For ^{119}Sn Mössbauer spectroscopy, thin powdered samples, prepared by grinding the crystalline material to prevent preferred orientation of the crystallites, were pressed into Kel-F sample holders. Mössbauer spectra were recorded at 80 K using an Elscint constant acceleration spectrometer with an MCDPC-IBM AT acquisition system manufactured by CMTE. The samples were cooled in a Technology Systems cryostat. The source was ^{119}Sn (5 mCi, Amersham), in a calcium stannate matrix. The velocity scale was calibrated with a standard iron foil absorber and a $^{57}Co/Rh$ source mounted on the reverse end of the transducer. Calibration spectra were thus recorded without interruption of the drive sequence. The calibration spectra were computer fitted to give a linear velocity scale and folding point. Folded ^{119}Sn spectra were computer fitted using a modified version of the program GMFP (35). All isomer shifts are referenced to a thin absorber of $CaSnO_3$ at room temperature.

Single colourless cubic crystals of $Sn(C{\equiv}CSiMe_3)_4$ and $Ge(C{\equiv}CSiMe_3)_4$ were grown from hexane. X-ray diffraction was performed on a Nicolet R3 using MoKα radiation at 183 K. The relevant information is available in Tables 9*a–f* (compound **2**) and Tables 10*a–f* (compound **3**).[6]

General preparative procedure of $(Me_3SiC{\equiv}C)_4M$

For the silicon species, the tetrakis species **1** and $Cl_3SiC{\equiv}CSiMe_3$ were prepared simultaneously.

[a]The values presented are mean values from within a given structure.
[b]Because of the extended conjugation, we include this in the dimetallated group.

To a solution of $Me_3SiC{\equiv}CH$ (7.9 mL, 70.8 mmol) in THF (40 mL) at 0°C was added *n*-BuLi (1.4 in hexanes, 51 mL, 72 mmol). This solution was added slowly over 30 min at 0°C to the metal tetrachloride (e.g., $SiCl_4$; 65 mL, 8 equiv., 567 mmol) in dichloromethane (CH_2Cl_2; 200 mL) and stirred over 18 h. Then the solvent was removed by simple distillation and the residue was distilled at 55°C/15 Torr (1 Torr = 133.3 Pa) to give 3.5 g of $Cl_3Si\text{-}C{\equiv}C\text{-}SiMe_3$ (15.1 mmol, 21% yield). Afterwards, the residue was washed with water, extracted with ether, and recrystallized several times in hexane to give 3 g of **1** (7.1 mmol, 41% yield) (36).

The syntheses of the other metallated (trimethylsilyl) acetylide compounds were performed with some modifications to the procedures reported in the literature. The syntheses were done as described above by the reaction of lithium salt of (trimethylsilyl)acetylide ($Me_3Si\text{-}C{\equiv}C\text{-}$, 4.0 equiv.) with the appropriate silyl, germyl, or stannyl chloride compounds in tetrahydrofuran or ether (37). In these cases, chlorometal derivatives were not obtained as coproducts.

Spectral data

*Tetrakis[(trimethylsilyl)ethynyl]silane ($(Me_3SiC{\equiv}C)_4Si$) **1**:* mp 154–159°C (from hexane) (lit. (15) mp 160°C (from petroleum ether): IR (CH_2Cl_2) ν(cm^{-1}): 2965 h, 2900 m, 2010 m, 1950 w, 1875 w, 1400 m, 1250 st, 900-720 st, 700 st, 480 st, 290 st; ^{1}H NMR ($CDCl_3$, 200 MHz): δ(ppm) = 0.21 (s); ^{13}C NMR ($CDCl_3$, 62.9 MHz) δ(ppm): 117.2, 104.2, −0.3; ^{29}Si NMR ($CDCl_3$, 49.69 MHz) δ(ppm): −17.5, −101.6; MS (EI, *m/z*): 416 (M^+, 21), 401 (34), 343 (12), 328 (11), 313 (100), 231 (29), 179 (32), 155 (56); HRMS, mass calcd. 416.1669; observed: 416.1663.

*Tetrakis[(trimethylsilyl)ethynyl]germane ($(Me_3SiC{\equiv}C)_4Ge$) **2** (ref. 36):* Yield: 94% (lit. (36) yield 58%); mp 175–176°C (from petroleum ether) (lit. ($CDCl_3$, 49.69 MHz) δ(ppm): −18.1; ^{119}Sn NMR ($CDCl_3$, 93.28 MHz) δ(ppm): −384.5; MS (EI, *m/z* reported for ^{119}Sn isotope): 508 (M^+, 15), 493 (17), 405 (16), 314 (72), 247 (83), 217 (35), 179 (80), 165 (86), 119 (30), 97 (100), 73 (79); HRMS (M^+ reported for ^{119}Sn isotope), mass calcd. 508.0916; observed: 508.0915.

Trimethylstannyl(trimethylsilyl)acetylene (Me_3Si-C≡C-$SnMe_3$) (ref. 38): Yield: 71% (lit. (38) yield 68%) bp ~25°C at 1 Torr; IR (neat) ν(cm^{-1}): 2965 st, 2920 st, 2905 st, 2370 w, 2075 w, 1450 m, 1405 m, 1305 w, 1245 st, 1190 w, 830 st, 750 st, 690 st; ^{1}H NMR ($CDCl_3$, 200 MHz) δ(ppm): 0.28 (s, 9H), 0.16 (s, 9H); ^{13}C NMR ($CDCl_3$, 62.9 MHz) δ(ppm): 117.6, 113.2, 0.5, −7.4; ^{29}Si NMR ($CDCl_3$, 49.69 MHz) δ(ppm): −20.9; ^{119}Sn NMR ($CDCl_3$, 93.28 MHz) δ(ppm): −73.6; MS (EI, *m/z* reported for ^{119}Sn isotope): 247 ($M^+ - CH_3$, 100), 217 (12), 185 (6); HRMS (M^+ reported for ^{119}Sn isotope), mass calcd. for $M^+ - CH_3$: 246.9965; observed for $M^+ - CH_3$: 246.9984.

Triphenylstannyl(trimethylsilyl)acetylene (Me_3SiC≡$CSnPh_3$) (ref. 39): Yield: 92% (lit. (39) yield 61%); mp 73–74°C (lit. (39) mp 74–76°C); ^{1}H NMR ($CDCl_3$, 200 MHz) δ(ppm): 7.75–7.65 (m, 6H), 7.5–7.4 (m, 9H), 0.3 (s, 9H); ^{13}C NMR ($CDCl_3$, 62.9 MHz) δ(ppm): 139.9, 136.7, 129.5, 129.2, 121.4, 108.7, 0.17; ^{29}Si NMR ($CDCl_3$, 49.69 MHz) δ(ppm): −19.5; ^{119}Sn NMR ($CDCl_3$, 93.28 MHz) δ(ppm): −175.4; MS (EI, *m/z* reported for ^{119}Sn isotope): 448 (M^+, 3), 433 (5), 371 (39), 341 (4), 294 (3), 274 (35), 221 (27), 197 (37), 159 (50), 135 (32), 120 (100), 97 (18); HRMS (M^+ reported for ^{119}Sn isotope), mass calcd.: 448.0669; observed: 448.0677.

*Tetrakis[(trimethylsilyl)ethynyl]plumbane ($(Me_3Si$-C≡C$)_4Pb$) **4***

A solution of methylmagnesium bromide (3 M in ether, 5.9 mL, 17.7 mmol) was added slowly to a solution of (trimethylsilyl)acetylene (Me_3Si-C≡C-MgBr, 2.5 mL, 17.7 mmol) in tetrahydrofuran (20 mL) at 0°C. The solution was stirred 1 h at 0°C and about 1.5 h at room temperature until no more bubbles were observed. After cooling at 0°C, lead tetraacetate (0.8 g, 1.8 mmol) was added through glass tubing under a nitrogen atmosphere over 30 min. The mixture was stirred 1 h at 0°C and 4.5 h at room temperature (brown solution). After work-up with 1% aqueous HCl and water, the product was extracted with diethyl ether and the solution dried over magnesium sulfate. The crude compound was recrystallized in hexane. Yield: 37% (lit. (36) yield 47%); mp 155°C (dec.) (lit. (36) mp 108°C (from petroleum ether)); ^{1}H NMR ($CDCl_3$, 200 MHz) δ(ppm): 0.21 (s); ^{13}C NMR ($CDCl_3$, 62.9 MHz), δ(ppm): 117.4, 111.7, −0.3; ^{29}Si NMR ($CDCl_3$, 49.69 MHz) δ(ppm): −18.0; ^{207}Pb NMR ($CDCl_3$, 52.33 MHz) δ(ppm): −760.7 (line width of 40 Hz); ^{207}Pb NMR (solid state without spinning, 20.93 MHz) δ(ppm): −551 (line width of 100 Hz); MS (EI, *m/z* reported for ^{208}Pb isotope): 581 ($M^+ - CH_3$, 11), 551 (4), 493 (41), 402 (20), 335 (13), 305 (100), 290 (95), 261 (23).

Acknowledgments

We gratefully acknowledge the financial support of the Natural Sciences and Engineering Research Council of Canada. We also thank Dow Corning Canada for providing some of the methylchlorosilanes used in this study.

x–y Coriolis interaction in the ν_5 and ν_8 bands of propyne-d_3

GEETHA RAJAPPAN AND V.A. JOB[1]

Spectroscopy Division, Bhabha Atomic Research Centre, Bombay, 400 085, India

Received March 22, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

GEETHA RAJAPPAN and V.A. JOB. Can. J. Chem. **71**, 1684 (1993).

High resolution Fourier transform spectra of the ν_5 and ν_8 bands of $CD_3C{\equiv}CH$ have been recorded and analyzed taking into account the strong x–y Coriolis interaction between these fundamentals. Fermi resonance of the ν_8 state with the $\nu_9 + \nu_{10}$ state, l-type doubling interaction between the $\pm l$ components of ν_8 and a weak k-type doubling interaction between the ν_5 and ν_8 states have also been included in the perturbation treatment. The parameters of the ν_5 and ν_8 states as well as some of the parameters of the unobserved $\nu_9 + \nu_{10}$ state have been determined. An estimate of the relative value of the transition moments has been obtained from the line intensities, which are strongly affected by the x–y Coriolis interaction.

GEETHA RAJAPPAN et V.A. JOB. Can. J. Chem. **71**, 1684 (1993).

On a enregistré les spectres à haute résolution par transformation de Fourier des bandes ν_5 et ν_8 du $CD_3C{\equiv}CH$ et on les a analysées en tenant compte de l'importante interaction x–y de Coriolis entre ces fondamentales. Dans le traitement de perturbation, on a aussi inclus la résonance de Fermi de l'état ν_8 avec l'état $\nu_9 + \nu_{10}$, l'interaction de duplication de type l entre les composantes $\pm l$ de ν_8 et la faible interaction de duplication de type k entre les états ν_5 et ν_8. On a déterminé les paramètres des états ν_5 et ν_8 ainsi que d'autres paramètres qui n'ont pas été observés pour l'état $\nu_9 + \nu_{10}$. On a pu évalué la valeur relative des moments de transition à partir des intensités des raies qui sont fortement affectées par l'interaction x–y de Coriolis.

[Traduit par la rédaction]

I. Introduction

The rotational structure of the ν_5 and ν_8 bands of propyne, $CH_3C{\equiv}CH$, has been studied by laser Stark spectroscopy (1–4) and Fourier transform spectroscopy (5). Even though the possibility of vibration–rotation interactions between these two fundamentals has been recognized (5), no attempt was made to include these interactions in the analyses. In propyne, these two fundamentals are separated by more than 100 cm^{-1} and, indeed, the interactions are weak. However, in the deuterated species, $CD_3C{\equiv}CH$, they are separated by only ~4.2 cm^{-1} and a strong interaction results. The dominant interaction between a nondegenerate a_1 mode and a degenerate e mode of a molecule belonging to the C_{3v} point group is x–y Coriolis interaction. It was pointed out by Di Lauro and Mills (6) that, in addition to shifting the line positions, the interaction can have a striking effect on the observed intensities of the spectral lines.

The ν_5 and ν_8 bands of $CD_3C{\equiv}CH$ have been studied under medium resolution by Speirs and Duncan (7). The resolution that was available to them permitted only a band contour analysis of the Q subband structure. Nevertheless, they were able to determine some of the molecular parameters, including the x–y Coriolis coupling constant and the relative values of the two transition moments. We have obtained the high-resolution Fourier transform spectrum of $CD_3C{\equiv}CH$ in the ν_5/ν_8 band region, and the analysis is presented in this paper.

II. Experimental details

A commercial sample of $CD_3C{\equiv}CH$ (Merck, Sharpe & Dohme, Canada) of 99% isotopic purity was used to record the spectrum in the region 800–900 cm^{-1} on a BOMEM DA3.002 Fourier transform spectrometer (globar source, KBr beam splitter, and HgCdTe detector) at an apodized resolution of 0.004 cm^{-1}. A sample pressure of 66 Pa was used in a folded cell of fixed path length 10 m. A total of 121 scans were coadded. Wavenumber calibration was done with respect to the NH_3 lines in this region (8), recorded in a separate run. A spectrum at a lower resolution of 0.1 cm^{-1} was also recorded at 195 K.

III. Results and discussion

Rotation about the x–y axes couples the ν_5 (a_1) and ν_8 (e) modes of $CD_3C{\equiv}CH$ through a second-order Coriolis interaction. A comprehensive treatment of this interaction may be found in ref. 6. All interactions as well as the allowed spectroscopic transitions in a C_{3v} molecule follow the selection rule

$$\Delta|k - l| = 0 \bmod 3$$

where l and k are signed quantities representing the components of the vibrational and total angular momenta along the C_3 axis. In addition, we have the selection rules based on the classification of the rovibrational levels under the full symmetry group (9), $A_1 \leftrightarrow A_1$, $A_2 \leftrightarrow A_2$, and $E \leftrightarrow E$ for all interactions, and $A_1 \leftrightarrow A_2$ and $E \leftrightarrow E$ for all electric dipole transitions.

In x–y Coriolis interaction, the relevant selection rules are $\Delta l = \pm 1$ and $\Delta k = \pm 1$. The energy levels of ν_5 and ν_8 are shown schematically in Fig. 1, with the interacting levels connected by dotted lines. We found that a complete interpretation of the spectrum required that three other interactions — a Fermi resonance with the E component of $\nu_9 + \nu_{10}$, "$\pm 2, \pm 2$" l-type resonance within the ν_8 manifold, and weak k-type doubling interaction between the ν_5 and ν_8 states — be taken into account. The Fermi interaction with the $\nu_9 + \nu_{10}$ state is also shown in Fig. 1 (broken lines). The l-type resonance connects the $-l$ and $+l$ components differing in k by two units. The $\pm l$ components connected through this interaction are the same two levels that interact with a particular K level of the ν_5 state through x–y Coriolis interaction. In addition, the $+l$ components of $K = |k| = 1$, i.e., $k = -1$, $l = -1$, and $k = +1$, $l = +1$, are coupled through

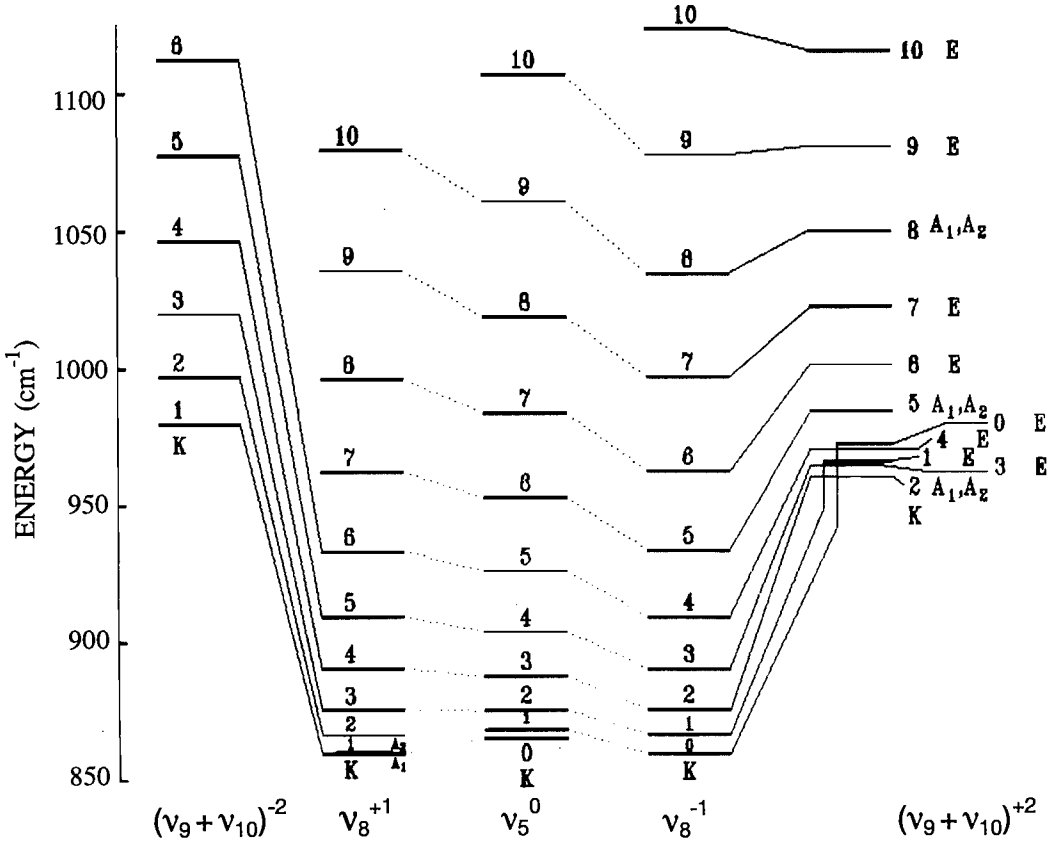

FIG. 1. Energy level diagram of ν_5 and ν_8 states and other interacting levels for $J = 10$. The levels connected through dotted lines are involved in x–y Coriolis interaction, and those connected by broken lines are in Fermi resonance.

this interaction, which results in the splitting of the A_1 A_2 pairs: the l-type doubling. The $K = 0$ levels of the nondegenerate state belong to either A_1 or A_2 species depending on whether J is even or odd. It is thus able to interact with only one component of the A_1 A_2 pairs of $K = 1$ of a degenerate state through x–y Coriolis coupling, leading to the so called "giant l-type doubling." The k-type doulbing interaction, which is not shown in Fig. 1, connects levels with $\Delta k = \pm 2$ and $\Delta l = \mp 1$. This interaction can cause A_1 A_2 splittings in the $-l$ component of $K = 2$.

An overview of the ν_5 and ν_8 bands of $CD_3C{\equiv}CH$, taken at a resolution of 0.1 cm^{-1} at 195 K is shown in Fig. 2. The low temperature suppresses the hot band transitions as well as high J transitions, making the Q branches more prominent. The different shapes of these subbands can easily be understood with the aid of Fig. 1. If two sets of levels are involved in a J-dependent perturbation, the upper(lower) set is pushed further up(down), the magnitude of the shift increasing with J. The net effect is an apparent increase in the B value of the upper set and an apparent decrease for the lower set. If the unperturbed B value of the upper state involved in a spectroscopic transition is slightly smaller than that of the lower state, the Q branches will be slightly "red"-degraded. A change in the apparent B value due to an interaction can increase this degradation or reverse it, depending on the relative position and closeness of the perturbing levels. The B value of the ν_8 state of $CD_3C{\equiv}CH$ is slightly smaller than that of the ground state, and thus the Q branches are expected to be red-degraded. The $^RQ_0$ branch, the upper state of which is unperturbed by the x–y Coriolis interaction, appears with the expected red degradation, in spite of the fact that the l-type resonance modifies it to some extent. We see from Fig. 1 that the $+l$ components of $K = 1$ and $K = 2$ are below the corresponding interacting levels of ν_5 while for $K > 3$ they lie above. The $^RQ_1$ branch thus appears strongly red-degraded, and the degradation is reversed from $^RQ_2$ onwards. With increasing K, the energy difference between the interacting levels also increases and the "violet" degradation decreases until at $K'' = 9$ the Q-branch appears as a line-like feature. The degradation changes direction for $K'' > 9$. All the K levels of the $-l$ component of ν_8 lie below the perturbing levels of ν_5, with the energy difference, ΔE, increasing with K. Thus the ^PQ branches are strongly red-degraded at low K, but become narrower with increasing K.

One notices from Fig. 2 that $^PQ_{10}$ appears shifted towards lower frequencies. All the J components show more or less the same shift, which seems to indicate a Fermi resonance. If the two levels involved in a Fermi resonance are both nondegenerate, all the K levels also are usually uniformly shifted since the ΔE's are nearly the same. When the interacting levels are degenerate, because of the different values of the z-axis Coriolis coupling constant, the different K stacks can get in and out of resonance.[2] In the case of the ν_8 state of $CD_3C{\equiv}CH$, the only suitable candidate as a Fermi res-

[2]The same situation prevails even in the case of two nondegenerate states where at least one of them is a combination of two degenerate states, for the second-order z-axis Coriolis interaction between the A_1 A_2 pairs can produce the same effect (10).

onance partner is the $\nu_9 + \nu_{10}$ (E) state, with a harmonic value of 942 cm^{-1} for G_v (7). With a $(A\zeta^z)_{\text{eff}}$ value of 4.855 cm^{-1} (i.e., $A(\zeta_9 + \zeta_{10})$) (7), the $k = \pm 9$, $l = \pm 2$ component of this state is shifted down by ~87 cm^{-1}, while the $k \cdot l = -9$ component of ν_8, for which $(A\zeta^z)_{\text{eff}}$ is ~1.159 cm^{-1} (7), is shifted up by ~21 cm^{-1} by the z-axis Coriolis coupling, bringing them into close resonance. The other K levels in the $-l$ manifold of ν_8 are also slightly affected by Fermi resonance, but the effect is negligible for the $+l$ components because of the large ΔE.

Energy level calculations

The energy levels are calculated by the diagonalization of a combined energy matrix of ν_5, ν_8, and $(\nu_9 + \nu_{10})$, with appropriate off-diagonal interaction matrix elements. The energy matrix can be factored into three smaller submatrices corresponding to the A_1, A_2, and E rovibrational species. The diagonal matrix elements are the unperturbed energy levels given by the standard polynomial expression,

$$[1]\quad E_{v,r} = G_v + B_v J(J+1) + (A_v - B_v)K^2 - D_v^J J^2(J+1)^2 - D_v^{JK} J(J+1)K^2 - D_v^K K^4 - [(2A\zeta^z)_v k \cdot l - \eta_v^J J(J+1)k \cdot l - \eta_v^K k^3 \cdot l]$$

where $K = |k|$ and the splitting of the $\pm l$ components through z-axis Coriolis coupling, given by the terms in square brackets, is relevant only for degenerate states. The choice of the relative vibrational phases is such that all off-diagonal matrix elements are real. The off-diagonal matrix elements we have used are given below and conform with those given by Di Lonardo, Fusina, and Johns (11) and Olson, Maki, and Sams (12). The numerical factors preceding these matrix elements and the relative signs are given differently by various authors, and this aspect should be taken into consideration while comparing the various results.

x–y *Coriolis interaction*

$$[2]\quad \langle \nu_5^0; k|\mathrm{H}|\nu_8^{\pm 1}; k \pm 1\rangle = \pm\sqrt{2}\, B\Omega_{58}\zeta_{58}[J(J+1) - k(k \pm 1)]^{1/2} = \pm\sqrt{2}\,\xi[J(J+1) - k(k \pm 1)]^{1/2}$$

where

$$[3]\quad \xi = B\Omega_{58}\zeta_{58} = \xi_0 + \xi_j J(J+1) + \xi_k[k^2 + (k \pm 1)^2]$$

and

$$[4]\quad \Omega_{58} = 1/2[(\nu_5/\nu_8)^{1/2} + (\nu_8/\nu_5)^{1/2}]$$

TABLE 1. Molecular parameters of the ground, ν_5, ν_8, and $\nu_9 + \nu_{10}$ states of CD_3CCH[a]

[d]$(A\zeta^z)_{eff}$ value included $|l|$.

k-*Type doubling*

$$[5] \quad \langle v_5^0; k|H|v_8^{\mp 1}; k \pm 2\rangle = \sqrt{2}\,\kappa f(k, k \pm 2)$$

where

$$[6] \quad f(k, k \pm 2) = [\{J(J+1) - k(k \pm 1) \cdot \{J(J+1) - (k \pm 1)(k \pm 2)\}]^{1/2}$$

Equations [2] and [5] should be multiplied by $\sqrt{2}$ where $K = 0$ for the nondegenerate state.

"±2, ±2" l-Type resonance

$$[7] \quad \langle v_8^{\mp 1}; k|H|v_8^{\pm 1}; k \pm 2\rangle = 2\,q_8\,f(k, k \pm 2)$$

Fermi resonance

$$[8] \quad \langle v_8^{\mp 1}; K|H|(v_9 + v_{10})^{\pm 2}; K\rangle = W$$

In equations [2]–[8] the upper and lower signs are correlated throughout.

Intensity calculations

In the calculation of intensities of transitions involving unperturbed states, the relative signs of the direction cosine matrix elements are of little consequence as the intensities are proportional to the square of these matrix elements. In the present case, the upper state is a mixture of ν_5, the $\pm l$ components of ν_8, and to a smaller extent $(\nu_9 + \nu_{10})$. It is necessary to sum the products of appropriate vibrational transition moments, eigenvectors, and direction cosine matrix elements before squaring, and the relative signs of the direction cosine matrix elements become important. The intensity expression and the direction cosine matrix elements we used are consistent with those given by Di Lauro and Mills (6). The nuclear spin statistical weight factors that we used for the A_1, A_2, and E rovibrational levels were 11, 11, and 16, respectively. These also include the k-degeneracy factor and it is not necessary to use the factor 2 when $K > 0$. It is, however, necessary to include a factor of 2 for transitions involving $K = 0$ of a nondegenerate state and $K = 1$ of a degenerate state.

Analysis of the spectra

The initial assignments were made in the ^RR, ^RQ, ^PP, and ^PQ branches of the ν_8 band corresponding to high K values, where the perturbation is not severe, and counterchecked with $Q(J) - P(J+1)$ and $R(J) - Q(J+1)$ combination differences calculated from the known ground state parameters (10). A least-squares fit of these frequencies gave an initial set of paramters that was used to calculate the frequencies and intensities of the low K transitions and make further assignments. The only clearly recognizable feature of the ν_5 band was the Q head. Therefore, in the initial stages of the analysis, the ν_5 state had to be included in the calculations only as a "shadow" state. Recently we carried out the analysis of the ν_9 (13) and $2\nu_9$ (10) bands of $CD_3C{\equiv}CH$, where it was necessary to include one of more shadow states, i.e., states to which transitions are not directly observed, but which manifest their presence only through the perturbations. Even though we were able to derive some of the parameters of these shadow states from the magnitude of the perturbations, there was always a lingering doubt about their accuracy, as many other parameters were constrained. Therefore, it was gratifying to see that the perturbation treatment predicted the ν_0 and B' of the ν_5 band with fairly good accuracy even when ν_5 was used only as a shadow state. In the final stages it was possible to identify many transitions of the ν_5 band and assign over 2000 transitions.[3] The A_1 A_2 splitting in the $K \cdot \Delta K = -3$ transitions, caused by k-type doubling, was resolvable only for $J > 40$. Only a few such transitions could be identified because of the diminished intensity at high J values. In the final fit 1592 transitions, 243 of which are parallel type, have been included. In the parallel band, $K = 0$, 1 are intense in the P branch, while it is the $K = 2$, 3 that are intense in the R branch. The standard deviation of the fit was 0.00068 cm^{-1}. The parameters derived from our analysis are given in Table 1.

[3]A complete list of frequencies and assignments is available from the authors or may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

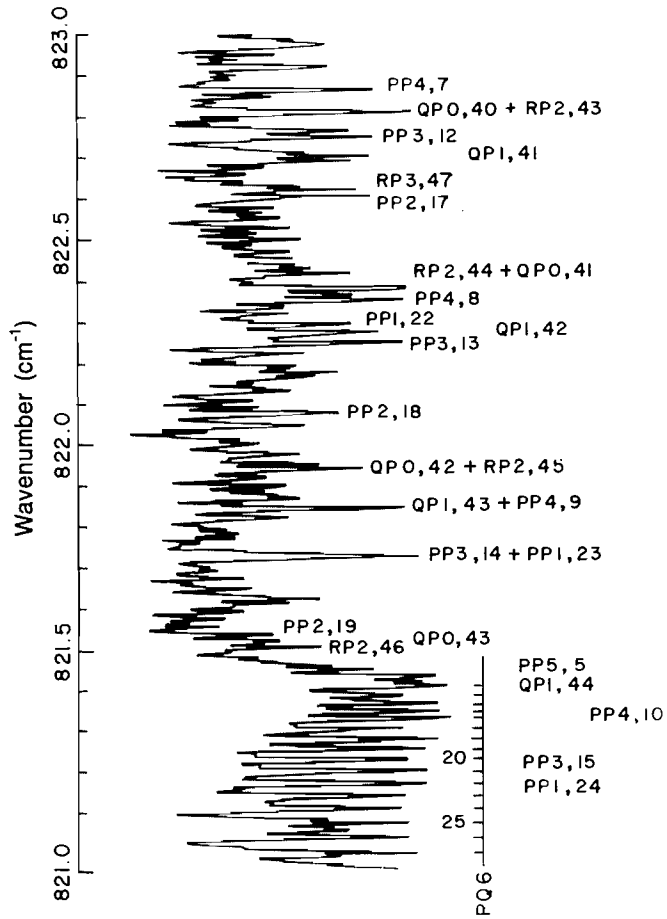

FIG. 3. A portion of the high-resolution spectrum of the ν_5 and ν_8 bands.

Figure 3 shows a section of the high-resolution spectra and the ν_5 and ν_8 transitions. The ν_5 transitions do not have the typical parallel band appearance in which the K components of a given J are clustered together. Not only do the K components appear in a haphazard manner, but their relative intensities also are unusual, and it would have been impossible to assign these transitions without the calculation of the perturbed frequencies and intensities. The most striking intensity changes are in the ${}^{Q}P_0$, ${}^{Q}P_1$, ${}^{Q}R_2$, ${}^{Q}R_3$, ${}^{P}R_1$, ${}^{P}R_2$, ${}^{P}R_3$, ${}^{R}P_2$, ${}^{R}P_3$, ${}^{R}P_4$, ${}^{R}R_0$, and ${}^{R}R_1$ branches, which are enhanced, and ${}^{Q}P_2$, ${}^{Q}P_3$, ${}^{Q}R_0$, ${}^{Q}R_1$, ${}^{P}P_1$, ${}^{P}P_2$, ${}^{R}P_0$, ${}^{R}P_1$, ${}^{R}R_2$, and ${}^{R}R_3$ branches, which are depleted in intensity. Even though we have not made any quantitative intensity measurements, from the relative intensities of the spectral lines we estimate the ratio of the transition moments, $(\mu_x \pm i\mu_y):\mu_z$, as 1.0:0.6, which corresponds to $M_5/M_8 = 0.85$. The value of 1.0 for this parameter, used by Speirs and Duncan (7) in their band contour analysis, appears to be on the high side, but their values of ζ_8 and ζ_{58} compare well with our values (0.4338 and 0.2325, respectively) derived from the parameters given in Table 1. The intensity perturbation is positive in the sense defined by Di Lauro and Mills (6), i.e., the relative sign of the transition moments is the same as the sign of the x–y Coriolis coupling parameter. It is interesting to note that, in a recent analysis of the corresponding bands of CD_3CN, Koivusaari and Anttila (14) have invoked similar perturbations, and the values of the interaction parameters are also comparable.

IV. Acknowledgments

We thank Dr. V.B. Kartha for his interest in this work and Dr. Romola D'Cunha for a critical reading of the manuscript. The assistance given by S.S. Bhattacharya in the preparation of the manuscript is gratefully acknowledged.

High-resolution laser spectroscopy of excited bending vibrations ($v_2 \leq 2$) of the $\tilde{B}^2\Sigma^+$ and $\tilde{X}^2\Sigma^+$ electronic states of SrOH: analysis of ℓ-type doubling and ℓ-type resonance

P.I. PRESUNKA AND J.A. COXON[1]

Department of Chemistry, Dalhousie University, Halifax, NS B3H 4J3, Canada

Received March 15, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

P.I. PRESUNKA and J.A. COXON. Can. J. Chem. **71**, 1689 (1993).

The $(02^00)\Sigma^+ \leftarrow (000)\Sigma^+$, $(02^20)\Delta \leftarrow (010)\Pi$, $(02^00)\Sigma^+ \leftarrow (010)\Pi$, and $(010)\Pi \leftarrow (000)\Sigma^+$ bands in the $\tilde{B}^2\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+$ electronic system of SrOH have been recorded at Doppler limited resolution using CW dye laser excitation with selective detection. Fluorescence from selected rotational levels of the $\tilde{B}^2\Sigma^+(02^00)\Sigma^+$ and $\tilde{B}^2\Sigma^+(02^20)\Delta$ vibronic states has been dispersed, providing access to the $(02^00)\Sigma^+$ and $(02^20)\Delta$ levels of the ground electronic state. Over 1200 line positions from all transitions were included in a global least-squares fit. The effects of a weak ℓ-type resonance between the $\ell = 0$ and $\ell = 2$ components of the $v_2 = 2$ vibrational level were observed in both electronic states and the off-diagonal matrix elements were evaluated in a case (b) basis. A previous analysis of the $\tilde{B}^2\Sigma^+(010)\Pi$ level that attributes the anomalous ℓ-type doubling to an electronic perturbation arising from the $\tilde{A}^2\Pi(010)$ polyad is inconsistent with our experimental results.

P.I. PRESUNKA et J.A. COXON. Can. J. Chem. **71**, 1689 (1993).

Travaillant à une résolution Doppler limitée et utilisant un colorant CW à excitation au laser avec détection sélective, on a enregistré les bandes $(02^00)\Sigma^+ \leftarrow (000)\Sigma^+$, $(02^20)\Delta \leftarrow (010)\Pi$, $(02^00)\Sigma^+ \leftarrow (010)\Pi$ et $(010)\Pi \leftarrow (000)\Sigma^+$ dans le système électronique $\tilde{B}^2\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+$ du SrOH. La dispersion de la fluorescence obtenue à partir de certains niveaux rotationnels des états vibroniques $\tilde{B}^2\Sigma^+(02^00)\Sigma^+$ et $\tilde{B}^2\Sigma^+(02^00)\Delta$ permet d'accéder aux niveaux $(02^00)\Sigma^+$ et $(02^20)\Delta$ de l'état électronique fondamental. On a inclus plus de 1200 positions de lignes provenant de toutes les transitions dans une procédure globale des moindres carrés. On a observé les effets d'une faible résonance de type ℓ entre les composantes $\ell = 0$ et $\ell = 2$ du niveau vibrationnel $v_2 = 2$ dans les deux états électroniques et on a évalué les éléments situés en dehors de la diagonale de la matrice en se basant sur le cas (b). Nos résultats expérimentaux ne concordent pas avec une analyse antérieure du niveau $\tilde{B}^2\Sigma^+(010)\Pi$ qui attribue le dédoublement anormal de type ℓ à une pertubation électronique provenant de la polyade $\tilde{A}^2\Pi(010)$.

[Traduit par la rédaction]

Introduction

Although high-resolution laser spectroscopy has been invaluable in elucidating the congested structure of electronic transitions involving the low-lying $\tilde{A}^2\Pi$ and $\tilde{B}^2\Sigma^+$ states of SrOH, previous investigations (1, 2) of the $\tilde{B}^2\Sigma^+$–$\tilde{X}^2\Sigma^+$ and $\tilde{A}^2\Pi$–$\tilde{X}^2\Sigma^+$ systems have provided detailed information only on vibrational levels with $v_i \leq 1$. In contrast, a substantial amount of data on excited vibrational levels exist for the related alkaline earth monohydroxide CaOH (3–6). However, access to excited vibrational levels of the group IIA hydroxides is experimentally difficult: not only do the Franck–Condon factors strongly favour $\Delta v_i = 0$ sequences, but the spectra contain strongly overlapped sequence structure due to small differences in the vibrational frequencies of the ground and excited electronic states. In the present work, vibrational selective detection leads to a substantial enhancement of laser induced fluorescence (LIF) arising from transitions involving excited bending vibrational levels in the $\tilde{B}$–$\tilde{X}$ system of SrOH. Since overlapping band systems are essentially completely suppressed, the complexity of the resulting spectra is greatly reduced, rendering assignment and analysis fairly straightforward.

Some of the bands observed in this work, specifically the $\tilde{B}^2\Sigma^+(02^20)\Delta \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$, $\tilde{B}^2\Sigma^+(010)\Pi \leftarrow \tilde{X}^2\Sigma^+(000)\Sigma^+$, and $\tilde{B}^2\Sigma^+(02^00)\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$ systems, are forbidden components of an allowed electronic transition. The notation used here to label the different vibrational levels follows that of Jarman and Bernath (7). Since the $\tilde{B}^2\Sigma^+$ and $\tilde{A}^2\Pi$ electronic states of SrOH are separated by only 1703.173 cm^{-1} (1, 2), the $\tilde{B}$ state can acquire $^2\Pi$ character through vibronic mixing. Jungen and Merer (8) have attributed this to a special case of the Herzberg–Teller interaction, whereby the mixing occurs via Renner–Teller coupling. Based on this mechanism, vibronically induced transitions are expected for most unsymmetrical linear triatomics. Other notable examples where nominally forbidden $\Delta v_2 = \pm 1$ bands in the bending mode of linear triatomics have been observed include NCS (9), HCN^+ (10), NCO (11, 12), and CaOH (7; see also footnote 2).

We report in this paper the first observation and rotational analysis of the $\ell = 0$ and $\ell = 2$ components of the (020) vibrational level in the $\tilde{B}^2\Sigma^+$ and $\tilde{X}^2\Sigma^+$ electronic states of SrOH. Although the $^2\Sigma^+$ and $^2\Delta$ vibronic states are well separated, by 32.703 and 30.259 cm^{-1} for the $\tilde{B}^2\Sigma^+$ and $\tilde{X}^2\Sigma^+$ electronic states, respectively, the effects of an ℓ-type resonance have been observed, and the off-diagonal matrix element connecting these states has been evaluated in a case (b) basis. An earlier investigation (1) of the $\tilde{B}^2\Sigma^+(010)\Pi \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$ transition determined the relative magnitude of the ℓ-type doublings; however, absolute e/f parity assignments were not possible. We have observed the $(010)\Pi$ levels of both states in perpendicular-type transitions, thereby enabling unambiguous parity assignment and accurately establishsing the vibrational term values. All data have been

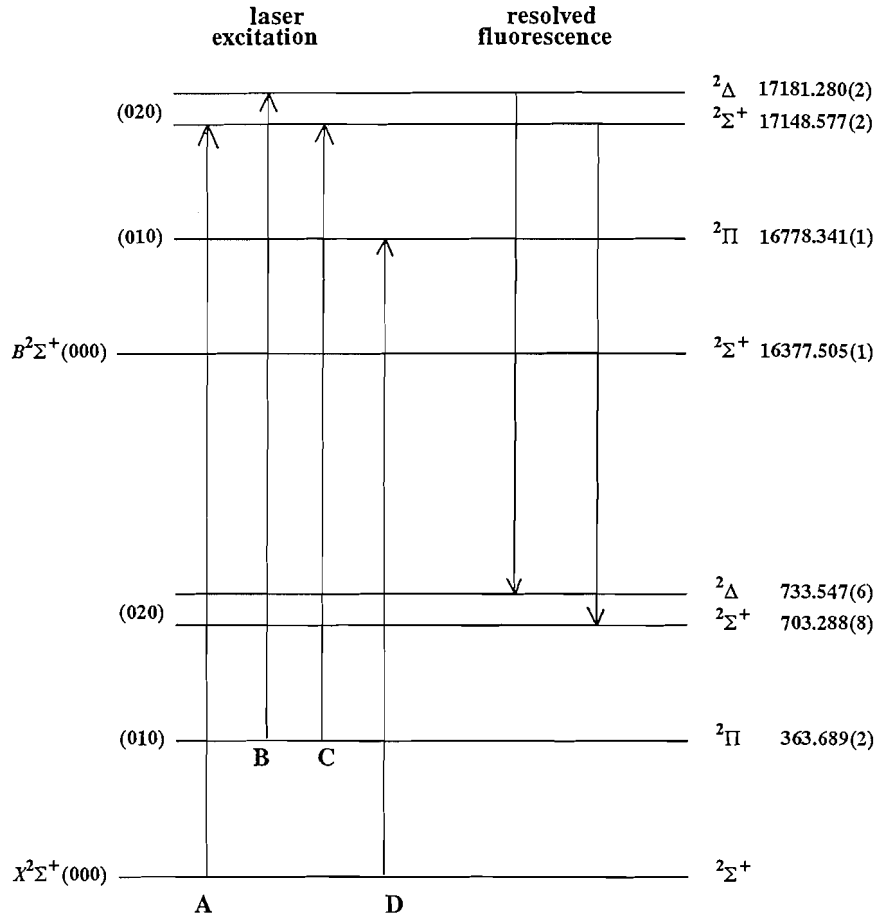

FIG. 1. Energy level diagram summarizing the six transitions analyzed in the present work. Frequency differences used in selective detection were 703, 368, 339, and 363 cm^{-1} for the A, B, C, and D transitions, respectively. The term value for $\tilde{B}^2\Sigma^+(000)\Sigma^+$ is taken from ref. (1).

combined in a simultaneous fit to obtain single-valued estimates of the molecular parameters for the $(010)\Pi$, $(02^00)\Sigma^+$, and $(02^20)\Delta$ vibronic levels of the $\tilde{B}^2\Sigma^+$ and $\tilde{X}^2\Sigma^+$ electronic states.

Experimental

Gas phase SrOH radicals were produced in a modified Broida oven by the reaction of Sr metal vapour with H_2O_2. Under our experimental conditions, the reaction was accompanied by an intense visible chemiluminescence. The flame was probed with the output of a Coherent 699-29 ring dye laser operating in single mode with rhodamine 6G dye. Excitation frequency measurements were provided directly by the internal wavemeter of the 699-29, the integrity of which was verified by recording I_2 fluorescence spectra during all scans. Comparison to the more precise measurements of the standard I_2 atlas (13, 14) resulted in small corrections ($\leq$0.005 cm^{-1}) to the wavemeter measurements where necessary.

Two distinct experimental schemes were used for this work: vibrational selective laser excitation and resolved fluorescence. In both cases the image of the laser-induced fluorescence was focused on the entrance slit of a 1.26-m Spex monochromator fitted with a 2400 groove mm^{-1} grating (Bausch and Lomb) blazed at 500 nm. The signal was detected with a selected GaAs photomultiplier tube (RCA C31034A-02) cooled to -20°C in an RF shielded housing. For the excitation scans, the laser beam was chopped at 269 Hz and phase-sensitive detection was employed. The vibrational selective detection scheme is described in more detail elsewhere (4). Briefly, the monochromator and laser were scanned simultaneously such that a constant frequency difference (corresponding to a ground state vibrational spacing) between the two was maintained. For example, during the $\tilde{B}^2\Sigma^+(02^00)^2\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+(000)^2\Sigma^+$ excitation scans, the monochromator frequency was tuned ~703 cm^{-1} to the red of the laser frequency such that fluorescence to $\tilde{X}^2\Sigma^+(02^00)\Sigma^+$ is seletively detected. We have found this technique particularly effective in suppressing LIF due to coincident excitations. Laser excitation was used to record spectra for the following transitions; $\tilde{B}^2\Sigma^+(02^00)\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+(000)\Sigma^+$, $\tilde{B}^2\Sigma^+(02^20)\Delta \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$, $\tilde{B}^2\Sigma^+(02^00)^2\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$, and $\tilde{B}^2\Sigma^+(010)\Pi \leftarrow \tilde{X}^2\Sigma^+(000)\Sigma^+$. These transitions and the frequency differences used are summarized in Fig. 1.

The experimental arrangement for resolved fluorescence is identical to that used in our previous investigations of excited vibrational levels of CaOH (3). The phase-sensitive detection equipment used in the excitation experiments was replaced by more sensitive photon counting electronics (PAR 1120 amplifier/discriminator and PAR 1105 photon counter). Depending on the strength of the LIF signal, the slit width was varied from 40 to 50 μm. The monochromator and detection system were interfaced to a MINC PDP-11 (Digital Equipment Corporation) allowing direct computer control of experiments as well as electronic data acquisition. Each resolved fluorescence scan of selected excitation features varied in range from 10 to 30 Å and was calibrated by 10 to 12 atomic uranium lines recorded simultaneously with the SrOH spectra. Using the U line positions of ref. 15, the drum wavelength was calibrated by least-squares fits to a five-parameter function (16). The accuracy of the resolved fluorescence measurements was periodically verified by determining the frequency of the output of the 699-29 using our monochromator set-up and comparing it to the value given by the wavemeter. No systematic error

was evident and the accuracy was determined on average to be better than 0.03 cm^{-1}.

In the present work, the technique of resolved fluorescence was applied to the parallel $\tilde{B}^2\Sigma^+(02^00)\Sigma^+ \rightarrow \tilde{X}^2\Sigma^+(02^00)\Sigma^+$ and $\tilde{B}^2\Sigma^+(02^20)\Delta \rightarrow \tilde{X}^2\Sigma^+(02^20)\Delta$ transitions to provide access to $v_2 = 2$ components of the $\tilde{X}$ state (see Fig. 1). In the former case, selected rovibronic levels of the $\tilde{B}^2\Sigma^+(02^00)\Sigma^+$ level are populated via optical pumping of both the $\tilde{B}^2\Sigma^+(02^00)\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+(000)\Sigma^+$ and $\tilde{B}^2\Sigma^+(02^00)\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$ transitions. Similarly, the $\tilde{X}^2\Sigma^+(02^20)\Delta$ level is observed following excitation of the $\tilde{B}^2\Sigma^+(02^20)\Delta \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$ system.

Rotational analysis and discussion

Rotational assignments of the laser excitation spectra were generally straightforward. Since excitation was from either the $(000)\Sigma^+$ or $(010)\Pi$ level of the ground state, for which molecular constants have been previously determined (1), the rotational quantum number of the P and R branches could be assigned by use of combination differences. Owing to a small effective spin-rotation splitting of the ground state, however, the rotational numbering could be changed by one unit depending on whether the line belonged to the F_1 or F_2 spin manifold. This ambiguity was resolved in the least-squares fits since only one of the two possibilities yielded an effective spin-rotation constant for the $\tilde{B}$ state levels of the same sign as that established by Nakagawa et al. (1). This method was not reliable for the intense Q branches, which are associated with the perpendicular transitions observed in excitation. The presence of a combination defect on account of the ℓ-type doubling, as well as the compact rotational structure of the Q branches, made such assignments questionable. Rotational assignments for the Q branches were therefore made on the basis of P–R separations in the resolved fluorescence scans. Moreover the rotational structure was often extremely congested and, despite the use of selective detection, overlapping band systems could not always be completely suppressed. In particular, the overlapping was somewhat problematic for the $\tilde{B}^2\Sigma^+(02^20)\Delta \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$ and $\tilde{B}^2\Sigma^+(02^00)\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$ transitions. The vibronic energies of these transitions are 16 817.591 and 16 784.888 cm^{-1}, respectively. Furthermore, since the frequency differences used in the detection schemes are similar (368 and 363 cm^{-1}, respectively), the P branches of the $\tilde{B}^2\Sigma^+(02^20)\Delta \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$ transition are overlapped by the stronger $\tilde{B}^2\Sigma^+(010)\Pi$–$\tilde{X}^2\Sigma^+(000)\Sigma^+$ R lines. To eliminate the possibility of erroneous assignments of rotational quantum number, resolved fluorescence spectra of adjacent rotational lines in each of the P and R (and Q) branches of all transitions were recorded. Tables 1–4 give the line positions for the four transitions investigated by laser excitation. Line positions are measured to an estimated accuracy of approximately 0.004 cm^{-1}.

The rotational assignments of the resolved fluorescence scans followed directly from the excitation spectra. For these transitions $\Delta K = 0$; consequently only two single (P and R) lines were observed in fluorescence provided only one rotational level of the upper state was populated. Tables 5 and 6 contain the line positions for the resolved fluorescence measurements.

Expressions for the rotational term energies of linear triatomic molecules in $^2\Sigma^+$ electronic states are given by (11, 12, 17);

(a) $v_2 = 0$ or 2, $\ell = 0$; $^2\Sigma^+$ vibronic state:

$$[1]\quad F_1(N,e) = B_vN(N+1) - D_vN^2(N+1)^2 + H_vN^3(N+1)^3 + 1/2\,\gamma_vN + 1/2\gamma_v^DN^2(N+1)$$

$$[2]\quad F_2(N,f) = B_vN(N+1) - D_vN^2(N+1)^2 + H_vN^3(N+1)^3 - 1/2\,\gamma_v(N+1) - 1/2\,\gamma_v^DN(N+1)^2$$

(b) $v_2 = 1$, $\ell = 1$; $^2\Pi$ vibronic state:

$$[3]\quad F_1(N,^e_f) = B_v[N(N+1)-1] - D_v[N(N+1)-1]^2 + H_v[N(N+1)-1]^3 + 1/2\,\gamma_vN + 1/2\gamma_v^DN^2(N+1) \pm 1/2\,q_vN(N+1) \pm 1/2\,q_v^D[N(N+1)]^2$$

$$[4]\quad F_2(N,^e_f) = B_v[N(N+1)-1] - D_v[N(N+1)-1]^2 + H_v[N(N+1)-1]^3 - 1/2\,\gamma_v(N+1) - 1/2\,\gamma_v^DN(N+1)^2 \mp 1/2\,q_vN(N+1) \mp 1/2\,q_v^D[N(N+1)]^2$$

(c) $v_2 = 2$, $\ell = 2$; $^2\Delta$ vibronic state:

$$[5]\quad F_1(N,^e_f) = B_v[N(N+1)-4] - D_v[N(N+1)-4]^2 + H_v[N(N+1)-4]^3 + 1/2\,\gamma_vN + 1/2\,\gamma_v^DN^2(N+1) + \Phi(N,^e_f)$$

$$[6]\quad F_2(N,^e_f) = B_v[N(N+1)-4] - D_v[N(N+1)-4]^2 + H_v[N(N+1)-4]^3 - 1/2\,\gamma_v(N+1) - 1/2\,\gamma_v^DN(N+1)^2 + \Phi(N,^e_f)$$

The designation of e/f parity throughout this work follows the definition given by Kopp and Hougen (18). The sign of the ℓ-type doubling parameter q_v is consistent with that used by Mulliken and Christy (19) for the Λ-doubling parameter q. The constants γ^D and q_v^D take account of centrifugal distortion on the effective spin-rotation and ℓ-type doubling parameters, respectively. The γ_v^D term was included only for the $\tilde{B}$ state vibrational levels, which exhibit an anomalously large γ_v due to the effects of an electronic perturbation caused by the nearby $\tilde{A}^2\Pi$ state. The $\Phi(N,^e_f)$ terms in eqs. [5] and [6] lead to ℓ-type splitting between the e and f parity levels of the $^2\Delta$ vibronic levels, given approximately as $q_{eff}N(N+1)[N(N+1)-2]$. Recent microwave measurements on the $\tilde{X}^2\Sigma^+$ ground sate of SrOH by Anderson et al. (20) have provided very accurate determinations of the molecular constants for the (000) level. Accordingly the parameters B_v'', D_v'', and γ_v'' were held fixed to the microwave values.

Initially, data from each of the vibronic transitions observed in this work were treated separately by least-squares fitting. As pointed out by Albritton et al. (21), molecular constants determined in this way are highly correlated and may differ significantly from their true values. In the present study several of the observed vibrational levels are common to more than one transition. Consequently, the final least-squares fit of the entire data simultaneously served to lessen the correlation of errors for the $\tilde{B}$ and $\tilde{X}$ state molecular constants. Resolved fluorescence data were given a lower weight than the more accurate excitation measurements, in accord with their respective uncertainties. In this fit the en-

ergy level expressions of eqs. [5] and [6] were not employed directly; rather, the ℓ-type doubling was modelled by inclusion of the off-diagonal $(02^00)\Sigma^+ \sim (02^20)\Delta$ matrix element in the matrix describing the Σ and Δ vibronic states for $v_2 = 2$. The combined data set contained over 1700 individual lines; however, owing to local perturbations in the $\tilde{B}$ state vibrational levels, only some 1200 lines were included in the final fit. These perturbations are clearly evident in Figs. 2–5, where reduced rotational term values of the $(02^00)\Sigma^+$, $(010)\Pi$, and $(02^20)\Delta$ vibronic levels of the $\tilde{B}$ state are plotted as functions of the rotational quantum number. The fitted parameters are listed in Table 7; we now consider each of the bands individually.

$\tilde{B}^2\Sigma^+(02^00)\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+(000)\Sigma^+$

As with $^2\Sigma^+$–$^2\Sigma^+$ transitions of diatomic molecules, strong P_1, P_2, R_1, and R_2 branches are observed for this transition. A strong perturbation occurs in the F_2 spin component as a result of a level crossing between $N = 9$ and 10 (see Fig. 2). In the region of the crossing, energy levels are shifted up to 1 cm^{-1}, and the effects of the perturbation in terms of high residuals are observed over an unusually long range in N ($N \leq 49$). Low N values of the F_1 spin component ($N \leq 22$) are also perturbed, but to a much lesser extent.

$\tilde{B}^2\Sigma^+(02^20)\Delta \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$

Since the $^2\Delta$ and $^2\Pi$ vibronic states follow Hund's case (b) coupling, strong Q_1 and Q_2 branches appear in addition to the P_1, P_2, R_1, and R_2 branches. Satellite branches, for which $\Delta N \neq \Delta J$, are not observed with any appreciable intensity. Each of the six main branches are doubled owing to ℓ-type doubling in both states. However, splitting of the e/f parity levels is much larger in the ground state $^2\Pi$ level so that doubled branches are observed even for low N values ($N \geq 9$). The F_1 levels are well behaved, but the e and f parity components of the $\tilde{B}^2\Sigma^+$ $(02^20)\Delta$ F_2-spin manifold both show indications of interactions with several different states (see Figs. 4 and 5). As a consequence, many line positions associated with the F_2 levels are omitted from the fit. The magnitude of the ℓ-type doubling constant q was well determined for both states, but the absolute sign and hence the actual parity assignments could not be established unequivocally from this transition alone; two equally satisfactory fits could be achieved by switching the parity assignments and adjusting the rotational quantum number accordingly. The effective ℓ-type doubling constant for the $^2\Delta$ state was determined to be $|q_{\text{eff}}| = 4.37(7) \times 10^{-9}$ cm^{-1} and is of opposite sign to that of the $^2\Pi$ state, $|q| = 3.9503(46) \times 10^{-4}$ cm^{-1}.

$\tilde{B}^2\Sigma^+(02^00)\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$

Although data for both levels of this band were available from other transitions observed in this work, an analysis of the $\tilde{B}^2\Sigma^+(02^00)\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$ band was undertaken to confirm on a purely experimental basis the e/f parity assignments of the $\tilde{X}^2\Sigma^+(010)\Pi$ level, thereby eliminating any ambiguity in the assignments of the $\tilde{B}^2\Sigma^+(02^20)\Delta$–$\tilde{X}^2\Sigma^+(010)\Pi$ band. The Q_1 and Q_2 branches accompanying a $^2\Sigma^+$–$^2\Pi$(b) transition are governed by the selection rule $e \leftrightarrow f$. The P and R branches follow different selection rules,

TABLE 2. Line positions[a] (cm^{-1}) for the $B^2\Sigma^+$–$X^2\Sigma^+$ (02^20)Δ–(010)Π band of SrOH. The table shows $\bar{\nu}_{obs}$, the measured wavenumbers (cm^{-1}), and the residuals, $\bar{\nu}_{obs} - \bar{\nu}_{calc}$

[a]Unless indicated otherwise, line positions have an assigned uncertainty of 0.004 cm^{-1}.
[b]Blended line with assigned uncertainty of 0.02 cm^{-1}.
[c]Perturbed line, excluded from the fit.

$e \leftrightarrow e, f \leftrightarrow f$. Accordingly the P_1 and R_1 branches involve excitation from only $\tilde{X}^2\Sigma^+(010)\Pi$ F_1,e levels, whilst the P_2 and R_2 branches arise from the corresponding F_2,f levels. In contrast, the Q_1 and Q_2 branches fix the energy positions of the F_1,f and F_2,e parity levels, respectively. Thus unperturbed data from the three main branches of either the F_1 or F_2 spin manifofld are sufficient to specify the magnitude and sign of q_v for the $\tilde{X}(010)\Pi$ level. In the present case, data are available from both spin components, and the sign of the ℓ-type doubling constant is established unequivocally. Our determination of $q_v = -3.9503(46) \times 10^{-4}$ cm^{-1} agrees remarkably well with the estimate by Nakagawa et al. (1) of the magnitude of q, $4.05(13) \times 10^{-4}$ cm^{-1}. The negative sign of q_v is consistent with the expression [13] of Nielsen and, moreover, a negative value for q_v of similar magnitude has also been observed for the $\tilde{X}^2\Sigma^+(010)\Pi$ vibrational level of CaOH (13). The $\tilde{X}^2\Sigma^+(010)\Pi$ vibrational level of SrOH is more accurately located at 363.689(2) cm^{-1}, as compared with the previous estimate of 360 ± 3 cm^{-1} (1). This establishes the splitting in the $\tilde{B}$ state between the $v_2 = 2$, $\ell = 0$ and $\ell = 2$ components as 32.703 cm^{-1}, yielding $g_{22} = 8.1758(7)$ cm^{-1}.

[a]Unless indicated otherwise, line positions have an assigned uncertainty of 0.004 cm^{-1}.
[b]Blended line with assigned uncertainity of 0.02 cm^{-1}.
[c]Perturbed line, excluded from the fit.

TABLE 4. Line positions[a] (cm^{-1}) for the $B^2\Sigma^+$–$X^2\Sigma^+$ (010)Π–(000)Σ^+ band of SrOH. The table shows $\bar{\nu}_{obs}$, the measured wavenumbers (cm^{-1}) and the residuals, $\bar{\nu}_{obs} - \bar{\nu}_{calc}$

[a]Unless indicated otherwise, line positions have an assigned uncertainty of 0.004 cm^{-1}.
[b]Blended line with assigned uncertainty of 0.02 cm^{-1}.
[c]Perturbed line, excluded from the fit.

TABLE 5. Line positions[a] (cm^{-1}) for the $B^2\Sigma^+$–$X^2\Sigma^+$ $(02^00)\Sigma^+$–$(02^00)\Sigma^+$ band of SrOH. The table shows $\bar{\nu}_{obs}$, the measured wavenumbers (cm^{-1}) and the residuals, $\bar{\nu}_{obs} - \bar{\nu}_{calc}$

$\tilde{B}^2\Sigma^+(010)\Pi \leftarrow \tilde{X}^2\Sigma^+(000)\Sigma^+$

In their analysis of the $\tilde{B}^2\Sigma^+(010)\Pi \leftarrow \tilde{X}^2\Sigma^+(010)\Pi$ transition, Nakagawa et al. (1) reported an anomalous ℓ-type doubling in the $\tilde{B}$ state whereby the F_1 spin manifold exhibited a much larger splitting than the corresponding F_2 levels. This effect was attributed to an electronic perturbation caused by the $\tilde{A}^2\Pi(010)$ $\mu^2\Sigma$ and $\kappa^2\Sigma$ vibronic states. Brazier and Bernath (2) have determined T_e = 14 674.332(2) cm^{-1} for $\tilde{A}^2\Pi(000)$, while for the $\tilde{B}^2\Sigma^+$ electronic state the (000) level lies at an energy of 16 377.505(1) cm^{-1} (1). Neglecting the spin-orbit and Renner–Teller effects in the $\tilde{A}^2\Pi$ state, the $\tilde{A}^2\Pi(010)$ polyad is located approximately 1700 cm^{-1} below the $\tilde{B}^2\Sigma^+(010)\Pi$ level, suggesting this perturbation to be a relatively long-range interaction. In the present work,

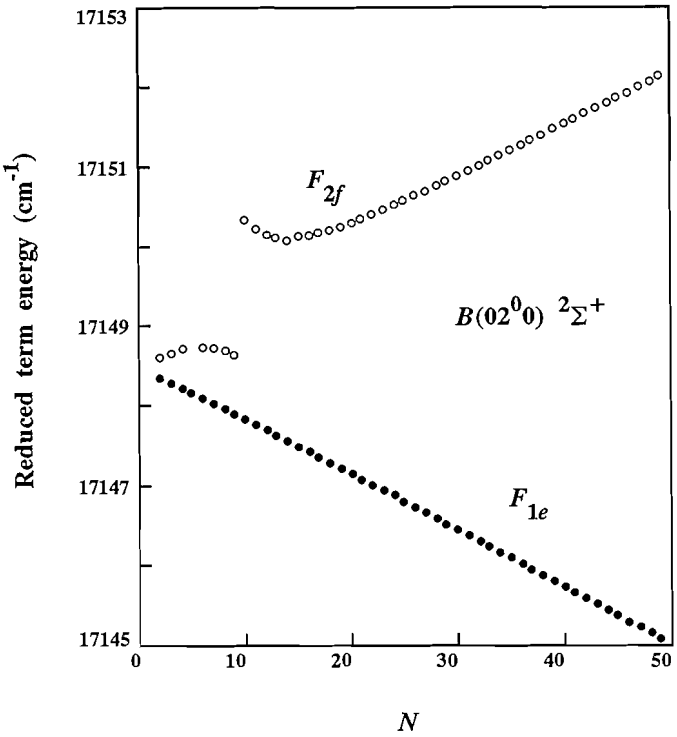

FIG. 2. Reduced term energy plot for the $\tilde{B}^2\Sigma^+(02^00)\Sigma^+$ state of SrOH showing a level crossing at $N \sim 10$ in the F_2 component. The vertical scale is expanded by substraction of $B_vN(N + 1) - D_vN^2(N + 1)^2$ from the term energies.

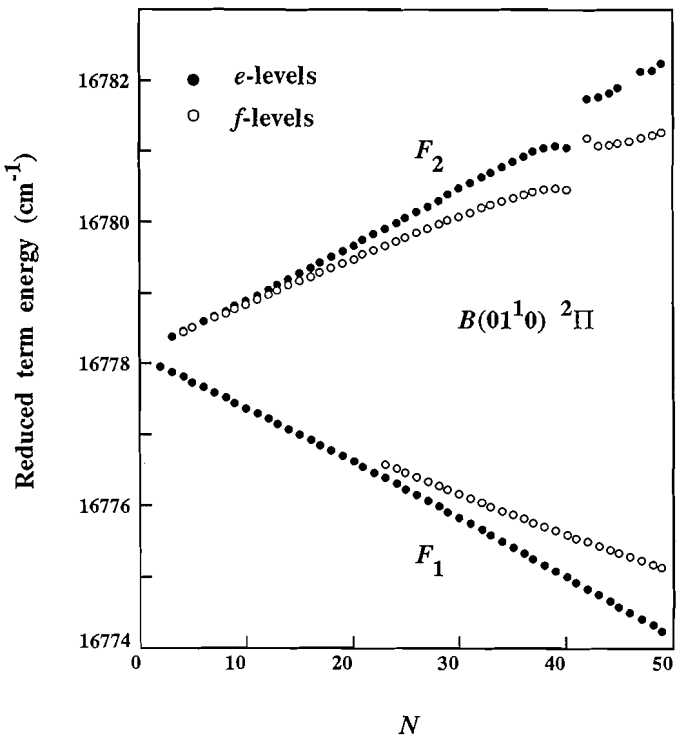

FIG. 3. Reduced term energy plot for the $\tilde{B}^2\Sigma^+(010)\Pi$ state of SrOH. The F_1 levels show no detectable perturbation, whereas the F_2 component shows evidence of a level crossing at $N \sim 41$. The vertical scale is expanded by subtraction of $B_vN(N + 1) - D_vN^2(N + 1)^2$ from the term energies.

we observe the $\tilde{B}^2\Sigma^+(010)\Pi$ level directly in excitation from $\tilde{X}^2\Sigma^+(000)\Sigma^+$ in a perpendicular-type transition. The plot in Fig. 3 of reduced rotational term energies for $\tilde{B}^2\Sigma^+(010)\Pi$ as a function of N indicates a level crossing in the F_2 manifold at $N \sim 41$. If the standard expressions for a $^2\Pi$ vibronic state are applied, all F_1 and F_2 levels up to $N = 16$ are well represented, giving $q_v = -3.622(8) \times 10^{-4}$ cm^{-1}, which is consistent with the sign and magnitude of the ground state value. Since the energy level shifts in the crossing region are of comparable magnitude to those in the perturbation of the $\tilde{B}^2\Sigma^+(02^00)\Sigma^+$ level, we expect the effects of this perturba-

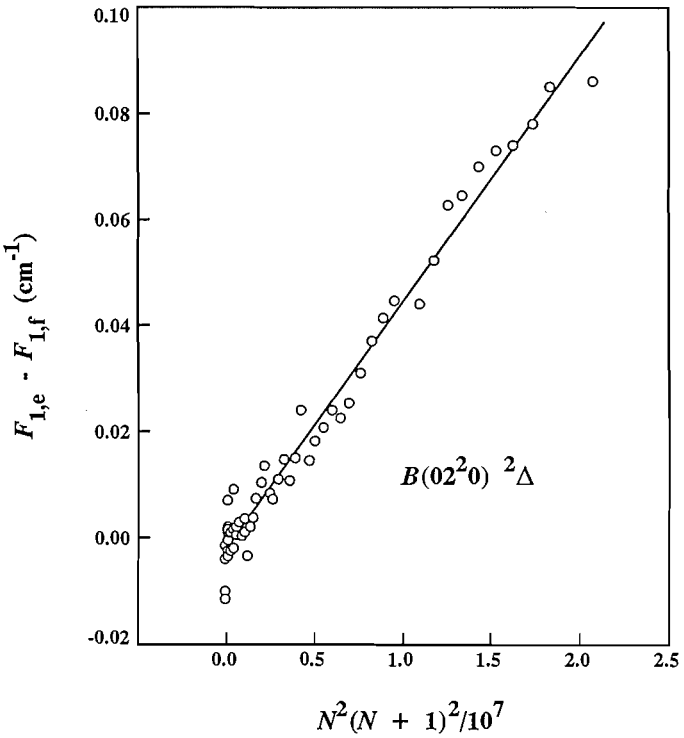

FIG. 4. Plot of e/f splitting in the F_1 levels of SrOH $\tilde{B}^2\Sigma^+(02^20)\Delta$.

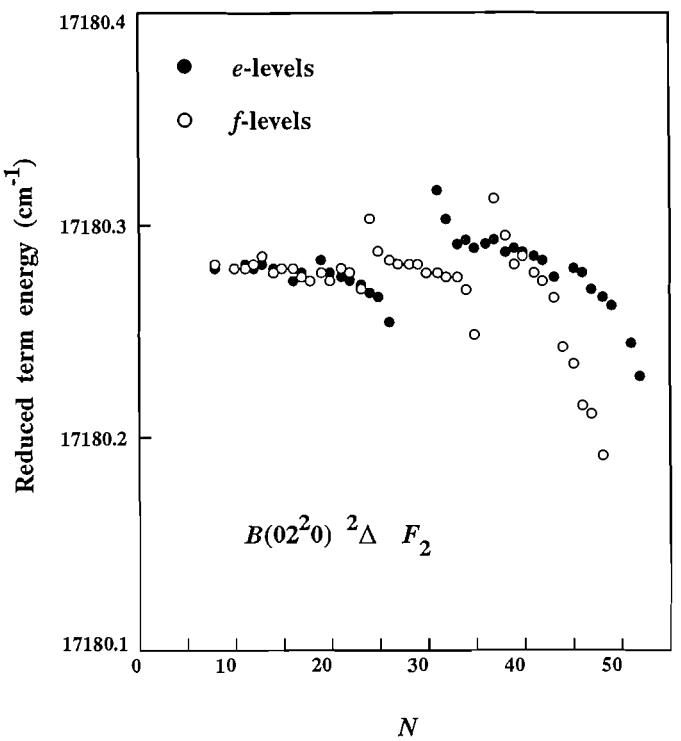

FIG. 5. Reduced term energy plot for the F_2 levels of SrOH $\tilde{B}^2\Sigma^+(02^20)\Delta$. The F_{2f} levels show clear indications of two level crossings at $N = 24$ and $N = 36$. In the F_{2e} levels, only one crossing at $N \sim 28$ is obvious. The negative deviation for $N > 40$ may be caused by extrapolation of the spin-rotation splitting rather than the effects of a perturbation. The vertical scale is expanded by subtraction of $B_vN(N+1) - D_vN^2(N+1)^2 - 1/2\ \gamma_v(N+1)$ from the term energies.

TABLE 8. Molecular constants (cm^{-1}) for the $B^2\Sigma^+$ and $X^2\Sigma^+$ states of SrOH

	$B^2\Sigma^+$	$X^2\Sigma^+$
α_2	1.05(7) × 10^{-3a}	7.3(4) × 10^{-4b}
γ_2	6.4(22) × 10^{-5a}	5.3(15) × 10^{-5b}
$\gamma_{\ell\ell}$	−6.76(5) × 10^{-5a}	−4.8(14) × 10^{-5b}
ω_2^0	399.785(2)^c	360.605(6)

[a]Calculated using B_{000} = 0.25224(2) cm^{-1} from Nakagawa et al. (1).
[b]Calculated using B_{000} from Anderson et al. (20)
[c]Calculated using T_e for $B^2\Sigma^+$ from Nakagawa et al. (1).

tion to extend over a considerable range of N, consistent with a perturbing level characterized by a similar B value. In the previous analysis (1) this perturbation was considered to be less extensive; only F_2 levels for $32 \leq N \leq 52$ were omitted from the fit. We believe the unequal e/f parity splittings in the F_1 and F_2 levels observed in the $\tilde{B}^2\Sigma^+(010)\Pi$–$\tilde{X}^2\Sigma^+(010)\Pi$ system are due to the level crossing occurring at $N = 41$ rather than a long-range interaction with the $\mu^2\Sigma$ and $\kappa^2\Sigma$ vibronic states of the $\tilde{A}^2\Pi(010)$ manifold. This is apparent for two reasons: first, ℓ-type doubling in the F_2 spin manifold of the $\tilde{B}^2\Sigma^+(01^10)^2\Pi$ state was observed by Nakagawa et al. (1) only as a splitting of the P_2 and R_2 branches at high N. Consequently, the ℓ-type splittings observed for the F_2 manifold are strongly influenced by the perturbing level. Second, a perturbation caused by interaction with the $\tilde{A}^2\Pi(010)\Sigma$ states would also affect the F_1 levels. We have found that the rotational term values of the F_1 spin manifold are well represented by the standard expression of eq. [3].

$\tilde{B}^2\Sigma^+(02^00)\Sigma^+ \rightarrow \tilde{X}^2\Sigma^+(02^00)\Sigma^+$ *and* $\tilde{B}^2\Sigma^+(02^20)\Delta \rightarrow \tilde{X}^2\Sigma^+(02^20)\Delta$

Having established the vibrational term energies of the upper vibrational levels, the origins of the resolved fluorescence transitions fix the position of the ground state $(02^20)\Delta$ and $(02^00)\Sigma^+$ levels. These levels are separated by 30.259 cm^{-1} (g_{22} = 7.5646(25) cm^{-1}). Despite the lower accuracy of the resolved fluorescence measurements, the effective ℓ-type doubling constant q_{eff} was determined to be 9.7(31) × 10^{-9} cm^{-1} for the $\tilde{X}^2\Sigma(02^20)\Delta$ state. Although poorly determined, this estimate is similar in magnitude to that of the $\tilde{B}$ state, as expected given the similar separations of the $^2\Sigma^+$ and $^2\Delta$ states.

Molecular constants

Vibrational–rotational interactions in linear triatomics, specifically the variation of the rotational constant B_v with increasing excitation of the degenerate bending mode, has been considered previously by Lide and Matsumura (22). Precise microwave measurements are reliably represented by:

$$[7] \quad B_v = \bar{B}_e - \alpha_2(v_2 + 1) + \gamma_{22}(v_2 + 1)^2 + \gamma_{ll}\ell^2$$

where $\bar{B}_e = B_e - 1/2\alpha_1 - 1/2\alpha_3$. Using the values of Nakagawa et al. (1) and Anderson et al. (20) for B_v of the (000) levels of the $\tilde{B}$ and $\tilde{X}$ states, respectively, α_2, γ_{22}, and γ_{ll} have been determined for both states, and are given in Table 8. The constant α_2, which represents the main influ-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

ence of vibration on B_v for low v_2, is positive for both the $\tilde{B}$ and $\tilde{X}$ states. The ground state value, $\alpha_2 = 7.3(4) \times 10^{-4}$ cm^{-1}, is very similar to that for CaOH (footnote 2) (6.4×10^{-4} cm^{-1}), CsOH (24) (6.34×10^{-4} cm^{-1}), and ^{85}RbOH (23) (1.11×10^{-3} cm^{-1}). In a detailed account of vibration–rotation interactions, Lide amd Matsumura (22) have attributed the positive sign of α_2 in the alkali monohydroxides to a dominant contribution from the $(\alpha_2)_{anh}$ term. This is seen primarily as a result of the small mass of the hydrogen atom combined with a small force constant for the metal–oxygen bond. We expect this argument to be equally valid for SrOH. Owing to the similar magnitude but opposite signs of γ_2 and γ_{ll}, the rotational constant B_v should decrease approximately linearly with increasing v_2.

The vibrational term energies for the bending mode, referred to the (000) level, are given by (25):

$$[8] \quad G_0(0,v_2,0) = \omega_i^0 v_2 + x_{22}^0 v_2^2 + g_{22}\ell^2$$

where ω_2^0 and x_{22}^0 have their usual meanings. Estimates of these parameters for both electronic states are given in Table 8. In the approximation that neglects third and higher order anharmonic constants, x_{22}^0 can be taken as equal to x_{22}. A comparison of the values of x_{22} for the two states indicates the bending potential is considerably more anharmonic for the $\tilde{B}$ state.

Rotational ℓ-type doubling and ℓ-type resonance

The phenomena of ℓ-type doubling and ℓ-type resonance arise from the combination of rotational asymmetry and Coriolis interactions of the degenerate bending mode with the stretching vibrations. In the contact-transformed Hamiltonian, the principal matrix element responsible for these interactions in a signed case (b) basis is (26,[3] 27) as follows:

$$[9] \quad \langle v_1,v_2^l,v_3; N,\ell| H | v_1,v_2^{l\pm2},v_3; N,\ell \pm 2\rangle = 1/4\, q_v[(v_2 \mp \ell)(v_2 \pm \ell + 2)[N(N+1) - \ell(\ell \pm 1)][N(N+1) - (\ell \pm 1)(\ell \pm 2)]]^{1/2}$$

The ℓ-type doubling parameter q_v experiences a small variation with rotational and vibrational quantum number and accordingly the following substitution is required (28):

$$[10] \quad q_{vJ} = q_e + \Sigma\, q_{vi}(v_i + d_i/2) + q_v^D N(N+1)$$

Direct microwave observations of ℓ-type splittings in the $v_2 = 2$ vibrational level of HCN and DCN (29) have shown this treatment to be inadequate for highly precise measurements. In a case (b) basis, matrix elements of the type[4]

$$[11] \quad \langle v_1,v_2^l,v_3; N,\ell| H | v_1,v_2^{l\pm4},v_3; N,\ell \pm 4\rangle = \rho_v\{[N(N+1) - \ell(\ell \pm 1)][N(N+1) - (\ell \pm 1)(\ell \pm 2)][N(N+1) - (\ell \pm 2)(\ell \pm 3)][N(N+1) - (\ell \pm 3)(\ell \pm 4)]\}^{1/2}$$

must also be considered for levels with $v_2 > 1$. However, since the contributions from q_v^D and ρ_v to the ℓ-type doubling in (020) are highly correlated (29), the present fits were performed with ρ_v fixed at zero, as in the similar treatment for OCS (30).

For $v_2 = 1$ of Σ electronic states, the off-diagonal matrix element connects states with $\ell = 1$ and $\ell = -1$ in the signed basis. Taking Wang combinations of the appropriate case (b) functions (31),

$$[12] \quad |\eta|K|SNJ\pm\rangle = 2^{-1/2}\,[|\eta KSNJ\rangle \pm (-1)^{J+S-1}|\eta - KSNJ\rangle]$$

where η represents the vibrational quantum number, the interaction is diagonalized and is represented by q_v in eqs. [3 and 4]. The net effect is a removal of the e/f degeneracy associated with the Π vibrational level and is referred to as ℓ-type doubling (32). The magnitude of the splitting is dependent upon q_v, where according to Nielsen et al. (33, 34)

$$[13] \quad q_v = -\frac{2B_e^2}{\omega_2}\left[1 + 4\sum_i \frac{\xi_{2i}^2\omega_2^2}{\omega_i^2 - \omega_2^2}\right]$$

Using the estimates of α_1 and B_{000} of refs. 1 and 19, taking $\omega_2 = \omega_2^o$, and setting α_3(SrOH) = α_3(RbOH) (23), the experimental values of q_v of $-3.622(8) \times 10^{-4}$ and $-3.9503(46) \times 10^{-4}$ cm^{-1} for the $\tilde{B}$ and $\tilde{X}$ states lead to estimates of $4\Sigma_i\, \xi_{2i}^2\omega_2^2/(\omega_i^2 - \omega_2^2)$ of 0.12 and 0.14, respectively. These results can be compared with the typical value of 0.3 for this Coriolis term found by Townes and Schalow (35).

The $\ell = 0$ and $\ell = \pm 2$ components of the $v_2 = 2$ vibrational level also interact via the matrix element of eq. [9]. By convention such an interaction is referred to as the ℓ-type resonance to indicate the approximate degeneracy of the interacting levels. The magnitude of the ℓ-type resonance interaction is dependent on the separation of the (02^00) and (02^20) levels. In the $\tilde{A}^2\Sigma^+(020)$ vibrational level of N_2O^+, where the ℓ-type resonance is particularly strong (36) ($g_{22} = 1.39(9)$ cm^{-1}), an ℓ-type uncoupling is observed. For weaker interactions the net effect is primarily a splitting of the e and f parity levels in the Δ state. In SrOH, the $^2\Sigma^+$ and $^2\Delta$ components of the $v_2 = 2$ vibrational level were observed for the $\tilde{B}$ and $\tilde{X}$ electronic states enabling the off-diagonal matrix element to be evaluated directly. This involved removing the diagonal term q_{eff} of eqs. [5] and [6] and constructing the appropriate interaction matrix. In the parity basis of eq. [12], the interaction matrix takes the form:

$$[14] \quad e\text{-levels} \quad \begin{vmatrix} E_{F2}(^2\Delta) & 0 & 0 \\ 0 & E_{F1}(^2\Delta) & W_{20} \\ 0 & W_{20} & E(^2\Sigma^+) \end{vmatrix}$$

$$[15] \quad f\text{-levels} \quad \begin{vmatrix} E_{F2}(^2\Delta) & 0 & W_{20} \\ 0 & E_{F1}(^2\Delta) & 0 \\ W_{20} & 0 & E(^2\Sigma^+) \end{vmatrix}$$

where $W_{20} = [q_v + q_v^D N(N+1)]\{[N(N+1)][N(N+1) - 2]\}^{1/2}$. For the $\tilde{B}^2\Sigma^+$ state, q_v and q_v^D are found to be $-3.22(9) \times 10^{-4}$ and $-1.18(22) \times 10^{-8}$ cm^{-1}, respectively. The small difference of q_v from that for (010) yields an estimate of q_{22} in eq. [10] of $4.0(9) \times 10^{-5}$ cm^{-1}. The q_v^D parameter, however, is significantly larger in magnitude than that of the (010) level. As discussed earlier, however, q_v^D for (020) is an ef-

[3]Note the typographical errors in eq. 3a on p. 18. The equation should read:

$$\langle v,\ell \pm 2,N|H|v,\ell,N\rangle = 1/4q_v\,\{[(v+1)^2 - (\ell \pm 1)^2][N^2 - (\ell \pm 1)^2][(N+1)^2 - (\ell \pm 1)^2]\}^{1/2}$$

[4]A reviewer suggested this modified form of the equation listed in ref. 29.

fective parameter that absorbs the effect of the matrix elements connecting states with $\Delta\ell = \pm 4$. For the $\tilde{X}$ state the ℓ-type doubling constant was found to be $-4.9(7) \times 10^{-4}$ cm^{-1}, with the constant q_v^D fixed to the $\tilde{B}(020)$ value.

Perturbations

The effects of rotational perturbations in the $\tilde{B}^2\Sigma^+$ vibrational levels lead to a contamination of the purely physical meaning of the molecular constants. Although this is mitigated to some extent in the least-squares fits by the exclusion of lines in the crossing regions, only a full deperturbation analysis can properly take account of the perturbations. In our experiments, observations of the perturbing states are limited to a few weak additional rotational lines in the crossing regions of the $(010)\Pi$ and $(02^00)\Sigma$ states; consequently, such an approach is not yet feasible. Nevertheless, based on these additional lines we have estimated the vibronic energy of the perturbing states of the $(010)\Pi$ and $(02^00)\Sigma^+$ vibrational levels to be 16 800 ± 15 and 17 152 ± 1 cm^{-1}, respectively. The most recent theoretical calculations place the $^2\Delta$ electronic state at 20 221 cm^{-1} (37), suggesting the perturbing states must be excited vibrational levels of the $\tilde{A}^2\Pi$ electronic state. Preliminary investigations carried out in this laboratory have determined T_{ev} of the $\tilde{A}^2\Pi(010)\kappa\Sigma$–$\tilde{X}^2\Sigma^+(000)\Sigma^+$ and $\tilde{A}^2\Pi(100)\Pi_{1/2}$–$\tilde{X}^2\Sigma^+(000)\Sigma^+$ bands to be 15 190.861(1) and 15 084.656(1) cm^{-1}, respectively. Adopting the spin-orbit coupling constant obtained in ref. 2, and neglecting anharmonicity, we find $\omega_1 = 542.1$ and $\omega_2 = 382.8$ cm^{-1}. Given the similarity of $3\omega_2 + 1/2A_o = 1758.0$ cm^{-1} and $T_e(\tilde{B}^2\Sigma^+) - T_e(\tilde{A}^2\Pi) = 1703.17$ cm^{-1}, it seems likely that the unidentified perturbers of the $\tilde{B}(010)$ and $\tilde{B}(02^00)$ levels belong to the upper spin-orbit manifold of the $\tilde{A}(310)$ and $\tilde{A}(320)$ vibronic states.

Based on the vibrational constants determined in this work and those of ref. 1, the unperturbed $(03^10)\Pi$ and $(200)\Sigma^+$ vibrational levels of SrOH are expected to lie within 25 cm^{-1} of one another in both the $\tilde{B}$ and $\tilde{X}$ electronic states. We thus expect a strong $(03^10) \sim (200)$ Coriolis interaction, resulting in considerable mixing of the vibrational eigenfunctions. As a result of intensity borrowing, it is possible that this perturbation may be used to provide a convenient window to access the (030) vibrational levels. In particular, the $\tilde{B}^2\Sigma^+(200)\Sigma^+ \leftarrow \tilde{X}^2\Sigma^+(03^10)\Pi$ and $\tilde{B}^2\Sigma^+(030) \leftarrow \tilde{X}^2\Sigma^+$-$(000)\Sigma^+$ transitions are expected to have an appreciable oscillator strength.

The energy levels of the lower valence and Rydberg states of selenoformaldehyde, CH_2Se, have been calculated by the SCF/CI method. Wavefunctions for the ROHF (restricted open shell Hartree–Fock) states were obtained with the Binnings–Curtis double-ζ basis set, augmented with Rydberg and polarization functions. Configuration interaction was applied to the parent configurations, PCMO (parent configuration molecular orbital). Oscillator strengths were evaluated for the allowed electric dipole transitions by the RPA (random phase approximation), and SOPPA (second-order polarization propagator approximation) methods. The spin-orbit contribution to the zero field splitting of the first triplet state, $^3A_2(n,\pi^*)$ as well as the oscillator strengths to the three spin components were calculated by perturbation theory. These calculations predict that the S_x, S_y, and S_z components are shifted by −96.091, −96.707, and +29.167 cm^{-1}, respectively, from their unperturbed position. The oscillator strengths for the three components f_x, f_y, and f_z of the $^3A_2(n,\pi^*) \leftarrow {}^1A_1$(g.s.) transition were calculated to be 3.45×10^{-7}, 1.15×10^{-7}, and 173.0×10^{-7}.

D.C. MOULE, L. CHANTRANUPONG, R.H. JUDGE et D.J. CLOUTHIER. Can. J. Chem. **71**, 1706 (1993).

Faisant appel à la méthode SCF/CI, on a calculé les niveaux d'énergie de la basse valence et des états de Rydberg du sélénoformaldéhyde, CH_2Se. On a obtenu les fonctions d'onde des états ROHF (couche ouverte restreinte de Hartree–Fock) en utilisant le double ensemble ζ de Binnings–Curtis de concert avec des fonctions de Rydberg et de polarisation. On a appliqué l'interaction de configuration aux configurations fondamentales, PCMO (orbitale moléculaire de la configuration fondamentale). Faisant appel aux méthodes de RPA (approximation aléatoire de la phase) et SOPPA (approximation du deuxième ordre de la polarisation du propagateur), on a évalué les forces de l'oscillateur pour les transitions électriques dipolaires permises. Utilisant la théorie de perturbation, on a calculé la contribution spin-orbite au couplage au dédoublement de champ zéro du premier état triplet, $^3A_2(n,\pi^*)$, ainsi que les forces d'oscillateur des composantes à trois spin. Ces calculs permettent de prédire que les composantes S_x, S_y et S_z sont déplacés respectivement de −96,091, −96,707 et +29,16 cm^{-1} par rapport à leur position non perturbée. On a calculé que les forces d'oscillateur des trois composantes f_x, f_y et f_z de la transition $^3A_2(n,\pi^*) \leftarrow {}^1A_1$(e.f.) sont respectivement $3{,}45 \times 10^{-7}$, $1{,}15 \times 10^{-7}$ et $173{,}0 \times 10^{-7}$.

[Traduit par la rédaction]

Introduction

The CH_2X molecules, where X = O, S, and Se, may be regarded as the molecular prototypes for correlating the spectral properties of the carbonyl, thiocarbonyl, and selenocarbonyl classes of molecules. The spectrum of formaldehyde, a stable molecule, has been exhaustively studied and has been the subject of several reviews (1, 2). Thioformaldehyde, on the other hand, is unstable and must be generated by pyrolysis or photolysis. As the substitution of sulphur for oxygen has the effect of lowering the excitation energies into more accessible regions of the spectrum, the lower systems of this molecule have recently received considerable attention (3). Like thioformaldehyde, selenoformaldehyde is unstable and must be synthesized by the technique of flash pyrolysis and subsequently detected in the effluent of a flow system. As a result of the experimental difficulties in handling this molecule, the spectroscopy is still not as well understood at this time as the other analogues.

Selenoformaldehyde was detected as a visible absorption spectrum by the long path length photographic technique (4) and at the same time by photoelectron spectroscopy (5). Shortly thereafter it was found as an emission in the cool flames of a F_2 and $(CH_3)_2Se_2$ mixture (6). Both the singlet $^1A_2(n-\pi^*)$ and the triplet $^3A_2(n-\pi^*)$ states are emissive and are accessible through laser-induced fluorescence (LIF) and laser-induced phosphorescence (LIP) spectroscopy. Excitation spectra of both systems have been studied under low resolution (7). In the case of the $S_0 \rightarrow S_1$ system, the 0_0^0 origin band has been observed as a moderately strong magnetic dipole band governed by a-type selection rules, whereas the first Herzberg–Teller band, 4_0^1, is a weak and extensive b-type perpendicular band. Both of these bands have been subjected to high-resolution rotational analyses (8). The bands of the $S_0 \rightarrow T_1$ singlet–triplet transition are very strong in the red end of the spectrum and the vibrational assignment did not present any great difficulty. The rotational analyses of these bands has proven to be more difficult. By analogy with the singlet-triplet bands of CH_2O and CH_2S, one expects prominent S and O branches characteristic of Hund's case (b) coupling in the excited state, in which the three spin

components of the nonrotating molecule are separated by energies small compared to the rotational intervals. However, at high resolution, the CH_2Se bands are found to have simple P-, Q-, and R-branch structure following $\Delta K = 0$ selection rules, with no evidence of spin splittings, despite a pronounced Zeeman effect indicating that the upper state has an appreciable magnetic moment.[2] Thus, the rotational structure suggests that the upper state is of singlet multiplicity whereas the magnetic effects are those of a triplet state. The most likely solution to this dilemma is to postulate that the triplet state of CH_2Se actually corresponds to Hund's case (ab) (9), in which two of the spin components are close together and the third is remote from them. If the observed transitions are to the remote level, then the rotational structure of the bands would be expected to be similar to that of a singlet–singlet transition in the absence of strong spin-rotation coupling between the three spin components. To our knowledge, the only type of molecule known to exhibit this type of spin splitting is carbon disulphide, in which the near-ultraviolet bands have been shown to result from a transition to one component of the $^3A_2$ state (10, 11). It is therefore of considerable interest to determine if selenoformaldehyde also has this type of anomalous triplet state energy level structure.

The purpose of this work is to evaluate the spin-orbit coupling between the $^3A_2(n$–$\pi^*)$ state and the other singlet and triplet states of CH_2Se and to calculate the zero field splittings (ZFS) between the three spin components of the nonrotating molecule. This information is intended to provide a starting point for attempts to more thoroughly understand the singlet–triplet bands. For this purpose, the relative strengths of the transitions to the three spin substates have also been estimated from perturbation theory.

Method

The HF/SCF calculations were carried out with the GAMESS system of programs (12). The Dunning/Hay (DH) double-ζ basis set (13) was used for carbon: $(9s,5p)/[3s,2p]$ augmented by d polarization functions α_d = 0.1875, 0.75, and 3.00 and Rydberg $3s$, $3p$ orbitals with exponents α_s = 0.023, α_p = 0.021 for the total basis C: $(10s,6p,3d)/[4s,3p,3d]$. For hydrogen: $(3s)/[2s]$, the addition of p polarization functions with exponents α_p = 0.25, 1.0, and 4.0. gave H: $(3s,3p)/[2s,3p]$. The Binnings/Curtis (BC) double-ζ basis set (14) $(14s,11p,5d)/[6s,4p,1d]$ was used for the selenium atom supplemented with d polarization function α_d = 0.315 and Rydberg $5s$ and $5p$ orbitals with exponents α_s = 0.016 and α_p = 0.014 for the basis, Se: $(15s,12p,6d)/[7s,5p,2d]$ Thus this calculation employed a total of 87 basis functions with 34 shells and 42 electrons to give as the ground state electron configuration:

$$(1a_1)^2(2a_1)^2(3a_1)^2(1b_1)^2(1b_2)^2(4a_1)^2(5a_1)^2(2b_1)^2(6a_1)^2$$
$$(2b_2)^2(7a_1)^2(3b_1)^2(1a_2)^2(3b_2)^2(8a_1)^2(9a_1)^2(10a_1)^2(4b_2)^2$$
$$(11a_1)^2(4b_1)^2(5b_2)^2(12a_1)^0(5b_1)^0(13a_1)^0(6b_2)^0(6b_1)^0(14a_1)^0$$
$$(7b_2)^0(7b_1)^0(15a_1)^0 \ldots$$

where $5b_2$ and $12a_1$ are the HOMO and LUMO orbitals, respectively.

Buenker and Peyerimhoff (15) have shown that the parent configuration molecular orbital technique, CI(PCMO),

is an excellent method for obtaining excitation energies in small polyatomic molecules. In this technique, the configuration interaction is applied to the SCF orbitals of the parent configuration. The details of this calculation are shown in Table 1 where the first column lists the ROHF/SCF open shell excitation energies of the parent configurations up to the 8.81 eV ionization limit (16) for the r_s ground state structure (17): C=Se = 1.753 Å, r(CH) = 1.090 Å, and α(HCH) = 117.9°. The second column lists excitation energies that were obtained for the fully optimized structural parameters found in columns 5–7. The corrections for the effects of electron correlation were made with the Graphical Unitary Group Approach (18), GUGA, which is available in the GAMESS package. For each state the parent configurations were used with all singles and doubles electron excitation. This active space consisted of 27 orbitals occupied by 12 electrons, with 15 core orbitals frozen. The CI excitation energy and the CI energy with the Davidson correction (19) (SD + Q), as well as the number of configuration state functions (CSF's), are given in Table 1.

The spin-orbit coupling constants were calculated at the MCSCF level with the $TRANST routine, which is incorporated in the GAMESS program. In this treatment, the Hamiltonian for spin-orbit coupling is given in terms of one-electron integrals while the need for two-electron terms is circumvented by use of a parameterized effective nuclear charge, Z_{eff}. Values of Z_{eff} for first and second row atoms of the Periodic Table have been recently calibrated by Koseki, Schmidt, and Gordon (20). Their procedure involves a calculation of the fine structure splittings between the $\Pi_{3/2}$ and $\Pi_{1/2}$ levels of AH molecules, where H is hydrogen and A the heavy atom. With the assumption that for hydrogen Z_{eff} = 1.0, they adjusted Z_{eff} for A until the experimental intervals were reproduced. In the case of Se, which lies in the third row of the Periodic Table, two separate values of the $\Pi_{3/2} - \Pi_{1/2}$ energy difference for SeH are available from electron detachment spectroscopy (21) and from electron spin resonance spectroscopy (22). The most recent estimate of the splitting (21) at -1815 ± 100 cm^{-1} required a Z_{eff} of 34.51 to reproduce the splitting, which is greater than Z_{true} = 34.0, whereas the second value (22) of -1600 ± 50 cm^{-1} yielded a Z_{eff} = 30.43. As Z_{eff} must be less than Z_{true}, the calibration favours the second observation. Table 2 gives the values of the spin-orbit coupling to the $^3A_2(n,\pi^*)$ T_1 triplet excited state and to the $^1A_1$ S_0 ground electronic state. The calculations were carried out with a fully optimized reaction space multiconfigurational self-consistent wavefunction (FORS/MCSCF) with 10 valence orbitals and 12 valence electrons. Planar structures were adopted for both states.

Since the $^3A_2(n,\pi^*)$ state is orbitally nondegenerate, the first nonzero spin-orbit contribution to the zero field splitting requires second-order perturbation theory. With the molecule oriented in the yz plane and the z axis directed along the C=Se bond, a consideration of the symmetry (23) of the orbital and spin wave functions shows that the perturbations between the S_z level of the $^3A_2(T_1)$ state and the other electronic states of $^1A_1$, $^3B_1$, and $^3B_2$ symmetry can be written as

$$[1]\quad \Delta E(S_z) = -\sum_m [\langle {}^1A_1, m \mid H_{SO} \mid {}^3A_2,T_1\rangle^2 [E_m({}^1A_1) - E({}^3A_2,T_1)]^{-1} + \langle {}^3B_1,m \mid H_{SO} \mid {}^3A_2,T_1\rangle^2 [E_m({}^3B_1) - E({}^3A_2,T_1)]^{-1} + \langle {}^3B_2,m \mid H_{SO} \mid {}^3A_2,T_1\rangle^2 [E_m({}^3B_2) - E({}^3A_2,T_1)]^{-1}]$$

where the sum is taken over the manifold of m states. Symmetry considerations likewise show that it is the electronically excited states of $^3A_1$, $^1B_1$, and $^3B_2$ symmetry that interact

[b]r(C═Se) = 1.753 Å, r(C—H) = 1.090 Å, α(HCH) = 117.9°, CI(SD + Q), Z_{eff}(Se) = 30.43.
[c]Oscillator strengths are $f \times 10^{-7}$; transition moments are $M \times 10^{-2}$.

with the x component of the $^3A_2(n,\pi^*)$ state while the $^3A_1$, $^1B_2$, and $^3B_1$ states mix and perturb the y component. Expressions similar to eq. [1] have been constructed (23) for the energy shifts to these levels.

Oscillator strengths can be obtained for the transitions to the S_x, S_y, and S_z spin components from perturbation theory. For z-polarized light (C═Se bond direction), the transition moment to the S_z component can be obtained from the expression

$$[2]\quad M(^1A_1,S_0 \rightarrow {}^3A_2,T_1) = \sum_s \frac{\langle {}^1A_1,s\,|H_{SO}|\,{}^3A_2,T_1\rangle}{[E(^3A_2,T_1) - E(^1A_1,s)]} M(^1A_1,S_0 \rightarrow {}^1A_1,s) + \sum_t \frac{\langle {}^1A_1,S_0\,|H_{SO}|\,{}^3A_2,t\rangle}{[E(^1A_1,S_0) - E(^3A_2,t)]} M(^3A_2,t \rightarrow {}^3A_2,T_1)$$

where $\langle {}^1A_1,s|H_{so}|{}^3A_2,T_1\rangle$ is the spin-orbit matrix element between the $^3A_2(n,\pi^*)$ triplet and the adjacent ground and singlet excited states $^1A_1,s$. $E(^1A_1,S_0)$–$E(^3A_2,t)$ is the perturbation gap between the interacting states and $M(^1A_1,S_0 \rightarrow {}^1A_1,s)$ the transition moment between ground state and the excited singlet states. Thus, it is possible to interpret the first term as the mixing of the triplet S_z $^3A_2(n,\pi^*)$ wavefunction by the adjacent singlet excited states and a borrowing or stealing of their allowed electronic transition strength. In a similar way the second term is a perturbation of the ground state $^1A_1(S_0)$ by members of the triplet manifold of states. Thus the perturbation treatment requires (*a*) the spin-orbit matrix elements between the $^3A_2(n,\pi^*)$ and the $^1A_1$, $^1B_1$, and $^1B_2$ states as well as the elements between the $^1A_1$(g.s.) and the $^3A_2$, $^3B_1$, and $^3B_2$ states; (*b*) excitation energies for the manifolds of singlet and triplet electronic states; and (*c*) transition moments between the $^1A_1$(g.s.) and all of the allowed singlet states as well as those between the $^3A_2(n,\pi^*)$ state and the other triplet states of the molecule

Oscillator strengths were calculated from the RPAC group of programs (24). Oscillator strengths are sensitive to the quality of the electronic wavefunctions and are difficult to evaluate. The random phase approximation (RPA) and the second-order polarization propagator (SOPPA) methods were used to determine the transition strengths. Table 3 lists the transition moments and the oscillator strengths for both the velocity and the length approximations.

Results and discussion

As only the first two electronic transitions have been observed in the visible spectrum of selenoformaldehyde, it is difficult to obtain a complete calibration for this model calculation. In wavenumbers, the positions for the 0_0^0 transitions that result from $n \rightarrow \pi^*$ excitation, $^1A_1 \rightarrow {}^1A_2/{}^1A_1 \rightarrow {}^3A_2$, lie at 13 555/12 171 cm^{-1} or, in eV, 1.681/1.509. As the spectroscopic analysis has shown that the excited $^1A_2(S_1)$ and $^3A_2(T_1)$ states are pseudo-planar, the maximum in the Franck–Condon intensity profile should lie close to the origins of the two electronic transitions. Our results, in eV, which are tabulated in Table 1, give the following energies: ROHF (microwave geometry) 0.9027/0.887, with optimized C_{2V} structure 0.957/0.798, with CI 1.458/1.260, and with CI(SD + Q) 1.737/1.541. It is clear that the calculations at the ROHF level of approximation badly underestimate the transition energies and are not significantly changed by optimization of the structure. The CI corrections for correlations markedly improve the agreement while the CI(SD + Q) correction slightly overestimates the energies of the two transitions. Our value of 1580 cm^{-1} for the S_1–T_1 interval compares favourably with the 1387 cm^{-1} observed in the spectrum of selenoformaldehyde. The pattern of the lower excited states is different from that found by Collins et al. (16), who predicted that the $^3A_1(\pi,\pi^*)$ state should have the lowest energy, 1.42 eV, and be followed by the $^3A_2(n,\pi^*)$ and $^1A_2(n,\pi^*)$ states at 1.62 and 2.02 eV.

The transitions to the higher electronic states of selenoformaldehyde have not been observed. The calculations show the next singlet state, at 5.336 eV, is of Rydberg character $^1B_2(n,5s)$ and is followed by the intervalence $^1A_1(\pi,\pi^*)$ state at 5.673 eV. This latter state with a populated π^* orbital could have a nonplanar structure. The ordering of the valence states follows the pattern of CH_2O except that the states with π,π^* configurations are at much lower energies. Two

manifolds of Rydberg states are generated from the present basis set, namely, those that arise from an electron promotion from the $n(5b_2)$ orbital and those which are from the $\pi(4b_1)$ orbital. The order of the n–$5p$ Rydberg states is n–$5p_z$, n–$5p_y$, and n–$5p_x$, which differs from the order found for formaldehyde where the Rydberg $3p_y$ and $3p_z$ orbital energies are reversed.

The matrix elements for spin-orbit coupling between the $^3A_2(n,\pi^*)$ state and the adjacent singlet and triplet valence states are quite large. For example, with the $Z_{eff} = 30.43$, the coupling to the singlet $^1A_1(\pi,\pi^*)$ state is -531.54 cm^{-1} and, to the corresponding triplet state, 723.14 cm^{-1}. At 698.64 cm^{-1}, the matrix element coupling to the A_1 (g.s.) ground state is also appreciable. On the other hand, the coupling elements to the Rydberg states are much smaller, 59.29 and 55.48 cm^{-1} for the $^1B_2(n,5s)$ and $^1B_2(n,5p_z)$ states, respectively. In the case of the $^1B_1(\pi,5s)$ electronic state where the configuration contains neither $(n)^1$ nor $(\pi^*)^1$ orbitals, the matrix element connecting the $^3A_2(n,\pi^*)$ state is very small, 2.19 cm^{-1}.

The spin-orbit displacements to each of the fine structure levels were evaluated from eq. [1]. For this purpose, the matrix elements for models (1) and (2) were taken from the first two columns of Table 2 and were combined with the CI(SD + Q) excitation energies of Table 1, column 4, to give the fine structure contributions of Table 2. The $^3A_1(\pi,\pi^*)$ state was found to make the greatest contribution to the ZFS and has the effect of pushing the S_x and S_y components of the $^3A_2(n,\pi^*)$ state downwards from their unperturbed positions by -98.53 cm^{-1}. The S_z level, on the other hand, is displaced -8.48 cm^{-1} downwards by the $A_1(\pi,\pi^*)$ state and upwards 39.27 cm^{-1} by the $^1A_1$(g.s.) ground state. The displacement by the $^1A_1(n,5p_y)$ Rydberg state of -0.18 cm^{-1} is not a significant factor. Thus, while the S_z level is not appreciably shifted from its unperturbed position, the S_x and S_y levels are depressed to lower energies by about -100 cm^{-1}. The other valence interaction is with the singlet and triplet $B_1(\sigma,\pi^*)$ states. In this case, while the displacement of the x component by the singlet $^1B_1(\sigma,\pi^*)$ state is -6.01 cm^{-1}, the corresponding y and z displacements by the $^3B_1(\sigma,\pi^*)$ are -6.68 cm^{-1}. The effect of this interaction is to depress all three levels by about the same amount. The perturbations by the Rydberg states are small. Moreover, since the singlet and triplet Rydberg state have almost the same energies and their spin-orbit matrix elements are nearly equal, they interact and shift all three spin components by roughly the same extent. Thus, while the interactions with the higher Rydberg states uniformly shift the three components in a downwards direction they do not alter their relative positions.

The location of the $^3A_1(\pi,\pi^*)$ state is critical to the positioning of the S_X, S_Y, and S_Z components. From Table 2 it is clear that the interactions with this state account for a large part of the displacements of the x and y components. The $^3A_1$ (π,π^*) state is only $2.199 - 1.541 = 0.658$ eV or 5306 cm^{-1} above the $^3A_2(n,\pi^*)$. The difficulty here is that Collins et al. (16) calculate a separation of $1.42 - 1.62 = -0.20$ or -1613 cm^{-1} between these levels, but in their case the $^3A_2(\pi,\pi^*)$ state was found to lie below the $^3A_2(n,\pi^*)$ state and would result in an upward perturbation of the (n,π^*) states. For this reason we focused on the three major interacting states: $^1A_1$(g.s.), $^3A_2(n,\pi^*)$, and $^3A_1(\pi,\pi^*)$. As a better approximation, we repeated the previous calculations but used instead the experimentally determined molecular structure (8) of the zero point level of the companion $^1A_2(n,\pi^*)$ singlet state. In this final calculation we obtained, E(SD + Q): $^3A_2(n,\pi^*) = 1.497$, $^1A_2(n,\pi^*) = 1.694$, which are in excellent agreement with the observed electronic origins, 1.509 and 1.681 eV. This same calculation yielded a value of $^3A_1(\pi,\pi^*) = 2.284$ eV and the coupling constants between the $^3A_2(n,\pi^*)$ and $^1A_1$(g.s.), $^3A_1(\pi,\pi^*)$ states of 755.27 and 754.34 cm^{-1}. Combined with the energies of the previous calculation, we obtain: $\Delta E(S_x) = -96.091$, $\Delta E(S_y) = -96.707$, and $\Delta E(S_z) = 29.167$ cm^{-1} as our most reliable calculation for the spin-orbit contribution to the zero field splitting. As a test of the method we performed similar calculations on the $^3A_2(n,\pi^*)$ state of the sulphur analogue, CH_2S. With the (DH) molecular orbital basis set we obtain for the three spin-orbit components: $\Delta(S_x) = -7.5139$, $\Delta(S_y) = -7.4828$, and $\Delta(S_z) = 0.8541$ cm^{-1}. From these values it is possible to derive the spectroscopic constants for spin-orbit coupling: $D = -8.3525$ and $E = 0.0156$ cm^{-1}. These constants may be compared to the experimentally determined values for $v = 0$; $D = -4.078$ and $E = 0.0942$ cm^{-1} obtained from long-path absorption studies (25) and $v_3 = 1$; $D = -4.3474$ and $e = 0.0853$ cm^{-1} from high-resolution LIP spectroscopy (26). The agreement between the calculated and observed constants is not unreasonable since the contributions from the spin–spin coupling have not been incorporated into the model calculations. Inclusion of this effect would move D and E closer to their observed values.

Table 3 gives the results of the intensity calculations. It is clear by comparing the results of the different methods that it is difficult to obtain accurate values of the oscillator strength. As a case in point, the RPA method yields oscillator strengths for the velocity and length formalisms of $f(v) = 0.240$ and $f(\ell) = 0.237$ for the $\pi \rightarrow \pi^*$ transition, whereas the SOPPA method gives $f(v) = 0.113$ and $f(\ell) = 0.174$. Thus the oscillator strengths by the two methods are quite different. The value obtained for this intervalence $\pi \rightarrow \pi^*$ transition is, however, comparable with the $f_z = 0.222$ calculated for formaldehyde (23). The strength of the $n \rightarrow 5s$ Rydberg transition at 0.060 appears to be satisfactorily accounted for and is similar to the 0.017 strength in the corresponding $n \rightarrow 3s$ transition in formaldehyde.

It is clear, from eq. [2], that the strengths of the singlet–triplet transitions depend not only on the spin-orbit matrix elements and the perturbation energy gaps, but also on the magnitude of the electronic transition moments. Four sets of intensity calculations are presented in Table 3. These calculations used the matrix elements from model (2) and the CI(SD + Q) energies and the length and velocity approximation of the RPA and SOPPA methods. Of these, we believe the RPA(length) form to be the most reliable. This calculation gave for the oscillator strength to the spin components, $f_x = 3.45 \times 10^{-7}$, $f_y = 1.15 \times 10^{-7}$, and $f_z = 173.0 \times 10^{-7}$. It is clear from these numbers that 98.8% of the strength of the $^1A_1$(g.s.) $\rightarrow$ $^3A_2(n,\pi^*)$ transition is induced in the $A_1(z)$ polarized direction. This is a consequence of the $H_{SO}(a_2)$ spin-orbit coupling between the z spin component of the $^3A_2(n,\pi^*)$ state and the $^1A_1(\pi,\pi^*)$ state and the adjacent $\pi \rightarrow \pi^*$ transition of high strength. The only other contributor to this component is the $n \rightarrow 5p_y$ transition, which provides only about 0.5% of the intensity.

The calculated strength to the $B_2(y)$ spin component is low, (1.15×10^{-7}) and comes from the couplings to the lower Rydberg $^1B_2(n,5s)$ and $^1B_2(n,5p_z)$ states. While these states do have a partial valence character, and the spin-orbit coupling constants are of an intermediate size, their low oscillator strengths mitigate against intensity borrowing. Similarly, the transition to the x component obtains intensity from the $\sigma \rightarrow \pi^*$ intervalence transition but, again, the low oscillator strength of this system (0.008) works against this mechanism.

Summary

The valence and low-lying Rydberg electronic states of selenoformaldehyde have been calculated by ab initio methods. The orbital basis set for the calculation was of double-ζ quality and was augmented with polarization and Rydberg functions. These were used in an ROHF procedure to generate the parent configuration molecular orbitals, CI(PCMO). The four valence states $^1A_1$(g.s.), $^3A_2(n,\pi^*)$, $^1A_2(n,\pi^*)$, and $^3A_1(\pi,\pi^*)$ were found to lie at relatively low energies and were separated from the higher valence and Rydberg states. Intensities were calculated by the RPA and SOPPA techniques and were found to correlate with those of formaldehyde. The matrix elements for the spin-orbit coupling of the $^3A_2(n,\pi^*)$ state to the intervalence and Rydberg states that lie below the first ionization limit were evaluated. The couplings to the intervalence states were found to be large, 200–800 cm^{-1}, whereas those to the Rydberg states were typically 60–80 cm^{-1}. The positions of the lower valence states have a critical influence on the separations of the three spin components of the $^3A_2(n,\pi^*)$ state. As a result of their close proximity and their quite large spin-orbit matrix elements, the $^1A_1$(g.s.) and $^1A_1(\pi,\pi^*)$ states interact with and repel the $^3A_2(n,\pi^*)$ state. As they lie on either side of the $^3A_2(n,\pi^*)$ state, the z spin-orbit component is pushed upwards and downwards by nearly equal amounts, which results in a small shift from the unperturbed position. The other major interaction is a repulsion between the x and y components of the $^3A_2(n,\pi^*)$ state and the $^3A_1(\pi,\pi^*)$ state. This has the effect of depressing the levels downwards to give as the final result: $\Delta E(S_x) = -96.091$, $\Delta E(S_y) = -96.707$, and $\Delta E(S_z) = 29.167$ cm^{-1}.

Intensities were calculated by perturbation theory where the intensity induced into the singlet–triplet transition can be described as a borrowing or stealing of the oscillator strength from neighbouring states of the correct symmetry. It is the $\pi \rightarrow \pi^*$ state with an f value of 0.237 that provides the strength for the singlet–triplet transition. This highly allowed intervalence transition also determines the polarization. The RPA(1) method, which appears to be the most dependable of those tested, yields oscillator strengths for the three components: $f_x = 3.45 \times 10^{-7}$, $f_y = 1.15 \times 10^{-7}$, and $f_z = 173.0 \times 10^{-7}$.

The present calculations strongly support the notion that the T_1 state of selenoformaldehyde corresponds to Hund's case (ab), rather than case (b). In CH_2O and CH_2S, the spin splittings in the nonrotating molecule are small and the predominant transition is from the ground state to the S_z component, induced by coupling with the $^1A_1(\pi,\pi^*)$ state. In the rotating molecule, the spin-rotation coupling mixes the S_z, S_y, and S_x components so that the intensity is shared between the three components. Similarly, in CH_2Se, the calculations show that almost all of the singlet–triplet transition intensity is to the S_z component due to mixing with the (π,π^*) state. However, in this case the S_x and S_y components are calculated to be 125 cm^{-1} below S_z so that the spin uncoupling will not appreciably redistribute the intensity between the three components. In this case, the 0_0^0 band of the singlet–triplet transition should follow a-type selection rules and show rotational structure very similar to that of a singlet–singlet transition. It is doubtful if the transitions to the other two components will be observed in the room temperature laser-induced phosphorescence spectrum since they are predicted to be 50–100 times weaker.

A universal Gaussian basis set (UGBSII) is reported for *ab initio* relativistic Dirac–Fock calculations on atoms and molecules. The Dirac–Fock–Coulomb energies obtained with this universal Gaussian basis set are presented for the neutral heavy atoms Yb ($Z = 70$), W ($Z = 74$), Pb ($Z = 82$), Ra ($Z = 88$), and Pu ($Z = 94$). The total Dirac–Fock–Coulomb energies computed with the UGBSII, for all the systems, are in better agreement with the corresponding numerical finite-difference results than those obtained with our previous universal Gaussian basis set (UGBSI). The UGBSII represents a very accurate Gaussian basis set for relativistic Dirac–Fock atomic calculations.

A.B.F. Da Silva, G.L. Malli et Yasuyuki Ishikawa. Can J. Chem. **71**, 1713 (1993).

On rapporte un ensemble gaussien universel (UGBSII) pour des calculs *ab initio* Dirac–Fock relativistes sur des atomes et des molécules. On présente les énergies Dirac–Fock–Coulomb obtenues à l'aide de cet ensemble gaussien pour les atomes lourds neutres Yb ($Z = 70$), W ($Z = 74$), Pb ($Z = 82$), Ra ($Z = 88$) et Pu ($Z = 94$). Les énergies totales Dirac–Fock–Coulomb calculées pour tous les systèmes à l'aide de UGBSII sont en meilleur accord avec les résultats numériques correspondants de différences finies que ceux obtenus à l'aide de notre ensemble gaussien antérieur (UGBSI). L'ensemble UGBSII représente un ensemble gaussien très précis pour des calculs atomiques relativistes de Dirac–Fock.
[Traduit par la rédaction]

Introduction

Gaussian-type functions (GTFs) have been widely used in relativistic calculations during the last decade (1–7). This is basically due to three reasons: first, if the nucleus is represented by a finite body of uniform proton-charge distribution, the solutions of the radial Dirac equation can be represented by GTFs (8–10), and therefore, the GTFs are capable of reproducing the correct relativistic kinematics near the origin. Second, the multicenter integrals over the GTFs can be evaluated exactly by closed analytical formulas. Third, the basis sets of GTFs are less prone to near linear dependency than the basis sets of Slater-type functions (STFs). In particular, well-tempered and geometrical GTFs have been used for Dirac–Fock–Coulomb (DFC) and Dirac–Fock–Breit (DFB) atomic calculations (5, 7).

Recently, we have introduced universal Gaussian basis set (UGBS) for relativistic atomic and molecular calculations (11–13). The total DFC energies obtained with our previous universal Gaussian basis set (12, 13) (designated hereafter as UGBSI) for the neutral heavy atoms ($Z > 70$) are within about 30 millihartrees of the corresponding DFC energies obtained with the numerical-finite-difference Dirac–Fock program (14). In this paper we report a universal Gaussian basis set (hereafter referred to as UGBSII) which leads to the DFC energies for the heavy atoms Yb ($Z = 70$), W ($Z = 74$), Pb ($Z = 82$), Ra ($Z = 88$), and Pu ($Z = 94$) within 2 millihartrees or less of the corresponding results obtained with the numerical-finite-difference program (14).

Computational

The relativistic universal Gaussian basis used in this work is generated by employing the integral discretization (ID) technique of the generator coordinate Hartree–Fock (GCHF) method (15, 16). In the GCHF method, the one-electron functions are chosen as integral transforms, viz.,

$$[1] \quad \psi_i(1) = \int \phi_i(1, \alpha) f_i(\alpha) d\alpha, \qquad i = 1, \ldots, n$$

where the ϕ_i, f_i, and α are the generator function, the weight function, and the generator coordinate, respectively. The application of the variational principle to the energy expectation value built with eq. [1] leads to the Griffin–Wheeler–Hartree–Fock (GWHF) equations:

$$[2] \quad \int [F(\alpha, \beta) - \varepsilon_i S(\alpha, \beta)] f_i(\beta) d\beta = 0, \qquad i = 1, \ldots, n$$

The integration of the GWHF equations is performed through integral discretization (ID) (15, 16), which is implemented through a relabelling of the generator coordinate space, α, viz.,

$$[3] \quad \Omega = \frac{\ln \alpha}{A}, \qquad A > 1$$

In the new generator coordinate space, Ω, an equally spaced N-point mesh, Ω_i, is chosen so that one can obtain an adequate numerical integration range for the relativistic $s_{1/2}$, $p_{1/2}$, $p_{3/2}$, $d_{3/2}$, $d_{5/2}$, $f_{5/2}$, and $f_{7/2}$ symmetries for several atoms. The integration range is characterized by a starting point, Ω_{min}, an increment, $\Delta\Omega$, and N (number of points). The same scaling parameter, $A = 6.0$, is used in all the calculations.

The exponents of the relativistic UGBSI and UGBSII used

Atom	E_{DFC} (UGBSI)	E_{DFC} (UGBSII)	Finite-difference[b] (E_{DFC})
Yb	−14067.6609	−14067.6795	−14067.7
W	−16156.2234	−16156.2476	−16156.2484
Pb	−20913.6876	−20913.7165	−20913.7184
Ra	−25027.9732	−25028.0165	−25028.0165
Pu	−29656.4431	−29656.5111	−29656.5122

[a]The basis-set size is the same in both UGBSI and UGBSII for all the atoms, viz., 32*s* 30*p* 20*d* 15*f*.

[b]E_{DFC} computed by using the Oxford numerical-finite-difference Dirac–Fock program (14), except Yb, for which Desclaux's program (17) was used because the Oxford program (14) presents serious convergence problems for a few atomic systems, including Yb.

in this work are generated by using the following discretization parameters in eq [3]:

Symmetry	Ω_{min}	$\Delta\Omega$	N
UGBSI: $s_{1/2}$, $p_{1/2}$, $p_{3/2}$, $d_{3/2}$, $d_{5/2}$, $f_{5/2}$, and $f_{7/2}$	−0.66	0.13	32
UGBSII: $s_{1/2}$, $p_{1/2}$, $p_{3/2}$, $d_{3/2}$, $d_{5/2}$, $f_{5/2}$, and $f_{7/2}$	−0.64	0.12	32

We have used the same basis set size (32*s* 30*p* 20*d* 15*f*) of Gaussian exponents, in both UGBSI and UGBSII, for the $s_{1/2}$, $p_{1/2}$, $p_{3/2}$, $d_{3/2}$, $d_{5/2}$, $f_{5/2}$, and $f_{7/2}$ symmetries. The Dirac–Fock–Coulomb (DFC) self-consistent-field (SCF) calculations with these two sets of universal Gaussian basis functions are performed using the DFC SCF methodology described previously (5). In our calculations we employ the finite-nucleus model of uniform proton-charge distribution and the restricted kinetic balance condition (one-to-one correspondence between the basis functions of the large and small components) (5).

[a]Numerical DFC orbital energies computed by using the Oxford numerical-finite-difference Dirac-Fock program (14).

Results and discussion

The Dirac–Fock–Coulomb (DFC) SCF calculations are performed on the heavy atoms: Yb ($Z = 70$), W ($Z = 74$), Pb ($Z = 82$), Ra ($Z = 88$), and Pu ($Z = 94$). The atomic masses used for Yb, W, Pb, Ra, and Pu are 173.04, 183.85, 207.19, 226.0, and 242.0, respectively. The speed of light used in our DFC SCF calculations is 137.0370 au. In Tables 1 and 2 are collected the starting exponent (α_{min}) and the corresponding Ω_{min} for each $s_{1/2}$, $p_{1/2}$, $p_{3/2}$, $d_{3/2}$, $d_{5/2}$, $f_{5/2}$, and $f_{7/2}$ symmetry of the UGBSI and UGBSII. The universal Gaussian exponents used in the 32*s* 30*p* 20*d* 15*f* UGBSI and UGBSII basis sets are generated using eq [3] and the parameters Ω_{min} and $\Delta\Omega$ in Tables 1 and 2. The results of the total DFC energies obtained with the universal Gaussian basis sets (UGBSI and UGBSII) are presented in Table 3.

It can be seen from Table 3 that the UGBSII yields total DFC energies within 2 millihartrees or less of the corresponding numerical-finite-difference values. However, the UGBSI yields total DFC energies that are within about 25–70 millihartrees of the corresponding numerical-finite-difference results. In particular, for the Ra (Z=88) atom, the total DFC energy obtained with the UGBSII is in excellent agreement with the corresponding numerical value computed with the numerical-finite-difference program (14). In this work we have investigated the best starting exponents (α_{min}) for each symmetry, since it was observed that the inclusion of diffuse functions (corresponding to low exponents) is as important as the addition of functions with higher exponents. In Tables 1 and 2, α_{min} represents for each $s_{1/2}$, $p_{1/2}$, $p_{3/2}$, $d_{3/2}$, $d_{5/2}$, $f_{5/2}$, and $f_{7/2}$ symmetry the best starting

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

exponent for all the atoms studied. It should be mentioned that the inclusion of additional higher exponent functions beyond the UGBS size given in Table 3 does not lead to substantial improvement in the total DFC energies computed with both the UGBSI and UGBSII.

Table 4 displays the DFC orbital energies for Ra (Z=88) obtained with the UGBSI and UGBSII. The last column in Table 4 shows the numerical-finite-difference DFC orbital energies computed with the numerical-finite-difference program (14). It can be seen from Table 4 that the DFC orbital energies of Ra obtained with the UGBSII are in better agreement with the corresponding numerical DFC orbital energies than those obtained with the UGBSI.

Conclusion

The universal Gaussian basis set (UGBSII) presented in this work yields Dirac–Fock–Coulomb energies, for the heavy atoms Yb (Z = 70), W (Z = 74), Pb (Z = 82), Ra (Z = 88), and Pu (Z = 94), within a few millihartrees or less as compared to the corresponding numerical-finite-difference values. The Dirac–Fock orbital energies obtained with the UGBSII for the Ra (Z = 88) atom are in very good agreement with the corresponding numerical Dirac–Fock orbital energies. In conclusion, it can be stated that the UGBSII is a very accurate basis set for relativistic Dirac–Fock atomic calculations, and could be useful in calculating spectroscopic states of atoms and molecules containing heavy atoms.

Diode laser spectrum and rovibrational analysis of the ν_6 band of vinyl fluoride

S. GIORGIANNI, P. STOPPA, M. PEDRALI, AND S. GHERSETTI[1]

Dipartimento di Chimica Fisica, Università di Venezia, D.D. 2137, I-30123 Venice, Italy

Received March 5, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

S. GIORGIANNI, P. STOPPA, M. PEDRALI, and S. GHERSETTI. Can. J. Chem. **71**, 1716 (1993).

The vibration–rotation spectrum of CH_2=CHF has been investigated in the ν_6 band region around 1305 cm^{-1} at Doppler limited resolution using a tunable diode laser spectrometer. The measurements have been performed at low temperature (240 K) to decrease hot band interferences. This fundamental of symmetry species A' gives rise to an **a**/**b** hybrid band, which was mainly composed of **a**-type transitions. Both J and K structures have been resolved in the $^{Q}Q_K(J)$ subbranches and the rovibrational analysis in the P, Q, and R branches has led to the identification of more than 1000 lines with $J \leq 43$ and $K_a \leq 14$. The ν_6 band is affected by first-order **b**-type and second-order **a**-type Coriolis resonances with the $\nu_9 + \nu_{11}$ combination, and the perturbation effect has been found stronger for the $K'_a = 11$ level. About 870 transitions free of major resonance contributions were fitted using Watson's A-reduction Hamiltonian in the I^r representation, and a set of effective rotational and quartic centrifugal distortion constants was determined for the $v_6 = 1$ state of CH_2=CHF.

S. GIORGIANNI, P. STOPPA, M. PEDRALI et S. GHERSETTI. Can. J. Chem. **71**, 1716 (1993).

On a étudié le spectre de vibration–rotation du CH_2=CHF dans la région de la bande ν_6 à environ 1305 cm^{-1} à une résolution limitée de Doppler en utilisant un spectromètre au laser à diode adressable. On a effectué ces mesures à basse température (240 K) pour diminuer les interférences dues à la bande chaude. Cette vibration de symétrie des espèces A' donne une bande hybride **a**/**b** composée principalement de transitions de type **a**. On a résolu les structures J et K dans les sous branches $^{Q}Q_K(J)$ et l'analyse rotavibrationnelle dans les branches P, Q et R a permis d'identifier plus de 1000 lignes avec $J \leq 43$ et $K_a \leq 14$. La bande ν_6 est affectée par les résonances de Coriolis d'ordre un de type **b** et d'ordre deux de type **a** avec la combinaison $\nu_9 + \nu_{11}$ et on a trouvé un effet de perturbation plus grand pour le niveau $K'_a = 11$. Environ 870 transitions libres de toute contribution de résonance significative sont adjustées en utilisant l'Hamiltonien de réduction A de Watson dans la représentation I^r et on a déterminé un ensemble de constantes effectives de distorsion centrifuge quartique et rotationnelle pour l'état $v_6 = 1$ du CH_2=CHF.

[Traduit par la rédaction]

Introduction

In the last few years, there has been continued progress in spectroscopic studies of vinyl fluoride motivated, in part, by its potential importance in atmospheric chemistry. This compound, which plays a significant role in photochemical processes (1, 2), is mainly employed as a monomer for the production of synthetic resins such as polyvinyl fluoride, and its release is accidental. Knowledge of the rovibrational spectrum and determination of accurate spectroscopic parameters are essential for detecting trace gases of this molecule; for this purpose high-resolution measurements are the best source of information.

Recently, we began an infrared study, under high resolution, of small halogenated molecules containing the >C=C< group, and different investigations concerning selected bands of CH_2=CF_2 and CH_2=CHCl have already been carried out (3–5). In the present work the diode laser measurements have been extended to the ν_6 band of CH_2=CHF lying near 1305 cm^{-1}; little is known, on the other hand, of the vibrational behaviour of this compound, for which no high-resolution results are available to date.

Studies on low-resolution infrared spectra were performed much earlier (refs. 6–8 and references quoted therein), and all the fundamentals together with some combination bands seem to have been already characterized. The analysis of medium-resolution spectra in the region 800–1000 cm^{-1} led to establishment of a Coriolis interaction between the ν_8, ν_{10}, and ν_{11} modes and to a calculation of the related coupling constants (9). Microwave spectra were measured many years ago (10, 11) and, again, more recently (12). The effect of jet cooling on the complex ν_8, ν_{10} band system near 936 cm^{-1} has also been investigated using diode laser spectoscopy (13). The theoretical and experimental structures of this molecule were recently derived using *ab initio* calculations and a reanalysis of existing microwave data (14).

The present paper deals with the results of Doppler-limited measurements of the ν_6 band of CH_2=CHF using a tunable diode laser spectrometer, and the interpretation of the Coriolis interaction mechanism.

Experimental

The sample of CH_2=CHF (purity ≃ 99%) was obtained commercially from Peninsular Chemical Research, Inc. and was used without further purification. The high-resolution spectra were recorded in the range 1280–1333 cm^{-1} using the tunable diode laser at the University of Venice, a brief description of which is given here.

The arrangement of the spectrometer is mainly based on the SP-5000 assembly of Laser Analytics, Inc. The crystal diode is mounted in a closed-cycle cryogenic refrigerator and a temperature stabilizer maintains the required temperature in the range 10–70 K. The output frequency is coarsely controlled by changing the temperature of the diode, and the fine adjustment of the frequency is provided by a variable and precisely tunable current for the diode, producing different laser modes. A sweeping current is used to continuously scan a laser mode.

In the present version the spectrometer setup is in a triple-beam configuration, which allows simultaneous recording of the sample spectrum, the calibration lines, and the interference fringes from a 2.59-cm solid germanium etalon (FSR ≃ 0.0475 cm^{-1}). The instrument is interfaced to a 286 PC that provides data acquisition, storage, and conversion into transmittance of the spectra.

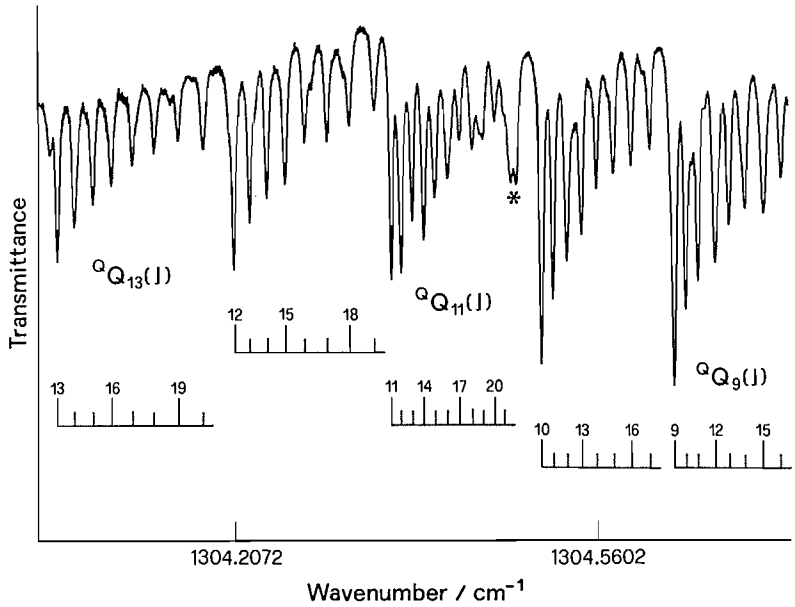

FIG. 1. A section of the central part of the Q-branch spectrum of the CH_2=CHF ν_6 band (T = 240 K, $P \simeq 1$ mbar, 49 cm cell) indicating the J assignment of the $^{Q}Q_9(J) - {}^{Q}Q_{13}(J)$ manifolds. Note the narrow spacings between the perturbed components in the $^{Q}Q_{11}(J)$ series and the unresolved peak marked by an asterisk including the transitions with J = 22–26.

The measurements were performed at pressures ranging from 1 to 3 mbar (1 bar = 100 kPa) with a 49 cm long absorption cell cooled to 240 K to reduce the interferences arising from hot bands. Absolute calibration of the spectra was based on the wavenumbers of well-known N_2O lines (15), and selected SO_2 transitions were measured on an FTIR spectrometer as described in ref. 16; the relative calibration was obtained using the germanium etalon patterns. The absolute wavenumber accuracy is estimated to be of the order of 0.001 cm^{-1} and the internal consistency within the same laser mode is better than 0.0005 cm^{-1}.

Analysis and perturbations

Vinyl fluoride is a planar molecule belonging to the symmetry point group C_s; the 12 fundamentals are distributed in the vibrational irreducible representation as 9 of species A' (ν_1–ν_9) and 3 of species A'' (ν_{10}–ν_{12}). The molecular symmetry plane contains the a and b axes, while the remaining c axis is perpendicular to it. Thus the A' vibrations will give rise to **a**/**b** hybrid bands though one of the components might be much weaker than the other, and the A'' modes will produce pure **c**-type bands. Since this molecule is a nearly prolate symmetric top (κ = −0.945) the structure of the absorptions would correspond to that of parallel (**a**-type) and perpendicular (**b**- and **c**-type) bands. The ν_6 vibration (≃1305 cm^{-1}), mainly due to the C=CH deformation mode, is of symmetry species A' and exhibits a predominant **a**-type envelope. Following the selection rules (ΔJ = 0, ±1; ΔK_a = 0; ΔK_c = ±1) several types of transitions are expected in the P, Q, and R branches, which are composed by even and odd subbands depending on ($K''_a + K''_c = J''$) or ($K''_a + K''_c = J'' + 1$), respectively.

A convenient starting point for the analysis of the spectrum is represented by the interpretation of the Q-branch features. The band center is dominated by a series of ^{Q}Q subbranches consisting of groups of lines that begin to show the fine structure as one moves away from the origin toward lower wavenumbers. The individual groups are defined by a K_a value and within each cluster the resolved J components progress from the most intense line ($J = K_a$) toward higher wavenumbers until they blend into the neighbouring block. As an example, a portion of the Q-branch spectrum containing the $^{Q}Q_9(J)$–$^{Q}Q_{13}(J)$ manifolds is depicted in Fig. 1, where the J assignment is also presented. As can be seen, the fine structure in the $^{Q}Q_{11}(J)$ cluster does not reflect a regular displacement and the observed irregularity indicates the existence of perturbations. In particular, unlike the behaviour in the other groups, the J components gradually shift toward lower wavenumbers with increasing J until they overlap for $J \simeq 22$, which means that the upper levels are depressed in energy by interaction effects; the wavenumbers of the more perturbed transitions (K_a = 10–12) are included in Table 3 (see later).

The analysis of the Q-branch data provided an approximate set of the ν_6 band parameters, which, when combined with the ground state constants from ref. 11, allowed prediction of a number of transitions in the P and R branches. From single subband analyses it appeared clear that significant deviations from the expected positions occur even for lines with different K_a values and not only for transitions with K_a = 11; the discrepancies become larger with increasing J, thus indicating a J-dependent resonance.

From symmetry considerations it follows that A' and A'' modes may interact through **a** as well as **b** Coriolis resonances, while vibrations having the same symmetry interact by a **c** Coriolis perturbation. In the range investigated the ν_6 vibration (≃1305 cm^{-1}) appears relatively isolated from other modes, with the exception of the $\nu_9 + \nu_{11}$ combination (A'') lying at about 1345 cm^{-1}. Although we have no direct observation for the latter band, it can couple with the fundamental mode via **a**- and **b**-type Coriolis resonances. In a first-order perturbation, the former involves rotational levels with the same J and K_a values while the latter links levels with the same J and with K_a values differing by ±1.

Assuming the same A and $\bar{B}$ values for the ground and the excited states, and considering a separation of about 40 cm^{-1}

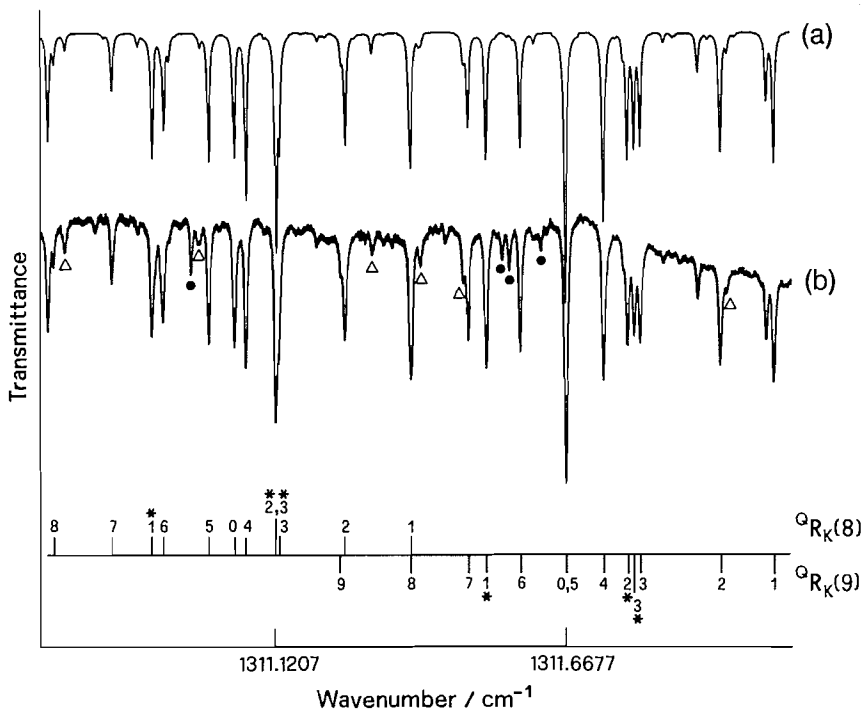

FIG. 2. A portion of the R-branch spectrum of the CH_2=CHF ν_6 band near 1311.5 cm^{-1} showing the K_a structure of the series $^{Q}R_K$ (8,9); asymmetry splitting is observed and transitions marked by an asterisk refer to the odd component. (*a*) Simulated spectrum. (*b*) Experimental spectrum (T = 240 K, $P \simeq$ 1.5 mbar, 49 cm cell); (△) lines due to the weak **b**-type component; (●) features very likely due to a different band.

between the ν_6 and the $\nu_9 + \nu_{11}$ vibrations, calculations in the prolate symmetric top limit indicate that the K_a levels of ν_6 come close to and cross the $(K_a - 1)$ levels of $\nu_9 + \nu_{11}$. In particular, from the reduced energy level scheme it appears that the K_a = 11 and 12 levels of ν_6 are just below and above the K_a = 10 and 11 levels of $\nu_9 + \nu_{11}$, respectively. These states are then expected to be most seriously influenced by a first-order **b** Coriolis resonance. Effects due to a first-order **a** Coriolis interaction seem to be of little significance, the energy levels with the same K_a value of the vibrations involved being widely spaced. Interestingly, a localized perturbation due to a second-order **a** Coriolis resonance with $\nu_9 + \nu_{11}$ is expected to occur for K_a = 7 and 8 levels of ν_6, which are slightly higher in energy than the K_a = 5 and 6 levels, respectively, of the former vibration. Since this interaction is of high order, it should produce only significant energy shifts under conditions of near-resonance.

The spectrum exhibits in most regions a structure similar to that observed in a parallel band of a symmetric top, and the $^{Q}P_K(J)$ and $^{Q}R_K(J)$ subbranches are composed of a series of transitions proceeding toward higher wavenumbers with decreasing K_a. A typical example is illustrated in Fig. 2, where a section of the R branch near 1311 cm^{-1} with the assignment of the K_a structure in the $^{Q}R_K(8,9)$ manifolds is reported. The effect of the asymmetry splitting can be seen in an irregular numbering of the lines with low K_a values; transitions with K_a = 1, 2 are widely split, with the even component lying on the higher wavenumber side. Lines arising from the **b**-type component are very weak and, since the identification in most of the cases becomes very difficult because of the overlap of the much stronger features from the **a**-type band, no rotational analysis has been attempted. Nevertheless, as can be observed in the upper trace of Fig. 2, the **b**-type characteristics appear well reproduced in the synthetic spectrum, generated with the molecular constants reported later.

Not surprisingly, when the J value increases the different subbands begin to run into one another and the fine structure becomes more difficult to identify; due to a larger asymmetry effect, the transitions with low K_a value give rise to spreading lines without exhibiting any regular pattern. A portion of the P branch near 1286 cm^{-1} showing the displacement of the K_a structure in the $^{Q}P_K(29,30)$ subbranches is illustrated in Fig. 3. As can be seen, the relatively small splitting for K_a = 6 increases strongly for K_a = 2 in $^{Q}P_K(30)$; in contrast to what was found in the R branch, the even component lies here at the lower wavenumber side. To show how well the determined parameters (see later) reproduce the observed characteristics, the wavenumbers of the assigned transitions occurring in the range of Fig. 3 are listed in Table 1, together with their residuals and the corresponding weights.

Results and discussion

The ground and excited rotational energy levels were computed employing the Watson's *A*-reduction Hamiltonian in the I^r representation,

$$\mathbf{H} = 1/2(B + C)\mathbf{P}^2 + [A - 1/2(B + C)]\mathbf{P}_a^2 - \Delta_J\mathbf{P}^4 - \Delta_{JK}\mathbf{P}^2\mathbf{P}_a^2 - \Delta_K\mathbf{P}_a^4 + \Phi_J\mathbf{P}^6 + \Phi_{JK}\mathbf{P}^4\mathbf{P}_a^2 + \Phi_{KJ}\mathbf{P}^2\mathbf{P}_a^4 + \Phi_K\mathbf{P}_a^6 + [1/2(B - C) - 2\delta_J\mathbf{P}^2 + 2\varphi_J\mathbf{P}^4](\mathbf{P}_b^2 - \mathbf{P}_c^2) + [(-\delta_K\mathbf{P}_a^2 + \varphi_{JK}\mathbf{P}^2\mathbf{P}_a^2 + \varphi_K\mathbf{P}_a^4), (\mathbf{P}_b^2 - \mathbf{P}_c^2)]_+$$

where $\mathbf{P}$, $\mathbf{P}_a$, $\mathbf{P}_b$, and $\mathbf{P}_c$ are the operators of the total angu-

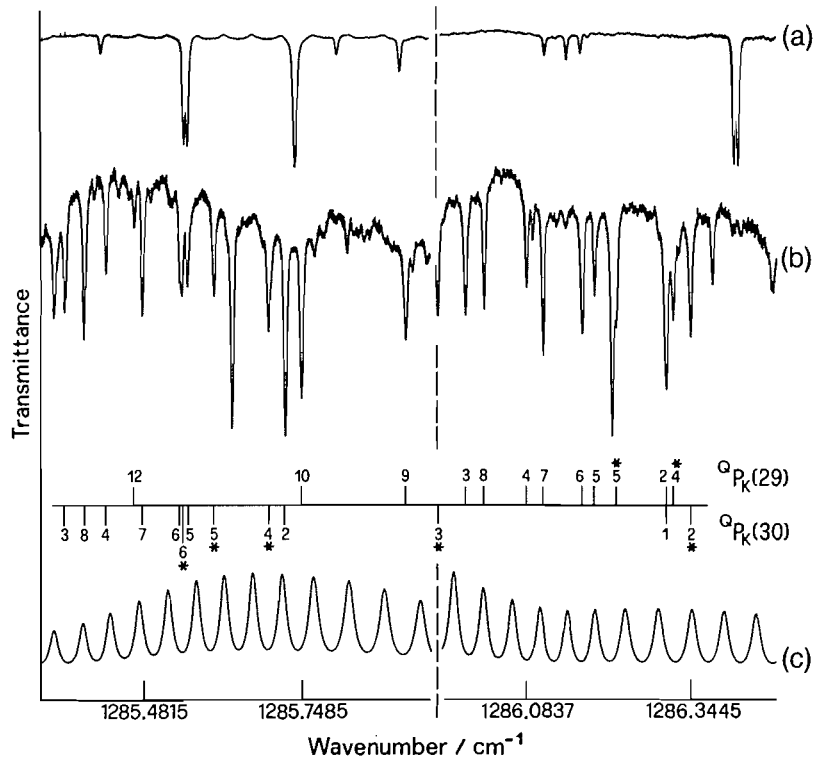

FIG. 3. Details of the P-branch spectrum of the CH_2=CHF ν_6 band around 1286 cm^{-1} exhibiting two consecutive laser modes. The K_a structure of the $^{Q}P_K(29,30)$ clusters is indicated; transitions marked by an asterisk belong to the odd component. (*a*) N_2O calibration lines; (*b*) experimental spectrum (T = 240 K, $P \simeq 3$ mbar, 49 cm cell); (*c*) germanium etalon patterns. Frequency scale is not precisely linear owing to nonlinear variation of diode laser emission frequency with injection current.

lar momentum and its components along the principal inertial axes.

The rovibrational analysis was performed according to commonly used procedures and the assignment of the structure was started, as previously mentioned, in the Q-branch region, where in most of the clusters regular absorption line patterns can be easily recognized. Preliminary line assignments were fitted by a least-squares routine, keeping the ground state constants fixed and refining the excited vibrational state parameters together with the band origin. Once the first set of upper state constants had been obtained, the analysis proceeded iteratively with additional identifications, revision of constants, and prediction of new transitions. However, such a standard procedure did not work well for all the assignments because of the perturbation effects, and even single subband fits for some K_a values yielded poor results.

From the present analysis about 1030 transitionos with $J \leq 43$ and $K_a \leq 14$ of the subbranches $^{e,o}P(0,-1)$, $^{e,o}R(0,1)$, and $^{e}Q(0,1)$ were identified. In absence of asymmetry splitting the assigned lines comprise only the set of even transitions; inclusion in the fit of the remaining odd transitions did not yield any substantial improvement in the molecular constants.

