in an anodic slime determined by four different methods

Method used	Weight percentage of selenium in slime
This work	10 ± 1
Volumetric (1)	10 ± 1
Polarographic (9)	10 ± 1
Spectrophotometric (13)	10 ± 1

To make use of the above reaction, certain variables that affect the reaction equilibrium must be investigated. For this purpose the effects of hydrogen ion concentration, FeII concentration, temperature, and time were investigated.

(a) Hydrogen ion concentration

The equilibrium constant is proportional to the sixth power of the hydrogen ion concentration. Therefore the FeII solution is prepared in concentrated HCl, so that the hydrogen ion concentration is 5 M. This acidity also inhibits the oxidation of the ferrous sulphate solution. H_2SO_4 could not be used because it decomposes KSCN, which is used for complexation of FeIII.

(b) FeII concentration

It was found experimentally that the FeII concentration must be 20–40 times larger than is stoichiometrically required. (For 1.0 mL of 10^{-3} M SeO_3^{2-}, 1.0 mL of 0.1 M FeII is enough.) Since FeII is oxidized by air during the reaction, use of higher concentrations of FeII should be avoided. As would be expecteed, large concentrations of FeIII favor the reverse reaction.

(c) Temperature

As was found in the previous experiment, for the reaction to be quantitative the FeII concentration had to be about 100 times higher than the selenite concentration. To check the temperature dependence, a mixture was prepared in which the FeII concentration was much less than it should be (5–10 times higher instead of 100 times). Under these conditions all the selenite cannot be reduced. When this solution was warmed up it showed higher absorbance values than the solution that was held at room temperature. This result may lead to the conclusion that the equilibrium was shifted to the right at higher temperatures. However, FeIII may be formed from two different reactions: either the above reaction (eq. [1]) is endothermic and more FeIII is formed by increasing the temperature, or FeII is oxidized by the air. To investigate the second possibility, an FeII solution with KSCN was warmed up in air; the colorless solution became red. It was concluded therefore that the oxidation of FeII by air increases with temperature. To eliminate the effect of the air oxidation of FeII, two reaction vessels containing the same amounts of FeII were prepared and SeO_3^{2-} solution was added to one vessel. Both solutions were kept at the same temperature for a certain time. Then KSCN was added and the absorbance of the selenite solution was measured using the FeII solution as the reference. This absorbance value must be proportional to the concentration of FeIII that is formed from the reaction of selenite with FeII. When the temperature was increased, the absorbance of the solution that contained selenite increased a little. The small increase of FeIII concentration with temperature tells us that selenite reduction is slightly endothermic. The larger temperature dependence of absorbance is because of the oxidation of FeII with air, and to eliminate it, this solution has to be used as the reference.

(d) Time

The FeIII concentration continued to increase for about 15 min after selenite and FeII were mixed. Therefore it was decided to wait 20 min for the completion of the reaction.

Conclusion

In nearly all selenium determination methods copper and tellurium seem to be the most serious interfering elements. They have to be separated either by precipitation or by exchange resins. The method suggested here is relatively simple and does not need expensive reagents or long and tedious separation procedures.

The structures of dioxolan-2-ylium cations; carbon–oxygen bond distances in acetoxonium ions

RONALD F. CHILDS,[1] RICHARD M. ORGIAS, COLIN J.L. LOCK, AND MALIVAGANAM MAHENDRAN
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received November 2, 1992

RONALD F. CHILDS, RICHARD M. ORGIAS, COLIN J.L. LOCK, and MALIVAGANAM MAHENDRAN. Can. J. Chem. **71**, 836 (1993).

The X-ray structures of four dioxolan-2-ylium cations, 2-phenyl-1,3-dioxolan-2-ylium trifluoromethanesulfonate, **6**, and 2-(4-methoxyphenyl)-1,3-dioxolan-2-ylium, **7**, 2-(2,4-pentadienyl)-1,3-dioxolan-2-ylium, **8**, and 2-(4-methoxyphenyl)-4,4-dimethyl-1,3-dioxolan-2-ylium, **9**, hexafluoroantimonates, have been determined. Crystals of **6** are monoclinic, $C2/c$, a = 28.934(5), b = 6.022(2), c = 14.831(3) Å, β = 113.37(1)°, Z = 8; 1944 reflections were used to determine the structure; R = 0.0488, wR = 0.0477. Crystals of **7** are monoclinic, $P2_1/c$, a = 11.948(4), b = 10.686(3), c = 10.853(2) Å, β = 106.31(2)°, Z = 4; 2260 reflections were used to determine the structure; R = 0.0551, wR = 0.0807. Crystals of **8** are monoclinic, $P2_1/c$, a = 10.549(2), b = 10.457(3), c = 11.702(2) Å, β = 105.69(1)°, Z = 4; 2190 reflections were used to determine the structure; R = 0.0337, wR = 0.0299. Crystals of **9** are orthorhombic, $Pmnb$, a = 8.297(4), b = 15.269(3), c = 12.638(2) Å, Z = 4; 1736 reflections were used to determine the structure; R = 0.0796, wR = 0.0726. Intensities were measured on Syntex $P2_1$ or Nicolet P3 diffractometers at −65°C with use of Mo Kα radiation. These structures are discussed in terms of the conjugation and charge distribution in these cations. In each case the cations are almost planar with very small twist angles between the plane of the C(2) substituent and that of the dioxolanylium ring. Cation **8** is the first reported example of the structure determination of an acyclic, substituted dienyl carbenium ion. The unsaturated five-carbon chain in **8** has an all-*trans* conformation about all the C—C bonds, but, apart from the C(2)—C(1′) distance, none of the other bond distances differ significantly from those found in corresponding neutral systems. The C(2)—C(1′) distance in **7** is significantly shorter than that of **6**, suggesting enhanced conjugation of the aryl ring with the positive centre in the former cation. This suggestion is supported by the significant quinonoid-type distortion that is observed in the *p*-methoxyphenyl ring of **7**. Systematic variations in the O(1)—C(5)/O(3)—C(4) bond distances are examined and it is shown that alkyl substitution at C(4)/C(5) leads to a large increase in their lengths, suggesting that the presence of a significant fraction of the positive charge is located on C(4) and (or) C(5). Support for this suggestion is found in a large variety of previously reported spectroscopic and calorimetric measurements.

RONALD F. CHILDS, RICHARD M. ORGIAS, COLIN J.L. LOCK et MALIVAGANAM MAHENDRAN. Can. J. Chem. **71**, 836 (1993).

Faisant appel à la diffraction des rayons X, on a déterminé les structures de quatre cations dioxolan-2-ylium : le trifluorométhanesulfonate de 2-phényl-1,3-dioxolan-2-ylium (**6**) et les hexafluoroantimonates de 2-(4-méthoxyphényl)-1,3-dioxolan-2-ylium (**7**), de 2-(penta-2,4-diényl)-1,3-dioxolan-2-ylium (**8**) et de 2-(4-méthoxyphényl)-4,4-diméthyl-1,3-dioxolan-2-ylium (**9**). Les cristaux du produit **6** sont monocliniques, $C2/c$, avec a = 28,934(5), b = 6,022(2) et c = 14,831(3) Å, β = 113,37(1)°, Z = 8 et R = 0,0488 et R_w = 0,0477 pour 1944 réflexions. Les cristaux du produit **7** sont monocliniques, $P2_1/c$, avec a = 11,948(4), b = 10,686(3) et c = 10,853(2) Å, β = 106,31(2)°, Z = 4 et R = 0,0551 et R_w = 0,0807 pour 2260 réflexions. Les cristaux du produit **8** sont monocliniques, $P2_1/c$, avec a = 10,549(2), b = 10,457(3) et c = 11,702(2) Å, β = 105,69(1)°, Z = 4 et R = 0,0337 et R_w = 0,0299 pour 2190 réflexions. Les cristaux du composés **9** sont orthorhombiques, $Pmnb$, avec a = 8,297(4), b = 15,269(3) et c = 12,638(2) Å, Z = 4 et R = 0,0796 et R_w = 0,0726 pour 1736 réflexions. On a mesuré les intensités avec des diffractomètres Syntex $P2_1$ ou Nicolet P3, à −65°C, utilisant le rayonnement Mo Kα. On discute de ces structures en fonction de la conjugaison et de la distribution de charge dans ces cations. Dans chaque cas, les cations sont pratiquement plans; ils ne présentent que des faibles angles de déformation entre le plan du substituant en C(2) et celui du cycle dioxolanylium. Le cation **8** est le premier exemple d'un ion carbénium diényle substitué et acyclique dont la structure soit rapportée. La chaîne insaturée à cinq atomes de carbone du composé **8** est dans la conformation complètement *trans* autour de toutes les liaisons C—C; toutefois, la distance C(2)—C(1′) mise à part, aucune des longueurs des autres liaisons ne diffère d'une façon marquée des longueurs que l'on retrouve normalement dans les composés neutres correspondants. La longueur de la liaison C(2)—C(1′) observée dans le composé **7** est considérablement plus courte que celle observée dans le composé **6**; ce résultat suggère la présence, dans la premier cation, d'une plus grande conjugaison du cycle aryle avec le centre positif. Cette suggestion est supportée expérimentalement par la distorsion importante de type quinonoïde qui est observée dans le cycle *p*-méthoxyphényle du composé **7**. On a examiné les variations systématiques observées dans les longueurs des liaisons O(1)—C(5)/O(3)—C(4) et on montre que la substitution par un groupe alkyle en positions C(4)/C(5) conduit à une forte augmentation de leurs longueurs suggérant qu'une fraction de charge importante se trouve en C(4) et (ou) en C(5). On retrouve un support expérimental pour cette suggestion dans une grande variété de mesures spectroscopiques ou calorimétriques rapportées antérieurement.

