The adduct **7***a* was obtained as an oil from column chromatography, and was distilled. The adduct **7***b* was recrystallized from ethyl acetate – hexane to afford white crystals, mp 113.5–113.8°C. The percentage yields of the products from **3***a*, **3***b*, **3***d*, and **3***e* were those isolated, and others were from GC determinations.

To trans*-ethyl crotonate (***3***c)*

During photoaddition, TLC analysis on silica plates (Merck Kieselgel, 60 F254) showed two spots at R_f 0.13 and 0.082 (hex-

[a]These compounds were obtained as pure samples as shown by GC, others were mixtures as indicated in the footnotes to Table 1.

[b]Crystals were obtained from the recrystallization of ethyl acetate – hexane (1:8), mp 113.5–113.8°C.

ane:Et_2O = 6:1). During chromatography a new spot was developed at R_f 0.11 at the cost of the R_f 0.13 spot. Repeated column chromatography gave an analytical sample with the ratio of R_f 0.13:R_f 0.11 of 3:1, and another with R_f 0.11 as the major portion.

Photocycloaddition to cyclic enones

CH_3CN solutions containing $DBMBF_2$ (0.5 M) and a cyclic enone (0.1–0.07 M) were distributed in several tubes and photolysed similarly under N_2. During photolysis, GC analysis showed the formation of only one product from **10***h* and **10***i*, but the initial product from **10***g* isomerized to the second one in slow photolysis. When $DBMBF_2$ was consumed the photolysate was diluted with ether and washed with aqueous $NaHCO_3$ solution (10%). The crude product showed, by TLC analysis, that the secondary products increased considerably during $NaHCO_3$ solution washing, as well as in the subsequent column chromatography. Column chromatography of the crude products from **10***g* and **10***h* gave only the secondary product as the major product; the original product became the minor product.

The crude product from **10***i* showed two TLC spots with hexane:CH_3CO_2Et 5:1 at R_f 0.25 and R_f 0.31 for *cis*-**11***i* (the original compound formed) and *trans*-**11***i* (isomerized); the R_f 0.31 spot was faint at the end of the photolysis but became stronger after $NaHCO_3$ washings and kept growing during chromatography. This was treated with preparative thin-layer chromatography (Merck Kieselgel 60) to give a sample containing the ratio of *trans*-**11***i*:*cis*-**11***i* = 89:11; and another with a ratio of 25:75. In $CDCl_3$ solution the former sample changed to a ratio of *trans*-**11***i*:*cis*-**11***i* ≥ 95:5 in a few weeks and the latter sample to a ratio of 49:51.

Similarly, TLC analysis of photolysate 2-cyclohexenone (**10***h*) gave a strong spot at R_f 0.17 (for *cis*-**11***h*), but a barely noticeable one at R_f 0.13 (for *trans*-**11***h* with hexane:CH_2Cl_2:Et_2O = 3:0.8:0.2). After washing with aqueous $NaHCO_3$ solution, the TLC picture was completely reversed, giving a strong R_f 0.13 spot, with a weak R_f 0.17 spot. Column chromatography gave samples of *trans*-**11***h* contaminated with 5–10% of *cis*-**11***h*.

This study is focussed on 2′-*O*-methyl-*cis*-adenosine 3′,5′-cyclic methyl monophosphate (*cis*-**4**; *cis* describes the relationship between OMe (bound to phosphorus) and the adenine base), which is regarded a model for enzyme-bound cyclic adenosine monophosphate (cAMP). In this complex the negative phosphate charge is shielded in part via complexation with cationic sites on the enzyme surface. We report synthesis, crystal structure, solution conformation (400 MHz ^{1}H NMR), and kinetic-mechanistic aspects of the alkaline hydrolysis of *cis*-**4**. The methanol solvate of *cis*-**4** crystallizes in the orthorhombic space group $P2_12_12_1$ and the cell dimensions are a = 8.170(2) Å, b = 9.249(1) Å, c = 23.699(4) Å; V = 1788.5(6) Å^3; Z = 4 molecules per cell. Least-squares refinement converged at R = 0.062 for 2006 observed reflections. The adenine bases are linked via N6—H···N1 and N6—H···N7 hydrogen bonds in such a way that infinite one-dimensional chains are formed. This hydrogen bond scheme is very similar to that observed in the structure of 2′-deoxy-3′,5′-di-*O*-acetyl adenosine. An additional hydrogen bond is formed between methanol, incorporated in the crystal structure, and the adenine base. The conformational preferences of the *cis*-**4** dissolved in methanol have been determined with 400 MHz ^{1}H NMR. It is found that the conformations observed in the solid and solution states are practically the same. Hydrolysis of the title compound yields two acyclic phosphate diesters (a 3′- and a 5′-phosphate diester). The intermediates formed during the hydrolysis reaction are most likely five-coordinated phosphorus (P^V) compounds with a trigonal bipyramidal geometry and an equatorial-axial located 3′,5′-dioxaphosphorinane ring.

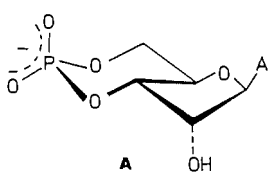
NIEK L.H.L. BROEDERS, ARTHUR P. VAN DER HEIDEN, LEO H. KOOLE, JAN A. KANTERS et ARIE SCHOUTEN. Can. J. Chem. **71**, 855 (1993).

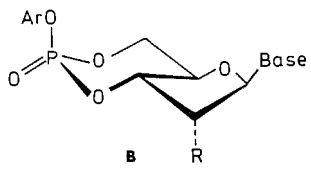
La présente étude est orientée vers le monophosphate cyclique-3′,5′ de méthyle de la 2′-*O*-méthyl-*cis*-adénosine (*cis*-**4**; *cis* se réfère à la relation entre le OMe (lié au phosphore) et la base adénine) qui est considéré comme un modèle pour le monophosphate cyclique de l'adénosine liée à un enzyme (cAMP). Dans ce complexe, la charge négative du phosphate est masquée en partie par une complexation avec les sites cationiques sur la surface de l'enzyme. On rapporte la synthèse et des études sur la détermination de la structure, de la conformation en solution (400 MHz, RMN du ^{1}H) et des aspects cinétique-mécanisme de l'hydrolyse alcaline du produit *cis*-**4**. La produit de solvatation de *cis*-**4** avec du méthanol cristallise dans le groupe d'espace orthorhombique $P2_12_12_1$ avec a = 8,170(2), b = 9,249(1) et c = 23,669(4) Å, V = 1788,5(6) Å^3, Z = 4 molécules par maille élémentaire. La structure a été affinée par la méthode des moindres carrés jusqu'à une valeur finale de R = 0,062 pour 2006 réflexions observées. Les bases adénines sont liées par des liaisons hydrogénes N6—H···N1 et N6—H···N7 d'une façon telle qu'il y a formation de chaînes unidimensionnelles infinies. Cette arrangement par liaisons hydrogènes est très semblable à celui observé dans la structure de la 2'-désoxy-3′,5′-di-*O*-acétyl adénosine. Une liaison hydrogène additionnelle se forme avec le méthanol, incorporé dans la structure cristalline, et la base adénine. Faisant appel à la RMN du ^{1}H, à 400 MHz, on a déterminé les préférences conformationnelles du produit *cis*-**4** en solution dans le méthanol. On a trouvé que les conformations observées en phase solide et en solution sont les mêmes. L'hydrolyse du composé mentionné dans le titre fournit deux esters acycliques de l'acide phosphorique (un diester 3′- et un diester 5′-phosphate). Ces intermédiaires qui se forment durant la réaction d'hydrolyse sont probablement des composés pentacoordinés du phosphore (P^V) de géométrie bipyramidale trigonale et comportant un cycle dioxaphosphorinane attaché aux positions équatoriale/axiale-3′,5′.

[Traduit par la rédaction]

Introduction

Adenosine 3′,5′-cyclic monophosphate (cAMP; **A**) plays an important regulatory role in both eukaryotic and prokaryotic cells (1, 2). In eukaryotic cells the major receptor for cAMP is the regulatory subunit of cAMP-dependent protein kinase (3). Binding of cAMP to the regulatory subunit releases the catalytic subunit that is responsible for the phosphorylation leading to activation of certain key metabolic enzymes (4). In prokaryotic cells the catabolite gene





activator protein (CAP) senses the level of cAMP and regulates transcription from several operons in the presence of cAMP (5, 6). The enzymatic, hydrolytic ring-opening con-

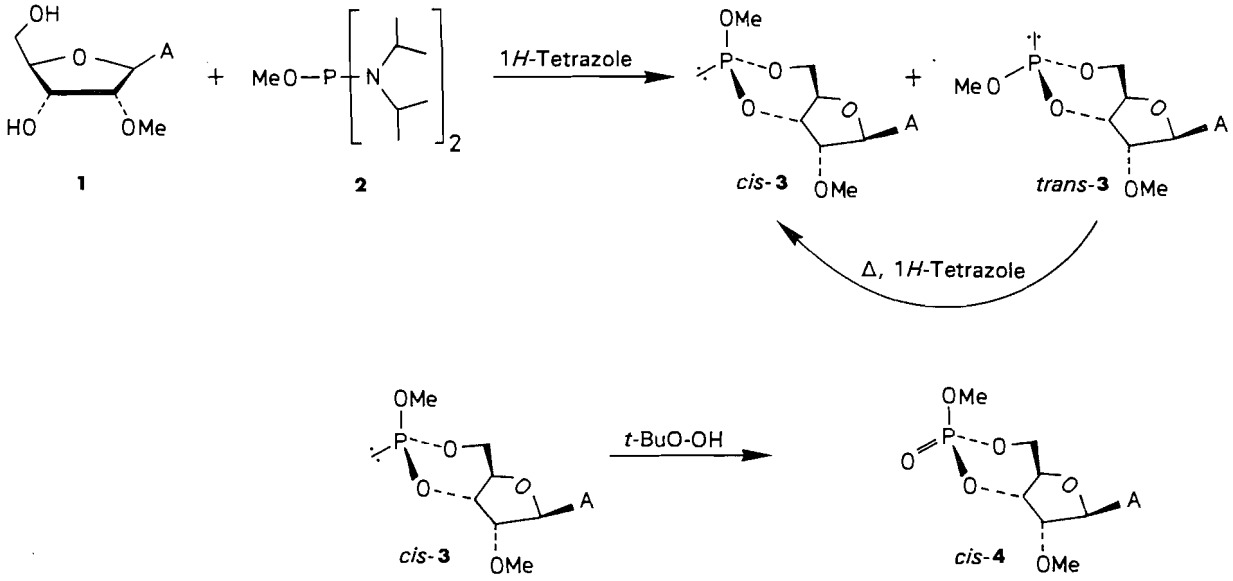

SCHEME 1

version of cAMP to 5′-adenosine monophosphate (5′-AMP) is accomplished by specific phosphodiesterases (7). A detailed understanding of the binding of cAMP to the active site of the enzyme is essential to understand the interaction of cAMP with protein kinases (in prokaryotic cells: CAP) or phosphodiesterases. X-ray studies of the cAMP binding domain of the crystal structure of the bacterial CAP dimer revealed that the interaction between cAMP and CAP is mainly based on ionic interactions and hydrogen bonds (8–10). Due to these ionic interactions the negative charge on the phosphoryl oxygen anions will be shielded. Because of the absence of negative charge, nucleophiles can attack phosphorus more readily. This means that the phosphorus atom has become more electrophilic due to the shielding of the negative charge.

Our interest is primarily focussed on the role of 3′,5′-linked phosphodiester in the mechanism of action of cAMP. Most likely a five-coordinated phosphorus (P^V) species is involved, either as an intermediate or as a transition state, in both the hydrolysis of cAMP to 5′AMP and the activation of protein kinases by cAMP (11). These ideas have prompted several groups, including ours, to investigate model systems for the proposed activated state of cAMP (12–16). Essentially, these models incorporate a stabilized five-coordinated phosphorus atom that is part of a 3′,5′-dioxaphosphorinane ring, which is *trans*-annelated with the ribose ring. These investigations support the idea that the 3′,5′-dioxaphosphorinane ring has access to both an equatorial–axial (e,a) *and* a diequatorial (e,e) orientation with respect to the trigonal bipyramidal (TBP) structure of the five-coordinated phosphorus. As an alternative approach, we have recently studied the alkaline hydrolysis of a set of cAMP models that feature a *cis*-aryl-3′,5′-cyclic phosphotriester structure (**B**) (17). These studies independently support the ideas that (*i*) hydrolysis proceeds via a five-coordinated phosphorus structure, and (*ii*) both (e,e) and (e,a) orientations of the 3′,5′-dioxaphosphorinane ring are feasible as long as five-coordination is present. In the course of these investigations we have synthesized and characterized 2′-*O*-methyl-*cis*-adenosine 3′,5′-cyclic methyl monophosphate (*cis*-**4**; *cis* describes the relationship between OMe (bound to P) and the A-base), which is the key compound of the present study. Compound *cis*-**4** features a methoxy group on the 2′-position of the ribose ring, as well as the adenine base, and can therefore be regarded as an improved model for the interaction between cAMP and an enzyme; this is compared with previous studies, which are mainly based on 2′-deoxy-3′,5′-cyclic phosphate derivatives from thymidine.

We report (*i*) the synthesis of *cis*-**4**, (*ii*) the crystal structure of *cis*-**4**, (*iii*) an NMR analysis of the conformational properties of *cis*-**4** in methanol, and (*iv*) observations concerning the alkaline hydrolysis of *cis*-**4** (i.e., kinetics and product distribution, and mechanistic aspects).

Experimental

Materials and chromatography

Merck silica gel 60 (particle size 0.063–0.200 mm) was used for column separations. Dry diethyl ether was obtained by storing diethyl ether, predried on calcium chloride, on sodium wire. Ethyl acetate was refluxed on calcium hydride prior to atmospheric distillation. Acetonitrile (DNA grade) was used as received. *tert*-Butyl hydroperoxide was used as a 80% (8.0 M) solution in di-*tert*-butyl hydroperoxide. 1*H*-Tetrazole was purified through sublimation. Reactions were routinely run at ambient temperature in an inert atmosphere of dry nitrogen or argon, unless otherwise noted.

NMR spectroscopy

^{1}H NMR spectra were recorded at 400.13 MHz on a Bruker AM 400 spectrometer. Tetramethylsilane (TMS) was used as the internal standard. ^{13}C and ^{31}P NMR were recorded at 100.62 and 162.98 MHz, respectively, on the same instrument. The ^{31}P NMR spectra were referenced against 85% H_3PO_4 as external standard.

*2′-O-Methyl-*cis*-adenosine 3′,5′-cyclic methyl monophosphite (*cis*-**3**)*

2′-*O*-Methyladenosine (2.25 g, 8.0 mmol) (23) and 1*H*-tetrazole (1.68 g, 24.0 mmol) were dissolved in 160 mL of acetonitrile. A solution of bis(*N*,*N*-diisopropylamino)methoxyphosphine (2.52 g, 9.6 mmol) in 10 mL of dichloromethane was added and the mixture was stirred for 20 h. ^{31}P NMR analysis indicated a *trans*-phosphite/*cis*-phosphite ratio of ca. 2:3 (δ (CH_3CN/CD_3CN 1:1 v/v): 129.7 ppm (*trans*), 123.5 ppm (*cis*)). To convert the *trans* epimer into the *cis* epimer, the temperature of the mixture was raised

to 40°C and maintained at this value for 90 h. ^{31}P NMR indicated complete conversion of the *trans* isomer. The solution was filtered and evaporated *in vacuo*. The solid was suspended in 50 mL of ethyl acetate and, after filtering, the filtrate was washed twice with a saturated sodium bicarbonate solution. The ethyl acetate layer was dried on magnesium sulfate. After filtering and evaporation of the filtrate, the residue was suspended in diethyl ether. After filtering, a white solid is obtained. Yield 0.92 g (39%). ^{31}P NMR (CD_3CN)δ: 123.5; ^{1}H NMR (CD_3CN)δ: 8.26 (1H, s, H8), 7.98 (1H, s, H2), 6.11 (2H, bs, NH_2), 5.95 (1H, bs, H1′), 4.90 (1H, ddd, H3′), 4.42 (1H, ddd, H5′), 4.34 (1H, bd, H2′), 4.28 (1H, ddd, H5″), 4.00 (1H, ddd, H4′), 3.59 (3H′s, d, OCH_3, $^3J_{POCH}$ = 12.0 Hz), 3.55 (3H′s, s, 2′-OCH_3); ^{13}C NMR (CD_3CN) δ: 157.0 (C4 or C6), 154.1 (C8), 150.3 (C6 or C4), 140.6 (C2), 121.0 (C5), 88.5 (C1′), 82.7 (C2′), 72.8 (C4′, $^3J_{POCC}$ = 7.2 Hz), 71.0 (C3′), 67.1 (C5′, $^2J_{POC}$ = 4.0 Hz), 59.5 (2′-OCH_3), 50.9 (OCH_3, $^2J_{POC}$ = 17.3 Hz).

*2′-O-Methyl-*cis*-adenosine 3′,5′-cyclic methyl monophosphate (*cis*-**4**)*

tert-Butyl hydroperoxide (0.15 mL, 1.2 mmol) was added to a solution of *cis*-**3** (100 mg, 0.29 mmol) in 3 mL of acetonitrile and the mixture was stirred for 15 h. After filtering, the filtrate was evaporated and dissolved in dichloromethane/methanol 95:5 (v/v). After addition of diethyl ether, a precipitate was formed, which was isolated by means of centrifugation. Afterwards, purification was obtained by means of column chromatography on a silica gel column with a gradient of methanol in acetonitrile (5 → 10 vol% methanol). Compound *cis*-**4** was obtained as a white solid. Recrystallization from methanol yielded colorless crystals. Yield 75 mg (72%). ^{31}P NMR (CD_3OD)δ: -3.00; ^{1}H NMR (CD_3OD) δ: 8.25 (2H′s, s, H8 and H2), 6.18 (1H, bs, H1′), 5.40 (1H, ddd, H3′), 4.66 (1H, ddd, H5″), 4.53 (1H, bd, H2′), 4.45 (1H, bt, H5′), 4.32 (1H, ddd, H4′), 3.94 (3H′s, d, OCH_3, $^3J_{POCH}$ = 11.2 Hz), 3.60 (3H′s, s, 2′-OCH_3); ^{13}C NMR (CD_3CN)δ: 157.4 (C4 or C6), 154.2 (C8), 150.2 (C6 or C4), 141.7 (C2), 120.7 (C5), 92.0 (C1′), 81.8 (C2′, $^3J_{POCC}$ = 7.6 Hz), 80.6 (C3′, $^2J_{POC}$ = 5.9 Hz), 72.1 (C4′, $^3J_{POCC}$ = 5.8 Hz), 71.3 (C5′, $^2J_{POC}$ = 8.9 Hz), 59.6 (2′-OCH_3), 55.1 (OCH_3, $^2J_{POC}$ = 6.0 Hz).

Hydrolysis of cis-**4**

cis-**4** (15 mg; 0.038 mmol) was transferred into a 5-mm NMR sample tube and dissolved in 360 μL of D_2O. After addition of 19 μL of a 2.00 M sodium hydroxide solution, initiating the hydrolysis, the solution turned yellowish. The reaction was monitored at 21°C by means of ^{31}P NMR: 8 FIDs were collected (time domain: 16K; size: 16K; sweep width: 4854 Hz) at distinct time intervals. The start of the 5th scan was chosen as the reaction time.

^{31}P NMR (D_2O) δ: 2.19 (5′-phosphate diester), 1.51 (3′-phosphate diester).[3]

Crystallographic measurements and structure resolution

$C_{12}H_{16}N_5O_6P \cdot CH_3OH$ fw = 389.30. Orthorhombic, a = 8.170(2) Å, b = 9.249(1) Å, c = 23.669(4) Å, V = 1788.5(6) Å^3, Z = 4, D_c = 1.446 g cm^{-3}, λ(MoKᾱ) = 0.71073 Å, t = 100 K, μ(MoKᾱ) = 2.1 cm^{-1}, F(000) = 816. Absent reflections: $h00$, h odd; $0k0$, k odd; and $00l$, l odd; space group $P2_12_12_1$ (D_2^4, No. 19).

A colorless crystal with dimensions (mm) 1.1 × 0.5 × 0.2 was used for data collection on an Enraf–Nonius CAD-4 diffractometer. Lattice parameters were determined from the setting angles of 25 reflections in the θ range 10.66°–19.20°. The intensities of 8388 reflections (2358 unique, R_{int} = 0.049) were collected at liquid nitrogen temperature (100 K) within the sphere of reflection limited by 2θ = 55° and $-10 \le h \le 0$, $-12 \le k \le 12$, and $-30 \le l \le 30$, using Zr-filtered MoKα radiation. The ω/2θ scan technique was applied with, Δω = (1.74 + 0.35 tan θ)°. The intensities of three standard reflections (024, 203 and 122) measured every hour showed an average deviation of less than 3% during the duration of the data collection. The intensities were corrected for Lorentz-polarization effects, but not for absorption. A total of 2006 reflections that satisfied the criterion $I \ge 2.5\sigma(I)$ were retained for the structure determination and refinement. σ(I) was derived from counting statistics. The structure was solved with the direct methods program of SHELXS86 (18), the coordinates of all non-hydrogen atoms being determined from an E-map. The hydrogen atoms were placed at idealized positions (C—H 1.00 Å) and refined riding on their bonded atoms, except those involved in hydrogen bonds. The three donor hydrogen atoms could be located in difference Fourier maps. As these atoms showed appreciable drifts upon refinement, they were fixed on the donor···acceptor vectors at 0.90 Å from the donor atoms, assuming linearity of the hydrogen bond. The overall isotropic thermal parameter of all hydrogen atoms refined to 0.056(5) Å^2. The absolute configuration was assigned in accordance with that reported for a number of nucleoside 3′,5′-cyclic monophosphates (see ref. 29 and Table 6). Anisotropic full-matrix least-squares refinement on F of 230 parameters converged at R = 0.062 and R_w = 0.043 with $w = 1/\sigma^2(F_o)$. The quantity minimized was $\Sigma\Delta F^2$, the goodness of fit, $s = [\Sigma w\Delta F^2/(m-n)]^{1/2}$, was 1.57 and the average and maximal shift-to-error ratio's 0.004 and 0.03, respectively. A final ΔF map showed maximal fluctuations of +0.65 and −0.42 e Å^{-3}, the positive maxima lying near the phosphorus atom. The scattering factors were those of Cromer and Mann (19) and anomalous dispersion terms from Cromer and Liberman (20). The least-squares refinement was performed with the SHELX76 program (21) and the program package EUCLID (22) was used for the calculations of geometries and preparation of illustrations. All calculations were done on an ULTRIX DECsystem-5000.

Results and discussion

Synthesis of cis-***4***

The preparation of *cis*-**4** is outlined in Scheme 1. 2′-*O*-Methyl adenosine (23) is brought into reaction with bis(*N*,*N*-diisopropylamino)methoxyphosphine and 1*H*-tetrazole as catalyst. This results in the formation of 2′-*O*-methyl-*cis*-adenosine 3′,5′-cyclic methyl monophosphite (*cis*-**3**) and its *trans* epimer in a ratio of ca. 3:2 (*cis*/*trans*). At elevated temperature and in the presence of 1*H*-tetrazole, the *trans* diastereoisomer completely inverts into the *cis* diastereoisomer. After evaporation of the volatiles of the reaction mixture, the residue is suspended in ethyl acetate and filtered. The filtrate is washed with a sodium bicarbonate solution. Evaporation of ethyl acetate, and suspension of the residue in diethyl ether, affords *cis*-**3** as a white solid (yield 39%). Oxidation of *cis*-**3**, using *tert*-butyl hydroperoxide as oxidation agent (24–26), yields pure crystalline *cis*-**4** (yield 72%) (see Scheme 1).

Crystal structure

The molecular structure of *cis*-**4** with its atomic numbering is shown in Fig. 1. The fractional coordinates, along with equivalent isotropic temperature factors, are summarized in Table 1. The bond distances and bond angles between non-hydrogen atoms are given in Tables 2 and 3, respectively. Table 4 contains only torsion angles involving the glycosidic link (C1′—N9), the ribose, and the six-membered dioxaphosphorinane ring. Table 5 lists the hydrogen-bond geometries (distances and bond angles). Calculated and observed structure factors, calculated hydrogen atom parameters, and anisotropic thermal parameters have been deposited as Tables S-1, S-2, and S-3, respectively.[4]

Conformation of the ribose ring

The ribose ring is found in the C3′-*endo* puckered form. The values for the phase angle of pseudorotation (P) and the puckering amplitude (ν_{max}), which can be calculated from the five ribose endocyclic torsion angles (ν_0 ... ν_4) (Table 4) using the pseudorotation concept (27), are 49.1° and 46.1°, respectively. From these values can be concluded that the structure of the ribose ring can best be described by a twist ($_4T^3$) conformation, which is characteristic for cyclic nucleotides (Table 6). From Table 6, showing the pseudoro-

[3]The assignment of the 3′- and 5′- phosphate diester lines in the ^{31}P NMR spectrum is based on a 2D ^{31}P–^{1}H correlation spectrum.

[4]These tables may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A OS2.

The calculated hydrogen atom parameters have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

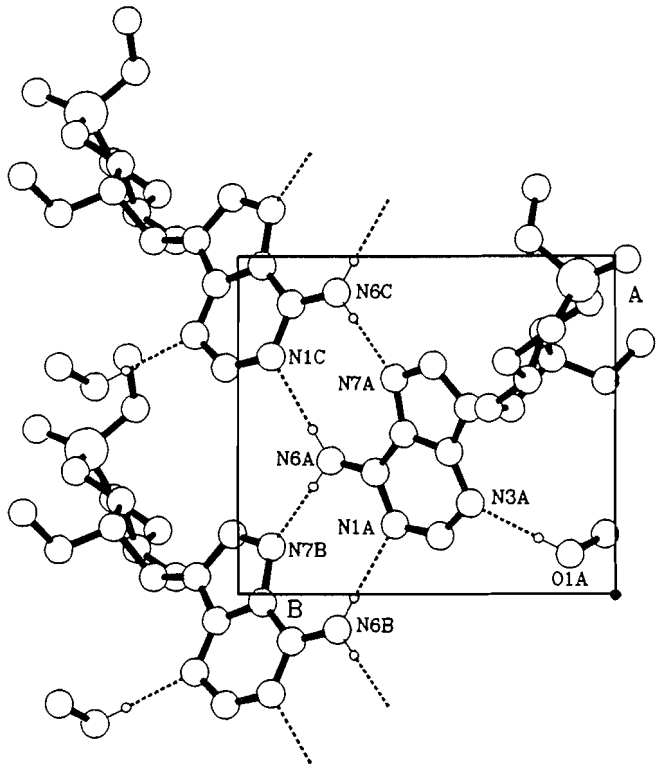

FIG. 2. Projection of a part of the structure down the *c* axis, showing the hydrogen-bonded chain in the *ab* plane. Hydrogen atoms not involved in hydrogen bonds have been omitted for clarity. The cell origin is indicated by the black dot. Molecule A is at $1 - x, -\frac{1}{2} + y, \frac{1}{2} - z$; molecule B is at $\frac{1}{2} - x, 2 - y, -\frac{1}{2} + z$; molecule C is at $1\frac{1}{2} - x, 2 - y, -\frac{1}{2} + z$;

tational parameters of several cyclic nucleotides, it can be observed that the values of phase angle and amplitude of pseudorotation (P and ν_{max}) vary within rather narrow ranges (P: 15°–51°; ν_{max}: 43°–50°). The pseudorotational parameters of the ribose ring in *cis*-**4** fit perfectly in the data ranges as shown in Table 6.

Conformation of the 3′,5′-dioxaphosphorinane ring

The 3′,5′-dioxaphosphorinane ring adopts a distorted chair conformation. To characterize this conformation we define three planes: plane 1 is the least-squares plane through the atoms O3′, O5′, C3′, and C5′ ($-0.411X + 0.286Y - 0.0091Z = 1$; $\sigma_{plane} = 0.016$ Å; X, Y, and Z are measured in angstroms along with the crystallographic a, b, and c axes); plane 2 is the plane through O3′, P, and O5′ ($-0.0512X + 0.0147Y + 0.0450Z = 1$); and plane 3 is the plane defined by the atoms C3′, C4′, and C5′ ($-0.00355X + 0.111Y + 0.0436Z = 1$). The dihedral angle between the planes 1 and 2 is 39.4°, whereas the dihedral angle between the planes 1 and 3 is 56.7°. This means that the ring resides in a distorted chair conformation in which P and C4′ are on opposite sides with respect to plane 1. The distances of the atoms P and C4′ to plane 1 are 0.59 and 0.69 Å, respectively. This leads to the conclusion that the P part is flattened in comparison with the C4′ part of the 3′,5′-dioxaphosphorinane ring. The distortion of the 3′,5′-dioxaphosphorinane ring can also be characterized by the significantly different values of the bond angles C3′—O3′—P (113.6°) and C5′—O5′—P (119.2°). The largest endocyclic torsion angle in the dioxaphosphorinane ring is found in the C3′—C4′ bond (C5′—C4′—C3′—O3′ = 64.7°), the *trans* junction with the ribose ring. The endocyclic P—O bonds show the smallest ring torsion angles (O3′—P—O5′—C5′ = −45.0°; C3′—O3′—P—O5′ = 45.2°) (Table 7). These values also demonstrate that the P part is flattened in comparison with the C4′ part of the six-membered ring. The values of the torsion angles of the 3′,5′-dioxaphosphorinane ring in *cis*-**4** shown in Table 7 fit perfectly within the data ranges defined by several 3′,5′-cyclic nucleotides (28–33).

TABLE 8. Proton–proton and proton-phosphorus coupling constants (in Hz) of *cis*-**4**, measured in methanol-d_4 at 20°C

Parameter	Value[a]	Parameter	Value[a]
$J_{H1'H2'}$	0.8	$J_{H4'H5''}$	4.7
$J_{H2'H3'}$	5.1	$J_{H5'H5''}$	−9.3

[a]Estimated error ±0.1 Hz.
[b]Estimated error ±0.2 Hz.

Geometry and orientation of the base

The torsion angle χ(O4′—C1′—N9—C4) about the glycosidic bond is −100.7° and corresponds to the *anti* conformation. The values of the bond lengths and angles for the purine base are similar to those reported for the standard adenine ring (34). Largest deviations were found for the N1—C2 and N7—C8 bonds (bond lengths smaller than the standard values by 0.023 and 0.022 Å, respectively). The least-squares plane through the nine atoms of the purine base is $-0.255X - 0.559Y + 0.789Z = 1.610$; $\sigma_{plane} = 0.019$ Å; where X, Y, and Z are measured in angstroms along with the crystallographic a, b, and c axes. The dihedral angle between the planes of the pyrimidine and imidazole ring is 1.7°. The largest torsion angle in the adenine ring is found about the N3—C4 and N7—C8 bonds (C2—N3—C4—C5 = −2.4°; C5—N7—C8—N9 = 1.6°), resulting in a small deviation from planarity (Table 4).

Molecular packing and hydrogen bonding

In Fig. 2 is illustrated that each NH_2 group in *cis*-**4** is hydrogen bonded by two molecules. There is one hydrogen bond between N6 and N7 ($\frac{1}{2} + x, 2\frac{1}{2} - y, 1 - z$) and one between N6 and N1 ($-\frac{1}{2} + x, 2\frac{1}{2} - y, 1 - z$) (see Table 5). The hydrogen bond accepting molecules are one translation apart along the *a* axis, leading to a one-dimensional chain of hydrogen-bonded molecules. The direction of the one-dimensional chain is almost parallel to the *a* axis. The hydrogen bonds between the bases are very similar to those in 2′-deoxy-3′,5′-di-*O*-acetyl adenosine (35). An additional hydrogen bond is formed between the OH group of the methanol molecule, which is incorporated in the crystal structure, and the adenine base: O1—H3···N3.

Conformation in solution

The conformation of *cis*-**4** in methanol-d_4 was determined at room temperature with ^{1}H NMR at 400.13 MHz. The set of experimental coupling constants are summarized in Table 8.

Conformation of the ribose ring

The conformational analysis of the sugar ring of *cis*-**4** was performed with the PSEUROT program (36). The sets of vic-

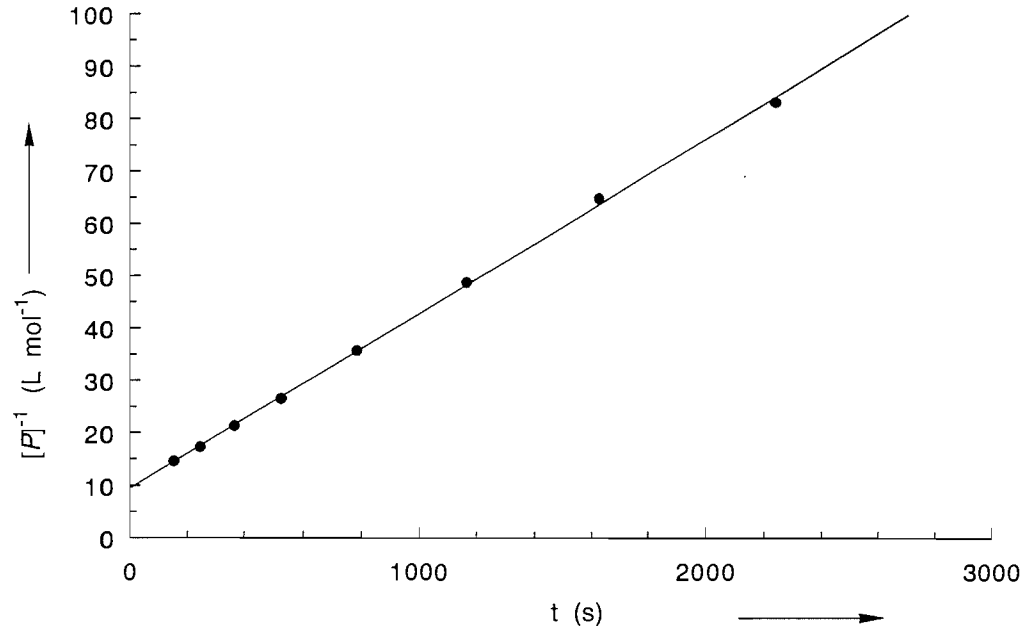

FIG. 3. Graphical presentation of the alkaline hydrolysis in D_2O of *cis*-**4** at 294 K, based on eq. [1]. Both initial concentrations of *cis*-**4** and hydroxide are 0.100 M. The values for k^{exp} and r are 0.0334 L. mol^{-1} s^{-1} and 0.999, respectively.

inal H–H coupling constants ($J_{H(1')H(2')}$, $J_{H(2')H(3')}$, $J_{H(3')H(4')}$) measured for *cis*-**4** (Table 8) were used as input data. PSEUROT calculates the best-fit conformational parameters of two sugar structures (a North (C3′-*endo*) and a South (C2′-*endo*) conformation) participating in a rapid conformational equilibrium as well as the equilibrium composition. PSEUROT converged toward a single conformation (North), characterized by a phase angle (P) of 23.7° and a maximum puckering amplitude (ν_{max}) of 41.4°. The five endocyclic torsion angles ($\nu_0 \ldots \nu_4$) can be calculated from P and ν_{max} according to the formula: $\nu_j = \nu_{max} \cdot \cos(P + (j - 2) \cdot 144)$ (27), i.e., $\nu_0 = -4.1°$, $\nu_1 = -20.9°$, $\nu_2 = 37.9°$, $\nu_3 = -40.4°$, $\nu_4 = 27.5°$. From these results it can be derived that the structure of the ribose ring in *cis*-**4** resides in a twist ($^3T_4$) conformation, which is closely related to the $_4T^3$ conformation in the solid state.

Conformation of the 3′,5′-dioxaphosphorinane ring

The rigidity of the *trans*-annealed six-membered ring allows us to take only a few conformations into account: (*i*) a chair, (*ii*) two boat conformations (one with P and C4′ as prow and one with O5′ and C3′ as prow), or (*iii*) a twist-boat geometry. Discrimination between these geometries is based on the values of two H–P coupling constants ($^3J_{PH(5')}$ and $^3J_{PH(5'')}$, describing the conformation around the O5′—C5′ bond) and two H–H coupling constants ($^3J_{H(4')H(5')}$ and $^3J_{H(4')H(5'')}$, characterizing the conformation around the C4′—C5′ bond). Generally the H–P coupling constants of phosphates fit into classic Karplus type relations (37–39). From the work of Bentrude and co-workers (40) on cyclic phosphates a *trans* orientation of a P—O—C—H fragment corresponds to a $^3J_{POCH}$ value of ≈22.5 Hz, whereas a *gauche* conformation is related to a $^3J_{POCH}$ value of ≈1 Hz. From Table 8 we conclude that H5″ and P adopt a *trans* orientation (P—O—C—H5′ ≃ ±60°). These results are in agreement with the chair conformation. The boat geometry, in which O3′, O5′, C3′, and C5′ are approximately in the same plane while P and C4′ are both located on the *exo* side of this plane, would yield approximately identical values for $^3J_{PH(5')}$ and $^3J_{PH(5'')}$, whereas the twist-boat and the boat conformation, in which O5′ and C3′ are located on the *endo* side of the least-squares plane through P, C4′, C5′, and O3′, would correspond to a large value for $^3J_{POCH(5')}$ (≈20–23 Hz) and a small value for $^3J_{POCH(5'')}$.

A second clue for characterization of the geometry of the 3′,5′-dioxaphosphorinane ring is provided by the coupling constants $^3J_{H(4')H(5')}$ and $^3J_{H(4')H(5'')}$, from which the conformation around the C4′—C5′ (γ) bond can be deduced. By using the generalized Karplus equation of Altona and co-

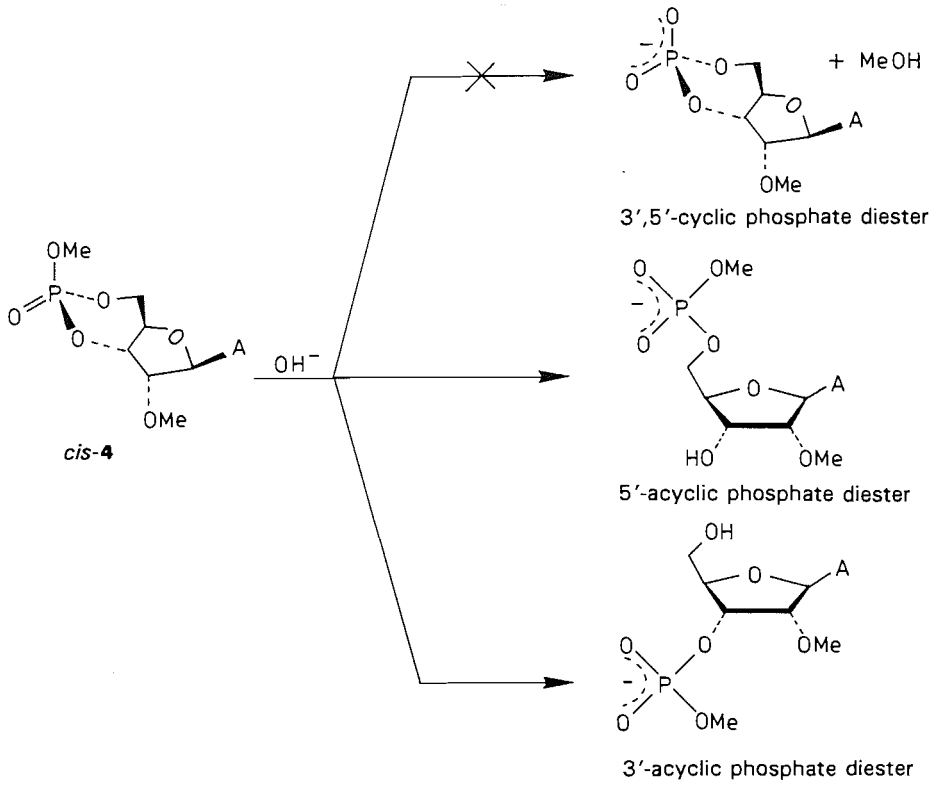

SCHEME 2

workers (41),[5] we calculated $^3J_{H(4')H(5')}$ and $^3J_{H(4')H(5'')}$ as a function of the torsion angle O5′—C5′—C4′—O4′ (see Fig. 2 in ref. 16). This graph indicates that the torsion angle adopts a value of approximately 180°, which is in agreement with the chair conformation of the six-membered ring.

Hydrolysis of cis-**4**

To obtain information about the mechanistic aspects of the alkaline hydrolysis of *cis*-**4** we investigated the kinetics and product distribution by means of ^{31}P NMR. The hydrolysis reaction was assumed to obey second-order kinetics (42, 43): first order in cyclic phosphate triester and first order in hydroxide. Using equivalent amounts of *cis*-**4** and OH^- the kinetic equation becomes:

$$[1] \quad \frac{1}{[P]} = k^{exp}t + \frac{1}{[P]_0}$$

with $[P]$ = concentration of *cis*-**4** at time $t = t$; $[P]_0$ = initial concentration of *cis*-**4**; k^{exp} = experimental second-order reaction rate constant.

Our data on the hydrolysis reaction of *cis*-**4** are visualized in Fig. 3; the linear relationship ($r = 0.999$) between $[P]^{-1}$ and t substantiates the assumption that the hydrolysis proceeds via a second-order reaction mechanism. In Table 9 and k^{exp} value is tabulated.

Two different acyclic products were formed: a 3′-phosphate diester and a 5′-phosphate diester (ratio 3′:5′ = 65:35) (see Scheme 2). Comparing the product distribution in the hydrolysis of *cis*-**4** with those of 2′-*O*-methyl-*cis*-adenosine 3′,5′-cyclic *phenyl* monophosphate (17) (Table 9), it is remarkable that during hydrolysis the latter compound affords 52% of 3′,5′-cyclic phosphate diester, whereas hydrolysis of *cis*-**4** yields no cyclic product at all. The reason for this difference may be found in the formation of different P^V-TBP intermediates during the hydrolysis reactions. The main difference between the P^V-TBPs is the location of the 3′,5′-dioxaphosphorinane ring: (e,e) or (e,a). Since phenoxide (pK_a (phenol) = 10.1) is a much better leaving group than the methoxide (pK_a (methanol) = 15.5), in the P^V-TBPs the phenoxy group is more axiophilic than the methoxy. Since expulsion of a ligand from the P^V-TBP only takes place on the axial site of the TBP, formation of the 3′,5′-cyclic phosphate can be expected during hydrolysis of 2′-*O*-methyl-*cis*-adenosine 3′,5′-cyclic *phenyl* monophosphate. Since methoxy has no axiophilic character, hydrolysis of *cis*-**4** yields no 3′,5′-cyclic phosphate at all; only acyclic phosphates are formed.

Conclusion

The molecular conformation of *cis*-**4** is not significantly different from the conformations of several cAMP analogs (28–33). The ribose ring of *cis*-**4** shows virtually the same configuration in the solid state and in solution. Comparison of the crystal structure of *cis*-**4** with a set of related systems (28–33) shows that the absence or presence of the substituent on C2′ is relatively unimportant.

[5]In this generalized equation, the standard Karplus relation is extended with a correction term which accounts for the influence of electronegative substituents on $^3J_{HH}$:

$$^3J_{HH} = 13.22\cos^2\phi - 0.99\cos\phi + \Sigma[0.87 - 2.46\cos^2(\xi_i\phi + 19.9|\Delta\chi_i|)]\Delta\chi_i$$

ϕ is the proton–proton torsion angle, $\Delta\chi_i$ is the difference in electronegativity between the substituent and hydrogen according to the electronegativity scale of Huggins, and ξ_i is a substituent orientation parameter.

Due to the *trans* fusion of the 3′,5′-dioxaphosphorinane ring to the five-membered ribose ring, the 3′,5′-dioxaphosphorinane ring of *cis*-**4** adopts a fixed distorted chair conformation in the solid state. In this distorted chair geometry the atoms O3′, O5′, C3′, and C5′ are located in approximately the same plane, whereas P and C4′ are situated on opposite sides of this plane. The P side of the six-membered ring is flattened in comparison with the C4′ side. This conformation resembles the distorted chair conformation found in the set of related systems mentioned above (28–33). With respect to the conformation of the 3′,5′-dioxaphosphorinane ring of *cis*-**4** in solution it must be mentioned that the available set of coupling constants do not allow us to discriminate between a chair conformation and a distorted chair conformation.

In the crystal structure the adenine ring is oriented in the *anti* conformation and the adenine bases are linked via N6—H1···N1 and N6—H2···N7 hydrogen bonds, in such a way that infinite one-dimensional chains are formed. This hydrogen bond scheme is very similar to that observed in the structure of 2′-deoxy-3′,5′-di-*O*-acetyl adenosine (35). An additional hydrogen bond is formed between the OH group of methanol and the adenine base.

Alkaline hydrolysis of *cis*-**4** yields two acyclic products: only 3′-phosphate diester and a 5′-phosphate diester. In comparison with the hydrolysis of 2′-*O*-methyl-*cis*-adenosine 3′,5′-cyclic phenyl monophosphate (17), no cyclic phosphate diester is formed. We conclude that hydrolysis of *cis*-**4** is "thermodynamically controlled," whereas hydrolysis of 2′-*O*-methyl-*cis*-adenosine 3′,5′-cyclic phenyl monophosphate (17) is more "kinetically controlled" due to the good leaving group character of phenoxide.

Formation of isomeric monohalo-*n*-alkanoic acids in the reactions of γ- and δ-*n*-alkanolactones with hydrogen halides

ALESSANDRO GRANATA AND ARTHUR S. PERLIN[1]
Department of Chemistry, McGill University, Montreal, Que., Canada H3A 2A7

Received December 18, 1992

ALESSANDRO GRANATA and ARTHUR S. PERLIN. Can. J. Chem. **71**, 864 (1993).

In 57% hydriodic acid or 48% hydrobromic acid, under reflux, *n*-alkanoic γ- or δ-lactones of from 5 to 18 carbon atoms undergo facile ring opening to monohalo-*n*-alkanoic acids. With both reagents the ratio of acid to lactone at equilibrium varies widely, ranging from about 1:3 for γ-valerolactone (C_5) to 3:1 or more for γ-octanolactone and the larger members of the series. Extensive scrambling of the halogen atoms accompanies the formation of the haloacids, whereby mixtures of monohalo isomers substituted at all positions from C-4 to the penultimate carbon are found. In an 18 h reaction with HBr, for example, γ-caprolactone was converted into a 1:3 mixture of 4- and 5-bromohexanoic acids, and γ-decanolactone into a 1:1.4:1.4:1.4:2.3:2.3 mixture of 4-, 5-, 6-, 7-, 8-, and 9-bromodecanoic acids. By contrast, the γ-lactones containing 14 or 16 carbon atoms gave only 10:1 mixtures of the 4- and 5-bromoacids, and at the level of 18 carbon atoms rearrangement was no longer evident; i.e., γ-octadecanolactone afforded only 4-bromooctadecanoic acid. Similar isomer distributions were obtained for the iodoacid homologs. Hydrochloric acid (37%) was far less effective in opening the lactone rings, and also in inducing rearrangement of the chlorine atoms introduced. Differences in entropy and in solvation appear to be the main factors contributing to the variations observed among isomeric lactones.

ALESSANDRO GRANATA et ARTHUR S. PERLIN. Can. J. Chem. **71**, 864 (1993).

Soumis à de l'acide iodhydrique à 57% ou à de l'acide bromhydrique à 48%, les γ- ou δ-lactones des acides *n*-alcanoïques comportant de 5 à 18 atomes de carbone donnent facilement lieu à une ouverture de cycle conduisant aux acides *n*-alcanoïques monohalogénés. Avec les deux réactifs, le rapport des concentrations d'acide et de lactone présentes à l'équilibre varie considérablement; il passe d'environ 1 : 3 pour la γ-valérolactone (C_5) à 3 : 1 ou plus pour la γ-octanolactone et les autres grands cycles de la série. La formation des haloacides s'accompagne de beaucoup de brouillage des halogènes; on retrouve des mélanges de dérivés monohalogénés dans lesquels les halogènes sont fixés sur chacun des carbones de l'acide, de la position 4 jusqu'à l'avant dernier carbone. Par example, lors d'une réaction de 18 h avec du HBr, la γ-caprolactone a été transformée en un mélange 1 : 3 des acides 4- et 5-bromohexanoïques alors que la γ-décanolactone est transformée en un mélange 1 : 1,4 : 1,4 : 1,4 : 2,3 : 2,3 des acides 4-, 5-, 6-, 7-, 8- et 9-bromodécanoïques. Par ailleurs, les γ-lactones contenant 14 ou 16 atomes de carbone ne donnent que des mélanges 10 : 1 des acides 4- ou 5-bromés alors que, au niveau de 18 atomes de carbone, on n'observe plus de transposition, c'est-à-dire que la γ-octadécanolactone ne fournit que de l'acide 4-bromoctanoïque. On a obtenu des distributions semblables avec analogues iodés. L'acide chlorhydrique (37%) est beaucoup moins efficace pour ouvrir les cycles des lactones et pour induire des transpositions des atomes de chlore introduits. Il semble que des différences d'entropie et de solvatation soient les principaux facteurs contribuant aux variations observées avec les lactones homologues.

[Traduit par la rédaction]

Introduction

In reactions with 57% hydriodic acid under reflux, aldonolactone derivatives of sugars are reduced to the corresponding γ-*n*-alkanolactones and (or) monoiodoalkanoic acids (1–3). The lactone–acid ratio at equilibrium varies widely (3) with the number of carbon atoms in these molecules. In 1–4 h reaction time, for example, D-erythrono-1,4-lactone afffords 3-iodobutanoic acid almost exclusively, whereas D-xylono-1,4-lactone gives a 4:1 mixture of γ-valerolactone and 4-iodopentanoic acid. Aldonolactones containing six to eight carbon atoms are converted into mixtures of γ-*n*-alkanolactone and iodoacid in which the latter becomes the preponderant product.

Another characteristic (3) of these reactions is a progression in the number of iodoacids produced, which is determined by chain length. Hence, 4-iodopentanoic acid (**2**) is the only five-carbon acid derivative obtained from γ-valerolactone (**1**), whereas there are two isomers (4- and 5-) of iodohexanoic acid, three isomeric (4-, 5-, and 6-) iodoheptanoic acids, and four (4-, 5-, 6-, and 7-) iodooctanoic acids. Moreover, the isomer substituted at the penultimate carbon is the major species in each mixture, e.g., 7-iodooctanoic acid (**4**) from γ-octanolactone (**3**).

These characteristics of lactone-ring opening by hydriodic acid have been demonstrated (3) not only for the aldonolactones but also, more simply, with the corresponding four- to eight-carbon γ-*n*-alkanolactones that are formed from them in the reduction reaction with hydriodic acid. The present study describes results obtained with homologous *n*-alkanolactones having from 8 to 18 carbon atoms, as well as a comparison between the action of hydriodic acid and those of hydrobromic and hydrochloric acids over the entire range of chain lengths.

Results and discussion

Lactone-ring opening by hydriodic and hydrobromic acids

As already noted for the reaction of hydriodic acid with γ-*n*-alkanolactones, the amount of iodoacid produced in 1 h relative to that of unreacted lactone increases sharply from a ratio of 0.4 for the 5-carbon compound through 10.1 for the 8-carbon member of the series (see Table 1). Data that have now been obtained for longer carbon chains are also presented in the table. The estimates of iodoacid:lactone ratios (A:L) are based on the relative intensities of ^{1}H nmr

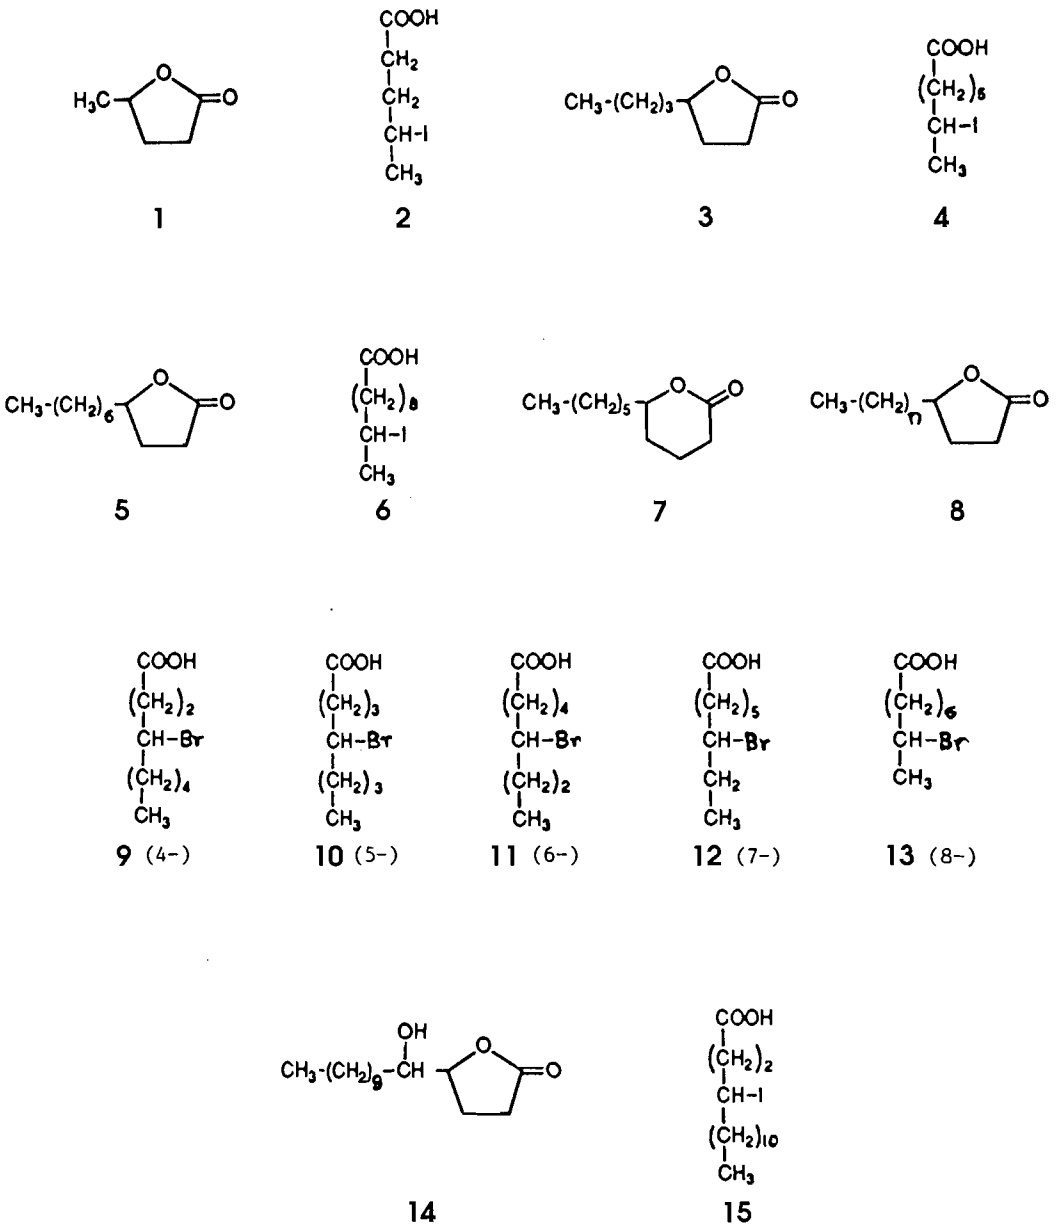
signals at δ ~4.2 and ~4.5, which are characteristic of methine protons deshielded by the α-iodine atom and the lactone-ring O atom, respectively. A high iodoacid content (ratio of 10) was again found for the product mixtures from the C_9 and C_{10} lactones, whereas the values were lower for the C_{11}(4.9) and C_{12}(2.3) homologues. These data are for a reaction time of 18 h, and as they were largely unchanged from results obtained with reaction periods of 4 h — which was true particularly for the series γ-valerolactone to γ-undecanolactone — it appeared that close to equilibrium conditions had been attained in most of the experiments (also see later).



Overall, there is a progressive increase in sensitivity of the lactones towards ring-opening displacement by the halide, from the γ-butyrolactone structure to which a methyl group is appended (γ-*valero* (**1**)), to one in which the ring substituent is *n*-butyl. Then, there is relatively little difference through to an *n*-heptyl substituent. The *n*-dodecanolactone examined was the δ-form, which, at 18 h, yielded a 3:7 mixture of lactone and iodoacid. Although this result is entered with the γ-lactone data, its inclusion is justified by comparative experiments with γ- and δ-aldonolactones, and by the fact that δ-undecanolactone gave data (Table 1) closely similar to that of its γ-C_{11} counterpart.

In reactions with 57% hydrobromic acid under reflux, the γ-alkanolactones show characteristics broadly similar to those with hydriodic acid (Table 1), the product ratios again being based on integration of nmr spectra. Hydrobromic acid is noticeably less effective in the ring opening of the γ-valero- to γ-octanolactones, whereas its impact on the 9- to 16-carbon lactones is closer to, or surpasses, that of hydriodic acid.

TABLE 1. Molar ratio of haloacid produced (A) to alkanolactone remaining (L) in an 18 h reaction period with 57% hydriodic or 48% hydrobromic acid

Lactone	Hydrogen halide	A:L	Lactone	Hydrogen halide	A:L
γ-Valero-	HI	0.4	γ-Undecano-	HI	4.9
	HBr	0.2		HBr	13.3
γ-Capro-	HI	0.8	δ-Undecano-	HI	4.6[a]
	HBr	0.4		HBr	11.5[a]
γ-Heptano-	HI	5.6	δ-Dodecano-	HI	2.3[a]
	HBr	1.6		HBr	32.3[a]
γ-Octano-	HI	10.1	γ-Tetradecano-	HI	20.0
	HBr	2.4		HBr	1.9
γ-Nonano-	HI	10.1	γ-Hexadecano-	HI	2.3
	HBr	8.3		HBr	1.9
γ-Decano-	HI	10.1	γ-Octadecano	HI	4.3
	HBr	11.5		HBr	3.3

[a]Lactone (L) was the rearranged γ isomer.

*Formation of isomeric monohalo-*n*-alkanoic acids*

Not only do these reactions produce the isomer corresponding to the expected halide displacement in the opening of the γ-lactone ring, i.e., the 4-halo derivative, but additional species in which carbon atoms of the chain exocyclic to the ring become substituted. For example, γ-octanolactone was found to yield an approximately 1:1.5:1.5:2 mixture of 4-, 5-, 6-, and 7-iodooctanoic acids. It seems probable (3) that this extensive isomerization involves the formation of a series of homologous olefinic and cationic (or radical) intermediates that accommodate migration of the iodine atom, from C-4 initially, towards the methyl terminus. However, substitution by halogen proceeds only to the *penultimate* carbon, corresponding overall to Markownikow addition of hydriodic acid.

The iodination products of γ-nonoic, -decanoic, and -undecanoic lactones were found, analogously, to be mixtures of correspondingly more numerous species. For example, the ^{13}C nmr spectrum of the 18 h reaction product from the C_{11} lactone (**5**) accounted for at least 60 individual resonances, including a minimum of 6 carboxyl signals. The ^{1}H nmr evidence that one prominent component was the 10-iodo isomer (**6**) was a strong doublet (δ 1.95) attributable to the deshielded CH_3 group.

The δ-isomer of undecanolactone (**7**) was converted into a mixture of iodoacids closely similar to that described for the γ-lactone, by reaction with HI for 18 h (Table 1). At 1 h and 4 h, however, none of the δ-lactone was detectable, which showed that opening of the six-membered ring occurred rapidly and quantitatively. Subsequently, isomerization reactions afforded not only the same mixture of iodoacids as obtained from the γ-lactone in 18 h, but 18% of the latter lactone as well.

The ^{13}C nmr spectra of the bromo- and iodoalkanoic acids

The mixed populations of haloacids obtained from the reaction of hydrogen bromide with the longer-chain lactones were more easily characterized by ^{13}C nmr spectroscopy than were the iodoacids, because stronger deshielding by the bromine atoms causes the ^{13}C nuclei to which they are attached to resonate in a region (δ 50–60) well separated from those of the other carbons. This provided evidence of a self-consistent pattern of chemical shifts and intensities within the series as the number of isomers progressed from two (for caprolactone) to eight (for dodecanolactone). Representative is the spectrum of the mixture recovered from the reaction of nonanolactone (**8**, $n = 4$) (Fig. 1), in which five signals for bromine-substituted carbons, attributed to monobromoacids **9**–**13**, are evident (δ 52–60). Complementing these are the five carboxyl ^{13}C signals at δ ~ 180. Results are given in Table 2 for all of the products obtained in a reaction period of 18 h, which, for most of the lactones, appear to be close to equilibrium values. Among these data are found nearly constant chemical shift values attributable to C-4 (δ ~ 57), and also for the ω − 1 and ω − 2 carbons (δ ~ 52 and δ ~ 60), which, respectively, are the most and least strongly shielded within each group. In general, the values are listed in the order shown on the basis of known additivity relationships (e.g., see ref. 4), and because as additional isomers appear with a progressive increase in chain length, their ^{13}C-Br signals conform to a seemingly consistent pattern of chemical shifts. Nevertheless, the reliability of these latter assignments is of lesser importance in the overall analysis because, within each set, these isomers were formed in approximately equal proportions (Table 2).

Comparable ^{13}C data were not readily accessible for the alkyl carbons of the iodoacids, because of an overlap between the range of chemical shifts for the substituted and methylenic carbons, and attempts to differentiate between them (by means of DEPT experiments) were only partially successful. However, data for the carboxyl carbons provided evidence that the compositions of the mixtures of iodoacids were closely similar to those of the bromoacids.

To a substantial degree, the patterns of $^{13}C{=}O$ signals in the two series were duplicates, and matched the data in Table 2 for the methine carbons. For example, representative data for the iodoacids (Table 3) show that the products of the reaction of the C_7–C_{10} lactones with HI for 18 h gave three, four, five, and six $^{13}C{=}O$ peaks, respectively (see, e.g., Fig. 1). The latter accounted for both the same number of isomers and for ratios of similar magnitude (i.e., largely independent of differences in T_1 and nOe) as had been deduced from ^{13}C-Br signals (Table 1) for the corresponding bromoacids. Table 3 also shows that the location of a halogen atom on C-4, or C-5, through to C-9, makes for small incremental differences in the shielded state of a carboxyl carbon, so that it resonates furthest downfield (δ ~ 180)

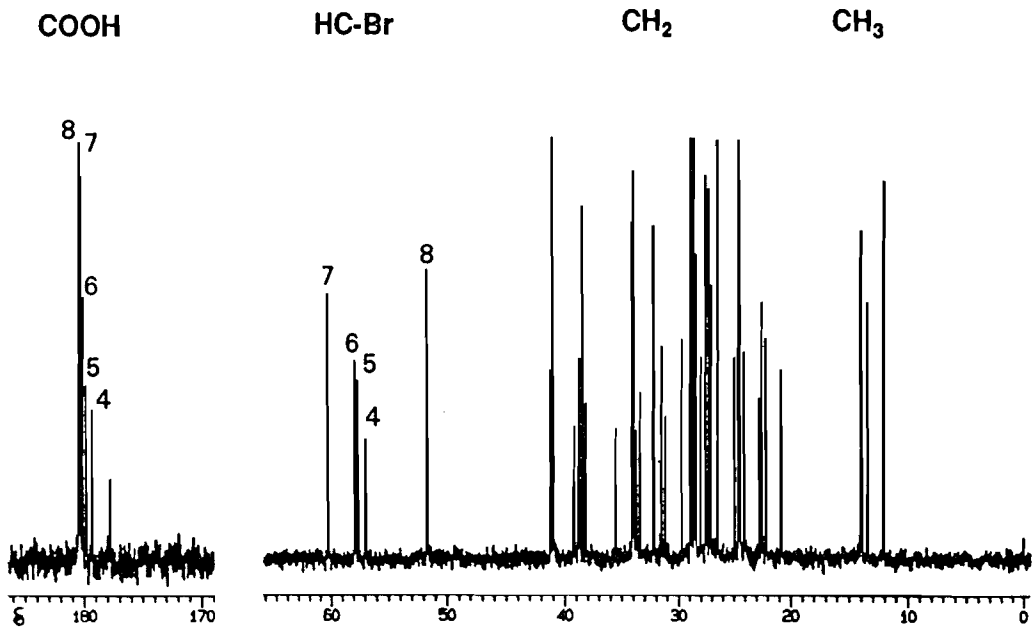

FIG. 1. The 67.8 MHz ^{13}C nmr spectrum of the mixture of monobromooctanoic acids isolated from the reaction of γ-nonanolactone with 48% hydrobromic acid under reflux for 18 h. The numbered signals in the region δ ~ 50–60 are those assigned to the individual isomers in which a bromine atom is attached to carbon-4, -5, -6, -7, or -8. Signals near δ 180, attributable to the carboxyl carbons of these monobromoacids, are designated accordingly. The minor signal at δ 177.8 is due to the C=O group of the unreacted lactone.

when the halogen is on the penultimate carbon (ω − 1), and at highest field (δ ~ 179) when it is on C-4. Although we are unable to assign the other individual peaks, which are due to C-5 through C-8, the consistency evident in the order of their occurrence as the length of the carbon chain is increased implies a simple linear progression of accompanying downfield shifts. It is also worth noting that the bromo acids gave $^{13}C{=}O$ results closely analogous to those in Table 3; this implies that the stronger deshielding effect by the bromine atom relative to the iodine atom, evident at the site of substitution, is not transmitted to the carboxyl carbons.

Limits to isomerization among longer-chain haloacids

Whereas the isomers substituted at the penultimate (ω − 1) carbon or its secondary neighbor (ω − 2) were the major products among the shorter-chain molecules, their percentages decreased as the number of carbon atoms reached 11 and 12 (Table 2). This suggested that factors controlling the migration of halogen atoms along the *n*-alkyl chains are subject to limiting conditions in the larger molecules.

In fact, a notable change in reaction characteristics was found with the C_{14} lactone, γ-tetradecanolactone (**8**, $n = 9$). Although 65% of this compound was converted into bromoacid (Table 1; more iodoacid was formed), little isomerization occurred (Table 2). By far the major product was the 4-isomer, and the only other species detected corresponded to about 10% of 5-bromotetradecanoic acid. However, the 18 h reaction had not reached equilibrium, as shown by the fact that a 65 h run resulted not only in a higher yield of bromoacid (A:L = 8:1), but also in the formation of a mixture of 9- and 10-isomers, all present in about the same proportion. By contrast, control experiments of 65 h with HBr for the C_{10} and C_{12} lactones gave essentially the same results as at 18 h, confirming that the data for them in Table 2 represent close to equilibrium conditions.

Among other reactions examined was that of a 15-carbon lactone, i.e., 5-hydroxy-γ-pentadecanolactone (**14**), with HI. By analogy with aldonolactones, it would be expected to undergo reduction and lactone-ring opening to yield 4-iodopentadecanoic acid (**15**), or more than one iodoacid if isomerization were to occur. In 18 h reaction time, according to the $^{13}COOH$ signals observed for the products isolated (Table 3), only four iodoacids had been formed. When the reaction time was increased to 36 h, the presence of two or three additional, more minor, species was detected. Consequently, the iodine atom introduced at C-4 during, or following, reduction of OH-5 of **14** was much more resistant to migration along the carbon chain than for lactones having 12 or fewer carbons.

It is worth noting that as an optically active form of **14** was available, it was used as an additional check on evidence that the products formed through hydriodic acid reduction and iodination undergo racemization. The mixture of iodoacids proved, in fact, to be optically inactive.

Supplementing the observation that the rate and (or) degree of isomerization of these haloacids becomes notably smaller when chain lengths reach a value of about 14 carbon atoms are the results obtained with the C_{16} and C_{18} lactones. That is, whereas they also undergo extensive lactone-to-acid interconversion (Table 1), it is not accompanied by appreciable isomerization. In addition to the 4-bromoacid (^{13}C-Br signal at δ 56.9, Table 2), γ-hexadecanolactone (**8**, $n = 11$) afforded a low yield of only one other isomer, likely the 5-bromide. In its reaction with HI, on the basis of the carboxyl ^{13}C data (Table 3), γ-hexadecanolactone gave four iodoacids; the isomer taken to be 4-iodohexadecanoic acid (δ 178.81) made up almost one-half of the mixture, whereas the 5-iodo isomer (δ 179.43) accounted for another one-quarter of the product.

Only a single product, likely 4-bromooctadecanoic acid, was produced in the 18 h reaction of γ-octadecanolactone (**8**, $n = 13$) with HBr (Table 2), and when the reaction time was increased to 65 h, only a trace proportion of a second species was detected.

Consequently, it is clear that the length of the carbon chain eventually introduces limits to the impetus for isomerization of the 4-haloalkanoic acid produced through lactone-ring opening. The presence of 14–16 carbon atoms in a molecule imposes a marked reduction in the rate of isomerization relative to 10–12 (or fewer) carbon atoms, whereas when the 4-haloacid contains 18 carbon atoms, it is a uniquely stable species within the series. This distinctiveness is emphasized by the fact that the 4-substituted isomer is the *least* populous (Tables 2 and 3) among the individual members of the C_6 to C_{12} mixtures of haloacids.

Sources of variations in haloacid composition

A number of possibilities have been considered to account for these marked variations in product composition among the equilibrated lactone–haloacid mixtures. In view of the large array of isomeric haloacids produced by the short-to-medium chain lactones (C_6 to C_{12}), we have surmised (3) that an increase in entropy will favor the occurrence of as many isomers as possible in each mixture, i.e., from the product monosubstituted on C-4, to that on the $\omega - 1$ carbon. This is consistent with the production of an overall lower yield of haloacid from the C_5 lactone, which yields only one isomer, than from, e.g., its C_9 homologue, which gives five isomers. Perhaps, however, such a factor decreases in importance as the carbon chain length reaches a level of 12 or more, because the ring opening of the lactones would then lead to increasing degrees of disorder associated with the release of increasingly more flexible alkyl chains. (Whether or not the reduction in entropy due to dimerization of the carboxylic acids would even out across the series is unclear.) As to enthalpy contributions, we are unaware of thermochemical data that may account for the observed differences in relative stability among individual isomers *within* each mixture, e.g., to account for the 1–2.3 difference found in the equilibrated populations of 4- and 9-bromodecanoic acids.

Among the longer-chain molecules, less effective solvation by the haloacid media also should be a factor. That the initial ring-opening step appears to occur with about equal facility for C_8 to C_{18} lactones (<30% of each lactone remains intact at 18 h, Table 1) is consistent with the fact that this step involves attack on the more hydrophilic site common to each of these molecules. However, solvation could be a limiting factor during the subsequent isomerization process, which may comprise (3) such steps as thermal elimination, protonation, and carbocation rearrangement,[2] because the longer the hydrocarbon chain of the 4-haloacid (or 5-, from a δ-lactone), the less effective its interaction with the hydrated hydrogen halide. Consequently, the marked decrease in the extent of isomerization of the haloacids having more than 12 carbon atoms may by analogy be related to well-known characteristics of long-chain *n*-alkyl derivatives that have a polar terminus, as found (7) in the formation of micelles or lipid bilayers.

[2]It is less likely that a free radical mechanism is involved, because no halogen atom is introduced at C-2, C-3, and CH_3, whereas these carbons are substituted, e.g., in the free radical chlorination of methyl heptanoate (5) (as kindly pointed out by a referee). Nevertheless, one analogy with the present data is the fact that the major product of this, and related, free radical halogenations (5, 6), is the isomer substituted at the penultimate position.

TABLE 4. Molar ratio of haloacid produced (A) to alkanolactone remaining (L) at different reaction periods with (ca. 37%) HCl

Lactone	Ratio acid/lactone 18 h	65 h
γ-Valerolactone	0.02	—
γ-Caprolactone	0.04	0.04
γ-Octanolactone	0.25	0.38
γ-Nonanolactone	0.38	—
γ-Decanolactone	0.16	0.17
γ-Undecanolactone	0.19	0.23
γ-Octadecanolactone	—	0.10

Reactions of lactones with 38% hydrochloric acid

In marked contrast to the facile conversion of *n*-alkano-γ- or δ-lactones into haloacids by HI or HBr, little reaction occurred under reflux in HCl (37%). As already described for reactions of the other haloacids, the extent of chloroacid formation was estimated by nmr spectroscopy from the relative intensities of the appropriate signals, i.e., those of ^{1}H-C-Cl and ^{1}H-C-O at δ 3.9 and 4.5, respectively (or the corresponding ^{13}C signals). Both γ-valerolactone and γ-caprolactone remained almost unaffected in the HCl solution (Table 4), although the longer-chain lactones gave appreciable yields of chloroacids. This difference parallels the increase in reactivity towards HI and HBr with respect to an increase in the length of the *n*-alkyl chain.

Some rearrangement was also observed, although relatively longer reaction times were required. For example, whereas the 18 h reaction product from γ-octanolactone exhibited mainly one signal (δ 62.80) attributable to ^{13}C-Cl, assumed to be that of C-4, several chloroacids were detected at 65 h. They were represented by peaks at δ 65.44, 63.22, 62.94, and 58.74, in a ratio of 1.1:1:1.2:1.5. By analogy with the other haloacids, the peaks are taken to be those of the 6-, 5-, 4-, and 7-chlorooctanoic acids, respectively, which shows that in this series also the penultimate carbon was the most highly substituted, despite the low overall level of chlorination. Supporting evidence was furnished by data for the carboxyl carbons, which have characteristics similar to those of the other haloacids. Referring again to the 65 h reaction product from γ-octanolactone, its ^{13}C spectrum contained peaks at δ 178.88, 178.67, 178.33, and 177.81, in a ratio of 1.7:1.5:1.2 (in addition to the much stronger lactone peak at δ 177.69) consistent with the presence of four isomeric chloroacids, among which the C-7 isomer was the major species.

Synthesis of-γ-tetra- and-γ-hexa-decanolactone

These syntheses involved the formation, initially, of the appropriate 4-keto-acid, by condensation of succinic anhydride with either decyl or dodecyl magnesium bromide in the presence of cadmium chloride (2, 8, 9). The ketone was reduced with borohydride to the 4-hydroxy-acid which, upon distillation, afforded the γ-lactone (**8**, $n = 9$, or **8**, $n = 11$).

Experimental

Nuclear magnetic resonance spectra were recorded with a Jeol CPF-270 spectrometer operating at 270 MHz for ^{1}H and 67.8 MHz for ^{13}C and (or) a Varian Unity 500 spectrometer operating at

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

500 MHz for ^1H and 125.7 MHz for ^{13}C. The solvent was $CDCl_3$ and chemical shifts are given with respect to TMS. Mass spectra were recorded with a double focusing Kratos MS25RFA mass spectrometer. Chemical ionization mass spectra were obtained with ammonia as the ionization reagent. Hydriodic acid (57%, <0.01% stabilizer) and hydrochloric acid (37%) were obtained from ACP Chemicals. Hydrobromic acid (48%) was obtained from Aldrich Chemical Co. The *n*-alkanolactones of from 8 to 12 carbon atoms were also obtained from Aldrich Chemical Co., whereas the C_{14}, C_{15}, C_{16}, and C_{18} lactones were prepared by slight modifications of established methods. The γ-tetradecanolactone and the γ-hexadecanolactone were obtained from the corresponding 4-ketoacids, whereas the C_{15} and the C_{18} lactones were synthesized by different routes. Representative examples of the lactone preparations and their reactions with haloacids are given below.

4-Keto-tetradecanoic acid

Cadmium chloride (3.27 g, 17.8 mM), previously dried at 120°C, was added to decylmagnesium bromide (Aldrich, 1 M solution in diethyl ether, 33 mL). The reaction mixture was heated to reflux under nitrogen for 45 m. Dry benzene (10 mL + 20 mL) was then added while the ether was distilled off, which was followed by a reflux period of 15 min. Succinic anhydride (3,0 g, 30 mM) was then added, the reaction mixture was heated under reflux for 4 h, and then stirred at room temperature for 18 h. The product, a dark brown paste, was poured onto 65 g of ice and the complex was decomposed with 1 N H_2SO_4. Ethyl ether (150 mL) was added, causing the solid to dissolve, the organic layer was separated, and the aqueous layer was washed with ether (2 × 100 mL). The combined ether fractions were washed with a saturated NaCl solution (2 × 50 mL) and water (50 mL), dried over anhydrous $MgSO_4$, and concentrated. A white solid was obtained, and was recrystallized from ether–hexane; yield 6.14 g (84%); mp 85–86°C; ^{13}C nmr (ppm): 209.1, 178.3, 42.8, 36.8, 31.9, 29.6, 29.4, 29.2, 27.7, 23.8, 22.7, 14.1; ms *m/z*: 242.1877 (M, $C_{14}H_{26}O_3$ = 242.1881). EI-mass spectrum *m/z*: 242, 169, 116, 111, 101, 98, 85, 71, 57, 51, 43. CI-mass spectrum (NH_3 induction) *m/z*: 260 [M + 18], 243 [M + 1], 242 [M].

4-Keto-hexadecanoic acid

The procedure and scale were as above, using dodecyl magnesium bromide (Aldrich). A portion of the crude product (8.1 g, 100%) was recrystallized from ether, mp 82–83°C (lit. (7) mp 91–92°C); ^{13}C nmr (ppm) 209.1, 178.8, 42.8, 36.8, 31.9, 29.7, 29.7, 29.5, 29.5, 29.4, 29.3, 29.2, 27.8, 23.8, 22.7, 14.1; ms *m/z*: 270.2194 (M − $C_{16}H_{30}O_3$ = 270.2181). EI-mass spectrum *m/z*: 270, 253, 197, 116, 111, 98, 85, 71. CI-mass spectrum (NH_3 induction) *m/z*: 288 [M + 18], 271 [M + 1], 253 [M − 17].

*γ-Tetradecanolactone (**8**, n = 9)*

The 4-keto-tetradecanoic acid (1.57 g, 6.5 mM) was stirred in EtOH (20 mL) at 5°C, while a solution of $NaBH_4$ (0.5 g, 13 mM) in 50 mL of 1 N NaOH was added dropwise. The reaction mixture was then stirred at room temperature for a further 3 h, acidified with dilute H_2SO_4, and extracted into CH_2Cl_2 (3 × 75 mL). The organic layer was washed with saturated NaCl solution (2 × 25 mL), dried over anhydrous $MgSO_4$, and concentrated. A white solid was obtained that, on distillation (150–155°C, 0.5 mM), afforded a colorless oil; yield 0.52 g (80%); ir (neat, cm^{-1}): 1773 (C=O); ^1H nmr: 4.5 (m 1H), 2.2–2.6 (m 3H), 1.5–2.0 (m 3H), 1.2–1.4 (s 16H), 0.8–0.10 (t, 3H); ms *m/z*: 226.1987 (M − $C_{14}H_{26}O_2$ = 226.1932); EI-mass spectrum *m/z*: 226, 208, 85, 69, 55. CI-mass spectrum (NH_3 induction) *m/z*: 244 [M + 18], 227 [M + 1].

*γ-Hexadecanolactone (**8**, n = 11)*

4-Keto-hexadecanoic acid was reduced by the same procedure as above. The product was a white solid; yield, 72.5%; mp 38°C (lit. (9) mp 40.7–41.3°C); ir (cm^{-1}): 1751 (C=O); ^1H nmr (ppm): 4.5 (m 1H), 3.45–3.6 (m 2H), 2.2–2.4 (m 1H), 1.5–2.00 (m 3H), 1.2–1.5 (s 20H), 0.8–0.9 (t 3H); ^{13}C nmr (ppm): 177.32, 81.08, 35.59, 31.91, 29.63, 29.53, 29.47, 29.35, 28.88, 28.02, 25.23, 22.68, 14.17; ms *m/z*: 254.2237 (M − $C_{16}H_{30}O_2$ = 254.2257). EI-mass spectrum *m/z*: 254, 236, 85. CI-mass spectrum (NH_3 induction) *m/z*: 272 [M + 18], 255 [M + 1].

*γ-Octadecanolactone (**8**, n = 13) (γ-stearic lactone)*

Prepared according to the method of Clutterbuck (10), the white solid was obtained in 25% yield, mp 45–47°C (lit. (8) mp 52–53°C; yield 30%); ir (film, cm^{-1}): 1751 (C=O), 1195; ^1H nmr: 4.4–4.6 (m 1H), 2.2–2.6 (m 6H), 1.4–1.8 (m 3H), 1.2–1.3 (s 24H), 0.0–0.9 (t 3H); ^{13}C nmr: 177.34, 81.08, 35.59, 31.93, 29.66, 29.53, 29.46, 29.35, 29.07, 28.88, 28.00, 25.23, 27.71, 22.70, 14.12; EI-mass spectrum *m/z*: 282 [M], 129, 97, 85 (major peak), 69, 60, 57, 43, 29.

*5-Hydroxy-γ-pentadecanolactone (**14**)*

This compound was prepared according to ref. 11, in an overall yield from glutamic acid of 43%. All of its spectra were in accord with those reported in ref. 11.

Reactions of the lactones with HI, HBr, and HCl

Representative are the following (the reactions were not protected against light or oxygen):

*Reaction of γ-undecanolactone (5-octyl-dihydro-2(3)-furanone) (**5**) with HI*

A solution of the lactone (0.40 g, 2.11 mM) in HI (57%, 5 mL), containing a suspension of red phosphorus (0.15 g), was heated under reflux for 18 h, and then cooled to room temperature. Saturated aqueous NaCl (5 mL) was added, followed by dichloromethane (50 mL), and the mixture was decolorized with concentrated sodium thiosulfate solution during the extraction. The organic layer was separated, washed with sodium chloride solution (2 × 5 mL), dried over anhydrous $MgSO_4$, and concentrated. A yellow oil was obtained, 0.65 g (95–99% yield), that according to ^1H and ^{13}C nmr spectra (see Tables 1–3) consisted of the lactone (9%) and a mixture of monoiodoundecanoic acids (91%).

*Reaction of γ-undecanolactone (**5**) with HBr*

A solution of the lactone (0.40 g, 2.11 mM) in HBr (48%, 5 mL) was heated under reflux for 18 h. The reaction mixture was worked up as above, with omission of the washing with thiosulfate. A yellow oil was obtained, 0.51 g (80% yield), that according to ^1H and ^{13}C nmr spectra (see Tables 1–3) consisted of the lactone (7%) and a mixture of monobromo-*n*-undecanoic acids (93%).

Reaction of γ-undecanolactone (5) with HCl

A solution of the lactone (0.38 g, 2.1 mM) in HCl (ca. 37%, 5 mL) was heated under reflux for 18 h, followed by work-up as above. A yellow oil was obtained, 0.48 g (99% yield), that according to ^1H and ^{13}C nmr spectra (see Table 4) consisted mostly of the lactone (84%) and a monochloroundecanoic acid (16%).

Estimation of product ratios

Ratios of haloacid produced to unreacted lactone (A:L) were estimated from the relative intensities of the ^1H nmr signals of the methine protons α to the halogen atom (δ ~ 4.2) and the lactone-ring oxygen (δ ~ 4.5), respectively. The ^{13}C nmr spectra were used to estimate ratios of the isomeric haloacids produced, based on the relative intensities of the resonances of the individual substituted carbons (H-^{13}C-X) and (or) of the individual carbonyl carbons. The ^{13}C data reported were obtained with a pulse angle of 40°, pulse delay of 0.80 s, and acquisition time of 1.0 s; comparative measurements of isomer ratios, based on the methine ^{13}C signals of the bromoacid mixture obtained from γ-undecanolactone, varied by a maximum of ~10% for pulse delays ranging from 0.80 to 2.0 s. (No allowance was made for possible variations in nOe values among the methine ^{13}C nuclei, or among the ^{13}CO nuclei.)

Gas–liquid chromatography, which was also examined as a means for product analysis in early experiments in this series (3), proved to be unsatisfactory because it was found that haloacid was readily reconverted into lactone within the chromatograph.

We investigate the energetics of rotation about the C—N bond in formamide at the molecular and atomic levels using the HF/6-31G**//HF/6-31G** level of theory. At the molecular level, the barrier to rotation results from a decrease in overall attractive energies upon rotation away from the planar conformation, primarily due to the lengthening of the C—N bond. At the atomic level, the barrier is due to the loss in interatomic attraction between the nitrogen and its bonded neighbors. We investigate the susceptibility of formamide to electrophilic attack at nitrogen and oxygen as well as nucleophilic attack at carbonyl carbon as a function of C—N bond rotation using the Laplacian model of reactivity. The model predicts the susceptibility to nucleophilic attack at carbonyl carbon to reach a maximum with a O—C—N—H torsional angle of 60°. As a mimic of solvent fields, we investigate the effect of solvation upon these predictions with the application of homogeneous electric fields. This geometry–reactivity relationship is related to proposed models of activation in the enzymatic catalysis of peptides.

KEITH E. LAIDIG et LYNN M. CAMERON. Can. J. Chem. **71**, 872 (1993).

Opérant au niveau HF/6-31G**//HF/6-31G** de la théorie, on a examiné l'énergie de rotation autour de la liaison C—N du formamide aux niveaux moléculaire et atomique. Au niveau moléculaire, la barrière à la rotation est le résultat d'une diminution des énergies globales d'attraction sur la rotation provoquant une déviation par rapport à la conformation planaire et elle est due principalement à une augmentation de la longueur de la liaison C—N. Au niveau atomique, la barrière est due à une perte de l'attraction interatomique entre l'azote et les voisins qui lui sont liés. Faisant appel au modèle laplacien de la réactivité, on a examiné la susceptibilité du formamide aux attaques électrophiles sur l'azote et sur l'oxygène ainsi qu'aux attaques nucléophiles sur le carbone du carbonyle en fonction de la rotation autour de la liaison C—N. Le modèle prédit que la susceptibilité à une attaque nucléophile au niveau du carbone du carbonyle atteint son maximum lorsque l'angle de torsion du O—C—N—H est égal à 60°. Pour représenter les champs de solvant, on a étudié l'effet de la solvatation sur ces prédictions en appliquant des champs électriques homogènes. Cette relation géométrie–réactivité est reliée aux modèles proposés pour l'activation dans la catalyse enzymatique des peptides.

Introduction

As an especially important model in the study of biological systems, there have been a number of investigations into the origin of the barrier to rotation in amides (1). The amide bond (or peptide bond) is the repeating structural unit linking amino acids together to form proteins and the hindered rotation about the C—N bond is responsible for the important secondary structure of polypeptides (2). Formamide is the smallest molecule incorporating this peptide bond and its barrier to rotation and its consequences will be the subject of this paper. We focus on the geometric changes and molecular and atomic energetics during the C—N bond rotation, and link these changes to the reactivity of the molecule.

The explanation for the hindered rotation most widely subscribed to invokes a resonance interaction that stabilizes the planar structure and delocalizes charge from the amide nitrogen to the carbonyl oxygen, schematically depicted in Fig. 1 (3). The contribution of the minor resonance structure on the right creates a double-bond-like character in the C—N interaction, hindering its rotation and inhibiting protonation at nitrogen. Recent studies brought this concept into question (1*a*) by comparing the distribution of electronic charge in the molecule predicted by the resonance model with that determined by theoretical calculation on the molecular and atomic levels, the latter by the application of the theory of atoms in molecules (4). This work and, subsequently, others (1*b*) demonstrated that the carbonyl group changes little during the process and that the dominant interaction is between the carbon and the nitrogen.[2]

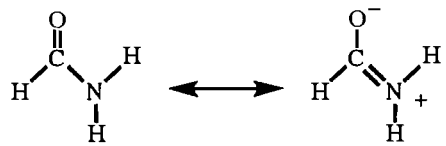

FIG. 1. A graphical depiction of the resonance interaction invoked as the explanation for the hindered rotation about the C—N bond in formamide. The formal charges suggested are the prediction of the resonance model as a result of delocalizing charge from the amide nitrogen to the carbonyl oxygen.

A recent theoretical investigation into the energetics of rotation and inversion processes demonstrated that the changes in the energetic contributions defined within the Hamiltonian could be readily reconciled with the geometric changes the molecule undergoes during these processes, thereby linking the geometrics and energetics in a dramati-

[1]Author to whom correspondence may be addressed.

[2]These conclusions have been contested recently (5*a*), but the arguments presented have been shown to be seriously flawed and without physical basis (5*b*).

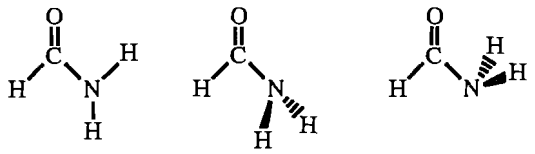

FIG. 2. A graphical depiction of the planar structure, **0**, and the two transition states, **TS(T)**, with its amide hydrogens *trans* to the carbonyl oxygen, and **TS(S)**, with its amide hydrogens *syn* to the carbonyl oxygen.

cally informative manner (6). The authors also briefly discussed the barrier to rotation in formamide, concluding that the molecule preferred the planar conformation as it was able to maximize the attractive energies despite larger repulsive energies. This peptide linkage and its hindered rotation are crucial to the conformational properties of biological systems. Given this, as well as its inherent interest, we have undertaken a detailed study of this rotational process using the same analytical approach, extending previous works by considering conformations throughout the rotation about the C—N bond at both the molecular and atomic levels.

We have employed the Laplacian model of chemical reactivity (7) to investigate the geometry–reactivity relationship during the C—N bond rotation in formamide. The oxygen of formamide is protonated in acidic solutions in favor of the nitrogen (8). Brown and co-workers extended this study to a range of amides in which the C—N bond is increasingly twisted and found that protonation at nitrogen became thermodynamically favored over protonation at oxygen (9). They also found that the C—N bond twisting increased the susceptibility of the carbonyl carbon to nucleophilic attack. We previously showed that the vulnerability to nucleophilic attack in formamide is correlated with the "holes" in the valence shell charge concentration (VSCC) of the carbonyl carbon (10). The rotation of the C—N bond from planarity pyramidalizes the carbon atom, enlarges the hole in the VSCC occupying the tetrahedral position, and leads to the enhanced reactivity of distorted amides. We have extended this to include study of both nucleophilic and electrophilic susceptibility during the bond rotation process. In addition, to mimic and investigate the effect of a solvent field, we have determined the nucleophilic susceptibility of each rotamer in the presence of homogeneous electric fields.

Methodology

We have considered a large number of conformers within the rotation process about the C—N bond in formamide. The planar conformation, **0**, and the two perpendicular transition states, one in which the amide hydrogens are *syn* to the carbonyl oxygen, **TS(S)**, and the other in which they are *trans* to it, **TS(T)** (see Fig. 2), were optimized using the constraint of C_S symmetry at the HF/6-31G** level of theory (11). Both transition states were characterized via the determination of the analytical second derivatives and were each found to possess one imaginary vibrational frequency, the normal coordinate of which would move the atoms towards **0**. The question of which is the transition state for the process under investigation is discussed below. We chose to use SCF procedures without the addition of electron correlation as the SCF wavefunctions generally obey the virial theorem (12) and the energetic contributions to the total energy are well defined.[3] Previous studies using MP2 correlation found barrier heights and conformations quite similar to those predicted here by the SCF procedures (*1b*). We performed multiconfiguration SCF (MCSCF) calculations using the 6-31G** basis with 4815 configurations for both **0** and **TS(T)**, and the resulting wavefunctions consisted of 99% of the ground state configuration in both cases. This demonstrates that this rotational process is primarily a ground state phenomenon and is well represented by our single-determinant SCF calculations. The conformers corresponding to the rotation about the C—N bond were also optimized using the HF/6-31G** basis, constraining only one O—C—N—H torsional angle and allowing all other internal coordinates to relax. In this manner, structures of C_1 symmetry, corresponding to points along the rotation coordinate, were calculated with torsional angles of 20°, 40°, 60°, 80°, and 100°, each referred to by its torsional angle, **20**, **40**, etc. The conformation in which the NH_2 group was held planar and made perpendicular to the carbonyl bond, **90P**, was also determined. The molecular calculations were done using the GAUSSIAN88 program suite (14). The MCSCF calculations were preformed with the GAMESS package (15). The HF/6-31G** wavefunction was used to determine the properties of the charge distribution and the atomic properties using the AIMPAC suite of programs (16).

We restricted ourselves to using energetic terms that are, in the absence of forces upon the nuclei or external fields, the only energetic quantities contained within the usual fixed nucleus Hamiltonian. We will group them into the attractive, or stabilizing, energies (V_a), the nuclear–electron attraction, and the repulsive, or destabilizing, energies (V_r), the sum of the electron–electron and nuclear–nuclear repulsions. These are related, by the viral theorem, to the total energy of the system (12). It should be remembered that the attractive energies are different in sign and that their components cancel one another in the sum to the total energy. In other words, given that the attractive energies are negative in sign, discussion of an increase in attractive energies implies a decrease in the absolute value and, similarly, an increase in the repulsive energies means an increase in its absolute value.

Molecular and atomic energetics

The total molecular energetics and their component parts are listed in Table 1, as are the relative values in comparison with the planar conformation, **0**. The total energy increases smoothly from the planar conformation to **TS(T)**, as do the torsion angles, Fig. 3. The energy change is initially quite small, being less than 1 kcal/mol to **20**, consistent with the very low vibrational frequency associated with out-of-plane torsion of NH_2. Our calculation predicts a frequency of 197.3 cm^{-1} at HF/6-31G**//HF/6-31G** for this mode. From **40** on to **100**, the energy decreases with roughly the same rate of change, a decrease of roughly 4.580 kcal/mol in the total energy for each 20°. From **100** on, the energy decreases much more slowly until **TS(T)** is reached, 18.665 kcal/mol above **0**. The conformation **90P** was pre-

[3]This is not necessarily the case with correlated methods. For example, there is no unique definition of a density matrix within the many-body perturbation series from which to calculate the molecular properties. See the appendix in ref. 13.

[a]The conformers are listed by the O—C—N—H torsional angle.
[b]The energies listed are the total, E, the attractive, V_a, the repulsive, V_r, and total potential energies, V, for each conformer. They have been corrected for the virial defect and are listed in atomic units.
[c]The relative total energies are taken with respect to the planar conformation and are listed in kcal/mol.
[d]The relative energies are taken with respect to the planar conformation and are listed in atomic units.

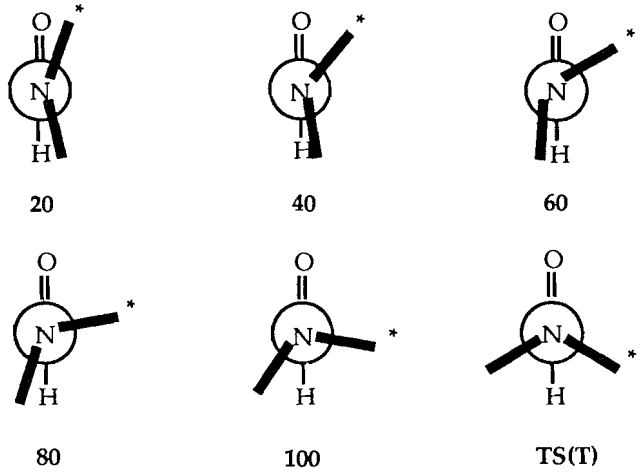

FIG. 3. The conformation rotamers during the C—N bond rotation, in which the N—H bonds are drawn with bold lines. The N—H that was constrained during the geometric relaxation is marked with an asterisk. The torsional angles are accurately depicted.

dicted to be 22.560 kcal/mol above the planar conformation and is not along the reaction coordinate.

The second transition state, **TS(S)**, is less destabilized than **TS(T)**, being 15.973 kcal/mol above **0**. This is the transition state used as the starting point of the potential energy surface walk of Wiberg and Breneman in their study of the rotation coordinate (1*b*). We were unsuccessful in our attempts to find **TS(S)** along the path of C—N rotation using the constrained approach discussed above. The change in O—C—N—H torsional angles in the coordinate walk of Wiberg and Breneman was not smoothly synchronous, having a large jump in one O—C—N—H torsion as the planar conformation was neared. The non-synchronicity of the internal coordinate change suggests that they are the result of a higher energy reaction coordinate and not the lowest energy pathway (17). Given the smooth synchronous change in internal coordinates and energies between **0** and **TS(T)**, we shall use it as the transition state in our C—N bond rotation study.

The geometric parameters change at rates in parallel with the changes in total energy, Table 2. As noted in other works, the C—O bond changes little along the reaction coordinate, shortening 0.014 Å by the transition state (1*a*). The C—N bond changes by five times as great an amount over the reaction coordinate, 0.073 Å, with a lengthening of roughly 0.015 Å per 20° C—N rotation, between **20** and **100**. Both N—H bonds lengthen slightly, as nitrogen pyramidalizes, while the C—H bond lengthens a similar amount. The bond angles involving N and H show the ever-increasing pyramidalization of N as the coordinate approaches the transition state.

As listed in Table 1, the energy changes can be broken into changes in the molecular attractive and repulsive potential energies, which, by virtue of the virial theorem, are related to the changes in the total energy. The energetic barrier to the C—N bond rotation is dominated by the decrease in attractive energy in the molecule. There is also a decrease in the repulsive energies of the system, but this is overcome by the loss in attraction and the system is destabilized. This loss in attraction is largely the result of the increase in the C—N interatomic distance with much smaller contribution from the increase in C—H and N—H distances. The decrease in the C—O bond length results in a gain in attractive energy during rotation, but as the C—O decrease is much smaller, so the attractive energy contributed is much smaller. Thus the barrier to rotation in formamide is the result of a loss in attractive energies due to the C—N bond lengthening during the process.

The atomic interactions are summarized in a quantitative manner by the properties of the charge density at the bond critical point between the two interacting atoms (18). The properties at the bond critical points between the pairs C—O and C—N are listed in Table 3. The C—N interaction decreases during the rotation, the magnitude of electronic charge dropping by roughly 10%. For C—O, the strength of interaction increases during rotation by roughly 2%. Both changes are in accord with expectations based upon the change in the bond lengths, the former bond lengthening by roughly five times the amount that the latter shortened. The large value of the charge density combined with the positive Laplacian at the bond critical point of C—O indicates an intermediate interaction. The depletion of charge in the interatomic region increases during the rotation, signalling the slowly increasing ionic character of the interaction. The negative

[a]The bond lengths are in angstroms and the bond angles and torsional angles are in degrees.
[b]The conformers are listed by O—C—N—H torsional angle, see text for definition.
[c]The hydrogen is fixed so as to define the O—C—N—H torsional angle.
[d]The pyramidalization of the carbonyl carbon is quantified by the angle between the C—H bond and the O—C—N plane.

[a]These are the properties of the charge density at the (3,−1) critical point between the two atoms, listed in atomic units.

Laplacian at the C—N critical point signals a shared, or covalent, interaction. The decrease in the absolute value of this during the rotation process indicates an increase in the concentration of charge between the two atoms. As the ability of the increasingly pyramidal nitrogen to withdraw charge from carbon decreases, the interaction becomes more and more evenly shared between the two atoms. The shortening of the C—O bond length increases the dominance of the oxygen atom on the interaction, while the lengthening of the C—N bond results in a more evenly shared interaction between the two.

The theory of atoms in molecules predicts the properties of atoms in the same way as the properties for the entire molecule (4). The atomic energetics are listed in Table 4 for all the rotamers. To briefly review the atomic properties, discussed previously (*1a*), on going from **0** to **TS** the changes in the atomic energy and population are much smaller for oxygen than for either carbon or nitrogen. The nitrogen atom shows the largest changes between **0** and **TS(T)**, losing population (−0.261 e) and becoming destabilized (+158.133 kcal/mol) as it pyramidalizes. The carbon gains population (+0.200 e) and is stabilized by a comparable amount (−90.989 kcal/mol). In contrast, the oxygen is relatively unchanged, losing a small amount of charge (−0.075 e) and becoming slightly more stable (−3.138 kcal/mol). This transformation is predicted by a simple hybridization model; the pyramidalizing N atom is less electronegative (it has less "s character"), loses charge to all its bonded neighbors during rotation, and is destabilized because of this.

We can attribute the changes in molecular energetic contributions to the total energy to changes within individual atoms. The nitrogen atom's contribution to both the attractive and repulsive energy decreases in magnitude during the rotation. The decrease in the atomic attraction energy $V_a(N)$ is greater than the decrease in the atomic repulsion energy $V_r(N)$, thus the atom is destabilized. In contrast, the carbon atom is stabilized by a larger increase in $V_a(C)$ than in $V_r(C)$. The oxygen atom is stabilized by the slightly greater decrease in repulsion energy over the decrease in attractive energies. Overall, the destabilizing loss in attractive energies for the nitrogen atom dominates the other atomic energy changes and is the origin of the barrier to rotation in formamide.

The amount of the total atomic attraction energy coming from the attraction of the nucleus to the electronic charge within its own atomic basin, the atomic value of $V_{neo}(\Omega)$ is also listed in Table 4. This "self-stabilization" of the atom

[a]All values are listed in units of 10^{-3} au.
[b]The O—C—N linkage remains roughly within the *XY* plane during the rotation process.
[c]The listed value is one of the two symmetrically related maxima in the VSCC of N, one on either side of the molecular plane.
[d]The two maxima on either side of the N VSCC are not equal, the first being *syn* to the O.
[e]This maxima is *syn* to the NH_2 group.
[f]The hole labeled "h_1" is *syn* to the "lone pair" in the VSCC of N.

can be used to determine if the change in attractive energy is due to inter- or intra-atom interaction. The loss in $V_{neo}(N)$ for nitrogen during rotation is 26.6% of the total loss in attractive energy, suggesting that the major portion of stabilization loss is due to a decrease in interatomic interaction. For carbon, the stabilization from $V_{neo}(C)$ is 45.6% of the total stabilization, gaining roughly half of its stabilization from the gain in charge within its basin. Similarly, the loss in attractive energies for the oxygen atom is due to a 48.3% loss of $V_{neo}(O)$. So, the rotational barrier is dominated by a loss of attractive energies between nitrogen and its bonded neighbors during its pyramidalization.

Molecular reactivity

The susceptibility of oxygen and nitrogen to electrophilic attack is predicted by the magnitude of the Laplacian at the nonbonded maxima in the VSCC of the two atoms (4). These entities are the physical manifestation of the chemical concept of "lone pairs" and their size and extent are the physical basis for the Lewis and VSEPR models of chemistry (19). The values of the charge concentration at the maxima in the VSCC of both oxygen and nitrogen are listed in Table 5 for each of the rotamers along the reaction coordinate. The nonbonded maximum in the VSCC of nitrogen steadily increases from the planar to the transition state, increasing the predicted susceptibility to electrophilic attack. The planar nitrogen has two symmetrically related maxima on either side of the molecular plane, but by **20** there is only one maximum, found roughly in the tetrahedral position. This charge concentration increases until a maximum is reached at **100** and then decreases slightly to **TS(T)**. The two nonbonded maxima in the VSCC of the oxygen both increase during the rotation from **0** to **TS(T)**. The nonbonded maximum *syn* to the NH_2 group starts out smaller than the *anti*, but as the C—N rotation reaches **80** the maxima values become nearly the same and remain similar until **TS(T)** is reached. The magnitude of the VSCC in nitrogen increases by 54.9% during the rotation while the oxygen VSCC increases by only 10%.

The susceptibility of the carbonyl carbon to nucleophilic attack is predicted by the magnitude of depletion of charge at the hole in the atom's VSCC. These are the regions of greatest *depletion of charge* in the VSCC about the carbon atom and thus the favored pathway for nucleophilic attack (4, 10). An important consequence of rotation is the slight pyramidalization of the carbonyl carbon away from the constrained N—H bond, O—C—N—(H) torsion angle in Table 2, reaching a maximum of 6.7° out of the O—C—N plane at **60**. We have depicted the minima of the VSCC of the carbonyl carbon in a plane orthogonal to the O—C—N plane in Fig. 4. The magnitude of charge depletion in the VSCC of the carbonyl carbon is also listed in Table 5 and graphed versus torsion angle in Fig. 5. As noted previously (10), the charge depletion in the VSCC *syn* to the nonbonded maximum on nitrogen (h_1) increases in parallel with the degree of pyramidalization of the carbonyl carbon, Table 2. Both reach a maximum near **60** (the change in the VSCC of carbon is depicted in Fig. 4*b*) and then decrease as the transition state is reached, with the depletion being less than in the planar structure. Similarly, the charge depletion *anti* to the nitrogen maximum and *syn* to the hydrogens of NH_2 (h_2) decreases to a minimum in the region of **60–80** and then increases. This model predicts that the susceptibility towards nucleophilic attack at carbonyl carbon, *syn* to the nitrogen "lone pair," reaches a maximum in the vicinity of **60** and then decreases as the C—N bond is rotated further.

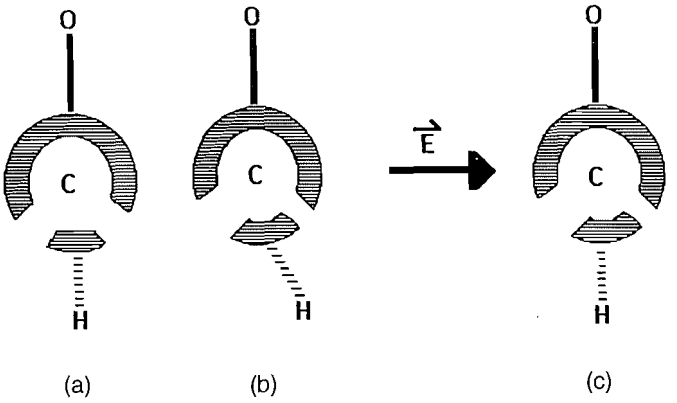

FIG. 4. A depiction of the VSCC (the dashed regions around C) of the carbonyl carbon in a plane perpendicular to the O—C—N plane and containing the holes in the valence shell. Figure 4*a* is the VSCC in the planar conformation, **0**; 4*b* depicts the reorganization of the VSCC of the carbonyl carbon after it has pyramidalized during C—N bond rotation; 4*c* depicts the reorganization of the VSCC under the influence of an electric field applied perpendicularly to the O—C—N plane. Notice that the internal fields (due to atomic motion) and the external fields yield the same changes within the VSCC.

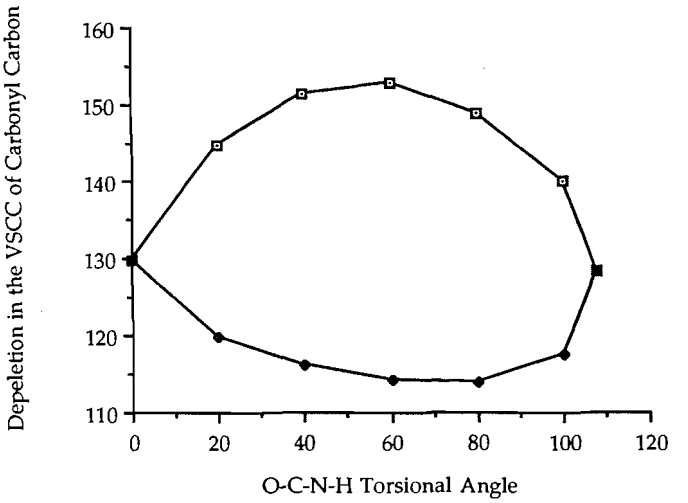

FIG. 5. This graph depicts the depletions in the VSCC of the carbonyl carbon as a function of torsion along the reaction coordinate; h_1, ⊡; h_2, ◆.

There has been some concern as to the stability of the predicted values of the Laplacian in the valence shell of carbonyl carbon to the effects of solvent or an approaching reacting molecule. To address this, we mimicked the effect of an external field upon these predictions by applying homogeneous electric fields to each rotamer along the reaction coordinate as a first-order approximation to the Onsager reaction field (20). The charge depletion at the holes in the resulting VSCC of the carbon are listed in Table 5. For the field orthogonal to the O—C—N plane, both positive and negative, the correlation between the pyramidalization of the carbonyl carbon and the charge depletion is kept. For example, the application of +0.01 au along the *Z* axis (roughly perpendicular to the molecular plane) results in a decrease in the charge depletion at the VSCC hole *syn* to the nitrogen maxima during the C—N bond rotation. This is the result of the reorganization of the valence shell of the carbonyl carbon under the influence of the electric field and is depicted in Fig. 4*c*, and demonstrates that the differences in the depletion on the two sides of the carbonyl carbon are physically significant and resistant to perturbation by external fields or reactant molecules. In addition, the systematic changes in the charge depletion when perturbed by applied electric fields show that the VSCC and its critical points respond in a physically reasonable manner.

Discussion

Proteases catabolize proteins by catalytic hydrolysis of the peptide bonds (21). One proposed mode for the activation of the peptide bond is the addition of strain and distortion to the peptide linkage at the protease active site (22). This mechanism is believed to involve either the distortion of the NH_2 away from planarity or the direct pyramidalization of carbonyl carbon by the nucleophilic characteristics of the active site. In both cases, the induced strain is proposed to raise the energy of the peptide linkage, effectively reducing the barrier to hydrolysis. Brown and co-workers synthesized a variety of distorted amides with fixed pyramidalization of nitrogen and studied their relative rates of hydrolysis in acidic media (9). These experiments reveal that the degree of nitrogen pyramidalization is directly related to the increasing N—C(O) bond length and that the more distorted the amide, the faster it is hydrolyzed. This distortion of the amide from its favored planar structure was proposed to result in an activation of the peptide bond, producing a system that is closer in energy to the hydrolysis transition state. Quite recently, Krug et al. undertook a detailed theoretical analysis of the acid, neutral, and base hydrolysis mechanisms of peptides (23). They concluded that the key feature of the hydrolysis mechanisms is the lengthening and weakening of the C—N bond, which follows the pyramidalization and (or) protonation of the amide nitrogen.

Our results strongly support these findings. We find that rotation about the C—N bond results in a weaker C—N interaction and, consequently, a longer bond. The increased C—N distance causes a large loss in the stabilizing attractive energy for the nitrogen atom. To maximize the self-stabilization within its own basin, nitrogen pyramidalizes, further decreasing its interaction with its bonded neighbors and increasing its susceptibility to electrophilic attack. Although the C atom gains charge during this process it pyramidalizes slightly to maximize its self-stabilization and minimize its interaction with nitrogen. The valence shell of carbon reorganizes during its pyramidalization, resulting in an increased depletion, or enlargement of the hole in the VSCC opposite the N—H bonds, and thus making it more susceptible to nucleophilic attack. This mode of activation or increased susceptibility may come about from either the rotation about the C—N bond or, more directly, from the pyramidalization of carbonyl carbon by the local environment.

Conclusion

We have presented a detailed energetic analysis of the barrier to rotation in formamide at both the molecular and atomic levels. The energetic barrier results from a loss of attractive energies, despite decreases in repulsive energies, due to the lengthening of the C—N bond as nitrogen py-

For personal use only.

ramidalizes. At the atomic level, the destabilization is dominated by the loss in interatomic attraction between the nitrogen and its bonded neighbors. The pyramidalization of nitrogen decreases its effective electronegativity, allowing its bonded neighbors to withdraw charge from it. The energetic stabilization gained by pyramidalization of N is large and determines the lowest energy pathway away from the planar conformation towards the transition state during the C—N rotation. We have also investigated the relationship between the geometrical changes and molecular susceptibility to electrophilic and nucleophilic reactivity. We found that the susceptibility to nucleophilic attack reached a maximum at the structure **60** and then decreased on to the **TS(T)**. The quantitative predictions made by the Laplacian model of reactivity were shown to be robust in the face of applied electric fields and the magnitudes of the depletion in the VSCC of the carbonyl carbon changed in readily understood ways. Our results were shown to be consistent with proposed models of enzymatic hydrolysis in peptides in that distortion around the carbonyl leads to enhanced susceptibility. We also found that our observations agree with solvolytic studies of strained amides and theoretical investigations of hydrolysis mechanisms.

Synthesis of diaminodideoxyalditol analogs of cisplatin as antitumor agents

S. HANESSIAN,[1] J.-Y. GAUTHIER, K. OKAMOTO, A.L. BEAUCHAMP, AND T. THEOPHANIDES
Department of Chemistry, Université de Montréal, Montréal (Québec), Canada H3C 3J7

Received November 27, 1992

S. HANESSIAN, J.-Y. GAUTHIER, K. OKAMOTO, A.L. BEAUCHAMP, and T. THEOPHANIDES. Can. J. Chem. **71**, 880 (1993).

Acyclic vicinal polyol complexes related to cisplatin were synthesized from D-mannitol by stereocontrolled manipulation of the hydroxy groups. Controlled cleavage of a 3,4-diazido hexitol gave the corresponding D-threitol and D-xylitol analogs, which were converted to their diamino platinum complexes. The antitumor activity of these compounds is reported.

S. HANESSIAN, J.-Y. GAUTHIER, K. OKAMOTO, A.L. BEAUCHAMP et T. THEOPHANIDES. Can. J. Chem. **71**, 880 (1993).

Des dérivés acycliques de diamino polyols vicinaux ont été synthétisés à partir du D-mannitol en utilisant des méthodes de transformations stéréocontrôlées. Le clivage sélectif du dérivé 3,4-diazido hexitol a donné les analogues correspondants du D-threitol et du D-xylitol. Les diamines ont été transformées en complexe de platine et l'activité antitumorale des complexes est rapportée.

Two decades after its discovery (1), *cis*-diammine dichloroplatinum(II) (cisplatin) and its structural variants (for recent reviews, see ref. 2) remain as one of the most widely used group of oncolytic drugs against a variety of cancers (3) (Fig. 1). To date, well over 1000 analogs of cisplatin have been synthesized and examined for antitumor activity, particularly against cancer of the testes, ovaries, bladder, head, and neck. Concurrently, the molecular mechanism of action of cisplatin has been the subject of intensive studies (4). The drug has been shown to bind covalently to chromosomal DNA in the cell nucleus, thus inhibiting replication (5). The site of most stable binding is at the N-7 position of guanine in the DNA, which results in the weakening of hydrogen bonding of the base pairs and the inevitable unwinding of the double helix (6).

In spite of its dramatic success in the treatment of certain types of cancer (7), cisplatin has a number of drawbacks that present difficulties in its continued use. Toxicity of several types (8), narrow range of activity, cross-resistance, and lack of solubility are among the more serious limitations. A number of derivatives in which the dichloro ligands have been changed to other anionic groups (e.g., 1,1-cyclobutanedicarboxylato (carboplatin)) (9) have shown reduced toxicity, presumably due to better pharmacokinetic properties. Several other second and third generation platinum complexes are known (2, 3).

We wish to report on the synthesis and antitumor properties of a series of stereochemically defined, novel platinum complexes derived from a diaminotetritol, -pentitol, and -hexitol, having the generalized structure shown in Fig. 1. After our work was completed a report of cisplatin analogs of 2,3-diamino-2,3-dideoxy-1,4-di-*O*-methyl-D- and -L-threitol was published by Haines *et al.* (10). Other examples of chiral or racemic diaminoalcohol complexes of platinum are found in the patent literature (11).

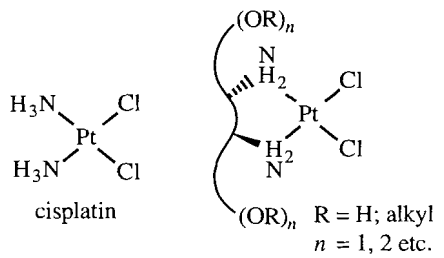

FIG. 1

The design of our alditol-derived platinum analogs took into consideration the distinctly superior activity of cisplatin compared to the *trans* isomer (1). Our synthetic plan took advantage of the C_2 symmetrical properties of D-mannitol and the possibility of preparing *trans*-oriented vicinal diaminodideoxy derivatives therefrom. As shown in Scheme 1, a double nucleophilic displacement of the crystalline dimesylate derivative **2**, employing tetra-*n*-butyl ammonium azide in toluene (12), gave the pivotal diazido derivative **3** as a syrup. The yield of **3** was lower when DMF or DMSO was used in the presence of sodium azide. Hydrolysis of the acetal functions led to the corresponding tetrol **4**, which was methylated in the usual way to give **5**. Hydrogenation of **4** and **5** individually, followed by treatment of the corresponding diamino derivatives with dipotassium tetrachloroplatinate, gave the crystalline complexes **6** and **7**, respectively. The double inversion of configuration in the displacement of **2** with azide ion was anticipated in the absence of neighboring group participation. The structure of **6** was unequivocally confirmed by single crystal X-ray analysis (see below).

With the availability of the diazidohexitol **4**, we could now address the problem of a single and double cleavage of the terminal vicinal glycol units in order to obtain four- and five-carbon diamino cisplatin polyols, respectively. The diazidohexitol **4**, when treated with 1 equivalent of sodium metaperiodate at 0°C, followed by reduction of the corresponding lactol, gave the diazidodideoxy-D-xylitol derivative **8** in good overall yield. Hydrogenation of **8** followed by formation of the platinum(II) complex gave **9** as bright yellow crystals.

Oxidation of **4** with 2 equivalents of sodium metaperiodate at 0°C, followed by reduction with sodium borohydride, gave the crystalline diazidodideoxy-D-threitol derivative **10**. Hydrogenation and treatment of the resulting diamino compound with dipotassium dichloroplatinate afforded the crystalline platinum(II) complex **11**. A number of other di-*O*-alkyl and mono-*O*-alkyl Pt(II) derivatives in this series were also prepared, and were obtained in crystal-

line form. All the complexes described were water soluble at concentrations ranging from 4 to 10 mg/mL at 25°C. The interaction of several of the diaminopolyol platinum(II) complexes reported here with guanosine, 5′-GMP, and 3′-GMP has been studied by FT-IR and ^{1}H NMR spectroscopy (13).

X-ray crystallographic analysis of compound **6**

Compound **6** crystallized as yellow plates belonging to space group $C222_1$ (polymorph I). A small amount of another polymorph, II (space group $P2_12_12_1$), appeared as yellow needles upon recrystallization from water. The crystal data and refined coordinates are listed in Tables 1 and 2, respectively.

Both crystalline modifications contain the monomeric square-planar *cis*-$PtCl_2$(L–L) complex. Molecule *c* (polymorph II) is shown in Fig. 2. The Pt atom and the middle of the C(3c)—C(4c) bond lie on an approximate twofold axis bisecting the N—Pt—N and Cl—Pt—Cl angles. Coordination is very similar in the two independent types of molecules (*a* and *b*) in polymorph I (drawings in supplementary material), but in these cases the twofold axis is imposed by crystallographic symmetry. Individual distances and angles are provided as supplementary material.[2] The mean Pt—Cl and Pt—N distances (2.32 and 2.03 Å, respectively) compare well with those found in $PtCl_2N_2$ systems with related ligands. The "bite" of the diamine reduces the N—Pt—N angle to 83.8° with a concomitant increase of the Cl—Pt—Cl angle to 94.5°, as found in other diamines forming five-membered chelate rings (14). The puckered chelate ring has the δ conformation (N—C—C—N = 45–56°). The $PtCl_2N_2$ unit is planar with 1σ for molecules *a* and *c*. In molecule *b*, the atom-to-plane distance reaches 0.20(4) Å, the $PtCl_2$ plane being twisted by 9.2° about the twofold axis with respect to the PtN_2 plane. The three independent molecules adopt different conformations of their -CH(OH)-CH_2OH "arms". This likely results from molecular packing, which is largely controlled by hydrogen bonding between water, coordinated chloride, and ligand -OH and -NH_2 groups.

Antitumor activity

The hydroxy analogs **6**, **9**, and **11** showed significant in vitro activity against sensitive strains of L1210 leukemia and P388 with ID_{50} values ranging between 2 and 4.45 μg/mL (cisplatin showed 0.25 μmL) (15). In vivo tests (subcutaneous and intravenous) against PU-239 showed levels of activity approaching that of cisplatin. In vivo test results with M5076 sarcona were inferior to cisplatin.

The *O*-methyl analog **7**, as well as *O*-methyl analogs of **9** and **11** (16), also showed significant in vitro and in vivo antitumor activity against several tumor lines. In vitro tests against sensitive *and* resistant strains of L1210 leukemia showed ID_{50} values of 6–15 μg/mL). The same trend was observed in vivo with values of ID_{50} 13–30 μM for the *O*-methyl analogs with good resistant/sensitive ratios compared to cisplatin (0.8 sens. and 9.9 resist. μM). In vitro activity was demonstrated by **7** and related *O*-methyl analogs of **9** and **11** (15) against P388 (sensitive and resistant with values ranging from 15 to 28 μg/mL (compare cisplatin with 0.25–485 μg/mL). The ratio activity of the *O*-methyl analogs resistant and sensitive strains is an interesting observation that indicates a potential for better cross-resistance.

Although more detailed biological studies are still required, the promising antitumor activity exhibited by these stereochemically well-defined, novel platinum(II) complexes derived from diaminodideoxy alditols should open newer avenues to explore in this important area of cancer chemotherapy.

SCHEME 1

Experimental

Melting points (mp) were determined on a Fisher–Johns apparatus and they are uncorrected. Optical rotations were measured at 25°C using a Perkin–Elmer model 241 automatic polarimeter. Chromatography was done on silica gel (Merck) according to Still et al. (17). Combustion analyses were done at Guelph Laboratories, Ltd., Guelph, Ontario.

*1,2:5,6-Di-*O*-isopropylidene-3,4-di-*O*-methanesulfonyl-*D*-mannitol (**2**)*

A solution of 1,2:5,6-di-*O*-isopropylidene-D-mannitol (25 g, 95 mmol) in dry methylene chloride (430 mL) and triethylamine (32 g, 0.3 mmol) was treated with methanesulfonyl chloride (26.6 g, 0.233 mmol) dropwise at 0°C under nitrogen atmosphere. After allowing the mixture to warm up to room temperature, it was washed abundantly with cold distilled water, and the organic phase was dried (sodium sulfate) and evaporated under vacuum. The resulting crude solid was recrystallized from a mixture of hot methanol and water to afford 34 g (85%) of long white needles, mp 142–143°C; $[\alpha]_D$ −5.3 (*c* 1, $CHCl_3$). Anal. calcd. for $C_{14}H_{26}O_{10}S_2$: C 40.19, H 6.22; found: C 40.11, H 6.02.

*3,4-Diazido-3,4-dideoxy-1,2:5,6-di-*O*-isopropylidene-*D*-iditol (**3**)*

To a solution of **2** (12 g, 28.7 mmol) in dry toluene (300 mL) was added sodium azide (50 g, 25 equiv.) and tetrabutylammonium chloride (25 g, 3 equiv.). The mixture was heated at reflux temperature under mechanical stirring for 16 h, poured into ice-water (500 mL), and extracted with ethyl acetate. The organic extract was washed with brine, dried over sodium sulfate, filtered, and evaporated. Chromatography of the residue on silica gel (40:2 toluene–acetone) afforded a pale yellow syrup (5.12 g, 57%), which when sublimed at 110°C (0.3 Torr; 1 Torr = 133.3 Pa) gave a low-melting crystalline product; $[\alpha]_D$ +130 (*c* 1, $CHCl_3$). Anal. calcd. for $C_{12}H_{20}N_6O_4$: C 46.15, H 6.41, N 26.92; found: C 45.92, H 6.22, N 26.86.

*3,4-Diazido-3,4-dideoxy-*D*-iditol (**4**)*

A solution **3** (1.32 g, 4.2 mmol) in a mixture of acetic acid (25 mL) and water (13 mL) was heated at 80°C for 75 min. Evaporation gave a dark-brown syrup that was dissolved in methanol and treated with activated charcoal. The pale yellow filtrate was evaporated to dryness to give a chromatographically homogeneous syrup (895 mg, 91%). A portion was crystallized from a mixture of ethyl acetate and hexanes, mp 87–88°C; $[\alpha]_D$ −124 (*c* 1, H_2O). Anal. calcd. for $C_6H_{12}N_6O_4$: C 31.03, H 5.20, N 36.19; found: C 31.21, H 5.13, N 35.94.

*3,4-Diazido-3,4-dideoxy-1,2:5,6-tetra-*O*-methyl-*D*-iditol (**5**)*

A solution of **4** (500 mg, 2.15 mmol) in dry *N*,*N*-dimethylformamide (7.5 mL) was transferred to a round-bottom flask containing sodium hydride (1.037 g, 20 equiv.) in dry *N*,*N*-dimethylformamide (5 mL) at 0°C under nitrogen atmosphere. Upon ceasing of the effervescence, methyl iodide (3.05 g, 10 equiv.) was added dropwise. The reaction mixture was then stirred at 0°C for 1 h, and neutralized with methanol followed by 1 N sulfuric acid. The mixture was evaporated, dissolved in chloroform (50 mL), and washed with distilled water and saturated sodium thiosulfate solution. The organic extract was dried (sodium sulfate) and evaporated under vacuum, and the resulting syrup chromatographed on silica gel (35:65 ethyl acetate – hexanes) to afford the pure product as a colorless syrup (554 mg, 89%); $[\alpha]_D$ 188 (*c* 1, $CHCl_3$).

*3,4-Diamino-3,4-dideoxy-*D*-iditol*

To a solution of **4** (406 mg, 1.75 mmol) in methanol (30 mL) and distilled water (5 mL) was added 10% palladium-on-charcoal (150 mg) suspended in water (5 mL). The mixture was hydrogenated under atmospheric pressure at room temperature for 12 h; the catalyst was then removed by filtration through Celite, washed with distilled water (~5 mL), and the filtrate was evaporated to dryness from absolute ethanol several times. A white solid was obtained (302 mg, 85%); recrystallization form hot ethanol – water afforded colorless needles, mp 160–161°C; $[\alpha]_D$ −104 (*c* 1, H_2O). Anal. calcd. for $C_6H_{16}N_2O_4$: C 40.00, H 8.89, N 15.56; found: C 39.87, H 8.66, N 15.01.

*(SP-4-2)-Dichloro(3,4-diamino-3,4-dideoxy-*D*-iditol-*N*,*N*′) platinum (**6**)*

The preceding diaminopolyol (487 mg, 2.7 mmol) in 2 mL of water was added to a solution containing K_2PtCl_4 (1.124 g, 2.7 mmol) in distilled water (12 mL). The mixture was stirred manually until it became homogeneous, and the solution was left standing in the dark. After 2 h bright yellow plates were obtained

and the crystallization was allowed to continue until the original red color of the solution became yellow or orange-yellow. The crystals were filtered, washed with cold water (2–3 mL), and dried in the absence of light, to afford bright yellow crystals (565 mg), mp 226–229°C (gradual darkening at 190°C); $[\alpha]_D$ 6.3 (*c* 0.4, H_2O). Concentration of the mother liquors in vacuo (50°C) yielded a second crop of **6** (91 mg). Anal. calcd. for $C_6H_{16}N_2O_4PtCl_2 \cdot H_2O$: C 15.52, H 3.90, N 6.03, Cl 15.27; found: C 15.41, H 3.58, N 6.11, Cl 15.03.

The procedure described above yielded yellow plates belonging to space group $C222_1$. By recrystallization from water, the same crystalline phase was obtained as the major component, but the sample also contained a small amount of yellow needles, which were identified as a second crystalline modification of the same compound with space group $P2_12_12_1$. X-ray work was carried out on both polymorphs (see below).

*2,3-Diazido-2,3-dideoxy-D-threitol (**10**)*

To a solution of **4** (500 mg, 2.15 mmol) in distilled water (10 mL) was added solid sodium metaperiodate (925 mg, 4.32 mmol) portionwise at 0°C, in the absence of light. The mixture was stirred for 2 h, and sodium borohydride (0.9 g) was added. After 2 h at 0°C, the solution was acidified with 1 N sulfuric acid, decolorized with sodium thiosulfate, and evaporated under vacuum. The residue was dissolved in water (25 mL) and extracted with ethyl acetate (5 × 40 mL); the combined organic extracts were decolorized

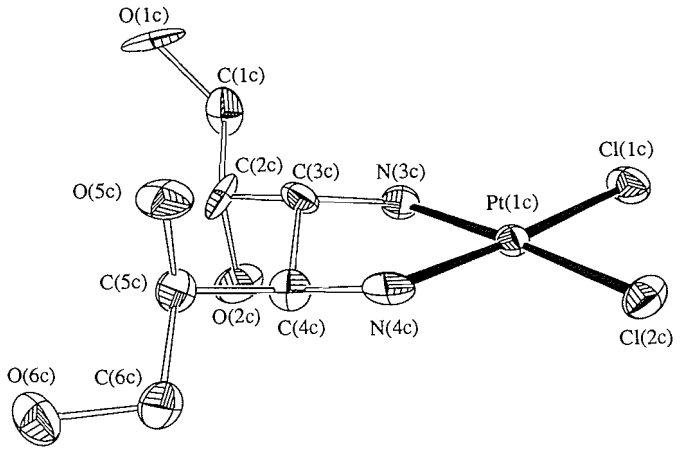

FIG. 2. ORTEP drawing of molecule *c* in polymorph II. Ellipsoids correspond to 50% probability. Hydrogens are omitted for simplicity. Drawings for the two independent molecules (*a* and *b*) of polymorph I are provided in the supplementary material.

with sodium thiosulfate, dried, and evaporated under vacuum to afford a colorless oil (390 mg, 95%). Thin-layer chromatography of the oil showed the presence of diol and triol in equal proportions. The product was recycled through the oxidative cleavage and the reduction as described above, and the reaction mixture was processed to afford the diol **10** in the form of white crystals. Recrystallization from chloroform–hexanes yielded 303 mg (82%) of product, mp 78–79°C; $[\alpha]_D$ +41.4 (*c* 0.5, MeOH). Anal. calcd. for $C_4H_8N_6O_2$: C 27.91, H 4.65, N 48.84; found: C 27.62, H 4.44, N 48.53.

2,3-Diamino-2,3-dideoxy-D-threitol

To a solution of the diazide **10** (487 mg, 2.83 mmol) in methanol – distilled water (1:1, 20 mL) was added palladium-on-charcoal (300 mg) suspended in methanol (5 mL). The mixture was hydrogenated under atmospheric pressure at room temperature for 12 h. The catalyst was then removed by filtration over Celite, and the filtrate was evaporated under vacuum. The residue was co-evaporated with ethanol to dryness to afford a colorless syrup (333 mg, 98% yield); $[\alpha]_D$ −151 (*c* 1, H_2O).

*(SP-4-2)-Dichloro(2,3-diamino-2,3-dideoxy-D-threitol-N,N′) platinum (**11**)*

The previous diamino derivative was dissolved in distilled water (0.7 mL) and added to a solution containing K_2PtCl_4 (1 equiv.) in distilled water (4.4 mL for 1 mmol). The mixture was stirred manually until it became homogeneous, and the solution was left standing in darkness. After 2 h, bright yellow crystals were formed. When the original red color of the solution became yellow or orange-yellow, the crystals were filtered, washed with cold water (1–2 mL), and dried under air suction in the absence of light for several hours, to afford bright yellow crystals (yield 60%), mp > 300°C; $[\alpha]_D$ −94 (*c* 0.083, H_2O). Anal. calcd. for $C_4H_{12}N_2O_2PtCl_2$: C 12.47; H 3.12, N 7.27, Cl 18.18; found: C 12.60, H 3.13, N 7.22, Cl 18.60.

*2,3-Diazido-2,3-dideoxy-D-xylitol (**8**)*

To a solution of **4** (1 g, 4.3 mmol) in distilled water (25 mL) was added sodium metaperiodate (920 mg) in distilled water (10 mL), portionwise at 0°C, and in the absence of light. The mixture was stirred 90 min at 0°C, then it was treated with sodium borohydride (1.75 g) in distilled water (20 mL). After 1 h, the reaction was acidified with 1 N sulfuric acid, decolorized with a few millilitres of saturated sodium thiosulfate, and evaporated under vacuum. The residue was dissolved in water (25 mL) and extracted with ethyl acetate (5 × 100 mL). The combined organic extract was decolorized with sodium thiosulfate, dried, and evaporated under vacuum

For personal use only.

and the residue was chromatographed on silica gel (85:15 ethyl acetate – hexanes) to afford the triol **8** (577 mg; 66% yield); $[\alpha]_D$ −239 (*c* 1.35, CH_3OH).

2,3-Diamino-2,3 dideoxy-D-xylitol

To a solution of **8** (577 mg, 28 mmol) in methanol (25 mL) was added palladium-on-charcoal (300 mg) suspended in methanol–water (1:1, 5 mL). The mixture was hydrogenated at room temperature under atmospheric pressure for 12 h. The catalyst was removed by filtration through Celite, the filtrate was evaporated under vacuum, and the residue was coevaporated with ethanol to dryness to afford a colorless syrup (421 mg, yield 98%); $[\alpha]_D$ −200 (*c* 1, H_2O).

(SP-4-3)-Dichloro(2,3-diamino-2,3-dideoxy-D-xylitol-N,N′*) platinum (9)*

The above diamino derivative was dissolved in distilled water (1 mL), and added to a solution containing K_2PtCl_4 (1 equiv.) in distilled water (5 mL). The mixture was stirred manually until homogeneous, and was left standing in the dark. After 2 h, bright yellow plates were formed. When the original red color of the solution became yellow or orange-yellow, the crystals were filtered, washed with cold water, and dried, in the absence of light for several hours, to afford bright yellow crystals (yield 57%); mp 255°C (dec.); $[\alpha]_D$ −52 (*c* 0.27, H_2O). Anal. calcd. for $C_5H_{14}N_2O_3PtCl_2$: C 14.46, H 3.37, N 6.75, Cl 16.87; found: C 14.40, H 3.38, N 6.80, Cl 17.32.

(SP-4-2)-Dichloro(3,4-diamino-3,4-dideoxy-1,2,4,6-tetra-O-*methyl-D-iditol*-N,N′*) platinum (7)*

A solution of **5** (0.5 g) was hydrogenated as described above and the resulting diamino derivative was treated with K_2PtCl_4 as described for **6**. The title compound **7** was obtained as a crystalline product in 52% yield, mp 286–287°C (dec.); $[\alpha]_D$ −25.2 (*c* 0.33, H_2O). Anal. calcd. for $C_{10}H_{22}N_6O_4PtCl_2$: C 23.91, H 4.81, N 5.57, Cl 14.11; found: C 23.98, H 4.72, N 5.56, Cl 14.48.

X-ray data collection and structure determination

Crystal data are provided in Table 1. Starting cell parameters and space group were determined from precession and cone-axis photographs. For both polymorphs, the space group was uniquely defined from the systematic absences: *hkl*, $h + k \neq 2n$ and 00*l*, $l \neq 2n$ for $C222_1$ (polymorph I); *h*00, $h \neq 2n$; 0*k*0, $k \neq 2n$; 00*l*, $l \neq 2n$ for $P2_12_12_1$ (polymorph II).

The intensity data were collected on an Enraf–Nonius CAD-4 diffractometer with graphite-monochromatized MoKα radiation, following the procedure described elsewhere (18). The data were corrected for the effects of Lorentz, polarization, and absorption (Gaussian integration, grid 10 × 10 × 10).

For polymorph I, the Patterson synthesis provided relative positions for the Pt atoms, but there were eight nonequivalent ways of positioning this pattern with respect to the origin in the $C222_1$ unit cell and each of these starting models showed pseudosymmetry. The ΔF map phased on any of these models showed, around each Pt atom, eight peaks corresponding to two superimposed square-planar units in which the Cl and N corners could not be differentiated. A small number of starting points could be rejected because they generated abnormally short intermolecular contacts. The remaining models were systematically tested. By structure factor and ΔF map calculations, resolution could generally progress up to a certain point, where inconsistencies developed in the positions of the ligand free "arms". The correct model turned out to contain two nonequivalent sets of Pt atoms occupying twofold axes (independent *4b* equipoints). The known absolute configuration was imposed. Isotropic refinement of the non-hydrogen atoms using full-matrix least squares converged to $R = 0.096$. The hydrogens on C and N atoms were fixed at idealized positions (N—H = 0.87, C—H = 0.95 Å, $B_{iso} = 6.0$ Å^2). Their parameters were not refined, but the coordinates were recalculated after each cycle of refinement. The hydrogens of the hydroxyl groups and water molecule were not detected. Anisotropic refinement of the non-hydrogen atoms converged to $R = 0.039$ and $R_w = 0.044$. The goodness-of-fit ratio was 1.60. The final ΔF map showed maximum residuals of ±1.3 e Å^{-3} within 1 Å from Pt atoms. The general background was lower than ±0.5 e Å^{-3}.

For polymorph II, the Pt atoms occupying a general equipoint were located from the Patterson map. The remaining non-hydrogen atoms were then found from a ΔF map. The structure was refined by full-matrix least squares. Isotropic refinement converged to $R = 0.052$. Hydrogens were handled as above. Anisotropic refinement of the non-hydrogen atoms converged to $R = 0.023$ and $R_w = 0.028$. The goodness-of-fit ratio was 1.12. The final ΔF map showed a general background below ±0.3 e Å^{-3}, except for a few peaks of ±|0.3–0.6| e Å^{-3} near Pt or Cl.

The scattering curves used were those of Cromer and Waber (19), except for hydrogen (20). The anomalous dispersion terms of Pt and Cl were taken from Cromer (21). The programs used are listed elsewhere (22).

Acknowledgments

Synthesis and biological evaluation of novel chiral non-racemic diaminoplatinum analogs based on a tetrahydropyran motif

STEPHEN HANESSIAN[1] AND JIANGUO WANG
Department of Chemistry, Université de Montréal, Montréal (Québec), Canada H3C 3J7

Received November 27, 1992

STEPHEN HANESSIAN and JIANGUO WANG. Can. J. Chem. **71**, 886 (1993).

Mono and dihydroxy diamino tetrahydropyran derivatives, readily available from L-arabinose, were prepared and converted into the corresponding diamino *cis*-platinum analogs. The presence of hydroxy groups imparts water solubility and enhanced antitumor activity.

STEPHEN HANESSIAN et JIANGUO WANG. Can. J. Chem. **71**, 886 (1993).

Des dérivés mono et dihydroxylé d'un diamino tétrahydropyran, aisément préparés à partir du L-arabinose, ont été synthétisés et convertis en complexes diamino *cis*-platines correspondants. La présence des groupes hydroxy augmente la solubilité de ces complexes tout en conservant leur activité antitumorale.

Introduction

In view of the clinical importance of the *trans*-1,2-diamino cyclohexane *cis*-platinum complex (DACH) (1), much effort has been expended in the synthesis of related cyclic analogs, particularly those incorporating polar functionality in order to maximize water solubility. A number of years ago, we initiated studies aimed at the synthesis of analogs of cisplatin that are derived from diamino dideoxy sugars. The antitumor activities of diaminodideoxyalditol platinumII derivatives are reported in the preceding paper (2). We now describe the synthesis and antitumor activity of a series of methyl 2,3-diamino-2,3-dideoxy-L-xylopyranosides, **2** and **3**, as well as that of 2,3-diamino-2,3-dideoxy-1,5-anhydro-L-xylitol **4**.

Results and discussion

Related derivatives prepared from other diamino sugars have recently been described in the literature (3). In designing these derivatives, particular attention was paid to the site and sense of chirality of the vicinal *trans* diamino groups, which were patterned after the biologically potent (*R*,*R*)-DACH derivative **1**. The presence of free hydroxy groups on the tetrahydropyran-type ring could not only increase water solubility, but also alter electrostatic stabilization due to the presence of polar groups. Moreover, the changes in the hydrophilic character of the complexes might lead to useful differences in their effective transport and distribution in plasma, and hence improve their chemotherapeutic index. Another reason for this investigation is that the stereochemistry of these complexes might have an effect on the antitumor activity. For example, the stereochemical features inherent in the chiral non-racemic analogs could change the selective interaction with certain receptors, membrane constituents, and the DNA helix itself. In patterning the new analogs after (*R*,*R*)-DACH, we chose vicinal diamines with a *trans* configuration, which is believed to be more active than the *cis* form. The disposition of hydroxy or methoxy groups was also fixed vis-a-vis the *trans* diamino function. Dichloride as well as cyclobutane-1,1-dicarboxylate ligands were used as the leaving group for some of the complexes. Since the bidentate ligand slows down the binding rates of the platinum complexes to components present in human plasma (4), these analogs may have a different physiological activity. The degree of hydrophilicity was expected to be controlled by the presence or absence of a hydroxy group at C-4 as in **2** and **3**, respectively, while the functional and stereochemical relevance of the anomeric methoxy group was to be evaluated by comparison to the anhydroalditol derivative **4**.

We chose L-arabinose as a starting material because it could be amenable to the chemical modifications we envisaged for the preparation of the *trans* diamino derivatives **2**, **3**, and **4**. Thus, the readily available epoxide **5** was transformed into the corresponding *O*-tetrahydropyranyl derivative **6**, obtained as a mixture of diasteroisomers (Scheme 1).

Ring opening of the epoxide **6** with azide ion using sodium azide and ammonium chloride in methoxyethanol (6) produced a separable 2:1 mixture of the 3-azido sugar derivative **7** and the diastereomeric OTHP derivatives corresponding to **8**. The $^4C_1$ and $^1C_4$ conformations of the pyranose rings in **7** and **8**, respectively, were confirmed by ^{1}H nmr spectroscopy. In the case of **8** the proton coupling constants ($J_{1,2}$ = 8 Hz, $J_{2,3}$ = 10 Hz, $J_{3,4}$ = 9 Hz) indicated that the hydrogens at C-1, C-2, C-3, and C-4 are in the *trans* axial orientation corresponding to a $^1C_4$ conformation. The ^{1}H nmr spectrum of isomer **7** could not be adequately analyzed because of the presence of diastereomers. However, after conversion to **9**, the coupling constants for the hydrogen atoms at C-1, C-2, C-3, and C-4 ($J_{1,2}$ = 3.5 Hz, $J_{2,3}$ = 10.5 Hz, $J_{3,4}$ = 3 Hz) indicated that the protons at C-1 and C-4 are in the equatorial position while the protons at C-2 and C-3 are in the axial position, which reflects a $^4C_1$ conformation. Interestingly, the two tetrahydropyranyl diastereomers of **9** could be separated by column chromatography. According to the Fürst–Plattner rule (7), the opening of conformationally biased epoxides such as **6***a* and **6***b* (Scheme 2), should proceed in a diaxial mode to afford **7** and **8**, respectively. The higher proportion of **7** than of **8** may be because the tetrahydropyranyloxy group in **6***b* is in a pseudoaxial position, which hinders the attack at the C-2

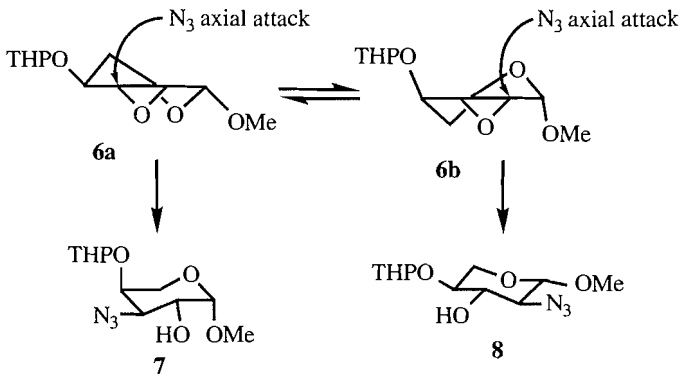

SCHEME 2

position due to nonbonded 1,3-diaxial interactions. *trans*-Diaxial opening of **6***a* is not impeded by neighboring groups, and could favor the formation of **7**, which also benefits from the axially orientated anomeric methoxy group (8).

Compounds **7** and **8** were individually manipulated and transformed into the same aziridine derivative **10** by different routes. Thus, mesylation of **8** followed by treatment with hydrazine monohydrate and Raney nickel (6) in methanol afforded the aziridine derivative **10** in excellent yield. Unfortunately, application of this method to the isomer **7** led to the reduced amine derivative, which did not undergo cyclization to the expected aziridine derivative **10**.

Therefore, an alternative two-step method (9) was used. Tosylation of **7** led to **9** in 82% yield. Reduction of the azido group with hydrazine hydrate in the presence of Raney nickel in refluxing methanol was followed by treatment of the resulting amino derivative with sodium acetate in DMF to effect the formation of the aziridine **10**. Unlike the epoxide analog **6**, opening of the aziridine ring in **10** with sodium azide proceeded in a site-selective manner to give the 3-azido derivative **11** as the major product, which could be isolated as diastereomeric OTHP ethers. In each of these, the molecule adopts a $^1C_4$ conformation, which was confirmed by ^1H nmr since the proton coupling constants ($J_{1,2}$ = 7.7 Hz, $J_{2,3}$ = 10.3 Hz, $J_{3,4}$ = 9.8 Hz, $J_{4,5ax}$ = 10.3 Hz) indicate that all the substituents are in the equatorial position. It is possible that under the slightly acidic conditions, the site-selective opening at C-3 is proceeding via the aziridinium ion. This type of activation may favor a diaxial opening to a greater extent than in the case of epoxide **6**.

When treated with acid, compound **11** led to the corresponding alcohol derivative **12**. Catalytic hydrogenation gave the crystalline diamino derivative **13**, which upon treatment with aqueous K_2PtCl_4 produced the desired complex **2**, as bright yellow crystals.

The methoxy series was prepared from the minor isomer **8** (Scheme 3). Thus, mesylation afforded **14**, which could be separated into two diastereomers. Selective cleavage of

the OTHP group in **14**, followed by methylation using a suspension of silver oxide in ether, gave **16**, which after treatment with hydrazine led to the aziridine derivative **17**. Ring opening with sodium azide led to **18**, which after catalytic hydrogenation gave the crystalline diamino derivative **19**. Finally, treatment with aqueous K_2PtCl_4 gave the intended platinum(II) complex **3**, which was isolated as bright yellow crystals.

The synthesis of the tetrahydropyran complex **4** from a common intermediate such as **12** presented logistical problems concerned with functional group compatibility. How could one reductively demethoxylate the anomeric position en route to the desired 1,5-anhydroalditol derivative? A method of choice involved treatment of a suitably N-protected derivative obtained from **12** with trimethylsilyl triflate and triethylsilane in the presence of a Lewis acid (10). However, previous studies showed that in the 2-*N*-acetylamino sugar series, the cleavage of the glycosidic carbon–oxygen bond did not take place under these conditions due to neighboring group participation (11).

After exploring a number of possibilities, the *N*-phthalimido derivative **20** proved to be the most compatible N-protective group (Scheme 4). Thus reductive demethoxylation of the corresponding acetate **21** afforded **22** without apparently affecting the azido or ester groups. Functional group manipulation led to the amino derivative **23**, which was hydrogenated, and then transformed into the platinum(II) complex **4** in the usual fashion.

In view of the known influence of the anionic counterparts of *cis*-platinum complexes of vicinal diamines on solubility and biological activity (12), we prepared the cyclobutane 1,1-dicarboxylate derivative **24** by adaptations of known procedures (ref. 13, Scheme 1). Thus, the complex **2** was transformed into the corresponding dinitrate and this was treated with dipotassium cyclobutane 1,1-dicarboxylate to give the corresponding crystalline complex **24**.

The structure of **24** was definitively ascertained by a single crystal X-ray diffraction determination on the dihydrate obtained by recrystallization in water. The ORTEP representation of one of two independent molecules is shown in Fig. 1. The structure of the second molecule (figure in the supplementary material)[2] is very similar. The coordination about Pt is roughly square-planar as expected, and the Pt—N and

[2]Detailed crystallographic results (ORTEP, drawing of molecule **2**, anisotropic temperature factors, hydrogen parameters, bond distances and angles, torsion angles, geometry of hydrogen bonds, least-squares plane calculations, and structure factors) (49 pages) may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen parameters, bond distances and angles, and geometry of hydrogen bonds and the ORTEP view of molecule **2** have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

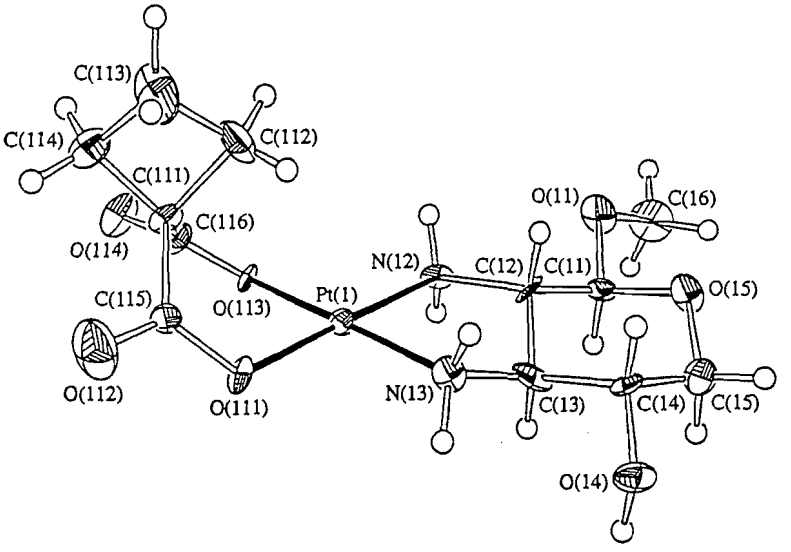

FIG. 1. ORTEP view showing the molecular conformation of compound **24**. Ellipsoids correspond to 40% probability. Hydrogens are shown as spheres of arbitrary size.

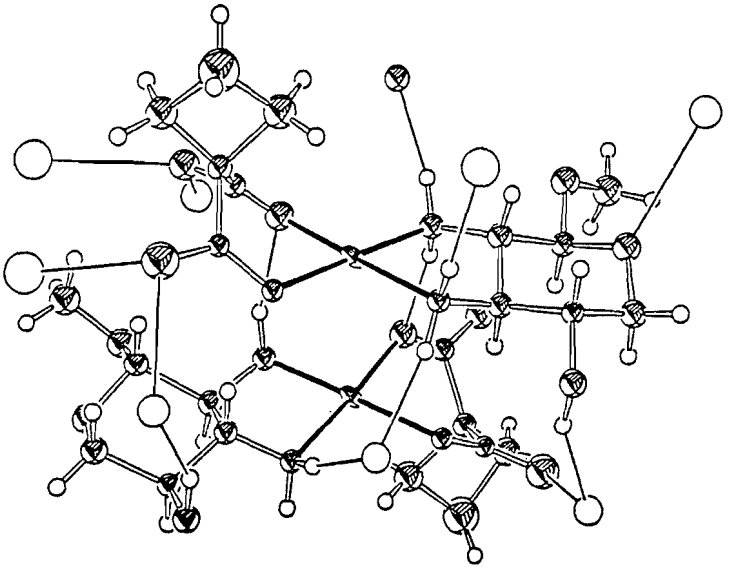

FIG. 2. View of the hydrogen-bonded dimeric unit including two independent complexes (Pt(1) above, Pt(2) below). Hydrogen bonding indicated by thin bonds. The water molecules are shown as undashed spheres without hydrogens.

Pt—O distances (mean 2.02 and 2.01 Å, respectively) are normal. The O—Pt—O angles (mean 89.3°) are close to ideality, but the "bite" of the diamine ligand imposes small N—Pt—N angles (mean 84.6°). The pyran ring is in the chair conformation, all the substituents on this ring are in a *trans* orientation relative to one another, and the coordinated dicarboxylate ligand is puckered, having the cyclobutane moiety significantly displaced above the coordination plane. The two types of molecules are packed as dimers in the crystal, with the square planes stacked to give a relatively short Pt—Pt distance of 3.33 Å (Fig. 2). The dimer is held together by a number of hydrogen bonds involving water molecules, the carboxylates, and the amino groups. Intermolecular hydrogen bonds are also found between the nitrogen atom of the amine group in one molecule and the oxygen atom of the carboxyl group in the other molecule.

Antitumor activity

Biological evaluation of the platinum complexes in vitro and in vivo gave interesting results. Compounds **2** (T/C 227, i.p. dose 25 mg/kg) and **4** (T/C > 236, i.p. dose 12.5 mg/kg) showed comparable activity to cisplatin (T/C > 236, i.p. dose 4 mg/kg) against P338 leukemia in vivo. The complex **3** (T/C 191, i.p. dose 25 mg/kg) was less active than the hydroxy analog **2**. Compound **24** (T/C 114, i.p. dose 25 mg/kg) showed much reduced activity in the same tests. In vivo testing against intraperitoneal L1210 implants showed that **2** (T/C 323, i.p. dose 50 mg/kg) was more active than **3** (T/C 218, i.p. dose 50 mg/kg). Cisplatin (i.p. dose 25 mg/kg) had an activity rating of T/C 323. The comparatively better in vitro activity of **2** over **3** was also evident when tested against strains of L1210, DDP5, P388, and their resistant lines, although DACH was considerably more ac-

tive. Compounds **2** and **3** had solubilities of 2 mg/mL and 1.5 mg/mL, respectively, in water. It is clear that the introduction of hydroxy groups in these analogs has a beneficial effect on the in vivo antitumor activity as well as on the water solubility of the complex.

Experimental

Melting points (mp) were determined on a Fisher–Johns melting point apparatus and are uncorrected. Optical rotations were measured at 25°C using a Perkin–Elmer automatic spectropolarimeter model 141. Proton magnetic resonance (^{1}H nmr) spectra were determined on either a 300 MHz Varian or a 400 MHz Bruker spectrometer in deuterated chloroform, methanol-d_4, dimethyl sulfoxide-d_6, or deuterium oxide (D_2O) with $CHCl_3$ (δ_{ppm} = 7.265), Me_4Si (δ_{ppm} = 0.00), or dioxane (δ_{ppm} = 67.40 for ^{13}C) as references. Coupling constants are expressed in hertz (Hz). The abbreviations used for the description of the peaks are as follows: s, singlet; d, doublet; dd, doublet of doublets; dt, doublet of triplets; ddd, doublet of doublet of doublets; t, triplet; q, quartet; m, multiplet; br, broad. The ^{13}C nmr spectra were recorded on a Varian VXR 300 at 75 MHz. Low-resolution mass spectra were determined on a VG Micro Mass 1212 mass spectrometer by using desorption chemical ionization (DCI), or by fast atom bombardment (FAB). High-resolution mass spectra were determined on a Kratos MS-50 TCTA mass spectrometer by using electron impact (EI) at 70 eV or by the fast atom bombardment (FAB) techniques. Infrared spectra (ir) were recorded on a Perkin–Elmer 781 infrared spectrophotometer. The spectra of solids were recorded as Nujol mulls or as concentrated solutions in carbon tetrachloride between sodium chloride plates. Liquid samples were determined as films between sodium chloride plates. Combustion analyses were performed by Guelph Laboratories Ltd, Guelph, Ont. Flash chromatography was done according to the procedure of Still *et al.* (14) using Kieselgel 60 silica gel.

Crystal data

$C_{12}H_{20}N_2O_7Pt \cdot 4.5H_2O$ fw = 580.45.

Monoclinic, *C*2, a = 13.233(6), b = 12.778(6), c = 23.305(7) Å, β = 96.96(3)°, V = 3912(3) Å^3, D_c = 1.971 g cm^{-3}, Z = 8, λ(MoKα) = 0.70930 Å, μ(MoKα) = 73.1 cm^{-1}, T = 220 K.

Data collection and structure determination

Cell dimensions and space group were obtained from precession and cone-axis photographs. The systematic absences (*hkl*, $h + k$ odd) were consistent with space groups *C*2, *Cm*, and *C*2/*m*, but the presence of the chiral ligand unambiguously identified *C*2. The specimen used for diffractometer work had the following dimensions (mm) between the indicated pairs of faces: 0.10 (001–00$\bar{1}$) × 0.25 ($1\bar{1}1$–$\bar{1}1\bar{1}$) × 0.37 (111–$\bar{1}\bar{1}\bar{1}$). Data collection was run as described in the previous paper (2). The whole sphere of data (13 625 reflections, $2\theta < 50°$) was collected. These data were corrected for absorption (Gaussian integration, grid 10 × 10 × 10, transmission range: 0.15–0.52). Equivalent reflections were averaged assuming symmetry 2 (R_{av} = 0.068), yielding 3595 unique *hkl* and *hkl* reflections (3167 with $I > 1.96\ \sigma I$ used to solve the structure) and 3260 Friedel equivalent reflections (2947 with $I > 1.96\ \sigma I$). The data were corrected for the effects of Lorentz and polarization.

The structure was solved by the direct methods of SHELX-86 (15), which provided coordinates for the two independent Pt atoms. All other calculations were done with the NRCVAX system (16). The remaining non-hydrogen atoms were located from ΔF maps. Anisotropic refinement of all non-hydrogen atoms was done on $|F_o|$ by full-matrix least squares. Ligand hydrogens were fixed at idealized positions (C(N)—H = 0.95 Å) with isotropic temperature factors adjusted in relation to the B_{eq} value of the attached atom. Water hydrogens were not visible in the ΔF map and were neglected. A secondary extinction coefficient was also refined (0.131 (17)). The final agreement factors were $R = \Sigma\|F_o| - |F_c\|/\Sigma|F_o| = 0.045$, $R_w = [\Sigma w\ (|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.049$ and the goodness-of-fit ratio was 2.94 for 480 parameters refined. The general background in the final ΔF map was below ±1.55 e/Å^3, except for nine peaks in the range ±|1.6–2.9|e/Å^3 within 1.2 Å from Pt. Friedel reflections were used to check the absolute configuration already known from the ligand chirality. Bijvoet analysis on the 100 most significant reflections rejected the other enantiomer whose probability is $<10^{-20}$. The refined coordinates are listed in Table 1.

*Methyl 2,3-anhydro-4-O-(2-tetrahydropyranyl)-β-L-lyxopyranoside (**6**)*

A solution of compound **5** (0.923 g, 6.32 mmol) and dihydropyran (3.0 mL, 32.9 mmol) in dry dichloromethane (50 mL) containing pyridinium *p*-toluenesulfonate (PPTS) (0.180 g, 0.720 mmol) was stirred for 1.5 h at room temperature. The solution was diluted with 50 mL ether, then washed with half-saturated NaCl (2 × 25 mL), dried (Na_2SO_4), and the solvent was evaporated to give a syrup that was applied to a silica gel column. Elution with ethyl acetate – hexanes (1:1) and concentration gave a mixture of the two isomers of the THP ether **6** (1.32 g, 91%) as a syrup; ^{1}H nmr (300 MHz, $CDCl_3$) δ: 1.51–1.92 (m, 12H), 3.46 (s, 3H, OCH_3), 3.47 (s, 3H, OCH_3), 3.30–3.66 (m, 8H), 3.80–4.05 (m, 6H), 4.74 (dd, 1H, J = 2.7 Hz, 5.0 Hz), 4.81 (dd, 1H, J = 2.8 Hz, 4.4 Hz), 4.95 (d, 2H, J = 3.0 Hz); ^{13}C nmr (75 MHz, $CDCl_3$) major isomer, δ: 19.70, 30.66, 50.83, 51.35, 55.53, 58.51, 63.03, 68.27, 94.66, 98.23; minor isomer, δ: 19.46, 25.17, 30.74, 50.31, 51.30, 55.58, 60.59, 62.68, 69.03, 94.75, 99.52; ms, *m/e*: 231 $(M + 1)^+$. Exact Mass calcd. for $C_{11}H_{18}O_5$: 230.1154; found: 230.1109.

*Methyl 3-azido-3-deoxy-4-O-(2-tetrahydropyranyl)-β-L-arabinopyranoside (**7**) and methyl 2-azido-2-deoxy-4-O-(2-tetrahydropyranyl)-β-L-xylopyranoside (**8**)*

To a solution of the epoxide **6** (26.4 g, 115 mmol) in 2-methoxyethanol–water (14:1, 1000 mL) was added sodium azide (30.0 g, 153 mmol) and ammonium chloride (12.3 g, 230 mmol). The mixture was heated at 110°C for 20 h, and evaporated to give a residue that was dissolved in dichloromethane. The solution was washed with water and the organic phase was dried ($MgSO_4$), then evaporated, to give a syrup that was applied to a silica gel column. Elution with ethyl acetate – hexanes (1:1) gave the two THP ether isomers of the 2-azido derivative, **8***a* and **8***b* (total 7.50 g, 24%), and an inseparable mixture of the two THP ether isomers of the 3-azido derivative **7** (14.8 g, 47.2%); **8***a*: $[\alpha]_D$ +11.9 (*c* 0.78, $CHCl_3$); ir ($CHCl_3$): 3380 (OH), 2110 (N_3) cm^{-1}; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 1.5–1.8 (m, 6H, H-2′, 3′, 4′), 3.26 (dd, 1H, J = 8.7 Hz, 10.3 Hz, H-2), 3.26 (dd, 1H, J = 10.5 Hz, 11.5 Hz, H-5ax), 3.44 (m, 1H, H-3), 3.56 (s, 3H, OCH_3), 3.57–3.62 (m, 2H, H-4, H-5′ax), 3.96 (dd, 1H, J = 5.5 Hz, 11.5 Hz, H-5eq), 4.01–4.05 (m, 1H, H-5′eq), 4.13 (d, 1H, J = 8.1 Hz, H-1), 4.54 (m, 1H, H-1′eq), 5.01 (d, 1H, J = 0.7 Hz); ms, *m/e*: 274 $(M + 1)^+$; **8***b*: ir ($CHCl_3$): 3400 (br, OH), 2110 (N_3) cm^{-1}; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 1.5–1.8 (m, 6H, H-2′, 3′, 4′), 2.76 (s, 1H, OH), 3.24 (dd, 1H, J = 10.2 Hz, 11.7 Hz, H-5ax), 3.28 (dd, 1H, J = 7.8 Hz, 9.8 Hz, H-2), 3.46 (m, 1H, H-3), 3.49–3.54 (m, 1H, H-5′ax), 3.55 (s, 3H, OCH_3), 3.63 (ddd, 1H, J = 5.4 Hz, 8.8 Hz, 10.2 Hz, H-4), 3.86 (m, 1H, H-5′eq), 4.15 (d, 1H, J = 7.8 Hz, H-1), 4.16 (dd, 1H, J = 5.4 Hz, 11.7 Hz, H-5eq), 4.75 (dd, 1H, J = 2.6 Hz, 5.4 Hz, H-1′); ms, *m/e*: 274 $(M + 1)^+$; ^{13}C nmr (75 MHz, $CDCl_3$) **8** (mixture of **8***a* and **8***b*), δ: 19.90, 20.53, 24.60, 24.95, 30.44, 31.02, 56.86, 56.96, 63.37, 63.84, 64.85, 64.95, 65.26, 65.48, 73.87, 73.39, 79.61, 100.90, 101.24, 103.10; **7**: ir ($CHCl_3$): 3450 (OH), 2105 (N_3) cm^{-1}; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 1.52–1.95 (m, 6H, H-2′, 3′, 4′), 2.18 (m, 1H, OH), 3.45 (2 × 5, 3H, OCH_3), 3.40–4.09 (m, 7H, H-2, 3, 4, 5, 5′), 4.80–4.91 (m, 2H, H-1, 1′); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 18.48, 19.21, 25.21, 25.24, 30.08, 30.66, 55.49, 55.53, 58.49, 61.10, 61.47, 61.68, 62.39, 62.47, 67.32, 67.65, 70.64, 75.79, 94.29, 99.26, 99.36, 101.08; ms, *m/e*: 274 $(M + 1)^+$.

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

*Methyl 2-azido-2-deoxy-3-*O*-methanesulphonyl-4-*O*-(2-tetrahydropyranyl)-β-L-xylopyranoside (**14**)*

To a cold solution of **8** (7.40 g, 27.1 mmol) and DMAP (catalytic amount) in pyridine (40 mL) was added dropwise a precooled (0°C) solution of methanesulphonyl chloride (6.5 mL, 84 mmol) in 40 mL pyridine, and the mixture was left at room temperature for 1 day. After hydrolysis of the excess of reagent, the solution was poured onto ice-water and extracted with chloroform. The extract was washed with cold hydrochloric acid (2%) and cold water, dried (Na_2SO_4), and evaporated to give a syrup. Flash column chromatography with ethyl acetate – hexane (1:3, then 1:1) gave the THP isomers **14***a* (4.09 g, 43%) and **14***b* (3.60 g, 38%); **14***a*: mp 89–91°C; $[\alpha]_D$ −26.9 (*c* 0.85, $CHCl_3$); ir ($CHCl_3$): 2110 (N_3), 1360, 1180 (S=O) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 1.50–1.90 (m, 6H, H-2′, 3′, 4′), 3.14 (s, 3H, OSO_2CH_3), 3.26 (dd, 1H, J = 10.5 Hz, 11.8 Hz, H-5ax), 3.41 (dd, 1H, J = 7.8 Hz,

10.4 Hz, H-2), 3.52 (m, 1H, H-5′ax), 3.58 (s, 3H, OCH_3), 3.75 (ddd, 1H, J = 5.7 Hz, 9.2 Hz, 10.5 Hz, H-4), 3.82 (m, 1H, H-5′eq), 4.20 (d, 1H, J = 7.8 Hz, H-1), 4.23 (dd, 1H, J = 5.7 Hz, 11.8 Hz, H-5eq), 4.39 (dd, 1H, J = 9.2 Hz, 10.4 Hz, H-3), 4.73 (dd, 1H, J = 2.1 Hz, 5.1 Hz, H-1′); **14***b*: $[\alpha]_D$ +82.7° (*c* 1.8, $CHCl_3$); ir ($CHCl_3$): 2110 (N_3), 1360, 1180 (S=O) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 1.50–1.90 (m, 6H, H-2′, 3′, 4′), 3.18 (dd, 1H, J = 10.3 Hz, 11.9 Hz, H-5ax), 3.20 (s, 3H, OSO_2CH_3), 3.44 (dd, 1H, J = 7.8 Hz, 10.3 Hz, H-2), 3.46 (m, 1H, H-5′ax), 3.58 (s, 3H, OCH_3), 3.99 (m, 1H, H-4), 4.03 (m, 1H, H-5′eq), 4.12 (dd, 1H, J = 5.2 Hz, 11.9 Hz, H-5eq), 4.22 (d, 1H, J = 7.8 Hz, H-1), 4.40 (t, 1H, J = 10.3 Hz, H-3), 4.68 (t, 1H, J = 3.3 Hz, H-1′); ms, *m/e*: 352 $(M + 1)^+$.

*Methyl 3-azido-3-deoxy-4-*O*-(2-tetrahydropyranyl)-2-*O*-tolylsulphonyl-β-*L*-arabinopyranoside (**9**)*

To a cold solution of the 3-azido derivative **7** (12.0 g, 44.0 mmol) in 90 mL of dry pyridine was added a catalytic amount of 4-dimethylaminopyridine, then, dropwise, a precooled (0°C) solution of tosyl chloride (8.60 g, 45.1 mmol) in 70 mL of dry pyridine at 5°C. The mixture was stirred at 40°C for 1 day, cold water (1 mL) was added to quench the reaction at 0°C, the resulting solution was poured onto 500 mL of ice-water, and then extracted with dichloromethane (4 × 150 mL). The combined extracts were washed with 1 N HCl, water, saturated $NaHCO_3$, water, and brine, dried (Na_2SO_4), and evaporated to give a syrup. Purification by flash chromatography, eluting with ethyl acetate – hexanes (2:3, then 3:1) gave a mixture of the THP ether isomers, **9***a* and **9***b* (15.4 g, 82%), which were difficult to separate on a large scale. However, the two isomers were partially separable by applying a small sample on a longer column; THP ether isomer **9***a*: $[\alpha]_D$ +70.0 (*c* 0.31, $CHCl_3$); ir ($CHCl_3$): 2100 (N_3) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.50–1.90 (m, 6H, H-2′, 3′, 4′), 2.45 (s, 3H, $ArCH_3$), 3.35 (s, 3H, OCH_3), 3.51 (m, 1H, H-5′), 3.67 (dd, 1H, J = 3.2 Hz, 10.5 Hz, H-3), 3.72 (dd, 1H, J = 1.2 Hz, 12.4 Hz, H-5), 3.80 (dd, 1H, J = 2.0 Hz, 12.4 Hz, H-5), 3.90 (m, 1H, H-5′), 3.95 (m, 1H, H-4), 4.74 (t, 1H, J = 3.6 Hz, H-1′), 4.83 (dd, 1H, J = 3.5 Hz, 10.5 Hz, H-2), 4.91 (d, 1H, J = 3.5 Hz, H-1), 7.35 (m, 2H, ArH), 7.87 (m, 2H, ArH); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 19.17, 21.55, 25.20, 30.44, 55.62, 58.14, 62.09, 62.47, 75.43, 76.09, 97.61, 101.15, 127.93, 129.67, 133.43, 144.99; THP ether isomer **9***b*: $[\alpha]_D$ +138.3 (*c* 0.12, $CHCl_3$); ir ($CHCl_3$): 2100 (N_3) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.50–1.88 (m, 6H, H-2′, 3′, 4′), 2.45 (s, 3H, $ArCH_3$), 3.36 (s, 3H, OCH_3), 3.43–3.52 (m, 1H, H-5′), 3.61 (dd, 1H, J = 1.0 Hz, 13.0 Hz, H-5), 3.72 (dd, 1H, J = 2.0 Hz, 13.0 Hz, H-5), 3.74 (dd, 1H, J = 3.3 Hz, 10.4 Hz, H-3), 3.85–3.93 (m, 1H, H-5′), 4.10 (m, 1H, H-4), 4.79 (t, 1H, J = 3.2 Hz, H-1′), 4.86 (dd, 1H, J = 3.5 Hz, 10.4 Hz, H-2), 4.91 (d, 1H, J = 3.5 Hz, H-1), 7.36 (m, 2H, ArH), 7.88 (m, 2H, ArH); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 18.53, 21.55, 25.18, 30.03, 55.68, 57.77, 58.00, 61.81, 71.18, 75.16, 94.31, 97.75, 127.96, 129.68, 133.50, 144.98.

*Methyl 2,3-dideoxy-2,3-epimino-4-*O*-(2-tetrahydropyranyl)-β-*L*-ribopyranoside (**10**)*

*Method A (from **9**)*

To a solution of **9** (14.0 g, 34.9 mmol) in 300 mL of DMF and distilled water (5:1) was added sodium acetate trihydrate (21.0 g, 154 mmol) and the mixture was heated to 85°C overnight with stirring. After removal of the solvent under reduced pressure, the residue was treated with acetone (50 mL) and the resulting white precipitate was filtered and washed with acetone. Evaporation of the filtrate gave crude product **10** (7.65 g, 95.6%) as a syrup that was used for next reaction without further purification. A small sample was applied to a silica gel column, eluting with dichloromethane/methanol (15:1) to give two tetrahydropyranyl isomers **10***a* and **10***b*.

*Method B (from **14**)*

Compound **14***a* (3.00 g, 8.55 mmol) in methanol (100 mL) was mixed with hydrazine monohydrate (99–100%) (4.6 mL, 82.5 mmol), Raney nickel (0.4 g) was added, and the mixture was heated to reflux until decomposition of the hydrazine was complete (monitored by tlc, approximately 5 h). The mixture was filtered and evaporated to a syrup that was applied to a silica gel column. Elution with ethyl acetate, then with ethyl acetate – methanol (10:1), gave compound **10***a* (1.90 g, 97%) as a syrup. **10***a*: $[\alpha]_D$ −80.5 (*c* 1.11, $CHCl_3$); ir ($CHCl_3$): 3300 (NH) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 1.55–1.90 (m, 6H), 2.19 (br s, 1H), 2.48 (br s, 1H), 3.44 (s, 3H), 3.42–3.46 (m, 1H), 3.51–3.56 (m, 1H), 3.82–3.86 (m, 2H), 4.13 (m, 1H), 4.83 (s, 1H), 4.98 (m, 1H); ms, *m/e*: 230 $(M + 1)^+$. The THP ether isomer **10***b* was obtained from compound **14***b* following the same procedure as above; **10***b*: $[\alpha]_D$ +116.5 (*c* 0.81, $CHCl_3$); ir ($CHCl_3$): 3300 (NH) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 1.50–1.95 (m, 6H), 2.19 (br s, 1H), 2.58 (br s, 1H), 3.40 (s, 1H), 3.42 (s, 3H), 3.55 (m, 1H), 3.78 (m, 1H), 3.98–4.06 (m, 2H), 4.77 (s, 1H), 4.80 (s, 1H); ms, *m/e*: 230 $(M + 1)^+$.

*Methyl 2-amino-3-azido-2,3-dideoxy-4-*O*-(2-tetrahydropyranyl)-β-*L*-xylopyranoside (**11**)*

A suspension of the aziridine derivative **10***a* (1.80 g, 7.86 mmol), sodium azide (2.00 g, 30.8 mmol), and ammonium chloride (0.85 g, 15.9 mmol) in 2-methoxyethanol (112 mL) and water (8 mL) was heated for 11 h at 110°C. The mixture was evaporated to dryness and the residue was extracted with dichloromethane (3 × 100 mL). The extract was washed with half-saturated $NaHCO_3$ (3 × 50 mL), dried (Na_2SO_4), and evaporated to give a yellow syrup that was applied to a silica gel column. Elution with dichloromethane–methanol (20:1) gave **11***a* (1.70 g, 80%) as a syrup; $[\alpha]_D$ −67.9 (*c* 0.99, $CHCl_3$); ir ($CHCl_3$): 3380, 3320 (NH), 2110 (N_3) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 1.55–1.90 (m, 6H, H-2′, 3′, 4′), 2.60 (dd, 1H, J = 7.7 Hz, 10.3 Hz, H-2), 3.23 (dd, 1H, J = 10.3 Hz, 11.3 Hz, H-5ax), 3.30 (t, 1H, J = 10.3 Hz, H-3), 3.51 (s, 3H, OCH_3), 3.56–3.61 (m, 1H, H-5′ax), 3.89 (dt, 1H, J = 5.0 Hz, 10.3 Hz, H-4), 3.95 (m, 1H, H-5′eq), 4.06 (d, 1H, J = 7.7 Hz, H-1), 4.13 (dd, 1H, J = 5.0 Hz, 11.3 Hz, H-5eq), 4.78 (m, 1H, H-1′); ms, *m/e*: 273 $(M + 1)^+$. Exact Mass calcd. for $C_{11}H_{21}N_4O_4$ (M + H): 273.1564; found: 273.1608.

The mixture of THP isomers of **11** was obtained from crude **10** following the same procedure as that for the preparation of **11***a*; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.48–1.85 (m, 12H, H-2′, 3′, 4′), 2.51 (dd, 1H, J = 7.7 Hz, 10.4 Hz, H-2), 2.56 (dd, 1H, J = 7.7 Hz, 10.4 Hz, H-2), 3.20 (dd, 1H, J = 10.4 Hz, 11.5 Hz, H-3), 3.24 (dd, 1H, J = 10.3 Hz, 11.6 Hz, H-3), 3.26–3.33 (m, 2H), 3.47, 3.48 (2 × 5, 6H, OCH_3), 3.49–3.63 (m, 3H), 3.81–3.91 (m, 3H), 4.00 (d, 1H, J = 7.7 Hz, H-1), 4.03 (d, 1H, J = 7.7 Hz, H-1), 4.09 (dd, 1H, J = 4.9 Hz, 11.4 Hz, H-5), 4.19 (dd, 1H, J = 5.3 Hz, 11.4 Hz, H-5), 4.72–4.76 (m, 2H, H-1′); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 18.29, 19.52, 24.93, 30.05, 30.42, 55.00, 56.82, 61.69, 62.87, 63.88, 66.01, 67.53, 67.58, 71.12, 95.02, 101.27, 104.99, 105.26.

*Methyl 2-amino-3-azido-2,3-dideoxy-β-*L*-xylopyranoside (**12**)*

To a solution of THP ether **11** (32 mg, 0.12 mmol) in ethanol (1.5 mL) was added pyridinium *p*-toluenesulfonate (PPTS) (59 mg, 0.24 mmol). The solution was stirred for 1 day at 70°C, evaporated to dryness, and the residue was applied to a silica gel column. Elution with dichloromethane–methanol–triethylamine (100:10:1) followed by concentration gave compound **12** (18 mg, 80%) as white crystals; mp 141–143°C; $[\alpha]_D$ +20 (*c* 0.24, ethanol); ir ($CHCl_3$): 3360, 3300, 3150 (br), 2105 (N_3) cm^{-1}; ^1H nmr (300 MHz, methanol-d_4) δ: 2.39 (dd, 1H, J = 7.8 Hz, 10.5 Hz, H-2), 3.16 (dd, 1H, J = 9.2 Hz, 10.5 Hz, H-3), 3.26 (dd, 1H, J = 10.4 Hz, 11.4 Hz, H-5ax), 3.48 (s, 3H, OCH_3), 3.60 (ddd, 1H, J = 5.3 Hz, 9.2 Hz, 10.4 Hz, H-4), 3.91 (dd, 1H, J = 5.3 Hz, 11.4 Hz, H-5eq), 4.08 (d, 1H, J = 7.8 Hz, H-1); ^{13}C nmr (75 MHz, methanol-d_4) δ: 56.41, 57.29, 67.92, 70.41, 70.88, 106.34; ms, *m/e*: 189 $(M + 1)^+$. Anal. calcd for $C_6H_{12}N_4O_3$: C 38.29, H 6.43, N 29.77; found: C 38.18, H 6.28, N 29.26.

Methyl 2,3-diamino-2,3-dideoxy-β-L-xylopyranoside (13)

To a solution of the azide **12** (395 mg, 2.10 mmol) in methanol-distilled water (1:1, 18 mL) was added 10% palladium-on-activated charcoal (230 mg) suspended in methanol (5 mL). The mixture was hydrogenated under atmospheric pressure at room temperature for 24 h. The catalyst was then removed by filtration through Celite, and the filtrate was evaporated and co-evaporated with ethanol to dryness to give **13** (290 mg, 85%) as white crystals; mp 200–202°C (dec.); $[\alpha]_D$ +84.5 (*c* 0.33, methanol); ir (Nujol): 3380, 3330, 3280 (NH_2) cm^{-1}; ^1H nmr (400 MHz, methanol-d_4) δ: 2.41 (dd, 1H, *J* = 7.4 Hz, 9.8 Hz, H-2), 2.49 (t, 1H, *J* = 9.8 Hz, H-3), 3.23 (dd, 1H, *J* = 10.0 Hz, 11.2 Hz, H-5ax), 3.39 (m, 1H, H-4), 3.48 (s, 3H, OCH_3), 3.90 (dd, 1H, *J* = 4.8 Hz, 11.2 Hz, H-5eq), 4.07 (d, 1H, *J* = 7.4 Hz, H-1); ms, *m/e*: 163 $(M + 1)^+$. Exact Mass calcd. for $C_6H_{13}N_2O_2$ (−OH): 145.0978; found: 145.0978.

(SP-4-3)-Dichloro(methyl 2,3-diamino-2,3-dideoxy-β-L-xylopyranoside-N,N′) platinum (2)

A solution of the diamine **13** (218 mg, 1.00 mmol) in distilled water (0.9 mL) was added to a solution of K_2PtCl_4 (430 mg, 1.03 mmol) in distilled water (3.9 mL). The mixture was stirred manually until homogeneous, then left standing in the dark. After 2 h, crystallization began in the form of bright yellow plates. When the original red color of the solution became yellow or orange-yellow the crystals were filtered, washed with cold water (3 times), and dried under vacuum in the absence of light for several hours to afford bright yellow crystals of **2** (325 mg, 43.7%); mp 270°C (darkening), 305–310°C (dec.); $[\alpha]_D$ +144 (*c* 0.06, H_2O); ir (Nujol): 3390 (OH), 3280, 3250, 3200, 3120 (NH_2) cm^{-1}; ^1H nmr (300 MHz, DMSO-d_6) δ: 2.21 (m, 1H, H-2), 2.35 (m, 1H, H-3), 2.89 (dd, 1H, *J* = 10.1 Hz, 11.2 Hz, H-5ax), 3.33 (s, 3H, OCH_3), 3.48 (m, 1H, H-4), 3.64 (dd, 1H, *J* = 5.3 Hz, 11.2 Hz, H-5eq), 4.24 (d, 1H, *J* = 7.8 Hz, H-1), 5.14 (d, 1H, *J* = 4.5 Hz, OH), 5.25–5.55 (m, 4H, NH_2); ^{13}C nmr (75 MHz, DMSO-d_6) δ: 56.2, 66.8, 67.2, 69.5, 103.3; ms, *m/e*: 433 (M + 2), 432 (M + 1). Anal. calcd. for $C_6H_{14}Cl_2N_2O_3Pt$: C 16.83, H 3.30, N 6.54, Cl 16.56; found: C 16.83, H 3.31, N 6.39, Cl 16.85.

Methyl 2-azido-2-deoxy-3-O-methanesulphonyl-β-L-xylopyranoside (15)

(A): To a solution of THP ether **14***a* (0.960 g, 2.74 mmol) in ethanol (35 mL) was added pyridinium *p*-toluenesulfonate (PPTS) (0.100 g, 0.40 mmol). The solution was stirred for 7 h at 55°C, and then evaporated. The residue was applied to a silica gel column. Elution with hexanes – ethyl acetate (4:5, then 1:2) and then concentration gave **15** (0.730 g, quantitative) as white crystals.

(B): The compound **15** can be prepared from **14***b* following the same procedure that was used in (A); mp 111–111.5°C; $[\alpha]_D$ +27.0 (*c* 1.05, $CHCl_3$); ir ($CHCl_3$): 3520 (OH), 2120 (N_3), 1350, 1180 (S=O) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 2.87 (d, 1H, *J* = 3.6 Hz, OH), 3.21 (s, 3H, SCH_3), 3.26 (dd, 1H, *J* = 10.4 Hz, 11.9 Hz, H-5ax), 3.44 (dd, 1H, *J* = 7.7 Hz, 9.7 Hz, H-2), 3.59 (3, 3H, OCH_3), 3.88 (m, 1H, H-4), 4.11 (dd, 1H, *J* = 5.7 Hz, 11.9 Hz, H-5eq), 4.22 (d, 1H, *J* = 7.7 Hz, H-1), 4.30 (t, 1H, *J* = 9.7 Hz, H-3); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 38.63, 57.20, 63.21, 64.89, 68.15, 83.55, 103.35; ms, *m/e*: 268 $(M + 1)^+$.

Methyl 2-azido-2-deoxy-3-O-methanesulphonyl-4-O-methyl-β-L-xylopyranoside (16)

To a solution of compound **15** (2.48 g, 9.30 mmol) in dry ether (300 mL) was added iodomethane (2.3 mL, 37.0 mmol), followed by dry, finely divided, silver oxide (4.30 g, 18.5 mmol) in portions. The suspension was heated under reflux for 4 days. After cooling, the mixture was filtered, and then evaporated to a syrup that was applied to a silica gel column. Elution with ethyl acetate – hexanes (1:1) followed by concentration gave **16** (2.34 g, 89.6%) as a colorless syrup; $[\alpha]_D$ +34.4 (*c* 1.51, $CHCl_3$); ir ($CHCl_3$): 2110 (N_3), 1360, 1180 (S=O) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 3.15 (s, 3H, SCH_3), 3.18 (dd, 1H, *J* = 10.2 Hz, 11.6 Hz, H-5ax), 3.41 (dd, 1H, *J* = 7.8 Hz, 10.2 Hz, H-2), 3.43 (ddd, 1H, *J* = 5.3 Hz, 9.2 Hz, 10.2 Hz, H-4), 3.48 (s, 3H, OCH_3), 3.58 (s, 3H, OCH_3), 4.16 (dd, 1H, *J* = 5.3 Hz, 11.6 Hz, H-5eq), 4.20 (d, 1H, *J* = 7.8 Hz, H-1), 4.33 (t, 1H, *J* = 9.7 Hz, H-3); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 38.96, 57.22, 58.53, 62.75, 63.73, 77.07, 81.90, 103.51; ms, *m/e*: 282 $(M + 1)^+$.

Methyl 2,3-dideoxy-2,3-epimino-4-O-methyl-β-L-ribopyranoside (17)

Compound **16** (2.29 g, 8.15 mmol) in methanol (100 mL) was treated with hydrazine monohydrate (99–100%) (5.5 mL) and Raney nickel (0.3 g). The mixture was heated at reflux until decomposition of the hydrazine was complete (monitored by tlc, approximately 5 h), the suspension was filtered, and the filtrate was evaporated to a syrup that was applied to a silica gel column. Elution with dichloromethane–methanol (20:1), followed by concentration, gave the aziridine **17** (0.90 g, 70%) as a syrup; $[\alpha]_D$ −19.9 (*c* 1.18, $CHCl_3$); ir ($CHCl_3$): 3280 (NH) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 2.20 (br s, 1H, H-2), 2.50 (br s, 1H, H-3), 3.43 (m, 1H, H-5ax), 3.44 (s, 3H, OCH_3), 3.46 (s, 3H, OCH_3), 3.60 (m, 1H, H-4), 3.77 (dd, 1H, *J* = 3.7 Hz, 12.5 Hz, H-5eq), 4.81 (s, 1H, H-1); ms, *m/e*: 160 $(M + 1)^+$.

Methyl 2-amino-3-azido-2,3-dideoxy-4-O-methyl-β-L-xylopyranoside (18)

A mixture of the aziridine **17** (0.840 g, 5.28 mmol), sodium azide (1.40 g, 21.4 mmol), and ammonium chloride (0.580 g, 10.8 mmol) in a mixture of 2-methoxyethanol (75 mL) and water (5.5 mL) was heated for 17 h at 110°C. The solution was evaporated directly to dryness and the residue was extracted with dichloromethane (4 × 25 mL). The extract was washed with half-saturated $NaHCO_3$ (3 × 25 mL), dried (Na_2SO_4), and evaporated to give a syrup that was applied to a silica gel column. Elution with dichloromethane–methanol (20:1) followed by concentration gave the azide **18** (0.850 g, 80%) as a syrup; $[\alpha]_D$ −5.2 (*c* 1.02, $CHCl_3$); ir ($CHCl_3$): 3380, 3300 (NH), 2100 (N_3) cm^{-1}; ^1H nmr (400 MHz, $CDCl_3$) δ: 2.56 (dd, 1H, *J* = 7.8 Hz, 10.3 Hz, H-2), 3.22 (dd, 1H, *J* = 10.1 Hz, 11.5 Hz, H-5ax), 3.24 (dd, 1H, *J* = 9.1 Hz, 10.3 Hz, H-3), 3.35 (ddd, 1H, *J* = 4.9 Hz, 9.3 Hz, 9.9 Hz, H-4), 3.50 (s, 3H, OCH_3), 3.51 (s, 3H, OCH_3), 4.03 (d, 1H, *J* = 7.6 Hz, H-1), 4.13 (dd, 1H, *J* = 4.9 Hz, 11.5 Hz, H-5eq); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 55.11, 56.95, 58.32, 64.12, 67.47, 78.77, 105.33; ms, *m/e*: 203 $(M + 1)^+$.

Methyl 2,3-diamino-2,3-dideoxy-4-O-methyl-β-L-xylopyranoside (19)

To a solution of the azide **18** (0.770 g, 3.80 mmol) in methanol-distilled water (1:1) (30 mL) was added 10% palladium-on-charcoal (400 mg) suspended in methanol (8 mL). The mixture was hydrogenated under atmospheric pressure at room temperature for 24 h. The catalyst was then removed by filtration through Celite. Evaporation of the filtrate followed by co-evaporation with ethanol gave compound **19** (0.630 g, 94%) as white crystals; mp 60–62°C; $[\alpha]_D$ +101 (*c* 0.60, methanol); ir ($CHCl_3$): 3340, 3270 (NH) cm^{-1}; ^1H nmr (400 MHz, methanol-d_4) δ: 2.41 (dd, 1H, *J* = 7.2 Hz, 9.5 Hz, H-2), 2.54 (t, 1H, *J* = 9.0 Hz, H-3), 3.06 (ddd, 1H, *J* = 4.6 Hz, 8.5 Hz, 9.3 Hz, H-4), 3.22 (dd, 1H, *J* = 9.3 Hz, 11.3 Hz, H-5ax), 3.43 (s, 3H, OCH_3), 3.47 (s, 3H, OCH_3), 4.07 (d, 1H, *J* = 7.2 Hz, H-1), 4.12 (dd, 1H, *J* = 4.5 Hz, 11.3 Hz, H-5eq); ms, *m/e*: 177 $(M + 1)^+$.

(SP-4-3)-Dichloro(methyl 2,3-diamino-2,3-dideoxy-4-O-methyl-β-L-xylopyranoside-N,N′) platinum (3)

A solution of the diamine **19** (0.590 g, 3.35 mmol) in distilled water (2.4 mL) was added to a solution of K_2PtCl_4 (1.40 g, 3.37 mmol) in distilled water (15 mL). The mixture was stirred manually until homogeneous, and was left standing in the dark. After 4 h, crystallization began, forming bright yellow plates. When the original red color of the solution became yellow or orange-yellow, the crystals were filtered, washed with cold water (5 × 4 mL), and dried under vacuum in the absence of light for several hours to afford bright yellow crystals of complex **3** (0.890 g, 60%);

mp 295°C (darkening), 325–330°C (dec.); $[\alpha]_D$ +121 (*c* 0.11, H_2O); ir (Nujol): 3500, 3180, 3100 (NH) cm^{-1}; ^1H nmr (300 MHz, DMSO-d_6) δ: 2.29–2.33 (m, 1H, H-2), 2.48–2.55 (m, 1H, H-3), 2.90 (m, 1H, H-5ax), 3.23–3.41 (m, 1H, H-4), 3.30 (s, 3H, OCH_3), 3.33 (s, 3H, OCH_3), 3.90 (dd, 1H, *J* = 4.8 Hz, 11.1 Hz, H-5eq), 4.25 (d, 1H, *J* = 7.7 Hz, H-1), 5.41–5.64 (m, 4H, NH); ^{13}C nmr (75 MHz, DMSO-d_6) δ: 56.33, 58.07, 63.26, 64.55, 64.92, 78.81, 103.28. Anal. calcd. for $C_7H_{16}Cl_2N_2O_3Pt$: C 19.01, H 3.65, N 6.34, Cl 16.04; found: C 18.52, H 3.56, N 5.99, Cl 16.44.

*Methyl 3-azido-2,3-dideoxy-2-phthalimido-β-L-xylopyranoside (**20**)*

To a cold (ice-water bath) solution of *N*-(ethoxycarbonyl) phthalimide (2.16 g, 10.4 mmol) in 25 mL of dry THF was added dry triethylamine (2.0 mL, 14.3 mmol), then a solution of amine derivative **12** (1.63 g, 8.67 mmol) in 30 mL of dry THF. The mixture was stirred at room temperature overnight, then at 55°C for 1 day. After removal of the solvent under reduced pressure the residue was directly applied to a silica gel, column eluting with ethyl acetate – hexanes (1:1, then 5:1) to give **20** (2.25 g, 81.5%) as white crystals; mp 95–96°C; $[\alpha]_D$ +14.1 (*c* 0.96, $CHCl_3$); ir ($CHCl_3$): 3400 (br, OH), 3010, 2100 (N_3), 1775, 1710 (C=O) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 2.82 (d, 1H, *J* = 4.0 Hz, OH), 3.40 (s, 3H, OCH_3), 3.49 (dd, 1H, *J* = 10.3 Hz, 11.5 Hz, H-5), 3.85 (dt, 1H, *J* = 5.3 Hz, 9.6 Hz, H-4), 4.02 (dd, 1H, *J* = 8.2 Hz, 11.4 Hz, H-2), 4.11 (dd, 1H, *J* = 5.3 Hz, 11.5 Hz, H-5), 4.30 (dd, 1H, *J* = 9.3 Hz, 11.4 Hz, H-3), 5.01 (d, 1H, *J* = 8.2 Hz, H-1), 7.75–7.78 (m, 2H, ArH), 7.88–7.90 (m, 2H, ArH); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 53.93, 56.71, 63.48, 66.46, 70.39, 99.70, 123.58, 131.31, 134.27; ms, *m/e*: 319 $(M + 1)^+$.

*Methyl 4-O-acetyl-3-azido-2,3-dideoxy-2-phthalimido-β-L-xylopyranoside (**21**)*

To a cold solution of **20** (1.68 g, 5.28 mmol) in 20 mL of ethyl acetate was added 4-dimethylaminopyridine (DMAP) (0.968 g, 7.90 mmol), then acetic anhydride (1.53 mL, 15.9 mmol) at 0°C. The mixture was stirred at room temperature for 30 min, then cooled to 0°C again. The reaction was quenched by the addition of 2 mL of saturated ammonium chloride and the solution was washed with water, 1 N HCl, water, saturated $NaHCO_3$, water, and brine, then dried with anhydrous magnesium sulfate. Removal of the solvent gave a syrup that was purified by flash chromatography (ethyl acetate – hexanes 1:2, then 2:3) to afford **21** (1.66 g, 87.3%) as white crystals; mp 89–90°C, $[\alpha]_D$ −27.2 (*c* 0.50, $CHCl_3$); ir ($CHCl_3$): 2100 (N_3), 1775, 1750, 1710 (C=O) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 2.12 (s, 3H, CH_3CO_2), 3.41 (s, 3H, OCH_3), 3.44 (dd, 1H, *J* = 9.9 Hz, 11.5 Hz, H-5), 4.07 (dd, 1H, *J* = 8.2 Hz, 11.5 Hz, H-2), 4.22 (dd, 1H, *J* = 5.5 Hz, 11.5 Hz, H-5), 4.51 (dd, 1H, *J* = 9.6 Hz, 11.5 Hz, H-3), 4.98 (ddd, 1H, *J* = 5.5 Hz, 9.6 Hz, 9.9 Hz, H-4), 5.01 (d, 1H, *J* = 8.2 Hz, H-1), 7.76 (m, 2H, ArH), 7.88–7.91 (m, 2H, ArH); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 20.62, 53.71, 56.64, 60.15, 63.42, 71.27, 99.60, 123.59, 131.34, 134.27, 167.67, 169.59; ms, *m/e*: 360 $(M)^+$. *4-O-Acetyl-1,5-anhydro-3-azido-2,3-dideoxy-2-phthalimido-L-xylitol (**22**)*

To a cold solution of **21** (0.500 g, 1.39 mmol) in 6 mL of dry dichloromethane was sequentially added triethylsilane (2.2 mL, 13.8 mmol), boron trifluoride etherate (0.20 mL, 1.63 mmol), and trimethylsilyl trifluoromethanesulfonate (1.34 mL, 6.93 mmol) at 0°C. The reaction mixture was allowed to warm to room temperature, and after 18 h it was diluted with 0.5 mL of methanol and stirred vigorously with solid $NaHCO_3$ (~1 g) for 2 h until pH 7, then filtered and evaporated to dryness. The residue was dissolved in water and extracted with dichloromethane three times. The organic extract was washed with saturated $NaHCO_3$, water, and brine, dried ($MgSO_4$), and evaporated to give a pale yellow residue. Purification by silica gel chromatography with ethyl acetate – hexanes (1:2, then 1:1) gave **22** (0.333 mg, 72%) as a syrup; $[\alpha]_D$ −58.2 (*c* 0.25, $CHCl_3$); ir ($CHCl_3$): 2100 (N_3), 1775, 1755, 1710 (C=O) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 2.12 (s, 3H, CH_3CO_2), 3.33 (dd, 1H, *J* = 10.4 Hz, 11.0 Hz, H-5ax), 3.85 (ddd, 1H, *J* = 0.9 Hz, 5.2 Hz, 11.0 Hz, H-1eq), 3.97 (t, 1H, *J* = 11.0 Hz, H-1ax), 4.17 (ddd, 1H, *J* = 0.9 Hz, 5.3 Hz, 11.0 Hz, H-5eq), 4.28 (dt, 1H, *J* = 5.2 Hz, 11.0 Hz, H-2), 4.62 (dd, 1H, *J* = 9.7 Hz, 11.0 Hz, H-3), 4.96 (ddd, 1H, *J* = 5.2 Hz, 9.7 Hz, 10.4 Hz, H-4), 7.75–7.79 (m, 2H, ArH), 7.86–7.90 (m, 2H, ArH); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 50.02, 60.86, 66.50, 67.61, 71.39, 77.09, 123.52, 123.60, 131.27, 134.23, 134.39, 169.80; ms *m/e*: 331 $(M+1)^+$. Exact Mass calcd. for $C_{15}H_{14}N_4O_5$: 330.0965; found: 330.0973.

*2-Amino-1,5-anhydro-3-azido-2,3-dideoxy-L-xylitol (**23**)*

To a solution of **22** (177 mg, 0.540 mmol) in 12 mL of 95% ethanol and THF (2:1) was added 1.3 mL of hydrazine monohydrate. The reaction mixture was stirred at room temperature for 19 h; the resulting white precipitate was filtered and washed with 95% ethanol a few times and the collected filtrate was then evaporated to dryness to give a residue that was purified by flash chromatography. Elution with dichloromethane–methanol (10:2) gave **23** (57 mg, 68%) as a syrup; ir ($CHCl_3$): 3350 (br), 2100 (N_3) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.75 (br s, 3H, OH, NH_2), 2.89 (dt, 1H, *J* = 4.3 Hz, 8.4 Hz, H-2), 3.21 (dd, 1H, *J* = 8.6 Hz, 11.7 Hz, H-1ax), 3.24 (t, 1H, *J* = 8.4 Hz, H-3), 3.34 (dd, 1H, *J* = 8.4 Hz, 11.4 Hz, H-5ax), 3.67 (dt, 1H, *J* = 4.4 Hz, 8.4 Hz, H-4), 3.89 (ddd, 1H, *J* = 0.7 Hz, 4.3 Hz, 11.7 Hz, H-1eq), 3.94 (ddd, 1H, *J* = 0.7 Hz, 4.4 Hz, 11.4 Hz, H-5eq); ^1H nmr (300 MHz, D_2O) δ: 2.81 (dt, 1H, H-2), 3.22–3.34 (m, 3H, H-1, -3, -5), 3.72 (dt, 1H, H-4), 3.97 (dd, 1H, H-1eq), 4.02 (dd, 1H, H-5eq).

*(SP-4-3)-Dichloro (2,3-diamino-1,5-anhydro-2,3-dideoxy-L-xylitol-N,N′) platinum (**4**)*

The azide derivative **23** (57 mg, 0.36 mmol) was hydrogenated with palladium-on-activated carbon (10%) under an atmosphere of hydrogen in methanol to afford a white residue that was used for next reaction without further purification. The diamine derivative in distilled water (0.3 mL) was added to a solution of K_2PtCl_4 (140 mg, 0.34 mmol) in distilled water (1.5 mL). The mixture was stirred manually until homogeneous, and was left standing in the dark. After 30 min crystallization began, to give yellow plates. When the original red color of the solution became yellow or orange-yellow, the crystals were filtered, washed with cold water, and dried in a desiccator under vacuum, in the absence of light for several hours, to afford bright yellow crystals of **4** (50 mg, 39%); mp > 290°C (dec.); ir (Nujol): 3400 (br, OH), 3260, 3170, 3100 (NH) cm^{-1}; ^1H nmr (300 MHz, DMSO-d_6) δ: 2.12–2.25 (m, 1H, H-3), 2.25–2.42 (m, 1H, H-2), 2.67 (t, 1H, *J* = 10.4 Hz, Hax-5), 3.07 (t, 1H, *J* = 10.4 Hz, Hax-1), 3.35–3.49 (m, 1H, H-4), 3.54 (dd, 1H, *J* = 5.2 Hz, 10.5 Hz, Heq-5), 3.76 (dd, 1H, *J* = 4.5 Hz, 10.4 Hz, Heq-1), 5.09 (d, 1H, *J* = 4.6 Hz, OH), 5.18–5.25 (m, 1H, NH), 5.35–5.40 (m, 2H, NH_2), 5.56–5.60 (m, 1H, NH). Anal. calcd. for $C_5H_{12}N_2O_2Cl_2Pt \cdot 0.5H_2O$: C 14.75, H 3.22, N 6.88, Cl 17.41; found: C 14.64, H 2.96, N 6.64, Cl 17.55.

*(SP-4-3)-Cyclobutane-1,1-dicarboxylato (methyl 2,3-diamino-2,3-dideoxy-β-L-xylopyranoside-N,N′) platinum (**24**)*

To a suspension of platinum complex **2** (100 mg, 0.23 mmol) in 35 mL of deionized water was added a solution of silver nitrate (79 mg, 0.46 mmol) in 5 mL of deionized water. The yellow suspension was stirred vigorously in the dark at room temperature for 1 day. The resulting white precipitate was filtered through Celite and the filtrate was concentrated to ca 3 mL, then transferred into a solution of dipotassium cyclobutane-1,1-dicarboxylic acid (52 mg, 0.24 mmol) in 0.5 mL of deionized water. The mixture was stirred manually until homogeneous and was left standing in the dark, allowing for a slow evaporation to produce crystals after 3 days. A week later, the crystals were filtered and washed with deionized water, then dried over P_2O_5 under vacuum to afford the carboplatinum complex **24** (95 mg, 81%) as white crystals; $[\alpha]_D$ +135 (*c* 0.058, H_2O); ir (Nujol): 3400 (br, OH), 3220, 3120 (NH), 1640,

1615 (C=O) cm^{-1}; ^1H nmr (300 MHz, DMSO-d_6) δ: 1.59–1.69 (m, 2H, cyclobutane H-3), 2.04–2.17 (m, 1H, H-2), 2.18–2.31 (m, 1H, H-3), 2.62–2.78 (m, 4H, cyclobutane H-2), 2.90 (t, 1H, J = 10.8 Hz, Hax-5), 3.34 (s, 3H, OCH_3), 3.36–3.48 (m, 1H, H-4), 3.62 (dd, 1H, J = 5.2 Hz, 11.2 Hz, Heq-5), 4.19 (d, 1H, J = 7.8 Hz, H-1), 5.18 (d, 1H, J = 5.4 Hz, OH), 5.32–5.39 (m, 1H, NH), 5.52–5.59 (m, 1H, NH), 5.93–6.05 (m, 2H, NH_2); ^{13}C nmr (75 MHz, DMSO-d_6) δ: 15.09, 30.06, 30.38, 55.51, 56.32, 62.12, 66.00, 67.50, 69.38, 103.35, 177.38, 177.45; ms, *m/e*: 500 $(M + 1)^+$, 499 $(M)^+$, 498 $(M - 1)^+$. Exact Mass (FAB) calcd. for $C_{12}H_{20}N_2O_7Pt$: 499.0919; found: 499.0938.

Design and synthesis of a cephalosporin–carboplatinum prodrug activatable by a β-lactamase

STEPHEN HANESSIAN[1] AND JIANGUO WANG
Department of Chemistry, Université de Montréal, Montréal (Québec), Canada H3C 3J7

Received November 27, 1992

STEPHEN HANESSIAN and JIANGUO WANG. Can. J. Chem. **71**, 896 (1993).

The design and syntheses of two cephalosporin–carboplatinum prodrugs that can be released by a β-lactamase are described. The hydrolysis of cephalosporins catalyzed by a β-lactamase with acetyl or DACCP as 3′-leaving groups is studied by ^{1}H nuclear magnetic resonance in deuterated buffer solutions. These notions provide a new approach to the use of platinum complexes for antitumor therapy.

STEPHEN HANESSIAN et JIANGUO WANG. Can. J. Chem. **71**, 896 (1993).

Deux agents antitumoraux du type «pro-drug» qui consistent en une unité cephalosporine et une unité de carboplatine ont été synthétisés. Les molécules ont le potentiel d'être hydrolyses par une β-lactamase qui libérerait l'agent antitumoral (DACCP). L'action enzymatique a été étudiée par la résonance magnétique nucléaire du proton.

Introduction

The development of chemotherapeutic agents for the treatment of neoplastic diseases has been an area of immense interest and importance during the last decades (1). The discovery of hybridoma technology (2) and the advent of monoclonal antibodies has also revolutionized many aspects of drug development (3). An obvious application has been in tumor immunotherapy (4), where monoclonal antibodies have been used as directed messengers through conjugation, delivery, and, ultimately, release of drugs at the tumor site.

There are, however, many problems remaining that have limited the more widespread use of this technique in clinical trials (5). Factors affecting the activity of immunotoxin conjugates include the number of target antigens on the cell surface (6), the route of entry into the cell by the conjugate (7), the limited numbers of drug molecules coupled to a single antibody (8), the heterogeneity of antigen expression (9), and maintaining the antigen recognition sites of the antibody after chemical conjugation to the drug. Most of the cytotoxic agents exert their activities once inside the cell, requiring that the monoclonal antibody carrier facilitate the delivery of the drug to its precise site of activity within the cell. Many monoclonal antibodies directed against tumor antigens are not effective in this regard (10).

An exciting development in this area of research has involved the conjugation of specific enzymes to monoclonal antibodies, and the enzymatic release of a drug at the tumor site. The advantage of this approach is that one can, in principle, deliver many drug molecules to the tumor site with each immunoconjugate molecule, and some of the limitations mentioned above could perhaps be overcome.

The mechanism by which most β-lactamases inactivate β-lactam antibiotics is through acylation of a serine residue at the active site of the enzyme (11). In the case of a cephalosporin, a potential leaving group (X) at the 3′-position is eliminated during the enzymatic reaction, which most probably proceeds in two steps (12).

In another context, the leaving group could be an antibacterial agent having a different mode of action than the cephalosporin. Thus, the enzymatic acylation of the cephalosporin moiety by a serine residue in endogenous proteins such as penicillin-binding proteins releases the antibacterial agent, hence the term dual action antibiotics (13).

Recently, the monoclonal antibody – enzyme conjugate technique has been applied to design the prodrugs related to vinca alkaloids (14), and to nitrogen mustards (15) using β-lactamases. The enzyme was obtained from *Enterobacter cloacae*, which offers a number of advantages (16), particularly in being tolerant of a wide variety of substituents at the 3′-position of cephalosporins.

As a general program aimed at the development of novel and effective *cis*-platinum analogs (17, 18), we have been investigating the prospects of applying the above-mentioned strategy to the design of a prodrug consisting of a cephalosporin–platinum complex. Figure 1 schematically illustrates the approach to cancer chemotherapy with a *cis*-platinum prodrug.

Results and discussion

We chose two platinum complexes, 4′-carboxyphthalato (1,2-cyclohexanediamine) platinum (DACCP), which is a potent antitumor agent (19), and a carboplatinum complex that contains a hydrophobic ester linking arm, as the releasable portion of the prodrug. The synthesis of the cephalosporin–DACCP prodrug **8** is illustrated in Scheme 1.

The synthesis started with the commercially available 7-aminocephalosporanic acid (7-ACA), which was converted to the known ester **2** (20). This was then coupled with trimellitic anhydride chloride to afford **3** as a mixture of Δ^2- and Δ^3-acyloxy methyl cephems (ratio 1.5:1). The Δ^2 isomer could be converted to the Δ^3 isomer via the sulfoxide **4**, a process that capitalizes on the fact that β,γ-unsaturated sulfoxides are thermodynamically more stable than the corresponding α,β-unsaturated sulfoxides (21). Reduction (22) of the Δ^3-cephem sulfoxide **4** by phosphorus trichloride gave Δ^3-cephem **5**. The diphenyl methyl ester was cleaved with trifluoroacetic acid (TFA) in the presence of anisole and the resulting carboxylic acid derivative **6** was subsequently converted into the monopotassium compound **7**. Complex formation with *trans*-1,2-diamino cyclohexane platinumII dinitrate (23) afforded the desired product **8** as a white amorphous powder, which was moderately soluble in DMSO and carbonate buffer (~2 mg/mL, pH 10), but very slightly soluble in water (<0.2 mg/mL).

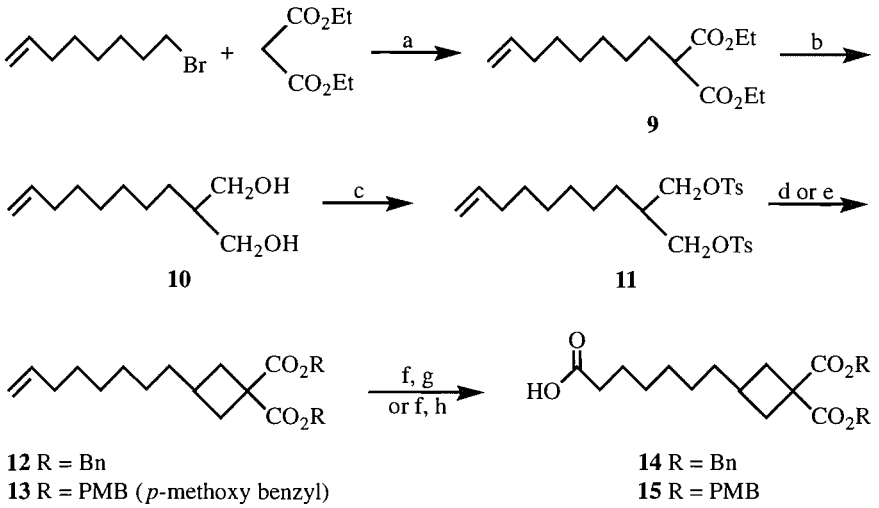
SCHEME 1

We then turned our attention to the synthesis of a second type of cephalosporin – DACH platinum complex. Here, we chose to introduce a hydrophobic linker to provide some flexibility and "distance" between the *cis*-platinum component and the activatable units. The synthesis of the linker is illustrated in Scheme 2.

Alkylation of malonic acid diethyl ester with 8-bromo-1-octene gave compound **9**, which was then reduced to the diol **10** with lithium aluminum hydride. Tosylation of **10** in dichloromethane in the presence of triethylamine gave the ditosyl derivative **11**. The formation of the cyclobutane ring was carried out by treatment of malonic acid dibenzyl ester



(a) NaH, THF, 55°C, 2 days; (b) LAH, THF, r.t., 30 min; (c) TsCl, Et_3N, CH_2Cl_2, r.t., 2 days; (d) dibenzyl malonate, $NaN(SiMe_3)_2$, dioxane, reflux, 1 day; (e) di-*p*-methoxybenzyl malonate, $NaN(SiMe_3)_2$, dioxane, reflux, 1 day; (f) O_3, CH_2Cl_2, −78°C, 5 h; (g) R=Bn: PDC, DMF, r.t., 14 h; (h) R=PMB: 2-methyl-2-butene, *t*-BuOH, $NaH_2PO_4 \cdot H_2O$, $NaClO_2$, r.t., 30 min.

SCHEME 2

and **11** with sodium bis(trimethylsilyl) amide in dioxane to give **12**, which was subsequently oxidized to the acid **14** in a two-step process. It is noteworthy that the normal conditions for malonate condensation (NaH, dioxane) (21) were not effective in the case of **11**. Unfortunately, after esterification of **14** with the Δ^3-cephem **2**, the dibenzyl ester of the resulting compound could not be cleaved by hydrogenation, and only several unidentified products were obtained. Other attempts at debenzylation either gave no reaction or complete degradation. We then decided to repeat the previous synthesis using the *p*-methoxybenzyl ester derivative (24) with *p*-methoxybenzyl chloride to give dimethoxybenzyl malonate. Condensation with ditosyl derivative **11** led to the cyclobutane compound **13**. Ozonolysis of **13** followed by oxidation with sodium chlorite in the presence of 2-methyl-2-butene and sodium dihydrogen phosphate (25) afforded the carboxylic acid **15** in good yield.

Esterification of **15** with **2** by using DCC and DMAP gave **16** as a mixture of two isomers (Δ^2:Δ^3 1.5:1) (Scheme 3). The Δ^2 isomer was converted to the Δ^3 isomer **18** by oxidation with *m*-CPBA and reduction with phosphorus trichloride via sulfoxide **17**. The protecting groups were cleaved with trifluoroacetic acid in the presence of anisole in one step to give tricarboxylic acid **19**. Treatment of this compound with 1 equivalent of aqueous 0.1 N potassium hydroxide solution at 5°C followed by lyophilization led to the desired monopotassium compound **20** and the Δ^2 isomer as a by-product. Finally, aqueous solutions of **20** and dinitrocyclohexane-1,2-diamine platinum(II) were mixed in an equimolar ratio to form the complex **21**, which was obtained as a white amorphous powder.

Model studies of enzymatic hydrolysis by ^1H nuclear magnetic resonance

Previous studies by Faraci and Pratt (12) showed that the enzymatic hydrolysis of cephaloridine and other cephem derivatives at pD 6.4 and pD 10.2 can be followed by ^1H nmr spectroscopy. Accordingly, a model study of the enzymatic hydrolysis was carried out utilizing 3-acetoxymethyl-7-phenylacetylamino cephem potassium salt **22** in phosphate buffer at pD 7 and in carbonate buffer at pD 10.1 (Scheme 4). In the presence of sufficient amounts of β-lactamase (EC 3.5.2.6, type III, from *Enterobacter cloacae*), the initial spectrum changed rapidly (<2 min) to that of the eliminated products (12, 26). Encouraged by, this we proceeded to test the enzymatic hydrolysis with the *cis*-platinum conjugate **8**.

Because of the poor solubility of complex **8** in neutral phosphate buffer solution, a carbonate buffer solution (pD 10.1) was used for the ^1H nmr study of β-lactamase catalyzed hydrolysis. In the presence of sufficient β-lactamase (from *E. cloacae*), the ^1H nmr spectrum of complex **8** changed rapidly to that of the eliminated compounds **23** and **25** (Scheme 5).

Figure 2 shows the ^1H nmr spectra of the cephalosporin–cisplatinum ester **8**, before and after treatment with the enzyme (A and B respectively). The product resulting from compound **22** is shown in C. It can be seen that B contains peaks from the products of enzymatic cleavage as expected. In a control experiment under the same conditions, **8** was stable to hydrolysis for over 2 h.

Conclusion

We have shown that carboplatinum prodrugs can be linked to a cephalosporin via an ester linkage as shown in structures **8** and **21**. The β-lactamase catalyzed hydrolysis of the cephalosporin derivative **8** with DACCP as the 3′-leaving group was studied by ^1H nmr in deuterated buffer solutions, showing that the carboplatinum subunit is indeed released as expected. These results could pave the way to further studies involving the effectiveness of monoclonal antibody – β-lactamase conjugates in releasing the platinum complexes in vivo and the obvious potential in tumor directed chemotherapy (27).

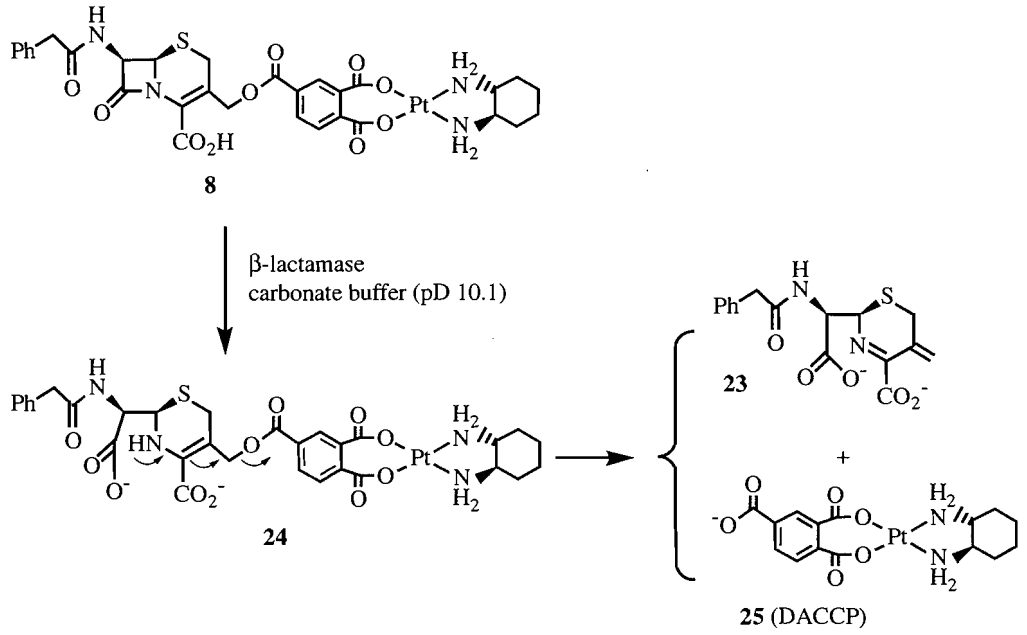
Experimental

Melting points (mp) were determined on a Buchi melting point apparatus and are uncorrected. Optical rotations were measured at 25°C using a Perkin–Elmer model 241 automatic polarimeter. Proton magnetic resonance (^{1}H nmr) spectra were determined on either a 300 MHz Varian or a 400 MHz Bruker spectrometer in deuterated chloroform, methanol-d_4, dimethyl sulfoxide-d_6, or deuterium oxide (D_2O) with $CHCl_3$ (δ_{ppm} = 7.265), Me_4Si (δ_{ppm} = 0.00), or dioxane (δ_{ppm} = 67.40 for ^{13}C) as references. Coupling constants are expressed in hertz (Hz). The abbreviations used for the description of the peaks are as follows: (s, singlet; d, doublet; dd, doublet of doublets; dt, doublet of triplets; ddd, doublet of doublet of doublets; t, triplet; q, quartet; m, multiplet; br, broad). The ^{13}C nmr spectra were recorded on a Varian VXR 300 at 75 MHz. Low-resolution mass spectra were determined on a VG Micro Mass 1212 mass spectrometer by using desorption chemical ionization (DCI), or by fast atom bombardment (FAB). High-resolution mass spectra were determined on a Kratos MS-50 TCTA mass spectrometer by using electron impact (EI) at 70 eV or by the fast atom bombardment (FAB) techniques. Infrared spectra (ir) were recorded on a Perkin–Elmer 781 infrared spectrophotometer. The spectra of solids were recorded as Nujol mulls. Liquid samples were determined as films between sodium chloride plates. Combustion analyses were performed by Guelph Laboratories Ltd., Guelph, Ontario.

Benzene-1,2,4-tricarboxylic acid 4-[[2R-(2α,6α,7β]-(2-benzhydryloxycarbonyl-8-oxo-7-phenylacetylamino-5-thia-1-azabicyclo[4.2.0]oct-3-en-3-yl)methyl] ester (Δ^2 isomer, 3a)



SCHEME 5

*and benzene-1,2,4-tricarboxylic acid 4-[(6*R-trans*)-(2-benzhydryloxycarbonyl-8-oxo-7-phenylacetylamino-5-thia-1-azabicyclo[4.2.0]oct-2-en-3-yl)methyl] ester (Δ³ isomer, 3*b*)*

To a cold (ice-water bath) solution of **2** (420 mg, 0.816 mmol) and DMAP (123 mg, 1.00 mmol) in 15 mL of dry THF was added a solution of trimellitic anhydride chloride (210 mg, 0.987 mmol) in 5 mL of dry THF. The mixture was stirred at that temperature for 30 min. After removing the solvent under vacuum, the residue was dissolved in 50 mL of ethyl acetate and acidified with 5% HCl. The ethyl acetate layer was washed with water and brine, dried ($MgSO_4$), and evaporated to give a slightly brown foam (560 mg, 99%). The crude product was purified by flash chromatography, eluting with ethyl acetate – hexanes (1:3) in the presence of 1% AcOH to give an inseparable mixture of the Δ^2 and Δ^3 isomers (ratio 1:1) of **3** as a foam; ir ($CHCl_3$): 3350, 1855, 1780 (C=O, β-lactam), 1730 (COOR), 1670 (CONH) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) for Δ^3 isomer, δ: 3.42, 3.62 (ABq, 2H, J_{gem} = 18.7 Hz, SCH_2), 3.66 (m, 2H, $PhCH_2$), 5.00 (d, 1H, J = 4.9 Hz, H-6), 5.08, 5.34 (ABq, 2H, J_{gem} = 13.3 Hz, CH_2O), 5.91 (dd, 1H, J = 4.9 Hz, 9.1 Hz, H-7), 6.03 (d, 1H, J = 9.1 Hz, NH), 6.95 (s, 1H, $OCHPh_2$), 7.24–7.41 (m, 15H, PhH), 8.07 (d, 1H, J = 7.9 Hz, aromatic H-6), 8.45 (dd, 1H, J = 1.3 Hz, 7.9 Hz, aromatic H-5), 8.53 (s, 1H, aromatic H-3). For Δ^2 isomer, δ: 3.65 (m, 2H, $PhCH_2$), 4.84, 4.96 (ABq, 2H, J_{gem} = 12.6 Hz, OCH_2), 5.14 (d, 1H, J = 1.5 Hz, H-2), 5.20 (d, 1H, J = 3.9 Hz, H-6), 5.60 (dd, 1H, J = 3.9 Hz, 8.5 Hz, H-7), 6.18 (d, 1H, J = 8.5 Hz, NH), 6.58 (d, 1H, J = 1.5 Hz, H-4), 6.88 (s, 1H, $OCHPh_2$), 7.24–7.41 (m, 15H, PhH), 8.01 (d, 1H, J = 7.9 Hz, aromatic H-6), 8.37 (dd, 1H, J = 1.3 Hz, 7.9 Hz, aromatic H-5), 8.48 (s, 1H, aromatic H-3); ms (FAB), m/e: 729 $(M + Na)^+$, 707 $(M + 1)^+$.

*Benzene-1,2,4-tricarboxylic acid 4-[(6*R-trans*)-(2-benzhydryloxycarbonyl-5,8-dioxo-7-phenylacetylamino-5-thia-1-azabicyclo[4.2.0]oct-2-en-3-yl)methyl] ester (4)*

A solution of **3** (500 mg, 0.726 mmol) in 10 mL of ethyl acetate was cooled to 0°C and *m*-chloroperbenzoic acid (50–60%, 250 mg) in 5 mL of ethyl acetate was added dropwise. After stirring at this temperature for 3 h, the solution was diluted with 60 mL of ethyl acetate and washed with water and brine. The organic phase was dried ($MgSO_4$) and evaporated to give **4** (495 mg, 97%) as a pale yellow residue that was used for next reaction without further purification. However, a small sample was dissolved in a mixed solvent of dioxane (10 mL) and deionized water (1 mL) and stirred at room temperature for 15 min. The solvent was removed under vacuum and the residue was purified by flash chromatography, eluting with dichloromethane–methanol – acetic acid (90:10:1) to afford the pure product **4**; $[\alpha]_D$ +37 (*c* 0.57, methanol); ir ($CHCl_3$): 3300, 1850, 1800, 1780 (C=O, β-lactam), 1720 (COOR), 1710 (CONH) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 3.29, 3.93 (ABq, 2H, J_{gem} = 18.8 Hz, SCH_2), 3.65 (s, 2H, $PhCH_2$), 4.53 (d, 1H, J = 4.1 Hz, H-6), 5.03, 5.53 (ABq, 2H, J_{gem} = 13.7 Hz, CH_2O), 6.11 (dd, 1H, J = 4.1 Hz, 9.6 Hz, H-7), 6.96 (s, 1H, $OCHPh_2$), 6.94 (d, 1H, J = 9.6 Hz, NH), 7.27 (m, 15H, PhH), 8.01 (d, 1H, J = 8.0 Hz, aromatic H-6), 8.40 (dd, 1H, J = 1.3 Hz, 7.9 Hz, aromatic H-5), 8.59 (s, 1H, aromatic H-3), 11.28 (br s, 2H, COOH); ^{13}C nmr (75 MHz, CD_3OD) δ: 43.22, 60.07, 65.48, 68.13, 81.40, 97.19, 122.15, 128.04, 128.11, 128.61, 128.98, 129.46, 129.52, 129.67, 130.30, 130.51, 131.07, 133.21, 133.82, 133.91, 135.42, 140.58, 161.35, 165.75, 168.20, 169.57, 170.60, 174.20; ms (FAB), m/e: 745 $(M + Na)^+$, 723 $(M + 1)^+$. Exact Mass calcd. for $C_{38}H_{30}N_2NaO_{11}S$: 745.1469; found: 745.1549.

Trifluoroacetic acid (1.5 mL, 19.5 mmol) was added dropwise to a solution of compound **5** (565 mg, 0.800 mmol) in anisole (0.52 mL, 4.80 mmol) and dichloromethane (12 mL) at 0°C (ice-water bath), and the mixture was stirred at a similar temperature for 2 h. After removal of the solvent under vacuum the residue was treated with 3 mL of ether and the resulting white precipitate was filtered and washed with ether (5 × 3 mL). This was dried under reduced pressure in a desiccator to give product **6** (410 mg, 95%) as white powder. The compound was used for the next reaction without further purification; $[\alpha]_D$ +25 (c 0.45, DMF); ir (Nujol): 3500–2500 (br, COOH, NH), 1780 (C=O, β-lactam), 1725 (COOR), 1660 (CONH) cm^{-1}; ^1H nmr (300 MHz, methanol-d_4–D_2O 1:1) δ: 3.49, 3.71 (ABq, 2H, J_{gem} = 18.0 Hz, SCH_2), 3.60 (m, 2H, $PhCH_2$), 5.07, 5.29 (ABq, 2H, J_{gem} = 12.5 Hz, $COOCH_2$), 5.08 (d, 1H, J = 4.6 Hz, H-6), 5.65 (d, 1H, J = 4.6 Hz, H-7), 7.22–7.35 (m, 5H, PhH), 7.75–8.42 (m, 3H, aromatic H); ms (FAB), *m/e*: 563 $(M + Na)^+$, 541 $(M + 1)^+$.

*Potassium benzene-1,2,4-tricarboxylic acid 4-[(6*R-trans*)-(2-carboxy-8-oxo-7-phenylacetylamino-5-thia-1-azabicyclo[4.2.0]oct-2-en-3-yl)methyl] ester (**7**)*

To a suspension of tricarboxylic acid **6** (100 mg, 0.185 mmol) in 10 mL of deionized water was slowly added 0.105 N aqueous potassium hydroxide (1.8 mL, 0.189 mmol) at 0°C, at which point the pH value was 6–7. The mixture was stirred at this temperature until most of the suspension had dissolved (pH ~4). The insoluble residue was filtered and the filtrate was lyophilized to give monopotassium salt **7** (102 mg, 95%) as a white powder; $[\alpha]_D$ +83 (*c* 0.9, H_2O); ^1H nmr (300 MHz, D_2O) δ: 3.50, 3.74 (ABq, 2H, J_{gem} = 17.9 Hz, SCH_2), 3.68, 3.74 (ABq, 2H, J_{gem} = 7 Hz, $PhCH_2$), 4.99, 5.20 (ABq, 2H, J_{gem} = 12.5 Hz, $COOCH_2$), 5.13 (d, 1H, J = 4.6 Hz, H-6), 5.67 (d, 1H, J = 4.6 Hz, H-7), 7.35–7.42 (m, 5H, PhH), 7.53 (d, 1H, J = 8.1 Hz, aromatic H-5), 8.05 (dd, 1H, J = 1.6 Hz, 8.1 Hz, aromatic H-6), 8.16 (d, 1H, J = 1.6 Hz, aromatic H-2).