In the choice of the ground state parameters we preferred the set of Gerry (11) to the more recent one of Hayashi and Inagusa (12); the former was derived using the Watson *A*-reduction Hamiltonian, while the latter was obtained in the Watson *S*-reduction expression. In particular, the constants of ref. 11, computed from a set of transitions with J ($\leq$40) and K_a ($\leq$8) values much higher than those of ref. 12, also include the sextic coefficients, some of which, not significantly determined, are substantially fitting parameters. Noting that the J and K_a values reached in the present assignments are higher than those employed in ref. 11, we attempted to improve the sextic terms for the ground state by performing a simultaneous fit of the ν_6 combination differences and the available microwave data. Since the $^{Q}P_K(J)$ and $^{Q}R_K(J)$ even transitions reach the upper level for which $K'_a + K'_c = J'$, in order to also obtain combination differences with Q-branch lines, we considered the set of $^{Q}Q_K(J)$ odd transitions, which in this case are coincident with the assigned even ones because of the absence of asymmetry splitting. Unfortunately, the low number of combinations with $J > 40$ and $K_a > 8$ and the greater accuracy of the microwave transitions, weighted 10^4 times the infrared data, did not allow a better determination of the sextic coefficients than that of ref. 11; therefore, a substantial improvement in the uncertainty of the constants can be reached only when combinations with much higher J and K_a values are available.

The assigned transitions, with the exception of those considered more strongly perturbed, were employed to determine the spectroscopic parameters of the ν_6 vibration. Unit weight was given to lines appearing as single transitions, while blended or scarcely resolved features were given a weight factor of 0.1. In the refinement procedure the ground state parameters were kept fixed, and only the band origin and the excited state constants were allowed to change. The variation of the sextic distortion terms led to poorly determined values without any significant improvement in the standard deviation of the fit; on this basis, the sextic coefficients were constrained to their ground state values. The

$\Phi_J \times 10^{12} = -0.3$, $\Phi_{JK} \times 10^{11} = -0.2$, $\Phi_{KJ} \times 10^9 = -0.14$, $\Phi_K \times 10^8 = 0.12$, $\varphi_J \times 10^{12} = 0.21$, $\varphi_{JK} \times 10^{10} = -0.22$, $\varphi_K \times 10^8 = 0.13$[c]

[a]Uncertainties given are one standard deviation in units of the last digit quoted.
[b]Constants from ref. 11.
[c]Ground state sextic coefficients (11) fixed for the upper level.

effective constants for the ν_6 state, derived from the final fit of about 870 lines ($\sigma \simeq 7 \times 10^{-4}$ cm^{-1}), are reported in Table 2; the rotational and quartic centrifugal distortion parameters are reasonably close to their ground state values, and hence the transitions included in the fit do not seem to be much affected by perturbations.

Significant and systematic differences in the residuals occur for several lines of different subbands and this effect has been ascribed to the Coriolis resonance with the $\nu_9 + \nu_{11}$ state. In particular, the first-order **b** Coriolis perturbation becomes stronger near the crossing, where the $K'_a = 10$, 11 levels are depressed in energy and the $K'_a = 12$, 13, 14 levels are pushed up. It is worthy of note that within each subband the interaction effect becomes stronger as J increases and no crossing has been observed in the features identified. This behaviour can be clearly observed in Table 3, which reports the wavenumbers of the assigned transitions having the upper level with $K'_a = 10$, 11, and 12; the largest discrepancies between observed and calculated values occur for $K'_a = 11$ ($J' = 26$) and $K'_a = 12$ ($J' = 31$) with $\Delta_{max} = -0.204$ and 0.048 cm^{-1}, respectively. Besides, the positive residuals for the $K'_a = 7$, 8 levels with J' values higher than 21 and 29, respectively, are explained by the second-order **a** Coriolis

TABLE 3. Assigned transitions with K'_a = 10, 11, and 12 of the ν_6 band of CH_2=CHF

[a]Asterisk indicates perturbed transition not used in the fit.
[b]O–C is (Obs. − Calc.) in cm^{-1}.

resonance still with the $\nu_9 + \nu_{11}$ state; the major interaction effect ($\Delta \simeq 0.012$ cm^{-1}) is observed for $K'_a = 7$ ($J' = 35$). However, because of different resonances occurring in this region and their counteracting effects, further transitions with different K_a values exhibiting a regular structure can be actually perturbed.

A complete list of all the assigned transitions is reported in the Appendix.

In conclusion, the rovibrational analysis of the ν_6 band of CH_2=CHF has led to the assignment of many transitions up to high J and K_a values, and to the determination of a set of effective molecular parameters. The observed irregularities

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

in the rotational structure have been attributed to perturbations with the $\nu_9 + \nu_{11}$ vibration, and the interaction mechanisms are consistent with the first-order **b**-type and the second-order **a**-type Coriolis resonances; moreover, the sense of the residuals suggests a value of 1345 ± 1 cm^{-1} for the band origin of the perturber $\nu_9 + \nu_{11}$. The simulated spectra, considering the intensities of contributions of **a**- and **b**-type components to be about 85 and 15%, respectively, agree quite well with the observed characteristics (see Fig. 2); this is clear evidence of the good accuracy of the parameters obtained in the present analysis.

Raman spectral studies of solutions at elevated temperatures and pressures. 13. Sodium formate – water

RICHARD J. BARTHOLOMEW AND DONALD E. IRISH[1]

Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Waterloo, Waterloo, ON N2L 3G1, Canada

Received March 16, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

RICHARD J. BARTHOLOMEW and DONALD E. IRISH. Can. J. Chem. **71**, 1728 (1993).

Raman spectra of the formate anion in water (H_2O and D_2O) have been measured for four concentrations under ambient conditions and for two concentrations at temperatures ranging from 49 to 239°C and a pressure of 10 MPa. Five of the six fundamental modes of vibration are polarized. This result is inconsistent with C_{2v} symmetry. The Fermi resonance doublet clearly results from the interaction of $2\nu_5$ and ν_1. The latter mode decreases in frequency as the temperature rises, thus increasing the coupling and hence the intensity of the $2\nu_5$ component. The coupling constant, W, and the positions of the unperturbed bands $2\nu_5^0$ and ν_1^0 have been calculated. No evidence to support a bifurcated structure for the solvated anion was found.

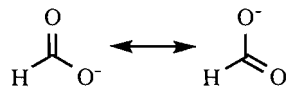
RICHARD J. BARTHOLOMEW et DONALD E. IRISH. Can. J. Chem. 71, 1728 (1993).

On a mesuré le spectre Raman de l'anion formiate dans l'eau (H_2O et D_2O), à quatre concentrations dans les conditions ambiantes et à deux concentrations à des températures allant de 49 à 239°C et à une pression de 10 MPa. Cinq des six modes de vibration fondamentaux sont polarisés. Ce résultat n'est pas en accord avec une symétrie C_{2v}. Le doublet de la résonance de Fermi résulte clairement d'une interaction de $2\nu_5$ et de ν_1. La fréquence de ce dernier mode diminue lorsqu'on augmente la température; il en résulte un couplage plus important et, en conséquence, une plus grande intensité de la composante $2\nu_5$. On a calculé la constante de couplage, W, et les positions des bandes $2\nu_5^0$ et ν_1^0 non perturbées. On n'a trouvé aucune indication pouvant suggérer l'existence d'une structure bifurquée pour l'anion solvaté.

[Traduit par la rédaction]

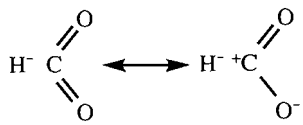
Introduction

The formate anion is frequently viewed as being a symmetric (C_{2v} symmetry) resonance hybrid of two important canonical forms:



I **II**

In sodium formate crystal the formate anion lies on a C_2 axis and has C_{2v} symmetry; the C—O bond length is 124.6 pm and the O—C—O bond angle is 126.3°. The electron distribution suggests that structures of the types:



III **IV**

also contribute to the overall structure (1).

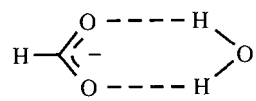
For solutions the traditional view of the symmetry of the formate ion (C_{2v}) has been challenged by Spinner (5, 6). He has argued that the ion exists not as a resonance hybrid but as two rapidly interconverting structures (**I** and **II**), undetectable on the NMR or X-ray time scales. Thus, he favours a C_s structure with two distinguishable vibrations, C—O and C=O. The evidence for this proposal rests largely on the number of polarized Raman bands. The vibrational representations for the two models are

$$C_s\colon \Gamma_{vib} = 5A' + A''$$

$$C_{2v}\colon \Gamma_{vib} = 3A_1 + 2B_1 + B_2$$

In both cases all modes are Raman active, but for C_s symmetry five bands are polarized, whereas for C_{2v} symmetry only three bands are polarized. Spinner observed five polarized bands (6). He suggested that medium effects and interionic forces are not responsible for this because they are not sufficiently strong and asymmetric for the two oxygen atoms to be in different environments.

In aqueous solution the water molecules near the formate anion can be expected to interact via hydrogen bonding and dipole–ion interactions and could conceivably introduce some distortion. Calculations (2–4) of the interaction between water and formate ion suggest that a bifurcated structure:



is more stable than a "traditional" linear hydrogen bond for a one-to-one interaction. It is dangerous, however, to extrapolate this result to infer the molecular arrangement of aqueous solutions. In fact, for dilute solutions Jorgensen and Gao (4) calculated a primary hydration number of 11 for the formate anion.

We felt the conclusions of Spinner (5, 6) were sufficiently radical that a further investigation was warranted. In particular, by raising the temperature, one can anticipate changing the forces between the anion and its surroundings; spectral changes might occur that could further elucidate the problem. In addition, from a practical point of view, it is now known that organic impurities in high-temperature fluids contribute to local corrosion in the tubes of boiler plants. Acetate, formate, and lactate ions have been identified (7).

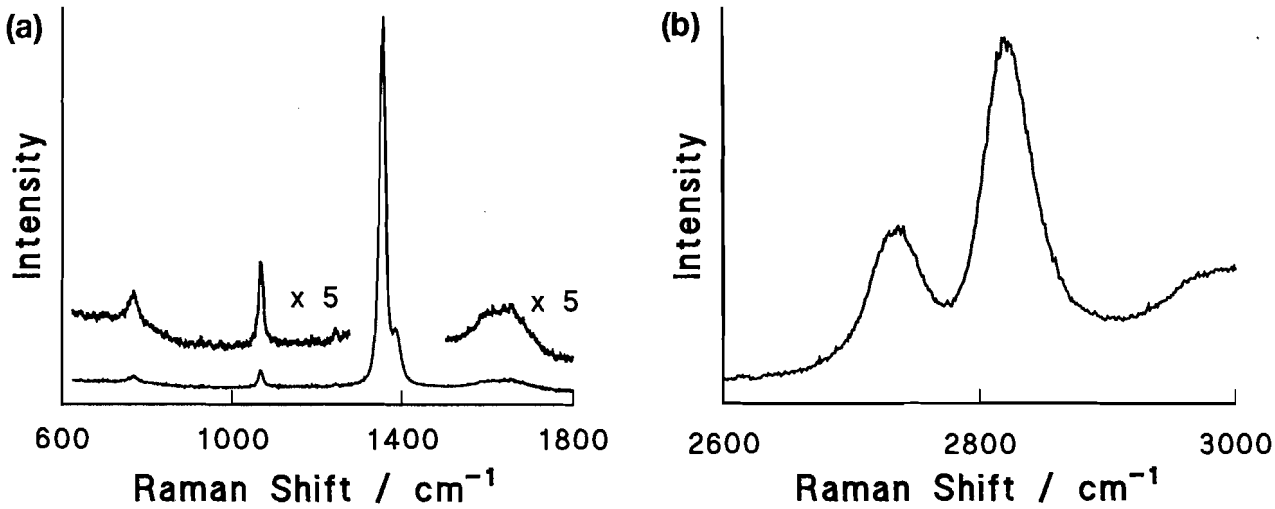

FIG. 1. Survey spectra of 5.6 *m* $NaHCOO/H_2O$ at room temperature. (The envelope at ca. 1600 cm^{-1} includes the 1638 cm^{-1} ν_2 bend of H_2O.)

Our interest in these technically important systems, as evident from our previous publications on Raman spectral studies of acetic acid (8) and acetate salts (9, 10) at elevated temperatures and pressures, was further motivation for this study of sodium formate in water. While several Raman spectral studies of aqueous formate have been conducted (5, 6, 11, 12), none, to our knowledge, has been performed at elevated temperatures and pressures. Our spectra were collected at various temperatures ranging from ambient to 239°C. Evidence of decomposition dictated the upper temperature limit.

Experimental

Sodium formate was supplied by Aldrich and had a stated purity of greater than 99%. No further purification was conducted. Sodium deuteroformate was obtained from M.S.D. Laboratories and had a stated purity of better than 99%. Again, no further purification was performed. Solutions were prepared on a molal scale (moles per kilogram of solvent). This is preferred for high-temperature work because the molal scale is independent of density. Either deionized Milli-Q water or D_2O (M.S.D. Laboratories 99.9% deuterium oxide) was used.

The construction and use of the high-pressure apparatus, capable of reaching pressures of 15 MPa, has been described previously (13). High temperatures were achieved with a furnace (13) connected to an LFE Corp. Series 128-10 temperature controller. The temperature was measured using a Chromel–Alumel thermocouple connected to a Fluke 8800a digital multimeter. Equilibration times were approximately 20–25 min at each temperature.

A Jarrell–Ash spectrometer with a 1.0-m Czerny–Turner scanning double monochromator with a digital cosecant stepping drive was used. The detector was a thermoelectrically cooled R.C.A. 31034 photomultiplier tube. Control of the monochromator and acquisition of spectral data were by an IBM PS/2 computer. Excitation was achieved by a Spectra-Physics model 165-08 laser operating at either 488.0 nm or 514.5 nm. The exciting wavelength sometimes had to be changed to avoid coincidence between laser plasma lines and vibrational bands of the sample. Powers, measured at the laser head with a Coherent model 210 power meter, ranged from 500 to 900 mW depending on the nature of the sample and the particular experiment. Late in the research some of the measurements were repeated at higher laser power, 1500 mW, using a Coherent Innova 305 laser. The mechanical slit width was set at 200μm. Depolarization measurements were made with a Polaroid analyser and a Karl Lambrecht polarization scrambler, mounted between the collection lens and the slits. For room temperature experiments, spectra were collected using melting point capillary tubes as sample cells.

Data manipulation was carried out on PCs with software written in our laboratory. The fitting of overlapping bands was performed using software based on the routine of Pitha and Jones (14) with modifications by Murphy and Bernstein (15). This routine approximates a Raman band as the product of Gaussian and Lorentzian contributions.

Results and discussion

Survey spectra (collected at room temperature) for solutions of 5.6 *m* $NaHCOO/H_2O$, 6.0 *m* $NaDCOO/D_2O$, and 5.3 *m* $NaHCOO/D_2O$ are shown in Figs. 1–3. Most of the bands are quite weak and thus study was limited to the stronger bands. This was especially necessary at elevated temperatures and pressures where the sample cells were much thicker and signals from weak bands were diminished.

The assignment of the aqueous formate anion spectrum is based on the study of Ito and Bernstein (12) and is given in Table 1. They assumed a C_{2v} symmetry. They did not report a Raman band for ν_4, the O—C—O asymmetric stretch (implied by C_{2v}); this is a weak band masked by $\nu_2(H_2O)$ but it is strong in the infrared. Spinner (5, 6) based his discussion on the assumption of C_s symmetry and the assignments implied by his analysis are given in parentheses in Table 1. He reported all six bands in the Raman spectrum. For the purposes of discussion we shall use Ito and Bernstein's assignment.

For 5.6 *m* $NaHCOO/H_2O$, the ν_4 band is extremely weak and broad and cannot be clearly distinguished from the scissoring band of H_2O. Spinner (6) assigned a frequency of ~1591 cm^{-1} to this vibration. For D_2O solvent the band is isolated and occurs at 1597 cm^{-1} (1587 cm^{-1} for $DCOO^-/D_2O$). On deuteration the C—H in-plane bend (ν_5), which is seen as a shoulder at 1381 cm^{-1} in Figs. 1 and 2, shifts to 1025 cm^{-1} (Fig. 3). The C—H out-of-plane bend (ν_6) at 1063 cm^{-1} appears to be the weak feature at 915 cm^{-1} (see Fig. 3) for the isotopomer.

The doublet at 2733 and 2819 cm^{-1} is attributed to a Fermi resonance. A characteristic Fermi resonance doublet occurs in this spectral region for aldehydes (16). It is believed to

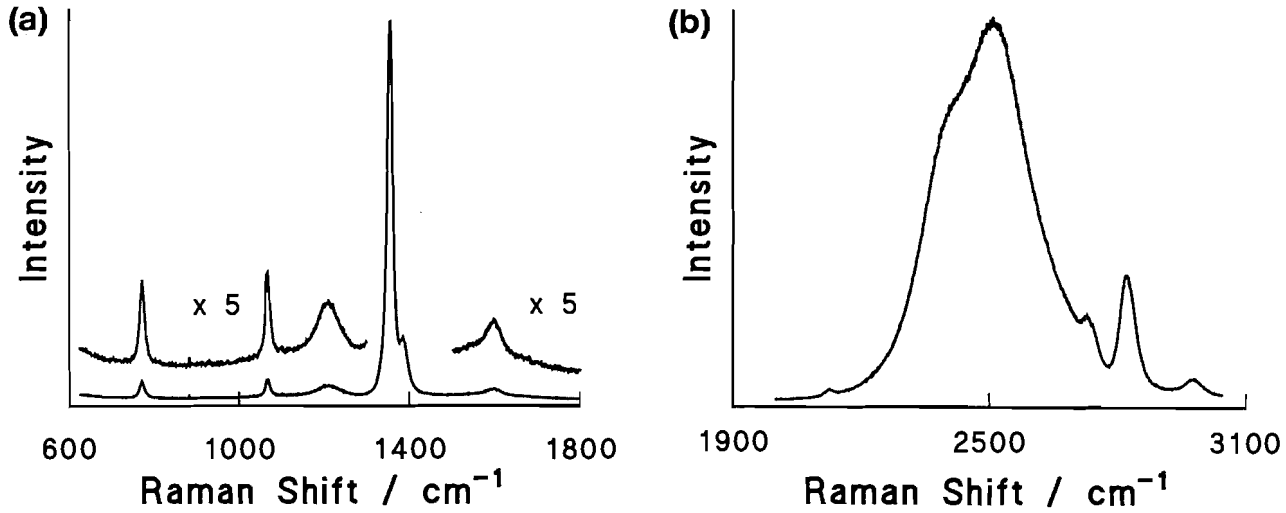

FIG. 2. Survey spectra of 5.9 *m* NaHCOO/D_2O at room temperature. (The band at 1202 cm^{-1} is ν_2 (D_2O).)

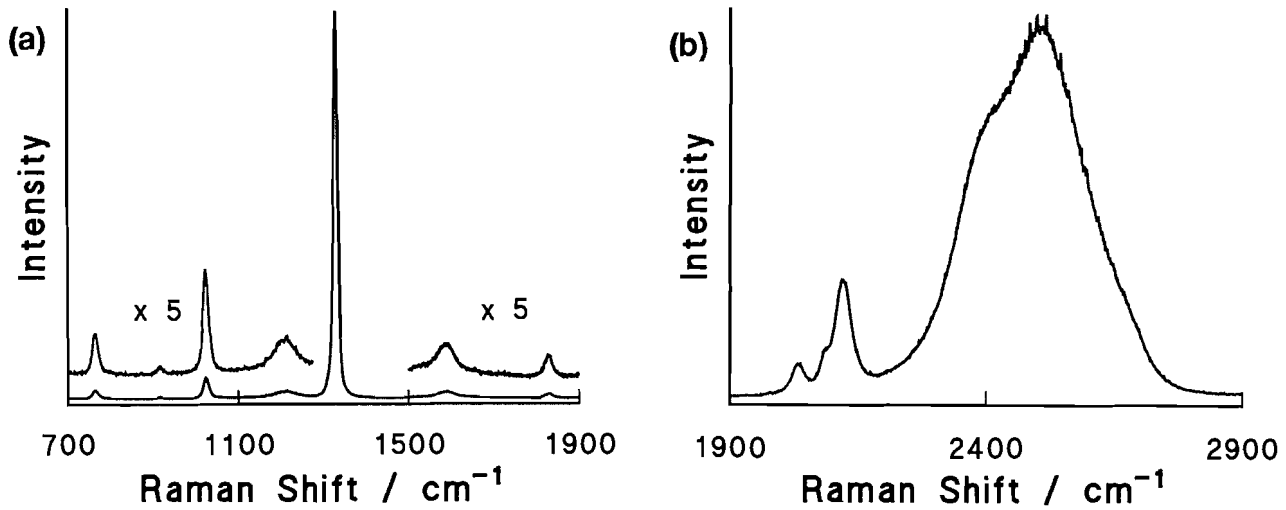

FIG. 3. Survey spectra of 6.0 *m* NaDCOO/D_2O at room temperature. (The band at 1202 cm^{-1} is ν_2 (D_2O); the band at 1829 cm^{-1} is tentatively assigned to $2\nu_6$.)

arise from interaction between the C—H stretch and the first overtone of the in-plane C—H bending vibration ($2 \times \nu_5$). The assignment also applies to the formate ion. On exchanging deuterium for hydrogen the doublet is shifted downward to 2028 and 2113 cm^{-1} and the resonance condition is maintained, indicating that both vibrations involve a C—H (or C—D) bond, thus excluding a resonance between $2\nu_2$ and ν_1.

Effect of concentration

Spectra were collected for solutions of NaHCOO in H_2O at concentrations of 9.5 *m*, 5.6 *m*, 2.7 *m*, and 1.3 *m*. Between 675 and 1800 cm^{-1} no significant changes in band positions or in band shapes occurred. Between 2900 and 3900 cm^{-1} (Fig. 4) the broad Raman band profile from the hydrogen-bonded O—H oscillators of water changes significantly. As the concentration rises, there is a decrease in the intensity of the broad shoulder (~3240 cm^{-1}) attributed to hydrogen bonding structure relative to the peak at 3400 cm^{-1}, an effect characteristic of "structure breakers" (17). A structure breaker is an ion that decreases the intermolecular coupling between water molecules. Common structure breakers include BF_4^- (17), I^- (17), and ClO_4^- (18).

Polarization studies

Polarization measurements were conducted on the fundamental vibrations and on the Fermi resonance doublet of the formate anion for several solutions that differed in concentration and solvent. An attempt to measure the parallel and perpendicular spectra at elevated temperatures and pressures, with sufficient quality, proved impractical. The solvent was changed to avoid the overlapping of solvent bands with bands of the formate anion: to measure ρ for ν_2, ν_3, ν_4, ν_5, and ν_6, D_2O was used as the solvent; to measure ρ for the Fermi resonance doublet, H_2O was used as the solvent. Polarization studies of neat CCl_4 were conducted to check the orientation of the polarization analyzer and the following average depolarization ratios were obtained:

$$\rho(216\ \text{cm}^{-1}) = 0.77;\ \rho(312\ \text{cm}^{-1}) = 0.78;$$

$$\rho(459\ \text{cm}^{-1}) = 0.03$$

These compare favourably with the theoretical values of 0.75, 0.75, and 0, respectively, and the values 0.758, 0.751, and 0.0039, respectively, reported by Murphy et al. (19). The depolarization ratios obtained from the various formate solutions are summarized in Table 2.

TABLE 1. Vibrational assignments for aqueous NaHCOO[a]

Assignment	Description	Position/cm^{-1}		
		5.6 m NaHCOO/H_2O	5.3 m NaHCOO/D_2O	6.0 m NaDCOO/D_2O
ν_3 (ν_5)	OCO scissoring	764	768	759
ν_6 (ν_6)	C—H out-of-plane bend	1063	1060	915
ν_2 (ν_4)	C—O sym. str. (C—O^- str.)	1350	1350	1324
ν_5 (ν_3)	C—H in-plane bend	1381	1379	1025
ν_4 (ν_2)	C—O asym. str. (C=O str.)	[b]	1597	1587
$2\nu_5$,[c] ν_1 ($2\nu_3$, ν_1)	Fermi resonance doublet	2733, 2819	2727, 2818	2028, 2113

[a]Assignments after ref. 12; the assignments of ref. 6 are presented in parentheses.
[b]Weak, partially masked by ν_2 (H_2O).
[c]Originally assigned to $\nu_2 + \nu_5$ in ref. 12.

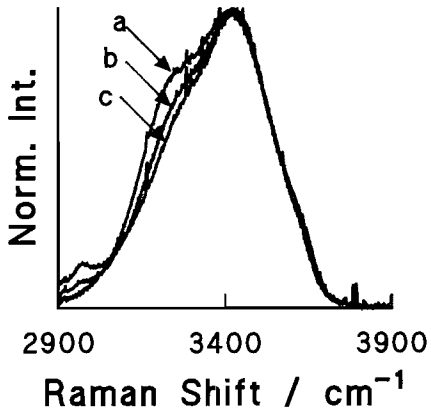

FIG. 4. Effect of $HCOO^-$ concentration on the shape of the OH stretching profile of water: (*a*) 0.63 *m*; (*b*) 2.7 *m*; (*c*) 9.5 *m*.

The results for 5.3 *m* NaHCOO/D_2O and 5.9 *m* NaHCOO/H_2O show that ν_2, ν_3, ν_4, ν_5, and both bands of the Fermi resonance doublet are polarized ($\rho < 0.75$) and ν_6 is depolarized. The depolarization ratios do not change significantly with increasing concentration. Because five of the six fundamentals are polarized, a formate ion in an aqueous environment appears not to have C_{2v} symmetry.

NaHCOO in H_2O at elevated temperatures and pressures

Spectra of 5.9 *m* NaHCOO/H_2O were collected at elevated temperatures and a pressure of 10 MPa in two separate sets of experiments. The first set included temperatures of 49, 100, 151, and 239°C and the second set included temperatures of 75, 127, 176, 198, and 225°C. The study concentrated on two spectral regions: 1250–1460 cm^{-1} and 2575–3025 cm^{-1}. Bands in the spectra were resolved into components by fitting Gaussian–Lorentzian product functions to the intensity envelope (15).

In the first region two bands were observed. The positions and relative intensities of these bands do not change significantly with increasing temperature; they remain centred at ~1348 and ~1381 cm^{-1}.

The spectral region from 2575 to 3025 cm^{-1} shows more interesting changes. The frequencies of the two bands of the Fermi resonance doublet decrease linearly with temperature (see Fig. 5). The data from the two sets of experiments were in agreement and were combined. A linear regression analysis of the combined data gave:

[1] $$\text{“}2\nu_5\text{”} = [-0.095(\pm 0.009)t + 2736(\pm 1.5)]\ \text{cm}^{-1}$$
$$r = -0.990$$

[2] $$\text{“}\nu_{\text{C—H str.}}\text{”} = [-0.088(\pm 0.009)t + 2822(\pm 1.5)]\ \text{cm}^{-1}$$
$$r = -0.994$$

where t is the temperature in Celsius and r is the correlation coefficient. The similarity of the slopes means the separation of the peaks is virtually independent of temperature.

The intensity of the $2\nu_5$ band increased with respect to the "C—H stretch" band. The temperature dependence of the intensity ratio is given by:

[3] $$\frac{I_{2\nu_5}}{I_{\nu_1}} = 1.12 \times 10^{-3}(\pm 4.8 \times 10^{-4})t + 0.408(\pm 0.077)$$
$$r = 0.909$$

If the wavefunctions involved in a Fermi resonance interaction are Ψ_i^0 and Ψ_n^0 and their eigenvalues are E_i^0 and E_n^0, the energies of the perturbed levels (20) are

[4] $$E = E_{\text{in}} \pm \tfrac{1}{2}\sqrt{\Delta^2 + 4W^2}$$

where $E_{\text{in}} = 0.5\,(E_i^0 + E_n^0)$; $\Delta = E_i^0 - E_n^0$ (separation of the unperturbed levels); W = Fermi coupling constant. By factoring out "hc", this expression can be rewritten in terms of wavenumbers (cm^{-1}):

[5] $$\nu = \nu_{\text{in}} \pm \tfrac{1}{2}\sqrt{\Delta^2 + 4W^2}$$

[6] $$X = \sqrt{\Delta^2 + 4W^2}$$

These equations can be used to calculate the unperturbed frequency of the C—H stretch, ν_1^0, in the following way:

[7] $$\nu_{2\nu_5} = \tfrac{1}{2}(\nu_1^0 + 2\nu_5^0) - \tfrac{1}{2}X$$

[8] $$\nu_{\text{C—H}} = \tfrac{1}{2}(\nu_1^0 + 2\nu_5^0) + \tfrac{1}{2}X$$

where $\nu_{2\nu_5}$ and $\nu_{\text{C—H}}$ represent the lower and upper fre-

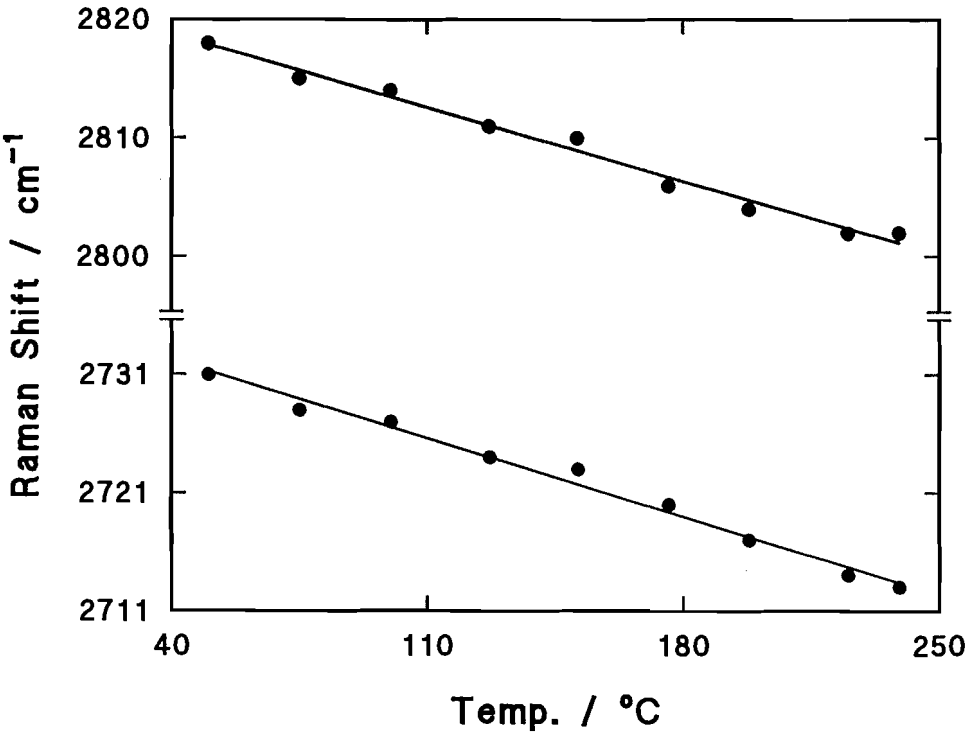

FIG. 5. Effect of temperature on the frequencies of the Fermi resonance doublet.

TABLE 3. Analysis of the Fermi resonance doublet, 5.9 *m*

Temperature/°C	ν_5^0/cm^{-1}	$2\nu_5^0$/cm^{-1}	Fermi doublet	ν_1^0/cm^{-1}	W/cm^{-1}	$\lvert\Delta\rvert$/cm^{-1}
49	1383	2766	2731, 2818	2783	42.7	17
75	1382	2764	2728, 2815	2779	42.9	15
100	1381	2762	2727, 2814	2779	42.7	17
127	1382	2764	2724, 2811	2771	43.4	7
151	1380	2760	2723, 2810	2773	43.0	13
176	1382	2764	2720, 2806	2762	43.0	5
198	1381	2762	2717, 2804	2759	43.5	3
225	1381	2762	2714, 2802	2754	43.8	8
239	1379	2758	2713, 2802	2757	44.5	1

quency bands of the Fermi resonance doublet, respectively, and $2\nu_5^0$ and ν_1^0 are the unperturbed frequencies, respectively. Adding these equations gives:

$$[9] \quad \nu_{2\nu_5} + \nu_{C—H} = \nu_1^0 + 2\nu_5^0$$

At 75°C, $\nu_{C—H}$ = 2815 cm^{-1}, $\nu_{2\nu_5}$ = 2728 cm^{-1}, ν_5^0 = 1382 cm^{-1}. In the absence of anharmonicity $2\nu_5^0$ is 2 × ν_5^0 = 2764 cm^{-1} and ν_1^0 is found to be 2779 cm^{-1}. This calculation was performed at each temperature and the values for ν_1^0, $2\nu_5^0$, Δ, and W are summarized in Table 3. The unperturbed frequency for ν_1^0 decreases with increasing temperature but ν_5^0, and therefore $2\nu_5^0$, remains virtually unchanged. As a consequence the two unperturbed frequencies shift closer together and the relative intensity of the low-frequency band of the doublet increases (as given by eq. [3]), as expected

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

from theory. At 239°C, $2\nu_5^0$ and ν_1^0 are virtually coincident but the relative intensity is not 1:1. We have no explanation for this, but anharmonicity in the $2\nu_5^0$ overtone may contribute to this discrepancy.

A similar set of experiments was conducted on 9.5 *m* $NaHCOO/H_2O$ using five different temperatures; consistent results were obtained.

Conclusions

The experiments and results presented above lead to several conclusions about the formate ion in aqueous solutions.

First, the results from the polarization studies do not support a C_{2v} symmetry for formate ion in aqueous solutions. However, the intensity from the C=O stretching band (implied by C_s symmetry) is weak (cf. the intensity of the C=O stretching band from acetone or other carbonyls); thus the intensity is more characteristic of the antisymmetric stretching mode of a $-CO_2$ group (C_{2v} symmetry) than of a C=O group (C_s symmetry). It is not clear whether the depolarization ratio results reflect the inherent symmetry of the formate ion, a lowering of symmetry because of solute–solvent interactions, or the limitations of the selection rules when applied to condensed phases. In the solid phase, where there are no solvent effects, most workers have assumed C_{2v} symmetry when interpreting their spectra (21–24). Spinner (5) has argued that when correct assignments are applied to Newman's (21) polarized infrared study of formate crystal a conclusion of C_{2v} symmetry cannot be correct. We favour an explanation involving aquation of formate anion, which perturbs the symmetry.

Second, a symmetrical bifurcated structure for the solvated anion is highly unlikely. This conclusion is based on a number of experiments that showed no change in the position of the C—O vibration (ν_2) with increasing concentration, with increasing temperature, or with changing the solvent from H_2O to D_2O. One would predict that the bifurcated structure would be perturbed and the resulting distortion would cause changes in band properties with changes in concentration, temperature, or solvent. The independence of the spectra from these variables suggests that the solvation structure is retained and is not the bifurcated structure.

Third, the components of the Fermi resonance doublet (band position and relative intensity) show a strong dependence on temperature. This results from the lowering of the frequency of the unperturbed C—H stretching mode, ν_1^0, with temperature.

Lastly, because of the changes in shape of the vibrational bands of water with addition of salt, formate can be considered a "structure breaking" ion.

Experiments at elevated temperatures, which show that a hydrogen–deuterium exchange reaction occurs at the H—C bond, have also been conducted on $HCOO^-/D_2O$. This reaction is still under study and the results will be published in a future paper.

An analysis of the $F'O_u^+$ ion-pair state of I_2 by a sequential three-photon excitation

FATEN S.M. ABD EL-HAMEED[1]

Department of Chemistry, McMaster University, Hamilton, ON L8S 4M1, Canada

Received March 1, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

FATEN S.M. ABD EL-HAMEED. Can. J. Chem. **71**, 1734 (1993).

A three-photon absorption technique that utilizes a visible $B^3\Pi(O_u^+)$–$X^1\Sigma_g^+$ transition followed by two-photon absorption was applied to characterize the high-lying vibrational levels of the $F'O_u^+$ ion-pair state of I_2, which correlates with $I^-(^1S) + I^+(^1D)$ at the dissociation limit. The multiphoton spectrum was examined at high resolution using either a single tunable dye laser (3P1C), or two independently tunable pump and probe dye lasers (3P2C), operating in the blue–green region. The one-color spectrum excited by a single laser shows transitions that have not been assigned by previous workers; these rotational lines are interpreted as being due partly to 3P1C transitions to the $F'O_u^+$ ion-pair state, for which molecular constants are derived to be (for $v' = 60$–74, $J' = 3$–100):

$$Y_{00} = 58\ 150.76(1) \quad Y_{10} = 92.98(11) \quad Y_{20} = -1.305(37) \times 10^{-2}$$

$$Y_{01} = 0.017\ 657\ 8(25) \quad Y_{11} = -9.098(05) \times 10^{-5} \quad Y_{02} = -2.06 \times 10^{-9}$$

(all in cm^{-1} with one standard deviation in the last quoted digit in parentheses).

FATEN S.M. ABD EL-HAMEED. Can. J. Chem. **71**, 1734 (1993).

On a appliqué une technique d'absorption de trois photons qui utilise une transition visible $B^3\Pi(O_u^+)$–$X^1\Sigma_g^+$ suivie par l'absorption de deux photons pour caractériser les niveaux vibrationnels élevés de l'état paire d'ions $F'O_u^+$ du I_2 qui, à la limite de dissociation, est en corrélation avec $I^-(^1S) + I^+(^1D)$. On a examiné le spectre multiphoton à haute résolution utilisant soit un laser à colorant ajustable simple (3P1C) ou deux lasers ajustables indépendamment (3P2C) opérant dans la région du bleu–vert. Le spectre monocolore obtenu par excitation à l'aide d'un seul laser présente des transitions qui n'ont pas été attribuées antérieurement par d'autres chercheurs; on attribue en partie ces raies de rotation à des transitions 3P1C conduisant à l'état de paire d'ions $F'O_u^+$ pour lequel on a déterminé que les constantes moléculaires sont (pour $v' = 60$–74, $J' = 3$–100) :

$$Y_{00} = 58\ 150{,}76(1) \quad Y_{10} = 92{,}98(11) \quad Y_{20} = -1{,}305(37) \times 10^{-2}$$

$$Y_{01} = 0{,}017\ 657\ 8(25) \quad Y_{11} = -9{,}098(05) \times 10^{-5} \quad Y_{02} = -2{,}6 \times 10^{-9}$$

Introduction

A large number of papers on the spectrum of diatomic iodine exist in the literature (1), but analysis of the higher electronic states tends still to be incomplete. There have been many problems in interpretating the existing spectroscopic data clearly and unambiguously (2).

Multiphoton absorption techniques using tunable laser beams have recently been introduced to clarify the assignment of the UV emission spectrum of molecular iodine. More than half of the 20 ion-pair states correlating with $I^-(^1S) + I^+(^3P, ^1D, ^1S)$ have been spectroscopically identified (3–8). Ishiwata et al. (9) reported an optical–optical double resonance (OODR) study of the $F'O_u^+$ state over the vibrational range $v' = 0$–38. Lehmann, Smolarek, and Goodman (10) observed under low resolution, using a single laser beam, seven multiphoton ionization (MPI) lines in the 19 500 cm^{-1} region of the spectrum, which they did not analyse.

In this paper we report a rotational analysis of the upper levels of the $F'O_u^+$ ion-pair state ($v' = 60$–74), which tends toward $I^-(^1S) + I^+(^1D)$ at the dissociation limit. Three types of double resonance signals induced by an overall three-photon process were detected and included in the analysis of the F' state: 3P1C denotes three-photon absorption from the probe laser only, 3P2C(1 + 2) corresponds to the excitation of I_2 to the appropriate $B(O_u^+)$ rovibronic level by the pump laser followed by two-photon simultaneous transition by the probe frequency to the upper F' state, and 3P2C (2 + 1) is a process involving absorption of one pump photon followed by a combination of the pump and probe laser pulses. The three-photon absorption scheme is shown in Fig. 1 as it applies to I_2. Furthermore, by combining our data with the data of Ishiwata et al. (9), we present Dunham coefficients for the state valid over the vibrational range $v' = 0$–74.

Experimental

The experimental setup used in the present work has been described in detail previously (11). Two independently tunable dye lasers were pumped by the divided output of a XeCl excimer laser developed from the model described by Kearsley *et al.* (12). This pump laser produce pulses of 15 ns duration and 1-MW peak power at a pulse repetition rate of 3 Hz.

In the 3P2C experiment, the I_2 molecules in the XO_g^+ ground state were excited to the BO_u^+ state by the broad-band pump laser (BDL, $\Delta\nu \sim 0.7\ cm^{-1}$). The narrow-band dye laser (NDL, $\Delta\nu - 0.1\ cm^{-1}$) was then used as a scanning probe to induce two-photon transitions to the high-lying states from the B-state rovibronic levels photo-selected by the BDL. In the 3P1C work, the NDL was used to excite the multiphoton spectra. The high-resolution spectra obtained by scanning the NDL were calibrated by simultaneously recording the single photon B–X LIF spectrum of I_2 (13), and the fixed BDL frequency in the 3P2C mode was determined precisely by photographing the laser output on a 1.5-m Bausch and lomb spectrograph calibrated against an Fe/Ne emission spectrum.

To achieve the necessary output power needed for the multiphoton absorption experiments while keeping the band width of the dye laser (NDL) constant, a passive external amplifier was used.

W = weak; VW = very weak; M = medium; S = strong; VS = very strong.

The amplification medium was a dye solution at the same concentration and flow rate as that of the oscillator. The amplifier cell was side-pumped by the excimer beam.

The excitation spectra were recorded by monitoring the filtered fluorescence at 250 nm with an electrothermally cooled PMT (EMI 9816 QB). The PMT anode output went to a fast preamplifier (Ortec 9305) and then to a two-channel boxcar integrator (Stanford Research Systems model SR- 250). The signal from the sample cell was processed through one channel while the other handled the signal from the calibration cell. Both channels were digitally recorded and stored using an on-line PDP-11 minicomputer. The data were later processed using peak-finding and interpolation routines.

Pure solid iodine (BDH 99.9%) was used without further purification and was sublimed into an evacuated quartz cell (3–4 Torr; 1 Torr = 133.3 Pa). The cell was then permanently sealed and used at room temperature.

Results and discussion

High-resolution one-color spectra

Under high resolution, a total of 65 3P1C lines were recorded for the F' state of the $^{127}I_2$ molecule over the 19 200–19 900 cm^{-1} energy region using C-500 laser dye in the NDL. Lehmann, Smolarek, and Goodman (10) scanned a very narrow energy region (19 500–19 580 cm^{-1}) during the course of a multiphoton ionization study (MPI) using a broadband laser ($\Delta\nu \sim 3$ cm^{-1}). Table 1 lists some of the strong peaks recorded during the course of this study as compared to those observed by Lehmann et al., only six of which appear to correlate with the strong features we recorded. No analysis for this portion of the spectrum was provided by Lehmann et al.; instead, they suggested that some high state(s) must be contributing to the resonance terms and that those features they observed may have resulted from four- or five-photon ionization. The multiphoton lines recorded in this study over the above-mentioned spectral region are most likely due to transitions to upper state(s) that lie about 58 000–59 000 cm^{-1} above the iodine ground state. The corresponding fluorescence, monitored at 250 nm, is from these levels to the X-state below its dissociation limit. These transitions would be strong according to the Franck–Condon principle. The pumped B–X transitions are nearly vertical transitions; therefore, a high population of the B-state levels is obtained. Vertical transitions from the B state would terminate on high levels of the F' state, due to the relative positions of the potential curves, and would be stronger, according to the Franck–Condon principle.

The apparently random frequency distribution of the observed 3P1C lines is due to two main constraints. To be allowed, transitions must satisfy two sets of selection rules such that the cross sections for both the first transition B–X and the second two-photon simultaneous transition out of the real intermediate state are nonzero. A further constraint on possible 3P1C transitions, resonance-enhanced through a real intermediate state, is that the resonance criterion:

$$[1] \quad 2\sigma_{21} = \sigma_{32}$$

must be fulfilled, where σ_{21} is the single-photon transition frequency and σ_{32} represents the frequency of the two-photon transition from the B state to the higher lying states. As a result, the high-resolution spectrum takes on a highly irregular appearance and classical methods of analysis are inapplicable.

The frequencies σ_{21} of the P and R lines of the B–X transition, in near resonance with each observed line frequency (3P1C), could be calculated from the constants given by Hutson et al. (14) and Tromp and LeRoy (15), respectively. A Fortran routine scanned over the ranges $v_1 = 0$–4 and $J_1 = 0$–150. About 10 possible resonance lines σ_{21} were found within ± 0.2 cm^{-1} of each 3P1C transition.

For each σ_{21}, the energy of the corresponding possible three-photon excited level (E_3) was calculated from:

$$[2] \quad E_3(v_3, J_3) = 3\sigma(3P1C) + E_1(v_1, J_1)$$

using a Fortran routine, where E_1 is the ground state term value relative to ($v_x = 0$, $J_x = 0$) and J_3 has the possible values ($J_2 + 2$), J_2, and ($J_2 - 2$) for a two-photon $\Delta\Omega = 0$ transition, O, Q, and S branches.

A Fortran program then separates those calculated E_3 values into groups of possible vibrational origins E_{30} for state 3 using an assumed B_3 value. It finds sets of lines for which a minimum number of E_{30} agree within 0.7 cm^{-1} and does a least-squares analysis on each set of lines. All these for all B_3 values are then sorted and separated into groups. Each group of origins so obtained represents a potential state 3 vibrational origin. The possible E_{30} values were then separated into progressions that could represent successive vibrational levels. After refinement of this preliminary analysis, the approximate vibrational spacing was found to be 92 cm^{-1} for the $^{127}I_2$ molecule.

TABLE 3. Molecular constants (cm^{-1}) of the $F'O_u^+$ state relative to $v' = 60$ from analysis of the spectrum of the $^{127}I_2$ molecule

Constant	3P1C analysis	3P2C analysis	Combined analysis
$Y_{0,0}$	58 150.7(46)	58 150.99(7)	58 150.76(1)
$Y_{1,0}$	93.02(03)	92.99(56)	92.98(11)
$Y_{2,0}$	−0.014 00(35)	−0.016 12(57)	−0.013 05(37)
$Y_{0,1}$	0.017 5494(45)	0.017 4588(41)	0.017 6578(25)
$Y_{1,1} \times 10^5$	−9.606(19)	−8.369 7(75)	−9.098 0(05)
$Y_{0,2} \times 10^9$	−2.600	−2.600	−2.600
Red. χ^2	0.86	0.73	0.86

The numbers in parentheses correspond to one standard deviation in the last quoted digit.

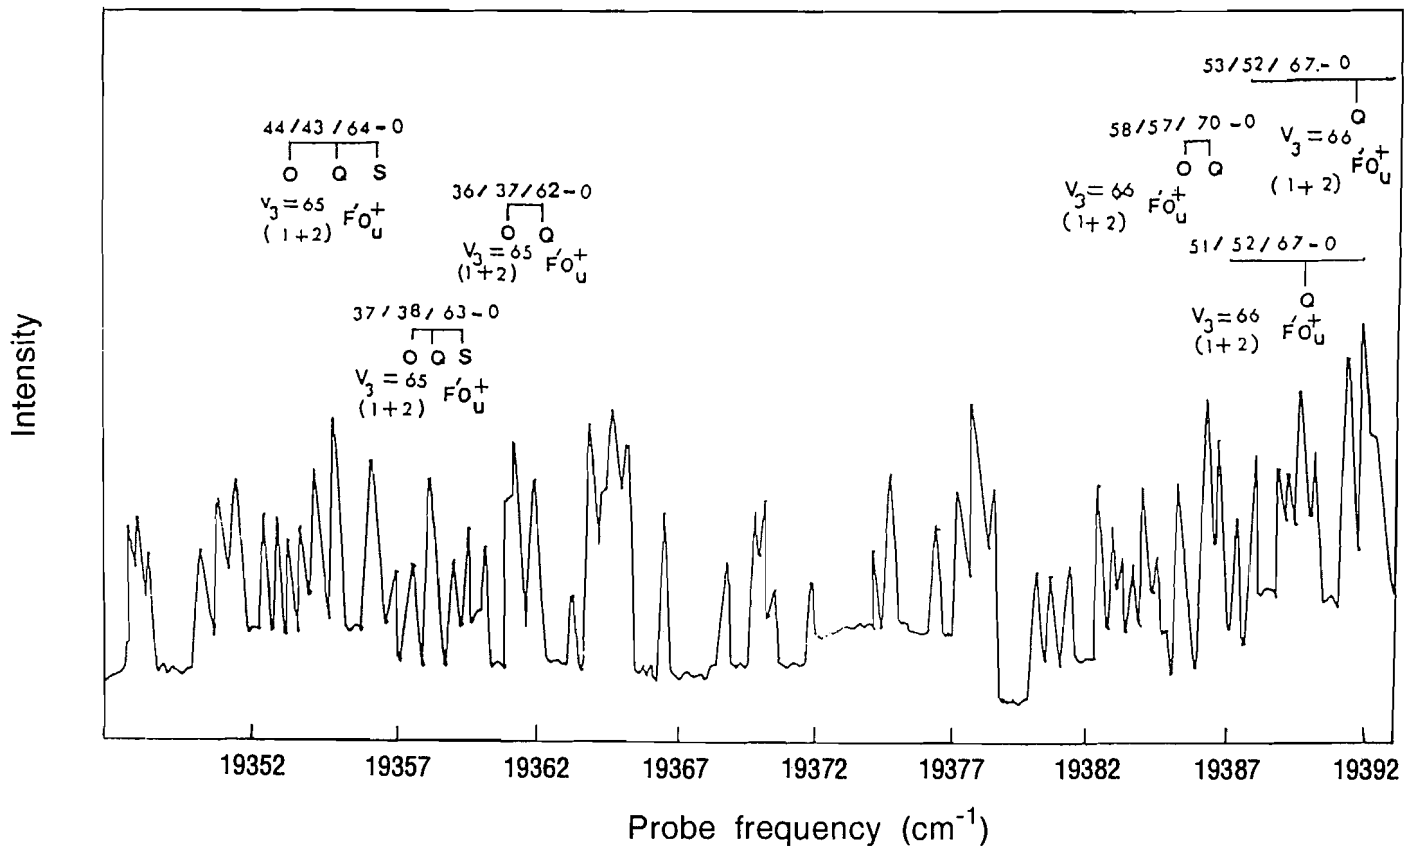

FIG. 3. 3P2C spectrum of $^{127}I_2$ molecule with the pump frequency set at 19 914.5 cm^{-1}.

Given the experimental 3P1C frequencies together with their possible assignments as pump lines and as members of the appropriate vibrational levels, a least-squares analysis was performed on the three-photon term values for each vibrational level and the rotational constants were determined.

A global least-squares fit with equal weightings was performed on all the rotational lines assigned to the $F'O_u^+$ state, using a multiple regression routine, to generate the Dunham coefficients for the upper state using:

$$[3] \quad E_3(v_3, J_3) = \Sigma_{m=0} \Sigma_{l=0} Y_{lm}(v_3 + 1/2)^l [J_3(J_3 + 1)]^m$$

for the $^{127}I_2$ isotope. Those derived molecular constants could be used to assign more 3P1C lines.

Three-photon transitions were observed for all the vibrational levels over the range $n = 0$–14, where n is an arbitrary number to be related later to the vibrational numbering. A list of 3P1C assignments for the normal molecule is given in Table 2. The molecular constants obtained from the 3P1C assignments are listed in Table 3. These parameters are given with respect to the lowest observed level ($v_3 = 60$). Figure 2 shows part of the spectrum recorded in the 19 600 cm^{-1} region for the normal isotope. The designation "R, Q" denotes an R-branch single photon B–X resonance transition from level J_1, followed by a two-photon Q-branch transition (hence $J_3 = J_1 - 1$). The figure also shows transitions to other systems (11).

Two-color spectra

With the analysis well underway, analysis of the observed 3P2C spectra was quite easy.

The two-photon-allowed rotational transitions from the pumped B state (by both (1 + 2) and (2 + 1) absorption pathways) follow the $\Delta J = 0, \pm 2$ selection rule. The ob-

served OODR high J transitions could be assigned as triplets of lines, corresponding to $\Delta J = -2$ (O-branch), $\Delta J = 0$ (Q-branch), and $\Delta J = +2$ (S-branch). The upper state term values ($E_3(v_3, J_3)$) were calculated from eq. [4] for the (1 + 2) and from eq. [5] for the (2 + 1) transitions:

$$[4] \quad E_3(v_3, J_3) = 2\sigma(\text{NDL}) + E_2(v_2, J_2)$$

$$[5] \quad E_3(v_3, J_3) = \sigma(\text{NDL}) + \sigma(\text{BDL}) + E_2(v_2, J_2).$$

The approximate vibrational spacing was found to be 92 cm^{-1} for $^{127}I_2$.

All the observed 3P2C transitions, both (1 + 2) and (2 + 1), terminating in the F' state, were recorded using the pump and probe frequencies within the C-500 dye profile. Most of the observed OODR lines for the F' state were recorded pumping the 40–0 and 60–0 band regions of the B–X system. The intense 3P2C-observed lines resulted from pumping the higher J-lines falling within the bandhead region rather than the low J's. Figure 3 shows a sample spectrum recorded for this state in the 19 350 cm^{-1} region, pumping at 19 914.5 cm^{-1}. The 3P2C spectral lines were observed to arise not only from a σ(BDL) + 2σ(NDL) absorption process, (1 + 2), but also from a σ(BDL) + σ(BDL) + σ(NDL) transition sequence, (2 + 1). Two O, Q, and S triplets are shown in the figure for the (1 + 2) absorption mode corresponding to the $v_3 = 65$ vibrational level with the Q-lines at 19 355 and 19 358.5 cm^{-1}. The figure also shows some strong lines for the $v_3 = 66$ vibrational level in the (1 + 2) mode.

Transitions were recorded over the $n = 0$–8 vibrational range for the F' state. A summary of the 3P2C assignments is given in Table 4. The term values for state 3 calculated according to eqs. [4] and [5] are used to calculate the molecular constants for the state using a multivariate least-

squares routine. The resulting molecular constants are listed in Table 3.

Spectral assignment of the $F'O_u^+$ state

Initial attempts to assign this state to a lower lying ion-pair state focused on the $DO_u^+(^3P_2)$, $F\ O_u^+(^3P_0)$, and $F'O_u^+(^1D)$ states. Previous work on both the D and F states (16) suggested that the vibrational spacing of these states would be much less than 92 cm^{-1} observed in this region of the spectrum. This leaves the F' state as a possible assignment for this upper state. Spectroscopic data for the low vibrational levels of the F' state were reported in refs. 9 and 17. As an initial step, the low v_3 data from ref. 9 were integrated into the analysis. Polynomial fits were made by letting the level designated as $n = 0$ take the values 58–62. The fits were judged by their standard deviations and also on how well the calculated values of $Y_{0,0}$ and $Y_{0,1}$ compared with the values obtained from the low v data. The fit that best represented the combination of both sets of data gave $n = v_3 - 60$. The results of this final fit are listed in Table 5.

The upper state of the analysed transitions was assigned as $F'O_u^+(^1D)$. The current study represents the first vibrational and rotational analysis of this ion-pair state in this energy region, as all previous work had been confined to low v analysis. This study also gives the first high-resolution 3P1C analysis for the iodine molecule in this energy region of the spectra. The MPI spectra recorded by Lehmann et al. (10), which they did not analyse, can be, in part, satisfactorily explained as resonance-enhanced 3P1C transitions to the $F'O_u^+$ state, see Table 2, and the rest of the lines from ref. 10 were assigned to three-photon states lying in the same energy region (11).

Acknowledgments

The author would like to express her gratitude to Professor G.W. King of the Chemistry Department at McMaster University, Hamilton, Ont., Canada, for suggesting the problem, in multiphoton laser spectroscopy, while supervising the author's doctoral study.

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

DIETMAR CHMIELEWSKI, NICK HENRY WERSTIUK, and TIMOTHY A. WILDMAN. Can. J. Chem. **71**, 1741 (1993).

The conformational preferences and barriers to internal rotation about the S—C(phenyl) bond have been investigated for thioanisole and its 2-fluoro, 2,6- and 3,5-difluoro, and 2,3,5,6-tetrafluoro derivatives. Measurements of long-range spin–spin couplings between the methyl carbon and the *para* ring proton indicate that the 2-fluoro and 3,5-difluoro compounds prefer conformations with all heavy atoms coplanar. The 2,6-difluoro and 2,3,5,6-tetrafluoro compounds prefer conformations in which the methyl carbon lies in or near the plane perpendicular to the aromatic ring. Semiempirical molecular orbital calculations with the MNDO method indicate that all of the molecules prefer perpendicular conformations while similar calculations with AM1 indicate that all prefer planar conformations. Apparently the conformational behaviour can be quite sensitive to subtle changes in intramolecular interactions, which may indicate improvements to these semiempirical methods. The NMR results have been used to derive an internally consistent set of rotational potentials. Synthetic photoelectron spectra derived from these potentials and the AM1 orbital energies are in good agreement with the experimental spectra.

DIETMAR CHMIELEWSKI, NICK HENRY WERSTIUK et TIMOTHY A. WILDMAN. Can. J. Chem. **71**, 1741 (1993).

On a examiné les préférences conformationnelles et les barrières à la rotation interne autour de la liaison S—C(phényle) dans le thioanisole et ses dérivés 2-fluoro-, 2,6- et 3,5-difluoro- et 2,3,5,6-tétrafluoro-. Des mesures des couplages spin–spin à longue distance entre le carbone du méthyle et le proton en *para* du cycle indiquent que, dans les conformations préférées des composés 2-fluoro- et 3,5-difluoro-, les atomes lourds sont coplanaires. Dans les conformations privilégiées des composés 2,6-difluoro- et 2,3,4,6-tétrafluoro- le carbone du groupe méthyle se trouve dans le, ou près du, plan perpendiculaire au noyau aromatique. Des calculs semiempiriques d'orbitales moléculaires avec la méthode MNDO indiquent que toutes les molécules préfèrent des conformations perpendiculaires alors que des calculs semblables à l'aide de la méthode AM1 indiquent que chacun préfère les conformations planaires. Il semble que le comportement conformationnel peut être très sensible à des changements subtils dans les interactions intramoléculaires; ceci peut indiquer des méthodes pour améliorer les méthodes semiempiriques. On a utilisé les résultats de la RMN pour développer un ensemble autocohérent de potentiels rotationnels. Les spectres photoélectroniques de synthèse derivés de ces potentiels et les énergies orbitalaires obtenues à l'aide de la méthode AM1 sont en bon accord avec les spectres expérimentaux.

Introduction

The important role of molecular conformation in the determination of chemical reactivity and molecular recognition is abundantly clear. In addition to experimental probes, quantum mechanical models of molecular electronic structure are increasingly important means of assessing subtle changes in conformational preferences and internal motions. Confidence in the use of computational methods is largely based on their demonstrable success in reproducing certain empirical results.

In this article, the conformational behavior of the thiomethyl group in a number of fluorothioanisoles is reported. The aims of this investigation are (1) to develop a consistent picture of the conformational behaviour of these thioanisoles and (2) to examine the reliability of results from semiempirical methods for such molecules. Long-range NMR spin–spin coupling constants are used to examine conformational preferences and to derive barriers to internal rotation. These preferences and barriers are compared with those from semiempirical molecular orbital (MO) calculations. The resulting empirical and semiempirical potentials are used to derive synthetic photoelectron spectra for comparison with the experimental spectra. This comparison serves to test the consistency of the experimental and computational results and to illustrate the utility of photoelectron spectroscopy (PES) for the study of conformational behaviour in highly flexible molecules.

In thioanisole (1, 2), as in thiophenol (3, 4), the barrier to internal rotation about the S—C1(phenyl) bond is determined largely by conjugation between the sulphur 3*p*-orbital and the π-system. This interaction gives rise to a predominantly twofold barrier to internal rotation. Molecular orbital calculations indicate the presence of a relatively small fourfold component, but this has not yet been observed experimentally. If the dihedral angle about the S—C1 bond is denoted by ϕ = Me—S—C1—C2, where $\phi = 0°$ or 180° corresponds to a structure in which the methyl carbon is coplanar with the aromatic ring, such barriers have the form

$$[1a] \quad V(\phi) = V_2 \sin^2(\phi)$$

if planar conformations ($\phi = 0°$ or 180°) are energetically more stable or

$$[1b] \quad V(\phi) = V_2[1 - \sin^2(\phi)] = V_2 \cos^2(\phi)$$

if the perpendicular conformations ($\phi = 90°$ or 270°) are preferred. For a mono-*ortho*-substituted compound, the *syn* conformation is arbitrarily selected as $\phi = 0°$; thus the *anti* conformation corresponds to $\phi = 180°$.

It is well known that certain long-range spin–spin coupling constants between nuclei in the side chain and the aromatic ring of benzene derivatives have a simple conformational dependence (5–7). In particular, the coupling over six formal bonds between the methyl carbon and the *para* ring proton, $^6J_p^{C,H}$, has the form

$$[2] \quad {}^6J_p^{C,H} = {}^6J_{90}^{C,H}\langle\sin^2(\phi)\rangle$$

where $^6J_{90}^{C,H}$ is an empirical constant appropriate to the class of compounds under investigation (−0.56(2) Hz) (1) and ⟨...⟩ denotes an expectation value. Because $\langle\sin^2(\phi)\rangle$ and thus $^6J_p^{C,H}$ may be computed as a function of V_2 in eq. [1] for hindered internal rotation, comparison of the experimentally measured value of $^6J_p^{C,H}$ with tables of computed values provides an estimate of the barrier height in addition to information concerning the conformational preference. Clearly, the success of this method relies upon the constancy of $^6J_{90}^{C,H}$. INDO FPT calculations on 2-fluoroanisole indicate that a single *ortho* fluorine substituent changes $^6J_{90}^{C,H}$ by 0.01 Hz at most and the intrinsic effect of two fluorine substituents on $^5J^{C,C}$ is typically a reduction of less than 5% (7). According to these findings, the expected variation of $^6J_{90}^{C,H}$ within the present series of compounds is on the order of the estimated error.

Although conformational preferences have a profound influence on chemical reactivity, their knowledge provides only a partial description of the underlying conformational distribution. Empirical evidence can be derived from relatively slow methods, like NMR, that provide averages over the conformational potential energy hypersurface, or from fast methods, like PES, that examine all conformations on the hypersurface. In this work, empirical potentials from eq. [2] and semiempirical potentials from MO calculations have been used in conjunction with computed angle-dependent orbital energies to generate synthetic photoelectron spectra. A comparison of synthetic and experimental spectra has been performed to support the interpretation of the NMR data and to determine the utility of PES for the study of conformational distributions.

Experimental and computational method

The compounds examined in this study were prepared by standard methods. The fluorothioanisoles were obtained by methylation of the corresponding fluorothiophenols with dimethyl sulphate. The fluorothiophenols were synthesized from the corresponding fluoroanilines (Aldrich) by the xanthate method (8).

Precision bore, 5 mm o.d. NMR tubes, containing solutions of about 5 mol% of the fluorothioanisole in acetone-d_6 and TMS, were degassed by several freeze–pump–thaw cycles. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AM500 or AC300 spectrometer at a probe temperature of 303 K unless otherwise indicated. The DEPT pulse sequence (9) was used to obtain proton-coupled ^{13}C spectra of the methyls.

Photoelectron spectra were recorded on a noncommercial instrument described previously (10). Spectra were obtained by signal averaging of 20–30 scans. Argon was used as a calibration standard.

Semiempirical MO calculations were performed using the packages AMPAC 2.10 and MOPAC 5.00 on a Sun 3/60 workstation. AM1 parameters for sulphur were incorporated from ref. 11. Full geometry optimizations were performed for fixed values of the Me—S—C1—C2 torsion angle at 15° increments between 0° and 180°. Convergence criteria were tightened through use of the keyword "PRECISE." Synthetic photoelectron spectra were computed with the program PESPEC (12) on the basis of the calculated angular dependencies of the orbital energies and heats of formation.

TABLE 1. Long-range ^{13}C,^{1}H coupling constants for thioanisoles

Compound	$^6J_p^{C,H}$ (Hz)	$\langle\sin^2(\phi)\rangle$	Preferred conformation[a]
Thioanisole	−0.147(3)[b]	0.26(1)	0°
2-Fluoro	−0.18(3)	0.32(6)	180°
2,6-Difluoro	−0.42(3)	0.75(6)	90°
3,5-Difluoro	<−0.1	<0.18	0°
2,3,5,6-Tetrafluoro	−0.36(2)	0.64(4)	90°

[a]ϕ = 0° and 180° or ϕ = 90° and 270° are equivalent by symmetry, except for 2-fluorothioanisole.
[b]Reference 1.

Results and discussion

Conformational preferences on the basis of long-range ^{13}C,^{1}H couplings

The long-range ^{13}C,^{1}H couplings are listed in Table 1, along with values of $\langle\sin^2(\phi)\rangle$ derived under the assumption that $^6J_{90}^{C,H}$ is −0.56(2) Hz in eq. [2] (1). Free rotation corresponds to $\langle\sin^2(\phi)\rangle$ = 0.5. For a simple, twofold barrier, values smaller than 0.5 indicate that planar conformations are preferred (ϕ = 0° or 180°) while values greater than 0.5 indicate that the methyl carbon prefers to lie in the plane perpendicular to the ring plane (ϕ = 90° or 270°). Qualitatively, the numbers in Table 1 are evidence that thioanisole and its 2-fluoro and 3,5-difluoro derivatives prefer planar conformations. The 2,6-difluoro and 2,3,5,6-tetrafluoro derivatives on the other hand prefer perpendicular conformations. This behaviour might be attributable to repulsions between the methyl and *ortho* fluorine substituents. Of course, within the σ–π separation approximation, the electronegative *ortho* fluorine substituent is expected to withdraw electron density from the σ-framework and donate electron density to the π-system, thereby lowering the barrier to internal rotation. This effect is insufficient to explain the preference for a nonplanar conformation.

In light of the above discussion, the conformational preference of 2-fluorothioanisole points to the dominant effect. If repulsions are more important than the substituent effect on the barrier, 2-fluorothioanisole should prefer the planar *anti* conformer to allow conjugation between sulphur orbitals and the π-system while avoiding methyl–fluorine repulsion. In fact, the magnitude of $^4J_o^{C,F}$ is 2.37(2) Hz at 303 K, smaller than the values in the 2,6-difluoro (3.62 Hz) and 2,3,5,6-tetrafluoro (3.93 Hz) derivatives. Because this coupling has a large proximate contribution that decreases as the nuclei are separated, the magnitude is an indication of the distance between the coupled nuclei (7, 13). This suggests that the methyl carbon and fluorine nuclei are well separated in the preferred conformation of 2-fluorothioanisole. Moreover, from variable-temperature NMR experiments, the magnitude of $^4J_o^{C,F}$ decreases as the probe temperature decreases: $^4J_o^{C,F}$ in 2-fluorothioanisole is about 1.45 Hz at 220 K. Because a reduction in temperature sharpens the distribution of conformations about the minimum energy conformation, this observation further supports the notion that the carbon and fluorine nuclei are distant from one another in the preferred conformation.

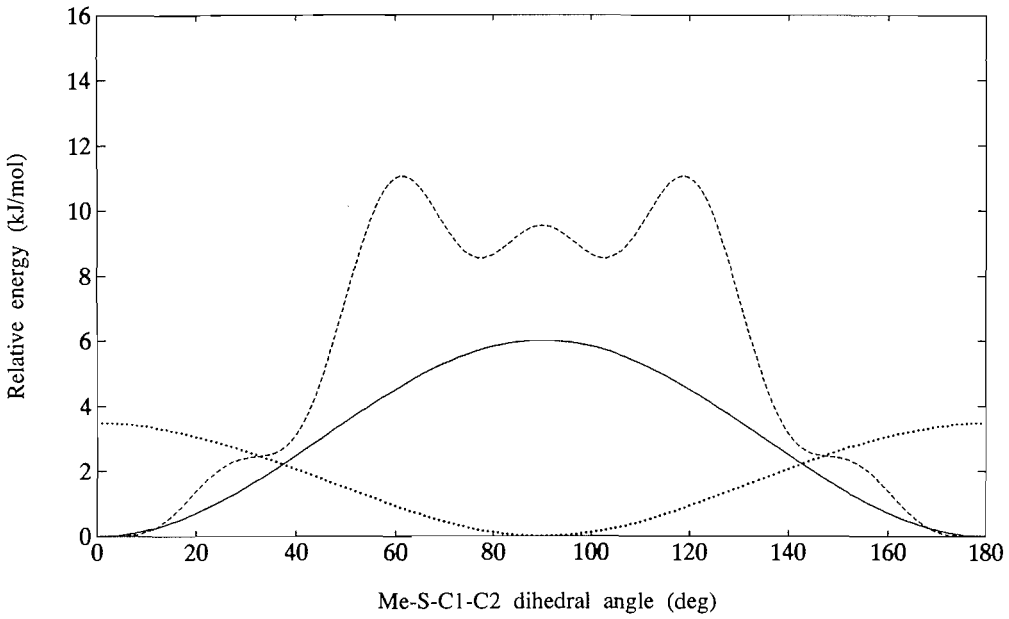

FIG. 1. Barriers to internal rotation about the exocyclic C1—S bond in thioanisole. Dotted (MNDO) and dashed (AM1) lines correspond to relative heats of formation from semiempirical computations. The solid line represents a purely twofold barrier derived from the observed value of $^6J_p^{C,H}$ in ref. 1.

TABLE 2. Barriers to internal rotation about the sulphur–phenyl bond in thioanisoles

Compound	V_2 (kJ mol^{-1}) MNDO[b]	AM1[c]	NMR	Preferred conformation[a]
Thioanisole	3.4	10.7	5.4[d]	0°
2-Fluoro	8.4	6.9	0	180°
2,6-Difluoro	14.8	2.3	6	90°
3,5-Difluoro	1.3	13.1	9	0°
2,3,5,6-Tetrafluoro	12.2	7.2	3	90°

Results of semiempirical MO calculations

The dependence of the relative energy on the Me—S—C1—C2 dihedral angle, ϕ, in thioanisole in shown in Fig. 1. A dotted line represents the relative heats of formation from MNDO (14) calculations. Barrier heights for all compounds are summarized in Table 2. For each molecule, the MNDO results indicate that the preferred conformer corresponds to a dihedral angle of about 90°. Even for 2-fluorothioanisole, for which the *anti* conformer is slightly lower in energy than the *syn*, both planar conformers are relative maxima. This finding is obviously contrary to the implications of the long-range $^{13}C,^1H$ couplings described in the preceding section: empirically, it is clear that thioanisole, 2-fluorothioanisole, and 3,5-difluorothioanisole prefer planar conformations. The pattern of the MNDO results may arise from the underestimation of resonance stabilization or the overestimation of steric repulsion in the MNDO model, which are recognized weaknesses (15). This deficiency was remedied by the modification of core repulsion functions (CRFs) in the AM1 method (15, 16), which generally appears to yield reliable estimates of heats of formation, geometries, and certain other properties at a fraction of the cost of ab initio computations (11).

The dashed line in Fig. 1 represents the relative heats of formation from calculations employing AM1. With the AM1 parametrization, all of the molecules prefer planar conformations, which is again at variance with the experimental results. However, the discrepancies now coincide with the presence of *ortho* fluorine substituents. This correspondence holds even in the case of a single *ortho* fluorine substituent: according to the AM1 results, 2-fluorothioanisole prefers the *syn* conformation (ϕ = 0°), but experimentally it prefers the *anti* conformation (ϕ = 180°), like 2-fluoroanisole (17). It seems that AM1 slightly underestimates the steric repulsions between the methyl and phenyl moieties or, alternatively, overestimates stabilization of the planar conformations through changes to the resonance integral parameters (11), leading to excessively high barriers in thioanisole and 3,5-difluorothioanisole and to incorrect conformational preferences in the 2-fluoro-, 2,6-difluoro-, and 2,3,5,6-tetrafluorothioanisoles.

Parenthetically, "hybrid calculations" that employed AM1 parameters for all atoms except sulphur and MNDO parameters for sulphur alone produced the correct conformational preferences for all compounds. Dewar describes the use of MNDO parameters within AM1 as "wholly unacceptable" (11), a view with which we concur.

It may be worthwhile to note that geometry-optimized, restricted Hartree–Fock (RHF) calculations with the STO-3G basis yield a twofold barrier of 14.85 kJ mol^{-1} for thiophenol, which is found to be preferentially planar (18). RHF computations with larger bases, even split-valence sets augmented by *d*-orbitals on heavy atoms, fail to reproduce the experimental preference. Inclusion of *d*-orbitals reduces the energy difference between the planar and perpendicular conformations but the latter remains the more stable. Of course, all such results refer to the gas phase while the present NMR experiments were performed on dilute solutions,

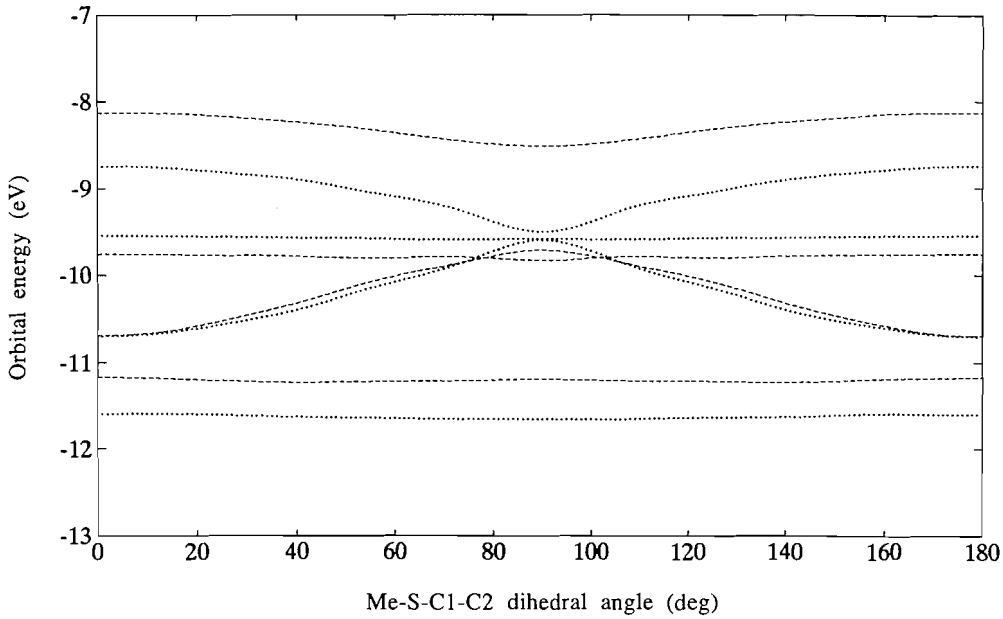

FIG. 2. Angle-dependent energies of the four highest occupied MOs of thioanisole from semiempirical calculations with MNDO (dotted lines) and AM1 (dashed lines) methods.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

for which solvent effects could play a role. However, an earlier comparison of barriers in *para*-substituted thiophenols determined by NMR and by microwave spectroscopy provides evidence that solvents have little effect (3).

MNDO and AM1 orbital energies were computed as a function of dihedral angle ϕ at 15° intervals, as mentioned above. Representative results for thioanisole appear in Fig. 2. The continuity of these curves was established by monitoring the smooth change in composition of the various MOs from calculations with different ϕ-values. The most noticeable difference between the methods is the lower ionization energy of the highest occupied molecular orbital, the sulphur lone pair, with AM1.

Potentials from long-range C,H couplings

Given the inability of both semiempirical methods to provide a satisfactory description of the conformational behaviour of the fluorothioanisoles under study, the possibility of using the coupling $^6J_p^{C,H}$ to develop an internally consistent set of potentials was investigated. Strict additivity of components was assumed. From RHF calculations with the STO-3G basis, the potential for internal rotation about the sulphur–phenyl bond in thioanisole is (19)

$$[3] \quad V(\phi) = (5.8 \pm 0.2)\sin^2(\phi) + (2.4 \pm 0.2)\sin^2(2\phi) - (0.6 \pm 0.2)\sin^2(3\phi)$$

The fourfold and sixfold components give rise to shallow secondary minima at $\phi = 90°$ and 270°. The relative maxima are thus shifted from 90° and 270° to about 60°, 120°, 240°, and 300°. For the present purpose, truncation of eq. [3] after the first term will suffice. The twofold component is consistent with the values of $^6J_p^{C,H}$ in the present and previous work (1), and with other methods that yield barriers between 2.5 and 18.4 kJ mol^{-1} (20).

From $^6J_p^{C,H}$ in 2,6-difluorothioanisole, $\langle\sin^2\phi\rangle$ is 0.75, which is consistent with a twofold barrier of the form

$$[4] \quad V(\phi) = V_2\cos^2(\phi) = (5.9 \pm 1.2)\cos^2(\phi)$$

The barrier height, 5.9 ± 1.2 kJ mol^{-1}, is obtained from comparison of the measured $\langle\sin^2\phi\rangle$ with a table of values computed from

$$[5] \quad \langle\sin^2\phi\rangle = \frac{\int d\phi \sin^2\phi \exp[-V(\phi)/k_BT]}{\int d\phi \exp[-V(\phi)/k_BT]}$$

for various barrier heights. Equation [4] can be rewritten as

$$[6] \quad V(\phi) \approx 6 - 12\sin^2(\phi) + 6\sin^2(\phi)$$

where the last term corresponds to the (truncated) potential in thioanisole itself. Under the assumption of strict additivity of potential components, the two *ortho* fluorine substituents reduce the twofold component by 12 kJ mol^{-1}. One might infer that each *ortho* substituent reduces V_2 by 6 kJ mol^{-1}. That would imply that the twofold component of the barrier in 2-fluorothioanisole is close to zero while the onefold component is 6 kJ mol^{-1}:

$$[7] \quad V(\phi) \approx V_1\sin^2(\phi/2) - 6\sin^2(\phi) + 6\sin^2(\phi) = V_1\sin^2(\phi/2)$$

where the first two terms represent the one- and twofold components due to a single *ortho* fluorine substituent and the last term represents the potential in thioanisole itself. This presumption is consistent with the AM1 results above, which indicate a 4 kJ mol^{-1} decrease in the twofold component if a single *ortho* fluorine substituent is present. V_1 is 2.6 kJ mol^{-1} according to the AM1 energies and only −0.4 kJ mol^{-1} according to the MNDO energies.

From $^6J_p^{C,H}$ in 2,3,5,6-tetrafluorothioanisole, $\langle\sin^2\phi\rangle$ is 0.64 and the twofold potential is found to be

$$[8] \quad V(\phi) = (3.0 \pm 0.9)\cos^2(\phi) \approx 3 - 3\sin^2(\phi)$$

In comparison with the potential for the 2,6-difluoro derivative, the addition of the *meta* fluorine substituents makes nonplanar conformations less stable. By combining this po-

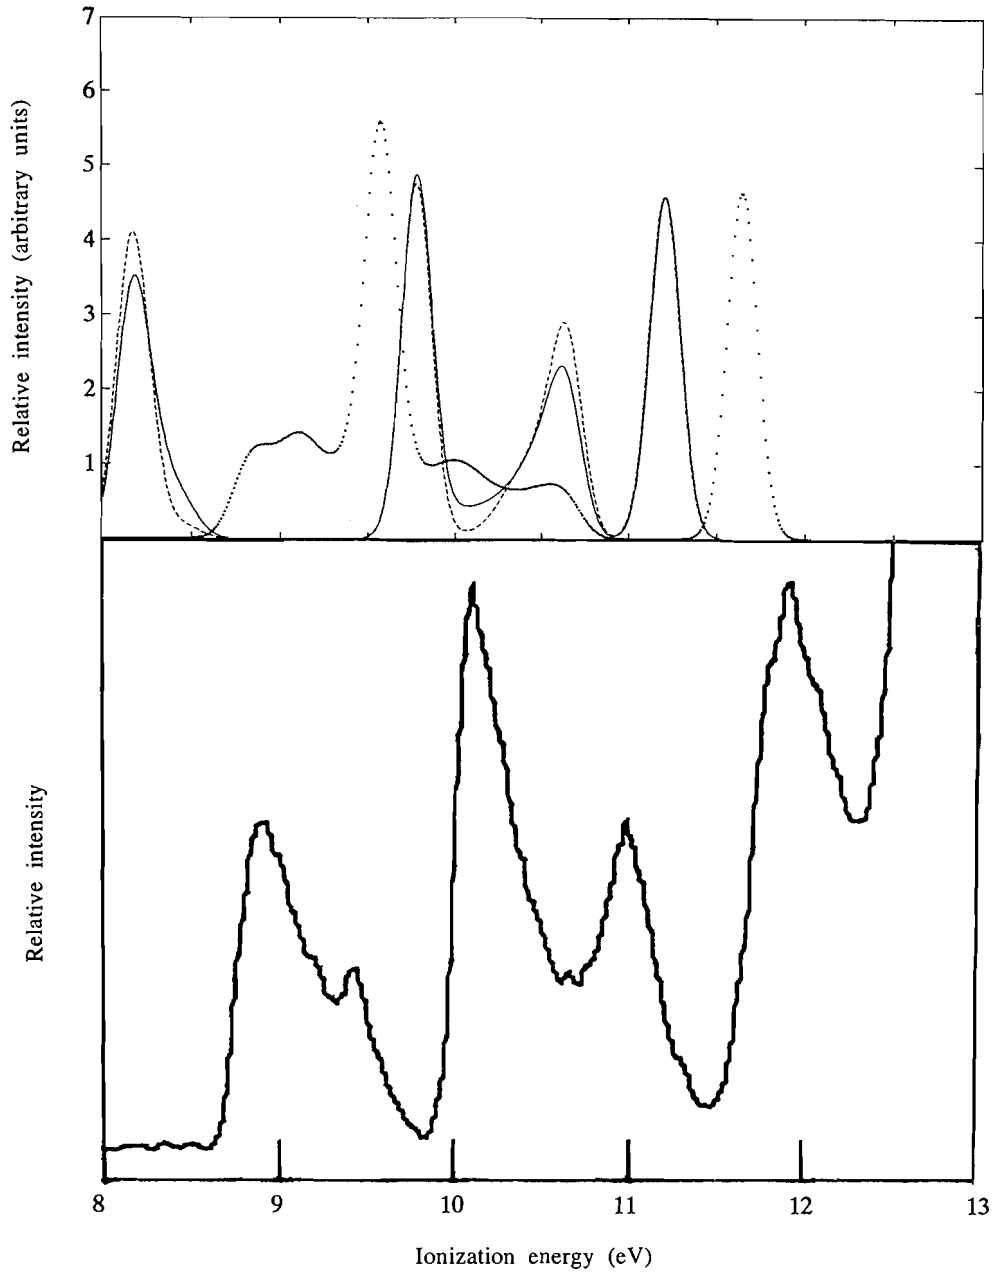

FIG. 3. The photoelectron spectrum of thioanisole. Synthetic spectra based on the MNDO (dotted line) and AM1 (dashed line) results appear in the upper panel. The solid line was obtained from the hindering potential derived from the NMR data and the AM1 orbital energies. The actual spectrum appears in the lower panel.

For personal use only.

tential with those for thioanisole and 2,6-difluorothioanisole, the potential for 3,5-difluorothioanisole is

$$[9] \quad V(\phi) = 6\sin^2(\phi) + [3 - 3\sin^2(\phi)] - [6 - 12\sin^2(\phi) + 6\sin^2(\phi)] = -3 + 9\sin^2(\phi)$$

i.e., the *meta* fluorine substituents raise the twofold barrier by about 3 kJ mol^{-1} relative to thioanisole. It follows that ${}^6J_p^{C,H}$ for 3,5-difluorothioanisole, which is certainly less than 0.1 Hz in magnitude, should be smaller than that for thioanisole itself (−0.147 Hz), as found experimentally. Thus, all of these findings are internally consistent. Barriers are summarized in Table 2.

Photoelectron spectra

Synthetic photoelectron spectra were generated by a method given previously (12). Briefly, the angular dependencies of the conformational energy and orbital energies are expressed as Fourier series. The intensity of a spectral band at a given ionization energy is proportional to the thermal population density of conformations at the corresponding dihedral angle. Calculations were made for a sample temperature of 300 K. Because a proper calculation of the vibronic structure is beyond the available resources, the intensity distribution is convoluted with a Gaussian lineshape (FWHH = 0.2 eV) to approximate the Franck–Condon envelope.

Three sets of calculations were performed for each com-

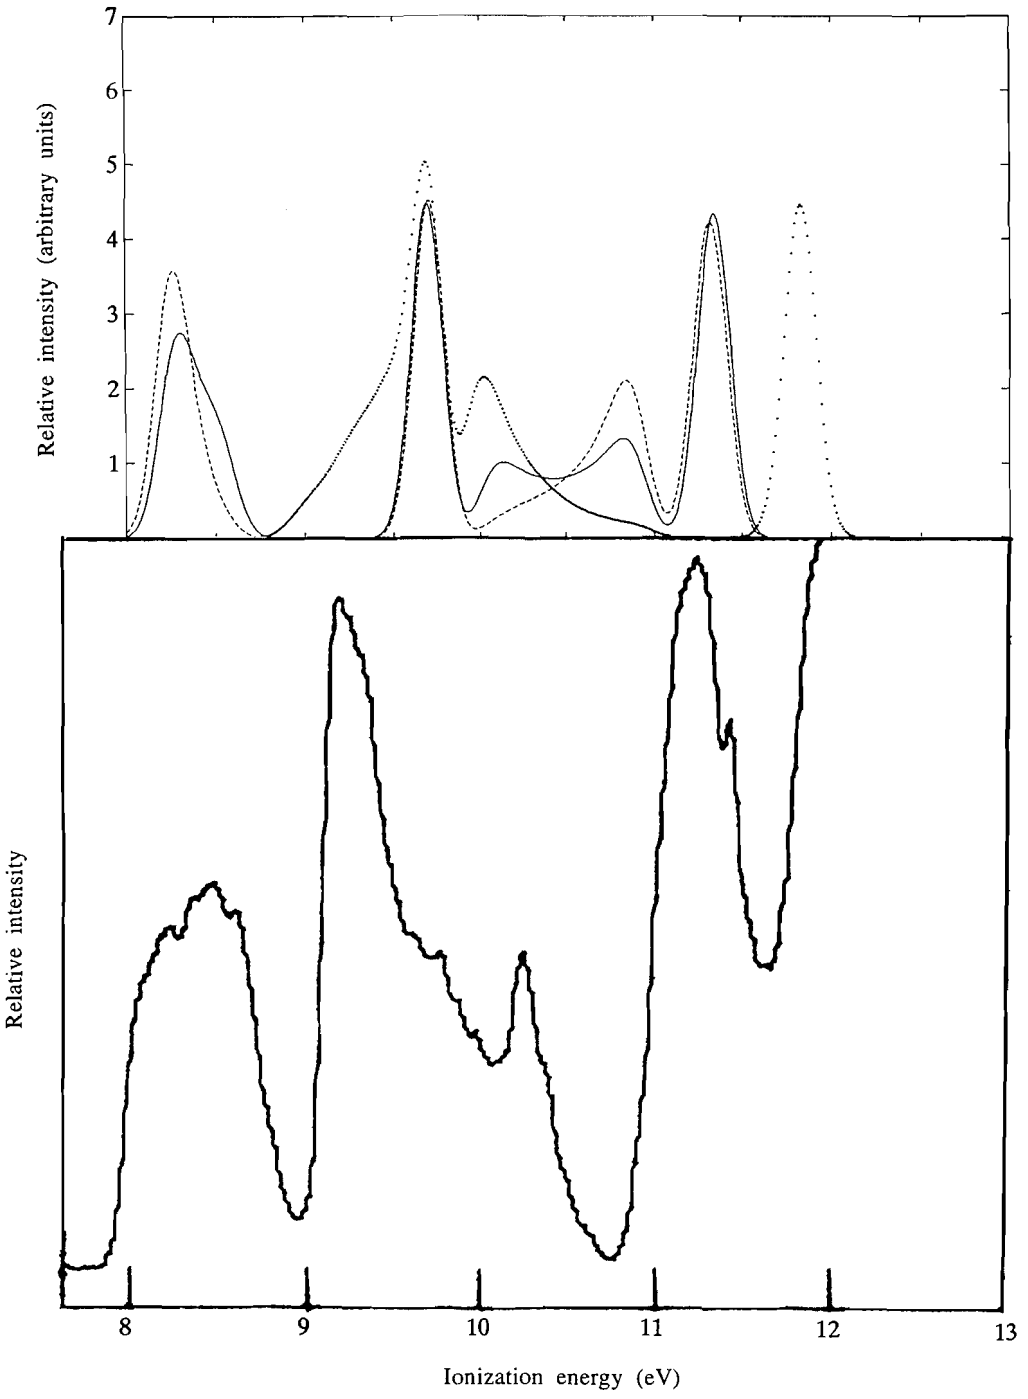

FIG. 4. The photoelectron spectrum of 2-fluorothioanisole. Synthetic spectra based on the MNDO (dotted line) and AM1 (dashed line) results appear in the upper panel. The solid line was obtained from the AM1 orbital energies and a purely onefold 6 kJ mol^{-1} barrier favouring the *anti* orientation. The actual spectrum appears in the lower panel.

pound: one in which the MNDO orbital energies and potentials were used to compute a synthetic spectrum (MNDO spectrum); one in which the AM1 results were used to compute a spectrum (AM1 spectrum); and one in which the AM1 orbital energies were used with the empirical potentials derived from $^6J_p^{C,H}$. Experimental and synthetic spectra appear in Figs. 3–7. For the synthetic spectra, dashed lines correspond to AM1 results, dotted lines correspond to MNDO results.

In comparison with the experimental spectra, it is apparent that the AM1 spectrum is a better reproduction if the molecule prefers a planar conformation, but the MNDO spectrum is better if the molecule prefers the perpendicular conformation. Because the angular dependencies of the orbital energies are quite similar, this observation merely reflects the fact that planar conformations are always preferred in the AM1 calculations and perpendicular ones are always preferred in the MNDO calculations, as described above. However, neither of these sets is consistent with the entire set of experimental spectra. Calculations that combine the internally consistent empirical potentials inferred from $^6J_p^{C,H}$ with the AM1 orbital energies yield a set of synthetic spec-

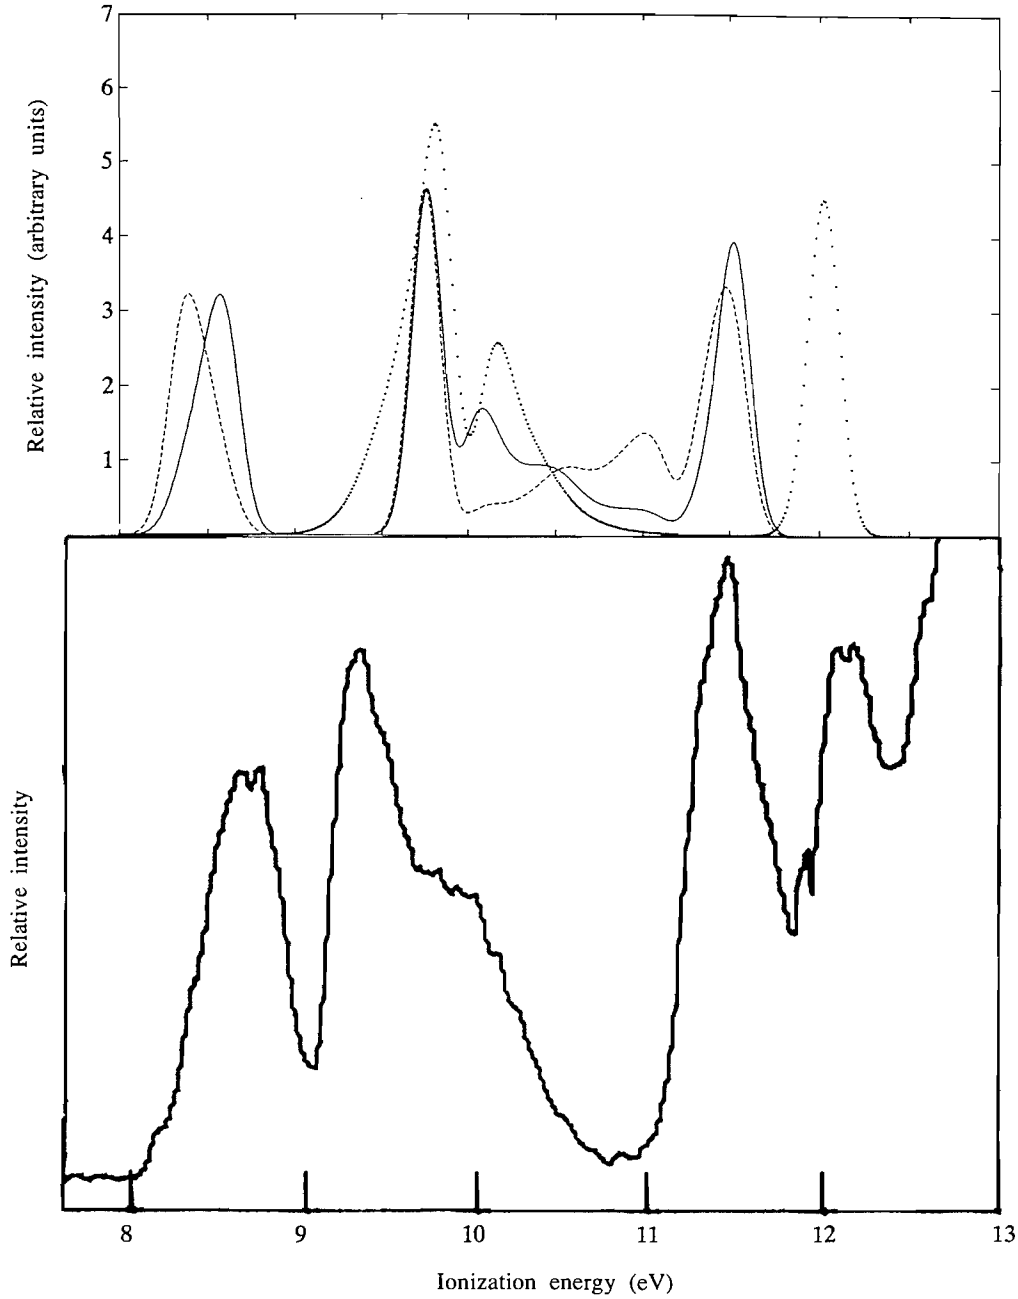

FIG. 5. The photoelectron spectrum of 2,6-difluorothioanisole. Synthetic spectra based on the MNDO (dotted line) and AM1 (dashed line) results appear in the upper panel. The solid line was obtained from the hindering potential derived from the NMR data and the AM1 orbital energies. The actual spectrum appears in the lower panel.

tra that is in good agreement with all of the experimental spectra. These synthetic spectra are plotted as solid lines in Figs. 3–7.

The synthetic spectra of thioanisole appear in Fig. 3. Clearly the spectrum based on the MNDO results bears little resemblance to the experimental one. This primarily reflects the method's incorrect description of the rotational potential. Both the spectrum based on the AM1 results and that based on the AM1 orbital energies with the potential derived from ${}^6J_p^{C,H}$ are better representations. Both also resemble the spectrum calculated previously on the basis of empirical data (21). The present calculations indicate strong temperature dependencies for the intensities of the high-energy shoulder on the lowest energy peak and the long, low-energy shoulder on the third peak, both shoulders being associated with nonplanar conformations. Such effects have been observed in the variable temperature photoelectron spectrum (22). Thus, the photoelectron spectrum does indicate that thioanisole prefers the planar conformation and the spectrum is not inconsistent with a twofold barrier of about 5 kJ mol^{-1}. Attempts to reproduce the experimental spectra more exactly are not warranted given the crudity of the present computational model and the available orbital energies.

For 2-fluorothioanisole, the breadth of the first and third peaks in Fig. 4 demonstrates that the methyl group can undergo a large amplitude libration about the planar minimum in the rotational potential because the twofold com-

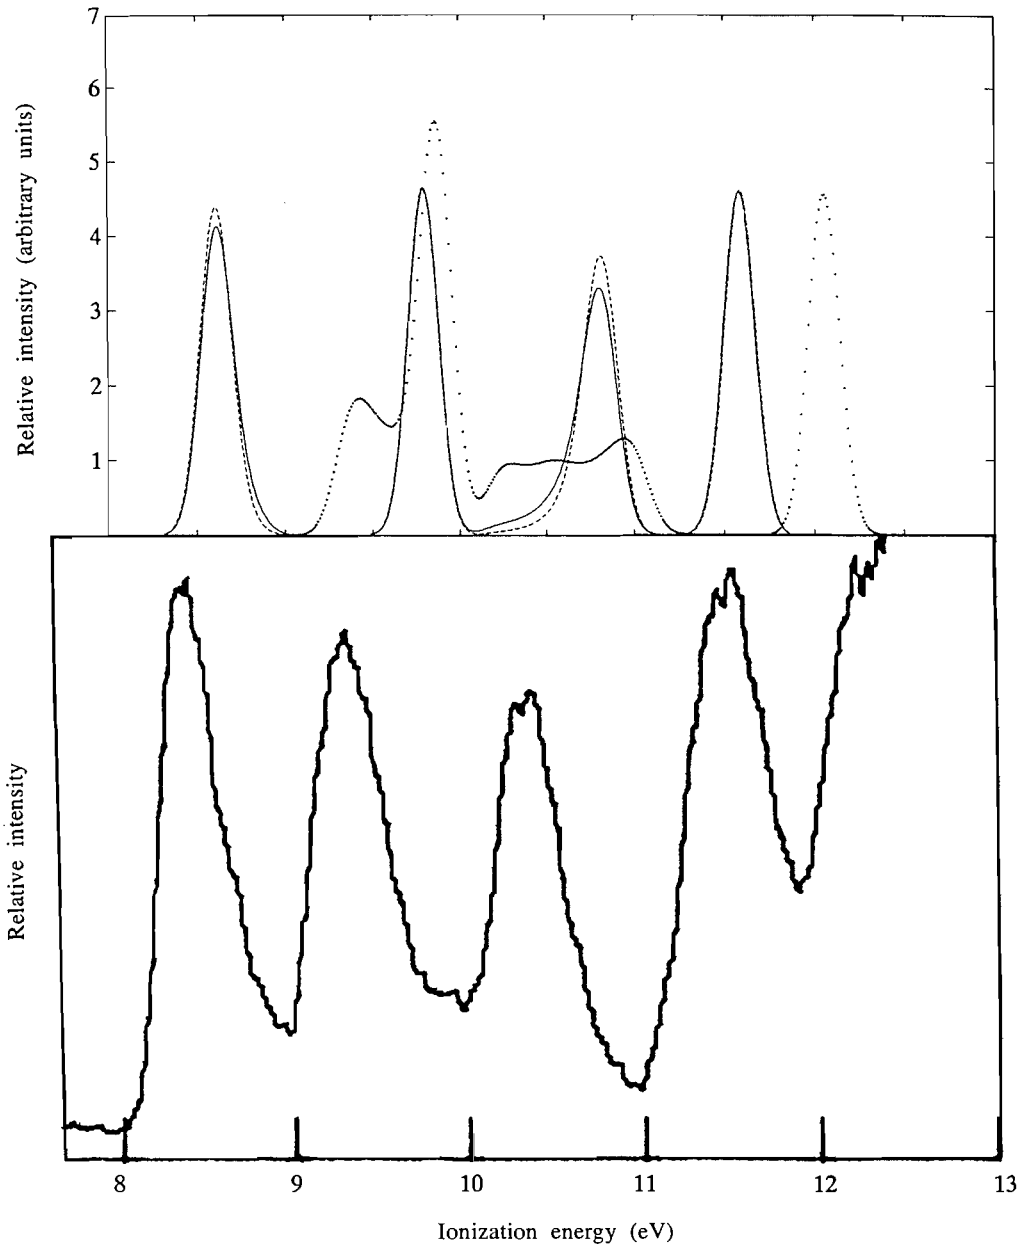

FIG. 6. The photoelectron spectrum of 3,5-difluorothioanisole. Synthetic spectra based on the MNDO (dotted line) and AM1 (dashed line) results appear in the upper panel. The solid line was obtained from the hindering potential derived from the NMR data and the AM1 orbital energies. The actual spectrum appears in the lower panel.

ponent of the potential is small. Because these orbital energies have relatively strong angular dependencies, this librational freedom is manifest in broadened peaks. The actual spectrum bears little similarity to the spectrum based on the MNDO results, but the other two synthetic spectra are reasonable facsimiles. With no twofold component to the barrier, the spectrum might be strongly dependent upon the *syn–anti* preference, but the computations give nearly identical spectra for both cases because of the near symmetry of the orbital energies about $\phi = 90°$. Thus, there is no strong evidence to support the preference for the *anti* orientation. The solid line in the upper panel of Fig. 4 was computed for a purely onefold barrier of 6 kJ mol^{-1}. As the height of the onefold component is increased in the calculations, the computed intensity in the 10.8 eV region increases relative to that in the 10.2 eV region. On this basis, the shape of the experimental spectrum suggests that the true barrier is of comparable or greater height.

The MNDO-based spectrum of 2,6-difluorothioanisole in Fig. 5 does not resemble the actual spectrum, despite the fact that the MNDO calculations reproduce the correct conformational preference. As for 2-fluorothioanisole, the first and third bands are indicative. The peak around 8.5 eV is somewhat narrower than the corresponding peak in Fig. 4, as found experimentally. The third band appears as a broad, high-energy shoulder in the 10–10.5 eV range. Unlike the corresponding band for 2-fluorothioanisole, this band is essentially featureless, as found experimentally. Notice that the intensity of the band *decreases* as the ionization energy increases. In the synthetic spectrum derived from the AM1

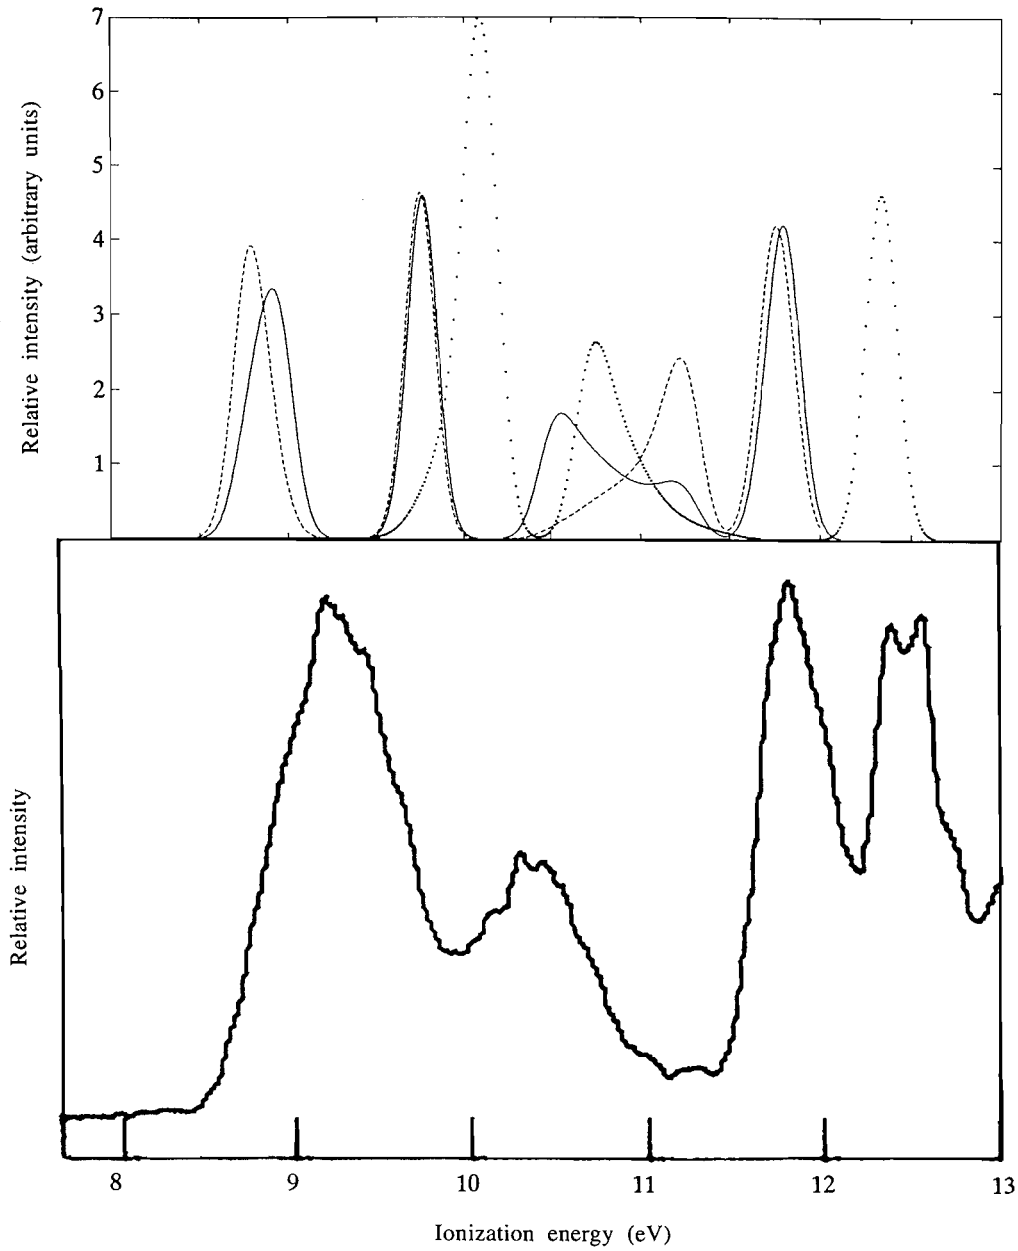

FIG. 7. The photoelectron spectrum of 2,3,5,6-tetrafluorothioanisole. Synthetic spectra based on the MNDO (dotted line) and AM1 (dashed line) results appear in the upper panel. The solid line was obtained from the hindering potential derived from the NMR data and the AM1 orbital energies. The actual spectrum appears in the lower panel.

results (dashed line in Fig. 5), which give the wrong conformational preference, the intensity increases with ionization energy because the conformations with the higher orbital energy have a lower thermal population. This feature provides strong evidence that 2,6-difluorothioanisole prefers conformations near $\phi = 90°$.

For the 3,5-difluoro derivative, both the AM1 and NMR potentials produce four relatively sharp, well-separated peaks, as shown in Fig. 6, despite the strong dependence of the first and third orbital energies on ϕ. The same pattern is found experimentally. This is consistent with a relatively high barrier and a preference for the planar conformation. According to the model, the low-energy shoulder of the third peak should grow as the temperature increases and nonplanar conformations become more abundant, but no attempt has been made in this laboratory to verify this prediction experimentally.

In the case of 2,3,5,6-tetrafluorothioanisole, the MNDO spectrum is somewhat similar to the actual spectrum in Fig. 7. According to the MNDO results, the two highest orbitals are nearly degenerate in the vicinity of $\phi = 90°$, giving rise to a single, intense peak in the spectrum. Both the barrier implied by the AM1 results and the barrier derived from ${}^6J_p^{C,H}$ yield spectra that are similar to the experimentally observed spectrum of 2,3,5,6-tetrafluorothioanisole, but neither method reproduces the intensity of the lowest energy peak because the two highest orbitals remain well separated in energy. The peak around 10.3 eV is more indicative. It is associated with the third highest occupied MO. Recall that the AM1 results indicate that the molecule prefers $\phi =$

For personal use only.

0° but the NMR results suggest $\phi = 90°$. From the dashed and solid curves in the upper panel of Fig. 7, a peak at lower energy with a high-energy shoulder is consistent with a preference for the perpendicular conformation. This is the more likely description of the actual spectrum in the lower panel. While the conformational preference implied by the experimental photoelectron spectrum is disputable, it seems clear that, even if planar conformations are preferred as AM1 suggests, the barrier is low, i.e., less than about 7 kJ mol^{-1}. Given the approximations involved in the synthesis of the spectra, the observed spectrum is probably consistent with the NMR potential.

Summary and conclusions

In this article, $^6J_p^{C,H}$ and the MNDO and AM1 semiempirical MO methods were used to investigate the conformational preferences and barriers to internal rotation about the exocyclic C1—S bond in a series of fluorothioanisoles. The NMR results indicated that these compounds preferred planar conformations unless both *ortho* positions are occupied by fluorine substituents. *ortho* Fluorine substituents tended to lower the twofold component of the barrier to internal rotation while *meta* fluorines raised this component. Neither semiempirical method could accurately predict the conformational preferences for all of the compounds, despite their apparent similarity: MNDO indicated that $\phi = 90°$ was energetically more favourable than $\phi = 0°$ or 180° in every case while AM1 indicated the opposite. On the basis of the empirical (NMR) and semiempirical rotational potentials and the orbital energies from the AM1 calculations, synthetic photoelectron spectra were generated. A comparison of the synthetic spectra with experimental spectra supported the conclusions derived from the $^6J_p^{C,H}$ measurements. The photoelectron spectra were indeed sensitive to the subtle conformational behaviour of these highly flexible molecules. However, the complexity of the integral equation relating the potential and orbital energies to the observed spectrum represents a significant impediment to the use of PES for obtaining quantitative information of the kind available from NMR.

Raman and infrared spectra, conformational stability, vibrational assignment, and *ab initio* calculations of *cis*-1,3-dichloropropene

J.R. DURIG,[1] T.G. COSTNER,[2] AND T.S. LITTLE

Department of Chemistry and Biochemistry, University of South Carolina, Columbia, SC 29208, U.S.A.

Received April 15, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

J.R. DURIG, T.G. COSTNER, and T.S. LITTLE. Can. J. Chem. **71**, 1751 (1993).

The Raman (3200–10 cm^{-1}) and infrared (3200–20 cm^{-1}) spectra of gaseous and solid *cis*-1,3-dichloropropene, *cis*-ClHC=CHCH$_2$Cl, have been recorded. Additionally, the Raman spectrum of the liquid with qualitative depolarization data has also been obtained. These spectral data have been interpreted on the basis that the molecule exists predominantly in the *gauche* (allylic chlorine atom oriented *gauche* to the double bond) conformation in all physical phases. Some bands in the infrared spectrum of the gas could be due to a second higher energy conformer but the lack of corresponding Raman bands casts doubt on such an assignment. *Ab initio* Hartree–Fock gradient calculations employing the RHF/6-31G* basis set are consistent with two minima that correspond to the two equivalent *gauche* forms for the potential surface for the internal rotation about the C—C bond. These minima occur at dihedral angles, $\measuredangle_{dih}$ ClCCC, of 122° and 238° (0° corresponds to the *syn* conformation) and the *gauche* to *gauche* barrier at the 180° transition state, which corresponds to the *anti* structure, is 342 cm^{-1}. The barrier from the *gauche* minima to the *syn* (0°) structure, which is also a transition state, is 2425 cm^{-1}. Complete equilibrium geometries for the *gauche* structure have been determined with the RHF/3-21G*, RHF/6-31G*, and MP2/6-31G* basis sets. A normal coordinate analysis utilizing a harmonic force field calculation with the RHF/3-21G* basis set has been carried out for the *gauche* conformer. The results are discussed and compared with the corresponding quantities obtained for some similar molecules.

J.R. DURIG, T.G. COSTNER et T.S. LITTLE. Can. J. Chem. **71**, 1751 (1993).

On a mesuré les spectres Raman (3200–10 cm^{-1}) et infrarouges (3200–20 cm^{-1}) du *cis*-1,3-dichloropropène, *cis*-ClHC=CHCH$_2$Cl, à l'état gazeux et solide. On a aussi obtenu le spectre Raman du liquide avec des données sur la dépolarisation qualitative. On interprète ces données spectrales sur la base d'une molécule qui existerait principalement dans la conformation *gauche* (l'atome de chlore allylique *gauche* par rapport à la double liaison) dans toutes les phases physiques. Quelques bandes du spectre infrarouge à l'état gazeux pourraient être dues à un deuxième conformère d'énergie plus élevée; toutefois, le manque de bandes correspondantes dans le spectre Raman jette un doute sur une telle attribution. Des calculs *ab initio* de gradient de Hartree–Fock réalisés à l'aide d'ensembles de base RHF/6-31G* sont en accord avec la présence de deux minima qui correspondent aux deux formes *gauche* équivalentes pour la surface de potentiel de la rotation interne autour de la liaison C—C. Ces minima se présentent aux angles dièdres, $\measuredangle_{dih}$ ClCCC, de 122° et 238° (0° correspond à la conformation *syn*) et la barrière *gauche* à *gauche* de l'état de transition de 180°, qui correspond à la structure *anti*, se présente à 342 cm^{-1}. La barrière pour le passage du minima *gauche* à la structure *syn* (0°), qui est aussi un état de transition, se présente à 2425 cm^{-1}. Utilisant des ensembles de base RHF/3-21G*, RHF/6-31G* et MP2/6-31G*, on a déterminé les géométries d'équilibre complètes de la structure *gauche*. Faisant appel à un ensemble de base RHF/3-21G* et utilisant un calcul de champs de force harmonique, on a effectué une analyse en coordonnées normales du conformère *gauche*. On discute des résultats obtenus et on les compare aux quantités correspondantes obtenues pour quelques molécules similaires.

[Traduit par la rédaction]

Introduction

The vibrational and rotational spectra of the allyl halides have been of interest for a number of years (1–23). Our recent investigations have included the determination of the potential functions governing internal rotation about the C(sp^3)—C(sp^2) bonds of the parent 3-halopropenes and some substituted derivatives (24–32). Allyl fluoride (24–26), chloride (27), bromide (28, 31), and iodide (32) have been determined to exist as a mixture of *syn* and *gauche* conformers, and for the fluoride we have shown that the conformer that has the halogen atom *syn* to the double bond is the more stable rotamer (24–26). For 3-chloropropene, the value of the energy difference (27) was inferred to be less than 100 cm^{-1} (286 cal/mol) and the spectral data merely indicated a very slight preference for the *syn* conformer for the gaseous state. For allyl bromide (28, 31) and iodide (32) the *gauche* structure is thermodynamically preferred.

Most recently, we extended our studies of the 3-halopropene series to include an investigation of the far-infrared and Raman spectra of a number of simple alkenes for which one of the vinylic hydrogen atoms was substituted by a methyl group or halogen atom. For *trans*-1,3-dichloropropene (33) we showed that both the *syn* and *gauche* conformers are present in the vibrational spectra and that the *gauche* conformer is thermodynamically preferred by 342 cm^{-1}, which is consistent with the previously reported NMR (34) and molecular mechanics (35) results.

To provide similar data for the corresponding molecule with the chlorine atom substituted *cis* to the CH_2Cl moiety, we initiated an infrared and Raman spectroscopic study of *cis*-1,3-dichloropropene. Shen (36) reported the electron diffraction data for *cis*-1,3-dichloropropene and the results indicated that only one rotamer (*gauche*) was present. It was found that the torsional potential function could be approximated by a quartic double minimum function with transition states at the *syn* (0°) and *anti* (180°) positions. This study

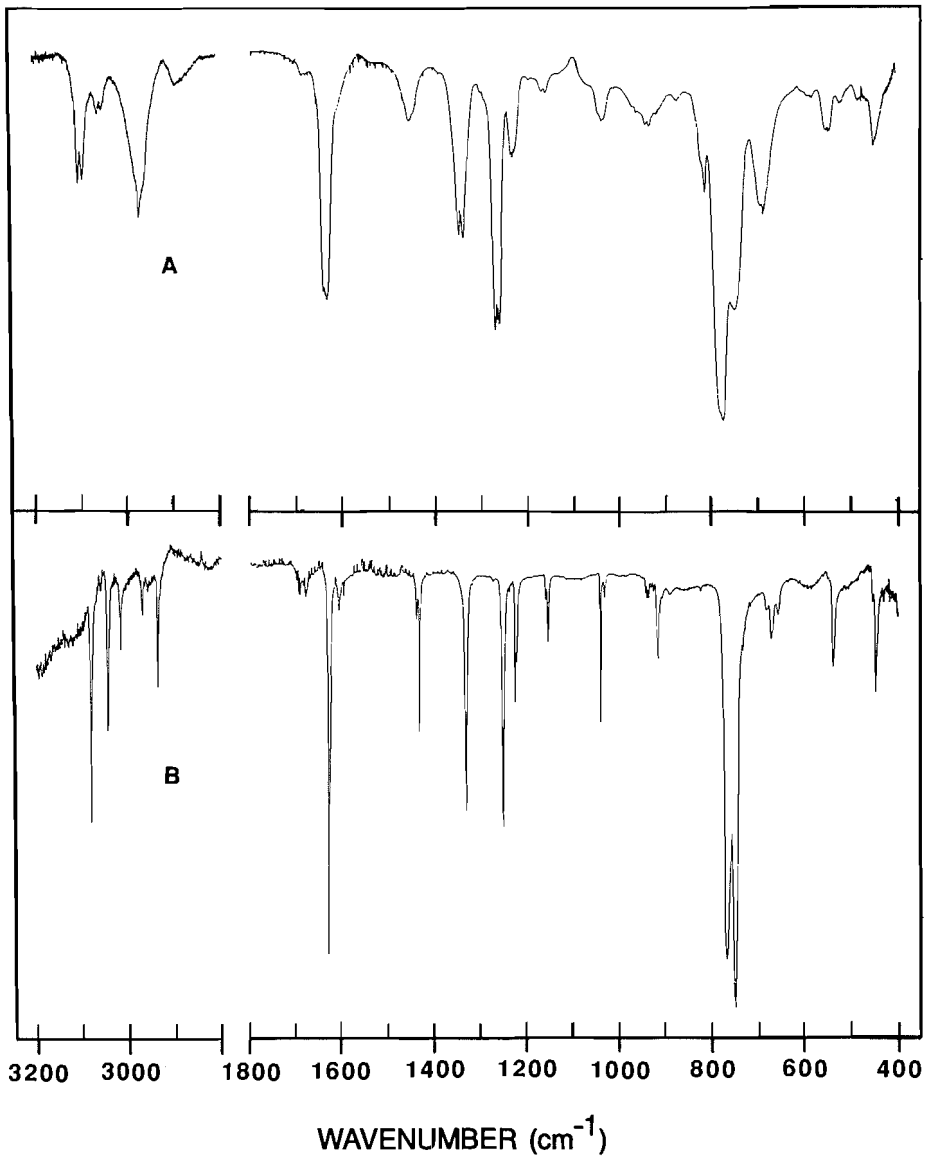

FIG. 1. Mid-infrared spectra of *cis*-1,3-dichloropropene: (*A*) gas and (*B*) annealed solid.

is in agreement with a previous NMR study (34) and molecular mechanics calculations (35) in which the authors found no evidence for a higher energy *syn* conformer. In each of these studies steric effects, arising from the two chlorine atoms eclipsing each other, were deemed to be the major cause for the nonexistence of a *syn* conformer.

Because an appreciable amount of a second higher energy conformer has been detected in the vibrational spectra of the 3-halopropenes (24–28, 31, 32) and *trans*-1,3-dichloropropene (33), the possibility remains that a small amount of it may exist for *cis*-1,3-dichloropropene. Therefore, we have undertaken the present spectroscopic study to carry out a conformational analysis, based on the previously unreported vibrational spectra, and to perform *ab initio* calculations for comparison with the results obtained from molecular mechanics calculations (35). The conformational stability, structural parameters, and torsional potential function are compared to the corresponding quantities for some related molecules.

Experimental

The sample of *cis*-1,3-dichloropropene was purchased from Columbia Organic Chemical Company (Columbia, S.C.) with a stated purity of >80%. Further purification was carried out with a low-temperature, low-pressure fractionation column. The sample was stored in the dark at Dry Ice temperature in an evacuated sample tube equipped with a greaseless stopcock.

The mid-infrared spectra (3200–400 cm^{-1}) of the gas and solid (Fig. 1) were recorded with a Digilab model FTS-14C Fourier transform interferometer equipped with a Ge/KBr beamsplitter, a Nichrome wire source, and a triglycine sulfate (TGS) detector. A KBr plate cooled with boiling liquid nitrogen was used as the sample substrate for the spectrum of the solid and a 12-cm cell equipped with CsI windows was used to contain the sample for obtaining the spectrum of the gas. The spectrum of the solid, at a resolution of 1 cm^{-1}, was obtained after several cycles of warming and cooling the sample until no changes were observed in the spectrum.

The far-infrared spectrum of the gas (Fig. 2) was recorded from the sample contained in a 1-m cell at a resolution of 0.10 cm^{-1} on a Nicolet model 200 SXV interferometer equipped with a vacuum bench and a liquid helium cooled germanium bolometer contain-

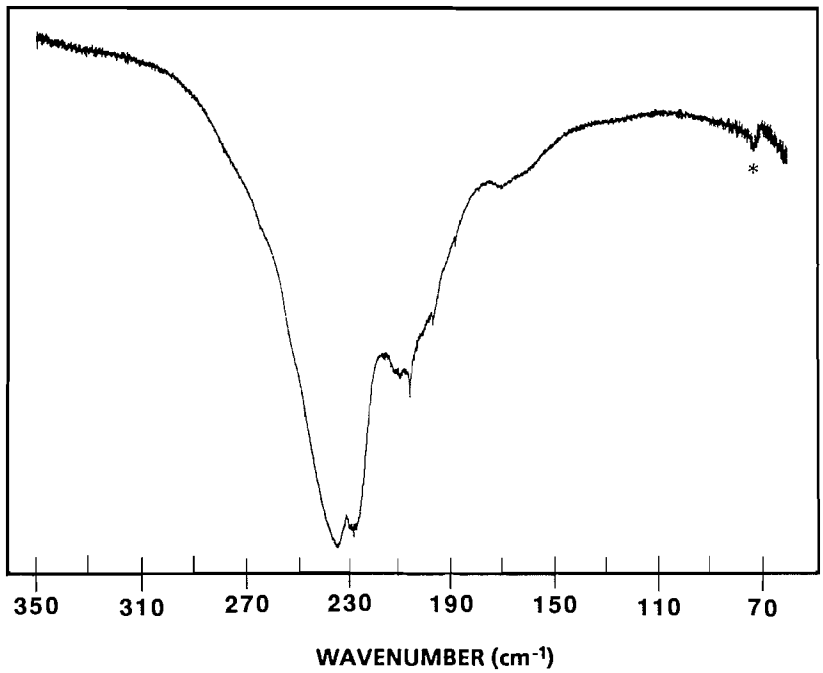

FIG. 2. Far-infrared spectrum of gaseous *cis*-1,3-dichloropropene. The asterisk (*) denotes absorption due to polyethylene.

ing a wedged sapphire filter and polyethylene windows. Interferograms for both the sample and empty reference cell were recorded 512 times, averaged, and transformed with a boxcar truncation function. Traces of water were removed by passing the gaseous sample through activated 3 Å molecular sieves using standard high-vacuum techniques.

The Raman spectra (Fig. 3) were recorded on a Cary model 82 spectrophotometer equipped with a Spectra-Physics model 171 argon ion laser operating on the 5145 Å line. The spectrum of the gas was recorded using a standard Cary multipass accessory and a laser power at the sample of 2 W. Reported frequencies are expected to be accurate to ± 2 cm^{-1}. The spectrum of the liquid was recorded from the sample sealed in a glass capillary. For the spectrum of the solid, the sample was deposited onto a blackened brass plate, held 15° from the normal, cooled by boiling liquid nitrogen, and contained in a cell fitted with quartz windows.

The FT–Raman spectrum of liquid *cis*-1,3-dichloropropene was recorded on a Bruker model IFS 66 interferometer equipped with a model FRA106 FT–Raman attachment. The excitation source was the 1.064 μm line from a CVI YAG-MAX model C-95 laser, giving a 2-mm beam with an optical noise of 4%. The Nd:YAG rod (65 mm long) was pumped by two 1.5-kW tungsten–halogen lamps. A liquid nitrogen cooled Ge detector was used to collect the spectrum. Detector cooling, laser warming, and stabilization for more than 30 min were allowed before data collection. These data were recorded by coaddition of 100 scans at 2 cm^{-1} resolution with a laser power of approximately 300 mW at the sample.

Vibrational assignment

The bands observed in the mid-infrared spectrum of gaseous *cis*-1,3-dichloropropene have hybrid contours. Furthermore, the Raman spectrum of the gas exhibits 14 *Q* branches, which persist in the corresponding spectrum of the solid. These spectral features are consistent with a conformer of C_1 symmetry in the fluid phases, i.e., the *gauche* form, and the persistence of this form in the solid. For this form, all 21 of the normal vibrational modes belong to the totally symmetric *A* species, which are expected to give rise to *Q* branches in the Raman spectra of the vapor and hybrid infrared band contours.

It has been shown that the number and position of hydrogen atoms bonded to substituted ethylenes can be characterized by group frequency correlations made from vibrational spectra (37). Our most recent studies of the 3-halopropenes (24–28, 31, 32) have shown a wide variation in the observed frequencies of the carbon–hydrogen and skeletal bending modes. The extent of mixing among the chosen set of symmetry coordinates for these vibrational modes is significantly influenced by the halogen substituent and the structural conformation.

A comparison of the observed vibrational spectra for *trans*-1,3-dichloropropene (33) with those for the *cis* molecule (Figs. 1–3) shows little sensitivity in the observed frequencies for the fundamentals associated with the -CH_2Cl moiety. The CH_2 antisymmetric stretch and CH_2 wag occur at the slightly higher frequencies of 3020 and 1264 cm^{-1} for the *cis* molecule, compared to 3005 and 1241 cm^{-1} for the *trans* molecule. These frequencies are only slightly different from the observed frequencies of 2999 and 1260 cm^{-1} for the corresponding vibrations of 3-chloropropene (27). The -CH_2 twist and rock both occur within 10 cm^{-1} of each other for the *cis* and *trans* dichloropropene molecules.

Of particular interest are the assignments of the two out-of-plane C—H bending modes of the vinyl group. Factors affecting the out-of-plane hydrogen deformation frequencies in olefins and their derivatives have been studied extensively (37). For a *cis*-disubstituted system, the out-of-plane hydrogen bends are either in-phase, with respect to the symmetry plane of the vinyl group, or out-of-phase. The out-of-phase, out-of-plane motion has little or no resultant dipole moment change and is expected to give rise to an infrared absorption of small intensity. This mode is assigned to the observed Raman frequency of 1036 cm^{-1} in the liquid phase. The calculated infrared intensity for this fun-

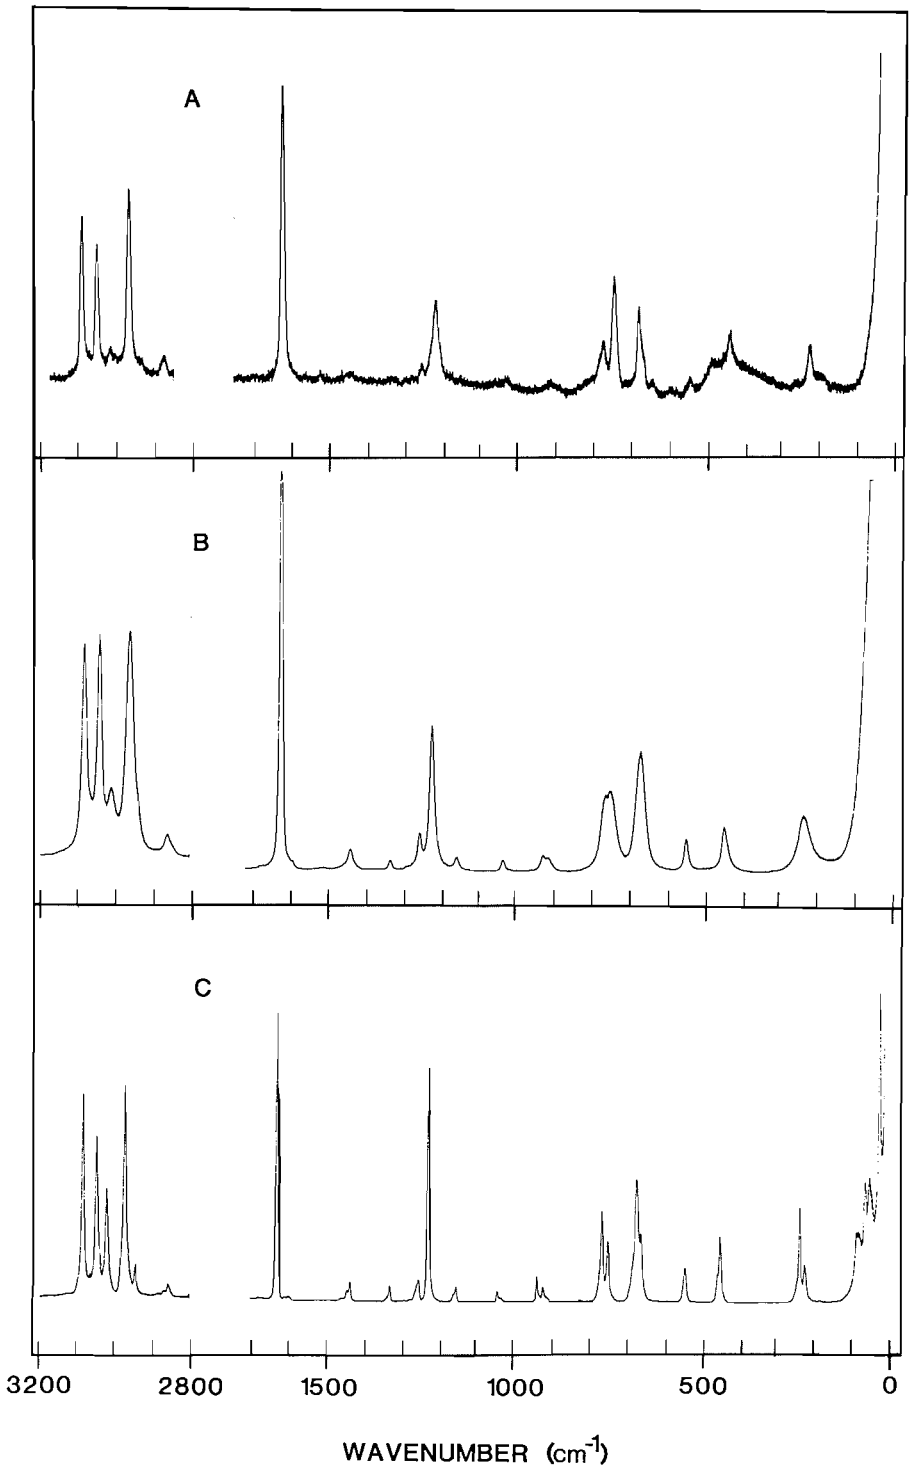

FIG. 3. Raman spectra of *cis*-1,3-dichloropropene: (*A*) gas; (*B*) liquid; and (*C*) annealed solid.

damental is small (see *Ab initio* calculations), but this mode is observed as an infrared band of moderate intensity. The in-phase, out-of-plane mode has been reported (37) to have a group frequency range of 675–730 cm^{-1} for *cis*-disubstituted ethylenes and is expected to give rise to a strong band in the infrared spectrum. This mode is assigned to the infrared band observed at 780 cm^{-1} and is calculated and observed to be the most intense feature in the infrared spectrum. The closely lying, and intense, absorption of one of the C—Cl stretching modes (751 cm^{-1}) would complicate these assignments in the absence of the normal coordinate analysis. From these results it is clear that the CH bend should be assigned to the higher frequency of 780 cm^{-1} and the C—Cl stretch to the frequency of 751 cm^{-1} in the infrared spectrum of the gas phase.

A review of the assignments for the skeletal bending modes of related molecules indicates considerable variation in the assigned frequency for a given vibration. For example, the CCC bending mode for allyl chloride (27) (3-chloropropene) is assigned to a band at 404 cm^{-1}, but for *trans*-1,3-

For personal use only.

dichloropropene (33) this vibration occurs near 150 cm^{-1}. This variation in assignment is consistent with the change in potential energy distribution among a similar set of symmetry coordinates. The change in potential energy is directly related to the structural conformation and the type and position of the substituent on the vinyl group. The CCC and CCCl bending modes for *cis*-1,3-dichloropropene, which occur in the plane of the vinyl group, are extensively mixed (see *Ab initio* calculations). The calculated scaled frequency of 205 cm^{-1} has a potential energy distribution representing approximately 50% each of the symmetry coordinates corresponding to the CCC and CCCl bending modes. Similarly, the calculated scaled frequency of 541 cm^{-1} has its potential energy nearly equally distributed over four symmetry coordinates. Based on these results, it would be misleading to assign the CCC and CCCl bending modes to any one observed frequency such as the 550 and 200 cm^{-1} bands, respectively. For *trans*-1,3-dichloropropene, the symmetry coordinate corresponding to the CCC bend has its maximum potential energy distribution corresponding to the observed frequency of 328 cm^{-1} for the *gauche* conformer but at 150 cm^{-1} for the *syn* conformer. Thus, it is not very instructive to compare frequencies for these low-frequency bending modes between individual conformers or among similar molecules. A summary of the observed vibrational frequencies and approximate description of the vibrational modes is provided in Table 1.

Also included in Table 1 are several infrared bands that appear in the spectrum of the gas but are absent in all other spectra. The most prominent of these occur at 813, 585, 520, and 476 cm^{-1}. These bands become less pronounced or disappear in the infrared spectrum of the solid, which indicates that they could arise from fundamental modes of a higher energy conformation. Alternatively, they may arise from combination or difference bands of the *gauche* form. If a higher energy conformer exists, then, based on related molecules, this conformer would have a *syn* (allylic chlorine *syn* to the double bond) structure. Calculated frequencies for this form indicate that the 585 cm^{-1} band would correspond to an A' mode and should become pronounced in the Raman spectrum of the gas at higher temperatures. Spectra obtained at 55°C did not reveal any such feature. If this conformer exists, then it would lie at a considerably higher energy, >1 kcal/mol, than the *gauche* form and should become pronounced with a relatively small increase in temperature. Therefore, the absence of discrete Raman features that coincide with these infrared frequencies, casts doubt that they arise from a higher energy form.

Ab initio calculations

The LCAO-MO-SCF restricted Hartree–Fock calculations were performed with the GAUSSIAN-90 program (38) using Gaussian-type basis functions. The energy minima with respect to nuclear coordinates were obtained by the simultaneous relaxation of all of the geometric parameters using the gradient method of Pulay (39). The structural parameters, rotational constants, and dipole moments for the *gauche* conformer determined with the RHF/3-21G*, RHF/6-31G*, and MP2/6-31G* basis sets are given in Table 2, along with the structural parameters obtained for the *gauche* conformer from an earlier electron diffraction study (36).

Considering the results obtained from the calculations with both the RHF/3-21G* and RHF/6-31G* basis sets, the bond distances agree to within 0.008 Å except for the C—Cl* (Cl atom of the -CH_2Cl group) bond distance. This parameter is calculated to have a value of 1.821 Å with the RHF/3-21G* basis set but is predicted to be 0.021 Å shorter when calculated with the RHF/6-31G* basis set. The shorter C—Cl* bond distance is more consistent with the results from the electron diffraction study, where a value of 1.806 ± 0.003 Å is reported (36). The bond angles typically agree within ~1° between the two basis sets.

The structures were also calculated by employing the 6-31G* basis set with electron correlation at the MP2 level. The absolute values for the structures are quite different from those obtained using the basis sets with Hartree–Fock limits. The carbon–hydrogen bond lengths calculated with the 6-31G* basis set with electron correlation are ~0.01 Å longer than those calculated with Hartree–Fock limits and those determined from the electron diffraction study (36). The longer C—H distances should be closer to the actual values since the C—H distances of 1.078 Å for the -CH_2Cl group are certainly too short.

The heavy atom bond lengths predicted from the MP2/6-31G* calculation are in better agreement with the structural parameters obtained from the electron diffraction study (36) than those from the calculations using the RHF/3-21G* and RHF/6-31G* basis sets, except for the C—C and C—Cl* bond distances. Clearly, both of these bond distances are calculated with the MP2/6-31G* basis set to be entirely too short by at least 0.010 Å. The bond angles, on the other hand, are hardly effected by using the different basis sets and all are within the uncertainties reported in the electron diffraction study (36). It is difficult to ascertain the reliability of the calculated and experimentally determined bond angles. Uncertainties of greater than 1° are reported in the electron diffraction study (36) and the determination of the values and uncertainties is based, in part, on assumed values for the HCC angles. According to our experiences, however, the *ab initio* calculated bond angles are generally reliable to about 1° except for dihedral angles for the *gauche* conformers.

Potential surface scan

The optimized geometry for the *gauche* conformer obtained with the RHF/6-31G* basis set was utilized to estimate an asymmetric torsional potential surface by allowing the torsional dihedral angle, $\measuredangle_{dih}$ ClCCC, to change from 180° to 0°, in increments of 10°, with calculation of the energy at each point. This rough estimation did not provide any indication of a second conformer at the *syn* (0°) position, which is consistent with the previously reported electron diffraction and molecular mechanics results for *cis*-1,3-dichloropropene (35, 36). Calculations at the *gauche* minimum and at the *anti* (180°) transition state, by relaxing all of the geometric parameters, result in the potential function given in Fig. 4. From these optimizations with the RHF/6-31G* basis set, the total energies are −1034.871097 and −1034.869537 hartree (1 hartree = 219 474 cm^{-1}) for the *gauche* and *anti* (180°) positions, respectively. Since the 3-halopropenes and substituted derivatives typically have a minimum at the *syn* (0°) position in their corresponding potential functions, an optimization was attempted at the *syn* (0°) position by relaxing all of the geometric parameters. A minimum energy structure was not found. A subsequent calculation, treating the *syn* (0°) position as a transition state, converged on an optimized structure with a total energy of

−1034.860048 hartree. Therefore, at this level of calculations, the *gauche* conformer is found to be the only stable conformer. The *gauche* to *gauche* barrier over the *anti* (180°) transition state and the *gauche* to *gauche* barrier over the *syn* (0°) transition state are found to be 342 and 2425 cm^{-1}, respectively.

Normal coordinate analysis

To obtain a more complete description of the molecular motions involved in the normal modes of *cis*-1,3-dichloropropene, and to aid in the vibrational assignment of the fundamentals, we carried out a normal coordinate analysis. The force field in Cartesian coordinates was calculated by the GAUSSIAN-90 program (38) with the RHF/3-21G* basis set. From previous studies (24), it was found that the differences in the values of force constants and frequencies are not significant when the smaller, as opposed to the larger, RHF/6-31G* basis set is used. These calculations were performed by using the Wilson FG matrix method (40). The following procedure was used to transform the force constants in Cartesian coordinates from the *ab initio* calculations to the required internal symmetry coordinates.

The Cartesian coordinates obtained for the optimized structure for the *gauche* conformer were input into a *G*-matrix program (41) with a complete set of 24 internal coordinates (Fig. 5). This set of 24 internal coordinates was used to form 21 symmetry coordinates together with three redundancies (Table 3). The *B*-matrix was used to convert the *ab initio* force field in Cartesian coordinates to the desired internal coordinates. The force fields for the *gauche* conformer are provided in Table 4. All diagonal elements of the force fields in internal coordinates were assigned scaling factors. Initially, all scaling factors were kept fixed at a value of 1.0 to produce pure *ab initio* calculated vibrational frequencies. Scaling factors of 0.9 for stretching coordinates, 0.8 for bending coordinates, and 1.0 for torsional coordinates were used to obtain the "fixed scaled" force field, resultant frequencies, and the potential energy distribution (P.E.D.), which are listed in Table 5. Even with these relatively crude scaling factors the predicted frequencies are in error by approximately 5%, which provides excellent support for the vibrational assignment.

Calculated Raman spectrum

A Raman spectrum for *cis*-1,3-dichloropropene was calculated (Fig. 6) using frequencies and scattering activities determined from the GAUSSIAN-90 program (38) using the RHF/3-21G* basis set. The GAUSSIAN-90 option to calculate the polarizability derivatives analytically was used. The Raman scattering cross sections, $\partial\sigma_j/\partial\Omega$, which are proportional to the Raman intensities, can be calculated from the scattering activities and the predicted frequencies for each normal mode using the relationship (42)

$$\frac{\partial\sigma_j}{\partial\Omega} = \left(\frac{2^4\pi^4}{45}\right)\left(\frac{(\nu_0 - \nu_j)^4}{1 - \exp\left[\frac{-hc\nu_j}{kT}\right]}\right)\left(\frac{h}{8\pi^2 c\nu_j}\right)S_j$$

where ν_0 is the exciting frequency, ν_j is the vibrational frequency of the jth normal mode, and S_j is the corresponding

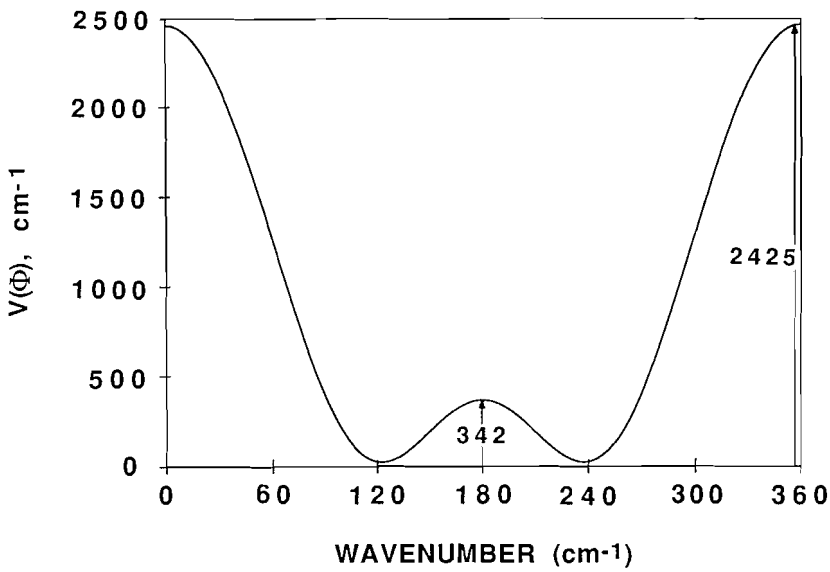

FIG. 4. The potential function governing internal rotation of *cis*-1,3-dichloropropene as determined by *ab initio* calculations with the RHF/6-31G* basis set. This potential surface was calculated by allowing for optimization at the transition states and at the *gauche* minimum by relaxing all of the geometric parameters.

Raman scattering activity. To obtain the polarized Raman scattering cross sections, the polarizabilities are incorporated into S_j by $S_j[(1 - \rho_j)/(1 + \rho_j)]$, where ρ_j is the depolarization of the jth normal mode. The Raman scattering cross sections and calculated frequencies are used together with a Lorentzian function to obtain the calculated spectrum. The predicted Raman spectrum for the *gauche* conformer of *cis*-1,3-dichloropropene, using scaled frequencies (Table 5), is

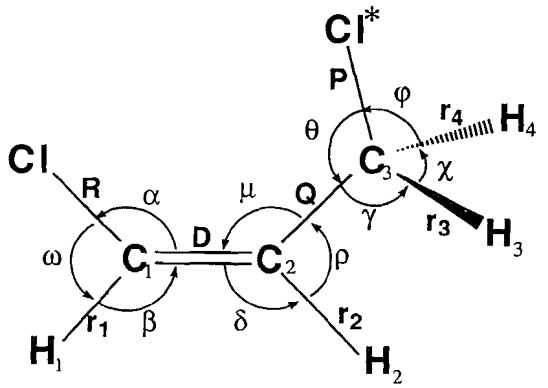

FIG. 5. Internal coordinates for *cis*-1,3-dichloropropene.

compared to the FT–Raman spectrum of the liquid phase (Fig. 6) and is remarkably similar, with the exception of the relative intensities of the C=C and C—Cl stretching modes, the C—C—Cl* bending mode, and the asymmetric torsional mode. In the 800–1300 cm^{-1} region, where the C—H bending motions occur and assignments are often difficult, the two spectra are very comparable. It should be noted that ν_{21}, the asymmetric torsional mode, was omitted from the calculated spectrum since its large calculated intensity interfered with the scaling of the vertical axis, and that the very weak band at ~330 cm^{-1} (Fig. 6) is due to an impurity arising from a small amount of *trans*-1,3-dichloropropene.