[Traduit par la rédaction]

Introduction

Dioxolan-2-ylium cations are an important subset of the widely encountered dialkoxy/hydroxy-substituted carbenium ions (1).[2] Their existence as transient species (called acetoxonium ions) was first proposed by Winstein and Buckles in 1942 to account for the rate enhancements and stereoselectivities associated with the solvolysis of 2-acetoxy-3-bromobutanes and 1-acetoxy-2-bromocyclohexanes (2). The involvement of dioxolanylium cations in the reactions of systems such as acetylated carbohydrates was rapidly recognized (3). The transition from reactive intermediate to

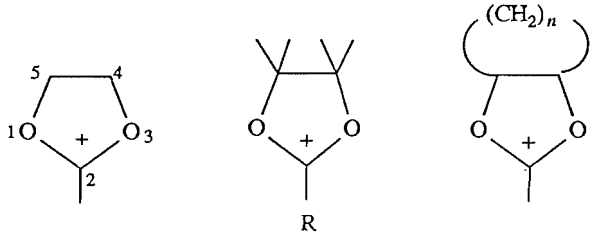
stable, characterizable carbocations was initiated in 1955 when Meerwein and colleagues first reported the isolation of a dioxolan-2-ylium salt (4). The ^{1}H NMR spectra of these ions were obtained by Winstein and co-workers in 1963 (5) and systematic NMR studies were reported by Hart and Tomalia in 1977 (6). Since this pioneering work, numerous studies of these cations have been reported and work still continues in order to understand the reactions and properties of these ions (7–10).[3]

Dioxolan-2-ylium cations are ambident and can undergo a variety of reactions with nucleophiles including addition to C(2) with the formation of cyclic products or addition to C(4)/C(5) with ring opening to form substituted esters (11). To understand these reactions it is important to know the structure of these cations and the way the structure varies as a function of substituent (12). The determination of the crystal structures of ions **1–5** has been reported (13–17) and the structure of the parent cation has been examined theoretically (18). In general, the five-membered ring of the dioxolan-2-ylium cation is planar, with relatively long O(3)—C(4)/O(1)—C(5) bonds. In the case of **3** and **4** the O(3)—C(4) bond distances are among the longest known C—O bonds (19).



1 **2** R = Me **3** R = C_6H_5 **4** n = 3 **5** n = 4

The value in examining the crystal structures of a series of closely related molecules is well established (20). In this present context the O(3)—C(4) bond distance and the relationship of this length to the S_N1 reaction profile discussed by Edwards, Jones, and Kirby is of considerable interest (21). Unfortunately, the errors associated with the limited number of reported structures of dioxolan-2-ylium cations makes examination of systematic trends in these ions difficult. For this reason we have determined the structures of a further group of these cations in which substitution at C(4), C(5), and C(2) is varied. This present work, in conjunction with the previous reports, clearly demonstrates that systematic structural changes occur in these dioxolan-2-ylium cations as the substitution pattern is changed.

Results

The cations chosen for study in this work were **6–9**. The first three of these represent systems in which the substituent on C(2) is changed while the rest of the ring remains constant. In the last case, **9**, methyl groups are added to C(4) while keeping C(2) constant. The purpose of placing substituents at C(4) while leaving C(5) unsubstituted was to provide, in one cation, examples of two differently substituted O—C single bonds.

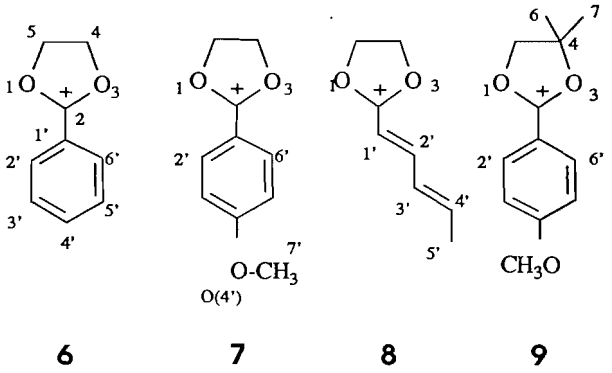
SCHEME 1



6 **7** **8** **9**

The cation **6** was prepared as its triflate salt by treatment of β-hydroxyethylbenzoate with triflic anhydride in CH_2Cl_2, Scheme 1. The procedure used to prepare **7** and **8** involved the treatment of β-bromoethyl or β-bromoisopropyl esters with $AgSbF_6$ in CH_2Cl_2, in a manner analogous to that used by Meerwein (4). After removal of the silver bromide, the cation salts were precipitated by the addition of anhydrous ether. In the case of **9**, the methallyl ester of *p*-methoxybenzoate was treated with HF/SbF_5 in CH_2Cl_2 (22, 23), Scheme 1. The salts were recrystallized from anhydrous CH_3CN/ether, **6–8**, or CH_2Cl_2/ether mixtures, **9**, to give single crystals suitable for X-ray diffraction. The cations were characterized by comparison of ^{1}H NMR spectra of solutions of the salts in CD_2Cl_2 with those previously reported (6). Cation **8**, a new material, had an NMR spectrum that was fully consistent with the assigned structure.

The structures of **6–9** were determined by X-ray diffraction. The crystals were mounted in Lindemann tubes in order to prevent contact with atmospheric moisture. Details of the structure solutions are given in Table 6, and the structures of the cations are shown in Figures 1–4. Atomic positional parameters are given in Tables 2–5. In the case of **7** the SbF_6^- group was disordered and two orientations of the counterion were assumed.

Discussion

The overall structures of **6–9** are similar to those previously reported for cations of this type (13–17). In each case

the 5-membered dioxolanylium rings are planar. The aryl rings in **6**, **7**, and **9** lie almost in the same plane as the atoms of the five-membered rings, being twisted from this plane by a small amount (see Table 7). The conformation of the aryl-substituted dioxolanylium cations found here supports one of the key structural assumptions made to account for the effect of a phenyl group on the hydrolysis of ortho esters (12, 24, 25). The anions have the expected structures, and bond lengths and angles are normal.

All intermolecular ion distances were equal to or greater than the sum of the van der Waals radii, except perhaps for the C(2)–anion distances. Each C(2) atom had an anion atom fairly close (O or F) on each side of the cation. Distances varied from 2.82 Å to 3.12 Å. While the shorter distances are less than the sum of the van der Waals radii for carbon and fluorine or oxygen (27), they may not be shorter than the distances involving C^+, for which we do not have a good van der Waals radius. Those atoms near C(2) are displaced away from C(1′) towards O(1) and (or) O(3), but not in a systematic manner. Ranges of angles are as follows: C(1′)—C(2)—X, 94.8°–107.9°; O(1)—C(2)—X, 79.5°–87.8°; O(3)—C(2)—X, 75.8°–99.6°. We do not think these distances and angles indicate any remarkable interactions, and are thus not important in the effects discussed hereafter.

The salt **8** is the first example of the structure determination of a cation with an acyclic polyenyl chain. As can be seen on inspection of Fig. 3, the dienyl chain in **8** exists in an *s-trans* conformation about both of the formal single bonds. The five carbon atoms of the chain lie in a plane, with the angle between this plane and that of the five-membered ring again being small (2.7°).