*(SP-4-2)-Dichloro[(1*R,2R*)-cyclohexane-1,2-diamine*-N,N′*] platinum*

A quantity of (1*R*,2*R*)-(−)-1,2-cyclohexanediamine (28) (0.923 g, 8.08 mmol), was dissolved in 8 mL of deionized water at room temperature, and the solution was then added to a solution of K_2PtCl_4 in 40 mL of deionized water. The red colored solution was stirred manually, and was left standing in the dark until the color became yellow or orange yellow. The resulting yellow precipitate was filtered, washed with deionized water 5 times, and dried over P_2O_5 in the absence of light under vacuum to give the platinum complex (2.71 g, 88.2%) as bright yellow crystals: $[\alpha]_D$ +85.3 (*c* 0.66, DMF); ir (Nujol): 3270, 3180, 3100 (NH) cm^{-1}; ^1H nmr (300 MHz, DMSO-d_6) δ: 0.86–1.01 (m, 2H, CH_2), 1.14–1.21 (m, 2H, CH_2), 1.40–1.42 (m, 2H, CH_2), 1.80–1.84 (m, 2H, CH_2), 2.07–2.10 (m, 2H, H-1, -2), 5.00–5.06 (m, 2H, NH), 5.54–5.57 (m, 2H, NH); ^{13}C nmr (75 MHz, DMSO-d_6) δ: 24.19, 31.39, 62.77.

*(SP-4-2)-Dinitro [(1*R,2R*)-cyclohexane-1,2-diamine*-N,N′*] platinum*

To a suspension of the above complex (150 mg, 0.395 mmol) in 50 mL of deionized water was added a solution of silver nitrate (132 mg, 0.777 mmol) in 3 mL of deionized water. The yellow suspension was stirred vigorously in the dark at room temperature for 1 day. The resulting white suspension was filtered with the aid of Celite and the filtrate was concentrated to 12.5 mL. The colorless solution of the platinum complex (0.0315 mmol/mL) was used directly for the next reaction. A small sample was lyophilized to dryness to afford a white powder: $[\alpha]_D$ + 64 (*c* 1.00, H_2O); ir (Nujol): 3240, 3205, 3140 (NH_2) cm^{-1}; ^1H nmr (300 MHz, D_2O) δ: 1.14–1.36 (m, 4H, H-4, -5), 1.58–1.61 (m, 2H, H-3, -6), 2.02–2.08 (m, 2H, H-3, -6), 2.35–2.42 (m, 2H, H-1, -2).

*(SP-4-2)-[4-[(6*R-trans*)-(2-Carboxy-8-oxo-7-phenylacetylamino-5-thia-1-azabicyclo[4.2.0]oct-2-en-3-yl)methoxycarbonyl] benzene-1,2-dicarboxylato][(1*R,2R*)-cyclohexane-1,2-diamine*-N,N′*] platinum (**8**)*

(SP-4-2)-Dinitro (1,2-cyclohexanediamine *N,N′*) platinum (76 mg, 0.176 mmol) was dissolved in 7 mL of deionized water and traces of insoluble material were removed by centrifugation. The supernatant was transferred into a 20-mL vial, and a solution of potassium salt **7** (102 mg, 0.176 mmol) in 3 mL of deionized water was added. The mixture was stirred at room temperature in the dark for 3 h, and the resulting precipitate was filtered, washed with deionized water, and dried over P_2O_5 under vacuum to give the platinum complex **8** (115 mg, 76%) as white powder: $[\alpha]_D$ +60 (*c* 0.33, DMSO); ir (Nujol): 3500–2500 (br, COOH, NH), 2400, 2290, 1780 (C=O, β-lactam), 1720 (COOR), 1640 (CONH) cm^{-1}; ^1H nmr (300 MHz, deuterated carbonate buffer, pD 10.1) δ: 1.09–1.36 (br m, 4H, cyclohexane CH_2), 1.53–1.62 (br m, 2H, cyclohexane CH_2), 1.90–2.07 (br m, 2H, cyclohexane CH_2), 2.38 (br m, 2H, cyclohexane H-1, -2), 3.49, 3.74 (ABq, 2H, J_{gem} = 17.5 Hz, SCH_2), 3.61–3.76 (m, 2H, $PhCH_2$), 4.98, 5.20 (ABq, 2H, J_{gem} = 12.3 Hz, $COOCH_2$), 5.13 (d, 1H, J = 4.6 Hz, H-6), 5.66 (d, 1H, J = 4.6 Hz, H-7), 7.32–7.45 (m, 5H, PhH), 7.51 (d, 1H, J = 8 Hz, aromatic H-5), 8.03 (dd, 1H, J = 1.5 Hz, 7.9 Hz, aromatic H-6), 8.13 (d, 1H, J = 1.4 Hz, aromatic H-2); ms (FAB), *m/e*: 847 $(M)^+$. Anal. calcd. for $C_{31}H_{32}N_4O_{10}PtS \cdot 4H_2O$: C 40.48, H 4.38, N 6.09; found: C 40.62, H 4.21, N 6.24.

*Malonic acid bis(*p*-methoxybenzyl) ester*

A mixture of dipotassium malonate (8.00 g, 45.0 mmol), *p*-methoxybenzyl chloride (13.0 mL, 2.1 equiv.), and dry DMF (160 mL) was stirred at 60 °C for 2 days and then diluted with 700 mL of ether, washed with water, 10% HCl, water, saturated $NaHCO_3$ solution, water, and brine. The organic phase was dried (Na_2SO_4) and evaporated to give a syrup that was purified by flash column chromatography, eluting with ethyl acetate – hexanes (1:3, then 1:1) to give the ester (7.20 g, 47%) as a colorless syrup that was crystallized at 0°C in a refrigerator; mp 28–29°C; ir ($CHCl_3$): 1745, 1730 (C=O) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 3.44 (s, 2H, H-2), 3.82 (s, 6H, OCH_3), 5.11 (s, 4H, $PhCH_2O$), 6.89 (m, 4H, aromatic H), 7.28 (m, 4H, aromatic H); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 41.50, 55.12, 66.96, 113.79, 127.16, 130.06, 159.59, 166.24; ms (FAB), *m/e*: 345 $(M + 1)^+$, 344 $(M)^+$. Exact Mass calcd. for $C_{19}H_{20}O_6$: 344.1260; found: 344.1226.

*2-(Oct-7-enyl)malonic acid diethyl ester (**9**)*

Sodium hydride (1.07 g, 27.0 mmol) was washed with dry THF twice and then suspended in 60 mL of dry THF. Diethyl malonate (4.2 mL, 27.0 mmol) was added dropwise at −20°C. The resulting clear solution was stirred for 5 min before adding 8-bromo-1-octene (2.9 mL, 17 mmol). The reaction was stirred at 55–60°C for 2 days and quenched with ethanol. After addition of ether (350 mL), the resulting white precipitate was filtered, the filtrate was washed with cold water, brine, and dried (Na_2SO_4). Evaporation of the solvent gave a oil that was purified by a flash column (ethyl acetate – hexanes 1:6, then 1:4) to give product **9** (4.50 g, 99%) as a colorless oil; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.27 (t, 6H, J = 7.1 Hz, CH_3), 1.26–1.40 (m, 8H, H-4, -5, -6, -7), 1.88 (m, 2H, H-3), 2.03 (m, 2H, H-8), 3.31 (t, 1H, J = 7.6 Hz, H-2), 4.19 (q, 4H, J = 7.1 Hz, $COOCH_2$), 4.91–5.02 (m, 2H, CH_2=), 5.80 (ddt, 1H, J = 6.8 Hz, 10.5 Hz, 17.3 Hz, C=CH).

*2-(Oct-7-enyl)propane-1,3-diol (**10**)*

To a cold (ice-water bath) solution of **9** (4.50 g, 16.6 mmol) in 100 mL of dry ether was added dropwise lithium aluminum hydride (1 M in THF solution, 34 mL, 34 mmol). After addition was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

complete the mixture was stirred at room temperature for 30 min. The reaction was quenched by slow addition of water at 0°C until effervescence stopped. The mixture was neutralized with 6 N HCL (~25 mL), saturated with solid NaCl, and then extracted with ether (3 × 60 mL). The combined extract was washed with saturated $NaHCO_3$ solution and brine, dried (Na_2SO_4), and evaporated to afford **10** (3.01 g, 98%) as a syrup that was used directly for the next reaction; ir ($CHCl_3$): 3350 (br, OH) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.19–1.41 (m, 10H, H-3, -4, -5, -6, -7), 1.71–1.82 (m, 1H, H-2), 2.00–2.07 (m, 2H H-8), 2.56 (s, 2H, OH), 3.65 (dd, 2H, J = 7.6 Hz, 10.7 Hz, H-1), 3.81 (dd, 2H, J = 3.8 Hz, 10.7 Hz, H-1), 4.95–5.03 (m, 2H, CH_2=), 5.81 (ddt, 1H, J = 6.7 Hz, 10.2 Hz, 17.1 Hz, C=CH-).

*2-(Oct-7-enyl)propane-1,3-diol di-*p*-toluenesulfonate (**11**)*

To a cold (ice-water bath) solution of **10** (162 mg, 0.870 mmol), triethylamine (0.44 mL, 3.1 mmol), and a catalytic amount of DMAP in 5 mL of dry dichloromethane was added slowly a solution of tosyl chloride (500 mg, 2.60 mmol) in 5 mL of dichloromethane. After stirring at room temperature for 2 days, the reaction was quenched by the addition of cold water (0.5 mL) at 0°C. The organic phase was dried over Na_2SO_4 and evaporated to give a syrup that was purified by flash chromatography on silica gel (ethyl acetate – hexanes 1:5, then 1:3, then 1:1) to give pure compound **11** (350 mg, 81%) as a syrup that crystallized on standing in a refrigerator; mp 49–50°C; ir ($CHCl_3$): 1640, 1600, 1465, 1360, 1190, 1175, 1095, 970, 815, 665 cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.11–1.34 (m, 10H, H-3, -4, -5, -6, -7), 1.92–2.04 (m, 3H, H-2, -8), 2.46 (s, 6H, $ArCH_3$), 3.94 (dq, 4H, J = 4.6 Hz, 6.1 Hz, 9.9 Hz, CH_2OSO_2), 4.91–5.02 (m, 2H, CH_2=), 5.79 (ddt, 1H, J = 6.7 Hz, 10.2 Hz, 17.1 Hz, C=CH-), 7.33–7.36 (m, 4H, ArH), 7.72–7.76 (m, 4H, ArH); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 21.46, 26.01, 26.61, 28.50, 28.57, 29.05, 33.48, 37.71, 68.56, 114.12, 127.67, 129.75, 132.23, 138.72, 144.85.

*3-(Oct-7-enyl) cyclobutane-1,1-dicarboxylic acid bis(*p*-methoxybenzyl) ester (**13**)*

To a cold solution of dimethoxybenzyl malonate (5.10 g, 14.8 mmol) in 100 mL of dry dioxane was added dropwise 15 mL of sodium bis(trimethylsilyl)amide (1 M in THF) at 0°C. The solution was stirred at this temperature for 5 min, at which point a solution of the ditosyl derivative **11** (7.35 g, 14.9 mmol) in 100 mL of dry dioxane was slowly added, followed by 15 mL of sodium bis(trimethylsilyl)amide THF solution. The reaction mixture was stirred at 12°C for 15 min, then heated to reflux for 16 h, diluted with 700 mL of ether, washed with 1 N HCl, water, saturated $NaHCO_3$, water, and brine, dried with anhydrous sodium sulfate, and evaporated to give a syrup. Purification by flash chromatography (ethyl acetate – hexanes 1:5, then 1:2) afforded the cyclobutane derivative **13** (3.80 g, 52%) as a colorless syrup; ir ($CHCl_3$): 1725 (C=O) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.15–1.40 (m, 10H, H-1′, -2′, -3′, -4′, -5′), 1.99–2.12 (m, 2H, H-6′), 2.15–2.19 (m, 2H, H-2, -4), 2.31 (m, 1H, H-3), 2.57–2.64 (m, 2H, H-2, -4), 3.80 (s, 6H, $PhOCH_3$), 4.91–5.03 (m, 2H, C=CH_2), 5.04 (s, 2H, $PhCH_2O$), 5.07 (s, 2H, $PhCH_2O$), 5.81 (ddt, 1H, J = 6.8 Hz, 10.3 Hz, 17.0 Hz, C=CH-), 6.81–6.87 (m, 4H, aromatic H), 7.16–7.27 (m, 4H, aromatic H); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 26.53, 28.71, 28.92, 29.15, 29.52, 33.63, 34.70, 36.31, 49.55, 55.08, 66.62, 66.75, 113.67, 114.02, 127.59, 129.70, 139.01, 159.39, 171.45, 171.78; ms, *m/e*: 494 $(M)^+$. Exact Mass calcd. for $C_{30}H_{38}O_6$: 494.2669; found: 494.2676.

*3-(6-Carboxyhexyl) cyclobutane-1,1-dicarboxylic acid bis(*p*-methoxybenzyl) ester (**15**)*

A solution of compound **13** (0.500 g, 1.01 mmol) in 15 mL of dry dichloromethane was cooled to −78°C, and ozone was bubbled into it over 1 h at this temperature. After passing argon through the solution for 30 min, 0.4 mL of dimethyl sulfide was added, followed by 0.5 mL of triethylamine. The solution was stirred for 10 min, and warmed to 0°C for 1 h until almost all of the ozonide disappeared (monitored by tlc). The reaction mixture was diluted with 50 mL of dichloromethane and washed with saturated $NaHCO_3$, water, and brine. The organic phase was dried (Na_2SO_4) and evaporated to dryness to give the aldehyde. The crude aldehyde was dissolved in 20 mL of *tert*-butyl alcohol and 5 mL of 2-methyl-2-butene, then a solution of sodium chlorite (0.810 g, 8.96 mmol) and sodium dihydrogenphosphate hydrate (0.940 g, 6.81 mmol) in 8 mL of deionized water was added dropwise over a 15 min period. The yellow mixture was stirred at room temperature for 30 min. After removal of the volatile components under vacuum, the yellow liquid residue was extracted with 20 mL of ether. The aqueous phase was acidified to pH 3 with 6 N HCl and extracted with ether (2 × 10 mL). The combined ether extracts were washed with water and brine, dried ($MgSO_4$), and evaporated to give a syrup that was purified by flash chromatography on a silica gel column, eluting with ethyl acetate – hexanes (1:3, then 1:2) in the presence of 0.5% acetic acid to give carboxylic acid **15** (0.405 g, 79%, two steps from olefin **13**) as white crystals; mp 56–57°C; ir ($CHCl_3$): 3400–2500 (br, COOH), 1725, 1705 (C=O) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.16–1.38 (m, 8H, H-1′, -2′, -3′, -4′), 1.58–1.63 (m, 2H, H-5′), 2.10–2.19 (m, 2H, H-2, -4), 2.33 (t, 2H, J = 7.4 Hz, H-6′), 2.20–2.35 (m, 1H, H-3), 2.57–2.64 (m, 2H, H-2, -4), 3.80 (s, 6H, $PhOCH_3$), 5.05 (d, 4H, J = 9.2 Hz, OCH_2Ph), 6.81–6.86 (m, 4H, aromatic H), 7.16–7.27 (m, 4H, aromatic H); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 24.42, 26.35, 28.81, 28.89, 29.45, 33.84, 34.65, 36.20, 49.53, 55.05, 66.63, 66.74, 113.66, 127.56, 129.68, 159.37, 171.42, 171.74, 179.80; ms (FAB), *m/e*: 535 $(M + Na)^+$, 513 $(M + 1)^+$. Exact Mass calcd. for $C_{29}H_{36}NaO_8$: 535.2309; found: 535.2248.

*[2R-(2α,6α,7β)-3-[[6-(2-Benzhydryloxycarbonyl-8-oxo-7-phenylacetylamino-5-thia-1-azabicyclo[4.2.0]oct-3-en-3-yl)methoxycarbonyl]hexyl]cyclobutane-1,1-dicarboxylic acid bis(*p*-methoxybenzyl) ester (Δ^2 isomer, **16**a) and (6*R*-trans)-3-[[6-(2-Benzhydryloxycarbonyl-8-oxo-7-phenylacetylamino-5-thia-1-azabicyclo[4.2.0]oct-2-en-3-yl)methoxycarbonyl]hexyl]cyclobutane-1,1-dicarboxylic acid bis(*p*-methoxybenzyl) ester (Δ^3 isomer, **16**b)*

To a cold (ice-water bath) solution of **15** (350 mg, 0.683 mmol) in 50 mL of dry dichloromethane was added DCC (210 mg, 1.02 mmol), DMAP (20 mg), and then a solution of **2** (420 mg, 0.816 mmol) in 150 mL of dry dichloromethane. The mixture was stirred at room temperature overnight, and washed with water, 10% HCl, water, saturated $NaHCO_3$ solution, water, and brine. The organic layer was dried (Na_2SO_4) and evaporated to give a residue that was applied to a column of flash silica gel. Elution with ethyl acetate – hexanes (2:1) gave an inseparable mixture of the Δ^2 and the Δ^3 isomers (ratio 3:2) of **16** (532 mg, 64.6%); For Δ^2 isomer, ir ($CHCl_3$): 3320 (NH), 1780 (C=O, β-lactam), 1730 (COOR), 1680 (CONH) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.15–1.58 (m, 10H, aliphatic CH_2), 2.13–2.34 (m, 5H, CH_2COOR, cyclobutane-CH_2, CH), 2.59–2.66 (m, 2H, cyclobutane-CH_2), 3.64 (ABq, 2H, J = 16.0 Hz, $PhCH_2CON$), 3.80 (s, 6H, $PhOCH_3$), 4.53, 4.59 (ABq, 2H, J_{gem} = 12.8 Hz, 3′-CH_2OCOR), 5.07 (d, 4H, J = 8.9 Hz, $COOCH_2Ph$), 5.09 (s, 1H, H-2), 5.19 (d, 1H, J = 4.0 Hz, H-6), 5.62 (dd, 1H, J = 4.0 Hz, 8.7 Hz, H-7), 6.35 (d, 1H, J = 8.7 Hz, CONH), 6.38 (d, 1H, J = 1.7 Hz, H-4), 6.82–6.87 (m, 4H, PMB-aromatic H), 6.89 (s, 1H, $COOCHPh_2$), 7.16–7.22 (m, 4H, PMB-aromatic H), 7.25–7.44 (m, 15H, aromatic H); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 24.48, 26.35, 28.84, 29.43, 33.70, 34.64, 36.19, 43.08, 49.50, 50.13, 53.26, 55.04, 60.15, 65.14, 66.61, 66.73, 78.99, 113.66, 119.12, 121.66, 126.58–129.66 (multiple peaks), 133.49, 138.74, 159.37, 164.11, 165.81, 170.84, 171.37, 171.69, 172.92; ms (FAB), *m/e*: 1031 $(M + Na)^+$, 1009 $(M + 1)^+$. For personal use only.

A solution of **16** (230 mg, 0.228 mmol) in 25 mL of ethyl acetate was cooled to 0°C and a solution of *m*-chloroperbenzoic acid (50–60%, 88 mg) in 10 mL of ethyl acetate was added dropwise. After stirring at that temperature for 3 h, the solution was diluted with 50 mL of ethyl acetate and washed with saturated $NaHCO_3$ solution, brine, and dried ($MgSO_4$). The solvent was evaporated to give a syrup that was purified by flash chromatography. Elution with ethyl acetate and hexane (1:1, then 3:1) gave a colorless syrup **17** (180 mg, 77%) that crystallized on standing in a refrigerator; $[\alpha]_D$ + 18.9 (*c* 1.35, $CHCl_3$); mp 123–124 °C; ir ($CHCl_3$): 3280 (NH), 1795 (C=O, β-lactam), 1730 (COOR), 1690 (CONH) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.14–1.58 (m, 10H, aliphatic CH_2), 2.15 (m, 2H, cyclobutane-CH_2), 2.25 (t, 2H, J = 7.6 Hz, CH_2COOR), 2.30 (m, 1H, cyclobutane-CH), 2.61 (m, 2H, cyclobutane-CH_2), 3.17, 3.78 (ABq, 2H, J_{gem} = 19.0 Hz, SCH_2), 3.61, 3.68 (ABq, 2H, J_{gem} = 5.6 Hz, $PhCH_2CON$), 3.81 (2 × s, 6H, $PhOCH_3$), 4.45 (dd, 1H, J = 1.5 Hz, 4.8 Hz, H-6), 4.37, 5.29 (ABq, 2H, J_{gem} = 14.3 Hz, 3′-CH_2OCOR), 5.06 (d, 4H, J = 9.5 Hz, $COOCH_2Ph$), 6.10 (dd, 1H, J = 4.8 Hz, 9.9 Hz, H-7), 6.76 (d, 1H, J = 9.9 Hz, CONH), 6.82–6.87 (m, 4H, PMB-aromatic H), 6.95 (s, 1H, $COOCHPh_2$), 7.17–7.20 (m, 4H, PMB-aromatic H), 7.27–7.48 (m, 15H, aromatic H); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 24.55, 26.37, 28.86, 29.46, 33.73, 34.68, 36.18, 43.26, 45.64, 49.54, 55.11, 58.91, 62.99, 66.62, 66.68, 66.80, 80.21, 113.70, 121.34, 125.01, 126.94, 127.42, 127.48, 127.56, 128.05, 128.10, 128.37, 128.48, 128.92, 129.24, 129.71, 133.46, 138.75, 138.85, 159.43, 159.50, 163.97, 171.11, 171.43, 171.74, 172.98; ms (FAB), *m/e*: 1047 $(M + Na)^+$, 1025 $(M + 1)^+$.

*(6*R-trans*)-3-[[6-(2-Benzhydryloxycarbonyl-8-oxo-7-phenylacetylamino-5-thia-1-azabicyclo[4.2.0]oct-2-en-3-yl)methoxycarbonyl]hexyl]cyclobutane-1,1-dicarboxylic acid bis(*p*-methoxybenzyl) ester (**18**)*

Phosphorus trichloride (12 μL, 0.138 mmol) was added to a solution of **17** (70 mg, 0.068 mmol) in 1.5 mL of dry DMF at −22°C. After stirring at this temperature for 1 h, the slightly red solution was diluted with 20 mL of ether, and washed with cold water (2 × 5 mL) and brine. The organic phase was dried ($MgSO_4$) and evaporated to give a syrup that was purified by flash chromatography. Elution with ethyl acetate – hexanes (1:3, then 1:2) afforded the desired product **18** (66.5 mg, 96%) as a colorless syrup; $[\alpha]_D$ −1.2 (*c* 3.05, $CHCl_3$); ir ($CHCl_3$): 3320 (NH), 1790 (C=O, β-lactam), 1730 (COOR), 1680 (CONH) cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$) δ: 1.16–1.59 (m, 10H, aliphatic CH_2), 2.17 (m, 2H, cyclobutane-CH_2), 2.25 (t, 2H, J = 7.6 Hz, CH_2COOR), 2.32 (m, 1H, cyclobutane-CH), 2.62 (m, 2H, cyclobutane-CH_2), 3.31, 3.50 (ABq, 2H, J_{gem} = 18.7 Hz, SCH_2), 3.61, 3.68 (ABq, 2H, J_{gem} = 16.0 Hz, $PhCH_2CON$), 3.81 (s, 6H, $PhOCH_3$), 4.79, 5.04 (ABq, 2H, J_{gem} = 13.7 Hz, 3′-CH_2OCOR), 4.95 (d, 1H, J = 4.8 Hz, H-6), 5.07 (d, 4H, J = 8.9 Hz, $COOCH_2Ph$), 5.88 (dd, 1H, J = 4.8 Hz, 9.1 Hz, H-7), 6.28 (d, 1H, J = 9.1 Hz, CONH), 6.84 (m, 4H, PMB-aromatic H), 6.94 (s, 1H, $COOCHPh_2$), 7.19 (m, 4H, PMB-aromatic H), 7.26–7.45 (m, 15H, aromatic H); ^{13}C nmr (75 MHz, $CDCl_3$) δ: 24.55, 26.22, 26.37, 28.87, 29.44, 33.73, 34.65, 39.19, 43.11, 49.50, 55.07, 57.15, 58.90, 62.63, 66.65, 66.77, 79.58, 113.66, 125.22, 126.86, 126.97, 127.48, 127.95, 128.04, 128.28, 128.40, 129.02, 129.31, 129.69, 133.47, 138.82, 138.99, 159.37, 160.42, 164.64, 171.01, 171.41, 171.72, 173.03; ms (FAB), *m/e*: 1031 $(M + Na)^+$, 1009 $(M + 1)^+$.

*(6*R-trans*)-3-[[6-(2-Carboxy-8-oxo-7-phenylacetylamino-5-thia-1-azabicyclo[4.2.0]oct-2-en-3-yl)methoxycarbonyl]hexyl]cyclobutane-1,1-dicarboxylic acid (**19**)*

Trifluoroacetic acid (0.95 mL, 12.3 mmol) was added dropwise to a solution of compound **18** (250 mg, 0.248 mmol) in anisole (0.40 mL, 3.68 mmol) and dichloromethane (6 mL) with cooling (ice-water bath) and the mixture was stirred at that temperature for 2 h. After removal of the volatile components, the residue was washed with dichloromethane and ether to give white powder **19**, which was used immediately for the next reaction without purification.

*(6*R-trans*-3-[[6-(2-Carboxy-8-oxo-7-phenylacetylamino-5-thia-1-azabicyclo[4.2.0]oct-2-en-3-yl)methoxycarbonyl]hexyl]cyclobutane-1,1-dicarboxylic acid potassium salt (**20**)*

To a mixture of compound **19** (0.25 mmol), ethyl acetate (3 mL), and deionized water (10 mL) was slowly added 0.105 N aqueous potassium hydroxide (2.4 mL, 0.25 mmol) at 0°C. The aqueous solution was then separated and washed with ether twice before lyophilizing to give a white powder **20** (80 mg). The organic phase was treated with 0.105 N KOH aqueous solution until pH 6.5. The aqueous layer was separated and washed with ether twice, then lyophilized to yield a further 58 mg of white powder **20**, bringing the total yield to 138 mg (87%, two steps from **18**); ^1H nmr showed that this powder was a mixture of the Δ^2 and Δ^3 (ratio 1:1.4) isomers; ^1H nmr (300 MHz, D_2O) δ: 1.24–1.68 (m, 20H, aliphatic CH_2), 2.08–2.17 (m, 4H, cyclobutane-CH_2), 2.24–2.38 (m, 2H, cyclobutane-CH), 2.46 (t, 4H, J = 7.4 Hz, CH_2COOR), 2.52–2.59 (m, 4H, cyclobutane-CH_2), 3.39, 3.66 (ABq, 2H, J_{gem} = 17.9 Hz, Δ^3-SCH_2), 3.76 (m, 4H, $PhCH_2$), 4.73, 4.89 (ABq, 2H, J_{gem} = 9.1 Hz, Δ^2-3′-CH_2O), 4.79, 4.98 (ABq, 2H, J_{gem} = 12.5 Hz, Δ^3-3′-CH_2O), 4.86 (d, 1H, J = 1.1 Hz, Δ^2-H-2), 5.15 (d, 1H, J = 4.7 Hz, Δ^2-H-6), 5.35 (d, 1H, J = 3.8 Hz, Δ^3-H-6), 5.47 (d, 1H, J = 3.8 Hz, Δ^3-H-7), 5.70 (d, 1H, J = 4.7 Hz, Δ^2-H-7), 6.52 (s, 1H, Δ^2-H-4), 7.41–7.51 (m, 10H, ArH).

*(SP-4-2)-[4-[(6*R-trans*)-(2-Carboxy-8-oxo-7-phenylacetylamino-5-thia-1-azabicyclo[4.2.0]oct-2-en-3-yl)methoxycarbonyl]hexyl]cyclobutane-1,1-dicarboxylato][(1*R,2R*)-cyclohexane-1,2-diamine-*N,N′*] platinum (**21**)*

(SP-4-2)-Dinitro (1,2-cyclohexanediamine-*N,N′*) platinum (16 mg, 0.036 mmol) was dissolved in 1 mL of deionized water and the trace of insoluble residue was removed by centrifugation. The supernatant was transferred into a 20-mL vial, then a solution of potassium salt **20** (23 mg, 0.036 mmol) in 1 mL of deionized water was added. The mixture was stirred at room temperature in darkness for 3 h and the resulting precipitate was filtered and washed with deionized water, then dried over P_2O_5 under vacuum to give the platinum complex **21** (21 mg, 64%) as a white powder; $[\alpha]_D$ +122 (*c* 0.50, DMSO); ^1H nmr (300 MHz, DMSO-d_6) δ: 1.00–1.50 (m, 16H, hexanyl H-1, -2, -3, -4, -5, cyclohexanyl H-4, -5, Hax-3, -6), 1.88–2.02 (m, 4H, cyclobutane H-2, -4, cyclohexanyl Heq-3, -6), 2.12–2.55 (m, 7H, cyclobutane H-2, -3, -4, hexanyl H-6, cyclohexanyl H-1, -2), 3.3–3.7 (m, 4H, $PhCH_2$, SCH_2), 4.55–6.45 (m, 8H, H-6, H-7, RCO_2CH_2, NH_2), 7.2–7.35 (m, 5H, ArH). Anal. calcd. for $C_{35}H_{46}N_4O_{10}PtS \cdot 3H_2O$: C 43.61, H 5.44, N 5.81; found: C 43.82, H 5.29, N 5.56.

*3-Acetoxymethyl-8-oxo-7-phenylacetylamino-5-thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylic acid potassium salt (**22**)*

To a suspension of 7-aminocephalosporanic acid (7-ACA) (1.20 g, 4.40 mmol) in 40 mL of mixed solvent (acetone–water 1:1) was carefully added $NaHCO_3$ (0.930 g, 11.0 mmol) with cooling (ice-water bath). After the addition was complete, the mixture was warmed to room temperature and stirred until the suspended solid had dissolved in the solvent. The reaction mixture was cooled (0°C) again and a solution of phenyl acetyl chloride (0.87 mL, 6.6 mmol) in 20 mL of acetone was slowly added. Stirring was continued at room temperature overnight. After removal of the solvent, the residue was overlaid with ethyl acetate and acidified with 1 N HCl. The separated aqueous phase was extracted with ethyl acetate three times and the combined extracts were washed with cold water and brine, dried with anhydrous sodium sulfate, and evaporated to give the crude phenylacetylaminocephalosporanic acid. To the residue, dissolved in 150 mL of ethyl acetate, was added, with manual stirring, potassium 2-ethyl hexanoate (0.5 M solution in ethyl acetate) (8.8 mL, 4.4 mmol). The resulting precipitate was filtered and washed with ethyl acetate, then dried under vacuum to afford the desired product **22** (1.56 g, 83%) as yellow crystals; ^1H nmr (300 MHz, deuterated carbonate buffer, pD 10.1) δ: 2.09 (s, 3H, CH_3), 3.34, 3.60 (ABq, 2H, J_{gem} =

17.9 Hz, SCH_2), 3.65, 3.72 (ABq, 2H, J_{gem} = 14.9 Hz, $PhCH_2$), 4.69, 4.86 (ABq, 2H, J_{gem} = 12.7 Hz, CO_2CH_2), 5.07 (d, 1H, J = 4.7 Hz, H-6), 5.62 (d, 1H, J = 4.7 Hz, H-7), 7.32–7.43 (m, 5H, ArH); ^{13}C nmr (75 MHz, D_2O) δ: 18.68, 23.80, 40.37, 55.70, 57.56, 62.53, 114.52, 125.80, 127.31, 127.60, 129.84, 133.01, 163.13, 166.84, 172.40, 173.45; ms (FAB), *m/e*: 428 $(M)^+$. Exact Mass calcd. for $C_{18}H_{17}KN_2O_6S$: 428.0445; found: 428.0468.

Preparation of 0.2 M phosphate buffer (pD 7.2)

A solution containing Na_2HPO_4 (204.5 mg, 1.44 mmol) and $NaH_2PO_4 \cdot 2H_2O$ (87.4 mg, 0.56 mmol) in 2 mL of deuterated water was lyophilized to dryness and the resulting white crystalline residue was dissolved in 10 mL of deuterated water.

Preparation of 0.25 M carbonate buffer (pD 10.1)

A solution containing Na_2CO_3 (159 mg, 1.50 mmol) and $NaHCO_3$ (84 mg, 1.00 mmol) in 2 mL of deuterated water was lyophilized to dryness and the resulting white residue was dissolved in 10 mL of deuterated water.

Preparation of β-lactamase buffer solution

The commercially available (Sigma Chemical Co.) penicillinase (EC 3.5.2.6) type III, from *Enterobacter cloacae* (67 units/mg protein for cepholoridine) was used as hydrolytic enzyme. To the original vial containing 0.15 mg (~10 units) protein was added 0.6 mL of deuterated phosphate buffer (pD 7.2, 0.2 M). The solution (10 units/0.6 mL) was kept in 0–5°C and was used for nmr studies. One unit will hydrolyze 1.0 μmol of cephaloridine per minute at pH 7.0 at 25°C.

Enzymatic hydrolysis of **22** *in 0.2 M phosphate buffer (pD 7.2)—(^1H nmr study)*

Potassium cephalosporinate **22** (5 mg, 11.6 μmol) was dissolved in 0.2 M deuterated sodium phosphate buffer (0.6 mL, pD 7.2) at 20°C. The ^1H nmr spectrum was taken at this temperature and then 0.2 mL (3.3 units) of β-lactamase buffer solution was added. The ^1H nmr spectrum at 20°C was taken immediately; ^1H nmr (300 MHz, deuterated phosphate buffer, pD 7.2) δ: 1.88 (s, 3H, CH_3), 3.35, 3.72 (ABq, 2H, J_{gem} = 14.7 Hz, SCH_2), 3.59, 3.65 (ABq, 2H, J_{gem} = 14.8 Hz, $PhCH_2$), 4.61 (d, 1H, J = 3.0 Hz, H-6), 5.41 (d, 1H, J = 3.0 Hz, H-7), 5.60 (s, 1H, C=CH_2), 5.65 (s, 1H, C=CH_2), 7.27–7.40 (m, 5H, PhH).

Enzymatic hydrolysis of **22** *in 0.25 M carbonate buffer (pD 10.1)—(^1H nmr study)*

Potassium cephalosporinate **22** (5 mg, 11.6 μmol) was dissolved in 0.25 M deuterated sodium carbonate buffer (0.6 mL, pD 10.1) at 20°C. The ^1H nmr spectrum was taken immediately and, subsequently, after 40 min. Then 0.2 mL (3.3 units) of β-lactamase buffer solution was added and the ^1H NMR spectrum was taken immediately (Fig. 2 **C**).

Enzymatic hydrolysis of **8** *in 0.25 M carbonate buffer (pD10.1)—(^1H nmr study)*

A suspension containing 10 mg of platinum complex **8** was stirred in 0.8 mL of deuterated carbonate buffer (pD 10.1) at 0–5°C for 30 min and the mixture was centrifuged. The supernatant was lyophilized and the resulting white powder was dissolved in 0.6 mL of D_2O. The ^1H nmr spectrum was taken immediately (Fig. 2 **A**). To this sample was added 0.1 ml (5 units) of β-lactamase buffer solution. The ^1H nmr was taken immediately at room temperature (Fig. 2 **B**): ^1H nmr (300 MHz, deuterated carbonate buffer, pD 10.1) δ: 1.1–1.4 (br m, 4H, cyclohexane-CH_2), 1.53–1.68 (br m, 2H, cyclohexane-CH_2), 1.95–2.14 (br m, 2H, cyclohexane-CH_2), 2.35 (br m, 2H, cyclohexane-H-1,2), 7.48 (d, 1H, J = 7.8 Hz, aromatic H-5), 7.83 (dd, 1H, J = 1.6 Hz, 7.8 Hz, aromatic H-6), 7.91 (d, 1H, J = 1.5 Hz, aromatic H-2); and 3.93, 3.75 (ABq, 2H, J_{gem} = 14.8 Hz, SCH_2), 3.60–3.71 (m, 2H, $PhCH_2$), 4.64 (d, 1H, J = 3.0 Hz, H-6), 5.44 (d, 1H, J = 3.0 Hz, H-7), 5.63 (s, 1H, C=CH_2), 5.68 (s, 1H, C=CH_2), 7.30–7.42 (m, 5H, ArH).

Substituent effects of rate constants for thermal [4π + 2π] cycloreversion of spiro-fused β-lactam oxadiazolines

MICHEL ZOGHBI AND JOHN WARKENTIN[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received November 6, 1992

MICHEL ZOGHBI and JOHN WARKENTIN. Can. J. Chem. **71**, 907 (1993).

Twelve Δ^3-1,3,4-oxadiazolines in which C-2 is also C-4 of a β-lactam moiety (spiro-fused β-lactam oxadiazoline system) were thermolyzed as solutions in benzene. Substituents in the β-lactam portion affect the rate constant for thermal decomposition of the oxadiazolines to N_2, acetone, and a β-lactam-4-ylidene. The total spread of first-order rate constants at 100°C was 47-fold and the average value was 6.7×10^{-4} s^{-1}. A phenyl substituent at N-1 or at C-3 was found to be rate enhancing, relative to methyl. At C-3, H and Cl were also rate enhancing, relative to methyl. The data are interpreted in terms of the differential effects of substituents on the stabilities of the ground states, and on the stabilities of corresponding transition states for concerted, suprafacial, [4π + 2π] cycloreversion. The first products, presumably formed irreversibly, are N_2 and a carbonyl ylide. The latter subsequently fragments to form acetone (quantitative) and a β-lactam-4-ylidene.

MICHEL ZOGHBI et JOHN WARKENTIN. Can. J. Chem. **71**, 907 (1993).

Douze Δ^3-1,3,4-oxadiazolines dans lesquelles le C-2 fait partie d'une β-lactame (système oxadiazoline avec fusion spiro sur une β-lactame) en solution dans le benzène ont été soumises à une thermolyse. Les substituants de la portion β-lactame affectent le constante de vitesse de la décomposition thermique des oxadiazolines en N_2, acétone et β-lactam-4-ylidène. À 100°C, le rapport des vitesses de réaction du premier ordre de la réaction la plus rapide et de la réaction la plus lente est égal à 47; la valeur moyenne est égale à $6{,}7 \times 10^{-4}$ s^{-1}. On a trouvé que la présence d'un groupe phényle en positions N-1 ou C-3 augmente la vitesse par rapport à celle d'un méthyle. Par rapport au méthyle en C-3, le H et le Cl augmentent aussi la vitesse de réaction. On interprète les données en fonction d'effets différentiels des substituants sur les stabilités des états fondamentaux et sur les stabilités des états de transition correspondants des cycloréversions [4π + 2π] suprafacialles concertées. Les premiers produits, qui se forment vraisemblablement d'une manière irréversible, sont le N_2 et l'ylure de carbonyle. Ce dernier se fragmente ultérieurement pour former de l'acétone (rendement quantitatif) et une β-lactam-4-ylidène.

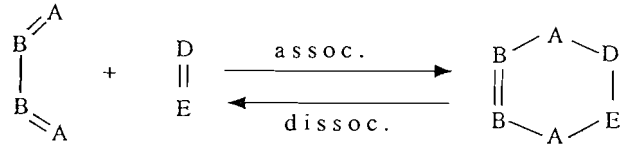
Introduction

Pericyclic processes[2] constitute an important mechanistic class of chemical reactions. Such processes are very useful for the construction of new ring systems from precursors with fewer rings (associative pericyclic reactions), and for generating the products of the reverse, dissociative reactions (Scheme 1). Probably the most familiar examples are the Diels–Alder and retro Diels–Alder reactions.

From a mechanistic perspective, either the forward or the reverse reaction could be selected for study because the transition structures are independent of the direction of approach to them. In practice such a choice may not be available if one of the reactions of Scheme 1 is inaccessible experimentally. Cycloadditions of 4π systems to N_2, for example, are not known. Therefore the mechanisms of pericyclic reactions involving N_2 as one component must be inferred from studies of the dissociative process, which is very well known.[3]

Thermal cycloreversions of Δ^3-1,3,4-oxadiazolines (**1**) lead to carbonyl ylide intermediates (**2**) that are known to undergo a variety of intramolecular and intermolecular reactions, including electrocyclizations (2) to oxiranes (**3**), 1,4-sigmatropic rearrangements to enol ethers (**4**) (3), cycloadditions to dipolarophiles (4), and fragmentations to carbenes and carbonyl compounds (4*b*–*d*, 5), Scheme 2.



SCHEME 1

Fragmentations of carbonyl ylides have assumed increased importance with the discovery that they can be unidirectional, as in the cases of 2,2-dialkoxyoxadiazolines (**5**) (6) and spiro-fused β-lactam oxadiazolines (**8**) (5*b*), which afford dialkoxycarbenes (**7**) and β-lactam-4-ylidenes (**10**), respectively, Scheme 3.

In this paper we report the effects of substituents (R^2–R^3) on the rates of thermolysis of spiro-fused β-lactam oxadiazolines (**8**) to form carbonyl ylides (**9**) and N_2.

Methods and results

Spiro-fused β-lactam oxadiazolines **8** were prepared by [2π + 2π] cycloaddition[4] of 2-imino-Δ^3-1,3,4-oxadiazolines (**11**) to ketenes (**12**) generated, in situ, from appropriate acid chlorides and triethylamine[5] (eq. [1]). Thermolyses were carried out in sealed NMR tubes immersed in a constant temperature oil bath. A tube was removed periodically

[1]Author to whom correspondence may be addressed.

[2]A pericyclic reaction is a concerted reaction that occurs through a cyclic transition state.

[3]The facile thermal cycloreversion of Δ^3-1,3,4-thiadiazolines to N_2 and thiocarbonyl ylides, for example (1).

[4]Although the result is readily accounted for in terms of [2π + 2π] cycloaddition, the actual mechanism is still a controversial subject (7).

[5]Details of the syntheses, including isomer ratios and spectra, are in the accompanying paper (8).

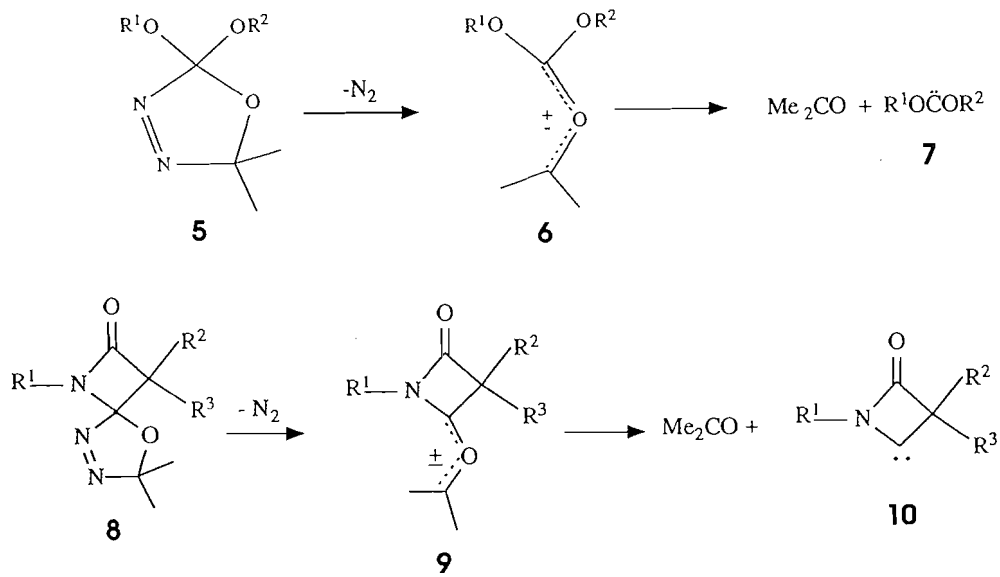

SCHEME 3

and chilled quickly to room temperature for integration of the ^{1}H NMR spectrum. Disappearance of the signals from the methyl groups at C-5 of the oxadiazoline ring, and appearance of the methyl signal of acetone were convenient for monitoring progress of the thermolyses. Reactions were followed to 75% or more of completion. Fits to the first-order rate law gave correlation coefficients ranging from 0.983 to 0.999. Even at high conversions, there was no evidence for consumption of acetone because the yields of acetone, by ^{1}H NMR spectroscopy, were at least 95%. The fates of the β-lactam-4-ylidenes (**10**) in benzene were not determined. Some of their chemistry, including reactions with hydrox-

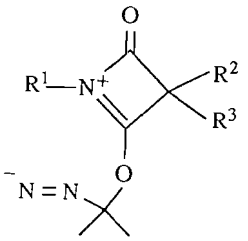
ylic compounds and with alkynes, has been described (5*b*, 9).

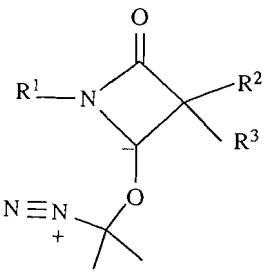
Discussion

The overall mechanism of thermal decomposition of Δ^3-1,3,4-oxadiazolines bearing a heteroatom substituent at C-2 is quite well established. In the first step, N_2 is lost to afford a carbonyl ylide intermediate (4). Evidence for the latter includes trapping of ylide intermediates from 2-alkoxy- and 2,2-dialkoxy-Δ^3-1,3,4-oxadiazolines (4*b*–*d*, 6). For the family **8**, evidence for a discrete carbonyl ylide intermediate is less direct, as bimolecular trapping reactions failed. However, in the case of **13**, a minor product isolated was **14**, which is most easily accounted for in terms of a 1,4-sigmatropic rearrangement of a carbonyl ylide intermediate (Scheme 4). It is most likely then that a carbonyl ylide intermediate is a feature common to the thermolyses of such oxadiazolines, and that the lifetimes of those ylides are sensitive to structural features within them.

There is general agreement that the mechanism of thermal cycloreversion of Δ^3-1,3,4-oxadiazolines involves concerted cleavage of both C—N bonds and disrotatory motion of the end carbons of the developing carbonyl ylide fragment. If that ylide is symmetrically substituted, the cycloreversion is more likely to be synchronous than if it is not. Although transition states involving very asynchronous bond cleavages, with or without charge separation (modelled with **15**, and **16**), can be imagined, it is unlikely that iminium ion character in an amide (**15**) or homoenolate character in a β-lactam system (**16**) would be very significant, especially



15



16

in benzene solvent. On the other hand, **16** is the more likely model for the *sense* of non-synchrony, if any, of the cycloreversions of **8** because the strain associated with introduction of double-bond character into the lactam ring is avoided and yet some relief of steric crowding is gained.

In addition to the question of non-synchronous but concerted cycloreversion and the consequent substituent effects on developing radical (or charged) sites at the transition state, there is the usual concern about the magnitude of substituent effects on the ground state energies. That these are not negligible is clear from the fact that pairs of diastereomers (**8***k* and **8***l*; **8***f* and **8***g*) that lead to enantiomeric carbonyl ylides differ in reactivity by factors of 1.5–5.4. At 100°C, those rate factors correspond to differences of 0.30 and 1.3 kcal mol^{-1}, respectively, in E_a. The ground state free energy difference ΔG (**8***f*–**8***g*), from equilibration of **8***f* and **8***g* with fluoride ion in THF at room temperature, is 0.8 kcal mol^{-1}, more than half as large as the difference (1.3 kcal mol^{-1}) between the activation energies for their decompositions. Therefore, if diastereomers of **8** have significantly different ground state free energies, it is likely that other **8** will show significant effects of both ground state and transition state free energy differences in their thermolysis kinetics. As a result, small rate factors in the family **8** must be interpreted with caution. The following analysis is subject to that caveat.

Taking **8***e* ($R^1 = R^2 = R^3 = R^4 = CH_3$) as reference (rel. rate = 1.0) is convenient because all of the other **8** decompose faster. The largest rate enhancement factors are 39, 47, 39, and 29 for thermolysis of **8***j*, **8***f*, **8***i*, and **8***h*, respectively (Table 1). They have, in common, an aryl group as R^1 (p-C_6H_4OMe or Ph) and the effect of p-anisyl relative to phenyl is small (<2), as judged from comparison of **8***h* with **8***f*. Three (**8***f*, **8***h*, **8***i*) also have, in common, H as R^2 or R^3. We suggest that two factors, electron withdrawal by substituents R^2 and (or) R^3 as well as low steric hinderance, are responsible for the high reactivities of **8***j*, **8***f*, **8***i*, and **8***h*. The former presumably operates by stabilizing the transition state for nitrogen loss (modelled with the carbonyl ylide) in which negative charge begins to build up at the ylide termini (Scheme 5). The latter should be important in permitting relatively facile cycloreversion to the "*exo*" ylide (Scheme 5).[6] In an all-planar geometry, the *endo* ylide has a large eclipsing interaction (R^1 against CH_3) whereas the *exo* ylide has CH_3 lying in the "dihedral gap" (large for small rings) between R^2 and R^3. With the more realistic assumption that neither ylide is all-planar at the energy minimum, the argument is similar. An *endo* ylide has to twist substantially to reduce eclipsing interactions whereas an *exo* ylide bearing H as R^2 or R^3 can relieve nonbonded interactions between CH_3 and the large group (R^3 or R^2) by allowing H to eclipse

[6]The *exo* and *endo* configurations are assigned on the basis of the higher priority of N over C.

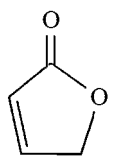
8*k*	Ph	Me	PhO	4.8×10^{-4}	13
8*l*	Ph	OPh	Me	7.2×10^{-4}	19

CH_3 more strongly. Although the steric effect is probably important, **8***j* decomposes quickly without that advantage, pointing to an electronic effect of electron-withdrawing chlorine substituents. The phenoxy substituent is rate enhancing also (**8***l*, rel. rate 19 vs. **8***d*, rel. rate 2.6), and about equal to azido (**8***f* vs. **8***i*) in that respect, both presumably because of their inductive, electron-withdrawing effects. Finally, the influence of phenyls (**8***c* vs. **8***e*) as R^2 and R^3 can be seen in the same light. Although the rate enhancement is only 3.2-fold for two phenyls over two methyls, it is qualitatively in keeping with the small electronegativity difference between the sp^2 and sp^3 carbons. As expected on the basis of the picture that has been developed above, a phenyl group as R^1 should also be rate enhancing, and this was found: **8***d* vs. **8***e*, 2.6-fold; **8***a* vs. **8***b*, **8***c* (2.5, 2.3-fold). Moreover, a phenyl substituent in the oxadiazoline ring is strongly rate enhancing.[7]

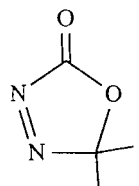
The different reactivities of diastereomers (**8***f* and **8***g*; **8***k* and **8***l*) are more difficult to explain. Although ylides from diastereomeric oxadiazolines must be identical in energy, the transition states leading to those ylides are still diastereomers, and ground state energy differences could either be diminished or intensified at those transition states, depending on the details of the molecular reorganization that is involved.

In each of the diastereomeric pairs, the faster rate is that for thermolysis of the *trans* isomer, which, for the case of the **8***f*, **8***g* pair, is the less stable thermodynamically (by 0.8 kcal mol^{-1}) as shown by equilibration of **8***f* with **8***g* by fluoride ion.[5] The ground state energy difference is unlikely to be of steric origin; if anything, the *cis* isomer is more hindered. Therefore, we propose that the *trans* isomer is destabilized by a dipole–dipole repulsion between the azo and phenoxy groups. As the transition state is approached, the spiro carbon becomes less positive, either because cycloreversion is non-synchronous in the sense of **16** or because both C-2 and C-5 of the oxadiazoline ring have begun to accumulate some of the negative charge of the ylide product. The maximum rate enhancement from the dipole repulsion feature cannot be calculated because the equilibrium constant (**8***f* ⇄ **8***g*) was determined at room temperature in tetrahydrofuran whereas the rates were measured in benzene at 100°C. For the **8***k*, **8***l* pair we assume that the *cis* isomer is again the more stable but the energy difference must be smaller, leading to a rate factor of only 1.5.

That the C—N (azo) bond is polar is evident from the fact that thermolysis rate constants of *cis* azo compounds, in which the bond dipoles are additive, decrease with increasing solvent polarity (10). That feature can best be explained (10) in terms of greater solvation of the ground states of *cis* azo compounds than that of the transition states for thermolysis. Even when the azo group is in conjugation with a carbonyl group its net effect is electron withdrawal, as illustrated with the carbonyl group stretching frequencies of γ-lactone **17** (1750 cm^{-1}) and the diaza analogue **18** (1835 cm^{-1}) (11).



17



18

In summary, concerted cycloreversion of **8** probably occurs through a transition state with carbonyl ylide character significantly developed. The ylide-like transition state has negative charge distributed over C-2 and C-5 of the fragmenting oxadiazoline, as opposed to positive charge at those

[7]Separation of the diastereomers of **13** was not achieved and only a crude estimate of the effect of a phenyl substituent, in the oxadiazoline ring, was possible. The rate constants for **13** at 50°C, and for **8***b* at 100°C, are similar.

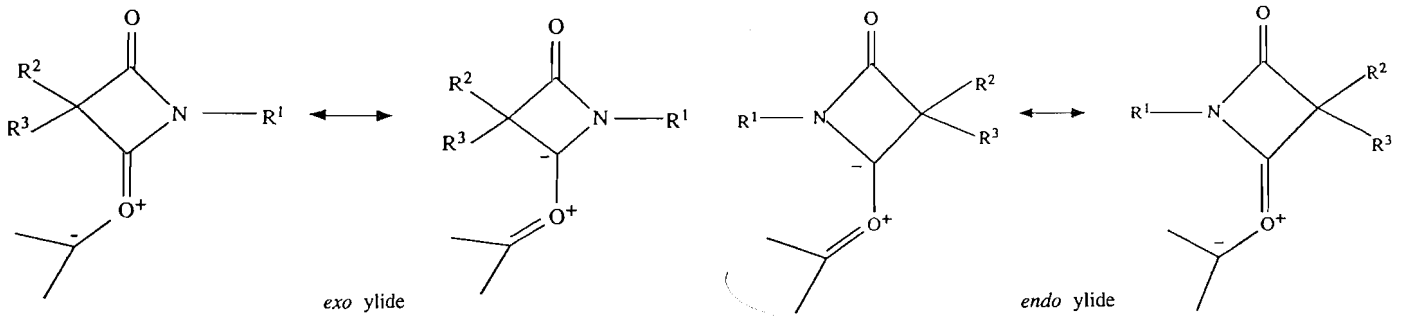

SCHEME 5

sites in the ground state. Moreover, steric interactions between *endo* substituents of the ylide are partly developed at the transition state. The observed substituent effects on thermolysis rate constants can be rationalized in terms of relief of ground state dipole–dipole repulsions, inductive effects of electron-withdrawing groups, and the low steric requirement of H.

Experimental

Thermolyses were carried out in medium-walled NMR tubes with solutions of **8** (25 mg, ca. 0.1 mmol) in C_6D_6 (0.5 mL) containing toluene (ca. 0.05 mmol). The solutions were degassed by means of three freeze–pump–thaw cycles at 10^{-2} Torr (1 Torr = 133.3 Pa) before the tubes were flame sealed, and transferred to a constant temperature bath at 100°C.

Tubes were removed from time to time, and chilled quickly to approximately room temperature with ice water. Integration of the oxadiazoline methyl signals against the methyl signal of the toluene reference afforded values of the concentrations of remaining oxadiazoline. The decompositions of **8** were followed through two to four half-lives. There was no difference, outside of experimental error, between rate constants from reactions followed for one half-life and those from the same reaction followed for four half-lives. Time outside the 100°C bath was not counted and time in the bath was not corrected for the warm-up period following insertion of a sample at room temperature. Standard first-order plots (typically six data points for two to four half-lives) gave the rate constants in Table 1. From the reproducibility of rate constants from duplicate runs conducted a day or more apart, those rate constants are associated with errors less than ±5% of the values quoted.

Spiro-fused β-lactam oxadiazolines by formal [2+2] cycloaddition of 2-imino-Δ^3-1,3,4-oxadiazolines to ketenes

MICHEL ZOGHBI AND JOHN WARKENTIN[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 16, 1993

MICHEL ZOGHBI and JOHN WARKENTIN. Can. J. Chem. **71**, 912 (1993).

Sixteen spiro-fused β-lactam oxadiazolines were prepared by treatment of 2-imino-Δ^3-1,3,4-oxadiazolines with carboxylic acid chlorides in the presence of triethylamine. Two others were prepared by methylation of β-lactam oxadiazoline anion equivalents with methyl iodide. Isomer ratios, spectra, stereochemistry, and relative thermodynamic stabilities of a pair of diastereomeric β-lactam oxadiazolines are reported. Three cases of failure of the approach are noted, to define some of the limitations. The oxadiazolines are known to undergo thermolysis, in solution, to afford N_2, a ketone, and a β-lactam-4-ylidene. Phenyl substitution at C5 of the oxadiazoline ring serves to decrease the thermolysis temperature by about 50°C but it also leads to the onset of a side reaction that lowers the yield of ylidene. This observation indicates a limitation of the oxadiazoline approach to the generation of β-lactam-4-ylidenes.

MICHEL ZOGHBI et JOHN WARKENTIN. Can. J. Chem. **71**, 912 (1993).

Par traitement de 2-imino-Δ^3-1,3,4-oxadiazolines appropriées par des chlorures d'acides en présence de triéthylamine, on a préparé 16 β-lactames oxadiazolines à fusion spiro. On en a préparé deux autres par méthylation des équivalents de l'anion de la β-lactame oxadiazoline par l'iodure de méthyle. On rapporte les rapports d'isomères, les spectres, la stéréochimie et les stabilités thermodynamiques relatives d'une paire de β-lactames oxadiazolines diastéréoisomères. On note trois cas d'échecs de l'approche; ils permettent de définir ses limitations. Il est connu que les oxadiazolines subissent une thermolyse en solution pour donner de l'azote, une cétone et un β-lactam-4-ylidène. La présence d'un substituant phényle en position C5 diminue la température de thermolyse par environ 50°C; toutefois, cette substitution provoque une réaction secondaire qui diminue le rendement en ylidène. Cette observation suggère une limitation à l'approche des oxadiazolines pour générer les β-lactam-4-ylidènes.

[Traduit par la rédaction]

Introduction

The overall reaction of imines with acid chlorides in the presence of a base is one that affords β-lactams. Although the mechanism of the reaction is not well understood,[2] and the rationales for any stereoselectivity are therefore on a tenuous footing, there is no doubt that the reaction is very useful for the construction of the β-lactam ring system.

Following the discovery that 2-alkoxy-Δ^3-1,3,4-oxadiazolines (**1***a*) undergo thermolysis to carbonyl ylides that, in turn, fragment to carbonyl compounds and carbenes (5), we recognized that it might be possible to construct analogous N-substituted oxadiazolines (**1***b*) as potential sources of aminocarbenes (Scheme 1). Moreover, those aminocarbenes might be β-lactam-4-ylidenes if it were possible to synthesize the family of compounds **4** (Scheme 2). One approach to such compounds (**4**) is the [2+2] cycloaddition of ketenes (or ketene equivalents) to 2-imino-Δ^3-1,3,4-oxadiazolines (**3**), Scheme 2.

In this paper we report the synthesis of 18 members of the family **4**, 1,7,8-triaza-5-oxa-2-oxospiro[3,4]oct-7-enes, which we refer to as β-lactam oxadiazolines.[3] Most of them were made by the general approach of Scheme 2 but two were prepared by methylation of a 3-lithio analogue of **4**. Some aspects of stereochemistry, relative thermodynamic stabilities of isomers, as well as effects of a phenyl substituent at C6 on kinetic stability and on the distribution among thermolysis products are reported also.

Methods, results, and discussion

2-Imino-Δ^3-1,3,4-oxadiazolines (**3**) were prepared by oxidative cyclization of semicarbazones (**2**) of ketones as described in the literature (7), reaction [1]. Although two of them had been reported earlier (7*b*, 7*d*), Table 1 lists them also in order to provide all of the diagnostic ^{13}C NMR spectroscopic data in one place. In each case only a single isomer of **3** was obtained and the *Z* configuration shown was assumed by analogy to structures assigned on the basis of single crystal X-ray diffraction (7*a*, 8). Their ^{13}C NMR spectra (C2: δ = 159.0–163.6; C5: δ = 120.2–126.2) identify them as 2-imino-Δ^3-1,3,4-oxadiazolines, given the method of preparation and those X-ray structures.

[1] $R^4R^5C{=}NNHCONHR^1$ (**2**) $\xrightarrow[\text{or } MnO_2]{Pb(OAc)_4}$ (**3**)

Synthesis of a β-lactam oxadiazoline (**4**), Table 2, was accomplished by addition of the acid chloride to a solution of **3** and triethylamine. That mode of mixing of the reagents is believed to result in the formation of a ketene intermediate (9) while the other mode, addition of amine to a solution of acid chloride and imine, is generally assumed to lead to an acyliminium ion intermediate (9).

Attack of the iminooxadiazoline on the ketene should occur preferentially from the less-hindered face of the carbonyl π-bond (Scheme 3) leading to dipolar intermediate **5***a*. The latter, by conrotatory closure (1) would afford that β-lactam oxadiazoline having the larger group (L in Scheme 3) *trans* to the oxadiazoline oxygen. Rotation about the N=C bond

[1]Author to whom correspondence may be addressed.

[2]The literature on this subject, the Staudinger reaction (1), is too extensive to be surveyed here. For recent articles and reviews that include the mechanistic aspects, see refs. 2–4.

[3]A preliminary report of some of this work has been published as a communication (6).

SCHEME 2

of **5***a* would convert it into **6***a* (not illustrated), which is simply the intermediate expected had the imine been of *E* rather than *Z* configuration. Such rotation is thought to be relatively facile in intermediates derived from imidates (10) because of the lower NC bond order (>N=COR ↔ >N—C=OR) in an imidate-derived intermediate. Although **3** are formally imidates, the azo group is powerfully electron withdrawing and modifies their properties.

Diastereoisomerism in the cycloadducts (Scheme 2) could arise from use of an unsymmetric ketene ($R^2 \neq R^3$) and a symmetric imine, because two stereocenters (C3, C4) are generated by cycloaddition, or from use of a symmetric ketene and an imine with a stereocenter. The potential for three stereocenters in the product(s) of cycloaddition was avoided in this study.

Diastereoisomeric products of cycloaddition were observed in some cases (**4***p* and **4***q*, **4***s* and isomer) but not in others (**4***g*, **4***i*, **4***j*), raising the interesting question of whether thermodynamics or kinetics is product controlling. The mechanism of Scheme 3 predicts kinetic control, and support for that mechanism came from the finding that the cycloaddition is under kinetic control. β-Lactam oxadiazoline **4***g*, formed as the exclusive product, was equilibrated with its *cis* isomer (**4***h*) upon treatment with fluoride ion in tetrahydrofuran. At equilibrium (25°C) the composition was **4***g*: **4***h* = 1:4.2. Examination of models suggests that the *trans* isomer is slightly less hindered than the *cis* isomer, although in both isomers the C6 methyl groups are far from the phenoxy substituent at C3. Consequently, the *trans* to *cis* isomerization is unlikely to be driven by steric hindrance. We propose, therefore, that there is a destabilizing dipole–dipole interaction in the *trans* isomer (**4***g*), from eclipsing of the C3-O and the C4-N(azo) dipoles that exceeds the corresponding interaction between the C3-O and C4-O bond dipoles in the *cis* isomer. A measure of the electron-withdrawing effect of the azo group is the σ-constant of the *p*-phenylazo substituent (0.34) (11). The value for the phenyl group (0.05) is small enough to suggest that alkylazo substituents will have σ_p-constants near 0.3, placing them between Cl and CO_2R in inductive electron-withdrawing power. A second indicator of the strong electron-withdrawing character of the azo group is the fact that α,β-diaza-α,β-unsaturated γ-lactones (Δ^3-1,3,4-oxadiazoline-2-ones) have CO stretching frequencies in the infrared near 1835 cm^{-1}, compared to 1750 cm^{-1} in α,β-unsaturated γ-lactones (7*c*, 7*d*, 12).

The assignment of stereochemistry to **4***p* and **4***q* rests on good analogy. Although the cycloaddition afforded both, the major isomer **4***p* was assigned the *trans* geometry, because **4***g* was the *only* product of cycloaddition of phenoxyketene to **3** (R^1=Ph, R^4=R^5=Me), and because the molecular structure of **4***g*, including the *trans* stereochemistry, rests firmly on X-ray crystallography.[4] Similarly, the azido compound **4***j* is most likely to be the *trans* isomer, as assigned. For the products of methylation (**4***m* and **4***n*) of a lithio lactam oxadiazoline, the assignment of stereochemistry could not be based on the same analogy, and the spectroscopic data did not afford any guidance for assignment of stereochemistry to those two compounds. However, the rate constant for thermolysis of **4***p* (*trans*) is about 5-fold larger than that for its *cis* diastereomer **4***q*. On that basis, **4***m* is *trans* and **4***n* is *cis*, because the former decomposes 1.5 times as fast as the latter, in benzene at 100°C (13*a*). Although those assignments are the most likely, a rate factor of 1.5 is not compelling evidence.

Iminooxadiazoline **3***g* is clearly a special case, in that it reacted, with 2:1 stoichiometry, with diphenylketene to afford **4***r*. The order of incorporation, whether **3***g* acts first as a nucleophile to acylate itself at the imino nitrogen, and the product then reacts as an imidate, or whether cycloaddition precedes N-acylation, is not clear.[5]

While it is evident, from the variety of substituents represented in Table 2, that many other spiro-β-lactam oxadiazolines should be accessible, there are limitations to the approach. Thus, attempts to add dimethylketene (from isobutyryl chloride) to **3***c* failed. Similarly, treatment of either **3***a* or **3***c* with phenylacetyl chloride – triethylamine failed to produce the corresponding β-lactam oxadiazolines. In each case of failure, most of the iminooxadiazoline was recovered.

Apart from the question of access to starting materials, potential users of a β-lactam-4-ylidene are interested in the

[4]C. Frampton, M. Zoghbi, and J. Warkentin, unpublished work.

[5]In anticipation of 1:1 stoichiometry, the reaction was conducted with one equivalent of diphenylacetyl chloride. Optimization of the yield through use of other ratios has not been attempted.

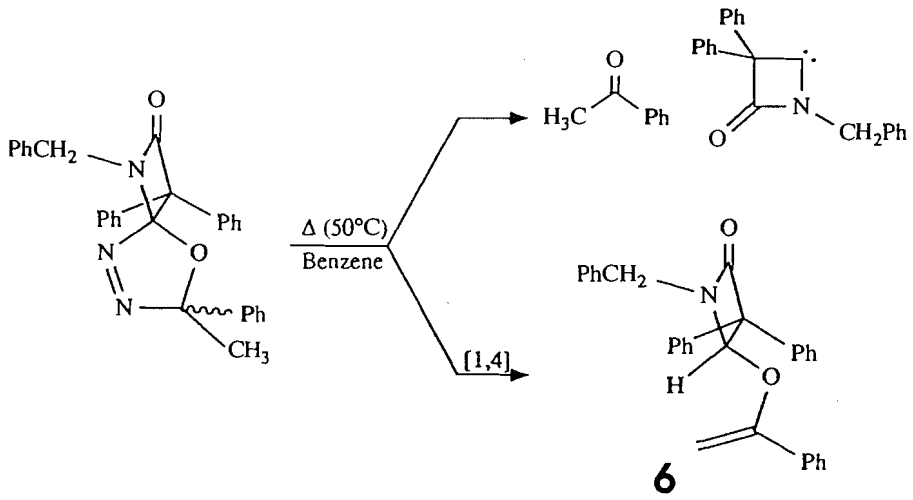
[d]These assignments may be reversed.

choice of available conditions for releasing the carbene. The C6 phenyl isomers **4***o* were prepared with the expectation that the phenyl group would enhance the rate constant for 1,3-dipolar cycloreversion to the carbonyl ylide, eq. [2]. As anticipated, thermolysis of **4***o* (unseparated diastereomers) was faster, with $t_{1/2}$ (50°C, major isomer) ≃90 min and $t_{1/2}$ (50°C, minor isomer) ≃2 × 10^2 min, compared to $t_{1/2}$ (100°C, **4***b*) = 115 min, all in benzene. A 50°C reduction of the

[2]



reaction temperature could be very significant for those ylidene reactions having negative $\Delta S^{\neq}$ values. The rate enhancement by phenyl comes at a small cost. Ylide fragmentation, apparently quantitative (NMR spectroscopy) for other **4**, constitutes about 76% of the fate of **4***o*.[6] The competition must be from 1,4-sigmatropic rearrangement of the carbonyl ylide, to form **6** (eq. [2]), as indicated by the vinyl and methine proton signals, in the ^{1}H NMR spectrum, that are characteristic of such products (13*b*).

Experimental

Materials

The 4-substituted semicarbazones (**2**) required for the preparation of 2-imino-Δ^3-1,3,4-oxadiazolines **3***a*–**3***c* (Table 1) were prepared by the method of Borsche (14) or by treating the appropriate ketone (R^4R^5CO) with a 4-substituted semicarbazide. Acetone-4-methylsemicarbazone was prepared from methylisocyanate, hydrazine, and acetone following Vogelsang's procedure (15). Acid chlorides required for ketenes, or ketene equivalents, were purchased from Aldrich Chemical Co., except for diphenylacetyl chloride and azidoacetyl chloride. The former was prepared as described below, and the latter was synthesized from ethyl chloroacetate by the method of Bertho and Maier (16). Arylimino oxadiazolines (7) and alkylamino oxadiazolines (7) were prepared by known methods.

2-Imino-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**3***g*, R^1 = H, R^3 = R^4 = Me) was prepared as follows (17). To acetone semicarbazone (3.45 g, 0.030 mol) in ice-cold methylene chloride, with dry N_2 bubbling through, was added 30 g of K_2CO_3. Vigorous stirring was started and lead tetraacetate (30.0 g, 0.007 mol) was added. After 30 min an aqueous solution of potassium carbonate (200 mL of 50% solution) was added. A brown sludge was removed by filtration of the entire mixture through a bed of Celite. The organic layer was separated and washed twice with ice-cold aqueous potassium carbonate before it was dried over magnesium sulfate. Evaporation of the solvent left a clear, colourless oil that soon solidified to a white solid (75% yield), mp 56–57°C; IR(CCl_4) ν: 3340, 1705, 1530 cm^{-1}; ^{1}H NMR (90 MHz, CCl_4) δ: 1.60 (s, 6H), 7.70 (s, br, 1H). Anal. calcd. for $C_4H_7N_3O$: C 42.47, H 6.19, N 37.16; found: C 42.30, H 6.27, N 36.98.

Diphenylacetyl chloride.

A mixture of diphenylacetic acid (21.2 g, 0.10 mol) and thionyl chloride (17.8 g, 0.15 mol) was heated on a steam bath for 1 h. The excess $SOCl_2$ was removed under vacuum and the residue was recrystallized from petroleum ether to afford 20.8 g (90%) of the title compound, mp 55–57°C (lit. (18) mp 51–53°C).

General procedure for [2 + 2] cycloaddition to form spiro β-lactam oxadiazolines (4)

The acid chloride (3.0 mmol) in dry methylene chloride (10 mL) was added, drop by drop, to a stirring solution of the iminooxadiazoline (2.5 mmol), triethylamine (6.0 mmol), and methylene chloride (20 mL) under N_2 at ca. −23°C. When addition was complete the cooling bath was removed, and stirring was continued overnight. The reaction solution was then washed with saturated sodium bicarbonate solution and with brine. Aqueous layers were rewashed twice with methylene chloride. The combined organic layers were dried ($MgSO_4$) and filtered. Removal of the solvent afforded the β-lactam oxadiazolines in nearly pure form. Purification was by centrifugal chromatography (Chromatotron, 2-mm plates) with diethyl ether in hexanes (1:4) as eluent. Structures were anchored, through spectroscopic data, to two molecular structures determined by single crystal X-ray diffraction.

trans-*1,7,8-Triaza-3-azido-6,6-dimethyl-5-oxa-2-oxo-1-phenylspiro[3.4]oct-7-ene,* **4**j

Azidoacetyl chloride (1.06 mmol) in dry methylene chloride (3 mL) was added over a period of 1 h, by means of a syringe pump, to a stirring solution of 5,5-dimethyl-2-phenylimino-Δ^3-1,3,4-oxadiazoline (1.06 mmol) and triethylamine (1.06 mmol) in methylene chloride (6.5 mL). The latter solution was under N_2 and it was kept at 0–5°C. When addition was complete the cooling bath was removed but stirring was continued overnight. The solvent was removed and the crude, brown, oily residue was triturated twice with ether. Evaporation of the ether left an orange oil that was chromatographed (Chromatotron, 2-mm silica plate) with ethyl acetate in hexane (1:5) as eluent. The major, first fraction was starting material followed by the title compound as a white solid, 20% yield; mp 99–100°C; IR (KBr) *v*: 2110 (N_3), 1778 (C=O), 1595 (N=N) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.54 (s, 3H), 1.67 (s, 3H), 4.65 (s, 1H) 7.10–7.45 (m, 5H); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 23.53, 24.69, 73.93 (C3), 121.09 (C9), 129.22 (C4), 120.83, 127.16, 129.33 (3 CH, aryl), 133.41 (N-C1, aryl), 160.13 (CO), signal at 123.14 ascribed to impurity; MS (ei) *m/z*: 244 ($M^+ - N_2$, trace), 176 (3%), 161 (12%), 146 (11%), 130

Synthesis of **4**p *and* **4**q

The general procedure described above gave, from 5,5-dimethyl-2-phenylimino-Δ^3-1,3,4-oxadiazoline and methoxyacetyl chloride, a mixture of **4***p* and **4***q*, formed in low yield, and oxadiazoline starting material. Attempts to separate the excess starting material from the products by chromatography were not successful. However, trituration of the crude material with hexane removed most of the more soluble iminooxadiazoline. The hexane insoluble residue was then chromatographed (Chromatoton, 2-mm silica plate) using ether (20%) in hexane to afford starting material followed by **4***q* (the minor β-lactam) and by **4***p*.

Isomerization of **4**g *to* cis-*1,7,8-triaza-6,6-dimethyl-5-oxa-2-oxo-1-phenyl-3-phenoxyspiro[3.4]oct-7-ene,* **4**h

Treatment of **4***g* (1.3 mmol) with tetra-*n*-butylammonium fluoride (2 mmol) in anhydrous THF (2 mL) at room temperature for 5 h was followed by evaporation of the solvent, addition of CH_2Cl_2 (4 mL) and 0.1 M HCl (2 mL). The aqueous layer was extracted three more times with CH_2Cl_2. The combined organic extract was washed with aqueous bicarbonate and with brine before being dried over $MgSO_4$. Evaporation of the solvent left **4***h* as a viscous yellow oil; IR (film) *v*: 1785 (C=O), 1595 (N=N) cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 1.38 (s, 3H), 1.56 (s, 3H), 5.79 (s, 1H) 6.96–7.40 (m, 10H); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 24.08, 24.35, 84.20 (C3), 122.37 (C6), 122.57 (C4), 115.50, 121.14. 123.00, 127.14, 129.36, 129.75 (6 CH, aryl), 133.51 (N-C1, aryl) 156.75 (OC1, aryl), 162.48 (CO); MS (ei) *m/z*: 209 (95%), 180 (100%), 132 (18%), 105 (33%), 77 (34%); MS (ci, NH_3) *m/z*: 341 (($M + NH_4$)$^+$, 50%), 326 (7%), 308 (11%), 210 (100%), 180 (32%), 118 (11%).

Synthesis of **4**m *and* **4**n *by methylation of* **4**g

The procedure used is based on that reported by Durst et al. (19). A solution of LDA in THF was prepared as follows. A dry 25-mL round-bottom flask, equipped with a magnetic stirring bar, was flushed with dry N_2 through a septum. Dry THF (9 mL) was introduced from a syringe followed by dry diisopropylamine (2.3 mmol, 0.32 mL). The flask was cooled with ice and *n*-butyllithium (2.3 mmol, as a solution in hexane[7]) was added drop by drop from a syringe. That solution was used after 15 min following completion of the addition.

The solution of LDA (2.3 mmol, calcd.) was added, *via cannula*, to a stirring solution of β-lactam oxadiazoline **4***g* (2 mmol) in dry THF (125 mL) at −78°C. The colour changed from yellow to orange and, after 10 min, to red. After 15 min iodomethane (0.85 g, 6 mmol) was added and the resulting mixture was stirred, at −78°C and under dry N_2, for 2 h before it was allowed to warm to room temperature over a period of 3 h. Dilute HCl (100 mL of 10%) was added followed by extraction (3×) with methylene chloride. The combined organic layer was washed with brine and dried over $MgSO_4$. Evaporation of the solvent left a brown slurry that was chromatographed (Chromatotron, 2-mm silica plate) with ether (25%) in hexane. The first fraction was **4***m*, followed by **4***n* and by starting material (**4***g*) in 12% yield.

Received November 24, 1992

WOLFGANG KLIEGEL, KLAUS DRÜCKLER, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **71**, 919 (1993).

Two synthetic routes leading to 4-(1′-azoniabicyclo[2.2.2]octanyl)-2,2-diphenyl-2-borata-1,3-dioxa-1,2,3,4-tetrahydronaphthalene, **5**, are described. Crystals of the product are orthorhombic, a = 18.099(2), b = 9.729(2), c = 12.113(2) Å, Z = 4, space group $Pca2_1$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.034 and R_w = 0.037 for 1421 reflections with $I \geq 3\sigma(F^2)$. Compound **5** represents the first structurally characterized crystalline adduct of a trialkylamine to a carbonyl compound in which the newly formed C—N bond is acyclic. The adduct is stabilized by the neighboring Lewis acid diphenylboryloxyaryl moiety. Bond distances involving the boron atom ((aryl)O—B = 1.515(4), (alkyl)O—B = 1.508(4), and C(phenyl)—B = 1.613(5) and 1.623(5) Å) represent relatively strong overall binding of the *O,O*-chelating ligand to the diphenylboron moiety.

WOLFGANG KLIEGEL, KLAUS DRÜCKLER, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **71**, 919 (1993).

On décrit deux voies de synthèse du 4-(1′-azoniabicyclo[2.2.2]octanyl)-2,2-diphényl-2-borata-1,3-dioxa-1,2,3,4-tétrahydronaphtalène (**5**) dont les cristaux sont orthorhombiques, groupe d'espace $Pca2_1$, avec a = 18,099(2), b = 9,729(2) et c = 12,113(2) Å et Z = 4. On a résolu la structure par des méthodes directes et on l'a affinée par la méthodes des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,034 et R_w = 0,037 pour 1421 réflexions avec $I \geq 3\sigma(F^2)$. Le composé **5** est le premier adduit cristallin d'une trialkylamine et d'un composé carbonylé avec liaison C—N acyclique à être caractérisé. L'adduit est stabilisé par la portion acide de Lewis diphénylboryloxyaryle adjacente. Les longueurs des liaisons impliquant le bore ((aryl)O—B = 1,515(4), (alkyl)O—B = 1,508(4) et C(phényl)—B = 1,613(5) et 1,623(5) Å) correspondent à des liaisons globales relativement fortes du ligand *O,O*-coordinant avec la portion diphénylbore.

[Traduit par la rédaction]

Introduction

The reaction product of salicylaldehyde **1** and the anhydride of diphenylborinic acid has been described in the literature (1) as an intramolecular O→B coordinated 2-diphenylboryloxybenzaldehyde **2**. The chelate structure **2** was established by an X-ray crystallographic analysis (2). It was of great interest to us to determine whether a strong nucleophile like a tertiary amine could compete with the carbonyl group as a Lewis base, breaking the chelate ring to form an open-chain N→B adduct **3**, or if the electron withdrawal from the carbonyl carbon atom would allow the addition of the nucleophile R_3N to the carbonyl group to give the zwitterionic adduct **5**. A similar structure, **6**, has been postulated for an intermediate borate complex in a reversible reaction during the boronic acid-catalyzed hydrolysis of an *N*-salicylidene amino acid (3). The importance of zwitterionic intermediates in the understanding of catalytic reactions in general (4) and enzyme-catalyzed reactions (3, 4) in particular, as well as our interest in the structure and function of stable *B,N*-betaines (5, 6), has motivated us to establish unambiguously the structure **5**. The nucleophilic addition of the amine at the carbonyl group to form the *O,N*-acetal moiety in **5** resembles the addition of a hydroxylamine at the salicylaldehyde carbonyl group leading to the product **7**, the structure of which has been established by an X-ray crystallographic analysis (7). Moreover, a complex like **5** would represent a stabilized derivative of the labile zwitterionic primary adduct **4** of an amine to salicylaldehyde. Such an adduct, **4**, corresponds directly to the proposed (8) mode of interaction between (tertiary) amines and the enol tautomers of β-dicarbonyl compounds, the latter being functionally related to salicylaldehyde.

Quinuclidine (1-azabicyclo[2.2.2]octane) was chosen as a suitable trialkylamine having a relatively low degree of steric hindrance and was reacted both directly with the diphenylboron chelate **2** and in an alternative three-component condensation with salicylaldehyde **1** and oxybis(diphenylborane). The latter reaction could involve either **2** or **4** as an intermediate. Both reactions produced colorless crystals having the same melting point and identical infrared spectra. The absence of a C=O absorption in the solid state (KBr pellet) infrared spectrum and the elemental composition strongly support the expected structure **5**. The ^{1}H nmr spectrum (DMSO-d_6 solution), however, shows two separate signals for the aldehyde methine proton, one at δ = 5.72 ppm (typical for an N—CH—O acetal grouping) and another one at 10.25 ppm (typical for an aldehyde (CH=O group), the two peaks comprising 88% and 12%, respectively, of the total peak area. A rearrangement by intramolecular exchange of the Lewis bases at the diphenylboryloxy moiety (**5** ⇔ **3**) does not seem very likely since the ^{1}H nmr spectrum also displays a peak corresponding to a phenolic OH proton at 10.94 ppm with 12% of the total peak area for one proton. This would indicate a partial hydrolysis (by solvent water) resulting in the liberation of salicylaldehyde **1**. An X-ray crystallographic analysis was undertaken in order to establish the structure of the crystalline addition product.

Experimental

4-(1'-Azoniabicyclo[2.2.2]octanyl)-2,2-diphenyl-2-borata-1,3-dioxa-1,2,3,4-tetrahydronaphthalene, 5 (R_3N = quinuclidine)

Method A

2-Diphenylboryloxybenzaldehyde[3] (1) (0.57 g, 2 mmol) is dissolved in 150 mL of dry diethyl ether, heating slightly. After the addition of a solution of quinuclidine (0.22 g, 2 mmol) in 10 mL of diethyl ether, crystallization starts spontaneously. One hour later the crystalline precipitate is filtered off and washed with diethyl ether. Yield: 0.67 g (85%). The same procedure, using absolute benzene (50 mL and 5 mL, respectively) as reaction medium yields 0.61 g (77%).

Method B

Oxybis(diphenylborane) (0.87 g, 2.5 mmol) is dissolved in 30 mL of absolute benzene and mixed with a solution of quinuclidine (0.56 g, 5 mmol) in 10 mL of absolute benzene with stirring. Turbidity develops, but disappears after the addition of salicylaldehyde (0.61 g, 5 mmol). After 1 h crystallization commences and is complete after about 6 h at room temperature. The crystals are filtered off and washed with diethyl ether. The colorless needles are analytically pure. Yield: 1.73 g (87%); mp 184–185°C (dec.).

Infrared (KBr): 1605, 1580 cm^{-1}. ^{1}H nmr (DMSO-d_6/TMS) δ (ppm): 1.51–1.98 (m, H—C(CH$_2$)$_3$), 2.96–3.23 (m, N(CH$_2$)$_3$), 5.72 (s, 88% of 1H, N—CH—O), 6.62–7.70 (m, 14 aromatic H), 10.25 (s, 12% of 1H, CH=O), 10.94 (s, 12% of 1H, OH). Anal. calcd. for $C_{26}H_{28}BNO_2$: C 78.60, H 7.10, B 2.72, N 3.53; found: C 78.56, H 7.16, B 2.75, N 3.47%. Crystals suitable for X-ray analysis were selected from the batch of crystals obtained from the benzene solution method B).

X-ray crystallographic analysis of 5 (R_3N = quinuclidine)

A crystal ca. 0.05 × 0.10 × 0.35 mm is size was mounted on a glass fiber. Unit-cell parameters were refined by least squares on

[3]Alternative nomenclature: (salicylaldehydato)diphenylboron (2); or systematically: 2,2-diphenyl-2-borata-1,3-dioxa-1,2-dihydronaphthalene.

setting angles for 25 reflections (2θ = 37.2–64.7°) measured on a diffractometer with Cu-K_α radiation (λ = 1.54178 Å). Crystal data at 21°C are as follows:

$C_{26}H_{28}BNO_2$ f.w. = 397.32

Orthorhombic, a = 18.099(2), b = 9.729(2), c = 12.113(2) Å, V = 2132.7(5) Å^3, Z = 4, ρ_c = 1.237 Mg m^{-3}, $F(000)$ = 848, μ(Cu-K_α) = 5.62 cm^{-1}. Absent reflections: $0kl$, l odd, and $h0l$, h odd, space group $Pca2_1$ (No. 29) from structure analysis.

Intensities were measured with graphite-monochromated Cu-K_α radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 32° min^{-1} over a range of (0.94 + 0.20 tan θ)° in ω (with up to 8 rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 155°. The intensities of three check reflections, measured every 200 reflections throughout the data collection, showed only small random variations. After data reduction,[4] decay and empirical absorption corrections (based on azimuthal scans for three reflections) were applied. Transmission factors range from 0.96 to 1.00. Intensities were measured for 2305 independent reflections of which 1421 had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = [S^2(C + 4B) + (0.02F^2)^2]/\mathrm{Lp}^2$ (S = scan speed, C = scan count, B = total background count, and Lp = Lorentz-polarization factor) and were employed in the solution and refinement of the structure.

The systematic absences are consistent with the space groups $Pcam$ and $Pca2_1$. The structure was solved by direct methods, the analysis being initiated (and successfully completed) in the non-centrosymmetric space group $Pca2_1$ on the basis of the E-statistics and structural considerations. With four molecules in the unit cell, an ordered structure in the centrosymmetric space group $Pcam$ is ruled out since the molecule cannot possess mirror symmetry. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in calculated positions (C—H = 0.98 Å, $B_H = 1.2B_{\text{bonded atom}}$). A correction for secondary extinction was applied, the final value of the extinction coefficient being 2.42 × 10^{-6}. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 9. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix least-squares refinement of 271 variables. Reflections with $I < 3\sigma(F^2)$ were not included in the refinement. Convergence was reached at R = 0.034 and R_w = 0.037 for 1421 reflections with $I \geq 3\sigma(F^2)$. Possible minor librational disorder of the C(15)—C(20) phenyl ring and minor rotational disordering of the quinuclidine moiety about the C(7)—N(1) bond or conformational flipping of the N(1)—C—C—C(10) fragment is noted. No attempt was made to model this minor disorder, but metrical parameters involving these regions of the molecule may be affected. A parallel refinement of the structure having the opposite polarity resulted in slightly higher residuals, the R and R_w ratios being 1.006 and 1.003, respectively. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

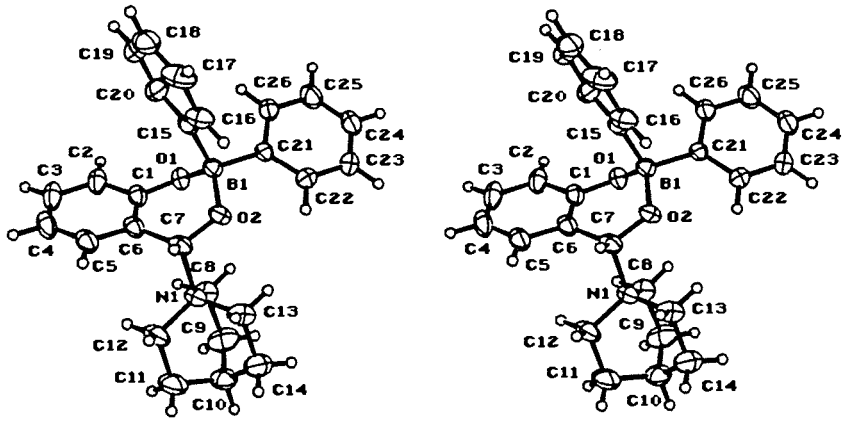

FIG. 1. Stereoview of **5** (R_3N = quinuclidine); 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

On the final cycle of refinement the maximum parameter shift corresponded to 0.01σ. The mean error in an observation of unit weight was 1.55. The final difference map showed maximum fluctuations of -0.10 to $+0.11$ e Å^{-3}. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths, bond angles, and intra-annular torsion angles are given in Tables 2–4, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and structure factors have been deposited.[5]

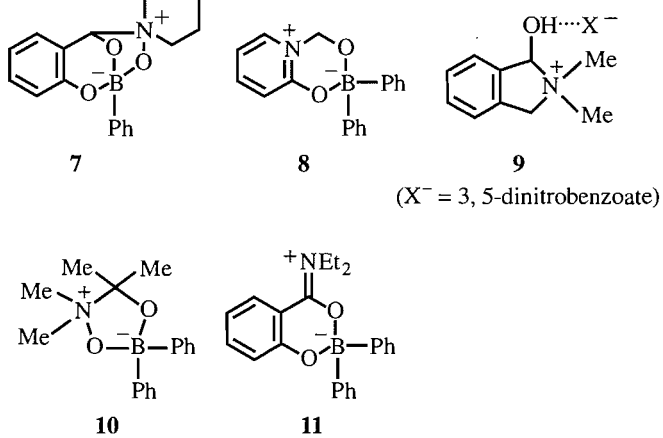
Results and discussion

The X-ray analysis confirms structure **5** for the crystalline compound. This is, to the best of our knowledge, the first structurally characterized crystalline open-chain[6] adduct of a trialkylamine to a carbonyl compound, stabilized by the neighboring Lewis acid diphenylboryloxyaryl moiety. Open-chain adducts of pyridine to carbonyl compounds, stabilized by trifluoroborane, have been predicted and calculated (by semi-empirical MNDO procedures) but could not be isolated (10). An $SbCl_5$-stabilized adduct of 4-*tert*-butylpyridine and 4-methoxybenzaldehyde, however, could be crystallized and has been characterized by an X-ray crystallographic analysis (10).

Stabilized adducts having the amine nitrogen inserted into a ring system along with the carbonyl carbon atom are already known and have been analyzed by single crystal X-ray analysis. Examples of this type of adduct include the phenylboronate-stabilized cyclic adduct **7** (7), the diphenylborinate-stabilized amine-aldehyde adducts like **8** (11), and others (6, 12, 13). The crystal structure of an intramolecular tertiary amine-aldehyde adduct **9**, stabilized by 3,5-dinitrobenzoic acid, has recently been published (14).

The carbonyl C=O double bond of salicylaldehyde **1** is lengthened to 1.261(4) Å in the diphenylborinate **2** and by an additional 0.1 Å in the quinuclidine adduct **5** (C(7)—O(2) = 1.362(4) Å). The C(7)—O(2) bond in **5**, however, still retains some double-bond character, the π-bond order being estimated at about 0.3 from plots of bond length vs. CO π-bond order (15). Similar carbonyl C=O bond lengths have been reported for the intramolecularly stabilized pyridine-formaldehyde adduct **8** (11) (1.363(4) Å) and for the cyclic intramolecular adduct **9** (14) (1.366(3) Å). The C—O bond in the *O,N*-acetal group of **7** (7) (1.378(2) Å) is significantly longer than that in **5**.

The N—C bond lengths in **5** and **7** follow the reverse of the trend noted for the C(7)—O bonds: that in **5** (N(1)—C(7) = 1.590(4) Å) is significantly longer than the corresponding bond in **7** (7) (1.565(2) Å) and marginally longer than the N—C bond of the *O,N*-acetal (semi-aminal) group of **9** (14) (1.581(4) Å). All of these N—C distances are unusually long, especially those in **5** and **9**, which exhibit N—C bond distances normally associated with sterically hindered systems such as the bulky substituted *O,N*-acetal moiety of the stabilized cyclic acetone adduct **10** (13) (1.584(3) Å). The



7 **8** **9**

(X^- = 3, 5-dinitrobenzoate)

10 **11**

relatively weak N(1)—C(7) bond in **5** could explain the solvolytic lability of the compound which can be observed in the solutions used for the nmr experiments (see above).

The increase of electron density at the carbonyl oxygen atom, caused by the addition of quinuclidine to salicylaldehyde **1** or to its diphenylboron complex **2**, is made evident by the shortening of the B—O(2) bond in **2** (1.569(4) Å) to 1.508(4) Å for the corresponding B(1)—O(2) bond in **5**.

The overall binding strength of the *O,O*-chelating ligand with respect to the diphenylboron moiety, defined as (mean C—B)/(mean O—B), ranges from 1.039 to 1.088 (mean 1.058) for "Ph_2BO_2" compounds having six-membered chelate rings (16). The value calculated for **5**, 1.070, represents relatively strong binding, while that for compound **2**, 1.044, indicates weak binding. In general, complexes of the diphenylborenium moiety, which behaves like a pseudo-metal cation, will undergo ligand exchange reactions if the difference in the overall binding strengths of the ligands is large enough. In view of the substantial difference between the binding parameters for **2** and **5**, it is not surprising that the latter can be synthesized directly from the salicylaldehyde complex.

The overall geometry of the molecule **5** displays a distorted "half-boat" arrangement of the six-membered boron chelate ring, with the fused benzene ring coplanar with the approximately planar O(1)—C(1)—C(6)—C(7) ring segment. The quinuclidine and one of the *B*-phenyl substituents are in axial positions. The axial B(1)—C(15) bond to the *B*-phenyl group (1.623(5) Å) is somewhat longer than the equatorial B(1)—C(21) bond (1.613(5) Å). Comparable differences between (pseudo-)axial and (pseudo-)equatorial B—C(aryl) bonds have been noted for a number of other diphenylboron chelates (17, 18, and references therein).

A *B,N*-betaine of type **5** can be considered, in a sense, as being a reduced form of the *B,N*-betaine **11**, both carrying the formal positive charge outside of the boron chelate ring in trialkyammonium and dialkyliminium groups, respectively. The structure of **11**, a diphenylboron chelate of *N,N*-diethylsalicylamide, has also been established by an X-ray crystallographic analysis (18). As can be expected from the different functionalities of the N—C—O moieties in the two compounds, the most drastic geometrical differences are found there: the N—C and C—O bonds in compound **11** both display partial double bond character and are thus substantially shorter than the corresponding bonds in **5**. The general geometry of the benzo-fused boron chelate rings is very similar in the two compounds.

The polar, but not chiral, crystal structure is built up from pairs of enantiomers (generated by the chiral carbon atom C(7) — the *S* isomer is depicted in Fig. 1). All intermolecular distances correspond to normal van der Waals interactions.

Received November 30, 1992

ANDREW W. HAKIN, SUSAN A.M. MUDRACK, and COLIN L. BESWICK. Can. J. Chem. **71**, 925 (1993).

Measurements have been made at 288.15, 298.15, and 308.15 K with a flow microcalorimeter and densimeter to obtain heat capacities and densities for L-ascorbic acid and sodium chloride in water. These data are reported in terms of apparent molar volumes ($V_{\phi,2}$) and apparent molar heat capacities ($C_{p,\phi,2}$). The volume of ionization (ΔV^0) and heat capacity of ionization (ΔC_p^0) for the acid at 298.15 K have been calculated using a method that does not require volumetric and thermochemical data for the sodium salts of the acid. Details of our methodology are presented.

ANDREW W. HAKIN, SUSAN A.M. MUDRACK et COLIN L. BESWICK. Can. J. Chem. **71**, 925 (1993).

Dans le but de déterminer les capacités calorifiques et les densités de l'acide L-ascorbique et du chlorure de sodium dans l'eau, on a effectué des mesures à 288,15, à 298,15 et à 308,15 K à l'aide du microcalorimétre à écoulement et d'un densimètre. On rapporte ces données en fonction des volumes molaires apparents ($V_{\phi,2}$) et des capacités calorifiques molaires apparentes ($C_{p,\phi,2}$). Faisant appel à une méthode qui ne nécessite pas d'avoir des données volumétriques ou thermodynamiques pour les sels de sodium de l'acide, on a calculé le volume d'ionisation (ΔV^0) et la capacité calorifique d'ionisation (ΔC_p^0) de l'acide à 298,15 K. On présente de détails de notre méthodologie.

[Traduit par la rédaction]

Introduction

Equilibrium constants for ionization of most organic acids that are important in biochemistry, marine chemistry, and analytical chemistry are available. For some of these acids we also have values of the enthalpy of ionization, ΔH^0, (either from calorimetry or d ln K/dT) and thence values of the entropy of ionization, ΔS^0 (1–3). There are, however, relatively few ΔC_p^0 and ΔV^0 values for ionization of organic acids in aqueous solution (4).

The research described here was intended to provide ΔC_p^0 and ΔV^0 for ionization of L-ascorbic (vitamin C) at 298.15 K. Because of the ease of oxidation of aqueous solutions of the sodium salt of L-ascorbic acid we have also focussed on development and application of methodology that can minimize such chemical problems, with the expectation that our method will also be applicable to other aqueous acid systems.

Experimental

L-Ascorbic acid (99+%) was obtained from Aldrich Chemical Company. The purity of the compound was determined by titration with potassium bromate and was found to be greater than 99.5%. Sodium chloride 99.99% was obtained from Aldrich Chemical Company and was used without further purification. Samples of the acid and NaCl were dried and stored over phosphorus pentoxide in a vacuum oven set at 50°C. All solutions were prepared by weight with bi-distilled, degassed water. New solutions of the acid were prepared daily.

Densities were measured relative to water with a vibrating tube flow densimeter (5) (Sodev O2D). The densimeter is connected to a programmable circulating thermostat and has a working temperature range of 0–75°C with a thermal stability of ±0.001°C. This experimental apparatus routinely measures densities with part per million precision.

Calibration constants for the densimeter at 288.15, 298.15, and 308.15 K were calculated from the measured time periods of vibration and the densities of dry nitrogen gas and water (6). Calibration constants were determined prior to and following each series of experiments.

Volumetric heat capacities were measured relative to water using a Picker flow microcalorimeter (7). Automated data collection is achieved by interfacing one component of the system, a Hewlett–Packard HP-3456A digital voltmeter, via an IOtech Personal488 PC/IEEE 488 controller, to a 386SX 16-MHz IBM-clone computer. A BASIC program controls data collection and storage and directs data to a commercial data visualization package for interpretation and the calculation of volumetric heat capacities.

An inherent problem of Picker flow microcalorimeters is that they generally suffer from small heat leaks (8). These heat leaks are greatly reduced by evacuating the chamber that houses the calorimetric cells to a vacuum of approximately 1.5×10^{-6} mbar (1 bar = 100 kPa). A 1-in. stainless steel vacuum line incorporating a Leybold D4A backing pump and an Edwards EO 50/60 air-cooled diffusion pump was constructed for this purpose. The calorimeter was connected to the vacuum line with a Cajon O-ring fitting. Small residual heat leaks are easily corrected for by a heat loss correction factor (9). This factor is determined periodically by measuring the specific heat capacities of aqueous sodium chloride solutions at the temperature of interest.

Results and discussion

Apparent molar volumes, $V_{\phi,2}$, were calculated from measured density data using the equation

$$[1] \qquad V_{\phi,2} = \left[\frac{M}{\rho}\right] - \left[\frac{\rho - \rho_1^0}{m\,\rho\,\rho_1^0}\right]$$

where m is the molality of the solution, M is the molecular weight of the solute, ρ_1^0 is the density of pure water, and ρ is the density of the solution under study.

The specific heat capacities of our solutions were calculated using eq. [2]

$$[2] \qquad C_{p,\phi,2} = Mc_p + \frac{(c_p - c_{p,1}^0)}{m}$$

where c_p is the specific heat capacity of the solution, and $c_{p,1}^0$ is the specific heat capacity of pure water.

Estimated uncertainties in apparent molar volumes, $\delta V_{\phi,2}$

[a]Estimated uncertainties for $V_{\phi,2}$ appear in parentheses.

were calculated using the equation reported by Hedwig (10), eq. [3], and appear in parentheses in Tables 2*a*, *b*, and *c*.

$$[3] \qquad \delta V_{\phi,2} = -\left[M + \frac{1000}{m}\right]\frac{\delta\rho}{\rho^2}$$

The uncertainty in solution density, δρ, was estimated to be 5×10^{-6} g cm^{-3}. The utility of eq. [3] is limited since it assumes that contributions to $\delta V_{\phi,2}$ arising from uncertainties in solution concentrations are negligible. Uncertainties in calculated $C_{p,\phi,2}$ data arise primarily from two sources (11): errors in experimental molalities, and errors associated with the measurement of the displacements of the heat capacity curves. In agreement with ref. 11 we estimate the total errors observed in $C_{p,\phi,2}$ data to be in the range ±1–4 J K^{-1} mol^{-1} for solutions more concentrated than 0.03 mol kg^{-1} rising to ±9 J K^{-1} mol^{-1} for solutions with a molality of 0.01 mol kg^{-1}. Estimated uncertainties in $V_{\phi,2}$ and $C_{p,\phi,2}$ show large increases at low concentrations. This trend emphasizes the problems associated with the collection of $V_{\phi,2}$ and $C_{p,\phi,2}$ data at low concentrations.

Apparent molar properties of completely dissociated electrolytes are well represented by extended Debye–Hückel equations of the form

$$[4] \qquad Y_{\phi,2} = Y_2^0 + \omega A_Y I^{0.5} + B_Y I + C_Y I^{1.5}$$

where Y represents the extensive thermodynamic property of interest, Y_2^0 is the standard state (infinite dilution) property, I is the ionic strength, and ω is the valence factor. Debye–Hückel limiting slopes (A_Y) have been compiled for various temperatures by Ananthaswamy and Atkinson (12).

Densities and heat capacities of aqueous sodium chloride solutions, in the concentration range 0.050–1.000 mol kg^{-1}, were measured at 288.15, 298.15, and 308.15 K to assess the accuracy of our experimental apparatus and to evaluate the relevant heat loss correction factors for our calorimeter.

Standard state volumes and heat capacities for the sodium chloride solutions were calculated using a least-squares fit of the relevant version of eq. [4] to our experimental data. Table 1 compares our values of V_2^0 and $C_{p,2}^0$ to values reported in the literature (13–21).

The densities, apparent molar volumes, and apparent molar heat capacities of our aqueous L-ascorbic acid solutions at 288.15, 298.15, and 308.15 K are reported in Tables 2*a*, *b*, and *c*. Trends observed in $V_{\phi,2}$ and $C_{p,\phi,2}$ as a function of concentration are reported as Figs. 1 and 2, respectively.

The partial dissociation of L-ascorbic acid in aqueous solution prevents us from modelling our apparent molar data with either Debye–Hückel type or non-electrolyte type equations. Rather, we must develop a methodology for combining these two types of equations. The formalism described by Harned and Owen (22) provides a good starting point in this development.

To a first approximation the apparent molar volume of a partly dissociated acid in aqueous solution can be represented by eq. [5].

$$[5] \qquad V_{\phi,2} = \alpha V_{\phi,2,i} + (1 - \alpha)V_{\phi,2,u}$$

This equation defines two contributions to the observed apparent molar volumes of the aqueous acid solutions: one represents the ionic species present in solution, $V_{\phi,2,i}$; and the other the undissociated acid, $V_{\phi,2,u}$. α represents the degree of dissociation of the acid. The difference between the ionic and the undissociated acid contributions to the apparent molar volume, $\Delta V_{\phi,2}$, is defined by eq. [6].

$$[6] \qquad \Delta V_{\phi,2} = V_{\phi,2,i} - V_{\phi,2,u}$$

Using eq. [6], eq. [5] can be rewritten in the form

$$[7] \qquad V_{\phi,2,u} = V_{\phi,2} - \alpha\Delta V_{\phi,2}$$

When the standard state volumes for the ionic species, V_i^0, and the undissociated species, V_u^0, are used in eq. [6] the re-

[a]Estimated uncertainties for $V_{\phi,2}$ appear in parentheses.

sulting equation, eq. [8], defines the volume of ionization of the acid, ΔV^0.

$$[8] \quad \Delta V^0 = V_i^0 - V_u^0$$

The first acid dissociation constant of L-ascorbic acid is reported to be $pK_1 = 4.10$. This value was obtained by Karrer, Schwarzenbach, and Schopp (23) using a hydrogen electrode at a temperature of 24°C. Dissociation constants for the acid at 25°C have been measured; however, they generally refer to solutions maintained at some fixed ionic strength (24). pK_2 of L-ascorbic acid is large enough that A^{2-} ions are not present to any significant concentration in acidic solutions, or even in slightly alkaline solutions.

Values of α at 298.15 K were calculated using an iterative procedure. An initial estimate of α was fed into the Davies equation (25), eq. [9], to produce an estimate of the activity coefficient, γ. The computed value of γ was in turn entered into eq. [10] to produce a new estimate of α. This successive approximation procedure was repeated until consistent values of α and γ were obtained.

$$[9] \quad \log \gamma = \frac{-A|z^+z^-|\sqrt{\alpha m}}{1 + \sqrt{\alpha m}} + 0.1|z^+z^-|\alpha m$$

$$[10] \quad K = \frac{\alpha^2\gamma^2 m}{(1 - \alpha)}$$

The Debye–Hückel constant, A, used in eq. [9] is the one reported by Robinson and Stokes (25) ($A = 0.5115$ at 298.15 K). This constant differs by a factor of 2.303 from the one reported by Ananthaswamy and Atkinson (12). The value of K used in eq. [10] was calculated from the pK_1 reported in ref. 23.

The apparent molar volumes of the ionic species, $V_{2,\phi,i}$, present in solution can be represented by a Debye–Hückel type equation.

$$[11] \quad V_{\phi,2,i} = V_i^0 + A_v\omega^{1.5}\alpha^{0.5}m^{0.5} + B_i\omega\alpha m$$

In a similar fashion the apparent molar volumes of the undissociated acid, $V_{\phi,2,u}$, can be modelled by eq. [12].

$$[12] \quad V_{\phi,2,u} = V_u^0 + B_u(1 - \alpha)m$$

Combining eqs. [11] and [12] with eq. [5] gives:

$$[13] \quad V_{\phi,2} = \alpha V_i^0 + A_v\omega^{1.5}\alpha^{1.5}m^{0.5} + B_i\omega\alpha^2 m + B_u(1 - \alpha)^2 m + (1 - \alpha)V_u^0$$

The terms $A_v\omega^{1.5}\alpha^{1.5}m^{0.5}$ and $B_i\omega\alpha^2 m$ are calculated to make only a very small contribution to $V_{\phi,2}$. Therefore, the apparent molar volumes of our L-ascorbic solutions can be modelled by the three-term equation

$$[14] \quad V_{\phi,2} = \alpha V_i^0 + (1 - \alpha)V_u^0 + B_u(1 - \alpha)^2 m$$

where V_i^0, V_u^0, and B_u are constants that can be calculated using a multiple regression fitting procedure. Our values of these constants, their standard errors, and the correlation coefficient of the fit are reported for the L-ascorbic acid system at 298.15 K in Table 3. The reported estimate of V_u^0 is in fair agreement with the extrapolated value of 105.17 cm^3 mol^{-1} obtained by Manzurola and Apelblat (26). Equation [8] yields $\Delta V^0 = -17.99 \pm 1.97$ cm^3 mol^{-1}. The reported

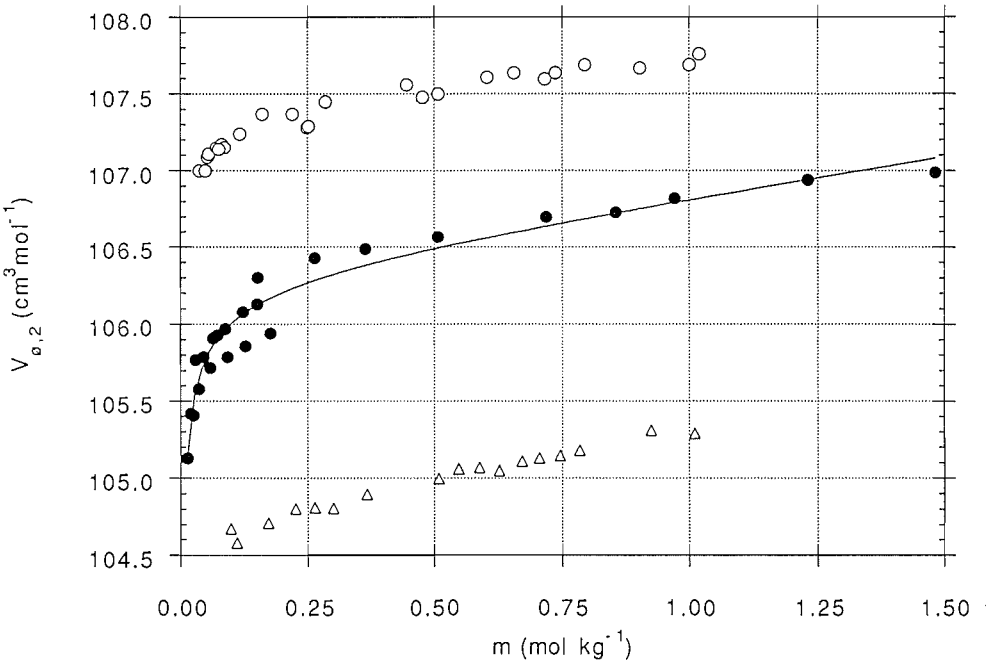

FIG. 1. Experimental apparent molar volumes, $V_{\phi,2}$, of aqueous L-ascorbic acid solutions as a function of concentration and temperature (○ = 308.15 K, ● = 298.15 K, Δ = 288.15 K). The least-squares fit of eq. [14] to our 298.15 K experimental data is shown as a solid curve.

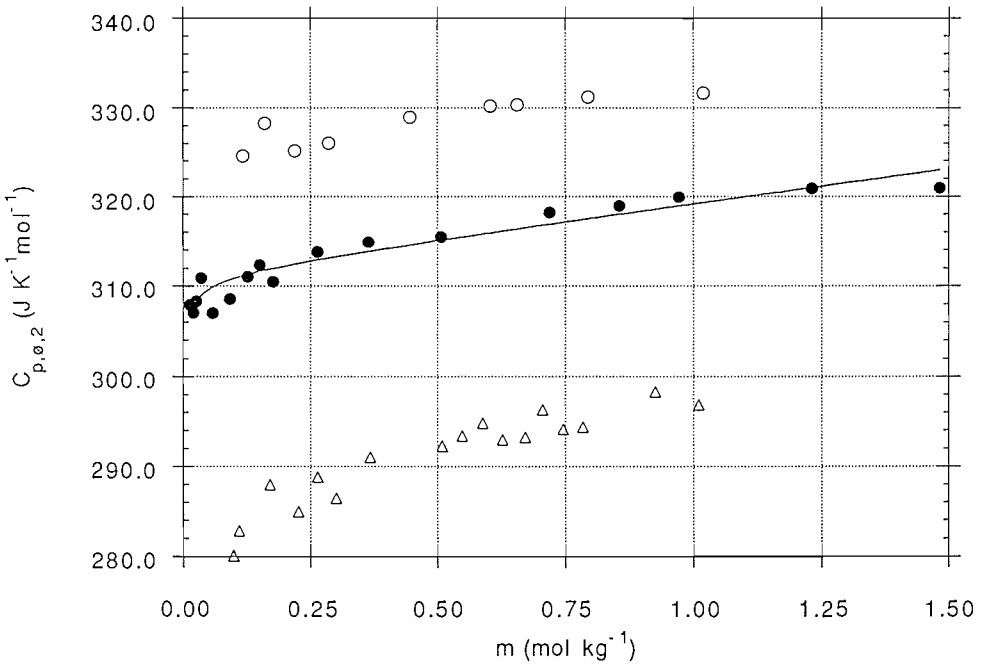

FIG. 2. The apparent molar heat capacities, $C_{p,\phi,2}$, of aqueous L-ascorbic acid solutions as a function of concentration and temperature (○ = 308.15 K, ● = 298.15 K, Δ = 288.15 K). The least-squares fit of the heat capacity form of eq. [14] to our 298.15 K experimental data is shown as a solid curve.

uncertainty in this number comes directly from the standard errors calculated in our fitting procedure.

This method of calculating ΔV^0 is particularly attractive for the L-ascorbic acid system. The usual route of obtaining volumes of ionization for weak acids requires accurate apparent molar volume data for the relevant sodium salt(s) of the acid (1, 27, 28). Solutions of sodium ascorbate in water are known to be very rapidly oxidized when exposed to the air. Accurate density and volume data for these systems are therefore very difficult to obtain.

To assess the validity of our methodology, eq. [14] was also fitted to apparent molar volume data for aqueous formic acid (27) and acetic acid (2, 27). Our calculated volumes of ionization obtained, ΔV^0 (formic acid) = -8.98 ± 0.16 cm^3 mol^{-1} and ΔV^0 (acetic acid) = -11.17 ± 1.25 cm^3 mol^{-1}, are in good agreement with the values of -8.43 and

TABLE 3. Calculated coefficients for eq. [14] for L-ascorbic acid in water at 298.15 K

	Value	Standard error on value
V_i^0 (cm^3 mol^{-1})	88.50	1.88
V_u^0 (cm^3 mol^{-1})	106.49	0.08
B_u (cm^3 kg mol^{-2})	0.5077	0.0868
Correlation coefficient	0.9754	

-11.50 cm^3 mol^{-1} previously reported in the literature (27). The latter values required apparent molar volume data for aqueous solutions of sodium formate and sodium acetate in their calculation.

Analysis of the experimental apparent molar heat capacity data for our acid system requires that we consider the contribution made by "relaxation" effects. These effects account for the temperature-dependent state of the equilibrium and related thermal effects (1). Relaxational contributions are defined by the expression $\Delta H(d\alpha/dT)$. Calculation of $(d\alpha/dT)$ requires equilibrium constants at several temperatures. These data are not available for the L-ascorbic acid system. We have therefore calculated a value of -74.97 ± 27 J K^{-1} mol^{-1} for ΔC_p^0 using the approach described earlier for volumes and the assumption that the relaxational contributions to our apparent molar heat capacity data are negligible. The uncertainty reported in this number comes from the standard errors calculated in our fitting procedure.

To obtain reliable estimates of V_i^0 and $C_{p,i}^0$ from eq. [14] it is necessary to obtain apparent molar volume and apparent molar heat capacity data at low concentrations, i.e., concentrations at which α rapidly increases. As previously noted, uncertainties in $V_{\phi,2}$, and $C_{p,\phi,2}$ increase with decreasing solution concentration. Precise apparent molar volume and apparent molar heat capacity data for the L-ascorbic acid system are therefore difficult to obtain in the low-concentration region. From this standpoint our fitting procedures were limited to using $V_{\phi,2}$ and $C_{p,\phi,2}$ data for solutions with concentrations greater than 0.01 mol kg^{-1}.

A lack of literature values for the first dissociation constant of L-ascorbic acid as a function of temperature has prevented our calculation of ΔC_p^0 and ΔV^0 for this system at temperatures other than 298.15 K. However, we are currently applying our methodology to other aqueous organic systems for which the temperature dependences of the acid dissociation constants are well documented. These studies will provide volumes and heat capacities of ionization as a function of temperature. There are very few systems for which these data are reported in the literature and even fewer systems for which these data are available at temperatures removed from 298.15 K.

Received December 8, 1992

STEPHEN A. WESTCOTT, TODD B. MARDER, R. THOMAS BAKER, and JOSEPH C. CALABRESE. Can. J. Chem. **71**, 930 (1993).

Reactions of certain iridium complexes with catecholborane (HBcat) gave boron-substituent redistribution products ($[Bcat_2]^-$, B_2cat_3) with concomitant formation of a complex mixture of iridium hydrides. While "$IrCl(PPh_3)(COE)_n$" generated in situ from $[Ir(\mu\text{-}Cl)(COE)_2]_2$ (COE = cyclooctene) (**2**) plus 2 equivalents of PPh_3 also promoted HBcat degradation, this catalyst system was extremely active and selective for alkene hydroborations. Oxidative addition of HBcat to the metal centre can be the sole reaction pathway, however, with iridium complexes containing electron-rich phosphines. The unsaturated boryl complex $IrHCl(Bcat)(PPr^i_3)_2$ was prepared and isolated in high yield from reaction of HBcat with **2** in the presence of four equivalents of PPr^i_3. Ancillary carbonyl ligands also appear to facilitate oxidative addition of HBcat to an iridium centre. Addition of HBcat to *trans*-$IrCl(CO)(PPh_3)_2$ gives the first structurally characterized metal-carbonyl boryl complex *trans*-$IrHCl(CO)(Bcat)(PPh_3)_2$ (**7**). Colourless crystals of **7** are triclinic, $P\bar{1}$ (No. 2) with two molecules per unit cell of dimensions a = 12.223(2) Å, b = 12.684(2) Å, c = 14.652(1) Å, α = 70.81(1)°, β = 72.47(1)°, and γ = 71.92(1)°.

STEPHEN A. WESTCOTT, TODD B. MARDER, R. THOMAS BAKER et JOSEPH C. CALABRESE. Can. J. Chem. **71**, 930 (1993).

Les réactions de certains complexes d'iridium avec le catécholborane (HBcat) conduisent à des produits de redistribution des substituants du bore ($[Bcat_2]^-$, B_2cat_3) avec la formation concomitante d'un mélange complexe d'hydrures d'iridium. Alors que le «$IrCl(PPh_3)(COE)_n$», généré in situ à partir du $[Ir(\mu\text{-}Cl)(COE)_2]_2$ (COE = cyclooctène) (**2**) et de deux équivalents de PPh_3, provoque aussi la dégradation du HBcat, ce système catalytique est extrêmement actif et sélectif pour les hydroborations d'alcènes. Toutefois, l'addition oxydante du HBcat sur un centre métallique peut n'être que la seule voie réactionnelle avec des complexes d'iridium contenant des phosphines riches en électrons. On a préparé le complexe boryle insaturé, $IrHCl(Bcat)(PPr^i_3)_2$, et on l'a isolé par réaction du HBcat avec le composé **2** en présence de quatre équivalents de PPr^i_3 avec un excellent rendement. Les ligands carbonyles ancillaires semblent rendre l'addition oxydante du HBcat sur un centre iridium plus facile. L'addition du HBcat sur le *trans*-$IrCl(CO)(PPh_3)_2$ conduit au premier complexe boryle métal-carbonyle caractérisé, le *trans*-$IrHCl(CO)(Bcat)(PPh_3)_2$ (**7**), qui se présente sous forme de cristaux incolores tricliniques, $P\bar{1}$ (No. 2), avec deux molécules par motif constitutif, a = 12,223(2), b = 12,684(2) et c = 14,652(1) Å, α = 70,81(1)°, β = 72,47(1)° et γ = 71,92(1)°.

[Traduit par la rédaction]

Introduction

There has been considerable recent interest in metal-catalyzed hydroboration of alkenes (for leading references, see ref. 1), owing largely to rate enhancements observed for less reactive boron reagents, such as catecholborane, HBcat (cat = 1,2-$O_2C_6H_4$) (2), as well as regio-, chemo-, and stereoselectivities that are complementary to or improved with respect to conventional procedures. While much effort has focussed on rhodium(I) complexes to catalyze such transformations (1, 3), recent work has demonstrated that analogous iridium compounds are also active catalyst precursors (4–7). Indeed, Sneddon and co-workers reported initially that complexes $[IrCl_2(\eta^5\text{-}C_5Me_5)]_2$ (**1**) (4) and *trans*-$IrCl(CO)(PPh_3)_2$ (5) catalyze the B-H addition of polyhedral boranes to alkynes to give a variety of alkenylboranes. Evans and Fu subsequently employed $[Ir(COD)(py)(PCy_3)]PF_6$ (COD = η^4-1,5-cyclooctadiene; py = pyridine) as a catalyst precursor for amide-directed hydroborations of alkenes using HBcat (6). In general, selectivities were higher using this iridium catalyst precursor than those observed with similar rhodium complexes. As part of our investigation into metal-catalyzed hydroborations of alkenes (1*h*, 3, 8), we examined the stoichiometric reactivity and catalytic activity of a number of iridium complexes with HBcat using multinuclear NMR spectroscopy, and we report herein our initial findings.

Results and discussion

Reactions of iridium complexes with HBcat

Initial work focussed on reactions of HBcat with iridium complexes that do not contain basic phosphine ligands. Addition of HBcat to a solution of $[IrCl_2(\eta^5\text{-}C_5Me_5)]_2$ (**1**) (9) in THF gave a complex mixture of iridium-hydride complexes. It was reported previously that reduction of dichloride **1** affords a number of binuclear μ-hydride complexes (10). While the observation of $[Bcat_2]^-$ (generated via the metal-mediated degradation of HBcat (11, 12)) in these solutions suggests that cationic iridium species are generated, we cannot rule out the possibility of zwitterionic compounds. The versatile $[Bcat_2]^-$ anion can coordinate to a metal centre in an η^6 fashion via one of its arene rings (1*h*, 8*b*).

Iridium hydrides were observed from reactions of HBcat with phosphine-free complexes $[Ir(\mu\text{-}Cl)(COE)_2]_2$ (**2**) (COE = η^2-cyclooctene) and $[Ir(\mu\text{-}Cl)(COD)]_2$ (**3**) as well. Interestingly, resonances corresponding to COD ligands in the ^1H NMR spectrum of the latter were notably absent. The lack of B-C resonances in the ^{11}B NMR spectra (13) suggests that the COD ligands are being hydrogenated and not hydroborated. Indeed, the major boron-containing species was degradation product B_2cat_3 (11, 12).

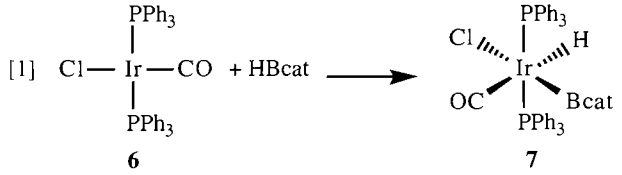
Not all products arising from reactions with these three phosphine ligand-free iridium complexes were identified, as HBcat degradation was extensive and invariably led to Ir metal.

In contrast, only one new phosphinoiridium complex was observed (by ^{31}P NMR spectroscopy) from the reaction of monophosphine-containing $[Ir(COD)(py)(PCy_3)]^+[OTf]^-$ (**4**) (14) with excess HBcat. Although no resonance corresponding to an iridium hydride was observed in the ^1H NMR spectra, the COD ligand appears to have been hydrogenated. Unfortunately, characterization of the products derived from this reaction was complicated by further HBcat degradation where even $[OTf]^-$ (1*h*) and pyridine[3] were susceptible to attack by boron species in solution. That **4** promoted HBcat degradation is somewhat surprising as this cationic iridium species is a highly active and selective catalyst precursor for amide-directed hydroborations (6).

The ubiquity of rhodium complexes containing PPh_3 in catalyzed hydroborations (1) prompted us to investigate the analogous PPh_3 chemistry with iridium. Addition of HBcat to a THF solution of "$IrCl(PPh_3)(COE)_n$", generated in situ from **2** and PPh_3,[4] gave a complex mixture of phosphinoiridium products where most of the HBcat had been converted to B_2cat_3. This result was not unexpected as addition of PPh_3 to **2** affords several Ir(III) complexes arising from *ortho*-metalation of one of the phenyl rings in PPh_3 to the metal centre (16).

Similar product distributions were observed in analogous reactions with "$IrCl(PPh_3)_2$". Reactions carried out in CH_2Cl_2 gave fewer products, however, with dihydride *mer-cis*-$IrH_2Cl(PPh_3)_3$ (**5**) (17) being the major phosphine-containing product (ca. 45% by ^{31}P NMR spectroscopy). Formation of this complex parallels an earlier observation (3, 8*b*) that addition of HBcat to Wilkinson's catalyst, $RhCl(PPh_3)_3$, gave oxidative addition product $RhHCl(Bcat)(PPh_3)_2$ (18) along with varying amounts of dihydride *mer-cis*-$RhH_2Cl(PPh_3)_3$.

It is interesting to note that an ancillary CO ligand can facilitate the oxidative addition of HBcat to a metal centre. Thus, the saturated iridium boryl complex *trans*-$IrHCl(CO)(Bcat)(PPh_3)_2$ (**7**) was prepared (eq. [1]) in high yield from reaction of HBcat with Vaska's complex *trans*-$IrCl(CO)(PPh_3)_2$ (**6**) (19).



[3]P. Nguyen, S.A. Westcott, T.B. Marder, and R.T. Baker. Unpublished results.

[4]Similar in situ alkene hydrogenation catalysts formed from $[Ir(\mu\text{-}Cl)(COE)_2]_2/PR_3$ with P:Ir < 2.5 were reported previously (15).

$^c[\Sigma w(|F_o| - |F_c|)^2/(NO - NV)]^{1/2}$.

Although CO inhibits orthometalation of the PPh_3 ligands and, hence, provides a coordination site required for oxidative addition of HBcat, the electron-withdrawing nature of this π acid is expected to destabilize the resulting M—B bonds. Indeed, a recent report showed that addition of HBcat to the osmium carbonyl $Os_3(\mu\text{-}H)_2(CO)_{10}$ affords $Os_3(\mu\text{-}H)_3(CO)_9(\mu_3\text{-}COBcat)$, where the boron is bound to the electron-rich oxygen of the unique carbonyl group (20).

Although a number of metal boryl complexes containing ancillary CO ligands were reported over 20 years ago, characterization of these compounds is based solely upon their melting points, IR, and ^{11}B NMR spectra (for a review, see ref. 21). As a result, the exact structure of these compounds remains uncertain. Complex **7**, on the other hand, represents the first example of a metal-carbonyl boryl compound to be characterized fully by IR, multinuclear NMR spectroscopy, and single crystal X-ray diffraction. A summary of the crystallographic data and parameters for data collection is presented in Table 1, selected bond distances and angles are given in Table 2, and final atomic coordinates are given in Table 3. The molecular structure of **7** consists of an octahedral arrangement of ligands with *trans* phosphine ligands and the catecholatoboryl group *trans* to chloride (Fig. 1). The hydride ligand is *cis* to the boryl group with an H—Ir—B angle of 78(1)°, and the boryl ligand plane is oriented parallel to the Ir—H—B plane. Interestingly, there is no close contact between the boron atom and the car-

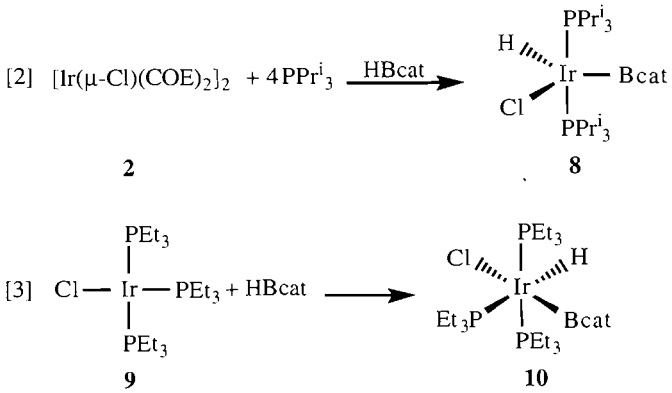
bonyl group (C—Ir—B = 90.1(2)°). The iridium–boron bond distance of 2.045(5) Å is consistent with other M—B σ bonds (7, 8, 22). For comparison, the Ir—B bond in *mer*-IrHCl(Bcat)(PMe_3)$_3$ is 2.023(10) Å (7). The oxidative addition of a B—H bond in B_5H_9 or the B—Br bond in 1- or 2-BrB_5H_8 to *trans*-IrCl(CO)(PMe_3)$_2$ was reported by Davison and co-workers (22*a*). From the former reaction, the colourless complex 2-[IrClH(CO)(PMe_3)$_2$]B_5H_8 was isolated. The ^{1}H and ^{31}P NMR and IR spectra of this species (22*a*) are similar to those for **7**. The molecular structure of 2-[$IrBr_2$(CO)(PMe_3)$_2$]B_5H_8 was determined (22) and the Ir—B bond distance was found to be 2.07(1) Å.

In contrast to reactions employing PPh_3, addition of HBcat to "IrCl(PPr^i_3)$_2$" (eq. [2]) gave the unsaturated hydrido-boryl complex IrHCl(Bcat)(PPr^i_3)$_2$ (**8**) in high yield with minimal HBcat degradation. The molecular structure of the rhodium analogue was reported recently (8*b*) and consists of a distorted trigonal-bipyramidal Rh(III) centre with apical PPr^i_3 ligands. Spectroscopic data for **8** are consistent with this structure. Likewise, by analogy with the PMe_3 analog (7), saturated iridium boryl *mer*-IrHCl(Bcat)(PEt_3)$_3$ (**10**) was prepared readily (eq. [3]) by addition of one equivalent of HBcat to a toluene solution of IrCl(PEt_3)$_3$ (**9**) (23).



In summary, stoichiometric reactions of HBcat with certain iridium complexes result in the degradation of HBcat. Oxidative addition to a basic metal centre can be the sole reaction pathway with iridium complexes containing basic

[a]All reactions were carried out in THF at room temperature in the presence of 2 mol% catalyst. Alkene:catecholborane:catalyst = 1.0:1.2:0.02. Product distributions determined by ^{13}C and ^1H NMR.

absence of a catalyst precursor occurs only at elevated temperatures (ca. 100°C). In all cases, we observed predominant formation of the terminal alkylboronate ester $CH_3(CH_2)_7Bcat$ (2) along with ca. 5% octane, arising from alkene hydrogenation. Stereochemical assignment of products is based upon ^1H, ^{11}B, and ^{13}C NMR spectroscopic data (1*h*). In contrast to its rhodium analogue (1*a*), hydroborations using either *trans*-$IrCl(CO)(PPh_3)_2$ (**6**) or isolated *trans*-$IrHCl(CO)(Bcat)(PPh_3)_2$ (**7**) proceeded only under photolytic conditions (see Experimental section). Initial loss of CO would provide the vacant coordination site at the metal centre required for catalysis (24). Complexes **6** and **7**, however, failed to catalyze the addition of HBcat to the more sterically hindered 4-vinylanisole (4-$MeOC_6H_4CH{=}CH_2$). Similarly, basic iridium complexes $IrHCl(Bcat)(PPr^i_3)_2$ (**8**) and $IrCl(PEt_3)_3$ (**9**) failed to hydroborate 4-vinylanisole.

Although complexes $[Ir(\mu\text{-}Cl)(COD)]_2$ (**3**) and $[Ir(COD)(py)(PCy_3)]^+[OTf]^-$ (**4**) catalyzed the hydroboration of 4-vinylanisole with moderate regiocontrol in favour of terminal alkylboronate ester **I** (Table 4), significant amounts (up to 10%) of hydrogenation product were also formed. More remarkable, however, is that reactions using $[IrCl_2(\eta^5\text{-}C_5Me_5)]_2$ (**1**) and "$IrCl(PPh_3)(COE)_n$" gave exclusive formation of terminal hydroboration product **I** with minimal hydrogenation. This is somewhat surprising as reactions in the absence of substrate promoted the rapid degradation of HBcat. It is plausible, therefore, that catalysis with these iridium precursors does not proceed via conventional pathways that invoke initial oxidative addition of HBcat to the metal centre (1*a*).

Hydroborations of 4-vinylanisole have been well studied and, depending on the catalyst precursor employed, can lead to exclusive formation of internal alkylboronate ester **II** (1*h*). We have found that use of iridium complexes **1** and "$IrCl(PPh_3)(COE)_n$", however, provide selective formation of terminal isomer **I**. Similar product distribution ranges have also been observed for hydroborations of 2-phenylpropene $Ph(Me)C{=}CH_2$, with certain Rh complexes giving as high as 95% selectivity to the internal product $Ph(Me)_2$-CBcat. Product distributions for hydroborations using **1** were complicated by formation of vinylboronate esters (arising presumably via dehydrogenative borylation). Analogous reactions employing "$IrCl(PPh_3)COE)_n$" afforded the corresponding terminal hydroboration product $Ph(Me)CHCH_2Bcat$ in excellent yield (98%) (8*d*). In summary, product distributions in hydroborations of vinylarenes can thus be tuned by judicious choice of catalyst precursor.

Conclusion

While oxidative addition of HBcat to several iridium complexes gave the expected iridium boryl compounds ($Ir\text{-}BR_2$), these species were ineffective as catalyst precursors for hydroborations of vinylarenes. In contrast, although "$IrCl(PPh_3)(COE)_n$" promoted HBcat degradation in the absence of substrate, this catalyst precursor is extremely active and selective for alkene hydroborations. Further work with this unique catalyst system is currently in progress.

Experimental section

General procedures

NMR spectra were recorded on General Electric QM-300 (^1H at 300 MHz, ^{13}C at 75.4 MHz, ^{31}P at 121 MHz) or Nicolet NMC (^{11}B at 96 MHz) instruments in THF-d_8 (tetrahydrofuran) unless stated otherwise. ^1H chemical shifts are reported in ppm relative to external TMS and referenced to residual protons in THF-d_8; coupling constants are in Hz. Multiplicities are reported as (br) broad, (ov) overlapping, (s) singlet, (d) doublet, (t) triplet, (q) quartet, and (m) multiplet. ^{11}B and ^{31}P chemical shifts are reported in ppm relative to the external standards $F_3B \cdot OEt_2$, and 85% H_3PO_4, respectively. THF and toluene were freshly distilled from sodium benzophenone ketyl. Catecholborane (Aldrich Chemical Co.) was distilled under reduced pressure. Alkenes were purchased from commercial suppliers and used as received. $[IrCl_2(\eta^5\text{-}C_5Me_5)]_2$ (25), $[Ir(\mu\text{-}Cl)(COE)_2]_2$ (26), $[Ir(\mu\text{-}Cl)(COD)]_2$ (27), $[Ir(COD)(py)(PCy_3)][OTf]$ (14), *trans*-$IrCl(CO)(PPh_3)_2$ (20), and $IrCl(PEt_3)_3$ (23) were prepared by established methods. Reagent purity was ascertained by ^1H NMR spectroscopy.

Reaction of HBcat with [$IrCl_2(\eta^5$-$C_5Me_5)]_2$ (1)

A solution of HBcat (36 mg, 0.3 mmol) in 1 mL of THF-d_8 was added dropwise to a suspension of **1** (40 mg, 0.05 mmol) in 1 mL of THF-d_8. Upon stirring for 0.5 h the resulting mixture became yellow in colour and was characterized spectroscopically by ^{1}H and ^{11}B NMR. Selected NMR spectroscopic data (in THF-d_8): $^{11}B\{^1H\}\delta$: 6.7 (s, minor), 14.9 (s, $[Bcat_2]^-$), 18.9 (br, B_2cat_3), 23.5 (s, HBcat), 24.4 (br s), 35.3 (br); $^1H\delta$: −17.44 (s, Ir-H), −16.40 (s, Ir-H), −14.39 (s, Ir-H, major), −12.49 (s, Ir-H), 1.76 (s, CH_3), 2.00 (s, CH_3, major), 2.07 (s, CH_3), 2.29 (s, CH_3), 6.6–7.1 (ov m, Bcat).

Reaction of HBcat with $[Ir(\mu\text{-}Cl)(COE)_2]_2$ (2)

A solution of HBcat (36 mg, 0.3 mmol) in 1 mL of THF-d_8 was added dropwise to a solution of $[Ir(\mu\text{-}Cl)(COE)_2]_2$ (45 mg, 0.05 mmol) in 1 mL of THF-d_8. Upon stirring for 0.5 h the resulting mixture became black in colour and was characterized spectroscopically by ^{1}H and ^{11}B NMR. Selected NMR spectroscopic data (in THF-d_8): $^{11}B\{^1H\}\delta$: 17.2 (br, minor), 19.5 (br, B_2cat_3); $^1H\delta$: −9.72 (s, Ir-H), −8.36 (s, Ir-H), −7.88 (s, Ir-H), −7.46 (s, Ir-H), −7.41 (s, Ir-H, major), −7.35 (s, Ir-H), −7.16 (s, Ir-H), 1.50 (s), 1.74 (br), 2.14 (br), 2.38 (br, minor), 4.83 (d, J = 9 Hz, minor), 5.55 (br, minor), 6.8–7.1 (ov m, Bcat).

Reaction of HBcat with $[Ir(\mu\text{-}Cl)(COE)_2]_2$/2 PPh_3

A solution of HBcat (36 mg, 0.3 mmol) in 1 mL of THF-d_8 was added dropwise to a premixed solution of $[Ir(\mu\text{-}Cl)(COE)_2]_2$ (45 mg, 0.05 mmol) and PPh_3 (26 mg, 0.1 mmol) in 1 mL of THF-d_8. Upon stirring for 0.5 h the resulting mixture became dark red in colour and was characterized spectroscopically by ^{1}H, ^{11}B, and ^{31}P NMR. Selected NMR spectroscopic data (in THF-d_8): $^{31}P\{^1H\}\delta$: −3.7 (br, minor), 15.8 (br), 22.1 (br), 24.3 (br), 31.2 (s), 33.3 (s), 34.6 (s, major); $^{11}B\{^1H\}\delta$: 17.7 (br, minor), 21.3 (br, B_2cat_3); $^1H\delta$: −19.93 (t, J_{HP} = 13 Hz, Ir-H), −18.86 (t, J_{HP} = 14 Hz, Ir-H), −17.90 (br, Ir-H), −8.84 (s, Ir-H), −8.63 (s, Ir-H), −8.31 (s, Ir-H), −7.39 (s, Ir-H), 1.51 (s), 1.55 (s), 2.14 (s), 5.59 (t, J = 5 Hz, minor) 6.6–7.7 (ov m, Bcat and PPh_3).

Reaction of HBcat with $[Ir(\mu\text{-}Cl)(COE)_2]_2$/4 PPh_3

A solution of HBcat (36 mg, 0.3 mmol) in 1 mL of THF-d_8 was added dropwise to a premixed solution of $[Ir(\mu\text{-}Cl)(COE)_2]_2$ (45 mg, 0.05 mmol) and PPh_3 (52 mg, 0.1 mmol) in 1 mL of THF-d_8. Upon stirring for 0.5 h the resulting mixture became light yellow in colour and was characterized spectroscopically by ^{1}H, ^{11}B, and ^{31}P NMR. Selected NMR spectroscopic data (in THF-d_8): $^{31}P\{^1H\}\delta$: −2.3 (br t, major), 7.3 (d, J_{PP} = 21 Hz, major), 11.9 (s), 15.5 (s, major), 18.8 (s), 22.2 (s), 25.5 (s), 26.2 (s, major); $^{11}B\{^1H\}\delta$: 16.4 (br, minor), 22.3 (br, B_2cat_3); $^1H\delta$: −21.20 (d, J_{HP} = 13 Hz, Ir-H, minor), −20.82 (t, J_{HP} = 14 Hz, Ir-H, minor) −12.44 (ov m, Ir-H, minor), −11.34 (complex d t, $J_{HPtrans}$ = 134 Hz, J_{HPcis} = 21 Hz, Ir-H, major), −8.0 (br, Ir-H, major), −7.97 to −7.11 (several s, Ir-H), 1.51 (s, major), 1.55 (s), 2.14 (s), 5.60 (t, J = 5 Hz, minor), 6.4–7.8 (ov m, Bcat and PPh_3). Selected NMR spectroscopic data for reactions carried out in CD_2Cl_2: $^{31}P\{^1H\}\delta$: 0.6 (t, J_{PP} = 13 Hz, **5**), 10.5 (d, J_{PP} = 13 Hz, **5**), 11.9 (s), 29.0 (s), 37.7 (s); $^{11}B\{^1H\}\delta$: 25.8 (br), 17.2 (br); $^1H\delta$: −20.78 (q, J_{HP} = 14 Hz, Ir-H, **5**), −19.04 (t, J_{HP} = 14 Hz), −10.62 (d t, $J_{HPtrans}$ = 130 Hz, J_{HPcis} = 20 Hz, Ir-H, **5**), 1.55 (s), 1.59 (s), 2.12 (s), 6.6--7.8 (ov m, Ph and Bcat).

Reaction of HBcat with $[Ir(\mu\text{-}Cl)(COD)]_2$ (3)

A solution of HBcat (36 mg, 0.3 mmol) in 1 mL of THF-d_8 was added dropwise to a solution of $[Ir(\mu\text{-}Cl)(COD)]_2$ (34 mg, 0.05 mmol) in 1 mL of THF-d_8. Upon stirring for 0.5 h the resulting mixture became light yellow in colour and was characterized spectroscopically by ^{1}H and ^{11}B NMR. Selected NMR spectroscopic data (in THF-d_8): $^{11}B\{^1H\}\delta$: 17.1 (br, minor), 22.9 (br, B_2cat_3); $^1H\delta$: 0.88 (d, J = 15 Hz, minor), 1.54 (s, major), 1.60 (s, minor), 2.14 (s), 6.8–7.1 (ov m, Bcat). The ^{1}H NMR spectra recorded after several hours are more complicated, however, as many iridium-hydride resonances are observed.

Reaction of HBcat with $[Ir(COD)(py)(PCy_3)]^+[OTf]^-$ (4)

A solution of HBcat (18 mg, 0.15 mmol) in 1 mL of CD_2Cl_2 was added dropwise to a solution of $[Ir(COD)(py)(PCy_3)]^+[OTf]^-$ (41 mg, 0.05 mmol) in 1 mL of CD_2Cl_2. Upon stirring for 0.5 h, the resulting mixture became light yellow in colour and was characterized spectroscopically by ^{1}H, ^{11}B, and ^{11}P NMR. Selected NMR spectroscopic data (in CD_2Cl_2): $^{31}P\{^1H\}\delta$: 53.4 (br); $^{11}B\{^1H\}\delta$: 9.0 (s), 22.2 (br, B_2cat_3), 30.5 (br); $^1H\delta$: 0.78–0.96 (ov m), 1.23 (s, major), 1.29 (br), 1.53 (br), 2.09 (br), 6.5–6.8 (ov m, Bcat), 7.53 (t, J = 6 Hz), 7.99 (ov m), 8.56 (d, J = 6 Hz). Reactions carried out in THF-d_8 or CD_2Cl_2 eventually became viscous.

Preparation of trans-*$IrHCl(CO)(Bcat)(PPh_3)_2$ (7)*

A solution of HBcat (36 mg, 0.3 mmol) in 5 mL of CH_2Cl_2 was added dropwise to a solution of *trans*-$IrCl(CO)(PPh_3)_2$ (**6**) (156 mg, 0.2 mmol) in 10 mL of CH_2Cl_2. After stirring for 1 h, the solvent was removed in vacuo and the colourless residue was triturated with Et_2O, filtered, and dried in vacuo to yield 157 mg (87%) of complex **7**. Complex **7** was characterized spectroscopically by ^{1}H, ^{11}B, and ^{31}P NMR. NMR spectroscopic data (in CD_2Cl_2): $^{31}P\{^1H\}\delta$: 7.9 (s); $^{11}B\{^1H\}\delta$: 30.8 (br), $^1H\delta$: −6.03 (t, J_{HP} = 17 Hz, 1H, Ir-H), 7.2–7.8 (ov m, 34H, Bcat and PPh_3); IR (CH_2Cl_2)ν_{IrH} = 2007, ν_{CO} = 2118 cm^{-1}. Solutions of **7** in CH_2Cl_2 decomposed eventually (days) to regenerate **6** along with concomitant formation of B_2cat_3 and presumably either H_2 or BH_3 (3).

Preparation of $IrHCl(Bcat)(PPr^i_3)_2$ (8)

A solution of PPr^i_3 (64 mg, 0.4 mmol) in 10 mL of toluene was added dropwise to a solution of $[Ir(\mu\text{-}Cl)(COE)_2]_2$ (89 mg, 0.1 mmol) in 10 mL of toluene. To this was added dropwise a solution of HBcat (36 mg, 0.3 mmol) in 5 mL of toluene. After stirring for 1 h, the solvent was removed in vacuo and the yellow residue was triturated with Et_2O, filtered, and dried in vacuo to yield 58 mg (93%) of complex **8**. Complex **8** was characterized spectroscopically by ^{1}H, ^{11}B, and ^{31}P NMR. NMR spectroscopic data (in THF-d_8): $^{31}P\{^1H\}\delta$: 46.9 (s); $^{11}B\{^1H\}\delta$: 40.1 (br); $^1H\delta$: −22.73 (t, J_{HP} = 7 Hz, 1H, Ir-H), 1.24 (dd, $^3J_{HH}$ = $^3J_{HP}$ = 7 Hz, 36H, PCHCH_3), 2.70 (d sept, $^3J_{HH}$ = $^3J_{HP}$ = 7 Hz, 6H, PCHCH$_3$), 6.80 (br, 2H, Bcat), 6.93 (br, 2H, Bcat).

Reaction of HBcat with $IrCl(PEt_3)_3$ (9)

A solution of HBcat (18 mg, 0.15 mmol) in 1 mL of CD_2CL_2 was added dropwise to a solution of $IrCl(PEt_3)_3$ (55 mg, 0.1 mmol) in 1 mL of CD_2Cl_2. Upon stirring for 0.5 h, the resulting mixture became light yellow in colour and was characterized spectroscopically by ^{1}H, ^{11}B, and ^{31}P NMR. NMR spectroscopic data (in CD_2Cl_2): $^{31}P\{^1H\}\delta$: −20.4 (t, J_{PP} = 6 Hz, **10**), −8.1 (d, J_{PP} = 6 Hz, **10**); $^{11}B\{^1H\}\delta$: 12.2 (s), 23.9 (br, B_2cat_3), 33.5 (br, **10**); $^1H\delta$: −10.84 (d t, $J_{HPtrans}$ = 131 Hz, J_{HPcis} = 20 Hz, 1H, Ir-H, **10**), 1.04 (d t, $^3J_{HP}$ = $^3J_{HH}$ = 7 Hz, 27H, PCH_2CH_3), 1.83 (dq, $^2J_{HP}$ = 14 Hz, $^3J_{HH}$ = 7 Hz, 18H, PCH_2CH$_3$), 6.8–7.0 (ov m, Bcat). Reaction mixtures decomposed rapidly to give a variety of new phosphinoiridium hydride complexes. Similar product distributions were observed for reactions carried out in toluene-d_8.

General procedure for the catalyzed hydroboration of alkenes

All reactions were carried out under an atmosphere of dry nitrogen using a continuous purge glovebox (Vacuum Atmospheres). Catecholborane (250 mg, 2.1 mmol), in 1 mL of THF-d_8, was added dropwise to a mixture of the alkene (2.0 mmol) and catalyst (0.04 mmol) in 1 mL of THF-d_8. Identical results were obtained if the alkene was added to a mixture of catecholborane and catalyst. The resulting solutions were stirred for 30 min and then analyzed by high-field ^{1}H, ^{13}C, and ^{11}B NMR spectroscopy (*1h*).

Catalyzed hydroborations using photolysis

For reactions using *trans*-$IrCl(CO)(PPh_3)_2$ (**6**), photochemical experiments were carried out in a sealed 5-mm NMR tube with a water-filtered 450-W medium-pressure Hg lamp. Saturated boryl complex **7** was the only phosphinoiridium complex present in solution, at detectable levels, upon completion of photolysis.

Molecular structure determination

Crystals of **7** · CH_2Cl_2 suitable for X-ray diffraction studies were obtained from CH_2Cl_2. Data were collected at low temperature on

an Enraf–Nonius CAD4 diffractometer using graphite-monochromated MoKα radiation (λ = 0.71069 Å) and ω scan methods. Standard reflection intensities were monitored periodically with little variation observed over the collection period. Azimuthal scans showed 15.3% variation in intensity and the data were corrected for absorption (DIFABS). The structure was solved by direct methods (SHELXS) (28). Refinement was performed using full-matrix least squares on F with anisotropic thermal parameters for all non-hydrogen atoms (29). The asymmetric unit consists of one Ir complex and one molecule of solvent in general positions. While other hydrogen atoms were idealized and refined, the hydride was taken from a difference map and refined. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$ with the weights, w, assigned as $[\sigma^2(I) + 0.0009I^2]^{-1/2}$. The atomic scattering factors were taken from the *International tables for x-ray crystallography*, Vol. IV (30). Details of the crystal structure determination including complete tables of coordinates, bond distances and angles, anisotropic thermal parameters, calculated and observed structure factors, and alternative ORTEP views of compound **7** have been deposited.[5]

Received September 14, 1992

QIYUAN CHEN, XIN ZHANG, CHING-HSIEN WU, and LOREN G. HEPLER. Can. J. Chem. **71**, 937 (1993).

We have made calorimetric measurements of thermal effects associated with adding NaOH(aq) or HCl(aq) to aqueous solutions (pH = 1.623) of ferric chloride + sodium citrate. Combination of these measured heats with concentrations of various species calculated from stoichiometric compositions and previously known K and ΔH values leads to ΔH values for four aqueous Fe(III)–citrate complexes. Further combination of ΔG^0 values from equilibrium constants with our ΔH values leads to ΔS^0 values, which are discussed in relation to conventional ideas about relationships between entropy and solute–water interactions.

QIYUAN CHEN, XIN ZHANG, CHIEN-HSIEN WU et LOREN G. HEPLER. Can. J. Chem. **71**, 937 (1993).

On a effectué des mesures calorimétriques des effets thermiques associés à l'addition de NaOH(aq) ou HCl(aq) à des solutions aqueuses (pH = 1,623) de chlorure ferrique + citrate de sodium. Une combinaison de ces chaleurs mesurées avec les concentrations des diverses espèces calculées à partir des compositions stoechiométriques et de valeurs déjà connues de K et de ΔH fournit les valeurs de ΔH pour quatre complexes aqueux de Fe(III)–citrate. Une autre combinaison des valeurs de ΔG^0 obtenues à partir de constantes d'équilibre avec les valeurs de ΔH fournit les valeurs de ΔS^0 dont on discute en fonction des idées conventionnelles concernant les relations entre l'entropie et les interactions soluté–eau.

[Traduit par la rédaction]

Introduction

Complexes of citric acid or citrate ions with various metal ions in aqueous solution are important in such fields as food chemistry and biochemistry. Stability constants are known for several metal ion – citrate complexes, but we do not know of any calorimetric investigations of any of these systems. In this paper we report the results of our calorimetric measurements on the aqueous iron(III)–citrate system.

Background information required for our investigations is as follows.

Bates and Pinching (1) carried out a thorough electrochemical investigation of aqueous citric acid, leading to standard state (infinite dilution) equilibrium constants for all three ionizations over the temperature range 0–50°C and thence to values for the enthalpies of all three ionization steps. We also have equilibrium constants (0.1 M KNO_3 solution) from Field et al. (2). Although the equilibrium constants from Bates and Pinching (1) are more accurate than the values from Field et al. (2), we choose to use these latter values as good averages for dilute solutions for which we do not have activity coefficients. These equilibrium constant values, along with enthalpies from Bates and Pinching (1), are listed in Table 1 with equations for the reactions to which they apply.

Field et al. (2) reported equilibrium constants for the Fe(III) – citric acid system, as summarized in Table 1. The species that Field et al. represented by $FeLH_{-1}^-$ is represented in Table 1 by $FeOHL^-(aq)$, which we[4] consider to be more realistic.

In addition to the equilibrium constants from Field et al. (1), we have an estimated constant (K_9, in Table 1) for $FeL_2^{3-}(aq)$ that Martin (3) provided in his useful review and analysis of citrate binding by Al^{3+} and Fe^{3+}.

In strongly acidic solutions in which there are no complexing species, Fe(III) is present as $Fe^{3+}(aq)$. As the pH increases, species such as $FeOH^{2+}(aq)$ become important. We used equilibrium constants tabulated by Martell and Smith (4) and Smith and Martell (5) and as calculated from $\Delta_f G^0$ values from the National Bureau of Standards (6) to establish that the only iron-hydroxy species in solution that should be considered in analyzing the results of our experiments is $FeOH^{2+}(aq)$. $Fe(OH)_3(ppct)$ occurs only at higher pH than in our calorimetric measurements.

The equilibrium constant and the enthalpy for $H^+(aq) + OH^-(aq) = H_2O(liq)$ from a critical review (7) are listed in Table 1.

In Fig. 1 we show a distribution diagram for the various iron species present in solutions having total iron and citrate concentrations in the same range as used in our calorimetric experiments.

Experimental

Certified ACS ferric chloride hexahydrate, $FeCl_3 \cdot 6H_2O$, was obtained from Fisher Scientific Co. Reagent grade (99.0% minimum assay) sodium citrate dihydrate, $Na_3C_6H_5O_7 \cdot 2H_2O$, was from Caledon Laboratories Ltd.

Sodium hydroxide solution was standardized by titration against potassium acid phthalate, and hydrochloric acid solution was standardized by titration with the previously standardized sodium hydroxide solution.

A stock solution for subsequent calorimetric measurements was prepared by dissolving ferric chloride hexahydrate in hydrochloric acid solution; this solution was then standardized by titration with aqueous EDTA. A known amount of sodium citrate dihydrate was then added to this acidic ferric chloride solution, followed by dilution with distilled water and hydrochloric acid to yield a final stock solution having pH = 1.623 and concentrations of Fe(III) and citric acid equal to 9.971×10^{-4} mol/L and 9.965×10^{-3} mol/L, respectively.

All pH measurements were made with an Accumet pH meter

(with combination pH-reference electrode from Orion Research Inc.), calibrated with standard buffer solutions from Fisher Scientific Co.

Our homemade solution calorimeter consisted of a glass Dewar vessel (360 cm^3 capacity) suspended in a brass can that was immersed in a constant temperature bath maintained at 25.00 ± 0.02°C, held constant to ±0.001°C during each measurement. Temperature changes in the calorimeter were measured with a thermistor (YSI 44005) combined with a current comparator resistance bridge (Guildline 9975). The calorimeter was calibrated electrically for each enthalpy measurement. We checked the accuracy of our calorimeter by way of test measurements of the enthalpy of solution of KCl(cr) in distilled water, the enthalpy of solution of 4-aminopyridine(cr) in excess aqueous perchloric acid, the enthalpy of solution of THAM(cr) in excess aqueous hydrochloric acid, and the enthalpy of neutralization of THAM(aq) by excess hydrochloric acid. Results of these measurements are in good agreement with "best" results from the literature (6, 8–13), as will be discussed elsewhere,[5] where we also provide a more detailed description of the calorimeter. Another test was provided by calculating the enthalpy of neutralization of OH^-(aq) by H^+(aq) as described in the fourth paragraph below.

Before carrying out calorimetric measurements as described below, we did "beaker experiments" in which we added known amounts of HCl or NaOH to known amounts of stock solution and measured the resulting pH. Amounts of NaOH and HCl for subsequent calorimetric measurements were chosen to produce changes in pH that would lead to appropriate changes in fractions of Fe(III) in various complexes.

Our experimental procedure for calorimetric measurements began with filling the calorimeter with a known amount of stock solution containing 9.971×10^{-4} mol/L Fe(III) and 9.965×10^{-3} mol/L citric acid at pH = 1.623. A glass ampoule containing a known amount of stock HCl or NaOH solution was attached to the end of the calorimeter's stirrer. The calorimeter and surrounding can were then immersed in the constant temperature bath. After the temperature–time drift became nearly constant, the calorimeter was calibrated electrically, followed by breaking the glass ampoule to permit the HCl or NaOH solution to mix with the acidic Fe(III) citric acid solution in the calorimeter, followed by another electrical calibration.

"Blank" calorimetric experiments were carried out to evaluate the total thermal effect associated with breaking the glass ampoules plus adding HCl(aq) or NaOH(aq) to aqueous HCl with initial pH = 1.623 (no Fe(III) or citric acid present). Amounts of HCl or NaOH were chosen so that the final pH of a solution would closely approximate that of a final solution resulting from adding HCl(aq) or NaOH(aq) to a stock solution containing Fe(III) and citric acid at initial pH = 1.623. In this way we obtained the heats that we represent later by q_{blank}.

In each of the blank experiments involving NaOH(aq) there was excess acid in the calorimeter so that the amount of reaction was determined by the number of moles of OH^-(aq) in the ampoule. Results of these measurements permitted calculation of the enthalpy of reaction of OH^-(aq) with H^+(aq) as follows. For this calculation we attributed the entire measured thermal effect (q) to the chemical reaction (neglecting the small contribution of bulb-breaking) and then obtained the ΔH as q/n, where n represents the number of moles of OH^-(aq) in the ampoule. In this way we found $\Delta H = -55.9 \pm 0.2$ kJ/mol as compared with a better standard value (8) of $\Delta H^0 = -55.815$ kJ/mol. Our ΔH, which refers to actual concentrations in our calorimeter rather than extrapolated to infinite dilution, is less accurate than the standard value because of our neglect of the *small* thermal effect of bulb-breaking and also because our measurements were done with excess H^+(aq) rather than excess OH^-(aq) to minimize complications due to small amounts of carbonate or silicate impurity in the NaOH(aq) solution.

[5]C. Dobrogowska and L.G. Hepler. To be published.

TABLE 2. Results of calorimetric measurements of thermal effects of adding NaOH(aq) or HCl(aq) to stock solution with initial pH = 1.623, total Fe(III) concentration = 9.971×10^{-4} mol/L, and total citrate concentration = 9.965×10^{-3} mol/L

Expt. no.	pH (final)	q_r (J)[a]	q_c (J)[b]
1	1.978	0.42	−0.35
2	4.811	37.32	23.00
3	2.804	−4.90	−9.89
4	0.980	11.83	12.80

[a]q_r is the total measured heat minus the "blank" heat, as described in the text.

[b]q_c is the heat associated with Fe(III)–citrate complexes, obtained as q_r minus contributions from reactions for which ΔH values are already known, as described in the text.

Results and calculations

Results of calorimetric measurements of thermal effects associated with adding HCl(aq) or NaOH(aq) to acidic solutions of Fe(III) and citric acid are summarized in Table 2. The "reaction heats" labelled q_r are calculated from the total measured heats q_m and the blank heats of combined bulb-breaking and mixing of the solution in the ampoule with the solution in the calorimeter (pH = 1.623, no Fe(III) or citric acid) according to

$$[1] \quad q_r = q_m - q_{blank}$$

We emphasize here that q_{blank} values are for amounts of NaOH(aq) or HCl(aq) that yield the same pH change in blank experiments as observed in the corresponding "reaction" experiment with a solution containing Fe(III) and citric acid.

Some of the heat represented by q_r is due to reactions for which we have equilibrium constants *and* ΔH^0 values (K_i and ΔH_i^0, i = 1 through 5 in Table 1). Knowledge of amount and stoichiometric composition of the original solution, initial pH = 1.623, amount of added HCl or NaOH, pH of final solution, and equilibrium constants listed in Table 1 permits calculation of the number of moles of various species in the final solution and number of moles of various species in the initial solution. All of these values permit us to calculate a "known" contribution q_{known} to q_r as

$$[2] \quad q_{known} = \Sigma(\Delta n_i)\Delta H_i^0$$

in which each Δn_i represents the change in number of moles of some species (as shown in Table 3) and each ΔH_i^0 represents the molar enthalpy of a corresponding reaction (as shown in Table 1). Next, we calculate the total heat q_c due to iron–citrate complexes as

$$[3] \quad q_c = q_r - q_{known}$$

This q_c is attributed to reactions involving Fe(III) and citric acid for which we have K_j values (j = 6 through 9 in Table 1).

Each of the calorimetric measurements for which results are summarized in Table 2 involved different concentrations of the four Fe(III) – citric acid species represented in Table 1 by FeL(aq), $FeHL^+$(aq), $FeOHL^-$(aq), and

TABLE 3. Changes in number of moles (Δn) of various species in calorimetric measurements in which NaOH(aq) or HCl(aq) was added to stock solution (see Table 2 for description of solution and calorimetric results)

	Δn for species below							
Expt. no.	$FeOH^{2+}$	H_3L	H_2L^-	HL^{2-}	FeL	$FeHL^+$	$FeOHL^-$	FeL_2^{3-}
1	-2.94×10^{-6}	-1.92×10^{-4}	1.73×10^{-4}	1.09×10^{-6}	2.40×10^{-5}	-3.43×10^{-5}	2.42×10^{-5}	1.78×10^{-6}
2	-4.11×10^{-6}	-2.59×10^{-3}	4.14×10^{-4}	1.65×10^{-3}	-1.97×10^{-4}	-7.28×10^{-5}	-1.10×10^{-5}	3.00×10^{-4}
3	-3.83×10^{-6}	-1.21×10^{-3}	1.05×10^{-3}	3.32×10^{-5}	-1.09×10^{-4}	-6.62×10^{-5}	8.02×10^{-5}	1.13×10^{-4}
4	7.38×10^{-6}	2.82×10^{-4}	-1.10×10^{-4}	-2.56×10^{-7}	-1.43×10^{-4}	-1.46×10^{-5}	-1.39×10^{-5}	-1.49×10^{-7}

TABLE 4. Changes of thermodynamic properties of reactions in iron(III)–citrate system

Reaction	ΔG^0 (kJ mol^{-1})	ΔH^0 (kJ mol^{-1})	ΔS^0 (J K^{-1} mol^{-1})
$Fe^{3+}(aq) + L^{3-}(aq) = FeL(aq)$	−63.8	−29 ± 3	117 ± 15
$Fe^{3+}(aq) + 2L^{3-}(aq) = FeL_2^{3-}(aq)$	−104	−18 ± 6	289 ± 15
$Fe^{3+}(aq) + H^+(aq) + L^{3-}(aq) = FeHL^+(aq)$	−70.6	−260 ± 10	−636 ± 40
$Fe^{3+}(aq) + L^{3-}(aq) + H_2O(liq) = FeOHL^-(aq) + H^+(aq)$	−48.5	−350 ± 10	−1012 ± 40

$FeL_2^{3-}(aq)$. It is therefore possible to write four simultaneous equations of the form

[4] $q_c = \Sigma(\Delta n_j)\Delta H_j$

in which each Δn_j represents the change in number of moles of one of the four iron–citrate complexes and each ΔH_j represents the molar enthalpy of forming that complex from $Fe^{3+}(aq)$ and $L^{3-}(aq)$ as represented by reaction equations in Tables 1 and 4. Solving these four simultaneous equations leads to the values for ΔH_j that are listed in Table 4. Combination of these ΔH values with the free energies calculated from $\Delta G^0 = -RT \ln K$ leads to the ΔS^0 values that are also listed in Table 4.

Uncertainties in our reported results are estimated as follows. First, it should be recognized that the K's (no activity coefficients) from Field et al. (2) are average values for specified "dilute" solutions. Because our "dilute" solutions had ionic strengths similar to those of the solutions investigated by Field et al. (2), it is a reasonable approximation to use their reported K values without activity coefficients in calculating the concentrations of various species. The ΔH_i^0 values used in eq. [2] appear to be quite accurate for $i = 1$ through 4 (see Table 1), but less accurate for $i = 5$, which makes only a small contribution to q_{known}. But it should be recognized that each of these ΔH_i^0 values refers to the infinite dilution state rather than to the "dilute" solutions of our experiments. Finally, it should be noted that each calorimetric experiment involved non-negligible changes (more than 5%) in concentrations of at least three different iron citrate species, making it necessary to solve simultaneous equations to obtain desired ΔH values for four different reactions, rather than the more accurate procedure of obtaining each ΔH of reaction separately from measured heats obtained from experiments involving only one dominant reaction. It is on the basis of all of these contributions to uncertainties that we have estimated the ±values shown in Table 4.

One way to make a tentative assessment of the reliability of thermodynamic properties associated with chemical reactions is to consider whether reported ΔS^0 values are "reasonable" in relation to ΔS^0 values for "similar" reactions, which also involves our ideas about the molecules and ions in our chemical systems.

We begin by noting that ΔS^0 values are negative for reactions of type

[5] $A(g) + B(g) = AB(g)$

in which there is a net decrease in number of molecules as the reaction proceeds from left to right. It is known from statistical mechanics that this overall loss of standard state entropy can be attributed to the loss of translational entropy that comes directly from the decreasing number of molecules. If this were the only factor to be considered, we would expect all of the ΔS^0 values in Table 4 to be negative.

For reactions in aqueous solution, however, it is necessary to consider the hydration of the solute species. We know in a general way that decreasing the absolute value of the charge on an ion results in an increase in entropy, which we attribute to a decrease in hydration or, expressed differently, release of (possibly only partly) bound water molecules to the bulk water. To illustrate this point we write

[6] $A(H_2O)_a + B(H_2O)_b = AB(H_2O)_c + (a + b - c)H_2O$

If $(a + b - c)$ is larger than unity, we have a net increase of "independent" particles as reaction proceeds from left to right, and we expect that ΔS^0 will be positive.

On the basis of the reasoning above and ΔS^0 values calculated (using properties reported in refs. 6 and 14) for reactions in which there is a net decrease in total charge and also a decrease in number of solute species, we expect that all of the ΔS^0 values in Table 4 should be positive. The reported ΔS^0 values for formation of FeL(aq) and $FeL_2^{3-}(aq)$ are positive, in accord with this expectation, but the two following ΔS^0 values are large and *negative*.

On the basis of the reasoning and observations summarized above, we suggest the following alternatives. (*i*) The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

qualitative reasoning above is seriously inadequate for species such as $FeHL^+(aq)$ and $FeOHL^-(aq)$. (*ii*) The iron–citrate system is more complex than indicated by the reported (2) equilibrium constants, which means that more or different equilibria must be considered. Here we are attributing the "unreasonable" ΔS^0 values to partially inadequate analysis of the electrochemical and spectrophotometric data by Field et al. (2), followed by our similarly inadequate analysis of our calorimetric data. (*iii*) Field et al. (2) or we have made substantial experimental errors.

It is our opinion that (*ii*) above is more likely than either (*i*) or (*iii*).

Photodimerization of α,ω-diarylbutadienes. I. Crystal and molecular structures of *trans,trans*-1-(2′-methoxyphenyl)-4-(4′-nitrophenyl)-1,3-butadiene and its photodimer

MARIO V. CAPPARELLI[1] AND PENELOPE W. CODDING

Departments of Chemistry and of Pharmacology and Therapeutics, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received February 1, 1993

MARIO V. CAPPARELLI and PENELOPE W. CODDING. Can. J. Chem. **71**, 942 (1993).

X-ray crystallographic studies showed that orange crystals of the title diarylbutadiene **1** undergo a topochemically controlled [2+2] photocycloaddition when exposed to visible light to produce the cyclobutane dimer **2**, which is yellow. The conformation of molecule **1** is planar with a maximum deviation from an all-atom mean plane, including substituents, of ≤ 0.28 Å. The crystal structure of **1** displays pairs of molecules packed in a head-to-tail arrangement across inversion centers that allows π orbital overlap between nearest neighbor butadiene double bonds. Intermolecular distances and angles between these photoreactive atoms are C···C, 3.517(2) Å and C—C···C, 92.0(2)°; and the dihedral angle between the plane of the four photoreactive atoms and the plane of the butadiene in one molecule is 72.9°. Molecule **2** lies on a crystallographic inversion centre, which constrains the cyclobutane ring to absolute planarity with C—C distances of 1.558(2) and 1.569(2) Å and C—C—C angle of 90.61(1)°. The dihedral angles between the cyclobutane ring and the two phenyl rings are 81.2° for the *p*-nitrophenyl and 54.0° for the *o*-methoxyphenyl. From the crystal structures of **1** and **2**, the displacement of each of the four photoreactive atoms during the solid-state dimerization can be estimated to be ca. 1.00 Å. Crystals of **1** are orthorhombic, *Pbca*, a = 7.471(1), b = 14.283(1), c = 25.940(1) Å, Z = 8, and those of **2** are monoclinic, $P2_1/c$, a = 11.5396(5), b = 16.129(1), c = 7.9035(3) Å, β = 90.264(3)°, Z = 4. Both structures were solved by direct methods and refined to final values of R = 0.0481 and 0.0512 using 2788 and 2333 observed ($I > 3\sigma(I)$) reflections, for **1** and **2**, respectively.

MARIO V. CAPPARELLI et PENELOPE W. CODDING. Can. J. Chem. **71**, 942 (1993).

Des études cristallographiques ont montré que lorsqu'on soumet les cristaux orange du diarylbutadiène **1** mentionné dans le titre à de la lumière visible, ils subissent une photocycloaddition [2+2] topochimiquement contrôlée qui conduit au cyclobutane dimère **2** qui est jaune. La conformation de la molécule **1** est plane et la déviation maximale du plan moyen des tous les atomes, y compris les substituants, est ≤ 0,28 Å. La structure cristalline du composé **1** présente des paires de molécules placées dans un arrangement tête à queue à travers les centres d'inversion ce qui permet un recouvrement d'orbitales π entre les doubles liaisons voisines les plus près du cyclobutadiène. Les distances intermoléculaires et les angles entres ces atomes photoréactifs sont C···C, 3,517(2) Å et C—C···C, 92,0(2)°; l'angle dièdre entre le plan des quatre atomes photoréactifs et le plan du butadiène d'une molécule est de 72,9°. La molécule **2** se trouve au centre d'inversion cristallographique, ce qui force le cyclobutane à exister sous une forme absolument plane avec des distances C—C de 1,558(2) et 1,569(2) Å et un angle C—C—C de 90,6(1)°. Les angles dièdres entre le cyclobutane et les deux noyaux phényles sont respectivement de 81,2° pour le *p*-nitrophényle et 54,0° pour le *o*-méthoxyphényle. Sur la base des structures des composés **1** et **2**, on peut évaluer que le déplacement de chacun des quatre atomes photoréactifs durant la dimérisation à l'état solide est d'environ 1,00 Å. Les cristaux du composé **1** sont orthorhombiques, *Pbca*, a = 7,471(1), b = 14,283(1) et c = 25,940(1) Å, Z = 8 alors que ceux du composé **2** sont monocliniques, $P2_1/c$, avec a = 11,5396(5), b = 16,129(1) et c = 7,9035(3) Å, β = 90,264(3)° et Z = 4. On a résolu les deux structures par des méthodes directes et on les a affinées jusqu'à des valeurs finales de R de 0,0481 et 0,0512 pour 2788 et 2333 réflexions observées ($I > 3\sigma(I)$) avec **1** et **2** respectivement.

[Traduit par la rédaction]

Introduction

Organic compounds are of interest as potential nonlinear optical (NLO) materials because they form molecular crystals (1, 2) in which individual molecules retain their identities to a much larger degree than in inorganic crystals. Accordingly, molecular polarizability and hyperpolarizability are exhibited as macroscopic crystal properties provided that the hyperpolarizable molecules crystallize in polar space groups (3). NLO effects arise from the polarization induced in a molecule by an electric field. Organic molecules with extensive conjugated systems and charge asymmetry may be suitable materials for second-order NLO properties, especially the α,ω-diarylpolyenes, D-(CH=CH)$_n$-A, with appropriate aromatic ring substituents to make the aryl groups efficient donors (D) and acceptors (A) (4).

As a part of a project aimed at the structural characterization of potential NLO organic compounds and the preparation of useful NLO crystals, the α,ω-diarylbutadienes were investigated. Here we present the crystal structure of *trans,trans*-1-(2′-methoxyphenyl)-4-(4′-nitrophenyl)-1,3-butadiene, **1**. All of the crystalline forms of this compound that we obtained were centrosymmetric and, therefore, unsuitable for NLO applications. During this study we observed that the orange crystals of **1** were sensitive to visible light and reacted to produce a yellow compound, which we characterized. The instability of compound **1** in the solid state suggests that butadiene-based NLO materials will frequently be unsuitable for the manufacture of electronic devices. The photoproduct crystal structure is also reported; it is a dimer of **1**: *r*-1, *t*-3-di(2′-methoxyphenyl)-*c*-2, *t*-4-di(4′-

nitro-*trans*-styryl)cyclobutane, **2**. The possibility of solid-state photodimerization of **1** is also discussed in terms of its crystal packing.

Experimental

Under ordinary room lighting, evaporation of a toluene solution of the original sample of **1** (supplied by Dr. C.W. Spangler, Northern Illinois University) resulted in crystals of both compounds, easily recognizable by their colors. Those of **2** were needles, too thin for single-crystal X-ray work, and were separated manually under the microscope and dissolved in acetone. Slow evaporation of this solution produced needles thick enough to be cut into suitable X-ray specimens.

Unit cell and intensity measurements were carried out on an Enraf–Nonius CAD4 diffractometer, using Ni-filtered CuKα radiation (λ = 1.54178 Å). Measurements for **1** were made at low temperature, to prevent or slow down crystal deterioration. Crystal data, intensity data collection parameters, and final refinement results are summarized in Table 1. Unit cell parameters were obtained from least-squares fit of the setting angles of 22/25 (for **1**/**2**, respectively) automatically centered reflections with θ values in the ranges 13.0–51.5°/24.2–44.6° (for **1**/**2**). Both space groups were uniquely determined by the systematic absences. Intensity data were measured using ω/2θ scan modes with variable scan speeds to a maximum θ = 75° for four octants/one quadrant (for **1**/**2**). Three standard reflections were monitored every 2000 s of exposure time. Those of **2** showed no significant variation in their intensities, but for **1** the values displayed a significant and apparently random fluctuation. To overcome this problem we measured each independent reflection in four different octants. This behavior was attributed mainly to ice formation on the crystal (although some degree of crystal deterioration cannot be ruled out) and was reflected in the relatively large values of R_{int} and S. The data were scaled using the check reflections and corrected by Lorentz and polarization effects.

The structures were solved by direct methods and refined by full-matrix least squares using anisotropic thermal parameters for the non-hydrogen atoms. Hydrogen atoms were initially placed at calculated positions and then allowed to refine with isotropic temperature factors. Weighting schemes were applied during the last cycles of refinement, and for **2** an empirical extinction correction was also made. No absorption corrections were applied. The calculations were done using the SHELXS86 (5), SHELX76 (6), and XANADU (7) programs, and programs ORTEPII (8) and PLUTO (9) were used for drawings. Complex neutral-atom scattering factors from the *International tables for crystallography* (10) were employed.

The final fractional coordinates and equivalent isotropic temperature factors of the non-H atoms were listed in Table 2. The bond lengths, bond angles, and torsion angles are given in Table 3.[2] The molecular structures and atomic labeling schemes are shown in Figs. 1 and 2. The labeling scheme identifies three separate regions in these molecules: the donor region which has the suffix "d", the acceptor region which has the suffix "a", and the chain region which has the suffix "c"; hence, the atoms in the butadiene chain are C1c, C2c, C3c, and C4c.

[2]Tables of anisotropic temperature factors for the non-hydrogen atoms, positional and isotropic thermal parameters for hydrogen atoms, and observed and calculated structure factors for compounds **1** and **2** were deposited as supplementary material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen positional parameters for **1** and **2** have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Results

Molecular geometry of the monomer (1)

The regular hexagonal geometry of six-membered aromatic rings is modified when hydrogen atoms are substituted by other functional groups (11–13). Accordingly, in both of the phenyl rings of **1** the bonds adjacent to the butadiene chain are significantly longer than the rest, while the endocyclic angles at C(1) are significantly smaller than 120° and those at C(2) and C(6) are widened. Although these are the types of deformations expected for an electron-releasing substituent at C(1a) and C(1d) (11, 14), substitution of hydrogen by carbon (which would have the same electronegativity as the ring) would also produce a narrowing to 117.5–118.0°, as found in **1** (12). The widening at C(2d) is smaller than that at the other three *ortho* positions due to the presence of the methoxy substituent, which normally produces a small decrease (ca. 0.1–0.2°) in the corresponding endocyclic angle (12, 15). The endocyclic angle at C(4a) shows a significant widening because of the electron-withdrawing character of the NO_2 group (15); its value is identical to the average of 122.1° obtained from structural studies of many *para*-substituted nitrobenzenes (11, 12).

The chain has a *trans,trans* configuration and a clear pattern of alternative longer and shorter bonds; as usual in conjugated systems, the single C—C bonds (C1d—C1c, C2c—C3c, and C4c—C1a) show partial double-bond character (16, 17). The central single bond is slightly shorter than the outer ones, but in contrast to *trans,trans*-1-(2′,6′-dichlorophenyl)-4-phenyl-1,3-butadiene (18), the difference is not significant. To minimize the H···H intramolecular repulsions, the chain adopts a "stretched" distortion so that all of the C—C—C angles in the chain are significantly larger than 120°. As in other all-*trans*-α,ω-diphenylpolyenes (16), the wider angles are those at the ends of the chain (at C(1c) and C(4c)), and correspond to the closer H···H contacts: H(2c)···H(6d), 2.23 Å; H(3c)···H(6a), 2.19 Å.

The molecule is planar, which maximizes the overlap of the atomic π orbitals and, therefore, the delocalization of the π system. The maximum deviation from the all-atom mean plane (r.m.s.d. = 0.105 Å, including substituents) is 0.28 Å for O(9a); the rest of the atoms are within 0.16 Å of the plane. The dihedral angles between the mean planes of the three moieties are 4.7° (donor/chain) and 4.2° (chain/acceptor).

Molecular geometry of the dimer (2)

In general, the pattern of bond lengths and angles in the phenyl rings of **2** is similar to that observed in **1**. Owing to the lower precision in the determination, the effects of the substituents on the ring geometry are less clear.

The pattern of bond lengths and angles in the C(2c)—C(3c)=C(4c)—C(1a) fragment is similar to that observed in **1**, but in **2** the putative single bond C(2c)—C(3c) is significantly longer than C(4c)—C(1a) due to the absence of conjugation. In comparison with the structure of **1**, the change from sp^2 to sp^3 hybridization in C(1c) and C(2c) is reflected in the C(1d)—C(1c) and C(1c)—C(2c) bond lengths, and in the angles at C(1c) and C(2c). The C(1d)—C(1c) and C(2c)—C(3c) distances are in good agreement with the av-

erage values of 1.504(1) and 1.499(3) Å found for these types of exocyclic bonds in substituted cyclobutanes (19).

The molecule lies at a crystallographic center of symmetry, which constrains the four-membered ring to absolute planarity. The substituents are in a *cis-trans-cis-trans* disposition with respect to the cyclobutane plane. The bond lengths and angles in the ring are within the range of values observed in other substituted cyclobutanes (17, 20). The two independent C—C distances are significantly different; the longest bond is found between the atoms attached to the *cis* substituents (C1c—C2c′) and is due to steric repulsions. The bulk of the substituents in **2** causes the difference between the long and short cyclobutane bond distances to be somewhat larger, Δ = 0.011 Å, than the difference between average bond lengths compiled for planar 1,2-substituted cyclobutanes, Δ = 0.007 Å (20).

The dihedral angles between the mean planes of the cyclobutane and the phenyl rings are 81.2° (acceptor/chain) and 54.0° (donor/chain).

Discussion

Crystal packing and photodimerization

In the crystal structure of **1** the molecules are arranged in an α-type packing mode (24), with a separation between the photoreactive atoms C(1c)···C(2c)′ of 3.517(2) Å, and an angle C(2c)—C(1c)···C(2c)′ of 92.0(2)°. The solid-state photochemical behavior of **1** is totally consistent with its crystal packing, which also explains why only one of the two double bonds of the chain is involved in the reaction and only one product, rather than a mixture of products, is formed. (Crystals of a similar α,ω-diarylbutadiene that crystallizes in a different space group are light stable.) The centrosymmetric molecular structure of **2** is also in agreement with the crystal packing of **1**, in which the reaction partners are arranged in a head-to-tail fashion across inversion centers. Hence, the solid-state reactivity of **1** is a typical example of a well-known type of topochemically controlled [2+2] photocycloaddition (2*c*, 21). The geometrical parameters θ_1, θ_2, θ_3, and d, defined by Venkatesan and Ramamurthy (22*a*) (see also refs. 22*b* or 22*c* for figures defining the d parameter) to measure the degree of overlap between the π orbitals of the reactive double bonds, have values of 0.0°, 92.0°, 72.9°, and 1.03 Å, which equal or are close to the ideal values of 0°, 90°, 90°, and 0.0 Å.

The differences between some of the molecular and crystal parameters of **1** and **2** are listed in Table 4. To calculate these values, two different ways of forming the dimer are considered: *path A* — the bonds formed during the reaction

[a]Equivalent isotropic thermal parameters are: $U_{eq} = (1/3)\ \Sigma_i\Sigma_j U_{ij}\mathbf{a}_i{}^*\mathbf{a}_j{}^*\mathbf{a}_i\mathbf{a}_j$.

are between C(1c)—C(2c)′ and C(1c)′—C(2c), in the numbering scheme of Fig. 3(*a*), or *path B* — the bonds formed in the dimerization are between C(1c)—C(2c) and C(1c)′—C(2c)′. The nature and size of the atomic movements accompanying the solid-state [2+2] photocycloaddition can be envisaged from Fig. 3(*b*), which gives a pictorial representation of path A, based on the molecular structure of **2**. The main differences in bond lengths and angles are due to the change of hybridization at the reacting atoms. There are also significant variations in several torsion angles. The modification in the torsion angle about C(1d)—C(1c) is dictated by the change from trigonal to tetrahedral geometry at the reacting atoms, whereas the variations in the other torsion angles are determined by nonbonded interactions, after the constraints imposed by conjugation are removed. Since the configuration about C(1c)—C(2c) is *trans* in the monomer and is *trans* about C(1c)—C(2c) and C(1c)′—C(2c)′ in the dimer, the dimerization probably occurs

via path A and, therefore, the pair of bonds formed during the reaction are C(1c)—C(2c)′ and C(1c)′—C(2c), which have *cis* configurations about them. Further support for path A is given in Table 4 where it is shown that path A requires the smaller adjustment in key torsion angles in the transformation from the structure found in crystals of **1** to the structure found in crystals of **2**.

If both the postulate of minimum amount of atomic movement (23) is obeyed and the center of symmetry is conserved during the reaction, the photochemically active atoms, C(1c) and C(2c), and their centrosymmetrically related partners, must move within the plane defined by themselves and the inversion center, hereinafter called the *reference plane*. Then, during the reaction each of these four atoms, C(1c), C(2c), C(1)′, and C(2c)′, would move less than 1.00 Å, for either path A or B. However, the assumptions made above should be regarded only as approximate idealizations; indeed, incomplete X-ray studies of partially photolyzed crystals of related butadienes (in this laboratory) and other photochemical reactions (24) have shown small but significant departures from coplanarity in the reacting atoms of the intermediate photoproducts. Also, Craig and coworkers (25) have proposed that, in some cases, eximers could be formed as a result of the asymmetrical excitation

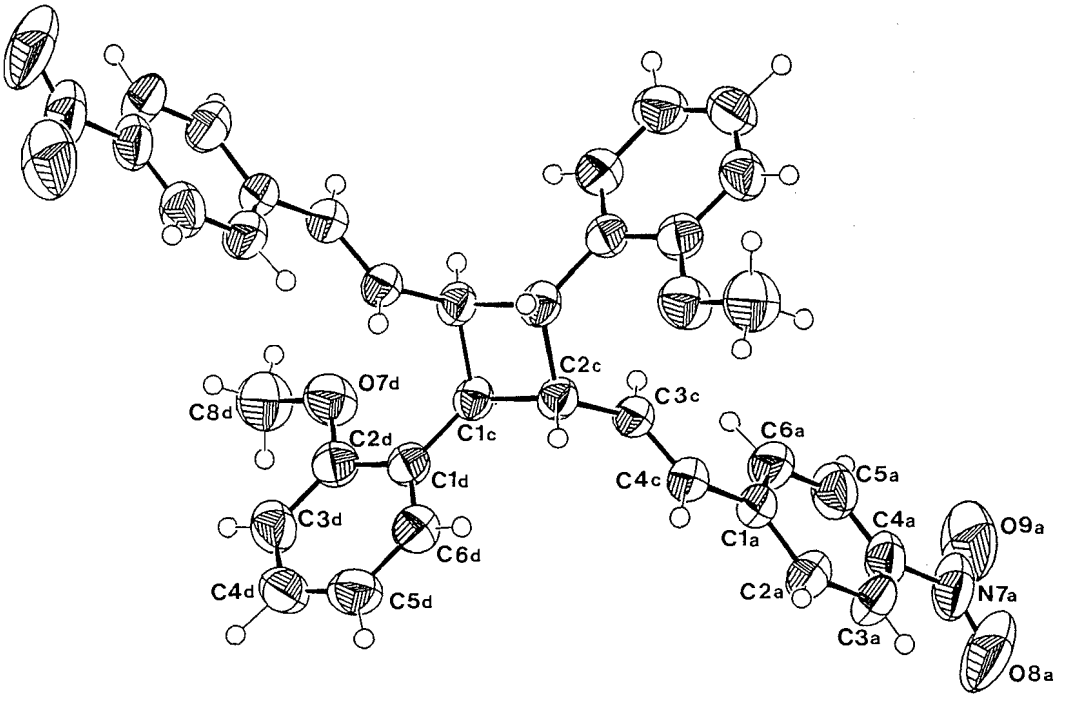

FIG. 2. Structure of **2** showing the thermal ellipsoids drawn at 50% probability and the atomic numbering scheme.

TABLE 4. Differences between key geometric features of compounds **1** and **2**. The columns give differences for compound **2** − compound **1** for each of reaction paths A and B (see text). Unlisted bond distances differed by ≤ |0.022 Å|, bond angles by ≤ |1.6°|, and torsion angles by ≤ |6.0°|

Feature	Path A [**2** − **1**]	Path B [**2** − **1**]
C(1c)—C(1d)	0.046 Å	0.046 Å
C(2c)—C(1c)	0.221 Å	0.232 Å
C(3c)—C(2c)	0.043 Å	0.043 Å
C(2c)—C(1c)—C(1d)	−7.2°	−8.2°
C(3c)—C(2c)—C(1c)	−9.5°	−3.9°
C(2d)—C(1d)—C(1c)—C(2c)	−1.2°	−111.0°
C(6d)—C(1d)—C(1c)—C(2c)	−3.8°	−113.7°
C(1d)—C(1c)—C(2c)—C(3c)	−65.2°	−169.4°
C(1c)—C(2c)—C(3c)—C(4c)	57.8°	−44.1°

of the ground-state equilibrium structures. Therefore, the displacements shown in Table 4 should be considered as the lower limits of atomic movement, rather than their actual values.

In the crystal structure of **1**, the *reference plane* (as defined above) is nearly parallel to the (110) plane, and in the crystal structure of **2** it is almost exactly parallel to (010): dihedral angles: 15.1° and 0.5°, respectively. The maximum deviation of any atom from the *reference plane* is approximately the same in both molecules, viz, 6.77 Å for O(8a) in **1** and 6.60 Å for O(9a) in **2**. Accordingly, the translations along [110] in **1** and along [010] in **2** also have similar values: 16.119 and 16.129 Å, respectively. A number of topotactic (single-crystal to single-crystal) photodimerizations (21*e*, 26) and other organic reactions (27) have been reported. In spite of the axial relationship indicated above, in the present case there is no topotaxy, probably because the changes in some molecular parameters, especially torsion angles, are too large. Examination of crystals of **1** under an optical microscope, over several days at room temperature, revealed progressive disruption of the crystal lattice, as shown by a slow development of cracks and an increasing opacity of the specimens.

In both crystals the packing is entirely due to van der Waals forces. The molecular volume in the crystals of **2** is larger by 21.6 $Å^3$, a difference that is mostly due to less efficient packing, owing to the molecular shape of this compound, rather than to the difference in the temperature of the structure determinations. The packing effect is partially overcome by shorter distances between the atoms C(1c)···C(2c)′ and C(1c)′···C(2c) in the dimer.

Conclusions

Molecules of the potential NLO material, **1**, are found to be unstable to exposure to light in the solid state. Formation of the dimer in crystals of **1** can be accomplished by atomic movements of approximately 1.0 Å to form **2**, a cyclobutane constrained by a centre of symmetry in the ring. The molecules of **1** display a planar structure in the solid state, indicating the existence of an extended π electronic system; thus, the molecular conformation and polar nature of **1** meet the molecular requirements for second-order NLO applications. Unfortunately, all known crystalline forms of **1** are centrosymmetric and can not have NLO properties. In addition, crystals of **1** are photoreactive; yet, suitable NLO materials must have an extraordinary stability with respect to high-intensity light sources. Nevertheless, the photodimerization that **1** undergoes appears to be a crystal lattice-controlled reaction leaving open the possibility that

G.W. BUCHANAN, A.B. DRIEGA, A. MOGHIMI, C. BENSIMON, and K. BOURQUE. Can. J. Chem. **71**, 951 (1993).

The X-ray crystal structure of the title material has been determined at −130°C. Low-temperature $^1H^1H$ COSY, $^{13}C^1H$ HETCOR, and DEPT ^{13}C NMR spectra have been recorded, which permit unambiguous assignments of all carbon resonances when ring inversion is slow on the NMR timescale. The limiting low-temperature solution phase ^{13}C spectrum has many common features with the solid phase ^{13}C CPMAS spectrum recorded at 300 K. Spectra for the 7,10-tetradeuterio derivative have also been obtained and substituent influences on ^{13}C shieldings are discussed in detail.

G.W. BUCHANAN, A.B. DRIEGA, A. MOGHIMI, C. BENSIMON et K. BOURQUE. Can. J. Chem. **71**, 951 (1993).

Opérant à −130°C, on a déterminé la structure cristalline du composé mentionné dans le titre. On a aussi enregistré les spectres RMN du ^{13}C à basse température, en modes $^1H^1H$ COSY, $^{13}C^1H$ HETCOR et DEPT; ces données permettent de faire une attribution non-ambiguë des résonances de tous les carbones lorsque l'inversion de cycle est lente à l'échelle de temps de la RMN. Le spectre du ^{13}C de la solution à la basse température limite présente plusieurs caractéristiques communes au spectre ^{13}C en CPMAS de la phase solide, déterminé à 300 K. On a aussi déterminé le spectre RMN du dérivé 7,10-dideutéré et on discute en détail des influences des substituants sur les blindages du ^{13}C.

Introduction

Stereochemical influences on NMR parameters in substituted cyclohexanes are most properly examined by recording spectra under low-temperature conditions where ring inversion is slow on the NMR timescale. Early definitive work in this area with respect to ^{13}C NMR was carried out using monosubstituted compounds (1–4). Consequently, axial and equatorial α, β, γ, and δ substituent effects have now been delineated for a wide variety of monosubstituted cyclohexane derivatives (1–7).

For molecules containing more than a single substituent, the problems of resonance assignment at low temperature can be significant. Herein we report the use of low-temperature homo- and heteronuclear COSY spectra, combined with the results of DEPT spectra, for the unambiguous assignment of cyclohexyl carbon resonances in *cis*-cyclohexyl-9-crown-3 ether **1**. A reversal of the normal β effect of axial vs. equatorial oxygen in *mono*substituted compounds has been found and is attributed to the dominance of the γ-*gauche* shielding effect of axial oxygen on the carbon that is β to equatorial oxygen in this *cis*-1,2-disubstituted compound.

For assignment of oxygenated methylene carbons, the results of deuterium incorporation and an inverse detected ^3J HETCOR experiment at low temperature were used.

A comparison has been made between the limiting low-temperature solution ^{13}C spectrum and that obtained in the solid phase at ambient temperature. The X-ray crystal structure has been determined and some of the stereochemical shielding trends are discussed in terms of torsional angle influences.

Results and discussion

The ORTEP diagram and numbering scheme for *cis*-cyclohexano-9-crown-3 ether **1** is shown in Fig. 1. Solution ^{13}C NMR spectra at 300 and 173 K are in Fig. 2, while low-temperature $^1H^{13}C$ HETCOR and $^1H^1H$ COSY spectra are shown in Figs. 3 and 4, respectively. The solid phase ^{13}C spectrum is presented in Fig. 5. Table 1 contains bond lengths and bond angles while torsional angles are collected in Table 2. Crystallographic data are listed in Table 3 and atomic parameters in Table 4. In Table 5 are presented the ^{13}C NMR data.[2]

(i) X-ray crystal structure

At −130°C, the nine-membered ring conformation of **1** exhibits O—C—C—O bond angles involving C7, C8, C9, and C10, which are *gauche* (67.4 and 78.0°, respectively) in accord with the expected geometry for these units in larger crown-type systems (8, 9). The O1—C1—C2—O2 angle of 58.9° is consistent with that expected in a *cis*-1,2-disubstituted cyclohexane. The X-ray crystal structure of 1,4,7-trioxanane (9-crown-3 ether, **2**, mp 0°C) is unknown. However, molecular mechanics calculations of its preferred conformations have been carried out (9) and low-temperature NMR and IR studies (10) of its solution and solid phase stereochemistries performed. The low-temperature ^{13}C NMR spectrum (10) shows six lines, consistent with a single asymmetric conformation for **2**. The present X-ray data for **1** also indicate an asymmetric nine-membered ring conformation, with the overall geometry similar to that of the calculated "*f*" conformation of **2** (9). This asymmetric "*f*" conformation was calculated to be the second lowest energy form of **2**, with steric energy only 0.83 kcal/mol above the minimum. Detailed comparisons of the X-ray data for **1** and the "*f*" conformation of **2** are presented below. To compare the two geometries, it should be noted that the mirror image of the calculated conformation (9) was refined in our X-ray structure and a transformation of ref. 9 atom numbers to the present numbering scheme is needed (i.e., C6 → C1, C7 → C2, O8 → O2, etc).

[1]Author to whom correspondence may be addressed.

[2]Tables of torsion angles for all atoms, anisotropic temperature factors, and structure factors have been deposited as supplementary data and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

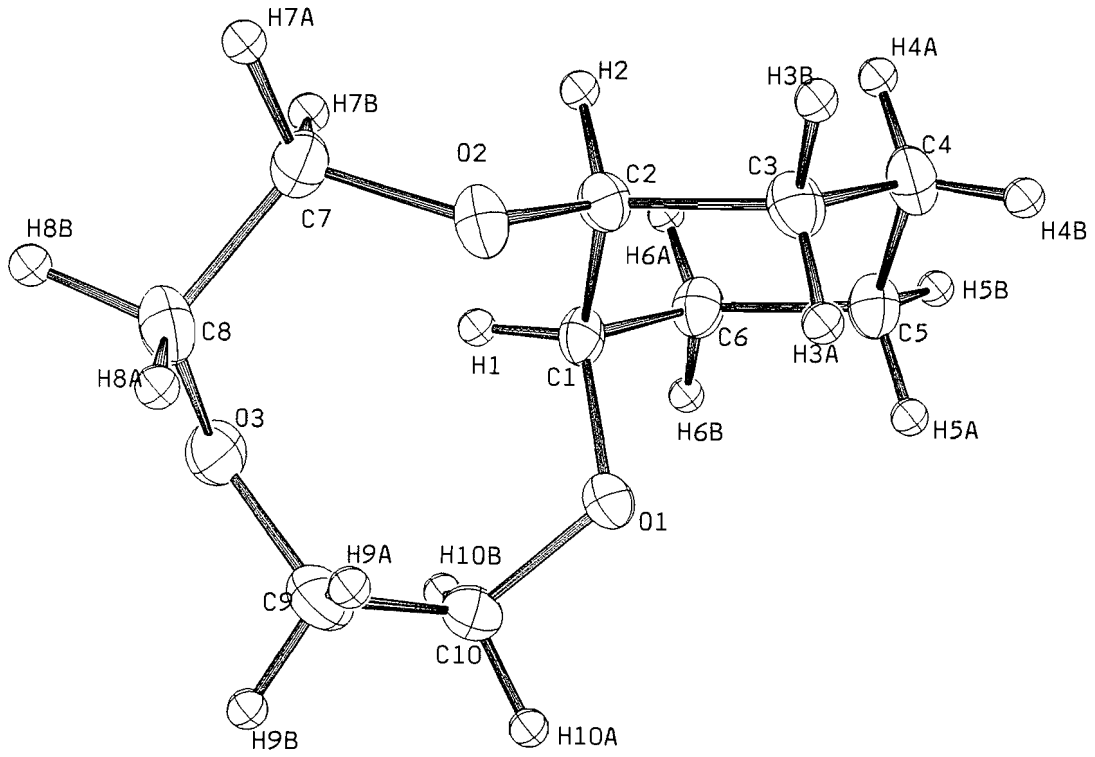

FIG. 1. The ORTEP plot for **1**.

Torsional network	θ° obsd. (**1**)	θ° calcd. ("*f*" conformation of **2** (9))
O1—C1—C2—O2	−58.9	63
C1—C2—O2—C7	−76.8	76
C2—O2—C7—C8	120.3	−116
O2—C7—C8—O3	−67.4	61
C7—C8—O3—C9	96.1	−95
C8—O3—C9—C10	−127.7	137
O3—C9—C10—O1	78.0	−78
C9—C10—O1—C1	−78.0	72
C10—O1—C1—C2	122.1	−120

Clearly, there is very good agreement between these two conformations, with the largest difference between calculated and observed torsional angles being 9.3°.

(ii) Solution NMR spectra

The five ^{13}C resonances observed for **1** at 300 K (Fig. 2) are consistent with rapid conformational interconversion on the NMR timescale at this temperature for both the six- and the nine-membered rings. The close correspondence between the solid phase ^{13}C spectrum and the solution ^{13}C spectrum at 173 K suggests that the "*f*" conformation is highly preferred in the nine-membered ring of **1** at 173 K. Minor amounts of other conformations may be present at higher temperatures but are not detectable at lower temperatures, where conformational interconversion is slow on the NMR timescale, due to ground state free energy differences that probably exceed 4 kJ/mol.

At 173 K, the two positive signals in the DEPT 135 spectrum arise from CH carbons, while the remaining eight negative lines are due to CH_2 sites. The CH resonance at 82.20 ppm can be assigned with confidence to C2, the carbon bearing equatorial oxygen, by analogy with well-established stereochemical trends (5, 11, 12). Its counterpart, the C1 site bearing axial oxygen, is shielded by 6.50 ppm and appears at 75.70 ppm.

In the low-temperature heteronuclear $^1H^{13}C$ COSY spectrum (Fig. 3), the methine protons attached to C1 and C2 are clearly visible and appear at ca. 4.30 and 3.20 ppm, respectively. There is a reverse correlation between ^{13}C and ^1H steric shifts here, since the deshielded C2 carbon is bonded to the most shielded proton while the shielded C1 carbon is bonded to the most deshielded proton.

With these proton assignments in hand, it is then possible to use the $^1H^1H$ COSY spectrum (Fig. 4) to assign protons on C3 and C6, respectively. Accordingly, the most deshielded proton on nonoxygenated carbon, appearing at ca. 1.85 ppm, must be bonded to C6, since it correlates to the ^1H resonance for the C1 proton at 4.30 ppm. Similarly, the C3 protons must appear near 1.65 ppm, since they correlate to the C2 resonance at 3.20 ppm. From the heteronuclear COSY spectrum, it then follows that C6 resonates at 30.07 ppm and C3 at 27.87 ppm. Finally, C5, being γ-*gauche* to the axial oxygen on C1, appears at 19.39 ppm and is shielded by 5.31 ppm relative to C4, which is γ-*trans* to the equatorial oxygen on C2.

The α and γ shielding trends at C1,2 and C4,5, respectively, are consistent with expectations based on α and γ substituent effects in related monosubstituted molecules (3, 5, 11); however, the β substituent effects on C3 and C6 are not. Indeed in **1**, C3, the carbon β to equatorial oxygen, is shielded by 2.20 ppm relative to C6. For a series of 23 monosubstituted cyclohexanes (5), it has been found that, with the exception of the $N(CH_3)_2$ group, carbons β to equatorial substituents are *deshielded* relative to their counterparts, which are β to axial functions.

It is important to note for **1** and indeed for all *cis*-1,2-disubstituted cases, however, that C3 is γ-*gauche* to the axial oxygen on C1 and thus may experience a shielding γ effect that overrides the β deshielding from the equatorial O at C2.

One can test this hypothesis semi-quantitatively by considering the known β deshielding effect of 2.17 ppm in the equatorial conformation of methoxycyclohexane (3, 5) and the observed γ-*gauche* shielding effect of 5.31 ppm in **1** due to the axial oxygen. On this basis, one would predict that C3 would be shielded relative to C6 in **1** by 5.31 − 2.17 = 3.14 ppm, a result that is within 1 ppm of that observed. These unambiguous findings for the shifts of C3 vs. C6 in this *cis*-1,2-disubstituted crown ether suggest that earlier tentative assignments for the corresponding carbons in *cis*-1,2-dicyclohexano-14-crown-4 ethers (13) at low temperature should be reversed, while those made for *cis*-dicyclohexano-18-crown-6 systems (14) are correct.

[a]0.1 M in CD_2Cl_2.

vs. C7,10 of the nine-membered ring of **1**, the synthesis of the 7,10-d_4 derivative has permitted attribution of the resonance at 70.76 ppm in the 300 K spectrum to C7,10. At 173 K, the chemical shift difference between C7 and C10 is only 0.77 ppm (i.e., 71.59 vs. 70.82). In contrast, the shift difference bteween C8 and C9 at 173 K is 4.31 ppm.

In the solid phase ^{13}C spectra (Fig. 5), the observed chemical shifts are within 1.5 ppm of those found in CD_2Cl_2 solution at 173 K. The dipolar dephased spectrum of the 7,10-d_4 derivative clearly shows that the C7,10 sites are the most shielded of the oxygenated carbons and that the chemical shift difference between these sites is less than 1 ppm. The shift difference between C8 and C9 is 3.8 ppm in the solid phase spectrum and 4.3 ppm in solution at 173 K. It is of interest to note that in *benzo*-9-crown-3, the chemical shift difference between C7 and C10 is 7.7 ppm, while that between C8 and C9 is 2.8 ppm.[3]

Distinction between C7 and C10 was obtained via an inverse detected ^3J HETCOR experiment at low temperature. The ^{13}C resonance for C1 at 75.7 ppm shows a correlation to the ^1H resonance at 3.7 ppm. From the ^1J HETCOR spectrum these H's are bonded to the ^{13}C at 70.8 ppm. Hence C10 must resonate at 70.8. From the COSY, one then can get the connectivity to the H9 protons and subsequently, from the ^1J HETCOR, it is clear that C9 resonates at 78.6.

The 4.3 ppm deshielding of C9 relative to C8 is most likely due to a combination of two factors. Initially, it was calculated (16) that expansion of the O—C—C—O angle in ethylene glycol from 67° to 78° will deshield the carbon by ca. 1 ppm. Hence the O3—C8—C7—O2 angle of −67.4° is expected to result in some shielding of C8 relative to C9, since the O3—C9—C10—O1 angle is 78.0°.

Also there is a substantial difference between the C7—**C8**—O3—C9 torsion angle (96.1°) and the value of 127.7° for the C10—**C9**—O3—C8 unit. Recent *ab initio* ^{13}C calculations from these laboratories (16) for ethylmethyl ether indicate such an expansion should deshield C9 by ca. 2 ppm.

With more sophisticated computing methods, it is hoped that reliable *ab initio* ^{13}C calculations for a more complex molecule such as **1** will soon be available. Coupled with

single crystal chemical shift anisotropy data, the underlying features governing stereochemically dependent ^{13}C shifts will no doubt be delineated in the near future.

Experimental

(i) Materials

Diglycolic acid methyl ester

Diglycolic acid (Aldrich) (17.4 g, 0.13 mol) was dissolved in 100 mL of anhydrous methanol, and thionyl chloride (22 mL, 0.30 mol) was added dropwise with cooling and stirring over a period of 10 min. Stirring was continued for 30 min and the excess methanol was then removed by rotary evaporation. The resulting viscous liquid turned to a semi-solid upon standing (yield = 20.9 g, 98%). ^{13}C NMR ($CDCl_3$) δ_C = 170.2, 68.1, and 52.5. This crude material was used for the next step without further purification.

Diethylene glycol-d_4

$LiAlD_4$ (18.2 g, 0.12 mol) was added with stirring to a 1.5 L round-bottom three-necked flask, equipped with condensor and dropping funnel, containing 800 mL of dry THF under a nitrogen atmosphere. The flask was cooled in an ice–salt bath and dimethyl diglycolate (18.2 g, 0.11 mol) dissolved in 20 mL of dry THF was added with stirring over a period of 45 min. Two additional 50 mL aliquots of dry THF were added to reduce the viscosity and the reaction mixture was allowed to warm to 40°C with stirring for an additional 30 min. The excess $LiAlD_4$ was destroyed by dropwise addition of 3 mL water, and dilute H_2SO_4 (30 mL, 20%) was added with stirring to break down the alkoxide complex. The aqueous layer was separated and washed with additional THF (3 × 100 mL). Solvent was removed from the combined organics by rotary evaporation. The crude product was dissolved in water (100 mL) and washed with 20 mL of CH_2Cl_2. Water was removed by evaporation under vacuum (3 h), with occasional gentle warming, to yield 11.9 g (95%) diethylene glycol-d_4. ^{13}C NMR ($CDCl_3$) δ_C = 72.0, 60.6 (quintet).

1,5-Dichloro-3-oxapentane-d_4

Thionyl chloride (18.3 mL, 0.25 mol) was added dropwise over a period of 30 min, with stirring, to cooled diethylene glycol-d_4 (12.1 g, 0.11 mol) under nitrogen. The mixture was refluxed for 24 h and excess thionyl chloride was removed at reduced pressure. The residue was poured onto ice (15 g) and then washed with CH_2Cl_2 (3 × 50 mL). The combined extracts were washed with saturated $NaHCO_3$ (2 × 10 mL), saturated NaCl (20 mL), and water (2 × 20 mL), and dried over anhydrous Na_2SO_4. The solvent was removed by evaporation at reduced pressure to yield 12.3 g (76%) 1,5-dichloro-3-oxapentane-d_4. ^{13}C NMR ($CDCl_3$) δ_C = 71.1, 42.1 (quintet).

Benzo-9-crown-3-d_4

A 2-L round-bottom flask was charged with catechol (16.3 g, 0.148 mol), water (1700 mL), and LiOH (12.4 g, 0.296 mol), and the mixture was stirred for 5 min. To this was added dropwise 1,5-dichloro-3-oxapentane-d_4 (21.7 g, 0.148 mol) and the reaction mixture was refluxed for 86 h. Upon cooling, the mixture was acidified to pH 2 by addition of dilute H_2SO_4 and was extracted with CH_2Cl_2 (3 × 100 mL). After washing with 5% NaOH (3 × 100 mL), saturated NaCl (100 mL), and water, the extracts were dried over anhydrous Na_2SO_4. After solvent removal, the resulting reddish slurry was purified by column chromatography on silica gel (grade 60, 230–400 mesh). Elution with 1:1 CH_2Cl_2:diethyl ether yielded, in the initial fractions, 10.0 g (33%) benzo-9-crown-3-d_4, mp 69–71°C (lit. (15) mp (for protio analog) 67–69°C). Later fractions contained 1.0 g (1.6%) dibenzo-18-crown-6-d_8, mp 162–164°C (lit. (15) mp (for protio analog) 164–165°C).

cis-*Cyclohexyl-9-crown-3-*d_4

Benzo-9-crown-3-d_4 (1.0 g, 0.004 mol), in methanol (40 mL) containing 5% Rh on alumina catalyst and 0.5 mL acetic acid, was

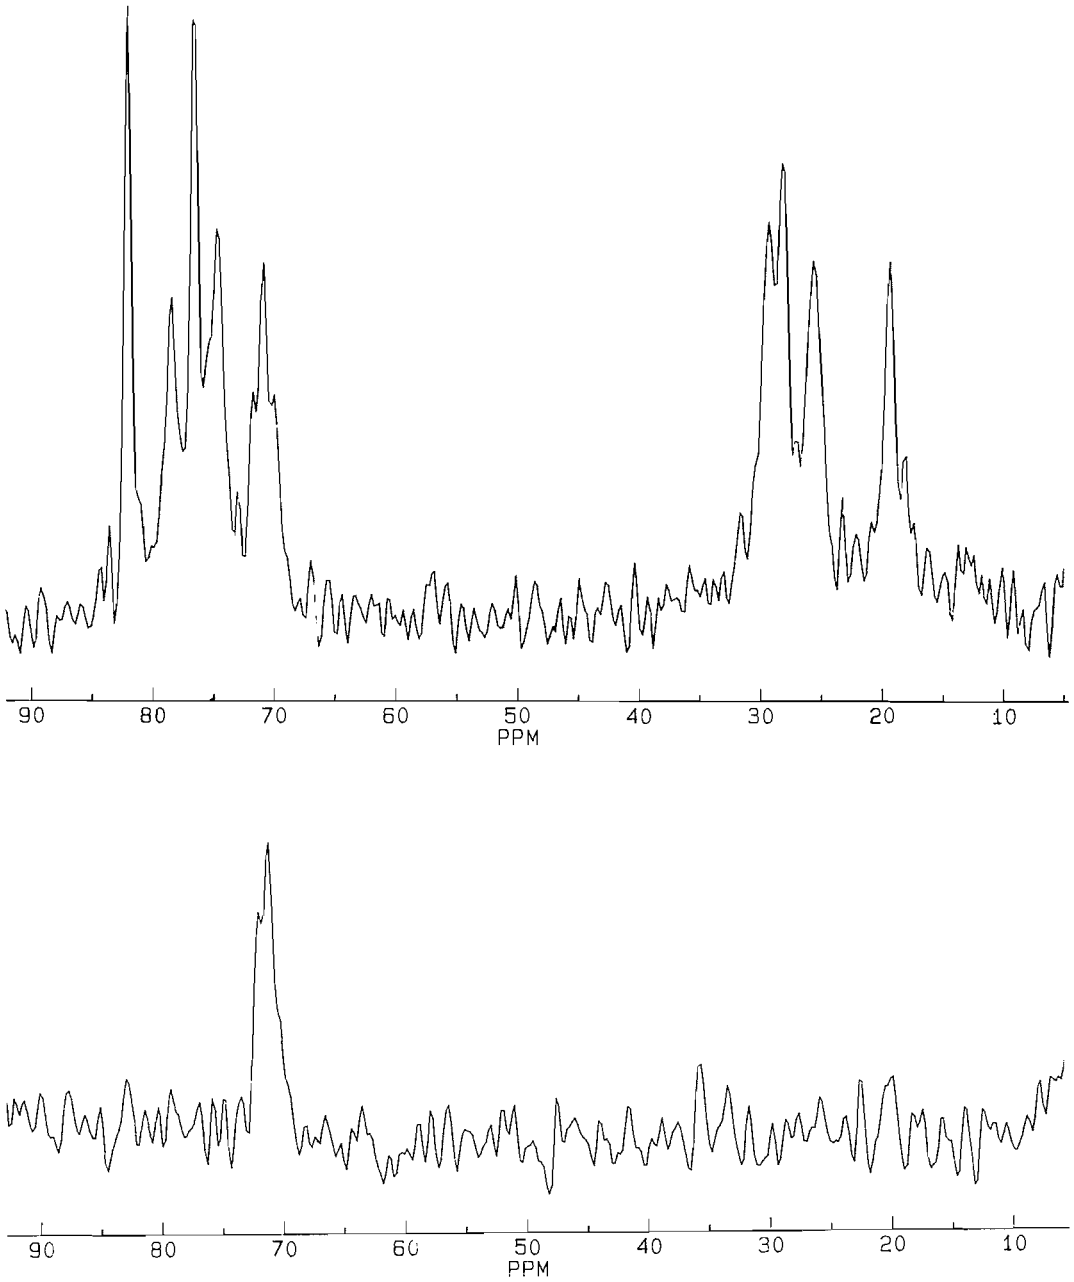

FIG. 5. Upper trace: 45.3 MHz ^{13}C CPMAS spectrum of **1**-C7,C10-d_4 at 300 K. Lower trace: same as upper except dipolar dephased.

hydrogenated for 6 h at 40°C and 5 atm (1 atm = 101.3 kPa) pressure using an American Instrument Co. high-pressure apparatus. After removal of the catalyst by filtration and solvent evaporation, the crude product was dissolved in 100 mL CH_2Cl_2 and washed with saturated NaCl and water. After drying over anhydrous Na_2SO_4, the solvent was removed to yield a viscous oil. Subsequent crystallization from *n*-hexane yielded 0.8 g (80%) of *cis*-cyclohexyl-9-crown-3-d_4, mp 41–42.5°C.

(ii) Spectra

Solution NMR spectra

All spectra were recorded using a Bruker AMX-400 spectrometer equipped with a 5-mm inverse probe and an Aspect X32 computer. An Aspect 3000 processing controller was employed and all standard microprograms used are in the Bruker Software Library.

The $^1H^1H$ COSY experiments were run using N-type phase cycling with a 45° mixing pulse. The free induction decays were acquired over 1024 data points for each of the 256 values of the evolution time, with a digital resolution of 5 Hz/point. The raw data were zero filled in F1 prior to transformation using the qsine window function for both F1 and F2. The matrix was symmetrized about the diagonal.

For the $^1H^{13}C$ HETCOR experiments, the free induction decays were typically acquired over 1024 data points for each of the 512 values of the evolution time, with a digital resolution of ca. 8 Hz/point in F2 and 4 Hz/point in F1. The raw data were zero filled in F1 prior to transformation using the qsine window function for both F1 and F2. The proton relaxation delays were set to 1 s. For one-bond couplings, delays were chosen to emphasize couplings of 135–140 Hz, while for the long-range HETCOR experiment, delays were set to correspond to couplings of 6 Hz.

For the DEPT 135 experiment, 32K data points were used with a digital resolution of 0.8 Hz/point. Proton relaxation delays were set to 1.0 s.

Solid phase ^{13}C spectra

The ^{13}C CPMAS spectra were recorded at 45.3 MHz using a Bruker CXP-180 spectrometer and techniques described previously (16). For the dipolar dephased spectra, the ^{1}H decoupler was gated off for a period of 40 μs during the delay before the ^{13}C acquisition.

(iii) X-ray crystallographic measurements and structure solution

A summary of the crystallographic data is given in Table 3. Diffration intensities were collected on a Rigaku diffractomer using MoKα radiation at −130°C. The θ/2θ scan technique with profile analysis (17) was employed. The space group was determined by systematic absences. Unit cell parameters were obtained by refinement of the setting angles of 24 reflections with 2θ values in the range of 30–49.9°C. Lorentz and polarization factors were applied but no correction for absorption was made. The structure was solved by direct methods plus Fourier maps and was refined by full-matrix least-squares analysis with weights based on counting statistics. Non-H atoms were refined anisotropically and H atoms were refined isotropically. All calculations were performed using the NRC VAX Crystal Structure programs (18). Anisotropic thermal parameters are available as supplementary data.

Large perturbations of long-range $^nJ(^1H,^1H)$ and $^nJ(^1H,^{19}F)$ by the intramolecular hydrogen bonds in 2-mercaptobenzaldehyde, salicylaldehyde, and some derivatives. Reference structures for intramolecular hydrogen bonds

TED SCHAEFER, RUDY SEBASTIAN, DAVID M. MCKINNON, PERRY W. SPEVACK, KERRY J. COX, and CRAIG S. TAKEUCKI. Can. J. Chem. **71**, 960 (1993).

Precise ^1H nuclear magnetic resonance spectral parameters are reported for salicyladehyde and its 3-fluoro and 5-fluoro derivatives in nonpolar solutions. Such data are also given for the 2-mercapto, 2-methylthio, and 2-methoxy derivatives of benzaldehyde. Comparison of the long-range coupling constants in the various compounds and their conformers shows a large perturbation of their magnitudes by hydrogen bond formation. For the salicylaldehyde system, the perturbation is particularly large for couplings involving the aldehyde proton and protons or fluorine nuclei placed *ortho* to the hydroxyl group. For example, ^5J_t (F, CHO) is reduced by about 50%. The perturbation, as expected, is much smaller for coupling constants of nuclei remote from the site of the hydrogen bond. In 2-mercaptobenzaldehyde the long-range coupling constants are also sensitive to hydrogen bond formation, those involving the sulfhydryl proton markedly so compared to the hydroxyl proton in salicylaldehyde. The strength of the C=O···H—S bond is discussed. It is argued that the reference conformer for the mercapto compound in such a discussion is less easily defined than for salicylaldehyde because C=O···S are similar to O=C—H···S energies. The experimental data for the CCl_4 solutions imply a free energy of formation of the C=O···H—S bond of 4.8(5) kJ/mol at 300 K. Molecular orbital computations on the four planar conformers of each salicylaldehyde and 2-mercaptobenzaldehyde with the 6-31 G**(5D) basis are reported. For salicylaldehyde, the O=C—H···O—H arrangement is taken as the reference conformer, with a computed energy of 25.7 kJ/mol relative to the hydrogen-bonded structure. For 2-mercaptobenzaldehyde, the H—C=O···S—H and O=C—H···S—H conformers are calculated to be isoenergetic, at 5.1 kJ/mol relative to the hydrogen-bonded conformer. Hence either arrangement serves as a reference structure in computations of the strength of the hydrogen bond. The computations are consistent with the experimental results for solutions of the molecules under discussion. An appendix gives the computed geometries of the eight planar conformers, as well as some atomic charges, allowing a rationalization of the relative energies of the conformers.

TED SCHAEFER, RUDY SEBASTIAN, DAVID M. MCKINNON, PERRY W. SPEVACK, KERRY J. COX et CRAIG S. TAKEUCHI. Can. J. Chem. **71**, 960 (1993).

On a déterminé des paramètres précis de résonance magnétique nucléaire du ^1H pour le salicylaldéhyde et ses dérivés 3-fluoro et 5-fluoro, en solutions non-polaires. On rapporte aussi des données semblables pour les dérivés 2-mercapto, 2-méthylthio et 2-méthoxy du benzaldéhyde. Une comparaison des constantes de couplage à longue distance dans les divers composés et dans leurs conformères indique que les ponts hydrogènes provoquent de grandes perturbations dans leurs amplitudes. Pour le système du salicylaldéhyde, la perturbation est particulièrement importante pour les couplages impliquant le proton de l'aldéhyde et les protons ou les noyaux de fluor placés en position *ortho* par rapport au groupe hydroxyle. Par example, la valeur de ^5J_t (F, CHO) est réduite de moitié. Comme on peut s'y attendre, la perturbation est plus faible pour les constantes de couplage des noyaux éloignés du site de la liaison hydrogène. Dans le 2-mercaptobenzaldéhyde, les constantes de couplage à longue distance sont aussi sensibles à la formation de liaisons hydrogènes, celles impliquant le proton sulfhydrile étant particulièrement influencées en comparaison avec celles du proton hydroxylique du salicylaldéhyde. On discute de la force de la liaison C=O···H—S. On suggère que le conformère de référence du composé mercapto est plus difficile à définir que celui du salicylaldéhyde parce que les énergies de des structures C=O···S et de O=C—H···S sont semblables. Les données expérimentales pour des solutions de CCl_4 impliquent que l'énergie libre de formation de la liaison C=O···H—S est de 4,8(5) kJ/mol à 300 K. On rapporte les résultats de calculs d'orbitales moléculaires effectués sur quatre conformères plans du salicylaldéhyde ainsi que du 2-mercaptobenzaldéhyde au niveau 6-31G G**(5D). Pour le salicylaldéhyde, l'arrangement O=C—H···O—H est pris comme conformère de référence et son énergie calculée est de 25,7 kJ/mol par rapport à celle de la structure comportant une liaison hydrogène. Pour le 2-mercaptobenzaldéhyde, on a calculé que les conformères H—C=O···S—H et O=C—H···S—H sont isoénergétiques, à 5,1 kJ/mol par rapport au conformère avec une liaison hydrogène. Les deux arrangements peuvent donc servir de structure de référence lors des calculs de la force de la liaison hydrogène. Les calculs sont en accord avec les résultats expérimentaux pour les solutions des molécules examinées. Un appendice donne les géométries calculées pour les huit conformères plans ainsi que quelques charges atomiques; elles permettent une rationalisation des énergies relatives des conformères.

[Traduit par la rédaction]

Introduction

The purposes of this report are three. The first is a demonstration that the intramolecular hydrogen bond in salicylaldehyde and some of its derivatives is associated with a large perturbation of the stereospecific long-range spin–spin coupling constants between the formyl proton and the ring protons or fluorine nuclei. The second purpose is the measurement of long-range coupling constants for 2-mercaptobenzaldehyde in order to assess the strength of the putative intramolecular hydrogen bond. The third purpose is to

[a]4.0 mol% in CS_2, containing also 10.0 mol% of C_6D_{12} and 0.5 mol% of TMS.
[b]~1 mol% in CCl_4 with C_6D_{12} and TMS as in footnote *a*.
[c]To high frequency of internal TMS at a transmitter frequency of 300.135$_2$ MHz.
[d]The standard deviations are less than or equal to 0.001 Hz except as indicated.
[e]X stands for methyl or hydroxyl protons, as appropriate; thus $^5J_{3X} \equiv {}^5J$(3, OCH_3) and $^4J_{3X} \equiv {}^4J$(3, OH).
[f]These signs and magnitudes, not previously determined (1), appear to be as given on the basis off the iterative procedure and of simulations with three other sign combinations.
[g]The sign is very likely positive and the magnitude, based on various simulations, is 0.015 ± 0.005 Hz.

provide some experimental and theoretical data relevant to the question of reference structures, those with respect to which the strengths of the H—C=O···H—O and H—C=O···H—S bonds should be computed. Reference structures are the subject of recent discussions (1–3).

Accordingly, precise analyses of the ^{1}H nmr spectra are reported for salicylaldehyde, its 3-fluoro and 5-fluoro derivatives, as well as for 2-methoxybenzaldehyde and 2-mercaptobenzaldehyde, all as solutions in nonpolar solvents. Together with previous precise spectral data for benzaldehyde and some of its derivatives, the present results are used to show that ^5J(H-3, CHO) is reduced by about 25% on formation of the H—C=O···H—O or H—C=O···H—S bonds and that ^5J(F-3, CHO) decreases by about 50%. The changes in the corresponding coupling constants for H-5 and F-5 are much smaller. Other perturbations involve the sulfhydryl proton, which couples not only to the aldehydic proton in 2-mercaptobenzaldehyde but also to H-6 in a manner implying the loss of stereospecificity of ^5J(H, SH).

The combined experimental and molecular orbital computational results suggest that the intramolecular hydrogen bond formed by the S—H group is about one-fifth as strong as that formed by the O—H group. Furthermore, these data imply that the O=C—H···O—H arrangement is the proper reference for the computation of the energy of the hydrogen bond in salicylaldehyde, whereas for the sulfur compound either structure, H—C=O···S—H or O=C—H···S—H, can play that role.

Experimental

The 2-mercaptobenzaldehyde was made from salicylaldehyde, following the procedure (4) for a synthesis of 2-mercapto-3-methoxybenzaldehyde, except that *N*,*N*-diethylthiocarbamoyl chloride was substituted for *N*,*N*-dimethylthiocarbamoyl chloride. The product was contaminated with some 2-hydroxybenzaldehyde. However, a dilute solution of the mixture in CCl_4/C_6D_{12}/TMS gave excellent ^{1}H nmr spectra, eventually yielding the spectral parameters for both compounds. The 5-fluorosalicylaldehyde was prepared from 4-fluorophenol via a modified Reimer–Tiemann reaction. The yield was very low; from 4.3 g of 4-fluorophenol only enough of the purified white crystalline product was obtained for the preparation of a ca. 1 mol% solution in 0.5 mL of the CCl_4/C_6D_{12}/TMS solvent mixture. The other compounds under investigation were of commercial origin. In each case, the solution of the compound was filtered into a 5-mm o.d. nmr sample tube and degassed by four to five cycles of the freeze–pump–thaw procedure. The tube was flame-sealed to give a reasonably symmetric top.

The ^{1}H nmr spectra were acquired on an AM 300 Bruker spectrometer at a probe temperature of 300 K. Acquisition times were not less than 40 s for the free induction decays, the final manual shimming having been done on the TMS response. The spectral windows ensured a digital resolution of at least 0.012 Hz/point. Zero-filling helped further to define line shapes. Judicious amounts of Lorentzian and Gaussian multiplication before Fourier transformation gave some resolution enhancement.

^{1}H{^{1}H} experiments (5) on 5-fluorosalicylaldehyde gave the signs of ^6J(OH), F) and ^5J(CHO, F) relative to the known signs of other coupling constants. Similar experiments yielded the relative signs of ^4J(H-3, SH), ^5J(CHO, SH), and ^5J(H-6, SH) for 2-mercaptobenzaldehyde. Other signs were either known or came from the iterative analyses and simulations of the second-order spectra (see tables).

AM1 (6), STO-3G (7), and 6-31G** (5D) (8) MO computations of the four planar conformers of each of 2-hydroxy and 2-mercaptobenzaldehyde employed the program GAUSSIAN 86 (9). Within the constraint of planarity all bond angles and lengths were optimized. The 6-31G** (5D) basis is recommended for computations in which hydrogen is involved in bridging interactions.

Results and discussion

Spectral analyses

The spectra were analyzed with the program NUMARIT (10), substantially modified by R. Sebastian. Tables 1–3 contain the ensuing chemical shifts and coupling constants. Figure 1 illustrates the determination of the sign of ^5J(SH, CHO) in 2-mercaptobenzaldehyde; it also demonstrates the resolution attainable in the spectra of the molecules under discussion.

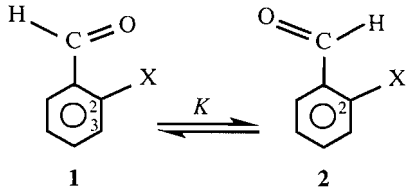
[h]Simulations with other sign combinations indicate these signs.