Discussion

From a careful inspection of the infrared spectra of the gas and the Raman spectra of the gas, liquid, and solid phases of *cis*-1,3-dichloropropene, it is clear that the conformer that persists in the spectrum of the annealed solid also predominates in the spectra of the gas and liquid phases. Possible spectral evidence to support the existence of a higher energy conformer was observed in the infrared spectrum of the gas, but was inconclusive since corresponding bands were not observed in the Raman spectrum of the gas. Therefore, we have interpreted all of the data on the basis that the *gauche* conformer is the only existing form of this molecule at ambient temperature. This conclusion is supported by *ab initio* calculations using the RHF/6-31G* basis set, which indicated that the *anti* (180°) and *syn* (0°) positions are transition states. This interpretation is in agreement with previous studies (34–36). For the *syn* conformer of 3-fluoropropene and 3-chloropropene, the nonbonded distance between the halogen atom and the vinylic hydrogen atom is near the sum of the van der Waals radii. Therefore, it is not surprising that when the hydrogen atom is substituted with a chlorine atom, steric forces predominate and this form of *cis*-1,3-dichloropropene is either unstable or occurs at a much higher energy than the *gauche* conformer. Additionally, the C—H bond on carbon-2 would eclipse the C—X bond on the CH_2X group in the *anti* position. This is why the struture corresponding to this conformer occurs as a transition state in the asymmetric potential functions of the 3-halopropenes.

The most pronounced spectral feature in the spectra of the gas or liquid, which disappears in the spectrum of the solid, is the infrared band observed at 813 cm^{-1} in the spectrum of the gas. If this intense band was due to a conformer peak, we would expect to observe more evidence throughout the vibrational spectrum for the existence of a *syn* conformer. However, it is possible that this infrared peak is a difference or combination band.

From the *ab initio* calculations with the RHF/STO-3G* basis set, the structure corresponding to the *syn* conformation occurs as a transition state in the potential surface governing internal rotation about the C—C bond. The structure corresponding to this transition state was optimized and frequencies and Raman scattering activities for the normal modes were calculated with the RHF/3-21G* basis set. A 5% population of the *syn* conformer was then added to the calculated Raman spectrum for the *gauche* form to obtain a calculated Raman spectrum for a mixed conformational system. Such a mixture would correspond to a conformational energy difference of approximately 600 cm^{-1} (1.7 kcal/mol). The only difference between this calculated spectrum and that of the pure *gauche* form (Fig. 6) was the presence of two very weak lines at 603 and 396 cm^{-1}. It is tempting to assign the weak line observed at 602 cm^{-1} in the Raman spectrum of the gas to the *syn* form, but this line did not appreciably increase in intensity as the temperature was increased. Therefore, if the *syn* conformer is present in ≤5% abundance it is likely that we would not have observed any evidence for its existence, and if present in >5% abundance more definitive evidence would probably have been observed.

The absence of an observed frequency for the asymmetric torsional mode of *cis*-1,3-dichloropropene precludes the estimation of the *gauche* to *gauche* barrier from experimental data, but comparisons to related molecules provide some information. The asymmetric torsional modes for the *gauche* conformers of the 3-halopropenes and substituted derivatives typically occur between 70 and 110 cm^{-1} and give rise to infrared bands having hybrid contours. The frequencies of these modes have been fairly well predicted by *ab initio* calculations using the RHF/3-21G* or RHF/STO-3G* basis sets. For example, the torsional mode for the *gauche* conformer of *trans*-1,3-dichloropropene (33) was predicted to occur at 87 cm^{-1} (RHF/3-21G*) and was observed in the far-infrared spectrum of the gas at 84.0 cm^{-1}. For *cis*-1,3-dichloropropene this mode is calculated to occur at 45 cm^{-1}, which seems too low when compared to the corresponding modes of some similar molecules. However, if the *gauche* to *gauche* barrier is as low as predicted by *ab initio* calculations (342 cm^{-1}), or estimated by the electron diffraction technique (~350 cm^{-1}) (36), then this would explain the considerably lower torsional frequency than those for 3-chloropropene (102 cm^{-1}) or *trans*-1,3-dichloropropene (84 cm^{-1}), which have *gauche* to *gauche* barriers of ~700 and ~400 cm^{-1}, respectively.

Another interaction affecting the torsional frequency is the extent of mixing of the torsional mode with other skeletal bending modes, which is present for 3-chloropropene (27) and *trans*-1,3-dichloropropene (33), but absent for *cis*-1,3-dichloropropene. Additionally, hyperconjugative interactions similar to those found in acetaldehyde (43) and fluoroacetyl chloride (44), both of which have the internal rotor bonded to an sp^2 carbon, may play a significant role in the ultimate value of this barrier. Further, for the *gauche* structure of *cis*-1,3-dichloropropene, one of the hydrogen atoms bonded to the sp^3 carbon eclipses the chlorine atom on the vinyl group, which would raise the total energy of the *gauche* structure relative to 3-chloropropene or *trans*-1,3-dichloropropene. For these latter two molecules the *gauche* structure results in two hydrogen atoms eclipsing each other and the nonbonded steric interactions would be minimal. This is evidenced by the change in the C—C—H_4 bond angle (RHF/6-31G*) between *cis*-1,3-dichloropropene (112.5°) and *trans*-1,3-dichloropropene (111.3°). Some steric repulsion exists for this structure of the *cis*-substituted molecule that would raise the energy of the *gauche* minima and, assuming the *gauche* to *gauche* transition state is approximately the same

[a]See Fig. 5 for atom numbering. The (†) and (§) denote the hydrogen atom bonded to carbon-1 and carbon-2, respectively, and the asterisk (*) denotes the chlorine atom bonded to the sp^3 carbon.
[b]Calculated using the RHF/3-21G* basis set.
[c]Calculated using scaling factors of 0.9 for stretches, 0.8 for bends, and 1.0 for the torsion.
[d]Calculated infrared intensities and Raman activities in km/mol and $Å^4$/amu, respectively.
[e]Taken from the spectrum of the gas phase. Frequencies denoted with an asterisk (*) are taken from the spectrum of the liquid phase.

energy, would consequently lower the *gauche* to *gauche* barrier over the *anti* (180°) transition state.

The potential function governing internal rotation of the CH_2Cl top of *cis*-1,3-dichloropropene has been determined using the RHF/6-31G* basis set and is consistent with the *gauche* minima lying 342 and 2425 cm^{-1} lower in energy than the *anti* (180°) and *syn* (0°) transition states, respectively. This potential function is in fair agreement with that obtained from molecular mechanics (35) calculations where the *syn* and *anti* barriers are 2169 cm^{-1} (6.2 kcal/mol) and

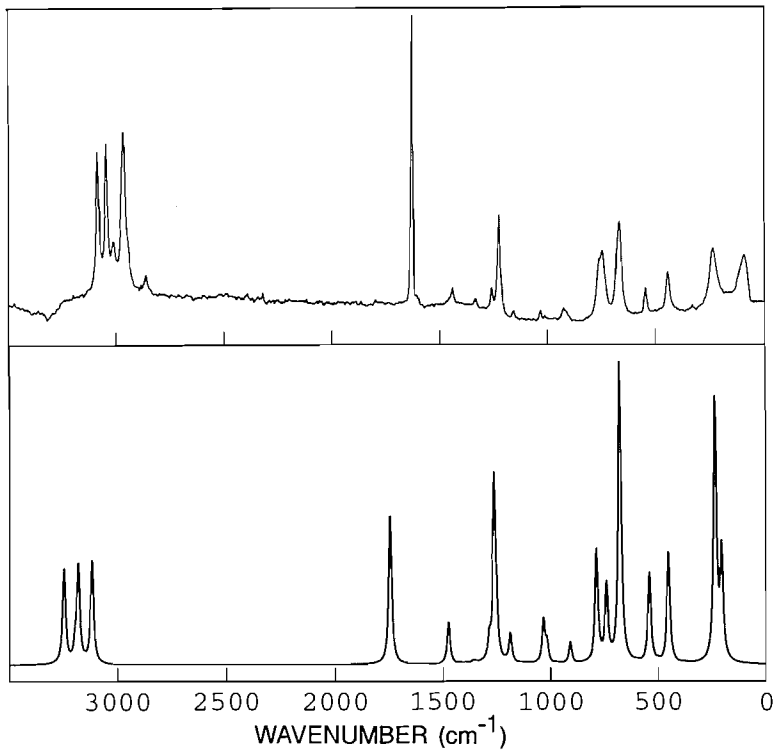

FIG. 6. Raman spectra of *cis*-1,3-dichloropropene: (top) FT–Raman spectrum of the liquid phase and (bottom) calculated at the RHF/3-21G* basis set.

804 cm^{-1} (2.3 kcal/mol), respectively. It could be argued that the *anti* barrier is overestimated by molecular mechanics calculations due to the fact that the value of 342 cm^{-1} (0.98 kcal/mol) obtained from *ab initio* calculations is much closer to the experimental value of 350 cm^{-1} (1.0 kcal/mol) obtained from the electron diffraction data (36).

The structural parameters calculated with the 6-31G* basis set with electron correlation at the MP2 level reasonably reproduce the values obtained from the electron diffraction results (36). The heavy atom bond distances calculated with this basis set are within 0.01 Å of the experimental values except for the C—C bond distance, which is calculated to be 0.021 Å longer as determined from the electron diffraction results (36). This value of 1.508 Å for the C—C distance is a little longer than one might expect when compared to the corresponding distance in some similar molecules, but the distance calculated with the MP2/6-31G* basis set (1.487 Å) is clearly too short by probably as much as 0.014 Å. On the other hand, the bond angles are very similar to those obtained experimentally (36). It is difficult to ascertain the reliability of the *ab initio* calculated bond angles since there were rather large uncertainties for several of the angles from the electron diffraction study (36) and some were assumed. As previously mentioned, *ab initio* calculated bond angles are generally reliable to about 1° except for dihedral angles for the *gauche* conformers. The *gauche* dihedral angle of 107.1°, from the molecular mechanics study (35), is clearly too small when compared to the *ab initio* (118.3°) and electron diffraction results (123° ± 5°).

The utility of using *ab initio* calculations with the RHF/3-21G* basis set to calculate the intensities of the Raman lines has been demonstrated. These results indicate that the Raman intensity data should be useful to improve vibrational assignments as well as for analytical identification purposes for these types of molecules. However, it is necessary to scale the calculated vibrational frequencies, which are then comparable to those obtained experimentally. Usually, the relative order of the vibrational fundamentals is correct. In the past, only Raman frequency data have been used for chemical information, but with high-speed inexpensive computers it should be possible to use both the frequency and intensity data from the Raman spectrum to obtain chemical information on a sample.

Raman studies of cyanate: Fermi resonance, hydration and hydrolysis to urea

MURRAY H. BROOKER[1] AND NANPING WEN

Chemistry Department, Memorial University of Newfoundland, St. John's, NF A1B 3X7, Canada

Received March 24, 1993

This paper is dedicated to Professor Gerald W. King on the occasion of his 65th birthday

MURRAY H. BROOKER and NANPING WEN. Can. J. Chem. **71**, 1764 (1993).

Raman spectra were measured for potassium cyanate in the solid phase and as aqueous solutions in H_2O and D_2O for freshly prepared and for aged solutions. The results indicated that the assignment of the Fermi doublet, ν_1 and $2\nu_2$, for solid potassium cyanate was reversed from the assignment for the aqueous solution. The Fermi doublet has an associated pair of hot bands at 1191 and 1315 cm^{-1} which originate from the 638 cm^{-1} ν_2 state, 010. Assignment of the hot bands was confirmed by studies of solid potassium cyanate at liquid-N_2 temperature, room temperature, and at 473 K. Raman spectra of aged aqueous potassium cyanate revealed that the cyanate ion hydrolyzed slowly and spontaneously at room temperature (even without added ammonium) to produce urea and a carbamate, carbonate equilibrium mixture in parallel reactions. Hydrolysis of cyanate in aqueous ammonium chloride solution resulted in almost total conversion of cyanate to urea. The reaction was not reversible under ambient conditions. Differences in peak frequencies and half-widths were observed for the cyanate dissolved in H_2O compared to solutions in D_2O. The results provide evidence for strong hydrogen bonding of cyanate to water and are consistent with greater structure in the D_2O solution. Theoretical *ab initio* calculations indicated that the water molecules hydrogen bond well at both the oxygen and nitrogen atoms of cyanate although the hydrogen bond to nitrogen was found to be slightly stronger.

MURRAY H. BROOKER et NANPING WEN. Can. J. Chem. **71**, 1764 (1993).

On a mesuré les spectres Raman du cyanate de potassium en phase solide et en solutions aqueuses dans le H_2O et le D_2O pour des solutions fraîchement préparées ainsi que pour des solutions qui avaient vieillies. Les résultats obtenus indiquent que l'attribution du doublet de Fermi, ν_1 et $2\nu_2$, pour le cyanate de potassium à l'état solide doit être inversé par rapport à ce qui est observé en solution aqueuse. La doublet de Fermi est associé à une paire de bandes chaudes à 1191 et 1315 cm^{-1} qui ont leur origine dans l'état ν_2, 010, à 638 cm^{-1}. On a pu confirmer l'attribution des bandes chaudes par des études sur le cyanate de potassium solide à la température de l'azote liquide, à la température ambiante et à 473 K. Les spectres Raman des solutions aqueuses du cyanate de potassium qui ont vieillies révèlent que l'ion cyanate s'hydrolyse lentement et spontanément à la température ambiante (même sans addition d'ammonium) pour former de l'urée et un mélange à l'équilibre de carbamate/carbonate provenant de réactions parallèles. L'hydrolyse du cyanate en solution aqueuse de chlorure d'ammonium provoque une conversion presque globale du cyanate en urée. La réaction n'est pas réversible dans les conditions ambiantes. On a observé des différences dans les fréquences et les demi-largueurs des bandes du cyanate dissous dans le H_2O par rapport aux solutions dans le D_2O. Les résultats suggèrent qu'il existe de fortes liaisons hydrogènes entre le cyanate et l'eau et ils sont en accord avec la plus grande structure en solution dans le D_2O. Des calculs théoriques *ab initio* indiquent que les molécules d'eau forment aussi facilement des liaisons hydrogènes avec les atomes d'oxygène que d'azote du cyanate, même si l'on a trouvé que la liaison hydrogène avec l'azote est légèrement plus forte.

1. Introduction

Wöhler (1) first synthesized urea in 1828 by evaporation to dryness of a mixture of aqueous ammonium sulphate and potassium cyanate. It has long been supposed that the ammonium cyanate produced in the metathesis reaction rearranged into urea. The mechanism has been the subject of considerable interest since both ionic and molecular mechanisms have been proposed. The relative merits of each mechanism have been reviewed by Frost and Pearson (2) and Moelwyn Hughes (3). As part of a comprehensive study of aqueous solutions of small molecules which contain N, C, O, and H the Raman spectrum of KOCN has been measured for the solid and aqueous phases. The Raman spectrum of potassium cyanate has been studied previously in aqueous solutions by Goubeau (4), Pal and Sen Gupta (5), and Cleveland (6). Difficulties in making vibrational assignments were encountered due to the cyanate ion hydrolysis. Infrared studies of potassium cyanate have been carried out with solid and aqueous solution by Waddington (7), Williams (8), Maki and Decius (9), and Decius and Gordon (10). Although the basic assignments for the three expected fundamental vibrations of cyanate were well established the actual data and the vibrational assignments were inconsistent. The region of the ν_1 fundamental was found to be complicated by Fermi resonance with $2\nu_2$.

Isolated cyanate ion, written in either canonical form, O=C=N$^-$ or N≡C—O$^-$, has a linear configuration with $C_{\infty v}$ symmetry. The vibration representation is $\Gamma_{vib} = 2\,\Sigma^+ + \Pi$ with all the vibrational modes both infrared and Raman active. The isolated, unperturbed cyanate ion should have three fundamental vibration frequencies, the symmetric stretching frequency, $\nu_1(\Sigma^+)$ or ν_{CO}, a degenerate bending frequency, $\nu_2(\Pi)$ or ν_{OCN}, with two degrees of freedom at right angles, and an antisymmetric stretching vibration, $\nu_3(\Sigma^+)$ or ν_{CN}. One of the overtones, $2\nu_2$, is of particular importance to the Raman spectra of solid and aqueous potassium cyanate because it is known that a component of this state, $2\nu_2(\Sigma^+)$, is in resonance with the $\nu_1(\Sigma^+)$ fundamental to give rise to a pair of bands of nearly equal intensity. These two vibrational states are neither pure CO stretching, ν_{CO} or $\nu_1(\Sigma^+)$, nor pure OCN bending, $2\nu_{OCN}$ or $2\nu_2(\Sigma^+)$, but they are mixed states often referred to ambiguously as the $\nu_1 + 2\nu_2$ doublet. The Raman spectra in the region of the Fermi doublet were found to be sensitive to the environment about

[1]Author to whom correspondence may be addressed.

the cyanate ion. The Fermi doublet then served as an experimental probe to study the interaction of cyanate to water and heavy water.

It was interesting to observe that after the aqueous cyanate solution had stood a few days, new peaks were observed. Cleveland (6) and Williams (8) have reported evidence for hydrolysis and assigned the new infrared peaks to ammonium, carbonate and bicarbonate ions formed by the hydrolysis reaction (eqs. [1.1] and [1.2]).

[1.1] $KOCN + 3H_2O + \rightarrow KHCO_3 + NH_4OH$

[1.2] $2KOCN + 4H_2O \rightarrow K_2CO_3 + (NH_4)_2CO_3$

However, the present study on aged aqueous potassium cyanate revealed the presence of considerable urea, carbamate, and carbonate formed by hydrolysis (Eq. 2). Urea is formed even in the absence of added ammonium salts.

[2] $3OCN^- + 3H_2O \rightarrow H_2NCO_2^- + (NH_2)_2CO + CO_3^{2-}$

There was no evidence for the presence of bicarbonate or ammonium ions in the aged solutions although small quantities of these ions would be expected since aqueous carbamate has been shown to exist in equilibrium with ammonium, carbonate and bicarbonate (11). Addition of potassium cyanate to aqueous ammonium chloride resulted in a greater yield of urea.

2. Experimental

The spectroscopic measurements were carried out on a Coderg PHO Raman spectrometer after sample excitation with a INNOVA 70-4 argon ion laser operating at approximately 300 mW at the sample with the 488.0 nm wavelength line. The usual right angle scattering geometry was employed with the incident light vertically polarized and the scattered light analyzed with polaroid film to give the $I_{\parallel}$ $[x(zz)y]$ and $I_{\perp}$ $[x(zx)y]$ scattering geometries. A quarter-wave plate before the entrance slit served to compensate for the grating polarization preference. Raman wavenumber calibration was achieved with the plasma lines of the laser, but when required a narrow-bandpass interference filter was used to remove the unwanted plasma lines. The spectral slit widths of the double monochromator were set at 2.0 cm^{-1} which is sufficiently narrow to avoid the need for a slit correction to the bandshape. The Raman scattering light was detected with a PMT cooled to −30°C, integrated with a photon counter and processed with a home-built boxcar averager interfaced to the Memorial University VAX 8800 computer. The scan rate was 50 cm^{-1} min^{-1} and two data points were collected per wavenumber. Spectra were signal-averaged, and smoothed twice with a Savitsky-Golay three-point smoothing function. Curve resolution of overlapped bands and calculations of band half-width and intensity were achieved with a standard computer fitting program. The experimental spectrum was fit to a minimum number of bands synthesized with a Gaussian–Lorenzian product function.

All chemicals were reagent grade used without further purification. Potassium cyanate was obtained from BDH Chemical Ltd. All samples were sealed in quartz tubing (4 mm id, 5 mm od). Solid potassium cyanate was sealed under vacuum to prevent reaction with water vapour. Aqueous solutions were sealed under their own vapour pressure to avoid loss of ammonia and carbon dioxide gases which are decomposition products of carbamic acid. Ordinary aqueous solutions of potassium cyanate were prepared with distilled water. Deuterated aqueous solutions of potassium cyanate were prepared with deuterium oxide (99.9 atom % D, MSD Isotopes). Aqueous samples were routinely centrifuged for 5 min to settle dust particles. The Raman spectra of the fresh aqueous solution were obtained and the samples were then stored in a light-proof place. Additional Raman studies were made after suitable time intervals.

The Raman spectrum of solid potassium cyanate at 77 K was obtained on the copper cold tip of an evaporating liquid nitrogen cryostat. The high temperature study of solid potassium cyanate was performed on the powder sample sealed under vacuum in a quartz tube and heated in an insulated furnace with a proportional temperature controller. The temperature was monitored with a chromel–alumel thermocouple and the quoted temperature at the sample was constant and accurate to ±0.5°C.

Theoretical calculations with *ab initio* methods were performed at the Hartree Fock level with MUNGAUSS (12) to obtain minimum energies, optimized geometries and electron densities.

3. Result and discussion

The Raman spectra are shown (Fig. 1) for solid potassium cyanate and for freshly prepared and aged aqueous solutions of potassium cyanate in H_2O and D_2O for the region from 300 to 2400 cm^{-1}. The peak frequencies, half-widths and assignments of the observed Raman bands for potassium cyanate in the different conditions are collected in Tables 1 to 4. The antisymmetric stretching vibration, ν_3 (Σ^+) or ν_{CN}, appears at about 2170 cm^{-1}. The degenerate bending mode, $\nu_2(\Pi)$ or ν_{OCN}, occurs as a band of medium intensity in the 640 cm^{-1} region. In solid KOCN the degeneracy of ν_2 was removed, and two vibrational bands at 628 and 638 cm^{-1} were found due to the bending vibrations of the cyanate ion split by the local electric field of the crystal lattice. The shoulder at about 2185 cm^{-1} in the spectrum of solid KOCN also appears to be due to the effects of the crystal packing. $\nu_1(\Sigma^+)$ expected about 1245 cm^{-1} was found to be in Fermi resonance with $2\nu_2(\Sigma^+)$. Decius and co-workers (9, 10) have studied the Fermi resonance of $\nu_1 + 2\nu_2$ for cyanate in matrix isolation. The Fermi resonance pattern in cyanate strongly resembles that observed in the Raman spectrum of gaseous and aqueous carbon dioxide (13, 14).

Fermi resonance

The undisturbed symmetric stretching frequency, $\nu_1(\Sigma^+)$, would be expected at about 1245 cm^{-1}. However, the first harmonic of the bending mode, $2\nu_2(\Sigma^+)$, is very close in energy to the $\nu_1(\Sigma^+)$ and has a component with the same symmetry type, (Σ^+), with the result that vibrational coupling occurs (Fermi resonance). The overtone borrows intensity from the fundamental and appears as a fairly strong Raman band. In addition the two states repel each other and neither is found at the expected frequency (Fig. 2). The relative intensities and the separation of the peak maxima for the fundamental and the overtone depend on how closely the two undisturbed frequencies fall and may be calculated approximately with the expression (15).

$$[3] \qquad \nu^0 = \tfrac{1}{2}(\nu_a + \nu_b) \pm \tfrac{1}{2}(\nu_a - \nu_b)\frac{I_a - I_b}{I_a + I_b}$$

The two values of ν^0 are the unperturbed frequencies; ν_a and ν_b are the observed frequencies, and I_a and I_b are the associated band intensities.

For fresh ordinary aqueous cyanate (refer to curve *b* in Fig. 1), the two strong bands at 1310 and 1223 cm^{-1} are due to the Fermi doublet, ν_1 and $2\nu_2$. It is reasonable to associate the lower frequency component of the Fermi doublet with $2\nu_2$ because of the lower intensity and the higher frequency component with ν_1 because of its greater intensity i.e., $\nu_1^0 > 2\nu_2^0$. The Fermi doublet of solid cyanate (see curve *a* in Fig.

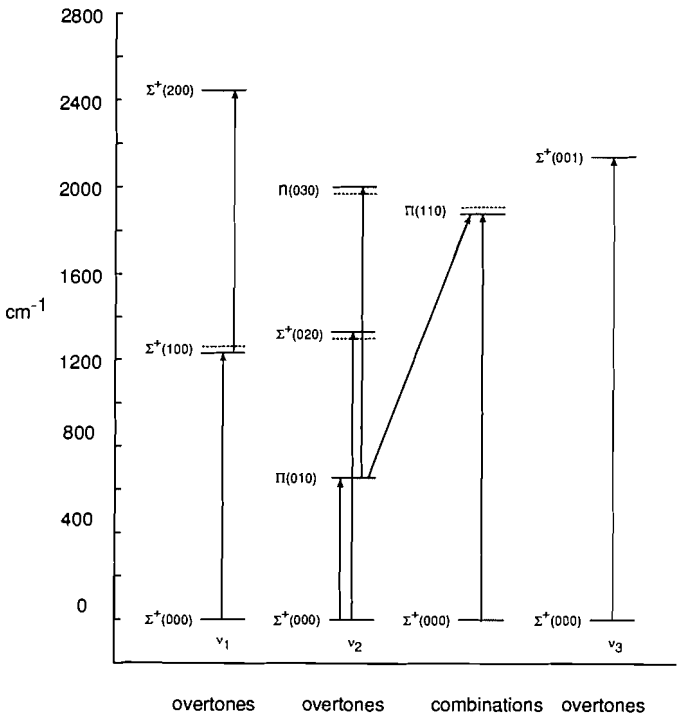

FIG. 2. Vibrational energy level diagram of the cyanate ion. The horizontal solid lines are at energies observed for the solid state, and the horizontal broken lines are at energies calculated for the undisturbed frequencies. The vertical arrows represent Raman transitions observed in this study.

1) appears at 1207 and 1300 cm^{-1}. When compared to the results for aqueous solution it can be seen that for solid KOCN the low frequency component of the Fermi doublet has become more intense and shifted to much lower frequency. Therefore, for solid KOCN the low frequency component has been associated with the ν_1. These result indicated that the assignment of the Fermi doublet, ν_1 and $2\nu_2$, for solid cyanate was reversed with respect to that for fresh aqueous cyanate. The unperturbed frequencies, ν_1^0 and $2\nu_2^0$, of cyanate in the states of solid, fresh ordinary aqueous and fresh deuterium aqueous were calculated from eq. [3] and the results listed in Tables 1, 2, and 3, respectively.

From Tables 1 and 2 it can be seen that the unperturbed frequency $2\nu_2^0$ of cyanate is very close to 1260 cm^{-1} in both solid and fresh ordinary aqueous states, but that the undisturbed frequency ν_1^0 shifts from 1245 cm^{-1} in the solid state to 1274 cm^{-1} in the fresh ordinary aqueous solution. Since the ν_2 mode remains near 635 cm^{-1} for solid and aqueous cyanate the change in the Fermi resonance pattern must be due to a frequency shift of the symmetric stretching mode. Strong interactions between cyanate ion and the water molecules appear to have a pronounced effect on the frequency of the ν_1 mode. The shift of ν_1^0 results in the inter-change of the assignment of the frequency sequence of the Fermi doublet from $\nu_1 > 2\nu_2$ for solid KOCN to $\nu_1 < 2\nu_2$ for aqueous OCN^-. In the case of fresh aqueous cyanate in deuterated water, the undisturbed frequencies ν_1^0 and $2\nu_2^0$ are about the same as for normal water and again the sequence of the Fermi doublet $\nu_1 < 2\nu_2$, is reversed from that found in solid potassium cyanate.

In addition to the intense Fermi doublet three additional bands appear in this region for solid KOCN at 1191, 1272, and 1315 cm^{-1}. The bands at 1191 and 1315 cm^{-1} have been assigned to a second Fermi doublet of hot bands (1191 cm^{-1}, (110) ← (010), and 1315 cm^{-1}, (030) ← (010)). A similar pair of hot bands were detected in the Raman spectrum of gaseous carbon dioxide (14). The appropriate transitions can be identified on the vibrational energy level diagram for the cyanate ion (Fig. 2). The hot bands originate from the 638 cm^{-1} ν_2 excited state of cyanate, (010), thermally populated at 295 K by a Boltzmann factor of $e^{-3.11} = 0.0446$. The assignment was confirmed by studies of solid KOCN at different temperatures. When the sample temperature was reduced to liquid-N_2 temperature, corresponding to a Boltzmann factor of $e^{-11.9} = 6.70 \times 10^{-6}$, the hot bands disappeared. However, when the sample temperature was raised to 473 K, corresponding to a Boltzmann factor of $e^{-1.94} = 0.144$, the intensities of the hot bands at 1191 and 1315 cm^{-1} obviously increased (Fig. 3). The cyanate ion isotopomer $O^{13}CN^-$ (about 1% abundance) can give rise to two Raman lines displaced to lower frequencies. One stands by itself at 1272 cm^{-1}, and the other apparently has not been resolved from the hot band at 1191 cm^{-1}. The Fermi resonance pair of hot bands have not been resolved from the broad bands of the ($\nu_1 + 2\nu_2$) pair in studies of the aqueous solutions of cyanate.

Hydration of cyanate

The differences between the spectrum of cyanate dissolved in normal and heavy water provides good evidence to indicate the presence of strong hydrogen bond interactions between cyanate and the water solvent. Identical peak positions and half-widths would be expected for aqueous cyanate dissolved in H_2O or D_2O in the absence of strong

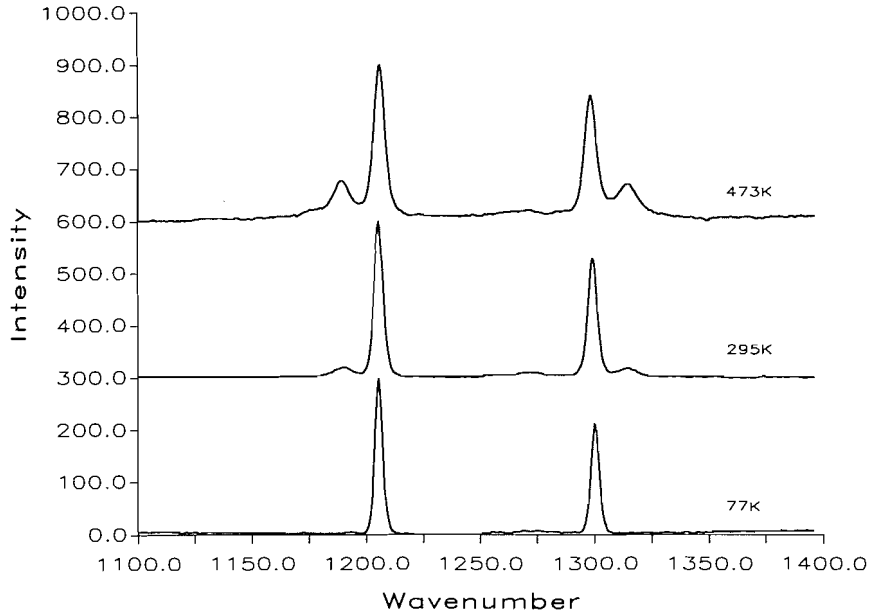

FIG. 3. Raman spectra of solid KOCN at different temperatures: (*a*) 473 K; (*b*) 295 K; (*c*) 77 K. Spectra are off-set for clarity.

interactions between the water and cyanate. In fact, there are significant differences (Tables 2 and 3). The unperturbed frequencies (ν_1^0) of aqueous cyanate were evaluated to be 1274 cm^{-1} in H_2O and 1268.3 cm^{-1} in D_2O. Although there is some uncertainty with these frequencies it is clear from the differences of the Fermi doublet for cyanate in H_2O and D_2O that there is a significant difference between the two systems. Furthermore, the $\nu_1(\Sigma^+)$ band at 1309.6 cm^{-1} was found to be significantly broader (half-width 48.4 cm^{-1}) in H_2O than the comparable band at 1313.2 cm^{-1} (half-width 39.2 cm^{-1}) in D_2O. The ν_3 mode of cyanate in H_2O was also considerably higher in frequency and broader (2167.9 cm^{-1}, half-width 23.9 cm^{-1}) than the comparable band in D_2O (2159.5 cm^{-1}, half-width 20.5 cm^{-1}). However, the most interesting difference was for the $\nu_2(\Pi)$ region were the peak position in D_2O was *higher* at (637.3 cm^{-1}) than in H_2O (631.8 cm^{-1}).

A qualitative explanation of the differences in the spectra of cyanate between water and heavy water can be developed from arguments based on differences in the zero point energies of vibrations which involve the motions of hydrogen (deuterium) in the hydrogen bond. Buckingham and Fan-Chen (16) have invoked similar arguments to explain differences in the physical properties of H_2O and D_2O. The decrease in frequency for the symmetric and antisymmetric modes of cyanate could be explained simply as a mass effect because the water, hydrogen-bonded to the O and/or N atoms would increase the apparent mass of these atoms (with D_2O more than H_2O). However, this explanation cannot explain the *increase* of the bending frequency for cyanate in D_2O compared to the H_2O solution and another explanation must be sought. When water hydrogen bonds to the cyanate at either the oxygen or nitrogen the O···H—O and O—H···N bonds tend to be linear hydrogen bonds. In the deuterium form the hydrogen bonds will have smaller thermal displacements perpendicular to the bond axis and will tend to be more linear, slightly shorter and stronger. In the case of the bending mode of cyanate in the deuterium solution the force constant will increase because the deuterium hydrogen-bond will provide a greater resistance to the bending motion. Similar arguments have been proposed to account for the unusual frequency shifts between the deuterium and protium solutions of carbonate and hydroxyborate (17, 18). In the *ab initio* calculations (described below) it was noted that the hydration of cyanate decreased the bond order of both the CN and the CO bonds. Hydrogen-bonding in deuterated solution may decrease the bond order more effectively than normal water with the result that the cyanate stretching force constants become slightly weaker in deuterium solution. This explanation is at least consistent with the experimental observations. Molecular dynamics models are not sensitive enough to probe such subtle differences and *ab initio* calculations treat hydrogen and deuterium as electronically equivalent (Born–Oppenheimer approximation).

In an effort to learn about the nature of the hydration of cyanate *ab initio* calculations have been performed to calculate optimum geometries and minimum energies for cyanate and cyanate hydrogen bonded to one and two water molecules. The results are collected in Table 5 for the 3-21G and 6-31G** basis sets. Since the 3-21G minimum basis set tended to over-emphasize the effect of hydrogen bonding the present discussion refers primarily to the results for the 6-31G** basis set. In all cases the cyanate retained a linear structure with the NCO angle of 180°. The *ab initio* calculations of free cyanate ion, cyanate ion bound to a water molecule through either the nitrogen or oxygen atom and cyanate ion bound to two water molecules through both nitrogen and oxygen atoms (refer to Table 4) gave a calculated bond order between C and N of about 2.6 and a bond order between C and O of about 1.5. The results were consistent with the deductions based on the Raman frequencies of the cyanate. Normally, a C=N double bond stretching vibration frequency is approximately 1650 cm^{-1}, and a C≡N triple bond stretching vibration frequency is close to 2250 cm^{-1}. The Raman spectrum of potassium cyanate indicated that the $\nu_3(\Sigma^+)$, i.e., ν_{CN}, was at about 2168 cm^{-1} which suggested a bond order of about 2.6 and not a full triple band. Similar arguments for the $\nu_1(\Sigma^+)$ suggested a bond

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

order of about 1.5 because the observed frequency of about 1260 cm^{-1} was about midway between the expected values for a single bond C—O (1000 cm^{-1}) and a double bond C=O (1600 cm^{-1}). The calculated optimum geometry for free cyanate resulted in approximately equal negative charge at the oxygen and nitrogen atoms (−0.74459 at N and −0.73462 at O, Table 5). It was also interesting to note that in all cases the sum of the CO and CN bond orders exceeded 4.0. Furthermore, as noted above, the total CO plus CN bond order decreased from 4.23 in free cyanate to 4.09 in cyanate hydrogen bonded to two water molecules. Apparently hydrogen bonding to water weakens the CO and CN bonds.

The results of the *ab initio* calculations indicated that relatively strong hydrogen bond interactions were possible for

both $NCO^- \cdots HOH$ and $OCN^- \cdots HOH$ conformers (Table 5). The minimum energies for the optimized geometries of $NCO^- \cdots HOH$ and $OCN^- \cdots HOH$ were −241.853783 and −241.854421 Hartree in 3-21G basis set, respectively (−243.242308 and −243.244640 Hartree in 6-31G** basis set). The hydrogen bond $OCN^- \cdots HOH$ with a bond order 0.151 in 3-21G basis set (0.100 in 6-31G** basis set) appeared slightly stronger than $NCO^- \cdots HOH$ with a bond order of 0.148 in 3-21G basis set (0.085 in 6-31G** basis set). Typical hydrogen bond lengths of about 1.9 Å were obtained for both the N···H (1.918 Å, in 6-31G**) and O···H (1.896 Å, in 6-31G**) hydrogen bonding configurations. The hydrogen bond angles O···H—OH and N···H—OH both tended to linear values of about 170°. The angle of attachment of the hydrogen bond to cyanate was markedly different for the two conformations. For the C—N···H interaction the bond angle was again close to linear (165°) whereas, for the C—O···H interaction the value was closer to trigonal (113°). These results were found to be consistent with a simple bonding model for cyanate that puts two lone pairs on the oxygen atom and one lone pair on the nitrogen. In solution it would seem very likely that the cyanate would have two water molecules of hydration at the oxygen and one at the nitrogen although this structure was not calculated. The results for cyanate hydrogen bonded simultaneously at both the oxygen and nitrogen ends gave similar hydrogen bond lengths and angles to those described above for the single water of hydration. Again the bond order of the N···H hydrogen bond was about 20% greater than for the O···H hydrogen bond which suggested a slight preference for cyanate hydration at the nitrogen. In summary the *ab initio* results indicated that cyanate has the excess charge distributed approximately equally well on the nitrogen and oxygen ends of the ion with the nitrogen slightly more negative.

The fact that the calculations indicated a stronger hydrogen bond from water to the N atom of cyanate than to the oxygen was consistent with the known stability of isocyanic acid (HNCO) compared to the cyanic acid isomer (NCOH) (19–21). It has been established from microwave studies (19) of isocyanic acid that the NCO angle was very close to 180° with a maximum error of 10° while the HNC angle was about 128°. Theoretical calculations have established isocyanic acid as the most stable isomer but these calculations indicated a small departure from linearity for the NCO angle (20, 21).

Cyanate hydrolysis

Since previous studies of aqueous cyanate (6, 8) described spectra that changed with time it seemed advisable to study the spectrum of a solution of potassium cyanate after different time intervals. It was found that the peaks which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

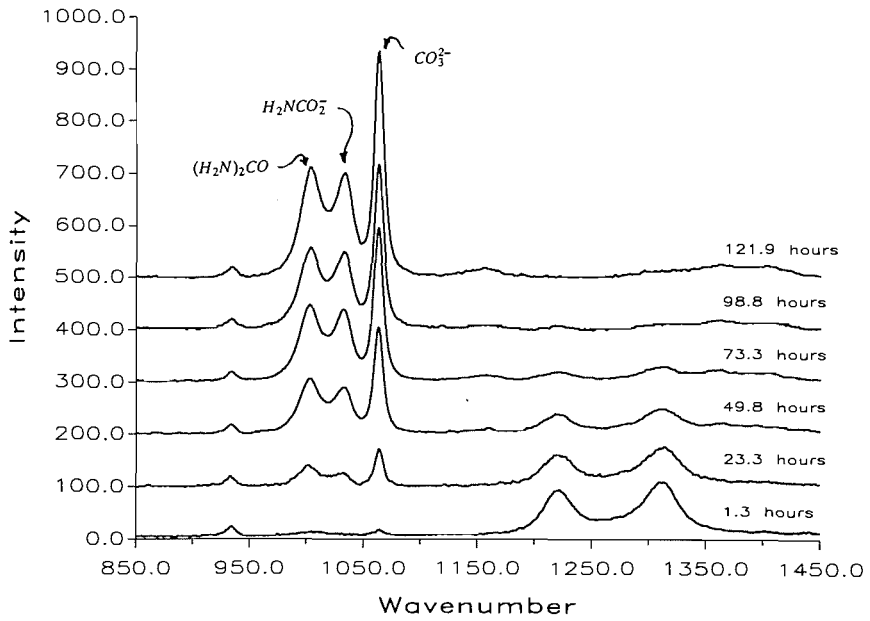

FIG. 4. Raman spectra of aged 2.0 M KOCN. The weak peak at 934 cm^{-1} is due to 0.1 M $NaClO_4$ added as an internal standard: (*a*) 1.3 h old; (*b*) 23.3 h old; (*c*) 49.8 h old; (*d*) 73.3 h old; (*e*) 98.8 h old; (*f*) 121.9 h old. Spectra are off-set for clarity.

were attributed to cyanate became less intense with time while new peaks which appeared at 1003, 1034, and 1065 cm^{-1} increased in intensity with the passage of time (Fig. 4). Cleveland (6) and Williams (8) suggested that the new peaks arose from the carbonate, bicarbonate, and ammonium, formed by hydrolysis of potassium cyanate (eqs. [1.1] and [1.2]). There can be no doubt that the new band at 1065 cm^{-1} was due ν_1 of carbonate since the frequency, half-width, and depolarization ratio were identical to that of a pure sodium carbonate solution. However, there was no evidence to suggest the presence of peaks due to bicarbonate or ammonium as suggested by Cleveland and Williams. The characteristic peaks for bicarbonate (13) and ammonium (22) are at 1017 and 1450 cm^{-1}. It was possible to identify the urea and carbamate ion as the source of the peaks at 1003 and 1034 cm^{-1} by comparison with spectra of known samples. The difference between our results and those of Cleveland and Williams can be accounted for by experimental differences in the sample control. In the present work the samples were maintained in sealed tubes which prevented the escape of gaseous ammonia. An aged sample (sealed) 2.0 M potassium cyanate aqueous solution had a pH value about 10 after hydrolysis was complete. At this pH there should be considerable ammonia but because of the presence of carbonate an equilibrium reaction results in carbamate formation. If open to the air the carbamate solution slowly loses ammonia and the solution becomes more acidic.

Wöhler (1) synthesized urea in 1828 by adding a solution of ammonium sulphate to a solution of potassium cyanate and evaporating the mixture to dryness. It has normally been supposed that ammonium cyanate was prepared in a metathesis reaction (eq. [4])

$$[4] \quad NH_4^+ + OCN^- \rightarrow NH_4OCN$$

followed by rearrangement of ammonium cyanate rearrange to form urea (eq. [5]).

$$[5] \quad NH_4OCN \rightarrow NH_2CONH_2$$

Raman spectrum of a similar mixture, 2.0 M ammonium chloride with 2.0 M potassium cyanate aqueous solution, was observed in region from 900 to 1800 cm^{-1} (curve *b* in Fig. 5). The very strong band at 1003 cm^{-1} was attributed to the $\nu_4(A_1)$ of urea and could be compared with the spectrum of pure aqueous urea (curve *a* in Fig. 5). The urea has been characterized not only by the 1003 cm^{-1} band but also by bands at 1155, 1597, and 1665 cm^{-1} bands (23). It is obvious that the urea is one of the hydrolysis products. The presence of carbonate was clearly indicated by characteristic peaks at 676 cm^{-1} $\nu_4(E')$, 1065 cm^{-1} $\nu_1(A_1')$ and a weak broad band at 1380 cm^{-1} $\nu_3(E')$. The band at 1034 cm^{-1} with medium intensity and overlapped with the 1003 cm^{-1} band has been attributed (11, 24) to carbamate ion, H_2NCOO^-. In a recent Raman investigation (11) of aqueous ammonium carbonate solutions it has been found that carbamate ion was a major equilibrium species but urea was not formed in this system.

$$[6] \quad CO_3^{2-} + NH_4^+ \rightleftarrows H_2NCOO^- + H_2O$$

The carbamate ion has been characterized by Raman bands at 563, 1034, and 1405 cm^{-1}. These additional characteristic frequencies of carbamate ion have also been detected in the Raman spectrum of aged ordinary aqueous cyanate (refer to curve *d* in Fig. 1).

According to our investigation, cyanate ion hydrolysis to form urea, carbamate, and carbonate slowly and spontaneously, even without added ammonium and at room temperature. In an open sample vessel the escape of ammonia would decrease the formation of urea and carbamate but the addition of ammonium (as in the Wöhler synthesis) can compensate for ammonia loss. The formation of urea occurs totally in solution and cannot be considered just a rearrangement of solid NH_4OCN. Further studies indicated that the hydrolysis of pure potassium cyanate was a very slow process (about 7 ~ 10 days at room temperature) while the reaction of ammonium and cyanate to urea was moderately

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12

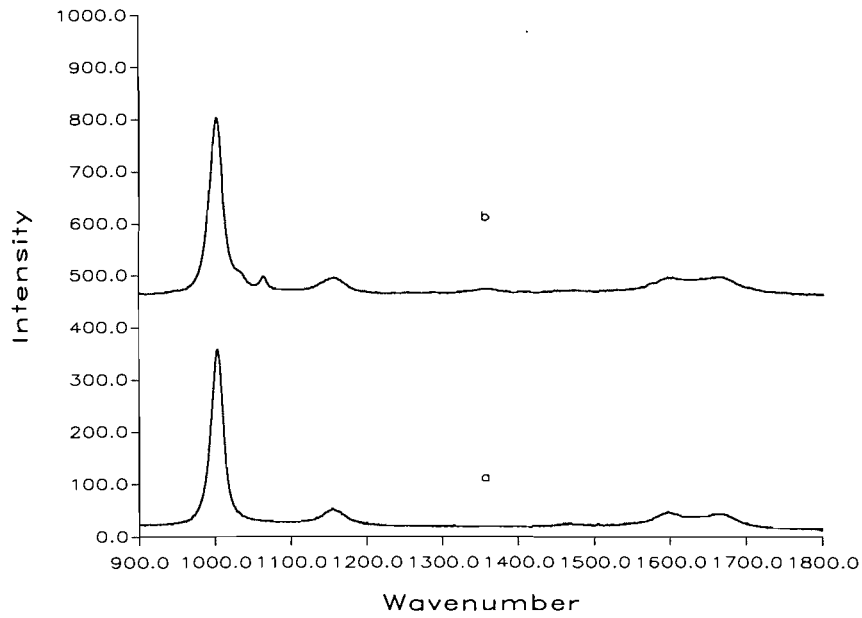

FIG. 5. Raman spectra of the aged solution from a solution which was 2.0 M NH_4Cl and 2.0 M KOCN (curve *b*) and 2.0 M urea made from pure urea dissolved in water (curve *a*). Spectra are off-set for clarity.

fast (about 2 ~ 3 days at room temperature). In an effort to determine if the reaction of cyanate proceeded by a direct nucleophilic attack of aqueous ammonia at the C of cyanate the hydrolysis was monitored for potassium cyanate dissolved in a 2.0 M ammonia solution. The rate and products of reaction for cyanate in ammonia solution were essentially identical to the reaction in pure water. The basic property of NCO^- should give rise to a small amount of isocyanic acid, HNCO (10^{-5} M) but here was no indication that the acid had a role in the reaction mechanism.

The possible hydrolysis processes might be as follows:

[7] $$OCN^- + 2H_2O \rightarrow CO_3^{2-} + NH_4^+$$

[8] $$CO_3^{2-} + NH_4^+ \rightleftarrows H_2NCOO^- + H_2O$$

[9] $$OCN^- + NH_4^+ \rightarrow H_2NCONH_2$$

The overall reaction can be written as:

[10] $$3OCN^- + 3H_2O \rightarrow H_2NCONH_2 + H_2NCOO^- + CO_3^{2-}$$

The molecular form of eq. [9] (as eq. [11]) cannot be excluded although Moelwyn Hughes (3) has suggested that the kinetic data were more consistent with an ionic mechanism.

[11] $$OCNH + NH_3 \rightarrow H_2NCONH_2$$

The formation of urea and the formation of carbamate were found to be independent parallel reactions. Studies of these systems as a function of concentration and temperature indicated that under normal aqueous conditions urea and carbamate were not in equilibrium and were not interconvertible. These facts do not appear to have been established previously. A detailed account of the rate process will be reported elsewhere.

1993 ALCAN Award Lecture
Chemical binding within and between inorganic rings; the design and synthesis of molecular conductors[1]

RICHARD T. OAKLEY
Department of Chemistry and Biochemistry, University of Guelph, Guelph, ON N1G 2W1, Canada

Received June 14, 1993

RICHARD T. OAKLEY. Can. J. Chem. **71**, 1775 (1993).

For a given number of skeletal atoms, the π-electron count of an unsaturated heterocycle can be modified by the incorporation of heteroatoms from different periodic groups. Sulfur and nitrogen are particularly effective in this regard, as their high electronegativity can stabilize electron-rich π-systems. A variety of aromatic, anti-aromatic, and radical systems can be prepared from admixtures of these elements. While the properties of these ring systems are interesting in their own right, the compounds are not without relevance in the design of new materials. The strong interannular interactions that are developed between these rings in the solid state makes them ideal candidates for the fabrication of molecular conductors. The origins and development of this area of research are the subjects of this presentation.

RICHARD T. OAKLEY. Can. J. Chem. **71**, 1775 (1993).

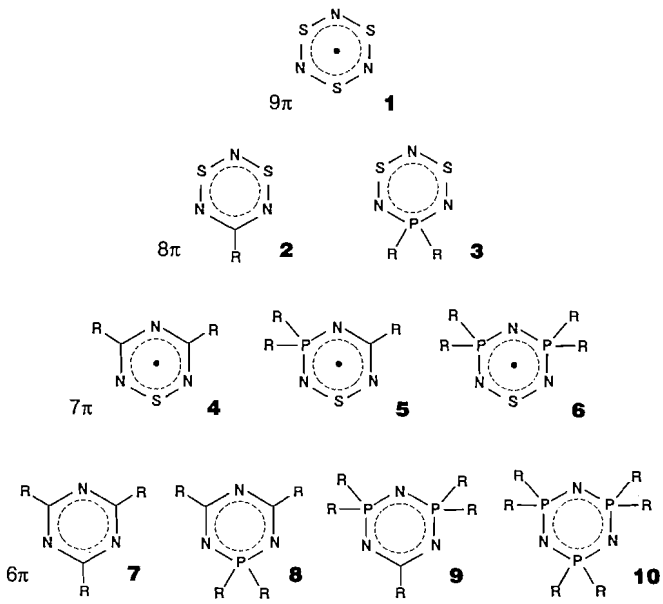
Pour une quantité donnée d'atome de squelette, le nombre d'électrons π contenus dans un hétérocycle insaturé peut être modifié par l'incorporation d'hétéroatomes de divers groupes périodiques. Les atomes de soufre et d'azote sont particulièrement utiles à ces fins car leur grande électronégativité permet de stabiliser des systèmes-π riches en électrons. On a préparé une variété de systèmes aromatiques, antiaromatiques et radicalaires par le mélange de ces éléments. Alors que les propriétés de ces systèmes cycliques présentent un intérêt inhérent à leur nature, ces composés ne sont toutefois pas sans intérêt pour la préparation de nouveaux matériaux. Les fortes interactions interannulaires qui se développent entre ces cycles à l'état solide en font des candidats idéaux pour la préparation de conducteurs moléculaires. Les origines et le développement de domaine de recherches font l'objet de cette présentation.

[Traduit par la rédaction]

Introduction

The present article continues a "tradition" initiated in 1992 by the Canadian Journal of Chemistry to provide a forum for the recipient of the annual ALCAN Award to summarize the highlights of the award lecture in a short monograph (1). Like my oral presentation at Sherbrooke, this account will focus more on recent events, but it is instructive (to me at least) to begin with a personal account of the historical origins of our research. This approach also provides me with an opportunity to identify and acknowledge the contributions of my students and collaborators.

The work to be described can be traced back to 1975, the year when superconductivity in $(SN)_x$ polymer was reported (2). As a graduate student working on phosphazene chemistry in Norman Paddock's laboratory at U.B.C., this discovery was of natural interest. My curiosity in structures containing conjugated SN units was further stimulated by an observation of my colleague Nick Westwood (then a postdoctoral fellow with Charles McDowell) that $(SN)_x$ could be vaporized to afford a species of formula $[S_3N_3]\cdot$ (3). At the time this radical represented one of the few known odd-electron species containing the $(SN)_x$ unit, and its generation from and reversion to the polymer were intriguing results that prompted many questions. Could new heterocycles, with unusual π-electron counts, be made? Might these serve as models for, or precursors to, novel polymeric systems? Within this context the isostructural (but not isoelectronic) replacement of —S= in $[S_3N_3]\cdot$ by either R_2P and (or) RC fragments represented an appealing synthetic challenge. The bottom row (compounds **7**–**10**) of the "family tree" illustrated in Scheme 1 were well-known (formally 6π-electron) compounds, and the potential for making 7π-electron radicals (**4**, **5**, and **6**) and 8π-electron anti-aromatic rings (**2** and **3**) seemed to provide an inspirational, if not logical, link to the ephemeral 9π-electron $[S_3N_3]\cdot$ species **1**.



SCHEME 1

Some years later, first at the University of Calgary, and then at the University of Guelph, my students and I had the opportunity to develop these ideas. At first our work was driven by the desire to explore synthetic approaches to novel radical and anti-aromatic ring systems, and to study their chemical and structural stability. In more recent years the

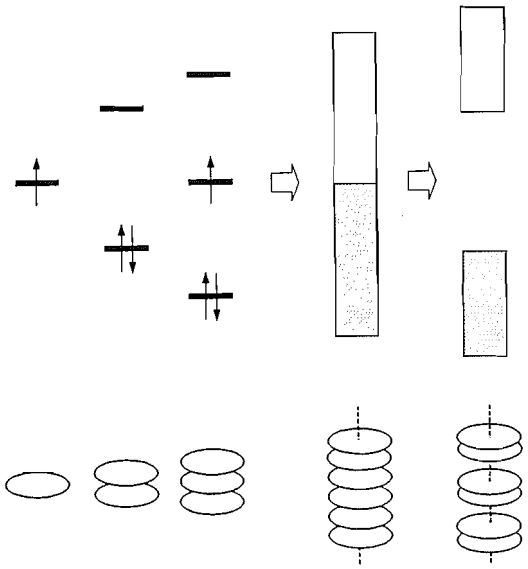

FIG. 1. Half-filled energy band associated with a uniformly spaced stack of π-radicals, and the energy gap arising from dimerization of the radicals.

work has evolved into the exploitation of the early results to fabricate molecules that, in the solid state, exhibit specific physical properties, notably electrical conductivity. These latter ideas were prompted by the early proposal of Robert Haddon that molecular conductors might be constructed from building blocks consisting of planar, neutral π-radicals (4). It is interesting that, while the design of molecular conductors from ionic radicals, in the form of charge transfer or Bechgaard salts (5), is now a well-developed field, the idea of using neutral radicals as plate-like building blocks has received relatively little attention. The dearth of results on these latter systems can perhaps be attributed, in part at least, to the experimental difficulty associated with preparing and characterizing any neutral radical. A second, and perhaps more difficult problem, has stemmed from the need to sculpt such radicals in a manner that obliges them to come together, in the solid state, in the stacked fashion illustrated in Fig. 1. The half-filled energy band, generated by the interaction of the unpaired π-electron on each molecular unit should, at first glance, afford a metallic ground state. Nature, however, is only partially impressed by this reasoning (vide infra), and both persistence and compromise have been necessary to achieve highly conductive materials.

The work described in this article represents a mélange of exploratory and targeted research in inorganic heterocyclic chemistry. I begin by outlining the results that emerged from our early pursuits of novel anti-aromatic and radical rings. In that way the chronological (but not necessarily logical) evolution towards the more directed work, to be described in later sections, can be better appreciated.

Aromatic and anti-aromatic rings

The possibility of observing aromatic/anti-aromatic effects in inorganic rings was first raised by Craig and Paddock who, in the late 1950s, mapped out (and later demonstrated) the physical and chemical consequences of cyclic π-delocalization in cyclophosphazenes (6). Similar ideas took root in cyclothiazene chemistry in the 1970s, with seminal papers by Gleiter (7) and Banister (8). The structural stability associated with aromatic $(4n+2)$ π-electron counts was recognized, and important examples of new aromatic systems, e.g., the binary rings $S_3N_3^-$ (9) and $S_4N_4^{2+}$ (10) and heterocyclic dithiatetrazocines $R_2C_2N_4S_2$ (11), were identified. The electron richness of these heterocycles, coupled with the differing electronegativities of their constituent atoms (S and N), leads to highly polarizable π-systems (12). In the early 1980s, soon after I began my NSERC University Research Fellowship at the University of Calgary, I explored the structural instabilities that these electronic features generate. The dramatic changes that accompany the protonation of S_4N_4 (13) and $S_3N_3^-$ (14), as well as the puckering of dithiatetrazocines in the presence of π-donor ligands ($R = NMe_2$), could all be interpreted in terms of severe localizations of anti-bonding π*-electron density (15).

Examples of anti-aromatic $(4n)$ π-electron rings were (predictably) more scarce. While still at Calgary, and in conjunction with Tris Chivers, Bill Laidlaw, and Neil Burford, I explored the synthesis and characterization of heterocyclic phosphadithiatriazines $R_2PN_3S_2$ **3**. The electronic structures of these rings are best described by an internal salt formulation but, to the extent that cyclic delocalization survives (through *d*-orbital involvement or hyperconjugation at phosphorus), they can be considered as anti-aromatic 8π-electron rings (16). Consistently they exhibit a low-energy π*–π* electronic absorption (a small HOMO–LUMO gap), and readily undergo cycloaddition reactions (with reverse electron demand) (17).

Hans Koenig, my first graduate student, continued to explore the relevance of aromatic concepts in inorganic rings by synthesizing and comparing the physical and chemical properties of the (deep blue) anti-aromatic 12π-benzodithiadiazine **11** and the (canary yellow) aromatic 14π-benzotrithiadiazepine **12** (18). The most appealing chemical finding related to their cycloaddition behaviour with norbornadiene (eqs. [1] and [2]). Both rings undergo a reversible cycloaddition with electron-rich olefins, but the equilibrium lies further to the right-hand side for addition to the *anti-aromatic* ring. Following the approach of Dewar, the two equilibrium constants for the addition can be converted into a *difference* in delocalization energies of ca. 5 kcal/mol, a value that is quite in keeping with the corresponding differences observed between classical aromatic and anti-aromatic annulenes of similar ring size. Later photoelectron and electron energy loss spectroscopic studies on these systems confirmed the expected trends in frontier orbital energies (19).

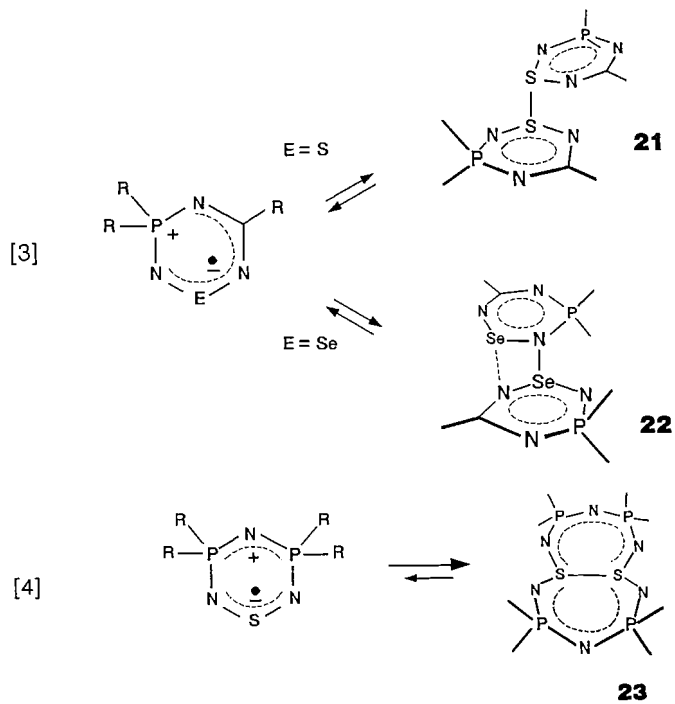
René Boeré, a NSERC postdoctoral fellow in my group, also pursued elusive anti-aromatic rings, most notably derivatives of the dithiatriazine RCN_3S_2 **2**. His approach, outlined in Scheme 2, required the use of persilylated amidines. These reagents, which are now widely used in much of our chemistry, are conveniently prepared by the Sanger reaction, i.e., the addition of $LiN(SiMe_3)_2$ to an aromatic nitrile (20). Persilylated amidines can be condensed with $S_3N_3Cl_3$ to produce the bicyclic derivatives **13** (21). In the case of R = phenyl, treatment of **13** with chlorine cleaves the -NSN- bridge, producing the dichlorodithiatriazine **14**. Reduction of **14** did not afford the monomeric 8π-electron ring **2** that we expected; eventual X-ray characterization of the isolated product revealed instead the dimeric system **15**, in which two CN_3S_2 rings are linked through two long (2.527 Å) S—S bonds (22). Evidently the monomer is sufficiently anti-aromatic that it dimerizes. Later computational work by my colleague John Goddard revealed a close energetic balance between the two spin states of the monomeric (gas phase) HCN_3S_2, the singlet being slightly favoured over the triplet by a Jahn–Teller distortion into C_s symmetry **16** (23). The proclivity for these rings to self-associate, however, was an exciting and important finding. The conversion of S—N π*-electrons to S—S σ-electrons encouraged us to pursue the design of other molecules that exhibit *inter*annular binding.

Neutral radical rings

Soon after my arrival at Guelph we started to look at neutral heterocyclic radicals. Our reasons were twofold. Firstly, my preoccupation with Scheme 1 required that we pursue 7π-radicals such as **4**, **5**, and **6**, and, secondly, we wished to explore the solid state structural ideas expounded by Robert Haddon (4). His neutral radical approach to molecular conductors required the use of odd-alternant hydrocarbons, i.e., ring systems capable of existing in a triad of oxidation states, neutral radical, aromatic ($4n$ + 2) cation, and anti-aromatic ($4n$) anion. While compounds such as **4** do not possess the fully nonbonding SOMO (singly occupied molecular orbital) that his model demanded, they had other features that made them attractive candidates for study. Pat Hayes (a research assistant), Robert Reed (an M.Sc. student), and René Boeré all contributed to this work, which involved the condensation of an imidoylamidine with sulfur dichloride to afford the cationic thiatriazine **17**. Reduction of the 6π-cations (typically with triphenylantimony) afforded the very stable 7π-radicals **4** (Scheme 3) (24), and further reduction with Na/NH_3(l) yielded the 8π-imides **18**, which were isolated, after protonation, as the corresponding imides **19** (25).

ESR studies on a series of thiatriazinyls revealed a spin density evenly spread over the three nitrogen centres; this distribution was, however, quite sensitive to the nature of the 3,5-substituents. The radicals associate, both in solution and the solid state; the crystal structure of the cofacial dimer **20** (R = Ph) exhibits a long (d(S—S) = 2.666 Å) interannular S—S bond. The corresponding selenatriazinyl radical dimerizes in a similar fashion, with a longer (d(Se—Se) = 2.792 Å) but stronger bond (26). Several conclusions related to molecular conductor design emerged from this work. In contrast to the 9π-radical $[S_3N_3]\cdot$, thiatriazinyls, with their lower π-electron counts, are very thermally stable. They also exhibit a triad of readily accessible oxidation states, a desirable feature for the efficient transfer of conduction electrons. The radicals associate but, unlike thiopyranyls, which dimerize through carbon (27), association of thiatriazinyls occurs at sulfur. However, while the dimerization is quite reversible, the interannular "bond" is still somewhat stronger, and more localized, than we desired. Moreover, the radicals are very electronegative, a feature that does not auger well for electron transport along a stacked array of radicals.

The characterization of the phosphorus-containing variants **5** (and also their selenium analogues) was pursued by Jim Bestari, who later became my first Ph.D. graduate. This was not an easy task, as the demands of selenium chemistry required some novel approaches to ring condensations. Likewise the simulation of the experimental ESR spectra required both persistence and patience. Once completed, however, the latter analyses echoed the earlier results on the phosphadithiatriazines **3**, in that the extent of electron delocalization across the phosphorus centres was minimal (28). The electronic structures of the compounds were, indeed, best represented by internal salt (zwitterionic) rather than delocalized formulations. In the solid state the sulfur-based compound forms a twisted (for steric reasons) cofacial dimer **21**, with a 2.481 Å S—S interannular bond (eq. [3]). By contrast, its selenium analogue associates not by an Se—Se linkage but rather via a long (1.99 Å) interannular Se—N bond (eq. [3]), to produce the dimer **22**, whose internal structural features resemble those of a 6π-cation/8π-anion pair.



[3]

[4]

In the "purely inorganic" (non-carbon containing) radicals **6**, spin localization is even more pronounced. Spin density is now restricted to the NSN (or NSeN) fragment, and again an internal salt formulation applies. Interestingly, as Tris Chivers and his group established, the sulfur compound rearranges upon association to form the macrocyclic structure **23** (eq. [4]). This process remains reversible; the macrocycle and the radical coexist in equilibrium, albeit one that heavily favours the dimer. The mechanism of the bond exchange necessary to interconvert **6** and its dimer intrigued us and, insofar as these radicals are best depicted as

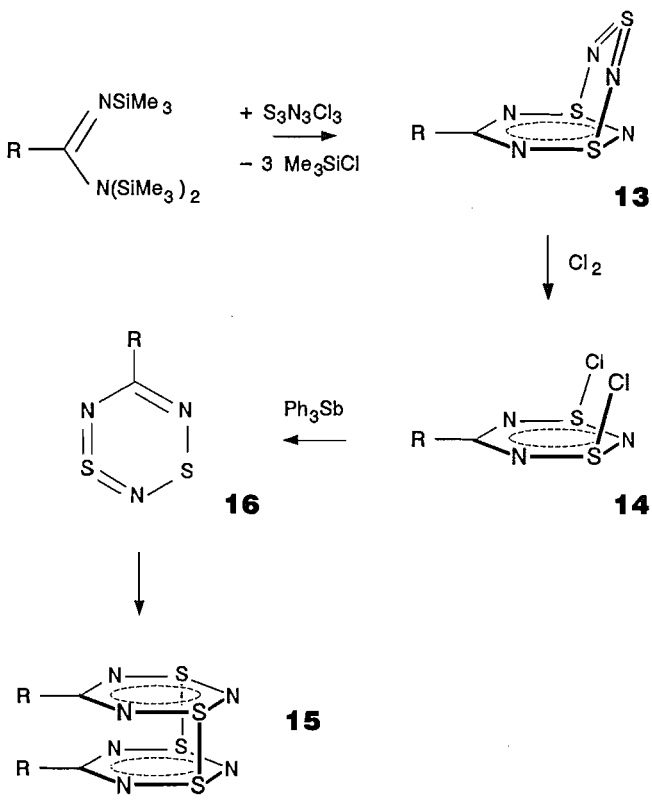
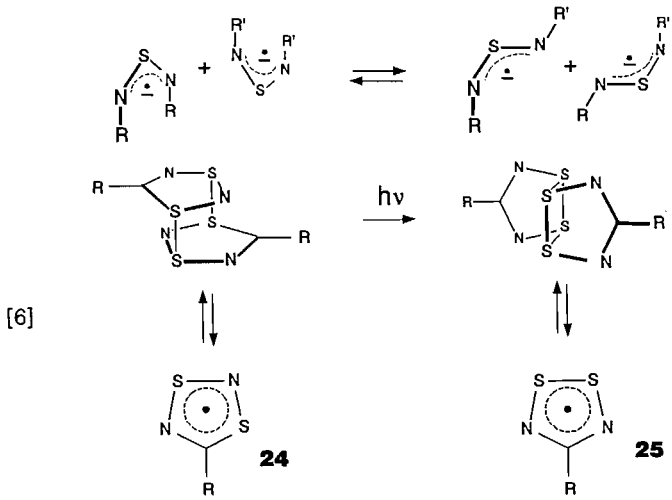


SCHEME 2

radical ion salts, we wondered whether simple acyclic sulfur diimide radical anions, i.e., $[RNSNR]^{-\cdot}$, might undergo a similar scrambling reaction based on the association and rearrangement of the resulting dimer. Jim Bestari set about exploring this possibility by studying the crossover reaction between radical anions of different sulfur diimides (29). The reaction (eq. [5]) worked surrprisingly well; the rearrangement required the addition of only catalytic amounts of reducing agent to the mixture of sulfur diimides. Moreover,

[5]



[6]

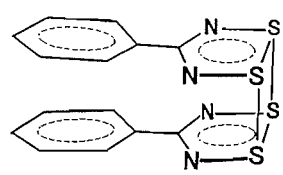
when relatively dissimilar R and R′ groups (e.g., Ar and Me_3Si) were employed, the equilibrium was shifted well to the right-hand side. The procedure thus afforded a simple preparative route to unsymmetrical sulfur diimides.

At the same time as we were investigating this radical rearrangement, Jack Passmore and his students at New Brunswick discovered a related reaction. By means of some elegant ESR experiments they observed that the 1,3,2,4-dithiadiazolyl radical **24** could be photochemically converted to its more stable 1,2,3,5-isomer **25** (30). The reaction was shown to be second order in radical, and an orbital symmetry analysis of the proposed mechanism, which involved the centrosymmetric association and rearrangement of the resulting dimer (eq. [6]), indicated that such a process should be photochemically allowed (31).

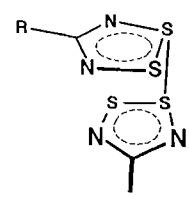
Pleasing though the identification of these radical rearrangements were, the recognition of such facile bimolecular pathways for structural change revealed a fundamental weakness of some heterocyclic frameworks based on catenated -S=N- units. These findings, coupled with results that we had obtained on the unimolecular rearrangements of closed-shell molecules (32, 33), reminded us that the design of molecular building blocks would require careful consideration of the kinetic and thermodynamic stability of the target molecules.

Neutral radical molecular conductors

By the end of the last decade, a wide variety of heterocyclic thiazyl radicals had been identified by ESR spectroscopy. As indicated earlier, some radical dimers had also been isolated and characterized by X-ray crystallography. The structural stability of some, and the propensity of others to rearrange, or decompose, had been recognized (34). Of the various candidates for applications in molecular materials, the thiatriazinyls that we had investigated early on showed some promise, but their dimerization constants were too high. Other systems, such as 1,3,2,4-dithiadiazolyls **24**, have been explored, but their tendency to rearrange has hampered structural characterization (35). The most promising candidates, certainly in our minds, were derivatives of the 1,2,3,5-dithiadiazolyl system **25** (this being the more stable of the two isomers noted above). These compounds have relatively high ionization potentials (36), and their exposed peripheries, replete with lone pairs, suggested to us that strong interannular interactions might be developed between adjacent rings in the solid state. Such attributes are vital for molecular metal design.

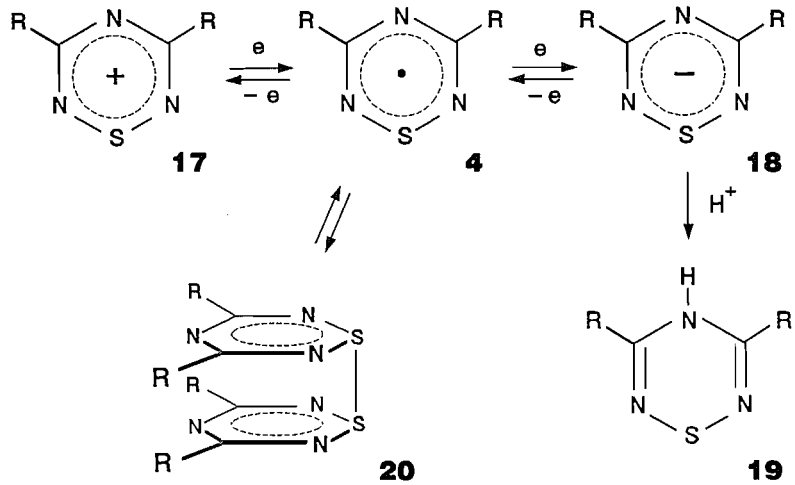


26



27

The first example (R = Ph) was fully characterized, both in solution and the solid state, by Arthur Banister's group at Durham in the early 1980s (37). While the crystal structure showed no indication of the stacked packing pattern alluded to in Fig. 1, the internal structural features of the dimer **26** were promising; the interannular S---S contact (mean value



SCHEME 3

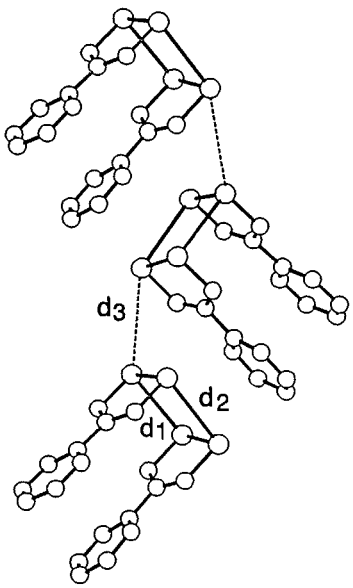


FIG. 2. Herring-bone stacking of $[PhCN_2Se_2]_2$ (d_1 = 3.160 Å, d_2 = 3.347 Å, and d_3 = 3.815 Å).

3.109 Å) was long, and the radical association enthalpy in solution was weak (38). Later structural work on related derivatives (R = CF_3 (39), NMe_2 (40), and Me (41)) revealed other dimerization modes, e.g., **27**, but afforded little encouragement that stacked structures were possible. Clearly, some modifications would be necessary if such rings were to be used as molecular building blocks. To this end a direct and flexible synthetic route was required, one which would also allow access to the corresponding selenium heterocycles.

[7] 
The time and effort invested in the synthesis of persilyated amidines now proved worthwhile. We found that the condensation of persilylated benzamidine with sulfur (or selenium) dichloride afforded, in excellent yield, the corresponding 4-phenyldithiadiazolium (or diselenadiazolium) chloride (eq. [7]). Reduction of the cations was a relatively straightforward task, and the radicals could be purified by vacuum sublimation (they are *surprisingly* thermally stable). The crystal structure of the selenium dimer $[PhCN_2Se_2]_2$ is illustrated in Fig. 2 (42). In contrast to its sulfur analogue, the packing pattern reveals a weak *inter*dimer Se---Se interaction that links dimers into infinite chains parallel to the z direction. The compound exhibits no measurable conductivity, but the observation that extended *inter*dimer interactions could be developed was enough to convince us to take a leap of faith. We therefore set about the design of new materials, a venture which has flourished thanks to a rewarding and enjoyable collaboration with Robert Haddon and his colleagues at AT&T Bell Laboratories.

Our architectural objective was simple enough in principle. We wished to design molecules, variations on the dithia- and diselenadiazolyl theme, with structural or electronic features incorporated into the exocyclic R-group that would promote the crystallization of uniformly spaced molecular stacks. Overlap of the π-SOMOs on adjacent rings should then afford a half-filled energy band. There is, however, a serious problem associated with this objective. As in any one-dimensional structure with a half-filled electronic band, the stacks are subject to a charge density wave (CDW) driven or Peierls instability (43), i.e., a tendency to dimerize (Fig. 1). This distortion, the solid state variant of a Jahn–Teller effect, opens up an energy gap at the Fermi level, and the materials slide into either semiconducting or insulating states, the final result depending on the magnitude of the residual band gap. It was into this trap that many of the early charge transfer salts first fell. The solution to the problem, the stabilization of highly conducting states, requires increasing the dimensionality of the overall structure; extended networks of lateral as well as longitudinal interannular contacts must be developed. There are at least two potential solutions to this problem. One is to compress the system, i.e., to apply physical pressure. The other is less direct, but sometimes more flexible; one applies "chemical pressure," i.e., the R-group is sculpted in such a way that the columnar stacks are packed as tightly as possible.

The control of molecular packing is still more of an art

form than a science (44), and many research groups are, with different goals in mind, pursuing the design of molecular systems that, when assembled within the demands of a crystal lattice, generate a specific supramolecular architecture. In our work we have adopted several design strategies. The primary objective has been to induce stacking, albeit of dimers. In those cases where stacking has been achieved we sought to make subtle molecular adjustments, in the hope of enhancing the lateral interactions noted above. The effects of replacing sulfur by selenium on both structure and transport properties have also been closely monitored.

One of our first architectural variations involved the placement of cyanophenyl (2-, 3-, and 4-), dicyanophenyl, or cyanofuryl substituents on the radical ring. This work was carried out largely by Robin Hicks at the start of his Ph.D. research (45, 46). The idea here was based on the well-known tendency of the nitrile group to influence packing. The structure of iodobenzonitrile, for example, consists of molecular ribbons held together by CN---I links (47). The necessary amidines were synthesized by the Sanger route, and the cations generated according to eq. [7]. Reduction and sublimation then afforded the radical dimers and, after some effort,[2] the crystal structures were established by X-ray crystallography. The results were mixed. Although the packing pattern of the 4-cyanophenyl compounds is ribbon-like, with CN---E (E = S, Se) contacts linking the molecular units, stacking of the dimers is not found. In the case of the 3,5-dicyanophenyl derivative (E = Se) stacking of dimers is observed, but the steric bulk of the organic ligand is such that the dimer columns are separated in pairs, with no extended lattice-wide network of interdimer Se---Se contacts (48). In the 3-cyanophenyl and 2-cyanophenyl derivatives, stacking is again observed, but now the dimer columns are linked by an extended array of lateral as well as longitudinal Se---Se interactions. The relative effects of longitudinal and lateral interactions are illustrated by the results of Extended Hückel band structure calculations on the crystal structures of the diselenadiazolyls shown in Fig. 3. The density of states for the 4-cyanophenyl compound reveals, as expected, a wide band gap, as only lateral contacts are available. In the 3,5-dicyanophenyl compound, where isolated pairs of stacks are observed, the band gap is diminished, as extended longitudinal contacts replace extended lateral interactions. In the 3-cyanophenyl derivative both types of interactions are present, and the combined effect leads to an overall decrease in the band gap. However, single crystal conductivity measurements on the 3-cyanophenyl derivative, which is the best of the three structures, reveal a room temperature conductivity of only 10^{-9} S cm^{-1}.

In the compounds outlined above, the size of the organic residue inevitably restricts the approach of the heterocyclic peripheries, and thus precludes low band gap materials. This limitation can be alleviated in several ways. One approach to increasing the solid state density of the radicals, and hence the number and magnitude of the interdimer contacts, involves the design of polyfunctional radicals, i.e., systems in which two or more radical centers are linked by a common bridging ligand. Steve Liblong (a NSERC postdoctoral fellow) and Kelly Young (a research assistant) helped start this

[2]Crystal growth by sublimation tends to produce twinned materials, especially when the packing pattern involves the columnar stacking that we desired.

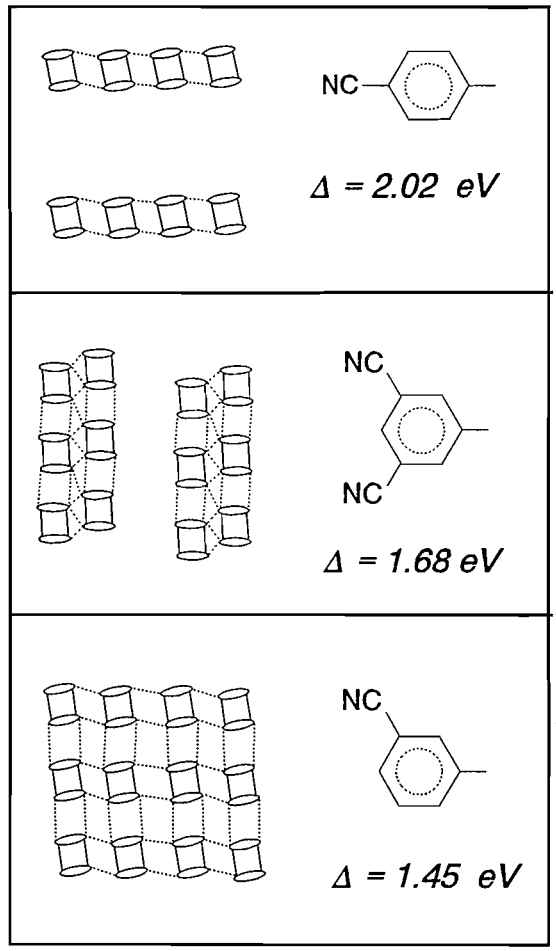

FIG. 3. Stacking patterns for selected monofunctional diselenadiazolyl dimers, and computed (EHMO) band gaps (Δ). In the 4-cyanophenyl compound, alternate layers are occupied by the organic ligand.

work, which was based initially on the 1,4- and 1,3-phenylene-bridged diradicals **28** and **29**. Purification and crystal growth of these materials required extremes in both temperature and pressure (vacuum), but we were eventually able to characterize both the sulfur and selenium derivatives of these two systems (E = S, Se). Figure 4 illustrates the herring-bone packing found in the 1,4-compounds (49). The structures are characterized by short intra- and interdimer S---S (or Se---Se) contacts that link consecutive ribs along the spine. There is also a series of short contacts that bind consecutive layers. Extended Hückel band structure calculations revealed a highly developed 2-dimensional electronic structure, and while the sulfur compound was found to be insulating, the selenium compound exhibited a pressed pellet conductivity near 10^{-2} S cm^{-1}.

Crystals belonging to the tetragonal space group $I4_1/a$ (the so-called α-phase) can be grown for the 1,3-derivatives of both sulfur and selenium (50). Within the unit cell there are fourfold pinwheel-like clusters of columnar stacks of diradicals that run parallel to the *y* axis. The stacks consist of molecular "plates" slightly offset from the ideal regular spacing sequence, i.e., a Peierls distortion. The plates do not, however, couple as discrete dimers, as do the 1,4-diradicals, but rather exhibit a subtle rocking, so as to produce a zigzag arrangement of short and long interannular contacts

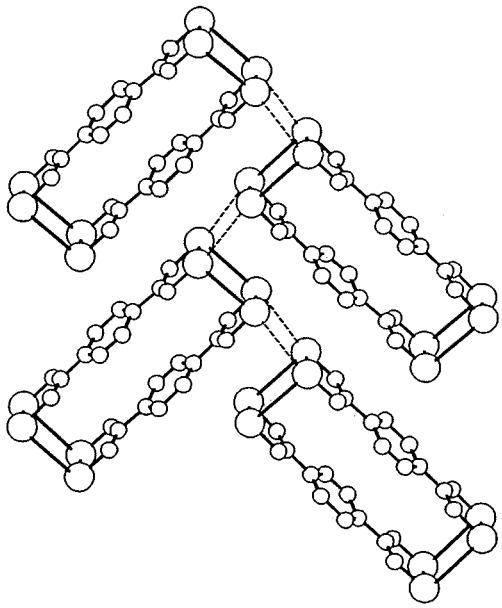

FIG. 4. Herring-bone stacking of the 1,4-benzene-bridged compounds **28** (E = S, Se). The mean intra- and interdimer E---E contacts are 3.121/3.275 Å (S/Se) and 3.500/3.578 Å (S/Se), respectively.

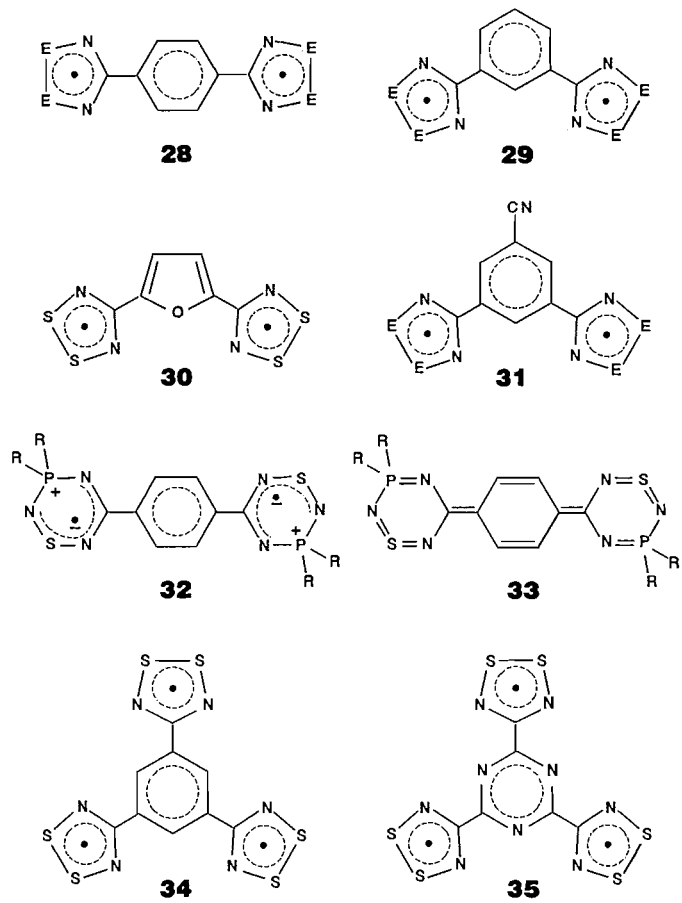
(Fig. 5). The selenium compound also forms a second, monoclinic phase (space group $P2_1/n$), when the material is sublimed at higher pressures and temperatures. This β-phase consists of discrete dimers that are not stacked; instead they interlock like links in a chain, with short interdimer contacts to either side as well as above and below (51). Overall, the structure possesses a weaker, but more 3-dimensional, network of interactions than is found in the α-phase.

Extensive magnetic and conductivity measurements have been performed on these 1,3-compounds. They are all essentially diamagnetic at room temperature, but the sulfur compound shows a large hysteretic increase in paramagnetism at elevated temperatures; the selenium compound (α-phase) shows a much smaller, but similar, effect. We have assigned this behaviour to the occurrence of phase kinks in the lattice, which serve to trap isolated spin-bearing rings. This phenomenon does not appear to serve as a source of carriers, as would be expected in most semiconductors. There is, for example, only a minor increase in conductivity of the sulfur compound associated with the paramagnetic "breakout". The results of variable temperature single crystal conductivity measurements on both phases of the 1,3-selenium compound are consistent with a conduction mechanism involving thermal activation of electrons. Experimental estimates for the band gaps of 0.55 and 0.77 eV have been derived for the α- and β-phases, respectively.

The unusual zigzag stacking found in the α-phase of the 1,3-derivatives prompted us to pursue molecular variants, including the furan-bridged and 5-cyanobenzene-bridged compounds **30** (46) and **31** (52). The former elected to crystallize in a totally different motif, one more reminiscent of the 1,4-derivatives **28**, and while the latter adopts a zigzag stacking arrangement, the lateral intercolumnar contacts are far less effective than those observed in the parent 1,3-derivatives, and the observed conductivities are correspondingly lower. As an offshoot to this work we were interested to see if quinoidal, as opposed to diradical, states might be observed for certain 1,4-phenylene-bridged systems. This possibility had been probed for the phenylene-bridged bis(1,3,2,4-dithiadiazolyls), for which a diradical dimer structure was found (53). Similarly, phenylene-bridged diradicals such as **32**, which are based on the PCN_3S skeleton **5** (Scheme 1), showed no indication, either in solution or the solid state, for the quinoidal structure **33** (54).

Determined to go beyond the diradical systems, Robin Hicks and Dietmar Kennepohl (a postdoctoral fellow) looked at the two triradical systems **34** and **35**. The 1,3,5-benzene-bridged compound was found to crystallize as girder-like



stacks (Fig. 6) with a bond alternation pattern reminiscent of the α-phase of the 1,3-compounds described earlier (55). The intercolumnar contacts were, however, even tighter. The minor molecular change on going from a benzene to a triazine bridge was intended to induce a general compression of the original structure. While, within two dimensions, our objective was achieved (57), the full crystal structure of **35** (space group $C2/c$) was quite different to that of **34** (space group $P2_1/c$); the change in space group, precipitated by a seemingly minor chemical modification, effectively eliminated the desired columnar stacking. Here, as elsewhere, we were chastened by Nature; the *a priori* prediction of crystal structures remains, at best, a sporting pastime.

Iodine doped radicals

We continue to design, prepare, and study neutral radicals. The derivatives characterized to date confirm that low band gap materials are possible, and the prospect of gener-

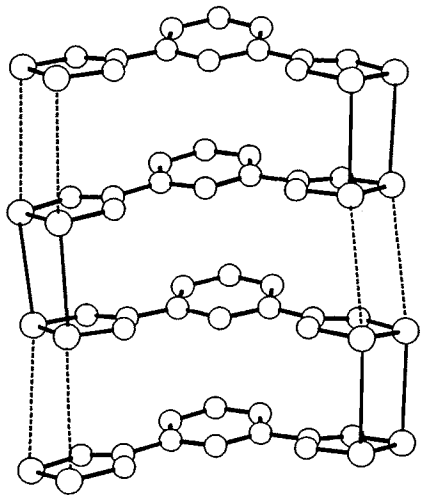

FIG. 5. Zigzag stacking of the 1,3-benzene-bridged compounds **29** (E = S, Se). The mean intra- and interdimer E---E contacts are 3.140/3.284 (S/Se) and 3.966/4.014 Å (S/Se), respectively.

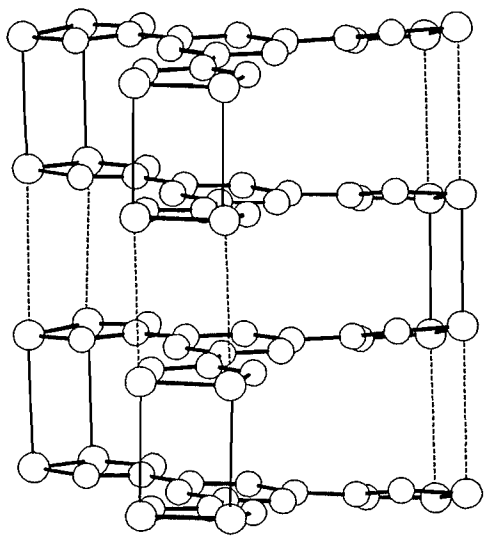

FIG. 6. Stacking of the 1,3,5-benzene-bridged triradical **34**. The mean intradimer and interdimer S---S contacts are 3.117 and 3.832 Å, respectively.

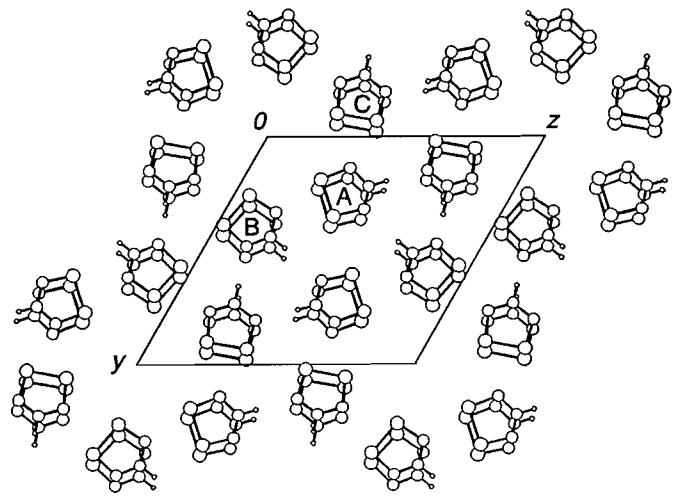

FIG. 7. Close-packed arrangement of molecular rings in the triclinic phase of $[HCN_2S_2]_2$. The three dimers in the asymmetric unit are labelled **A**, **B**, and **C**.

ating new variants remains as enticing as ever. A totally different lure, one which we resisted for a long time, involves *p*-type doping radicals, i.e., the removal of electrons from the half-filled energy band of Fig. 1 and the generation of a stable stack of uniformly spaced molecular plates.

This doping work began with an accidental finding, at a time when we were investigating the prototypal radicals $[HCN_2E_2]\cdot$ (E = S, Se) (57). Our original intent here was to incorporate the smallest possible ligand, a hydrogen atom, in the hope of generating high-density materials. The selenium derivative consists of dimers arranged in a slipped stack structure that exhibits very short *inter*dimer as well as *intra*dimer contacts, and the room temperature conductivity is 7×10^{-6} cm^{-1}. As a result of its relatively high vapour pressure and low thermal stability, however, this compound does not lend itself to detailed physical study.

Later work on the sulfur radical $[HCN_2S_2]^{\cdot}$ revealed that its dimer was dimorphic. When prepared by sublimation under an atmosphere of argon, the dimer grows as needles belonging to the monoclinic space group $P2_1/n$ (58); a second, triclinic phase, space group $P\bar{1}$ is generated when the sublimation is performed in vacuo. The structures of both modifications consist of stacked dimers, with three dimers per asymmetric unit. The triclinic phase exhibits, however, a rather unusual feature. Essentially, the structure consists of close-packed "tubes," each tube (with a 7.43 Å internal diameter) being built from a near-hexagonal merry-go-round composed of six dimers. This remarkable tubular structure invited a doping experiment, and we quickly set about trying to incorporate iodine into the lattice.

Robin Hicks and Dietmar Kennepohl started the doping experiments, and later were joined by two new graduate students, Noel George and Craig MacKinnon. After some effort we found that when the native radical and iodine are coevaporated in a sealed evacuated tube, lustrous silver-black rods of composition $[HCN_2S_2]_6[I]_{1.1}$ can be grown (59). Careful X-ray work revealed a crystal structure very similar to that of the parent material. The doped crystals belong to the hexagonal space group $P6_1$, and the structure again exhibits a close-packed arrangement of tubes, each tube being constructed from a pinwheel array of six HCN_2S_2 rings. The important structural differences between the doped and undoped phases can be understood with reference to Fig. 8, which illustrates the columnar motifs formed by the innermost sulfur atom of each HCN_2S_2 ring. In the undoped structure the dimers, each represented by a single sulfur atom per ring, form layers with a mean intradimer S---S distance of 3.104 Å and a mean interdimer S---S separation of 3.779 Å. In the doped structure the sulfur atoms lie on a sixfold screw axis, with a regular S---S separation (along the stack) of 3.352 Å. The iodines, which lie within the cavity in a spiral wrapped tightly about the 6_1 axis, are disordered. Examination of the physical properties of this compound has been hampered by its air sensitivity, but its conductivity, 10^2 S cm^{-1} along the needle axis, has been established.

The preparation of this highly conductive doped material, isolable as a discrete crystalline phase, was an exciting finding, and we are now pressing on to see if the idea is

generally applicable. Fortunately, the synthetic approach appears not to be limited to volatile radicals. For example, coevaporation of the 1,4-phenylene-bridged bis(dithiadiazolyl) (**28**, E = S) and iodine affords air-stable needles of stoichiometry $[(S_2N_2C)C_6H_4(CN_2S_2)][I]$, formally the iodide salt of a radical cation. The room temperature crystal structure (space group *Immm*) consists of one-dimensional arrays of evenly spaced (3.415 Å) molecular plates, with interspersed columns of disordered iodines (Fig. 9). The single crystal conductivity at room temperature of this material is also 10^2 S cm^{-1} (60), but its stability in air has allowed more detailed physical studies. The conductivity is metallic at room temperature, but near 190 K a CDW-driven instability sets in, and the material becomes an insulator. Analysis of the CDW wavevector has provided a measure of the bandfilling, and hence the degree of charge transfer from radical to iodine. Based on this data, the material can be formulated as $[(S_2N_2C)C_6H_4(CN_2S_2)]^{0.5+}[I]^{0.5-}$.

Summary

The paradigms and prejudices that chemists use to explain and predict molecular structure have allowed the construction of exotic molecules, both large and small. One of the challenges for the future lies in the exploitation of this knowledge to fabricate molecules that will serve as building blocks for specific solid state (crystal) structures. The research described above has been so motivated. It began, however, not with attempts to address the final targeted objectives, but with exploratory work on the preparation and characterization of thiazyl and selenazyl heterocycles with novel electron counts. These rings are electron rich, and as such possess notoriously weak skeletal bonds. Stable variants can, however, be made, and *inter-* as well as *intra*-annular bonding is observed in many of these compounds. Methods for the conversion of these localized interannular *bonds* into more extensive and lattice-wide *bands* have been developed, and we have been able to generate single-component molecular solids with semiconductive properties. Preliminary results on the iodine doping of some of these systems indicate that highly conductive phases can be made, and we look forward with excitement to the discoveries that lie ahead. Basic research in molecular chemistry has opened a window of opportunity for the advancement of materials science.

Acknowledgements

I am grateful to the Canadian Society for Chemistry for selecting me as this year's recipient of the ALCAN Lecture award, and to ALCAN for its continuing support of chemical research in the Canadian academic community. The work described above has been sustained by grants from the Natural Sciences and Engineering Research Council of Canada and, in the early years, the Research Corporation. I thank both agencies for this funding. I am endebted to the past and present members of my research group, and to my colleagues and collaborators, most of whose names I have noted above, for their enthusiastic and invaluable support. Acknowledgement of the contributions of one individual is notably absent. Wally Cordes, at the University of Arkansas, has provided, amongst other things, the X-ray structural results for virtually every paper I have published in the past 17 years. For some of the samples that I have sent him in recent times, he may never forgive me. For the personal and professional enrichment that our collaboration has brought me, I can never repay him.

Association of neutral red with micelles and its effect on the pK_a

ROBIN K. DUTTA AND SUBRAY N. BHAT[1]
Department of Chemistry, North-Eastern Hill University, Shillong-793003, India

Received June 22, 1992[2]

ROBIN K. DUTTA and SUBRAY N. BHAT. Can. J. Chem. **71**, 1785 (1993).

The interactions of neutral red with cationic surfactants, viz., *N*-hexadecylpyridinium chloride and alkyltrimethylammonium bromides; a nonionic surfactant, viz., Triton X100; and an anionic surfactant, viz., sodium dodecyl sulfate, were investigated spectroscopically. The equilibrium constants for the association of the indicator with the micelles were determined from the apparent association constants at constant pH at 298 K. The effects of the indicator–micelle association on the apparent pK_a of the indicator in aqueous surfactant solutions are discussed. It was shown that the apparent pK_a of the indicator in cationic surfactant solution can be predicted from knowledge of the indicator–micelle association constant.

ROBIN K. DUTTA et SUBRAY N. BHAT. Can. J. Chem. **71**, 1785 (1993).

Faisant appel à la spectroscopie, on a examiné les interactions entre le rouge neutre et des agents tensioactifs cationiques (le chlorure de *N*-hexadécylpyridinium et les bromures d'alkyltriméthylammonium), un agent tensioactif non ionique (le Triton X100) et un agent tensioactif anionique (le dodécylsulfate de sodium). En se basant sur les constantes apparentes d'association, à pH constant, à 298 K, on a déterminé les constantes d'équilibre pour l'association de l'indicateur avec les micelles. On discute des effets de l'association indicateur–micelle sur le pK_a apparent de l'indicateur dans des solutions aqueuses d'agent tensioactif. On a démontré que l'on peut prédire le pK_a apparent de l'indicateur dans la solution d'agent tensioactif cationique à partir d'une connaissance de la constante d'association indicateur–micelle.

Introduction

Micelles are frequently employed in combination with acid–base indicators in analytical chemistry to shift the chemical equilibrium and pK_a of the indicator to a desired degree (1). The effect of micelles on the pK_a of an indicator is due to micellar catalysis of the acid dissociation reaction (2). The shifts in the pK_a have been attributed to an electrostatic potential at the micelle surface (3), to ion exchange between the micelle surface and the bulk aqueous phase (4), and to low interfacial effective dielectric constant, interfacial salt effect, and ion-pair formation between oppositely charged indicator species and monomeric surfactant head groups (5). Nevertheless, most of the indicator equilibria in micellar medium studied so far are cases in which the indicator species are completely incorporated into the micelles. Even recently, it was considered pointless to analyse the observed p$K_{a,app}$'s of indicators in which both the conjugate acid–base forms are not fully solubilized by the micelles (5*d*). The association constants of indicators with micelles may be quite informative about the pK_a shifts of such partly solubilized indicators, as any observation can be better understood with the help of equilibrium properties (3*b*). In the present paper we report the results of a systematic study of the preferential association of 3-amino-7-dimethylamino-2-methyl phenazinium chloride (neutral red), with micelles of cationic, nonionic, and anionic surfactants at constant pH, and the effect of such associations on the observed p$K_{a,app}$ of the indicator (6). The structures of neutral red in its base (NR) and acid (NR^+H) forms are shown in Scheme 1.

Experimental

Neutral red, a Sigma product, was recrystallized twice from a water–ethanol mixture and dried before use. *N*-Hexadecylpyridinium chloride (cetylpyridinium chloride, CPC) was obtained from Hexel Corporation, U.S.A. Hexadecyltrimethylammonium bromide (CTAB), dodecyltrimethylammonium bromide (DTAB), and Triton X100 ($(CH_3)_3CCH_2C(CH_3)_2C_6H_4(OCH_2CH_2)_{10}OH$, TX100) were Sigma products. Tetradecyltrimethylammonium bromide (TTAB) was obtained from Sisco Research Laboratories, India. All cationic surfactants were recrystallized from acetone. Sodium dodecyl sulfate (SDS), obtained from Aldrich, was first washed with ether and then recrystallized from ethanol and the recrystallized samples were dried in a vacuum desiccator. TX100 was used as such. Buffer constituents were of AR grade. Triply distilled water, prepared by adding $KMnO_4$ in the first distillation, was used as solvent.

The visible absorption spectra were recorded by a Hitachi-330 spectrophotometer using a matched pair of cells of 1-cm path length fitted in a thermostated cell holder. The pH of the solutions was measured using a Systronics Digital pH meter model-335. All the experiments were carried out at 298 (±0.1) K.

Results and discussion

p$K_{a,w}$ of neutral red

Neutral red, in aqueous solution, exists in two forms, viz., NR^+H and NR, which are in equilibrium with each other. NR, which has an absorption maximum at 450 nm, is yellow in color, whereas NR^+H, a red-colored product, is reported to have an absorption maximum between 535 and 545 nm (7). The position of the λ_{max} of NR^+H is dependent upon the constituents of the buffer. The variation of the λ_{max} of neutral red in different buffer media has been attributed to formation of dimers and higher aggregates of the dye where buffers are believed to influence the aggregation equilibrium differently (5*c*, 7). We have observed that in phthalate buffer of pH 4 (0.05 mol dm^{-3} potassium hydrogen phthalate) the λ_{max} is 538 nm, whereas in phosphate buffer, i.e., in the presence of 0.05 mol dm^{-3} KH_2PO_4 and 0.001 mol dm^{-3} HCl, it is 527 nm. The visible spectra of the acid–base titration of neutral red using phosphate buffer (0.05 mol dm^{-3} KH_2PO_4 with added NaOH or HCl) pass through a sharp isosbestic point at 477 nm, whereas such a sharp isosbestic point was not observed in phthalate buffer (0.05 mol dm^{-3} potassium hydrogen phthalate with added NaOH) medium.

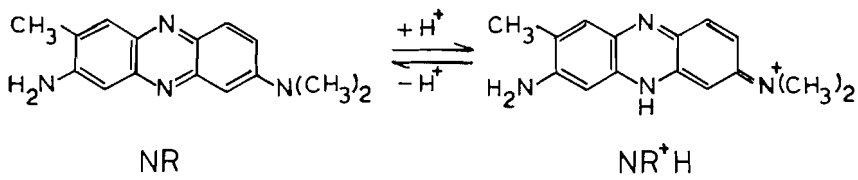

SCHEME 1

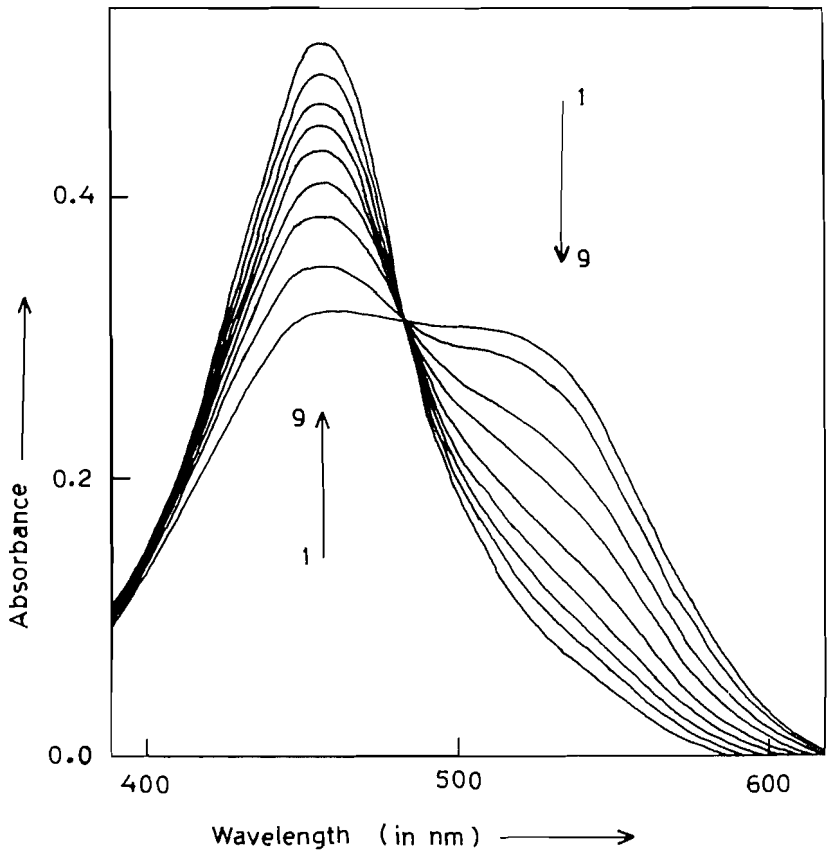

FIG. 1. Spectra of neutral red (4×10^{-5} mol dm^{-3}) at various concentrations of CPC at pH 7.25; concentrations of CPC $\times 10^{-4}$ mol dm^{-3}: 1 = 0.0, 2 = 1.2, 3 = 2.4, 4 = 3.6, 5 = 5.9, 6 = 9.5, 7 = 14.2, 8 = 24.1, and 9 = 114.9.

We feel that the absence of a clear isosbestic point in the spectra of neutral red, as reported by Drummond et al. (*5c*), was because these authors used more than one buffer system in the same experiment. The p$K_{a,w}$ of neutral red determined using KH_2PO_4 (0.05 mol dm^{-3}), NaOH, and HCl (for varying pH) was found to be 6.75 (±0.02), whereas the reported values vary from 6.5 to 7.4 (*5c*, 8).

Determination of K_{ass} *at constant pH*

The visible absorption spectra of neutral red in varying concentrations of CPC at pH 7.25 (0.05 mol dm^{-3} KH_2PO_4 + 0.036 mol dm^{-3} NaOH) are shown in Fig. 1. As the concentration of CPC was increased from 0 to 1.15×10^{-2} mol dm^{-3}, the absorption on the higher wavelength side (λ_{max} = 527 nm) decreased, whereas that on the lower wavelength side (λ_{max} = 460 nm) increased and a sharp isosbestic point was observed at 482 nm. The positions of the absorption maxima and the isosbestic point were not affected when the surfactant was changed from CPC to CTAB, TTAB, and DTAB. The presence of the isosbestic point indicates the existence of an equilibrium between the indicator species in aqueous and micellar pseudophases. The shift in the λ_{max} from 450 nm (in water) to 460 nm (in surfactant) is due to the association of the basic form of neutral red with the CPC micelles. The λ_{max} was found to be same in buffered micellar media of pH 7.25 (0.05 mol dm^{-3} KH_2PO_4 + 0.036 mol dm^{-3} NaOH), 7 (0.05 mol dm^{-3} KH_2PO_4 + 0.029 mol dm^{-3} NaOH), and 5.87 (0.05 mol dm^{-3} KH_2PO_4 + 0.0043 mol dm^{-3} NaOH). The effect of an increase in CPC concentration at constant pH is similar to that of an increase in pH of the aqueous indicator solution. It can be mentioned here that the pH of phosphate buffer solutions of pH 7.25, 7.00, and 5.87 (compositions as mentioned above) are unaffected on addition of cationic surfactants up to a concentration of ca. 0.02 mol dm^{-3}. This observation parallels that reported by Bunton and Minch (9).

The acid–base equilibrium of an indicator is represented by

$$[1] \quad A_w^z \overset{K_{a,w}}{\rightleftharpoons} B_w^{z-1} + H_w^+$$

where A_w^z and B_w^{z-1} are the acid and its conjugate base forms and $K_{a,w}$ is the acid dissociation constant of the indicator in

TABLE 1. Association constants of neutral red with surfactants at various pH, K_{ass}, and the equilibrium constants (independent of pH) K_s and K_e at 298 (±0.1) K

Surfactant	pH (±0.01)	The cmc of the surfactant in buffer medium (× mol dm^{-3})	K_{ass} (× mol dm^{-3})	K_s (× mol dm^{-3})	pK_e
CPC	7.25[a]	1.2×10^{-4}	3800 (±50)	5000	3.05
CPC	7.00[b]	1.7×10^{-4}	3060 (±50)	4990	3.05
CPC	5.87[c]	7.0×10^{-4}	580 (±20)	4980	3.05
CTAB	7.00[b]	7.0×10^{-5}	3630 (±50)	5920	2.98
TTAB	7.00[b]	7.0×10^{-4}	2440 (±50)	3980	3.15
DTAB	7.00[b]	7.0×10^{-3}	900 (±20)	1470	3.58
TX100	7.00[b]	5.0×10^{-4}	610 (±20)		
SDS	9.20[d]	7.4×10^{-4}	1400 (±50)		

[a]Buffer composition: 0.05 mol dm^{-3} KH_2PO_4 + 0.036 mol dm^{-3} NaOH.
[b]Buffer composition: 0.05 mol dm^{-3} KH_2PO_4 + 0.029 mol dm^{-3} NaOH.
[c]Buffer composition: 0.05 mol dm^{-3} KH_2PO_4 + 0.0043 mol dm^{-3} NaOH.
[d]Buffer composition: 0.01 mol dm^{-3} $Na_2B_4O_7$.

water. It follows from the definition of $K_{a,w}$ that at constant pH

$$[2] \quad [In_w] = [B_w^{z-1}](1 + [H_w^+]/K_{a,w}) = [A_w^z](1 + K_{a,w}/[H_w^+])$$

where $[In_w]$ is the total indicator concentration. In other words, it is possible to consider the total concentration of the indicator for an equilibrium study in buffered medium since the relative concentrations of the two indicator species remain the same irrespective of the total concentration at constant pH.

The expression of the association equilibrium of the indicator with the micelles can be simplified if eq. [2] holds in the micellar pseudophase. This would be so if the buffers were able to control the pH of the micellar surfaces, about which there have been differing reports in the literature (10, 11). Quina et al. (10) are of the opinion that buffers do not control the pH of the micellar surface. Frahm and Diekmann (11) observed that, within experimental uncertainties, the micellar surface potential is independent of the surfactant concentration (up to 10 times the critical micelle concentration). Nevertheless, in the present case, the intensity of the absorption band due to the acid form of the dye decreases with increase in concentration of the cationic surfactant and the band almost disappears at higher concentrations of surfactant (e.g., at and above ca. 1.15×10^{-2} mol dm^{-3} of CPC at a pH of 7.25; Fig. 1). This indicates that only NR is partitioned between the aqueous and micellar pseudophases, whereas NR^+H is largely in water. Therefore, for the present case, the total concentration of the indicator in the micellar pseudophase can be approximated to the total concentration of NR in the micellar pseudophase, i.e., we can consider a total indicator concentration term $[In_m]$ for the indicator in the micellar pseudophase.

Thus,

$$[3] \quad In_w + S_m \underset{\longleftarrow}{\overset{K_{ass}}{\longrightarrow}} In_m$$

or

$$[4] \quad K_{ass} = [In_m]/([In_w] \cdot [S_m])$$

where K_{ass} is the association constant of indicator with micelles at constant pH and $[S_m]$ is the micellized surfactant. In principle, eqs. [3] and [4] should be applicable for any indicator–micelle association interaction at any pH. However, in the presence of other types of molecular interactions, e.g., ion-pair formation between oppositely charged indicator species and monomeric surfactant, the equations are not applicable.

The association constants, K_{ass}, of indicator with micelles at constant pH were determined using Ketelaar's equation (12):

$$[5] \quad \frac{[In]_0}{(d-d_0)} = \frac{1}{(\epsilon_{ass}-\epsilon_0)} + \frac{1}{K_{ass}(\epsilon_{ass}-\epsilon_0)[S_m]_0}$$

where $[In]_0$ is the total concentration of the indicator, d and d_0 are the optical densities of the indicator in the presence and absence of the surfactant, respectively, ϵ_{ass} and ϵ_0 are the extinction coefficients of the indicator in the micelle-associated and free states, respectively, and $[S_m]_0$ is the total concentration of micellized surfactant, i.e., $[S_m]_0$ = (total concentration of surfactant − cmc) where cmc is the critical micelle concentration of the surfactant in the buffered medium, obtained from changes in absorbance of the indicator with addition of the surfactant.

The plots of $[In]_0/(d - d_0)$ *vs.* $(1/[S_m]_0)$ are quite linear, which suggests the validity of the assumption that the change in the ratio of acid to base forms of neutral red in the micellar pseudophase with change in surfactant concentration is within the experimental uncertainty. The K_{ass} values obtained from such plots are summarized in Table 1. It can be seen from the data that, in the case of CPC, K_{ass} increases with increase in pH of the medium. This can be attributed to the fact that at higher pH the concentration of the nonionic form of the indicator is high and it has preferential affinity towards the cationic micelles (rather than the cationic form). The value of K_{ass} of the indicator with CTAB (which has the same hydrocarbon chain length as CPC but a different head group) at constant pH 7 (0.05 mol dm^{-3} KH_2PO_4 + 0.029 mol dm^{-3} NaOH) was found to be higher than that with CPC. This indicates that the association of the indicator with cationic micelles not only depends on the hydrocarbon chain length but also on the head group of the surfactant. It is quite interesting to note that, as in the case

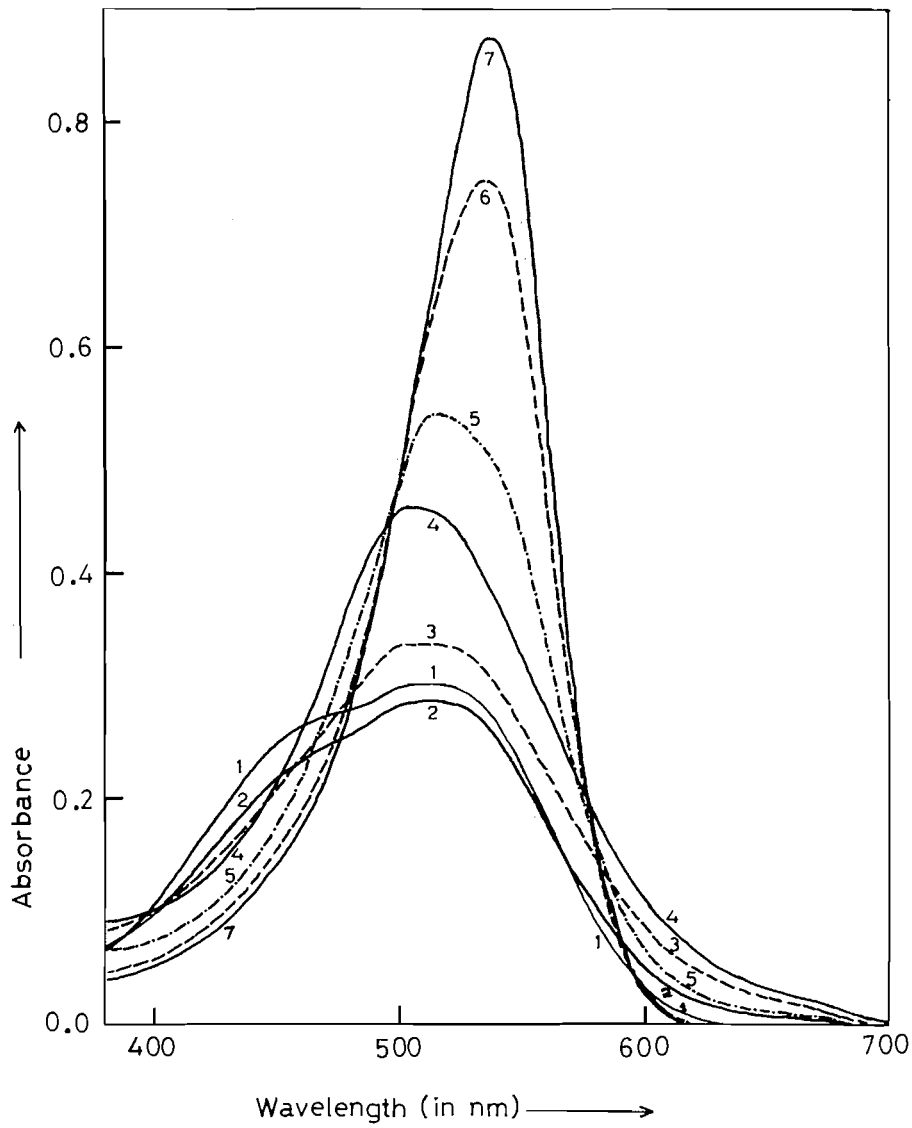

FIG. 2. Spectra of neutral red (3.2×10^{-5} mol dm^{-3}) at various concentrations of SDS at pH 7; concentrations of SDS $\times 10^4$ mol dm^{-3}: 1 = 0.0, 2 = 2.0, 3 = 2.8, 4 = 4.0, 5 = 8.0, 6 = 14.0, and 7 = 200.

of aqueous medium, the plot of the (log cmc) of CTAB, TTAB, and DTAB in buffered medium of pH 7 vs. hydrocarbon chain length is quite linear (13). This probably implies that even though the presence of the buffer components lowers the cmc, the process of micelle formation in the buffered medium is otherwise similar to that in pure water. The effect of surfactant counterions Cl^- or Br^- on K_{ass} cannot be inferred from the present study as the relatively large concentration of phosphate ion in the buffer solutions ensures that the counterion is mainly phosphate.

The spectra of neutral red (at constant pH 7) in varying amounts of TX100 are almost similar to those of neutral red in CPC and this indicates that the TX100 micelles associate with NR in preference to NR^+H. At higher concentrations of TX100, a weak shoulder at ca. 538 nm appears, which can be ascribed to a comparatively weaker but appreciable interaction of NR^+H with the micelles. The presence of an NR^+H–micelle association does not invalidate eqs. [3] and [4] as K_{ass} includes the associations of both species (i.e., NR and NR^+H) with micelles. The low K_{ass} of the indicator with TX100 (Table 1) suggests that the interaction is weak.

The spectra of neutral red in varying amounts of SDS at pH 7 are shown in Fig. 2. The lack of a single isosbestic point indicates the presence of more than one type of equilibrium between the indicator and the surfactant. At very low concentrations of SDS (i.e., below the cmc, the cmc in this buffer found, from surface tension measurements, to be ca. 7.4×10^{-4} mol dm^{-3}) the indicator absorbs in the high-wavelength region, ca. 580–680 nm. This absorbance has been attributed to the doubly protonated neutral red that is obtained in strong acidic medium of pH <1 in aqueous medium (7). Recently we showed that phenazinium dyes, which are generally protonated in highly acidic medium (below pH 1), can undergo protonation in submicellar anionic surfactant solutions even in neutral media, where the protonation is enforced by the strong hydrophobicity of the dye–surfactant ion pair (14). So, the absorption band above 580 nm can be attributed to doubly protonated neutral red in the dye–surfactant ion pair, viz., $NR^{2+}H_2 \cdot SDS^-$. At higher concentration of SDS (above the cmc) the λ_{max} was found to be 538 nm. The absorbance at this wavelength can be attributed to micelle-associated NR^+H. The determination of K_{ass}

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

of the indicator with SDS micelle at this pH was not possible due to the presence of more than one type of interaction. The spectral changes of the indicator with addition of SDS at pH 4.5 (acetate buffer) were almost similar to those at pH 7. However, at pH 9.2 (borate buffer), the spectral data (Fig. 3) show that there is no interaction (e.g., formation of $NR^{2+}H_2 \cdot SDS$) in the submicellar concentration range, whereas at higher concentration of surfactant (above the cmc) there is a clear isosbestic point at 466 nm, indicating the presence of an equilibrium. As the concentration of SDS is increased, the absorbance of the band on the higher wavelength side (λ_{max} = 538 nm) increases. Unlike the results obtained in CPC and TX100, the increase in intensities at higher wavelengths is much more comparable to the decrease in intensities of the 450-nm band (which shifts to 461 nm with increase in concentration of SDS). With the addition of more and more SDS, the anionic micelles associate with NR^+H in preference to NR. Therefore, the new band at λ_{max} = 538 nm can be ascribed to NR^+H_m. Absorption in the region of ca. 580–680 nm is absent above the cmc, possibly due to association of indicator with micelles, whereupon the protonated ion pairs are dissociated (Figs. 2 and 3). The shift of the 450-nm band of NR to 461 nm indicates that the conjugate base form, NR, is also associated (even though to a lesser extent than NR^+H) with the anionic micelles of SDS.

It has been seen that neutral red associates with cationic micelles only in the deprotonated form, NR. The association of the protonated form, NR^+H, is negligible compared to that of NR because of electrostatic repulsion between similar charges on the indicator and the micelle. Such behaviour is expected when the indicator is less hydrophobic (or more water soluble). Thus, substituting $[In_m]$ by $[B_m^{z-1}]$ in eq. [4] gives

$$[6] \quad K_{ass} = [B_m^{z-1}]/([In_w][S_m])$$

Now, we can examine the overall equilibrium constant, K_e, of neutral red in the cationic micellar medium (15):

$$[7] \quad NR^+H_w + S_m \overset{K_e}{\rightleftharpoons} NR_m + H_w^+$$

This equilibrium is the product of the partial equilibria [8] and [9]:

$$[8] \quad NR^+H_w \overset{K_{a,w}}{\rightleftharpoons} NR_w + H_w^+$$

and

$$[9] \quad NR_w + S_m \overset{K_s}{\rightleftharpoons} NR_m$$

where K_s is the pH-independent association constant of NR_w with similarly charged micelles (16) and is related to K_{ass} and K_e by

$$[10] \quad K_s = K_{ass}(1 + [H_w^+]/K_{a,w})$$

and

$$[11] \quad K_e = K_s \cdot K_{a,w}$$

A direct determination of K_s for the base form of neutral red is difficult as the indicator is unstable in strong basic medium, the condition required for the same. The equilibrium constants K_s and K_e calculated for neutral red with cationic micellar systems at various pH are included in Table 1. It can be seen from the table that K_s and K_e are independent of pH and are true thermodynamic quantities.

$pK_{a,app}$ of neutral red

The apparent dissociation constant, $K_{a,app}$ of an indicator in micellar solution is defined (9) as

$$[12] \quad K_{a,app} = \frac{[\text{total indicator in conjugate base form}]\,[H_w^+]}{[\text{total indicator in acid form}]}$$

For neutral red in cationic micellar medium:

$$[13] \quad K_{a,app} = ([NR_m] + [NR_w])\,[H_w^+]/[NR^+H_w]$$

or,

$$[14] \quad K_{a,app} = K_{a,w} + K_{ass} \cdot [S_m]\,([H_w^+] + K_{a,w})$$

or,

$$[15] \quad K_{a,app} = K_{a,w}(1 + K_s \cdot [S_m])$$

Thus, once the value of K_{ass} at (a suitable) fixed pH or the value of K_s is known, $K_{a,app}$ of the indicator at any concentration of the surfactant can be predicted. The $pK_{a,app}$ thus predicted for neutral red at various concentrations of CPC are shown in Fig. 4 along with the experimentally determined values. Here it can be mentioned that an error in the experimental $pK_{a,app}$ values is expected to be involved due to the variation in ionic strength of the medium, as the experimental values were determined using buffer (3*a*, 17). However, the variation in ionic strength of the medium (due to addition of NaOH) was within 0.04. It has been reported that when the ionic strength of the medium was varied from 0.1 to 0.5, the pK_a of neutral red altered by ca. 0.07 (18). Therefore the variation in the ionic strength or the interfacial salt effect is not likely to have any significant effect on the acid–base equilibria of neutral red in micellar medium (5*c*). The predicted $pK_{a,app}$, obtained from K_{ass} of different pH, were within the experimental error limit of ±0.1. The $pK_{a,app}$'s (predicted as well as observed) decrease with increase in concentration of CPC and finally level off. Our observations parallel those of Rychlovsky and Nemcova (19) who had observed such a trend in similar systems. The decrease in $pK_{a,app}$ with increase in concentration of CPC is expected from the fact that the higher the micelle concentration, the greater is the incorporation of NR into the micelles (in preference to that of NR^+H), which causes an increase in the relative concentration of the conjugate base form of the indicator at the expense of the acid form. It can be noted here that the predicted and observed pK_a values for the indicator in TTAB also agreed well with each other.

The acid–base equilibria of neutral red in aqueous nonionic and anionic surfactants were studied by Drummond et al. (5*c*). As both the base and conjugate acid forms of the indicator associate with nonionic micelles, such acid–base equilibria cannot be explained simply in terms of indicator–micelle association. In nonionic surfactants, considering partition of both forms of the indicator between the micellar pseudophase and aqueous phase, one can predict the $pK_{a,app}$. But for such predictions, the dissociation constant of the indicator in the micellar pseudophase is required. As in the case of nonionic micelles, both forms of the indicator associate with anionic micelles. Drummond et al. (5*c*) were of the opinion that ion-pair formation between NR^+H and the anionic headgroup of SDS, a "specific molecular interac-

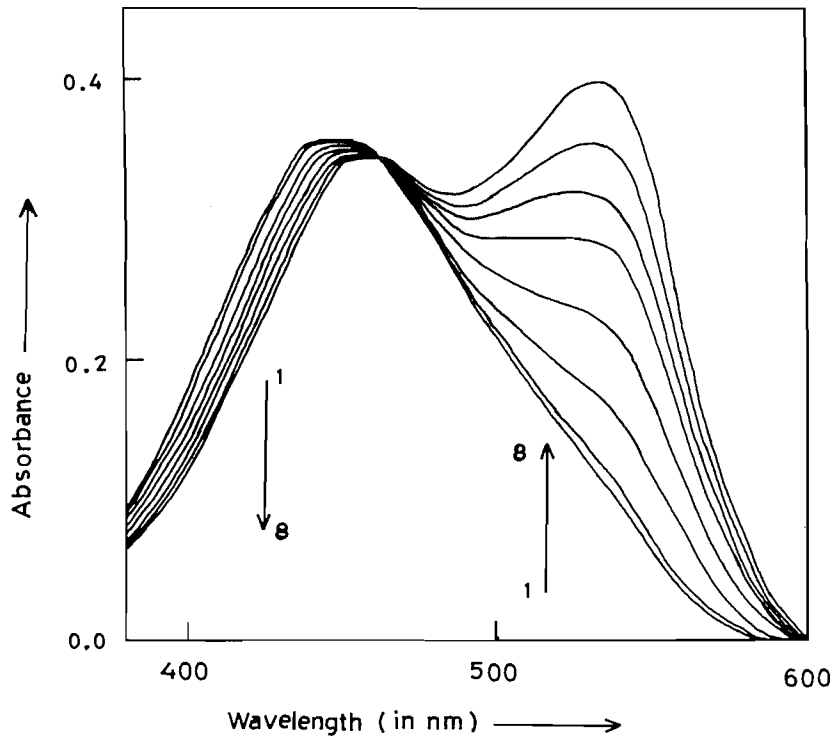

FIG. 3. Spectra of neutral red (4×10^{-5} mol dm^{-3}) at various concentrations of SDS at pH 9.2; concentrations of SDS $\times 10^4$ mol dm^{-3}: 1 = 0.0, 2 = 7.5, 3 = 10.0, 4 = 12.6, 5 = 17.6, 6 = 25.1, 7 = 50.2, and 8 = 251.0.

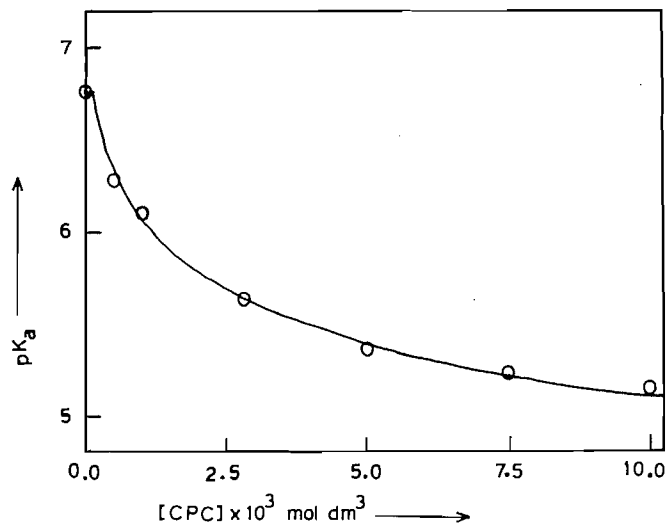

FIG. 4. Plot of predicted and observed $pK_{a,app}$ of neutral red in aqueous micellar medium of CPC *vs.* concentration of CPC; solid curve: predicted; O: observed.

tion," is one of the factors that affects the $pK_{a,app}$ of neutral red in SDS. Our observation indicates that the so-called specific molecular interaction is not simply an ion pair between NR^+H and SDS head groups but in fact $NR^{2+}H_2 \cdot SDS^-$, where the strong hydrophobicity of the hydrocarbon tail of the monomeric surfactant induces the second protonation.

Conclusion

The apparent association constants of neutral red with micelles at constant pH can be determined by the present method. The equilibrium constant for the association of the indicator with the cationic micelles can be determined from the apparent association constant. The apparent pK_a of the indicator in cationic micellar solutions can be predicted from the equilibrium constants.

X-ray crystal structure of [Ni(III)(cyclam)$(NO_3)_2$](ClO_4) and electron transfer reactions of the Ni(III)/Ni(II) couple

A. McAuley, T. Palmer, and T.W. Whitcombe
Department of Chemistry, University of Victoria, Victoria, BC V8W 3P6, Canada

Received March 19, 1993

A. McAuley, T. Palmer, and T.W. Whitcombe. Can. J. Chem. **71**, 1792 (1993).

The synthesis and crystal structure of [Ni(cyclam)$(NO_3)_2$](ClO_4) are described ($P1$, a = 8.347(4) Å, b = 15.960(7) Å, c = 7.656(3) Å, α = 90.33(6)°, β = 110.97(4)°, γ = 104.45(5)°, V = 917.0(7) Å^3, R = 0.0425, R_w = 0.0384). The crystal contains two unique Ni(III) cations within the unit cell, with a network of hydrogen bonding interactions linking one of the cations into a stacked configuration while the other cation contains a strong internal hydrogen bond. This provides an interesting inorganic example of multi-site cooperative binding involving a metal complex cation. By use of electron transfer data from known outer-sphere redox reagents, measurement of the cross-reactions with $[Ni(cyclam)]^{3+/2+}$ in 3 M nitrate media yielded a self-exchange rate constant of 1.4×10^5 M^{-1} s^{-1}. The structural data have been utilized to obtain a calculated estimate of the self-exchange rate constant (1.0×10^8 M^{-1} s^{-1}) for this couple. The relationship between these two values is explored. The lack of adiabaticity is reflected in a value ≈0.01 for κ_{el}, not only for this couple but also for other related cyclam complexes.

A. McAuley, T. Palmer et T.W. Whitcombe. Can. J. Chem. **71**, 1792 (1993).

On décrit la synthèse et la structure cristalline du [Ni(cyclame)$(NO_3)_2$](ClO_4) ($P1$, a = 8,347(4), b = 15,960(7) et c = 7,656(3) Å, α = 90,33(6), β = 110,97(4) et γ = 104,45(5)°, V = 917,0(7) Å^3, R = 0,0425 et R_w = 0,0384). Le cristal comporte deux cations Ni(III) indépendants dans la maille élémentaire avec un réseau d'interactions de liaisons hydrogènes liant un des cations dans une configuration empilée alors que l'autre cation est impliqué dans une forte liaison hydrogène interne. Ceci fournit un exemple inorganique intéressant d'une liaison coopérative à plusieurs centres impliquant un cation métallique complexe. Utilisant des données de transfert électronique obtenues à partir de réactifs rédox de sphère externe connue, des mesures de sections droites du $[Ni(cyclame)]^{3+/2+}$ dans un milieu de nitrate 3 M on fournit une constante de vitesse d'auto-échange de $1,4 \times 10^5$ M^{-1} s^{-1}. On a utilisé les données structurales pour obtenir une évaluation calculée de la constante de vitesse d'auto-échange ($1,0 \times 10^8$ M^{-1} s^{-1}) de ce couple. On étudie la relation entre ces deux valeurs. Le manque d'adiabicité se traduit par une valeur d'environ 0,01 pour κ_{el} tant pour ce couple que pour d'autre complexes de cyclames apparentés.

[Traduit par la rédaction]

Introduction

Although numerous Ni(II) macrocyclic complexes have been characterized structurally, there is a paucity of comparable data for complexes with higher valent nickel (1–6). This is, in part, due to the relative instability of the nickel(III) oxidation state which, in some instances, results in redox degradation of the complex before crystallization can occur. Nevertheless, a few examples of stable Ni(III) species have been reported (7–10, footnote 1) with ligands exhibiting a variety of ligand field strengths. With the growing awareness (11, 12) of the role that Ni(III) may play in the biological and catalytic reactions involving this metal ion (13), the investigation of the structural parameters of such systems is increasingly of interest.

In addition, the investigation of Ni(III) structures provides some of the parameters necessary for more detailed investigations of the electron transfer process during oxidation or reduction (14). *Ab initio* calculation of the Marcus-type self-exchange rate constants rely upon an exact knowledge of the bond lengths in both oxidation states. Attempts to rationalize measured self-exchange rate constants with the theoretically predicted values have met with varying degrees of success (14–18), although the Marcus–Sutin model has predicted rate data over many orders of magnitude to within a factor of 30.

In the present paper details are presented of the synthesis and crystal structure of the Ni(III) cation, [Ni(cyclam)-$(NO_3)_2]^+$, (cyclam = 1,4,8,11-tetraazacyclotetradecane) together with an investigation into the electron transfer reactions of $[Ni(cyclam)]^{3+}$ under conditions in which axial ligation by two nitrate ions would be ensured. The self-exchange rate for $[Ni(cyclam)(NO_3)_2]^{+/0}$ obtained from these measurements is compared with a value predicted based upon a Marcus–Sutin calculation (15). Similar calculations for the systems $[Ni(cyclam)(OH_2)_2]^{3+/2+}$, $[Ni(cyclam)Cl_2]^{+/0}$, $[Ni([9]aneN_3)_2]^{3+/2+}$ ([9]aneN$_3$ = 1,4,7-triazacyclononane), and a hypothetical square planar $[Ni(cyclam)]^{3+/2+}$ are provided for comparison along with their measured self-exchange rates.

Experimental

Synthesis

To a hot solution of 1.5 M nitric acid (≈20 mL), sufficient Ni(cyclam)$(ClO_4)_2$ was added to saturate the solution. The reaction mixture rapidly turned dark green and, upon cooling, yielded X-ray quality crystals of [Ni(cyclam)$(NO_3)_2$](ClO_4). Owing to the instability of the Ni(III) ion in solution, no further attempts were made to re-crystallize the compound. Analysis for Ni-$C_{10}H_{24}N_6O_{10}Cl$. Calcd.: Ni 12.2; C 24.98; H 5.02; N 17.41; O 33.16; Cl 7.35; found: Ni 12.3; C 25.16; H 5.00; N 17.52; O 35.45; Cl 6.96.

Crystallography

A dark green crystal was mounted inside a Lindemann tube using epoxy resin. An initial unit cell was obtained by Weissenberg and precession photography. The crystal was transferred to a Picker Four-circle Diffractometer and the unit cell refined using 27 reflections in the 2θ range, 24 to 50°. The data were collected using 200 steps of 0.01° in 2θ at 0.25 s per step. Background counting for 25 s was carried out before and after each reflection measure-

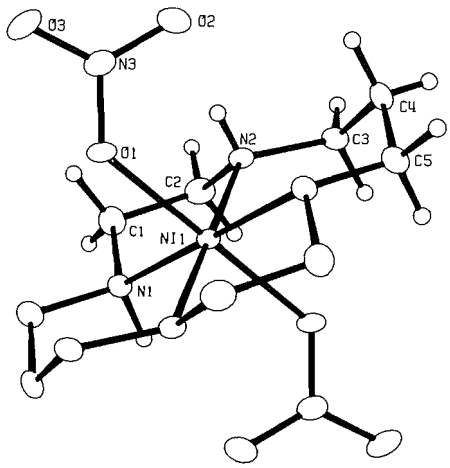

FIG. 1. ORTEP diagram of the $[Ni(cyclam)(NO_3)_2]^+$ cation at the cell origin. Atomic labelling scheme is as shown.

ment. Three standard reflections were measured at the beginning of every 50 reflections, with no significant decay being observed.

A total of 3212 reflections were obtained of which 2936 were within the limits $I > 2\sigma(I)$. Refinement was achieved through the use of MULTAN (19) to locate the two nickel atoms and the least squares difference maps generated with SHELX76 (20) to locate the remaining atoms. The atomic scattering factors and Ni *f*-curve were taken from the usual source (21). Absorption corrections were performed using a local modification of an existing program (22). The hydrogen atoms were locatable from the difference maps for this structure and were included in the final stages of refinement. Final values of $R = 0.0384$ and $R_w = 0.0425$ were obtained with all non-hydrogen atoms anisotropic. A final difference map gave a maximum residual electron density of 1.0 e/Å^3, with a maximum shift/e.s.d. of 0.150 for one of the non-coordinating oxygen atoms.

Experimental techniques

Cyclic voltammograms were obtained using a PAR 273 Potentiostat/Galvanostat connected to an IBM PC. The program "HEADSTART" (23) was used to control the instrument. A bridged cell was employed which consisted of one compartment containing the working and counter platinum electrodes and a second compartment containing the Ag/AgCl reference electrode, with the two compartments separated by a glass frit. The reference electrode compartment was filled with 2 M $HClO_4$ as the supporting electrolyte. The working cell contained either nitrate or perchlorate media. No correction was applied for the junction potential across the bridge since its effect was considered negligible.

Stopped-flow measurements were obtained with an Applied Photophysics DX-17MV instrument equipped with an Acorn computer. Details of measurements of observed electron transfer rates are provided are provided in Table 7. The $[Ni(cyclam)]^{3+}$ ion was generated immediately prior to the reaction by chemical oxidation using Co^{3+} as oxidant (24).

Ultraviolet/visible spectra were obtained using a Cary 5 NIR Spectrometer. Electron spin resonance spectra were obtained on a Varian E6S spectrometer. Microanalytical results were provided by Canadian Microanalytical Services, New Westminster, B.C.

Results and discussion

Crystallography

The asymmetric unit in this crystal was found to consist of two "half" molecules of the $[Ni(cyclam)(NO_3)_2]^+$ cation, together with a single perchlorate anion. One of the cations is shown in Fig. 1, together with the atomic labelling scheme. The ORTEP diagram of the remaining cation is included in the supplementary material.[2] The crystallographic data and associated fractional atomic coordinates, selected bond lengths, and selected angles for each ion are contained in Tables 1 to 4. Table 5 contains the mean planes calculated for both Ni cations together with pertinent atomic positions.

TABLE 1. Crystallographic parameters for $[Ni(cyclam)(NO_3)_2](ClO_4)$

Parameter	Value
Formula	$C_{10}H_{24}N_6O_{10}NiCl$

$I > 2\sigma(I)$	2936
No. of parameters	352
Residual electron density	1.0 e/Å^3
Maximum final shift/e.s.d.	−0.150
R, R_w[a]	0.0384, 0.0425

[a] $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$, $R_w = [\Sigma(|F_o| - |F_c|)^2/\Sigma w(|F_o|)^2]^{1/2}$.

The nickel atom, Ni1, shown in Fig. 1, lies on a special position (0, 0, 0) at the corner of the unit cell, which is an inversion center and hence, the complete cation is generated by symmetry operators. The second nickel atom in the unit cell (Ni2) also occupies an inversion center at the special position ($\frac{1}{2}$, $\frac{1}{2}$, 0). The cation is labelled in a manner similar to that shown in Fig. 1, except a "1" has been added to the numbering scheme. The perchlorate ions do not occupy positions of site symmetry.

All of the atoms, including the hydrogen atoms, were locatable from the Fourier difference maps. This provides an

[2]Table of experimental crystallographic data, Tables S2-S8, containing fractional coordinates, bond lengths, bond angles, interatomic distances, and anisotropic temperature parameters for the complexes (10 pages), Table listing calculated and observed structure factors (13 pages), Figure S1 illustrating the alternate $[Ni(cyclam)(NO_3)_2]^+$ cation, and the calculations of the theoretical self-exchange rate constants (4 pages) have been deposited as supplementary data and may be purchased from The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Supplementary table of crystallographic parameters for $[Ni(cyclam)(NO_3)_2](ClO_4)$ (2 pages), bond angles (Table S2, 1 page), bond angles involving H atoms (Table S8, 1 page), have also been deposited with the Cambridge Crystallographic Data Centre and are available on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

[a]Estimated standard deviations are given in parentheses. Coordinates are × 10″ where n = 5, 5, 4, 4, 4 for Ni, Cl, N, O, C. Temperature parameters are × 10″ where n = 4, 4, 3, 3, 3 for Ni, Cl, N, O, C.

opportunity for examination of the disposition of the protons within the macrocyclic ligand and to ascertain the extent of hydrogen bonding within the crystalline lattice.

The differing nature of the hydrogen bonding interactions leads to the identification of the two $[Ni(cyclam)(NO_3)_2]^+$ cations within the unit cell, as can be seen in Fig. 2. The chain of cations positioned at the unit cell origin is linked together by a series of interactions between the oxygen atoms of the bound NO_3^- anions and the protons attached to the nitrogens of the macrocyclic ligands. The distances for the intramolecular O—H (2.386 and 2.469 Å) and an intermolecular O—H (2.294 Å) interactions are consistent with reported distances for hydrogen bonding (25). The intermolecular bond, being slightly shorter, is presumed also to be the strongest interaction. Despite bifurcation of the hydrogen bonding to the proton, H2, it is involved in both of the shorter interactions, suggesting that O2 favours bonding with this proton.

The orientation of the nitrate ion is such that it is positioned to accommodate the interactions with all four points within the cell (Ni1 and the three protons). However, in describing the structure, the NO_3^- may be viewed as bisecting the six-membered chelating ring as opposed to bisecting the five-membered ring. This might be anticipated since this would minimize the interaction of the oxygen atoms with the carbon backbone of the ligand owing to the larger size of the chelating ring.

[a]All distances are in angstroms (Å). Estimated standard deviations are given in parentheses.

The second series of cations in the unit cell do not display a similar network of interactions and, in fact, are positioned so as to minimize the spatial interactions of adjacent molecules. The mean plane described by $(Ni2)(N)_4$ is at an angle of 22.15° relative to the plane described by $(Ni1)(N)_4$ (see Table 5), which results in a twisting of this series of cations, as can be seen in Fig. 2. One consequence of this crystal packing is that the NO_3^- is free to orient in any direction relative to the macrocyclic ligand. In this second case, the nitrate ion is now positioned directly over one of the protons on the ligand nitrogen and at a "bond interaction" distance of only 2.003 Å. This is a short contact for this type of compound and is indicative of a moderately strong hydrogen bond, which might be maintained upon dissolution of the complex.

Other than the positioning of the nitrate moieties, there is very little structural difference between the two cations. The largest discrepancy in bond lengths is 0.010(5) Å (excluding the nitrate ion). Similarly, the internal angles are essentially the same, with only a slight difference observed (1.2(2)°) for the Ni—N—C angle in the six-membered ring. However, none of the structural differences is sufficiently significant to render either cation unique. In both cases, the macrocycle is in a *trans* III geometry, as might be anticipated, with a mean Ni—N bond length of 1.973(4) Å.