It is clear that the conformations adopted by all these cations are such that there can be effective conjugation between the substituent on C(2) and the charged system on the five-membered rings. Examination of the data given in Table 1 shows that this conjugation also results in relatively short C(2)—C(1′) bond distances in cations **6**–**9**. The average C(2)—C(1′) distance in the aryl-substituted cations **6**, **7**, and **9** is 1.42(1) Å, which is significantly less than the corresponding distance in aryl esters (1.487(12) Å) (difference 4.2σ where $\sigma = \sqrt{(\sigma_1^2 + \sigma_2^2)}$) (26). Previous analyses of the NMR spectra of these cations have shown that there is a transfer of charge onto the aryl rings of 2-substituted dioxolanylium cations (6, 7).

It is interesting that the C(2)—C(1′) bond distance in **7** is significantly shorter (difference 3.2σ) than the corresponding bond in **6**, suggesting that conjugation of the aryl ring with the cationic centre at C(2) is more important in the former ion. This is not unexpected given the presence of a methoxy group on C(4′) in **7** and the possibility of transfer of some of the charge to this function. Examination of the aryl-ring C—C bond distances in **7** (Table 1) is informative in that it is apparent that there is a considerable distortion of the C—C bond distances in the benzenoid ring. The C(2′)—C(3′) and C(5′)—C(6′) bond distances (mean 1.354(10) Å) are significantly shorter than the remainder of the aryl C—C bonds (mean 1.405(11) Å), indicating the presence of a "quinonoid" structure in the six-membered ring, Scheme 2. No significant differences are observed in the C(4′)—O(4′) bond lengths from those normally encountered with anisole derivatives (26). (In the case of **9** the errors associated with the structure determination make analysis of bond distances in the aryl rings difficult.) A quinonoid-type distortion of the C—C bond distances comparable to that found here in the aryl ring of **7** has recently been observed in other protonated *p*-methoxyphenylcarbonium ions (28). On the basis of INDO calculations and the NMR chemical shift correlations with σ observed by Hart and Tomalia (6), Pittman et al. (18) have suggested that this type of conjugative interaction of a

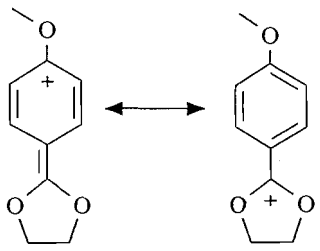

SCHEME 2

p-methoxyphenyl group with a dioxolanylium cation is relatively unimportant. The structural changes observed here would seem to be at odds with this suggestion.

It is instructive to examine the C—C bond distances in the pentadienyl fragment of **8** and compare them with what would be expected for an unsaturated ester, Scheme 3 (26). The only significant difference in distances between **8** and the corresponding neutral ester is for the C(2)—C(1′) bonds (difference 4.8σ). All of the other bond distances in the dienylic chain differ by less than 3σ from the corresponding bond lengths in the model. It is clear that there is a considerable degree of bond alternation in the unsaturated chain of **8** with a large fraction of the positive charge residing on the dioxolanylium ring. While the differences in individual bond distances in the unsaturated chain of **8** and the model are not significant, there does appear to be a consistent pattern to these differences that would suggest that the unsaturated chain in **8** is starting to exhibit changes in the various bond distances towards those expected for a simple pentadienyl cation. Thus the C(1′)—C(2′) formal double bond in the cation is longer than that of the model compound while both the C(2′)—C(3′) and C(4′)—C(5′) single-bond distances are shorter in the cation than those of the model. Comparison of the chemical shifts of the various protons of the pentadienyl chain as **8** is formed from its neutral precursor indicate that positive charge is being delocalized to some extent in this unsaturated substituent.

C—O bond distances

There are four C—O bonds in the five-membered ring of a dioxolan-2-ylium cation. In discussing the variations in the distances of these bonds it is useful to combine the results

[a]$U_{eq} = 1/3(U_{11} + U_{22} + U_{33} + 2U_{13} \cos \beta)$.

obtained here with the structures of **1**–**5** previously reported (13–17).

In all the dioxolan-2-ylium cations the O(1)—C(2) and O(3)—C(2) bonds are intermediate in length between those of C—O single and double bonds. The mean distance of these C—O bonds in cations **6**–**9** and **3** with an aryl or unsaturated substituent at C(2) is 1.291(2) Å.[4] Cations with an alkyl substituent at C(2) (**1**, **2**, **4**, and **5**) have significantly shorter O(1)—C(2)/O(3)—C(2) bonds (mean 1.261(5) Å, difference 5.2σ). The longer O(1)—C(2)/O(3)—C(2) mean bond distance in the aryl-substituted cations presumably reflects the delocalization of charge onto these unsaturated substituents with a resulting diminution of double-bond character in the C—O bonds, Scheme 2.[5] This structural difference in the alkyl- and aryl-substituted dioxolan-2-ylium ions is of interest in terms of the extensive discussion that has taken place over the relative stabilizing effects of methyl and phenyl substituents at C(2) in these cations (12, 22, 24, 25, 29, 30).

In contrast to the O(1)—C(2)/O(3)—C(2) bond lengths, the O(3)—C(4) and O(1)—C(5) distances in these dioxolan-2-ylium cations show no significant dependence on the nature of the substituent on C(2). Thus the lengths of these bonds in **6**, **7**, and **1**, where the C(2) substituent varies from phenyl, *p*-methoxyphenyl, to methyl, are not significantly different. The small chemical shift dependence observed for the C(4)/C(5) proton resonances as the C(2) substituent is varied is clearly not reflected in detectable changes in the lengths of the O(3)—C(4) and O(1)—C(5) bonds (6).

The O(3)—C(4) and O(1)—C(5) bond lengths in the dioxolan-2-ylium cations show a large dependence on the substituents on C(4)/C(5). The errors associated with the structure determination of cation **9** make it impossible to detect significant differences in the lengths of the individual O(3)—C(4) and O(1)—C(5) bonds in a single cation. The ions can be grouped according to the number of substituents at C(4) or C(5), however, and, when this is done, it is apparent that there is a consistent pattern to the various bond distances observed in these cations (see Table 8).

The O—CH_2 bond distances in these dioxolan-2-ylium

[4]The errors for mean bond lengths are given by $\sigma_D = \sqrt{\Sigma_n(D - d_n)^2/n(n-1)}$ where D is the mean bond distance of n independent variables.

[5]The relative order of the stabilizing ability of methyl and phenyl substituents on carbocations can change depending on the system in question, ref. 29. In the dioxolan-2-ylium cation the recent results of Kresge, Larsen, and co-workers establish that phenyl is a better charge-stabilizing group than methyl, ref. 30.

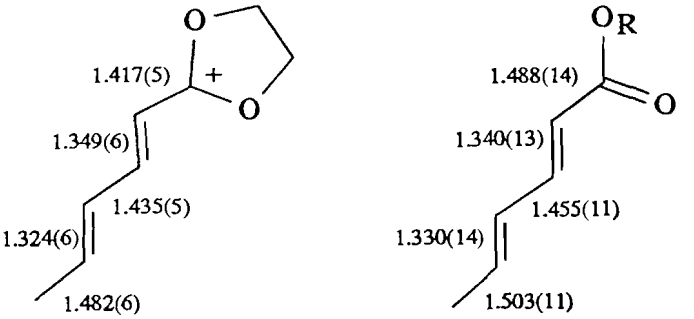
[a] $U_{eq} = 1/3(U_{11} + U_{22} + U_{33})$.

cations are remarkably uniform. Within the structures determined here and that of **1**, there are some 10 examples of O(3)—C(4)/O(1)—C(5) bonds where C(4) or C(5) is a CH_2 group. The mean O—CH_2 bond distance of this group of cations is 1.474(2) Å. Directly comparable distances have been found for the O—CH_2 bond in other cations such as the 6-ethoxytetrahydropyrylium ions (31).

As alkyl substituents are joined to C(4) and (or) C(5) the O(3)—C(4) and (or) O(1)—C(5) bond distances are lengthened substantially from the 1.474(2) Å observed for the O—CH_2 cases. A significant increase in the mean O(3)—C(4)/O(1)—C(5) bond distance is observed as first one, then two, alkyl substituents are joined to C(3) or C(4) (see Table 8).

The O—C(alkyl) bond distances in alkyl esters form a good reference point for the O(3)—C(4) and O(1)—C(5) bonds in these dioxolanylium cations, and the relevant data taken from the extensive analysis of the bonding in esters undertaken by Allen and Kirby (32) are shown in Table 8. Two points stand out on comparison of the data given in this table. In the first place all the O(3)—C(4) and O(1)—C(5) bond distances in these cations are significantly longer than the corresponding O—C bonds in esters or, indeed, 1,3-dioxolans (32).[6] Comparable long O—C bonds have been observed with 6-ethoxytetrahydropyrylium cations (31).[7]

The second important aspect is the differing sensitivity



SCHEME 3

towards substitution at the alkyl carbon of the dioxolanylium cations, as compared to neutral esters. The length of an O—C bond is expected to increase as the number of alkyl substituents at the carbon is increased. This is well demonstrated by the data for esters shown in Table 8. The notable feature of the changes in bond distance of these cations is, however, that the magnitude of the increase is very much larger than that of the esters.