^5J(H, CHO) in salicylaldehyde

In benzaldehyde, ^5J(H, CHO) is 0.431(2) Hz for a CS_2/C_6D_{12} solution (11), an average of ^5J(H-3, CHO) ≡ ^5J_t and



1 2

^5J(H-5, CHO) ≡ ^5J_c in **1** (X = H). It is assumed that ^5J_c effectively vanishes (12, 13) and therefore that ^5J(H, CHO) is a good indicator of the equilibrium between **1** and **2** (X ≠ H). A recent study of the solvent and temperature dependence of ^5J(H, CHO) for X = Cl in acetone-d_6 and CD_3CN solutions (13) suggests a small solvent perturbation, <0.01 Hz, of this coupling constant but that the ratio of ^5J(H-3, CHO) to ^5J(H-5, CHO) is a reliable measure of K.

Turning to X = OCH_3 (Table 1), the analysis gives ^5J(H-5, CHO) as 0.859(1) Hz, twice the magnitude of ^5J(H, CHO) in benzaldehyde, to within experimental error, and indicating that K is very large at 300 K. ^5J(H-3, CHO), however, is −0.006(1) Hz, according to the least-squares iterative analytical procedures; this coupling constant is not observable as a splitting in the spectrum. In any event, the sum of

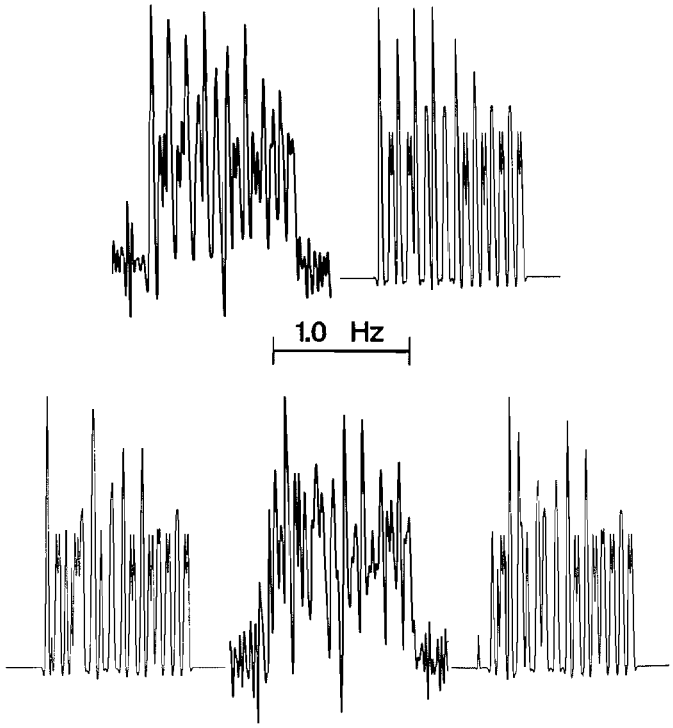

FIG. 1. The top of the figure displays the aldehydic ^{1}H nmr spectrum of a ca. 1 mol% solution of 2-mercaptobenzaldehyde in CCl_4 solution at 300 K. The span of the spectrum is just over 1 Hz. To resolve some of the small displayed splittings, whose magnitude is <0.03 Hz, a small amount of a Gaussian function is applied to the summed free induction decays. The computed spectrum takes this enhancement into account and uses the spectral parameters in Table 3. At the bottom and centre of the figure the aldehydic multiplet is shown under conditions in which the peak at highest frequency for H-6 is very weakly perturbed with a second radiofrequency field. The computed spectrum on the left assumes that ^5J(SH, CHO) < 0, that on the right, ^5J(SH, CHO) > 0. It is somewhat difficult to match exactly the amplitudes of the second field in the experimental and theoretical spectra. Yet it is clear that ^5J(SH, CHO) > 0, as confirmed by further experiments.

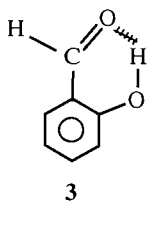
the two coupling constants is perturbed by not more than 0.01 Hz by the methoxy substituent.

Now, in salicylaldehyde only the hydrogen-bonded structure, **3**, need be considered at 300 K. ^5J(H-3, CHO) is



3

0.633(2) Hz, a reduction of about 25% from the expected ^5J_t value. Furthermore, ^5J(H-5, CHO) is −0.036(2) Hz, so that the sum of the two ^5J values, at 0.597(4) Hz, is only 70% of the sum in 2-methoxybenzaldehyde. Of course, the orientation of the formyl group in **3** is opposite to that in the main conformer, **2**, of the 2-methoxy derivative but it may be noted that in acetone-d_6 solutions the sums are 0.117(1) + 0.733(1) or 0.850(2) Hz for X = F at 300 K (12) and 0.062 + 0.808 or 0.870(1) Hz for X = Cl at 292 K (13). The finite ^5J(H-3, CHO) values are associated with significant populations of **1**, analogous to **3**, and their sums with ^5J(H-5, CHO) are consistent with a strong perturbation of ^5J(H-3, CHO) by the hydrogen bond in **3**, as distinct from a perturbation by an electronegative substituent, Cl, F, or OCH_3 placed *ortho* to the formyl group.

^{5}J(F, CHO) in 3- and 5-fluorosalicylaldehydes

^5J(F-3, CHO) is 1.892(2) Hz while ^5J(F-5, CHO) is −0.224(2) Hz in these fluorosalicylaldehydes (Table 2). By way of contrast, ^5J(F, CHO) in 3-fluorobenzaldehyde has a value of 1.889(1) Hz in a CS_2/C_6D_{12} solution at 300 K (12). ^5J(H-5, CHO) for this compound indicates an *O-cis* fractional population of 0.538(4). On this basis, write $^5J_c(0.46_2) + {}^5J_t(0.53_8) = 1.889$ Hz, where ^5J_t corresponds to an all-*trans* arrangement of the bonds between ^{1}H and ^{19}F. Now, if ^5J_c is taken as −0.224(2) Hz, the value for 5-fluorosalicylaldehyde, then ^5J_t becomes 3.70 Hz. These values of ^5J_c and ^5J_t predict ^5J(F, CHO) in 3,5-difluorobenzaldehyde to be 1.74 Hz, whereas it has been measured as 1.722(2) Hz for a CS_2/C_6D_{12} solution in this laboratory. These comparisons suggest a minor perturbation of ^5J(F-5, CHO) by the intramolecular hydrogen bond but that ^5J(F-3, CHO) is reduced by very nearly 50%. If ^5J_c vanishes in the absence of the hydrogen bond, that is, ^5J(F, CHO) in 5-fluorosalicylaldehyde is a consequence of a perturbation by the hydrogen bond, then ^5J_t becomes 3.51 Hz as deduced from the data for 3-fluorobenzaldehyde, but 3.44 Hz using ^5J(F, CHO) for the 3,5-difluoro derivative. In any event, ^5J(F-3, CHO) in 3-fluorosalicylaldehyde is reduced by at least 45% from the value anticipated in the absence of the hydrogen bond.[2]

Confirmation that it is the hydrogen bond, and not substitution by an electronegative group, which causes the large reduction in ^5J(F-3, CHO), comes from our analyses of the ^{1}H nmr and ^{19}F nmr spectra of 2,3-difluorobenzaldehyde in CS_2/C_6D_{12} and acetone-d_6 solutions. ^5J(H-5, CHO) is 0.845(2) Hz for the nonpolar solution, consistent with the essential absence of the *O-cis* conformer (see discussion of 2-fluorobenzaldehyde above). In the polar solution, ^5J(H-5, CHO) is 0.715(1) Hz, implying that the fractional population of the polar *O-cis* conformer is now 0.15. But ^5J(F-3, CHO) is 0.510(2) Hz in this solution, so that ^5J_t(F-3, CHO) is predicted as 0.51/0.15 or 3.4 Hz, very close to the unperturbed magnitude under discussion above and certainly far from the 1.9 Hz occurring in 3-fluorosalicylaldehyde.

^{5}J(H, CHO) in 2-mercapto and 2-thiomethylbenzaldehyde

For the 2-thiomethyl compound, ^5J(H-3, CHO) and ^5J(H-5, CHO) are 0.335(4) and 0.486(3) Hz, respectively. Their sum, 0.821(7) Hz, is consistent with a small perturbation of ^5J(H, CHO) by the substituent, while the individual values are discussed further below in connection with reference structures for intramolecular hydrogen bond computations. Turning to the 2-mercapto derivative, the strong perturbation of ^5J(H, CHO) is clear from the 0.579(1) Hz for ^5J(H-3,

[2]Our INDO MO FPT (14) computations give ^5J_t and ^5J_c as 3.67 and −0.26 Hz, respectively. for 3-fluorobenzaldehyde and 3.54 Hz for ^5J(F, CHO) in 3-fluorosalicylaldehyde. Analogous results come from CNDO/2 or INDO MO FPT calculations of ^5J(H, CHO) in benzaldehyde and salicylaldehyde. Thus, the stereospecificities of ^5J(F, CHO) and ^5J(H, CHO) are semiquantitatively reproduced, but the perturbations by the intramolecular hydrogen bonds are not.

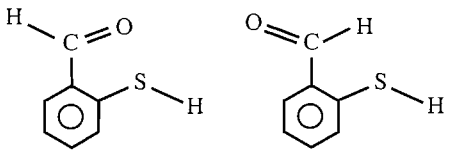
CHO). This number is taken as strong evidence for the presence of an intramolecular C=O···H—S bond, not previously investigated. A naive approach takes the ratio of the two ^5J(H, CHO) values, 0.579 and 0.073 Hz, and deduces that 5.2 kJ/mol is the free energy difference at 300 K favoring the intramolecular hydrogen bond; naive because ^5J(H, CHO) is perturbed by the hydrogen bond and also because **4** and **5** are probably of similar stability, as judged by



4 **5**

the conformational properties of 2-thiomethylbenzaldehyde for which the ratio of **1** to **2** is 41 to 59 at 305 K (15). A better approximation to the free energy difference is obtained by the recognition that, in **4** and **5**, ^5J(H, CHO) behaves "normally," so that it is effectively zero in **4** and 0.85(1) Hz in **5**. If $p_1 = 0.69p_5$, as for the thiomethyl derivative, and $p_5 = 0.073/0.85(1)$, the population of the intramolecularly hydrogen-bonded conformer follows as 0.86. Hence the free energy difference is 4.4(1) kJ/mol, suggesting a relatively weak hydrogen bond. These matters are discussed further below.

Perturbations of J*(H, SH) and* J*(H, OH)*

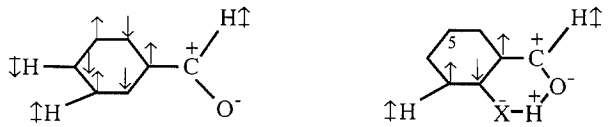
The most remarkable perturbations of the coupling constants involving the hydroxyl or sulfhydryl protons, caused by the intramolecular hydrogen bond, are those of $^{4,5}J$(H, SH). First, ^5J(H-4, SH), at 0.188 Hz, and ^5J(H-6, SH), at 0.259 Hz, have lost their stereospecificity. For example, the assumption that such coupling constants involving the protons placed *meta* to the SH group are large for the all-*trans* arrangement of the intervening bonds and very small or negligible for the other, gives 45 ± 5% for the Cl···H—S conformer of 2,4-dichlorothiophenol in CCl_4 solution (16), in close agreement with the equilibrium deduced from the dipole moment (17). In sharp contrast, ^5J(H-6, SH) > ^5J(H-4, SH) for 2-mercaptobenzaldehyde, which, however, exists as the intramolecularly hydrogen-bonded conformer to the extent of at least 85%. ^5J(H, SH) is thought to consist of a stereospecific σ electron component, just like ^5J(H, CHO), and a component dependent on a σ–π interaction mechanism proportional to $\sin^2\theta$, where θ is the angle by which the S—H bond twists out of the aromatic plane (18). It is unlikely that the average value of $\sin^2\theta$ in the hydrogen-bonded conformer is significant. In 2-mercaptobenzaldehyde, ^6J(H-5, SH) is −0.029(1) Hz while ^6J(H, SH) at θ = 90° lies near −1.0 Hz in thiophenol and some of its derivatives (19, 20). Consequently, the perturbation of ^5J(H, SH) by the formation of the intramolecular hydrogen bond must occur by another mechanism. Other peculiarities are represented by the presence of ^5J(SH, CHO), at 0.135(1) Hz, and ^4J(H-3, SH), which is 0.216(1) Hz. The latter is normally negative (19–21) and dominated by a σ–π electron mechanism.

Compared to $^{4,5}J$(H, OH) in phenol (22), and some derivatives (23), formation of the hydrogen bond in salicylaldehyde causes a relatively small perturbation of the coupling constants of the hydroxyl proton. Thus, while ^5J(H-6, OH) is 0.060(1) Hz, its magnitude is considerably smaller than the 0.487(2) Hz measured for ^5J(H-4, OH); the stereospecificity of ^5J(H, OH) is largely retained. Again, ^5J(OH, CHO) is indicated as 0.008(2) Hz by the spectral analysis, but is hardly significant. Yet, it is known that compression of the H—C=O···H—O bond in salicylaldehyde derivatives (1) can lead to a ^5J(OH, CHO) as large as that reported here for 2-mercaptobenzaldehyde.

Consideration of all the coupling data in Tables 1–3 leads to the tentative conclusion that the perturbations of the coupling constants involving the formyl proton have a different origin than those involving the hydroxyl or sulfhydryl protons. While our extensive CNDO/2 and INDO MO FPT computations do not account for the perturbations and are not reported here (but see footnote 2 for an example of such computations), a rationalization of the perturbations is attempted next.

An attempted rationalization of the large perturbation of J

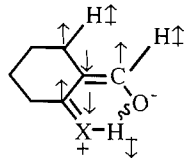
The high polarity of the carbonyl bond is attested by extensive molecular orbital calculations. The role of oxygen is to polarize the bond, leading to a severely electron-deficient carbon atom (24). The valence bond structure, **A**, emphasizes this polarity and can be used to rationalize certain peculiarities (11) of ^nJ(H, CHO). This structure has been



A **B**

invoked to rationalize the positive values of ^6J(H, CHO) in some 3,5-disubstituted benzaldehydes, in which ^6J(H, CHO) can be as large as 0.1 Hz (11). If the formation of the intramolecular hydrogen bond serves mainly to further stabilize the ionic structure, as in **B**, then a negative π-electron contribution[3] to ^5J(H, CHO) is implied (arrows indicate π-electron spin polarization, crossed arrows the spin state of protons). The consequence is a reduction in the magnitude of ^5J(H, CHO). Of course, the degrees of spin polarization in the coupling pathways leading to H-5 and H-3 need not be equal, so that the −0.04 Hz measured for ^5J(H-5, CHO) in salicylaldehyde is qualitatively consistent with the negative π coupling contribution.

Alternatively, structure **C** may play a role in the spin polarization of the π electrons; an electron has been moved



C

from the sulfur or oxygen orbitals to the previously electron-deficient carbon atom of the carbonyl group. The spin polarization implied by **C** accounts for the signs of ^5J(H-6, XH), ^5J(CHO, SH), and perhaps for the enhanced ^4J(H-6, CHO) in 2-mercaptobenzaldehyde. However, **C** must be more important for the sulfur than for the oxygen com-

[3]In benzaldehyde itself, ^5J(H, CHO) is an almost purely σ-electron coupling interaction in the sense that no $^6J(CH_3, CHO)$ is detectable in 3,5-dimethylbenzaldehyde, for example (11).

TABLE 4. Molecular orbital results for the conformational energies of 2-hydroxybenzaldehyde and 2-mercaptobenzaldehyde

	Relative energy (kJ/mol)					
	AMI[a]		STO-3G		6-31G**(5D)

[e]The total energy is −740.947 351 au.

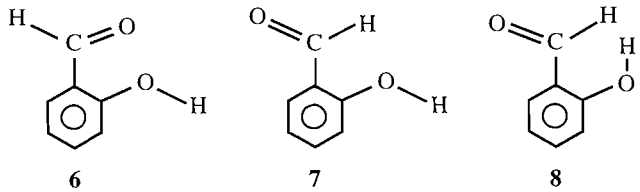
pound, intuitively an unlikely situation even if such structures need not play an important thermodynamic role. Furthermore, the sign of ^4J(H-3, SH) is not accounted for by **C**.

The present discussion illustrates that the formation of the intramolecular hydrogen bond perturbs the spin–spin coupling mechanisms for the nuclei in the hydrogen-bonded moieties in a subtle way, not yet understood. Indeed, the weaker hydrogen bond causes the larger perturbations, that is, for the sulfhydryl proton. It is also true, however, that the S—H moiety is much more polarizable than the hydroxyl group (see Appendix).

The reference conformations for the intramolecular hydrogen bonds

(i) Salicylaldehyde

Computations on salicylaldehyde have taken different conformations with respect to which the energy of the hydrogen bond is assessed. An early computation (25*a*) uses **6**, whereas another (1) prefers **7**. The most recent molecular



6 **7** **8**

orbital calculation (2) employs a 6-31G basis and argues that **6** represents the correct reference for the estimation of the strength of the intramolecular hydrogen bond. The hydrogen bond energy then becomes 49.8 kJ/mol and is thought to be overestimated by not more than 6.3 kJ/mol (basis set limitations); **8** is computed as 36.8 kJ/mol less stable than the hydrogen-bonded conformer. The conformation **7** is not discussed.

In Table 4, the three computational approaches agree qualitatively among each other, and also with the 6-31G basis (2), as to the relative stabilities of **6** and **8**. As might be expected from the interatomic distances and (or) bond polarities in **6–8**, it is **7** which is by far the most stable; the larger basis set, 6-31G** (5D), has its energy as 25.7 kJ/mol relative to the hydrogen-bonded conformer. While differences in zero-point energies together with corrections for finite temperatures will alter the enthalpy differences at ambient temperature by perhaps 5%, in our opinion **7** is the proper reference conformation for the hydrogen bond in salicylaldehyde. The high energy computed for **6** agrees qualitatively with the absence of the corresponding conformer of 2-methoxybenzaldehyde in the nonpolar solution.[4] The relative 6-31G** (5D) energies of **7** and the hydrogen-bonded conformer agree best with the energy of the hydrogen bond deduced from the torsional frequency of the hydroxyl group and the hydroxyl proton chemical shift (26). These deductions, however, are extrapolated from calculations (27) of the change in the shielding of the hydroxyl proton caused by electric fields present in the intermolecular hydrogen bond formed by phenol.

(ii) 2-Mercaptobenzaldehyde

The experimental results show that when the in-plane S—R group is turned away from the formyl substituent, as in 2-thiomethylbenzaldehyde, the H—C=O···SR and O=C—H···SR interactions are of very similar energy. These results imply two possible reference structures for 2-mercaptobenzaldehyde. This implication is borne out by the 6-31G** (5D) computations in Table 4. Structures of the type H—C=O···S—H, **4**, and O=C—H···S—H, **5**, are calculated to be 5.07 and 5.08 kJ/mol more energetic, respectively, than that of type H—C=O···H—S. The O=C—H···H—S interaction is most unstable, at 14.03 kJ/mol. The AM1 and STO-3G MO energies are included in Table 4 for comparison, but are here considered as inadequate indicators of the relative conformational stabilities.

The combined fractional population of **4** and **5** was experimentally deduced above as 0.14 at 300 K in CCl_4 solution, corresponding to a free energy difference of 4.4 kJ/mol in favor of the hydrogen-bonded conformer. To a first approximation the 6-31G** (5D) energies are consistent with experiment. A rigorous comparison would require the computation of not only zero-point energy and entropy differences between conformers but also the solvent stabilization of the various conformers.

The contrast between the C=O···S—H and C=O···O—H interactions is striking.[5] Partly, at least, it has

[4]In a rare gas matrix at 12 K, salicylaldehyde photolyzes to **7** (25*b*).

[5]The question of appropriate reference structures in the computation of the strength of intramolecular hydrogen bonds has recently been discussed for a thioxoketone and its thienol tautomer (3).

to do with the relatively high polarizability of sulfur, discussable in the guise of the the directional character of the mainly 3*p* orbital on sulfur (19, 28). Thus, structural data for crystals show that electrophilic moieties prefer the 3*p* direction at divalent sulfur, whereas nucleophilic groups tend to approach sulfur in the R—S—R^1 plane (29). Application to the present intramolecular case suggests that **4** is relatively stable because the 3*p* orbital on sulfur is oriented approximately perpendicular to the molecular plane; further, that a twist of the S—H group out of the molecular plane with a concomitant twist of the 3*p* orbital into that plane will destabilize **4**, as is indeed the result in 2-*S*-*tert*-butylbenzaldehyde (30). In consequence, the reference structure for an intramolecular hydrogen bond formed by the S—H group depends on the orientation of the orbitals on sulfur. For example, the intramolecular hydrogen bond in 2-mercaptophenol stabilizes the structure in which the S—H bond lies in a plane perpendicular to the rest of the molecule (19). The reference structure is surely not the one in which the O—H group is rotated away by 180° from the other substituent, leaving the 3*p* orbital in the molecular plane. This structure entails 3*p* · · · O—H repulsions which are not relevant to the strength of the O—H · · · S interaction. The reference structure is the more stable of the planar H—S · · · O—H or S—H · · · O—H structures.

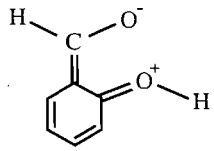
Appendix

The 6-31G**(5D) geometries of the four planar conformers of salicylaldehyde and 2-mercaptobenzaldehyde are reproduced in Scheme 1. Bond lengths are given in Ångstroms and bond angles in degrees.

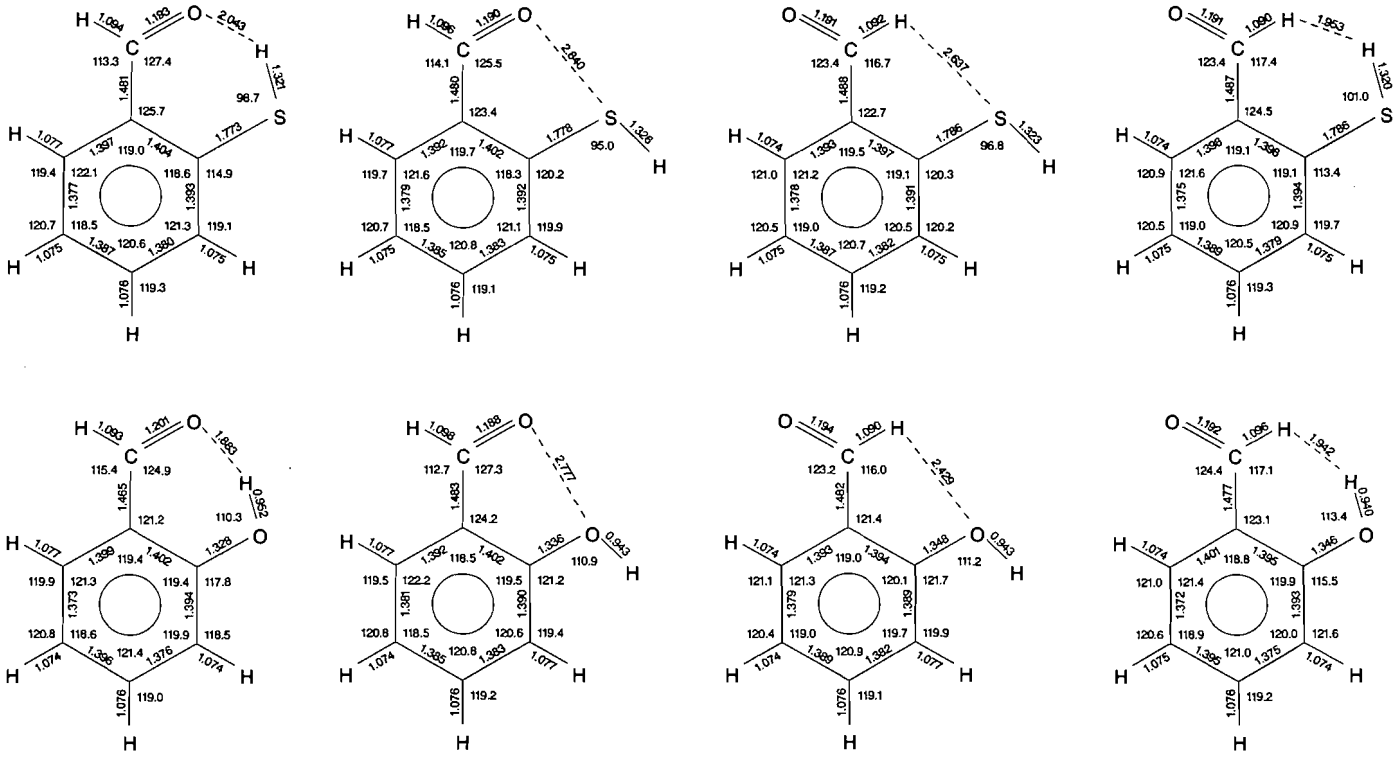
Differences in these quantities exist between the conformers, of course, but are hardly large enough to explain the large perturbations of the coupling constants caused by the intramolecular hydrogen bonds. However, certain regularities related to the hydrogen bond strengths are apparent. For example, the relatively strong cross conjugation of the hydroxyl and formyl substituents, indicated by resonance structure **D**, is reflected in the C—C bond lengths



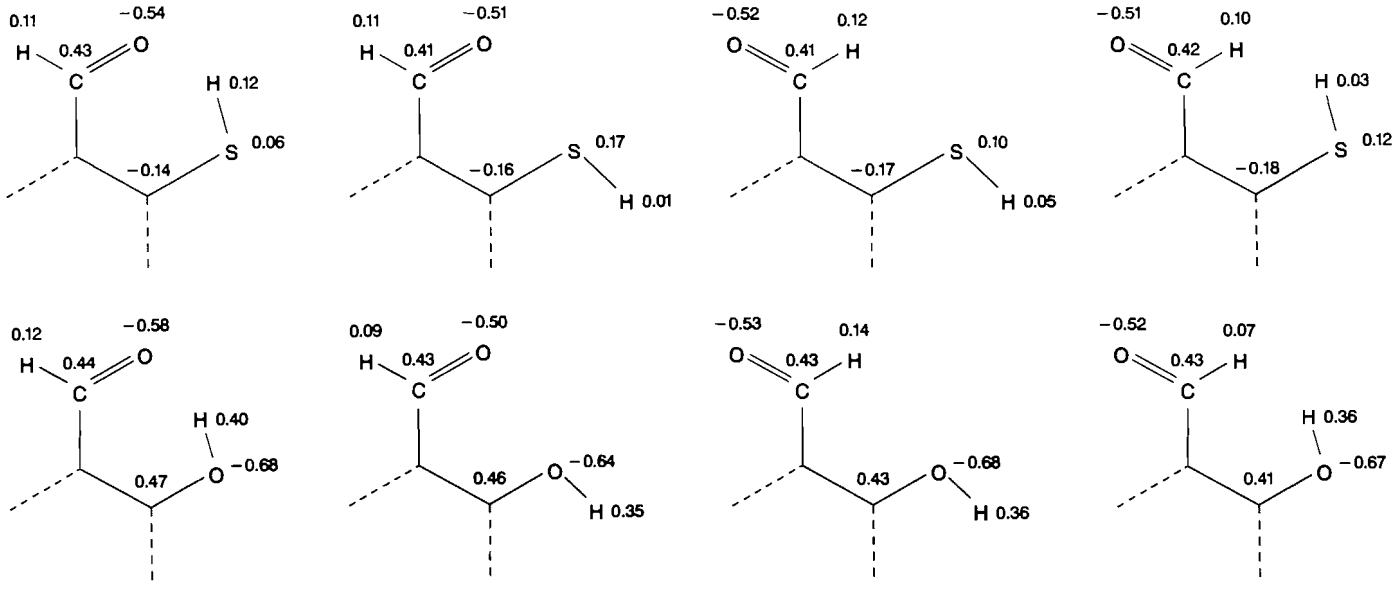
D

within the aromatic ring. These bond length variations are enhanced somewhat in the hydrogen-bonded conformer and, in addition, the C—C(HO) bond shortens by as much as 0.02 Å, as does the C—OH bond. In contrast, the changes in bond lengths are much smaller on formation of the hydrogen bond in 2-mercaptobenzaldehyde; the C—CHO length shortens by rather less than 0.01 Å. The relatively weak intramolecular hydrogen bond in the sulfur compound is also consistent with the exocyclic bond angles computed for the two compounds. Compare, for example, the angles defining the interior of the six-membered, hydrogen-bonded exocycle in the two compounds.

The computed Mulliken atomic charges in Scheme 2 provide a zero-order interpretation of the relative conformer energies given in Table 4. Thus, the instability of the C=O · · · O—H arrangement can be assigned to the electrostatic repulsion between the large negative charges on the two oxygen atoms. When distances between charges, as given in Scheme 1, are also considered, the order of stability of the four planar conformers of salicylaldehyde is seen



SCHEME 1



SCHEME 2

to be reasonable. Furthermore, note that formation of the hydrogen bond is calculated to further polarize the C=O and O—H bonds.

This enhanced polarization on hydrogen bond formation is less striking for the C=O bond in 2-mercaptobenzaldehyde, but is remarkably large for the S—H bond. On comparison of the C=O···H—S and C=O···S—H conformers, one notes an increase of 0.11 (electron units) in the positive charge, from 0.01 to 0.12, on the hydrogen atom. While both atoms in the S—H bond carry positive charge, the relative magnitudes of these charges are reversed by the formation of the hydrogen bond. The positive charge on the sulfur atom also rationalizes the small energy differences between these two conformers. Finally, the smaller magnitudes of the charges on the atoms of the S—H bond, compared to those for the O—H bond, are consistent with, first, the weaker hydrogen bond in the sulfur compound and, second, the much smaller energy differences (Table 4) between the conformers of this compound as compared to those between salicylaldehyde conformers.

Pattern recognition for screening of crude oils using multivariate circular profiles

EDWARD P.C. LAI,[1] RÉGI D. GIROUX, NAILIN CHEN, AND RUNDE GUO

Centre for Analytical and Environmental Chemistry, Ottawa–Carleton Chemistry Institute, Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received November 20, 1992

EDWARD P.C. LAI, RÉGI D. GIROUX, NAILIN CHEN, and RUNDE GUO. Can. J. Chem. **71**, 968 (1993).

An appropriate pattern recognition method has been designed to visually discriminate between crude oils belonging to different geographic origins. Each oil is represented by a circular profile that consists of parameter axes that radiate from the centre like spokes on a wheel. One objective of this approach is to provide an optimum set of axes that will best differentiate one circular profile from another. Several parameters were considered for evaluating the oils: photoacoustic spectroscopy (PAS), carbon-13 nuclear magnetic resonance (^{13}C NMR, for $\%C_A$ = aromatic carbon content), high-performance liquid chromatography (HPLC, for unsaturated, aromatic, and polar compounds), initial boiling point (IBP), American Petroleum Institute (API) gravity, and ultraviolet–visible spectrophotometry (for λ_{max} = maximum absorption wavelength and ϵ_{max} = maximum molar absorptivity). By computerized statistical evaluation, the selected parameters are PAS and HPLC for unsaturated, aromatic, and polar compounds.

EDWARD P.C. LAI, RÉGI D. GIROUX, NAILIN CHEN et RUNDE GUO. Can. J. Chem. **71**, 968 (1993).

On a mis au point une méthode appropriée de reconnaissance des formes qui permet de distinguer visuellement entre des huiles brutes d'origines différentes. Chaque huile est représentée par une profil circulaire comportant des paramètres axiaux qui s'écartent du centre comme les rayons d'une roue. L'objectif de cette approche est de fournir un ensemble optimal de paramètres axiaux qui permettra de distinguer un profil circulaire d'un autre. On a considéré plusieurs paramètres pour évaluer les huiles : la spectroscopie photoacoustique (SPA), la résonance magnétique nucléaire du carbone-13 (RMN du ^{13}C, pour le $\%C_A$ = concentration de carbone aromatique), la chromatographie liquide à haute performance (CLHP, pour les composés insaturés, aromatiques et polaires), le point d'ébullition initial (PEI), la densité de l'Institut Américain des Pétroles (API) et la spectrophotométrie ultraviolette–visible (pour le λ_{max} = longueur d'onde d'absorption maximale et le ϵ_{max} = absorbance molaire maximale). Sur la base d'une évaluation statistique par ordinateur, les paramètres choisis sont la SPA et la CLHP pour les composés insaturés, aromatiques et polaires.

[Traduit par la rédaction]

Introduction

Crude oil or petroleum is a complex mixture that consists of many hundreds of different hydrocarbons plus traces of impurities. The hydrocarbons present in crude oil can be divided into three main groups: (*a*) paraffins (or alkanes), which are straight or branched hydrocarbon chains of general formula C_nH_{2n+2}; (*b*) naphthenes (or cycloalkanes), which are saturated ring structures of general formula C_nH_{2n}; (*c*) aromatics, which are hydrocarbons containing one or more benzene rings (C_6H_6). In addition, there is a fourth type, olefins (or unsaturates), which is formed during processing by the dehydrogenation of paraffins and naphthenes (1). Crude oil also contains small quantities of non-hydrocarbon impurities (oxygen, sulfur, nitrogen, and metals), which are generally present as components of complex molecules predominantly hydrocarbon in character. The complexity of the mixture has been shown by a partial analysis of a crude oil: 37 individual hydrocarbons were isolated from about 16.5% of the total mass of the oil (2). Since crude oil is a very complex mixture, no single measurement can be used for identification purposes. Refinery laboratories are equipped with capillary gas chromatographs and other sophisticated instruments to perform very detailed analyses of the crude oils their plants process. For less critical end uses, however, relatively simple analytical tests are run on the crude and the results of these are used with empirical correlations to evaluate the crude oils as feedstocks for the particular refinery (1). Alternatively, before making a preliminary purchase or environmental decision, some easily measured parameters are needed to give a rough indication of the relative proportions of the different components present and some idea of the physical and optical properties of the crude oil.

A great deal of effort has been devoted to the characterization and classification of petroleum samples. The most reliable methods used more than one analytical technique of data collection and then combined the results into a prediction. A wide variety of methods have been suggested for interpreting the data collected, ranging from visual analysis to sophisticated statistical or pattern recognition methods. Curtis first used pattern recognition techniques for typing and identification of oil spills (3). Clark and Jurs employed pattern recognition methods, based on 13 descriptors characterizing their gas chromatograms, to classify crude oils (4). Application of pattern recognition techniques to petroleum pollution research was first undertaken by Duewer et al. (5). Kwan and Clark also successfully assessed oil contamination in the marine environment by pattern recognition analysis of the paraffinic hydrocarbon content of mussels (6).

The subject of pattern recognition involves any attempt at developing descriptions (or models) of phenomena that in some way mimic human thinking. This includes research in the areas of artificial intelligence, interactive graphic computers, computer aided design, psychological and biological pattern recognition, and a variety of others. Computerized pattern recognition would seem to be the best solution for qualitative identification in screening analysis. A computer using artificial intelligence methods can rapidly search large amounts of multivariate data for obscure relationships between, for example, structure and activity (7). Given a spectrum of an unknown to interpret, each pattern recognition procedure attempts to answer a simple question: does the

unknown compound belong to any of the structural classes X_1, X_2, . . ., X_n? To answer this question, previous work must have been performed to parameterize the spectrum such that each of these n structural classes can possibly be identified. In most cases this preliminary step draws upon a database of known spectra representing each of the structural classes. Work is then performed to discover the parameters that will provide the desired discrimination. The manner in which this task is accomplished distinguishes one pattern recognition technique from another. In each case, the process is completed with the calculation of n mathematical constructs (functions, vectors, etc.) that define the region of the plotted space occupied by spectra of each of the structural classes. The pattern recognition approach to automated spectral interpretation effectively distills information from the database into a form (the chosen parameters and the calculated mathematical constructs) that subsequently can be used independently. It defines screening tools that make no effort to identify the specific structure involved and merely try to suggest structural elements that the unknown may contain. A major advantage is that no a priori assumptions are made regarding the spectral information used to distinguish a structural class.

The principal component analysis is often used as a method of reducing the dimensionality of a data set; it can project data from higher dimensional space onto two dimensions for display. A p-dimensional plot was studied as a pattern recognition approach to represent two groups of infrared spectra (8). A set of carboxylic acid spectra was represented as circles, and the spectra of a set of substituted benzenes were depicted as squares. Each spectrum was reduced to a point with p coordinates (i.e., the absorbance in each of p-specific frequency windows; $p = 3$). If the frequency windows had been chosen such that carboxylic acid spectra yielded different absorbance values than the spectra of substituted benzenes, the p-dimensional plot would reveal a grouping of the spectra according to their respective structural classes. In this way, the chosen dimensions were said to discriminate the spectra of carboxylic acids from those of substituted benzenes. Similar pattern recognition was used to develop a potential method involving high-resolution pyrolysis (Py) and gas chromatography (GC) for the detection of carriers of the cystic fibrosis gene (9). The analyses were directed towards three specific goals: (*a*) finding discriminants that could separate the 72 heterozygote pyrochromatograms from the 72 normal pyrochromatograms on the basis of chemical differences between the two groups; (*b*) studying the structure of the Py/GC data to seek obscure relationships with mapping-and-display and clustering methods; and (*c*) developing the ability to predict class membership of unknowns. One of their ways of looking at the confounding eigenvector projections of the data was to plot the 144 pyrochromatograms in a two-dimensional map using the first two principal components derived from their n-dimensional data. Although this pattern recognition approach of discriminating between groups showed some order of discrimination, the boundaries that divide the groupings were not evident. The presentation of results was difficult to follow because much of the useful information employed for coming to such final classifications could not be readily retrieved.

In 1988, Rose-Pehrsson et al. evaluated an array of surface acoustic wave sensors as a monitor for the detection of hazardous vapours at sub-part-per-million concentrations (10). Each sensor was coated with a sorbent material selected to contribute unique chemical information. Bar graphs were first used to display the relative response patterns of eight coatings to nine test vapours and their binary mixtures. A hierarchical cluster analysis routine, using the Euclidean distance metric and flexible fusion, was then employed for the clustering of mixtures. The y axis of the resulting dendogram compared the responses of the coatings to the vapours. Coatings that were fused together by horizontal lines lower on the y scale were similar, while coatings fused at a higher level were different. Finally, visual display of the large data matrix of coating responses to the vapours and mixtures was simplified through the use of circular profiles. A circular profile consisted of pattern vectors that were drawn as axes radiating from a centre like spokes on a wheel. The length of each axis depended on the response of one sensor to a vapour. The open ends of adjacent axes were next connected by lines to form a polygonal figure.

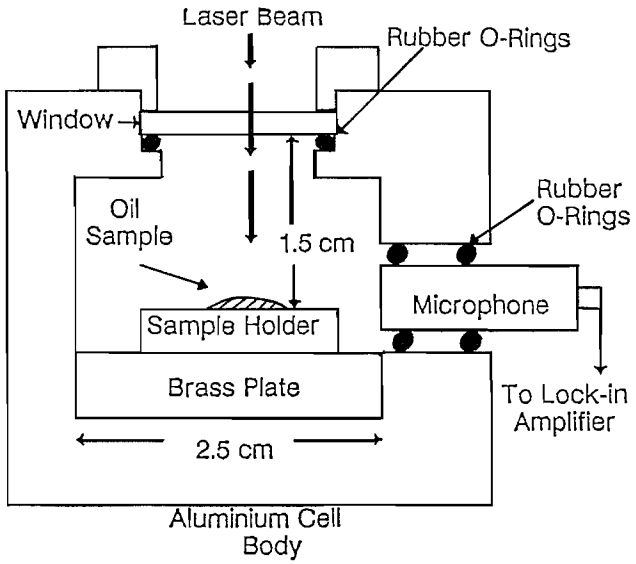

FIG. 1. Photoacoustic cell.

The present work was aimed at discriminating one crude oil from another using circular profiles as the pattern recognition method of choice. Several parameters were considered for constructing the circular profiles of crude oils. They were photoacoustic spectroscopy (PAS), carbon-13 nuclear magnetic resonance (^{13}C NMR, for $\%C_A$ = aromatic carbon content), high-performance liquid chromatography (HPLC, for unsaturated, aromatic, and polar compounds), initial boiling point (IBP), American Petroleum Institution (API) gravity, and UV–visible spectrophotometry (for λ_{max} = maximum absorption wavelength and ϵ_{max} = maximum molar absorptivity).

Experimental

Photoacoustic spectroscopy

A schematic diagram of the photoacoustic cell is shown in Fig. 1. A crude oil sample (60 μL in volume) was deposited on a sample holder made of grey rubber (13 mm diameter, 3 mm height) so as to form a 5 mm diameter oil drop. The loaded sample holder was

placed in the acoustically closed cell (2.5 cm inside diameter, 1.5 cm depth), sitting in a constant position relative to a sensitive microphone (Olympus Optical ME6, Tokyo, Japan). PAS measurements of the crude oil were attained by setting up the cell in the experimental arrangement shown in Fig. 2. A He-Ne laser beam (Spectra-Physics 157-1, 632.8 nm, 17 mW, 1.5-mm spot size), mechanically chopped at 32 Hz for optimum experimental photoacoustic signal-to-noise (considering the f^{-1} dependence of the PAS signal amplitude, signal saturation effects, the microphone transfer function, acoustic resonance of the sample cell, and the characteristics of background noise), was directed down onto the cell. Absorption of laser light by the sample generated a photoacoustic signal, which was detected by the microphone. The microphone output voltage was processed by a lock-in amplifier (Stanford Research Systems 510, Sunnyvale, Calif.). A special computer program (Stanford Research Systems 565) calculated and optimized the phase angle for the measurement of the signal amplitude. The PAS system was initially calibrated by using neutral density filters of known optical densities in the incident light path. A plot of PAS signal amplitude for a piece of black rubber (13 mm diameter, 3 mm height) versus laser power (from 3 mW to 18 mW) verified the linearity of the system response. PAS signals were then recorded for the seven crude oils under investigation.

The reduced crude oils were obtained from Imperial Oil Enterprises Ltd. (Sarnia, Ont.). Crude oils A and B are originally from Nigeria and Saudi Arabia, while oils C–G are from Venezuela. A Pasteur pipette was used to collect the oil samples from their glass containers. For oils A and B, samples were taken from the top and bottom layers of the bulk. Each sample measurement was repeated six times to determine its reproducibility. As for crude oils C, D, E, F, and G, measurements were repeated six times for the top layers only. New Castrol XRL 10W-30 motor oil was also measured to serve as a blank, while the piece of black rubber was used as a reference for normalization of the signals from the seven crude oils.

UV–visible spectrophotometry

Crude oils A–G were weighed out directly in volumetric flasks and dissolved in chloroform to give concentrations on the order of 10.0 ± 0.2 μg/mL. From a UV–visible spectrophotometer (Perkin–Elmer Lambda 4B, Norwalk, Conn.), the maximum absorption wavelength (λ_{max}) and maximum molar absorptivity (ϵ_{max}) of each oil solution were measured.

HPLC

Hydrocarbon class fractionation of crude oils was achieved with HPLC (11). The crude oils were dissolved in chloroform and ultrasonicated for 3 min to prepare 5.0 mg/mL sample solutions. Separations into unsaturated, aromatic, and polar compounds were performed on a Whatman Partisil-10 PAC column (Maidstone, England) using a Perkin–Elmer Series 4 liquid chromatograph and a Dionex VDM-1 variable-wavelength absorption detector (Sunnyvale, Calif.) operating at 254 nm. Retention data of model compounds were first produced to calibrate the retention characteristics of the HPLC system. With 5%:95% chloroform:heptane as the mobile phase at a flow rate of 2.0 mL/min, unsaturated compounds eluted first, followed by an envelope of aromatics. Polars were retained on the column but could be stripped by backflushing the system with 95%:5% chloroform:heptane at 8 min after the aromatics had eluted. Before the next sample was injected, the column was equilibrated with 5%:95% chloroform:heptane over 3 min or more to allow the absorbance baseline to return to zero.

^{13}C NMR

Quantitative ^{13}C NMR analysis of the crude oils was performed in the Department of Chemistry, Carleton University, according to previously reported procedures (11–14). Samples were prepared in the following ratio: 2 mL of crude oil, 1 mL of $CDCl_3$ containing 1% TMS, and 50 mg of paramagnetic chromium(acetylacetonate)$_3$ to serve as a relaxation agent. All spectra were obtained on a Varian Gemini spectrometer (Mississauga, Ont.) operating at 200 MHz in the pulse Fourier transform mode. A pulse width of 90° was used and free induction decay (FID) data were acquired over 1.023 s after each pulse. Full proton spin decoupling was gated off during the delay between pulses of 10 s. As many as 1000 scans were accumulated in the 10–60 ppm and 120–160 ppm characteristic shift ranges and integrated three times. After result averaging, the 120–160 ppm integral was expressed as a percentage of the total integral to yield a value of $\%C_A$ (aromatic carbon content).

Other parameters

The other two parameters used in the present pattern recognition study, IBP and API gravity (=141.5/specific gravity at

Results and discussion

Photoacoustic spectroscopy

Photoacoustic spectroscopy offers a simple and fast screening analysis of crude oils. This method is based on the formation of acoustic waves from a sample under irradiation by modulated light (15). After absorption of radiation, nonradiative relaxations are responsible for heating the sample. Part of the thermal energy is transferred through the sample surface to the gas (e.g., air) contacting the sample. Periodic heating of the gas causes variation in its pressure,

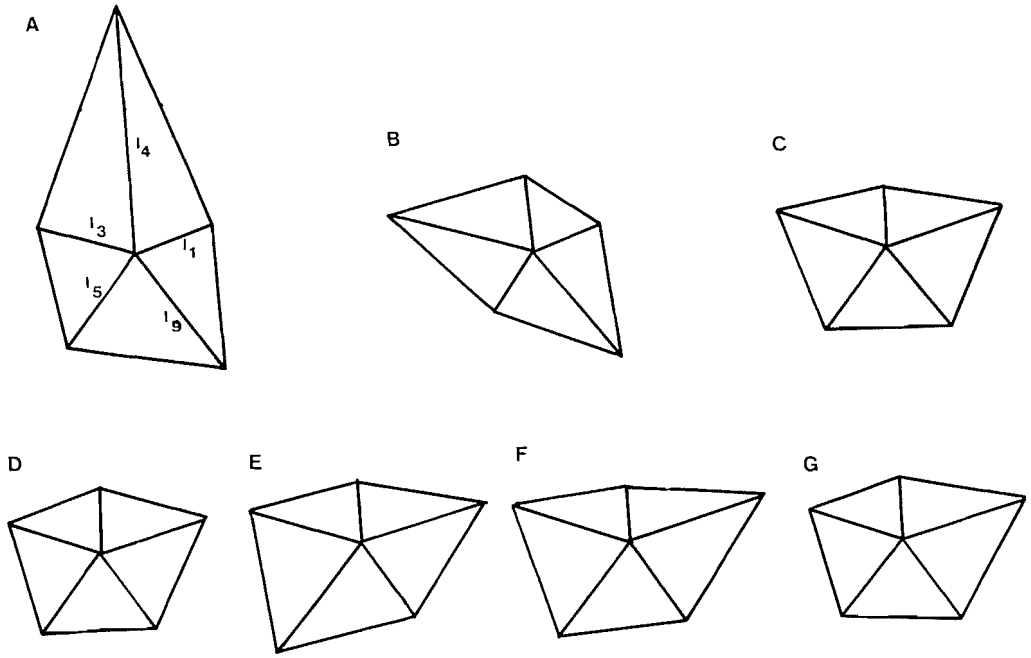

FIG. 5. Five-parameter circular profiles for crude oils A–G, using only I1, I3, I4, I5, and I9.

which is detected by a sensitive microphone to produce a voltage signal. A PAS spectrum may be obtained by recording the microphone signal as a function of the incident wavelength. The characteristic feature of PAS compared to conventional absorption spectrophotometry is that the PAS signal depends on both the optical properties and the thermoelastic parameters of the sample. The sample thickness contributing to surface heating and thermal gas oscillations is given by $L = 2(\pi\alpha/f)^{1/2}$, where f is the modulation (or chopping) frequency and α is the sample's thermal diffusivity (e.g., $\alpha = 9.1 \times 10^{-4}$ cm^2 s^{-1} for *n*-octane). Since the modulation frequency was set at 32 Hz for optimum signal-to-noise, the sample thickness contributing to surface heating was $L = 2(3.1416 \times 9.1 \times 10^{-4}\ \text{cm}^2\ \text{s}^{-1}/32\ \text{Hz})^{1/2} = 0.2$ mm. Therefore only a small oil drop (60 μL in volume, 5 mm in diameter) was required to obtain a good PAS signal for reproducible measurement.

Crude oils vary in color from light yellow, green, red, brown, to black (16). The darker browns and blacks are caused by the asphaltic-resinous material in the crude oil. The majority of the colors are due to molecules with aromatic character that have large π-electron systems, such as found in the condensed ring compounds or the polyunsaturated alkanes with aromatic groups attached where the π electrons are conjugated. The extent of the conjugation affects the color and, as the size of the conjugated electron system grows, the color of the compound moves from the ultraviolet, eventually extending into the visible spectrum (see Fig. 3). In this work, PAS measurements were made at a wavelength of 632.8 nm, which is in a region of weak optical absorption by the oils, to prevent signal saturation (17) without the need for sample dilutions. In accordance with the theory of photoacoustics, the onset of signal saturation occurs at an absorption coefficient of $\beta_{onset} = (\pi f/\alpha)^{1/2} \approx 3 \times 10^2$ cm^{-1} under the given experimental conditions (18). As long as the absorption coefficients of the crude oils at 632.8 nm fall below this value, no signal saturation would occur and the linear dynamic range (i.e., discriminating power) of PAS would be maximized.

The results of PAS measurements on crude oils A–G and Castrol XRL 10W-30 motor oil are shown in Table 1. After each oil was measured, a reference signal was obtained from

a piece of black rubber to check if the PAS sensitivity remained constant. Firstly, the negligible PAS signal amplitude obtained for new Castrol XRL motor oil indicated that no laser energy was absorbed by the sample holder under the clear oil, in accordance with the contribution of the sample thickness to surface heating discussed above. Measurements were next obtained for both the top and bottom layers of oils A and B, in order to determine if oxidation of the top layers had occurred over a storage period of 2 years in capped containers. A Student's *t*-test was conducted to compare the PAS signal amplitudes for the top and bottom layers of each oil. The result showed that the two layers were significantly different only at the 50% confidence level for oil A and below 50% for oil B. This suggested that there was no significant difference in PAS signals between the top and bottom layers of either oil. Consequently, PAS measurements of the bottom layers were discontinued for the other crude oils. As shown in Table 1, the dissimilar PAS signals (mean ± standard deviations, $n = 6$) for the seven crude oils clearly demonstrate that PAS is a sensitive method that is capable of differentiating one crude oil from another. It was therefore used as one of the nine parameters in the pattern recognition analysis as described in detail below.

Pattern recognition

The nine parameters employed for pattern recognition analysis were PAS, ^{13}C NMR (for $\%C_A$), HPLC (for unsaturated, aromatic and polar compounds), IBP, API gravity, and UV–visible spectrophotometry (for λ_{max} and ϵ_{max}). The HPLC and λ_{max} data for each oil were scaled down to the order of 10^2, to compensate the effect of differing measurement magnitudes and to allow easy comparison with the other data. The scaled data may now be considered as the elements of a vector matrix $\boldsymbol{U}$ as illustrated in Table 2. Figure 4 shows the corresponding nine-parameter circular profiles for the crude oils. Each circular profile is constructed by drawing nine axes from a central point. Each axis represents the measurement of one parameter, although it does not include any information about experimental errors or measurement uncertainties for the sake of clarity in visual characterization. The order of the nine measured parameters in the circular profile follows the order of parameter placement in the vector matrix $\boldsymbol{U}$ given in Table 2, with the PAS measurement starting as the upper vertical line in the 12 o'clock position and the other measurements following a clockwise direction. The angle between each pair of adjacent axes is equal to 360° divided by the number of parameters. Thus far, both the selection of the nine parameters and the order of their arrangement in the circular profile are arbitrary. Nevertheless, these circular profiles show clearly both dissimilarities and similarities that exist among the seven crude oils. Although the nine-parameter circular profiles were satisfactory as discrimination patterns for the crude oils, the determination of nine parameters for each oil was time consuming, costly, and probably redundant in chemical information. Therefore a more concise circular profile should be derived by removing all those parameters that either are not very sensitive to different crude oils or can be expressed as a linear combination of the other parameters.

The most appropriate and effective technique for qualitative identification of the best parameters is computerized statistical evaluation. By using the Statistical Program of the Social Science (SPSS) at Carleton University on a UNIX system, relative standard deviations (%RSD), a matrix of correlation coefficients, and a multiple linear regression analysis were obtained for the nine parameter values. Table 3 shows the new designations and the standard deviation results from the SPSS analysis of the nine parameters individually. To construct a circular profile or any recognition pattern that discriminates between different oils, the selected parameters should ideally have the largest %RSD's. A large %RSD indicates that the parameter is sensitive to the different oils as the magnitudes of the measurements vary significantly. According to Table 3, I4 had the largest %RSD, followed by I1, I5, K9, and I3. It is notable that I2, I6, I7,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

and I8 had relatively low %RSD's, which indicated that these four parameters were not sensitive to the different oils and were therefore reasonable candidates to be removed from the nine-parameter circular profiles. Since I8 had the lowest %RSD, it could be rejected immediately.

Further rejection of parameters could be achieved by statistical considerations of linear dependency. Table 4 shows a matrix of correlation coefficients for the nine parameters, which investigates the interdependence of the measurements. Values greater than ± 0.750 are considered highly correlated and are denoted by an asterisk to indicate that the two parameters being compared are linearly dependent on one another. In terms of pattern recognition, this signifies similarity as opposed to dissimilarities. If a parameter is dependent on or is a linear combination of other parameters, its use in pattern recognition is no longer important as it will only reflect similarities in the circular profiles. It can be seen in Table 4 that a high degree of correlation existed between I1 and I2, I1 and I6, I1 and I7, as well as I1 and I9. The parameters I2, I6, and I7 were therefore linearly related to I1 and were rejected from the circular profiles. As a result, a five-parameter circular profile was left behind, consisting only of I1, I3, I4, I5, and I8. In constructing the five-parameter circular profiles shown in Fig. 5, the order of parameter arrangement in the clockwise direction followed a decreasing value of the parameter's %RSD (see Table 3). I4 had the largest %RSD and was therefore drawn as the upper vertical line (in the 12 o'clock position). Next, I1 had the second largest %RSD and was drawn to the right of I4, and so on.

As an additional observation from Table 4, I9 seemed to be highly correlated to as many as four other parameters. From a computerized least-squares multiple linear regression analysis, I9 was found to be 88.4% expressable in terms of I1 and I4 with a 1.4% probability that such correlation occurred by chance. The linear combination expression was

$$I9 = 53.31 - 0.53\,I1 + 0.14\,I4$$

Consequently, I9 was later removed from the five-parameter circular profiles. Figure 6 shows the new four-parameter circular profiles for crude oils A–G. These simple four-parameter circular profiles still retain the capability for computerized discrimination among the seven crude oils (which cannot be actually identified by visual inspection because of the similarity in their dark brown colors). No two oil types are without distinguishable qualities, and subtle differences among the oils are qualitatively enhanced when the four parameters combine to obtain an overview of every circular profile. Note that the reduced set of four selected parameters (I1 = PAS, I3 = HPLC for unsaturated compounds, I4 = HPLC for aromatic compounds, and I5 = HPLC for polar compounds) were established for the crude oils presented here; they are not invariant if either different or additional oil types are studied. Although a computerized analysis greatly reduces the number of parameters for use in a circular profile, the final desired number will always be a personal choice. Usually a greater number of oil-sensitive parameters will give a better (or more accurate) pattern recognition. However, due to the time requirements and cost of multiple analyses, an optimum number of parameters must be reached in order to ensure the effectiveness of screening analysis (by visual evaluation of patterns) without producing redundant analytical information. Further reduction from four parameters to three was not considered because the next questionable parameter, I3, was actually generated simultaneously with I4 and I5 in one single HPLC determination.

Conclusion

Pattern recognition in the form of multivariate circular profiles has been shown to be an effective method for the screening analysis of crude oils. Circular profiles constructed from four statistically selected parameters could successfully discriminate between the seven crude oils (A from Nigeria, B from Saudi Arabia, and C–G from Venezuela). Computerized statistical analysis really makes this pattern recognition an effective technique for chemical characterization and classification. In order of decreasing sensitivity to oil differences, HPLC (for aromatic compounds), PAS, HPLC (for polar compounds), and HPLC (for unsaturated compounds) represent the best of the nine parameters studied in differentiating the crude oils. Particularly, PAS is now established as a useful technique that facilitates the fast screening analysis of crude oils. It does not require the preparation of sample solutions; the measurement can be made directly on neat oils in less than 5 min, each on a separate disposable sample holder. Since the PAS signal is apparently a function of so many undefined (and undefinable) variables, no special efforts were made to relate the signal to the other parameters. Although this work demonstrates the usefulness of circular profiles as applied to a small number of samples only, the method could serve as a powerful tool in reducing massive amounts of data to meaningful analytical information. Finally, further development of this work would include selective OH^- chemical ionization mass spectrometry to provide positive identification of the geographical area of origin and to possibly identify the individual oil fields (19).

The kinetics of oxidation of bis(1,4,7-triazacyclononane)nickel(II), $[Ni(tacn)_2]^{2+}$, by the peroxodisulphate anion has been studied in water as a function of $S_2O_8^{2-}$ concentration and temperature. The reaction is first order in both the nickel(II) complex and $S_2O_8^{2-}$, with a second-order rate constant of 1.13 mol dm^{-3} s^{-1} at 298 K. The activation energy for the reaction is 38.3 ± 1.8 kJ mol^{-1}. The reaction was also studied at 298 K in a series of mixed aqueous solvents. Rate retardation relative to water was observed in all solvent mixtures studied. Correlation of the solvent effects on the kinetics of reaction has been made with the free energy of transfer of the initial state and the transition state.

ROBERT I. HAINES, LORI BUTT, MURRAY K. PARK et DEBBIE WHEELER. Can. J. Chem. **71**, 976 (1993).

On a étudié la cinétique de l'oxydation du bis(1,4,7-triazacyclononane)nickel(II), $[Ni(tacn)_2]^{2+}$, par l'anion peroxodisulfate en solution aqueuse et en fonction de la concentration de $S_2O_8^{2-}$ et de la température. La réaction est du premier ordre tant en complexe de nickel(II) qu'en $S_2O_8^{2-}$ et, à 298 K, la constante de vitesse de la réaction du deuxième ordre est égale à 1,13 mol dm^{-3} s^{-1}. L'énergie d'activation de la réaction est de 38,3 ± 1,8 kJ mol^{-1}. On a aussi étudié la réaction à 298 K dans divers solvants aqueux mixtes. On a observé que toutes ces réactions sont plus lentes que celles réalisées dans l'eau. On a effectué une corrélation des effets de solvant sur la cinétique de la réaction avec l'énergie libre de transfert de l'état initial et de l'état de transition.

[Traduit par le rédaction]

Introduction

Over the past several years, there has been interest in the kinetics of redox reactions involving the peroxodisulphate anion, $S_2O_8^{2-}$, and transition metal complexes (1). Several of these studies examine the effects of added organic solvents on reaction rates (2) and explain the findings in terms of initial state (I.S.) versus transition state (T.S.) solvation. Changes in solvation of the initial state on going from water to binary aqueous mixtures, $\delta_m\mu^0$(I.S.), are estimated from solubilities of salts of the individual reactant species in the respective solvent mixtures. From these solubility measurements, transfer chemical potentials of the salts from water into the binary aqueous mixtures are calculated. Transfer chemical potentials of the single ions, $\delta_m\mu^0(X^{n\pm})$, of the reactants are estimated by subtraction of internally consistent literature values of the transfer function of the appropriate counterions. Finally, $\delta_m\mu^0$(I.S.) is obtained as the algebraic sum of $\delta_m\mu^0(X^{n\pm})$ of the reactants.

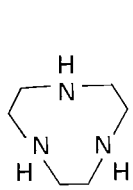
The activation free energy of transfer of the transition state, $\delta_m\Delta G^{\ddagger}$, from water into mixed solvents is calculated from reaction rates in the appropriate media, using the relationship:

$$[1] \quad \delta_m\Delta G^{\ddagger} = -RT\ln(k_{mixture}/k_{water})$$

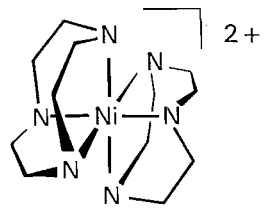
where k_{water} is the rate constant for reaction in aqueous solution and $k_{mixture}$ is that for the appropriate binary aqueous mixture. Comparisons of the kinetic and thermodynamic transfer functions have been used to gain insight into the mechanisms of inorganic reactions, and the role of solvation therein. This approach has been reviewed (3).

We recently investigated the oxidation of nickel(II) tetraazamacrocycles by $S_2O_8^{2-}$, with a view to applying the I.S. versus T.S. solvation approach to solvant effects on the system (4). For these reactions, however, marked ion pairing between the reactants was kinetically observable, where electron transfer occurred within the solvent cage of the ion pair. The extent of ion pairing appeared to be independent of substituents on the ligands, suggesting close approach of the peroxodisulphate ion to the nickel centre along the axial direction.

To test whether the square-planar geometry of the nickel(II) tetraazamacrocycles lends special stability to the ion pairs, we have chosen to study the peroxodisulphate oxidation of the substitutionally inert, octahedral nickel(II) complex $[Ni(tacn)_2]^{2+}$ (where tacn = 1,4,7-triazacyclononane) (5).



tacn



$[Ni(tacn)_2]^{2+}$

The $[Ni(tacn)_2]^{2+}$ ion is known to be stable in aqueous acidic solutions for relatively long periods (6). The tervalent product, $[Ni(tacn)_2]^{3+}$ has been well characterized (7) and many kinetic studies have shown the Ni(II) complex to be smoothly oxidized to the 3+ state by a variety of oxidants via outer-sphere mechanisms (8).

This paper presents a mechanistic study of the $S_2O_8^{2-}$ oxidation of $[Ni(tacn)_2]^{2+}$ as a function of temperature and solvent composition, with a view to interpreting the mechanism in terms of the solvation properties of the participating species.

Experimental

Materials

The title nickel(II) complex was prepared as the perchlorate salt according to the literature (9) and recrystallized from water prior

to use. (**Warning!** Transition metal complex perchlorates are violently heat- and shock-sensitive in the dry state). **Handle with caution!**) The macrocyclic ligand was synthesized by a modified literature procedure (10). AnalaR grade potassium peroxodisulphate (BDH) was first washed several times with distilled water, then recrystallized four times from cold water, rinsed with ice-water, and dried over P_4O_{10} in vacuo. This procedure has been found necessary to obtain reproducible, clean kinetics. Lithium perchlorate was prepared by neutralization of perchloric acid with lithium carbonate and was recrystallized three times from water. All other reagents and solvents were of AnalaR grade and were used without further purification. All solutions were prepared using double-distilled, deionized water.

Stock solutions of perchloric acid were analyzed by titration against primary standards. Lithium perchlorate solutions, used as supporting electrolyte, were analyzed by conversion to the corresponding acid using Dowex ion exchange resin, then titrated as above.

Kinetics

Kinetics were performed under pseudo-first-order conditions, using an excess of peroxodisulphate. The concentration of $[Ni(tacn)_2]^{2+}$ used was 1.0×10^{-4} mol L^{-1}. Absorbance changes with time were measured using 1-cm pathlength quartz cells in the thermostatted cell compartment of a Beckman DU-65 recording spectrophotometer. Data were collected using Beckman Datacapture software on a Wise AT-compatible microcomputer. First-order rate constants, k_{obs}, were calculated from the slopes of linear regres-

sion plots of $\ln(A_\infty - A_t)$ versus time. Reported values of k_{obs} are the means of at least three measurements; the relative standard deviations for all reported values were within 1%. Ionic strength was kept constant at 1.00 mol dm^{-3} for the temperature dependence studies in aqueous solution, using lithium perchlorate – perchloric acid mixtures. For the kinetic studies in binary aqueous mixtures, ionic strength was maintained at 0.100 mol dm^{-3} using lithium perchlorate – perchloric acid. This value was used to avoid precipitation of potassium perchlorate, whose solubility decreases with increasing mole fraction of organic cosolvent. All solvent mixtures used were made up as percent by volume. Absorbance measurements for all kinetics were made at 370 nm.

Solubilities

Saturated solutions of the complexes were prepared by addition of an excess of the solid complex to stoppered flasks, each containing the appropriate solvent mixture. The flasks were stored in a water bath, thermostatted at 298.0 ± 0.1 K, and were agitated periodically. The solutions were centrifuged and aliquots were removed daily for analysis, until constant values were obtained.

UV–visible spectroscopy was used to analyze the solutions for the perchlorate salt of the complex, using the band of 510 nm (ε_{510} = 6.13 ± 0.08). The molar absorptivity of this band was determined by correlating absorbances of a series of solutions of the nickel(II) complex with nickel concentrations, measured by atomic absorption spectrometry. Visible spectra were measured using 1-cm pathlength quartz cells in the thermostatted cell compartment of a Beckman DU 65 recording spectrophotometer.

Results

The title reaction produced a green solution with a UV–visible spectrum characteristic of the nickel(III) complex. Stoichiometric titrations showed a nickel(II) complex to $S_2O_8^{2-}$ ratio of 2:1 for all solvent mixtures studied, within 2%. The overall reaction is described by:

$$[2] \quad 2[Ni(tacn)_2]^{2+} + S_2O_8^{2-} \rightarrow 2[Ni(tacn)_2]^{3+} + 2SO_4^{2-}$$

Excellent first-order kinetics for product formation were observed over at least four half-lives for all solvent mixtures studied, with no discernible interference by SO_4^{-} radicals (11). Addition of allyl acetate as a radical scavenger (12) to the system had no effect on reaction rates. This indicates that the election transfer reaction is not occurring via an SO_4^{-} radical pathway.

Observed first-order rate constants for oxidation of the nickel(II) complex in water, as a function of temperature and peroxodisulphate concentration, are listed in Table 1. Figure 1 depicts the plots of k_{obs} versus $[S_2O_8^{2-}]$, showing the reaction to be first order in peroxodisulphate concentration.

The reaction rate was found to be independent of $[H^+]$ between 0.010 and 0.20 mol dm^{-3}, giving overall a relatively simple second-order rate law:

$$[3] \quad \text{Rate} = +\tfrac{1}{2}\, d[Ni(tacn)_2^{3+}]/dt = k_3[Ni(tacn)_2^{2+}][S_2O_8^{2-}]$$

Values for the second-order rate constant, k_2 were calculated using a least-squares fit of the k_{obs} versus $[S_2O_8^{2-}]$ data and are included in Table 1. From the temperature dependence, an activation energy of 38.3 ± 1.8 kJ mol^{-1} was determined. The activation enthalpy and entropy of the reaction were calculated to be 35.8 ± 1.8 kJ mol^{-1} and −109 ± 6 J K^{-1} mol^{-1}, respectively.

Table 2 lists the observed pseudo-first-order and derived second-order rate constants for the title reaction in a series of binary aqueous solvent mixtures. Trends in reaction rate with mole fraction of added cosolvent (Fig. 2) show retardation with increasing organic component.

The oxidation of $[Ni(tacn)_2]^{2+}$ by $S_2O_8^{2-}$ is several orders of magnitude faster than the oxidation of organic solvents such as alcohols (13, 14), and acetone (15). Thus possible side reactions of the oxidant with added cosolvents may be discounted in the present system.

Table 3 lists the solubilities of $[Ni(tacn)_2](ClO_4)_2$ in water and in a series of binary aqueous mixtures, at 298 K. Although there is little variation in solubility with solvent composition for the aqueous methanol mixtures, the solubility increases dramatically with increasing acetone concentration.

Discussion

Mechanism

Redox reactions involving metal ions or organic reductants and peroxodisulphate characteristically proceed via rate-determining fission of the peroxo bond (1), a step that may be assisted by the presence of a metal ion. A common mechanistic scheme for the oxidation of a cationic complex $[ML]^{n+}$ by $S_2O_8^{2-}$ may be described by eqs. [4–6]:

$$[4] \quad [ML]^{n+} + S_2O_8^{2-} \overset{K_{ip}}{\rightleftharpoons} \underbrace{\{ML^{n+}, S_2O_8^{2-}\}}_{\text{ion pair}}$$

$$[5] \quad \{ML^{n+}, S_2O_8^{2-}\} \xrightarrow{k_5} [ML]^{(n+1)+} + SO_4^{-} + SO_4^{2-}$$

$$[6] \quad [ML]^{n+} + SO_4^{-} \xrightarrow{\text{fast}} [ML]^{(n+1)+} + SO_4^{2-}$$

The rate law derived from this scheme is:

$$[7] \quad \text{Rate} = \{2k_5K_{ip}/(1 + K_{ip}[S_2O_8^{2-}])\}[S_2O_8^{2-}][ML^{n+}]$$

Such a rate law is expected to show curvature in the dependence of the observed first-order rate constant on peroxodisulphate concentration, if the ion-pairing constant is sufficiently large.

In the present system, where ML^{n+} represents $[Ni(tacn)_2]^{2+}$, no curvature in the k_{obs} versus $[S_2O_8^{2-}]$ plots was seen. This suggests that the ion-pairing constant is small and the approximation $(1 + K_{ip}[S_2O_8^{2-}]) \approx 1$ is valid over the range of oxidant concentrations used. Hence the rate law simplifies to:

$$[8] \quad \text{Rate} = k_{obs}[Ni(tacn)_2^{2+}] = 2k_5K_{ip}[S_2O_8^{2-}][Ni(tacn)_2^{2+}]$$

This contrasts with previous findings for oxidation of nickel(II) tetraazamacrocycles, where significant curvature in plots of the type shown in Fig. 1 led to kinetically determined ion-pairing constants of about 20 (4). For the $[Ni(tacn)_2]/S_2O_8^{2-}$ system, close approach of the anion to the nickel(II) centre is not possible, due to steric hindrance by the tacn ligands. Hence it is quite reasonable to presume that K_{ip} for this system would be considerably less than for the nickel(II) tetraazamacrocycles. Ion pairing between the reactants in the present study cannot be discounted, however, and the observed second-order rate constant must be considered as a composite term, where:

$$[9] \quad k_{obs}/[S_2O_8^{2-}] = 2k_5K_{ip}$$

Since the ion-pairing term appears to be relatively small, an activation entropy and enthalpy for the bimolecular rate-determining step has been calculated. The values obtained are compared in Table 4 with published activation parameters for reactions involving peroxodisulphate and transition metal complexes, as well as silver(I). It is apparent from these data that $[Ni(tacn)_2]^{2+}$ behaves similarly to other cationic complexes in its reaction with $S_2O_8^{2-}$. The activation enthalpy is significantly lower than that for thermal dissociation of the oxidant (22), suggesting cation(complex)-assisted peroxo-bond elongation in the transition state. The activation entropies are consistently large and negative for the reactions of the cationic complexes. Entropy values become less negative with decreasing positive charge on the complex. The activation parameters for the $[Co(cydta)]^{2-}/S_2O_8^{2-}$ system are anomalous, and clearly indicate a different mechanism. The enthalpy corresponds to that for thermal decomposition of $S_2O_8^{2-}$ into SO_4^{-} radicals (22).

Solvent effects

For reactions occurring in mixed aqueous solvents, the activation free energy of transfer, $\delta_m\Delta G^{\ddagger}$, measures the change in activation energy for the reaction as one changes the medium from water to the appropriate binary aqueous mixture. Table 5 lists the calculated values of $\delta_m\Delta G^{\ddagger}$ (according to eq. [1]) for a series of solvent mixtures. It is clear

that $\delta_m\Delta G^{\ddagger}$ increases as we go to more organic-rich solvent mixtures (more hydrophobic). This could be due to either (*a*) a stabilization of the initial state (reactants) or (*b*) destabilization of the transition state (or some combination of these), as the solvent composition is varied. To determine which case obtains, it is necessary to estimate the change in solvation of the initial state with solvent composition.

Table 5 presents single-ion transfer chemical potentials of the $[Ni(tacn)_2]^{2+}$ and $S_2O_8^{2-}$ ions in solvent mixtures corresponding to those of kinetic studies. The values for the nickel(II) complex cation were calculated from solubilities of the perchlorate salt in those solvents, using the relationship:

$$[10] \quad \delta_m\mu^0(MX_2) = 3RT \ln(S_w/S_x)$$

where MX_2 represents a 1:2 electrolyte, whose solubility is S_w in water and S_x in a mixture with mole fraction of cosolvent equal to x. As described in the Introduction, the single-ion transfer functions for the nickel(II) complex cation were obtained by subtraction of $2\delta_m\mu^0(ClO_4^-)$ from those of the salt. Values for $\delta_m\mu^0(S_2O_8^{2-})$ from water into aqueous methanol (23), *tert*-butyl alcohol (24) and acetone (25), and corresponding values for the perchlorate ion (26, 27) were taken from the literature. The extrathermodynamic assumption $\delta_m\mu^0(Ph_4As^+ \text{ or } Ph_4P^+) = \delta_m\mu^0(BPh_4^-)$ (TATB/TPTB) was used to arrive at the single-ion values throughout this work. Algebraic combination of these parameters gives $\delta_m\mu^0$(I.S.) from water into the mixed solvents. Figure 3 compares the single-ion transfer parameters of the reactants with $\delta_m\mu^0$(I.S.) and $\delta_m\Delta G^{\ddagger}$.

The transfer potential of $[Ni(tacn)_2]^{2+}$ into aqueous methanol mixtures is quite small, but the trend in the initial state transfer potential is one of destabilization with increasing mole fraction (Fig. 3(*a*)). In both aqueous *tert*-butyl alcohol and aqueous acetone mixtures (Fig. 3(*b*,*c*), there is a marked stabilization of the nickel(II) complex cation with increasing amount of cosolvent, which compensates for the destabilization of the hydrophilic peroxodisulphate anion. Thus, although there are significant changes in solvation of the individual reactant ions on changing solvent composition, the strongly hydrophobic periphery of the tacn ligands results in a stabilization, in spite of the 2+ charge on the complex ion.

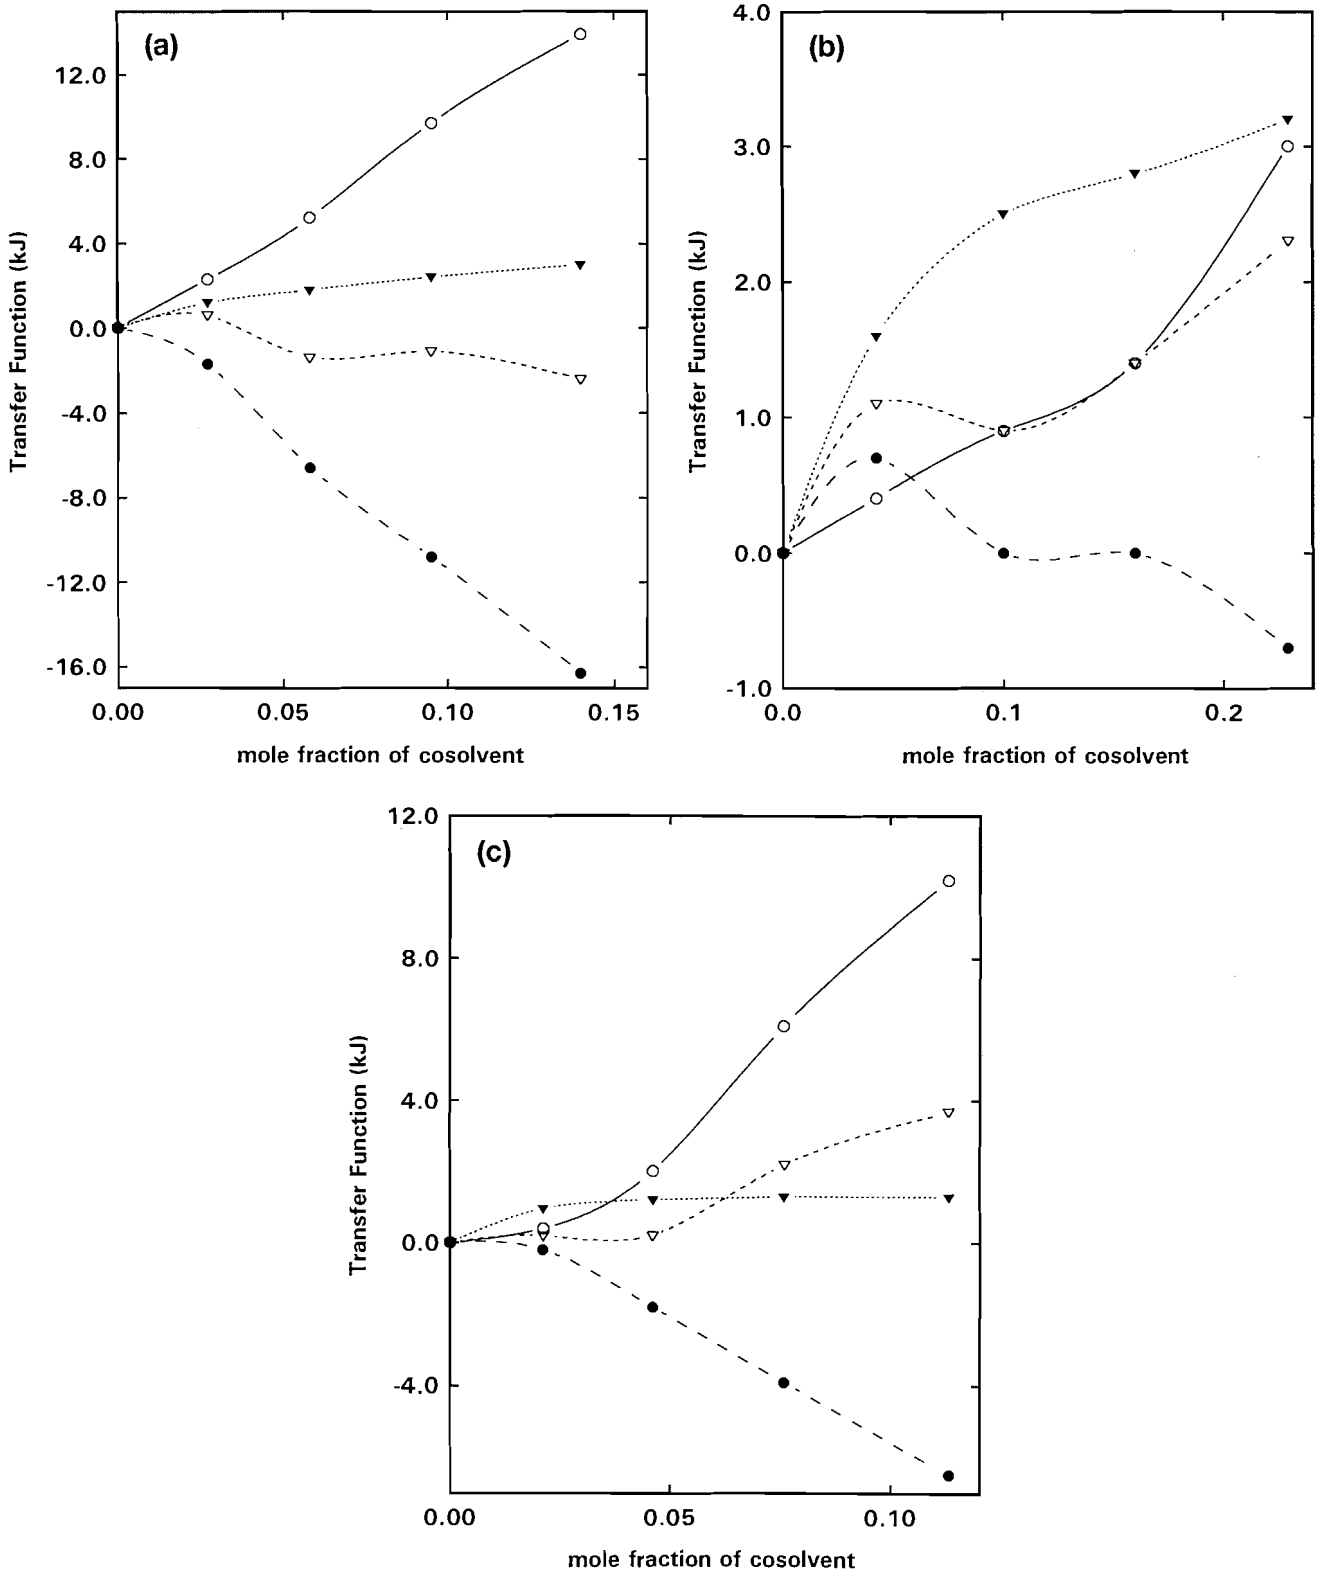

FIG. 3. Comparison of the transfer chemical potentials of $[Ni(tacn)_2]^{2+}$ (●), $S_2O_8^{2-}$ (○), and $\delta_m\mu^0$(I.S.) (▽) with the activation free energy of transfer, $\delta_m\Delta G^{\ddagger}$ (▼) from water into the following binary aqueous mixtures: (a) methanol–water; (b) *tert*-butyl alcohol water; (c) acetone–water (temperature 298 K).

Hence there is only a relatively small change in the initial state solvation with solvent composition.

There is a similar small change in the free energy of transfer of the transition state into these binary aqueous mixtures. In the transition state, ion pairing of the reactants is envisaged. One might expect a significant stabilization of such an ion pair in binary aqueous mixtures, because of charge neutralization. However, the periphery of the ion pair

should maintain hydrophobic character at the tacn side, and hydrophilic character at the peroxodisulphate side. As noted earlier, due to the substitutional inertness of the octahedral nickel(II) complex cation, approach of the $S_2O_8^{2-}$ anion to the inner sphere of the nickel complex is not possible. Even in the highest mole fractions of cosolvents, no ion pairing was kinetically observable, lending further support to the view that charge neutralization in an intimate ion pair is not a dominant feature.

The general observation of decreasing reaction rate with increasing mole fraction of organic cosolvent in the present system agrees with other studies of solvent effects on the oxidation of transition metal complexes by the peroxodisulphate anion (24, 28, 29). In those studies, ion pairing was not kinetically observable, due to expected lower ion-pairing constants between the anionic oxidant and singly charged metal complexes.

A new annulation method. Total syntheses of the sesquiterpenoids (±)-chiloscyphone and (±)-6-*epi*-chiloscyphone

EDWARD PIERS[1] AND HOI LUN ALLAN TSE
Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, B.C., Canada V6T 1Z1

Received February 12, 1993

EDWARD PIERS and HOI LUN ALLAN TSE. Can. J. Chem. **71**, 983 (1993).

The efficacy of a new annulation method, developed for the construction of functionalized bicyclic compounds, is illustrated by conversion of the β-keto esters **18** and **19** into the bicyclo[4.3.0]non-1-enes **33** and **34**, respectively, and by transformation of 2-methoxycarbonylcyclopentanone (**20**) into the bicyclo[4.3.0]non-6-ene **38** and the bicyclo[5.3.0]dec-7-enes **48** and **51**. Application of the method to total syntheses of the structurally unusual sesquiterpenoids (±)-chiloscyphone (**16**) and (±)-6-*epi*-chiloscyphone (**17**) is described.

EDWARD PIERS et HOI LUN ALLAN TSE. Can. J. Chem. **71**, 983 (1993).

On met en évidence l'efficacité d'une nouvelle methode d'annellation, développée pour la construction de composés bicycliques fonctionnalisés, en effectuant la conversion des β-céto esters **18** et **19** en bicyclo[4.3.0]non-1-ènes, **33** et **34** respectivement, ainis que la transformation de la 2-méthoxycarbonylcyclopentanone (**20**) en bicyclo[4.3.0]non-6-ène (**38**) et en bicyclo[5.3.0]déc-7-ènes, **48** et **51**. On décrit l'application de la méthode à la synthèse totale des sesquiterpénoïdes de structures inhabituelles, (±)-chiloscyphone (**16**) et (±)-6-*épi*-chiloscyphone (**17**).

[Traduit par la rédaction]

Introduction

The discovery and development of new annulation methods for the construction of functionalized carbocycles continues to be of importance in synthetic organic chemistry. In fact, such processes often play key roles in the total synthesis of natural products. Since the discovery of the Robinson annulation method more than 50 years ago (1), many different, synthetically effective six-membered ring annulation processes have been developed (1, 2). More recently, primarily in connection with research programs aimed at achieving total syntheses of natural products, operationally diverse annulation methods leading to functionalized carbocycles of various ring sizes have been described (3).

Recent reports from this laboratory have described in detail three annulation sequences that can be represented in general terms by the theoretical combination of the synthon **1** (a = acceptor center, d = donor center, see ref. 4) with each of the synthons **2**–**4** to produce methylenecyclopentane (**5**) (5), (*Z*)-ethylidenecyclopentane (**6**) (6), and methylenecyclohexane (**7**) (7) annulation products, respectively. In these processes, α,β-unsaturated ketones of general structure **8** serve as synthetic equivalents to the substrate synthon **1**, while structurally interesting bifunctional organocopper(I) species derived from the chloro trimethylstannanes **9**–**11** function as effective equivalents to the reagent synthons **2**–**4**.

We report in this paper the details of a new annulation method (8) that, although also based primarily on organotin chemistry, is quite different from those represented by the conversion of **8** into **5**–**7**. This method can be represented in general terms by the (theoretical) combination of the donor–donor synthon **12** (R = CO_2Me or a group derived therefrom) with an acceptor–acceptor synthon **13**, to form bicyclic substances of general structure **14**. In practice, cyclic β-trimethylstannyl α,β-unsaturated esters **15** and 1,ω-dihaloalkanes serve as synthetic equivalents to the synthons **12** and **13**, respectively. As described below, this method has successfully led to five-, six-, and seven-membered ring annulations. Furthermore, the method has been applied to the total syntheses of the sesquiterpenoid (±)-chiloscyphone (**16**) and of its C-6 epimer **17**.

Results and discussion

(a) Preparation of the cyclic β-trimethylstannyl α,β-unsaturated esters 24–26

The β-trimethylstannyl α,β-unsaturated esters **24–26** that were employed in this study were conveniently prepared from the corresponding 2-methoxycarbonylcycloalkanones **18–20**, as shown in Scheme 1. Thus, sequential treatment of 2-methoxycarbonylcyclohexanone (**18**) (9) with sodium hydride and trifluoromethanesulfonic anhydride in diethyl ether at 0°C gave, in 79% yield, the enol trifluoromethanesulfonate **21**. In similar fashion, the β-keto esters **19**[2] and **20** were converted efficiently into substances **22** and **23**, respectively.

Replacement of the trifluoromethanesulfonyloxy group present in each of compounds **21–23** by a trimethylstannyl function was accomplished by reaction of these materials with lithium (phenylthio)(trimethylstannyl)cuprate (12) in THF containing a small amount of hexamethylphosphoramide (HMPA). These reactions were clean and efficient and the ^{1}H nmr spectrum of each of the products **24–26** exhibited the expected nine-proton signal (δ 0.16) due to the trimethylstannyl moiety.

(b) Annulation reactions involving substrates 24–26

The efficient conversions of the cyclohexenecarboxylates **24** and **25** into the functionalized bicyclo[4.3.0]nonenes **33** and **34** are summarized in Scheme 2. Treatment of **24** with lithium diisopropylamide (LDA) (1.5 equiv.) in THF containing HMPA (3 equiv.), followed by addition of 1-chloro-3-iodopropane, provided the expected alkylation product **27** (78%). Similarly, **28** was obtained in 89% yield from **25**. As expected (13), the latter alkylation process was completely stereoselective, with the alkylating reagent approaching the substrate enolate anion from the side of the molecule opposite to the secondary methyl group.

Reduction of each of the esters **27** and **28** with diisobutylaluminum hydride in diethyl ether afforded the alcohols **29** and **30**. Treatment of the latter substances with *tert*-butyldimethylsilyl chloride – imidazole in *N*,*N*-dimethylformamide provided, in excellent overall yields, the functionalized cyclohexenes **31** and **32**.

Completion of the five-membered ring annulation sequences required alkyllithium-mediated transmetallation of the trimethylstannyl function in **31** and **32**, followed by intramolecular displacement of chloride ion by the resultant vinyllithium center. When **31** was treated with methyllithium in THF under different reaction conditions (e.g., 1.3 equiv. MeLi, −78°C, 3 h; 4 equiv. MeLi, −78°C, 4.5 h), no reaction occurred. In each case, starting material was recovered in high yield. Even when **31** was treated with a large excess (~20 equiv.) of methyllithium in THF at −20°C for 7 h, the material isolated from the reaction mixture consisted mainly of **31** (~75%) accompanied by a minor amount (~25%) of the desired product **33**. Clearly and, perhaps not surprisingly (14), the transmetallation of the (sterically hindered) trimethylstannyl function in **31** with methyllithium is, at least in THF, a very sluggish process.

It is known (14) that the rate of tin–lithium exchange reactions can be increased by use of solvents that coordinate with metal cations more efficiently than THF. Indeed, when a solution of **31** in THF containing 3 equiv. of HMPA was treated with methyllithium (−20°C, 30 min), 6-(*tert*-butyldimethylsiloxymethyl)bicyclo[4.3.0]non-1-ene (**33**) was obtained in 92% yield. In similar fashion, the substrate **32** was transformed into the bicyclic alkene **34** (94%). Thus, under appropriate conditions, the five-membered ring annulations are clean and efficient.

A successful six-membered annulation of the cyclopentenecarboxylate **26** is shown in Scheme 3. Alkylation (LDA, THF–HMPA) of **26** with 1,4-dibromobutane gave (72%) the β,γ-unsaturated ester **35**, which was cleanly reduced to the alcohol **36**. Treatment of **36** with *tert*-butyldimethylsilyl trifluoromethanesulfonate and 2,6-lutidine[3] in dichloromethane (15) gave the required silyl ether **37**.

Reaction (−20°C, 30 min) of **37** with methyllithium in THF–HMPA provided a mixture of the desired bicyclic alkene **38** and the monocyclic diene **39**, in a ratio of ~6:1 (analysis by glc). Column chromatography of this mixture

[2]2-Methoxycarbonyl-3-methylcyclohexanone (**19**) was prepared by reaction of 2-methoxycarbonyl-2-cyclohexen-1-one (10) with lithium (phenylthio)(methyl)cuprate (11) in tetrahydrofuran (THF) – diethyl ether (see Experimental).

[3]Reaction of **36** with (t-Bu)Me_2SiCl–imidazole in *N*,*N*-dimethylformamide gave a mixture of **36** and the corresponding chloride in a ratio of ~1:1. Use of (t-Bu)$Me_2SiOSO_2CF_3$ precluded the possibility of the unwanted side reaction.

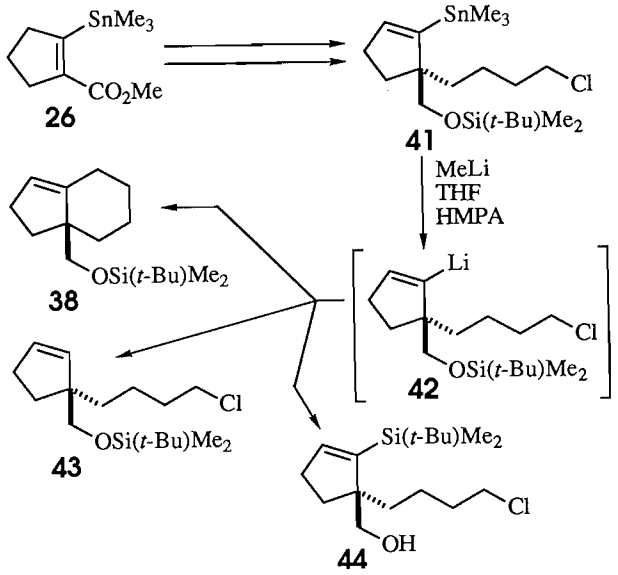
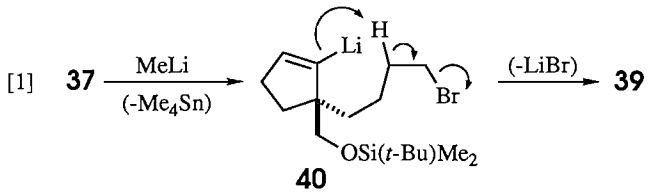


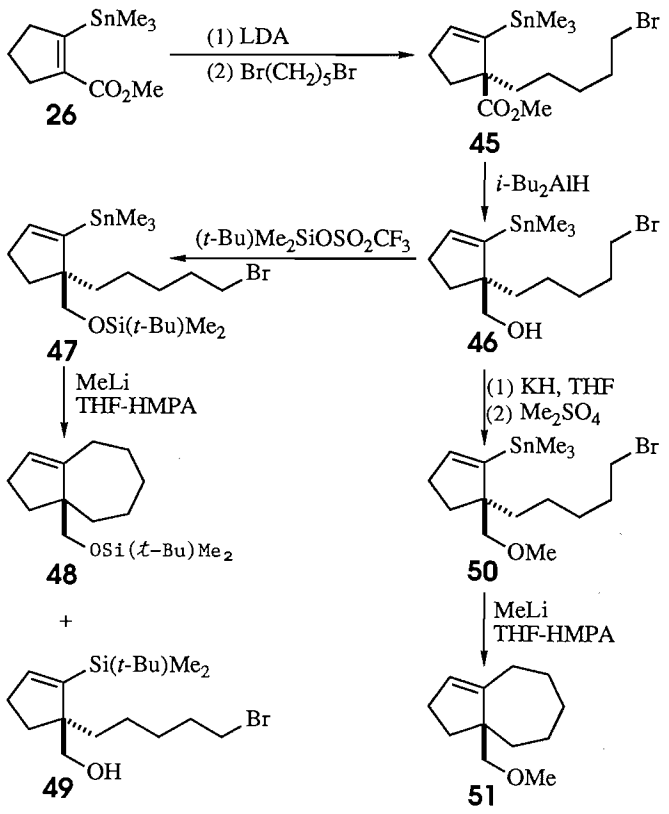
SCHEME 4

on silver nitrate impregnated silica gel produced **38** and **39** in isolated yields of 61 and 7%, respectively.

It seems likely that the diene **39** is formed from the same intermediate that gives rise to the bicyclic substance **38**. Thus, cyclization of the vinyllithium species **40** (formed by transmetallation of **37**) would afford **38**. On the other hand, an intramolecular elimination process via a six-centered transition state (see **40**, eq. [1]) would produce **39**. Fortunately, of these two competitive processes, the cyclization reaction predominates.



It is interesting to note that an earlier attempt to produce the annulation product **38** from the chloride **41** (Scheme 4) did not give satisfactory results. Alkylation of **26** with



SCHEME 5

1-bromo-4-chlorobutane, followed by functional group manipulations identical with those described earlier (Scheme 2), gave the chloride **41**. Treatment of the latter substance with methyllithium in THF–HMPA under conditions identical with those used for the chlorides **31** and **32** (Scheme 2) gave three products. Two of these were formed in minor amounts (~10% in each case) and, on the basis of spectral data, were shown to be the (desired) annulation product **38** and the substance **43** resulting from transmetallation–protonation (Scheme 4). Interestingly, the major product **44** (~75%) proved to be that resulting from transfer of the *tert*-butyldimethylsilyl group from oxygen to carbon. Thus, the competition between ring closure of the intermediate vinyllithium species **42** (cyclic six-centered transition state, chloride ion as leaving group) and silyl group transfer (cyclic five-centered transition state) favored the latter process. Fortunately, this unsatisfactory result could be largely overcome by changing the leaving group from chloride to bromide (vide supra).

Use of the cyclopentenecarboxylate **26** as a substrate for seven-membered ring annulations is summarized in Scheme 5. Alkylation of **26** with 1,5-dibromopentane and reduction of the ester function of the resultant product **45** provided, efficiently, the alcohol **46**, which was readily transformed into the silyl ether **47**. When **47** was allowed to react with methylithium in THF–HMPA, two products were obtained in yields of 35 and 17%. These substances were accompanied by a considerable amount of intractable material. Spectral data showed that the major isolated material was the bicyclo[5.3.0]oct-7-ene **48**, while the minor substance was the silyl-transfer product **49**. Thus, in this case, with bro-

For personal use only.

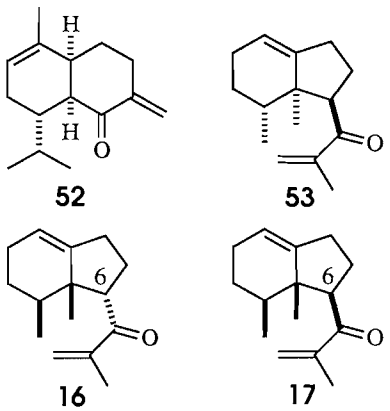
mide ion as the leaving group, the rate of ring closure (cyclic seven-membered transition state) is about twice that of migration of the (*t*-Bu)Me_2Si function from oxygen to carbon via a cyclic five-membered transition state.

Reaction of the alcohol **46** with potassium hydride – dimethyl sulfate afforded the methyl ether **50** in 84% yield. Treatment of this material with methyllithium in THF–HMPA provided one major product, the bicyclic olefinic ether **51**, accompanied by traces of unidentified side products and some intractable material. The fact that the isolated yield (54%) of the annulation product **51** was modest was probably due, at least in part, to the volatility of this substance.

The results of this brief study, as summarized above, showed that the originally envisaged annulation processes, as generalized by **12** + **13** → **14**, are viable synthetic operations. The overall method, which has led to the production of five-, six-, and seven-membered rings, should find use for the preparation of functionalized carbocyclic systems. An application of this chemistry in natural product synthesis is presented in the next section of this paper.

*(c) Total syntheses of (±)-chiloscyphone (**16**) and (±)-6-epi-chiloscyphone (**17**)*

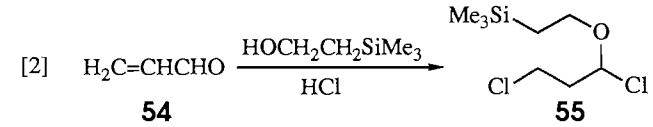
The sesquiterpenoid (−)-chiloscyphone, the main constitutent of the essential oil of the liverwort *Chiloscyphus polyanthus* (L.) Corda, was first isolated by Hayashi et al. (16) and was later proposed (17, 18) to possess the constitution and absolute configuration shown in **52**. However, a subsequent synthesis of racemic **52** by Gras (19) revealed that the original structural proposals (16–18) were incorrect. In 1982, Connolly et al. (20) showed that (−)-chiloscyphone possesses the constitution and *relative* stereostructure depicted in formula **53**. Later, based on synthetic work and circular dichroism studies, Tori et al. (21) concluded that **53** also represents the correct absolute configuration of this natural product. This deduction also turned out to be incorrect and the fact that (−)-chiloscyphone possesses the constitution and absolute configuration shown in formula **16** was finally determined by an X-ray crystallographic study (22).



52 **53** **16** **17**

In the paragraphs that follow, we give an account of the use of the new annulation method described previously (vide supra) for total syntheses of (±)-chiloscyphone (**16**) and its C-6 epimer **17**.[4]

The route envisaged for the synthesis of (±)-**16** involved initially the alkylation of the β-trimethylstannyl α,β-unsaturated ester **25** with a 1,3-dihalo-1-alkoxypropane. The alkylating agent employed for this purpose was 1,3-dichloro-1-(2-trimethylsilylethoxy)propane (**55**), which was readily prepared (24) by treatment of acrolein (**54**) with 2-(trimethylsilyl)ethanol and dry hydrogen chloride (eq. [2]).



54 **55**

The C-1 chloride of **55** would be expected to be more easily displaced by a nucleophile than the C-3 chloride. Therefore, alkylation of the enolate anion of **25** with **55** should produce a product that contains an oxygen function on the carbon that would (eventually) become C-6 of (±)-**16**. This function would have to be used as a handle for the introduction of the carbonyl-containing side chain present in the natural product.

Treatment of the lithium enolate of **25** with the dichloride **55** provided a mixture of products that contained two major substances, **56** and **57**,[5] along with a number of very minor, unidentified side products (Scheme 6). Although flash chromatography (25) of this mixture on silica gel provided pure **56** (41%), the epimeric compound **57** could not be obtained free of minor contaminants. However, treatment of the mixture containing (mainly) **57** with diisobutylaluminum hydride, followed by silylation (15) of the resultant alcohol **66** and product purification (flash chromatography, distillation), gave the pure diether **67** (9% overall yield from **25**). Cyclization (MeLi, THF–HMPA) of **67** afforded the bicyclic alkene **68** (78%).

The three-step transformation of pure **56** into the functionalized bicyclo[4.3.0]non-1-ene **60** (Scheme 6) was achieved cleanly and efficiently (58% overall yield).

Chemoselective cleavage of the *tert*-butyldimethylsilyl ether function of **60** was easily accomplished by treatment of this substance with tetra-*n*-butylammonium fluoride in THF. Oxidation of the resultant primary alcohol **61** with pyridinium chlorochromate (PCC) gave the aldehyde **62**. Treatment of the corresponding hydrazone with sodium methoxide in diethylene glycol at 210°C provided the desired deoxygenated compound **63** (71% from **60**). In similar fashion, the diether **68** (epimer of **60**) could be converted, via the intermediates **69** and **70**, into the bicyclic ether **71** (56% overall yield).

The configurational assignments with respect to intermediates **63** and **71** require comment. As mentioned previously, alkylation of the enolate anion of **25** would undoubtedly occur, for steric reasons, from the face of the enolate opposite the adjacent secondary methyl group (13). Consequently, the relative configurations of C-5 and C-6 in substances **63** and **71** could be assigned with confidence. On the other hand, data derived from the ^1H nmr spectra of **63** and **71** allowed assignment of the C-7 configurations. In what appears to be the most stable conformation of compound **63**, the dihedral angle between H_A and H_C is close to 90° and, therefore, a very weak coupling between these two protons would be expected. In fact, in the ^1H nmr spectrum of **63** H_A gives rise to a doublet at δ 3.47, with a coupling constant (presumably J_{AB}) of 4 Hz.

[4]For other synthetic work related to chiloscyphone, see refs. 21 and 23.

[5]The relative configurations of these substances were subsequently assigned by use of ^1H nmr spectral data derived from the bicyclic intermediates **63** and **71**, respectively (vide infra).

$[(EtO)_2P(O)\text{-}\bar{C}H\text{-}OCH_2CH_2OMe]Li^+$ **77**

CHART 1

In the case of compound **71**, molecular models indicate that, in the most stable conformation of this substance, the dihedral angles between H_A and H_B and between H_A and H_C are approximately 150° and 30°, respectively. Therefore, the magnitudes of J_{AB} and J_{AC} would be expected to be quite similar. In the ^1H nmr spectrum of **71**, the signal due to H_A appears as a triplet (J = 9 Hz) at δ 3.25.

Attempts to convert the ether **63** into the secondary alcohol **64** initially proved to be problematic. However, it was eventually found that the desired transformation could be achieved efficiently by use of lithium tetrafluoroborate.[6] Thus, treatment of **63** with a 1:1 mixture of boron trifluoride etherate and lithium fluoride in acetonitrile at room temperature afforded the alcohol **64** in 87% yield. Oxidation of the latter substance with PCC produced the ketone **65** (83%).

Lithium tetrafluoroborate mediated cleavage of the ether linkage of compound **71**, followed by oxidation of the resultant alcohol **72**, also produced, in 74% overall yield, the ketone **65**.[7]

The homologation of the ketone **65** was not straightforward. The carbonyl group in this substance is sterically quite hindered and, therefore, the 1,2-addition of nucleophiles to this function would be expected to be sluggish. Indeed, the failure to obtain the desired adducts from treatment of **65** with a variety of nucleophilic reagents (vide infra) was, no doubt, due to the fact that, in these cases, proton transfer (enolate anion formation) takes place in preference to addition.

Treatment of **65** with (methoxymethylene)triphenylphosphorane (**73**) (Chart 1) in THF (25°C) or dimethyl sulfoxide (70°C) (27) gave back only starting material. Similarly, reaction of **65** with each of the reagents **74** (28), **75** (29), and **76** (30) under conditions similar to those prescribed in the literature produced, in each case, little or no desired product. Upon work-up, each reaction mixture yielded primarily the starting material **65**.

Kluge and Cloudsdale (31) have reported that the reagent **77** (Chart 1) undergoes efficient 1,2-addition to readily enolizable ketones at low temperatures. Reaction of **65** with **77** (5 equiv.) in THF at −98°C did provide the desired 1,2-addition adduct, but the yield was low (less than 30%). In addition, approximately 40% of **65** was recovered.

A report by Conia and Limasett (32) has disclosed that methylenation of hindered ketones can be accomplished efficiently by treatment of the substrate with $Ph_3P{=}CH_2$ derived from reaction of $(Ph_3PMe)Br$ with sodium *tert*-amylate.

[6]This reagent has been used effectively for the conversion of 2-(trimethylsilyl)ethyl glycosides into the parent carbohydrates (26). We are grateful to Professor Lipshutz for suggesting this reagent to us.

[7]Obviously, the ketone **65** could have been derived from the *mixture* of **56** and **57** via a *single* synthetic sequence. However, in the interest of spectrally characterizing all of the synthetic intermediates involved, compounds **56** and **57** were each converted into **65** via separate synthetic pathways (Scheme 6).

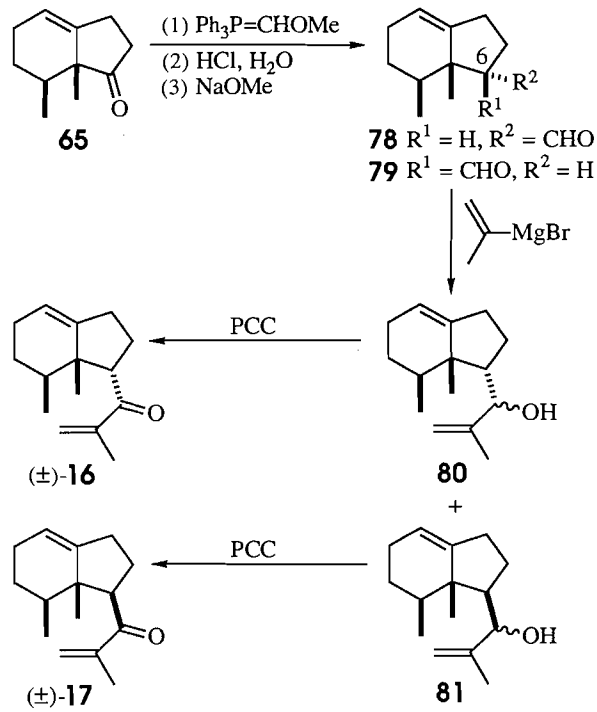

SCHEME 7

This method proved to be reasonably effective for the homologation of **65**. Thus, reaction of **65** with (methoxymethylene)triphenylphosphorane (**73**), prepared by reaction of $(Ph_3PCH_2OMe)Cl$ with $NaOC(Et)Me_2$ in benzene, followed by acid hydrolysis of the resultant mixture of enol ethers, gave a mixture of the two aldehydes **78** and **79** in ratio of ~1:4 (analysis by glc) (Scheme 7). The overall yield of this two-step process was 43%.

Base-catalyzed equilibration of the mixture of epimers **78** and **79** with sodium methoxide in methanol produced a 1:1 mixture of the two substances. Further treatment of this mixture with sodium methoxide and prolonged reaction times did not alter the product ratio. Thus, somewhat surprisingly, **78** and **79** do not differ in stability. Consequently, the expectation that, in the envisaged synthesis of (±)-chiloscyphone (**16**), the configuration at C-6 (chiloscyphone numbering system) could be controlled by thermodynamically controlled equilibration of **78** and **79** proved to be faulty.

Unfortunately, the aldehydes **78** and **79** could not be separated by chromatography on silica gel. However, the mixture of alcohols **80** and **81** derived from reaction of **78** and **79** with isopropenylmagnesium bromide were separable by flash chromatography (25) and were obtained in isolated yields of 33 and 42%, respectively.

Oxidation of **80** with PCC provided (±)-chiloscyphone (**16**), a colorless oil, in 59% yield. Similarly, racemic 6-*epi*-chiloscyphone (**17**) was obtained by oxidation of **81**.

Although we were not able to procure an authentic sample of (−)-**16**, the spectral data derived from our synthetic material agreed very well with those reported for natural (−)-**16** (18) and synthetic (±)-**16** (23). On the other hand, the ^{1}H nmr spectrum of (±)-6-*epi*-chiloscyphone (**17**), although similar, is clearly distinguishable from that of racemic **16**.

Experimental

General information

Distillation temperatures (short-path Kugelrohr distillations) are uncorrected. Proton nuclear magnetic resonance (^{1}H nmr) spectra were taken on $CDCl_3$ solutions. Signal positions (δ values) were measured relative to the Me_4Si resonance (internal standard) or the $CHCl_3$ signal (δ 7.25). The tin–proton coupling constants (J_{Sn-H}) are given as an average of the ^{117}Sn and ^{119}Sn values. For compounds containing the Me_3Sn function, high-resolution mass spectrometric measurements are based on ^{120}Sn and were measured on the (M^+ − Me) peak (33). Gas–liquid chromatographic (glc) analyses were performed on Hewlett-Packard models 5880 or 5890 gas chromatographs equipped with flame ionization detectors and 25 m × 0.21 mm fused silica columns coated with cross-linked SE-54. Thin-layer chromatography (tlc) analyses were carried out on commercial aluminum-backed silica gel plates (E. Merck, Type 5554). Conventional chromatography was done with 70–230 mesh silica gel (E. Merck), while flash chromatography was carried out with 230–400 mesh silica gel as described by Still et al. (25).

Note. All reactions were carried out under an atmosphere of dry argon in glassware that had been flame-dried under an argon flow.

Note. All compounds for which exact masses (high-resolution mass spectrometry) are reported gave clean ^{1}H nmr spectra and were homogeneous by glc and tlc analyses.

2-Methoxycarbonyl-3-methylcyclohexanone (19)

To a cold (−20°C), stirred solution of lithium (phenylthio)-(methyl)cuprate (11) (44.7 mmol) in a mixture of dry THF (140 mL) and dry Et_2O (32 mL) was added a solution of 4.92 g (31.9 mmol) of 2-methoxycarbonyl-2-cyclohexen-1-one (10) in 10 mL of dry THF and the reaction mixture was stirred at −20°C for 1 h. Saturated aqueous ammonium chloride (30 mL) and petroleum ether (200 mL) were added, the mixture was allowed to warm to room temperature, and stirring was continued until a clear, colorless organic layer was formed. The mixture was filtered to remove the solid material, the filtrate was washed with water and brine, and was then dried ($MgSO_4$). Removal of the solvent and distillation (80–90°C/0.1 Torr; 1 Torr = 133.3 Pa) of the residue provided 4.47 g (82%) of **19**, which, in $CDCl_3$ solution, consisted of a mixture of **19** and the corresponding enol tautomer (ratio approximately 2:1, respectively). The colorless oil exhibited ir (neat): 3450, 1735, 1700 cm^{-1}; ^{1}H nmr (80 MHz) δ: 1.03, 1.07 (d, d, 3H total, J = 6 Hz in each case), 1.25–2.90 (diffuse m, 7H), 3.05 (d, 0.7 H, J = 11 Hz), 3.75 (s, 3H), 12.26 (s, 0.3 H). Exact Mass calcd. for $C_9H_{14}O_3$: 170.0942; found: 170.0942.

Methyl 2-(trifluoromethanesulfonyloxy)-1-cyclohexene-carboxylate (21)

To a cold (0°C), stirred suspension of NaH (92 mg, 3.85 mmol) in 12 mL of dry Et_2O was added slowly a solution of 2-methoxycarbonylcyclohexanone (**18**) (9) (0.5 g, 3.2 mmol) in 3 mL of dry Et_2O. After the mixture had been stirred at 0°C for 10 min, trifluoromethanesulfonic anhydride (403 mg, 3.85 mmol) was added and stirring was continued at 0°C for 1 h. Saturated aqueous ammonium chloride (2 mL) and Et_2O (15 mL) were added and the resultant mixture was stirred at 25°C for 5 min. The phases were separated and the organic layer was washed (water, brine), dried ($MgSO_4$), and concentrated. Distillation (80–90°C/0.1 Torr) of the residual oil gave 732 mg (79%) of **21**, a colorless oil that displayed ir (neat): 1710, 1650, 1420, 1210 cm^{-1}; ^{1}H nmr (80 MHz) δ: 1.50–1.95 (m, 4H), 2.15–2.60 (m, 4H), 4.76 (s, 3H). Exact Mass calcd. for $C_9H_{11}F_3O_5S$: 288.0279; found: 288.0281.

Methyl 6-methyl-2-(trifluoromethanesulfonyloxy)-1-cyclohexene-carboxylate (22)

This material was prepared from 2-methoxycarbonyl-3-methylcyclohexanone (**19**) via a procedure identical with that described above. From 1.59 g (9.34 mmol) of **19** there was obtained 2.58 g (91%) of **22** (distillation temperature 90–100°C/0.1 Torr), a col-

orless oil that exhibited ir (neat): 1710, 1420, 1210 cm^{-1}; ^1H nmr (80 MHz) δ: 1.01 (d, 3H, J = 7 Hz), 1.40–2.00 (m, 4H), 2.25–2.50 (m, 2H), 2.90 (m, 1H), 3.80 (s, 3H). Exact Mass calcd. for $C_{10}H_{13}F_3O_5S$: 302.0437; found: 302.0437.

Methyl 2-(trifluoromethanesulfonyloxy)-1-cyclopentene-carboxylate (23)

This material was prepared from 2-methoxycarbonylcyclopentanone (**20**) via a procedure identical with that described above, except that the work-up procedure was changed as follows. The reaction mixture was diluted with Et_2O (10 mL) and then was filtered through a short column of Florisil (elution with Et_2O). The combined eluate was concentrated and the residue was distilled (70–80°C/0.1 Torr) to provide, from 0.5 g (3.52 mmol) of **20**, 714 mg (74%) of **23** as a colorless oil that displayed ir (neat): 1720, 1660, 1420, 1210 cm^{-1}; ^1H nmr (80 MHz) δ: 1.90–2.25 (m, 2H), 2.55–2.90 (m, 4H), 3.80 (s, 3H). Exact Mass calcd. for $C_8H_9F_3O_5S$: 274.0123; found: 274.0119.

Methyl 2-(trimethylstannyl)-1-cyclohexenecarboxylate (24)

To a cold (−20°C), stirred solution of lithium (phenylthio)-(trimethylstannyl)cuprate (12) (13.8 mmol) in 40 mL of dry THF was added a solution of the enol triflate **21** (2.65 g, 9.2 mmol) in 5 mL of dry THF. After the mixture had been stirred at −20°C for 1 h, dry HMPA (27.6 mmol) was added, the mixture was allowed to warm to 0°C, and was then stirred for an additional 1 h. Saturated aqueous ammonium chloride (25 mL) and a 3:7 mixture of Et_2O – petroleum ether (200 mL) were added and the mixture was stirred until the organic layer was colorless. The mixture was filtered to remove the solid material. The filtrate was washed (saturated aqueous copper(II) sulfate, water, brine), dried ($MgSO_4$), and concentrated. Flash chromatography (1:4 benzene – petroleum ether) of the residue on silica gel, followed by distillation (85–95°C/0.1 Torr) of the oil thus obtained, gave 2.1 g (75%) of **24** as a colorless oil that exhibited ir (neat): 1690, 1250, 770 cm^{-1}; ^1H nmr (270 MHz) δ: 0.16 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.65 (m, 4H), 2.42 (m, 4H), 3.77 (s, 3H). Exact Mass calcd. for $C_{10}H_{17}O_2Sn$ (M^+−Me): 289.0250; found: 289.0250.

Methyl 6-methyl-2-(trimethylstannyl)-1-cyclohexenecarboxylate (25)

This material was prepared from the enol triflate **22** via a procedure very similar to that described above. Flash chromatography (3:17 benzene – petroleum ether) of the crude product obtained from 2.58 g (8.55 mmol) of **22**, followed by distillation (90–100°C/0.1 Torr) of the oil thus obtained, provided 2.43 g (89%) of **25** as a colorless oil that exhibited ir (neat): 1690, 1250, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.16 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.10 (d, 3H, J = 7 Hz), 1.62 (m, 4H), 2.40 (m, 2H), 2.80 (m, 1H), 3.78 (m, 3H). Exact Mass calcd. for $C_{11}H_{19}O_2Sn$ (M^+−Me): 303.0407; found: 303.0406.

Methyl 2-(trimethylstannyl)-1-cyclopentenecarboxylate (26)

The enol triflate **23** (2.5 g, 9.12 mmol) was converted into **26** via a procedure very similar to that described above. Purification of the crude product by flash chromatography (3:7 benzene – petroleum ether) and distillation (70–80°C/0.1 Torr) afforded 2.05 g (78%) of **26** as a colorless oil that showed ir (neat): 1700, 1260, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.16 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.94 (m, 2H), 2.63 (m, 4H), 3.71 (s, 3H). Exact Mass calcd. for $C_9H_{15}O_2Sn$ (M^+−Me): 275.0094; found: 275.0092.

Methyl 1-(3-chloropropyl)-2-(trimethylstannyl)-2-cyclohexene-carboxylate (27)

To a cold (−48°C), stirred solution of LDA (3.7 mmol) and HMPA (7.4 mmol) in 7 mL of dry THF was added a solution of the ester **24** (746 mg, 2.48 mmol) in 3 mL of dry THF. After the mixture had been stirred at −48°C for 40 min, 1-chloro-3-iodopropane (1.01 g, 4.94 mmol) was added and the resultant solution was stirred at −48°C for 40 min. Saturated aqueous ammonium chloride (~1 mL) was added, the mixture was allowed to warm to room temperature, and was then diluted with 100 mL of Et_2O. The resultant mixture was washed (saturated aqueous copper(II) sulfate, water, brine), dried ($MgSO_4$), and concentrated. Flash chromatography (6:94 Et_2O – petroleum ether) of the residual material, followed by distillation (125–135°C/0.1 Torr) of the oil thus obtained, gave 728 mg (78%) of **27** as a colorless oil that displayed ir (neat): 1710, 1440, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.15 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 1.50–1.90 (m, 6H), 1.95–2.25 (m, 4H), 3.50 (m, 2H), 3.68 (s, 3H), 5.98 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{13}H_{22}{}^{35}ClO_2Sn$ (M^+−Me): 365.0331; found: 365.0321.

Methyl cis-1-(3-chloropropyl)-6-methyl-2-(trimethylstannyl)-2-cyclohexenecarboxylate (28)

This material was obtained from the ester **25** via a procedure very similar to that described above. Flash chromatography (2:3 benzene – petroleum ether) of the crude product derived from 500 mg (1.38 mmol) of **25**, followed by distillation (135–145°C/0.1 Torr) of the resultant oil, provided 551 mg (89%) of **28** as a colorless oil that showed ir (neat): 1710, 1210, 770 cm^{-1}; ^1H nmr (270 MHz) δ: 0.15 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 0.92 (d, 3H, J = 6 Hz), 3.53 (m, 2H), 3.69 (s, 3H), 6.03 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{14}H_{24}{}^{35}ClO_2Sn$ (M^+−Me): 379.0486; found: 379.0485.

Methyl 1-(4-bromobutyl)-2-(trimethylstannyl)-2-cyclopentene-carboxylate (35)

To a cold (−48°C), stirred solution of LDA (3.63 mmol) and HMPA (7.26 mmol) in 20 mL of dry THF was added a solution of the ester **26** (700 mg, 2.42 mmol) in 3 mL of dry THF. After the solution had been stirred at −48°C for 40 min, it was cooled to −78°C and 1,4-dibromobutane (7.85 g, 36.3 mmol) was added. The mixture was stirred at −78°C for 10 min and at −48°C for 40 min. Saturated aqueous ammonium chloride (~1 mL) was added and the mixture was allowed to warm to room temperature. Diethyl ether (150 mL) was added and the mixture was washed (saturated aqueous copper(II) sulfate, water, brine), dried ($MgSO_4$), and concentrated. Most of the excess 1,4-dibromobutane was removed by careful distillation (125–130°C/30 Torr), the residue was subjected to flash chromatography (7:93 Et_2O – petroleum ether), and the oil thus obtained was distilled (120–130°C/0.1 Torr) to give 792 mg (72%) of **35** as a colorless oil, which exhibited ir (neat): 1710, 1160, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.13 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.10–1.53 (m, 3H), 1.60–2.05 (m, 4H), 3.40 (t, 2H, J = 7 Hz), 3.68 (s, 3H), 6.00 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{13}H_{22}{}^{79}BrO_2Sn$ (M^+−Me): 408.9787; found: 408.9796.

Methyl 1-(5-bromopentyl)-2-(trimethylstannyl)-2-cyclopentene-carboxylate (45)

Alkylation of the ester **26** (300 mg, 1.04 mmol) with 1,5-dibromopentane was accomplished via a procedure very similar to that described above. Removal of excess 1,5-dibromopentane from the crude product by distillation (55–65°C/0.1 Torr), flash chromatography (7:93 Et_2O – petroleum ether) of the residual material, and distillation (150–160°C/0.1 Torr) of the oil thus obtained afforded 330 mg (72%) of **45** as a colorless oil that displayed ir (neat): 1710, 1220, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.14 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.00–1.65 (m, 5H), 1.66–2.15 (m, 4H), 2.17–2.70 (m, 3H), 3.40 (t, 2H, J = 7 Hz), 3.65 (s, 3H), 5.98 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{14}H_{24}{}^{79}BrO_2Sn$ (M^+−Me): 422.9982; found: 422.9980.

3-(3-Chloropropyl)-3-(hydroxymethyl)-2-(trimethylstannyl)-cyclohexene (29)

To a cold (−20°C), stirred solution of the ester **27** (500 mg, 1.32 mmol) in 10 mL of dry Et_2O was added slowly a solution of i-Bu_2AlH (3.3 mL, 3.3 mmol) in hexanes and the mixture was stirred at −20°C for 1 h. Saturated aqueous ammonium chloride (2 mL) and petroleum ether (30 mL) were added, the mixture was allowed to warm to room temperature, and stirring was continued until the organic phase was clear and precipitation of the aluminum salts was complete. The mixture was filtered through a short column of Florisil (elution with Et_2O). Concentration of the fil-

trate, followed by distillation (125–135°C/0.1 Torr) of the crude product, afforded 419 mg (90%) of the alcohol **29** as a colorless oil that showed ir (neat): 3350, 1030, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.17 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 1.30 (m, 1H, exchanged with D_2O), 1.45–1.75 (m, 8H), 1.80–2.20 (m, 2H), 3.30–3.62 (m, 4H), 6.08 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{12}H_{22}{}^{35}ClOSn$ (M^+−Me): 337.0382; found: 337.0382.

cis-*3-(3-Chloropropyl)-3-(hydroxymethyl)-4-methyl-2-(trimethylstannyl)cyclohexene (**30**)*

Reduction of the ester **28** was accomplished via a procedure very similar to that described above, except that the reaction was carried out at 0°C for 2 h. Distillation (125–135°C/0.1 Torr) of the crude product derived from 95 mg (0.24 mmol) of **28** produced 76 mg (86%) of **30** as a colorless oil that displayed ir (neat): 3400, 1030, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.19 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 1.00 (d, 3H, J = 6 Hz), 1.25 (m, 2H), 1.40–1.88 (m, 6H), 1.92–2.25 (m, 2H), 3.15–3.78 (m, 4H), 6.18 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{13}H_{24}{}^{35}ClOSn$ (M^+−Me): 351.0538; found: 351.0538.

*3-(4-Bromobutyl)-3-(hydroxymethyl)-2-(trimethylstannyl)-cyclopentene (**36**)*

Reduction of the ester **35** (792 mg, 1.87 mmol) as described above, followed by distillation (135–145°C/0.1 Torr) of the crude product, provided 792 mg (98%) of **36** as a colorless oil that exhibited ir (neat): 3400, 1020, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.17 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.13–1.50 (m, 5H), 1.60–2.05 (m, 4H), 2.30–2.55 (m, 2H), 3.30–3.55 (m, 4H), 6.03 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{12}H_{22}{}^{81}BrOSn$ (M^+−Me): 382.9857; found: 283.9851.

*3-(5-Bromopentyl)-3-(hydroxymethyl)-2-(trimethylstannyl)-cyclopentene (**46**)*

Distillation (150–160°C/0.1 Torr) of the crude product obtained by reduction (see procedure above) of the ester **45** (313 mg, 0.17 mmol) afforded 277 mg (94%) of the alcohol **46**, a colorless oil that exhibited ir (neat): 3400, 1020, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.13 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.03–1.60 (m, 7H), 1.61–2.08 (m, 4H), 2.23–2.63 (m, 2H), 3.25–3.55 (m, 4H), 6.00 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{13}H_{24}{}^{79}BrOSn$ (M^+−Me): 395.0007; found: 395.0004.

*3-(3-Chloropropyl)-3-(*tert*-butyldimethylsiloxymethyl)-2-(trimethylstannyl)cyclohexene (**31**)*

A solution of the alcohol **29** (419 mg, 1.19 mmol), imidazole (325 mg, 4.76 mmol), and *tert*-butyldimethylsilyl chloride (360 mg, 2.38 mmol) in 2 mL of dry *N*,*N*-dimethylformamide was stirred at room temperature for 17 h. The mixture was treated with Et_2O (35 mL) and the resultant solution was washed (water, brine), dried ($MgSO_4$), and concentrated. Distillation (135–145°C/0.1 Torr) of the crude product gave 520 mg (94%) of the silyl ether **31**, a colorless oil that displayed ir (neat): 1460, 1260, 1080, 850, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.06 (s, 6H), 0.15 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 0.92 (s, 9H), 1.35–1.75 (m, 8H), 1.90–2.23 (m, 2H), 3.30–3.63 (m, 4H), 5.96 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{18}H_{36}{}^{35}ClOSiSn$ (M^+−Me): 451.1246; found: 451.1247.

cis-*3-(3-Chloropropyl)-3-(*tert*-butyldimethylsiloxymethyl)-4-methyl-2-(trimethylstannyl)cyclohexene (**32**)*

Conversion of the alcohol **30** (400 mg, 1.09 mmol) into the ether **32** was accomplished via a procedure very similar to that described above. Distillation (135–145°C/0.1 Torr) of the crude product gave 495 mg (94%) of **32** as a colorless oil that showed ir (neat): 1460, 1260, 1090, 850, 770 cm^{-1}; ^1H nmr (400 MHz) δ: 0.03, 0.04 (s, s, 3H each), 0.14 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 0.90 (s, 9H), 0.96 (d, 3H, J = 6 Hz), 1.25 (m, 1H), 1.54 (m, 1H), 1.65 (m, 2H), 1.71–1.83 (m, 3H), 2.07 (m, 2H), 3.44 (s, 2H), 3.50 (m, 2H), 5.94 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{19}H_{38}{}^{35}ClOSiSn$ (M^+−Me): 465.1402; found: 465.1404.

*3-(4-Bromobutyl)-3-(*tert*-butyldimethylsiloxymethyl)-2-(trimethylstannyl)cyclopentene (**37**)*

A solution of the alcohol **36** (150 mg, 0.38 mmol), 2,6-lutidine (130 mg, 1.03 mmol), and *tert*-butyldimethylsilyl trifluoromethanesulfonate (152 mg, 0.76 mmol) in dry CH_2Cl_2 (1.0 mL) was stirred at 25°C for 30 min. Water (1 mL) and CH_2Cl_2 (25 mL) were added and the mixture was stirred for 5 min. This mixture was washed with water and brine, dried ($MgSO_4$), and concentrated. The residual material was passed through a short column of silica gel (elution with CH_2Cl_2). Removal of the solvent from the eluate, followed by distillation (125–135°C/0.1 Torr) of the residual oil, provided 178 mg (92%) of the silyl ether **37**, a colorless oil that displayed ir (neat): 1460, 1260, 850, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.03 (s, 6H), 0.13 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 0.88 (s, 9H), 1.15–2.03 (diffuse m, 8H), 2.20–2.53 (m, 2H), 3.25–3.55 (m, 4H), 5.88 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{18}H_{36}{}^{79}BrOSiSn$ (M^+−Me): 495.0740; found: 495.0751.

*3-(5-Bromopentyl)-3-(*tert*-butyldimethylsiloxymethyl)-2-(trimethylstannyl)cyclopentene (**47**)*

Conversion of the alcohol **46** (70 mg, 0.17 mmol) into the silyl ether **47** was carried out via a procedure very similar to that described above (preparation of **37**). Distillation (125–135°C/0.1 Torr) of the crude product gave 81 mg (90%) of **47**, a colorless oil that exhibited ir (neat): 1460, 1260, 850, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.05 (s, 6H), 0.15 (s, 9H, $^2J_{Sn-H}$ = 54 Hz) 0.91 (s, 9H), 1.05–2.13 (diffuse m, 10H), 2.18–2.55 (m, 2H), 3.30–3.58 (m, 4H), 5.90 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{19}H_{38}{}^{79}BrOSiSn$ (M^+−Me): 509.0897; found: 509.0901.

*3-(5-Bromopentyl)-3-(methoxymethyl)-2-(trimethylstannyl)-cyclopentene (**50**)*

To a stirred suspension (room temperature) of KH (80 mg, 2.0 mmol) in dry THF (1 mL) was added, sequentially, a solution of the alcohol **46** (328 mg, 0.8 mmol) in dry THF (2 mL) and dimethyl sulfate (544 mg, 4.0 mmol). After the mixture had been refluxed for 7.5 h, it was cooled and poured slowly into 10 mL of aqueous ammonium hydroxide (1.0 M). The resultant mixture was extracted with Et_2O (2 × 10 mL). The combined extracts were washed with water and brine, dried ($MgSO_4$), and concentrated. Flash chromatography (1:4 CH_2Cl_2 – petroleum ether) of the crude product, followed by distillation (125–135°C/0.1 Torr) of the material thus obtained, produced 283 mg (84%) of the ether **50**, a colorless oil that showed ir (neat): 1450, 1100, 770 cm^{-1}; ^1H nmr (80 MHz) δ: 0.10 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.13–2.05 (diffuse m, 10H), 2.23–2.50 (m, 2H), 3.00–3.50 (m, 4H), 3.18 (s, 3H), 5.88 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{14}H_{26}{}^{79}BrOSn$ (M^+−Me): 409.0162; found: 409.0157.

*General procedure for the transmetallation–cyclization of the vinylstannane halides **31**, **32**, **36**, **47**, and **50***

To a cold (−20°C), stirred solution of the vinylstannane (1 equiv.) in the specified volume of dry THF was added, sequentially, HMPA (3 equiv.) and a solution of MeLi (1.5 equiv.) in Et_2O. After the mixture had been stirred at −20°C for 30 min, saturated aqueous NH_4Cl (~1 mL) was added and the resultant mixture was allowed to warm to room temperature. Diethyl ether was added and the mixture was washed sequentially with water, saturated aqueous $CuSO_4$, and water. The organic solution was dried ($MgSO_4$) and concentrated. The crude product was purified by column chromatography and (or) by distillation.

*6-(*tert*-Butyldimethylsiloxymethyl)bicyclo[4.3.0]non-1-ene (**33**)*

Distillation (85–95°C/0.1 Torr) of the crude product derived from transmetallation–cyclization of the vinylstannane chloride **31** (50 mg, 0.11 mmol; 1 mL of dry THF) provided 26.5 mg (92%) of the bicyclic alkene **33**, a colorless oil that showed ir (neat): 1460, 1250, 1090, 1070, 850 cm^{-1}; ^1H nmr (80 MHz) δ: 0.05 (s, 6H), 0.93 (s, 9H), 0.70–1.30 (m, 2H), 1.43–1.88 (m, 4H), 1.88–2.45 (m, 6H), 3.25, 3.44 (d, d, 1H each, J = 10 Hz in each case), 5.45 (m, 1H). Exact Mass calcd. for $C_{12}H_{21}OSi$ (M^+−*t*-Bu): 209.1362; found: 209.1360.

*cis-5-Methyl-6-(*tert*-butyldimethylsiloxymethyl)bicyclo[4.3.0]non-1-ene (**34**)*

Distillation (85–95°C/0.1 Torr) of the crude product obtained from transmetallation–cyclization of the vinylstannane chloride **32** (50 mg, 0.10 mmol; 1 mL of dry THF) gave 28 mg (94%) of the bicyclic alkene **34**, a colorless oil that exhibited ir (neat): 1460, 1250, 1090, 840 cm^{-1}; ^1H nmr (400 MHz) δ: 0.00 (s, 6H), 0.87 (s, 9H), 0.99 (d, 3H, J = 6 Hz), 1.13 (m, 1H), 1.31 (m, 1H), 1.45 (m, 1H), 1.55–1.70 (m, 3H), 1.98–2.13 (m, 3H), 2.20 (m, 1H), 2.39 (m, 1H), 3.31, 3.47 (d, d, 1H each, J = 10 Hz in each case), 5.40 (m, 1H). Exact Mass calcd. for $C_{13}H_{23}OSi$ (M^+-t-Bu): 223.1513; found: 223.1522.

*1-(*tert*-Butyldimethylsiloxymethyl)bicyclo[4.3.0]non-6-ene (**38**) and 3-(3-butenyl)-3-(*tert*-butyldimethylsiloxymethyl)-cyclopentene (**39**)*

The crude product obtained from transmetallation–cyclization of the vinylstannane bromide **37** (195 mg, 0.38 mmol; 3 mL of dry THF) consisted of two compounds Column chromatography of this mixture on silver nitrate impregnated silica gel (1:4 $AgNO_3$ – silica gel, elution with 1:19 Et_2O – petroleum ether), followed by distillation (90–100°C/0.1 Torr) of each of the oils thus obtained, gave 64.4 mg (61%) of the bicyclic alkene **38** (the chromatographically less polar product and 7.7 mg (7%) of the diene **39**.

Compound **38** exhibited ir (neat): 1460, 1260, 1100, 850 cm^{-1}; ^1H nmr (80 MHz) δ: 0.05 (s, 6H), 0.92 (s, 9H), 1.00–1.68 (m, 6H), 1.95–2.45 (m, 6H), 3.35, 3.60 (d, d, 1H each, J = 10 Hz in each case), 5.30 (m, 1H). Exact Mass calcd. for $C_{12}H_{21}OSi$ (M^+-t-Bu): 209.1362; found: 209.1360.

The diene **39** displayed ir (neat): 1630, 1250, 1100, 840 cm^{-1}; ^1H nmr (80 MHz) δ: 0.00 (s, 6H), 0.87 (s, 9H), 1.36–1.68 (m, 4H), 1.80–2.50 (diffuse m, 4H), 3.38 (s, 2H), 4.80–5.15 (m, 2H), 5.38–5.60 (m, 1H), 5.60–5.90 (m, 2H). Exact Mass calcd. for $C_{12}H_{21}OSi$ (M^+-t-Bu): 209.1362; found: 209.1361.

*1-(*tert*-Butyldimethylsiloxymethyl)bicyclo[5.3.0]dec-7-ene (**48**) and 2-(*tert*-butyldimethylsilyl)-3-(5-bromopentyl)-3-(hydroxymethyl)cyclopentene (**49**)*

The mixture of two products obtained from transmetallation of the vinylstannane bromide **47** (76 mg, 0.15 mmol; 2 mL of dry THF) was subjected to column chromatography on silica gel. Sequential elution with heptane and 3:7 Et_2O – petroleum ether, followed by distillation (95–105°C/0.1 Torr; 110–120°C/0.1 Torr) of the two oils thus obtained, gave 14 mg (35%) of the bicyclic alkene **48** and 9 mg (17%) of the alkene alcohol **49**, respectively.

Compound **48** displayed ir (neat): 1450, 1250, 1100, 850 cm^{-1}; ^1H nmr (80 MHz) δ: 0.02 (s, 6H), 0.91 (s, 9H), 1.00–2.60 (diffuse m, 14H), 3.38 (br s, 2H), 5.40 (m, 1H). Exact Mass calcd. for $C_{13}H_{23}OSi$ (M^+-t-Bu): 223.1518; found: 223.1524.

Compound **49** exhibited ir (neat): 3370, 1460, 1260, 1020, 840 cm^{-1}; ^1H nmr (80 MHz) δ: 0.13 (s, 6H), 0.93 (s, 9H), 1.10–2.10 (diffuse m, 11H), 2.20–2.60 (m, 2H), 3.25–3.60 (m, 4H), 6.28 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{13}H_{24}{}^{79}BrOSi$ (M^+-t-Bu): 303.0780; found: 303.0783.

*1-(Methoxymethyl)bicyclo[5.3.0]dec-7-ene (**51**)*

The crude product derived from transmetallation–cyclization of the vinylstannane bromide **50** (61 mg, 0.14 mmol; 2 mL of dry THF) was subjected to flash chromatography on silica gel (elution with 1:6 CH_2Cl_2 – petroleum ether). Distillation (105–110°C/0.1 Torr) of the oil thus obtained provided 14 mg (54%) of the bicyclic alkene **51**, a colorless oil that showed ir (neat): 1440, 1110 cm^{-1}; ^1H nmr (80 MHz) δ: 1.00–2.51 (diffuse m, 14H), 3.15 (br s, 2H), 3.30 (s, 3H), 5.43 (m, 1H). Exact Mass calcd. for $C_{12}H_{20}O$: 180:1514; found 180.1517.

*1,3-Dichloro-1-(2-trimethylsilylethoxy)propane (**55**)*

Dry hydrogen chloride was passed into a well-stirred, cold (−10°C) mixture of 2-(trimethylsilyl)ethanol (9.3 g, 78.8 mmol) and acrolein (4.4 g, 78.8 mmol) until the required amount (5.8 g, 158 mmol) had been added. The mixture was diluted with dry CH_2Cl_2 (35 mL) and was then dried ($MgSO_4$). Removal of the solvent, followed by distillation (90–100°C/0.1 Torr) of the resultant oil, gave 14.1 g (78%) of **55** as a colorless oil, which exhibited ir (neat): 1250, 1120, 840 cm^{-1}; ^1H nmr (80 MHz) δ: 0.06 (s, 9H), 1.00 (m, 2H), 2.45 (m, 2H), 3.50–4.10 (m, 4H), 5.80 (t, 1H, J = 5 Hz). Exact Mass calcd. for $C_6H_{14}{}^{35}ClOSi$ ($M^+-CH_2CH_2{}^{35}Cl$): 165.0502; found: 165.0504.

*Preparation of compounds **56** and **67***

To a cold (0°C), stirred solution of LDA (1.04 mmol) in 11 mL of dry THF was added 2.08 mmol of HMPA and the solution was cooled to −48°C. A solution of the enoate **25** (220 mg, 0.69 mmol) in 2 mL of dry THF was added. After the solution had been stirred at −48°C for 40 min, it was cooled to −78°C and the dichloro ether **55** (318 mg, 1.39 mmol) was added. The mixture was stirred at −78°C for 40 min. Saturated aqueous NH_4Cl (2 mL) was added, the mixture was allowed to warm to 25°C, was diluted with water (35 mL), and was then extracted with Et_2O (3 × 35 mL). The combined extracts were washed successively with saturated aqueous $CuSO_4$, water, and brine, and were then dried ($MgSO_4$) and concentrated. Analysis (tlc) of the crude product indicated the presence of the epimeric products **56** (major) and **57** (minor), along with a number of minor components. Flash chromatography (1:9 Et_2O – petroleum ether) of the mixture provided two main fractions. Distillation (150–160°C/0.1 Torr) of the more polar fraction (one spot by tlc) afforded 145 mg (41%) of the ester **56**, a colorless oil that displayed ir (neat): 1725, 1250, 1070, 840, 770 cm^{-1}; ^1H nmr (400 MHz) δ: 0.00 (s, 9H), 0.12 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 0.90 (dd, 2H, J = 9.5, 8.0 Hz), 0.96 (d, 3H, J = 7 Hz), 1.60 (m, 1H), 1.72 (m, 1H), 1.90–2.16 (m, 5H), 3.48 (m, 1H), 3.56–3.76 (m, 3H), 3.66 (s, 3H), 3.86 (dd, 1H, J = 10, 3 Hz), 5.97 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{19}H_{36}{}^{35}ClO_3SiSn$ (M^+ − Me): 495.1144; found: 495.1138.

Analysis (tlc) of the less polar fraction indicated that it contained primarily the ester **57**, along with minor side products. Distillation (150–160°C/0.1 Torr) of this material provided 54 mg of a colorless oil. Attempts to obtain, efficiently, pure **57** from this mixture were fruitless. Therefore, a solution of this material (54 mg) in a 2 mL of dry Et_2O was treated with a solution of i-Bu_2AlH in hexanes (0.63 mL, 0.63 mmol) and the solution was stirred at 25°C for 3 h. Saturated aqueous NH_4Cl (0.5 mL) and petroleum ether (7 mL) were added; the mixture was stirred until precipitation of the aluminum salts was complete and was then filtered through a plug of sand. The filtrate was dried ($MgSO_4$) and concentrated. Distillation (150–160°C/0.1 Torr) of the remaining material gave 36.5 mg of a colorless oil. A solution of this material in 1 mL of dry CH_2Cl_2 at 25°C was treated with 2,6-lutidine (24 mg, 0.22 mmol) and t-$BuMe_2SiOSO_2CF_3$ (37 mg, 0.14 mmol) and the mixture was stirred for 30 min. Saturated aqueous $NaHCO_3$ (0.5 mL) and Et_2O (12 mL) were added. The mixture was washed with water and brine and was then dried ($MgSO_4$) and concentrated. Flash chromatography (petroleum ether), followed by distillation (160–170°C/0.1 Torr) of the material thus obtained, provided 39 mg (9% overall yield from the enone **25**) of compound **67**, a colorless oil that showed ir (neat): 1470, 1260, 1080, 850, 770 cm^{-1}; ^1H nmr (400 MHz) δ: 0.02 (s, 9H), 0.05 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 0.06, 0.08 (s, s, 3H each), 0.91 (s, 9H), 1.02 (d, 3H, J = 7 Hz), 0.91–1.09 (m, 2H), 1.48 (m, 1H), 1.56–1.70 (m, 2H), 1.72–1.81 (m, 1H), 1.92–2.01 (m, 1H), 2.11 (m, 2H), 3.55 (m, 1H), 3.58 (s, 2H), 3.67 (m, 2H), 3.75–3.85 (m, 1H), 4.01 (dd, 1H, J = 9.5, 3.5 Hz), 6.04 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{24}H_{50}{}^{35}ClO_2Si_2Sn$ (M^+ − Me): 581.2060; found: 581.2065.

*Preparation of the silyl ether **59***

To a stirred solution of the ester **56** (145 mg, 0.28 mmol) in 3 mL of dry Et_2O at 25°C was added a solution of i-Bu_2AlH in hexanes (1.7 mL, 1.7 mmol). After the mixture had been stirred for 3 h, saturated aqueous NH_4Cl (1 mL) and petroleum ether (10 mL) were added and stirring was continued until precipitation of the aluminum salts was complete. The mixture was filtered

For personal use only.

through a plug of sand and the filtrate was dried ($MgSO_4$) and concentrated. Distillation (150–160°C/0.1 Torr) of the remaining liquid gave 109 mg (81%) of the alcohol **58**, a colorless oil that exhibited one spot by tlc analysis and exhibited the expected spectral data.

A stirred solution of this material (109 mg) in 1.5 mL of dry CH_2Cl_2 at 25°C was treated with 2,6-lutidine (69 mg, 0.54 mmol) and *t*-$BuMe_2SiOSO_2CF_3$ (108 mg, 0.41 mmol). After the solution had been stirred for 30 min, saturated aqueous $NaHCO_3$ (0.5 mL) and Et_2O (12 mL) were added and the resultant mixture was washed with water and brine and was then dried ($MgSO_4$) and concentrated. Flash chromatography (1:19 CH_2Cl_2 – petroleum ether), followed by distillation (160–170°C/0.1 Torr) of the resultant liquid, afforded 115 mg (68% from the ester **56**) of the silyl ether **59**, a colorless oil that exhibited ir (neat): 1250, 1070, 840, 770, cm^{-1}; ^1H nmr (400 MHz) δ: 0.02 (s, 9H), 0.04, 0.06 (s, s, 3H each), 0.16 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 0.89 (s, 9H), 0.90–1.00 (m, 2H) 1.04 (d, 3H, *J* = 7 Hz), 1.60 (m, 2H), 1.92 (m, 1H), 1.99 (m, 2H), 2.06 (m, 2H), 3.39 (d, 1H, *J* = 9.5 Hz), 3.43–3.64 (m, 4H), 3.68 (m, 1H), 4.03 (d, 1H, *J* = 9.5 Hz), 5.92 (t, 1H, *J* = 4 Hz). Exact Mass calcd. for $C_{24}H_{50}{}^{35}ClO_2Si_2Sn$ (M^+-Me): 581.2060; found: 581.2075.

*Preparation of the bicyclic diethers **60** and **68***

These substances were derived from transmetallation–cyclization of the vinylstannane halides **59** and **67**, via a procedure identical with that described earlier (vide supra).

Flash chromatography (1:9 CH_2Cl_2 – petroleum ether) of the crude product derived from transmetallation–cyclization of **59** (3.14 g, 5.73 mmol; 20 mL of dry THF), followed by distillation (130–140°C/0.1 Torr) of the liquid thus obtained, provided 1.94 g (86%) of the bicyclic diether **60**, a colorless oil that displayed ir (neat): 1460, 1250, 1090, 850 cm^{-1}; ^1H nmr (400 MHz) δ: −0.01 (s, 9H), 0.01, 0.02 (s, s, 3H each), 0.89 (s, 9H), 0.88–0.95 (m, 2H), 0.98 (d, 3H, *J* = 7 Hz), 1.52 (m, 1H), 1.79 (m, 2H), 1.92–2.13 (m, 4H), 2.36 (m, 2H), 3.20, 3.57 (d, d, 1H each, *J* = 10 Hz in each case), 3.37, 3.61 (m, m, 1H each), 3.94 (d, 1H, *J* = 4 Hz), 5.47 (m, 1H). Exact Mass calcd. for $C_{18}H_{35}O_2Si_2$ (M^+-t-Bu): 339.2176; found: 339.2169.

Flash chromatography (petroleum ether) of the crude product derived from transmetallation–cyclization of **67** (1.20 g, 2.02 mmol; 10 mL of dry THF), followed by distillation (130–140°C/0.1 Torr) of the liquid thus obtained, gave 623 mg (78%) of the bicyclic diether **68**, a colorless oil that showed ir (neat): 1460, 1250, 1100, 860, 780 cm^{-1}; ^1H nmr (400 MHz) δ: −0.01, 0.01 (s, s, 3H each), 0.02 (s, 9H), 0.86 (s, 9H), 0.90 (m, 2H), 1.07 (d, 3H, *J* = 7 Hz), 1.38 (m, 2H), 1.56–1.67 (m, 1H), 1.78–1.91 (m, 1H), 2.02 (m, 3H), 2.06–2.17 (m, 1H), 2.45–2.56 (m, 1H), 3.31–3.45 (m, 2H), 3.57 (m, 1H), 3.73, 3.75 (d, d, 1H each, *J* = 10.5 Hz in each case), 5.47 (m, 1H). Exact Mass calcd. for $C_{18}H_{35}O_2Si_2$ (M^+-t-Bu): 339.2176; found: 319.2188.

*Preparation of the alcohol ethers **61** and **69***

A solution of *n*-Bu_4NF (1.93 g, 7.37 mmol) and the diether **60** (1.95 g, 4.91 mmol) in 11 mL of dry THF was stirred at room temperature for 18 h. The mixture was diluted with Et_2O (50 mL), was washed with water and brine, and was then dried ($MgSO_4$) and concentrated. Removal of volatile material (0.1 Torr, room temperature), followed by distillation (105–115°C/0.1 Torr) of the remaining liquid, afforded 1.34 g (96%) of the alcohol **61**, a colorless oil that exhibited ir (neat): 3400, 1250, 1100, 850 cm^{-1}; ^1H nmr (400 MHz) δ: 0.00 (s, 9H), 0.90 (m, 2H), 1.00 (d, 3H, *J* = 7 Hz), 1.17 (dd, 1H, *J* = 8, 4 Hz, exchanged with D_2O), 1.55 (m, 1H), 1.65 (m, 1H), 1.76–1.96 (m, 2H), 1.98–2.17 (m, 3H), 2.40 (m, 2H), 3.38 (m, 2H, simplified on addition of D_2O), 3.50 (dd, 1H, *J* = 12, 8 Hz, collapsed to a d (*J* = 12 Hz) on addition of D_2O), 3.62 (m, 1H), 3.67 (d, 1H, *J* = 4 Hz), 5.68 (m, 1H). Exact Mass calcd. for $C_{16}H_{28}OSi$ (M^+-H_2O): 264.1910; found: 264.1910.

In very similar fashion, distillation (105–115°C/0.1 Torr) of the crude product obtained from the diether **68** (623 mg, 1.57 mmol; 5 mL of dry THF) gave 381 mg (86%) of the alcohol **69**, a colorless oil that displayed ir (neat): 3450, 1250, 840 cm^{-1}; ^1H nmr (400 MHz) δ: 0.03 (s, 9H), 0.97 (m, 2H), 1.25 (d, 3H, *J* = 7 Hz), 1.41–1.57 (m, 2H), 1.63 (m, 1H), 1.79 (m, 1H), 2.01–2.21 (m, 4H), 2.44–2.58 (m, 1H), 3.25 (dd, 1H, *J* = 8, 4 Hz, exchanged with D_2O), 3.45 (m, 1H), 3.65 (m, 2H), 3.72 (dd, 1H, *J* = 12, 8 Hz, collapsed to a d (*J* = 12 Hz) on addition of D_2O), 3.79 (dd, 1H, *J* = 12, 4 Hz, collapsed to a d (*J* = 12 Hz) on addition of D_2O), 5.45 (m, 1H). Exact Mass calcd. for $C_{16}H_{28}OSi$ (M^+-H_2O): 264.1910; found: 264.1920.

*Preparation of the aldehydes **62** and **70***

To a stirred solution of the alcohol **61** (330 mg, 1.06 mmol) in 18 mL of dry CH_2Cl_2 was added solid pyridinium chlorochromate (573 mg, 2.66 mmol). The resultant mixture was stirred at 25°C for 1 h. Dry Et_2O (70 mL) was added; the mixture was stirred for 15 min and was then filtered through a short column of neutral alumina (elution with Et_2O). The filtrate was concentrated and the crude product was passed through a short column of silica gel (elution with 1:1 CH_2Cl_2 – petroleum ether). Concentration of the eluate and distillation (95–105°C/0.1 Torr) of the remaining liquid gave 263 mg (88%) of the aldehyde **62**, a colorless oil that exhibited ir (neat): 1710, 1250, 840 cm^{-1}; ^1H nmr (300 MHz) δ: 0.00 (s, 9H), 0.91 (m, 2H), 0.99 (d, 3H, *J* = 7 Hz), 1.62–1.82 (m, 4H), 2.10–2.30 (m, 4H), 2.30–2.45 (m, 1H), 3.40, 3.64 (m, m, 1H each), 4.18 (d, 1H, *J* = 4.5 Hz), 5.72 (m, 1H), 9.76 (s, 1H).

Similarly, distillation (95–100°C/0.1 Torr) of the crude product derived from oxidation of the alcohol **69** (200 mg, 0.71 mmol) with pyridinium chlorochromate afforded 166 mg (83%) of the aldehyde **70**, a colorless oil that exhibited ir (neat): 1710, 1250, 860 cm^{-1}; ^1H nmr (270 MHz) δ: 0,00 (s, 9H), 0.93 (m, 2H), 1.31 (d, 3H, *J* = 7 Hz), 1.38–1.68 (m, 4H), 1.95–2.24 (m, 4H), 2.36–2.54 (m, 1H), 3.49 (m, 1H), 3.57–3.72 (m, 2H), 5.59 (m, 2H), 9.92 (s, 1H).

*Preparation of the alkene ethers **63** and **71***

A stirred solution of the aldehyde **62** (260 mg, 0.03 mmol) and anhydrous hydrazine (600 mg, 18.6 mmol) in 3 mL of MeOH was refluxed for 1 h. The solvent was removed under reduced pressure and the residual material was diluted with benzene. The benzene was removed under reduced pressure. This procedure was repeated. The residual material was placed under vacuum (0.1 Torr, 25°C) to remove last traces of solvent. The resultant viscous oil was dissolved in 2 mL of dry diethylene glycol containing 150 mg (2.78 mmol) of dry sodium methoxide and the mixture was heated at 210°C for 1.8 h. After the mixture had been cooled to 25°C, it was diluted with water (25 mL) and was then extracted with Et_2O (3 × 20 mL). The combined extracts were washed with water and brine, and were then dried ($MgSO_4$) and concentrated. Flash chromatography (1:4 CH_2Cl_2 – petroleum ether) of the crude product and distillation (90–100°C/0.1 Torr) of the liquid thus obtained provided 210 mg (84%) of the alkene ether **63**, a colorless oil that displayed ir (neat): 1250, 1100, 840 cm^{-1}; ^1H nmr (400 MHz) δ: −0.01 (s, 9H), 0.78 (s, 3H), 0.87 (d, 3H, *J* = 7 Hz), 0.90 (m, 2H), 1.35–1.50 (m, 2H), 1.71–1.91 (m, 2H), 1.93–2.15 (m, 3H), 2.25–2.50 (m, 2H), 3.35, 3.60 (m, m, 1H each), 3.47 (d, 1H, *J* = 4 Hz), 5.38 (m, 1H). Exact Mass calcd. for $C_{16}H_{30}OSi$: 266.2066; found: 266.2062.

In a very similar fashion, flash chromatography (1:9 CH_2Cl_2 – petroleum ether) of the crude product obtained from the aldehyde **70** (159 mg, 0.57 mmol), followed by distillation (105–110°C/0.1 Torr) of the liquid thus obtained, produced 118 mg (78%) of the alkene ether **71**, a colorless oil that showed ir (neat): 1250, 1110, 840 cm^{-1}; ^1H nmr (270 MHz) δ: 0.00 (s, 9H), 0.82 (s, 3H), 0.90 (m, 2H), 0.99 (d, 3H, *J* = 7 Hz), 1.37 (m, 3H), 1.43–1.60 (m, 1H), 1.90–2.13 (m, 4H), 2.35–2.52 (m, 1H), 3.25 (t, 1H, *J* = 9 Hz), 3.42, 3.57 (m, m, 1H each), 5.28 (m, 1H). Exact Mass calcd. for $C_{16}H_{30}OSi$: 266.2066; found: 266.2068.

*Preparation of the alkene alcohols **64** and **72***

To a stirred suspension of dry LiF (360 mg, 13.8 mmol) in 7 mL of dry MeCN was added $BF_3 \cdot Et_2O$ (1.96 g, 13.8 mmol). The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

mixture was stirred at 25°C for 5 min and then a solution of the alkene ether **63** (368 mg, 1.38 mmol) in 2 mL of dry CH_2Cl_2 was added. Stirring (25°C) was continued for 2.5 h. Saturated aqueous $NaHCO_3$ (2 mL) and water (25 mL) were added and the mixture was extracted with Et_2O (3 × 35 mL). The combined extracts were washed with water and brine and were then dried ($MgSO_4$) and concentrated. Distillation (85–95°C/0.1 Torr) of the residual liquid provided 200 mg (87%) of the alcohol **64**, a colorless oil that displayed ir (neat): 3350, 1460, 1070, 970 cm^{-1}; ^1H nmr (400 MHz) δ: 0.80 (s, 3H), 0.93 (d, 3H, J = 7 Hz), 1.26 (m, 1H), 1.40–1.56 (m, 2H), 1.64 (m, 1H), 1.85 (m, 1H), 1.95–2.16 (m, 3H), 2.31–2.53 (m, 2H), 3.92 (d, 1H, J = 4 Hz), 5.49 (m, 1H). Exact Mass calcd. for $C_{11}H_{18}O$: 166.1357; found: 166.1356.

Similarly, cleavage of the ether **71** (116 mg, 0.44 mmol) with $LiF–BF_3 \cdot Et_2O$, followed by flash chromatography (3:7 Et_2O – petroleum ether) and distillation (95–100°C/0.1 Torr) of the crude product, produced 68 mg (93%) of the alcohol **72**. This colorless oil exhibited ir (neat): 3350, 1460, 1430, 1080 cm^{-1}; ^1H nmr (270 MHz) δ: 0.86 (s, 3H), 1.02 (d, 3H, J = 7 Hz), 1.33–1.50 (m, 4H), 1.55 (m, 1H), 1.95–2.20 (m, 4H), 2.36–2.52 (m, 1H), 3.73 (t, 1H, J = 9 Hz), 5.33 (m, 1H). Exact Mass calcd. for $C_{11}H_{18}O$: 166.1357; found: 166.1361.

*Preparation of the ketone **65** from the alcohols **64** and **72***

A mixture of the alcohol **64** (125 mg, 0.75 mmol) and pyridinium chlorochromate (325 mg, 1.51 mmol) in 7 mL of dry CH_2Cl_2 was stirred at 25°C for 1 h. Dry Et_2O was added and stirring was continued for 15 min. The mixture was filtered through a plug of neutral alumina (elution with Et_2O) and the filtrate was concentrated. Flash chromatography (1:2 CH_2Cl_2 – petroleum ether) of the residual material, followed by distillation (85–90°C/0.1 Torr) of the liquid thus obtained, provided 102 mg (83%) of the ketone **65**, a colorless oil that exhibited ir (neat): 1735, 1460, 1030 cm^{-1}; ^1H nmr (270 MHz) δ: 1.02 (s, 3H), 1.14 (d, 3H, J = 7 Hz), 1.35–1.64 (m, 3H), 2.05 (m, 2H), 2.10–2.25 (m, 1H), 2.40–2.52 (m, 2H), 2.56–2.71 (m, 1H), 5.55 (m, 1H). Exact Mass calcd. for $C_{11}H_{16}O$: 164.1200; found: 164.1200.

Oxidation of the alcohol **72** (65 mg, 0.39 mmol) via a procedure identical with that described above gave 51 mg (80%) of the ketone **65**, which displayed spectra identical with those summarized above.

*(±)-Chiloscyphone (**16**) and (±)-6-*epi*-chiloscyphone(**17**)*

To a stirred mixture of $(Ph_3PCH_2OMe)Cl$ (732 mg, 2.14 mmol) and dry benzene (4 mL) was added a solution of $NaOC(Et)Me_2$ in benzene (1.78 mL, 2.14 mmol) and the resultant dark-red solution was stirred at 25°C for 10 min. A solution of the ketone **65** (50 mg, 0.31 mmol) in 1 mL of dry benzene was added and the mixture was stirred at 25°C for 1.5 h. Water (0.5 mL) was added dropwise and the resultant yellow suspension was filtered through a plug of silica gel (elution with Et_2O). The filtrate was concentrated and a solution of the residue in THF (2.5 mL) containing 1 M hydrochloric acid (1 mL) was stirred at 25°C for 34 h. Et_2O (25 mL) was added, and the mixture was washed sequentially with saturated aqueous $NaHCO_3$, water, and brine and was then dried ($MgSO_4$) and concentrated. Flash chromatography (1:2 CH_2Cl_2 – petroleum ether) of the residual material produced 24 mg (43%) of a mixture of the aldehydes **78** and **79** (ratio 1:4, analysis by glc). A solution of this mixture in dry MeOH (1 mL) containing 21 mg (0.39 mmol) of NaOMe was stirred at 25°C for 1 h. Analysis (glc) of an aliquot showed that the aldehydes **78** and **79** were present in a ratio of 1:1. Addition of additional amounts of NaOMe and use of longer reaction times did not alter this ratio. Saturated aqueous NH_4Cl (10 mL) was added and the mixture was extracted with Et_2O (3 × 8 mL). The combined extracts were washed (water and brine), dried, and concentrated. The crude product was filtered through a short column of silica gel (elution with 1:2 CH_2Cl_2 – petroleum ether), thus affording 21 mg of a 1:1 mixture of the aldehydes **78** and **79** (ir (neat): 2710, 1720, 1460, 1380 cm^{-1}. Exact Mass calcd. for $C_{12}H_{18}O$: 178.1358; found: 178.1361).

A solution of this mixture and isopropenylmagnesium bromide (0.48 mmol) in 1.3 mL of dry THF was stirred at 25°C for 1 h. Saturated aqueous NH_4Cl (1.5 mL) and water (10 mL) were added and the mixture was extracted with Et_2O (3 × 10 mL). The combined extracts were washed (water, brine), dried ($MgSO_4$), and concentrated. Flash chromatography (1:9 Et_2O – petroleum ether) of the residual material (1:1 mixture of the alcohols **80** and **81**, analysis by glc) gave 8.7 mg (13% from the ketone **65**) of the less polar alcohol **80** and 11.1 mg (17% from the ketone **65**) of the more polar alcohol **81**. The ir spectrum of each of these alcohols showed absorptions at 3450, 1640, and 900 cm^{-1}.

A mixture of the less polar alcohol **80** (8.7 mg), dry CH_2Cl_2 (1 mL), and pyridinium chlorochromate (17 mg) was stirred at 25°C for 2.25 h. Dry Et_2O (7 mL) was added, the mixture was stirred for 15 min, and was then filtered through a plug of neutral alumina (elution Et_2O). The filtrate was concentrated. Column chromatography (1:4 CH_2Cl_2 – petroleum ether) of the crude product, followed by distillation (85–95°C/0.1 Torr) of the liquid thus obtained, provided 5 mg (7.5% from the ketone **65**) of (±)-chiloscyphone (**16**), a colorless oil that exhibited ir (neat): 1670, 1630, 1450, 1370, 1080 cm^{-1}; ^1H nmr (400 MHz) δ: 0.85 (d, 3H, J = 6 Hz), 0.97 (s, 3H), 1.33–1.46 (m, 3H), 1.64–1.76 (m, 1H), 1.85 (br s, 3H), 1.90–2.02 (m, 2H), 2.02–2.15 (m, 1H), 2.53 (m, 2H), 3.58 (dd, 1H, J = 8, 1.3 Hz), 5.41 (m, 1H), 5.73, 5.94 (s, s, 1H each). Exact Mass calcd. for $C_{15}H_{22}O$: 218.1670; found: 218.1671.

Oxidation of the more polar alcohol **81** (11.1 mg) was effected via a procedure identical with that described above. Column chromatography (1:19 Et_2O – petroleum ether) of the crude product and distillation (80–90°C/0.1 Torr) of the liquid thus obtained provided 4 mg (6% from the ketone **65**) of (±)-6-*epi*-chiloscyphone (**17**), a colorless oil that displayed ir (neat): 1670, 1630, 1460, 1390, 1090 cm^{-1}; ^1H nmr (270 MHz) δ: 0.72 (d, 3H, J = 6 Hz), 0.90 (s, 3H), 1.43 (m, 3H), 1.70–1.85 (m, 1H), 1.91 (br s, 3H), 1.95–2.08 (m, 3H), 2.12–2.32 (m, 1H), 2.48–2.65 (m, 1H), 3.18 (dd, 1H, J = 12, 8 Hz), 5.30 (m, 1H), 5.72, 5.97 (s, s, 1H each). Exact Mass calcd. for $C_{15}H_{22}O$: 218.1670; found: 218.1670.

Tandem Wessely oxidation and intramolecular Diels–Alder reactions. IV. The synthesis of (±)-coronafacic acid[1]

PETER YATES,[2] N.K. BHAMARE, THIERRY GRANGER, AND T.S. MACAS
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received August 26, 1992[3]

PETER YATES, N.K. BHAMARE, THIERRY GRANGER, and T.S. MACAS. Can. J. Chem. **71**, 995 (1993).

Ethyl *E*-5-(4-ethyl-2-hydroxyphenyl)-2-pentenoate (**7**), prepared in four steps from *m*-ethylphenol (**9**), was converted via Wessely oxidation with lead tetraacetate followed by intramolecular Diels–Alder reaction in boiling xylene to ethyl 1-acetyloxy-6-ethyl-2,3,3a,4,5,7a-hexahydro-8-oxo-1,5-methano-1*H*-indene-*anti*-4-carboxylate (**16**). Hydrogenation of **16** followed by mild hydrolysis gave ethyl 6-ethyloctahydro-1-hydroxy-8-oxo-1,5-methano-1*H*-indene-*anti*-4-carboxylate (**24**), which on oxidation with periodate gave 4-(ethoxycarbonyl)-6-ethyloctahydro-1-oxo-1*H*-indene-5-carboxylic acid (**26**). Oxidative decarboxylation of this gave a mixture of ethyl 6-ethyl-2,3,3a,6,7,7a-hexahydro-1-oxo-1*H*-indene-4-carboxylate (**31**) and ethyl 6-ethyl-2,3,3a,4,7,7a-hexahydro-1-oxo-1*H*-indene-4-carboxylate (**32**); the latter was converted to the former by ethanolic sodium ethoxide. Hydrolysis of **31** with hot hydrochloric acid gave (±)-coronafacic acid (**4**).

PETER YATES, N.K. BHAMARE, THIERRY GRANGER et T.S. MACAS. Can. J. Chem. **71**, 995 (1993).

Le *E*-5-(4-éthyl)-2-hydroxyphényl)-2-pentanoate d'éthyle (**7**), préparé en quatre étapes à partir du *m*-éthylphénol (**9**), a été soumis à une oxydation de Wessely suivie d'une réaction intramoléculaire de Diels–Alder dans le xylène bouillant pour fournir du 1-acétyloxy-6-éthyl-2,3,3a,4,5,7a-hexahydro-8-oxo-1,5-méthano-1*H*-indène-*anti*-4-carboxylate d'éthyle (**16**). L'hydrogénation de **16**, suivie d'une hydrolyse douce, conduit au 6-éthyloctahydro-1-hydroxy-8-oxo-1,5-méthano-1*H*-indène-*anti*-4-carboxylate d'éthyle (**24**) qui, par oxydation à l'aide de periodate, conduit à l'acide 4-(éthoxycarbonyl)-6-éthyloctahydro-1-oxo-1,5-méthano-1*H*-indène-*anti*-carboxylique (**26**). Une décarboxylation oxydante de ce produit conduit à un mélange de 6-éthyl-2,3,3a,6,7,7a-hexahydro-1-oxo-1*H*-indène-4-carboxylate d'éthyle (**31**) et de 6-éthyl-2,3,3a,4,7,7a-hexahydro-1-oxo-1*H*-indène-4-carboxylate d'éthyle (**32**); sous l'action de l'éthylate de sodium dans l'éthanol, le composé **32** se transforme en composé **31**. L'hydrolyse du composé **31** par de l'acide chlorhydrique chaud fournit l'acide (±)-coronafacique (**4**).

[Traduit par la rédaction]

It has been shown previously (1) that a tandem Wessely oxidation – intramolecular Diels–Alder reaction sequence can be used to synthesize isotwistenones of type **3** from *o*-(3-alkenyl)phenols (**1**) via 6-acetyloxy-6-(3-alkenyl)-2,4-cyclohexadien-1-ones (**2**) (Scheme 1). Although the overall yields are sometimes modest, this is offset by the brevity of this pathway for the synthesis of bridged tricyclic ketones from aromatic precursors. Furthermore, this method, unlike some others involving intramolecular Diels–Alder reactions (cf., for example, ref. 2) results in the concomitant introduction of an oxygen function adjacent to the ketonic group. Hydrolysis of the acetyloxy group gives an α-ketol, which can serve two useful synthetic purposes. First, it constitutes a route to tricyclic α-ketols related to natural products (cf. ref. 3). Second, it provides a site for highly selective oxidative cleavage of the tricyclic compound to a *cis*-fused bicyclic keto acid that can be used for further synthetic elaboration, as is the case in the present work, which concerns the synthesis of (±)-coronafacic acid (**4**).

Coronafacic acid is the acid obtained on hydrolysis of the phytotoxic amide, coronatine (**5**), which is produced by bacteria of several *Pseudomonas* species and causes chocolate spot disease in Italian rye grass and outgrowths on potato tuber tissues (4). Coronafacic acid itself has also been isolated directly from the culture broths in some cases (4, 5). The absolute stereochemistry of coronafacic acid as determined by X-ray crystallography and ORD measurements is that shown in **4** (6). It should be pointed out, however, that this does not rigorously establish the stereochemistry of the corresponding moiety in coronatine since equilibration of configuration at C-6 and C-7a can occur and, in fact, both *cis*- and *trans*-fused forms of **4** are obtained in its hydrolysis (5).[4]

Several syntheses of coronafacic acid have been reported previously. Ichihara et al. have described two syntheses, one involving an intermolecular and the other an intramolecular Diels–Alder reaction (7), and Jung and co-workers reported three syntheses, one involving an anionic oxy-Cope rearrangement and the others intramolecular Diels–Alder reactions (8). Liu and Llinas-Brunet effected a synthesis utilizing an intermolecular Diels–Alder reaction (9). Other syntheses of coronafacic acid have been reported by Tsuji (10) and by Ohira and co-workers (11). Its biosynthesis has been investigated by Parry and Mafoti (12).

Our own synthesis was based on the premise that an appropriately substituted isotwistene derivative of type **3**, after hydrolysis to the corresponding α-ketol, could be oxidatively cleaved by periodate to give a *cis*-fused oxohexahydroindenecarboxylic acid of type **6** that could be converted to coronafacic acid. The Wessely substrate chosen for this purpose was the phenol **7**.[5] This was prepared from

[1]For the previous paper in this series, see ref. 1*a*.

[2]EDITOR'S NOTE: We wish to acknowledge with grateful thanks the many years of service that Professor Peter Yates devoted to chemistry in Canada. We also remember with gratitude his contributions, as an editor and author, to the Canadian Journal of Chemistry. Professor Yates passed away on November 16, 1992, and we dedicate this paper to his memory.

[3]Revision received April 2, 1993.

[4]The term "coronafacic acid" is now used to denote the *cis* form.

[5]All compounds prepared in the present investigation were achiral or racemic; the latter are represented by a single enantiomer without implication of absolute configuration.

m-ethylphenol (**9**) by the route shown in Scheme 2, which follows closely the route we used previously for the synthesis of the corresponding methyl-substituted compound **8** (1). The structures of the intermediates **10–12** and of **7** were established by their elemental composition and their ir and ^{1}H and ^{13}C nmr spectra, which, *mutatis mutandis*, resembled those of analogous compounds prepared previously (1, 13) (see experimental section). The Wittig reaction of **12** with (ethoxycarbonyl)triphenylphosphorane gave the *E* isomer **7** as the major product accompanied by a small amount of the *Z* isomer **13** (<5%, as shown by ^{1}H nmr spectroscopy).

The mixture of **7** and **13** was subjected to Wessely oxidation with lead tetraacetate in acetic acid to give a mixture of the cyclohexadienones **14** and **15**, whose spectra corresponded with those of analogous compounds obtained previously. This mixture was not purified, but heated in dilute solution in boiling xylenes to effect an intramolecular Diels–Alder reaction. The product was a mixture of the epimeric isotwistenones **16** and **17** (ca. 20:1) (Scheme 3), which could be separated by column chromatography. The structure of the major product **16** was again established by comparison of its spectra with those of **18** and **19** and other close analogues (1, 13). This comparison shows that, as in the earlier cases, the Diels–Alder product is the quasi *ortho* regioisomer **16**, rather than the quasi *meta* regioisomer **20** (14). The minor product **17** was not fully characterized, but its spectra leave little doubt that it is the C-8 epimer of **16**.

Compound **16** was hydrolyzed with aqueous barium hydroxide to the α-ketol **21** and the corresponding carboxylic acid. It had originally been planned to cleave **21** by sodium periodate or lead tetraacetate oxidation. However, model studies with the α-ketol **19** showed that complex mixtures were formed that contained little if any of the desired keto acid **22** (13). Since it is known that β,γ-unsaturated acids are susceptible to ready oxidation (15), and since it was planned to saturate the ethylenic double bond of the oxidation product, the order of the reduction and hydrolysis steps was reversed (Scheme 4). Hydrogenation of **16** gave the dihydro product **23**. The relative configuration at C-6 was not determined but is likely to be *exo* since this stereochemistry would be expected to arise by addition of hydrogen from the less hindered side of the ethylenic double bond. Hydrolysis of **23** gave the α-ketol **24** together with the corresponding carboxylic acid **25**, which could be esterified to give **24**. Treatment of **24** with aqueous sodium periodate gave the desired oxidative cleavage product **26**. Analogous hydrogenation and hydrolysis reactions converted **17**, the C-4 epimer of **16**, via **27** to products considered to be **28** and **29**, the C-4 epimers of **24** and **25**, respectively (Scheme 5). These were not fully characterized because of the small amounts available and their irrelevance to the main synthetic scheme. Interestingly, attempted oxidative cleavage of **28** with aqueous sodium periodate left it unchanged, presumably because steric in-

teractions in the transition states for either *endo* or *exo* attack by periodate inhibit the formation of **30**.

Oxidative decarboxylation of **26** with lead tetraacetate and cupric acetate monohydrate in pyridine gave a 1:2 mixture of the Δ^4 and Δ^5 isomers **31** and **32** (Scheme 6). Treatment of this mixture with ethanolic sodium ethoxide converted **32** to **31**. The preparation of **31** by another route has been reported previously (9). The assignment of stereochemistry is ambiguous because of the possibility of inversion at C-6 and C-7a under the basic reaction conditions. Fortunately this ambiguity is of no consequence since it is known that hydrolysis of **31** or the corresponding methyl ester with hot aqueous acid results in equilibration at C-6 and C-7a and the formation of coronafacic acid (**4**). In our case, hydrolysis of **31** with hot 30% hydrochloric acid gave a mixture that after several recrystallizations afforded pure coronafacic acid, mp 122–123°C, undepressed on admixture with an authentic sample of (±)-coronafacic acid, whose spectra were identical with those of the authentic sample.[6]

Synthetic yields were good to excellent throughout. The sequence of central interest, Wessely oxidation – intramolecular Diels–Alder reaction, converted **7** to **16** in 71% yield. The yield for each step of the sequence (hydrogenation, hydrolysis, periodate cleavage) that converted **16** to **26** was 94% or higher. The remaining steps from **26** to **4** (oxidative decarboxylation and hydrolysis) proceeded with excellent conversion (each about 88%), but the total synthetic yield can only be estimated (60%) because at each step equilibration of isomers was required to maximize yields. The conversion of **7** to coronafacic acid was thus carried out with a yield of about 28%, confirming the value of the Wessely oxidation – Diels–Alder reaction sequence for the synthesis of natural products. It is perhaps ironic that although, in general, the method provides a high degree of stereochemical control in the synthesis of tricyclic and derived bicyclic systems, this selectivity was not invoked in the present case because of the special circumstance that the relative configuration of coronafacic acid is achievable under equilibrium-controlled conditions. However, this does not detract from the potential of this method for the synthesis of *cis*-fused bicyclic systems.[7]

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Infrared (ir) spectra were recorded in $CHCl_3$ solution; peaks are strong unless indicated to be medium (m) or weak (w). ^1H and ^{13}C nuclear magnetic resonance (nmr) spectra were recorded in $CDCl_3$ solution unless otherwise specified. Signal multiplicities (s,d,t,q) and parities (e,o) for the latter are based on SFORD and APT spectra, respectively. Solutions in organic solvents were dried over anhydrous $MgSO_4$ and the solvents were evaporated with a rotary evaporator at water aspirator pressure.

*7-Ethylcoumarin (**10**)*

m-Ethylphenol (**9**) (61.10 g, 0.500 mol) and concentrated sulfuric acid (125 mL) were heated with stirring in an oil bath at 110–112°C and treated over a 9 h period with six portions (each ca. 6 g) of malic acid (73.8 g, 0.55 mol); thereafter the amounts of malic acid added were doubled. The reaction mixture was stirred at the same temperature for a further 15 h and then cooled in an ice bath. The rapidly stirred reaction mixture was treated slowly with water (50 mL) with stirring over a period of 1 h and then poured slowly into a mixture of ethyl acetate (500 mL) and ice (1 L). The organic layer was separated and the aqueous layer was washed with ethyl acetate (2 × 200 mL). The combined organic solutions were washed with saturated aqueous $NaHCO_3$ (4 × 200 mL) and saturated brine (200 mL), dried, and evaporated to give a yellow liquid that solidified on standing overnight. The solid was recrystallized from carbon tetrachloride to give **10** (70.55 g, 0.405 mol, 81%), mp 41–42°C; ir ν_{max}: 1733, 1631 (m) cm^{-1}; ^1H nmr δ: 1.27 (t, J = 9 Hz, 3H), 2.72 (q, J = 9 Hz, 2H), 6.29 (d, J = 9.2 Hz, 1H), 7.05 (m, 2H), 7.36 (d, J = 7 Hz, 1H), 7.65 (d, J = 9.5 Hz, 1H); ^{13}C nmr δ: 160.9 (s)), 154.3 (s), 149.3 (s), 143.4 (d), 127.8 (d), 124.4 (d), 116.7 (s), 115.7 (d), 115.4 (d), 29.0 (t), 15.1 (q); ms m/z: 174 (100%). Anal. calcd. for $C_{11}H_{10}O_2$: C 75.84, H 5.79; found: C 75.86, H 5.81.

*7-Ethyl-3,4-dihydrocoumarin (**11**)*

7-Ethylcoumarin (**10**) (10.09 g, 57.0 mmol) was dissolved in ethyl acetate (250 mL) and 10% Pd/C (0.5 g) was added. The mixture was shaken in a Parr hydrogenation apparatus with hydrogen at 3 atm (1 atm = 101.3 kPa) for 10 h, after which no further uptake of hydrogen could be observed. The mixture was filtered and the filtrate was evaporated to give **11** as a colorless liquid

[6]We are most grateful to Professors A. Ichihara (Hokkaido University), M.E. Jung (University of California, Los Angeles), and H.-J. Liu (University of Alberta) for authentic samples and (or) spectra of (±)-coronafacic acid.

*7-Ethyl-2-chromanol (**12**)*

7-Ethyl-3,4-dihydrocoumarin (**11**) (13.8 g, 77.4 mmol) in dry toluene (250 mL) was cooled to −78°C and treated over a 2 h period with diisobutylaluminum hydride (25% in toluene; 55.6 mL, 82 mmol). After a further 2 h water (100 mL) was added at −78°C, and the reaction mixture was allowed to warm to room temperature. After standing for 2 h it was filtered through Celite. The Celite was washed with ether (100 mL) and the aqueous layer of the filtrate was extracted with ether (3 × 250 mL). The combined organic solutions were washed with water (200 mL) and saturated brine (100 mL), dried, and evaporated to give a pale yellow liquid (13.2 g), which was distilled (bp 132–133°C/0.25 Torr) to give **12** as a clear, colorless liquid (12.8 g, 72.0 mmol, 93%) that crystallized upon standing: mp 46–47°C; ir ν_{max}: 3484, 3311 cm^{-1}; ^1H nmr δ: 1.17 (t, J = 7 Hz, 3H), 1.7–2.1 (m, 2H) 2.3–3.0 (m, 4H), 3.80 (bs, 1H), 5.47 (t, 1H), 6.5–7.0 (m, 3H); ^{13}C nmr δ: 152.8 (s), 143.9 (s), 129.1 (d), 120.6 (d), 119.2 (s), 116.1 (d), 92.3 (d), 28.6 (t), 27.4 (t), 20.2 (t), 15.5 (q); ms m/z: 178 (31%). Ethyl E- *and* Z-*5-(4-ethyl-2-hydroxyphenyl)-2-pentenoate (**7** and **13**)*

7-Ethyl-2-chromanol (**12**) (10.7 g, 60.1 mmol) in dry benzene (100 mL) was treated with (carboethoxymethylene)triphenylphosphorane (21.0 g, 62.1 mmol) in dry benzene (100 mL) over a period of 3 h. The solution was stirred for a further 24 h and the solvent was evaporated to give a viscous, pale yellow oil containing a mixture of **7**, **13**, and triphenylphosphine oxide, which was flash chromatographed on a silica column (hexane – ethyl acetate, 9:1) to give a mixture of **7** and **13** as a pale yellow oil (13.3 g, 53.5 mmol, 89%); tlc and ^1H nmr spectroscopy showed that the *Z* isomer **13** was a minor component (<5%). Compound **7** has ir ν_{max}: 1721, 1669 (m) cm^{-1}; ^1H nmr δ: 1.19 (t, J = 7 Hz, 3H), 1.27 (t, J = 8 Hz, 3H), 2.3–2.9 (m, 6H), 4.14 (q, J = 8 Hz, 2H), 5.84 (dt, J = 16 Hz, J = 1.5 Hz, 1H), 5.85 (br s, 1H), 6.5–7.1 (m, 3H); ^{13}C nmr δ: 167.4 (s), 153.9 (s), 149.5 (d), 143.9 (s), 130.0 (d), 124.5 (s), 121.5 (d), 120.1 (d), 115.0 (d), 60.4 (t), 32.6 (t), 28.6

(t), 14.3 (q); ms *m/z*: 248 (52%). Anal. calcd. for $C_{15}H_{20}O_3$: C 72.55, H 8.12; found: C 72.62, H 7.98.

*Ethyl 1-acetyloxy-6-ethyl-2,3,3a,4,5,7a-hexahydro-8-oxo-1,5-methano-1*H*-indene*-anti- *and* syn-*4-carboxylate (**16** and **17**)*

A solution of the mixture of isomeric phenols **7** and **13** (20:1; 12.4 g, 50 mmol) in acetic acid (50 mL) was added with stirring over a 3 h period to an ice-cold solution of lead tetraacetate (44.3 g, 100 mmol) in acetic acid (25 mL), and the reaction mixture was stirred for a further 6 h. The acetic acid was evaporated, the residue was extracted with ether (4 × 100 mL), and the extracts were washed with saturated aqueous $NaHCO_3$ (3 × 100 mL) and saturated brine (100 mL). The ethereal solution was dried and the ether was evaporated to give a pale yellow, viscous oil that was flash chromatographed on silica (hexane – ethyl acetate, 88:12) to give **14** containing a small amount of **15** as a viscous, yellow oil (11.03 g, 36 mmol, 72%); ir ν_{max}: 1751, 1715, 1672 (w) cm^{-1}; ^1H nmr δ: 1.0–1.4 (m, 6H), 1.6–2.6 (m, 9H), 4.15 (q, J = 7 Hz, 3H), 6.10 (dd, J = 12 Hz, 2H), 6.25 (d, J = 1.5, 1H), 6.75 (d, J = 16 Hz, 1H), 6.85 (d, J = 16 Hz, 1H).

The mixture of compounds **14** and **15** (10.7 g, 35.0 mmol) was dissolved in freshly distilled xylenes (1 L) and the solution was added dropwise over a 6 h period to boiling xylenes (500 mL). The reaction mixture was boiled under reflux for a further 6 h, the xylenes were evaporated, and the products were chromatographed on a silica column (hexane – ethyl acetate, 9:1) to give a mixture of **16** and **17** as a viscous, yellow oil that was further purified by distillation (bp 94–98°C/0.3 Torr), giving **16** as a colorless oil (9.53 g, 33 mmol, 89%); ir ν_{max}: 1754, 1733 cm^{-1}; ^1H nmr δ: 1.01 (t, J = 8 Hz, 3H), 1.25 (t, J = 7 Hz, 3H), 1.7–2.7 (m, 8H), 2.02 (s, 3H), 3.40 (m, 2H), 4.09 (q, J = 7 Hz, 2H), 5.78 (m, 1H); ^{13}C nmr δ: 205.6 (s), 171.8 (s), 169.7 (s), 141.4 (s), 122.9 (d), 84.0 (s), 61.1 (t), 54.3 (d), 46.9 (d), 46.0 (d), 39.7 (d), 30.5 (t), 28.6 (t), 27.4 (t), 21.6 (q), 14.2 (q), 11.2 (q); ms *m/z*: 306 (18%). Anal. calcd. for $C_{17}H_{22}O_5$: C 66.65, H 7.24; found: C 66.80, H 7.34.

The *syn* isomer **17** (0.215 g, 0.75 mmol, 2%) was isolated from the mixture of **16** and **17** on the same column with 85:15 hexane – ethyl acetate; ir ν_{max}: 1751, 1739 cm^{-1}; ^1H nmr δ: 1.15 (t, J = 7 Hz, 3H), 1.85–3.0 (m, 8H), 3.18 (br s, 1H), 3.7 (m, 1H), 4.15 (q, J = 7 Hz, 2H), 5.76 (m, 1H).

*Ethyl 6-ethyl-2,3,3a,4,5,7a-hexahydro-1-hydroxy-8-oxo-1,5-methano-1*H*-indene*-anti-*4-carboxylate (**21**) and the corresponding carboxylic acid*

A solution of **16** (0.918 g, 3.0 mmol) in ethanol (30 mL) was added dropwise over a period of 1 h to an ice-cold solution of $Ba(OH)_2 \cdot 8H_2O$ (0.413 g, 1.5 mmol) in ethanol (15 mL). After a further 4 h of stirring at room temperature, ethanol was evaporated and the residue was acidified with dilute hydrochloric acid and extracted with ether (3 × 50 mL). The extracts were washed with saturated aqueous $NaHCO_3$ (3 × 20 mL) and the ether was evaporated to give **21** as an oil (0.554 g, 2.1 mmol, 70%); ir ν_{max}: 1730 cm^{-1}; ^1H nmr δ: 1.00 (t, J = 8 Hz, 3H), 1.26 (t, J = 7 Hz, 3H), 1.7–3.2 (m, 9H), 3.18 (br, s, 1H, absent after D_2O treatment), 3.43 (m, 1H), 4.10 (q, J = 7 Hz, 2H), 5.86 (m, 1H); ^{13}C nmr δ: 212.0 (s), 172.1 (s), 140.8 (s), 124.3 (d), 79.0 (s), 61.1 (t), 53.7 (d), 48.3 (d), 47.3 (d), 40.0 (d), 33.3 (t), 28.6 (t), 27.4 (t), 14.2 (q), 11.3 (q); ms *m/z*: 264 (5%). Exact Mass calcd. for $C_{15}H_{20}O_4$: 264.1361; found: 264.1365.

The $NaHCO_3$ washings were acidified with dilute hydrochloric acid and extracted with ether (3 × 20 mL). Evaporation of the ether gave the carboxylic acid corresponding to the ester **21** as a viscous yellow oil (0.155 g, 0.66 mmol, 22%); ir ν_{max}: 3367 (br), 1727 cm^{-1}; ^1H nmr δ: 1.05 (t, J = 7 Hz, 3H), 1.75–3.2 (m, 9H), 3.45 (m, 1H), 5.9 (m, 1H).

*Ethyl 1-acetyloxy-6-ethyloctahydro-8-oxo-1,5-methano-1*H*-indene*-anti-*4-carboxylate (**23**)*

To compound **16** (9.18 g, 30 mmol) in ethyl acetate (250 mL) was added 10% Pd/C (0.5 g) and the mixture was hydrogenated at 1 atm until uptake of hydrogen ceased. The reaction mixture was filtered and evaporated to give a colorless oil that on standing gave crystalline **23** (8.98 g, 29 mmol, 97%), mp 67–68°C; ir ν_{max}: 1761, 1730 cm^{-1}; ^1H nmr δ: 0.86 (t, J = 6 Hz, 3H), 0.9–3.0 (m ,13H), 1.25 (t, J = 7 Hz, 3H), 2.07 (s, 3H), 4.17 (q, J = 7 Hz, 2H); ^{13}C nmr δ: 209.8 (s), 172.8 (s), 169.9 (s), 89.7 (s), 61.1 (t), 48.3 (d), 45.2 (d), 43.1 (d), 36.5 (d), 30.4 (t), 29.8 (t), 28.7 (t), 21.7 (t), 14.3 (q), 11.4 (q); ms *m/z*: 308 (29%). Anal. calcd. for $C_{17}H_{24}O_5$: C 66.23, 1H 7.83; found: C 66.20, H 7.91.

Ethyl 6-ethyloctahydro-1-hydroxy-8-oxo-1,5-methano-1-H-*indene*-anti-*4-carboxylate (**24**) and 6-ethyloctahydro-1-hydroxy-8-oxo-1,5-methano-1*H*-indene*-anti-*4-carboxylic acid (**25**)*

Compound **23** (7.70 g, 250 mmol) was dissolved in ethanol (300 mL) and the solution was added dropwise over a period of 3 h to an ice-cold solution of $Ba(OH)_2 \cdot 8H_2O$ (3.94 g, 12.5 mmol) in ethanol (150 mL). After further stirring at room temperature for 8 h, the ethanol was evaporated, and the residue was acidified with dilute hydrochloric acid and extracted with ether (3 × 200 mL). The combined extracts were washed with saturated aqueous $NaHCO_3$ (3 × 50 mL) and saturated brine (50 mL) and evaporated to give a colorless oil that solidified on standing at room temperature to give **24** (6.18 g, 23.23 mmol, 93%), mp 71–72°C; ir ν_{max}: 3521, 1733, 1709 cm^{-1}; ^1H nmr δ: 0.84 (t, J = 7 Hz, 3H), 1.21 (t, J = 7 Hz, 3H), 1.1–1.2 (m, 2H), 1.40 (dt, J = 14 Hz, J = 4 Hz, 1H), 1.7–2.0 (m, 5H), 2.20 (quintet, J = 3 Hz, 1H), 2.45 (d, J = 3 Hz, 1H), 2.75 (quintet, J = 5 Hz, 1H), 2.95 (d, J = 10 Hz, 1H), 3.10 (s, 1H; absent after D_2O treatment), 4.1 (m, 2H); ^{13}C nmr δ: 217.8 (s), 210.8 (s), 173.8 (s), 84.0 (s), 61.0 (s), 47.0 (d), 43.0 (d), 35.5 (d), 29.2 (s), 23.9 (d), 14.3 (q), 11.6 (q); ms *m/z*: 266 (22%). Anal. calcd. for $C_{13}H_{22}O_4$: C 67.67, H 8.27; found: C 67.55, H 8.35.

The combined $NaHCO_3$ washings were acidified with dilute hydrochloric acid and extracted with ether (3 × 50 mL), and the combined extracts were washed with water (3 × 50 mL). Evaporation gave a colorless, thick oil (80 mg, 0.33 mmol, 1.35%) that was crystallized from chloroform to give **25**, mp 166–167°C; ir ν_{max}: 3390 (br), 1730, 1709 cm^{-1}; ^1H nmr δ: 0.85 (t, J = 7 Hz, 3H) 1.15 (q, J = 7 Hz, 2H) 1.35 (dt, J = 14 Hz, J = 3 Hz, 2H), 1.7–2.15 (m, 5H), 2.23 (q, J = 3 Hz, 1H), 2.55 (q, J = 3 Hz, 1H), 2.68 (q, J = 3 Hz, 1H), 2.9 (br s, 1H); ^1H nmr δ(acetone-d_6): 0.83 (t, J = 7 Hz, 3H), 1.16 (quintet, J = 7 Hz, 2H), 1.26–1.44 (m, 4H), 1.66–2.15 (m, 7H), 2.48–2.59 (m, 2H), 2.79–2.89 (br s, 1H); ^{13}C nmr δ(acetone-d_6): 206.8 (e), 174.9 (e), 72.0 (o), 49.4 (o), 46.3 (o), 37.9 (o), 36.5 (o), 35.4 (o), 31.0 (e), 30.20 (e), 28.8 (e), 24.0 (e), 11.7 (o); ms *m/z*: 238 (31%).

*Esterification of **25**. Formation of **24***

Esterification of **25** (70 mg, 0.28 mmol) in refluxing ethanol (25 mL) and a catalytic amount of concentrated sulfuric acid for 3 h and chromatography of the product on silica gave **24** (50 mg, 0.19 mmol, 58%) and an oily mixture of **24** and a second product (10 mg), whose ^1H nmr spectrum showed the signals of **24** together with signals at δ 6.58 and 6.85.

*4-(Ethoxycarbonyl)-6-ethyloctahydro-1-oxo-1*H*-indene-5-carboxylic acid (**26**)*

Compound **24** (3.80 g, 14.3 mmol) was shaken with aqueous sodium periodate (0.21 M; 500 mL) until solution was effected. After 4 h of stirring at room temperature a solid began to deposit. After 8 h of stirring the reaction mixture was filtered to give a white powder (2.8 g) that was crystallized from 2-propanol–hexane to give **26**, mp 151–152°C. A further amount of product was obtained by extraction of the filtrate with ether (3 × 50 mL). The ethereal extracts were extracted with saturated aqueous $NaHCO_3$ (3 × 15 mL) and the $NaHCO_3$ extracts were acidified with dilute hydrochloric acid and extracted with ether (3 × 30 mL). The ether was evaporated to give **26** (total yield 3.77 g, 13.4 mmol, 94%); ir ν_{max}: 3450 (br), 1730, 1701 cm^{-1}; ^1H nmr δ: 0.93 (m, 3H), 1.26 (t, J = 7 Hz, 3H), 0.9–3.0 (m, 13H), 4.22 (q, J = 7 Hz, 2H), 8.44 (br s, 1H, absent after D_2O treatment); ^{13}C nmr δ: 219.8 (e), 180.3 (e), 175.5 (e), 61.2 (e), 48.2 (o), 47.8 (o), 40.7 (o), 39.4 (e), 36.8

(o), 34.7 (o), 24.2 (e), 23.8 (e), 21.5 (e), 14.3 (o), 12.2 (o); ms *m/z*: 282 (26%). Anal. calcd. for $C_{15}H_{22}O_5$: C 63.81, H 7.85; found: C 63.97, H 7.98.

*Ethyl 1-acetyloxy-6-ethyloctahydro-8-oxo-1,5-methano-1*H-*indene*-syn-*indene-4-carboxylate (27)*

Compound **17** (0.184 g, 0.6 mmol) with Pd/C (20 mg) in ethyl acetate (30 mL) was hydrogenated at 1 atm until there was no further uptake of hydrogen. The catalyst was filtered and the filtrate was evaporated to give **27** as a colorless oil (0.150 g, 0.49 mmol, 81.5%); ir ν_{max}: 1767, 1736 cm^{-1}; ^1H nmr δ: 1.23 (t, J = 7 Hz, 3H), 1.4–3.0 (m, 10H), 2.05 (s, 3H), 3.41 (m, 1H), 4.10 (q, J = 7 Hz, 2H).

Ethyl 6-ethyloctahydro-1-hydroxy-8-oxo-1,5-methano-1-H-*indene*-syn-*4-carboxylate (28) and 1-hydroxy-6-ethyloctahydro-8-oxo-1,5-methano-1*H-*indene*-syn-*4-carboxylic acid (29)*

A solution of **27** (123 mg, 0.4 mmol) in ethanol (30 mL) was added dropwise over a period of 30 min to a stirred ice-cooled solution of $Ba(OH)_2 \cdot 8H_2O$ (63 mg, 0.2 mmol) in ethanol (15 mL). After further stirring at room temperature for 6 h, the ethanol was evaporated and the residue was acidified with dilute hydrochloric acid, and extracted with ether (3 × 20 mL). The combined extracts were washed with saturated aqueous $NaHCO_3$ (2 × 10 mL). Evaporation of the ether gave **28** as a colorless oil (50 mg, 0.19 mmol, 48%); ir ν_{max}: 3450 (br), 1736 cm^{-1}; ^1H nmr δ: 0.79 (t, J = 7 Hz, 3H), 1.15 (t, J = 7 Hz, 3H), 1.28–1.4 (dt, J = 14 Hz, J = 3 Hz, 2H), 1.05–1.2 (m, 2H), 1.65–1.95 (m, 4H), 2.15 (quintet, J = 3 Hz, 1H), 2.40 (d, J = 3 Hz, 1H), 2.70 (quintet, J = 6 Hz, 1H), 2.90 (d, J = 12 Hz, 1H), 3.25 (br s, 1H; absent after D_2O treatment), 4.05 (m, 2H).

The $NaHCO_3$ washings were acidified with dilute hydrochloric acid and extracted with ether (3 × 10 mL). Evaporation of the ether gave **29** (30 mg, 0.125 mmol, 36%).

Esterification of 29. Formation of 28

To a solution of **29** (30 mg, 0.125 mmol) in ethanol (20 mL) was added 3 drops of concentrated sulfuric acid and the solution was boiled under reflux under argon for 3 h. Ethanol was evaporated and the residue was diluted with water and extracted with ether (2 × 10 mL). The extracts were washed with saturated aqueous $NaHCO_3$ (10 mL) and the ether was evaporated to give an oil (20 mg), whose ^1H nmr spectrum corresponded with that of **28** with additional signals at δ 6.8 (d, J = 8 Hz), 6.95 (d, J = 8 Hz).

Treatment of 28 with aqueous sodium periodate

Compound **28** (40 mg, 0.15 mmol) was treated with 0.21 M aqueous sodium periodate (100 mL) for 8 h. The ethanol was evaporated and the residue was acidified with dilute hydrochcloric acid and extracted with ether (3 × 20 mL). The extracts were washed with aqueous $NaHCO_3$ (2 × 10 mL). Evaporation of the ether returned **28** as an oil (30 mg, 0.11 mmol, 75%). The $NaHCO_3$ washings were acidified with dilute hydrochloric acid and extracted with ether (3 × 10 mL). Evaporation of the ether gave an oil (3 mg, 0.01 mmol, 7%), whose spectra resembled those of compound **26**. Three further treatments with 0.21 M aqueous sodium periodate failed to give any further quantity of **26**, and **28** was recovered in every case. It is therefore concluded that the small amount of **26** arose from **24** present as a contaminant in **28**.

*Ethyl 6-ethyl-2,3,3a,6,7,7a-hexaahydro- and 6-ethyl-2,3,3a,4,7,7a-hexahydro-1-oxo-1*H-*indene-4-carboxylate (31 and 32)*

A solution of **36** (1.04 g, 3.7 mmol) in dry benzene (250 mL) was degassed by passing argon through it for 30 min and was stirred at room temperature in a flask covered with aluminum foil. Lead tetraacetate (3.10 g, 7.0 mmol) and $Cu(OAc)_2 \cdot H_2O$ (0.2 g, 1 mmol) were added, followed by dropwise addition, with a syringe, of dry pyridine (5 mL) over a period of 15 min. The resulting solution was stirred at room temperature for 1 h and boiled under reflux for 3 h. The benzene layer was decanted after the mixture had cooled to room temperature and the sticky residue was extracted with ether (2 × 50 mL). The combined benzene and ether extracts were washed with saturated aqueous $NaHCO_3$ (2 × 50 mL), cold dilute hydrochloric acid (3 × 50 mL), and saturated brine (100 mL). The solution was dried and the solvents were evaporated to give a 1:2 mixture of **31** and **32** as a yellow oil (0.766 mg, 3.25 mmol, 88%); ir ν_{max}: 1736, 1721, 1656 (w) cm^{-1}; ^1H nmr δ: 0.8–1.4 (m, 6H), 1.65–3.0 (m, 11H), 4–4.4 (m, 2H), 5.39 (br s, 0.7H), 7.0 (d, J = 12 Hz, 0.3H).

Conversion of 32 to 31

A solution of the mixture of **31** and **32** (708 mg, 3 mmol) in dry ethanol (50 mL) was treated at ice temperature over a period of 15 min with ethanolic sodium ethoxide (1.43 g, 21 mmol), freshly prepared from sodium (483 mg) and dry ethanol (7 mL). The mixture was stirred at room temperature under argon for 48 h. The ethanol was evaporated; the residue was acidified with cold dilute sulfuric acid, and extracted with ether (4 × 50 mL). The extracts were washed with saturated aqueous $NaHCO_3$ (3 × 50 mL) and saturated brine (50 mL), dried, and evaporated to give **31** as a colorless oil (645 mg, 27.3 mmol, 91%); ir ν_{max}: 1736, 1715, 1645 (w) cm^{-1}; ^1H nmr δ: 0.8–1.1 (m, 3H), 1.2–1.4 (m, 3H), 1.45–2.8 (m, 9H), 3.1 (quintet, 1H), 3.3 (br s, 1H), 4.2 (m, 2H), 6.95 (m, 1H); ^{13}C nmr δ: 220.6 (e), 167.3 (e), 144.6 (o), 131.2 (e), 61.4 (e), 46.6 (o), 37.8 (e), 34.7 (o), 29.1 (o), 28.0 (e), 27.5 (e), 26.1 (e), 14.4 (o), 11.2 (o).

Coronafacic acid (4)

A mixture of **31** (50 mg, 0.21 mmol) and 30% hydrochloric acid (10 mL) was boiled under reflux for 3 h. The solution was extracted with ether (3 × 25 mL) and the ethereal extracts were extracted with saturated aqueous $NaHCO_3$ (3 × 20 mL). The $NaHCO_3$ extracts were acidified with 6 N sulfuric acid and extracted with ether (3 × 25 mL). These ethereal extracts were washed with water (2 × 20 mL), dried, and evaporated to give a mixture of **4** and **33** as a solid (38 mg, 18 mmol, 87%). Three crystallizations of this mixture from carbon tetrachloride gave samples of **4** of increasing purity (mp 114–117°C, 116–118°C, and 120–121°C); a final recrystallization from diisopropyl ether (11) gave pure (±)-coronafacic acid, mp 122–123°C, undepressed on admixture with an authentic sample of (±)-coronafacic acid (see footnote 7); ir ν_{max}: 3480 (br), 1736, 1715, 1645 (w) cm^{-1}; ^1H nmr δ: 0.97 (t, J = 7 Hz, 3H), 1.0–1.1 (m, 1H), 1.4–1.6 (m, 3H), 1.8–1.9 (m, 1H), 2.2–2.4 (m, 4H), 2.6 (m, 1H), 3.1 (m, 1H), 7.1 (m, 1H), 10.2 (v br s, 1H); ^{13}C nmr δ: 220.3 (e), 172.1 (e), 146.9 (o), 130.0 (e), 46.6 (o), 38.2 (e), 37.9 (o), 36.0 (o), 28.1 (e), 27.7 (e), 25.7 (e), 11.2 (o).

Ternary complexes of copper(II) and their use in the spectrophotometric determination of copper in alloys and rocks

ABD-ELHAFEEZ E. ALI

Chemistry Department, Faculty of Science at Sohag, Assiut University, Egypt

Received January 21, 1992[1]

ABD-ELHAFEEZ E. ALI. Can. J. Chem. **71**, 1002 (1993).

Some intensely coloured Cu(II)–L_1–2′,7′-dichlorofluorescein ternary complexes were studied. The absorbance characteristics for these ternary complexes were determined. The molar ratio for these complexes is $Cu:L_1:L_2 = 1:2:1$ and the formula $[Cu(L_1)_2]^{2+} \cdot [Cl_2FlCOO^-]^-$ is proposed. The effect of substituent groups of the L_1 and L_2 ligands on the complexing activity with copper(II) was studied. The interference of some cations and anions in the determination of the Cu(II) by the developed methods was examined. Highly sensitive and selective methods are proposed for the spectrophotometric determination of copper(II) in limestone and copper alloys.

ABD-ELHAFEEZ E. ALI. Can. J. Chem. **71**, 1002 (1993).

On a étudié quelques complexes tertiaires extrêmement colorés de Cu(II)–L_1–2′,7′-dichlorofluorescéine. On a déterminé les caractéristiques d'absorbance de ces complexes. On suggère que le rapport molaire dans ces complexes est $Cu : Li_1 : L_2 = 1 : 2 : 1$ et que la formule est $[Cu(L_1)_2]^{2+} \cdot [Cl_2FlCOO^-]^-$. On a étudié l'effet des substituants des ligands L_1 et L_2 sur propriétés complexantes avec le cuivre(II). On a évalué les interférences de quelques cations et de quelques anions sur la détermination du Cu(II) par les méthodes développées. On propose des méthodes extrêmement sensibles et sélectives pour la détermination spectrophotométrique du cuivre(II) dans le calcaire et les alliages de cuivre.

Several authors have studied the reactions of Cu(I) with most of the phenanthroline derivatives (1–4), but the reaction of these ligands with Cu(II) has not been reported before in the literature. The spectrophotometric determination of copper has been the subject of several studies (5–14).

This work is devoted to the study of the reactions between copper(II), phenanthroline and its derivatives, and fluorescein (FlCOOH) or 2′,7′-dichlorofluorescein (Cl_2FlCOOH). These coloured complexes were used to develop selective and highly sensitive methods for the spectrophotometric determination of copper(II) in some of its alloys and in limestone.

Experimental

Reagents

All reagents used were of AR grade unless otherwise stated. Doubly distilled water was used throughout. The copper(II) solution was standardized by EDTA titration. Ethanolic stock solutions (10^{-3} to 5×10^{-3} M) of the L_1 and L_2 ligands were prepared. The anions (citrate, tartrate, chloride, carbonate, bicarbonate, phosphate, sulphide, nitrate, and sulphate) were used in the form of their sodium or potassium salts, while the cations (Fe(III), Sn(II), Cr(III), Al(III), Zn(II), Cd(II), Co(II), Ni(II), Bi(III), Hg(II), Mn(II), Ga(III), In(III), Y(III), and alkali and alkaline-earth metals) were taken as chloride, sulphate, or nitrate. Ammonium acetate was used as a buffer solution. The pH values were adjusted using solutions of hydrochloric acid and sodium hydroxide.

Apparatus

Absorption spectra were recorded using a CECIL recorder spectrophotometer model 599. An Orien Research model 601/digital Ionlyzer pH meter standardized with buffer solution at pH 4.0 and 9.15 was used for all pH measurements.

Results and discussion

1,10-Phenanthroline and its derivatives are interesting complexing agents for Cu(I) (1–4), but no information has been reported about coloured complexes for these reagents with Cu(II). This is probably because Cu(I) has chromophoric properties and so the *d* electrons of the Cu(I) atoms form a close conjugation chain with the system of the phenanthroline rings, but Cu(II) does not. No reactions take place between Cu(II) and pyridine, bipyridyl, or terpyridyl, and the secondary ligands studied (FlCOOH and Cl_2FlCOOH). From slightly basic medium, deep red and violet coloured Cu(II)–L_1–L_2 ternary complexes have been extracted by chloroform. (L_1 represents 1,10-phenanthroline (phen.), 2,9-dimethyl-1,10-phenanthroline (neocup.), 4,7-diphenyl-1,10-phenanthroline (bathophen.), and 2,3,8,9-dibenzo-4,7-diphenyl-5,6-dilydro-1,10-phenanthroline (cuprotest.) and L_2 is 2′,7′-dichlorofluorescein.) The possibility of extracting these ternary complexes from slightly alkaline medium into various organic solvents such as carbon tetrachloride, benzene, chloroform, cyclohexane, isoamyl alcohol, and ether was studied. From the analytical point of view, the extraction solvent should completely extract the ternary complex but not the ligands. These conditions were fulfilled only by chloroform.

Optimum conditions, spectra, and stoichiometry of the complexes

A study of the absorbance of the Cu(II) ternary complexes extracted from aqueous media over a range of pH indicates that the absorbance value of the extract at its maximum absorption (530 nm) is independent of pH over the range 6.4–9.6. Waiting times of shaking for 8 and 10 min were selected as optimal values for the quantitative extraction of the ternary complex by chloroform. Absorption spectra of the extracted Cu(II) ternary complexes and the ligands in chloroform were recorded from 400 to 600 nm. Figure 1 shows the spectra of the extracted Cu(II)–cuprotest.–Cl_2FlCOOH complex and the ligands in chloroform. The spectra of the ternary complexes examined are of similar nature. The spectrum in Fig. 1 displays a shoulder at 502 nm followed by a band with a sharp peak at 530 nm. The spectra of the extracted ligands (L_1 and L_2) in chloroform exhibit practically no absorption from 400 to 600 nm, hence no spectral interference from the reagent blanks with the

[1]Revision received July 16, 1992.

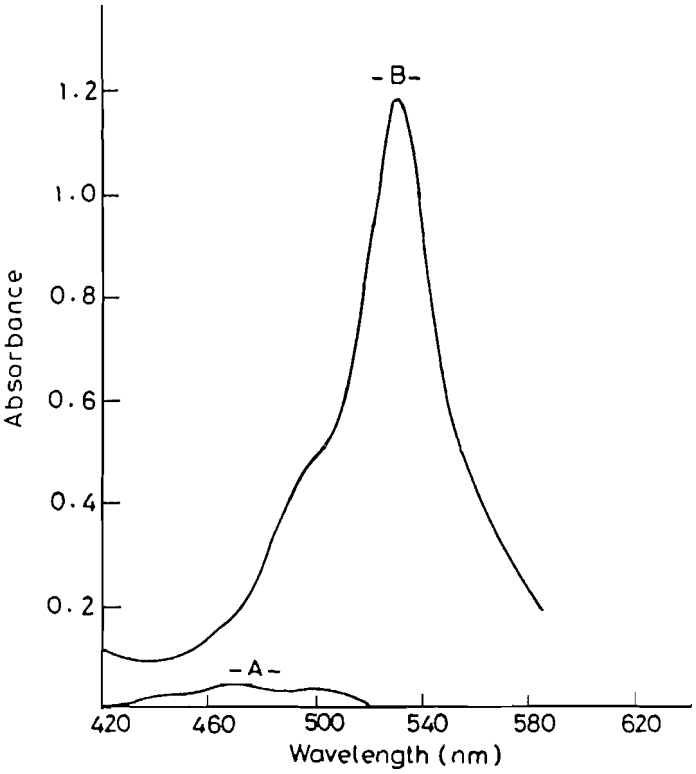

FIG. 1. Absorption spectra of the extracted 2,7-dichlorofluorescein (A) and its ternary complex with copper(II) and cuprotest. in $CHCl_3$ (B) (10^{-4} M) (spectrum of the extract of cuprotest. in $CHCl_3$ exhibits no absorption from 420 to 600 nm).

ternary complexes is expected (Fig. 1). The absorbance characteristics of the examined complexes were determined and the results are shown in Table 1. This table also contains the specific absorptivities of the complexes (15).

Molar ratios of the constituents of the ternary complexes were determined using two methods, that developed by Asmus (16) and the method of Koch and Ackerman (17). The former method is well known and the latter involves plotting $\log A_x/(A_0 - A_x)$ versus $\log Cl_2$, where A_0 is the absorbance of the ternary complex and A_x is the absorbance in the presence of different concentrations of L_2. This graph was linear and its slope was close to 1, indicating the number of the molecules of L_2 in the complex. Both methods showed that the composition of the complex was 1:2:1 and the formula $[Cu(L_1)_2]^{2+} \cdot [Cl_2FlCOO^-]^-$ is proposed. Thus, the suggested mechanism for this reaction can be represented as follows:

(*a*) Formation of colourless cationic complex

[1] $Cu^{2+} + 2L_1 \rightleftharpoons [Cu(L_1)_2]^{2+}$

(*b*) Formation of coloured ternary complex

[2] $[Cu(L_1)_2]^{2+} + Cl_2FlCOOH \rightleftharpoons [Cu(L_1)_2]^{2+} \cdot [Cl_2FlCOO^-]^- + H^+$

The coupling of chelate rings (eq. [1]) is across the two nitrogen atoms of L_1. Equation [2] shows the dependence of the formation of the ternary complex on the pH of the aqueous medium.

Influence of the substituents of the ligands on their complexing activity with Cu^{2+}

No reaction takes place between Cu^{2+}, the applied primary ligands, and fluorescein (FlCOOH), while Cl_2FlCOOH forms an intensely coloured ternary complex with Cu^{2+} and L_1. There is no doubt about a connection between the two chlorine atoms of Cl_2FlCOOH and its action in forming intensely coloured ternary complexes. This is due to the net effect of the electron-withdrawing inductive influence and the electron-donating mesomeric influence of its two chlorine atoms on its carboxylic group, which in turn increases the dissociation constant of Cl_2FlCOOH in comparison to FlCOOH; hence its ionizable hydrogen atom is more easily detached than that from FlCOOH. Thus, in the case of Cl_2FlCOOH, formation of the coloured complexes proceeds according to eq. [2].

It is clear also that a certain role is played by the type and position of substituents in the L_1 molecule. No coloured $CuL_1 \cdot Cl_2$FlCOOH complexes are formed by using pyridine, bipyridyl, terpyridyl, and bathocuproine. The ϵ of the coloured complexes formed decreases in the order: Cu–bathophen.–L_2 >> Cu–phen.–L_2 > Cu–cuprotest.–L_2 > Cu–neocup.–L_2 (Table 1). It is clear that the electron-donating effect of the two methyl groups in neocup. hinders the formation of the coloured ternary copper complex. On the contrary, the two phenyl groups are in the *para* position with respect to the two nitrogen atoms of the bathophen. molecule and this assists the quantitative formation of the coloured ternary complex that shows the highest molar absorptivity (Table 1).

Calibration, precision, interferences, and application

Beer's law is obeyed over the range 0.03–3.0 μg mL^{-1} Cu(II) for complexes 1 and 3, 6.5–60.0 μg mL^{-1} Cu(II) for 2, and 0.3–9.5 μg mL Cu(II) for 4 (see Table 1). Complex 2 is of little practical importance, since it has the lowest sensitivity in comparison to complexes 1, 3, and 4 (Table 1). The molar absorptivities are presented in Table 1. Bathophen. + Cl_2FlCOOH has the highest sensitivity and cuprotest. + Cl_2FlCOOH is the most selective for the spectrophotometric determination. They were used for the analysis of the copper in pure solutions and in its alloys, respectively (Tables 2–4).

The evaluation of the determination of trace amounts of Cu(II) at three concentration levels (2, 3, and 4 μg mL^{-1}) shows good precision and accuracy (Table 2).

With a view to applying cuprotest. and Cl_2FlCOOH for practical purposes, the effects of various cations, especially those accompanying copper in alloys such as zinc, tin, and nickel in brass, bronze, and cupronickel, were examined. Mn(II), Co(II), and Cd(II) can be tolerated at a 20:1 w/w ratio to copper(II) (4 μg mL^{-1}) and Al(III), Cr(III), and Fe(III) at a 30:1 ratio. Bi(III), Ga(III), Y(III), and In(III) give a +4.4% error at a 50-fold ratio to 4.0 μg mL^{-1} Cu(II). Acetate, citrate, oxalate, and tartrate do not interfere. The effects on the determination of copper of alkali, alkaline-earth metals, CO_3^{2-}, HCO_3^-, Cl^-, SO_4^{2-}, NO_3^-, and PO_4^{3-} as common ions and Zn(II), Fe(III), Mn(II) as trace constituents in sedimentary rocks, in addition to Ni(II), Zn(II), and Sn(II) as main components in copper alloys, were examined. The results of the interference studies are given in Table 3.

The results of the studies of the interferences given in

	A		
Sn(II), 2.0	6.0	6.07	+1.17
	B		
Ca, 1000.0	6.0	6.03	+0.5

Table 3 indicate that the proposed method is suitable for the determination of microamounts of copper(II) in sedimentary rocks and in cupronickels, brasses, and bronzes with the systems $Cu_{100-x}M_x$, where M = zinc, nickel, or tin and $0 \leq x \leq 90$.

Recommended procedure for determination of copper(II) in sedimentary rocks and alloys

An accurately measured amount of the sample can be dissolved in concentrated HCl or concentrated HNO_3 or in a mixture of the two acids. The acidic solution of the sample is neutralized with concentrated ammonia solution, diluted with redistilled water to a definite volume, and the copper(II) is determined by the method outlined below. The interferences of the common ions in the Cu(II) samples were studied by a preparation of synthetic mixtures of a composition corresponding to the samples.

A buffered 1.0 mL (2 μg mL^{-1} Cu) of the sample is placed in a separatory funnel, diluted to about 10 mL with redistilled water, and mixed with about 10 mL of chloroform containing about 2 mL each of solutions of $Cl_2FlCOOH$ and cuprotest. (5×10^{-3} M). The mixture is shaken and, after separation of the phases, the organic layer is transferred into a 10-mL standard flask and the volume is brought up to the mark with chloroform. The absorbance of the coloured ternary copper complex is measured at its maximum absorption against a reagent blank prepared in the same way and the concentration of the copper in the sample is determined by the standard method.

The precision and accuracy of the cuprotest. and $Cl_2FlCOOH$ method for the determination of copper(II) in bronzes and limestone were verified for synthetic samples containing 6.0 μg mL^{-1} of Cu(II) in the presence of 2.0 μg mL^{-1} Sn(II) and 1000.0 μg mL^{-1} Ca^{2+}, respectively, and the results are presented in Table 4.

The results indicate an average recovery of 101.71 (with mean relative error +1.17) and 100.5 (with mean relative error +0.5) for the spectrophotometric determination of the copper(II) in bronze and limestone, respectively, using cuprotest. and 2′,7′-dichlorofluorescein (Table 4).

Other well-known reagents have been proposed for the spectrophotometric determination of copper (Table 5) but most of them are less sensitive than the proposed methods. The proposed method (No. 13, Table 5 and No. 3, Table 1) is 50–100 times more sensitive than the well-known diethyl dithiocarbamate and hydroxyquinoline methods and about 20 times more sensitive than such recent methods as Nos. 10 and 11 (Table 5).

Cuprotest. and 2′,7′-dichlorofluorescein have advan-

tages for the spectrophotometric microdetermination of copper in bronzes and limestone. Moreover, the study of the interference of zinc and nickel in the determination of Cu(II) by cuprotest. and $Cl_2FlCOOH$ (Table 3) showed that this method can be applied to the determination of Cu(II) in brasses and cupronickels. Bathophen. and 2′,7′-dichlorofluorescein are not suitable for the determination of copper(II) in these substances, but can be applied as a highly sensitive method for the determination of copper(II) in the presence of alkali and alkaline-earth metals.

Proton nuclear magnetic resonance studies of nucleosides: hindered internal rotation in *N*-dimethylaminomethylene derivatives of adenosine, guanosine, and cytidine

EMMANUEL YAW OSEI-TWUM

Research Institute, King Fahd University of Petroleum and Minerals, Dhahran 31261, Saudi Arabia

Received March 9, 1993

EMMANUEL YAW OSEI-TWUM. Can. J. Chem. **71**, 1006 (1993).

Studies of the internal rotation about the C—N bond of the dimethylaminomethylene (DMAM) group of DMAM-adenosine, **1**, DMAM-guanosine, **2**, and DMAM-cytidine, **3**, was determined by high-resolution ^{1}H NMR spectroscopy. Arrhenius plots ($\ln k = \ln A - E_a/RT$) were used to determine the barriers to internal rotation, E_a, of the compounds. They were found to be 58.0 ± 2.4 kJ mol^{-1}, 71.2 ± 1.4 kJ mol^{-1}, and 62.8 ± 2.4 kJ mol^{-1} for **1**, **2**, and **3**, respectively. At the same time the coalescence temperatures, t_c, for the compounds were determined and found to be 93.5°C for **1**, 124.7°C for **2**, and 119.6°C for **3** in DMSO. In D_2O, compound **1** was found to have a t_c of 104.5°C. The compound decomposed so rapidly at this temperature that the barrier to internal rotation could not be determined. The results indicate that the oxo function in the nucleobase has a considerable effect on the barrier to internal rotation and coalescence temperature.

EMMANUEL YAW OSEI-TWUM. Can. J. Chem. **71**, 1006 (1993).

Faisant appel à la RMN du ^{1}H, on a réalisé des études sur la rotation interne de la liaison C—N du groupe diméthylaminométhylène (DMAM) de la DMAM-adénosine (**1**), de la DMAM-guanosine (**2**) et de la DMAM-cytidine (**3**). On a utilisé des courbes d'Arrhénius ($\ln k = \ln A - E_a/RT$) pour déterminer les barrières à la rotation interne, E_a, de ces composés. On a trouvé qu'elles étaient respectivement de 58,0 ± 2,4, 71,2 ± 1,4 et 62,8 ± 2,4 kJ mol^{-1} pour les composés **1**, **2** et **3**. On a aussi déterminé les températures de coalescence, t_c, de ces composés et on a trouvé qu'elles étaient respectivement de 93,5, 124,7 et 119,6°C pour les composés **1**, **2** et **3**. Pour le composé **1** dans le D_2O, on a trouvé que la t_c est de 104,5°C. À cette température, le composé se décompose tellement rapidement que l'on n'a pas pu déterminer sa barrière à la rotation interne. Les résultats indiquent que la fonction oxo de la nucléobase possède un effet important sur la barrière à la rotation interne ainsi que sur la température de coalescence.

[Traduit par la rédaction]

Introduction

N-Dimethylaminomethylene derivatives of purine and pyrimidine nucleosides similar to those shown in Scheme 1 were first reported by Zemlicka (1). They have since found uses in nucleic acid chemistry. Their use as protecting group in the synthesis of nucleoside analogs, nucleotides, and oligonucleotides has been reported (2–7). Their spectroscopic properties (8) and chromatographic and mass spectral characteristics (9, 10) have also been studied. The investigation of analogs of DMAM-adenosine as probes for the study of chemical determinants of bending in DNA fragments were recently reported (11).

The barriers to internal rotation about the exocyclic C—N bond in cytosine derivatives and other pyrimidines, as well as in adenine derivatives, have been studied using proton and ^{13}C NMR spectroscopy (12–19). There is, so far, no report on the barrier to internal rotation about the terminal C—N bond of the dimethylaminomethylene derivatives of these nucleosides or their corresponding nucleobases even though the methyl groups have been reported as a doublet in the ^{1}H NMR spectra of the adenosine and cytidine compounds (2*b*, 5, 6), indicating that they are nonequivalent.

This study is an attempt to determine the coalescence temperatures as well as the barriers to internal rotation about the exocyclic C—N bond of these derivatives. In these compounds, the terminal *N*-dimethylamino group is linked to the ring of the base through an exocyclic C—N double bond. Unlike the parent compounds, and their corresponding *N*-dimethylamino derivatives, all three derivatives have one more contributing structure to the resonance hybrid (Scheme 2). The compounds are, therefore, expected to have higher coalescence temperatures, t_c, and higher barriers to internal rotation than the *N*-dimethylamino derivatives of the parent compounds.

3	299	167

Methods, results, and discussion

Dimethylaminomethylene nucleosides

The nucleosides containing the amino function reacted readily with excess dimethylformamide dimethyl acetal at room temperature. This was followed by treatment with excess water to provide the dimethylaminomethylene deriva-

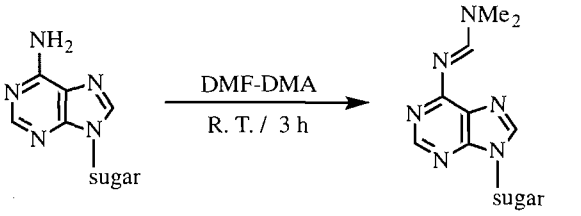

SCHEME 3

tives. The reaction of the DMF–DMA with ribonucleosides is known to result in the formation of 2′,3′-*O*-dimethylaminomethylene derivatives (2*a*). The 2′,3′-*O*-DMAM group is readily hydrolysed in H_2O. The reaction is illustrated in Scheme 3. At higher temperatures (60°C and above), the guanine nucleoside was observed to be slowly methylated at N1. However, the reaction did not prove to be quantitative, thus the more selective low-temperature reaction was chosen.

Formation of the derivatives was confirmed by positive fast atom bombardment (FAB+) mass spectrometry and NMR. Table 1 gives the pseudo-molecular ions of the starting nucleosides (and ions of their respective bases) and those of the derivatives.

Nuclear magnetic resonance

The ^{1}H NMR spectra of the compounds indicated the nonequivalence of the methyl groups. Figure 1 shows the ^{1}H NMR spectrum of DMAM-adenosine with the methyl signals at 3.15 and 3.21 ppm.

The rate constants, k, for the exchange of the methyl groups were determined at temperatures at and above the coalescence. The rate constants for DMAM-adenosine are given in Table 2. Using these values in the Arrhenius plots, the barriers to internal rotation were obtained for compounds **1**, **2**, and **3**. The values are given in Table 3. Figure 2 shows the Arrhenius plot for DMAM-adenosine.

The presence of one more contributing structure to the resonance hybrid (structure *b* in Scheme 2), as a result of the extended conjugation in the nucleobase, appears to be of considerable importance to the double bond character of the terminal C—N bond in these compounds. The energy of activation for **1**, 58.0 kJ/mol, is found to be higher than those for the dimethylamino adenine derivatives, 49.4 (19) and 51.0 (20) kJ/mol.

Compounds **2** and **3** have barriers (71.2 and 62.8 kJ/mol, respectively) that are comparable to the barriers for dimethylamino cytosine derivatives (12, 16, 19). They are, however, higher than those of *N*,*N*-dimethylamino pyrimidines, 38–59 kJ/mol (14). These results indicate that the oxo function has considerable influence on the barrier to internal rotation of these compounds. Like the cytosine derivatives, their barriers to internal rotation are lower than those of the amides; the activation energy for dimethylformamide (DMF) is reported to be 85.77 kJ/mol (21). This is probably due to the amidine, rather than the amido, character of the compounds.

The coalescence temperatures for all three compounds are much higher than those reported for the *N*,*N*-dimethylamino-adenine and -cytosine derivatives. The maximum reported for any of these derivatives is 37°C (12, 16). The high coalescence temperatures of the compounds under study can be accounted for in terms of the extended conjugation in the nucleobases and of the solvent effect. This extended conjugation would lead to a further restriction in the rotation of the C—N bond. The solvent has been shown to have an effect on the coalescence temperature (16). The t_c for DMF in $CDCl_3$ is reported to be 120°C. To find out whether there is any solvent effect on the t_c, a 0.1 M solution of DMF in DMSO-d_6 was studied over a temperature range of 80°C to 150°C. The methyl signals of DMF were observed to coalesce at about 145°C. This was helpful in removing any doubts that the methyl signals of the compounds could be those of DMF since this solvent could not be completely removed after the reaction.

N-Dimethylaminomethylene-adenosine was also studied in D_2O. The coalescence temperature was found to be approximately 104.5°C in D_2O. This higher t_c in D_2O may be explained in terms of a hydrogen-bonding interaction between the solvent and the substrate molecules. The barrier to internal rotation was not determined in this solvent due to a rapid hydrolysis of the compound at this high temperature.