Comparison of the mean bond length for this Ni(III) complex with similar species (7–10, footnote 1) indicates that for an octahedral Ni(III) ion, the equatorial Ni—N distance has a mean value of 1.973 ± 0.006 Å. The corresponding Ni(II) ions give a mean value of 2.081 ± 0.026 Å, with an average change of 0.11 Å in the equatorial Ni—N bond length between the two oxidation states. Owing to the Jahn–Teller distortion exhibited by low spin d^7 ions, the decrease along the axial directions is only ≈0.05 Å, but very dependent upon the nature of the axial ligation.

An interesting comparison is provided by the square planar Ni(II) and Ni(III) ions in tetra-aza macrocyclic complexes. The former has been shown (26) to have a mean Ni—N distance of 1.945 ± 0.029 Å. In the only square planar Ni(III) complex (9) to have been characterized structurally, the Ni—N bond was found to be 1.84(1) Å. The change in bond length is ≈0.11 Å, suggesting that the contraction is independent of the coordination number of the nickel ion or de-

pendent only upon the change in oxidation state, as might be anticipated. However, as pointed out by one of the referees, the nitrogen atom hybridization is sp^2 in the tervalent planar complex while it is sp^3 in the planar Ni(II) complex ions. The change in hybridization accounts for some of the bond length reduction observed. Nonetheless, the values are of interest in that they provide indications of potential overall changes in bond lengths accompanying such redox processes.

[a]Not used in calculations.

For both $[Ni(cyclam)(NO_3)_2]^+$ cations in the present structure, each Ni(III) ion is situated exactly in the plane as a result of space group symmetry. In the free state or in a hypothetical polymorph, where Ni would not sit on an inversion center, this constraint need not apply. However, the nickel atom would probably be close to the plane described by the four nitrogen donors.

Curiously, conventional drawings of the cyclam ring coordinated to a metal center usually depict the six-membered ring in a boat configuration with the apical carbon above the NiN_4 plane. This is not the case in these cations, since all of the carbon atoms in one-half of the molecule (split through the middle of the five-membered ring) lie either above or below the plane.

Electrochemistry

To investigate the extent of complexation of the $[Ni(cyclam)]^{3+}$ cation in aqueous nitrate media and to derive an approximate (or relative) equilibrium constant, the redox potentials for the complexed $Ni^{3+/2+}$ couple were measured by cyclic voltammetry in $H^+/NaNO_3$ media, at various ionic strengths (Table 6) resulting in an observed anion concentration dependent redox potential, $E^C_{1/2}$. For these experiments, the reference electrode was in a separate compartment, isolated by a fine glass frit, and was maintained in an electrolyte of constant composition and ionic strength. The advantage of this arrangement is that it eliminates any effects that changing the supporting electrolyte composition might have on the reference electrode potential. The disadvantage is that the presence of a junction potential across the frit prevents an accurate absolute determination of $E_{1/2}$ and only a relative value is obtained.

For the equation (27),

$$E^C_{1/2} = E^F_{1/2} + (RT/nF) \ln (K_{ox}/K_{red}) + (p - q)(RT/nF) \ln (x)$$

$E^F_{1/2}$ is the "free" (anion-independent) potential, K_{ox} and K_{red} are the stability constants of the oxidized and reduced complexes with the anion respectively, and $(p - q)$ represents the change in the number of anions coordinated. Only relative values are necessary since $E^F_{1/2}$ is available from a measurement of the redox potential in perchlorate media (the base line) under the same conditions. From the data, a mean value of 0.805 ± 0.004 V may be ascribed to $E^F_{1/2}$. A plot of $E^C_{1/2}$ for the nitrate complex versus ln $[NO_3^-]$ is linear, with a slope of −0.456 and an intercept of 0.754. Using the above value for $E^F_{1/2}$ results in $K_{ox}/K_{red} = 7.3$, and a value of −1.77 for $(p - q)$. Both of these results are consistent with expectations, since $(p - q)$ represents the change in coordination number accompanying the redox reaction and, in this case, corresponds to the complexation of two nitrate ions. The ratio of the equilibrium constants implies a value of ≈ 7 for K_{ox}. This is similar to the value of 7.8 calculated for the Ni(III) complex ion using the Eigen–Fuoss equation (28, 29) and an approximate value of ≈6 obtained by UV/Visible spectroscopy (30).

Kinetics studies

In order to investigate the electron transfer self-exchange reaction of the $[Ni(cyclam)(NO_3)_2]^{+/0}$ couple, the rate con-

[a]All rate constants are in units of s^{-1}. Temperature = 20.0 ± 0.1°C; ionic strength 3.0 M; $[H^+]$ = 0.1 M; λ = 380 nm.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

stants were obtained for the cross-reaction with [Ni(sar)]$^{3+/2+}$ (sar = 3,5,10,13,16,19-hexaazabicyclo[6.6.6]icosane). The latter couple has recently been investigated[3] by CD and found to have an absolute self-exchange rate of 5300 M^{-1} s^{-1}, consistent with the values obtained for other $[NiN_6]^{3+/2+}$ couples (31). In addition, the position and intensity of the UV/Visible spectroscopic features for both $[Ni(sar)]^{2+}$ and $[Ni(sar)]^{3+}$ make it ideally suitable for study.

The presence of the ion, $[Ni(cyclam)(NO_3)_2]^+$, was ensured by the use of a large excess nitrate ion (I = 3.0 M H^+/$NaNO_3$). At the concentrations used in this study, with $K_{eq} \approx 7$, >98% of the Ni(III) ion is present as the di-nitrato complex. The Ni(III) ion was generated immediately prior to use in the stopped-flow instrument by the addition of aqueous Co^{3+}. Completion and stoichiometry of the oxidation were monitored on trial solutions by UV/Visible and EPR spectroscopy. The EPR spectra were consistent with a low-spin d^7 ion, with two axial oxygen donor ligands in a frozen matrix ($g_\parallel$ = 2.027, $g_\perp$ = 2.240).

The data obtained for the cross reaction of $[Ni(cyclam)(NO_3)_2]^+$ and $[Ni(sar)]^{2+}$ are presented in Table 7. The small driving force for the reaction (ΔE = 0.052 V) resulted in an equilibration between the two species, with the necessary recourse to concentration studies dependent on oxidant and reductant. A known excess concentration of both "Ni(II)(cyclam)$(NO_3)_2$" and Ni(II)(sar) was included in the reaction mixture, so that the equilibrium would be established as first-order in both directions. The rate law for this system

$$Ni(cyclam)(NO_3)_2^+ + Ni(sar)^{2+} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ni(cyclam)(NO_3)_2 + Ni(sar)^{3+}$$

$$\frac{d[Ni(III)]}{dt} = (k_1[Ni(sar)^{2+}] + k_{-1}[Ni(cyclam)(NO_3)_2]) \times [Ni(cyclam)(NO_3)_2^+]$$

is a function of both Ni(II) species, and the data yields values of $k_1 = (8.42 \pm 0.24) \times 10^4$ M^{-1} s^{-1} and $k_{-1} = (1.10 \pm 0.10) \times 10^4$ M^{-1} s^{-1}. Application of these values to a Marcus-type cross correlation, where K_{12} = 7.65 is obtained directly from k_1/k_{-1}, gives "forward" and "reverse" self-exchange rate constants of 1.38×10^5 and 1.36×10^5 M^{-1} s^{-1}, respectively, for the $[Ni(cyclam)(NO_3)_2]^{+/0}$ couple, under the experimental conditions employed.

[3]A.M. Sargeson, private communication.

An examination of the oxidation of $[Ni(cyclam)]^{2+}$ in 3.0 M $H^+/NaNO_3$ by $Co^{3+}_{(aq.)}$ was performed using stopped-flow techniques as part of this investigation. The relatively low pK_a of the $Co^{3+}_{(aq.)}$ ion usually results in the rate law having two terms, with an inverse hydrogen ion dependence resulting from the deprotonated species (32). In the present study, this behaviour was not observed. Rather, for $[Ni(cyclam)]^{2+}$ oxidation, a complex behaviour with a non-stoichiometric hydrogen ion dependence was obtained, where x = 0.5, k_a = 540,

$$k_{obs} = k_a + \frac{k_b K_H}{[H^+]^x}$$

and k_b = 1070 (assuming K_H to still be 2×10^{-3} M). A similar expression was found for the reaction using $[Ni(sar)]^{2+}$ with values of x = 0.1, k_a = 200, and $k_b = 1.7 \times 10^4$. These results are not simply a result of using 3 M ionic strength media, since the $[Ni(cyclam)]^{2+}$ oxidation was investigated in 3 M ClO_4^- media and the values obtained were within acceptable error limits of previous investigations (24). Since the deviation from the expression normally anticipated is common to both sets of data obtained in nitrate media, and the $[Ni(sar)]^{3+/2+}$ couple does not exhibit any equilibration with nitrate, the presumption is that the $Co^{3+}_{(aq.)}$ ion is associating with the supporting electrolyte. However, attempts to detect complex formation using UV/Visible spectroscopy were not successful. An alternate explanation may involve a nitrate-mediated electron transfer via a hydrogen-bonded species similar to that observed in the solid state. However, it is difficult to envisage the kinetic order observed arising from such a reaction pathway.

Calculation of self-exchange rates

The Marcus theory has been adapted (14, 15) to calculate, from first principles, the self-exchange rate constant of a redox couple. This requires a knowledge of the following parameters: the equilibrium constant (K_o) which is the work necessary to bring two ions together in solution and is based on the Debye–Huckel approach; the nuclear factor (κ_n) which may be calculated from the energies of reorganization for the inner- and outer-sphere nucleii based upon the equilibrium bond lengths and vibrational force constants; the electronic factor (κ_{el}) which arises from the overlap integral of the potential energy surfaces and is a measure of the adiabaticity of the reaction; a vibrational term (ν_n) which describes the vibrational interactions within the complex and the surrounding media, and provides the maximum limiting rate for the reorganization of the molecule. The resulting equation

TABLE 8. Calculated self-exchange rates for $Ni^{3+/2+}$ couples[a]

Redox couple	ΔG^*_{in}	ΔG^*_{out}	κ_N	ν_N	K_0	k_{11} (calcd)	k_{11} (obsd)
$Ni(cyc)^{3+/2+}$	12.3	23.6	4.5×10^{-7}	7.9×10^{12}	0.09	3.3×10^5	$(2 \times 10^3)^{b,c}$
$Ni(cyc)(OH_2)_2^{3+/2+}$	19.5	21.2	6.4×10^{-8}	9.3×10^{12}	0.15	8.7×10^4	2×10^{3c}
$Ni(cyc)Cl_2^{+/0}$	10.0	22.9	1.5×10^{-6}	6.4×10^{12}	0.42	4.2×10^6	3.4×10^{4d}
$Ni(cyc)(NO_3)_2^{+/0}$	9.9	17.9	1.7×10^{-5}	8.1×10^{12}	0.75	1.0×10^8	1.4×10^{5e}
$Ni([9]aneN_3)_2^{3+/2+}$	24.2	21.4	1.2×10^{-8}	9.6×10^{12}	0.15	1.7×10^4	6.0×10^{3d}

[a] ΔG^*_{in} and ΔG^*_{out} are given in kJ/mol. The units of ν_n are s^{-1}. The units of K_0 and M^{-1}. The rate constants are expressed in units of M^{-1} s^{-1} · cyc-cyclam or 1,4,8,11-tetraazacyclotetradecane. [9]aneN$_3$-1,4,7-triazacyclononane.

[b] The value shown is that evaluated from direct measurement of the self exchange rate for the "Ni(cyclam)$^{3+/2+}$" couple in aqueous solution. It is presented for both the square planar couple and the octahedral aquo couple. However, it is likely that it pertains to the $[Ni(cyclam)(OH_2)_2]^{3+/2+}$ self exchange.

[c] Reference 33.

[d] Reference 31.

[e] This work.

combines these parameters to give the self-exchange rate constant, k_{11}:

$$k_{11} = K_o \kappa_n \kappa_{el} \nu_n$$

It is not the intent of this paper to derive this expression in detail nor to expand upon the calculation of these values except where germane to the following discussion. Full details of the calculations have been included as supplementary material.

Table 8 contains the relevant data employed in the calculation of the self-exchange rate constants for the couples, $[Ni(cyclam)(OH_2)_2]^{3+/2+}$, $[Ni(cyclam)(Cl)_2]^{+/0}$, $[Ni(cyclam)(NO_3)_2]^{+/0}$, sq.pl./sq.pl. $[Ni(cyclam)]^{3+/2+}$, and $[Ni([9]aneN_3)_2]^{3+/2+}$. The last couple is included in order to provide a comparison with a known octahedral/octahedral system and to confirm the suitability of parameters used in other calculations. From the data presented in Table 8, it is apparent that the major contribution leading to the differentiation of the electron transfer rates originates with the nuclear term, κ_n. This is not surprising since this term reflects the relative magnitudes of the inner- and outer-sphere reorganization energies. While the latter is fairly constant (ΔG^*_{out}), reflecting the similarity in the ionic radii of these complexes, the inner-sphere reorganization energy (ΔG^*_{in}) is intimately dependent upon the changes in bond lengths and geometry that accompany the electron transfer reaction.

As may be seen from these tabulated rate constants, with the exception of $[Ni([9]aneN_3)_2]^{3+/2+}$, there is a significant discrepancy between the theoretical values and those obtained experimentally through a Marcus-type cross correlation. A feature is that the ratio of k_{obs} to k_{calc} is roughly constant not only for the postulated sq.pl./sq.pl. $[Ni(cyclam)]^{3+/2+}$ but also for the oct./oct. $[Ni(cyclam)(Cl)_2]^{+/0}$, $[Ni(cyclam)(NO_3)_2]^{+/0}$, and $[Ni(cyclam)(OH_2)_2]^{3+/2+}$ complexes, giving values of 0.006, 0.008, 0.0014, and 0.023, respectively. For the latter complexes, this implies strongly that there is a commonality of reaction mechanism amongst these three species.

The origin of the differences between the theoretical and observed self-exchange rate constants lies in the assumption that $\kappa_{el} = 1$ (i.e., the reactions observed are adiabatic). The axial ligands in the "Ni(cyclam)" complexes may not necessarily be constrained and, hence, these complexes do not represent ideal outer-sphere redox couples. Such an effect would serve to lower the adiabaticity. An average value of 0.01 for κ_{el}, as determined for the present complexes, would be consistent with κ_{el} found for other transition metal complexes (14–16) and would account for the discrepancy. It is of interest to note that the calculated and observed values for $[Ni([9]aneN_3)_2]^{3+/2+}$ agree remarkably well. In this complex the metal ion is constrained within an octahedral geometry by the facial tridentate macrocyclic ligand. It has been suggested that $[Ni([9]aneN_3)_3]^{3+/2+}$ is an adiabatic electron transfer reagent (31) and the present calculations appear to support that assertion.

Abductive networks: generalization, pattern recognition, and prediction of chemical behavior

JOHN L.E. CAMPBELL AND KEITH E. JOHNSON[1]
Department of Chemistry, The University of Regina, Regina, SK S4S 0A2, Canada

Received February 16, 1993

JOHN L.E. CAMPBELL, and KEITH E. JOHNSON. Can. J. Chem. **71**, 1800 (1993).

Using commercially available software, it is possible to reduce numerical data to a mathematical representation called an abductive network (AN). In the current communication, we describe several simple examples which illustrate the interesting, and potentially useful properties of abductive networks. We show that when applied to the correlation of Kovats indices with molecular refractivities and dipole moments of substituted phenols, abductive networks more accurately predict Kovats indices than do counter-propagation neural networks or linear regression equations. When applied to the modeling of quantitative structure–activity relationships (QSAR) for local anesthetics, AN's are marginally superior to regression. AN's offer the advantage that correlations may be drawn between variables which are not easily related within a mathematical context.

JOHN L.E. CAMPBELL et KEITH E. JOHNSON. Can. J. Chem. **71**, 1800 (1993).

Utilisant un programme commercialement disponible, il est possible de réduire des données numériques en une représentation mathématique que l'on appelle un réseau abductif. Dans le présent travail, on décrit plusieurs exemples simples qui illustrent les propriétés intéressantes et potentiellement utiles des réseaux abductifs. On montre que lorsqu'on les applique à la corrélation des indices de Kovats avec les réfractivités moléculaires et les moments dipolaires de phénols substitués, les réseaux abductifs permettent de prédire les indices de Kovats avec plus de précision que les réseaux neurales de contre-propagation ou que les équations de régression linéaire. Lorsqu'on les applique à faire un modèle des relations quantitatives structure/activité des anesthésiques locaux, les réseaux abductifs ne sont que marginalement supérieurs à la régression. Les réseaux abductifs offrent l'avantage que les corrélations peuvent être développées entre des variables qui ne sont facilement reliées dans un contexte mathématique.

A general description of the properties of neural networks has recently been presented by Jansson (1). As this author points out, research concerning practical applications of networks has been severely hampered, somewhat ironically, by its very proponents. Visions of thinking, learning machines uttered by some workers have certainly earned contempt from onlookers, and perhaps rightly so; such visions are terribly unrealistic at present. However, simple applications of network technology are currently not only possible, but successful as well. In the last year, several papers describing the use of networks in solving chemical problems have appeared in the literature (2, 3). Peterson has demonstrated the use of neural networks in the modelling and prediction of Kovats indices (used to characterize chromatographic retention behavior) for substituted phenols (2). It was shown that when linear regression analysis affords poor correlation, neural networks provide greater accuracy in modeling of Kovats indices. Schadmer et al. have reported the use of neural networks in correlating the process parameters for reactive ion etching, with the optical and mass spectra of the plasma (3). Research concerning neural networks has been underway for several decades (4, 5). In the past several years, a relatively new product of this research, called an abductive network (AN), has appeared (6). By means of examples, we demonstrate that AN's can accurately generalize and recognize patterns in data presented to them; if carefully generated, AN's can make accurate predictions based on as yet unseen data. In the current communication, we describe several simple examples in which AN's were synthesized using commercially available software (AIM[2]) and shown to be capable of accurately predicting chemical behavior. In experiments analogous to Peterson's, we find that abductive networks more accurately predict Kovats indices than do counter-propagation neural networks, or equations from linear regression.

The principles of neural network function and synthesis are well described in the literature (1, 4, 5). For a description of the principles of abductive networks, see Montgomery and Drake (6). In general, networks consist of an interconnected array of functional elements sometimes referred to as "nodes." A simple abductive network is illustrated in Fig. 1. Though they have the common task of cor-

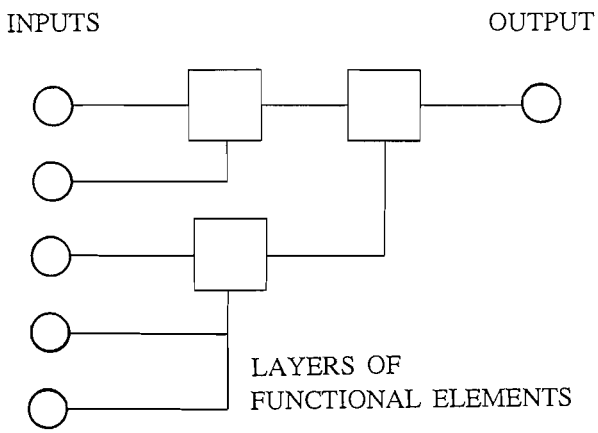

FIG. 1. A simple Abductive Network (AN) which correlates five input variables with a single output.

relating some set of input and output variables, the various networks differ in the nature and connectivity of their functional elements, and in the means by which the networks are synthesized. In general, the output of a functional element is a polynomial function of its input variables. The nodes of neural networks consist of linear-weighted sums of the input variables (1). Those of an abductive network, however, may also incorporate third degree polynomial functions in up to three input variables (6). The coefficients of the polynomial terms are "weighting" factors determined during synthesis. The algorithm by which AIM generates an abductive network is proprietary in nature and so for the purpose of this communication, suffice it to say that network synthesis is accomplished by "training" the network with a database of example inputs and outputs, and entails adjustment of the weighting factors until the network can calculate the database outputs with a minimum of error. If successful, the resulting network will have "learned" to model the contents of the database, *i.e.* to generate all the training set output values from the corresponding inputs. The AN is, effectively, an algebraic generalization of the data from which it was synthesized. A comparison of the performance of abductive networks with that of back-propagation neural networks, claims that the former is characterized by a considerably lower (*ca.* one order of magnitude) standard error (6). The abductive network was synthesized in less than 1% of the time required for training of the back-propagation network. As the name implies, the structure of a neural network is based on an analogy with neurons. The structure of an abductive network, on the other hand, is not limited to biological analogies (6), and is therefore expected to be more flexible.

The AIM algorithm incorporates automatic determination of optimum network structure and connectivity, an obvious advantage for the non-expert. This is accomplished by minimizing a modelling criterion called the *predicted squared error*, or PSE (6, 7):

$$\mathrm{PSE} = \mathrm{FSE} + \mathrm{CPM} \times (2K/N) \times s_p^2$$

FSE is the *fitting squared error* of a given network model with respect to the training data, K is the number of coefficients (proportional to network complexity), N is the number of training data, and s_p^2 is an *a priori* estimate of the variance. The *complexity penalty multiplier*, CPM, may be specified by the user, its default value being unity. As the complexity of the model increases, the FSE decreases (in the same way as increasing the number of variable parameters in regression leads to a better fit). However, as the model complexity increases, so does K, and hence the second term, the *complexity penalty* term, also increases. The level of complexity corresponding to the minimum PSE may therefore be varied through manipulation of the complexity penalty term, *e.g.* lowering the CPM has the effect of shifting the optimum PSE towards higher levels of network complexity. This is evident in Fig. 5 of ref. 6. In short, the CPM determines the degree of complexity which the AIM algorithm will allow in hypothesized networks; network synthesis terminates if increased complexity fails to improve model performance.

Synthesis of a network involves the recognition of patterns in the training data. In a sense the network is a generalization, or re-expression of patterns in the training data, and the structure of the network is dependent upon them. If the patterns have any real significance, as opposed to being coincidental, the network may be capable of correlating real physical quantities in a meaningful way. We should therefore suspect that if properly trained, the network may be capable of making accurate predictions from data to which it has not yet been exposed. Forcing the network to recognize real as opposed to spurious patterns may be accomplished through two means. Obviously, one should synthesize the network from data which are expected to have some real significance, *e.g.* inputs: mass, volume; output: density. Limiting the degree of complexity which the network is allowed to assume prevents overfitting to the data, while at the same time, allowing recognition of meaningful patterns.

As a simple example of pattern recognition by an AN, consider the numbers 0 through 127, which can each be expressed as a 7 bit binary number. A database was generated consisting of 128 data sets, each of which comprised 8 pieces of data: 7 input variables corresponding to each of 7 bits, and 1 output variable corresponding to the decimal equivalent. Thirty-two of the 128 sets were randomly selected as a basis for synthesis of an AN. Run on an 80286/287 (12 MHz) processor, such a synthesis takes about a minute, and the resulting network, when given *any* 7 bit integer, can correctly calculate the decimal equivalent. The network reduces to a weighted sum of 7 linear functions of the input variables, *i.e.* $\mathrm{DECIMAL} = \Sigma\ (c_{i1} + c_{i2} * \mathrm{BIT}_i)$ where $i = 1, 2, 3, \ldots 7$. One finds it difficult to argue that in synthesizing such a network, AIM has not *learned* to convert 7 bit binary numbers to their decimal equivalents, as simple and insignificant a task as this may be.

Peterson has shown that for modelling and prediction of Kovats indices based on solute molecular refractivity and dipole moment, a counter-propagation neural network (CPNN) is superior to multivariate linear regression (2). Kovats indices form the dependent variables in certain quantitative structure-chromatographic retention relationships (QSRR, 2). The Kovats index, I, may be written as $I = a\mathrm{MR} + b\mathrm{D}^2 + c$, where MR and D are the respective molecular refractivities and dipole moments of the solute; a, b, and c are constants particular to the column material. For a set of 20 phenols, Peterson has modeled Kovats indices for dimethylpolysiloxane (SE-30), (3-cyanopropyl)methylpolysiloxane (OV-225), and polyneopentyl glycol adipate (NGA) using multivariate linear regression (MLR), and by training CPNN's. The database from which the calculations were performed consisted of twenty sets of the inputs MR and D^2, and outputs I(SE-30), I(OV-225), and I(NGA), *i.e.* one set for each phenol; the I span the range *ca.* 1000–2700. For training of the CPNN, the I values were scaled so that all values lay in the range 0–0.5; in general, neural networks are incapable of handling large numbers. In each of twenty experiments (for a given Kovats index) 19 of the sets were used to train a network (or for MLR), and the result was then tested on the set which had been excluded. These "leave-one-out" calculations serve as a measure of the ability to predict Kovats indices from as yet unseen MR and D^2 data. Using data from ref. 2, we have repeated these calculations by synthesizing an analogous series of AN's. AN's were synthesized from unscaled data; AIM incorporates automatic input normalization. Our results for the AN, and Peterson's results for the CPNN and MLR treatments, are summarized in Table 1. The values tabulated are average root-mean-squared errors, *i.e.* the RMSE averaged over the

number of observations in the data set, 20 in this case. The RMSE for each set was calculated from 19 observations in the case of training, and a single observation in the case of testing. It is clear from the testing sets of Table 1 that in predicting Kovats indices, the networks afford greater accuracy than linear regression. For OV-225 and NGA indices, the abductive network makes predictions which are significantly more accurate than those of the neural net; for all three indices, the AN predictions are associated with a significantly lower standard deviation than those of either the CPNN or MLR treatments. It is notable that for CPNN's, the quoted errors are those obtained for an optimized level of network complexity (see ref. 2); the abductive networks were synthesized using software default parameters. As described below, it is possible to improve performance of the SE-30 AN by restricting its complexity relative to the default limits. Synthesis of the AN's (60, twenty for each index) in batch mode took about 3 min on an 80486/33 PC and about 20 min on an 80286/287/12 PC. CPNN's described by Peterson consisted of at least 16 functional elements. In contrast, the corresponding abductive networks comprised, maximally, 6 elements, 4 of which serve to normalize and rescale the data (see Fig. 2). This may be owing to the AN's inclusion of nonlinear functional elements, *i.e.* inclusion of such terms may reduce the complexity required to model the data.

Peterson performed an analogous set of calculations for a 43-phenol data set in which the OV-225 and NGA indices were correlated with the inputs I(SE-30) and MR. In this case linear regression (MLR) was found to be considerably more accurate than CPNN modelling (2). The results of these calculations and those of an analogous series of AN experiments are summarized in Table 2. Though the CPNN is considerably less accurate than MLR, the AN treatment yields results comparable to, albeit not as good as, MLR. At any rate, considering both the 20- and 43-phenol experiments, it is clear that overall, the abductive network proves superior to either the neural network or linear regression treatments.

The ability of an AN to accurately *generalize* data from which it is synthesized, depends on the degree of complexity that the network is allowed to assume. The ability of the resulting network to make accurate predictions, however, will depend on whether or not its structure corresponds to some physically significant relation between input and output variables. By controlling its complexity, it may be possible to force the network to recognize real rather than spurious patterns, *i.e.* noise. We have repeated the leave-one-out calculations (as in Table 1) using three levels of complexity restrictions: (*A*) unrestricted, CPM = 0.01; (*B*) default, CPM = 1.0; (*C*) restricted relative to default, CPM = 1.5. The results of these experiments are summarized in Table 3. We observe that high accuracy in fitting of training data is associated with diminished accuracy in subsequent predictions; we suggest that networks most capable of prediction are those whose average RMSE's in training and testing are most similar. In other words, there is a trade-off between performance of the network on the data from which it was synthesized (*i.e.* generalization, recognition of meaningful patterns), and that on data to which it has not yet been exposed (*i.e.* predictive ability). Note that this is also evident in the data of Table 2, in which the most successful treatments (AN and MLR) have similar training/testing average RMSE's.

Of significant interest to pharmacological investigators, are the identification of quantitative structure–activity relationships (QSAR's). For example, several groups have attempted to relate the ability of compounds to act as local anaesthetics with molecular properties such as molecular polarizability α, ionization potential I, and van der Waals volume V_w (8). Correlations of the form log (MBC) = $a + b\beta$ have been investigated; MBC is the minimum concentration (mM) necessary for complete blocking of excitability, a and b are constants, and the parameter β is either α, V_w, or the product αI (8). We have performed a set of leave-one-out calculations for a set of 39 compounds using both linear regression, and AN's; data were taken from ref. 8; log (MBC) spans the range from −4.20 to 3.09. The results of these calculations are summarized in Table 4. It is seen that the AN yields marginally better results for both generalization and prediction of log (MBC). Notably, standard deviations for prediction by the AN are significantly smaller than for the linear regression equations. Abductive networks using all three quantities as input variables yield significantly lower prediction errors. Though it is reasonably straightforward to perform multivariate regression, this assumes that one has knowledge of the order of the equation with respect to each of the independent variables. The utility of the AN lies in the fact that one need not possess this knowledge, *i.e.* it is determined automatically during synthesis of the network. We must be careful to state that AIM generates functions/networks which *mimic* relationships amongst variables. Only in cases where these relationships may be written in terms of polynomial functions, *i.e.* AIM functional elements, can we say that AIM is capable of actually finding them. Synthesis of the AN is, effectively, a curve-fitting procedure which assumes no prior knowledge of the form of the equations!

As a general strategy for modelling with AN's, we suggest that leave-one-out calculations be performed using a series of allowed network complexities. In cases where many data sets are involved, leave-N-out calculations may be appropriate. Our results suggest that the optimum network is that for which the average RMSE for training and testing are the least different. The magnitude of the average RSME is a measure of the quality of the training data. Obviously it is desireable to train networks with the most reliable data, and so it would be useful to have some means of detecting

[b]RMSE averaged over 39, 1-compound testing sets; standard deviations in parentheses.

errors in potential training data. Minimizing such errors, in addition to minimizing RMSE's, should also reduce the tendency towards overfitting the network. It should be possible to detect errors in training data during the course of leave-one-out calculations. For example, consider such a set of calculations involving N data sets, and yielding N test results and their associated errors, from which may be calculated an *average absolute error* and corresponding standard deviation. Sets yielding errors which are widely divergent from the norm could then be excluded from further use on the basis of standard statistical tests: Q-tests, z-statistics *etc*. Such methods of detecting errors in training data have yet to be explored, and are probably deserving of some attention.

In conclusion, their ability to recognize patterns in numerical data leads us to envisage a wide variety of applications for network modelling. For example, the ability to synthesize an abductive network which successfully predicts correlations amongst training variables might be taken as confirmation of a real relationship between those variables. We have had some success in predicting the association constant for supramolecular complexes consisting of a macrocycle and a variety of substituted phenols, though the paucity of available data does not currently allow firm conclusions to be drawn (unpublished work). Here we attempted to correlate the association constant with the Hammet σ values of the phenol substituents. In conjunction with other techniques, such modelling might facilitate the design of molecules which have known differential association constants with a variety of receptors; this may have applications in the design of molecular devices. In principle, any model which may be generalized to a set of input and output parameters can be investigated with networks; logical variables, when given numeric values, and empirical data, may also be employed. The great power of networks lies in their ability to recognize relationships among variables which might otherwise remain hidden; these relationships need not have any mathematical foundation corresponding to a set of equations. For example, it may be

possible, using networks, to correlate experimentally observed primary and secondary protein structure, so as to predict the folding of proteins on the basis of amino acid sequence, and perhaps other descriptors. Though limited success has been achieved empirically in this area, a strictly theoretical treatment of the problem is daunting indeed; it is simply too complex (admittedly, this may change as contemporary computers become increasingly powerful). Through their ability to recognize patterns in data, networks may provide means of dealing with complex problems which are otherwise difficult or intractable. In the applications discussed here, abductive networks exhibit performance which is, on the whole, superior to that of neural networks or more standard regression techniques. It remains to be seen whether or not this applies more generally. The degree of complexity which can be accommodated by AN's is unclear. All of the examples discussed here involved single or double layer networks with fewer than ten functional elements; current software allows up to 9 layers and perhaps hundreds of nodes. Other work indicates that AN's are capable of modelling more complex systems of equations (9); further applications are necessary in order to evaluate the capabilities and limitations of abductive networks, and indeed, networks in general.

The synthesis and characterization of a new 14-membered tetraazamacrocyclic ligand 5,12-dimethyl-7,14-diphenyl-1,4,8,11-tetraazacyclotetradecane-4,11-diacetic acid (H_2L^1) is reported. Cobalt(III), nickel(II), and copper(II) complexes with this ligand were prepared and characterized by infrared, electronic, and electron spin resonance (esr) spectra and in one case by X-ray crystallography. The complex $CuL^1 \cdot 2CH_3CH_2OH$ (**3**) crystallized in the triclinic system, space group $P\bar{1}$, with a = 8.440(2), b = 13.445(2), c = 7.523(1) Å, α = 99.30(1), β = 106.57(1), γ = 87.00(1)° and Z = 2 (R = 0.027, R_w = 0.028 for 2618 reflections). The complex shows a distorted *trans*-octahedral geometry with four amino nitrogens in a plane and two apical carboxylate oxygen donors.

Introduction

There has been great interest in the coordination chemistry of polyaza macrocycles (1, 2). These ligands have been shown to be capable of producing generally strong ligand fields, but their inherent disadvantage is that they cannot completely "wrap up" the majority of transition metals, producing a completely filled coordination sphere. The solution to this would be either to increase the size and the number of donor atoms of the macrocycles or to append coordinating groups to the periphery of the macrocycle, which themselves may coordinate and thus increase the ligating ability of the macrocycles.

We are interested in the coordination chemistry of *N*-functionalized polyazamacrocycles and mixed oxygen–nitrogen donor macrocycles. Their specific complexation behaviour is clearly of interest in many areas such as the design of potential lanthanide ion selective reagents (3–5), the design of complexes to act as medical imaging agents (6), and for the treatment of heavy metal intoxication in the case of metal poisoning (7, 8). Our initial studies in this area have involved the synthesis and characterization of a series of *N*-acetic acid functionalized tetraazamacrocycles and mixed oxygen–nitrogen donor macrocycles and their coordination chemistry with transition metals, lanthanides, and actinides (9–14). The present paper describes the synthesis and characterization of 5,12-dimethyl-7,14-diphenyl-1,4,8,11-tetraazacyclotetradecane-4,11-diacetic acid (H_2L^1) (Fig. 1) and its metal complexes with Co(III), Ni(II), and Cu(II) salts.

1,4,8,11-tetraazacyclotetradecane (L) was prepared as previously described (15). Proton NMR spectra were recorded with a JEOL FX90Q spectrometer. Infrared spectra were obtained with Nicolet 170Sx spectrometer. Electronic spectra were recorded as mull using a Cary 5E spectrometer. The esr spectra were recorded with a Bruker ESP 300 X-band spectrometer at room temperature and 77 K. Room temperature magnetic moments were measured using a Cahn 7600 Faraday magnetic balance. Microanalyses were performed by the Center of Structure and Elemental Analysis, China University of Science and Technology.

Synthesis of ligands and complexes

H_2L^1 (A)

To 16.70 g (0.12 mol) of bromoacetic acid in 100 mL dry methanol was added 6.72 g (0.12 mol) of KOH in 200 mL of dry methanol. L (19.0 g, 0.050 mol) in 100 mL dry methanol and 12.70 g (0.12 mol) of powered anhydrous sodium carbonate were then added, and the mixture was stirred at 60°C for 24 h. The reaction mixture was cooled, and the white precipitate of $NaHCO_3$ was filtered off. After nearly complete evaporation of the solvent on a rotary evaporator, the residue was dissolved in 50 mL water and the solution was filtered to remove any solid. The filtrate was acidified to pH 5 with dilute hydrochloric acid. The product H_2L^1 precipitated upon standing as a white powder, which was filtered off, washed with water and ethanol, and air dried. Yield 14.5 g (58%). It does not dissolve appreciably in common solvents. Anal. calcd. for $C_{28}H_{40}N_4O_4$: C 67.71, H 8.12, N 11.28; found: C 67.78, H 7.95, N 11.14. IR (KBr, cm^{-1}): 2660–2900 (NH_2^+); 1600 (COO^-).

$H_2L^1 \cdot 2HCl \cdot 4H_2O$ (B)

A (10.0 g, 0.020 mol) was dissolved in 20 mL dilute NaOH solution, then 20 mL concentrated HCl was added immediately and a white precipitate formed slowly. The mixture was stirred at room temperature for 6 h and filtered. The white solid was recrystallized from water to give colourless crystals 9.5 g (74%). Anal. calcd. for $C_{28}H_{40}N_4O_4 \cdot 2HCl \cdot 4H_2O$; C 52.41, H 7.85, N 8.73; found: C 52.72, H 7.47, N 8.75. IR (KBr, cm^{-1}): 3410 (OH); 2600–2900 (NH_2^+); 1730 (COOH). ^1H NMR (D_2O): (δ (relative intensity)): 0.95(6) (doublet, CH_3), 1.74 (4) (multiplet, C—CH_2—C), 2.66(8) (multiplet, CH_2—N), 3.09(4) (multiplet, C—CH—N), 3.80(4) (singlet, CH_2COOH), 7.42(10) (doublet, phenyl).

$NiL^1 \cdot 2H_2O$ (1) and $CoL^1Cl \cdot 4H_2O$ (2)

B (320 mg, 0.50 mmol) and $NiCl_2 \cdot 6H_2O$ (240 mg, 1.0 mmol) were dissolved in 20 mL water, and the pH was successively adjusted to 5 with NaOH. After refluxing for 2 h, violet crystals formed. These were collected and recrystallized from $EtOH/H_2O$ (1:1). Yield; 195 mg (66%). Anal. calcd. for $C_{28}H_{38}N_4O_4Ni \cdot 2H_2O$: C 57.06, H 7.18, N 9.51; found: C 56.95, H 7.29, N 9.29. IR (KBr, cm^{-1}): 3435 (OH); 3106 (NH); 1628 (COO^-). $CoL^1Cl \cdot 4H_2O$ (**2**) was prepared in a similar manner by using $CoCl_2 \cdot 6H_2O$ and was obtained as red crystals. Yield 53%. Anal. calcd. for $C_{28}H_{38}N_4O_4CoCl \cdot 4H_2O$: C 50.87, H 7.01, N 8.48; found: C 50.96, H 7.24, N 8.27. IR (KBr, cm^{-1}): 3463, 3398 (OH); 3103 (NH); 1648 (COO^-).

$CuL^1 \cdot 3H_2O$ (3)

B (320 mg, 0.50 mmol) and $CuSO_4 \cdot 5H_2O$ (125 mg, 0.50 mmol) were dissolved in 20 mL water and the pH was adjusted to 2, and warmed in an oil bath (80°C) for 2 h and filtered. The deep blue filtrate was placed in a refrigerator overnight. Blue crystals formed, which were filtered off, and air dried. Yield 175 mg (57%). Anal. calcd. for $C_{28}H_{38}N_4O_4Cu \cdot 3H_2O$: C 54.93, H 7.24, N 9.15; found: C 54.97, H 7.25, N 8.96. IR (KBr, cm^{-1}): 3394 (OH); 3132 (NH); 1612 (COO^{-1}).

$Cu_2L^1Cl_2$ (4)

B (320 mg, 0.50 mmol) and $CuCl_2 \cdot 2H_2O$ (205 mg, 1.2 mmol) were dissolved in 20 mL water and the pH was successively adjusted to 5 and filtered. The filtrate was heated in an oil bath (80°C) for 2 h. Deep green crystals formed, which were filtered off, and air dried. Yield 240 mg (69%). Anal. calcd. for $C_{28}H_{38}N_4O_4Cu_2Cl_2$: C 48.57, H 5.53, N 8.09; found: C 48.35, H 5.45, N 7.95. IR (KBr, cm^{-1}): 3160 (NH); 1640 (COO^-).

X-ray crystallographic analysis of $CuL^1 \cdot 2CH_2CH_2OH$ (3)

Blue crystals of **3** suitable for an X-ray structural determination were obtained by the vapour diffusion of ethyl ether into an ethanolic solution.

The data were collected at a temperature of −117(1)°C, on a Rigaku AFC6S diffractometer (MoKα radiation, graphite monochromator) in the ω–2θ scan mode to $2\theta_{max} = 50°$. Lorentz and polarization corrections were applied. The structure was solved by direct methods (16, 17) using the TEXSAN (18) crystallographic software package. Refined parameters were calculated by using anisotropic thermal parameters for non-hydrogen atoms and isotropic factors for all hydrogen atoms.

A summary of crystal data is given in Table 1. Atomic positional parameters are given in Table 2 and selected bonded distances and angles are given in Table 3. The full description of the structural determination, thermal parameters (Table S-1), hydrogen atom positional parameters (Table S-2), a full listing of bond distances and angles (Table S-3), observed and calculated structure factors ($10|F_o|$ and $10|F_c|$) (Table S-4), and least-squares planes data (Table S-5) are deposited as supplementary material.[2]

Result and discussion

meso-2,4,4,11,13,13-hexamethyl-1,5,10,14- tetraazacyclooctadecane (12) and *C-meso*-2,2,4,13,13,15-hexamethyl-1,5,12,16-tetraazacyclodocosane (13) (analogues of tet-a) with a large excess of bromoacetic acid in alkaline methanol medium gave only the di-*N*-substituted product. It may be concluded that the reaction of a hexamethyltetraazamacrocycle (tet-a or its analogues) with an alkylating agent is stereospecific. In L the alkylation may take place in the 1- and 8-positions as the nitrogen atoms in these two positions are less sterically hindered than those in tet-a, since the phenyl group is less bulky than two methyl groups. By controlling the ratio of L and bromoacetic acid the di-*N*-substituted (H_2L^1) product can be prepared. We have found that the mono-*N*-substituted, tri-*N*-substituted, and per-*N*-substituted products also can be isolated by alkylation of L or H_2L^1 with bromoacetic acid by controlling the ratio of L (for mono- and per-*N*-substituted products) or H_2L^1 (for tri- and per-*N*-substituted products) and bromoacetic acid. The work on these three substituted ligands is in progress.[3]

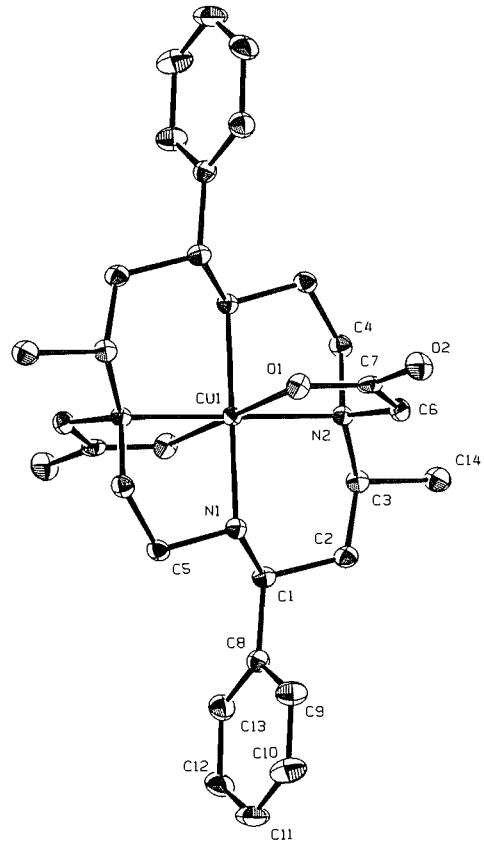

FIG. 2. Structural representation of CuL^1 (**3**) with hydrogen atoms omitted (40% probability thermal ellipsoids).

The difunctionalized ligand H_2L^1, in principal, occurs in several configurations arising from the presence of chirally substituted nitrogen centers. The existence of all these stereoisomers is possible. It has six potentially coordinating atoms. The metal complexes were studied in part in solution, but mainly by preparing some crystalline compounds.

Description of the structure of $CuL^1 \cdot 2CH_3CH_2OH$

The structure of CuL^1 (**3**) is illustrated in Fig. 2. The complex shows a distorted *trans*-octahedral geometry with four amino nitrogens in a plane and two apical carboxylate oxygen donors. The molecule has a centre of symmetry at Cu1 with the result that the phenyl, methyl, and carboxylate groups are each *trans*. The four nitrogens and the metal ion are exactly in a plane. The conformation of each six-membered chelate ring is that of a *chair* while the five-membered chelate rings are a twisted "envelope" with C5 and C4 as the flap. The five-membered chelate rings involving the carboxylates are close to planar. The benzene ring and five-membered carboxylate chelate ring have dihedral angles of 81.63 and 89.03°, respectively in relation to the N_4 mean plane. Cu—N (secondary) (2.109(2) Å) distances are longer than Cu—N (tertiary) (2.056(2) Å). This is probably due to the electron-attracting inductive effect of the appended carboxylate groups. The strongest distortion is due to the Jahn–Teller effect and leads to axial Cu—O bond lengths of 2.248(1) Å, which are much longer than those in related complexes of some tetraazamacrocyclic tetraacetates where carboxylate oxygens coordinate to copper in equatorial positions (Cu—O = 1.965(5)) (19); Cu—O = 1.957(7), 1.982(5) (20), but are slightly shorter than those

TABLE 4. Spectral and magnetic data

in the similar complex $[CuL^3]^{2-}$ (L^3 = 1,4,8,11-tetraazacyclotetradecane-*N*,*N'*,*N''*,*N'''*-tetraacetic acid), in which the copper ion also has a distorted *trans*-octahedral geometry with two Cu—O distances of 2.302(5) and 2.278(6) Å, respectively (21). It is also interesting to compare the structure of CuL^1 with the structure of NiL^2 (H_2L^2 = 5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane-*N*,*N''*-diacetic acid; Fig. 1) for which a *cis*-octahedral structure was found (9). This phenomenon is probably due to the fact that the two macrocycles prefer different basic conformations when they coordinate to metal ions (22). In CuL^1, the macrocycle is in the *trans*-III conformation according to the nomenclature of Bosnish *et al.* (23). In NiL^2, the coordination is achieved by folding the macrocycle, which allows both of the carboxylic oxygen atoms to coordinate in a *cis*-arrangement. Here the macrocycle is in the *cis*-V conformation (9, 23). Because two tertiary nitrogen donors are present in these two ligands, their relative stereochemistries are fixed so long as they remain coordinated to the metal, since the conjugate base pathway for inversion is no longer available. The two ethanol molecules in **3** are hydrogen-bonded to the two coordinated carboxyl oxygens (O(1)—O(3) = 2.722(2) Å). There are no other intermolecular contacts.

Spectroscopy and magnetism

H_2L^1 forms complexes with Co(III), Ni(II), Cu(II) with a metal-to-ligand ratio of 1:1 and also a 2:1 Cu(II) complex (**4**), which is insoluble in most solvents. The infrared spectra of **1**, **2**, and **3** are very similar in the range 4000–500 cm^{-1}, indicating the likelihood of a similar structural arrangement. Solid state, mull transmittance electronic spectra (Table 4) for all the complexes show a strong band at 306–320 nm which is associated with intraligand charge transfer. **1** exhibits *d–d* bands at 345, 525, 850, and 990 nm, which can be associated with a tetragonal arrangement involving a *trans*-N_4O_2 chromophore. The *d–d* bands for **2** at 365 and 512 nm can be associated with a similar geometrical arrangement around a cobalt(III) centre. Actually a preliminary structural study of **1** confirmed that it also has a *trans*-octahedral structure similar to **3**.[3] **3** exhibits a *d–d* band at 620 nm while **4** has a broad band at 605 nm.

Room temperature magnetic measurements (Table 4) show that **1** has a magnetic moment of 3.20 BM, indicating that the Ni(II) ion is in a high spin state. **2** is diamagnetic indicating the presence of a low spin Co(III) state. The formation of a cobalt(III) complex from a cobalt(II) salt is not considered unusual with ligands of this sort, especially since the reaction mixture was exposed to air. **3** has a magnetic moment of 1.87 BM suggesting the presence of a dilute Cu(II) centre. The magnetic moment for **4** is 1.72 BM per copper centre and is close to the spin-only value for copper(II), but much lower than that in **3**. The question as to whether any spin coupling occurs in this complex can only be answered with a variable temperature magnetic study, which has not, as yet, been carried out. The dinuclear nature of the complex is, however, evident both from the analytical data and the magnitude of the magnetic moment. Structurally, free carboxylate groups could provide a bridging medium for linking the copper centres in a polynuclear arrangement.

Powder esr spectra (Table 4) of **3** exhibit three peaks both at room temperature and 77 K indicating a rhombic distorted octahedral coordination sphere. In ethanolic solution, at room temperature, the esr spectrum is indicative of an axial species ($g_\perp = 2.05$, $g_\parallel = 2.12$) but in frozen solution it gives an uninformative spectrum with $g_{av} = 2.10$. Compound **4** exhibits a very broad, single resonance in the solid state at room temperature centred at $g = 2.10$ and an axial spectrum at 77 K with $g_\perp = 2.10$, $g_\parallel = 2.20$. Electron spin-resonance data for **4** appear normal for a copper(II) species suggesting that spin exchange in this system is very weak.

Received April 20, 1993

SHINICHI NISHIKIORI, CHRISTOPHER I. RATCLIFFE, and JOHN A. RIPMEESTER. Can. J. Chem. **71**, 1810 (1993).

The molecular motion of guest molecules in Cd(*mtn*)Ni(CN)$_4$ · 0.5G clathrates (*mtn* = *N*-methyl-1,3-diaminopropane, G = toluene, nitrobenzene, dichloromethane, and chloroform) were studied by using CP/MAS ^{13}C and ^{2}H NMR techniques. At room temperature, application of ^{13}C CP/MAS NMR with dipolar dephasing showed the presence of large amplitude molecular motion in all cases. Temperature dependent ^{2}H NMR spectra for the toluene-d_8 clathrate shows that the methyl group rotated at all temperatures down to 77 K. Also, a 2-site in-plane reorientation process of the entire molecule is activated above 180 K, which goes over into axially symmetric in-plane rotation around 450 K. Severely restricted motions were also observed for the nitrobenzene and haloalkane guests. The rather complicated dynamic behaviour of the guest molecules at low and room temperatures can be attributed to the presence of static disorders which disappear at higher temperatures due to time averaging.

SHINICHI NISHIKIORI, CHRISTOPHER I. RATCLIFFE et JOHN A. RIPMEESTER. Can J. Chem. **71**, 1810 (1993).

Utilisant des techniques de rmn du ^{1}H et du ^{13}C en CP/MAS, on a étudié la mouvement moléculaire des molécules hôtes dans des clathrates de Cd(*mtn*)Ni(CN)$_4$ · 0,5G (*mtn* = *N*-méthyl-1,3-diaminopropane, G = toluène, nitrobenzène, dichlorométhane ou chloroforme). À la température ambiante, l'utilisation de la rmn par CP/MAS avec déphasage dipolaire démontre, dans tous les cas, la présence d'un mouvement moléculaire d'une grande amplitude. Le spectre rmn du ^{2}H en fonction de la température du clathrate du toluène-d_3 montre que le groupe méthyle subit une rotation à toutes les températures, jusqu'à 77 K. De plus, un processus de réorientation dans le plan, de la molécule dans son ensemble, impliquant deux sites est activé au-dessus de 180 K et il se transforme en rotation dans le plan, axialement symétrique, autour de 450 K. On a aussi observé des mouvements extrêmement restreints avec le nitrobenzène et les haloalcanes agissant comme hôtes. On peut attribuer le comportement dynamique relativement complexe des molécules hôtes à basse température et à température ambiante à la présence de désordres statiques qui disparaissent à des températures plus élevées à cause d'une moyenne provoquées par le temps.

[Traduit par la rédaction]

Introduction

In several recent reviews (1, 2) it was indicated that solid-state NMR techniques are playing an increasingly important role in the definition of structure and order in guest–host materials. The use of ^{13}C CP/MAS NMR, together with temperature-dependent ^{2}H NMR lineshape studies, is an especially powerful combination in tackling problems of this nature, and we apply these to several new systems generally related to the Hofmann clathrates.

In the continuing structural studies of Hofmann type clathrates, a series of clathrates Cd(*mtn*)Ni(CN)$_4$ · 0.5G (*mtn* = *N*-methyl-1,3-diaminopropane, G = guest molecule) was synthesized with a number of features significantly different from the Hofmann and related clathrates (3). The new clathrate host Cd(*mtn*)Ni(CN)$_4$ has a structure which is independent of the various possible organic guests, and which has been defined by X-ray diffraction for the cyclohexane clathrate (3). The molecules which can act as guest are defined by the size and shape of the cavity, a 7 Å × 7 Å × 5 Å rectangular box with a four-fold axis perpendicular to its square faces, which is relatively rigid due to a three-dimensional framework of bridging cyano groups (3). One expects that the dynamic state of the guest molecule will be determined primarily by the guest–cage interactions.

Host–guest systems may be viewed as simple models for molecular recognition and are important for throwing light on how the guest and its dynamics influence, and are influenced by the shape and symmetry of the host cavity it occupies. We have studied molecular motions in several *mtn* clathrates containing guest molecules of various shapes by NMR techniques. A study of the unusual behaviour of the cyclohexane – *mtn* clathrate was presented separately (4). Evidence was found for reorientation about the molecular three-fold axis, as well as inversion of the cyclohexane molecule, and the motional rates were obtained by simulation of the ^{2}H NMR lineshapes for intermediate motional rates. In this work we present results and appropriate motional models for guest molecules of lower symmetry than cyclohexane such as toluene, nitrobenzene, dichloromethane, and chloroform, which show the importance of the interaction of the symmetry of both the guest and the host cavity in determining the dynamics and the effects of disorder present in the host.

Experimental

The clathrates were prepared by the method reported in a previous paper (3) and analysed by X-ray powder diffraction. Deuteriated materials used in the preparations $C_6D_5CD_3$ and $C_6H_5CD_3$ (99.6 atom% D), $C_6D_5NO_2$ (99.6 atom% D), CD_2Cl_2 (99.8 atom% D), and $CDCl_3$ (99.8 atom% D) were purchased from MSD Isotopes.

^{13}C CP/MAS NMR spectra, some recorded with interrupted decoupling (5) of 40 μs, were obtained using a Bruker MSL 300 spectrometer and a Doty Scientific Inc. 5 mm MAS probe. Spinning rates were typically about 5 kHz. The ^{2}H NMR lineshapes were measured using a Bruker CXP 180 spectrometer at 27.63 MHz by means of a variable temperature N_2 gas-flow probe with a Bruker

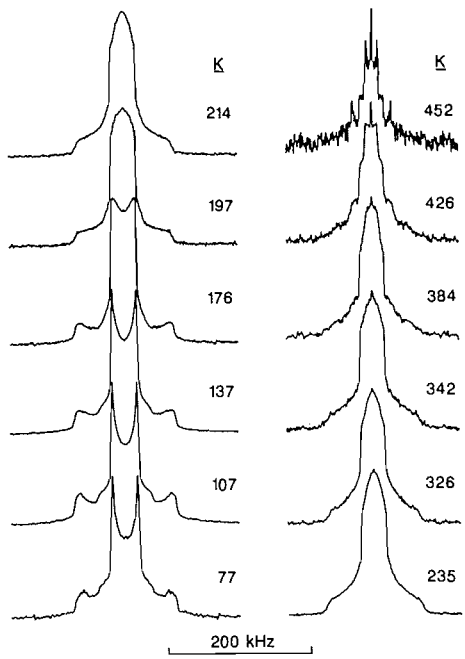

FIG. 2. ^2H NMR lineshapes of Cd(*mtn*)Ni(CN)$_4 \cdot 0.5C_6D_5CD_3$ as a function of temperature.

B-VT-1000 temperature controller. A phase alternated quadrupole echo pulse sequence (6) was used with a delay time of 35 μs between *X* and *Y* pulses of 2.6–3.0 μs. Dynamically averaged ^2H NMR lineshapes in the fast motion limit were calculated by using well-established methods (7, 8) as described previously (4).

Results and discussion

Toluene clathrate

The ^{13}C CP/MAS NMR spectra obtained for the host lattice of the toluene clathrate (Fig. 1) show lines at 128.9 and

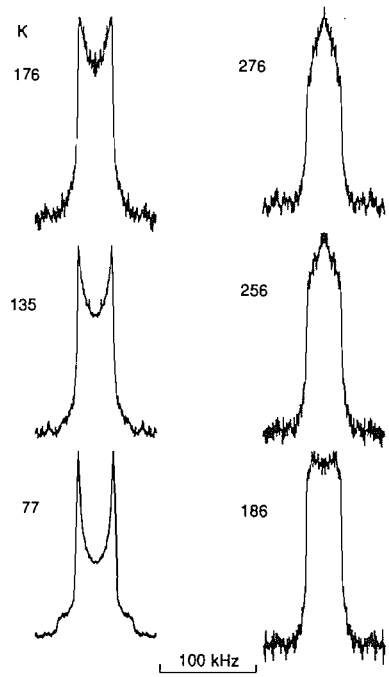

FIG. 3. ^2H NMR lineshapes of Cd(*mtn*)Ni(CN)$_4 \cdot 0.5C_6H_5CD_3$ as a function of temperature.

132.5 ppm for the ^{14}N quadrupole perturbed cyanide carbon, and at 28.5, 38.4, 43.5, and 54.7 ppm for the *N*-methyl-1,3-diaminopropane. The methyl and quaternary carbons show little loss of intensity in the dipolar dephased spectra, as expected. These features are the same as those for results previously obtained for the cyclohexane clathrate (4), and also for the other clathrates studied here.

On examining the toluene carbon lines with and without dipolar dephasing, it is clear that the lines due to the proton-bearing carbons (C2,3,4,5,6) have lost about half their intensity in the dephased spectrum, and that the methyl group intensity does not change at all. This is a clear indication that the whole toluene molecule is involved in some kind of large amplitude molecular motion.

To investigate this further, ^2H NMR lineshapes were examined for a sample prepared with perdeuteriated toluene as a function of temperature (Fig. 2) and for a sample deuteriated only on the methyl group (Fig. 3). At 77 K, the $C_6D_5CD_3$ lineshape consists of two overlapping powder doublets, the narrower component being an axially symmetric pattern ($\eta = 0$) with a quadrupole coupling constant, $\chi = 51$ kHz, the broader component having only general symmetry with $\chi = 180$ kHz and $\eta = 0.052$. Only the narrow component is present for the $C_6H_5CD_3$ clathrate. These values agree with reported values for neat toluene at 77 K, 52 kHz, $\eta = 0$, and 179.9 kHz, $\eta = 0.056$ (9), which correspond to the rotating methyl group C—D's and aromatic C—D's respectively. The motional state of the enclathrated and neat toluenes at 77 K therefore is identical.

Above 137 K, the lineshapes begin to change, and reach a limit at about 214 K. Again, it appears that there are two components to the lineshape of the $C_6D_5CD_3$ clathrate, so that the division of the C—D bonds into aromatic and methyl subgroups still seems to hold. The lack of apparent doublet splitting must be attributed to large asymmetry parameters, indicating the presence of non-axially symmetric motions.

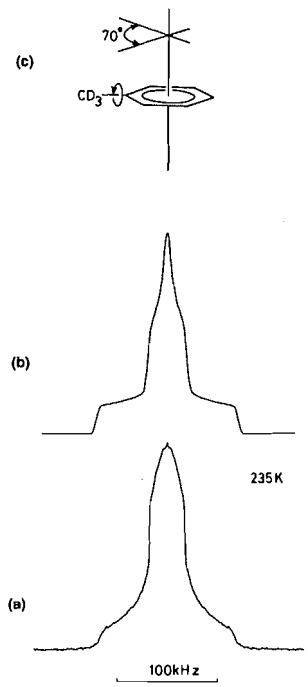

FIG. 4. (*a*) ^2H NMR lineshape of Cd(*mtn*)Ni(CN)$_4 \cdot 0.5C_6D_5CD_3$ at 235 K, (*b*) simulated lineshape for an in-plane motion of toluene-d_8 between two sites separated by 70° as shown in (*c*).

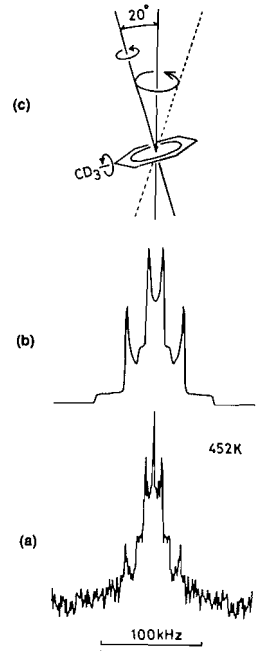

FIG. 5. (*a*) ^2H NMR lineshape of Cd(*mtn*)Ni(CN)$_4 \cdot 0.5C_6D_5CD_3$ at 425 K, (*b*) simulated lineshape for a toluene-d_8 molecule rotating as shown in (*c*).

If the motion is to preserve the equivalence of all the aromatic C—D's it must be an in-plane motion. Considering that the clathrate cage is a slightly flattened square box with the toluene molecule flat in the box, the following motions may be considered. From inspection of the structural information, the toluene molecule is restricted from performing a complete in-plane rotation by the *mtn* molecules which make up the sides of the box. The in-plane motion could be a large angle libration, with a broad potential well centered roughly on a diagonal of the square of the box, or a jumping between two sites with the potential wells displaced on either side of the diagonal. The simulation in Fig. 4 is for a two-site model, with the two sites 70° apart. The agreement with experiment is reasonable, but far from exact, and only a slight improvement could be achieved by allowing for a conical rotation of the out-of-plane axis (e.g. cone angle 12° with in-plane motion between the two sites 66° apart). Evidently, a more complex model is required. In fact, the appearance of the lineshapes of both $C_6D_5CD_3$ and $C_6H_5CD_3$ samples is more suggestive of a distribution of degrees of motional averaging. In this regard, there are a number of implications for the disorder of the toluene and the *mtn* groups which must be taken into account when the structure of the clathrate is considered. Since the toluene appears to have room to move only within one quarter of the square of the cavity, there must be orientational disorder of the long toluene axis throughout the crystal. This will give rise to a distribution of toluene sites when neighbouring toluene orientations are considered, and hence there will be a distribution of motional amplitudes and averaged lineshapes. Furthermore, there is also a disorder in the positions of the NH_2 and $NHCH_3$ groups of the *mtn* molecules of the host which must also contribute to the distribution of the reorientational potentials. These two groups could not be distinguished in the X-ray structural determination (10). There are also some obvious spin–lattice relaxation (T_1) effects on the appearance of the spectra, viz. in the 77 K spectrum of the $C_6D_5CD_3$ sample the broad C_6D_5 component is much weaker than the CD_3 line due to the latter group being in a state of relatively rapid motion and thus having a considerably shorter relaxation time. Spin–lattice relaxation time (T_1) measurements as a function of temperature (either ^1H or ^2H NMR) might be informative with respect to an average activation energy for the motion and the distribution of correlation times for the motions arising from the disorder. The latter may cause a skewed B.P.P. plot (11).

Between 348 and 452 K the lineshape becomes temperature dependent again, indicating the onset of a new motion. The motion reaches its fast limit above 452 K, and now the lineshape consists of two axially symmetric patterns with $\chi = 22$ and 75 kHz. The simplest explanation is that the toluene molecule has now become an axial rotor by overcoming the barriers to in-plane rotation. One might also speculate that the new motion might be closely associated with the onset of dynamic disorder of the *mtn* molecules. This would make the cavity much more symmetric on time average. The doublets are narrower than calculated for a simple in-plane rotation, however (see Table 1). Formally, agreement with experiment can be obtained by allowing the rotation axis to fluctuate over the surface of a cone, where the additional reduction in doublet splitting is equal to $0.5\ (3\cos^2\theta - 1)$, with θ the angle between the cone surface and the symmetry axis (Fig. 5). A close match between experiment and calculation is obtained with $\theta = 17°$ when the calculation is based on the 77 K spectral parameters (see Table 1).

Nitrobenzene clathrate

Figure 6 shows ^{13}C CP/MAS NMR spectra of nitrobenzene enclathrated in the Cd(*mtn*)Ni(CN)$_4$ host lattice obtained at room temperature. The C2,3,4,5,6 lines of the nitrobenzene overlap the cyano carbon peaks, however, it is possible to see that there is significant intensity even in the dipolar dephasing experiment, thus again suggesting the

presence of significant motional amplitudes of the nitrobenzene molecule. Examination of the ^2H NMR lineshapes (Fig. 7, Table 2) gives an indication that a slow motion sets in above 230 K. However, it does not appear to have reached the fast motion limit at the highest temperature of study, 420 K. This again is probably associated with disordering of both the guest orientations and the *mtn*'s $NH_2/NHCH_3$ groups. In fact, the nitrobenzene clathrate is problematical in that structural considerations (based on the framework of the cyclohexane clathrate) suggest that it cannot fit into the cavity without significant van der Waals' overlap with the host. Its structural similarity to the cyclohexane clathrate is based on a powder X-ray diffraction determination (10) of its unit cell parameters (a = 14.22 Å, c = 7.83 Å). Perhaps one should allow for a distortion of the structure, especially of the *mtn* groups which are important in forming the sides of the cavity, to allow for a better fit of the nitrobenzene. At 420 K the pattern is not very well defined but seems to indicate a large η, with one of the electric field gradient tensor components unchanged from the rigid lattice condition. This could be accounted for by two-fold flips of the nitrobenzene about the C—N axis, if the lineshape is attributed

[b]Values obtained for the pure guest materials at 77 K.

only to the C—D bonds off the flipping axis. The ^2H nucleus on the flipping axis may have a much longer relaxation time than the off-axis ones, thus making it much more difficult to observe. Alternatively, it could arise from a distribution of in-plane motions (for example, two sites 52° apart) similar to the toluene low temperature motion.

The amount of information obtainable is much more limited than for the toluene clathrate, however, the general picture is that nitrobenzene is much more restricted than toluene in the Cd(*mtn*)$Ni(CN)_4$ clathrate.

Chloroform clathrate

In the ^{13}C CP/MAS NMR spectrum, the chloroform line at 79.5 ppm retains about 28% of its intensity on applying the dipolar dephasing experiment, again indicating that appreciable molecular motion is likely. Figure 8*a* shows the ^2H NMR lineshape at room temperature. The lineshapes represent axially symmetric tensors, but their width, which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

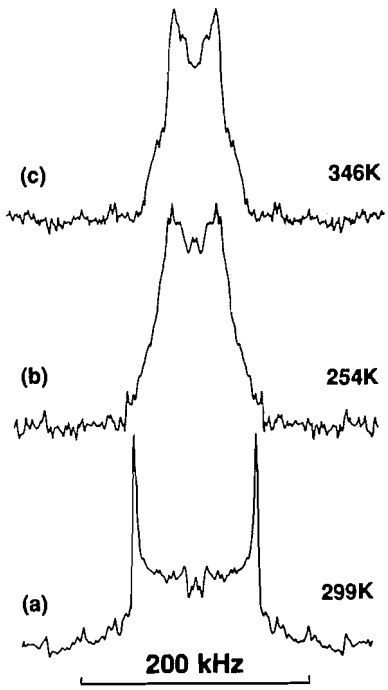

FIG. 8. ^{2}H NMR lineshapes of Cd(*mtn*)Ni(CN)$_4 \cdot 0.5CDCl_3$ at 299 K (*a*), and that of Cd(*mtn*)Ni(CN)$_4 \cdot 0.5CD_2Cl_2$ at 254 K (*b*) and at 346 K (*c*).

gradually decreases with increasing temperature, is significantly less than that of the static molecule determined from pure solid $CDCl_3$ at 77 K (see values of χ in Table 2). The natural orientation for the chloroform molecule is with its three-fold axis along the four-fold axis of the cavity, since this puts the least restriction on the three Cl atoms and allows the molecule to fit into the cavity. The molecule probably reorientates in the 12-fold potential around this axis: the fact that we see no effect of the quadrupolar Cl atoms on the ^{13}C spectrum suggests that the Cl's are self-decoupled because of motion. Such a motion alone would produce no narrowing of the ^{2}H spectrum since the C—D bond would be along the rotation axis. The observed small ^{2}H linewidth reduction could then arise through reorientation of the molecular three-fold axis over a cone about the four-fold axis of the cavity (e.g. cone angle of 17.9° at 299 K).

Dichloromethane clathrate

Again, some intensity is maintained in the dipolar dephased ^{13}C CP/MAS NMR spectrum of the guest, indicating that some molecular motion occurs. The ^{2}H NMR lines are considerably narrower than for the chloroform clathrate (Fig. 8*b*, *c*), and at room temperature the motion still appears to occur at an intermediate rate. As with the low temperature motion of the toluene clathrate, the lineshapes are not characteristic of a single tensor, and a distribution of motional amplitudes arising from the various orientational disorders present seems likely. However, at 346 K the lineshape is approaching that expected for an axially symmetric tensor (Table 2).

Note that tensors averaged to axial symmetry arise when n-fold ($n \geq 3$) reorientation occurs, and the reduction in linewidth is given by $(3 \cos^2 \theta - 1)/2$ where θ is the angle between the C—D bond and the rotation axis. With $\angle$ HCH = 112° this reduction factor is 0.031 for reorientation about the molecular two-fold axis (rotation 1), 0.5 for reorientation about the axis parallel to the Cl—Cl direction (rotation 2), and 0.531 for reorientation about the third orthogonal axis (rotation 3). For the static molecule χ = 167.3 kHz, measured in pure solid CD_2Cl_2 at 77 K. From this the reduced χ values for motions about the three axes are 5.2, 83.7, and 88.8 kHz, respectively. Clearly the first is much smaller than the observed values and this rules out n-fold reorientation about the molecular two-fold axis. Careful consideration of the structure and the ^{2}H NMR results then leads to the following self-consistent picture with regard to the location and orientation of the dichloromethane in the cavity. If the centre of mass of the CD_2Cl_2 is located at the centre of the cavity, then the H atoms can be rotated over a sphere and not come into contact with any of the host atoms. However, the Cl atoms will have severe van der Waals' overlap when they approach the top and bottom square faces of the cavity. This suggests that the preferred location for the Cl atoms is in the square plane in the middle of the cavity, and therefore the two H's are located on either side of this plane. There is then no overlap if the guest is rotated about the four-fold axis of the cavity (rotation 3). The H's could still rotate about the axis parallel to the Cl—Cl vector, but the rotation symmetry in the cavity is now reduced to two-fold, and 180° rotation has no averaging effect on the ^{2}H tensors. The observed χ are reduced by more than the factor of 0.531 expected for rotation 3. This can be accommodated by smaller amplitude motions about the other two axes.

Conclusion

For all of the Cd(*mtn*)Ni(CN)$_4$ clathrates considered, there is some degree of motional freedom, however, enclathration seems to impose rather severe limits on the motions so that these are spatially quite restricted. This is in agreement with the earlier statement that the cage should be seen as quite a rigid, anisotropic box. In the case of toluene and dichloromethane, the motions found should show marked effects of disorder in attempts to solve the structures by diffraction methods. One pattern which has emerged from the study is that the guest dynamics are very much influenced by the disorders present: the *mtn* groups which distort the potential away from true four-fold symmetry, and the guest orientations in neighbouring cages which may have substantial electrostatic effects. The high lattice symmetry apparent from diffraction is achieved only because of static disorder. In the NMR studies the effects of disorder on the lineshapes disappear only when reorientation rates become rapid enough so that even the local symmetries are high on time average.

Lignes monovariantes de l'isotherme 75°C du système quaternaire réciproque : H_3PO_4–K_2SO_4–H_2SO_4–K_3PO_4–H_2O

NÉJI BOURGUIBA[1] ET TAHAR JOUINI

Département de chimie, faculté des sciences de Tunis, Campus universitaire, 1060 Tunis, Tunisie

Reçu le 19 juillet 1993

NÉJI BOURGUIBA et TAHAR JOUINI. Can. J. Chem. **71**, 1816 (1993).

Toutes les lignes monovariantes de l'isotherme isobare (75°C, 1 atm) du système quaternaire H_3PO_4–K_2SO_4–H_2SO_4–K_3PO_4–H_2O sont étudiées. Elles ont été déterminées par analyse chimique de solutions correspondant à des mélanges situés dans les volumes tri-phasés. Les intersections de ces lignes, qui sont des points invariants quaternaires, ont été localisées en préparant des mélanges à l'intérieur des tétraèdres d'invariance quaternaires isothermes, et en analysant les solutions correspondantes en équilibre avec trois sels. Les composés qui se manifestent sont K_2SO_4, $K_2SO_4 \cdot KHSO_4$, $K_2SO_4 \cdot 7KHSO_4 \cdot H_2O$, $KHSO_4$, une solution solide de substitution $K_8(H_2PO_4)_{1+x}(HSO_4)_{7-x}$, $0 \leq x \leq 1$, $KH_2PO_4 \cdot KHSO_4$, $KH_5(PO_4)_2$, KH_2PO_4, $3K_2HPO_4 \cdot KH_2PO_4 \cdot 2H_2O$, K_2HPO_4 et $K_3PO_4 \cdot 3H_2O$. Les huit premiers sels possèdent des domaines à l'intérieur du prisme de Janecke. Par contre les nappes de cristallisation des trois derniers sont pratiquement confondues avec les courbes de solubilité du système ternaire limite K_3PO_4–H_3PO_4–H_2O. L'ensemble des résultats obtenus est discuté et interprété.

NÉJI BOURGUIBA and TAHAR JOUINI. Can. J. Chem. **71**, 1816 (1993).

The boundary curves and quaternary invariant points of the reciprocal system H_3PO_4–K_2SO_4–H_2SO_4–K_3PO_4–H_2O were investigated at 75°C and 1 atm by chemical analysis of solutions in equilibria, respectively, with two or three salts. Eleven compounds occur in this system. Only eight of them have crystallization areas inside Janecke's prism; these are K_2SO_4, $K_2SO_4 \cdot KHSO_4$, $K_2SO_4 \cdot 7KHSO_4 \cdot H_2O$, $KHSO_4$, $KH_2PO_4 \cdot KHSO_4$, $KH_5(PO_4)_2$, KH_2PO_4, and a solid solution $K_8(H_2PO_4)_{1+x}(HSO_4)_{7-x}$, $0 \leq x \leq 1$, of substitution type continuous between the two limiting compositions $KH_2PO_4 \cdot 7KHSO_4$ and $KH_2PO_4 \cdot 3KHSO_4$. The crystallization fields of $3K_2HPO_4 \cdot KH_2PO_4 \cdot 2H_2O$, K_2HPO_4, and $K_3PO_4 \cdot 3H_2O$ are very close to the solubility curves of the ternary system K_3PO_4–H_3PO_4–H_2O. Results are explained and discussed.

Introduction

Le procédé PENNZOIL (1), en vue de préparer HCl, permet l'obtention de $KHSO_4$ avec un coût presque nul :

$$H_2SO_4 + KCl \rightarrow KHSO_4 + HCl$$

$KHSO_4$ pourrait à son tour servir de point de départ pour préparer, par attaque de l'apatite naturelle, des engrais phosphopotassiques (2–8). Cette action produit un mélange hétérogène. Après dégagement des composés volatils (HF, SiF_4, CO_2...) et séparation de l'insoluble constitué surtout de phosphogypse, la solution aqueuse résultante contient essentiellement les ions H^+, K^+, PO_4^{3-} et SO_4^{2-}.

Toute application industrielle devra se baser sur l'étude du diagramme faisant intervenir ces ions en présence d'eau : H_3PO_4–K_2SO_4–H_2SO_4–K_3PO_4–H_2O. Il s'agit d'un système quaternaire réciproque caractérisé par la réaction de double décomposition :

$$2H_3PO_4 + 3K_2SO_4 \underset{\longleftarrow}{\overset{H_2O}{\longrightarrow}} 3H_2SO_4 + 2K_3PO_4$$

La température optimale de l'attaque sulfurique de l'apatite est comprise entre 70 et 80°C. Cela nous a incité à mener cette étude à 75°C.

Toutes les isothermes ternaires limitant ce système ont été établies à 75°C et décrites dans un travail antérieur (9).

Nous poursuivons, dans ce mémoire, l'investigation du système quaternaire réciproque H_3PO_4–K_2SO_4–H_2SO_4–K_3PO_4–H_2O en établissant les lignes monovariantes et les points invariants de l'isotherme 75°C et 1 atm (1 atm = 101,3 kPa).

1. Auteur à qui adresser toute correspondance.

Techniques expérimentales

Les techniques expérimentales relatives aux mesures de solubilité, à la mise à l'équilibre, aux produits utilisés et au mode de représentation ont été décrites dans une publication antérieure (9).

La détermination des caractéristiques des lignes monovariantes du système étudié a été réalisée au moyen de méthodes adaptées aux différents éléments à étudier :

(*a*) Les lignes monovariantes ont été définies au moyen de mélanges situés dans les volumes à trois phases où coexistent deux solides en présence d'une solution. Un tel volume est engendré par le triangle dont les deux sommets, représentant les solides concernés, restent fixes, le troisième relatif à la solution est mobile et décrit la ligne monovariante correspondante. À l'équilibre les solutions sont analysées et les phases solides identifiées.

(*b*) Les points invariants quaternaires ont été déterminés en préparant des mélanges à l'intérieur des tétraèdres d'invariance quaternaire isotherme, définis par les quatre points représentant respectivement les trois solides et la solution en équilibre. L'analyse de cette solution permet une localisation précise du point invariant.

(*c*) Les phases solides connues sont identifiées par leurs diffractogrammes X sur poudre. Celles inconnues sont d'abord caractérisées par les méthodes des ensembles (10) et des restes (11).

Les compositions limites de la solution solide $K_8(H_2PO_4)_{1+x}(HSO_4)_{7-x}$ ($KH_2PO_4 \cdot 7KHSO_4$ et $KH_2PO_4 \cdot 3KHSO_4$) ont été précédemment précisées par analyse chimique des cristaux correspondants (9).

Analyse bibliographique

Ce système n'a fait l'objet d'aucune étude à 75°C. Seule une étude à 25°C a été effectuée (12). Les phases solides signalées par l'auteur sont KH_2PO_4, $KH_2PO_4 \cdot KHSO_4$, $KH_2PO_4 \cdot 3KHSO_4$, $KHSO_4$, K_2SO_4, $K_2SO_4 \cdot 3KHSO_4$ (ou $K_2SO_4 \cdot 6KHSO_4$). Cette étude est incomplète dans le sens où les lignes de niveau d'eau constant et les ternaires limites font défaut. De plus la stoechiométrie de l'une des

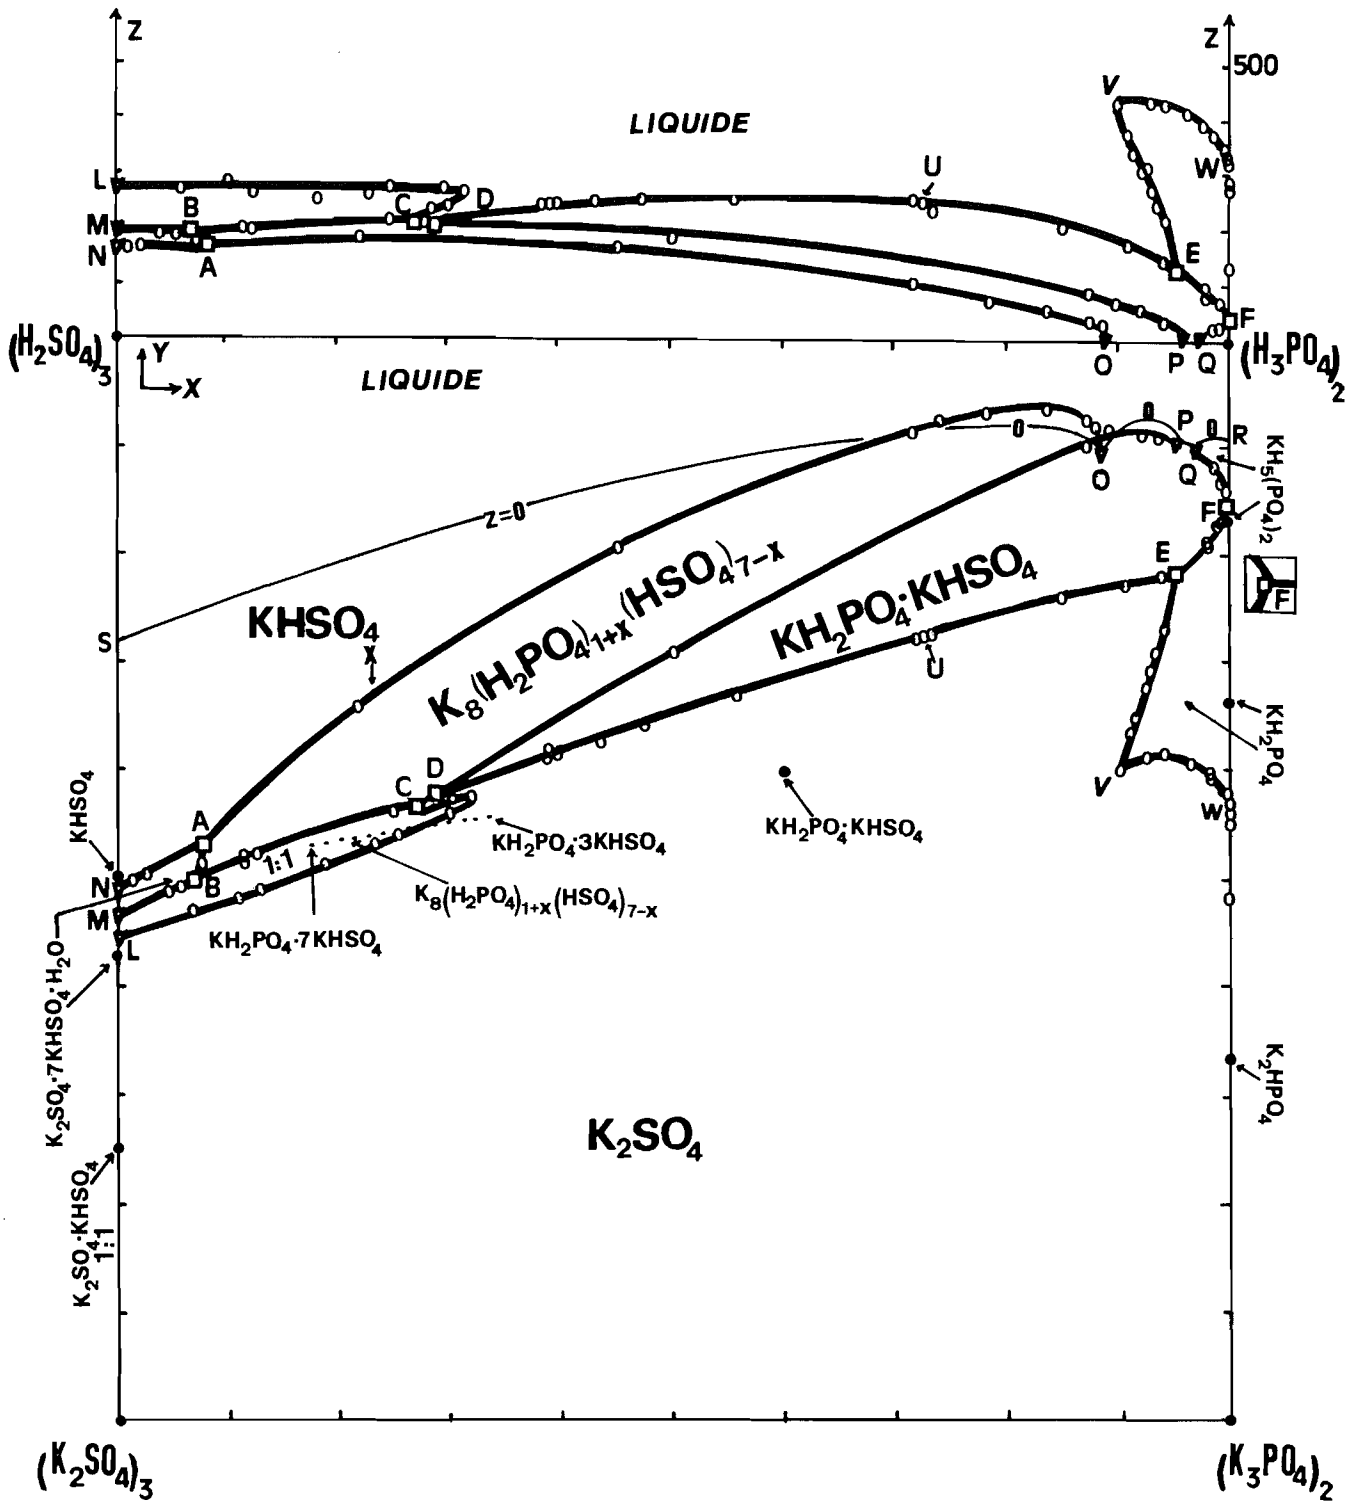

FIG. 1A. Projection sur les plans horizontal et frontal des lignes de deux sels de l'isotherme 75°C du système quaternaire réciproque H_3PO_4–K_2SO_4–H_2SO_4–K_3PO_4–H_2O. ○ : Point appartenant à une ligne monovariante, □ : invariant quaternaire isotherme, ▽ : invariant ternaire isotherme, (.....): solution solide.

phases solides fait l'objet d'un doute de la part de l'auteur ($K_2SO_4 \cdot 3KHSO_4$ ou $K_2SO_4 \cdot 6KHSO_4$), et a donné lieu à des résultats contradictoires dans la littérature (cf. la référence 13). Nous avons montré dans un travail antérieur (13), par une détermination structurale aux rayons X, que la formule exacte de ce sulfate acide est $K_2SO_4 \cdot 7KHSO_4 \cdot H_2O$. Une autre phase décrite, dans la référence 12, comme étant un composé défini ($KH_2PO_4 \cdot 3KHSO_4$) est en fait une solution solide de substitution, $K_8(H_2PO_4)_{1+x}(HSO_4)_{7-x}$, $0 \leq x \leq 1$, continue entre les deux compositions limites $KH_2PO_4 \cdot 7KHSO_4$ et $KH_2PO_4 \cdot 3KHSO_4$. Nous avons délimité, dans une publication antérieure (9), le domaine de cristallisation de cette phase, et indexé les diagrammes de poudre des composés limites.

TABLEAU 1. Lignes monovariantes du système quaternaire réciproque : H^+, K^+, PO_4^{3-}, SO_4^{2-}, H_2O–isotherme 75°C

Lignes	Phases solides en équilibre
NA	$KHSO_4 + K_2SO_4 \cdot 7KHSO_4 \cdot H_2O$
BC	$K_2SO_4 \cdot KHSO_4 + K_8(H_2PO_4)_{1+x}(HSO_4)_{7-x}$
BA	$K_2SO_4 \cdot 7KHSO_4 \cdot H_2O + KH_2PO_4 \cdot 7KHSO_4$
MB	$K_2SO_4 \cdot 7KHSO_4 \cdot H_2O + K_2SO_4 \cdot KHSO_4$
LC	$K_2SO_4 \cdot KHSO_4 + K_2SO_4$
CD	$K_2SO_4 + KH_2PO_4 \cdot 3KHSO_4$
AO	$KHSO_4 + KH_2PO_4 \cdot 7KHSO_4$
DP	$KH_2PO_4 \cdot KHSO_4 + KH_2PO_4 \cdot 3KHSO_4$
DE	$KH_2PO_4 \cdot KHSO_4 + K_2SO_4$
EVW	$K_2SO_4 + KH_2PO_4$
EF	$KH_2PO_4 + KH_2PO_4 \cdot KHSO_4$
QF	$KH_2PO_4 \cdot KHSO_4 + KH_5(PO_4)_2$

On relève également dans la littérature l'étude de quelques coupes isopléthiques :

K_2SO_4–H_3PO_4–H_2O partiellement effectuée à 20°C (14), pour des concentrations pondérales en P_2O_5 inférieures à 50%. Les phases solides observées sont K_2SO_4 et $KH_2PO_4 \cdot KHSO_4$.

K_2SO_4–KH_2PO_4–H_2O qui présente à 80°C deux branches de cristallisation relatives respectivement à K_2SO_4 et à KH_2PO_4 (15).

$KHSO_4$–H_3PO_4–H_2O et $KHSO_4$–KH_2PO_4–H_2O partiellement établies à 80°C (15).

Résultats expérimentaux

Toutes les isothermes 75°C des systèmes ternaires limitant le quaternaire considéré ont été, dans une première étape, déterminées (9).

Étude des lignes monovariantes du système quaternaire réciproque H^+, K^+, PO_4^{3-}, SO_4^{2-} et H_2O à 75°C et 1 atm

Douze lignes monovariantes ont été définies et cinq points invariants quaternaires isothermes ont été localisés. Les résultats sont résumés aux tableaux 1 et 2.

La figure 1*A* représente les projections, sur les plans horizontal et frontal des lignes de deux sels ainsi que la ligne SR de côte en eau $Z = 0$ qui représente les courbes de solubilité du système ternaire anhydre H_2SO_4–H_3PO_4–K_2SO_4–H_3PO_4 (9).

Les agrandissements de deux parties encombrées de la figure 1A sont représentés dans les figures 1B et 1C.

L'examen de ce diagramme suggère les observations suivantes :

1. Huit domaines d'existence, relatifs respectivement aux sels suivants, se manifestent à l'intérieur du prisme de Janecke : K_2SO_4, $K_2SO_4 \cdot KHSO_4$, $K_2SO_4 \cdot 7KHSO_4 \cdot H_2O$, $KHSO_4$ une solution solide de substitution $K_8(H_2PO_4)_{1+x}$-$(HSO_4)_{7-x}$, $0 \leq x \leq 1$, $KH_2PO_4 \cdot KHSO_4$, $KH_5(PO_4)_2$ et KH_2PO_4.

Les compositions limites de la solution solide continue, $KH_2PO_4 \cdot 7KHSO_4$ et $KH_2PO_4 \cdot 3KHSO_4$, ont été déterminées par analyse chimique des cristaux correspondants. Les paramètres de leurs mailles ainsi que les diagrammes de poudre indexés ont été fournis dans une publication antérieure (9).

2. Les domaines de $KHSO_4$, $KH_2PO_4 \cdot KHSO_4$, $K_8(H_2PO_4)_{1+x}$ $(HSO_4)_{7-x}$ et $KH_5(PO_4)_2$ sont délimités dans le carré de base respectivement par les branches SO, OP, PQ et QR, appartenant à la ligne de niveau $Z = 0$. Elles constituent les courbes de solubilité du système ternaire réciproque précédemment décrit (9).

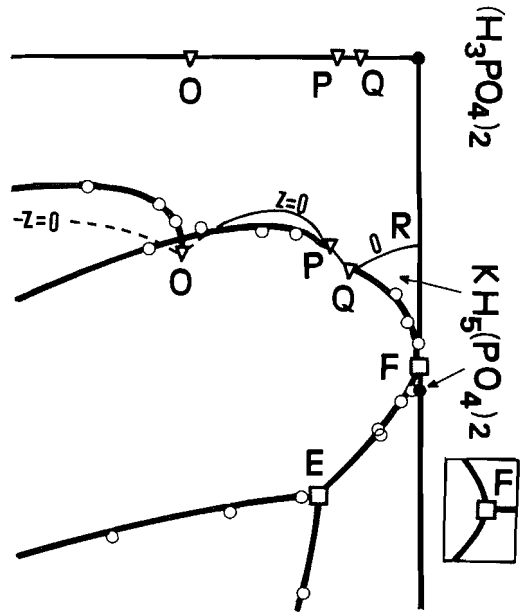

FIG. 1B. Agrandissement de la région acide de l'isotherme 75°C du système quaternaire réciproque H_3PO_4–K_2SO_4–H_2SO_4–K_3PO_4–H_2O.

3. (*a*) Les lignes de deux sels AB, AN, EVW et EF sont à saturation congruente; elles sont caractérisées par des équilibres du type

$$\text{liquide} \rightleftharpoons S_1 + S_2$$

S_1 et S_2 étant deux phases solides. Ces lignes ne peuvent être franchies par les chemins de cristallisation. En particulier l'évaporation de solutions leur appartenant provoque la précipitation de deux sels. Le chemin de cristallisation résultant suit cette ligne monovariante en s'éloignant du segment joignant les points représentatifs des deux sels qui coprécipitent.

(*b*) Les lignes de deux sels : BM, BC, CD, LC DE, FQ et DP sont à saturation non congruente; elles sont caractérisées par des équilibres du type

$$\text{liquide} + S_1 \overset{I}{\rightleftharpoons} S_2$$

De telles lignes peuvent être franchies par les chemins de cristallisation. C'est pourquoi certains auteurs les représentent par une ligne discontinue. En particulier l'évaporation de solutions leur appartenant provoque le déplacement de l'équilibre dans le sens *I* et le dépôt d'un seul sel (S_2). Le chemin de cristallisation résultant ne suit pas cette ligne, il se déplace sur la nappe de S_2. En projection son point représentatif s'éloigne de S_2 selon un segment de droite, dont le prolongement passe par S_2.

(*c*) La ligne AO est à saturation congruente entre A et X et non congruente au delà. Le point X est tel que la tangente en X à AO passe par le point représentatif de $KHSO_4$.

4. Les lignes de deux sels DE et EW, possèdent chacune un point, respectivement U et V, de côte en eau maximum, admettant par conséquent une tangente horizontale. Chacun de ces points doit être situé, sur la projection horizontale, à l'intersection de la ligne de deux sels correspondante et de

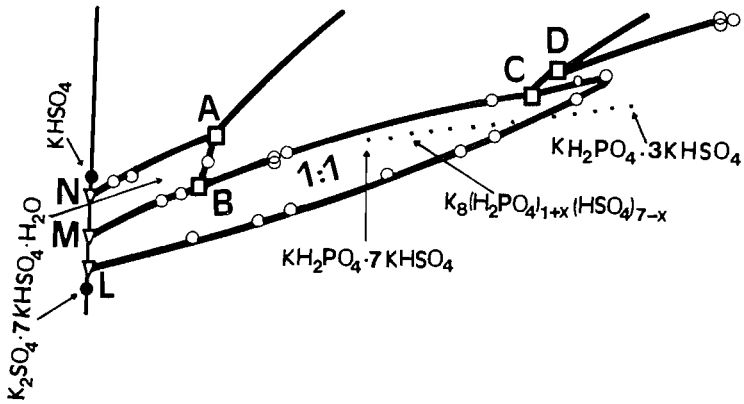

FIG. 1C. Agrandissement d'une région de l'isotherme 75°C du système quaternaire réciproque H_3PO_4–K_2SO_4–H_2SO_4–K_3PO_4–H_2O.

TABLEAU 2. Coordonnées des points représentatifs des invariants quaternaires du système quaternaire réciproque : H^+, K^+, PO_4^{3-}, SO_4^{2-}, H_2O–isotherme 75°C

Points invariants	Solution saturée							Phases solides en équilibre
	Coordonnées de Janecke			Composition pondérale				
	X	*Y*	*Z*	$\%K_2O$	$\%SO_3$	$\%P_2O_5$	$\%H_2O$	
A	7,70	52,78	174,6	22,89	38,00	1,88	37,23	$KHSO_4$ + $K_2SO_4 \cdot 7KHSO_4 \cdot H_2O$ + $KH_2PO_4 \cdot 7KHSO_4$
B	7,28	49,67	178,0	23,94	37,45	1,74	36,87	$K_2SO_4 \cdot KHSO_4$ + $K_2SO_4 \cdot 7KHSO_4 \cdot H_2O$ + $KH_2PO_4 \cdot 7KHSO_4$
C	27,42	56,34	210,8	20,75	29,30	6,55	43,40	K_2SO_4 + $K_2SO_4 \cdot KHSO_4$ + $KH_2PO_4 \cdot 3KHSO_4$
D	29,14	57,44	207,7	20,49	28,97	7,05	43,49	K_2SO_4 + $KH_2PO_4 \cdot KHSO_4$ + $KH_2PO_4 \cdot 3KHSO_4$
E	95,15	78,08	123,6	16,12	3,03	35,15	45,70	K_2SO_4 + $KH_2PO_4 \cdot KHSO_4$ + KH_2PO_4
F	100,0	84,58	40,62	15,84	0,00	51,61	32,55	$KH_2PO_4 \cdot KHSO_4$ + KH_2PO_4 + $KH_5(PO_4)_2$

la droite passant par les points représentatifs de ces deux sels : respectivement ($KH_2PO_4 \cdot KHSO_4$ et K_2SO_4) et (KH_2PO_4 et K_2SO_4).

5. Miscibilité des sulfates dans les solutions saturées en phosphates. Seuls les phosphates acides $KH_5(PO_4)_2$ et KH_2PO_4 possèdent des domaines à l'intérieur du prisme de Janecke.

Les lignes de deux sels faisant intervenir les autres phosphates du système ternaire K_3PO_4–H_3PO_4–H_2O :

$$K_3PO_4 \cdot 3H_2O + K_2SO_4,\ K_2HPO_4 + K_2SO_4,$$

$$3K_2HPO_4 \cdot KH_2PO_4 \cdot 2H_2O + K_2SO_4$$

ainsi que la ligne de deux sels (KH_2PO_4 + K_2SO_4) à partir du point W, sont confondues avec les courbes de solubilité du système ternaire K_3PO_4–H_3PO_4–H_2O. Elles se projettent par conséquent sur le côté K_3PO_4–H_3PO_4 du carré de base. Cela traduit l'insolublité de K_2SO_4 dans les solutions saturées en phosphates à partir de W, c'est-à-dire, au delà des rapports molaires $K_3PO_4/H_3PO_4 \geq 0.71$.

L'allure de la ligne E V W est révélatrice à cet égard : K_2SO_4 est soluble dans les solutions saturées en KH_2PO_4 de composition comprise entre les points E et V. À partir de V sa solubilité décroît pour s'annuler en W qui représente une solution pratiquement ternaire ne contenant pas d'ions SO_4^{2-}.

Un phénomène dans une certaine mesure similaire se manifeste dans le système quaternaire CaO–P_2O_5–SO_3–H_2O (16), où du fait de l'insolubilité des sulfates de calcium dans les solutions saturées en phosphates, les lignes de deux sels du système quaternaire sont confondues avec les courbes de solubilité du système ternaire CaO–P_2O_5–H_2O.

Notons également la particularité que présente $KH_2PO_4 \cdot KHSO_4$: insoluble en présence de KH_2PO_4 et $KH_5(PO_4)_2$ dans la solution représentée par le point F (en effet, F est pratiquement contenu dans le plan K_3PO_4–H_3PO_4–H_2O), il est cependant soluble dans les solutions monovariantes, contenant l'un ou l'autre de ces sels, représentées respectivement par les lignes FE et FQ qui sont situés à l'intérieur du prisme de Janecke.

Ces résultats sont appliqués à la fabrication d'engrais phosphopotassiques dans une publication (en préparation) où nous avons étudié les nappes du liquidus du système. Leur connaissance est en effet nécessaire à la délimitation précise

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

des domaines de solubilité des différents sels qui cristallisent dans ce diagramme.

Preparation and nuclear magnetic resonance characterization of N-bonded complexes of platinum(II) with phosphorus-nitrogen rings containing three-coordinate chalcogens: X-ray structure of $[PtCl_2(PEt_3)]_2(Ph_4P_2N_4Se_2Et_2)$

TRISTRAM CHIVERS,[1] DANIEL D. DOXSEE, ROBERT W. HILTS, AND MASOOD PARVEZ
Department of Chemistry, The University of Calgary, Calgary, AB T2N 1N4, Canada

Received April 21, 1993

TRISTRAM CHIVERS, DANIEL D. DOXSEE, ROBERT W. HILTS, and MASOOD PARVEZ. Can J. Chem. **71**, 1821 (1993).

The reaction of 1,5-$Ph_4P_2N_4S_2Ph_2$ with $[PtCl_2(PEt_3)]_2$ in chloroform at 60°C produces the 1:1 adduct *trans*-$PtCl_2(PEt_3)(Ph_4P_2N_4S_2Ph_2)$ in which the platinum is attached to a nitrogen atom on the basis of ^{31}P nmr spectroscopy. By contrast, the corresponding reactions of 1,5-$Ph_4P_2N_4Se_2R_2$ (R = Me, Et, Ph) produce the 2:1 adducts $[PtCl_2(PEt_3)]_2(Ph_4P_2N_4Se_2R_2)$ (**7***a*, R = Me; **7***b*, R = Et; **7***c*, R = Ph) which have been characterized by ^1H, ^{31}P and ^{77}Se nmr spectroscopy and, in the case of **7***b*, by X-ray crystallography. Crystals of **7***b* are monoclinic, space group $C2/c$, with a = 27.803(7) Å, b = 12.378(7) Å, c = 15.752(8) Å, β = 115.49(2)°, V = 4893(3) Å^3, and Z = 4. The least-squares refinement with anisotropic thermal parameters for all non-hydrogen atoms converged at R = 0.037 and R_w = 0.022. The platinum centres in **7***b* are attached to distal nitrogen atoms of the disordered $P_2N_4Se_2$ ring. The reaction of the six-membered ring $Ph_4P_2N_3SPh$ with $[PtCl_2(PEt_3)]_2$ in dichloromethane at 23°C occurs in a regiospecific manner to give the 1:1 adduct $PtCl_2(PEt_3)(Ph_4P_2N_3SPh)$ in which, on the basis of ^{31}P nmr spectroscopy, the platinum is coordinated to a nitrogen atom between phosphorus and sulfur.

La réaction du 1,5-$Ph_4P_2N_4S_2Ph_2$ avec le $[PtCl_2(PEt_3)]_2$, dans le chloroforme à 60°C conduit à un adduit 1:1, le *trans*-$PtCl_2(PEt_3)(Ph_4P_2N_4S_2Ph_2)$, dans lequel le platine est attaché à l'atome d'azote d'après la rmn du ^{31}P. Par opposition, les réactions correspondantes des 1,5-$Ph_4P_2N_4Se_2R_2$ (R = Me, Et et Ph) conduisent à des adduits 2:1, les $[PtCl_2(PEt_3)]_2(Ph_4P_2N_4Se_2R_2)$ (**7***a*, R = Me; **7***b*, R = Et; **7***c*, R = Ph), qui ont été caractérisés par rmn du ^1H, du ^{31}P et du ^{77}Se et, dans le cas du composé **7***b*, par diffraction des rayons X. Les cristaux du composé **7***b* sont monocliniques, groupe d'espace $C2/c$, avec a = 27,803(7), b = 12,378(7) et c = 15,752(8) Å, β = 115,49(2)°, V = 4893(3) Å^3 et Z = 4. L'affinement par la méthode des moindres carrés pour les paramètres thermiques anisotropiques pour tous les atomes différents de l'hydrogène convergent à R = 0,037 et R_w = 0,022. Les centres de platine du composè **7***b* sont attachés aux atomes d'azote distales du cycle $P_2N_4Se_2$ désordonné. La réaction du cycle à six chainons $Ph_4P_2N_3SPh$ avec le $[PtCl_2(PEt_3)]$, dans le dichlorométhane à 23°C, se produit d'une facon régiospécifique pour donner l'adduit 1:1 $PtCl_2(PEt_3)(Ph_4P_2N_3SPh)$ dans lequel, d'après la rmn du ^{31}P, le platine est coordiné à un atome d'azote entre le phosphore et le soufre.

[Traduit par la rédaction]

Introduction

The coordination chemistry of unsaturated sulfur–nitrogen and selenium–nitrogen rings has been an active area of investigation recently (1). We have been particularly interested in exploring the range of metal complexes that can be formed by the folded $P_2N_4E_2$ rings **1** and **2** (2–4). The presence of the NPR_2 units in **1** and **2** provides a brace that serves to maintain the integrity of the ring and yields structural information through ^{31}P nmr spectroscopy. To date the following bonding modes have been established for **1** and **2**: η^1-N (2, 4), η^2-E,E′ (3–6) and η^2-E,N-μ,η^1-E′ (3, 4, 7). The combination of η^1-N and η^2-E,E′, i.e. μ^2,η^3-E,E′,N has also been observed for both **1** and **2** (2, 4). The $P_2N_4E_2$ ring can accommodate three (E = S) (2) or two (E = Se) (4) *N*-bonded $PtCl_2(PEt_3)$ groups. In addition, the organolithium derivatives $Li[Ph_4P_2N_4S_2R]$ form η^1-S bonded complexes with platinum(II) or palladium(II) (8).

The S,S′- and Se,Se′-diorgano derivatives of these eight-membered rings, **3** and **4**, are readily prepared (9, 10). The $P_2N_4E_2$ ring in **3** and **4** adopts a chair conformation with the two chalcogen atoms disposed on either side of the P_2N_4 plane and the exocyclic substituents on S or Se occupying axial positions (9, 10). These ring systems are potential precursors of hybrid inorganic polymers containing alternating PN and EN (E = S, Se) units. Polymers containing two PN and one SN groups in a repeating unit have been prepared from cyclic precursors (*six*-membered rings) (11, 12).

We report here the formation of platinum(II) complexes of **3** and **4**, which were prepared in order to compare the ligand behaviour of the open rings **3** and **4** with that of the corresponding folded rings **1** and **2** and, in particular, to determine (*a*) the site of coordination, (*b*) the effect of coordination on the structure of the $P_2N_4E_2$ ring, (*c*) the number of Pt(II) groups that can be attached to the $P_2N_4E_2$ ring, and (*d*) any differences between the coordinating ability of the sulfur and selenium systems. A platinum(II) complex of the related six-membered ring **5** was also characterized.

formed under an atmosphere of prepurified nitrogen or argon using standard Schlenk or dry box techniques. Solvents (acetonitrile, chloroform, dichloromethane, hexanes, diethyl ether) were dried with the appropriate desiccant and purged with N_2 or argon. The compounds 1,5-$Ph_4P_2N_4Se_2R_2$ (R = Me, Et, Ph) (9), $Ph_4P_2N_3SPh$ (13), and $[PtCl_2(PEt_3)]_2$ (14) were prepared by the literature procedures. The compound 1,5-$Ph_4P_2N_4S_2Ph_2$ was obtained in 59% yield from $Ph_2PN_2(SiMe_3)_3$ and three molar equivalents of PhSCl by a modification of the literature method (10) in which acetonitrile was used as a solvent instead of CH_2Cl_2. The solubility of the Ph_2S_2 by-product in acetonitrile facilitates the purification of the product by obviating the need to wash it with n-pentane.

Instrumentation

^{31}P nmr spectra were obtained on a Bruker AM-400 MHz spectrometer operating at 161.978 MHz. ^{31}P chemical shifts are reported in ppm relative to external 85% H_3PO_4. Proton nmr spectra were recorded on a Bruker ACE-200 MHz spectrometer at 200.1 MHz. ^{77}Se nmr spectra were recorded at 76.311 MHz on the Bruker AM-400 instrument. The lock signal for the ^{31}P and ^{77}Se nmr spectra was provided by sealed D_2O inserts. ^{77}Se chemical shifts are referenced to external Ph_2Se_2 [$\delta^{77}Se$ + 461 ppm relative to $SeMe_2$ (0 ppm)]. Elemental analyses were performed by the microanalytical service within the Chemistry Department at The University of Calgary.

*Preparation of trans-[$PtCl_2(PEt_3)(Ph_4P_2N_4S_2Ph_2)$], **6***

A solution of 1,5-$Ph_4P_2N_4S_2Ph_2$ (0.200 g, 0.31 mmol) in $CHCl_3$ (20 mL) was added by cannula to a solution of $[PtCl_2(PEt_3)]_2$ (0.118 g, 0.154 mmol) in $CHCl_3$ (20 mL). The resulting pale yellow solution was heated at 60°C for 1 h and then stirred for 1 h at 23°C. The solvent was removed under vacuum and the yellow residue was recrystallized from chloroform – diethyl ether at −18°C to give **6** · Et_2O as pale yellow needles (0.107 g, 0.097 mmol, 31%). Anal. calcd. for $C_{46}H_{55}Cl_2N_4OP_3PtS_2$: C 50.09, H 5.03, N 5.08; found: C 50.83, H 4.44, N 5.71. ^1H nmr ($CDCl_3$), δ(ppm): 7.22–8.48 (m, PC_6H_5 and SC_6H_5, 30H), 3.34 (q, $O[CH_2CH_3]_2$, 4H, ^3J(H—H) = 7.5 Hz, 1.07 (t, $O(CH_2CH_3)_2$, 6H, ^3J(H—H) = 7.5 Hz), 1.51 (dq, PCH_2CH_3, 6H, ^2J(P—H) = 12 Hz, ^3J(H—H) = 7.5 Hz), 0.76 (dt, PCH_2CH_3, 9H, ^2J(P—H) = 17 Hz, ^3J(H—H) = 7.5 Hz). ^{31}P nmr (CH_2Cl_2), δ(ppm): 41.5 (dd, ^3J(P—P) = 5 Hz, ^4J(P—P) = 6 Hz, ^2J(Pt—P) = 30 Hz), 31.3 (d, ^4J(P—P) = 7 Hz), −1.4 (d, ^3J(P—P) = 5 Hz, ^1J(Pt—P) = 3696 Hz).

*Preparation of [$PtCl_2(PEt_3)]_2(Ph_4P_2N_4Se_2Me_2$), 7*a

A cold (−78°C) solution of $[PtCl_2(PEt_3)]_2$ (0.309 g, 0.402 mmol) in CH_2Cl_2 (15 mL) was added dropwise by cannula to a slurry of 1,5-$Ph_4P_2N_4Se_2Me_2$ (0.247 g, 0.402 mmol) in CH_2Cl_2 (15 mL) at −78°C. The mixture was allowed to reach room temperature and stirred for 45 min to give a yellow solution. The volume of the solution was reduced under vacuum to ca. 10 mL and the addition of hexanes (5 mL) produced a yellow precipitate of $[PtCl_2(PEt_3)]_2$ (1,5-$Ph_4P_2N_4Se_2Me_2$) (0.538 g, 0.389 mmol, 97%). Yellow crystals of **7***a* · CH_2Cl_2 were obtained from CH_2Cl_2 solutions layered with hexanes at 0°C. Anal. calcd. for $C_{39}H_{58}Cl_6N_4P_4Pt_2Se_2$: C 31.92, H 3.98, N 3.82; found: C 32.35, H 4.04, N 4.07. ^1H nmr (CD_2Cl_2, 23°C), δ(ppm): 7.1–8.4 (m, C_6H_5, 20H), 5.32 (s, CH_2Cl_2, 2H), 1.5–2.0 (m, CH_2CH_3, 12H), 0.6–1.2 (m, CH_2CH_3 and CH_3Se, 24H). ^{31}P nmr (CH_2Cl_2), δ(ppm): 44.3 (s, Ph_2P), −0.2 (s, Et_3P, ^1J(P—Pt) = 3620 Hz).

*Preparation of [$PtCl_2(PEt_3)]_2(Ph_4P_2N_4Se_2Et_2$), 7*b*, and [$PtCl_2(PEt_3)]_2(Ph_4P_2N_4Se_2Ph_2$), 7*c

Compounds **7***b* and **7***c* were obtained as yellow crystals in ca. 95% yield from $[PtCl_2(PEt_3)]_2$ and 1,5-$Ph_4P_2N_4Se_2Et_2$ or 1,5-$Ph_4P_2N_4Se_2Ph_2$, respectively, by a procedure similar to that described for the preparation of **7***a*. The products were recrystallized from CH_2Cl_2 solutions layered with hexanes at 0°C.

7*b*: Anal. calcd. for $C_{40}H_{60}Cl_4N_4P_4Pt_2Se_2$: C 34.05, H 4.30, N 3.97; found: C 33.59, H 4.43, N 3.89. ^1H nmr (CD_2Cl_2, 23°C), δ(ppm): 7.1–8.4 (m, C_6H_5, 20H), 1.5–1.9 (m, PCH_2CH_3 and $SeCH_2CH_3$, 16H), 0.7–1.2 (m, PCH_2CH_3) and $SeCH_2CH_3$, 24H). ^{31}P nmr (CH_2Cl_2), δ(ppm): 44.9 (s, Ph_2P), −0.6 (d, Et_3P, ^1J(P—Pt) = 3600 Hz, ^3J(P—P) = 3 Hz).

7*c*: Anal. calcd. for $C_{48}H_{60}Cl_4N_4P_4Pt_2Se_2$: C 38.26, H 4.01, N 3.71; found: C 37.38, H 4.08, N 3.63. ^1H nmr (CD_2Cl_2, 23°C), δ(ppm): 7.1–8.6 (m, PC_6H_5 and SeC_6H_5, 30H), 1.41 (q, CH_2CH_3, 12H), 0.74 (t, CH_2CH_3, 18H). ^{31}P nmr (CH_2Cl_2), δ(ppm): 43.3 (s, Ph_2P), −1.4 (d, Et_3P, ^1J(P—Pt) = 3646 Hz, ^3J(P—P) = 5 Hz).

Preparation of trans-[$PtCl_2(PEt_3)(Ph_4P_2N_3SPh)$], **8**

A solution of $[PtCl_2(PEt_3)]_2$ (0.200 g, 0.26 mmol) in CH_2Cl_2 (20 mL) at 23°C was added dropwise by cannula (10 min) to a solution of $Ph_4P_2N_3SPh$ (0.272 g, 0.52 mmol) in CH_2Cl_2 (20 mL) at 23°C. The resulting yellow solution was stirred for 1 h and then solvent was removed under vacuum. Recrystallization of the residue from diethyl ether at 23°C afforded yellow crystals of *trans*-[$PtCl_2(PEt_3)(Ph_4P_2N_3SPh)$] (0.211 g, 0.233 mmol, 45%). Anal. calcd. for $C_{36}H_{40}Cl_2N_3P_3PtS$: C 47.74, H 4.45, N 4.64; found: C 46.81, H 4.73, N 4.53. ^1H nmr ($CDCl_3$), δ(ppm): 6.85–8.3 (m, PC_6H_5 and SC_6H_5, 25H), 1.72 (dq, PCH_2CH_3, 6H, ^2J(P—H) = 12 Hz, ^3J(H—H) = 8 Hz), 0.98 (dt, PCH_2CH_3, 9H, ^3J(P—H) = 17 Hz, ^3J(H—H) = 8 Hz). ^{31}P nmr (CH_2Cl_2), δ(ppm): 20.5 (d, ^3J(P—P) = 10 Hz, ^2J(Pt—P) = 40 Hz), 10.0(s), 1.2 (d, ^3J(P—P) = 10 Hz, ^1J(Pt—P) = 3637 Hz).

X-ray crystallographic analysis of **7***b*

Yellow crystals of **7***b* were obtained from a CH_2Cl_2 solution layered with hexane. The crystal was attached to a glass fibre with epoxy. Pertinent crystallographic data are listed in Table 1.

The unit cell constants were determined from the setting angles of 25 reflections with $18.76° < 2\theta < 21.29°$. All measurements were made on a Rigaku AFC6S diffractometer with the ω–2θ scan technique and calculations were done using the teXsan programs (15). An empirical absorption correction using the program DIFABS

(16) was applied. The data were corrected for Lorentz and polarization effects.

The structure was solved by direct methods (17) and expanded using Fourier techniques (18). All non-H atoms, except the methylene carbon atom attached to Se which was disordered over two sites, were refined anisotropically and were allowed isotropic temperature factors; the Se atom was also disordered over two sites. All H atoms except those on the ethyl group attached to Se were included in the refinement at geometrically idealized positions. In the full-matrix least-squares refinement, the function minimized was $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2/\sigma^2(F_o^2)$. Conventional atomic scattering factors (19), corrected for anomalous dispersion (20), were used. Positional parameters are given in Table 2 and selected bond distances and bond angles are summarized in Table 3.

Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, complete tables of bond lengths and bond angles, and structure factors have been deposited.[2]

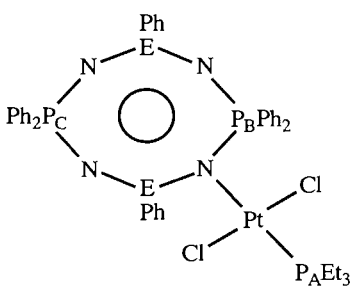
Results and discussion

Synthesis and ^{31}P nmr characterization of **6**

The reaction of two molar equivalents of 1,5-$Ph_4P_2N_4S_2Ph_2$, **3**, with $[PtCl_2(PEt_3)]_2$ in chloroform at 60°C produces the 1:1 adduct **6** in about 30% yield. On the basis of the ^{31}P nmr spectra of the reaction mixture, the low yield of **6** is attributed to the equilibrium shown in reaction [1]. Unlike the selenium-containing rings **4***a–c*, a 2:1 adduct could not be obtained either by the reaction of **6** with $[PtCl_2(PEt_3)]_2$ or by treatment of **3** with an excess of $[PtCl_2(PEt_3)]_2$.

[1] $2Ph_4P_2N_4S_2Ph_2 + [PtCl_2(PEt_3)]_2 \rightleftharpoons 2trans\text{-}PtCl_2(PEt_3)(\eta^1\text{-}N\text{-}Ph_4P_2N_4S_2Ph_2)$

The composition and structure of **6** were established on the basis of the ^1H and ^{31}P nmr spectra. The ^{31}P nmr spectrum of **6** shows three equally intense resonances at −1.4, +31.3, and +41.5 ppm consistent with the proposed *N*-bonded structure. The resonance at −1.4 ppm is a doublet ($^3J(P_A—P_B)$ = 5 Hz) with platinum satellites ($^1J(Pt—P_A)$ = 3696 Hz) and is attributed to the PEt_3 ligand. The value of the $^{195}Pt—^{31}P$ coupling constant is typical for complexes of the type *trans*-$PtCl_2(PEt_3)L$, where L is an *N*-bonded unsaturated PNS ring (2, 21). The resonances at 31.3 and 41.5 Hz are assigned to the inequivalent ring phosphorus atoms P_C and P_B, respectively, which exhibit a mutual coupling of 7 Hz. The resonance at 41.5 ppm appears as a doublet of doublets and so is readily attributed to P_B.



6

Synthesis and nmr characterization of 7a–c

In contrast to the behaviour of **3**, the reaction of two molar equivalents of **4***a–c* with the dimer $[PtCl_2(PEt_3)]_2$ yielded only the 2:1 adducts **7***a–c*. These adducts could be obtained as yellow, air-sensitive solids in essentially quantitative yields by using the stoichiometry shown in reaction [2].

[2] $Ph_4P_2N_4Se_2R_2 + [PtCl_2(PEt_3)]_2 \rightarrow [PtCl_2(PEt_3)]_2(Ph_4P_2N_4Se_2R_2)$

7*a*, R = Me; **7***b*, R = Et; **7***c*, R = Ph

The composition of the 2:1 adducts **7***a–c* was established by elemental analyses and by the integrated ^1H nmr spectra (see Experimental section). The ^{31}P nmr spectra of **7***a–c* all exhibit a singlet at 43–45 ppm (cf. $\delta(^{31}P)$ = 32–34 ppm for **4***a–c* (9)) for the heterocyclic phosphorus atoms in addition to a resonance at 0 to −2 ppm ($^1J(Pt—P)$ = 3600–3650 Hz) for the PEt_3 ligand. The $J(PEt_3—PPh_2)$ coupling of 3–5 Hz is observed (as a doublet) in the PEt_3 resonance of **7***b* and **7***c*, but it was not resolved in the case of **7***a*. Thus the ^{31}P nmr data rule out a structure for **7***a–c* in which the two $PtCl_2(PEt_3)$ groups are attached to nitrogen atoms which are bonded to the same phosphorus atom or a structure in which the platinum atoms are coordinated to selenium, but do not distinguish between "distal" or "vicinal" *N*-bonded arrangements (see Fig. 1). The ^{77}Se nmr spectrum of **7***a*, however, consists of a virtual triplet, centered at 944 ppm, characteristic of an AA'X spin system (where X is ^{77}Se (natural abundance = 7.7%) for the most abundant isotopomer and the phosphorus atoms (represented by A and A') are *magnetically inequivalent*). The "averaged" value of 40 Hz for $^2J(P—Se)$ obtained from the ^{77}Se nmr spectrum of **7***a* is smaller than the value of 86 Hz found for the ligands **4***a–c* (9*b*). These ^{77}Se nmr data rule out the "vicinal" *N*-bonded structure for **7***a* (see Fig. 1(*b*)), since this isomer should exhibit two resonances for the inequivalent selenium atoms. In support of the inference based on the ^{31}P nmr spectra of **7***a–c*, the Se-coordinated structure (an A_2X spin system, see Fig. 1(*c*)) which should give rise to a 1:2:1 triplet, may also be discounted on the basis of the ^{77}Se nmr data. Thus the ^{77}Se nmr spectrum of **7***a* is only consistent with the "distal" *N*-bonded structure (see Fig. 1(*a*)). This conclusion has been confirmed by an X-ray crystal structure determination of **7***b*.

X-ray crystal structure of $[PtCl_2(PEt_3)]_2(Ph_4P_2N_4Se_2Me_2)$, **7**b

The X-ray analysis of **7***b* establishes that the two $PtCl_2(PEt_3)$ groups are attached to opposite (distal) nitrogen atoms of the $P_2N_4Se_2$ ring with the PEt_3 ligands *trans* to nitrogen. An ORTEP drawing of the structure with the atomic numbering scheme is displayed in Fig. 2.

In the solid state, the complex lies on a twofold axis with the SeC_2H_5 group disordered in such a way that the Se and methylene carbon atoms lie over two sites (Se(1), Se(2) and C(191), C(192), respectively) with half-occupancy factors; the thermal parameters of the methyl carbon atom C(20) indicate a large degree of thermal motion. For clarity, Fig. 2 depicts one long chair conformation of the disordered $P_2N_4Se_2$ ring. There are three possible conformations of the $P_2N_4Se_2$

ring which could contribute to the disordered structure, viz. boat–boat (BB), crown (CR), or long chair (LC) (see Fig. 3).[3] Three combinations of these ring conformations could give rise to the observed disorder. These are (*i*) equal contributions of BB and CR, (*ii*) equal contributions of two LC conformations, or (*iii*) equal contributions of BB, CR, and two LC conformations. Although it is not possible to distinguish between these alternatives on the basis of the crystallographic data, option (*ii*) (two LC conformations involved in a rotational disorder) seems the most likely explanation since the other combinations require equal contributions of energetically different species.

As a result of the disorder the P—N bond distances fall within the range 1.57(1)–1.65(1) Å with a mean value of 1.61 Å, and the Se—N bond distances vary from 1.56(1) to 1.99(1) with a mean value of 1.77 Å. These distances can be compared with the values of 1.605(3) and 1.773(1) Å found for the P—N and Se—N bonds, respectively, in the uncomplexed ligand 1,5-$Ph_4P_2N_4Se_2Me_2$, **4***a* (9). The geometry of the rest of the molecule is not affected by the disorder. The Pt—N bond length of 2.130(8) Å is indicative of a weak interaction. For comparison, the Pt—N bond length in $[PtCl_2(PEt_3)]_2(Ph_4P_2N_4Se_2)$, a closely related "distal" platinum(II) complex of **2** is 2.162(9) Å (4), while values of 2.02–2.03 Å are found for complexes of chelating, anionic Se—N ligands (22).

Preparation and ^{31}P nmr characterization of **8**

Investigations of the Lewis base properties of the six-membered ring **5** have shown that the interaction of the P_2N_3S ring with Lewis or Brønsted acids is not regiospecific. Whereas methylation occurs at a nitrogen between phosphorus and sulfur, protonation takes place at the unique nitrogen atom (23). Furthermore, the 1:1 boron trihalide adducts of **5** are mixtures of symmetrical and unsymmetrical *N*-bonded isomers and the formation of a 2:1 BCl_3 adduct is indicated on the basis of ^{31}P nmr investigations. It was of interest, therefore, to include an examination of the ligand behaviour of **5** towards platinum(II) in the current investigation.

The six-membered ring **5** reacts with $[PtCl_2(PEt_3)]_2$ in dichloromethane at room temperature to give the 1:1 adduct **8** in essentially quantitative yield according to the ^{31}P nmr spectrum of the reaction mixture. Attempts to attach a second platinum to the P_2N_3S ring by heating **8** with $[PtCl_2(PEt_3)]_2$ in boiling dichloromethane or chloroform were unsuccessful.

The composition of **8** was established by elemental analyses and the ^1H nmr spectrum (see Experimental section).

[3]This terminology for the conformation of eight-membered rings is taken from ref. 21.

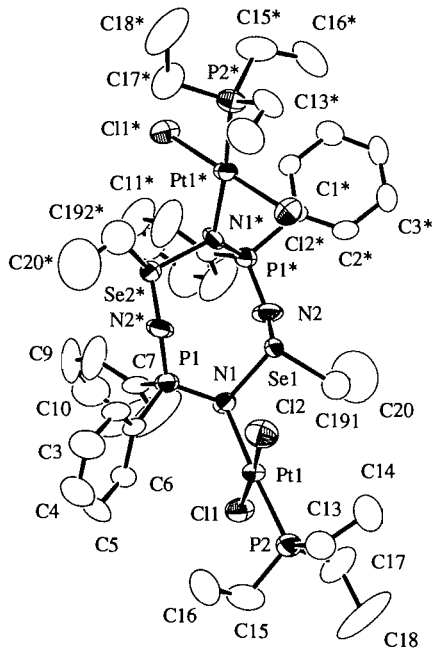

FIG. 2. ORTEP drawing for one long chair conformation of $[PtCl_2(PEt_3)]_2[Ph_4P_2N_4Se_2Et_2]$, *7b*, showing the atomic numbering scheme.

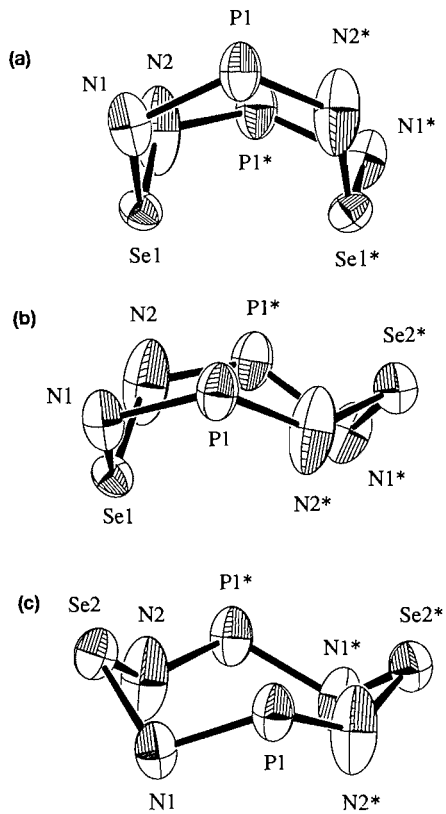

FIG. 3. ORTEP drawings of three conformations of the $P_2N_4Se_2$ ring in *7b*; (*a*) boat–boat (BB), (*b*) crown (CR), (*c*) long chair (LC). Only one of the LC conformations is shown.

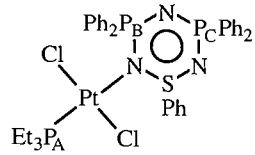
The ^{31}P nmr spectrum of **8** is uniquely consistent with a structure in which the $PtCl_2(PEt_3)$ group is attached to one of the sulfur-bonded nitrogen atoms and the PEt_3 ligand is *trans* to nitrogen. Three equally intense resonances are observed at 1.2, 10.0, and 20.5 ppm. The resonance at 1.2 ppm, which appears as a doublet (^3J(P—P) = 10 Hz) with platinum satellites (^1J(Pt—P) = 3637 Hz), is readily attributed to the PEt_3 ligand, while the signals at 10.0 and 20.5 ppm are assigned to the inequivalent ring phosphorus atoms P_C and P_B, respectively. The former appears as a singlet while the latter is a doublet (^3J(P—P) = 10 Hz) with platinum satellites (^2J(Pt—P)~40 Hz). The two-bond coupling between the inequivalent heterocyclic phosphorus atoms, P_B and P_C, could not be resolved. In the *N*-methylated derivative of **5** this coupling is *ca.* 6 Hz, but it was not resolved in the unsymmetrical 1:1 adducts of **5** with BX_3 (X = Cl, F) (23).



8

Previous studies of the interaction of PNS rings with electrophiles, have shown that the site of electrophilic attack is governed by electrostatic effects (24, 25). In the specific case of the P_2N_3S ring, however, the interaction with BCl_3 or methyl triflate is not regiospecific whereas protonation occurs exclusively at the unique nitrogen atom. It is possible, therefore, that the observed regiospecific adduct formation with the electrophile $PtCl_2(PEt_3)$ is controlled by steric effects.

Conclusions

The eight-membered rings 1,5-$Ph_4P_2N_4E_2R_2$ (E = S, Se) form either 1:1 (E = S) or 2:1 (E = Se) adducts with platinum(II). By contrast, the folded eight-membered ring $Ph_4P_2N_4S_2$ (**1**) forms the 1:1, 2:1, and 3:1 adducts $[PtCl_2(PEt_3)]_n(Ph_4P_2N_4S_2)$ (n = 1–3) (2). An X-ray structure of the 2:1 adduct of the open ring 1,5-$Ph_4P_2N_4Se_2Et_2$ (**4***b*) reveals features similar to those found for the corresponding adduct of the folded ring (4). In both cases the platinum atoms are attached to "distal" nitrogen sites of the $P_2N_4Se_2$ rings and the Pt—N distances are indicative of a weak interaction. The $P_2N_4Se_2$ ring in the 2:1 adduct of **4***b* exists as a mixture of at least two conformations but, as a result of the disorder, it is not possible to assess the effect of adduct formation on the geometrical parameters of the heterocyclic ring. In contrast to the behavior of Lewis and Brønsted acids, adduct formation between the six-membered ring $Ph_4P_2N_3SPh$ and platinum(II) occurs in a regiospecific manner to give the isomer in which the metal is attached to a nitrogen between the phosphorus and sulfur atoms.

Light-induced change of the molecular charge in a spironaphthoxazine compound

PAUL RYS,[1] RUTH WEBER, AND QINGLAN WU

Department of Industrial and Engineering Chemistry, Swiss Federal Institute of Technology, ETH, ETH-Zentrum, CH-8092 Zürich, Switzerland

Received March 4, 1993

PAUL RYS, RUTH WEBER, and QINGLAN WU. Can. J. Chem. **71**, 1828 (1993).

To evaluate the experimental conditions for the light-induced change of the molecular charge, the dependence of the photochromic reaction behaviour of the indolino spiro naphthoxazine compound 1,3,3-trimethyl-spiro[2*H*-indol 2,3′-[3*H*]naphth[2,1-*b*]-[1,4]oxazine] on the pH value of the solution is investigated. In the absence of UV light an acid–base equilibrium between the spiro form and a protonated closed form is established. By irradiation under appropriate acidic conditions the spiro form can be transformed into an open cationic form through the merocyanine form. Between the two open forms an acid–base equilibrium is established. Except for the closed protonated form the structures are confirmed by mean of NMR. The kinetics of the thermal ring-closing reaction of both forms are investigated by flash photolysis. It is shown that the ring-closing reaction proceeds exclusively via the merocyanine form. The p*K* values determined for both equilibria give the pH range, in which the light-induced change of the molecular charge occurs.

PAUL RYS, RUTH WEBER et QINGLAN WU. Can. J. Chem. **71**, 1828 (1993).

Dans le but d'évaluer les conditions expérimentales conduisant à un changement induit par la lumière de la charge moléculaire, on a étudié la dépendance du comportement de la réaction photochromique du composé indoline spiro naphtoxazine, 1,3,3-triméthyl-spiro[2*H*-indole-2,3′-[3*H*]napht[2,1-*b*]-[1,4]oxazine], sur la valeur du pH de la solution. En l'absence de lumière UV, il s'établit un équilibre acide–base entre la forme spiro et une forme protonée fermée. Par irradiation dans des conditions acides appropriées, on peut transformer la forme spiro en une forme cationique ouverte par le biais de la forme mérocyanine. Il s'établit un équilibre acide–base entre les deux formes ouvertes. À l'exception de la forme protonée fermée, on a confirmé les structures par RMN. Faisant appel à la photolyse éclair, on a étudié la cinétique de la réaction thermique de fermeture de cycle des deux formes. Il est démontré que la réaction de fermeture de cycle se produit uniquement par le biais de la forme mérocyanine. Les valeurs de p*K*, déterminées pour les deux équilibres, fournissent les valeurs de pH dans lesquelles le changement de charge moléculaire induit par la lumière se produit.

[Traduit par la rédaction]

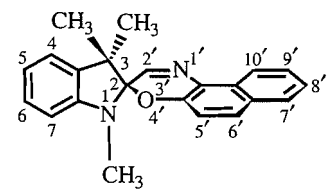
Introduction

Recently, the photochromic behaviour of indolinospiro-oxazine derivatives has been intensively investigated (1–6). This is mainly due to their rapid photoresponsive change of the molecular structure and the better photodurability as compared to the indolinospiropyran derivatives. The photochromism and the acid–base behaviour of indolinospiro compounds is summarized in Scheme 1.

By UV irradiation the C—O bond of the colourless spiroform A is cleaved and the coloured merocyanine form B is formed. The reverse reaction proceeds thermally or photochemically (5–11). In the case of spiropyran derivatives it has been established (12–18) that the zwitterionic B-form can be protonated to the cationic C-form. The same is expected for spirooxazine compounds.

Due to the different electronic structures and molecular geometries of the A-, the B-, and the C-forms, their physical and chemical properties, such as colour, polarity, charge, and their acidity and basicity are also different. The possibility to switch between the various forms and thus the various properties by turning the UV light on and off makes the spiro compounds interesting for practical purposes (6, 7). For optical data recording or regulation of light fluxes the interconversion between the spiro form A and the open form B is important. The merocyanine form B is obtained if the pH of the solution is in the range $pH > pK_1 > pK_2$. Most investigations dealing with the photochromism of spiro compounds have been carried out in this pH range (19–26). To obtain a light-induced change of the molecular charge the pH of the solution must be in the range $pK_1 < pH < pK_2$. Under these conditions the neutral spiro form A is transformed into the positively charged C-form by UV light. In the case of adsorbed spiropyran derivatives the light-induced change of the molecular charge can influence considerably the behaviour of the substrate, such as in polymer membranes (27, 28) or enzymes (29).

The present study aims at achieving a better understanding of the light-induced, reversible transformation of the A- into the C-form of the spironaphthoxazin compound 1,3,3-trimethyl-spiro[2*H*-indol 2,3′-[3*H*]naphth[2,1-*b*]-[1,4]-oxazine] **SP**.



Compound **SP**

The structures of the various forms are investigated by ^1H NMR experiments. The acid–base equilibria described in Scheme 1 as well as the kinetics of the thermal decolouration of the B- and the C-forms are studied quantitatively in buffered 50% (v/v) ethanol–water solutions at various pH values.

Experimental

Synthesis

The spirooxazin **SP** was synthesized following a method described in the literature (30).

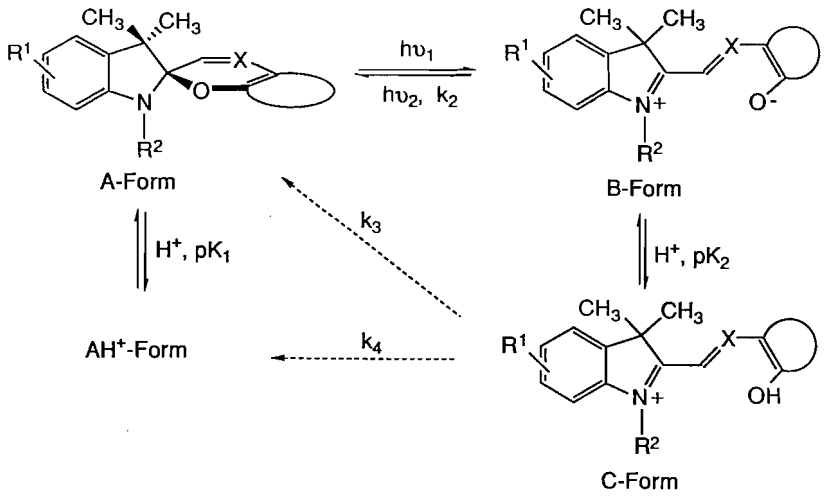

SCHEME 1. Photochromism of indolinospiro compounds under neutral and acidic conditions; X = CH: spiropyrane; X = N: spiroxazine; R_1, R_2: substituents.

TABLE 1. Buffer systems used to prepare the aqueous ethanolic solutions

Buffer system	pH range
0.01 M potassium hydrogen phthalate 0.01 M HCl	2.7–4.0
0.01 M potassium hydrogen phthalate 0.01 M NaOH	5.0
0.01 M potassium dihydrogen phosphate 0.01 M NaOH	6.0–8.0
0.005 M sodium bicarbonate 0.01 M NaOH	10.0

^1H NMR

The ^1H NMR spectra of the various forms of compound **SP** were determined in acetone-d_6 at −80°C on a Brucker AM300 WB. The concentration of the solution investigated was 0.03 M. After measuring the spectrum of the closed A-form, the NMR tube was transferred into a thermostated vessel and the solution was irradiated with UV light for 5 min. The spectrum of the B-form was measured immediately after irradiation. To obtain the spectrum of the C-form, 1–2 drops of 98% D_2SO_4 was added into the irradiated solution.

Kinetic studies and determination of pK_1 and pK_2

The kinetic studies and the determination of the dissociation constants of the AH^+- and the C-forms were carried out in buffered aqueous ethanolic solutions of compound **SP**. The buffer systems used to prepare the solutions are listed in Table 1, the various pH values were obtained according to 31.

The ionic strength of the buffer solutions was adjusted to 0.1 M by adding sodium chloride.

The spirooxazin compound **SP** was dissolved in ethanol and mixed with the buffer solutions in the ratio of 1:1 by volume. The concentration of compound **SP** in the final solution was $c = 2.317 \times 10^{-5}$ M.

The pH of the buffered ethanolic solutions was measured using a glass electrode. The values were corrected for solvent effects by subtracting 0.26 from the measured pH. The correction term was determined from a master curve obtained by measuring the pH of a set of standard solutions (32–35).

The dissociation constants pK_1 and pK_2 were determined from the pH dependence of the absorption of the AH^+-form at 350 nm and of the B- and C-forms at 620 nm and 530 nm, respectively.

The kinetics of the thermal ring-closing reactions and the VIS spectra of the irradiated solutions were studied using flash photolysis. The solutions were irradiated by a flash from a high-pressure mercury lamp. Immediately after irradiation, the absorption of the solutions was measured continuously at 530 and 620 nm.

Results and discussion

Photochromism and acid–base equilibria

The pH dependence of the UV spectra of compound **SP** in aqueous ethanolic solutions (1:1) before irradiation is shown in Fig. 1. Under slightly acidic conditions (curve 1) the spectrum of the colourless spiro form A with a maximum absorption at λ = 230 nm is obtained. With acidified solutions an additional peak appears at λ = 215 nm, the intensity of which increases with increasing acid concentration. This indicates the formation of a protonated form AH^+. The curves in Fig. 1 show three isobestic points at λ = 230, 260, and 290 nm, respectively. Thus, the total concentration of the A- and the AH^+-forms remains constant and an acid–base equilibrium is established between the two forms.

Figure 2 shows the VIS spectra of irradiated solutions of compound **SP** under neutral (curve 1) and acidic (curve 2) conditions, respectively. By irradiation of the neutral solution, the spiro form A is transformed into the merocyanine form B, which absorbs at λ_{max} = 620 nm. In ref. 6 the VIS spectrum of an irradiated solution of **SP** in pure ethanol at −75°C shows the maximum of absorption at 612 nm and a shoulder at 578 nm. A shoulder might be the explanation of the unsymmetrical shape of curve 1 in Fig. 2. As curve 2 in Fig. 2 shows, a new form is produced by irradiation of the acidic solution. In similar investigations with spiropyran derivatives (12–18) a protonated open structure is suggested for the form existing under the experimental conditions applied. The structure of the C-form in Scheme 1 with the long conjugated π-electron system may account for the maximum absorption at λ = 530 nm seen in Fig. 2.

To confirm the structure of the various forms suggested in Scheme 1, ^1H NMR spectra of neutral and acidic solutions before and after irradiation were measured. Since the thermal ring-opening reaction can be neglected at −80°C, the spectrum of the pure A-form is obtained at this temperature from the neutral solution. After irradiation, the peaks of the

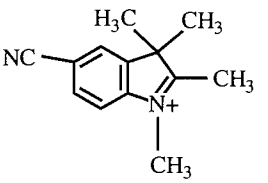
A- and the B-forms coexist in the measured ^{1}H NMR spectrum. From the intensities of the signals an approximate conversion of about 40% can be estimated. In the spectrum of the acidified irradiated solution no peaks of the A- and the B-forms were found. This indicates a complete conversion to the C-form.

Due to the low solubility of compound **SP** in aqueous ethanol, the ^{1}H NMR spectra had to be measured in acetone-d_6. The protonated form AH^+, postulated from the results of the UV/VIS spectroscopy (Fig. 1), could not be found in this solvent. Thus, no information about the structure of the AH^+ form was available from NMR spectroscopy.

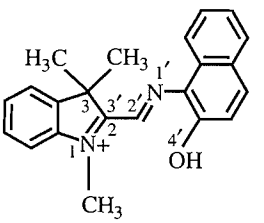
The significant peaks to distinguish between the spiro and the open structures of compound **SP** are those of the methyl groups at the C3 atom of the indolering. The existence and localization of the positive charge postulated for the open forms B and C can be discussed by means of the signals of the methyl group at the indole nitrogen atom. The chemical shifts measured in the spectra are listed in Table 2.

In the ^{1}H NMR spectrum of the neutral solution two singlets at 1.27 and 1.31 ppm, respectively, are seen for the two methyl groups at the C3 atom, which indicates that the two groups must be diastereotopic. This is in agreement with the unsymmetrical substitution of the spiro carbon. In the open merocyanine form, however, the two methyl groups become equivalent and therefore they are expected to show up as a single peak. Indeed this is the case with both the B- and the C-forms, as is shown in Table 2. Based on the NMR spectra, the postulated open structure of the C-form, which allows for the free rotation of the naphthol ring, could be confirmed.

The singlets of the methyl protons at the nitrogen atom of the indole ring are found at 2.73, 3.68, and 4.47 ppm for the A-, the B-, and the C-forms, respectively. The shift of the signal to lower magnetic fields indicates a decreasing electron density and thus an increasing positive charge at the indole nitrogen atom. The existence of a positive charge localized on the indole nitrogen in the C-form of compound **SP** can further be confirmed by the similarity of the chemical shifts of the peaks of the N-CH_3 protons of the C-form to those of the positively charged model compound 5-cyano-1,3,3-trimethyl-2-methylen-3*H*-indol.



δ_{NCH_3} = 3.94 ppm (solv. CD_3CN)



SP, C-Form

δ_{NCH_3} = 4.47 ppm (solv. CD_3COCD_3)

There are three positions in the B-form that can be protonated, namely, the indole nitrogen, the nitrogen N1′, and the oxygen O4′. Since the positive charge of the zwitterionic B-form is localized on the indole nitrogen and the difference of the chemical shifts of the proton at carbon C2′ in the B- and C-forms (Table 2) is very small, the protonation at one of the two nitrogen atoms can be excluded. Thus, the most probable position for a protonation of the B-form is the oxygen atom O4′, as suggested in Scheme 1.

According to the UV spectra in Fig. 1 an acid–base equilibrium between the spiroform A and a protonated form AH^+ is established under the experimental conditions applied. To determine the corresponding equilibrium constant K_1, the absorption of a number of buffered aqueous ethanolic solutions of compound **SP** was measured at λ = 350 nm. The results are shown in Table 3.

Using eq. [1]

$$[1] \quad pK = pH + \log \frac{A_{(\lambda)} - A_{M(\lambda)}}{A_{HM(\lambda)} - A_{(\lambda)}}$$

with pK: −log (acidity constant),

$A_{(\lambda)}$: measured absorption at the wavelength λ,

and the $A_{(\lambda)}$ values listed in Table 3, pK_1 = 2.26 ± 0.06 is obtained.

In Scheme 1 an acid–base equilibrium is also postulated between the open forms B and C of compound **SP**. The equilibrium is coupled to the kinetics of the thermal decolouration reactions of the two forms. By continuous absorption measurements at λ = 620 nm and λ = 530 nm the concentrations of the B- and the C-forms were measured as a function of time starting immediately after the irradiation of the solutions. For any solution investigated, the ratio of the absorption of the B-form and the C-form is constant over the reaction time, as shown in Fig. 3. Consequently, the acid–base equilibrium between the two forms is established during the decolouration reaction and eq. [1] can be used to determine pK_2. From the $A_{(\lambda)}$ values shown in Table 4, pK_2 = 4.00 ± 0.05 is obtained.