In a previous paper on the tetrahydropyrylium cations we suggested the long O–alkyl bonds coupled with the changes in bond angles at the alkyl carbons could be accounted for by an ionic contribution to this bond with positive charge residing on the alkyl carbon atom (31). The results of this present study of the C—O bond distances in dioxolanylium cations fully support this suggestion. As the alkyl group bonded to oxygen becomes more highly substituted and better able to support a positive charge, the longer is the O—C bond distance, Scheme 4.

It is not customary to draw the third structure shown in Scheme 4 when considering the resonance structures of an alkoxy- or, for that matter, a hydroxy-substituted carbenium ion and it is worth reviewing other lines of evidence that support its involvement. There is good evidence that this third structure is an important resonance contributor and that a considerable fraction of the positive charge resides on the alkyl carbon of dioxolanylium and other alkoxy-substituted carbenium ions. In the first place, the calculations of Pittman et al. (18) and the detailed ^{13}C NMR and ESCA spectroscopic studies of Paulsen and Dammeyer (16) indicate the presence of positive charge at C(4) and C(5) in dioxolan-2-ylium cations. The calorimetric studies of Larsen et al. are particularly compelling (22, 24). It was shown by these workers that methyl substitution at C(2) of a 2*H*-3,4-dihydrofuranylium cation leads to a 3.1 kcal mol^{-1} stabilization of the cation.[8] Indeed, it was noted by these workers that the effect of methyl substitution at C(2), the alkyl carbon, is almost as large as that of placing a methyl group at C(2) of a dioxolan-2-ylium cation! Larsen et al. also found that the relative heats of protonation of ethyl esters are significantly more exothermic than those of the corresponding methyl esters (24). Both of these calorimetric examples show that substitution at the alkyl carbon atom of an alkoxy carbenium ion leads to a significant thermodynamic stabilization of the cation. Further support for the involvement of the third structure in Scheme 4 can be found from values of the substituent constants of alkoxy groups. For example, σ^+ values

[6] In the dimer of 1,3-dioxolan the average C—O distance is 1.41 Å, ref. 33.

[7] The bond angle of the dioxolan-2-ylium cations is less definitive than that of the tetrahydropyrylium salts, presumably as a result of the constraints imposed by the five-membered rings and eclipsed methyl groups at C(4) and C(5) in the former cations. Again, however, the trend in cations **2** and **3** is for a flattening of C(4) and C(5) as the O(3)—C(4) and O(1)—C(5) bonds are lengthened (13, 14). The complexity of bond angle changes accompanying the lengthening of a C—O bond of esters has previously been noted by Edwards, Jones, and Kirby (21).

[8] The C(2) position of a dihydrofuranylium cation corresponds to C(4) or C(5) in a dioxolan-2-ylium ion.

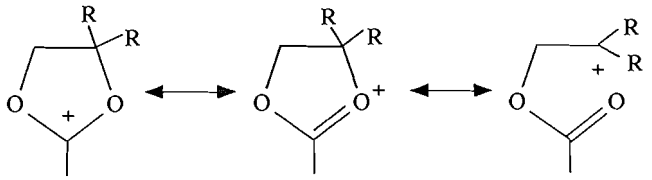
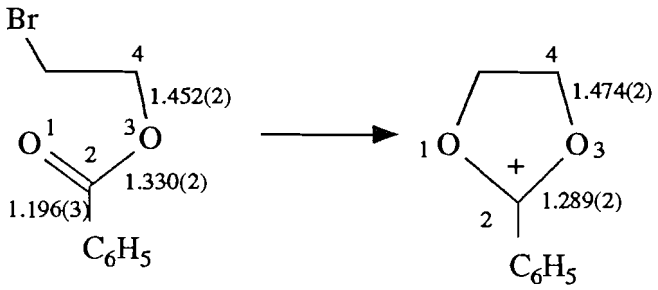


SCHEME 4



SCHEME 5

of alkoxy substituents become increasingly negative as the alkyl carbon becomes more substituted, indicating that the larger alkoxy groups are better able to stabilize a positive charge.[9] One also notes that the well-known facile cleavage of the O—C bond of *tert*-butyl esters and ethers under acid-catalyzed conditions is consistent with this picture of the charge distribution in alkoxy cations.

There is then a well-established and diverse body of evidence to indicate that a significant fraction of the positive charge resides on the alkyl carbon atom of an alkoxy-substituted carbenium ion. What this present work has done is show that the variations in spectroscopic, thermodynamic, and kinetic properties of these alkoxy cations can be related to systematic differences in their structures.

In conclusion, it is interesting to reflect on the relative importance of the first two resonance contributors shown in Scheme 4. One way of approaching this is to consider the O—C bond length changes that occur on the formation of a dioxolan-2-ylium cation, Scheme 5.

It can be seen from the data presented in Scheme 5 that the formation of the ring results not only in the elongation of the O(3)—C(4) bond discussed above, but also in a contraction of the O(3)—C(2) bond.[10] Thus the decrease in bond order of the O(3)—C(4) bond that results from this expansion is to some extent compensated for by an increase in that of the O(3)—C(2) bond. The question at issue is the degree of coupling of these changes and whether the sum of the bond valences of the two O(3)—C bonds remains close to 2, as in the starting ester, or is higher, indicating a significant involvement of the second resonance structure in Scheme 4. In principle this question could be examined by using the well-known bond distance/bond order relationship developed initially by Pauling (see ref. 35) or by seeking a correlation between the O(3)—C(2) and O(1)—C(2) bond distances on substitution at C(2) of this and related cations. The errors associated with some of these structures, however, do not permit these analyses to be carried out with any degree of confidence. When the structures of further series of alkoxy-substituted cations are determined it should be possible to address this question.

Experimental section

NMR spectra were obtained on Varian EM-390, and Bruker WM-250 and Bruker WM-500 spectrometers. All spectra were related to tetramethylsilane. Mass spectra were obtained on an VG-ZAB-E mass spectrometer operating at an ionization potential of 70 eV and a source temperature of 200°C.

Ether was freshly distilled from lithium aluminum hydride immediately before use. CH_2Cl_2 and CH_3CN were refluxed over phosphorus pentoxide and distilled under a nitrogen atmosphere. 2-Bromoethyl 4-methoxybenzoate, **11** (36), 2-bromopropyl 4-methoxybenzoate, **13** (37), and 2-methyl-2-propenyl 4-methoxybenzoate, **14** (38), were prepared by standard procedures. The structures of each of these materials were verified by NMR spectroscopy before use in the preparation of the cations.

2-Bromoethyl 2,4-pentadienoate, **14**, was prepared using the procedure of Rehberg (37). The properties of the ester are as follows: bp 78°C at 0.5 Torr (1 Torr = 133.3 Pa); ^{1}H NMR δ: 1.80 (3H, d, Me), 3.6 and 4.4 (each 2H, t, CH_2), 7.3 (6H, m, vinyl H); MS (*m/e*): M^+ obsd.: 217.9947; M^+ calcd.: 217.9942.

Preparation of cations

2-Phenyl-1,3-dioxolan-2-ylium trifluoromethanesulfonate, **6**, was prepared by reaction of **10** with triflic anhydride. The solid obtained was recrystallized from CH_3CN/ether mixtures at −15°C to give crystals suitable for X-ray diffraction studies.

2-(Methoxyphenyl)-1,3-dioxolan-2-ylium hexafluoroantimonate, 7, and 2-(2,4-pentadienyl)-1,3-dioxolan-2-ylium hexafluoroantimonate, **8**, were prepared from **11** and **12**, respectively, by use of the method of Meerwein (4). The products were recrystallized from CH_3CN/ether mixtures at −15°C to give crystalline samples suitable for X-ray diffraction studies. The ^{1}H NMR spectrum of **8** in CD_2Cl_2 consisted of peaks at δ 2.1 (3H, m, CH_3), 5.59 (4H, s, CH_2), 7.7–8.3 (4H, m, vinyl H).