The rapid hydrolysis is also observed for all the compounds in DMSO-d_6 at a much higher temperature (above 100°C). Studies showed that **3** rapidly formed the starting nucleoside and *N*,*N*-dimethylformamide at about 140°C. When a drier solvent was used, the compound, which was studied up to 150°C, was found to be quite stable even at the highest temperature. The compounds are known to decompose in both acidic and basic solutions and should therefore be handled with care in aqueous solutions.

In several cases the DMAM function has been used as protecting group in the synthesis of nucleosides, nucleotides, and oligonucleotides. In at least one case (22), the biological activity of derivatives of guanosine 3′,5′-cyclic phosphate was studied. In such studies a question that may be asked is whether the effect of the internal rotation of the exocyclic C—N bond would lead to unexpected results. This

study indicates that the t_c's of these compounds are so high that in biological systems the methyl groups would remain nonequivalent and the effect of the rotation of the C—N bond will not be observed.

Experimental

The identity of each derivative was confirmed by positive fast atom bombardment (FAB+) mass spectrometry. The FAB mass spectra were obtained on a triple-sector (EBE) JMS-HX100 mass spectrometer (JEOL, Tokyo, Japan) equipped with a saddle field neutral beam gun. Xenon fast atoms were used to bombard the sample, dissolved in glycerol, on a stainless steel probe. The probe was introduced into a EI-FAB source. The accelerating voltage was 5 kV.

Proton and ^{13}C NMR spectra were obtained with a JNM-GX270 spectrometer (JEOL, Tokyo, Japan) using a 90 degree pulse and a pulse delay of 1 s. Tetramethylsilane was used as internal reference for both ^1H and ^{13}C spectra. For the determination of t_c and E_a, the ^1H NMR spectra were obtained as a function of temperature. The probe temperature was set electronically and the difference in temperature between the sample and the thermocouple corrected for with the temperature compensation feature of the spectrometer. Measurements were taken between 30 and 150°C. The probe was tuned at each temperature to correct for drifts in the field with temperature changes. The results were, however, obtained without correcting for shifts in chemical shifts with respect to temperature changes.

The coalescence temperatures were estimated by plotting the chemical shift differences of the methyl groups as a function of temperature and using a third-order polynomial for curve-fitting. They were then accurately determined by spectral acquisition at temperatures close to the estimated values.

Synthesis of dimethylaminomethylene nucleosides

Synthesis of the dimethylaminomethylene derivatives of nucleosides has been described elsewhere (9, 10). Briefly, the compounds were prepared by allowing a mixture of 0.1 mmol of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

nucleoside and 1 mmol of dimethylformamide dimethylacetal (DMF–DMA) to stand in 1 mL dry DMF at room temperature for 3 h (see Scheme 3). Water (100-fold) was added and the sample was evaporated to dryness under a steam of nitrogen. The sample was then taken up in either deuterated dimethyl sulfoxide (DMSO-d_6) or deuterium oxide (D_2O) for NMR analysis.

MARGARET M. KAYSER, KRISTA L. HATT, HESHUI YU, and DONALD L. HOOPER. Can. J. Chem. **71**, 1010 (1993).

A study by NMR spectroscopic methods and trapping experiments of the mechanism of Wittig reactions between stabilized phosphoranes and unsymmetrically substituted cyclic anhydrides suggests that two reactions are involved: (1) a low-energy, reversible formation of acyclic adducts; and (2) a higher energy "Wittig olefination" reaction leading to enol-lactones. The latter, more selective, transformation requires a more highly organized transition state in which π-stacking and stabilizing complexations are important factors.

MARGARET M. KAYSER, KRISTA L. HATT, HESHUI YU et DONALD L. HOOPER. Can. J. Chem. **71**, 1010 (1993).

Une étude par des méthodes de RMN et des expériences de piégeage réalisées en vue d'élucider le mécanisme des réactions de Wittig entre des phosphoranes stabilisés et des anhydrides cycliques substitués d'une façon non symétrique suggèrent que deux réactions sont impliquées : (1) une formation réversible, de faible énergie, d'adduits acycliques et (2) une réaction d'oléfination de Wittig, d'énergie élevée, conduisant à des énol-lactones. Cette dernière réaction, une transformation plus sélective, fait appel à un état de transition très organisé dans lequel un empilement π et des complexations stabilisantes sont des facteurs importants.

Introduction

The condensation of stabilized phosphoranes with substituted cyclic anhydrides provides an excellent route to the corresponding enol-lactones (1–5). However, for several anhydrides studied, regioselectivity of the enol-lactones produced could not be reliably predicted on the basis of steric or electronic effects of the substituents (1–3). This was particularly evident in phthalic anhydrides with oxygen-containing groups (-OCH_3 or -NO_2) in position 3, where regioselectivity projections based on the electronic and (or) steric effects did not correspond to the experimental results (1).

Initially, we suggested that the unexpectedly high proportion of enol-lactones resulting from condensation at the carbonyl group adjacent to the oxygen-bearing substituents might be due to the stabilizing complexation between the electron deficient phosphorus atom of the ylide and the oxygen atom of the substituent (1–3). Our more recent studies of the mechanism showed that condensations of cyclic anhydrides with stabilized phosphoranes lead, in a low-energy, reversible process, to acyclic adduct(s). The enol-lactones are subsequently formed via a higher energy irreversible transformation (6). Taking into account a facile reversibility of acyclic adduct(s) formation, it was not possible to determine if the initial addition products are converted to enol-lactones, or if there exists an alternate, higher energy, pathway leading directly from cyclic anhydrides to enol-lactones. In view of these developments the role of neighbouring substituents on stabilization or destabilization of the transition state and hence on the regioselectivity of these reactions needed to be reinvestigated and refined.

The condensations of 3-methoxyphthalic and 3-nitrophthalic anhydrides, as well as several substituted maleic and succinic anhydrides, with stabilized ylides **1** and **8** were followed by ^1H and ^{31}P NMR. The reversibility of the initial condensation step was confirmed for several reactions of phthalic, maleic, and succinic anhydrides. Experiments designed to trap intermediates were carried out, and the trapped regioisomers were identified. This paper describes the above study and discusses mechanistic implications of the results obtained.

Results and discussion

The general approach used is illustrated by the extensively investigated reactions of methyl(triphenylphosphoranylidene)acetate **1** with 3-methoxyphthalic anhydride **2** and 3-nitrophthalic anhydride **5**. The outlines for the reactions are illustrated in Scheme 1 and Scheme 3, respectively.

The effects of 3-methoxy and 3-nitro substituents on the rate of enol-lactone formation

The room temperature (25°C) condensation of 3-methoxyphthalic anhydride **2** with ylide **1**, monitored by ^1H NMR, showed that the reaction is 50% complete in approximately 25 min (Table 1). Under the same conditions condensation of 3-nitrophthalic anhydride **5** with ylide **1** does not progress beyond the formation of acyclic intermediates, and the conversion to enol-lactones is observed only on heating above 50°C (Fig. 1). This experiment did not provide an explanation for the sluggish formation of enol-lactones; which might be caused (*a*) by a slower conversion of the 3-nitrophthalic anhydride to enol-lactones, or (*b*) by a greater stability of the acyclic products. The results obtained so far suggested that, in order to understand the mechanism of the formation of enol-lactones, it is necessary to establish the role played in these reactions by the acyclic intermediates.

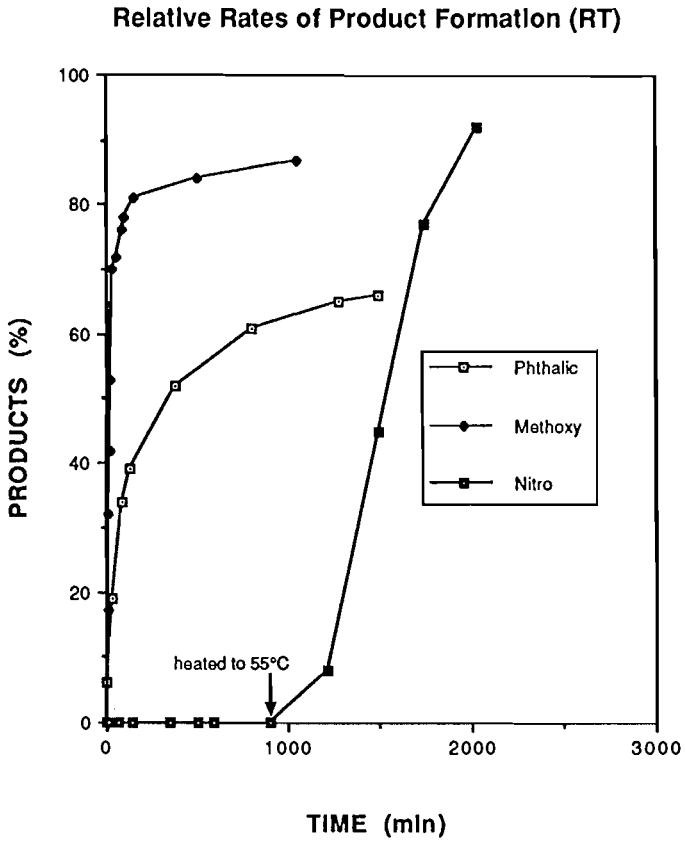

FIG. 1. The relative rates of enol-lactone formation in the reactions of 3-methoxy, 3-nitro, and unsubstituted phthalic anhydrides with ylide **1** at room temperature.

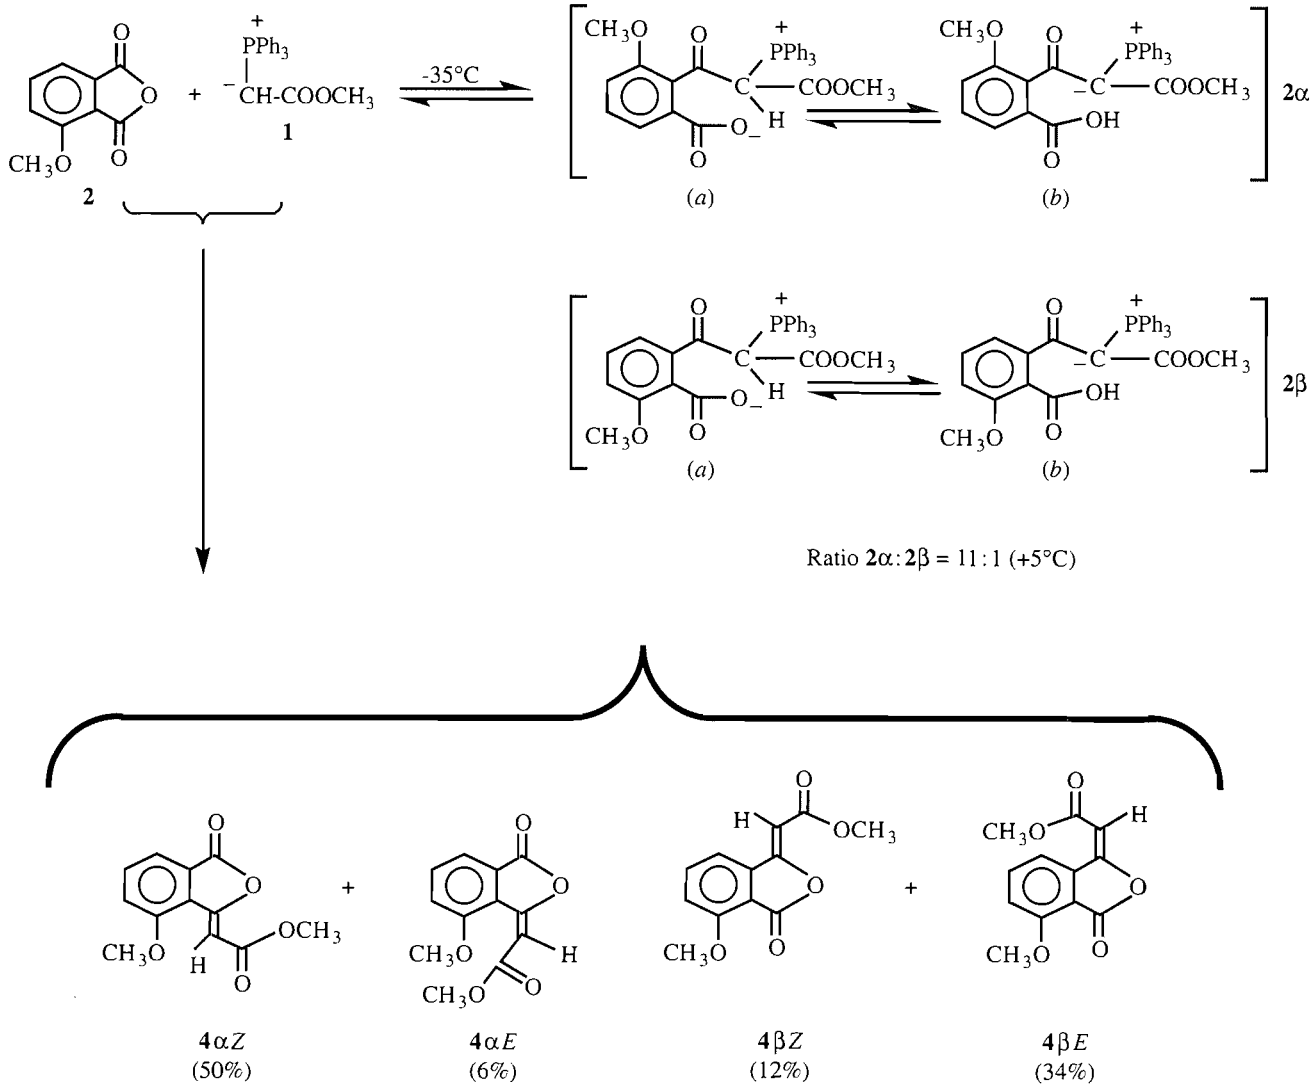
2α and **2**β at any time. The spectrum recorded immediately upon mixing showed that the reaction mixture was composed of 72% ylide (3.50 ppm), 14% acyclic intermediate (3.00 ppm, only one broad signal was observable), and 14% enol-lactone products, (Table 1). As the reaction progressed the proportion of the intermediate dropped rapidly, accompanied by a simultaneous increase in the quantity of the enol-lactones. After 20 min only a trace amount of an intermediate was observable in the ^{1}H NMR spectrum, and this situation persisted until all the remaining ylide was converted into products. The relative proportions of the four products were established from the integration of their methoxy and vinylic proton signals (1).

When the same reaction was initiated at −35°C (Scheme 1), two signals for the acyclic intermediates appeared immediately and, as enol-lactones did not form at low temperature, an important accumulation (>50%) of the intermediates was observed below 10°C (Table 2). As the reaction progressed the initial ratio of the two intermediates (3:7 recorded at −35°C) changed with the rising temperature until at 5°C the minor intermediate was visible only as a shoulder on the major methoxy signal (Table 2).

Our interpretation of these results is as follows: immediately upon mixing of the 3-methoxyphthalic anhydride **2** with ylide **1** at −35°C, the condensation occurs at both carbonyl groups, with the α-carbonyl adduct being produced in excess. As the temperature is raised stepwise, the α/β ratio increases slowly, indicating the shift toward the more stable adduct. The P–O affinity may be a key factor in stabilization of the **2**α adduct, as illustrated in Fig. 2*a*. When the reaction temperature reaches the point where the formation of enol-lactone can occur, the **4**α and **4**β enol-lactones appear.



SCHEME 1

The slightly higher proportion of the **4α** enol-lactone produced corroborates the previously postulated π-stacked transition state (1), incorporating a stabilizing complexation between the 3-methoxy substituent and an electron-deficient phosphorus atom as illustrated in Fig. 3 (1). Such complexation justifies, at least in part, the formation of electronically and sterically unfavourable **4α** regioisomers (7). It is important to note that the product ratio (**4α**:**4β**) does not reflect the ratio of isomeric acyclic intermediates (**2α**:**2β**) at the temperature at which the enol-lactones appear (Scheme 1). These results put in question the role of acyclic adducts as true intermediates in the transformation of cyclic anhydrides to enol-lactones.

The proportion of esters **3α** and **3β** trapped with CH_2N_2 did not correspond to the ratio of the acyclic adducts **2α** and **2β** any more than did the ratio of enol-lactones. Treatment of the reaction mixture with CH_2N_2 at the time of the maximum buildup of the intermediates (5°C) when the ratio of **2α**:**2β** was approximately 11:1, gave a 5:3 mixture of **3α** and **3β** (Scheme 2). Subsequent trapping experiments carried out at various temperatures between −5°C and 15°C consistently produced significant quantities of **3β** (35–45%), showing that the initial addition of the ylide to the anhydride is an equilibrium and that the reaction with CH_2N_2 is faster with the **3β** intermediate.

The structural identities of the two isomeric acyclic adducts were established from their spectral data and were confirmed by the X-ray crystal structure obtained for the minor **3β** isomer.[2]

The reversibility of the condensation of ylide **1** with 3-methoxyphthalic anhydride was verified by the following experiment. The low temperature condensation reaction monitored by ^1H NMR was allowed to proceed until 50% of the ylide was converted into acyclic intermediates, at which point freshly distilled benzaldehyde was added to the reaction solution. The signals of both the ylide and the intermediate slowly disappeared and the only observable product, besides the recovered anhydride, was methyl cinnamate.

FIG. 2. Proposed stabilization of the acyclic adducts by strong P–O complexation in **2**α (*a*) and by H-bonding in compounds **5**β (*b*) and **5**α (*c*). The stabilizing H-bonding for the isomeric adduct **2**β, similar to that depicted in (*b*), should be considerably weakened by the competing conjugation of the electron pair from the oxygen atom with the electron-poor aromatic ring.

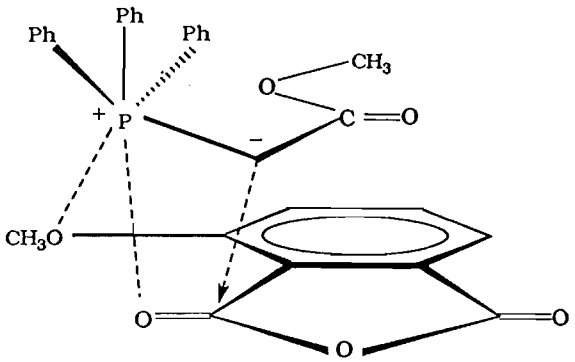

FIG. 3. The proposed stabilization of the transition state by complexation of the 3methoxy substituent with an electron-deficient phosphorus of the ylide.

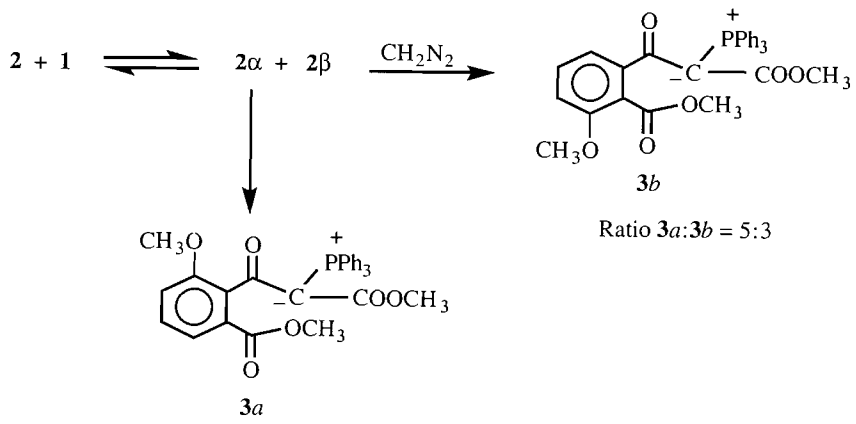
3-Nitrophthalic anhydride

The reaction of ylide **1** with 3-nitrophthalic anhydride **5**, both freshly crystallized (Scheme 3), yielded the acyclic intermediates very rapidly at room temperature (25°C). The subsequent transformation to enol-lactones required a longer reaction time and a considerably higher temperature (above 50°C) in order to occur. Thus, at room temperature there was a large buildup of acyclic intermediates **5**α and **5**β in the ratio 1:8, which remained relatively unchanged until the reaction mixture was heated above 50°C (Table 3). It appears, therefore, that the presence of an electron-withdrawing 3-nitro substituent does not reduce the rate of formation of acyclic adducts; it does, however, affect the step leading to enol-lactones.

During the low temperature study, a bright yellow colour developed immediately upon mixing at −40°C, and the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.



SCHEME 2

spectrum recorded within 10 min showed that the reaction mixture was composed of the ylide (25%) and two acyclic adducts (75%) in the ratio 5α:5β = 1:4 (Table 4). As the temperature was raised, a little more of the anhydride **5** was converted into acyclic intermediates, but the ratio α/β changed only slightly until about 50°C, when the relative proportion of 5α was further reduced and enol-lactones started to appear.[3]

It may be concluded that the higher stability of the 5β is enhanced by internal H-bonding of the *ortho* acid group with the substituent. Such intramolecular H-bonding, between the acid functionality and a highly negative oxygen atom of the nitro substituent, illustrated in Fig. 2*b*, should be especially strong. It would be expected to delay recyclization of the 5β acyclic adduct and consequently interfere with the formation of enol-lactones.

While the 5β adduct is the major regioisomer, the formation of enol-lactones favours the α-condensation. It may be that the stabilizing complexation with an oxygen-bearing nitro group, as shown in Fig. 4, lends a slight bias in favour of the α carbonyl group. It should be added, however, that in this case the α attack is also promoted by electronic effects, while being opposed by steric effects of the substituent (7).

Trapping of the intermediates with CH_2N_2, at 15°C, gave a high percentage (above 80%) of 7β, (identified from its ^{13}C and ^1H NMR spectra) compared with less than 20% of the 7α isomer. These values reflect almost exactly the ratio of the two intermediates 5α and 5β at the time of trapping, suggesting that the reaction with diazomethane is faster than retro-condensation (Scheme 4).

The reversibility of the formation of 5α and 5β was confirmed independently. Thus, upon mixing freshly crystallized ylide **1** and sublimed 3-nitrophthalic anhydride **5** at room temperature, a strong (65%) signal for the 5β appeared immediately. After 30 min at 25°C the bright yellow equilibrated reaction mixture consisted of approximately 80% intermediate (3.00 ppm) and 20% ylide **1** and conjugate acid **1***a* exchanging pair (broadened signal at 3.58 ppm). When freshly distilled benzaldehyde was added, the colour disappeared instantaneously, and so did the intermediate and the remaining ylide; the only signals observable were those for *trans*-methyl cinnamate and a small peak (<10%) for the methoxy group of the conjugate acid $Ph_3PCH_2COOCH_3Br$ **1***a* at 3.61 ppm.

Reactions with carboethoxyethylidene triphenylphosphorane ***8***.

To assess the importance of the stabilization of the acyclic adducts through proton exchange and H-bonding, we followed condensations of anhydrides **2** and **5** with carboethoxyethylidene triphenylphosphorane **8**, an ylide that does not possess an exchangeable hydrogen atom. Both reactions gave enol-lactones rapidly at room temperature. Interestingly, the reaction with 3-nitrophthalic anhydride was considerably faster than that with 3-methoxyphthalic anhydride. In the former case, the ^1H NMR spectrum recorded immediately on mixing of the reagents showed that the reaction was already completed and only the signals for enol-lactone and triphenylphosphine oxide were observable. In the latter case, the disappearance of **8** could be monitored for about an hour, with the last traces of the ylide still detectable a few hours later (Scheme 5).

The two reactions were entirely regio- and stereoselective, leading in both cases to a single enol-lactone in 100% yield based on ^1H NMR evidence. However, while the reaction of **8** with 3-methoxyphthalic anhydride gave selectively the 9α*E* enol-lactone, the reaction with 3-nitrophthalic anhydride produced exclusively the 10β*E* product. Similarly, 100% β selectivity was also observed in the reaction of 3-nitrophthalic anhydride with the fluorinated ylide $Ph_3PC(F)COOEt$ **11**. The only product isolated from this condensation showed a highly deshielded doublet at 9.7 ppm, characteristic of the aromatic proton *ortho* to the ylidene substituent in phthalic *E* enol-lactones (1).

A study of the condensation of ylide **8** with unsubstituted phthalic anhydride, reported previously (6), implied that an unstable intermediate formed during the reaction is in rapid equilibrium with the starting materials and cannot be observed by ^1H NMR as a distinct species even at low (−40°C) temperature. Its fleeting existence can be deduced from the

[3]Interestingly, when the same reaction was carried out with 3-nitrophthalic anhydride contaminated with 3-nitrophthalic acid, the two acyclic adducts 5α and 5β were present in a 1:1 ratio. The conversion to enol-lactones was very slow even above 55°C. It appears that an excess of acidic protons in the reaction mixture stabilizes 5α, possibly by an internal H-bonding (Fig. 2*c*), thus leading to its accumulation. Under these circumstances both regioisomers are slow to recyclize and formation of enol-lactones is further delayed.

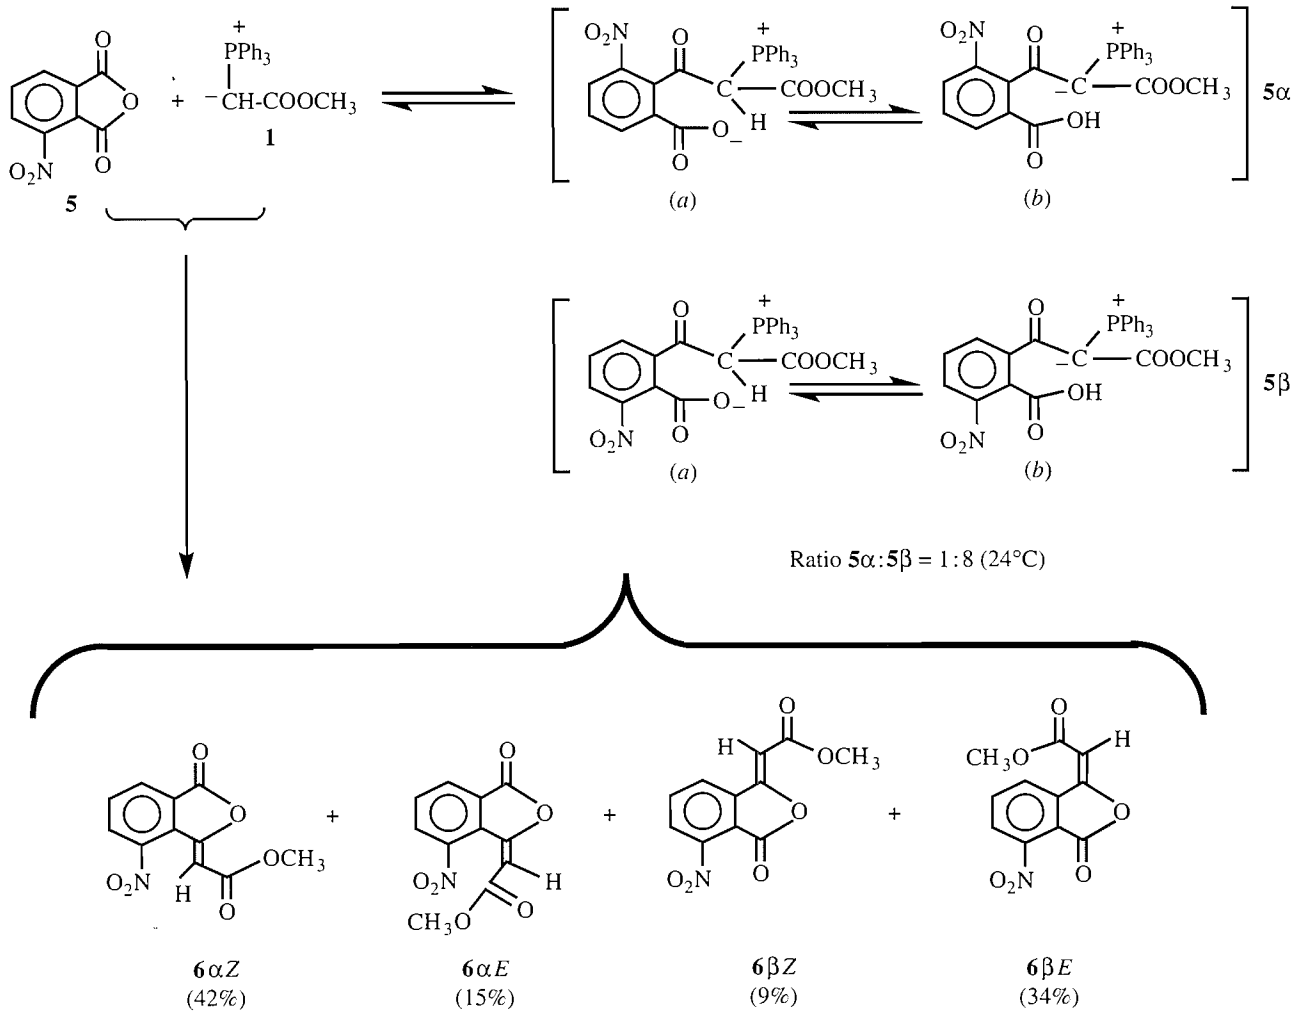

SCHEME 3

broadening of the methyl and methylene (CH_3CH_2O-) proton signals and a transient broad peak in the ^{31}P NMR spectrum. The situation is very similar in the corresponding reactions of **8** with the 3-substituted phthalic anhydrides. Here also, we were unable to trap any intermediates, and consequently regioselectivity of the initial attack (if distinct from the regioselectivity of enol-lactone products) cannot be determined.

The lack of success in trapping acyclic compounds during the reactions with ylide **8**, suggests that, if they do form at all (as appears to be the case judging by the broadening of the ^{31}P signal), they are highly unstable species in rapid equilibrium with the starting materials. In view of this, we may conclude that proton exchange within the **2**α,**2**β and **5**α,**5**β pairs contributes significantly to the stability of the adducts. The internal H-bonding, and complexations of electron-deficient phosphorus with substituent (vide supra) provide additional stabilization for these adducts.

Other interesting observations, which were not apparent from the reactions with ylide **1**, came to light and are summarized as follows:

1. The generation of highly stabilized acyclic adducts obscures the reaction leading to enol-lactones. When this effect is abstracted, it becomes possible to see that an electron-withdrawing nitro substituent accelerates (as might be expected) the rate of an ylide's attack compared to the rate of attack of the same ylide on an anhydride substituted with an electron-donating methoxy group. Hence, the sluggish formation of enol-lactones during the condensation of **1** with **5**, compared to the condensation of **1** with **2** (Fig. 1), can be linked to a higher stability of the acyclic compounds **5**α and **5**β.

2. The formation of acyclic products is a reversible process, with an equilibrium lying to the left when unstable, readily recyclable, adducts are produced (as in the reaction of ylide **8** with phthalic anhydride), or far to the right, when highly stabilized, not readily recyclable, products are formed (ylide **1** with **5**). This conclusion is supported by an earlier observation (8) that unsubstituted glutaric anhydride reacts with stabilized ylides to give a stable acyclic intermediate, but is converted to enol-lactones only with difficulty (several days of heating), while 2,2-*gem*-disubstituted glutaric anhydride, which recyclizes readily due to the Thorpe–Ingold

gem-dialkyl effect (9), produces enol-lactones considerably more rapidly.

Furthermore, in the reactions of 3-methoxy- and 3-nitrophthalic anhydrides with ylide **1**, the proportions of acyclic adducts were found to be different from the proportions of enol-lactones formed. These results suggest that two different reactions with different regioselectivity patterns are involved: the lower energy reversible condensation, leading to acyclic intermediates, and the higher energy irreversible formation of enol-lactones. To verify the above conclusions, we investigated the reactions of several substituted maleic and succinic anhydrides with stabilized ylides, following methodology employed in the study of 3-substituted phthalic anhydrides. The results, summarized in Table 5, show that in the majority of cases studied the ratios of enol-lactones obtained bear no relationship to the regioselectivity

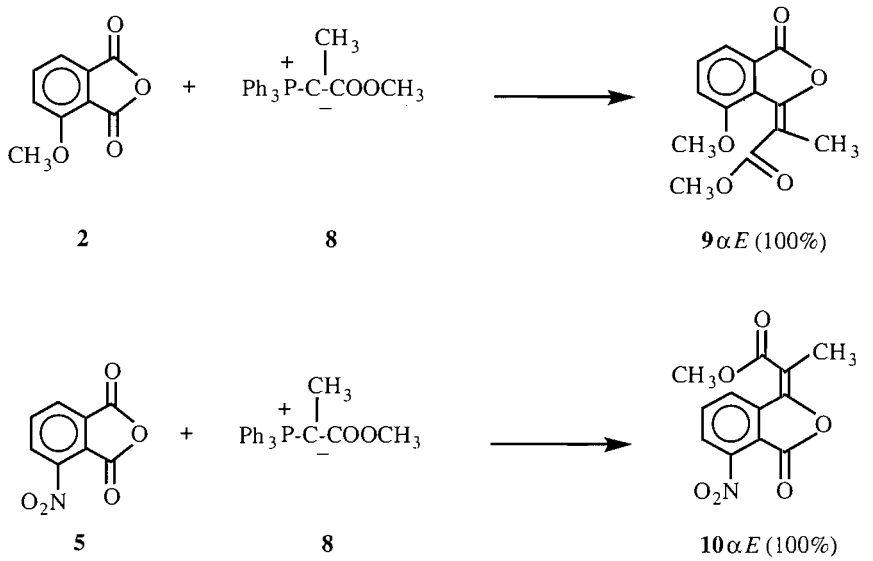

SCHEME 5

of the formation of acyclic adducts. It is most clearly evident in the reactions of ylide **1** with phenylmaleic, methoxymethylmaleic, and methoxysuccinic anhydrides where two acyclic adducts are formed at low temperatures, while the corresponding enol-lactones are produced in very high yields with 100% regioselectivity for α or β carbonyl groups depending on the substrate (1, 2, 3, 10).

The mechanisms of reactions of stabilized ylides with cyclic anhydrides have been the subject of much speculation and several reaction pathways have been proposed (1–4, 11–14). The data obtained in this study indicate that the formation of acyclic intermediate(s) is a reversible process, with an apparently quite low energy transition state. To obtain an acyclic adduct nucleophilic addition must proceed via a tetrahedral intermediate (15); in other words it must involve an unstable betaine intermediate or betaine-like transition state. The formation of acyclic products is clearly sterically dependent, as illustrated by regioselective formation of β adducts in 2,2-dimethyl- and 2,2-diphenylsuccinic anhydrides (Table 5). However, when steric congestion is not very severe, as is the case in planar maleic anhydrides or in mono substituted succinic anhydrides, the addition occurs at both carbonyl groups. The electronic/complexation effects of the substituents appear to have limited effect on the course of these reactions.

The formation of enol-lactones appears to follow a different route involving a more organized, higher energy, transition state. We suppose that this is a pathway entailing an oxaphosphetane intermediate or an "oxaphosphetane-like" transition state, thus corresponding to an extensively investigated mechanism of reactions of nonstabilized and semi-stabilized ylides with aldehydes and ketones (16–18). The principal difference between Wittig reactions with aldehydes and ketones and Wittig reactions with cyclic anhydrides lies in the fact that in the former, "salt-free," condensations, the betaine intermediates do not appear to play a role; betaine has never been trapped or detected (16–18) and, according to the calculations (19, 20), it should be a higher energy species than oxaphosphetane. In the latter case, presence of an excellent leaving group at the carbonyl centre obviously lowers the energy of the betaine-like transition state and provides a low-energy alternate pathway to acyclic addition products. The enol-lactones, therefore, are not formed unless the formation of acyclic adducts is reversible. The irreversible formation of such adducts, observed in reactions of stabilized ylides with acyclic anhydrides and acid halides

(11), is probably responsible for the fact that these compounds do not give olefination products.

The higher energy, but also more highly organized, transition state leading to enol-lactones explains adequately the regio- and stereoselectivity observed in reactions of stabilized ylides with cyclic anhydrides. It is in agreement with Chopard's explanation of high *E*-selectivity observed in the reactions of stabilized ylides with phthalic anhydrides (12) and our justification of regioselectivity observed in 2-methoxymaleic (3), 2-methoxysuccinic (2), and 3-methoxy- and 3-nitrophthalic anhydrides (1).

The reaction of stabilized ylides with cyclic anhydrides can be described in kinetic terms as follows. Compounds A and B are rapidly and reversibly converted to an adduct AB; a product P is formed at a relatively slow rate. In such cases, unfortunately, there is no observable kinetic difference between the mechanism in which P is formed by the first-order rearrangement of AB, and one in which it is formed by a second-order reaction of A with B in which AB is not an intermediate, as shown in reactions 11 and 12 of ref. 21.

$$A + B \leftrightharpoons AB \rightarrow P \quad (11)$$

and

$$P \leftarrow A + B \rightleftharpoons AB \quad (12)$$

Although it is not possible to distinguish between these two possibilities on the basis of their kinetics, we interpret the observed results on the premise that the formation of acyclic "intermediates" and the formation of enol-lactones are two independent reactions, which proceed to different products via different reaction pathways (equation 12). The low-energy, reversible formation of acyclic adducts is in evidence when stabilized acyclic compounds can be produced. One can imagine that, at the limit, when the acyclic products are particularly stable or difficult to recyclize (six(or more)-member cyclic anhydrides) or the reagent ylide is too reactive to be displaced, the reaction becomes irreversible and consequently the corresponding enol-lactones are not produced. The alternate route, shown in equation 11, requires evocation of a betaine intermediate or a betaine-like transition state during the recyclization process. The subsequent

reorganization of that betaine via higher energy oxaphosphetane would then lead to enol-lactone. The betaine (or oxaphosphetane) in that case would be a common intermediate for the formation of acyclic adducts and enol-lactones. Considering the difference in regioselectivity of these two products, we consider the "two independent reactions scenario" illustrated by equation 12 more plausible (Scheme 6).[4]

Conclusion

In this paper we have described the study of condensations of stabilized ylides with substituted cyclic anhydrides. Based on these results, as well as the results of several prior investigations, we conclude that the reactions of stabilized ylides with cyclic anhydrides give acyclic addition products via a low-energy, reversible pathway, probably involving a betaine-like transition state, while the enol-lactones (the "Wittig" products) are formed through a higher energy route, most likely involving a highly organized transition state and possibly an unstable oxaphosphetane intermediate.

In five-member cyclic anhydrides, the stability of acyclic intermediates can vary from a transient species, rapidly equilibrating with the starting materials, through adducts stabilized by internal proton exchange readily observable in low-temperature, NMR to intramolecularly H-bonded compounds stable up to 45–50°C. Intermediates that can form strong intramolecular H-bonds, or are otherwise stabilized, are slow to recyclize and consequently are slow to form Wittig products.

In general, the stabilizing complexation between an electron-deficient phosphorus atom of the ylide and an electron-rich oxygen atom of a strategically located substituent on the anhydride ring has a controlling effect on the regioselectivity of the formation of enol-lactones.

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Infrared spectra were obtained on a Perkin–Elmer 297 infrared spectrophotometer. Nuclear magnetic resonance spectra were recorded on the Varian XL-200 spectrometer and on the Nicolet 360 NB spectrometer of the Atlantic Regional Magnetic Resonance Centre. All spectra were in $CDCl_3$ solutions unless otherwise specified, with TMS as internal reference (^1H and ^{13}C) or 85% H_3PO_4 as external standard (^{31}P). Temperature control was by the usual Nicolet method. Calibration of the thermocouple showed an estimated error of less than 1° in the temperature range used. Mass spectra were obtained on a Kratos MS 550 TC mass spectrometer. Gas chromatography analyses were carried out with a Shimadzu GC 9A chromatograph, using 5% OV101 on Supelcoport 100–120 mesh column. Chromatographic separations were performed on a Chromatotron 7924T radial thin-layer chromatograph.

General procedures

*Room temperature reactions of anhydrides **2** and **5** monitored by ^1H NMR*

An ylide (0.3 mmol) was dissolved in $CDCl_3$ (3 mL) and the spectrum was recorded. An anhydride (0.3 mmol) suspended in 0.5 mL $CDCl_3$ was added to the ylide. The mixture was shaken and the spectrum was recorded immediately. The composition of the reaction mixture was determined from integration of ^1H NMR spectra taken at regular intervals. After the reaction was completed, the enol-lactone products were separated from the triphenylphosphine oxide by chromatography on silica gel. The product distribution was compared with that obtained in the condensation reactions carried out in refluxing THF (1).

Low-temperature reactions were run on the same scale as described above. General procedures for low-temperature condensations and for reactions carried out under anhydrous conditions are described in previous papers (12, 13).

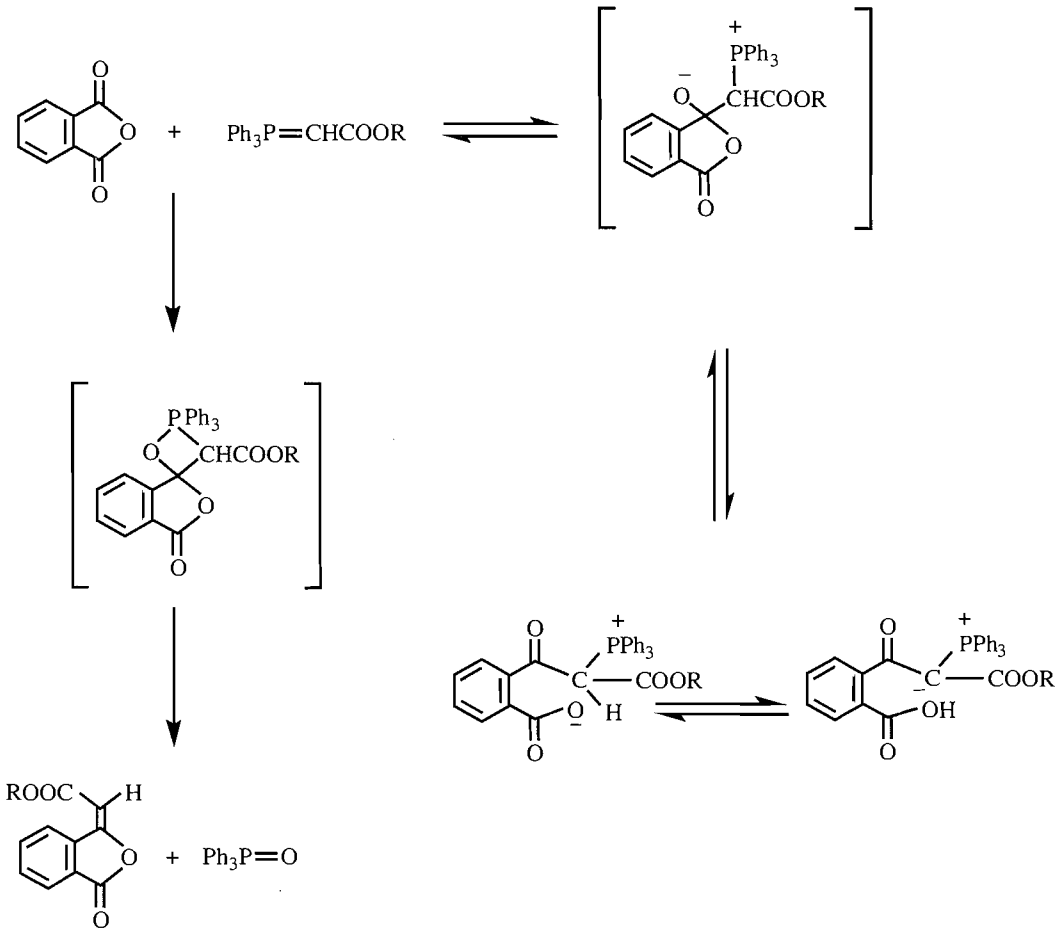
*Trapping of 3-methoxyphthalic anhydride **2** + ylide **1** with CH_2N_2*

3-Methoxyphthalic anhydride **2** (200 mg, 1.12 mmol) suspended in 10 mL of $CHCl_3$ was cooled to −5°C. Ylide **1** (375 mg, 1.12 mmol) dissolved in 10 mL of $CHCl_3$ and precooled to −5°C was added to the anhydride at −5°C and this temperature was maintained for 1, 5, 30, and 150 min. After the appropriate time, the reaction was quenched with a slight excess of diazomethane and left overnight before removing the ether. The ^1H NMR spectrum of the crude reaction mixture was recorded. In all cases studied the intermediates formed were trapped in ratios ranging from 5:3 to 5:4. Sometimes small quantities of the enol-lactones were also produced. The isomers formed were difficult to separate, and several chromatographic runs were required to obtain pure samples for ^1H NMR and mass spectra. The ^{13}C NMR spectra were run on mixtures of the two isomers and consequently the peak assignments reported here are tentative. The isomers were separated by repeated chromatography on silica gel. The minor, **3β**, isomer was eluted first with $CHCl_3$ (+ 0.8% MeOH) and was recrystallized from methanol to give white crystals melting at 199–203°C. 1-Methoxycarbonyl-2-(3′,2′-methoxycarbonylmethoxyphenyl)-2-oxoethylidenetriphenylphosphorane, **3β**: ^1H NMR δ: 3.11 (s, 3H, OCH_3), 3.70 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3), 6.91 (d, 1H), 7.15 (d, 1H), 7.34 (t, 1H), 7.44–7.98 (15 aromatic protons); ^{13}C NMR δ: 49.71, 51.67, 56.11, 72.10 (J_{PC} = 127 Hz), (overlapping aromatic carbons), 144.7 (J_{PC} = 8 Hz), 156.43, 166.75, 167.6 (J_{PC} = 5 Hz), 191.32(d); *m/z*: M^+ 526, 467($M^+ - COOCH_3$), 277(100), 248 ($M^+ - Ph_3POH$), 217, 77, 55. The major, **3α**, isomer was eluted second with $CHCl_3$ (+ 2% MeOH) and was recrystallized from methanol to give white crystals with melting point 224–226°C. 1-Methoxycarbonyl-2-(2′,3′-methoxycarbonylmethoxyphenyl)-2-oxoethylidenetriphenylphosphorane, **3α** : ^1H NMR δ: 3.01 (s, 3H, OCH_3), 3.74 (s, 3H, OCH_3), 3.85 (s, 3H, OCH_3), 7.05 (d, 1H), 7.25–7.96 (15 aromatic protons); ^{13}C NMR δ: 49.43, 51.87, 55.96, 70.9 (J_{PC} = 127 Hz) (overlapping aromatic carbons), 155.49 (J_{PC} = 4 Hz), 167.30, 167.60 (d), 189.77 (J_{PC} = 4 Hz); *m/z*: 525 ($M^+ - 1$), 494 ($M^+ - CH_3OH$), 466 ($M^+ - COOCH_3$), 276 (100), 261, 247, 77, 55. Overall yield of the two intermediates was 62%. These phosphoranes were completely unreactive towards benzaldehyde. Even after 24 h refluxing in toluene, no product was observed and the two intermediates were recovered unchanged.

*Trapping of 3-nitrophthalic anhydride **5** + ylide **1** with CH_2N_2*

3-Nitrophthalic anhydride **5** (196 mg, 1.0 mmol), recrystallized from $CHCl_3$ and suspended in 5 mL of $CHCl_3$, was added to the solution of methyl(triphenylphosphoranylidene)acetate **1** (339 mg, 1.0 mmol) in 5 mL of $CHCl_3$ at room temperature. A bright yellow solution was formed immediately upon mixing. The reaction was left 10 min before quenching with a slight excess of diazomethane (0.2 M in Et_2O, 6 mL). After standing overnight in the fumehood the solvent was evaporated and the ^1H NMR spectrum of the crude product (73%, 431 mg) was recorded. The mixture contained two isomers in the ratio 85:15. The major isomer **7β** was crystallized from ethanol to give a yellow compound, approximately 90% pure. After several crystallizations a pure sample of the major isomer was obtained. We were unable to get an equally pure sample of the minor isomer. 1-Methoxycarbonyl-2-(2′,3′-methoxycarbonylnitrophenyl)-2-oxoethylidenetriphenylphosphorane, **7β**: mp 165–167°C; ^1H NMR δ: 2.97 (s, 3H, OCH_3), 3.78 (s, 3H, OCH_3), 8.16–7.39 (m, 18H, aromatic protons); ^{13}C NMR δ:

[4]The referees for this paper indicated that the possibility of a common intermediate (betaine or oxaphosphetane) for the two reactions cannot be entirely rejected.



SCHEME 6

49.55, 52.35, 71 (J_{PC} = 125 Hz), 124.7–134.6 (overlapping aromatic carbons), 141.75 (J_{PC} = 8 Hz), 147.02, 165.63 (J_{PC} = 4.8 Hz), 167.96, 186.29; ^{31}P NMR δ: 16.08; *m/z*: 541 (M^+), 510 (M^+-OCH_3), 482 ($M^+-COOCH_3$), 349 (100), 277, 263. Exact Mass calculated for $C_{30}H_{24}NO_7P$: 541.12904; found: 541.1345. Minor isomer 1-methoxycarbonyl-2-(3′,2′-methoxycarbonylnitrophenyl)-2-oxoethylidenetriphenylphosphorane, **7**α: ^{1}H NMR δ: 3.07 (s, 3H, OCH_3), 3.73 (s, 3H, OCH_3), 8.16–7.39 (aromatic protons); ^{31}P NMR δ: 16.84.

*Reversibility study for the reaction of 3-nitrophthalic anhydride **5** with ylide **1***

3-Nitrophthalic anhydride **5** (63 mg, 0.31 mmol) suspended in 5 mL $CDCl_3$ and methyl(triphenylphosphoranylidene)acetate **1** (112 mg, 0.32 mmol) dissolved in 5 mL $CDCl_3$ were mixed at room temperature to give a bright yellow solution. The reaction was monitored by ^{1}H NMR until most of the ylide was converted into acyclic intermediates, at which point a slight excess of benzaldehyde was added to the reaction mixture. The disappearance of the intermediates could be easily followed by NMR. Overnight the solution turned colourless and the ^{1}H NMR showed the formation of methyl cinnamate. Under the reaction conditions described no enol-lactone products were formed. The products, methyl cinnamate and triphenylphosphine oxide were separated by chromatography. *trans*-Methylcinnamate was eluted with ether/petroleum ether (10:90) followed by triphenylphosphine oxide with 100% ether. Yield: triphenylphosphine oxide 69% (60 mg) and *trans*-methylcinnamate 88% (45 mg).

*Reversibility study for the reaction of 3-methoxyphthalic anhydride **2** with ylide **1***

3-Methoxyphthalic anhydride **2** (56 mg, 0.32 mmol) suspended in $CDCl_3$ (5 mL) and ylide **1** (112 mg, 0.32 mmol) dissolved in $CDCl_3$ (5 mL) were pre-cooled and mixed at −30°C. The temperature was raised slowly, over the period of 2.5 h, to 0–5°C. At that point 50% of the ylide was converted into the acyclic intermediates, but no enol-lactones could be detected by ^{1}H NMR. Freshly distilled benzaldehyde (34 mg, 0.32 mmol) dissolved in a few drops of $CDCl_3$ was added and the reaction mixture was allowed to warm to room temperature over 30 min. The ^{1}H NMR spectrum showed that the only products present were methyl cinnamate, 3-methoxyphthalic anhydride, and triphenylphosphine oxide. Chromatographic separation gave methyl cinnamate, triphenylphosphine oxide, and 3-methoxyphthalic acid, the result of the hydrolysis of the corresponding anhydride.

*Reaction of 3-methoxyphthalic anhydride **2** with carboethoxyethylidene triphenylphosphorane **8***

The ^{1}H NMR monitored reaction was carried out as described in the general procedure. On a slightly larger scale, ylide **8** (200 mg, 0.55 mmol) and 3-methoxyphthalic anhydride **2** (98 mg, 0.55 mmol) were dissolved in dry $CHCl_3$ (10 mL) and stirred at room temperature overnight under N_2. The solvent was removed under vacuum and the residue was separated by chromatography on silica gel with 20% acetone – 80% petroleum ether to give **9**α*E* (119 mg, 88%) and triphenylphosphine oxide. The enol-lactone **9**α*E*: mp 110–111°C. IR ($CHCl_3$) ν_{max}: 1775, 1700 cm^{-1}; ^{1}H NMR δ: 1.33 (t, 3H, CH_3CH_2), 2.20 (s, 3H), 3.97 (s, 3H, OCH_3), 4.30 (q, 2H,CH_3CH_2), 6.95 (d, 1H, aromatic), 7.59 (t, 1H, aromatic), 8.01 (d, 1H, aromatic); ^{13}C NMR δ: 14.21, 29.71, 56.20, 61.35, 112.94, 115.35, 117.79, 132.76, 136.94, 139.00, 149.59, 158.77, 163.83, 168.17; *m/z*: 262 (M^+), 217 ($M^+-OCH_2CH_3$), 189 ($M^+-COOCH_2CH_3$), 149 (100). Exact Mass calcd. for $C_{14}H_{14}O_5$: 262.08412; found: 262.0824.

A study of the intramolecular acyloin condensation using diesters tethered by their alkoxide groups was undertaken. The goal was to provide a method for optimizing the yield of mixed acyloin products from the reaction of two different esters by utilizing tethered dissimilar esters as substrates. The results of the study show that the yield of the acyloin condensation is dependant on the tether length. Tethers of 8 and 14 carbons in length give yields comparable to those obtained from an intermolecular control reaction while shorter tethers give reduced yields of product. However, the use of mixed tethered diesters and a crossover experiment between two different tethered substrates provides a statistical distribution of products. These observations have been interpreted as resulting from a fragmentation of the initially formed radical anion intermediate that destroys the tethered nature of the substrate(s).

TIM S. DAYNARD, PAUL S. EBY et JOHN H. HUTCHINSON. Can. J. Chem. **71**, 1022 (1993).

On a entrepris une étude de la condensation intramoléculaire aux acyloïnes impliquant des diesters reliés par leurs groupes alcoolates. Le but du travail était de développer une méthode permettant d'optimiser le rendement en acyloïnes mixtes par réaction de deux esters différents reliés entre eux. Les résultats de l'étude montrent que le rendement de la condensation aux acyloïnes dépend de la longueur de la jonction. Des jonctions de 8 et 14 carbones conduisent à des rendements qui sont comparables à ceux obtenus avec des réactions sous contrôle intermoléculaire; des jonctions plus courtes conduisent à des rendements plus faibles. Toutefois, l'utilisation de diesters mixtes reliés et une expérience d'échange entre deux substrats différents reliés fournissent des distributions statistiques de produits. On interprète ces observations en fonction d'une fragmentation de l'intermédiaire anion radicalaire formé initialement qui provoque une destruction de la jonction du (ou des) substrat(s).

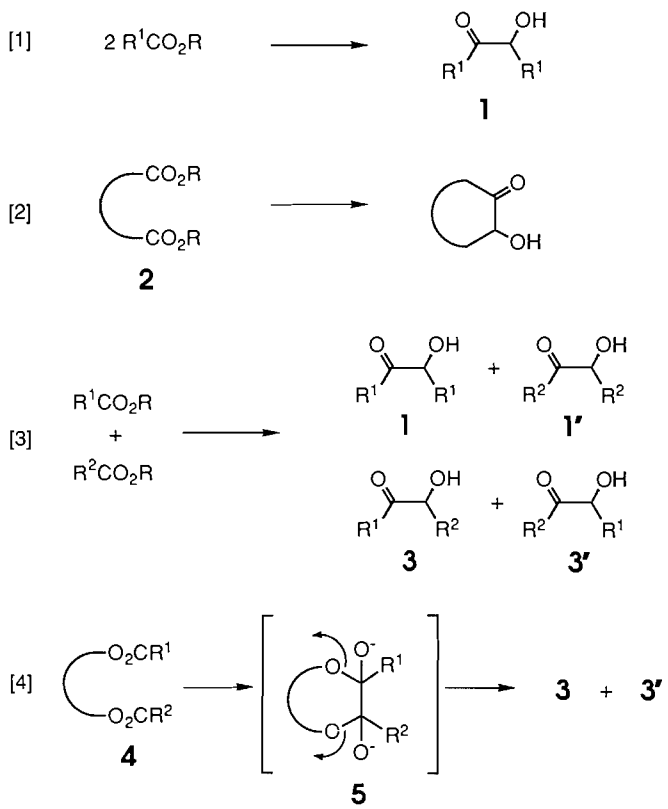
The acyloin condensation is the reductive coupling of two esters (eq. [1]) and it is a powerful method of carbon–carbon bond formation resulting in the formation of an α-hydroxyketone **1** (1). This reaction is particularly useful in the case of diesters **2** where an intramolecular cyclization yields a cyclic acyloin product (eq. [2]) (1*a*, 2). With the introduction of chlorotrimethylsilane (TMSCl) as an alkoxide scavenger, the usefulness of this methodology has been extended considerably (3). Yields are increased and in some cases (e.g., the formation of four-membered rings) no product is formed at all in the absence of TMSCl (4, 5).

This procedure is limited, however, when two dissimilar esters are used, eq. [3]. Here four products are formed, in statistical yields, resulting from the random intermolecular reaction of both esters and thus the maximum yield of the desired products (**3** and **3′**) is only 50%. The separation of such a mixture is difficult and adds to the undesirability of the method. As a consequence, there are only a few reports of the mixed acyloin reaction in the literature (6).

An interesting possibility for improving the yield of the mixed acyloin products **3** and **3′** involves the use of tethered unsymmetrical diester substrates **4**. This approach relies on an intramolecular cyclization of a substrate in which two different esters are tethered via the alkoxide portions, as in eq. [4], to yield the mixed acyloins **3** and **3′** as the predominant products.

In this paper we will present the first data on the use of tethered esters as substrates in the acyloin reaction. In particular, we will focus on determining the optimum chain length for the tether (carried out on a series of symmetrical diesters) and the extension of this to unsymmetrical diesters. Lastly, these results and their implications on the currently accepted mechanisms will be discussed.



Results

We chose to study a series of tethered bis-hexanoyl esters as substrates in the acyloin condensation to determine which

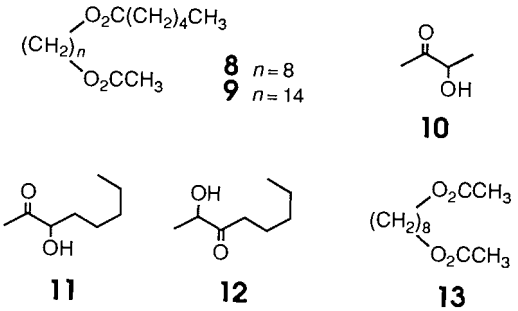
tether afforded the product (capronoin, **7**) in the highest yield. Substrates **6***b–g* were prepared from hexanoyl chloride, the appropriate diol, and Et_3N in dichloromethane. In addition, a compound with a silicon tether (**6***a*) was prepared from diisopropyldichlorosilane, hexanoic acid, and Et_3N in dichloromethane. The results of the condensations with the tethered substrates are given in Table 1. For comparison (and to confirm our methodology), the intermolecular reaction between methyl hexanoate was carried out using fine sodium sand in refluxing toluene under nitrogen and **7** was then isolated in 68% yield. A similar yield (80%) was reported for this reaction when it was carried out in refluxing xylene (7). All the remaining condensation reactions were performed in the presence of TMSCl (8).

The reaction of the diisopropylsilyl tethered derivative **6***a* produced a complex mixture of nonpolar by-products with only a trace amount of the product **7** (5%) isolable. When ethylene glycol (**6***b*) or 1,3-propanediol (**6***c*) was used the yields, although improved, were still disappointing at only 20%. Increasing the tether length to $n = 5$, 8, and 14 gave increased yields of 42, 76, and 73% respectively. The yields for the 8- and 14-carbon tethered substrates are roughly the same as for the control intermolecular reaction. This requires ring sizes of 12 and 18 for the intermediate produced via an intramolecular process (**5**, eq. [4]). Such rings are readily formed in the cyclic acyloin reaction (cf. eq. [2]), with reported yields of 76 and 96% for the 12- and 18-membered tethers, respectively (1*a*).

A 10-membered tether, prepared from triethylene glycol, was also tested (compound **6***g*). It was hoped that the ether oxygens could act as a template to coordinate Na^+ and that, in addition, the transannular interaction would be reduced, thereby permitting high yields of the intramolecular acyloin product. This was not the case and again the yield was low with a considerable amount of nonpolar by-products being formed.

Since both the 8- and 14-carbon tethered esters gave results comparable to the intermolecular case we were confident that the tether was not impeding the reaction. However, the result gave no indication whether the product resulted from *intra-* or *inter*-molecular reactions. To determine this, we prepared two hexanoyl-acetyl diesters joined by either an 8-carbon (**8**) or a 14-carbon (**9**) chain. The substrates were prepared in two steps by sequential esterification of the diol using the previously described conditions. The diesters were then reacted under the normal acyloin reaction conditions and the results are listed in Table 2.



8 $n=8$
9 $n=14$

10 **11** **12** **13**

Included in Table 2 are the results for the untethered intermolecular reaction between methyl hexanoate and butyl acetate. A total yield of 38% of the combined unsymmetrical acyloin products **11** and **12** was obtained in addition to 20% of capronoin **7**. The other symmetrical product, acetoin (3-hydroxy-2-butanone, **10**), was lost during the aqueous work-up. However, the ratio of the unsymmetrical acyloin to capronoin is 2:1, indicating that a statistical product distribution was obtained. Virtually identical yields and therefore product distributions were obtained when both the 8- and 14-carbon tethered substrates were reacted (**8** and **9**, respectively). Even at very high dilution (slow addition of the

For personal use only.

diester over 6 h to give a final concentration of 0.04 M, conditions that should promote an intramolecular reaction) the ratio of the unsymmetric to symmetric products isolated was close to 2:1. The yields in this case were slightly reduced due to the prolonged reaction time.

To confirm if an intermolecular reaction is indeed taking place, a crossover experiment was performed between the bis-hexanoyl ester of 1,8-octanediol **6***e* and the corresponding bis-acetate **13** (Table 2). Equimolar amounts of both bis-esters were reacted under the usual conditions and, after work-up and chromatography, the mixed acyloin products **11** and **12** were isolated in 40% combined yield. Capronoin was obtained in 17% yield.

These results indicate that the tethered systems are reacting in an intermolecular sense and that the tether is not conferring any advantage upon the system. Thus the *intra*-molecular acyloin reaction fails in the case where the two esters are tethered via the alkoxide groups. In addition, for short tethers the yields are low.

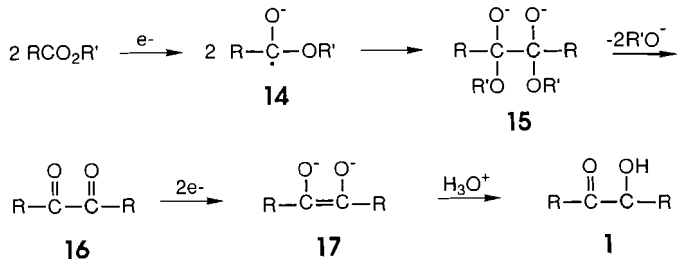
Discussion

The results obtained for the crossover experiment and the reaction of the mixed tethered diesters (**8** and **9**, Table 2) indicate that the reaction is proceeding via an intermolecular process. One possibility for this apparent lack of intramolecular reactivity could be because the conformation required for an intramolecular reaction is not readily accessible. Therefore the reaction proceeds more rapidly with a second molecule in an intermolecular sense. However, the results obtained using the cyclic acyloin reaction with diesters (eq. [2]) show that ring sizes from 4 to over 30 are formed in high yield without the need for high-dilution conditions (1*a*). Even the highly strained 4-, 8-, 9-, and 10-membered rings are readily prepared and they are obviously the product of highly strained intermediates. For the 8-carbon tethered systems (**6***e* and **8**) an intramolecular reaction would proceed via a 12-membered ring while the 14-carbon tether present in **6***f* and **9** would give rise to an 18-membered ring intermediate (**5**, eq. [4]). Both ring sizes are large and therefore should have no steric or strain impediment to their formation, especially when considered in context of the cyclic acyloin results.

Furthermore, if the bimolecular process is rapid and is competing with the unimolecular route, a high dilution experiment should increase the amount of product formed in an intramolecular sense. This is not the case; the high-dilution experiment yields a statistical distribution of products (Table 2).

Additionally, if an intermolecular acyloin condensation is occurring between two diester molecules, perhaps one would expect the yields from each tethered substrate (**6***a–g*) to be similar since the probability of an intermolecular collision and reaction is the same in each case. This is not the observed result. We feel that the results obtained are not consistent with a purely bimolecular acyloin condensation between two diester molecules.

To understand these results, we have reexamined the proposed mechanisms for the reaction. The mechanism of the acyloin condensation has not been conclusively elucidated and in fact much speculation regarding the nature of the intermediates exists. The situation is complicated further by the fact that acyloin condensations may be carried out using different metals (e.g., Na, K, or Na–K couples) on a



SCHEME 1

variety of substrates (e.g., esters, anhydrides, and acid chlorides) in solvents such as toluene, diethyl ether, and liquid NH_3. Each set of conditions may favour a particular mode of reactivity, giving rise to the acyloin, as well as by-products, in varying amounts (9).

The most commonly reported mechanism and the one most often described in undergraduate texts (for example, ref. 10) is shown in Scheme 1. This has been disputed (11) and is almost certainly not the complete mechanism. Bloomfield, Owsley et al. propose an alternative mechanism (12), which is given in Scheme 2. Both mechanisms, however, require that the reacting carbonyl carbons be joined (C—C bond in **15**, Scheme 1, and C—O—C bridge in **18**, Scheme 2) prior to expulsion of the alkoxide groups, i.e., the tether would bring the reaching centres together and then be expelled. This would favour an intramolecular process, which seems to be in disagreement with our results.

In addition, both mechanisms commence with a single electron transfer to one ester group to form a radical anion **14**. The fate of **14** is worth considering (Scheme 3) for it has been proposed that such radical anions may decompose to afford an alkoxide and an acyl radical **24** (13). The acyl radical could then decarbonylate to give CO and an alkyl radical. Alternatively the radical anion can fragment to generate a carboxylate anion and an alkyl radical. The combination of radical intermediates could then give rise to nonpolar products such as RH, RCOR, and RR. Indeed such products have been observed (especially in the case where the alkyl radical formed is particularly stable, as for benzyl (14) and allylic (13) radicals) and this explanation has been used to account for them. A more detailed discussion of the proposed mechanisms in Schemes 1 and 3 for the acyloin condensation in conjunction with TMSCl is given by Ruhlmann (3*b*).

This is not the only way to account for the observed by-products. Bloomfield and Owsley suggest that fragmentation of the radical intermediate **19** can account for the radical products observed. Also, fragmentation of the anion **20** could, they suggest, result in anion formation, which would be particularly favourable with tertiary, benzylic, and allylic systems (12). Thus, in some cases, free radicals may not be involved other than as very transient radical anion intermediates.

The results obtained from our experiments with tethered diesters would be consistent with a fragmentation process in which the tether is somehow cleaved, thus allowing randomization of the ester groups. An obvious candidate for fragmentation (and one that was previously proposed to explain by-product formation (13)) is the radical anion **14**. The radical anion **14** would not be particularly stable, especially in refluxing toluene (or even refluxing xylene). Parentheti-

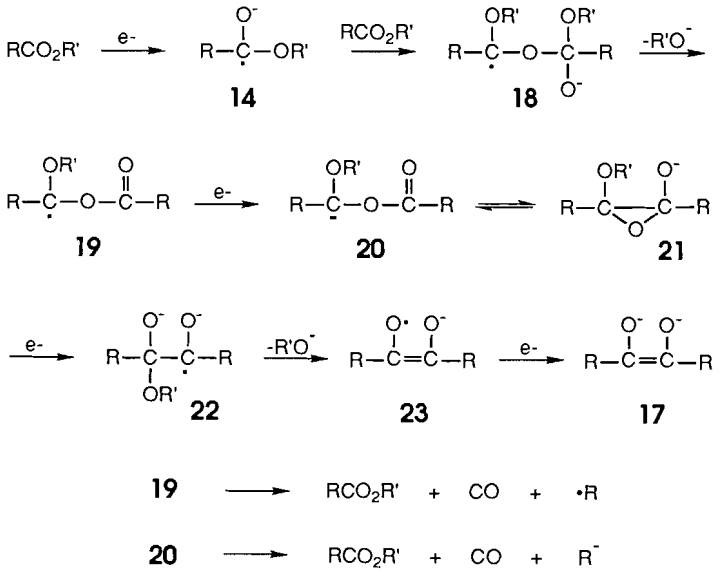
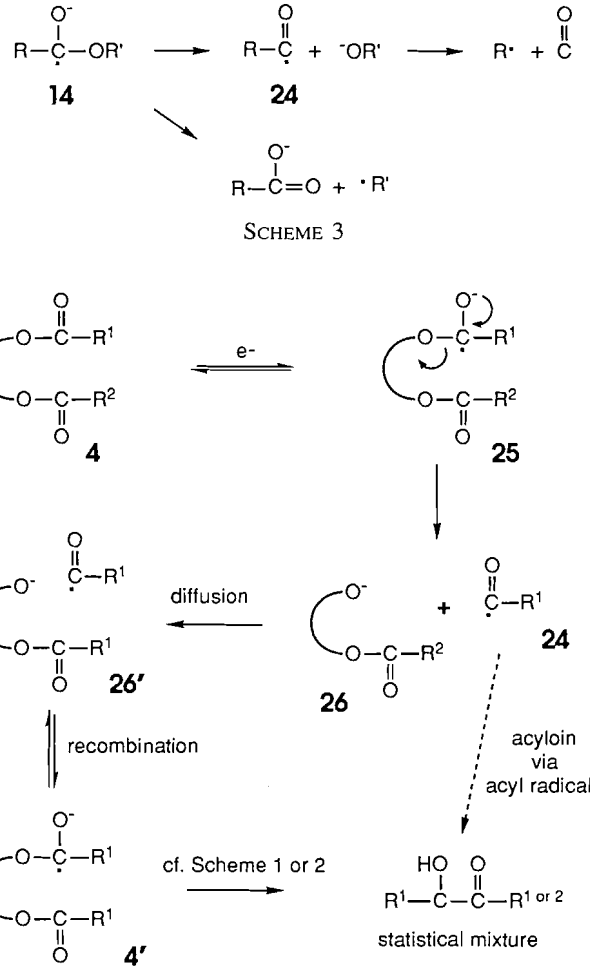


SCHEME 2



SCHEME 3

SCHEME 4

cally, the fragmentation of intermediates **19** or **20** (Scheme 2) would lead to loss of CO and destruction of the starting material and would not explain the results. We propose, therefore, that the fragmentation of **14** does indeed occur. Furthermore, the fragmentation must occur early in the reaction sequence *prior* to the joining of the two carbonyl carbons and the fragmentation must be rapid since a long-lived intermediate would allow an intramolecular reaction to occur.

Scheme 4 outlines a possible mechanism to explain the observed results. Electron transfer to the diester **4** produces the radical anion **25**; this then fragments to afford an acyl radical **24** and an alkoxide **26**. Diffusion and recombination with other fragments (e.g., **26'**) would lead to complete randomization of the substrate(s). If this fragmentation step is rapid and reversible, the reaction could proceed as previously proposed. Alternatively, if the acyl radical and the alkoxide do not recombine or if the recombination is slow in comparison to reaction of the alkoxide with chlorotrimethylsilane, the acyloin mechanism must proceed via an acyl radical. The radical anion **14** (Schemes 1 and 2) could not, therefore, be involved as the key reacting intermediate for C—C bond formation in this case.

This proposed mechanism could provide an explanation for the reduced yields observed in those substrates linked by short tethering units (Scheme 5).[2] In these cases, an equilibrium between the open chain and the cyclic form of the intermediate alkoxides could slow down or impede the recombination step thus giving rise to by-products resulting from decomposition of the acyl radical. Such an equilibrium may favor a cyclic intermediate in the case of short tethers (n = 0, 1, 3) while favoring the open chain form in the case of longer tethering units ($n > 5$). In the case of the triethylene glycol tether, chelation of the alkoxide intermediate by sodium (**27**) would result in a decrease in the rate of recombination with the acyl radical. Again, this would lead to an increase in the amount of by-products arising from further reaction of the acyl radical. Finally, fragmentation ofl the silicon-tethered substrate would produce a silyloxide **28**, which may eliminate RCO_2^- and further decompose to produce polymers and side products before it can recombine.

[2]We thank one of the reviewers for helpful comments regarding this point.

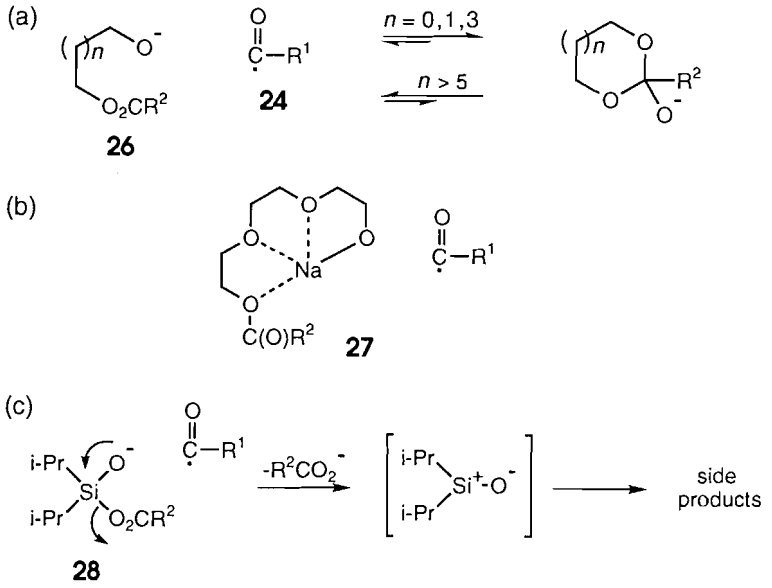

SCHEME 5

Thus, the mechanistic proposals described herein can account for the observation that tethered substrates react in an intermolecular sense and that the decreased yields observed for some substrates may be the result of sequestering the alkoxide (by formation of cyclic intermediates, chelates, or decomposition; Scheme 5).

Conclusion

In conclusion, the reaction of diesters tethered via their alkoxide portions has been shown to produce a statistical distribution of products. This is true for mixed diester substrates and for the crossover experiment involving two different symmetrical diesters. A bimolecular reaction between two substrate molecules appears unlikely since there appears to be little hindrance to an intramolecular process due to the large ring sizes that would be involved. Also there is the analogy with the cyclic acyloin condensation condensation in which highly strained cyclic intermediates are formed. It seems reasonable to account for the observed results by proposing that the first-formed radical anion intermediate **14** can fragment, thus destroying the tethered nature of the substrate. Our experiments do not, however, allow us to determine whether the acyloin condensation is then occurring by random recombination of the acyl radical and the alkoxide to regenerate a radical anion or if an acyl radical is a key intermediate in this process.

Experimental section

Proton nuclear magnetic resonance spectra were obtained on a Bruker AM250 or AM300 spectrometer and proton shifts are relative to tetramethylsilane (TMS) as internal standard. Melting points were measured on an Electrothermal IA 9100 melting point apparatus in open capillary tubes and are uncorrected. Infrared spectra were obtained using a Perkin–Elmer 681 spectrophotometer. Elemental analyses were carried out by Oneida Research Services, Inc., Whiteboro, N.Y., and high-resolution mass spectra were obtained from McGill University Biomedical Mass Spectrometry Unit, Montreal. Dichloromethane and toluene were freshly distilled from CaH_2 under a nitrogen atmosphere prior to use. TMSCl was distilled under nitrogen. $MgSO_4$ was used to dry all worked-up reactions and all NMR samples were run using $CDCl_3$ as solvent. Starting materials were obtained from Aldrich Chemical Company, Inc.

Diisopropylsilyl dihexanoate, ***6****a*

To a solution of dichlorodiisopropylsilane (2.5 g, 13.5 mmol) and Et_3N (3.76 mL, 27 mmol) in CH_2Cl_2 (55 mL) at 0°C under nitrogen was slowly added hexanoic acid (3.39 mL, 27 mmol). A white precipitate formed immediately. After 1 h, the solvent was removed, hexane was added, and the mixture was filtered through Celite. Evaporation of the solvent provided ***6a*** (4.5 g, 96% yield) as a pale yellow oil, which was used without further purification. IR (film): 2960, 2880, 1735, 1465, 1170, 885 cm^{-1}; ^1H NMR δ: 0.89 (6H, bt), 1.08 (12H, d, J = 8.1 Hz), 1.2–1.4 (10H, m), 1.62 (4H, m), 2.37 (4H, t, J = 7.7 Hz).

1,2-Ethanediol dihexanoate, ***6****b*

To a solution of ethanediol (520 mg, 8.4 mmol), pyridine (3.39 mL, 42 mmol), and DMAP (25 mg) in CH_2Cl_2 (30 mL) at 0°C was added dropwise hexanoyl chloride (2.75 mL, 18.5 mmol) in CH_2Cl_2 (10 mL). After 3 h the mixture was poured into 1 N HCl, extracted (3X) with CH_2Cl_2, washed with saturated $NaHCO_3$–brine solution, dried, and evaporated. The residue (2.79 g) was purified by column chromatography on silica gel (eluting with hexane–EtOAc 10:1) to afford the diester ***6b*** (2.10 g, 97% yield) as a colourless oil. IR (film): 2960, 2930, 2870, 1740, 1160 cm^{-1}; ^1H NMR δ: 0.89 (6H, bt), 1.3 (8H, m), 1.62 (4H, m), 2.32 (4H, t, J = 7.7 Hz), 4.28 (4H, s); MS (CI (CH_4)) m/z: 259 (MH^+,4), 241 (1), 143 (100), 99 (11). Anal. calcd. for $C_{14}H_{26}O_4$: C 65.09, H 10.14; found: C 65.28, H 10.17.

The following compounds were prepared using the procedure described above:

1,3-Propanediol dihexanoate, ***6****c*

Using 1,3-propanediol (912 mg) there was obtained 2.93 g (90%) of ***6c*** as a colourless oil. IR (film): 2960, 2935, 2870, 1740, 1170 cm^{-1}; ^1H NMR δ: 0.89 (6H, bt), 1.3 (8H, m), 1.61 (4H, m), 1.95 (2H, pentet, J = 6.5 Hz), 2.29 (4H, t, J = 7.7 Hz), 4.15 (4H, t, J = 6.5 Hz); MS (CI (CH_4)) m/z: 329 (MH^+, 17), 157 (100). Anal. calcd. for $C_{15}H_{28}O_4$: C 66.14, H 10.36; found: C 66.31, H 10.08.

1,5-Pentanediol dihexanoate, ***6****d*

Using 1,5-pentanediol (624 mg) there was obtained 1.72 g (96%) of ***6d*** as a colourless oil. IR (film): 2955, 2930, 2860, 1740, 1170 cm^{-1}; ^1H NMR δ: 0.88 (6H, bt), 1.2–1.5 (10H, m), 1.5–1.7 (8H, m), 2.29 (4H, t, J = 7.8 Hz), 4.06 (4H, t, J = 6.4 Hz); MS

(CI (CH_4)) *m/z*: 301 (MH^+, 76), 300 (1.3), 203 (4.9), 186 (14), 185 (100), 184 (4). Anal. calcd. for $C_{17}H_{32}O_4$: C 67.96, H 10.74; found: C 68.12, H 11.13.

*1,8-Octanediol dihexanoate, **6**e*

Using 1,8-octanediol (1.23 g) there was obtained 2.63 g (92%) of ***6e*** as a colourless oil. IR (film): 2930, 2860, 1735, 1170 cm^{-1}; ^1H NMR δ: 0.89 (6H, bt), 1.32 (16H, m), 1.55–1.70 (8H, m), 2.29 (4H, t, J = 7.5 Hz), 4.05 (4H, t, J = 6.7 Hz). Exact Mass calcd. for $C_{20}H_{38}O_4 + H^+$: 343.2848; found: 343.2848. Anal. calcd. for $C_{20}H_{38}O_4$: C 70.13, H 11.18; found: C 70.38, H 11.06.

*1,14-Tetradecanediol dihexanoate, **6**f*

Using 1,14-tetradecanediol (2.28 g) there was obtained 2.73 g (65%) of ***6f*** as a waxy solid, mp 27–29°C. IR (film): 2940, 2850, 1735, 1460, 1170 cm^{-1}; ^1H NMR δ: 0.89 (6H, bt), 1.2–1.4 (28H, m), 1.5–1.7 (8H, m), 2.29 (4H, t, J = 7.4 Hz), 4.05 (4H, t, J = 6.7 Hz). Exact Mass calcd. for $C_{26}H_{50}O_4 + H^+$: 427.3787; found: 427.3786. Anal. calcd. for $C_{26}H_{50}O_4$: C 73.19, H 11.81; found: C 73.16, H 11.78.

*Triethylene glycol dihexanoate, **6**g*

Using triethylene glycol (1.26 g) there was obtained 2.76 g (96%) of ***6g*** as a colourless oil. IR (film): 2960, 2930, 1735, 1170 cm^{-1}; ^1H NMR δ: 0.89 (6H, bt), 1.2–1.4 (8H, m), 1.5–1.7 (4H, m), 2.32 (4H, t, J = 7.7 Hz), 3.65 (4H, s), 3.70 (4H, m), 4.23 (4H, m). Exact Mass calcd. for $C_{18}H_{34}O_6 + NH_4^+$: 364.2699; found: 364.2698. Anal. calcd. for $C_{18}H_{34}O_6$: C 62.40, H 9.89; found: C 61.92, H 10.01.

*8-Acetoxy-1-octanyl hexanoate, **8***

Step 1. 8-Hydroxy-1-octanyl hexanoate

To a solution of 1,8-octanediol (6.14 g, 42 mmol), pyridine (11.3 mL, 140 mmol), and DMAP (100 mg) in DMF (200 mL) at 0°C was added hexanoyl chloride (4.17 mL, 28 mmol) dropwise. The mixture was stirred for 2 h at room temperature then poured onto 1 N HCl, and extracted (3X) with EtOAc. The organic layers were combined, washed with water, then with saturated $NaHCO_3$–brine solution, dried, and evaporated. Chromatography of the residue (silica gel; hexane–EtOAc 2:1) afforded 8-hydroxy-1-octanyl hexanoate (4.3 g, 63%) as an oil. IR (film): 3400 (br), 2930, 2850, 1735, 1170 cm^{-1}; ^1H NMR δ: 0.89 (3H, bt), 1.2–1.4 (12H, m), 1.5–1.7 (6H, m), 2.29 (2H, t, J = 7.5 Hz), 3.64 (2H, t, J = 6.6 Hz), 4.05 (2H, t, J = 6.6- Hz); MS (CI (CH_4)) *m/z*: 245 (MH^+, 100), 227 (2), 129 (10), 117 (8), 111 (16), 99 (9).

*Step 2. 8-Acetoxy-1-octanyl hexanoate, **8***

To a solution of the hydroxyester from Step 1 (2.1 g, 8.6 mmol), pyridine (3.47 mL, 43 mmol), and DMAP (50 mg) in CH_2Cl_2 (80 mL) at 0°C was added acetyl chloride (732 μL, 10.3 mmol) dropwise. After 30 min at room temperature the mixture was poured into 1 N HCl, extracted (3X) with EtOAc, washed with water, and then with saturated $NaHCO_3$/brine solution. The organic layer was dried, filtered, and evaporated to give an oil, which was chromatographed on silica gel (hexane–EtOAc 5:1) to afford **8** (2.37 g, 96%) as an oil. IR (film): 2935, 2860, 1740, 1240, 1170 cm^{-1}; ^1H NMR δ: 0.89 (3H, bt), 1.2–1.3 (12H, m), 1.5–1.6 (6H, m), 2.05 (3H, s), 2.29 (2H, t, J = 7.5- Hz), 4.05 (2 overlapping triplets, 2H each, J = 6.5 Hz and 6.5 Hz). Exact Mass calcd. for $C_{16}H_{30}O_4 + H^+$: 287.2222; found: 287.2222. Anal. calcd. for $C_{16}H_{30}O_4$: C 67.10, H 10.56; found: C 66.97, H 10.45.

*14-Acetoxy-1-tetradecanyl hexanoate, **9***

Following the procedures described for the preparation of 8-acetoxy-1-octanyl hexanoate, **8**, 1,14-tetradecanediol was initially converted into 14-hydroxy-1-tetradecanyl hexanoate (48%), mp 40–42.5°C. IR (KBr): 3450 (br), 2920, 2850, 1740, 1465, 1170 cm^{-1}; ^1H NMR δ: 0.89 (3H, bt), 1.2–1.4 (30H, m), 1.5–1.7 (6H, m), 2.29 (2H, t, J = 7.8 Hz), 3.63 (2H, t, J = 6.7 Hz), 4.06 (2H, t, J = 6.4 Hz); MS (CI (CH_4)) *m/z*: 329 (MH^+, 100), 311 (1), 111 (4), 99 (7).

Subsequent reaction with acetyl chloride provided the title compound 14-acetoxy-1-tetradecanyl hexanoate, **9**, as an oil (82%). IR (film): 2920, 2850, 1735, 1235, 1170 cm^{-1}; ^1H NMR δ: 0.89 (3H, bt), 1.2–1.4 (24H, m), 1.5–1.7 (6H, m), 2.04 (3H, s), 2.28 (2H, t, J = 7.7 Hz), 4.04 (2 overlapping triplets, 2H each, J = 6.4 Hz and 6.4 Hz). Exact Mass calcd. for $C_{22}H_{42}O_4 + H^+$: 371.3161; found: 371.3162.

*Preparation of capronoin, **7***

Method A. Intermolecular acyloin condensation of methyl hexanoate

Sodium metal (0.38 g, 16.5 mmol) and toluene (40 mL) were heated to reflux with vigorous mechanical stirring until the sodium formed a fine sand. To this was added methyl hexanoate (1.03 g, 7.95 mmol) in toluene (20 mL) dropwise over 45 min. Stirring was continued for a further 1.5 h, the solution was cooled, and MeOH (5 mL) added. The mixture was poured into water–EtOAc and acidified with 3 N HCl. Extraction with EtOAc followed by washing with water, then with saturated $NaHCO_3$–brine solution, drying, and evaporation provided 861 mg of a yellow oil. Purification by column chromatography on silica gel (hexane–EtOAc 10:1, then 5:1) afforded capronoin **7** (540 mg, 68%) as an oil. IR (film): 3490 (br), 2960, 2935, 2880, 2860, 1725, 1470 cm^{-1}; ^1H NMR δ: 0.89 (6H, bt), 1.2–1.4 (8H, m), 1.4–1.9 (6H, m), 2.45 (2H, m), 3.50 (1H, d, J = 4.8 Hz; exchangeable with D_2O), 4.16 (1H, m). Exact Mass calcd. for $C_{12}H_{24}O_2 + H^+$: 201.1855; found: 201.1854.

*Method B. intramolecular acyloin condensation of 1,8-octanediol dihexanoate, **6**e*

Sodium metal (0.92 g, 40 mmol) and toluene (27 mL) were stirred vigorously at reflux using a mechanical stirrer until the sodium formed a fine sand. To this was added the diester ***6e*** (2.74 g, 8 mmol) and TMSCl (5.28 mL, 41.6 mmol) in toluene (10 mL) dropwise over 30 min. After a further hour the solution was cooled and MeOH (5 mL) was added, followed by 1 N HCl. The mixture was extracted with EtOAc, washed with saturated $NaHCO_3$–brine solution, then with water, dried, and evaporated to give an oil (2.2 g). Purification on silica gel eluting with hexane–EtOAc 12:1, then 3:1, afforded capronoin **7** (1.21 g, 76%).

The following tethered diesters were reacted using the procedure described in Method B to yield capronoin **7**:

1. Diisopropylsilyl dihexanoate ***6a*** (1.3 g, 3.8 mmol) yielded capronoin **7** (36 mg, 5%).
2. 1,2-Ethanediol dihexanoate ***6b*** (1.03 g, 4 mmol) yielded capronoin **7** (173 mg, 22%).
3. 1,3-Propanediol dihexanoate ***6c*** (1.04 g, 3.8 mmol) yielded capronoin **7** (149 mg, 20%).
4. 1,5-Pentanediol dihexanoate ***6d*** (500 mg, 1.7 mmol) yielded capronoin **7** (144 mg, 42%).
5. 1,14-Tetradecanediol dihexanoate ***6f*** (2.5 g, 5.9 mmol) yielded capronoin **7** (866 mg, 73%).
6. Triethylene glycol dihexanoate ***6g*** (1.38 g, 4 mmol) yielded capronoin **7** (40 mg, 5%).

*Preparation of acyloins **11** and **12**: intermolecular reaction between methyl hexanoate and* n*-butyl acetate*

A mixture of sodium metal (1.04 g, 45 mmol) and toluene (30 mL) was heated at reflux with vigorous mechanical stirring until the sodium formed a fine sand. To this was added methyl hexanoate (1.17 g, 9 mmol), *n*-butyl acetate (1.05 g, 9 mmol), and TMSCl (5.94 mL, 46.8 mmol) in toluene (4 mL) dropwise over 30 min. The mixture was worked up as previously described to afford 1.6 g of an oil. Column chromatography on silica gel (hexane–EtOAc 12:1, then 3:1) afforded capronoin **7** (388 mg, 20%) and a 1:1 mixture of mixed acyloin products **11** and **12** (492 mg, 38% combined yield) as a colourless oil. IR (film): 3460 (br), 2960, 2930, 2860, 1715 cm^{-1}; ^1H NMR (mixture of isomers) δ: 0.89 (3H, bt), 1.2–1.9 (7H, m), 1.38 (1.5H, d, J = 7.1 Hz), 2.20 (1.5H, s), 2.45 (1H, m), 3.46 (0.5H, d, J = 4.6 Hz), 3.57 (0.5H, d, J = 4.7 Hz), 4.2 (1H, m). Anal. calcd. for $C_8H_{16}O_2$: C 66.63, H 11.18; found: C 66.72, H 11.21.

The following reactions were performed using the procedure described above:

1. 8-Acetoxy-1-octanyl hexanoate **8** (2.29 g) afforded capronoin **7** (320 mg, 20%) and a 1:1 mixture of **11** and **12** (424 mg, 37%).

2. 14-Acetoxy-1-tetradecanyl hexanoate **9** (1.27 g) afforded capronoin **7** (132 mg, 20%) and a 1:1 mixture of **11** and **12** (167 mg, 34%).

3. 1,8-Octanediol dihexanoate **6***e* (1.15 g, 3.3 mmol) and 1,8-octanediol diacetate **13** (0.77 g, 3.3 mmol) afforded capronoin **7** (228 mg, 17%) and a 1:1 mixture of **11** and **12** (387 mg, 40%).

*Preparation of acyloins **11** and **12**. High-dilution experiment*

To 90 mL of toluene was added sodium metal (460 mg, 20 mmol) and this was stirred vigorously with a mechanical stirrer at reflux until the sodium formed a fine sand. The diester **8** (1.16 g, 4.05 mmol) and TMSCl (2.64 mL, 20.8 mmol) in toluene (10 mL) were added dropwise over 6 h and reflux, then continued for a further hour. The mixture was worked up and purified as previously described to yield capronoin **7** (133 mg, 16%) and a 1:1 mixture of **11** and **12** (154 mg, 26%).

Functionalization of spirocyclopentadienes using organomolybdenum reagents: approaches to the synthesis of (±)-silphinene[1]

DEREK J. NORRIS, JOHN F. CORRIGAN, YAN SUN, NICHOLAS J. TAYLOR, AND SCOTT COLLINS[2]
Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received February 14, 1993

DEREK J. NORRIS, JOHN F. CORRIGAN, YAN SUN, NICHOLAS J. TAYLOR, and SCOTT COLLINS. Can. J. Chem. **71**, 1029 (1993).

(η^5-Indenyl)molybdenum dicarbonyl complexes of 1,3-dienes, including spirocyclopentadienes, can be cleanly prepared from stoichiometric amounts of 1,3-dienes and [(η^5-indenyl)$Mo(CO)_2(CH_3CN)_2$][BF_4] (**1**) in dichloromethane solution. Nucleophilic addition of lithium dimethylcuprate to the complexed diene occurs in the expected manner to provide η^3-allylmolybdenum complexes in high yield. Applications of this chemistry towards the synthesis of (±)-silphinene are described. The allylmolybdenum complexes [(η^5-C_9H_7)(η^3-$C_{10}H_{15}$)$Mo(CO)_2$] (**8**) and [(η^5-C_9H_7)(η^3-$C_{15}H_{23}$)$Mo(CO)_2$] (**33**) were structurally characterized by X-ray crystallography. Compound **8**: space group $P2_1/n$ with a = 9.393(1) Å, b = 10.469(2) Å, c = 17.704(2) Å, β = 91.05(1)°, Z = 4, and V = 1770.5(4) Å^3. Compound **33**: space group $P2_1/c$ with a = 17.616(4) Å, b = 7.688(2) Å, c = 15.873(2) Å, β = 90.12(2)°, Z = 4, and V = 2149.7(6) Å^3.

DEREK J. NORRIS, JOHN F. CORRIGAN, YAN SUN, NICHOLAS J. TAYLOR et SCOTT J. COLLINS. Can. J. Chem. **71**, 1029 (1993).

Utilisant des quantités stoechiométriques de 1,3-dièns et de [(η^5-indényl)$Mo(CO)_2(CH_3CN)_2$] [BF_4] (**1**) en solution dans le dichlorométhane, on a préparé proprement des complexes (η^5-indényl)molybdène dicarbonyle de 1,3-dièns comprenant des spirocyclopentadièns. L'addition nucléophile de diméthylcuprate de lithium sur le dièn complexé se fait d'une façon attendue et fournit des complexes η^3-allylmolybdène avec des rendements élevés. On décrit l'application de cette chimie à la synthèse du (±)-silphinène. On a caractérisé les complexes allylmolybdène [(η^3-C_9H_7)(η^3-$C_{10}H_{15}$)$Mo(CO)_2$] (**8**) et [(η^5-C_9H_7) (η^3-$C_{15}H_{23}$)$Mo(CO)_2$] (**33**) par diffraction des rayons X. Composé **8** : groupe d'espace $P2_1/n$, avec a = 9,393(1), b = 10,469(2) et c = 17,704(2) Å, β = 91,05(1)°, Z = 4 et V = 1770,5(4) Å^3. Composé **33** : groupe d'espace $P2_1/n$, avec a = 17,616(4), b = 7,688(2) et c = 15,873(2) Å, β = 90,12(2)°, Z = 4 et V = 2149,7(6) Å^3.

[Traduit par la rédaction]

Introduction

The addition of nucleophiles to dienes coordinated to a transition metal centre occurs with predictable regio- and stereochemistry (for reviews, see ref. 1). These features have been exploited in organic synthesis in which η^4-cyclohexa- and cycloheptadiene complexes of a cationic $CpMo(CO)_2$ moiety have figured prominently (see, inter alia, ref. 2). The usual synthetic route to such complexes involves hydride abstraction from (η^3-allyl)$CpMo(CO)_2$ complexes (e.g., using [Ph_3C][BF_4]), the latter compounds being prepared via a two-step route from $Mo(CO)_6$ and an allyl halide (3). It is less well appreciated that diene complexes of the (η^5-indenyl)-molybdenum dicarbonyl moiety can be directly prepared from an appropriate cationic molybdenum complex (e.g., **1**, eq. [1]) and an excess of a 1,3-diene (4). This latter approach is an attractive one in synthesis, provided that the 1,3-diene is readily available *or*, more importantly, can be used in stoichiometric amounts.

In this paper we disclose that direct functionalization of 1,3-dienes in the latter manner is efficient.

Nucleophilic additions of carbanions to diene complexes of molybdenum can be accomplished with a variety of reagents (2–4); in the absence of any electronic bias, nucleophilic attack occurs at the least-substituted terminus of the diene (4*f*) and in cyclic dienes *exo* to the metal centre (e.g., eq. [2]) (1–4).

While the chemistry of cyclohexa- and cycloheptadiene complexes of molybdenum has been extensively developed by others (2, 4), very little, if any, work has been reported for cyclopentadiene complexes. We envisaged that if aromatization of cyclopentadienes could be prevented on complexation to molybdenum, some useful chemistry for functionalization of five-membered rings might ensue. In practice, this proved possible by direct complexation of spirocyclopentadienes; we illustrate the potential of this methodology in an attempted synthesis of (±)-silphinene (for some previous syntheses of this compound, see ref. 5).

Results and discussion

Direct complexation of 1,3-dienes to molybdenum

The direct reaction of 1,3-cyclohexadiene (15 equiv.) with [(η^5-indenyl)$Mo(CO)_2(CH_3CN)_2$][BF_4] (**1**) was previously reported by Green et al. (4*h*) and provided cyclohexadiene complex **2** in 50% yield. We repeated this reaction and obtained complex **2** in slightly higher yield (63%, Scheme 1). When only 1 equivalent of diene was employed the yield was only slightly diminished (61%).

Direct stoichiometric complexation of spirocyclopentadienes **3** and **4** to cationic precursor **1** was also successful and provided access to cyclopentadiene complexes **5** and **6** in 82 and 65% yield, respectively (Scheme 1). Thus, it appears that stoichiometric complexation of dienes using complex **1** is reasonably general and affords diene complexes in one step in good to excellent yields.

While complex **2** underwent efficient reaction with MeMgBr in THF to provide the expected allylmolybdenum product **7** (4), the analogous reactions of diene complexes **5** and **6** were complicated by the concomitant formation of inseparable molybdenum-containing by-products.[3] However, the use of Me_2CuLi in THF provided access to allyl

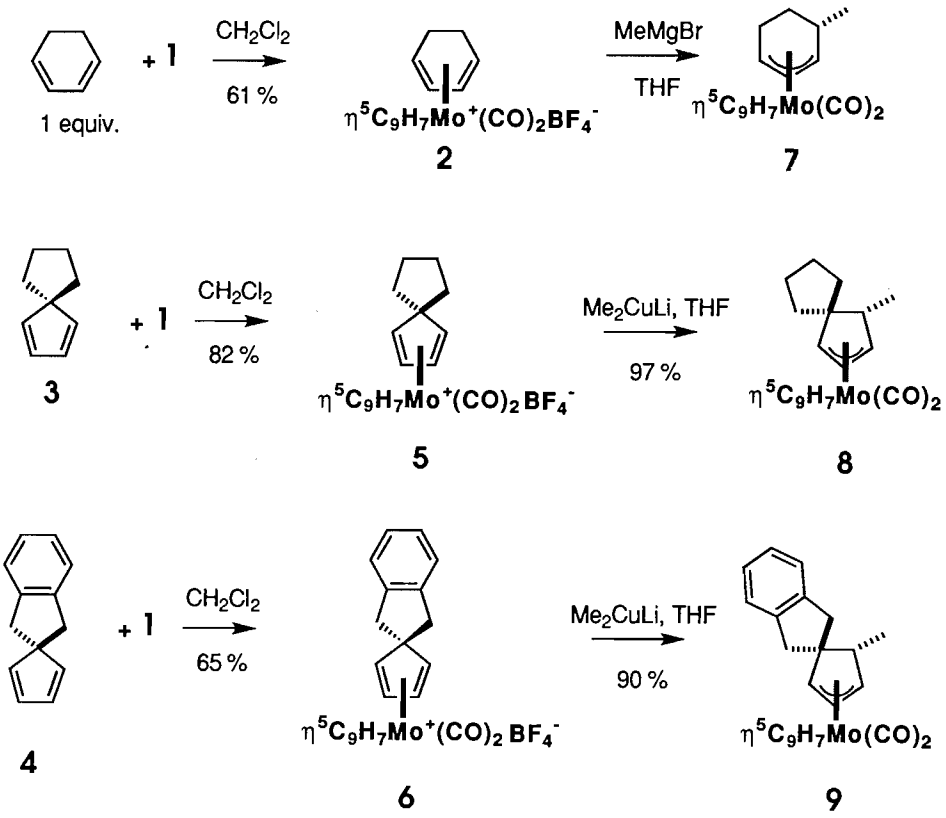
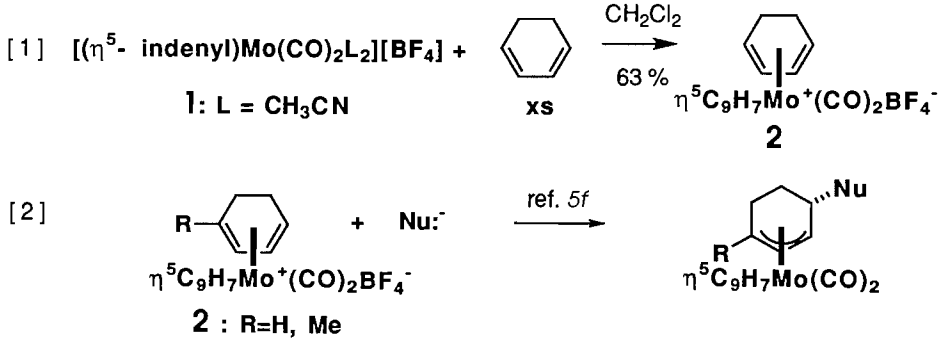


SCHEME 1



complexes **8** and **9** in excellent yield (Scheme 1). An X-ray structure of complex **8** confirmed that the methyl group of the cuprate was delivered to the diene in the expected fashion: *exo* to the metal and at the diene terminus (Fig. 1; Tables 1–3).

Having established that direct complexation of spirocyclopentadienes to molybdenum and subsequent delivery of a nucleophile could be accomplished in an efficient manner, we decided to investigate whether this methodology could be exploited in synthesis.

Approaches to the synthesis of silphinene. Synthetic analysis

We selected as our target (±)-silphinene (**11**), a natural product that has been prepared by a number of other groups (5). We envisaged that tricyclic spirocyclopentadiene **10** (Scheme 2) might serve as a precursor to **11** via stereoselective complexation with **1**, regioselective nucleophilic addition of Me_2CuLi to the derived diene molybdenum complex **12** at C-4 to provide **13**, followed by, for example, reductive decomplexation of molybdenum via the cationic nitrosyl complex **14** (3).

We recognized that there were several obstacles inherent in this synthetic approach. Complexation would have to occur on the *endo* face of diene **10** in order for subsequent *exo* delivery of the methyl group to occur in the nucleophilic addition step. We had hoped that the presence of the 9-methyl group might sterically block the *exo* face of diene **10**, thus preventing the favoured *exo* approach of reagents to the bicyclo[3.3.0]octadiene ring system inherent in this intermediate. We also envisaged that this same methyl group might direct nucleophilic attack towards C-4 (by sterically blocking C-1) of the complexed diene, and exert a similar effect on the reduction of nitrosyl complex **14**.

[3]Although we do not have conclusive evidence for the structure of these by-products, they are allylmolybdenum complexes that appear to result from a *reduction* of the diene complex at C-1.

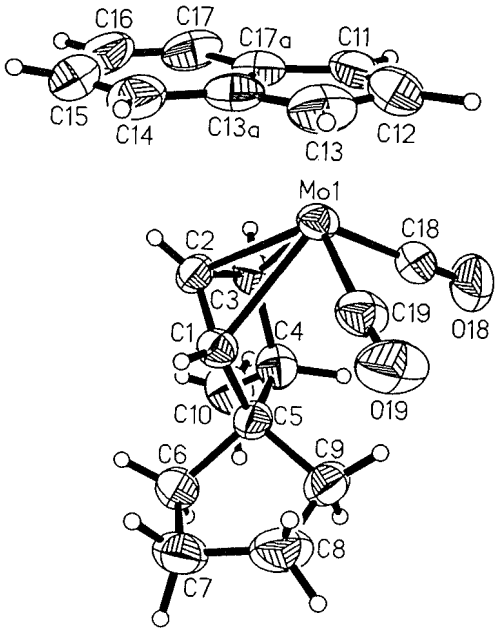

FIG. 1. Molecular structure of allylmolybdenum complex **8** with 30% thermal probability ellipsoids depicted. For selected bond lengths and angles, see Table 2.

As detailed below, although selective *endo* complexation of diene **10** proved possible, we have been unable to transform the diene complex **12** to the desired allyl complex **13**.

*Preparation of tricyclic diene **10***

Tricyclic diene **10** was prepared from cyclopentadiene and 3-hydroxy-2,2-dimethylpropanal as illustrated in Scheme 3. Condensation of this aldehyde with cyclopentadiene under the conditions developed by Stone and Little (6) provided fulvene **15** in 40–50% yield. The low yields obtained are a reflection of competing retro-aldol reaction of the aldehyde; 6-isopropylfulvene was also obtained as a major by-product. Reduction of the exocyclic double bond of **15** ($LiAlH_4$), followed by Swern oxidation (7) of alcohol **16** and subsequent intramolecular cyclization of aldehyde **17**, provided volatile, bicyclic, fulvene **18** in 50% overall yield. Nucleophilic addition of the dianion derived from 3-chloropropanol (8) to the exocyclic double bond of **18** and oxidation of the derived alcohol **19** (TPAP, NMO, 4A sieves) (9) provided aldehyde **20** in 35% yield from **18**.[4] Addition of excess MeMgBr to **20** provided a ~1:1 mixture of diastereomeric alcohols (**21**) in quantitative yield; these were converted to the target compound **10** and its C-9 epimer **23** (1:1.2) via base-mediated cyclization of the derived tosylates (56% combined yield from **20**). Dienes **10** and **23** could be separated by flash chromatography on silica gel impregnated with $AgNO_3$. Under these conditions, compound **10** undergoes preferential decomposition and was obtained in 55% yield from the crude mixture.

Assignment of stereochemistry to compounds **10** and **23** proved to be somewhat problematic. The ^1H NMR spectra of these compounds were very similar, the only significant differences were that the signal due to H1 in **10** was shifted 0.2 ppm to lower field when compared with **23** and the signal due to H5a in **10** was also shifted to lower field by the same amount (Scheme 3). Difference NOE spectra of both **10** and **23** were recorded while irradiating the signal due to H1 in each case. In the former case, the signal due to the C-9 methyl group exhibited slight enhancement, whereas in the latter case the signal due to H9 was subject to enhancement. While these results are consistent with the structures assigned to these dienes, unambiguous confirmation of stereochemistry at C-9 was based on an X-ray crystal structure of an organomolybdenum complex derived from **23** (vide infra).

*Complexation of dienes **10** and **23***

Attempted complexation of dienes **10** and **23** using cationic precursor **1** under the conditions previously developed was completely unsuccessful; starting materials were recovered even after extended reaction times. We reasoned that complexation of these dienes to the molybdenum centre was energetically much less favourable than for the model systems studied earlier, possibly due to steric hindrance.

However, it did prove possible to prepare molybdenum complexes of these dienes by generation of the unligated cationic (η^5-indenyl)$Mo(CO)_2$ moiety (by treatment of the dimer [(η^5-indenyl)$Mo(CO)_2$]$_2$ with $AgBF_4$, ref. 4) in the presence of an equimolar amount of diene **10** or **23** in CH_2Cl_2 solution (Scheme 4). Under these conditions, compound **10** provided a 2:1 mixture of two stereoisomeric complexes **12** and **24** in a combined yield of 71% whereas diene **23** provided epimeric complexes **25** and **26** in about the same ratio and in a combined yield of 85%.

At this point it was not clear whether complexation of **10** (or **23**) had occurred predominantly in the desired fashion (i.e., on the *endo* face of the diene). For comparison purposes, 9-normethyl diene **28** (prepared from alcohol **19** — see experimental section) was also complexed to molybdenum in the same fashion and complexes **29** and **30** were obtained in a 1:2 ratio. Complexes **12**, **25**, and **29** were structurally analogous, based on a comparison of their ^1H NMR spectra, as were their diastereomers **24**, **26**, and **30**. In particular, the signals due to the olefinic protons of the coordinated diene in the former series of complexes were at consistently higher field than for the latter series (see experimental section).

We had expected that diene **28** would undergo selective *exo* complexation in the usual fashion, as the steric impediment of the C-9 methyl group present in **10** (or **23**) had been removed. We therefore concluded that the *major* isomer produced in this case (**30**) was *exo* and by analogy so were the *minor* isomers (**24** and **26**) produced via complexation of **10** or **23**.

Nucleophilic additions to organomolybdenum complexes

Additional support for this conclusion was based on the reactions of the 1:2 mixture of diene complexes **29** and **30** with Me_2CuLi. Under the usual conditions (THF, −20°C) a *single* allylmolybdenum complex **31** was obtained in 57% yield and diene **28** was also produced in 30% yield (Scheme 4). The regiochemistry of methyl addition was readily established; only two allyl proton signals were observed in the ^1H NMR spectrum of **31**, a result that is only compatible with nucleophilic attack at C-1 in complexes **29** and (or) **30**.

A similar result was obtained in the less coordinating sol-

[4]Other oxidation methods (e.g., PCC; Swern) were uniformly unsuccessful in providing aldehyde **20**.

[a]Equivalent isotropic U defined as one third of the trace of the orthogonalized U_{ij} tensor.

vent, diethyl ether; complex **31** was obtained in 60% yield along with 36% of diene **28**. Reaction of **29** and **30** with MeMgBr (obtained from Aldrich Chemical Co. as a solution in ether) in CH_2Cl_2 solution at −78°C also led to the same product distribution (63% **31**; 33% **28**). Based on these results, it seemed clear that the major, *exo*, complex **30** was undergoing nucleophilic addition in the normal fashion (i.e., addition of Me_2CuLi *anti* to the metal and at the least substituted, terminal, position of the diene) to give complex **31** whereas the minor *endo* isomer **29** was undergoing selective decomplexation to **28** under these conditions.

Support for this hypothesis was based on the following observation: addition of a slight excess of THF-d_8 (i.e., ~2 equiv.) to a solution of complexes **29** and **30** in CD_2Cl_2 at room temperature led to selective destruction of the former complex as revealed by ^{1}H NMR spectroscopy of the

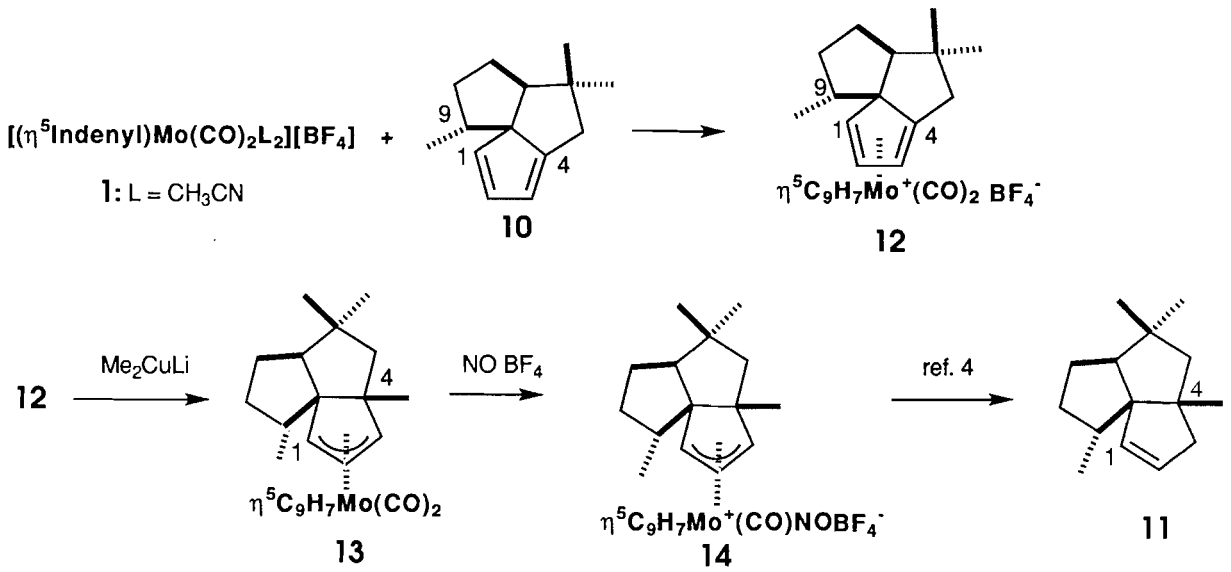

SCHEME 2

mixture. Although free diene **28** was not detected under these conditions, further addition of THF-d_8 led to decomposition of **30** as well and to formation of **28**. It thus appears that donor solvents will displace **28** from the molybdenum centre in complexes **29** and **30** with the former isomer being exceptionally labile towards nucleophilic substitution.[5]

Similar behaviour was observed when complexes **12** and **24** or **25** and **26** were treated with Me_2CuLi in diethyl ether (or MeMgBr in CH_2Cl_2). In the former case, allylmolybdenum complex **32** (structurally analogous to **31** based on spectroscopic data) was produced in 21% yield with diene **10** being produced in 44% yield, whereas in the latter case complex **33** was produced in 21% yield with diene **23** being recovered in 76% yield (Scheme 4). It thus appears that the desired transformation of **12** to silphinene (Scheme 2) is precluded by the unexpected lability of these complexes to donor solvents.

The structure of complex **33** could be confirmed by X-ray crystallography as suitable single crystals of this compound could be obtained by evaporation of a hexane solution (Fig. 2; Tables 1, 4, and 5). As the molecular structure depicted in Fig. 2 reveals, the molybdenum is coordinated to the *exo* face of the tricyclic framework, nucleophilic attack of Me_2CuLi has occurred *anti* to the metal centre at Cl, and the stereochemistry at C-9 is epimeric to that required for the synthesis of silphinene.

From this structure, it is clear that **33** is derived from diene complex **26**, the minor isomer produced on complexation of diene **23**. Hence, the stereochemistry of dienes **10** and **23** could be firmly established. The structural assignments of the other organometallic complexes prepared are based on the similarity in their spectral characteristics and the arguments presented above.

It should be noted that although the geometry about the allyl group of complex **33** does not differ much from that observed in compound **8** (compare Table 2 with Table 5), there is a distinct departure from linearity at the C(24) carbonyl carbon in complex **33** (see Fig. 2 and Table 5; Mo—C(24)—O(24) = 172.8 (2)°) that is not evident at either of the carbonyl groups in the structure of **8**. This bending may

[5]Nucleophilic displacement of the indenylmolybdenum moiety from unhindered diene complexes using strong donor ligands (e.g., bipy, dppe) has been reported (4*a*,*c*).

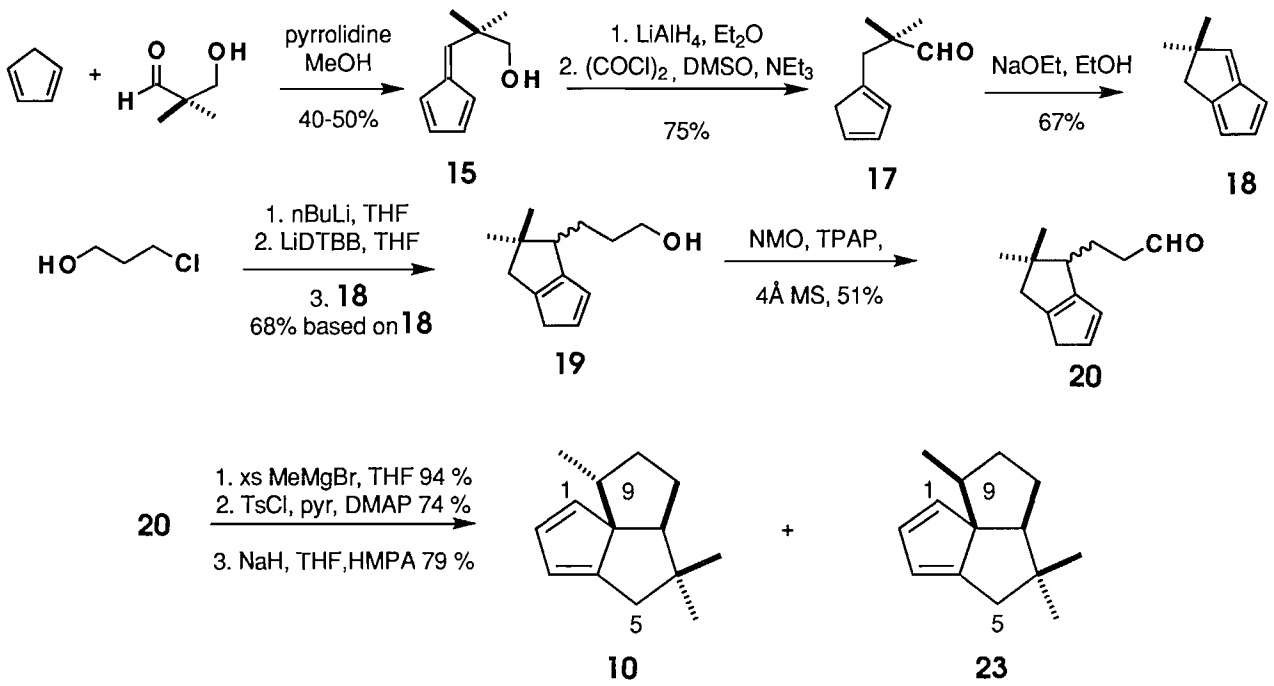

SCHEME 3

be due to steric repulsion between O(24) and the C(15) methyl group; short intramolecular contacts of 2.58 and 3.146(4) Å are observed between O(24) and H(15Y) and O(24) and C(15), respectively. The latter contact is well below the sum of the van der Waals radii for oxygen and a methyl group (3.40 Å).

Conclusions

Efficient and direct functionalization of spirocyclopentadienes is possible using indenylmolybdenum complex **1** or other precursors of the cationic indenylmolybdenum dicarbonyl moiety. Subsequent nucleophilic additions to these diene complexes can be an efficient process and provide a protocol for stereoselective alkylation of five-membered rings. Application of this methodology to the total synthesis of (±)-silphinene was prevented because of the unexpected lability of advanced intermediate **12** towards donor solvents required for the nucleophilic addition process. However, stereoselective complexation of diene **10** on the *endo* face of this compound proved possible. It is conceivable that sterically more hindered analogs of complex **1** (e.g., $[Cp^*Mo(CO)_2(CH_3CN)_2]$ $[BF_4]$ (ref. 10)) may enhance the stereoselectivity of diene complexation and hinder nucleophilic attack at the metal centre, a process that likely accounts for the lability of diene complexes such as **12**.

Experimental section

All reactions involving air- or moisture-sensitive reagents or compounds were performed under an atmosphere of dry N_2 or Ar using oven- or flame-dried glassware. Air- or moisture-sensitive compounds were stored in a Braun glove box under N_2 and weighed out as required. All solvents and reagents were obtained from commercial sources and purified as required. Diethyl ether, tetrahydrofuran, hexanes, and dimethoxyethane (DME) were distilled under N_2 from sodium and benzophenone. Dichloromethane, triethylamine, hexamethylphosphoramide (HMPA), pyrrolidine, acetonitrile, and dimethyl sulphoxide (DMSO) were distilled under N_2 (or in vacuo) from CaH_2. Cyclopentadiene was obtained by thermal cracking of dicyclopentadiene.

Molybdenum complex **1** was prepared from $[(h^5\text{-indenyl})\text{-}Mo(CO)_2]_2$ as described in the literature (4*g*). The latter dimeric complex was prepared from indene and $Mo(CO)_6$ as described in the literature (11). Spirocyclopentadiene **3** was prepared from cyclopentadiene and 1,4-dibromobutane with a slight modification of the literature conditions (12).

Reactions were monitored using thin-layer chromatography (TLC) performed on commercial, silica-coated, aluminum plates (silica gel 60, F254) purchased from E. Merck Co. Flash column chromatography was performed on silica gel 60 (230–400 mesh) supplied by E. Merck Co.

Boiling and melting points recorded are uncorrected. Elemental analyses were performed by M-H-W Laboratories (Phoenix, Ariz.). Low- and high-resolution mass spectra were performed on a Kratos MS-890 instrument at the University of Guelph. Infrared spectra (IR) were recorded on a Bomem MB-100 spectrophotometer. ^1H NMR and ^{13}C NMR spectra were obtained using either a Bruker AM-250 or AC-200 spectrometer; ^1H NMR chemical shifts are referenced with respect to residual undeuterated solvent while ^{13}C NMR shifts are referenced with respect to deuterated solvent.

*Indan-2-spiro-(cyclopenta-2',4'-diene) **4***

To a suspension of sodium hydride (3.3 g, 138 mmol) in 50 mL of THF at −30°C was added a solution of cyclopentadiene (2.8 g, 39 mmol) and α,α'-dibromo-*ortho*-xylene (10 g, 38 mmol) in 25 mL of THF via addition funnel over a period of 6 h. The reaction mixture was stirred for an additional 20 h at room temperature and then quenched with water. The reaction mixture was diluted with Et_2O and the organic phase was washed with water and brine and dried over $MgSO_4$. The organic phase was filtered, concentrated in vacuo, and dissolved in hexane. To remove uncyclized impurities, BuLi (17 mL, 2.5 M in hexanes, 42 mmol) was added to the hexane solution and the salts that formed from these compounds were filtered off under nitrogen. The filtrate was quenched with water and worked up as usual. The solid residue was sublimed (60–65°C, 0.1 Torr) (1 Torr = 133.3 Pa) to give **4** (0.96 g, 15%); melting point 70–71°C. ^1H NMR (250 MHz, $CDCl_3$) δ: 7.2–7.1 (m, 4H), 6.3 (m, 2H, AA'), 6.2 (m, 2H, BB'), 2.99 (s, 4H).

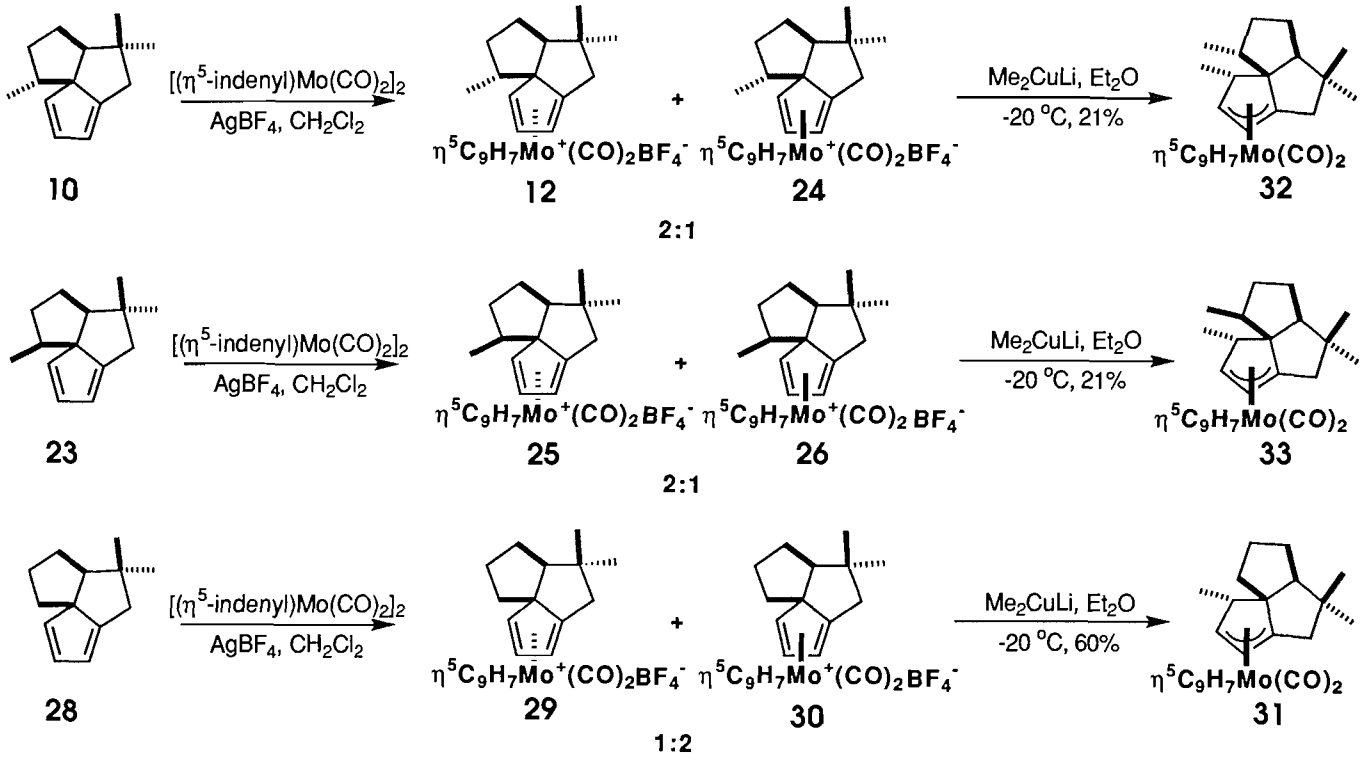

SCHEME 4

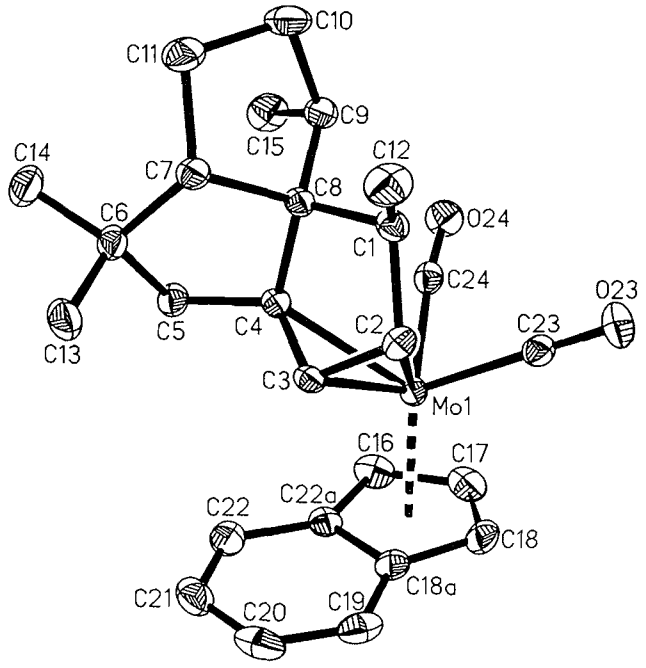

FIG. 2. Molecular structure of allylmolybdenum complex **33** with 30% thermal probability ellipsoids depicted; H-atoms have been removed for clarity. For selected bond lengths and angles see Table 5.

^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 143.5, 143.2, 128.8, 126.3, 124.5, 64.0, 37.6. MS *m/z*: 168 (M^+). Anal. calcd. for $C_{13}H_{12}$: C 92.81, H 7.19; found: C 92.78, H 7.38.

Preparation of diene complex 5

To a solution of spirodiene **3** (1.2 g, 2.6 mmol) in 25 mL CH_2Cl_2 was added complex **1** (330 mg, 2.7 mmol) in 5 mL of CH_2Cl_2. The reaction was stirred for 10 h and then filtered. Et_2O (50 mL) was added to precipitate complex **5**, which was collected by filtration, rinsed with 2 × 10 mL of Et_2O, and dried in vacuo (1.0 g, 82%). IR (CH_2Cl_2): 2022, 1966 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.79 (m, 2H, AA′), 7.41 (m, 2H, BB′), 6.40 (d, 2H, *J* = 2.9 Hz), 5.73 (t, 1H, *J* = 2.9 Hz, coupled to 6.40), 5.41 (t, 2H, *J* = 2.9 Hz), 4.85 (t, 2H, *J* = 2.9 Hz, coupled to 5.41), 1.86 (t, 2H, *J* = 7.1 Hz), 1.61 (m, 2H), 1.48 (m, 2H), 1.14 (t, 2H, *J* = 7.0 Hz). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 227.2, 129.9, 125.6, 112.0, 95.6, 93.0, 92.2, 85.1, 71.4, 51.7, 36.9, 24.7, 24.6. Anal. calcd. for $C_{20}H_{19}BF_4MoO_2$: C 50.67, H 4.04; found: C 50.17, H 4.20.

Preparation of diene complex 6

Complex **6** was obtained in 65% yield (202 mg) from **1** (260 mg, 0.59 mmol) and diene **4** (100 mg, 0.59 mmol) using the same procedure as that described for the preparation of complex **5**. IR (CH_2Cl_2): 2025, 1970 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.78 (m, 2H, AA′), 7.42 (m, 2H, BB′), 7.11 (m, 3H), 6.92 (br d, 1H, *J* = 5.7 Hz), 6.41 (d, 2H, *J* = 2.9 Hz), 5.77 (t, 1H, *J* = 2.9 Hz, coupled to 6.41), 5.46 (t, 2H, *J* = 2.9 Hz), 4.88 (t, 2H, *J* = 2.9 Hz, coupled to 5.46), 3.17 (s, 2H), 2.49 (s, 2H). ^{13}C NMR (50 MHz, CD_2Cl_2) δ: 226.4, 139.8, 139.2, 130.8, 127.6, 127.4, 125.8, 124.7, 112.1, 93.8, 93.1, 92.2, 85.4, 71.6, 57.0, 44.0. Anal. calcd. for $C_{24}H_{19}BF_4MoO_2$: C 54.96, H 3.65; found: C 54.82, H 3.85.

Preparation of allylmolybdenum complex 8

To a suspension of complex **5** (1.0 g, 2.1 mmol) in 40 mL of THF was added lithium dimethyl cuprate (21 mmol) prepared in THF from CuI (21 mmol) and MeLi (21 mL, 2.0 M in ether) at −20°C. The reaction was stirred for 1 h and quenched with a pH 8 mixture of aqueous NH_4Cl and NH_3. Hexane (30 mL) was added to the reaction mixture and the organic phase was syringed onto a small plug of silica gel and flushed with hexane into a round-bottom flask that was purged with N_2. The solvent was removed in vacuo to give **8** (770 mg, 91%). IR (CH_2Cl_2): 1936, 1856 cm^{-1}. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.1–6.9 (m, 4H), 5.89 (m, 1H), 5.80 (m, 1H), 5.62 (t, 1H, *J* = 2.9 Hz), 3.58 (dd, 1H, *J* = 3.1 Hz, *J* = 3.9 Hz), 2.84 (t, 1H, *J* = 3.4 Hz), 1.6–1.2 (overlapping m,

Single crystals suitable for X-ray diffraction studies were grown by slow evaporation of a hexane solution.

X-ray structure determination of complex 8

A yellow plate fragment of dimensions 0.48 × 0.47 × 0.52 mm, corresponding to the forms (100), (001), and (010), respectively, and glued to a glass fiber using epoxy resin was mounted on a Siemens R3m/v diffractometer. The unit cell parameters were determined and refined from a set of 25 general reflections ($24.5 < 2\theta < 30.5°$) well distributed in reciprocal space.

Intensity data were collected with graphite monochromated MoKα radiation at 295 K by employing the ω-scan technique over a 2θ range of 4.0–50.0° with variable scan speeds (2.93–29.30° min^{-1}). Background measurements using the stationary crystal, stationary counter method were made at the beginning and end of each scan, each for 25% of the total scan time. Two standard reflections were measured after every 100 reflections and showed no significant loss in intensity during data acquisition.

Intensities were corrected for Lorentz and polarization effects.

A face-indexed numerical method was employed to correct for adsorption effects. Of the 3124 independent reflections collected, 2760 were considered observed ($F > 6.0\ \sigma(F)$) and were used in the structure solution and refinement. The minimum and maximum transmission factors through the crystal were calculated to be 0.6891 and 0.7437.

The structure was solved by Patterson and Fourier methods and refined by full-matrix least-squares techniques using the Siemens SHELXTL PLUS software. Anisotropic refinement of all non-hydrogen atoms revealed the positions of all the hydrogens atoms from a difference map. In the final cycles of refinement, the hydrogen atoms were refined isotropically in their found positions with the exception of one H atom on the indenyl ligand (H(16)), which was unstable during refinement and was therefore constrained at its calculated position.

Scattering factors for non-hydrogen atoms were taken from the *International tables* (13*a*) while the data of Stewart et al. were used for hydrogen atoms (13*b*). Selected details of the crystallographic data, data collection, and final refinement appear in Table 1, atomic coordinates and isotropic thermal parameters appear in Table 2, while selected bond lengths and angles appear in Table 3. Full details of the structure determination have been deposited.[6]

Preparation of complex ***9***

Complex **9** was obtained in 97% yield (640 mg) from **6** (766 mg, 1.47 mmol) using the same procedure as that described for the preparation of complex **8**. IR (CH_2Cl_2): 1938, 1859 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 7.1–6.9 (m, 8H), 5.91 (m, 1H), 5.82 (m, 1H), 5.64 (t, 1H, J = 2.9 Hz), 3.67 (t, 1H, J = 3.4 Hz), 3.1 (d, 1H, A of AX spin system, J = 15.6 Hz), 2.92 (t, 1H, J = 3.4 Hz), 2.73 (d, 1H, B of BC spin system, J = 15.5 Hz), 2.62 (d, 1H, C of BC spin system, J = 15.5 Hz), 2.2 (d, 1H, J = 15.6 Hz, X of AX spin system), 1.67 (q, 1H, J = 6.9 Hz), 0.75 (d, 3H, J = 6.9 Hz), 0.08 (t, 1H, 3.4 Hz). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 238.0, 235.8, 143.2, 143.1, 125.9, 125.8, 124.9, 124.2, 124.1, 123.7, 123.2, 122.7, 111.8, 109.9, 88.7, 81.3, 80.2, 78.3, 77.3, 70.8, 60.4, 48.0, 45.2, 21.7. HRMS calculated for $C_{25}H_{22}{}^{92}MoO_2$: 446.0682$_7$; found (EI): 446.06557.

6-(2-Hydroxy-1,1-dimethylethyl)fulvene ***15***

To a solution of 2,2-dimethyl-3-hydroxy propionaldehyde (3.2 g, 31 mmol) and cyclopentadiene (5.2 g, 78 mmol) in 30 mL of methanol was added pyrrolidine (3.5 mL, 42 mmol). The reaction was stirred for 24 h at 25°C and another 5.2 g of cyclopentadiene and 3.5 mL of pyrrolidine were added. The reaction was allowed to stir for another 24 h and acetic acid (2.5 g, 42 mmol) was then added. The mixture was diluted with water and extracted with 50 mL Et_2O. The aqueous phase was washed with 2 × 50 mL Et_2O. The combined organic extracts were washed with water, saturated Na_2CO_3, and brine, and dried over $MgSO_4$. The mixture was filtered and the solvent removed in vacuo. The crude reaction mixture was purified by column chromatography, eluting first with hexane, then with 20% Et_2O – hexane to provide fulvene **15** (2.3 g, 50%). IR (neat): 3347, 3071, 2957, 2869, 1634, 1468, 1379 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 6.62 (t, 2H, J = 1.5 Hz), 6.40 (m, 2H), 6.16 (m, 1H), 3.57 (d, 2H, J = 6.6 Hz, collapsed to singlet with D_2O wash), 1.49 (t, 1H, J = 6.6 Hz, exchanges with D_2O), 1.3 (s, 6H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 149.3, 144.9, 134.9, 129.1, 128.2, 119.8, 72.0, 41.2, 25.7. MS m/z: 150 (M^+). Anal. calcd. for $C_{10}H_{14}O$: C 79.96, H 9.39; found: C 79.86, H 9.22.

2,2-Dimethyl-3-cyclopentadienyl-1-propanol ***16***

To a solution of fulvene **15** (1.01 g, 6.7 mmol) in 50 mL dry Et_2O at 0°C was added slowly $LiAlH_4$ (254 mg, 6.7 mmol) via a solid addition funnel. The reaction was warmed to room temperature and after 1 h was cooled to 0°C; water (250 μL), 15% NaOH (250 μL), and water (250 μL) were added sequentially dropwise via syringe with vigorous stirring. The mixture was diluted with Et_2O and filtered through a pad of Celite, washing with an additional 2 × 50 mL of Et_2O. The filtrate was concentrated in vacuo and distilled (bulb to bulb, 60–65°C, 0.1 Torr) to provide the title compound (1.02 g, 100%). IR (neat): 3365, 3061, 2916, 1604, 1468, 1368 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 6.4–6.0 (m, 3H), 3.3 (d, 2H, J = 6.4 Hz, collapses to singlet with D_2O wash), 2.93 (m, 2H), 2.34 (br s) and 2.30 (br s, combined 2H), 1.3 (t, 1H, J = 6.4 Hz, exchanges with D_2O), 0.87 (s, 6H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 146.0, 143.7, 136.39, 132.7, 132.3, 131.0, 129.7, 129.4, 71.4, 45.7, 41.1, 39.2, 38.6, 36.1, 35.9, 24.2, 24.1. MS m/z: 152 (M^+). Anal. calcd. for $C_{10}H_{16}O$: C 78.90, H 10.59; found: C 78.74, H 10.80.

2,2-Dimethyl-3-cyclopentadienyl propionaldehyde ***17***

To a solution of oxalyl chloride (2.8 g, 22 mmol) in 20 mL of CH_2Cl_2 at −55°C was added DMSO (3.5 g, 45 mmol), slowly via syringe. A bubbler was used to release pressure. After 5 min, alcohol **16** (1.7 g, 12 mmol) in 20 mL of CH_2Cl_2 was added. The reaction was stirred for 2 h at −55°C, and then treated with Et_3N (9.1 g, 90 mmol). The mixture was brought to room temperature and excess water and Et_2O were added. The aqueous phase was washed with 2 × 20 mL of Et_2O. The combined organic extracts were washed with 2 × 50 mL of 1 M AcOH, water, saturated Na_2CO_3, and brine, and dried over $MgSO_4$. The solvent was removed in vacuo at 0°C and the crude material was subjected to column chromatography (hexanes). Bulb-to-bulb distillation (40–45°C, 0.1 Torr) provided compound **17** (1.3 g, 75%). IR (neat): 3059, 2928, 2703, 1728, 1462, 1367, 1100, 1028 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 9.56 (s, 1H), 6.4–6.0 (m, 3H), 2.96 (br s) and 2.84 (br s, combined 2H), 2.62 (br s) and 2.56 (br s, combined 2H), 1.07 (s, 6H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 206.2, 142.0, 138.4, 135.6, 133.6, 132.2, 131.7, 130.6, 130.3, 62.1, 49.2, 45.0, 41.4, 37.4, 21.73, 21.6. MS m/z: 150 (M^+). Anal. calcd. for $C_{10}H_{14}O$: C 79.96, H 9.39; found: C 79.76, H 9.42.

7,7-Dimethylbicyclo[3.3.0]octa-1.3.5-triene ***18***

To 500 mL of 0.35 M sodium ethoxide in EtOH was added aldehyde **17** (10.5 g, 70 mmol) in 400 mL of EtOH over a period of 8 h. The reaction was stirred for an additional 2 h, then diluted with excess water and extracted with 4 × 100 mL of pentane. The combined organic extracts were washed with water (2 × 400 mL) and brine, and then dried over $MgSO_4$. The solvent was removed in vacuo at −10°C. Bulb-to-bulb distillation (25°C, 0.1 Torr) provided fulvene **18** (6.2 g, 67%). IR (neat): 3100, 3074, 3036, 2958, 2864, 1631, 1590, 1481, 1318, 1247, 1150 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 6.80 (dd, 1H, J = 1.91 Hz, J = 5.11 Hz, coupled to 5.86 and 6.10), 6.53 (br d, 1H, J = 1.58 Hz, coupled to 5.86), 6.10 (dd, 1H, J = 0.68 Hz, J = 5.11 Hz, coupled to 5.86 and 6.80), 5.86 (m, 1H), 2.5 (d, 2H, J = 1.98 Hz, coupled to 5.86), 1.28 (s, 6H). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 151.6, 150.5, 150.0, 141.8, 115.4, 112.5, 54.7, 39.6, 28.2. MS m/z: 132 (M^+). Anal. calcd. for $C_{10}H_{12}$: C 90.85, H 9.15; found: C 90.68, H 9.24.

6-(3-Hydroxypropyl)-7,7-dimethylbicyclo[3.3.0]-octa-(2–3),(1–5)-diene ***19***

To a solution of 3-chloro-1-propanol (2.97 mL, 35.6 mmol) in 25 mL of THF at −78°C was added a solution of *n*-BuLi (14.8 mL, 2.5 M in hexanes, 37.0 mmol). The mixture was stirred for 0.5 h.

[6]Complete sets of tables of crystallographic and refinement data, atomic coordinates and isotropic thermal parameters, bond lengths, bond angles, anisotropic thermal parameters, H-atom coordinates and isotropic thermal parameters, and structure factors for both compound **8** and **33** may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of crystallographic and refinement data, atomic coordinates, bond lengths and angles, and H-atom coordinates have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 IEZ, U.K.

To this solution was added the dark green-blue radical anion of 4,4′-di-*tert*-butylbiphenyl formed from reacting 4,4′-di-*tert*-butylbiphenyl (19.1 g, 72 mmol) and lithium metal (493 mg, 71 mmol) in 100 mL of THF at −5°C under an Ar atmosphere. The reaction was stirred for 10 min and fulvene **18** (1.8 g, 13.6 mmol) in 15 mL of THF was added. The reaction was stirred for 1 h, then warmed to room temperature. The reaction was quenched with water and diluted with Et_2O. The aqueous phase was washed with 2 × 20 mL of Et_2O and the combined organic extracts were washed with water and brine, and dried over $MgSO_4$. The solvent was removed in vacuo and the crude material was subjected to column chromatography, eluting first with hexane followed by 20% Et_2O – hexane to give **19** (1.8 g, 68%). IR (neat): 3332, 3072, 2909, 1615, 1457, 1379, 1364, 1057 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.87 (m, 1H), 5.8 (m, 1H), 3.7 (q, 2H, J = 6.4 Hz, collapses to triplet with D_2O wash), 3.24–3.19 (m, 2H), 2.30–2.22 (m, 3H), 2.0–1.80 (m, 1H), 1.77–1.45 (m, 2H), 1.43–1.30 (m, 2H), 1.1 (s, 3H), 0.86 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 156.6, 151.7, 151.1, 146.9, 134.3, 133.9, 130.5, 130.1, 120.0, 119.6, 63.3, 63.2, 52.7, 51.3, 49.2, 48.0, 47.4, 46.1, 44.7, 43.8, 40.9, 38.2, 37.8, 32.1, 31.9, 29.9, 28.2, 26.4, 24.9, 24.7, 23.1. MS *m/z*: 192 (M^+). Anal. calcd. for $C_{13}H_{20}O$: C 81.20, H 10.48; found: C 81.42, H 10.68.

6-(3-p-Toluenesulphonyloxypropyl)-7,7-dimethylbicyclo-[3,3,0]octa-(2–3),(1–5)-diene ***27***

To a solution of alcohol **19** (1.0 g, 5.2 mmol), pyridine (1.3 mL, 15.6 mmol), and catalytic DMAP (61 mg, 0.5 mmol) in 10 mL of CH_2Cl_2, was added *p*-toluenesulphonyl chloride (1.5 g, 7.8 mmol) in small portions over a period of 2 h at 5°C. The reaction was warmed to room temperature and stirred for 2.5 h, at which time it was poured into ice water and diluted with Et_2O. The organic phase was washed with 1 M AcOH, water, saturated Na_2CO_3, and brine, and dried over $MgSO_4$. The mixture was filtered and the solvent removed in vacuo. The crude material was subjected to column chromatography, eluting with 5% Et_2O – hexane to yield **27** (1.3 g, 70%) and unreacted **19** (18%). IR (neat): 3066, 2927, 1598, 1457, 1362, 1180, 1098, 962, 929 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 7.6 (d, 2H, J = 8.3 Hz), 7.3 (d, 2H, J = 8.3 Hz), 5.74 (m, 2H), 4.03 (t, 2H, J = 6.4 Hz), 3.14–3.12 (m, 2H), 2.4 (s, 3H), 2.20–2.05 (m, 3H), 2.00–1.85 (m, 1H), 1.76–1.61 (m, 1H), 1.50–1.37 (m, 1H), 1.25–1.10 (m, 1H), 0.99 (s, 3H), 0.77 (s, 3H). A satisfactory analysis of this compound was not obtained due to its thermal instability at room temperature, it was converted directly to tricyclic diene **28**.

6,6-Dimethyltricyclo[6.3.0.07.8]undeca-1,3-diene ***28***

To a solution of HMPA (550 μL, 3.16 mmol) and NaH (160 mg, 6.7 mmol) in 13 mL of THF was added **27** (1.0 g, 2.9 mmol) in 7 mL of THF. The reaction was stirred for 4 h with 5 min periods of sonication every 20 min. The reaction was quenched with water at 0°C and diluted with pentane. The organic phase was washed with saturated copper sulfate, water, and brine, and dried with $MgSO_4$. The mixture was filtered and the solvent removed in vacuo at 0°C. The crude mixture was subjected to column chromatography eluting with pentane to provide **28** (400 mg, 79%). IR (neat): 3082, 3061, 3022, 2948, 2862, 1613, 1524, 1455, 1381, 1363 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 6.17 (d, 1H, J = 5.1 Hz), 6.08 (dd, 1H, J = 5.1 Hz, J = 1.6 Hz), 5.84 (br s, 1H), 2.30 (br d, 1H, long range coupled to 5.84, J = 12.8 Hz, A of AB spin system), 1.91 (d, 1H, J = 12.8 Hz, B of AB spin system), 1.81–1.60 (m, 7H), 1.01 (s, 3H), 0.72 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 161.9, 143.6, 129.8, 121.7, 72.3, 52.2, 47.8, 41.3, 33.6, 31.8, 31.4, 27.6, 25.4. MS *m/z*: 174 (M^+). Anal. calcd. for $C_{13}H_{18}$: C 89.58, H 10.42; found: C 89.51, H 10.59.

6-(2-Formylethyl)-7,7-dimethylbicyclo[3.3.0]octa-(2–3),(1–5)-diene ***20***

To a mixture of alcohol **19** (1.1 g, 5.7 mmol), powdered 4 Å molecular sieves (15 g), and 4-methylmorpholine-*N*-oxide (1.2 g, 10.2 mmol) in 30 mL of CH_2Cl_2 was added tetrapropylammonium perruthenate (TPAP, 108 mg, 0.31 mmol) in small portions. The reaction was stirred at room temperature until all of **19** was consumed as judged by TLC. The reaction was then poured directly onto a small plug of silica gel and eluted with CH_2Cl_2. The solvent was removed in vacuo and the crude material subjected to bulb-to-bulb distillation (60–65°C, 0.1 Torr), providing aldehyde **20** (554 mg, 51%). IR (neat): 3068, 2952, 2867, 2717, 1726, 1447, 1382, 1365, 1261, 1057 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 9.81 (t, 1H, J = 1.6 Hz), 5.83 (m, 2H), 3.2 (m, 2H), 2.82–2.50 (m, 3H), 2.30–2.18 (m, 2H), 2.00–1.81 (m, 1H), 1.63–1.49 (m, 1H), 1.1 (s, 3H), 0.92 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 202.0, 156.0, 151.0, 134.5, 134.4, 129.0, 120.4, 120.0, 119.6, 58.2, 52.0, 48.6, 47.4, 46.1, 44.3, 43.6, 42.9, 40.4, 37.9, 29.9, 28.3, 24.6, 23.0, 21.0. MS *m/z*: 190 (M^+). Anal. calcd. for $C_{13}H_{18}O$: C 82.05, H 9.54; found: C 81.87, H 9.34.

[R,R] and [R,S] 6-(3-Hydroxybutyl)-7,7-dimethylbicyclo[3.3.0]octa-(2–3),(1–5)-diene ***21***

To a solution of MeMgBr (18.1 mmol) in 20 mL of THF at −25°C was added aldehyde **20** (862 mg, 4.53 mmol) in 20 mL of THF. The reaction was stirred for 15 min, then quenched with water and extracted with Et_2O. The aqueous phase was extracted 2 × 20 mL of Et_2O and the combined organic extracts were washed with water, brine, and dried over $MgSO_4$. The mixture was filtered and the filtrate concentrated in vacuo. The crude material was subjected to column chromatography eluting with 20% Et_2O – hexane to provided alcohols **21** (877 mg, 94%). IR (neat): 3345, 3073, 2913, 1458, 1373, 1115 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 5.85 (m, 2H), 3.90–3.75 (m, 1H), 3.2 (m, 2H), 2.35–2.20 (m, 3H), 1.84–1.40 (m, 4H), 1.2 (several overlapping doublets, total 3H), 1.1 (s, 3H), 0.86 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 157.2, 157.1, 151.7, 146.7, 134.1, 130.0, 119.9, 119.5, 68.2, 67.9, 57.7, 49.3, 49.2, 47.3, 46.0, 43.6, 40.8, 38.3, 38.2, 28.0, 25.0, 24.8, 24.5, 23.3, 23.2, 22.9, 18.0. MS *m/z*: 206 (M^+). High-resolution mass spectrum calcd. for $C_{14}H_{22}O$: 206.16705; found: 206.16620.

*[R,R] and [R,S] 6-(3-*p*-Toluenesulphonyloxybutyl)-7,7-dimethylbicyclo[3.3.0]octa-(2–3),(1–5)-diene* ***22***

Compounds **22** were obtained in 74% yield (1.1 g), from **21** (880 mg, 4.3 mmol) using the same procedure described in the synthesis of **27**. IR (neat): 3066, 2960, 2869, 1601, 1465, 1366, 1184, 1101 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 7.8 (d, 2H, J = 8.3 Hz), 7.3 (d, 2H, J = 8.3 Hz), 5.78 (m, 1H), 5.70 (m, 1H), 4.70–4.60 (m, 1H), 3.16 (m, 2H), 2.43 (s, 3H), 2.20–2.10 (m, 3H), 2.0–1.1 (m, 4H), 1.32 (two overlapping d, total 3H, in a 1.1:1 ratio, J = 6.2 Hz, coupled to 4.62), 1.0 (s, 3H), 0.74 (s, 3H). A satisfactory elemental analysis of these compounds could not be obtained and they were generally converted to dienes **10** and **23** without purification.

rac-*[7S,8R,9R]-6,9,9Trimethyltricyclo[6.3.0.0^{7,8}]undeca-1,3-diene* ***10*** *and* rac-*[7S,8R,9S]-6,9,9-trimethyltricyclo-[6.3.0.0^{7,8}]undeca-1,3-diene* ***23***

A 1:1 isometric mixture of **10** and **23** was obtained in 79% yield (445 mg total wt.) from **22** (1.1 g, 3 mmol) using the same procedure described for the preparation of compound **28**. The two isomers were separated by column chromatography on $AgNO_3$-impregnated silica gel, eluting with pentane, to provide **23** (221 mg) and **10** (112 mg). The $AgNO_3$-impregnated silica gel was prepared by stirring 200 g silica gel with 400 mL of 20% aqueous $AgNO_3$, filtering, washing with THF, and drying in vacuo.

Data for **10**: IR (neat): 3082, 3061, 3024, 2950, 2866, 1612, 1525, 1454, 1383, 1363 cm^{-1}. ^1H NMR (200 MHz, $CDCl_3$) δ: 6.26 (d, 1H, J = 5.1 Hz), 6.15 (dd, 1H, J = 5.1 Hz, J = 1.5 Hz), 5.89 (br s, 1H), 2.47 (br d, 1H, J = 13.0 Hz, A of AB spin system, long range coupled to 5.89), 2.1 (m, 1H, coupled to 0.72), 1.93 (d, 1H, J = 13.0 Hz, B of AB spin system), 1.94–1.60 (m, 4H), 1.46–1.34 (m, 1H), 1.03 (s, 3H), 0.73 (s, 3H), 0.72 (d, 3H, J = 6.7 Hz). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 160.2, 140.5, 131.2, 122.4, 75.6, 53.1, 47.3, 41.7, 39.7, 36.7, 31.8, 27.9, 26.3, 15.4.

Preparation of endo- *and* exo-*diene complexes* ***29*** *and* ***30***

To a solution of [(η^5-indenyl)$Mo(CO)_2]_2$ (369 mg, 0.69 mmol) and diene **28** (240 mg, 1.377 mmol) in 16 mL of CH_2Cl_2 was added $AgBF_4$ (269 mg, 1.38 mmol) via a solid addition funnel. The reaction was stirred for 2 h, then filtered. The product was precipitated out in pure form by the addition of 30 mL of Et_2O. The product was filtered and dried in vacuo to yield an isomeric mixture of **29** and **30** in a 1:2 ratio (538 mg, 74%). IR (CH_2Cl_2): 2011, 1952 cm^{-1}. ^1H NMR **29** (200 MHz, $CDCl_3$) δ: 7.75 (m, 2H, total), 7.45 (m, 2H, total), 6.35 (m, 2H), 5.69 (t, 1H, J = 2.9 Hz), 5.09 (m, 1H), 4.20 (m, 2H, two overlapping signals), 2.65 (d, 1H, J = 20 Hz, A of AB spin system), 2.22 (d, 1H, J = 20 Hz, B of AB spin system), 1.88–1.44 (m, 7H, total), 1.25 (s, 3H), 1.07 (s, 3H). ^1H NMR **30** (200 MHz, $CDCl_3$) δ: 7.75 (m, 2H, total), 7.45 (m, 2H, total), 6.41 (d, 2H, J = 2.8 Hz), 5.65 (t, 1H, J = 2.8 Hz), 5.6 (m, 1H), 5.03 (m, 1H), 4.94 (m, 1H), 2.20 (d, 1H, J = 12.2 Hz, A of AB spin system), 1.85 (d, 1H, J = 12.2 Hz, B of AB spin system), 1.88–1.44 (m, 7H, total), 1.07 (s, 3H), 1.00 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 230.5, 229.0, 227.7, 224.0, 154.7, 130.2, 130.1, 129.9, 126.0, 125.9, 124.2, 113.8, 112.3, 112.1, 110.9, 109.4, 105.1, 104.9, 104.5, 95.2, 91.1, 84.9, 80.5, 68.0, 57.0, 52.5, 48.4, 41.9, 40.5, 38.9, 37.3, 32.2, 31.8, 28.9, 28.6, 26.8, 26.1, 25.9, 25.7. Anal. calcd. for $C_{24}H_{25}BF_4MoO_2$: C 54.57, H 4.77; found: C 54.11, H 4.87.

Preparation of endo- *and* exo-*diene complexes* ***12*** *and* ***24***

An isomeric mixture of **12** and **24** was obtained in a 2:1 ratio (180 mg, 71% crude yield) from **10** (88 mg, 0.47 mmol) using the same procedure described in the previous experiment except that the complexes were not precipitated out of solution with ether, this caused partial decomposition of these materials. IR (CH_2Cl_2): 2022, 1958 cm^{-1}. ^1H NMR **12** (250 MHz, $CDCl_3$) δ: 7.76–7.71 (m, 2H), 7.54–7.33 (m, 2H), 6.39 (br s, 1H), 6.32 (br s, 1H), 5.64 (m, 1H), 4.88 (br s, 1H, coupled to 4.21 and 3.91), 4.21 (br s, 1H), 3.91 (m, 1H), 2.63 (d, 1H, J = 20.6 Hz, A of AB), 2.47 (br d, 1H, J = 7.0 Hz), 2.24 (d, 1H, J = 20.6 Hz, B of AB), 1.9–1.2 (m, 7H, total), 1.25 (s, 3H), 1.02 (s, 3H), 0.80 (d, 3H, J = 6.4 Hz). ^1H NMR **24** (250 MHz, $CDCl_3$) δ: 7.76–7.71 (m, 2H), 7.54–7.33 (m, 2H), 6.42 (br s, 1H), 6.35 (br s, 1H), 5.95 (m, 1H, coupled to 5.00 and 4.81), 5.64 (m, 1H), 5.00 (br s, 1H), 4.81 (m, 1H), 2.07 (d, 1H, J = 11.6 Hz), 1.9–1.2 (m, 7H, total), 1.15 (s, 3H), 1.14 (d, 3H, J = 6.7 Hz), 1.02 (s, 3H). A satisfactory analysis could not be obtained because of the lability of these compounds in solvents used for their recrystallization.

Preparation of endo- *and* exo-*diene complexes* ***25*** *and* ***26***

An isomeric mixture of **25** and **26** was obtained in a 2:1 ratio (230 mg, 85% crude yield) from **23** (94 mg, 0.5 mmol). IR (CH_2Cl_2): 2019, 1958 cm^{-1}. ^1H NMR **25** (200 MHz, $CDCl_3$) δ: 7.85 (m, 1H), 7.68 (m, 1H), 7.46 (m, 2H), 6.34 (m, 1H), 6.26 (m, 1H), 5.75 (t, 1H, J = 3.0 Hz), 5.43 (m, 1H, coupled to 4.18 and 3.82), 4.18 (br s, 1H), 3.82 (m, 1H), 2.45 (d, 1H, J = 6.5 Hz, A of AB), 2.05 (d, 1H, J = 6.5 Hz, B of AB), 1.7 (m, 7H, total), 1.37 (s, 3H), 1.05 (s, 3H), 0.76 (d, 3H, J = 7.0 Hz). ^1H NMR **26** (200 MHz, $CDCl_3$) δ: 7.85 (m, 1H), 7.68 (m, 1H), 7.46 (m, 2H), 6.44 (m, 1H), 6.31 (m, 1H), 5.70 (t, 1H, J = 2.9 Hz), 5.64 (m, 1H, coupled to 5.19 and 4.57), 5.19 (dd, 1H, J = 2.2 Hz, J = 3.8 Hz), 4.57 (t, 1H, J = 2.2 Hz), 2.37–2.28 (m, 1H), 2.15 (d, 1H, J = 8.6 Hz), 1.1 (s, 3H), 1.05 (s, 3H), 1.04 (d, 3H, J = 5.6 Hz). A satisfactory analysis could not be obtained because of the lability of these compounds in solvents used for their recrystallization.

Preparation of allylmolybdenum complex ***31***

To a suspension of **29** and **30** (101 mg, 0.19 mmol) in 4 mL of Et_2O at −20°C was added Me_2CuLi (1.0 mmol). The reaction was stirred for 1 h, then quenched with a pH 8 solution of NH_4Cl and aqueous NH_3. Hexane (5 mL) was added and the organic phase syringed onto a small plug of silica gel and flushed, under N_2, with hexane into a round-bottom flask that was previously purged with N_2. The solvent was removed in vacuo and the crude material subjected to column chromatography, eluting with hexane under N_2. Recovered diene **28** (11 mg, 33%) eluted first and removal of the solvent from a second yellow fraction provided **31** (52 mg, 60%). IR (CH_2Cl_2): 1930, 1853 cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$) δ: 7.15–6.93 (m, 4H), 5.88 (m, 1H), 5.78 (m, 1H), 5.67 (t, 1H, J = 2.9 Hz), 2.72 (d, 1H, J = 3.8 Hz), 2.10 (d, 1H, J = 12.6 Hz, A of AB spin system), 1.66 (q, 1H, J = 7.1 Hz), 1.60–1.32 (m, 5H), 1.23 (d, 1H, J = 12.6 Hz, B of AB spin system), 1.00 (s, 3H), 0.98 (s, 3H), 0.88 (d, 3H, J = 7.1 Hz), 0.76–0.70 (m, 1H), −0.08 (d, 1H, J = 3.8 Hz). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 237.4, 234.9, 124.7, 124.6, 123.0, 122.4, 112.1, 109.5, 93.2, 89.1, 81.3, 79.8, 77.3, 69.9, 68.9, 53.5, 49.4, 43.8, 40.0, 39.5, 32.0, 29.1, 27.2, 26.9, 23.2. MS *m/z*: 458 (M^+). Anal. calcd. for $C_{25}H_{28}MoO_2$: C 65.79, H 6.18; found: C 65.39, H 6.28.

Preparation of allylmolybdenum complex ***32***

η^3-Allyl complex **32** was obtained in 21% yield (14 mg) from **12** and **24** (77 mg, 0.14 mmol), using the same procedure described for the preparation of **31**. Compound **10** (11.8 mg, 44%) was also recovered. IR (CH_2Cl_2): 1929, 1854 cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$) δ: 7.14–6.95 (m, 4H), 5.88 (m, 1H), 5.80 (m, 1H), 5.68 (t, 1H, J = 2.9 Hz), 2.77 (d, 1H, J = 3.8 Hz), 2.12 (d, 1H, J = 12.7 Hz, A of AB spin system), 2.01 (q, 1H, J = 7.1 Hz), 1.87 (m, 1H), 1.69 (m, 1H), 1.5 (m, 3H), 1.16 (d, 1H, J = 12.7 Hz, B of AB spin system), 1.05 (m, 1H), 0.98 (s, 3H), 0.96 (s, 3H), 0.88 (d, 3H, J = 7.1 Hz), 0.66 (d, 3H, J = 6.6 Hz), −0.24 (d, 1H, J = 3.8 Hz). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 235.7, 235.5, 124.8, 124.6, 123.1, 122.5, 112.5, 109.4, 104.3, 90.1, 89.2, 82.5, 80.15, 70.8, 70.2, 58.6, 43.8, 40.4, 39.2, 37.1, 37.0, 32.9, 28.0, 24.4, 21.1, 17.5. MS *m/z*: 472 (M^+). Anal. calcd. for $C_{26}H_{30}MoO_2$: C 66.38, H 6.43; found: C 65.95, H 6.61.

Preparation of allylmolybdenum complex ***33***

η^3-Allyl complex **33** was obtained in 22% yield (14 mg) from **25** and **26** (75 mg, 0.138 mmol), using the same procedure as for **31**. Also recovered was diene **23** (19.8 mg, 76%). IR (CH_2Cl_2): 1933, 1854 cm^{-1}. ^1H NMR (250 MHz, $CDCl_3$) δ: 7.17–6.93 (m, 4H), 5.79 (m, 1H), 5.77 (m, 1H), 5.69 (t, 1H, J = 2.9 Hz), 2.85 (d, 1H, J = 3.8 Hz), 2.14 (d, 1H, J = 12.5 Hz), 1.67 (q, 1H, J = 7.0 Hz), 1.62–1.26 (m, 5H), 1.16–1.07 (m, 2H), 1.04 (s, 3H), 0.98 (s, 3H), 0.90 (d, 3H, J = 7.1 Hz), 0.89 (d, 3H, J = 7.0 Hz), −0.06 (d, 1H, J = 3.8 Hz). MS *m/z*: 472 (M^+). Anal. calcd. for $C_{26}H_{30}MoO_2$: C 66.38, H 6.43; found: C 66.31, H 6.49. Crystals suitable for X-ray diffraction studies were grown by slow evaporation from a hexane solution.

X-ray structure determination of complex ***33***

A needle fragment of dimensions 0.62 × 0.08 × 0.11 mm, corresponding to the forms {010}, {100}, and {102}, respectively, and glued to a glass fiber using epoxy resin was mounted on a Siemens R3m/v diffractometer. The unit cell parameters were determined and refined from a set of 25 general reflections ($20.0 < 2\theta < 30.0°$) well distributed in reciprocal space.

Intensity data were collected with graphite monochromated MoKα radiation at 292 K by employing the ω-scan technique over a 2θ range of 4.0–50.0° with variable scan speeds (2.93–29.30° min^{-1}) and a 1.30° scan width. Background measurements using the stationary crystal, stationary counter method were made

at the beginning and end of each scan, each for 25% of the total scan time. Two standard reflections were measured after every 100 reflections and showed no significant loss in intensity during data acquisition.

Intensities were corrected for Lorentz and polarization effects. A face-indexed numerical method was employed to correct for adsorption effects. Of the 3801 independent reflections collected, 3082 were considered observed ($F > 6.0\ \sigma(F)$) and were used in the structure solution and refinement. The minimum and maximum transmission factors through the crystal were calculated to be 0.8531 and 0.9531.

The structure was solved by Patterson and Fourier methods and refined by full-matrix least-squares techniques using the Siemens SHELXTL PLUS software. Anisotropic refinement of all non-hydrogen atoms revealed the positions of all the hydrogens atoms from a difference map. In the final cycles of refinement, the hydrogen atoms were refined isotropically in their found positions.

Scattering factors for non-hydrogen atoms were taken from the *International tables* (13*a*) while the data of Stewart et al. were used for hydrogen atoms (13*b*). Selected details of the crystallographic data, data collection, and final refinement appear in Table 1, atomic coordinates and isotropic thermal parameters appear in Table 4, while selected bond lengths and angles appear in Table 5. Full details of the structure determination have been deposited (see footnote 6).

Étude par spectrophotométrie UV d'aldéhydes et d'amides parahydroxycinnamiques. Comparaison de leurs capacités complexantes vis à vis de $ZnBr_2$

HUBERT DURAN, ELISABETH DURAN, LILIANE GORRICHON[1] ET MARCEL PERRY

Synthèse et physicochimie organique, Unité de recherche associée au Centre national de la recherche scientifique, n° 471, Université Paul Sabatier, 118 route de Narbonne, 31062 Toulouse CEDEX, France

Reçu le 15 décembre 1992

HUBERT DURAN, ELISABETH DURAN, LILIANE GORRICHON et MARCEL PERRY. Can. J. Chem. **71**, 1041 (1993).

La capacité complexante des sels de zinc vis à vis des cinnamaldéhydes et des *N*-pyridyl cinnamides a été envisagée pour modéliser le site actif de la cinnamyl alcool déshydrogénase (CAD), un enzyme à zinc intervenant dans la lignification. Les parahydroxycinnamaldéhydes **4***a*–**6***a* sont des substrats spécifiques de cet enzyme alors que les cinnamides ont été synthétisés comme des ligands bidentés du zinc présentant une activité inhibitrice vis à vis de la CAD. L'interaction C=O...Zn est étudiée par des méthodes UV. Les constantes de stabilité sont faibles avec les aldéhydes (K = 3–16 L mol^{-1}) et (2–12) × 10^3 plus fortes avec les cinnamides correspondants, l'aminopyridine participant à la complexation. La stoechiométrie des complexes est ML (M : sel, L : ligand) avec les aldéhydes monosubstitués, et M_2L avec **5***a* ou **6***a*, correspondant à une seconde complexation par «effet catéchol». Avec les *N*-pyridylcinnamides la stoechiométrie des complexes est ML ou ML_2. Un fort effet bathochrome est observé, plus important pour les aldéhydes que pour les amides (conjugaison croisée); et une corrélation existe entre la bande d'absorption UV des ligands et de leurs complexes de zinc.

HUBERT DURAN, ELISABETH DURAN, LILIANE GORRICHON, and MARCEL PERRY. Can. J. Chem. **71**, 1041 (1993).

The ability of zinc salts to be complexed by cinnamaldehydes and *N*-pyridyl cinnamides has been investigated for modeling the active site of cinnamyl alcohol dehydrogenase (CAD), a zinc enzyme involved in the lignification process. Parahydroxycinnamaldehydes **4***a*–**6***a* are specific substrates of the enzyme while cinnamides were synthesized as bidendate ligands towards zinc, and present inhibitory effects toward CAD. The interaction C=O...Zn was studied by UV methods and was observed in each example; the complexation constants are rather low with aldehydes (K = 3–16 L mol^{-1}) and of the order (2–12) × 10^3 stronger with the corresponding cinnamides, due to the aminopyridine moiety participation. The stoichiometry of the complexes was found to be ML (M: salt, L: ligand) with monosubstituted aldehydes and M_2L with **5***a* or **6***a*, which was attributed to an additional complexation caused by the catechol effect. With the *N*-pyridylamides the complexation occurs according to a 1:1 (ML) or 1:2 (ML_2) stoichiometry. Strong bathochromic effects were also observed; they are more important with the aldehydes than with the amides (cross conjugation). Bathochromic effects due to the substitution of the aromatic ring are shown by a relationship between the ligands and their zinc complexes.

La complexation de composés cinnamiques et leur photoisomérisation en présence d'acides de Lewis ont fait l'objet d'études physicochimiques approfondies (1–5). En comparaison la complexation de composés cinnamiques polyphénoliques a été assez peu étudiée malgré l'importance de ces composés dans la constitution de polymères naturels tels que les tannins ou les lignines (6, 7).

Nous nous sommes intéressés à la complexation par les sels de zinc des cinnamaldéhydes **1***a*–**6***a*, et des *N*-pyridylcinnamides **1***b*–**6***b*.

Ces composés interviennent comme substrats (aldéhydes

	R^1	R^2	R^3	
1*a*	H	H	H	**1***b*
2*a*	H	OMe	H	**2***b*
3*a*	OMe	H	H	**3***b*
4*a*	OH	H	H	**4***b*
5*a*	OH	OMe	H	**5***b*
6*a*	OH	OMe	OMe	**6***b*

4*a*–**6***a*) (8, 9) ou inhibiteurs (10) (amide **5***b*) d'une déshydrogénase à zinc, l'alcool cinnamylique déshydrogénase (CAD) qui catalyse la dernière étape de la biosynthèse des monomères des lignines. Le zinc en activant la fonction aldéhyde du substrat favorise sa réduction par le cofacteur NADPH dans le site actif de l'enzyme. Les amides ont été synthétisés pour leur capacité à complexer le zinc de l'enzyme cible et pour leur analogie de structure avec les substrats aldéhydes, ce qui devait assurer leur reconnaissance et leur transport au site actif de l'enzyme. La comparaison des propriétés complexantes entre aldéhydes et amides peut permettre d'éclairer le rôle d'un ligand bidenté du type *N*-2-pyridylcinnamides dans la complexation du zinc et dans l'inhibition enzymatique observée avec ce type de composé (10). Dans cette modélisation nous nous sommes particulièrement intéressés à l'interaction entre le carbonyle des ligands et les sels de zinc.

Le rôle catalytique du zinc est connu pour de nombreux enzymes comme les alcools déshydrogénases (11). La structure du site actif autour de l'ion zinc dans l'alcool déshydrogénase de foie de cheval (LADH) est tétraèdrique, comme dans la plupart des métalloenzymes à zinc. L'ion zinc du site actif de cette déshydrogénase est coordiné à deux thiolates de résidus de cystéine, à un groupe imidazole de l'histidine et à une molécule d'eau comme quatrième ligand (12). L'alcool cinnamylique déshydrogénase (CAD) ne peut être obtenu en quantité suffisante pour l'étude directe des

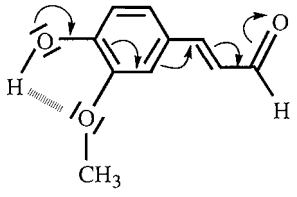
interactions entre enzyme et substrats (13). Les halogénures de zinc ont été largement utilisés comme modèle du site actif de l'alcool déshydrogénase (LADH), des similitudes spectroscopiques ayant été observées entre les complexes métalliques en solvant aprotique et le complexe LADH–substrat (14, 15). La complexation des substrats par les sels de zinc s'est avérée une modélisation acceptable de ces interactions au niveau du site actif de la protéine. Nous avons pris des conditions voisines de celles décrites dans les exemples avec la LADH et avons préféré le bromure de zinc au chlorure en raison de la meilleure solubilité dans les solvants aprotiques; de plus, il est moins hygroscopique. Les complexations ont été réalisées dans un solvant anhydre, sous atmosphère inerte pour éviter l'hydratation de la fonction carbonyle complexée à l'ion zinc (16). Les aldéhydes constituant des ligands peu favorables à la complexation, nous avons choisi le diéthyléther comme solvant car étant faiblement polaire et peu solvatant de manière à faciliter la comparaison entre aldéhydes et *N*-pyridylamides. L'étude présentée permet aussi d'examiner l'influence du degré de substitution du noyau aromatique et la participation de groupements phénol et (ou) méthoxyle à la complexation, en particulier pour les composés di- ou tri-substitués **5** et **6**. Les études de complexation des amides monosubstitués ayant déjà été réalisées (17), nous rapportons ici les résultats relatifs aux aldéhydes **1***a*–**6***a* et aux amides **5***b* et **6***b*, ainsi que la comparaison des données obtenues entre les deux séries.

Résultats

Propriétés spectrales UV

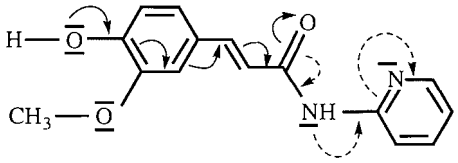
1. Aldéhydes ***1***a–***6***a *(tableau 1)*

Nous examinons l'absorption du chromophore correspondant à la transition $\pi \rightarrow \pi^*$ de ces composés. La longueur d'onde d'absorption des ligands est modifiée par la nature et la position des substituants fixés sur le noyau aromatique ($\Delta\lambda = \lambda_X^L(\text{ligand}) - \lambda_H^L(\text{cinnamaldéhyde})$) (1). La présence en *para* d'un substituant sur le noyau aromatique des aldéhydes induit un effet bathochrome de 32 nm pour un méthoxyle et de 34 nm pour un hydroxyle, alors que le méthoxyle en *méta* n'apporte aucune modification lorsqu'il est seul. Dans le cas des composés di- et tri-substitués possédant un hydroxyle en *para* et un ou deux méthoxyles en *méta* cet effet bathochrome augmente : 49 nm pour **5***a*, 57 nm pour **6***a* (tableau 1). Cet effet peut être expliqué par la présence d'une liaison hydrogène intramoléculaire qui renforce le caractère donneur du groupe hydroxyle en *para*. Cette hypothèse est confortée par les observations des spectres IR des composés **4***a* et **5***a*, montrant une fréquence $\nu_{\text{OH libre}}$ pour le *para* coumaraldéhyde **4***a* (**4***a* ν_{OH} = 3602 cm^{-1} dans CCl_4 M/400) et une fréquence $\nu_{\text{OH associé}}$ par liaison hydrogène intramoléculaire pour **5***a* (**5***a* ν_{OH} = 3546 cm^{-1} dans CCl_4 M/400) en accord avec des données de la littérature pour une liaison hydrogène entre les hydroxyles d'orthodiphénols (18, 19).



5*a*

Pour les amides correspondants on observe un phénomène similaire à celui des aldéhydes, seul l'effet bathochrome observé est plus faible : 49 nm pour **5***a* alors qu'il est de 33 nm pour **5***b*; la présence du groupe pyridyle induit une conjugaison croisée qui diminue l'effet bathochrome.



5*b*

2. Complexes des aldéhydes ***1***a–***6***a

Nous avons montré dans le cas des cinnamides **1***b*–**4***b* que l'addition d'acides de Lewis entraînait la formation de complexes faisant intervenir la fonction *N*-pyridylamide et le sel de zinc, complexes de stoechiométrie ML (**1***b*, **2***b*) ou ML et ML_2 (**3***b*, **4***b*). Ces résultats ont été confirmés par la caractérisation à l'échelle macroscopique de ces complexes (17).

Dans le cas des aldéhydes l'étude par spectrophotométrie UV fait aussi apparaître une forte perturbation de la transition $\pi \rightarrow \pi^*$ des aldédydes en présence de $ZnBr_2$; la complexation induit un effet bathochrome important par rapport au ligand (de 36 nm pour la complexation de **1***a* à 58 nm pour **6***a*).

La présence de substituants hydroxyle ou (et) méthoxyle sur le noyau aromatique renforce aussi cet effet bathochrome; on passe d'un λ_{max} de 315 nm pour le complexe Zn(II)–cinnamaldéhyde **1***a* à des valeurs de 357, 376 et 394 nm pour Zn(II)–*p*-coumaraldéhydes **4***a*, Zn(II)–coniferaldéhyde **5***a* et Zn(II)–sinapaldéhyde **6***a* (tableau 1).

Constantes de stabilité

Si l'on examine les ligands **1**–**6**, quatre cas sont à considérer : (*i*) les aldéhydes monosubstitués **1***a*–**4***a*; (*ii*) les *N*-2-pyridylamides monosubstitués **1***b*–**4***b* antérieurement décrits (17)–(20) (*iii*) les aldéhydes di- ou tri-substitués **5***a* et **6***a*; (*iv*) les amides di- ou tri-substitués **5***b*–**6***b*. Les fonctions susceptibles de participer à la complexation sont la fonction aldéhyde (ligand monodenté), les fonctions adjacentes sur le noyau aromatique OH, OMe par «effet catéchol» et la fonction *N*-pyridylamide (ligand bidenté).

1. Aldéhydes monosubstitués ***1***a–***4***a

R = H, *m*OMe, *p*OMe, *p*OH

Quand à une solution de ligand **1***a*–**4***a* on ajoute une solution de sel de zinc, une décroissance graduelle de ε_L et une augmentation de ε_C de l'absorption maximum du complexe (λ_{max}) sont observées. La présence d'un point isosbestique dans ces spectres (fig. 1) indique que le système contient deux chromophores en interconversion, le ligand libre et le complexe ligand – sel de zinc.

La courbe de variation $D_{exp} = f(\rho)$ (fig. 2) où ρ est le rapport de concentration en acide de Lewis sur la concentration en ligand (ρ = [$ZnBr_2$]/[L]) montre que la formation du complexe cinnamaldéhyde monosubstitué – bromure de zinc est en accord avec un mécanisme en une étape, avec une

ficative de la constante de stabilité observée pour les deux longueurs d'onde (tableau 2).

Les résultats mathématiques montrent que la complexation des ligands **1***a*–**4***a* avec le bromure de zinc est effectivement en accord avec une stoechiométrie 1/1; la complexation de ces aldéhydes avec le bromure de zinc s'effectue par la fonction carbonyle mais les constantes de stabilité de ces complexes sont faibles. Les substituants *para*-hydroxyles, donneurs par effet mésomère, induisent un grand changement dans la structure électronique du ligand lors de la complexation avec le bromure de zinc, avec des plus fortes valeurs de K (15,9 L mol^{-1}) pour le coumaraldéhyde **4***a* que pour les composés **1***a* et **2***a*.

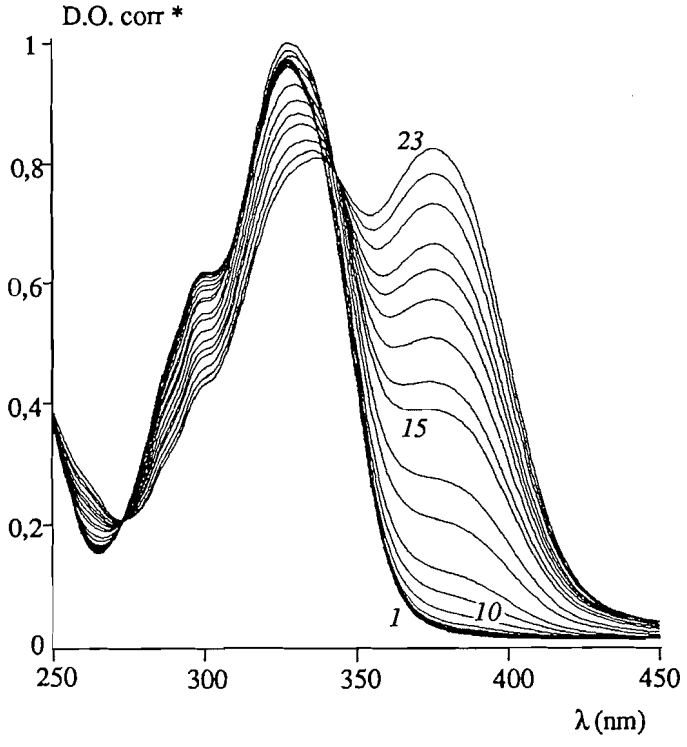

FIG. 3. Complexation du coniferaldéhyde **5***a* par addition de $ZnBr_2$ dans le diéthyléther à 25°C. *D.O.$_{corr.}$ = densité optique corrigée du facteur de dilution.

2. Aldéhydes di- et tri-substitués **5**a *et* **6**a

Ces composés présentent deux sites de complexation possibles et peuvent complexer les sels de zinc par l'oxygène du carbonyle et par les fonctions OH et OMe adjacentes sur le noyau aromatique. Lors de l'addition du bromure de zinc deux phases successives sont observées avec les composés **5***a* et **6***a*. Quand des faibles concentrations en sel métallique sont additionnées à une solution de ligand libre ($\rho < 150$) un faible effet bathochrome (2–3 nm) et une augmentation de ε_{max} sont observés. Pour les faibles valeurs de ρ les courbes présentent un premier point isosbestique (fig. 3, spectre 1–9). Si on continue l'addition de $ZnBr_2$, les complexes intermédiaires **5′** et **6′** disparaissent et une seconde bande d'absorption correspondant à la formation des complexes **5***a* et **6***a* apparaît (tableau 1).

La présence d'un point isosbestique à 345 nm (ou 356 nm) indique que seul un complexe intermédiaire **5′** (ou **6′**) intervient dans la formation des complexes finaux C5 (ou C6). Pour les ligands **5***a* et **6***a* la complexation de l'oxygène du carbonyle avec le bromure de zinc est donnée par la constante K_2 qui est du même ordre de grandeur que pour les aldéhydes monosubstitués **3***a* et **4***a*. La complexation de l'oxygène du carbonyle affecte la transition $\pi \rightarrow \pi^*$ du système conjugué, alors que par «l'effet catéchol» il se forme le complexe intermédiaire (λ_{max} **5′** = 330 nm; λ_{max} **6′** = 338 nm).

À titre de comparaison nous avons étudié dans des conditions identiques l'eugénol **7**. La complexation de **7** ne peut intervenir que par «effet catéchol», par l'intermédiaire des

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

hydroxyle et méthoxyle adjacents sur le noyau aromatique. L'addition d'un acide de Lewis ($ZnBr_2$) produit un effet bathochrome de 2 nm et une augmentation de ε_{max}. Ces observations sont identiques à celles observées précédemment pour les composés **5***a* et **6***a*.

Ces résultats confortent l'hypothèse retenue pour la complexation du coniferaldéhyde **5***a* et du sinapaldéhyde **6***a*. Il y a dès l'addition de $ZnBr_2$ complexation du sel par «effet catéchol» (entraînant un effet bathochrome de 2 nm), puis la complexation du carbonyle par le zinc intervient sur ce premier intermédiaire pour conduire à une stoechiométrie M_2L. C'est la constante K_2, représentative de la force de l'interaction C=O...Zn, qui nous intéresse dans le cadre de la modélisation du site enzymatique. Les valeurs obtenues sont respectivement de 13,6 et 8,9 L mol^{-1} pour **5***a* et **6***a* du même ordre de grandeur que celles obtenues pour la complexation du *p*-coumaraldéhyde **4***a* (K = 15,9 L mol^{-1}) ou du paraméthoxycinnamaldéhyde **3***a* (K = 11,7 L mol^{-1}).

3. Amides di- et tri-substitués **5**b *et* **6**b

La complexation des deux composés **5***b* et **6***b* peut faire intervenir deux types de ligands bidentés : les oxygènes des fonctions fixées sur le noyau aromatique (effet catéchol), et la fonction *N*-pyridylamide. Les spectres de complexation des phénolamides **5***b* et **6***b* présentent deux points isosbestiques (tableau 2); il existe un équilibre entre au moins deux complexes dont l'un est «intermédiaire». Les équilibres qui font intervenir trois espèces (L, ML, ML_2 ou M_2L) sont examinés :

$$[1]\quad L + M \rightleftharpoons ML \underset{+M}{\rightleftharpoons} M_2L$$

$$[2]\quad L + M \rightleftharpoons ML \underset{+L}{\rightleftharpoons} ML_2$$

De ces deux équilibres, la meilleure solution mathématique correspond à l'équilibre [2] qui fait intervenir la forme ML_2. Cette forme est majoritaire pour les faibles valeurs de ρ (ρ = [ZnBr2]/[L]) et peut être associée au complexe intermédiaire absorbant à 346 nm pour **5***b* et 351 nm pour **6***b*. Les constantes d'équilibre trouvées pour ces phénolamides sont élevées (équation [2] : $K_1 = 1{,}1 \times 10^5$ L mol^{-1} et $K_2 = 1{,}23 \times 10^5$ L mol^{-1} pour **5***b*).

Alors que pour les aldéhydes cinnamiques **5***a* et **6***a* possédant un site catéchol et un carbonyle, on observe une complexation de type M_2L faisant intervenir les deux sites de complexation, pour les amides cinnamiques équivalents **5***b* et **6***b*, seul le site amidopyridine complexe le bromure de zinc pour donner des stoechiométries de type ML ou ML_2. Ces résultats sont corroborés par la synthèse des complexes de zinc dont l'analyse élémentaire est en accord avec ces propositions (voir partie expérimentale). On retrouve à ce niveau des résultats analogues à ceux obtenus antérieurement pour la complexation des amides *para* hydroxylés et *para* méthoxylés (11).

L'ensemble des valeurs des constantes de complexation pour **1***a*–**6***a* et **1***b*–**6***b* et des longueurs d'onde d'absorption maximum sont rassemblés dans le tableau 2.

Discussion

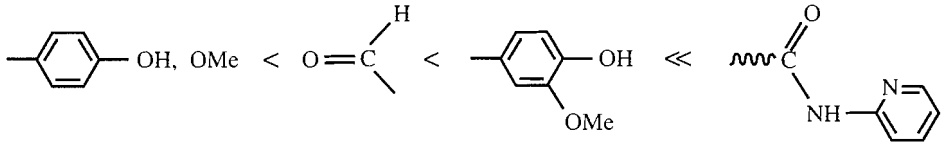
Si nous considérons l'ordre de grandeur des constantes de stabilité déterminées pour les différents complexes issus des aldéhydes **1***a*–**6***a* et des amides **1***b*–**6***b* nous observons que :

une seule fonction OH ou OMe n'est pas suffisante pour observer des complexes avec $ZnBr_2$;

la fonction carbonyle des aldéhydes cinnamiques complexe le zinc avec des constantes faibles de 3,2–15,9 L mol^{-1}; il est donc impossible d'isoler ces complexes, le phénomène n'étant mis en évidence qu'en déplaçant l'équilibre à l'aide d'un large excès de sels de zinc;

la complexation par «effet catéchol» lorsqu'elle peut avoir lieu est plus forte que la complexation par le carbonyle de l'aldéhyde ($K \sim 750/3{,}2$–$15{,}9$ L mol^{-1} respectivement);

enfin, la complexation par «effet catéchol» n'intervient pas avec les *N*-pyridylcinnamides, la fonction amide constituant dans ce cas un bien meilleur ligand bidenté pour conduire à des complexes ML ou (et) ML_2 ($K \sim 5 \times 10^3$–$1{,}1 \times 10^5$ L mol^{-1}).



K : – 3,2–15,9 ~750 5 x 10^3–1,1 x10^5

Les effets bathochromes dus à la substitution du noyau aromatique sont importants pour les ligands et plus marqués encore pour les complexes.

Nous avons rapporté les valeurs des λ_{max} des complexes en fonction des λ_{max} des ligands libres (fig. 4). Pour les amides nous obtenons de bonnes corrélations aussi bien pour les complexes de type ML que ML_2, ce qui a posteriori confirme la stoechiométrie des complexes déduite des calculs mathématiques. La pente de la droite de corrélation avec les complexes ML_2 (courbe C) est très inférieure à celle obtenue avec les complexes ML (courbe B) (C : pente = 1,04, N = 6, cc = 0,99 (ML_2); B : pente = 1,63, N = 5, cc = 0,999 (ML)); les effets électroattracteurs du zinc sont diminués car ils sont partagés entre les deux groupements carbonyle conjugués. De même, la pente de la droite de corrélation pour les complexes ML pour les amides est inférieure à celle observée avec les aldéhydes (courbe A) (p = 1,34, cc = 0,99, N = 5); la double liaison carbonyle peut être conjuguée avec le motif aminopyridine ou avec le motif aromatique. La linéarité de la relation λ_{max} des complexes = $f(\lambda_{max}$ des ligands libres) pour ces trois séries de complexes met en évidence que la bande d'absorption des ligands libres et des complexes sont de même nature et correspondent à la transition $\pi \rightarrow \pi^*$ modifiée par la complexation.

Si nous examinons ces résultats du point de vue de la modélisation de l'interaction Zn–substrat au niveau du site actif de l'enzyme cible, la cinnamylalcool déshydrogénase,

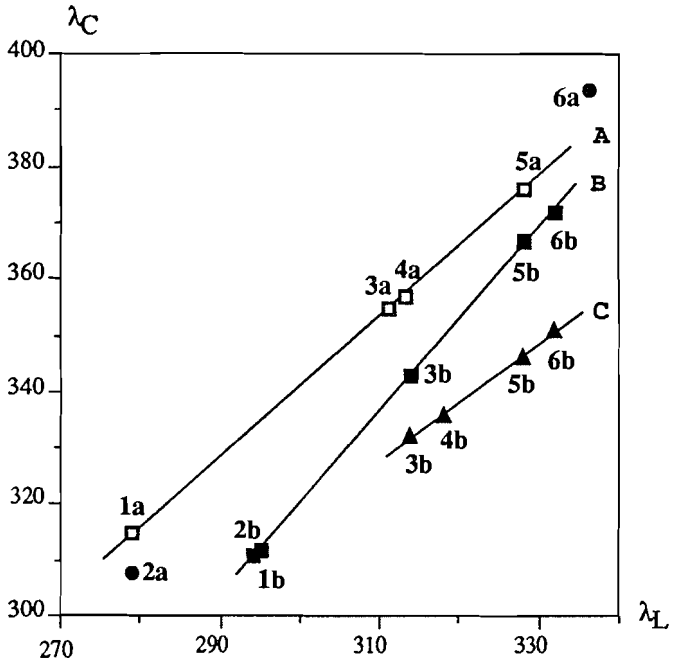


FIG. 4. Effet des substituants sur les longueurs d'onde d'absorption maximum des complexes aldéhydes ou amides cinnamiques – sels de zinc en fonction des longueurs d'onde d'absorption maximum des aldéhydes ou amides libres. □, ● : Complexe C=O....Zn avec les aldéhydes; ■ : complexe C=O....Zn avec les amides; ▲ : complexe C=O....Zn....O=C avec les amides.

nous sommes amenés à comparer les valeurs des constantes de stabilité pour les complexes de type ML entre CHO....Zn dans les aldéhydes et *N*-pyridyl C=O....Zn dans les amides. Ces valeurs varient sensiblement entre les aldéhydes eux-mêmes. Le cinnamaldéhyde qui n'est pas un substrat naturel de l'enzyme présente des constantes de stabilité quatre à cinq fois plus faibles que celles des aldéhydes substrats parahydroxylés **4***a*–**6***a*. Le paracoumaraldéhyde **4***a* et le coniferaldéhyde **5***a* qui ont la meilleure affinité pour l'enzyme (7), présentent les valeurs de constantes de stabilité les plus élevées dans la série. Néanmoins, ces résultats doivent être examinés avec précaution et ces valeurs de constantes restent en valeur absolue très faibles de 2 à 12 × 10^3 fois inférieures à celles obtenues pour les complexes issus des amides correspondants.

En conclusion, ces observations peuvent être mises en parallèle avec nos hypothèses de travail; les amides ont été initialement synthétisés pour leur aptitude à complexer le zinc de l'enzyme cible et pour leur analogie de structure avec les substrats aldéhydes, ce qui devait assurer leur reconnaissance et leur transport au site actif de l'enzyme. Les résultats de l'étude de complexation au niveau de l'interaction C=O...Zn d'une part, les propriétés inhibitrices vis à vis de la CAD observées d'autre part avec l'amide **5***b*, confortent dans une certaine mesure les deux termes de l'hypothèse.

En effet, l'étude physicochimique de la complexation des aldéhydes et des amides cinnamiques nous a permis de préciser ou de confirmer les points suivants :

1. Les aldéhydes **1***a*–**4***a* non substitués et substitués par un méthoxyle ou un hydroxyle se complexent avec le bromure de zinc par l'oxygène du carbonyle avec une faible constante de complexation et une stoechiométrie 1/1.

2. Les aldéhydes **5***a* et **6***a* se complexent par les fonctions OH et OCH_3 portées par le noyau phényle (K_1 = 750 L mol^{-1}) et par l'oxygène de la fonction carbonyle avec une constante faible (**5***a* K_2 = 13,6 L mol^{-1}, **6***a* K_2 = 8,9 L mol^{-1}), selon une stoechiométrie M_2L. Les effets bathochromes dus à la complexation sont de 48 et 58 nm, ce qui suggère la participation d'une forme quinonique (21).

3. Les phénolamides complexent fortement le zinc par l'intermédiaire de la fonction amido-pyridine K = 11 × 10^4 L mol^{-1}. Ces amides ont des constantes de complexation 2 à 12 × 10^3 fois plus grandes que les aldéhydes substrats **4***a*–**6***a*. Ces données sont cohérentes avec l'activité biologique de ces composés qui sont des inhibiteurs de l'enzyme cible (10).

Partie expérimentale

Matériel

Les aldéhydes et les amides cinnamiques ont été préparés à partir des acides cinnamiques correspondant en les activant par le chlorure de *N*,*N*-diméthyl-chloroéthylèniminium, en les réduisant en aldéhydes par l'hydrure de lithium et de tritertbutoxyaluminium, en les condensant avec l'amidure de l'aminopyridine pour les amides selon les conditions précédemment décrites (22–24). Le bromure de zinc (Aldrich) est séché à 150°C sous une pression de 10^{-2} mbar pendant 4 h (1 bar = 100 kPa). Le diéthyléther est distillé sur sodium. Les spectres infrarouges sont enregistrés sur un appareil Perkin–Elmer, modèle 783. Les spectres ultraviolets sont enregistrés à l'abri de la lumière du jour pour éviter une irradiation UV des ligands, et sous une atmosphère inerte afin de prévenir l'hydratation des sels de zinc.

Conditions de l'étude UV

Les ligands aldéhydes et amides sont préparés à une concentration de 4 × 10^{-5} mol L^{-1} dans le diéthyléther anhydre auxquels sont ajoutés à la seringue une solution de $ZnBr_2$ dans le diéthyléther (7,4 × 10^{-3} mol L^{-1} dans Et_2O), la solution est homogénéisée, puis le spectre UV est enregistré. Le rapport ρ est défini comme étant [M]/[L] (M = $ZnBr_2$, L = Ligand).

Les spectres enregistrés sont ceux d'une solution (V = 3 cm^3) d'aldéhydes de molarité donnée à laquelle sont ajoutés des volumes connus (v cm^3) de solution de bromure de zinc. Pour l'étude de la complexation, la densité optique expérimentale est corrigée d'un facteur de dilution ($V + v/V$) afin de se retrouver à molarité constante en aldéhyde :

$$\text{D.O.}_{\text{corr.}} = \left(\frac{V+v}{V}\right) \times \text{D.O.}_{\text{exp.}}$$

Les constantes de stabilité des complexes et leurs coefficients d'extinction molaire sont déterminés selon la méthode de Shapiro et Johnston (25) décrite dans la note concernant les amides monosubstitués (17).

Les constantes de stabilité K, K_1, K_2 sont données en fonction de x, y (qui sont les concentrations molaires respectives de ML et M_2L en équilibre) et de m_0 et l_0 (les concentrations initiales de $ZnBr_2$ et du ligand). Le coefficient de reliabilité est donné par

$$\text{Re} = \left[\frac{\sum_{i=1}^{p} (A_{i\,\text{exp}} - A_{i\,\text{calc}})^2}{\sum_{i=1}^{p} A_{i\,\text{exp}}^2}\right]^{1/2}$$

et l'erreur quadratique :

$$Q = \sum_{i=1}^{p} (A_{i\text{exp}}^2 - A_{i\,\text{calc}})^2$$

TABLEAU 3. Analyse élémentaire des complexes des amides **5***b* en **6***b* avec $ZnBr_2$

Stoechiométrie			Analyse élémentaire % calc.		% trouvé
5*b*	ML	C	36,36	C	36,42
		H	2,85	H	2,89
		N	5,65	N	5,80
	ML_2	C	47,06	C	46,29
		H	3,69	H	3,80
		N	7,32	N	7,27
	ML	C	36,57	C	36,52
		H	3,07	H	3,07
6*b*		N	5,33	N	5,31
	ML_2	C	46,54	C	48,25
		H	3,91	H	4,08
		N	6,78	N	6,99

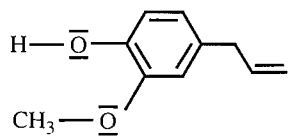
Préparation des complexes des amides **5**b *et* **6**b

Les synthèses des complexes des amides **5***b* et **6***b* sont réalisées selon la méthode précédemment décrite (17).

Dans la méthode A on introduit le sel de zinc selon une stoechiométrie 1 : 1; dans la méthode B on introduit un excès de sel de zinc.

Les analyses élémentaires sont données dans le tableau 3.

Étude de la complexation de l'eugénol **7**



La complexation de l'eugénol est étudiée dans les conditions décrites dans la note sur les amides (17).

À une solution d'eugénol sont ajoutés des incréments de bromure de zinc en solution dans le diéthyléther. En faisant varier le rapport sel sur ligand on observe la formation d'un complexe absorbant à 284 nm alors que l'eugénol **7** absorbe dans le diéthyléther à 282 nm; on note également un point isosbestique à 270 nm. Eugénol **7** : λ_{max} (nm) = 282, ε_{max} = 3 200 L mol^{-1} cm^{-1}. Complexe eugénol **7** – $ZnBr_2$: λ_{max} (nm) = 284, ε_{max} = 3 700 L mol^{-1} cm^{-1}. La constante de complexation K calculée selon le modèle M + L $\rightleftharpoons$ ML est de 58 L mol^{-1} (Q = 2,8 × 10^{-5}, Re = 0,005).

Dissociation constants of some alkanolamines

S. XU, F.D. OTTO, AND A.E. MATHER[1]

Department of Chemical Engineering, University of Alberta, Edmonton, Alta., Canada T6G 2G6

Received April 7, 1992[2]

S. XU, F.D. OTTO, and A.E. MATHER. Can. J. Chem. **71**, 1048 (1993).

The dissociation constants of piperidine (PD), 1-piperidineethanol (1-PE), *N*-methylmorpholine (MML), 4-(2-hydroxyethyl)morpholine (4-EML), and tropine (TP) have been determined at 15.0, 25.0, 35.0, 45.0, and 60.0°C. The standard state enthalpy changes of the dissociation reaction for these amines have been obtained from the dependence of the dissociation constants upon temperature.

S. XU, F.D. OTTO et A.E. MATHER. Can. J. Chem. **71**, 1048 (1993).

On a déterminé, à des températures de 15,0, 25,0, 35,0, 45,0 et 60,0°C, les constantes de dissociation de la pipéridine (PD), de la pipéridineéthanol-1 (PE-1), de la *N*-methylmorpholine (MML), de la (hydroxy-2-éthyl)-4-morpholine (EML-4) et de la tropine (TP). L'influence de la température sur les constantes de dissociation permet d'obtenir les changements d'enthalpie de l'état standard des réactions de dissociation de ces amines.

Introduction

Aqueous alkanolamine solutions are widely used for the removal of acid gases such as H_2S, COS, and CO_2 from gaseous streams. It has been found that the dissociation constant of the alkanolamine is one of the very important factors in the selection of an amine solution or in the elucidation of a kinetic mechanism of absorption of the acid gas in the amine solution. A knowledge of the acid–base properties of these amine solvents plays an important role in our understanding of the relationships between molecular structures, chemical-physical properties of individual atoms or groups of atoms within molecules, and liquid–gas equilibrium constants or reaction rate constants.

The dissociation constants for some conventional alkanolamines were presented by Perrin (1), and more recently by other authors (2–6), at several temperatures and various ionic concentrations. Also, Antelo et al. (7) studied the influence of the ionic composition of the medium on the dissociation constants of some conventional amines. Nevertheless, the dissociation constants of less common alkanolamines are still unavailable. The purpose of the present investigation is to provide dissociation constants for some of these alkanolamines at several temperatures.

Experimental section

Analytical grade piperidine (PD), 1-piperidineethanol (1-PE), and 4-(2-hydroxyethyl)morpholine (4-EML), all with purities of ≥99%, were supplied by Aldrich Chemical (Milwaukee, Wis.). As analyzed by gas chromatography, the purity of the tropine (TP, Aldrich Chemical) was higher than 98% and the rest was water. *N*-Methylmorpholine (MML) with a purity of 99% was provided by Alfa Division of Ventron Chemicals Company. These chemicals were used as received.

The accuracy of the buffer solutions used to calibrate the pH meter was ±0.01 and ±0.02, respectively, at 25°C for pH 4.00, 7.00, and 10.00. The titration acid was 0.1000 ± 0.005 M hydrochloric acid. These chemicals were provided by the Fisher Scientific Company. All solutions were prepared using reverse osmosis water, which was made by passing triple-distilled water through anion exchange, cation exchange, activated carbon, and a 0.45-μm cartridge. The conductivity of the reverse osmosis water was higher than 0.06 μS cm^{-1}. The nitrogen used for blanketting the titration of the dissociation constant was supplied by Union Carbide Canada. It had a purity of 99.99% without any oxygen.

TABLE 1. Values of pK_a for several alkanolamines

Amine	Temperature (°C) 15.0	25.0	35.0	45.0	60.0	Reference
PD	11.443	11.123	10.818	10.526	10.19[a]	Perrin (1)
PD	11.44	11.16	10.81	10.53	10.18	This work
2-PE	10.47	10.14	9.82	9.52	9.16	Xu et al. (6)

MML	7.62	7.40	7.28	7.16	6.94	This work
4-EML	7.20	7.01	6.88	6.67	6.56	This work
TP	10.80	10.48	10.23	10.04	9.72	This work

[a]At 59.6°C.

The dissociation constants of the amine solvent were determined by potentiometric titration with standard hydrochloric acid in a special jacketted beaker that could be kept at a constant temperature within ±0.05°C. The solutions used in this experiment were protected by high-purity nitrogen. The pH meter, a model 520 digital pH/ion meter made by the Fisher Scientific Company, was read directly with an accuracy of ±0.002 pH and a reproducibility of ±0.001 pH. The pH meter, combined with glass and reference electrodes, was calibrated by the buffer solutions in the range of pH 4–10 before determination of the dissociation constant. After the dilute amine solutions were prepared, they were stripped by nitrogen to remove trace amount of gases such as oxygen. The solutions were then stored under a nitrogen atmosphere.

The pK_a values of the amines were directly calculated from the titration curve of the pair of pH values and acid volume titrated. The activities of the species in the solution were corrected by the activity coefficients obtained from the Debye–Hückel equation. Further detailed information about the experimental procedure is provided by Xu et al. (6).

Results and discussion

The values of pK_a for several uncommon amines measured in this work are listed in Table 1. Since the operating temperature is limited by the standard buffer solutions, the dissociation constants of the amines were determined in the temperature range from 15.0 to 60.0°C. Comparing the pK_a values of PD measured in this work with these of Perrin (1), the accuracy of this experiment is within ±0.02 pK_a.

Table 1 shows that the values of pK_a for PD are the high-

est among those measured. In the family of piperidines, the value of pK_a may depend on the number of hydroxyethyl groups attached to the nitrogen atom or on the position of the hydroxyethyl group in the cyclic system. For example, the dissociation value of 2-PE, in which the hydroxyethyl group is connected at the α position of the cyclic system, is higher than that of PD; the dissociation constant of 1-PE is the highest in the family of piperidines in that its hydroxyethyl group is directly attached to the nitrogen atom. This characteristic is similar to that of conventional alkanolamines, in that the value of pK_a of a secondary amine is larger than that of a tertiary amine, and also the value of a sterically hindered amine is larger than that of a tertiary amine. It is interesting that although both morpholine and piperidine are secondary amines, and have almost the same molecular structures, their dissociation constants are very different, with pK_a values of 8.33 (1) and 11.44, respectively, at 25°C. This may be due to the effects of an oxygen atom connected to the naphthenic ring group, since a pair of isolated electrons of the nitrogen atom in morpholine are attracted to the oxygen atom so that the electronegativity of morpholine increases, and its ability to combine with the H^+ ion in water decreases. Furthermore, comparing the values of pK_a in the family of morpholines, the value of pK_a of morpholine, 8.33, is larger than that of *N*-ethylmorpholine, 7.67 (1), and larger than that of *N*-methylmorpholine, 7.40, and that of 4-EML, 7.01, at 25°C. It can readily be seen that the value of pK_a is also affected by the length of the carbon chain and the atoms attached to the chain. The higher the electronegativity of the atom in this compound, the lower the pK_a value of the compound. 4-EML, therefore, has the lowest pK_a value in Table 1. Although TP is one of the tertiary amines, its pK_a is higher than that of other tertiary amines as a result of its special molecular structure.

According to the experimental data, the values of pK_a for these alkanolamines can be correlated by the following equation:

$$[1] \quad pK_a = C_1 + \frac{C_2}{T}$$

where T is in K. The parameters in the equation for the alkanolamines are given in Table 2. The standard state enthalpy change (ΔH^0) of the reaction of amine dissociated in water can be calculated from the van't Hoff equation. Based on the experimental work, the standard state enthalpy changes (ΔH^0) of the amines decreases with the decrease in pK_a of the amine except for the sterically hindered amine 2-PE. The standard state enthalpy change (ΔH^0) of the sterically hindered amine, 2-PE, is the highest among those amines tested, which means that the pK_a value of 2-PE is sensitive to the temperature change. Also, the standard state enthalpy change of 2-amino-2-methyl-1-propanol (AMP), one of the primary sterically hindered amines, has the highest standard state enthalpy change of conventional amines (6).

TABLE 2. The parameters of eq. [1] and the standard enthalpy changes of alkanolamines

Coordination-induced keto–enol tautomerization in the formation of Ni^{2+} and Cu^{2+} complexes of a fluorinated keto-diol[1]

JAGADESE J. VITTAL AND CHRISTOPHER J. WILLIS[2]
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received February 2, 1993

JAGADESE J. VITTAL and CHRISTOPHER J. WILLIS. Can. J. Chem. **71**, 1051 (1993).

The fluorinated keto-diol $(CF_3)_2C(OH)CH_2C(=O)CH_2C(CF_3)_2OH$ forms stable, neutral, 1:1 complexes of Ni^{2+} (**6***a*) and Cu^{2+} (**6***b*) with tetramethylethylenediamine (TMED) as coligand. The structure of each complex has been determined crystallographically; they are isomorphous and isostructural, monoclinic with space group *Cc* (No. 9). Complex **6***a*, $C_{15}H_{20}F_{12}N_2NiO_3$, has a = 11.495(2), b = 15.516(2), c = 12.323(2) Å, β = 99.88(1)°, V = 2165.4(6) Å^3, Z = 4. Complex **6***b*, $C_{15}H_{20}CuF_{12}N_2O_3$, has a = 11.603(2) b = 15.661(2), c = 12.276(2) Å, β = 99.75(2)°, V = 2198.5(6) Å^3, Z = 4. In each, the metal is in square-planar geometry bonded to two alkoxide groups and two N atoms of TMED. A previous assignment of a zwitterionic structure to these complexes has been shown to be incorrect. Instead, the ligand is coordinated as the di-ionized enol tautomer $(CF_3)_2C(-O^-)CH_2C(-O^-)=CHC(CF_3)_2OH$, the C=C double bond being external to the six-membered chelate ring. The remaining OH group of the ligand forms part of a second six-membered ring held together by hydrogen bonding.

JAGADESE J. VITTAL et CHRISTOPHER J. WILLIS. Can. J. Chem. **71**, 1051 (1993).

Le céto-diol fluoré $(CF_3)_2C(OH)CH_2C(=O)CH_2C(CF_3)_2OH$ forme des complexes stables, neutres, 1 : 1 de Ni^{2+} (**6***a*) et de Cu^{2+} (**6***b*) avec la tétraméthyléthylènediamine comme coligand. On a déterminé la structure de chaque complexe par cristallographie; ils sont isomorphes et isostructuraux et appartiennent au groupe d'espace monoclinique *Cc* (No. 9). Les paramètres du complexe **6***a*, $C_{15}H_{20}F_{12}N_2NiO_3$, sont a = 11,495(2), b = 15.516(2), c = 12,323(2) Å, β = 99,88(1)°, V = 2165,4(6) Å^3, Z = 4. Les paramètres du complexe **6***b*, $C_{15}H_{20}CuF_{12}N_2O_3$ sont a = 11,603(2), b = 15.661(2), c = 12,276(2) Å, β = 97,75(2)°, V = 2198,5(6) Å^3, Z = 4. Dans chacun de ces complexes, le métal a une géométrie carré-plan lié à deux groupes alcoolates et à deux atomes d'azote de la TMED. On démontre que la structure de zwittérion proposée antérieurement pour ces complexes est incorrecte. Le ligand est plutôt coordonné sous forme de tautomére énol diionisé, $(CF_3)_2C(-O^-)CH_2C(-O^-)=CHC(CF_3)_2OH$ avec la double liaison C=C à l'extérieur du cycle chélaté à six chaînons. Le groupe OH restant appartient à un second cycle à six chaînons, le tout étant maintenu ensemble par des liaisons hydrogènes.

[Traduit par la rédaction]

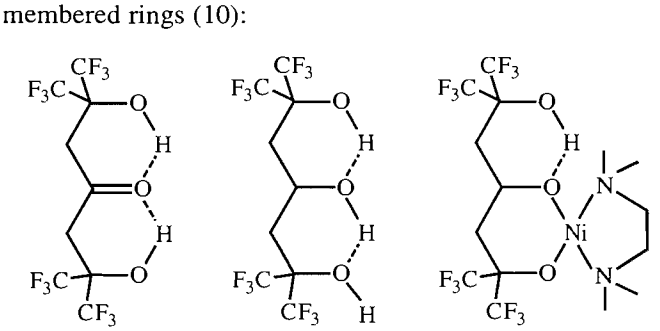
Introduction

Coordination to a metal ion of a ketone function in the form of its ionized enol tautomer is a familiar process. Complexes are frequently stabilized by delocalization in a chelate ring, of which the β-diketone systems are the most common. Stabilization may also occur through conjugation of the C=C bond in the enol with a C=N bond in a Schiff-base type of ligand. For example, it has long been known that β-diketones will condense with diamines in the presence of Ni^{2+} (1, 2) or Cu^{2+} (3, 4) to give neutral complexes of tetradentate, dinegative, ligands of the type $[R\text{-}C(\text{-}O^-)=CHC(R)=N\text{-}CH_2\text{-}]_2$. Additional conjugation may be present if R is phenyl.

It is unusual for an alkoxide to form by the coordination of an enolate in the absence of such interaction of the C=C bond with other bonds in the ligand molecule, but in this paper we describe the structures of stable complexes of Ni^{2+} and Cu^{2+} formed in this way. In each case, a six-membered chelate ring is formed by bonding to the enolate and to a highly fluorinated alkoxide, but the C=C bond is external to this ring.

The ready formation of alkoxides of transition metals by the coordination of fluorinated alkoxide ions is well established (5). Stability is considerably enhanced by chelation, and the highly fluorinated diol perfluoropinacol, $HOC(CF_3)_2C(CF_3)_2OH$, in its di-ionized, bidentate, form, is particularly suitable for the preparation of complexes of a variety of metals (5–7).

Thermal reaction of acetone with hexafluoroacetone gives both a 1:1 and a 1:2 adduct: the keto-alcohol $CH_3COCH_2C(CF_3)_2OH$, **1**, and the keto-diol 1,1,1,7,7,7-hexafluoro-2,6-bis(trifluoromethyl)-4-heptanone-2,6-diol $(CF_3)_2C(OH)CH_2COCH_2C(CF_3)_2OH$, **2** (8, 9). A recent structural study on the latter shows intramolecular hydrogen bonding between the carbonyl oxygen atom and both OH groups, forming two six-membered rings (10):



2 **3** **4**

Reduction of the keto-diol **2** gives the fluorinated triol **3**, which, in the di-ionized form, acts as a bidentate ligand to Ni^{2+}, giving the complex **4** in which the metal is four-coordinate (9). The failure of **3** to coordinate as a tridentate ligand is presumably due to steric constraints and the stability of the remaining H-bonded ring in **4**.

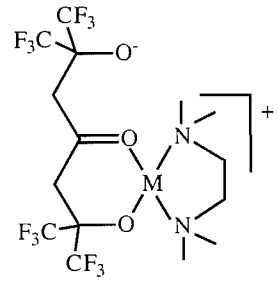
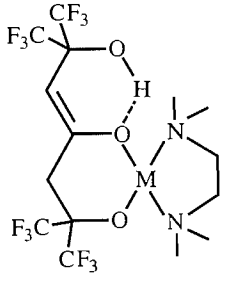
$R_f = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.
$R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$.
GOF = $\Sigma w(|F_o| - |F_c|)^2$/(no. of reflections − no. of parameters)$^{1/2}$.

Carbonyl oxygen is not a strong donor, and we had difficulty in preparing stable complexes of the ionized keto-alcohol **1**. Only with a tridentate macrocyclic amine as coligand was it possible to isolate a cationic complex in which **1** had chelated to five-coordinate Ni^{2+} (9). It was therefore surprising that the di-ionized keto-diol **2** was found to give stable, neutral, complexes with both Ni^{2+} and Cu^{2+}. Tetramethylethylenediamine (TMED) was used as coligand, and visible spectra showed the metal to be four-coordinate. Because of the geometry of the ligand **2**, it was considered very unlikely that the two fluorinated alkoxides could chelate to the same metal atom, and structure **5**, with a separation of formal charge, was therefore assigned. The C=O stretching frequency of the ligand was apparently reduced by ~50 cm^{-1} in each of the complexes, consistent with coordination of the ketone group. However, an alternate model in which ligand **2** bridged between two metal centres could not be ruled out.



5



6*a*, M = Ni^{2+}; **6***b*, M = Cu^{2+}

To clarify the structures of these complexes, we have now undertaken an X-ray crystal structure determination of the Ni^{2+} and Cu^{2+} derivatives. It shows that our earlier assignment of type **5** structures was incorrect. Instead, ligand **2** has undergone keto–enol tautomerization on coordination, giving an unsaturated triol, and the bonding system in each complex is as shown at **6**.

Experimental

X-ray structure determination

Compounds **6***a* and **6***b* were prepared as previously reported (9). Single crystals were obtained by diffusion of pentane into a solution of the complex in dichloromethane at 5°C. The two compounds were examined by similar experimental procedures, as given below, and were subsequently found to be isomorphous and isostructural.

Densities were measured by the neutral buoyancy method in mixtures of dibromoethane and carbon tetrachloride. Crystals were mounted on glass fibres using epoxy resin in air. Data collection was carried out on an Enraf–Nonius CAD4F diffractometer using monochromated MoKα radiation at 23°C. Photo and automatic indexing routines, followed by least-squares fits of 21 accurately centered reflections ($12.1 \leq 2\theta \leq 14.3°$ for **6***a* and **6***b*), gave cell constants and an orientation matrix (11). Intensity data were recorded in ω–2θ mode, at variable scan speeds (0.915–4.12 deg min^{-1}) and a scan width of 0.8 + 0.35 tan θ, with a maximum time per datum of 60 s. Static background measurements were made at the end points of the width 0.9 + 0.35 tan θ. Three standard reflections were monitored every 120 min.

In all, 3325 ($-14 \leq h \leq 14$, $-1 \leq k \leq 20$, $-16 \leq l \leq 1$) and 2642 ($-15 \leq h \leq 0$, $0 \leq k \leq 20$, $-15 \leq l \leq 15$) reflections for **6***a* and **6***b*, respectively, were measured in the 2θ range 0–55°. The NRCVAX crystal structure programs (12) running on a SUN 3/80 workstation were used to process the data. Gaussian absorption corrections were applied. The cell parameters and the systematic absences (13) were consistent with either space group *Cc* (No. 9) or space group *C*2/*c* (No. 15). The *N*(*z*) statistics (14) strongly indicated the noncentrosymmetric space group. In addition, the expected molecular structure for $Z = 4$ did not possess 1 or 2-fold symmetry and hence the space group *C*2/*c* was not considered further. Successful structure solution and refinement confirmed the choice of the space group. Refinements were by full-matrix least-squares techniques on *F*. The metal, fluorine, and all the methyl carbon atoms were assigned anisotropic thermal parameters and were refined in the least-squares cycles. All the hydrogen atoms were located successfully by difference Fourier. The isotropic thermal parameters for **6***a* and the positional parameters for the enolic H atoms in **6***a* and **6***b* were refined. The isotropic temperature factor was fixed at $U = 0.05$ for the enolic H atom in **6***b*. All

[a] B_{iso} for non-H atom is the mean of the principal axes of the thermal ellipsoid.

other hydrogen atoms were placed in ideal positions (C—H = 1.08 Å) and their thermal parameters were assigned to ride 10% more on the attached carbon atoms.

Crystal **6**a

The dark red data crystal (dimensions 0.13 × 0.15 × 0.31 mm) has six faces, with indices {110}, (10-2), and (-10-2). The distances between the faces were measured under a filar microscope for absorption; transmission factors range from 0.8432 to 0.8817. The equivalent reflections were averaged to give 2665 unique reflections. Full-matrix least-squares refinement of 220 variables and 1758 observations with $I \geq 2.5\sigma(I)$ converged at $R_f = 0.058$, $R_w = 0.031$, and GOF, $S = 2.21$, using a weighting scheme based on counting statistics. In the final difference Fourier synthesis, the electron density ranged from 0.67 to −0.46 e A^{-3}. The maximum shift/σ ratio was 0.037. The inverted model converged at $R_f = 0.060$ and $R_w = 0.033$.

Crystal **6**b

The dark pink data crystal (with dimensions 0.14 × 0.14 × 0.41 mm) had seven faces. The face indices were {110}, (-111), (-1-11), and (-10-2). The transmission factors ranged from 0.7635 to 0.8591. The atomic coordinates of **6***a* were used for the initial least-squares refinement of **6***b*. Full-matrix least-squares refinement of 219 variables and 1689 observations with $I \geq 2.5\sigma(I)$ converged at $R_f = 0.067$, $R_w = 0.042$, and GOF = 2.79, using a weighting scheme based on counting statistics. The inverted model also converged at $R_f = 0.067$, $R_w = 0.042$, and GOF = 2.74. Between these two models the latter (inverted model) was preferred over the other since the esd's were slightly better and variations in C—F distances and F—C—F angles were smaller. In the final difference Fourier synthesis, the electron density ranged from 0.56 to −0.45 e A^{-3}. The maximum shift/σ ratio was 0.074.

The experimental details, crystal data, and positional and thermal (B_{iso}) parameters for **6***a* and **6***b* are given in Tables 1 and 2, respectively, while selected bond distances and bond angles are given in Table 3. Tables of anisotropic thermal parameters, hydrogen atom parameters, weighted least-squares planes, selected torsion angles, and structure factors for both compounds are available as supplementary material.[3]

Structure description and comparison

ORTEP views of the complexes **6***a* and **6***b*, showing the atom numbering scheme, are shown as Figs. 1 and 2, respectively. Each complex consists of discrete molecular units in which coordination to the metal occurs from one fluorinated alkoxide and from the central oxygen atom on the ligand, O(2), giving a six-membered

chelate ring. Geometry at the metal is slightly distorted square-planar for each metal. In **6***a*, bond angles at Ni total 361° and the metal is 0.070(4) Å out of the least-squares plane of the four coordinated atoms; corresponding figures for **6***b* are 360° and 0.018(5) Å. The chelate ring is in a distorted "boat" conformation.

Metal–oxygen bond lengths are in the range usually found for fluorinated alkoxides of these metals (5) and for β-diketone complexes. Carbon–oxygen bond lengths in the chelate rings are in the range 1.32–1.37 Å; as usual, these are shorter than the C—O bonds found in unfluorinated alkoxides. However, C(1)—O(2) is 1.317(10) in **6***a* and 1.357(13) in **6***b*, in each case significantly longer than the value of 1.202(6) Å found for the double bond in the uncoordinated ligand **2** (10). At the same time, the C(9)—C(10) bond length shortens from an average of 1.51(2) Å in the ligand to 1.365(11) and 1.322(15) Å on complex formation. Bond angles at C(10), within the hydrogen-bonded ring, were 124.1(8)° and 121.9(10)°, consistent with sp^2 hybridization. These data support the bonding of the enol tautomer in each complex.

Confirmation of this comes from the detection of the migrated proton in a hydrogen-bonded ring in each complex, the dimensions being very similar to those found in the parent ligand (10).

Discussion

The revision of the structures of **6***a* and **6***b* explains why ligand **2** complexes more readily than the keto-alcohol **1**, in which keto–enol tautomerization stabilized by hydrogen bonding is not possible. It is clear that our previous interpretation of the infrared spectrum of the complexes was incorrect. The C=O vibration, found at 1730 cm^{-1} in free ligand **2**, is replaced by absorptions at 1650 and 1646 cm^{-1} in **6***a* and **6***b*, respectively, and these must be assigned to the C=C bonds present in the complexes, rather than to coordination-shifted carbonyl absorptions.

Since the electronic structure of the complexes would be very similar if the C=C bond were in the ring containing the metal ion (that is, running between C(8) and C(9)), we assume steric factors are responsible for it appearing in the H-bonded ring. The preference of each metal ion for square-planar coordination imposes greater restraints on the conformation of that chelate ring than the requirements of the less rigid ring containing the loosely bonded hydrogen atom.

This result confirms the importance of hydrogen bonding in highly fluorinated alcohols and demonstrates the surprising ease with which di-alkoxides of such highly oxophilic metals as nickel and copper may be formed from ketone functions in ligands of suitable geometry.

The reaction of 2,2-diphenyl-1-(2,4,6-trinitrophenyl)hydrazine with the enolate of acetone, followed by acidification, yields the title compound 2,2-diphenyl-1-(5-acetonyl-2,4,6-trinitro-1,3-cyclohexadienyl)hydrazine, $C_{21}H_{19}N_5O_7$. The identity of the latter was confirmed by a combination of mass spectrometry, FTIR, elemental analysis, and ^{1}H NMR. Crystals were grown from dichloromethane – 95% ethanol and the structure was determined by X-ray diffraction. Crystals are monoclinic, $P2_1/c$, a = 9.254(3), b = 13.531(3), c = 17.39(5) Å, β = 106.18(2)° at 225 K. R = 0.073, R_w = 0.038 for reflections with $I > 2\sigma(I)$. The Zachariasen extinction factor, g, refined to 18(3) × 10^{-4}. The cyclohexadiene ring is puckered with a primarily *twist-boat* conformation. Atoms C(1) to C(3), C(6), the nitro group on C(2), and the hydrazine moiety (N(8)—N(7)—H(7) attached to C(1)) all lie close to a common plane. The planes of the two phenyl rings, the acetonyl substituent, and the C(6) nitro group are each roughly perpendicular to this plane. The C(5) acetonyl and C(6) nitro groups are *trans* to each other.

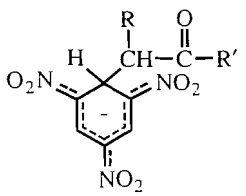
DONNA L. DRAPER, RICHARD J. BARTON, BEVERLY E. ROBERTSON, BARBARA R. NELSON et JOHN A. WEIL. Can. J. Chem. **71**, 1057 (1993).

La réaction de la 2,2-diphényl-1-(2,4,6-trinitrophényl)hydrazine avec l'énolate de l'acétone, suivie par une acidification, conduit au composé mentionné dans le titre, la 2,2-diphényl-1-(5-acétonyl-2,4,6-trinitro-1,3-cyclohexadiényl)hydrazine, $C_{21}H_{19}N_5O_7$. L'identité de ce dernier a été confirmée par une combinaison de spectrométrie de masse, d'IR par TF, d'analyse élémentaire et de RMN du ^{1}H. On a obtenu les cristaux à partir d'une solution dichlorométhane – éthanol à 95% et on a déterminé la structure par diffraction des rayons X. Les cristaux sont monocliniques, $P2_1/c$, a = 9,254(3), b = 13,531(3) et c = 17,39(5) Å, β = 106,18(2)°, à 225 K. R = 0,073 et R_w = 0,038 pour les réflexions avec $I > 2\sigma I$. Le facteur d'extinction, g, s'affine à 18(3) × 10^{-4}. Le noyau cyclohexadiéne existe principalement sous une conformation *bateau déformé*. Les atomes C(1) à C(3), C(6), le groupe nitro attaché au C(2) et la portion hydrazine (N(8)—N(7)—H(7) attachée au C(1)) se retrouvent tous dans un plan commun. Les plans des deux noyaux phényles, du substituant acétonyle et du groupe nitro en C(6) sont chacun approximativement perpendiculaires à ce plan. Les groupes acétonyle en C(5) et nitro en C(6) sont *trans* l'un par rapport à l'autre.

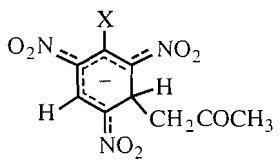
[Traduit par la rédaction]

Introduction

It has long been known (1) that 2,4,6-trinitrobenzene (TNB) and its 1-X-substituted derivatives (1-X-TNB) react with the enolate carbanions of ketones, aldehydes, keto esters, and amides to form stable covalently bonded σ adducts. In the literature these adducts are often referred to as σ complexes or Meisenheimer complexes. A typical TNB–carbonyl σ adduct is represented by **1**.



1



2

The presence of strong electron-withdrawing groups (NO_2) reduces the electron density of the aromatic ring. This not only facilitates the approach of the carbanion, but also stabilizes the negative charge of the σ adduct by conjugative withdrawal of the electron density into the nitro groups.

The formation of the σ adduct is characterized by the two-step process in which the enolate is generated in a pre-equilibrium step (eq. [1]) by reaction of an α-hydrogen-containing carbonyl compound with a base B^- prior to the rate-determining addition of the enolate to the TNB ring (eq. [2]). While enolates are potentially bidentate (addition to C or to O), in all the systems studied only carbon-bonded adducts were observed.

In the case of 1-X-TNBs there are two potential addition sites: C(1) to form the 1,1 adduct (*ipso*) and C(3) (or C(5)) to form the 1,3 adduct. Enolate attack at C(3) is the kinetically favored reaction because these carbons are less sterically hindered than C(1) with its X substituent. It is the 1,3 adduct that is formed when enolates are reacted with 1-X-TNBs.

In the synthesis of 2,2-diphenyl-1-(5-acetonyl-2,4,6-trinitro-1,3-cyclohexadienyl)hydrazine (**A**), the title compound, the 1-X-TNB species 2,2-diphenyl-1-(2,4,6-trinitrophenyl)-hydrazine (**D**) was reacted with the acetone enolate. Similar reactions of other 1-X-TNBs with the acetone enolate are described in the literature. These include X = OPh, Cl, OCH_3, SO_3Na, CH_3, COOH, SCH_3, and $COOCH_3$ (2–4). In all these reactions the product is the 1,3 adduct **2**.