The coupling between the acid–base equilibrium and the thermal decoloration reactions

The continuously measured decrease of the absorption of the B- and C-forms of compound **SP** is shown in Fig. 4 for pH = 5.0. For all solutions investigated, the thermo decolouration of both forms is seen to be a first-order reaction, the kinetics of which can be described by eqs. [2] and [3].

$$[2] \quad -\frac{d[B]}{dt} = k_{Bexp}[B]$$

$$[3] \quad -\frac{d[C]}{dt} = k_{Cexp}[C]$$

with [B], [C]: concentrations of the B- and the C-forms and

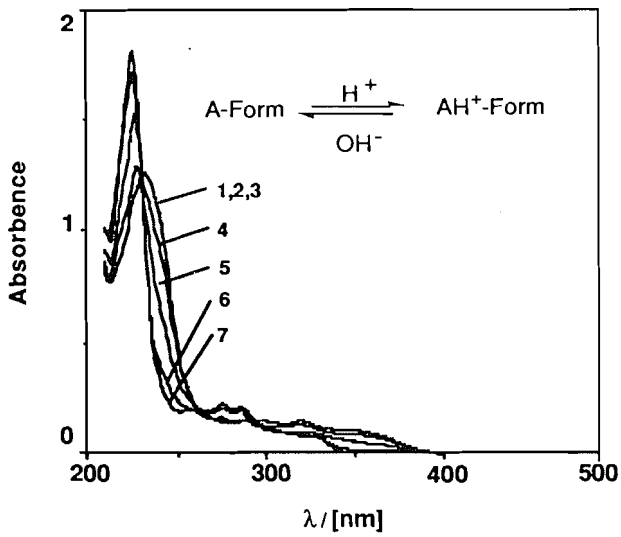

FIG. 1. UV/VIS spectra of 50% aqueous ethanolic solutions of compound **SP** in dependence on the pH value, T = 20°C; c = 2.317 × 10^{-5} M; no UV irradiation. 1: pH = 4.52; 2: pH = 3.88; 3: pH = 3.19; 4: pH = 2.67; 5: pH = 2.04; 6: pH = 1.44; 7: pH = 1.28.

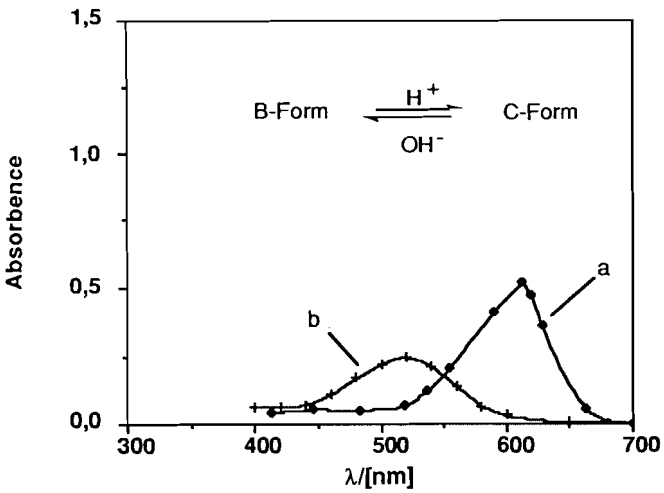

FIG. 2. VIS spectra of irradiated 50% aqueous ethanolic solutions of compound **SP** under neutral (a: pH = 7.0) and acidic (b: pH = 3.0) conditions, T = 20°C; c = 2.317 × 10^{-5} M.

TABLE 2. Chemical shifts of the essential peaks in the ^{1}H NMR spectra of the A-, B-, and C-forms of compound **SP** in acetone-d_6 at −80°C

Proton	Chemical shift (ppm)		
	A-form	B-form	C-form
$C(3)(CH_3)_2$	1.27; 1.31	1.86	2.06
$N(1)CH_3$	2.73	3.68	4.47
C(10′)-H	8.53	8.30	8.61
C(2′)-H	7.95	10.09	10.17

k_{Bexp}, k_{Cexp}: experimentally determined reaction rate constants.

The reaction rate constants calculated from the experimental results are listed in Table 4 together with the corresponding pH values of the solution.

TABLE 3. Absorption of compound **SP** at λ = 350 nm in dependence on the pH value of the solutions

pH	1.64	1.71	2.05	2.78	3.68	4.48	6.80
$A_{(350\ nm)}$	0.093	0.120	0.193	0.413	0.468	0.500	0.527

T = 20°C; solvent: ethanol/water = 1/1 (v/v); c = 2.18 × 10^{-4} M; A_M = 0.527; A_{HM} = 0.000.

For any chosen pH value of the solutions investigated, the reaction rate constants of the decolouration of the B- and the C-forms are equal within experimental error. With increasing pH, k_{Bexp} and k_{Cexp} increase, and for pH > 5 approach the constant value 0.152 ± 0.002 s^{-1}. Similar effects have been found for spiropyran derivatives (36). Scheme 1 outlines decolouration pathways considered, which are coupled to the acid–base equilibrium between the B- and the C-forms. Taking into account the first-order kinetics of the decolouration reactions, the change of the total concentration of the B- and the C-forms is described by eq. [4].

$$[4] \quad -\frac{d([B] + [C])}{dt} = k_2[B] + (k_3 + k_4)[C]$$

By introducing the equilibrium constant K_2

$$[5] \quad K_2 = \frac{[H^+][B]}{[C]}$$

into eq. [4] and eliminating the concentration of the C-form, eq. [6] is obtained.

$$[6] \quad \frac{d[B]}{dt} = -\frac{k_2K_2 + (k_3 + k_4)[H^+]}{K_2 + [H^+]}[B]$$

For a constant pH value, eq. [6] describes a first-order reaction with the overall reaction rate constant k_{Bcal}.

$$[7] \quad k_{Bcal} = \frac{k_2K_2 + (k_3 + k_4)[H^+]}{K_2 + [H^+]}$$

For the C-form, the same calculation leads to eqs. [8] and [9].

$$[8] \quad \frac{d[C]}{dt} = -\frac{k_2K_2 + (k_3 + k_4)[H^+]}{K_2 + [H^+]}[C]$$

$$[9] \quad k_{Ccal} = \frac{k_2K_2 + (k_3 + k_4)[H^+]}{K_2 + [H^+]}$$

Comparison of eqs. [7] and [9] shows, that k_{Bcal} and k_{Ccal} are identical for any chosen pH value. Furthermore, if $(k_3 + k_4) \ll k_2$ and $[H^+] < K_2$ then k_{Bcal} and k_{Ccal} approach the constant value k_2. Thus, eqs. [7] and [9] show qualitatively the same pH dependence of the reaction rate constants as the experimentally determined values listed in Table 3.

Introducing k_2 = 0.152 ± 0.002 s^{-1} into eq. [7] or [9], the expression [10] with the fit parameter $(k_3 + k_4)$ and K_2 is obtained.

$$[10] \quad k_{Ccal} = k_{Bcal} = k_{cal} = \frac{k_2K_2 + (k_3 + k_4)[H^+]}{K_2 + [H^+]}$$

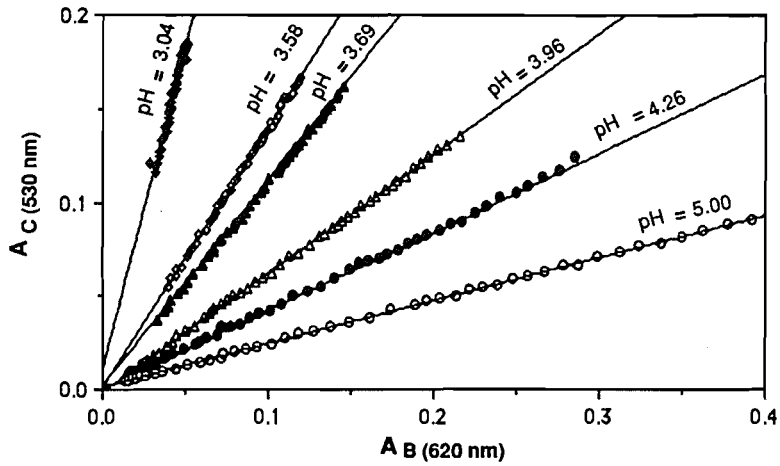

FIG. 3. Absorption $A_{B(530\ nm)}$ and $A_{C(620\ nm)}$ of compound **SP** during the thermal decolouration reaction.

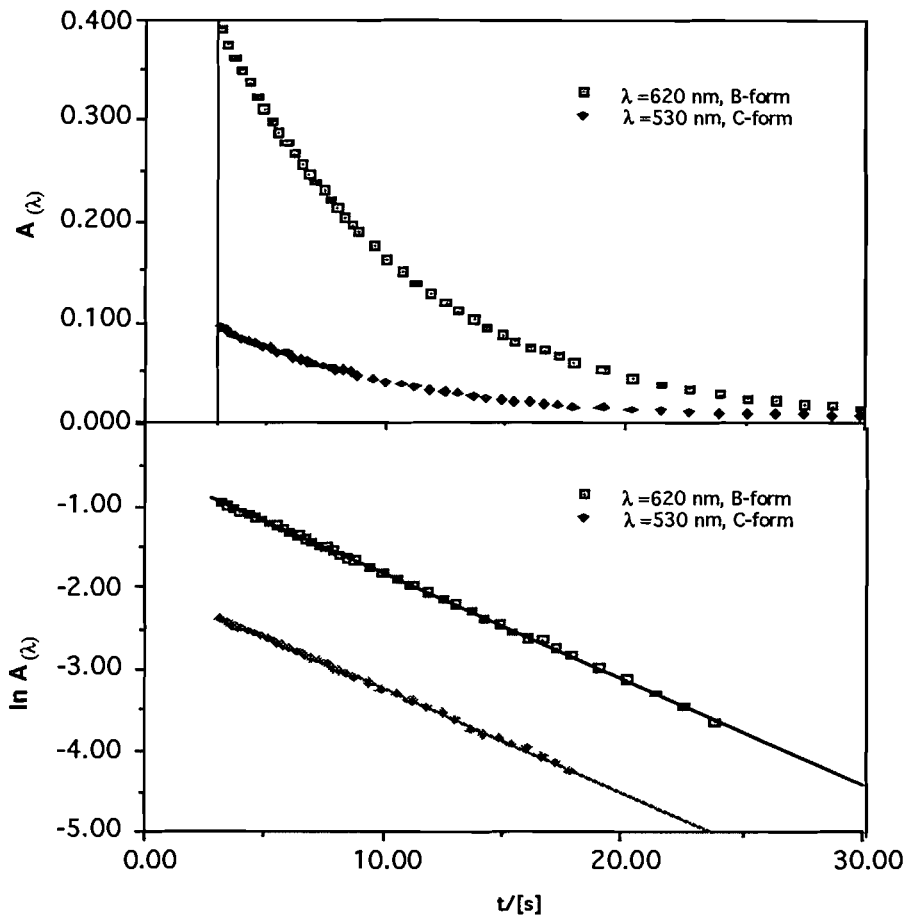

FIG. 4. Time dependence of the absorption ($A_{(\lambda)}$ and ln $A_{(\lambda)}$) of the B- and the C-forms of compound **SP** in the solution of pH = 5.0 during the decolouration reaction.

Using eq. [10], the best fit for the experimentally determined values k_{Bexp} and k_{Cexp} is obtained with $(k_3 + k_4) = 0$ and $pK_2 = 3.95$. In Fig. 5 the experimental results are presented together with the fitting curve. The fit parameter $pK_2 = 3.95$ and the experimentally determined value $pK_2 = 4.0 \pm 0.05$ are in good agreement within experimental error.

Since $(k_3 + k_4) = 0$, the direct decolouration from the C-form to the A- or AH^+-form as considered in Scheme 1 can be neglected. Thus, the ring closure of the C-form proceeds via the B-form. This is in agreement with the fact observed in the experiments, that the equilibrium between the B- and the C-forms is established during the decolouration and the reaction rate constants k_{Bexp} and k_{Cexp} are the same for both forms.

Conclusion

To study the light-induced change of the molecular charge, the pH dependence of the photochromic properties of the

spirooxazin compound **SP** in buffered aqueous ethanolic solutions was investigated. In the absence of UV light, the compound mainly existed in the uncharged spiroform A. By irradiation, the zwitterionic merocyanine form B was produced. In acidified solutions, an acid–base equilibrium between the spiroform A and AH^+ was established. By acidifying an irradiated solution, the merocyanine form B could be protonated. With the help of ^1H NMR measurements, the structure of the new form C was identified as a ring-open structure with the positive charge localized on the nitrogen atom of the indole ring. Furthermore, the existence of an acid–base equilibrium between the B- and the C-forms was confirmed by flash photolysis experiments. Results from the present studies would suggest that the ring closure of the C-form proceeds via the B-form. As the B-form undergoes decolouration, the equilibrium between the B- and the C-forms is shifted towards the formation of the B-form, thus compensates its disappearance.

The dissociation constants of the AH^+- and the C-forms were determined as $pK_1 = 2.3$ and $pK_2 = 4.0$, respectively. Thus, a light-induced transformation between the neutral spiroform A and the positively charged C-form could be achieved in the pH range $2.3 < pH < 4.0$.

ROBERT C. BURK
Centre for Analytical and Environmental Chemistry, Carleton University, Ottawa, ON K1S 5B6, Canada

Received November 13, 1992[2]

MARK L. O'NEILL, PEETER KRUUS, and ROBERT C. BURK. Can. J. Chem. **71**, 1834 (1993).

Spectroscopic studies of the compound 2-nitroanisole in supercritical fluids CO_2 and N_2O show that π^* values vary linearly with density. The solubility trends in these single component supercritical fluid solvents qualitatively followed the trends in solvent power predicted from π^*. However, the relative solvent power predicted for CO_2 and N_2O based on π^* resulted in an opposite order to what was determined experimentally through solubility measurements. The π^* parameter may be of some use for solubility prediction if only a limited set of solute–solvent systems are considered. Measurements of π^*, especially those in binary supercritical fluid solvents, suggest that π^* could be a valuable tool for probing the solute-organized cybotactic region.

MARK L. O'NEILL, PEETER KRUUS et ROBERT C. BURK. Can. J. Chem. **71**, 1834 (1993).

Des études spectroscopique du 2-nitroanisole dans les liquides supercritiques CO_2 et N_2O présente des valeurs de π^* qui varient d'une façon linéaire avec la densité. Les variations de solubilité dans ces fluides supercritiques à un seul composant suivent qualitativement les tendances du pouvoir de solvant que l'on peut prédire à l'aide de π^*. Toutefois, les pouvoirs relatifs de solvant prédits pour le CO_2 et le N_2O sont opposés à ceux déterminés expérimentalement par les mesures de solubilité. Le paramètre π^* peut s'avérer utile pour prédire la solubilité si on ne considère qu'un ensemble limité de systèmes soluté–solvant. Les mesures de π^*, spécialement celles dans des solvants supercritiques binaires, suggèrent que π^* peut s'avérer un outil utile pour étudier la région cybotactique d'un soluté organisé.

Introduction

The use of supercritical fluids (SCFs) in extraction technology has become more common over the past several years (1, 2). One of the advantages of SCFs over liquid solvents is that their high compressibilities allow for substantial and continuous changes in density and other physicochemical properties without changing the chemical nature of the solvent.

Theories of solvation for liquid state solvents are well established (3, 4), but extensions of these to supercritical fluids are often not available. The characterization of solute–solvent interactions through such things as shifts in the ultraviolet–visible absorption maxima of organochromophores (solvatochromic shifts) should make it possible to predict solubilities in fluid solvents, including SCFs. Solvatochromic shifts are indicative of the types of interactions between the solvent and the solute in the immediate vicinity of the solute, referred to as the solute's cybotactic region. The resulting changes in the physical properties of the supercritical fluid are reflected by changes in the solvatochromic parameter π^*.

Several groups have used the solvatochromic parameter π^* to predict solvent strength (5–9). Some studies have also examined the behaviour of π^* in SCF solvents (10, 11). The variability of solvent power through density in one-component SCF solutions makes it possible to test the validity of the linear free energy relations underlying the concept of solvatochromic shifts. Here the relation tested is that between the logarithm of the solubility and π^*.

Binary SCF solvents are often used in SCF extractions as they can improve the solvent power and selectivity. An organic cosolvent (i.e., the minor component of the solvent mixture) can have the ability to extend the range of the desirable characteristics of the fluid to much lower pressures while retaining the major advantages of SCFs (1). In binary solvent systems a preferential enrichment (clustering) by one of the solvent components in the cybotactic region of a compound is detectable by changes in π^*. It is of interest here to quantify this effect in both single and binary SCF solvents in order to accurately predict changes in the solvent power from π^* values.

Linear free energy relations

Linear free energy relationships for solutions are used to quantify solvent effects on many types of physicochemical properties. The shifts of $p\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ electronic transition energies of solute molecules due to interactions between solvent and solute molecules can be characterized by the general relationship (6):

$$[1] \quad XYZ = XYZ^0 + h(\delta_h^2) + s(\pi^* + d\delta) + a\alpha + b\beta$$

Here XYZ is some specific physical characteristic of the solute such as the position of maximum absorption in a UV–VIS or NMR spectrum, a free energy or heat of solution, or the logarithm of a solubility or some other equilibrium constant. XYZ^0 refers to the value of that given characteristic at given reference conditions. We will be concerned with the position of the maximum in the UV–VIS absorption peak, ν_{max}, and the logarithm of the solubility.

The latin alphabet coefficients in eq. [1] (a, b, d, h, s) correspond to properties of the solute, and the greek alphabetic symbols (α, β, δ, δ_h, π^*) to those of the solvent. The parameter $d\delta$ is a polarizability correction term for solvent type, which is zero when nonchlorinated and nonaromatic solvents are used. The α and b parameters refer to the hy-

[1]Author to whom correspondence may be addressed.
[2]Revision received June 18, 1993.

drogen-bond donor (HBD) acidities of the solvent and the solute, respectively, while β and *a* refer to their hydrogen-bond acceptor (HBA) basicities. The terms ($a\alpha$) and ($b\beta$) can also be reduced to zero if nonprotic solutes and solvents are employed. The *h* parameter, a differential cavity term, is a function of solute molecular size. From the Frank–Condon Principle, the change in molecular volume on going from the ground to excited state species of the solute is very small (12), and the overall contribution of $h(\delta_h^2)$ is negligible. For the purposes of this study, eq. [1] can therefore be reduced to the form

$$[2] \quad \nu_{max} = \nu^0_{max} + s\pi^*$$

In such cases, interactions between solute and solvent are restricted to nonspecific dispersion-type forces, and a linear relation between π^* and solvent strength is predicted (9). There are no further variables present that could explain any nonlinearity in this predicted linear relation.

The solute parameter *s* is a measure of the susceptibility of the solute to changes in solvent polarity. The value of *s* for a specific solute can be obtained using solvents of known π^* value, as *s* is the slope of a graph of the absorption maximum energy, π_{max}, versus π^*. To decrease errors due to instrument resolution and spectral anomalies, solutes with large *s* values should be employed. A negative *s* value is indicative of a solute that has an electronically excited state that is stabilized more than its ground state with increases in solvent π^* value, reducing the energy of the $p \rightarrow \pi^*$ or $\pi \rightarrow \pi^*$ transitions and thus reducing the energy of the absorption maximum.

In binary solvent mixtures, the cosolvent can show enrichment in the cybotactic region due to more favourable solute–cosolvent intermolecular interactions (13). This should be reflected in the solvatochromic shifts observed. In the specific case of a solute that has an excited electronic state of higher polarity than its ground state, small additions of a polar cosolvent to a less polar primary solvent should show relatively large changes in π^* due to greater interactions with the excited state species of the solute. Further incremental additions of cosolvent will affect π^* to a point, beyond which more additions will have minimal effect (i.e., π^* asymptotically approaches the value for pure cosolvent). This can be thought of as the cybotactic saturation point of the cosolvent about the solute.

The mole fraction of cosolvent in the cybotactic region (i.e., the local mole fraction) was estimated by Yonker et al. (8) by use of the following equation

$$[3] \quad \Delta\pi^* = \pi^*_m - \pi^*_c = \pi^*_m - (X_{12}\,\pi^*_1 + X_{32}\,\pi^*_3)$$

where π^*_m and π^*_c are the measured and calculated values for the binary mixture, X_{12} and X_{32} are the local mole fractions of cosolvent and primary solvent about the solute approximated by the bulk fluid values, and π^*_1 and π^*_3 are the solvatochromic parameters for the pure cosolvent and primary solvent.

Experimental

Materials and equipment

The solute chosen to be studied was 2-nitroanisole (**1**, Aldrich Gold Label, 99+%), due to its reasonable *s* value (−2.43 ± 0.20), absorption maximum position ($\nu_0 = 32.56 \times 10^{+3}$ cm^{-1}), and widespread use in many previous studies (2, 8, 9). The polyaromatic hydrocarbons chrysene (**2**), *meta*-terphenyl (**3**), and anthracene (**4**) were chosen for study mainly because of their physicochemical nature and the availability of their SCF solubility data (14, 15). All solids were recrystallized before use. The absorption maxima of **1–4** were determined in various pure solvents (pentane, hexane, cyclohexane, ethyl ether, acetone, ethyl acetate, tetrahydrofuran, dimethyl sulfoxide). All of the solvents used were spectro grade (ACS/Caledon, Anachemia, Fisher Scientific, Eastman–Kodak); their absorption spectra were measured versus air in the range 250–400 nm. Liquid solution spectra were run on a Perkin–Elmer Lambda 4B UV–VIS spectrophotometer using quartz cells of 1.00 cm path length with pure solvent as the reference.

Supercritical fluid solvents used were CO_2 (Air Products, 99.8% pure in the gas phase, dip tube) and N_2O (Air Products, 99.0+% pure in the gas phase). Tetrahydrofuran (THF) was used as a cosolvent in CO_2. Care should be taken in the handling of high-pressure N_2O, especially when using organic cosolvents, because of its strong oxidizing power.

A Milton–Roy UV–visible Critical Extraction Monitor (CEM) with a thermostatted high-pressure optical cell (6000 psi (1 psi = 6.89 kPa), 25–60°C, spectral bandwidth 3 nm) was used to obtain supercritical phase spectra of compound **1**. The CEM was first tested with liquid solutions and the results were compared to spectra obtained from the Lambda 4B. This comparison showed the CEM to have a systematic error of 260 cm^{-1}, which was corrected for in subsequent data.

A high-pressure Milton–Roy miniPump piston pump (type NSI-33R, model 920231) was used to pressurize the supercritical solvent. The system pressure was measured with an Alltech flow-through pressure gauge (0–6000 psig) to ±20 psig. The internal volume of the system was intentionally increased by approximately 50% to dampen the effect of the cycling of the pump. Flow of the solution through the cell was limited so that temperature equilibration to above the critical temperature (T_c) of the solution was obtained before it entered the cell space. The pressure drop downstream from the gauge to the cell was calculated to be negligible at the flow rates used. For all SCF spectra measured the temperature of the CEM cell was kept constant at 40.0 ± 0.5°C using the Milton–Roy CEM cell heater.

Procedure

Solutions were prepared in a high-pressure vessel of approximately 150 mL internal volume by first adding solute (approximately 12 mg of **1**), and then cosolvent if required. The vessel was then chilled in ice water and the desired solvent (CO_2 or N_2O) was condensed into it. The solutions were allowed to equilibrate at room temperature for a minimum of 12 h before use. The system was flushed with at least two system volumes of solution (approximately 10 mL solution) before measuring a spectrum.

The CEM is a single beam type spectrophotometer. Baselines of blank solutions were therefore tested initially before any solution spectra, and all SCF spectra were subsequently corrected for baseline variation. Spectral data from the CEM were obtained as digital readout. The most accurate method to get an absorption maximum was found to be a plot of the change in absorbance, over a 2.5 nm wavelength range, versus the mean wavelength. The differentiated data produce an intercept with the *x*-axis that designates the absorption maximum.

Spectroscopic measurement of CO_2 and N_2O solutions on the CEM were performed twice, with two separately prepared solutions, in alternating order, and of slightly different concentration of solute (80 and 110 ppm). The order of pressures and of solutions used was varied to ensure reproducibility in the experimental procedure and the data.

The apparatus setup and procedure used for measuring solubilities in SCF systems was taken from Burk *et al.* with only a few alterations (15). Solute solubilities were obtained by passing solvent at a given pressure through a 1/4-in. stainless steel tube, ca. 15 cm in length, packed with solute. Screens (10 μm mesh size) were placed inside end-fittings to prevent solid solute from being

pushed through. A restrictor made of 1/16-in. stainless steel tubing with a crimped end was used as the outlet. This was heated to prevent crystallization of solute during decompression. The solute was trapped in a gas-tight glass U-tube, which was cooled in ice water externally and packed with stainless steel balls to ensure that all solute was being collected. The glass tube was plugged with Pyrex wool near the end to trap any solid particulates that may get blown through. Flow rates of outgases were measured with a bubble flow meter to allow for back-calculations of solvent flow rates, and to ensure that the flow rates were slow enough to allow the solvent to become saturated with solute before deportment from the column. The trap was then rinsed, using spectro grade dichloromethane (Caledon), into a 10.00 mL volumetric flask. The quantitation of solutes was performed on a Varian Saturn II GC–MS, instrument.

Results and discussion

Solvatochromic shifts

Liquid solutions

A ν^0_{max} (intercept) of $(32.60 \pm 0.02) \times 10^{+3}$ cm^{-1} and an s value (slope) of (-2.42 ± 0.15) were determined from an ν_{max} versus π^* plot from measured spectra of **1** in various non-HBD (Handinson–Brobst–Thompson) liquid solvents. This compares reasonably well with the accepted values for **1** quoted in the experimental section. With both solute and solvent having only HBA character, the shifts in ν_{max} are free of hydrogen-bonding effects. The values of π^* used for various liquids were taken from ref. 7.

Varying the solute concentration from approximately 80 to 110 ppm showed no effect on the ν_{max} values of the liquid spectra measured. This eliminated the problem of attempting to keep the solution composition constant throughout the experiments with SCF solvents.

The UV–VIS spectra of **2–4** were also measured in several liquid solvents for the purpose of comparison of solvatochromic trends with solubility data. The solvents used provided a π^* range of −0.08 (hexane) – 1.0 (dimethyl sulfoxide). The s values proved to be very small and difficult to determine accurately due to the relatively inert behaviour of these of solutes towards changes in solvent type.

Supercritical fluid solutions

Figures 1*a* and 1*b* show the variation of π^* with reduced density (ρ_{red}) for CO_2 and N_2O, respectively. The values for π^* were obtained by correlation with the s value of **1** determined from liquid solution measurements. The densities and critical parameter values of the SCF solvents were calculated from the Handinson–Brobst–Thompson (HBT) equation of state, and commonly used mixing rules when required (4). The values determined for π^* indicate that CO_2 and N_2O should show similar solvent powers as nonpolar to slightly polar organic solvents. Both CO_2 and N_2O are assumed to have negligible hydrogen-bonding effects with **1** due to their essentially only HBA character at the densities used here (16).

The data in Figs. 1*a* and 1*b* also show that the π^* values obtained for CO_2 differ from previously reported data (2, 5, 9), even after correcting for systematic errors and allowing for a significant experimental uncertainty. Some of this error may be accounted for by the slightly different temperatures at which the data were obtained. Large discrepancies are commonly seen in the measured π^* values for solvents using various chromophores (12), and are attributed to solute-specific effects. However, the π^* values for CO_2 and N_2O from the literature were obtained using the same solute probe (2-nitroanisole). The errors in the calculated ρ values for all SCF mixtures from the HBT equation of state are assumed to be negligible compared to instrumental errors from the CEM.

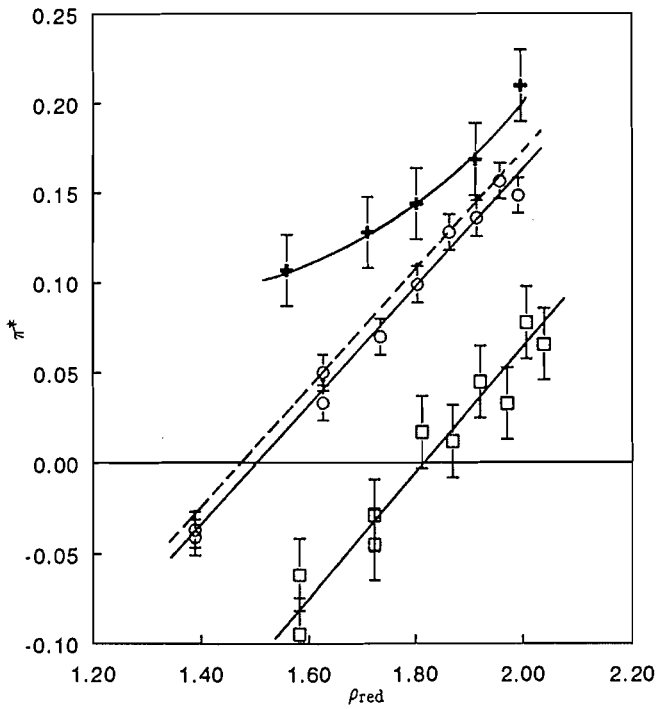

FIG. 2. Experimental π^* values for CO_2 (circles), N_2O (squares), and CO_2/2.0 mol% THF (crosses) versus reduced density (ρ_{red}) at 40°C using 2-nitroanisole. The dashed line corresponds to the calculated CO_2/THF π^* values based on a bulk mole fraction average.

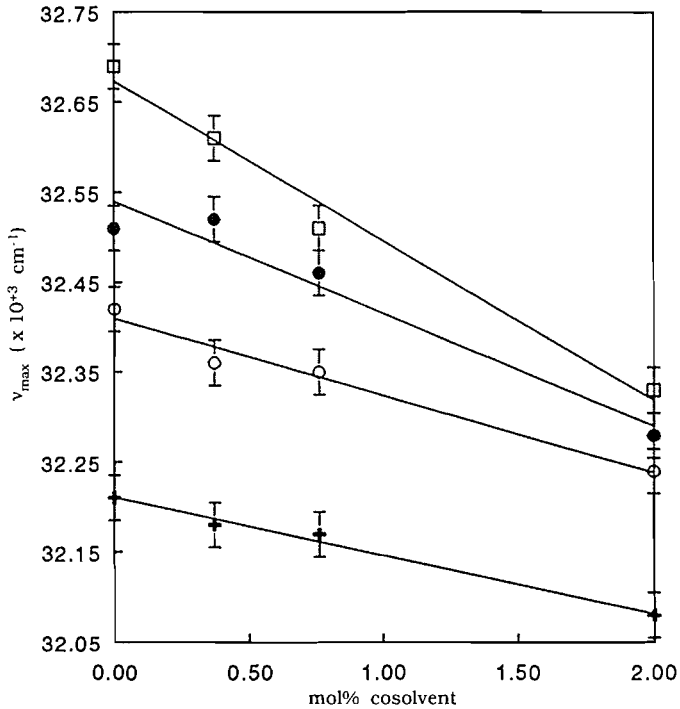

FIG. 3. Absorbance maxima energy (ν_{max}) for 2-nitroanisole versus mol% cosolvent at pressures of 103 bar (squares), 138 bar (filled circles), 173 bar (hollow circles), 310 bar (crosses). All values were obtained at 40°C.

It is worth noting that studies using Nile Red as a solute in SCF solutions produced inadequate resolution of solvent strength differences with pressure using π^* (17). There is, however, excellent correlation in the $\Delta\nu_{max}$ values obtained for the Nile Red data and the data reported here for **1** in liquid solutions (i.e., $\Delta\nu_{max} \simeq 1.5 \times 10^{+3}$ cm^{-1} with a $\Delta\pi^* \cong 1.1$ for both chromophores).

Figure 2 shows the variation of π^* with reduced density for CO_2, N_2O, and CO_2/2.0 mol% THF. THF was chosen as the cosolvent for CO_2 because of its low cutoff wavelength, and its physicochemical properties (i.e., HBA, non-HBD, polarity, and π^* value). It also proved to be miscible with CO_2 in the required composition range.

The positive slopes for both CO_2 and N_2O in Figs. 1*a* and 1*b*, respectively, are explained by the increase in the absolute number of solute–solvent interactions when density is increased. These π^* values indicate that CO_2 is the stronger solvent. This seems counterintuitive considering that N_2O has a small dipole moment (0.17 D). Assuming the polarizability of N_2O to be no larger than for CO_2, the stronger solvent power as measured spectroscopically must be a result of a larger degree of clustering of solvent molecules in the cybotactic region of the solute. The π^* values for N_2O may be affected to a certain degree by an increase in the number of unfavourable solvent–solvent interactions (increasing with density) that occur during nonspecific-type molecular interactions. This effect may be great enough in N_2O, as compared to CO_2, to effectively decrease clustering in the cybotactic region of **1**, destabilizing the electronic states of the solute.

Figure 2 shows that CO_2/THF has higher π^* values than CO_2. The variation in π^* with ρ also appears to be nonlinear. The increase in π^* values from the pure solvent values can be attributed to the contribution of stronger dipolar interactions between THF and the solute molecules. A nonlinear trend in values may be attributed to preferential clustering of the cosolvent molecules about the solute. When the experimentally determined data are compared to the calculated values based on a bulk mole fraction average, the largest amount of clustering is seen at lower pressures. Since solute–cosolvent effects dominate at lower densities where the fluid is more compressible, higher densities should produce a π^* trend that asymptotically approaches that of the calculated bulk fluid values. This is also suggested by the data in Fig. 2.

The effect of cosolvent concentration on the absorption maximum of the solute can be seen in Fig. 3. The largest changes in ν_{max} with respect to cosolvent mole fraction are seen at lower pressures due to the drastic effect pressure has on the bulk fluid density in this highly compressible region. The effect of pressure on ν_{max} is less pronounced as the amount of cosolvent is increased, and can be interpreted as a decrease in compressibility of the fluid in the solute cybotactic region due to preferential cosolvent clustering (18).

A local mole fraction cosolvent in the cybotactic region (X_{12}^{loc}) can be obtained from spectroscopic data based on a simple mole fraction average calculation:

$$[4] \quad X_{12}^{loc} = (\pi_m^* - \pi_3^*)/(\pi_1^* - \pi_3^*)$$

In Fig. 4, the X_{12}^{loc} calculated using eq. [4] are plotted versus pressure. These curves show definite trends in the reduction of X_{12}^{loc} with increasing pressure. The relative clustering (calculated X_{12}^{loc} versus the bulk fluid X_{12}) is much larger at lower pressures, and clearly shows the preferential clustering effect of the cosolvent. The results using eq. [4] are only

semiquantitative as errors produced from absorption values used to calculate π^* values are relatively large at such low cosolvent mole fractions. The determined X_{12}^{loc} values are, however, in agreement with more quantitative clustering data reported in ref. 18. Kim and Johnston report, at a bulk cosolvent concentration of 2.0 mol%, a reduction in the average cosolvent enrichment (cosolvents: acetone, methanol, ethanol, and *n*-octane) of the cybotactic region from about 14 mol% at 80 bar to only about 4 mol% at 300 bar (1 bar = 100 kPa).

Solvatochromic data provide information concerning the solute-organized cybotactic region of both single-component and binary-component SCF solvents (18, 19). The use of such solvatochromic parameters is, however, restricted to compounds that absorb light in the UV–visible spectrum. As well, π^* values themselves have proven to be somewhat solute specific.

Solubility

Predicting solvent power

Very little work has been done on the quantitative prediction of solvent power in SCF systems. The bulk of the quantification data on solubilities and increases in solvent power was done for systems that have specific solute–solvent interactions (e.g., H-bonding) (13, 20, 21). Much less success has been realized for the seemingly simpler systems possessing only nonspecific-type interactions (i.e., dispersion forces). There has been some use made of solvatochromic data for binary solvent systems, and there is a possibility that these could be of significant utility for solubility predictions (18).

The Hildebrand solubility parameter (δ_h) is the most commonly used parameter for the prediction of solubilities in liquids. Through empirical formula, it has been extended for use in the supercritical regime (22). Conceptually, it is a measure of the amount of energy necessary to create a cavity amongst solvent molecules for the solvation of a solute, better known as the cohesive energy density. As both δ_h and π^* vary linearly with fluid density in single-component SCF solvents, then δ_h also varies linearly with π^*. This indicates that for CO_2 and N_2O the number of solvent–solute interactions, which increases with increasing density, is the determining factor in predicting solvent power both for π^* and δ_h.

A comparison of π^* and δ_h data for CO_2/THF shows a similar, apparently nonlinear, trend to that seen in Fig. 2. The calculated δ_h values vary linearly with density as they are influenced solely by that parameter; preferential clustering is not considered. The π^* parameter therefore seems to be a more universal parameter for the prediction of solvent power, into which the strengths of nonspecific interactions are incorporated. This would be especially true for multicomponent SCF solvents.

It is generally not this easy to predict solubilities immediately from π^*, as solute character must also be considered. In our case, solute–solvent interactions may be considered identical when comparing solvatochromic and solubility data, due to the nature of **1**. It should be noted that π^* correlates well with a variety of other "solvent scales" when only restricted solvent–solute combinations are used (23), identical to the restrictions placed on the systems studied here.

Comparison to solubility data

The solubilities of **2** and **3** in both CO_2 and N_2O are plotted in Fig. 5 as the logarithm of the solute mole fraction versus solvent reduced density. Depicting the solubility in

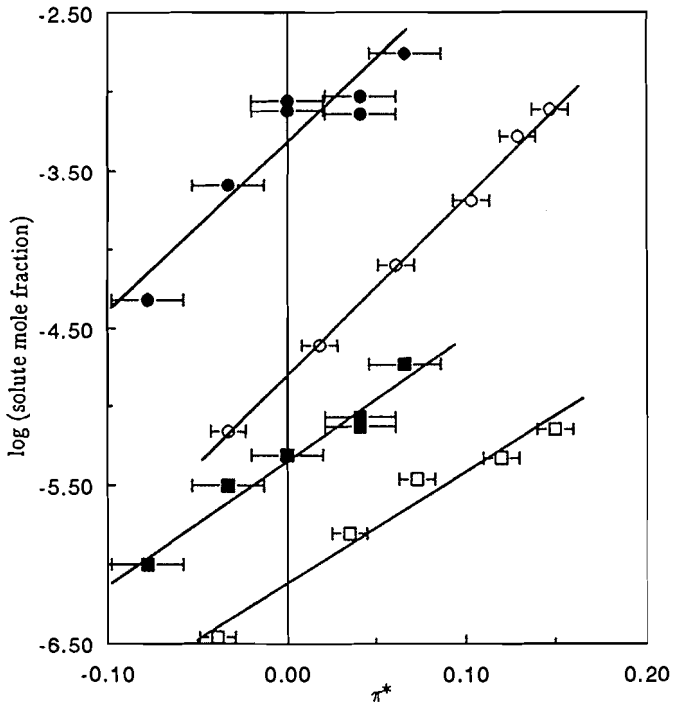

FIG. 6. Solute solubility in CO_2 (hollow symbols) and N_2O (filled symbols) versus the solvatochromic parameter (π^*) at a temperature of 40°C. The circular symbols correspond to *meta*-terphenyl, the square symbols to chrysene.

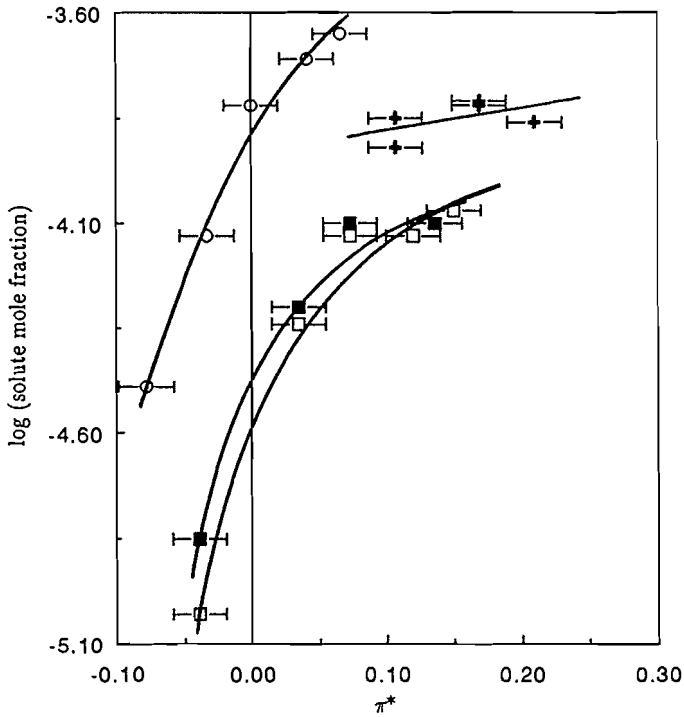

FIG. 8. Anthracene solubility versus solvatochromic parameter (π^*) in CO_2 for this study (hollow squares) at 40°C and from ref. 14 (solid squares) at 35°C; in N_2O (circles) and in CO_2/1.7 mol% THF (crosses), both at 40°C.

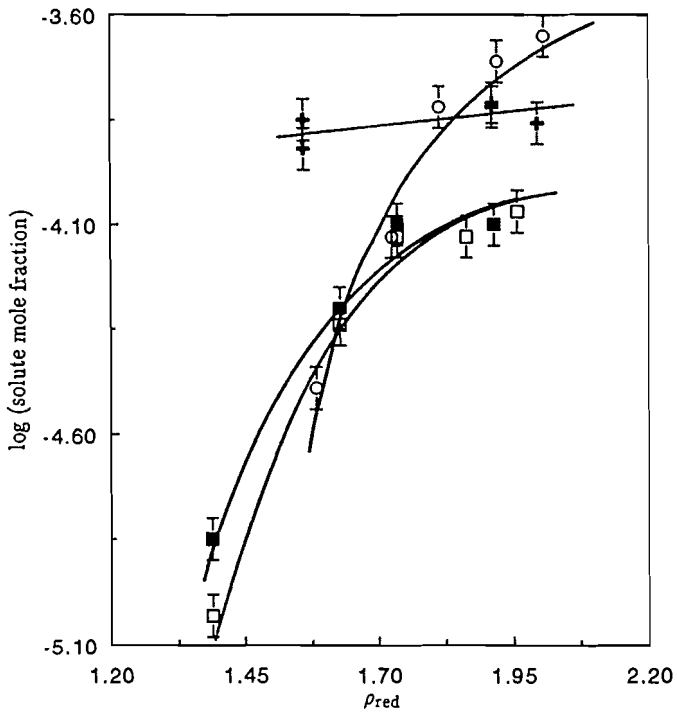

FIG. 7. Anthracene solubility versus reduced density (ρ_{red}) in CO_2 for this study (hollow squares) at 40°C and from ref. 14 (solid squares) at 35°C; in N_2O (circles) and in CO_2/1.7 mol% THF (crosses), both at 40°C.

its more common form as (the log of) the number of grams of solute per millilitre of solvent produces identical trends. The absolute solubilities of both **2** and **3** in CO_2 and N_2O are comparable, in agreement with a corresponding states concept. The major contribution to errors in solubility measurements was in the accurate determination of outgas flow rates from the heated restrictor, which could vary up to ±10% during a single measurement. For Figs. 6 and 8, however, the major contribution to experimental error in ν_{max} was found to be larger than that for solubilities, and thus are the only error estimates shown.

A serious problem arises in the prediction of absolute solvent strength, as trends appear to be reversed from that predicted through solvatochromic data. The discrepancy is shown graphically in the plot of solubility versus π^* (Fig. 6), which indicates that N_2O has greater solvating power than CO_2 at the same π^* value.

Figure 6 indicates the susceptibility of the solute to changes in solvent strength for **2** and **3**, as demonstrated by a consistent slope seen between the two solvents for each solute. Further experimentation may prove that the slopes of the solubility isotherms (logarithm of solubility versus π^*) are constant for a given solute, as are solute s values in solvatochromic data, in which case π^* would be quantitatively useful in predicting solubility trends in SCFs.

Comparison of the slopes of solubility isotherms to solute s values for **2**, **3**, and **4** was unsuccessful due to problems previously described in obtaining s values for such nonpolar substances. As well, experimentation to obtain solubility data for **1** was unsuccessful due to problems related to the use of liquid solutes.

For **4**, agreement with literature data is promising (15, 16). However, a definite nonlinear relationship is indicated be-

For personal use only.

tween solubility and reduced density, and thus with π^* as well (Figs. 7 and 8). Although this deviates from theories of linear solvation energy relationships, comparisons of data trends will still be made. Solubility data for **4** in CO_2 and N_2O indicate the same trend of relative solubilities that was seen in **2** and **3**, and the same reversal of solvent strength when solubility is plotted versus π^*.

The most interesting result comes in the comparison of the binary solvent solubility data to the single-component SCF solvents in Fig. 8. The solubility is only slightly higher for **4** in the binary solvent than in CO_2, and lower than that for N_2O at higher densities. The rate of solubility increase with reduced density or π^* is also significantly lowered. These effects are the result of cybotactic saturation by the cosolvent, which reduces the effect of pressure on changes to the solvent strength. These trends were also seen in the solvatochromic data.

Although solvatochromic data prove to be inappropriate for the prediction of solvent power or absolute solubilities, they have shown promise of providing valuable information concerning the cybotactic region of the solute in both single and binary SCF solvents. These data may also prove to be an asset in the prediction of relative solubility trends for cases where there is limited data on a specific solute–solvent pair.

Studies on the $B_{AL}2$ mechanism for ester hydrolysis

JUDY E. DOUGLAS, GRANT CAMPBELL, AND DONALD C. WIGFIELD
The Ottawa–Carleton Chemistry Institute, Carleton University Campus, Ottawa, ON K1S 5B6, Canada

Received April 15, 1993

JUDY E. DOUGLAS, GRANT CAMPBELL, and DONALD C. WIGFIELD. Can. J. Chem. **71**, 1841 (1993).

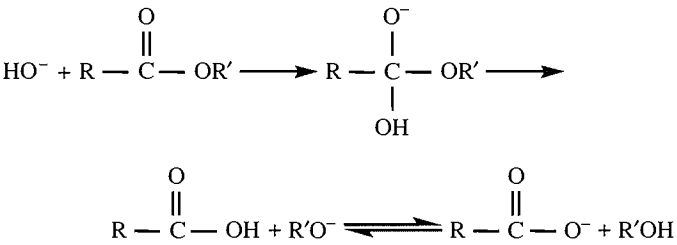
The preparation and alkaline hydrolysis of ^{18}O-methyl 2,2-dimethylpropanoate and ^{18}O-methyl triphenylacetate are reported. From mass spectral analysis of the carboxylic acid products, it is concluded that the former substrate is hydrolyzed exclusively by the $B_{AC}2$ mechanism, whereas the latter substrate proceeds 95% by the $B_{AC}2$ mechanism and 5% by the $B_{AL}2$ mechanism. The balance between these two mechanisms is discussed.

JUDY E. DOUGLAS, GRANT CAMPBELL et DONALD C. WIGFIELD. Can. J. Chem. **71**, 1841 (1993).

On a réalisé la préparation et l'hydrolyse alcaline du 2,2-diméthylpropanoate de ^{18}O-méthyle et du triphénylacétate de ^{18}O-méthyle. En se basant sur l'analyse des spectres de masse des acides carboxyliques produits, on peut conclure que le premier substrat s'hydrolyse exclusivement par un mécanisme $B_{AC}2$ alors que le dernier substrat s'hydrolyse à 95% par le mécanisme $B_{AC}2$ et 5% par le mécanisme $B_{AL}2$. On discute de la balance entre ces deux mécanismes.
[Traduit par la rédaction]

Introduction

This paper examines a mechanistic question that is over 40 years old, which has never been properly resolved, and which has been largely ignored for the past 30 years. It was recognized in 1941 that esters could, in principal, be hydrolyzed by as many as eight possible mechanisms (1). Ingold, in his classic 1953 book, revised in 1969 (2), classified these using a convenient notation in which the common base-catalyzed mechanism:



is referred to as $B_{AC}2$. In this notation, the letter B indicates that the reaction is base-catalyzed; the symbol "AC" indicates that acyl–oxygen bond breakage occurs; and the number 2 refers to the bimolecular nature of the reaction. Isotopic labelling studies and kinetics established (2) that in basic media most esters are hydrolyzed by this mechanism, and, indeed, most texts do not even mention the other possibilities. One of these possibilities, the $B_{AL}2$ mechanism, shown below,

is, however, at least on paper, a very reasonable mechanism and it is surprising to find that this mechanism has occurred so rarely. Ingold (2) noted both the rather special case of β-lactone hydrolysis (3), and also the transesterification work of Bunnett and co-workers in which a $B_{AL}2$-type mechanism leads to a different product (4), and states that "the generality of the $B_{AL}2$ mechanism . . . has been established . . . despite its usual eclipse by the $B_{AC}2$ mechanism . . ." However, *no* example of a $B_{AL}2$ hydrolysis of an actual ester was cited. Gould's view, in his 1959 book, was that the mechanism was "extremely rare; observed only for hydrolysis of β-lactones in the absence of both strong base and strong acid." (5). More recent texts have become more vague on the question of whether or not the mechanism can actually be observed, and tend to mention only the lactone and the methanolysis results (6).

In fact, there appears to be only one example in the entire chemical literature of an unambiguous $B_{AL}2$ hydrolysis[1] of an ester, and this dates from over 30 years ago. In 1962 Barclay, Hall, and Cooke presented isotopic analysis data on the hydrolysis of methyl 2,4,6-tri-*tert*-butylbenzoate, which unambiguously established that the mechanism of hydrolysis was $B_{AL}2$ (7). Evidently in this case the bulky *ortho* substituents rendered impossible the attack on the carbonyl to initiate the $B_{AC}2$ mechanism, and the $B_{AL}2$ mechanism, with attack on the relatively unhindered methyl group, occurred instead. Both *ortho tert*-butyl groups were apparently required in order to change the mechanism; it was reported that methyl 2-methyl-4,6-di-*tert*-butylbenzoate is hydrolyzed by a mixture of $B_{AL}2$ and $B_{AC}2$ mechanisms, and other hindered esters exclusively by $B_{AC}2$ (7). This important paper has not had the attention it perhaps deserves; it is not mentioned by Ingold (2), or in other texts (6), and has, in the past 15 years, been cited only twice. In contrast to this report, the hydrolysis of the closely related 2,4,6-triphenylbenzoate has been reported to proceed by the $B_{AC}2$ mechanism (9).

It is clear that the $B_{AL}2$ mechanism is an extraordinarily rare process. What is not so clear is whether this is because it has simply not been extensively looked for, and has been "eclipsed" by the $B_{AC}2$ mechanism, or whether it is, despite its attractiveness on paper, an intrinsically unfavourable mechanism. In an effort to find other examples of this mechanism, not involving the benzoate group, and to try to gain some further understanding of the balance between the $B_{AC}2$ and the $B_{AL}2$ mechanisms, we have investigated the hydrolysis of two more potential candidates — methyl 2,2-dimethylpropanoate (methyl trimethylacetate, methyl pivalate) and methyl triphenylacetate — both of which offer significant steric hindrance to attack on carbonyl ($B_{AC}2$), but little impediment to attack on the methyl group ($B_{AL}2$). Herein we report our findings.

[1]It should be noted, however, that several apparent examples of $B_{AL}2$ methanolysis have been reported; see, for example, refs. 4, 8.

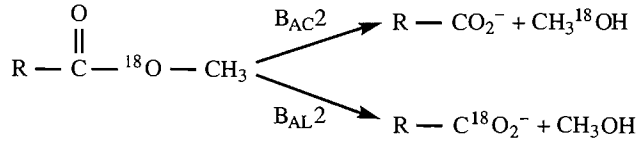
Results

The most clearcut strategy for detection of the $B_{AL}2$ hydrolysis mechanism is by ^{18}O labelling of the methoxy group of the ester. Hydrolysis by the $B_{AL}2$ mechanism will lead to ^{18}O incorporation into the carboxylic acid product, whereas the $B_{AC}2$ mechanism will result in loss of the ^{18}O as $Me^{18}OH$. Unlike other oxygen labelling studies, this strategy does not suffer from oxygen exchange ambiguities.



Hydrolysis of ^{18}O-methyl 2,2-dimethylpropanoate

Methyl 2,2-dimethylpropanoate may be prepared by methanolysis of the commercially available 2,2-dimethylpropanyl chloride. In view of the high cost of ^{18}O-labelled methanol, considerable effort was expended in order to maximize the conversion of the acid chloride to the ester with the minimum excess of labelled methanol. The maximization of conversion was important not only for reasons of cost; any acid chloride impurity in the ester sample for hydrolysis would give rise to unlabelled carboxylic acid, thus vitiating the mechanistic conclusion. It was found that conducting the reaction in dichloromethane with a pyridine catalyst, using a 20% molar excess of methanol over acid chloride, achieved the desired result.

To effect hydrolysis of methyl 2,2-dimethylpropanoate, it was found that a 1 M sodium hydroxide solution caused essentially complete hydrolysis at room temperature in 80 h. These conditions were therefore used to hydrolyze samples of the prepared ^{18}O-methyl 2,2-dimethylpropanoate; the resulting 2,2-dimethylpropanoic acid was converted to the TMS ester and analysed by mass spectrometry. The key peaks in the mass spectrum are those at m/z 159 and 161, corresponding to M − 15 (loss of methyl) in the unlabelled and labelled silyl ester, respectively. A small (M − 15) + 2 peak in these compounds occurs inevitably due to the isotopic composition of silicon, and thus the extent of labelling in the sample is estimated by the comparison of the 161:159 peak intensity ratios in the TMS esters of both the hydrolyzed sample and authentic unlabelled 2,2-dimethylpropanoic acid. In both cases this peak intensity ratio was 0.044, thus clearly showing that the hydrolyzed sample contained no detectible ^{18}O. It must therefore be concluded that the hydrolysis of methyl 2,2-dimethylpropanoate proceeds completely, within experimental detection limits, through the $B_{AC}2$ mechanism. Evidently the three methyl groups are insufficient to interfere with this normal mechanism of ester hydrolysis to an extent that would permit the $B_{AL}2$ mechanism to compete.

Hydrolysis of ^{18}O-methyl triphenylacetate

We next turned our attention to the more severely hindered methyl triphenylacetate system. In this case the acid chloride, triphenylacetyl chloride, was not commercially available and was prepared by thionyl chloride treatment of triphenylacetic acid. This was a very slow reaction and, in our hands, required two successive 6-h periods with the reaction under reflux, fresh thionyl chloride being used for the second reflux period. Conversion of this acid chloride to the desired methyl ester was also a difficult reaction, and was eventually managed by a 25-h reflux reaction in benzene, using a pyridine catalyst and an 18-fold excess of methanol over acid chloride. Once again, conditions were worked out on unlabelled materials, followed by preparation of the labelled ester using ^{18}O-methanol.

Hydrolysis of methyl triphenylacetate proved to be an extremely slow reaction, and one that we were not able to bring to completion. In our experience, heating with 1 M sodium hydroxide at 100°C for 287 h caused a conversion of only approximately 40%. This was sufficient, however, to allow mass spectral analysis of the isotopic content of the carboxylic acid product, since the molecular mass of the unconverted methyl ester is less than that of the TMS ester of the acid product and therefore its mass spectrum does not interfere with the mass spectral peaks of interest. As in the case of the 2,2-dimethylpropanoate series, the peaks on which the isotopic content is estimated are the M − 15 and the (M − 15) + 2 peaks of the TMS ester; in the triphenylacetate series these occur at m/z 345 and 347, respectively.

Comparison of the 345 and 347 mass spectral peaks of the TMS ester of authentic triphenylacetic acid and that produced through the hydrolyses of the ^{18}O-labelled ester showed a consistent small, but definite, enhancement of the 347 peak in the latter cases. This enhancement corresponds to the presence of 5% ^{18}O-labelled triphenylacetic acid to 95% unlabelled acid. This result indicates that once again the predominant mechanism of hydrolysis is $B_{AC}2$, but in this case 5% of the reaction has proceeded through the rare $B_{AL}2$ mechanism.[2]

Discussion

The notion that the $B_{AL}2$ mechanism is a reasonably accessible one, whose only reason for rare occurrence is its "eclipse" by the more usual $B_{AC}2$ mechanism, appears to be dispelled by the present results. In the case of hydrolysis of methyl triphenylacetate we have a reaction verging on impossible, yet which still proceeds 95% by the usual $B_{AC}2$ mechanism. The $B_{AL}2$ mechanism is not particularly impeded by any obvious steric factors, and yet, even under circumstances which practically bring the $B_{AC}2$ mechanism to a halt, it can only compete to the extent of about 5%. Clearly the $B_{AL}2$ mechanism must be intrinsically unfavourable and it is this reason why it has been so rarely observed. Only one case has ever been uncovered in which the $B_{AL}2$ mechanism predominates (7), and perhaps this one example, with the extraordinary steric hindrance of two *ortho tert*-butyl groups, is unique in its promotion of the $B_{AL}2$ mechanism.

The kinetic results on the hydrolysis of methyl 2,4,6-tri-*tert*-butylbenzoate reported by Barclay, Hall, and Cooke (7), together with our own results on the incomplete conversion of methyl triphenylacetate, allow a slightly deeper analysis of the problems surrounding the $B_{AL}2$ mechanism. Barclay et al. reported values of E_a and of $\log_{10}$ PZ of 25.07 kcal/mol and 10.93, respectively, and commented that the $\log_{10}$ PZ factor was over 100 times more favourable than other

[2]A referee pointed out that this experimental result, given the unusually harsh hydrolysis conditions (100°C, 287 h), could conceivably have resulted from a hydrolysis that was primarily a $B_{AL}2$ process, followed by loss of the ^{18}O in the carboxylic acid by exchange with solvent. To ensure that this exchange did not occur, triphenylacetic acid was subjected to these conditions using $H_2{}^{18}O$ as solvent. Subsequent mass spectral analysis showed no detectable ^{18}O incorporation into the acid.

reported values for alkaline hydrolyses of benzoic esters. While this is certainly true, it is not an unusual value for a second-order reaction in solution (10), and it is still a substantially negative factor on the rate, corresponding to an entropy of activation of over -100 J mol^{-1} K^{-1}. In fact, the free energy barrier to this reaction of approximately 120 kJ mol^{-1} at 100°C appears to be about two-thirds enthalpy and one-third entropy. Taking the concentrations, extent of conversion, and temperature of our partial conversion of methyl triphenylacetate, and assuming a second-order process, the free energy barrier is calculated to be approximately 135 kJ mol^{-1}.

Taking these values, and comparing them with those for alkaline hydrolyses of less hindered esters (10–12), it is evident that the increase of steric hindrance causes a steady increase in the energy of activation (11.5 kcal/mol for methyl acetate (11); 13.8 kcal/mol for ethyl benzoate (11); around 20 kcal/mol for a variety of 2,6-dimethylbenzoates (12); and the 25.07 kcal/mol value for methyl 2,4,6-tri-*tert*-butylbenzoate (7), which apparently proceeds by the $B_{AL}2$ mechanism). These values are partially compensated for by increasingly favourable pre-exponential factors, or entropies of activation, and, despite the change of mechanism, the $\log_{10}$ PZ factor reported by Barclay *et al.* is not out of line with this trend.

What is clear from these considerations is that, even when steric hindrance seriously impedes the $B_{AC}2$ mechanism, and increases the activation barrier to well over 100 kJ mol^{-1}, the $B_{AL}2$ route is just not available to take over the reaction. In that sense it is not merely "eclipsed" by the usual $B_{AC}2$ mechanism; it is a highly unfavourable reaction with an intrinsic energy barrier, regardless of steric hindrance, of at least 120–130 kJ mol^{-1}. For this improbable mechanism to be realized, two conditions apparently must be met: (*a*) this barrier must be overcome, which implies a slow reaction even at >100°C; and (*b*) the $B_{AC}2$ mechanism must, by some device, be made even more difficult and energy requiring. This is a tough requirement, and to find even one more example, beyond the one demonstrated by Barclay, Hall, and Cooke, may represent a substantial challenge.

Experimental

Infrared spectra were obtained on a Perkin–Elmer 1600 Series FTIR. Proton magnetic resonance spectra were obtained on a Varian XL-200 spectrometer; peak positions are recorded in ppm (δ) with respect to TMS. Mass spectra were obtained on a VG 7070E mass spectrometer.

^{18}O-Methyl trimethylacetate

A solution of trimethylacetyl chloride (0.211 g, 1.75 mmol), ^{18}O-methanol (85 μL, 2.10 mmol), and pyridine (4 drops) in dichloromethane (3 mL) was heated under reflux for 3 h. The resulting clear solution was diluted with dichloromethane (5 mL) and water (5 mL). The layers were separated, and the organic layer successively extracted with 1 M HCl solution (3 × 3 mL), water (1 × 3 mL), saturated $NaHCO_3$ solution (2 × 3 mL), and water (1 × 3 mL). The original organic layer, the first three extracts, and the last three extracts were each back-extracted with dichloromethane (2 × 3 mL). The combined organic extracts were dried over $MgSO_4$ and the solvent evaporated under reduced pressure to yield a clear liquid (0.169 g, 82% yield); bp 100°C (lit. (13) bp 100–102°C); ν_{max} (CH_2Cl_2): 1738 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 1.70 (9H, s), and 3.70 ppm (3H, s).

Triphenylacetyl chloride

A suspension of triphenylacetic acid (1.0 g, 3.5 mmol) in thionyl chloride (20 mL) was heated under reflux for 6 h. The solution was evaporated under reduced pressure, fresh thionyl chloride was added, and the solution again heated under reflux for a further 6 h. The acid gradually dissolved to give a yellow solution. The thionyl chloride was evaporated under reduced pressure to give yellow crystals, IR analysis of which showed no detectable carboxylic acid remaining. The acid chloride, ν_{max} 1810 cm^{-1} ($CHCl_3$), was used directly for preparation of the methyl ester.

^{18}O-Methyl triphenylacetate

A solution of triphenylacetyl chloride (120 mg, 0.39 mmol), ^{18}O-methanol (300 mL, 7.06 mmol), and pyridine (5 drops) in benzene (5 mL) was heated under reflux for 25 h. The solution was then washed successively with 1 M HCl solution (3 × 5 mL), water (1 × 5 mL), saturated $NaHCO_3$ solution (2 × 5 mL), and water (2 × 5 mL), dried ($MgSO_4$), and evaporated to give flaky white crystals, mp 185–186°C (lit. (13) mp 186°C); ν_{max}: 1733 cm^{-1} ($CHCl_3$); ^{1}H NMR ($CDCl_3$) δ: 3.79 (3H, s) and 7.27 ppm (15 H, s).

Base hydrolysis of ^{18}O-methyl trimethylacetate

A solution of ^{18}O-methyl trimethylacetate (0.167 g, 1.44 mmol) in 1.0 M NaOH solution (20 mL) was kept at room temperature for 80 h. The resulting clear solution was acidified to approximately pH 3 by the careful addition of 1.0 M HCl solution, and then extracted with dichloromethane (3 × 3 mL). The combined extracts were dried ($MgSO_4$) and evaporated under reduced pressure to yield white crystals whose IR spectra showed the complete replacement of the peak at 1738 cm^{-1} (ester) by one at 1701 cm^{-1} (carboxylic acid). The mass spectrum of the TMS ester, prepared by addition of 20 μL of 20% Trisyl BSA in pyridine to 1 mg of carboxylic acid, was identical to that from authentic trimethylacetic acid, and showed no measurable enhancement of the m/z 161:159 ratio.

Base hydrolysis of ^{18}O-methyl triphenylacetate

A solution of ^{18}O-methyl triphenylacetate (36 mg, 0.12 mmol) in a mixture of dioxane (6 mL) and 1.0 M NaOH solution (5 mL) was heated under reflux in the presence of a boiling chip for 287 h in a system protected with a drying tube containing NaOH pellets. Periodic additions of dioxane were made to maintain the 11 mL volume. The resulting solution was carefully acidified to approximately pH 3 using 1.0 M HCl solution. Water (5 mL) and chloroform (5 mL) were added, the organic layer removed, and the aqueous layer extracted with further portions of chloroform (3 × 5 mL). The combined organic extracts were washed with water (1 × 10 mL), dried ($MgSO_4$), and evaporated, to yield a white powder, whose IR spectrum showed the presence of both ester (1733 cm^{-1}) and carboxylic acid (1697 cm^{-1}). Studies on mixtures of ester and acid of known proportion showed that this hydrolysis mixture consisted of 60% ester and 40% acid. GC – mass spectrometry of the TMS ester of the acid, prepared as described above, showed an enhancement of the m/z 347:345 ratio consistent with the presence of 5% ± 1% ^{18}O-labelled triphenylacetic acid to 95% unlabelled acid.

Novel [2.2]paracyclophane derivatives via charge-transfer complexation

ASHRAF A. ALY, ALAA A. HASSAN, AND ABOUL-FETOUH E. MOURAD[1]
Chemistry Department, Faculty of Science, El-Minia University, El-Minia, A.R. Egypt

Received March 8, 1993

ASHRAF A. ALY, ALAA A. HASSAN, and ABOUL-FETOUH E. MOURAD. Can. J. Chem. **71**, 1845 (1993).

The transannular electronic interactions in [2.2]paracyclophanes affect the selectivity of the tricyanovinylation reaction with tetracyanoethylene (TCNE). In addition to the normal *N*-tricyanovinyl product, 4-amino[2.2]paracyclophane reacts with TCNE to give oxaziridine derivatives. In the case of reaction with 4-*N*-methylamino[2.2]paracyclophane, the unusual *N*-tricyanovinylated product as well as 4-(*N*-carbonitrile-*N*-methyl)amino[2.2]paracyclophane was isolated. The reaction of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) with 4-amino[2.2]paracyclophane results in formation of 2-cyano-3-(4-[2.2]paracyclophanyl)amino-5,6-dichloro-1,4-benzoquinone.

ASHRAF A. ALY, ALAA A. HASSAN et ABOUL-FETOUH E. MOURAD. Can. J. Chem. **71**, 1845 (1993).

Les interactions électroniques transannulaires des [2.2]paracyclophanes affectent la sélectivité de la réaction de tricyanovinylation du tétracyanoéthylène (TCNE). En plus du produit *N*-tricyanovinyle normal, la réaction du 4-amino[2.2]paracyclophane avec le TCNE fournit des derivés oxaziridines. Dans le cas de la réaction avec le 4-*N*-méthylamino[2.2]paracyclophane, on a isolé le dérivé inhabituel *N*-tricyanovinylé ainsi que le 4-(*N*-carbonitrile-*N*-méthyl)amino[2.2]paracyclophane. La réaction de la 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) avec le 4-amino[2.2]paracyclophane conduit à la formation de la 2-cyano-3-(4-[2.2]paracyclophanyl)amino-5,6-dichloro-1,4-benzoquinone.

Introduction

As part of a program designed to synthesize heterocyclics via charge-transfer (CT) complexation between heterocyclic compounds as electron donors and electron-deficient compounds as electron acceptors, we recently reported the synthesis of some interesting heterocyclic systems such as pyrazolopyrimidines (1), indanopyrazolopyrimidines (2), and pyrazoloquinazolines (3) via CT-complexation between pyrazole derivatives and tetracyanoethylene (TCNE), 2-(dicyanomethylen)indane-1,3-dione ((CNIND), as well as 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), respectively.

One of the reasons for the continuing interest in the reactivity of [2.2]paracyclophane derivatives (4) is that their chemical behaviour differs considerably from that of classical aromatic systems (5–9).

In the present investigation, we turned our attention to 4-amino[2.2]paracyclophane (**1**) and its *N*-methyl derivative **5** as electron donors, aiming to shed more light on the impact of the transannular electronic interactions existing in the [2.2]paracyclophane nucleus on its behaviour towards TCNE and DDQ as π-acceptors. This aim can in principal be achieved by comparing the behaviour of the phane system with that of model compounds such as 2,5-dimethylaniline. 2,5-Dimethylaniline reacts with TCNE to give mainly the *N*-tricyanovinyl derivative (ca. 95%) (10). The attack of TCNE on the nitrogen atom of the free amino group is more favourable than on the carbon atom in the *para*-position, since the amino group is the more nucleophilic center.

Results and discussion

Interaction between 4-amino[2.2]paracyclophane (**1**) and TCNE in absolute ethyl acetate results in the formation of 4-*N*-tricyanovinyl-amino[2.2]paracyclophane (**2**), i.e., the expected product, 2-(4-[2.2]paracyclophanyl)-3,3-dicyanooxaziridine (**3**), and tetracyanoethane (**4**) (Fig. 1). It is worth noting that **3** is the first oxaziridine derivative formed by CT-complexation between TCNE and the primary aromatic amine. Figure 2 illustrates a plausible mechanism for its formation. This sequence shows initial formation of a CT-complex that absorbs at 620 nm followed by elimination of malononitrile, then addition of an H_2O molecule to the C=N bond followed by dehydrogenation by another molecule of TCNE, affording the oxaziridine derivative **3** and tetracyanoethane (**4**). The enhancement of formation of **2** and **3** may be explained as due to the transannular electronic interactions in 4-amino[2.2]paracyclophane (**1**), which tend to increase the nucleophilic character of the amino group through the donation of π-electrons from the unsubstituted half of **1** to the aminosubstituted half.

It has been reported that tertiary and secondary aromatic amines are tricyanovinylated at the *para*-position on reaction with TCNE (10). Using 4-*N*-methylamino[2.2]paracyclophane (**5**) as a secondary aromatic amine, the reaction with TCNE gave the unexpected *N*-tricyanovinylation product **6** as well as 4-(*N*-carbonitrile-*N*-methyl)amino[2.2]paracyclophane (**7**). The mechanism of formation of **7** is illustrated in Fig. 3, which indicates initial formation of a CT-complex (absorbing at 610 nm), followed by formation of *N*-tricyanovinylated intermediate **6**. Hydrolysis of **6** and elimination of one molecule of malononitrile from **14** results in formation of **7**. The formation of *N*-tricyanovinyl derivative **6** can be attributed to the effect of the transannular electronic interactions (see Fig. 4), which play an important role in increasing the electron-donating character of the nitrogen atom so that the electronic factor predominates with respect to the steric one. The structure of **6** is confirmed by the disappearance of the NH proton (IR, ^{1}H NMR spectra, cf. Experimental). (The NH proton in **5** appears as a multiplet at $\delta = 2.70–2.61$ ppm and ν(NH) ≈ 3325 cm^{-1} (11).)

The participation of moist air in formation of compounds **3** and **7** as illustrated in the proposed mechanism, in Figs. 2 and 3, was confirmed by adding both donors **1** and **5** to TCNE under nitrogen and dry conditions. Only stable CT-complexes were formed, which dissociate into their com-

[1]Author to whom correspondence may be addressed.

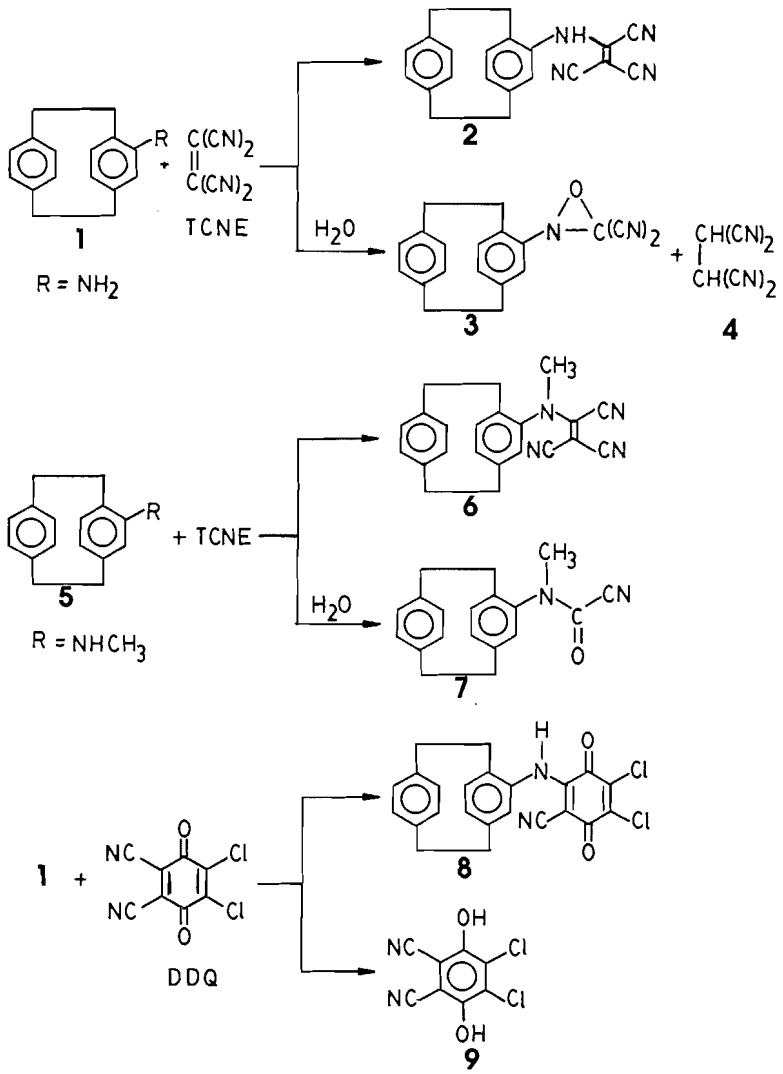

FIG. 1. Interaction of **1** and **5** with π-acceptors.

ponents after time and do not follow the given sequence of chemical reaction.

Addition of DDQ to **1** results in formation of a CT-complex (absorbing at 580 nm), accompanied by elimination of HCN, giving rise to the reaction product **8** in addition to DDQ-H_2 (**9**), as shown in Fig. 1. The proposed mechanism of formation of **8** and **9** is given in Fig.5.

In conclusion, the transannular electronic interaction existing in [2.2]paracyclophanylamines tends to change the mode of reaction with π-acceptors significantly as compared to normal aromatic amines; consequently, interesting and unexpected reaction products were obtained that cannot be easily prepared by conventional synthetic methods.

Experimental

Melting points are uncorrected. UV/vis: Perkin–Elmer Lambda 2 spectrophotometer. IR: Nicolet 320 FT-IR(KBr). ^{1}H and ^{13}C NMR: Bruker WM 400 (400.1 MHz). MS: Finigan 8430 at 70 eV. Elemental analyses: microanalytical unit at Cairo University.

Electron acceptors

Tetracyanoëthylene (Aldrich) was recrystallized from chlorobenzene and sublimed. 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone (Aldrich) was recrystallized from benzene–chloroform (2:3).

Electron donors

4-Amino[2.2]paracyclophane (**1**) and 4-*N*-methylamino[2.2]-paracyclophane (**5**) were prepared according to refs. 12 and 11, respectively.

Reaction of 4-amino[2.2]paracyclophane (1) with TCNE

A solution of **1** (0.223 g, 0.001 mol) in 10 mL of absolute ethyl acetate was added to a solution of TCNE (0.256 g, 0.002 mol) in 10 mL of absolute ethyl acetate and the reaction mixture was stirred for 48 h at room temperature. On concentration and chromatography on thin-layer plates (Merck Silica Gel 60 PF 254) using toluene – ethyl acetate (1:1), two zones were well separated. The first zone contained compound **2** and the second zone contained compound **3**. The base line of the tlc rechromatographed using toluene – ethyl acetate (1:2) contained the tetracyanoethane (**4**).

2: Yellow crystals, yield 41%, mp 204–206°C (toluene). Electrocatalytic hydrogenation of ketones and of α- and β-diketones on Raney metal electrodes

AMOY KAM CHEONG, YVON BOLDUC, AND JEAN LESSARD[1]

Laboratoire d'électrochimie et d'électrocatalyse, Département de chimie, Université de Sherbrooke, Sherbrooke, QC J1K 2R1, Canada

Received February 1, 1993

AMOY KAM CHEONG, YVON BOLDUC, and JEAN LESSARD. Can. J. Chem. **71**, 1850 (1993).

The electrocatalytic hydrogenation (ECH) of various ketones was investigated at codeposited Raney metal electrodes in aqueous methanol. The influence of different parameters (pH, supporting electrolyte, and water percentage) on the ECH of cyclohexanone and acetophenone was studied. The relative ease of electrohydrogenation of a variety of monoketones was determined in competitive electrolyses. The ECH of α- and β-diketones was carried out and different products were obtained selectively by the right choice of catalytic material and electrolysis conditions. The diastereoselectivity of the formation of diols was also determined.

AMOY KAM CHEONG, YVON BOLDUC et JEAN LESSARD. Can. J. Chem. **71**, 1850 (1993).

Nous avons étudié l'hydrogénation électrocatalytique (HEC) de plusieurs cétones sur des électrodes codéposées de métaux de Raney en milieu méthanol–eau. L'étude de l'influence de plusieurs paramètres (pH, électrolyte-support et pourcentage d'eau) sur l'HEC de la cyclohexanone et de l'acétophénone a été effectuée. Nous avons comparé la facilité relative de l'électrohydrogénation de différentes monocétones lors d'électrolyses compétitives. Lors de l'HEC d'α- et β-dicétones, différents produits ont été obtenus sélectivement, selon le choix du catalyseur et des conditions d'électrolyse. La diastéréosélectivité lors de la formation des diols a aussi été déterminée.

Introduction

Electrocatalytic hydrogenations (ECH) have been known since the beginning of the century (1–3). They involve the electrochemical reduction of water (eq. [1]) at the surface of a metal electrode M. The chemisorbed hydrogen M(H) thus formed reacts with the adsorbed organic substrate M(Y=Z) (eq. [3]), this step being the same as in catalytic hydrogenation. A competing reaction is the formation of molecular hydrogen

[1] $H_2O + e^- \rightarrow M(H) + OH^-$

[2] $Y = Z + M \rightarrow M(Y{=}Z)$

[3] $2M(H) + M(Y = Z) \rightarrow M(YH\text{-}ZH)$

[4] $M(YH\text{-}ZH) \rightarrow YH\text{-}ZH + M$

[5] $M(H) + e^- + H_2O \rightarrow H_2 + M + OH^-$

[6] $2M(H) \rightarrow H_2 + M$

(eq. [5] and (or) [6]). The efficiency of ECH will depend on the competition arising between reactions [3] and [5] and (or) [6]. This competition depends on the substrate, the electrode material and surface, and, for a given substrate and electrode, on the electrolysis conditions. Electrocatalytic hydrogenations are very clean since only hydrogenation and hydrogen evolution are involved. In ECH, the current efficiency of the hydrogenation reflects the competition between these two processes. Raney metal based electrodes have proven to be very efficient for the ECH of various substrates (4–13).

Compared to catalytic hydrogenation, ECH presents several advantages: the kinetic barrier relative to the splitting of gaseous hydrogen is bypassed, elevated temperatures and pressures of hydrogen are avoided, and poisoning of the catalyst is diminished due to the cathodic potential applied (5, 14). ECH is advantageous when compared to electrohydrogenation by direct electronation–protonation. The formation of chemisorbed hydrogen by electrolysis of water takes place at a less negative potential than the direct electroreduction of most organic substrates, hence the lower energy required. Furthermore, side reactions such as dimerization (resulting in pinacols, for example, during reduction of ketones) can be avoided. As a consequence, much work is being done on the application of this electroorganic technique.

This paper reports the results of a study of the ECH of various ketones on Raney metal electrodes and in aqueous methanol. First we describe the influence of different conditions of electrolysis on the electrohydrogenation of cyclohexanone and acetophenone, and on the chemoselectivity of the competitive electrohydrogenations of pairs of ketones (cyclohexanone, acetophenone, benzylacetone, and 2-octanone). We also report the results of the ECH of two α-diketones (benzil and 1-phenyl-1,2-propanedione) and of two β-diketones (1,3-diphenyl-1,3-propanedione and 2,4-pentanedione).

Results and discussion

The catalytic electrodes consisted of Raney nickel (RaNi) or Raney cobalt (RaCo) or Devarda copper (DeCu) particles embedded in a nickel matrix. The preparation of such electrodes has been described elsewhere (6–9). Prior to the electrocatalytic hydrogenation, that is, before adding the organic substrate, electrolysis of water was carried out at a constant current so that the cathode material was saturated with adsorbed hydrogen. The potential was then brought to a more positive value until the current reached zero (no hydrogen evolution) and was maintained at that value during the electrohydrogenation. This potential varied with the pH of the medium. In alkaline solutions it was about −1 V (vs. SCE), and in neutral or slightly acidic media it was about −0.65 V (vs. SCE). The addition of the substrate (1 or 2 mmol) caused an increase in current that gradually diminished during the electrolysis. The latter was stopped after the

1	KOH	0.99	27	21
2	NaOH	1.04	75	55
3	Bu_4NOH	1.05	46	42
4	H_3BO_3/NaCl	0.74	25	22
5	CH_3COOH/CH_3COONa	0.63	0[d]	0[d]

[a,b,c]Same as in Table 1. The percentage of water is 7. The supporting electrolyte concentrations and the pH were the same as those indicated in Table 1.
[d]Hydrogen evolution was the sole electrochemical process.

theoretical charge required for complete hydrogenation of the organic substrate was passed: 2 F for 1 mol of monoketone and 4 F for 1 mol of diketone. It is noteworthy that though there was no hydrogen evolution in the absence of the organic substrate at the zero current potential, hydrogen evolution did occur in the presence of the substrate, which in some cases resulted in low or even zero current efficiency of electrohydrogenation.

We investigated the influence of the electrode material, the pH of the solution, the supporting electrolyte, and the percentage of water in the solvent mixture on the ECH of cyclohexanone and of acetophenone. In all the experiments, only one product was observed in each case: cyclohexanol and 1-phenylethanol, respectively. ECH of cyclohexanone was performed on RaNi (Table 1) and on RaCo (Table 2) and was more efficient on RaNi than on RaCo, as shown by the chemical yields and current efficiencies, which are much higher on RaNi. Attempts to electrohydrogenate cyclohexanone on DeCu were unsuccessful, hydrogen evolution being the sole electrochemical process occurring. Thus, the activity of Raney metals in the ECH of cyclohexanone is the same as in catalytic hydrogenation in general: RaNi > RaCo > DeCu (15). Acetophenone was electrohydrogenated on all three types of electrode materials (Tables 3–5). Again, the yields and current efficiencies were higher on RaNi (Table 3). But, with this substrate, the electrohydrogenations were more efficient on DeCu (Table 5) than on RaCo (Table 4). Thus the relative efficiencies of RaCo and DeCu electrodes in electrocatalytic hydrogenations are not only related to the catalytic material itself but depend also on the type of substrate.

On RaNi, in very alkaline media, ECH of cyclohexanone led to excellent chemical yields and current efficiencies (Table 1, entries 1–3, 7, and 8), the best results being obtained with NaOH (entry 2). Satisfactory results were obtained in less alkaline media (entries 4 and 5). However, when an acetate buffer was used, no hydrogenation took place (entry 6), hydrogen evolution being the sole electrochemical process observed. This can be explained by the strong adsorption of the acetic acid, which would prevent the adsorption of cyclohexanone (or displace it), thus inhibiting its hydrogenation. In contrast, the ECH of acetophenone was very efficient in the acetate buffer (Table 3, entry 2). Because of the presence of the phenyl ring, acetophenone would be more strongly adsorbed than cyclohexanone and would be more able to displace the acetic acid adsorbed on RaNi

3	Cyclohexanone:benzylacetone	91:9
4	2-Octanone:acetophenone	29:71[c]
5	Acetophenone:benzylacetone	100:0

[a]Equimolar amounts of both substrates were simultaneously added to the solution (0.3 M Bu_4NOH in methanol:water 80:20).

[b]Products were analyzed and ratios were determined by vpc after a charge corresponding to 0.5 mole of electrons per mole of ketone.

[c]After a charge corresponding to 2 moles of electrons per mole of ketone.

and react with chemisorbed hydrogen. Furthermore, a carbonyl group conjugated with a phenyl ring is probably more reactive towards chemisorbed hydrogen (see Table 6 and discussion below). The fact (*i*) that acetophenone was not electrohydrogenated in the acetate buffer on the less active RaCo and DeCu electrodes (hydrogen evolution being the sole electrochemical reaction occurring) and (*ii*) that the zero current potential was the same on all three electrodes (−0.62 to −0.65 V vs. SCE) strongly suggests that the electrohydrogenation on RaNi electrodes does not proceed by direct electroreduction of protonated acetophenone.

Although chloride ions are known to poison Raney nickel during catalytic hydrogenation (16), electrohydrogenation in the $H_3BO_3/NaCl$ medium was successful on all three electrodes (see Tables 1–5). The adsorption of chloride ions is probably prevented when the catalyst is submitted to a cathodic potential (9). In fact, the ECH of acetophenone in $H_3BO_3/NaCl$ was more efficient than in the alkaline medium on all three electrodes (Tables 3–5). The ECH of cyclohexanone on RaNi was as efficient in $H_3BO_3/NaCl$ as in the alkaline media (Table 1) but, on the RaCo electrode, the ECH was more efficient in the NaOH medium (Table 2). The effect of varying the water percentage in methanol had little effect, as shown in entries 1, 7, and 8 of Table 1.

Experiments were carried out to study the relative ease of ECH of pairs of monoketones on RaCo electrodes in alkaline medium and the results are shown in Table 6. In each case, equimolar amounts of both substrates were added to the electrolytic solution, and the charge necessary to reduce one-fourth of the total molar quantity of ketones (0.5 mol of electrons for 1 mol of ketone) was passed. The relative ease of ECH is in the order acetophenone > 2-octanone > cyclohexanone ≫ benzylacetone. Acetophenone is more easily electrohydrogenated than 2-octanone because of conjugation of the carbonyl group with the phenyl ring. Direct electroreduction of unprotonated acetophenone at −1.0 V vs. SCE is much less probable than its electrocatalytic hydrogenation. The difference between 2-octanone and cyclohexanone (entry 1) is most probably of steric origin, the approach of the carbonyl group of cyclohexanone to the surface of the catalyst being more sterically hindered due to the axial hydrogens of the ring. A phenyl ring one carbon away from the carbonyl group hinders the hydrogenation (entries 3 and 5). The less efficient electrohydrogenation of benzylacetone could be accounted for by: steric hindrance to adsorption of the carbonyl group by the phenyl group, and (or) preferential adsorption of the phenyl ring rendering more difficult the approach of the carbonyl to the catalyst surface, and (or) partial poisoning of the catalyst surface due to the strong adsorption of the product, 1-phenyl-2-propanol. It is worth noting that the ECH of benzophenone was unsuccessful in all media and on all three electrodes. This can be attributed to the strong adsorption of the product, benzhydrol, preventing the adsorption of benzophenone. The current dropped to zero after the passage of a few coulombs only.

Reduction of α-diketones

ECH of benzil occurred with good yields on all three of catalytic electrodes (Table 7). On RaNi, the hydrogenations gave hydrobenzoins, of which the *meso* form was predominant. In the acetate buffer medium, the relative percentages of *meso* and *threo* isomers were constant throughout the electrolysis. In the KOH medium, the *meso* isomer alone was present at the beginning of the electrolysis and the *threo* form appeared later, with its percentage increasing gradually. Following this observation, we studied the behavior of *meso*

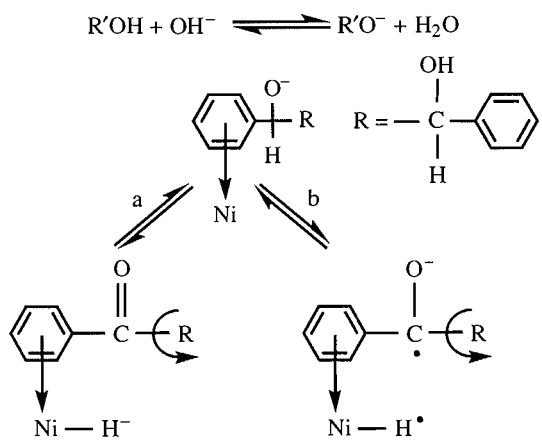

SCHEME 1

hydrobenzoin in alkaline medium (Table 8). Isomerization to the *threo* form was found to occur only in the presence of a RaNi electrode charged with chemisorbed hydrogen (entries 3 and 4). Furthermore, the isomerization was faster when the RaNi electrode was polarized (entry 4). We also observed the isomerization of *threo* hydrobenzoin into the *meso* form under the conditions of entry 4, up to 26% after 26 h (see entry 6). In the absence of a RaNi electrode (entry 1) or in the presence of a RaNi electrode from which chemisorbed hydrogen was removed by heating under vacuum (entry 2), there was no isomerization. There was no isomerization either in the presence of a RaCo electrode charged with hydrogen and polarized (entry 5). We propose a dehydrogenation–hydrogenation mechanism that involves the conjugate base of hydrobenzoin generated in the alkaline medium (Scheme 1). The alkoxide anion can undergo dehydrogenation either by losing a hydride anion (path a) or a hydrogen atom (path b). A simple rotation along the C—R axis followed by addition of hydride (path a) or of a hydrogen atom (path b) gives the *threo* isomer. The RaCo catalyst, which is known to be less active than RaNi, would not be active enough to dehydrogenate the alkoxide ion. The RaNi catalyst would be deactivated by removing the chemisorbed hydrogen, most probably because of the formation of oxides since the RaNi was in contact with air for a few minutes after the chemisorbed hydrogen has been removed. It is quite conceivable that a polarized catalyst could be more active in the dehydrogenation–hydrogenation process involving path b, that is, hydrogen atoms. The loss of a hydride ion should be more difficult on a negatively charged catalyst, so we favor path b over path a. The loss of a hydrogen atom from hydrobenzoin to form a neutral radical would be more difficult than from the conjugate base to form a radical anion (ketyl radical) since the *meso* → *threo* isomerization was not observed in a neutral medium. Vara Prasad *et al.* (17, 18) also proposed a dehydrogenation–hydrogenation pathway analogous to path b of Scheme 1 as one of the possible mechanism for the isomerization of allylic alcohols into aldehydes through the enol form on Raney nickel.

[a]The electrolysis conditions are the same as in Table 7.
[b]The supporting electrolyte was H_3BO_3/NaCl.
[c]The supporting electrolyte was CH_3COOH/CH_3COONa.
[d]Ketol **1**: $PhCH(OH)COCH_3$; ketol **2**: $PHCOCH(OH)CH_3$.

On RaCo and DeCu, which are less active catalysts for hydrogenation, only one carbonyl group of benzil was reduced, giving benzoin (Table 7, entries 3–5). In alkaline medium (entry 3), we observed that the benzoin formed was oxidized back into benzil so the yield was not calculated. Benzoin is known to be easily oxidized (19, 20). Using pure benzoin, we showed that its oxidation (dehydrogenation) required both the presence of the catalyst and basic conditions. Raney metals are known to catalyse not only hydrogenations but also dehydrogenations and we assume that benzoin is dehydrogenated on the surface of the metal (eq. [7]) and that this process is much more rapid in an alkaline medium than in a neutral one. In the absence of RaCo or DeCu, in alkaline medium, some oxidation of benzoin to benzil did take place but at a much slower rate. This oxidation can only be explained by the presence in the electrolyte of traces of oxidizing agents, even if the experiments were performed under a nitrogen or argon atmosphere.

$$\text{[7]}\quad \underset{\text{Ph-C(=O)-CH(OH)-Ph}}{\text{O OH}} + \text{M} \xrightarrow{\text{OH}^-} \underset{\text{Ph-C(=O)-C(=O)-Ph}}{\text{O O}} + 2\,\text{MH}_{ads}$$

We have also studied the ECH of biacetyl. The study in alkaline solutions was precluded because of rapid aldol condensation. In neutral solutions, ECH mainly gave acetoin on both RaNi and RaCo electrodes. No hydrogenation occurred on DeCu electrodes, hydrogen evolution again being the sole electrochemical process observed.

1-Phenyl-1,2-propanedione was also subject to an aldol condensation in alkaline solutions. ECH of this diketone was therefore carried out in neutral media only (Table 9). On RaNi, two different electrolytes were used: H_3BO_3/NaCl (entry 1) and the acetate buffer (entry 2). As with cyclohexanone and acetophenone, the ECH of 1-phenyl-1,2-propanedione was more efficient in the boric acid medium (94% of diols, 6% of ketols, current efficiency of 80%) than in the acetate buffer (53% of diols, 47% of ketols, current efficiency of 68%). The *erythro* isomer of the diols was predominant and, of the two ketols **1** and **2**, ketol **1**, corresponding to the hydrogenation of the more reactive conjugated carbonyl, largely predominated. On the less active RaCo and DeCu electrodes, the electrohydrogenations were carried out only in the boric acid medium and stopped at the ketols, with ketol **1** again predominating (entries 3 and 4).

Reduction of β-diketones

Tables 10 and 11 show the results concerning the ECH of 1,3-diphenyl-1,3-propanedione and of 2,4-pentanedione, respectively. In the alkaline medium (KOH 0.14 M), these 1,3-diketones ($pK_a \sim 9$ (21)) should exist as their conjugate base, the conjugated enolate. In the neutral medium, the enol form most probably predominates. The percentage of enol form in pure diphenylpropanedione can be up to 100% (22). The enol form content is 80% in pure pentanedione and 83% in its solution in absolute alcohol (23).

On RaNi, the ECH of 1,3-diphenyl-1,3-propanedione (Table 10) yielded a mixture of 1,3-diphenyl-1,3-propanediols (**4**) and 1,3-diphenyl-1-propanol (**3**). In the alkaline medium, the monoalcohol **3** was the major product (72%, entry 2). On RaCo (entry 3), the ECH in the alkaline medium was much less efficient than on RaNi but the sole product obtained was the monoalcohol **3**. On DeCu, there was no electrohydrogenation at all, only hydrogen evolution occurred. The monoalcohol **3** most probably comes from the ECH of chalcone resulting from the dehydration of the intermediate β-hydroxyketone (Scheme 2), a relatively easy process either in an acidic or a basic medium (24). The relative proportions of diols **4** and monoalcohol **3** depend on the relative rates of hydrogenation and dehydration of the intermediate β-hydroxyketone (Scheme 2). In the alkaline medium, the hydrogenation would be faster than the dehydration whereas in the boric acid medium, the hydrogenation would be slower than the dehydration. On RaCo, which is less active than RaNi, hydrogenation of the β-hydroxyketone would be slower than its dehydration.

ECH of 2,4-pentanedione occurred on RaNi only and was very inefficient, hydrogen evolution being faster than electrohydrogenation (Table 11). In this case, the rate of dehydration of the intermediate β-hydroxyketones was slower than

its hydrogenation and only the diols were obtained. With both β-diketones studied, there was little diastereoselectivity for diol formation. The ratio *RS*:*RR* + *SS* was about 50:50 with the diphenylpropanedione and about 60:40 with the pentanedione.

Conclusion

Generally, electroreduction of ketones takes place at quite negative potentials, i.e., from −1.2 to −2.2 V (vs. ECS) for cyclohexanone and from −1 to −1.6 V (vs. ECS) for acetophenone (25). In the case of α-diketones, the reported potentials are about −1 and −2 V (vs. ECS) for the reduction of the first and second carbonyl group, respectively. Thus the reduction at Raney metal electrodes requires less energy (−0.7 to −1.0 V vs. ECS). Furthermore, no pinacol was detected. These are two advantages of ECH over electroreduction. By the right choice of electrode material and conditions of electrolysis, the ECH of benzil gave selectively either benzoin or hydrobenzoin, showing that chemoselective reductions of one carbonyl of α-diketones can be carried out by ECH.

The diastereoselectivity observed for the diol formation in the ECH of α-diketones and β-diketones was comparable to that encountered in catalytic hydrogenations. In the literature, Raney nickel powder has been modified by optically active tartaric acid (26–32) and used in catalytic hydrogenations or in electrocatalytic hydrogenations of various monoketones and diketones. We modified our codeposited RaNi electrodes with the reported procedure and used these modified electrodes for the ECH of benzil. The *threo* hydrobenzoin isolated from the mixture of the *threo* and *meso* forms had an optical yield of 7.3%. When tartaric acid was added to the electrolytic solution and the ECH carried out with a modified RaNi electrode, the optical yield increased to 22%.

Experimental

Vapor phase chromatographic analyses were performed on a Hewlett Packard 5710A chromatograph equipped with a flame ionization detector, an HP 3390A integrator, and a DB-5 fused capillary column 30 m long. NMR spectra were recorded on a Bruker WM250 spectrometer coupled with an Aspect 2000 computer. The mass spectra were recorded on a VG ZAB-1F spectrometer. IR spectra were recorded on a Perkin–Elmer 781 spectrometer. Optical rotations were measured with a Perkin–Elmer 141MC polarimeter.

The products were all commercially available: cyclohexanone from Anachemia; acetophenone and 2,4-pentanedione from Fisher; benzylacetone, 2-octanone, benzil, 1-phenyl-1,2-propanedione, and 1,3-diphenyl-1,3-propanedione from Aldrich. The authentic products of electrohydrogenation were purchased: cyclohexanol, 2-octanol, 2,4-pentanediol, benzoin, hydrobenzoin and 1-phenyl-1,2-propanediol from Aldrich; 1-phenylethanol from Fluka; and 4-phenyl-2-butanol from Lancaster Synthesis. Distilled water and commercial methanol (BDH Assured ACS) were used for the solutions.

The Raney metal electrodes were prepared following the detailed procedure described earlier (6–9). Leaching (or activation) of the electrodes was performed in a 30% NaOH solution at 70°C during 6h, then at room temperature overnight.

The electrolyses were carried out with a PAR 173 potentiostat connected to an ECS 410 coulometer and a Dynascan Corporation 2830 multimeter. A two-compartment H-type cell, having a Nafion 324 (E.I. du Pont de Nemours) membrane or a fine glass frit as separator, was used. The counter-electrode was a graphite rod (7 mm) or a platinum plate (3 cm^2). A Cole Parmer saturated calomel electrode placed in a separate compartment was used to monitor the cathode potential.

The solutions were prepared by dissolving the supporting electrolyte in the methanol:water (w/w) mixture. The pH was measured with a Sargent Welch 6000 pH meter and a Cole Parmer glass

electrode that was calibrated beforehand with commercial aqueous buffer solutions. It should be noted here that the real values of pH (if calibration had been made with buffers prepared in methanol:water solvents) should be higher; for example the calculated value for the acetate buffer in methanol is 7.1 compared to a measured value of 6.5 in methanol:water. The solution was poured into the cell (125 mL in each compartment) and deaerated. The activated cathode, the anode, and the reference electrode were immersed. Electrolysis of water was carried out at a constant current (100 mA) for a passage of 440 C, after which the potential was shifted to a more positive value until the current reached zero. One (or two) mmoles of substrate was then added, which induced an increase in the current. A charge equivalent to 2 F/mol of organic substrate (in the case of monoketones) or 4 F/mol (in the case of diketones) was passed. Aliquots were extracted with ether after the addition of saturated NaCl solution, and analyzed by vpc, with comparison with authentic samples. Yields and mass balance were determined by the internal standard method using authentic samples. In the case of 1,3-diphenyl-1,3-propanedione, mass spectrometry, IR, and ^{1}H NMR spectra were consistent with the structure of the products, and the distribution of diastereomers was determined by ^{1}H NMR.

BERNARD PIROTTE, PASCAL DE TULLIO, BERNARD MASEREEL, MARC SCHYNTS, JACQUES DELARGE, LÉON DUPONT, and LÉOPOLD THUNUS. Can. J. Chem. **71**, 1857 (1993).

The acido-basic behavior of 4-acylamino-4*H*-1,2,4-triazoles and of the related structures, 4-acylamino-4*H*-1,2,4-triazolium salts, 4-acylamino-1,2,4-triazoline-3-thiones, and 4-acylamino-1,2,4-triazolin-3-ones, has been compared. Among the triazolium salts examined, the 1-carboxymethyl-4-phenylacetylamino derivative has been selected as a particular triazolium salt bearing two acidic centres, a carboxylic acid group and an exocyclic amide group. This compound has been isolated in three different ionic forms corresponding to different protonation and deprotonation states of the molecule. For these compounds, IR, NMR, and X-ray data were compared and the preferential localization site of the labile proton on the betainic intermediate structure has been discussed. Taking into account that deprotonation of the amide function of 4-acylamino-4*H*-1,2,4-triazolium salts may introduce a negative pole in the proximity of the strong electrophilic carbon atom in the 2-position of the ring, reactivity of different triazolium salts toward the nucleophilic addition of the hydride ion has been compared. In particular, 4-acylamino-4*H*-1,2,4-triazolium salts free of alkyl substituent on the amide nitrogen failed to give the corresponding 4-acylamino-Δ2-1,2,4-triazolines after reaction with the hydride ion, while, under the same conditions, the 4-*N*-methyl derivatives were transformed into this unusual ring system in good yields. In this case, no decrease of reactivity toward the nucleophilic agent was observed since, as a result of the N-alkylation, no deprotonation of the amide group can occur in these alkaline experimental conditions.

BERNARD PIROTTE, PASCAL DE TULLIO, BERNARD MASEREEL, MARC SCHYNTS, JACQUES DELARGE, LÉON DUPONT et LÉOPOLD THUNUS. Can. J. Chem. **71**, 1857 (1993).

Le comportement acido-basique de 4-acylamino-4*H*-1,2,4-triazoles et de structures associées, à savoir, les sels de 4-acylamino-4*H*-1,2,4-triazolium, les 4-acylamino-1,2,4-triazoline-3-thiones et les 4-acylamino-4*H*-1,2,4-triazolin-3-ones, a été comparé. Parmi les sels de triazolium examinés, le 1-carboxyméthyl-4-phénylacétylamino-4*H*-1,2,4-triazolium a été sélectionné en raison de la présence sur la molécule de deux groupements acides, une fonction acide carboxylique et une fonction amide exocyclique. Ce composé a été isolé sous trois formes ioniques différentes correspondant à trois états de protonation et de déprotonation différents de la molécule. Pour ces composés, les données IR, RMN et cristallographiques ont été comparées, et le site de localisation préférentiel du proton labile sur la structure bétaïnique intermédiaire a été discuté. Tenant compte du fait que la déprotonation de la fonction amide des sels de 4-acylamino-4*H*-1,2,4-triazolium est susceptible d'introduire un pôle négatif à proximité de l'atome de carbone fortement électrophile en position 2 du cycle, la réactivité de différents sels de triazolium vis-à-vis de l'addition nucléophile de l'ion hydrure a été comparée. En particulier, les sels de 4-acylamino-4*H*-1,2,4-triazolium ne possédant pas de substituant alkyle sur l'azote amide ne permirent pas d'obtenir les 4-acylamino-Δ2-1,2,4-triazolines correspondantes après réaction avec l'ion hydrure, tandis que, dans les mêmes conditions, les dérivés 4-*N*-méthylés furent transformés en cet hétérocycle avec de bons rendements. Dans ce cas, il n'y a pas de diminution de la réactivité vis-à-vis de l'agent nucléophile puisque, en raison de la N-alkylation, la déprotonation du groupe amide ne peut avoir lieu dans ces conditions expérimentales alcalines.

Introduction

Although the synthesis of 4-amino-4*H*-1,2,4-triazole was described much earlier (1), little has appeared in the literature on 4-acylamino derivatives and related structures, i.e., 4-acylamino-4*H*-1,2,4-triazolium salts, 4-acylamino-1,2,4-triazoline-3-thiones, and 4-acylamino-1,2,4-triazolin-3-ones.

The chemistry of 4-amino-4*H*-1,2,4-triazolium salts has been explored by Becker and Timpe and co-workers (2–11). Moreover, the synthesis of some 4-acylaminotriazolin-3-ones and -thiones free of an alkyl substituent on the (N)-2 position have also been reported (12–18). The present work describes unknown aspects of the chemistry and physicochemical properties of 4-acylamino-4*H*-1,2,4-triazoles and related triazolium salts, triazolinethiones, and triazolinones. Acidity of the exocyclic amide function of the different classes of compounds is of particular interest since some of these products have been selected as potential bioactive molecules (18–22). In fact, their bioavailability and (or) interaction with their biological targets will depend upon their ionic and stereoelectronic nature at physiological pH.

In addition, the present work describes a new synthetic pathway to the very unstable 4-amino- and 4-*N*-methyl-*N*-acylamino-Δ2-1,2,4-triazolines via borohydride reduction of the corresponding 4-amino- and 4-*N*-methyl-*N*-acylamino-

4*H*-1,2,4-triazolium salts. The behavior of triazolinethiones to oxidation in presence of a peracid is also reported.

Results and discussion

*(a) 4-Acylamino-4*H*-1,2,4-triazoles*

4-Phenylacetylamino-4*H*-1,2,4-triazole (**2**) was obtained from acylation of 4-amino-4*H*-1,2,4-triazole (**1**) with phenylacetyl chloride as previously described (Scheme 1) (19). This model compound exhibits the amphoteric character of 4-acylamino-4*H*-1,2,4-triazoles. In spite of the acylation of the exocyclic amino group, one of the ring nitrogens conserves a pronounced basic character as demonstrated by the easy alkylation of this position to give the corresponding 4-acylamino-4*H*-1,2,4-triazolium salts. Moreover, a stable and crystallizable hydrochloride salt **3** was isolated from the reaction of **2** with hydrochloric acid.

On the other hand, the acidity of the exocyclic amide proton of **2** may be compared to some extent to that of dihydrazides (23), and the sodium salt **4** was isolated from the reaction of **2** with a stoichiometric amount of sodium hydroxide in methanolic solution.

IR and NMR spectra of compounds **2**, **3**, and **4** are in accordance with expected electronic effects associated with their different ionic nature. Table 1 reports, for **2**, **3**, and **4**, the IR amide carbonyl absorption wavelength and the chemical shifts in DMSO-d_6 of the different protons of each molecule.

The high IR absorption band assigned to the amide carbonyl band of **3** is in accordance with those observed for 1-alkyl-4-acylamino-4*H*-1,2,4-triazolium salts (5) (see also compounds **10**, **11***a*, *b*, and **14**). The carbonyl absorption band at 1580 cm^{-1} for **4** associated to a strong one at 1365 cm^{-1} is typical of an anionic amide group and has been observed for the zwitterionic compounds **5**, **8**, **9**, and **13**. These values can be compared to some extent to the symmetric and asymmetric C—O bands near 1600 and 1400 cm^{-1} for salts of carboxylic acids.

For compound **3** the NMR data reflect that protonation of the triazole ring logically induces a strong deshielding, in particular, of the two ring hydrogens (3-H and 5-H). In contrast, the negative charge located on the exocyclic amide group of **4** induces a marked shielding of the overall protons and especially of the methylene hydrogens as a result of their proximity to the anionic group.

Of particular interest is the reaction of **2** with diazomethane which does not lead to the exocyclic N-methylation, as expected by analogy with carboxylic acids, but to the formation of the 1-methyl-1,2,4-triazolium derivative via alkylation of the ring nitrogen. Figure 1 illustrates the probable reaction mechanism and presents the ring nitrogen as the main nucleophilic center of the deprotonated molecule. Further confirmation of the low reactivity of the anionic amide group is given by the fact that zwitterionic compounds like **5**, **9**, or **13** do not react with CH_3I or $(CH_3)_2SO_4$ under various conditions; moreover, compound **11***a* fails to react with diazomethane.

*(b) 4-Acylamino-1-alkyl-4*H*-1,2,4-triazolium salts*

Becker and Timpe reported access to 4-acylamino-1-alkyl-4*H*-1,2,4-triazolium salts via two different pathways: alkylation of 4-acylamino-4*H*-1,2,4-triazoles (i.e., **9** via **2**) or acylation of 1-alkyl-4-amino-4*H*-1,2,4-triazolium salts (i.e., **13** via **12**) (5). These two processes were used to obtain various 4-acylamino-1-alkyl-4*H*-1,2,4-triazolium salts of therapeutic interest, for which detailed synthetic procedures have been described in part in a previous report (19).

The present report investigates in more details the interesting acido-basic behavior of the 4-acetyl and the 4-phenylacetylaminotriazolium derivatives.

Alkylation of **2** with bromoacetic acid in nitromethane did not permit direct isolation of the carboxylic acid derivative of structure **10** (as the bromide). The crude product obtained crystallized in cold water to give a solid (**6**), which was identified as a mixed salt containing equal amounts of the carboxylic acid **10**, as the bromide, and of the betaine **7**.

Direct isolation of the acid **10** was accomplished via catalytic deprotection of the tert-butyl ester **9** in nitromethane with gaseous HCl. This interesting triazolium salt has been isolated in three different protonated forms. The sparingly soluble betaine **7** was isolated in methanolic solution after exact neutralization of the carboxylic proton of the mixed salt **6** (19). A crystallographic study of betaine **7** reveals the establishment of a strong hydrogen bond between the amide group and the carboxylic group of a neighbouring molecule (24).

As expected from the stronger acidic character of the exocyclic amide proton of 4-acylaminotriazolium salts compared to 4-acylaminotriazoles, compound **7** reacts with weak bases, i.e., sodium hydrogen carbonate, to give the corresponding sodium salt **8**, which has been isolated as the dihydrate and characterized by X-ray crystallography (25).

NMR data of **7**, **8**, and **10** are in accordance with expected electronic effects associated with their different ionic nature (see Table 2). The successive deprotonations logically induce a progressive shielding of the different hydrogen atoms as expected from the increasing electronic density that results from the increasing global negative charge of the molecule.

Chemical shift data for the mixed salt **6** appear to be intermediate in value between those of the acid hydrochloride **10** and the betaine **7**. Thus, in accordance with the rapid proton exchange existing between the two species in solution, the NMR spectrum of **6** corresponds to an average picture of the two chemical entities.

Examination of the NMR chemical shifts of a series of 4-acylaminotriazolium salts (Table 2) led us to the conclusion that the betaine **7**, which can adopt two tautomeric forms **7***a* and **7***b* in solution (Fig. 2), seems to exist mainly as the **7***b* tautomer.

Indeed, the chemical shifts obtained in DMSO-d_6 on compound **7** (see Table 2) resemble those of compound **9** for which the presence of a negative charge exclusively located on the exocyclic amide function induces a marked shielding of the (Ph)-methylene and 3-H protons, but exerts a lower influence on the (N)-methylene protons (compare **11***a* with **9** and **10** with **7**). The chemical shift of the (N)-methylene protons of **7** (5.10 ppm) cannot be compared to that reported for the same protons of **18** (4.62 ppm) for which the N-methylation of the exocyclic amide moiety directs the negative charge exclusively on to the carboxylate group. Therefore, according to these data, predominance of the **7***a* tautomer in solution, which would result in the localization of the negative charge mainly on the carboxylate moiety, seems to be less probable.

Observation in solution (NMR data) that the amide function of **10** appears to be the first deprotonation site has not

SCHEME 1

been fully confirmed in the solid state (X-ray data). In fact, the crystal structures of **7** (24) and **8** (25) indicate, for the carboxylic function, atomic distances *d*(C—O) of 1.263 and 1.232 Å for **7**, and 1.248 and 1.246 Å for **8**. As a result, **8** clearly exhibits the carboxylate ion geometry (twofold *d*(C—O) near 1.25 Å (26)). But, for compound **7**, even if the distances *d*(C—O) do not correspond to the pure carboxylate ion geometry, they are far from those reported for

TABLE 1. IR absorption wavelength (cm^{-1}) of the amide carbonyl bond and ^1H NMR chemical shifts (δ, ppm) in DMSO-d_6 (HMDS) for compounds **2**, **3**, and **4**

	C=O	Ph-CH_2-CO	C_6H_5	3-H + 5-H
Hydrochloride **3**	1730	3.67	7.30	9.20
Neutral **2**	1692	3.60	7.30	8.58
Sodium salt **4**	1580	3.20	7.15	8.45

a pure carboxylic acid (*d*(C—O) near 1.31 Å; *d*(C=O) near 1.21 Å). In addition, bond lengths and angles reported for the amide function of **7** (*d*(C—O) = 1.222 Å; *d*(C—N) = 1.351 Å; N—C—O = 122.9°) and of **8** (*d*(C—O) = 1.264 Å; *d*(C—N) = 1.319 Å; N—C—O = 126.0°) may be compared, to some extent, to those reported for dihydrazides and their anionic salts (i.e., $CH_3CONHNHCOCH_3$: *d*(C—O) = 1.220 Å; *d*(C—N) = 1.340 Å; N—C—O = 122.3° (27); $CH_3CONHN^-COCF_2NO_2 \cdot NH_2NH_3^+$: *d*(C—O) = 1.249 Å; *d*(C—N) = 1.324 Å; N—C—O = 130.3° (28)). Thus, for these two chemical classes, deprotonation of the amide function results in the lengthening of the C—O bond associated with the contraction of the C—N bond, and in a significant increase of the N—C—O bond angle. Therefore, in accordance with the X-ray data, betaine **7** in the solid state does not show a clear deformation of the amide function that could be explained by a significant deprotonation.

Moreover, in accordance with the expected pK_a values attributable to the two acidic groups of **10**, the carboxylic function logically exhibits the strongest acidic character and must be the first deprotonation site. In fact, the pK_a value of this function, according to the presence of a quaternary nitrogen in the α-position of the carboxylic group, could be estimated as not far from those of amino-acid hydrochlorides (pK_a = 2–2.5).

The pK_a values attributed to the exocyclic amide function of different 4-acylaminotriazolium salts have been determined (see Table 3). These results, in fact, indicate a strong acidic character for this function, which appears to be equal to, or, in some cases, higher than conventional carboxylic acids (pK_a = 4–4.5), but lower than amino-acid hydrochlorides. However, this observation explains the ability of weak bases (i.e., $NaHCO_3$) to deprotonate 4-acylaminotriazolium salts.

The esters **14** and **11***a* logically exhibit a stronger acidic character since the first deprotonation for **21** and **7** leads to the formation of a carboxylate anion group expected to be a lower electron-withdrawing group than the ester function.

The specific chemical reactivity of the 4-acylamino-4*H*-1,2,4-triazolium salts is essentially confined to the 5-position of the molecule (11), which exhibits a considerable electrophilic character. We have compared the reactivity toward nucleophilic addition of different 4-acylamino-4*H*-1,2,4-triazolium salts with or without an alkyl substituant on the exocyclic amide nitrogen. In fact, it may be expected that deprotonation of the exocyclic amide group in slight alkaline conditions, which therefore introduces a delocalized negative charge on this position, increases the electron density at the 5-position of the ring and, as a result, may decrease its susceptibility to nucleophilic addition.

The strong electrophilic character of the carbon atom in this position was exploited for the transformation of 4-(*acyl*)amino-4*H*-1,2,4-triazolium salts into their corresponding 4-(*acyl*)amino-1,2,4-triazoline-3-thiones by heating the former in pyridine (or a mixture of pyridine and triethylamine) in presence of elemental sulfur (Scheme 2) (19). The basic solvent catalyses the deprotonation of the slightly acidic hydrogen atom in the 5-position to give an ylide or a carbene intermediate able to react with the sulfur atom (7, 10). The *N*-methyl derivatives reacted comparably with sulfur in pyridine (Scheme 2), but the reaction conditions were found to be milder in this case (15 min at 50°C instead of 1 h at reflux (19)). This result could be explained by the higher reactivity of the *N*-methyl derivatives **22** (R′ = CH_3) since alkyl substitution of the amide nitrogen prevents the deprotonation of this position by the basic solvent. As a result, no decrease of the electrophilic character of the 5-position can be accomplished by the proximity of an electron-donor anionic amide group.

The ring opening of azolium salts (29), and in particular of 4-acylaminotriazolium salts (4–7), in aqueous alkaline solution has already been studied. It results from the nucleophilic addition of the hydroxide ion to the strong electrophilic iminium moiety of the ring. Susceptibility of this moiety to hydride addition has also been studied for a long time for different azolium salts, i.e., for thiazolium (30, 31) and oxazolinium (32, 33) salts, to give the corresponding thiazolidines and oxazolidines, respectively. However, no comparable studies have been conducted on the 4-amino-4-*H*-1,2,4-triazolium derivatives.

We have observed that the hydrophilic water soluble 4-aminotriazolium derivative **12** can be reduced in aqueous solution with sodium borohydride into the corresponding hydrophobic Δ2-triazoline **30** (Scheme 3). As expected, the NMR spectrum of **30** shows a strong shielding of most of the protons of the molecule since the positive charge on the ring, and its aromatic character, has disappeared after hydride addition (i.e., the 3-H hydrogen atom is found at 9.15 ppm in **12** and at 6.65 ppm in **30**). Under the same reduction conditions the 4-acylaminotriazolium salts such as **9** and **13** do not react with sodium borohydride. Whatever the conditions employed, the starting material was recovered unchanged even in the presence of a large excess of sodium borohydride.

In contrast, the corresponding N-CH_3 derivatives **31** readily react with sodium borohydride to give the corresponding 4-acylamino-Δ2-1,2,4-triazolines **32** (Scheme 4). The chemical structure of these unusual triazolines has been confirmed by NMR, IR, mass spectroscopy, and elemental analysis.

As observed with **30**, hydride addition on the 4-acylaminotriazolium salt **31** is responsible for a strong shielding of most protons, and comparable chemical shifts are found on the two NMR spectra (i.e., 3-*H*, N-CH_2-N, N-CH_2-CO). In addition, differentiation of the methylene protons is observed and might result from restricted free rotation at the N—N bond as a probable result of steric hindrance between the methyl radical linked to the exocyclic tertiary amide nitrogen and the ring methylene moiety.

Addition of CF_3COOD to the NMR sample doesn't modify the spectrum. As a result, compounds **32***a–b* do not exhibit a net basic character (no significative deshielding of any protons indicating protonation of a basic position) and appear to be stable in the presence of a strong acid.

(c) 4-Acylamino-2-alkyl-1,2,4-triazoline-3-thiones and -3-ones

As explained above, the triazolinethiones may be obtained via treatment of the corresponding triazolium salts with sulfur in pyridine (or a mixture of pyridine and triethylamine). Different triazolinethiones have also been prepared via acylation of the amine intermediate **27** (19). They were eventually transformed into the corresponding carboxylic acids after removal of the *tert*-butyl protecting group (19). The pK_a values for the exocyclic amide function of the former have been compared to those of the corresponding triazolium salts. These values were logically found to be higher for triazolinethiones than for triazolium salts (compare Tables 3 and 4) since the electron-withdrawing effect of an ar-

[a]Reference 19.

omatic cationic ring is expected to be more pronounced than those of a non-aromatic and non-cationic ring.

The pK_a values of the exocyclic amide group of the corresponding 4-acylaminotriazolinones have also been determined (see Table 4). These compounds were synthesized via alkaline hydrolysis into **29** of the *S*-methylthiouronium derivative **28**, resulting from treatment of **27** with methyl iodide (19), and acylation of the exocyclic amino group of **29** (19) (see Scheme 2). Direct transformation of the triazolinethiones into the triazolinones via treatment of **25**, **26**, or **27** with hydrogen peroxide in acetic acid or with *meta*-chloroperoxybenzoic acid was unsuccessful, although this process was earlier reported for different thiono compounds (34, 35). Surprisingly, the corresponding triazolium salts have been isolated in good yields under these oxidative conditions (Scheme 2).

We observe that the pK_a values of the exocyclic amide function are approximately 0.8–1.0 pH units lower for triazolinethiones than for the corresponding triazolinones. It can be concluded that the electron-withdrawing effect on the amide function is significantly more pronounced for the triazolinethione ring. These results are consistent with the experimental NMR chemical shifts (19), which, to some extent, reflects the different electron-withdrawing impact of the two ring systems (see Table 4). In fact, the overall protons of all the triazolinethiones were found to be more deshielded than those of the triazolinones. Moreover, a slight difference (0.3 pH units) exists between the acetyl and the phenylacetyl derivatives as a result of expected electron-withdrawing effects.

The second pK_a values for the carboxylic acids (**33**, **34**, **35**, and **37**) are found to be 0.5–0.7 pH unit higher than those of the corresponding esters (**25**, **26**, **36**, and **38**) because of the lower electron-withdrawing effect of the carboxylate function (resulting from the first neutralization) compared to the ester function.

In conclusion, the acido-basic character of potential bioactive molecules may influence not only their interaction with biological targets (recognition by specific enzymes or receptors, charge distribution compatibility, interaction with active site amino-acids of target enzymes, . . .), but also their bioavailability (absorption, plasma half life, elimination, . . .).

Therefore, since the 4-amino-4*H*-1,2,4-triazole ring system has been extensively explored in medicinal chemistry and will find new applications in the future, the present results are important for predictive behavior of 4-acylamino-1,2,4-triazoles and related structures in biological systems. In particular, in spite of an apparent similarity, 4-acylamino-4*H*-1,2,4-triazolium salts and their 4-*N*-alkyl-acylamino analogs are expected to exert very different biological responses with regard to their different reactivity and charge distribution at physiological pH.

Moreover, the strong acid character of 4-acylaminotriazolium salts, which is comparable in some cases with that of carboxylic acids, may help the design of bioactive molecules for which a deprotonated form at the neutral pH contributes to their biological activity. In contrast, if a negative charge on the molecule could be unfavorable (i.e., for its recognition by a specific target), it would be preferable to examine (4-acylamino)triazolinones rather than (4-acylamino)triazolinethiones, even if these two ring systems appear to be very similar. In fact, some of these thiono derivatives, which are stronger acids, could exist in a partial ionic form at physiological pH.

Experimental

Melting points were determined in a Büchi–Tottoli cappilary melting point apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 297 spectrophotometer. The ^1H NMR spectra were taken on either a Brucker AW-80 (80 MHz) or a Brucker AM-400 (400 MHz) instrument in DMSO-d_6 or in $CDCl_3$. The ^{13}C NMR spectra were recorded on a Brucker AM-400 instrument. Chemical shifts are expressed in ppm downfield from internal HMDS (for DMSO-d_6) or TMS (for $CDCl_3$). ^1H NMR data are tabulated in the following order: chemical shift, multiplicity, number of protons, attribution. Elemental analyses were realized on a Heraeus Micro U instrument. Mass spectra were recorded on a LKB-GC 9000S mass spectrometer or a KRATOS MS-80 RFA mass spectrometer (FAB technique). The syntheses of compounds **1**, **2**, **6**, **7**, **9**, **12**, **13**, **21**, **25–29**, **31**, and **33–38** has been described elsewhere (19, 20). For the other compounds, their preparation was realized as follows.

Synthesis

*4-Phenylacetylamino-4*H*-1,2,4-triazole hydrochloride* **3**

To a solution of 4-phenylacetylamino-4*H*-1,2,4-triazole **2** (19) (1.0 g, 4.95 mmol) in ethanol (10 mL) was added aqueous 5 N HCl (1.0 mL). The solvents were removed under reduced pressure. The resulting solid was crystallized from a 1:3 mixture of methanol–acetone (90%): mp 131–133°C; IR and ^1H NMR (DMSO-d_6, HMDS, 80 MHz), see Table 1. Anal. calcd. for $C_{10}H_{10}N_4O \cdot HCl$: C 50.32, H 4.64, N 23.47; found: C 50.14, H 4.77, N 23.29.

*4-Phenylacetylamino-4*H*-1,2,4-triazole sodium salt* **4**

A solution of 4-phenylacetylamino-4*H*-1,2,4-triazole **2** (1.0 g, 4.95 mmol) in methanol (20 mL) was mixed with a solution of sodium hydroxide (0.2 g, 5.0 mmol) in methanol (10 mL). Addition of diethyl ether (100 mL) gave rise to the precipitation of **4**, which was filtered, washed with a 1:3 mixture of methanol – diethyl ether, and dried under vacuum (very hygroscopic) (80%): mp 210–215°C; IR and ^1H NMR (DMSO-d_6, HMDS, 80 MHz), see Table 1.

*1-Methyl-4-phenylacetylimino-4*H*-1,2,4-triazolium inner salt* **5**

To a solution of 4-phenylacetylamino-4*H*-1,2,4-triazole **2** (1.0 g, 4.95 mmol) in methanol (40 mL) was added an ethereal solution of diazomethane until a slight yellow color persisted. The solvents were removed under reduced pressure and the residue was dissolved in dichloromethane (20 mL). The residual insoluble material was removed by filtration and the filtrate, diluted with petroleum ether (40–60°C) (40 mL), yielded the crystalline **5**, which

was filtered, washed with petroleum ether (40–60°C), and dried (75%), mp 149–151°C; IR, ν_{max}: 1585 (C—O asym.), 1525 (C=N), 1510 (C=N), and 1360 (C—O sym.) cm^{-1}; ^1H NMR (DMSO-d_6, HMDS, 80 MHz) δ: 3.25 (s, 2H, CH_2), 3.85 (s, 3H, CH_3), 7.15 (m, 5H, C_6H_5), 8.90 (s, 1H, 3-H), 10.28 (s, 1H, 5-H). Anal. calcd. for $C_{11}H_{12}N_4O$: C 61.10, H 5.59, N 25.91; found: C 60.99, H 5.72, N 25.83.

Sodium (4-phenylacetylimino-4H-1,2,4-triazolio)acetate dihydrate ***8***

To a solution of (4-phenylacetylamino-4*H*-1,2,4-triazolio)acetate **7** (19) (0.5 g, 1.92 mmol) in water (50 mL) was added a solution of sodium hydrogen carbonate (0.1612 g, 1.92 mmol) in water (5 mL). After 15 min at room temperature, the solvent was removed under reduced pressure and the solid residue so obtained was dissolved in methanol (50 mL). Traces of insoluble material were removed by filtration. Addition of diethyl ether (100 mL) to the filtrate gave rise to the precipitation of the crystalline **8**, which was filtered, washed with methanol – diethyl ether (1:2), and dried (90%); mp 105–110°C (dec.); IR, ν_{max}: 1635 (C—O carboxylate asym.) 1580 (C—O amide asym.), and 1380 (C—O sym.) cm^{-1}; ^1H NMR (DMSO-d_6, HMDS, 80 MHz), see Table 2. Anal. calcd. for $C_{12}H_{11}N_4O_3Na \cdot 2H_2O$: C 45.29, H 4.75, N 17.60; found: C 45.38, H 4.80, N 17.52.

1-Carboxymethyl-4-phenylacetylamino-4H-1,2,4-triazolium chloride ***10***

Into a solution of 1-*tert*-butoxycarbonylmethyl-4-phenylacetylimino-4*H*-1,2,4-triazolium inner salt **9** (19) (1.0 g, 3.16 mmol) in hot nitromethane (20 mL) was passed anhydrous HCl during 15 min. The solution was warmed 2 h at 90°C, after which time the solvent was removed under reduced pressure. The residue was dispersed in CH_2Cl_2 (50 mL) and the insoluble material was filtered and recrystallized in hot nitromethane. The compound crystallizes with one solvent molecule (85%); mp 162–165°C; IR, ν_{max}: 1745 (C=O carboxylic acid) and 1715 (C=O amide) cm^{-1}; ^1H NMR (DMSO-d_6, HMDS, 80 MHz), see Table 2 except δ 4.35 (s, 3H, CH_3NO_2). Anal. calcd. for $C_{12}H_{13}N_4O_3Cl \cdot CH_3NO_2$: C 43.64, H 4.51, N 19.58; found: C 43.54, H 4.70, N 19.49.

1-Tert-Butoxycarbonylmethyl-4-phenylacetylimino-4H-1,2,4-triazolium inner salt ***9***

To a solution of *tert*-butyl (4-phenylacetylamino-2,3-dihydro-3-thioxo-4*H*-1,2,4-triazol-2-yl)acetate **26** (19) (2.0 g, 8.68 mmol) in acetic acid (20 mL) was added a 30% solution of hydrogen peroxide in water (2.4 mL). After stirring for 15 min at room temperature, the solution was concentrated under reduced pressure, and the solid residue so obtained was dissolved in water (80 mL). The insoluble material was filtered and the filtrate was adjusted to pH 7.0 with sodium hydrogen carbonate. The solution was extracted three times with chloroform (120 mL). The combined organic layers were dried over anhydrous magnesium sulfate and filtered. The filtrate was concentrated under reduced pressure and the residue was purified by dissolution in chloroform (40 mL) followed by addition of petroleum ether (40–60°C) (160 mL) yielding the crystalline **9**, which was filtered, washed with petroleum ether (40–60°C), and dried (65%); mp 184–186°C; IR and NMR spectra identical with the compound obtained after direct alkylation of **2** (20).

4-Acetylimino-1-tert-butoxycarbonylmethyl-4H-1,2,4-triazolium inner salt ***13***

Compound **13** was obtained as described for **9** (see above) starting from (4-acetylamino-2,3-dihydro-3-thioxo-4*H*-1,2,4-tria-

1-tert-*Butoxycarbonylmethyl-4-phenylacetylamino-4*H-*1,2,4-triazolium chloride* ***11***a

Into a solution of 1-*tert*-butoxycarbonylmethyl-4-phenylacetylimino-4*H*-1,2,4-triazolium inner salt **9** (19) (1.0 g, 3.16 mmol) in dichloromethane (20 mL) was passed anhydrous HCl during 5 min at room temperature. Addition of diethyl ether (80 mL) gave rise to the precipitation of the crystalline **11***a*, which was filtered, washed with diethyl ether, and dried (95%); mp 161–163°C; IR, ν_{max}: 1755 (C=O ester), 1697 (C=O amide), and 1234 (C—O ester) cm^{-1}; ^1H NMR (DMSO-d_6, HMDS, 80 MHz), see Table 2. Anal. calcd. for $C_{16}H_{21}N_4O_3Cl$: C 54.47, H 6.00, N 15.88; found: C 54.07, H 6.48, N 15.63.

1-tert-*Butoxycarbonylmethyl-4-phenylacetylamino-4*H-*1,2,4-triazolium trifluoroacetate* ***11***b

Compound **11***b* was obtained as described for **11***a* (see above) except that anhydrous HCl was replaced with trifluoroacetic acid (1.1 molar equivalent) (80%); mp 148–152°C; IR, ν_{max}: 1750 (C=O ester), 1705 (C=O amide), 1630 (C—O carboxylate asym.), and 1425 (C—O carboxylate sym.) cm^{-1}; ^1H NMR (DMSO-d_6, HMDS, 80 MHz), see Table 2. Anal. calcd. for $C_{18}H_{21}N_4O_5F_3$: C 50.23, H 4.92, N 13.02; found: C 50.58, H 5.15, N 12.88.

4-Acetylamino-1-tert-*butoxycarbonylmethyl-4*H-*1,2,4-triazolium chloride* ***14***

Compound **14** was obtained as described for **11***a* (see above) starting from 4-acetylimino-1-*tert*-butoxycarbonyl-4*H*-1,2,4-triazolium inner salt **13** (85%); mp 161–163°C; IR, ν_{max}: 1742 (C=O ester), 1719 (C=O amide), and 1251 (C—O ester) cm^{-1}; ^1H NMR (DMSO-d_6, HMDS, 80 MHz), see Table 2. Anal. calcd. for $C_{10}H_{17}N_4O_3Cl$: C 43.40, H 6.19, N 20.25; found: C 43.66, H 6.25, N 20.30.

tert-*Butyl [4-amino-Δ2-1,2,4-triazolin-1-yl]acetate* ***30***

A solution of 4-amino-1-*tert*-butoxycarbonylmethyl-4*H*-1,2,4-triazolium bromide **12** (19) (1.0 g, 3.58 mmol) in water (10 mL), and chloroform (40 mL), were kept in an ice bath during the dropwise addition of a freshly prepared aqueous solution of sodium borohydride (0.5 g in 5 mL) under vigourous stirring. After complete addition, the organic layer was separated. The aqueous phase was extracted once with chloroform (20 mL), and the combined organic layers were dried over anhydrous magnesium sulfate. After filtration and removal of the solvent under reduced pressure, the final product was isolated as an oil (92%); IR, ν_{max}: 3430 (N—H), 3349 (N—H), 2979 (C—H aliph.), 2934 (C—H aliph.), 1739 (C=O ester), and 1156 (C—O ester) cm^{-1}; ^1H NMR (DMSO-d_6, HMDS, 80 MHz) δ: 1.30 (s, 9H, $C(CH_3)_3$), 3.42 (s, 2H, N-CH_2-N), 4.00 (s, 2H, N-CH_2-CO), 4.10 (br s, 2H, NH_2), 6.65 (s, 1H, 3-H); after addition of CF_3COOD, δ: 1.35 (s, 9H, $C(CH_3)_3$), 5.05 (s, 2H, N-CH_2-CO), 8.25 (s, 1H), 8.90 (s, 1H).

*[4-(*N*-Methyl-*N*-phenylacetylamino)-Δ2-1,2,4-triazolin-1-yl]acetic acid* ***32***a

To a solution of 1-carboxymethyl-4-(*N*-methyl-*N*-phenylacetylamino)-4*H*-1,2,4-triazolium bromide **31***a* (19) (0.3 g, 0.76 mmol) in water (3 mL) was added dropwise a solution of sodium borohydride (0.15 g) in water (1.5 mL). After 5 min at room temperature, the solution was adjusted to pH 3 with 0.1 N HCl and then extracted (×3) with chloroform (20 mL). The combined organic layers were dried over anhydrous magnesium sulfate. After filtration and removal of the solvent under reduced pressure, the residue was dissolved in ethyl acetate (5 mL). Insoluble material was removed by filtration, and the filtrate, mixed with petroleum ether

(40–60°C) (20 mL), gave rise to the precipitation of the crystalline **32***a* (57%); mp 124–127°C; IR, ν_{max}: 1714 (C=O carboxylic acid), 1664 (C=O amide), and 1609 (C=N) cm^{-1}; ^1H NMR (DMSO-d_6, HMDS, 80 MHz) δ: 2.90 (s, 3H, N-CH_3), 3.45 (m, 1H, H_a of N-CH_2-N), 3.70 (s, 2H, Ph-CH_2), 3.80 (m, 1H, H_b of N-CH_2-N), 4.02 (m, 1H, H_a of N-CH_2-CO), 4.41 (m, 1H, H_b of N-CH_2-CO), 6.90 (s, 1H, 3-H), 7.15 (m, 5H, C_6H_5); MS (FAB) *m/z*: 277 [MH^+], 275 [$MH^+ - H_2$, hydride abstraction]. Anal. calcd. for $C_{13}H_{16}N_4O_3$: C 56.51, H 5.81, N 20.28; found: C 56.10, H 6.07, N 20.70.

tert-*Butyl* [*4-(N-methyl-*N*-phenylacetylamino)-Δ2-1,2,4-triazolin-1-yl*]*acetate* ***32***b

To a solution of 1-*tert*-butoxycarbonylmethyl-4-(*N*-methyl-*N*-phenylacetylamino)-4*H*-1,2,4-triazolium bromide **31***b* (20) (0.3 g, 0.68 mmol) in water (4 mL) was added dropwise a solution of sodium borohydride (0.15 g) in water (1.5 mL). After 5 min at room temperature, the oily precipitate was extracted (×3) with chloroform (20 mL). The combined organic layers were dried over anhydrous magnesium sulfate, filtered, and concentrated under reduced pressure to give **32***b* as an oil (85%); IR, ν_{max}: 2978 (C—H aliph.), 2932 (C—H aliph.), 1738 (C=O ester), 1674 (C=O amide), 1604 (C=N), and 1230 (C—O ester) cm^{-1}; ^1H NMR (DMSO-d_6, HMDS, 80 MHz) δ: 1.30 (s, 9H, $C(CH_3)_3$), 2.87 (s, 3H, N-CH_3), 3.42 (m, 1H, H_a of N-CH_2-N), 3.70 (s, 2H, Ph-CH_2), 3.75 (m, 1H, H_b of N-CH_2-N), 4.00 (m, 1H, H_a of N-CH_2-CO), 4.38 (m, 1H, H_b of N-CH_2-CO), 6.90 (s, 1H, 3-H), 7.15 (m, 5H, C_6H_5); ^1H NMR ($CDCl_3$, TMS, 400 MHz) δ: 1.50 (s, 9H, $C(CH_3)_3$), 3.10 (s, 3H, N-CH_3), 3.64 (d, 1H, H_a of N-CH_2-N, J = 17.2 Hz), 3.81 (s, 2H, Ph-CH_2), 3.89 (d, 1H, H_b of N-CH_2-N), 4.17 (d, 1H, H_a of N-CH_2-CO, J = 2.0 Hz), 4.47 (d, 1H, H_b of N-CH_2-CO), 6.40 (s, 1H, 3-H), 7.29 (m, 5H, C_6H_5); ^{13}C NMR ($CDCl_3$, TMS, 400 MHz) δ: 28.08 (s, 3C, 3 × *C*H_3), 30.06 (s, 1C, N-*C*H_3), 40.48 (s, 1C, Ph-*C*H_2), 56.07 (s, 1C, N-*C*H_2-CO), 70.47 (s, 1C, N-*C*H_2-N), 81.93 (s, 1C, *C*$(CH_3)_3$), 126.82 (s, 1C, *C* arom., *para*), 128.64 (s, 2C, *C* arom., *meta*), 129.02 (s, 2C, *C* arom., *ortho*), 134.86 (s, 1C, *C* arom., subst.), 141.63 (s, 1C, *C*=N), 168.27 (s, 1C, *C*=O), 173.82 (s, 1C, *C*=O); MS *m/z* (RI %): 332 (3) [M^+], 276 (4) [$M^+ - CH_2$=$C(CH_3)_2$], 231 (7) [$M^+ - COOC(CH_3)_3$], 184 (13) [$M^+ - PhCH_2CONCH_3$], 149 (15) [$PhCH_2CONHCH_3^+$], 128 (33) [$M^+ - PhCH_2CONCH_3 - CH_2$=$C(CH_3)_2$].

Determination of dissociation constants

The pK_a values of the triazole derivatives were determined on a Metrohm 670 Titroprocessor using a Metrohm 665 Dosimat and a Metrohm 6.0204.100 combined pH glass electrode. The pK_a values of the water soluble carboxylic acids were established, either in water, or in a 1:1:3 mixture of dimethylformamide, methanol, and water. The resulting ΔpK_a values calculated for the different carboxylic acids were used to correct the experimental values obtained in the same 1:1:3 solvent mixture for the corresponding sparingly water soluble *tert*-butyl esters.

Monotonic titration

Monotonic titration: Increment: 2 μL; rate for the volume of increment: 10 mL/min; maximum drift for measurement: 10 mV/min; delay time for measurement acquisition: 52 s; output for each increment: pH; output for each increment: total vol.

Method applied to water soluble products

The product (2.5×10^{-5} mol), dissolved in water (1 mL), was introduced in a micro titration cell. 1.0 N NaOH was added in a monotonic titration mode using a 2-μL step addition. The pH was determined at all steps and the titration curve was established. The equivalent point was automatically calculated. Three points just before and after the half-neutralization point were chosen. For each point, the pH and the added volume of NaOH were introduced in an appropriate calculation program from which the pK_a values were obtained taking into account the activity of the ions in solution. The mean of the six results with the standard deviation was calculated.

Method applied to water insoluble products

The above experimental conditions and calculation procedure were applied to the sparingly water soluble products except that the samples (2.5×10^{-5} mol) were dissolved in a dimethylformamide (0.2 mL) – methanol (0.2 mL) – water (0.6 mL) mixture.

Palladium(0)-catalyzed conversion of vinyl trifluoromethanesulfonates into α,β-unsaturated nitriles

EDWARD PIERS[1] AND FRASER F. FLEMING

Department of Chemistry, University of British Columbia, 2036 Main Mall, University Campus, Vancouver, BC V6T 1Z1, Canada

Received March 31, 1993

EDWARD PIERS and FRASER F. FLEMING. Can. J. Chem. **71**, 1867 (1993).

Treatment (benzene, room temperature) of each of the vinyl trifluoromethanesulfonates **16–23** with dry lithium cyanide in the presence of catalytic amounts of tetrakis(triphenylphosphine)palladium(0) and the crown ether 12-crown-4 provides good to excellent yields of the corresponding α,β-unsaturated nitriles **24–31**.

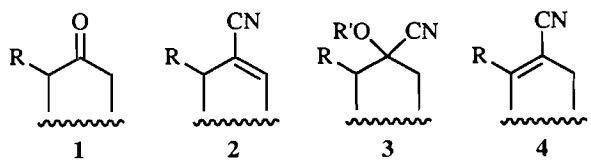
EDWARD PIERS et FRASER F. FLEMING. Can. J. Chem. **71**, 1867 (1993).

Le traitement (benzène, température ambiante) de chacun des trifluorométhanesulfonates de vinyle **16–23** par du cyanure de lithium sec, en présence de quantités catalytiques de tétrakis(triphénylphosphine)palladium(0) et d'éther 12-couronne-4 conduit à d'excellents rendements des nitriles α,β-insaturés correspondants, **24–31**.

[Traduit par la rédaction]

Introduction

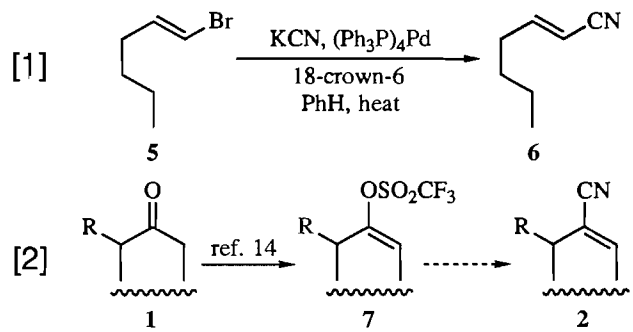
In connection with projects directed toward the total synthesis of natural products, we required a method for the conversion of unsymmetrically substituted cyclic ketones (see general formula **1**) into the corresponding α,β-unsaturated nitriles **2**. One-carbon homologations of ketones into unsaturated nitriles have traditionally been accomplished via a two-step method involving conversion of the carbonyl substrate into a cyanohydrin derivative **3**, followed by subjection of the latter species to a suitable elimination procedure (1–6). However, if this type of process is applied to unsymmetrically substituted ketones, the product usually consists of a mixture of the two possible positional isomers **2** and **4** (1, 4–6).



1 **2** **3** **4**

A number of methods for the transformation of vinyl halides into α,β-unsaturated nitriles have been developed (7–10, and citations therein). With respect to the present work, the reports by Yamamura and Murahashi (7) and Prochazka and Siroky (10) are particularly pertinent. These groups showed that treatment of vinyl halides with potassium cyanide in the presence of catalytic amounts of tetrakis(triphenylphosphine)palladium(0) and the crown ether 18-crown-6 in hot benzene provides, efficiently, the corresponding vinyl nitriles. For example, (*E*)-1-bromo-1-hexene (**5**) was converted into the nitrile **6** in high yield (7) (eq. [1]).

It is now well known, primarily from the important studies by Stille and co-workers (11–13), that vinyl trifluoromethanesulfonates (triflates) participate effectively in palladium(0)-catalyzed cross-coupling processes. Therefore, since the conversion of ketones into vinyl triflates is usually achieved easily and efficiently (14), we were attracted by the possibility of effecting the desired conversion of **1** into **2** via the intermediacy of vinyl triflates **7**, as shown in general terms in eq. [2]. We report in this paper the details of a study (15) that showed that, under carefully defined conditions, α,β-unsaturated nitriles can be derived, cleanly and efficiently, from vinyl triflates.[2]



Results and discussion

*(a) Preparation of the vinyl triflates **16–23***

The structural formulas of the ketones **8–15**[3] employed in this study are shown in Chart 1. Collectively, these substances exhibit various ring sizes and an interesting assortment of functional groups.

The effective method of McMurry and Scott (14) was employed to convert the ketones **8–15** into the corresponding vinyl triflates **16–23**, respectively (see Chart 1). The results of these transformations are summarized in Table 1. In general, the reactions proceeded in good-to-excellent yields (66–84%) and the crude products were conveniently purified by flash chromatography on silica gel (21).