2-(4-Methoxyphenyl)-4,4-dimethyl-1,3-dioxolan-2-ylium hexafluoroantimonate, **9**, was prepared by treating **14** (0.41 g) dissolved in CH_2Cl_2 (4 mL), contained in a Schlenck tube under N_2 and cooled to −78°C, with a cooled mixture of $HSbF_6$ (157 μL) in CH_2Cl_2 (2 mL). The tube and its contents were shaken vigorously and left at −78°C for 1.5 h. Dry ether (5 mL) was added to the solution, and the tube was tightly sealed and stored in a freezer at −15°C. Crystallization ensued to yield colourless rectangular prisms suitable for X-ray diffraction.

Structure determinations

All crystals studied were handled under a dry nitrogen atmosphere at all times. Crystals chosen for study were mounted in Lindemann glass capillary tubes. In all cases Buerger-type precession photographs were used to determine potential space groups and to establish approximate unit cell dimensions before the crystals were transferred to the diffractometer. X-ray studies were carried out on Syntex $P2_1$ or Nicolet automatic diffractometers equipped with low-temperature apparatus. All measurements were made at −65°C with graphite monochromated Mo Kα radiation (λ = 0.71069 Å). Unit cell parameters were determined from a least-squares fit of χ, φ, and θ for 15 reflections. Intensities were measured with θ–2θ scans, and were corrected for Lorentz-polarization effects. Standard reflections were measured every 100 reflections collected. Methods of intensity measurement and initial data treatment have been described previously (39, 40). Corrections were not made for absorption. This will make maximum errors in F_o of 0.6%, **6**; 7.5%, **7**; 12.8%, **8**; 11.6%, **9**. The structure of **6** was solved by direct methods and those of **7**, **8**, and **9** by the Patterson method. All other atoms were located from differ-

[9] σ^+ values of alkoxy groups are −OMe, −0.76; OEt, −0.81; OPr^i, −0.85; OH, −0.92, ref. 34. No value for OBu^t seems to be available.

[10] The bond distances of the ester are derived from the analysis of Allen and Kirby (19).

ence syntheses. Full-matrix least-squares calculations minimized $\Sigma w(|F_o| - |F_c|)^2$ and were terminated when Δ/σ_{max} was less than 0.1. In general non-hydrogen atoms were given anisotropic temperature factors, except for the disordered fluorine atoms in **7** and C(2′), O(4′), C(7′) in **9**, which went non-positive definite, if attempts were made to refine the atoms anisotropically. Although the standard reflections indicated that **9** was reasonably stable in the X-ray beam, the crystal was not particularly well formed. A refinement of the occupancies of the disordered fluorine positions in **7** (F(1), F(2), F(3), F(4), F(11), F(21), F(31), F(41)) showed that the values were close to 0.5, so the occupancies were fixed at this value. For **6** and **7**, hydrogen atoms were located and refined with isotropic temperature factors. For **8**, hydrogen atoms were refined for one cycle with isotropic temperature factors, when they were located, but were not refined further. Few hydrogen atoms could be located for **9** so they were placed in calculated positions and were not refined. For **6**, **7**, and **8**, the structures were refined with the use of SHELX (41) on a VAX 6800 computer and used reflections with $I > 0$. The structure of **9** was solved with use of SHELXTL PC (42) on a LASER 386 micro-computer and used all reflections. For this structure reflections with $3\sigma_I \geq I \geq -3\sigma_I$ were treated by the method of French and Wilson (43). Higher R values were observed for **7** and **9**. This was partly caused by crystal imperfection, but in the latter case a contributing factor was that all reflections were used for structure refinement. The major peaks and valleys in the final difference maps for **7**, **8**, and **9** were all near the Sb atom. Cell diagrams for **6**, **7**, and **8** were prepared with use of SNOOPI (44). Scattering factor curves were taken from the *International tables* (45) and anomalous dispersion corrections were made to the curves for O, F, S, and Sb (46). Details of data acquistion and structure refinement are given in Table 6. The atomic positional coordinates are given in Tables 2–5.[11]

The photocycloaddition of dibenzoylmethanatoboron difluoride ($DBMBF_2$) with conjugated enones and en-esters

YUAN L. CHOW,[1] SHI-SEN WANG, AND XIAN-EN CHENG

Received April 13, 1992

YUAN L. CHOW, SHI-SEN WANG, and XIAN-EN CHENG. Can. J. Chem. **71**, 846 (1993).

Dibenzoylmethanatoboron difluoride ($DBMBF_2$), the BF_2 complex of dibenzoylmethane, reacted from its singlet excited state with α,β-unsaturated ketones and esters to give 1,5-diketones by a [2+2] cycloaddition and ring-opening sequence in an analogous pathway to that observed in the photocycloaddition to olefins and dienes. The present photoreaction is unexpected since conjugated enones and en-esters are poor electron donors to comply with the previously proposed charge transfer requirement in $DBMBF_2$ photoreactions. The photocycloaddition to these substrates was highly regioselective and stereoselective, giving the head-to-head orientation, which could be enhanced by α-methyl substitution; β-methyl substitution increased the alternate head-to-tail orientation. The photolysis of a mixture of $DBMBF_2$ and a cyclic enone also caused the latter to dimerize to give head-to-head and head-to-tail dimers in significant yields. These photodimerizations were apparently caused by $DBMBF_2$ sensitization. The mechanism of the sensitization is discussed.

YUAN L. CHOW, SHI-SEN WANG et XIAN-EN CHENG. Can. J. Chem. **71**, 846 (1993).

Le difluorure de debenzoylméthanobore (BF_2DBM), le complexe du BF_3 avec le dibenzoylméthane, réagit avec les cétones et les esters α,β-insaturés par son état singulet et conduit à des 1,5-dicétones par une séquence d'une cycloaddition [2+2] et d'une ouverture de cycle semblable à celle observée lors de sa photocycloaddition sur des oléfines et des dienes. La photoréaction observée ici est inattendue puisque les énones et les esters conjugués sont des mauvais donneurs d'électrons qui ne peuvent que difficilement se plier aux exigences proposées antérieurement suggérant des transferts de charge pour les photoréactions impliquant le BF_2DBM. La photocycloaddition de ces substrats est hautement régiosélective et stéréosélective; elle conduit à une orientation tête-à-tête qui pourrait être améliorée par une substitution par un méthyle en α alors qu'une substitution par un méthyle en β augmente l'orientation tête-à-queue. La photolyse d'un mélange de BF_2DBM et d'une énone cyclique provoque une dimérisation de cette dernière conduisant à des dimères tête-à-tête et tête-à-queue avec des rendements significatifs. Ces photodimérisations sont apparemment causées par une sensibilisation par le BF_2DBM. On discute du mécanisme de sensibilisation.

[Traduit par la rédaction]

Introduction

A variety of β-diketones react readily from their enol form with BF_3 etherate to give the tetracoordinate boron difluoride complexes (1–10) that show greatly enhanced absorbance without noticeably shifting the maxima (7, 10, 11), and that also show reduction potentials lower by 0.2 volt than the parent β-diketones (2). Using dibenzoylmethanatoboron difluoride($DBMBF_2$) as a model compound, we have shown that it interacts with various olefins from the lowest singlet excited state through exciplexes possessing different extents of electron transfer (12–14). The interaction with electron-rich conjugated dienes approaches the diffusion-controlled rate (12) and generates olefin cation radicals that undergo the typical dimerization and rearrangement reported previously (14). On the other hand, those reactions with simple olefins are slower, leading to [2+2] cycloaddition to give **1**, and subsequent rearrangement–hydrolysis to 1,5-diketones **2** in high quantum yields as shown in Scheme 1 (13). Mechanistic studies on these photocycloadditions were also described recently (13).

While the role of electron transfer controlling the [2+2] photocycloaddition to olefins and dienes was being investigated, we discovered that $DBMBF_2$ also undergoes photocycloaddition with α,β-unsaturated ketones and esters. Since these conjugated carbonyl compounds are poor electron donors, the inevitable conclusion is that electron transfer probably exerts feeble control over the cycloaddition with enones. This observation suggests that the generally accepted concept of exciplexes based on charge (or electron) transfer (15, 16) is no longer adequate to explain the driving force of the [2+2] photocycloaddition of $DBMBF_2$. In anticipation of further mechanistic studies, we describe the preparative aspects of photocycloaddition to conjugated enones and enesters. As these reactions are analogous to the de Mayo reation (17) and comprise a broad spectrum of synthetically useful photolytic cyclobutane formations (18), and the quantum efficiency of the product formation ranges from good to excellent under defined conditions, they merit detailed studies. The synthetic utility of this reaction was considerably enhanced when it was discovered that the BF_2 complexes derived from alkyl β-diketones also undergo efficient photocycloadditions with benzene derivatives (14).