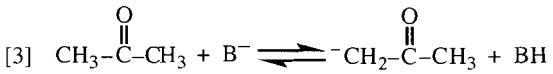
[2] TNB + R–$\bar{C}$H–C(=O)–R′ ⇌ **1**

However, the product from the reaction of **D** with the acetone enolate is not the 1,3 adduct (i.e., which is not observed to exist as a stable species) but rather $\mathbf{A}^-$ (eq. [5]), the product of conjugate addition (Michael reaction) (5). Equations [3–7] give the proposed reaction paths for the formation of **A** from **D** and are divided into three separate steps: (*a*) formation of the acetone enolate, (*b*) formation of the conjugate base of **A**, and (*c*) protonation of the conjugate base of **A**. The enolate is formed in step *a* by adding a non-nucleophilic base (e.g., K_2CO_3, triethylamine, *N*,*N*-dimethyl-4-aminopyridine, or lithium diisopropylamide (LDA)) to acetone (eq. [3]). The amount of enolate formed in this step depends on the pK_a of the base: <1% using K_2CO_3 with a pK_a = 10.3, and ~100% using LDA with pK_a = 37.

Because **D** contains an acidic proton, there are two electrophilic species in solution that potentially can react with the enolate to give $\mathbf{A}^-$. These are **D** and its conjugate base $\mathbf{D}^-$. (The potassium salt $K^+\mathbf{D}^-$ has been characterized (6).) A reaction path for each of these species is given in step *b*. If the enolate attacks $\mathbf{D}^-$, the formation of $\mathbf{A}^-$ would most likely proceed via Path I (eq. [4] and [5]). If the enolate attacks **D**, Path II (eq. [6]) would probably be followed. In step *c*, $\mathbf{A}^-$ is protonated using acetic acid or HCl to form **A**, the title compound. Further studies of this reaction are in progress.[2]

The present paper gives the X-ray crystallographic structure of **A** along with supporting spectroscopic data from proton nuclear magnetic resonance, infrared, and mass spectroscopy, and elemental analysis.

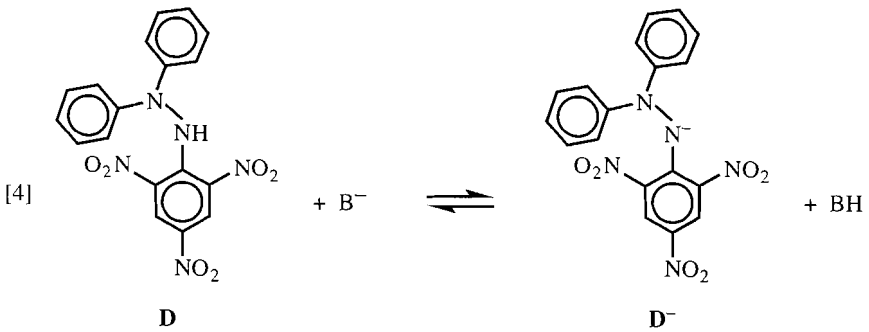
(a) Formation of the acetone enolate



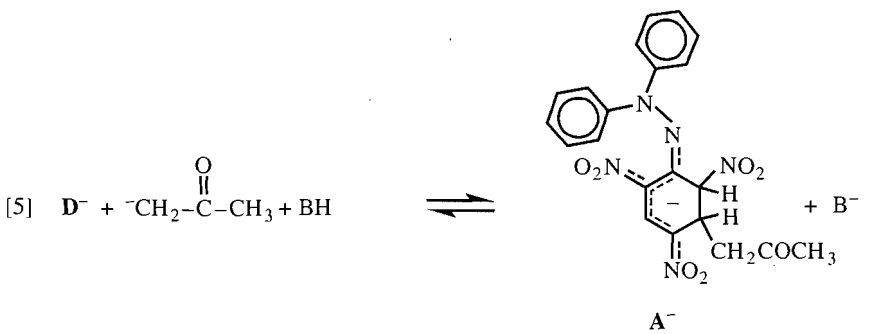
[3] $CH_3–C(=O)–CH_3 + B^- \rightleftharpoons {}^-CH_2–C(=O)–CH_3 + BH$

(b) Formation of the conjugate base of **A**

Path I

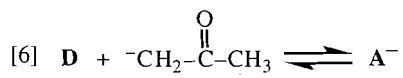


[4] **D** + B^- ⇌ $\mathbf{D}^-$ + BH



[5] $\mathbf{D}^-$ + ${}^-CH_2–C(=O)–CH_3$ + BH ⇌ $\mathbf{A}^-$ + B^-

Path II



[6] **D** + ${}^-CH_2–C(=O)–CH_3$ ⇌ $\mathbf{A}^-$

Experimental

Crystal data

$C_{21}H_{19}N_5O_7$ Molar mass = 453.41 g mol^{-1}
Monoclinic, $P2_1/c$, a = 9.254(3), b = 13.531(3), c = 17.391(5) Å, β = 106.18(2)°, T = 225 K, V = 2091(1) Å^3, Z = 4, D_x = 1.413 g cm^{-3}, μ(MoKα) = 1.41 cm^{-1}, F_{000} = 944, λ(MoKα$_1$) = 0.70926 Å.

A was prepared by reacting 1.0 g (0.0025 mol) of **D**, 1.10 g (0.015 mol) of finely ground anhydrous potassium carbonate, and 15 mL of glass-distilled reagent-grade acetone (dried over molecular sieves) at reflux temperature for 48 h. The mixture was then filtered to remove any unreacted potassium carbonate, and the filtrate evaporated to dryness at 40°C on a rotary evaporator. The crude residue was washed with four 30-mL portions of distilled water. After each washing the dark red-brown solution was decanted into a filter and allowed to drip into a stirred solution of 30 mL of glacial acetic acid and 15 mL of 30% hydrogen peroxide. **A** precipitated as a dark orange solid. The solid was filtered and washed 4 times with a minimum of 95% ethanol, and crystallized from dichloromethane – 95% ethanol to yield 0.27 g (20%) of pure product, mp, 150–153°C (dec.).

[a]$U_{eq} = \frac{1}{3}\Sigma_i\Sigma_j U_{ij} a_i^* a_j^* \mathbf{a}_i \cdot \mathbf{a}_j$.

Proton nuclear magnetic resonance spectra of **A** at 294 K were run on a Bruker AM300 spectrometer with TMS as the internal standard. Tables 1 and 2 give the chemical shifts and coupling constants for the salt $K^+\mathbf{A}^-$ and for **A** respectively.

A high-resolution positive-ion fast atom bombardment (FAB) mass spectrum of **A** was run on a VG Analytical 70-250 SEQ hybrid mass spectrometer. The largest mass-to-charge ratio found was 454.1370. This corresponds to the ratio for the protonated **A** cation with a molar mass M + 1, calculated to be 454.1363.

The Fourier-transform infrared spectrum of **A** showed carbonyl stretching at 1711 cm^{-1} and aliphatic C—H stretching at 2900–3000 cm^{-1}, confirming the presence of the acetonyl group.

Elemental analysis of carbon, hydrogen, and nitrogen gave C 55.79%, H 4.24%, N 15.15%, and O 24.82% (by difference). The calculated values are C 55.61%, H 4.23%, N 15.45%, and O 24.71%.

A crystal with dimensions 0.56 × 0.40 × 0.18 mm was selected for X-ray study.

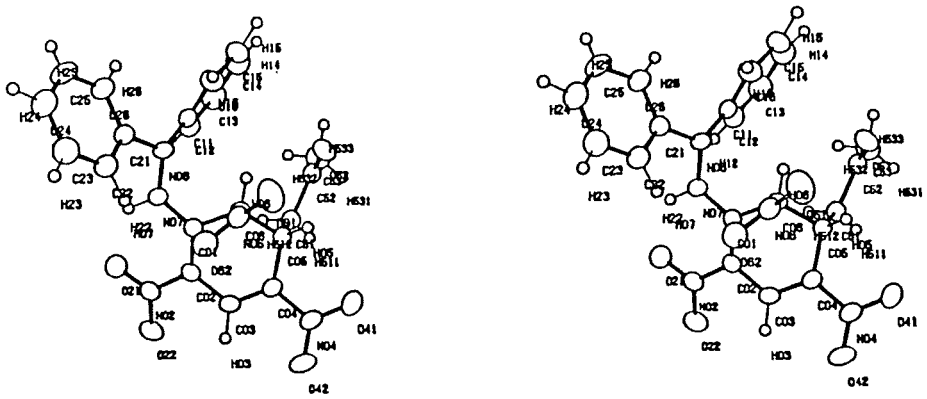

FIG. 1. Stereoscopic view of the **A** molecule.

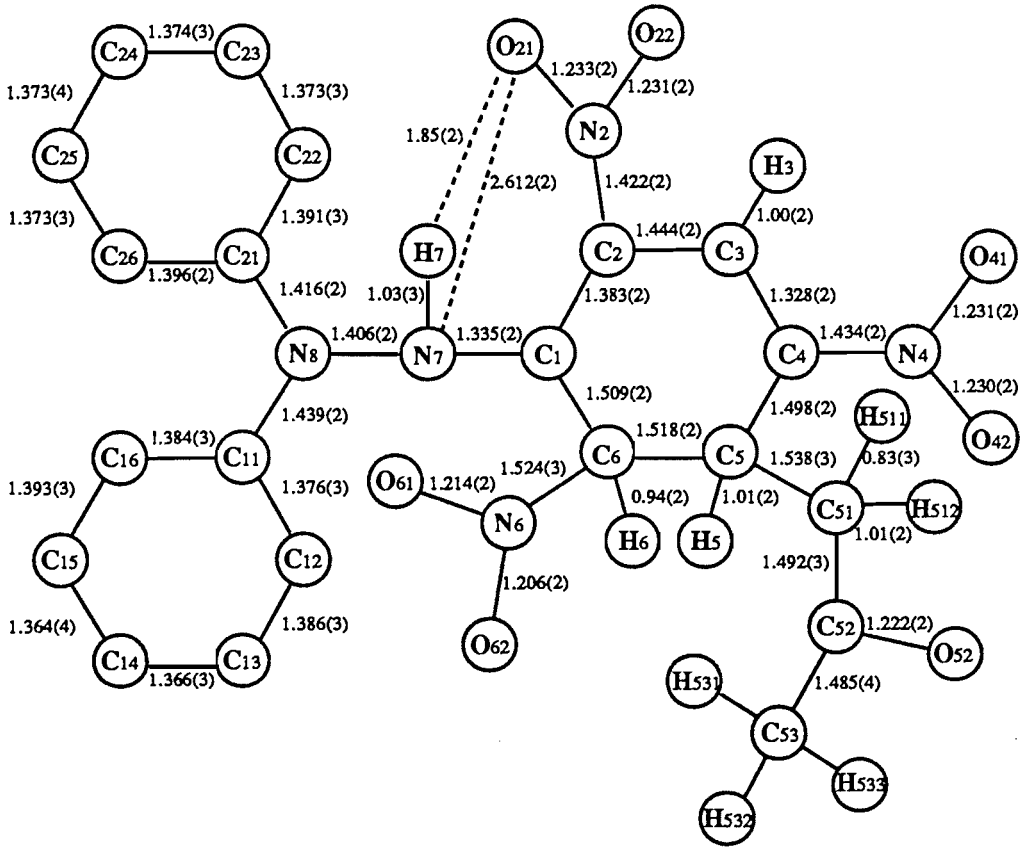

FIG. 2. Atom labels and bond lengths with esd values for **A**.

The space group was determined to be $P2_1/c$ from precession photographs. The lattice constants were determined by a least-squares fit to the positions of 28 reflections in the range $22° \leq 2\theta \leq 49°$. Intensity data for 3684 reflections were collected on a modified Picker four-circle diffractometer with graphite-monochromated radiation in the range $3 \leq 2\theta \leq 50°$, using MoKα radiation and the θ–2θ scan mode. Three reference reflections were measured after each group of 47 reflections. Their intensities did not change significantly. The 3035 reflections with $I/\sigma(I) \geq 2.0$, where $\sigma(I)$ is based on the machine-instability factor and counting statistics, were used in the refinement.

The intensities were corrected for Lorentz and polarization effects, but no corrections were made for absorption or anomalous dispersion. The structure was solved by direct methods and refined by least squares using the XTAL crystallographic system of programs (7). Weights were calculated as $\sigma^{-2}(F)$, where $\sigma(F)$ and $|F|$ are calculated from $\sigma(I)$ and I using Baysian statistics. Refinement at this stage, with anisotropic temperature factors applied to the non-hydrogen atoms and isotropic temperature factors applied to the hydrogen atoms, led to unacceptably high values of wR. (0.18). An isotropic extinction parameter was then refined according to the method of Zachariasen (8) and wR was reduced to 0.045 and the extinction parameter g refined to $41(7) \times 10^{-4}$. The weighting scheme was then modified to remove dependence of the average value of $w\Delta^2$ ($\Delta = |F_o| - |F_c|$) on $|F_o|$ and $\sin\theta/\lambda$ (9). The value of g was reduced to $18(3) \times 10^{-4}$ by further refinement, and R_w was reduced to 0.038.

The final value of the unweighted R factor was 0.073. The average and maximum shift/error ratio were 2×10^{-3} and 5×10^{-2}, respectively. The residual electron densities in the final difference maps were bounded by 0.53 and -0.68 e Å^{-3}.

The extinction coefficient $18(3) \times 10^{-4}$ is unusually large for an

organic crystal. Furthermore, its value is strongly dependent on the least-squares weighting scheme. Weight modification has the effect of decreasing the influence on least-squares refinement of reflections affected by larger random or systematic error relative to those less affected. These results imply that the true variance of the strong reflections was more severely underestimated by the unmodified weights than were the variances of the weaker reflections, and (or) that the model for the effects of secondary extinction is not adequate and systematic error associated with secondary extinction remains after corrections based on the Zachariasen model had been applied.

Results and discussion

The atom coordinates[3] and equivalent isotropic temperature factors for the non-hydrogen atoms are listed in Table 3 and a stereoscopic view of the **A** molecule is given in Fig. 1. The atom-numbering scheme and bond lengths are shown in Fig. 2, and the bond angles in Fig. 3.

The puckering of the cyclohexadiene ring was analyzed

by the method of Cremer and Pople (10). The puckering amplitude Q is 0.437. The pseudo-rotation angles are φ = 259.4° and θ = 67.9°, defined with respect to C(1). These parameters imply significant puckering with a conformation which is primarily *twist-boat*, as shown in Fig. 4.

Figure 5 indicates the definitions of various planes of molecular groups. Selected dihedral and torsional angles are listed in Tables 4 and 5.

In Fig. 5, atoms C(1) to C(3), C(6), the nitro group on C(2), and the hydrazine moiety N(8)—N(7)—H(7) lie close to the common plane A fitted to their positions by least squares. The two planes, B and C, fitted to the two phenyl rings, and the planes D and G, fitted to the acetone substituent and the C(6) nitro group, respectively, are all roughly perpendicular to plane A. Intramolecular hydrogen bonding[4] between H(7) and O(21) forces the C(2) nitro group to be coplanar with C(1) to C(3). This allows the N(2) p orbital containing the nonbonding electron pair to be parallel to (and overlapping) the p orbitals of C(1) and C(2), enabling the lone pair to participate in the π-electron system. That such participation occurs is indicated by the shortened length of the C(2)—N(2) bond: 1.422(2) Å in **A** versus 1.475(10) Å in nitromethane (11). Similar shortening is observed in the **D** molecule (12).

The C(5) acetonyl and the C(6) nitro groups are *trans* to each other and their conformation is axial with respect to the ring, allowing maximum separation and thus minimum steric interference with each other. The C(6) nitro group is also oriented so that its plane, G, is approximately parallel with plane B of the C(11) phenyl group. Thus steric interactions between these two groups are minimized. The acetonyl group projects outward from the ring, with plane D perpendicular to plane A. This conformation minimizes any interactions with the cylochexadiene ring system.

To minimize steric interactions between the two phenyl substituents, planes B and C are oriented 66° with respect to each other. This angle is 20° larger than that in D (12) and is assumed to be caused by the twisting of the C(11)–C(16) phenyl ring (plane B) to minimize steric interactions with the axial nitro group (plane G).

Various important canonical structures contributing to the

[4]The infrared spectrum of **A** shows N—H to be hydrogen bonded.

For personal use only.

spatially averaged geometric configuration of the trinitrocyclohexadiene ring are shown in Fig. 6. The 0.055(3) Å shortening of C(3)—C(4) compared to C(1)—C(2) is contributed by some combination of structures **2** and **5**. The length of C(3)—C(4), 1.328(2) Å, is consistent with the double bond in cyclohexa-1,3-diene (1.332 Å) (13). C(2)—C(3) is slightly shorter than the typical Csp^2—Csp^2 single bond (1.455 Å) in conjugated aliphatic systems (13) with this shortening contributed by structures **3** and **4**. Due to interactions of the nitrogen lone-pair electrons with the π system of the cyclohexadiene ring, the C(2)—N(2) and C(4)—N(4) bonds are considerably shorter than the C—N bond (1.475 Å) in nitromethane (11). Structures **4** and **5** contribute to this shortening. C(6)—N(6), however, is much longer than the nitromethane C—N bond and is very close to that (1.533 Å) observed in compounds with a nitro group on a tertiary carbon (13).

Due to the intramolecular hydrogen bond and the resulting coplanarity of the σ-bond system of the N(7) atoms with that portion of the trinitro ring system in plane A, the N(7) *p* orbital containing lone-pair electrons is parallel to (and overlapping) the C(1)—C(2) π system, allowing participation of the lone-pair electrons. This results in a shortening of the C(1)—N(7) bond to a length similar to that of the C(3)—N(2) bond (1.329 Å) found in pyrazole (13). Canonical structures **2**–**5** illustrate this participation. The C(1)—N(7) bond in **D** is similarly shortened but is slightly longer (1.348(7) and 1.355(6) Å) than in **A**.

Like the N(7) atom, N(8) is also sp^2 hybridized (with some sp^3 character), which allows it to remain in plane A. This minimizes the steric interactions between the two phenyl groups at one end of the hydrazine linkage and the cyclohexadiene ring at the other. The N—N bond is similar in length to that of **D** (1.381(5) and 1.400(5) Å).

The C—O (1.222(2) Å) and the Csp^3—Csp^2 (1.485(4) Å) bonds in the acetonyl group are slightly shorter than those found in aliphatic linear unsubstituted ketones (13).

MONIQUE PAGÉ, JEAN-YVES HUOT, and CARMEL JOLICOEUR. Can. J. Chem. **71**, 1064 (1993).

The density, isobaric specific heat capacity, and isentropic compressibility of water–ethanolamine (W–EA) mixtures have been measured at three temperatures (10, 25, and 40°C) over the entire composition range. The results were used to calculate various thermodynamic excess functions of these mixtures, namely: the excess molar volume (V^E_m), excess molar isentropic and isothermal compressibilities ($\kappa^E_{S,m}$, $\kappa^E_{T,m}$), excess molar isobaric and isochoric heat capacities ($C^E_{p,m}$, $C^E_{V,m}$), and excess molar isobaric expansion $(\partial V^E_m/\partial T)_p$. The corresponding partial molar quantities for ethanolamine in the mixtures were also computed. These excess and partial molar quantities were compared with those observed earlier in the water – ethylene glycol (W–EG) (1) and in the water–2-methoxyethanol (W–ME) (2) mixtures. The similarities and differences in the properties of these systems are interpreted on the basis of the specific molecular features of the cosolvents and the concepts of cooperative fluctuations and hydrogen-bonding connectivity in liquid water and dilute aqueous solutions.

MONIQUE PAGÉ, JEAN-YVES HUOT et CARMEL JOLICOEUR. Can. J. Chem. **71**, 1064 (1993).

On a mesuré la densité, la capacité calorifique spécifique isobare et la compressibilité isentropique des mélanges eau–éthanolamine (W–EA) à trois températures (10, 25 et 40°C) et pour le domaine de composition. On a utilisé les résultats pour calculer les différentes fonctions thermodynamiques d'excès de ces mélanges et, en particulier : le volume molaire d'excès (V^E_m), la compressibilité isothermique et isentropique molaires d'excès ($\kappa^E_{S,m}$,$\kappa^E_{T,m}$), les capacités calorifiques isochore et isobare molaires d'excès ($C^E_{p,m}$,$C^E_{V,m}$) et l'expansion isobare molaire d'excès $(\partial V^E_m/\partial T)_p$. On a également calculé les quantités molaires partielles d'éthanolamine dans ces mélanges. On a comparé les quantités molaires en excès et les quantités molaires partielles avec celles observées antérieurement dans des mélanges d'eau–éthylèneglycol (W–EG) (1) et d'eau–méthoxy-2-méthanol (W–ME) (2). On interprète les similitudes et les différences dans les propriétés de ces systèmes sur la base des caractéristiques moléculaires spécifiques des cosolvants et des concepts de fluctuations coopératives et de connectivité des liaisons hydrogènes dans l'eau liquide et dans les solutions aqueuses diluées.

[Traduit par la rédaction]

Introduction

As part of an ongoing program in studies of molecular interactions in aqueous–organic mixtures, we are pursuing detailed thermodynamic investigations on selected water–cosolvent systems (1, 2). The cosolvents studied were chosen from among those that, in some of their physicochemical or molecular properties, may be considered as "analogues" of liquid water. Such solvents would be characterized typically by low molecular weights (small sizes), multiple polar groups, and a propensity towards extensive three-dimensional hydrogen bonding; H_2O_2, hydrazine, and ethylene glycol would be choice examples of these cosolvents (3). The solvents investigated in our work were also selected with reference to their industrial applications and their overall interest as mixed aqueous–organic solvent systems.

The main theme of this work is the study of excess thermodynamic functions corresponding to first, second, and third derivatives (with respect to P or T) of the Gibbs free energy of the water–cosolvent mixtures. It has now been amply shown (4, 5) that, while the first derivative properties (V, H, S) can reveal some of the peculiarities of aqueous solutions, the singularities of water and dilute aqueous systems are best evidenced in second or higher derivative functions (e.g., κ, α, C_p, $\partial\kappa/\partial T$, . . ., etc.); the latter are directly related to the thermodynamic fluctuations in the system and are highly discriminant towards low-energy interactions and the extent of their cooperativity.

In previous reports (1, 2), we presented thermodynamic data for the water – ethylene glycol (W–EG) and water–methoxyethanol (W–ME) systems. The thermodynamic excess functions in both systems could be qualitatively interpreted in accordance with a scheme proposed earlier by Lumry et al. (5). In the latter, the water–cosolvent composition scale was subdivided into three regions in which the following effects were assigned as predominant: (*i*) $0 < x_2 \leq 0.1$: the cosolvent disrupts the cooperative fluctuation units of liquid water; (*ii*) $0.1 < x_2 \leq 0.3$: the cosolvent eliminates the extensive hydrogen-bonding connectivity between water molecules; (*iii*) $x_2 \geq 0.3$: progressive replacement of water–cosolvent interactions by cosolvent–cosolvent interactions.

In addition, comparing the data for the W–ME and W–EG systems, sharp differences were noted in the composition range $0 < x_2 \leq 0.1$, particularly with second derivative partial molar properties of the cosolvent. Differences in C_p, and C_V due to the greater hydrophobic character of ME relative

to EG were found to be parallel to those observed upon decreasing the temperature of water, but this observation did not extend to compressibilities (κ), and thermal expansion coefficients ($(\partial V/\partial T)_p$). This suggests that enthalpy and entropy fluctuations in aqueous solutions are affected similarly by hydrophobic hydration and by lowering the temperature, while fluctuations involving volume changes behave rather differently. In other words, in the water-rich region, there was little correlation between energy and volume fluctuations (as measured by $(\partial V/\partial T)_p$) in W–EG and W–ME mixtures.

In this report, we present detailed thermodynamic data for mixtures of water with ethanolamine (W–EA). This cosolvent was selected according to the criteria mentioned above, i.e., extensive H-bonding and high cohesive energy. It is further interesting since it should allow simple visualization of differences in the hydration of the R-NH_2 and R-OH groups by direct comparison of the properties of the W–EA and W–EG mixtures. Finally, the broad use of EA as a solvent, or as an organic base in many aqueous industrial formulations, should gain from improved knowledge of the thermodynamic properties of water–ethanolamine mixtures.

Experimental

Ethanolamine (H_2N-CH_2-CH_2-OH) was purchased from Fluka (stated purity >99.7 mol%) and was used without further purification. The residual water content was determined by Karl Fisher titration. All solutions were prepared by mass using deionized (Millipore ion exchange, MilliQ system) distilled water.

Solution densities (ρ) and isobaric volumic heat capacities (c_p^v) were measured independently using a flow densimeter and a flow microcalorimeter following methods described in details by Picker et al. (6, 7). The detection limits of the instruments used were respectively $\pm 2 \times 10^{-6}$ g cm^{-3} and $\pm 1 \times 10^{-5}$ J K^{-1} cm^{-3}. The temperature of the instruments was regulated to ± 0.001°C with a SODEV Programmable Circulating Thermostat (8).

The differential C_p measurements on W–EA solutions were carried out relative to water for dilute solutions ($x < 0.4$), and relative to pure ethanolamine for more concentrated solutions. Power losses were accounted for through proper calibration, and care was exercised to insure that mixing effects at the moving boundary between solvent and solution did not introduce significant artifacts. The isobaric specific heat capacities (c_p) were calculated from isobaric volumic heat capacities (c_p^v) and the measured densities as:

$$[1] \quad c_p = c_p^v/\rho$$

The densities and isobaric specific heat capacities are reported in Table 1.

The isentropic compressibility values (κ_S) were obtained from speed-of-sound measurements at atmospheric pressure using a Nusonic instrument (Mapco, model 6105) (9). The working cell (20 cm^3) was thermostated to ± 0.001°C and connected to a 250-cm^3 reservoir; the latter served as a closed transfer and mass-dilution vessel for incremental composition changes. The cell constants were determined through calibration with degassed deionized water in the temperature range 9–42°C using values from Del Grosso and Mader (10). The reproducibility of the speed-of-sound measurements was usually 0.02 m s^{-1}. The experimental results are given in Table 2.

The apparent molar volumes ($V_{2,\phi}$), apparent molar isobaric heat capacities ($C_{p,2,\phi}$), and apparent molar isentropic compressibilities $k_{S,2,\phi}$ were obtained according to the following relations (11):

$$[2] \quad V_{2,\phi} = M/\rho - [1000(\rho - \rho^*)/m\rho\rho^*]$$

$$[3] \quad C_{p,2,\phi} = Mc_p + [1000(c_p - c_p^*)/m]$$

$$[4] \quad k_{S,2,\phi} = \kappa_S V_{2,\phi} + [1000(\kappa_S - \kappa_S^*)/m\rho\rho^*]$$

where m is the molality of the solution, ρ and ρ^*, c_p and c_p^* and κ_S and κ_S^* represent the densities, the isobaric specific heat capacities, and the isentropic compressibilities for the solution and solvent respectively (1).

The molar excess thermodynamic functions (X_m^E) of the mixtures were calculated from

$$[5] \quad X_m^E = X_m - X_m^{id}$$

where X_m is the measured molar property for the solvent mixture, and X_m^{id} is the ideal value of this property; the latter is calculated as (except for the Gibbs energy and the entropy):

$$[6] \quad X_m^{id} = xX_m^*(\text{EA}) + (1 - x)X_m^*(H_2O)$$

where X_m^* denotes the molar properties of the pure components.

The partial molar quantities were calculated from the corresponding apparent molar quantities using the following relation:

$$[7] \quad X_2 = X_{2,\phi} + x(1 - x)\,[\partial X_{2,\phi}/\partial(1 - x)]_{T,p}$$

The values of the partial derivatives were obtained through spline function fitting procedures on the $X_{2,\phi}$ vs. X curve.

To facilitate interpretation and comparison with related systems, a number of other functions (excess or partial molar) were also calculated, namely isochoric heat capacities and isothermal compressibilities. The molar isochoric heat capacity ($C_{\tilde{V},m}^*$) of a pure liquid can be obtained from:

$$[8] \quad C_{\tilde{V},m}^* = C_{p,m}^* - T[\partial V_m^*/\partial T)_p]^2/10k_{T,m}^*$$

where $k_{T,m}^*$ is the molar isothermal compressibility of the liquid. The latter is obtained from the molar isentropic compressibilities ($k_{S,m}^*$) as:

$$[9] \quad k_{T,m}^* = k_{S,m}^* + T(\partial V_m^*/\partial T)_p^2/10C_{p,m}^*$$

Relations similar to eqs. [9] and [10] were applied to the properties of the solvent mixtures to calculate the molar excess functions ($C_{V,m}^E$) and ($k_{T,m}^E$). The corresponding partial molar properties were also computed using the expressions (12):

$$[10] \quad k_{T,2} = k_{S,2} - [TV_m\alpha/\kappa_T][2(\partial V_m/\partial T)_p - (V_m\alpha C_{p,2}/C_{p,m})]$$

$$[11] \quad C_{V,2} = C_{p,2} - (T\alpha/\kappa_T)[2(\partial V_2/\partial T)_p - (\alpha k_{T,2}/\kappa_T)]$$

where α is the thermal expansibility coefficient.

Finally, the internal pressure (p_i) and cohesive energy density ($\Delta U_m/V_m$) of the mixtures were also calculated as:

$$[12] \quad p_i = T\alpha/10\kappa_T$$

and

$$[13] \quad \Delta U_m/V_m = (\Delta_{vap}H_m - RT)/V_m$$

For a mixture, the enthalpy of vaporization ($\Delta_{vap}H_m$) is given by

$$[14] \quad \Delta_{vap}H_m = \Sigma_i\, x_i\Delta_{vap}H_{m,i} - \Delta H_m^E$$

Results and discussion

The experimental results for the water–ethanolamine (W–EA) mixtures are collected in Tables 1 and 2, which report the solution properties, ρ, c_p, and κ_S and the derived apparent molar quantities $V_{2,\phi}$, $C_{p,2,\phi}$, $k_{S,2,\phi}$ for ethanolamine. In the following sections, we will illustrate the total molar excess functions X_m^E of these mixtures and the partial molar quantities (X_2) of the ethanolamine cosolvent. In line with the theme of this and previous studies, we will emphasize differences in the composition dependence of the various (T, P) derivatives of the Gibbs excess energy. We will also attempt to underline differences in the trends observed in these derivatives when comparing the data for W–EA, W–

ME, and W–EG mixtures, in relation to the molecular features of the cosolvents.

Several thermodynamic quantities measured on neat EA, or EA infinitely diluted in water, are collected in Tables 3 and 4 and compared with available literature data (13–18). The agreement between the data reported here and previous results is satisfactory except for $C^0_{p,2}$ of EA in water. In this case, the discrepancy is greater than the combined experimental uncertainties and may originate in protonation effects; the relative importance of the latter increases at high dilution, and this will affect the infinite extrapolated dilution value (in the present work, the protonation of EA in water was repressed using 0.06 M NaOH, instead of water, for measurements in dilute solutions).

Bulk properties of the W–EA mixtures

The cohesive energy density ($\Delta U_m/V_m$) and the internal pressure ($p_i = -(\partial U_m/\partial V_m)_T$) of the W–EA mixtures (19) are plotted in Fig. 1 as function of the EA mole fraction (x_2); the dotted curves illustrate the corresponding properties in the W–EG system (1). From comparisons of the properties of numerous solvents, it was concluded earlier (19) that p_i reflects mostly molecular interactions other than hydrogen bonding (dispersion, dipolar, and multipolar interactions). Since the cohesive energy density reflects the summation of all types of interaction energies, the difference ($\Delta U_m/V_m - p_i$) should emphasize the hydrogen-bonding contribution to the internal energy of the liquid.

Comparing the data for the W–EA and W–EG mixtures, both the internal pressures and cohesive energy densities (per unit volume) are found strikingly similar in these two systems. From the relative p_i values, the non H-bonding energy contribution in pure EA would be slightly higher (10–20%) than in EG.[3] Hence, from the relative cohesive energy densities, and the reasoning outlined above, the H-bonding contribution should be lower in EA than in EG. On the other hand, comparing the W–EA results with corresponding data for the W–ME system (not shown, ref. 2) reveals marked differences, namely, lower p_i values (in cosolvent-rich compositions) and much lower cohesive energy densities over all mixture compositions. Consequently, from these macroscopic measures of molecular interactions in the W–EA and W–EG systems, one would expect their thermodynamic excess functions to be qualitatively and quantitatively similar, though both sharply contrasting with those of the W–ME mixtures.

Molar excess functions (X^E_m)

The Gibbs excess energy (ΔG^E_m) of the W–EA mixtures at 25°C is shown as a function of composition in Fig. 2. The first temperature derivatives (ΔS^E_m, ΔH^E_m) of ΔG^E_m are also reported in Fig. 2 and the pressure derivative (ΔV^E_m) is shown in Fig. 3. All of the X^E_m vs. x_2 curves are negative and very nearly symmetrical (i.e., minima in all curves at x_2 = 0.4–0.5), more so than in W–EG mixtures. All excess functions are more negative in W–EA mixtures than in W–EG or W–ME mixtures (the latter were, however, highly skewed towards the water-rich compositions (2)). Comparing the data for these three systems further shows that the enthalpy–entropy compensation is less important in the W–EA system than in the other two. Typically, at the minimum on the curves, ($\Delta G^E_m/T\Delta S^E_m$) ≃ 0.5 in W–EA, ≃0.15 in W–EG, and ≃0.4 in W–ME. Considering the preceding comments on the similarity of internal pressures and cohesive energies, the relative magnitudes of the excess functions in W–EA vs. W–EG mixtures are surprising. The large negative ΔG^E_m in W–EA mixtures must be due to exothermic interactions between W and EA molecules. Indeed, the standard hydration enthalpy of an aliphatic -NH_2 group is approximately 3 kJ mol^{-1} more exothermic than that of an -OH group (21). This interpretation is also supported by the observation of less negative ΔG^E_m values in aqueous mixtures of *N*-methyl-2-aminoethanol and *N*,*N*-dimethyl-2-aminoethanol (14).

The V^E_m values of the W–EA mixtures exhibit a composition dependence very similar to the G^E_m values. As noted earlier, the minimum V^E_m is approximately twofold more negative for EA than for EG, and the V^E_m vs. x_2 curve is very nearly symmetrical ($x_{2,min}$ = 0.48). These observations further point to strong W–EA interactions, which must be attributed to the NH_2 . . . water interactions. Overall, from the shapes of the H^E_m (or TS^E_m) and V^E_m curves, it is apparent that the consequences of molecular interactions on the enthalpy (or entropy) and on the packing density (free volume) are better correlated in the W–EA system than in the W–EG (1) or the W–ME (2) systems.

The molar excess isothermal compressibilities ($k^E_{T,m}$) of W–EA mixtures are plotted in Fig. 4 and again compared

with the corresponding values for W–EG mixtures (molar excess isentropic compressibilities $k^E_{S,m}$ lead to very similar curves). The shapes and relative magnitudes of the $k^E_{T,m}$ curves in Fig. 4 are closely related to the V^E_m curves (Fig. 3). Hence, the pressure dependence of the excess volume, $k^E_{T,m}$, which reflects the magnitude of density fluctuations, does not appear to be very sensitive towards specific hydration effects involving EA or EG molecules. It is also interesting to note that $k^E_{T,m}$ values in the W–ME mixtures (not shown) are twice as negative as in the W–EA mixtures; this is likely a consequence of the high molar compressibility of the ME cosolvent.

The molar excess isobaric ($C^E_{p,m}$) and isochoric ($C^E_{V,m}$) heat capacities of W–EA mixtures are illustrated in Fig. 5 with reference to data for the W–EG mixtures. As found earlier for the latter (1), the composition dependence of $C^E_{p,m}$ (EA) exhibits a maximum at $x_2 \approx 0.2$, the amplitude of which is three times lower than that for the W–EG system. For the W–EA system, however, both $C^E_{p,m}$ and $C^E_{V,m}$ vs. x_2 curves exhibit a "W" shape (22). Similar features were observed in several nonaqueous solvent mixtures and were interpreted as partly due to cooperative molecular arrangements induced in the mixtures. Such a composition dependence of $C^E_{p,m}$ contrasts rather sharply with that observed with hydrophobic cosolvents, where a marked positive contribution is found in the water-rich compositions.

Finally, the molar excess isobaric expansions $(\partial V^E_m/\partial T)_p$ for W–EA and W–EG systems are compared in Fig. 6. The variations as a function of x_2 are sharply different in these systems; although $(\partial V^E_m/\partial T)_p$ is positive over the whole mole fraction range for the W–EG system, there is a sign change at $X \approx 0.2$ in W–EA mixtures.

The molar excess functions (X^E_m) examined above provide a useful representation of the non-ideality of mixtures for the various properties considered. However, as noted earlier (1, 5), their interpretation is difficult due to variations in the properties of the neat liquids (with T or P). Partial molar quantities are better suited for comparisons among the properties of different aqueous mixtures, particularly near the ends of the composition scale.

Partial molar thermodynamic properties of EA in W–EA mixtures

The partial molar volume (V_2) of EA in W–EA mixtures is illustrated in Fig. 7 as a function of x_2 at 10, 25, and 40°C. As with EG, V_2(EA) exhibits a sharp decrease and a minimum at low x_2 value. These features are often found in aqueous organic mixtures (23–28), and are especially pronounced for hydrophobic cosolvents (26, 29, 30).

It is most unlikely, however, that the enhanced minima in the V_2 vs. x_2 curve found with the W–EA system, relative to the W–EG mixtures, are due to the greater hydrophobic character of EA. There is no indication of this in the excess properties examined above; moreover, the x_2 value at the minimum V_2 would be expected to be lowest for the more hydrophobic cosolvent (26, 29, 30), in contrast to the situation depicted in Fig. 7.

The second derivative partial molar properties ($k_{T,2}$, $C_{p,2}$, $C_{V,2}$, and $(\partial V_2/\partial T)_p$) are reported in Figs. 8–11 as functions of x_2. As noted before, these properties are directly related to thermodynamic fluctuations (more precisely to changes in the latter induced by incremental changes in composition). There is, however, no simple formalism that allows

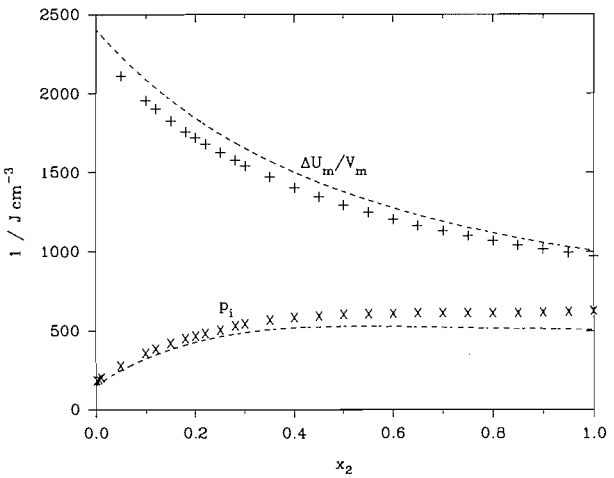

FIG. 1. Cohesive energy densities, $\Delta U_m/V_m$, and internal pressures, p_i, of W–EA (+, X) and W–EG (dotted lines) mixtures at 25°C.

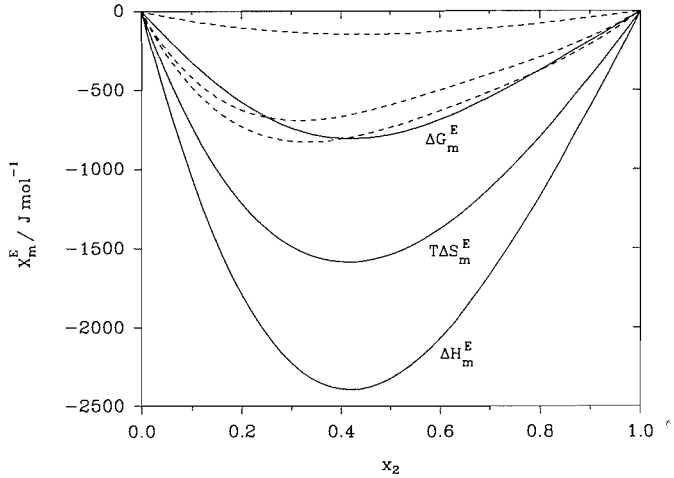

FIG. 2. Molar excess thermodynamic properties, G_m^E, H_m^E, and $T\Delta S_m^E$ for W–EA (full lines) and W–EG (dotted lines) mixtures at 25°C.

the separation of partial molar quantities into contributions originating from the solute or the solvent; hence, the distinction between effects due to water–water, water–cosolvent, and cosolvent–cosolvent interactions can only be inferred by varying the nature of the cosolvent and its concentration.

A cursory examination of the data in Figs. 8–11 reveals a remarkable similarity in the second derivative partial molar properties in these aqueous mixtures, particularly $k_{T,2}$ and $C_{V,2}$; the latter, respectively, reflect the fluctuations in density and internal energy. With the other partial molar quantities ($C_{V,2}$ and $(\partial V_2/\partial T)_p$) some differences are noted, but these can be seen to originate largely in the properties of the pure EA and EG (as suggested in the discussion of molar excess functions).

The variation in $C_{p,2}$ with x_2 at low x_2 values is less pronounced in the W–EA data than in the W–EG data. This tends to confirm that the hydrophobic character of the EA molecule is lower than that of the EG molecule. On the other hand, the higher value of the partial molar expansibility $(\partial V_2/\partial T)_p$ indicates better correlation between energy and volume fluctuations, except in the water-rich compositions ($x < 0.1$), i.e., low values of $(\partial V/\partial T)_p$ are typical of water and dilute aqueous solutions.

From this overview of partial molar quantities in W–EA and W–EG mixtures, two significant features are readily apparent. First, the second derivative properties are not dominated by the important differences in the first derivative properties of the W–EA and W–EG mixtures, i.e., marked differences in the heat of mixing of EA and EG with water, or in the heat of hydration of the -NH_2 and -OH groups, do not overwhelm the composition dependence of

the second derivative partial molar quantities. Indeed, the latter are more responsive towards the weak molecular interactions that are responsible for thermodynamic fluctuations.

Second, in view of the similarity of the second derivative functions in W–EA and W–EG mixtures, the separation of the composition range into three regions proposed earlier for W–EG mixtures (1) and other systems (5) would obviously be applicable to the W–EA mixture. In the $0 < x \leq 0.1$ region (corresponding to loss of cooperative fluctuations in liquid water), changes in quantities such as $k_{T,2}$ (Fig. 8) and $C_{p,2}$ (Fig. 9) with x_2 are less abrupt with EA than with EG. This would be consistent with the lower hydrophobic character of EA. In the $x > 0.3$ region, some of the second derivative properties of the W–EA system exhibit greater variations than those of the W–EG system; this could be understood from a larger variety of interactions possible between W and EA molecules, due to the presence of two different functional groups on the EA molecule, i.e., providing additional states that can contribute to thermodynamic fluctuations (increasing the width, or second moment, of the distribution functions representing these states). However, these effects are mostly apparent in the correlation between the energy and the volume fluctuations, such as in the volume expansion contribution to $C_{p,2}$, i.e., $(C_{p,2} - C_{V,2})$, or in $(\partial V_2/\partial T)_p$, which are of course related quantities (eq. [11]).

The third derivative partial molar quantities $(\partial k_{T,2}/\partial T)$ and $(\partial C_{p,2}/\partial T)$ were also calculated and are illustrated in Figs. 12 and 13; again, comparing EA and EG (the corresponding thermal expansion function $(\partial^2 V_2/\partial T^2)_p$ exhibits uncertainties too large for useful comparison). While the second derivatives are related to the magnitude of the H, S, or V fluctuations (second moment, or the width of the distribution function for the states involved), the third derivatives reflect the skewness (third moment) of these distribution functions. The quantitative similarity in the functions plotted in Figs. 12 and 13 for W–EA and W–EG mixtures is remarkable, given the important differences noted earlier in the first derivative molar excess functions H^E_m, TS^E_m, and V^E_m. The slightly larger values in the third derivative properties of EA compared to EG again appear consistent with a broader range of molecular interactions in W–EA, as com-

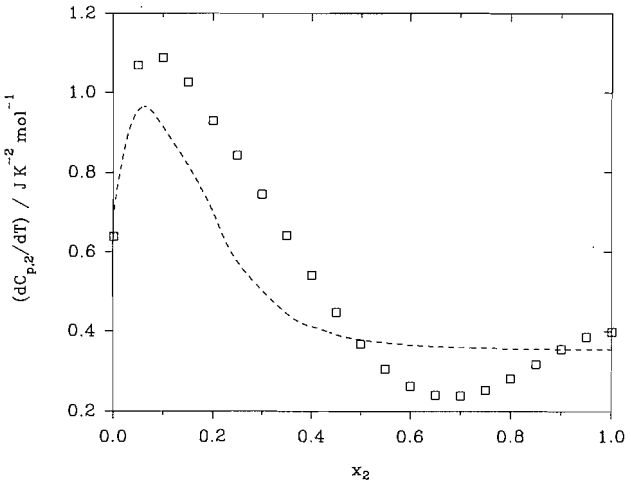

FIG. 13. Temperature coefficients of partial molar isobaric heat capacities, $\partial C_{p,2}/\partial T$, at 25°C of EA (□) in W–EA mixtures and of EG (dotted line) in W–EG mixtures.

pared to W–EG, due to the asymmetry of the EA molecules. From the data reported earlier on the W–ME system (2), it can be calculated that the third derivative quantities of a more hydrophobic cosolvent (methoxyethanol compared to ethylene glycol) are markedly different from those reported here for the hydrophilic, or weakly hydrophobic, EA and EG. From the observations presented here, the third derivative functions would seem to provide a clean distinction between hydrophobic and hydrophilic cosolvents, especially in water-rich systems.

Conclusion

The comprehensive thermodynamic investigation of the water–ethanolamine system, and a comparison of the results with similar data for water – ethylene glycol (1) and water–methoxyethanol (2), reveals important similarities and differences. While the various molar excess functions (X^E_m) in the three systems exhibit common qualitative features, major quantitative differences are found, even when comparing the two most hydrophilic solvents (EG and EA), which also have comparable molecular sizes and two hydrogen-bonding groups.

In comparisons involving the partial molar quantities of the cosolvent (X_2), it is further confirmed that the hydrophobic hydration effects in W–ME mixtures (2) are best distinguished from those in W–EA or W–EG mixtures through the second derivative properties (reflecting the width, or second moment, of the state distribution functions). On the other hand, comparisons between corresponding quantities in the W–EG and W–EA system show very similar second derivative properties; they further show a high degree of similarity between third derivative functions. This is quite remarkable considering the chemical differences in the EA and EG molecules, but lends additional support to the concept proposed earlier by Lumry et al. (5) as summarized in the introduction.

Investigation of the mechanism of alkyl radical elimination from ionised pentenyl methyl and hexenyl methyl ethers by analysis of the collision-induced dissociation mass spectra of $C_4H_7O^+$ and $C_5H_9O^+$ ions

ANDREW D. WRIGHT AND RICHARD D. BOWEN[1]

Received February 15, 1993

ANDREW D. WRIGHT and RICHARD D. BOWEN. Can. J. Chem. **71**, 1073 (1993).

Collision-induced dissociation (CID) mass spectra are reported for $C_4H_7O^+$ and $C_5H_9O^+$ ions generated by loss of an alkyl radical from 11 isomers of $C_5H_9OCH_3^{+\bullet}$ and 8 isomers of $C_6H_{11}OCH_3^{+\bullet}$ produced by ionisation of alkenyl methyl ethers derived from stable alkenols. The oxonium product ions have acyclic structures ($CH_2{=}CHCH{=}O^+CH_3$ for $C_4H_7O^+$; $CH_2{=}CH(CH_3)C{=}O^+CH_3$, $CH_3CH{=}CHCH{=}O^+CH_3$, or $CH_2{=}(CH_3)CCH{=}O^+CH_3$ in the case of $C_5H_9O^+$). Elimination of a methyl radical does not always occur by simple α-cleavage. Expulsion of an alkyl substituent attached to a carbon atom at either end of the C=C double bond also takes place readily; this process sometimes competes with or pre-empts α-cleavage, as is shown by ^{2}H-labelling experiments. Plausible mechanisms for this σ′-cleavage are considered. A route involving a 1,2-H shift to the radical centre of a distonic ion, followed by γ-cleavage of the resultant ionised enol ether, is shown to provide the most accurate unifying description of this unusual fragmentation. The mechanistic significance of this interpretation of the σ′-cleavage is discussed by analysing the reverse reaction (addition of an alkyl radical to a methyl cationated enal) in frontier molecular orbital terms. A comparison is made between the mechanisms by which an alkyl radical is lost from ionised alkenyl methyl ethers by σ′-cleavage and the parallel process starting from ionised carboxylic acids or isomeric distonic ions derived from these $C_nH_{2n+1}CO_2H^{+\bullet}$ species. Both classes of fragmentation are best understood to occur via γ-cleavage of a distonic ion of general structure $R^1CH_2CH{\cdot}C^+(X)OR^2$ (R^1 = alkyl; X = OH, R^2 = H; or X = H, R^2 = CH_3), thus yielding $(R^1)\cdot$ and $CH_2{=}CHC^+(X)OR^2$.

ANDREW D. WRIGHT et RICHARD D. BOWEN. Can. J. Chem. **71**, 1073 (1993).

Nous reportons ici les spectres CID (Collision-Induced Dissociation) des ions $C_4H_7O^+$ and $C_5H_9O^+$ générés par perte d'un radical alkyle à partir de 11 isomères de $C_5H_9OCH_3^{+\bullet}$ et 8 isomères de $C_6H_{11}OCH_3^{+\bullet}$. Ces isomères de départ sont produits lors de l'ionisation d'éthers stables de méthyle et de pentène, et de méthyle et d'hexène. Les ions fragments oxoniums produits ont des structures acycliques ($CH_2{=}CHCH{=}O^+CH_3$ pour $C_4H_7O^+$; $CH_2{=}CH(CH_3)C{=}O^+CH_3$, $CH_3CH{=}CHCH{=}O^+CH_3$ ou $CH_2{=}(CH_3)CCH{=}O^+CH_3$ dans le cas de $C_5H_9O^+$. D'aprés les spectres CID, il apparait que l'élimination du radical méthyle ne se produit pas toujours par simple rupture α. De même, l'expulsion du substituant alkyle attaché à un atome de carbone, à un bout ou à l'autre de la double liaison, est aussi observé. Ce processus entre parfois en compétition ou même devance la rupture du type α, comme le montre les expériences de marquage par ^{2}H. Nous avons considéré les mécanismes possibles de cette rupture σ′ et, en particulier, un chemin réactionnel impliquant un déplacement 1,2 d'hydrogène vers le centre radicalaire de l'ion distonique, suivi d'une rupture du type γ de l'éther d'énol ionisé qui en résulte, semble donner une description globale et précise de ce type inhabituel de fragmentation. La signification mécanistique de cette rupture σ′ est interprétée par l'analyse de la réaction inverse (d'addition d'un radical alkyle à un ‹‹cation ène aldéhydique de méthyle›› en termes de frontières d'orbitales moléculaires. Une comparaison est faite entre les mécanismes par lesquels un radical alkyle est perdu à partir d'éthers de méthyle et d'alcènes par rupture σ′ et le processus parallèle commençant par des acides carboxyliques ionisés ou des ions isomères distoniques dérivés des espèces $C_nH_{2n+1}CO_2H^{+\bullet}$. Les deux types de fragmentation sont bien connues pour donner lieu, par l'intermédiaire d'une rupture γ, à un ion distonique de structure générale $R'CH_2CH{\cdot}C^+(X)OR^2$ (R' = alkyl; X = OH, R^2 = H; ou X = H, R^2 = CH_3) et donc conduisent à la production de $(R')\cdot$ et $CH_2{=}CHC^+(X)OR^2$.

A. Introduction

The chemistry of many $C_nH_{2n}O^{+\bullet}$ species in the gas phase is well documented (for an overview, see ref. 1). Until very recently, however, relatively little attention (2–4) had been given to $C_nH_{2n}O^{+\bullet}$ ions generated from alkenyl methyl ethers. A survey (5) of the mass spectra of these $C_mH_{2m-1}OCH_3$ compounds revealed that alkyl radical loss often dominates the fragmentation of the corresponding radical cations, especially when $m \geq 4$. More detailed investigations of the reactions of $C_3H_5OCH_3^{+\bullet}$ and $C_4H_7OCH_3^{+\bullet}$ species formed from alkenyl methyl ethers showed that several routes operate for alkyl radical expulsion (6, 7). At least some of these processes involve rearrangement to distonic (8) ions (9) (DIs, which are structures that have the notional charge and radical sites localised on different "heavy" atoms, typically separated by one or more sp^3 carbon atoms).

The principal objective of the research reported in this paper is to delineate the mechanism(s) for alkyl radical elimination from $C_mH_{2m-1}OCH_3^{+\bullet}$ species (m = 5, 6). The chemistry of these radical cations is of interest in its own right. In addition, extrapolation of the trends observed for $C_5H_9OCH_3^{+\bullet}$ and $C_6H_{11}OCH_3^{+\bullet}$ should permit the reactions of homologous and analogous systems to be understood or even predicted, thus enhancing the analytical value of mass spectrometry.

A subsidiary aim is to study the nature of the isomerisation steps involving the radical centre of DIs. Several of the routes for alkyl radical loss from ionised alkenyl methyl ethers cannot be formulated in terms of direct fragmentation of the original structure (5–7, 10, 11). In particular, two key rearrangement processes are found that involve the radical site of a DI. The former is a formal 1,2$^+$-CH-OCH$_3$ shift to the radical centre of a β-DI (i.e., one in which the charge and radical sites are separated by a single sp^3 carbon atom). Thus, $CH_3{\cdot}CHCH_2{}^+CHOCH_3$ is isomerised to CH_3-$(CH_2{\cdot})CH^+CHOCH_3$ (i.e., $\cdot CH_2(CH_3)CH^+CHOCH_3$) by this

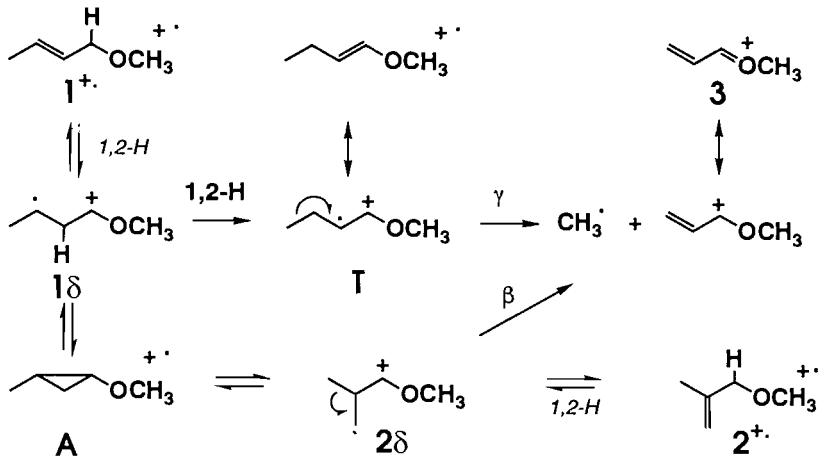

SCHEME 1

"carbene" rearrangement. This step can be conveniently visualised to occur via an ionised methoxycyclopropane (i.e., $CH_3{\cdot}CHCH_2{}^+CHOCH_3 \rightleftharpoons CH_3\overline{CHCH_2}CHOCH_3{}^{+\cdot} \rightleftharpoons CH_3(CH_2{\cdot})CH^+CHOCH_3$), but the cyclic species may merely represent the transition state for this isomerisation, rather than a genuine intermediate. The second type of rearrangement is a 1,2-H shift to the radical centre; this step converts a β-DI into an α-DI (e.g., $CH_3{\cdot}CHCH_2{}^+CHOCH_3 \rightarrow CH_3CH_2{\cdot}$-$CH^+CHOCH_3 \leftrightarrow CH_3CH_2CH{=}CHOCH_3{}^{+\cdot}$). These α-DIs, in which the charge and radical sites are localised on adjacent carbon atoms, are actually representations of ionised methyl enol ethers. Preliminary results on the fragmentation of $C_5H_9OCH_3{}^{+\cdot}$ and $C_6H_{11}OCH_3{}^{+\cdot}$ species reveal that α-DIs are probably the reacting configuration for alkyl radical expulsion from at least some of these radical cations (11). Consequently, the 1,2-H shift converting a β- into an α-DI promises to be of crucial significance in the reactions of $C_5H_9OCH_3{}^{+\cdot}$ and $C_6H_{11}OCH_3{}^{+\cdot}$ ions.

In the wider context, rearrangements in which ionised substituted cyclopropanes can be considered to play an important part have previously been postulated in other systems, including ionised alkenols (1, 12–14) and carboxylic acids (15–18). In the case of the latter class of compounds, a 1,2-H shift converting a β-DI into an α isomer was also observed (16–18). Indeed, compelling evidence was presented to show that alkyl radical loss always occurs from metastable $C_nH_{2n+1}CO_2H^{+\cdot}$ species via eventual isomerisation to an α-DI (here an ionised, 1,1-enediol), followed by C—C bond fission to give a protonated acrylic acid (18). A comparison between the "free-radical" chemistry of the $C_nH_{2n-1}OCH_3{}^{+\cdot}$ and $C_nH_{2n+1}CO_2H^{+\cdot}$ systems should, therefore, be informative.

B. Summary of the routes for alkyl radical loss from $C_3H_5OCH_3{}^{+\cdot}$ and $C_4H_7OCH_3{}^{+\cdot}$ species

The parent ionised ether, $CH_2{=}CHCH_2OCH_3{}^{+\cdot}$, loses a methyl group containing the carbon of the original methoxy group (6). This fragmentation, which is characterised by an extremely large and relatively specific kinetic energy (KE) release, is atypical of alkyl radical elimination from ionised alkenyl methyl ethers. The KE release ($T_{1/2}$) estimated from the width at half-height of the associated dish-topped metastable peak is 42 kJ mol^{-1} (6), indicating that this fragmentation takes place with a substantial reverse critical (19) energy. Only one of the higher homologues behaves in a remotely similar fashion: a minor component (~6%) of methyl loss from $CH_2{=}CH(CH_3)CHOCH_3{}^{+\cdot}$ occurs with a large KE release, as is shown by the dish-topped peak ($T_{1/2}$ = 50 kJ mol^{-1}) for $^{13}CH_3{\cdot}$ expulsion from $CH_2{=}CH(CH_3)CHO$-$^{13}CH_3{}^{+\cdot}$ (7). All other alkyl radical losses, including the bulk of methyl elimination ($CH_3{\cdot}$) from $CH_2{=}CH(CH_3)CHO$-$^{13}CH_3{}^{+\cdot}$, yield quite narrow Gaussian metastable peaks, with $T_{1/2}$ values typically in the range 1.5–2.5 kJ mol^{-1} (7).[2] Moreover, the O-alkyl group is not expelled. Thus, $CH_3CH{=}CHCH_2OCD_3{}^{+\cdot}$, $CH_2{=}(CH_3)CCH_2OCD_3{}^{+\cdot}$, $CH_3CH{=}CH$-$(CH_3)CHOCD_3{}^{+\cdot}$, and $CH_2{=}(CH_3)C(CH_3)CHOCD_3{}^{+\cdot}$ all lose only $CH_3{\cdot}$ in methyl radical elimination. Consequently, alkyl radical expulsion from ionised alkenyl methyl ethers derived from allylic alcohols containing four or more carbon atoms typically involves only the atoms of the alkenyl group. Moreover, the $T_{1/2}$ values suggest that this fragmentation usually does not ential a large reverse critical energy.

Many ionised ethers formed from secondary or tertiary allylic alcohols readily lose an α-alkyl group. The obvious explanation for this fragmentation is α-cleavage, eq. [1], but there is clear evidence (7, 10, 11) that this process is not always the simple σ-cleavage that it appears to be at first glance, especially when a methyl group is expelled. Fur-

[1] 
R^1, R^2, R^3, R^4, = H, alkyl

thermore, alkyl groups attached to either of the carbon atoms joined by the double bond are also eliminated with great facility (5, 7, 10, 11). This σ′-cleavage, which sometimes competes with the apparently more favourable α-cleavage alternative (10), can be explained in terms of rearrangements involving DIs and ionised methoxycyclopropanes (5, 7, 10, 11).

C. Mechanisms for σ′-cleavage

The two most plausible mechanisms for the σ′-cleavage are illustrated in Scheme 1 for the archetypical $C_4H_7OCH_3{}^{+\cdot}$

[2]R.D. Bowen, A.W. Colburn and P.J. Derrick. Unpublished results.

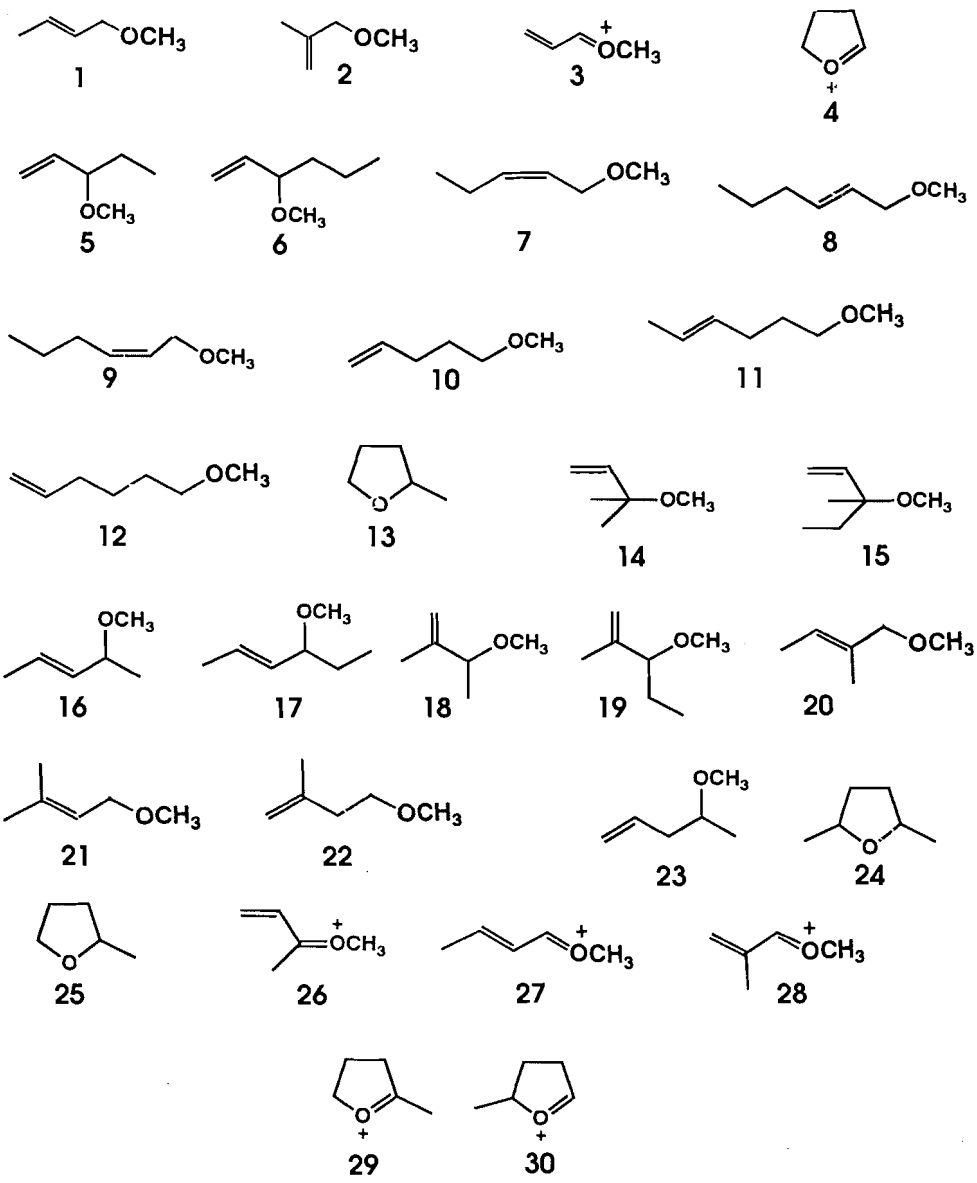
species, $CH_3CH{=}CHCH_2OCH_3^{+\cdot}$, $\mathbf{1}^{+\cdot}$, and $CH_2{=}(CH_3)CCH_2OCH_3^{+\cdot}$, $\mathbf{2}^{+\cdot}$. Interconversion of $\mathbf{1}^{+\cdot}$ and $\mathbf{2}^{+\cdot}$ is possible via isomerisation to the corresponding DIs, **1**δ and **2**δ, respectively; **1**δ and **2**δ then interconvert by ring closure to **A**. Loss of the methyl group originally attached to the double bond is possible by direct β-cleavage of **2**δ. Alternatively, a 1,2-H shift to the radical site of **1**δ affords the ionised enol ether, **T**, which then expels a methyl group by undergoing γ-cleavage. The crucial step in the second route is probably **1**δ → **T**; such 1,2-H shifts involving radical centres normally occur less rapidly than the analogous processes at cationic sites (20–22). Consequently, it is likely that **1**δ → **T** is the slow and rate-limiting step in this mechanism for $CH_3\cdot$ expulsion from $\mathbf{1}^{+\cdot}$ and $\mathbf{2}^{+\cdot}$. This view is consistent with earlier work on the related radical cations formed from ionised carboxylic acids. A 1,2-H shift to the radical centre of a β-DI certainly takes place in many of these systems (e.g., $CH_3CH\cdot(CH_3)CHC^+(OH)_2 \rightarrow CH_3CH_2(CH_3)C\cdot C^+(OH)_2$) (16–18). Moreover, these 1,2-H shifts were generally found to occur more slowly than the corresponding 1,2-$^+C(OH)_2$ shifts (this step is analogous to that (**1**δ ⇌ **A** ⇌ **2**δ) by which $\mathbf{1}^{+\cdot}$ and $\mathbf{2}^{+\cdot}$ are proposed to interconvert) (18).

A variation of the mechanism involving eventual γ-cleavage can be put forward in which the ionised enol ether is formed directly from the ionised alkenyl methyl ether via a 1,3-H shift (e.g., $\mathbf{1}^{+\cdot} \rightarrow$ **T**, Scheme 1). This change does not affect the predictions made for the structure of the product ion generated by eventual γ-cleavage of $C_5H_9OCH_3^{+\cdot}$ and $C_6H_{11}OCH_3^{+\cdot}$ species. However, three factors militate against the occurrence of the 1,3-H shift. Firstly, such processes involve significant and sometimes very substantial additional energy barriers, even in open-shell systems. These barriers may arise from the unfavourable orbital symmetry entailed in suprafacial concerted 1,3-H shifts (23, 24). Secondly, 1,3-H shifts of this type involve additional energetic and (or) geometric constraints that do not apply to consec-



Structures of precursors and product ions relevant to the tables

utive 1,2-H shifts. This conclusion applies regardless of whether the shifts are considered to terminate at a cationic or a radical centre. In the former case (a 1,3-H shift to the cationic site in $CH_3CH^+CH{\cdot}CH_2OCH_3$, if $\mathbf{1}^{+\cdot}$ is depicted in this way), studies on $CH_3CH_2CH_2CH^+—OCH_3$ reveal that the corresponding process forming $CH_3CH^+CH_2CH_2OCH_3$ cannot take place at, or close to, the thermochemical threshold (25). In the latter case (a 1,3-H shift to the radical centre in $CH_3CH{\cdot}CH^+CH_2OCH_3$, if $\mathbf{1}^{+\cdot}$ is represented in this fashion), earlier work reveals no precedent whatever for a 1,3-H shift to a radical site (18), though 1,4- and 1,5-H shifts are known to be facile and 1,2-H shifts certainly occur in some circumstances. Thirdly, it will be shown in the subsequent discussion (Sect. E.2(*a*)) that the mechanism involving 1,2-H shifts can be logically extended to explain alkyl radical loss via eventual δ-cleavage of several $C_5H_9OCH_3^{+\cdot}$ and $C_6H_{11}OCH_3^{+\cdot}$ species. No such extension of the mechanism involving the 1,3-H shift is possible. Therefore, the formulation involving consecutive 1,2-H shifts offers a more general and unifying description of γ- and δ-cleavage.

In the schemes in this paper, 1,2 shifts to radical centres are shown in bold type, to distinguish them from the corresponding shifts to cationic sites, which are shown in italic type. Many of the steps (but probably not the 1,2-H shifts to a radical site) depicted in the schemes are likely to be at least partially reversible, especially at low internal energies; these steps are represented by equilibrium arrows.

In the parent $C_4H_7OCH_3^{+\cdot}$ system, the alternative descriptions of the σ′-cleavage cannot be distinguished by investigating the structure of the $C_4H_7O^+$ product ion because both routes result in formation of the same product ion, $CH_2=CHCH=O^+CH_3$, **3**. However, for the higher homologues $C_5H_9OCH_3^{+\cdot}$ and $C_6H_{11}OCH_3^{+\cdot}$, the processes corresponding to β-cleavage of **2**δ and γ-cleavage of **T** sometimes lead to isomeric products that can be differentiated by analysis of their collision-induced dissociation (CID) spectra (11). This paper presents an analysis of the CID mass spectra of $C_4H_7O^+$ and $C_5H_9O^+$ ions generated by electron ionisation and subsequent alkyl radical elimination from numerous isomers of $C_5H_9OCH_3$ and $C_6H_{11}OCH_3$ derived from stable alkenols.

D. Structure of the $C_4H_7O^+$ product ions

Table 1 gives the CID spectra of $C_4H_7O^+$ ions formed from eight isomers of $C_5H_9OCH_3^{+\cdot}$ and $C_6H_{11}OCH_3^{+\cdot}$. All the ions have closely similar spectra. Consequently, it is logical to conclude that the same product ion, **3**, is produced by alkyl radical expulsion from these ionised ethers. In contrast, the CID spectrum of the cyclic oxonium ion, $\overline{CH_2CH_2CH_2CH=O}^+$, **4**, ($[M - H]^+$ generated by ionisation and methyl radical loss from $\overline{CH_2CH_2CH_2CH(CH_3)O}$, **13**) is clearly distinct from that of **3**. There are three major differences between the spectra of **3** and **4**. First, the spectrum of **3** shows appreciable peaks at *m/z* 56 and 55 (corresponding to loss of $CH_3{\cdot}$ and CH_4, respectively). Secondly, the base peak in the spectrum of **4** is at *m/z* 43; the analogous peak in the spectrum of **3** is merely of minor importance (RI = 6–8%). Finally, the signals at *m/z* 41 (corresponding to $CH_2=O$ elimination), 39, 29, 27, and 15 are substantially enhanced in the spectrum of **3**.

The formation of **3**, instead of **4** (which is actually thermodynamically more stable than **3** by approximately 50 kJ mol^{-1} (26)) is intelligible on the basis of the following mechanisms.

D.1. Ethers of allylic alcohols

*(a) Loss of an α-substituent (**5**$^{+\cdot}$ and **6**$^{+\cdot}$)*

A simple cleavage (eq. [2]) rationalises this fragmentation for relatively fast dissociations. However, other processes

[2] 
involving hydrogen exchange may compete with direct cleavage when ions of longer lifetimes and lower average internal energies dissociate. This caveat applies particularly when a methyl radical is expelled. Thus, the lower homologue $CH_2=CH(CD_3)CHOCH_3^{+\cdot}$ loses not only $CD_3{\cdot}$ (direct α-cleavage) but also $CHD_2{\cdot}$, $CH_2D{\cdot}$, and even a little $CH_3{\cdot}$ (7).

There is an interesting correlation in this respect with alkyl radical loss from α-DIs formed from ionised carboxylic acids, in which the leaving group ability (LGA) of a methyl group (0.022) was found to be grossly inferior to that (1.000) defined for an ethyl group (18). The comparatively poor LGA associated with the methyl group apparently persists in the α-cleavage of ionised alkenyl methyl ethers via eq. [2], thus permitting hydrogen exchange to compete with methyl radical elimination.

*(b) Loss of a γ-substituent (**7**$^{+\cdot}$, **8**$^{+\cdot}$, and **9**$^{+\cdot}$)*

Isomerisation via the appropriate DIs (and, possibly, ionised alkylmethoxycyclopropane) explains this reaction, as illustrated in Scheme 2 for $\mathbf{7}^{+\cdot}$. Details of the final step (γ-cleavage (7δ → **U** → products) or β-cleavage via **B**) cannot be elucidated since both possibilities lead to the same products.

*D.2. Ethers of non-allylic alcohols (**10**$^{+\cdot}$, **11**$^{+\cdot}$ and **12**$^{+\cdot}$)*

A combination of 1,4-, 1.5-, and 1,6-H shifts, followed by eventual γ-cleavage of an ionised enol ether, provides a logical explanation for the formation of **3** from these ionised ethers. Thus, a 1,4-H shift coupled with a 1,4-H shift leads from $\mathbf{11}^{+\cdot}$ to **V** which then expels $C_3H_7{\cdot}$, Scheme 3. Similarly, a 1,6-H shift and subsequent 1,4-H shift in $\mathbf{12}^{+\cdot}$ gives **V**. Other combinations of H shifts are also possible. It is significant that none of these ionised ethers fragments to give **4**; in contrast, ionised homoallyl methyl ether does yield **4** by loss of $CH_3{\cdot}$ (7). Unfortunately, the abundance of $C_4H_7O^+$ ions in the conventional mass spectra of $C_5H_9OCH_3^{+\cdot}$ and $C_6H_{11}OCH_3^{+\cdot}$ species derived from homoallylic alcohols is insufficient to allow reliable CID spectra to be recorded.

E. Structure of the $C_5H_9O^+$ product ions

Table 2 contains the CID spectra of $C_5H_9O^+$ ions generated from 16 isomers of $C_5H_9OCH_3^{+\cdot}$ and $C_6H_{11}OCH_3^{+\cdot}$. Four types of spectra are found. The first three classes comprise spectra that are attributable to a single product ion ($CH_2=CH(CH_3)C=O^+CH_3$, **26**, $CH_3CH=CHCH=O^+CH_3$, **27**, and $CH_2=(CH_3)CCH=O^+CH_3$, **28**, respectively). The fourth category consists of spectra that are a combination of the spectrum of **26** with that of **27** or **28**. As was the case with the homologous $C_4H_7O^+$ ions, there is no evidence for formation of cyclic oxonium ions ($\overline{CH_2CH_2CH_2(CH_3)C=O}^+$, **29**, or $CH_3\overline{CHCH_2CH_2CH=O}^+$,

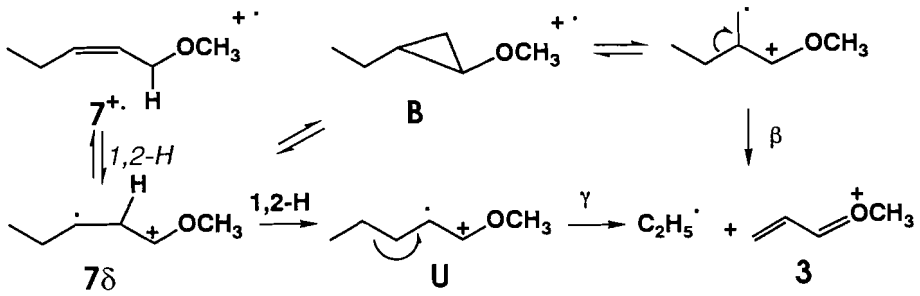
[a]Intensities were normalised to a value of 100 units for the most intense fragment ion peak.
[b]Essentially identical to the spectrum of $[M - CH_3]^+$ generated from **25**.



SCHEME 2

30). The CID spectra of the cyclic oxonium ions differ markedly from those of their acyclic conjugated isomers. Thus, the spectrum of **29** shows distinctive signals at *m/z* 67 and 57 (corresponding to CO elimination, as is also observed for the lower homologue, **4**); in addition, the peaks at *m/z* 29 and 27 are noticeably enhanced. Similarly, the spectrum of **30** is dominated in a unique way by the intense peak at *m/z* 43.

The following mechanisms explain the formation of **26**, **27**, and **28** from the ionised alkenyl methyl ethers.

E.1. Loss of an entire alkyl substituent

(a) Ethers of allylic alcohols

*(i) α-Cleavage (**14**$^{+\cdot}$, **15**$^{+\cdot}$, **17**$^{+\cdot}$, and **19**$^{+\cdot}$).* This mechanism provides an adequate interpretation for the dissociation of ethers derived from tertiary alcohols, or for elimination of an α-ethyl group from ionised ethers derived from secondary allylic alcohols. This route for loss of $CH_3\cdot$ and $C_2H_5\cdot$ from **14**$^{+\cdot}$ and **15**$^{+\cdot}$, respectively, leads to **26**, eq. [3]. Similarly, expulsion of $C_2H_5\cdot$ from **17**$^{+\cdot}$ and **19**$^{+\cdot}$ affords **27** and **28**, respectively, eqs. [4] and [5].

*(ii) α- and σ′-Cleavage (**16**$^{+\cdot}$ and **18**$^{+\cdot}$).* In contrast, elimination of a methyl group from the ionised secondary ethers, **16**$^{+\cdot}$ and **18**$^{+\cdot}$, in which there is both an α- and either a γ- or β-methyl substituent, is not so simple. Both **16**-*1,1,1-D_3*$^{+\cdot}$ and **18**-*1,1,1-D_3*$^{+\cdot}$ expel $CH_3\cdot$ as well as the expected $CD_3\cdot$, even in fast dissociations occurring in the ion source (5). Moreover, $CH_3\cdot$ loss from these species increases in importance as the internal energy of the fragmenting ions decreases. Indeed, $CD_3\cdot$ loss is practically pre-empted by $CH_3\cdot$ elimination for these metastable $C_6H_9D_3O^{+\cdot}$ ions, which expel 93–95% $CH_3\cdot$ and only 5–7% $CD_3\cdot$, with no contribution from $CH_2D\cdot$ or $CHD_2\cdot$ loss. Both $CH_3\cdot$ and $CD_3\cdot$ expulsion give rise to relatively narrow Gaussian metastable peaks ($T_{1/2}$ = 1.7 kJ mol^{-1}, in each case) (footnote 2). These comparatively small KE releases are consistent with dissociation of the reacting configuration by C—C cleavage without a sizeable reverse critical energy. The analogous $C_5H_9OCD_3^{+\cdot}$ radical cations eliminate only $CH_3\cdot$ over a range of internal energies, so precluding any explanation of the unexpected $CH_3\cdot$ loss from **16**-*1,1,1-D_3*$^{+\cdot}$ and **18**-*1,1,1-D_3*$^{+\cdot}$ based on fission of the *O*-methyl bond (5).

The CID spectra of the $[M - CD_3]^+$ ions formed from **16**-

qualitative agreement with those reported in ref. 2.

age. The σ′-cleavage is evidently very facile, since it competes effectively with an apparently favourable α-cleavage that leads to a conjugated secondary oxonium ion (**27** or **28**). The main factor promoting σ′-cleavage is that it affords a tertiary conjugated oxonium ion (**26**-*1,1,1-D*$_3$), which should be even more stable than **27** or **28**. Accurate thermochemical data for **26**, **27**, and **28** are not yet available. Fortunately, however, reliable enthalpies of formation are accessible for the analogous oxonium ions $CH_2{=}CH(CH_3)C{=}OH^+$, $CH_3{-}CH{=}CHCH{=}OH^+$, and $CH_2{=}(CH_3)CCH{=}OH^+$ from the proton affinities of the corresponding C_4H_6O carbonyl compounds. These ΔH_f values (567, 603, and 607 kJ mol^{-1}, respectively (27)) reveal that the tertiary oxonium ion analogous to **26** is 35–40 kJ mol^{-1} more stable than the secondary oxonium ions corresponding to **27** and **28**. A parallel trend should operate in the energetics of **26**, **27**, and **28**; therefore, it is likely that **26** will be approximately 35–40 kJ mol^{-1} lower in energy than **27** or **28**. This difference in the stability of the product ions formed by the α- and σ′-cleavage processes is amply sufficient to allow the latter fragmentation to compete, even though it must entail more rearrangement than simple α-cleavage.

The ionised alkenols $CH_3CH{=}CH(CD_3)CHOH^{+\cdot}$ and $CH_2{=}(CH_3)C(CD_3)CHOH^{+\cdot}$ corresponding to **16**-*1,1,1-D*$_3^{+\cdot}$ and **18**-*1,1,1-D*$_3^{+\cdot}$ also show a tendency to undergo $CH_3{\cdot}$ loss via σ′-cleavage (1, 10). However, the situation is complicated for the ionised alkenols by the additional possibility that ketonisation may precede methyl radical expulsion.

Again, it is impossible to distinguish between β-cleavage (via rearrangement of **16**-*1,1,1-D*$_3^{+\cdot}$ and **18**-*1,1,1-D*$_3^{+\cdot}$ to **18**δ-*1,1,1-D*$_3^{+\cdot}$) and γ-cleavage (via a 1,2-H-shift in **16**δ-*1,1,1-D*$_3^{+\cdot}$, followed by fragmentation of **W**-*1,1,1-D*$_3^{+\cdot}$), Scheme 4. Both these routes yield **26**-*1,1,1-D*$_3^{+\cdot}$ as the product ion.

The CID spectra of the $[M - CH_3]^+$ ions formed from the unlabelled ethers **16** and **18** correspond to a combination of

28

portion of those of **27** and **28**, respectively. These data are further evidence that rapid elimination of $CH_3\cdot$ from **16**$^{+\bullet}$ and **18**$^{+\bullet}$ occurs by α- and σ′-cleavages in comparable amounts. However, the fact that the CID spectra of $[M - CH_3]^+$ formed from **16**$^{+\bullet}$ and **18**$^{+\bullet}$ are significantly different indicates that the steps by which **16**$^{+\bullet}$ and **18**$^{+\bullet}$ interconvert do not take place rapidly and reversibly before $CH_3\cdot$ loss at high internal energies.

It is intriguing to note that σ′-cleavage becomes important only when the substituent that must be expelled by α-cleavage is a methyl group (i.e., for **16**$^{+\bullet}$ and **18**$^{+\bullet}$). Methyl loss via σ′-cleavage competes only very poorly with elimination of the α-ethyl substituent in the higher homologues **17**$^{+\bullet}$ and **19**$^{+\bullet}$ (5). This contrast probably reflects the much greater LGA (18) of $C_2H_5\cdot$ compared to $CH_3\cdot$ (see also section D.1(*a*)).

A final point concerns the abundance of the signals at *m/z* 69 (CH_4 expulsion) in the CID spectra of **26**, **27**, and **28**. The tertiary ion, **26**, shows only a weak peak, but **27** and **28** show intense and moderate signals, respectively. This trend suggests that CH_4 loss is preferentially associated with the $CH{=}O^+CH_3$ entity, which is present in **27** and **28**, but not in **26**.

*(iii) σ′-Cleavage (**20**$^{+\bullet}$ and **21**$^{+\bullet}$).* The CID spectra show that $CH_3\cdot$ elimination from **20**$^{+\bullet}$ and **21**$^{+\bullet}$ yields **28** and **27**, respectively. This behaviour is consistent with the mechanism involving a 1,2-H shift to the radical centre of the appropriate DI, followed by γ-cleavage (**20**$^{+\bullet}$ → **20**δ → **X** → $CH_3\cdot$ + **28**; **21**$^{+\bullet}$ → **21**δ → **Y** → $CH_3\cdot$ + **27**, respectively, Scheme 5). On the other hand, the observed specificity of methyl loss from **20**$^{+\bullet}$ and **21**$^{+\bullet}$ is the reverse of that which would be anticipated on the basis of β-cleavage of the relevant DI (**20**$^{+\bullet}$ → **20**δ → $CH_3\cdot$ + **27**; **21**$^{+\bullet}$ → **21**δ → **D** → **21**δ′

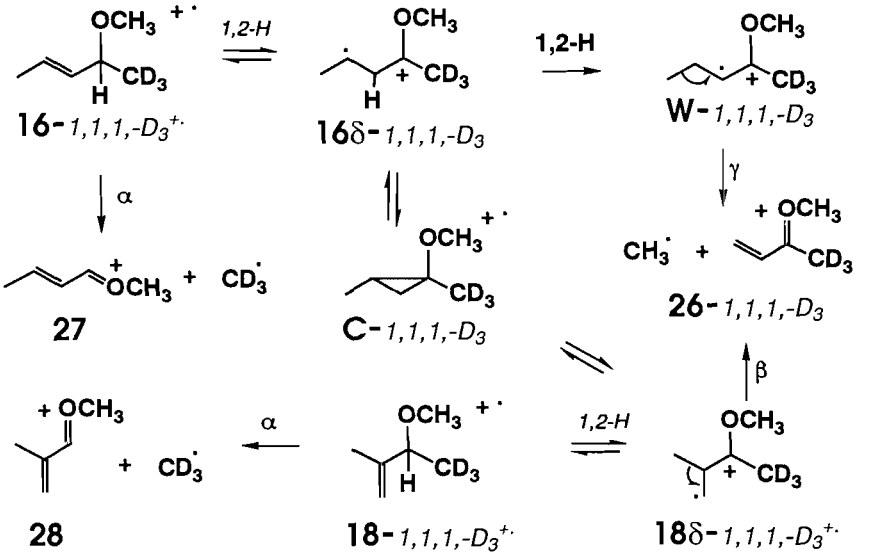
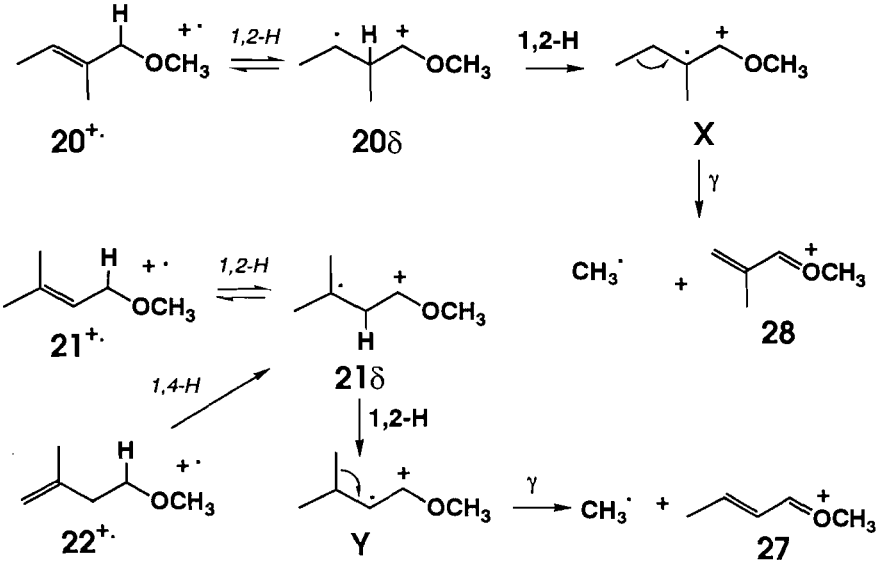


SCHEME 4



SCHEME 5

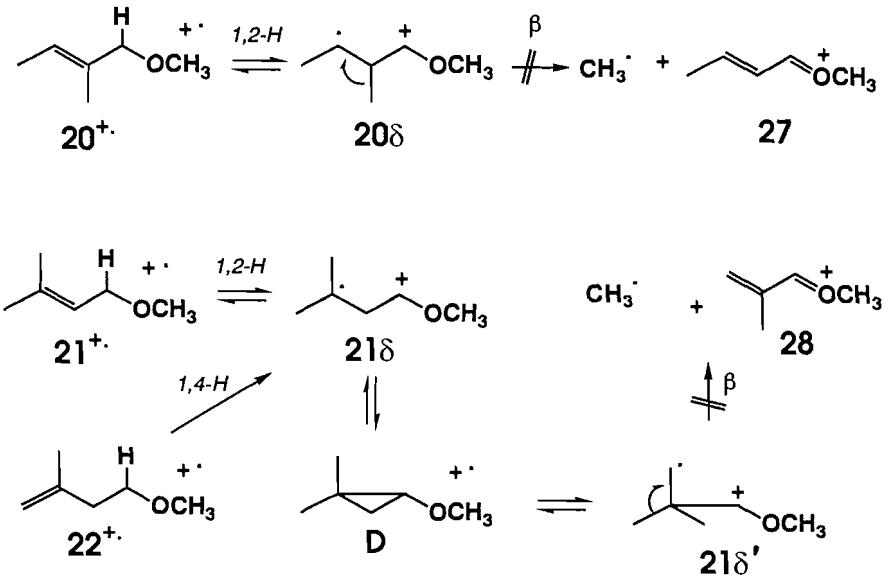
→ CH_3· + **28**, respectively, Scheme 6). Therefore, in these cases at least, the mechanism involving β-cleavage cannot account for σ′-cleavage.

This observation indicates that the reverse reaction, addition of CH_3· to the C=C double bond of a methyl-cationated enal, occurs more readily via a conjugate mechanism, e.g., eq. [6], than by simple attachment to the β-carbon, e.g., eq. [7]. Precisely parallel behaviour has been reported (16–18) in the fragmentation of β-DIs derived from ionised carboxylic acids. The reverse reaction (in this case, addition of CH_3· to protonated crotonic or methacrylic acid ($CH_3CH{=}CHC^+(OH)_2$ or $CH_2{=}(CH_3)CHC^+(OH)_2$, respectively)) occurs by attachment to the γ-carbon. In both systems, the preference shown in the reverse reaction for binding to the γ-carbon, via conjugate addition of CH_3· to a protonated acrylic acid or a methyl-cationated enal, can be understood qualitatively in terms of the nucleophilic (28, 29) properties of radicals.

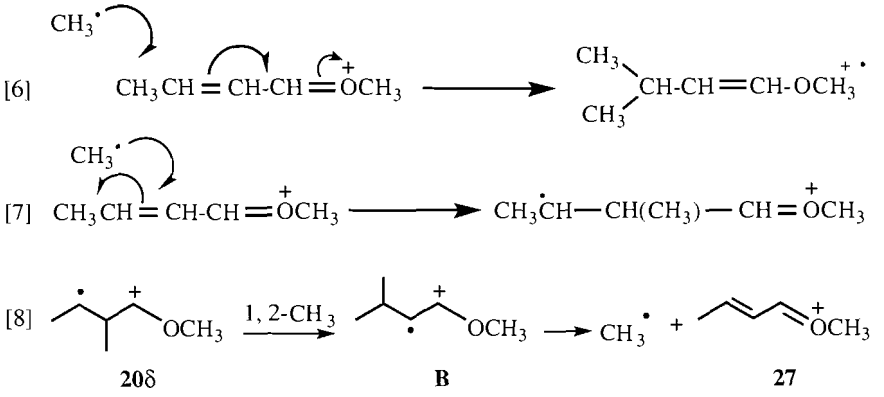
Further light is shed on this site selectivity by considering the interactions that take place between the singly occupied molecular orbital (SOMO) of the radical and lowest unoccupied molecular orbital (LUMO) of the methyl-cationated enal. According to frontier orbital theory (FOT) (30), such SOMO–LUMO interactions are especially important in reactions involving radicals that have a high-energy SOMO; CH_3· falls into this category (31). The LUMO of the cationated enal should approximately resemble that of allyl cation; in other words, the electron density should be greater on the terminal carbon atoms (the γ and α positions) than on the central carbon atom (the β position). Therefore, the initial interaction that leads to binding of CH_3· to the γ-carbon atom of the cationated enal is more favourable than that leading to binding to the β-carbon atom.

The energy barrier towards a 1,2-H shift to the radical site of the DIs such as **20**δ must be less than that for β-cleavage. If this were not so, **20**δ would fragment via β-cleavage

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.



SCHEME 6



(**20**δ → CH_3· + **27**) instead of undergoing a 1,2-H shift and subsequent γ-cleavage (**20**δ → **X** → CH_3· + **28**). As mentioned previously, 1,2-H shifts to radical centres are less facile than those to cationic sites because they have additional critical energies (16–18, 20–22). Consequently, the energy barrier towards β-cleavage (and, by microscopic reversibility, that for addition of CH_3· to the β-carbon of a methyl-cationated enal) must be quite large.

A second significant conclusion concerns the relative ease of 1,2-H and 1,2-CH_3 shifts to radical centres. A 1,2-CH_3 shift, followed by γ-cleavage, would lead to the same product ion (**27**) as that formed by direct β-cleavage, e.g., eq. [8]. This is contrary to the observed specificity shown in the fragmentation of **20**$^{+\cdot}$. Indeed, there is no evidence that any of the ionised ethers studied in this work dissociate via steps involving 1,2-alkyl shifts to the radical centre of a DI. Therefore, 1,2-H shifts occur more readily than 1,2-alkyl shifts to radical sites, at least in these systems. Similar conclusions were reached in the earlier investigation of the reactions of DIs derived from ionised carboxylic acids. Whereas 1,2-H shifts to radical centres were definitely observed, no example of a comparable 1,2-alkyl shift was uncovered (16–18).

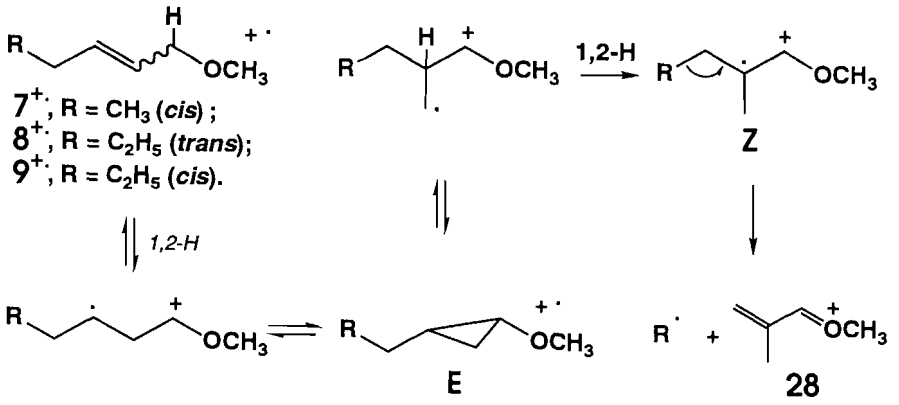
*(b) Ethers of non-allylic alcohols (**22**$^{+\cdot}$ and **23**$^{+\cdot}$)*

In the case of **22**$^{+\cdot}$, the structure of the $C_4H_7O^+$ product ion appears to be **27**. The mechanism of Scheme 5 explains this result (a 1,4-H shift converts **22**$^{+\cdot}$ into **21**δ, which then rearranges to **Y** prior to methyl radical elimination). In contrast, the mechanism involving β-cleavage (**22**$^{+\cdot}$ → **21**δ → **D** → **21**δ' → CH_3· + **28**, Scheme 6) predicts formation of the wrong product ion. Therefore, the behaviour of **22**$^{+\cdot}$ offers further evidence that the σ'-cleavage is more accurately described in terms of 1,2-H shifts and γ-cleavage than by β-fission.

The fragmentation of **22**$^{+\cdot}$ differs conspicuously from that of the lower homologue, $CH_2{=}CHCH_2CH_2OCH_3^{+\cdot}$, which expels CH_3· with production of a cyclic oxonium ion, $\overline{CH_2CH_2CH_2CH{=}O}^+$ (7). A similar route does not operate for CH_3· loss from **22**$^{+\cdot}$, since the CID spectra of the resultant ion is obviously distinct from those of $CH_3\overline{CHCH_2CH_2CH{=}O}^+$ and $\overline{CH_2CH_2CH_2(CH_3)C{=}O}^+$.

The $[M - CH_3]^+$ signal in the conventional mass spectrum of **23** is only weak (5). The CID spectrum of this ion resembles that of **28**. However, the resemblance is not conclusively close. In addition, the CID spectrum of $[M - CH_3]^+$ formed from **23** shows many features that are found in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.



SCHEME 7

spectrum of the $C_4H_7O^+$ ion generated by methyl expulsion from $\mathbf{16}^{+\cdot}$. The latter spectrum corresponds to a combination of those of **26** and **27**, as is discussed above (Sect. E.1(*a*)(*ii*)). In view of these uncertainties, no definite mechanistic conclusions are possible. Formation of a mixture of **26** and **27**, after isomerisation of $\mathbf{23}^{+\cdot}$ to $\mathbf{16}^{+\cdot}$ via a series of hydrogen shifts, is perhaps the most likely possibility.

E.2. Loss of an alkyl group smaller than an intact β- or γ-substituent

(a) Ethers of allylic alcohols ($7^{+\cdot}$, $8^{+\cdot}$, and $9^{+\cdot}$)

This peculiar reaction corresponds to formal δ-cleavage; it is important for ionised ethers of primary allylic alcohols in which there is an ethyl or larger alkyl substituent on the γ-carbon atom. Thus, loss of R· occurs from $RCH_2CH{=}CHCH_2OCH_3^{+\cdot}$. It is favoured at lower internal energies (12 eV, as opposed to 70 eV ionising electron energies (5)), and it competes effectively with loss of the entire γ-substituent in the dissociation of metastable ions. For example, metastable $\mathbf{7}^{+\cdot}$ expels C_2H_5· (σ′-cleavage) and CH_3· (δ-cleavage) in comparable quantities (29 and 47%, respectively). Metastable $\mathbf{5}^{+\cdot}$ behaves similarly (footnote 2), as would be expected given the ease of interconversion of these species via DIs and ionised ethylmethoxycyclopropane, $C_2H_5\overline{CHCH_2}\overline{CHOCH_3}^{+\cdot}$. However, at higher internal energies, CH_3· expulsion from $\mathbf{5}^{+\cdot}$ is of negligible significance because it is pre-empted by α-cleavage (C_2H_5· loss) (5).

The CID spectra establish that CH_3· loss from $\mathbf{7}^{+\cdot}$ and C_2H_5· elimination from $\mathbf{8}^{+\cdot}$ or $\mathbf{9}^{+\cdot}$ yield **28** as the product ion. The formation of a branched oxonium ion, rather than the linear species, **27**, is at first sight surprising since $\mathbf{7}^{+\cdot}$, $\mathbf{8}^{+\cdot}$, and $\mathbf{9}^{+\cdot}$ all contain unbranched alkenyl chains with a terminal methoxy group. Nevertheless, a mechanism involving DIs, ionised ethylmethoxycyclopropane, a 1,2-H shift, and eventual γ-cleavage explains this process, Scheme 7.

The success of Scheme 7 in interpreting this reaction is further evidence that the σ′-cleavage proceeds via a 1,2-H shift to the radical site of a DI followed by γ-cleavage of the appropriate ionised enol ether. No mechanism involving β-cleavage can account for this process.

The occurrence of δ-cleavage of $\mathbf{7}^{+\cdot}$, $\mathbf{8}^{+\cdot}$, and $\mathbf{9}^{+\cdot}$, together with the apparent ease of interconversion of metastable $\mathbf{7}^{+\cdot}$ and $\mathbf{5}^{+\cdot}$ via DIs and ionised ethylmethoxycyclopropane, suggests strongly that the skeletal rearrangement corresponding to a 1,2-$^+$CHOCH$_3$ shift has a lower critical energy than the 1,2-H shift to the radical site of the appropriate DI. If this were not so, a 1,2-H shift to the radical centre in the DI ($RCH_2CH{\cdot}CH_2CH^+OCH_3$) formed from $\mathbf{7}^{+\cdot}$, $\mathbf{8}^{+\cdot}$, and $\mathbf{9}^{+\cdot}$ would preempt isomerisation via **E**; the resultant ionised enol ether ($RCH_2CH_2CH{\cdot}CH^+OCH_3$) would then expel RCH_2· via γ-cleavage, thus circumventing R· loss. For similar reasons, it is difficult to account for CH_3· elimination from metastable $\mathbf{5}^{+\cdot}$ unless the skeletal rearrangement occurs more readily than α-cleavage at low internal energies. It has already been shown that the 1,2-H shift to the radical site of the DIs has a smaller critical energy than β-cleavage. Consequently, the order of increasing critical energy for the isomerisation and dissociation steps in the fragmentation of $C_mH_{2m-1}OCH_3^{+\cdot}$ species is 1,2-$^+$CHOCH$_3$ rearrangement < 1,2-H shift to a radical centre < β-cleavage. The same trend was found in the decomposition of radical cations formed from $RCO_2H^{+\cdot}$ species (16–18).

However, one difference between the chemistry of the $C_mH_{2m-1}OCH_3^{+\cdot}$ and $RCO_2H^{+\cdot}$ radical cations becomes apparent at this point. Loss of C_2H_5· from $\mathbf{8}^{+\cdot}$ and $\mathbf{9}^{+\cdot}$ is interpreted in Scheme 7 as occurring after a 1,2-H shift to a radical centre. In the $RCO_2H^{+\cdot}$ system, radical losses after such 1,2-H shifts were confined to cases in which CH_3· was expelled (16–18).

(b) Ethers of non-allylic alcohols ($12^{+\cdot}$)

Only weak $[M - C_2H_5]^+$ signals are present in the normal mass spectra of most linear isomers of $C_6H_{11}OCH_3$ derived from non-allylic primary alcohols (5). In the case of **12**, the $C_5H_9O^+$ signal is sufficiently strong to permit a reliable CID spectrum to be recorded. This spectrum indicates that the structure of the product ion is predominantly **28**. A similar conclusion was reached in an earlier combined CID and labelling study of the mechanism of C_2H_5· elimination from $\mathbf{12}^{+\cdot}$ (4). In view of this detailed investigation, which showed that $\mathbf{12}^{+\cdot}$ expels C_2H_5· by at least two routes, no further mechanistic analysis is attempted.

Other types of isomerisation of these $C_mH_{2m-1}OCH_3^{+\cdot}$ radical cations could, in principle, intervene. For example, a facile 1,5-H shift in $\mathbf{11}^{+\cdot}$ would afford the γ-DI $CH_3CH_2{\cdot}CHCH_2CH_2CH^+OCH_3$. Many γ-DIs readily undergo skeletal rearrangement (32, 33) via steps that can be understood in terms of formation of an ion-neutral complex (INC (34–37). This isomerisation is sometimes referred to as a 1,2-[enol olefin] shift. In this case, cleavage of the bond connecting the α- and β-carbons gives the INC [CH_3CH_2-$CH{=}CH_2$ $CH_2{=}CHOCH_3^{+\cdot}$]. Recombination of the components via addition of the 1-butene to ionised methyl vinyl

ether with the opposite regiospecificity to that of the step forming the INC could then give access to $CH_3CH_2(CH_2\cdot)$-$CHCH_2CH^+OCH_3$. An α-DI, $CH_3CH_2(CH_3)CH\cdot CH_2{}^+OCH_3$, may then be formed via further hydrogen shifts. This α-DI could then expel either $C_2H_5\cdot$ or $CH_3\cdot$, via γ-cleavage, with production of a stable conjugated oxonium ion $RCH{=}CHCH{=}O^+CH_3$ (R = CH_3 or C_2H_5, respectively). Unfortunately, the abundances of the $[M - CH_3]^+$ and $[M - C_2H_5]^+$ ions in the conventional spectrum of **11** are too low to permit reliable CID spectra to be measured. Therefore, the extent to which these rearrangements actually occur cannot be elucidated from the current data. However, the absence of appreciable $[M - CH_3]^+$ and $[M - C_2H_5]^+$ signals in the spectrum of **11** suggests that these processes compete only poorly with that resulting in $C_3H_7\cdot$ loss (Sect. D.2), at least at high internal energies.

Conclusions

Elimination of an alkyl radical from ionised pentenyl and hexenyl methyl ethers takes place via several distinct routes. All these routes result in formation of acyclic conjugated oxonium ions. For ionised ethers of tertiary allylic alcohols, loss of an α-alkyl substituent occurs readily by direct cleavage. Similarly, ionised secondary ethers also appear to fragment via α-cleavage provided an ethyl or larger radical is expelled. The corresponding species containing an α-methyl substituent dissociate via two mechanisms, involving loss of the α-methyl group (α-cleavage) and expulsion of a methyl group attached to the double bond (σ′-cleavage). This σ′-cleavage is favoured at low internal energies. Ionised ethers of primary allylic alcohols also undergo σ′-cleavage; in addition, these ions decompose via formal δ-cleavage if the alkenyl chain is sufficiently long. A mechanism in which a 1,2-H shift to the radical site of a DI leads to an ionised enol ether that then fragments via γ-cleavage provides a satisfactory unifying explanation for the σ′- and δ-cleavage processes. Dissociation is evidently specifically associated with γ-cleavage of the ionised enol ether in which the formal cationic and radical sites are located on adjacent carbon atoms, one of which carries the methoxy group. This mechanism can be extended to explain the elimination of an alkyl radical from ionised ethers derived from certain non-allylic alcohols.

The preference for dissociation via γ-cleavage reveals that the reverse process, conjugate addition of an alkyl radical to a methyl-cationated enal, occurs more readily than addition to the β-carbon atom. This phenomenon is an illustration of the nucleophilic properties associated with alkyl radicals having a high-energy SOMO.

In general, the isomerisation process corresponding to a 1,2-$^+CHOCH_3$ shift in the DI $R^1CH\cdot CHR^2CH^+OCH_3$ (i.e., leading to $R^2CH\cdot CHR^1CH^+OCH_3$, via $R^1\overline{CHCHR^2}CHO$-$CH_3{}^{+\cdot}$) has a lower critical energy than a 1,2-H shift to the same radical centre to yield $R^1CH_2\cdot CR^2CH^+OCH_3$. Both these processes require less energy than β-cleavage of either DI to give, respectively, $R^2CH{=}CHCH{=}O^+CH_3 + \cdot R^1$ or $R^1CH{=}CHCH{=}O^+CH_3 + \cdot R^2$.

The unusual 1,2-H shifts to the radical site take place more readily than the analogous 1,2-alkyl shifts in these systems. In contrast to 1,2-H shifts, which play an important part in the chemistry of these $C_nH_{2n}O^{+\cdot}$ species, there is no evidence for the occurrence of 1,2-alkyl shifts to the radical centre.

The reactions of the DIs generated from these $C_mH_{2m-1}OCH_3{}^{+\cdot}$ species show many similarities to those of DIs formed from $RCO_2H^{+\cdot}$. In particular, both classes of radical cations expel an alkyl radical via γ-cleavage; moreover, 1,2-H shifts to radical centres are observed, and isomerisation steps involving 1,2-$^+CHOCH_3$ or 1,2-$^+C(OH)_2$ shifts take place. The relative ease of several key steps follows the same trend for both types of DIs (1,2-$^+CHOCH_3$ or 1,2-$^+C(OH_2)$ shifts occur more readily than 1,2-H shifts to radical sites, which are more facile than β-cleavage). Furthermore, certain apparently plausible steps (e.g., 1,2-alkyl shifts to a radical centre) are not observed in the dissociation of either kind of DI. These common features reflect the reactivity of free radicals that is manifested in the chemistry of these DIs.

Experimental

The ethers required in this work were prepared from the corresponding alkenols by condensation of a suspension of the appropriate sodium alkoxide in triglyme (triethyleneglycol dimethyl ether $CH_3O(CH_2CH_2O)_3CH_3$) with a slight deficiency (0.8 equivalents of iodomethane). The general procedure for this process has been published (5); further details are available on request. The unlabelled alkenols were commercial samples of high purity. The ^2H-labelled alkenols were synthesised by the following conventional routes: $CH_3CH{=}CH(CD_3)CHOH$ and $CH_2{=}(CH_3)C(CD_3)CHOH$ were made by addition of 0.8 equivalents of the appropriate enals ($CH_3CH{=}CHCHO$ and $CH_2{=}(CH_3)CCHO$, respectively) to an ethereal solution of CD_3MgI at −78°C; $CH_2{=}CH(CD_3)_2COH$ was made by addition of 0.8 equivalents of $(CD_3)_2CO$ to a solution of $CH_2{=}CHMgBr$ in tetrahydrofuran at 30–40°C. No impurities could be detected by mass spectrometry or ^1H NMR in any of the alkenyl methyl ethers used in this work.

The CID spectra were measured on a Kratos Analytical Concept II HH four-sector mass spectrometer (EBEB geometry). The collision cell was floated at 4 kV above ground potential; the collision gas was helium, and the precursor ion beam was attenuated to 70% of its initial intensity. The data quoted in Tables 1–3 are integrated spectra, compiled from 15 individual scans. These spectra are essentially free from contributions arising from the dissociation of ions that have not been energised by collision.

Coordination chemistry of thioether–pyridazine macrocycles. III. Synthetic, structural, and spectroscopic studies of Cu(II), Cu(II)Cu(I), and Cu(I) complexes of a hexathiapyridazinophane macrocyclic ligand

LIQIN CHEN, LAURENCE K. THOMPSON,[1] AND JOHN N. BRIDSON

Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received February 1, 1993

LIQIN CHEN, LAURENCE K. THOMPSON, and JOHN N. BRIDSON. Can. J. Chem. **71**, 1086 (1993).

The preparation and properties of the thioether–pyridazine macrocycle (L4; $C_{16}H_{20}S_6N_4$) containing two pyridazine subunits, and its Cu(II), Cu(II)Cu(I), and Cu(I) complexes are described. The ligand is characterized by ^1H nuclear magnetic resonance and mass spectrometry, and the complexes by infrared, eleetronic spectra, and magnetism, and in some cases by X-ray crystallography. The complex $[Cu_2(L4)Cl_4]_x$ (**1**) crystallized in the triclinic system, space group $P\bar{1}$ with a = 8.6204(8) Å, b = 9.850(1) Å, c = 8.348(1) Å, α = 111.46(1)°, β = 102.50(1)°, γ = 71.818(9)°, V = 622.6(1) Å^3, and Z = 1 (R = 0.043, R_w = 0.042 for 1312 reflections). Two monodentate pyridazine rings in the same ligand bind to one *trans* square-planar copper centre (CuN_2Cl_2) with two sulfurs from each ligand binding to another *trans* square-planar copper centre (CuS_2Cl_2) to form a polynuclear chain. The complex $[Cu(L4)Cl_2]$ (**3**) crystallized in the triclinic system, space group $P\bar{1}$, with a = 11.001(1) Å, b = 12.888(2) Å, c = 8.704(1) Å, α = 102.89(1)°, β = 103.36(1)°, γ = 75.84(1)°, V = 1145.8(3) Å^3, and Z = 2 (R = 0.056, R_w = 0.044 for 2059 reflections). A *trans* square-planar structure (CuN_2Cl_2) exists for **3** with monodentate pyridazines. $[Cu(L4)(NO_3)_2]$ (**4**) crystallized in the orthorhombic system, space group $P2_12_12_1$, with a = 15.148(2) Å, b = 15.562(3) Å, c = 11.064(1) Å, V = 2608.2(7) Å^3, and Z = 4 (R = 0.039, R_w = 0.034 for 1864 reflections). Two monodentate pyridazine rings and two bidentate nitrates bind to a pseudo-octahedral copper(II) centre.

LIQIN CHEN, LAURENCE K. THOMPSON et JOHN N. BRIDSON. Can. J. Chem. **71**, 1086 (1993).

On décrit la préparation et les propriétés du macrocycle thioéther-pyridazine (L4; $C_{16}H_{20}S_6N_4$) contenant deux sous-unités pyridazinesainsi que celles de ses complexes avec le Cu(II), le Cu(II)Cu(I) et le Cu(I). On a caractérisé le ligand par RMN du ^1H et par spectrométrie de masse et les complexes par spectroscopies infrarouge et électronique ainsi que par magnétisme et, dans certains cas, par diffraction des rayons X. Le complexe $[Cu_2(L4)Cl_4]_x$ (**1**) cristallise dans le système triclinique, groupe d'espace $P\bar{1}$, avec a = 8,6204(8), b = 9,850(1) et c = 8,348(1) Å, α = 111,46(1)°, β = 102,50(1)° et γ = 71,818(9)°, V = 622,6(1) Å^3 et Z = 1 (R = 0,043 et R_w = 0,042 pour 1312 réflexions). Deux noyaux pyridazines monodentates du même ligand se lient à un centre cuivre plan-carré *trans* (CuN_2Cl_2) alors que deux atomes de soufre de chaque ligand se lient à un autre centre cuivre plan-carré *trans* (CuS_2Cl_2) pour former une chaîne polynucléaire. Le complexe $[Cu_2(L4)Cl_2]$ (**3**) cristallise dans le système triclinique, groupe d'espace $P\bar{1}$, avec a = 11,001(1), b = 12,888(2) et c = 8,704(1) Å, α = 102,89(1)°, β = 103,36(1)° et γ = 75,84(1)°, V = 1145,8(3) Å^3 et Z = 2 (R = 0,056 et R_w = 0,044 pour 2059 réflexions). Il existe une structure (CuN_2Cl_2) plan-carré *trans* pour **3** avec pyridazines monodentates. Le $[Cu(L4)(NO_3)_2]$ (**4**) cristallise dans le système orthorhombique, groupe d'espace $P2_12_12_1$, avec a = 15,148(2), b = 15,562(3) et c = 11,064(1) Å, V = 2608,2(7) Å^3 et Z = 4 (R = 0,039 et R_w = 0,034 pour 1864 réflexions). Deux noyaux pyridazines monodentates et deux nitrates bidentates se lient à un centre cuivrique pseudo-tétraédrique.

[Traduit par la rédaction]

Introduction

The recent development of the coordination chemistry of thioethers has been stimulated by the discovery of thioether coordination to copper in the blue copper proteins (1). Metal ligation through sulfur donor centres has been considered to contribute not only to anomalously high redox potentials of these proteins but also to their exceptionally rapid electron transfer reactions. As a result, the current literature on copper complexes reveals many studies on thioether ligands, including homoleptic macrocyclic thioethers (2–12), open chain polythioethers (13), chelating ligands with built in thioether and azole functions (14), and macrocyclic thioethers with benzene, pyridine, furan, and thiophene heterocyclic subunits (15–20).

Our interest in mixed sulfur-nitrogen ligands involving thioether and diazine ligands stems from our earlier studies on open-chain tetradentate (N_4) thioether–pyridazine ligands (21–27), which involved non-coordinating thioether linkages and formed binuclear copper(II) complexes with, in some cases, positive (0 → +0.5 V vs. SCE) reduction potentials. The combination of pyridazine and thioether groups, suitably disposed for simultaneous coordination, might be expected to produce binuclear copper(II) complexes with more positive reduction potentials. However, our initial studies in this area, which have involved the syntheses and structural and spectroscopic studies of a series of copper(II), copper(I), and silver(I) complexes of thioether–pyridazine macrocycles containing one, two, and three pyridazine subunits (L3, L2, L1, Fig. 1) (28, 29), have shown that, so far, simultaneous intraligand NS coordination does not occur. The present paper describes the copper coordination chemistry of the 2:2 macrocyclic ligand L4 (Fig. 1), which involves 1,4,7-trithiaheptyl linkages between the pyridazine subunits. In one case the ligand acts as an N_2S_2 donor, but in a polymeric arrangement.

Experimental section

Commercially available reagents (Aldrich) were used without further purification. Infrared spectra were recorded using a Mattson Polaris FT instrument and electronic spectra with a Cary 5E spectrometer. Mass spectra were obtained using a VG Micromass 7070 HS spectrometer and nmr spectra using a GE 300 MHz instrument. X-ray diffraction data were collected using a Rigaku AFC6S

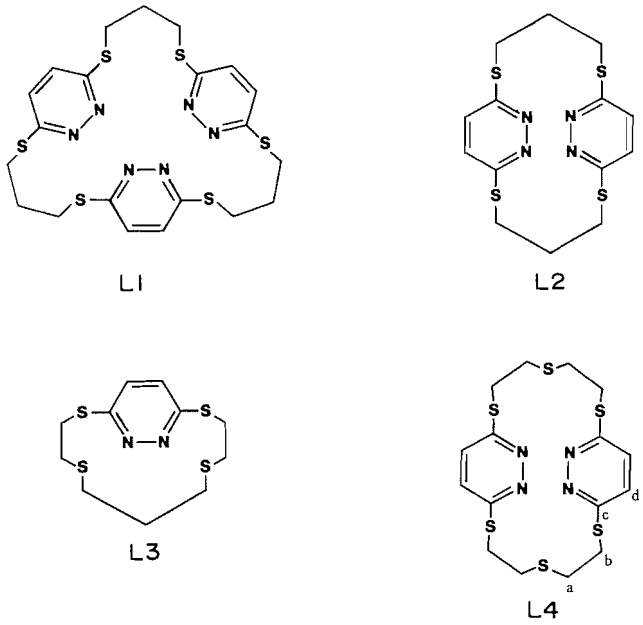

FIG. 1. Structural representation of the ligands L1, L2, L3, L4.

instrument and room temperature magnetic susceptibility data were measured by the Faraday method using a Cahn 7600 magnetic susceptibility system. Elemental analyses were performed by Canadian Microanalytical Service, Delta, B.C., Canada.

Synthesis of ligand and complexes

Safety note

Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small amounts of material should be prepared and these should be handled with caution. The complex described in this report has, so far, been found to be safe when used in small quantities.

L4

2-Mercaptoethyl sulfide (8.56 g, 50.0 mmol) was added to anhydrous ethanol (100 mL) in which sodium metal (2.30 g, 100.0 mmol) had been dissolved, and the resulting solution was stirred for 30 min. 3,6-Dichloropyridazine (7.68 g, 50.0 mmol) was then dissolved in anhydrous ethanol (100 mL) and both solutions were added dropwise simultaneously to anhydrous ethanol (500 mL) using pressure-equalizing funnels, over a period of 6 h during which time a white precipitate formed. The mixture was stirred overnight and then filtered. The white solid was washed with ethanol and deionized water, dried in vacuo, and recrystallized from $CHCl_3$ and then $MeNO_2$ to give white crystals. Yield 4.2 g.

The solvent of the original filtrate was removed using a rotary evaporator, the residue extracted with $CHCl_3$ and the extract washed several times with deionized water and dried over anhydrous Na_2SO_4. The concentrated extract was chromatographed on silica gel, eluted with $CHCl_3$, and the volume of the eluate reduced to a few mL on a rotary evaporator; white crystals were obtained (0.5 g). These two parts of the product have the same melting point 217–219°C (total yield 40.4%). Mass spectrum, major mass peaks (*m/e* (relative intensity)): 460(1) P, 401(22), 374(11), 231(47), 144(32), 87(100). ^1H nmr (Fig. 1) ($CDCl_3$/TMS) (δ ppm (relative intensity)): 3.07(8) (triplet, CH_2(a)), 3.62(8) (triplet, CH_2(b)), 7.04(4) (singlet, pyridazine (H_d)). ^{13}C nmr ($CDCl_3$/TMS) (δ ppm) 29.7 (C_a), 30.1 (C_b), 125.5 (C_d), 158.0 (C_c).

$[Cu_2(L4)Cl_4]_x$ (1)

Method A

To a solution of $CuCl_2 \cdot 2H_2O$ (85 mg, 0.50 mmol) in 20 mL CH_3CN was added a solution of L4 (92 mg, 0.20 mmol) in 20 mL $CHCl_3$. The resulting dark green solution was filtered and allowed to stand at room temperature overnight. Dark brown crystals formed which were filtered, washed with CH_3CN, and dried in air. Yield 125 mg (78%). Anal. calcd. for $[C_{16}H_{20}N_4S_6Cl_4Cu_2] \cdot 0.5CHCl_3$: C 25.11, H 2.62, N 7.10; found: C 24.75, H 2.70, N 7.27.

Method B

Cu powder (190 mg, 3.0 mmol) was added to a solution of $CuCl_2 \cdot 2H_2O$ (51 mg, 0.30 mmol) in CH_3CN (20 mL). The mixture was stirred for 6 h under N_2 and the resulting colourless solution filtered into a solution of L4 (92 mg, 0.20 mmol) in $CHCl_3$ (20 mL). The yellow solution was exposed to air for a couple of weeks and brown crystals formed. Yield 75 mg (52%). Suitable crystals were chosen for x-ray diffraction.

$[Cu_2(L4)Br_3]$ (2) was prepared in a similar manner by reaction of L4 with $CuBr_2$ following method A and was obtained as reddish brown crystals. Yield 110 mg (67%). Anal. calcd. for $[C_{16}H_{20}N_4S_6Cu_2Br_3]$: C 23.22, H 2.44, N 6.77; found: C 23.66, H 2.66, N 6.94.

$[Cu(L4)Cl_2]$ (3)

$CuCl_2 \cdot 2H_2O$ (34 mg, 0.20 mmol) was dissolved in CH_3CN (20 mL) and added to a solution of L4 (92 mg, 0.20 mmol) in $CHCl_3$ (20 mL). The resulting green solution was filtered and allowed to stand at room temperature overnight. Bright green crystals formed, which were filtered off, washed with CH_3CN and $CHCl_3$, and air dried. Yield 85 mg (71%). Anal. calcd. for $[C_{16}H_{20}N_4S_6Cl_2Cu]$: C 32.29, H 3.39, N 9.41; found: C 32.08, H 3.44, N 9.38.

$[Cu(L4)(NO_3)_2]$ (4)

A solution of L4 (55 mg, 0.12 mmol) in $CHCl_3$ (20 mL) was added to a solution of $Cu(NO_3)_2 \cdot 3H_2O$ (97 mg, 0.40 mmol) in CH_3CN (20 mL). The resulting solution was filtered and then refluxed for 2 h to form a dark green solution. The solution was allowed to stand at room temperature overnight. Bluish green crystals formed which were filtered, washed with CH_3CN, and dried in air. Yield 46 mg (59%). Anal. calcd. for $[C_{16}H_{20}N_4S_6Cu(NO_3)_2]$: C 29.64, H 3.11, N 12.96; found: C 29.75, H 3.13, N 13.13.

$Cu(L4)(ClO_4) \cdot H_2O$ (5)

A solution of L4 (46 mg, 0.10 mmol) in $CHCl_3$ (20 mL) was added to solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (85 mg, 0.23 mmol) in CH_3CN (20 mL). The resulting deep green solution was filtered and allowed to stand at room temperature. The colour of the solution began to change from deep green to green to yellow and finally pale yellow crystals formed overnight. These crystals were filtered, washed with CH_3CN and $CHCl_3$ and dried in air. Yield 56 mg (86%). Anal. calcd. for $[C_{16}H_{20}N_4S_6Cu]$ $(ClO_4) \cdot H_2O$: C 29.95, H 3.46, N 8.73; found: C 29.93, H 3.45, N 8.65. **5** was also prepared by direct reaction of Cu(I) perchlorate and L4 in CH_3CN/$CHCl_3$.

$[Cu(L4)Cl] \cdot 0.5H_2O$ (6) and $[Cu(L4)Br] \cdot 0.5CHCl_3$ (7)

Cu powder (190 mg, 3.0 mmol) was added to a solution of $CuCl_2 \cdot 2H_2O$ (51 mg, 0.30 mmol) in CH_3CN (20 mL). The mixture was stirred for 6 h under N_2 and the resulting colourless solution filtered into a solution of L4 (92 mg, 0.20 mmol) in $CHCl_3$ (20 mL) under a nitrogen atmosphere. The pale yellow solution was left at room temperature overnight and pale yellow crystals formed. Yield 84 mg (74%). Anal. calcd. for $[C_{16}H_{20}N_4S_6CuCl] \cdot 0.5H_2O$: C 33.79, H 3.72, N 9.85; found: C 33.68, H 3.57, N 9.63. $[Cu(L4)Br] \cdot 0.5CHCl_3$ (**7**) was prepared similarly by using $CuBr_2$ and obtained as pale yellow crystals. Yield 105 mg (75%). Anal. calcd. for $[C_{16}H_{20}N_4S_6CuBr] \cdot 0.5CHCl_3$: C 29.85, H 3.11, N 8.44; found: C 29.80, H 3.12, N 8.44.

X-ray crystallographic analysis of $[Cu_2(L4)Cl_4]_x$ (1)

The diffraction intensities of a brown regular polyhedron crystal of $[Cu_2(L4)Cl_4]_x$ (**1**) of approximate dimensions 0.300 × 0.200 × 0.150 mm were collected using a Rigaku AFC6S diffractometer with graphite monochromatized CuKα radiation. Cell constants and the orientation matrix were obtained by a least-squares refinement using the setting angles of 20 carefully centred reflec-

tions in the range $19.96 < 2\theta < 52.33°$. Based on a statistical analysis of the intensity distribution, and the successful solution and refinement of the structure, the space group was determined to be $P\bar{1}$. Machine and data collection parameters and crystal data are given in Table 1. The data were collected at 25 ± 1°C using ω–2θ scan technique to a maximum 2θ value of 120.1°. Omega scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.30° with a take-off angle of 6.0°. Scans of (1.68 + 0.30 tan θ)° were made at a speed of 8.0°/min (in ω). The weak reflections ($I < 10.0\sigma(I)$) were rescanned (maximum of two rescans) and the counts were accumulated to assure good counting statistics. The ratio of peak counting time to background counting time was 2:1.

A total of 1989 reflections were collected. The intensities of three representative reflections, which were measured after every 150 reflections remained constant throughout data collection (no decay correction applied). An empirical absorption correction was applied, using the program DIFABS (30), which resulted in transmission factors ranging from 0.40 to 1.00. The data were corrected for Lorentz and polarization effects.

The structure was solved by direct methods (31, 32). The non hydrogen atoms were refined anisotropically. The final cycle of full-matrix least-squares refinement was based on 1312 observed reflections ($I > 3.00\sigma(I)$) and 179 variable parameteers and converged with unweighted and weighted agreement factors of $R = \Sigma\|F_o| - |F_c\|/\Sigma|F_o| = 0.043$ and $R_w = [(\Sigma w(|F_o| - |F_c|)^2/\Sigma w F_o^2)]^{1/2} = 0.042$. The standard deviation of an observation of unit weight was 1.93. The weighting scheme was based on counting statistics and included a factor ($p = 0.01$) to down weight the intense reflections. Plots of $\Sigma w(|F_o| - |F_c|)^2$ versus $|F_o|$, reflection order in data collection, $\sin\theta/\lambda$, and various classes of indices showed no unusual trends. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.65 and −0.49 electrons/Å^3, respectively, and have no chemical significance. Neutral atom scattering factors (33) and anomalous dispersion terms (34, 35) were taken from the usual sources. All calculations were performed using the TEXSAN (36) crystallographic software package using a VAX 3100 workstation. Hydrogen atoms were located in a difference map but not refined. Thermal parameters were set at 1.2 times the isotropic thermal parameter of the bonded C atoms.

Atomic positional parameters are given in Table 2 and selected bonded distances and angles are given in Table 5. Thermal parameters (Table S-1), hydrogen atom parameters (Table S-2), a full

Results and discussion

The synthesis of L4 was achieved in moderately high yield by a traditional high dilution cyclization reaction and no trace of any 11-membered macrocycle containing one pyridazine subunit and 33-membered macrocycle containing three pyridazine subunits was detected. The 1:2 and 1:1 complexes of L4 with $CuCl_2$ were prepared by controlling the molar ratio of ligand and copper salt. It is of interest to note that complex **1** can be synthesized from either copper(I) or copper(II) starting materials. Synthesis from copper(I) chloride clearly would require a source of adventitious chloride, which may result from disproportionation of the excess copper(I) chloride present. Moreover, since both copper(I) chloride and bromide complexes are readily prepared, and quite stable, it is perhaps not surprising that a mixed oxidation state complex (**2**) can be synthesized. Presumably the synthesis of **2** was accompanied by some ligand hydrolysis to provide a source of reducing thiol, as would also be the case for **5**. However, in both syntheses no such byproducts were isolated. The complexes did not dissolve appreciably in any solvent and were studied exclusively in the solid state.

Description of the structures of $[Cu_2(L4)Cl_4]_x$ (1), $[Cu(L4)Cl_2]$ (3), and $[Cu(L4)(NO_3)_2]$ (4)

The structure of a fragment of $[Cu_2(L4)Cl_4]_x$ (**1**), which includes the two different copper centres, is illustrated in Fig. 2*a*. The overall structure is that on an infinite, single stranded polymer with the macrocyclic ligand behaving in a tetradentate fashion, binding a *trans* square-planar copper(II) centre inside the macrocyclic cavity via two separate pyridazine nitrogens, and linking external *trans* square-planar copper(II) centres by exocyclic sulfur atoms (Fig. 2*b*). Unlike the situation in $[Cu(L2)Cl_2]$ (28), where, as a result of the smaller macrocyclic ring the square-planar CuN_2Cl_2 centre effectively exists outside the macrocyclic cavity, in **1** Cu(1) is bound within the macrocyclic cavity. Furthermore, opposite, rather than adjacent, pyradazine nitrogens are bound to the copper centre in **1**. The two copper(II) centres are very close to being exactly square-planar with angles around Cu(1)

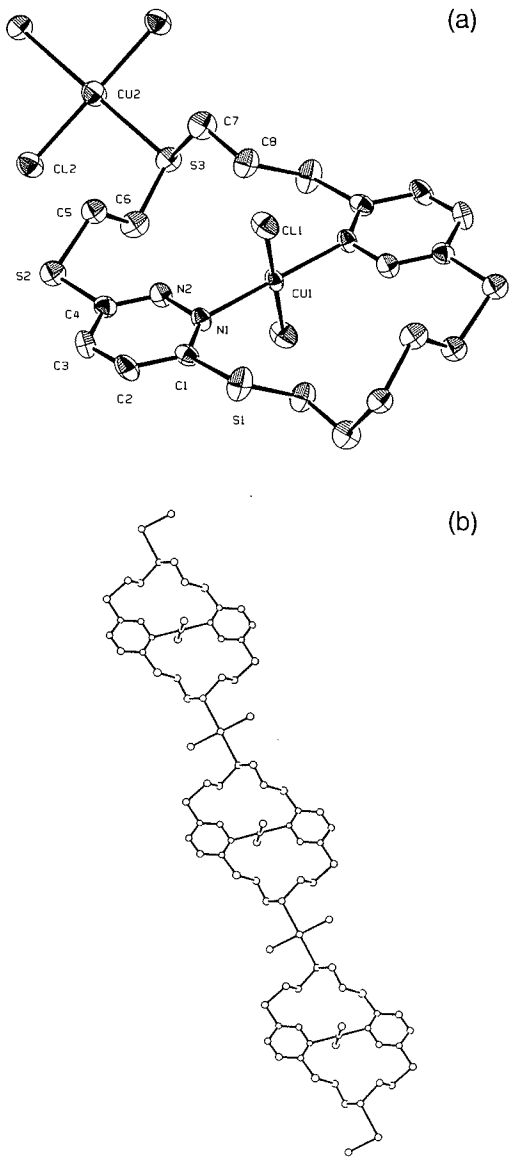

FIG. 2. (*a*) Molecular structure of $[Cu_2(L4)Cl_4]_x$ (**1**) (40% probability thermal ellipsoids) showing a single dinuclear fragment. (*b*) Structural representation of $[Cu_2(L4)Cl_4]_x$ (**1**) illustrating the single stranded polymer.

in the range 88.1–91.9°, and around Cu(2) in the range 88.4–91.6°, and copper–nitrogen, copper–sulfur, and copper–chlorine distances are normal for systems of this sort. The *endo / exo* coordination of L4 in **1** is reminiscent of the bonding of L1 in the complex $[Cu_3(L1)_2Cl_6]$ (28), in which two square-planar copper(II) centres are bound "internally," one within each ligand via two independent pyridazine nitrogens, and the third pyridazine in each ligand is bound to a third square-planar copper(II) centre. However, for the first time, the ligand L4 exhibits the desired mixed N / S coordination mode, but unfortunately it occurs in an intermolecular, rather than an intramolecular fashion.

The structure of $[Cu(L4)Cl_2]$ (**3**) is illustrated in Fig. 3 and consists of an almost square-planar *trans* copper(II) center bound by two opposite pyridazine nitrogens, one from each pyridazine ring and two chlorines. The coordination sphere is similar to one of the copper centers in **1**. The copper–nitrogen and copper–chlorine distances are slightly different

O(1)—Cu(1)—O(2)	55.3(2)	O(1)—Cu(1)—N(2)	151.4(2)
O(5)—Cu(1)—O(2)	126.3(2)	O(5)—Cu(1)—N(2)	80.8(2)
O(2)—Cu(1)—N(2)	149.9(2)		

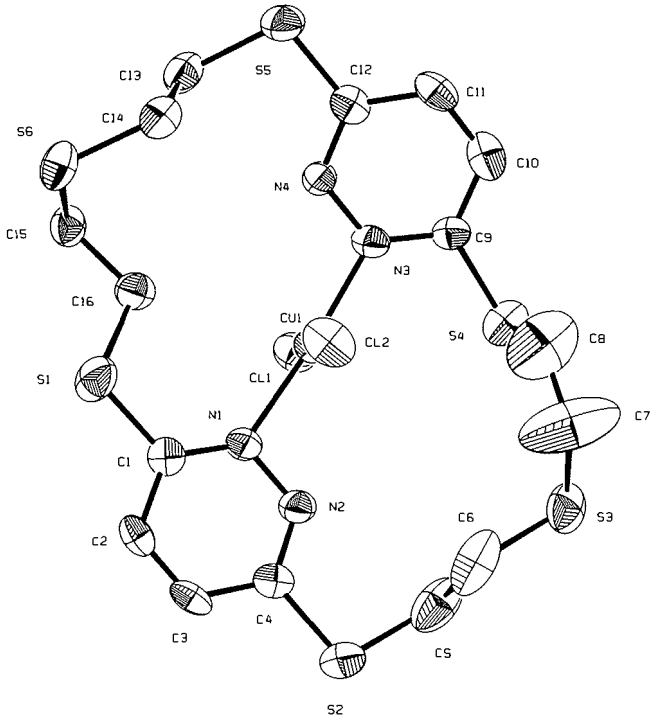

FIG. 3. Molecular structure of [Cu(L4)Cl_2] (**3**) (40% probability thermal ellipsoids).

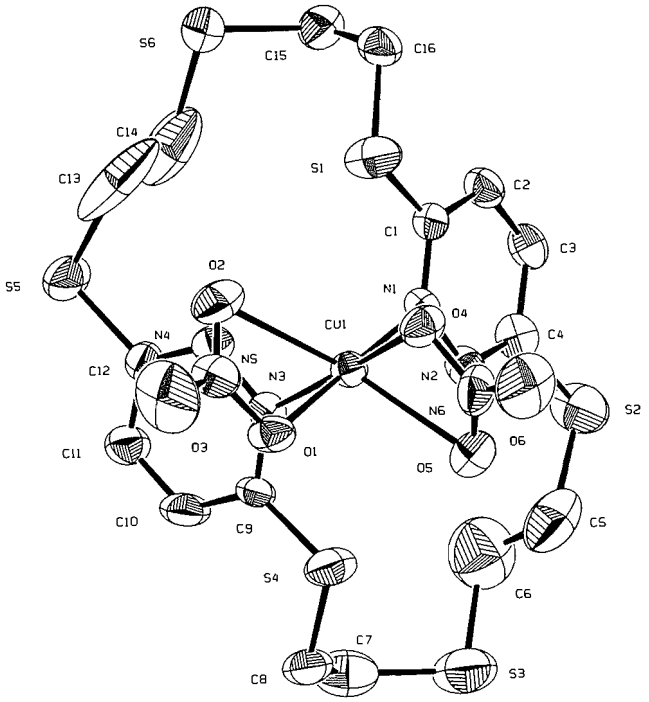

FIG. 4. Molecular structure of [Cu(L4) $(NO_3)_2$] (**4**) (40 % probability thermal ellipsoids).

from those in **1** but still in the normal range for ligands of this sort. The angles around the copper fall in the range 88.1–91.9°, comparing very closely with those in **1**.

The structure of [Cu(L4) $(NO_3)_2$] (**4**) is illustrated in Fig. 4 and consists of a highly distorted *cis*-octahedral copper(II) center bound by two opposite *cis*-pyridazine nitrogens, one from each pyridazine ring and two bidentate nitrates. Two copper–oxygen distances (1.980(12), 1.933(12) Å) and the short copper–nitrogen distances (1.992(6), 1.982(6) Å) are normal, but two of the in-plane angles are significantly different from 90° (N(3)—Cu(1)—N(2) 80.9(2)°, O(4)—Cu(1)—N(1) 93.2(2)° to imply a distorted structure. Two copper–oxygen distances (Cu(1)—O(5) 2.461(6) Å, Cu(1)—O(2) 2.547(6) Å) are quite long, but still within a reasonable bonding distance. When bonding to a single metal atom a nitrate group may behave as a monodentate ligand or a symmetrical or unsymmetrical bidentate ligand. It is suggested (37) that a nitrate is to be considered a bidentate ligand if the difference in the two closest metal–oxygen distances is less than 0.7 Å. In **4** the difference between the distances of Cu—O(5) and Cu—O(1) is 0.567 Å and the difference between Cu—O(5) and Cu—O(4) is 0.474 Å. It

[a]Mull transmittance.

is clear that from the structural information the nitrates are bidentate, and the copper centre is best regarded as a highly distorted *cis*-octahedral species.

Spectroscopy and magnetism

The ligand L4 has a simple infrared spectrum with a sharp νCN band at 1580 cm^{-1}. This band shifts 8–23 cm^{-1} to lower energy in all the complexes (Table 8), suggesting the coordination of pyridazine rings (28, 29). With ligands L1 and L2 sulfur coordination was accompanied by a small shift in this band to higher energy (1–2 cm^{-1}), while for nitrogen coordination shifts to lower energy were observed (−5 to −11 cm^{-1}) (28). The shifts to lower energy for **1**, **3**, and **4** are clear cut because X-ray data confirm pyridazine nitrogen coordination. For complex **2** two νCN bands are, in fact, observed at 1600 and 1560 cm^{-1}, suggesting the presence of two different pyridazine rings. The higher energy band is assigned to an uncoordinated pyridazine ring, in keeping with similar observations for L1 and L2 (28). Complex **2** is clearly a Cu(II) / Cu(I) species and, because of its lack of solubility, is likely to have a polymeric structure similar to **1**. Low energy *d–d* absorption also suggests sulfur coordination. The copper(II) site probably lies within the macrocyclic ring and involves a four-coordinate $CuNSBr_2$ chromophore, with one pyridazine nitrogen and one sulfur adjacent to a pyridazine involved in bonding to copper. A reasonable suggestion for the copper(I) site would be a CuS_2Br species bridging the macrocyclic rings and bound in an exocyclic fashion by each NS_3 ring.

The copper(I) perchlorate complex (**5**) has two prominent νCN bands at 1600 and 1557 cm^{-1}, suggesting the presence of both coordinated and uncoordinated pyridazine. A strong band at 1096 cm^{-1} indicates ionic perchlorate. It is suggested that structurally **5** involves a mixed NS donor set, possibly $CuNS_2$, but the coordination number and molecular nature of the complex must await a structural determination. The overall infrared spectra of **6** and **7** are very similar, suggesting comparable structures, which are likely to be polymeric and similar to **1**. The presence of only one νCN band at lower energy, in each case, suggests coordination of both pyridazine rings. Structurally the most reasonable suggestion for **6** and **7** involves a three-coordinate CuN_2X and an external CuS_2X species (X = Cl, Br) in a polymeric arrangement similar to **1**.

In the far infrared region, the Cu—N (pyridazine) stretching vibrations would be expected at quite low energy (38), but because of complexities in the spectra an unequivocal assignment of this band could not be made. Absorptions in **1** at 306 and 295 cm^{-1} can be associated with two different *trans* dichloro-copper(II) species. Complex **3** exhibits one strong band at 308 cm^{-1}, also consistent with a similar *trans* chromophore. A strong absorption at 239 cm^{-1} for the copper bromide complex **2** is assigned to Cu—Br stretch. In **4** there are two strong bands at 304 and 323 cm^{-1}, which are associated with Cu—O (NO_3^-) stretch. The ($\nu_1 + \nu_4$) nitrate combination bands of **4** are observed at 1758, 1753, 1721, 1709 cm^{-1} (39), and are associated with two different coordinated nitrates. The separation of each pair of bands is usually a reasonable indication of the bonding mode of such a group (39) and differences of 37 and 44 cm^{-1} are large enough to suggest a bidentate role for two different coordinated nitrates. In this case, X-ray data formally define the coordinated nitrates in a bidentate mode. For each nitrate, therefore, one oxygen is strongly coordinated, and one weakly coordinated.

Room temperature magnetic moments for compounds 1–4 (Table 8) all exceed the spin-only value for a one-unpaired electron system and suggest the presence of dilute copper(II) centers in all cases, with no spin exchange. The large distances separating the copper(II) centres in **1**, and the lack of appropriate magnetically active bridging groups would suggest the absence of any spin–spin interactions in this system. The normal value for **2** confirms the presence of just one paramagnetic copper(II) centre. Solid state, mull transmittance, electronic spectra for **1**–**3** are characterized by the presence of one major visible *d–d* absorption (Table 8). The *d–d* absorption energy of the chloro-complexes is comparable, as would be expected, but the very low energy band observed for **2** is consistent with copper(II) centres bound to N, S, and Br donors. The higher energy absorption for **4** is in agreement with the six-coordinate structure and mixed CuN_2O_4 chromophore. Other bands at higher energy observed for **1** and **2** (19600, 18500 cm^{-1}, respectively) are consistent with halogen-to-copper charge transfer.

2-Carbomethoxy-1,3-butadiene: an electronically activated diene in [4 + 2] cycloadditions with electron-deficient dienophiles

CLAUDE SPINO[1] AND JASON CRAWFORD
University of Victoria, Chemistry Department, P.O. Box 3055, Victoria, B.C., Canada V8W 3P6

Received December 10, 1992

CLAUDE SPINO and JASON CRAWFORD. Can. J. Chem. **71**, 1094 (1993).

Cross Diels–Alder reactions between 2-carbomethoxy-1,3-butadiene **1** and electron-rich dienes were carried out. It was found that diene **1** had a higher reactivity than even the well-known Danishefsky diene in its Diels–Alder cycloaddition with electron-deficient dienophiles. In addition, (*Z*)-1-methylthio-3-carbomethoxy-1,3-butadiene **11** was found to have a higher reactivity than (*Z*)-1-methylthio-1,3-butadiene and (*Z*)-2-carbomethoxy-1,3-hexadiene, while both (*E*)- and (*Z*)-1,2-(bis)-carbomethoxy-1,3-butadiene **14** reacted efficiently with maleic anhydride to give the corresponding cycloadduct **15**.

CLAUDE SPINO et JASON CRAWFORD. Can. J. Chem. **71**, 1094 (1993).

Nous avons effectué des réactions de Diels–Alder croisées entre le 2-carbomethoxy-1,3-butadiene **1** et des dienes riches en électrons. Les résultats obtenus indiquent que **1** est plus réactif que le diène de Danishefsky, dans les cycloadditions avec des dièenophiles pauvres en électrons. De plus, le (*Z*)-1-methylthio-3-carbomethoxy-1,3-butadiene **11** a montré une plus grande réactivité que le (*Z*)-1-methylthio-1,3-butadiene et (*Z*)-2-carbomethoxy-1,3-hexadiene tandis que le (*E*)- et (*Z*)-1,2-(bis)-carbomethoxy-1,3-butadiene **14** ont réagi avec l'anhydride maléique pour donner le produit de cycloaddition **15**.

The facile dimerization of 2-carbomethoxy-1,3-butadiene **1** to give dimethyl mikanecate **4** has been known for some time (Scheme 1) (1, 2). Although the unusual ease with which this [4+2] cycloaddition takes place has been noted, a rationalization of this phenomenon has yet to be offered. A recent communication by Jung and Zimmerman provided the first kinetic data on this dimerization (3). They proposed that the high dienophilic character of the C1—C2 bond in **1** and the possibility that **1** may be more stable in its *E*-(*s-cis*) conformation could be major factors in accelerating this Diels–Alder reaction. We provide evidence herein that another electronic factor plays a significant role in the rate acceleration of this dimerization and that in fact **1** should be regarded as an electronically activated diene.

A 96% yield of dimer **4** was obtained by heating sulfolene **2** at 110°C (Scheme 1, method A) (1*a*) or by treating allylic bromide **3** with base at 25°C (Method B) (1*b*). However, in the presence of the electron-rich diene **5***a* (Y = Me) (4) and the very reactive diene **5***b* (Y = OMe) (4*b*), either method led to a mixture of dimer **4** and cross cycloadduct **6** (Table 1). In most cases, the dimerization product prevailed unless a large excess of the electron-rich diene was used. Note that the lower temperature seems to favor dimerization over cross-cycloaddition (entries 3, 4, 5, and 8). These results indicate that diene **1**, as a dienophile, cycloadds more rapidly to itself, an electron-deficient diene, than it does to the electron-rich dienes **5***a* and **5***b*. Note that the reactivity of diene **1** is underestimated here since diene **1** is generated slowly (3–4 h) and must be at low concentration relative to the other diene.

We ruled out the possibility of a local concentration effect, where molecules of diene **1** would dimerize faster because they were generated in proximity to one another, by stirring 1 equivalent each of sulfolene **2** and diene **5***b* with excess methyl acrylate (10 equiv.) in refluxing toluene (Scheme 2). After 4 h, diene **1** had reacted completely to give **7** and Danishefsky's diene **5***b* had reacted to the extent of 93% to give adduct **8** (gc analysis). Also detected were **6***b* (<5%) and **4** (traces). Control experiments in which each diene was reacted separately with excess methyl acrylate confirmed that diene **1** reacted more rapidly with methyl acrylate than did Danishefsky's diene **5***b*. We believe that diene **1** reacted as soon as it was generated since it (or dimer **4**) was not detected in significant amount throughout the reaction (the extrusion of SO_2 in **2** takes ~4 h). The reaction of **3** and **5***b* with methyl acrylate (10 equiv.) at 25°C following method B gave mostly dimer **4** (73%), adduct **7** (8%), and **6***b* (7%) (yields based on **3**). Diene **5***b* did not react at all with methyl acrylate under those conditions. The ethyl ester analog of **1** reacts as a dienophile with cyclopentadiene (excess) at 25°C in quantitative yield (5). As a diene, **1** is more reactive than **5***b* toward both methyl acrylate and itself. It also appears to be less reactive than cyclopentadiene. As a dienophile, **1** is more reactive than methyl acrylate towards both itself and **5***b*. We believe that this increased dienophilicity is due to a strong polarization of the C1—C2 double bond in **1**, as suggested by Jung and Zimmerman (3).

The regiochemistry of the dimer **4** (>97%) cannot be accounted for by any reasonable ionic pathway. Also, we repeated the dimerization of **1** from **2** or **3** and its cycloaddition with methyl acrylate in the absence of light and in the presence of 2,6-di-*tert*-butylphenol or hydroquinone with no effect on the rate of reaction. The above reactions thus appear to be proceeding via a normal thermal [4+2] cycloaddition mechanism.

We then prepared compounds **11** and **14** to examine the effect of an electron-donating or -withdrawing group at an end position on the reactivity of diene **1** (Schemes 3 and 4). Dihydrothiophene **9** was prepared from methyl acrylate following the method of Belleau and co-workers (6*a*). After

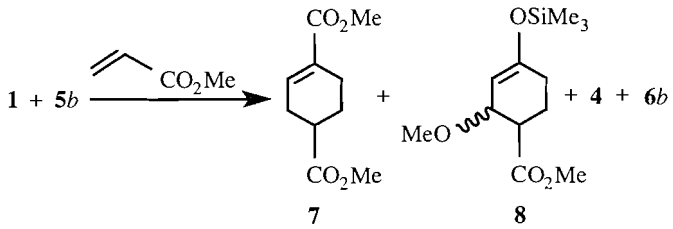
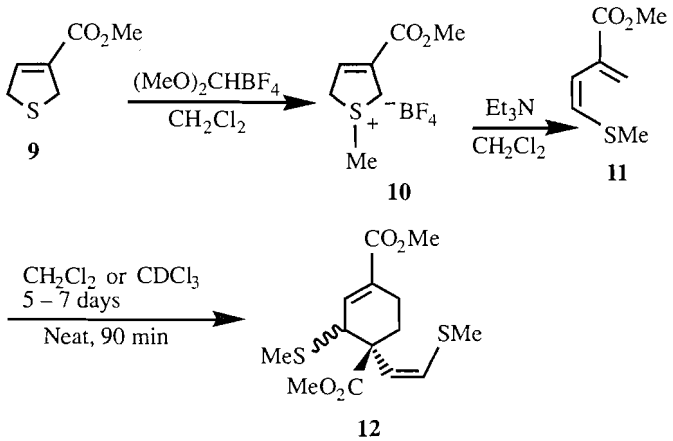


SCHEME 2



SCHEME 3

methylation with Borch's salt (7), the resulting sulfonium salt **10** underwent an elimination reaction with triethylamine at 25°C to yield the (*Z*)-enethiol ether **11**. Upon standing at 25°C in solvent, **11** dimerized to give a 9:1 mixture of stereoisomeric **12** in 5–7 days. However, when concentrated, **11** dimerized in 90 min in 89% yield. The ^{1}H nmr spectra of both isomers of **12** were consistent with (*Z*)-enethiol ether structures, indicative of a concerted cycloaddition mechanism. The slower dimerization of **11** compared to **1** is probably due to the severe steric interactions in the former when it adopts a *cisoid* conformation. Clearly the 2-carbomethoxy group activates **11** toward dimerization since the known (*Z*)-1-methylthio-1,3-butadiene does not undergo Diels–Alder reactions (8). However, the sulfur also plays an activating role since the carbon analog of **11**, (*Z*)-1-ethyl-2-carbomethoxy-1,3-butadiene, does not dimerize readily (9).

Finally, the dianion of sulfolene **2** was acylated with methyl chloroformate to give a 78% yield of **13** (10). Upon heating in toluene for 12 h, **13** underwent a sigmatropic elimination of SO_2 to afford the stable, but volatile, diene **14** as a 1:1 mixture of *E* and *Z* isomers. Heating **13** for 12 h in toluene containing maleic anhydride gave 87% of two isomeric cycloadducts **15** in a near 1:1 ratio, along with a small amount of unreacted (*E*)-**14**. Compound **15** undergoes a retro-Diels–Alder reaction upon chromatography on silica gel, to give back **14** and maleic anhydride. The ease of cycloaddition of **14**, especially the *E* isomer, with maleic anhydride is noteworthy. Studies to better assess the reactivities of **11** and **14** are underway and will be reported in a more detailed article in due course.

The above results cannot be reconciled with Frontier Molecular Orbital (FMO) theory arguments (11). Indeed, the HOMO of dienes like **1** have been shown to be of lower energy than that of 1,3-butadiene itself by approximately 0.2 eV (12). The results from the cross-cycloaddition experiments between **1** and Danishefsky's diene indicate that the high dienophilic character of **1** is not the sole factor in accelerating its dimerization and therefore the high eneophilic character of **1** must also play a role. Butadienes with other electron-withdrawing groups at C2 have also been shown to dimerize readily (6, 13) and it is likely that they, and dienes **11** and **14**, are all activated in a similar way. Importantly, studies on the dimerization of 2-cyano-1,3-butadiene and its cycloaddition reactions with electron-deficient dienophiles indicate that it has a comparable reactivity to **1** (13). 2-Cyano-1,3-butadiene is more stable in its (*Z*)-(*s-trans*) conformation relative to less eneophilic dienes such as 2,3-dimethyl-1,3-butadiene.[2] This suggests that it, and diene **1**, owe their eneophilicity to a factor other than an enhanced population of the *s-cis* conformation.

We therefore conclude that an electronic factor is activating *diene* **1** with respect to thermal [4 + 2] cycloadditions

[2]The ethyl ester analog of **1** dimerizes (90% yield) when generated in the presence of an excess of 2,3-dimethyl-1,3-butadiene (see ref. 5). Molecular Mechanics calculations using CSC Chem 3D plus™ software showed that while diene **1** was found to have a preferred (*E*)-(*s*)-*cis* conformation approximately 1.5 kcal/mol lowest in energy, 2-cyano-1,3-butadiene and 2,3-dimethyl-1,3-butadiene were more stable in their (*s*)-*trans* conformation by about 1 kcal/mol and 0.4 kcal/mol, respectively.

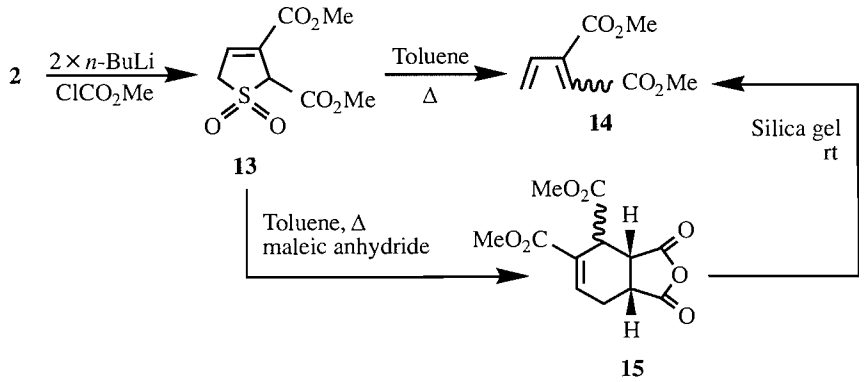

SCHEME 4

with electron-deficient dienophiles. Although we cannot draw conclusions, from our present studies, about the nature of this electronic effect, one possibility is that the cycloadditions of **1** with dienophiles proceed via a transition state (TS) having a high double-bond character between C2 and C3, such as was calculated for the reaction of butadiene with ethylene by Hehre and co-workers (14*a*) and Bach *et al.* (14*b*). Such a transition state could be stabilized due to conjugation with the ester group at C2. It is conceivable that the activation energy of such cycloadditions (from a cross-conjugated six-atom π-system in the starting diene to a conjugated four-atom π-system in the TS) may be lower than that of other cycloadditions involving dienes without a C2-conjugating group or other stabilizing effects (from a conjugated four-atom π-system in the starting diene to a non-conjugated two-atom π-system in the TS).

In any case, we have provided evidence that an electronic factor, at present unknown, is responsible for the activation of 2-carbomethoxy-1,3-butadiene. We believe that the above results could have far-reaching consequences for the theoretical aspect of the Diels–Alder reaction. We are initiating ab initio calculations of dienes like **1**, as well as extending the present studies to include other dienes, to gain a better understanding of the fundamental principles underlying their reactivity.

^{13}C magnetic resonance studies. 144.[1] An examination of β-enolization in the bicyclo[3.3.1]- and [3.2.2]nonan-2-one system

DAVID J. MUIR AND J.B. STOTHERS
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received February 8, 1993

DAVID J. MUIR and J.B. STOTHERS. Can. J. Chem. **71**, 1099 (1993).

While 3,3-dimethylbicyclo[3.3.1]nonan-2-one (**5**) is stable under strongly basic conditions (*t*-BuO$^-$/*t*-BuOH/185°C), its isomer, 3,3-dimethylbicyclo[3.2.2]nonan-2-one (**6**), is slowly transformed to **5**. Similarly, 3,3-dimethylbicyclo-[3.2.2]non-6-en-2-one (**8***b*) rearranges to a [3.3.1] isomer but the latter is not stable. Experiments with 3,3-dimethylbicyclo[3.3.1]non-6-en-2-one (**7**) revealed that it is converted to five compounds, none of which is **8***b*. The major product, 8,8-dimethylbicyclo[4.3.0]non-1$^{(6)}$-en-7-one (**11**) arises from β-enolate rearrangement. Enone **11** undergoes slow reduction to *cis*- and *trans*-8,8-dimethylbicyclo[4.3.0]nonan-7-one, presumably by single electron transfer. Experiments with **11** alone showed that β-enolate rearrangement of **7** → **11** is unidirectional. Haller–Bauer cleavage to acidic products occurs as a minor process in the reactions of the unsaturated ketones. The structures of the products were established primarily from their ^{1}H and ^{13}C magnetic resonance spectra.

DAVID J. MUIR et J.B. STOTHERS. Can. J. Chem. **71**, 1099 (1993).

Alors que la diméthyl-3,3-bicyclo[3.3.1]nonanone-2 (**5**) est stable dans des conditions fortement basiques (*t*-BuO$^-$/*t*-BuOH/185°C), son isomère la diméthyl-3,3-bicyclo[3.2.2]nonanone-2 (**6**) se transforme lentement en diméthyl-3,3-bicyclo[3.3.1]nonanone-2 (**5**). De la même façon, la diméthyl 3,3-bicyclo[3.2.2]nonèn-6-one-2 (**8***b*) se transpose en un isomère [3.3.1] instable. Des expériences révèlent que la diméthyl-3,3-bicyclo[3.3.1]nonèn-6-one-2 (**7**) se transforme en cinq composés parmi lesquels on ne retrouve pas le composé **8***b*. Le produit majoritaire, la diméthyl-8,8-bicyclo[4.3.0]nonèn-1$^{(6)}$-one-7 (**11**) provient d'une transposition β-énolate. L'énone **11** subit une lente réduction en *cis*- et *trans*-diméthyl-8,8-bicyclo[4.3.0]nonanone **7** probablement par simple transfert d'électron. Des expériences réalisées avec le composé **11** uniquement révèlent que la transposition β-énolate **7** → **11** est unidirectionnelle. Le clivage Haller–Bauer en produits acides intervient comme un processus mineur dans les réactions des cétones insaturées. On a établi la structure des produits principalement à partir de leurs spectres de résonnance magnétique nucléaire du ^{1}H et du ^{13}C.

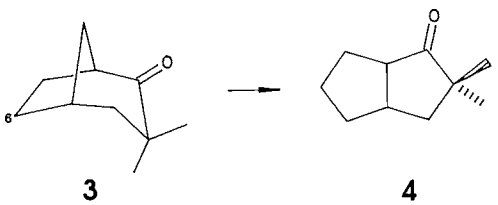
[Traduit par la rédaction]

Introduction

The discovery of the homoenolization process by Nickon and Lambert, who found that 3,3-dimethylbicyclo[2.2.1]-heptan-2-one (camphenilone) is racemized by treatment with strong base at elevated temperatures, *t*-BuO$^-$/*t*-BuOH/185°C (1), revealed that proton abstraction occurred from sites more than one bond from the carbonyl group. Their finding led to studies of several related polycyclic ketones of which the majority were found to exhibit abstraction from β-carbons, or β-enolization (2), with a few examples of γ-enolate formation (3). More recently, some examples of β-enolization in acyclic (4) and monocyclic systems (5) have been described. With few exceptions (6), α-enolization has been blocked in these homoenolizable ketones by α-methyl substitution or structurally such that only anti-Bredt α-enolates could form.

The β-enolization process may be viewed as the formation of a cyclopropoxide anion, e.g., **A** in Scheme 1, whose fate is governed by the regioselectivity of its subsequent protonation, via path *a* to return to the initial ketone or path *b* to form an isomeric ketone. The regioselectivity of the process has attracted some interest because of the potential utility for new synthetic approaches to carbon skeletons not readily accessible by other routes. Sequences in which a β-enolate rearrangement is a key step have been developed for linear and angular triquinanes (7) and a [3.3.3]propellane.[2] Since paths *a* and *b* may proceed with either retention or inversion of configuration, the stereoselectivity of protonation has mechanistic interest and may be established by isotopic labelling experiments.

The regio- and stereoselectivity of β-enolization has been examined in detail for several saturated bicyclic ketones. For example, the [2.2.2] and [3.2.1] ketones, **1** and **2**, are slowly equilibrated under the usual homoenolization conditions (8) while **3** rearranges slowly but irreversibly to **4** (9). It was also found that, under these conditions, Δ^5-**1** rearranged >100 times faster than **1** to a mixture of Δ^2- and Δ^3-**2**, with the equilibrium more strongly biased toward the [3.2.1] skeleton (10). Each of these reactions proceeds cleanly with little evidence of other products. In contrast, Δ^6-**3** is transformed to a mixture of six products, none of which is an unsaturated ketone (11). As an extension of these studies of simple bicyclic systems, we have examined the behavior of the related [3.3.1] and [3.2.2] ketones, **5**, **6**, **7**, and **8***b*, under typical homoenolization conditions. We wish to present the results of these experiments in this paper.



3 **4**

Results and discussion

Ketone **5** (12) was obtained by methylation (MeI/$NaNH_2$/Et_2O) of bicyclo[3.3.1]nonan-2-one prepared from cyclohexanone by the four-step sequence described by Inouye et al. (13). Following our standard methods (14), **5** was dissolved in anhydrous *t*-BuO$^-$/*t*-BuOH (1.00 M) to furnish a solution 0.25 M in **5**. Aliquots of this solution were rapidly transferred to glass tubes under nitrogen, degassed, and sealed

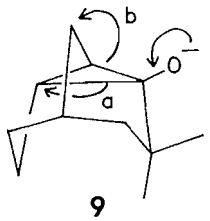
b R = Me

under vacuum. After heating at 185°C in an oil-bath for various times (24, 48, 112, 240 h), the tubes were cooled and the neutral product isolated by pentane extraction. The alkaline washings were acidified and extracted with ether to isolate any acidic product but none was found even after 240 h at 185°C. In all cases, **5** was the only component detected (glc and ^{13}Cmr) in the neutral fractions and was recovered in >85% yields.

Under the same reaction conditions, however, **6** was found to rearrange slowly to **5**. Neutral fractions (>85% yields) containing 56:44, 42:58, and 35:65 mixtures of **6**:**5** were isolated after 96, 192, and 240 h, respectively, with no evidence of acidic products. Ketone **6** was prepared by catalytic hydrogenation of **8***b*, obtained by α,α-dimethylation of **8***a*, which was generated by ring expansion of bicyclo[2.2.2]octenone as described in an earlier report (15).

Ketones **5** and **6** are, in principle, interconvertible through the β-enolate **9**, which can be generated by abstraction of a proton from C-8 in **5** and C-7 or -8 in **6**. Subsequent cleavage via paths *a* or *b* would led to **5** or **6**, respectively. The results above showed that **9**, or an equivalent species, is formed from **6**, but there was no evidence that **9** is generated from **5**.



To examine this point, **5** was treated with *t*-BuO$^-$/*t*-BuOD at 185°C for various times and the ^{2}H content of the recovered **5**-d_x samples was assayed by mass spectrometry and ^{2}Hmr. The ^{2}H spectra of samples collected after treatment for 3, 6, 12, and 24 h in the deuterated base contained only two signals indicating that exchange occurred at C-1 (δ 2.38) and the *exo*-methyl site (δ 1.13). Earlier work (16) had shown that bridgehead exchange occurs under milder conditions (101°C in NaOMe/MeOD) and the methyl assignment followed from previous studies, which established that *exo*-methyl exchange is significantly faster than that at *endo*-methyl sites

TABLE 1. Deuterium incorporation in **5** at 185°C

Time (h)	Atoms D/molecule[b]	% Exchange/hydrogen[a] H-1	*exo*-Methyl
3	1.12	0.89	0.08
6	1.33	0.90	0.14
12	1.67	0.90	0.25
24	2.20	0.88	0.44

[b]Determined by mass spectrometry.

in many related systems (2). From the proton spectrum of **5**, we can be certain that signals from other deuterated sites in **5**-d_x would not be obscured by the observed signals. The incorporation data are listed in Table 1. There was no evidence of proton abstraction from C-8 in **5**; thus, it must be a very slow process if, in fact, **9** is formed from **5**. An upper limit for a rate constant for C-8 exchange can be estimated to be ca. 10^{-7} s, which is an order of magnitude less than the observed rate for the **6** → **5** rearrangement. It may be noted that the ^{13}C spectra of the **5**-d_x samples confirm the ^{13}C assignments reported by Yamada et al. (12), since bridgehead (C-1) deuteration produced ^{2}H-induced isotope shifts of 125 and 111 ppb for the methylene signals at δ_C 29.5 (C-9) and 32.5 (C-8).

The fate of **7** under the homoenolization conditions was then examined. This ketone was prepared from bicyclo[3.3.1]nona-2,6-dione (17) through the sequence described by Bishop et al. (18), but using a modified procedure for ketalization of the dione (19). A series of runs (6, 12, 24, 48, and 72 h) gave neutral fractions (72–76% yields), containing five components after the longer reaction times, while small amounts of a single acidic component were obtained; the acid fraction represented 12% of the product after 72 h.

The ^{13}C spectra of the neutral products, isolated after 3 and 6 h, revealed two neutral components, in addition to **7**. Both were ketones and the more abundant contained a disubstituted double bond. Although attempts to isolate pure samples of this new ketone by column chromatography were unsuccessful, its ^{13}C shieldings strongly support structure **10**,

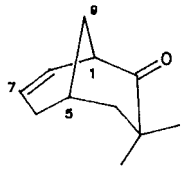
[a]In ppm from TMS in $CDCl_3$ solutions.

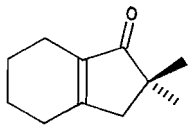
the Δ^7-isomer of **7**. The data are listed in Table 2 with those for **7** and **8***b*. The specific assignments for **7** followed from the results of $^1H\{^1H\}$ and $^{13}C\{^1H\}$ correlation spectra; the long-range $^{13}C\{^1H\}$ interactions of the methyl protons were found using the FLOCK sequence (20). For **10** and **7**, the shielding differences for the carbonyl and methine carbons are entirely consistent with isomerization of **7** to its Δ^7 isomer. The −6.2 ppm shift of the carbonyl signal in **10** relative to **7** is indicative of a homoconjugative interaction in a β,γ-enone (21) and the +4.6 and −3.6 ppm shifts for C-1 and -5, respectively, are as expected for this change in the position of the double bond. Since the allylic protons in **7** are the most acidic, equilibration of **7** and **10** may be anticipated under the strongly basic conditions and, in fact, the relative proportion of **7** and **10** was 3:2 in all of the neutral product mixtures.

The third ketone detected in the products from the shorter reaction times was readily isolated from the neutral mixture by chromatography on alumina. Its ^{13}Cmr spectrum contained signals for a tetrasubstituted double bond, δ_C 136.0 and 170.3, and a carbonyl carbon, δ_C 213.3, as well as those for five methylene carbons and a pair of equivalent methyl groups. The absence of methine signals clearly showed that a major skeletal change had occurred and the data indicated that this compound was **11**. The ^{13}C spectrum was the same as that of an authentic sample, prepared by 2,2-dimethylation of 4,5,6,7-tetrahydrindan-1-one (22); thus, the structural assignment was confirmed.

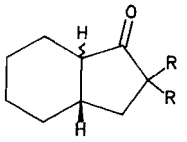
In the product mixtures from runs longer than a few hours, the presence of two additional compounds was apparent from glc analysis and ^{13}Cmr. Flash chromatography furnished a sample containing ca. 80% of these compounds and ca. 20% of a mixture of **7** and **10**. The ^{13}Cmr spectrum showed that these are ketones, δ_C 222.4 and 224.4, containing no olefinic carbons. There were signals for two methyl, five methylene, two methine, and one quaternary carbon for each of the two compounds. Identical sets of signals were found in the ^{13}C spectrum of the product from tetra-*n*-propylammonium per-ruthenate (TPAP) oxidation (23) of the alcohol mixture obtained by reduction of authentic **11** with lithium in liquid ammonia (24). Thus, these are the *cis* and *trans* isomers **12***b*. Specific ^{13}C assignments for the skeletal carbons of each isomer were made by comparison of the observed shieldings with the data for the parent ketones **12***a* (25). The ^{13}C data are collected in Table 3 from which it is evident that the methyl substituents have little effect on the shieldings of the methylene carbons in the six-membered ring. The synthetic sample was a 60:40 mixture of *cis*- and *trans*-**12***b*, while a 52:48 mixture was isolated from the runs with **7**.



10

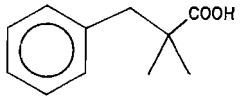


11



12

a R = H
b R = Me



13

The acidic fraction contained a single carboxylic acid that exhibited a remarkably simple ^1Hmr spectrum having two singlets in the high-field region, δ 1.23 (6H) and 2.92 (2H), accompanied by low-field absorption, 7.15–7.35 ppm (5H), characteristic of a phenyl group. The ir, ms, and ^1H and ^{13}Cmr data indicated that the acid was **13** and this assignment was confirmed by the synthesis of an authentic sample from hydrocinnamic acid.

The compositions of the products isolated from the experiments with **7** are listed in Table 4 as a function of time. Although **8***b* was not detected in the neutral mixtures from the runs with **7**, its behavior under homoenolization conditions was of interest. A series of experiments showed that **8***b* is transformed slowly to **7** and, thence, to its rearrangement products. The compositions of the neutral products isolated in 72–80% yields are collected in Table 5. The acidic fractions, constituting <5% of the product after the longer reaction times, contained a single component, **13**. It may be noted that the ratio of **7** to **10** was 3:2, as in the product mixtures from **7** itself.

A series of runs with **11** was also carried out and the results clearly showed that the major mode of reaction involved reduction to *cis*- and *trans*-**12***b* in *t*-BuO^-/*t*-BuOH at 185°C, together with a minor process leading to a relatively small acidic fraction. Both glc analysis and ^{13}Cmr showed that the neutral fractions contained only **11** and the **12***b* isomers; there was no evidence of the presence of **7** and (or) **10**. The product compositions after various reaction times are listed in Table 6.

The generation of the neutral product mixtures found for the unsaturated ketones may be interpreted as outlined in Scheme 2. Irreversible rearrangement of the [3.2.2] ketone

for ketones **19** (3) and **20** (11). It is interesting that the reduction of **20** (→ **21**) is faster than that observed for either **11** or **19** under these conditions. Both **11** and **19** (generated by γ-enolate rearrangement of **22**) are the primary rearrangement products whose concentrations increase in the early stages of reaction, before passing through a maximum and then decreasing as these are slowly consumed by reduction. In contrast, no unsaturated ketones were found as products from homoenolization of Δ^6-**3**, although **20**, or an isomeric enone, must be an intermediate in the generation of **21**, which is the major product from Δ^6-**3**.

In all experiments **13** was the only acidic product, presumably arising by dehydrogenation of **23**, or a double bond isomer. Haller–Bauer cleavage of **10**, after addition of *tert*-butoxide anion to the carbonyl carbon, would generate **23** (R = *tert*-butyl), a cyclohexenyl analog of **13**, as outlined in Scheme 3. Migration of the double bond in **23** should occur readily under these strongly basic conditions because of the acidity of the allylic protons; this is analogous to the observed equilibration of **7** and **10**. It is conceivable that hydride transfer to **11** from an intermediate cyclohexenyl anion could occur, thereby generating a cyclohexadienyl analog of **13**. Allylic proton abstraction from the latter species and subsequent hydride loss would lead to the formation of **13**.

In summary, the saturated [3.3.1] ketone **5** shows no tendency to rearrange to the [4.3.0] ring skeleton. Its unsaturated analog **10** undergoes this transformation, but, under the homoenolization conditions, the olefinic bond in the initial **8***b* via β-enolate **14**, or an equivalent species, affords **7**, which would be expected to equilibrate rapidly with **10** through a common allylic anion. Proton abstraction from C-9 in **10** could lead to the formation of β-enolate **15**, or an equivalent intermediate, which undergoes unidirectional cleavage to the [4.3.0] skeleton. This rearrangement is strictly analogous to that of **3** → **4** (9) but is significantly faster. The **3** → **4** conversion exhibited a half-life of ca. 60 h while more than 50% of the **7**:**10** mixture is consumed in less than 12 h (Table 4). While formation of an isomeric β-enolate from **7** may be envisaged, we suggest that this is less likely since **5** is stable under these conditions. In any event, it is clear that the incorporation of a double bond in the [3.3.1] skeleton enhances β-enolate formation. An analogous enhancement for **1** and **2** was noted in the Introduction. In principle, γ,δ-enone **16** or the β,γ isomer would be the initial product(s) from cleavage of **15** and, under the basic conditions, can be expected to isomerize rapidly. Only α,β-enone **11** was identified among the products, but traces of other isomers may have escaped detection.

The formation of the saturated ketone **12***b* clearly shows that **11** undergoes slow reduction. We propose that single electron transfer from the *tert*-butoxide anion to the carbonyl carbon of **11** to generate ketyl **17** or homolysis of the addition product **18** are the most probable intermediates in this process. Similar reduction processes have been observed

rearrangement product **11** is subsequently reduced to furnish the saturated [4.3.0] system as the end product.

Experimental

Boiling points and melting points are uncorrected. Gas–liquid chromatography (glc) was done with Varian 940 or 3300 instruments using 1/8-in. columns of OV-101 (10 ft, 1.5% and 6 ft, 5%, respectively) on Chromosorb G. Tetrahydrofuran (THF) and ether were dried over sodium/benzophenone and freshly distilled before use.

Infrared spectra were recorded with a Bruker/IBM FTIR instrument. Mass spectral data were obtained with a Finigan MAT 8230 spectrometer at 70 eV for routine spectra and 20 eV for precise mass measurements. The nmr spectra were recorded with Varian Gemini-200, XL-200, or XL-300 instruments, with digital resolution of 0.1 (^{1}H) and 0.6 Hz (^{13}C). The protonation level for each carbon signal was found from APT or DEPT spectra. Assignments for the sp^3 carbon signals were aided by $^{13}C\{^1H\}$ correlations. Comparisons of the intensities of clearly resolved signals (CH_3 vs. CH_3 and CH_2 vs. CH_2) permitted estimation of the compositions of some product mixtures. The HETCOR sequence of the Varian software with 2048 × 512 data point matrices was used to show one-bond interactions and the FLOCK sequence (20) to identify longer range interactions. The HOMCOR sequence of the Varian software was used to record $^1H\{^1H\}$ COSY-45 spectra with 1024 × 1024 data matrices.

Materials

The parent ketones required to prepare the reactants for these experiments were obtained by published procedures. The four-step sequence from cyclohexanone employed by Inouye et al. (13) gave bicyclo[3.3.1]nonan-2-one, which was methylated in 67% yield, as described below, to furnish **5** (12). Bicyclo[3.3.1]nona-2,6-dione was obtained from Meerwein's ester as reported by Lightner et al. (17) and monoketalized, as described by Momose et al. (19). Then, with minor modifications, the sequence employed by Bishop et al. (18) was followed. The carbonyl group was reduced and the hydroxyketal treated with *p*-toluenesulfonyl chloride. Elimination of the tosyl group by refluxing in pyridine and deketalization with *p*-TsOH furnished bicyclo[3.3.1]non-6-en-2-one. Ring expansion of bicyclo[2.2.2]otenone by ketonization of its cyclopropanated silyl enol ether gave bicyclo[3.2.2]non-6-en-2-one (**8***a*) (15).

General procedure for the α,α-dimethylation of the bicyclic ketones

To a stirred suspension of freshly powdered $NaNH_2$ (30 mmol) in dry ether (5 mL) was added a solution of the ketone (5 mmol) in dry ether (5 mL) and the mixture heated under reflux for 2 h with vigorous stirring. The mixture was cooled and methyl iodide (30 mmol) was added slowly before the mixture was refluxed for 16 h, at which time a second addition of methyl iodide (10 mmol) was made. After a reflux period of 3 h, the mixture was cooled to 0°C and the excess $NaNH_2$ destroyed by the addition of cold water (20 mL). The ether layer was separated and the aqueous phase extracted with ether (2 × 25 mL). The combined extracts were washed with brine before drying over anhydrous $MgSO_4$. Evaporation of the solvent afforded the desired dimethylated ketone. The purification method, yield, and physical data for each product are listed below.

3,3-Dimethylbicyclo[3.3.1]non-6-en-2-one (7): isolated in 85% yield by flash chromatography (fc) with hexane as eluent; ir (liquid film): 1700 m^{-1}; ^{13}Cmr ($CDCl_3$) see Table 2; ^{1}Hmr ($CDCl_3$) δ: 1.11 (s, 3H, Me), 1.08 (s, 3H, Me), 1.77 ("dt," 1H, J = 13.8, 2.5 Hz, *endo*-H-4), 1.84 (dd, 1H, J = 5.3, 13.8 Hz, *exo*-H-4), 1.90 (bd, 1H, J = 12 Hz, *anti*-H-9), 2.00 (bd, 1H, J = 12 Hz, *syn*-H-9), 2.12 (bd, 1H, J = 18 Hz, *endo*-H-6), 2.34 (bd, 1H, J = 18 Hz, *exo*-H-6), 2.45 (m, 1H, H-5), 2.65 (m, 1H, H-1), 5.64 (m, 1H, H-7), 5.78 (m, 1H, H-8). Exact Mass calcd. for $C_{11}H_{16}O$: 164.1202; found: 164.1203.

3,3-Dimethylbicyclo[3.2.2]non-6-en-2-one (8b): isolated in 73% yield by fc (hexane – ethyl acetate, 95:5) and slowly crystallized on standing to a waxy solid that sublimed readily at room temperature to provide an analytical sample; mp 38–39°C; ir ($CHCl_3$): 1694 cm^{-1}; ^{13}Cmr ($CDCl_3$): see Table 2; ^{1}Hmr ($CDCl_3$) δ: 1.14 (s, 3H, Me), 1.16 (s, 3H, Me), 1.6–1.95 (m, 6H), 2.64 (m, 1H, H-5), 3.17 (m, 1H, H-1), 6.0 (bdd, 1H, J = 7, 8 Hz, H-6), 6.35 (bt, 1H, J = 8 Hz, H-7). Exact Mass calcd. for $C_{11}H_{16}O$: 164.1202; found: 164.1200.

3,3-Dimethylbicyclo[3.2.2]nonan-2-one (6)

To a solution of **8***b* (254 mg) in ethyl acetate (10 mL) was added palladium on activated carbon catalyst (10% Pd, 70 mg) and the mixture placed in a Parr hydrogenation bottle. Then the bottle was filled to 58 psi (1 psi = 6.9 kPa) with hydrogen before shaking for 30 min at room temperature. The mixture was filtered and the solvent evaporated to furnish **6** quantitatively; ir (liquid film): 1692 cm^{-1}; ^{13}Cmr ($CDCl_3$) δ_C: 30.8 $(CH_3)_2$, 21.8 (2), 24.8 (2), 45.1, (5 × CH_2), 29.4, 46.6 (2 × CH), 45.0 (quat C), 220.1 (C=O); ^{1}Hmr ($CDCl_3$) δ: 1.18 (s, 6H, Me_2), 1.6–1.8 (m, 8H), 2.17 (m, 1H, H-5), 2.58 (m, 1H, H-1). Exact Mass calcd. for $C_{11}H_{18}O$: 166.1358; found: 166.1360.

For the homoenolization experiments, samples were chromatographed over silica before use.

8,8-Dimethylbicyclo[4.3.0]non-1(6)-en-7-one (11)

To diisopropylamine (0.6 mL) in 12 mL of THF at −60°C was added *n*-butyllithium (1.5 mL, 2.5 M in hexane) and the mixture stirred for 10 min. Then, 4,5,6,7-tetrahydrohydrindan-1-one (360 mg) (22) was added and the mixture stirred for 10 min before methyl iodide (0.5 mL) was added and stirring was continued for 15 min. The mixture was then poured into 1 M HCl solution (25 mL) and the product was isolated by ether extraction. After a second methylation cycle, the product was purified by column chromatography on silica to give **11** (390 mg, 89% yield); ir (liq. film) 1649, 1698 cm^{-1}; ^{13}Cmr ($CDCl_3$) δ_C: 25.3 $(CH_3)_2$, 20.2, 21.8, 22.3, 28.4, 47.2 (5 × CH_2), 43.2 (quat C), 135.9, 170.2 (C=C), 213.2 (C=O); ^{1}Hmr ($CDCl_3$) δ: 1.06 (s, 6H, $(CH_3)_2$), 1.55–1.75 (m, 4H), 2.03–2.13 (m, 2H), 2.22–2.28 (m, 2H), 2.29–2.34 (m, 2H, H-9). Exact Mass calcd. for $C_{11}H_{16}O$: 164.1202; found: 164.1200. This compound was identical to one of the products from the homoenolization experiments with **7**.

cis- *and* trans-*8,8-Dimethylbicyclo[4.3.0]nonan-7-one (12*b*)*

Following the procedure of House et al. (24), a solution of enone **11** (35 mg) in THF (2 mL), containing *tert*-butyl alcohol (40 μL), was added to a cold (−78°C) solution of lithium (6 mg) in ammonia (4 mL). After the addition, the cold-bath was removed and the mixture allowed to reflux for 2 h. The reaction was quenched by the addition of water (2 mL) and the ammonia was allowed to evaporate before water (10 mL) and ether (10 mL) were added. The organic layer was separated and the aqueous phase extracted twice with Et_2O (10 mL). The solvent was evaporated and the residual oil (34 mg) was oxidized directly by the addition of *N*-methylmorpholino-*N*-oxide (35 mg) in CH_2Cl_2 (10 mL) with

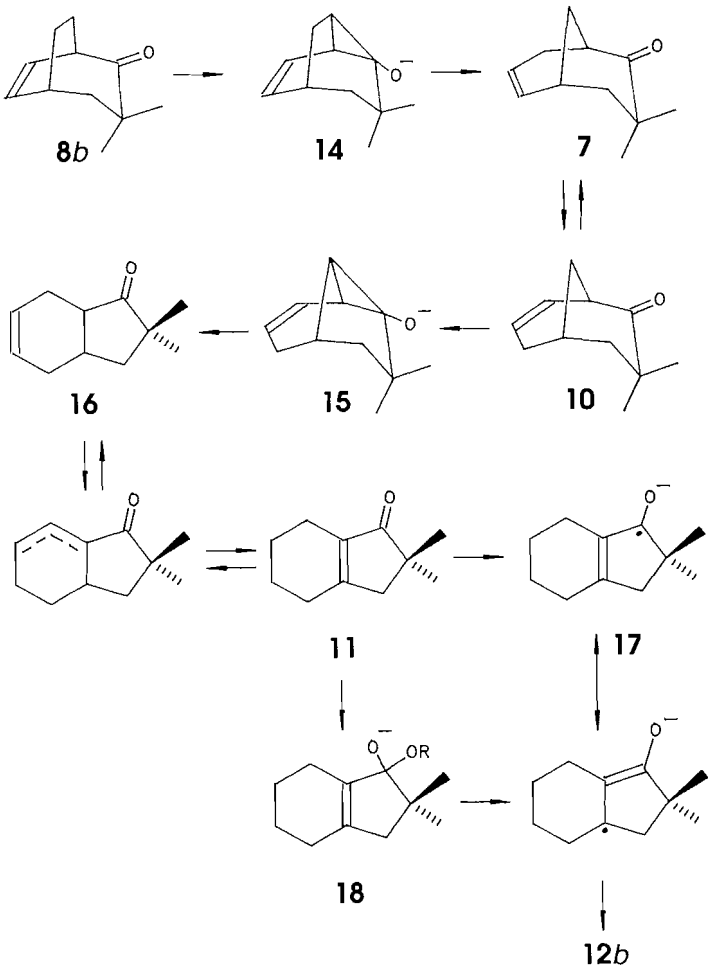
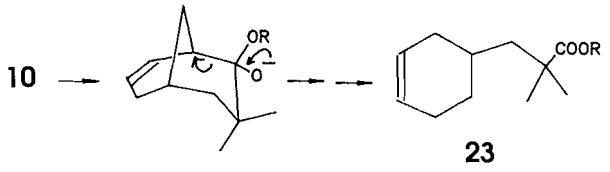


SCHEME 2



SCHEME 3

1 mg of tetra-*n*-propyl ammonium per-ruthenate (23). This reaction mixture was allowed to stand for 0.5 h before dilution with 20 mL of CH_2Cl_2. The solution was washed with 15 mL of each of saturated aqueous Na_2SO_3, brine, saturated aqueous $CuSO_4$, and brine before drying over anhydrous $MgSO_4$. Evaporation of the solvent left an oil (28 mg, 79% overall yield), which by ^{13}Cmr and glc was a 60:40 mixture of the desired *cis*- and *trans*-**12***b*; ir (liquid film): 1738 cm^{-1}; ^{13}Cmr ($CDCl_3$): see Table 3. Exact Mass calcd. for $C_{11}H_{18}O$: 166.1358; found: 166.1366 (*cis* isomer), 166.1353 (*trans* isomer); these data were obtained by gc/ms using a 30-m capillary column coated with DB-5.

2,2-Dimethyl-3-phenylpropanoic acid (13)

Methyl hydrocinnamate (500 mg) was methylated as described above for **11** (diisopropylamine (0.5 mL), THF (12 mL), n-BuLi (1.8 mL, 2.5 M in hexane), methyl iodide (0.5 mL). After a second methylation cycle, the methyl ester of **13** (550 mg, 94% crude yield) was isolated. The crude ester (37 mg) was heated in 3 M NaOH solution at 80°C for 5 h. The reaction mixture was extracted with ether (2 × 50 mL) and the aqueous phase acidified to pH 2 before extraction with ether (3 × 50 mL). After drying over $MgSO_4$, the solvent was removed to yield **13** (28 mg, 82%) with the following properties: ir (liquid film): 2400–3400, 1701 cm^{-1}; ^{13}Cmr ($CDCl_3$) δ_C: 24.7 (2 × CH_3), 45.9 (CH_2), 43.5 (quat C), 126.6, 128.1 (2), 130.3 (2) (5 × aryl CH), 137.6 (aryl C), 184.5 (COOH); ^{1}Hmr ($CDCl_3$) δ: 1.23 (s, 6H, Me_2), 2.92 (s, 2H, H-3), 7.15–7.35 (m, 5H, aryl H). Exact Mass calcd. for $C_{11}H_{14}O_2$: 178.0994; found: 178.0996.

Received July 1, 1992[2]

JANUSZ RAK, JERZY BŁAŻEJOWSKI, and RANDY J. ZAUHAR. Can. J. Chem. **71**, 1106 (1993).

Relative stabilities and features of tautomers of *N*,*N*-dimethyl-*N'*-(1-nitro-9-acridinyl)-1,3-propanediamine (known as nitracrine by the World Health Organization (WHO) or as Ledakrin in Poland), which exhibits antitumour activity, and its three nitro isomers were examined by AM1 and, in some cases, by PM3 and ab initio (STO-3G) methods. The lowest energy form of three compounds was always an imino tautomer, while the energy of the amino tautomers was a few kcal mol^{-1} higher and that of the *aci* forms (in the case of the 2- and 4-nitro isomers) was more than 25 kcal mol^{-1} higher. Each tautomer can further exist in several structural forms (conformers or stereoisomers). In some of them internal hydrogen bonding interactions are feasible. The barriers to rotation of the -NHR group, as well as to inversion of the -NHR group (in amino tautomers of nitracrine and its 2-nitro isomer) and of the whole molecule (in the case of non-planar imino structures), were also evaluated, as were enthalpies of formation (total energies), entropies, free energies, dipole moments, and energies of HOMO and LUMO orbitals. Molecular electrostatic potential maps reveal that only in nitracrine are both $-NO_2$ and -NHR groups surrounded by a negative electrostatic potential, whereas in other isomers the -NHR fragment is surrounded by a positive electrostatic potential while the $-NO_2$ group remains in the region of a negative electrostatic potential. The possible influence of physicochemical features on the biological activity of the molecules is also considered.

JANUSZ RAK, JERZY BŁAŻEJOWSKI et RANDY J. ZAUHAR. Can. J. Chem. **71**, 1106 (1993).

Faisant appel à des méthodes AM1 et, dans quelques cas, à des méthodes PM3 et ab initio (STO-3G), on a étudié les stabilités relatives et les caractéristiques des tautomères de la *N*,*N*-diméthyl-*N'*-(1-nitro-9-acridinyl)-propane-1,3-diamine (nitracrine — OMS ou Ledakrin en Pologne), qui présente une activité antitumorale, et trois de ses isomères nitrés. Dans ces composés, la forme d'énergie minimale est toujours un tautomère imino. L'énergie des tautomères amino est toujours quelques kcal mol^{-1} plus élevée alors que celle des formes *aci* (dans les cas des isomères 2- et 4-nitro) est plus de 25 kcal mol^{-1} plus élevée. Chaque tautomère peut ensuite exister sous plusieurs formes structuralement différentes (conformères ou stéréoisomères). Dans quelques-unes d'entre elles, il est possible d'avoir des liaisons hydrogènes internes. On a aussi évalué les barrières à la rotation interne du groupe -NHR et à l'inversion du groupe -NHR (dans les tautomères animés de la nitracrine et de son isomère 2-nitro) et de la molécule complète (dans le cas des structures imino non-planaires) ainsi que les enthalpies de formation (énergies totales), les entropies, les énergies libres, les moments dipolaires et les énergies des orbitales moléculaires OH et BV. Les cartes de potentiel électrostatique moléculaire révèlent que seule la nitracrine contient des groupes $-NO_2$ et -NHR entourés par un potentiel électrostatique négatif; dans les autres isomères, le fragment -NHR se trouve dans la région d'un potentiel électrostatique positif alors que le fragment $-NO_2$ demeure dans la région d'un potentiel électrostatique négatif. On considère aussi la possibilité d'une influence des caractéristiques physicochimiques sur l'activité biologique des molécules.

[Traduit par la rédaction]

Introduction

Nitracrine, i.e., *N*,*N*-dimethyl-*N'*-(1-nitro-9-acridinyl)-1,3-propanediamine, belongs to the family of 9-acridinamine derivatives which have been intensively investigated over the last few decades by Ledóchowski and others, from the point of view of their utility as anticancer agents (1). Of several hundred compounds synthesized, only nitracrine was found to exhibit antitumour activity and has been successfully used as a drug in Poland (1–3). Recent work has also shown the compound to have a range of other biological activities (4, 5). Efforts devoted to syntheses have been accompanied by complementary studies of the structure (6–10), properties (1, 11–14), and mechanism of the biological action (1, 4, 5, 15–25) of nitracrine and other compounds. X-ray analyses revealed that the monohydriodide of nitracrine, in which protonation takes place at N(36), crystallizes into the imino form (**1**), a characteristic of which is that H(25) migrates from exocyclic to endocyclic nitrogen. In this structure, moreover, the central ring system is folded at an angle along the C(9)...N(10) axis and the nitro group is tilted with a torsion angle of ca. 60° to atoms in the acridine ring (1, 6, 7). On the other hand, the 2-nitro isomer exists as a planar amino tautomer (**2**), with coplanarity between the acridine nucleus and the nitro group (8, 9). Since only nitracrine exhibits enhanced antineoplastic activity and its 2-nitro isomer does not (1, 15, 16), it would suggest that the imino tautomeric structure, which in the case of nitracrine could be forced by steric overcrowding, is the one responsible for its unique biological properties (10). The prototropic tautomerism whose consequence is the transformation between amino and imino structures is a general phenomenon characteristic of 9-acri-

dinamines (5, 9, 10, 26–29). We have studied this problem in the case of 9-acridinamine (30), as well as for both neutral nitracrine and its isomers (31, 32) and protonated forms of the compounds (32, 33), employing UV absorption (31–33) and luminescence (32, 33) techniques, as well as theoretical methods (30, 31). This work is devoted to detailed studies on the structural features, behaviour, and physicochemical properties of nitracrine and its nitro isomers, with regard to tautomeric phenomena, employing AM1, PM3, and ab initio (STO-3G) methods. The electrostatic potential around the molecules was also analyzed to show sites of potential specific interactions and to facilitate insight into the origin of these interactions, as well as into the nature of metabolic transformations.

Molecular orbital calculations have proved useful in studies of tautomeric phenomena (34–36). The systems investigated were relatively large; therefore we chose the semiempirical AM1 method, which has recently been used very successfully when examining structure, energetics, and properties of various tautomeric forms (36–39). It also correctly reproduced tautomeric equilibria in several systems (36, 37, 40, 41). Selected structures primarily optimized with AM1 were subsequently reexamined on the level of PM3 and ab initio (STO-3G) methods.

Methods

MO calculations

The molecules were modelled using SYBYL Molecular Modelling Software, Version 5.2 (provided by TRIPOS Associates, Inc.). Their geometries were then optimized, by minimizing the energy with respect to all internal coordinates (without any symmetry constraint), employing the semiempirical AM1 method (42) (incorporated in MOPAC, version 6.0 (43)) (the calculations were carried out using the "precise" option to provide the strictest convergence criterion (44)). Selected structures thus established were subsequently reoptimized employing PM3 (45) (incorporated in MOPAC) and ab initio (considering all electrons) STO-3G (46, 47) (incorporated in HONDO (48), version 8.1) methods. The rotation of the -NHR fragment around the C(9)—N(23) bond in the amino tautomer of nitracrine and its 2-nitro isomer was examined by maintaining the dihedral angle C(14)C(9)N(23)C(24), describing the position of the -NHR group relative to the acridine moiety, at a certain value and completely optimizing the remaining structural parameters of the molecules. The geometries and energies of molecules in the transition state for the rotation or inversion were studied combining the following three procedures: *saddle point* geometry estimation (49), gradient minimization at the *saddle point* (NLLSQ (43)), and evaluation of the force constants (43), and always afforded a single negative frequency for the molecule in the transition state. The MOPAC and HONDO routines were used to evaluate heats of formation (total energies), entropies, dipole moments, and energies of HOMO and LUMO orbitals (all thermochemical quantities refer to 298 K).

Molecular electrostatic potential (MEP)

The most "accurate" value of the electrostatic potential around a molecule is presumably obtained by applying the SCF procedure to the electronic wave function and combining the result with the core potential. However, at distances greater than 4 Å (sometimes even at 2–3 Å) it is very well represented by a point charge potential (50–52). In this latter case MEP (V_i) at a given site i around the molecule is given by the formula:

$$[1] \quad V_i = \frac{1}{4\pi\epsilon_0} \sum_{j=1}^{n} \frac{q_j}{r_{ij}}$$

where ϵ_0 is the permittivity of free space, q_j represents the net charge at atom j of the molecule, r_{ij} is the distance between atom j and site i, and n denotes the number of atoms in the molecule (51, 52). If point charge q_i is present at site i, the energy of electrostatic interaction between this charge and a molecule is equal to q_iV_i. Three-dimensional (3-D) MEP maps show equipotential surfaces that correspond to an electrostatic interaction energy of $|2|$ kcal mol^{-1} for a unit positive test charge. The two-dimensional (2-D) MEP maps, corresponding to the mean plane of the molecules, present lines that are sets of points of constant values of electrostatic energy. For V_i calculations, generally, net atomic charges corresponding to the lowest energy structures obtained from optimization with AM1 were used (Table 5 in the Supplementary material; see footnote 3).

It was proved that charges obtained by other semiempirical quantum chemistry methods (INDO, CNDO, MNDO) afforded MEP almost identical to that mentioned above. Moreover, it is shown for one chosen molecule that MEP obtained from AM1 atomic point charges corresponds quite well to MEP calculated from ab initio Mulliken point charges, as well as atom-centered charges obtained by fitting them, in a least-squares sense, to the electrostatic potential resulting from the electronic wavefunctions, relevant to the points on the van der Waals type surfaces around molecules (for the latter purpose the ESP routine, incorporated in MOPAC 6.0, was applied).

The calculations were done on Hewlett–Packard model 730 and VAX model 3600 computers.

Results and discussion

Geometry of isolated molecules

Nitracrine and its 3-nitro isomer can potentially exist in two tautomeric forms, amino and imino (e.g., **2** and **1**), whereas 2-nitro and 4-nitro isomers can also exist in a third *aci* form (e.g., **3**) (31). All the molecules investigated are asymmetrical. Thus, several conformers or stereoisomers can usually be considered for a given tautomeric form. They result from various possible arrangements of the -NHR and -NO_2 groups on the acridine skeleton, which may itself be expected to be nearly planar in amino and *aci*, and nonplanar in imino, tautomers. The alkyl chain can admit open

[3]Supplementary material available: Tables 3 and 4 in which are compared Z matrices of nitracrine (imino tautomer) and its 2-nitro isomer (amino tautomer), respectively, resulting from the AM1 geometry optimization with those obtained from the crystallographic data; Table 5 in which the AM1 net atomic charges for the lowest energy amino and imino structures are presented. These tables may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of bond lengths and angles (Tables 3 and 4) have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

conformation (type A; Figs. 1–5 and Table 1) or a conformation in which H(25) and N(36) are involved in the internal hydrogen bond (type AH). It appears suitable to consider only two types of the former conformation, which result from the rotation of the whole open chain around the N(23)—C(24) bond. When the internal H-bond appears in the -NHR group, it is worthwhile also considering two types that differ in the arrangement of the six-membered ring system formed relative to the acridine moiety and that can be transformed into each other by rotating the whole chain again around the N(23)—C(24) bond. The -NHR fragment can be located either perpendicular to the acridine ring, in two positions with a lone electron pair at the nitrogen atom directed either towards or away from the ring with the attached nitro group, or in the plane of the acridine moiety, allowing this group to again assume two arrangements relative to the nitro group. The analysis regarding rotation of the -NHR fragment revealed that it is worthwhile considering eight various amino conformers for each isomer (four of type A and four of type AH). The number of structures considered in the case of each imino tautomer was always four and resulted from the nonplanarity of the central ring system and mutual arrangement of H(25) and the substituent at N(23) relative to the nitro group. However, only two boundary structures appear to be stable. In the case of the *aci* tautomer of 2-nitro and 4-nitro isomers the number of structures originally created was eight, considering possible arrangements of the -NHR group relative to the *aci*-nitro group. In this case it appears worthwhile to consider only four structures for the 2-nitro isomer and six for the 4-nitro isomer (since in the latter case the *aci*-nitro group can be additionally engaged in the hydrogen-bonding interactions with the endocyclic nitrogen). Finally, two *aci*-anion structures were considered for each isomer mentioned, since these species were previously found in strongly alkaline media. Altogether, the 54 structures seem to represent the most probable conformers and (or) stereoisomers of various possible forms of the compounds studied. These are listed in Table 1 and some of them are shown in Figs. 1–5. The total number of structures subjected to geometry optimization was over 100.

Quantum chemistry methods predict an almost planar acridine skeleton in amino tautomers, particularly if the alkyl chain admits open conformation (Table 2). In all imino tautomers the central ring system is folded along the C(9)...N(10) axis, and the whole skeleton is nonplanar. In *aci* and *aci*-anion forms of C-264 and C-265 the central ring system shows less deviation from planarity than in the case of the corresponding imino structures. Generally speaking, C-283 seems to have the most deformed skeleton among the molecules studied.

The nitro group is almost planar to the neighbouring benzene ring in all forms of C-264 and C-257, also the nitro group in the imino and *aci* tautomers of C-265 is only slightly distorted from planarity with the acridine moiety. Remarkable distortion from such planarity is seen in all forms of C-283, as well as in the amino and *aci*-anion forms of C-265, although the $-NO_2$ group is more twisted in the C-283 than in the C-265 forms. Distortion of C-283 from planarity and deformation of the whole molecule is mostly due to steric overcrowding and interaction of the electronegative $-NO_2$ group with negatively charged nitrogen(s) of the -NHR fragment situated near each other in *peri* positions (for charge distribution see Table 5 in the Supplementary material). In C-265 the steric effect may be expected to be less essential. The lone electron pair at N(10), being in a *peri* position relative to the nitro group, however, causes a strong electrostatic repulsive interaction whose consequence is the distortion of this group from planarity with the acridine moiety in the amino and *aci*-anion forms.

The AM1 method predicted that the most stable form of 9-acridinamine should be one with the amino group planar to the aromatic ring (30). If the -NHR fragment were situated to enable the strongest conjugation between the lone electron pair at N(23) and the acridine aromatic system, the C(11)C(9)N(23)C(24) angle would be equal to ca. 30°. Because of steric hindrances in nitracrine and its isomers caused by the substituent at N(23), the amino group is always twisted against the acridine nucleus (Table 2).

The substituent at N(23) of the imino and *aci* tautomers is always directed away from the concave side of the acri-

dine nucleus folding, and hydrogen (25), in the imino forms, lies on the line connecting C(9) and N(10).

To learn how far structures obtained by AM1 optimization correspond to crystal phase structures, we compared appropriate *Z* matrices for the C-283 (imino form) and C-264 (amino form) molecules (Tables 3 and 4 in the Supplementary material). For this comparison the theoretically derived structures that seemed to be closest to the solid phase struc-

tures were chosen. Bond lengths are usually shorter in the crystal phase than those predicted for isolated molecules. Bond angles and dihedral angles are comparable for isolated molecules and for those forming a lattice, except for the parts concerning the arrangement and structure of the alkyl substituent. For the C-283 imino tautomer the AM1 method predicts a completely extended conformation of the alkyl chain, whereas in the crystal phase the chain is folded, adopting the most favourable structure for the crystal packing (1, 6, 7, 53). In the case of the C-264 amino tautomer, formation of the internal hydrogen bond forces almost the same configuration of the whole -NHR fragment in both the isolated molecule and the crystal phase, except for its arrangement relative to the acridine nucleus. The lowest energy conformation of the isolated molecule is such that the amino group is almost perpendicular to the acridine moiety, and the lone electron pair at N(23) is directed towards the nitro group (Figs. 1–5), whereas in the crystal phase, packing of the molecules produces a conformation in which the N(23)C(24)C(30)C(33)N(36)H(25) ring is situated almost in the plane of the acridine nucleus, thus creating the minimal volume for the whole molecule (8, 53). In this latter structure the lone electron pair at N(23) is directed away from the nitro group. Despite the differences mentioned, comparison reveals that the AM1 method provides correct structural information for the compounds studied.

A similar conclusion arises from comparison of PM3 and STO-3G optimized geometries with those for the crystal phase.

Intramolecular hydrogen bonding interactions

The presence of proton donor (=NH, -OH) and proton acceptor (≡N, -NO_2) sites in the molecules creates an opportunity for the formation of internal hydrogen bonds.

A hydrogen bond involving H(25) and N(36) occurs in the C-264 amino tautomer, forming the crystalline phase (8). Such a hydrogen bond is possible in the case of all amino tautomers and requires a particular arrangement of the alkyl substituent. The distances between the atoms forming this bond are rather typical for weak hydrogen-bond-type interactions (Table 2). The structures with the alkyl chain involved in the internal hydrogen bond usually exhibit lower enthalpies of formation than the relevant open chain conformations (this is not actually seen in the case of C-283) (Table 1). The former are, therefore, more stable from the energetic point of view. On the other hand, the entropy factor acts in favour of open chain structures. The result is that free energies (ΔG_f) exhibit a reverse tendency in comparison with that observed for ΔH_f values, i.e., they are lower for the open chain structures. Differences in ΔH_f and ΔG_f values for various A and AH type structures of a given isomer are, however, rather small, which means that all of these structures may be expected.

Quantum chemistry methods also predict the existence of a hydrogen bond between H(25) and one of the oxygen atoms of the nitro group. Such a hydrogen bond has been considered in 1-nitro-9-acridinamine (29). The H(25)···O(26) bond appears in both structures of nitracrine having an open alkyl chain, and in those in which a bifurcated hydrogen bond is

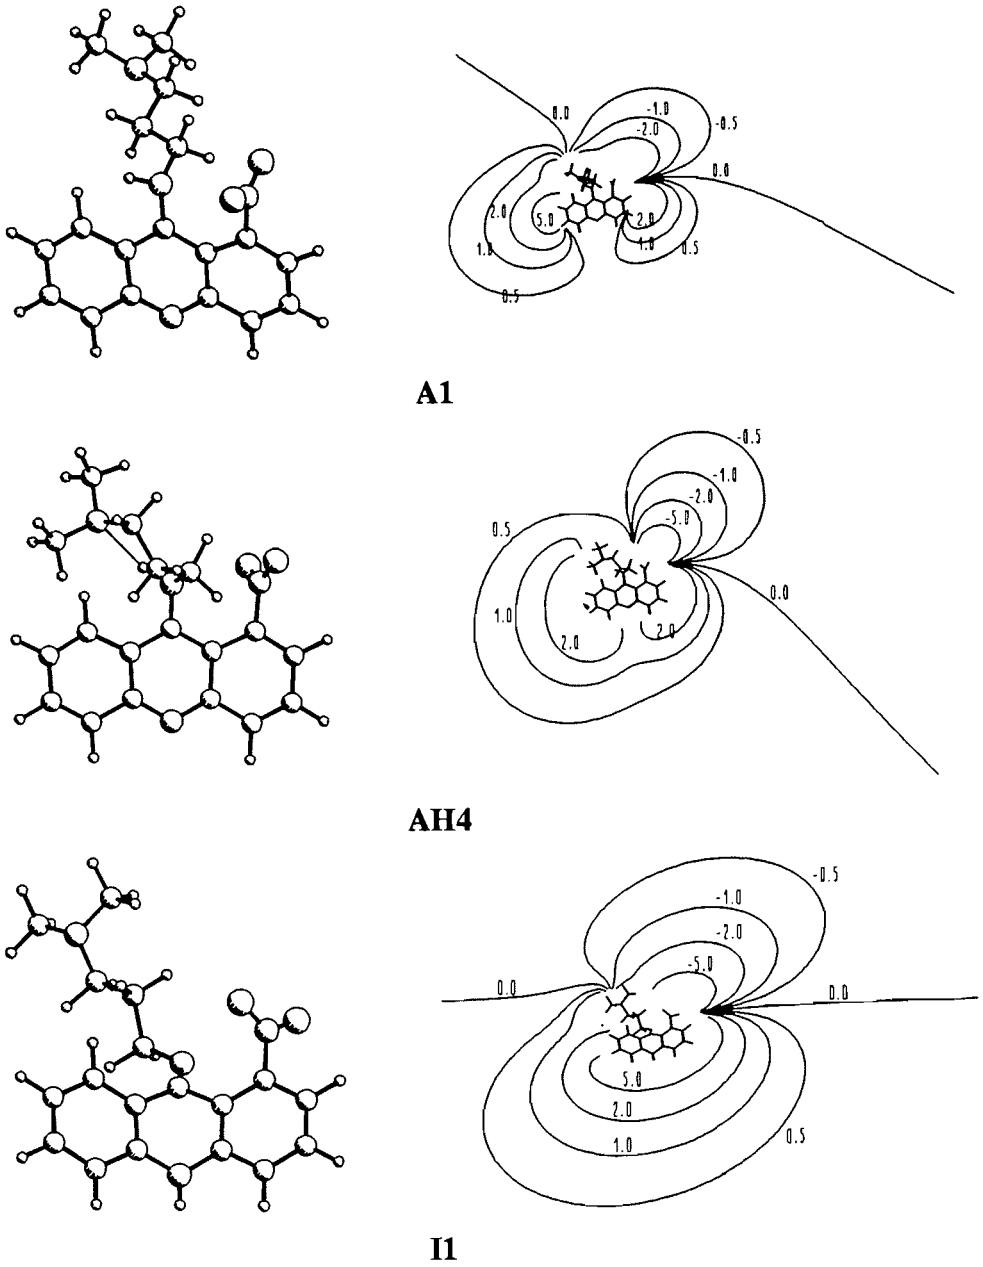

FIG. 1. AM1 geometry of the lowest energy tautomeric forms of nitracrine (thin line indicates hydrogen bond) together with the 2-D maps of MEP.

formed (Figs. 1 and 5). The H(25)···O(26) distance (Table 2) is fairly characteristic for weak hydrogen-bonding interactions. Moreover, the thermochemical characteristics (ΔH_f, ΔG_f) (Table 1) do not favour structures for which this bond is predicted.

An intramolecular hydrogen bond is further predicted in the imino tautomer of C-265 between H(25) attached to the endocyclic nitrogen and one of the oxygen atoms of the nitro group (Fig. 4). Its existence accounts for the relatively strong energy stabilization of the imino structures of C-265 (Table 1). Furthermore, this bond presumably causes the nitro group in the imino form to be much less distorted from planarity with the aromatic system than that in the amino forms of C-265 (Table 2).

Lastly, the intramolecular hydrogen bonds may occur within the *aci*-nitro group in *aci* tautomers of C-264 and C-265 (Figs. 2, 4, and 5) and also between the endocyclic nitrogen and hydrogen of the *aci*-nitro group in C-265 (Fig. 1). Since the energetic factor excludes the existence of molecules in *aci* forms we did not consider further details concerning these latter hydrogen-bonding interactions.

The AM1 method, primarily employed in this work, has been used with success in several hydrogen-bonding studies (42, 54, 55), although it often underestimates hydrogen-bonding interactions (39, 42, 56). It may be, therefore, that all hydrogen bonds discussed above are in reality thermodynamically more stable. This seems to be confirmed by the results of the ab initio (STO-3G) calculations (Table 1).

Structural transformations

The spatial arrangement of atoms is undoubtedly an important factor accounting for the biological activity of molecules. Knowledge of the lowest energy structures may be

insufficient if the possibility of them being transformed to somewhat higher energy stable states (corresponding to local minima) exists. Information in Table 1 reveals that such structures can actually occur. Various states can first of all be achieved as a result of rotation of the -NHR fragment, in amino tautomers, and inversion of the whole molecule, in the case of imino tautomers.

The energy changes upon rotation of the -NHR group in C-283 and C-264 are shown in Figs. 6 and 7. Rotation of the -NHR fragment is always accompanied by inversion at N(23), in both nitracrine and C-264 and, in addition, by rotation around the N(23)—C(24) bond in the case of C-264. The highest barrier to rotation of the -NHR group in C-264, determined by AM1, is equal to 5.6 kcal mol^{-1} and is most probably a consequence of the loss of conjugation between the lone electron pair at N(23) and the acridine aromatic system rather than a steric effect (30). In the case of nitracrine the highest energy barrier is equal to 10.7 kcal mol^{-1} and corresponds to the situation in which the -NHR fragment passes the nitro group. In such an arrangement strong repulsive interactions must occur between the two groups mentioned. The energy barrier to the rotation in C-283 seems to be too high to be overcome at room temperature. It may, therefore, be expected that the -NHR fragment in nitracrine undergoes only rocking movements, whereas in C-264 it may also rotate under certain conditions. Inversion at N(23), which sometimes accompanies rotation of the whole -NHR group, requires the overcoming of much lower barriers. Structures of C-283 and C-264 shown as examples in Fig. 8 correspond to the *saddle points* for the above pro-

cess and to energy barriers of 1.2 and 0.3 kcal mol^{-1}, respectively.

In imino structures in which a double C(9)—N(23) bond hinders the rotation of the =NR group, the molecular transformation can be the inversion of the whole molecule towards its mirror image. In the case of inversion of two I1 type structures, chosen as examples, the barriers for the process are equal to 5.8 and 3.0 kcal mol^{-1}, respectively (the corresponding transition state structures are shown in Fig. 8). In this tautomeric form nitracrine also undergoes a structural transformation more difficult than the 2-nitro isomer does.

Physicochemical characteristics

Comparison of heats of formation predicted by AM1 and PM3, as well as STO-3G energies, indicates that imino tautomers should, at least in the gaseous phase, be favoured energetically before the relevant amino forms (Table 1). The differences between AM1 values of ΔH_f or ΔG_f for amino and imino forms decrease in the order: C-265 > C-283 > C-264 > C-257, which implies that in compounds in which, either as a result of steric overcrowding (C-283) or because of *peri* interactions (C-283 and C-265), the nitro group is markedly distorted from planarity to the acridine aromatic system, the imino forms should predominate. Characteristic of *aci* tautomers of C-264 and C-265 are the fairly high values of ΔH_f, and the existence of both compounds in these forms seems highly unlikely. The equilibrium constants calculated using AM1 values for the lowest energy structures (with the open alkyl chain in the case of amino forms) (Table 1), $K = c_{amino}/c_{imino}$, are equal to 0.0028, 0.0682, 0.0614, and 1.7×10^{-5}, for C-283, C-264, C-257, and C-265, respectively. One can expect, therefore, that the compounds should be present mainly in imino form in the gaseous phase. This may, however, change in the liquid or solid phases, where equilibrium between these two tautomeric forms may be strongly influenced by solute–solvent

(STO-3G) geometries.

interactions (35) or by the energetics of crystal formation. This conclusion is supported by the results of several of our earlier studies (31–33, 57). As regards the solid phase, it is worth remembering that C-283 actually crystallizes in the most stable imino form (6), whereas crystals of C-264 contain molecules of the less stable amino tautomeric form, in which the alkyl substituent is organized in a conformation with an internal hydrogen bond (8). It may, therefore, be that the energy required by the C-264 molecule to change its conformation from imino to amino is provided by the excess energy evolved upon the formation of the crystal. Moreover, the entropy factor prefers the formation of crystals from units containing an internal hydrogen bond. *aci* Tautomers in anionic form are characterized by relatively low ΔH_f values. The existence of such a form has actually been confirmed only in the case of the 2-nitro isomer (31).

Dipole moment values (μ) for amino tautomers generally increase in the sequence of 1- to 4-nitro isomers, whereas they decrease in the same order for imino tautomers (Table 1). Relatively low values of μ are predicted for all forms of C-283. Thus, both amino and imino structures of nitracrine seem to be the least polar of the compounds studied. It may be expected that the polarity of molecules strongly affects solute–solvent interactions and also tautomeric equilibria. Some aspects of this problem were discussed by us earlier (31, 32, 57).

According to Koopman's theorem (58), the energies of the lowest unoccupied (LUMO) and highest occupied (HOMO) molecular orbitals, multiplied by −1, can be regarded, in the first approximation, as the electron affinity and ionization potential of a molecule, respectively (59, 60). Furthermore, these quantities can be related to the reductive and oxidative capability of a molecule (30, 61, 62). Thus, the lower the energy of HOMO, the higher the oxidation potential, and the lower the energy of LUMO, the lower the reduction po-

tential of a molecule. According to the AM1 data the LUMO energies of imino tautomers are higher than those characterizing the relevant amino forms (Table 1). This means that the reduction of the imino tautomers should proceed with more difficulty than that of the amino forms. On the other hand, theory does not generally differentiate the reductive capability of nitracrine and its isomers, which corresponds quite well to the experimentally obtained values (the half-wave potentials, in V, are equal to 0.60 and 0.56, 0.74 and 0.58, 0.65 and 0.58, 0.65 and 0.56, for C-283, C-264, C-257, and C-265, respectively (1, 11, 12)). The above-mentioned findings do not seem to indicate that nitracrine undergoes reduction more easily than any of its nitro isomers, as has been suggested by some authors (11, 12).

The problem discussed may have some significance in understanding differences in the biological activity of nitracrine and its isomers, which is connected with the fact that a reduced form of nitracrine occurs at site -NO_2 as a result of metabolic transformations (5, 20). Such a metabolite has not been found, so far, in the case of the remaining nitro isomers of C-283. The question, therefore, is why only nitracrine undergoes reduction and its isomers do not, especially since theory and experiment predict fairly similar electrochemical behaviour for all the compounds studied. It is probable that factors other than physicochemical control the process.

Electrostatic potential around isolated molecules

Maps of the molecular electrostatic potential (MEP) were obtained by employing eq. [1] and using net atomic point charges. It is shown in Fig. 9 that such maps resulting from various charge distributions correspond to each other reasonably well.

The two- (2-D) (Figs. 1–4), as well as three-dimensional (3-D) (Fig. 10) MEP maps reveal that, essentially, two zones of the potential appear around all the noncharged molecules. The negative region is always in the neighbourhood of the nitro group. Thus, in changing the position of this group from 1 to 4 the negative pole migrates from one to another side of a molecule. Simultaneously, the positive pole moves in the opposite direction. The -NHR group in the amino tautomer of C-283 appears in the region of a negative electrostatic potential. In the imino tautomer of nitracrine the alkyl chain remains on the boundary of the two opposite potentials. In C-264, C-257, and C-265, the -NHR fragment is always surrounded by a zone of positive electrostatic potential.

Conclusions

The theoretical studies revealed that nitracrine has a chance to exist in a fairly rigid structure due to the immediate engagement of both -NHR and -NO_2 fragments in hydrogen bonds. Furthermore the presence, in *peri* positions, of two

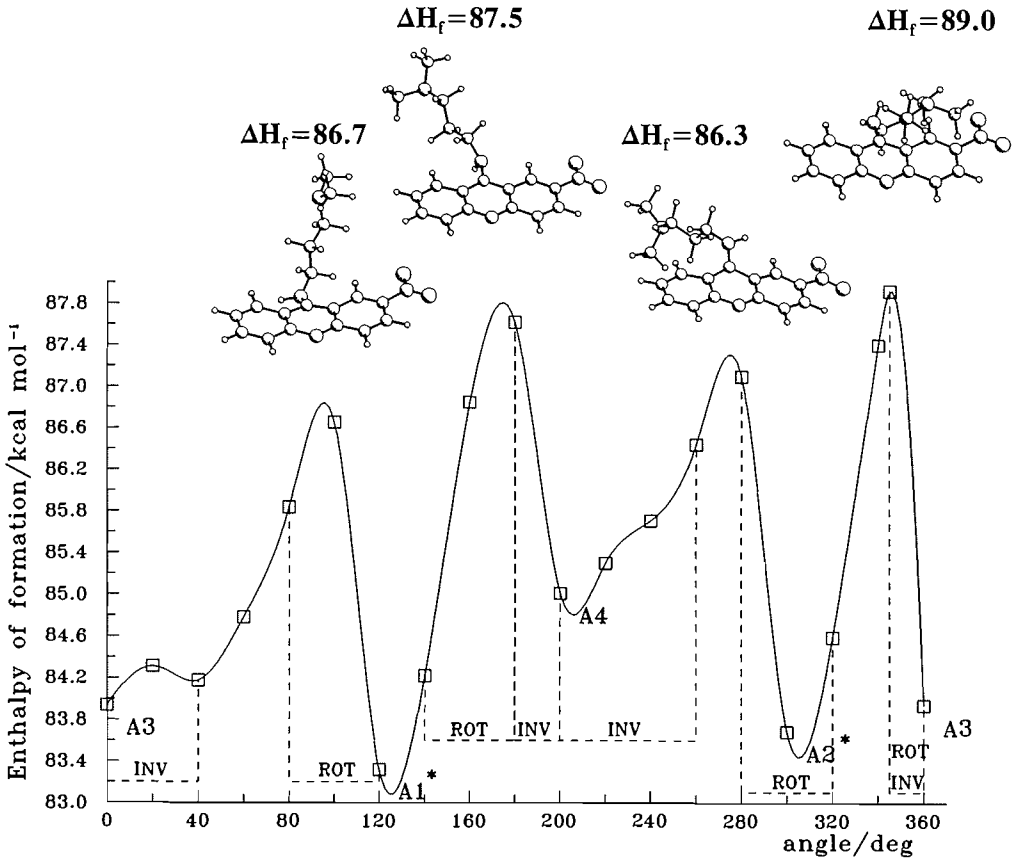

FIG. 7. Enthalpy determined by AM1 versus C(14)C(9)N(23)C(24) angle upon rotation of the -NHR fragment in C-264. A3 and A4 denote structures demonstrated in Fig. 5, whereas A1* and A2* structures are the mirror images of A1 and A2; INV and ROT indicate the range of the angle in which rotation of the -NHR fragment against the acridine moiety is accompanied by inversion at N(23) and rotation around the N(23)—C(24) bond, respectively.

voluminous and polar groups causes tremendous distortion from planarity of the whole acridine skeleton and practical loss of conjugation between these groups and the aromatic system. In consequence, nitracrine is less susceptible to any molecular transformations, e.g., those accompanying rotation of the -NHR fragment and inversion of the whole skeleton. These features undoubtedly distinguish nitracrine and can be significant for its unique behaviour.

Further, perhaps, even more distinct differences are revealed on examining electrostatic potential maps. Nitracrine is the only one of the compounds studied in which both -NHR and -NO_2 groups remain in the zone of the same negative potential. At the same time the zone of an opposite electrostatic potential surrounds the endocyclic nitrogen atom. This creates very convenient conditions for participation in intermolecular interactions. These interactions include, first and foremost, solute–solvent interactions, as well as those leading to the formation of associates. The distribution of the electrostatic potential around molecules may also play a role in molecular recognition, as well as in interactions with receptors and other macromolecules in living organisms (53, 63). If these interactions included the cross-linking of DNA, the endocyclic nitrogen would be one bonding centre and the nitrogen at the end of the alkyl substituent another bonding centre. Such a convenient distribution of the electrostatic potential does not exist in any other nitro isomer of nitracrine.

As mentioned earlier, certain findings indicate that nitra-

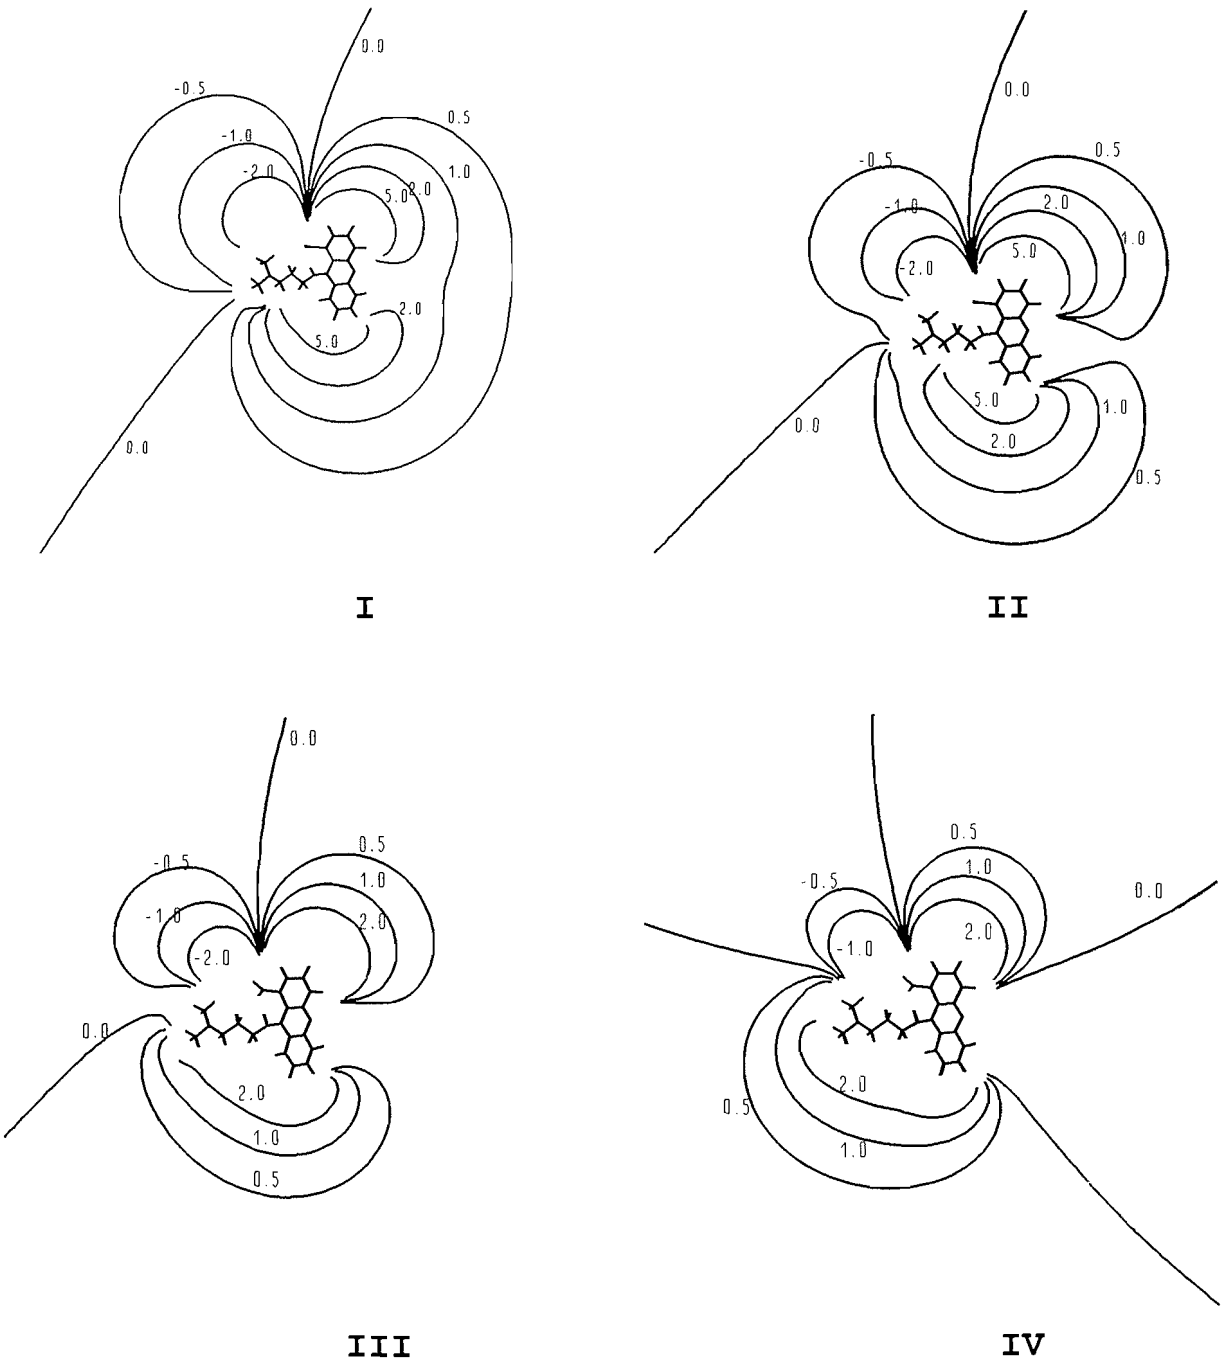

FIG. 9. 2-D MEP maps relevant to the A2 structure of nitracrine obtained using AM1 net atomic charges (I), charges fitted to the potential calculated from the AM1 wavefunction (II), Mulliken net atomic charges from the ab initio (STO-3G) calculations (III), and charges fitted to the potential calculated from the ab initio (STO-3G) wavefunction (IV).

crine undergoes reductive metabolism in which the $-NO_2$ group is changed to -NHOH (5, 20). The AM1 method predicts that all the compounds studied exhibit comparable capability to undergo reduction (reflected by energies of LUMO). It might, therefore be, that the presence of both -NHR and $-NO_2$ groups in close proximity, and in the region of a negative electrostatic potential, facilitates reduction. This would be so if the positive interaction region of an enzyme were matched with the negative region of nitracrine.

The role played by prototropic tautomerism in the biological activity of the compounds studied is rather difficult to answer. Both energy and free energy data indicate that nitracrine and its nitro isomers should exist predominantly in the imino tautomeric form (contrary to 9-acridinamine where the amino form is thermodynamically favoured (30)). However, differences in ΔH_f and ΔG_f are not too high, which implies that molecules can exist equally well, in both above forms, in equilibrium. This was fully confirmed by examining absorption and emission spectra (31, 32, 57). Recently Boyd and Denny (10), using high-resolution proton magnetic resonance spectroscopy, deduced that under certain conditions (similar to physiological conditions) nitracrine and the 4-nitro isomer exist in the imino configuration

while the 2- and 3-nitro isomers exist in the amino structure. Our data thus show only qualitative correlation with those of Boyd and Denny. Nevertheless, both demonstrate that imino configuration may be a key factor in biological activity of molecules. To support this, the biological activity of the 4-nitro isomer has also recently been revealed (refs. cited in ref. 10).