*(b) Conversion of the vinyl triflates **16–23** into the α,β-unsaturated nitriles **24–31** (Chart 1, Table 1)*

Exploratory studies involved attempts to convert the vinyl triflate **16** into the unsaturated nitrile **24**. Initially, conditions similar to those employed by Yamamura and Murahashi (7) for the transformation of vinyl halides into nitriles were

[1]Author to whom correspondence may be addressed.

[2]For a recent report describing the Ni(0)- and Pd(0)-mediated conversion of aryl triflates into benzonitrile derivatives, see ref. 16.

[3]Substances **8**, **11**, and **15** are commercially available, while the remaining ketones were prepared during the course of other studies in our laboratory (compounds **9** and **10**, ref. 17; compounds **12–14**, refs. 18–20, respectively).

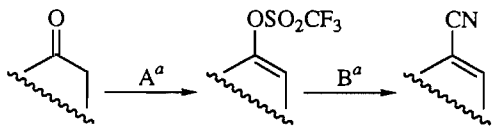
TABLE 1. Conversion of ketones into α,β-unsaturated nitriles



Entry	Ketone	Vinyl triflate (yield, %)[b]	Reaction time for B (h)	Nitrile (yield, %)[b]
1	**8**	**16** (75)	2	**24** (80)
2	**9**	**17** (80)	2	**25** (89)
3	**10**	**18** (76)	2.5	**26** (87)
4	**11**	**19** (66)	3	**27** (78)
5	**12**	**20** (73)	2	**28** (85)
6	**13**	**21** (84)	20	**29** (76)[c]
7	**14**	**22** (72)	2	**30** (78)
8	**15**	**23** (82)[d]	4	**31** (59)[e]

[a]A: (*i*-Pr)$_2$NLi (1.15 equiv.), THF, −78°C, 2 h; PhN(SO$_2$CF$_3$)$_2$ (1.1 equiv.), −78°C → room temperature. B: LiCN (2 equiv.), $(Ph_3P)_4Pd$ (0.07 equiv.), 12-crown-4 (0.07 equiv.), PhH, room temperature.

[b]Yield of chromatographically purified and, where appropriate, distilled product.

[c]An additional amount (0.07 equiv.) of $(Ph_3P)_4Pd$ was added after a reaction time of 6.5 h.

[d]Compound **23** was obtained by treatment of **15** with KH in THF (room temperature), followed by addition of PhN(SO$_2$CF$_3$)$_2$.

[e]Additional amounts (0.07 equiv.) of $(Ph_3P)_4Pd$ were added after reaction times of 1, 2, and 3 h.

examined. However, when **16** was treated (benzene, reflux, 8 h) with potassium cyanide in the presence of $(Ph_3P)_4Pd$ and 18-crown-6, a mixture of two products was obtained. Analyses of the mixture by gas–liquid chromatography (glc) and ^{1}H nmr spectroscopy showed that the two components were present in a ratio of about 5:1. Furthermore, although the two substances were inseparable by column chromatography on silica gel, comparison of the ^{1}H nmr spectrum with spectra of pure samples of **24** and **32** (*vide infra*) showed that the two products were **24** and **32**, respectively (eq. [3]).

The formation of the unsaturated nitrile **32** was unexpected. Subsequent attempts to maximize the formation of this substance did not lead to synthetically useful results but did provide a means of obtaining, in very low yield, a sample of pure **32** for characterization purposes. Thus, a benzene solution of $(Ph_3P)_4Pd$ (0.07 equiv.), 12-crown-4 (0.35 equiv.), and the enol triflate **16** (1.0 equiv.) was refluxed for 20 min. The resultant dark brown solution was treated with dry lithium cyanide (5.5 equiv.) and reflux was continued for a further 20 min. Work-up and flash chromatography of the crude material gave recovered vinyl triflate **16** (85%) and a small amount (15% based on recovered **16**) of the nitrile **32** (eq. [4]).

The infrared (ir) spectrum of **32** showed the expected absorptions (2217, 1638 cm^{-1}) for the unsaturated nitrile function. The ^{1}H nmr spectrum exhibited the following signals: δ 0.98, 1.00 (s, s, 3H each), 1.93 (t, 2H, J = 6 Hz, H_C), 2.29–2.36 (m, 2H, H_B), 2.55–2.59 (m, 2H, H_D), 3.48–3.56 (m, 4H, ketal methylene protons), 6.59–6.63 (m, 1H, H_A). The signal assignments were confirmed by suitable decoupling experiments. Thus, irradiation at δ 2.33 (H_B) changed the triplet at 1.93 (H_C) to a singlet, sharpened the multiplet at 2.55–2.59 (H_D) to a broad singlet ($w_{1/2}$ = 4 Hz), and simplified the signal due to H_A (6.59–6.63) to a triplet (J = 2 Hz); irradiation at δ 2.57 (H_D) simplified the multiplet at 2.29–2.36 (H_B) and changed the multiplet at 6.59–6.63 (H_A) to a triplet (J = 4 Hz); irradiation at δ 6.61 (H_A) sharpened the multiplet at 2.29–2.36 (H_B) and changed the multiplet at 2.55–2.59 (H_D) to a triplet (J = 2 Hz).

Further evidence for the structure of **32** was derived from a nuclear Overhauser enhancement (nOe) difference experiment and two SINEPT (22) experiments. Thus, in the nOe experiment, irradiation of the olefinic proton resonance (H_A, δ 6.61) caused signal enhancement at 2.29–2.36 (H_B) but not at 2.55–2.59 (H_D). In the two SINEPT experiments, both optimized for a $^3J_{C-H}$ of 7 Hz, irradiation of the signal at δ 3.48–3.56 (ketal methylene hydrogens) gave strong polarization transfer through three-bond coupling to the quaternary ketal carbon (δ 95.3), while irradiation at δ 6.61 (H_A) gave strong polarization transfer through three-bond coupling to the nitrile carbon (δ 118.9) but not to the quaternary ketal carbon. These observations are entirely consistent with structure **32**.

Experiments aimed at suppressing the formation of the "undesired" α,β-unsaturated nitrile **32** examined the use of a number of different solvents (*N*,*N*-dimethylformamide, hexamethylphosphoramide, THF, benzene) at different

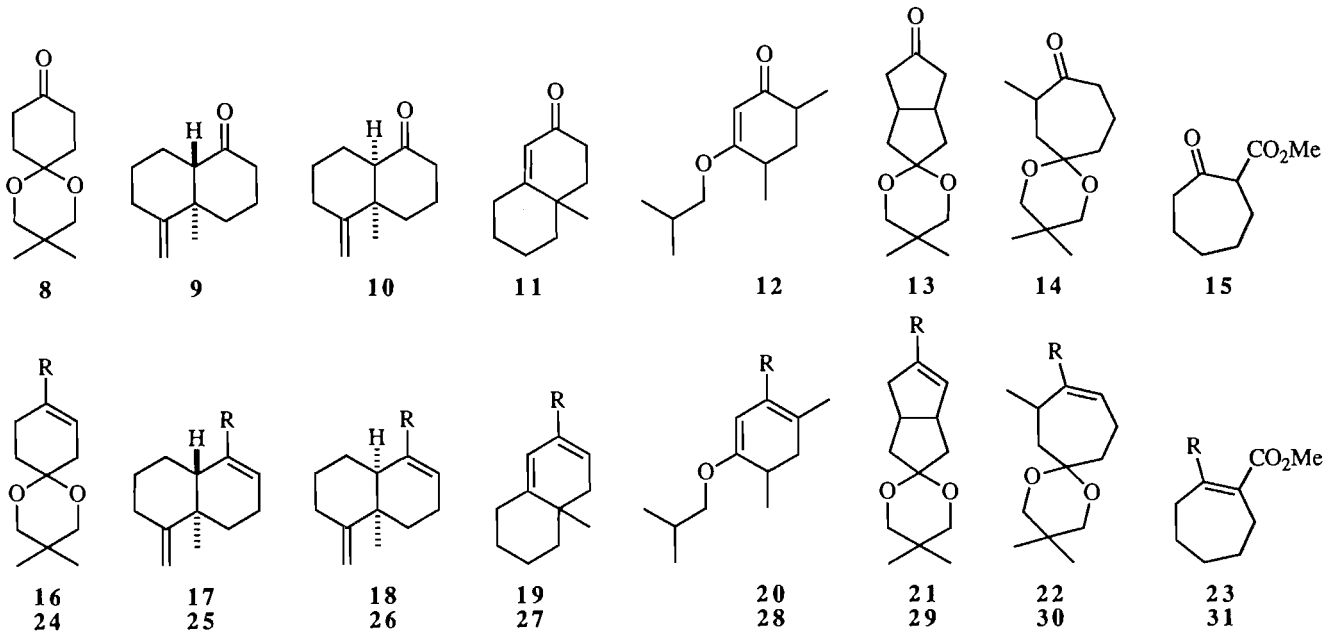

CHART 1

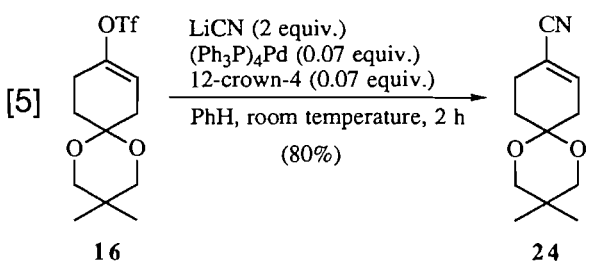
temperatures. Eventually it was found that treatment of **16** with KCN, 18-crown-6, and $(Ph_3P)_4Pd$ in benzene at room temperature for 4 h gave a mixture of starting material and the desired nitrile **24** in a ratio of ~ 3:1, respectively. Only a trace of **32** could be detected. A longer reaction time (47 h) led to almost complete consumption of the vinyl triflate **16** and produced **24** and **32** in a ratio of about 17:1, respectively.

The latter results were encouraging and led to the discovery that, at room temperature in benzene, reaction of the vinyl triflate **16** with lithium cyanide in the presence of $(Ph_3P)_4Pd$ and 12-crown-4 produced only the unsaturated nitrile **24**. After extensive experimentation, during which the reaction temperature and the relative concentrations of reagents and catalysts were varied, the conversion of **16** into **24** was found to proceed cleanly and efficiently (80%) using *dry* LiCN (2 equiv.), $(Ph_3P)_4Pd$ (0.07 equiv.), and 12-crown-4 (0.07 equiv.) in benzene (~5.5 mL per mmol of **16**) at room temperature. Under these conditions, complete conversion of **16** into **24** was achieved within 2 h (eq. [5]).



The spectral data derived from compound **24** are fully consistent with the assigned structure. Data obtained from nmr spectroscopy, including ^1H nmr decoupling and nOe experiments and two SINEPT (22) experiments, provided conclusive evidence for the substitution pattern on the cyclohexene ring (see experimental for details).

The generality of this new method for the conversion of vinyl triflates into α,β-unsaturated nitriles was demonstrated, at least to some degree, by transformation of substrates **17–23** into the corresponding products **25–31** (see Chart 1 and Table 1). For most of these cases (Table 1, entries 1–5, 7) the procedure developed for the acquisition of **24** from **16** (eq. [5]) worked well. These processes were efficient (78–89% yields) and were complete within reaction times of 2–3 h at room temperature. On the other hand, the reactions involving triflates **21** and **23** (Table 1, entries 6, 8) were somewhat sluggish. In these cases, an acceptable rate of conversion of substrate into product could be achieved by adding additional amounts of the catalyst $(Ph_3P)_4Pd$ to the reaction mixtures at appropriate times, as summarized in Table 1.

The method is compatible with the presence of a variety of functional groups. Thus, collectively, the substrates **16–23** contain ketal, alkene, conjugated diene, enol ether, and ester functions.

Each of the α,β-unsaturated nitriles listed in Table 1 exhibit spectra in full accord with the structural assignment. Appropriate ^1H nmr nOe difference experiments and, for the nitriles **24–26**, SINEPT (22) experiments, provided corroborative evidence for the structures of the nitrile products.

(c) Mechanistic considerations

On the basis of proposals for reaction pathways related to Pd(0)-catalyzed cross-coupling of vinyl triflates with organostannanes (11, 12, 23) and taking into account the recent important mechanistic studies of Stang *et al.* (24, 25) on related Pt(0)-mediated processes, it is reasonable to propose that the Pd(0)-catalyzed conversion of vinyl triflates into nitriles proceeds via the catalytic cycle shown in general terms in Scheme 1. Oxidative addition of palladium(0) to the C—O bond of the vinyl triflate provides the ionic (11, 24) palladium(II) species **33**. Reaction of **33** with cyanide ion (derived from the LiCN · 12-crown-4 complex), would produce

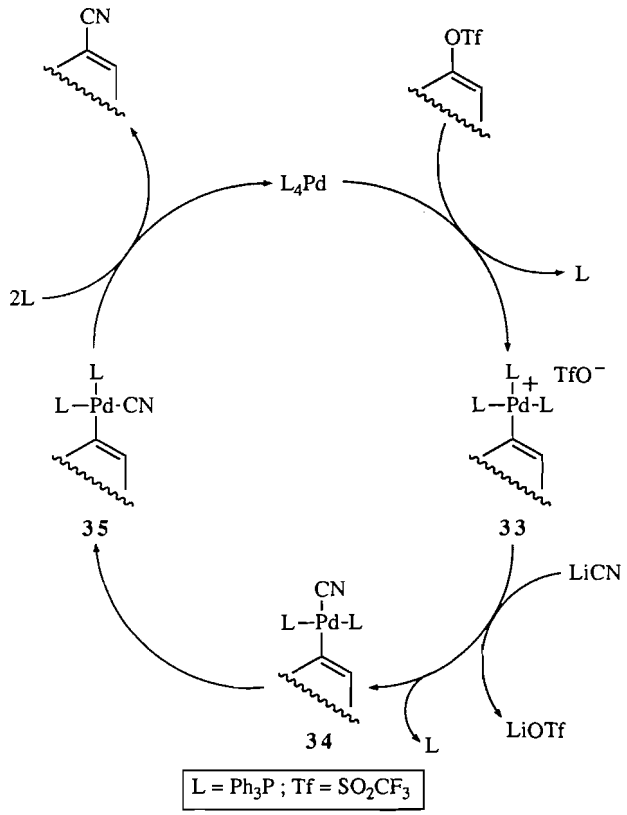

SCHEME 1

the *trans* palladium(II) cyanide **34**. Isomerization of **34** to the *cis* isomer **35**, followed by a (rapid) reductive elimination process would provide the α,β-unsaturated nitrile product.

Conclusion

The work described in this paper culminated in a synthetically effective method for the conversion of vinyl triflates into the corresponding α,β-unsaturated nitriles. Since vinyl triflates are readily available from ketones via a variety of methods (14) and since α,β-unsaturated nitriles are versatile synthetic intermediates, the chemistry developed in this study should prove to be useful in the area of organic synthesis.

Experimental

General information

Distillation temperatures, which refer to short-path (Kugelrohr) distillations, and melting points are uncorrected. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded on $CDCl_3$ solutions and signal positions (δ values) are given relative to the resonance of Me_4Si. Carbon nuclear magnetic resonance (^{13}C nmr) spectra were taken on $CDCl_3$ solutions and resonances were measured relative to that of $CDCl_3$ (δ 77.0). Signals with negative intensities in an attached proton test (APT) are so indicated by (−ve) following the chemical shift. Flash chromatography (21) was carried out with 230–400 mesh silica gel (E. Merck). Thin-layer chromatography (tlc) was performed on commercial aluminum-backed silica gel plates. Gas–liquid chromatography (glc) was carried out with instruments equipped with 25 m × 0.21 mm fused silica columns coated with cross-linked SE-54. Reagents and solvents were purified and dried using standard methods. Aqueous NH_4Cl–NH_4OH (pH 8) refers to a solution prepared by addition of ~50 mL of aqueous NH_3 (30%) to ~950 mL of saturated aqueous NH_4Cl.

Note: All reactions were carried out under an atmosphere of dry argon in flame- or oven-dried glassware.

General procedure for the preparation of vinyl triflates

A solution of the ketone (1.0 equiv.) in dry THF (0.45 mL per mmol of ketone) was added, dropwise, to a cold (−78°C), stirred solution of lithium diisopropylamide (1.15 equiv.) in dry THF (3.4 mL per mmol of ketone). After the solution had been stirred at −78°C for 2 h, *N*-phenyltrifluoromethanesulfonimide (1.10 equiv.) was added as a finely powdered solid, the solution was warmed to room temperature, and stirring was continued for a further period of time (specified as reaction time in the descriptions below). Work-up and purification of the crude product as described provided the desired vinyl triflate.

*Vinyl triflate **16***

The ketone **8** (5.0 g, 25.3 mmol) was converted into the vinyl triflate **16** (reaction time 16 h). The entire reaction mixture was filtered through a short column (5.5 × 5 cm) of Florisil (elution with petroleum ether, ~250 mL). Concentration of the combined filtrate and flash chromatography of the residual material on silica gel (5.5 × 15 cm column, 9:1 petroleum ether – Et_2O) afforded 6.22 g (75%) of the vinyl triflate **16** as a white solid. Recrystallization (hexane–Et_2O) gave white, plate-like crystals (mp 24–25°C) that displayed ir (KBr): 3076, 1695, 1206, 1142 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.96 (s, 3H), 1.02 (s, 3H), 2.11 (t, 2H, J = 6 Hz), 2.40–2.47 (m, 2H), 2.50–2.56 (m, 2H), 3.50 (d, 2H, J = 10 Hz), 3.56 (d, 2H, J = 10 Hz), 5.62 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{12}H_{17}F_3O_5S$: 330.0749; found: 330.0740.

*Vinyl triflate **17***

The ketone **9** (2.47 g, 13.9 mmol) was transformed into the vinyl triflate **17** (reaction time 2 h). Concentration (reduced pressure) of the entire reaction mixture, followed by flash chromatography (4.5 × 15 cm silica gel column, 9:1 petroleum ether – Et_2O) of the residual material and distillation (81–86°C/0.3 Torr (1 Torr = 133.3 Pa)) of the acquired oil, produced 3.44 g (80%) of **17**. This colorless oil exhibited ir (neat): 3088, 1681, 1645, 1208, 1144; ^{1}H nmr (400 MHz) δ: 1.03 (s, 3H), 1.29–1.67 (m, 4H), 1.73–1.80 (m, 1H), 1.84–1.98 (m, 2H), 2.17–2.24 (dd, 1H, J = 14, 4 Hz), 2.26–2.36 (m, 2H), 2.46 (td, 1H, J = 14, 4 Hz), 4.64 (br s, 1H), 4.72 (br s, 1H), 5.70–5.74 (m, 1H). Exact Mass calcd. for $C_{13}H_{17}F_3O_3S$: 310.0850; found: 310.0845.

*Vinyl triflate **18***

This substance was derived from the ketone **10** (719 mg, 4.04 mmol) (reaction time 1 h). Aqueous NH_4Cl–NH_4OH (pH 8) (10 mL) was added to the reaction mixture and the mixture was extracted three times with Et_2O. The combined organic extracts were washed with brine until the aqueous phase was neutral (pH paper) and then were dried ($MgSO_4$) and concentrated. Flash chromatography (4.5 × 15 cm silica gel column, petroleum ether) of the crude material, followed by distillation (128–134°C/0.3 Torr) of the oil thus obtained, gave 950 mg (76%) of the vinyl triflate **18**, a colorless oil that displayed ir (neat): 3092, 1687, 1638, 1208, 1145 cm^{-1}; ^{1}H (400 MHz) δ: 1.12–1.18 (m, 1H), 1.20 (s, 3H), 1.28–1.40 (m, 1H), 1.46–1.57 (m, 1H), 1.68–1.77 (m, 1H), 1.93–2.09 (m, 3H), 2.16–2.33 (m, 4H), 4.79 (s, 1H), 4.82 (s, 1H), 5.57 (t, 1H, J = 4 Hz). Exact Mass calcd. for $C_{13}H_{17}F_3O_3S$: 310.0850; found: 310.0843.

*Vinyl triflate **19***

This material was obtained from the enone **11** (300 mg, 1.83 mmol) (reaction time 1 h). Removal of the solvent (reduced pressure) from the reaction mixture, followed by flash chromatography (2.7 × 15 cm silica gel column, petroleum ether) of the remaining material and distillation (90–95°C/0.3 Torr) of the acquired liquid gave 356 mg (66%) of the vinyl triflate **19**, a colorless oil that showed ir (neat): 1658, 1612, 1210, 1143 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.04 (s, 3H), 1.25–1.37 (m, 2H), 1.47–1.60 (m, 1H), 1.63–1.74 (m, 2H), 1.77–1.85 (m, 1H), 2.14 (dd, 1H, J = 16, 8 Hz), 2.23–2.30 (m, 2H), 2.35 (br d, J = 16 Hz), 5.48 (s,

1H), 5.52–5.57 (m, 1H). Exact Mass calcd. for $C_{12}H_{15}F_3O_3S$: 296.0694; found: 296.0686.

Vinyl triflate 20

The ketone **12** (1.0 g, 5.1 mmol) was converted into the vinyl triflate **20** (reaction time 16 h). Concentration (reduced pressure) of the reaction mixture, followed by flash chromatography of the crude product on silica gel (4.5 × 15 cm column, petroleum ether) gave an oil that, upon distillation (84–88°C/0.3 Torr), produced 1.21 g (73%) of **20**, a colorless oil that exhibited ir (neat): 1681, 1624, 1208, 1143 cm^{-1}; ^1H nmr (400 MHz) δ: 0.97 (d, 6H, J = 6 Hz), 1.08 (d, 3H, J = 7 Hz), 1.80 (s, 3H), 1.96–2.05 (m, 2H), 2.53 (dd, 1H, J = 16, 7 Hz), 2.40 (br hextet, 1H, J = 7 Hz), 3.39–3.54 (m, 2H), 4.78 (s, 1H). Exact Mass calcd. for $C_{13}H_{19}F_3O_4S$: 328.0956; found: 328.0949.

Vinyl triflate 21

This material was derived from the ketal ketone **13** (624 mg, 2.79 mmol) (reaction time 2 h). The entire reaction mixture was passed through a short column (5 × 4 cm) of silica gel (elution with Et_2O, 250 mL). Concentration of the combined eluate and flash chromatography (3.8 × 15 cm silica gel column, 17:3 petroleum ether – Et_2O) of the residual oil provided 835 mg (84%) of the vinyl triflate **21** as a white solid. Recrystallization (hexane–Et_2O) afforded white crystals (mp 80.0–81.5°C) that displayed ir (KBr): 3092, 1662, 1206, 1143 cm^{-1}; ^1H nmr (400 MHz) δ: 0.95 (s, 3H), 0.98 (s, 3H), 1.65–1.75 (m, 2H), 2.24–2.42 (m, 3H), 2.77–2.90 (m, 2H), 3.17–3.26 (br m, 1H), 3.46 (s, 2H), 3.48 (s, 2H), 5.59 (br s, 1H). Exact Mass calcd. for $C_{14}H_{19}F_3O_5S$: 356.0905; found: 356.0912.

Vinyl triflate 22

The ketone **14** (1.0 g, 4.42 mmol) was transformed into the vinyl triflate **22** (reaction time 2.5 h). Concentration (reduced pressure) of the reaction mixture, flash chromatography (4.5 × 15 cm column of silica gel, 9:1 petroleum ether – Et_2O) of the remaining material, and distillation (90–94°C/0.3 Torr) of the acquired oil afforded 1.15 g (72%) of the vinyl triflate **22**, a colorless oil that displayed ir (neat): 1674, 1210, 1144 cm^{-1}; ^1H nmr (400 MHz) δ: 0.95 (s, 3H), 0.99 (s, 3H), 1.22 (d, 3H J = 7 Hz), 1.92–2.22 (m, 6H), 2.81–2.91 (m, 1H), 3.45–3.52 (m, 4H), 5.88 (br t, 1H, J = 6 Hz). Exact Mass calcd. for $C_{14}H_{21}F_3O_5S$: 358.1061; found: 358.1065.

Vinyl triflate 23

To a well-stirred suspension of potassium hydride (~380 mg, ~9.5 mmol) in dry THF (16 mL) at room temperature was added a solution of the keto ester **15** (800 mg, 4.71 mmol) in dry THF (2 mL). The mixture was stirred for 1 h and then powdered $PhN(SO_2CF_3)_2$ (2.02 g, 5.65 mmol) was added in one portion. Stirring was continued for 16 h. Water was added and the mixture was extracted three times with Et_2O. The combined extracts were washed (brine), dried ($MgSO_4$), and concentrated. Flash chromatography (3.8 × 15 cm silica gel column, 4:1 petroleum ether – Et_2O) of the residual oil and distillation (75–78°C/0.3 Torr) of the acquired oil produced 1.17 g (82%) of the vinyl triflate **23**, a colorless oil that showed ir (neat): 1733, 1655, 1211, 1145 cm^{-1}; ^1H nmr (400 MHz) δ: 1.63–1.83 (m, 6H), 2.51–2.56 (m, 2H), 2.58–2.63 (m, 2H), 3.81 (s, 3H). Exact Mass calcd. for $C_{10}H_{13}F_3O_5S$: 302.0436; found: 302.0440.

General procedure for the preparation of α,β-unsaturated nitriles

Lithium cyanide, obtained from Morton Thiokol Inc. (Alfa Products), was dried at 40–50°C under reduced pressure (vacuum pump) for 2 h.

To a sample of dry lithium cyanide (2.0 equiv.) were added tetrakis(triphenylphosphine)palladium(0) (0.07 equiv.) and neat 12-crown-4 (0.07 equiv.). A solution of the vinyl triflate (1.0 equiv.) in dry benzene (5.6 mL per mmol of vinyl triflate) was added. The resultant mixture was stirred at room temperature until the reaction was determined to have reached completion (analyses by glc or tlc). In those cases in which the reaction was sluggish, additional amounts of $(Ph_3P)_4Pd$ (0.07 equiv.) were added periodically until the reaction was complete or nearly complete. Water (~1.5 mL per mmol of vinyl triflate used) was added and the mixture was stirred vigorously until no further effervescence occurred. The aqueous layer was separated and extracted three times with Et_2O. The combined organic extracts were washed (brine), dried ($MgSO_4$), and concentrated. Flash chromatography of the crude product on silica gel, along with distillation or crystallization, provided the desired product.

α,β-Unsaturated nitrile 24

The vinyl triflate **16** (4.81 g, 14.5 mmol) was converted into the nitrile **24** (reaction time 2 h). Flash chromatography (7.5 × 15 cm silica gel column, 7:3 petroleum ether – Et_2O) of the crude product gave 2.4 g (80%) of **24** as a white solid. Recrystallization (petroleum ether) provided white flakes (mp 72–73°C) that displayed ir (KBr): 2211, 1642, 1114 cm^{-1}; ^1H nmr (400 MHz) δ: 0.94 (s, 3H), 1.03 (s, 3H), 2.01 (t, 2H, J = 6 Hz), 2.32–2.39 (m, 2H), 2.50–2.55 (m, 2H), 3.47 (d, 2H, J = 11 Hz), 3.57 (d, 2H, J = 11 Hz), 6.44–6.48 (m, 1H). In decoupling experiments, irradiation at δ 2.32–2.39 (allylic protons vicinal to CN) changed the signals at 2.01, 2.50–2.55, and 6.44–6.48 to a singlet, a doublet (J = 4 Hz), and a triplet (J = 4 Hz), respectively; irradiation at δ 2.50–2.55 simplified the multiplet at 2.32–2.39 to a broad triplet (J = 6 Hz) and collapsed the signal at 6.44–6.48 to a broad singlet. In a nOe difference experiment, irradiation at δ 6.44–6.48 caused signal enhancement at 2.50–2.55; ^{13}C nmr (75.3 MHz) δ: 22.5 (−ve), 22.7 (−ve), 25.3, 26.8, 30.2, 35.4, 70.3, 95.3, 111.9, 119.0, 141.3 (−ve). In SINEPT experiments optimized for a $^3J_{C-H}$ of 7 Hz, irradiation at δ 3.52 (both pairs of OCH_2 hydrogens) gave strong polarization transfer through three-bond coupling to the quaternary ketal carbon (δ 95.3) and the ketal CH_2O carbon (δ 70.3), while irradiation at δ 6.46 (olefinic proton) gave strong polarization transfer through three-bond coupling to the quaternary ketal carbon (δ 95.3) and the nitrile carbon (δ 119.0). Exact Mass calcd. for $C_{12}H_{17}NO_2$: 207.1260; found: 207.1258.

α,β-Unsaturated nitrile 25

This substance was obtained from the vinyl triflate **17** (805 mg, 2.6 mmol) (reaction time 2 h). Flash chromatography (3.5 × 15 cm column of silica gel, 9:1 petroleum ether – Et_2O) of the crude product and distillation (120–126°C/0.3 Torr) of the acquired oil provided 432 mg (89%) of **25**, a colorless oil that showed ir (neat): 3086, 3035, 2213, 1641 cm^{-1}; ^1H nmr (400 MHz) δ: 0.95 (s, 3H), 1.34–1.67 (m, 3H), 1.80 (dd, 1H, J = 12, 4 Hz), 1.91–2.07 (m, 3H), 2.18–2.52 (m, 4H), 4.61 (s, 1H), 4.73 (s, 1H), 6.61–6.65 (m, 1H). In a nOe difference experiment, irradiation at δ 6.63 caused an increase in the intensity of the signal at 2.27–2.38 (allylic CH_2 protons); ^{13}C nmr (75.3 MHz) δ: 16.6 (−ve), 24.2, 25.2, 27.2, 31.5, 32.0, 37.4, 44.0 (−ve), 105.7, 115.7, 118.4, 144.8 (−ve), 154.8. In a SINEPT experiment optimized for a $^3J_{C-H}$ of 7 Hz, irradiation at 6.63 gave strong polarization transfer through three-bond coupling to the nitrile carbon (δ 118.4) and the tertiary angular carbon (δ 44.0). Exact Mass calcd. for $C_{13}H_{17}N$: 187.1361; found: 187.1362.

α,β-Unsaturated nitrile 26

The vinyl triflate **18** (35 mg, 0.113 mmol) was converted into the nitrile **26** in a reaction time of 2.5 h. Flash chromatography (0.7 × 8 cm silica gel column, 9:1 petroleum ether – Et_2O) of the crude product and distillation (103–110°C/0.3 Torr) of this material provided 18.4 mg (87%) of **26**, a colorless oil that displayed ir (neat): 3088, 3034, 2216, 1636 cm^{-1}; ^1H nmr (400 MHz) δ: 1.14 (s, 3H), 1.18–1.26 (m, 1H), 1.36–1.73 (m, 3H), 1.98–2.11 (m, 3H), 2.16–2.39 (m, 4H), 4.79 (s, 1H), 4.81 (s, 1H), 6.57 (t, 1H, J = 4 Hz); ^{13}C nmr (75.3 MHz) δ: 23.9, 24.3 (−ve), 25.6, 28.5, 29.3, 32.9, 37.3, 44.2 (−ve), 108.3, 117.2, 119.5, 143.8 (−ve). Irradiation at δ 6.57 in a SINEPT experiment optimized for a $^3J_{C-H}$ of 7 Hz gave a strong polarization transfer through three-bond coupling to the nitrile carbon (δ 119.5) and to the tertiary angular

carbon (δ 44.2). Exact Mass calcd. for $C_{13}H_{17}N$: 187.1361; found: 187.1355.

α,β-Unsaturated nitrile 27

This material was obtained from the vinyl triflate **19** (183 mg, 0.62 mmol) in a reaction time of 3 h. Flash chromatography (1.8 × 15 cm column of silica gel, 19:1 petroleum ether – Et_2O) of the crude product and distillation (100–103°C/0.3 Torr) of the acquired liquid provided 83.6 mg (78%) of the nitrile **27**, a colorless oil that showed ir (neat): 3047, 2221, 1640 cm^{-1}; ^1H nmr (400 MHz) δ: 0.98 (s, 3H), 1.22–1.36 (m, 1H), 1.46–1.75 (m, 4H), 1.78–1.86 (m, 1H), 2.15–2.28 (m, 4H), 5.57 (s, 1H), 6.48 (t, 1H, J = 5 Hz). Exact Mass calcd. for $C_{12}H_{15}N$: 173.1204; found: 173.1205.

α,β-Unsaturated nitrile 28

The vinyl triflate **20** (197 mg, 0.60 mmol) was converted into the nitrile **28** in a reaction time of 2 h. Flash chromatography (1.8 × 15 cm column of silica gel, 19:1 petroleum ether – Et_2O) of the crude product and distillation (113–118°C/0.3 Torr) of the acquired liquid provided 105 mg (85%) of the nitrile **28**, a colorless oil that exhibited ir (neat): 3082, 2217, 1641, 1604 cm^{-1}; ^1H nmr (400 MHz) δ: 0.97 (d, 6H, J = 6 Hz), 1.03 (d, 3H, J = 7 Hz), 1.95–2.11 (m, 2H), 2.07 (s, 3H), 2.40 (hextet, 1H, J = 7 Hz), 2.54 (dd, 1H, J = 20, 7 Hz), 3.40–3.55 (m, 2H), 4.85 (s, 1H). Exact Mass calcd. for $C_{13}H_{19}NO$: 205.1467; found: 205.1467.

α,β-Unsaturated nitrile 29

This material was derived from the vinyl triflate **21** (160 mg, 0.453 mmol). After a reaction time of 6.5 h, an additional amount of $(Ph_3P)_4Pd$ (0.07 equiv.) was added to the reaction mixture. The total reaction time was 20 h. Flash chromatography (1.8 × 15 cm silica gel column, 4:1 petroleum ether – Et_2O) of the crude material gave 80 mg (76%) of the nitrile **29** as a white solid. Recrystallization (petroleum ether) provided white flakes (mp 58–59°C) that displayed ir (KBr): 3064, 2216, 1615, 1116 cm^{-1}; ^1H nmr (400 MHz) δ: 0.97 (s, 6H), 1.65 (dd, 1H, J = 13, 8 Hz), 1.76 (dd, 1H, J = 13, 6 Hz), 2.24–2.45 (m, 3H), 2.80–2.93 (m, 2H), 3.30–3.38 (m, 1H), 3.41–3.52 (m, 4H), 6.49–6.53 (m, 1H). In a nOe difference experiment, irradiation at δ 6.51 caused enhancement of the resonance at 3.30–3.38 (angular allylic hydrogen). Exact Mass calcd. for $C_{14}H_{19}NO_2$: 233.1416; found: 233.1415.

α,β-Unsaturated nitrile 30

This substance was obtained from the vinyl triflate **22** (206 mg, 0.574 mmol) in a reaction time of 2 h. Flash chromatography (1.8 × 15 cm silica gel column, 7:3 petroleum ether – Et_2O) of the crude product and distillation (75–78°C/0.3 Torr) of the acquired oil provided 105 mg (78%) of the nitrile **30**, a colorless oil that showed ir (neat): 3035, 2213, 1625, 1120 cm^{-1}; ^1H nmr (400 MHz) δ: 0.95 (s, 3H), 0.98 (s, 3H), 1.26 (d, 3H, J = 7 Hz), 1.47–1.60 (m, 2H), 2.11–2.35 (m, 4H), 2.58–2.69 (m, 1H), 3.41–3.48 (m, 4H), 6.72–6.79 (m, 1H). In a nOe difference experiment, irradiation at δ 6.75 caused enhancement of the signal at 2.20–2.35. Exact Mass calcd. for $C_{14}H_{21}NO_2$: 235.1572; found: 235.1572.

α,β-Unsaturated nitrile 31

This material was derived from the vinyl triflate **23** (55.4 mg, 0.183 mmol). After reaction times of 1, 2, and 3 h, additional amounts of $(Ph_3P)_4Pd$ (0.07 equiv.) were added to the reaction mixture. The total reaction time was 4 h. Flash chromatography (0.7 × 15 cm silica gel column, 7:3 petroleum ether – Et_2O) of the crude product, followed by distillation (125–131°C/0.3 Torr) of the acquired oil, afforded 19.2 mg (59%) of the nitrile **31**, a colorless oil that displayed ir (neat): 2216, 1722, 1107 cm^{-1}; ^1H nmr (400 MHz) δ: 1.54–1.69 (m, 4H), 1.80–1.88 (m, 2H), 2.59–2.69 (m, 4H), 3.85 (s, 3H). Exact Mass calcd. for $C_{10}H_{13}NO_2$: 179.0946; found: 179.0945.

Received October 1, 1992[3]

MARTIN B. HOCKING and FRANCIES W. VAN DER VOORT MAARSCHALK. Can. J. Chem. **71**, 1873 (1993).

Dimethyl acetylenedicarboxylate was reacted with 1,2,5-triphenylphosphole under mild conditions, and four products isolated. Regardless of conditions used, every preparation gave low yields of dimethyl 3,6-diphenylphthalate coincident with loss of the phosphorus bridge. NMR data and X-ray crystal structures are provided for a yellow, and a red, 2:1 adduct. The yellow adduct, tetramethyl 1,6,7-triphenyl-6-phospha(V)-tricyclo[7.3.1.$0^{1,9}$]nona-3,5,7-triene-2,3,4,5-tetracarboxylate **6**, crystallized in the triclinic space group $P\bar{1}$ (No. 2) with two molecules in the unit cell. Refinement (a = 11.259(1) Å, b = 12.947(3) Å, c = 13.784(3) Å, α = 112.25(2)°, β = 103.44(1)°, and γ = 101.80(1)°) converged at R = 0.0453 (R_w = 0.0453) for 537 parameters using 2880 reflections with $I > 2\sigma(I)$. The red adduct, trimethyl 1,2,5-triphenylphosphoranylidene-4-methoxycyclopent-2-ene-5-one-2,3,4-tricarboxylate, an exocyclic phosphorane **8**, crystallized in the monoclinic space group $P2_1/c$ (No. 14) with four molecules in the unit cell. Refinement of this structure (a = 13.233(5) Å, b = 15.712(5) Å, c = 17.191(7) Å, α = 90°, β = 110.35(4)°, and γ = 90°) converged at R = 0.0916 (R_w = 0.0937) for 400 parameters using 2052 reflections with $I > 2.5\sigma(I)$. Small amounts of a white or buff amorphous material, which could represent a polymeric product from the lost phosphorus bridge, were also obtained. Thermal rearrangement of the yellow adduct gave a colourless 6,5,3 tricyclic isomer **11**, possibly via the isomeric cyclopropyl derivative **15** or the nine-membered phosphonin **7**. The structure of **11** was confirmed by mild oxidation of the colourless rearrangement product to its P-oxide. This product, tetramethyl 2,3,6-triphenyl-2-phosphatricyclo[6.1.$0^{1,8}$.$0^{5,9}$]-2-oxonona-3,6-diene-1,7,8,9-tetracarboxylate **12**, was also colourless. It crystallized in the orthorhombic space group $Pbc2_1$ (No. 29) with four pairs of molecules in the unit cell. Refinement of this structure (a = 8.918(1) Å, b = 22.605(4) Å, and c = 30.169(6) Å) converged at R = 0.0747 (R_w = 0.0757) for 321 parameters using 3255 reflections with $I \geq 3\sigma(I)$. Unequivocal structures for these adducts and derivatives finally confirms, and establishes further understanding of, the complex reactions of the triphenylphosphole with dimethyl acetylenedicarboxylate.

MARTIN B. HOCKING et FRANCIES W. VAN DER VOORT MAARSCHALK. Can. J. Chem. **71**, 1873 (1993).

On a fait réagir l'acétylènedicarboxylate de diméthyle avec le 1,2,5-triphénylphosphole dans des conditions douces et on a isolé quatre produits. Quelles que soient les conditions utilisées, chaque préparation a conduit à de faibles rendements de 3,6-diphénylphtalate de diméthyle qui résulte de la perte du pont phosphoré. On rapporte les données RMN et les structures cristallines déterminées par diffraction des rayons X d'un adduit jaune et d'un adduit 2 : 1 qui est rouge. Les cristaux de l'adduit jaune, le 1,6,7-triphényl-6-phospha(V)-tricyclo[7.3.1.$0^{1,9}$]nona-3,5,7-trième-2,3,4,5-tétracarboxylate de tétraméthyle; **6**, sont tricliniques, groupe d'espace $P\bar{1}$ (No. 2) avec a = 11,259(1), b = 12,947(3) et c = 13,784(3) Å, α = 112,25(2)°, β = 103,44(1)° et γ = 101,80(1)° et deux molécules par motif. L'affinement de 537 paramètres provenant de 2880 réflexions avec $I > 2\sigma(I)$ converge à R = 0,0453 (R_w = 0,0453). Les cristaux de l'adduit rouge, le phosphorane exocyclique **8**, le 1,2,5-triphénylphosphoranylidène-4-méthoxycyclopent-2-èn-5-one-2,3,4-tricarboxylate de triméthyle, sont monocliniques, groupe d'espace $P2_1/c$ (No. 14) avec a = 13,233(5), b = 15,712(5) et c = 17,191(7) Å, α = 90°, β = 110,35(4)° et γ = 90° et quatre molécules par motif. L'affinement de 400 paramètres provenant de 2052 réflexions avec $I > 2\sigma(I)$ converge à R = 0,0916 (R_w = 0,0937). On a aussi isolé de faibles quantités d'un produit amorphe blanc ou coquille d'oeuf qui correspond peut-être à un polymère provenant de la perte du pont phosphoré. La transposition thermique de l'adduit jaune conduit à un isomère 6,5,3 tricyclique incolore, **11**, qui pourrait se former par le biais du dérivé cyclopropyle isomère **15** ou de la phosphonine à neuf chainons **7**. On a confirmé la structure du composé **11** par une oxydation douce du produit de réarrangement incolore en son P-oxyde. Les cristaux de ce produit, le 2,3,6-triphényl-2-phosphatricyclo[6.1.$0^{1,8}$.$0^{5,9}$]-2-oxonona-3,6-diène-1,7,8,9-tétracarboxylate de tétraméthyle, **12**, sont incolores et orthorhombiques, groupe d'espace $Pbc2_1$ (No. 29) avec a = 8,918(1), b = 22,605(4) et c = 30,169(6) Å et quatre paires de molécules par motif. L'affinement de 321 paramètres provenant de 3255 réflexions avec $I > 2\sigma(I)$ converge à R = 0,0747 (R_w = 0,0757). La détermination univoque des structures de ces adduits et de leurs dérivés élargit et confirme notre compréhension des réactions complexes du triphénylphosphole avec l'acétylènedicarboxylate de diméthyle.

[Traduit par la rédaction]

Introduction

The first reactions of 1,2,5-triphenylphosphole, **1** with dimethyl acetylenedicarboxylate gave only dimethyl 3,6-diphenylphthalate **3**, a cycloaddition occurring with concomitant extrusion of the phosphorus-containing group (1). Loss of the Ph—P bridge probably occurred via a reverse Diels–Alder reaction causing loss of an appropriate fragment in the manner first proposed by Alder and Rickert, and confirmed by Cope and others (2, 3). While this reaction provided a useful component of the structure confirmation for the first synthesis of this phosphole it was not particularly valuable synthetically (4). More potentially useful was the reaction conducted under inert atmosphere and room temperature conditions, when Hughes and Uaboonkul isolated the phthalate ester **3** as obtained earlier and, in addition, two adducts that retained the phosphorus moiety (5). They assigned the spiro-biphosphole structure **4** to the yel-

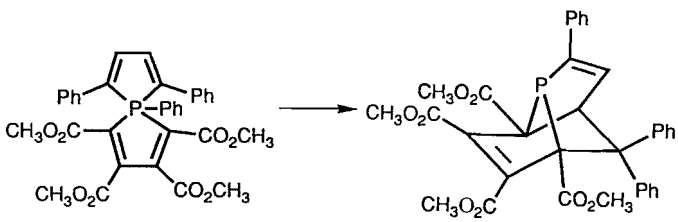
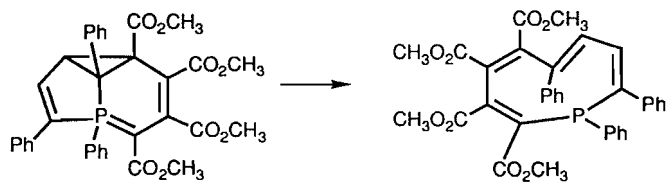
low 2:1 (ester to phosphole) adduct. An additional red crystalline product (mp 218–220°C (dec.)) was isolated and established to be a 4:1 adduct but without structural assignment (5). They also found that the yellow spiro-biphosphole could be rearranged thermally in chloroform to a colourless isomer initially formulated as **5**, and smoothly converted this to its P-oxide.



4 5

Later spectroscopic and synthetic tests by Waite and Tebby led to structural reassignments of the yellow 2:1 adduct to the tricyclic, ester-stabilized, alkylidene phosphorane structure **6**, and of its colourless rearrangement product to the phosphonin, a nine-membered cyclic phosphine **7** (6). These workers, who used freshly redistilled dimethyl acetylenedicarboxylate in their reactions, did not obtain any of the initially reported red adduct from their preparations.

With the current availability of higher frequency and pulsed NMR techniques not accessible to either of the previous groups, we sought to reexamine the well-reasoned though rather unusual structures assigned to the yellow 2:1 adduct and its colourless rearrangement product, and in addition to attempt to determine the structure of the red 4:1 adduct reported by the first group.



6 7

Results and discussion

Primary products

Reaction of 1,2,5-triphenylphosphole with dimethyl acetylenedicarboxylate at room temperature gave 6–10% yields of the colourless dimethyl 3,6-diphenylphthalate **3**, much lower than the 71% obtained under severe conditions (1, 2) but similar to the 9% previously obtained under mild conditions (5). This product was not examined further.

The yellow 2:1 acetylene ester:phosphole adduct was obtained in 31–35% yields, similar to that reported from the first preparation (5), and regardless of whether the reaction was conducted with neat reactants or in benzene, or whether or not freshly distilled ester or an inert atmosphere was used. Varied reaction conditions did, however, affect the yields of

other products, as discussed later. Elemental analysis confirmed that a 2:1 adduct had been obtained, and that this sample had crystallized almost mole for mole with acetone. Melting point and spectroscopic properties of this product were essentially in agreement with those previously reported (Tables 1–3).

However, despite the detailed analysis of high-frequency proton and phosphorus NMR spectra and decoupling experiments together with various pulsed NMR techniques, it was still not possible to unequivocally assign a structure to the yellow adduct.

An X-ray structure determination on a suitable single crystal of the yellow 2:1 adduct gave confirmation that structure 6, previously assigned by Waite and Tebby (6), was the correct assignment (Tables 4–8). Figure 1 gives an ORTEP representation of the molecular structure, including the resolved hydrogen atoms. Noteworthy in this rigid framework of fused six, five, and three-membered rings is the strain imposed on the C4—P—C1 and the P—C1—C2 bonds, which are each compressed to about 12° less than the normal sp^2 bond angles. The internal angles of the cyclopropane are all very close to the expected 60°. Bonds from the cyclopropane ring fusion to the rest of the molecule show little evidence of strain, except for an expansion of the C4—C5—C6 angle of about 12° from the normal sp^3. Carbon–carbon bond lengths correspond quite closely to those expected for isolated single and double bonds and show negligible evidence of any electron delocalization. The shortened phosphorane carbon to phosphorus bond, the presence of which had been previously demonstrated by protonation (6), is also clearly evident from this structure determination.

The yield of red adduct varied widely with reaction conditions, unlike the yield insensitivity found for the preparation of yellow adduct **6**. About 6.5% of a red crystalline adduct was obtained from room temperature reactions using neat reagents whether the acetylene ester was used as supplied, or was redistilled just before use. Conducting the reaction in benzene caused the isolated yield to drop to 0.4%. The red product obtained here, however, melted at 198–201°C without decomposition, rather than the 218–220°C (dec.) previously reported for a red adduct (5). It also was a 2:1 product (acetylene ester:phosphole), from NMR spectra and the X-ray crystal structure, rather than the 4:1 ad-

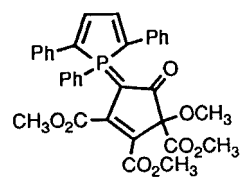
duct reported previously. At no time was the 4:1 adduct observed, despite the testing of a variety of reaction conditions and recovery techniques.

As with the yellow 2:1 adduct, it was possible to discern many of the principal structural features of the red adduct from the high-frequency NMR data (Tables 1–3), but it was still not possible to derive an unequivocal structure entirely from this information. An X-ray crystal structure determination established that this adduct was also a phosphorane, a phosphacyclopentadienylidene bonded to the α position of a stabilizing conjugated cyclopentenone, **8** (Fig. 2, and Tables 9–12). In this adduct the phosphole ring remains intact, as found previously in ylide preparations related to the testing of 1,2,5-triphenylphosphole as a phosphine for Wittig reactions (7). Carbon–carbon single bonds of the cyclopentenone involved in electron delocalization are foreshortened by about 0.1 Å as compared to the 1.53 and 1.57 Å of the single bonds not so involved (Table 6). The carbon–carbon single bonds in both the starting phosphole



8

and the red adduct also are similarly foreshortened. However, there is no significant change in the lengths of the carbon–carbon single and double bonds in the phosphole ring of the adduct as compared to the starting phosphole, these being 1.38 and 1.47 Å, and 1.35 and 1.44 Å (8), respectively. All the sp^2 carbons of both five-membered rings have bond angles somewhat compressed from a normal noncyclic sp^2 carbon, the most pronounced being the compression for the P—C4—C3 angle, with a value of 106°. But

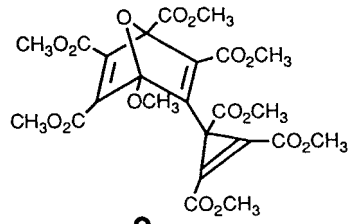
[a]Estimated standard deviations are given in parentheses. Mean phenyl carbon – carbon distance and standard deviation was 1.380(7) Å, range 1.352 – 1.401(5–12) Å. Mean carbon–oxygen distances and standard deviations were C=O, 1.203(5); (CO)—O, 1.343(5); and O—CH_3, 1.448(8) Å.

none of the angles are significantly different from the expectation for a cyclopentane or cyclopentadiene.

A further product was isolated from these reactions that contained only 4 moles of dimethyl acetylenedicarboxylate and no phosphole or fragment thereof. This product, like the red adduct isolated here, was not observed previously from these reactions. Yields of 0.7–1.8% were obtained, the lowest recoveries being achieved in those reactions which started with freshly redistilled acetylene ester. This suggested that the isolated product may well have been present as an impurity in the starting ester, a suspicion confirmed by literature references to this occurrence (9–12). Our detailed NMR studies of this tetramer of dimethyl acetylenedicarboxylate, a cyclopropenyl derivative of oxynorbornadiene, **9**, are in accord with the published structure. We are further examining some evidence of isomerism observed in some of the high-frequency NMR spectra of this compound.



9

A white, or off-white, highly insoluble material **10** was also isolated from some of these reactions. It was not possible to fully characterize this amorphous powder because of the small amounts obtained, low solubility, and its intractibility, but later we speculate briefly on the possible nature of this material.

Secondary products

The yellow 2:1 adduct **6** was rearranged by the previous group to a colourless isomer formulated as **5**, in 23% yield, by boiling a chloroform solution of the yellow adduct under reflux for 4 h (5). Repetition of this procedure confirmed that the low yield was the result of poor conversion of starting material rather than diversion of starting material to other products via side reactions. We therefore tested the use of a higher boiling solvent, 1,2-dichloroethane for this procedure. At the 22° higher temperatures much improved yields of 72–88% of the purified rearrangement product were obtained. Most improvement was obtained with short-term (5 h) reflux, or with longer refluxing times under nitrogen. The melting point and other physical properties of this rearranged material were in good agreement with the previously published data (5, 6).

Significant changes were evident in the proton NMR of the rearrangement product as compared to that of the yellow adduct **6** (Tables 1–3). Neither of the methine protons

[a]The symmetry positions are for the second atom. They are defined: 1 = x, y, z, A negative symmetry position denotes inversion. The translations (T) are applied finally.

was at high enough field to be assignable as a cyclopropyl hydrogen, and the higher field methine was now only proton coupled (and not to phosphorus). One of the methoxyls had also shifted ca. 0.5 ppm upfield. But again, despite detailed NMR studies, the structure could not be completely assigned with confidence. Even the quite reasonable assumption that there was no longer a cyclopropyl moiety in the rearranged product, from the loss of the resonance at the appropriate shift for cyclopropyl hydrogen in the ^{1}H NMR spectrum, would have turned out to be wrong, as will be seen shortly.

When checking the decoupled ^{31}P NMR spectrum of the rearranged product **5** after it had stood for a few days in deuteriochloroform, two ^{31}P resonances were noted, the new one probably that of the P oxide. A portion of the rearranged adduct was therefore oxidized and this product, the oxide of the rearrangement product, **12**, was purified and crystallized for X-ray work to ensure molecular stability of the crystal during data collection. The proton NMR spectrum of the oxide gave very similar methoxyl and methine shifts to those of the rearranged yellow adduct, except that the methine now showed a small coupling to phosphorus (Table 1). There was, however, a nearly 0.5 ppm downfield shift of the vinyl proton, explained by its proximity to the newly formed phosphoryl group, plus a sharply increased coupling of this proton to phosphorus, from 8 to 31 Hz. The same number and types of carbons were present in the two compounds from the ^{13}C NMR spectra. The only changes observed were in the P—C coupling constants, which were anticipated from the change in phosphorus oxidation state. The IR spectra of the two compounds were also very similar. For these reasons it is thought that the oxidation of the rearranged adduct under mild conditions only oxidized the phosphorus of the rearrangement product **11** and did not introduce any further skeletal rearrangements.

Two enantiomers of the oxide **12** crystallized together in the unit cell, so that the X-ray structure determination required resolution of the atom locations of both enantiomers (Fig. 3, Tables 13–16). The continued presence of a cyclopropyl component in the oxide **12** was unexpected. Although this product is still a fusion of six, five, and three-membered rings, as found in the yellow adduct **6**, quite complex steps are necessary to obtain the new bond locations. In the oxidized product **12** phosphorus is a component of only the six-membered ring rather than common to both the five and the six-membered rings, and the cyclopropyl no longer has any hydrogen substituents. Bond angles in the cyclopropane are all normal. Only the bond angles C3—C4—C5 and C4—C5—C6, C4—C3—C8, and C3—C8—C7 show any significant distortions caused by the

strained ring fusions. The first three are compressed 5°–8° from the normal and the last expanded to about the same extent. Bond lengths are all unremarkable.

Reaction and rearrangement pathways

The likely steps involved in the formation of the yellow 2:1 adduct **6** of dimethyl acetylenedicarboxylate to the phosphole **2** can be plausibly outlined as shown in Scheme 1. Provision of polar versus nonpolar conditions (neat reagents versus reaction in benzene) made a negligible difference to the yield, suggesting that none of the rates of the individual steps of initial formation of the zwitterion **13**, ring closure to structure **14** nor the following electrocyclic rearrangement to the product **6**, are overwhelmingly rate-determining. Our experimental observations are completely in accord with this reaction path, which is very similar to that previously proposed for this reaction by Waite and Tebby (6).

Scheme 2 gives a suggested pathway for rearrangement of adduct **6** to the colourless isomer **11**. It involves intermediate formation of a cyclopropane, which is retained in the final product. The carbocation formed is secondary and

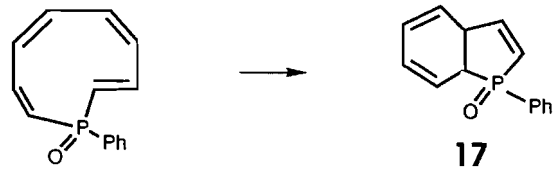
6 11 12

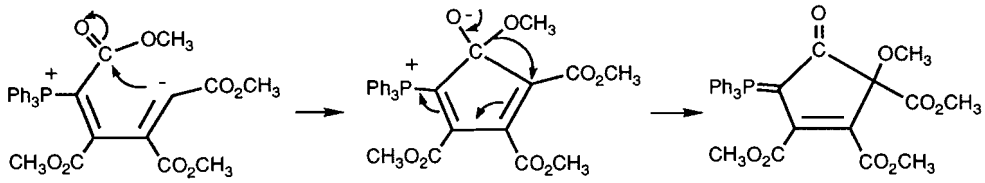
allylically stabilized and the anionic center required is stabilized via the adjacent carbonyl.

While it is possible to involve the *cis, cis, trans, cis* phosphonin **7** proposed by Waite and Tebby (6) in the pathway to the observed product **11**, this would require an additional step to reach structure **15**. Support is given to this possibility, however, from atom and electronic proximities noted from molecular models of this geometry as well as from the facile formation of the dihydrophosphindole oxide **17** from the *cis, cis, cis, trans* phosphonin oxide **16** (13). The presence of two benzo groups in the phosphonin prevents formation of the phosphindole (14).

A possible pathway to the red 2:1 adduct **8** from the acetylene ester plus phosphole is given in Scheme 3. Support for this suggestion is given by the pathway proposed for the related phosphorane product **20**, probably formed via similar steps from the acetylene ester and triphenylphosphine (15, 16). The structure of this final product was confirmed by an X-ray single crystal determination on the



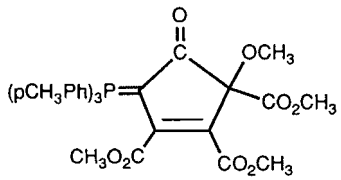
16 17



18 19 20

related compound **21** prepared from tri-*p*-tolylphosphine and the acetylene ester, which is also analogous to the red adduct **8** (17).

An equally plausible outcome from intermediate **18** on paper could have been the phosphole **22**, from direct closure of the zwitterion. As far as we are aware, however, compound **22** has not been isolated from any reaction of the acetylene ester with triphenylphosphine. It has at least been implicated in this reaction by the observed formation of another stable product, compound **23**, via migration of a phenyl group of intermediate **22** (18).



21

Compound **4**, analogous to **22**, was proposed as the structure of an adduct from the reaction of 1,2,5-triphenylphosphole with the acetylene ester. But we now know that it is not likely that spiro-biphosphole **4** forms from this interaction, even as an intermediate, since it would be difficult to sketch a plausible pathway from the spiro product to any of the adducts yet isolated from this reaction.

It should be mentioned here by way of a further precedent for the structure assigned to the red adduct that structure **25** has been proposed for a yellow 2:1 adduct of dimethyl acetylenedicarboxylate with the phosphindole **24**

[a]Estimated standard deviations are given in parentheses. Mean phenyl carbon – carbon distance and standard deviation was 1.405(19) Å, range 1.370–1.446(14–23) Å. Mean carbon–oxygen distances and standard deviations were C=O, 1.188(15); (CO)—O, 1.345(17); and O—CH_3, 1.488(15) Å.

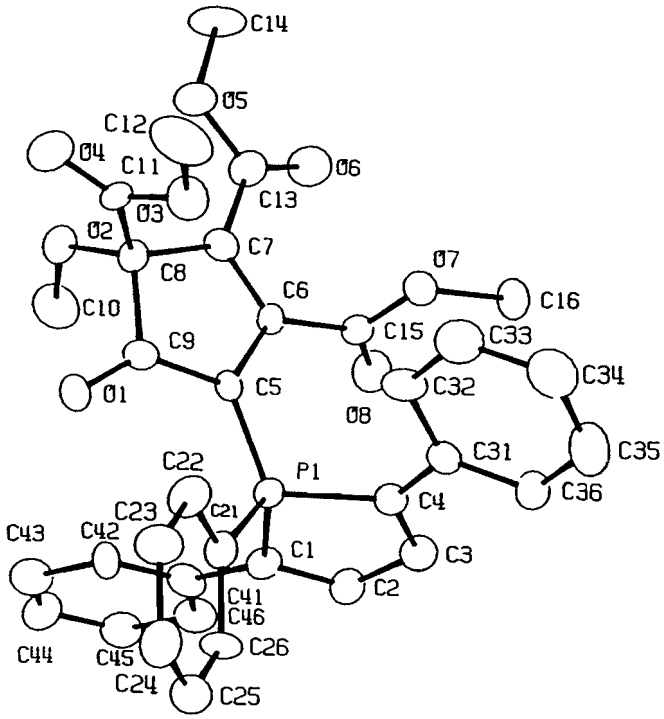

FIG. 2. ORTEP drawing of the crystal structure of the red 2:1 adduct **8**.

(19). It was suggested that the observed loss of the atom of oxygen in the formation of **25** occurred via an intermediate oxirane rearrangement product.

Finally, a brief speculation on the nature of the white or buff, highly insoluble, amorphous powder that was also isolated from some of the phosphole – acetylene ester reactions. This is quite possibly poly(phenylphosphinidene), $(C_6H_5P)_n$, or an oxidized version of this, $(C_6H_5P)_n(C_6H_5PO)_m$, formed from the 1:1 acetylene adduct that lost the phosphorus bridge to yield dimethyl 3,6-diphenylphthalate. Or it could be a copolymer of the phosphorus fragment with some incorporation of acetylene ester $(C_6H_5P)_n(CH_3O_2C\text{-}C{\equiv}C\text{-}CO_2CH_3)_m$, since the NMR shows the presence of ester methyl. In the absence of sufficient material for full characterization of this product these possibilities could not be better established. However, support for these suggestions is obtained from the reported isolation of poly(phenylphosphinidene oxide) from an analogous reaction of pentaphenylphosphole oxide with benzyne (20).

Experimental

Infrared spectra were obtained on KBr pellets scanned on a Perkin Elmer model 1330 instrument calibrated with polystyrene film.

[a]The symmetry positions are for the second atom. They are defined: $2 = -x, \frac{1}{2} + y, \frac{1}{2} - z$, A negative symmetry position denotes inversion. The translations (T) are applied finally.

Where useful, absorptions have been noted thus: s = strong, m = medium, w = weak, b = broad. UV spectra were obtained on a Philips PU 8740 UV/VIS spectrophotometer. Routine NMR spectra were recorded on a Perkin Elmer R-12 60 MHz instrument using solutions in deuteriochloroform at room temperature, unless otherwise specified. More detailed NMR experiments were performed on a Bruker WM 250 instrument, or, particularly for optimum resolution of coupled ^{31}P spectra, at 145.78 MHz on a Bruker AMX 360 spectrometer. Decoupling, nuclear Overhauser effect, or DEPT experiments were conducted wherever necessary to aid in assignments. Melting points were conducted on a Reichert type 7905 hot stage microscope or on a Gallenkamp model MF-370 Kofler aluminum block apparatus and are uncorrected. Mass spectra were determined on a Finnigan 3300 GC/MS system. Elemental analysis was by Canadian Microanalytical Service Ltd., Vancouver.

Reaction of 1,2,5-triphenylphosphole with neat dimethyl acetylenedicarboxylate

The finely ground phosphole (2.04 g; 6.52 mmol) was placed in a 100 mL round bottom flask fitted with a septum and flushed with oxygen-free nitrogen for 10 min. Dimethyl acetylenedicarboxylate (as supplied, Aldrich), 20 mL (163 mmol), was added via a syringe, with stirring. The initially yellow solution became red during 1 h, and then gradually turned dark brown.

After stirring the reaction mixture for 2 days at room temperature under nitrogen, it was filtered to recover 207 mg of white crystals, mp 183–186°C, identified as dimethyl 3,6-diphenylphthalate **3** by melting point and ^1H NMR (60 MHz), 7.5–7.0 ppm (multiplet, 12H), 3.6 (singlet, 6H). Filtration of the mother liquor after standing a further 2 days, no longer under nitrogen, gave a further 1.43 g of orange crystals. A portion of this recrystallized from ethanol, ethanol–chloroform, and then 100% ethanol gave 0.56 g of yellow crystals, mp 159–161°C without decomposition. This was identified from the X-ray structure determination as tetramethyl 1,6,7-triphenyl-6-phospha(V)tricyclo[7.3.1.$0^{1,9}$]nona-3,5,7-triene-2,3,4,5-tetracarboxylate, the yellow adduct **6**. ^1H NMR (250 MHz) ppm: aromatic plus one vinyl proton 6.6–7.5 (16H), ester methyl resonances at 3.41 (3H), 3.44 (3H), 3.63 (3H), 3.86 (3H), and one methine resonance as a doublet of doublets centered at 3.52 ppm. ^{13}C NMR (250 MHz) ppm: carbonyl carbons 168.4, 166.6, 166.0, 165.7; ester methyl carbons, 52.6, 52.3, 51.4, 50.5; methine carbon doublet centered at 34.5, J_{PC} 7.8 Hz; quaternary carbons, doublet centered at 34.8, J_{PC} 83.0 Hz; 49.5, J_{PC} 3.5 Hz; peak positions (relative intensities) for aromatic and olefinic carbons, some overlap and some coupled to phosphorus 146.1

[a]Estimated standard deviations are given in parentheses. Coordinates × 10^n where n = 5,4,4,4, for P,O,N,C Temperature parameters × 10^n where n = 4,3,3,3, for P,O,N,C.

[b]U_{eq} = the equivalent isotropic temperature parameter. $U_{eq} = 1/3\ \Sigma_i\Sigma_j U_{ij} a_i * a_j * (a_i \cdot a_j)$. Primed values indicate that U_{iso} is given. $T = \exp - (8\pi^2 U_{iso} \sin^2 \theta/\lambda^2)$.

(3.8), 145.7 (3.7), 133.0 (12.6), 132.8 (9.2), 131.8 (2.7), 131.4 (1.9), 131.2 (2.2), 131.0 (1.5), 130.1 (5.8), 129.5 (6.9), 129.12 (17.5), 129.05 (10.2), 128.6 (7.4), 128.2 (13.4), 128.0 (14.7), 126.9 (9.6), 126.8 (7.4), 120.0 (1.3), 118.5 (1.2). A combined total of 1.203 g of **6** was recrystallized twice more from acetone and dried in vacuo for an analytical sample. Anal. (adduct cocrystallized with 0.74-mol of acetone, determined by integrated 60 MHz ^{1}H NMR) calcd. for $C_{34}H_{29}PO_8 \cdot 0.74\ C_3H_6O$: C 68.02, H 5.27, P 4.84%; found: C 67.87, H 5.16, P 3.77%. Mass spectrum, methane CI, 200°C probe temp. (relative intensity), calcd. for $C_{34}H_{29}O_8P$: 596; found: M + 1, 597(100); M + 29, 625(15); M + 41, 637(6).

Further recrystallizations of the yellow adduct **6** from acetone and 95% ethanol produced X-ray quality crystals, mp 167–169°C. UV (95% EtOH) λ_{max} nm (log ϵ): 202 (4.77), 225 (4.47), 269 (4.27), 349 (4.00), 392 (3.78). IR (KBr) cm^{-1}: 3060w, 2950w, 1735s, 1700w, 1680m, 1650s, 1635m, 1500m, 1430m, 1340m, 1310m, 1280m, 1235s, 1210s, 1140m, 1110m, 1065w, 760m, 700m, 695m.

The residual mother liquors were combined and chromatographed on 40–140 mesh silica gel (Bakersil, 128 g) in a 4 cm diameter column. Rechromatography of combined similar fractions (from TLC tests) on Davisil 62 silica gel (60–200 mesh) enabled a further 99 mg of yellow crystals of **3** and a total of 255 mg of red crystals of impure adduct **8** to be recovered. Recrystallization of the red adduct twice more from acetone gave pure material, mp 198–201°C.

[a]Estimated standard deviations are given in parentheses. Mean phenyl carbon – carbon distance and standard deviation was 1.402(18) Å, range 1.351–1.461(15–23) Å. Mean carbon–oxygen distances and standard deviations were C=O, 1.199(13); (CO)—O, 1.330(13); and O—CH_3, 1.466(15) Å.

Recrystallization of pure red compound **8** from 95% ethanol gave X-ray quality crystals, mp 198–199°C without decomposition. UV (95% EtOH) λ_{max} nm (log ϵ): 203 (4.74), 224 (4.37), 273 (4.09), 384 (4.27). IR (KBr) cm^{-1}: 3060w, 2950w, 1750s, 1690m, 1645m, 1545m, 1495w, 1435w, 1350m, 1330m, 1235s, 1210s, 1180s, 1160m, 1115m, 1055w, 760m, 750m, 690m, 580w. ^1H NMR (250 MHz) ppm: aromatic 7.9–7.09 (17H), methoxyl hydrogen resonances at 3.71 (3H), 3.62 (3H), 3.25 (3H), 3.16 (3H). ^{13}C NMR (250 MHz) ppm: carbonyl carbons 167.9, 166.0, 162.4, 157.6, ester methyl carbons 52.6, 52.3, 51.6, 51.3; quaternary carbon 29.7; peak positions (relative intensities) for aromatic and olefinic carbons, some overlap and some coupled to phosphorus 137.1 (3.2), 136.8 (3.6), 136.7 (3.6), 136.4 (3.3), 136.3 (1.4), 134.9 (1.1), 134.7 (1.4), 134.0 (4.4), 133.4 (2.2), 133.3 (6.4), 133.1 (6.0), 131.3 (1.7), 131.23 (1.9), 131.16 (1.6), 129.9 (7.9), 129.8 (8.0), 129.5 (7.2), 129.3 (9.0), 129.1 (17.7), 128.3 (0.8), 127.4 (6.6), 127.3 (7.6), 127 (7.2), 126.9 (6.4), 117.4 (1.3), 116.0 (1.2), 114.2 (0.6), 109.9 (0.7), 109.7 (0.7). Mass spectrum, methane CI, 350°C probe temp., calcd. for $C_{34}H_{29}O_8P$: 596; found: M + 1, 597. Recrystallization several times from toluene gave what appeared to be a different polymorph of the same compound, mp 251–252°C, and an identical 250 MHz ^1H NMR, identified to be trimethyl 1,2,5-triphenylphosphoranylidene-4-methoxycyclopent-2-ene-5-one-2,3,4-tricarboxylate, **8**, from the X-ray determination.

An off-white powder identified as **10** (11.8 mg; mp 185°C) was also isolated. UV (95% EtOH) λ_{max} nm: 202, 219, 257, 368; molecular weight and hence extinction coefficients not known. IR (KBr) cm^{-1}: 3060, 3010, 2960, 1740, 1590, 1500, 1460, 1435, 1360, 1290, 1250, 1200, 1180, 1110, 1000, 1055, 910, 700, 520. ^1H NMR (250 MHz), high intensity peak positions, ppm (intensity): 7.26 (19), 7.10 (1.7), 4.90 (1.2), 4.12 (1.4), 4.06 (1.6), 3.98 (10.4, 3H), 3.96 (10.4, 3H), 3.82 (10.3, 3H), 3.65 (10.1, 3H), 3.59 (10.6, 3H), 3.39 (10.2, 3H), 3.28 (1.2), 3.21 (1.1), 2.16 (1.3). ^{31}P NMR (250 MHz): +55.77 ppm.

From the column fractions a total of 0.41 g of an acetylene tetramer was also isolated, identified as tetramethyl 4-methoxy-5[1,2,3-tris (methoxycarbonyl)-2-cyclopropen-1-yl]-7-oxabicyclo[2,2,1]hepta-2,5-diene-1,2,3,6-tetracarboxylate **9**, via comparison of the physical properties with published values (refs. 9–12). IR (KBr) cm^{-1}: 3000w, 2960m, 2850w, 1875m, 1755s, 1735s, 1720s, 1620m, 1435s, 1350s, 1335s, 1295s, 1275s, 1205s, 1140s, 1060s, 1003m, 980m, 965m, 905w, 770w, 720w. ^1H NMR (60 MHz) ppm: 3.89 (12H), 3.78 (3H), 3.75 (3H), 3.67 (3H), 3.61 (3H); in acetone-d_6 (60 MHz): 3.86 (3H), 3.78 (6H), 3.76 (3H), 3.7 (3H), 3.66 (3H), 3.6 (3H), 3.54 (3H). ^1H NMR in $CDCl_3$ (250 MHz) each integrating for 3H: 3.87, 3.85, 3.84, 3.83, 3.74, 3.70, 3.63, and 3.56 ppm.

Reaction of 1,2,5-triphenylphosphole with dimethyl acetylenedicarboxylate in benzene

A solution of 2.3 g (6.52 mmol) of the finely ground phosphole was made up under oxygen-free nitrogen in 50 mL of benzene dried over Molecular Sieve 4A by gentle warming in a water bath. After cooling the solution to room temperature, dimethyl acetylenedicarboxylate (Aldrich), 20 mL (163 mmol), was added to the solution all at once via a syringe. The initially yellow solution changed to deep red within minutes and then turned dark brown.

After stirring the solution for 2 days at room temperature, the reaction mixture was filtered to give 1.10 g of yellow solid, mp 163–165°C, which was identified as the previously isolated yellow adduct **6**. Further impure **6** (0.395 g) was obtained in a second crop, which when recrystallized yielded a further 0.26 g of pure material, mp 159–163°C.

The volume of the mother liquor was reduced and the solution was allowed to crystallize further to yield white needles (0.29 g), mp 186–189°C, ^1H NMR (60 MHz) ppm: 7.5–7.0 (12H), 3.6 (6H). This was identified as dimethyl 3,6-diphenylphthalate **3** from the NMR spectrum.

The collected mother liquors were reduced in volume and the residue was taken up in a minimum volume of chloroform, chromatographed on silica gel (Merck 70–230 mesh, 120 g) in a 2.5 cm diameter column, and eluted with chloroform. Selected fractions were crystallized from acetone to yield a further 0.15 g of impure yellow adduct **6** and 18 mg of the red adduct **8**. A quantity of the acetylene tetramer **9** (0.313 g) was also isolated, mp 89–91°C, and ^1H NMR was identical to that of the previously isolated material.

A small amount of off-white powder **10** (110 mg) was also obtained. UV (95%EtOH) λ_{max} nm: 202, 219, 257, 368, again molecular weight unknown. IR (KBr) cm^{-1}: 3060w, 3010m, 2960w, 1740s, 1710s, 1590s, 1500s, 1460s, 1435s, 1360m, 1290s, 1250s, 1200s, 1180s, 1110m, 1065m, 1055w, 1010m, 910m, 700m, 695m, 520m. ^1H and ^{31}P NMR spectra were identical to those of **10** isolated from the 1,2,5-triphenylphosphole reaction with neat DMADC. This was not further characterized.

The last fraction of the previous column was reduced in volume and chromatographed on silica gel (Merck 70–230 mesh, 160 g) in a 2.5 cm diameter column. Crystallization of combined similar fractions from CCl_4 enabled recovery of 0.299 g of a tan powder, UV (95% EtOH) λ_{max} nm: 200, 219, 261 (molecular weight unknown). IR (KBr) cm^{-1}: 3400br, 3055w, 2950w, 1725m, 1650br, 1440w, 1385m, 1220 broad, 1140m, 1065m, 1050w, 750w, 700w, 560w, which also could not be identified.

Reaction of phosphole 2 with neat freshly distilled acetylene ester

The acetylene ester (20 mL) was distilled under reduced pressure (2 Torr; 1 Torr = 133.3 Pa) in an inert atmosphere to recover a sharp cut of 15 mL of the pure material. The residual viscous oil from the distillation was dissolved in 95% ethanol and allowed to crystallize to yield 2.13 g of clear crystals, identified by IR as the tetramer of the acetylene ester, **9**.

The distilled acetylene ester (15 mL, 122 mmol) was added all at once via syringe to 4.01 g (1.28 mmol) of finely ground 1,2,5-triphenylphosphole, in a flask that had been previously flushed with oxygen-free nitrogen. The mixture was allowed to react at room temperature, with occasional mixing, for several days. Toluene

[a]Estimated standard deviations are given in parentheses. Mean phenyl carbon – carbon–carbon bond angle and standard deviation was 119.9(12)°, range 116.8°–123.5(10–15)°. Range of carbon–oxygen–carbon and carbon–carbon–oxygen bond angles was 105.5°–125.9(8–10)°.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

(100 mL) was added and the mixture filtered to yield 2.63 g of yellow crystals, mp 162–165°C, which was confirmed to be the yellow adduct **6**. A second crop of crystals, which were red (0.76 g), mp 197–199°C, was obtained on cooling the mother liquor. This was identified as the red adduct **8**.

The filtrate from the red crystals was then chromatographed on Merck Kieselgel 60 (70–230 mesh ASTM) using diethyl ether as eluent. The first 100 mL fraction yielded 120 mg of clear crystals of the acetylene tetramer **9**, identified by IR. Evaporation of the second 100 mL fraction gave colourless crystals, 279 mg, mp 187–191°C, identified by IR as dimethyl 3,6-diphenylphthalate **3**. The third 100 mL fraction yielded 0.881 g of red crystals of **8**, mp 193–199°C. This fraction was combined with the red adduct **8** recovered by crystallization (0.76 g) and recrystallized from 10 mL of toluene to yield 0.312 g of pure material, mp 197–199°C.

Rearrangement of the yellow adduct ***6***

(a) By literature method

The adduct **6** (112 mg) was dissolved in 50 mL of chloroform and refluxed for 3 h according to the published method (5). The solvent was removed under reduced pressure and the residue crystallized from 95% ethanol to yield 79 mg of yellow crystals, mp and mixture mp with starting material 163–165°C, and confirmed by ^{1}H NMR. A second crop of 27.5 mg of impure yellow crystals was mostly the rearrangement product **11** by ^{1}H NMR. The samples were combined (107 mg) in 50 mL of 1,2-dichloroethane and refluxed for 5 h. Crystallization of the evaporation residue as before gave 98 mg of colourless crystals of the rearrangement product **11**, mp 183–185.5°C. This was identified as tetramethyl 2,3,6-triphenyl-2-phospha(III)tricyclo[6.5.0^{1,8}.0^{5,9}]-nona-3,6-diene-1,7,8,9-tetracarboxylate, compound **11**, via an X-ray structure

[a]The symmetry positions are for the second atom. They are defined: $2 = -x, -y, \frac{1}{2} + z$; $3 = x, \frac{1}{2} - y, \frac{1}{2} + z$; $4 = -x, \frac{1}{2} + y, z$. A negative symmetry position denotes inversion. The translations (T) are applied finally.

determination carried out on crystals of the oxide of this compound produced under mild conditions (see below).

(b) By improved modification

A solution of the yellow adduct **6** (1.013 g) in 100 mL of 1,2-dichloroethane was boiled under reflux for 12 h. Progress of the reaction was followed by thin-layer chromatography (Polygram silica gel G, UV 254) using 5% acetone – 95% toluene for development. When the reaction was complete colourless crystals of the rearrangement product **11** (0.731 g) were isolated as described above, mp 210–213°C. UV (95% EtOH) λ_{max} nm (log ε): 201 (4.80), 248 (4.39). IR (KBr) cm^{-1}: 3030w, 3010w, 2955w, 2840w, 1750–1710s, 1640w, 1600w, 1485w, 1430s, 1375w, 1320m, 1230s, 1200s, 1120w, 1105w, 1060w, 945w, 850w, 815w, 760m, 700m, 640w, 520w. ^{1}H NMR (360 MHz) ppm: aromatic/olefinic protons 7.54–6.9; triplet centered at 6.4, J_{PH} 8.83, J_{HH} 8.76; doublet centered at 4.85, J_{HH} 8.45; ester methyl protons 3.82, 3.75, 3.68, 2.89. ^{13}C NMR (360 MHz) ppm: carbonyl carbons 168.8, 167.1, 166.2, and 163.6; primary carbon (CH) 53 (DEPT 90°); quaternary carbon 47.6 J_{PC} 38.5 Hz; quaternary carbon 49.5, J_{PC} 20.5 Hz; quaternary carbon 40, J_{PC} 2.6 Hz (DEPT 135°); ester methyl carbons 51.6, 51.9, 52.7, 53.1, peak positions (relative intensities) for aromatic and olefinic carbons, some overlap and some coupled to phosphorus 152.2 (1.3), 145.5 (1.0), 145.3 (1.3), 141.0 (1.1), 140.9 (1.2), 136.8 (0.55), 133.9 (2.1), 132.7 (1.1), 132.6 (1.1), 129.7 (2.9), 129.6 (3.0), 129.5 (4.7), 128.8 (5.9), 128.2 (0.76), 128.1 (1.2), 128.0 (13.1), 127.9 (10.8), 127.8 (10.8), 127.7 (4.2), 127.6 (2.7), 127.32 (5.8), 127.25 (5.9), 126.6 (4.8). Decoupled ^{31}P NMR, ppm: −34.8 SR (standard reference) 85% ortho phosphoric acid. Mass spectrum (relative intensity) calcd. for $C_{34}H_{29}O_8P$: 596, ^{13}C satellite 597(38); found: methane negative ion CI (probe temp. 280°C): M^-, 596(100); (M^-) + 1, 597(37); methane CI (probe temp. >350°C), M + 1, 597.

Oxidation of the rearranged yellow adduct

The rearranged yellow adduct **11** (0.602 g) was dissolved in 50 mL of a 30:70 mixture of ethyl acetate and 95% ethanol, then 3.5 mL of 30% hydrogen peroxide was added. The mixture was refluxed for 7 h after which 25 mL of water was added and the organic solvent removed from the mixture by evaporation under reduced pressure. The residual aqueous phase was extracted with chloroform (3 × 50 mL), and the combined chloroform extracts were reduced in volume and ethyl acetate added. Colourless crystals of the oxide of the rearrangement product (0.312 g, mp 251–254°C), for which structure **12** was established later, were obtained from this solution. UV (95%EtOH) λ_{max} nm (log ε): 202 (4.66), 268 (4.18). IR (KBr) cm^{-1}: 3030m, 3010m, 2955w, 2840w, 1750–1705s, 1640m, 1600w, 1485w, 1430s, 1375m, 1320w, 1250–1230s, 1200s, 1120m, 1105w, 1060m, 945m, 850w, 815w, 760s, 700s, 640w, 520m. ^{1}H NMR (360 and 250 MHz) ppm: aromatic/olefinic protons 8.2–6.85; doublet of doublets centered at 4.72, J_{HH} 8.20 Hz, J_{PH} 1.82 Hz; methyl ester protons 3.86, 3.75, 3.69, 2.99. ^{13}C NMR given in next preparation. ^{31}P–^{1}H coupled NMR (360 MHz): appears as a doublet of triplets J_{PH1} 12.9 Hz, J_{PH2} 12.9 Hz, J_{PH3} 30.8 Hz. Decoupled ^{31}P NMR 12.6 ppm, standard reference 85% ortho phosphoric acid. Mass spectrum (relative intensity) calcd. for $C_{34}H_{29}O_9P$: 612, ^{13}C satellite 613(38); found: methane negative ion CI (probe temp. 350°C) M^-, 612(100); (M^-) + 1,613(39).

*X-ray quality crystals from the oxide of the rearranged yellow adduct, **12***

The title compound **12** (0.312 g) was crystallized from 20 mL of warm ethyl acetate to yield 0.219 g of colourless crystals, mp 252–254°C, too small for X-ray. X-ray quality crystals of the product were obtained from a low-recovery recrystallization from ethyl acetate, mp 252–254°C, on which an X-ray structure determination established that this was tetramethyl 2,3,6-triphenyl-2-phosphatricyclo[6.1.0^{1,8}.0^{5,9}]-2-oxonona-3,6-diene-1,7,8,9-tetracarboxylate, compound **12**. ^{13}C NMR (360 MHz) ppm: carbonyl carbons 167.5, 166.1, 163.2, 165.0, J_{PC} 4.8 Hz; methine carbon 51.7, J_{PC} 13.1 Hz; tertiary carbons at 53.9, J_{PC} 3.3 Hz; 52.4, J_{PC} 3.3 Hz; 52.3; 45.5, J_{PC} 75.1 Hz; ester methyl carbons at 53.3, 52.9, 52.1, and 52.0; peak positions (relative intensities) for aromatic and olefinic carbons, some overlap and some coupled to phosphorus 156.6 (1.3), 145.8 (3.1), 140.9 (1.2), 139.9 (1.0), 137.2 (1.3), 137.1 (1.2), 133.3 (2.3), 132.8 (1.2), 131.6 (1.3), 131.49 (2.9), 131.47 (2.9), 130.3 (1.0), 129.82 (0.7), 129.76 (0.7), 129.6 (1.0), 129.4 (1.0), 128.9 (4.8), 128.1 (16.0), 127.8 (5.0), 127.6 (1.0), 126.9 (5.7), 126.8 (5.0).

*Effect of alcoholic carbonate on oxide of rearrangement product, **12***

A small sample of the oxide of the rearrangement product, **12**, was dissolved in 10 mL of 95% EtOH and 0.5 g of K_2CO_3 was added. During warming the solution colour changed from the initial colourless to purplish pink. Crystallization from ethyl acetate after removal of the potassium carbonate produced white crystals with different NMR properties than the starting material: decoupled ^{31}P NMR (250 MHz) ppm: 19.8, SR 85% ortho phosphoric acid; ^{1}H NMR (250 MHz) ppm: aromatic and olefinic protons, 7.52–7.09; aromatic or olefinic proton centered at 6.57 (possible doublet of doublets), J_1 34.55 Hz, J_2 3.69 Hz; methine proton centered at 4.34, J 21.162 Hz; ester methyl protons at 3.77, 3.66, 3.55, and 2.98.

X-ray crystallography

The crystals of all three compounds gave well-defined extinctions between crossed polars. Crystals were mounted in glass Lindemann tubes, and Weissenberg and precision photography using Cu K_α radiation was used to determine unit cells and space groups, in all cases at 20°C. The experimental parameters and crystal data for all three compounds are given in Table 4. In all cases scattering factors for uncharged atoms were used (21). Supplementary material, (Tables S1–S8), including complete bond length and angle data and hydrogen atom fractional atomic coordinates where determined, anisotropic temperature parameters, and observed and calculated structure factors for all three crystals, has been deposited.[4]

[4]This supplementary material can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A OS2, Canada.

Tables of hydrogen atom coordinates and bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Data collection and processing for yellow adduct ***6***

The crystal was found to be triclinic, space group $P\bar{1}$ (No. 2), and approximate unit cell dimensions were established. The unit cell and matrix were refined using 25 2θ measurements in the range 24–41°, each measured in both the positive and negative directions. Intensity measurements were made in the 2θ range, 0.1°–45° from $hkl = -11,0,-13$ to 11,12,12. Three standard orientation reflections 0,0,9; 6,0,0; and 0,8,0 were measured every 400 reflections. The standard intensity reflections were 5,2,−4; 6,−1,−2; and 5,−5,0, also measured every 3600 seconds of X-ray time. The measurements were corrected for absorption, using an empirical absorption correction on the Nonius ($\mu = 0.86$ cm^{-1}), then the EMPABS program[5] was run on the mainframe computer. The phase problem was solved by direct methods. All atoms, including H, were found for the main molecule. Methyl hydrogens on acetone were calculated using AFIX in the SHELX program.[6] The refinements converged with a maximum shift/e.s.d. (non-H) of 0.04 and the final difference map had a maximum of 0.21 e Å^{-3} and a minimum of 0.12 e Å^{-3}, indicating that nothing had been missed. The final residuals were $R = 0.0453$, $R_w = 0.0453$, for 537 parameters and 2880 independent observations. Results are given in Tables 5–8.

X-ray data collection and processing for the red 2:1 adduct ***8***

This crystal was monoclinic, space group $P2_1/c$(No. 14), and approximate unit cell dimensions were established. The unit cell and matrix were refined using 20 2θ measurements in the range 12°–36°, each measured in both the positive and negative directions. Intensity measurements were made in the 2θ range, 0.1°–45° from $hkl = -14,0,0$ to 14,15,18 at 20°C. The scanning was in 200 steps of 0.01° in 2θ counting for 0.25 s/step with background counting for 25 s at each end of the scan. Three standard orientation and intensity reflections 0,6,0; 0,0,6; and 6,0,0 were measured before every 50 reflections and were corrected for absorption using ABSB02 ($\mu = 0.98$ cm^{-1}) as an absorption correction.[7]

The phase problem was solved by MULTAN.[8] Phosphorus and all carbon and oxygen atoms were found for the main molecule and for the cocrystallized ethanol. Ethanol was slightly disordered. Distance C52-O53 was DFIX'd at 2.15. The poor ethanol angle was not resolvable by crystallography, and this kept the *R*-value high. The refinement converged with a maximum shift/e.s.d.(non-H) of 0.128 (ethanol) and 0.023 otherwise. The final difference map had a maximum of 0.67 e Å^{-3} and a minimum of 0.15 e Å^{-3}, and indicated that nothing had been missed. The final residuals were $R = 0.0916$, $R_w = 0.0937$, for 400 parameters and 2052 independent observations. Results are given in Tables 9–12.

X-ray data collection and processing for the oxide of the rearrangement product ***12***

This crystal was orthorhombic, space group $Pbc2_1$ (No. 29). Approximate unit cell dimensions and other data are given in Table 4. The unit and cell matrix were refined using 25 2θ measurements in the range 40°–64°, each measured in both the positive and negative directions. Intensity measurements were made in the 2θ range, 0°–130° from $hkl = 0,0,0$ to 9,26,35 at 20°C. Three standard orientation reflections 4,0,0; 0,0,16; and 0,12,0 were measured before every 400 reflections. The standard intensity reflections were the same three reflections, also measured every 3600 seconds of X-ray time, approximately every 50 reflections. The measurements were corrected for absorption using an empirical absorption correction, on the Nonius ($\mu = 12.5$ cm^{-1}), then the EMPABS program (22) was run on the mainframe computer. The phase problem was solved by SHELXS Patterson methods. Because two molecules made up the asymmetric unit, all carbons could not be made anisotropic due to the SHELX-76 limitations on the number of parameters, so the six phenyl rings were left isotropic. Only four hydrogens were sought and refined (those on C2, C3, C102, and C103). We did not look for or calculate phenyl or methyl hydrogens. The refinements converged with a maximum shift/e.s.d. of 0.07, including the four located hydrogens. The final difference map had a maximum of 0.61 e Å^{-3} and a minimum of 0.22 e Å^{-3}, and indicated that nothing had been missed. The final residuals were $R = 0.0747$, $R_w = 0.0757$, for 321 parameters and 3255 independent observations. Results are given in Tables 13–16.

Summary

As has been found with the reaction of dimethyl acetylenedicarboxylate with *N*-substituted pyrroles (23) and with furans (e.g., refs. 24, 25), the adducts of this ester with 1,2,5-triphenylphosphole are complex and similarly varied. We found few, if any, direct equivalencies in mode of reaction to the phosphorus heterocycle as compared to those observed for the nitrogen and oxygen heterocycles. The X-ray structure component of this work unequivocally confirms the cyclopropane-containing structure **6** for the yellow 2:1 adduct of the acetylene ester, formerly deduced solely from derivatives and spectroscopically. We also correct the various previously assigned structures of the thermal rearrangement product of this yellow adduct to structure **11** and that of its oxide to **12**, which both still contain cyclopropyl moieties. Finally, we isolated for the first time a red 2:1 adduct of the acetylene ester to phosphole and have established its structure to be the cyclopent-3-enone stabilized phosphorane **8**. In this product the phosphole ring remains intact, the only example among the adducts isolated. Preparation, isolation, and full characterization of the several products of the reaction of acetylene ester with the phosphole under different conditions as described here should also dispel the impression given by the literature (e.g., ref. 19) that these two compounds do not react under normal conditions.

Order–disorder transitions in adamantane derivatives: vibrational spectroscopic and ^{13}C NMR studies of 1-chloroadamantane

YINING HUANG, RALPH M. PAROLI, D.F.R. GILSON,[1] AND I.S. BUTLER[1]

Department of Chemistry, McGill University, 801 Sherbrooke St., West, Montreal, QC H3A 2K6, Canada

Received January 19, 1993

YINING HUANG, RALPH M. PAROLI, D.F.R. GILSON, and I.S. BUTLER. Can. J. Chem. **71**, 1890 (1993).

The order–disorder behaviour of 1-chloroadamantane (1-$C_{10}H_{15}Cl$) has been investigated by differential scanning calorimetry, and variable-temperature vibrational and ^{13}C NMR spectroscopy. The factor group splittings in the vibrational spectra are in accord with the known crystal structures of the two phases. The ^{13}C spin-lattice relaxation times and dipolar dephasing measurements have been analysed to give the barriers to rotation in both phases and to determine the nature of the rotations in each phase. In the ordered phase, the motion is limited to rotation about the molecular axis. In the disordered phase, additional motions occur about axes through the tertiary carbon atoms.

YINING HUANG, RALPH M. PAROLI, D.F.R. GILSON et I.S. BUTLER. Can. J. Chem. **71**, 1890 (1993).

Faisant appel à la calorimétrie à balayage différentielle, à la RMN du ^{13}C et à la spectroscopie vibrationnelle à température variable, on a étudié le comportement ordre–désordre du 1-chloroadamantane (1-$C_{10}H_{15}Cl$). Les dédoublements des facteurs de groupe des spectres de vibration sont en accord avec les structures cristallines connues des deux phases. On a analysé les temps de relaxation spin-réseau du ^{13}C et les mesures de déphasage dipolaire pour obtenir les barrières à la rotation dans les deux phases et pour déterminer la nature des rotations dans chaque phase. Dans la phase ordonnée, la mouvement se limite à une rotation autour de l'axe moléculaire. Dans la phase désordonnée, des mouvements additionnels se produisent autour des axes des atomes de carbone tertiaires.

Introduction

Adamantane and many of its derivatives possess orientationally disordered structures (1–3) in which the high-temperature phases are usually characterized by extensive molecular motions about one or more axes and, in some cases, translational diffusion (4–11). Interpretations of the mechanisms of the transition to the ordered phase are hindered by the lack of information on the crystal structure of the low-temperature ordered phase and the molecular dynamics associated with the transition. The 1-haloadamantanes, although they have the same molecular symmetry, exhibit marked differences in their phase transition behaviour (2, 3). 1-Fluoroadamantane displays one solid–solid phase transition, but this phase change is not of the order–disorder type (3–5) and both phases are orientationally disordered. On the other hand, 1-chloro- and 1-bromoadamantane have disordered high-temperature phases and undergo one and two phase transformations, respectively, with the lowest temperature phases being ordered. The 1-iodo compound also has a single phase transition but overall molecular tumbling in the high-temperature phase does not occur and the molecules only undergo a 12-fold uniaxial rotation (6).

1-Chloroadamantane, where the melting and transition temperatures are 442.5 and 244.2 K with transition entropies of 11.01 and 24.61 J K^{-1} mol^{-1}, respectively (2), is one of few compounds for which the crystal structures of both the ordered and disordered phases have been reported (7, 8). The low entropy of fusion indicates that the high-temperature phase is disordered, and, in common with most singly substituted adamantane derivatives, the structure is face-centred cubic, space group $Fm3m$, with four molecules per unit cell. The ordered phase is monoclinic, space group $P2_1/c$, also with four molecules per unit cell.

Although 1-chloroadamantane has been investigated by several different experimental methods, the molecular dynamics remain unclear, especially for the disordered phase (9–11). On the basis of proton NMR studies, Virlet et al. (6) concluded that the motion in phase I of 1-bromoadamantane is a fast endospherical reorientation. Using the same technique, Ursu *et al.* (9, 11) suggested that the motion in phase I for both 1-chloro- and 1-bromoadamantane is a combination of a rotation about the molecular C_3 axis and a jump reorientation of this axis in the lattice, but did not specify about which crystallographic axes this reorientation of the C_3 axis is taking place. In the low-temperature phase, only one barrier was indicated by proton T_1 measurements and a C_3 uniaxial rotation was assumed to be responsible for the relaxation (9).

The results of an incoherent quasi-elastic neutron scattering study have suggested that there are two types of motion occurring in the high-temperature phase of 1-chloroadamantane: tumbling of the molecular C_3 axis among six fourfold crystallographic axes along the [100] directions, and a uniaxial rotation about the molecular threefold axis (10). The barrier to molecular tumbling is about twice that of uniaxial rotation. Incoherent neutron scattering studies have been widely used to provide models of the molecular motions in plastic crystals. Since the timescale of neutron scattering is fast, this technique is particularly useful for characterizing motions on the timescale of 10^{-11} to 10^{-13} s. However, this method offers little information about the slower motions in the disordered phases. NMR spectroscopic methods, however, are more sensitive to the presence of slow motions and can be used to detect such motions in both disordered and ordered phases, determine the barriers to motions, and identify the nature of the reorientations.

The factor group method (12), by which the splittings of vibrational peaks can be correlated with the changes in symmetry that occur at the phase transition, provides an indirect method of obtaining structural information. In the present work, we have examined the FT-IR and Raman spectra of the two different phases of 1-chloroadamantane and measured ^{13}C spin-lattice relaxation times and dipolar dephasing times. The dipolar dephasing technique has been

widely used to obtain chemical structural information and to assign the resonance signals. Although it is well known (13, 14) that molecular motion has a great impact on the dephasing of carbon signals, especially for methylene and methine carbons, this method has not been widely used in the study of molecular motions. However, the technique can be readily used to identify the motions existing in orientationally disordered crystals, such as 1-substituted adamantane derivatives (15).

Experimental

1-Chloroadamantane (1-$C_{10}H_{15}Cl$, Alfa products, 98%) was purified by repeated slow vacuum sublimation (21°C, 10^{-3} Torr; 1 Torr = 133.3 Pa). The purified material was analyzed by gas chromatography and was greater than 99.5% pure.

Differential scanning calorimetry (DSC) measurements were performed on a Perkin–Elmer DSC-7 calorimeter, calibrated for both temperature and enthalpy scales using the phase and melting transitions of cyclohexane (Aldrich Chemical Co, "Gold" grade), at a scanning rate of 2.5 K min^{-1}.

The IR spectra (1 cm^{-1} resolution) were recorded on an Analect AQS-18 FT-IR spectrometer equipped with a DTGS detector. The spectra were obtained using KBr pellets, which were allowed to relax for at least 1 month prior to use. The Raman spectra (1–2 cm^{-1} resolution) were acquired on a Instruments S.A. spectrometer with a Jobin Ramanor U-1000 double monochromator using the 514.5-nm line of a Spectra Physics model 164 argon-ion laser (~250 mW power at the sample) as the excitation source. The samples were sealed in glass capillary tubes and mounted on the cold finger of a cryostat by using indium foil as the conducting junction. The temperature was controlled, for both the IR and Raman studies, by a Cryodyne Cryocooler model 21 cryostat (Cryogenics Technology Inc.) and was measured with a silicon diode temperature sensor attached to a Cryophysics model 4052 controller.

The ^{13}C spin-lattice relaxation and dipolar dephasing time measurements were performed on a Chemagnetics M100 spectrometer operating at 25.2 MHz. The samples were packed in a bullet-type zirconia rotor (9.5 mm diameter). The sample temperature was regulated to within ±2 K by a Chemagnetics RKC REX-C1000 temperature controller. The ^{13}C spin-lattice relaxation times were measured by the standard inversion–recovery pulse sequence, using seven or more τ values and a delay of at least 5 times T_1. The 90° pulse widths were between 5 and 6 μs. The number of transients required to obtain good signal-to-noise ratios were 32 and 128 for the disordered and ordered phases, respectively. A nonlinear, three-parameter-fit program was used to calculate the T_1 values. The spinning speed of the sample was between 3 and 4 kHz.

The pulse sequence used for the dipolar dephasing experiment was that proposed by Bodenhausen et al. (16) and described by Alemany et al. (14). The contact time for cross polarization was 4 ms for phase II of 1-chloroadamantane but, due to the extensive motion occurring in the high-temperature phase, the carbon spins were difficult to polarize and a 20 ms contact time was necessary.

Results and discussion

The DSC results were obtained for both cooling and heating directions and the transition was observed at 240 and 245 K, with enthalpy and entropy of transition of 5.35 kJ mol^{-1} and 22.0 J K^{-1} mol^{-1}, respectively. The results are in reasonable agreement with those previously reported (2) except for the small hysteresis in transition temperature. The latter is consistent with the relatively low entropy of transition (17).

Typical vibrational spectra are shown in Figs. 1 and 2. In the infrared spectrum, the broad C—H stretching region displayed considerable splitting when the sample was cooled

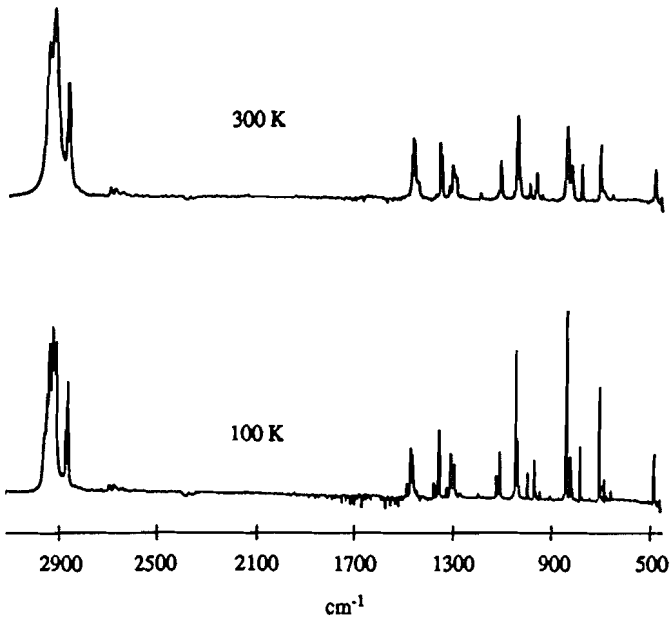

FIG. 1. Infrared spectra of phases I and II of 1-chloroadamantane.

from phase I to the ordered phase II. In the remaining regions of the spectrum, nearly all the peaks split into doublets. The notable exceptions were those at 1343 and 1350 cm^{-1}, the CH_2 wag and CCH deformation, respectively, which collapse to a single peak in phase II. The relative intensities of some of the peaks also change at the transition, with the CCC bending and CC stretching (1036 cm^{-1}), CH_2 wagging and CCH deformation (1459, 1346 cm^{-1}), and C—Cl stretch (828 cm^{-1}) modes showing the most pronounced effects. In the Raman spectra, most of the peaks exhibited the same splitting into two components and the most obvious changes in intensity occurred for the C—C—Cl bend at 215 cm^{-1}, and the C—C—C bend and C—C stretch at 1104 cm^{-1}.

The vibrational representation for the free 1-chloroadamantane molecule transforms as $\Gamma_{vib} = 16a_1 + 8a_2 + 24e$, where the a_1 and e modes are both IR and Raman active and the a_2 modes are inactive in both the IR and Raman spectra. Thus, there should be a total of 40 IR/Raman active modes, and a total of 29 Raman and 26 IR bands were observed, Table 1. Coincidence of the fundamentals in the infrared and Raman spectra of phase II confirms that the unit cell is not centrosymmetric. Moreover, since the space group of the ordered phase is $P2_1/c$, the $C_{10}H_{15}Cl$ molecule, with molecular symmetry C_{3v}, can only occupy sites with C_1 symmetry in the C_{2h} factor group and all the vibrational modes should split into four components, with the a_g and b_g modes being active in the Raman and the a_u and b_u modes being active in the infrared spectra. The correlation diagram is given in Fig. 3. Since no peak in either spectrum was split into more than a doublet, the observed splittings are in agreement with the factor group predictions.

The spin-lattice relaxation times of the three different protonated carbons, C_β, C_δ, and C_γ, were measured with respect to temperature in both the disordered and ordered phases. Figure 4 shows the temperature dependences of the T_1 values in each phase. In phase I, the T_1 values for all three carbons decreased with decreasing temperature and started approaching a minimum just before the transition tempera-

ture. The dominant relaxation mechanism of the methylene and methine carbons is the dipole–dipole interaction between the ^{13}C nuclei and their attached protons, and T_1 is given by eq. [1].

$$[1] \quad 1/T_1 = (3\gamma_H^2 \gamma_{C2} h^2/10 r_{CH}^6) \Sigma A_i f(\omega_H,\omega_C,\tau_i)$$

where

$$f(\omega_H,\omega_C,\tau_i) = \tau_i/[1 + (\omega_H - \omega_C)^2\tau^2] + 3\tau_i/[1 + \omega_{C2}\tau^2] + 6\tau_i/[1 + (\omega_H + \omega_C)^2\tau^2]$$

and the A_i terms are constants related to the changes in the second moments that result from the different motions. In a completely rigid lattice, or in the case of fast isotropic rotation, the ratio of the T_1 values for the methine and meth-

ylene carbons of 1-chloroadamantane should be 2:1, or close to it. In the disordered phase I of 1-chloroadamantane, however, the order of T_1 was $C_\gamma > C_\beta > C_\delta$ and the average ratios $T_1(\gamma)/T_1(\beta)$ and $T_1(\gamma)/T_1(\delta)$ were 1.5 and 5.9, respectively. These results are almost exactly the same as those observed for phase I of 1-bromoadamantane (15), indicating that the motions modulating the relaxation process in phase I of both compounds are the same, and are not due to isotropic rotation. Furthermore, this motion may be different from that in the disordered phase of 1-fluoroadamantane since the ratios of T_1 $(\gamma)/T_1(\beta)$ and $T_1(\gamma)/T_1(\delta)$ are different, although the T_1 order for the three protonated carbons is the same. According to the neutron scattering results (10), the tumbling motion for 1-chloroadamantane in phase I is the reorientation of the molecular axis among six fourfold crystallographic [100] directions, while the molecular axis of the 1-fluoro derivative tumbles between the eight [111] directions (5). A uniaxial rotation about the molecular axis also occurs in phase I of both compounds. This fast C_3 rotation is not the dominant cause of the overall relaxation process since the combined jumps of the C—Cl axis among the six crystallographic [100] directions should average the intramolecular dipolar interaction close to zero, which is close to isotropic reorientation. If it dominated relaxation, then the order of the T_1 values would be $C_\gamma > C_\beta \approx C_\delta$, which is not the case, and, therefore, an additional motion must contribute to the relaxation. The change in second moment is reciprocally related to the T_1 minimum for each carbon, and calculations show that the second moment changes on going from a rigid lattice to a 120° jump about a C_3' axis (along the C_γ—H directions) yield the order of the T_1 minima: $C_\gamma > C_\beta > C_\delta$, which is qualitatively consistent with the experimental observations.

The activation energies for rotation for each carbon in phase I are given in Table 2. The transition to phase II occurred before the minima in T_1 were reached and, therefore, separation of the motions into the uniaxial and tumbling contributions was not possible. However, the average value is in good agreement with that obtained from ^1H NMR spin-lattice relaxation time measurements (8), but the barrier is much higher than those obtained in the neutron scattering study (9) for molecular tumbling among the [100] directions (10.28 kJ mol^{-1}) and for C_3 rotation (21.41 kJ mol^{-1}). Since the NMR experiment has a slower timescale than does neutron scattering, it is not surprising that the two techniques are sensitive to different motions. The activation energy for the possible C_3' rotation for 1-chloroadamantane is smaller than that for the same motion in the 1-bromo analogue (33.0 kJ mol^{-1}).

At the transition, all three carbons showed obvious discontinuities in their T_1 values. In phase II, the relaxation times have the relation: $T_1(\delta) \approx T_1(\gamma) \approx 2T_1$ (β) (average $T_1(\delta)/T_1(\beta) = 1.95$, $T_1(\gamma)/T_1(\beta) = 1.91$). These results indicate that the dominant motion in the ordered phase has changed to a rotation about the molecular threefold axis. Since phase II is ordered, the rotation about the C—Cl axis must be the 120° jump between crystallographically equivalent sites, without introducing any disorder. A calculation of the change of second moment from the rigid lattice to C_3 rotation yields the following T_1 minima relation: $1.6\,T_1(\beta) \approx T_1(\delta) \approx T_1(\gamma)$, which is consistent with the experimental observations. By fitting the T_1 curve for each carbon, the barrier to motion was obtained, and the resulting values are listed in Table 2. The values are in good agreement with that obtained by proton T_1 measurements (8).

At the transition from phase I to phase II, the molecular tumbling is restricted, leaving rotation about the C_3 axis as the only motion responsible for relaxation. This is confirmed by the dipolar dephasing time measurements, which determine how fast a polarized carbon loses its magnetization after proton spin locking is terminated. The decay rate of the carbon signal intensity depends on the dipole–dipole interactions between the proton and carbon spins. Generally, for a molecule in a rigid lattice, dephasing is most rapid

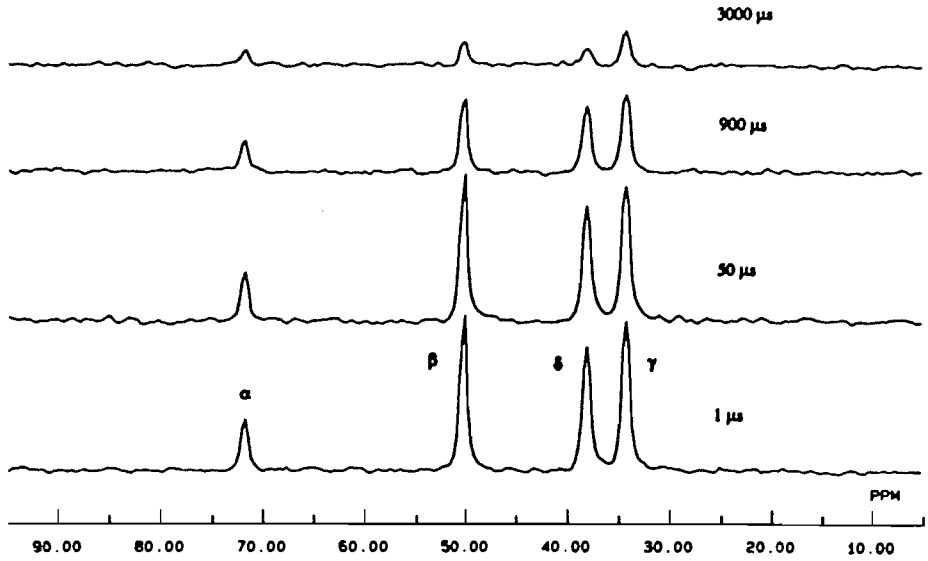

FIG. 5. Dipolar dephased spectra of phase I.

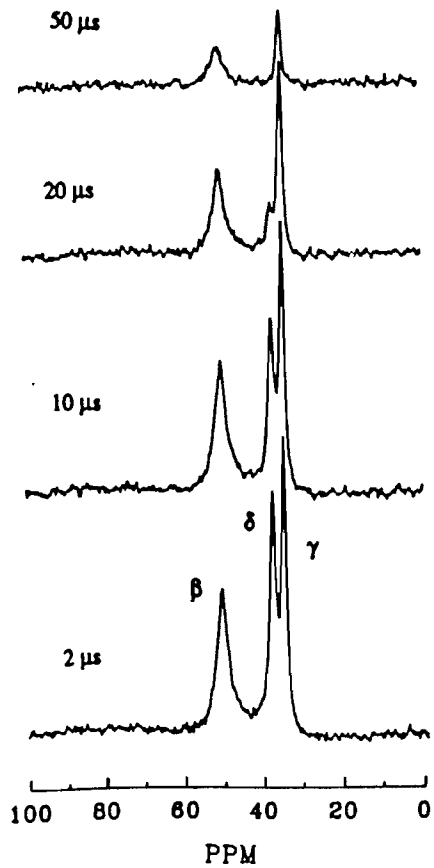

FIG. 6. Dipolar dephased spectra of phase II.

for those carbons having directly bonded protons, such as CH and CH_2 groups, while nonprotonated carbons retain phase coherence for longer times, because there is only a small effective dipolar interaction from neighboring groups. Methyl carbons usually experience a moderate degree of C—H dipolar coupling because the internal motion tends to weaken the dipolar interactions. The decrease in signal intensity during the dephasing time is characterized by a constant T'_2. Alemany et al. (14) have shown that fast decays, due to strong $^{13}C-^{1}H$ dipolar coupling, follow a second-order exponential decay (Gaussian decay):

$$[2] \quad I_G = I_{OG} \exp(-t_{dd}^2 / 2T_{2G}'^2)$$

where I_{OG} is the signal intensity at zero time and T'_{2G} is the Gaussian decay constant. Slow decays (weak dipolar interactions) can be fitted by a first-order exponential decay (Lorentzian decay):

$$[3] \quad I_L = I_{OL} \exp(-t_{dd}/T'_{2L})$$

Sometimes, the experimental data may be resolved into multicomponent decays, such as a two-component Gaussian–Lorentzian decay, described by eq. [4].

$$[4] \quad I = I_{OG} \exp(-t_{dd}^2/2T_{2G}'^2) + I_{OL} \exp(-t_{dd}/T'_{2L})$$

If rapid molecular reorientation occurs in the crystal lattice, then the rate of signal decay is diminished as the motion attenuates the effective $^{13}C-^{1}H$ dipolar interaction. This can be used to assign the motions occurring in different phases of the orientationally disordered solids. Figures 5 and 6 show the dipolar dephased spectra for different delay times, and Figs. 7 and 8 show the dependence of the intensities on the delay time, for 1-chloroadamantane in phases I and II, respectively. In the disordered phase, the intensities of all the α, β, γ, and δ carbons decayed very slowly and followed a Lorentzian decay. The decay constants for each carbon are given in Table 3. Although the β, γ, and δ carbons have directly attached protons, they decayed as slowly as the nonprotonated α-carbon, with similar Lorentzian decay constants, indicating that the motion modulates the three types of C—H vectors in a similar manner.

The intensities of the β, γ, and δ carbons in phase II decayed much faster than they did in phase I, indicating that the freedom of motion is drastically reduced. The relaxations of the β and γ carbons contain both Gaussian and Lorentzian components, suggesting that the motion still weakens the dipolar interaction but to a much lesser extent than in phase I. In particular, the decay of the signal for C_δ is much faster than for the other two carbons, Table 2, im-

[a]Measured at 283 and 263 K for phases I and II, respectively.

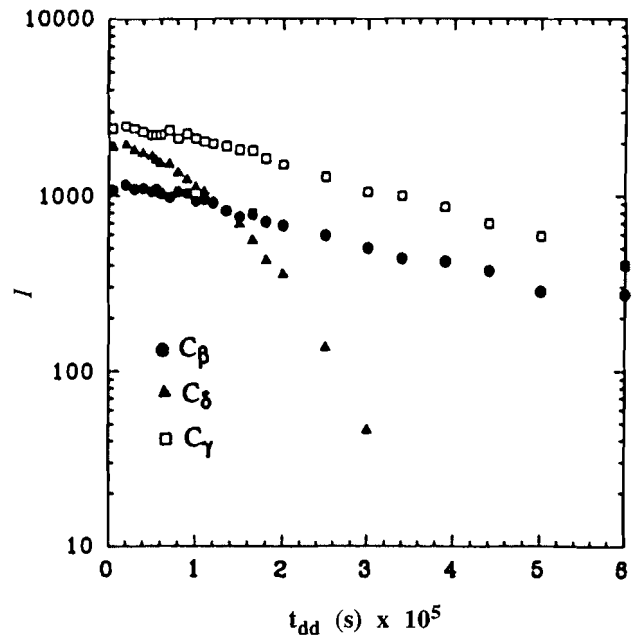

FIG. 8. Intensities (arbitrary units) of the dipolar dephased signals versus delay time for phase II of 1-chloroadamantane at 263 K.

plying that the dipolar interaction for this carbon is still strong, and was fitted to a Gaussian decay only. The protons in the axial positions on C_δ lie parallel to the axis of rotation and, therefore, no reduction in dipolar coupling occurs as a result of the rotation. Figures 7 and 8 show clearly that, after a delay time of 50 ms, the C_δ signal has completely disappeared in phase II, but remains unchanged in phase I.

The ^{13}C spin-lattice relaxation and dipolar dephasing time behaviour of 1-chloroadamantane in phases I and II is very similar to that of phases I and III of the 1-bromo compound and we conclude that the rotational motions in these two compounds are the same, but different from the fluoroadamantane case.

EDWARD A. OUGH, MARTIN J. STILLMAN, and KATHERINE A.M. CREBER. Can. J. Chem. **71**, 1898 (1993).

Absorption and magnetic circular dichroism (MCD) spectra are reported for the metallophthalocyanine-*N*-isologs: magnesium-3,4-pyridinoporphrazine ($MgPcN_4(-2)$), zinc-3,4-pyridinoporphyrazine ($ZnPcN_4(-2)$), and zinc-3,4-pyridazinoporphyrazine ($ZnPcN_8(-2)$). Band deconvolution calculations, which couple both the absorption and the MCD spectra, are reported for each complex. The presence of the peripherally fused pyridine rings in $MgPN_4(-2)$ and $ZnPcN_4(-2)$ reduces the molecular symmetry and splits the degenerate Q band into its x and y components with zero field splitting parameters (ΔQ_{xy}) of 224 and 279 cm^{-1}, respectively. Band fitting results for $ZnPcN_8(-2)$ show that with the fused pyridazine rings the degeneracy in the ^1E_g excited state is retained and the MCD envelope in the region of the Q_{00} transition can be described by an MCD A term. Comparison of the fitted band energies with the results reported for ZnPc(−2) (T. Nyokong, Z. Gasyna, and M.J. Stillman. Inorg. Chem. **26**, 1087 (1987)) and MgPc(−2) (E.A. Ough, T. Nyokong, K.A.M. Creber, and M.J. Stillman. Inorg. Chem. **27**, 2725 (1988)) shows that as the number of nitrogens substituted increases from 0 to 8, the Q band blue shifts from 671 nm in ZnPc(−2) to 664 nm in $ZnPcN_4(-2)$ (midpoint between the x and y components) to 654 nm in $ZnPcN_8(-2)$ and from 672 nm in MgPc(−2) to 666 nm in $MgPcN_4(-2)$ (midpoint). These results demonstrate that chemical modification (symmetric and asymmetric) of the peripherally fused benzene rings influences both the energy and the symmetry of the states that form the inner 18-π-electron system.

EDWARD A. OUGH, MARTIN J. STILLMAN et KATHERINE A.M. CREBER. Can. J. Chem. **71**, 1898 (1993).

On a déterminé les spectres d'absorption et de dichroïsme circulaire magnétique (DCM) des *N*-isologues suivants de métallonaphthalocyanines : magnésium-3,4-pyridinoporphrazine ($MgPcN_4(-2)$), zinc-3,4-pyridinoporphrazine ($ZnPcN_4(-2)$) et zinc-3,4-pyridazinoporphrazine ($ZnPcN_8(-2)$). Pour chacun des complexes, on a effectué des calculs de déconvolution de bande qui permettent de coupler les spectres d'absorption et de DCM. La présence de noyaux pyridines condensés d'une façon périphérique dans de $MgPcN_4(-2)$ et dans le $ZnPcN_4(-2)$ réduit la symétrie moléculaire et dédouble la bande Q dégénérée en ses composants x et y avec des paramètres de couplage de champ zéro (ΔQ_{xy}) de 224 et 279 cm^{-1} respectivement. Un ajustement des bandes du $ZnPcN_8(-2)$ montre qu'avec les cycles pyridazines condensés la dégénérescence de l'état excité ^1E_g est conservée et que l'enveloppe du DCM dans la région de la transition Q_{00} peut être décrite par un terme A du DCM. Une comparaison des énergies des bandes ajustées avec les résultats rapportés pour le ZnPc(−2) (T. Nyokong, Z. Casyna et M.J. Stillman. Inorg. Chem. **26**, 1087 (1987)) et pour le MgPc(−2) (E.A. Ough, T. Nyokong, K.A.M. Creber et M.J. Stillman. Inorg. Chem. **27**, 2725 (1988)) montre que lorsque le nombre d'atomes d'azote substitués augmente de 0 à 8, la bande Q se déplace de 671 nm dans le ZnPc(−2) à 664 nm dans le $ZnPcN_4(-2)$ (point moyen entre les composantes x et y) et à 672 nm dans le $ZnPcN_8(-2)$, et de 672 nm dans le MgPc(−2) à 666 nm dans le $MgPcN_4(-2)$ (point moyen). Ces résultats démontrent que la modification chimique (symétrique et asymétrique) des noyaux benzéniques condensés en périphérie influence à la fois l'énergie et la symétrie des états qui forment le système interne de 18-électrons-π.

[Traduit par la rédaction]

Introduction

In recent years there has been considerable effort to examine how changes to the 18-π-electron, 16-membered, polyene aromatic ring of porphin affect its chemical, electrochemical, photochemical, and spectroscopic properties (1–3). Amongst the molecules examined have been tetraazatetrabenzoporphyrins, the phthalocyanines. Introduction of the 4-fold symmetry axis from both the bridging aza groups and the peripherally fused benzenes leads to dramatically changed chemical and optical properties of phthalocyanines when compared to unsubstituted porphyrins (1–8). Despite the magnitude of these molecular changes, metallophthalocyanines are symmetric molecules and exhibit a characteristic optical spectrum that is dominated by allowed π–π* transitions to a number of singlet excited states between 800 and 250 nm. Each of these states is doubly degenerate, which allows the technique of magnetic circular dichroism (MCD) to probe their electronic composition through measurement of the transition energy, molar absorptivity, and angular momentum (1, 2, 9). The MCD spectrum has, in the past, provided exquisite detail about the electronic structure of both porphyrins and phthalocyanines (1, 2, 6–11). However, few data have been reported for phthalocyanines in which peripheral substitution reduces the molecular symmetry below C_{4v}. Such molecules exhibit spectral properties midway between symmetric phthalocyanines and the unsymmetric chlorophylls.

Substitution at the periphery of both phthalocyanines and porphyrins offers a means of tuning the redox chemistry (1–3), linking the macrocycles into polymeric networks, and, in the case of the phthalocyanines, increasing their solubility (3–5). While studies of the chemical and physical properties of porphyrins have been aided by their solubility in a wide variety of solvents, similar studies of phthalocyanines

have been hindered by their limited solubility in these solvents. The solubility of phthalocyanines can be enhanced by the choice of the central metal, by the addition of axial ligands to form soluble five- and six-coordinate MPc complexes, and by chemical modification of the peripherally fused benzene rings. Group I and II metallophthalocyanines exhibit high solubilities in a wide range of spectroscopic and electrochemically useful solvents. While axial ligands do enhance the solubility of many metallophthalocyanines, the bound ligand or excess free ligand greatly reduces the transparency in the 200–300 nm region. In tetrasulphonated phthalocyanines the sulphate groups enhance the solubility of the phthalocyanine but severe aggregation makes interpretation of the spectroscopic data difficult (1).

Analysis of optical and magnetic data obtained from nonsymmetric species is difficult because the effect of the distortion on the states involved must be determined. The MCD experiment is an ideal tool in that it provides, directly from solutions at room temperature, values for the angular momentum in the specific state. If new orbitals or new vibronic couplings become allowed as a result of the geometric distortions then the angular momentum will not be conserved. Apart from modifications to the ring itself, the free base phthalocyanine (H_2Pc) offers the most significant reduction in symmetry that has been readily studied (1). The optical spectrum is characterized by two major bands in the Q region, at 650 and 697 nm (1, 6, 7). The reduction from D_{4h} to D_{2h} symmetry breaks the degeneracy of the $e_g(\pi^*)$ orbitals and the MCD spectra clearly identify the split Q_x (negative B term in the MCD spectrum) and Q_y (positive B term in the MCD spectrum) components (1, 6, 7). Unsymmetric peripheral substitution in protoporphyrin IX removes the degeneracy of the E_g excited states through rhombic distortion of the molecule (8). The zero field splitting parameters for metalloporphyrins can be measured from MCD and absorption spectra, but the compression of the electronic transitions into a narrow spectral range makes accurate determination of these parameters difficult. The intense, narrow, and relatively isolated Q_{00} transition (1) in metallophthalocyanines can be used to study rhombic distortions and to determine zero field splitting parameters. The MCD technique provides unambiguous assignment criteria that can be used to calculate the extent of the splitting induced by the reduction in symmetry. A simplified molecular orbital diagram based on Gouterman's four-orbital calculations (9), which identifies the one-electron transitions that give rise to the first five allowed transitions in symmetric, closed-shell metallophthalocyanines (1, 10, 11), is shown in Fig. 1. Each of the resulting excited states are orbitally degenerate and positive A terms will be observed in the MCD spectrum.

In the late 1950s and early 1960s cobalt and nickel salts were reacted in a urea melt with cinchomeronic acid (3,4-dicarboxypyridine) to form phthalocyanine derivatives where the peripherally fused benzene rings were replaced with fused pyridines (12–16). Absorption spectra of various metal-3,4-pyridinoporphrazines (metallophthalocyanine-*N*-isologs; $MPcN_4(-2)$) indicated the presence of two overlapping bands where a single degenerate Q band was normally situated (12, 14). During its synthesis, $MPcN_4(-2)$ can be formed as one or more of the four possible structural isomers displayed in Fig. 2. Because three isomers have reduced symmetries it is reasonable to assume that the two overlapping bands occur either from a mixture of structural isomers or from a single structural isomer exhibiting significant rhombic distortion.

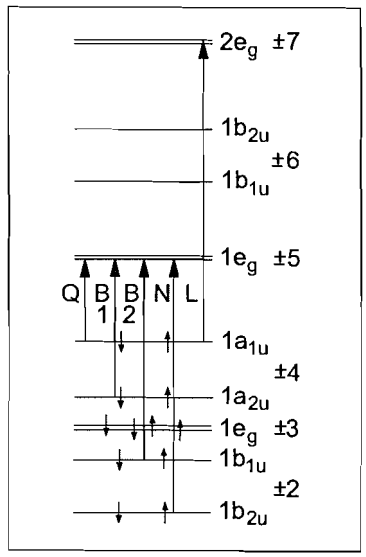

FIG. 1. Selected molecular orbitals of the phthalocyanines with D_{4h} symmetry. The order of the orbitals has been adapted from ref. 9.

In this paper, we report absorption and MCD spectra for $MgPcN_4(-2)$, $ZnPcN_4(-2)$, and the symmetric D_{4h} zinc-tetra-3,4-pyridizoporphrazine ($ZnPcN_8(-2)$). Deconvolution calculations are used to obtain band centre energies and the method of moments has been used to obtain the magnetic moments of the transitions that contribute to the observed spectral envelopes, especially the in Q region between 500 and 700 nm.

Experimental section

Materials and methods

$MgPcN_4(-2)$ was prepared by heating 1.0 g $MgCl_2$ (BDH), 1.0 g urea (BDH), 3.0 g 3,4-pyridine dicarboxylic acid (Aldrich), and 0.03 g ammonium molybdate (BDH) together at 160°C for 20 mins. $ZnPcN_4(-2)$ was prepared using the above method by replacing $MgCl_2$ with $ZnCl_2$. Both complexes were purified by literature methods (12, 14–16). The first step in the preparation of $ZnPcN_8(-2)$ was the oxidation of phthalazine (Aldrich) to 4,5-dicarboxypyridazine using potassium permanganate (BDH). The 4,5-dicarboxypyridazine (3.0 g) was heated with 1.0 g $ZnCl_2$, 1.0 g urea, and 0.03 g ammonium molybdate at 160°C for 20 mins. The purification method used for $ZnPcN_4(-2)$ was used to purify $ZnPcN_8(-2)$. Dimethylacetamide (DMA; BDH), dimethyl sulphoxide (DMSO; BDH), isopropanol (iPrOH; BDH), and tetrabutylammonium cyanide (TBACN; Aldrich) were used without purification.

Spectroscopic methods

All spectra were recorded as either DMA, DMSO, or iPrOH solutions at concentrations of approximately 10^{-6} mol L^{-1} which gave maximum absorbances of 1.0–1.5 in the Q-band region. Absorption spectra were recorded using a Cary model 219 spectrophotometer and digitized on an IBM S9001 computer. MCD spectra were recorded at room temperature using a Jasco J500 C spectropolarimeter controlled by a IBM S9001 computer using the computer program CDSCAN5 (17), with a field of 5.5 T provided by an Oxford Instruments SM2 superconducting magnet. The MCD signal intensity was calibrated using aqueous cobalt (II) sulphate ($\Delta\epsilon_M(510\text{ nm}) = -1.9 \times 10^{-2}$ L mol^{-1} cm^{-1} T^{-1}).

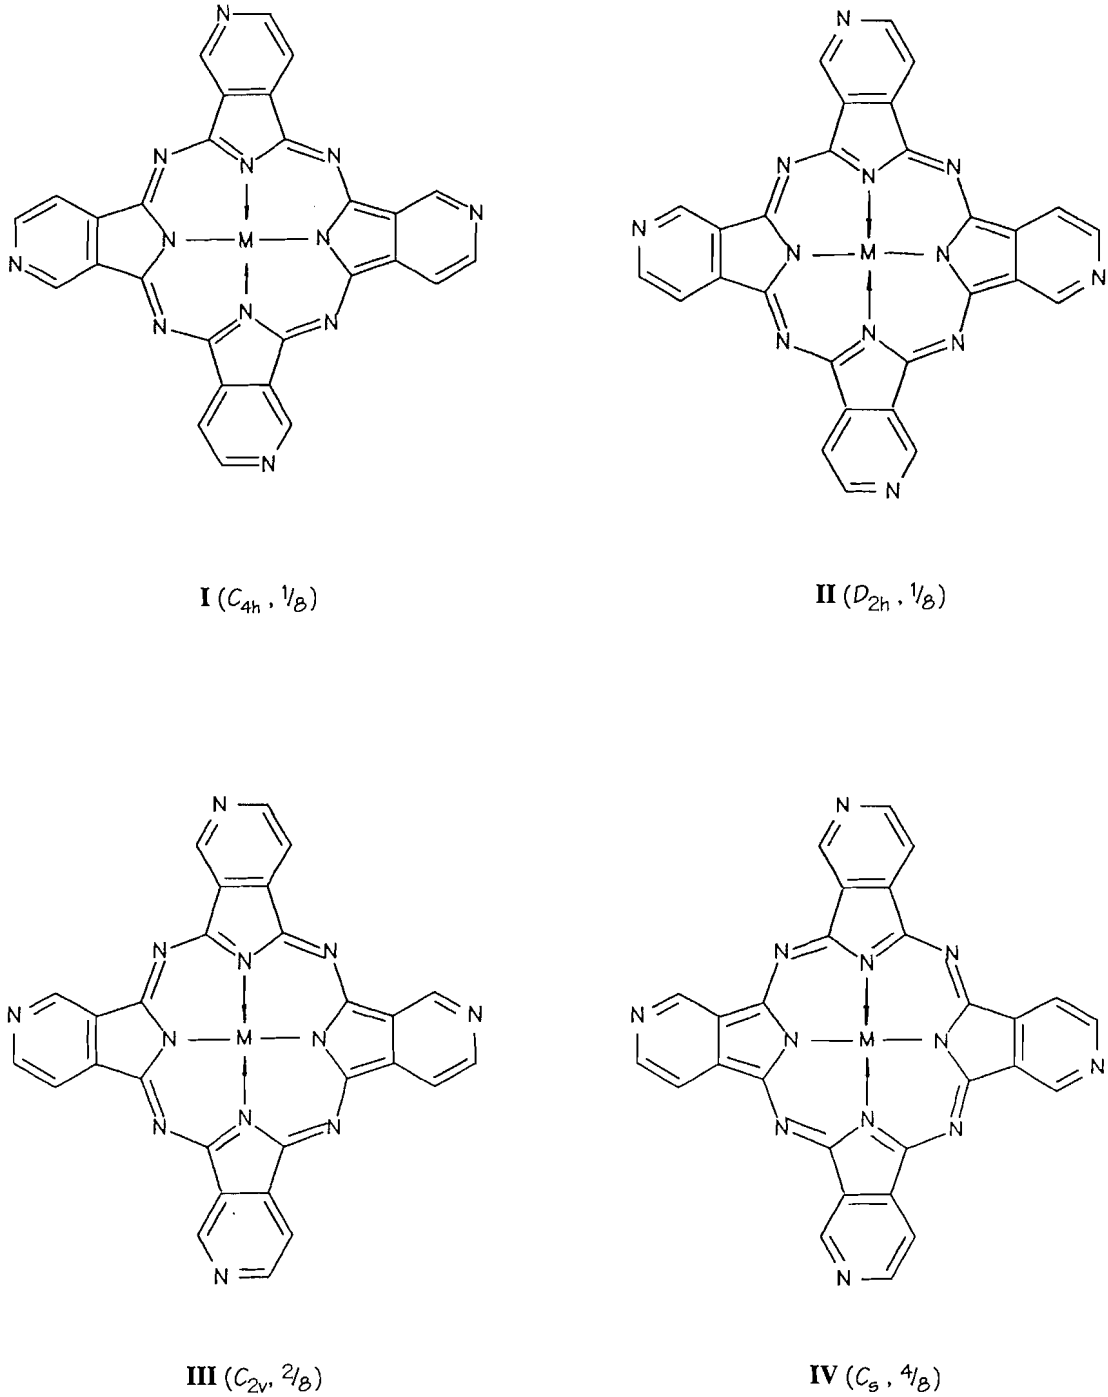

FIG. 2. The four structural isomers of $MPcN_4(-2)$. The symmetry group of each isomer is listed below the isomer and in parentheses, the statistical fraction formed during the reaction.

Data analysis

As in our previous work, Gaussian band shapes were used to fit the absorption and MCD spectra. A Simplex routine was used to fit the MCD spectra and a least-squares minimization routine based on second derivatives was used to fit the absorption data (18*a*). The database management program Spectra Manager (18*b*) was used to manipulate the spectral data.

Results

Spectral data

The room temperature absorption and MCD data for $MgPcN_4(-2)$, $ZnPcN_4(-2)$, $TBA[(CN)ZnPcN_4(-2)]$, and $ZnPcN_8(-2)$ are shown in Figs. 3, 5, 6, and 7. The observed band maxima are tabulated in Table 1. The results of deconvolution calculations for $MgPcN_4(-2)$ and $TBA[(CN)ZnPcN_4(-2)]$ in the visible region are shown in Figs. 4 and 8, and for $MgPcN_4(-2)$, $ZnPcN_4(-2)$, and $ZnPcN_8(-2)$ in the 300–500 nm region as Figs. 9, 10*a*, and 10*b*. The fitting parameters are tabulated in Tables 2–4. Common features in the absorption spectra of symmetric metallophthalocyanines are (*i*) an intense, narrow *Q* band located near 670 nm, which is associated with a positive MCD *A* term; (*ii*) a series of weak overlapping bands to the blue side of the *Q* band

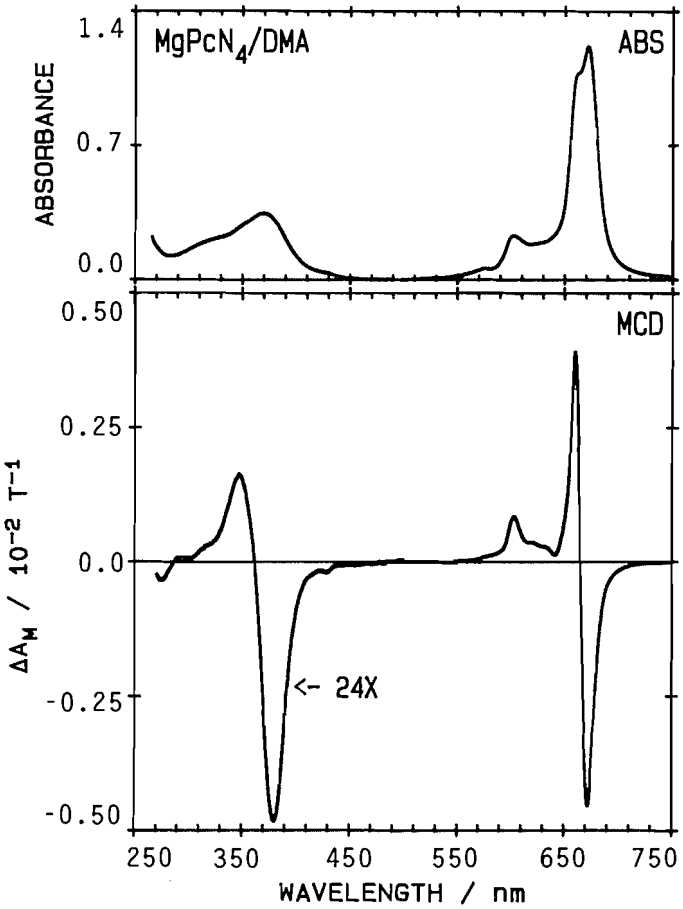

FIG. 3. Absorption and magnetic circular dichroism (MCD) spectra for $MgPcN_4(-2)$ in DMA. Spectra were measured in 1-cm path length square UV cells or 1-cm path length cylindrical MCD cells.

assigned as a combination of several vibrational progressions, Q_{vib}; (*iii*) a "window" region between 580 and 450 nm; and finally, (*iv*) between 400 and 250 nm, a region of more intense, broader bands that essentially overlap to the solvent cutoff at 250 nm (1). MCD *A* terms are measured under each of the major absorption bands (1, 10, 11, 19–22).

The absorption and MCD spectra for $MgPcN_4(-2)$ shown in Fig. 3 essentially exhibit these features. Although the split *Q* band envelope observed between 650 and 680 nm is associated with a derivative-shaped MCD envelope, the results of band deconvolution calculations, shown as Fig. 4, *conclusively show that the two components are polarized in the* x *and* y *directions*. We can then unambiguously assign the band as arising from the *Q* state where the degenerate components split as a result of the molecular geometry.

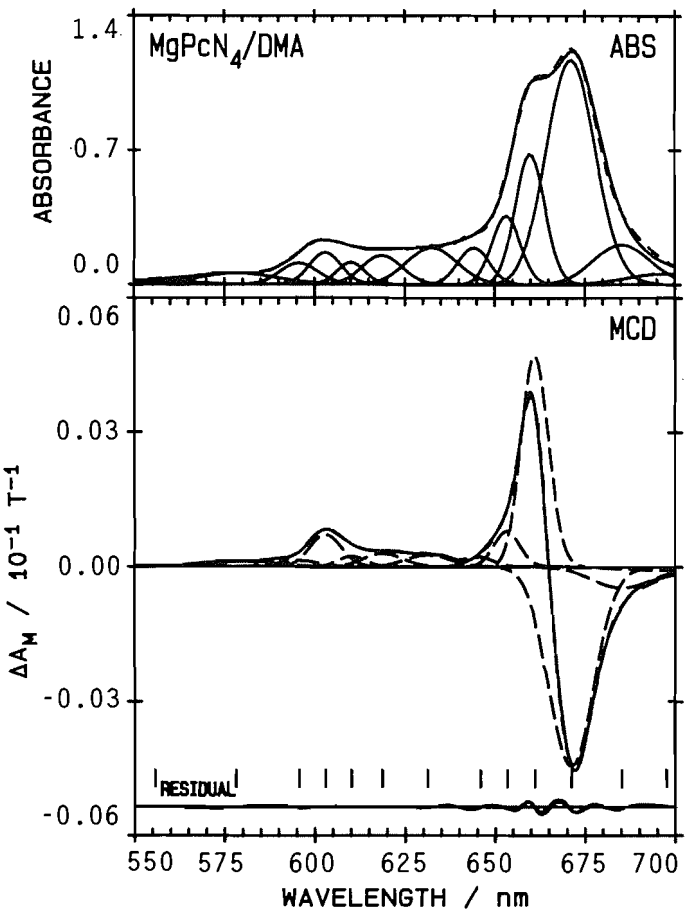

FIG. 4. Results of a band analysis for $MgPcN_4(-2)$ in DMA in the visible region (bands 1–13). (Top) Absorption: (——) experimental data; (----) fitted data; (——) individual bands. (Bottom) MCD (——) experimental data; (---) fitted data; (---) B terms.

Molecular aggregation can be ruled out as the cause of this splitting, since aggregation causes extensive broadening in the *Q* region (1). The apparent derivative shape of the MCD spectral envelope between 625 and 700 nm can be accounted for by two overlapping oppositely signed *B* terms separated by 224 cm^{-1}. With the exception of the *Q* band, the remainder of both the absorption and MCD spectra bear close similarities to those of unsubstituted diamagnetic main group phthalocyanines (1). The *B* region in main group phthalocyanines is difficult to assign in the absence of deconvolution data as the bands are significantly overlapped. We describe later the fits obtained for the *B* region; suffice to say that because the *Q* band region required MCD *B* terms, no degenerate states will be found and the entire MCD spectrum is dominated by *B* terms. The molecular symmetry must be less than D_{4h}.

The *Q* region absorption and MCD spectra of $ZnPcN_4(-2)$ and TBA[$(CN)ZnPcN_4(-2)$], shown in Figs. 5 and 6, respectively, closely resemble those of $MgPcN_4(-2)$. Both complexes exhibit a split *Q* band in the absorption spectrum and deconvolution of the $ZnPcN_4(-2)$ spectrum in the *Q* region (not shown) fits these two bands to two overlapping, oppositely signed, MCD *B* terms separated by 279 cm^{-1}, Table 3. The spectral envelope exhibited by TBA[$(CN)ZnPcN_4(-2)$] in the *B* region is consistent with the spectra

[a]Statistics are as follows. *B*-band region: $\lambda_{260-500\ nm}$, $\chi^2 = 1.37 \times 10^{-3}$, $\Sigma(\Delta A)^2 = 4.09 \times 10^{-7}$. *Q*-band region: $\lambda_{500-700\ nm}$, $\chi^2 = 4.51 \times 10^{-4}$, $\Sigma(\Delta A)^2 = 2.38 \times 10^{-4}$.

[b]$D_0 = \langle A\rangle_0/326.6$ where the units of D_0 (dipole strength) are D^2 (D: Debye units).

[c]$\langle\Delta A_M\rangle_0$ is the zeroth moment of the MCD. When fitting with a *B* term, the program calculates $\langle\Delta A_M\rangle_0$. The Faraday term value of $\mathcal{B}_0$ is calculated directly from the moments as follows: $\mathcal{B}_0 = \langle\Delta A_M\rangle_0/152.5$; $A_1 = \langle\Delta A_M\rangle_1/152.5$.

[d]The units of $\mathcal{B}_0$ are D^2/cm^{-2}.

[e]The concentration (*C*) of the solute is not known.

of other phthalocyanines where cyanide is an axial ligand (1, 19, 20). In these data, we find that the lowest energy *B* band, *B*1, red shifts out of the main envelope and two bands are clearly seen. In symmetric metallophthalocyanines this region can be fit with two *A* terms (1, 10, 11). We will see in Fig. 10*b*, that two sets of oppositely signed *B* terms fill the MCD envelope adequately.

The absorption and MCD spectra of $ZnPcN_8(-2)$ are displayed in Fig. 7. The predominant spectral feature is the single intense absorbance band centred on 654 nm. The MCD spectrum in this region exhibits the symmetric derivative shape expected for a degenerate excited state. It is interesting that, as with some other MPc species, there is greater resolution in the MCD spectrum in the Q_{vib} region. In particular, a common feature of Q_{vib} envelopes, the positive MCD band at 600 nm, is more pronounced than is usually found. The results from spectral deconvolution of the *Q* region are presented in Fig. 8 and demonstrate that the 654-nm band can only be fit to an MCD *A* term (a residual *B* term is necessary because of field-induced mixing between this state and all other states). The absorption band maxima recorded from all the absorption spectra are listed in Table 1. In the absence of a strongly coordinated axial ligand we observe, Fig. 10*b*, that the *B*1 and *B*2 bands collapse to a single broad band centred on 380 nm as seen for ZnPc(−2) in DMA (19).