Results

The photocycloaddition of $DBMBF_2$ with en-esters **3***a*–**3***c* and enones **3***d*–**3***f* was carried out under similar conditions to those described for similar reactions with simple olefins (13). Generally, $DBMBF_2$ (0.05 M) and a substrate (0.5 M) in acetonitrile were irradiated in a Rayonet photoreactor equipped with RPR 3500 lamps. The progress of the photoreactions was monitored by GC and (or) TLC analysis showing the disappearance of $DBMBF_2$ and reaching the maximum of the product yield after 1 h for methyl methacrylate, after about 2 h for *trans*-3-penten-2-one, and after 4 h for vinylmethyl ketone. For acyclic substrates, the reactivity is in the decreasing order: methyl methacrylate (**3***b*) > mesityl oxide (**3***f*) > *trans*-3-penten-2-one (**3***e*) > vinylmethyl ketone (**3***d*) > ethyl acrylate (**3***a*) > ethyl crotonate (**3***c*). For facile visualization of the sequence of the photocycloaddition, the possible orientation and mode of ring

openings are shown in Scheme 2, which will be used for discussion later. The quantum yields were determined at [DBMBF$_2$] = 0.05 M and the concentration of substrates **3** at 0.5 M in acetonitrile (see Scheme 2). However, photolysis of dibenzoylmethane in the presence of one of these substrates failed to give the adducts.

The photolysis of DBMBF$_2$ in the presence of ethyl acrylate (**3***a*) and methyl methacrylate (**3***b*) gave one product in each case; **7***a* and **7***b* were isolated in excellent yields. These structures were shown to be **7**, which could be derived from the head-to-head (HH) adduct **4**, on the basis of the NMR coupling pattern of the methylene protons that exhibited magnetic non-equivalence of the geminate pairs. Compound **7***b*, which was isolated as a crystalline product, showed two groups of symmetrical multiplets at 2.48 and 2.98 ppm (2H each) that undoubtedly arose from the two adjacent groups of magnetically non-equivalent methylenes. It must be pointed out that if the product were **8***b*, the methylene protons should be a singlet. For **7***a*, the two corresponding methylene groups showed large geminal couplings owing to magnetic non-equivalence; even the CH_2 protons of the ethyl group are magnetically non-equivalent, showing two double quartets at 3.86 and 3.96 ppm. In addition, they show complimentary IR, ^{13}C NMR, and mass spectral data to support the proposed structures.

The photocycloaddition to ethyl *trans*-crotonate (**3***c*) gave a more complex product pattern than those shown above. It gave 16% of **8***c*, arising from alternative regioselective addition (head-to-tail, HT). The structural assignment was supported by appropriate spectral data in which neither methine proton was found below 4 ppm; i.e., none of them was connected directly to two neighboring carbonyl groups. Only one compound of **8***c* out of possible *threo* and *erythro* isomers was obtained, but its stereochemistry remained unknown. The major product was **7***c-erythro*; upon adsorption on silicic acid it slowly epimerized to give **7***c-threo*. By repeated preparative thin-layer chromatography both compounds could be isolated, but only as partially pure samples that were eventually used for spectroscopic examinations. The use of methyl *trans*-crotonate for photocycloaddition and similar chromatographic separation gave the corresponding *erythro* and *threo* samples. The NMR spectra of the dia-

For personal use only.

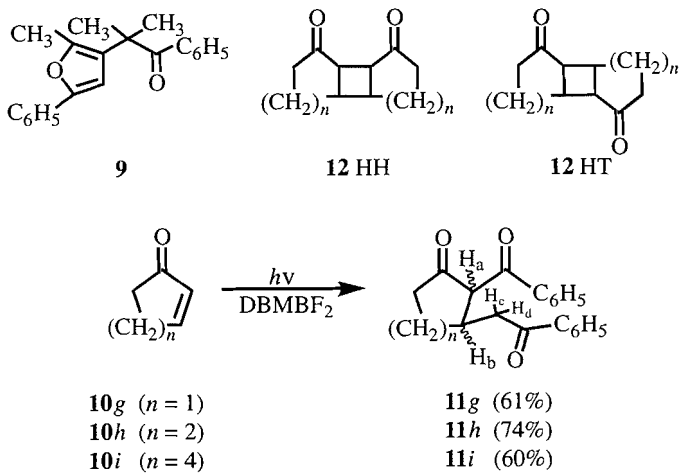
stereoisomers of **7***c* show double doublets for the methylene protons at point c and a typical doublet at about the 4.5 ppm region for the methine proton at point a activated by two carbonyl groups. In agreement, the latter hydrogen was slowly exchanged in several days in $CDCl_3$-D_2O (1 drop) solution in the presence of a trace of pyridine. No other hydrogen was exchanged under the conditions. These data confirmed the structure but did not differentiate the stereochemistry. The assignment of *erythro* and *threo* configurations was derived from mechanistic consideration as discussed later.

The photocycloadditions of $DBMBF_2$ with vinylmethyl ketone (**3***d*) and *trans*-3-penten-2-one (**3***e*) were terminated on the consumption of $DBMBF_2$ and gave good yields of head-to-head adducts **7** and **6** as mixtures. However, photolysis of **7***d* and **7***e* in acetonitrile under similar irradiation conditions caused extensive decomposition without yielding **6***d* or **6***e*, respectively; such retroactive formations could be possible via a type II cyclobutane formation and the alternative ring opening. Owing to difficulties in obtaining pure **3***e* free of **3***f*, the photocycloaddition to **3***e* was plagued with unwanted side products; a detailed investigation was not continued. The structure of **6***d* was readily decided by well-defined ^1H NMR spectra; the lack of chiral centers gave a straightforward triplet, double triplet, and doublet for the proton at the points a, b, and c, respectively. For **7***d*, due to the presence of the chiral center at carbon a, the geminal protons in two methylene groups were magnetically nonequivalent, showing a big geminal coupling. The ^1H NMR spectra of **6***e* and **7***e* were more complex than those of **6***d* and **7***d*, but the chemical shifts for the methine proton vicinal to the two carbonyl groups were 5.74 and 4.66 ppm (both doublets), respectively, and very close to those corresponding doublets shown by **6***d* and **7***d* (5.57 and 4.42 ppm). In addition, **7***e* slowly epimerized in storage to give the other diastereoisomer in a similar pattern to that observed for **7***c*.

The photocycloaddition of $DBMBF_2$ in CH_3CN under nitrogen to mesityl oxide **3***f* showed a high quantum efficiency (ϕ = 0.17) to give **7***f* (48%) and furan **9** (35%), in addition to a small amount of **8***f* (3%) after 2 h irradiation. Extended irradiation beyond this point caused a slow decrease of **7***f* (to about 40% after 5 h, obviously arising from photodecomposition), and complete disappearance of **8***f* to give only **9**; the latter transformation was catalysed by a trace amount of HF generated in the system, but not due to irradiation. Because of its good quantum efficiency this reaction was used as a model to show the reaction profile. The photoreaction in CH_3CN under N_2 is shown in Fig. 1; under air, the formation rates slowed and caused slightly lower yields, but the general reaction pattern was not changed. In benzene and CH_2Cl_2 the photoreaction was faster, to reach the maximum amounts of **7***f* (31–35%) after 1.2–1.5 h irradiation; this decreased to 25% after 5 h; furan **9** gradually increased to 40–45% yields after 5 h irradiation. In tetrahydrofuran, the cyclization of **8***f* to **9** was slow, resulting in yields of 25 and 13%, respectively, in addition to 21% of **7***f* after irradiation for 5 h.

The furan **9** was readily identified from ^{13}C NMR spectra showing only one carbonyl carbon at 203.1 ppm and two α-carbons for a furan ring at 151.4 and 147.1 ppm (19). The IR absorption at 1673 cm^{-1} and the lack of alkyl hydrogens in ^1H NMR (except methyl singlets) support the furan structure derived from **8***f*. The structure of **8***f* was confirmed by the clearly defined ABX system in the ^1H NMR spectrum (see Table 1) and supported by pertinent IR and ^{13}C NMR data to show the presence of three carbonyl groups. An acid-catalysed cyclization of **8***f* to form furan **9** could be easily envisioned. The structure of **7***f* was readily concluded by an AB quartet and one hydrogen singlet (at 5.74 ppm) in the ^1H NMR spectrum in addition to the IR and ^{13}C NMR spectra. Although the chemical shift of the one-proton singlet is relatively deshielded, the compound is not **6***f* because of magnetic non-equivalence of the two *geminal* dimethyl groups, and also because of the mass spectral fragmentation patterns (see below). In some cases when the photoreaction was run in CH_3CN, an additional small GC peak (triketone **6***f*) was observed in a chromatographic fraction; the GC–MS of this extra peak showed the compound to possess, by either EI or CI modes, a strong fragment *m/e* 224 common to **6***d*, **6***e*, and **6***f*. This peak must arise from a McLafferty rearrangement in all compounds **6** to give a dibenzoylmethane cation radical, which was not present and could not be formed from any of the compounds **7** or **8**.