Acknowledgments

We would like to thank Dr. A. Liwo for permitting us to use the program for calculations and drawing the molecular electrostatic potential maps. This work was supported by the Polish State Committee for Scientific Research (KBN) under grants DS/5-300-7-016-1 and BW/5-300-4-067-1.

Anomalous stabilizing and destabilizing effects in some cyclic π-electron systems

PETER POLITZER,[1] M. EDWARD GRICE, JANE S. MURRAY, AND JORGE M. SEMINARIO
Department of Chemistry, University of New Orleans, New Orleans, LA 70148, U.S.A.

Received March 19, 1993

PETER POLITZER, M. EDWARD GRICE, JANE S. MURRAY, and JORGE M. SEMINARIO. Can. J. Chem. **71**, 1123 (1993).

Ab initio computational studies have been carried out for three molecules that are commonly classed as antiaromatic: cyclobutadiene (**1**), 1,3-diazacyclobutadiene (**7**), and 1,4-dihydropyrazine (**6**). Their dinitro and diamino derivatives were also investigated. Stabilizing or destabilizing energetic effects were quantified by means of the isodesmic reaction procedure at the MP2/6-31G*//HF/3-21G level, and calculated molecular electrostatic potentials (HF/STO-5G//HF/3-21G) were used as a probe of electron delocalization. Our results do not show extensive delocalization in the π systems of any one of the three parent molecules. The destabilization found for **1** and **7** is attributed primarily to strain and to repulsion between the localized π electrons in the C=C and C=N bonds, respectively. However, **6** is significantly stabilized, presumably due to limited delocalization of the nitrogen lone pairs. NH_2 groups are highly stabilizing, apparently because of lone pair delocalization. NO_2 is neither uniformly stabilizing nor destabilizing.

PETER POLITZER, M. EDWARD GRICE, JANE S. MURRAY et JORGE M. SEMINARIO. Can. J. Chem. **71**, 1123 (1993).

On a étudié au moyen de calculs *ab initio* trois molécules qui sont communément classées comme des antiaromatiques : le cyclobutadiène (**1**), le diaza-1,3-cyclobutadiène (**7**) et la dihydro-1,4-pyrazine (**6**). On a également étudié leurs dérivés dinitro et diamino. On a quantifié les effets énergétiques stabilisants ou déstabilisants en faisant appel au procédé de la réaction isodesmique au niveau MP2/6-31G*//HF/3-21G, et on a utilisé les potentiels électrostatiques moléculaires calculés, (HF/STO-5G//HF/3-21G) comme preuve de la délocalisation de l'électron. Nos résultats ne révèlent pas une forte délocalisation dans le système π des trois molécules apparentées. La déstabilisation trouvée pour les composés **1** et **7** est attribuée principalement à la contrainte et à la répulsion existante entre les électrons π localisés des liaisons C=C et C=N respectivement. Cependant le composé **6** est stabilisé de façon significative, probablement à cause de la délocalisation limitée du doublet libre de l'azote. Les groupes NH_2 sont fortement stabilisés, apparemment à cause de la délocalisation du doublet libre. Le NO_2 n'est ni uniformément stabilisé ni déstabilisé.

[Traduit par la rédaction]

Introduction

A monocyclic fully conjugated (closed loop) planar π-electron system may be either aromatic or antiaromatic depending upon whether it is stabilized or would be destabilized, respectively, by π-electron delocalization (1–4). Simple molecular orbital considerations for planar rings have led to the generalizations that aromaticity is associated with the presence of $(4n + 2)$ π electrons ($n = 0, 1, 2, 3, \ldots$) and antiaromaticity with $4n$ ($n = 1, 2, 3, \ldots$) (3–5). An interesting example of the latter is the highly unstable cyclobutadiene molecule (**1**), which has four π electrons. By analogy to benzene, one might anticipate a square, resonance-stabilized structure, **2**; however, it is well established both experimentally (6–8) and computationally (9–11) that cyclobutadiene is a rectangular diene, **1**. As March has pointed out, ". . . simple cyclobutadienes, which could easily adopt a square planar shape if that would result in aromatic stabilization, do not in fact do so and are not aromatic" (ref. 3, p. 52).

1 **2** **3**

Antiaromatic destabilization does not necessarily preclude the existence of cyclic systems that formally have $4n$ π electrons, and many such compounds have been prepared and characterized (2–4, 12, 13). Structural factors can play an important role; cyclooctatetraene (**3**), a stable compound that has eight π electrons, is considered to be neither aromatic nor antiaromatic, because it has a highly puckered tub-shaped conformation that impedes π delocalization (3).

Very recently, the synthesis of the dihydrodiimidazopyrazines **4** and **5** has been reported (14); these are derivatives of 1,4-dihydropyrazine, **6**. If the lone pair electrons on the nitrogens of **6** are assumed to be of π-type, then this molecule has eight conjugated π electrons and satisfies the $4n$ rule. Indeed **6** is normally classed as antiaromatic (13, 15–17), which would then formally apply to **4** and **5** as well.

Our objective in this project has been to examine computationally any anomalous energetic features of **1** and **6**, and how these are affected by two significantly different substituents, NO_2 and NH_2. We also include 1,3-diazacyclobutadiene, **7**, in this analysis, since we and others have shown that ring nitrogens tend to stabilize both strained and unstrained molecules (18–20). If the lone pairs of the nitrogens in **7** are primarily in the ring plane, as in pyridine for example, then **7** has four π electrons and is formally antiaromatic. An unavoidable problem in trying to assess such energetic effects as aromatic stabilization, antiaromatic destabilization, strain, etc., is that these are not rigorously defined; they depend upon the choice of reference systems. Our approach has been to apply the widely used isodesmic reaction method (21, 22), and to refer the system of interest to the smallest possible molecules having the same types of bonds. Thus the anomalous energy associated with **8**, for example, is obtained by computing ΔE for eq. [1]:

7

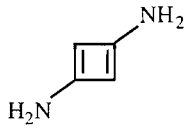
[1] $4H_3C-NH_2 + 2H_2C = CH_2 + 2H_2N-NO_2 \longrightarrow$  $+ 4CH_4 + 4NH_3$

8

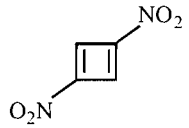
If the bonds in **8** were energetically unchanged from the corresponding ones on the left side of eq. [1], then ΔE would be zero. $\Delta E < 0$ would indicate that stabilizing factors are associated with **8**; $\Delta E > 0$ would imply destabilization. It should be noted that this procedure gives the net result of *all* stabilizing and destabilizing contributions; thus one cannot separate, for example, the effects of antiaromaticity and strain.

Methods

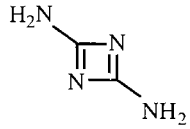
Optimized geometries were computed with GAUSSIAN 92 (23) at the *ab initio* HF/3-21G level for **1**, **6**, and **7**, and for their NH_2 and NO_2 derivatives, **8**–**13**. The corresponding MP2/6-31G* energies were used to determine the isodesmic ΔE values for these molecules, using reactions analogous to eq. [1]. The energies of the reference systems were also obtained by MP2/6-31G*//HF/3-21G calculations.



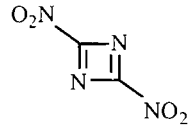
9



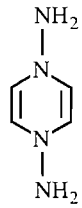
10



11



12



13

As part of our analysis, we calculated the electrostatic potential, $V(\boldsymbol{r})$, that is created in the space around each molecule by its nuclei and electrons. This is given rigorously by eq. [2]:

$$[2] \quad V(\boldsymbol{r}) = \sum_A \frac{Z_A}{|\boldsymbol{R}_A - \boldsymbol{r}|} - \int \frac{\rho(\boldsymbol{r}')d\boldsymbol{r}'}{|\boldsymbol{r}' - \boldsymbol{r}|}$$

Z_A is the charge on nucleus A, located at $\boldsymbol{R}_A$, and $\rho(\boldsymbol{r})$ is the electronic density, which we obtain from the molecular wave function. $V(\boldsymbol{r})$ is a real physical property, which can be determined experimentally as well as computationally (24), and is now widely used in interpreting and predicting reactive behavior (25). In the present work, however, we have used it as a sensitive probe of electron delocalization. We computed $V(\boldsymbol{r})$ for **1** and **6**–**13** at the HF/STO-5G//HF/3-21G level, which we have found, in extensive applications, to be effective for this property (25).

Results

Our calculated isodesmic energies are listed in Table 1, along with key optimized bond lengths and also the most negative values, V_{min}, of the electrostatic potentials associated with these molecules. All of the four-membered-ring systems were found to be essentially planar, as also was **8**. Since the 3-21G basis set sometimes overestimates amine bond angles (26), and thus may erroneously predict planarity (27), we repeated the optimization of **9** at the HF/6-31G* level and verified that it is planar.

The nonplanarity of **6** is due primarily to the pyramidal configurations of the two amine nitrogens, which give rise to two possible conformers, **6***a* and **6***b*, which we find to have the same HF/3-21G energy. In **6***a* and **6***b*, the N—N—H angles are in the range 142°–144°. In both conformers, there is also a slight puckering of the six-membered ring; the dihedral angle around the N—N axis is 7.2° in **6***a* and 1.2° in **6***b*. The greater degree of puckering in **6***a* may reflect an effort to minimize the repulsion between the nitrogen lone pairs.

The other nonplanar molecule is **13**, in which both the ring and the amine nitrogens have pyramidal configurations. An interesting feature of **13** is that it does not possess a plane of symmetry passing through the four nitrogens; instead, the amine groups are rotated so that there are dihedral angles of 83.5° involving each pair of bonded nitrogens and their respective lone pairs. These angles are very similar to the corresponding ones in 1,1-dimethylhydrazine, $(H_3C)_2N-NH_2$, which we found earlier to be 82.0° (28). (The locations of

the most negative electrostatic potentials associated with the lone pairs, V_{min}, were used in determining these dihedral angles (28).)

Within each subgroup in Table 1, the molecules are listed in order of decreasing isodesmic ΔE values. As anticipated, both **1** and **7** show considerable destabilization, although it is less in the case of **7**. On the other hand, the ΔE for **6** indicates stabilization, despite its normally being considered to be antiaromatic (13, 15–17). The introduction of NH_2 groups has a pronounced stabilizing effect in each instance, whereas NO_2 stabilizes **1**, but destabilizes **6** and **7**.

Discussion

The diene nature of cyclobutadiene, **1**, is emphasized by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12

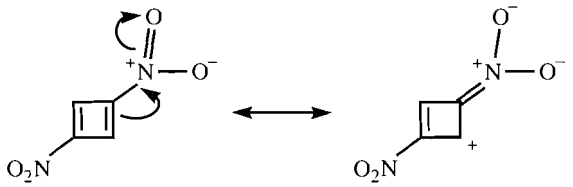
its computed electrostatic potential, which shows a V_{min} of −13.1 kcal/mol above and below the C=C double bonds (Table 1); this is the same as was found for ethylene (29). The isodesmic ΔE of **1** presumably reflects both antiaromaticity and strain; its large positive magnitude, +53.0 kcal/mol, is fully consistent with the antiaromaticity contribution having been estimated as being larger than 12–16 kcal/mol (30) and the strain energy as at least 35 kcal/mol (31).

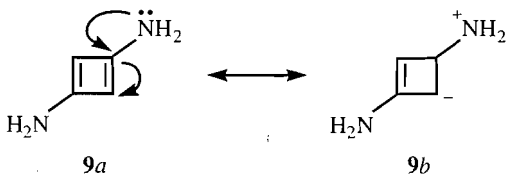
If antiaromatic destabilization is regarded as being associated with π delocalization (1–4), then a question arises as to the physical basis for the "antiaromatic" destabilizing energy of **1**, in view of the evidence that its π electrons are quite localized. We suggest that this may reflect, at least in part, the repulsive interaction between these π electrons, which are forced by the molecular framework to be in relatively close proximity, approximately one C—C bond length apart. The same reasoning may explain why this C—C bond is unusually long, by approximately 0.06 Å. By this interpretation, it is the π *localization,* rather than delocalization, that involves instability. The same explanation may apply to **7**, except that some of the C=N π charge may have been attracted to the nitrogens, making the repulsive interaction weaker.

Table 1 shows that both NO_2 and NH_2 substituents stabilize cyclobutadiene, especially the latter. They achieve this, however, in opposite ways. The NO_2 group is strongly electron withdrawing, through both induction and resonance; contributions from structures such as **10***b* can be anticipated. Indeed the C—N distances in **10** are 0.1 Å shorter than in nitromethane, for example (22), and there is no longer a negative electrostatic potential above the C=C bonds (Table 1). It had earlier been proposed that the withdrawal of electronic charge from cyclobutadiene has a stabilizing effect (30), and this is exactly what our results show.



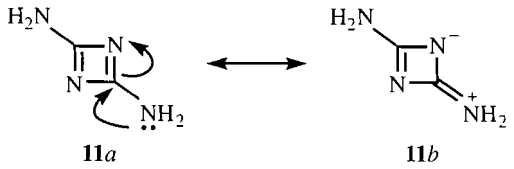
10*a* **10***b*

The reverse happens in the case of **9**. There is extensive resonance donation of charge by the amine groups to the ring, as shown below; the C—N bonds in **9** are fully 0.14 Å shorter than in methylamine (22), and the V_{min} of the nitrogen lone pairs is only −23.6 kcal/mol (Table 1), which is a relatively weak lone pair potential for nitrogen. To put this in perspective, V_{min} is −109 kcal/mol for NH_3 in its pyramidal conformation and −60 kcal/mol when it is planar (32); for methylamine, V_{min} = −105 kcal/mol (33). Most striking, however, are the strong negative potentials near the unsubstituted carbons, −41.1 kcal/mol. These are even more negative than the V_{min} of fluorine in hydrogen fluoride, −32 kcal/mol,[2] and attest to the importance of the contributions of structures like **9***b*. This delocalization of electronic charge into the ring is presumably the reason for the marked stabilizing effect of the NH_2 group. The unsubstituted carbons in **9** should be quite favorable sites for electrophilic attack.



9*a* **9***b*

This is seen again, even more dramatically, in comparing **7** and **11**. Whereas the bond lengths in **7** clearly distinguish between C—N single and double bonds, the distinction is absent in **11**, apparently due to resonance such as is depicted below. Consistent with this picture, the lone pair



11*a* **11***b*

V_{min} of the ring nitrogens changes from −73.0 kcal/mol in **7** to a very highly negative −109.6 kcal/mol in **11**; the latter is similar to ammonia (see above) and is much more negative than pyridine, −92.9 kcal/mol (34). Thus the ring nitrogens in **11** can be anticipated to have very significant basic character, which is consistent with its structural similarity to guanidine, $(H_2N)_2C{=}NH$. The stabilization brought about by the NH_2 groups amounts to +32.5 − (−39.0) = 71.5 kcal/mol in **11**, compared to +53.0 − 18.2 = 34.8 kcal/mol in **9**.

The dinitro derivative **12** presents a rather complicated situation, in which it is difficult to evaluate all of the possible factors. The ring nitrogens are also electron attracting (34, 35), as well as the NO_2 groups; thus they are both competing for the polarizable electronic charge. Neither is as negative as it would be in the absence of the other; this can be seen by comparing the V_{min} of the ring nitrogens in **7** and **12**, and the V_{min} of the nitro group oxygens in **12** and **10**, as well as the C—NO_2 and N—O bond lengths in **12** and **10**, which show that the former has less resonance of the type depicted in structure **10***b*. Thus the withdrawal of charge from the ring through which the NO_2 groups stabilize **10** relative to **1** apparently does not occur to the same extent in **12**, and the net result is that the latter is actually destabilized by 8.6 kcal/mol relative to **7**.

Like the other parent molecules, **1** and **7**, 1,4-dihydropyrazine, **6**, clearly is a diene; this is confirmed by the C=C distances and the V_{min} associated with these bonds (Table 1). It is interesting that the diene character of **6** is maintained even when its nitrogens are forced to be planar, which should promote π delocalization; the planar conformation of **6**, which is 7.0 kcal/mol higher in energy than the pyramidal (at the MP2/6-31G*//HF/3-21G level), the lengths of the C=C bonds are 1.318 Å and their V_{min} are −21.4 and −21.6 kcal/mol. There is evidently no driving force for extensive π delocalization of these lone pairs.

In contrast to **1** and **7**, **6** has a negative isodesmic energy, which indicates a stabilizing effect. We suggest that this may reflect, in part, some degree of delocalization of the nitrogen lone pairs. (The nitrogens in **6** are not responsible for its

[2]T. Brinck. Private communication.

entire stabilization, since we found an isodesmic ΔE of −24.0 kcal/mol for the hydrocarbon analog of **6**, 1,4-cyclohexadiene.) The presence of NO_2 groups in **8** decreases the stabilization of the system, perhaps because the electron-withdrawing power of the NO_2 groups diminishes the extent of delocalization of the lone pairs to the ring.

While the introduction of NH_2 substituents leads to a very large stabilizing isodesmic ΔE for **13**, it does not appear that this can be attributed to delocalization of π charge into the ring, as in **9** and **11**. Such an interpretation would be inconsistent with the strongly negative lone pair V_{min} of the pyramidal NH_2 groups (Table 1) and their being rotated around the N—N bonds, as mentioned above. While the rotations around the N—N bonds and also the lengths of these bonds are reminiscent of 1,1-dimethylhydrazine, $(H_3C)_2N—NH_2$ (28), the V_{min} of the nitrogens are even more negative in the latter: −88.2 and −97.5 kcal/mol, compared to −67.7 and −90.5 kcal/mol, respectively, in **13**. This suggest that there does occur some significant delocalization in **13**, involving the lone pairs of both types of nitrogens, analogous to what was proposed above for **6**. This would help to explain the large stabilizing isodesmic ΔE that we obtain for **13**.

Summary

Our computed structures show that neither cyclobutadiene, **1**, nor 1,3-diazacyclobutadiene, **7**, avails itself of the opportunity for π delocalization in analogy to its six-membered cyclic counterpart, benzene or pyrazine. Instead their π electrons are highly localized in the C=C and C=N double bonds, and it is to the repulsion between these electrons that we attribute a major portion of the "antiaromatic" destabilization of these molecules.

1,4-Dihydropyrazine, **6**, is also a diene, and has pyramidal nitrogens in its most stable conformation; we believe that some delocalization of the nitrogen lone pairs occurs, and is partially responsible for **6** being significantly stabilized. Even when **6** is forced into a planar conformation, which should promote cyclic π delocalization, this option is not followed.

Amine substituents have highly stabilizing effects in all three cases investigated: **9**, **11**, and **13**. This appears to be due to delocalization of the amine lone pairs in each instance. It is more difficult to generalize about the effects of nitro groups, which are neither uniformly stabilizing nor destabilizing.

Reçu le 16 décembre 1992

JEAN-MICHEL OGER, AGNÈS FARDEAU, PASCAL RICHOMME, HÉLÈNE GUINAUDEAU et ALAIN FOURNET. Can. J. Chem. **71**, 1128 (1993).

Une série de 11 alcaloïdes, dérivés d'un nouveau type de benzyltétrahydroisoquinoléine de substitution originale, a été isolée de l'écorce de tronc d' *Aniba canelilla* H.B.K. (Lauraceae). L'examen de ces composés, par plusieurs techniques spectroscopiques de résonance magnétique nucléaire (^{1}H, ^{13}C, nOe différence, COSY H–H et C–H, COLOC) a permis d'identifier : quatre benzylisoquinoléines monosubstituées sur le cycle C par un hydroxyle en position 11, la (−)-norcanelilline **2**, la (+)-canelilline **3**, l'anicanine **4** et la canelillinoxine **5**; deux tétrahydroprotoberbérines monosubstituées sur le cycle D en position 9, la (−)-anibacanine **6** et la (+)-manibacanine **8**; deux tétrahydroprotoberbérines monosubstituées sur le cycle D en position 11, la (−)-pseudoanibacanine **7** et la (+)-pseudomanibacanine **9**; et trois protoberbérines de la même série que les précédentes avec un substituant méthylique en position 8α ou 8β, la (−)-α-8-méthylpseudoanibacanine **10**, la (−)-β-8-méthylpseudoanibacanine **11** et la (−)-α-8-méthylanibacanine **12**. L'examen de l'ensemble des alcaloïdes isolés permet d'envisager chez *A. canelilla* l'existence de deux systèmes enzymatiques distincts, l'un permettant la bioconversion des alcaloïdes de type réticuline et coclaurine en proaporphines et aporphines classiques, l'autre conduisant à la biogenèse des protoberberines de type anibacanine et psuedoanibacanine à partir des benzyltétrahydroisoquinoléines de type canelilline.

JEAN-MICHEL OGER, AGNÈS FARDEAU, PASCAL RICHOMME, HÉLÈNE GUINAUDEAU, and ALAIN FOURNET. Can. J. Chem. **71**, 1128 (1993).

Eleven benzyltetrahydroisoquinoline alkaloids, with an original substitution pattern, were isolated from the stem bark of *Aniba canelilla* H.B.K. (Lauraceae). Structural studies of these compounds including ^{1}H, ^{13}C, nOe difference, COSY H–H and C–H, and COLOC nuclear magnetic resonance spectroscopy led to the identification of four benzylisoquinolines, monosubstituted on ring C with an hydroxyl at C-11, (−)-norcanelilline **2**, (+)-canelilline **3**, anicanine **4**, and canelillinoxine **5**; two tetrahydroprotoberberines monosubstituted on ring D at C-9, (−)-anibacanine **6** and (+)-manibacanine **8**; two tetrahydroprotoberberines monosubstituted on ring D at C-11, (−)-pseudoanibacanine **7** and (+)-pseudomanibacanine **9**; and three protoberberines with the same substitution pattern on rings A and D with a methyl substituent at the 8α or 8β position, (−)-α-8-methylpseudoanibacanine **10**, (−)-β-8-methylpseudoanibacanine **11**, and (−)-α-8-methylanibacanine **12**. An examination of all isolated alkaloids suggests the existence of two enzymatic systems in *A. canelilla*. In the first enzymatic system, reticuline- and coclaurine-type alkaloids are involved in the bioconversion of classical proaporphine and aporphine alkaloids. In the second system, canelilline-type alkaloids are intermediate in biosynthesis of anibacanine and pseudoanibacanine protoberberine alkaloids.

Introduction

Poursuivant l'étude des drogues végétales à activité antiparasitaire (1, 2), nous nous sommes intéressés à l'étude des constituants alcoloïdiques d'une Lauracée bolivienne, *Aniba canelilla* H.B.K. Cette espèce arborescente, originaire des régions tropicales de la Bolivie, possède un bois apprécié localement pour sa résistance aux attaques parasitaires ainsi que pour sa dureté.

Le genre *Aniba*, largement répandu en Amérique du Sud, comprend 41 espèces répertoriées. Ces espèces sont classées en plusieurs groupes et sous-groupes en fonction de l'anatomie des anthères et de l'épiderme inférieur des feuilles.

Aniba canelilla et *A. ferrea*, deux espèces du groupe des *Macroporantherae* (3) se différencient des autres espèces d'*Aniba* par l'histologie de leur tronc qui se rapproche de celle du genre *Licaria*.

Un examen préliminaire de la fraction basique des écorces de tronc a permis l'isolement et l'identification de la (+)-noranicanine **1** (4). L'originalité de cette benzyltétrahydroisoquinoléine réside dans la présence d'un cycle C monosubstitué en *meta*. La structure inédite de ce nouvel alcaloïde, confirmée par synthèse totale, permet d'envisager l'existence d'une nouvelle série de dérivés isoquinoléiques.

La poursuite de l'étude de contenu alcaloïdique des écorces de tronc d'*A. canelilla* a conduit à l'identification de 20 alcaloïdes dont 11 sont apparentés à la noranicanine **1**. Les neuf composés connus sont cinq benzyltétrahydroisoquinoléines ((+)-réticuline, (−)-coclaurine, (+)-*N*-méthylcoclaurine, armépavine et (−)-norjuziphine), une proaporphine ((−)-glaziovine) et trois aporphines ((+)-apoglaziovine, (+)-norisocorydine et (+)-isoboldine). Ils ont été identifiés par comparaison de leurs données spectrales avec celles décrites dans la bibliographie et, quand cela a été possible, avec un échantillon authentique.

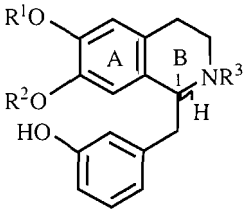
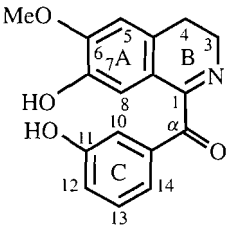
Résultats et discussion

La (−)-norcanelilline **2**, de formule brute $C_{17}H_{19}NO_3$, présente un spectre de masse, obtenu par ionisation chimique (NH_3), avec un ion M+1 à *m/z* 286 et un fragment intense à *m/z* 178. Le spectre de masse en impact électronique présente un pic moléculaire très faible (0,15%) et le pic de base à *m/z* 178 dû à la rupture de la liaison benzylique. La masse de ce fragment indique la présence d'un noyau isoquinoléique disubstitué par un hydroxyle et un méthoxyle et porteur d'une fonction amine secondaire, le singulet de trois protons caractéristique d'une fonction *N*- méthyle étant absent du spectre de rmn ^1H (cf. tableau 1). La présence d'un fragment à *m/z* 107 suggère l'existence d'un groupement benzylique monohydroxylé. La séquence de substitution des noyaux aromatiques, comme dans le cas de la noranicanine **1**, est aisément déduite de l'étude des principaux signaux du spectre de rmn ^1H. En effet le spectre de rmn du proton de la norcanelliline **2** présente de grandes similitudes avec celui de la noranicanine **1**, en particulier en ce qui concerne les signaux dûs aux protons du





1 $R^1 = R^2 = Me$, $R^3 = H$, *1R*
2 $R^1 = Me$, $R^2 = R^3 = H$, *1S*
3 $R^1 = R^3 = Me$, $R^2 = H$, *1S*
4 $R^1 = R^2 = R^3 = H$

5

noyau benzylique (pseudotriplet dû au proton en 13 à δ 7,14 ppm), ainsi que la position dans les champs faibles du signal donné par le proton en 1. La présence d'un seul singulet de trois protons à δ 3,82 ppm confirme le type de substitution du cycle. A. Le singulet dû au proton en 8 (δ 6,77 ppm) étant déplacé vers les champs faibles, la fonction hydroxyle doit être portée par le carbone 7 alors que le groupe méthoxyle doit être en 6. Les positions des substituants du cycle A sont confirmées par deux expériences de type COSY C–H et COLOC. La première attribue les déplacements chimiques des protons et des carbones directement liés (cf. tableaux 1 et 2), et la seconde met notamment en évidence des corrélations ^3J entre : le carbone 1 à 56,4 ppm et le proton à 6,77 ppm (H-8); les protons du méthoxyle à 3,82 ppm et le carbone qui le porte à 145,7 ppm; ce même carbone et le proton à 6,77 ppm (H-8). Ces données permettent de positionner sans ambiguïté le méthoxyle en 6 et donc l'hydroxyle en 7. La (−)-norcanelilline correspond donc à la 1-(3′-hydroxybenzyl)-6-méthoxy-7-hydroxy-1,2,3,4,-tétrahydroisoquinoléine. L'identité des données spectrales de la norcanelilline et du composé **2** obtenu par synthèse totale confirme cette structure (5).

L'attribution complète du spectre de rmn ^{13}C (cf. tableau 2) a été déduite d'une expérience de type DEPT et des expériences de corrélation carbone–proton à deux dimensions précédemment citées.

L'enregistrement de la courbe de dichroïsme circulaire de la noranicanine **1** (4) nous ayant montré que les règles empiriques énoncées par Leet et al. (6) semblaient respectées dans cette nouvelle série de benzyltétrahydroisoquinoléines, nous proposons une configuration 1-*S* de la (−)-norcanelilline sur la base de la mesure de son pouvoir rotatoire.

La (+)-canelilline **3** de formule brute $C_{18}H_{21}NO_3$ présente un spectre de masse très voisin de celui de la (−)-norcanelilline **2** avec un pic moléculaire, supérieur de 14 uma, très faible à *m/z* 299 (0,06%) et un pic de base à *m/z* 192, également supérieur de 14 uma, accompagné des ions caractéristiques d'un noyau tétrahydroisoquinoléique à *m/z* 177 et 162 (7).

La présence d'un pic à *m/z* 107 est compatible avec l'existence d'un noyau benzylique monosubstitué par un hydroxyle. Le spectre de rmn ^1H (cf. tableau 1) de la (+)-canelilline **3** met en évidence la présence d'une fonction *N*-méthyle (δ 2,47 ppm) et d'un méthoxyle (δ 3,84 ppm). Les protons aromatiques résonnent à δ 6,55 (H-5), 6,61 ppm (H-10), H-12 et H-14) et à δ 7,08 ppm (pseudotriplet, intégrant pour un proton, caractéristique du proton en 13). Un singulet d'un proton à δ 6,35 ppm correspond au proton en 8, son déplacement chimique caractéristique indique que le carbone 7 est porteur d'une fonction hydroxyle.

Le pouvoir rotatoire positif ($[\alpha]_D$ +43) suggère une configuration absolue 1-*S*.

L'ensemble des attributions des résonances du spectre de rmn ^{13}C (cf. tableau 2) a été réalisé par analyse du spectre GASPE et par corrélation directe hétéronucléaire.

La dernière benzyltétrahydroisoquinoléine isolée au cours de ce travail est l'anicanine **4** de formule brute $C_{19}H_{23}NO_3$. Présent à l'état de trace, cet alcaloïde n'a été isolé qu'en mélange avec l'armépavine dans une proportion de 1 : 2. Le spectre de masse du mélange (ic) ne permet pas de déceler la présence de deux composés, en effet les deux alcaloïdes sont de même nature et ne diffèrent que par la place de l'hydroxyle sur le cycle C. Les ions fragments observés, de mêmes masses, ne peuvent donc différer que par leur abondance relative. Les pics les plus importants sont observés à *m/z* 314 (100%) correspondant à l'ion M+1, et à *m/z* 206 (40%). La masse de ce dernier ion indique que les deux alcaloïdes sont porteurs sur le noyau isoquinoléique d'une fonction *N*-méthyle et de deux méthoxyles. La présence d'un pic de faible intensité à *m/z* 107 (3%) permet de déduire la monosubstitution du cycle C, dans les deux molécules, par un hydroxyle phénolique.

Les signaux dûs aux deux alcaloïdes sont observables sur le spectre de rmn du proton. Les données spectrales (rmn ^1H, spectrométrie de masse) de l'alcaloïde en mélange avec l'armépavine sont en tous points identiques à ceux d'un échantillon d'anicanine **4** obtenu par hémisynthèse (voir partie expérimentale).

Le quatrième alcaloïde nouveau décrit dans ce travail est un dérivé phénolique benzylisoquinoléique oxydé et a été nommé la canelillinoxine **5**. La formule brute $C_{17}H_{15}NO_4$ est déduite du spectre de masse qui présente un pic moléculaire à *m/z* 297 (32%) et un pic de base à *m/z* 269 (M − 28) flanqué d'un pic important à *m/z* 268 (90%) (M − 29) qui correspond à la perte d'un groupement C=O; un ion à *m/z* 121 est dû à une fragmentation entre le carbone 1 et le carbone α et correspond à la partie oxybenzylique de la molécule, indiquant la monosubstitution par une fonction hydroxyle du noyau benzénique. Le spectre infrarouge

présente une bande à 1670 cm^{-1} caractéristique d'une céto-imine (8). La présence, sur le spectre de rmn ^{1}H (cf. tableau 1), de deux pseudotriplets de deux protons chacuns à 2,79 et 3,85 ppm (J = 7,5 Hz) indique la nature dihydroisoquinoléique de la molécule; le déplacement vers les champs faibles du deuxième triplet est caractéristique de la présence de la céto-imine (8). Dans la région des protons aromatiques, deux singulets (δ 6,72 ppm et 6,92 ppm) sont dûs aux protons en 5 et 8 respectivement. La multiplicité des quatre autres signaux (δ 7,01 ppm d élargi, δ 7,28 ppm dd, δ 7,51 ppm d et δ 7,38 ppm s élargi) indique que le cycle C porte l'hydroxyle phénolique en position *meta* de la liaison benzylique comme pour les alcaloïdes **1**, **2**, **3**, et **4**. Le déplacement vers les champs faibles du signal du proton en 8 (δ 6,92 ppm, s) ainsi que de celui donné par le proton en 14 (δ 7,51 ppm, d) est dû également à la présence de la céto-imine. La canelillinoxine **5** est donc un dérivé oxydé de la (−)-norcanelilline **2**.

Les sept alcaloïdes suivants appartiennent tous au groupe des protoberbérines.

L'alcaloïde **6**, la (−)-anibacanine, et l'alcaloïde **7**, la (−)-pseudoanibacanine, possèdent la même formule brute, $C_{18}H_{19}NO_3$, déduite de leur spectre de masse. Dans les deux cas, on observe un pic moléculaire important à m/z 297 et le pic de base à m/z 178, accompagné d'un pic intense à m/z 176, résultant de la rupture des liaisons benzyliques du noyau C par un mécanisme de type rétro Diels–Alder. Ces deux derniers fragments sont indicatifs de la substitution de la partie tétrahydroisoquinoléique des deux molécules par une fonction hydroxyle et une fonction méthoxyle. La présence d'un ion de masse m/z 120 dans les deux spectres suggère une monosubstitution du cycle D par un hydroxyle phénolique.

Le spectre de rmn du proton des deux molécules (cf. tableau 3) présente les caractéristiques générales des tétrahydroprotoberbérines, en particulier les deux doublets de un proton (J_{gem} = 15,5 Hz) dûs au groupement

méthylénique en 8. Les déplacements chimiques de ces protons à δ 3,49 et 4,19 ppm dans le cas de la (−)-anibacanine **6** indiquent une substitution du carbone 9; ceux à δ 3,61 et 3,93 ppm dans le cas de la (−)-pseudoanibacanine **7** suggèrent la non substitution de ce même carbone (9, 10). Le groupement méthoxyle résonne dans des champs équivalents pour les deux alcaloïdes, vers 3,8 ppm. Les déplacements chimiques des protons en 1 et en 4 sont proches sur les deux spectres à δ ~6,8 ppm et ~6,6 ppm respectivement. La différence de 0,23 ppm entre ces deux déplacements chimiques permet de placer le groupement méthoxyle en 3 et l'hydroxyle phénolique en 2 (10). Ces éléments sont confirmés par une expérience de type COSY retardée qui, dans un premier temps, permet d'identifier des couplages benzyliques d'une part entre les signaux des proton en 4 et en 5 et d'autre part entre le singulet aromatique du proton en 1 et le doublet dédoublé du proton en 14. La corrélation longue-distance observée entre le singulet de 3 protons (OCH_3) vers 3,8 ppm et celui vers 6,6 ppm autorise alors la localisation définitive de l'hydroxyle en position 2 et du méthoxyle en position 3 sur le cycle A. Les deux spectres diffèrent par la position des signaux dûs aux protons du cycle D ce qui confirme la position différente de l'hydroxyle phénolique sur ce cycle.

Le spectre de rmn ^{1}H de la (−)-anibacanine **6** présente à δ 6,57 ppm et 6,75 ppm deux doublets (J = 8,0 Hz) et un

[f]125 MHz.
[g]67 MHz.

pseudotriplet à δ 7,03 ppm (J = 8,0 Hz) ce qui indique que l'hydroxyle phénolique est porté par le carbone 9 ou 12.

L'analyse des résultats d'une expérience rmn de type nOe (voir partie expérimentale) met en évidence en particulier une proximité spatiale du proton en 12 (δ 6,75 ppm) et d'un des protons en 13 (δ 3,29 ppm), ce qui est en faveur de la substitution du carbone 9 par l'hydroxyle phénolique comme l'indique la position des signaux des protons méthylèniques en 8. La confirmation de cette substitution est apportée par l'analyse de la corrélation hétéronucléaire C–H longue distance (COLOC) qui met en évidence un couplage ^3J entre le carbone 13 (δ 35,8 ppm) et le proton en 12 (δ 6,75 ppm). Les attributions précises des signaux du spectre de rmn ^1H relatives aux protons 5, 6, 8 et 13 de cette tétrahydroprotoberbérine **6** et des composés **7**, **8**, **9**, **10**, **11**, **12** ci-après décrits, ont été réalisées sur la base de la mesure de leurs déplacements chimiques et constantes de couplage, conformément aux travaux publiés par Tourwé et al. (11).

L'attribution complète des signaux de rmn ^{13}C (cf. tableau 4) a été réalisée à l'aide des spectres de corrélation hétéronucléaire directe et longue distance.

En ce qui concerne la (−)-pseudoanibacanine **7**, les protons du cycle D résonnent sous forme d'un systéme ABX à 6,90 (d, J_o = 8,0 Hz), 6,67 (dd, J_o = 8,0 Hz; J_m = 2,0 Hz) et 6,62 (d, J_m = 2,0 Hz). L'hydroxyle phénolique est porté par le carbone 10 ou par le carbone 11. L'expérience de corrélation homonucléaire longue distance (réalisée dans $CDCl_3$–C_5D_5N) montre un couplage entre les deux protons méthyléniques en 8 et le proton en 9 (δ 6,90 ppm) ainsi qu'entre les protons méthylèniques en 13 et le proton en 12 (δ 6,62 ppm); ces résultats permettent de placer l'hydroxyle en position 11.

L'attribution complète des signaux de rmn ^{13}C (cf. tableau 4) a été réalisée à l'aide des spectres de corrélation C–H directe en longue distance.

La configuration absolue des protoberbérines pouvant, selon la règle empirique énoncée par Kametani et Ihara (12), être reliée au signe du pouvoir rotatoire de la molécule, nous proposons la configuration absolue 14-*S* pour la (−)-anibacanine **6** et la (−)-pseudoanibacanine **7**.

Les deux tétrahydroprotoberbérines suivantes, la (+)-manibacanine **8** et la (+)-pseudomanibacanine **9**, présentent des caractéristiques spectrales très proches de celles des deux alcaloïdes précédents. En effet, les spectres de masse de **8** et de **9** présentent un ion moléculaire à m/z 311, supérieur de 14 uma à ceux des composés **6** et **7**, correspondant à la formule brute $C_{19}H_{21}NO_3$. Le pic de base à m/z 190 accompagné d'un pic important à m/z 192 est également de 14 uma supérieur au pic correspondant observé pour la (−)-anibacanine **6** et la (−)-pseudoanibacanine **7**, le pic à m/z 120 étant également présent. Ces valeurs suggèrent la présence de deux méthoxyles au lieu d'un hydroxyle et d'un méthoxyle sur la partie isoquinoléique des deux composés, la substitution du cycle D restant inchangée. Cette hypothèse est confirmée, d'une part par la présence de deux signaux correspondant à deux méthoxyles sur le spectra de rmn du proton (cf. tableau 3) des deux alcaloïdes, et d'autre part par la différence des déplacements chimiques (Δδ) des protons en 1 et 4 qui est ici de 0,12 ppm (valeur caractéristique d'une telle substitution (9)). Les autres signaux ne sont pas modifiés. Le pouvoir rotatoire de ces deux alcaloïdes étant positif, la (+)-manibacanine **8** et la (+)-pseudomanibacanine **9** possèderaient une configuration 14 *R* (12).

Les trois dernières tétrahydroprotoberbérines isolées sont des dérivés, méthylés en 8, de la (−)-anibacanine **6** et de la (−)-pseudoanibacanine **7**.

For personal use only.

Les spectres de masse des trois nouveaux composés **10**, **11** et **12** présentent un schéma de fragmentation similaire. Le pic moléculaire à *m/z* 311 est de faible intensité. Le pic de base à *m/z* 296 correspond à la perte d'un groupement méthyle. Les deux autres fragments de fréquence non négligeable à *m/z* 178 et à *m/z* 134, observables sur le spectre, résultent de la rupture des liaisons benzyliques et correspondent au fragment isoquinoléique de la molécule pour le premier, et à la partie benzylique de la molécule portant le groupement méthyle du carbone 8 pour le deuxième. L'ensemble de ces fragmentations montre que ces trois alcaloïdes portent le même type de substitution que les alcaloïdes **6** et **7**.

Les spectres de rmn du proton de la (−)-α-8-méthylpseudoanibacanine **10** et de la (−)-β-8-méthylpseudoanibacanine **11** (cf. tableau 3) sont semblables, dans la région des protons aromatiques et des méthoxyles, au spectre de la (−)-pseudoanibacanine **7**. De plus, un doublet de trois protons (δ ~1,4 ppm, *J* ~6,5 Hz) est attribuable à un groupement méthyle placé en 8 ou en 13. La présence d'un quadruplet (*J* ~6,5 Hz) correspondant à un proton géminé au groupement méthyle est observable à des champs différents sur les spectres de **10** (δ 4,11 ppm) et de **11** (δ 3,69 ppm) ce qui suggère que le groupement méthyle est porté par le carbone 8 dans des configurations différentes.

Afin d'obtenir une meilleure résolution des signaux donnés par les protons aliphatiques, le spectre de rmn ^{1}H a également été enregistré dans l'acétonitrile deutérié (cf. tableau 3). Les protons portés par les carbones 13 et 14 apparaissent, dans ce cas, sous forme de trois doublets dédoublés à δ 3,02 ppm ($J_{13\alpha,14}$ 4,0 Hz J_{gem} 16,5 Hz) et à δ 2,59 ppm ($J_{13\beta,14}$ 11,0 Hz, J_{gem} 16,5 Hz) pour les protons en 13 et à δ 4,12 ppm ($J_{13,14}$ 4,0 et 11,0 Hz) pour le proton en 14 sur le spectre de la (−)-α-8-méthylpseudoanibacanine **10**; les signaux dûs à ces protons sont plus difficilement observables sur le spectre de la (−)-β-8-méthylpseudoanibacanine **11** étant donné la superposition de ces signaux avec ceux donnés d'une part par le proton en 8 et par les protons en 5 et 6 d'autre part. Seul le doublet dédoublé dû à un des protons en 13 est clairement visible à δ 3,15 ppm ($J_{13\alpha,14}$ 3,0 Hz, J_{gem} 16,0 Hz), alors que le signal donné par le proton en 14 se superpose partiellement au signal du proton geminé au groupement méthyle en 8 à δ 3,57 ppm.

Le déplacement chimique vers les champs faibles du proton en 8 ainsi que du proton 14 dans le cas de la (−)-α-8-méthylpseudoanibacanine **10** est indicatif d'une relation *trans* de ces deux protons (13). Dans le cas de la (−)-β-8-methylpseudoanibacanine **11** ces mêmes protons résonnent à des champs plus forts indiquant une relation *cis*. Cette configuration respectivement *trans* pour le composé **10** et *cis* pour le composé **11** peut également être déduite de l'examen du spectre de rmn ^{13}C (cf. tableau 4) de chacun des deux alcaloïdes. En effet, les deux spectres diffèrent essentiellement par le déplacement chimique du carbone 14 ainsi que par celui de groupement méthyle. Il est connu que dans le cas d'une configuration *trans* ces deux carbones résonnent dans des champs légèrement plus élevés (δ 50,7 et 18,1 respectivement pour le composé **10**) que dans le cas d'une configuration *cis* (δ 59,5 et 22,5 respectivement pour le composé **11**) (13). En effet cette différence de déplacement chimique est liée au type de jonction des deux cycles du noyau quinolizidine, dans le cas du composé **10** la jonction est *cis*, alors qu'elle est *trans* dans le cas de **11** (13).

Étant donné que le pouvoir rotatoire des deux composés **10** et **11** est négatif la configuration du carbone 14 serait *S*. En effet, la synthèse des énantiomères de la *O*-méthylcorytenchirine et de la corydalydine a montré que seule la configuration du carbone 14 a une influence sur le signe du pouvoir rotatoire (14).

Les protons en 8 et en 14 de la (−)-α-8-méthylpseudoanibacanine **10** étant en relation *trans*, la configuration en 8 doit être *R*. Par contre cette relation étant *cis* dans le cas de la (−)-β-8-méthylpseudoanibacanine **11**, la configuration du carbone 8 doit être *S*.

Le spectre de rmn du proton de la (−)-α-8-méthylanibacanine **12** (cf. tableau 3), troisième tétrahydroprotoberbérine méthylée sur le carbone 8, présente un ensemble de signaux dûs aux protons aromatiques similaire à celui observé sur le spectre de la (−)-anibacanine **6**, permettant ainsi de placer l'hydroxyle phénolique du cycle D en 9. Le groupement méthyle et le proton geminé résonnent, comme dans le cas de la (−)-α-8-méthylpseudoanibacanine **10** sous forme respectivement d'un doublet à δ 1,39 ppm et d'un quadruplet à δ 4,35 ppm (*J* = 6,5 Hz). La position de ce dernier signal, la présence du doublet dédoublé dû au proton en 14 (δ 4,23 ppm $J_{13,14}$ 4,5 et 11,0 Hz), ainsi que le pouvoir rotatoire négatif, suggèrent une configuration absolue 8*R*, 14*S* pour le composé **12**. Le groupement méthyl est donc en position α.

À la suite de l'isolement de l'ensemble de ces alcaloïdes plusieurs remarques doivent être faites.

Il est tout d'abord intéressant de noter que les benzyltétrahydroisoquinoléines originales présenteraient les deux configurations possibles au niveau du carbone 1. La noranicanine **1** est de configuration 1-*R* alors que la norcanelilline **2** et son dérivé *N*-méthylé, la canelilline **3**, seraient de configuration 1-*S*.

Alors qu'une proaporphine et des aporphines dérivant des benzyltétrahydroisoquinoléines de substitution classique comme la coclaurine et la réticuline ont été isolées, aucune tétrahydroprotoberbérine tétrasubstituée (2,3,9,10 ou 2,3,10,11) n'a été isolée. Par contre, il est raisonnable de penser que les tétrahydroprotoberbérines décrites dans ce travail dérivent biogénétiquement de la (+)-noranicanine **1** (pour la (+)-manibacanine **8** et la (+)-pseudomanibacanine **9**) ou de la (−)-norcanelilline **2** (pour la (−)-anibacanine **6** et la (−)-pseudoanibacanine **7**).

L'hypothèse de la présence de deux systèmes enzymatiques différents dans *A. canelilla* peut donc être envisagée. Le premier transformant coclaurine, réticuline et leurs dérivés en aporphines, le second utilisant anicanine et canelilline comme substrat pur la biogenèse des protoberbérines (schéma 1).

Partie expérimentale

Appareillage

Les spectres uv ont été effectués sur un spectrophotomètre Hitachi U-2000. Les spectres ir ont été enregistrés sur un spectrophotomètre Perkin Elmer 580. Les pouvoirs rotatoires ont été mesurés à la longueur d'onde de la raie *D* du sodium à l'aide d'un polarimètre Schmidt–Haensch Polartronic I. Les spectres de rmn ont été effectués dans différents solvants deutériés à l'aide des spectromètres suivants : Jeol GSX 270 WB (270 MHz), Bruker AMWB 300 (300 MHz), Bruker AMWB 500 (500 MHz), Bruker AC 200 (200 MHz) et Bruker WB 360 (360 MHz).

Matériel végétal

Les écorces de tronc d'*Aniba canelilla* ont été récoltées à Fatima de Chimanes (Département du Beni, Bolivie) en 1988. Un

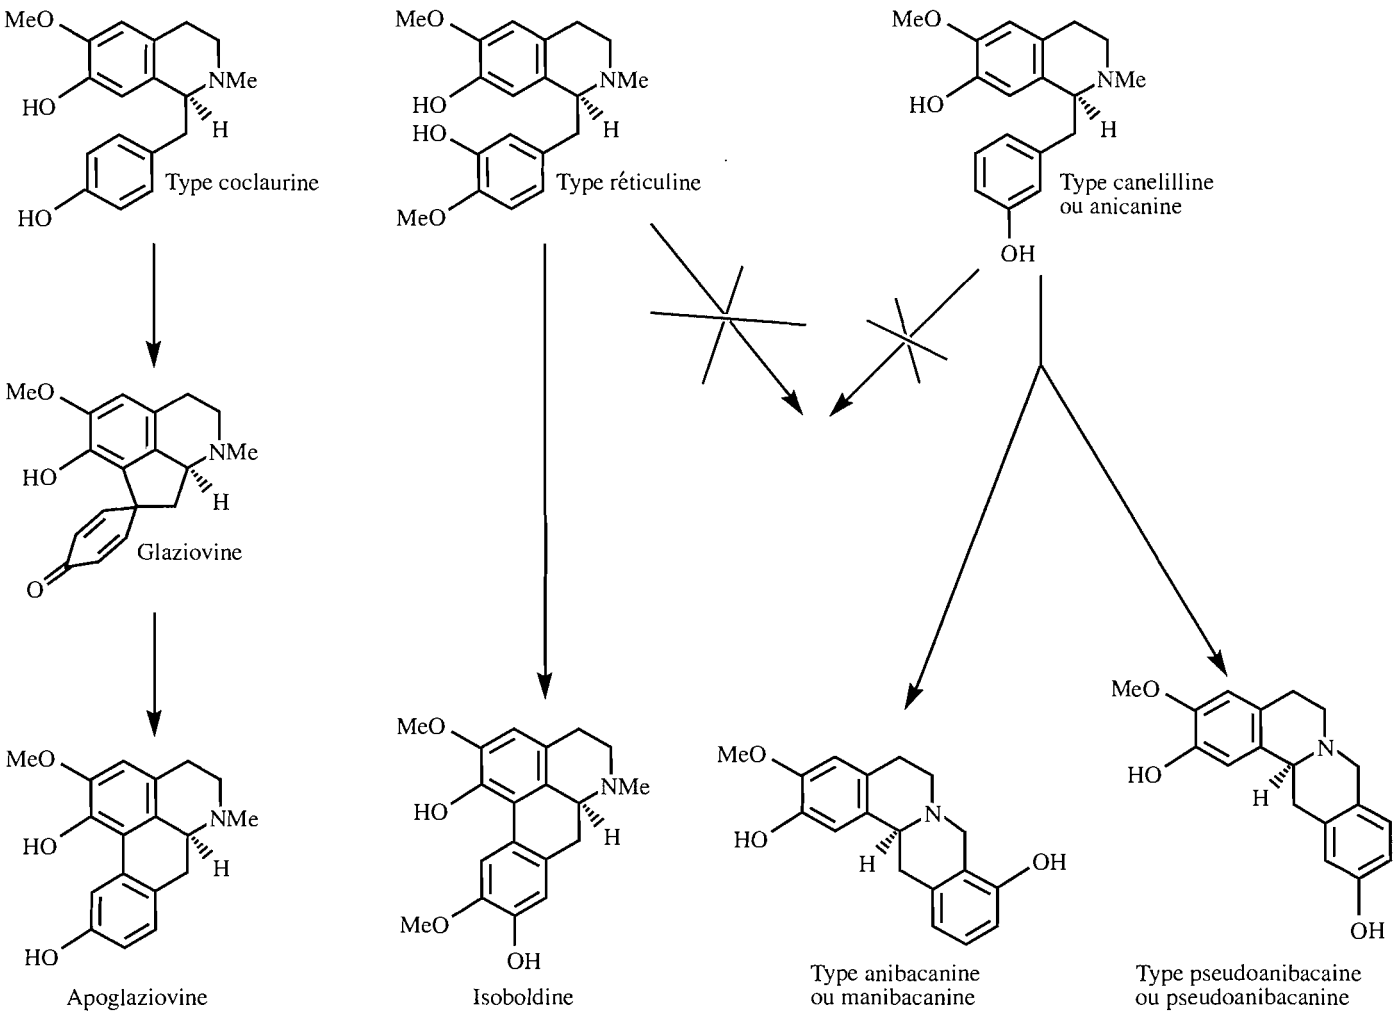

SCHÉMA 1. Hypothèse de biogenèse des alcaloïdes isoquinoléïques chez *Aniba canelilla*.

échantillon d'herbier est déposé à l'Herbier National de Bolivie à la Paz sous la référence A.F. 855.

Extraction et isolement des alcaloïdes

La drogue pulvérisée (3370 g) a été épuisée par l'hexane en milieu neutre dans un extracteur de type Soxhlet. Après élimination du solvant sous pression réduite un résidu de 58,8 g a été obtenu. Après alcalinisation par l'ammoniaque (15%), la poudre végétale a ensuite été extraite par le chloroforme dans un apareil de type Soxhlet. L'extrait brut résultant de l'évaporation partielle sous pression réduite du chloroforme a été épuisé par une solution aqueuse acide (HCl 4%). Après alcalinisation des eaux acides, les alcaloïdes ont été réextraits par le chloroforme. L'élimination du solvant sous pression réduite conduit à 34 g d'alcaloïdes. Le fractionnement des alcaloïdes totaux est réalisé sur colonnes de silice (Merck 0,040–0,063 mm) moyenne pression et ouverte, du chloroforme progressivement enrichi par du méthanol étant utilisé comme éluant. La purification des différents constituants est obtenue par ccm préparative ou par cristallisation. Ont ainsi été obtenus : (+)-réticuline (5231 mg), (−)-coclaurine (2245 mg), (+)-*N*-méthylcoclaurine (5131 mg), (−)-norjuziphine (20 mg), (−)-glaziovine (20 mg), (+)-apoglaziovine (10 mg), (+)-norisocorydine (175 mg) et (+)-isoboldine (1054 mg), (+)-noranicanine **1** (12 mg), (−)-norcanelilline **2** (373 mg), (+)-canelilline **3** (30 mg), anicanine **4** (1 mg), canelillinoxine **5** (4,5 mg), (−)-anibacanine **6** (1886 mg), (−)-pseudoanibacanine **7** (2505 mg), (+)-manibacanine **8** (5 mg), (+)-pseudomanibacanine **9** (2 mg), (−)-α-8-méthylpseudoanibacanine **10** (539 mg), (−)-β-8-méthylpseudoanibacanine **11** (40 mg), (−)-α-8-méthylanibacanine **12** (47 mg).

(−)-Norcanelilline **2**: $C_{17}H_{19}NO_3$; $[\alpha]_D$ −18 (*c* 1, $CHCl_3$); uv λ_{max} (MeOH) nm (log ε) : 226 épaulement (4,11), 283 (3,78); ir ν_{max} cm^{-1} (KBr) : 3290, 3230, 1610, 1595; rmn ^1H (cf. tableau 1); rmn ^{13}C (cf. tableau 2); smie (70 eV) *m/z* : 285 (M^+, 0,15%), 282 (5%), 179 (14%), 178 (100%), 163 (20%), 107 (3%); smic (NH_3). *m/z* : 286 ($[MH]^+$, 100%), 179 (8%), 178 (39%), 163 (8%), 107 (3%).

(+)-Canelilline **3** : $C_{18}H_{21}NO_3$; $[\alpha]_D$ +43 (*c* 0,5, MeOH); uv λ_{max} (MeOH) nm (log ε) : 223 épaulement (4,05), 281 (3,79); rmn ^1H (cf. tableau 1); rmn ^{13}C (cf. tableau 2); smie (70 eV) *m/z* : 299 (M^+, 0,06%), 193 (19%), 192 (100%), 177 (21%), 107 (3%).

Anicanine **4** : $C_{19}H_{23}NO_3$; uv λ_{max} (MeOH) nm (log ε) : 222 épaulement (4,10), 281 (3,64); rmn ^1H (cf. tableau 1); rmn ^{13}C (cf. tableau 2); smic (NH_3) *m/z* : 314 ($[MH]^+$, 100%), 206 (47%), 107 (1%).

La *N*-méthylation de la 1-(3′-benzyloxybenzyl)-6,7-diméthoxy-1,2,3,4-tétrahydroisoquinoléine (4) est réalisée par réaction avec l'aldéhyde formique en solution dans un mélange (1 : 1) de méthanol et de dichlorométhane; après refroidissement à −5°C du mélange réactionnel, l'intermédiaire iminium est réduit en amine. La débenzylation de cette amine par chauffage à 100°C dans un mélange (1 : 1) d'acide acétique et d'acide chlorhydrique conduit à l'anicanine **4**.

Canelillinoxine **5** : $C_{17}H_{15}NO_4$; uv λ_{max} (MeOH) nm (log ε) : 265 (3,78), 324 (3,58); ir ν_{max} (KBr) : 3350–3200, 1670, 1610 cm^{-1}; rmn ^1H (cf. tableau 1); smie *m/z* : 297 (M^+, 32%), 269 (100%), 268 (90%), 254 (7%), 253 (15%), 121 (47%), 93 (17%).

Une étude électrochimique du sulfate de titanyle utilisé en tant que médiateur redox de la réduction du 4,4′-dinitrodibenzyle est réalisée par polarographie et voltammétrie cyclique en milieu H_2SO_4 5 N/EtOH 50:50. Le rôle de Ti^{3+} électrogénéré intervenant comme réducteur chimique de ce substrat est également défini. Les résultats obtenus ont permis de dégager les conditions les plus favorables pour la réalisation de synthèses plus sélectives. Ainsi, lors d'électrolyses à potentiel constant en présence de $TiOSO_4$, le dérivé diaminé est obtenu très pur avec un rendement de 93% alors qu'il est de 75% sans médiateur. La réduction chimique en phase homogène du 4,4′-dinitrodibenzyle par Ti^{3+} préalablement électrogénéré est particulièrement sélective. La valeur du rapport des concentrations Ti^{3+}/dérivé dinitré conditionne la nature des produits formés. Le 4-amino-4′-nitrodibenzyle a été synthétisé avec un rendement de 70% dans le cas d'un rapport 6:1. Ses propriétés électrochimiques et spectrales sont définies. Pour des rapports supérieurs, la quantité de dérivé monoaminé diminue tandis que celle du diaminodibenzyle augmente jusqu'à atteindre 100%. Une comparaison est faite avec trois autres dérivés, les 1,5- et 1,8-dinitronaphtalènes et le 2,2′-dinitrodiphényle. Dans les mêmes conditions, le 1-amino-8-nitronaphtalène n'est pas détecté tandis que le 1-amino-5-nitronaphtalène et le 2-amino-2′-nitrodiphényle sont obtenus avec des pourcentages de 49% et 25%.

ANNE-MARIE MARTRE, VIRGINIA DANCIU, and GUY MOUSSET. Can. J. Chem. **71**, 1136 (1993).

The electrochemical behavior of titanium oxysulfate, used as a redox mediator in the reduction of 4,4′-dinitrodibenzyl, is studied in a 5 N H_2SO_4/EtOH 50:50 medium. The role played by electrogenerated Ti^{3+} ions in the chemical reduction of nitro groups is also defined. The results obtained allow the determination of the most suitable conditions leading to selective syntheses. Macroscale electrolyses at a constant potential in the presence of $TiOSO_4$ give 4,4′-diaminodibenzyl with a great purity and a higher yield (93%) than without mediator (75%). The homogeneous chemical reduction of 4,4′-dinitrodibenzyl by first electrogenerating the Ti^{3+} ions, then adding the organic substrate, is particularly selective. The nature of the reduction products depends on the [Ti^{3+}]/[dinitro derivative] ratio. The 4-amino-4′-nitrodibenzyl is synthesized in a 70% yield for a 6:1 ratio whereas the amount of diamino derivative increases and can constitute the sole reduction product for higher ratios. A comparison is made with 1,5- and 1,8-dinitronaphthalenes and 2,2′-dinitrodiphenyl. Using a 6:1 ratio, 1-amino-8-nitronaphthalene is not obtained while 45% of 1-amino-5-nitronaphthalene and 25% of 2-amino-2′-nitrodiphenyl are formed by reduction of the corresponding dinitro derivatives.

Introduction

Dans le cadre d'une étude générale concernant l'électroréduction de dérivés dinitrés aromatiques, un travail récent dans notre laboratoire a porté sur l'étude analytique de la réduction du 4,4′-dinitrodibenzyle (DNDB) en milieux aprotique ou hydroalcoolique en fonction du pH (1) ainsi qu'en présence de tensio-actifs (2). Ce dernier cas nous a permis de montrer l'importance des phénomènes d'adsorption à la surface de l'électrode.

La réduction électrochimique de dinitroarènes a fait l'objet de travaux antérieurs mentionnant tous la complexité des mécanismes et le grand nombre de produits susceptibles de se former (3–15). Afin d'améliorer la sélectivité de la réaction et plus particulièrement en vue d'obtenir des composés monoaminés, nous nous sommes intéressés à la réduction électrochimique ou chimique du 4,4′-dinitrodibenzyle et à titre de comparaison à celle de trois autres dérivés dinitrés, les 1,8- et 1,5-dinitronaphtalènes et le 2,2′-dinitrodiphényle en présence d'un médiateur.

Une première partie, à caractère analytique, a pour but de mieux connaître le rôle du sulfate de titanyle ($TiOSO_4$) choisi comme médiateur redox Ti^{3+}/Ti^{4+}. Ce dernier a été employé antérieurement pour la synthèse du 1,8-diaminonaphtalène (16). Nous avons envisagé la réduction de $TiOSO_4$ et celle du DNDB d'abord séparément puis en mélange et enfin l'examen, en fonction du temps, de l'évolution du DNDB en présence de l'ion Ti^{3+} électrogénéré.

L'étude a été faite dans les conditions de milieu identiques à celles des électrolyses à potentiel constant en vue de la synthèse d'amines, c'est-à-dire principalement H_2SO_4 5 N/EtOH (50:50) à 60°C. Les milieux $HClO_4$/EtOH et H_2SO_4

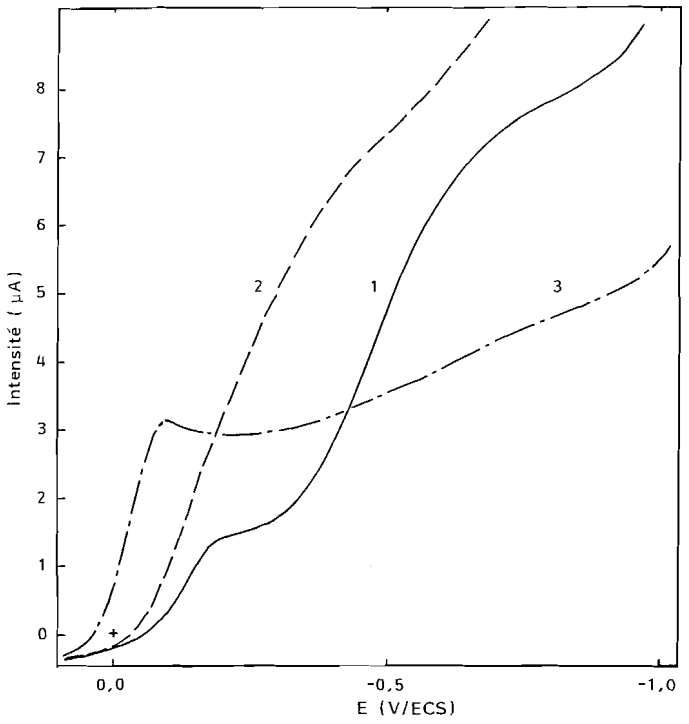

FIG. 1. Polarogrammes de réduction à 60°C. (1) $TiOSO_4$ ($3{,}3 \times 10^{-3}$ M) en milieu H_2SO_4(5 N)/EtOH 50 : 50; (2) $TiOSO_4$ ($3{,}3 \times 10^{-3}$ M) en milieu H_2SO_4(5 N); (3) DNDB (1×10^{-4} M) en milieu H_2SO_4(5 N)/EtOH 50 : 50.

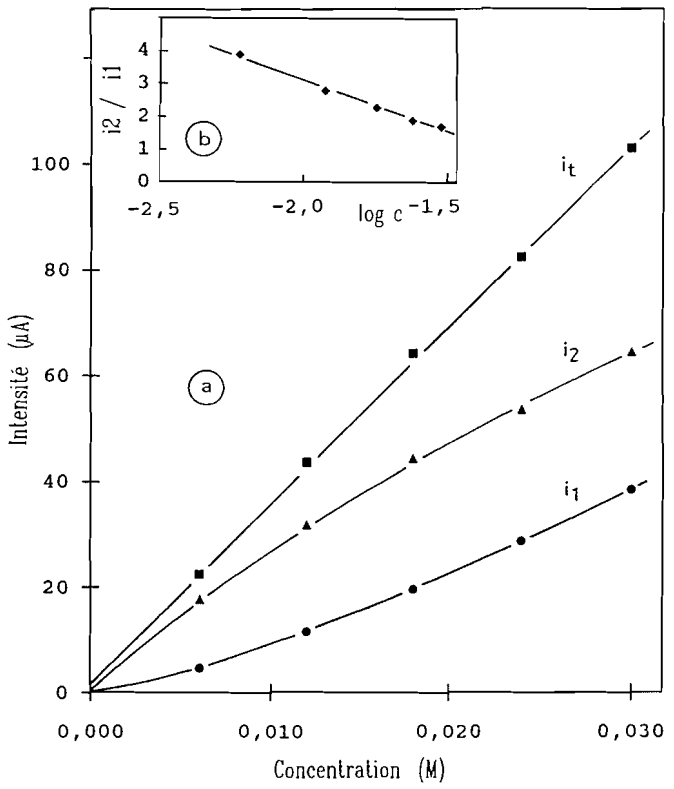

FIG. 2. (*a*) Variations des intensités des vagues de réduction de $TiOSO_4$ en fonction de la concentration. (*b*) Variation du rapport des intensités des deux vagues en fonction du logarithme de la concentration.

sans alcool ont été parfois utilisés à des fins d'interprétation.

Seule l'électrode de mercure permet une étude analytique satisfaisante, la limite cathodique est à environ −1,0 V. Les électrodes solides ne sont pas adaptées : en voltammétrie cyclique, sur électrodes de platine et de monel, la limite d'électro-inactivité de l'électrolyte se situe vers −0,35 V. Sur carbone vitreux, le domaine de potentiel est un peu plus étendu et atteint −0,60, −0,70 V mais ne permet pas d'observer la réduction de $TiOSO_4$.

Une deuxième partie est consacrée à la réalisation d'électrolyses mixtes des dérivés dinitrés en présence de sel de titane ou à des réductions chimiques par l'intermédiaire de Ti(III) électrogénéré par réduction préalable de $TiOSO_4$. Dans chacun des cas, nous examinons l'influence de la quantité de médiateur par rapport à celle de dérivé dinitré sur la nature et les proportions des produits de synthèse.

Comportement électrochimique du sulfate de titanyle, médiateur de réduction du 4,4′-dinitrodibenzyle

Réduction électrochimique du sulfate de titanyle

Polarographie

En milieu H_2SO_4 5 N/EtOH 50:50, le sulfate de titanyle ne se solubilise pas instantanément : la solution est laiteuse à la température ambiante, elle devient limpide et incolore à 60°C.

La réduction polarographique s'effectue en deux étapes d'importances inégales (fig. 1, courbe 1). La hauteur de la première vague est pratiquement indépendante de la pression de mercure, ce qui est caractéristique d'une vague cinétique. L'évolution de l'intensité du courant de diffusion de chacune des vagues (i_1 ou i_2) n'est pas proportionnelle à la concentration mais le rapport i_2/i_1 est une fonction linéaire du logarithme de ce paramètre (fig. 2, *a* et *b*). Seule, la somme des intensités, $(i_1 + i_2)$ est proportionnelle à la concentration et à la racine carrée de la hauteur de la colonne de mercure.

L'analyse logarithmique de la première vague (fig. 3, courbe 1) est une droite dont la pente de 60 mV par unité logarithmique indique un système réversible, $E_{1/2} = -0{,}122$ V ($[TiOSO_4] = 3{,}3 \times 10^{-3}$ M). Celle de la deuxième vague (fig. 3, courbe 2), formée de trois segments de pentes différentes, traduit le caractère complexe de cette étape. Le potentiel est −0,480 V lorsque $i = i_d/2$.

L'addition d'un tensio-actif, le BRIJ 35 (polyoxyéthylène dodécyl éther $C_{12}H_{25}(OCH_2CH_2)_{23}OH$), même en faible quantité, provoque la disparition presque totale de la première étape après une évolution de son potentiel vers les valeurs moins négatives et un déplacement de celui de la deuxième vers des valeurs plus négatives, l'intensité de cette vague devenant en fin d'évolution égale à la somme des deux présentes sans tensio-actif.

En milieu H_2SO_4 5 N sans alcool, on observe une seule vague de réduction située à des potentiels moins négatifs que les deux précédentes (fig. 1, courbe 2). Son intensité est proportionnelle à la concentration de $TiOSO_4$. L'analyse logarithmique (fig. 3, courbe 3) fait apparaître deux cinétiques successives, la deuxième étant beaucoup plus lente que la première. À mi-hauteur de la vague, $E = -0{,}220$ V. Par additions progressives d'alcool, on constate la scission progressive de la vague initiale obtenue en absence d'alcool avec formation d'une deuxième étape à des potentiels plus négatifs

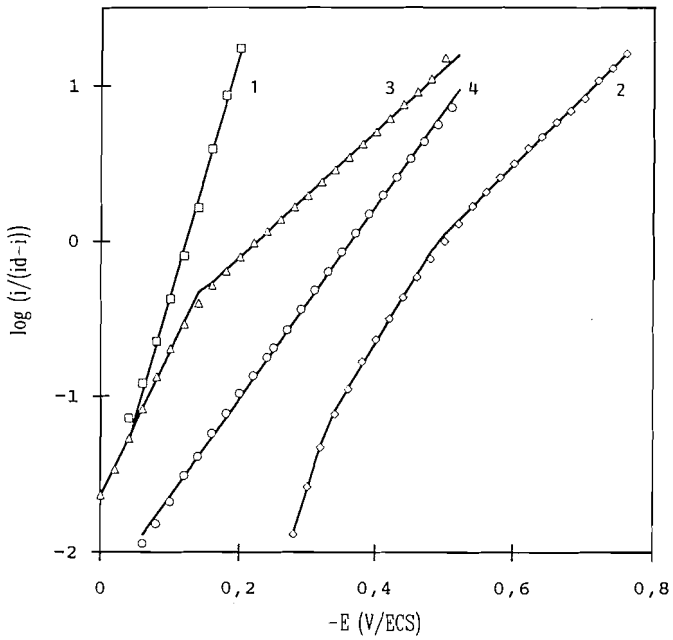

FIG. 3. Analyse logarithmique des vagues polarographiques de $TiOSO_4$ dans différents milieux à 60°C. (1) et (2) H_2SO_4(5 N)/EtOH 50 : 50 (1ère et 2e étape); (3) H_2SO_4(5 N); (4) $HClO_4$(5 N)/EtOH 50 : 50.

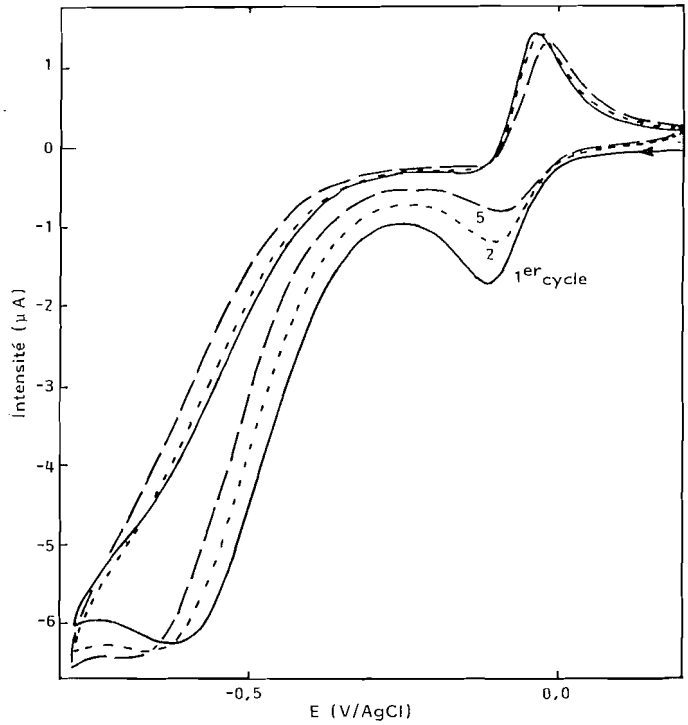

FIG. 4. Voltammogrammes de réduction sur électrode de mercure de $TiOSO_4$ ($5{,}6 \times 10^{-3}$ M) en milieu H_2SO_4(5 N)/EtOH 50 : 50 à 60°C. Cycles successifs : 1er, 2e et 5e cycles à v = 0,05 V s^{-1}.

et la diminution régulière de l'intensité de la première étape, ce qui correspond au passage de la courbe 2 à la courbe 1 sur la fig. 1.

En milieu $HClO_4$ 5N/EtOH, 50 : 50 (acide non complexant), on obtient une vague unique pour laquelle $\log(i/(i_d - i))$ varie linéairement en fonction du potentiel (fig. 3, courbe 4), avec une pente de 160 mV (vague irréversible, $E_{1/2} = -0{,}360$ V).

Voltammétrie cyclique

La réduction de $TiOSO_4$, sur électrode stationnaire de mercure (fig. 4), est également observée en deux étapes comme en polarographie tandis que la réoxydation au balayage retour a lieu en une étape unique dont l'intensité dépend du temps de balayage. Les potentiels des deux pics cathodiques et du pic anodique sont respectivement :

$$E_{Pc}(1) = -0{,}140 \text{ V} \quad E_{Pc}(2) = -0{,}50 \text{ V}$$

$$E_{Pa} = -0{,}06 \text{ V(Ag/AgCl)}$$

$$(v = 0{,}1 \text{ V s}^{-1},\ c = 2 \times 10^{-3} \text{ M})$$

Dans les mêmes conditions de vitesse et de domaine de balayage, jusqu'à −0,90 V, seule l'intensité du pic de réoxydation est proportionnelle à la concentration en $TiOSO_4$ (cette proportionnalité a été mesurée entre 5×10^{-4} et 8×10^{-3} M). Lorsque la vitesse de balayage est plus grande, l'intensité du pic de réoxydation (i_a) augmente proportionnellement plus que celles des pics de réduction, ce qui est également caractéristique d'une étape cinétique mais elle est linéaire en fonction de la racine carrée de la vitesse.

Au cours de plusieurs cycles successifs sur un même échantillon, l'intensité du premier pic diminue tandis que celle du deuxième augmente (fig. 4). Cette diminution est d'autant plus sensible que la vitesse de balayage est plus lente : à v = 10 mV s^{-1}, le premier pic a pratiquement disparu dès le deuxième balayage en tension. Le pic de réoxydation est peu modifié. Lors de la succession des cycles, on note également une évolution des potentiels de réduction : celui de la première étape se déplace vers des valeurs moins négatives et celui de la deuxième vers des valeurs plus négatives. Le potentiel du pic de réoxydation évolue vers des valeurs moins négatives.

De même qu'en polarographie, l'addition de BRIJ 35 entraîne la disparition du premier pic de réduction et le déplacement du deuxième vers des potentiels plus négatifs avec une augmentation de son intensité. Le pic anodique est déplacé vers les potentiels moins négatifs.

En absence d'alcool, la réduction en milieu H_2SO_4 a lieu en une seule étape quasi-réversible. Pour une vitesse de balayage v = 0,1 V s^{-1}, les potentiels des pics cathodique et anodique sont respectivement $E_{Pc} = -0{,}25$ V et $E_{Pa} = -0{,}025$ V (Ag/AgCl) (système lent). La réduction en milieu $HClO_4$/EtOH est irréversible, $E_{Pc} = -0{,}60$ V.

Déterminations coulométriques

Des coulométries et macroélectrolyses à potentiel contrôlé à −0,60 V, sur nappe de mercure, ont permis de déterminer que la quantité totale d'électricité mise en jeu est de 1 F mol^{-1}. Au cours des électrolyses, la solution prend une coloration bleu–violet clair, caractéristique des sels de Ti(III).

Discussion

Les premières études de la réduction électrochimique des sels de titane ont été effectuées principalement en milieux aqueux acides (17–25). Elles ont montré que la nature de l'acide et sa concentration sont des facteurs importants dans l'évolution des polarogrammes. La complexation de Ti(IV) avec les anions a été mise en évidence. En milieu acide sul-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

furique, l'équilibre suivant a été proposé (21*a*) en présence d'ions H^+ et d'ions SO_4^{2-} :

$$TiO^{2+} \xrightleftharpoons{H^+} \underset{\text{instable}}{[Ti(OH)]^{3+}} \xrightleftharpoons{SO_4^{2-}} [Ti(OH)(SO_4)_n]^{(3-2n)+}$$

(A) (B)

$$\xrightleftharpoons{H^+} [Ti(OH_2)(SO_4)_n]^{(4-2n)+}$$

(C)

L'espèce A existe en solutions très diluées tandis que la formation de l'espèce C est obtenue pour des plus fortes concentrations en ions H^+ et sulfate. Cette dernière est la plus facilement réductible et sa réduction est réversible. L'espèce B existe aux concentrations intermédiaires. Elle a été plus particulièrement mise en évidence en milieu H_2SO_4 4 M (21). En milieu H_2SO_4 2 M/EtOH (1 : 3), d'autres auteurs (26) ont observé la réduction polarographique de Ti(IV) en deux étapes ayant sensiblement la même importance aux potentiels respectifs ($E_{1/2}$) de −0,18 et −0,43 V(ECS) pour une concentration en substrat de 5×10^{-4} M. Nos résultats montrent que l'importance relative des deux étapes dépend à la fois de la proportion acide/alcool et de la concentration en substrat (figures 1 et 2).

En milieu H_2SO_4/EtOH, la présence d'une étape cinétique et l'évolution de son intensité en fonction de la quantité d'alcool en solution prouve la participation de ce dernier (S) dans la formation de deux espèces électroactives (Ox_1) et (Ox_2) réduites à des potentiels différents :

$$A + S \rightleftarrows Ox_1$$

$$Ox_1 \underset{k_2}{\overset{k_1}{\rightleftarrows}} Ox_2$$

Il est connu que Ti(IV) peut complexer les alcools et former ainsi des espèces souvent utilisées en chimie organique dans la réalisation de réactions d'oxydation (27). Nous pouvons admettre l'établissement d'un équilibre comparable à celui proposé en milieu aqueux mais faisant intervenir les espèces $[Ti(HOR)(SO_4)_n]^{(4-2n)+}$ et $[Ti(OR)(SO_4)_n]^{(3-2n)+}$ avec R = C_2H_5, la présence d'alcool ou d'alcoolate dans les complexes entraînant de plus une meilleure séparation des vagues. L'hypothèse de différentes valeurs de *n* s'accorde avec l'existence de plusieurs segments dans l'analyse logarithmique de la deuxième étape. Il est à noter que nous avons observé un comportement électrochimique identique à celui de $TiOSO_4$ avec $Ti(SO_4)_2$ et $TiCl_4$,THF qui, en solution, doivent évoluer vers les mêmes espèces.

Lors d'additions de BRIJ 35, tensio-actif fortement adsorbable à la surface de l'électrode de mercure, la suppression progressive de la première étape et le déplacement de la seconde vers des potentiels plus négatifs traduit l'existence, à l'interface électrode–solution, d'une couche de tensio-actif qui rend la réduction des diverses espèces plus difficile. Il a été également noté que l'éthanol en forte concentration peut entraîner, par formation d'une couche adsorbée, le dédoublement de certaines étapes complexes (28). De même, on peut penser que la diminution de la première étape lors de cycles successifs est la conséquence d'une forte adsorption d'espèces réduites contenant ou non des molécules d'alcool. Une vitesse de balayage lente favorisera l'établissement de l'équilibre d'adsorption entraînant ainsi une diminution plus importante de la première étape à partir du deuxième cycle.

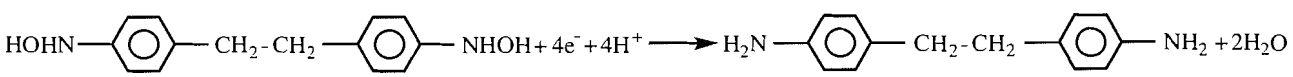
Réduction électrochimique du DNDB en absence de $TiOSO_4$

En milieu H_2SO_4/EtOH 50 : 50, la solubilité du DNDB à 60°C est limitée à environ 5×10^{-4} M. Le polarogramme présente deux vagues successives mettant en jeu respectivement huit et quatre électrons par molécule (fig. 1, courbe 3). La première possède un maximum d'adsorption et son potentiel de demi-vague $E_{1/2}$ est de l'ordre de −0,020 V. La deuxième étape est très étalée en potentiel ce qui ne permet pas une détermination précise de $E_{1/2}$.

En voltammétrie cyclique, quelle que soit la concentration, la première étape cathodique est toujours composée de deux pics rapprochés dont le potentiel est compris entre 0 et −0,05 V (Ag/AgCl). La deuxième étape, lente, est peu importante. On peut situer le potentiel de pic au voisinage de −0,75 V. Au balayage retour, aucun pic n'est observé.

Les mécanismes de réduction qui sont les mêmes qu'en milieu acide tamponné ont été donnés dans une étude antérieure (1). Globalement, la première étape conduit à la dihydroxylamine avec mise en jeu de huit électrons et huit protons :

La seconde correspond au passage de la dihydroxylamine à la diamine par échange de quatre électrons et quatre protons :



Comportement électrochimique du mélange $TiOSO_4$ + DNDB

Dans le cas d'additions de DNDB à une solution de $TiOSO_4$ ou inversement dans celui d'additions de $TiOSO_4$ à une solution de DNDB, la polarographie ne permet plus de séparer assez nettement les différents transferts électroniques et n'apporte pas d'informations supplémentaires exploitables ce qui nous a conduit à utiliser de préférence la voltammétrie cyclique.

Nous avons étudié plus particulièrement l'effet du DNDB sur les voltammogrammes de $TiOSO_4$ (fig. 5). Lors d'additions successives de DNDB, le pic complexe (à 0, −0,050 V) de la première étape de sa réduction précède toujours celui de $TiOSO_4$ et les secondes étapes de réduction des deux composés sont superposées. Au balayage retour, le pic d'oxydation de Ti(III) diminue notablement et parfois disparaît.

Dans les conditions de concentrations pour lesquelles le

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

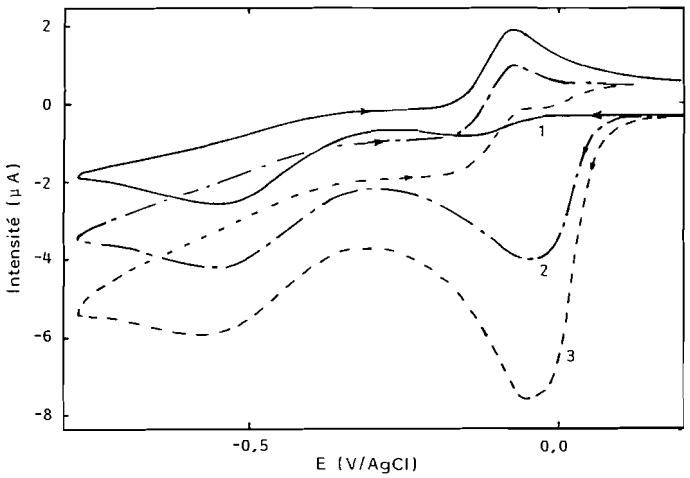


FIG. 5. Voltammogrammes de mélanges $TiOSO_4$ + DNDB sur électrode de mercure $v = 0{,}2$ V s^{-1}. (1) $TiOSO_4$ $1{,}2 \times 10^{-3}$ M; (2) = (1) + DNDB 10^{-4} M; (3) = (1) + DNDB 2×10^{-4} M.

DNDB est soluble, on note des comportements spécifiques en fonction de la vitesse de balayage en tension. Aux faibles vitesses, $v \leq 50$ mV s^{-1}, l'intensité relative de la deuxième étape cathodique a une croissance plus rapide que celle qui résulterait de la seule augmentation de la concentration en DNDB et son potentiel est légèrement déplacé vers des valeurs plus négatives. Au balayage retour, le pic anodique devient de plus en plus petit jusqu'à disparaître des voltammogrammes. À $v = 200$ mV s^{-1} (fig. 5), l'intensité du deuxième pic cathodique n'augmente pas en proportion de la quantité de DNDB ajouté et son potentiel reste constant tandis qu'au balayage retour, le pic anodique diminue également mais sans disparaître. Ainsi, le rapport des intensités des deux pics de réduction (i_2/i_1) est d'autant plus grand que la vitesse est plus petite.

L'ensemble de ces résultats montre que parallèlement à la réduction électrochimique du DNDB, une réaction chimique peut avoir lieu en solution entre le DNDB et le Ti(III) généré à la première étape; elle redonne du Ti(IV) et produit l'hydroxylamine. Si cette réaction chimique a lieu (balayage lent), du Ti(IV) et une quantité additionnelle d'hydroxylamine sont formés au voisinage de l'électrode, ce qui cause une augmentation du courant i_2. Le Ti(III) généré par réduction de Ti(IV) au deuxième pic est consommé par le DNDB, d'où, au balayage retour, la diminution du pic d'oxydation et même sa disparition si le balayage est suffisamment lent et la concentration de DNDB assez élevée. Si la réaction chimique n'a pas lieu (balayage rapide), l'hydroxylamine produite par réduction électrochimique à la première étape est réduite en amine au niveau du deuxième pic. L'intensité du pic d'oxydation correspond alors à la quantité de Ti(IV) généré aux premier et deuxième pics.

Réduction chimique du DNDB par Ti(III) électrogénéré

Le DNDB est ajouté à une solution de Ti(III) obtenu par réduction électrochimique de $TiOSO_4$ et l'évolution de la solution en fonction du temps est suivie par voltammétrie cyclique pour différentes concentrations des deux substrats.

La figure 6 représente l'évolution du mélange Ti(III)/DNDB dans un rapport 12 : 1 ($2{,}4 \times 10^{-3}$ M/2×10^{-4} M) nécessaire à la transformation complète du dérivé dinitré en dérivé diaminé (DADB) :

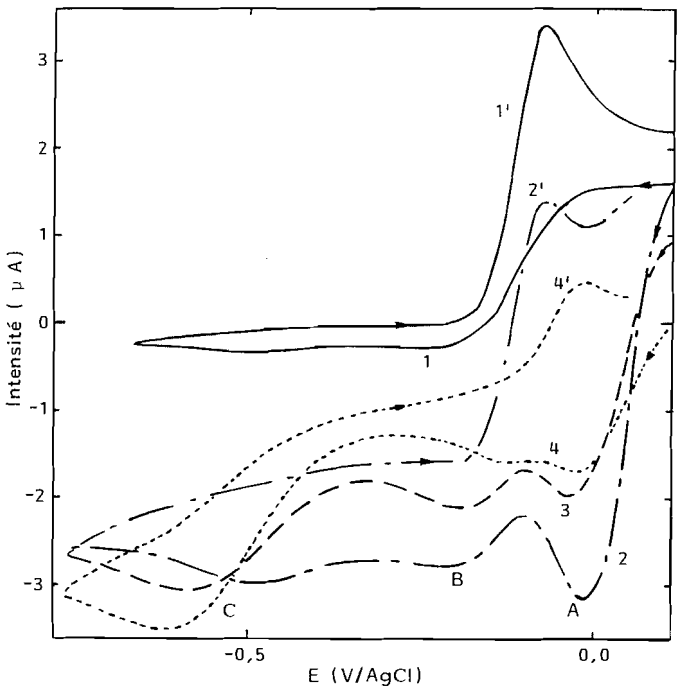

FIG. 6. Evolution en fonction du temps des voltammogrammes du mélange Ti(III)/DNDB 12 : 1. (1) Ti(III) $2{,}4 \times 10^{-3}$ M; (2) = (1) + DNDB 2×10^{-4} M; (3) = (2) après 8 min; (4) = (2) après 40 min. (Le balayage retour de la courbe 3 n'est pas représenté pour faciliter la lecture de l'ensemble.)

$$\text{DNDB} + 12\ \text{Ti(III)} + 12\ \text{H}^+ \rightarrow \text{DADB} + 12\ \text{Ti(IV)} + 4\ \text{H}_2\text{O}$$

La courbe 1 est le voltammogramme de Ti(III) avant l'introduction du produit organique. Au potentiel de départ du balayage (+0,150 V), on note la valeur positive de l'intensité par suite de l'oxydation de Ti(III) à la surface de l'électrode. Au cours d'un balayage aller (en direction des potentiels négatifs), ce courant s'annule au-delà de −0,150 V ce qui indique que Ti(IV) formé est, dans ces conditions, sous la forme la plus facilement réductible (comparaison des figures 4 et 6). En balayage retour, on reconnaît le pic unique de réoxydation de Ti(III).

Après additions de DNDB (courbes 2 à 4), la valeur de l'intensité au potentiel initial diminue de plus en plus en fonction du temps jusqu'à devenir nulle. Au balayage aller, le premier pic cathodique de la courbe 2 correspond à la réduction du DNDB. Sa diminution en fonction du temps est due à la réduction chimique progressive du substrat organique par Ti(III) en solution. L'effet médiateur du couple redox Ti(III)/Ti(IV) se traduit sur les voltammogrammes par l'apparition puis l'augmentation du pic C et la décroissance du pic de réoxydation.

La même expérience a été réalisée avec un rapport Ti(III)/DNDB de 6 : 1 en conservant la concentration en DNDB égale à 2×10^{-4} M. Des observations analogues aux précédentes peuvent être faites mais après un temps de réaction de 40 min, la voltammétrie de contrôle montre que le premier pic de réduction conserve une intensité plus importante que lorsque le rapport est 12 : 1. Le potentiel de ce pic étant celui de la réduction des groupement NO_2, la seule voltammétrie ne permet pas de dire s'il s'agit de la réduction

d'une quantité plus importante de DNDB non réduit ou s'il y a également en solution d'autres espèces nitrées résultant d'une réduction partielle du DNDB initial. Les électrolyses à potentiel constant, analysées dans la seconde partie, qui ont permis d'identifier les produits de réduction et de déterminer leurs pourcentages, ont confirmé cette dernière hypothèse et permettent d'attribuer ce pic principalement à la réduction du 4-amino-4′-nitrodibenzyle.

Sélectivité de l'ion Ti(III) électrogénéré dans la réduction de dérivés dinitrés aromatiques

L'utilisation de médiateurs est très développée dans les procédés d'électrosynthèses et plusieurs mises au point récentes ont présenté et comparé les principaux procédés d'électrolyses indirectes (29–31). Dans le cas de la réduction de dérivés nitrés par des médiateurs redox inorganiques, les composés du titane ont déjà été utilisés soit sous forme de chlorure (32–34) ou de sulfate (35–37) en solution dans les acides correspondants, soit sous forme d'oxyde déposé sur des électrodes de titane (38–41). En présence de $Ti(SO_4)_2$, la réduction électrochimique de dérivés dinitrés tels que le *m*-dinitrobenzène, le 2,4-dinitrotoluène, le 2,4-dinitrophénol et l'acide 4,4′-dinitrostylbène-2,2′-disulphonique que nous n'avons pas abordée dans ce travail a conduit aux diamines (35).

La très faible solubilité en milieu aqueux et même en milieu hydroalcoolique des dérivés dinitrés et spécialement du DNDB nous a orienté vers leur réduction par l'intermédiaire d'un médiateur. Nous avons pu constater en effet une accélération de la réaction en raison de la possibilité de formation d'un complexe plus soluble de type nitronate (33) ou du rôle de «transporteur d'électrons» du médiateur (16, 35, 36). De plus, le choix de paramètres tels que la nature et la concentration de ce dernier, la température, offre une meilleure sélectivité pour la réaction.

Les cinétiques de réduction du DNDB sur cathodes de plomb, étain et cuivre ainsi qu'en présence de sels d'étain ont été étudiées antérieurement et ont conduit à la détermination de la constante de vitesse et de l'énergie d'activation de l'électroréduction potentiostatique et galvanostatique du DNDB en milieu hydroalcoolique (42–44).

Dans cette partie, nous nous intéressons plus spécialement à la réduction mixte DNDB – sel de titane en milieu H_2SO_4 5N/EtOH 50 : 50 à 60°C et à des fins de comparaison, à celles des trois autres dérivés dinitrés, les 1,5- et 1,8-dinitronaphtalènes (1,5-DNN et 1,8-DNN) et le 2,2′-dinitrodiphényle (2,2′-DNDP), dans les mêmes conditions expérimentales.

Tout d'abord, nous avons vérifié que ces composés avaient des comportements polarographiques similaires. Comme il a été signalé dans la partie analytique pour le DNDB, seule la première étape qui conduit à la dihydroxylamine en mettant en jeu globalement huit électrons et huit protons est bien définie. Les potentiels $E_{1/2}$ sont donnés dans le Tableau 1.

Les synthèses ont été réalisées selon deux procédés :

(*i*) Le premier est une électrolyse à potentiel constant pour laquelle le substrat organique et le sulfate de titanyle sont mis simultanément en solution dans l'électrolyte. La valeur du potentiel imposé est comprise entre −0,50 et −0,60 V suivant les composés. L'électrolyse est arrêtée lorsque la quantité d'électricité qui a traversé la cellule correspond au moins au nombre théorique de coulombs nécessaire à la réduction du dérivé dinitré en son homologue diaminé. La réduction simultanée de Ti(IV) rend la valeur imprécise. En fin d'électrolyse, la solution est pratiquement incolore ou très légèrement colorée par la présence de Ti(III).

TABLEAU 1. Potentiels de la première étape de réduction de dérivés dinitrés en milieu H_2SO_4/EtOH 50 : 50 à 60°C

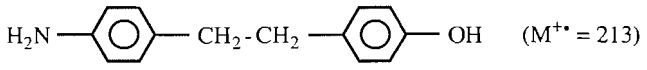
Composés	DNDB	1,5-DNN	1,8-DNN	2,2′-DNDP
$E_{1/2}$ (V/ECS)	−0,020	+0,015	−0,010	−0,115

(*ii*) Le second procédé est une réduction chimique du substrat organique par l'ion Ti^{3+} électrogénéré. Il se déroule en deux temps : la première phase est donc la réduction électrochimique à potentiel constant (E = −0,60 V) de $TiOSO_4$ seul en solution. Lorsque cette réduction est achevée, le dérivé nitré, mis en solution dans quelques millilitres de DMF pour favoriser sa dissolution, est introduit immédiatement dans la cellule en évitant toute entrée d'air. Les mêmes conditions de température et d'agitation sont maintenues. La réaction est considérée comme terminée lorsque la solution de couleur bleu–violet est redevenue incolore, ce qui demande 1–2 h.

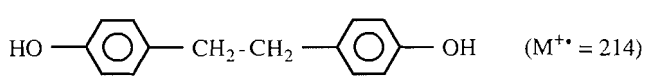
Electrolyses mixtes dinitroarènes – sulfate de titanyle
Electrolyse du DNDB

La concentration en DNDB a été fixée pour toutes les expériences à 10^{-3} M. En absence de médiateur, la réduction électrochimique au potentiel E = −0,60 V a un rendement faradique de 90% par rapport à la réduction en diamine. L'analyse chromatographique des produits de réduction indique l'obtention de 75% de DADB, 1% de DNDB non réduit, 13% de divers sous-produits non identifiés. Deux pics très rapprochés de pourcentages respectifs 2 et 9% précèdent celui du DADB. L'analyse par spectrométrie de masse couplée à la chromatographie en phase vapeur a mis en évidence deux composés de masses molaires M = 213 et M = 214 dont la fragmentation principale fournit respectivement les ions à m/z = 106 et m/z = 107.

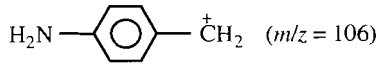
Ces résultats sont compatibles avec les formules



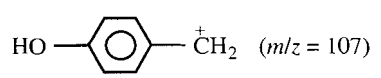
et



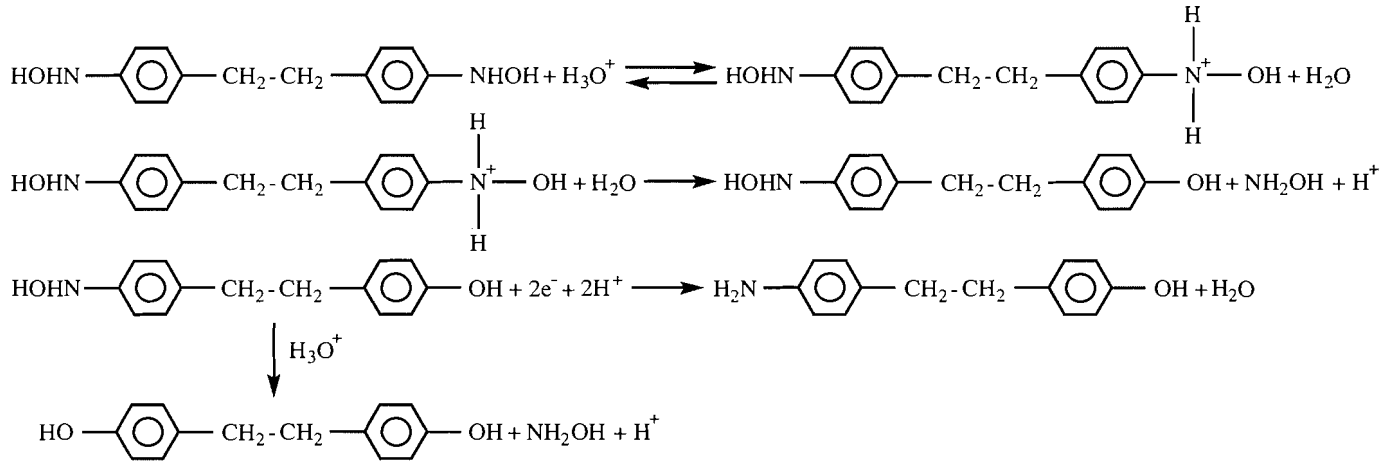
Une coupure benzylique donne les fragments



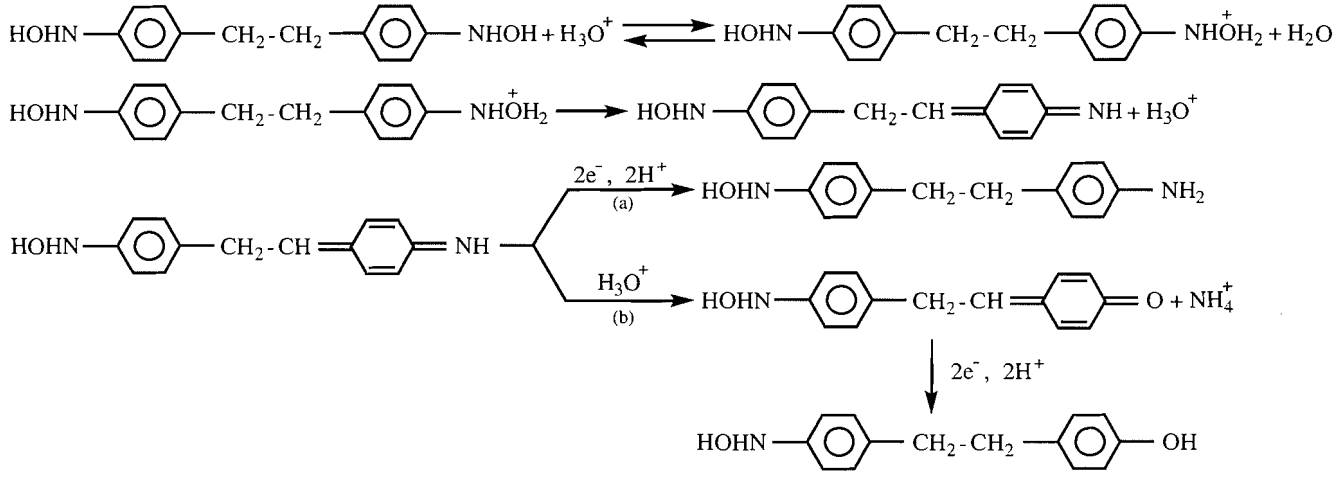
et



La formation de ces deux produits peut être expliquée par une décomposition des hydroxylamines en milieu fortement acide :



On ne peut cependant exclure un mécanisme impliquant la formation intermédiaire d'une structure de type quinone-imine plus facilement réduite que la molécule de départ :



En présence de $TiOSO_4$, plusieurs essais ont été réalisés avec des concentrations croissantes de médiateur afin de déterminer la quantité minimale de ce dernier nécessaire à l'obtention du meilleur rendement possible en diamine.

1. Une concentration de $0,5 \times 10^{-3}$ M modifie peu les résultats obtenus sans médiateur. Dans ces conditions, la réduction fournit 76% de DADB avec des traces des produits de décomposition.

2. Pour une concentration de 2×10^{-3} M, le pourcentage de DADB est de 92% et celui du produit de départ de 3%. Dans ce cas, il est intéressant de noter la suppression des composés secondaires hydroxylés, ce qui permet d'isoler le DADB très pur.

3. Une quantité plus importante de $TiOSO_4$ (6×10^{-3} M) n'a plus d'influence significative sur les résultats, ce qui confirme son rôle de médiateur : l'ion Ti^{4+} régénéré après échange électronique avec le dérivé nitré est à nouveau réduit en Ti^{3+} au potentiel imposé pour l'électrolyse mais le processus catalytique est limité par la cinétique de la réaction chimique.

Electrolyses des 1,5-DNN, 1,8-DNN et 2,2'-DNDP

La réduction électrochimique des autres dérivés dinitrés a été réalisée pour une concentration en substrat organique de 2×10^{-3} M et une concentration en $TiOSO_4$ de 6×10^{-3} M.

La réduction du 1,5-DNN conduit à un bon rendement en 1,5-DAN (93%) et à des traces de produit de départ non réduit. Les résultats sont comparables à ceux obtenus avec le DNDB.

Le cas du 1,8-DNN est beaucoup plus complexe. Seulement 5 à 6% de 1,8-DAN et plusieurs sous-produits dont la formation est vraisemblablement favorisée par la proximité des deux groupements fonctionnels sur les noyaux aromatiques ont été analysés par chromatographie. Nos résultats sont en accord avec ceux cités par d'autres auteurs (7, 10 et réf. citées). Il est connu (6, 9) que par transposition de Gatterman, les hydroxylamines peuvent conduire à des composés hydroxylés ou éthoxylés dans l'éthanol. L'analyse des spectres de masse pourrait faire envisager la formation minoritaire de tels produits mais dans cette étude, nous n'avons pas chercher à les identifier de manière plus précise.

Dans le cas du 2,2'-DNDP, trois produits de réduction ont été détectés par les différentes méthodes d'analyse parmi lesquels le dérivé diaminé est en quantité prépondérante (68%). La benzo[*c*]cinnoline (14%) a également été caractérisée. Sa formation, signalée par d'autres auteurs (3, 8 et réf. citées), résulte d'une suite de réactions faisant intervenir le 2-nitroso-2'-hydroxylamino biphényle. Pour le troisième produit, la spectrométrie de masse permet d'envisager, suivant le même mécanisme que celui développé précédemment pour le DNDB, l'obtention du 2-nitroso-2'-hydroxy biphényle

m/z = 199 ($M^{\bullet+}$); 182 (M – OH); 169 (M – NO)

Réductions chimiques par Ti^{3+} électrogénéré

Réduction du DNDB

Les premiers essais ont été réalisés avec une quantité de Ti^{3+} correspondant à 12 équivalents de DNDB (transformation en diamine) dont la concentration est toujours 10^{-3} M.

Les diverses techniques de chromatographie ont mis en évidence trois produits sans autres impuretés dans les proportions respectives 39, 8 et 53%. Il s'agit du DADB, du DNDB non réduit et d'un nouveau composé. D'autres techniques (RMN, IR, spectrométrie de masse) ont permis de caractériser ce dernier comme étant le 4-amino-4′-nitrodibenzyle (ANDB). Ce composé n'a pas été obtenu électrochimiquement sinon à l'état de traces, ni à notre connaissance par d'autres modes de synthèse.

Nous avons alors examiné l'influence du rapport Ti^{3+}/DNDB sur les réactions. Un excès de réactif conduit au DADB seul avec un très bon rendement. En abaissant la proportion de Ti^{3+}, la formation de ANDB est favorisée. C'est le rapport 6 : 1 qui semble le meilleur et il est possible, dans ce cas, d'isoler 70% de ANDB. Pour un rapport inférieur, une quantité plus importante de DNDB n'est pas réduite ce qui diminue le rendement.

Le tableau 2 présente l'évolution des pourcentages des différents produits de réduction avec la quantité de Ti^{3+} mise en jeu.

TABLEAU 2. Pourcentages des produits de la réduction chimique du DNDB en fonction de la quantité de Ti^{3+}

Ti^{3+}/DNDB	DADB (%)	ANDB (%)	DNDB (%)
24 : 1	98	0	2
12 : 1	39	53	8
6 : 1	19	69	10

Des mesures complémentaires ont permis de vérifier ou de définir les caractéristiques électrochimiques et spectrales de l'ANDB. Nous avons comparé son comportement à celui du DNDB. En milieu H_2SO_4 5 N/EtOH à 60°C, le potentiel de pic de la première étape en voltammétrie cyclique est −0,110 V (Ag/AgCl) (v = 0,1 V s^{-1}), soit légèrement plus négatif que celui du DNDB. En milieu diméthylformamide (DMF), dans lequel les mécanismes des dérivés nitrés sont bien connus, les deux étapes classiques, dans un rapport 1 : 3, sont observées aux potentiels $E_{1/2}(1)$ = −0,680 V et $E_{1/2}(2)$ = −1,77 V (Ag/AgI/(I^-)). Les valeurs citées pour le DNDB étaient $E_{1/2}(1)$ = −0,625 V et $E_{1/2}(2)$ = −1,76 V (1). La formation du radical anion, à la première étape de réduction en milieu DMF, a été mise en évidence par spectrométrie de RPE (fig. 7). Sa structure fine est identique à celle du radical anion du DNDB (1) et les constantes de couplage (en mT) sont respectivement : a(N) = 0,953; $a(H_o)$ = 0,313; $a(H_m)$ = 0,107; $a(H_{CH_2})$ = 0,267.

Réduction des 1,5-DNN, 1,8-DNN et 2,2′-DNDP

Afin de connaître si ce procédé de synthèse de produits monoaminés s'appliquait, dans les mêmes conditions, à d'autres composés, nous avons étendu notre recherche aux trois dérivés dinitrés (1,5-DNN, 1,8-DNN et 2,2′-DNDP). Des études antérieures ont montré que des réductions chimiques dans différents milieux permettent d'obtenir ou non des dérivés nitroaminés (45–54).

Comme dans le cas du DNDB, la concentration en substrat organique est toujours de 10^{-3} M et deux concentrations en $TiOSO_4$ préalablement réduit ont été utilisées correspondant aux rapports 12 : 1 et 6 : 1 nécessaires à la transformation théorique en diamine et en monoamine. Les tableaux 3, 4 et 5 résument, pour chaque dérivé, les pourcentages respectifs de produits diaminé, amino-nitré et non réduit obtenus.

TABLEAU 3. Pourcentages des produits de la réduction chimique du 1,5-DNN en fonction de la quantité de Ti^{3+}

Ti^{3+}/1,5-DNN	1,5-DAN (%)	1,5-ANN (%)	1,5-DNN (%)
12 : 1	74	20	5
6 : 1	17	49	32

TABLEAU 4. Pourcentages des produits de la réduction chimique du 1,8-DNN en fonction de la quantité de Ti^{3+}

Ti^{3+}/1,8-DNN	1,8-DAN (%)	1,8-ANN (%)	1,8-DNN (%)
12 : 1	40	0	Traces
6 : 1	5	0	58

TABLEAU 5. Pourcentages des produits de la réduction chimique du 2,2′-DNDP en fonction de la quantité de Ti^{3+}

Ti^{3+}/2,2′-DNDP	2,2′-DNDP (%)	2,2′-ANDP (%)	2,2′-DNDP (%)
12 : 1	92	6	2
6 : 1	36	25	39

Les données de ces tableaux entraînent plusieurs remarques : la réduction chimique par Ti(III) du 1,5-DNN et celle du 2,2′-DNDP conduisent essentiellement à deux composés : les dérivés diaminé et nitroaminé avec une augmentation sensible de ce dernier lorsque le rapport passe de 12 : 1 à 6 : 1 mais au détriment du rendement de la réaction car une quantité importante de dérivé dinitré n'est plus réduite. On peut également noter que la benzo[*c*]cinnoline n'est pas formée par ce procédé.

Comme par réduction électrochimique, la 1,8-DNN ne donne pas de résultats très satisfaisants dans ces conditions expérimentales. S'il est possible d'obtenir 40% de 1,8-DAN avec le rapport 12 : 1, les analyses n'ont pas mis en évidence le dérivé monoaminé mais l'obtention de sous-produits probablement instables déjà signalés précédemment. Une grande quantité de produit de départ non réduit se retrouve en fin de réaction dès que ce rapport diminue.

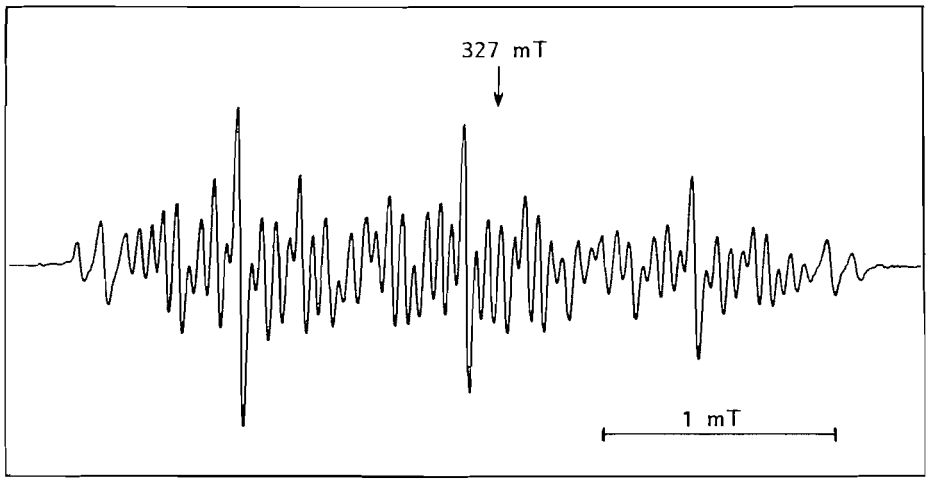

FIG. 7. Spectre de RPE du radical anion du 4-amino 4′-nitrodibenzyle en milieu DMF. Electrolyse à courant constant (80 μA).

Conclusion

L'étude analytique de la réduction électrochimique de $TiOSO_4$ a permis de définir le rôle de médiateur du couple redox Ti^{3+}/Ti^{4+} dans la réduction du DNDB en milieu hydroalcoolique à forte teneur en alcool.

Dans la réduction électrochimique du DNDB, la présence de ce médiateur améliore le rendement en diamine qui peut être obtenue particulièrement pure en raison de la disparition des produits secondaires qui se forment lors de la réduction sans médiateur. Cependant, cette méthode ne permet pas, à cause de la proximité des potentiels de réduction des deux groupements NO_2, l'obtention du dérivé monoaminé. Par contre, la réduction chimique par l'ion Ti^{3+} préalablement électrogénéré est sélective. Selon la valeur du rapport des concentrations Ti^{3+}/DNDB, les dérivés diaminé ou monoaminé peuvent être préparés. C'est une méthode qui s'avère être bien adaptée à la synthèse du 4-amino-4′-nitrodibenzyle.

Les résultats obtenus par ces mêmes procédés avec le 1,5-DNN, le 1,8-DNN et le 2,2′-DNDP montrent l'influence de la position des groupements fonctionnels sur les cycles aromatiques, leur distance plus ou moins grande pouvant modifier la nature et la quantité des produits formés.

Nous avons pu constater que le matériau d'électrode et la nature du médiateur interviennent également sur les mécanismes de réduction. Une étude est en cours sur ce sujet.

Partie expérimentale

Solvants et produits

L'eau des différentes solutions est de l'eau distillée et l'alcool de l'éthanol. Les acides sulfurique et perchlorique sont des produits Prolabo de qualité RP Normapur pour analyses et Normapur 70–72%.

Le sel de titane est un produit commercial Aldrich de formule $TiOSO_4$, x H_2SO_4, x H_2O. Sa composition a été déterminée par thermogravimétrie et dosage acide–base. La valeur de x a été trouvée égale à 0,95. La masse molaire correspondante est M = 270. Dans ce texte, il est écrit en abrégé $TiOSO_4$. D'autres composés du titane comme le sulfate de titane Prolabo ou le complexe tétrachlorure de titane – tétrahydrofuranne Fluka ont également été expérimentés.

Le 4,4′-dinitrodibenzyle est un produit industriel recristallisé trois fois dans le toluène. Les autres dérivés dinitrés sont des produits commerciaux : 1,5-dinitronaphtalène et 1,8-dinitronaphtalène (Aldrich) et 2,2′-dinitrodiphényle (EGA-Chemie). Les composés diaminés commerciaux : 4,4′-diaminodibenzyle, 1,5-diaminonaphtalène et 1,8-diaminonaphtalène (Aldrich) ainsi que la benzo[*c*]cinnoline (EGA-Chimie) ont permis de confirmer l'identification des produits de réduction. Le 2,2′-diaminodiphényle et le 2-amino-2′-nitrodiphényle ont été préparés antérieurement (3, 45–47, 50, 55). La synthèse et les caractéristiques spectroscopiques du 1-amino-5-nitronaphtalène sont également citées dans la littérature (51, 56). (Les abréviations DN.., DA.. et AN.. désignent respectivement les dérivés dinitrés, diaminés et amino-nitrés.)

Instrumentation électrochimique

Les principales techniques électrochimiques analytiques utilisées dans ce travail sont la polarographie et la voltammétrie cyclique à balayage linéaire en tension sur électrode de mercure. Les ensembles expérimentaux ont déjà fait l'objet de descriptions détaillées de notre part (1). Les tensions sont indiquées comme précédemment soit par rapport à l'électrode de référence au calomel saturé (ECS), soit en voltammétrie (électrode PAR 303) par rapport à l'électrode Ag/AgCl qui diffère de 20 mV de la précédente. Les cellules électrochimiques, à doubles parois, sont thermostatées par circulation d'eau à 60°C. Un réfrigérant fixé sur le couvercle réduit l'effet d'évaporation de l'alcool. Avant chaque expérience, les solutions sont toujours soigneusement désaérées par un courant d'argon. Une légère surpression de ce gaz est ensuite maintenue dans la cellule.

Le dispositif des électrolyses préparatives comprend un potentiostat Tacussel PRT 100-1X couplé à un intégrateur IG5-N et à un ampèremètre enregistreur qui permet de suivre l'évolution de l'intensité en fonction du temps. La cellule à trois compartiments est placée dans un bain-marie à 60°C. La cathode est une nappe de mercure de 72 mm de diamètre, l'anode une plaque de plomb et l'électrode de référence l'électrode ECS.

Extraction des produits de réduction

Après l'électrolyse, le catholyte est concentré puis neutralisé par une solution de soude jusqu'à pH basique. Les produits sont extraits à l'éther et la solution éthérée, après séchage sur $MgSO_4$, est évaporée sous vide.

Séparation des produits de réduction

Les produits sont isolés par chromatographie sur colonne de silice Kieselgel 60 Merck (granulométrie 0,063–0,200 mm). L'éluant toluène–acétone (80 : 20 v/v) qui permet une bonne solubilisation et la séparation des composés a dû être remplacé par le mélange toluène–méthanol (90 : 10 v/v) car l'acétone réagit sur les fonctions amines et forme les imines correspondantes détectées par chromatographie en phase vapeur et confirmées par les analyses de spectrométrie de masse.

Techniques de caractérisation des produits de réduction

Les techniques sont principalement les suivantes :

Chromatographie en phase vapeur (CPV)

Le chromatographe Shimatzu est équipé d'une colonne capillaire Méthylsilicone DB1 (J & W Scientific) de 30 m × 0,25 mm. La température du détecteur (FID) et de l'injecteur est de 300°C, celle du four est gérée par une programmation de température (palier à 100°C pendant 1 min, puis chauffage de 100 à 290°C à 5°C min^{-1} et palier pendant 20 min à 290°C). Le gaz vecteur est l'hélium (1,5 bar en entrée de colonne) (1 bar = 100 kPa).

Chromatographie sur couche mince (CCM)

Sur des plaques de silice Kieselgel 60, l'éluant est un mélange toluène–acétone ou toluène–méthanol dans un rapport volumique de 80 : 20 ou 90 : 10. Les plaques sont révélées par irradiation ultraviolette (λ = 250 nm).

Spectrométrie de masse

Les analyses par spectrométrie de masse (impact électronique) couplée à la chromatographie en phase gazeuse ont été faites par le Service Central d'Analyse du CNRS.

Spectrométrie de RMN ^1H

Les produits sont mis en solution dans $CDCl_3$. Le spectromètre est un appareil Bruker MSL 300.

Spectroscopie IR

Les échantillons, sous forme de pastilles avec KBr (1/100 mg), sont traités sur un appareil Nicolet FT-IR.

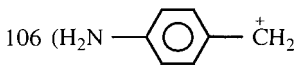
Spectrométrie de RPE

Le spectre est enregistré sur un appareil Bruker ER 200 D dans les conditions décrites précédemment (1).

Caractéristiques des produits de réduction

DADB

Cristaux beige-nacré; F = 134°C. Spectre IR : ν_{NH_2} = 3435 et 3350 cm^{-1}, ν_{arom} = 1620 et 1510 cm^{-1}. Spectre de RMN ^1H δ(ppm) : 2,75 (s,4H,CH_2), 3,6 (s,4H,NH_2), 6,65 (d,4H,arom), 7,0 (d,4H,arom). Spectre de masse : m/z = 212 ($M^{\cdot+}$);

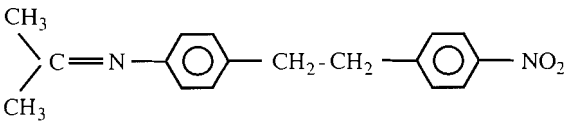


106 (H_2N — C$_6$H$_4$ — CH_2^+).

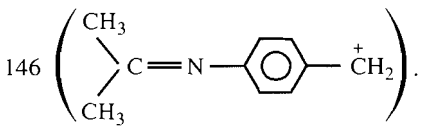
ANDB

Cristaux orange; F = 132°C. Spectre IR : ν_{NH_2} = 3451 et 3375 cm^{-1}, ν_{NO_2} = 1515 et 1340 cm^{-1}, ν_{arom} = 1630 et 1505 cm^{-1}. Spectre de RMN ^1H δ(ppm) : 2,8–2,95 (m,2H,CH_2), 2,95–3,1 (m,2H,CH_2), 3,0–5,0 (étalé,2H,NH_2), 6.75 (d,2H,arom), 6.95 (d,2H,arom), 7,3 (d,2H,arom), 8,15 (d,2H, arom). Spectre de masse : m/z = 242 ($M^{\cdot+}$); 106 (H_2N — C$_6$H$_4$ — CH_2^+).

Produit auxiliaire obtenu en présence d'acétone :



Spectre de masse : m/z = 282 ($M^{\cdot+}$);



146 ($(CH_3)_2C{=}N$ — C$_6$H$_4$ — CH_2^+).

1,5-DAN

Spectre de RMN ^1H δ(ppm) : 4,15 (s,4H,NH_2), 6,7–6,8 (m,2H,arom), 7,2–7,3 (m,4H,arom).

1,5-ANN

Specte de RMN ^1H δ(ppm) : 4,3 (s,2H,NH_2), 6,9 (d,1H,arom), 7,45–7,6 (m,2H,arom), 7,9 (d,1H,arom), 8,1 (d,2H,arom). Spectre de masse : m/z = 188 ($M^{\cdot+}$); 158 (M − NO); 142 (M − NO_2).

1,8-DAN

Spectre de RMN ^1H δ(ppm) : 4,5 (s,4H,NH_2), 6,6 (d,2H,arom), 7,1–7,3 (m,4H,arom). Spectre de masse : m/z = 158 ($M^{\cdot+}$); 141 (M − NH_3); 130 (M − HCN − H).

2,2'-DADP

Spectre de RMN ^1H δ(ppm) : 3,6 (s,4H,NH_2), 6,75–6,9 (m,4H,arom). 7,1–7,25 (m,4H,arom). Spectre de masse : m/z = 184 ($M^{\cdot+}$); 167 (M − NH_3).

2,2'-ANDP

Spectre de RMN ^1H δ(ppm) : 3,3 (s,2H,NH_2), 6,7–6,9 (m,2H,arom), 7,0 (d,1H,arom), 7,1–7,3 (m,1H,arom), 7,4–7,6 (m,2H,arom), 7,6–7,8 (m,1H,arom), 8,0 (d,1H,arom). Spectre de masse : m/z = 214 ($M^{\cdot+}$); 197 (M − OH); 180 (benzo[*c*]cinnoline); 167 (M − HNO_2).

Benzo[c]cinnoline

Spectre de RMN ^1H δ(ppm) : 7,8–8,0 (m,4H,arom), 8,5–8,6 (m,2H,arom), 8,7–8,8 (m,2H,arom). Spectre de masse : m/z = 180 ($M^{\cdot+}$); 152 (M − N_2).

Received January 7, 1993

M. Jesus Vazquez, Emilio Quiñoa, Ricardo Riguera, and Aurelio San Martin. Can. J. Chem. **71**, 1147 (1993).

A new asterosaponin, named helianthoside (**1**), has been isolated from the butanolic extract of the starfish *Heliaster helianthus* and its structure established on the basis of extensive spectroscopic experiments and chemical correlations. Helianthoside is the first asterosaponin with a C3′-sulphated xylopyranose. The absolute stereochemistry at C24 was determined by the Trost–Mosher method.

M. Jesus Vazquez, Emilio Quiñoa, Ricardo Riguera et Aurelio San Martin. Can. J. Chem. **71**, 1147 (1993).

On a isolé une nouvelle astérosaponine dénommée hélianthoside (**1**) à partir d'un extrait d'étoile de mer, *Heliaster helianthus*, dans le butanol et on a établi sa structure à partir de nombreuses expériences spectroscopiques et des corrélations chimiques. L'hélianthoside est la première astérosaponine avec une xylopyranose sulfatée en C3′. On a déterminé la stéréochimie absolue en C24 par la méthode de Trost–Mosher.

[Traduit par la rédaction]

Introduction

Asterosaponins are a well-established class of marine metabolites with complex structures that can be classified in two major groups: (*i*) those characterized by a $\Delta^{9(11)}$-3β,6α-diol steroidal aglycone with an oligosaccharide moiety attached at C6 and a sulphate residue at C3 and (*ii*) those derived from a polyhydroxysteroidal aglycone. The latter occur in minute amounts and are generally based on a cholestane skeleton with a varying degree of hydroxylation involving carbons C4, C5, C6, C7, C8, C12, C14, C15, and C16, with a carbohydrate portion featuring one or two sugar units attached to C3 and (or) to the side chain. In the latter case, a number of variants have been described which differ in the exact location of the sulphate groups on the aglycone or sugar component. Recently, a very small number of polyhydroxysteroid saponins have been isolated from other marine organisms such as sponges (1) and tunicates (2).

As part of our work on marine organisms, we describe in this paper the structure of a novel sulphated monoglycosidic polyhydroxysteroid (**1**, Fig. 1) that we have isolated from the starfish *Heliaster helianthus* and named helianthoside. Complete structural analysis and signal assignment are based on extensive 1D and 2D nmr experiments, FAB mass spectral data, and selective hydrolysis and methylation. Use of the Trost–Mosher (3) method showed an *S* absolute configuration at the stereogenic centre C24.

An isomer of helianthoside, compound **2**, was also isolated. This compound was previously reported by Kitagawa and Kobayashi in *Pisaster ochraceus* (4).

Results and discussion

Starfish collected at Valparaiso, Chile, were extracted with methanol, and the extract was washed with solvents of successively lower polarity. The defatted methanol extract was partitioned into a mixture of *n*-butanol and water, and the polar material was recovered from the butanolic extract by successive chromatography on Amberlite XAD-2 and Sephadex LH-20, droplet countercurrent chromatography (dccc), and reversed-phase hplc, giving the polyhydroxysteroid saponins **1** (12 mg, $[\alpha]_D^{20}$ −15.3) and **2** (17 mg, $[\alpha]_D^{20}$ +90.4).

The positive ion FAB mass spectrum of **1** showed the molecular species $[(M + Na)]^+$ at *m/z* 709 and $[(M + K)]^+$ at *m/z* 725, with the molecular weight M, of 686 amu, corresponding to the monosodium salt formula $C_{32}H_{56}NaO_{12}S$. The peak observed at *m/z* 589 indicated the loss of a sodium sulphate group to leave $[(M + Na) - NaHSO_4]^+$. The fragments corresponding to the cleavage of the sugar (Fig. 1) were observed at *m/z* 307 $[C_9H_{16}NaO_8S]^+$ and 263 $[C_6H_9NaO_8S]^+$. Solvolysis of **1** in dioxane–pyridine afforded the desulphated derivative **1***a*, which under FAB (positive ion mode) produced the species $[(M + Na)]^+$ at *m/z* 607 and $[(M + Na) - C_5H_9O_5]^+$ at *m/z* 458, due to the loss of a pentose.

The negative FAB mass spectrum of **1** corroborated the above results, giving a molecular anion species $[(M - H)]^-$ at *m/z* 663, where the molecular weight M is 664 amu, corresponding to the molecular formula $C_{32}H_{57}O_{12}S$.

After acid hydrolysis and derivatization as an alditol acetate, gc–ms showed the sugar component to be xylose.

The ^{1}H nmr spectrum of **1** (see Tables 2 and 3) contains signals for two quaternary methyls at δ_H 1.08 and 1.13 and three secondary methyls at δ_H 0.98 (d, J = 5.96 Hz), 1.08 (d, J = 6.16 Hz), and 1.15 (d, J = 4.79 Hz) that are characteristic of steroidal aglycones, and for a number of methine protons geminal to oxygen in the region 5.25–3.50 ppm. It also showed one β-anomeric proton at 4.97 ppm (d, J = 7.50 Hz).

The ^{13}C and DEPT data of **1** (Table 1), recorded in pyridine-d_5, showed peaks for 32 carbons. The aglycone part featured three quaternary carbons, nine methylenes, nine methines, and five methyl groups. There were signals at δ_C 76.0, 74.8, 68.4, 64.9, and 85.1 ppm for five carbons bonded to oxygen. The chemical shift of the peak at 85.1 ppm suggests a side-chain carbon bound to a sulphate or sugar unit.

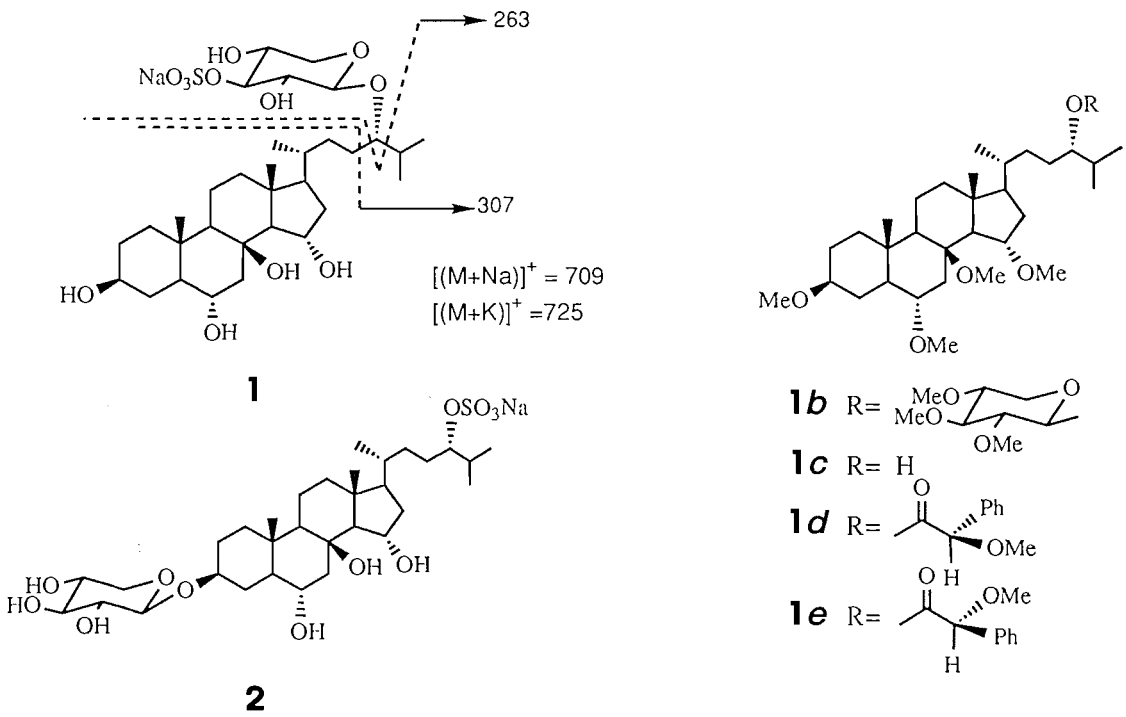

FIG. 1

The sugar part presented signals at 101.5 ppm for the anomeric carbon and at 66.2 ppm for the C5′ methylene group of a pentose; the remaining carbons were unambiguously identified on the basis of selective 1D TOCSY (5) and HMQC (6) experiments.

The above data coincide almost perfectly with those reported by Minale and co-workers (7) for compound **2**. Accordingly, we centered our subsequent efforts on identifying the exact location of the sulphate and the sugar. The location of the sulphate group at C3′ of the xylose was deduced by comparison of the ^{13}C chemical shifts for C2′, C3′ and C4′ in **1** with those of the desulphated compound **1***a* obtained by solvolysis (see Table 1); while the C3′ signals of **1** and **1***a* are practically the same, the C2′ and C4′ signals exhibit the expected β effect (+2 ppm) (7).

Further structural information on **1** was obtained in a series of 2D experiments performed using the inverse probehead technique (AMX 500). HMQC allowed the complete correlation of all the carbon and proton signals; RELAYED H,C-COSY (8) provided information on the connectivity of the molecule and the location of the oxygenated carbons at C3, C6, C15, and C24. The equatorial orientation of the hydroxyl groups at C3, C6, and C15 followed from their observed *J* values.

The glycoside bond was located at C24 by HMBC (9), which among other relevant correlations (Table 3) showed those between the anomeric carbon C1′ on the one hand and H24, the $H_2$5′ pair ($^3J_{CH}$ correlation), and H2′ ($^2J_{CH}$) in the other. HMBC also showed that xylose was present as a pyranose and not as a furanose; correlations between C4′ and H3′ and $H_2$5′ were found, but not between C4′ and H1′.

In keeping with the above conclusions, when the desulphated derivate **1***a* was subjected to exhaustive methylation it yielded a permethylated derivative containing seven methoxy groups, **1***b*, which under acid conditions yielded 3β,6α,8β,15α-tetramethoxy-5α-cholestan-24-ol (**1***c*). Furthermore, nmr data showed **2** to have the same aglycone as **1**.

The above findings show compound **1** to be 24-*O*-(β-xylopyranosyl)-5α-cholestane-3β,6α,8β,15α,24-pentaol 3′-*O*-sulphate.

Comparison with ^{13}C nmr data of known steroids suggests that the absolute configuration at C24 is *S*. We nevertheless decided to prove this by applying the Mosher–Trost nmr method to C24 of **1***c* (see ref. 10 for a recent example). We accordingly prepared the (+)-(*R*)-MPA (MPA = α-methoxyphenylacetic acid) and (−)-(*S*)-MPA esters, **1***d* and **1***e*, respectively. The ^1H nmr spectrum of **1***d* showed among other shifts the 6H doublet for the isopropyl methyl protons at δ_H 0.91, while in **1***e* they resonated at δ_H 0.84 and 0.86. The isopropyl group of **1***d* therefore lies on the same side as the phenyl group of the mandelate, which proves **1** and **2** to be 24*S*.

Of the 100 or so polyhydroxysteroid saponins isolated so far from echinoderms and other families, only 12 compounds with a sulphated sugar are known, all with the sugar attached to the side chain. *Dermasterias imbricata* (11) and *Patiria miniata* (12) afford disaccharides with sulphate groups on C3′ and C5′ of a furanose directly bound to the side chain, while the sulphate is located at C4′ of a pyranose in *Coscinasterias tenuspina* (13), *Astropecten scoparius* (14), and *Pisaster brevispinus* (15), at C6′ of a pyranose in *Pisaster ochraceus* (4) and *Pycnopodia helianthoides* (16), and on a furanose in *Patiria miniata* at C2′, in *Oreaster reticuiatus* (17) at C3′, and in *Astropecten scoparius*, *Asterina pectinifera* (18), and *Patiria pectinifera* (19) all at C5′. Helianthoside (**1**) is thus the first reported asterosaponin with a C3′-sulphated pyranose.

The presence in the same starfish of isomeric saponins such as **1** and **2** is not infrequent. *Pycnopodia helianthoides* af-

[a]Assignments confirmed by HMBC.
[b]For nmr data taken in CD_3OD see ref. 4.

fords two saponins with identical aglycone and sugar in which the sugar and the sulphate group are respectively located at C24 and C3 in one, and at C3 and C24 in the other. *Asterias amurensis* (20) has two saponins with the same aglycone and sugar, and with a sulphate group placed either at C4′ or at C15. The fact that isomeric compounds like **1** and **2** with very similar ^{13}C nmr data are found in the same starfish is interesting from a biogenetical point of view and underlines the importance of chemical correlations in the correct structural analysis of asterosaponins.

We found in our study none of the known saponins recently reported (21) to have been isolated from *Heliaster helianthus*.

Experimental

General

Optical rotation was measured in MeOH in a Perkin–Elmer 141 polarimeter using a sodium lamp operating at 589 nm. One-dimensional nmr spectra were recorded in C_5D_5N at 298 K, ^{13}C nmr and DEPT spectra on a Bruker WM-250 spectrometer at 250 and 60.13 MHz, selective 1D TOCSY spectra on a Bruker AMX-400 spectrometer, and a proton spectrum on a Bruker AMX-500 at 500.14 MHz. The hplc was performed with a Waters model 6000A apparatus equipped with an R401 differential refractometer; dccc was carried out with an Eyela model 300-S apparatus equipped with 300 tubes. Fast atom bombardment mass (FAB ms) spectra were obtained on a Kratos MS50 mass spectrometer with a Kratos FAB source of 2–8 kV Xe atoms; samples were dissolved in a 1:1 glycerol–thioglycerol matrix with NaCl and KCl as additives for positive ion mode, and in a glycerol matrix for negative ion mode. Electronic impact mass (EI ms) spectra were obtained on a Hewlett–Packard 5988 A mass spectrometer, bombarding with electrons of 70 eV energy. The gc–ms analyses were carried out with a 5890 gas chromatograph and a Supelco SP™-2330 capillary column (15 m, i.d. 0.25 mm, film thickness 0.20 μm, carrier gas He 1 mL/min, 240°C), with T_1 = 80°C maintained for 2 min, then 2°C/min up to 100°C, 30°C/min up to 170°C, and 4°C/min up to 240°C, maintained for 10 min; for detection a Hewlett–Packard mass spectrometer was used. All solvents were dried and distilled under argon.

Two-dimensional nmr experiments

All two-dimensional nmr measurements were performed on a Bruker AMX-500 spectrometer with a Bruker X-32 computer running the UXNMR software package. Inverse ^1H–^{13}C correlation experiments with ^1H–^1H RELAYS (sl = 19 ms) were performed in phase sensitive mode (tppi) using the BMLTP sequence for mixing; the spectral widths (t_2) were 3012.05 and 45.52 Hz; 1024 experiments of 96 scans each (relaxation delay 1 s, mixing time 3.8 ms) were acquired in 2 K data points and subjected to QSINE transformation. The two-dimensional ^1H–^{13}C heteronuclear shift correlation (HMQC) spectra (512 × 2K) for directly bonded protons and carbons were obtained by accumulating 48 scans per t_1, with a relaxation delay of 1 s and J_{CH} = 130 Hz. The two-dimensional ^1H–^{13}C heteronuclear shift correlation (HMBC) spectrum (1024 × 2K) of helianthoside was obtained by accumulating 128 scans per t_1; the relaxation delay was 1.5 s and the value of J_{CH} selected was 9 Hz. The data were zero-filled to 1024 in F_1 and subjected to a QSINE transformation.

Extraction and isolation

The starfish *Heliaster helianthus* (3 kg) was collected by hand in December 1990 from intertidal rocks at Valparaiso (Chile) and was immediately freeze-dried. The specimens were identified by Dr. Cecilia Osorio, University of Chile. A voucher is deposited at the Facultad de Ciencias, University of Chile, Santiago. The remaining freeze-dried starfish (1.2 kg) were homogenized in methanol (four times) and the extract was evaporated to dryness under reduced pressure. The dry extract was dissolved in 70:30 MeOH–H_2O, defatted with CH_2Cl_2 (2 × 600 mL), and partitioned between *n*-BuOH and H_2O (4 × 400 mL). The *n*-BuOH extract (3.8 g) was concentrated and passed through a column of Amberlite XAD-2, which was first washed with water (3 L) and then eluted with MeOH (4 L). The methanol eluates were dried under reduced pressure at room temperature to give 1.5 g of a glassy material, which when chromatographed on Sephadex LH-20 (flow rate 60 mL/h) with methanol as eluant and tlc monitoring (silica gel, 12:3:5 *n*-BuOH/AcOH/H_2O) gave three main fractions. The second fraction (700 mg) was subjected to dccc (ascending mode, 7:13:8 $CHCl_3$/MeOH/H_2O, flow rate 12 mL/h), giving four fractions. The second fraction was subjected to repetitive reversed phase hplc on a 30 cm × 19 mm i.d. C_{18} μ-Bondapack column, eluting with 70:30 MeOH/H_2O; it afforded 17 mg of pure **2** (retention time 4.08 min). The third dccc fraction was subjected to hplc as before, eluting with 60:40 MeOH/H_2O; it gave 12 mg of pure helianthoside (**1**), retention time 6.30 min.

Helianthoside (**1**): $C_{32}H_{57}NaO_8S$; $[\alpha]_D^{20}$ −15.3, MeOH (1.70 mg/mL); mp 210–212°C; ^1H nmr: see Tables 1 and 2, ^{13}C nmr: see Table 3, FAB-ms (positive ion mode; *m/z* %): 709 ($[(M + Na)]^+$, 70), 589 ($[(M + Na) - NaHSO_4]^+$, 41), 307 ($[C_9H_{16}NaO_8S]^+$, 64), 285 ($[C_9H_{17}O_8S]^+$, 100), and 263 ($[C_6H_9NaO_8S]^+$, 58). FAB ms (negative ion mode, *m/z* %): 663 ($[(M - H)]^-$, 100); no further fragments were observed.

Compound **2**: $C_{32}H_{57}NaO_8S$; $[\alpha]_D^{20}$ +90.4, MeOH (1.15 mg/mL); mp 206–208°C; ^1H nmr (C_5D_5N) δ_H: 0.88 (d, 3H, J = 13 Hz, 21-Me), 0.10 (d, 3H, J = 13 Hz, 27-Me), 1.04 (d, 3H, J =

Solvolysis of helianthoside (1)

A solution of compound **1** (10 mg) in a mixture of dioxane (1 mL) and pyridine (1 mL) was heated at 120°C overnight in a stoppered reaction vial. After the solution had cooled, the solvents were removed under reduced pressure and the residue was partitioned between water (3 mL) and *n*-BuOH (2 mL). The extraction was repeated three times and the combined organic extracts were washed with water and evaporated to dryness under reduced pressure. The residue was purified by hplc on a 30 cm × 19 mm i.d. C_{18} μ-Bondapack column, eluting with 70:30 MeOH/H_2O, to give one major compound (7 mg, retention time 16.35 min), identified as 24-*O*-(β-D-xylopyranosyl)-5α-cholestane-3β,6α,8β,15α,24-pentaol (**1***a*).

Compound **1**a: $C_{32}H_{58}O_8$; ^{1}H nmr (C_5D_5N) δ_H: 0.98 (d, 3H, J = 13 Hz, 21-Me), 1.10 (d, 3H, J = 13 Hz, 27-Me), 1.14 (d, 3H, J = 13 Hz, 26-Me), 1.26 (s, 3H, 18-Me), 1.32 (s, 3H, 19-Me), 3.22 (dd, 1H, H-4 eq), 3.42 (dd, 1H, J = 6 and 18 Hz, H-7 eq), 3.65 (t, 1H, J = 17 Hz, H-5′ eq), 3.88 (t, 1H, J = 16 Hz, H-2′), 3.91 (m, 1H, H-3 ax), 4.20 (dd, 1H, H-4′), 4.17 (t, 1H, J = 15 Hz, H-3′), 4.37 (t, 1H, J = 10, H-5′ ax), 4.95 (d, 1H, J = 15 Hz, H-1′); ^{13}C nmr: see Table 1. FAB-ms (negative ion mode; m/z %): 569 ([(M − H)]$^-$, 100), 419 ([(M − H) − $C_5H_{10}O_5$]$^-$, 70).

Methylation of compound **1**a *and hydrolysis of* **1**b

A solution of **1***a* (2 mg) in anhydrous dimethyl formamide (1 mL) was stirred with NaH at 60°C for 2 h under an Ar atmosphere. The mixture was treated with CH_3I (0.25 mL) under ice cooling and was stirred at room temperature for a further 12 h in the dark. The reaction mixture was then poured into ice-water and extracted with $CHCl_3$ (3 × 2 mL). The $CHCl_3$ extract was washed with saturated aqueous NaCl solution, and then dried over $MgSO_4$ and concentrated under reduced pressure to give the permethylated compound **1***b* as an oily residue.

Compound **1**b: $C_{39}H_{72}O_8$; ^{1}H nmr (CCl_3D) δ_H: 0.89 (d, 3H, J = 14 Hz, 21-Me), 0.92 (d, 6H, J = 13 Hz, 26-Me and 27-Me), 1.25 (s, 3H, 18-Me), 1.30 (s, 3H, 19-Me), 3.33, 3.34, 3.46, 3.58, 3.59, 3.60, 3.61 (s, 21H, OMe). EI-ms (m/z %): 668 ([M]$^+$, 40), 466 ([M − $C_8H_{16}O_5$]$^+$, 70).

A solution of the permethylated compound **1***b* in anhydrous MeOH (1 mL) and CH_2Cl_2 (1 mL) with *p*-toluenesulphonic acid (cat.) was stirred at 35°C for 24 h. After cooling, it was neutralized with KH_2PO_4 and extracted with $CHCl_3$ (3 × 2 mL). The $CHCl_3$ extract was washed with saturated aqueous NaCl solution, dried over $MgSO_4$, and concentrated to dryness under reduced pressure. The residue was purified by hplc on a 25 cm × 10 mm i.d. Spherisorb column, eluting with 75:25 AcOEt–hexane, to give two major peaks: 1 mg of **1***c* (retention time 4.3 min) and 1 mg of tetra-*O*-methylxylpyranose (**1***f*, retention time 6.8 min).

Compound **1**c: $C_{31}H_{56}O_5$; ^{1}H nmr (CCl_3D) δ_H: 0.89 (d, 3H, J = 14 Hz, 21-Me), 0.92 (d, 6H, J = 13 Hz, 26-Me and 27-Me), 1.25 (s, 3H, 18-Me), 1.30 (s, 3H, 19-Me), 3.33, 3.46, 3.59, 3.61 (s, 12H, OMe). EI-ms (m/z %): 372 ([M]$^+$, 60).

Preparation of the partially methylated alditol acetates of **1**f

The sugar was dissolved in MeOH (1 mL), $NaBH_4$ (1 mg) was added, and the mixture was stirred at room temperature for 2 h. After addition of AcOH to eliminate excess $NaBH_4$, the mixture was concentrated to dryness under reduced pressure and the resulting alditol was acetylated with Ac_2O–pyridine (1:1, 1 mL) by refluxing overnight. The solution was washed with saturated aqueous $CuSO_4$ solution and extracted with CH_2Cl_2. The alditol acetate was identified as 5-*O*-acetyl-1,2,3,4-tetra-*O*-methylxylitol by gc–ms.

Compound **1**d, *the (+)-(*R*)-MPA ester of* **1**c

To 0.4 mg of **1***c* dissolved in dry methylene dichloride (1 mL) were added 0.2 mg of (+)-(*R*)-MPA, excess DCC, and a catalytic amount of dimethylaminopyridine. The mixture was stirred at room temperature for 24 h and washed with saturated aqueous $NaHCO_3$ solution (2 × 2 mL) and 1 N HCl (2 × 2 mL). The organic layer was washed with brine, dried over $MgSO_4$, and concentrated under reduced pressure. The residue was purified on a silica gel column (9 cm × 0.3 cm), eluting with hexane and increasing amounts of AcOEt, to give the (+)-(*R*)-MPA ester of **1***c*.

Compound **1**d: $C_{40}H_{64}O_7$; ^{1}H nmr (CCl_3D) δ_H: 0.89 (d, 3H, J = 14 Hz, 21-Me), 0.91 (d, 6H, J = 13 Hz, 26-Me and 27-Me), 1.25 (s, 3H, 18-Me), 1.30 (s, 3H, 19-Me), 3.33, 3.46, 3.52, 3.59, 3.61 (s, 15H, OMe).

Compound **1**e, *the (−)-(*S*)-MPA ester of* **1**c

As above, but using the (−)-(*S*)-acid instead of the (+)-(*R*)-acid to obtain the (−)-(*S*)-MPA ester of **1***c*.

Compound **1**e: $C_{40}H_{64}O_7$; ^{1}H nmr (CCl_3D) δ_H: 0.84 (d, 3H, J = 13 Hz, 26-Me), 0.86 (d, 3H, J = 13 Hz, 27-Me), 0.89 (d, 3H, J = 14 Hz, 21-Me), 1.25 (s, 3H, 18-Me), 1.30 (s, 3H, 19-Me), 3.33, 3.46, 3.52, 3.59, 3.61 (s, 15H, OMe).

Stereocontrolled construction of 1,7-dimethyl A.B.C.[6.6.6] tricycles. Part I. Transannular Diels–Alder reactions of 14-membered macrocycles containing *trans*-dienophiles

YAO-CHANG XU, ANDREW L. ROUGHTON, RAYMOND PLANTE, SOLO GOLDSTEIN, AND PIERRE DESLONGCHAMPS[1]

Laboratoire de synthèse organique, Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Received February 18, 1992

YAO-CHANG XU, ANDREW L. ROUGHTON, RAYMOND PLANTE, SOLO GOLDSTEIN, and PIERRE DESLONGCHAMPS. Can. J. Chem. **71**, 1152 (1993).

Transannular Diels–Alder reactions of 14-membered macrocyclic trienes possessing a methyl substituent on both the diene and dienophile moiety have been investigated. Macrocyclic structures **1***a*, **1***b*, and **1***c* having *cis-trans-trans* (CTT), *trans-cis-trans* (TCT), and *trans-trans-trans* (TTT) geometries could be stereoselectively constructed by coupling appropriately functionalized dienes **5** and dienophile **4** following an intramolecular displacement of an allylic halide by the anion of an appropriately located dimethyl malonate unit. The transannular Diels–Alder reaction performed on **1***a* led to a mixture of four major tricyclic products, including **34** possessing the unexpected *trans-anti-cis* (TAC) stereochemistry. When heated at 300°C, macrocycle **1***b* underwent an unique conversion via an ene–retroene, Diels–Alder process, producing the unexpected tricycle **41** (racemic form) containing five contiguous chiral centers. A rationale for the above experimental facts is presented. In contrast to the previous results, the transannular Diels–Alder reaction of macrocycle **1***c* was straightforward, producing a 95% isolated yield of *trans-anti-cis* (TAC) tricycle **34**. This investigation demonstrates a general methodology for the stereocontrolled synthesis of 1,2-dimethyl A.B.C[6.6.6] tricyclic compounds, which are potential precursors to polycyclic natural products such as steroids and terpenes.

YAO-CHANG XU, ANDREW L. ROUGHTON, RAYMOND PLANTE, SOLO GOLDSTEIN et PIERRE DESLONGCHAMPS. Can. J. Chem. **71**, 1152 (1993).

La réaction de Diels–Alder transannulaire macrocycles à 14 chaînons contenant un diène et un diénophile substitués par un radical méthyl est décrite. Les macrocycles **1***a*, **1***b* et **1***c* de géométrie *cis-trans-trans* (CTT), *trans-cis-trans* (TCT), et *trans-trans-trans* (TTT) ont été préparés de manière stéréosélective par le couplage des diènes **5** et du diénophile **4** suivi par un déplacement intramoléculaire d'un halogénure allylique par l'anion d'une unité malonate. Le macrocycle **1***a* fournit par une réaction de Diels–Alder transannulaire un mélange de quatre produits tricycliques dont **34**, produit inattendu, de stéréochimie *trans-anti-cis* (TAC). Par chauffage à 300°C le macrocycle **1***b* subit une transformation unique par une suite de réactions ène–rétroène, Diels–Alder conduisant au tricycle inattendu **41** (forme racémique) qui possède cinq centres chiraux contigus. Une rationalisation de ces faits expérimentaux est proposée. Contrairement aux résultats précédents, la réaction Diels–Alder transannulaire effectuée sur le macrocycle **1***c* donna comme attendu le tricycle *trans-anti-cis* (TAC) **34** avec un rendement de 95% en produit isolé. Dès lors cette étude démontre une méthodologie générale permettant de synthétiser de manière stéréocontrôlée des structures tricycliques 1,2-diméthyl A.B.C.[6.6.6], précurseurs potentiels de produits naturels tels les stéroïdes et les terpènes.

Introduction

Recent research in our laboratories has centered on the development of general methodologies that can be used to prepare polycyclic compounds in a stereocontrolled manner (1, 2). Our approach, illustrated in Scheme 1, makes use of the transannular Diels–Alder reaction on macrocyclic trienes like **1** to give A.B.C.[6.6.6] tricyclic compounds such as **2**. The [4+2] cycloaddition adducts **2**, which possess four newly created chiral centers as well as different substituents and functional groups on the three fused six-membered rings, are potential precursors to polycyclic natural products such as steroids and terpenes (3).

Our earlier studies (4) involving the syntheses of carbon macrocycles having various ring size (10–14 carbons) by base-assisted intramolecular displacement reaction laid the foundation for the development of this new methodology. Having successfully constructed the necessary macrocyclic triene, the first transannular Diels–Alder reaction of 13-membered macrocycles was found to produce B.C.D.[6.6.5] tricyclic compounds (2*f–j*). Further investigations of the transannular Diels–Alder cycloaddition in 14-membered macrocycles such as **1** with no methyl (2*d*, *e*) or with one methyl substituent (2*a*, *b*) showed them to be very promising for the construction of A.B.C.[6.6.6] tricyclic compounds. In both cases, racemic tricyclic products could be obtained in good yields and excellent stereoselectivities of the four contiguous asymmetric centers. In the course of our study, a total synthesis of a steroid derivative using the transannular Diels–Alder approach was reported by Takahashi et al. (5).

In this article, we would like to report further investigations (1) of the transannular Diels–Alder reaction in a 14-membered macrocycle system containing a methyl substituent on both the diene and dienophile moiety. As indicated in Scheme 1, the cycloaddition in macrocycle **1** would lead to the formation of 1,7-dimethyl tricyclic product **2**. The skeleton of such a tricyclic system having two methyl groups, on C(1) and C(7), is a common constituent of many natural diterpene and triterpene products. This study can therefore lead to the development of new strategies for the synthesis of some of these polycyclic natural products.

Methods and discussion

Our general approach towards the tricyclic compounds bearing two methyl groups at C(1) and C(7) positions is

SCHEME 1

outlined in Scheme 1. The target product **2** could be obtained by the transannular [4+2] cycloaddition in 14-membered macrocycle **1**, which, in turn, could be easily prepared from acyclic triene **3** via an intramolecular displacement of the allylic halide by base-generated dimethyl malonate anion. Triene **3** having different olefin geometries could be derived from the coupling reaction of appropriately functionalized dienes **5** and *E*-dienophile **4**.

Synthesis of E-*dienophile 4*

The basic strategy for the preparation of this trisubstituted olefin is based on the palladium-catalyzed coupling reaction of 2-carbomethoxypropyl zinc iodide **10** (6) and vinyl iodide **11** (7) as depicted in Scheme 2.

The preparation of zinc iodide **10** was readily achieved starting from commercially available γ-butyrolactone **6**. Methanolysis (methanol–pyridine) of acyl chloride **7**, which was obtained from **6** by reaction with thionyl chloride in the presence of zinc chloride (8), provided methyl 4-chlorobutyrate **8**. A halide exchange reaction on **8** (potassium iodide in acetone) gave the corresponding alkyl iodide **9**, which was treated with metal zinc at 60°C to give the desired product **10**.

The preparation of vinyl iodide **11** was realized stereoselectively starting from 4-butynol using Negishi's procedures (7) followed by silylation (9) of the primary alcohol. The coupling reaction of **11** and **10** provided *E*-dienophile **12**, no *Z* isomer being observed by nmr spectroscopy. The desired malonate **4** was obtained by treatment of **12** with lithium diisopropylamide followed by the addition off methyl chloroformate (10).

Syntheses of dienes 5

The syntheses of 2-methyl-substituted 2,4-diene **5***a* (*Z-E*), **5***b* (*E-Z*), and **5***c* (*E-E*) are outlined in Scheme 3 starting from the commercially available *Z*-2-butene-1,4-diol **13**. Swern oxidation of the monoprotected diol **14** (11) led to the α,β-unsaturated aldehyde **15***a* with the *Z*-olefin geometry retained (12). The selective *E* olefination of the aldehyde was performed via a Wittig–Horner–Emmons reaction with ethyldiisopropyl-2-phosphonopropionate and sodium hydride to provide the *Z-E* diene **16***a* (13), which was subsequently converted to the allylic alcohol **17***a* by diisobutylaluminium hydride (DIBAL-H) reduction. The desired allylic chloride **5***a* was finally obtained from **17***a* via Meyers' procedures (lithium chloride, methanesulfonyl chloride, and *s*-collidine in dimethylformamide (DMF) (14)).

Oxidation of mono-protected diol **14** with pyridinium chlorochromate at room temperature yielded the thermodynamically stable *E*-unsaturated aldehyde **15***b* (15), isomer of **15***a*. Condensation of **15***b* with ethyl bis(trifluoroethyl)-2-phosphonopropinate following Still's procedure (16) gave stereoselectively *E-Z* diene ester **16***b*, which was then reduced to alcohol **17***b* by diisobutylaluminium hydride. Protection of the allylic alcohol with *tert*-butyldiphenylchlorosilane in the presence of triethylamine (17) resulted in the formation of silyl ether **18***b*. Treatment of **18***b* with pyridinium *p*-toluenesulfonate in isopropanol selectively removed the tetrahydropyranyl ether to produce allylic alcohol **19***b*,[2] which was converted to allylic chloride **5***b* by the use of the previously mentioned Meyers' method (14).

Similarly, treatment of **15***b* with Wittig reagent derived from ethydiisopropyl-2-phosphonopropionate afforded the *E-E* diene ester **16***c* (13). This stereoselective *E*-olefination reaction from **15***b* to **16***c* could also be realized in good yield by commercially available triethyl-2-phosphonopropionate and sodium hydride. Diisobutylaluminium hydride reduc-

tion of **16***c* followed by protection of the resulting allylic alcohol with *tert*-butyldiphenylchlorosilane (17) yielded diene diether **18***c*. Selective removal of the tetrahydropyranyl ether was realized by the previously mentioned method[2] to afford allylic alcohol **19***c*, which was then converted to allylic chloride **5***c* having the *E-E* diene geometry (14).

Preparations of macrocycles 1

The precursors of macrocycles **1***b* (*trans-cis-trans*, TCT) and **1***c* (*trans-trans-trans*, TTT), namely acyclic trienes **22***b* and **22***c*, are readily synthesized by coupling the appropriately functionalized basic building blocks, dienes **5***b* and **5***c*, with dienophile **4**. Thus, deprotection of *E*-dienophile **4** with tetrabutylammonium fluoride (18) provided alcohol **20**, which was subsequently transformed into the methanesulfonate ester **21** with methanesulfonyl chloride and triethylamine (Scheme 4). The coupling reactions were performed by treatment of dienophile **21** with sodium hydride to form the sodium enolate, followed by addition of dienes **5***b* and **5***c* to produce alkylated products **22***b* and **22***c*, respectively, in good yields (19). Introduction of the second malonate connector into the acyclic trienes was accomplished by displacement of the methanesulfonate ester group of trienes **22***b* and **22***c* with the sodium salt of dimethyl malonate in the presence of potassium iodide. The cleavage of the silyl ether protecting group of trienes **23***b* and **23***c* was effected with *n*-Bu_4NF in good yields (18). The resulting allylic alcohol **24***b* was then transformed into the corresponding allylic chloride **25***b* by Meyers' procedure (14), while the allylic alcohol **24***c* was converted to the allylic bromide **25***c* using carbon tetrabromide and triphenylphosphine in dichloromethane (20). A slight decomposition was observed when allylic halides **25***b* and **25***c* were submitted to purification by flash chromatography. This problem, however, could be avoided if the crude allylic halides were filtered through a short-path silica gel column and used for the next reaction immediately without purification by chromatography.

Having built the requisite carbon chain and appropriate functional groups at each end, acyclic trienes **25***b* and **25***c* were ready for the construction of 14-membered macrocycles. The macrocyclizations were performed by slow addition of a solution of allylic chloride **25***b* or allylic bromide **25***c* in tetrahydrofuran to a stirred suspension of cesium carbonate in a mixture of DMF and THF at about 80°C under dilution conditions so as to avoid dimerization (2). Macrocyclic products **1***b* (TCT) and **1***c* (TTT) were respectively obtained in good yields, as white solids, via an intramolecular displacement of allylic halides by base-generated dimethyl malonate anion. Small quantities (≤10%) of the corresponding macrocyclic dimers **26***b* and **26***c* were also isolated. The structures of macrocycles **1***b* and **1***c* were established by spectroscopic characterization including carbon-13 and proton nmr, infrared, and mass spectra. The conservation of the double bond geometries in the cyclization has been clearly established by comparing the proton nmr data of the cyclic products with those of their acyclic triene precursor. Furthermore, the structure of macrocycle **1***b* was confirmed by X-ray analysis (21).

The isolation of the stable 14-membered macrocycle **1***c* having *trans-trans-trans* (TTT) olefin geometries should be noted because previous attempts to isolate such macrocycles had failed due to the facile transannular Diels–Alder reaction under the cyclization conditions (2*b*, 2*e*). The introduction of a methyl substituent on the diene as in **1***c* considerably lowers its reactivity in the transannular Diels–Alder reaction. This is indeed true since the Diels–Alder reaction of **1***c* requires temperatures as high as 250°C (vide infra).

SCHEME 3

It should be also noted that in the case of TTT acyclic triene **25***c*, the allylic bromide was employed for macrocyclization instead of the allylic chloride, which was used extensively in our previous studies (2). As presented in Scheme 5, our original plan to synthesize *trans-trans-trans* macrocycle **1***c* was based on the cyclization of allylic chloride triene **27** (X = Cl). Such an approach was expected to be advantageous due to the reduced steric interactions (methyl group remote from the reaction site) for the cyclization process. However, no macrocyclic product **1***c* could be obtained after several attempts employing the usual cyclization conditions; only decomposition of starting material **27** was observed under various conditions of temperature and reaction time. This failure in transforming acyclic triene **27** to **1***c* prompted us to use the corresponding acyclic triene bromide **27** (X = Br), which is expected to be more reactive than the chloride. Macrocyclization of **27** (X = Br) under the same conditions provided a 24% yield of macrocycle **1***c*. Attempts to increase the yield failed, and we found that allylic bromide **27** decomposed quickly under the cyclization conditions. The instability of such a compound could be rationalized by the fact that **27** (X = Br) can easily form a stable

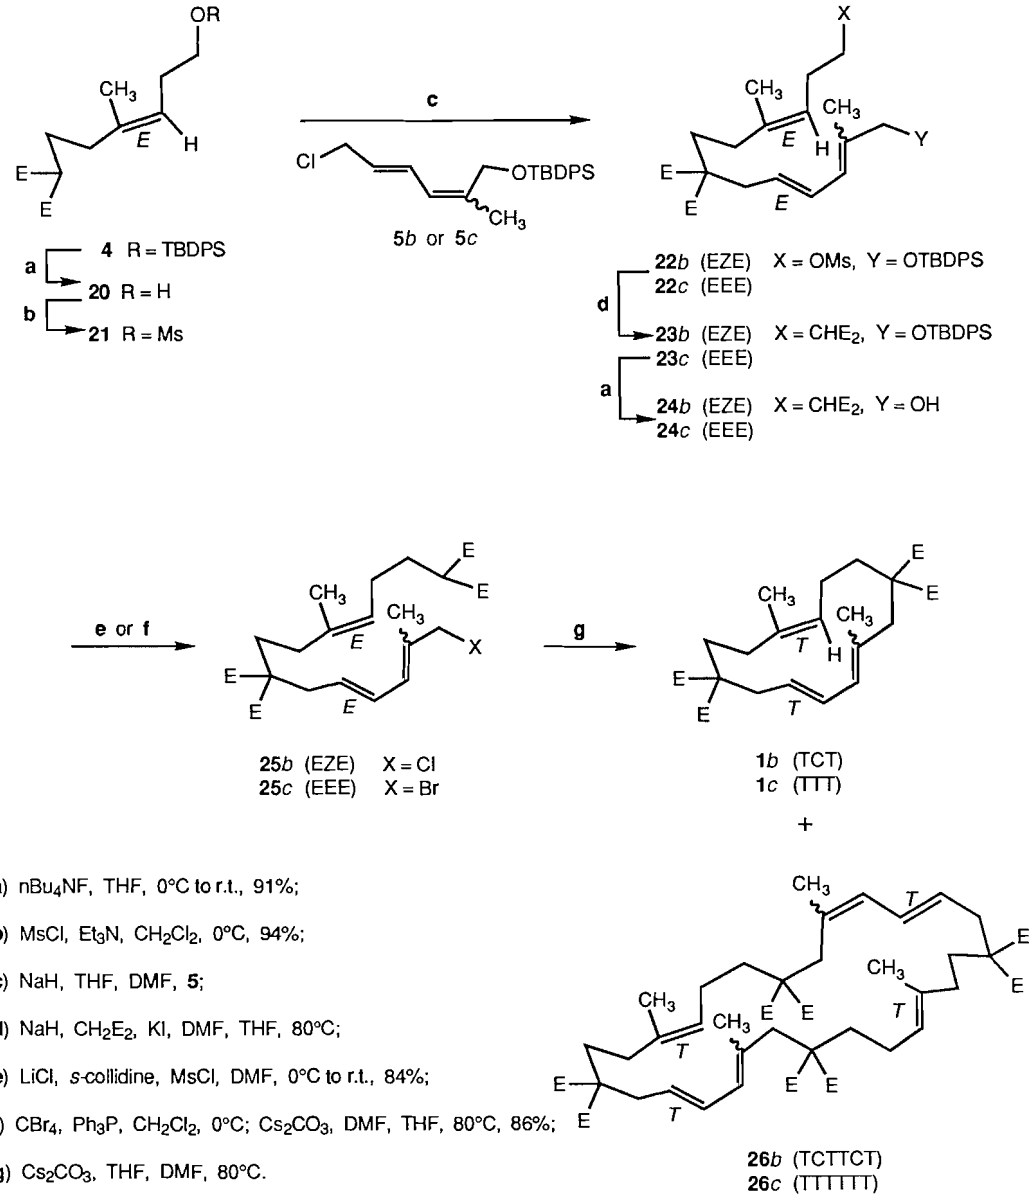
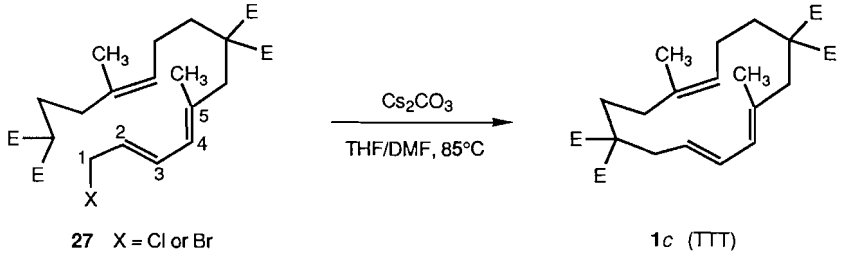


SCHEME 4



SCHEME 5

allylic carbocation, which is further stabilized by the presence of the methyl group. To circumvent this problem, our original plan was modified so that the cyclization would take place on the side of the diene bearing the methyl group as indicated by structure **25***c*, since we anticipated that **25***c* would be more stable than **27**. Indeed, the allylic bromide **25***c* was found to be stable even under flash chromatographic conditions and it cyclized efficiently to give **1***c* in 73% yield along with 5% of the dimer **26***c*.

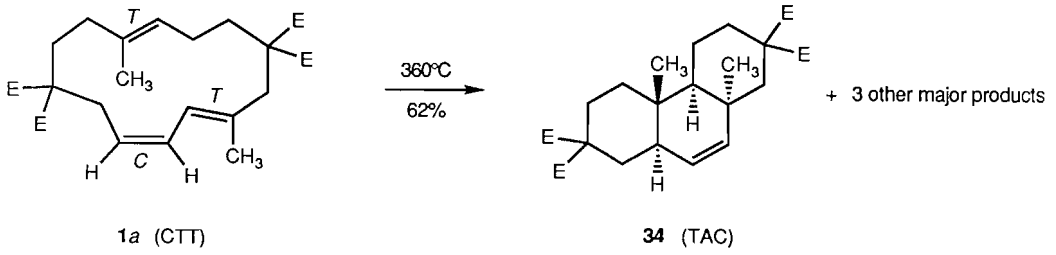


SCHEME 7

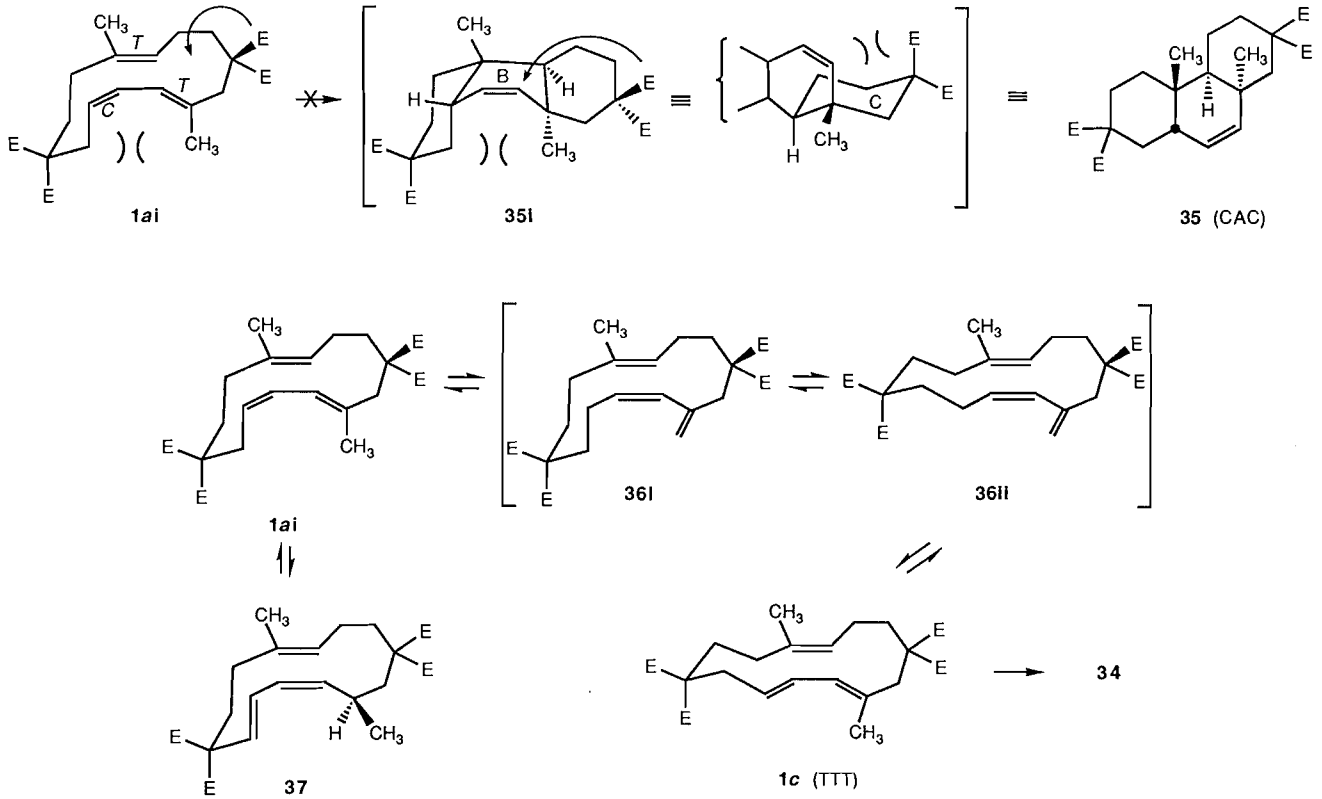
trans (CTT) geometry was accomplished following the procedures described in Scheme 6. The coupling reaction of diene **5***a* with dienophile **4** was conducted in the presence of sodium hydride to provide *Z-E-E* acyclic triene **28** (19), which was then converted to the methanesulfonate ester **30** by desilylation (n-Bu_4NF (18)) following mesylation of the resulting alcohol **29** (MsCl and Et_3N). After replacement of the mesylate group by dimethylmalonate, the resulting triene **31** was hydrolyzed to the allylic alcohol **32** (11), which was subsequently converted to the allylic chloride **33** (14). The cyclization step was then conducted in a similar fashion as described before to provide macrocycle **1***a* (CTT) as a crystalline solid. Again, the structure of **1***a* was established by spectroscopic data (nmr, ir, ms).

Synthesis of tricycles, Transannular Diels–Alder reaction

1. From CTT macrocycle ***1****a*

The transannular Diels–Alder reaction of CTT **1***a* was carried out by thermolysis in a sealed quartz tube at 360°C for 80 min to yield a mixture of four major products (Scheme 7). Each compound contributed between 10 and 19% to the total crude reaction mixture as determined by vapour phase chromatography (vpc). Thin-layer chromatography of the crude reaction mixture also revealed the presence of several other minor products. The identification and characterization of the major products was attempted, but failed due to the difficulty in isolating each compound in a pure state. The presence of tricycle **34** having the *trans-anti-cis* (TAC) stereochemistry was, however, demonstrated by comparing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.



SCHEME 8

the products of the reaction mixture with an authentic sample of **34** prepared by the Diels–Alder reaction of TTT macrocycle **1***c* (vide infra, cf. Scheme 10).

The formation of this complex mixture of tricyclic products can be explained in the following way. In principle, a macrocyclic triene can yield two different diastereoisomers. However, and as previously discussed (2*a*), there are cases where one of the expected diastereoisomers cannot be formed because of a conformational restriction imposed by the fact that the Diels–Alder reaction must take place via a boat transition state. As shown in Scheme 8, the CTT macrocyclic triene **1***a* is expected to produce only the CAC tricycle **35** via the chair–boat–chair conformation **35***i*. Examination of molecular models reveals however that this process is, sterically, extremely crowded: the *cisoid* conformation **1***ai* of the diene that is required for the Diels–Alder reaction is severely hindered sterically due to the presence of the methyl group on the diene, and also due to steric repulsion between one of the ester functions and the diene moiety (Scheme 8); these effects are best seen in the conformation **35***i* of the Diels–Alder product **35** from which the CAC tricycle should be produced: one methyl group in the boat ring B is very severely hindered, and the β-ester function in ring C is in a 1,3 diaxial disposition relative to the olefin of ring B. These severe steric interactions will raise considerably the energy of this process and will allow competing processes to take place.

The unexpected formation of the TAC tricycle **34** as well as the formation of the other major products may be explained in the following way. CTT tricycle **1***a* in conformation **1***ai* can undergo a 1,5 sigmatropic hydrogen migration to give **36** in conformation **36***i*. This new macrocyclic triene can then undergo another 1,5 sigmatropic hydrogen migration via conformation **36***ii* to give TTT macrocyclic triene **1***c*, which can then give the TAC tricycle **34** (vide infra). The other tricyclic products may come from the [4+2] cycloaddition of **36** or via other unknown side reactions. For instance, CTT macrocycle **1***ai* could undergo another 1,5 sigmatropic hydrogen migration to give the isomeric macrocycle **37**, which can also produce tricycles via the transannular Diels–Alder reaction. It should be pointed out that the 1,5 sigmatropic hydrogen migration in a macrocyclic triene followed by a [4+2] cycloaddition process has already been previously observed in our laboratory (2*f*).

*2. From TCT macrocycle 1*b

The transannular Diels–Alder reaction of TCT macrocycle **1***b* was carried out at 300°C in a fashion similar to that described for **1***a*, and the interpretation of the results is presented in Scheme 9. To our surprise, a totally unexpected tricyclic product **41** having a methyl-substituted olefin was isolated in 66% yield. The presence of the methyl group on the double bond in ring B and of the secondary methyl group in ring C was shown by proton nmr, the former one being a singlet at 1.62 ppm and the latter a doublet at 0.92 ppm. The presence of only one rather than two vinyl protons further indicated that the tricycle did not have an expected structure. The overall structure and relative stereochemistry of tricycle **41** was established unambiguously by X-ray analysis (21). It is interesting to note that this compound exists in the solid state in conformation **41***ii* in which the secondary methyl group in ring C is axially oriented.

We previously predicted (2*a*) that 14-membered macrocyclic trienes having a *trans-cis-trans* geometry should give only one tricycle having the *cis-anti-cis* (CAC) stereochem-

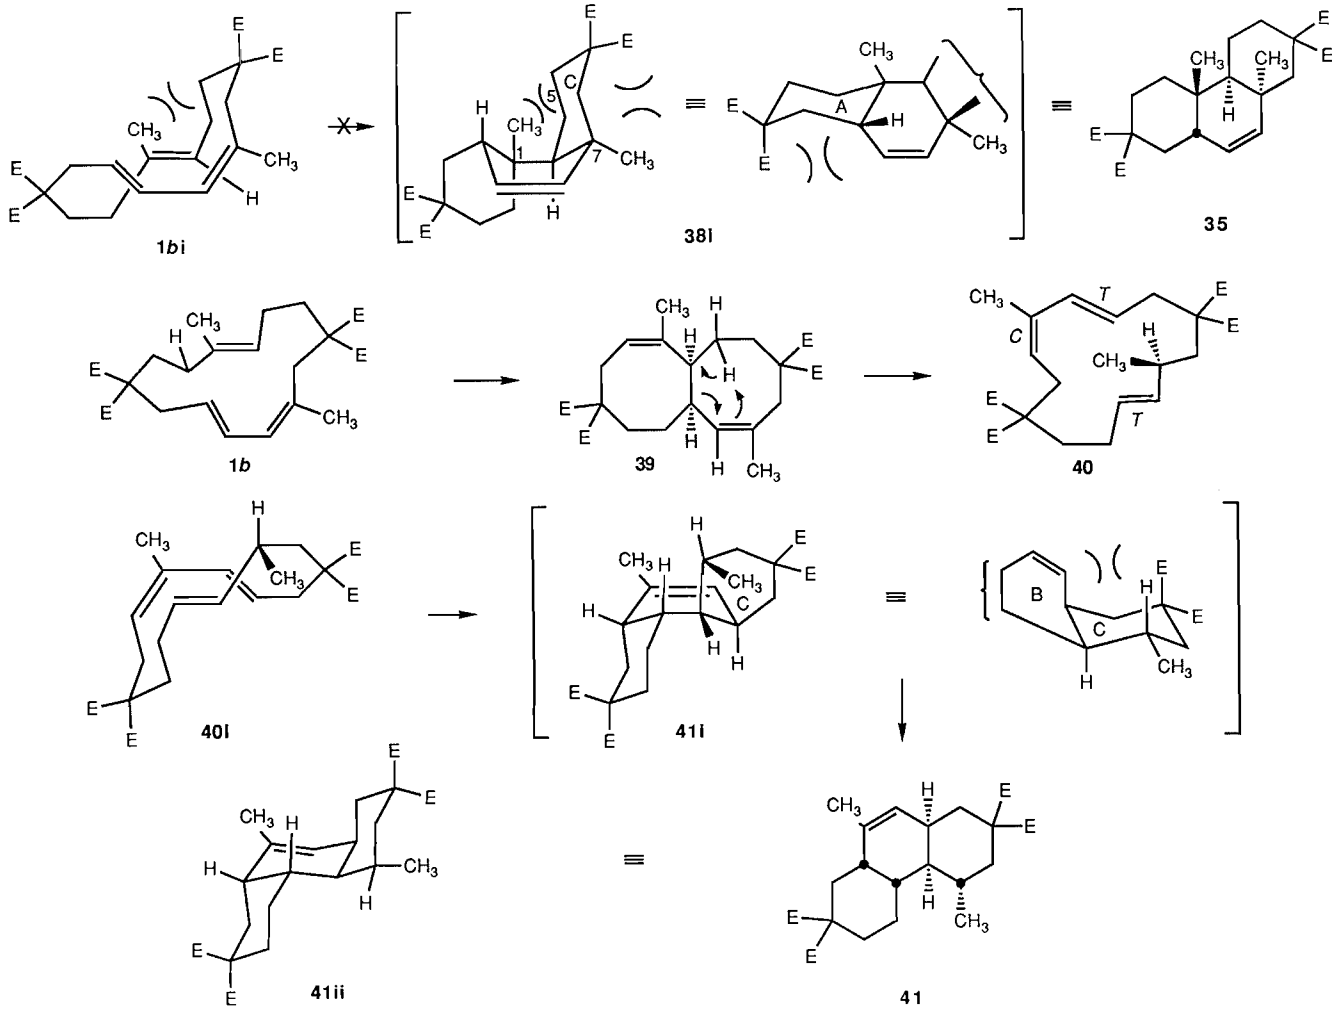
For personal use only.



SCHEME 9

istry. It was therefore expected that the TCT macrocycle **1***b* would give the CAC tricycle **35** via conformation **1***bi*. Examination of this process in more detail reveals, however, that it must have a relatively high activation energy due to severe steric interactions caused by the presence of the methyl groups and the ester functions. This can best be seen in conformation **38***i*: the methyl group at C1 is sterically hindered by ring C while the other one at C7 is experiencing a 1,3 diaxial steric interaction with one of the esters of ring C. There is also a 1,3 diaxial steric interaction between the axial ester function in ring A and the olefin of ring B. It is therefore not surprising that macrocycle **1***b* underwent other reactions having a lower activation energy.

The formation of the CAC tricycle **41** having a methyl-substituted olefin can be rationalized by a transannular ene, a retroene, and finally a transannular Diels–Alder reaction as presented in Scheme 9. Thus, the transannular ene reaction would transform macrocycle **1***b* into the *cis*-bicyclic intermediate **39** having two eight-membered rings. This would then be followed by a retroene reaction from **39** to produce the macrocyclic triene **40**. This overall transformation is the equivalent of an oxidation–reduction process whereby the diene and dienophile have been interchanged. The new CTT macrocycle **40** can now easily undergo a transannular Diels–Alder reaction because both methyl groups are no longer located on carbon atoms directly involved in bond formation and therefore are almost completely devoid of severe steric repulsion during this process. Indeed, compound **40** would react via conformation **40***i*, which will produce tricycle **41** in conformation **41***i* having ring B in a boat form and an equatorially oriented secondary methyl group in ring C. In **41***i*, there is only one 1,3 diaxial interaction between an ester function in ring C and the olefin of ring B. Conformation **41***i*, once produced, would then revert to the more stable chair–half-chair–chair conformation **41***ii* having the secondary methyl group axially oriented as shown by X-ray crystallography.

The above interpretation is also in accord with previous studies on less substituted TCT macrocyclic trienes. Indeed, we found (2*e*) that when the TCT macrocyclic trienes bear no methyl groups on the diene and the dienophile, only the theoretically expected CAC tricycle corresponding to **35** (CH_3 = H) was obtained. This is of course not surprising as all the undesired steric effects that unduly raised the transition state energy in **38***i* have now been removed. On the other hand, we also observed (2*b*, 23) that when there is no substituent on the diene and only one methyl group on the dienophile, an intermediate situation occurs. In these cases two processes occur: one equivalent to **1***b* → **35** (40%) and the second equivalent to **1***b* → **41** (60%). In the dimethyl case, the process **1***b* → **35** does not take place because there is

additional steric hindrance that further increases its energy barrier.

Our overall interpretation was further confirmed by detecting the presence of bicyclic intermediate **39** at shorter reaction time in a proton nmr monitored experiment. The intermediate **39** could not, however, be obtained pure by chromatography. Table 1 lists the chemical shifts for the characteristic olefin and methyl protons, which changed with time upon heating the macrocycle **1***b* at 300°C. The proton nmr data in entry 2 of Table 1 were obtained by subtracting the ^{1}H nmr data of both starting material **1***b* (entry 1) and product **41** (entry 3) from that of the reaction mixture after 0.5 h at 300°C. This set of ^{1}H nmr data in entry 2 is in full agreement with the proposed bicyclic structure **39**. The failure to isolate or even detect the TCT macrocyclic intermediate **40** can be explained by its higher reactivity in leading to tricycle **41** at 300°C via the transannular Diels–Alder reaction. In fact a macrocyclic TCT system similar to intermediate **40** was found to undergo a transannular Diels–Alder reaction at 250°C (*2e*).

The observation of this unique conversion, namely, **1***b* → **39** → **40** → **41** is mechanistically very interesting, since it is the first example of larger ring transformations through a transannular ene–retroene, Diels–Alder process, leading stereoselectively to a racemic tricyclic product **41** containing five contiguous chiral centers.

3. From TTT macrocycle **1***c*

In contrast to the previous results of CTT and TCT macrocycles, the transannular Diels–Alder reaction of TTT macrocycle **1***c* turned out to be straightforward. As illustrated in Scheme 10, thermolysis of **1***c* in toluene at 200°C for 18 h provided a 95% isolated yield of tricyclic compound **34** having the *trans-anti-cis* (TAC) stereochemistry, which was firmly established by X-ray analysis (22).

Theoretically, it is expected that the transannular Diels–Alder reaction of a 14-membered TTT macrocycle triene will produce a mixture of two tricycles having the TAC and CAT stereochemistry (*2a*). This was indeed observed in the case of a TTT macrocycle having a methyl group on the dienophile, which gave a 2:1 mixture of TAC and CAT tricycles (*2b*). In the present case, the TAC tricycle is formed exclusively and this result can be easily understood by examining the steric effects involved at the transition level of the two competing processes.

Tricycle TAC **34** and CAT **42** will be formed in conformations **34***i* and **42***i*, respectively, via the Diels–Alder reaction of macrocyclic triene **1***c* reacting in conformations **1***ci* and **1***cii*. Again, steric effects are best analyzed in the conformation in which the reaction products are formed. In stereoisomer **34***i*, there is a 1,3 diaxial steric interaction between the β-ester of ring C and the olefin of ring B. In stereoisomer **42***i*, there are two major steric interactions. The first one is essentially identical to that found in **34***i* (a 1,3 diaxial interaction between the α-ester of ring A and the olefin of ring B). The second one is the result of a 1,3 diaxial interaction between the methyl group at C7 and the β-ester in ring C, expected to be at least 2.5 kcal/mol. On that basis, one should anticipate the exclusive formation of TAC tricycle **34**, in agreement with the experimental result.

We also used molecular modeling to examine these assumptions. We recently (23) described a study of a 14-membered TTT macrocyclic triene, like **1***c* but lacking the methyl substituent of the diene moiety, using the Sybyl software.[3] The transition states of the chair–boat–chair (CBC) and chair–boat–boat (CBB) leading to the corresponding TAC and CAT macrocycles were mimicked and a Boltzman distribution based on their steric energies gave a calculated TAC:CAT ratio in complete agreement with the experimental results. As mentioned above, since the only difference between the two cases is a methyl substituent on the diene moiety, we reasoned that appropriate modifications might produce a fair description of transition structures for the present case as well. Thus the previously obtained transition state mimics (24) were modified by addition of a methyl substituent on the diene (a model of **1***c*), followed by a systematic conformational analysis (10° step) using the Search algorithm within Sybyl. The torsion angle between the forming bonds and the torsion angle in the butadiene moiety were kept at 0° as found by ad initio calculations for the transition state of butadiene and ethylene (24). Distances between the termini of the dienophile and the diene were left at 3 Å as in our previous study and the lowest energy conformers obtained in each case were minimized using the above-mentioned constraints. The four structures thus obtained and their respective steric energies are shown in Fig. 1. The lowest energy structures **A** (chair–boat–chair) and **B** (chair–boat–boat) would produce TAC tricycle **34** while the structures **C** and **D**, which are quite a bit higher in energy, would produce CAT tricycle **42**. A Boltzman distribution at 473 K of these four transition-state-like structures could lead to a product ratio TAC:CAT of 99:1, in excellent agreement with the experimental result.

Finally, as mentioned above, the Diels–Alder reaction of TTT macrocycle **1***c* requires a temperature of 250°C whereas that of the corresponding TTT macrocycle having no substituents on the diene takes place at ≤80°C (*2b*, *2d*). This is readily explained by the fact that when the methyl-substituted *trans-trans* diene takes the required *cisoid* conformation to undergo the cycloaddition, there is an additional severe steric repulsion between the methyl group and the diene moiety (cf. **1***ci*).

In résumé, CTT and TCT macrocycles **1***a* and **1***b* failed

to give the predicted CAC tricycle **35** because of severe steric hindrance at the transition level of the transannular Diels–Alder reaction. Macrocycle **1***a* gave a mixture of TAC tricycle **34** plus three unidentified isomers. The formation of **34** from macrocycle **1***a* can be explained by the isomerization of **1***a* into TTT macrocycle **1***c* via two consecutive 1,5 sigmatropic hydrogen migrations. The specific formation of tricycle **41** from macrocycle **1***b* took place via the intermediate formation of bicycle **39** via an ene–retroene process. Finally, TTT macrocycle **1***c* gave only TAC tricycle **34**; none of the other predicted CAT tricycle **42** was observed, a result which is explained on the basis of relative steric hindrance at the Diels–Alder transition state level.

In conclusion, this investigation has demonstrated a general methodology for the stereocontrolled synthesis of 1,7-dimethyl A.B.C.[6.6.6] tricyclic compounds. The macrocyclic trienes were constructed in good yields using an intramolecular displacement of allylic halides by a malonate anion in the acyclic triene precursors, which were assembled by coupling the diene and dienophile moieties. The

For personal use only.

formation of unexpected tricycles from the CTT and TCT macrocycles has provided interesting information on competing transannular processes. The transannular Diels–Alder reaction of the TTT macrocycle stereoselectively produced a TAC tricyclic compound in excellent yield. This synthetic route could prove useful for the synthesis of suvanine (25), and kaurane and atisane diterpenes (26), which have the TAC stereochemistry with substituents at positions 8 and 10. The synthesis of these polycyclic natural products is currently under investigation.

Experimental

General

The ir spectra were taken on a Perkin–Elmer 681 spectrophotometer. Proton nmr spectra were recorded on a Bruker WP-80 or Bruker WM-250 instrument. The following abbreviations were used: s, singlet; d, doublet; dd, doublet of doublets; dt, doublet of triplets; ddd, doublet of doublets of doublets; ddt, doublet of doublets of triplets; t, triplets; q, quartet, and m, multiplet. Chemical shifts are reported in δ values relative to tetramethylsilane or chloroform as internal standard. Carbon nuclear magnetic resonance spectra were recorded on a Bruker WP-80 or Bruker WM-250 instrument (chloroform as internal standard). Mass spectra were obtained on a Micromass ZAB-2F instrument. Melting points were determined on a Büchi M-50 or on a Reichert apparatus and are uncorrected.

Thin-layer chromatography was performed using silica gel 60 F-250. For flash chromatography, Merck Kieselgel 60 (230–400 mesh A.S.T.M.) was used. All solvents used in chromatography were distilled. Unless otherwise noted, starting materials and reactants were obtained commercially and were used as such or purified by standard means. All solvents and reactants purified and dried were stored under argon.

Anhydrous reactions were performed under an inert atmosphere of argon. Organic solutions were dried over magnesium sulfate, and were evaporated on a rotatory evaporator and under reduced pressure.

4-Chlorobutyryl chloride 7

To a stirred mixture containing thionyl chloride (32.8 g, 19.9 mL, 0.28 mmol) and anhydrous zinc chloride (1.5 g, 11 mmol) at room temperature was rapidly added γ-butyrolactone **6** (21.6 g, 0.25 mol). The resulting mixture was then heated at 55°C for 22 h. The crude mixture was purified by distillation under reduced pressure to give **7** as a colorless oil (23.0 g, 65%). Boiling point: 51–59°C (5.0 Torr; 1 Torr = 133.3 Pa) (lit. (8) bp 69–74°C (14 Torr).

Methyl 4-chlorobutyrate 8

To a solution of pyridine (12.9 g, 13.2 mL, 0.136 mol) in methanol (6.53 g, 8.3 mL, 0.200 mol) was added, in dropwise fashion at 0°C, 4-chlorobutyryl chloride **7** (23.0 g, 0.163 mol). The mixture was then stirred at 25°C for 18 h following addition of precooled sulfuric acid (11.0 N, 55%, 75 mL). The mixture was extracted with diethyl ether (3 × 50 mL). The combined organic phases were washed with water and dried over Na_2SO_4. After filtration, the solvents were removed under reduced pressure and the residue was purified by vacuum distillation to provide methyl 4-chlorobutyrate **8** (17.1 g, 77%) as a colorless oil. Boiling point: 27–29°C (0.7 Torr) (lit. (8) bp 50–52°C (2–3 Torr); ir (neat): 2950, 1730, 1440, 1368, 1215 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.10 (tt, 2H, J = 7.2 Hz, 6.3 Hz, $-CH_2CH_2CH_2-$), 2.51 (t, 2H, J = 7.2 Hz, $-CH_2COOCH_3$), 3.60 (t, 2H, J = 6.3 Hz, $-CH_2Cl$), 3.69 (s, 3H, $-COOCH_3$).

Methyl 4-iodobutyrate 9

Methyl 4-chlorobutyrate **8** (8.96 g, 65.5 mmol) in 65 mL of acetone was then heated to reflux for 42 h in the presence of sodium iodide (11.7 g, 78.6 mmol). The solution was cooled and filtered and the solvent was then evaporated. The residue was dissolved in 100 mL of diethyl ether, washed with aqueous sodium thiosulfate solution (5%), and then with saturated sodium chloride solution. The organic phase was dried over $MgSO_4$, filtered, and evaporated. The oily residue was purified by distillation under reduced pressure to give **9** (11.6 g, 77.5%) as a colorless oil. Compound **9** decomposes slowly even at −20°C under argon atmosphere. Boiling point 53–54°C (0.7 Torr), 50–52°C (0.35 Torr); ir (neat): 2940, 1735, 1435, 1365, 1200, 1120, 1018 cm^{-1}.

Methyl (E)-3-methyl-1-tert-butyldimethylsilyloxy-3-octenoate 12

To a flask containing the Zn–Cu couple (4.17 g, 63.9 mmol) under an argon atmosphere was added a solution of methyl 4-iodobutyrate **9** (9.51 g, 41.7 mmol) in a mixture of benzene and DMF (32 mL/5.6 mL). The resulting mixture was stirred at 25°C for 1 h and at 60°C for 3 h. A suspension of tetrakis(triphenylphosphine)palladium(0) (4.06 g, 3.53 mmol) in 28 mL of benzene was introduced by cannula and the mixture was stirred at 60°C for 5 min. Vinyl iodide **11** (9.06 g, 27.8 mmol) in 11 mL of benzene was added and the resulting mixture was stirred at 60°C for another hour. The reaction was stopped by addition of 150 mL ethyl acetate followed by filtration to remove the Zn–Cu. The orange filtrate was kept in a refrigerator overnight and the volatiles were then removed by evaporation. After addition of 50 mL ethyl acetate, the mixture was filtered again. The red solid was washed with 100 mL ethyl acetate and the filtrate was concentrated under reduced pressure to give a crude oily residue, which was passed through a short-path silica gel using hexane – ethyl acetate (10:1) as eluant. The oil obtained after evaporation was purified by flash chromatography with a mixture of hexane and ethyl acetate (20:1) as eluant to give compound **12** (5.38 g, 64.5%); ir (neat): 2950, 2920, 2860, 1740, 1435, 1252, 1100, 835 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.04 (s, 6H, t-Bu-$(CH_3)_2Si$-), 0.89 (s, 9H, $(CH_3)_3CSi(CH_3)_2$)), 1.60 (d, 3H, J = 1.0 Hz, CH_3-C=C-), 1.66 (tt, 2H, J = 7.5 Hz, 7.6 Hz, $-CH_2CH_2CH_2COOCH_3$), 2.01 (dt, 2H, J = 6.2 Hz, 7.5 Hz, $-CH_2CH_2CH_2COOCH_3$), 2.19 (t, 2H, J = 7.1 Hz, $-OCH_2CH_2C$=C-), 2.30 (t, 2H, J = 7.6 Hz, $-CH_2COOCH_3$), 3.65 (t, 2H, J = 7.1 Hz, $-OCH_2CH_2$-), 3.66 (s, 3H, $-COOCH_3$), 5.14 (m, 1H, -C=CH-); ^{13}C nmr ($CDCl_3$) δ: 16.2, 18.1, 24.8, 25.8, 27.1, 33.3, 43.0, 51.1, 62.2, 125.1, 133.2, 173.9; ms m/e: 243 ($M^+ - C_4H_9$). Exact Mass ($M - C_4H_9$) calcd.: 243.1416; found: 243.1416.

Methyl (E)-3-octenoate 4

To a solution of the methyl ester **12** (1.00 g, 3.3 mmol) in 20 mL of THF was added, at −78°C under an argon atmosphere, a solution of lithium diisopropylamide (3.3 mmol) in THF. After stirring the mixture at −78°C for 30 min, methyl chloroformate (256 μL, 312 mg, 3.3 mmol) was introduced dropwise by syringe. The reaction was quenched with 50 mL of saturated ammonium chloride solution and extracted with a solvent mixture of hexane and ether (1:2). The organic phase was washed with water, dried over $MgSO_4$, filtered, and then concentrated under reduced pressure. The crude residue was purified by flash chromatography with a 20:1 mixture of hexane and ethyl acetate as eluant to give product **4** (792 mg, 67%) as a clear oil; ir (neat): 1740, 1435, 1255, 1150, 1100, 840 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.04 (s, 6H, t-Bu-$CH_3)_2Si$-), 0.88 (s, 9H, $(CH_3)_3CSi(CH_3)_2$), 1.59 (s, 3H, CH_3-C=C-), 1.92–2.04 (m, 4H, $-CH_2CH_2CH(COOCH_3)_2$), 2.19 (t, 2H, J = 7.1 Hz, $-OCH_2CH_2C$=CH-), 3.38 (t, 1H, J = 7.2 Hz, $-CH(COOCH_3)_2$), 3.65 (t, 2H, J = 7.1 Hz, $-OCH_2CH_2$-), 3.73 (s, 6H, $-CH(COOCH_3)_2$), 5.11 (t, 1H, J = 6.2 Hz, CH_3C=CH-); ms m/e: 301 ($M^+ - C_4H_9$). Exact Mass ($M - C_4H_9$) calcd.: 301.1471; found: 301.1460.

2-Butene-1-ol 14

(Z)-2-Butene-1,4-diol **13** (49.5 mL, 52.9 g, 0.60 mol) and 3,4-dihydro-2H-pyran (54.7 mL, 50.5 g, 0.60 mol) were dissolved in 200 mL of CH_2Cl_2 and 500 mL of THF at 0°C. To this solution was then added p-toluenesulfonic acid monohydrate (2.65 g, 14 mmol) and the resulting mixture was stirred at 0°C for 2 h and at 20°C for

20 min. Solid sodium bicarbonate (2.35 g, 28 mmol) was added and the solution was stirred for 5 min. After filtration, the solvents were removed and the crude oil obtained was purified by flash chromatography with a 9:1 mixture of CH_2Cl_2 and acetone as eluant to provide monoprotected alcohol **14** (50.7 g, 49.1%) as an oil; ir (CH_2Cl_2): 3600, 3620–3300, 2940, 1200, 1120, 1024 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.43–1.88 (m, 6H, -(CH_2)$_3$$CH_2$O-), 2.04 (t, 1H, J = 2.5 Hz, -CH_2O*H*), 3.49–3.58 and 3.81–3.90 (2m, 2H, -CH_2CH_2O-), 4.10–4.32 (m, 4H, -CH_2CH=CH-CH_2-), 4.69 (t, 1H, J = 3.0 Hz, -OC*H*O-), 5.66–5.77 and 5.81–5.92 (2m, 2H, -C*H*=C*H*-); ^{13}C nmr ($CDCl_3$) δ: 18.9, 25.1, 30.2, 57.8, 61.8, 62.2, 97.4, 127.3, 132.2; ms *m/e*: 155 (M^+ − OH). Exact Mass (M^+ − OH) calcd.: 155.1072; found: 155.1075.

(Z,E)-Diene ester ***16****a*

To a stirred solution of oxalyl chloride (5.0 mL, 55 mmol) in 125 mL of CH_2Cl_2 was added, at between −50 and −60°C, a solution of DMSO (8.5 mL, 110 mmol) in 25 mL of CH_2Cl_2. After stirring the mixture for 2 min, alcohol **14** (8.61 g, 50 mmol) in 50 mL of CH_2Cl_2 was introduced over a 5 min period. The stirring was continued for an additional 45 min following addition of diisopropylethylamine (43.5 mL, 250 mmol). After 5 min, the reaction mixture was allowed to warm to −10°C. The oxidation was stopped by addition of water (125 mL). The aqueous phase was extracted with CH_2Cl_2 (2 × 180 mL) and the combined organic phases were washed with saturated NaCl solution (200 mL), dried over $MgSO_4$, filtered, and evaporated. The oil, which contained *cis*-α,β-unsaturated aldehyde **15***a*, was used for the next reaction without further purification.

To a stirred suspension of NaH (2.47 g, 60% in oil, 62 mmol) in 100 mL of THF was rapidly added, at 0°C under an argon atmosphere, a solution of ethyldiisopropyl-2-phosphonopropinate (16.5 g, 62 mmol) in 60 mL of THF. Once the evolution of hydrogen gas ended, the solution was cooled to −78°C. Crude aldehyde **15***a* in 15 mL of THF was introduced and the resulting mixture was stirred at −78°C for 30 min and at 0°C for 15 min. The reaction was stopped by addition of saturated ammonium chloride (100 mL) and diethyl ether (150 mL). The aqueous phase was extracted with diethyl ether. The combined organic phases were washed with brine, dried over $MgSO_4$, and then filtered. After removal of volatiles, the oily residue was purified by flash chromatography using a 7:2 mixture of hexane and ethyl acetate to provide **16***a* (6.63 g, 52% for two steps) as an oil; ir (neat): 2940, 2870, 1710, 1633, 1600, 1245, 1201, 1025, 905, 870 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.29 (t, 3H, J = 7.5 Hz, CH_3CH_2O-), 1.49–1.88 (m, 6H, -(CH_2)$_3$$CH_2$O-), 1.94 (d, 3H, J = 1.0 Hz, CH_3C=CH-), 3.49–3.58 and 3.84–3.94 (2m, 2H, -CH_2CH_2O-), 4.22 (q, 2H, J = 7.5 Hz, CH_3CH_2O-), 4.31 and 4.49 (2ddd, 2H, J = 14 Hz, 1.0 Hz, 6.2 Hz, -CH_2OTHP), 4.66 (t, 1H, J = 2.5 Hz, -OC*H*O-), 5.93 (dt, 1H, J = 11.2 Hz, 6.2 Hz, -OCH_2CH=CH-), 6.43 (ddt, 1H, J = 11.2 Hz, 11.0 Hz, 1.0 Hz, -OCH_2CH=C*H*CH-), 6.48 (dq, 1H, J = 11.0 Hz, 1.0 Hz, -OCH_2CH=C*H*=C-CH_3); ^{13}C nmr ($CDCl_3$) δ: 12.1, 14.1, 19.1, 25.2, 30.4, 60.3, 61.9, 63.0, 98.0, 125.4, 128.7, 131.9, 134.1.

Allylic alcohol ***17****a*

General procedure A

To a stirred solution of ester **16***a* (6.44 g, 25 mmol) in 450 mL of CH_2Cl_2 was added, over a period of 15 min at −78°C under an argon atmosphere, a solution of diisobutylaluminum hydride (1 M, 55 mL, 55 mmol). After 30 min, 16 g of solid $Na_2SO_4 \cdot 10$ H_2O was added. The reaction mixture was allowed to warm to room temperature following addition of 200 mL acetone. The reaction mixture was stirred for an additional hour, the solids were removed by filtration, and the filtrate was evaporated to dryness. The crude residue was purified by flash chromatography using a 7:3 mixture of hexane and ethyl acetate to provide alcohol **17***a* (3.48 g, 66%) as an oil; ir (neat): 3600–3100, 2940, 2860, 1655, 1200, 1020, 902, 868 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.49–1.77 (m, 7H, -(CH_3)$_3$$CH_2$O- and -$CH_2$O*H*), 1.79 (s, 3H, CH_3C=CH-), 3.49–3.58 and 3.86–3.95 (2m, 2H, -OCH_2CH_2O-), 4.11 (s, 2H, -CH_2OH), 4.21–4.46 (m, 2H, -CH_2OTHP), 4.67 (t, 1H, J = 2.5 Hz, -OC*H*O-), 5.59–5.69 (m, 1H, -CH_2CH=CH(CH=C-)), 6.32–6.47 (m, 2H, -CH_2CH=C*H*C*H*=C-); ^{13}C nmr ($CDCl_3$) δ: 13.6, 19.1, 25.2, 30.4, 61.9, 62.6, 67.7, 97.5, 118.6, 126.3, 126.6, 139.3.

Allylic chloride ***5****a*

General procedure B

To a solution containing alcohol **17***a* (467 mg, 2.2 mmol) vacuum dried (heat-gun), lithium chloride (374 mg, 8.8 mmol), and *s*-collidine (0.58 mL, 532 mg, 4.4 mmol) in 12 mL of DMF was added, dropwise at 0°C under an argon atmosphere, methanesulfonyl chloride (0.34 mL, 504 mg, 4.4 mmol). The resulting mixture was stirred at 0°C for 1 h and then at 25°C for an additional hour. The reaction mixture was poured into 10 mL of ice water, and extracted with a 2:1 mixture of diethyl ether and hexane (3 × 25 mL). The combined organic phases were washed successively with precooled, saturated $Cu(NO_3)_2$ solution and water. After drying over $MgSO_4$, the mixture was filtered through a short-path column containing silica gel and Celite on top. After removal of the solvents, allylic chloride **5***a* was obtained (504 mg, 99%) as an oil that was used for the next reaction without further purification and characterization.

(E)-α,β-Unsaturated aldehyde ***15****b*

To a solution of alcohol **14** (10.0 g, 58 mmol) and sodium acetate (14.4 g, 170 mmol) in 250 mL of CH_2Cl_2 over type 4Å molecular sieves (20 g) was added, portionwise at 0°C under an argon atmosphere, pyridinium chlorochromate (18.9 g, 87 mmol). The reaction mixture was then stirred at room temperature until disappearance of starting material, monitored by tlc. A solution of hexane and diethyl ether (500 mL, 1:1) was added, and the resulting mixture was filtered until colorless (three filtrations) using a Büchner funnel containing Celite, silica gel, and sodium sulfate (after the second filtration, the filtrate was treated with activated carbon for a few minutes). The solvents were removed by evaporation, and the crude residue was purified by flash chromatography using a 1:1 mixture of hexane and diethyl ether to afford aldehyde **15***b* (5.44 g, 55%) as a clear oil; ir (CH_2Cl_2): 2943, 1690, 1120, 1040 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.51–1.82 (m, 6H, -(CH_2)$_3$$CH_2$O), 3.50–3.56 and 3.77–3.88 (2m, 2H, -CH_2CH_2O-), 4.20–4.57 (m, 2H, -OCH_2CH=CH-), 4.68 (t, 1H, J = 2.5 Hz, -OC*H*O-), 6.38 (ddt, 1H, J = 16.0 Hz, 8.7 Hz, 2.5 Hz, -CH_2CH=C*H*CHO), 6.87 (dt, 1H, J = 16.0 Hz, 3.0 Hz, -CH_2CH=CHCHO), 9.58 (d, 1H, J = 8.7 Hz, CH=CHC*H*O); ^{13}C nmr ($CDCl_3$) δ: 18.9, 25.1, 30.1, 61.9, 65.3, 98.2, 131.3, 153.2, 193.1; ms *m/e*: 169 (M^+ − H). Exact Mass (M − H) calcd.: 169.0865; found: 169.0865.

(E,Z)-Diene ester ***16****b*

To a stirred solution of ethyl bis(trifluoroethyl)-2-phosphonopropionate (10.0 g, 29.0 mmol) and 18-crown-6 ether (38.0 g, 144.0 mmol) in 450 mL of THF was added at −78°C under argon a solution of potassium bis(trimethylsilyl)amide (0.657 M, 44 mL, 28.9 mmol) in toluene. The mixture was stirred for 5 min at −78°C before the *trans*-aldehyde **15***b* (4.9 g, 29.0 mmol) dissolved in 50 mL of THF was introduced by cannula over a period of 30 min. The cloudy mixture was stirred at −78°C for 1 h and then slowly allowed to warm to room temperature. A saturated ammonium chloride solution (300 mL) was added and the products were extracted with ether (3 × 150 mL). The combined organic phases were dried, filtered, and concentrated to a yellow oil that was purified by flash chromatography using a 9:1 mixture of hexane and ethyl acetate to furnish ester **18***b* (6.5 g, 88%) as a colorless oil; ir ($CHCl_3$): 3000–2850, 1700, 1640, 1605, 1452, 1375, 1218, 1167, 1118, 1022 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.29 (ddt, 1H, J = 15.4 Hz, 11.2 Hz, 1.6 Hz, THPOCH$_2$-CH=C*H*-), 6.42 (d, 1H, J = 11.2 Hz, -CH=CH-C*H*=C-), 5.95 (dt, 1H, J = 15.4 Hz, 6.0 Hz, THPO-CH$_2$-C*H*=CH-), 4.65 (t, 1H, J = 3.4 Hz, -OC*H*O-), 4.34 and 4.08 (2dd, 2H, J = 13.6 Hz, 5.8 Hz,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

THPOCH_2CH=), 4.22 (q, 2H, J = 7.1 Hz, OCH_2CH$_3$), 3.92–3.82 and 3.56–3.47 (2m, 2H, OCHOCH_2), 1.96 (s, 3H, -CH=C(CH_3), 1.88–1.49 (m, 6H, -OCH$_2$(CH_2)$_3$-), 1.32 (t, 3H, J = 7.1 Hz, -CH$_2$CH_3); ms m/e: 254 (M^+), 153 (M^+ − OTHP).

Allylic alcohol ***17***b

The reaction was carried out according to the previously described general procedure A. Thus, the reaction of ethyl ester **16***b* (6.5 g, 25.6 mmol) with diisobutylaluminum hydride (1.0 M, 56.4 mL, 56.4 mmol) and $Na_2SO_4 \cdot 10\ H_2O$ (16.2 g, 50.3 mmol) furnished alcohol **17***b* (5.3 g, 98%) as a colorless oil; ir (neat): 3410, 2940–2865, 1450, 1125, 1025 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.55 (dd, 1H, J = 15.0 Hz, 11.0 Hz, THPOCH$_2$CH=C*H*-), 5.96 (d, 1H, J = 11.2 Hz, -C*H*=C(CH$_3$)-), 5.74 (dt, 1H, J = 15.0 Hz, 6.2 Hz, THPOCH$_2$-C*H*=CH-), 4.65 (t, 1H, J = 3.5 Hz, -O-C*H*-O-), 4.32–4.24 and 4.06–3.98 (2dd, 2H, J = 13.0 Hz, 6.9 Hz, THPO-CH_2CH=), 4.25 (d, 2H, J = 5.8 Hz, =C(CH$_3$)CH_2OH), 3.92–3.83 and 3.55–3.47 (2m, 2H, -OCHOCH_2-), 1.88 (s, 3H, =C(CH_3)-), 1.86–1.49 (m, 6H, -OCH$_2$(CH_2)$_3$-), 1.35 (t, 1H, J = 5.9 Hz, -CH$_2$O*H*).

Diene diether ***18***b

General procedure C

To a stirred solution of alcohol **17***b* (1.9 g, 9.0 mmol) and imidazole (1.4 g, 20.5 mmol) in 80 mL of THF was added dropwise over 5 min under argon, and at room temperature, *tert*-butylchlorodiphenylsilane (2.8 mL, 10.7 mmol). After stirring the cloudy white suspension for 1 h, a saturated ammonium chloride solution (50 mL) was added. The reaction mixture was extracted with a 2:1 mixture of hexane and ether (3 × 50 mL). The combined organic phases were washed with water, dried over $MgSO_4$, filtered, and concentrated to a crude residue that was purified by flash chromatography using a 98:2 mixture of hexane and ethyl acetate as eluant to afford **18***b* (4.0 g, 98%) as a colorless oil; ir ($CHCl_3$): 3075–3010, 2940, 2860, 1430, 1365, 1115, 1078, 1025 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.72–7.62 and 7.44–7.36 (2m, 10H, *Ph*$_2$Si-), 6.26 (dd, 1H, J = 14.8 Hz, 10.2 Hz, THPOCH$_2$CH=C*H*-), 5.87 (d, 1H, J = 11.8 Hz, -C*H*=C(CH$_3$)-), 5.64 (dt, 1H, J = 14.7 Hz, 6.4 Hz, THPOCH$_2$-C*H*=), 4.60 (t, 1H, J = 3.6 Hz, -OC*H*O-), 4.29 (s, 2H, =C(CH$_3$)CH_2OSi-), 4.18 and 3.91 (2dd, 2H, J = 12.5 Hz, 6.6 Hz, THPOCH_2-), 3.88–3.80 and 3.53–3.44 (2m, 2H, -O-CH_2-), 1.89 (s, 3H, -CH=C(CH_3)-), 1.88–1.43 (m, 6H, -O-CH$_2$(CH_2)$_3$-), 1.05 (s, 9H, -(CH_3)$_3$C).

Diene alcohol ***19***b

General procedure D

To a stirred solution of diene diether **18***b* (4.0 g, 8.9 mmol) in 180 mL of isopropanol was added, under argon at room temperature, pyridinium *p*-toluenesulfonate (400 mg). The resulting mixture was heated at 75°C for 3 h. After adding 100 mL of a saturated $NaHCO_3$ solution, the mixture was extracted with ether (4 × 100 mL). The combined organic phases were washed with brine, dried over $MgSO_4$, filtered, and concentrated to a crude oil that was purified by flash chromatography using a 4:1 mixture of hexane and ethyl acetate as eluant to afford **19***b* (2.8 g, 85%) as a colorless oil; ir (neat): 3340, 3070–3000, 2930, 2858, 1470, 1430, 1112, 1070, 1000 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.71–7.67 and 7.44–7.35 (2m, 10H, Ph_2Si=), 6.16 (dd, 1H, J = 14.9 Hz, 11.0 Hz, -CH=C*H*-), 5.84 (d, 1H, J = 11.8 Hz, =CH-C*H*=C(CH$_3$)-), 5.66 (dt, 1H, J = 15.0 Hz, 5.9 Hz, HOCH$_2$C*H*=), 4.30 (s, 2H, -CH_2OSi-), 4.05 (t, 2H, J = 6.0 Hz, HOCH_2-CH=), 1.90 (s, 3H, =C(CH_3)-), 1.13 (t, 1H, J = 6.0 Hz, *H*OCH$_2$-), 1.05 (s, 9H, -(CH_3)$_3$C); ms m/e: 366 (M^+), 335 (M^+ − OCH$_3$), 309 (M^+ − C_4H_9).

Allylic chloride ***5***b

The reaction was carried out according to the general procedure B described before. Thus, the reaction of alcohol **19***b* (180 mg, 0.49 mmol), lithium chloride (63 mg, 1.5 mmol), *s*-collidine (97 μL, 0.74 mmol), and methanesulfonyl chloride (57 μL, 0.74 mmol) in 2 mL of DMF afforded the allylic chloride **5***b* (188 mg, 99%) as an oil, which was used immediately in the coupling reaction without further purification and characterization.

(E,E)-Diene ester ***16***c

To a stirred suspension of NaH (1.48 g, 60% in oil, 37 mmol) in 60 mL of THF was rapidly added at 0°C under argon a solution of ethyl diisopropyl-2-phosphonopropionate (9.86 g, 37 mmol) in 35 mL of THF. Once the evolution of hydrogen gas ended, the solution was cooled to −78°C. Aldehyde **15***b* (5.2 g, 30 mmol) in 10 mL of THF was introduced and the resulting mixture was stirred at −78°C for 1.5 h and then at 0°C for 30 min. The reaction was stopped by addition of saturated ammonium chloride solution (75 mL) and ether (125 mL). The aqueous phase was extracted with ether (3 × 100 mL). The combined organic phases were washed with brine, dried, filtered, and evaporated to a crude residue that was purified by flash chromatography using a 7:3 mixture of hexane and ethyl acetate to furnish ester **16***c* (6.28 g, 82%) as a colorless oil; ir (CH_2Cl_2): 2940, 1700, 1644, 1610, 1230, 1038, 1025, 922 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.30 (t, 3H, J = 7.5 Hz, CH_3CH$_2$O-), 1.51–1.84 (m, 6H, (CH_2)$_3$CH_2O-), 1.94 (d, 3H, J = 1.0 Hz, CH_3C=CH-), 3.48–3.57 and 3.83–3.92 (2m, 2H, -OCH_2CH$_2$-), 4.21 (q, 2H, J = 7.5 Hz, -OCH_2CH$_3$), 4.37–4.41 (m, 2H, -OCH_2CH=CH), 4.66 (t, 1H, J = 2.5 Hz, -OC*H*O-), 6.13 (dt, 1H, J = 15.3 Hz, 5.6 Hz, -OCH$_2$C*H*=CH-), 6.59 (ddt, 1H, J = 15.3 Hz, 1.6 Hz, 11.5 Hz, -OCH$_2$CH=C*H*CH=), 7.18 (d, 1H, J = 11.5 Hz, =CHC*H*=CCH$_3$); ^{13}C nmr ($CDCl_3$) δ: 12.4, 14.1, 19.2, 25.2, 30.4, 60.3, 61.9, 66.7, 97.8, 126.7, 127.3, 136.9, 137.1, 168.1; ms m/e: 254 (M^+). Exact Mass (M^+) calcd.: 254.1518; found: 254.1513.

Allylic alcohol ***17***c

The reduction was carried out according to the general procedure A described before. Thus, the reaction of ester **16***c* (6.08 g, 24 mmol) with diisobutylaluminum hydride (1 M in dichloromethane, 53 mL, 53 mmol) and $Na_2SO_4 \cdot 10\ H_2O$ (15 g, 46.6 mmol) in 450 mL of CH_2Cl_2 afforded alcohol **17***c* (4.43 g, 87%) as a colorless oil; ir (CH_2Cl_2): 3620, 1200, 1075, 1035, 1020 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.35 (t, 1H, J = 5.0 Hz, -CH$_2$O*H*), 1.47–1.90 (m, 6H, (CH_2)$_3$CH$_2$O-), 1.79 (s, 3H, CH_3-), 3.48–3.57 and 3.84–3.94 (2m, 2H, -CH$_2$CH_2O-), 4.01–4.34 (m, 4H, -CH_2OH and CH_2OTHP), 4.66 (t, 1H, J = 2.5 Hz, -OC*H*O-), 5.80 (dt, 1H, J = 15.0 Hz, 5.0 Hz, -CH$_2$C*H*=CHCH=C), 6.09 (d, 1H, J = 11.0 Hz, -CH$_2$CH=CHC*H*=C), 6.51 (ddt, 1H, J = 15.0 Hz, 11.0 Hz, 1.0 Hz, -CH$_2$CH=C*H*CH=C); ^{13}C nmr ($CDCl_3$) δ: 13.8, 19.1, 25.2, 30.4, 61.9, 67.4, 67.6, 97.5, 123.5, 128.4, 128.7, 137.9; ms m/e: 212 (M^+). Exact Mass (M^+) calcd. 212.1412; found: 212.1410.

Diene diether ***18***c

The reaction was carried out according to the previously described general procedure C. Thus, the reaction of alcohol **17***c* (1.137 g, 5.36 mmol), imidazole (0.833 g, 12.24 mmol), and *tert*-butylchlorodiphenylsilane (1.64 mL, 1.73 g, 6.31 mmol) in 32 mL of THF afforded diene diether **18***c* (2.29 g, 95%) as a colorless oil; ir (neat): 3080–3010, 2945, 2860, 1450, 1360, 1120–1000 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.06 (s, 9H, -(CH_3)$_3$C), 1.47–1.95 (m, 6H, -(CH_2)$_3$CH$_2$O-), 1.71 (s, 3H, -CH_3), 3.48–3.57 and 3.84–3.94 (2m, 2H, -CH$_2$CH_2O-), 4.00–4.10 and 4.30–4.39 (2m, 2H, -CH_2OTHP), 4.10 (s, 2H, -CH_2OSi-), 4.68 (t, 1H, J = 2.8 Hz, -OC*H*O-), 5.77 (dt, 1H, J = 15.0 Hz, 6.4 Hz, OCH$_2$C*H*=CHCH=C), 6.21 (d, 1H, J = 11.2 Hz, -CH=CHC*H*=C), 6.54 (dd, 1H, J = 15.1 Hz, 11.2 Hz, -CH$_2$CH=C*H*CH=C), 7.35–7.48 and 7.65–7.72 (2m, 10H, Ph_2Si-).

Diene alcohol ***19***c

The reaction was carried out according to the previously described general procedure D. Thus, the reaction of diene diether **18***c* (734.4 mg, 1.63 mmol) with pyridinium *p*-toluenesulfonate (73.4 mg) in 20 mL of isopropanol provided allylic alcohol **19***c* (484.9 mg, 81%) as a colorless oil; ir (neat): 3340, 3050, 2940, 2860, 1470, 1430, 1370, 1110, 1070 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

1.07 (s, 9H, -(CH_3)$_3$C), 1.32 (t, 1H, J = 5.9 Hz, -CH_2OH), 1.72 (s, 3H, -CH_3), 4.20 (s, 2H, -CH_2OSi-), 4.23 (t, 2H, J = 5.7 Hz, HOCH_2CH=), 5.83 (dt, 1H, J = 15.0 Hz, 6.1 Hz, HOCH_2CH=CH-), 6.20 (d, 1H, J = 11.2 Hz, -CH=CHCH=C), 6.53 (dd, 1H, J = 15.1 Hz, 11.1 Hz, -CH=CHCH=C), 7.30–7.48 and 7.65–7.71 (2m, 10H, Ph_2Si-).

Allylic chloride **5**c

The reaction was carried out according to the general procedure B as described before. Thus, alcohol **19***c* (1.096 g, 2.99 mmol) reacted with lithium chloride (0.507 g, 11.97 mmol), *s*-collidine (0.79 mL, 0.724 g, 5.98 mmol), and methanesulfonyl chloride (0.46 mL, 0.681 g, 5.98 mmol) in 19 mL of DMF to give **5***c* (1.109 g, 96%) as a yellowish oil; ^{1}H nmr ($CDCl_3$) δ: 1.26 (s, 9H, -(CH_3)$_3$C), 1.71 (s, 3H, -CH_3), 4.11 (s, 2H, -CH_2OSi-), 4.18 (d, 2H, J = 6.9 Hz, ClCH_2CH=), 5.78 (dt, 1H, J = 14.8 Hz, 7.3 Hz, -CH_2CH=CH-), 6.21 (d, 1H, J = 10.0 Hz, -CH=CHCH=C-), 6.57 (dd, 1H, J = 14.8 Hz, 11.2 Hz, -CH=CHCH=C), 7.35–7.48 and 7.65–7.75 (2m, 10H, Ph_2Si-).

Alcohol **20**

General procedure E

To a stirred solution of silyl ether **4** (490.5 mg, 1.37 mmol) in 12 mL of THF was added dropwise over 12 min at 0°C under argon a solution of tetrabutylammonium fluoride (1.5 mL, 1 M, 1.5 mmol) in THF. The resulting mixture was stirred at 0°C for 10 min and then at room temperature for 2.5 h. The solvent was removed by evaporation and the resulting yellow residue was purified by flash chromatography using a 7:3 mixture of hexane and ethyl acetate as eluant to afford colorless oil **20** (305.4 mg, 91%); ir (neat): 3420, 2955, 2880, 1740, 1437, 1380, 1240, 1155, 1050 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.64 (s, 3H, =C-CH_3), 2.10–2.00 (m, 4H, =C(CH_3)-CH_2CH_2-), 2.28 (q, 2H, J = 7.0 Hz, HOCH_2CH_2=CH), 3.34 (t, 1H, J = 7.0 Hz, -CH_2CH(CO_2CH_3)$_2$), 3.63 (m, 2H, HOCH_2CH_2-), 3.73 (s, 6H, CH(CO_2CH_3)$_2$), 5.16 (t, 1H, J = 7.0 Hz, -CH=C(CH_3)-); ms m/e: 244 (M^+), 213 (M^+ − OCH_3).

Methanesulfonate ester **21**

General procedure F

To a stirred solution of the alcohol **20** (277 mg, 1.1 mmol) and triethylamine (0.24 mL, 1.7 mmol) in 16 mL of CH_2Cl_2 was added, dropwise over 5 min at 0°C under argon, methanesulfonyl chloride (0.10 mL, 1.3 mmol). The mixture was stirred at 0°C for 1 h and then poured into 80 mL of H_2O. The aqueous layer was extracted with CH_2Cl_2 (4 × 50 mL) and the combined organic phases were washed with water, dried over $MgSO_4$, filtered, and concentrated to a crude residue that was purified by flash chromatography using a 3:1 mixture of hexane and ethyl acetate to provide **21** (346 mg, 94%) as a colorless oil; ir (neat): 2950, 2850, 1730, 1440, 1358, 1230, 1172 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.64 (d, 3H, J = 1.1 Hz, =C(CH_3)-), 2.03–2.00 (m, 4H, -C(CH_3)CH_2CH_2-), 2.46 (q, 2H, J = 7.0 Hz, MsOCH_2CH_2-), 3.00 (s, 3H, -SO_2CH_3), 3.33 (m, 1H, -CH(CO_2CH_3)$_2$), 3.74 (s, 6H, -(CO_2CH_3)$_2$), 4.18 (t, 2H, J = 6.9 Hz, MsOCH_2CH_2-), 5.13 (t, 1H, J = 6.0 Hz, -CH=C(CH_3)-); ms m/e: 322 (M^+), 290 (M^+ − CH_3OH).

Triene **22**b

General procedure G

To a stirred suspension of NaH (46 mg, 60%, 1.2 mmol) in 6 mL of THF was added dropwise at 0°C under argon a solution of the mesylate **21** (340 mg, 1.1 mmol) in 6 mL of THF. The mixture was slowly warmed to room temperature and stirred for 45 min. After cooling again to 0°C, a solution of the crude allylic chloride **5***b* (540 mg, 1.4 mmol) in 6 mL of DMF was added dropwise over 15 min. The resulting mixture was stirred at room temperature for 36 h before it was poured into 60 mL of saturated ammonium chloride solution. The aqueous phase was extracted with a 2:1 mixture of ether and hexane (5 × 40 mL). The combined organic phases were washed with water, 5% $NaHCO_3$ solution, and brine, then dried, filtered, and concentrated. The thick yellow residue was purified by flash chromatography using a 5:1 mixture of hexane and ethyl acetate to give triene **22***b* (355 mg, 50%) along with both starting materials **21** and **5***b* in about 10% each. Compound **22***b*: ir (neat); 3070–3000, 2950, 2860, 1740, 1430, 1360, 1178, 1112 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.05 (s, 9H, -(CH_3)$_3$C), 1.58 (d, 3H, J = 0.9 Hz, -CH_2CH_2C(CH_3)=), 1.80–1.95 (m, 7H, (CO_2CH_3)$_2$CRCH_2CH_2- and =CH-CH=C(CH_3)-), 2.41 (q, 2H, J = 7.0 Hz, -CH_2CH_2OMs), 2.59 (d, 2H, J = 7.5 Hz, (CO_2CH_3)$_2$CRCH_2-CH=), 2.98 (s, 3H, -SO_2CH_3), 3.67 (s, 6H, (CO_2CH_3)$_2$), 4.14 (t, 2H, J = 7.0 Hz, -CH_2OMs), 4.25 (s, 2H, -CH_2OSi-), 5.08 (t, 1H, J = 7.3 Hz, -C(CH_3)=CHCH_2-), 5.32 (dt, 1H, J = 14.8 Hz, 7.4 Hz, -CH_2CH=CH-), 5.80 (d, 1H, J = 11.0 Hz, =CHCH=C(CH_3)-), 6.08 (dd, 1H, J = 14.8 Hz, 11.0 Hz, -CH_2CH=CH-), 7.35–7.48 and 7.65–7.71 (2m, 10H, Ph_2Si-); ms m/e: 670 (M^+), 631 (M^+ − C_4H_9).