Spectral envelope deconvolution calculations

As with our previous analyses of the spectral data for ZnPc(−2) (10), MgPc(−2) (11), and MgPc(−1) (21), exact band positions can be determined through the use of deconvolution techniques. The deconvolution calculations were carried out on coupled pairs of absorption and MCD spectra (1, 18*a*). In the pairing of the fitting to associated absorption and MCD spectra we aim to place the same number of bands, with similar band centre and band width parameters, in both spectra. Although several band shapes are possible for these calculations, we feel that the Gaussian shape is satisfactory in accurately reproducing the absorption and MCD spectral envelopes of the experimental data. This is a compromise, but the previously reported spectral fits (10, 11, 21) and the data presented here do show placement of bands where one would expect them and the resultant fit forms reasonable envelopes in *both* the absorption and MCD spectra. The most significant constraint on the fitting is the requirement to place bands in both the absorption and MCD envelopes at the same energy and with similar band width values. While we aim for identical band widths, we have found that in general the MCD bands must be fitted with narrower bands than in the associated absorption band. This effect is not so pronounced when low temperature spectral data are used (J. Mack and M.J. Stillman, unpublished data). In fits of many other metallophthalocyanines, the band width

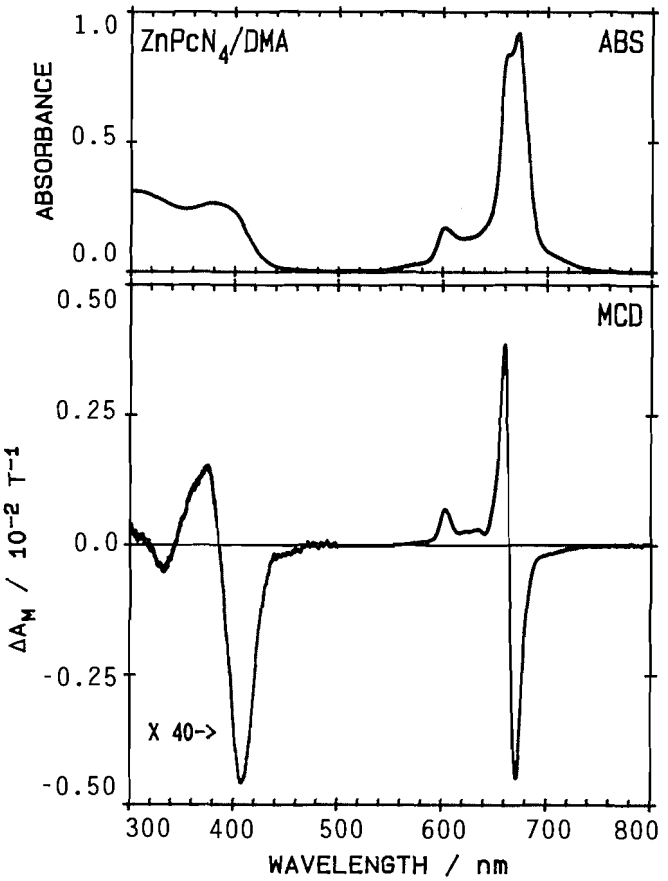

FIG. 5. Absorption and magnetic circular dichroism (MCD) spectra for $ZnPcN_4(-2)$ in DMA.

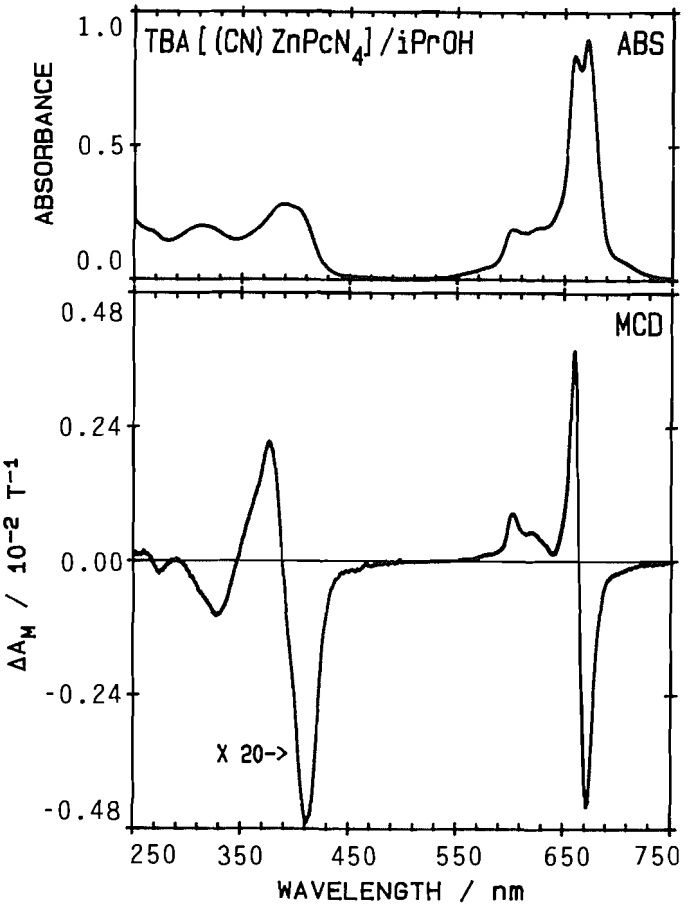

FIG. 6. Absorption and magnetic circular dichroism (MCD) spectra for TBA[(CN)$ZnPcN_4(-2)$] in iPrOH.

of the MCD *Q* band *A* term is as much as 30–40% narrower than the corresponding absorption band. Several reasons can be suggested for the discrepancy with the data described here. Amongst them, minor fractions of impurities will tend to broaden the absorption band more than the MCD band, leading to the incorporation of spurious bands to the red of the *Q* band maximum (see especially Fig. 8), and the effect of a zero field splitting induced by the solvent is most likely.

The absorption and MCD spectral fits for $MgPcN_4(-2)$, $ZnPcN_4(-2)$, and $ZnPcN_8(-2)$ are divided into the 500–800 nm (*Q*) and 250–500 nm (*B*) regions. Deconvolution of the *Q* region for both $MgPcN_4(-2)$ (Fig. 4) and $ZnPcN_4(-2)$ (not shown) required 13 bands to fill the absorption and the MCD spectral envelopes. Each absorption band was fitted with MCD *B* terms; therefore, the electronic states in these complexes are nondegenerate. Included in the MCD plots is the residual, which is the difference between the experiment and fitted envelopes. The random shape of the MCD residuals indicates that there is little systematic error in the fitted MCD envelope. The greatest noise occurs in the 650–700 nm region where two *B* terms were fit to the two overlapping absorption bands. Attempts to fit one or two MCD *A* terms in this region did not significantly reduce the residual noise or enhance the quality of the spectral fit. The bands at 671 nm (14 902 cm^{-1}) and 661 nm (15 126 cm^{-1}), for $MgPcN_4(-2)$, and at 671 nm (14 910 cm^{-1}) and 658 nm (15 189 cm^{-1}), for $ZnPcN_4(-2)$, have been assigned as the zero field split *x* and *y* components of the *Q* band, as in the D_{2h} $H_2Pc(-2)$ (1, 6, 7).

The *B* region (250–450 nm) of the phthalocyanine-*N*-isologs is complicated by the presence of several overlapping bands of relatively equal intensity. Twelve and eleven bands are required to fit this spectral region for $MgPcN_4(-2)$ (Fig. 9) and $ZnPcN_4(-2)$ (Fig. 10*a*). When the absorption spectrum has the complexity that the *B* region displays, the MCD spectrum provides the necessary and critical information that allows sensible fits to be obtained. Since the absorption bands in the *B* region were fit to MCD *B* terms, the spectral envelope in this region is dominated by transitions to nondegenerate states as well. The residuals show little systematic noise, a result that indicates a satisfactory fit of the MCD spectra. The fitting parameters for $MgPcN_4(-2)$ and $ZnPcN_4(-2)$ are summarized in Tables 2 and 3.

Deconvolution results for the 500–800 nm (*Q*) and the 290–500 nm (*B*) regions of $ZnPcN_8(-2)$ are plotted in Figs. 8 and 10*b*. In the *Q* region, a coupled pair of *A* and *B* term was used to fit the band centred on 654 nm (15 282 cm^{-1}). The quality of the MCD spectrum between 300 and 500 nm is low because of the limited solubility of $ZnPcN_8(-2)$ in DMSO. The poor quality makes the fit of this region (Fig. 10*b*) difficult. The fitting parameters for $ZnPcN_8(-2)$ are summarized in Table 4.

Moments analysis of the Q band region

Before we describe application of the method of moments, we need to summarize the origin of the MCD spectral intensity. The MCD spectrum arises from a combination

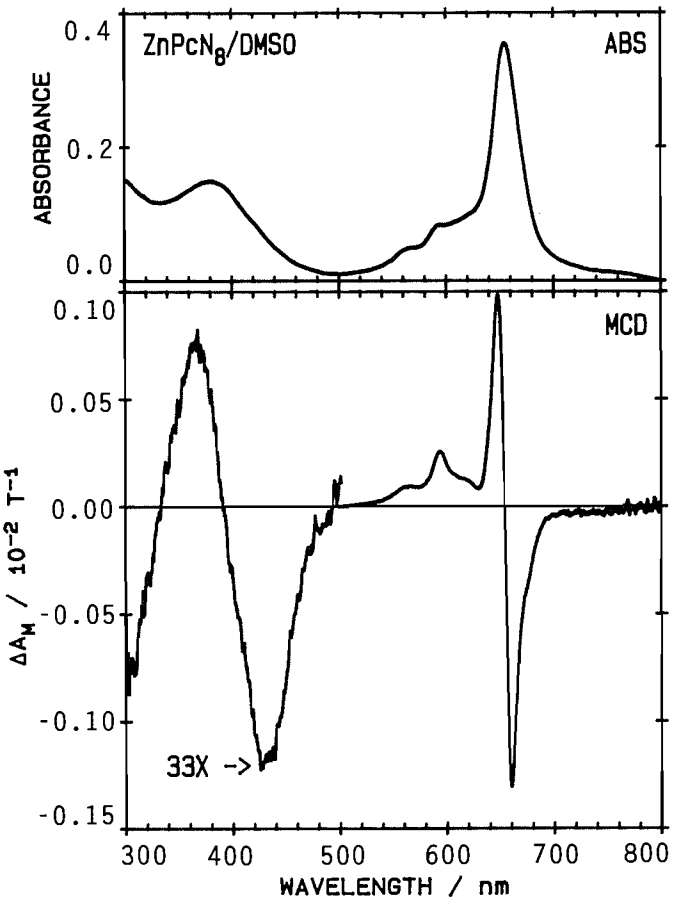

FIG. 7. Absorption and magnetic circular dichroism (MCD) spectra for $ZnPcN_8(-2)$ in DMSO.

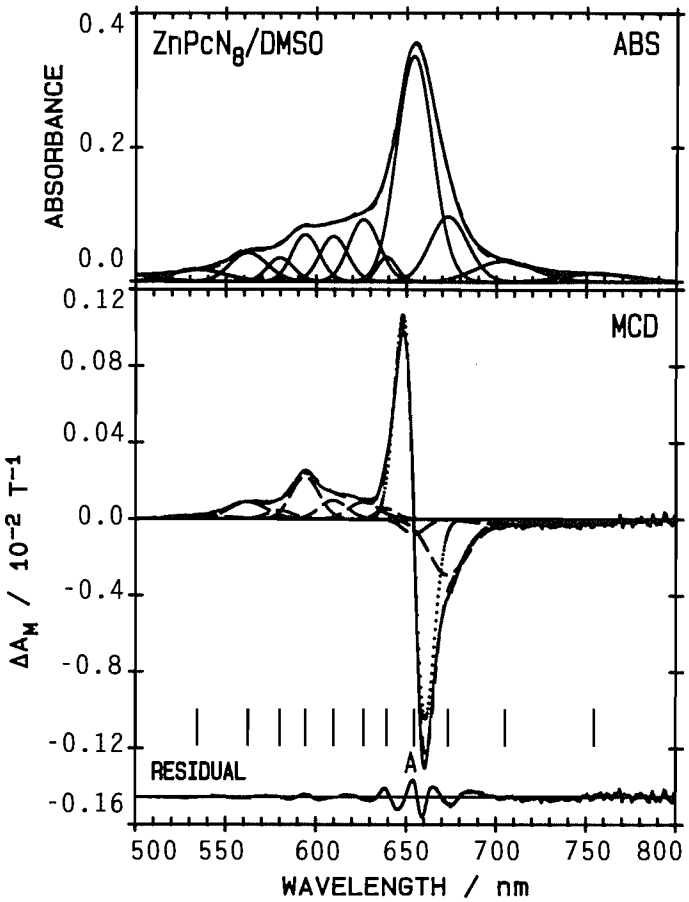

FIG. 8. Results of a band analysis for $ZnPcN_8(-2)$ in DMA in the visible region (bands 1–11). (Top) Absorption: (——) experimental data; (----) fitted data; (——) individual bands. of three spectral features (22, 23), namely, (*i*) *A* terms, (*ii*) *B* terms, and (*iii*) a *C* term. Intensity at a single wavelength

$$\Delta A = 326.6\ \mu_B\ Bcl[\mathcal{A}_1(-\partial f/\partial\epsilon) + (\mathcal{B}_0 + \mathcal{C}_0/kT)f]$$

where $\Delta A = A_L - A_R$ for the absorption of left and right circularly polarized light, respectively. *B* is the magnetic field intensity (tesla) in the direction of the optical axis (*z*); *c* and *l* are the concentration and cell path length, respectively; ϵ is the energy at this point of the MCD lineshape, and μ_B is the Bohr magneton with units $cm^{-1}\ T^{-1}$. The Faraday parameters $\mathcal{A}_1$, $\mathcal{B}_0$, and $\mathcal{C}_0$ are defined according to Piepho and Schatz (23), and are used with the dipole strength, D_0, which is calculated from the absorption spectrum according to $A = 326.6clD_0f$, the line shape for the *A* term, $(-\partial f/\partial\epsilon)$, is the derivative of the lineshape, *f*, that defines the shape of the *B* and *C* terms. Each term can be either positive or negative in sign. Only the *C* term is necessarily temperature dependent. *f* is chosen here to be the Gaussian lineshape. For a full description of current usage of these symbols, see the book by Piepho and Schatz (23).

Theoretical analysis for the $^1A_{1g} \rightarrow {}^1E_u$, electronic transitions for D_{4h} metallophthalocyanines (and metalloporphyrins) relates the magnetic moment of the excited state M_{jj} to the magnitude of the $\mathcal{A}_1$ term. However, calculation of $\mathcal{A}_1$ is necessarily difficult because of the presence of matrix elements involving the electric dipole operator in addition to the magnetic dipole operator (23). Evaluation of $\mathcal{A}_1/D_0$ overcomes this restriction as D_0 involves the same electric dipole moment matrix elements. Thus the value of $\mathcal{A}_1/D_0$ simply reports the value of the measured orbital angular momentum of the excited state in terms of $i\langle e_x|L_z|e_y\rangle$.

While the deconvolution provides a good estimate of $\mathcal{A}_1$, $\mathcal{B}_0$, $\mathcal{C}_0$, and D_0, the most valuable contribution is in pairing absorption and MCD bands to obtain accurate band centres and polarization information. Errors introduced by a poor match of the lineshape and irregularities introduced by vibronic effects effectively reduce the accuracy of the magnitudes calculated. We can extract the values of the Faraday $\mathcal{A}_1$, $\mathcal{B}_0$, and $\mathcal{C}_0$ parameters by using the Method of Moments (22, 23). The method involves integration over the complete absorption and MCD lineshape. Because the technique is applicable only to isolated transitions, the *Q* band of phthalocyanines is an ideal case. For diamagnetic, symmetric molecules the ground state will be orbitally nondegenerate so $\mathcal{C}_0$ must equal 0. Transitions from the ground to the excited state will be characterized by *A* and *B* terms in the MCD spectrum. The magnitude of the *A* term depends on the orbital angular momentum of the excited state.

The results of a moments analysis for the *Q* region (500–750 nm) of $MgPcN_4(-2)$, $ZnPcN_4(-2)$, and $ZnPcN_8(-2)$ and the previously reported results for (im)ZnPc(−2), (CN^-)-ZnPc(−2) (10, 19), and $(im)_2MgPc(-2)$ (11) are listed in Table 5. The moments calculations were carried out using

the program TNMOMET4 (T. Nyokong and M.J. Stillman, unpublished program) on the well-resolved and isolated *Q* bands.

Discussion

The majority of experimental and theoretical studies of phthalocyanines have been performed on symmetric phthalocyanine molecules with D_{4h} metal or D_{2h} free base symmetry (1, 6, 7). The rich ultraviolet–visible (250–800 nm) spectrum observed for phthalocyanines originates from molecular orbitals within the aromatic 18-π-electron system and from overlapping orbitals on the central metal (1). Reported absorption maxima for the Q_{00} transition in octasubstituted phthalocyanines (1, 24, 25) indicate a distinct perturbation of the core π system. Clearly, peripheral substitution influences the transition energies and the redox potentials of the 18-π-electron system. Asymmetric peripheral substitution is expected to reduce the molecular symmetry that defines the π system, which will be manifested by a splitting of degenerate states. The studies reported here describe the effect of introducing one and two nitrogen atoms into the fused benzene rings. Reduction of the tetragonal (D_{4h}) symmetry by the introduction of fused pyridine rings and its restoration through the introduction of fused pyridazine rings was monitored by absorption and MCD spectroscopy.

Assignment of the Q_{00} band in $MgPcN_4(-2)$ and $ZnPcN_4(-2)$

Used alone, absorption spectroscopy is not sufficient to probe the electronic structure of porphyrins and phthalocyanines. MCD spectroscopy has proven invaluable in the studies of phthalocyanines (1, 2) and porphyrins (8, 26). The MCD technique is sensitive to the symmetry, spin degeneracy, and orbital degeneracy within a molecule (1, 8, 26, 27).

The spectral envelopes of $MgPcN_4(-2)$ (Fig. 3) and $ZnPcN_4(-2)$ (Figs. 5 and 6) exhibit significant zero field splitting of the *Q* band. Spectral deconvolution of the *Q* region requires two MCD *B* terms here, which suggests that the asymmetry of the peripheral groups imparts a rhombic distortion on the inner 18-π-electron system. Before definitely assigning these two bands as the *x* and *y* components of the zero field split *Q* band, the possibility that these bands arise from different structural isomers needs to be addressed.

The structural isomers of $MPcN_4(-2)$

The four structural isomers of the $MPcN_4(-2)$ molecule are shown in Fig. 2. Only the isomer with C_{4h} symmetry will have degenerate excited states (28). Based on a statistical analysis, the relative abundance of the four structural isomers (**I, II, III,** and **IV**) is predicted to be 1:1:2:4. If the four isomers are synthesized in the predicted ratio, the observed absorption and MCD spectra represent the weighted spectral intensity of individual isomers. Assuming that all four isomers are present in solution, we can use the electronic spectra to determine whether the isomers have similar or different transition energies. When the isomers have different transition energies, the bands in the *Q* region should be broadened and the spectral envelope should be less resolved than the same region in $MgPc(-2)$ (11) and $ZnPc(-2)$ (1, 11, 20, 21). Aside from the split bands in the region of the Q_{00} transition, the *Q* region of $MgPcN_4(-2)$ and $ZnPcN_4(-2)$ displays the spectral sharpness and clarity seen in the unsubstituted phthalocyanines.

If all four isomers are present and their transition energies are similar, we should be able to determine if peripheral substituents distort the D_{4h} symmetry of the 18-π-electron system. If D_{4h} symmetry is maintained, the shape of the 500–700 nm (*Q* region) spectral envelope should resemble the same region in unsubstituted metallophthalocyanines. The split *Q* band in $MgPcN_4(-2)$ and $ZnPcN_4(-2)$ is not seen in the room temperature spectra of $MgPc(-2)$ (11) or $ZnPc(-2)$ (10). A reduction from tetragonal symmetry in isomers **II–IV** is expected to broaden the Q_{00} band and introduce high- and low-energy shoulders. The sharpness of the split *Q* bands in $MPcN_4(-2)$ and the absence of shoulders indicates that only one structural isomer is present.

Although there is limited information on the mechanism for the formation of phthalocyanines and their derivatives (29), analysis of the absorption and MCD spectra of $MPcN_4(-2)$ indicates that the pyridine rings in 3,4-pyridocarboxylic acid influence the template synthesis of $MPcN_4(-2)$. Since the spectral fits of $MgPcN_4(-2)$ (Fig. 4) and $ZnPcN_4(-2)$ (Fig. 7) were unable to place a MCD *A* term in the *Q* region, isomer **I** cannot be the synthesis product. If the precursor molecules are required to be aligned in an ordered arrangement, isomer **IV** is also ruled out as the product. The synthesis of isomers **II** and **III** can be explained by

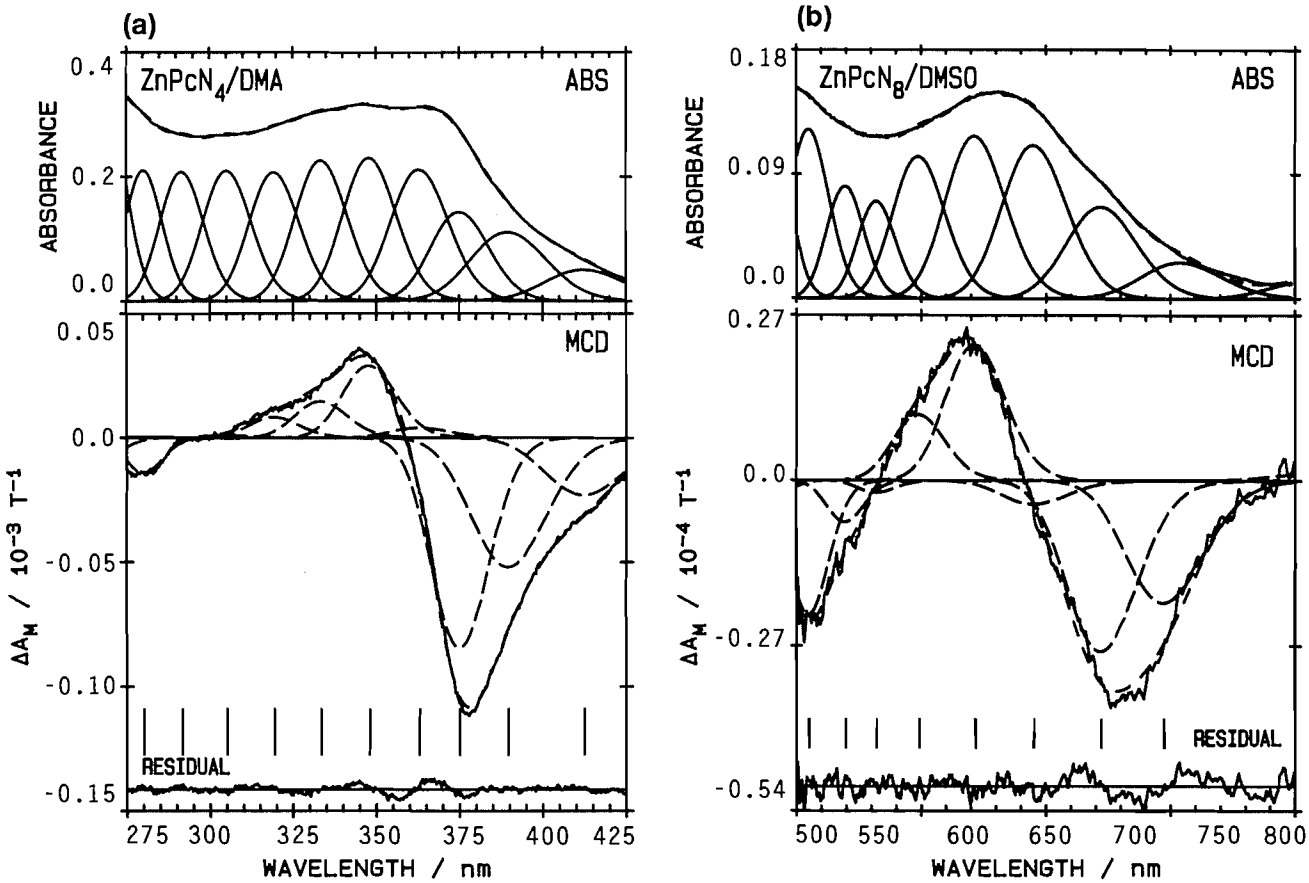

FIG. 10. (*a*) Results of a band analysis for $ZnPcN_4(-2)$ in DMA in the ultraviolet region (bands 14–23). (Top) Absorption: (——) experimental data; (----) fitted data; (——) individual bands. For personal use only.

mechanisms that require the precursor molecules to arrange in a specific orientation. There is, however, a difference in the number of steps required to form the products. Isomer **III** is synthesized in a two-step reaction, where two precursor molecules react to form an intermediate complex and then two intermediate complexes react to form isomer **III**, while isomer **II** forms via a template reaction of four precursor molecules. Since phthalocyanines form by concerted template reactions (29) and since isomer **III** does not form by a true template reaction, we assign isomer **II** as the synthesis product.

Zero field splitting of the excited states in $MPcN_4(-2)$

The absorption spectrum of FePc · HCl (30) exhibits the split *Q* band similar to that observed in the spectra of $MgPcN_4(-2)$ and $ZnPcN_4(-2)$. The origin of the split *Q* band in FePc · HCl is attributed to ring protonation that lowers the molecular symmetry from D_{4h} to C_s (30). We suggest that a simple rhombic distortion of the D_{4h} 18-π-electron system occurs in $MPcN_4(-2)$. The single degenerate *Q* band in the spectra of D_{4h} $ZnPcN_8(-2)$ (Fig. 8) supports the rhombic distortion of the *Q* band excited state in $MPcN_4(-2)$.

Comparison of the deconvolution data for $ZnPc(-2)$, $ZnPcN_4(-2)$, $ZnPcN_8(-2)$, $MgPc(-2)$, and $MgPcN_4(-2)$

The spectral fits for (im)ZnPc(−2) (10), $ZnPcN_4(-2)$ and $ZnPcN_8(-2)$, $(im)_2MgPc(-2)$ (11), and $MgPcN_4(-2)$ are presented as energy level diagrams in Fig. 11. The fitted band centre energies in the *Q* region are plotted in Fig. 12. A blue shift in band centre energies occurs as the nitrogen content of the peripherally fused rings is increased. There is a shift from 14 906 cm^{-1} in (im)ZnPc(−2), to 15 050 cm^{-1} in $ZnPcN_4(-2)$ (this is the midpoint between the 14 910 cm^{-1} (−) and 15 189 cm^{-1} (+) MCD bands), to 15 282 cm^{-1} in $ZnPcN_4(-2)$, and from 14 874 cm^{-1} in $(im)_2MgPc(-2)$, to 15 014 cm^{-1} in $MgPcN_4(-2)$ (midpoint between the (14 902 cm^{-1} (−) and 15 126 cm^{-1} (+) bands). If the blue shift is related to the number of nitrogen atoms included in the fused rings, then the energy of the Q_{00} transition, or the average energy for the split *x* and *y* components for $ZnPcN_4(-2)$, should be midway between the band centre energies for ZnPc(−2) (10) and for $ZnPcN_8(-2)$. The midpoint between the *Q* bands for (im)ZnPc(−2) and for $ZnPcN_8(-2)$ occurs at 15 094 cm^{-1}, which is very close to the midpoint (15 050 cm^{-1}) of the Q_x and Q_y bands for $ZnPcN_4(-2)$. The zero field splitting of the *Q* band in $ZnPcN_4(-2)$ is 279 cm^{-1} and in $MgPcN_4(-2)$ it is 224 cm^{-1}. The larger rhombic distortion in $ZnPcN_4(-2)$ may be due to a small displacement of the zinc ion out of the plane of the $PcN_4(-2)$ ring.

Moments analysis

The isolation of the *Q* band (Q_{00} + Q_{vib} transitions) from other ring transitions in $MPcN_{4,8}(-2)$ complexes allows the use of the MCD spectral results to determine the angular

[a]Calculated by setting $\langle A \rangle_1 = 0$; see ref. 23, eq. 7.3.4.

[b]Calculated from $\langle A \rangle_0 = 326.6\, D_0 cl$ (ref. 23, eq. A.4.19); the concentrations have not been included in the moments calculations of either absorption or MCD data; however, the parameter of interest, $\mathcal{A}_1/D_0$ factors out both c and l. The units of the dipole strength, D_0 are D^2 (D = Debye units). Note that the data for (im)ZnPc and (CN^-)ZnPc (*) are in $\Delta\epsilon$ and $\Delta\epsilon_M$ units.

[c]$\langle \Delta A_M \rangle_1 = \int \Delta A(\epsilon - \bar{\epsilon}) d\epsilon$; with units of μ_B, tesla, and cm^{-1}; ref. 23, eq. A.4.16.

[d]$\mathcal{A}_1 = \langle \Delta A_M \rangle_1 / 326.6\ \mu_B$ and has units of D^2.

[e]$\mathcal{A}_1/D_0 = \langle \Delta A_M \rangle_1 / (\mu_B \langle A \rangle_0)$; $\mu_B = 0.4669\ cm^{-1}\ T^{-1}$.

[f]$\langle \Delta A_M \rangle_0 = \int \Delta A d\epsilon$.

[g]$B_0/D_0 = \langle \Delta A_M \rangle_0 / (\mu_B \langle A \rangle_0)$; $\mu_B = 0.4669\ cm^{-1}\ T^{-1}$; B_0 has the units of D^2/cm^{-2}.

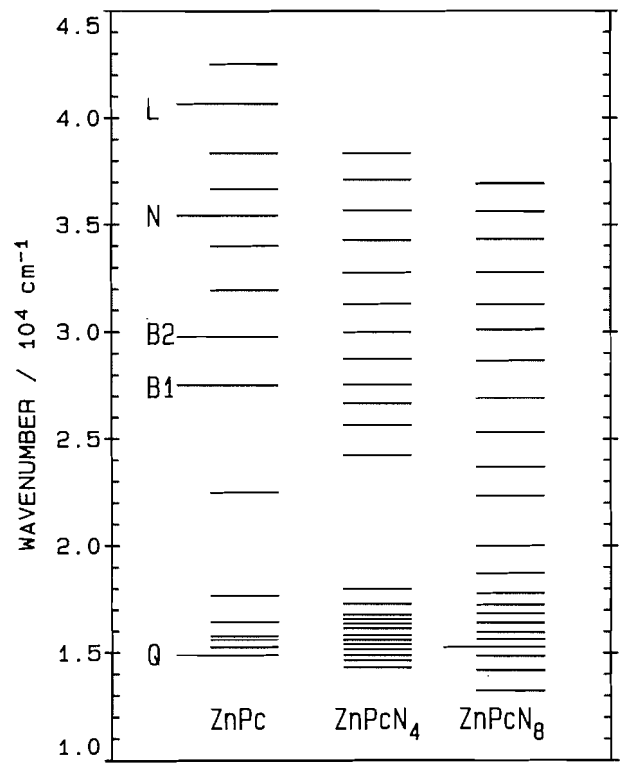

FIG. 11. Comparison of the energy levels, between 12 000 cm^{-1} and 40 000 cm^{-1}, of (im)ZnPc(−2) (ref. 10), $ZnPcN_4(-2)$, and $ZnPcN_8(-2)$ calculated by band deconvolution of the absorption and MCD spectra.

momentum of the excited state. Since the Q band is generally isolated from the charge transfer bands of transition metal phthalocyanines, it is possible to compare the magnetic moments of a wide range of substituted and unsubstituted metallophthalocyanines.

The $\mathcal{A}_1/D_0$ values for $MgPcN_4(-2)$ (3.06) and $ZnPcN_4(-2)$ (4.72 and 3.65) are consistently above the mid-range values previously reported: 1.3–3.55 for LZnPc(−2) (19); 2.49–2.78 for $L_2MgPc(-2)$ (11); and 2.7–3.11 for $L_2Fe(II)Pc(-2)$. Because of the large zero field splittings, 279 cm^{-1} in $ZnPcN_4(-2)$ and 224 cm^{-1} in $MgPcN_4(-2)$, the $\mathcal{A}_1/D_0$ values for the $MPcN_4(-2)$ complexes were predicted to be below those for more symmetrical D_{4h} MPc complexes, which inherently have smaller zero field splitting values. This prediction is based on the inverse relationship between the MCD intensity and the energy separation between the zero field split excited states (23). The moments data reported here are the first for peripherally substituted phthalocyanines. The blue shift in the band centres calculated from the first moment of the absorption $\langle A \rangle_1$, suggests an explanation for the unexpected values for $\mathcal{A}_1/D_0$. The presence of the peripheral nitrogens increases the size of the aromatic ring current that is responsible for the angular momentum. Unlike the case where substitution at the periphery extends the delocalization, which would then result in a red shift for the Q band, these nitrogens interact differently with the ground and excited states. We would have expected the $\mathcal{A}_1/D_0$ value for $ZnPcN_8$ to be the largest; however, it is clear from the fits (Fig. 8) that the dipole strength obtained by integration will be much too large because of extra bands to the red of the band maximum.

Conclusions

Absorption and MCD spectra are reported for the metallophthalocyanine-*N*-isologs: $ZnPcN_4(-2)$, $MgPcN_4(-2)$, and $ZnPcN_8(-2)$. Qualitative analysis of the spectra of $ZnPcN_4(-2)$ and $MgPcN_4(-2)$ indicated that only one of the four structural isomers of $MPcN_4(-2)$ is formed during synthesis. The isomer with D_{2h} symmetry is tentatively assigned as the synthesis product. Quantitative analysis of the spectral results for $ZnPcN_4(-2)$ and $MgPcN_4(-2)$ yielded zero field splitting parameters (ΔQ_{xy}) of 279 and 224 cm^{-1} and band center energies (midpoint between the Q_x and Q_y bands) of 664 nm (15 050 cm^{-1}) and 666 nm (15 014 cm^{-1}), respectively. No appreciable zero field splitting was observed in the spectra of $ZnPcN_8(-2)$ and spectral deconvolution placed the degenerate Q band at 654 nm (15 282 cm^{-1}). Spectral band deconvolution showed a blue shift in the band center energy of the Q band as the nitrogen content of the fused peripheral rings was increased. The first moments re-

A new synthesis of *in situ* cyclopropanones and the observation of a thermal cyclopropanone–dienol rearrangement

C. BLACK, P. LARIO, A.P. MASTERS, T.S. SORENSEN,[1] AND F. SUN
The Department of Chemistry, University of Calgary, Calgary, AB T2N 1N4, Canada

Received April 15, 1993

C. BLACK, P. LARIO, A.P. MASTERS, T.S. SORENSEN, and F. SUN. Can. J. Chem. **71**, 1910 (1993).

A new *in situ* low-temperature synthesis of cyclopropanones from α,α′-dibromo ketones is described. The synthetic procedure is particularly well suited to NMR tube-scale experiments, which then easily allows one to spectroscopically characterize low-temperature solutions of these unstable molecules. Nine systems were studied, seven of which give high yields of the cyclopropanones at −78°C or, in one case, −93°C. The major rearrangement pathway of these cyclopropanones leads to an α,β-unsaturated ketone. The mechanism of this reaction has been studied in some detail, including deuterium isotope studies, and the direct observation of enols, silyl enol ethers, and dimers. The rearrangement reaction is postulated to involve the intermediacy of an oxyallyl, the transfer of a hydrogen from the *anti*-alkyl substituent of this oxyallyl to the oxyallyl oxygen atom, which leads to an enol, and then finally tautomerization of the enol to the ketone. The thermal stability of the cyclopropanones is directly related to the ease of this rearrangement and, in two cases studied here, the rearrangement takes place rapidly even at −95°C and the cyclopropanones could not be observed. There is a remarkably strong correlation between cyclopropanone structure and reactivity, with the main structural factor being the external angles of the cyclopropanone substituents.

C. BLACK, P. LARIO, A.P. MASTERS, T.S. SORENSEN et F. SUN. Can. J. Chem. **71**, 1910 (1993).

On décrit une nouvelle synthèse *in situ* et à basse température des cyclopropanones à partir d'α,α′-dibromocétones. La méthode de synthèse est particulièrement adaptée à des études dans des tubes de RMN; cette particularité permet d'obtenir facilement une caractérisation spectroscopique à basse température de solutions de ces espèces instables. On a étudié neuf systèmes, dont sept qui donne d'excellents rendements en cyclopropanones à −78°C ou, dans un cas, à −93°C. La voie réactionnelle du réarrangement principal de ces cyclopropanones conduit à une cétone α,β-insaturée. On a étudié en détail le mécanisme de cette réaction, incluant des études d'effet isotopique du deutérium ainsi que l'observation directe d'énols, d'éthers énoliques silylés et de dimères. On suggère que la réaction de réarrangement implique un oxyallyle comme intermédiaire, le transfert d'un hydrogène à partie du substituant alkyle *anti* de cet oxyallyle vers l'atome d'oxygène de l'oxyallyle, qui conduit à un énol, et finalement une tautomérisation de l'énol en cétone. La stabilité thermique des cyclopropanones est directement reliée à la facilité de ce réarrangement et, dans deux cas étudiés ici, ce réarrangement se produit tellement rapidement même à −95°C que les cyclopropanones n'ont pu être observées. Il existe une forte corrélation importante entre la structure de la cyclopropanone et la réactivité, le facteur structural principal étant les angles externes des substituants de la cyclopropanone.

Turro and co-workers pioneered the first preparations (as *in situ* solution species) of several simple cyclopropanones, using the cycloaddition of a diazoalkane to a ketone (1). Subsequently, cyclopropanones have been made by other methods, notably by the rearrangement of allene oxides (2), from hindered α-bromo ketones (3), and from the electrochemical reductive debromination of α,α′-dibromo ketones (4). Classic studies by Loftfield have also implicated cyclopropanones as unseen intermediates in the "normal" Favorski rearrangement (5).

In this paper, we describe a relatively simple *in situ* preparation of cyclopropanones from α,α′-dibromo ketones, using an organometallic reagent for the reductive elimination. The initial work involved the carbonyl anion of manganese ($Mn(CO)_5^-$), but further experimentation has shown that an isoelectronic chromium salt is considerably more reactive, as well as being cheaper and more conveniently prepared. This anion, $Cr(CO)_4NO^-$, as the PPN^+ salt, is quite soluble in THF or methylene chloride, even at −95°C. Furthermore, most of the dibromides react immediately with the reagent at −78°C (or −95°C) to produce very high *in situ* yields of the corresponding cyclopropanone, together with $Cr(CO)_4NOBr$ and PPN^+Br^-. However, the method is apparently limited to tri- or tetra-substituted cyclopropanones.

Because all of the cyclopropanones in this study are unstable at ambient temperature, this synthetic procedure works well for conducting NMR tube-scale reactions at low temperatures, since CD_2Cl_2 can be used as solvent, the chromium by-product produces only one ^{13}C peak, and the PPN^+ peaks are at intermediate chemical shifts in the ^{13}C NMR and low field in the ^1H NMR, relative to the cyclopropanone peaks.

The synthetic method has some advantages over the diazoalkane–ketene or allene oxide reactions in that some bicyclo[*n*,1,0]cyclopropanones are accessible.

Because of very distinctive thermal stability differences between various cyclopropanones, this study has evolved to include the following (**1–9**). Attempts were made to directly observe and characterize (*in situ* ^1H and ^{13}C NMR) all of these examples. This group of cyclopropanones was shown to experimentally encompass a range of very different thermal stabilities, which we have qualitatively correlated with the external angles θ and ϕ, as shown in structure **A**.

Results and discussion

The NMR spectrum of a typical cyclopropanone preparation is shown in Fig. 1 to illustrate both the high yield in the reaction and to show the typical quality of the ^1H NMR spectra obtained in most cases. Only cyclopropanones **1** and **2** have been previously reported (1).

In characterizing the cyclopropanones, there are a number of distinct NMR spectral differences compared to the

starting dibromo ketones, e.g., CH_3 ^{1}H signals are about 1 ppm higher field (see Fig. 1), and in the ^{13}C NMR spectra the —C=O peak moves considerably downfield (in the range δ ~ 230 ppm) and there is of course a large change in the α and α′ carbons.

A

Since it was not possible to obtain analytical data on the cyclopropanones, we also verified the cyclopropanone formation in several cases (**1**, **2**, and **9**) by preparing the corresponding [3+4] furan cycloaddition adduct, as originally described by Fort (6), and used repeatedly by later researchers. Furthermore, the distinctive IR carbonyl stretching frequency was measured in several instances, so we believe that there is no question about the identity of the cyclopropanones reported here.

TABLE 1. Approximate thermal stability of cyclopropanones **1–9**

Cyclopropanone	Approximate $t_{1/2}$ (min)	Temperature (°C)
1	30	−10
2	30	−40
3	<2	−78
	<5	−95
4	10	−10
5	30	0
6	30	−70
7	10	20
8	<2	−78
9	10	20

Cyclopropanones **1, 2, 4, 5, 7**, and **9** were easily prepared and observed at −78°C. Their approximate thermal stabilities are shown in Table 1. Cyclopropanone **6** was marginally stable at −78°C, but could be studied at −93°C. Cyclopropanones **3** and **8** could not be observed, even at −95°C (the freezing point of the solvent). From attempts to prepare **8** at −78°C, where furan or cyclopentadiene was initially present in the solvent, we were able to obtain the

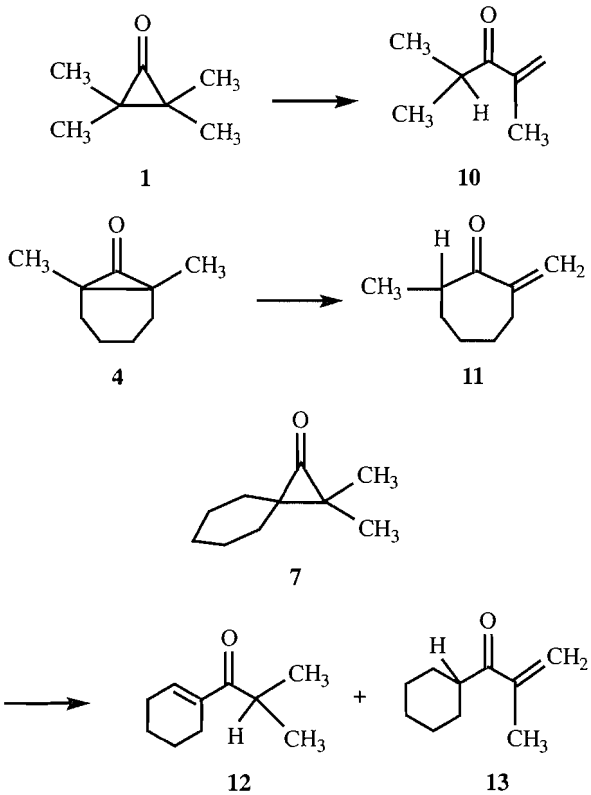
corresponding [3+4] cycloadducts (no $AlCl_3$ needed). This result constitutes reasonable evidence that **8** was formed as at least a transient species. Other evidence (see later) also indicates that **3** and **8** are formed at −78°C but rearrange on a time scale faster even than the dibromo ketone addition time (ca. 2 min).

One can see from the Table 1 comparisons that even small structural changes result in large changes in thermal stability. Largely because **8** could not be directly observed, the synthesis of the unsymmetrical cyclopropanone **6** was undertaken. Comparing the stability of **1** and **6**, and projecting this stability difference to **8**, one can easily understand why **8** was not directly observed. A discussion of why **3** and **8** are so unstable will be presented later.

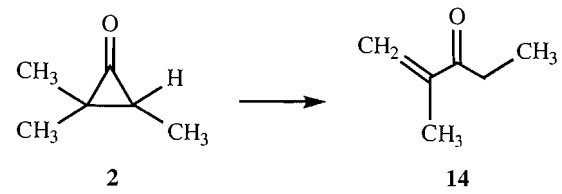
Nature of the cyclopropanone thermal rearrangement reactions

Before discussing this topic in detail, there are two generalizations that one can make: (1) the more thermally stable the cyclopropanone, the "cleaner" the rearrangement process; and (2) the more concentrated the solution, the "cleaner" the rearrangement, i.e., there appear to be bimolecular steps involved.

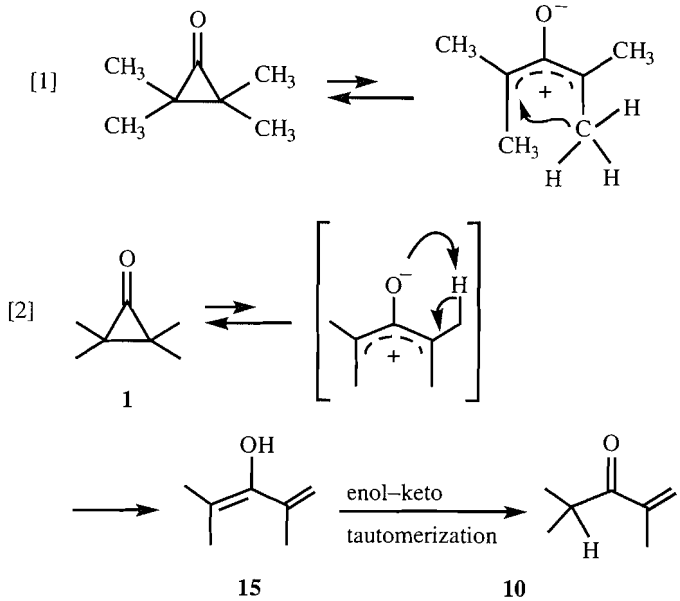
The major monomeric product in all cases is an α,β-unsaturated ketone, e.g., ketone **10** is formed from **1**, and the yields of this ketone product are reasonably good in the case of **4, 5, 7**, and **9**, and less so for **1, 2**, and **6**. Furthermore, in the case of the bicyclic cyclopropanones **4** and **5** (and indirectly implied for **3**, see later), the α,β-unsaturation is *exclusively* in the exocyclic position, e.g., **4** → **11**. In the case of the unsymmetrical cyclopropanones **6** and **7**, one observes both α,β-unsaturated ketones, e.g., **7** → **12** and **13**. However, cyclopropanone **2** gives ketone **14** as the only monomeric product.



Ratio **12/13** = ca. 2:1

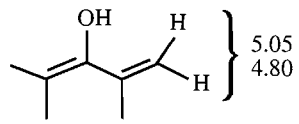


The rearrangement of **1** to **10** has been previously observed and a suggested mechanism (*4a*) involved a direct hydrogen shift from the *syn*-methyl of the oxyallyl equilibrium partner of **1**, as shown in eq. [1]. It seems clear to us that an oxyallyl must indeed be the reactive intermediate but that a hydrogen on an *anti*-methyl group is the one that is shifted (i.e., in order to explain the results for the bicyclic cases). There is in fact a considerable amount of evidence from our work that the ketone product arises by way of the corresponding enol (dienol) **15**, i.e., eq. [2]. The evidence for this enol intermediate can be summarized as follows:

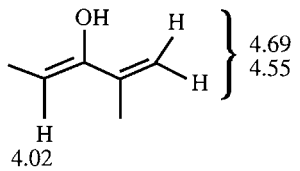


1. In the case of the cyclopropanone rearrangements of **1** and **2**, one can see an extra pair of $=CH_2$ proton peaks in the ^1H NMR spectrum (in addition to those from the α,β-unsaturated ketone), which appear during the rearrangement and have disappeared by the end of the reaction, i.e., they arise from a transient species. Their chemical shift position is considerably upfield from those of the corresponding ketone peaks, indicating the absence of a conjugated carbonyl group. The position of these peaks can be compared with those of the silyl enol ether **23** (see later), which has $=CH_2$ peaks at δ 4.99 and 4.67. We suggest therefore that the transient peaks referred to above originate from the enols **15** and **16**. Enol **15** has previously been described in pioneering work by Hoffmann and Schmidt (7), and a comparison of ^1H NMR data (δ 4.77 and 4.92 in CCl_4 solvent) indicates a close fit. Furthermore, in enol **16**, the proton on the enol double bond is assigned to a quartet at δ 4.02, very similar in chemical shift to that reported (8) for the simple enol **17**. Unfortunately, one cannot unambiguously locate the -OH signal. The high-field CH_3 region of the ^1H NMR spectra of the rearranging **1** and **2** contain a large number of peaks. However, for **1**, three of these have intensity changes appropriate for the transient existence of enol **15** and their

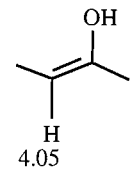
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.



15



16

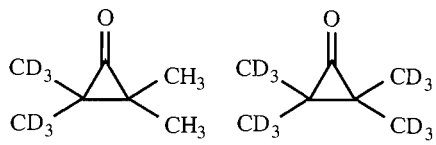


17

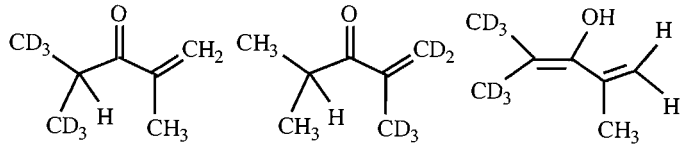
chemical shift positions also agree well with those reported (7). For enol **16**, a peak at δ 1.81 can be assigned to the enol.

2. Both the hexadeutero and dodecadeuterocyclopropanones **18** and **19** were prepared and characterized by ^1H, ^2H, and ^{13}C NMR spectroscopy. As one perhaps expects, **18** shows a sizeable (ca. 4) isotope effect in favoring ketone **20** as the major ketone rearrangement product (the overall reaction yield, as with **1**, is mediocre). However, a majority of the product from reaction of the deuterated side of the molecule is a d_5 species, **21**, in which a proton occupies the methine position, i.e., an intermolecular crossover has occurred. This result clearly rules out any mechanism in which a deuterium shift directly produces the ketone.

However, an enol intermediate would probably tautomerize by a bimolecular mechanism, so the appearance of



18 19



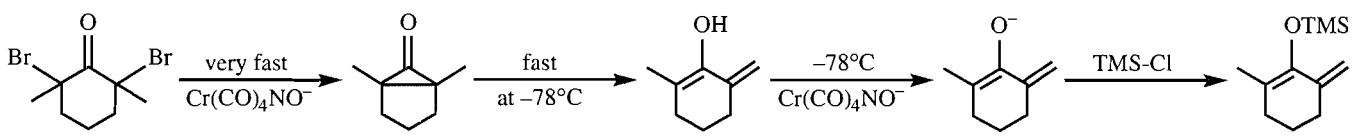
20 21 22

ketone **21** is not unexpected, given the dominant presence of enol **22** in the solution as a source of methine hydrogen for this bimolecular ketonization process. In the work of Hoffmann and Schmidt (7), rather large isotope effects were observed for the ketonization of enol **15**-OD compared to **15**, and the operation of such an effect in our case would further enhance the specific formation of ketone **21**.

The perdeutero ketone **19** was prepared because we wanted to see if there was any evidence for a kinetic isotope effect in the formation of an enol, which in turn could provide evidence on whether the C—H(D) bond-breaking step shown in eq. [2] is a rate-limiting step. In this case, however, we were unable to observe the formation of any rearranged ketone. As previously noted, one sees a number of other NMR peaks (besides those for **10**) due to competing decomposition pathways for **1**. In the case of **19**, it appears that the formation of the α,β-unsaturated ketone has been slowed down to such an extent that *only* competing processes are occurring. Nevertheless, the presence of a sizeable kinetic isotope effect in forming **10** is not ruled out.

3. The presence of an enolate intermediate can be directly implied in the cyclohexyl case **3**. At −78°C, with addition of the dibromo ketone to the $Cr(CO)_4NO^-$ solution over a 2-min period, one observes a ca. 1.5–2:1 stoichiometry ($Cr(CO)_4NO^-$: dibromo ketone). Conducting the reaction in the presence of TMS-Cl, one obtains a modest isolated yield of the silyl enol ether **23**. Both the 1.5–2:1 stoichiometry and the trapping of this silyl ether are consistent with the following mechanism (eq. [3]):

[3]

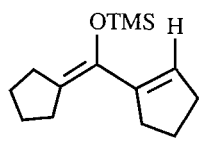


3 23

+ $Cr(CO)_4NOBr$ + $Cr(CO)_4NOH$

Thus, the chromium reagent is also a moderately strong base (9) in addition to the reductive debromination capability. If, as in this case, the cyclopropanone → enol transformation takes place on a time scale faster than the dibromo ketone can be added, then there is "excess" chromium reagent present for a second reaction with the enol to form the enolate. In the "normal" reactions, all of the $Cr(CO)_4NO^-$ has been consumed in a 1:1 reaction with dibromo ketone before *any* enol is formed. A related silyl enol ether **24** can also be trapped in the case of the reactive cyclopropanone **8**, again with approximate 2:1 stoichiometry.

4. The accumulation of an enol intermediate at any time in the overall rearrangement of the cyclopropanone is likely to induce side reactions. Thus, it is known that putative oxyallyl species rapidly react with nucleophiles (4*a*, 10). It is quite conceivable that an enol will serve this purpose, which



24

could then lead to the formation of dimeric products. In the overall transformation:

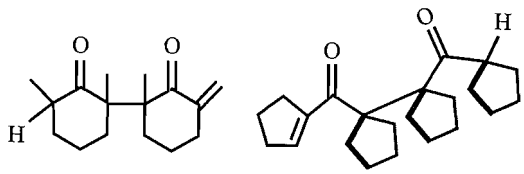
$$\text{cyclopropanone} \xleftarrow{\rightarrow (a)} [\text{oxyallyl}] \xrightarrow{(b)} \text{enol} \xrightarrow{(c)} \text{ketone}$$

it seems a reasonable assumption that step c will have a similar rate (for a given temperature) in all cases. The ac-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

cumulation of enol in the reaction depends therefore on the ratio of steps a–b/step c. In the case of cyclopropanones **4, 5, 7**, and **9**, in which near-ambient temperatures are involved for steps a–b, the c process can be assumed to be fast, there is thus no accumulation of enol, and good yields of the α,β-unsaturated ketone are formed (the latter *is not* likely to be reactive in the presence of an oxyallyl intermediate). In the case of cyclopropanones **1** and **2**, steps (a)–(b) are faster, hence lower temperatures are needed for the NMR study; step (c) is consequently slower at this lower temperature, and observable enol accumulates. This enol, in addition to tautomerizing, can also react with the oxyallyl intermediate itself in those situations where the reaction is ongoing, i.e., unreacted cyclopropanone is also still present. Also, the yields of the ketone are higher when the solutions are more concentrated, consistent with a mechanism in which an enol intermediate is tautomerized by a *bimolecular* process, whereas earlier steps leading to the enol appear experimentally to be first order (or pseudo-first order).

5. In the case of cyclopropanones **3** and **8**, we have already noted that the rearrangements are very fast at −78°C. Although only small amounts of monomeric α,β-unsaturated ketones are formed in these cases, one can in fact isolate reasonable yields of dimeric products from the reaction, compound **25** from **3** and **26** from **8**. Both were fully characterized by a range of 2D NMR techniques. In the case of



25 **26**

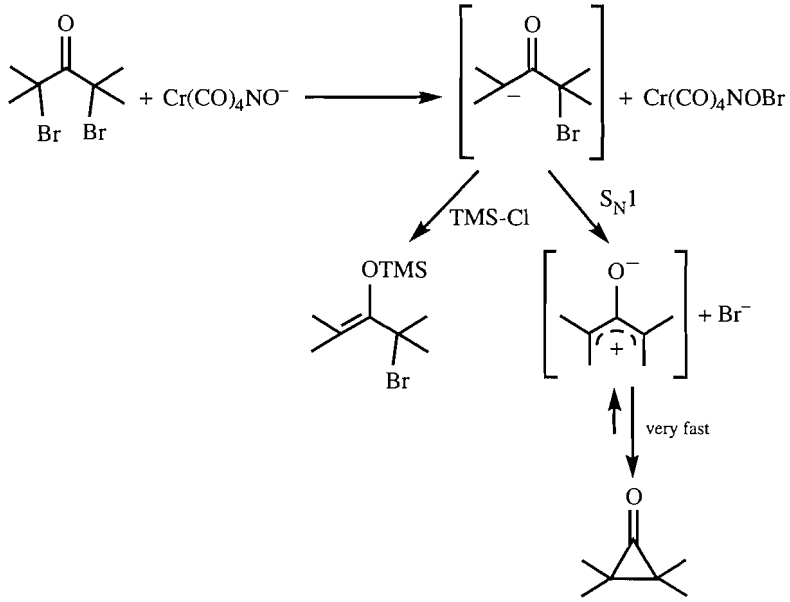
(two stereoisomers in a ca. 10:1 ratio)

25, one again notes the presence of the exocyclic $=CH_2$ functionality and there was no evidence that a corresponding endocyclic dimer was present in the product mixture. These particular dimeric products can be rationalized as a carbon alkylation of an oxyallyl intermediate by the corresponding enol (or enolate), i.e., as discussed in the previous section.

Mechanism of the original cyclopropanone formation

The accumulated evidence from studies of the Favorski reaction can be interpreted in terms of initial oxyallyl formation from a bromo enolate intermediate (11). There is good evidence that our reactions proceed in a similar manner, i.e., eq. [4].

[4]



Thus, in the case of primary and secondary centers on the α and α′ ketone positions, we see essentially no cyclopropanone formation, presumably because other reactions compete with a slower S_N1 loss of Br^-. Indeed, when these primary and secondary systems are reacted with $Cr(CO)_4NO^-$ in the presence of TMS-Cl, good yields of the corresponding α′-bromosilylenol ethers were isolated.[2] However, in the tertiary cases, only cyclopropanones were observed (loss of Br^- faster than any trapping of the bromo enolate).

The subsequent disrotatory closure (12) of an oxyallyl to a cyclopropanone is expected to be very rapid, with almost no activation barrier (theoretical calculations) (13).

It might be argued that a bromo enolate intermediate could also form an allene oxide via nucleophilic attack by the enolate oxygen (allene oxides are known to rearrange to cyclopropanones (2). However, one might expect such a reaction to actually be enhanced in the primary and secondary dibromo ketones, contrary to what one observes in the TMS-Cl trapping reactions, assuming one can use these reactions as a measure of the bromo enolate lifetime.

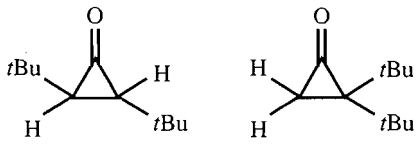
Cyclopropanone stabilities

All of the early work of Turro (1) involved *in situ* solution formation of cyclopropanones, which in most cases ap-

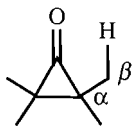
[2]A.P. Masters, T.S. Sorensen, and F. Sun. Unpublished results.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

peared to polymerize at ambient temperatures. Pazos and Greene (3) and later Crandall et al. (*2a*) isolated stable cyclopropanones, the *tert*-butyl-substituted derivatives **27** and **28**. The general assumption would be that the bulky *t*Bu groups hinder "polymerization", but it should also be noted that these two examples have *no* β-hydrogens of the type shown in structure **B**, which are being transferred (rearranged) in our cyclopropanone systems, so the stability of **27** and **28** may also be due to this absence.



27 **28**



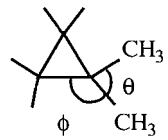
B

In assessing the wide range of thermal stabilities exhibited by the cyclopropanones **1–9**, one needs to look both at the cyclopropanones themselves and at the stability of the oxyallyl partner, which is almost certainly the reactive form. In support of this assumption, Cordes and Berson recently determined (14) a forward E_a for a cyclopropanone $\rightleftarrows$ oxyallyl reaction of about 16–18 kcal/mol, and while this number will vary greatly in different systems and in different solvents, it is still a relatively low barrier. In addition, recent high-level *ab initio* calculations show fairly small ground-state energy differences between some cyclopropanones and the corresponding oxyallyl partner (15).

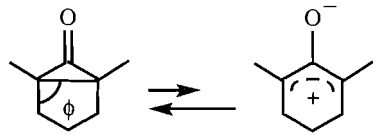
The important steric factors in determining the thermal stability of the cyclopropanones, as intimated in the Introduction, are the angles θ and ϕ in structure **A**. Thus, X-ray structures of unconstrained cyclopropane rings show, not unexpectedly, that both of these angles are larger than the tetrahedral sp^3 angle. A search of the Cambridge data file (16) for subunit **C** gives $\theta_{av.} = 113.3°$, $\phi_{av.} \sim 118°$ (34 structures). One can see that cyclopropanones **3** and **8** involve ϕ and θ angles that are, respectively, too small, and one sees dramatic stability increases (Table 1) when only one more carbon atom is included in these external rings, i.e., **3** vs. **4** and **8** vs. **9**. The corresponding oxyallyl partners have to some extent opposite steric problems; thus a six-membered oxyallyl should be quite "favorable" in a relative sense, but a seven-membered ring less so, as shown in eq. [5].

Given these steric constraints, one expects the equilibrium constant for [oxyallyl]/[cyclopropanone] to be increased in the case of **3** and **8**, and, since more oxyallyl means more reactivity, these cyclopropanones are very unstable.

In summary, we have developed a high-yield cyclopropanone synthesis that can be used at temperatures as low as −95°C and is suitable for *in situ* NMR monitoring. This has allowed for the preparation of bicyclic cyclopropanones. Cyclopropanones are very reactive molecules, and one major rearrangement route is isomerization to an α,β-unsaturated ketone. We have shown by a variety of means that this rearrangement probably involves an enol intermediate, in which a β-hydrogen from the *anti*-alkyl substituent in an oxyallyl intermediate is transferred to oxygen. In ring systems, this leads to an exocyclic double bond. We have also rationalized why various cyclopropanones exhibit very different thermal stabilities.

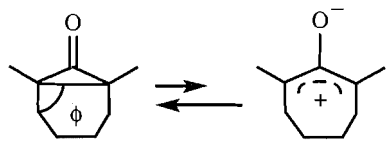


C



3, ϕ too small favorable sp^2 bond angle

[5]



4, ϕ larger slightly more steric strain

Experimental

Gas chromatography was performed on a Hewlett–Packard model 5890A, with either a 10 m 0V1 530 μ or a packed 3% 0V1 (8 ft × 2 mm i.d.) column. NMR spectroscopy was carried out on a Varian XL-200, Bruker ACE-200, or, where noted, Bruker AM-400 (δ values in $CDCl_3$, *J* in hertz). For ^1H NMR, s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet, b = broad. For ^{13}C {^1H} NMR, q = quaternary, multiplicities were determined from DEPT 90 or 135 spectra. Mass spectra were determined with a Kratos MS-90 (peak intensities in parentheses), a VG Micromass 7070F, or a Hewlett Packard 5971A mass spectrometer. Infrared spectra were determined on a Nicolet 5-DX or a Mattson model 4030, both FT instruments, peaks being reported as very strong (vs), strong (s), medium (m), or weak (w).

Preparation of the dibromo ketones

All of the dibromo ketones were prepared by direct bromination of the corresponding ketone, and only one of these is unreported. In general, these dibromides are not very stable and should be stored in a freezer.

trans-*2,8-Dibromo-2,8-dimethylcyclooctanone*

Bromine (1.1 mL) was added dropwise with stirring to a solution of *trans*-2,8-dimethylcyclooctanone (17) (1.47 g, 9.54 mmol) in 15 mL chloroform and 0.3 mL 48% HBr. The reaction was then heated to reflux for 20 h, cooled, diluted with 30 mL chloroform, and then washed successively with 10% $NaHSO_3$, 10% Na_2CO_3, and water. After drying ($MgSO_4$) and solvent removal, a crude oil residue was obtained, 2.09 g. In hexane, crystals of the title compound were obtained (0.91 g), which could be recrystallized from the same solvent, mp 38–40°C. ^1H NMR (200 MHz): 2.45–2.75 (m, 4 H); 2.17 (s, 6 H); 1.6–1.9 (m, 4 H); 1.31 (m, 2 H). ^{13}C NMR: 202.5 (Cq); 71.2 (Cq × 2); 43.2 (CH_2 × 2); 34.0 (CH_3 × 2); 25.3 (CH_2 × 2); 21.1 (CH_2). MS, *m/z*: 312 (3), 233 (10), 151 (100). Exact Mass calcd. for $C_{10}H_{16}O_{79}Br_2$: 309.9563; found: 309.9587.

An attempt was made to prepare the dibromide of dicycloheptyl ketone but, although the monobromo ketone is easily obtained, attempts to introduce a second bromine resulted in an intractable mixture. The dicycloheptyl ketone was prepared by a procedure

identical to that used for the known dicyclohexyl ketone (18). ^{1}H NMR (200 MHz): 2.55–2.75 (m, 2 H); 1.9–0.8 (m, ca. 24 H). ^{13}C NMR: 198.4 (Cq); 51.0 (CH × 2); 30.2, 28.3, 26.8 (all CH_2 × 2). MS, *m/z*: 222, 125, 97 (100), 55.

General procedure for in situ *cyclopropanone preparation*

The salt $PPN^+Cr(CO)_4NO^-$ was prepared as described (9). Reactions were carried out in 10-mL oven-dried Schlenk tubes fitted with a septum and magnetic stirrer, and generally cooled to −78°C. The chromium salt can be weighed and transferred to the Schlenk tube in air. After nitrogen purging, the solvent was added and stirring commenced. The dibromide solution was added by syringe, the rate of addition normally being about 2 min, but occasionally faster or slower addition rates were used. Methylene chloride was normally used as the solvent, about 1–2 mL used to dissolve the chromium salt and a similar volume used for the dibromo ketone solution (0.2–0.4 mmol scale). In most cases, a slight molar excess of chromium salt was weighed out (ca. 5%). The deep red color of the salt serves as an indicator for the reaction, and in some cases, i.e., **3** and **8**, the continued addition of the dibromide solution was halted when the deep red color of the salt had "prematurely" disappeared. After completion of the reaction, most work-ups involved the addition of a 3× volume of pentane or hexane. These were added slowly so that no appreciable warming took place. A precipitate (PPN^+Br^-) forms at this stage. Eventually, the solution was allowed to slowly warm to 20°C ($Cr(CO)_4NOBr$ decomposes to insoluble material) and the mixture was then filtered through Celite to leave an essentially inorganics-free solution.

For the NMR studies, 10–25 mg of the dibromide were generally used, and a total of ca. 0.5 mL of CD_2Cl_2 was used as solvent. The reactions were conducted in the 5 mm NMR tube by adding the requisite amount of the dry chromium salt. The tube was then cooled and kept at −78°C while purging with nitrogen. About 0.4 mL of solvent was added to dissolve the salt. The dibromide in ca. 0.1 mL of solvent was then added by syringe to the top of the salt solution and the tube stoppered and mixed at −78°C by shaking. NMR peaks were referenced relative to $CDHCl_2$ = 5.32 and $^{13}CD_2Cl_2$ = 53.8.

2,2,3,3-Tetramethylcyclopropanone ***1***. IR: 1839, 1820 cm^{-1}. The ^{1}H NMR spectrum of a typical preparation is shown in Fig. 1. ^{1}H NMR: 1.17 (s, 12 H), reported (1) 1.19. ^{13}C NMR: 229.8 (C=O); 24.4 (Cq × 2); 16.6 (CH_3 × 4).

2,2,3-Trimethylcyclopropanone ***2***. IR: 1850, 1813 cm^{-1}. ^{1}H NMR: 1.91 (qt, J = 7.5, 1 H); 1.31 (s, 3 H); 1.08 (d, J = 7.5, 3 H); 1.06 (s, 3H). This data is at some variance with that reported (1). 1.4–1.1 (m, 1 H); 1.36 (s, 3H); 1.22 (d, J = 5); 1.12 (s, 3 H). ^{13}C NMR: 226.7 (C=O); 25.1 (CH); 23.2 (Cq); 21.8, 13.9, 7.8 (all CH_3).

cis-*1,6-Dimethylbicyclo[4.1.0]heptan-7-one* ***4***. ^{1}H NMR: 1.76 (m, 2 H); 1.35–1.55 (m, 4 H); 1.15–1.22 (m, 4 H); 1.14 (s, 6 H). ^{13}C NMR: 232.1 (C=O); 27.6 (CH_2 × 2); 23.9 (Cq); 21.7 (CH_2 × 2); 16.1 (CH_3 × 2).

cis-*1,7-Dimethylbicyclo[5.1.0]octan-8-one* ***5***. ^{1}H NMR: 1.7–1.8 (m, 5 H); 1.47–1.55 (m, 5 H); 1.18 (s, 6 H). ^{13}C NMR: 228.2 (C=O); 33.6 (CH_2); 31.1 (b, CH_2 × 2); 28.7 (Cq); 26.7 (CH_2 × 2); 14.8 (CH_3 × 2). The peak at 31.1 is quite broad, a likely indication of some slow conformational interchange process.

2,2-Dimethylspiro[2.4]heptan-1-one ***6***. ^{1}H NMR: 1.45–1.7 (m, 6 H); 1.75–1.95 (m, 2 H); 1.13 (s, 6 H). ^{13}C NMR: 230.4 (C=O); 33.8 (Cq); 28.8 (CH_2 × 2); 27.2 (CH_2 × 2); 22.7 (Cq); 16.4 (CH_3 × 2).

2,2-Dimethylspiro[2.5]octan-1-one ***7***. IR: 1823 cm^{-1}. ^{1}H NMR: 1.3–1.7 (m, 10 H); 1.21 (s, 6 H). ^{13}C NMR: 228.2 (C=O); 31.3 (Cq); 27.4 (CH_2 × 2); 25.9 (Cq); 25.6 (CH_2 × 2); 25.2 (CH_2); 16.3 (CH_3 × 2). Changes in the profile of the broad ^{1}H cyclohexyl proton peaks with temperature may indicate a mixture of two chair conformational isomers.

Dispiro[5.0.5.1]tridecan-13-one ***9***. IR: 1829, 1813 cm^{-1}. ^{1}H NMR: 1.66 (bs, ca. 10 H); 1.56 (m, ca. 4 H); 1.37 (bs, ca. 6 H). ^{13}C NMR: 227.1 (C=O); 32.6 (Cq × 2); 26.7 (CH_2 × 4); 25.5 (CH_2 × 2); 25.2 (CH_2 × 4).

2,2-Dimethyl-3,3-dimethyl-d_6*-cyclopropanone* ***18***. ^{1}H NMR: 1.15 (s, 6 H). ^{13}C NMR: 229.5 (C=O); 24.18 (Cq, next to CH_3); 23.96 (Cq, next to CD_3); 16.5 (CH_3 × 2); 15.8 (heptet, J = 19, CD_3 × 2).

2,2,3,3-Tetramethyl-d_{12}*-cyclopropanone* ***19***. ^{2}H NMR: 1.13 (s, 12 ^{2}H). ^{13}C NMR: 229.6 (C=O); 23.6 (Cq × 2); 15.5 (heptet, J = 20, CD_3 × 4).

Furan and cyclopentadiene trapping reactions

From cyclopropanone ***9***

A standard procedure was used to prepare the cyclopropanone **9** at −78°C (0.34 mmol of the $Cr(CO)_4NO^-$ and 0.28 mmol of the dibromide). The reaction mixture was then diluted with 7:1 pentane:furan at −78°C, followed by the addition of 0.020 g anhydrous $AlCl_3$. The mixture was vigorously stirred for 15 min at −78°C. Warming and work-up (flash chromatography, CH_2Cl_2) of the reaction led to 0.0312 (43%) of the pure crystalline adduct, *2,2,4,4-bis(pentamethylene)-8-oxabicyclo[3.2.1]hept-6-en-3-one*, mp 78–79°C. ^{1}H NMR: 6.355 (2 H); 4.907 (2 H); 2.10 (2 H); 1.0–1.9 (m, 19 H). ^{13}C NMR: 217.09 (q); 133.45 (CH × 2); 81.39 (CH × 2); 55.3 (q × 2); 33.72 (CH_2 × 2); 29.62 (CH_2 × 2); 25.69 (CH_2 × 2); 21.46 (CH_2 × 2); 21.26 (CH_2 × 2). Anal. calcd. for $C_{17}H_{24}O$: C 78.42, H 9.29; found: C, 78.02, H 9.23.

From cyclopropanones ***1*** *and* ***2***

Using an identical procedure to that described for **9**, the known furan adducts of **1** and **2** were prepared (1).

From presumed cyclopropanone ***8***

The reactions were carried out in the standard way except that a four-fold excess of either cyclopentadiene or furan was mixed with the CH_2Cl_2 solvent used to dissolve the chromium salt. The cyclopentadiene adduct has been reported (19). The furan adduct, *2,2,4,4-bis(tetramethylene)-8-oxabicyclo[3.2.1]hept-6-en-3-one*, was separated by preparative TLC using CH_2Cl_2 as eluant. ^{1}H NMR (400 MHz): 6.321 (2 H); 4.480 (2 H); 2.563 (m, 2 H); 2.18 (m, 2 H); 2.08 (m, 2 H); 1.5–1.85 (m, 8 H); 1.07 (m, 2 H). ^{13}C NMR (100 MHz): 216.1 (q); 133.9 (CH × 2); 84.9 (CH × 2); 61.0 (q × 2); 38.2 (CH_2 × 2); 31.2 (CH_2 × 2); 26.2 (CH_2 × 2); 25.8 (CH_2 × 2). MS, *m/z*: 232 (M^+), 164, 136 (100), 135, 107, 96. Exact Mass calcd. for $C_{15}H_{20}O_2$: 232.1463; found: 232.1462.

Formation of enols from ***1*** *and* ***2***

The cyclopropanones were prepared in 5 mm NMR tubes and the ^{1}H NMR spectra were carefully monitored while gradually warming the solutions. In the case of **1**, peaks assigned to the enol began slowly building up at about 240 K. On reaching ambient temperature, these peaks had disappeared. In addition to the peaks reported in the text, there are CH_3 peaks at 1.86 (bs), 1.64 (bs), and 1.62 (s), which are assigned to the enol (7). In the case of **2**, enol peaks started appearing at 220 K, and in addition to the peaks reported in the text, there is a CH_3 peak at 1.81 (s), which can be assigned to the enol.

α,β-Unsaturated ketones

The ketones from **1** and **2**, 2,4-dimethylpent-1-en-3-one, **10**, and 2-methylpent-1-en-3-one, **14**, respectively, were characterized by ^{1}H NMR comparison to the known compounds. The ketone from **4**, *2-methylene-7-methylcycloheptanone*, **11**, was isolated by preparative GC (oil). ^{1}H NMR (200 MHz): 5.99 (m, 1 H); 5.26 (m, 1 H); 2.9–1.2 (m, 9 H); 1.10 (d, J = 6.5, 3 H). ^{13}C NMR (100 MHz): 204.8 (Cq); 148.3 (Cq); 122.3 (CH_2); 45.2 (CH); 34.5 (CH_2); 33.4 (CH_2), 30.6 (CH_2), 30.1 (CH_2), 17.2 (CH_3). MS *m/z*: 138, 110, 95 (100), 82, 81, 68, 67. Exact Mass calcd. for $C_9H_{14}O$: 138.1044; found: 138.1044. The ketone from **5**, *2-methylene-8-methylcyclooctanone*, was also isolated by preparative GC (oil). ^{1}H NMR (200 MHz): 5.78 (m, 1 H); 5.20 (bs, 1 H); 2.80–3.00 (m, 1 H); 2.75–2.40 (m, 2 H); 1.9–1.2 (m, 8 H); 1.08 (d, J = 6.5, 3 H). ^{13}C NMR (100 MHz): 209.8 (Cq); 149.6 (Cq); 121.1 (CH_2); 41.1 (CH); 37.7 (CH_2); 31.8 (CH_2); 30.9 (CH_2); 25.7 (CH_2); 25.5

For personal use only.

(CH_2); 17.3 (CH_3). MS, *m/z*: 152, 124, 109, 96, 95, 82, 81, 67 (100). Exact Mass calcd. for $C_{10}H_{16}O$: 152.1201; found: 152.1195. The known ketone from **9**, cyclohexyl 1-cyclohexenyl ketone, was isolated in 96% yield (flash chromatography, CH_2Cl_2) as an oil. ^1H NMR (400 MHz): 6.88 (quintet, $J \sim 2$, 1 H); 2.96 (t, t, $J = 11.2$, 3.3, 1 H); 2.24 (m, 4 H); 1.55–1.9 (m, 9 H); 1.1–1.5 (m, 5 H). Reported (20): 6.83 (1 H). ^{13}C NMR (100 MHz): 205.01 (q); 138.75 (CH); 138.12 (q); 44.15 (CH); 29.73 ($CH_2 \times 2$); 26.06 (CH_2); 25.92 ($CH_2 \times 2$); 23.35 (CH_2); 22.04 (CH_2); 21.61 (CH_2). MS, *m/z*: 222 (M^+), 192 (66), 163 (38), 109 (100). Reported (20): 192 (21), 163 (3), 109 (100). From **7**, a mixture of isopropyl 1-cyclohexenyl ketone (21), **12**, and cyclohexyl isopropenyl ketone (22), **13**, (ca. 2:1) was produced in good yield. ^1H NMR for **12** (400 MHz, CD_2Cl_2): 0.99 (d, $J = 6.5$); 2.09 (bs); 2.21 (bs); 3.28 (heptet, $J = 6.5$); 6.93 (bs); the remaining peaks are overlapped with **13**. GC–MS, *m/z*: 152 (M^+), 109 (100), 99, 81, 79. For **13**, ^1H NMR (400 MHz, CD_2Cl_2): 1.78 (s); 3.02 (poorly resolved multiplet); 5.80 and 5.97 (both bs); the remaining peaks are overlapped with **12**. GC–MS, *m/z*: 152 (M^+), 110, 83, 69 (100), 55, 41. From **6**, the two monomeric ketones were produced in poor yield and from the GC–MS, most of the material is a dimer. For the known isopropyl 1-cyclopentenyl ketone (21), ^1H NMR (400 MHz, CD_2Cl_2): 5.82 and 5.97 (both bs). GC–MS, *m/z*: 138 (M^+), 95 (100), 67. For the known (22) cyclopentyl isopropenyl ketone, ^1H NMR (400 MHz, CD_2Cl_2): 6.77 (bs). GC–MS, *m/z*: 138 (M^+), 97, 69 (100).

Preparation of the deuterated derivatives

Acetone-d_6 (≥99.8% *d*) was converted to 2,4-dimethylpentan-3-ol-d_6 or -d_{12} by way of the isopropyl alcohol, bromide, Grignard reagent, and reaction of the latter with either 2-methylpropanal or ethyl formate. The alcohol was oxidized to the ketone using Jones reagent, care being taken during the ketone isolation (fractional distillation of the excess solvent) because of the volatility of the ketone. The ketone was brominated using the same procedure as for the h_{12} compound. Based on the mass and ^1H NMR spectra at intermediate stages in the synthesis, there was no loss of deuterium content over the course of the overall synthesis.

*Rearrangements of deuterated cyclopropanones **18** and **19***

From **18**, the α,β-unsaturated ketone (a mixture of isotopomers **20** and **21**) was obtained by preparative GC. ^1H NMR (400 MHz): 5.95 (relative area 1.0); 5.78 (area 0.97); 3.28 (bs) and 3.32 (center of a heptet) with combined area 1.11; 1.88 (area 3.0); 1.12 (d, $J = 6.5$, area 2.1). ^2H NMR (61.42 MHz): 5.92 and 5.76 (both bs, relative areas both ca. 0.3); 1.81 (bs, relative area 1.0); 1.07 (bs, relative area 7.7). The lack of a methine deuterium (^2H NMR) and the absence of a "singlet" at ca. 1.1 (^1H NMR) rule out the presence of significant amounts (<10%) of the two other possible isotopomers. The peaks at 3.28 and 3.32 in the ^1H NMR spectrum are a direct measure of the ratio **20/21** and a careful integration of these gave a 4:1 ratio for **20/21**. Obviously, in a quantitative reaction, one should get isotopomer mixtures in which the protium and deuterium content will be equal when averaged over all isotopomers. However, for our actual case, it appears that the enol in which a deuterium has migrated is more likely to undergo one of the side reactions.

For reactions involving the perdeutero species **19**, a 1:1 mixture of **19** and **1** was used for a competitive rearrangement rate study, employing the ^{13}C quaternary NMR signals, 23.6 vs. 24.4, for monitoring purposes. Disappointingly, both peaks decreased at about the same rate. However, in the ^2H NMR spectrum of the final crude reaction mixture, there were no detectable ^2H peaks characteristic of the rearranged perdeutero ketone, whereas the ^1H NMR spectrum showed rearranged ketone **10** in >50% yield.

*Trimethylchlorosilane (TMS-Cl) trapping reactions involving enolates from rearrangement of presumed cyclopropanones **3** and **8***

These were conducted at −78°C by including 50% molar excess of TMS-Cl in the methylene chloride solvent (there is no reaction between the chromium salt and TMS-Cl at −78°C) used to dissolve the $Cr(CO)_4NO^-$ salt. The dibromo ketone solution was added until the deep red color of the salt had disappeared (a precipitate is present), which generally meant that only slightly more than one half of the dibromo ketone solution (calculated on a 1:1 molar basis) was actually added. Silyl enol ether **23**, *1-trimethylsilyloxy-2-methyl-6-methylene-1-cyclohexene*, was obtained as an oil from **3**, after the usual work-up followed by a rapid preparative TLC using 1:1 hexane–CH_2Cl_2 as eluant. ^1H NMR (400 MHz): 4.992 and 4.668 (1 H each, exomethylene protons); ca. 2.38 (m, 2 H); ca. 2.14 (m, 2 H); ca. 1.66 (m, 2 H); 1.542 (s, 3 H); 0.078 (s, 9 H). Exact Mass calcd. for $C_{11}H_{20}OSi$: 196.1283; found: 196.1291. Interestingly, the hydrolysis product is the endocyclic ketone. In the case of **8**, the crude silyl enol ether **24**, *1-[1'-cyclopentene]-1-trimethylsiloxy-2,2-tetramethyleneethene*, was not purified, but could be characterized from the ^1H and ^{13}C NMR spectra and the Exact Mass. ^1H NMR (200 MHz): 5.71 (s, 1 H); 1.3–2.7 (m, ca. 14 H); 0.17 (s, 9 H). ^{13}C NMR (50 MHz): 141.6 (Cq); 139.6 (Cq); 127.7 (CH); 126.0 (Cq); 34.1, 32.2, 31.1, 30.2, 27.5, 26.0, 23.7 (all CH_2); 0.61 ($CH_3 \times 3$). MS, *m/z*: 236 (70, M^+), 208 (82), 180 (72), 167 (50), 75 (72), 73 (100). Exact Mass calcd. for $C_{14}H_{24}OSi$ (from GC–MS): 236.1597; found: 236.1586.

*Dimer **25***

The yield of this dimer, *3-methylene-1,1',3'-trimethyldicyclohexan-2,2'-dione*, was optimized by the very rapid addition of the dimbromo ketone to the chromium salt solution (ca. 60% yield). The crude material contains a ca. of 10:1 mixture of two diastereomers of **25**. On silica gel/CH_2Cl_2 flash chromatography, there is some resolution of this pair, the major isomer being obtained from the first fractions in ca. 95% purity (^1H NMR) as an oil that solidifies. ^1H NMR (400 MHz): 5.124 (t, d, $J = 2.3$, 0.9, 1 H); 5.773 (t, $J = 2.3$, 1 H); 2.9–3.1 (1); 2.5–2.9 (3 H); 1.4–2.15 (9 H); 1.174 (d, $J = 0.75$, 3 H); 1.011 (d, $J = 0.72$, 3 H); 0.964 (d, $J = 6.4$, 3 H). ^{13}C NMR (100 MHz): 216.3 (q); 207.0 (q); 145.9 (q); 120 (CH_2); 49.8 (q); 41.6 (CH); 36.9, 35.5, 35.4, 32.6, 22.0, 21.6 (all CH_2); 18.9, 18.5, 14.9 (all CH_3). One quaternary carbon is unassigned. MS (for **25**), *m/z*: 248 (M^+), 151, 126, 124 (100). Exact Mass calcd. for $C_{16}H_{24}O_2$: 248.1776; found: 248.1782. The minor disastereomer (400 MHz) shows peaks at 5.65 and 5.09 for the exomethylene protons; 1.14 (3 H); 1.12 (3 H); 1.055 (d, $J = 7$, 3 H). The detailed NMR splittings observed for this minor isomer (i.e., like the major isomer, both quaternary methyls are finely resolved doublets with $J \sim 0.7$ Hz) clearly identify this material as a diastereomer of the **25** structure.

*Dimer **26***

The yield of this dimer was maximized with slow addition of the dibromo ketone to the chromium salt. After work-up and flash chromatography (CH_2Cl_2), an 86% yield of a pale yellow oil was obtained (0.55 mmol scale). IR: 1694, 1648 cm^{-1} (both strong). ^1H NMR (400 MHz): 6.243 (quintet, $J = 2.2$, 1 H); 3.050 (quintet, $J = 7.8$, 1 H); 2.616 (m, 2 H); 2.519 (m, 2 H); 2.346 (m, 2 H); 2.18 (m, 2 H); 1.838 (quintet, $J = 7.8$, 4 H); 1.5–1.9 (m, 18 H). ^{13}C NMR: 218.7 (q); 206.5 (q); 144.5 (q); 136.6 (CH); 67.2 (q); 66.0 (q); 47.4 (CH); 35.2 (CH_2); 34.2 (CH_2); 33.8 ($CH_2 \times 2$); 33.2 ($CH_2 \times 2$); 32.6 ($CH_2 \times 2$); 26.7 ($CH_2 \times 2$); 26.0 ($CH_2 \times 2$); 25.7 ($CH_2 \times 2$); 22.3 (CH_2). MS, *m/z*: 328 (M^+), 232 (21), 191 (19), 136 (27), 135 (24), 97 (83), 95 (100). The spectroscopic data establish that two carbonyls are present, one α,β-unsaturated. The molecule has twofold symmetry involving 12 methylene carbons (six sets of two). This data establishes the structure as *4-cyclopentyl-1-(1-cyclopentene)-2,2,3,3-bis-tetramethylenediylbutane-1,4-dione*, **26**. Exact Mass calcd. for $C_{22}H_{32}O_2$: 328.24023; found: 328.2386. COSY and HETCOR 2D-spectra allowed a partial assignment of the ^1H and ^{13}C NMR spectra, for example, the cyclopentene and outer cyclopentane rings can be verified by the connectivity of the carbon skeleton.

Golgi membrane *endo*-α-D-mannosidase releases the disaccharide αDGlc(1→3)DMan (**34**) from the $GlcMan_9GlcNAc_2$ oligosaccharide of immature *N*-linked glycoproteins. To convert the hydrolysis product **34** into a potent inhibitor of the enzyme, chemical modifications at the 1- and 2-positions of the mannose unit of **34** were performed. These include replacement of OH-1 by hydrogen (**6**), fluorine (**12**), and *p*-nitrophenoxy (**5**). Two potent inhibitors resulted, as reported recently, when both OH-1 and OH-2 of **34** were replaced by a double bond (glucal derivative **8**) or replaced by hydrogen (1,2-dideoxy **9**). **9** proved 40 times stronger as an inhibitor than 1-deoxy **6**. However, further modifications at the 4- and 6-positions of **9**, namely deoxygenation, methylation, and replacement of OH-6 by an amino group, were now found to largely abolish the activity, demonstrating that OH-4 and OH-6 of **9** are involved in H-bonding with the enzyme.

ULRIKE SPOHR, MIMI BACH et ROBERT G. SPIRO. Can. J. Chem. **71**, 1919 (1993).

Sous l'influence de l'*endo*-α-D-mannosidase de la membrane de Golgi, l'oligosaccharide $GlcMan_9GlcNAc_2$ de glycoprotéines immatures liées par l'azote fournit le disaccharide αDGlc(1→3)DMan (**34**). Dans le but de transformer le produit d'hydrolyse **34** en un inhibiteur puissant de l'enzyme, on a effectué des modifications chimiques aux positions 1 et 2 de l'unité mannose du composé **34**. Celles-ci comprennent le remplacement du OH-1 par un hydrogène (**6**), un fluor (**12**) ou un groupe *p*-nitrophénoxy (**5**). Tels que rapportés récemment, deux inhibiteurs puissants sont obtenus lorsque les groupes hydroxyles en positions 1 *et* 2 du composé **34** sont tous les deux remplacés par une double liaison (dérivé glucal **8**) ou par des hydrogènes (dérivé 1,2-didésoxy, **9**). Le composé **9** s'avère 40 fois plus puissant comme inhibiteur que le dérivé 1-désoxy, **6**. Toutefois, on a maintenant trouvé que d'autres modifications dans les positions 4 et 6 du composé **9**, soit la désoxygénation, la méthylation et le remplacement du OH-6 par un groupe aminé, ont pour effet d'éliminer l'activité; ces résultats démontrent que les groupes OH-4 et OH-6 du composé **9** sont impliqués dans la liaison hydrogène avec l'enzyme.

[Traduit par la rédaction]

Introduction

During the biosynthesis of asparagine-linked glycoproteins, an oligosaccharide of the type $Glc_3Man_9GlcNAc_2$ is assembled on dolichyl pyrophosphate and transferred *en bloc* to the asparagine residues of the polypeptide chains (1–4) (Fig. 1). The immature protein-bound oligosaccharide is then subjected to a sequence of trimming reactions involving various glycohydrolases before transformation into complex type or high-mannose type side chains. The trimming sequence is initiated in the rough endoplasmic reticulum by the stepwise removal of the glucose units, catalyzed by at least two glucosidases, namely I and II, and leading to *N*-linked $Man_9GlcNAc_2$, which is further processed by the action of mannosidase I and, after GlcNAc transfer, by that of mannosidase II.

Recently, Lubas and Spiro (5, 6) discovered a novel glycoprotein-processing glycosidase present in the Golgi membranes from rat liver. The natural substrate of this *endo*-α-D-mannosidase was found to be incompletely deglucosylated $GlcMan_9GlcNAc_2$, which it converts into $Man_8GlcNAc_2$ with the release of αDGlc(1→3)DMan (Fig. 1). It was shown that the *endo*-mannosidase provides an alternative pathway during the blockage of trimming glucosidases by inhibitors (7, 8) and also in the glycoprotein processing by glucosidase II deficient mutant cells (9, 10). That glucosidase absence or inhibition leads only to a partial blockage of complex oligosaccharide synthesis has been observed in several instances (11, see also refs. 3–10 of ref. 10). This has been accounted for by the deglucosylation effected by *endo*-mannosidase, although the then prevailing di- and triglucosylated species $Glc_3Man_9GlcNAc_2$ and $Glc_2Man_9GlcNAc_2$ constitute weaker substrates than $GlcMan_9GlcNAc_2$ (6). It was therefore desirable to develop potent inhibitors of *endo*-mannosidase to achieve a more complete blockage of oligosaccharide formation and an extensive chemical and biological study was undertaken. The biological results of this investigation were recently disclosed (12).

We now wish to report on the syntheses of a series of these inhibitors derived from the hydrolytic product of the enzyme, namely αDGlc(1→3)DMan (**34**), by modification of substituents of the mannose unit, while two accompanying papers describe the syntheses and properties of disaccharidic congeners of 1-deoxymannojirimycin (13, 14).

Some of the biological data reported recently (12) are summarized in Table 1. The most potent inhibitor resulted when the mannose unit of **34** was replaced by 1-deoxymannojirimycin (1,5-dideoxy-1,5-imino-D-mannitol) to produce **35** (13), which was found to inhibit the cleavage of

[a]% Potency relative to **35**.

$GlcMan_9GlcNAc$ at IC_{50} = 1.7 μmol in vitro. In accordance with previous observations with 1,5-dideoxy-1,5-iminoalditols (15), **35** proved to be 90 times stronger as an inhibitor than its 5-oxygen analogue **6** (Table 1), which is derived from αDGlc(1→3)DMan (**34**) by deoxygenation at the 1-position. An inhibitor almost equally as strong as **35** was obtained when the OH-1 and OH-2 groups of **34** were replaced by a double bond to give the glucal derivative **8**. Glycals have been found in several cases (16) to serve as *pseudo*-substrates of some glycosidases to form, under hydroxylation, a 2-deoxyhexose derivative. Remarkably, also the saturation product of glucal **8**, namely **9**, resulting from deoxygenation at the 2-position of anhydromannitol **6**, proved a very potent inhibitor. In contrast, deoxygenation at the 2-position of aza analogue **35** to give 1,2-dideoxy **36** (13) essentially abolished activity. Apparently, the interaction of NH-5 of **35** with the protein induces a different conformational change in the catalytic region of the protein than when O-5 is at its place. Further modifications of the anhydrohexitol unit of 1,2-dideoxy **9** are also reported in this communication.

Discussion

With the aim to convert the product of the hydrolytic action of *endo*-α-D-mannosidase, namely αDGlc(1→3)DMan (**34**), into a potent inhibitor for the enzyme, structural modifications at the 1- and 2-positions of the mannose unit of **34** were performed.

The nitrophenyl aglycon was introduced by melting octaacetate **1**[3] with *p*-nitrophenol and zinc chloride (17) (Scheme 1) to produce **3** in 38% yield. The α-configuration of the new linkage was confirmed by the coupling constant $J_{C1,H1}$ 175.8 Hz for C-1 in the C–H coupled ^{13}C NMR spectrum (18). Zemplen deacetylation of **3** then provided **5** in 95% yield; **5** proved an even weaker inhibitor than **27** (12).

Deoxygenation at the 1-position of **27** was achieved by reductive debromination of bromide **2**[3] with tributyltin hydride to give crystalline **4** in 65% yield. Zemplen deacetylation of **4** led to **6** in quantitative yield. The ^1H and ^{13}C NMR data are presented in Tables 2 and 3 and are in agreement with the structural assignments.

To prepare the mannosyl fluoride **12**, the blocked disaccharide **10**[3] was treated with diethylaminosulfur trifluoride in dichloromethane at −30°C (19) to give the α-fluoride **11** in 83% yield. The α-configuration followed from the coupling constants $J_{C1,H1}$ 185.0 Hz, $J_{C1,F}$ 225.1, and $J_{H1,F}$ 49.0 Hz in the ^{13}C and ^1H NMR spectra. Catalytic hydrogenation over 5% palladium-on-carbon provided **12** in 91% yield. **12** was found 3 times as strong an inhibitor as 1-deoxy **6** (12).

Since glycals proved to be potent inhibitors of some glycosidases (16), 3-*O*-(α-D-glucopyranosyl)-D-glucal (**8**) was prepared by the action of zinc and acetic acid on bromide **2** to provide hexaacetate **7** in 65% yield followed by Zemplen deacetylation (96% yield). Glucal **8** was then saturated to the 1,2-dideoxy derivative **9** by catalytic hydrogenation.

When the strong inhibitory properties of the 1,2-dideoxy disaccharide **9** became known (12), further modifications at the 4- and 6-positions of the hexitol unit of **9** were undertaken (Scheme 2). As a common intermediate, the disaccharide **16** was prepared: 1,5-Anhydrohexitol **13** (20) was converted into the *p*-methoxybenzylidene acetal **14** in 83% yield; **14** was glucosylated with bromide **15** (21) under halide ion catalyzed conditions (21) to afford **16** in 56% yield. **16** was also deblocked to **9** (Scheme 1) by catalytic hydro-

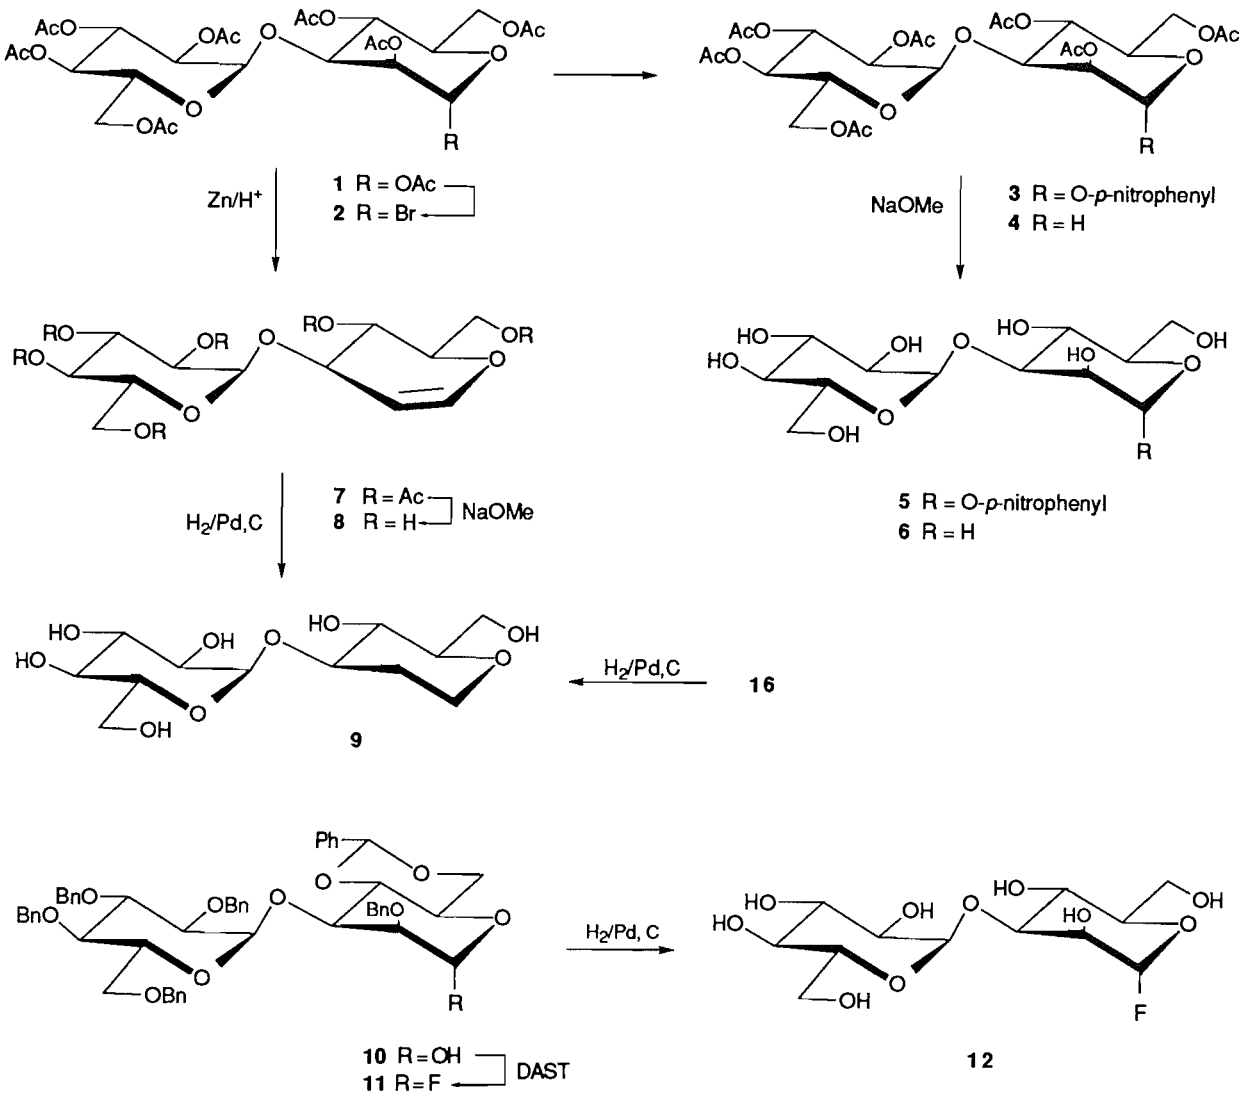

SCHEME 1

genolysis. Reductive cleavage of the *p*-methoxybenzylidene ring of **16** (Scheme 2) was performed with sodium cyanoborohydride and trimethylsilyl chloride as electrophile (22) and provided the 6-hydroxy compound **17** in 74% yield as well as the 4-hydroxy isomer **27** in 8.8% yield.

17 was methylated to **19** (83% yield) using methyl iodide and sodium hydride. Mesylation of **17** with methanesulfonyl chloride led to mesylate **18** (91% yield), which showed the characteristic downfield shifts of H-6A and H-6B in the ^{1}H NMR spectrum. The mesyloxy group in **18** was substituted by iodide to form **20** (65% yield), which was reduced with tributyltin hydride to give **21** (54% yield). Partial loss of the *p*-methoxybenzyl group occurred during the reduction and the 6-deoxy-4-hydroxy derivative **22** was also isolated in 30% yield. The mesyloxy group of **18** was easily replaced by azide to provide **23** in quantitative yield. Catalytic hydrogenation over 5% palladium-on-carbon of the 6-*O*-methyl, 6-deoxy, and 6-azido-6-deoxy derivatives **19**, **21**, and **23** led to the deblocked disaccharides **24**, **25**, and **26**. The 6-amino-6-deoxy compound **26** was obtained only 90% homogeneous.

To liberate the 4-position of intermediate **16**, the reductive cleavage of the *p*-methoxybenzylidene ring was undertaken using sodium cyanoborohydride in the presence of trifluoroacetic acid (22). The desired 4-hydroxy compound **27** was isolated in 54% yield, as well as 15% of the regio isomer **17**. Proof for the structural assignment of **27** was obtained from the ^{1}H NMR spectrum of the acetate **28** in which the downfield shift of H-4 could be observed. **27** was then methylated in the usual way to **29** (87% yield). For deoxygenation of the 4-position of **27** the Barton–McCombie procedure (23) was applied and the intermediate methyl xanthate (**30**) was reduced to 4-deoxy **31** (73% yield from **27**). Catalytic hydrogenolysis then provided 4-*O*-methyl **32** and 4-deoxy **33** in high yields.

The ^{1}H and ^{13}C NMR data are reported in Tables 2 and 3 and fully support the various structural assignments. Conformational preferences about the interglycosidic torsion angles ϕ/ψ of 1-deoxy **6** and 1,2-dideoxy **9** were determined at near $-50°/-10°$ (13) by HSEA calculations (24). Observed and theoretical nuclear Overhauser enhancements calculated for the low-energy conformer of **9** at $\phi/\psi = -45°/-15°$ are reported in Table 4. Nonbonded interactions between H-1′ and H-3, as well as H-2e and H-5′, were found

[a]0.05 M solutions in D_2O with dioxane as internal reference at 67.4 ppm were measured at 75 MHz and 295 K. The assignments were made by inspection and are tentative.
[b,c]The corresponding assignments of the chemical shifts are tentative and may be reversed.
[d]$J_{C1,F}$ 221.4 Hz, $J_{C1,H1}$ 183.6 Hz.
[e]$J_{C2,F}$ 37.0 Hz.
[f]CH_3O 60.82 ppm.
[g]CH_3O 59.34 ppm.

to be similar to those determined for inhibitor 1-deoxy-3-*O*-(α-D-glucopyranosyl)-mannojirimycin (**35**) (13), suggesting that both inhibitors show similar conformational preferences.

Both monodeoxygenation (**33**, **25**) and mono-*O*-methylation (**32**, **24**) at the 4- and 6-positions of **9** essentially abolished the activities (Fig. 2), indicating that these hydroxyl groups are involved in polar interactions with the enzyme,

as was found for the complexation of the NH-5 analogue **35** (12, 14). In the case of the OH-6 group, its polar interaction cannot be substituted by that of an amino group, since 6-amino congener **26** was also found inactive. Similar observations were made in combining site studies with the lectin IV of *Griffonia simplicifolia* when essential hydroxyl groups of the Lewis b tetrasaccharide could not be substituted for by amino groups (25).

Experimental

General methods

The ^{1}H NMR spectra were measured at 300 MHz and 360 MHz (Bruker AM 300 and WM 360) with tetramethylsilane as internal

standard for $CDCl_3$ solutions. Reference standard for D_2O solutions was acetone (2.225 ppm). The ^{13}C NMR spectra were recorded at 75 MHz with dioxane (67.4 ppm) as reference for D_2O solutions and the $CDCl_3$ signal (77.0 ppm) as reference in $CDCl_3$ solutions. Optical rotations were measured at room temperature (23 ± 1°C) in a 1-dm cell on a Perkin–Elmer 241 polarimeter. Thin-layer chromatography (TLC) was performed on precoated plates of silica gel (60-F254, E. Merck, Darmstadt) and visualized by spraying with 5% sulfuric acid in ethanol followed by heating. For column chromatography silica gel 60 (230–400 mesh, E. Merck, Darmstadt) and distilled solvents were used. Solvents and reagents were purified and dried according to standard procedures. Melting points are uncorrected.

p-*Nitrophenyl 2,4,6-tri*-O-*acetyl-3*-O-*(2,3,4,6-tetra*-O-*acetyl-α-*D*-glucopyranosyl)-α-*D*-mannopyranoside (3)*

A mixture of octaacetate **1** (161.0 mg, 0.24 mmol),[3] *p*-nitrophenol (92.6 mg, 0.67 mmol), and zinc chloride (4 mg) was heated with magnetic stirring in an oil bath at 160°C for 35 min. The melt was allowed to reach room temperature and was dissolved in dichloromethane. A TLC check indicated that ~40% of the starting material was still left. The solution was washed with aqueous 1 N sodium hydroxide until colorless and then with water until neutral, followed by drying and evaporation. The resultant material was chromatographed on a column of silica gel (hexane–dichloromethane – ethyl acetate, 3:2:2) to provide **3** (67.4 mg, 38%) as an amorphous solid; $[\alpha]_D$ +1.3 (*c* 0.5, chloroform). ^1H NMR ($CDCl_3$) δ: 8.22 and 7.2 (2d, each 2H, Ph), 5.64 (d, 1H, $J_{1,2}$ 1.5 Hz, H-1), 5.45 (dd, $J_{2,3}$ 3.5 Hz, H-2), 5.39 (t, 1H, $J_{3,4} \sim J_{4,5}$ 9.5 Hz, H-4), 5.38 (t, 1H, $J_{2',3'} \sim J_{3',4'}$ 10.0 Hz, H-3′), 5.34 (d, 1H, $J_{1',2'}$ 4.0 Hz, H-1′), 5.05 (t, 1H, $J_{4',5'}$ 10.0 Hz, H-4′), 4.79 (dd, 1H, H-2′), 4.41 (dd, 1H, H-3), 4.28 (dd, 1H, $J_{6A',6B'}$ 12.5 Hz, $J_{6A',5'}$ 4.5 Hz, H-6A′), 4.22–3.97 (m, 4H, H-6A, H-6B, H-6B′, H-5′), 3.86 (ddd, 1H, $J_{5,6A}$ 2.5 Hz, $J_{5,6B}$ 5.5 Hz, H-5), 2.30, 2.09, 2.01, 2.00 (4s, each 3H, $4CH_3CO$), 2.06 (s, 9H, $3CH_3CO$); ^{13}C NMR ($CDCl_3$) δ: 170.50, 170.41, 170.31, 169.70, 169.59 (CH_3CO), 159.91, 143.19, 125.82, 123.01 (aromatic C), 96.69, 95.58 (C-1, C-1′, $J_{C,H}$ 175.77 Hz, 174.94 Hz), 72.20 (C-3), 70.76 (C-2′), 69.96, 69.79, 69.06 (C-2, C-3′, C-5), 68.33, 68.08 (C-4′, C-4), 67.60 (C-5′), 61.88 (C-6, C-6′), 20.73, 20.56 (CH_3CO). Anal. calcd. for $C_{32}H_{39}NO_{20}$: C 50.73, H 5.19, N 1.85; found: C 50.70, H 5.30, N 1.95.

2,4,6-Tri-O-*acetyl-1,5-anhydro-3*-O-*(2,3,4,6-tetra*-O-*acetyl-α-*D*-glucopyranosyl)-*D*-mannitol (4)*

Bromide **2** (135.1 mg, 0.19 mmol),[3] tributyltin hydride (231 μL, 0.86 mmol), and 2,2′-azobis(isobutyronitrile) (7.85 mg) in toluene (5.7 mL) were heated for 1 h at 80°C. The solvent was evaporated and the resultant material was applied to a column of silica gel (hexane – ethyl acetate, 1:1) to give **4** (75.4 mg, 65%) as a solid; mp 156–157°C (ethanol); $[\alpha]_D$ +40.8 (*c* 0.5, chloroform). ^1H NMR ($CDCl_3$) δ: 5.36 (t, 1H, $J_{3',4'} \sim J_{3',2'}$ 10.0 Hz, H-3′), 5.28 (t, overlapped, H-4), 5.27 (overlapped, H-2), 5.26 (d, 1H, $J_{1',2'}$ 4.0 Hz, H-1′), 5.04 (t, 1H, $J_{4',5'}$ 10.0 Hz, H-4′), 4.76 (dd, 1H, H-2′), 4.30–4.02 (m, 6H, H-6A′, H-6B′, H-5′, H-6A, H-6B, and H-1A at 4.09, $J_{1,2}$ 1.5 Hz), 3.95 (dd, 1H, $J_{2,3}$ 3.5 Hz, $J_{3,4}$ 9.5 Hz, H-3), 3.61 (bd, $J_{1A,1B}$ 13.0 Hz, H-1B), 3.47 (ddd, 1H, $J_{5,6A}$ 5.5 Hz, $J_{5,6B}$ 2.5 Hz, H-5), 2.25, 2.10, 2.09, 2.0 (4s, each 3H, $4CH_3CO$), 2.08 (s, 9H, $3CH_3CO$). ^{13}C NMR ($CDCl_3$) δ: 170.78, 170.72, 170.59, 170.50, 169.77 (CH_3CO), 96.48 (C-1′), 76.85, 75.36, 70.80 (C-2′), 69.78 (C-3′), 69.15, 68.40, 68.19, 68.19, 68.12, 62.70 and 61.81 (C-6, C-6′) and 20.97, 20.79, 20.64, 20.59 (CH_3CO). Anal. calcd. for $C_{26}H_{36}O_{17}$: C 50.32, H 5.85; found: C 50.31, H 5.71.

p-*Nitrophenyl 3*-O-*(α-*D*-glucopyranosyl)-α-*D*-mannopyranoside (5)*

Heptaacetate **3** (51.9 mg, 0.068 mmol) was deacetylated in methanolic 0.25 N sodium methoxide (3 mL) for 1 h. The solution was made neutral with Amberlite IRC 50 (H^+) and evaporated. The resultant material was passed through a column of Sephadex LH 20 (ethanol–water, 1:1) to provide **5** (30.0 mg, 95%) as a white solid; $[\alpha]_D$ +157.5 (*c* 0.5, water). The ^1H and ^{13}C NMR data are reported in Tables 2 and 3.

1,5-Anhydro-3-O-*(α-*D*-glucopyranosyl)-*D*-mannitol (6)*

Heptaacetate **4** (50 mg, 0.081 mmol) was deacetylated in methanolic 0.15 N sodium methoxide for 1 h. The solution was neutralized with Amberlite IRC 50 (H^+) and evaporated. The material was passed through a column of Sephadex LH 20 (ethanol–water, 1:1) to provide **6** (26 mg, quant.) as a white powder; $[\alpha]_D$ +60 (*c* 0.5, water). The ^1H and ^{13}C NMR data are reported in Tables 2 and 3.

4,6-Di-O-*acetyl-1,5-anhydro-2-deoxy-3*-O-*(2,3,4,6-tetra*-O-*acetyl-α-*D*-glucopyranosyl)-*D*-*arabino*-hex-1-enitol (7)*

A mixture of bromide **2** (0.13 mmol) and sodium acetate (20 mg) in 50% acetic acid (0.5 mL) was added at −10°C to a mixture of zinc (180 mg) and copper sulfate (18 mg) in 50% acetic acid (0.5 mL). The temperature was raised to 0°C and the reaction mixture was stirred for 5 h. It was diluted with dichloromethane, filtered, and the filtrate was washed with water, aqueous saturated sodium hydrogen carbonate, and water, followed by drying and evaporation. The crude product was purified on a column of silica gel (hexane – ethyl acetate, 2:1, 1:1) to provide **7** (47 mg, 65%) as a white solid; mp 125.5–126.5°C (ethanol); $[\alpha]_D$ +54 (*c* 0.3, chloroform). ^1H NMR ($CDCl_3$) δ: 6.46 (dd, 1H, $J_{1,2}$ 6.0 Hz, $J_{1,3} \sim$ 1 Hz, H-1), 5.43 (t, 1H, $J_{3',4'} \sim J_{2',3'}$ 9.5 Hz, H-3′), 5.29 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 5.16 (dd, 1H, *J* 6.5 Hz, 5.5 Hz, H-4), 5.06 (t, 1H, $J_{4',5'}$ 9.5 Hz, H-4′), 4.85 (dd, 1H, H-2′), 4.82 (dd, 1H, $J_{2,3}$ 3.5 Hz, H-2), 4.36 (dd, 1H, $J_{6A,6B}$ 13.0 Hz, $J_{6A,5}$ 6.5 Hz, H-6A), 4.27–4.0 (m, 6H, H-6B, H-6A′, H-6B′, H-5′, and H-3 at 4.23, H-5 at 4.04), 2.11, 2.10, 2.09, 2.08, 2.04, 2.01 (6s, each 3H, $6CH_3CO$). ^{13}C NMR ($CDCl_3$) δ: 170.51, 170.33, 169.88, 169.49 (CH_3CO), 145.08 (C-1), 99.90 (C-2), 95.81 (C-1′), 74.20, 71.18 (C-3, C-5), 70.51 (C-2′), 69.81 (C-3′), 68.46, 68.31 (C-4, C-4′), 67.75 (C-5′), 61.86, 61.44 (C-6, C-6′), 20.74, 20.64, 20.56 (CH_3CO). Anal. calcd. for $C_{24}H_{32}O_{15}$: C 51.42, H 5.75, found: C 51.76, H 5.93.

1,5-Anhydro-2-deoxy-3-O-*(α-*D*-glucopyranosyl)-*D*-*arabino*-hex-1-enitol (8)*

Hexaacetate **7** (130 mg, 0.23 mmol) was deacetylated in methanolic 0.09 N sodium methoxide (1.1 mL) for 1.5 h. The solution was made neutral with Amberlite IRC 50 (H^+) and evaporated. The reaction product was purified on a column of Iatrobeads® (chloroform–methanol–water, 65:30:2) followed by gel filtration on a column of Sephadex LH 20 (ethanol–water, 1:1) to provide the title compound **8** (68.8 mg, 96%) as a white solid; $[\alpha]_D$ +46.4 (*c* 0.2, water). The ^1H and ^{13}C NMR data are reported in Tables 2 and 3.

1,5-Anhydro-2-deoxy-3-O-*(α-*D*-glucopyranosyl)-*D*-*arabino*-hexitol (9)*

(*a*) A mixture of glucal **8** (46 mg, 0.149 mmol) and 5% palladium-on-carbon (42 mg) in methanol (4 mL) was hydrogenated in the hydrogen stream for 1 h. Filtration, solvent evaporation, and gel filtration on a column of Sephadex LH 20 (ethanol–water, 1:1) provided **9** (45.2 mg, 98%) as a white solid, $[\alpha]_D$ +89.8 (*c* 0.2, water). The ^1H and ^{13}C NMR data are reported in Tables 2 and 3.

(*b*) A mixture of **16** (110 mg, 0.14 mmol) and 5% palladium-on-carbon (110 mg) in methanol (6 mL) was hydrogenated in the hydrogen stream for 2.5 h. Usual processing and gel filtration provided a product identical to **9** (43.5 mg, 101%).

2-O-*Benzyl-4,6*-O-*benzylidene-3*-O-*(2,3,4,6-tetra*-O-*benzyl-α-*D*-glucopyranosyl)-α-*D*-mannopyranosyl fluoride (11)*

Diethylaminosulfur trifluoride (50 μL, 0.38 mmol) was added to a stirred solution of **10** (201 mg, 0.228 mmol)[3] in dichloromethane (1 mL) at −30°C. Stirring was continued for 30 min at −30°C and 25 min at room temperature. The mixture was cooled down again to −30°C and methanol (1.5 mL) was added to quench the reaction. The remainder obtained on solvent evaporation was dissolved in dichloromethane, and the organic solution was washed

For personal use only.

with aqueous saturated sodium hydrogen carbonate and water, dried, and evaporated. The resultant product was purified on a column of silica gel (hexane – ethyl acetate, 6:1) and obtained as a syrup (168 mg, 83%), $[\alpha]_D$ +47.4 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.5–6.9 (m, 30H, 6Ph), 5.53 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 5.52 (dd, 1H, $J_{1,2} \sim 1$ Hz, $J_{1,F}$ 49.0 Hz, H-1), 5.45 (s, 1H, C*H*Ph), 3.53 (dd, 1H, $J_{2',3'}$ 9.5 Hz, H-2'); ^{13}C NMR ($CDCl_3$) δ: 106.91 ($J_{C,F}$ 225.1 Hz, $J_{C,H}$ 185.0 Hz, C-1), 102.47 (*C*HPh), 97.0 (C-1'). Anal. calcd . for $C_{54}H_{55}FO_{10}$: C 73.45, H 6.28; found: C 73.33, H 6.27.

*3-O-(α-D-Glucopyranosyl)-α-D-mannopyranosyl fluoride (**12**)*

11 (147.8 mg, 0.167 mmol) in 95% ethanol (12 mL) was hydrogenated in the presence of 5% palladium-on-carbon (140 mg) at atmospheric pressure for 1 h. The catalyst was removed by filtration and the solvent evaporated. Gel filtration of the product on a column of Sephadex LH 20 (ethanol–water, 1:1) and lyophilization of an aqueous solution provided title compound **12** (52.4 mg, 91%) as a white solid; $[\alpha]_D$ +89.7 (*c* 0.53, water). The ^{1}H and ^{13}C NMR data are reported in Tables 2 and 3.

*1,5-Anhydro-2-deoxy-4,6-*O*-p-methoxybenzylidene-D-*arabino*-hexitol (**14**)*

A solution of 1,5-anhydro-2-deoxy-D-*arabino*-hexitol (**13**) (835 mg, 5.63 mmol) (20), *p*-methoxybenzaldehyde dimethyl acetal (1.3 mL, 7.63 mmol), and *p*-toluenesulfonic acid monohydrate (300 mg) in acetonitrile (24 mL) was kept overnight. It was neutralized with triethylamine and the material obtained on evaporation applied to a column of silica gel (hexane – ethyl acetate, 2:1) to provide **13** (1.25 g, 83%) as a solid; mp 113.5–115°C (dichloromethane, ether, hexane); $[\alpha]_D$ −34 (*c* 0.4, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.42 and 6.9 (2d, each 2H, Ph), 5.53 (s, 1H, C*H*Ph) 4.26 (dd, 1H, $J_{6a,6e}$ 10.5 Hz, $J_{5,6e}$ 4.5 Hz, H-6e), 4.00 (ddd, 1H, $J_{1e,1a}$ 11.5 Hz, $J_{1e,2a}$ 5.0 Hz, $J_{1e,2e}$ 1.5 Hz, H-1e), 3.89 (ddd, 1H, $J_{2ax,3}$ 10.5 Hz, $J_{2e,3}$ 5.5 Hz, $J_{3,4}$ 8.0 Hz, H-3), 3.81 (s, 3H, CH_3O), 3.69 (t, 1H, $J_{6a,5}$ 10.0 Hz, H-6a), 3.58 (dt, 1H, $J_{1a,2a}$ 12.5 Hz, $J_{1a,2e}$ 2.5 Hz, H-1a), 3.43 (t, 1H, $J_{4,5}$ 8.5 Hz, H-4), 3.33 (dt, 1H, H-5), 2.04 (m, 1H, $J_{2e,2a}$ 13.5 Hz, H-2e), 1.82 (m, 1H, H-2a). Anal. calcd. for $C_{14}H_{18}O_5$: C 63.15, H 6.81; found: C 62.89, H 6.94.

*1,5-Anhydro-2-deoxy-4,6-*O*-p-methoxybenzylidene-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-D-*arabino*-hexitol (**16**)*

A solution of 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl bromide (**15**) (21) (13.5 mmol) in dichloromethane (14 mL) was transferred into a mixture of alcohol **14** (1.2 g, 4.51 mmol), tetraethylammonium bromide (2.1 g, 10.0 mmol), *N,N*-dimethylformamide (2.5 mL), Hünig's base (2.8 mL, 16.1 mmol), and 4 Å molecular sieves (powdered, 5 g) in dichloromethane (3 mL). The mixture was concentrated in a stream of nitrogen and kept stirring for 60 h. Then the reaction was quenched by the addition of moist pyridine (1 mL) and after 1 h it was diluted with dichloromethane and filtered through a pad of Celite. The solution was washed with saturated aqueous sodium hydrogen carbonate and water, followed by drying and evaporation. Purification was achieved by column chromatography on silica gel (hexane – ethyl acetate, 5:1, 4:1, containing 0.05% triethylamine) to provide solid **16** (1.98 g, 56%); mp 124–126°C (dichloromethane, ether, hexane); $[\alpha]_D$ +28 (*c* 0.3, chloroform, 0.1% triethylamine). ^{1}H NMR ($CDCl_3$) δ: 7.40–6.80 (m, 24H, 5Ph), 5.49 (s, 1H, C*H*PhOMe), 5.46 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 5.05–4.31 (4ABq, 8H, 4CH_2Ph), 4.24 (dd, 1H, $J_{6a,6e}$ 10.0 Hz, $J_{6e,5}$ 5.0 Hz, H-6e), 4.07 (q, 1H, H-3), 3.96 (2H, m, H-1A, t, $J_{2',3'}$ 10.0 Hz, $J_{3',4'}$ 9.0 Hz, H-3'), 3.87 (td, 1H, $J_{4',5'}$ 10.0 Hz, H-5'), 3.76 (s, 3H, CH_3O), 3.73 (t, overlapped, $J_{3,4} \sim J_{4,5}$ 9.0 Hz, H-4), 3.69 (t, H-6A, overlapped by H-6A', H-6B'). 3.56 (t, 1H, H-4'), ~ 3.54 (H-1B), 3.48 (dd, 1H, H-2'), 3.37 (dt, 1H, $J_{5,6a}$ 10.0 Hz, H-5), 1.95 (m, 2H, H-2A, H-2B). Anal. calcd. for $C_{48}H_{52}O_{10}$: C 73.08, H 6.64; found: C 72.84, H 6.59.

*1,5-Anhydro-2-deoxy-4-*O*-p-methoxybenzyl-3-*O*-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-D-*arabino*-hexitol (**17**)*

Trimethylsilyl chloride (560 μL, 4.4 mmol) was added dropwise to a stirred mixture of **16** (580 mg, 0.74 mmol), sodium cyanoborohydride (280 mg, 4.46 mmol), and 4 Å molecular sieves (0.5 g) in acetonitrile (15 mL) at ice-bath temperature. After 6 h at room temperature, it was poured into aqueous saturated sodium hydrogen carbonate and extracted with dichloromethane. The organic solution was washed with water, dried, and evaporated. Subsequent column chromatography on silica gel (hexane – ethyl acetate, 4:1 to 1:1 containing 0.05% triethylamine) provided as a minor component the 4-hydroxy compound **27** (50.9 mg, 8.8%) followed by the major product **17** (430 mg, 74%); $[\alpha]_D$ +47 (*c* 0.6, chloroform, 0.1% triethylamine). ^{1}H NMR ($CDCl_3$) δ: 7.40–6.80 (m, 24H, 5Ph), 5.12 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 5.01–4.44 (5ABq, 10H, 4CH_2Ph, CH_2PhOMe), 4.05 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3'), 3.94 (m, 1H, $J_{5',4'}$ 10.0 Hz, H-5'), 3.85 (ddd, 1H, $J_{1A,1B}$ 11.5 Hz, $J_{1A,2a}$ 4.0 Hz, $J_{1A,2e} \sim 1$ Hz, H-1A), 3.76 (s, 3H, CH_3O), 3.72 (dd, 1H, $J_{6A',6B'}$ 10.5 Hz, $J_{6A',5'}$ 4.0 Hz, H-6A'), 3.63 (overlapped, H-4'), 3.57 (dd, 1H, H-2'), 3.36 (t, 1H, $J_{3,4} \sim J_{4,5}$ 9.0 Hz, H-4), 3.36 (dt, H-1B), 3.22 (ddd, 1H, $J_{5,6B}$ 2.5 Hz, H-5), 2.19 (m, 1H, $J_{2e,2a}$ 13.0 Hz, H-2e), 1.71 (dq, 1H, $J_{2a,1B} \sim J_{2a,3} \sim$ 12.5 Hz, H-2a). Anal. calcd. for $C_{48}H_{54}O_{10}$: C 72.89, H 6.88; found: C 72.60, H 7.09.

*1,5-Anhydro-2-deoxy-6-*O*-methanesulfonyl-4-*O*-p-methoxybenzyl-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-D-*arabino*-hexitol (**18**)*

Methanesulfonyl chloride (53 μL, 0.69 mmol) was added dropwise to a stirred solution of **17** (273 mg, 0.35 mmol) in pyridine (6 mL) at ice-bath temperature. After 2 h at this temperature, the mixture was poured into ice-water, followed by extraction with dichloromethane and washing of the organic solution with saturated aqueous sodium hydrogen carbonate, drying, and evaporation. Purification of the crude product on a column of silica gel (hexane – ethyl acetate, 4:1, 3:1, 2:1, containing 0.05% triethylamine) afforded mesylate **18** (273 mg, 91%) as a tough syrup; $[\alpha]_D$ +49 (*c* 0.6, chloroform, 0.05% triethylamine). ^{1}H NMR ($CDCl_3$) δ: 7.40–6.80 (m, 24H, 5Ph), 5.09 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 5.07–4.43 (5ABq, 10H, 4CH_2Ph, CH_2PhOMe), 4.38 (dd, 1H, $J_{6A,6B}$ 10.5 Hz, $J_{6A,5}$ 1.5 Hz, H-6A), 4.28 (dd, 1H, $J_{6B,5}$ 4.5 Hz, H-6B), 4.05 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3'), 3.93 (m, 1H, $J_{4',5'}$ 10.0 Hz, H-5'), 3.86 (ddd, 1H, $J_{1A,1B}$ 11.5 Hz, $J_{1A,2a}$ 4.0 Hz, $J_{1A,2e}$ 1.0 Hz, H-1A), 3.77 (s, 3H, CH_3O), 3.71 (dd, overlapped, $J_{6A',5'}$ 4.5 Hz, H-6A'), 3.63 (t, overlapped, H-4'), 3.57 (dd, 1H, H-2'), 3.36 (m, 3H, with H-5, H-1B), 3.01 (s, 3H, CH_3O), 2.21 (m, 1H, $J_{2e,2a}$ 13.5 Hz, $J_{2e,3}$ 4.5 Hz, H-2e), 1.72 (dq, 1H, $J_{2a,1B} \sim J_{2a,3} \sim$ 12.0 Hz, H-2a). Anal. calcd. for $C_{49}H_{56}O_{12}S$: C 67.72, H 6.50; found: C 67.74, H 6.53.

*1,5-Anhydro-2-deoxy-4-*O*-p-methoxybenzyl-6-*O*-methyl-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-D-*arabino*-hexitol (**19**)*

Sodium hydride (80% oily suspension, 30 mg, 1 mmol) was added to a solution of **17** (143 mg, 0.18 mmol) in *N,N*-dimethylformamide (3 mL) at ice-bath temperature. After 20 min, this was followed by the addition of methyl iodide (50 μL, 0.54 mmol). After 2 h, the reaction was quenched by the dropwise addition of methanol. It was diluted with dichloromethane, washed with water, dried, and evaporated. Column chromatography on silica gel (hexane – ethyl acetate, 2:1, containing 0.05% triethylamine) provided **19** (120 mg, 83%) as a tough (*very* viscous) syrup; $[\alpha]_D$ +34 (*c* 0.3, chloroform, 0.05% triethylamine). ^{1}H NMR ($CDCl_3$) δ: 7.40–6.78 (m, 24H, 5Ph), 5.12 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 5.04–4.42 (5ABq, 10H, 4CH_2Ph, CH_2PhOMe), 4.04 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3'), 3.93 (ddd, 1H, $J_{4',5'}$ 10.0 Hz, $J_{5',6A'}$ 4.0 Hz, $J_{5',6B'}$ 1.7 Hz, H-5'), 3.88 (ddd, 1H, $J_{1A,1B}$ 11.5 Hz, $J_{1A,2a}$ 5.0 Hz, $J_{1A,2e}$ 1.0 Hz, H-1A), 3.76 (s, 3H, CH_3O), 3.72 (dd, overlapped, $J_{6A',6B'}$ 10.5 Hz, H-6A'), 3.63 (t, overlapped, H-4'),

For personal use only.

3.56 (overlapped, H-2′), 3.33 (s, 3H, CH_3O), 3.26 (overlapped, H-1B), 2.16 (m, 1H, $J_{2e,2a}$ 13.0 Hz, $J_{2e,3}$ 4.5 Hz, H-2e), 1.74 (dq, 1H, $J_{2a,1B} \sim J_{2a,3}$ 12.5 Hz, H-2a). Anal. calcd. for $C_{49}H_{56}O_{10}$:C 73.11, H 7.01; found: C 73.04, H 7.02.

*1,5-Anhydro-2,6-dideoxy-6-iodo-4-*O-p-*methoxybenzyl-3-*O-*(2,3,4,6-tetra-*O-*benzyl-α-D-glucopyranosyl)-D-*arabino-*hexitol (20)*

A stirred mixture of **18** (173 mg, 0.20 mmol) and potassium iodide (200 mg) in *N,N*-dimethylformamide (7 mL) was heated at 95–100°C for 13 h. It was diluted with dichloromethane, washed with water, dried, and evaporated. Column chromatography on silica gel (hexane – ethyl acetate, 5:1, 4:1, containing 0.05% triethylamine) provided the title compound **20** (116 mg, 65%) as a crystallizing syrup; $[\alpha]_D$ +46 (*c* 0.3, chloroform, 0.03% triethylamine). ^{1}H NMR ($CDCl_3$) δ: 7.40–6.75 (m, 24H, 5Ph), 5.15–4.35 (5ABq, 10H, 4CH_2Ph, CH_2PhOMe), 5.07 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.06 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3′), 3.95 (m, overlapped, H-5′), 3.91 (ddd, overlapped, $J_{1A,1B}$ 12.5 Hz, $J_{1A,2a}$ 5.0 Hz, $J_{1A,2e}$ 1.0 Hz, H-1A), 3.77 (s, 3H, CH_3O), 3.73 (dd, overlapped, $J_{6A',6B'}$ 10.5 Hz, $J_{6A',5'}$ 4.0 Hz, H-6A′), 3.66 (t, 1H, $J_{4',5'}$ 9.5 Hz, H-4′), 3.62 (dd, overlapped, $J_{5',6B'}$ 1.8 Hz, H-6B′), 3.57 (dd, 1H, H-2′), 3.46 (dd, 1H, $J_{6A,6B}$ 11.0 Hz, $J_{5,6A}$ 3.0 Hz, H-6A), 3.39 (overlapped, H-1B), 3.37 (dd, 1H, $J_{5,6B}$ 5.5 Hz, H-6B), 3.30 (t, 1H, $J_{3,4} \sim J_{4,5}$ 8.5 Hz, H-4), 2.91 (m, 1H, H-5), 2.22 (m, 1H, $J_{2e,2a}$ 12.5 Hz, $J_{2e,3}$ 4.5 Hz, H-2e), 1.76 (dq, 1H, $J_{2a,3} \sim J_{2a,1B}$ 12.5 Hz, H-2a).

*1,5-Anhydro-2,6-dideoxy-4-*O-p-*methoxybenzyl-3-*O-*(2,3,4,6-tetra-*O-*benzyl-α-D-glucopyranosyl)-D-*arabino-*hexitol (21)* *and 1,5-anhydro-2,6-dideoxy-3-*O-*(2,3,4,6-tetra-*O-*benzyl-α-D-glucopyranosyl)-D-*arabino-*hexitol (22)*

The iodo compound **20** (116 mg, 0.13 mmol), tributyltin hydride (150 μL, 0.56 mmol), and 2,2′-azobis(isobutyronitrile) (10 mg) in toluene (3 mL) were heated at 83°C for 30 min. Evaporation and subsequent column chromatography on silica gel (hexane – ethyl acetate, 4:1, 3:1 containing 0.05% triethylamine) provided in the first fraction **21** (54 mg, 54%) as a solid; $[\alpha]_D$ +35 (*c* 0.3, chloroform, 0.03% triethylamine). ^{1}H NMR ($CDCl_3$) δ: 7.40–6.77 (m, 24H, 5Ph), 5.12 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 5.06–4.44 (5ABq, 10H, 4CH_2Ph, CH_2PhOMe), 4.05 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3′), 3.94 (m, 1H, $J_{4',5'}$ 9.5 Hz, H-5′), 3.79 (overlapped, H-1A), 3.76 (s, 3H, CH_3O), 3.73 (dd, overlapped, $J_{6A',6B'}$ 10.5 Hz, $J_{6A',5'}$ 3.5 Hz, H-6A′), 3.64 (t, overlapped, H-4′), 3.61 (overlapped, H-6B′), 3.56 (dd, 1H, H-2′), 3.31 (dt, $J_{1B,2a}$ 12.5 Hz, H-1B), 3.26 (m, H-5), 2.17 (m, 1H, $J_{2e,2a}$ 12.5 Hz, $J_{2e,3}$ 5.0 Hz, H-2e), 1.73 (dt, 1H, $J_{2a,3}$ 12.5 Hz, H-2a), 1.23 (d, 3H, $J_{5,6}$ 6.5 Hz, H_3-6). Continued elution provided **22** (25 mg, 30%) as a syrup; $[\alpha]_D$ +31 (*c* 0.1, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 20H, 4Ph), 4.94 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.96–4.43 (4ABq, 8H, 4CH_2Ph), 4.01 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3′), 3.93 (ddd, 1H, $J_{4',5'}$ 10.0 Hz, $J_{5',6A'}$ 4.0 Hz, $J_{5',6B'}$ 1.5 Hz, H-5′), 3.86 (ddd, 1H, $J_{1A,1B}$ 12.0 Hz, $J_{1A,2a}$ 4.5 Hz, $J_{1A,2e}$ 1.0 Hz, H-1A), 3.69 (dd, 1H, $J_{6A',6B'}$ 10.5 Hz, H-6A′), 3.60 (overlapped, H-4′), 3.59 (dd, overlapped, H-6B′), 3.54 (dd, 1H, H-2′),~3.42 (m, overlapped, H-3), 3.40 (dt, $J_{1B,2a}$ 12.5 Hz, $J_{1B,2e}$ 2.0 Hz, H-1B), 3.26 (m, 1H, H-5), 3.19 (t, 1H, $J_{3,4} \sim J_{4,5}$ 9.0 Hz, H-4), 1.98 (m, 1H, $J_{2e,2a}$ 12.5 Hz, $J_{2e,3}$ 5.0 Hz, H-2e), 1.74 (dq, 1H, $J_{2a,3}$ 12.0 Hz, H-2a), 1.29 (d, 3H, $J_{5,6}$ 6.5 Hz, H_3-6).

*1,5-Anhydro-6-azido-2,6-dideoxy-4-*O-p-*methoxybenzyl-3-*O-*(2,3,4,6-tetra-*O-*benzyl-α-D-glucopyranosyl)-D-*arabino-*hexitol (23)*

A mixture of mesylate **18** (90 mg, 0.10 mmol) and sodium azide (90 mg, 1.38 mmol) in *N,N*-dimethylformamide (3 mL) was heated at 105°C for 2 h. It was poured into water, extracted with dichloromethane, and the organic solution was washed with water, dried, and evaporated. Column chromatography on silica gel (hexane – ethyl acetate, 4:1, 3:1, containing 0.05% triethylamine) provided azide **23** (84 mg, 99%) as a syrup; $[\alpha]_D$ +75 (*c* 0.3, chloroform, 0.03% triethylamine). ^{1}H NMR ($CDCl_3$) δ: 7.40–6.75 (m, 24H, 5Ph), 5.10 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 5.06–4.43 (5ABq, 10H, 4CH_2Ph, CH_2PhOMe), 4.05 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3′), 3.94 (m, 1H, $J_{4',5'}$ 10.0 Hz, H-5′), 3.87 (ddd, 1H, $J_{1A,1B}$ 11.5 Hz, $J_{1A,2a}$ 4.5 Hz, $J_{1A,2e}$ 1.0 Hz, H-1A), 3.75 (s, 3H, CH_3O), 3.64 (overlapped, H-4′), 3.57 (dd, 1H, H-2′), 2.20 (m, 1H, $J_{2e,2a}$ 13.0 Hz, $J_{2e,3}$ 4.5 Hz, H-2e), 1.74 (dq, 1H, $J_{2a,1B} \sim J_{2a,3}$ 12.5 Hz, H-2a). Anal. calcd. for $C_{48}H_{53}N_3O_9$: C 70.66, H 6.55, N 5.15; found: C 70.97, H 6.81, N 4.83.

*1,5-Anhydro-2-deoxy-3-*O-*(α-D-glucopyranosyl)-6-*O-*methyl-D-*arabino-*hexitol (24)*

19 (95 mg, 0.12 mmol) and 5% palladium-on-carbon (95 mg) in methanol (5 mL) were hydrogenated in the hydrogen stream for 3 h. Work-up and gel filtration as described for **9** provided **24** (39.7 mg, 104%) as a white solid after freeze-drying an aqueous solution; $[\alpha]_D$ +105 (*c* 0.3, water). The ^{1}H and ^{13}C NMR data are reported in Tables 2 and 3.

*1,5-Anhydro-2,6-dideoxy-3-*O-*(α-D-glucopyranosyl)-D-*arabino-*hexitol (25)*

A mixture of **21** (54 mg, 0.07 mmol) and 5% palladium-on-carbon (55 mg) in methanol (4 mL) was hydrogenated in the hydrogen stream for 2.5 h. Usual processing and gel filtration provided **25** (21 mg, 102%) as a white solid after freeze-drying its aqueous solution; $[\alpha]_D$ +99 (*c* 0.3, water). The ^{1}H NMR spectrum indicated the presence of ~7% triethylamine in the compound. The ^{1}H and ^{13}C NMR data are reported in Tables 2 and 3.

*6-Amino-1,5-anhydro-2,6-dideoxy-3-*O-*(α-D-glucopyranosyl)-D-*arabino-*hexitol-hydrochloride (26)*

A mixture of azide **23** (65 mg, 0.08 mmol), 5% palladium-on-carbon (45 mg), and triethylamine (40 μL) in methanol (4 mL) was hydrogenated for 2 h in the hydrogen stream. The material obtained on filtration and evaporation was passed through a short column of silica gel (dichloromethane – 12% methanol). The product, 5% palladium-on-carbon (60 mg) and methanolic 0.12 N hydrochloric acid (700 μL, 0.084 mmol) in methanol (4 mL) were hydrogenated in the hydrogen stream for 2 h. Usual work-up and gel filtration as described for **9** provided **26** (18 mg, 66%) as a white solid after freeze-drying an aqueous solution. The ^{1}H NMR spectrum indicated only 90% homogeneity. The ^{1}H and ^{13}C NMR data are reported in Tables 2 and 3.

*1,5-Anhydro-2-deoxy-6-*O-p-*methoxybenzyl-3-*O-*(2,3,4,6-tetra-*O-*benzyl-α-D-glucopyranosyl)-D-*arabino-*hexitol (27)*

Trifluoroacetic acid (440 μL, 5.71 mmol) was added to a stirred mixture of **16** (750 mg, 0.95 mmol), sodium cyanoborohydride (358 mg, 5.70 mmol), and 4 Å molecular sieves (0.5 g) in *N,N*-dimethylformamide (20 mL) at 0°C. The mixture was kept at room temperature for 4 days and three more additions of trifluoroacetic acid (440 μL each time) were made. Then, the mixture was poured into aqueous saturated sodium hydrogen carbonate and extracted with dichloromethane, followed by washing of the organic solution with water, drying, and evaporation. The remainder was purified by column chromatography (hexane – ethyl acetate, 4:1 to 1:1, containing 0.05% triethylamine) to provide **27** (406 mg, 54%) as a crystallizing syrup; $[\alpha]_D$ +29 (*c* 1.8, chloroform, 0.05% triethylamine). ^{1}H NMR ($CDCl_3$) δ: 7.40–6.80 (m, 24H, 5Ph), 5.01 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.96–4.43 (4ABq, 1s, 10H, 4CH_2Ph, CH_2PhOMe), 4.00 (t, 1H, $J_{2',3'}$ 10.0 Hz, $J_{3',4'}$ 9.0 Hz, H-3′), 3.93 (2m, 2H, H-1A, H-5′), 3.78 (s, 3H, CH_3O), 3.73 (dd, 1H, $J_{6A,6B}$ 10.5 Hz, $J_{6A,5}$ 2.5 Hz, H-6A), 3.69 (dd, 1H, $J_{6A',6B'}$ 10.0 Hz, $J_{6A',5'}$ 4.0 Hz, H-6A′), 3.59 (H-4′), 3.55 (dd, H-2′), 3.41 (dt, overlapped, H-1B), 3.38 (H-5), 1.97 (td, 1H, $J_{2e,2a}$ 13.5 Hz, H-2e), 1.75 (m, H-2a). Anal. calcd. for $C_{48}H_{54}O_{10}$: C 72.89, H 6.88; found: C 72.89, H 6.96. Continued elution of the column provided the isomer **17** (113 mg, 15%).

An analytical sample of **27** (10 mg, 0.13 mmol) was acetylated conventionally with pyridine – acetic anhydride to provide *4-*O-*acetyl-1,5-anhydro-2-deoxy-6-*O-p-*methoxybenzyl-3-*O-*(2,3,4,6-tetra-*O-*benzyl-α-D-glucopyranosyl)-D-*arabino-*hexitol (28)*, which

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

was characterized by ^{1}H NMR spectroscopy. ^{1}H NMR ($CDCl_3$) δ: 7.40–6.85 (m, 24H, 5Ph), 4.95 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.91 (overlapped, $J_{3,4} \sim J_{4,5}$ 9.5 Hz, H-4), 4.92–4.42 (4ABq, 1s, 10H, 4CH_2Ph, CH_2PhOMe), 3.97 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3′), 3.93 (overlapped, H-1A), 3.88 (m, 1H, $J_{4',5'}$ 10.0 Hz, H-5′), 3.79 (s, 3H, CH_3O), 3.68 (dd, 1H, $J_{6A',6B'}$ 10.5 Hz, $J_{6A',5'}$ 4.0 Hz, H-6A′), ~3.65 (H-3), 3.59 (dd, 1H, $J_{6B',5'}$ 1.5 Hz, H-6B′), 3.57 (t, 1H, H-4′), 3.48 (dd, 1H, H-2′), 3.46 (m, H-5, H-6), 3.38 (m, H-1B), 2.15 (m, 1H, $J_{2a,2e}$ 13.5 Hz, H-2e), 1.80 (m, 1H, H-2a), 1.74 (s, 3H, CH_3CO).

*1,5-Anhydro-2-deoxy-6-*O-p-*methoxybenzyl-4-*O-*methyl-3-*O-*(2,3,4,6-tetra-*O-*benzyl-α-D-glucopyranosyl)-D-*arabino-*hexitol (29)*

Sodium hydride (80% oily suspension, 30 mg, 1 mmol) was added at ice-bath temperature to a solution of **27** (150 mg, 0.19 mmol) in *N,N*-dimethylformamide (2 mL). After 20 min, methyl iodide (50 μL, 0.54 mmol) was added. After 2 h, the reaction was quenched by the addition of methanol. The mixture was diluted with dichloromethane, followed by washing with water, drying, and evaporation of the organic solution. The remainder on evaporation was applied to a column of silica gel (hexane – ethyl acetate, 3:1, containing 0.05% triethylamine to provide **29** (133 mg, 87%) of a crystallizing syrup, $[\alpha]_D$ +49 (*c* 0.4, chloroform, 0.02% triethylamine). ^{1}H NMR ($CDCl_3$) δ: 7.40–6.85 (m, 24H, 5Ph), 5.15 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 5.01–4.43 (5ABq, 10H, 4CH_2Ph, CH_2PhOMe), 4.00 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3′), 3.90 (m, H-5′), 3.87 (m, H-1A), 3.76 (s, 3H, CH_3O), 3.71 (dd, 1H, $J_{6A',6B'}$ 10.5 Hz, $J_{6A',5'}$ 4.3 Hz, H-6A′), 3.56 (dd, overlapped, H-2′), 3.42 (s, 3H, CH_3O), 3.33 (dt, $J_{1A,1B} \sim J_{1B,2a} \sim$ 13.5 Hz, H-1B), 3.24 (m, 1H, H-5), 2.08 (m, 1H, H-2e), 1.74 (m, 1H, H-2a). Anal. calcd. for $C_{49}H_{56}O_{10}$: C 73.11, H 7.01; found: C 73.30, H 7.00.