The photocycloaddition of $DBMBF_2$ to cyclic enones **10** in CH_3CN solution was relatively fast with 2-cyclooctenone (**10***i*), but became more inefficient with 2-cyclohexenone (**10***h*) and 2-cyclopentenone (**10***g*), in that order. The reactions afforded the dimers **12** as well as the cycloadducts **11** of these cyclic enones as shown by GC–MS analysis of the crude products. Under comparable conditions of



10*g* (*n* = 1) **11***g* (61%)
10*h* (*n* = 2) **11***h* (74%)
10*i* (*n* = 4) **11***i* (60%)

[$DBMBF_2$] = 0.05 M and [enone] = 0.5 M in CH_3CN, the mole ratio of dimers **12** to adducts **11** were 1:4 for **10***g*, 29:71 for **10***h*, and 74:26 for **10***i*. For each cyclic enone, the dimers were mixtures of four possible isomers, showing two major peaks in GC analysis; for the case **10***h*, two additional minor peaks close to the major ones were also detected. The dimers from **10***g* and **10***h* were also prepared by direct photolysis to give these major peaks (20, 21); one peak represented the head-to-tail cycloadduct and the other the head-to-head cycloadduct. The ratios of (head-to-head):(head-to-tail) from $DBMBF_2$ sensitization and direct photolysis were not significantly different; 66:34 against 63:37 for cyclohexenone (**10***h*), and 46:54 against 41:59 for cyclopentenone (**10***g*). However, direct irradiation of 2-cyclooctenone (**10***i*) in CH_3CN under comparable conditions gave an intractable complex mixture in which the reported (22) dimers were swamped by other products. As expected, the rates of dimer formation compared to those of cycload-

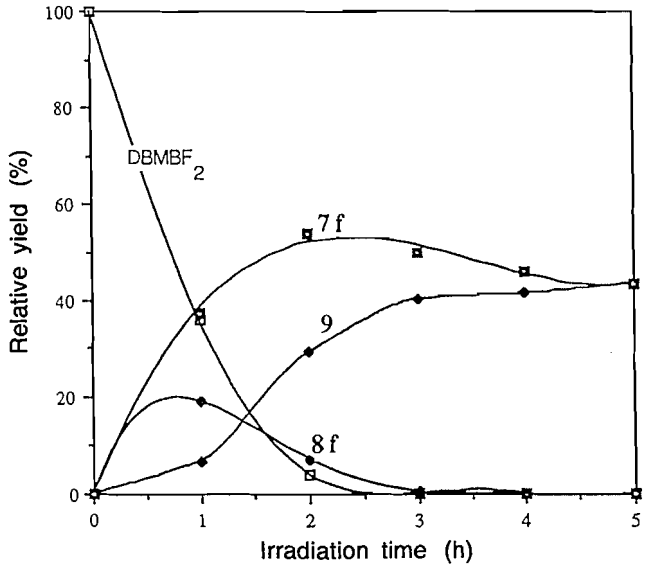


FIG. 1. The formation profile of the photoaddition of $DBMBF_2$ (0.05 M) with mesityl oxide (0.5 M) in CH_3CN; the yields were calculated against the internal standard.

ducts **11** rapidly increased with higher concentrations of cyclic enones **10** at a fixed concentration of [$DBMBF_2$]; for example, the percentage of **12** increased from 26 to 75% (of consumed **10***h*) when cyclohexenone **10***h* changed from 0.5 M to 3.0 M at [$DBMBF_2$] = 0.03 M.

In the photoreactions, only one cycloadduct was formed and isomerized to the other during isolation. The primary cycloadduct was the *cis* isomer of **11**, which was isomerized to *trans*-**11** during photolysis and isolation. In the $DBMBF_2$ photocycloaddition to 2-cyclohexenone **10***h*, GC and TLC analysis showed the formation of *cis*-**11***h*, which isomerized only slowly to form a trace of *trans*-**11***h*. The isomerization was rapid under alkaline conditions on addition of $NaHCO_3$ solution; the process afforded *trans*-**11***h*, which showed H_a at 4.51 ppm with J_{ab} = 9.2 Hz supporting the *trans* configuration. The remaining *cis*-**11***h* was isolated as a mixture, and showed the corresponding H_a chemical shift at 4.86 ppm with J_{ab} = 4.9 Hz. In the photocycloaddition to 2-cyclopentenone, the primary adduct isomerized more rapidly during photolysis, which showed slightly acidic conditions. As the photoreaction was slow, isomerized secondary product accumulated to be isolated as the major product, which showed H_a at 4.21 ppm with J_{ab}=10.0 Hz; this was assigned as *trans*-**11***g*. A small amount of the primary product (*cis*-**11***g*) was isolated as a mixture to give the chemical shift of H_a at 4.76 (d) with J_{ab} = 7.7 Hz. The coupling constants of the *cis*-**11***g* stereoisomer were very close to that of *cis*-1-benzoyl-2-phenacylcyclopentane (6.8 Hz) (14). On the other hand, J_{ab} of *trans*-**11***g* was close to that calculated for the corresponding *trans* isomer (11.9 Hz)(14). These agreements serve to support the stereochemical assignment for the two products.

The photocycloaddition of $DBMBF_2$ to 2-cyclooctenone was relatively fast, yielding, in addition to dimers **12***i*, only *cis*-**11***i*, but showed a trace of *trans*-**11***i* in the TLC analysis at the end of reaction (4 h). The addition of aqueous $NaHCO_3$ solution and work-up caused partial isomerization to *trans*-**11***i*. Both isomers were isolated by preparative TLC to give samples each contaminated by the other. In $CDCl_3$ solution, *cis*-**11***i* slowly transformed to *trans*-**11***i*, which showed H_a at 4.88 ppm (d) with J_{ab} = 11.0 Hz; the corresponding parameters for *cis*-**11***i* were H_a at 4.93 ppm (d) with J_{ab} = 3.6 Hz. The *J* values not only were close to the observed *J* value of 4.2 Hz for *trans*-1-benzoyl-2-phenacylcyclooctane, but also agreed well with the calculated values for the corresponding *cis* and *trans* isomers at 11.8 and 5.5 Hz respectively (14). In addition, all of these cycloadducts **11** exhibited the complementary IR and ^{13}C NMR data to show the presence of three carbonyl groups, and ^1H NMR signals of two double doublets for the magnetically nonequivalent geminal methylene group in the phenacyl moiety. It should be added that the chemical shifts of H_a were <5.00 ppm; this, combined with the observation of double doublets assigned to the methylene group of the phenacyl moiety, provided evidence to eliminate the structures corresponding to **6** and **8** for these cycloadducts.

Discussion

The product pattern of the $DBMBF_2$ photoadditions to α,β-unsaturated carbonyl compounds follows the basic pattern observed for similar photoadditions to simple olefins (14), but exhibits more complexity with respect to regioselectivity and side reactions owing to the presence of a carbonyl group. This is shown in the formation of compounds **8***c* and **8***f* arising from head-to-tail cycloadduct **5**, and the formation of **6***d*, **6***e*, and **6***f* arising from a side reaction. The photocycloaddition to cyclic enones is regioselective and stereoselective to give only one adduct, the *cis* adduct of **11**, which isomerizes through facile enolization to give the *trans* adduct of **11**. Though the proofs of the *cis–trans* configuration in **11***g* and **11***i* are not unequivocal, the pattern of the formation leaves no doubt that one compound is stereospecifically formed; in view of the fact that the cyclobutane intermediate **4** imposes a steric constraint, it is most likely that *cis* adducts of **11** are formed. In the case of the cycloaddition to 2-cyclohexenone, GC and TLC analysis at various intervals coupled with ^1H NMR analysis of stereochemistry confirm this sequence. As this reaction sequence is also followed in the cycloaddition to other cyclic olefins (14), the conclusion of a highly stereoselective $DBMBF_2$ cycloaddition is established. The allied cycloaddition to acyclic compounds **3** must be equally stereoselective. Although the *erythro* and *threo* configuration of **7***c* have not been experimentally proven, the pattern of the formation of the single product and the subsequent isomerization agree with the mechanistic conclusion. The primary cycloadduct from *trans*-crotonates must be an enantiomeric pair of (*RS–SR*) configuration, that is, **7***c-erythro*, which is isomerized to the *RR–SS* pair (**7***c-threo*). Owing to the slow but spontaneous epimerization at the doubly activated carbon centers in **6** and **7**, these products could not be obtained in a pure state; some elemental analyses have been carried out with mixtures of diastereoisomers.