Triene **22**c

The reaction was carried in a similar fashion as described in the general procedure G. Thus, the reaction of dienophile **21** (201.1 mg, 0.62 mmol) with NaH (29.0 mg, 60%, 0.73 mmol) and diene **5***c* (310.0 mg, 0.81 mmol) in a mixture of DMF and THF (1:1, 6 mL) afforded triene **22***c* (289.6 mg, 70%) and recovered starting material **21** (35.4 mg, 18%). Compound **22***c*: ir (neat): 3020, 2940, 2850, 1740, 1430, 1350, 1170, 1110 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.06 (s, 9H, -(CH_3)$_3$C), 1.64 (s, 3H, =CCH_3),1.68 (s, 3H, =CCH_3), 1.84–2.00 (m, 4H, C(CO_2CH_3)$_2$CH_2CH_2-), 2.45 (q, 2H, J = 7.2 Hz, -CH_2CH_2OMs), 2.72 (d, 2H, J = 7.5 Hz, -CH_2CH=CH-), 2.99 (s, 3H, -SO_2CH_3), 3.73 (s, 6H, C(CO_2CH_3)$_2$), 4.07 (s, 2H, -CH_2OSi-), 4.17 (t, 2H, J = 7.0 Hz, -CH_2OMs), 5.13 (t, 1H, J = 7.4 Hz, -(CH_3)C=CHCH_2-), 5.42 (dt, 1H, J = 14.8 Hz, 7.4 Hz, -CH_2CH=CHCH=C), 6.07 (d, 1H, J = 11.5 Hz, -CH=CHCH=C), 6.33 (dd, 1H, J = 14.7 Hz, 10.8 Hz, -CH=CHCH=C), 7.34–7.47 and 7.64–7.71 (2m, 10H, Ph_2Si-).

Tetraester **23**b

General procedure H

To a stirred suspension of NaH (84 mg, 60% in oil, 2.1 mmol) in a mixture of DMF and THF (1:1, 6 mL), dimethyl malonate (0.27 mL, 2.3 mmol) was added dropwise at 0°C under argon. After stirring the mixture at 0°C for 45 min, a solution of triene **22***b* (311 mg, 0.46 mmol) in a mixture of DMF and THF (1:1, 6 mL) was introduced by syringe, followed by addition of potassium iodide (7.6 mg, 46 mmol). The resulting mixture was heated at 80°C for 18 h before it was poured into 60 mL of H_2O. The mixture was extracted with CH_2Cl_2 (3 × 40 mL) and ether (3 × 40 mL). The combined organic phases were washed with H_2O, dried over $MgSO_4$, filtered, and concentrated to a crude residue that was purified by flash chromatography using a mixture of hexane and ethyl acetate (85:15) to afford **23***b* (235 mg, 72%) as a colorless oil; ir (neat): 3070–3000, 2955, 2860, 1735, 1435, 1200, 1110 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.05 (s, 9H, -(CH_3)$_3$C), 1.52 (d, 3H, =C(CH_3)-CH_2CH_2), 1.85–2.00 (m, 11H, -CH_2CH_2CH=C(CH_3)CH_2CH_2-, and SiOCH_2-C(CH_3)=), 2.58 (d, 2H, J = 7.3 Hz, =CHCH_2CR(CO_2CH_3)$_2$), 3.24–3.40 (m, 1H, -CH-(CO_2CH_3)$_2$), 3.66–3.75 (3s, 12H, 4 × -OCH_3), 4.25 (s, 2H, -CH_2OSi-), 4.95–5.50 (m, 2H, -CH_2CH= and MsOCH_2CH_2-CH=), 5.70–6.25 (m, 2H, -C(CH_3)=CHCH=), 7.38–7.75 (m, 10H, Ph_2Si-).

Tetraester **23**c

The reaction was prepared as described in the general procedure H. Thus, the reaction of dimethyl malonate (0.25 mL, 2.15 mmol) with NaH (77.4 mg, 60%, 1.94 mmol) and triene **22***c* (289.6 mg, 0.43 mmol) in the presence of KI (7.1 mg, 43 mmol) yielded the tetraester **23***c* (273.3 mg, 90%); ^{1}H nmr ($CDCl_3$) δ: 1.05 (s, 9H, -(CH_3)$_3$C), 1.56 (s, 3H, =CCH_3), 1.67 (s, 3H, =CCH_3), 1.80–2.05 (m, 8H, -CH_2CH_2CH=C(CH_3)CH_2CH_2-), 2.71 (d, 2H, J = 7.5 Hz, -CH_2CH=CH-), 3.35 (m, 1H, -CH(CO_2CH_3)$_2$), 3.72

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

and 3.75 (2s, 12H, 4 × -OCH_3), 4.06 (s, 2H, -CH_2OSi-), 5.11 (t, 1H, J = 7.0 Hz, -(CH$_3$)C=CHCH$_2$-), 5.43 (dt, 1H, J = 15.0 Hz, 7.0 Hz, -CH=CHCH=CH-), 6.07 (d, 1H, J = 11.0 Hz, -CH=CHCH=C), 6.33 (dd, 1H, J = 15.0 Hz, 11.0 Hz, -CH=CHCH=C-), 7.30–7.47 and 7.63–7.70 (2m, 10H, Ph_2Si-).

Allylic alcohol ***24****b*

The reaction was performed in a similar fashion as described in the general procedure E. Thus, the silyl ether **23***b* (231 mg, 0.33 mmol) was treated with tetrabutylammonium fluoride (1.0 M in THF, 0.49 mL, 0.49 mmol) in 3 mL of THF to give the alcohol **24***b* (110 mg, 72%) as a colorless oil; ir (neat): 3500, 2950, 2860, 1735, 1438, 1200 cm^{-1}; ^{1}H nmr (CDCl$_3$) δ: 1.38 (t, 1H, J = 5.0 Hz, -CH$_2$OH), 1.56 (s, 3H, -CH$_2$CCCH_3)=), 1.85 (s, 3H, =CHCH=C(CH_3)-), 1.87–2.04 (m, 8H, -CH_2CH_2CH=C(CH$_3$)-CH_2CH_2-), 2.69 (d, 2H, J = 7.6 Hz, -CH_2CR(CO$_2$CH$_3$)$_2$), 3.35 (t, 1H, J = 7.1 Hz, -CH(CO$_2$CH$_3$)$_2$), 3.72 and 3.73 (2s, 12H, 4 × -OCH_3), 4.22 (d, 2H, J = 4.8 Hz, HOCH_2-), 5.09 (t, 1H, J = 7.0 Hz, -CH$_2$CH=), 5.42 (dt, 1H, J = 14.9 Hz, 7.5 Hz, -CH=CHCH=C-), 5.89 (d, 1H, J = 11.4 Hz, -CH=CHCH=C-), 6.36 (dd, 1H, J = 14.9 Hz, 11.1 Hz, CH=CHCH=C-); ms m/e: 468 (M$^+$), 450 (M$^+$ − H$_2$O).

Allylic alcohol ***24****c*

The reaction was carried out as described in the general procedure E. Thus, the silyl ether **23***c* (273.3 mg, 0.39 mmol) was treated with tetrabutylammonium fluoride (1.0 M in THF, 0.7 mL, 0.70 mmol) in 6 mL of THF to furnish the alcohol **24***c* (174.0 mg, 95%) as a colorless oil; ir (neat): 3520, 2950, 2850, 1735, 1435, 1200 cm^{-1}; ^{1}H nmr (CDCl$_3$) δ: 1.42 (t, 1H, J = 5.8 Hz, -CH$_2$OH), 1.56 (s, 3H, =CCH_3), 1.76 (s, 3H, =CCH_3), 1.80–2.08 (m, 8H, -CH_2CH_2CH=C(CH$_3$)CH_2CH_2-), 2.72 (d, 2H, J = 7.6 Hz, -CH_2CH=CHCH=C), 3.35 (t, 1H, J = 7.1 Hz, -CH(CO$_2$CH$_3$)), 3.72 and 3.73 (2s, 12H, 4 × -OCH_3), 4.05 (d, 2H, J = 5.9 Hz, -CH_2OH), 5.09 (t, 1H, J = 7.0 Hz, CH$_2$CH=CCCH$_3$-), 5.48 (dt, 1H, J = 14.9 Hz, 7.6 Hz, -CH=CHCH=C-), 6.01 (d, 1H, J = 10.4 Hz, -CH=CHCH=C-), 6.32 (dd, 1H, J = 14.9 Hz, 10.8 Hz, -CH=CHCH=C-).

Allylic chloride ***25****b*

The reaction was carried out as described in the general procedure B. Thus, treatment of allylic alcohol **24***b* (58.8 mg, 0.13 mmol) with lithium chloride (21.2 mg, 0.50 mmol), *s*-collidine (66.3 μL), and methanesulfonyl chloride (39 μL, 0.50 mmol) in DMF provided the allylic chloride **25***b* (51.0 mg, 84%) as a colorless oil that was used immediately in the next cyclization step without further purification and characterization.

Allylic bromide ***25****c*

To a stirred solution of the allylic alcohol **24***c* (22.0 mg, 47 μmol) and CBr$_4$ (19.4 mg, 58 μmol) in 0.6 mL of CH$_2$Cl$_2$ was added, dropwise at 0°C under argon, a solution of PPh$_3$ (17.3 mg, 66 μmol) in 0.4 mL of CH$_2$Cl$_2$. The resulting mixture was allowed to warm to room temperature and then stirred for about 2 h until the starting material **24***c* was consumed. After the solvent was evaporated, the crude residue was purified by flash chromatography using a 5:1 mixture of hexane and ethyl acetate to give allylic bromide **25***c* (21.4 mg, 40 μmol, 86%) as an oil that was used immediately in the next cyclization step without further purification and characterization.

TTC macrocycle ***1****b*

General procedure I

To a stirred suspension of Cs$_2$CO$_3$ (161.0 mg, 0.493 mmol) in a mixture of DMF and THF (1:1, 20 mL) was slowly added, at 70°C under argon by automatic syringe pump over a period of 12 h, a solution of allylic chloride **25***b* (51.3 mg, 0.105 mmol) in a mixture of DMF and THF (1:1, 15 mL). After the addition was completed, the stirring was continued for 9 h longer at 70°C. The solid was removed by filtration, and the filtrate was concentrated. The crude residue thus obtained was purified by flash chromatography using a 9:1 mixture of hexane and ethyl acetate to give two products, which were further purified by recrystallization from a minimum amount of CH$_2$Cl$_2$ in hexane to afford macrocyclic monomer **1***b* (34.0 mg, 72%) and macrocyclic dimer **26***b* (10 mg, 11%).

Compound ***1****b*: mp 140–143°C; ir (CHCl$_3$): 3020, 2945, 2850, 1727, 1435, 1225 cm^{-1}; ^{1}H nmr (CDCl$_3$) δ: 1.57 (s, 3H, -CH$_2$CH$_2$C(CH_3)=), 1.62 (s, 3H, =CHCH=C(CH_3)-), 1.80–1.91 and 1.97–2.08 (2m, 8H, -CH_2CH_2C(CH$_3$)=CHCH_2CH_2-), 2.67 (d, 2H, J = 7.7 Hz, =CH-CH_2CR(CO$_2$CH$_3$)$_2$), 2.90 (s, 2H, =C(CH$_3$)CH_2CR(CO$_2$CH$_3$)$_2$), 3.72 (s, 12H, 4 × -OCH_3), 5.07 (t, 1H, J = 5.0 Hz, -CH$_2$CH=C(CH$_3$), 5.17 (dt, 1H, J = 14.1 Hz, 7.2 Hz, -CH$_2$CH=CH-), 5.92–6.11 (m, 2H, -CH=CHCH=C(CH$_3$)-); ms m/e: 450 (M$^+$). Diels–Alder reaction of ***1***a

Solid macrocycle ***1a*** (5.0 mg, 11 μmol) was heated in a vacuum-sealed quartz tube (20 cm long, 8 mm diameter) at 360°C for 80 min. After the tube was cooled to room temperature, the residue in the tube was dissolved in CH_2Cl_2 and then transferred into a flask. After the solvent was evaporated, the residue was purified by flash chromatography with a 12:7:1 mixture of $CHCl_3$, hexane, and Et_2O to provide a mixture (3.1 mg, 62%) that displayed only one spot on tlc but contained several tricyclic isomers as observed by gc. Attempts to separate each isomer of the mixture by flash chromatography using different solvent systems were unsuccessful. Proton nmr of the mixture is very complicated, but it does contain all the characteristic peaks for tricycle **34** whose spectral data are provided below.

The gc analysis of the reaction mixture before flash chromatography reveals four major products, each contributing between 10 and 19% yield, along with a number of minor ones (<9%).

Diels–Alder reaction of ***1***b

Solid macrocycle ***1b*** (18.8 mg, 41.7 μmol) was placed in the bottom of a quartz tube, which was then sealed under vacuum. The tube was heated to 300°C for 2 h. The crude residue was transferred to a flask with CH_2Cl_2 and then purified by flash chromatography with a 97:3 mixture of hexane and ethyl acetate to give tricycle **41** (12.4 mg, 66%) as a crystalline solid; mp 119–122°C; ir (neat): 2960, 2850, 1738, 1450, 1240, 1100 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.92 (d, 3H, J = 6.9 Hz, CH_3CH-), 1.25–2.60 (m, 15H, all other CH_2 and C*H*), 1.62 (s, 3H, CH_3C=), 3.63–3.75 (m, 12H, 4 × -OCH_3), 5.19 (s, 1H, -C*H*=CCH_3); ^1H nmr (C_6D_6) δ: 0.82 (d, 3H, J = 6.9 Hz, C*H*CH-), 1.05–2.60 (m, 15H, all other CH_2 and C*H*), 1.62 (s, 3H, CH_3C=CH), 3.30–3.35 (m, 12H, 4 × -OCH_3), 5.20 (s, 1H, -C*H*=CCH_3). The relative stereochemistry for compound **41** was further confirmed by X-ray crystallography.

Diels–Alder reaction of ***1***c

A solution of macrocycle ***1c*** (13.0 mg, 28.9 μmol) in 2 mL of toluene was heated in a vacuum-sealed quartz tube at 200°C for 17 h. After the tube was opened, the reaction mixture was trans-

ferred into a flask with CH_2Cl_2 and then evaporated. The residue was purified by flash chromatography using a 5:1 mixture of hexane and ethyl acetate to give TAC tricyclic compound **34** (12.5 mg, 27.8 μmol, 96%) as a crystalline solid; mp 146–148°C; ir (neat): 2945, 2870, 1738, 1435, 1230 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.88 (s, 3H, -CH_3), 0.91 (s, 3H, -CH_3), 1.10–2.23 (m, 14H, all other CH_2 and CH), 3.68, 3.70, 3.73 and 3.74 (4s, 12H, 4 × -OCH_3), 5.19 (d, 1H, J = 9.9 Hz, -CH=C*H*C-), 5.40 (dd, 1H, J = 9.9 Hz, 1.9 Hz, CHC*H*=CH-). The structure of the compound **34** was further confirmed by X-ray crystallography.

The synthesis and transannular Diels–Alder reactions of 14-membered macrocyclic trienes containing a methyl-substituted diene and a methyl-substituted *cis*-dienophile moiety are described. As a result of the dienophile *cis* geometry the 1,7-dimethyl A.B.C.[6.6.6] tricycles obtained from the Diels–Alder reaction have a different stereochemistry at the four chiral centers than similar tricycles that were the subject of the preceding paper in this series. Thus *trans-syn-cis* (TSC) tricycle **30** was the sole product obtained from the *trans-cis-cis* (TCC) macrocycle **1***b*. In a similar fashion TCC macrocycle **1***d* afforded only *trans-syn-cis* (TSC) tricycle **31**. On the contrary, the transannular Diels–Alder reaction in *cis-trans-cis* (CTC) macrocycle **1***a* and *trans-trans-cis* (TTC) macrocycle **1***c* led to a mixture of the same four tricyclics (**30**, **32–34**) but in different ratio. The above experimental results are rationalized by taking into consideration the interconversion of macrocyclic trienes **1***a*, **1***b*, and **1***c*. Pathways for these interconversions are also proposed.

YAO-CHANG XU, ANDREW L. ROUGHTON, PIERRE SOUCY, SOLO GOLDSTEIN et PIERRE DESLONGCHAMPS. Can. J. Chem. **71**, 1169 (1993).

La synthèse ainsi que la réaction de Diels–Alder transannulaire, des triènes macrocycliques à 14 chaînons dont l'unité diène et l'unité *cis*-diénophile portent un substituant méthyle, seront décrites. La cycloaddition transannulaire génère des tricycles A.B.C.[6.6.6]-1,7-diméthyle. Cependant, dû à la géométrie *cis* du diénophile, la stéréochimie observée pour les quatre centres chiraux est différente de celle obtenue pour des composés similaires qui ont été examinés dans l'article précédent de cette série. Ainsi le tricycle **30**, de stéréochimie *trans-syn-cis* (TSC), a été le seul produit obtenu à partir du macrocycle **1***b*, de stéréochimie *trans-cis-cis* (TCC). De la même manière le macrocycle TCC **1***d* a fournit uniquement le tricycle TSC **31**. Contrairement à ces résultats, les macrocycles *cis-trans-cis* (CTC) **1***a* et *trans-trans-cis* (TTC) **1***c* ont fourni, dans des proportions différentes, un mélange des mêmes quatre produits (**30**, **32–34**). Ces résultats expérimentaux ont été rationalisés prenant en considération l'interconversion des triènes macrocycliques **1***a*, **1***b* et **1***c*. On a proposé aussi des mécanismes pour ces interconversions.

Introduction

In the preceding article (1), we reported the syntheses and transannular Diels–Alder reactions of 14-membered macrocyclic trienes containing *E* dienophiles. As indicated in Scheme 1, the A.B.C.[6.6.6] tricyclic compound **2**, which may be derived from macrocycle **1**, contains two methyl groups at the quaternary C1 and C7 positions and could be constructed in a stereoselective manner by changing the geometry of the diene double bonds. This new methodology, which is complementary to other methods such as aldol condensations (2), biomimetic cyclization (3), intramolecular Diels–Alder reaction (4), and intramolecular Michael addition (5), provides a powerful tool for the synthesis of polycyclic natural products such as steroids and terpenes (6).

In this article, we would like to report our continued investigation (7) of this new methodology specifically applied to the macrocyclic system **1**, which contains a *cis* dienophile.

Preparation of dienophiles and dienes

In the preceding publication, a stereoselective synthesis of an *E* dienophile was reported, and this basic building block was used in the syntheses of three macrocycles (1). In this series, a *Z* dienophile was used as a basic building block in constructing four other macrocyclic trienes. Since both *Z* and *E* dienophiles are required for our systematic studies, a method for the simultaneous synthesis of both isomers was desirable.

Scheme 2 illustrates the synthetic route to both dienophiles via a Wittig reaction as the key step. The coupling reaction of commercially available (ethyl)triphenylphosphonium bromide with tetrahydropyranyl bromide ether **3**, which was prepared from 2-bromoethanol and 3,4-dihydro-2*H*-pyran (8), gave rise in the presence of potassium bis(trimethylsilyl)amide as a base to phosphonium salt **4**, in good yield (9). Swern oxidation (10) of alcohol **5**, which was obtained by mono-protection of commercially available 1,3-propanediol (11), furnished aldehyde **6** in 86% yield, thus setting the stage for the olefination reaction.

The Wittig olefination reaction was carried out in tetrahydrofuran at 0°C by adding aldehyde **6** to a solution of the phosphonium ylide, generated from **4** and butyllithium, to provide an isomeric mixture of *Z* and *E* dienophiles **7** with both hydroxyl groups protected. The ratio of *Z* and *E* isomers is roughly 43:57 as determined by integration of the proton nmr signals.

Attempts to separate the isomeric mixture **7** by chromatography met with little success. It was finally found, however, that after selective removal of the tetrahydropyranyl protecting group with pyridinium *p*-toluenesulfonate in isopropanol at 75°C[2] the resulting alcohols of the isomeric mixture **8** could be separated by the use of medium-pres-

sure chromatography. It is interesting to note that the isomeric mixture of alcohols resulting from desilylation of **7** was practically inseparable.

After separation, both alcohols **8***a* and **8***b* were subjected, in separate experiments, to the same transformations as indicated in Scheme 2, in order to produce the proper functionality necessary for the coupling reaction with dienes. Thus, **8***a* and **8***b* were converted in good yields to their respective methanesulfonate esters **9***a* and **9***b*. Potassium-iodide-catalyzed alkylation of methanesulfonate esters **9***a* and **9***b* with the sodium-hydride-generated enolate of dimethyl malonate in a mixture of DMF and THF (1:1) at 85°C afforded methyl octenoates **10***a* and **10***b*, respectively. Desilylation of **10***a* and **10***b* by tetrabutylammonium fluoride (12) in THF then gave alcohols **11***a* and **11***b*, which were similarly converted, as described above, to their methanesulfonate esters **12***a* and **12***b* as the desired dienophiles. A stereoselective synthesis of *Z* dienophile **12***a* was also developed in our laboratory; the details will be reported in near future (13).

In the studies of transannular Diels–Alder reactions for this series, four different diene moieties were required. Syntheses of dienes **16***b* (*E-Z*) and **16***c* (*E-E*) used as depicted in Scheme 4 were reported in the preceding article (1). The other two dienes **16***a* (*Z-E*) and **18** (*E-Z*) were derived from dienes **13** and **17** (1), respectively, by functional group manipulations. As presented in Scheme 3, hydroxyl group protection in **13** with *tert*-butylchlorodiphenylsilane gave diene diether **14** (11). Selective deprotection of the tetrahydropyranyl ether (THP) with pyridinium *p*-toluenesulfonate (PPTS) ether was performed with isopropanol[2] to give allylic alcohol **15**, which could be transformed into allylic chloride **16***a* by use of Meyers' method (14). Similarly, allylic alcohol **17** could be converted to allylic chloride **18** (14).

Preparation of macrocycles

Our basic strategy for the synthesis of acyclic trienes, which are the immediate precursors of macrocycles, is based on the coupling reaction of dienes and dienophiles, which has been used extensively in our laboratory (7). As presented in Scheme 4, the coupling reactions were conducted by alkylation of the sodium-hydride-generated enolate of dimethyl malonate **12***a* with allylic chlorides **16***a*, **16***b*, or **16***c* in a mixture of THF and DMF (15), which provided three acyclic trienes **19***a* (*Z-E-Z*), **19***b* (*E-Z-Z*), and **19***c* (*E-E-Z*), respectively, in good yields. Introduction of the malonate connector was accomplished by substitution of the methanesulfonate ester groups of **19***a*, **19***b*, and **19***c* with the sodium salt of dimethyl malonate in the presence of a catalytic amount of potassium iodide to produce **20***a*, **20***b*, and **20***c*, respectively. Deprotection of the silyl ether groups was carried out by treatment of **20***a*, **20***b*, and **20***c* with tetrabutylammonium fluoride in THF (12) to give **21***a*, **21***b*, and **21***c*. The allylic alcohol **21***b* was converted to allylic chloride **22***b* by Meyers' method (LiCl, CH_3SO_2Cl, and *s*-collidine in DMF (14)). The allylic chloride has been used very often for the preparation of macrocycles in our laboratory (7). However, it was recently found that the corresponding allylic bromide is superior to the allylic chloride for the macrocyclization process (1). Therefore, allylic alcohols **21***a* and **21***c* were transformed into allylic bromides **22***a* and **22***c*, respectively, using PPh_3 and CBr_4 in CH_2Cl_2 (16). Allylic halides **22***a*, **22***b*, and **22***c* decomposed slowly when they were purified by flash chromatography; however, this problem could be avoided if the newly prepared allylic halides were filtered through a short-path silica gel column and then used immediately for the next cyclization reaction.

Having synthesized the requisite carbon chain and appropriate functional groups at each end, the acyclic trienes **22***a–c* were ready for the construction of macrocycles. All macrocyclizations were performed in the same way by slowly adding a solution of allylic halides **22***a*, **22***b*, **22***c* in THF to a stirred suspension of cesium carbonate in a mixture of DMF and THF (1:1) at about 80°C under dilute conditions to avoid dimerization (7). Macrocyclic products **1***a* (*cis-trans-cis*, CTC), **1***b* (TCC), and **1***c* (TTC) were formed as white solids in very good yields (66–93%) via an intramolecular displacement of allylic halides by the base-generated dimethyl malonate anion. In all cases, no detectable amount of dimerization product was observed by ^{1}H nmr spectra. However, a side-product **23**, which was derived from an S_N2'-like mechanism, was obtained from **22***c* but in less than 5% yield.

The structures of macrocycles **1***a*, **1***b*, and **1***c* were rigorously established by spectroscopic data including ^{13}C and ^{1}H nmr, ir, and high- and low-resolution ms. The conservation of the double bond geometries in the macrocyclic products has been confirmed by comparing the ^{1}H nmr data with those of their triene precursors such as **22** or **21**. Further confirmation of the structures by X-ray crystallography was also obtained for macrocycles **1***a*[3] and **1***b* (17).

Macrocycle **1***d*, which has methyl substituents at the C2 and C7 positions and which possesses the same olefin geometries (*trans-cis-cis*) as macrocycle **1***b*, was synthesized via a slightly different procedure than that used for the preparation of other macrocycles. As presented in Scheme 5, the *Z* dienophile **24**, previously prepared in our laboratory (1), was first converted to its enolate anion with sodium hydride in tetrahydrofuran. The coupling reaction (15)

SCHEME 4

of this enolate with allylic chloride **18** took place at room temperature (DMF–THF) to give *E-Z-Z* triene **25**. After treatment of **25** with tetrabutylammonium fluoride in THF (12), the resulting alcohol **26** was converted to its methanesulfonate ester **27** with methanesulfonyl chloride and triethylamine. Introduction of the malonate connector to give **28***a* was accomplished according to the previously described procedures. Treatment of compound **28***a* with pyridium *p*-toluenesulfonate in methanol at 55°C (8) resulted in the formation of alcohol **28***b*, which was subsequently transformed into allylic chloride **29** by Meyers' procedure (14). Without further purification, triene allylic chloride **29** was immediately subjected to the previously described cyclization conditions. TCC macrocycle **1***d* was thus obtained as a crystalline solid in 69% overall yield from alcohol **28**. Again, the structure of macrocycle **1***d* was rigorously established by spectroscopic analysis including nmr, ir, and ms as well as X-ray crystallography (17).

Diels–Alder reaction of TCC macrocycles **1***b and* **1***d*

In the case of TCC macrocycle **1***b*, the cycloaddition reaction was carried out at 320°C in a sealed tube for 90 min, providing the crystalline *trans-syn-cis* (TSC) tricycle **30** (Scheme 6) in 87% isolated yield. The structure of **30** was rigorously established by X-ray crystallographic analysis (18).

In principle, a macrocyclic triene can yield two different diastereoisomeric products. However, and as previously discussed (7*a*), there are cases where a particular diastereoisomer cannot be formed because of conformational restrictions due to the fact that the Diels–Alder reaction must take place via a boat transition state. Such a situation occurs in the case of a TCC macrocycle, which is predicted to give exclusively a TSC tricycle since a CST tricycle cannot be

SCHEME 5

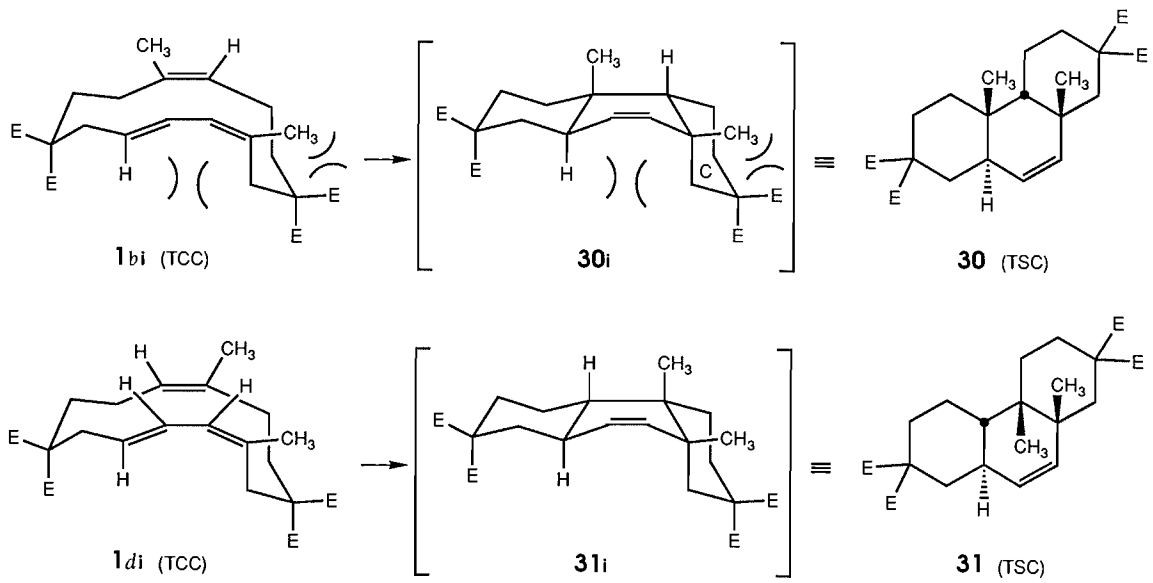
formed. The above experimental result is thus readily explained. Indeed, macrocycle **1***b* must react via conformation **1***bi* to produce the TSC tricycle **30** in the chair–boat–chair conformation **30***i*. The high temperature (320°C) required is primarily due to a steric repulsion that occurs when the *trans-cis* diene takes the *cisoid* conformation necessary for the cycloaddition as shown in **1***bi*. There is also a steric interaction between the methyl group of the diene and one of the ester functions. This is best visualized in conformation **30***i* of the Diels–Alder product where the methyl group at C7 is in a 1,3 diaxial disposition relative to the axial ester of ring C. The above result is also in complete agreement with the previously reported (7*b*) cycloaddition of a TCC macrocyclic triene having only one methyl group on the dienophile. In this case, a TSC macrocycle is again exclusively formed but a slightly lower temperature (300°C) appears to be required because there is less steric hindrance due to the absence of the methyl group on the diene moiety.

In a similar fashion, TCC macrocycle **1***d* was transformed into TSC tricycle **31** in 90% yield (Scheme 6). The stereochemistry of **31** was confirmed by X-ray diffraction analysis (19). Thus, as expected, the macrocyclic triene reacted via the *cisoid* conformation **1***di*, which gave **31** in conformation **31***i*, having steric interactions similar to those taking place during the conversion of TCC macrocycle **1***b* into TSC tricycle **30**.

Diels–Alder reaction of CTC macrocycle **1***a and TTC macrocycle* **1***c*

Upon heating at 325°C in toluene in a sealed quartz tube for 18 h, CTC macrocycle **1***a* was converted into a mixture

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.



SCHEME 6

of four tricyclic isomers **30** and **32–34** in a 7:20.6:5.9:1 ratio as determined by ^{1}H nmr spectroscopy. The first isomer **30** was shown to have the TSC tricyclic geometry by comparison with an authentic sample obtained from the Diels–Alder reaction of macrocycle **1***b*. Isomers **33** and **34** could be obtained pure by chromatography and characterized by the usual spectroscopic techniques. Isomer **33** was shown to have the CSC stereochemistry by X-ray diffraction analysis.[4] Assignment of the basic skeleton of isomer **32** could be made by ^{1}H nmr spectroscopic analysis of the mixture. Isomers **32** and **34** have been tentatively assigned the CST and TST relative stereochemistry.

We have found that when TTC macrocycle **1***c* is heated at 200°C for 4 h, it is quantitatively isomerized into CTC macrocyclic triene **1***a*, indicating that the triene having a second *cis* olefin is more stable. It was also found that upon heating at 310°C, TTC macrocycle **1***c* gave the same mixture of tricyclic isomers as that observed with **1***a*, but in a different ratio, namely, 2.3:1:29.9:5.3.

It is thus very likely that **1***a* and **1***c* are interconverted prior to the Diels–Alder reactions. Also, **1***a* and (or) **1***c* must probably undergo an isomerization into macrocycle **1***b* since we previously observed that **1***b* yields exclusively the TSC isomer **30**, which is one of the four isomers observed from **1***a* and **1***c*.

It is possible to understand why such a complex mixture was obtained and to propose pathways for the interconversion of macrocyclic trienes **1***a*, **1***b*, and **1***c*. The facile conversion of macrocyclic triene **1***a* into **1***c* can be explained by two consecutive hydrogen migrations via the intermediate formation of macrocycle **35** as shown in Scheme 7. The isomerization of macrocycle **1***a* into macrocycle **1***b* is a more complex process that can take place via four consecutive 1,5 hydrogen migrations. Macrocycle **1***a* would first be converted to TCC macrocycle **36**, which can then give CCC macrocycle **37**. Finally, CTC macrocycle **38** would be obtained from **37**, and converted into TCC macrocycle **1***b*. The isomerization of a CC diene into a CT or TC diene has previously been observed in our laboratory (*7b*).

Assuming that macrocycles **35**, **36**, and **38** do not undergo a cycloaddition because they would produce tricycles containing a seven-membered ring, the formation of the mixtures of stereoisomers **30** and **32–34** having respectively the TSC, CST, CSC, and TST stereochemistry would be the result of cycloaddition of macrocycles CTC (**1***a*), TCC (**1***b*), TTC (**1***c*), and CCC (**37**), which would be thermally interconvertible prior to the Diels–Alder reaction. These interconversions are summarized in Fig. 1.

First, CTC macrocyclic trienes are predicted (*7a*) to give only one tricyclic isomer having the *cis-syn-trans* (CST) stereochemistry. In the case of CTC macrocycle **1***a*, this means that it should react via conformation **1***ai*, which would undergo a cycloaddition to produce CST tricycle **32** in conformation **32***i* as illustrated in Scheme 8. The required *cisoid* conformation of the diene moiety is highly hindered (cf. **1***ai*), and the resulting product will have ring B in a boat form that is very severely encumbered by the presence of the methyl group at C7. In addition, this methyl group also experiences a 1,3 diaxial steric interaction with the axial ester of ring C. The energy barrier for this cycloaddition must be quite high and it is therefore not surprising that other processes can compete with the formation of this CST tricycle.

We have previously shown that TCC macrocycle **1***b* gives TSC tricycle **30** exclusively and this result has been already rationalized (Scheme 6).

TTC macrocyclic trienes are predicted (*7a*) to give the TST and the CSC tricycles. Indeed, TTC macrocycle **1***c* can either take conformation **1***ci* (Scheme 9) to produce the TST tricycle **34** (via **34***i*) or conformation **1***cii* to yield the CSC tricycle **33** (via **33***i*). Both processes are somewhat hindered, but the formation of the TST isomer should be favored since it appears to be less sterically crowded.

Finally, the cycloaddition of CCC macrocycle **37** is predicted to give the CSC tricycle **33**. This cycloaddition involves rather severe steric interactions at the transition state, resulting from a diene having a *cis-cis* configuration. In-

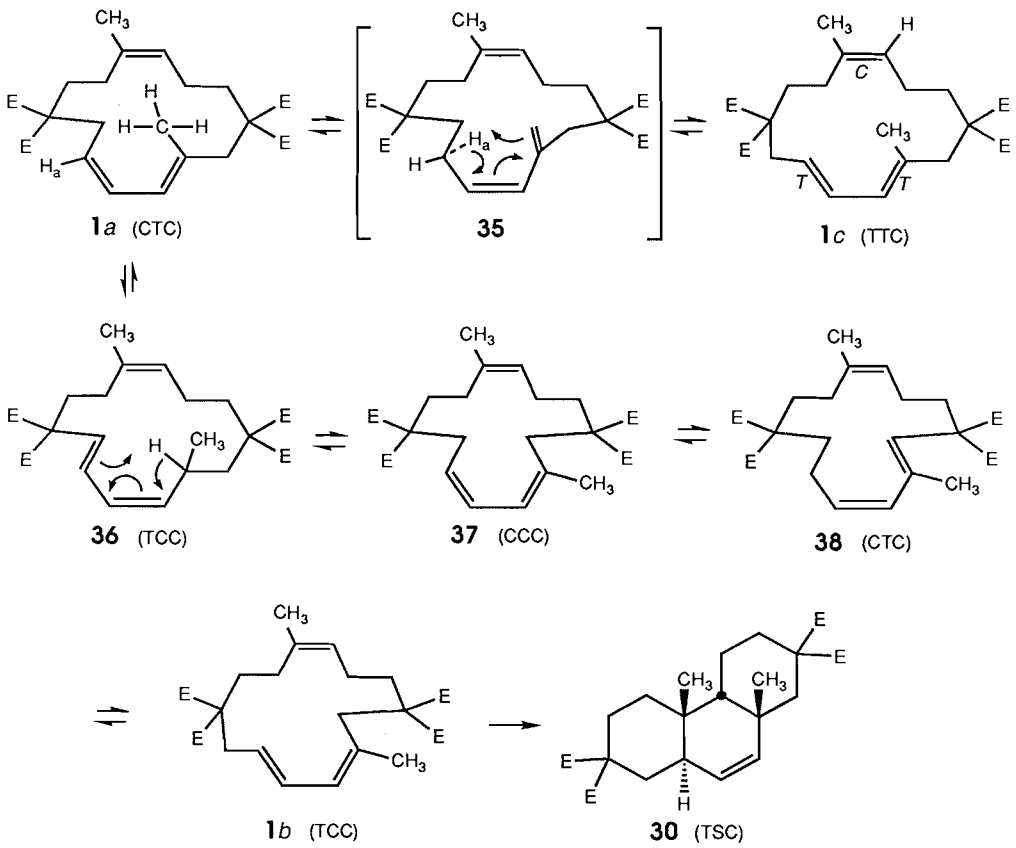

SCHEME 7

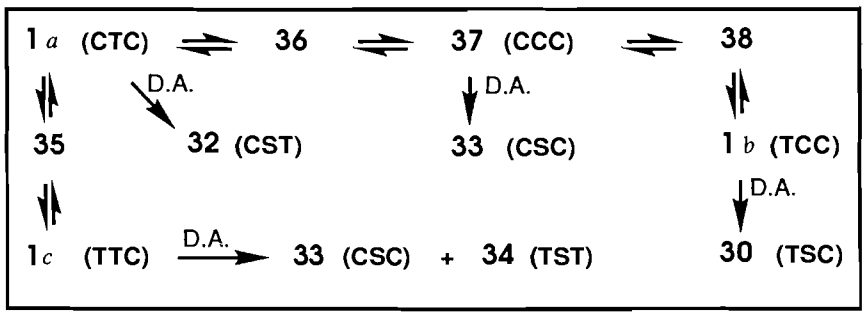

FIG. 1. Summary of possible interconversion.

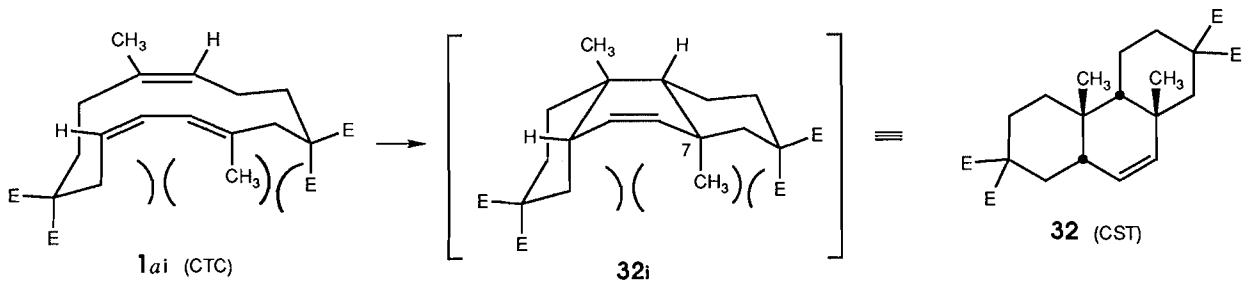
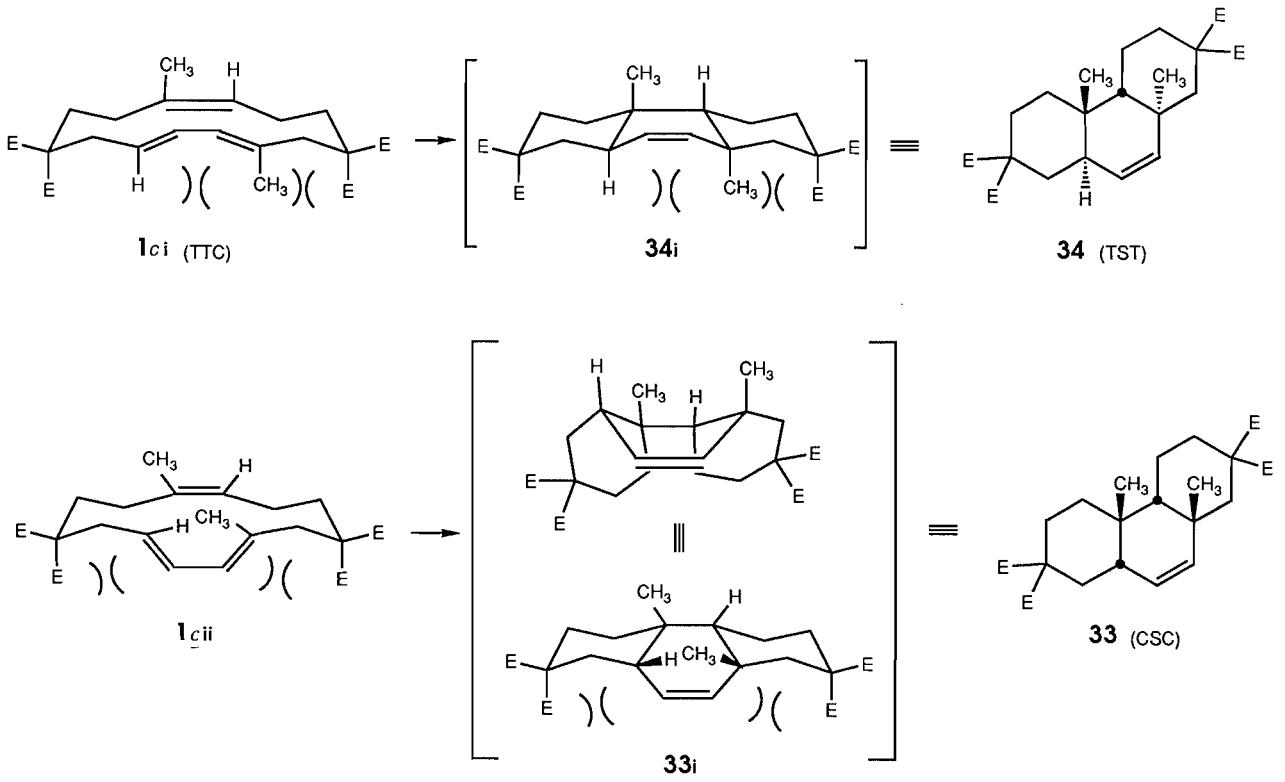


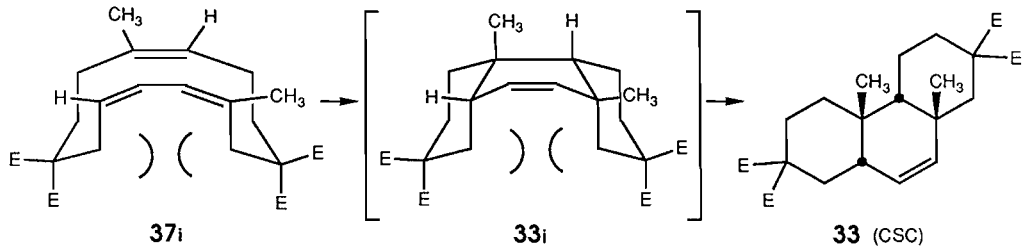
SCHEME 8

deed, CCC macrocycle **37** must react via the very crowded *cisoid* conformation **37***i* (Scheme 10) to yield tricycle **33** in the high-energy conformation **33***i*.

All the cycloadditions must take place via transition states that experience severe steric repulsions. It is therefore not surprising that the macrocycles are thermally interconverted



SCHEME 9



SCHEME 10

prior to the cycloaddition reaction. The exclusive formation of TSC tricycle **30** from TCC macrocycle **1***b* shows that its thermal isomerization to the other macrocycles is, however, higher is energy than the cycloaddition reaction to give TSC tricycle **30**. The different ratios of stereoisomers obtained from macrocycles **1***a* and **1***c* indicate that the Diels–Alder reaction can compete to some extent with the isomerization process of the macrocycles, although this process is known to take place at lower temperature. This may be because the Diels–Alder reaction is probably more favorable from an entropy point of view than the sigmatropic 1,5 hydrogen migration. Finally, an unexplained result is the large percentage of CSC tricycle **33** obtained from **1***c*. On the basis of steric effect arguments, it can be predicted that TST tricycle **34** and CSC tricycle **33** should have been the major and the minor isomer, respectively (Scheme 9). Of course, CSC tricycle **33** can also be obtained from CCC macrocycle **37**. However, on that basis CSC tricycle **33** should have been produced in large amount from CTC macrocycle **1***a*, as **1***a* is an intermediate in the interconversion of macrocycles **1***c* (TTC) and **37** (CCC).

In conclusion, four macrocyclic trienes (two TCC, one CTC, and one TTC) were successfully synthesized in good yield. The TCC macrocycles **1***b* and **1***d* gave, respectively, the TSC tricycles **30** and **31** via a transannular Diels–Alder reaction. On the other hand, the transannular Diels–Alder reaction of CTC macrocycle **1***a* and TTC macrocycle **1***c* led to a mixture of the same four tricycles (**30** (TSC), **32** (CST), **33** (CSC), and **34** (TST)) but in a different ratio. These results are explained by taking into consideration the interconversion of macrocyclic trienes **1***a* (CTC), **1***b* (TCC), **1***c* (TTC), and **37** (CCC) prior to the Diels–Alder reaction. A useful summary of the results obtained with the various dimethyl-substituted macrocyclic trienes reported in this paper and the preceding one (1) is shown in Fig. 2. This information is presently being used for the elaboration of new routes for the synthesis of various polycyclic natural products of the diterpene and triterpene family.

Experimental

2-(2-Bromoethyloxy)tetrahydropyran 3

To a stirred solution of 2-bromoethanol (19.2 g, 154 mmol) in 200 mL of CH_2Cl_2 were added at 0°C under argon pyridinium *p*-toluenesulfonate (PPTS) (387 mg, 1.5 mmol) and 3,4-dihydro-

FIG. 2. Summary of transannular Diels–Alder reactions of disubstituted macrocyclic trienes.

2*H*-pyran (21.0 mL, 230 mmol). The resulting mixture was stirred at room temperature for 2.3 h and then poured into a saturated $NaHCO_3$ solution (120 mL). The organic phase was washed with water, dried, and concentrated to a crude residue that was purified by distillation (1.4 Torr (1 Torr = 133.3 Pa), 63–64°C) to give colorless oil **3** (25.7 g, 81%); ir (neat): 2945, 2850, 1125, 1030 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.50–1.86 (m, 6H, -OCHOCH$_2$(CH_2)$_3$-), 3.48–3.54 (m, 2H, BrCH_2-), 3.48–3.57 and 3.85–3.94 (2m, 2H, -OCHOCH_2-), 3.72–3.82 and 3.97–4.06 (2dt, 2H, J = 11.2 Hz, 6.2 Hz, -CH_2OTHP), 4.68 (t, 1H, J = 3.3 Hz, -OC*H*O).

2-Triphenylphosphonium bromide ***4***

To a stirred solution of (ethyl)triphenylphosphonium bromide (32.3 g, 87 mmol) in 200 mL of THF was added dropwise, at 0°C under argon, potassium hexamethyldisilazane (0.5 M in toluene, 174 mL, 87 mmol). The resulting suspension was stirred at 0°C for 0.5 h and then a solution of compound **3** (25.8 g, 125 mmol) in 70 mL of THF was introduced dropwise over 20 min. The orange mixture was warmed to room temperature and then stirred for 50 h. The resulting thick, pink mixture was filtered through a Buchner funnel and the solid was washed several times with THF. The filtrate collection flask was changed and the solid was washed with CH_2Cl_2 until only solid, grey, KBr remained in the funnel. The CH_2Cl_2 filtrate was concentrated to an off-white crude salt (40.8 g) that was recrystallized from CH_2Cl_2 and hexane to give pure compound **4** (38.0 g, 88%) as clear crystals; ir ($CHCl_3$): 3060–3010, 2950–2860, 1442, 1115, 1038 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.44 (dd, 3H, J = 19.8 Hz, 7.1 Hz, -CH(CH_3)-), 1.32–1.64 (m, 6H, -OCH$_2$(CH_2)$_3$-), 1.70–1.87 and 2.20–2.30 (2m, 2H, -CHCH_2-CH$_2$OTHP), 3.45–3.54 and 3.79–3.85 (2m, 2H, -CHOCH_2-), 3.88–4.17 (m, 2H, -CH_2OTHP), 4.57–4.59 and 4.62–4.64 (2m, 1H, -OC*H*O-), 4.87–5.08 and 5.13–5.28 (2m, 1H, -C*H*PCH$_2$-), 7.62–8.01 (m, 15H, P*Ph*$_3$).

*3-*tert*-Butyldiphenylsilyloxy 1-propanol* ***5***

To a stirred solution of 1,3-propanediol (20.0 g, 263 mmol) and imidazole (3.58 g, 52.6 mmol) in 180 mL of THF was added at room temperature under argon *tert*-butylchlorodiphenylsilane (13.7 mL, 52.6 mmol). After the mixture was stirred for 25 h, 100 mL of water was introduced. The aqueous layer was extracted with hexane (5 × 100 mL) and the combined organic layers were washed with H_2O, dried over $MgSO_4$, filtered, and concentrated to a crude brown residue that was purified by flash chromatography (hexane – ethyl acetate, 9:1) to afford **5** (15.86 g, 96%) as a colorless oil; ir ($CHCl_3$): 3620–3510, 3080–3020, 2960–2860, 1430, 1115, 1068 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.05 (9H, s, -(CH_3)$_3$CSi-), 1.52–1.98 (m, 2H, -CH_2CH$_2$OH), 2.35 (t, 1H, J = 5.4 Hz, -CH$_2$O*H*), 3.86 (q, 2H, J = 5.7 Hz, -CH_2OH), 3.88 (t, 2H, J = 5.7 Hz, -CH_2OSi-), 7.46–7.66 (m, 10H, *Ph*$_2$Si-).

Aldehyde ***6***

To a stirred solution of oxalyl chloride (4.8 mL, 55.3 mmol) in 115 mL of CH_2Cl_2 was added dropwise, at −78°C under argon over a period of 20 min, a solution of DMSO (7.9 mL, 110.6 mmol) in 25 mL of CH_2Cl_2. The stirring was continued for 20 min before adding a solution of alcohol **5** (15.8 g, 50.3 mmol) in 50 mL of CH_2Cl_2 over 25 min. After the mixture was stirred at −78°C for 45 min, triethylamine (35 mL) was introduced. The reaction mixture was warmed to room temperature for 1 h, followed by addition of 100 mL of water. The aqueous layer was extracted with CH_2Cl_2 (3 × 100 mL) and the combined organic phases were washed with water and brine, dried over $MgSO_4$, filtered, and concentrated to a yellow residue that was purified by flash chromatography (hexane – ethyl acetate, 9:1) to give aldehyde **6** (13.6 g, 86%); ir ($CHCl_3$): 3080–3010, 2960–2860, 2740, 1728, 1430, 1115 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.05 (s, 9H, -(CH_3)$_3$CSi-), 2.61 (dt, 2H, J = 5.6 Hz, 2.8 Hz, -CH_2CHO), 4.03 (t, 2H, J = 6.1 Hz, -CH_2OSi-), 7.35–7.81 (m, 10H, *Ph*$_2$Si-), 9.83 (t, 1H, J = 2.4 Hz, -C*H*O); ms m/e: 255 ($M^+ - C_4H_9$).

3-Hexene diether ***7***

To a stirred solution of phosphonium bromide **4** (25.9 g, 51.9 mmol) in 200 mL of THF, butyllithium (1.6 M in hexane, 29.7 mL, 47.6 mmol) was added dropwise at 0°C under argon. After the mixture was stirred for 40 min, a solution of aldehyde **6** (13.5 g, 43.3 mmol) in 70 mL of THF was introduced dropwise over 35 min. The stirring was continued at 0°C for 3 h, followed

by addition of a mixture (petroleum ether – hexane, 1:1). After the mixture was filtered through a Celite plug on a fritted-disk funnel, the filtrate was concentrated to a crude yellow oil (15.2 g). The solid remaining in the funnel was dissolved in H_2O, which was then extracted with ether (5 × 100 mL). The combined organic phases were dried, filtered, and concentrated to a crude residue (5.0 g) that was combined with the original crude material. Purification by flash chromatography (hexane – ethyl acetate, 96:4) gave pure product **7** (12.0 g, 61%) as a colorless oil. The following spectral data were obtained from a mixture of *Z*- and *E*-**7**; ir (neat): 3075, 2940, 2860, 1430, 1115, 1036 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.04 (s, 9H, -(CH_3)$_3$C), 1.59 (s, 3H, -CH=C(CH_3)-, *E*), 1.71 (d, 3H, *J* = 1.3 Hz, -CH=C(CH_3)-, *Z*), 1.30–1.89 (m, 6H, -OCH$_2$(CH_2)$_3$-), 2.20–2.35 (m, 4H, CH_2CH=C(CH_3)CH_2-), 3.62 and 3.63 (2t, 2H, *J* = 7.1 Hz, -CH_2OSi-), 3.32–3.52 and 3.71–3.88 (2m, 4H, -OCH_2-CH$_2$-, -CH_2OTHP), 4.54–4.58 (m, 1H, -OC*H*O-), 5.12–5.24 (m, 1H, -C*H*=C(CH_3)-), 7.33–7.49 and 7.62–7.70 (2m, 10H, Ph_2Si-). The ratio for *Z* and *E* isomers is approximately 43:57 as determined by ^1H nmr.

Alcohols ***8***a *and* ***8***b

General procedure A

To a stirred solution of *Z*- and *E*-**7** (8.0 g, 17.7 mmol) in 370 mL of isopropanol was added under argon pyridinium *p*-toluenesulfonate (0.89 g, 3.2 mmol) and the resulting mixture was heated to 80°C for 4 h. The reaction was stopped by addition of H_2O (200 mL) and ether (300 mL). The aqueous phase was extracted with ether (2 × 100 mL). The combined organic phases were dried, filtered, and concentrated to a crude oil (6.7 g). Initial attempts to separate the isomers by flash chromatography met with only limited success. Considerably better separation was obtained by the use of medium-pressure chromatography under a pressure of 30 psi (1 psi = 6.9 kPa) with a 85:15 mixture of hexane and ethyl acetate as eluant. Purification of 1 g crude oil gave rise to *Z* isomer **8***a* (355 mg) and *E* isomer **8***b* (522 mg) along with a mixture of **8***a* and **8***b* (80 mg). Based on this set of data, the yield for this reaction is 98%.

Spectral data for ***8***a: ir ($CHCl_3$): 3618, 3460, 3075–3055, 2960–2860, 1430, 1385, 1110, 1055 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.04 (s, 9H, -(CH_3)$_3$C), 1.72 (d, 3H, *J* = 1.3 Hz, -CH=C(CH_3)-), 2.26 (t, 2H, *J* = 6.4 Hz, -CH=C(CH_3)CH_2-), 2.32 (qd, 2H, *J* = 6.8 Hz, 0.7 Hz, SiOCH$_2$CH_2-), 3.62 (t, 2H, *J* = 6.4 Hz, -CH_2OH), 3.64 (t, 2H, *J* = 6.7 Hz, -SiOCH_2-), 5.31 (t, 1H, *J* = 7.0 Hz, -C*H*=C(CH_3)-), 7.34–7.47 and 7.64–7.73 (2m, 10H, Ph_2Si-).

Spectral data for ***8***b: ir (neat): 3360, 3070–3045, 2925–2858, 1430, 1385, 1110, 1050 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.04 (s, 9H, -(CH_3)$_3$C), 1.45 (s, 1H, -CH$_2$O*H*), 1.59 (m, 3H, -CH=C(CH_3)-), 2.24 (t, 2H, *J* = 6.6 Hz, -CH=C(CH_3)CH_2-), 2.29 (q, 2H, *J* = 6.9 Hz, -SiOCH$_2$CH_2-), 3.64 (t, 2H, *J* = 6.2 Hz, -CH_2OH), 3.65 (t, 2H, *J* = 6.8 Hz, -SiOCH_2-), 5.25 (td, 1H, *J* = 7.3 Hz, 1.3 Hz, -C*H*=C(CH_3)-), 7.27–7.46 and 7.63–7.70 (2m, 10H, Ph_2Si-); ms *m/e*: 311 ($M^+ - C_4H_9$).

Mesylates ***9***a *and* ***9***b

General procedure B

To a stirred solution of alcohol **8***a* (130 mg, 0.35 mmol) and triethylamine (180 g, 1.75 mmol) in 8 mL of CH_2Cl_2, methanesulfonyl chloride (50 mg, 0.42 mmol) was added dropwise at 0°C under argon. The stirring was continued at 0°C for 1 h before the mixture was poured into H_2O (40 mL). The aqueous phase was extracted with CH_2Cl_2 (4 × 10 mL) and the combined organic phases were washed with H_2O, dried over $MgSO_4$, filtered, and concentrated to a crude residue that was purified by flash chromatography (hexane – ethyl acetate, 9:1) to furnish mesylate **9***a* (145 mg, 93%) as a clear oil; ^1H nmr ($CDCl_3$) δ: 1.04 (s, 9H, -(CH_3)$_3$C), 1.73 (m, 3H, -CH=C(CH_3)-), 2.26 (m, 2H, -CH_2CH=), 2.42 (t, 2H, *J* = 7.2 Hz, =C(CH_3)CH_2-), 2.91 (s, 3H, -SO_2CH_3), 3.64 (t, 2H, *J* = 6.8 Hz, -SiOCH_2-), 4.18 (t, 2H, *J* = 7.0 Hz, -CH_2OSO_2-), 5.32 (m, 1H, -C*H*=C-), 7.34–7.44 and 7.65–7.68 (m, 10H, Ph_2Si-).

The mesylation for alcohol **8***b* was carried out exactly as described above. Thus, treatment of alcohol **8***b* (580 mg, 1.6 mmol) with triethylamine (0.33 mL, 1.9 mmol) and methanesulfonyl chloride (0.15 mL, 1.9 mmol) in 20 mL of CH_2Cl_2 yielded *Z*-mesylate **9***b* (685 mg, 97%); ir (neat); 3070–3018, 2930, 2860, 1430, 1380, 1358, 1175, 1110 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.06 (s, 9H, -(CH_3)$_3$C), 1.63 (m, 3H, -CH=C(CH_3)-), 2.25–2.51 (m, 4H, -CH_2CH=C(CH_3)CH_2-), 2.95 (s, 3H, -SO_2CH_3), 3.67 (t, 2H, *J* = 6.7 Hz, -SiOCH_2-), 4.26 (t, 2H, *J* = 7.1 Hz, -CH_2OSO_2-), 5.28 (m, 1H, -C*H*=C(CH_3)-), 7.28–7.85 (m, 10H, Ph_2Si-); ms *m/e*: 389 ($M^+ - C_4H_9$).

Dimethyl malonates ***10***a *and* ***10***b

General procedure C

To a stirred suspension of NaH (130 mg, 5.4 mmol) in a mixture of DMF and THF (1:1, 40 mL) was added dropwise, over 20 mins at 0°C under argon, dimethyl malonate (800 mg, 6.0 mmol). The stirring was continued at 0°C for 1 h before adding a solution of mesylate **9***a* (540 mg, 1.2 mmol) in 2 mL of THF and KI (20 mg, 0.12 mmol). The resulting mixture was heated at 70°C for 36 h, then poured into 200 mL of water. The aqueous phase was extracted with hexane–ether (1:1, 3 × 200 mL), and the combined organic phases were washed with H_2O, dried over $MgSO_4$, filtered, and concentrated to a crude residue that was purified by flash chromatography (hexane – ethyl acetate, 9:1) to give **10***b* (509 mg, 88%) as a colorless oil; ^1H nmr ($CDCl_3$) δ: 1.04 (s, 9H, -(CH_3)$_3$C), 1.67 (m, 3H, -CH=C(CH_3)-), 1.92–2.04 (m, 4H, -CH=(CH_3)CH_2CH_2-), 2.18–2.28 (m, 2H, -SiOCH$_2$CH_2-), 3.32 (t, 1H, *J* = 7.0 Hz, -C*H*(CO_2CH_3)$_2$), 3.62 (t, 2H, *J* = 6.9 Hz, -SiOCH_2-), 3.73 (s, 6H, 2 × -OCH_3), 5.19 (m, 1H, -C*H*=C-), 7.34–7.43 and 7.65–7.69 (2m, 10H, Ph_2Si-).

The preparation of **10***b* was carried out in the same way as described above. Thus, treatment of dimethyl malonate (0.865 mL, 7.6 mmol) with NaH (272 mg, 60%, 6.8 mmol) in THF–DMF mixture (1:1), followed by addition of mesylate **9***b* (675 mg, 1.5 mmol) in 2 mL of THF, afforded product **10***b* (631 mg, 87%) as a colorless oil; ir (neat): 3070–3000, 2950, 2860, 1738, 1430, 1385, 1230, 1155, 1115 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.05 (s, 9H, -(CH_3)$_3$C), 1.57 (s, 3H, -CH=C(CH_3)-), 1.99–2.03 (m, 4H, -CH=C(CH_3)CH_2CH_2-), 2.27 (q, 2H, *J* = 6.8 Hz, -SiOCH$_2$CH_2-), 3.36 (m, 1H, -C*H*(CO_2CH_3)$_2$), 3.64 (t, 2H, *J* = 6.6 Hz, -SiOCH_2-), 3.72 and 3.73 (2s, 6H, 2× -OCH_3), 5.17 (m, 1H, -C*H*=C-), 7.35–7.78 (2m, 10H, Ph_2Si-); ms *m/e*: 425 ($M^+ - C_4H_9$).

Alcohols ***11***a *and* ***11***b

General procedure D

To a stirred solution of silyl ether **10***a* (316 mg, 0.655 mmol) in 6 mL of THF, tetrabutylammonium fluoride (1.0 M in THF, 1.2 mL, 1.2 mmol) was added at 0°C under argon. The mixture was warmed to room temperature and stirred for 2.5 h. The solvent was removed by evaporation and the oily residue was purified by flash chromatography (hexane – ethyl acetate, 7:3) to give alcohol **11***a* (119 mg, 74%) as a viscous oil; ir (neat): 3420, 2955, 2870, 1738, 1438, 1230, 1155, 1050 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.71 (d, 3H, -CH=C(CH_3)-), 1.95–2.12 (m, 4H, =C(CH_3)CH_2CH_2-), 2.22 (qd, 2H, *J* = 6.7 Hz, 1.0 Hz, HOCH$_2$CH_2-), 3.35 (t, 1H, *J* = 7.0 Hz, -C*H*(CO_2CH_3)$_2$), 2.61 (t, 2H, *J* = 6.4 Hz, HOCH_2-), 3.74 (s, 6H, 2× -OCH_3), 5.20 (td, 1H, *J* = 6.8 Hz, 1.1 Hz, -C*H*=C-); ms *m/e*: 244 ($M^+ - H_2O$).

The desilylation of **10***b* was carried out in the same way as described above. Thus, treatment of silyl ether **10***b* (603 mg, 1.3 mmol) with tetrabutylammonium fluoride (1.0 M in THF, 1.4 mL, 1.4 mmol) in THF yielded alcohol **11***b* (277 mg, 91%) as a colorless oil that has spectral data identical with the same compound reported in the preceding article.

Mesylates ***12***a *and* ***12***b

The mesylation of **12***a* was carried out in the same way as described in the general procedure B. Thus, treatment of alcohol **11***a*

(100 mg, 0.41 mmol) with triethylamine (86.1 μL, 0.45 mmol) and methanesulfonyl chloride (35 μL, 0.45 mmol) at 0°C in CH_2Cl_2 yielded mesylate **12***a* (110 mg, 83%) as a colorless oil; ir (neat): 2960, 2866, 1732, 1435, 1355, 1225, 1172 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.72 (d, 3H, J = 1.2 Hz, -CH=C(CH_3)-), 1.93–2.11 (m, 4H, -CH=C(CH_3)CH_2CH_2-), 2.42 (q, 2H, J = 7.0 Hz, $MsOCH_2$-CH_2-), 3.01 (s, 3H, $-SO_2CH_3$), 3.33 (t, 1H, -$CH(CO_2CH_3)_2$), 3.74 (s, 6H, 2× -OCH_3), 4.17 (t, 2H, J = 6.9 Hz, -CH_2OMs), 5.17 (t, 1H, J = 7.5 Hz, -CH=C-); ms m/e: 322 (M^+), 290 (M^+ – CH_3OH).

The preparation of **12***b* from **11***b* was reported in the preceding article: the same reaction procedure as described in the general procedure B was used.

(Z,E)-Diene diether ***14***

To a solution of alcohol **13** (619.2 mg, 2.9 mmol) and imidazole (453.0 mg, 6.7 mmol) in 18 mL of THF, *tert*-butylchlorodiphenylsilane (0.89 mL, 3.4 mmol) was added at 0°C under argon. The mixture was stirred for 1 h before a saturated ammonium chloride solution (25 mL) was added. The aqueous layer was extracted with a mixture of hexane and ether (2:1, 3 × 25 mL). The combined organic layers were washed with water, dried over $MgSO_4$, filtered, and concentrated to a crude residue that was purified by flash chromatography (hexane – ethyl acetate, 98:2) to give **14** (1298.7 mg, 2.88 mmol, 99%). The clear oil was used immediately for the next reaction without characterization.

Diene alcohol ***15***

The hydrolysis of the THP ether was carried out in a similar fashion as described in the general procedure A. Thus, treatment of THP ether **14** (1298.7 mg, 2.88 mmol) with pyridinium *p*-toluenesulfonate (131.0 mg) in 35 mL of isopropanol afforded alcohol **15** (911.6 mg, 2.49 mmol, 86%) as a colorless oil; ir (neat): 3340, 3040, 2950, 2860, 1450, 1375, 1110 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.08 (s, 9H, -(CH_3)$_3$C), 1.26 (t, 1H, J = 5.7 Hz, -CH_2OH), 1.70 (s, 3H, -CH_3), 4.13 (s, 2H, -CH_2OSi-), 4.34 (t, 2H, J = 6.2 Hz, -CH_2OH), 5.62 (dt, 1H, J = 10.3 Hz, 6.9 Hz, $HOCH_2CH$=CH-), 6.30–6.51 (m, 2H, $HOCH_2CH$=CHCH=C-), 7.35–7.48 and 7.65–7.73 (2m, 10H, Ph_2Si-).

Allylic chloride ***16***a

General procedure E

To a round-bottom flask containing flame-dried LiCl (69.6 mg, 1.64 mmol) was introduced, under argon, a solution of alcohol **15** (150.2 mg, 0.41 mmol) in 2.5 mL of DMF and *s*-collidine (0.11 mL, 99.9 mg, 0.82 mmol). The solution was then cooled to 0°C before methanesulfonyl chloride (63μL, 93.2 mg, 0.81 mmol) was added dropwise over 10 min. The resulting mixture was stirred at 0°C for 1 h and at 25°C for an additional hour. The reaction was stopped by adding 15 mL of ice water. The aqueous phase was extracted with ether (5 × 10 mL) and the combined organic phases were washed with cold, saturated, copper nitrate solution, and then with water. After drying over $MgSO_4$, the mixture was filtered through a short-path column containing silica gel and Celite. The filtrate was evaporated to a crude oil, **16***a* (155.7 mg, 0.40 mmol, 99%), which was used immediately for the next coupling reaction without further purification and characterization.

Allylic chloride ***18***

The preparation of allylic chloride **18** was accomplished in a similar fashion as described in the general procedure E. Thus, treatment of allylic alcohol **17** (2.2 g, 10.4 mmol) with LiCl (1.32 g, 31.2 mmol), *s*-collidine (2.1 mL, 15.6 mmol), and methanesulfonyl chloride (1.2 mL, 15.6 mmol) in DMF (37 mL) at 0°C yielded **18** (2.4 g) as a crude oil that was used immediately in the coupling reaction without further purification and characterization.

Mesylate triene ***19***a

General procedure F

To a stirred suspension of NaH (12.3 mg, 60%, 0.31 mmol) in 2 mL of THF was added at 0°C under argon a solution of dimethyl malonate **12***a* (90.1 mg, 0.28 mmol) in 2 mL of THF. The mixture was stirred at 0°C for 45 min, at room temperature for 30 min, and then cooled to 0°C. A solution of the crude allylic chloride **16***a* (155.7 mg, 1.40 mmol) in 4 mL of DMF was introduced dropwise by syringe. The stirring was continued at 0°C for 2 h and then at room temperature for 15 h. The mixture was poured into a saturated ammonium chloride solution (15 mL). The aqueous layer was extracted with ether–hexane (2:1, 4 × 10 mL). The combined organic phases were washed with H_2O, $NaHCO_3$ solution (5%), and brine and dried over $MgSO_4$. After removal of the solvents, the residue was purified by flash chromatography (hexane – ethyl acetate, 85:15) to give triene **19***a* (127.1 mg, 0.19 mmol, 68%) along with recovered starting material (12.6 mg, 14%); ir (neat): 3060–3020, 2950, 2855, 1732, 1430, 1360, 1175, 1110 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.08 (s, 9H, -(CH_3)$_3$C), 1.68 (s, 3H, -CH_2C(CH_3)=$CHCH_2$-), 1.65–1.75 (m, 4H, -CH_2CH_2C-(CH_3)=CH-), 1.90 (s, 3H, -CH-CHCH=C(CH_3)-), 2.36 (q, 2H, J = 7.2 Hz, -$CH_2CH_2OSO_2$-), 2.85 (d, 2H, J = 8.1 Hz, -CH_2CH=CHCH=C-), 2.97 (s, 3H, $-SO_2CH_3$), 3.71 (s, 6H, 2× -OCH_3), 4.13 (s, 2H, -CH_2OSi-), 4.14 (t, 2H, J = 7.0 Hz, -CH_2SO_2-), 5.10 (t, 1H, J = 7.0 Hz, -CH_2C(CH_3)=$CHCH_2$-), 5.24 (dt, 1H, J = 11.0 Hz, 6.0 Hz, -CH=CHCH=C-), 6.38 (t, 1H, J = 11.2 Hz, -CH=CHCH=C-), 6.52 (d, 1H, J = 11.3 Hz, -CH=CHCH=C-), 7.35–7.45 and 7.65–7.71 (2m, 10H, Ph_2Si-); ms m/e: 670 (M^+), 613 (M^+ – C_4H_9).

Mesylate triene ***19***b

A similar procedure as that described above was employed. Thus, treatment of **12***a* (110 mg, 0.34 mmol) with NaH (15 mg, 60%, 0.63 mmol), followed by allylic chloride **16***b* (162 mg, 0.42 mmol) in a mixture of THF and DMF, afforded triene **19***b* (175 mg, 77%) as a colorless oil; ir (neat): 3070–3020, 2950, 2860, 1730, 1428, 1357, 1174, 1110 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.04 (s, 9H, -(CH_3)$_3$C), 1.64 (d, 3H, J = 1.2 Hz, -CH_2CH_2C(CH_3)=), 1.84–1.86 (m, 7H, -CH_2CH_2- and -CH=CHCH=C(CH_3)-), 2.35 (q, 2H, J = 6.3 Hz, -CH_2CH_2OMs), 2.60 (d, 2H, J = 7.6 Hz, -CH_2CH=CHCH=C-), 2.97 (s, 3H, $-SO_2CH_3$), 3.68 (s, 6H, 2 × -OCH_3), 4.12 (t, 2H, J = 6.8 Hz, -CH_2OMs), 4.25 (s, 2H, -CH_2OSi-), 5.08 (t, 1H, J = 7.4 Hz, -CH_2CH_2CH=), 5.32 (dt, 1H, J = 14.8 Hz, 7.4 Hz, -CH=CHCH=C-), 5.80 (d, 1H, J = 11.0 Hz, -CH=CHCH=C-), 6.08 (dd, 1H, J = 14.8 Hz, 11.0 Hz, -CH=CHCH=C-), 7.35–7.44 and 7.65–7.70 (m, 10H, Ph_2Si-); ms m/e: 670 (M^+), 613 (M^+ – C_4H_9).

Mesylate triene ***19***c

The general procedure F described above was employed. Thus, treatment of **12***a* (380.1 mg, 1.18 mmol) with NaH (52.4 mg, 60%, 1.31 mmol), followed by crude allylic chloride **16***c* (589.9 mg, 1.53 mmol) in a mixture of THF and DMF, furnished triene **19***c* (461.9 mg, 0.69 mmol, 59%) along with recovered starting material (121.3 mg, 32%); ir (neat): 3070–3020, 2950, 2858, 1735, 1440, 1360, 1265, 1170, 1110 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.06 (s, 9H, -(CH_3)$_3$C), 1.70, (s, 3H, -CH_2CH=C(CH_3)CH_2-), 1.71 (s, 3H, -CH=CHCH=C(CH_3)-), 1.90–1.94 (m, 4H, =C(CH_3)CH_2CH_2-), 2.40 (q, 2H, J = 7.0 Hz, -CH_2CH_2OMs), 2.75 (d, 2H, J = 7.5 Hz, -CH_2CH=CHCH=C), 2.98 (s, 3H, $-SO_2CH_3$), 3.74 (s, 6H, 2× -OCH_3), 4.07 (s, 2H, -CH_2OSi-), 4.16 (t, 2H, J = 6.8 Hz, -CH_2OMs), 5.12 (t, 1H, J = 6.7 Hz, -CH_2CH_2CH=), 5.43 (dt, 1H, J = 14.9 Hz, 7.4 Hz, -CH=CHCH=C-), 6.08 (d, 1H, J = 10.0 Hz, -CH=CHCH=C-), 6.36 (dd, 1H, J = 15.0 Hz, 11.0 Hz, -CH=CHCH=C-), 7.35–7.44 and 7.65–7.70 (m, 10H, Ph_2Si-); ms m/e: 670 (M^+), 639 (M^+ – OCH_3), 613 (M^+ – C_4H_9).

Dimethyl malonate triene ***20***a

The general procedure C described before was employed. Thus, treatment of dimethyl malonate (0.11 mL, 127.1 mg, 0.96 mmol) with NaH (33.6 mg, 60%, 0.84 mmol), followed by mesylate triene **19***a* (125.2 mg, 0.19 mmol) and KI (3.1 mg, 19 μmol) in a mixture of THF and DMF (1:1, 8 mL), at 80°C for 20 h yielded dimethyl malonate triene **20***a* (121.0 mg, 0.17 mmol, 90%) as a

viscous oil, which was used for the following reaction without characterization.

Dimethyl malonate triene ***20***b

The general procedure C described before was employed. Thus, treatment of dimethyl malonate (0.145 mL, 1.3 mmol) with NaH (45 mg, 60%, 1.1 mmol), followed by mesylate triene **19***b* (170 mg, 0.253 mmol) and KI (4.2 mg, 25 μmol) in a mixture of THF and DMF (8 mL), at 85°C for 16 h yielded **20***b* (136 mg, 76%) as a viscous oil; ir (neat): 3070–3000, 2950, 2855, 1735, 1435, 1200, 1110 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.04 (s, 9H, -(CH_3)$_3$C), 1.60 (s, 3H, -$CH_2CH_2C(CH_3)$=), 1.80 (s, 4H, -CH_2CH_2-CR(CO_2CH_3)$_2$), 1.85 (s, 3H, =CHCH=C(CH_3)-), 1.92 (m, 4H, -CH_2CH_2CH-(CO_2CH_3)$_2$), 2.58 (d, 2H, J = 7.5 Hz, =CHCH_2CR(CO_2CH_3)$_2$), 3.33 (t, 1H, J = 7.1 Hz, -CH(CO_2CH_3)$_2$), 3.67, 3.71 (2s, 12H, 4 × -OCH_3), 4.25 (s, 2H, -CH_2OSi-), 5.04 (t, 1H, J = 7.0 Hz, -CH_2CH_2CH=), 5.33 (dt, 1H, J = 14.9 Hz, 7.6 Hz, -CH_2CH=CH-), 5.80 (d, 1H, J = 11.2 Hz, =CHCH=C(CH_3)-), 6.07 (dd, 1H, J = 14.7 Hz, 11.0 Hz, -CH_2CH=CH-), 7.34–7.47 and 7.64–7.70 (2m, 10H, *Ph*Si-); ms *m/e*: 706 (M^+), 675 ($M^+ - OCH_3$), 649 ($M^+ - C_4H_9$).

Dimethyl malonate triene ***20***c

The general procedure **20***c* described before was employed. Thus, treatment of dimethyl malonate (0.231 mL, 2.02 mmol) with NaH (71.8 mg, 60%, 1.80 mmol), followed by mesylate triene **19***c* (267.3 mg, 0.40 mmol) and KI (6.6 mg, 0.04 mmol) in a mixture of THF and DMF (1:1, 18 mL), at 85°C for 15 h yielded **20***c* (256.2 mg, 0.36 mmol, 91%) as a viscous oil; ir (neat): 3070–3000, 2950, 2855, 1740, 1435, 1340, 1200, 1110 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.06 (s, 9H, -(CH_3)$_3$C), 1.68 (br, s, 7H, -CH_2CH=C(CH_3)-CH_2CH_2-), 1.87 (s, 3H, =CHCH=C(CH_3)-), 1.88–2.01 (m, 4H, -CH_2CH_2CH=), 2.73 (d, 2H, J = 7.5 Hz, -CH=CHCH_2-), 3.35 (t, 1H, J = 7.2 Hz, -CH(CO_2CH_3)$_2$), 3.72 and 3.74 (2s, 12H, 4 × -OCH_3), 4.07 (s, 2H, -CH_2OSi-), 5.07 (t, 1H, J = 6.8 Hz, -$CH_2C(CH_3)$=$CH$$CH_2$-), 5.43 (dt, 1H, J = 14.7 Hz, 7.1 Hz, -CH=CHCH=C-), 6.07 (d, 1H, J = 11.0 Hz, -CH=CHCH=C-), 6.35 (dd, 1H, J = 14.6 Hz, 10.8 Hz, -CH=CHCH=C-), 7.34–7.47 and 7.64–7.70 (2m, 10H, Ph_2Si-); ms *m/e*: 706 (M^+), 675 ($M^+ - OCH_3$), 649 ($M^+ - C_4H_9$).

Allylic alcohol ***21***a

The general procedure D described before was employed. Thus, treatment of silyl ether **20***a* (121.0 mg, 0.17 mmol) with nBu$_4$NF (1 M in THF, 0.37 mL, 0.37 mmol) in 3 mL of THF at room temperature for 5 h yielded allylic alcohol **21***a* (70.6 mg, 0.15 mmol, 88%) as a viscous oil; ir (neat): 3530, 3020, 1950, 1860, 1735, 1438, 1200, 1100 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.65 (s, 3H, -(CH_3)C=CH-), 1.76 (s, 3H, -CH=CHCH=C(CH_3)-), 1.78–2.02 (m, 9H, -$CH_2CH_2C(CH_3)$=$CHCH_2CH_2$- and -CH_2OH), 2.84 (d, 2H, J = 7.5 Hz, -CH_2CH=CHCH=), 3.34 (t, 1H, J = 7.2 Hz, -CH(CO_2CH_3)$_2$), 3.72 and 3.73 (2s, 12H, 4 × -OCH_3), 4.10 (d, 2H, J = 5.6 Hz, -CH_2OH), 5.06 (t, 1H, J = 6.0 Hz, -$CH_2C(CH_3)$=$CH$$CH_2$-), 5.21–5.34 (m, 1H, -$CH$=CHCH=), 6.28–6.39 (m, 2H, -CH=$CHCH$=); ms *m/e*: 468 (M^+), 466 ($M^+ - H_2$), 450 ($M^+ - H_2O$). Exact Mass ($M^+ - H_2$) calcd.: 466.2203; found: 466.2195.

Allylic alcohol ***21***b

The general procedure D described before was employed. Thus, treatment of silyl ether **20***b* (112 mg, 0.159 mmol) with nBu$_4$NF (1.0 M in THF, 0.286 mL, 0.286 mmol) in 2 mL of THF at room temperature for 2.5 h yielded allylic alcohol **21***b* (45 mg, 60%) as a colorless oil; ir (neat): 3500, 2950, 2860, 1735, 1435, 1200 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.65 (d, 3H, J = 1.0 Hz, -$CH_2C(CH_3)$=$CHCH_2$-), 1.85 (br s, 7H, -CH_2CH_2CR(CO_2CH_3)$_2$ and =CHCH=C(CH_3)-), 1.89–2.00 (m, 4H, -CH_2CH_2CH-(CO_2CH_3)$_2$), 2.70 (d, 2H, J = 7.5 Hz, =CHCH_2CR(CO_2CH_3)$_2$), 3.35 (t, 1H, J = 7.2 Hz, -CH(CO_2CH_3)$_2$), 3.73 (s, 12H, 4 × -OCH_3), 4.22 (s, 2H, -CH_2OH), 5.06 (t, 1H, J = 6.0 Hz, -CH_2CH_2CH=), 5.41 (dt, 1H, J = 14.9 Hz, 7.5 Hz, -CH_2-CH=CH-), 5.89 (d, 1H, J = 10.9 Hz, -CH=CHCH=C-), 6.40 (dd, 1H, J = 14.9 Hz, 11.1 Hz, -CH=CHCH=C-); ms *m/e*: 450 ($M^+ - H_2O$).

Allylic alcohol ***21***c

The general procedure D described before was employed. Thus, treatment of silyl ether **20***c* (406.1 mg, 0.57 mmol) with nBu$_4$NF (1.0 M in THF, 1.15 mL, 1.15 mmol) in 8 mL of THF at room temperature for 2 h yielded allylic alcohol **21***c* (241.1 mg, 0.515 mmol, 90%) as a viscous oil; ir (neat): 3530, 3020, 2960, 2855, 1435, 1440, 1220, 1170 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.66 (s, 3H, -CH_2CH=C(CH_3)CH_2-), 1.76 (s, 3H, -CH=CHCH=C(CH_3)-), 1.83–2.02 (m, 9H, -CH_2CH_2CH=C(CH_3)CH_2CH_2- and -CH_2OH), 2.74 (d, 2H, J = 7.6 Hz, -CH_2CH=CHCH=), 3.34 (t, 1H, J = 7.1 Hz -CH(CO_2CH_3)$_2$), 3.73 (s, 12H, 4 × -OCH_3), 4.05 (d, 2H, J = 6.2 Hz, -CH_2OH), 5.09 (t, 1H, J = 6.2 Hz, -CH_2CH=C(CH_3)CH_2-), 5.49 (dt, 1H, J = 15.0 Hz, 7.5 Hz, -CH=CHCH=), 6.03 (d, 1H, J = 10.7 Hz, -CH=CHCH=C(CH_3)-), 6.35 (dd, 1H, J = 15.0 Hz, 10.8 Hz, -CH=CHCH=C-); ms *m/e*: 468 (M^+), 450 ($M^+ - H_2O$).

Allylic bromide ***22***a

General procedure G

To a stirred solution of allylic alcohol **21***a* (52.5 mg, 0.11 mmol) and CBr_4 (42.0 mg, 0.127 mmol) in 1.2 mL of CH_2Cl_2 was added dropwise at 0°C under argon over a period of 15 min a solution of PPh_3 (37.6 mg, 0.143 mmol) in 0.7 mL of CH_2Cl_2. The resulting mixture was allowed to warm to room temperature and then stirred for 2 h. The volatile was evaporated to dryness and the residue was purified by flash chromatography (hexane – ethyl acetate) using a short-path column to afford allylic bromide **22***a* (43.2 mg, 0.081 mmol, 74%) and recovered starting material **21***a* (8.8 mg, 17%). Compound **22***a* was used immediately for the next macrocyclization without characterization.

Allylic chloride ***22***b

The general procedure E described before was employed. Thus, treatment of allylic alcohol **21***b* (45 mg, 96 μL) with LiCl (12.7 mg, 288 μmol), *s*-collidine (38 μL, 288 mmol), and methanesulfonyl chloride (22 μL, 288 mmol) in DMF (0.5 mL) at 0°C for 6 h yielded allylic chloride **22***b* as a crude oil (45 mg), which was used immediately in the cyclization step without further purification and characterization.

Allylic bromide ***22***c

The general procedure G described before was employed. Thus, treatment of alcohol **21***c* (46.4 mg, 99 μmol) with CBr_4 (37.8 mg, 114 μmol) and PPh_3 (33.8 mg, 129 μmol) in 1.6 mL of CH_2Cl_2 at room temperature for 2 h yielded allylic bromide **22***c* (46.0 mg, 87 μmol, 87%) as an oil; ir (neat): 3030, 2950, 2860, 1740, 1440, 1250, 1200 cm^{-1}; ^1H nmr (C_6D_6) δ: 1.59 (s, 3H, -CH_2CH=C(CH_3)CH_2-), 1.64 (s, 3H, -CH=CHCH=C(CH_3)-), 1.94–2.21 (m, 8H, -CH_2CH_2CH=C(CH_3)CH_2CH_2-), 2.91 (d, 2H, J = 7.5 Hz), 3.34 and 3.38 (2s, 12H, 4 × -OCH_3), 3.41 (t, 1H, J = 7.0 Hz, -CH(CO_2CH_3)$_2$), 3.59 (s, 2H, -CH_2Br), 5.01 (t, 1H, J = 6.0 Hz, -CH_2CH=C(CH_3)CH_2-), 5.65 (dt, 1H, J = 15.0 Hz, 7.6 Hz, -CH=CHCH=), 5.78 (d, 1H, J = 10.9 Hz, -CH=CHCH=C(CH_3)-), 6.20 (dd, 1H, J = 15.0 Hz, 10.9 Hz, -CH=CH=); ms *m/e*: 532 (M^+), 530 (M^+), 501 ($M^+ - OCH_3$), 499 ($M^+ - OCH_3$), 451 ($M^+ - Br$).

CTC macrocycle ***1***a

General procedure H

To a stirred suspension of Cs_2CO_3 (152.0 mg, 0.467 mmol) in THF–DMF (1:1, 40 mL) at 74°C was added slowly, by automatic syringe pump over a period of 5.5 h under argon, a solution of allylic bromide **22***a* (43.2 mg, 81 μL) in THF–DMF (1:1, 15 mL). After completion of the addition, the stirring was continued for 17 h at 74°C. The solid was removed by filtration and the filtrate was evaporated to dryness, in vacuo. The crude residue thus obtained was purified by flash chromatography (hexane – ethyl ace-

tate, 5:1) to give cyclized product **1***a* (32.9 mg, 73 μmol, 90%) as a solid; mp 185–187°C; ir (neat): 3025, 2950, 2850, 1735, 1448, 1275, 1220, 1170, 1070 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.56 (s, 3H, $-CH_2CH{=}C(CH_3)CH_2-$), 1.66 (s, 3H, $=CHCH{=}C(CH_3)-$), 1.70–1.98 (m, 8H, $-CH_2CH_2CH{=}C(CH_3)CH_2CH_2-$), 2.85 (d, 2H, J = 7.8 Hz, $-CH_2CH{=}CH-$), 2.86 (s, 2H, $-CH_2C(CH_3){=}$), 3.72–3.74 (2s, 12H, 4 × $-OCH_3$), 5.00 (q, 1H, J = 8.8 Hz, $-CH{=}CHCH{=}$), 5.11 (t, 1H, J = 6.0 Hz, $-CH_2CH{=}C(CH_3)CH_2-$), 6.27–6.45 (m, 2H, $-CH{=}CHCH{=}$), ms *m/e*: 450 (M^+), 435 ($M^+ - CH_3$), 432 ($M^+ - H_2O$), 418 ($M^+ - CH_3OH$). Exact Mass (M^+) calcd.: 450.2253; found: 450.2250. The structure of compound **1***a* was further confirmed by X-ray crystallography.

TCC macrocycle ***1***b

The general procedure H described above was employed. Thus, a solution of crude allylic chloride **22***b* (45 mg) in THF–DMF (1:1, 6 mL) was added slowly at 70°C over a period of 1.5 h to a Cs_2CO_3 (150 mg, 0.46 mmol) suspension in THF–DMF (1:1, 50 mL). The stirring was continued for an additional 2.5 h after addition. Work-up of the reaction mixture followed by flash chromatography and crystallization (CH_2Cl_2–hexane) furnished a crystalline compound **1***b* (27 mg, 63% for two steps from alcohol **21***b*); mp 178–181°C; ir ($CHCl_3$): 3035–3000, 2950, 2860, 1730, 1435, 1220 cm^{-1}; ^1H nmr (C_6D_6): δ: 1.52 (s, 3H, $-CH_2CH_2C(CH_3){=}$), 1.57 (s, 3H, $=CHCH{=}C(CH_3)-$), 1.76–2.32 (m, 8H, $-CH_2CH_2CH{=}C(CH_3)CH_2CH_2-$), 2.88–3.30 (m, 4H, $-H_2CH{=}CHCH{=}C(CH_3)CH_2-$), 3.32 and 3.34 (2s, 12H, 4 × $-OCH_3$), 4.98 (t, 1H, J = 6.6 Hz, $-CH_2CH_2CH{=}$), 5.38 (dt, 1H, J = 15.0 Hz, 7.7 Hz, $-CH_2CH{=}CH-$), 5.80 (d, 1H, J = 11.0 Hz, $-CH{=}CHCH{=}C-$), 6.32 (dd, 1H, J = 14.7 Hz, 11.1 Hz, $-CH{=}CHCH{=}C-$); ms *m/e*: 450 (M^+). Exact Mass (M^+) calcd.: 450.2253; found: 450.2250. The structure of this compound was further confirmed by X-ray crystallography.

TTC macrocycle ***1***c

The general procedure H described above was employed. Thus, a solution of allylic bromide **22***c* (42.8 mg, 80.6 μmol) in THF–DMF (1:1, 10 mL) was added slowly at 72°C over a period of 13.5 h to a Cs_2CO_3 (131.0 mg, 402.0 μmol) suspension in THF–DMF (1:1, 34 mL). The stirring was continued for an additional 36 h after completion of the addition. Work-up of the reaction mixture followed by flash chromatography (hexane – ethyl acetate; 5:1) furnished macrocycle **1***c* (28.0 mg, 62.2 μmol, 77%) and by-product **23** (1.0 mg, 2.2 mmol, 3%).

Compound ***1***c: mp 115–117°C; ir (neat): 3025, 2950, 1740, 1440, 1240 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.64 (s, 3H, $-CH_2CH{=}C(CH_3)-CH_2-$), 1.67 (s, 3H, $-CH{=}CHCH{=}C(CH_3)-$), 1.68–2.50 (br m, 8H, $-CH_2CH_2CH{=}C(CH_3)CH_2CH_2-$), 2.60–3.22 (br m, 4H, $-CH_2CH{=}CHCH{=}C(CH_3)CH_2-$), 3.72 and 3.74 (2s, 12H, 4 × $-OCH_3$), 5.01 (t, 1H, J = 6.0 Hz, $-CH_2CH{=}C(CH_3)CH_2-$), 5.80 (dt, 1H, J = 15.1 Hz, 7.6 Hz, $-CH{=}CHCH{=}$), 6.10 (d, 1H, J = 10.9 Hz, $-CH{=}CHCH{=}$), 6.29 (dd, 1H, J = 14.6 Hz, 10.8 Hz, $-CH{=}CHCH{=}$); ms *m/e*: 450 (M^+), 445 ($M^+ - CH_3$), 442 ($M^+ - H_2O$), 418 ($M^+ - CH_3OH$). Exact Mass (M^+) calcd.: 450.2253; found: 450.2250.

Compound ***23***: mp 140–142°C; ir (neat): 3090–3000, 2960, 2860, 1740, 1450, 1200 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.40–1.85 and 1.95–2.27 (2m, 8H, $-CH_2CH_2CH{=}C(CH_3)CH_2CH_2-$), 1.67 and 1.72 (2s, 6H, $=C(CH_3)-$ and $CH_2{=}C(CH_3)-$), 2.58–2.70 and 2.88–3.00 (2m, 2H, $-CH_2CH{=}CH-$), 3.61–3.67 (m, 1H, $-CHRC(CH_3){=}CH_2$), 3.71, 3.73, 3.74 (3s, 12H, 4 × $-OCH_3$), 4.74 and 4.86 (2s, 2H, $-C(CH_3){=}CH_2$), 5.18 (t, 1H, J = 7.2 Hz, $-CH{=}C(CH_3)-$), 5.49 (dt, 1H, J = 15.4 Hz, 7.8 Hz, $-CH_2CH{=}CH-$), 6.10 (dd, 1H, J = 15.4 Hz, 7.7 Hz, $-CH_2CH{=}CH-$); ms *m/e*: 450 (M^+). Exact Mass (M^+) calcd. 450.2253; found: 450.2258.

Triene diether ***25***

The general procedure F previously described was employed. Thus, treatment of dimethyl malonate **24** (2.89, 7.8 mmol) with NaH (344 mg, 60% in oil, 14.3 mmol), followed by crude allylic chloride **18** (2.2 g, 9.4 mmol) in a mixture of THF and DMF (1:1, 180 mL) at room temperature for 16.5 h, yielded acyclic triene **25** (1.5 g, 35%) as a colorless oil; ir (neat): 2950, 2860, 1738, 1450, 1200, 1110 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.04 (s, 6H, $(CH_3)_2Si-$), 0.88 (s, 9H, $-(CH_3)_3C$), 1.64 (d, 3H, J = 1.3 Hz, $-CH_2CH{=}C(CH_3)CH_2-$), 1.89 (d, 3H, J = 1.6 Hz, $=CHCH{=}C(CH_3)-$), 1.45–1.99 (m, 10H, $=C(CH_3)CH_2CH_2-$ and $-OCHOCH_2(CH_2)_3-$), 2.13 (qd, 2H, J = 7.1 Hz, 1.1 Hz, $-CH_2CH_2OSi-$), 2.90 (s, 2H, $=CHCH{=}C(CH_3)CH_2-$), 3.54 (t, 2H, J = 7.0 Hz, $-CH_2OSi-$), 3.71 (s, 6H, 2 × $-OCH_3$), 3.40–3.53 and 3.80–3.92 (2m, 2H, $-OCHOCH_2-$), 4.01 (dd, 1H, J = 12.3 Hz, 6.9 Hz, $-CHHOTHP$), 4.26 (dd, 1H, J = 12.9 Hz, 5.6 Hz, $-CHHOTHP$), 4.63 (t, 1H, J = 3.0 Hz, $-OCHO-$), 5.12 (td, 1H, J = 7.2 Hz, 1.4 Hz, $-CH_2CH_2CH{=}$), 5.70 (dt, 1H, J = 14.9 Hz, 6.5 Hz, $-CH_2CH{=}CH-$), 5.98 (d, 1H, J = 11.0 Hz, $=CHCH{=}C(CH_3)-$), 6.48 (dd, 1H, J = 15.0 Hz, 11.1 Hz, $-CH_2CH{=}CH-$); ms *m/e*: 552 (M^+), 537 ($M^+ - CH_3$), 495 ($M^+ - C_4H_9$).

Triene alcohol ***26***

The general procedure D previously described was employed. Thus, treatment of silyl ether **25** (504 mg, 0.91 mmol) with nBu$_4$NF (1 M in THF, 1.6 mL, 1.6 mmol) in 8 mL of THF at room temperature for 2 h yielded triene alcohol **26** (397 mg, 0.90 mmol, 99%) as a colorless oil, which was used in the following mesylation without further characterization.

Triene mesylate ***27***

The general procedure B previously described was employed. Thus, treatment of alcohol **26** (397 mg, 0.91 mmol) with triethylamine (0.19 mL, 1.4 mmol) and methanesulfonyl chloride (77 μL, 1.0 mmol) in CH_2Cl_2) (12 mL) at 0°C for 1 h gave mesylate **27** (480 mg) as a crude oil, which was used immediately for the following alkylation without further purification and characterization.

Dimethyl malonate triene ***28***a

The general procedure C previously described was employed. Thus, treatment of dimethyl malonate (0.52 mL, 4.6 mmol) with NaH (164 mg, 60%, 4.1 mmol), followed by mesylate **27** (480 mg, obtained as a crude oil from the above reaction) and KI (15 mg, 91 μmol) in THF–DMF (1:1, 24 mL) at 85°C for 17 h, yielded **28***a* (366 mg, 73% for two steps from alcohol **26**) as a colorless oil; ir (neat): 2950, 2860, 1734, 1437, 1210 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.64 (s, 3H, $-CH_2CH_2CH{=}C(CH_3)-$), 1.71 (s, 3H, $=CHCH{=}C(CH_3)-$), 1.45–1.80 (m, 6H, $-OCHOCH_2(CH_2)_3-$), 1.80–2.04 (m, 8H, $-CH_2CH_2CH{=}C(CH_3)CH_2CH_2-$), 2.89 (s, 2H, $=CHCH{=}C(CH_3)CH_2-$), 3.34 (t, 1H, J = 7.0 Hz, $-CH(CO_2CH_3)_2$), 3.71 and 3.73 (2s, 12H, 4 × $-OCH_3$), 3.45–3.90 (m, 2H, $-OCHOCH_2-$), 4.00 (dd, 1H, J = 12.0 Hz, 7.0 Hz, $-CHHOTHP$), 4.26 (dd, 1H, J = 13.1 Hz, 5.6 Hz, $-CHHOTHP$), 4.63 (t, 1H, J = 3.0 Hz, $-OCHO-$), 5.05 (t, 1H, J = 6.0 Hz, $-CH_2CH_2CH{=}$), 5.70 (dt, 1H, J = 15.1 Hz, 6.1 Hz, $-CH_2CH{=}CH-$), 5.97 (d, 1H, J = 11.3 Hz, $=CHCH{=}C(CH_3)-$), 6.47 (dd, 1H, J = 15.0 Hz, 11.1 Hz, $-CH_2CH{=}CH-$); ms *m/e*: 552 (M^+), 534 ($M^+ - H_2O$), 520 ($M^+ - CH_3OH$), 467 ($M^+ - THP$).

Triene allylic alcohol ***28***b

The general procedure A previously described was employed. Thus, treatment of THP ether **28***a* (366 mg, 0.663 mmol) with pyridinium *p*-toluenesulfonate (20 mg, 80 μmol) in methanol (7 mL) at 55°C for 75 min yielded allylic alcohol **28***b* (295 mg, 95%) as a viscous oil; ir (neat): 3500, 2955, 2860, 1735, 1435, 1210 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.25 (m, 1H, $-CH_2OH$), 1.64 (s, 3H, $-CH_2CH_2CH{=}C(CH_3)-$), 1.70 (s, 3H, $=CHCH{=}C(CH_3)-$), 1.78–2.04 (m, 8H, $-CH_2CH_2CH{=}C(CH_3)CH_2CH_2-$), 2.91 (s, 2H, $=CHCH{=}C(CH_3)CH_2-$), 3.43 (t, 1H, J = 7.0 Hz, $-CH(CO_2CH_3)_2$), 3.72, 3.73 (2s, 12H, 4 × $-OCH_3$), 4.19 (t, 2H, J = 5.8 Hz, $-CH_2OH$), 5.05 (t, 1H, J = 6.0 Hz, $-CH_2CH_2CH{=}$), 5.76 (dt, 1H, J = 15.0 Hz, 5.8 Hz, $-CH_2CH{=}CH-$), 5.97 (d, 1H, J = 11.1 Hz, $=CHCH{=}C(CH_3)-$), 6.49 (dd, 1H, J = 15.0 Hz, 11.1 Hz, $-CH_2CH{=}CH-$).

Allylic chloride ***29***

The general procedure E previously described was employed. Thus, treatment of allylic alcohol **28***b* (150 mg, 0.32 mmol) with LiCl (41 mg, 0.96 mmol), *s*-collidine (63 μL, 0.48 mmol), and methanesulfonyl chloride (37 μL, 0.48 mmol) in DMF (1.2 mL) at 0°C for 3 h yielded allylic chloride **29** as a crude oil (140 mg), which was used immediately in the next cyclization without purification and characterization.

TTC macrocycle ***1***d

The general procedure H previously described was employed. Thus, a solution of allylic chloride **29** (140 mg, obtained as a crude oil from the above reaction) in THF–DMF (1:1, 18 mL) was added slowly by syringe pump at 70°C over 1 h to a Cs_2CO_3 (469 mg, 1.4 mmol) suspension in THF–DMF (1:1, 50 mL). The stirring was continued for an additional 2 h after completion of the addition. Work-up of the reaction mixture followed by flash chromatography (hexane – ethyl acetate – CH_2Cl_2; 75:9:16) and crystallization (CH_3OH) provided macrocycle **1***d* (100 mg, 69% for two steps from alcohol **28***b*) as a crystalline solid; mp 167–170°C; ir ($CHCl_3$): 3030, 2960, 2860, 1730, 1450, 1215 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.57 (s, 3H, -$CH_2CH_2C(CH_3)$=), 1.66 (d, 3H, J = 1.0 Hz, =CHCH=C(CH_3)-), 1.15–1.70 (br m, 8H, -CH_2CH_2-CH=C(CH_3)CH_2CH_2-), 2.77 (d, 2H, J = 7.9 Hz, =CHCH_2CR-(CO_2CH_3)$_2$), 2.80–3.10 (m, 2H, =C(CH_3)CH_2CR(CO_2CH_3)$_2$), 3.73 (s, 12H, 4 × -OCH_3), 5.14 (m, 1H, -CH_2CH_2CH=), 5.31 (dt, 1H, J = 14.9 Hz, 7.9 Hz, -CH_2CH=CH-), 6.00 (d, 1H, J = 10.9 Hz, =CHCH=C(CH_3)-), 6.48 (dd, 1H, J = 14.8 Hz, 11.1 Hz, -CH_2CH=CH-); ms *m/e*: 450 (M^+). Exact Mass (M^+) calcd.: 450.2253; found: 450.2246. The structure of this macrocycle was further characterized by X-ray crystallography.

Diels–Alder reaction of ***1***a

A solution of macrocycle **1***a* (10.4 mg, 23.1 μmol) in 0.8 mL of toluene was sealed in a quartz tube (20 cm long, 8 mm diameter) under vacuum and then heated at 320°C for 18 h. After the tube was opened, the mixture was transferred into a flask and then evaporated to dryness. The residue thus obtained was eluted through a silica gel column (hexane – ethyl acetate, 7:3) to give a mixture (8.8 mg, 19.6 μmol, 85%), containing four tricyclic compounds **30**, **32**, **33**, and **34**. The characteristic spectral data for the mixture were obtained; ir (neat): 2960, 2870, 1735, 1440, 1250, 1170 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.78–1.12 (8s, -CH_3), 1.13–2.90 (m, all other CH and CH_2), 3.60–3.80 (14s, -OCH_3), 5.13–6.00 (m, -CH=CH-). The ratio for compounds **30**, **32**, **33**, and **34** was found to be 7.0:20.6:5.9:1.0 as determined by the ^1H nmr integration of their methyl peaks and olefin proton peaks. The assignment is the following:

Compound ***30***: 0.95 (s, 3H, -CH_3), 1.12 (s, 3H, -CH_3), 5.16 (d, 1H, J = 10.5 Hz, -CHRCH=CH-), 5.31 (dd, 1H, J = 10.5 Hz, 3.0 Hz, -CHRCH=CH-).

Compound ***32***: 0.78 (s, 3H, -CH_3), 1.07 (s, 3H, -CH_3), 1.12–2.68 (br m, 14H, all other CH and CH_2), 3.74, 3.72, 3.69, 3.68 (4s, 12H, 4 × -OCH_3), 5.45 (dd, 1H, J = 10.5 Hz, 1.8 Hz, -CHRCH=CH-), 5.97 (dt, 1H, J = 10.5 Hz, 1.8 Hz, -CHRCH=CH-).

Compound ***33***: 0.87 (s, 3H, -CH_3), 1.10 (s, 3H, -CH_3), 5.22 (dd, 1H, J = 10.5 Hz, 1.8 Hz, -CHRCH=CH-), 5.35 (dd, 1H, J = 10.5 Hz, 3.0 Hz, -CHRCH=CH-). The structure of this compound was further characterized by X-ray crystallography and shown to have the CSC stereochemistry.

Compound ***34***: 0.83 (s, 3H, -CH_3), 0.85 (s, 3H, -CH_3), 5.50 (dd, 1H, J = 10.5 Hz, 2.8 Hz, -CHRCH=CH-), 5.72 (dd, 1H, J = 10.5 Hz, 1.6 Hz, -CHRCH=CH-).

Separation of the four isomers from the mixture was attempted by flash chromatography with different solvent systems. A mixture of hexane and ethyl acetate (9:1) was found to be the best system, the use of which in flash chromatography of the mixture provided two fractions. Fraction 1, which contained tricycles **32** and **34**, was then purified by plate chromatography with silica gel (toluene–acetone, 9:1) to give pure tricycle **34**. Fraction 2, which contained tricycles **30** and **33**, was purified by plate chromatography with silica gel (toluene–acetone, 98:2) to give pure tricycle **33**.

Thermolysis of TTC macrocycle ***1***c

Neat macrocycle **1***c* (4.0 mg, 8.9 μmol) was sealed in a quartz tube under vacuum and then heated in an oven at 200°C for 4 h. After the tube was opened, the product was transferred into a flask with CH_2Cl_2 and then evaporated to dryness. Purification of the residue by flash chromatography (hexane – ethyl acetate; 7:3) furnished CTC macrocycle **1***a* (4.0 mg, 100%), which had spectral properties identical with the compound obtained from the cyclization of acyclic triene **22***a*.

Diels–Alder reaction of ***1***c

A solution of **1***c* (20.1 mg, 44.7 μmol) in 1.5 mL of toluene was sealed in a quartz tube under vacuum and then heated in an oven at 310°C for 18 h. After the tube was opened, the mixture was transferred into a flask and then evaporated to dryness. The ^1H nmr of the crude residue indicated the presence of the same four tricyclic compounds **30**, **32**, **33**, and **34**. The crude residue was then purified by flash chromatography (hexane – ethyl acetate, 9:1) to give two fractions (fraction 1: 3.2 mg, 7.1 μmol, 16%; fraction 2: 16.3 mg, 36.2 mmol, 81%). Fraction 1 contained tricycles **32** and **34** in a ratio of 1:5 by ^1H nmr and 1:5.6 by gc. Fraction 2 contained tricycles **30** and **33** in a ratio of 1:14 by ^1H nmr and 1:12 by gc. The overall ratio of **30**, **32**, **33**, and **34** was found to be 2.3:1.0:29.9:5.3.

Spectral data for fraction 1: ir (neat): 1960, 1860, 1740, 1440, 1250 cm^{-1}; ms *m/e*: 450 (M^+). The ^1H nmr data for fraction 1 are identical with those of tricycles **32** and **34** obtained from the Diels–Alder reaction of **1***a*.

The ir spectral data for fraction 2: (neat): 2960, 2860, 1735, 1450, 1200 cm^{-1}; ^1H nmr data for fraction 2 are identical with those of tricycles **33** and **30** obtained from the Diels–Alder reaction of **1***c*.

Diels–Alder reaction of ***1***b

The crystalline macrocycle **1***b* (11.5 mg, 26 μmol) was sealed in a quartz tube under vacuum and then heated in an oven at 320°C for 1.5 h. After the tube was opened, the mixture was transferred into a flask with CH_2Cl_2 and then evaporated to dryness. The residue thus obtained was purified by flash chromatography (hexane – ethyl acetate, 9:1) to give tricycle **30** (10 mg, 87%) as a crystalline compound: mp 68–71°C; ir ($CHCl_3$): 3022, 2950, 2870, 1730, 1435, 1250 cm^{-1}; ^1H nmr (C_6D_6) δ: 0.88 (s, 3H, -CH_3), 1.06 (s, 3H, =CHCR(CH_3)-), 1.43–2.60 (m, 14H, all CH and CH_2), 3.27, 3.28, 3.31, 3.32 (4s, 12H, 4 × -OCH_3), 5.17 (dd, 1H, J = 10.0 Hz, 1.4 Hz, -CHRCH=CH-), 5.25 (dd, 1H, J = 10.0 Hz, 2.7 Hz, -CHRCH=CH-); ms *m/e*: 450 (M^+). Exact Mass (M^+) calcd.: 450.2253; found: 450.2246. The structure of this tricycle was further characterized by X-ray crystallography.

Diels–Alder reaction of ***1***d

The crystalline macrocycle **1***d* (25.0 mg, 56 μmol) was sealed in a quartz tube under vacuum and then heated in an oven at 360°C for 1 h. After the tube was opened, the mixture was transferred into a flask with CH_2Cl_2 and then evaporated to dryness. The residue thus obtained was purified by flash chromatography (hexane – ethyl acetate, 4:1) to give tricycle **31** (22.6 mg, 90%) as a crystalline solid; mp 138–140°C; ir ($CHCl_3$): 3020, 2955, 2870, 1730, 1435, 1245 cm^{-1}; ^1H nmr (C_6D_6) δ: 0.69 (s, 3H, -CH_3), 0.78 (s, 3H, =CHCR(CH_3)-), 1.20–2.78 (m, 14H, all CH and CH_2), 3.26, 3.27, 3.30, and 3.34 (4s, 12H, 4 × -OCH_3), 5.26 and 5.31 (2d, 2H, J = 11.0 Hz, -CH=CH-); ms *m/e*: 450 (M^+). Exact Mass (M^+) calcd.: 450.2253; found: 450.2246. The structure of this compound was further characterized by X-ray crystallography.

Several angularly functionalized decalins, synthethized during the preparation of three keto diacetate decalins, models for clerodane diterpenoids, were tested for antifeedant activity against the spruce budworm, *Choristoneura fumiferana*. Definite biological activity was observed for some of these compounds. A structure–activity relationship was discussed on the basis of these results.

A.E. SCHWERDTFEGER, T.H. CHAN, A.W. THOMAS, G.M. STRUNZ, A. SALONIUS et M. CHIASSON. Can. J. Chem. **71**, 1184 (1993).

On a synthétisé plusieurs décalines, fonctionnalisées à la position angulaire, au cours de la préparation de trois cétones diacétates. On a vérifié l'activité biologique de ces composés contre la tordeuse des bourgeons de l'épinette, *Choristoneura fumiferana*. Quelques-uns de ces composés présentent une activité biologique non ambiguë. Sur la base de ces résultats, on discute d'une relation structure–activité.

Introduction

The spruce budworm, *Choristoneura fumiferana* (Clem.), is one of the most widely distributed and destructive defoliators of spruce–fir forests in eastern North America (2). In eastern Canada the larvae of the budworm begin to feed on the buds or the newly opened shoots of the host tree in mid-May, while they consume the greatest amount of foliage during their sixth instar in late June. A pest control strategy involving the use of antifeedants, to interfere with the feeding behaviour of insects, may offer advantages over conventional pest control methods since the antifeedant could protect current year foliage while leading indirectly to budworm mortality without being generally toxic.

Clerodin (**1**) (3) and azadirachtin (**2**) (4) are two natural products that possess marked antifeedant properties. Chang and Nakanishi (5) have isolated the iridoid specionin (**3**), from leaves of *Catalpa speciosa* and found it to be an effective antifeedant against the spruce budworm. Specionin has recently been synthesized (6, 7).

Because of the complexity of structures of known antifeedants such as clerodin (**1**) and azadirachtin (**2**), synthetic chemists have turned to the more practical approach of preparing simpler analogs of these compounds. In 1981 Kojima and Kato (8) prepared the clerodin homologs **4** and **5**, which were found to be biologically active against *Spodoptera litura* at 500 and 250 ppm, respectively. At the same time Ley and co-workers (9) prepared the *trans* and *cis* epoxydiacetate clerodin analogs **6** and **7**, which were found to be biologically active at 100 and 1000 ppm when tested against *Locusta migratoria*. Ley and co-workers (10) have also prepared azadirachtin analogs such as **8** and **9**, of which **9** (active at 1 ppm) is almost as active as azadirachtin itself in some bioassays.

A few years ago we found that the specionin analog **10** exhibits moderate activity against the spruce budworm (11). More recently we reported the synthesis and biological activity of several polyoxygenated decalins, of which compounds **11**–**14** were found to exhibit moderate antifeedant activity against the spruce budworm at a concentration of 0.2% wet weight (1).

A common structural feature of all natural insect antifeedants is the close proximity of the polyoxygenated functions. It is possible that such a dense array of oxygen functions may be required for biological activity. As part of our effort to study the structure–activity relationship of insect antifeedants, we describe here the preparation of three polyoxygenated angularly functionalized decalins **15**–**17**, possessing some structural features in common with the clerodanes, as potential antifeedants against the spruce budworm.

Chemical synthesis

Previously in our laboratory (12) it was found that the decalin **20** could be prepared by a tandem Michael–Claisen annelation sequence (see Scheme 1). The conjugate addition of siloxy diene **18** to 2-cyclohexen-1-one provided the isomeric Michael adducts **19**, which were cyclized by a Claisen condensation.

We then reported the angular hydroxymethylation of decalin **20** with diisopropylethylamine and benzyl chloromethyl ether in the presence of paraformaldehyde to provide the benzyloxymethoxymethyl derivative **22** in 75% yield (13) (see Scheme 2).

The trapping of intermediate aldol **21** could also be accomplished with acetic anhydride to form compound **23**. The hydroxymethylation procedure was then also applied to keto ester **24** as well as to decalin **27** to prepare compounds **25** and **26** as well as angularly functionalized decalin **28** (13) (see Scheme 3). It is interesting to note that in the case of the keto ester **24**, the unprotected aldol **26** was isolated directly.

17 R = R'= Me

In the hope of preparing a decalin compound functionalized at the angular position with an ester moiety, decalin **20** was treated with potassium *tert*-butoxide in THF and the resulting anion was quenched with 3 equivalents of methyl chloroformate. However, this provided the O-alkylated product **29** in 93% yield (see Scheme 4). This is not surprising since it is known that ethyl chloroformate frequently gives predominantly O-alkylation (14, 15). The O-alkylation as confirmed by the presence of only one (unsaturated) carbonyl signal in the ^{13}C nmr spectrum at 183.8 ppm, as well as by the presence of the carbonate signal at 163.6 ppm.

Recently Mander and Sethi (16) described the C-acylation of lithium enolates by methyl cyanoformate, which provided high yields of β-keto esters. These reaction conditions were modified and applied to Michael adduct **19**. Thus, compound **19*E*** was treated with potassium *tert*-butoxide in THF, to promote the Claisen condensation, and the resulting anion quenched with methyl cyanoformate, providing after 30 h at room temperature the diacylated product **30** in 23% yield together with 29% of compound **31** and 38% recovered decalin **20** (see Scheme 5).

Subjecting decalin **20** to the same conditions provided **31** as the sole product in 48% yield together with 25% starting material. The structure of compound **31** was confirmed by the presence of an unsaturated carbonyl carbon signal at 189.2 ppm and a carbonate signal at 165.1 ppm in the ^{13}C nmr spectrum. The presence of the CN functionality was

evident from the weak peak at 2361 cm^{-1} in the ir spectrum.

In our report on the angular hydroxymethylation of decalin **20** we have detailed the utility of the following chemical transformation (eq. [1] in Scheme 6) in establishing the structure of compound **22** (13). Treatment of **22** with Raney nickel provided both the desulfurized product (**32**) and the product resulting from overreduction (**33**).

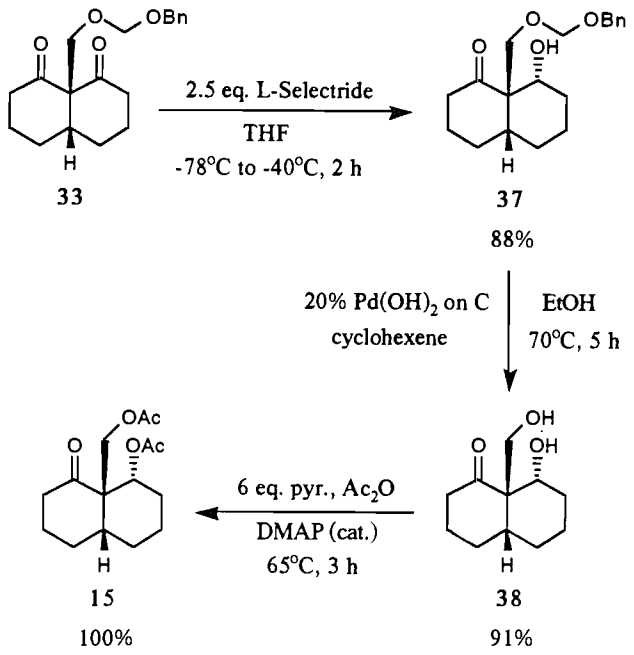

SCHEME 7

These same reaction conditions could also be applied to ketal **34**, which was obtained in 53% yield, together with 35% recovered starting material, from compound **22** via a variation of the Noyori (17) reaction conditions (13). When ketal **34** was treated with Raney nickel in absolute ethanol for 4 days, a 1:2 mixture of enone **35** and compound **36** was produced in 90% yield. Enone **35** was also obtained in 60% yield together with 18% recovered **32** by subjecting compound **32** to the modified Noyori (17) reaction conditions. The symmetrical diketone **33** and the two ketals **34** and **35** served as intermediates in the preparation of the angularly functionalized decalin compounds **15**–**17**.

Preparation of keto diacetate ***15***

The synthesis of compound **15** began with the reduction of ketone **33** with L-Selectride, which afforded keto-alcohol **37** in 88% yield (see Scheme 7). D_2O exchange indicated that the proton α to the newly formed secondary alcohol was axial (J = 11.1 Hz and J = 3.7 Hz). Since the substrate is a *cis*-fused decalin, there are two possible chair–chair conformers: one in which the secondary (equatorial) alcohol is *cis* to the protected hydroxymethylene unit, **37c** in Fig. 1, and the other where the two moieties exist in a *trans* relationship, **37t** in Fig. 1. A sterically hindered base such as L-Selectride would be expected to approach the *cis*-fused decaline from the convex face, thus leading to the formation of **37t**, where the secondary alcohol and the protected hydroxymethylene moiety are oriented *trans* to each other. The relative stereochemistry was later established as *trans* through the X-ray structure determination[3] **40**, thus confirming that indeed α alcohol **37** was formed in the L-Selectride reduction.

Subsequent catalytic hydrogenolysis (18) of keto-alcohol **37** with 20% palladium hydroxide on carbon in ethanol at 70°C using cyclohexene as a hydrogen source provided keto-diol **38** in 91% yield. Keto-diol **38** was treated with pyridine in acetic anhydride in the presence of a catalytic amount of DMAP (19) to give the corresponding diacetate (**15**) in quantitative yield (see Scheme 7).

Compound **37** could also be acetylated to provide the monoacetate (**39**) in 75% yield (see Scheme 8).

Keto-diol **38** was converted to its isopropylidene derivative by treatment with 2,2′-dimethoxypropane in dry acetone in the presence of 10-camphorsulfonic acid (20) at room temperature to provide the crystalline ketal **40** in 90% yield (see Scheme 9 and Fig. 2).

Preparation of keto diacetate ***16***

The keto diacetate **16** was prepared starting from intermediate **35**. The conjugate addition of an excess of lithium dimethylcuprate to enone **35** gave, after 4 h at −35°C, the β-alkylated ketone **41** as a single isomer in 95% yield after purification (see Scheme 10). The approach of the lithium dimethylcuprate reagent from the α face would have been sterically hindered due to the concave nature of the *cis*-fused decaline. The crude ketone **41** could be directly treated with lithium aluminum hydride in ether at 0°C for 3 h to provide the alcohol (**42**) in 89% overall yield for the two steps after purification. The alcohol is a 3:1 mixture of isomers.

When the alcohol mixture (**42**) was subjected to mildly acidic treatment (5% HCl) for 3 h at room temperature, keto-alcohols **43***a* and **43***b* were obtained in a 3:1 ratio in 80% combined yield.

The keto-alcohols (**43***a* and **43***b*) proved to be suitable candidates for nOe experiments, which served to establish the stereochemistry of the secondary alcohols (see Fig. 3). The ^{1}H nmr spectrum of the major isomer (**43***a*) in $CDCl_3$ solvent is rather complex with most of the proton signals appearing together in selected narrow regions of the spectrum. However, the ^{1}H nmr spectrum run in C_6D_6 was simplified, allowing the individual proton signals to be more easily distinguished. Thus an nOe experiment was carried out in C_6D_6, which confirmed the structure of **43***a* to be as shown in Scheme 10.

The mutual enhancement of the signals of protons H_a and H_b suggests that these protons are both axial, thus indicating that the secondary alcohol and the benzyloxymethoxymethylene moiety exist in a *trans* relationship in the major keto-alcohol isomer **43***a*. The β orientation of the methyl group, already alluded to earlier, is further confirmed by the fact that irradiation of this signal enhances the signals of both the H_a and H_b protons.

Similarly for the minor isomer (**43***b*), the ^{1}H nmr spectrum of the compound in C_6D_6 solvent proved to be less complex than the ^{1}H nmr spectrum of the same compound in $CDCl_3$. An nOe experiment was carried out to establish the stereochemistry of compound **43***b*. In this case there was no mutual enhancement of protons H_a and H_b or of proton H_a and the methyl group. Irradiation of the methyl group signal did effect a 6% enhancement of the signal of proton H_b. Irradiation of the proton H_b signal effected a 3% enhancement of the methyl group signal. It was thus concluded that the structure of keto-alcohol isomer **43***b* is as shown in Scheme 10 and that in this case the secondary alcohol and the benzyloxymethylene functionality exist in a *cis* relationship.

The keto-alcohol major isomer **43***a* was then subjected to hydrogenolysis conditions (18) to give, after 20 h at 70°C,

[3]We thank Dr. Rosi Hynes from the McGill X-ray Facility for the X-ray structure determination.

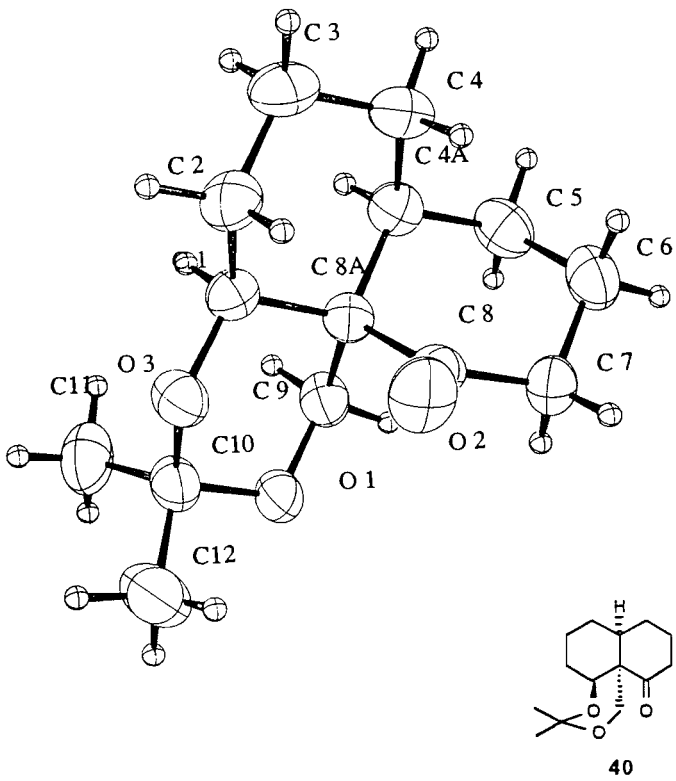

FIG. 2

65% of keto-diol **44***a* together with 35% recovered **43***a*. The keto-diol **44***a* was then treated with acetic anhydride in pyridine in the presence of a catalytic amount of dimethylaminopyridine (19) to afford the monomethyl keto diacetate **16**.

Preparation of keto diacetate 17

The ketal **34** served a precursor to the *gem*-dimethyl decalin compound **17**. When the ketal was treated with 2 equivalents of lithium dimethylcuprate the β-alkylated enone **45** was produced in 86% yield after stirring for 3 h at −30°C. When a larger excess of lithium dimethylcuprate was employed, the desired β,β-dialkylated ketone **46** was formed in 85% yield after purification (see Scheme 11). The crude product could be directly treated with lithium aluminum hydride to provide alcohol **47** in 78% overall yield for the two steps after purification (see Scheme 12).

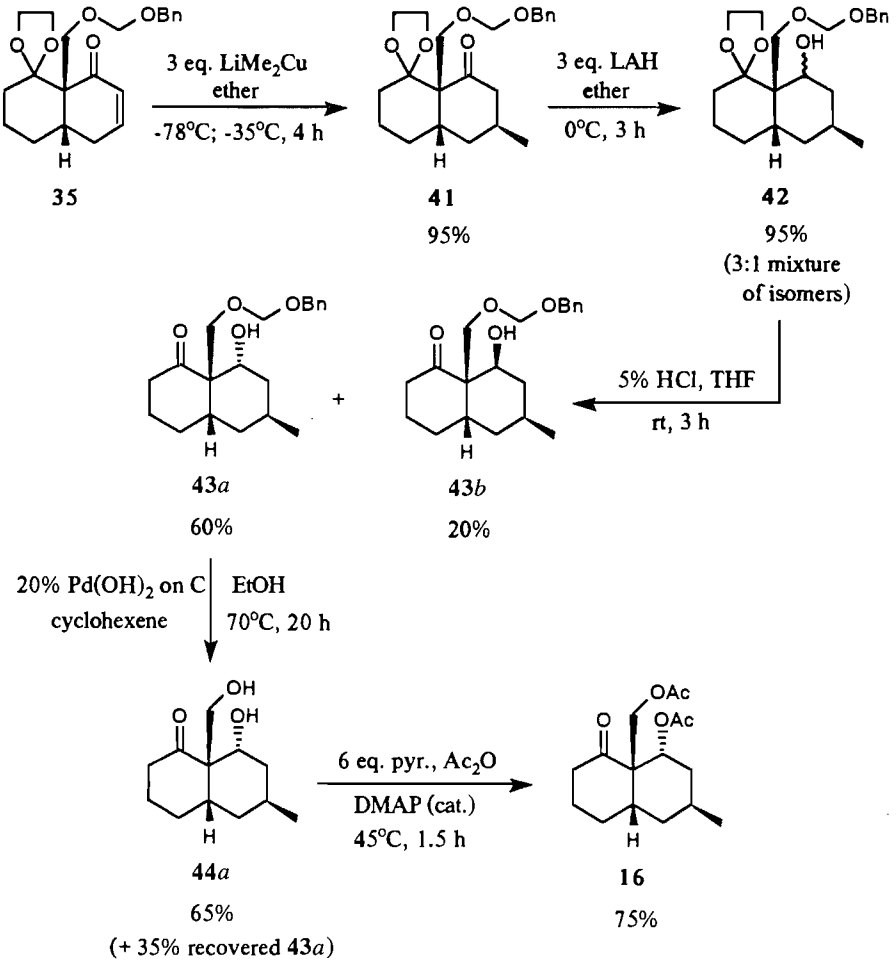

SCHEME 10

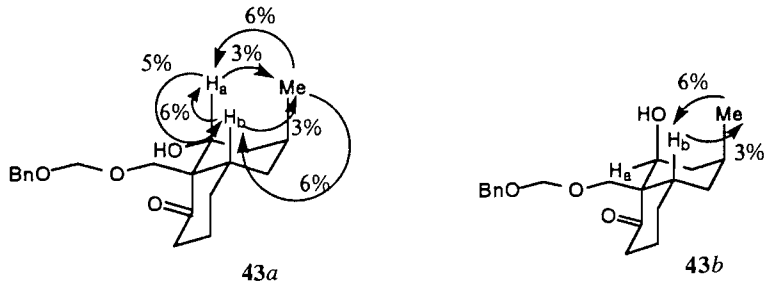

FIG. 3

The alcohol was then subjected to the catalytic hydrogenolysis conditions (18), which produced a mixture of three products together with 35% recovered starting material as shown in Scheme 12. The desired keto-diol **48** was formed in 20% yield along with 15% keto-alcohol **49** and 7% of the diol **50** with the protected carbonyl. Compound **50** could be deprotected under mildly acidic conditions (5% HCl) to provide 95% of the desired keto-diol **48**. Keto-alcohol **49** could be resubjected to the reaction conditions to provide the keto-diol **48** in quantitative yield. The stereochemistry of keto-diol **48** was confirmed by an X-ray structure determination (see Fig. 4).[4]

[4]We thank Dr. J. Britten from the McGill X-ray Facility for the X-ray structure determination.

Keto-diol **48** was then treated wth 2:1 acetic anhydride:dichloromethane in pyridine containing a catalytic amount of DMAP (19) to provide, after 1.5 h at room temperature, a mixture of the monoacetate **51** and the desired diacetate **17** (see Scheme 13). When monoacetate **51** was resubjected to the reaction conditions at 45°C for 1.5 h it was smoothly transformed into the diacetate **17** in 95% yield.

Biological assay

Four sets of biological assays were conducted on 23 of the synthetic compounds. Each set involved the simultaneous bioassay of six compounds plus a control and used 350 larvae, except the 4th set which had only five compounds plus a control and used 300 larvae. Each bioassay involved feed-

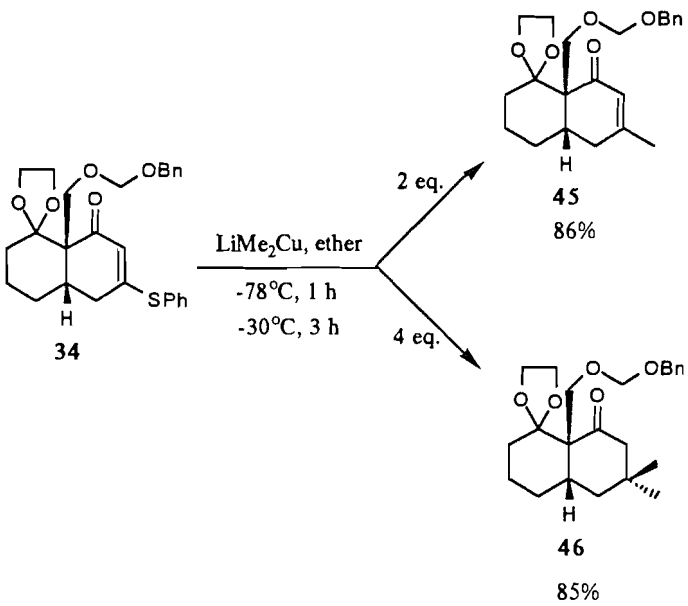

SCHEME 11

ing laboratory-colony spruce budworm larvae on artificial diet (21) containing 0.2% (wet weight) of the test compounds. In each bioassay, newly emerged larvae were reared individually at 26°C, 17 h photoperiod, 50 replicates per test compound. At the point when approximately 50% of the control larvae had reached the final (6th) instar, all the larvae were sacrificed and their developmental stage determined. Because the data were nonparametric, the rank transformation approach, RT-1 (22), was used prior to statistical analysis. For each set of data, the entire set of observations was ranked from smallest to largest, with the least developed larvae, instar 2, having rank 1, the second least developed, instar 3, having rank 2, etc. Average ranks were assigned in the case of ties (23). A one-way analysis of variance on the rank values allowed us to test for differences between compounds using the F-test; when significant differences were detected, a Tukey-type multiple comparison test, using rank sums, was performed to locate the differences (23, 24). For each set of bioassays, the compounds are listed in descending order according to their mean rank values (Tables 1–4). Compounds in the same set having the same code were not significantly different at the 5% level ($P > 0.05$) in their effect on the development rate of budworm larvae. Because the mean rank values, per se, have no biological meaning, mean instar values and the proportion of 6th instars are included in Tables 1–4. Both variables showed the same trend as the ranked values; as mean rank values decreased, both mean instar and the proportion of 6th instars decreased.

Discussion

The biological assay showed that the development of larvae reared from second instar on test diets was significantly retarded by compounds **22**, **30**, **31**, **32**, **35**, **37**, and **28**, but not by the other compounds. The level of activity of compounds, **30**, **35**, **37**, and **28** is comparable to that of the specionin analog **10**, as well as compounds **11–14** reported previously by our laboratory (1, 11). However, the activity of compounds **22** and **32** is slightly better than the activity of the latter compounds. The activity of compound **31** is superior to the activity exhibited by all the other compounds.

Several conclusions can be drawn from the structure–activity relationship observed. The nature of the oxygen function is of critical importance, with the hydroxy and ketal groups generally giving the inactive compounds, with the exception of the moderate activity demonstrated by compounds **35** and **37**. Surprisingly, the diacetates **15**, **16**, and **17** showed no significant activity. It was expected that since both the *trans*- and *cis*-fused epoxy diacetate decalins **6** and **7** synthesized by Ley and co-workers (9) showed definite activity against *Locusta migratoria*, the diacetates **15–17** would also show some activity against *Choristoneura fumiferana*. This suggests that the oxirane functionality at C-8 contributes signficantly to the activity. Interestingly, the simple decalins **28**, **22**, and **32**, featuring an angular benzyloxymethoxymethyl moiety, are active. The definite activity exhibited by compound **31** may be due to the presence of a nitrile functionality in this molecule.

For all the compounds (**46**, **45**, **47**, **16**, **41**, **48**, **17**) bearing a methyl group at the C-3 position, little or no biological activity was observed. Equally interesting is the observation that all of the active compounds (except **37**) in the present series are conjugated enones. It is possible that the ability to alkylate a biological nucleophile by the oxygen function is required for biological activity. Thus, the presence of either an oxirane (as in clerodine and specionin), dihydrofuran (as in azadirachtin and clerodin), or an enone (for Michael addition) may fulfill this role. We intend to further investigate the structure–activity relationship.

Conclusion

The biological activity exhibited by the simple decalins **22**, **28**, and **32** suggests that the angular benzyloxymethoxymethyl moiety and the enone function may be in part responsible for the observed activity. The nitrile functionality also promotes activity, as illustrated by the definite biological activity exhibited by decalin **31**.

Experimental

Melting points were determined on a Gallenkamp block and are uncorrected. The ^{1}H nmr spectra were taken on Varian XL-200 and XL-300 instruments and the data are reported in ppm relative to the $CHCl_3$ reference line with the multiplicity, coupling constants, and the number of protons given in parentheses. The ^{13}C nmr spectra were recovered on a Varian XL-300 (75.4 MHz) spectrometer. The ir spectra were obtained on an Analect AQS-18 FT-IR instrument. Solution spectra were obtained using sodium chloride solution cells of 0.2 mm thickness. Low-resolution mass spectra were recorded on a Du Pont 21-492B mass spectrometer operating at an ionization potential of 70 eV or on a Hewlett–Packard 5980A mass spectrometer using ammonia chemical ionization and are reported as m/z (relative intensity %). All high-resolution mass spectra were recorded on a ZAB 2F HS instrument using ammonia chemical ionization. Column chromatography was performed on Merck silica gel 60 (230–400 mesh). For all moisture-sensitive reactions, glassware was oven-dried at ca. 200°C and cooled in a desiccator. X-ray diffraction measurements were made on a Rigaku AFC6S diffractometer and the calculations were performed using the NRCVAX (25) and the TEXSAN (26) crystallographic software packages.

3-Phenylthio-8-(methoxycarbonyl)oxy-2,4,4a,5,6,7-hexahydronaphthalene-1-one (29)

To a solution of decalin **20** (0.203 g; 0.744 mmol) in 15 mL THF at 0°C under argon was added KO*t*Bu (0.086 g; 0.768 mmol).

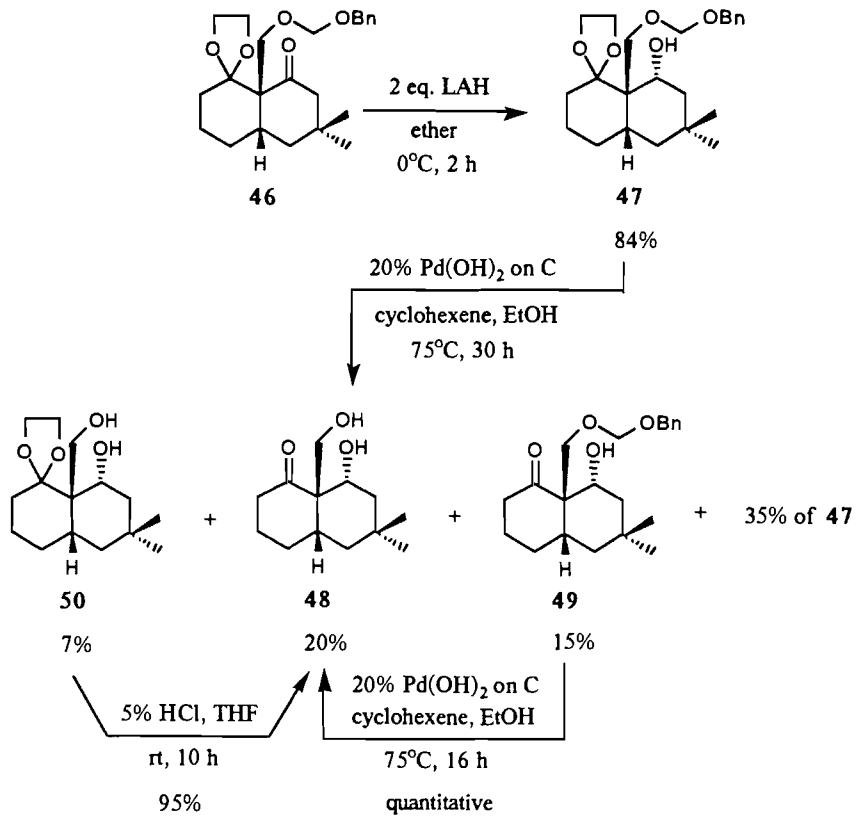

SCHEME 12

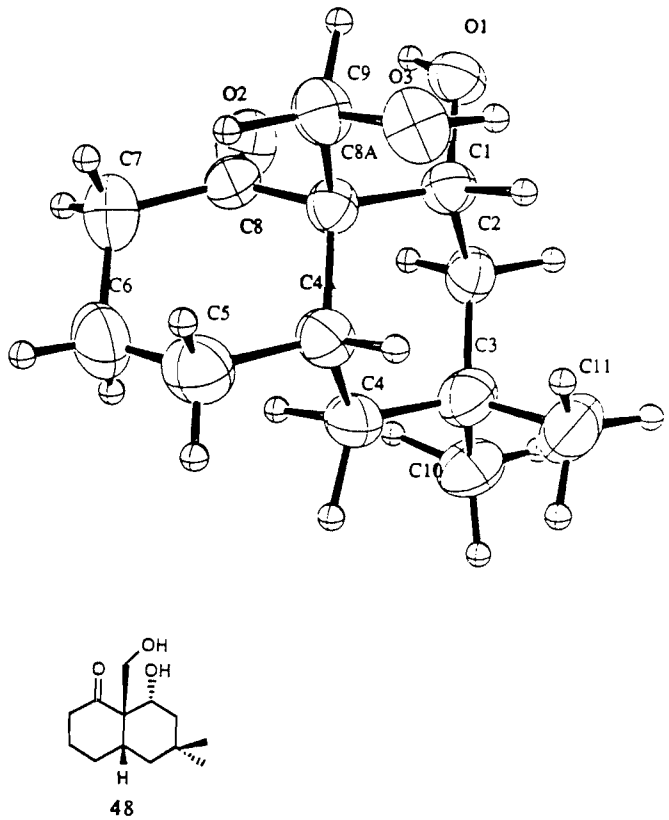

FIG. 4

After 20 min methyl chloroformate (0.17 mL; 2.22 mmol) was added. The reaction mixture was stirred for 1 h and then quenched by the addition of saturated ammonium chloride solution. The mixture was extracted with ether (3 × 25 mL) and the combined extracts were dried ($MgSO_4$), filtered, and the solvent removed to provide 0.260 g crude material. Column chromatography (1:4 EtOAc:hexane) provided the O-alkylated product **29** (0.228 g, 93%) as a beige oil that crystallized on standing (mp 77–78°C); ir ($CHCl_3$, cm^{-1}): 3012, 1762, 1664, 1608, 1586, 1443, 1268, 1196, 784; ^1H nmr ($CDCL_3$, ppm): 7.36–7.53 (m, 5H), 5.42 (s, 1H), 3.80 (s, 3H), 2.80–3.03 (m, 1H), 2.40–2.55 (m, 2H), 2.26–2.39 (m, 2H), 1.55–2.07 (m, 4H); ^{13}C nmr ($CDCl_3$, ppm): 183.8, 163.6, 153.8, 152.5, 135.3, 130.1, 129.8, 127.8, 122.2, 121.9, 55.1, 36.7, 35.7, 29.3, 29.0, 20.3; ms: 330 (19, M^+), 270(32), 77(23), 55(25), 44(100), 31(75), 28(34).

*1-(Methoxycarbonyl)oxy-3-phenylthio-7-methoxycarbonyl-8-hydroxy-4,4a,5,6-tetrahydronaphthalene (**30**) and 3-phenylthio-8-(methoxycarbonyl)oxy-8-cyano-2,4,4a,5,6,7-hexahydronaphthalene-1-one (**31**)*

Potassium *tert*-butoxide (0.050 g; 0.44 mmol) was added to a solution of *E* Michael adduct **19***E* (0.124 g; 0.41 mmol) in 5 mL THF at 0°C under argon. After stirring for 20 min, methyl cyanoformate (0.18 mL; 2.27 mmol) was added. The reaction mixture was allowed to warm to room temperature and stirred for 8 h. The red mixture was then diluted with 5 mL ether and quenched with 10 mL water. The aqueous layer was extracted with ether (3 × 15 mL) and the combined organic extracts were dried ($MgSO_4$), filtered, and the solvent removed to provide 0.127 g crude material. Column chromatography (1:4 EtOAc: hexane) provided **30** (0.036 g, 23%) and **31** (0.038 g, 29%), along with some recovered decalin **20** (0.042 g, 38%).

30: ir (neat, cm^{-1}): 2948, 1752, 1743, 1709, 1603, 1582, 1437,

*3-Phenylthio-8-(methoxycarbonyl)oxy-8-cyano-2,4,4a,5,6,7-hexahydronaphthalene-1-one (**31**)*

Potassium *tert*-butoxide (0.195 g; 1.74 mmol) was added to a solution of decalin **20** (0.330 g; 1.20 mmol) in 15 mL THF at 0°C under argon. After stirring for 20 min at 0°C, methyl cyanoformate (0.80 mL; 10.1 mmol) was added and the reaction mixture was allowed to warm to room temperature and stirred for 30 h. The red mixture was then diluted with 200 mL ether and quenched with 200 mL saturated ammonium chloride solution. The aqueous layer was extracted with ether (3 × 75 mL) and the combined extracts were dried ($MgSO_4$), filtered, and the solvent removed to provide 0.460 g crude material. Column chromatography (1:4 EtOAc:hexane) provided the product **31** (0.192 g, 48%) along with some recovered decalin **20** (0.079 g, 25%). See procedure above for spectral data of **31**.

Ethylene ketal of cis-*8a-[[(benzyloxy)methoxy]methyl]-4a,5,6,8a-tetrahydronaphthalene-1,8(4*H*,7*H*)-dione (**35**) and ethylene ketal of* cis-*8a-[[(benzyloxy)methoxy]methyl]-3,4,4a,5,6,8a-hexahydronaphthalene-1,8-(2*H*,7*H*)-dione (**36**)*

To a solution of the ethylene ketal **34** (0.224 g; 0.48 mmol) in 17 mL absolute ethanol at room temperature under argon was added Raney nickel (1.421 g). The mixture was stirred for 4 days at room temperature at which time the catalyst was removed by filtration and the solvent removed to provide 0.198 g crude material. Column chromatography (1:4 EtOAc:hexane) provided **35** (0.065 g, 37%) and **36** (0.109 g, 62%).

35: ir ($CHCl_3$, cm^{-1}): 3012, 2949, 1662, 1217, 1078; ^{1}H nmr ($CDCl_3$, ppm): 7.28–7.35 (m, 5H), 6.92–7.06 (m, 1H), 6.06(d, J = 10 Hz, 1H), 4.73 and 4.70 (AB, J = 6 Hz, 2H), 4.55 (s, 2H), 4.39 (AB, J = 10 Hz, 1H), 3.65–3.89 (m, 5H), 2.78–2.98 (m, 2H), 2.05–2.30 (m, 1H), 1.39–1.99 (m, 6H); ^{13}C nmr ($CDCl_3$, ppm): 200.3, 150.3, 138.0, 130.6, 128.4, 127.9, 127.6, 110.8,

95.2, 69.5, 67.1, 65.1, 64.6, 56.6, 33.7, 32.7, 29.2, 25.5, 18.8; ms: 359(25, M + H^+), 329(19), 251(93), 189(100). Exact Mass calcd. for $C_{21}H_{26}O_5$ + H^+: 359.1857; found: 359.1858.

36: ir ($CHCl_3$, cm^{-1}): 2958, 1734, 1699, 1457, 1232, 1077; ^1H nmr ($CDCl_3$, ppm): 7.27–7.45 (m, 5H), 4.75 and 4.70(AB, J = 6 Hz, 2H), 4.57 (s, 2H). 4.34 (AB, J = 9.5 Hz, 1H), 3.65–3.90 (m, 5H), 1.39–2.59 (m, 13H); ^{13}C nmr ($CDCl_3$, ppm): 210.5, 138.0, 128.5, 128.3, 127.8, 127.6, 110.1, 95.2, 69.5, 67.1, 66.2, 64.1, 59.6, 42.1, 37.0, 32.8, 26.9, 26.8, 23.8, 19.2; ms: 361 (10, M + H^+), 331(24), 329(13), 254(17), 253(100), 223(10). Exact Mass calcd. for $C_{21}H_{28}O_5$ + H^+: 361.2017; found: 361.2015.

Ethylene ketal of cis-*8a-[[(benzyloxy)methoxy]methyl]-4a,5,6,8a-tetrahydronaphthalene-1,8(4*H*,7*H*)-dione (35)*

To a solution of trimethylsilyltriflate (0.01 mL; 0.052 mmol) in 0.10 mL CH_2Cl_2 at −78°C under argon was added 1,2-bis(trimethylsiloxy)ethane (1.70 mL; 6.93 mmol), followed by the starting material **32** (0.075 g; 0.24 mmol) in 0.40 mL CH_2Cl_2. The reaction mixture was then slowly warmed to −45°C and stirred at this temperature for 20 h. The mixture was then further warmed to −15°C and stirred for an additional 20 h. The reaction was then quenched by the addition of pyridine (0.02 mL; 0.25 mmol) at −15°C, and poured into saturated sodium bicarbonate. The aqueous layer was extracted with ether (3 × 10 mL) and the combined extracts were dried ($MgSO_4$), filtered, and the solvent removed to provide 0.090 g crude material. Column chromatography 1:4 EtOAc:hexane) provided the product **35** (0.050 g, 60%) as a clear oil. For spectral data: see the preceding experiment.

cis-*8a-[[(Benzyloxy)methoxy]methyl]-1α-hydroxy-1,3,4,4a,5,6,8a-septahydronaphthalene-8(2*H*,7*H*)-one (37)*

To a solution of the starting material **33** (0.222 g; 0.701 mmol) in 11.5 mL THF at −78°C under argon was added 1 M L-Selectride (1.75 mL; 1.75 mmol). The solution was stirred for 1 h at −78°C, followed by 2 h at −40°C. The reaction mixture was then diluted with 10 mL ether and quenched with 10 mL saturated ammonium chloride solution at −40°C. The organic layer was separated and the aqueous layer was extracted with ether (3 × 15 mL). The combined extracts were dried ($MgSO_4$), filtered, and the solvent removed to provide 0.425 g crude material. Column chromatography (1:4 EtOAc:hexane) provided the keto-alcohol **37** (0.197 g, 88%) as a clear oil; ir ($CHCL_3$, cm^{-1}): 3500, 2939, 1694, 1453, 1288, 1028, 748, 697; ^1H nmr ($CDCl_3$, ppm): 7.31–7.44 (m, 5H), 4.79 (s, 2H), 4.62 (s, 2H), 3.98 (s, 2H), 3.49–3.51 (m, 2H), 1.25–2.50 (m, 13H); D_2O exchange clarifies the multiplet at 3.49–3.51 to: 3.51 (dd, J = 11.8 Hz and J = 4.4 Hz, 1H); ^{13}C nmr ($CDCl_3$, ppm): 217.0, 137.7, 128.4, 128.0, 127.8, 95.0, 72.8, 69.7, 67.3, 58.3, 40.1, 39.2, 31.9, 28.3, 25.4, 23.8, 21.5; ms: 319 (37, M^+), 289(8) (212)(18), 211(100). Exact Mass calcd. for $C_{19}H_{26}O_4$ (M^+): 319.1910; found: 319.1909.

cis-*8a-(Hydroxymethyl)-1α-hydroxy-1,3,4,4a,5,6,8a-septahydronaphthalene-8(2*H*,7*H*)-one (38)*

To a solution of the keto-alcohol **37** (0.148 g; 0.46 mmol) in 6.5 mL absolute ethanol was added 20% palladium hydroxide on carbon (0.282 g), followed by cyclohexene (6.60 mL; 65.7 mmol). The mixture was heated to 70°C and stirred for 5 h. The catalyst was then removed by filtration and the solvent removed. Column chromatography (1:1 EtOAc:hexane) provided the keto-diol **38** (0.085 g, 91%); ir ($CHCl_3$, cm^{-1}): 3505, 3015, 2947, 1693, 1226, 1066, 792; ^1H nmr ($CDCL_3$, ppm): depending on the concentration of the sample in $CDCl_3$, the spectrum is either 4.43 (t, J = 11.5 Hz, 1H), 3.87 (t, J = 9.8 Hz, 2H), 3.80 (d, J = 10 Hz, 1H), 3.47 (dt, J = 4.4 Hz and J = 11.5 Hz, 1H), 2.54–2.79 (m, 1H), 1.16–2.38 (m, 12H) or ^1H nmr ($CDCl_3$, ppm): 4.39 (d, J = 11 Hz, 2H), 3.85 (d, J = 11.5 Hz, 3H), 3.42 (dd, J = 11 Hz and J = 2 Hz, 1H), 2.54–2.79 (m, 1H), 1.16–2.38 (m, 12H); D_2O exchange: 4.38 (d, J = 11.5 Hz, 1H), 3.77–3.97 (m, 1H), 3.36–3.52 (dd, J = 3.8 Hz and J = 11.2 Hz, 1H); ^{13}C nmr ($CDCl_3$, ppm): 217.2, 80.5, 71.5, 57.9, 40.8; 39.6, 32.3, 28.2, 25.8, 23.9, 22.1; ms: 216 (11, M + NH_4^+), 200 (22, M + $2H^+$), 199 (100, M + H^+).

cis-*8a-[[(Benzyloxy)methoxy]methyl]-1α-acetoxy-1,3,4,4a,5,6,8a-septahydronaphthalene-8(2*H*,7*H*)-one (39)*

To a solution of the monoalcohol **37** (0.060 g; 0.19 mmol) in 1.80 mL acetic anhydride at room temperature under argon was added pyridine (0.05 mL; 0.62 mmol), followed by dimethylaminopyridine (0.0210 g; 0.17 mmol). The mixture was heated to 70°C and stirred at this temperature for 48 h, by which time the yellow solution had turned brown. The mixture was allowed to cool to room temperature, was diluted with ether (2 mL), and quenched with saturated ammonium chloride solution (5 mL). The aqueous layer was extracted with ether (3 × 10 mL) and the combined ether extracts were dried ($MgSO_4$), filtered, and the solvent removed to provide the monoacetate **39** (0.049 g, 75%) as a clear oil; ir (neat, cm^{-1}): 2931, 2867, 1749, 1714, 1453, 1378, 1233, 1105, 1029, 738, 699; ^1H nmr ($CDCl_3$, ppm); 7.24–7.38 (m, 5H), 4.86 (dd, J = 3.8 Hz and 8.2 Hz, 1H), 4.71 and 4.67 (AB, J = 8 Hz, 2H), 4.55 (s, 2H), 3.94 and 3.70 (AB, J = 9.4 Hz, 2H), 2.11–2.63 (m, 3H), 2.00 (s, 3H), 1.28–1.96 (m, 8H); ^{13}C nmr ($CDCl_3$, ppm): 211.2, 170.1, 137.6, 128.4, 127.8, 127.7, 95.1, 76.6, 74.0, 69.6, 68.3, 56.2, 40.4, 37.4, 27.2, 26.1, 22.5, 21.4, 19.9; ms: 378 (34, M + NH_4^+), 361 (4, M + H^+), 348(8), 331(25), 281(6), 271(26), 254(16), 253(100), 223(26), 193(22), 179(6), 163(6), 151(7), 108(6). Exact Mass calcd. for $C_{21}H_{28}O_5$ + H^+: 361.2017; found: 361.2015.

cis-*8a-Oxymethyl-9,1α,*O*-isopropylidene-1,3,4,4a,5,6,8a-septahydronaphthalene-8-(2*H*,7*H*)-one (40)*

To a solution of the starting material **38** (0.062 g; 0.311 mmol) in 2.0 mL spectrograde acetone under argon at room temperature was added 2,2′-dimethoxypropane (0.17 mL; 1.40 mmol) and a catalytic amount of camphor sulphonic acid. The mixture was stirred at room temperature for 3 h, at which time a few drops of concentrated aqueous ammonium hydroxide were added and the solvent was evaporated. Ether and water were added and the aqueous layer was extracted with ether. The combined ether extracts were dried ($MgSO_4$), filtered, and the solvent evaporated to provide 0.068 g crude material. The crude material was purified by simply filtering it through a silica gel plug to provide the product **40** (0.068 g, 90%) as white crystals (mp 86–88°C); ir ($CHCl_3$, cm^{-1}): 2944, 1711, 1453, 1384, 1234, 1197, 1102, 1059; ^1H nmr ($CDCl_3$, ppm): 4.43 and 3.83 (AB, J = 12 Hz, 2H), 3.51 (dd, J = 4.2 Hz and 12 Hz, 1H), 2.69–2.87 (m, 1H), 2.05–2.33 (m, 2H), 1.54–2.05 (m, 10H), 1.44 (s, 3H), 1.36 (s, 3H); ^{13}C nmr ($CDCl_3$, ppm): 210.5, 99.5, 75.7, 69.4, 52.9, 41.4, 39.1, 29.7, 27.5, 27.1, 25.2, 24.1, 22.6, 18.6; ms: 256 (7, M + NH_4^+), 239 (100, M + H^+), 181(19), 151(9). Exact Mass calcd. for $C_{14}H_{22}O_3$ + H^+: 239.1647; found: 239.1648.

X-ray structure determination of ***40***

The data were collected on a Rigaku AFC6S diffractometer with a graphite monochromator with CuKα radiation (λ = 1.5405 Å). The linear absorption coefficient for CuKα is 6.4 cm^{-1}. Cell constants and an orientation matrix for data collection, obtained by least squares using the setting angles of 22 reflections with 2θ angle in the range 84.00–109.00°, corresponded to a monoclinic cell with dimensions: a = 6.7423(4) Å; b = 16.354(2) Å; c = 12.149(1) Å; β = 105.012(7)°; V = 1293.9(2) $Å^3$. For Z = 4 and F. W. = 238.32, the calculated density is 1.223 Mg/m^3. The space group was determined to be $P2_1/n$. The data were collected at a temperature of 20 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 110.0°. A correction for secondary extinction (coefficient = 1.917373) was applied; σ = 0.077671. The standard intensities dropped an average of 2.83%; merging R = 0.9% for 163 symmetry equivalent pairs. No correction was made for absorption. The structure was solved by direct methods. All non-H atoms were refined anisotropically and H atoms were found in a difference map and refined isotropically. Full-matrix least-squares refinement converged to R = 0.036, R_w = 0.035. The standard

For personal use only.

deviation of an observation of unit weight was 4.82. The maximum shift/σ ratio was 0.032. The weighting scheme was based on counting statistics. The weight modifier K in KF_o^2 is 0.000010. The maximum and minimum peaks on the final difference Fourier map correspond to 0.14 and −0.13 e/Å^3, respectively. All calculations were made with the NRCVAX (25) crystallographic software package. Figure 2 was prepared from the output of ORTEPII (27).

cis-*8a-Acetoxymethyl-1α-acetoxy-1,3,4a,4,5,6,8a-septahydronaphthalene-8(2H,7H)-one* (**15**)

To a solution of the diol **38** (0.028 g; 0.14 mmol) in 2.0 mL acetic anhydride at room temperature under argon was added pyridine (0.070 mL; 0.87 mmol), followed by a catalytic amount of dimethylaminopyridine. The mixture was heated at 50°C and stirred for 3 h at which time the reaction was complete. The mixture was allowed to cool down and was then diluted with ether (2 mL) and quenched with saturated ammonium chloride solution (5 mL). The aqueous layer was extracted with ether (3 × 10 mL). The combined ether extracts were dried ($MgSO_4$), filtered, and the solvent was removed to provide 0.059 g crude material. Column chromatography (eluting first with 1:4 EtOAc:hexane and then with 1:1 EtOAc:hexane) provided the diacetate **15** as a pale orange oil (0.054 g, quantitative) that crystallized on standing (mp 83–85°C); ir ($CHCl_3$, cm^{-1}): 3029, 2947, 1741, 1736, 1374, 1233, 1212, 1042, 784; ^{1}H nmr ($CDCl_3$, ppm): 4.76 (dd, J = 3.7 Hz and J = 9.5 Hz, 1H), 4.36 (s, 2H), 2.41–2.59 (m, 2H), 2.04 (s, 3H), 2.02 (s, 3H), 1.37–2.39 (m, 11H); ^{13}C nmr ($CDCl_3$, ppm): 210.0, 170.6, 170.2, 73.7, 63.6, 55.5, 40.4, 38.2, 27.2, 27.1, 26.1, 22.6, 21.4, 20.8, 20.3; ms: 300 (100, M + NH_4^+), 283 (9, M + H^+), 223(33). Exact Mass calcd. for $C_{15}H_{22}O_5$ + H^+: 283.1544; found: 283.1544.

Ethylene ketal of cis-*8a-[[(benzyloxy)methoxy]methyl]-3β-methyl-4,4a,5,6,8a-pentahydronaphthalene-1,8(2H,7H)-dione* (**41**)

To a suspension of cuprous iodide (0.1224 g; 0.62 mmol) in 1.3 mL dry ether at −35°C under argon was added 1.4 M MeLi (0.89 mL; 1.25 mmol). The mixture was then cooled to −78°C and the starting enone **35** (0.075 g; 0.21 mmol) in 3.3 mL dry ether was added. After stirring at −78°C for 15 min, the reaction mixture was warmed to −35°C and stirred for 4 h. The reaction was then quenched by the addition of saturated ammonium chloride solution (4.0 mL). The aqueous phase was extracted with ether (3 × 10 mL) and the combined ether extracts were dried ($MgSO_4$), filtered, and the solvent removed. Column chromatography (1:4 EtOAc:hexane) provided the monomethyl product **41** (0.076 g, 95%) as a clear oil; ir ($CHCl_3$, cm^{-1}): 2958, 1711, 1456, 1229, 1170, 1041, 720; ^{1}H nmr ($CDCl_3$, ppm): 7.25–7.34 (m, 5H), 4.72 (s, 2H), 4.58 (s, 2H), 4.19 (AB, J = 10 Hz, 1H), 3.78–3.95 (m, 5H), 1.30–2.61 (m, 12H), 0.98 (d, J = 6.5 Hz, 3H); ^{13}C nmr ($CDCl_3$, ppm): 210.8, 138.0, 128.4, 127.8, 127.7, 110.4, 95.3, 70.3, 69.6, 64.6, 63.9, 59.7, 48.9, 34.2, 32.2, 28.9, 27.5, 25.5, 21.4, 20.4; ms: 375 (19, M + H^+), 345(13), 268(17), 267(100), 237(12). Exact Mass calcd. for $C_{22}H_{30}O_5$ + H^+: 375.2172; found: 375.2171.

Ethylene ketal of cis-*8a-[[(benzyloxy)methoxy]methyl]-1α-hydroxy-3β-methyl-1,4,4a,5,6,8a-hexahydronaphthalene-8(2H,7H)-one* (**42**)

To a solution of the crude starting material **41** (0.073 g; 0.20 mmol) in 9.0 mL ether at 0°C under argon was added lithium aluminum hydride (0.024 g; 0.62 mmol). After stirring for 3 hr at 0°C, the reaction was quenched with 5 mL saturated ammonium chloride solution. The aqueous layer was extracted with ether (3 × 10 mL ether) and the combined ether extracts were dried ($MgSO_4$), filtered, and the solvent removed. Column chromatography of the crude material (1:4 EtOAc:hexane) provided the product **42** (0.077 g, 89% from enone **35**), a pale yellow oil, as a mixture of two isomers in a ratio of 3:1. These isomers could not be separated in an EtOAc:hexane or a benzene:acetone solvent system and were thus carried on to the next step as a mixture; ir ($CHCl_3$, cm^{-1}): 3494, 2952, 1456, 1176, 1081, 1041; ^{1}H nmr ($CDCl_3$, ppm): 7.30–7.41 (m, 5H), 4.76 and 4.79 (two s in a 3:1 ratio, 2H), 4.61 and 4.64 (two s in a 3:1 ratio, 2H), 4.13–4.37 (m, 1H), 3.83–4.08 (m, 4H), 3.74–3.82 (m, 2H), 1.10–2.80 (m, 12H), 0.88 and 0.95 (two d in a 1:3 ratio, J = 6.2 Hz, 3H); D_2O exchange simplifies one of the multiplets to: 1.10–2.56 (m, 11H); ^{13}C nmr ($CDCl_3$, ppm): 138.0, 128.4, 128.0, 127.7, 114.4, 95.4, 69.5, 69.0, 65.6, 64.9, 63.7, 47.6, 38.9, 38.3, 36.1, 33.7, 30.4, 27.3, 25.2, 22.5. All signals in the ^{13}C nmr spectrum are doubled.

cis-*8a-[[(Benzyloxy)methoxy]methyl]-1α-hydroxy-3β-methyl-1,4,4a,5,6,8a-hexahydronaphthalene-8(2H,7H)-one* (**43**a) *and* cis-*8a-[[(benzyloxy)methoxy]methyl]-1β-hydroxy-3β-methyl-1,4,4a,5,6,8a-hexahydronaphthalene-8-(2H,7H)-one* (**43**b)

To a solution of the alcohol mixture **42** (0.065 g; 0.17 mmol) in 1.20 mL THF at room temperature was added 5% HCl (0.39 mL; 0.54 mmol). After stirring for 4 h at room temperature, sodium bicarbonate solution and ether were added. The aqueous layer was extracted with ether and the combined ether extracts were dried ($MgSO_4$), filtered, and the solvent removed. Column chromatography (1:3 EtOAc:hexane) of the crude material provided the keto-alcohols **43***a* (0.034 g, 60%) and **43***b* (0.011 g, 20%).

43*a*: ir ($CHCl_3$, cm^{-1}): 2949, 1691, 1457, 1111, 1036; ^{1}H nmr ($CDCl_3$, ppm): 7.25–7.42 (m, 5H), 4.78 (s, 2H), 4.60 (s, 2H), 3.93 and 3.78 (AB, J = 9.2 Hz, 2H), 3.69–3.85 (m, 1H), 1.35–2.90 (m, 12H), 1.20–1.35 (m, 1H), 0.97 (d, J = Hz, 3H); ^{1}H nmr (200 MHz, C_6D_6): 7.10–7.50 (m, 5H, hidden under C_6D_6 solvent), 4.69 and 4.64 (AB, J = 6 Hz, 2H), 4.61 and 4.55 (AB, J = 11.2 Hz, 2H), 3.93 and 3.69 (AB, J = 9 Hz, 2H), 3.75 (dt, J = 3 Hz and J = 8 Hz, 1H), 2.40–2.54 (m, 1H), 2.33 (t, J = 6 Hz, 2H), 2.10–2.25 (m, 1H), 1.82–2.06 (m, 1H), 1.48–1.82 (m, 4H), 1.24–1.46 (m, 2H), 1.01–1.17 (m, 1H), 0.84 (d, J = 6.8 Hz, 3H); ^{13}C nmr ($CDCl_3$, ppm): 216.6, 137.7, 128.4, 128.0, 127.7, 95.0, 69.7, 69.6, 67.8, 57.3, 40.6, 38.3, 34.7, 33.8, 26.2, 24.7, 21.9, 19.7.

43*b*: ^{1}H nmr ($CDCl_3$, ppm): 7.26–7.44 (m, 5H), 4.77 (s, 2H), 4.62 (s, 2H), 4.15–4.18 (dd, J = 4 Hz and J = 10 Hz, 1H), 4.11 and 3.85 (AB, J = 10 Hz, 2H), 3.09 (d, J = 5 Hz, 1H), 2.34–2.72 (m, 2H), 2.16–2.34 (m, 1H), 1.65–2.09 (m, 5H), 1.16–1.65 (m, 4H), 0.94 (d, J = 6.6 Hz, 3H); ^{1}H nmr (200 MHz, C_6D_6): 7.06–7.46 (m, 5H, hidden under C_6D_6 solvent), 4.68 (s, 2H), 4.50 (s, 2H), 4.32 and 3.88 (AB, J = 10 Hz, 2H), 3.88–3.99 (m, 1H), 2.94 (d, J = 5.2 Hz, 1H), 2.25–2.37 (m, 1H), 2.03–2.24 (m, 1H), 1.74 (dt, J = 4 Hz and J = 12 Hz, 1H), 1.32–1.61 (m, 4H), 1.01–1.21 (m, 4H), 0.78 (d, J = 6 Hz, 3H); ^{13}C nmr ($CDCl_3$, ppm): 215.2, 137.9, 128.5, 128.1, 127.8, 95.2, 70.1, 69.8, 66.5, 56.9, 39.3, 38.5, 38.3, 35.5, 27.0, 26.6, 24.4, 22.2.

cis-*8a-Hydroxymethyl-1α-hydroxy-3β-methyl-1,4,4a,5,6,8a-hexahydronaphthalene-8(2H,7H)-one* (**44**a)

To a solution of the alcohol **43***a* (0.018 g; 0.05 mmol) in 0.8 mL absolute ethanol under argon was added 20% palladium hydroxide on carbon (0.030) g) and cyclohexene (0.80 mL; 7.9 mmol). The mixture was stirred at 70°C for 20 h, whereupon the catalyst was removed by filtration through a Celite pad. Column chromatogrpahy (1:3 EtOAc:hexane) of the crude material provided the keto-diol **44***a* (0.009 g, 65%) together with some recovered keto-monoalcohol **43***a* (0.006 g, 35%).

44*a*: ir ($CHCl_3$, cm^{-1}): 3503, 2949, 1693, 1421, 1230, 1073; ^{1}H nmr ($CDCl_3$, ppm): 4.38 (t, J = 11.7 Hz, 1H), 3.70–3.90 (m, 3H), 3.34 (d, J = 11.7 Hz, 1H), 2.55–2.73 (m, 1H), 2.26–2.43 (m, 1H), 1.82–2.22 (m, 5H), 1.45–1.74 (m, 3H), 1.14–1.34 (m, 2H), 0.98 (d, J = 7.2 Hz, 3H); D_2O simplifies the region downfield of 3.5 ppm to: 4.27 and 3.84 (AB, J = 11.7 Hz, 2H), 3.82 (dd, J = 3 Hz and J = 8 Hz, 1H); ^{13}C nmr ($CDCl_3$, ppm): 218.0, 75.0, 70.5, 57.9, 40.0, 37.9, 35.3, 34.0, 26.3, 26.1, 22.4, 18.7.

cis-*8a-Acetoxymethyl-1α-acetoxy-3β-methyl-1,4,4a,5,6,8a-hexahydronaphthalene-8(2H,7H)-one* (**16**)

To a solution of the methyl keto-diol **44***a* (0.016 g; 0.075 mmol) in 1.50 mL acetic anhydride under argon was added pyridine (0.04 mL; 0.50 mmol) and a catalytic amount of DMAP. The

mixture was stirred at 45°C for 1.5 h, whereupon saturated ammonium chloride solution and ether were added. The aqueous layer was extracted with ether and the ether extracts were dried ($MgSO_4$), filtered, and the solvent removed. Column chromatography (1:3 EtOAc:hexane) of the crude material afforded the diacetate **16** (0.017 g, 75%); ir ($CHCl_3$, cm^{-1}): 2949, 1731, 1702, 1458, 1378, 1248, 1035; ^1H nmr ($CDCl_3$, ppm): 4.86 (br t, J = 3 Hz, 1H), 4.27 and 4.22 (AB, J = 10.6 Hz, 2H), 2.45–2.63 (m, 1H), 2.10 (s, 6H), 1.07–2.37 (m, 11H), 0.88 (d, J = 6.1 Hz, 3H); ^{13}C nmr ($CDCl_3$, ppm): 211.7, 170.6, 169.0, 74.2, 64.4, 53.1, 40.9, 35.9, 35.6, 35.0, 27.4, 22.5, 21.8, 21.4, 20.9; ms: 314 (100, M + NH_4^+), 237(40). Exact Mass calcd. for $C_{16}H_{24}O_5 + H^+$: 297.1073; found: 297.2702.

Ethylene ketal of cis-*8a-[[(benzyloxy)methoxy]methyl]-3-methyl-4a,5,6,8a-tetrahydronaphthalene-1,8(4*H,7H*)-dione (**45**)*

To a suspension of copper iodide (0.030 g; 0.16 mmol) in 0.50 mL dry ether at −30°C under argon was added 1.4 M MeLi (0.23 mL; 0.32 mmol). The first few drops cause the appearance of a bright yellow precipitate, due to the presence of excess copper iodide. As one approaches the "end-point," this precipitate disappears. Enough MeLi is added so that there is only a slight excess of copper iodide. The mixture was then cooled down to −78°C and the protected enone **44** (0.041 g; 0.088 mmol) in 1.5 mL dry ether was added, causing the mixture to turn orange and thicken. The mixture was stirred for 1 h at −78°C and then quenched by the addition of saturated ammonium chloride solution at −30°C and extracted with ether (3 × 10 mL). The organic extracts were dried ($MgSO_4$), filtered, and the solvent removed to provide 0.031 g crude material. Column chromatography (1:4 EtOAc:hexanes) provided the product **45** (0.027 g, 86%) as a clear oil; ir ($CHCl_3$, cm^{-1}): 3016, 1654, 1205, 1026, 774, 738, 675; ^1H nmr ($CDCl_3$, ppm): 7.29–7.40 (m, 5H), 5.91 (s, 1H), 4.73 and 4.68 (AB, J = 8 Hz, 2H), 4.55 (s, 2H), 4.38 (AB, J = 10 Hz, 1H), 3.67–3.86 (m, 5H), 2.78–2.95 (m, 2H), 1.94 (s, 3H), 1.50–2.05 (m, 7H); ^{13}C nmr ($CDCl_3$, ppm): 198.8, 162.1, 138.0, 128.4, 127.9, 127.6, 127.5, 110.8, 95.2, 69.5, 67.2, 65.1, 64.6, 55.1, 34.3, 33.5, 32.9, 25.5, 24.5, 18.7; ms: 373 (55, M + H^+), 265(100), 203(50). Exact Mass calcd. for $C_{22}H_{28}O_5 + H^+$: 373.2014; found: 373.2015.

Ethylene ketal of cis-*8a-[[(benzyloxy)methoxy]methyl]-3,3-dimethyl-2,4a,5,6,8a-pentahydronaphthalene-1,8(4*H,7H*)-dione (**46**)*

To a suspension of copper iodide (0.206 g; 1.09 mmol) in 4 mL dry ether at −30°C under argon was added 1.4 M MeLi (1.5 mL; 2.13 mmol). The mixture was cooled down to −78°C and a solution of the ketal **34** (0.130 g; 0.278 mmol) in 2.0 mL dry ether was added. The thick orange mixture was stirred for 15 min at −78°C, followed by 4 h at −30°C. The reaction was then quenched by the addition of saturated ammonium chloride solution at −30°C and extracted with ether (3 × 10 mL). The combined ether extracts were dried ($MgSO_4$), filtered, and the solvent removed to provide 0.099 g crude material. Column chromatography provided the β,β-dialkylated product **46** (0.091 g, 85%) as a clear oil, which crystallized (mp 79–80°C) upon standing; ir ($CHCl_3$, cm^{-1}): 2958, 1696, 1229, 1049, 759; ^1H nmr ($CDCl_3$, ppm): 7.22–7.43 (m, 5H), 4.72 (q, J = 6 Hz, 2H), 4.57 (s, 2H), 4.38 (AB, J = 10 Hz, 1H), 3.67–3.84 (m, 5H), 2.74–2.88 (m, 1H), 2.11–2.50 (m, 4H), 1.34–1.90 (m, 5H), 1.13–1.28 (m, 1H), 1.01 (s, 3H), 0.93 (s, 3H); ^{13}C nmr ($CDCl_3$, ppm): 211.0, 138.1, 128.4, 128.0, 127.6, 110.0, 95.2, 69.5, 67.0, 64.1, 64.0, 58.0, 55.7, 40.5, 33.1, 32.6, 32.3, 31.4, 26.8, 26.5, 18.8; ms: 388 (7, M^+), 297(32), 267(47), 112(70), 99(99), 91(100), 86(86), 55(48), 41(30), 28(39). Exact Mass calcd. for $C_{23}H_{32}O_5 + H^+$: 389.2329; found: 389.2328.

Ethylene ketal of cis-*8a-[[(benzyloxy)methoxy]methyl]-1α-hydroxy-3,3-dimethyl-1,4,4a,5,6,8a-hexahydronaphthalene-1,8(2*H,7H*)-dione (**47**)*

To a solution of the crude starting material **46** (0.114 g; 0.294 mmol) in 8.0 mL ether at 0°C under argon was added lithium aluminum hydride (0.024 g; 0.63 mmol). The mixture was stirred for 2.5 h at 0°C and then diluted with more ether (5 mL) and quenched with saturated ammonium chloride solution (7 mL). The aqueous layer was extracted with ether (3 × 10 mL) and the ether extracts were dried ($MgSO_4$), filtered, and the solvent evaporated to provide 0.099 g crude material. Column chromatograph (1:4 EtOAc:hexane) provided the alcohol **47** (0.085 g, 78% from ketal **34**) as a pale yellow oil; ir ($CHCl_3$, cm^{-1}): 3493, 3009, 2965, 1455, 1208, 1168, 1107, 1034, 1006, 924; ^1H nmr ($CDCl_3$, ppm): 7.22–7.41 (m, 5H), 4.82 (s, 2H), 4.63 (s, 2H), 3.65–4.18 (m, 8H), 2.12–2.31 (m, 1H), 1.99 (t, J = 17 Hz, 2H), 1.40–1.80 (m, 6H), 1.10–1.31 (m, 1H), 0.95 (s, 3H), 0.94 (s, 3H); ^{13}C nmr ($CDCl_3$, ppm): 138.0, 128.4, 128.0, 127.7, 114.3, 95.2, 70.6, 69.6, 67.9, 63.5, 62.2, 46.8, 44.1, 40.3, 33.2, 31.8, 31.3, 30.8, 26.4, 26.0, 18.5; ms: 391 (22, M + H^+), 373(23), 329(18), 299(57), 284(18), 283(100), 269(42), 265(31), 253(20), 251(8), 238(10), 237(64), 235(23), 222(15), 221(77), 191(11), 175(41), 99(20). Exact Mass calcd. for $C_{23}H_{34}O_5 + H^+$: 391.2483; found: 391.2485.

cis-*8a-(Hydroxymethyl)-1α-hydroxy-3,3-dimethyl-1,4,4a,5,6,8a-hexahydronaphthalene-8(2*H,7H*)-one (**48**)*

To a solution of the protected dimethyl monoalcohol **47** (0.089 g; 0.228 mmol) in 2.2 mL absolute ethanol was added 20% palladium hydroxide on carbon (0.151 g), followed by cyclohexene (4.70 mL; 46.5 mmol). After stirring the mixture overnight at 70°C, the catalyst was removed by filtration and the solvent removed, providing 0.035 g crude material. Column chromatography (1:1 EtOAc:hexane) provided the dimethyl keto-diol **48** (0.011 g, 20%) as a white solid (mp 149–151°C), the protected dimethyl diol **50** (0.005 g, 7%) as a white solid (mp 120–121°C), the deprotected dimethyl keto-alcohol **49** (0.011 g, 15%), and some recovered starting material **47** (0.031 g, 35%). Resubjecting **49** to the reaction conditions provided **48** in quantitative yield.

Exact Mass calcd. for $C_{13}H_{22}O_3 + H^+$: 227.1647; found: 227.1647.

49: ^1H nmr ($CDCl_3$, ppm): 7.35 (s, 5H), 4.82 (s, 2H), 4.64 (s, 2H), 4.00 (s, 2H), 3.49–3.81 (m, 2H), 1.05–2.55 (m, 11H), 0.95 (s, 3H), 0.93 (s, 3H).

50: ir ($CHCl_3$, cm^{-1}): 3510, 2959, 1418, 1199, 1118, 1016; ^1H nmr ($CDCl_3$, ppm): 4.40 and 3.57 (AX, J = 11.8 Hz, 2H), 3.80–4.18 (m, 7H), 1.88–2.06 (m, 2H), 1.35–1.83 (m, 7H), 1.18–1.30 (m, 1H), 0.93 (s, 6H), 0.75–0.88 (m, 1H).

*Preparation of dimethyl keto-diol **48** from the ketal **50***

To a solution of the ketal **50** (0.023 g; 0.082 mmol) in 0.40 mL THF at room temperature was added 5% HCl (0.18 mL; 0.25 mmol). After stirring for 10 h at room temperature, sodium bicarbonate solutions and ether were added. The aqueous layer was extracted with ether and the combined ether extracts were dried ($MgSO_4$), filtered, and the solvent removed. Column chromatography (1:2 EtOAc:hexane) of the crude material provided the keto-diol **48** (0.022 g, 95%). The spectral data for the keto-diol are given at the end of the preceding experimental procedure.

*X-ray structure determination of **48***

All measurements were made on a Rigaku AFC6S diffractometer with graphite monochromated CuKα radiation (λ = 1.54178 Å). Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 16 carefully centered reflections in the range $21.22° < < 37.88°$, corresponded to a triclinic cell with dimensions a = 8.455(6) Å; b = 12.68(1) Å; c = 6.241(8) Å; V = 621(1) $Å^3$; α = 96.8 (1)°;

For personal use only.

$\beta = 105.25(8)°$; $\gamma = 101.94(8)°$. For $Z = 2$ and F. W. = 226.31, the calculated density is 1.210 g/cm^3. Based on packing considerations, a statistical analysis of intensity distribution, and the successful solution and refinement of the structure, the space group was determined to be $P\bar{1}$ (no. 2). The data were collected at a temperature of 20 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 119.6° Omega scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.59° with a take-off angle of 6.0°. Scans of $(1.78 + 0.30 \tan \theta)°$ were made at a speed of 32.0°/min (in omega). The weak reflections ($I < 10.0\sigma(I)$) were rescanned (maximum of 2 rescans) and the counts were accumulated to assure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. The intensities of three representative reflections that were measured after every 150 reflections remained constant throughout data collection. No decay correction was applied. The linear absorption coefficient for CuKα is 6.4 cm^{-1}. An empirical absorption correction, using the program DIFABS (28), was applied, which resulted in transmission factors ranging from 0.61 to 1.49. The data were corrected for Lorentz and polarization effects. The structure was solved by direct methods. Full-matrix least-squares refinement with anisotropic factors given to all non-H atoms converged to $R = 0.055$, $R_w = 0.037$. The standard deviation of an observation of unit weight was 4.04. The weighting scheme was based on counting statistics and included a factor ($p = 0.00$) to downweight the intense reflections. The maximum shift/error in the final cycle was 0.00. The maximum and minimum peaks on the final difference Fourier map correspond to 0.18 and −0.21 e/Å^3, respectively. Neutral atom scattering factors were taken from Cromer and Waber (29). Anomalous dispersion effects were included in F_{calc} (30); the values for $\Delta f'$ and $\Delta f''$ were those of Cromer (31). All calculations were performed using the TEXSAN (26) crystallographic software package of Molecular Structure Corporation. Figure 4 was prepared from the output of ORTEPII (27).[5]

cis-*8a-(Acetoxymethyl)-1α-acetoxy-3,3-dimethyl-1,4,4a,5,6,8a-hexahydronaphthalene-8(2*H,*7*H)*-one (17)*

To a solution of the dimethyl keto-diol **48** (0.021 g; 0.095 mmol) in 3 mL of 2:1 acetic anhydride:methylene chloride (as the starting material would not dissolve in acetic anhydride alone) under argon at room temperature was added pyridine (0.050 mL; 0.58 mmol) and a catalytic amount of DMAP. The mixture was then stirred at 50°C for 1.5 h, at which time the solvent was removed. To the residue was added ether and saturated ammonium chloride solution. The aqueous layer was extracted with ether and the combined ether extracts were dried ($MgSO_4$), filtered, and the solvent removed to give 0.032 g crude material. Column chromatography (1:10 spectrograde acetone:benzene) provided both the monoacetate **51** (0.006 g, 23%) and the diacetate **17** (0.019 g, 65%). These two compounds were inseparable in an EtOAc:hexane solvent system. Resubjecting the monoacetate to the reaction conditions for 1.5 h at 45°C, with 4 equivalents rather than 6 equivalents of pyridine, smoothly transformed it into the diacetate.

[5]Details of experimental procedures and tables of all atomic positional and thermal parameters, and atomic distances and angles, for the crystallographic structure of compounds **40** and **48** have been deposited as Supplementary Material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of positional parameters and atomic distances and angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Laboratoire de chimie des matériaux inorganiques, Unité de recherche associée au Centre National de la recherche scientifique n° 1311, Université Paul Sabatier, 118 Route de Narbonne, 31062 Toulouse Cédex, France

Reçu le 23 juillet 1992[2]

YOUSSEF KANDRI RODI, LUCIEN LOPEZ, CHRISTIAN MALAVAUD, MARIE-THÉRÈSE BOISDON et JEAN-PIERRE FAYET. Can. J. Chem. **71**, 1200 (1993).

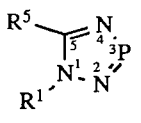
La synthèse de nouveaux 1,2,4,3-triazaphospholes est décrite : des 5-méthylthio 1,2,4,3-triazaphospholes substitués en 1, 2 ou 4. Le dérivé substitué en 1,5 **6** est stable tandis que les composés **14** et **16** substitués en position-2,5 sont en équilibre avec leurs tétramères $[\mathbf{14}]_4$ et $[\mathbf{16}]_4$. Les 5-méthylthio 4-alkyl 1,2,4,3-triazaphospholes n'existent que sous leurs formes tétramériques $[\mathbf{12}]_4$ et $[\mathbf{13}]_4$. La complexation dépolymérisante de $[\mathbf{12}]_4$ par un acide de Lewis, conduit au triazaphosphole complexé $\mathbf{12},BF_3$. La position du reste triméthylsilyle du composé **16**, obtenu par silylation de **15**, a été confirmée par RMN de ^{15}N. L'étude de la stabilité de ces systèmes par la méthode MNDO est en accord avec les résultats expérimentaux, comme l'action des 1,4-diaza-1,3-diènes avec les triazaphospholes qui conduit aux dérivés spiranniques du phosphore tétracoordonné : **21–25**.

YOUSSEF KANDRI RODI, LUCIEN LOPEZ, CHRISTIAN MALAVAUD, MARIE-THÉRÈSE BOISDON, and JEAN-PIERRE FAYET. Can. J. Chem. **71**, 1200 (1993).

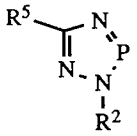
The synthesis of new 1,2,4,3-triazaphospholes is described: a number of 5-methylthio 1,2,4,3-triazaphospholes, substituted in the 1, 2, or 4 position. The 1,5-disubstituted compound **6** is stable, whereas 2,5-disubstituted compounds **14** and **16** undergo an equilibrium with their tetrameric form, the cyclotetraphosphazanes $[\mathbf{14}]_4$ and $[\mathbf{16}]_4$. 5-Methylthio 4-alkyl 1,2,4,3-triazaphospholes exist only in the tetrameric forms $[\mathbf{12}]_4$ and $[\mathbf{13}]_4$. $[\mathbf{12}]_4$ can be depolymerized by complexation with a Lewis acid, giving the complexed triazaphosphole $\mathbf{12} \cdot BF_3$. The ^{15}N NMR spectrum of compound **16**, the N-silylated derivative of **15**, allows us to confirm the position of the trimethylsilyl group. MNDO calculations are in good agreement with experimental results, such as the reaction of 1,4-diazadienes with triazaphospholes providing new tetracoordinated phosphorus spirocompounds **21–25**.

Introduction

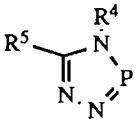
Les 1,2,4,3-triazaphospholes peuvent exister sous trois formes isomères : **1**, **2**, **3**.



1

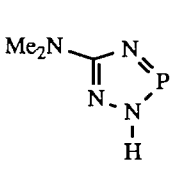


2

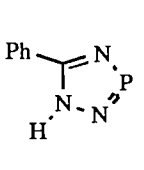


3

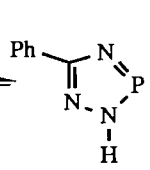
Seuls les dérivés disubstitués en 1,5 (**1**) et en 2,5 (**2**) par des groupements alkyles, dialkylamino- ou aryles sont stables (1, 2). La complexation par un acide de Lewis (BF_3) en position 2 stabilise l'isomère **3**; elle a permis une détermination de la structure d'un isomère **3** (R = R' = iPr) par diffraction des rayons X, ainsi que l'observation par RMN de ^{31}P d'isomères complexés par BF_3 (3), comme cela a déjà été signalé pour les 1,3,2-diazaphospholes (4). Les dérivés monosubstitués sont rares; seuls les composés **4** (2*b*) et **5** (2*c*) ont été décrits.



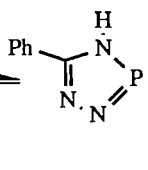
4 (2b)



5 H-1 (2c)



5 H-2



5 H-4

Nous avons récemment obtenu le 1-méthyl 5-méthylthio 1,2,4,3-triazaphosphole **6** par action de l'iodure de méthyle sur un sel de triazaphospholinium (5) :

1. Auteurs à qui adresser toute correspondance.
2. Revision reçue le 3 mai 1993.

6

La présence de l'atome de soufre en position 5 introduit un facteur de délocalisation électronique dans ces molécules et nous a incité à étudier la synthèse de triazaphospholes substitués par des groupements 5-méthylthio. Nous avons effectué des calculs MNDO sur divers 1,2,4,3-triazaphospholes pour essayer d'interpréter leurs différences de stabilité. Enfin nous avons étudié l'addition des 1,4-diaza 1,3-dienes sur ces 5-méthylthio triazaphospholes : la réaction dépend de l'électrophilie de l'atome de phosphore.

Résultats et discussion

1. Synthèse des iodhydrates de 3-méthylthio semicarbazides

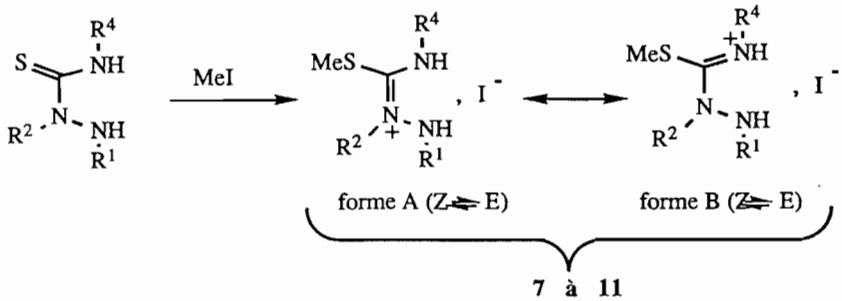
Les triazaphospholes **1**, **2**, **3** sont obtenus, le plus souvent, par action de la tris(diméthylamino)phosphine sur les chlorhydrates (ou iodhydrates) d'amidrazones correspondants (1, 2*b*, 2*d*, 3), dont la synthèse nécessite plusieurs étapes (3, 6).

Nous avons utilisé une réaction analogue à partir des iodhydrates de 3-méthylthio semicarbazides **7**–**11**, qui sont obtenus avec de bons rendements par addition de l'iodure de méthyle sur les thiosemicarbazides correspondantes (7).

2. Synthèse des 5-méthylthio 1,2,4,3-triazaphospholes

L'ensemble des réactions de la tris(diméthylamino)-phosphine effectuées sur les iodhydrates des 3-méthylthio semicarbazides **7**–**11** est présenté dans le schéma 1.

Les 3-méthylthio semicarbazides conduisent, suivant la position et la nature du substituant sur l'azote, à trois types de dérivés : (*i*) des composés stables du phosphore dicoordonné **6** et **15**; (*ii*) des composés du phosphore dicoordonné **14** et **16** en équilibre thermique observable avec leurs tétramères : composés du phosphore tricoordonné $[\mathbf{14}]_4$ et $[\mathbf{16}]_4$; (*iii*) des tétramères $[\mathbf{12}]_4$ et $[\mathbf{13}]_4$.



forme A (Z ⇌ E) forme B (Z ⇌ E)

R^2	H	H	Me	H	H
R^4	H	H	H	Me	Et

Synthèse des tétramères [12]$_4$ et [13]$_4$

À partir des 3-méthylthio semicarbazides **10** et **11**, on obtient respectivement les tétramères $[\mathbf{12}]_4$ et $[\mathbf{13}]_4$, mis en évidence par RMN de ^{31}P et par spectrométrie de masse par ionisation chimique, dans le méthane. Par chauffage de $[\mathbf{12}]_4$ et de $[\mathbf{13}]_4$, dans le toluène ou la pyridine à l'ébullition, on n'observe pas en RMN de ^{31}P, d'équilibre tétramère ⇌ monomère, comme dans le cas de cyclotétraphosphazanes dérivant de 4,5-benzo 1,3,2-diazaphospholes (4). Le composé $[\mathbf{12}]_4$ est facilement dépolymérisable par action du trifluorure de bore. Le monomère complexé **12**,BF_3 a été caractérisé par analyse et par spectrographie de RMN de ^1H, ^{31}P, ^{13}C, ^{11}B, par IR et par son spectre de masse. Ces données sont en faveur d'une complexation de BF_3 en position 2 (J_{PF} = 35 Hz), comme dans le 4,5-diisopropyl 1,2,4,3-triazaphosphole (3).

*Synthèse des monomères **6** et **15***

Le composé **6** a déjà été préparé par action de l'iodure de méthyle sur un sel de triazaphospholinium (5). Il s'obtient également à partir de l'iodhydrate de 3-méthylthio semicarbazide **9** et de la tris(diméthylamino)phosphine. Le dérivé **15**, obtenu à partir de la 3-méthylthio semicarbazide **8**, est solide à la température ordinaire. Ses caractéristiques physicochimiques (RMN ^1H, ^{13}C, IR, spectre de masse) indiquent qu'il s'agit d'un dérivé du phosphore dicoordonné monomère; cependant il peut exister sous trois formes isomères selon la position du proton sur les azotes 1, 2 ou 4. Le spectre RMN de ^{31}P du mélange réactionnel de **15** dans le toluène montre deux signaux P^{II} à 250 et 246 ppm et un massif bien résolu entre 71,15 et 63,8 ppm, alors que le spectre de **15** isolé puis dissous dans la pyridine présente, à température ambiante, un seul signal large entre 254 et 250 ppm. Ce signal pourrait correspondre à un échange rapide entre les trois isomères facilité par la basicité de la pyridine. Quand on chauffe la solution jusqu'à 90°C, l'allure du signal reste inchangée; par contre, quand on refroidit

SCHÉMA 1. Synthèse des 5-méthylthio 1,2,4,3-triazaphospholes.

jusqu'a −35°C, on observe un affinement du signal vers 252 ppm et l'apparition de plusieurs signaux dans le domaine des composés du phosphore tricoordonné : un signal large vers 58 ppm, qui pourrait être l'oligomère du composé **15** H-2 et un système AA'XX' (δ = 74,1 et 63,3 ppm; $J_{PNP} + J'_{PNP}$ = 136 Hz) analogue à ceux que l'on observe dans les 1,2,4,3-triazaphospholes 4,5-disubstitués (3); nous pensons donc que ce système est dû à la présence de l'oligomère de **15** H-4. Quand on revient à la température ordinaire, les signaux des composés du phosphore tricoordonnè disparaissent, et on observe à nouveau le signal large vers 252 ppm, montrant qu'il s'agit d'un équilibre thermique.

À partir des composés du phosphore dicoordonné **15** et **6**, nous avons préparé les composés du phosphore tétracoordonné **17** et **18** par addition d'ammoniac en présence de soufre (schéme 2).

Cette addition d'ammoniac, en présence de soufre, a déjà été observés sur des 1,2,4,3-triazaphospholes disubstitués par des groupements aryles ou alkyles (8). Le composé **18** réagit lentement avec la pyridine. Au bout d'une heure, on observe la précipitation d'un nouveau produit **19**, forme salifiée de **18**.

Synthèse des tétramères [14]$_4$ et [16]$_4$ en équilibre avec leur forme monomère

Le dérivé [**14**]$_4$ obtenu par action de la méthylthiosemicarbazide **7** sur la tris(diméthylamino)phosphine et le dérivé [**16**]$_4$ est obtenu à partir de **15** (schéma 1). Leurs spectres de masse obtenus par ionisation chimique (CH_4), montrent qu'il s'agit de tétramères. À la température ordinaire, ces dérivés sont des oligomères de composés du phosphore dicoordonné; si on les chauffe en solution dans la pyridine, on observe en RMN de ^{31}P les signaux des monomères **14** et **16**. Les caractéristiques de ces équilibres sont rassemblées dans le tableau 1.

Lors de la silylation de **15** par action de l'hexaméthyldisilazane (schéma 1), le groupement $SiMe_3$ pourrait se fixer en 1, 2 ou 4. Les spectres RMN de ^{15}N (9) permettent de distinguer les 1,2,4,3-triazaphospholes disubstitués en 1,5 ou en 2,5 (les monomères disubstitués en 4,5 ne sont pas stables). Nous n'avons pas enregistré le spectre de RMN de ^{15}N de **14**, sa solubilité étant insuffisante dans le toluène à

T = 110°C	20%	0%	80%	100%

chaud. Dans le tableau 2, nous comparons les spectres RMN de ^{15}N de **6** et **16** à ceux de **1** (R^1=Me, R=Ph) et **2** (R^2=Me, R=Ph) (9).

La valeur de $\delta^{15}N^{1}$ (−165 ppm) du composé **6** est bien caractéristique d'un triazaphosphole disubstitué en 1,5; quant à la valeur de $\delta^{15}N^{1P}$ (−50 ppm) du dérivé **16**, elle correspond bien à celle d'un isomère disubstitué en 2,5.

3. Etude de la stabilité relative des 1,2,4,3-triazaphospholes

Généralement les hétérocycles du phosphore dicoordonné présentent une bonne stabilite : phosphinines (17), 1,2,3-diazaphospholes (18), etc. Pourtant nous venons de voir que certains triazaphospholes à double liaison P=N peuvent donner lieu à des équilibres monomère–oligomère ou s'oligomériser spontanément de façon irreversible. L'expérience montre que les dérivés des trois triazaphospholes isomères **1**, **2**, **3** ont des stabilités différentes : les plus stables sont les dérivés de l'isomère **2** alors que ceux de l'isomère **3** existent seulement sous forme complexée ou sous forme de tetramère (3); quant aux derivés de l'isomère **1**, leur stabilité dépend des substituants. Plusieurs études théoriques ont été consacrées à des composés du phosphore dicoordonné : HP=NH (10, 11), $HP=CH_2$ (11), HP=O (14); triazaphospholes (12), dérivés de phosphinines (15, 16), etc.

Nous avons essayé d'expliquer la stabilité relative des triazaphospholes et certains aspects de leur réactivité en utilisant la méthode MNDO (21, 22), moins rigoureuse que les méthodes employées dans les exemples précédents mais beaucoup plus simple et qui donne souvent des résultats intéressants. Les calculs théoriques ont été effectués pour l'ensemble des conformations des triazaphospholes. Les approximations de base dans la méthode MNDO utilisée inclue un modéle semi-empirique pour les intégrales à deux centres (21). Pour juger de la fiabilité de cette méthode, on peut comparer les valeurs calculées en MNDO pour les chaleurs de formation, les géométries moléculaires, les potentiels d'ionisation et les moments dipolaires aux valeurs expérimentales (22); on constate le bon accord, ce qui justifie l'utilisation de la methode. Dans le tableau 3, sont rassemblées les énergies totales et les charges électroniques portées par les atomes de quelques 1,2,4,3-triazaphospholes : les trois isomères monosubstitués (R-1 = R-2 = R-4 = H, R-5 = SCH_3), leurs complexes et enfin une série d'isomères disubstitués (R-1 = R-4 = CH_3, R-2 = CH_3 ou $Si(CH_3)_3$, R-5 = CH_3, SCH_3).

Les énergies totales sont voisines (ΔE = 3 eV) dans les trois isomères non substitués. La monosubstitution en 5 (R^5 = SCH_3) stabilise fortement les formes monomères, puisque les valeurs des énergies électroniques totales diminuent de prés de 400 eV. Dans la série des isomères disubstitués par des groupements CH_3 (R^1, R^2, R^4, R^5 = CH_3), l'isomère 4,5-dimethyl 1,2,4,3-triazaphosphole a une énergie électronique totale très supérieure à celle des autres isomères (+150 eV). Ce résultat pourrait expliquer le fait que les triazaphospholes disubstitués en 4,5 monomères ne sont pas connus, contrairement aux derivés substitués en 1,5 et 2,5. Enfin le calcul montre la très grande stabilisation des trois isomères par un acide de Lewis, le trifluorure de bore, les énergies passant de −1200 à −2400 eV.

Charges partielle

La liaison P=N est fortement polarisée dans tous les dérivés étudiés, comme cela avait déjà été montré dans le cas

[a]Dans la colonne N-R, est indiquée la nature du reste R suivie du numéro de l'atome d'azote concerné, puis, le cas échéant, du site de complexation.

de HP=NH (11), avec une séquence décroissante : dérivés 2-substitués > dérivés 1-substitués > dérivés 4-substitués.

L'atome d'azote N-4 porte la charge négative la plus grande, ce que confirme l'expérience puisque la complexation avec BF_3 se fait bien sur cet azote pour les isomères disubstitués-1,5 (*2f*) et 2,5 (9). Dans l'isomère CH_3-4, la complexation avec BF_3 se fait en N-2 (3), sans doute à cause de la substitution de N-4, L'atome de phosphore, compte tenu de son électronégativité, est toujours polarisé positivement par rapport aux atomes d'azote. Cette charge varie en fonction des isomères selon la même séquence.

L'action des diazadiènes sur les 1,2,4,3-triazaphospholes illustre parfaitement ce résultat : ce sont les 1,2,4,3-triazaphospholes disubstitués en 2,5 qui sont les plus réactifs (13).

Moment dipolaire

Les moments expérimentaux sont en bon accord avec les moments calculés.[3] Remarquons que les molécules les moins polarisées sont H-2 et Me-2 (cf. tableau 3) dont les moments dipolaires respectifs sont 2,08 et 2,37 D. Les moments dipolaires théoriques sont ordonnés suivant la séquence : $\mu(R4) > \mu(R\text{-}1) > \mu(R\text{-}2)$.

On remarque que les molécules qui ont tendance à s'oligomériser possèdent un moment dipolaire élevé : les dérivés substitués en 4,5.

4. Action des 1,4-diaza 1,3-diènes sur les 5-méthylthio 1,2,4,3-triazaphospholes

La caractérisation par voie chimique des composés du phosphore dicoordonné est un problème intéressant, puisque ces composés peuvent être en équilibre avec leurs oligomères quelquefois en quantité si faible que les méthodes spectroscopiques ne permettent pas leur detection. Donc nous avons proposé une méthode de caractérisation spécifique des hétérocycles à motif -N-P=N-, basée sur l'électrophilie du phosphore, en utilisant comme réactifs les diazadiènes (13) et non une cycloaddition [2 + 4] sur la double liaison P=N. On obtient des composés spiranniques du schéme 3. Ces composés spiranniques du phosphore tétracoordonné, possédant un environnement de quatre atomes d'azote, sont

3. Avec le 5-phényl 1-méthyl 1,2,4,3 triazaphosphole (μ_{exp} 5.66 D) et avec le 2-méthyl 5-isopropyl 1,2,4,3 triazaphosphole (μ_{exp} 2.28 D).

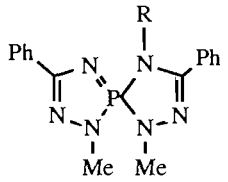
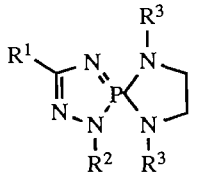
rares. À notre connaissance, seuls, deux dérivés de composés analogues, préparés par d'autres voies, sont décrits (19, 20) :



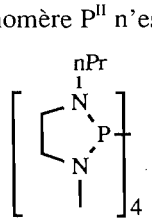
R = H, Me (19)



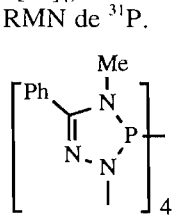
(20)

Il nous a paru intéressant d'étudier l'action des 1,4-diaza 1,3-diènes **20** sur les différents 5-méthylthio 1,2,4,3-triazaphospholes que nous avons synthétisés (schéma 3). Quand la réactivité du triazaphosphole est insuffisante, nous avons utilisé son complexe avec BF_3, car la complexation augmente la charge positive de l'atome de phosphore et probablement son électrophilie (schéma 3).

Le diaza-4,5 diène-1,3 **20***a* (R=*n*Pr) est plus réactif, car plus nucléophile, que le diazadiène **20***b* (R=Ph). On remarque aussi que les triazaphospholes disubstitués en 2,5 sont les dérivés qui réagissent le mieux. Par exemple **15** qui existe exclusivement sous forme monomère réagit totalement en un quart d'heure, à température ambiante. La réaction est plus lente (2–3 h) et nécessite une température plus élevée quand le triazaphosphole est en équilibre avec sa forme tétramère : c'est le cas des dérivés **14** et **16**. On a montré que l'étape initiale de cette réaction est une attaque nucléophile du doublet libre de l'un des atomes d'azote du diazadiène, sur l'atome de phosphore dicoordonné. Les tétramères P^{III} qui ne sont pas en équilibre avec la forme monomère P^{II}, ne réagissent pas; ce réactif peut donc constituer un test pour cet équilibre. D'autre part, les triazaphospholes disubstitués-2,5 réagissent en 1 h à la température ordinaire, tandis que les composés disubstitués-1,5 réagissent en 60 h à 80–100°C (13). Lorsque l'on chauffe **6** avec **20***a* pendant 2 jours dans le benzène à 80°C, on obtient seulement 10% du dérivé spirannique **24***a*, caractérisé par son déplacement chimique de RMN de ^{31}P. Dans les mêmes conditions, **20***b* ne réagit pas avec **6**. Notons que **20***a* n'a pas réagi sur $[\mathbf{12}]_4$ aprés 48 h à 100°C dans le toluène ou la pyridine. Nous avons déjà étudié l'action de **20***a* sur les tétramères $[\mathbf{26}]_4$ et $[\mathbf{27}]_4$, dont la forme monomère P^{II} n'est pas observable par RMN de ^{31}P.



$[\mathbf{26}]_4$



$[\mathbf{27}]_4$

$[\mathbf{26}]_4$ n'a pas réagi, même après chauffage pendant plusieurs jours à 100°C dans la pyridine (ou $NO_2C_6H_5$), tandis que $[\mathbf{27}]_4$ réagit quand on le chauffe à 100°C pendant 2 h dans la pyridine (14). Il semble donc que $[\mathbf{12}]_4$ n'est pas en équilibre avec son monomère, le groupement SMe augmentant la stabilité de $[\mathbf{12}]_4$ qui devient alors comparable à celle de $[\mathbf{26}]_4$. On peut aussi supposer que l'électrophilie de l'atome de phosphore de **12** est réduite par la présence de SMe. Cette dernière hypothèse semble plus plausible, si la réaction se fait sous contrôle des charges, puisque la complexation de **6** par BF_3, en augmentant la charge positive sur P, entraine une réaction instantanée de **20** pour donner les dérivés spiranniques **24**,BF_3. De même la réaction entre **12**,BF_3 et **20** est instantanée (schéme 3). D'aprés les spectres RMN de ^1H, le spirophosphazène obtenu est probablement complexé sur l'azote N-2 du cycle triazaphospholique. La liaison azote–bore est trés forte : en effet la décomplexation de **24**,BF_3 par addition d'une quantité stoechiométrique de DBU nécessite 2 jours à température ambiante.

Ainsi les diazadiénes **20** constituent non seulement des réactifs de détection du phosphore dicoordonné à enchainement -N-P=N- mais aussi peuvent permettre une appréciation qualitative de son électrophilie.

Conclusion

La synthèse de ces nouveaux 1,2,4,3-triazaphospholes indique clairement que l'introduction d'un groupement thiométhyle en position 5 conduit à une destabilisation par rapport aux triazaphospholes issus d'amidrazones. Les 5-méthylthio 1,2,4,3-triazaphospholes substitués en position 2 illustrent ce comportement. C'est ainsi que l'on a pu mettre en évidence, l'existence d'un équilibre thermique : phosphazane $P^{III} \rightleftharpoons$ phosphazène P^{II}. Il en est de même du 5-méthylthio 1,2,4,3-triazaphosphole **15** en solution dans la pyridine, mis en évidence à basse température.

Les résultats (ènergie totale et charges) des calculs effectués par la méthode MNDO apportent un élément de prévision de la réactivité de ces hétérocycles; les résultats expérimentaux confirment ces prévisions : site de complexation, addition des diazadiènes ou observation de l'équilibre. Cependant la stabilité relative des trois isomères est conservée.

L'introduction d'un reste fonctionnel en position-5 ou -2 des groupements -SMe ou -$SiMe_3$ ouvre des possibilités de réaction trés intéressantes.

Partie expérimentale

Les spectres IR ont été réalisés sur un spectromètre Perkin Elmer à transformée de Fourier, modèle 1760 X.

Les spectres de masse ont été effectués sur spectromètre Varian Mat 311 A, soit par impact électronique, soit par desorption de champ (NH_3, CH_4).

Les spectres de RMN de ^{31}P (32,44 MHz) et de ^1H (80 MHz) ont été obtenus sur un spectromètre Bruker AC 80, ceux de ^{13}C sur spectromètres Bruker AC 80 (20,15 MHz), AC 200 (50,32 MHz), AC 250 (62,90 MHz).

Les spectres de RMN de ^{15}N et ^{19}F ont été réalisés sur un spectromètre Bruker AM 300 WB; les déplacements chimiques sont donnés par rapport à CH_3NO_2 pour l'azote ^{15}N et CF_3COOH pour le fluor ^{19}F (en réf. externe).

Les analyses élémentaires ont été effectuées par le service central de microanalyse de CNRS et par le laboratoire d'analyse de l'École Nationale Supérieure de Chimie de Toulouse.

Iodhydrates de 3-méthylthio semicarbazide 7–11

Ils ont été préparés selon la référence 7. Certains sont nouveaux.

1-Phényl 3-méthylthio semicarbazide 7 : (68%) *F* 183°C; δH (80 MHz; C_5D_5N) : 2,81 (3H, s, CH_3), 6,8–7,2 (5H, m, Ph), 10,5 (4H, s, NH); δC (50,32 MHz; DMSO-D_6) : 13,60 (CH_3), 110–145 (m, CHPh), 170,50 (>C=N-). 5-Méthylthio 1,2,4,3-triazaphosphole ***6****, 15 et cyclotétraphosphazanes* ***[12]4****,* ***[13]4***

Un mélange équimoléculaire de tris(diméthylamino)phosphine et d'iodhydrate de méthylthiosemicarbazide (2×10^{-3} mol) dans 10 mL de toluène fraîchement distillé, est chauffé au reflux. La diméthylamine formée, entraînée par un courant d'azote sec, est titrée par une solution molaire d'acide chlorhydrique. On neutralise environ 90% de la quantité théorique d'amine en 3 heures. On décante très rapidement, à chaud sous argon, pour éliminer l'iodhydrate de diméthylamine.

Pour **6**, la solution obtenue est concentrée sous vide puis distillée sous pression réduite.

Pour **15**, $[\mathbf{12}]_4$ et $[\mathbf{13}]_4$: dans le filtrat apparaît très rapidement, en refroidissant, un précipité que l'on recristallise dans le toluène. La précipité, lavé à l'hexane, est séché sous vide sur P_2O_5.

1-Méthyl 5-méthylthio 1,2,4,3-triazaphosphole ***6*** *:* (82%) Eb 45°C/0,5 Torr (1 Torr = 133,3 Pa); ν_{max}, cm^{-1} (CH_2Cl_2) : 1619 (C=N); δP (32,44 MHz; C_6D_6) : 261 (s); δH (80 MHz, $CDCl_3$) : 2,67 (3H, s, SCH_3), 3,86 (3H, d, *J* 0,9, NCH_3); δC (50,32 MHz; C_6D_6) : 16,42 (SCH_3), 32,60 (d, *J* 3,6, NCH_3), 160,40 (d, *J* 15,9, >C=N-); SM (70 eV) *m/z* : 63 [12, $(CH_3)_2$ SH^+], 74 (100, PN_2CH_3), 89 (34, M^+-58), 102 (43, M^+-PN), 119 (12, M^+-28), 147 (35, M^+). Ketene-enols **4** and **5** have been generated by laser flash photolysis of *ortho*-benzoylbenzaldehyde (**3**) and kinetically and spectroscopically characterized. In benzene or acetonitrile, the *E* ketene-enol, **4**, shows absorption at 340 and 400 nm and a lifetime in excess of 1 ms, whereas the *Z* ketene-enol, **5**, shows maxima at 360 and 430 nm and a lifetime of only 1.5 μs. At shorter time scales we observed a weak absorption (λ_{max} = 580 nm) tentatively assigned to biradical **6** with a lifetime of 140 ns. The *E* ketene-enol is readily quenched by oxygen, dienophiles, methanol, and water, with quenching rate constants ranging from 3.6×10^3 M^{-1} s^{-1} (for methanol as a quencher) to 2.2×10^8 M^{-1} s^{-1} (for diethyl ketomalonate). At high water concentrations (typically >10 M) a new species, **7**, was detected showing maximum absorption at 510 nm and a growth lifetime of 7 μs. In deuterated water and using the same concentration as before we observed a formation lifetime for **7** of 10 μs, which results in an isotope effect of ~1.5. It is proposed that **5** is the main precursor for **7**. Steady-state irradiation of **3** in deaerated methanol leads to the formation of dihydroanthraquinone (**9**), a strongly colored and fluorescent (λ_{max} = 475 nm, τ_f = 29 ns) species, whereas 3-phenylphthalide (**2**, R = Ph) is the main product when the irradiation is performed in benzene. Steady-state quenching of product formation by diethyl ketomalonate gives a Stern–Volmer constant of 380 M^{-1} from which we conclude that **5** is the ketene-enol responsible for product formation, in agreement with the laser flash photolysis results.

J.C. NETTO-FERREIRA et J.C. SCAIANO. Can. J. Chem. **71**, 1209 (1993).

On a préparé les cétènes-énols **4** et **5** par photolyse flash au laser de l'*ortho* benzoylbenzaldéhyde (**3**) et on les a caractérisés cinétiquement et spectroscopiquement. Dans le benzène ou dans l'acétonitrile, le *E* cétène-énol, **4**, absorbe à 340 et à 400 nm et a un temps de vie de >1 ms tandis que le *Z* cétène-énol, **5**, montre des maxima à 360 et à 430 nm avec un temps de vie de 1,5 μs. Nous avons observé, dans des intervalles de temps plus courts, une faible absorption (λ_{max} = 580 nm) que nous avons attribué au biradical **6**, avec un temps de vie de 140 ns. Le *E* cétène-énol est facilement bloqué par l'oxygène, les diénophiles, le méthanol et l'eau avec des constantes de blocage allant de $3,6 \times 10^3$ M^{-1} s^{-1} (pour le méthanol comme agent de blocage) à $2,2 \times 10^8$ M^{-1} s^{-1} (pour le cétomalonate d'éthyle). Des concentrations élevées en eau (typiquement >10 M) permettent de déceler une nouvelle espèce présentant une absorption à 510 nm et un temps de croissance de 7 μs. Dans l'eau deutériée aux mêmes concentrations, on observe un temps de formation de **7** à 10 μs résultant d'un effet isotopique de 1,5 environ. On suggère que le composé **5** est le précurseur principal du composé **7**. L'irradiation à l'état stationnaire du composé **3** dans le méthanol désaéré conduit à la formation de la dihydroanthraquinone (**9**), un composé fortement coloré et fluorescent (λ_{max} = 475 nm, τ_f = 20 ns) tandis que le phthalide de phényl-3 (**2**, R = Ph) est le produit majoritaire lorsque l'irradiation a lieu dans le benzène. Le blocage à l'état stationnaire des produits obtenus à partir du cétomalonate d'éthyle donne une constante de Stern–Volmer de 380 M^{-1} qui nous porte à conclure que le composé **5** est le cétène-énol responsable de la formation des produits en accord avec les résultats de la photolyse flash au laser.

[Traduit par la rédaction]

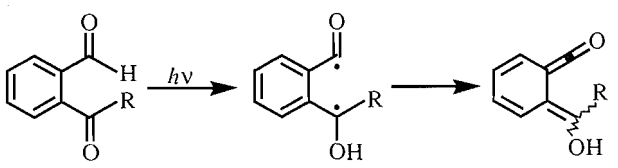
Introduction

Photoenolization of *ortho*-alkyl ketones is now a very well understood process. In most cases the transients involved in this intramolecular hydrogen abstraction reaction are well characterized as is the mechanism for the photoenolization process (1–20).

This is not the case for *ortho*-formyl aromatic aldehydes or ketones. Similarly to *ortho*-alkyl-substituted aromatic ketones, these compounds can form *ortho*-quinodimethane-like structures by intramolecular hydrogen abstraction (reaction [1]). However, little is known about the transients involved in this process, especially for the case of *ortho*-acylbenzaldehydes.

From the photochemical point of view, *ortho*-phthaldehyde (**1**; R = H) is the most studied *ortho*-dicarbonyl compound (21–26). In this case, intramolecular hydrogen abstraction leads to the formation of a 1,4 biradical (τ = 1.6 μs). Two triplet states, which are not responsible for product formation, are the precursors of this biradical, having lifetimes of 6 and 36 ns. Photolysis of *ortho*-phthalaldehyde leads to the formation of phthalide (**2**, R = H) and an isomeric mixture of dimeric products (21–25). Similar photochemical behavior has been observed for 2,3- and 3,4-diformylpyridines (27), 2,3-diformylquinolines (27), and 2,3- and 3,4-diformylthiophenes and selenophenes (28).

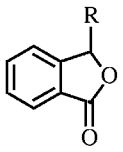
[1]



1; R = alkyl, aryl, H

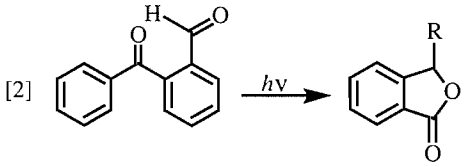
Recently, the ketene-enol probably involved in the decay

of the biradical from *ortho*-phthalaldehyde has been characterized by nitrogen matrix isolation studies (29).



2

The involvement of this kind of ketene-enol intermediate was also confirmed by low-temperature infrared studies on *ortho*-benzoylbenzaldehyde (**3**) (30). This compound is known to form 3-phenylphthalide (**2**, R = Ph) in an almost quantitative yield upon irradiation at low temperature (reaction [2]) (31).



[2]

3 **2**; R = Ph

The reactions of ketenes have been the subject of a recent review (32), and their reaction with water has been the subject of theoretical studies (33, 34).

In this paper we report an extensive study of the photochemistry of **3** in which we identify and characterize the transients involved in the phototransformation of reaction [2]. Our approach involves a combination of laser flash photolysis, steady-state irradiation, and emission and absorption spectroscopy.

Experimental part

Materials

The solvents benzene (Aldrich), acetonitrile (Fisher), and methanol (Aldrich) were used as received and were all Spectrograde.

Maleic anhydride (Aldrich), diethyl ketomalonate (Aldrich), dimethyl acetylenedicarboxylate (Aldrich), water (Omni, HPLC grade), and deuterated water (MSD isotopes) were used as received.

ortho-Benzoylbenzaldehyde was synthesized from the methyl ester of *ortho*-benzoylbenzoic acid using a literature procedure (35, 36). Its physical and spectroscopic properties agree well with the values found in the literature and are in accord with the proposed structure: mp 66–67°C (lit. (36) mp 64–67°C); ^{1}H NMR ($CDCl_3$) δ (ppm): 9.98 (s, 1H), 7.75 (m, 9H); MS *m/z* (%): 210 (100, M^+), 181(94), 105(28), 77(39).

General techniques

UV–VIS spectra were recorded with a HP-8451A diode array spectrometer. Phosphorescence and fluoroescence spectra were recorded with a Perkin Elmer LS-50 spectrofluorimeter.

GC analyses were carried out on a Perkin Elmer model 8320 capillary gas chromatograph employing a 12-m J&W bonded-phase vitreous BP1 silicone column. GC–MS analyses were performed in a Hewlett–Packard model 5995 system using a similar column.

Melting points were determined in a Mel-Temp apparatus and were not corrected.

The ^{1}H NMR spectrum was recorded on a Varian 200 MHz spectrometer model Gemini-200, using $CDCl_3$ as a solvent.

Product studies and quantum yield determinations

Typical samples were 1.0 mL containing 0.02 M ketone in benzene or methanol and were deaerated by bubbling with oxygen-free nitrogen. The samples were contained in Pyrex tubes and irradiated in a merry-go-round with nine RPR-3000 Å lamps. The products were characterized by GC–MS. Dodecane was used as internal standard in the steady-state quenching experiments.

For the quantum yield determinations the photofragmentation of valerophenone in benzene was employed as actinometer, taking the quantum yield of acetophenone formation as 0.30 (37).

Laser flash photolysis

Samples were contained in cells constructed of 7 mm × 7 mm Suprasil tubing and were deaerated by bubbling oxygen-free nitrogen. The samples were irradiated with the pulses (308 nm, ~5 ns, ≤25 mJ/pulse) from a Lumonics model 510 excimer laser operated with Xe–HCl–He mixtures. The signals from an RCA-4840 photomultiplier were initially captured by a Tektronix 2440 transient digitizer and then transferred to a Macintosh IIci computer that controlled the experiment and provided suitable storage, processing, and hard-copy capabilities. This system operated under LabVIEW-2.2 software and will be described in detail elsewhere. The system is otherwise similar to that employed in earlier work (38, 39).

Results

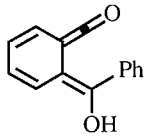
Phosphorescence spectroscopy

The phosphorescence spectrum for ketone **3** in an EPA (diethylether:isopentane:ethanol) glass at 77 K shows vibrational structure characteristic of a n,π^* triplet ketone. From the 0,0 emission band in this spectrum we obtain a triplet energy of 69.5 kcal/mol, which is very close to the value of 69 kcal/mol for benzophenone (40, 41). Clearly the emitting chromophore is localized on the benzophenone moiety. The small difference may reflect out-of-plane twisting of the *o*-formyl phenyl system.

Laser flash photolysis studies

(a) Transient characterization

Irradiation of a 3.0 mM solution of **3** in benzene or acetonitrile with the 308-nm pulses from an excimer laser leads to the formation of a readily detectable transient that shows absorptions at 340 and 400 nm (Fig. 1*a*). The decay monitored at either of these two maxima shows short- and long-lived transients; the latter has a lifetime in excess of 1 ms. It was not quenched by the usual triplet quenchers such as dienes and was only moderately quenched by oxygen. To this species we assign the structure **4**, corresponding to the *E* ketene-enol, consistent with the intramolecular hydrogen transfer mechanism usually observed in the case of photoenolizable ketones (vide infra) (3, 16).



4

On shorter time scales, the spectrum recorded 0.5 μs after laser excitation is considerably different from that recorded at a delay of 5 μs (Fig. 1*b*). In the former case the decay shows contributions from a short- and a long-lived transient (Fig. 2). Subtracting the spectrum at 5 μs delay, i.e., that due to **4**, from the early spectrum corresponding to the sum of the short- and long-lived transients, we obtain maxima at 360 and 430 nm for the short-lived species (Fig. 3). To this intermediate, having a lifetime of 1.5 μs, we assign structure **5**, corresponding to the *Z* ketene-enol. This is the first example where the *Z* and *E* enols show significant spectral differences.

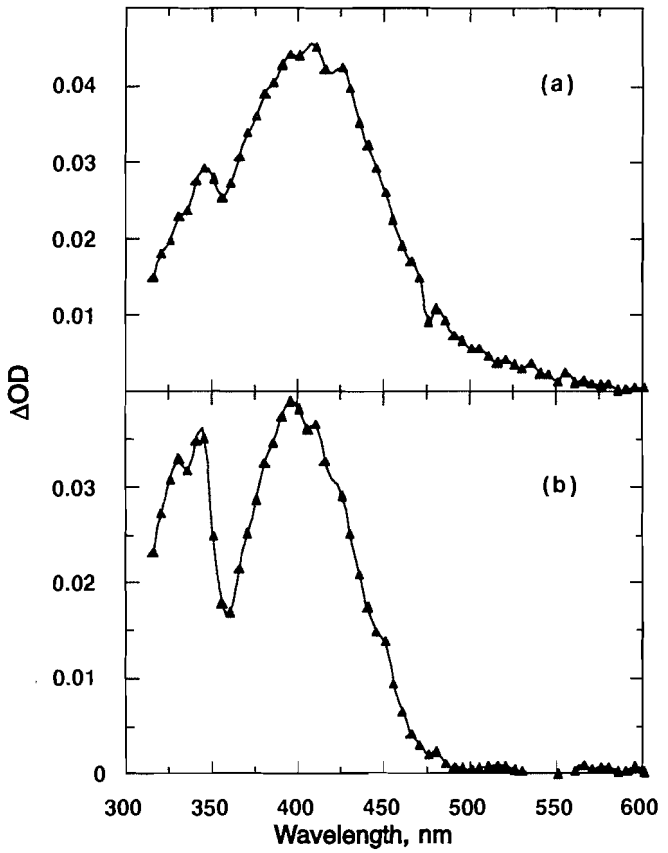

FIG 1. (*a*) Transient absorption spectrum obtained on 308-nm excitation of 3.0 mM *ortho*-benzoylbenzaldehyde (**3**) in benzene and recorded 0.5 μs after the laser pulse. (*b*) Same as above but recorded 5 μs after the laser pulse.

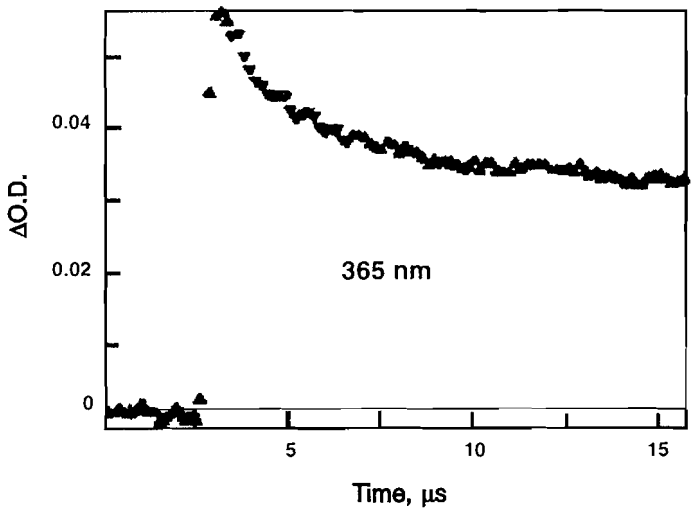

FIG. 2. Decay trace monitored at 365 nm due to the transient generated by excitation of 3.0 mM *ortho*-benzoylbenzaldehyde (**3**) in benzene.

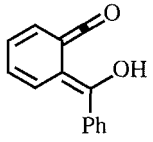

5

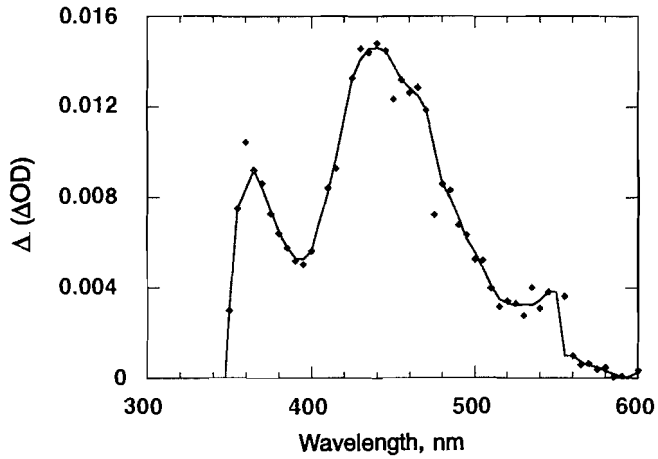

FIG. 3. Difference spectrum from the subtraction of spectrum in Fig. 1*b* from the one in Fig. 1*a* and attributed to the *Z* ketene-enol.

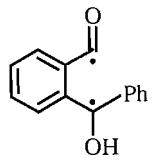
In benzene, at 320 nm, we observe the formation of a new species, that grows-in with first-order kinetics and a lifetime of 1.5 μs at room temperature. Since **2** (R = Ph) has a strong absorption at this wavelength we can attribute this signal to product formation. The fact that **5** is decaying with the same lifetime as **2** is growing-in indicates that the former species is the precursor of the latter (**2**, R = Ph).