The regioselectivity in the $DBMBF_2$ cycloaddition is clean with cyclic enones and is shown as head-to-head in our description. This regioselectivity also prevails with **3***a*, **3***b*, and **3***d* but starts to decline in the presence of a β-methyl substituent, as in **3***c*. With two β-methyl substituents, **3***f* gives substantial amounts of **8***f* in the final form of **9**; **8***e* is assumed to be formed from **3***e*, but this could not be substantiated due to experimental difficulties. It is clear that an α-methyl substitution enhances the head-to-head regiose-

[a]These spectra were taken in C_6D_6, but others were in $CDCl_3$.
[b]The sample was a mixture containing other isomers (diastereoisomers).
[c]This sample contains the ratio **7***c-erythro*:**7***c-threo* of 3:1 as calculated on the NMR signal of H_a.
[d]These samples contain *cis*-isomer (9–10%) as calculated on the NMR signal of H_a: its NMR parameters are *cis*-**11***g* doublet at 4.75 ppm, J_{ab} = 7.7 Hz, and *cis*-**11***h* doublet at 4.86 ppm, J_{ab} = 4.9 Hz.
[e]This sample contains a trace amount (<5%) of *cis*-**11***i*.
[f]This sample contains about 25% of *trans*-**11***i*.

lectivity **4**, while a β-methyl substitution does the opposite, facilitating the formation of **5**. At this stage the overall picture is too complex to rationalize the effects of a polar carbonyl group and a substituent toward the orientation. The answer appears to be hidden in the nature (polarity and (or) orbital interactions) of the exciplex formed from singlet excited $DBMBF_2$; this should be the direction of future efforts. The isolation of small amounts of **6** in the photocycloaddition to enones **3***d*–**3***f*, but not to en-esters **3***a*–**3***c*, must mean that the intermediate **4** (head-to-head adduct), can ring-open in the alternative mode to give **6***d*–**6***f* even if the BF_2 group still maintains the binding to the original benzoyl oxygen. This indicates that a carbonyl group is a better electron sink than an ester group.

During photoreaction, the formation of cyclic enone dimers **12** is unexpected and must mean sensitization of enones **10** through excitation transfer to generate *a reactive state*. Although enone **10***h* at 0.5 M also can dimerize under the photolytic conditions (20, 21), $DBMBF_2$ possesses a high molar extinction coeficient (ϵ = 40 000) and absorbs >99% of the light intensity at 350 nm at the concentrations used in the photoreactions. In view of the fact that the dimerization of **10***h* could be caused by triplet sensitization (naphthalene triplet, E_T = 61 kcal/mol), to give about the same HH:HT ratio (21) as that obtained in the $DBMBF_2$ photolysis, there is no doubt that the same reactive state of **10***h* has been obtained by sensitization. The $DBMBF_2$ triplet energy has been determined to be 62 kcal/mol (11). There is a train of critical studies reported from various groups claiming that these enones have different reactive states for various photoreactions (22–27). For **10***i*, it is most likely that ground state *trans*-2-cyclooctenone is generated from $DBMBF_2$ sensitization and undergoes dimerization in analogy to the results from direct excitation (22), though direct photolysis in CH_3CN gave a complex mixture in our hands without giving a clean dimer mixtures of **12***i* as obtained by $DBMBF_2$

[a]The same samples as cited in Table 1 were used for measurement.
[b]These spectra were taken in C_6D_6, but others in $CDCl_3$.
[c]One signal was buried in the solvent peaks.

sensitization. It is speculated that *trans*-2-cyclooctenone, being a twisted ground state molecule (22), has a long lifetime, and can be photolysed to give other products. For **10***h* and 4,4-dimethyl-2-cyclohexenone, a twisted (or relaxed) state, either on the ground (26) or an excited state energy surface (25), has been suggested to undergo dimerization, cycloaddition, and rearrangement (23–27). It is reported that 2-cyclopentenone undergoes photodimerization from some kind of triplet state as concluded from laser photolysis (24). Since **10***g* does not twist easily, its spectroscopic triplet state has a relatively long lifetime (24, 25), but it is doubtful that this is the reactive state. Our results show that these reactive states of cyclic enones can be reached by $DBMBF_2$ sensitization.

As the lowest spectroscopic singlet and triplet states of **10***g* and **10***h* are 80–83 and 74(π,π^*) kcal/mol (20), respectively, sensitization to these states by $DBMBF_2$ is not likely. If a sensitization to a non-spectroscopic triplet state (with $E_T < 62$ kcal/mol) is accepted, a number of mechanistic possibilities can be considered. First of all, the concept of a non-vertical energy transfer (21) can be invoked to account for these $DBMBF_2$ sensitizations, though this explanation is close to an exercise in frustration as many factors remain unknown. Secondly, Hammond's group (21) has reported that at higher concentrations of **10***h* (>0.01 M) the absorption spectra do not follow Beer's law, but show the molar extinction coefficient rising at about 0.01–0.1 M. We have observed that at [**10***h*] up to 0.5 M, the absorption can be red-shifted to show the cutoff of absorption at 380 nm. The absorption at these high wavelengths may be attributed to aggregates that undoubtedly can be sensitized to the excimer (of **10***h*) whose triplet energy must be lower than that of **10***h*; about 62 kcal/mol may be regarded as a reasonable triplet energy of the excimer that can transform to the dimer. The lack of phosphorescence from these cyclic enones prevents us from confirming this idea. However, the presence of molecular aggregate in the ground state of **10***h* has been shown to be questionable when the absorption spectra at 0.01–0.3 M were examined with 1-cm and 0.1-cm UV cells.[2] The absorbance follows Beer's law. The result reported by Hammond's group may have been caused by either a wide slit opening or stray light in their spectrophotometer.[2]

Thirdly, we may assume a kind of exciplex formation be-

tween enone **10** and singlet excited state $DBMBF_2$ through a combined driving force of charge transfer and exciton resonance.[2] Such a singlet state exciplex may be transformed to a triplet state exciplex and finally dissociated to a *relaxed* triplet state of **10** and $DBMBF_2$. This idea may be regarded as an elaboration of the first non-vertical energy transfer. Whatever the explanation, it is in general agreement with the higher yield ratio of dimers **12** to cycloadducts **11** at higher concentrations of enones **10**; i.e., cycloadduct **11***h* is formed in much higher percentages at lower concentrations of **10***h*. Such a photodimerization is characteristic of a cyclic enone and has never been reported from acyclic α,β-unsaturated carbonyls **3***a*–**3***f*, which fact may also support the concept of strained twisted enone precursors (22); such precursors from **3***a*–**3***f* would be rapidly nullified by the rotation of the carbonyl group around the α C—CO bond. This study has clarified the product patterns and stereoselectivity of the photocycloaddition to α,β-unsaturated carbonyl compounds. We intend to investigate the reaction mechanism in the future.

Experimental section

Material and general conditions

Commercially available enones and en-esters were purified and their IR and NMR spectra were compared with the reported spectra for authenticity. The samples were distilled before use. 2-Cyclooctenone was prepared from cyclooctanone by the published procedure (28). $DBMBF_2$ (mp 192–194°C) was prepared in the previous experiment (13, 14). Other experimental conditions, analytical procedures, and instrumentations were the same as those reported in refs. 13 and 14.

Photocycloaddition to acyclic α,β-unsaturated carbonyl compounds

A CH_3CN solution (15 mL) containing $DBMBF_2$ (0.75 mmol, 0.05 M) and a freshly distilled enone (7.5 mmol, 0.5 M) was distributed in three Pyrex tubes (100 mm × 13 mm), and was purged using N_2. These tubes were irradiated with RPR 3500 Å lamps. The photolysate was analysed by GC and (or) TLC to show the formation of the products and the consumption of $DBMBF_2$. The photolysis was stopped after the disappearance of $DBMBF_2$. To the photolysate, a calculated amount of n-$C_{20}H_{42}$ (Internal standard) was added for GC analysis.

For work-up of the photolysate, ether (20 mL) was added and the total solution was washed with aqueous $NaHCO_3$ (10%) solution three times. The crude product was chromatographed on a silica gel column using hexane–CH_3CO_2Et eluent; this afforded fractions containing various proportions of products. Column chromatography or preparative thin-layer chromatography can be repeated with certain fractions to afford analytical samples. The spectral data of the products are given in Tables 1–4 and the elemental anlysis data in Table 5.