The biradical **6**, precursor of the ketene-enols **4** and **5**, has a very weak absorption (only 0.005 absorbance units) at 580 nm, as previously indicated (31), with a lifetime of 140 ns. This species is quenched by oxygen (k_q = 2.8 × 10^9 M^{-1} s^{-1}) in benzene, but not by 1,3-cyclohexadiene, a typical triplet quencher, which is fully consistent with its assignment as the 1,4-biradical. We note that, just as in other systems involving photoenolization, this biradical can also be viewed as the triplet state of the ketene-enol.



6

Attempts to detect the triplet state of **3** were (not surprisingly) unsuccessful. Addition of 1,3-cyclohexadiene in concentrations of 0.025 M had virtually no effect (≤10%) on the yield of ketene in benzene. Thus, if the precursor of the ketene is the triplet ketone one must conclude that its lifetime is less than 2 ns. Naturally, an alternative explanation would be that the reaction leading to the ketene does not take place from the triplet manifold; given the phosphorescence spectrum of **3** (vide supra) and the fact that benzophenones normally undergo intersystem crossing with unit efficiency this explanation appears unlikely.

(b) Intermolecular reactivity

The *E* ketene-enol **4** can be quenched by dienophiles, methanol, water, and oxygen. For example, oxygen quenching is rather sluggish with k_q = 2.5 × 10^6 M^{-1} s^{-1}; reaction of photoenols with oxygen has been reported before (42, 43). For diethyl ketomalonate we measured a quenching rate constant of 2.2 × 10^8 M^{-1} s^{-1}. Dimethyl

TABLE 1. Quenching rate constants for the *E* ketene-enol **4** derived from **3**[a]

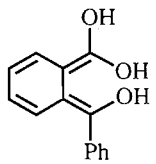
Quencher	$k_q(M^{-1}\ s^{-1})$	
	4	**8**[b]
Oxygen	2.5×10^6	
Maleic anhydride	4.1×10^6	1.4×10^4
Diethyl ketomalonate	2.2×10^8	7.8×10^5
Dimethyl acetylenedicarboxylate	$<10^3$	
Methanol	3.6×10^3	7.9×10^3
Water	1.1×10^3	

[a]In acetonitrile.
[b]From Ref. 48.

acetylenedicarboxylate in concentrations up to 0.08 M did not have any effect on the lifetime of the *E* ketene-enol.

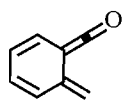
In neat methanol (ca. 25 M) the lifetime for **4** is greatly decreased (τ = 12 μs). A plot of the rate constant for ketene decay as a function of methanol concentration in the 0–6 M range led to a linear plot and a quenching rate constant of $\sim 3 \times 10^3\ M^{-1}\ s^{-1}$. Interestingly, extrapolation to neat methanol yields almost exactly the observed lifetime of 12 μs.

Quenching by water follows a linear dependence with water concentration (0–12 M range examined) and is remarkable since, besides the considerable shortening of the lifetime for **4**, one can observe the formation of a new species. The formation of this new intermediate is most readily observed when the water concentration exceeds 10 M. The broad absorption centered at 510 nm (Fig. 4) grows-in with first-order kinetics and a lifetime of 7 μs for its formation (see insert in Fig. 4). That this quenching process involves some form of hydrogen transfer can be shown by using deuterated water as a quencher. In this case the species absorbing at 510 nm grows-in with a lifetime of 10 μs, resulting in a deuterium isotope effect of ~1.5 (44). To this species we assign structure **7**, corresponding to the ketene-hydrate, formed by a nucleophilic attack of water on the ketene. It should be noted that the formation of **7** is much faster than the decay of **4**, by at least an order of magnitude. We were initially puzzled by this observation; however, we believe that **7** results from water addition to **5**, rather than **4**. While the extensive spectral overlap in the presence of water makes it difficult to carry out accurate kinetic measurements on **5**, the traces at 430 nm reveal quite clearly that **5** is decaying in the same time scale in which **7** is formed. From the growth kinetics for **7**, one can estimate a rate of reaction of **5** with water of $\sim 1.5 \times 10^4\ M^{-1}\ s^{-1}$. Of course, the ketene-hydrate (or carboxylic acid enol) is expected to form the carboxylic acid (in a process too slow for our detection system) and ultimately to form the same lactone as reaction [2]. This mechanism is similar to that proposed for the reaction of arylketenes with alcohols (45). Other ketene hydrates have recently been reported (46, 47). Quenching of the ketene-enol by water in methanol solvent was slightly faster than in acetonitrile ($k_q > \sim 1 \times 10^4\ M^{-1}\ s^{-1}$).



7

Table 1 shows quenching rate constants for several quenchers. These values are comparable to those reported for the quenching of the vinylketene **8** (10, 48).



8

Product studies and quantum yield determinations

Irradiation of deaerated samples containing **3** in benzene leads to the formation of 3-phenylphthalide (**2**, R = Ph) as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12

For personal use only.

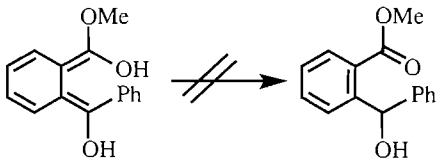
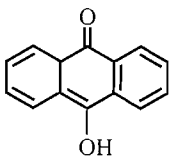
the main product (see Scheme 1), together with a small amount of anthraquinone. In methanol, which as already pointed out is a good quencher for the *E* ketene-enol (**4**), we observed the development of an intense yellow color in the solution after a few minutes of irradiation. In fact, this colored species is so long-lived in the absence of oxygen that under continuous irradiation its formation could be monitored in a conventional UV–visible spectrophotometer (Fig. 5). This new species is strongly fluorescent, showing emission with λ_{max} 475 nm, and a fluorescence lifetime of 29 ns. Oxygen bubbling causes an almost complete disappearance of the yellow color and eliminates the fluorescence emission. Surprisingly, GC analysis of the irradiation product from **3** in methanol did not show the formation of any new product, although the amount of anthraquinone formed in this case is considerably higher than in benzene. Interestingly no evidence was found for the formation of **11**, a possible product from the rearrangement of **10**.



10 **11**

This observation can be explained by assuming that in methanol the formation of dihydroanthraquinone (**9**), a highly colored and fluorescent species (10, 11, 49–51), is probably favored by an increase in the electrophilicity of the carbon atom responsible for the cyclization reaction. The overall process is shown in Scheme 1.



9

Quantum yield determinations were carried out using the formation of acetophenone from valerophenone as a relative actinometer (Φ = 0.30) (37). In benzene we measured a value of 0.18 ± 0.02 for the quantum yield of formation of 3-phenylphthalide (**2**, R = Ph) under nitrogen.

Steady state quenching

As proposed before, the irradiation of *ortho*-benzoylbenzaldehyde (**3**) can lead to the formation of two isomeric ketene-enols, **4** and **5**, and inspection of their structures and transient behavior leads us to assume that product formation must come from the short-lived species, the *Z* isomer **5**. To confirm this reasoning we decided to use the fact that diethyl ketomalonate is an excellent quencher for the *E* ketene-enol **4** (vide supra), and tried to quench product formation under steady-state irradiation conditions. To carry out these measurements, several samples, each containing 1 mL of a stock solution of **3** in benzene and different concentrations for the quencher, were irradiated in a merry-go-round inside a Rayonet photoreactor equipped with nine RPR-3000 Å lamps. Figure 6 shows a plot of relative quantum yield against diethyl ketomalonate from which one can obtain K_{SV} = 380 M^{-1}. Assuming the reactive species is **5**, and taking into account its lifetime, leads to a rate constant for quenching of 2.5 × 10^8 M^{-1} s^{-1}, a value remarkably similar to that measured directly for **4** (2.2 × 10^8 M^{-1} s^{-1}). In contrast, if one were to assume the reactive species to be **4**, then, given the known lifetime (>1 ms) and experimentally measured rate constant, one would have predicted a Stern–Volmer slope of ≥2 × 10^5 M^{-1}, in sharp disagreement with the experimental value of 380 M^{-1}. Thus, comparison of transient and quantum yield data identify **5** as the reactive species leading to product formation.

Discussion

The excited triplet state of *ortho*-benzoylbenzaldehyde, **3**, shows typical benzophenone-like characteristics. Compound **3** can be viewed as having two chromophores, resembling benzophenone and benzaldehyde. The triplet state from the latter is expected to be located at higher energy (~4–5 kcal/mol higher) than the benzophenone triplet.

Photolysis of **3** involves the expected photoenolization, a process that has been well characterized in many other aromatic ketones with labile hydrogens in the *ortho* position (3, 16). The case of **3** is rather special since the transient products are the ketene-enols **4** and **5**. We assume that the precursor to these enols is the triplet state of **3**; while this species has not been detected, its lifetime would be expected to be very short. The observation is in line with those for other photoenolizable benzophenones (10–12, 50, 52).

Interestingly, **4** and **5** show significant differences in their absorption spectra, as illustrated in Figs. 1*b* and 3. MM2 calculations suggest that the enol moiety can approach planarity most easily in the case of **5**; increased conjugation presumably leads to the red shift in the case of the short-lived **5**.

Two results are rather surprising: (*a*) that reaction of the ketene with water and alcohols would follow first-order kinetics and (*b*) that formation of **7** would involve either **5** (the *Z* ketene-enol) exclusively, or at least that formation from this precursor would be much faster and more efficient than from **4**.[2] There are clear examples in the literature where water addition has been demonstrated to frequently (but not always) (44) require two molecules of water (47, 53, 54) and theoretical work provides an interpretation for this observation (33, 34). If we think of these two water molecules as one for adding and the second one as "assisting" the addition, we can conceive that in the case of **5** the hydroxylic group already present can provide this assistance in an intramolecular fashion. Naturally, in the case of **4** the -OH group is not suitably oriented to assist water addition or at least not to do this with comparable efficiency. In addition, the fact that **5** is more planar than **4** may facilitate the nucleophilic attachment by water by delocalizing more easily the negative charge generated, in a manner similar to that proposed for phenylketene (55).

The isotope effect observed in the hydration reaction (H/D ~ 1.5) is in line with those observed by other groups for other ketene reactions with water, which values frequently fluctuate between 1.5 and 2.5 (44, 54–57).

Synthesis and fluorescence studies of oligoethylene glycols labeled with naphthalene by a phosphate triester linkage

SAM LEE AND MITCHELL A. WINNIK[1]

Department of Chemistry and Erindale College, University of Toronto, 80 St. George St., Toronto, Ont., Canada M5S 1A1

Received October 28, 1992

SAM LEE and MITCHELL A. WINNIK. Can. J. Chem. **71**, 1216 (1993).

A series of oligoethylene glycols, incorporating two pendant naphthyl groups along the interior of the chain using a phosphate triester linkage, have been prepared. The synthetic methodology has been discussed in the context of eventually providing a route to polymers labeled in a similar fashion. The steady state fluorescence behavior of these compounds is reported briefly. Relatively little excimer emission is observed. The synthetic intermediates to the phosphates, the 2-(1-naphthyl)ethyl *N*,*N*-diisopropylphosphoramidites of triethylene glycol and tetraethylene glycol, show exciplex fluorescence. The fluorescence from these latter compounds exhibits some sensitivity to solvent quality.

SAM LEE et MITCHELL A. WINNIK. Can. J. Chem. **71**, 1216 (1993).

On a préparé une série d'oligoéthylène glycols incorporant deux groupes naphtyles pendants à l'intérieur de la chaîne au moyen d'un lien triésterphosphorique. On discute de la méthode de synthèse dans le but de trouver éventuellement une voie d'accès aux polymères marqués de la même façon. On rapporte brièvement le comportement de la fluorescence de ces composés à l'état stationnaire. On observe relativement peu d'émission d'excimère. Les intermédiaires obtenus, lors de la synthèse des phosphates, les (naphtyl-1)éthyl-2 *N*,*N*-diisopropylphosphoramidites du triéthylène glycol et du tétraéthylène glycol montrent la fluorescence de l'exciplexe. La fluorescence de ces derniers composés est d'une certaine manière sensible à la qualité du solvant.

[Traduit par la rédaction]

Introduction

We have used fluorescence techniques extensively to study the kinetics of end-to-end cyclization in polymer chains (1, 2). Our interest in cyclization experiments stems from the idea that when chromophores are attached to the ends of flexible molecules (or polymers), the quenching kinetics can be used as a tool to study issues of conformation and dynamics in these molecules (3, 4). The cyclization rate is sensitive not only to the chain length and the chemical structure (chain stiffness) of the polymer, but also to polymer–solvent interactions.

An interesting variation on this theme would be to examine the case where the two excimer-forming chromophores occupy well-defined sites in the chain interior. Such experiments would probe the backbone-to-backbone cyclization of a linear polymer chain. It is well known that the ends of a polymer chain move faster than the interior segments: the dangling chain ends introduce extra drag on the interior groups undergoing large amplitude motion. Recently, Perico et al. developed a model that describes the relaxation behavior of bond segments at specified locations within the polymer chain (5–8). This model suggests that the rate of cyclization will depend on the specific location of the cyclizing groups within the chain interior. We believe that it is important to have a means of testing these ideas.

We require linear polymers that contain two chromophores separated by a well-defined number of monomer units and that are symmetrically positioned within the chain. These polymers must exhibit a narrow molecular weight distribution and be free from any adventitious quenchers and fluorescent impurities. At present, no synthetic strategies have been developed to generate the desired materials.

Our approach to this synthetic problem is to couple an alcohol-derivatized fluorescent label to hydroxy-terminated polymers. The chosen protocol is an adaptation of the "phosphite triester" method currently used in solid-phase oligonucleotide synthesis (9–14). This report describes the adopted strategy and the synthesis of some model compounds (oligomers) to test this strategy.

Results and discussion

Synthesis

The well-established synthetic protocols that have been developed for DNA synthesis are based on features that are equally attractive to our work with polymers. The key step, involving the reaction of a derivatized phosphoramidite with an appropriate alcohol to form a phosphite bond, proceeds through a rapidly generated and highly reactive tetrazoylphosphoramidite (11, 12, 15). Exceptional reactivity is required when a polymer with an excess of 10^3 monomer units contains only a single hydroxyl group on each end with possible limited accessibility due to steric constraints presented by the coiled chain. Phosphoramidite chemistry is a particularly efficient reaction, generating internucleotide links in near-quantitative yields. Since the purification of a polymer sample, where the distinctiveness of the product is based only on the presence of two functional groups, is difficult and time consuming, highly efficient reactions are desirable. The final product, after oxidative work-up, is a phosphate triester linking together three different alcohols, which is the exact type of connectivity required for linking a pendant probe molecule to a fixed point within a linear polymer chain. Finally, the polymers studied most frequently, polyethylene glycol and polystyrene, are stable to the reactive phosphite intermediates generated in each step of this synthetic sequence.

In adapting this methodology to polymers, we began by examining the reactions with oligomeric model compounds. This allows us to carry out functionalization reac-

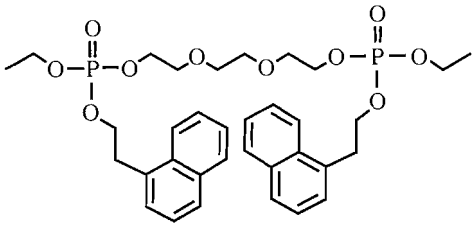
tions in which the intermediates and products can be well characterized. Hence, polyethylene glycols have been used as models for the chemistry of larger polymers. In the study of polymers, pyrene would be the natural choice of the excimer-forming chromophore. For these shorter chains, we speculated that pyrene excimer formation might be too extensive. With the ready availability of 2-(1-naphthyl)-ethanol as a reagent, we chose to prepare molecules containing two naphthyl groups attached to the ends of the polyethylene glycol oligomers.

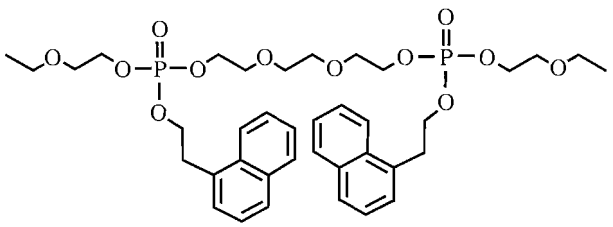
Scheme 1 outlines the synthesis of the desired phosphoramidites. The dichloridite of 1-naphthalene ethanol was prepared by the reaction of the alcohol with phosphorus trichloride using a modification of the standard literature procedure for such compounds (16, 17): by using a five-fold excess of phosphorus trichloride, the phosphorodichloridite, **1**, can be obtained in near quantitative yield, compared to a maximum of 80% often reported in literature preparations of similar derivatives (17). A high conversion becomes important when we eventually use the precious starting material, 4-(1-pyrenyl)butanol, which gives derivatives that are more difficult to isolate. The phosphitylating agent, **2**, was also prepared by using standard literature procedures. Both the dichloridite, **1**, and the chloridite, **2**, were isolated by simple vacuum distillation.

The phosphitylating agent, **2**, can be used in two distinct approaches to generate the desired end products. We chose to react **2** with triethylene glycol and with tetraethylene glycol to obtain the bis-phosphoramidites **3** and **4**, respectively. These two intermediates exhibit interesting fluorescence behavior on their own.

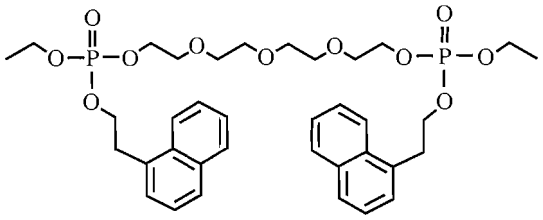
The final reaction in the sequence involves the activation and removal of each of the two diisopropylamino protecting groups on the bis-phosphoramidite with a weak acid, tetrazole. A highly reactive tetrazoylphosphoramidite intermediate is generated, which undergoes nucleophilic displacement in the presence of an alcohol to form a phosphite. The optimal conditions for this step were not investigated. Taking guidance from the work of Ogilvie, Damha, and co-workers (18, 19), who synthesized branched RNA fragments using a similar coupling approach, a reactant ratio of 1:3:12 bis-phosphoramidite:alcohol:tetrazole was used in THF at room temperature. This is an extremely rapid reaction. Monitored by TLC for the disappearance of the bis-phosphoramidite (as the hydrolysis product) and the appearance of the bis-phosphite, the reaction was found to be complete within 5–10 min in comparison to an average of 2 h used by Damha et al. to synthesize branched RNA fragments. The difference in the rate of reaction may be due, in part, to reduced steric constraints from an extremely flexible oligoethylene glycol chain, and to the ease of activation of these bis-phosphoramidites by tetrazole compared to the RNA derivatives (19). The corresponding bis-phosphate triester was obtained after oxidative work-up, by adding an excess of aqueous iodine solution to the bis-phosphite. In this manner, two sets of compounds were obtained. The first set, obtained from the bis-phosphoramidite **3**, are oligoethylene glycols where the two naphthalene probes are separated by three oxyethylene monomer units. The ends of this labelled glycol are flanked by either one or two monomer units (compounds **131** and **232**, respectively). The second set, obtained from the bis-phosphoramidite **4**, have four oxyethylene monomer units separating the two chromophores. The ends of this labelled glycol are also flanked by either one or two monomer units (compounds **141** and **242**, respectively)



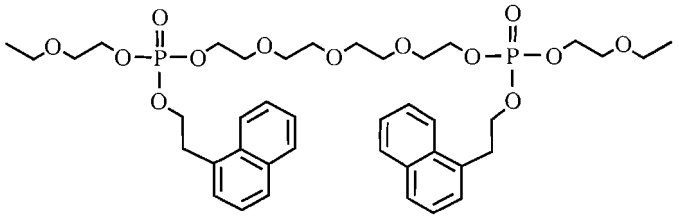
131



232

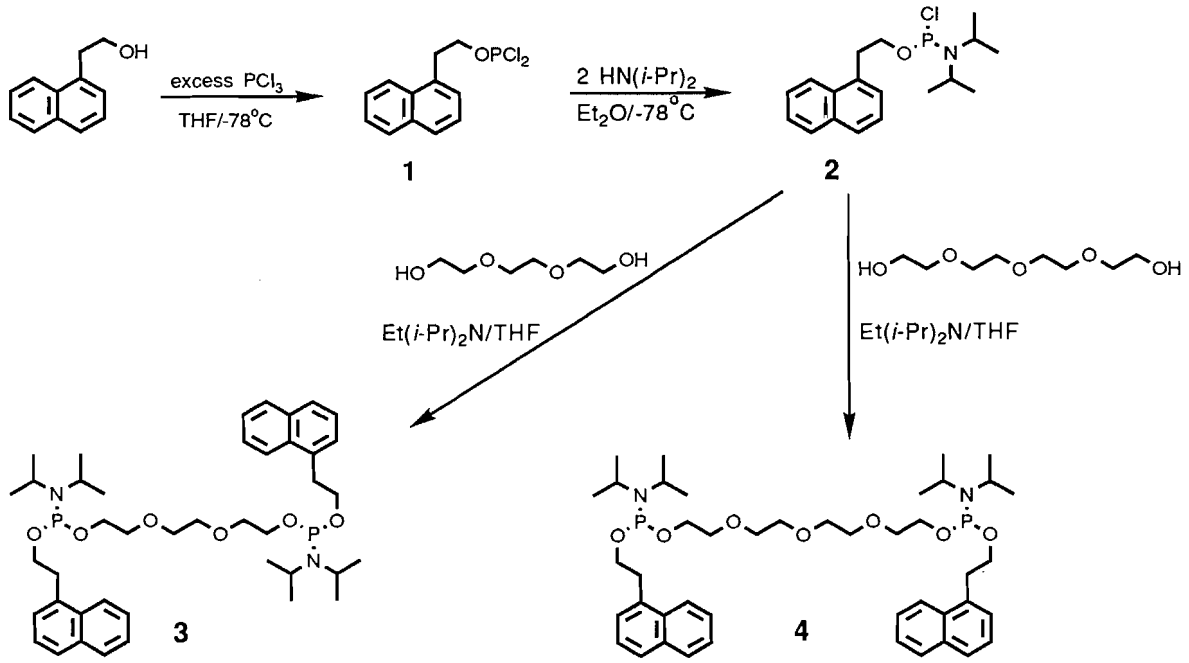


141

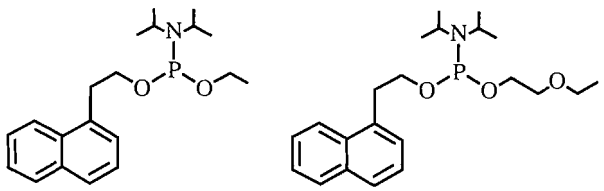


242

An alternative coupling strategy involves the synthesis of the simple phosphoramidites, **5** and **6**, from the phosphitylating agent **2**. Each of these two phosphorylating reagents can be coupled to triethylene glycol and to tetraethylene glycol to give the same bis-phosphates. Reaction of 3:1:12 phosphoramidite (**6**):tetraethylene glycol:tetrazole in THF at room temperature gave **242** in 72% yield, comparable to the yields obtained using the former coupling strategy.

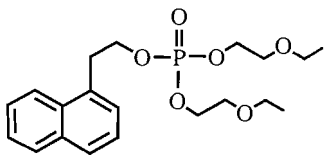


SCHEME I



5 6

For fluorescence studies, the phosphate, **7**, was also synthesized to serve as a model compound.



7

Fluorescence

The steady state fluorescence spectrum of the model phosphate **7**, in THF, is shown in Fig. 1. The fluorescence spectra of the phosphoramidites **3**, **4**, and **6**, also presented in Fig. 1, are normalized to the 0–0 fluorescence band of the model phosphate at 323 nm. All four compounds exhibit the structured fluorescence characteristic of the locally excited naphthalene chromophore with two major peaks at 323 and 338 nm, two smaller peaks at 328 and 333 nm, and a shoulder at 350 nm. However, the phosphoramidites all show an additional long tail, extending to longer wavelengths, which peaks at about 485 nm. The proportionate size of this tail does not change from a concentration of 3×10^{-6} to 4×10^{-5} M. This extra emission comes from the *intramolecular* exciplex formed from the interaction of the excited naphthalene moiety with the amino (or the phosphoramidite) group.[2] While the amount of intramolecular exciplex emission is not extensive, the amount of fluorescence self-quenching in these molecules is considerable. When the total fluorescence intensity from the phosphate **7** is compared with the total fluorescence intensity from the phosphoramidite **6**, at equal concentrations, the phosphoramidite only exhibits 17% of the total fluorescence emission from **7**.

The bis-phosphoramidites **3** and **4** show even more exciplex emission than **6**. The excited chromophore can form a complex, either with the "proximal" amino group in a way similar to that of the model phosphoramidite **6**, or with the "distal" amino group at the other end of the molecule via end-to-end cyclization. In the case of **4**, where the phosphoramidite groups are separated by four monomer units, the exciplex emission is indeed greater than in **6**, but only by a small amount. The shorter bis-phosphoramidite **3**, where the phosphoramidite groups are separated by three monomer units, exhibits substantially greater exciplex emission than either **4** or **6**.

These observations provide some qualitative information about the timescale of terminal cyclization in triethylene glycol and tetraethylene glycol when they are "end-labelled" with exciplex-forming phosphoramidites. Exciplex formation between excited state naphthalene and the proximal amino group is, clearly, very fast. In the longer bis-phosphoramidite **4**, the effect of the distal amino group is minimal because the excited naphthalene is, on average,

[2]The phosphate group alone does not appear to have an effect on exciplex formation or fluorescence quenching. The fluorescence spectrum and the total fluorescence intensity of **6**, **7**, and 2-(1-naphthyl)ethanol in THF do not change when either triethyl phosphate or triethyl phosphite is present at a concentration of 0–10^{-2} M.

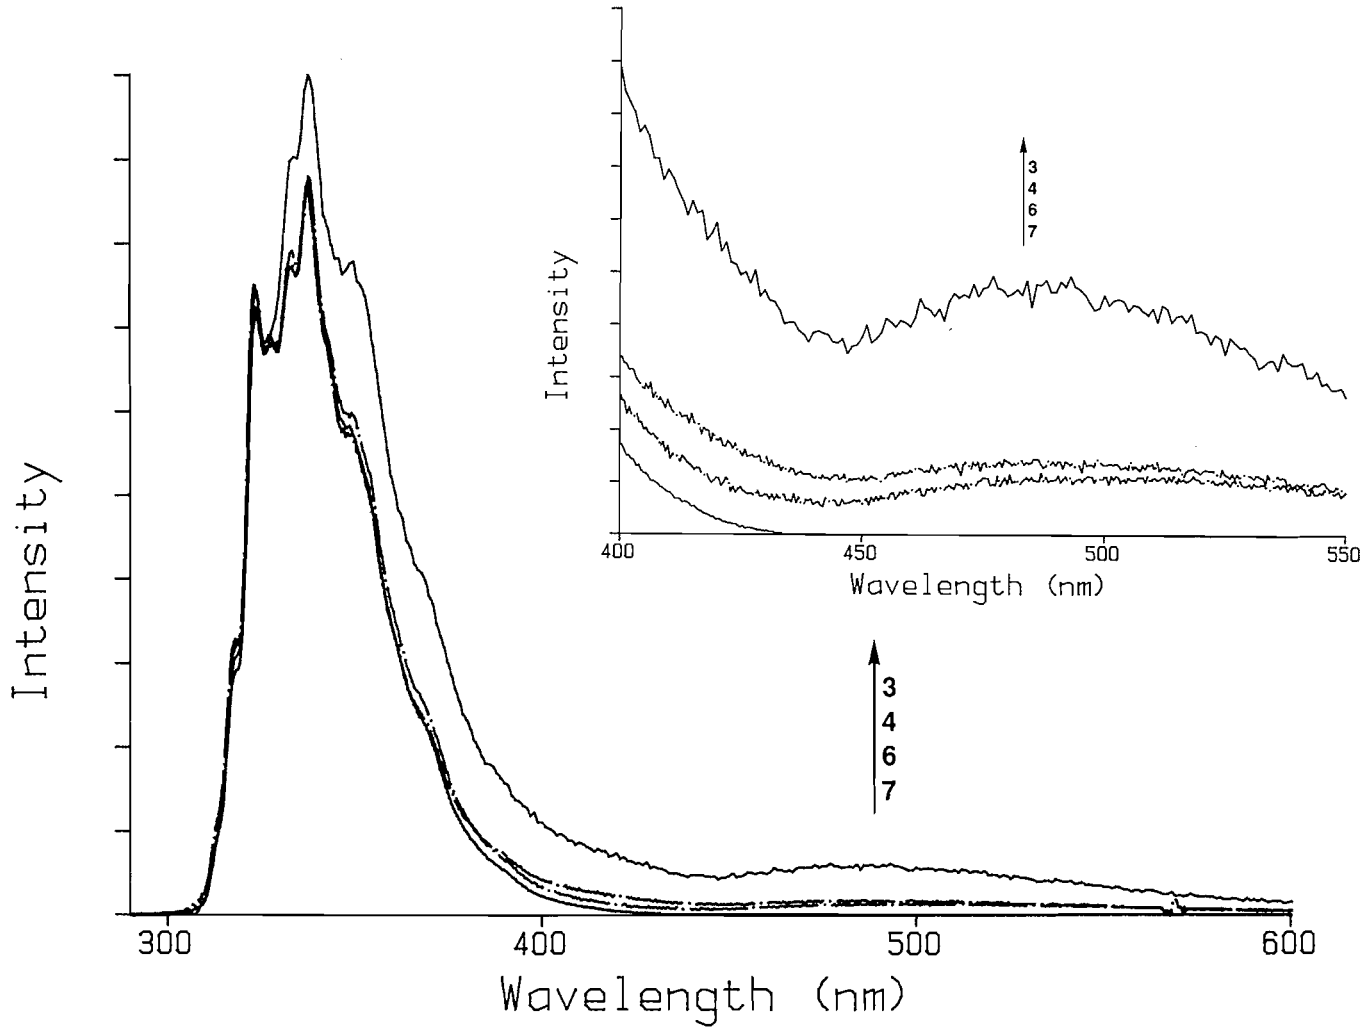

FIG. 1. Normalized fluorescence spectra of the model phosphate (**7**), model phosphoramidite (**6**), and the bis-phosphoramidites (**3** and **4**) in THF at room temperature. [Chromophore] = 10^{-6} M for all four compounds. $\lambda_{excitation}$ = 282 nm. Inset: expansion of the 400–550 nm region.

quenched by the proximal amino group before it can encounter the amino group at the other end of the chain. In the shorter bis-phosphoramidite **3**, cyclization of the chain ends is much faster, and quenching of the excited naphthalene chromophore by the distal amino group is now competitive with quenching by the proximal amino group. If the lifetime of **6** were known, a lower limit for the rate of terminal cyclization by **3** and an upper limit for the terminal cyclization by **4** could be established.

The fluorescence spectra of these same compounds in diethyl ether were also recorded (Fig. 2). The broad, structureless exciplex band of each phosphoramidite was obtained by subtracting the normalized fluorescence spectrum of the model phosphate from each of the corresponding phosphoramidites. Two broad peaks are observed: one centred at 360 nm and the other at 485 nm. The band centred at 360 nm might be due to a second, higher energy, exciplex. The increased amount of exciplex emission by the phosphoramidites in this solvent can be explained, in part, by the polarity of the solvent. It is well known that exciplex intensity increases with decreasing solvent polarity. However, while the bis-phosphoramidite **3** shows the greatest amount of exciplex fluorescence, as expected, the bis-phosphoramidite **4** exhibits less exciplex emission than that of the model phosphoramidite **6**. The nature of this reversal might be due to the solvent quality. Diethyl ether is a non-solvent for polyethylene oxide and a very poor solvent for polyethylene glycol. The degree of incompatibility depends on the number of monomer units in the polymer chain. While triethylene glycol is solvated as a random coil by diethyl ether, it is possible that tetraethylene glycol contains a sufficient number of oxyethylene monomer units to cause the coil to collapse. This might then raise the conformational barriers to exciplex formation.

Excitation spectra can provide some information about the ground state conformation of the chromophores within the coil. Figure 3 compares the excitation spectrum obtained by monitoring the emission at 323 nm (fluorescence from locally excited naphthalene) with the spectrum obtained by monitoring the emission at 485 nm (fluorescence from the exciplex). If a ground state naphthalene–amine complex existed prior to excitation, the excitation spectrum for the exciplex would be red-shifted relative to the spectrum for the single naphthalene. The identical excitation spectra ob-

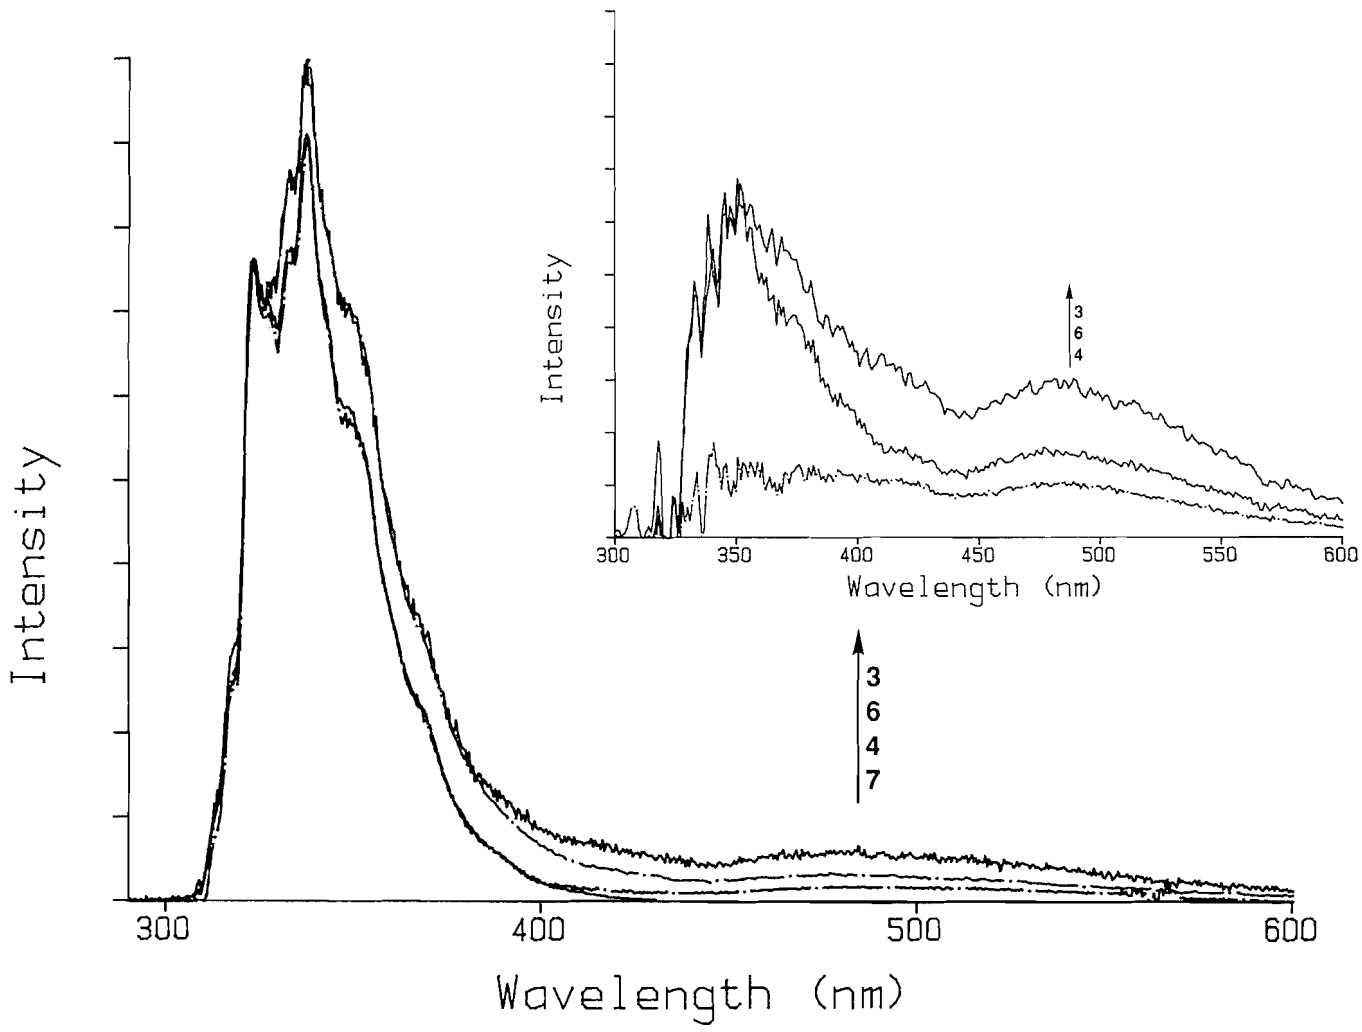

FIG. 2. Normalized fluorescence spectra of the model phosphate (**7**), model phosphoramidite (**6**), and the bis-phosphoromadites (**3** and **4**) in diethyl ether at room temperature. [Chromophore] = 10^{-6} M for all four compounds. $\lambda_{excitation}$ = 282 nm. Inset: exciplex bands obtained by subtraction of the phosphate fluorescence spectrum from the corresponding phosphoramidite fluorescence spectrum.

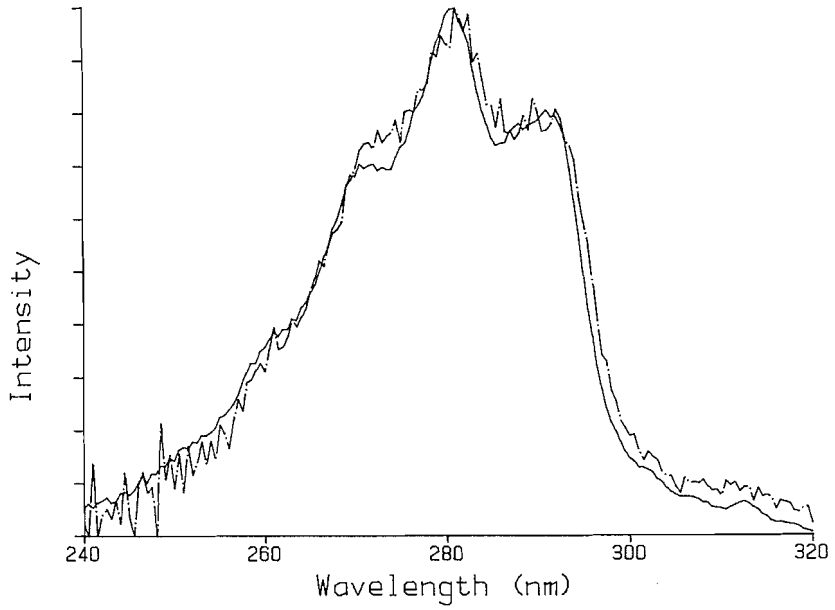

FIG. 3. Excitation spectra of the bis-phosphoramidite **4** in diethyl ether monitored at 323 nm (——) and at 485 nm (–·–·–).

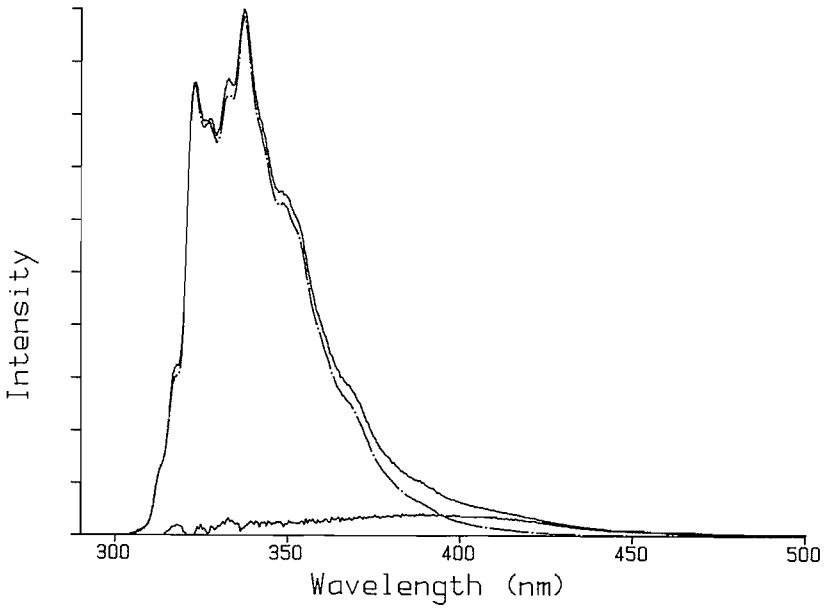

FIG. 4. Normalized fluorescence spectra of the bis-phosphate **242** (——) and the model phosphate **7** (—·—) in diethyl ether, normalized at 323 nm. [Glycol] = 10^{-6} M for both compounds. $\lambda_{excitation}$ = 282 nm. The excimer band was obtained from subtraction of the normalized spectra.

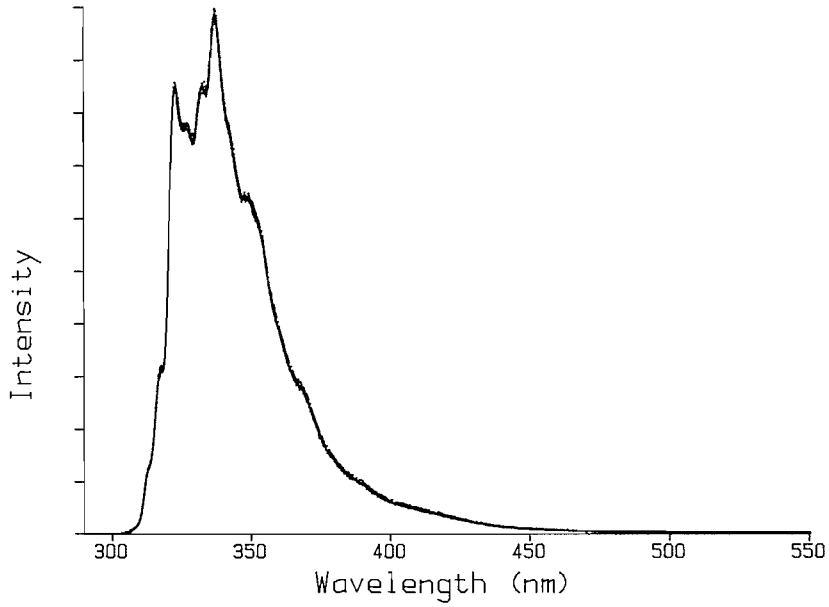

FIG. 5. Normalized fluorescence spectra of **131**, **232**, **141**, and **242** in diethyl ether, normalized to the 0–0 band at 323 nm. [Bis-phosphate] = 10^{-6} M for all four compounds. $\lambda_{excitation}$ = 282 nm.

served in this system indicate an absence of any strong preassociation between the naphthalene and amine groups prior to excitation. If the coil of the bis-phosphoramidite **4** is indeed collapsed relative to that of **3**, it is still swollen with enough solvent to permit conformational changes.

The fluorescence spectrum of the bis-phosphate **242** is compared with the model phosphate **7** in Fig. 4. The structured fluorescence characteristic of the single excited naphthalene chromophore is apparent in the fluorescence of **242**. In this case, the long tail extending to longer wavelengths is due to excimer emission. This broad, structureless band, centred at 400 nm, can be obtained by subtraction of the normalized spectra. Since the intramolecular excimer is formed via backbone-to-backbone cyclization of the oligoethylene glycol, the bis-phosphates, where the naphthalene probes are separated by three monomer units, would be expected to show more excimer emission than the bis-phosphates with the naphthalene probes separated by four monomer units. Furthermore, since longer dangling side chains present greater drag on the interior groups undergoing cyclization, the **232** and **242** bis-phosphates should cyclize at a slower rate (i.e., show less excimer emission) than the **131** and **141** bis-phosphates, respectively.

All four bis-phosphates have identical fluorescence spec-

For personal use only.

tra in diethyl ether (Fig. 5). Similar results are also obtained in THF. The fact that they all show the same relative amount of excimer emission suggests that the rate of backbone-to-backbone cyclization is the same for all four compounds. This would mean that the rates of cyclization are affected similarly by the bulky end groups to a point where variations in the rate, resulting from a closer spacing between the naphthalene probes or from introducing longer dangling chain ends, cannot be detected. Fluorescence decay data have been obtained to support these conclusions. They will be presented in a future publication.

Experimental

General methods

All reactions were performed under an argon atmosphere. Thin-layer chromatography was performed on no. 5735 or no. 5554 Merck Kieselgel 60 F-254 analytical silical gel sheets. Preparative column chromatography was performed on 70–230 mesh silica gel (Aldrich, 60A). 4A Molecular sieves (BDH) were activated by heating at 450°C overnight.

NMR spectra were recorded on a Varian Associates XL-200 (^{31}P and ^{13}C), Gemini-300 (^{31}P), or XL-400 (^{1}H and ^{13}C) spectrometer at room temperature. ^{31}P NMR chemical shifts were referenced to 85% H_3PO_4 (external standard) where positive values indicate shifts downfield from the reference. All deuterated solvents (Aldrich) were used as received. ^{13}C and ^{31}P spectra were recorded in the proton decoupled mode. ^{13}C and ^{1}H NMR peak assignments were made with the aid of ^{13}C-APT, ^{1}H-COSY, and ^{1}H–^{13}C HETCOR spectra recorded on a Varian XL-400 spectrometer. IR spectra were recorded on a Nicolet 5DX FT-IR spectrometer. Mass spectra were recorded on a VG 70-250S mass spectrometer. UV spectra were recorded on an HP 8452A diode array spectrometer. Elemental analyses were performed by Galbraith Laboratories (Knoxville, Tenn.).

Reagents and chemicals

THF (Caledon) and diethyl ether (Caledon) were refluxed and distilled from sodium benzophenone ketyl. Dichloromethane (Caledon), triethylamine (BDH), diisopropylamine (BDH), diisopropylethylamine (Aldrich), acetonitrile (Caledon), and all glycols (Aldrich) were refluxed and distilled from calcium hydride. Absolute ethanol (Caledon) was refluxed and fractionally distilled from sodium. Phosphorus trichloride (BDH) was freshly distilled before use. Tetrazole (Dalton) was sublimed before use. A 0.1 M aqueous iodine solution, used for oxidative work-up, was made by dissolving iodine (2.6 g) in a mixture of 2,6-lutidine (80 mL) and water (2 mL).

Fluorescence spectra

Reagent grade diethyl ether (Caledon) and spectroscopic grade THF (Caledon) were refluxed and distilled from lithium aluminum hydride. Sample solutions were degassed by vigorously bubbling with argon (Union Carbide, <0.5 ppm oxygen, <3 ppm water), saturated with the solvent, for 20 min. Steady state fluorescence spectra were recorded at room temperature on a SPEX Fluorolog 2 spectrometer, at a right angle geometry, using 1-mm slits on both the excitation and emission sides. Emission spectra were corrected for scattering and the wavelength sensitivity of the photomultiplier tube.

*2-(1-Naphthyl)ethyl phosphorodichloridite (**1**)*

1-Naphthalene ethanol (Aldrich, 9.0 g, 0.05 mol in 100 mL THF) was added dropwise over 1 h to a cooled solution (−78°C) of phosphorus trichloride (25 mL, 0.29 mol) dissolved in THF (50 mL). The resulting solution was allowed to warm to room temperature and was stirred magnetically for an additional 5 h. The THF and excess phosphorus trichloride were removed under reduced pressure at room temperature to leave a clear, colourless liquid. This oil was vacuum distilled to give 13.7 g (96%) of the desired product: bp 111°C (0.05 Torr; 1 Torr = 133.3 Pa); IR (neat): 740, 775, 800, 1020, 1390, 1470, 1510, 1600 cm^{-1}; ^{31}P NMR ($CDCl_3$): 178.56; ^{1}H NMR ($CDCl_3$): 3.37 (t, 2H, $^{3}J_{HH'}$ = 7.4 Hz, $C_{10}H_7CH_2$), 4.46 (dt, 2H, $^{3}J_{PH}$ = 8.6 Hz, $^{3}J_{HH'}$ = 7.4 Hz, $POCH_2$), 7.26–7.95 (m, 7H, naphthyl-*H*); ^{13}C NMR ($CDCl_3$): 33.39 (d, $^{3}J_{PC}$ = 2.9 Hz, $C_{10}H_7CH_2$), 68.13 (d, $^{2}J_{PC}$ = 10.1 Hz, $POCH_2$), 123.18, 125.46, 125.71, 126.34, 127.25, 127.76, 128.93, 131.84, 132.47, 133.84 (naphthyl-*C*); mass spectrum, *m/e* (rel. intensity): 276 M + 4$^+$ (5), 274 M + 2$^+$ (17), 272 M$^+$ (19), 155 (100), 141 (56), 128 (13), 115 (25).

2-(1-Naphthyl)ethyl N,N-*diisopropylphosphoramidochloridite (**2**)*

Freshly distilled 2-(1-naphthyl)ethyl phosphorodichloridite (13.7 g, 0.05 mol) was distilled in diethyl ether (50 mL). The magnetically stirred solution was cooled to −78°C and diisopropylamine (14.1 mL, 0.10 mol in 100 mL diethyl ether) was added dropwise over 90 min. The resulting white slurry was stirred and allowed to slowly warm to room temperature overnight. The mixture was filtered through a coarse sintered-glass Schlenk tube under argon and the filtrate was concentrated to a cloudy, colourless oil under reduced pressure at room temperature. This material was purified by vacuum distillation to yield 13.4 g (79%) of the product as a clear, colourless oil: bp 137°C (0.05 Torr); IR (neat): 780, 880, 920, 980, 1160, 1370, 1400, 1460, 1510, 1600 cm^{-1}; ^{31}P NMR ($CDCl_3$): 182.05; ^{1}H NMR ($CDCl_3$): 0.97 (d, 6H, $^{3}J_{HH'}$ = 6.9 Hz, diastereotopic $CH(CH_3)_2$), 1.13 (d, 6H, $^{3}J_{HH'}$ = 6.8 Hz, diastereotopic $CH(CH_3)_2$), 3.23 (t, 2H, $^{3}J_{HH'}$ = 7.1 Hz, $C_{10}H_7CH_2$), 3.58 (m, 2H, $NCHMe_2$), 4.01 (m, 1H, diastereotopic $POCH_2$), 4.15 (m, 1H, diastereotopic $POCH_2$), 7.11–7.88 (m, 7H, naphthyl-*H*); ^{13}C NMR ($CDCl_3$): 23.23 (d, $^{3}J_{PC}$ = 10.6 Hz, diastereotopic $CH(CH_3)_2$), 23.96 (d, $^{3}J_{PC}$ = 5.6 Hz, diastereotopic $CH(CH_3)_2$), 34.19 (d, $^{3}J_{PC}$ = 6.9 Hz, $C_{10}H_7CH_2$), 45.91 (d, $^{2}J_{PC}$ = 12.9 Hz PNCH), 66.39 (d, $^{2}J_{PC}$ = 16.8 Hz, $POCH_2$), 123.98, 125.64, 125.72, 126.25, 127.43, 127.58, 129.04, 132.61, 134.20, 134.35 (naphthyl-*C*); mass spectrum, *m/e* (rel. intensity): 339 M + 2$^+$ (3), 337 M$^+$ (9), 302 (5), 155 (100), 141 (19), 128 (8), 115 (11).

Representative procedure for the synthesis of the phosphoramidites: 2-(1-naphthyl)ethyl-(2-ethoxyethyl N,N-*diisopropylphosphoramidite) (**6**)*

Freshly distilled 2-(1-naphthyl) *N,N*-diisopropylphosphoramidochloridite (3.0 g, 8.9 mmol) and diisopropylethylamine (15 mL, 86 mmol) were dissolved in dichloromethane (50 mL). The resulting solution was stirred magnetically at room temperature while 2-ethoxyethanol (0.9 mL, 9 mmol) was added dropwise to the solution over 5 min. The resulting mixture was stirred for an additional 2 h. At the end of the reaction, the mixture was diluted with 50 mL dichloromethane and washed twice with saturated brine. The organic layer was dried over sodium sulfate and the solution was concentrated under reduced pressure. The crude product was flash chromatographed on silica gel (90% hexane – 10% triethylamine eluent) to yield 3.0 g (86%) of the product as a clear, colourless oil: R_f 0.58 (90% hexane – 10% triethylamine); IR (neat): 780, 1020, 1125, 1185, 1360, 1395, 1460, 1510, 1600 cm^{-1}; UV (THF) λ_{max} nm (ε): 226 (3.36 × 10^4), 274 (6450), 282 (7560), 314 (370); ^{31}P NMR (C_6D_6): 147.69; ^{1}H NMR (C_6D_6): 1.07 (t, 3H, $^{3}J_{HH'}$ = 7.0 Hz, CH_2CH_3), 1.11 (d, 6H, $^{3}J_{HH'}$ = 6.8 Hz, diastereotopic $CH(CH_3)_2$), 1.15 (d, 6H, $^{3}J_{HH'}$ = 6.8 Hz, diastereotopic $CH(CH_3)_2$), 3.306 (q, 1H, $^{3}J_{HH'}$ = 7.0 Hz diastereotopic OCH_2CH_3), 3.309 (q, 1H, $^{3}J_{HH'}$ = 7.0 Hz diastereotopic OCH_2CH_3), 3.367 (br t, 1H, diastereotopic $POCH_2CH_2O$), 3.373 (br t, 1H, diastereotopic $POCH_2CH_2O$), 3.47 (t, 2H, $^{3}J_{HH'}$ = 5.5 Hz, $C_{10}H_7CH_2$), 3.58 (m, 2H, $NCH(CH_3)_2$), 3.75 (m, 1H, diastereotopic $C_{10}H_7CH_2CH_2$), 3.84 (m, 1H, diastereotopic $C_{10}H_7CH_2CH_2$), 4.02 (m, 2H, $POCH_2CH_2O$), 7.18–8.02 (m, 7H, naphthyl-*H*); ^{13}C NMR (C_6D_6): 15.46 (OCH_2CH_3), 24.67 (d, $^{3}J_{PC}$ = 7.4 Hz, $CH(CH_3)_2$), 35.37 (d, $^{3}J_{PC}$ = 6.6 Hz, $C_{10}H_7CH_2$), 43.13 (d, $^{2}J_{PC}$ = 12.4 Hz, PNCH), 63.07 (d, $^{2}J_{PC}$ = 16.4 Hz, $C_{10}H_7CH_2CH_2$), 64.16 (d, $^{2}J_{PC}$ = 16.6 Hz, $POCH_2CH_2O$), 66.48 (OCH_2CH_3), 70.96 (d, $^{3}J_{PC}$ = 7.3 Hz, $POCH_2CH_2O$), 124.15, 125.57, 125.68, 126.02, 127.28,

*2-(1-Naphthyl)ethyl-di-(2-ethoxyethyl) phosphate (**7**)*

2-Ethoxyethanol (4.4 mL, 45 mmol) was added to a cooled solution (0°C) of freshly distilled 2-(1-naphthyl)ethyl phosphorodichloridite (5.3 g, 19 mmol) and triethylamine (10 mL, 72 mmol) in THF (100 mL). The resulting white slurry was stirred for 5 h at room temperature before it was oxidized by the dropwise addition of 0.1 M aqueous iodine solution until a pale yellow colour persisted. The mixture was diluted with dichloromethane (50 mL) and washed twice with 5% aqueous sodium bisulfite and twice with saturated brine. The aqueous layers were combined and back-extracted twice with dichloromethane. The combined organic layers were dried over sodium sulfate and concentrated to a clear, pale yellow liquid. The crude product was flash chromatographed on silica gel (diethyl ether – methanol, gradient 0–5% methanol, eluent) to give 6.0 g (78%) of the purified material: R_f 0.24 (50% diethyl ether – 50% dichloromethane); IR (neat): 780, 800, 1040, 1130, 1275, 1390, 1455, 1510, 1595 cm^{-1}; UV (THF) λ_{max} nm (ε): 226 (6.79 × 10^4), 272 (5580), 282 (6430), 292 (4430), 314 (335); ^{31}P NMR (C_6D_6): 0.44; ^{1}H NMR (C_6D_6): 1.00 (t, 6H, $^3J_{HH'}$ = 7.0 Hz, C*H*$_3$), 3.19 (q, 4H, $^3J_{HH'}$ = 7.0 Hz, C*H*$_2$CH$_3$), 3.29 (m, 4H, POCH$_2$C*H*$_2$O), 3.36 (t, 2H, $^3J_{HH'}$ = 7.4 and 7.5 Hz, $C_{10}H_7CH_2$), 4.07 (m, 4H, POC*H*$_2$CH$_2$O), 4.36 (dt, 2H, $^3J_{HH'}$ = 7.4 Hz, $^3J_{PH}$ = 8.6 Hz, $C_{10}H_7CH_2CH_2$); 7.17–7.98 (m, 7H, naphthyl-*H*); ^{13}C NMR (C_6D_6): 15.26 (*C*H$_3$), 34.05 (d, $^3J_{PC}$ = 6.0 Hz, $C_{10}H_7CH_2$), 66.38 (*C*H$_2$CH$_3$), 66.75 (d, $^2J_{PC}$ = 5.7 Hz, $C_{10}H_7CH_2CH_2$), 67.39 (d, $^2J_{PC}$ = 5.7 Hz, PO*C*H$_2$CH$_2$O), 69.48 (d, $^3J_{PC}$ = 6.9 Hz, POCH$_2$*C*H$_2$O), 123.96, 125.72, 125.78, 126.41, 127.47, 127.68, 129.03, 132.56, 133.60, 134.35 (naphthyl-*C*); mass spectrum, *m/e* (rel. intensity): 397 MH$^+$ (11), 269 (1), 243 (2), 154 (100), 115 (5). Anal. calcd. for $C_{20}H_{39}O_6P$: C 60.60, H 7.37, P 7.81; found: C 60.55, H 7.41, P 7.86.

*Representative procedure for the synthesis of the bis-phosphates: α,ω-triethylene glycol-bis-[2-(1-naphthyl)ethylethyl phosphate] (**131**)*

The freshly chromatographed phosphoramidite, **3** (3.0 g, 4.0 mmol), was coevaporated four times with dry diethyl ether to remove the residual triethylamine in the oil. This oil was dissolved in THF (90 mL) and 1 g of molecular sieves was added to the solution, which was then stirred magnetically for 10 min at room temperature, to dry the phosphoramidite. Ethanol was added to this mixture (1.0 mL, 17 mmol) and the coupling reaction was started by the addition of tetrazole (4.0 g, 60 mmol in 60 mL acetonitrile). The reaction was monitored by silica gel TLC (50% diethyl ether – 40% hexane – 10% triethylamine) by observing the disappearance of the bis-phosphoramidite (as the hydrolysis product) and the appearance of the bis-phosphite. In all cases, the reaction was essentially complete within 5–10 min. After 15 min, the phosphite triester intermediate was oxidized with an excess of 0.1 M aqueous iodine solution. The iodine solution was added dropwise until the orange-red colour persisted for over 5 min in the reaction mixture. The mixture was diluted with diethyl ether (150 mL) and washed twice with 5% aqueous sodium bisulfite and twice with saturated brine. The aqueous layers were combined and back-extracted three times with dichloromethane. The combined organic layers were dried over sodium sulfate and concentrated to a pale yellow oil. The crude product was flash chromatographed on silica gel (50% dichloromethane – 50% diethyl ether, followed by 50% dichloromethane – 40% diethyl ether – 10% methanol) to give 1.3 g (48%) of the purified material: R_f 0.66 (50% dichloromethane – 40% diethyl ether – 10% methanol); IR (neat): 780, 805, 1010, 1275, 1395, 1455, 1510, 1595 cm^{-1}; ^{31}P NMR ($CDCl_3$): −0.46; ^{1}H NMR ($CDCl_3$): 1.24 (br t, 6H, C*H*$_3$), 3.46 (t, 4H, $^3J_{HH'}$ = 7.3 Hz, $C_{10}H_7CH_2$), 3.52 (s, 4H, C*H*$_2$C*H*$_2$), 3.54 (m, 4H, POCH$_2$C*H*$_2$O), 4.03 (m, 8H, POC*H*$_2$CH$_2$O and C*H*$_2$CH$_3$), 4.36 (q, 4H, $C_{10}H_7CH_2CH_2$); 7.36–8.04 (m, 14H, naphthyl-*H*); ^{13}C NMR ($CDCl_3$): 15.84 (d, $^3J_{PC}$ = 6.8 Hz, *C*H$_3$), 33.53 (d, $^3J_{PC}$ = 6.6 Hz, $C_{10}H_7CH_2$), 63.68 (d, $^2J_{PC}$ = 5.9 Hz, *C*H$_2$CH$_3$), 66.25 (d, $^2J_{PC}$ = 5.9 Hz, PO*C*H$_2$CH$_2$O), 67.12 (d, $^2J_{PC}$ = 6.1 Hz, $C_{10}H_7CH_2CH_2$), 69.74 (d, $^3J_{PC}$ = 6.9 Hz, POCH$_2$*C*H$_2$O), 70.27 (*C*H$_2$*C*H$_2$), 123.19, 125.27, 125.46, 126.02, 127.06, 127.34, 128.62, 131.72, 132.75, 133.62 (naphthyl-*C*); mass spectrum (FAB, *p*-nitrobenzyl alcohol), *m/e* (rel. intensity): 675 MH$^+$ (18), 155 (100); high-resolution mass spectrum (FAB, *p*-nitrobenzyl alcohol), calcd. for $C_{34}H_{45}O_{10}P_2$: 675.2488 MH$^+$; found: 675.2513.

*α,ω-Triethylene glycol-bis-[2-(1-naphthyl)ethyl-2-ethoxyethyl phosphate] (**232**)*

The phosphoramidite, **3** (3.4 g, 4.5 mmol), was dissolved in THF (90 mL) along with 2-ethoxyethanol (1.5 mL, 15 mmol). The coupling reaction was initiated by adding tetrazole (5.0 g, 71 mmol) and the mixture was stirred for 15 min before it was oxidized to give 2.4 g (71%) of the product as a clear, colourless oil following work-up and flash chromatography: R_f 0.61 (50% dichloromethane – 40% diethyl ether – 10% methanol); IR (neat): 780, 800, 1040, 1130, 1275, 1355, 1395, 1455, 1510, 1595 cm^{-1}; ^{31}P NMR ($CDCl_3$): −0.39; ^1H NMR ($CDCl_3$): 1.14 (t, 6H, $^3J_{HH'}$ = 7.0 Hz, CH_3), 3.46 (q, 4H, $^3J_{HH'}$ = 7.0 Hz, CH_2CH_3), 3.47 (t, 4H, $^3J_{HH'}$ = 7.3 Hz, $C_{10}H_7CH_2$), 3.52 (s, 4H, CH_2CH_2), 3.54 (m, 8H, $POCH_2CH_2OEt$ and $POCH_2CH_2OCH_2CH_2$), 4.07 (m, 8H, $POCH_2CH_2OCH_2CH_2$ and $POCH_2CH_2OEt$), 4.38 (q, 4H, $C_{10}H_7CH_2CH_2$); 7.36–8.04 (m, 14H, naphthyl-*H*); ^{13}C NMR ($CDCl_3$): 14.90 (CH_3), 33.48 (d, $^3J_{PC}$ = 6.5 Hz, $C_{10}H_7CH_2$), 66.34 (CH_2CH_3), 66.37 (d, $^2J_{PC}$ = 6.5 Hz, $POCH_2CH_2OCH_2CH_2$), 66.56 (d, $^2J_{PC}$ = 6.0 Hz, $POCH_2CH_2OEt$), 67.24 (d, $^2J_{PC}$ = 6.0 Hz, $C_{10}H_7CH_2CH_2$), 68.92 (d, $^3J_{PC}$ = 7.0 Hz, $POCH_2CH_2OEt$), 69.71 (d, $^3J_{PC}$ = 6.0 Hz, $POCH_2CH_2OCH_2CH_2$), 70.27 (CH_2CH_2), 123.22, 125.27, 125.46, 126.03, 127.05, 127.33, 128.61, 131.73, 132.75, 133.62 (naphthyl-*C*); mass spectrum (FAB, *p*-nitrobenzyl alcohol), *m/e* (rel. intensity): 763 MH^+ (9), 155 (100); high-resolution mass spectrum (FAB, *p*-nitrobenzyl alcohol), calcd. for $C_{38}H_{53}O_{12}P_2$: 763.3012 MH^+; found: 763.3045.

*α,ω-Tetraethylene glycol-bis-[2-(1-naphthyl)ethylethyl phosphate] (**141**)*

The phosphoramidite, **4** (5.2 g, 6.5 mmol), was dissolved in THF (60 mL) and activated with tetrazole (6.0 g, 86 mmol). Ethanol (1.1 mL, 19 mmol) was added to the mixture, which was oxidized after 15 min, to give 3.2 g (68%) of the product as a clear, colourless oil following work-up and flash chromatography: R_f 0.66 (50% dichloromethane – 40% diethyl ether – 10% methanol); IR (neat): 780, 800, 1030, 1270, 1395, 1450, 1510, 1595 cm^{-1}, ^{31}P NMR ($CDCl_3$): −0.49; ^1H NMR ($CDCl_3$): 1.24 (br t, 6H, $^3J_{HH'}$ = 7.0 and 7.3 Hz, CH_3), 3.46 (t, 4H, $^3J_{HH'}$ = 7.2 and 7.3 Hz, $C_{10}H_7CH_2$), 3.51 (m, 8H, $CH_2CH_2OCH_2$), 3.57 (t, 4H, $^3J_{HH'}$ = 4.7 and 4.8 Hz, $POCH_2CH_2O$), 4.02 (q, 4H, $^3J_{HH'}$ = 7.0 Hz, CH_2CH_3), 4.05 (m, 4H, $POCH_2CH_2O$) 4.36 (q, 4H, $C_{10}H_7CH_2CH_2$); 7.30–8.04 (m, 14H, naphthyl-*H*); ^{13}C NMR ($CDCl_3$): 15.68 (d, $^3J_{PC}$ = 6.7 Hz, CH_3), 33.37 (d, $^3J_{PC}$ = 6.5 Hz, $C_{10}H_7CH_2$), 63.48 (d, $^2J_{PC}$ = 5.9 Hz, CH_2CH_3), 66.13 (d, $^2J_{PC}$ = 5.9 Hz, $POCH_2CH_2O$), 66.94 (d, $^2J_{PC}$ = 6.0 Hz, $C_{10}H_7CH_2CH_2$), 69.55 (d, $^3J_{PC}$ = 7.1 Hz, $POCH_2CH_2O$), 70.11 ($CH_2CH_2OCH_2CH_2$), 123.04, 125.11, 125.29, 125.86, 126.90, 127.17, 128.45, 131.56, 132.60, 133.46 (naphthyl-*C*); mass spectrum (FAB, *p*-nitrobenzyl alcohol), *m/e* (rel. intensity): 719 MH^+ (8), 155 (100); high-resolution mass spectrum (FAB, *p*-nitrobenzyl alcohol), calcd. for $C_{36}H_{49}O_{11}P_2$: 719.2750 MH^+; found: 719.2772.

*α,ω-Tetraethylene glycol-bis-[2-(1-naphthyl)ethyl-2-ethoxyethyl phosphate] (**242**)*

Addition of tetrazole (6.0 g, 86 mmol in 90 mL acetonitrile) to a solution containing the phosphoramidite **4** (5.3 g, 6.7 mmol), 2-ethoxyethanol (1.7 mL, 18 mmol), and THF (60 mL) was followed by 15 min of stirring to give 4.2 g (78%) of the product as a clear, colourless oil after oxidative work-up and flash chromatography: R_f 0.61 (50% dichloromethane – 40% diethyl ether – 10% methanol); IR (neat): 780, 800, 1030, 1270, 1350, 1395, 1455, 1510, 1595 cm^{-1}; ^{31}P NMR ($CDCl_3$): −0.40; ^1H NMR ($CDCl_3$): 1.14 (t, 6H, $^3J_{HH'}$ = 7.0 Hz, CH_3), 3.46 (q, 4H, $^3J_{HH'}$ = 7.0 Hz, CH_2CH_3), 3.48 (t, 4H, $^3J_{HH'}$ = 7.4 and 7.5 Hz, $C_{10}H_7CH_2$), 3.51 (m, 8H, $CH_2CH_2OCH_2CH_2$), 3.54 (m, 4H, $POCH_2CH_2OCH_2CH_2$), 3.59 (m, 4H, $POCH_2CH_2OEt$), 4.08 (m, 8H, $POCH_2CH_2OCH_2CH_2$ and $POCH_2CH_2OEt$), 4.38 (q, 4H, $C_{10}H_7CH_2CH_2$); 7.36–8.04 (m, 14H, naphthyl-*H*); ^{13}C NMR ($CDCl_3$): 14.86 (CH_3), 33.43 (d, $^3J_{PC}$ = 6.6 Hz, $C_{10}H_7CH_2$), 66.28 (CH_2CH_3), 66.35 (d, $^2J_{PC}$ = 5.9 Hz, $POCH_2CH_2OCH_2CH_2$), 66.50 (d, $^2J_{PC}$ = 6.0 Hz, $POCH_2CH_2OEt$), 67.17 (d, $^2J_{PC}$ = 6.1 Hz, $C_{10}H_7CH_2CH_2$), 68.88 (d, $^3J_{PC}$ = 7.0 Hz, $POCH_2CH_2OEt$), 69.64 (d, $^3J_{PC}$ = 7.1 Hz, $POCH_2CH_2OCH_2CH_2$), 70.24 ($CH_2CH_2OCH_2CH_2$), 70.25 ($CH_2CH_2OCH_2CH_2$), 123.18, 125.22, 125.41, 125.98, 127.00, 127.28, 128.56, 131.68, 132.70, 133.57 (naphthyl-*C*); mass spectrum (FAB, *p*-nitrobenzyl alcohol), *m/e* (rel. intensity): 807 MH^+ (12), 155 (100); high-resolution mass spectrum (FAB, *p*-nitrobenzyl alcohol), calcd. for $C_{40}H_{57}O_{13}P_2$: 807.3274 MH^+; found: 807.3297.

Received August 24, 1992[2]

ROBERT CRÊNEVERT, RENÉ GAGNON, DANIEL CHAMBERLAND, and MICHEL SIMARD. Can. J. Chem. **71**, 1225 (1993).

The macrocyclic polyether 18-crown-6 forms crystalline complexes with methyl sulfonates. Most complexes have a 2:1 (sulfonate:crown) stoichiometry whereas small aliphatic sulfonates give a 1:1 ratio. In the 2:1 ratio complexes, the guest molecules are coordinated above and below the crown in such a way that the dipoles are compensated. In the 1:1 ratio complexes, there is a polymeric type association with the two ends of the sulfonate interacting with different crown molecules. A crystal structure is reported for each type of complex. The complex 18-crown-6 · $CH_3SO_3CH_3$ (**7**) crystallizes in the monoclinic system, space group $P2_1/c$ with $Z = 4$. The unit cell dimensions are as follows: $a = 8.525(4)$, $b = 16.401(7)$, $c = 15.071(6)$ Å, $\beta = 113.92(3)°$. Final $R_w = 0.064$ for 3650 reflections. The complex 18-crown 6 · $(C_6H_5SO_3Me)_2$ (**1**) crystallizes in the monoclinic system, space group $P2_1/c$ with $Z = 2$. The unit cell dimensions are as follows: $a = 8.101(3)$, $b = 17.136(5)$, $c = 12.990(5)$ Å, $\beta = 121.30(3)°$. Final $R_w = 0.048$ for 2913 reflections.

ROBERT CHÊNEVERT, RENÉ GAGNON, DANIEL CHAMBERLAND et MICHEL SIMARD. Can. J. Chem. **71**, 1225 (1993).

Le polyéther macrocyclique 18-couronne-6 forme des complexes cristallins avec des sulfonates de méthyle. La plupart des complexes ont un rapport sulfonate/couronne de 2 : 1 alors que deux sulfonates de petite taille conduisent à des rapports 1 : 1. Dans les complexes de rapport 2 : 1, les sulfonates sont situés de part et d'autre de la couronne de façon à compenser les dipôles. Dans les autres complexes, il y a une association de type polymérique où les deux extrémités du sulfonate interagissent avec des couronnes différentes. Une structure cristalline est rapportée pour chaque type de complexes. Le complexe 18-couronne-6 · $CH_3SO_3CH_3$ (**7**) cristallise dans le système monoclinique, groupe d'espace $P2_1/c$ avec $a = 8{,}525(4)$, $b = 16{,}401(7)$, $c = 15{,}071(6)$ Å, $\beta = 113{,}92(3)°$ et $Z = 4$. La valeur finale de $R_w = 0.064$ avec 3650 reflexions. Le complexe 18-couronne-6 · $(C_6H_5SO_3Me)_2$ (**1**) cristallise dans le système monoclinique, groupe d'espace $P2_1/c$ avec $a = 8{,}101(3)$, $b = 17{,}136(5)$, $c = 12{,}990(5)$ Å, $\beta = 121{,}30(3)°$ et $Z = 2$. La valeur finale de $R_w = 0{,}048$ avec 2913 réflexions.

Introduction

The ability of synthetic receptor molecules such as crown ethers to complex inorganic or organic cations has been the subject of numerous reports during the last two decades (1). The study of well-defined complexes formed between crown compounds and neutral molecules represents a much less explored area. The latter complexes are widely recognized as model systems for molecular recognition of neutral polar molecules, which play an important role in biological systems. Small neutral molecules can form adducts with crown ethers if they present one or both of the following structural features: a relatively large dipole moment and X—H bonds (X = O, N, C) able to form hydrogen bonds with oxygens of the crown ligand in a complementary spatial arrangement (2–5). Several complexes of this kind have a 1:2 stoichiometric ratio of host/guest and the guest molecules are coordinated above and below the crown in such a way that the dipoles are compensated. All complexes are far reported contain either polar O—H bonds (2, 6) (water, alcohols, gem-diols, diacids), polar N—H bonds (urea and analogues (7, 8), amides (9)), or polar C—H bonds (nitriles (10, 11), nitro compounds (10–12), dimethyl sulfone (13), dimethyl sulfate (14), dimethyl diesters (15, 16)).

Another type of neutral component complex has been obtained with weakly acidic compounds such as phenols, carboxylic acids, and weak inorganic acids (17–20). The guest usually contains only one hydrogen suitable for hydrogen bonding and one water molecule per guest serves as a linkage between the acid and the crown (2–4).

Although a number of crystallographic, thermodynamic, and molecular mechanics studies have been performed, the nature of the interactions between the partners in such complexes is only partly understood (21–29). We report here the formation of well-defined complexes between 18-crown-6 and several methyl sulfonates.

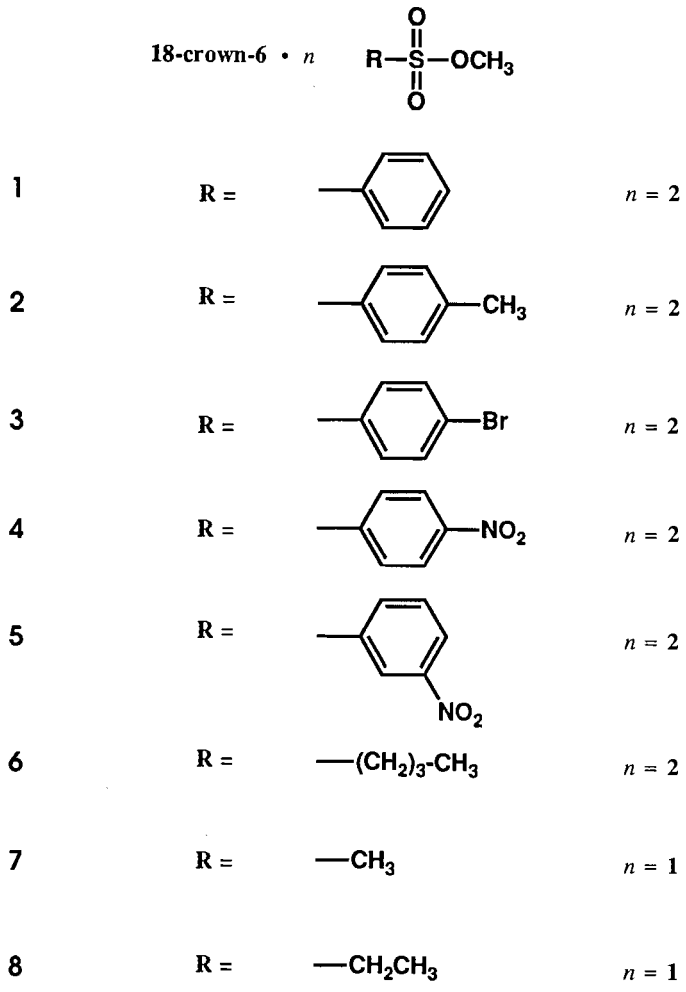

SCHEME 1

Experimental

The NMR spectra were taken on a Varian XL-200 multinuclear spectrometer. The infrared spectra, obtained from a KBr pressed disc, were run on a Beckman 4250 or an FT-IR Bomem MB 102 spectrometer. The microanalyses were performed on a Carlo Erba Strumentazione-1106 elemental analysis instrument.

Preparation of the complexes (general procedure)

The methyl sulfonate (2 mmol) is dissolved in dry tetrahydrofuran (10 mL) and this solution is added to a solution of 18-crown-6 (2 mmol) in dry tetrahydrofuran (10 mL). The complex crystallizes upon addition of diethyl ether an cooling. The colorless solid complex is filtered and dried under vacuum. The complex is recrystallized in the appropriate solvent and dried under vacuum until constant melting point is obtained. Physical data pertaining to the individual complexes are given below.

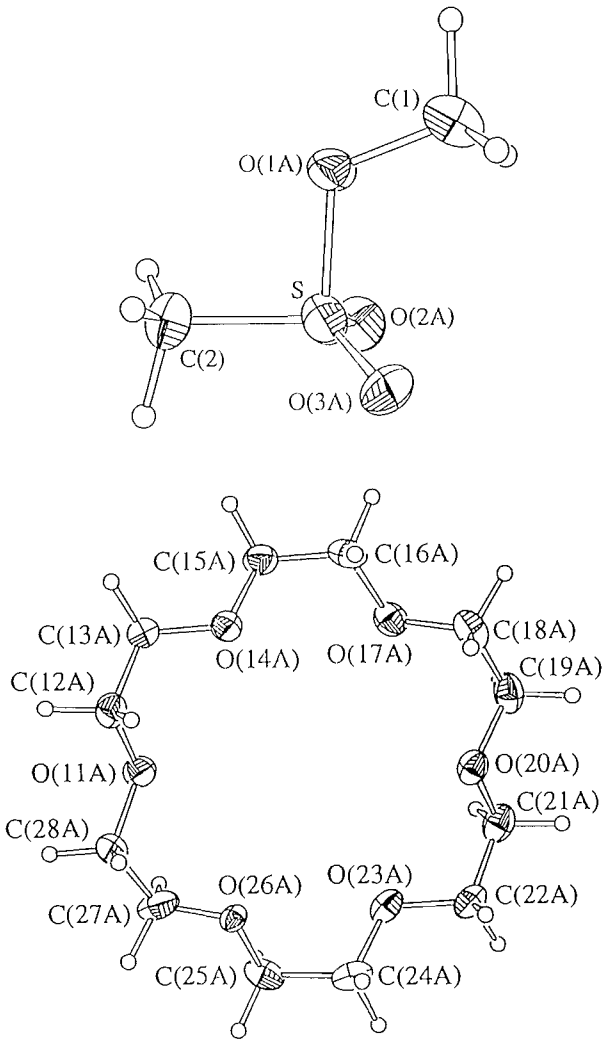

FIG. 3. ORTEP view of the two molecules in complex **7** (models A only) with the numbering scheme adopted. Ellipsoids drawn at 40% probability level. Hydrogens represented by spheres of arbitrary size.

44.3, 55.1 (OCH_3), 70.6 (crown). Anal. calcd. for $C_{15}H_{32}O_9S_1$: C 46.38, H 8.29; found: C 46.77, H 7.96.

Crystallographic characterization of complexes 1 and 7

The intensity data were collected on a Nonius diffractometer using the $\omega/2\theta$ mode and graphite monochromatized CuKα radiation. The unit cell dimensions were computed from the angular settings of 24 well-centered reflections in the range $40 \leq 2\theta \leq 50°$ (**1**) or $45 \leq 2\theta \leq 55°$ (**2**). The final parameters and other crystal data of interest are presented in Table 1 and data collection and refinement indicators are in Table 2. The structures were solved by direct methods using NRCVAX and difference Fourier synthesis using SHELX-76.[3] Disorder model introduced to account for high residual peaks in the sulfonate vicinity, with occupancies initially refined, then fixed in final refinement cycles. Full-matrix least-squares refinement based on F's all non-hydrogen atoms anisotropic, hydrogen atoms isotropic. Hydrogen atoms found from a difference Fourier map and (or) calculated, disorder H-atoms introduced at ideal positions ($D_{C-H} = 0.95$ Å) with B_{iso} refined.

[3]The programs used here are NRCVAX, program system for structure analysis (Gabe, LePage, Charland, and Lee (30)), SHELX-76, program for structure analysis (Sheldrick (31)), and ORTEP, stereodrawings (Johnson (32)).

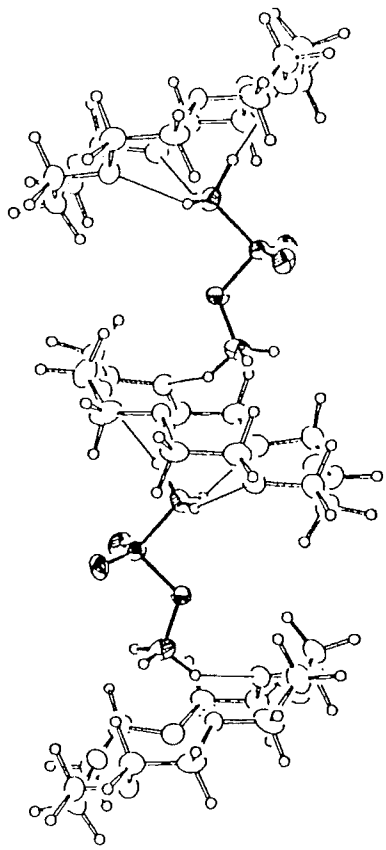

FIG. 4. ORTEP view of the association (sulfonate model A, crown model A) of the polymeric type 1:1 complex of the $C_{14}H_{30}O_9S$ compound (**7**). Pseudo hydrogen bonds represented by thin bonds.

Secondary extinction coefficients not refined. The scattering curves for the non-hydrogen atoms were taken from Cromer and Mann (33) and those for the H-atoms from Stewart, Davidson, and Simpson (34). Anomalous dispersion contributions (df' and df'') were from Cromer and Liberman (35).

Results and discussion

The methyl sulfonates were prepared under phase-transfer catalysed conditions according to a known procedure (36). Sulfonate – crown ether complexes were prepared in good yield (71–86%) by mixing the methyl sulfonate and 18-crown-6 in tetrahydrofuran. The complexes **1**–**8** (Scheme 1) are stable solids with sharp melting points. In most cases, the melting point of the complex is above those of the constituents. For instance, the melting point of complex **1** (69–70°C) is above those of the crown (40°C) or the sulfonate (liquid at room temperature). The stoichiometry of compounds **1**–**8** was determined by elemental analysis (carbon, hydrogen) and by integration of signals of the constituents in NMR. The analyses are in agreement with those observed in the X-ray determination for compounds **1** and **7**. Both the frequencies and spectral activity of the crown ether bands in the infrared spectra of the complexes are comparable to those found in various complexes in which the crown is known to have a regular D_{3d} symmetry. CH_2 rocking bands at ~960 cm^{-1} and C—C stretching at ~835 cm^{-1} are singlets in complexes **1**–**8**. Distortion of the crown causes a splitting of these vibrational bands (3, 20). These observations suggest that the shape of the crown in the complexes described here is es-

sentially that of a regular crown of symmetry D_{3d}, although some distortion is probably present, especially in the 1:1 ratio complexes.

The ^1H and ^{13}C NMR signals of the crown protons and carbons in complexes **1–8** are on average close to the shifts of the free crown hydrogens and carbons in the same solvent ($CDCl_3$). The average chemical shift of protons is 3.65 ppm compared to 3.67 ppm for the free crown and the average position of carbons is 70.51 ppm compared to 70.76 ppm for the free crown.

To gain further insight in the structures, X-ray analyses were undertaken. We report here the structures of 18-crown-6 · 2 methyl benzenesulfonate (**1**) and 18-crown-6-methyl methanesulfonate (**7**).[4]

Crystal structure of 18-crown-6 · 2(methyl benzenesulfonate) complex (*1*)

The final atomic coordinates and the equivalent U values of the anisotropic temperature factors are given in Table 3. A stereoview showing the molecular conformations and the atomic numberings of both constituents is shown in Fig. 1.

The centrosymmetrical 18-crown-6 ligand adopts approximative D_{3d} conformation with C—O—C—C and O—C—C—O torsion angles near 180° (average value 178.6°) and 70° (average value 70.5°), which is the expected *gauche* conformation of the ethyleneoxy units (Table 5). The C—O and C—C bond distances average 1.41 and 1.49 Å while the O—C—C and C—O—C angles average 109.1° and 112.6°, respectively (Table 4). The values are consistent with those reported for the majority of 18-crown-6 complexes that exhibit the pseudo D_{3d} conformation.

The sulfonate molecule is disordered over two conformations of unequal proportion (70:30). A view of the major model association is shown in Fig. 2. The sulfonate molecules are coordinated above and below the crown in such a way that the dipoles are compensated. The methyl group of each sulfonate molecule yields three C—H---O contacts to alternate oxygen atoms of the crown.

The hydrogen bonding contacts and geometries can be found in Table 6. The C—H---O bridge angles are 125°, 138°, and 143° with methyl C---O distances of 3.262, 3.327, and 3.310 Å and CH---O distances of 2.64, 2.53, 2.42, shorter than the sum of the van der Waals radii (2.7 Å). The most important geometrical characteristic of hydrogen bonds is that the distance between the proton and the acceptor atom is shorter than the sum of their van der Waals radii (37, 38). The existence of only one H---O short contact indicates the lower stability of the minor association (supplementary data).

Crystal structure of 18-crown-6-methyl methanesulfonate complex (7)

This complex contains more disorder than the previous one; the crown has two occupancies (A and B) of almost equal population (55:45) and the sulfonate molecule is dis-

[4]A satisfactory X-ray analysis of complex **2** (18-crown-6 · methyl *p*-toluenesulfonate) has also been obtained. This structure is very similar to the structure of **1** and is not described here.

TABLE 7. Final atomic coordinates with their e.s.d's (S × 10^5; O, C, × 10^4) and equivalent isotropic temperature factors (× 10^3) for the $C_{14}H_{30}O_9S$ compound **7**

[a]Labels A and B stand for major (occ.:0.55) and minor (occ.: 0.45) crown disorder.

equal population (55:45) and the sulfonate molecule is disordered over one major and two minor orientations. The atomic numbering is given in the diagram in Fig. 3. The bond distances and angles, calculated from the final atomic coordinates (Table 7), are given in Table 8. The crown ligand has a pseudo D_{3d} symmetry in both conformation A and B with C—O—C—C and O—C—C—O torsion angles (Table 9) near 180° (average values 173.1° (A) and 176.1° (B)) and 70° (average values 71.1° (A) and 72.1° (B)). The C—O and C—C bond distances average 1.41 (A), 1.41 (B) and 1.51

[a]Calculated hydrogen atoms.
[b]$x, 1/2 - y, 1/2 + z$.
[c]$x, 1/2 - y, -1/2 + z$.

(A), 1.44 (B), respectively. The O—C—C and C—O—C angles average 109.4° (A), 108.9° (B) and 112.3° (C), 112.0° (B).

In this 1:1 ratio complex, the sulfonate molecule acts as a bifunctional guest linking the crown molecules and thus giving rise to infinite chains. Similar complexes were observed with dimethyl sulfate or dimethyl acetylenecarboxylate (14, 16) but complex **7** is unique because two different methyl groups, CH_3—O and CH_3—SO_3, are involved in the association. A view of the major model association (sulfonate A, crown model A) of the polymeric type 1:1 complex **7** is shown in Fig. 4. The hydrogen bonding contacts and geometries can be found in Table 10. On the CH_3—SO_3 end of the sulfonate molecule, all three methyl hydrogen atoms participate in interactions with altemate oxygen atoms of the crown. The C—H---O bridge angles are 175°, 147°, and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12
For personal use only.

152°; the corresponding C---O distances are 3.377, 3.257, and 3.328 Å whereas CH---O distances are 2.32, 2.46, and 2.46 Å, shorter than the sum of the van der Waals radii.

On the CH_3—O end of the sulfonate molecule, where hydrogens are much less acidic than CH_3—SO_3 methyl hydrogens, interactions are very weak. In the association model in Fig. 4, there is only one weak interaction (C---O = 3.394 Å, CH---O = 2.64 Å, and C—H---O angle = 137°). The other two hydrogens are directed away from the crown ether.[5]

The hydrogen bond is one of the significant factors in the formation of natural or synthetic supramolecular structures. The recent reports on molecular recognition are concerned almost exclusively with strong hydrogen bonding of the conventional type (O—H---O, N—H---O). The present work shows that molecular arrays can be constructed with weaker C—H---X hydrogen bonds.

Styrylbenzodiazinones 2. Chromo- et fluoroionophores dérivés du monoaza-15-couronne-5. Synthèse et structure

LOUIS CAZAUX,[1] MOURAD FAHER, CLAUDE PICARD ET PIERRE TISNÈS

Synthèse et physicochimie organique, Unité de recherche associée au Centre national de la recherche scientifique n° 471, Université Paul Sabatier, 118 route de Narbonne, 31062 Toulouse Cédex, France

Reçu le 25 février 1993

LOUIS CAZAUX, MOURAD FAHER, CLAUDE PICARD et PIERRE TISNÈS. Can. J. Chem. **71**, 1236 (1993).

Au cours d'un travail sur les dérivés styryliques de benzodiazinones, nous avons préparé la 7-*N*,*N*-diméthylamino-3-méthyl-1,4-benzodiazine-2-one **4***a* ainsi que deux chromo- et fluoroionophores dérivés du monoaza-15-couronne-5 et de styrylbenzodiazinones. Une étude structurale de ces composés par RMN ^1H et ^{13}C, spectrophotométrie UV et modélisation moleculaire a été réalisée. Contrairement aux styrylbenzoxazinones, les styrylbenzodiazinones présentent une isomérisation *Z*/*E* dans l'acétonitrile. Cette isomérisation est photoinduite, catalysée par les ions métalliques et constitue un phénomène réversible. D'autre part, une réaction d'alkylation efficace de la fonction lactame des benzodiazinones est décrite.

LOUIS CAZAUX, MOURAD FAHER, CLAUDE PICARD, and PIERRE TISNÉS. Can. J. Chem. **71**, 1236 (1993).

In connection with our work on styryl derivatives of benzodiazinones, we have prepared the 7-*N*,*N*-dimethylamino-3-methyl-1,4-benzodiazin-2-one **4***a* and two chromo- and fluoroionophores derived from the monoaza-15-crown-5 and styrylbenzodiazinones. A structural study of these compounds by ^1H and ^{13}C NMR, UV spectrophotometry, and molecular modelling was carried out. Unlike styrylbenzoxazinones, styrylbenzodiazinone derivatives showed a *Z*/*E* isomerization in acetonitrile solution. The isomerization was photoinduced, was catalysed by metallic ions, and was a reversible process. As well, an efficient alkylation reaction of the lactam function of benzodiazinones is described.

Les chromo- et fluoroionophores ont été largement développés ces dernières années en particulier en relation avec des macrocycles de type éther-couronne (1). La sensibilité des sondes spectrophotométriques et plus encore fluorométriques peut être ainsi liée à la sélectivité de ces derniers vis-à-vis des cations métalliques et plus généralement au phénomène de reconnaissance ionique ou moléculaire. L'observation du phénomène et sa quantification à des fins, par exemple, de dosage nécessite la perturbation d'un système conjugué sous l'effet de l'association supramoléculaire. Pour cette raison les systèmes styryliques ont été l'objet de plusieurs études sur les combinaisons suivantes : dinitrostilbène (2), styrylbenzoxazinone (1), mérocyanine (3) ou coumarine 153 (4) couplés au monoaza-15-couronne-5, styrylbenzothiazole associé au benzo-15-couronne-5 (5).

Dans cette étude, nous décrirons d'abord la synthèse et l'analyse structurale des aminobenzodiazinones **4***a*,*b* et **5***a*,*b* et de deux nouveaux ionophores **1** et **2** dérivés du monoaza-15-couronne-5 et de deux styrylbenzodiazinones (schéma 1). Une discussion sur les caractéristiques structurales et spectrales des ionophores s'appuiera notamment sur l'étude des styrylbenzodiazinones (6) où le composé **6** dépourvu du motif ether-couronne peut servir de modèle au système **1**.

Nous examinerons le problème structural propre à ces systèmes styryliques, à savoir l'isomérie rotationnelle autour de la liaison N–C (7, 8) et l'existence d'une liaison H intramoléculaire entre un CH éthylénique et le groupe carbonyle qui favoriserait l'un des rotamères (8).

À ce problème nous en ajouterons un autre mis en évidence dans la seule série des styrylbenzodiazinones. C'est une modification structurale photoréversible catalysée par les ions métalliques.

Résultats

Synthèse

Les *aminobenzodiazinones* n'ont pas été décrites jusqu'à présent. Le schéme logique de leur synthèse était bien évidemment l'hétérocyclisation par un ester α cétonique de la 4-*N*,*N*-diméthylamino-1,2 phénylène-diamine **8** (schéma 2).

Cette triamine a été précédemment décrite (9), sous forme de trichlorhydrate, par réduction de la 3,4-dinitro-*N*,*N*-diméthylaniline dans l'acide chlorhydrique avec du chlorure d'étain(II). Plusieurs essais de neutralisation de ce trichlorhydrate, suivis de la condensation avec le pyruvate d'éthyle, se sont révélés infructueux. Nous avons toujours observé une détérioration rapide de la benzodiazinone **4** dans le milieu réactionnel. Dans le cas des diméthylamino-benzoxazinones, Le Bris (10) avait également noté une dégradation rapide, catalysée par des impuretés, de ce type de colorant.

Au vu de ces résultats, nous avons préféré utiliser comme synthon la 3-amino-4-nitro-*N*,*N*-diméthylaniline **9** et procéder à une hydrogénation catalytique du groupement nitro afin d'atteindre le composé **8**. La diamine **9** a été préparée en quatre étapes à partir de la 3-fluoroaniline **13** selon les méthodes de Hodgson et Nicholson (11) et de Arcos et Miller (12). Le traitement de la 3-fluoroaniline par l'anhydride acétique, suivie d'une réaction de nitration nous a fourni le 5-fluoro-2-nitro acétanilide **11**. L'action du chlorhydrate de diméthylamine sur ce dernier composé conduit au 5-*N*,*N*-diméthylamino-2-nitro acétanilide qui, par hydrolyse basique afin de régénérer la fonction amine primaire, nous a permis d'atteindre le synthon **9** avec un rendement global de 22% à partir de la fluoroaniline de départ. L'hydrogénation catalytique de **9**, puis la réction in situ en milieu éthanolique, sous atmosphère inerte, du pyruvate d'éthyle conduit quantitativement à la benzodiazinone **4**, plus exactement à un mélange des deux isomères **4***a* et **4***b*.

En effet, le spectre RMN ^1H du produit **4** à 200 MHz dans $CDCl_3$ montre la présence de deux groupes méthyle à 2,54 et 2,62 ppm ainsi que deux types de groupes diméthylamino ($\Delta\delta$ = 0,07 ppm). Une analyse en chromatographie HPLC permet de quantifier les isomères **4***a* et **4***b* dans des proportions respectives 70 : 30. Une purification par recristallisation dans l'éthanol et par chromatographie HPLC préparative nous a permis d'isoler chacun de ces deux isomères (**4***a*, Rdt = 70%; **4***b*, Rdt = 25%).

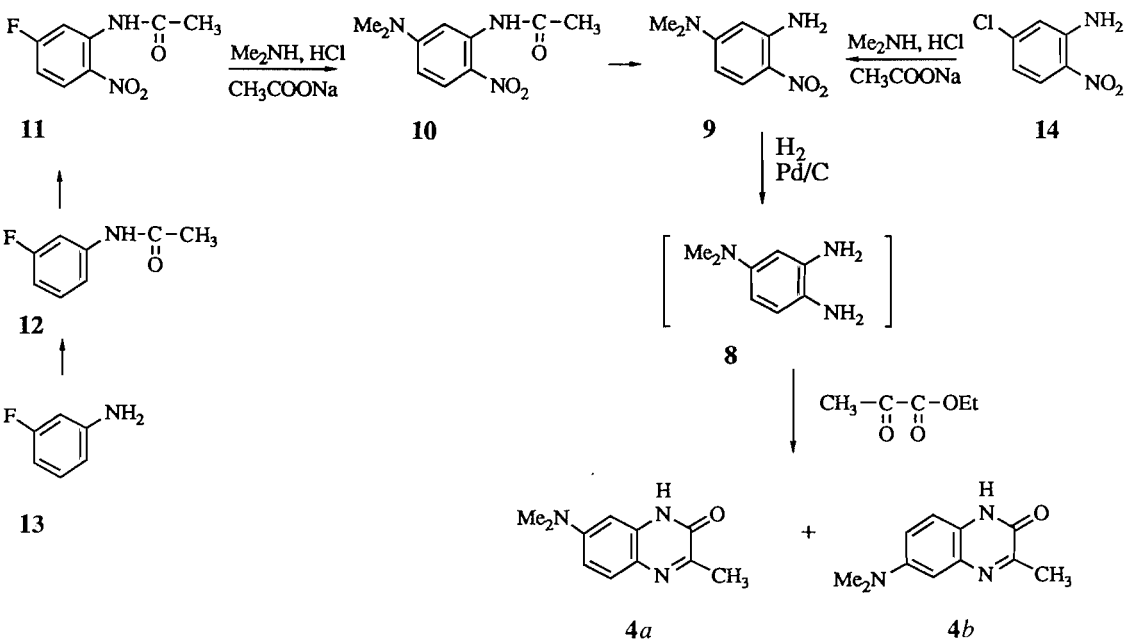
SCHÉMA 1



11 **10** **9** **14** **12** **8** **13** **4***a* **4***b*

SCHÉMA 2

Cette première approche nous ayant permis d'accéder aux benzodiazinones **4***a* et **4***b*, nous avons envisagé de préparer le synthon **9** par une voie plus directe. En nous inspirant des travaux de Arcos et Miller (12) sur la substitution d'un fluor par le groupement diméthylamino, nous avons appliqué cette réaction sur la 5-chloro-2-nitroaniline **14**, produit commercial. Bien que la substitution nucléophile soit rendue plus délicate dans ce cas (chlore à la place du fluor, présence sur le noyau aromatique d'un groupement donneur amino) nous avons pu optimiser les conditions de la réaction (durée de chauffage, proportion des réactifs) et obtenir ainsi **9** en une seule étape avec un rendement de 67% en produit isolé.

Nous avons également cherché à obtenir des *diméthylamino-benzodiazinones alkylées sur l'azote lactamique* afin, par exemple, de pouvoir moduler leur lipophilie. Deux approches peuvent être envisagées : la première consiste à effectuer l'hétérocyclisation à partir d'une triamine présentant les fonctions amines primaire, secondaire et tertiaire, et présente l'avantage de ne conduire qu'à un seul isomère analogue de **4***a*; la seconde, d'une utilisation plus générale, consiste à effectuer l'alkylation de l'atome d'azote lactamique de la benzodiazinone elle-même. Lorsque l'on oppose (schéma 3) la triamine **15**, obtenue par réduction de **10** avec AlH_3, au pyruvate d'éthyle, aucun produit de condensation n'a pu être détecté. En ce qui concerne la seconde approche, nous n'avons pas réussi à alkyler la benzodiazinone **4***a* par l'action du paratoluène sulfonate de méthyle et de K_2CO_3 en utilisant les mêmes conditions opératoires que pour l'obtention de **3** (6). Cependant le recours à l'iodure de méthyle et au carbonate de césium dans l'acétone, à température ambiante, nous a permis d'obtenir les composés **5***a* et **5***b* avec des rendements quantitatifs à partir de leurs précurseurs **4***a* et **4***b* (schéma 3).

Les *fluoroionophores* **1** et **2** ont été préparés suivant des méthodes décrites (6) par condensation entre le *N*-(4-formylphényl)-aza-15-couronne-5 et la benzodiazinone correspondante (**3** et **4***a* respectivement). La méthode à l'anhydride acétique fournit **1** avec un rendement de 35% et celle à la pipéridine **2** avec un redement de 10%.

Caractéristiques structurales

Les caractéristiques structurales RMN ^1H et ^{13}C, dans $CDCl_3$, des styrylbenzodiazinones **1**, **2** et des aminobenzodiazinones **4***a*,*b* et **5***a*,*b* sont reportées dans les tableaux 1 et 2. Nous y avons également reporté les caractéristiques

spectrales des composés **3** et **6** étudiés dans notre publication à suivre (6).

En RMN ^{13}C les attributions ont été effectuées sur la base des spectres ^{13}C couplés ^{1}H off resonance à 6,29 MHz, des spectres *J* modulé ou des spectres corrélés ^{1}H–^{13}C.

Aminobenzodiazinones

Les analyses centésimales et les déterminations de la masse moléculaire par spectrométrie de masse des composés **4***a* et **4***b* ont permis de démontrer sans ambiguïté l'existence d'une isomérie de position dans ces deux composés.

La structure des aminobenzodiazinones **4***a*, **4***b* et **5***a*, **5***b* a été établie par RMN ^{1}H par comparaison des valeurs de déplacement chimique expérimentales et calculées. Ces dernières ont été déterminées à partir de la benzodiazinone **3** et de son homologue non méthylé sur l'atome d'azote lactamique (6) et des incréments du groupe diméthylamino en *ortho* (−0,66 ppm) et en *méta* (−0,18 ppm) déduits du benzène et du diméthylaminobenzène (13). À titre d'exemple nous avons reporté dans le tableau 3 les valeurs calculées et expérimentales, ainsi que les écarts correspondants dans le cas des composés **5***a* et **5***b*.

Une démarche analogue effectuée en RMN ^{13}C en utilisant les incréments du groupe diméthylamino sur un noyau aromatique (14) permet de confirmer cette attribution. Dans ce cas, la différenciation des deux isomères se fait sur les carbones k et n du noyau benzénique (notation du tableau 2). En effet les valeurs calculées pour ces deux carbones tertiaires sont respectivement 98,1 et 130,2 ppm pour la structure **4***a*, **5***a* et 114,9 et 113,9 ppm pour la structure **4***b*, **5***b*.

Les propriétés photophysiques de ces quatre diaminobenzodiazinones permettent également une attribution de structures. En effet **4***a* et **5***a* présentent des propriétés marquées de fluorescence, alors que **4***b* et **5***b* en sont dépourvues. Ceci peut s'expliquer du fait que, dans la structure **a** (groupe NMe_2 en position 7), le chromophore peut être décrit par les deux formes mésomères **a** et **a'** (schéma 4), la forme **a'** étant prédominante dans l'état excité, tandis que pour l'isomère **b** (groupe NMe_2 en position 6) il ne peut y avoir extension de conjugaison du doublet et l'azote du groupe diméthylamino vers le cycle diazinone, d'où l'absence de fluorescence dans ce cas.

Cette attribution de structures pour **4***a* et **4***b* est également en accord avec les proportions relatives de ces deux composés obtenues lors de la réaction d'hétérocyclisation à partir de la triamine **8** (schéma 5). Un calcul de distribution de charge par MNDO sur cette triamine **8** a permis d'établir que l'atome d'azote en *para* du groupe NMe_2 est plus nucleophile (−0,4320) que celui situé en *méta* (−0,4274). D'autre

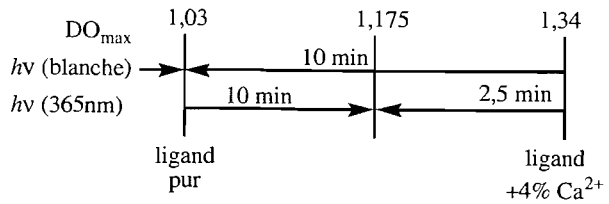
TABLEAU 5. Influence sur la DO_{max} du composé **6** dans l'acétonitrile de deux types d'irradiation en *absence* ou en *présence* de Ca^{2+}[a]



[a]Le temps nécessaire pour atteindre la position d'équilibre est indiqué au-dessus de chaque flèche.

part il a été montré par Le Bris que les 2-aminophénols réagissent dans un premier temps sur la fonction cétone du pyruvate d'éthyle pour former la liaison imine de l'hétérocycle (15). Nous retrouvons ce même mécanisme dans le cas de l'addition de 1,2-diaminobenzènes sur des β-céto-esters conduisant à des benzodiazépines (16). En tenant compte de ces deux considérations, nucléophilie plus grande de l'atome d'azote en *para* du NMe_2 de **8** et formation de la liaison imine dans une première étape, la réaction d'hétérocyclisation est donc orientée préférentiellement vers l'isomère **4*a***, obtenu expérimentalement avec un rendement de 70%.

Styrylbenzodiazinones

Les spectres RMN ^1H des composés **1** et **2** réalisés dans $CDCl_3$ montrent un systéme AB attribué aux protons H_a et H_b de la liaison styrylique avec une constante de couplage de 16 Hz qui indique une configuration *E*. La largeur à mi-hauteur du signal du proton H_a (1,5 Hz) est supérieure à celle du signal de H_b (1,0 Hz) du fait du couplage ^4J avec les protons BB′ de la partie benzénique portant l'éther-couronne. Le système AA′BB′ de cette dernière partie et les protons aromatiques du motif benzodiazinone ont d'autre part des déplacements chimiques et des constantes de couplage très proches de ceux de **6** et du leurs précurseurs **3** et **4*a*** respectivement.

Les attributions RMN ^{13}C ont été effectuées pour **1** par analogie avec la styrylbenzodiazinone homologue **6** et pour **2** par analogie avec **6** pour la partie styrylique et avec **4*a*** pour le motif aminobenzodiazinone.

Équilibre photoréversible

Lors de l'étude de complexation des ionophores **1** et **2** par les ions alcalins et alcalino-terreux dans l'acétonitrile nous avons constaté que la densité optique (DO) à la longueur d'onde d'absorption maximale de ces composés variait beaucoup dès l'ajout d'une petite quantité de sel métallique.

L'analyse sommaire de ce phénomène en préalable à l'étude de complexation[2] nous a donc paru indispensable. Nous l'avons menée à la fois sur les ionophores **1** et **2** ainsi que sur l'analogue linéaire **6**, dépourvu de motif éther-couronne pour lequel nous avons montré[2] qu'il ne possède pas de propriétés complexantes significatives contrairement aux composés **1** et **2**.

Absorption UV

On suit les variations en fonction du temps de la densité optique de ces composés dans l'acétonitrile à la longueur d'onde d'absorption maximale après addition d'une quantité catalytique de perchlorate de calcium (rapport Ca^{2+}/ligand, ρ = 0,04) avant et après irradiation à la lumière blanche ou à longueur d'onde de 365 nm (tableaux 4 et 5, figure 1).

On observe avec les trois composés un phénomène identique décomposable en quatre stades (figures 1*a*, *b*). Avec la styrylbenzodiazinone **6**, par exemple, une solution $4,08 \times 10^{-5}$ M dans l'acétonitrile présente (*i*) un maximum d'absorption à 441 nm (bande de transfert électronique) et une DO égale à 1,026; (*ii*) l'addition d'une faible quantité de perchlorate de calcium (ρ = 0,04) à la solution précédente, directement dans la cuve, provoque une forte augmentation de DO (31%) en l'espace d'environ 1 h; (*iii*) l'exposition de cette solution pendant environ 10 min à la lumière blanche ramène la DO à sa valeur en absence d'ion Ca^{2+}; puis (*iv*)

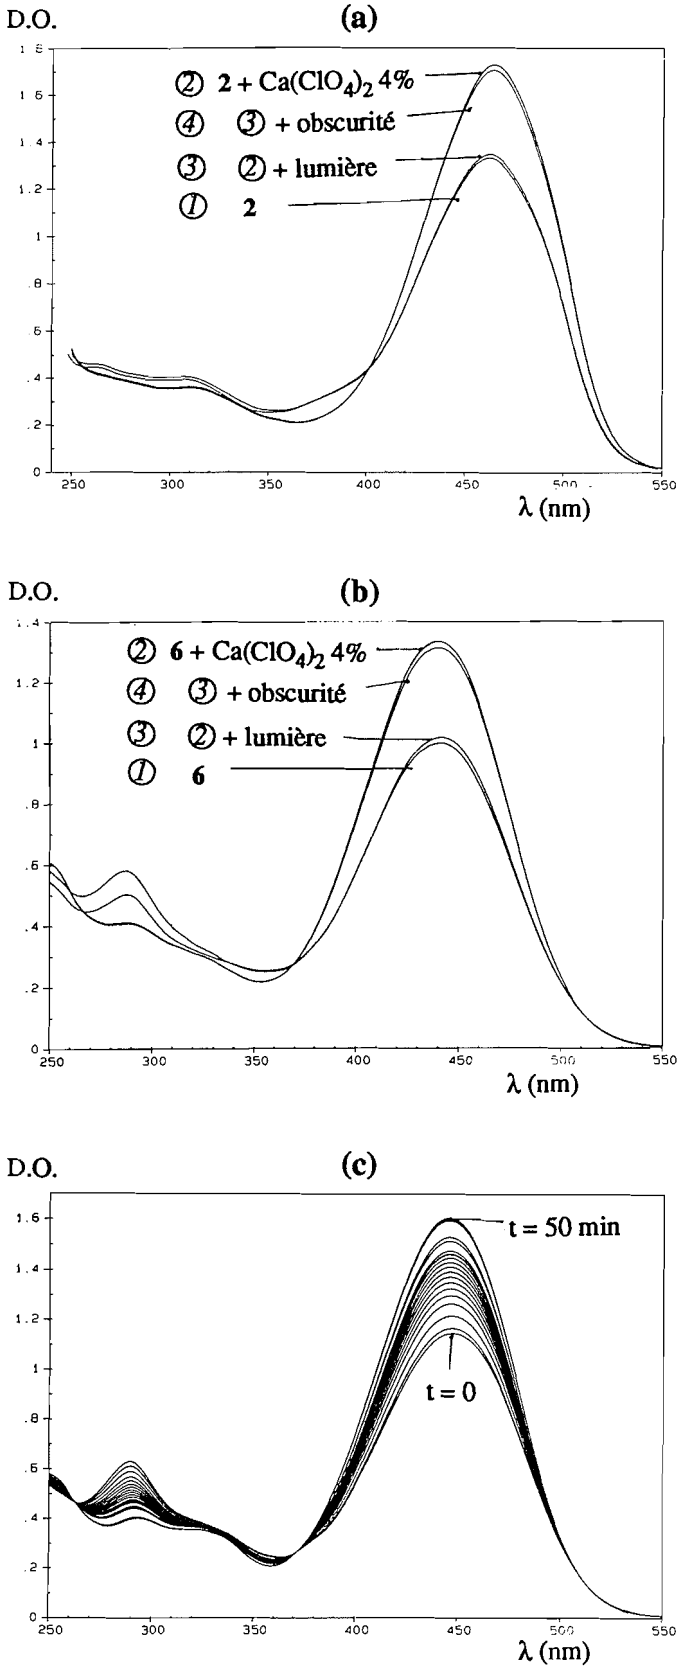

FIG. 1. Evolution du spectre d'absorption UV dans l'acétonitrile des composés **2** (*a*) et **6** (*b*) : ligand seul (1), après ajout de 4% de $Ca(ClO_4)_2$ (2), exposition à la lumière blanche (3) et retour à l'obscurité (4); (*c*) étude cinétique de la transformation du composé **1** dans l'acétonitrile après ajout de 4% de $Ca(ClO_4)_2$.

un maintien de 2 h à l'obscurité permet de retrouver la valeur maximale (1,342). Le phénomène est donc important (27–45% selon les composés) et réversible, et la longueur d'onde maximale ne varie pas de manière significative au cours du cycle.

De plus, le même phénomène a été observé lors de l'étude de complexation avec les différents ions étudiés (alcalins, alcalino-terreux et Zn^{2+}) dans l'acétonitrile ($\varepsilon = 34$). Un essai sur le composé **6** dans le dioxanne ($\varepsilon = 2$) avec le perchlorate de calcium conduit au même résultat. La nature de l'ion et du solvant semble donc avoir peu d'effet sur le phénomène étudié.

Il est aussi à noter qu'une irradiation sous lampe UV à vapeur de mercure (6 W) à 365 nm (tableau 5) du composé **6** dans l'acétonitrile augmente la DO de 18% lorsque l'équilibre est atteint (t = 10 min) alors que l'exposition à la lumière blanche ne la modifie pas; la même expérience en présence du perchlorate de calcium indique une décroissance du même ordre. Cependant, alors que l'action de la lumière blanche ramène la DO à sa valeur sans Ca^{2+}, l'action de l'autre source lumineuse tend à la ramener à une valeur intermédiaire. Le phénomène est ici encore réversible par mise à l'obscurité.

Enfin, aucune variation de DO n'est observée sur la benzodiazinone **3** par addition de 4% de perchlorate de calcium.

Une *étude cinétique* de la variation de DO dans l'acétonitrile après addition de 4% de perchlorate de calcium sur les trois composés a montré la présence de deux points isosbestiques (figure 1*c*) indiquant la non accumulation d'un intermédiaire. Après traitement des données par le programme LSG (Least Squares Guggenheim) les trois constantes de vitesse de la cinétique de pseudo premier ordre ont été déterminées à 25°C :

$$k_1\,(\mathbf{1}) = 3{,}98 \times 10^{-4} \pm 0{,}1\ s^{-1}$$
$$k_1\,(\mathbf{2}) = 2{,}48 \times 10^{-3} \pm 0{,}05\ s^{-1}$$
$$k_1\,(\mathbf{6}) = 1{,}24 \times 10^{-3} \pm 0{,}05\ s^{-1}$$

RMN ^1H

Afin de mieux préciser le phénomène nous avons essayé de le suivre par RMN ^1H sur le composé **6** en solution dans CD_3CN la plus diluée possible ($3{,}5 \times 10^{-3}$ M). Contrairement à notre observation dans $CDCl_3$ (6), le composé pur présente (figure 2) deux types de doublets pour les protons styryliques : l'un à grande constante de couplage (16 Hz) représente environ 80%, l'autre à constante de couplage moyenne (9 Hz) environ 20%. Les valeurs de ces constantes de couplage sont en accord avec une isomérie *E*/*Z*. Les déplacements chimiques observés pour les protons H_a et H_b des espèces *Z* (6,66 et 7,90 ppm) et *E* (7,51 et 8,00 ppm) présentent une différence notable sur H_a. Un comportement proche a été relevé récemment (17) pour le 4-(dicyanométhylène)-2-méthyl-6-[*p*-(diméthylamino)styryl]-4*H*-pyrane (DCM) dans DMSO-d_6; soit respectivement 6,2 et 6,9 ppm pour H_a et H_b de l'espèce *Z*, 7,04 et 7,44 ppm pour les mêmes protons de l'espèce *E*. Les constantes de couplage observées sont de 12,6 (*Z*) et 16 Hz (*E*).

D'autre part, l'addition de 3% de perchlorate de calcium à la solution précédente entraîne une disparition complète de l'espèce *Z* au profit de *E*. Toutefois, une exposition à la

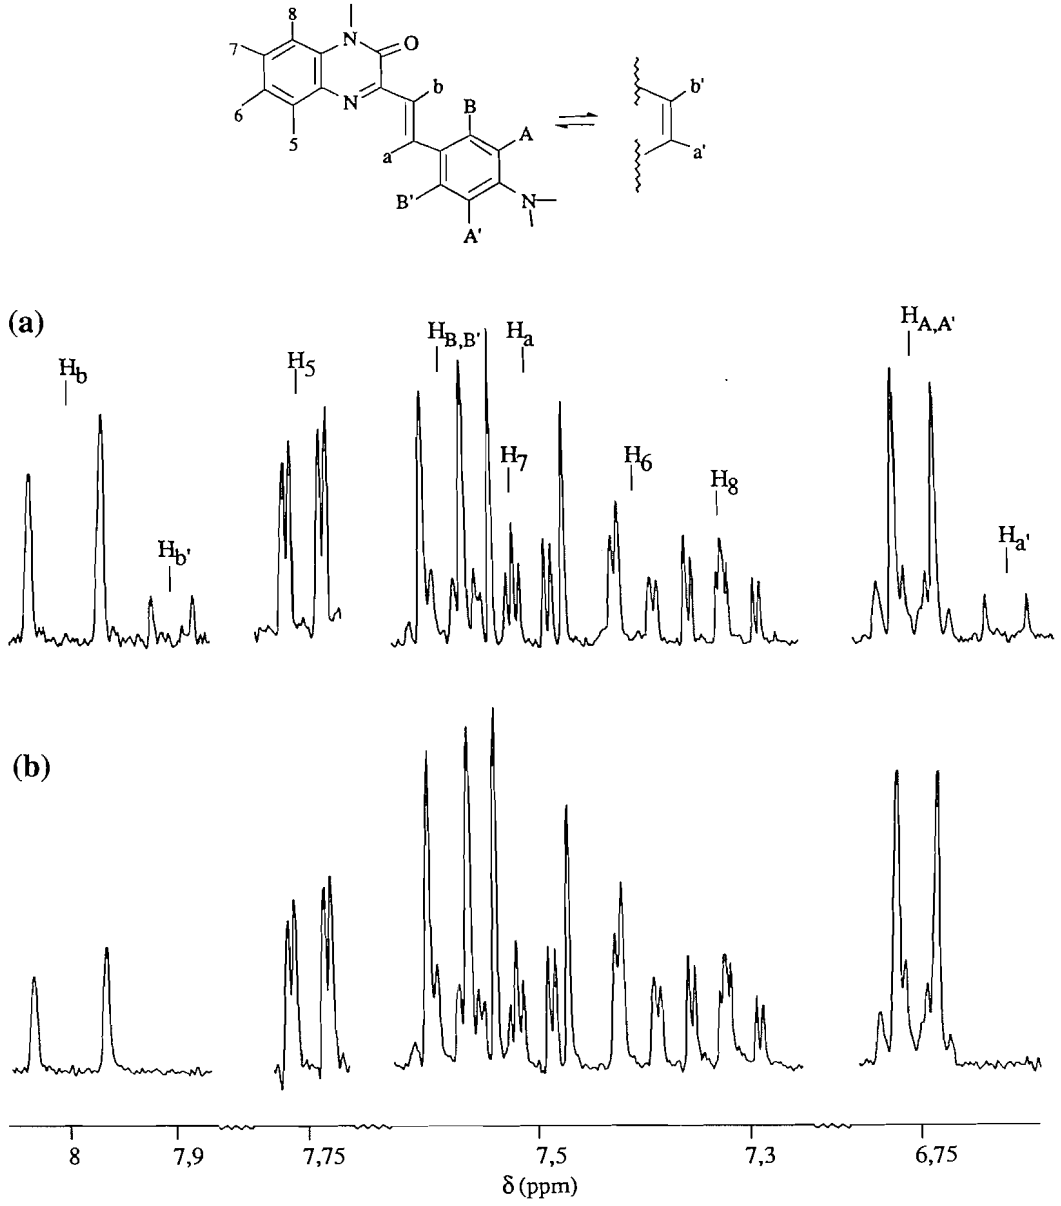

FIG. 2. Spectres RMN ^1H à 250 MHz du composé **6** ($3,5 \times 10^{-3}$ M dans CD_3CN) en absence (*a*) ou en présence (*b*) de 3% de perchlorate de calcium.

lumière du jour pendant 5 h ne fait pas réapparaître l'espèce *Z*.

Modélisation moléculaire

En complément à une étude de mécanique moléculaire (6) et dans des conditions identiques, nous avons calculé l'énergie des isomères *Z* (s-*cis* et s-*trans*) du composé **6** (schéma 6). Ainsi, avec le champ de force MM2*, nous trouvons des énergies respectives de 47,2 et 48,3 kcal/mol pour les isomères *Z*,s-*cis* et *Z*, s-*trans* respectivement. Pour les isomères *Z*, comme pour les isomères *E*, le rotamère s-*cis* est favorisé; dans ce cas, d'un peu plus de 1 kcal/mol. En raison de la gène stérique introduite par les interactions entre l'hydrogène H_B du groupe phényle et soit l'azote iminique soit le carbonyle des déviations importantes par rapport à la planéité sont observées : les angles de torsion φ_1 et φ_2 sont ainsi respectivement de 33° et −55° pour l'isomère *Z*,s-*cis*, −136° et −43° pour l'isomère *Z*, s-*trans*. À titre de comparaison les valeurs correspondantes pour les isomères *E*,s-*cis* et *E*,s-*trans* sont respectivement de 16° et −28° et de −154° et −30°.

Discussion

Modification structurale photoréversible catalysée par les ions métalliques

Le phénomène observé implique une augmentation de DO à 440–464 nm en présence de quantités catalytiques (4%) d'ion métallique dans l'acétonitrile ou le dioxanne ($\sim 5 \times 10^{-5}$ M). Il n'est observé ni avec la benzodiazinone **3** ni avec les styrylbenzoxazinones (8). Il implique donc la participation d'un groupe lactame (plus polarisé que le groupe lactone) et d'un système styrylique. L'autoassociation ne peut en être l'explication[3] car nous avons montré (partie expérimentale) qu'elle était négligeable vraisemblablement en raison de la non planéité du système révélé par modélisation moléculaire du composé **6**. La deuxième étape du phénomène observé est une diminution de la bande à forte longueur d'onde par irradiation à la lumière blanche retrouvant rapidement une valeur proche de sa valeur primitive notée en absence de Ca^{2+}. Lorsque l'irradiation (à 365 nm) s'écarte de la longueur d'onde d'absorption maximale (440–464 nm) l'équilibre primitif n'est pas retrouvé. Un retour à la DO maximale à l'obscurité (3ème étape) referme le cycle et montre bien que nous sommes en présence d'un équilibre photo réversible catalysé par les ions métalliques.

Pour expliquer ces phénomènes on postulera un équilibre *Z*/*E* au niveau de la liaison styrylique pour lequel les arguments suivants militent. D'abord, de tels équilibres sont courants avec les systèmes styryliques, par exemple références 5*a*, 17, 19–21.

Ainsi on observe par photoisomérisation de *trans*-stilbène (21) un abaissement très important de la longueur d'onde d'absorption de la bande de transfert électronique (295 → 224 nm) et une diminution de son intensité importante (>50%). Pour les isomères *Z* et *E* du dérivé styrylique du benzothiazole (5*a*) (schéma 7) une diminution de 15 nm dans l'acétonitrile est observée pour les bandes d'absorption à forte longueur d'onde quand on passe du *E* (440 nm) au *Z* (425 nm) accompagnée d'une baisse de DO d'environ 80%. Toutefois la photoisomérisation par irradiation à 365 nm ne conduit pas à une complète transformation de l'isomère *E* en *Z*. Dans ces conditions pour nos composés, une proportion importante d'isomère *Z* peut très bien n'être décelée que par la diminution de la bande propre à l'isomère *E*, sa bande caractéristique étant masquée précisément par cette dernière.

La deuxième argument est l'observation pour **6** (CD_3CN, $3{,}5 \times 10^{-3}$ M) en l'absence de Ca^{2+} de deux doublets dont la constante de couplage (J = 9 Hz) est caractéristique d'un isomère *Z* (~20%) aux côtés des deux doublets de forte constante de couplage (J = 16 Hz) attribuables à l'isomère *E*. De plus, l'addition de 3% de $Ca(ClO_4)_2$ fait disparaître les deux doublets de 9 Hz. D'après ce résultat et la variation de DO en UV on peut déduire que l'état photostationnaire atteint dans l'acétonitrile représenterait de 20 à 30% d'isomère *Z* à la concentration 5×10^{-5} M en absence d'ion métallique. La transformation en présence d'ion Ca^{2+} est un processus lent ($k \sim 10^{-3}$ s^{-1}) et direct (sans accumulation d'intermédiaire) conduisant au seul isomère *E*; elle est photoréversible.

Un essai d'irradiation d'une solution de **6** (5×10^{-5} M) dans l'acétonitrile dans une cuve en quartz à 350 nm pendant 1 h (voir partie expérimentale) conduit à une décoloration complète de la solution. La bande à 445 nm disparaît complètement sans apparition de bande nouvelle; un retour à l'état stationnaire antérieur n'intervenant pas après ajout de 4% de perchlorate de Ca^{2+}, la cuve étant maintenue à l'obscurité jusqu'à 12 h. Il est possible qu'une réaction photochimique irréversible se soit alors produite comme, par example, la dimérisation qui a été observée récemment pour les benzodiazinones (22) ou plus vraisemblablement des polymérisations en raison de la disparition presque complète des signaux en RMN ^1H. L'isomère *Z* attendu n'est pas observé dans ces conditions.

Cet isomère *Z* serait en fait, d'après notre résultat de mécanique moléculaire, l'isomère s-*cis*.

Dans ces conditions, l'isomérisation catalysée par les ions métalliques pourrait impliquer (schéma 8) un chélate intermédiaire par transfert de charge déstabilisant la forme *Z* et donc favorisant le passage à la forme *E* la plus stable à l'obscurité. La barrière de l'isomérisation $Z \rightleftharpoons E$ serait abaissée par suite de contraintes stériques dans cet intermédiaire. La formation de cet intermédiaire serait elle-même facilitée par la torsion φ_1 autour de la liaison C—C ($\varphi_1 = 32°$ d'après notre calcul de mécanique moléculaire) dans l'isomère *Z*,s-*cis* et par l'abaissement de la barrière à la rotation autour de cette liaison induite par la chélation du carbonyle lactamique avec un cation M^{n+}.

Lorsqu'à partir de la forme *E* pure, en présence de M^{n+} et à l'obscurité, on irradie l'échantillon, on observe des équilibres photostationnaires dont la position varie selon la longueur d'onde du rayonnement et sa puissance. Le maximum de forme *Z* est obtenu par irradiation à la lumière blanche, seul rayonnement utilisé englobant la longueur d'onde maximale d'absorpiton des composés étudiés. En l'absence de M^{n+} les mêmes positions de l'équilibre photostationnaire tendent à être atteintes mais plus lentement, l'action catalytique du métal ne jouant plus.[4]

À propos du schéma 8, il nous paraît difficile de dire si une liaison H stabilisante intervient dans l'isomère *E*,s-*trans* dont nous avons vu (6) qu'il en existerait 30% dans le chloroforme d'après les durées de vie de fluorescence. Par contre, dans l'acétonitrile, en présence d'un excès de sel alcalino-terreux cette forme est très vraisemblablement exclue en raison de l'affinité des oxygènes lactamiques pour ces ions.

Le phénomène observé dans l'acétonitrile est donc compatible avec une isomérie *Z*/*E*, l'isomère *E* étant le seul isomère en présence de quantité catalytique de sel métallique (3–4%). Les phénomènes spécifiques à un ion donné, dûs à la présence du motif éther-couronne dans les composés **1** et

3. Des augmentations de DO analogues sont par exemple observées avec les acides nucléiques (18) ou l'orthophénantroline (voir partie expérimentale).

4. Comme dans le cas des *cis*- et *trans*-stilbène (23), la répulsion stérique entre cycles aromatiques est responsable des torsions (φ_1 et φ_2) observées et leur couplage avec la torsion autour de la liaison éthylénique (θ) conduit à l'isomérisation.

SCHÉMA 8

2, ne sont observés que pour des ajouts supplémentaires de sels métalliques.[2] On peut considérer que, quelque soit l'équilibre de complexation étudié, seul l'isomère *E* participe à cet équilibre rendant possible la détermination des constantes de complexation et l'utilisation du composé **1** au dosage sélectif de l'ion calcium.[2]

Partie expérimentale

Les points de fusion (*F*) ont été déterminés au banc Köfler. Les spectres de RMN ^1H et ^{13}C ont été enregistrés sur les appareils Bruker AC-200 et AC-250 (avec le TMS comme référence interne, les déplacements étant exprimés en ppm). Pour une description détaillée des spectres RMN ^1H, il faut se reporter au tableau 1 et pour les spectres RMN ^{13}C au tableau 2. Les spectres infrarouge ont été mesurés sur un spectrophotomètre Perkin–Elmer 833 (en pastille de KBr à moins de spécification contraire). Les spectres de masse ont été efectués sur un appareil Nermag R 10--10C (mode d'ionisation : DCI/NH_3). Les analyses centésimales ont été réalisées au service commun de microanalyse élémentaire UPS-INP à Toulouse. Les spectres d'absorption ont été effectués sur un spectrophotomètre Perkin–Elmer Lambda 17 et les spectres d'émission sur un spectrofluorimètre Perkin–Elmer LS-3B, les cuves de mesure étant thermostatées à 25 ± 1°C.

Les calculs de mécanique moléculaire ont été effectués sur une station Silicon Graphics IRIS 4D30 à l'aide du programme MACROMODEL V3.5X.

Les séparations par chromatographie liquide (CPL) sont réalisées sur colonne de silice Merck Kieselgel 60 (70–230 mesh). La pureté des produits a été vérifiée par chromatographie sur couche mince (CCM) sur plaque de gel de silice Merck 60 F 254 prête à l'emploi.

L'acétonitrile de chez BDH (Hipersolv) a été utilisé comme solvant pour les mesures d'absorption. Les perchlorates de cations alcalins et alcalinoterreux, provenant de chez Strem et Aldrich, étaient de la plus haute qualité disponible et ont été utilisés sans purification supplémentaire.

Les composés **3** et **6** ont été préparés selon la référence 6.

*3-Fluoro acétanilide : **12***

Il a été préparé par action de l'anhydride acétique sur la 3-fluoroaniline dans l'acide acétique. La recristallisation a été effectuée dans l'eau; Rdt 70%, cristaux blancs, *F* = 85°C (litt. (11) 85%C); IR : 3330 (NH), 1670 (C=O) cm^{-1}; RMN ^1H ($CDCl_3$) : 2,16 (s, 3H, CH_3), 6,53–7,60 (m, 5H, NH et arom.).

*5-Fluoro-2-nitro acétanilide : **11***

Il a été préparé à partir de **12** selon la référence 11 et purifié par CPL (éluant dichlorométhane); Rdt 56%, aiguilles jaune pâle, *F* = 87°C (litt. (11) 85°C); IR : 3340 (NH), 1710 (C=O), 1490 (NO_2 asym.), 1310 (NO_2 sym.) cm^{-1}; RMN ^1H ($CDCl_3$) : 2,30 (s, 3H, CH_3), 6,76 (m, 1H, H4, $J_{4\text{-}F}$ = 12, $J_{4\text{-}3}$ = 9 et $J_{4\text{-}6}$ = 3 Hz), 8,17 (dd, 1H, H3, $J_{3\text{-}F}$ = 6 Hz), 8,52 (dd, 1H, H6, $J_{6\text{-}F}$ = 12 Hz).

*5-(*N,N*-Diméthylamino)-2-nitro acétanilide : **10** :* 3,54 g (0,0179 mol) de **11**, 2,19 g (0,027 mol) de chlorhydrate de diméthylamine et 2,73 g (0,033 mol) d'acétate de sodium anhydre dans 14 mL d'éthanol sont chauffés à 100°C dans un tube de verre scellé pendant 8 h. Après refroidissement, le milieu réactionnel est versé dans de l'eau froide. Le précipité formé est filtré et recristallisé dans l'éthanol. Rdt 55%, fines aiguilles jaunes, *F* = 188°C (litt. (12) 187,5–188,5°C); IR : 3310 (NH), 1705 (C=O), 1490 (NO_2 asym.), 1310 (NO_2 sym.) cm^{-1}; RMN ^1H ($CDCl_3$) : 3,10 (s, 6H, $N(CH_3)_2$), 2,23 (s, 3H, CH_3), 6,30 (dd, 1H, H4, $J_{4\text{-}3}$ = 9 et $J_{4\text{-}6}$ = 3 Hz), 8,07 (d, 1H, H6), 8,08 (d, 1H, H3). Anal. calc. pour $C_{10}H_{13}N_3O_3$: C 53,81, H 5,87, N 18,82; trouvée : C 53,65, H 5,78, N 18,63.

*3-Amino-4-nitro-*N,N*-diméthylaniline : **9***

*À partir de **10** :* **10** subit une hydrolyse basique dans la soude aqueuse 1 N à 50°C pendant 8 h pour donner **9**. Rdt 100%, solide jaune clair, *F* = 138–140°C (litt. (12) 134–135°C); IR : 3475, 3360 (NH_2), 1525 (NO_2 asym.), 1365 (NO_2 sym.) cm^{-1}; RMN ^1H ($CDCl_3$) : 3,07 (s, 6H, $N(CH_3)_2$), 5,74 (d, 1H, H2, $J_{2\text{-}6}$ = 3 Hz), 6,08 (dd, 1H, H6, $J_{6\text{-}5}$ = 9 Hz), 6,17 (s élargi, 2H, NH_2), 7,99 (d, 1H, H5). Anal. calc. pour $C_8H_{11}N_3O_2$: C 53,03, H 6,12, N 23,19; trouvée : C 53,60, H 6,29, N 23,29.

*À partir de **14** :* 3,09 g (0,0179 mol) de **14**, 2,93 g (0,036 mol) de chlorhydrate de diméthylamine et 4,4 g (0,054 mol) d'acétate de sodium anhydre dans 15 mL d'éthanol sont chauffés à 130°C dans un tube de verre scellé pendant 3 jours. Après refroidissement, le milieu réactionnel est versé dans de l'eau froide. Après extraction de la phase aqueuse par du dichlorométhane, séchage de la phase organique sur $MgSO_4$ et évaporation du solvant, le milieu réactionnel est purifié par CPL (éluant acétate d'éthyle – éther de pétrole 50 : 50). On obtient ainsi 2,27 g de **9** (Rdt 70%).

*7-*N,N*-Diméthylamino-3-méthyl-1,4-benzodiazine-2-one : **4**a et 6-*N,N*-diméthylamino-3-méthyl-1,4-benzodiazine-2-one : **4**b*

Le composé **9** (1 g, 5,52 mmol) dans 70 mL d'éthanol absolu est soumis à une hydrogénation catalytique en présence de Pd/C à 10% (0,4 g) à température ambiante et sous pression atmosphérique. On additionne ensuite au milieu réactionnel, conservé sous atmosphère inerte, 0,77 g (6,63 mmol) de pyruvate d'éthyle

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.200.69.106 on 09/08/12

et on chauffe à reflux pendant 4 h. On filtre à chaud la solution sur Célite et le solvant est évaporé. Une recristallisation dans l'éthanol du résidu d'évaporation fournit 0,729 g de **4***a*. Une purification des eaux-mères par HPLC préparative (colonne RSIL C18, éluant méthanol–eau 40 : 60) fournit 0,056 g de **4***a* et 0,28 g de **4***b*.

4*a* : Rdt 70%, cristaux jaunes, F = 260°C; IR ($CHCl_3$) : 3388 (NH), 1660 (C=O), 1624 (C=N) cm^{-1}; UV et fluorescence dans chloroforme (éthanol) : λ_{max}^{abs} = 380 (381) nm, ε = 15 600 (16 000) M^{-1} cm^{-1}, λ_{max}^{em} = 448 (501,5) nm, Φ_f (référence sulfate de quinine) (0,29); RMN ^1H ($CDCl_3$) : 2,54 (s, 3H, CH_3), 3,07 (s, 6H, NMe_2); SM : *m/e* 204 $[M+H]^+$, 100%. Anal. calc. pour $C_{11}H_{13}N_3O$: C 65,01, H 6,45, N 20,67; trouvée : C 65,05, H 6,43, N 20,24.

4*b* : Rdt 25%, cristaux jaunes, F = 258°C; IR ($CHCl_3$) : 3388 (NH), 1662 (C=O), 1626 (C=N) cm^{-1}; UV dans chloroforme (éthanol) : λ_{max}^{abs} = 263 (260) nm, ε = 31 300 (34 000) M^{-1} cm^{-1}; RMN ^1H ($CDCl_3$) : 2,62 (s, 3H, CH_3), 3,0 (s, 6H, NMe_2); SM : *m/e* 204 $[M+H)^+$, 100%. Anal. calc. pour $C_{11}H_{13}N_3O$: C 65,01, H 6,45, N 20,67; trouvée : C 64,94, H 6,69, N 20,83.

*1,3-Diméthyl,7-*N,N*-diméthylamino-1,4-benzodiazine-2-one :* **5**a

À une solution de 0,200 g (9,85 × 10^{-4} mol) de **4***a* dans 25 mL d'acétone sec, on ajoute 0,160 mL (2,57 × 10^{-3} mol) d'iodure de méthyle et 0,609 g (1,87 × 10^{-3} mol) de carbonate de césium. Le milieu hétérogène est chauffé à reflux pendant 1,5 h, sous atmosphère d'azote. Une purification par CPL (éluant : dichlorométhane – acétate d'éthyle 40 : 60) fournit 0,201 g de **5***a*. Rdt 94%, cristaux jaunes, F = 170°C; IR : 1644 (C=O), 1620 (ep., C=N) cm^{-1}; UV et fluorescence dans chloroforme (éthanol) : λ_{max}^{abs} = 379 (384) nm, ε = 17 300 (16 100) M^{-1} cm^{-1}, λ_{max}^{em} = 439 nm; RMN ^1H ($CDCl_3$) : 2,51 (s, 3H, CH_3), 3,07 (s, 6H, $N(CH_3)_2$), 3,63 (s, 3H, NCH_3). Anal. calc. pour $C_{12}H_{15}N_3O$: C 66,34, H 6,96, N 19,34; trouvée : C 66,40, H 6,95, N 19,38.

*1,3-Diméthyl,7-*N,N*-diméthylamino-1,4-benzodiazine-2-one :* **5**b

Il a été préparé à partir de **4***b* selon la méthode utilisée pour **5***a*. Rdt 98%, cristaux jaunes, F = 141°C; IR : 1637 (C=O), 1620 (ép., C=N) cm^{-1}; UV dans chloroforme (éthanol) : λ_{max}^{abs} = 261 (260) nm, ε = 21 100 (27 100) M^{-1} cm^{-1}; RMN ^1H ($CDCl_3$) : 2,58 (s, 3H, CH_3), 3,01 (s, 6H, $N(CH_3)_2$), 3,66 (s, 3H, NCH_3). Anal. calc. pour $C_{12}H_{15}N_3O$: C 66,34, H 6,96, N 19,34; trouvée : C 66,02, H 6,82, N 19,24.

*1-Méthyl-3-(*p*-13-aza-1,4,7,10-tétraoxacyclopentadécane-13-ylstyryl)-1,4-benzodiazine-2-one :* **1** : 0,150 g (4,64 × 10^{-4} mol) de *p*-formyl-*N*-phénylaza-15-c-5 éther préparé selon la référence 24 et 0,080 g (4,60 × 10^{-4} mol) de benzodiazinone **3** sont chauffés en présence d'anhydride acétique (1 mL) à 135°C pendant 2 h. L'excès d'anhydride acétique est éliminé par coévaporation avec de l'eau. Le résidu sec est traité à l'acétone à froid et la suspension solide obtenue est filtrée. On obtient ainsi 0,077 g de **1**. Rdt 35%, cristaux rouge-brun, F = 199°C; IR : 1650 (C=O) cm^{-1}; UV dans acétonitrile : λ_{max}^{abs} = 448 nm, ε = 22 900 M^{-1} cm^{-1}; RMN ^1H ($CDCl_3$) : 3,6 (massif, 23H, CH_3 et éther couronne); SM : *m/e* 480 $[M+H]^+$, 100%. Anal. calc. pour $C_{27}H_{33}N_3O_5$: C 67,62, H 6,94, N 8,76; trouvée : C 67,29, H 6,80, N 8,86.

*3-(*p*-13-Aza-1,4,7,10-tétraoxacyclopentadécane-13-ylstyryl)-7-(*N,N*-diméthylamino)-1,4-benzodiazine-2-one :* **2**

On chauffe à 110–120°C pendant 24 h 0,400 g (1,24 × 10^{-3} mol) de *p*-formyl-*N*-phénylaza-15-c-5-éther et 0,252 g (1,24 × 10^{-3} mol) de **4***a* dans 10 mL de pyridine et 2 mL de pipéridine. Après avoir laisser revenir le milieu réactionnel à température ambiante, on filtre le précipité et le filtrat de couleur orange-rouge fluorescent est coévaporé plusieurs fois avec du toluène. Le résidu d'évaporation est ensuite purifié par CPL (éluant dichlorométhane–méthanol 95 : 5). Après recristallisation dans le toluène, on obtient 0,063 g de **2**. Rdt 10%, cristaux rouge-brun, **F** = 254°C; IR ($CHCl_3$) : 1653 (C=O) cm^{-1}; UV dans acétonitrile : λ_{max}^{abs} = 465 nm, ε = 25 000 M^{-1} cm^{-1}; RMN ^1H ($CDCl_3$) : 3,08 (s, 6H, NMe_2), 3,67 (m, 20H, éther couronne); SM : *m/e* 509 $[M+H]^+$, 100%. Anal. calc. pour $C_{28}H_{36}N_4O_5$: C 66,12, H 7,13, N 11,02; trouvée : C 66,20, H 7,15, N 10,96.

Autoassociation

Le phénomène d'autoassociation se traduit par une variation du coefficient d'absorption molaire en fonction de la concentration. Cette évolution en fonction de la molalité de grandeurs spectrales caractéristiques du substrat comme le coefficient d'extinction molaire ε (25) ou de grandeurs volumiques caractéristiques de la solution (masse volumique (26)), résulte de processus autoassociatifs qui conduisent à des agrégats dynamiques (dimère : A_2, ..., i-mère : A_i), en équilibre avec le monomère A_1. La constante d'équilibre pour le $(i-1)i^{ième}$ équilibre a pour expression

$$K_{i-1} = C_i/(C_{i-1} \cdot C_1)$$

C_i, C_{i-1} et C_1 étant respectivement les concentrations en entités i-mère, $(i-1)$- mère et monomère. Dans la littérature ce type d'association indéfini est traité principalement sur la base du modèle isodesmique (25). Il implique l'égalité de toutes les constantes d'équilibre régissant les processus élémentaires d'autoassociation : $K_1 = K_2 = \ldots = K_{i-1} = K$. De plus, sachant que le coefficient d'extinction molaire est la résultante des contributions additives des coeffificients d'extinction caractéristiques des molécules individuelles (27) et qu'il est fonction de leur environnement (état monomère ou molécules associées) il nous est possible de simplifier ce constat en retenant la dichotomie suivante. Seules trois contributions au coefficient d'extinction molaire seront prises en compte : celle des molécules monomère (ε_1) et, pour un agrégat de i molécules, celles des deux molécules à l'extérieur de l'agrégat (ε_{ext}) et des $i-2$ molécules à l'intérieur de l'agrégat (ε_{int}). Ainsi le coefficient d'extinction molaire observé (ε_{obs}) à une longueur d'onde donnée variera en fonction de la concentration des espèces selon :

$$\varepsilon_{obs} = (C_1 \cdot \varepsilon_1 + C_{int} \cdot \varepsilon_{int} + C_{ext} \cdot \varepsilon_{ext})/C_t$$

la concentration totale (C_t) étant donnée par :

$$C_t = C_1 + 2\sum_{i=2}^{\infty} C_i + \sum_{i=2}^{\infty} (i-2)C_i$$

Le traitement informatique (26) des variations de ε_{obs} en fonction de la concentration en soluté (C_t) permet d'atteindre de manière itérative la constante d'association K contenue dans le modèle $\varepsilon_{obs} = f(\varepsilon_1, \varepsilon_{int}, \varepsilon_{ext}, K)/C_t$.

Avec l'orthophénantroline dans l'acétonitrile, on trouve K = $8 \times 10^4 \pm 3 \times 10^3$ M^{-1}. Par contre, aucune variation de ε_{obs} n'a été notée avec la styrylbenzodiazinone **6** dans ce même solvant pour des concentrations variant de 5×10^{-7} à 10^{-4} M avec ou sans 4% Ca^{2+}.

Equilibre photoréversible

On ajoute à l'obscurité 0,04 équivalents de perchlorate de calcium à une solution de ligand (~5×10^{-5} M) dans l'acétonitrile ou le dioxanne; après stabilisation de la densité optique on irradie cette solution à la lumière blanche. Quelques minutes (~10 min) après irradiation on obtient une DO minimale voisine de la DO initiale du ligand pur. On remet enfin cette solution à l'obscurité jusqu'à stabilisation de la DO (~2 h) qui retrouve sa valeur maximale.

Cinétique d'isomérisation par un sel métallique

Après addition à l'obscurité de 0,04 équivalent de perchlorate de calcium à une solution de ligand (~5×10^{-5} M) dans l'acétonitrile, un balayage répété du spectre UV entre 250 et 550 nm est effectué jusqu'à stabilisation de la densité optique (~1,57). La cinétique elle-même a été effectuée dans les mêmes conditions au maximum d'absorption (440 nm) avec un temps de cycle de 1 min. Le traitement des données a été réalisé avec le programme LSG (Least Squares Guggenheim).

Essai de photoisomérisation

Une solution 5×10^{-5} M du composé **6** dans l'acétonitrile placée dans une curve en quartz a été irradiée à 350 nm en utilisant un récteur Rayonet pendant 1 h. La décoloration totale de la solution jaune de départ correspond à la disparition complète de la bande à 440 nm sans apparition de bande nouvelle. La même expérience réalisée sur une solution $3{,}5 \times 10^{-3}$ M dans CD_3CN donne un spectre RMN ^1H ne présentant aucun signal bien résolu.

Remerciements

Les auteurs remercient A. Lopez (UPR CNRS 8221, Toulouse) pour nous avoir permis de traiter les problèmes relatifs à l'autoassociation et pour ses utiles conseils, ainsi que le Centre National de la Recherche Scientifique et la Direction de la Recherche et des Études Doctorales pour leur soutien financier.

MARTA LUIZ, MARÍA I. GUTIÉRREZ, GRACIELA BOCCO, and NORMAN A. GARCÍA. Can. J. Chem. **71**, 1247 (1993).

The influence of solvent polarity on the dye-sensitized photooxidation (singlet molecular oxygen ($O_2(^1\Delta_g)$) mediated) of a series of *para*-substituted phenolates was studied. Kinetic evidence obtained shows that the overall and the pure chemical interactions, phenolate–$O_2(^1\Delta_g)$, depend on the solvent polarity in a different way. This is clearly reflected in the efficiency of $O_2(^1\Delta_g)$ photooxidation of the substrates: surprisingly, the photooxidation quantum yield increases as the overall quenching rate constant decreases. The substrate photooxidation quantum yields obtained ranged from 0.05 to 0.15, the upper limit corresponding to a moderately polar medium (a benzene–methanol mixture) and the lower to an aqueous medium. We conclude that a high solvent polarity favours only the obtainment of the encounter complex ($O_2(^1\Delta_g)$–phenolate), whereas the reactive step is affected in much the same way as those processes where charges are neutralized along the reaction pathway. The results obtained are discussed in terms of a partly polar excited state complex between $O_2(^1\Delta_g)$ and the phenolates. The rate constant for the reactive pathway in both organic and aqueous media is correlated with the Hammet-type substituent constant R^-.

MARTA LUIZ, MARÍA I. GUTIÉRREZ, GRACIELA BOCCO et NORMAN A. GARCÍA. Can. J. Chem. **71**, 1247 (1993).

On a étudié l'influence de la polarité du solvant sur la sensibilisation par photo-oxydation du colorant (via l'oxygène moléculaire à l'état singulet ($O_2(^1\Delta_g)$), d'une série de phénolates substitués en position *para*. Les preuves cinétiques obtenues démontrent que l'interaction globale et l'interaction purement chimique phénolate–$O_2(^1\Delta_g)$ dépendent de manière différente de la polarité du solvant. Cet effet se manifeste clairement dans l'efficacité de la photo-oxydation $O_2(^1\Delta_g)$ des substrats : de façon surprenante, le rendement quantique de la photo-oxydation augmente lorsque la constante globale de blocage diminue. Les rendements quantiques de la photo-oxydation des substrats se situent entre 0,05 et 0,15, la limite supérieure correspondant à un milieu modérément polaire (un mélange de benzène–méthanol), et la limite inférieure correspondant à un milieu aqueux. Nous concluons qu'une forte polarité du solvant favorise uniquement le complexe de rencontre phénolates–$O_2(^1\Delta_g)$, où l'étape réactive est affectée comme le sont les processus où les charges sont neutralisées au cours de la réaction. On discute des résultats obtenus en fonction d'un complexe à l'état excité partiellement polaire entre $O_2(^1\Delta_g)$ et les phénolates. On établit une corrélation entre la constante de vitesse pour l'étape réactive dans un milieu organique et dans un milieu aqueux avec une constante R^- de substituant du type Hammett.

[Traduit par la rédaction]

Introduction

Type II (singlet molecular oxygen ($O_2(^1\Delta_g)$) mediated) photooxidation of phenols and, especially, dye-sensitized reactions, have received much attention over the last few years in connection with the behaviour role of compounds involved in biological media (1–6) as well as the possibility of processing waste water by sunlight irradiation (7–17). More specifically, the importance of understanding environmental pathways for phenolic chlorinated and nitro derivatives (the main parent compounds employed in industrial syntheses of phenolic pesticides) led us to carry out a variety of studies (8–15, 17).

Most $O_2(^1\Delta_g)$ reactions, including those of phenols, involve parallel physical and chemical interactions of the excited oxygen species with the oxidizable substrate P (eqs. [1] and [2]):

$$[1] \quad O_2(^1\Delta_g) + P \xrightarrow{k_q} O_2(^3\Sigma_g) + P$$

$$[2] \quad O_2(^1\Delta_g) + P \xrightarrow{k_r} \text{products}$$

$$[3] \quad O_2(^1\Delta_g) \xrightarrow{k_d} O_2(^3\Sigma_g^-)$$

The sum $k_q + k_r$ is usually denoted by k_t, the overall rate constant for the whole quenching process. Equation [1] represents the physical event that gives rise to the ground-state triplet oxygen species [$O_2(^3\Sigma_g^-)$]. On the other hand, chemical interaction yields photooxidation products (eq. [2]). A third way of deactivating $O_2(^1\Delta_g)$, by collision with solvent molecules, is represented by eq. [3].

The actual significance in terms of real photodegradation of a $O_2(^1\Delta_g)$-mediated event is given by the effective quantum yield of photooxidation (18) (ϕ_r; eq. [4]):

$$[4] \quad \phi_r = \phi_\Delta k_r[P]/(k_d + k_t[P])$$

The only data required to solve eq. [4] are the kinetic rate constants and the quantum yield of $O_2(^1\Delta_g)$ generation by the dye sensitizer (ϕ_Δ).

It is surprising that even though the rate constants k_t for a vast number of compounds have been reported (for compilations see refs 19 and 20), kinetic discrimination between chemical and physical $O_2(^1\Delta_g)$ quenching has been achieved in only a few cases (19). Kinetic discrimination is of paramount significance not only for distinguishing between the

two types of interactions, but is also indispensable in predicting reactivity towards $O_2(^1\Delta_g)$ and the extent of physical interaction, which are of utmost importance in terms of biological protection. The above examples suggest that a basic knowledge of the factors affecting the distribution of physical and chemical contributions is crucial to understanding $O_2(^1\Delta_g)$-mediated photooxidations.

In this work we carried out a kinetic study on the interaction of a series of *para*-substituted phenols with $O_2(^1\Delta_g)$ in alkaline media with emphasis on the solvent effect on the reactive and the purely physical pathways for the overall $O_2(^1\Delta_g)$ scavenging process.

Experimental

Chemicals

Rubrene, eosin (Eos), Rose Bengal (RB) 4-chlorophenol (4-CP), 4-bromophenol (4-BrP), 4-iodophenol (4-IP), 4-phenylphenol (4-PhP), and 9,10-dimethyl anthracene (DMA) were purchased from Aldrich. The phenols and DMA were purified by double sublimation. Purified 4-fluorophenol (4-FP) was kindly provided by Dr. Gerardo Arguello. Methionine was supplied by Sigma. The solvents benzene (Bz), methanol (MeOH), and acetonitrile (MeCN) were all of the highest available purity. Water was triply distilled. All measurements were made on freshly prepared solutions. A Na_2HPO_4/NaOH buffer was employed to adjust aqueous solutions to pH 11. Solutions in organic solvent mixtures (Bz–MeOH 4:1 by volume and MeCN–MeOH 1:1 by volume) labelled as "alkaline" contained 0.01 M KOH. Only the ionized (phenolate) form of the substituted phenols was spectrophotometrically detected in all described solvents.

Methods

Ground-state absorption spectra were recorded on a Hewlett Packard 8452A diode array spectrophotometer. A Metrolab RC 325B digital instrument was employed for single wavelength measurements.

Singlet molecular oxygen was generated photochemically (eq. [5]) by the sensitizers (S) (either rubrene (2×10^{-5} M), Eos ($abs_{530} = 0.5$ nm) or RB ($abs_{560} = 0.5$ nm)) through energy transfer from the excited triplet S ($^*S^3$) to dissolved ground-state oxygen.

$$[5] \quad {}^*S^3 + O_2(^3\Sigma_g^-) \xrightarrow{k_{ET}} S + O_2(^1\Delta_g)$$

In organic solvents k_t was determined according to Carlsson *et al.* (21) on the basis of self-sensitized photooxidation of rubrene. The ratio of initial rates of rubrene photooxidation in the absence (V_0) and presence (V) at different concentrations of the phenols was plotted against the phenol concentration, and k_t was calculated from eq. [6]:

$$[6] \quad V_0/V = 1 + k_t[P]/(k_{rRub} \times [\text{rubrene}])$$

Under our experimental conditions, $k_{rRub} \times$ [rubrene], i.e., the product of the rate constant for rubrene photooxidation times the hydrocarbon concentration, was very small compared to k_d and was thus negligible (21). The k_d values employed in the calculations were 3.8×10^4 s^{-1} in Bz–MeOH (19) and 3×10^4 in MeCN–MeOH, the last being determined by time-resolved phosphorescence detection of $O_2(^1\Delta_g)$ emission. It was assumed that the rate constant k_d is pH-independent.

For water solutions (pH 11), k_t was calculated from eq. [7] (graphical method) (19) by using Eos as dye sensitizer and assuming eq. [2] to be the only source of both phenol and oxygen uptake.

$$[7] \quad (\text{rate})^{-1} = (I_a\,\phi_\Delta)^{-1}\{(k_t/k_r) + k_d/k_r\,[P]\}$$

where rate and I_a denote the velocity of P uptake and the intensity of light absorbed by the sensitizer, respectively. A k_d value of 2.5×10^5 s^{-1} was employed in the calculations (23).

The k_r values obtained for P in all water solutions at pH 11 and in alkaline organic solvents were determined by the method of Foote and Ching (24) (eq. [8]):

$$[8] \quad k_r = k_{rR}\,\text{slope}_T/\text{slope}_R$$

which compares the slopes of the first-order plots for substrate irradiation time for the oxidizable substrate and a reference of known k_r (k_{rR}). The references used were DMA (in organic media) and methionine (in water). Both compounds have proven to be *exclusive* chemical (reactive) quenchers of $O_2(^1\Delta_g)$ (19, 25, 26). The k_{rR} values employed for the hydrocarbon (1) and the amino acid (25, 26) were 1.2×10^7 M^{-1} s^{-1} and 2.0×10^7 M^{-1} s^{-1}, respectively.

The rate of P photooxidation in organic media was determined spectrophotometrically. In water, the oxygen uptake instead of the P uptake was measured. The accuracy of this methodology for substituted phenols has been discussed elsewhere (15).

Estimated error margins were in the range of ±10–12% for k_t and ±5–7% for k_r.

The ϕ_r values were calculated by means of eq. [4] at a phenolate concentration of 1 mM and a ϕ_Δ value of 0.75 for RB in water (27).

The irradiation setup, including the specific electrode (Orion 97-08) has already been described (8). The temperature was kept at 22 ± 1°C throughout.

Results and discussion

Irradiation of air-equilibrated solutions of P with visible light in the presence of either Eos or RB in water (pH 11) strongly modifies their absorption spectra, as shown for 4-ClP in Fig. 1. Similar qualitative spectral changes were observed for all P compounds studied (also in alkaline organic solvents) provided appropriate $O_2(^1\Delta_g)$ sensitizers were used.

The reaction is virtually stopped by the presence of 1 mM NaN_3 and halted altogether when N_2-bubbled solutions are used. For 4-PhP it was established that the spectral changes were greater, at the same irradiation fluence, when H_2O was substituted by D_2O as a solvent (17). According to currently accepted criteria (28), these observations indicate that the dye-sensitized photooxidation occurs largely via a $O_2(^1\Delta_g)$-mediated process. This is also consistent with a number of reported findings on the photooxidizability of the ionized form of variously substituted phenols (6–17).

The overall and reactive rate constants for $O_2(^1\Delta_g)$ scavenging were determined as described in the experimental section. Typical results are shown in Figs. 2 (main: k_t in water; inset: k_t in organic medium) and 3 (k_r in water), respectively.

We chose the *para*-substituted phenolate series for three reasons: (*a*) to maintain a unique ring-substitution pattern; (*b*) because of the large k_t values of these compounds, which exceed those of the non-ionized forms at least by one order of magnitude (3, 4, 7); and (*c*) because of the high proportion of reactive interaction with $O_2(^1\Delta_g)$ (very much higher than that for the molecular form).

The results obtained are shown in Table 1.

Bimolecular reactions of $O_2(^1\Delta_g)$ with substrates such as indoles, amines, sulphides, and phenols (4, 23, 29–31) can take place through a mechanism involving an excited encounter complex (see scheme, eq. [9]).

The data compiled in Table 1, particularly the general correlation of k_t for each P (Table 1) with the solvent polarity (H_2O > MeCN–EtOH > Bz–MeOH), provide evidence for a mechanism involving a charge transfer component

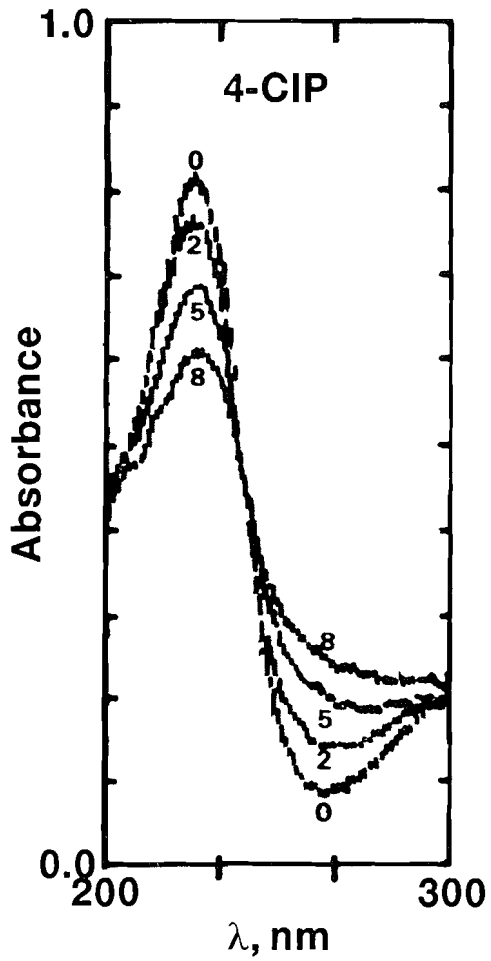

FIG. 1. Changes in the absorption spectrum of a solution (2×10^{-4} M) of 4-ClP in water, pH 11. Sensitizer: Eos, $Abs_{517} = 0.4$. Numbers correspond to irradiation time, in minutes.

within the intermediate complex. The dramatically smaller k_t value of 4-NO_2P, where the electron-releasing ability of the phenolate is diminished, also supports this hypothesis.

$$[9]\quad O_2(^1\Delta_g) + P \underset{k_{-D}}{\overset{k_D}{\rightleftarrows}} [O_2(^1\Delta_g)\text{--}P] \xrightarrow{k_P} \text{products}$$

$$[O_2(^3\Sigma_g^-)\text{--}P] \longrightarrow O_2(^3\Sigma_g^-) + P$$

According to eq. [9], competition between the excited complex photochemistry and photophysics controls the photooxidative pathway.

Careful observation of the data in Table 1 in terms of the solvent polarity reveals some facts that were not immediately apparent in a combined analysis, namely, both the reactive and overall rate constants increase as the solvent polarity increases; also, their relative weight (k_r / k_t ratio), which is higher for the less polar media, varies from the value unity for pure chemical interactions to a very small value in the organic-solvent mixture for most of the phenolates studied. Furthermore, the effect on the rate constants of a given phenolate is not proportional to that of the solvent polarity; in fact it is much higher for k_t than for the corresponding k_r value. In addition, this holds whether physical interaction or chemical reaction controls the whole $O_2(^1\Delta_g)$ quenching, even though it is more pronounced for *exclusively* chemical quenchers. In other words, the fraction of encounter complex that yields products increases as the polar environment decreases. As a result, even when the overall quenching process seems to be considerably more efficient in aqueous medium, the effective quantum yields (ϕ_r) for photooxidation are slightly higher in the Bz–MeOH mixture (column six in Table 1).

We believe that these apparently intricate results can be interpreted in a simple manner in terms of the evolution of the excited encounter complex: as all the experimental evidence indicates, increasing solvent polarity markedly favours the overall quenching process because of the charge transfer component involving the encounter complex. The encounter complex can undergo both deactivation (thereby resulting in physical quenching, which can be regarded as a photophysical deactivation step yielding the unstable ground-state complex) and chemical reaction. The reactive pathway, favoured by less polar media, appears to be an entropy-controlled step, as hypothesized for the phenolic derivative α-tocopherol (29). As a consequence, the reactive step is affected by the solvent polarity in much the same way as those processes in which charges are neutralized along the reaction pathway.

We tried to correlate the kinetic data shown in Table 1 through a Hammett equation or one of its extended forms, which have been widely employed for studying and interpretating organic reactions and their mechanisms. Although it is not always easy to find an appropriate *Hammett-type* substituent constant for a given class of chemical reaction, we adopted the R^- constant, developed by Hansch *et al.* (32), which we attempted to correlate with the k_r values in Table 1. The R^- constant was defined for molecules such as phenolates and anilinium ions possessing lone electron pairs and substituents conjugated with the reaction site, as in the case with our *para*-substituted phenolates. In 1978, Thomas and Foote (4) reported one such treatment (Hammett plot) involving σ^+ values for a series of trisubstituted phenols (molecular species) in organic solvents. The substituents were highly electron-releasing alkyl derivatives and the $O_2(^1\Delta_g)$ interaction was, in practice, entirely due to physical quenching. In our case, we employed the rate constant for the chemical reaction since this step occurs in all cases (only chemical interaction occurs with 4-ClP, 4-BrP, and 4-IP) and can be quantified by direct individual measurements (see Methods). This is shown graphically in Fig. 4, which includes the data for 4-PhP in water (17) and those for 4-nitrophenol (4-NO_2P) (13) in organic and aqueous media. As can be seen, there is a fairly linear relationship in both aqueous and organic media.

The extrapolation of the curve obtained in Bz–MeOH *predicts* a very small reactive rate constant for 4-NO_2P, which is consistent with previously reported data (13). We detected no photooxidation of 4-NO_2P in Bz–MeOH even upon prolonged sensitized irradiation (13).

Concluding remarks

In conclusion, the evidence obtained in this work demonstrates that there is no simple straightforward interpretation for the solvent effect on the kinetics of $O_2(^1\Delta_g)$ interactions with a series of *para*-substituted phenolates. This is clearly reflected in the efficiency of $O_2(^1\Delta_g)$ photooxidation of the substrates. The results can be rationalized by postulating the intermediacy of an encounter complex from

which both reactive and pure physical interactions can take place.

In summary, a substantial amount of information on the photooxidative kinetic behaviour of phenols under environmental conditions is discussed. This information can contribute to the understanding of the photochemical fate of these compounds, widely distributed in nature, from both the biological and the chemical point of view.

Solution and solid state studies of mixed ligand binuclear complexes containing one binucleating ligand

PUSHPA PATEL AND P.K. BHATTACHARYA[1]

Department of Chemistry, Faculty of Science, M.S. University of Baroda, Baroda-390 002, India

Received June 18, 1992[2]

PUSHPA PATEL and P.K. BHATTACHARYA. Can. J. Chem. **71**, 1253 (1993).

Stability constants of homobinuclear binary Cu(II) complexes of the dinucleating ligands, having equivalent coordination sites, 5,5′-methylene-bis-salicylaldehyde (H_2A^1), 5,5′-methylene-bis-(3-bromosalicylaldehyde) (H_2A^2), and 5,5′-methylene-bis-(3-nitrosalicylaldehyde) (H_2A^3), and mixed ligand Cu(II) complexes with one of the above ligands and bipyridyl (L^1) or 1,10-phenanthroline (L^2) as second ligand, have been determined potentiometrically in water:dioxane medium (50:50 and 30:70, v/v using a computer programme. The values of $\Delta \log K' = [\log K^{M}_{MAHL} - (\log K^{M}_{MAH} + \log K^{M}_{ML})]$ and $\Delta \log K'' = [\log K^{M_2}_{M_2AL_2} - (\log K^{M_2}_{M_2A} + 2 \log K^{M}_{ML})]$ have been compared within the series of complexes having different H_2A and L. Probable explanations for the stability order have been extended. The complexes $(Cu_2AL_2)(ClO_4)_2$ have been isolated and characterized by elemental analysis, electronic and ESR spectral, and magnetic studies.

PUSHPA PATEL et P.K. BHATTACHARYA. Can. J. Chem. **71**, 1253 (1993).

Opérant dans un milieu formé d'eau et dioxane (50 : 50 ou 30 : 70, v/v), faisant appel à la potentiométrie et à un programme pour ordinateur, on a déterminé les constantes de stabilité des complexes homobinucléaires binaires du Cu(II) avec les ligands bivalents comportant des sites de coordination équivalents, 5,5′-méthylène-bis-salicylaldéhyde (H_2A^1), 5,5′-méthylène-bis-(3-bromosalicylaldéhyde) (H_2A^2) et 5,5′-méthylène-bis-(3-nitrosalicylaldéhyde) (H_2A^3), et les complexes du Cu(II) avec des ligands mixtes comportant un de ceux mentionnés ci-dessus et soit le bipyridyl (L^1) ou la 1,10-phénanthroline (L^2) comme second ligand. On a comparé les valeurs du $\Delta \log K' = [\log K^{M}_{MAHL} - (\log K^{M}_{MAH} + \log K^{M}_{ML})]$ et du $\Delta \log K'' = [\log K^{M_2}_{M_2AL_2} - (\log K^{M_2}_{M_2A} + 2 \log K^{M}_{ML})]$ pour la série de complexes portant divers H_2A et L. On a étendu les explications possibles pour l'ordre des stabilités. On a isolé et caractérisé les complexes $(Cu_2AL_2)(ClO_4)$ par analyse élémentaire, par leurs spectres électronique et RPE et par des études magnétiques.

[Traduit par la rédaction]

Introduction

The study of binuclear complexes is a topic of considerable current interest, (see, for example, ref. 1) because of their use as models for a number of important biological systems containing two active metal sites (2). It has been shown that ligands having two or more coordinating sites can easily form homo- and heteropolynuclear complexes (3–11).

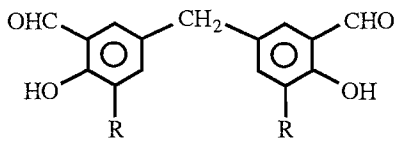
From a literature survey, it appears that there are mainly two types of ligands that can simultaneously coordinate with two metal ions. In the first type, the two coordinating sites are equivalent, while they are nonequivalent in the second type. The study of homo- and heterobinuclear complexes of such ligands in solution has at least two interesting aspects. Firstly, such study leads to the advancement of the knowledge, in coordination chemistry, of binucleating ligands and, secondly, to the possible application of these results to speciation of natural multicomponent systems.

Some of the polyfunctional ligands that form binuclear complexes in solution are amino acids such as histidine (4), L-(3,4-dihydroxyphenyl) alanine (L-dopa) (6), and DL-isoserine (11); dipeptides such as β-alanyl L-histidine (5) and L-histidyl glycine (10); hydroxypolycarboxylate ligands such as citrate (3, 8); and aminopolycarboxylates such as EDTA (12).

Binary (13) and ternary complexes containing salicylaldehyde have been studied earlier. In ternary complexes (dipyridyl–Cu–salicylaldehyde), it was shown that $\Delta \log K$ is less negative because of the π-acidic nature of dipyridyl and the affinity of M–dipyridyl for O^-–O coordinating salicyl aldehyde (14). The stability of the ternary complexes was shown to be dependent on substitution on the dipyridyl or salicylaldehyde (15).

In the present study we synthesized dinucleating ligands, comprising two chelating arms (salicylaldehyde), attached to the methylene group. 5,5′-Methylene-bis-salicylaldehyde (H_2A^1), 5,5′-methylene-bis-(3-bromosalicylaldehyde) (H_2A^2), and 5,5′-methylene-bis-(3-nitrosalicylaldehyde) (H_2A^3) were synthesized and their binary mono- and binuclear Cu(II) complexes, CuAH and Cu_2A, and the mixed ligand complexes CuAHL and Cu_2AL_2, where L = bipyridyl (L^1) or 1,10-phenanthroline (L^2), were studied in solution.

The complexes Cu_2AL_2 were isolated and characterized. The general structural formula of the ligand H_2A is as follows:



R = H, Br, NO_2

Experimental

All the reagents used were of A.R. grade. The ligand 5,5′-methylene-bis-salicylaldehyde (H_2A^1) was prepared by the method reported in the literature (16). 5,5′-Methylene-bis-(3-bromosalicylaldehyde) (H_2A^2) and 5-5′-methylene-bis-(3-nitrosalicylaldehyde) (H_2A^3) were prepared by bromination and nitration of 5,5′-methylene-bis-salicylaldehyde, as was done in the case of salicylaldehyde (17, 18). The titrations were carried out in water-dioxane (50:50, v/v and 30:70, v/v) for the system Cu–H_2A^3–L. The correction in pH parameters has been made using the method detailed earlier (15). The summary of other experimental parameters for the Cu(II) binary and mixed ligand systems is given as follows:

Experimental method: pH titration using pH meter (G.P. Electronics, Accuracy ±0.01 pH unit)

pH range: protonation: 6.00–10.8 pH, Cu(II) complexation: 3.20–5.50 pH

Temperature: 30°C

Method of calculation: SCOGS (ref. 19)[3]

Species considered: protonation: AH_2, AH, A

Cu(II) binary system: AH_2, AH, A, Cu(II), CuAH, and Cu_2A

Cu(II) mixed ligand system: AH_2, AH, A, LH, L, Cu(II), CuAH, Cu_2A, CuL, CuL_2, LCuAH, and Cu_2AL_2

The refined values of the protonation constants were used as fixed parameters for the refinement of binary complexes and the values of the protonation constants and the binary constants were used as fixed parameters for the refinements of mixed ligand species. The values of proton–ligand formation constants of ligands H_2A and formation constants of the binary and mixed ligand complexes and their Δ log K values are presented in Tables 1 and 2. The deviations in values indicate random error in the titrations, dependent on the precision of the instruments.

Isolation of some complexes

The mixed ligand binuclear complexes (Cu_2AL_2, $ClO_4)_2$ were isolated by addition of Cu:Bipyridyl or Cu:1,10-phenanthroline (1:1) complex (4 mmol) in water:ethanol (60:40, v/v) (70 mL) to a potassium salt of 5,5′-methylene-bis-salicylaldehyde (2 mmol) in 40 mL ethanol, with stirring. A dark green coloured clear solution was obtained. Stirring was continued for half an hour. $NaClO_4$ (4 mmol), in water:ethanol (50:50 v/v) (30 mL), was added to the resultant solution. A dark green solid separated out. This was filtered, washed with ethanol, dried, and crystallized from 1:1 DMF:water. These isolated complexes were characterized by metal estimation, elemental analysis, spectral studies, and magnetic moment measurement at room temperature.

The electronic spectra were recorded on a UV-Shimadzu-240 spectrophotometer and the ESR spectra of the complexes were recorded on a Bruker ESP-300 X-band spectrometer at room temperature as well as in DMF solution at 77 K.

Discussion

In the proton NMR spectra of the ligands H_2A, the δ values for -CHO, -OH, and aromatic ring protons are comparable with those for salicylaldehyde. This indicates that both aldehyde moieties are equivalent and there are no external aryl–aryl interactions between the two aromatic phenyl rings in the dinucleating ligands.

The binucleating ligands (H_2A) have two dissociable phenolic -OH groups on two phenyl rings separated from each other. It is, therefore, expected that the two -OH groups should dissociate independently of each other and both proton–ligand formation constants (K_1H and K_2H) of the dinucleating ligands H_2A^1, H_2A^2, and H_2A^3 should be similar and comparable with the protonation constant of the salicylal-

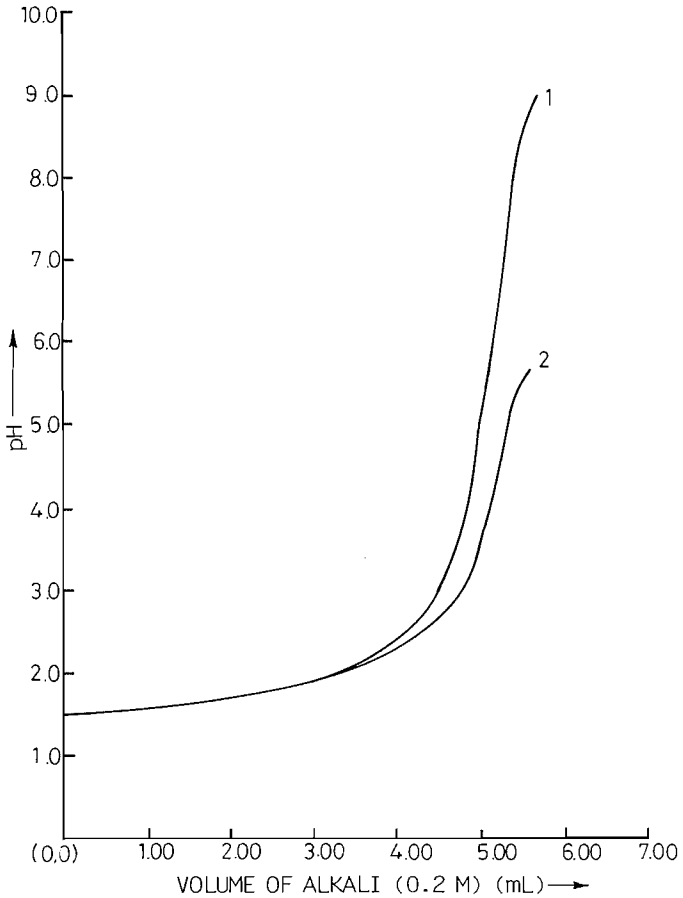

FIG. 1. 1. H_2A^3(0.001 M); 2. Cu:H_2A^3((0.003:0.001 M) (70:30 v/v, dioxane:water).

dehyde, bromosalicylaldehyde, and nitrosalicylaldehyde, respectively. However, it was observed that the values of the first proton-ligand formation constants are slightly higher than those of salicylaldehyde and derivatives, indicating that the dissociation of the two phenolic -OH groups takes place in steps, i.e., the dissociation of proton at one phenolic end may be affecting the dissociation of the other phenolic proton due to internal electronic effects.

It has been noted in the literature (3–12) that ligands with two well-separated coordinating sites behave like two individual ligands. In ligands H_2A^1, H_2A^2, and H_2A^3, also, both coordinating sites are equivalent and separated from each other; therefore it is interesting to study the tendency of the two sites to coordinate with the metal ions.

On coordination of the metal ion to the dinucleating ligand AH_2, complex MAH is first formed, and on coordination of a second metal ion to MAH, formation of the second complex M_2A takes place. The reactions can be shown as follows:

[1] $H_2A + Cu^{2+} \rightleftharpoons CuAH^+ + H^+$

[2] $CuAH^+ + Cu^{2+} \rightleftharpoons Cu_2A^{2+} + H^+$

As is evident from the ligand and Cu + A curve (Fig. 1), there is no hydroxo complex formation until pH 5.5, beyond which precipitation takes place. Consideration of mixed hydroxo species Cu_2AOH and $Cu_2A(OH)_2$ in the calculation of formation constants for CuAH and Cu_2A (in the pH range 3.2–5.5) does not give refinement of results. As is observed in the species distribution curves (Fig. 2), total Cu(II) is present in the form of free Cu(II), CuAH, and Cu_2A. The percentage of Cu(II) in Cu_2A is to be considered twice the percentage of Cu_2A.

As there are two well-separated coordination sites, the coordination of a metal ion to one coordination site should not affect the coordination of a second metal ion to the second coordination site, i.e., the values of log K^{Cu}_{CuAH} and log $K^{CuAH}_{Cu_2A}$ should be comparable. If electrostatic repulsion between CuAH and Cu^{2+} is considered, log $K^{CuAH}_{Cu_2A}$ should be lower than log K^{Cu}_{CuAH}. However, in the present investigation the value of log K^{Cu}_{CuAH} is lower than that of log $K^{CuAH}_{Cu_2A}$. The value of log $K^{Cu_2}_{Cu_2A}$ is more than twice that of log $K^{Cu}_{Cu\text{-}sal}$. This may be because of the restriction of rotation of the two phenyl rings around the central C atom of the methylene group, on coordination of Cu(II) at both the sites. An alternate explanation could be that there is a favourable electronic effect at the second $O\text{–}O^-$ site on coordination of Cu(II) to the first $O\text{–}O^-$ site and hence the coordination of the second Cu(II) to the binucleating ligand is facilitated. These move the equilibrium reaction [2] more to the right side. These are, however, probable additional explanations and further confirmation will be needed.

In the case of ligands H_2A^2 and H_2A^3, log K^{Cu}_{CuAH} and log $K^{CuAH}_{Cu_2A}$ values are less than the values in the case of H_2A^1. This is because of electron-withdrawing groups over the salicylaldehyde moieties, which result in a decrease in the π-electron-donating tendency of the ligands H_2A^2 and H_2A^3 to the Cu(II) ions, resulting in lower formation constants for the complexes.

In the case of mixed ligand complexes, the formation constants of the species CuAHL and Cu_2AL_2 could be refined. The distribution curve (Fig. 3) (plot of concentration of the species vs. pH) of the system Cu–H_2A^2–bipy shows that CuAHL formation takes place at lower pH (below pH 3). The formation of the Cu_2AL_2 complex starts around pH 3.5 and increases with pH. The concentration of species CuAH and Cu_2A is very low. The formation of CuL is almost complete at very low pH. At pH 3, there are mainly two species, CuL (~58%) and CuAHL (~38%).

Hence, the reaction can be shown as follows in three steps.

1. $Cu + L \rightleftharpoons CuL$
2. $CuL + H_2A \rightleftharpoons CuAHL + H^+$
3. $CuL + CuAHL \rightleftharpoons Cu_2AL_2 + H^+$

L = bipyridyl or 1,10-phenanthroline

The values of the formation constants of the ternary complexes. CuAHL and Cu_2AL_2 are higher than expected from statistical considerations.

$$\Delta \log K' = [\log K^{M}_{MAHL} - (\log K^{M}_{MAH} + \log K^{M}_{ML})]$$

and

$$\Delta \log K'' = [\log K^{M_2}_{M_2AL_2} - (2 \log K^{M}_{ML} + \log K^{M_2}_{M_2A})]$$

The values of $\Delta \log K'$ and $\Delta \log K''$ are observed to be positive. This can be explained on the basis of π-acidity of ligands L, as in the case of Cu–dipy–salicylaldehyde complex (14).

In ternary complexes the electron density over the metal ion gets reduced due to $M \rightarrow L$ π-interaction and hence ML

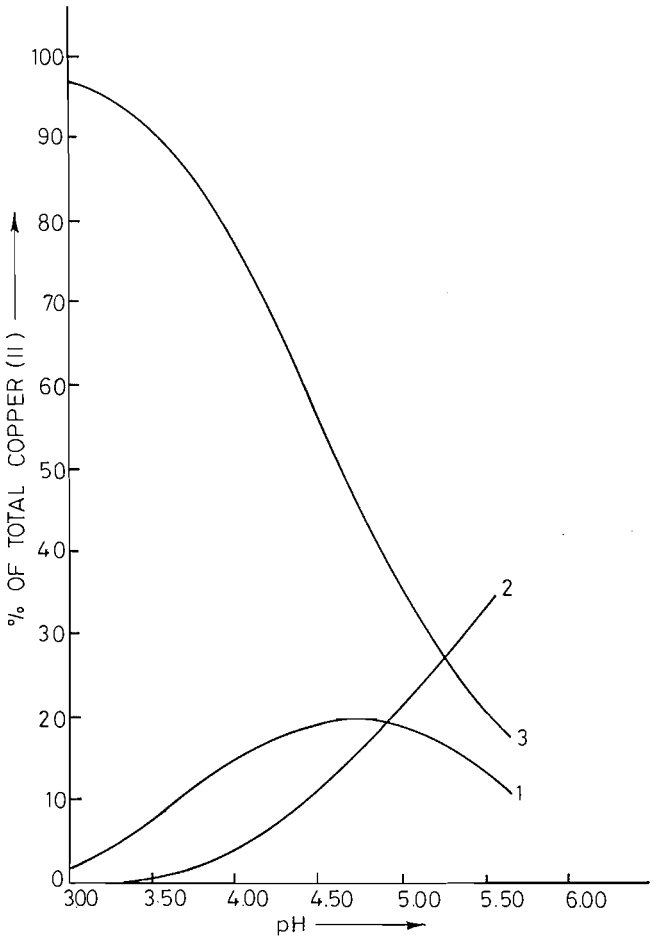

FIG. 2. Species distribution for the [$Cu^{(II)}$–H_2A^2] binary system at an M:A ratio of 2:1 (0.003:0.0015 M). 1. (CuAH); 2. (Cu_2A); 3. free Cu(II).

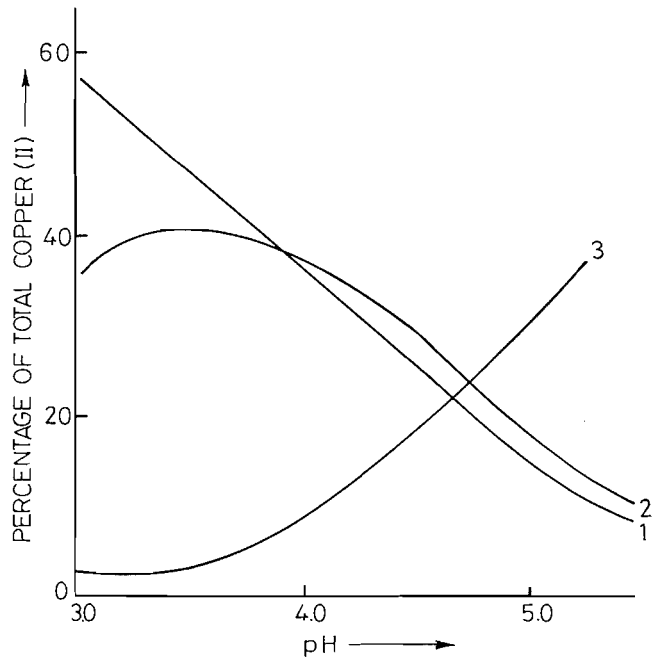

FIG. 3. Species distribution for the [Cu(II)–H_2A^2–bipy] ternary system at an M:A:L ratio of 2:1:2. 1. CuL; 2. CuAHL; 3. Cu_2Al_2.

attains a more class A character, preferring coordination with O^-–O coordinating ligands. This results in the greater stabilization of the ternary complexes and positive Δ log K values.

It is also interesting to observe the effect of the nature of substitution over the ligand A on the formation of the ternary complexes. It was observed earlier (14) that in the case of mononuclear complexes CuAL, where L = bipyridyl or 1,10 phen and A = bromo- or nitrosalicylaldehyde, the stabilization of the ternary complex is lower and hence Δ log K is less positive than in the case of complexes CuAL where A = salicylaldehyde. This is because the electron-withdrawing effect of the bromo and nitro groups causes reduction in the electron density over the coordinating atoms O^-–O and hence the stabilization of the ternary complexes is lower.

In the present study it has been observed that the Δ log K values of the complexes CuAHL and Cu_2AL_2, where A = A^2 and A^3, i.e., dibromo- and dinitro-substituted 5,5′-methylene-bis-salicylaldehyde, are more positive than those of complexes CuA^1HL and $Cu_2A^1L_2$. This can be explained by considering that the presence of substituents on the phenyl rings will further restrict the rotation of the CuL bound to the phenyl rings, around the -CH_2 group. This will orient the two rings of A suitably for coordination with CuL, which was not the case for H_2A^1 without substituents. This will result in greater stabilization of the complexes CuAHL and Cu_2AL_2, where A = H_2A^2 or H_2A^3, compared to the complexes CuA^1HL and $Cu_2A^1L_2$, respectively.

Characterization and magnetic study

The elemental analysis (Table 3) of the binuclear Cu(II) mixed ligand complex corresponds to the expected formula. The general structure of the complexes is shown in Fig. 4.

The electronic spectral studies of the complexes show the expected bands in the visible range. The presence of only one band at 610 nm, as in mononuclear Cu(II) complexes (14), indicates that both Cu(II) centres are behaving as equivalent independent centres.

To ensure that the complex does not break apart in DMF solution, the electronic spectrum of the complex was obtained in this solution. It was compared with the solid reflectance spectra. The peak positions in the two spectra are similar, showing that the mixed ligand complex remains as such in the solution.

IR spectra of the complexes exhibit the expected bands of H_2A and L, supporting the mixed ligand character of the complexes. IR spectral bands corresponding to ClO_4 were used to establish its ionic nature. There is one band obtained at ~1100 cm^{-1}, corresponding to ν_{asy} (Cl-O). The absence of ν_{sym} (Cl-O) at 900 cm^{-1} indicates T_d symmetry and the presence of ionic ClO_4^-.

The magnetic moments of the complexes were measured at room temperature. The value of magnetic susceptibility for each Cu(II) centre corresponds to one unpaired electron. This indicates the absence of magnetic interaction between the two Cu(II) centres, and was further confirmed by ESR spectral studies of the complexes in DMF in the glassy state at liquid nitrogen temperature as well as at room temperature. The spectra exhibit $g_{\|}$ = 2.26 and $g_{\perp}$ = 2.06, corre-

sponding to the distorted octahedral symmetry. No half-filed transition at $g = 4$ is observed, indicating the absence of spin exchange interactions between the Cu(II) centres. This supports the distant orientation of the two Cu(II) centres, as indicated by the formation constant studies in solution.

JOAN TORRENT-BURGUÉS and SABINO VEINTEMILLAS-VERDAGUER. Can. J. Chem. **71**, 1259 (1993).

The solubility and activity coefficients of lead chloride in aqueous potassium nitrate solutions, at 25°C and at boiling, are reported. The activity product constant of lead chloride at boiling has been determined. The Pitzer equations have been applied to the system and have allowed us to determine unknown ionic interaction parameters at 25°C. The calculation of the lead chloride supersaturation is illustrated using the activities instead of the concentrations.

On a déterminé la solubilité et les coefficients d'activité du chlorure de plomb en solution aqueuse de nitrate de potassium, à 25°C et à l'ébullition. On a déterminé la constante du produit d'activité du chlorure de plomb à l'ébullition. On a appliqué les équations de Pitzer au système et elles nous ont permis de déterminer des paramètres d'interactions ioniques inconnues, à 25°C. On illustre le calcul de la sursaturation du chlorure de plomb à l'aide d'activitiés au lieu de concentrations.

[Traduit par la rédaction]

Introduction

Lead chloride crystals have found new applications as acousto-optical material (1, 2). In spite of the low solubility of the salt, it is possible to grow monocrystals of centimetric size from solution by adding a salt that increases the solubility of the lead chloride and (or) by using high temperatures with the techniques of growth from boiling solutions (3, 4). Knowledge of the solubility and activity coefficients of the salt is important in order to calculate the supersaturation and to define the best conditions for nucleation and crystal growth.

In this paper a physico-chemical study of saturated lead chloride solutions in the presence of potassium nitrate, at 25°C and at boiling, is presented. A revision of the data treatment for lead chloride solutions at 25°C, ranging from dilution to saturation, is made, following which the activity coefficients at boiling are estimated using an extrapolation method from solubility measurements, and an estimated activity product constant is reported. Carmody (5) reported the activity coefficients of lead chloride from emf measurements as well as the value of E^0 (Pb^{2+}/Pb) calculated with an extrapolation process (see eq. [3] below). The same set of data were treated by Scatchard and Tefft (6) using a different extrapolation process, which led to slightly different values of E^0 and the activity coefficients. The Pitzer equations have enabled us to adjust the experimental data of emf and to obtain a reliable value for the activity coefficient at saturation and also for the standard potential of the system Pb^{2+}/Pb. The mixture parameters of the system $PbCl_2$–KNO_3 at 25°C are obtained using the Pitzer equations. The activity coefficients are used in the calculation of the supersaturation of lead chloride in $PbCl_2$–H_2O solutions.

[2]Revision received May 10, 1993.

Experimental method

Solubility measurements of lead chloride were made using Carlo Erba A.R. lead chloride, Merck A.R. potassium nitrate, and concentrated nitric acid.

Solubility measurements of lead chloride at 25°C were made in a closed thermostatted cell (±0.1°C). An excess of lead chloride was added to the aqueous KNO_3 solution, of known concentration. The pH was adjusted to 4 by adding nitric acid, in order to prevent the formation of the hydroxy compound, and the solution was then stirred during 24–48 h to ensure saturation. The measurements at boiling and atmospheric pressure were made in a special reactor formed, basically, by a distillation balloon, heated uniformly by a heating blanket, and a reflux column. The top of the distillation balloon was isolated to minimize the heat loss. An excess of lead chloride was added to the aqueous KNO_3 solution, of known concentration, and the pH was adjusted to 2.8. The boiling bubbles, as well as the convection flow, ensured the stirring of the solution. The saturation procedure finished when we observed lead chloride recrystallization, which usually occurred after 24 h.

When saturation was established, the composition of the solution was determined, as well as its density. The lead chloride concentration was determined for an accurately weighed quantity of solution, using a standardized titration method of lead with EDTA. The solubilities, reported in units of molality (m), have an uncertainty of ±0.001

Densities were determined by weighing a known volume of the saturated solution. For boiling conditions, a Lunge–Rey pipette was employed. The densities reported have a precision of ±0.001 at 25°C and of ±0.01 at boiling.

Results and discussion

The experimental results of solubility and density, at 25°C and at boiling, are presented in Tables 1 and 2, respectively. The dependence of the lead chloride solubility, m_1, on the potassium nitrate concentration, m_2, can be expressed at 25°C by the relation:

1.0475	0.0930	1.080	0.175	0.252	0.175

[1a] $$m_1 = 0.0401 + 0.0855m_2 - 0.0682m_2^2 + 0.0334m_2^3$$

At boiling, the relation:

[1b] $$m_1 = 0.141 + 0.0722m_2$$

can reasonably be applied over the entire potassium nitrate concentration range, but shows significant deviations at low concentrations. For this reason, a double adjustment is preferred:

[1c] $$m_1 = 0.124 + 0.1266m_2 - 0.0217m_2^2$$

in the range 0–2.14 molal, and

[1d] $$m_1 = 0.143 + 0.0714m_2$$

in the range 2.14–7 molal. The data at 25°C are more accurate than at boiling due to the experimental conditions.

Since the lead chloride activity is constant at saturation of the salt, when the temperature is fixed, we can calculate the activity coefficients of $PbCl_2$ in the different solutions with the expression

[2] $$m\gamma_\pm = (m\gamma_\pm)_0$$

where the subscript zero refers to a known saturated solution, which can be a single saturated solution of lead chloride.

Activity coefficients at 25°C

The literature data on the activity coefficients at saturation present some scatter due, principally, to the calculation method. We revised it using the more recent treatment of Pitzer (7) for electrolyte solutions, which has been proven to work well in a number of systems. Carmody (5) obtained the emf data for the cell $Pb(Hg)/PbCl_2(aq.)/AgCl,Ag$:

[3] $$E = E^0 - RT/(2F)\ln a(PbCl_2) = E^0 - 3RT/(2F)\ln(4^{1/3}m\gamma_\pm)$$

The differences between the reported values of E^0 (5, 6), are due to the method of extrapolation to infinite dilution of the experimental values.

It is known that the lead ion and the chloride ion are associated in solution. The activity coefficients of lead chloride at 25°C show values lower than those predicted by the limiting equation of Debye–Hückel at all concentrations, and in consequence the Guggenheim equation shows a high negative value of the β parameter. But the Guggenheim equation does not fit the experimental values very well. Thus it seems convenient to use the Pitzer equation, which accounts for the ionic association through the term in $\beta^{(2)}$ (8, 9), even though it was proposed originally for 2:2 electrolytes. The Pitzer equation for lead chloride takes the following form:

TABLE 2. Solubility and mean ionic activity coefficients of lead chloride in potassium nitrate solutions at boiling

6.949	0.628	1.38	105	0.045

[4] $$\ln\gamma_\pm = 2f^\gamma + 4/3\,mB^\gamma + 2^{3/2}m^2C^\Phi$$

[5a] $$f^\gamma = -A_\Phi\left[\frac{I^{1/2}}{1 + 1.2I^{1/2}} + \frac{2}{1.2}\ln(1 + 1.2I^{1/2})\right]$$

[5b] $$B^\gamma = 2\beta^{(0)} + 2\beta^{(1)}/(\alpha_1^2I)\,[1 - (1 + \alpha_1I^{1/2} - 0.5\alpha_1^2I)\exp(-\alpha_1I)] + 2\beta^{(2)}/(\alpha_2^2I)\,[1 - (1 + \alpha_2I^{1/2} - 0.5\alpha_2^2I)\exp(-\alpha_2I)]$$

The activity coefficient in eq. [3] can be replaced by the Pitzer equation and the resulting expression can be reordered to perform a regression of least squares, in order to determine the parameters of the Pitzer equation and the value of E^0. Due to the ion association of the lead chloride, the term in $\beta^{(2)}$ will be retained in the fit, while the term in C^Φ, which accounts for the triple ion interactions, will be eliminated because of the low values of the ionic strengths. This simplification is also justified by the small standard deviation of the fit ($\sigma = 0.0026$) and the good correlation coefficient ($r = 0.9995$). The values of α_1 and α_2 used were 2.0 and 12.0 (8, 9), respectively. The three parameters β of the fit are reported in Table 3. This set of parameters have more physical meaning than the set of parameters $\beta^{(0)}$, $\beta^{(1)}$, and C^Φ, also reported in Table 3, which give slightly better fit, but the large values obtained have little physical sense and also work badly in further applications, i.e., in the mixture equation.

TABLE 3. Pitzer equation parameters for different electrolytes at 25°C

Electrolyte	$\beta^{(0)}$	$\beta^{(1)}$	C^{Φ}	$\beta^{(2)}$	σ
$PbCl_2$[a]	1.2031	−4.8081		−12.9063	0.0026
$PbCl_2$[b]	17.3018	−28.5171	−79.214		0.0023
$Pb(NO_3)_2$[c]	−0.03615	0.285	0.00533		
KCl[c]	0.04835	0.2122	−0.00084		
KNO_3[c]	−0.0816	0.0494	0.00660		

[a]This work, eqs. [4] and [5] with $\alpha_1 = 2$, $\alpha_2 = 12$, and $C^{\Phi} = 0$.
[b]The same, with $\alpha_1 = 2$ and $\beta^{(2)} = 0$.
[c]In ref. 18.

The obtained value of $E^0 = 343.0$ mV is the same as that reported by Scatchard and Tefft (6). Taking the potential of the silver chloride electrode to be 222.3 mV (10) and the lead – lead amalgam potential to be 5.8 mV (5, 10), the standard potential of the redox pair Pb/Pb^{2+} is E^0 (Pb/Pb^{2+}) = 126.5 mV.

With the value of E^0 and the experimental value of E at saturation, we obtain from eq. [3] $\gamma_{\pm}$(sat) = 0.413, a value that is reproduced by the Pitzer equation with the reported parameters. This value is very close to that of 0.412 recommended by Goldberg (11). With this value of $(\gamma_{\pm})_0$ and eq. [2], the activity coefficients reported in Table 1 were obtained for the $PbCl_2$(sat)–KNO_3 mixtures at 25°C.

It is possible to estimate the activity coefficients of the components in a mixture, using the corresponding Pitzer equations (9, 12) and the corresponding parameters of each single electrolyte resulting from combination of an anion and a cation in the mixture. The activity coefficient of the lead chloride (noted by MX, M = Pb and X = Cl) in a mixture with potassium nitrate (noted by NY, N = K and Y = NO_3), with the corresponding molalities m_1 and m_2, is

$$[6]\quad \ln \gamma_{MX} = 2f^{\gamma} + 4m_1[2/3\, B_{MX} + m_1 B'_{MX} + 2/3\, IC_{MX}] + m_2[2/3\, B_{MY} + 2m_1 B'_{MY} + 2/3\,(I + m_1)\, C_{MY}] + m_2[4/3\, B_{NX} + 4m_1 B'_{NX} + 4/3\,(I + m_1)\, C_{NX}] + m_2^2[2B'_{NY} + 4/3\, C_{NY}] + 2/3\, m_2(2\Theta_{XY} + \Theta_{MN}) + 4/3\, m_1 m_2(\Psi_{MXY} + \Psi_{MNX}) + 1/3\, m_2^2(\Psi_{MNY} + 2\Psi_{NXY})$$

where the term f^{γ} is expressed as indicated in eq. [5*a*], and the terms B_{MY}, B_{NX}, B'_{MY}, B'_{NX}, B'_{NY}, and C are

$$[7a]\quad B = \beta^{(0)} + 2\beta^{(1)}/(\alpha_1^2 I)\,[1 - (1 + \alpha_1 I^{1/2})\exp(-\alpha_1 I^{1/2})]$$

$$[7b]\quad B' = 2\beta^{(1)}/(\alpha_1 I)^2[-1 + (1 + \alpha_1 I^{1/2} + 0.5\alpha_1^2 I)\exp(-\alpha_1 I^{1/2})]$$

$$[7c]\quad C = C^{\Phi}/(2|Z_M Z_X|^{1/2})$$

and the terms for lead chloride B_{MX} and B'_{MX} are

$$[7d]\quad B_{MX} = \beta^{(0)} + 2\beta^{(1)}/(\alpha_1^2 I)\,[1 - (1 + \alpha_1 I^{1/2})\exp(-\alpha_1 I^{1/2})] + 2\beta^{(2)}/(\alpha_2^2 I)\,[1 - (1 + \alpha_2 I^{1/2})\exp(-\alpha_2 I^{1/2})]$$

$$[7e]\quad B'_{MX} = 2\beta^{(1)}/(\alpha_1 I)^2\,[-1 + (1 + \alpha_1 I^{1/2} + 0.5\alpha_1^2 I)\exp(-\alpha_1 I^{1/2})] + 2\beta^{(2)}/(\alpha_2 I)^2\,[-1 + (1 + \alpha_2 I^{1/2} + 0.5\alpha_2^2 I)\exp(-\alpha_2 I^{1/2})]$$

The values of all parameters appearing in eqs. [7*a*]–[7*e*] are given in table 3.

Table 1 shows the large difference between the experimental activity coefficients of $PbCl_2$ and those estimated assuming $\Theta,\Psi = 0$. Therefore it is necessary to introduce the mixture parameters. A regression of $\ln(\gamma_{exp}) - \ln(\gamma_{\Theta,\Psi=0})$ using eqs. [6] and [7] ($\sigma = 0.005$) allows us to determine the following combinations of mixture parameters;

$$2\Theta(ClNO_3) + \Theta(PbK) = -1.791$$

$$\Psi(PbClNO_3) + \Psi(PbKCl) = 12.025$$

$$\Psi(PbKNO_3) + 2\Psi(KClNO_3) = -1.840$$

Taking $\Theta(ClNO_3) = 0.016$ and $\Psi(KClNO_3) = -0.006$ (12) we obtain $\Theta(PbK) = -1.823$ and $\Psi(PbKNO_3) = -1.828$, the combination $\Psi(PbClNO_3) + \Psi(PbKCl) = 12.025$ remaining unresolved.

With the values of the mixture parameters, the activity coefficients of $PbCl_2$ in the mixture can be reproduced with great precision (see Table 1). These parameters can also be used to calculate the activity coefficients of KNO_3 in the mixture:

$$[8]\quad \mathrm{Ln}\,\gamma_{NY} = f^{\gamma} + m_2[2B_{NY} + m_2 B'_{NY} + (4m_1 + 3m_2)\, C_{NY}] + 2m_1[B_{NX} + m_2 B'_{NX} + 2(m_1 + m_2)\, C_{NX}] + m_1[B_{MY} + m_2 B'_{MY} + 2(m_1 + m_2)\, C_{MY}] + 2m_1^2[B'_{MX} + C_{MX}] + m_1(2\Theta_{XY} + \Theta_{MN}) + m_1^2(\Psi_{MXY} + \Psi_{MNX}) + m_1 m_2(\Psi_{MNY} + 2\Psi_{NXY})$$

where B, B', and C have the same meaning as indicated before in eqs. [7].

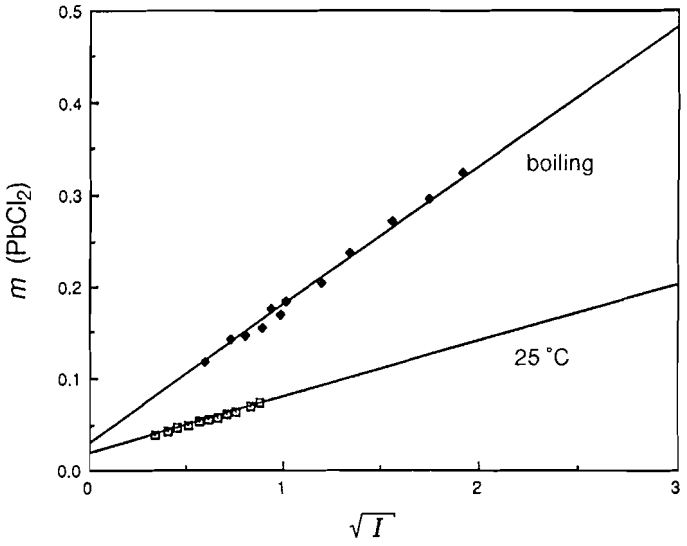

FIG. 1. Lead chloride solubility as a function of the square root of the ionic strength in $PbCl_2$–KNO_3 solutions, at 25°C and at boiling.

Activity coefficients at boiling

At boiling temperature there are no previous data for the activity coefficients of lead chloride. The approach is reduced to knowing the activity coefficient at saturation of a single lead chloride solution, and then to applying eq. [2]. We tested some extrapolation methods reported in the literature (13, 14) for salts of low solubility, but the problem is that the solubility of lead chloride is relatively high for applying these methods. Nevertheless, we observed that the plot of the lead chloride solubility ($m(PbCl_2)$) versus the square root of the ionic strength ($I^{1/2}$), for the different potassium nitrate solutions, shows a good linearity at the lower concentrations and allows us to make a less problematic extrapolation at $I = 0$. According to ref. 13 the extrapolation gives us $(K_{SP}/4)^{1/3} = (m\gamma_{\pm})_0$. This method was tested at 25°C (Fig. 1) using all the solutions of Table 1 except the two most concentrated, which start to deviate from linearity. We obtain $(\gamma_{\pm})_0 = 0.45$ for the activity coefficient at saturation of lead chloride. This activity coefficient shows an error of +0.04 with respect to that determined from emf measurements, but could be considered acceptable for the characteristics of the method.

We applied the same method to the boiling solutions, and a good linearity is also observed in Fig. 1 for the first 12 solutions of Table 2 (no consideration was taken of the small differences, less than 1°C, in the boiling temperatures of the solutions used in the fit). The extrapolation at $I = 0$ gives us the activity product constant of 8.8×10^{-5} and a value of $(\gamma_{\pm})_0 = 0.24$. Using this value and eq. [2] the values of activity coefficients reported in table 2 were obtained. Though the concentrated solutions have boiling temperatures that differ appreciably from 100°C (up to 5°C for the most concentrated), the correction due to this difference in temperature is small and lower than the experimental error. Therefore, it has been neglected.

Due to the approximate character of the method proposed before and in order to compare results, we employed another method making use of the following equation (15, 16):

$$[9] \qquad \Delta_{sol}H = \nu RT^2 \left(\frac{\delta \ln m}{\delta T}\right)_{sat} \left[1 + \left(\frac{\delta \ln \gamma}{\delta \ln m}\right)_T\right]$$

where $\Delta_{sol}H$ is the heat absorbed per mole of solute dissolved in the nearly saturated solution, or the heat evolved per mole of crystallization. From the data on solubility (16) and on activity coefficients at 25°C we calculated $(\delta \ln m/\delta T)_{sat} = 0.0184$ and $(\delta \ln \gamma/\delta \ln m)_{25°C} = -0.342$. From eq. [9], with $\nu = 3$ for lead chloride, we obtain the value of $\Delta_{sol}H = 26.85$ kJ at 25°C. With the assumption that $(\delta \ln \gamma/\delta \ln m)_T$ is practically independent of temperature (16), we can determine $\Delta_{sol}H$ at 100°C in the same way. We have calculated $(\delta \ln m/\delta T)_{sat} = 0.0112$ and then $\Delta_{sol}H = 25.6$ kJ, at 100°C. It can be assumed that $\Delta_{sol}H$ depends linearly on the temperature, $\Delta_{sol}H = K_1 + K_2T$, over a sufficiently broad temperature range (16). With the values of $\Delta_{sol}H$ at 25°C and 100°C, the resulting values of K_1 and K_2 are 31.9 kJ and -17 J K^{-1}, respectively.

To obtain the value of the activity product constant, K_{ap}, at 100°C we use the van't Hoff equation, $d \ln K/dT = \Delta H°/RT^2$, and the activity product constant at 25°C, $K_{ap} = 1.6 \times 10^{-5}$. The value of $\Delta H°$, at 25°C, obtained from literature values (17) of $\Delta_f H°$ for $Pb^{2+}(aq)$, $Cl^-(aq)$, and $PbCl_2(2)$, is 23.4 kJ mol^{-1}. This value is very different from the value of $\Delta_{sol}H$ obtained at 25°C, which is usual in electrolyte solu-

tions since the heat of dilution is very large. Comparing the values of $\Delta_{sol}H$ at 25 and 100°C, it is seen that the influence of the temperature is less than that of dilution. Consequently, we take, in the van't Hoff equation, $\Delta H°$ as a constant value equal to 23.4 kJ mol^{-1}. After integration of the van't Hoff equation we obtain, at 100°C, $K_{ap} = 1.1 \times 10^{-4}$, and from it an activity coefficient $(\gamma_\pm)_0 = 0.25$, which are in accordance with the previously obtained values, taking into account the experimental and method errors.

Supersaturation

In industrial crystallization and growth of monocrystals it is important to know and control the driving force for crystallization in the system. The stoichiometric supersaturation ratio

$$[10a] \quad \beta_m = m/m_{sat}$$

or the stoichiometric relative supersaturation

$$[10b] \quad \sigma_m = \beta_m - 1$$

are usually used because they are the most simple, but they are not correct thermodynamically. According to the definition of the driving force for crystallization

$$[11] \quad \Delta\mu = \mu - \mu_{sat} = RT \ln(a/a_{sat}) = RT \ln(\beta_a)$$

where β_a is the supersaturation ratio. For electrolytes the previous expression can be transformed to

$$[12] \quad \Delta\mu = vRT \ln(m\gamma_\pm/(m\gamma_\pm)_{sat}) = vRT \ln(\beta_a{}^*)$$

where the supersaturation ratio $\beta_a{}^* = \beta_a{}^{1/\nu}$. It is simple to see that $\beta_a{}^*$ reduces to β_m when the activity coefficients are not considered or when the simplification $\gamma = \gamma_{sat}$ is assumed.

Table 4 shows the differences between the values of σ_m and $\sigma_a{}^*$ for supersaturated solutions of lead chloride at 25°C, and for supersaturated solutions of lead chloride in the presence of potassium nitrate 0.11 *m* at 25°C. The activity coefficients have been calculated with the Pitzer equations and the parameters reported in this work.

At boiling, we do not have the parameters of the Pitzer or another electrolyte equation. To calculate the activity coefficients at saturated and supersaturated solutions we used the activity coefficient dependence observed in Fig. 1 and we adjusted them to the empirical equation

$$[13] \quad 1/\gamma_\pm = 1 + 5.389\, I^{1/2} - 0.413 m_1 - 0.443 m_2 + 2.026 m_1 m_2$$

where $m_1 = m(PbCl_2)$ and $m_2 = m(KNO_3)$. Table 5 shows the dependence of β_m and $\beta_a{}^*$ versus $m - m_{sat}$ for three concentrations of KNO_3.

The activity-based supersaturation is generally lower than the concentration-based supersaturation, and this difference increases as the solution complexity increases (as is usual in many industrial processes). If we consider that nucleation and crystal growth phenomena are strongly nonlinear with supersaturation, any empirical correlation for the estimation of nucleation or crystal growth rate will work better if done as a function of the true thermodynamic supersaturation. The kinetic coefficients obtained in this way for one substance will work better in many chemical environments. A relation between concentration and activity coefficients that can be obtained from solubility measurements is needed.

FULVIO CORRADINI, LUIGI MARCHESELLI, LORENZO TASSI, GIUSEPPE TOSI, and SALVATORE FANALI. Can. J. Chem. **71**, 1265 (1993).

Conductivities of the electrolytes NaBr, NaPi, HPi, $NaBPh_4$, and Ph_4PBr in ethane-1,2-diol were determined in the $-10 \leq t \leq +80$°C temperature range. The experimental data were analyzed by the Fuoss–Hsia equation, which provides further informative parameters such as the dissociation constant (K) of the ion pairs formed in solution, the limiting equivalent conductivity (Λ_0), and the ion-size parameter ($\mathring{a}$). Thermodynamic behaviour of these electrolytes was derived from analysis of the K values. Single-ion conductivities were evaluated on the basis of the assumption of Ph_4PBPh_4 as reference electrolyte.

FULVIO CORRADINI, LUIGI MARCHESELLI, LORENZO TASSI, GIUSEPPE TOSI et SALVATORE FANALI. Can. J. Chem. **71**, 1265 (1993).

On a déterminé la conductivité des électrolytes NaBr, NaPi, HPi, $NaBPh_4$ et Ph_4PBr dans l'éthane-1,2-diol, à des températures allant de −10 à +80°C. On a analysé les données par l'équation de Fuoss–Hsia qui fournit d'autres paramétres plus utiles, comme la constante de dissociation (K) des paires d'ions qui se forment en solution, la conductivité équivalente limite (Λ_0) et le paramètre de la grosseur de l'ion ($\mathring{a}$). On a dérivé le comportement thermodynamique de ces électrolytes par une analyse des valeurs de K. On a évalué les conductivités des ions uniques en se basant sur l'hypothèse que le Ph_4PBPh_4 est l'électrolyte de référence.

[Traduit par la rédaction]

Introduction

Ethane-1,2-diol (ED) has attracted much attention in recent years as a nonaqueous solvent for many electrochemical investigations as well as for various practical applications (1). The great interest that this medium holds for many authors can probably be ascribed to its unusual chemical-physical properties, which make it a very singular solvent. ED is amphiprotic in nature, thoroughly miscible with a variety of other solvents (polar, such as water, and quasi-apolar, such as dioxane); because of its high density and viscosity it may be considered an excellent viscoelastic regulating medium for reaction bath and as thermoregulator fluid. Further, its high dipole moment (μ = 2.28 D) (2) and a moderately high dielectric constant (ε = 40.97 at 25°C) (3) cause it to be placed between the dissociating solvents in the general classification of Charlot and Trémillon (4).

Although a number of precise conductivity measurements of electrolytes in other solvents are reported in the literature, relatively few such studies have been made on ethane-1,2-diol. Now, following our interest in this field, an attempt has been made to investigate the nature of ion–ion and ion–solvent interactions of such electrolytes as sodium picrate (NaPi), NaBr, $NaBPh_4$, Ph_4PBr (all ionophore solutes because of their ionic structure in the crystalline state), and the ionogen picric acid (HPi) dissolved in ED, through the measurement of their conductivities at 19 temperatures ranging from −10 to +80°C.

Since few transference-number data for ED solutions of these salts are available in the literature, single-ion conductivities have been evaluated employing the two reference tetraphenyl derivative electrolytes, in an effort to provide reliable values of ionic mobilities.

Experimental section

Materials

The solvent ethane-1,2-diol (containing less than 0.10% g of water, as determined by Karl–Fischer titrations) was high purity grade reagent from Carlo Erba (Milan). It was stored over 3Å molecular sieves for many days before use and the final purity was checked by gas chromatography, confirming the absence of other significant organic components. The solvent has a density of 1.109913 g cm^{-1}, viscosity 17.14 cP, and a specific conductivity of 0.255 μS cm^{-1} at 25°C.

The NaBr was from Aldrich Chemicals, of Suprapure guaranteed quality, and was utilized without further purification after desiccation at 105°C and preservation in vacuo over P_2O_5 prior to use.

Tetraphenylphosphonium bromide (Fluka) was purified by recrystallization (×2) from a binary mixture of acetone and 2-propanol (v:v 9:1), while $NaBPh_4$ (Fluka) was recrystallized (×2) from pure acetone. Both salts were dried at 80°C and preserved in vacuo over P_2O_5 for some time before use.

Sodium picrate was prepared from picric acid and NaOH, starting from their equimolar solutions in water–ethanol (v:v 1:1) and working at high temperature. The precipitate was filtered and washed many times with the same solvent mixture and dried in vacuo over P_2O_5. The final product was checked by elemental analysis before use and the results are reported here: Anal. calcd. for $C_6H_2N_3O_7Na$: C 28.70, N 16.74, H 0.80%; found: C 28.42, N 16.81, H 0.75%.

Apparatus and procedures

Conductivity measurements were made by a Wayne Kerr 6425 Precision Component Analyzer, operating in the 2.5×10^{-9}–10 S

TABLE 2. Coefficients a_i and standard deviations σ(ln K) of eq. [2] for some electrolytes in ethane-1,2-diol

Solute	a_0	a_1	a_2	a_3	$10^2\sigma(\ln K)$
$NaBPh_4$	−1844.9	−0.68700	38575	336.57	4.7
Ph_4PBr	−3343.4	−1.1265	77838	599.43	6.0
NaBr	−1705.5	−0.61055	37539	308.79	3.7
NaPi	−2358.4	−0.84134	51784	427.03	7.5
HPi	−279.43	−0.12219	4310.9	51.839	5.4

range (end scale), with a sensitivity ±0.01 nS, and employing platinized platinum electrodes (cell constant k = 10.538 cm) with a field frequency of 1 kHz. The measuring cell was embedded in a polyurethane protective jacket, and the temperature control was provided by a Lauda K2R thermostatic bath maintained to within ±0.02°C over the investigated temperature range.

The constancy of temperature was checked by a thermoresistance Pt 100 (Tersid, Milan) immersed in the sample in the measurement cell, and by recording the resistance values by the same WK 6425 PCA bridge cited above.

Densities and viscosities were measured as previously reported (5).

Karl–Fischer titrations were performed with an automatic titration system (Crison model KF 431) equipped with a digital buret (Crison model 738).

Solutions of electrolytes at different concentrations were obtained by successive dilution of stock solutions, freshly prepared by weight; concentrations in volume were then calculated from weight concentrations and densities.

Conductivity readouts were recorded when they become invariant with time; this took about 30 min for each measurement.

Several independent solutions were prepared and as many runs as necessary were performed to ensure the reproducibility of the results. Solvent conductivity corrections were applied to all the data at the different temperatures.

Results and discussion

The measured equivalent conductivities and the corresponding molarities of solutions for the chosen salts in ED are given in Tables 1–5 of the Supplementary Material[2] available for $NaBPh_4$, Ph_4PBr, NaBr, NaPi, and HPi, respectively. The data were analyzed by means of the more general Fuoss–Hsia equation (6, 7):

$$[1] \quad \Lambda = \Lambda_0 - S(c\gamma)^{1/2} + Ec\gamma \lg c\gamma + J_1 c\gamma - J_2(c\gamma)^{3/2} - K_A c\gamma f_{\pm}^2 \Lambda$$

where the symbols have their usual meaning (8).

The above equation provides the limiting equivalent conductivity Λ_0, the ionic association constant K_A (dissociation constant $K = K_A^{-1}$), and the interionic distance parameter $\mathring{a}$. The calculations were performed on a computing program by means of an iterative procedure. The initial Λ_0 values were obtained from an Onsager plot at each selected temperature, and the first $\mathring{a}$ value was fixed at 5 Å. Generally, only a few iterations were necessary to obtain the final results.

The dissociation constant

The K values provided by the Fuoss–Hsia theory are summarized in Table 1 for all the chosen electrolytes and for any selected temperature in the range from −10 to +80°C.

TABLE 3. K_{max} and corresponding values of t_{max} for the dissociation of some electrolytes in ethane-1,2-diol

Solute	Equation [2]		Harned's theory	
	K_{max}	t_{max}	K_{max}	t_{max}
$NaBPh_4$	7.04×10^{-2}	33.9	3.09×10^{-2}	34.3
Ph_4PBr	6.08×10^{-2}	34.0	2.77×10^{-2}	33.5
NaBr	1.03×10^{-1}	29.4	5.39×10^{-2}	33.0
NaPi	8.68×10^{-2}	34.1	3.81×10^{-2}	34.1
HPi	2.49×10^{-3}	34.4	2.47×10^{-3}	38.4

Each set of dissociation constant values for each solute was fitted by means of the integrated van't Hoff equation

$$[2] \qquad \ln K = a_0 + a_1 T + a_2/T + a_3 \ln T$$

which represents the most reliable data-fit model for analyses of this type. In fact eq. [2], whose a_i coefficients for each electrolyte in this solvent are reported in Table 2, reproduces the experimental values of Table 1 with a good approximation, as one can deduce from the standard deviation values $\sigma(\ln K)$ summarized in the last column.

Figure 1 reproduces the trend of experimental K values and the best-fitting curves expressed by eq. [2]. A brief examination of this figure provides some particularly interesting suggestions that may be pointed out as follows.

1. The dissociation of picric acid and of ion pairs of the other electrolytes shows a generally convex trend of the K vs. T curves and, as a consequence, all the curves are characterized by a relative maximum in the temperature range investigated.

2. The two precursor reference electrolytes, $NaBPh_4$ and Ph_4PBr, show slightly different dissociation constant values over all the studied temperature range, with a moderately high value for the sodium salt. Probably, the large delocalization of the electrical charge on the "bolaform" tetraphenyl ions reduces the degree of interaction with other charged species, releasing in this way the counterion in solution and

freeing it from the electrical attractions responsible to a large extent for ion-pair formation.

3. The higher K values are observed for NaBr and NaPi, showing these electrolytes to have similar behaviour in ED solutions. A probable explanation for this experimental evidence could be the relative strength of the solvation bonds towards the different ions. In fact, the sodium ion appears strongly solvated in these solutions and, as a consequence, the solvation shell could mask the central ion towards the counterions. Similar considerations may apply for the salifiable anions, Br^- and Pi^- respectively, taking into account that on progressively increasing the ionic dimensions may observe a progressive decrease in the relative strength of the solvation network; this should lead to a parallel decrease in the dissociation constant values of the electrolyte considered.

Table 3 reports a comparison of the K_{max} and the corresponding t_{max} values for these electrolytes. These values have been obtained by fitting eq. [2] and applying Harned's theory (9), but poor agreement is observed in this case for the weak electrolyte HPi.

Starting from eq. [2], the thermodynamic data for the apparent dissociation reaction of picric acid (10) and the true dissociation of other electrolytes in ED solutions were evaluated by applying the standard equations in the form:

$$[3] \quad \Delta H^0 = R(a_1T^2 - a_2 + a_3T)$$

$$[4] \quad \Delta S^0 = R[a_0 + 2a_1T + a_3(1 + \ln T)]$$

where the a_i terms are the coefficients of Table 2. The results are summarized in Tables 6 and 7 of the Supplementary Material[2] and in graphic form in Fig. 2.

As can be noted, many uncertainties affect ΔG^0, ΔH^0, and ΔS^0 values, owing to the experimental errors in K evaluation and partly associated with the interpolating function $K = K(T)$, i.e., the van't Hoff equation [2].

In spite of these difficulties, the thermodynamic data could be a powerful tool in accounting for the solute-solvent interactions. As appears from Fig. 2, enthalpic and entropic variations seem to be comparable in magnitude on the whole for all the salts, excluding HPi, which is a medium-weak electrolyte in ED solution. However, the common trend of Fig. 2 is represented by a negative temperature coefficient $d\Delta Y/dT$, where $Y = H^0$ and S^0 respectively.

We next attempt to obtain some useful structural information by considering the entropy changes in detail. One may assume that at the highest temperatures an ordered structure exists in the neighbourhood of the charged solute species, in the form of ion pairs or free ions. This, however, is in apparent contrast to the thermokinetic steady state that is reached at each selected temperature.

A reliable explanation probably lies in the decreasing value of the dielectric constant of the solvent as the temperature increases (3), reducing in this way the electrostriction effects between moving species. Furthermore, the dramatic decrease in the viscosity with rising temperature (11) should provide a considerable decrease of the mechanical friction and viscokinetic delay for all constituent species of the system, i.e., ion pairs, free ions, and molecules. This situation should facilitate the arrangement and the correct orientation, induced by the strong and thermally unaffected electrical fields of the charged species, of the solvent molecules forming the solvation shell.

It should be noted that ED probably solvates anions by a more effective hydrogen bonding network, and cations through dipole and induced-dipole interactions. Thus, at the highest temperatures, its solvation power seems to increase with the size and polarizability of the ions in the series

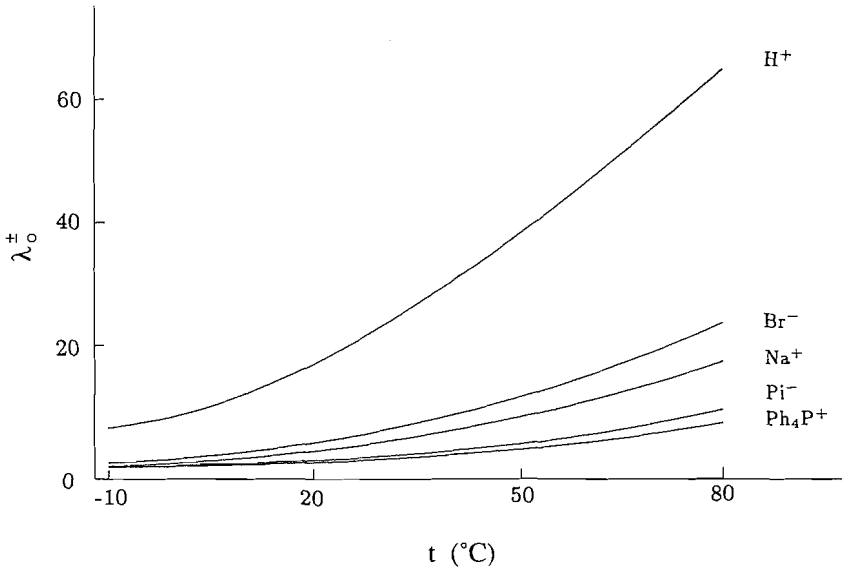

FIG. 3. Limiting ionic conductivities ($\lambda_0^{\pm}$/cm^2 S mol^{-1}) of some species in ethane-1,2-diol at different temperatures.

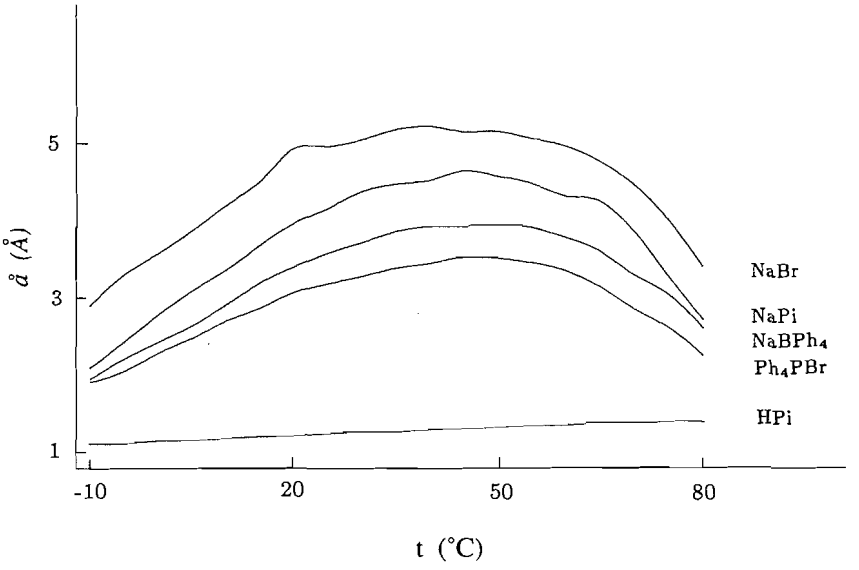

FIG. 4. Interionic distance parameter ($\mathring{a}$/Å) versus temperature for some electrolytes in ethane-1,2-diol at different temperatures.

$Br^- < BPh_4^- < Pi^-$ and $H^+ < Na^+ < Ph_4P^+$. The negative charge on the Pi^- anion is widely spread over all three nitro groups and hence is more delocalized than is the case for other isocharged species. It is to be expected, therefore, that the first anion should be solvated by ED molecules more strongly than the others.

From these arguments and from the evidence obtained about the chosen electrolytes, it may be concluded that the dissociation of salts in ED solutions is a process controlled by enthalpic rather than entropic factors.

The limiting equivalent conductivity