*1,5-Anhydro-2,4-dideoxy-6-*O-p-*methoxybenzyl-3-*O-*(2,3,4,6-tetra-*O-*benzyl-α-D-glucopyranosyl)-D-*threo-*hexitol (31)*

A mixture of **27** (270 mg, 0.34 mmol), sodium hydride (80% oily suspension, 50 mg, 1.67 mmol), and 3 crystals of imidazole in tetrahydrofuran (7 mL) was stirred for 30 min. Then carbon disulfide (205 μL, 3.41 mmol) was added, followed by the addition of methyl iodide (85 μL, 1.37 mmol), after 30 min. The mixture was stirred for another 30 min and then diluted with dichloromethane, and the organic solution was washed with aqueous sodium hydrogen carbonate, water, dried, and evaporated. The yellowish solid (**30**) was reduced with tributyltin hydride (400 μL, 1.49 mmol) in toluene (6 mL) at reflux temperature for 4 h. Evaporation and column chromatography on silica gel (hexane – ethyl acetate, 4:1, 3:1, containing 0.05% triethylamine) provided **31** (194 mg, 73%) as a crystallizing syrup. $[\alpha]_D$ +40 (*c* 0.3, chloroform, 0.03% triethylamine). ^{1}H NMR ($CDCl_3$) δ: 7.40–6.85 (m, 24H, 5Ph), 5.01–4.43 (5ABq, 10H, 4CH_2Ph, CH_2PhOMe), 4.89 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.01 (m, H-1A), 3.98 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3′), 3.84 (m, 1H, H-5′), 3.79 (s, 3H, CH_3O), 3.71 (dd, overlapped, $J_{6A',6B'}$ 10.5 Hz, $J_{6A',5'}$ 3.8 Hz, H-6A′), 3.62 (dd, 1H, $J_{6B',5'}$ 2.0 Hz, H-6B′), 3.61 (t, 1H, $J_{4',5'}$ 9.5 Hz, H-4′), 3.55 (dd, 1H, H-2′), 3.38 (overlapped, H-1B), 1.89 (m, 1H, H-4e), 1.85 (m, 1H, H-2e), 1.69 (dq, 1H, $J_{2a,2e} \sim J_{2a,1a} \sim J_{2a,3} \sim$ 12.5 Hz, $J_{2a,1e}$ 4.5 Hz, H-2a), 1.33 (q, 1H, $J_{4a,4e} \sim J_{3,4a} \sim J_{5,4a} \sim$ 12.0 Hz, H-4a). Anal. calcd. for $C_{48}H_{54}O_9$: C 74.40, H 7.02; found: C 73.97, H 7.01.

*1,5-Anhydro-2-deoxy-3-*O-*(α-D-glucopyranosyl)-4-*O-*methyl-D-*arabino-*hexitol (32)*

A mixture of **29** (120 mg, 0.15 mmol) and 5% palladium-on-carbon (120 mg) in methanol (7 mL) was hydrogenated for 3 h in the hydrogen stream. Processing and gel filtration as described for **9** provided **32** (48.5 mg, 100%) as a white solid after freeze-drying an aqueous solution; $[\alpha]_D$ +116 (*c* 0.5, water). The ^{1}H and ^{13}C NMR data are reported in Tables 2 and 3.

*1,5-Anhydro-2,4-dideoxy-3-*O-*(α-D-glucopyranosyl)-D-*threo-*hexitol (33)*

A mixture of **31** (164 mg, 0.21 mmol) and 5% palladium-on-carbon (160 mg) in methanol (7 mL) was hydrogenated in the hydrogen stream for 2.5 h. Usual processing and gel filtration as described for **9** provided **33** (56.7 mg, 91%) as a white solid after freeze-drying an aqueous solution; $[\alpha]_D$ +146 (*c* 0.4, water). The ^{1}H and ^{13}C NMR data are reported in Tables 2 and 3.

Acknowledgements

Dr. Frank M. Unger's support of this project at Chembiomed Ltd. is gratefully acknowledged. We are deeply indebted to Professor R.U. Lemieux, Department of Chemistry, University of Alberta, thanks to whom the completion of the project and the preparation of this paper were possible. We thank Mrs. B. Jamieson-Hinz for the preparation of starting materials. The biological part of this work was supported by Grant DK17477 from the National Institutes of Health (to R.G.S.).

Received June 10, 1993

ULRIKE SPOHR, MIMI BACH, and ROBERT G. SPIRO. Can. J. Chem. **71**, 1928 (1993).

The syntheses of 1-deoxy-3-*O*-(α-D-glucopyranosyl)-mannojirimycin (**9**) and its 2-deoxy, 2-*O*-methyl, 4-deoxy, 4-*O*-methyl, 6-deoxy, 6-*O*-methyl, *N*-methyl, and *N*-propyl congeners are described. Since **9** was previously shown to effectively inhibit *endo*-α-D-mannosidase, a glycoprotein-processing hydrolase, these chemical modifications were designed to assist in the assessment of intermolecular hydrogen bonds of the inhibitor–enzyme complex. The previously reported data require that all hydroxyl groups of the deoxymannojirimycin unit of **9**, namely, OH-2, OH-4, OH-6, and also the NH-5 group, interact with charged and polar groupings of the enzyme, since deoxygenations and alkylations abolished or significantly reduced activities. Conformational analysis of **9** and some of its congeners based on NMR chemical shifts, experimental and theoretical nuclear Overhauser enhancements, and HSEA calculations were performed. The chemical modifications of the glucose unit of **9** are described in the accompanying paper.

ULRIKE SPOHR, MIMI BACH et ROBERT G. SPIRO. Can. J. Chem. **71**, 1928 (1993).

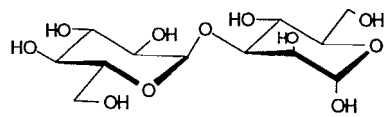
On décrit la synthèse de la 1-désoxy-3-*O*-(α-D-glucopyranosyl)mannojirimycine (**9**) et de ses dérivés 2-désoxy, 2-*O*-méthyle, 4-désoxy, 4-*O*-méthyle, 6-désoxy, 6-*O*-méthyle, *N*-méthyle et *N*-propyle. Puisqu'il a été démontré antérieurement que le composé **9** inhibe d'une façon efficace l'*endo*-α-D-mannosidase, une hydrolase conduisant à des glycoprotéines, les modifications chimiques réalisées avaient pour but d'aide à évaluer les liaisons hydrogènes impliquées dans le complexe inhibiteur–enzyme. Les données rapportées antérieurement (les désoxygénations et les alkylations éliminent ou réduisent fortement les activités) suggèrent que tous les groupes hydroxyles de l'unité désoxymannojirimycine du composé **9**, soit les groupes OH en 2, 4 et 6 ainsi que le groupe NH en 5, interagissent avec les groupes chargés et polaires de l'enzyme. En se basant sur les déplacements chimiques en RMN, sur des effets d'Overhauser nucléaire expérimentaux et théoriques ainsi que sur des calculs HSEA, on a réalisé une analyse conformationnelle du composé **9** et de quelques-uns de ses dérivés. Les modifications chimiques de l'unité glucose du composé **9** sont décrites dans une publication adjointe.

[Traduit par la rédaction]

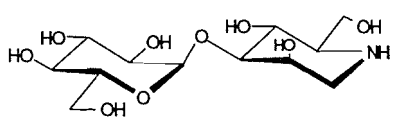
Introduction

The disaccharide 1-deoxy-3-*O*-(α-D-glucopyranosyl)-mannojirimycin (**9**) has been shown to strongly inhibit the action of *endo*-α-D-mannosidase (1), a glycoprotein-processing hydrolase that releases αDGlc(1→3)DMan from incompletely deglucosylated $GlcMan_9GlcNAc_2$ oligosaccharide of immature *N*-linked glycoproteins (2, 3). Although deoxymannojirimycin itself is known to be a strong *exo*-mannosidase inhibitor (4), it was found inactive towards *endo*-mannosidase (3). Apparently, the glucose unit is required for the recognition both of substrates and inhibitors (3) by the enzyme.

It was of interest to further investigate the involvement of the various substituents of inhibitor **9** in the complexation reaction with the enzyme by studying the effect of chemical modifications on the inhibitory properties, thus gaining insights into the topography recognized by the hydrolase. It is to be noted in this regard that extensive protein–oligosaccharide binding studies have been performed with numerous lectins (5–9), monoclonal antibodies (10–12), and enzymes such as amyloglucosidase (13–15) and glycosyltransferases (16–18). The results indicated that in these cases the acceptor protein recognizes only part of the oligosaccharide surface while leaving a considerable portion of the ligand in contact with water. This was confirmed for the complexation of the Lewis b tetrasaccharide by the lectin IV of *Griffonia simplicifolia* (5, 6) by the X-ray crystal structure of the complex (19).



αDGlc(1→3)DMan



9

The approach developed by Lemieux and co-workers (5, 6) for protein–oligosaccharide binding studies, namely, the use of all monodeoxy and mono-*O*-methyl congeners of the parent compound for the appreciation of intermolecular hydrogen bonds, was applied in this investigation, and the bi-

ological results were recently published (1). The present communication reports on the syntheses and properties of **9** and its congeners modified in the 1-deoxymannojirimycin unit.

Discussion

Synthesis

For the synthesis of 1-deoxy-3-*O*-(α-D-glucopyranosyl)-mannojirimycin (**9**) (Scheme 1), the 1-deoxymannojirimycin derivative **1** reported by Fleet et al. (20) was used as the starting material. Diol **1** was protected at the 6-position either by selective acetylation with acetyl chloride at −78°C to provide **2** (75% yield) or by conversion of **1** into the oxazolidone derivative **13** (91% yield) by treatment with sodium methoxide. The ^{1}H NMR spectrum of acetate **2** showed very broad signals and duplication of the acetyl signal due to the hindered rotation of the *N*-benzyloxycarbonyl grouping about the N—C amide bond at room temperature. The ^{13}C NMR spectrum also displayed signal duplications. The 3-hydroxyl group of acetate **2** proved to be of very low reactivity in comparison to OH-3 of oxazolidone derivative **13**. No glucosidation of **2** was achieved under halide ion catalyzed conditions using bromide **14** (21). Therefore, the glucosidation was carried out with chloride **3** (22) and mediated by silver trifluoromethanesulfonate at −10°C to produce an α:β-mixture of **4** and **5** in the ratio 3.5:1. Repeated column chromatography provided the α-anomer **4** in 66% and the β-anomer **5** in 19% yield. An easier separation of the anomers was achieved after deacetylation of the anomeric mixture of **4** and **5** with triethylamine in aqueous methanol for 7 days to provide the anomers **6** and **7**. Under these conditions oxazolidone formation could be avoided. The anomeric assignments for **6** and **7** followed from the coupling constants $J_{C1',H1'}$ 168.0 Hz for **6** and $J_{C1',H1'}$ 160.5 Hz for **7** in the C–H coupled ^{13}C NMR spectrum (23). **6** was hydrogenolyzed in the presence of 5% palladium-on-carbon and 1 equivalent of hydrochloric acid to afford the target compound **9**. The ^{1}H and ^{13}C NMR data are presented in Tables 1 and 2 and are in full agreement with the structural assignment.

In contrast to acetate **2**, oxazolidone derivative **13** could be glucosylated with bromide **14** under halide ion catalysis, leading to **15** (60% yield). **15** was also obtained by treatment of **4** with sodium methoxide (81% yield). **15** was hydrogenolyzed to the oxazolidone derivative **16**, which showed the CO signal at 160.66 ppm in the ^{13}C NMR spectrum. Saponification of the cyclic carbamate in **15** with ethanolic potassium hydroxide provided **17**, the debenzylation of which also led to **9**.

6-*O*-Methyl congener **10** was prepared from the 6-hydroxy disaccharide **6** by treatment with methyl iodide and silver oxide in toluene (**8**, 91% yield) followed by hydrogenolytic debenzylation.

Disaccharide **9** was converted into the *N*-methyl and *N*-propyl derivatives **11** and **12** in high yields by reductive amination using formaldehyde in the presence of palladium/hydrogen and propionaldehyde in the presence of sodium cyanoborohydride (24).

The synthesis of the 6-deoxy congener **21** is outlined in Scheme 2. Although the 6-position of disaccharide **6** could be methylated under mild conditions to give **8** (Scheme 1), the benzyloxycarbonyl group proved unsuitable in attempts to halogenate or mesylate this position. Therefore this group was replaced by a benzyl group by treating amine **17** (Scheme 2) with benzyl bromide in the presence of potassium carbonate to produce **18** in 94% yield. Mesylation of **18** with methanesulfonyl chloride in pyridine at temperatures as low as −20°C produced a mixture of presumably the 6-*O*-methanesulfonyl ester and the 6-chloro-6-deoxy derivative **19** while a complete conversion into **19** (80% yield) was achieved on heating at 50°C for 1 h. **19** was then reduced with tributyltin hydride to the 6-deoxy derivative **20** (63% yield), which was debenzylated by catalytic hydrogenation over 5% palladium-on-carbon to afford **21** in high yield.

The syntheses leading to the 2-*O*-methyl and 2-deoxy congeners of **9**, namely, **36** and **37**, are presented in Scheme 3. The 4-*O*-benzyl-*N*-benzyloxycarbonyl-2-*O*-methyl derivative of 1-deoxymannojirimycin (**28**) was synthesized in a reaction sequence analogous to the one developed by Fleet et al. for the preparation of the 2,4-di-*O*-benzyl derivative **1** (20). Conventional methylation of 6-azido-3-*O*-benzyl-6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose (25) gave the 5-*O*-methyl ether **22**, which was methanolyzed to the methyl glycosides **23** in high yield. Conversion into the trifluoromethanesulfonyl ester (intermediate **24**) followed by reduction of the azido group with triphenylphosphine, cyclization with inversion of configuration at C-2 (intermediate **25**), and *N*-benzyloxycarbonylation led to the bicyclic furanoside **26** in 68% yield. **26** was hydrolyzed to the reducing sugar (intermediate **27**) with subsequent reduction using sodium borohydride to produce **28** in 51% yield. The synthesis of the corresponding 1,2-dideoxy fagomine derivative **29** was reported by Fleet and Smith (26).

Both **28** and **29** were converted into the oxazolidones **30** and **31** in high yields by treatment with sodium methoxide. Glucosylation of **30** and **31** with bromide **14** under halide ion catalyzed conditions led to the α-linked disaccharides **32** and **33**, which were isolated in yields of 67 and 65%, respectively. Saponification of **32** and **33** using ethanolic potassium hydroxide to give **34** and **35** was followed by catalytic hydrogenolysis and provided the 2-*O*-methyl and 2-deoxy disaccharides **36** and **37** in high yields.

In the synthesis of the 4-*O*-methyl and 4-deoxy congeners of **9**, namely, **52** and **53** (Scheme 4), the 4-*O*-allyl disaccharide **45** served as an intermediate for both structures. The synthesis started from 3-*O*-allyl-1,2-*O*-isopropylidene-6-*O*-*p*-toluenesulfonyl-α-D-glucofuranose (27), which was converted conventionally into the methyl glycosides **38** by azide replacement, benzylation, and methanolysis. 1-Deoxymannojirimycin derivative **43** was then prepared from **38** as reported for **1** (20) and applied to the preparation of **28** via triflate **39**, which was reduced and cyclized with inversion of configuration at C-2 followed by *N*-benzyloxycarbonylation to give **41** (55%). Hydrolysis of the glycoside and subsequent reduction with sodium borohydride led to **43** (59% yield) from which **44** was obtained by treatment with sodium methoxide. Halide-ion catalyzed α-glucosidation of **44** with **14** provided disaccharide **45** in 61% yield. The 4-position of **45** was then liberated by isomerization of the allyl group to a 1-propenyl group with tris(triphenylphosphine)-rhodium(I)chloride (28), which was hydrolyzed using mercuric chloride to give alcohol **46** in 94% yield. **46** was converted into the 4-*O*-methyl derivative **47** with methyl iodide and sodium hydride (88% yield). For conversion into the 4-deoxy derivative **49**, the methyl xanthate **48** was prepared from **46** using sodium hydride, carbon disulfide, and

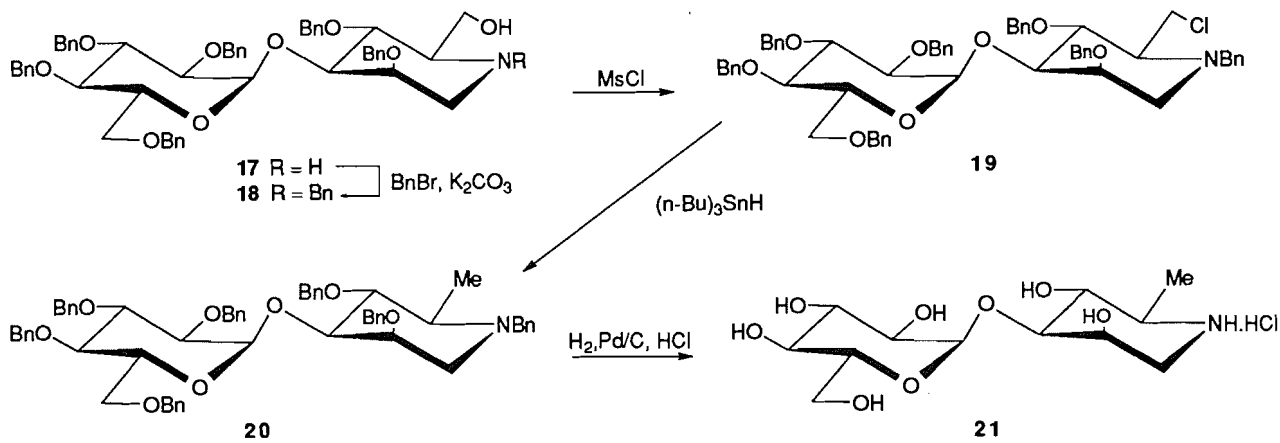
[d]NCH_2 54.94, CH_2 16.39 ppm.
[e]CO 160.66 ppm.



SCHEME 2

methyl iodide (29). This intermediate was reduced with tributyltin hydride to provide **49** in 79% yield. Saponification of the cyclic carbamate in **47** and **49** followed by catalytic hydrogenolysis of the benzyl groups then led to the 4-*O*-methyl and 4-deoxy disaccharides **52** and **53** in high yields.

NMR and conformational studies

The ^1H and ^{13}C NMR parameters for αDGlc(1→3)-1-DMJ (**9**) are reported in Tables 1 and 2 together with those for structural modifications involving changes of the 1-DMJ unit. The data are in full accord with the structural assignments. The ^1H NMR vicinal coupling constants of both units are typical for the $^4C_1$ conformation of pyranoid rings. Some flattening, though, in the DMJ-piperidine ring of the bicyclic derivative **16** may be expected.

HSEA calculations (30) predict for **9** a conformational preference with minimum energy at $\phi/\psi = -50°/-10°$. In this conformer, H-1′ is found at a close distance across the glycosidic linkage to H-3 (2.40 Å) and to O-4 (2.74 Å), while H-5′ is in nonbonded interaction to H-2 (2.27 Å). The nonbonded interaction of H-1′ to O-4 accounts for the intermediate deshielding of 0.14 ppm with respect to the chemical shift of H-1′ in the 4-deoxy congener **53** (31). NOE experiments with irradiation of H-1′ of **9** resulted in a strong intraunit enhancement of H-2′ and interunit enhancement to H-3 (Table 3, Fig. 1). Irradiation of H-2 caused an interunit NOE to H-5′, the signal of which, however, overlapped with the also enhanced H-3 signal. Relative theoretical NOE values were derived for the low-energy conformer of $\phi/\psi = -45°/-15°$ ($E = -1.7$) and provided a better agreement with the experimental data than those derived for the minimum energy conformer of $\phi/\psi = -50°/-10°$ ($E = -1.8$), particularly, with respect to the internuclear distance between H-2 and H-5′.

4-Deoxy congener **53** allowed additional NOE experi-

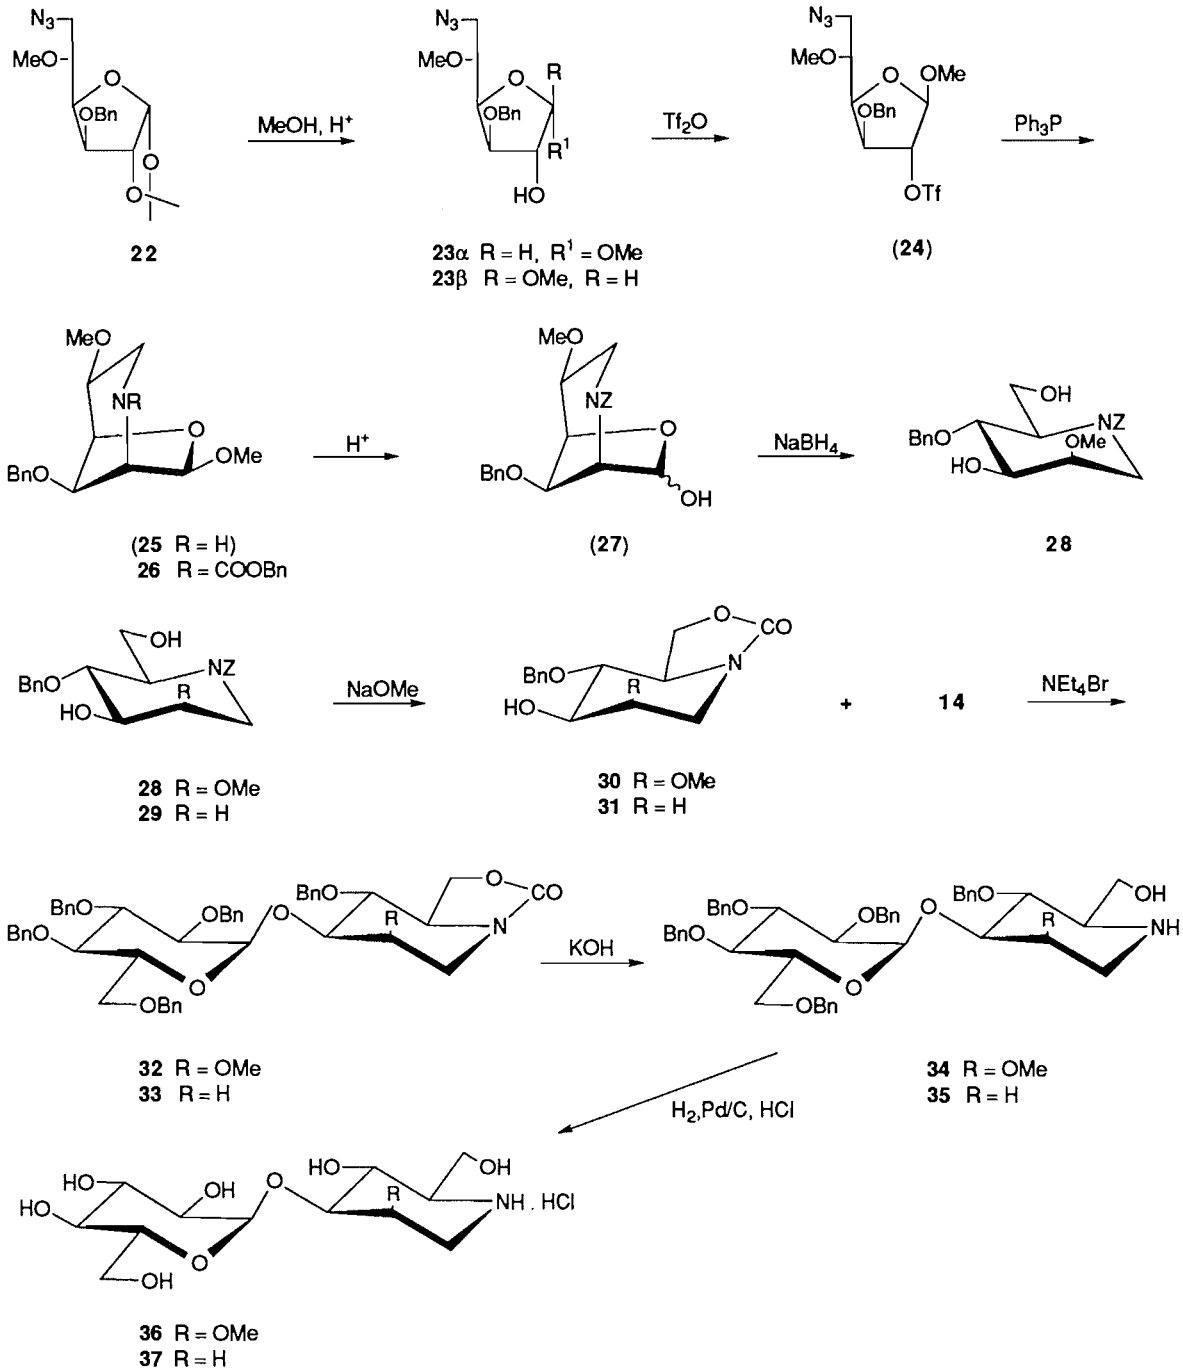

SCHEME 3

ments, since not only H-1′ and H-2, but also H-3 and H-4e provided well-separated signals in the ^{1}H NMR spectrum. HSEA calculations indicate somewhat more flexibility about the glycosidic bond and predict an energy minimum for conformations of $\phi/\psi = -55°$, $-50°/-25°$, $-20°$ ($E = -1.9$) in which H-1′ is in interunit nonbonded interaction to H-3 and H-4e, and H-5′ to H-2. Indeed, irradiation of H-1′ resulted in enhancements of H-3 and H-4e (Table 3), and, conversely, irradiation of H-3 and H-4e caused signal enhancements of H-1′ and also a smaller enhancement of H-5′ in the case of H-3. H-5′ was also enhanced when the H-2 signal was saturated. A reasonably good agreement of the experimental NOE data with the theoretical values was achieved when those were derived for the low-energy conformer of $\phi/\psi = -45°/-25°$ ($E = -1.7$), which appears to approximately represent the average internuclear proton distances of the conformers in equilibrium.

HSEA calculations for the 2-deoxy congener **37** indicate

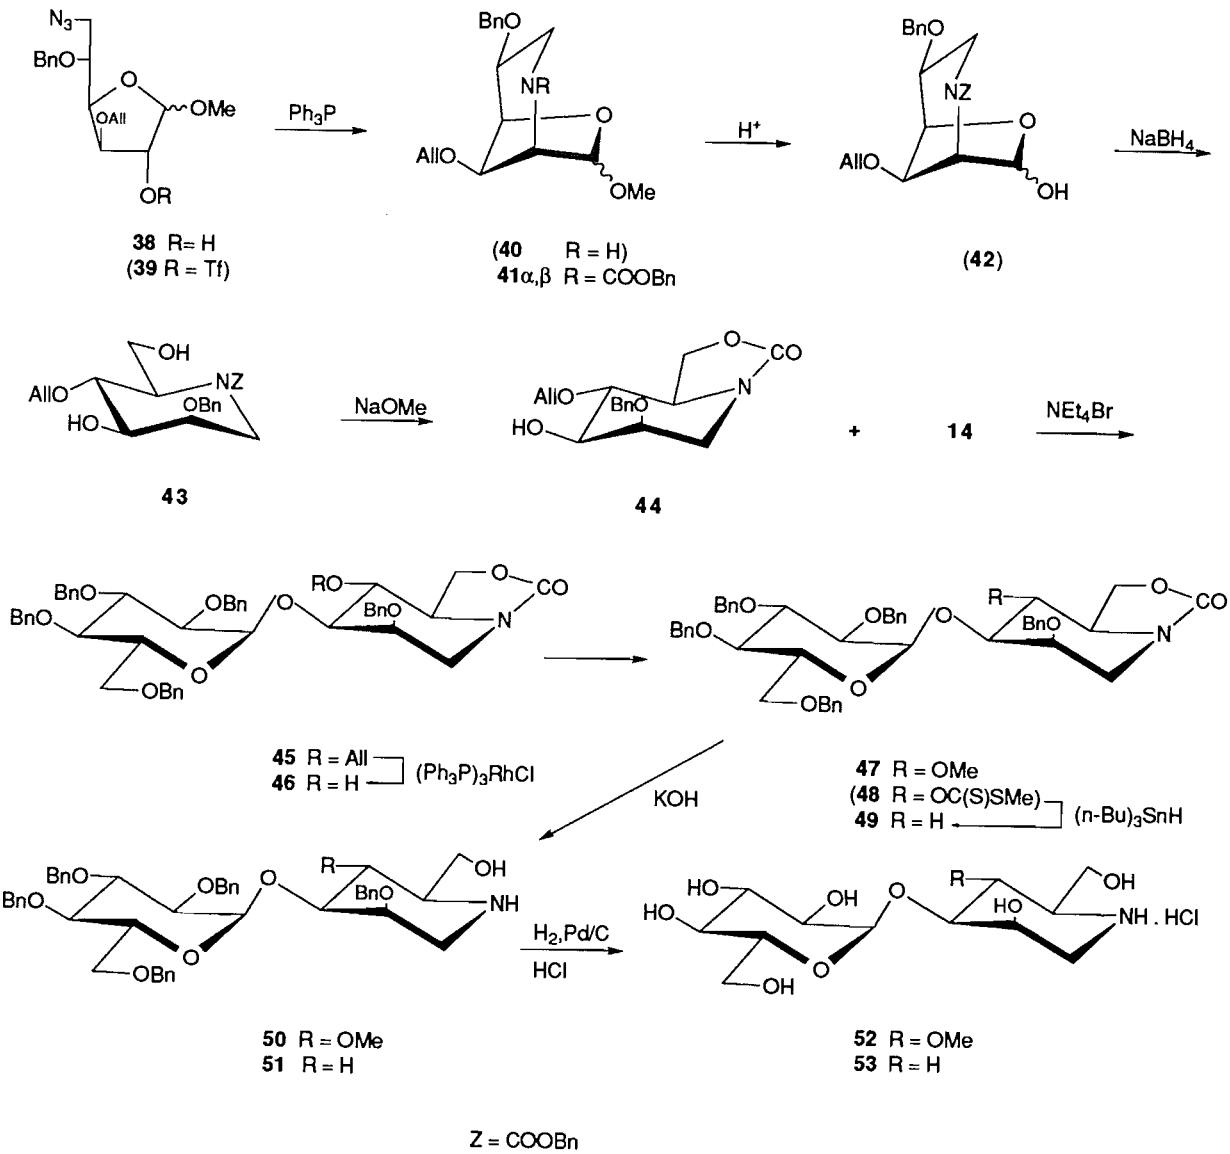

SCHEME 4

that the conformational preference of the parent compound **9** also applies to **35**, since in contrast to O-4, the axial O-2 of **9** is not involved in interunit nonbonded interactions. In fact, since none of the structural modifications, except deoxygenation of the 4-position, had marked effects on the ^1H and ^{13}C NMR chemical shift of the glucose unit (Tables 1 and 2), the interglycosidic conformational properties of **9** appear maintained in these congeners.

The biological data of this investigation (1) are discussed in the succeeding paper (32), which reports the syntheses of congeners of **9** modified in the glucose unit.

Experimental

Theoretical methods

Conformational preferences about the glycosidic torsion angles were calculated using the HSEA program (30). The calculations were done in 5° steps for the ϕ and ψ angles. The atomic coordinates were derived from neutron diffraction studies of methyl α-D-glucopyranoside and methyl α-D-mannopyranoside (33) with ω-angles of −60° and 180°, respectively. The deoxy functions were generated by bond modifications of methyl α-D-mannopyranoside using a C—H bond length of 1.10 Å. The internuclear distances provided by the HSEA calculations for a specific conformer (Table 3) were used for the determination of the theoretical nuclear Overhauser enhancements. The computer program developed by Helmut Beierbeck was used for this purpose (34).

NMR spectroscopy

The ^1H NMR spectra were measured at 300 MHz and 360 MHz (Bruker AM 300 and WM 360) with tetramethylsilane as internal standard for $CDCl_3$ solutions. Reference standard for D_2O solutions was acetone (2.225 ppm). The ^{13}C NMR spectra were recorded at 75 MHz with dioxane (67.4 ppm) as reference for D_2O solutions and the $CDCl_3$ signal (77.0 ppm) as reference in $CDCl_3$ solutions. The steady-state NOE experiments were performed at 298 K and 360 MHz with 0.05 M solutions in D_2O. Irradiation time was 5 s and the saturation of signals was achieved by multiple frequency irradiation per signal (35, 36).

General methods

Optical rotations were measured at room temperature (23 ± 1°C) in a 1-dm cell on a Perkin–Elmer 241 polarimeter. Thin-layer chromatography was performed on precoated plates of silica gel (60-F254, E. Merck, Darmstadt) and visualized by spraying with 5% sulfuric acid in ethanol followed by heating. For column chroma-

tography silica gel 60 (230–400 mesh, E. Merck, Darmstadt) and distilled solvents were used. Solvents and reagents were purified and dried according to standard procedures. Melting points are uncorrected.

6-O-Acetyl-2,4-di-O-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-D-mannitol (2)

Acetyl chloride (82 μL, 1.15 mmol) was added to a solution of diol **1** (20) (304 mg, 0.64 mmol) in dichloromethane (20 mL) and pyridine (200 μL, 2.5 mmol) at −78°C. After 1 h at this temperature, more acetyl chloride (25 μL, 0.35 mmol) was added. The reaction mixture was kept for another hour at −78°C. Then the excess of reagent was quenched by the addition of methanol (50 μL). The solution was diluted with dichloromethane, washed with water, dried, and evaporated. The crude product was purified on a column of silica gel (hexane – ethyl acetate, 3:1, 2:1) yielding crystallizing acetate **2** (249 mg, 75%). The analytical sample was recrystallized from ether – hexane; mp 69–71°C; $[\alpha]_D$ −19 (*c* 0.6, chloroform). ^{1}H NMR ($CDCl_3$, signals broad, mixture of two rotamers in the ratio ~3:2) δ: 7.4–7.1 (m, 15H, 3Ph), 5.2–5.02 (m, 2H, $COOCH_2Ph$), 4.13 (d, 1H, *J* 11.5 Hz, 1 CH_2Ph), 4.12 (d, 1H, *J* 11.5 Hz, 1 CH_2Ph), 3.86–3.6 (m, 2H, H-1, H-1′), 3.18–3.00 (m, 1H, H-5), 2.35–2.26 (m, 1H, OH), 1.92 and 1.77 (2s, 3H, CH_3CO). ^{13}C NMR ($CDCl_3$, δ for minor rotamer in parentheses) δ: 75.98 (74.81) (C-4),[3] 72.20 (C-2)$^+$, 71.35 (2 CH_2Ph), 68.04 (C-3)$^+$, 67.34 ($COOCH_2Ph$), 61.09 (C-6), 52.18 (51.41) (C-5), (37.43), 36.88 (C-1). Anal. calcd. for $C_{30}H_{33}O_7$: C 69.35, H 6.40, N 2.70; found: 69.55, H 6.58, N 2.66.

2,3,4,6-Tetra-O-benzyl-α-D-glucopyranosyl chloride (3) (22)

Oxalyl chloride (160 μL, 1.83 mmol) was added to a stirred solution of 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose (740 mg, 1.37 mmol) and *N*,*N*-dimethylformamide (150 μL, 2.11 mmol) in dichloromethane (15 mL). The mixture was stirred for 20 min and then poured into ice-water. The organic solution was washed with ice-water, dried, and evaporated to provide chloride **3** (quant.) as a syrup.

6-O-Acetyl-2,4-di-O-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-D-mannitol (4) and -β-D-glucopyranosyl)-D-mannitol (5)

A solution of chloride **3** (7.92 mmol) in dichloromethane (12 mL) was added at −78°C to a stirred mixture of alcohol **2** (2.0 g, 3.85 mmol), silver trifluoromethanesulfonate (2.31 g, 8.99 mmol), *sym*-collidine (418 μL, 3.16 mmol), and 4 Å molecular sieves (1.5 g) in dichloromethane (5.0 mL). The temperature was gradually raised to −10°C and after 2 h at this temperature, *sym*-collidine (630 μL, 4.97 mmol) was added. The mixture was filtered through Celite, the organic solution was washed with aqueous saturated sodium hydrogen carbonate and water, followed by evaporation. Two column chromatographic separations on silica gel (hexane – ethyl

[3]Tentative assignments are marked with +.

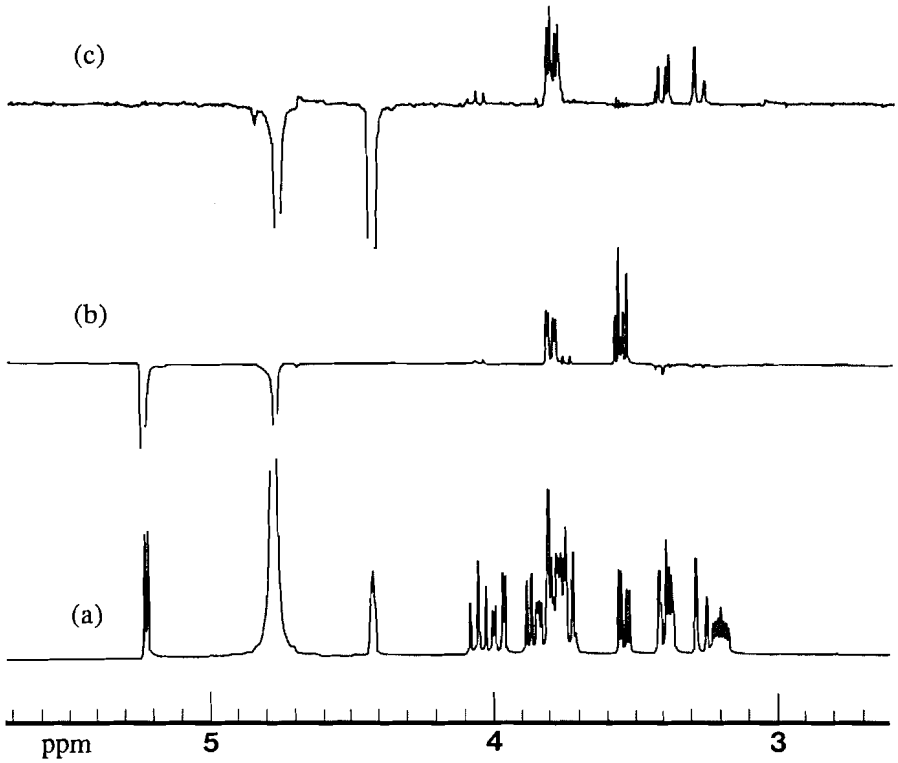

FIG. 1. NOE difference spectra for disaccharide **9**; (*a*) reference spectrum; (*b*) irradiation of H-1′; (*c*) irradiation of H-2.

acetate, 6:1, 5:1) provided the β-isomer **5** (0.774 g, 19%) as a tough syrup; $[\alpha]_D$ +5 (*c* 0.2, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.4–7.0 (m, 35H, 7Ph), 5.2–3.1 (complex m, 29H), 1.89 and 1.81 (2s, 3H, CH_3CO). Anal. calcd. for $C_{64}H_{67}NO_{12}$: C 73.76, H 6.48, N 1.34; found: C 74.18, H 7.06, N 1.34. Continued elution of the column provided the α-isomer **4** (2.64 g, 66%) as a tough syrup; $[\alpha]_D$ +33 (*c* 0.4, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.40–7.00 (m, 35H, 7Ph), 5.2–2.95 (complex m, 29H), 1.83 and 1.76 (2s, 3H, CH_3CO). Anal. calcd. for $C_{64}H_{67}NO_{12}$: C 73.76, H 6.48, N 1.34; found: C 73.62, H 6.44, N 1.34.

*2,4-Di-*O*-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-D-mannitol (6) and -β-D-glucopyranosyl)-D-mannitol (7)*

(*a*) A solution of compound **4** (1.37 g, 1.31 mmol) in methanol (48 mL), triethylamine (20 mL), and water (9.6 mL) was kept at room temperature for 7 days. It was evaporated and the crude product purified on a column of silica gel (hexane – ethyl acetate, 4:1 to 2:1) to provide, in the first fraction, acetate **4** (0.179 g, 13%). Further development gave compound **6** (0.894 g, 68%) as a tough syrup; $[\alpha]_D$ +14.6 (*c* 0.2, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers) δ: 7.4–6.95 (m, 35H, 7Ph), 5.17–2.83 (complex m, 30H). ^{13}C NMR ($CDCl_3$, δ for minor rotamer in parentheses) δ: 156.10 (CO), 99.24 ($J_{C,H}$ 168.0 Hz, C-1′), 59.14 (C-6), 53.82 (53.34) (C-5), (39.19) 38.63 (C-1). Anal. calcd. for $C_{62}H_{65}NO_{11}$: C 74.45, H 6.55, N 1.40; found: C 74.44, H 6.56, N 1.37.

(*b*) An anomeric mixture of compounds **4** and **5** (415 mg, 0.40 mmol) was deacetylated as described under (*a*). Chromatographic separation on a column of silica gel (hexane – ethyl acetate, 4:1, 3:1) provided, in the first main fraction, the α-isomer **6** (230 mg, 58%). Continued elution provided the β-isomer **7** (51 mg, 13%) as a tough syrup; $[\alpha]_D$ −10.4 (*c* 0.2, chloroform). ^{1}H NMR ($CDCl_3$, mixture of two rotamers, broad) δ: 7.4–7.0 (m, 35H, 7Ph), 5.0–3.1 (complex m, 30H). ^{13}C NMR ($CDCl_3$, δ for minor isomer in parentheses) δ: 156.1 (CO), 105.68 ($J_{C,H}$ 160.5, C-1′), 59.68 (59.53) (C-6), 54.83 (54.50) (C-5), (39.49) 39.04 (C-1). Anal. calcd. for $C_{62}H_{65}NO_{11}$: C 74.45, H 6.55, N 1.40; found: C 74.53, H 6.54, N 1.40.

*2,4-Di-*O*-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-6-*O*-methyl-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-D-mannitol (8)*

Methyl iodide (172 μL, 2.76 mmol) was added to a stirred mixture of **6** (150 mg, 0.15 mmol) and silver oxide (320 mg, 1.38 mmol) in toluene (5 mL) at 0°C. After 3 h, the temperature was raised to room temperature and stirring continued for 5 days. More methyl iodide (120 μL, 1.93 mmol) was added, followed by stirring for another day. The solids were removed by filtration and the solvent was evaporated. The remainder was applied to a column of silica gel (hexane–dichloromethane – ethyl acetate, 5:1:1) to provide **8** (137.6 mg, 91%) as a tough syrup; $[\alpha]_D$ +37 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers) δ: 7.4–7.0 (m, 35H, 7Ph), 5.2–2.9 (complex m, 32H), 3.11 and 3.04 (2s, 3H, CH_3O). Anal. calcd. for $C_{63}H_{67}NO_{11}$: C 74.61, H 6.66, N 1.38; found: C 74.66, H 6.56, N 1.45.

*1,5-Dideoxy-3-*O*-(α-D-glucopyranosyl)-1,5-imino-D-mannitol-hydrochloride (9)*

A mixture of compound **6** (369 mg, 0.37 mmol), 5% palladium-on-carbon (370 mg), methanolic 0.12 N hydrochloric acid (3.8 mL, 0.46 mmol), and methanol (20 mL) was hydrogenated in a hydrogen stream for 1.5 h. The catalyst was removed by filtration and it was codistilled a few times with water. The product was passed through a column of Sephadex LH 20 (ethanol–water, 1:1) and obtained as a white, hygroscopic solid (125 mg, 96%) after freeze-drying its aqueous solution; $[\alpha]_D$ +62.5 (*c* 0.24, water). The ^{1}H and ^{13}C NMR data are reported in Tables 1 and 2. Likewise, **17** can be debenzylated to **9**.

*1,5-Dideoxy-3-*O*-(α-D-glucopyranosyl)-1,5-imino-6-*O*-methyl-D-mannitol-hydrochloride (10)*

A mixture of **8** (159 mg, 0.157 mmol), 5% palladium-on-carbon (112 mg), and methanolic 0.12 N hydrochloric acid (1.65 mL,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12

For personal use only.

0.19 mmol) in methanol (7 mL) was hydrogenated in the hydrogen stream for 2 h. Further processing as described for the preparation of **9** provided the title compound **10** (59 mg, 100%) as a white solid; $[\alpha]_D$ +75.2 (*c* 0.5, water). The ^{1}H and ^{13}C NMR data are reported in Tables 1 and 2.

*1,5-Dideoxy-3-*O*-(α-D-glucopyranosyl)-1,5-imino-*N*-methyl-D-mannitol-hydrochloride (**11**)*

A mixture of **9** (30.8 mg, 0.085 mmol), palladium black (8 mg), methanolic 0.1 N sodium methoxide (851.5 μL), and 37% formaldehyde solution (40 μL, 0.49 mmol) in methanol (2.2 mL) was hydrogenated in the hydrogen stream for 1 day. Then more palladium black (5 mg) and 37% formaldehyde solution (40 μL, 0.49 mmol) were added and hydrogenation continued for another day. The catalyst was removed by filtration and the solution neutralized with methanolic 0.12 N hydrochloric acid (710 μL, 0.085 mmol). It was evaporated and the remainder applied to a column of Sephadex LH 20 (ethanol–water, 1:1). Freeze-drying an aqueous solution of the resultant material provided **11** (27.7 mg, 87%) as a solid; $[\alpha]_D$ +64 (*c* 0.5, water). The ^{1}H and ^{13}C NMR data are reported in Tables 1 and 2.

*1,5-Dideoxy-3-*O*-(α-D-glucopyranosyl)-1,5-imino-*N*-n-propyl-D-mannitol-hydrochloride (**12**)*

Sodium cyanoborohydride (12.8 mg, 0.20 mmol) was added to a stirred mixture of **9** (49.6 mg, 0.14 mmol) and propionaldehyde (56.6 μL, 0.79 mmol) in methanol (2 mL) at room temperature. After 2 h, the solvent was evaporated to provide a milky residue which was applied to a column of Iatrobeads® (chloroform–methanol–water, 65:35:8). The resultant material was dissolved in methanol (1 mL) and methanolic 0.12 N hydrochloric acid solution (1.15 mL, 0.14 mmol) was added, followed by evaporation and codistillation with water. Subsequent gel filtration on a column of Sephadex LH 20 (ethanol–water, 1:1) provided **12** (51 mg, 101%) as a white solid; $[\alpha]_D$ +51.4 (*c* 0.5, water). The ^{1}H and ^{13}C NMR data are reported in Tables 1 and 2.

*2,4-Di-*O*-benzyl-*N*,6-*O*-carbonyl-1,5-dideoxy-1,5-imino-D-mannitol (**13**)*

A solution of **1** (300 mg, 0.63 mmol) in methanolic 0.5 N sodium methoxide (3 mL) was kept at room temperature for 15 h. The solution was made neutral with Amberlite IRC 50 (H^+), filtered, and evaporated. The resulting product was applied to a column of silica gel (dichloromethane – ethyl acetate 4:1, 3:1) to provide **13** (210 mg, 91%) as a white foam; $[\alpha]_D$ +5.9 (*c* 0.4, chloroform). IR ($CHCl_3$): 1755 (CO) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.40–7.25 (m, 10H, 2Ph), 5.03, 4.86, 4.61, 4.37 (2ABq, each 2H, $J_{A,B}$ 11.5 Hz, 2CH_2Ph), 4.33 (dd, 1H, $J_{6A,6B}$ 8.5 Hz, $J_{6A,5}$ 7.2 Hz, H-6A), 4.26 (dd, 1H, $J_{1A,1B}$ 14.0 Hz, $J_{1A,2}$ 2.5 Hz, H-1A), 4.03 (dd, 1H, $J_{6B,5}$ 3.0 Hz, H-6B), 3.83 (m, 1H, H-2), 3.70 (bdd, 1H, H-3), 3.59 (t, 1H, $J_{4,5} \sim J_{3,4}$ 9.0 Hz, H-4), 3.51 (m, 1H, H-5), 2.92 (dd, 1H, $J_{1B,2}$ 1.5 Hz, H-1B), 2.48 (bs, 1H, OH). Anal. calcd. for $C_{21}H_{23}NO_5$: C 68.28, H 6.28, N 3.79; found: C 67.98, H 6.21, N 3.77.

*2,3,4,6-Tetra-*O*-benzyl-α-D-glucopyranosyl bromide (**14**) (21)*

Oxalyl bromide (200 μL, ~1.85 mmol) was added to a stirred solution of 2,3,4,6-tetra-*O*-benzyl-D-glucopyranose (800 mg, 1.48 mmol) in dichloromethane (10 mL) and *N,N*-dimethylformamide (500 μL, 7.0 mmol). After 20 min at room temperature, the mixture was poured into ice-water and the organic solution was washed twice with ice-cold water, dried, and evaporated to provide **14** (quant.) as a syrup.

*2,4-Di-*O*-benzyl-*N*,6-*O*-carbonyl-1,5-dideoxy-1,5-imino-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-D-mannitol (**15**)*

(*a*) A solution of bromide **14** (1.48 mmol) in dichloromethane (2 mL) was transferred into a mixture of alcohol **13** (190 mg, 0.51 mmol), tetraethylammonium bromide (220 mg, 1.05 mmol), *N,N*-dimethylformamide (700 μL), and 4 Å molecular sieves (powdered, 0.5 g) in dichloromethane (1.5 mL). After stirring for 4 days, the reaction was quenched by the addition of methanol (300 μL) and stirring continued for 1 h. The mixture was diluted with dichloromethane, filtered through a pad of Celite, and the solution washed with aqueous sodium bicarbonate and water, followed by drying and evaporation. Purification was achieved by two column chromatographic separations on silica gel (hexane – ethyl acetate, 4:1 to 1:1 and hexane–dichloromethane – ethyl acetate, 5:2:1) to provide **15** (276 mg, 60%) as a slowly crystallizing syrup; $[\alpha]_D$ +15.6 (*c* 0.4, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.4–7.1 (m, 30H, 6Ph), 5.05 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.24 (t, 1H, $J_{5,6A} \sim J_{6A,6B}$ 8.5 Hz, H-6A), 4.15 (dd, 1H, $J_{1A,1B}$ 14.5 Hz, $J_{1A,2}$ 2.2 Hz, H-1A), 3.82 (dd, 1H, $J_{6B,5}$ 3.5 Hz, H-6B), 2.78 (bd, 1H, $J_{1B,2} < 1$ Hz, H-1B). ^{13}C NMR ($CDCl_3$) δ: 157.5 (CO), 100.29 (C-1′), 65.76 (C-6), 57.45 (C-5), 40.82 (C-1). Anal. calcd. for $C_{55}H_{57}NO_{10}$: C 74.05, H 6.44, N 1.57; found: C 74.36, H 6.68, N 1.63.

(*b*) A solution of **4** (190 mg, 0.18 mmol) in methanolic 0.5 N sodium methoxide (1.1 mL) was kept at room temperature for 20 h. The solution was made neutral with Amberlite IRC 50 (H^+), filtered, and evaporated. Chromatographic purification of the remainder on a column of silica gel (hexane – ethyl acetate, 2:1, 1:1) provided a product identical to **15** (132 mg, 81%).

*N,6-O-Carbonyl-1,5-dideoxy-3-*O*-(α-D-glucopyranosyl)-1,5-imino-D-mannitol (**16**)*

A mixture of **15** (125 mg, 0.140 mmol) and 5% palladium-on-carbon (70 mg) in 95% ethanol (4 mL) was hydrogenated in a hydrogen stream for 1.5 h. The catalyst was removed by filtration, followed by evaporation of the solvent. Freeze-drying an aqueous solution provided **16** (50 mg, 102%) as a white solid; $[\alpha]_D$ +70.5 (*c* 0.4, water). The ^{1}H and ^{13}C NMR data are reported in Tables 1 and 2.

*2,4-Di-*O*-benzyl-1,5-dideoxy-1,5-imino-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-D-mannitol (**17**)*

A mixture of **15** (527 mg, 0.59 mmol) in 5% potassium hydroxide in 90% ethanol (15 mL) was heated at 80°C for 4 h. It was neutralized with acetic acid, followed by solvent removal. The material was taken up in dichloromethane and the solution was washed with a little water, dried, and evaporated to provide **17** as a tough syrup (488 mg, 95%). An analytical sample was purified by column chromatography on silica gel (dichloromethane – 3% methanol). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 30H, 6Ph), 5.00 (bs, 1H, H-1′), 4.04 (overlapped, H-3′), 3.88 (m, H-2), 3.53 (dd, 1H, $J_{2',1'}$ 3.5 Hz, $J_{2',3'}$ 9.5 Hz, H-2′), 3.12 (dd, 1H, $J_{1A,1B}$ 13.5 Hz, $J_{1A,2}$ 4.0 Hz, H-1A), 2.59 (bd, 1H, H-1B).

*N-Benzyl-2,4-di-*O*-benzyl-1,5-dideoxy-1,5-imino-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-D-mannitol (**18**)*

A mixture of **17** (461 mg, 0.53 mmol), potassium carbonate (50 mg, 0.36 mmol), and benzyl bromide (166 μL, 1.40 mmol) in *N,N*-dimethylformamide (5 mL) was stirred for 2 h at 18°C. The solids were removed by filtration and the solution was concentrated. Column chromatography of the crude product on silica gel (hexane – ethyl acetate, 4:1) provided **18** (480 mg, 94%); $[\alpha]_D$ +38 (*c* 1.3, chloroform). ^{13}C NMR ($CDCl_3$) δ: 98.97 (C-1′), 60.89 (C-5), 58.54, 58.22 (C-1, C-6), 46.63 (NCH_2Ph). Anal. calcd. for $C_{61}H_{65}NO_9$: C 76.62, H 6.85, N 1.47; found: C 76.38, H 6.93, N 1.55.

*N-Benzyl-2,4-di-*O*-benzyl-6-chloro-1,5,6-trideoxy-1,5-imino-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-D-mannitol (**19**)*

Methanesulfonyl chloride (50 μL, 0.65 mmol) was added to a solution of **18** (336 mg, 0.35 mmol) in pyridine (5 mL). After 40 min at 22°C, the mixture was heated at 50°C for 1 h. Then it was poured into ice-water and extracted with dichloromethane, followed by washing of the organic solution with water, drying, and evaporation. The resultant material was applied to a column of silica gel (hexane – ethyl acetate, 4:1) to provide **19** (275 mg, 80%) as a tough syrup; $[\alpha]_D$ +31 (*c* 0.7, chloroform). ^{1}H NMR ($CDCl_3$, broad signals) δ: 7.45–7.05 (m, 35H, 7Ph), 4.90 (overlapped, H-1′), 4.11 (m, 1H, $J_{4',5'}$ 9.5 Hz, H-5′), 4.03 (overlapped, H-3′),

3.88 (overlapped, H-2), 3.60 (t, 1H, $J_{3',4'}$ 9.5 Hz, H-4'), 3.49 (dd, 1H, $J_{1',2'}$ 3.5 Hz, $J_{2',3'}$ 9.5 Hz, H-2'), 3.36 (dd, 1H, $J_{6A',6B'}$ 10.5 Hz, $J_{6A',5'}$ 3.0 Hz, H-6A'), 3.22 (bd, 1H, H-6B'), 2.99 (dd, 1H, $J_{1A,2}$ 6.5 Hz, $J_{1A,1B}$ 12.5 Hz, H-1A), 2.26 (bd, 1H, H-1B). ^{13}C NMR ($CDCl_3$) δ: 98.51 (C-1'), 57.49 (C-1), 47.51 (NCH_2Ph), 42.02 (C-6). Anal. calcd. for $C_{61}H_{64}ClNO_8$: C 75.17, H 6.62, Cl 3.64, N 1.44; found: C 75.07, H 6.60, Cl 4.19, N 1.51.

N-Benzyl-2,4-di-O-benzyl-1,5,6-trideoxy-1,5-imino-3-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-D-mannitol (20)

The chloro compound **19** (254 mg, 0.26 mmol), tributyltin hydride (420 μL, 1.56 mmol), and 2,2'-azobis(isobutyronitrile) (15 mg) in toluene (10 mL) were heated at 95–100°C for 3 h. Evaporation, followed by two column chromatographic purifications on silica gel (toluene – ethyl acetate, 20:1, hexane – ethyl acetate, 6:1) provided **20** (155 mg, 63%); $[\alpha]_D$ +11.3 (*c* 0.2, chloroform). ^{1}H NMR ($CDCl_3$, signals broad) δ: 7.40–7.05 (m, 35H, 7Ph), 5.03 (bs, 1H, H-1'), ~4.09 (m, overlapped, H-3'), 3.50 (dd, 1H, $J_{1',2'}$ 3.5 Hz, $J_{2',3'}$ 9.5 Hz, H-2'), 3.40 (bdd, 1H, $J_{6A',6B'}$ 10.5 Hz, H-6A'), 3.29 (bd, 1H, H-6B'), 1.30 (bd, 3H, $J_{5,6}$ 5.5 Hz, H_3-6). Anal. calcd. for $C_{61}H_{65}NO_8$: C 77.93, H 6.97, N 1.49; found: C 77.93, H 6.82, N 1.46.

1,5,6-Trideoxy-3-O-(α-D-glucopyranosyl)-1,5-imino-D-mannitol-hydrochloride (21)

A mixture of **20** (143 mg, 0.15 mmol), 5% palladium-on-carbon (143 mg), and methanolic 0.12 N hydrochloric acid (1.5 mL, 0.18 mmol) in methanol (5 mL) was hydrogenated in the hydrogen stream for 2 h. Usual processing followed by gel filtration (Sephadex LH 20, ethanol–water, 1:1) provided **21** (52 mg, 99%) as a white powder after freeze-drying an aqueous solution; $[\alpha]_D$ +71 (*c* 0.4, water). The ^{1}H and ^{13}C NMR data are reported in Tables 1 and 2.

6-Azido-3-O-benzyl-6-deoxy-5-O-methyl-1,2-O-isopropylidene-α-D-glucofuranose (22)

Sodium hydride (50% oily suspension, 4.81 g, 0.1 mol) was added slowly to a stirring solution of 6-azido-3-*O*-benzyl-6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose (25) (26 g, 0.077 mol) at ice-bath temperature. After 20 min, methyl iodide (9 mL, 0.097 mol) was added and stirring continued for 30 min at ice-bath temperature, then another 30 min at room temperature. The reaction was quenched by the careful addition of methanol at 0°C, followed by evaporation of the solvent. The remainder was taken up in dichloromethane and the organic solution was washed with water, dried, and concentrated. Column chromatographic purification of the crude product on silica gel (hexane – ethyl acetate, 7.5:1) provided **22** (24.2 g, 89%) as an oil; $[\alpha]_D$ −65 (*c* 0.9, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.45–7.25 (m, 5H, Ph), 5.88 (d, 1H, $J_{1,2}$ 4.0 Hz, H-1), 4.69 and 4.55 (ABq, 2H, $J_{A,B}$ 11.5 Hz, CH_2Ph), 4.61 (d, 1H, H-2), 4.19 (dd, 1H, $J_{3,4}$ 2.8 Hz, $J_{4,5}$ 8.5 Hz, H-4), 4.08 (d, 1H, H-3), 3.74 (m, 1H, H-5), 3.68 (dd, 1H, $J_{6,6'}$ 12.5 Hz, $J_{6,5}$ 2.5 Hz, H-6), 3.40 (s, 3H, CH_3O), 3.38 (dd, 1H, $J_{5,6'}$ 4.5 Hz, H-6'), 1.50 and 1.32 (2s, each 3H, $(CH_3)_2C$). Anal. calcd. for $C_{17}H_{23}N_3O_5$: C 58.44, H 6.63, N 12.03; found: C 58.40, H 6.63, N 11.87.

Methyl 6-azido-3-O-benzyl-6-deoxy-5-O-methyl-α- and -β-D-glucofuranoside (23α, 23β)

A solution of **22** (24 g, 0.068 mol) in methanolic 1 N hydrochloric acid (220 mL) was kept overnight at room temperature. It was neutralized with sodium hydrogen carbonate and evaporated. The remainder was taken up in dichloromethane, followed by washing of the organic solution with water, drying, and evaporation. Column chromatographic purification on silica gel (hexane – ethyl acetate, 3.5:1) provided in the first fraction the α-anomer **23α** (5.24 g, 24%) as an oil; $[\alpha]_D$ +41.4 (*c* 0.4, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.25 (m, 5H, Ph), 5.01 (d, 1H, $J_{1,2}$ 4.5 Hz, H-1), 4.74 and 4.58 (ABq, 2H, $J_{A,B}$ 11.5 Hz, CH_2Ph), 4.23 (m, 1H, H-2), 4.21 (dd, 1H, $J_{3,4}$ 4.5 Hz, $J_{4,5}$ 7.5 Hz, H-4), 4.03 (dd, 1H, $J_{2,3}$ 2.2 Hz, H-3), 3.70 (m, 1H, H-5), 3.64 (dd, 1H, $J_{5,6A}$ 2.5 Hz, $J_{6A,6B}$ 13.0 Hz, H-6A), 3.49 and 3.40 (2s, each 3H, $2CH_3O$), 3.37 (dd, 1H, $J_{5,6B}$ 4.5 Hz, H-6B), 2.84 (d, 1H, $J_{2,OH}$ 5.5 Hz, OH). Anal. calcd. for $C_{15}H_{21}N_3O_5$: C 55.72, H 6.55, N 12.99; found: C 55.65, H 6.59, N 12.82. Continued elution provided an α,β mixture of **23** (3.31 g, 15%) and finally the pure β anomer **23β** (10.9 g, 49%, total yield 88%) as an oil; $[\alpha]_D$ −71 (*c* 0.4, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.25 (m, 5H, Ph), 4.80 (bs, 1H, $J_{1,2}$ ~ 1 Hz, H-1), 4.67 and 4.62 (ABq, 2H, $J_{A,B}$ 12.0 Hz, CH_2Ph), 4.30 (dd, 1H, $J_{3,4}$ 4.7 Hz, $J_{4,5}$ 8.5 Hz, H-4), 4.20 (bs, 1H, H-2), 3.97 (dd, 1H, $J_{2,3}$ 1.6 Hz, H-3), 3.76 (m, 1H, H-5), 3.73 (dd, 1H, $J_{6A,6B}$ 13.0 Hz, $J_{5,6A}$ 2.5 Hz, H-6A), 3.40 (dd, overlapped, $J_{5,6B}$ 4.5 Hz, H-6B), 3.394 and 3.390 (2s, each 3H, $2CH_3O$), 1.67 (d, 1H, $J_{2,OH}$ 3.5 Hz, OH). Anal. calcd. for $C_{15}H_{21}N_3O_5$: C 55.72, H 6.55, N 12.99; found: C 55.73; H 6.27, N 12.88.

Methyl 3-O-benzyl-N-benzyloxycarbonyl-2,6-dideoxy-2,6-imino-5-O-methyl-β-D-glucofuranoside (26)

Trifluoromethanesulfonic anhydride (4.1 mL, 24.4 mmol) was added at −50°C to a stirred solution of **23β** (5.34 g, 16.5 mmol) and pyridine (6 mL, 74.2 mmol) in dichloromethane (100 mL). After 1 h, another portion of the anhydride (1.5 mL, 8.9 mmol) was added and stirring continued for 30 more min at −50°C. The mixture was poured into ice-water, followed by extraction with dichloromethane, washing of the organic solution with water, drying, and evaporation. The remainder (**24**) was taken up in dichloromethane (51 mL) and reduced with triphenylphosphine (5 g, 19 mmol) by refluxing for 2 h. The mixture was allowed to reach room temperature and a solution of saturated aqueous potassium carbonate (10 mL) was added, followed by vigorous stirring overnight. The organic layer was separated, washed with water and evaporated. The resulting product (**25**) was taken up in ether (63 mL). Saturated aqueous sodium hydrogen carbonate (42 mL) and benzyl chloroformate (3.25 mL, 22.8 mmol) were added with vigorous stirring. After 30 min, the organic layer was separated, washed with water, dried, and evaporated. The crude product was applied to a column of silica gel and eluted with hexane-ethyl acetate, 3:1, 2:1 to afford pure **26** (4.6 g, 68%) as a tough syrup; $[\alpha]_D$ −68 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$, duplication of signals due to rotamers, a:b ~ 4:1) δ: 7.40–7.15 (m, 10H, 2Ph), 5.10 (d, overlapped, $J_{1,2}$ 3.0 Hz, H-1a), 5.05 (d, 1H, $J_{1,2}$ 3.0 Hz, H-1b), 4.89 (t, 1H,$J_{2,3}$ 3.5 Hz, H-2a), 4.68 (t, overlapped, $J_{2,3}$ 3.5 Hz, H-2b), 4.46 (dd, 1H, *J* 7.0 and 12.5 Hz, H-5b), 4.40 (overlapped, H-4a), 4.39 (overlapped, H-4b), 4.29 (dd, 1H, *J* 7.0 and 12.0 Hz, H-5a), 4.07 (dd, 1H, H-3a), 3.98 (dd, 1H, H-3b), 3.68–3.60 (m, H-6a, H-6b), 3.494, 3.489 (2s, each 3H, CH_3O-a, CH_3O-b), 3.37, 3.34 (2s, each 3H, CH_3O-a, CH_3O-b), 3.36–3.26 (m, 2H, H-6'a, H-6'b). Anal. calcd. for $C_{23}H_{27}NO_6$: C 66.81, H 6.58, N 3.39; found: C 66.82, H 6.78, N 3.37.

4-O-Benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-2-O-methyl-D-mannitol (28)

A mixture of **26** (2.1 g, 5.07 mmol), dioxane (21.5 mL), trifluoroacetic acid (11 mL), and water (11 mL) was stirred for 3.5 h. Then a solution of sodium acetate (3.6 g) in water (53 mL) was added. The product was extracted with dichloromethane, followed by drying and evaporation of the organic solution. The resultant material (**27**) was dissolved in 95% ethanol (25 mL) and a suspension of sodium borohydride (600 mg, 15.9 mmol) in 50% ethanol (4 mL) was added at 0°C. After stirring for 30 min at room temperature, the reaction was quenched by the addition of ammonium chloride followed by evaporation. The remainder was extracted with dichloromethane, the organic solution was washed with a little water, dried, and evaporated. The reaction product was purified on a column of silica gel (dichloromethane – ethyl acetate, 1:1, 1:2, 1:3, 0:1) to afford **28** (1.044 g, 51%); $[\alpha]_D$ −36 (*c* 0.7, chloroform). Anal. calcd. for $C_{22}H_{27}NO_6$: C 65.82, H 6.78, N 3.49; found: 65.06, H 6.84, N 3.43.

4-O-Benzyl-N,6-O-carbonyl-1,5-dideoxy-1,5-imino-2-O-methyl-D-mannitol (30)

A solution of **28** (520 mg, 1.30 mmol) in methanolic 0.5 N sodium methoxide (4 mL) was kept for 2 h at room temperature. The solution was deionized with Amberlite IRC 50 (H^+), filtered, and evaporated. The remainder was applied to a column of silica gel (dichloromethane – ethyl acetate, 1:1) to afford pure **30** (308 mg, 81%) as a solid; mp 99.5–100.5°C (dichloromethane, ether, hexane); $[\alpha]_D$ +40 (*c* 0.3, chloroform). IR ($CHCl_3$): 1754 (CO) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 5H, Ph), 5.01 and 4.65 (ABq, 2H, $J_{A,B}$ 11.5 Hz, CH_2Ph), 4.30 (dd, 1H, $J_{6A,6B}$ 9.0 Hz, $J_{6A,5}$ 7.5 Hz, H-6A), 4.17 (dd, 1H, $J_{1A,1B}$ 14.5 Hz, $J_{1A,2}$ 2.0 Hz, H-1A), 3.96 (dd, 1H, $J_{6B,5}$ 3.0 Hz, H-6B), 3.68 (unres. m, 1H, H-3), 3.60 (bs, 1H, H-2), 3.54 (t, 1H, $J_{3,4} \sim J_{4,5}$ 9.5 Hz, H-4), 3.49 (m, H-5), 3.44 (s, 3H, CH_3O), 2.84 (dd, 1H, $J_{1B,2}$ 1.5 Hz, H-1B), 2.56 (bd, 1H, OH). Anal. calcd. for $C_{15}H_{19}NO_5$: C 61.42, H 6.53, N 4.78; found: C 61.17, H 6.55, N 4.75.

*4-O-Benzyl-N,6-O-carbonyl-1,2,5-trideoxy-1,5-imino-D-*arabino*-hexitol (31)*

A solution of **29** (26) (360 mg, 0.97 mmol) in methanolic 0.5 N sodium methoxide (3.5 mL) was kept at room temperature for 1.5 h. The solution was neutralized with Amberlite IRC 50 (H^+), filtered, and evaporated. Column chromatography on silica gel (dichloromethane – ethyl acetate, 1:1) afforded **31** (227 mg, 89%) as a white solid; $[\alpha]_D$ +76 (*c* 0.3, chloroform). IR ($CHCl_3$): 1794 (CO) cm^{-1}. ^1H NMR ($CDCl_3$) δ: 7.40–7.25 (m, 5H, Ph), 4.88 and 4.67 (ABq, 2H, $J_{A,B}$ 11.5 Hz, CH_2Ph), 4.29 (dd, 1H, $J_{6A,6B}$ 8.5 Hz, $J_{6A,5}$ 7.5 Hz, H-6A), 3.89 (dd, $J_{5,6B}$ 5.5 Hz, H-6B), 3.82 (ddd, 1H, $J_{1e,1a}$ 13.5 Hz, $J_{1e,2a}$ 5.5 Hz, $J_{1e,2e}$ 1.5 Hz, H-1e), 3.68 (ddd, 1H, $J_{2a,3}$ 11.5 Hz, $J_{2e,3}$ 4.5 Hz, $J_{3,4}$ 9.0 Hz, H-3), 3.50 (ddd, 1H, $J_{4,5}$ 9.0 Hz, H-5), 3.15 (t, 1H, H-4), 2.93 (bs, 1H, OH), 2.85 (dt, $J_{1a,2a}$ 13.5 Hz, $J_{1a,2e}$ 3.5 Hz, H-1a), 1.95 (m, 1H, $J_{2e,2a}$ 13.0 Hz, H-2e), 1.56 (dq, 1H, H-2a). Anal. calcd. for $C_{14}H_{17}NO_4$: C 63.87, H 6.51, N 5.32; found: C 63.88, H 6.53, N 5.26.

*4-O-Benzyl-N,6-O-carbonyl-1,5-dideoxy-1,5-imino-2-O-methyl-3-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-D-*mannitol *(32)*

A solution of bromide **14** (2.58 mmol) in dichloromethane (4 mL) was transferred into a mixture of **30** (202 mg, 0.69 mmol), tetraethylammonium bromide (300 mg, 1.43 mmol), *N,N*-dimethylformamide (0.7 mL), and 4 Å molecular sieves (powdered, 0.7 g) in dichloromethane (2 mL). After stirring for 3 days, the mixture was processed as described for the preparation of **15** with subsequent column chromatography on silica gel (hexane – ethyl acetate, 4:1 to 1:1) to afford crystalline **32** (377 mg, 67%); mp 114–115°C (dichloromethane, ether, hexane); $[\alpha]_D$ +72 (*c* 0.3, chloroform). ^1H NMR ($CDCl_3$) δ: 7.35–7.10 (m, 25H, 5Ph), 5.14–4.43 (5ABq, 10H, $5CH_2Ph$), 4.96 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 4.24 (t, 1H, $J_{6A,6B}$ 8.8 Hz, $J_{6A,5}$ 8.0 Hz, H-6A), 4.10 (overlapped, H-3'), 4.06 (dd, 1H, $J_{1A,1B}$ 14.5 Hz, $J_{1A,2}$ 2.5 Hz, H-1A), 3.84 (bs, 1H, H-2), 3.79 (dd, 1H, $J_{6B,5}$ 3.0 Hz, H-6B), 3.56 (dd, 1H, $J_{2',3'}$ 9.5 Hz, H-2'), 3.49 (m, 2H, H-3, H-5), 3.28 (s, 3H, CH_3O), 2.71 (bd, 1H, $J_{1B,2} < 1$ Hz, H-1B). ^{13}C NMR ($CDCl_3$) δ: 157.81 (CO), 100.37 (C-1'), 65.77 (C-6), 57.27 (C-5), 56.43 (CH_3O), 40.05 (C-1). Anal. calcd. for $C_{49}H_{53}NO_{10}$: C 72.13, H 6.55, N 1.72; found: C 71.78, H 6.68, N 1.76.

*4-O-Benzyl-N,6-O-carbonyl-1,2,5-trideoxy-1,5-imino-3-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-D-*arabino*-hexitol (33)*

A solution of bromide **14** (2.5 mmol) in dichloromethane (5 mL) was transferred into a mixture of **31** (197 mg, 0.75 mmol), tetraethylammonium bromide (300 mg, 1.43 mmol), *N,N*-dimethylformamide (0.7 mL), and 4 Å molecular sieves (powdered, 0.7 g), in dichloromethane (2 mL). After stirring for 3 days, the mixture was processed as described for **15** with subsequent column chromatography on silica gel (hexane – dichloromethane – ethyl acetate, 4:4:1, 3:5:1, 2:5:1.5) to provide **33** (379 mg, 65%) as a solid. The analytical sample was recrystallized from ethanol; mp 113–114°C, $[\alpha]_D$ +89 (*c* 0.8, chloroform). ^1H NMR ($CDCl_3$) δ: 7.40–7.15 (m, 25H, 5Ph), 5.08 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 5.06–4.43 (5ABq, 10H, $5CH_2Ph$), 4.23 (t, 1H, $J_{6A,6B} \sim J_{6A,5}$ 8.0 Hz, H-6A), 4.02 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3'), 3.90 (m, 1H, H-5'), 3.76 (bdd, 1H, $J_{1e,1a}$ 13.5 Hz, $J_{1e,2a}$ 4.5 Hz, $J_{1e,2e} \sim 1$ Hz, H-1e), 3.71 (dd, overlapped, H-6B), ~3.63 (overlapped, H-4'), 3.57 (dd, 1H, H-2'), 3.49 (m, 1H, H-5), 3.22 (t, 1H, $J_{3,4} \sim J_{4,5}$ 9.0 Hz, H-4), 2.78 (dt, 1H, $J_{1a,2a}$ 13.5 Hz, $J_{1a,2e}$ 2.5 Hz, H-1a), 2.25 (m, 1H, $J_{2e,2a}$ 13.0 Hz, H-2e), 1.57 (dq, 1H, H-2a). ^{13}C NMR ($CDCl_3$) δ: 156.67 (CO), 99.64 (C-1'), 65.84 (C-6), 57.17 (C-5), 38.72 (C-1), 31.10 (C-2). Anal. calcd. for $C_{48}H_{51}NO_9$: C 73.36, H 6.54, N 1.78; found: C 73.11, H 6.35, N 1.82.

4-O-Benzyl-1,5-dideoxy-1,5-imino-2-O-methyl-3-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-D-mannitol (34)

A mixture of **32** (334 mg, 0.41 mmol) in 5% potassium hydroxide in 90% ethanol (10 mL) was heated at 65°C for 4 h. It was processed as described for **17** followed by column chromatography on silica gel (dichloromethane – 5% methanol) to afford **34** (295 mg, 91%); $[\alpha]_D$ +35 (*c* 0.7, chloroform). ^1H NMR ($CDCl_3$, broad signals) δ: 7.35–7.10 (m, 25H, 5Ph), 4.98 (overlapped, H-1'), 4.15 (overlapped, H-5'), 4.09 (t, overlapped, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3'), 3.54 (dd, overlapped, H-2'), 3.27 (s, 3H, CH_3O), 3.15 (bd, 1H, $J_{1A,1B}$ 13.0 Hz, H-1A), 2.48 (H-1B).

*4-O-Benzyl-1,2,5-trideoxy-1,5-imino-3-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-D-*arabino*-hexitol (35)*

A mixture of **33** (306 mg, 0.39 mmol) and potassium hydroxide (0.5 g) in 90% ethanol (10 mL) was heated at 68°C for 1 h. It was processed as described for **17** followed by column chromatography on silica gel (dichloromethane – 5% methanol) to provide **35** (245 mg, 83%); $[\alpha]_D$ +58 (*c* 1.0, chloroform). ^1H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 25H, 5Ph), 5.12–4.42 (5ABq, 10H, $5CH_2Ph$), 5.08 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 4.04 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3'), 3.93 (m, 1H, H-5'), 3.72 (overlapped, H-6'), 3.63 (overlapped, H-4'), 3.55 (dd, 1H, H-2'), 3.02 (m, 1H, $J_{1e,1a}$ 12.5 Hz, H-1e), 2.61 (dt, 1H, $J_{1a,2a}$ 13.0 Hz, $J_{1a,2e}$ 1.5 Hz, H-1a), 2.23 (m, 1H, $J_{2a,2e}$ 13.5 Hz, H-2e), 1.59 (dq, 1H, H-2a).

1,5-Dideoxy-3-O-(α-D-glucopyranosyl)-1,5-imino-2-O-methyl-D-mannitol-hydrochloride (36)

A mixture of **34** (140 mg, 0.19 mmol), 5% palladium-on-carbon (145 mg), and methanolic 0.12 N hydrochloric acid (2 mL, 0.24 mmol) in methanol (3 mL) was hydrogenated in the hydrogen stream for 2 h. Usual processing followed by gel filtration as described for **9** provided **36** (68 mg, 98%) as a solid after freeze-drying an aqueous solution; $[\alpha]_D$ +73 (*c* 0.4, water). The ^1H and ^{13}C NMR data are reported in Tables 1 and 2.

*1,2,5-Trideoxy-3-O-(α-D-glucopyranosyl)-1,5-imino-D-*arabino*-hexitol-hydrochloride (37)*

A mixture of **35** (242 mg, 0.32 mmol), 5% palladium-on-carbon (240 mg), and methanolic 0.12 N hydrochloric acid (3.34 mL, 0.40 mmol) was hydrogenated in the hydrogen stream for 2 h. Usual work-up and gel filtration as described for **9** provided **37** (104 mg, 94%) as a white solid after freeze-drying an aqueous solution. The ^1H and ^{13}C NMR data are reported in Tables 1 and 2.

Methyl-3-O-allyl-6-azido-5-O-benzyl-6-deoxy-α- and -β-D-glucofuranoside (38)

The title compound was prepared conventionally from 3-*O*-allyl-1,2-*O*-isopropylidene-6-*O*-*p*-toluenesulfonyl-α-D-glucofuranose (27). Replacement of the *p*-toluenesulfonyloxy group by azide, benzylation of the 5-position, and subsequent methanolysis as described for **23** provided the title compound as an oil. **38** proved labile on storage. α-Anomer: ^1H NMR ($CDCl_3$) δ: 7.35–7.20 (m, 5H, Ph), 5.87 (m, 1H, $CH_2{=}CH$), 5.28 and 5.17 (2m, 2H, $CH_2{=}CH$), 5.02 (d, 1H, $J_{1,2}$ 4.5 Hz, H-1), 4.71 and 4.59 (ABq, 2H, $J_{A,B}$ 11.5 Hz, CH_2Ph), 4.26 (dd, 1H, $J_{3,4}$ 4.0 Hz, H-4), 4.22–4.15 (m, 2H, H-2, $1CH_2CH{=}CH_2$), 4.00–3.92 (m, 3H, H-3, H-5, $1CH_2CH{=}CH_2$), 3.62 (dd, 1H, $J_{6A,6B}$ 13.5 Hz, $J_{6A,5}$ 2.5 Hz, H-6A),

3.49 (s, 3H, CH_3O), 3.41 (dd, 1H, $J_{5,6B}$ 5.0 Hz, H-6B). β-Anomer: ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 5H, Ph), 5.88 (m, 1H, CH_2=C*H*), 5.27 and 5.18 (2m, 2H, CH_2=CH), 4.82 (d, 1H, $J_{1,2} \sim 1$ Hz, H-1), 4.72 and 4.60 (ABq, 2H, $J_{A,B}$ 11.0 Hz, CH_2Ph), 4.37 (dd, 1H, $J_{3,4}$ 5.2 Hz, $J_{4,5}$ 8.5 Hz, H-4), 4.21 (bs, 1H, H-2), 4.11 and 4.03 (2m, 2H, CH_2CH=CH_2), 4.02 (m, overlapped, H-5), 3.92 (dd, 1H, $J_{3,2}$ 1.2 Hz, H-3), 3.69 (dd, 1H, $J_{6A,6B}$ 13.0 Hz, $J_{6A,5}$ 2.5 Hz, H-6A), 3.42 (dd, 1H, $J_{6B,5}$ 4.5 Hz, H-6B), 3.40 (s, 3H, CH_3O).

*Methyl 3-*O*-allyl-5-*O*-benzyl-*N*-benzyloxycarbonyl-2,6-dideoxy-2,6-imino-α- and -β-*D*-glucofuranoside (**41**α,β)*

Trifluoromethanesulfonic anhydride (2.6 mL, 15.45 mmol) was added at −50 to −40°C to a solution of **38** (3.66 g, 10.5 mmol) and pyridine (3.6 mL, 44.5 mmol) in dichloromethane (70 mL). After 40 min at this temperature, it was processed as described for **26**. The resultant material (**39**) was dissolved in dichloromethane (40 mL) and reduced with triphenylphosphine (3.3 g, 12.6 mmol) for 20 min at room temperature and then for 2 h at reflux temperature. The mixture was allowed to reach room temperature and was vigorously stirred after the addition of saturated aqueous potassium carbonate (10 mL). After 12 h, the organic layer was separated, washed with water, and evaporated. A mixture of the resulting product (**40**), saturated aqueous sodium hydrogen carbonate (30 mL), and benzylchloroformate (2 mL, 14.0 mmol) in ether (45 mL) was vigorously stirred for 20 min. The organic layer was separated, washed with water, and evaporated, followed by column chromatography on silica gel (hexane – ethyl acetate, 3:1) to provide in the first fraction the α-anomer **41**α (330 mg, 7.2%); $[\alpha]_D$ +40 (*c* 0.9, chloroform). ^{1}H NMR ($CDCl_3$, mixture of two rotamers) δ: 7.40–7.15 (m, 10H, 2Ph), 5.83–5.66 (m, 1H, CH_2=C*H*), 4.27 (dd, overlapped, $J_{5,6}$ 6.5 Hz, H-6), 3.37 (s, 3H, CH_3O), 3.01–2.90 (m, H-6′). Anal. calcd. for $C_{25}H_{29}NO_6$: C 68.32, H 6.65, N 3.19; found: C 68.46, H 6.64, N 3.25. Continued elution afforded the β-anomer **41**β (2.21 g, 48%); $[\alpha]_D$ −132 (*c* 0.9, chloroform). ^{1}H NMR ($CDCl_3$, mixture of two rotamers) δ: 5.85–5.66 (m, CH_2=C*H*), 5.10 (d, 1H, $J_{1,2}$ 3.0 Hz, H-1a), 5.06 (d, 1H, $J_{1,2}$ 3.0 Hz, H-1b), 4.78 (t, 1H, $J_{2,3}$ 3.5 Hz, H-2a), 4.41 (dd, H-4a, H-4b), 4.38 (dd, $J_{5,6}$ 7.5 Hz, H-6b), 4.18 (dd, 1H, $J_{5,6}$ 7.0 Hz, $J_{6,6'}$ 12.5 Hz, H-6a), 4.00 (dd, 1H, $J_{3,4}$ 5.7 Hz, H-3a), 3.91 (overlapped, $J_{3,4}$ 5.5 Hz, $J_{2,3}$ 3.5 Hz, H-3b), 3.84–3.76 (m, H-5a, H-5b), 3.50 (s, 3H, CH_3O), 3.40 (H-6′a), 3.37 (H-6′b). Anal. calcd. for $C_{25}H_{29}NO_6$: C 68.32, H 6.65, N 3.19; found: C 68.35, H 6.79, N 3.20.

*4-*O*-Allyl-2-*O*-benzyl-*N*-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-D-mannitol (**43**)*

50% Trifluoroacetic acid (25 mL) was added at ice-bath temperature to a solution of **41**β (2.45 g, 5.57 mmol) in dioxane (25 mL). After 4 h at room temperature, a solution of sodium acetate (4.1 g) in water (60 mL) was added. The product was extracted with dichloromethane, followed by drying and evaporation of the organic solution. The remainder was dissolved in 95% ethanol (41 mL) and a suspension of sodium borohydride (720 mg, 19 mmol) in 50% ethanol (6 mL) was added at ice-bath temperature. After 30 min at room temperature, it was worked up as described for **28** with subsequent column chromatography on silica gel (dichloromethane – ethyl acetate, 3:1, 2:1, 1:1) to afford **43** (1.40 g, 59%) as a syrup, $[\alpha]_D$ −22 (*c* 1.8, chloroform). Anal. calcd. for $C_{24}H_{29}NO_6$: C 67.43, H 6.84, N 3.28; found: C 67.57, H 6.92, N 3.30.

*4-*O*-Allyl-2-*O*-benzyl-*N*,6-*O*-carbonyl-1,5-dideoxy-1,5-imino-D-mannitol (**44**)*

A solution of **43** (1.74 g, 4.07 mmol) in methanolic 0.5 N sodium methoxide (13 mL) was kept at room temperature for 5 h. The solution was made neutral with Amberlite IRC 50 (H^+), filtered, and evaporated. The resultant solid material was purified on a column of silica gel (dichloromethane – ethyl acetate, 3:1, 2:1) to provide **44** (1.15 g, 89%). The analytical sample was recrystallized from dichloromethane, ether, hexane; mp 119.5–120.5°C; $[\alpha]_D$ −49 (*c* 0.4, chloroform). IR ($CHCl_3$): 1760 (CO) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.40–7.25 (m, 5H, Ph), 5.90 (m, 1H, CH_2=C*H*), 5.26 and 5.19 (2m, 2H, CH_2=CH), 4.84 and 4.36 (ABq, 2H, $J_{A,B}$ 10.5 Hz, CH_2Ph), 4.46 and 4.12 (2m, 2H, CH_2=CH-CH_2), 4.43 (dd, overlapped, 1H, $J_{5,6A}$ 7.5 Hz, H-6A), 4.25 (dd, 1H, $J_{1A,1B}$ 14.5 Hz, $J_{1A,2}$ 2.5 Hz, H-1A), 4.22 (dd, 1H, $J_{6A,6B}$ 8.5 Hz, $J_{5,6B}$ 2.5 Hz, H-6B), 3.81 (m, 1H, H-2), 3.62 (bdd, 1H, $J_{2,3}$ 3.0 Hz, $J_{3,4}$ 8.5 Hz, H-3), 3.49 (m, 2H, H-4, H-5), 2.90 (dd, 1H, $J_{1B,2}$ 1.0 Hz, H-1B). Anal. calcd. for $C_{17}H_{21}NO_5$: C 63.94, H 6.63, N 4.39; found: C 64.10, H 6.60, N 4.40.

*4-*O*-Allyl-2-*O*-benzyl-*N*,6-*O*-carbonyl-1,5-dideoxy-1,5-imino-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-D-mannitol (**45**)*

A solution of bromide **14** (8.3 mmol) in dichloromethane (15 mL) was added to a mixture of **44** (0.99 g, 3.10 mmol), tetraethylammonium bromide (1.2 g, 5.7 mmol), *N*,*N*-dimethylformamide (2.7 mL), and 4 Å molecular sieves (powdered, 3 g) in dichloromethane (4 mL). After stirring for 3 days, more bromide (2.9 mmol) was added and stirring continued for 2 more days. Usual processing as described for **15** was followed by two column chromatographic purifications on silica gel (hexane – ethyl acetate, 4:1 to 1:2 and hexane–dichloromethane – ethyl acetate, 5:2:1) to provide pure **45** (1.6 g, 61%) as a white foam, $[\alpha]_D$ −1.3, $[\alpha]_{365}$ −32.9 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.15 (m, 25H, 5Ph), 5.73 (m, 1H, CH_2=C*H*), 5.13 and 5.05 (2m, 2H, CH_2=CH), 5.04 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.40 (t, 1H, $J_{6A,6B} \sim J_{5,6A}$ 8.5 Hz, H-6A), 4.19 (dd, 1H, $J_{6B,5}$ 3.5 Hz, H-6B), 4.16 (overlapped, dd, 1H, $J_{1A,1B}$ 14.5 Hz, $J_{1A,2}$ 2.5 Hz, H-1A), 2.79 (bd, 1H, H-1B). ^{13}C NMR ($CDCl_3$) δ: 157.63 (CO), 134.79 (CH_2=*C*H), 116.56 (*C*H_2=CH), 99.96 (C-1′), 65.62 (C-6), 57.32 (C-5), 40.63 (C-1). Anal. calcd. for $C_{51}H_{55}NO_{10}$: C 72.75, H 6.58, N 1.66; found: C 72.65, H 6.70, N 1.69.

*2-*O*-Benzyl-*N*,6-*O*-carbonyl-1,5-dideoxy-1,5-imino-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-D-mannitol (**46**)*

A mixture of **45** (1.2 g, 1.43 mmol), tris(triphenylphosphine)-rhodium(I)chloride (89 mg, 0.096 mmol), 1,4-diazabicyclo[2.2.2]-octane (40 mg, 0.36 mmol), 95% ethanol (84 mL), toluene (36 mL), and water (12 mL) was boiled under reflux for 10 h with stirring. The solvent was removed and the residue dissolved in acetone (116 mL) containing mercuric oxide (24 mg). A solution of mercuric chloride (3.2 g) in acetone–water (9:1, 72 mL) was added and the mixture stirred for 30 min. After solvent removal, the residue was taken up in dichloromethane, the solution washed with aqueous saturated potassium bromide and water, followed by evaporation. Chromatography on a column of silica gel (hexane – ethyl acetate, 2:1, 1:1, 1:2) gave alcohol **46** (1.07 g, 94%) as a white foam; $[\alpha]_D$ 0, $[\alpha]_{365}$ −6.4 (*c* 0.4, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.15 (m, 25H, 5Ph), 4.91 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.39 (t, 1H, $J_{6A,6B} \sim J_{6A,5}$ 8.5 Hz, H-6A), 4.27 (dd, 1H, $J_{5,6B}$ 3.5 Hz, H-6B), 4.20 (dd, 1H, $J_{1A,1B}$ 14.5 Hz, $J_{1A,2}$ 2.0 Hz, H-1A), 4.04 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 9.0 Hz, H-3′), 4.02 (t, 1H, $J_{3,4} \sim J_{4,5}$ 9.0 Hz, H-4), 3.91 (m, 1H, H-5′), 3.88 (m, 1H, H-2), 3.59–3.49 (m, 4H, H-5, H-2′, H-4′, H-6A′), 3.45 (dd, 1H, $J_{6A',6B'}$ 10.5 Hz, $J_{5',6B'}$ 2.0 Hz, H-6B′), 3.34 (dd, 1H, $J_{2,3}$ 2.5 Hz, H-3), 2.86 (bd, 1H, H-1B). ^{13}C NMR ($CDCl_3$) δ: 157.60 (CO), 100.41 (C-1′), 65.10 (C-6), 57.26 (C-5), 41.01 (C-1). Anal. calcd. for $C_{48}H_{51}NO_{10}$: C 71.89, H 6.41, N 1.75; found: C 71.48, H 6.37, N 1.79.

*2-*O*-Benzyl-*N*,6-*O*-carbonyl-1,5-dideoxy-1,5-imino-4-*O*-methyl-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-D-mannitol (**47**)*

To a solution of **46** (300 mg, 0.37 mmol) in *N*,*N*-dimethylformamide (1.2 mL), sodium hydride (80% oily suspension, 22 mg, 0.73 mmol) was added at ice-bath temperature with stirring. After 15 min, methyl iodide (45 μL, 0.72 mmol) was added and stirring was continued for 30 min at 0°C and then for 1.5 h at room temperature. The reaction was quenched by a few drops of methanol.

For personal use only.

It was diluted with dichloromethane, washed with water, dried, and evaporated. The resultant material was applied to a column of silica gel (hexane – ethyl acetate, 2:1, 1:1) to afford **47** (305 mg, 88%); $[\alpha]_D$ −6.3 (*c* 0.3, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.15 (m, 25H, 5Ph), 5.08 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.40 (t, 1H, $J_{5,6A} \sim J_{6A,6B}$ 8.5 Hz, H-6A), 4.17 (overlapped dd, 1H, $J_{5,6B}$ 3.0 Hz, H-6B), 4.14 (dd, 1H, $J_{1A,1B}$ 14.5 Hz, $J_{1A,2}$ 2.5 Hz, H-1A), 4.02 (overlapped, H-2), 3.52 (s, overlapped, CH_3O), 2.76 (bd, 1H, H-1B). ^{13}C NMR ($CDCl_3$) δ: 157.61 (CO), 99.86 (C-1′), 65.65 (C-6), 61.52 (CH_3O), 57.45 (C-5), 40.60 (C-1). Anal. calcd. for $C_{49}H_{53}NO_{10}$: C 72.13, H 6.55, N 1.72; found: C 72.04, H 6.62, N 1.73.

*2-O-Benzyl-N,6-O-carbonyl-1,4,5-trideoxy-1,5-imino-3-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-D-*lyxo*-hexitol (49)*

Sodium hydride (80% suspension, 52 mg, 1.73 mmol) was added to a solution of **46** (350 mg, 0.44 mmol) and a crystal of imidazole in tetrahydrofuran (5 mL). After 30 min, carbon disulfide (400 μL, 6.65 mmol) was added and, after another 30 min, methyl iodide (110 μL, 1.77 mmol). The mixture was kept stirring for 30 min, was diluted with dichloromethane, followed by washing of the organic solution with water, drying, and evaporation. The resultant yellowish solid (**48**) was taken up in toluene (5 mL) and reduced with tributyltin hydride (350 μL, 1.30 mmol) at reflux temperature for 4 h. The product obtained on evaporation was purified on a column of silica gel (hexane–dichloromethane – ethyl acetate, 5:1:0.5, 5:1:1) to provide pure **49** (270 mg, 79%); $[\alpha]_D$ +7.2 (*c* 0.4, chloroform. ^{1}H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 25H, 5Ph), 4.89 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.38 (t, 1H, $J_{6A,6B} \sim J_{6A,5}$ 8.5 Hz, H-6A), 4.15 (dd, 1H, $J_{1A,1B}$ 14.5 Hz, $J_{1A,2}$ 2.5 Hz, H-1A), 4.01 (t, 1H, $J_{2',3'}$ 9.5 Hz, $J_{3',4'}$ 8.5 Hz, H-3′), 3.97 (dd, 1H, $J_{6B,5}$ 4.5 Hz, H-6B), 3.83 (m, 1H, $J_{5',4'}$ 9.5 Hz, H-5′), 3.77 (m, 1H, H-2), 3.72 (m, 1H, H-5), 3.63 (m, 1H, H-3), 3.60–3.49 (m, 4H, H-4′, H-6A′, H-6B′ and H-2′ at 3.57), 2.75 (bd, 1H, H-1B), 2.13 (q, 1H, $J_{4a,4e} \sim J_{3,4a} \sim J_{4a,5}$ 11 Hz, H-4a), 1.75 (m, 1H, H-4e). ^{13}C NMR ($CDCl_3$) δ: 157.54 (CO), 95.97 (C-1′), 66.84 (C-6), 52.63 (C-5), 42.07 (C-1), 29.47 (C-4). Anal. calcd. for $C_{48}H_{51}NO_9$: C 73.36, H 6.54, N 1.78; found: C 73.06, H 6.49, N 1.84.

2-O-Benzyl-1,5-dideoxy-1,5-imino-4-O-methyl-3-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-D-mannitol (50)

A mixture of **47** (245 mg, 0.30 mmol) and potassium hydroxide (500 mg) in 90% ethanol (10 mL) was heated at 75°C for 4 h. The mixture was processed in the usual way and the resulting product purified on a column of silica gel (dichloromethane – 5–7% methanol) to provide **50** (175 mg, 74%) as a tough syrup; $[\alpha]_D$ +31 (*c* 0.7, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.35–7.15 (m, 25H, 5Ph), 5.09 (bs, 1H, H-1′), 3.56 (dd, overlapped, $J_{1',2'}$ 3.5 Hz, $J_{2',3'}$ 9.5 Hz, H-2′), 3.45 (s, 3H, CH_3O), 3.08 (dd, 1H, $J_{1A,1B}$ 14.0 Hz, H-1A), 2.54 (bd, 1H, H-1B).

*2-O-Benzyl-1,4,5-trideoxy-1,5-imino-3-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-D-*lyxo*-hexitol (51)*

A mixture of **49** (278 mg, 0.35 mmol) and potassium hydroxide (500 mg) in 90% ethanol (10 mL) was heated at 70°C for 10 h. Usual work-up with subsequent column chromatography on silica gel (dichloromethane – 4–6% methanol) provided **51** (239 mg, 89%) as a tough syrup; $[\alpha]_D$ +52 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 25H, 5Ph), 4.88 (bs, overlapped, H-1′), 3.96 (t, 1H, $J_{3',4'} \sim J_{2',3'} \sim 9$ Hz, H-3′), 3.58 (dd, overlapped, H-2′).

1,5-Dideoxy-3-O-(α-D-glucopyranosyl)-1,5-imino-4-O-methyl-D-mannitol-hydrochloride (52)

A mixture of **50** (140 mg, 0.18 mmol), 5% palladium-on-carbon (140 mg), and methanolic 0.12 N hydrochloric acid (1.7 mL, 0.20 mmol) in methanol (4 mL) was hydrogenated in the hydrogen stream for 3 h. Usual work-up and gel filtration as described for **9** provided **52** (52.5 mg, 79%) as a white solid after freeze-drying an aqueous solution; $[\alpha]_D$ +92 (*c* 0.4, water). The ^{1}H and ^{13}C NMR data are reported in Tables 1 and 2.

*1,4,5-Trideoxy-3-O-(α-D-glucopyranosyl)-1,5-imino-D-*lyxo*-hexitol (53)*

A mixture of **51** (235 mg, 0.31 mmol), 5% palladium-on-carbon (235 mg), and methanolic 0.12 N hydrochloric acid (2.9 mL, 0.35 mmol) in methanol (5 mL) was hydrogenated in the hydrogen stream for 2.5 h. Usual work-up and gel filtration as described for **9** provided **53** (107 mg, 100%) as a white solid after freeze-drying an aqueous solution; $[\alpha]_D$ +106 (*c* 0.3, water). The ^{1}H and ^{13}C NMR data are reported in Tables 1 and 2.

Acknowledgements

Dr. Frank M. Unger's support of this project at Chembiomed Ltd. is gratefully acknowledged. We are deeply indebted to Professor R.U. Lemieux, Department of Chemistry, University of Alberta, who made possible the completion of the project and the preparation of this paper. We thank Mrs. B. Jamieson-Hinz for the preparation of starting materials and Dr. H. Beierbeck for his help with the calculation of theoretical nuclear Overhauser enhancements. The biological part of this work was supported by Grant DK17477 from the National Institutes of Health (to R.G.S.).

Inhibitors of *endo*-α-mannosidase. Part III.[1] Congeners of 1-deoxy-3-*O*-(α-D-glucopyranosyl)-mannojirimycin modified in the glucose unit

ULRIKE SPOHR[2] AND MIMI BACH

Chembiomed Ltd., Edmonton, and Department of Chemistry, University of Alberta, Edmonton, AB T6G 2G2, Canada

Received June 10, 1993

ULRIKE SPOHR and MIMI BACH. Can. J. Chem. **71**, 1943 (1993).

The syntheses of congeners of 1-deoxy-3-*O*-(α-D-glucopyranosyl)-mannojirimycin (**1**), a strong inhibitor of the glycoprotein-processing *endo*-mannosidase, are described. The chemical modifications of **1** involved all monodeoxygenations and mono-*O*-methylations of the glucose unit and the replacement of this unit by D-galactose, D-xylose, and 2-chloro-2-deoxy-D-glucose. As reported previously, none of the modifications of **1**, including deoxygenations and *O*- and *N*-methylations of the deoxymannojirimycin unit, improved the inhibitory properties, but demonstrated the high specificity in the recognition of **1** by the enzyme and allowed the assignment of intermolecular hydrogen bonds of the inhibitor · enzyme complex. Essential for complex formation were found NH-5, OH-2, OH-4, and OH-6 of the DMJ unit, as well as OH-3′, OH-4′, and CH_2-6′ of the glucose unit. The residual activities on deoxygenating the OH-2′ and OH-6′ groups of **1** suggest their involvement at the periphery of the binding site.

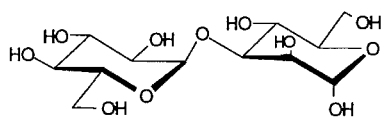
ULRIKE SPOHR et MIMI BACH. Can. J. Chem. **71**, 1943 (1993).

On décrit la synthèse de congénères de la 1-désoxy-3-*O*-(α-D-glucopyranosyl)mannojirimycine (**1**), un inhibiteur puissant de l'*endo*-mannosidase qui peut agir sur les glycoprotéines. Les modifications chimiques de **1** impliquent toutes des monodésoxygénations et des mono-*O*-méthylations de l'unité glucose et le remplacement de cette unité par du D-galactose, du D-xylose et du 2-chloro-2-désoxy-D-glucose. Comme il a été rapporté antérieurement, aucune des modifications du composé **1**, y compris les désoxygénations et les *O*- et *N*-méthylations de l'unité désoxymannojirimycine, n'améliore les propriétés inhibitrices; toutefois, ces modifications ont permis de démontrer la grande spécificité de la reconnaissance du composé **1** par l'enzyme et ont permis d'attribuer les liaisons hydrogènes intramoléculaires du complexe inhibiteur · enzyme. On a trouvé que les unités NH-5, OH-2, OH-4 et OH-6 de l'unité DMJ ainsi que les unités OH-3′, OH-4′ et CH_2-6′ de l'unité glucose sont essentielles à la formation de complexes. Les activités résiduelles observées lors de la désoxygénation des groupes OH-2′ et OH-6′ du composé **1** suggèrent qu'ils sont impliqués à la périphérie du site de liaison.

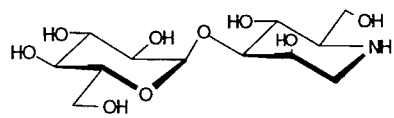
[Traduit par la rédaction]

Introduction

The glycoprotein-processing *endo*-α-D-mannosidase discovered by Spiro and Lubas (1, 2) releases the disaccharide αDGlc(1→3)DMan from immature *N*-linked glycoproteins containing the incompletely deglucosylated polymannose oligosaccharide $GlcMan_9GlcNAc_2$ with the formation of $Man_8GlcNAc_2$. The action of the enzyme was effectively inhibited by the disaccharide 1-deoxy-3-*O*-(α-D-glucopyranosyl)-mannojirimycin (**1**) (3).



αDGlc(1→3)DMan



1

In the search for inhibitors with even greater potencies or better bioavailability all substituents of **1** were chemically modified, mainly by monodeoxygenation and mono-*O*-methylation and the effects of alteration on the inhibitory potencies observed, thus allowing for the assessment of intermolecular hydrogen bonds of the oligosaccharide · enzyme complex as demonstrated by Lemieux and coworkers (4, 5) for the complexation of oligosaccharides by lectins. The biological data of this investigation were published recently (3). While the chemical modifications of the deoxymannojirimycin unit of **1** are reported in the accompanying paper (6), the syntheses and properties of congeners of **1** modified in the glucose unit are described in this communication.

Discussion

Synthesis

The syntheses of congeners of αDGlc(1→3)-1-DMJ (**1**) (6) modified in the glucose unit are outlined in Schemes 1 and 2. The 1-deoxymannojirimycin derivative **2** (6, 7), which has a free hydroxyl group at the 3-position, was used as the glycosyl acceptor. The chloro sugars **3** (2-*O*-methyl), **5** (3-deoxy) (8), **6** (4-deoxy), **10** (4-*O*-methyl), **11** (galactosyl) (9), **12** (6-deoxy), **13** (xylosyl) (10), **50** (3-*O*-methyl), and **51** (6-*O*-acetyl) (11) were prepared from the corresponding hemiacetals by treatment with oxalyl chloride and *N*,*N*-dimethylformamide (12, 13). These precursors were de-

7 8 9

scribed in the literature (14–19), except for 4-*O*-methyl **9**, which was synthesized from an anomeric mixture of **7** (20) by conventional methylation with methyl iodide and sodium hydride to give **8**, followed by deallylation (**9**).

The 2-chloro-2-deoxy and 2-deoxy chlorides **4** (21) and **49** (22) were prepared from 3,4,6-tri-*O*-benzyl-D-glucal as reported.

Since the glycosyl acceptor **2** was of low reactivity (6), all glycosidation reactions were promoted by silver trifluoromethanesulfonate in the presence of *sym*-collidine and 4 Å molecular sieves in dichloromethane at low temperature. Usually, an α:β mixture was produced with a ratio varying from 3:1 to 0.9:1 in a combined yield of 93–66%. Higher α:β ratios were observed for couplings employing galactosyl chloride **11**, 2-*O*-methyl, 3-*O*-methyl, and 4-*O*-methyl chlorides **3**, **50**, and **10** than for those employing 3-deoxy, 4-deoxy, 6-deoxy, and 2-chloro-2-deoxy halides **5, 6, 12,** and **4**. However, in the preparation of the 2′-deoxy disaccharide **52** (73% yield) (Scheme 2), no significant amount of the β-isomer was detected as this was likely to be instable under the reaction conditions. In most of the cases, the anomers could be separated by column chromatography, except for the 4′-*O*-methyl, 6′-deoxy, and xylosyl disaccharides **22, 26**, and **28**, which were isolated as anomeric mixtures, but could be separated readily after deacetylation.

The ^{1}H NMR spectra of the coupling products were broad and showed duplications of the acetyl signals due to the restricted rotation of the benzyloxycarbonyl group about the C—N amide bond (6). Signal duplication was also observed in the ^{13}C NMR spectra. For unambiguous identification, both α- and β-anomers were isolated and characterized. To ascertain the anomeric configurations, C—H coupled ^{13}C NMR spectra were recorded for all β-anomers and some α-anomers. The C-1′ coupling constants $J_{C1',H1'}$ for the β-anomers were found in the range 158.0–162.3 Hz and those for the α-anomers from 166.2 to 171.8 Hz, in agreement with earlier observations (23).

Deacetylations of α-anomers **14, 16, 18, 20, 24**, and the α,β-mixtures **22** + **23**, **26** + **27**, **28** + **29** (Scheme 1) were carried out with triethylamine in aqueous methanol for several days at room temperature to provide the alcohols **30–40** in overall yields of 75% as well as some unreacted starting acetate. A different approach was employed for the 2′-deoxy, 3′-*O*-methyl, and 6′-*O*-acetyl disaccharides **52, 53**, and **55** (Scheme 2). Treatment with methanolic sodium methoxide produced the oxazolidone derivatives **57, 58**, and **59** in high yields (6). 6′-OH disaccharide **59** was converted into the 6′-*O*-methyl derivative **60** (91% yield) by reaction with methyl iodide and silver oxide in toluene. The cyclic carbamates in **57, 58**, and **60** were readily saponified with alcoholic alkali (6) to afford the secondary amines **61, 62**, and **63** in an overall yield of 80% from the benzyloxycarbonyl precursors **52, 53**, and **55**. Catalytic hydrogenation over 5% palladium-on-carbon in the presence of 1 equivalent of hydrochloric acid provided the disaccharides **41–48** (Scheme 1) and **64–66** (Scheme 2) after gel filtration in high yields.

The ^{1}H and ^{13}C NMR data of all deblocked compounds are presented in Tables 1 and 2 and fully confirm the structural assignments. The ^{1}H NMR coupling constants are in agreement with the $^4C_1$ conformation of the pyranose rings. Comparison of the ^{1}H NMR chemical shifts of the DMJ unit of all congeners with those of the parent compound **1** shows that modification of the glucose unit has only minor effects on these shifts, indicating that the conformational preferences about the interglycosidic torsion angles are similar in all compounds. Conformational analysis based on HSEA calculations and nuclear Overhauser enhancements predicted a conformational preference of Φ/Ψ near −50°/−10° (6).

The recognition of αDGlc(1→3)-1-DMJ (1) by endo-*mannosidase*

While αDGlc(1→3)-1-DMJ (**1**) proved a strong inhibitor of the cleavage of $Glc Man_9 GlcNAc$ by *endo*-mannosidase with IC_{50} = 1.7 μmol, modifications of its substituents either led to essentially inactive or weaker compounds, as reported recently (3) and summarized in Fig. 1.

The data require that both OH-3′ and OH-4′ of the glucose unit are involved in strong polar interactions deep in the combining site, since deoxygenation at these positions to give **43** and **44** and *O*-methylation to give **65** and **45** abolished the activity. The polar interaction undergone by equatorial OH-4′ of **1** can be maintained by an axial OH-4′, since galactosyl congener **46** retained substantial activity (17%). That the CH_2-6′ grouping of the glucose unit is essential for providing the required complementarity for complex formation, is indicated by the inactivity displayed by the xylosyl derivative **48**, which has the CH_2OH-6′ grouping replaced by hydrogen. Although OH-6′ can be substituted for by hydrogen to give 6′-deoxy **47** while still retaining 17% activity, *O*-methylation led to inactive **66** for steric reasons. It is therefore expected that OH-6′ is hydrogen bonded to amino acids near the periphery of the binding site (4). Also, OH-2′ of this unit must be located at the periphery of the binding site and possibly interact with water, since deoxygenation (**64**), *O*-methylation (**41**), and chlorination (**42**) produced active, albeit weaker, inhibitors.

Equally intimate as the acceptance of the glucose unit of **1** is the binding of the DMJ unit. While *N*-methylation of **1** produced an inhibitor with a residual activity of around 10%, *N*-*n*-propylation led to an inactive compound, indicating a strong steric interference to binding. It has been observed that *N*-alkylation of 5-deoxy-5-imino sugar analogues may or may not increase the inhibitory properties (24–26). Deoxygenation or *O*-methylation at the 2-, 4-, and 6-positions of **1** virtually abolished the activity, although a marginal activity was detected for 4-deoxy and 4-*O*-methyl congeners. The strong

inhibitory properties towards glycosidases of glycosylamines, 5-amino-5-deoxyhexopyranoses, and 1,5-dideoxy-1,5-iminohexitols have been ascribed to the formation of an ion pair at the catalytic site of the protonated inhibitor and a negatively charged group of the protein likely involved in catalysis (27). In the case of the *endo*-mannosidase, the thus adjusted conformation of the catalytic site requires that all three hydroxyl groups of the DMJ unit of **1** are available for interaction with polar or charged groups of the protein. It is interesting that the active site adjusts differently in the complexation of the neutral O-5 analogue of **1**, namely, αDGlc(1→3)-1,5-anhydro-D-mannitol (3, 28), in which case the replacement of OH-2 by hydrogen increased the activity 40-fold.

Besides these polar interactions, it is to be expected that the complex is stabilized by hydrophobic interactions between nonpolar side chains of the protein and nonpolar patches on the sides of the pyranose rings, such as the α-side of the DMJ unit with CH-1, CH-2, CH-3, and CH-5.

Further synthetic and biological studies of the substrate specificity of *endo*-mannosidase are the subject of a different communication.[3]

Experimental

General methods

The ^{1}H NMR spectra were measured at 300 MHz and 360 MHz (Bruker AM 300 and WM 360) with tetramethylsilane as internal standard for $CDCl_3$ solutions. Reference standard for D_2O solutions was acetone (2.225 ppm). The ^{13}C NMR spectra were recorded at 75 MHz with dioxane (67.4 ppm) as reference for D_2O solutions and the $CDCl_3$ signal (77.0 ppm) as reference in $CDCl_3$

[a]0.05 M solutions in D_2O with dioxane as internal reference at 67.4 ppm were measured at 75 MHz and 295 K. The assignments were made by inspection and are tentative.
[b,c] assignments are tentative and may be reversed.

solutions. Optical rotations were measured at room temperature (23 ± 1°C) in a 1-dm cell on a Perkin–Elmer 241 polarimeter. Thin-layer chromatography was performed on precoated plates of silica gel (60-F254, E. Merck, Darmstadt) and visualized by spraying with 5% sulfuric acid in ethanol followed by heating. For column chromatography silica gel 60 (230–400 mesh, E. Merck, Darmstadt) and distilled solvents were used. Solvents and reagents were purified and dried according to standard procedures. Melting points are uncorrected.

3,4,6-Tri-O-*benzyl-2*-O-*methyl-α,β-D-glucopyranosyl chloride (3)*

Oxalyl chloride (97 μL, 1.11 mmol) was added to a stirred solution of 3,4,6-tri-*O*-benzyl-2-*O*-methyl-D-glucopyranose (14) (385 mg, 0.83 mmol) and *N,N*-dimethylformamide (91 μL, 1.28 mmol) in dichloromethane (9 mL). The mixture was stirred for 20 min and then poured into ice-water. The organic solution was washed with ice-water, dried, and evaporated to provide chloride **3** (quant.) as a syrup. ^1H NMR ($CDCl_3$, α:β = 1:2.2) δ: 7.4–7.05 (m, 15H, 3Ph), 6.26 (d, $J_{1\alpha,2}$ 4.0 Hz, H-1α), 5.09 (d, $J_{1\beta,2}$ 8.5 Hz, H-1β), 4.08 (m, $J_{4,5}$ 10.0 Hz, H-5α), 3.96 (t, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3α), 3.67 (s, CH_3O-β), 3.54 (s, CH_3O-α).

2,4,6-Tri-O-*benzyl-3-deoxy-α-D*-ribo-*hexopyranosyl chloride (5) (8)*

2,4,6-Tri-*O*-benzyl-3-deoxy-D-*ribo*-hexopyranose (15) (251 mg, 0.58 mmol) was converted into chloride **5** just prior to use as reported for the preparation of **3**. ^1H NMR ($CDCl_3$, α:β = 3:1) δ: 7.45–7.20 (m, 15H, 3Ph), 6.19 (bd, 1H, $J_{1,2}$ 3.5 Hz, $J_{1,3eq} < 1$ Hz, H-1), 5.21 (d, $J_{1,2}$ 8.0 Hz, H-1β), 3.97 (ddd, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 3.5 Hz, $J_{5,6'}$ 2.5 Hz, H-5), 3.77 (dd, 1H, $J_{6,6'}$ 11.0 Hz, H-6), 3.67 (dt, overlapped, $J_{2,3eq} \sim 4.5$ Hz, H-2), 3.64 (H-6′), 2.35 (btd, 1H, $J_{3eq,3ax}$ 12.0 Hz, $J_{3eq,4} \sim 4.5$ Hz, H-3eq), 1.97 (q, 1H, $J_{3ax,4} \sim J_{2,3ax} \sim 11.5$ Hz, H-3ax).

2,3,6-Tri-O-*benzyl-4-deoxy-α-D*-xylo-*hexopyranosyl chloride (6)*

2,3,6-Tri-*O*-benzyl-4-deoxy-D-*xylo*-hexopyranose (16) (392.6 mg, 0.90 mmol) was converted into chloride **6** just prior to use as reported for the preparation of **3**. ^1H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 15H, 3Ph), 6.09 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 4.76 and 4.66 (ABq, 2H, $J_{A,B}$ 12.0 Hz, CH_2Ph), 4.74 and 4.70 (ABq, 2H, $J_{A,B}$ 12.0 Hz, CH_2Ph), 4.52 (s, 2H, CH_2Ph), 4.25 (m, 1H, H-5), 3.98 (ddd, 1H, $J_{2,3}$ 9.3 Hz, $J_{3,4eq}$ 5.0 Hz, $J_{3,4ax}$ 11.0 Hz, H-3), 3.61 (dd, 1H, H-2), 3.47 (d, 2H, $J_{6,5}$ 4.5 Hz, 2H-6), 2.10 (ddd, 1H, $J_{4eq,5}$ 2.0 Hz, $J_{4eq,4ax}$ 13.0 Hz, H-4eq), 1.61 (q, 1H, H-4ax).

Allyl 2,3,6-tri-O-*benzyl-4*-O-*methyl-α,β-D-glucopyranoside (8)*

Sodium hydride (528 mg, 22 mmol) was added to a stirred solution of allyl, 2,3,6-tri-*O*-benzyl-α,β-D-glucopyranoside (**7**, 5.51 g, 11.2 mmol) in *N,N*-dimethylformamide (70 mL) at ice-bath temperature. After 20 min, methyl iodide (1.37 mL, 22 mmol) was added and stirring continued for 4 h at room temperature. The excess of reagents was quenched by the addition of methanol (1 mL). The mixture was diluted with dichloromethane, poured into ice-water, and the aqueous layer was extracted with dichloromethane. The combined organic solutions were washed with water, dried, and evaporated to leave the title compound **8** (5.7 g, quant.) as an oil. The analytical sample was purified by column chromatography on silica gel (hexane–chloroform – ethyl acetate, 20:1:1). Evaporation of the first fraction provided the α-anomer, which was characterized; $[\alpha]_D$ +57 (*c* 1.0, chloroform). ^1H NMR ($CDCl_3$) δ: 7.4–7.2 (m, 15H, 3Ph), 5.93 (m, 1H, CH_2=C*H*), 5.31 and 5.20 (2m, 2H, CH_2=CH), 4.94 and 4.79 (ABq, 2H, $J_{A,B}$ 11.0 Hz, CH_2Ph), 4.81 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 4.76 and 4.63 (ABq, 2H, $J_{A,B}$ 12.5 Hz, CH_2Ph), 4.63 and 4.50 (ABq, 2H, $J_{A,B}$ 12.5 Hz, CH_2Ph), 4.16 and 4.01 (2m, 2H, CH_2=CH-CH_2), 3.89 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.72–3.61 (m, 3H, H-6, H-6′, H-5), 3.51 (dd, 1H, H-2), 3.46 (s, 3H, CH_3O), 3.34 (t, 1H, $J_{4,5}$ 9.0 Hz, H-4). Anal. calcd. for $C_{31}H_{36}O_6$: C 73.79, H 7.19; found: C 73.70, H 7.33.

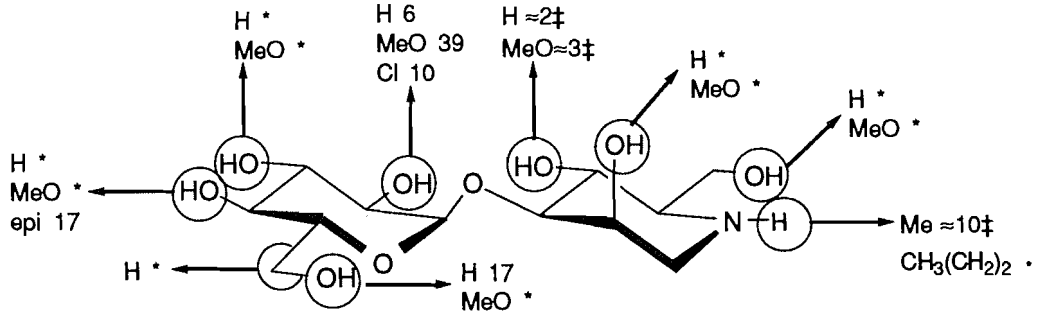

FIG. 1. The effect of chemical modification of **1** on the activity as inhibitor of *endo*-mannosidase in relative potencies (percentage of potency of **1**). ‡Approximate rel. potencies based on IC_{50} values as derived from inhibition data obtained for two inhibitor concentrations (3). *Denotes inactivity (rel. potency < 1).

2,3,6-Tri-O-benzyl-4-O-methyl-D-glucopyranose (9)

A mixture of crude **8** (5.7 g, 11.3 mmol), tris(triphenylphosphine)rhodium(I) chloride (805 mg, 0.87 mmol), 1,8-diazabicyclo[2.2.2]octane (342 mg, 3.05 mmol), and 95% ethanol–toluene–water (7:3:1, 77 mL) was boiled under reflux for 5 h. The solvent was evaporated and the remainder was taken up in acetone (70 mL) containing mercuric oxide (294 mg). A solution of mercuric chloride (14.4 g) in acetone–water (9:1, 50 mL) was added and the mixture stirred for 30 min. After solvent removal, the residue was taken up in dichloromethane, the solution washed with aqueous saturated potassium bromide and water, and the organic solution concentrated. Purification on a column of silica gel (hexane – ethyl acetate, 3:1) provided **9** (2.32 g, 44%) as a solid. The analytical sample was recrystallized from ether/hexane; mp 91–92°C; $[\alpha]_D$ +39 (*c* 0.3, chloroform). ^{1}H-nmr ($CDCl_3$, α:β = 1:0.6) δ: 7.42–7.24 (m, 15H, 3Ph), 5.20 (d, $J_{1\alpha,2}$ 3.5 Hz, H-1α), 5.03–3.97 (m, 3CH_2Ph, H-1β), 3.93 (ddd, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 2.5 Hz, $J_{5,6'}$ 3.5 Hz, H-5α), 3.85 (t, 1H, $J_{3,4}$ 9.5 Hz, H-3α), 3.72 (dd, $J_{6,6'}$ 11.0 Hz, $J_{6,5}$ 2.0 Hz, H-6β), 3.69 (dd, $J_{6,6'}$ 11.0 Hz, H-6α), 3.67 (H-6′β), 3.64 (dd, H-6′α), 3.54 (t, overlapped by H-2α, $J_{2,3} \sim J_{3,4}$ 9.0 Hz, H-3β), 3.53 (dd, H-2α), 3.47 (s, CH_3O-α), 3.465 (s, CH_3O-β), 3.43 (ddd, H-5β), 3.33 (dd, $J_{1\beta,2}$ 7.8 Hz, H-2β), 3.33 (t, H-4α), 3.27 (t, $J_{4,5}$ 9.5 Hz, H-4β). Anal. calcd. for $C_{28}H_{32}O_6$: C 72.39, H 6.94; found: C 71.78, H 6.92.

2,3,6-Tri-O-benzyl-4-O-methyl-α,β-D-glucopyranosyl chloride (10)

9 (550 mg, 1.18 mmol) was converted into **10** as described for the preparation of **3**. ^{1}H NMR ($CDCl_3$, α:β = 3:1) δ: 7.4–7.15 (m, 15H, 3Ph), 6.01 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 3.95 (m, 1H, $J_{4,5}$ 10.0 Hz, H-5), 3.89 (t, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.46 (s, CH_3O), 3.41 (t, 1H, H-4).

2,3,4-Tri-O-benzyl-6-deoxy-α,β-D-glucopyranosyl chloride (12)

2,3,4-Tri-*O*-benzyl-6-deoxy-D-glucopyranose (17) (552.2 mg, 1.27 mmol) was converted into chloride **12** just prior to use as described for the preparation of **3**. ^{1}H NMR ($CDCl_3$, α:β = 2.2:1) δ: 7.45–7.2 (m, 15H, 3Ph), 5.98 (d, $J_{1\alpha,2}$ 4.0 Hz, H-1α), 5.19 (d, $J_{1\beta,2}$ 8.0 Hz, H-1β), 5.00–4.61 (m, 6H, 3CH_2Ph), 4.07 (m, H-5α), 4.00 (t, $J_{2,3} \sim J_{3,4}$ 9.0 Hz, H-3α), 3.69 (dd, H-2α), 3.60 (m, H-2β, H-3β), 3.49 (m, H-5β), 3.29 (t, $J_{4,5} \sim J_{3,4}$ 9.0 Hz, H-4β), 3.18 (t, $J_{4,5}$ 9.5 Hz, H-4α), 1.35 (d, $J_{5,6}$ 6.0 Hz, H_3-6β), 1.28 (d, $J_{5,6}$ 6.0 Hz, H_3-6α).

6-O-Acetyl-2,4-di-O-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-O-(3,4,6-tri-O-benzyl-2-O-methyl-α-D-glucopyranosyl)-D-mannitol (14) and -β-D-glucopyranosyl)-D-mannitol (15)

A solution of chloride **3** (0.82 mmol) in dichloromethane (5 mL) was added at −78°C to a stirred mixture of **2** (7) (210 mg, 0.40 mmol), silver trifluoromethanesulfonate (220 mg, 0.86 mmol), *sym*-collidine (43.9 μL, 0.33 mmol), and 4 Å molecular sieves (500 mg) in dichloromethane (1.5 mL). The temperature was gradually raised to 0°C and after 7 h the reaction was quenched by the addition of *sym*-collidine (75 μL, 0.57 mmol). The mixture was filtered through Celite, the organic solution washed with aqueous saturated sodium hydrogen carbonate and water, followed by evaporation. Column chromatography on silica gel (hexane – ethyl acetate, 5:1, 4:1) provided in the first main fraction the β-isomer **15** (90.1 mg, 23%); $[\alpha]_D$ −17.8 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.40–7.00 (m, 30H, 6Ph), 5.20–3.0 (complex m, 30H), 3.58 (s, 3H, CH_3O), 1.91 and 1.82 (2s, 3H, CH_3CO). ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 170.62 (CH_3CO), 156.23 (OCO), 104.72 ($J_{C,H}$ 160.6 Hz, C-1′), 61.40 (61.21) (C-6), 60.59 (CH_3O), 52.97 (52.35) (C-5), (38.37) 37.83 (C-1), (20.74) 20.57 (CH_3CO). Evaporation of the second main fraction provided **14** (200 mg, 51%); $[\alpha]_D$ +34.1 (*c* 0.3, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.40–7.00 (m, 30H, 6Ph), 5.2–3.0 (complex m, 30H), 3.34 (s, 3H, CH_3O), 1.94 and 1.85 (2s, 3H, CH_3CO).

6-O-Acetyl-2,4-di-O-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-O-(3,4,6-tri-O-benzyl-2-chloro-2-deoxy-α-D-glucopyranosyl)-D-mannitol (16) and -β-D-glucopyranosyl)-D-mannitol (17)

A solution of chloride **4** (21) (0.60 mmol) in dichloromethane (2 mL) was added at −65°C to a stirred mixture of **2** (186 mg, 0.19 mmol), silver trifluoromethanesulfonate (165.9 mg, 0.65 mmol), *sym*-collidine (31 μL, 0.23 mmol), and 4 Å molecular sieves (800 mg) in dichloromethane (1.5 mL). The temperature was allowed to gradually rise to −20°C within 3 h. More *sym*-collidine (40 μL, 0.30 mmol) was added and, after 1 h at room temperature, the mixture was processed in the usual way. Column purification on silica gel (hexane – ethyl acetate, 5:1) provided, according to the ^{1}H NMR spectrum, an α:β mixture (231 mg, 67%) in the ratio 0.9:1. Separation of the anomers was achieved by repeated column chromatography on silica gel 60H (for thin-layer chromatography, E. Merck, Darmstadt) using hexane–chloroform – ethyl acetate, 14:14:1. Evaporation of the earlier fractions provided the α-anomer **16** (87.8 mg, 25%) as a syrup; $[\alpha]_D$ +45.6 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.4–7.0 (m, 30H, 6Ph), 5.3–2.95 (complex m, 27H), 1.93 and 1.86 (2s, 3H, CH_3CO). ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 170.56 (CH_3CO), 156.09 (CO), 99.62 ($J_{C,H}$ 168.7 Hz, C-1′), 61.80 (61.66) (C-6), 60.21 (C-2), 52.51 (51.83) (C-5), (38.12), 37.49 (C-1), (20.74) 20.62 (CH_3CO). Anal. calcd. for $C_{57}H_{60}ClNO_{11}$: C 70.54, H 6.23, Cl 3.65, N 1.44; found: C 70.14, H 6.46, Cl 3.98, H 6.46. Continued development eluted the β-anomer **17** (75 mg, 22%) as a syrup; $[\alpha]_D$ −10.8 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.4–7.1 (m, 30H, 6Ph), 5.25–3.25 (complex m, 27H), 1.93 and 1.82 (2s, 3H, CH_3CO). ^{13}C nmr ($CDCl_3$, δ minor rotamer in parentheses) δ: 156.19 (CO), 101.88 (C-1′), 61.73 (C-2′), 61.50 (61.31) (C-6), 52.87 (52.16) (C-5), (38.08) 37.56 (C-1), (20.79) 20.61 (CH_3CO). Anal. calcd. for $C_{57}H_{60}ClNO_{11}$: C 70.54,

For personal use only.

H 6.23, N 1.44; found: C 70.34, H 6.15, N 1.39. A second batch of α,β-mixture (42 mg) was separated by thin-layer chromatography (Whatman, silica gel 150A PLK5F, hexane–chloroform – ethyl acetate, 14:14:1, fourfold development). Elution of the higher zone provided the α-anomer **16** and elution of the lower zone the β-anomer **17** in slightly higher yields.

6-O-Acetyl-2,4-di-O-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-O-(2,4,6-tri-O-benzyl-3-deoxy-α-D-ribo-hexopyranosyl)-D-mannitol (18) and -β-D-ribo-hexopyranosyl)-D-mannitol (19)

A solution of chloride **5** (0.57 mmol) in dichloromethane (3 mL) was added at −78°C to a stirred mixture of **2** (166.8 mg, 0.32 mmol), silver trifluoromethanesulfonate (164 mg, 0.64 mmol), *sym*-collidine (30 μL, 0.23 mmol), and 4 Å molecular sieves (1 g) in dichloromethane (1.5 mL). Within 2 h the temperature was raised to −30°C and more *sym*-collidine (35 μL, 0.26 mmol) was added. After 1 h at room temperature, it was worked up in the usual way. Chromatographic separation on a column of silica gel (hexane – ethyl acetate, 5:1) provided in the earlier fractions the β-anomer **19** (121.2 mg, 40%) as a syrup; $[\alpha]_D$ +10 (*c* 0.6, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.4 –7.05 (m, 30H, 6Ph), 5.24–3.15 (complex m, 26H), 2.46 (dt, 1H, $J_{3ax',3eq'}$ 13.0 Hz, $J_{2',3eq'} \sim J_{3eq',4'} \sim$ 4.5 Hz, H-3eq′), 1.92 and 1.82 (2s, 3H, CH_3CO), 1.51 (q, 1H, $J_{2',3ax'} \sim J_{3ax',4'} \sim$ 12 Hz, H-3ax′). ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 170.8 (CH_3CO), 156.1 (CO), 106.8 ($J_{C,H}$ 161.7 Hz, C-1′), 61.44 (61.25) (C-6), 53.12 (52.48) (C-5), (38.50) 37.94 (C-1), 35.06 (C-3′), (20.81), 20.62 (CH_3CO). Anal. calcd. for $C_{57}H_{61}NO_{11}$: C 73.14, H 6.57, N 1.50; found: C 73.28, H 6.47, N 1.51. Continued elution provided the α-anomer **18** (140.0 mg, 47%) as a syrup; $[\alpha]_D$ +47 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.4–7.1 (m, 30H, 6Ph), 5.2–3.03 (complex m, 26H), 2.32 (m, 1H, $J_{3eq',3ax'}$ 13.0 Hz, H-3eq′), 1.85 and 1.74 (2s, 3H, CH_3CO), 1.75 (q, 1H, $J_{2',3ax'} \sim J_{4',3ax'} \sim$ 12 Hz, H-3ax′). ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 170.5 (CH_3CO), 156.1 (CO), 96.48 ($J_{C,H}$ 166.2 Hz, C-1′), 61.96 (61.78) (C-6), 52.56 (51.94) (C-5), (38.10) 37.52 (C-1), 29.73 (C-3′), (20.68) 20.50 (CH_3CO). Anal. calcd. for $C_{57}H_{61}NO_{11}$: C 73.14, H 6.57, N 1.50; found: C 73.20, H 6.38, N 1.17.

6-O-Acetyl-2,4-di-O-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-O-(2,3,6-tri-O-benzyl-4-deoxy-α-D-xylo-hexopyranosyl)-D-mannitol (20) and -β-D-xylo-hexopyranosyl)-D-mannitol (21)

A solution of chloride **6** (0.90 mmol) in dichloromethane (4 mL) was added at −65°C to a stirred mixture of **2** (234.7 mg, 0.45 mmol), silver trifluoromethanesulfonate (256 mg, 1.0 mmol), *sym*-collidine (47.5 μL, 0.36 mmol), and 4 Å molecular sieves (1 g) in dichloromethane (2 mL). Within 2 h, the temperature was raised to −55°C. More *sym*-collidine (60 μL, 0.48 mmol) was added. After 1 h at room temperature, the mixture was worked up in the usual way, followed by column chromatography on silica gel (hexane – ethyl acetate, 5:1) to provide an anomeric mixture of **20** and **21**. A second chromatographic purification (carbon tetrachloride – ethyl acetate, 8:1) provided the α-anomer **20** (230.7 mg, 55%) as a syrup; $[\alpha]_D$ +54 (*c* 0.4, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.4–7.1 (m, 30H, 6Ph), 5.2–3.0 (complex m, 26H), 1.95 (unresolv. ddd, 1H, $J_{4eq',4ax'}$ 13.0 Hz, H-4eq′), 1.82 and 1.73 (2s, 3H, CH_3CO), 1.55 (q, 1H, H-4ax′). Anal. calcd. for $C_{57}H_{61}NO_{11}$: C 73.14, H 6.57, N 1.50; found: C 73.21, H 6.65, N 1.54. Continued development of the column eluted the β-anomer **21** (153.6 mg, 36%) as a syrup; $[\alpha]_D$ −19.8 (*c* 0.4, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.4–7.05 (m, 30H, 6Ph), 5.2–3.1 (complex m, 26H), 2.05 (unresolv. ddd, 1H $J_{4eq',4ax'}$ 12.5 Hz, H-4eq′), 1.89 and 1.80 (2s, 3H, CH_3CO), 1.38 (q, 1H, $J_{3',4ax'} \sim J_{4ax',5'} \sim$ 12 Hz, H-4ax′); ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 105.14 ($J_{C,H}$ 161.1 Hz, C-1′), 61.41 (61.22) (C-6), 53.04 (52.35) (C-5), (38.44) 37.89 (C-1), 33.76 (C-4′), 20.61 (CH_3CO). Anal. calcd. for $C_{57}H_{61}NO_{11}$: C 73.14, H 6.57, N 1.50; found: C 72.94, H 6.64, N 1.51.

6-O-Acetyl-2,4-di-O-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-O-(2,3,6-tri-O-benzyl-4-O-methyl-α-D-glucopyranosyl)-D-mannitol (22) and -β-D-glucopyranosyl)-D-mannitol (23)

A solution of chloride **10** (1.18 mmol) in dichloromethane (7 mL) was added to a stirred mixture of **2** (253 mg, 0.49 mmol), silver trifluoromethanesulfonate (380 mg, 1.48 mmol), *sym*-collidine (51 μL, 0.39 mmol), and 4 Å molecular sieves (500 mg) in dichloromethane (2.0 mL) at 0°C. Stirring was continued for 2.5 h. Then more *sym*-collidine (150 μL, 1.14 mmol) was added, followed by conventional work-up. Chromatographic isolation of the product on a column of silica gel (hexane – ethyl acetate 5:1, 4:1, 3:1) provided a 2.5:1 mixture of **22** and **23** (310 mg, 66%). This mixture was not further characterized, but was deacetylated.

6-O-Acetyl-2,4-di-O-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-O-(2,3,4,6-tetra-O-benzyl-α-D-galactopyranosyl)-D-mannitol (24) and -β-D-galactopyranosyl)-D-mannitol (25)

A solution of chloride **11** (9) (0.94 mmol) in dichloromethane (6.5 mL) was added to a stirred mixture of **2** (265 mg, 0.51 mmol), silver trifluoromethanesulfonate (310 mg, 1.20 mmol), *sym*-collidine (55 μL, 0.42 mmol), and 4 Å molecular sieves (500 mg) in dichloromethane (1.5 mL) at −78°C. The temperature was gradually raised to 0°C and, after 7 h, *sym*-collidine (180 μL, 1.36 mmol) and methanol (200 μL) were added. The mixture was processed in the usual way and the product mixture purified on a column of silica gel (hexane – ethyl acetate, 5:1). Evaporation of the first main fraction provided **24** (357.9 mg, 67%) as a tough syrup; $[\alpha]_D$ +38.5 (*c* 1.0, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.4–7.0 (m, 35H, 7Ph), 5.2–3.0 (complex m, 29H), 1.82 and 1.73 (2s, 3H, CH_3CO). Anal. calcd. for $C_{64}H_{67}NO_{12}$: C 73.76, H 6.48, N 1.34; found: C 73.60, H 6.49, N 1.41. Continued elution of the column furnished the β-anomer **25** (38.8 mg, 7.3%) as a tough syrup; $[\alpha]_D$ −18.9 (*c* 0.3, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.4–7.0 (m, 35H, 7Ph), 5.2–3.1 (complex m, 29H), 1.82 and 1.73 (2s, 3H, CH_3CO). ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 170.4 (CH_3CO), 156.22 (CO), 104.83 ($J_{C,H}$ 160.7 Hz, C-1′), 61.22 (C-6), 52.85 (52.21) (C-5), (37.82) 37.35 (C-1), 20.62 (CH_3CO).

6-O-Acetyl-2,4-di-O-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-O-(2,3,4-tri-O-benzyl-6-deoxy-α-D-glucopyranosyl)-D-mannitol (26) and -β-D-glucopyranosyl)-D-mannitol (27)

A solution of chloride **12** (1.25 mmol) in dichloromethane (2 mL) was added at −40°C to a stirred mixture of alcohol **2** (287 mg, 0.55 mmol), silver trifluoromethanesulfonate (360 mg, 1.40 mmol), *sym*-collidine (58 μL, 0.44 mmol), and 4 Å molecular sieves (300 mg) in dichloromethane (1 mL). After 1 h at this temperature, the temperature was allowed to reach 0°C within 3 h. The reaction was quenched by the addition of *sym*-collidine (150 μL, 1.14 mmol) followed by usual work-up. Column chromatography on silica gel (hexane – ethyl acetate, 6:1) provided the anomeric mixture of **26** and **27** (464 mg, 90%), which was not further characterized, but deacetylated.

6-O-Acetyl-2,4-di-O-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-O-(2,3,4-tri-O-benzyl-α-D-xylopyranosyl)-D-mannitol (28) and -β-D-xylopyranosyl)-D-mannitol (29)

Chloride **13** (10) was prepared from 2,3,4-tri-*O*-benzyl-D-xylopyranose (18) as described for **3**. A solution of **13** (0.72 mmol) in dichloromethane (4.5 mL) was transferred into a stirred mixture of **2** (263 mg, 0.51 mmol), silver trifluoromethanesulfonate (334 mg, 1.3 mmol), *sym*-collidine (55 μL, 0.42 mmol), and 4 Å molecular sieves (0.5 g) in dichloromethane (1 mL) at −78°C. The mixture was allowed to reach 0°C within 4.5 h and more *sym*-col-

For personal use only.

lidine (100 μL, 0.76 mmol) was added. It was processed as described for the preparation of **14**, followed by chromatography on a column of silica gel (hexane – ethyl acetate, 5:1, 4:1), which provided a 2:1 mixture of the anomers **28** and **29** (432.5 mg, 93%) according to the ^{1}H NMR spectrum. This mixture was not further characterized but deacetylated.

*2,4-Di-*O*-benzyl-*N*-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-*O*-(3,4,6-tri-*O*-benzyl-2-*O*-methyl-α-D-glucopyranosyl)-D-mannitol (**30**)*

A solution of **14** (193 mg, 0.20 mmol) in methanol (5 mL), triethylamine (2 mL), and water (1 mL) was kept at room temperature for 4 days. It was evaporated to dryness and the resultant material was applied to a column of silica gel (hexane–dichloromethane – ethyl acetate, 5:1:1, 4:1:1) to provide the title compound **30** (144 mg, 78%) as a tough syrup; $[\alpha]_D$ +44.2 (*c* 0.2, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of rotamers) δ: 7.4–7.0 (m, 30H, 6Ph), 5.20–2.90 (complex m, 31H), 3.42 (s, 3H, CH_3O). Anal. calcd. for $C_{56}H_{61}NO_{11}$: C 72.79, H 6.65, N 1.52; found: C 73.05, H 6.68, N 1.45.

*2,4-Di-*O*-benzyl-*N*-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-*O*-(3,4,6-tri-*O*-benzyl-2-chloro-2-deoxy-α-D-glucopyranosyl)-D-mannitol (**31**)*

A mixture of **16** (60 mg, 0.065 mmol), methanol (1.43 mL), triethylamine (572 μL), and water (286 μL) was kept at room temperature for 3 days. Evaporation, followed by column chromatography on silica gel (hexane – ethyl acetate, 2:1), provided syrupy **31** (54.6 mg, 95%); $[\alpha]_D$ +69 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of rotamers) δ: 7.4–7.0 (m, 30H, 6Ph), 5.15–2.9 (complex m, 28H). ^{13}C NMR ($CDCl_3$) δ: 99.25 (C-1′), 60.44 (C-6, C-2′), 55.59 (C-5), 38.0 (C-1). Anal. calcd. for $C_{55}H_{58}ClNO_{10}$: C 71.15, H 6.30, N 1.51; found: C 70.95, H 6.51, N 1.36.

*2,4-Di-*O*-benzyl-*N*-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-*O*-(2,4,6-tri-*O*-benzyl-3-deoxy-α-D-*ribo*-hexopyranosyl)-D-mannitol (**32**)*

A mixture of **18** (121 mg, 0.13 mmol), methanol (3.2 mL), triethylamine (1.28 mL), and water (0.64 mL) was stirred at room temperature for 5 days. Evaporation and column chromatography on silica gel (hexane – ethyl acetate, 3:1) provided **32** (88.5 mg, 77%) as a tough syrup; $[\alpha]_D$ +36 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of rotamers) δ: 7.43–7.05 (m, 30H, 6Ph), 5.2–2.9 (complex m, 27H), 2.30 (m, 1H, H-3eq′), 1.71 (q, 1H, $J_{3ax',3eq'} \sim J_{2',3ax'} \sim J_{3ax',4'} \sim 12$ Hz, H-3ax′). ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 156.10 (CO), 97.52 ($J_{C,H}$ 167.9 Hz, C-1′), 58.93 (C-6), 53.70 (53.26) (C-5), (39.19) 38.60 (C-1), 29.74 (C-3′). Anal. calcd. for $C_{55}H_{59}NO_{10}$: C 73.89, H 6.65, N 1.57; found: C 73.92, H 6.75, N 1.55.

*2,4-Di-*O*-benzyl-*N*-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-*O*-(2,3,6-tri-*O*-benzyl-4-deoxy-α-D-*xylo*-hexopyranosyl)-D-mannitol (**33**)*

A solution of **20** (230.6 mg, 0.25 mmol) in methanol (6.1 mL), triethylamine (2.43 mL), and water (1.2 mL) was kept at room temperature for 6 days. The material resulting on evaporation was applied to a column of silica gel (hexane – ethyl acetate, 3:1) to provide syrupy **33** (172 mg, 78%); $[\alpha]_D$ +44 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of rotamers) δ: 7.4–7.05 (m, 30H, 6Ph), 5.2–2.9 (complex m, 27H), 2.01 (ddd, 1H, $J_{4ax',4eq'}$ 13.0 Hz, $J_{3',4eq'}$ 5.0 Hz, $J_{4eq',5'}$ 2.0 Hz, H-4eq′), 1.62 (q, 1H, H-4ax′). ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 156.06 (CO), 99.71 ($J_{C,H}$ 166.9 Hz, C-1′), 58.06 (C-6), 53.90 (53.46) (C-5), (39.38) 38.75 (C-1), 33.09 (C-4′). Anal. calcd. for $C_{55}H_{59}NO_{10}$: C 73.89, H 6.65, N 1.57; found: C 73.70, H 6.65, N 1.62.

*2,4-Di-*O*-benzyl-*N*-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-*O*-(2,3,6-tri-*O*-benzyl-4-*O*-methyl-α-D-glucopyranosyl)-D-mannitol (**34**) and -β-D-glucopyranosyl)-D-mannitol (**35**)*

An anomeric mixture of compounds **22** and **23** (295 mg, 0.31 mmol) in methanol (7.5 mL), triethylamine (3 mL), and water (1.5 mL) was kept for 7 days at room temperature. It was evaporated and the resultant material applied to a column of silica gel (hexane–dichloromethane – ethyl acetate, 4:1:1) to provide in the first fraction starting material **22** and **23** (58 mg, 20%). Evaporation of the second fraction gave α-isomer **34** (145.1 mg, 51%); $[\alpha]_D$ −3 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers) δ: 7.45–7.10 (m, 30H, 6Ph), 5.2–2.84 (complex m, 31H), 3.37 (s, 3H CH_3O). ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 156.10 (CO), 99.28 ($J_{C,H}$ 168.5 Hz, C-1′), 60.42 (CH_3O), 59.12 (C-6), 53.87 (53.39) (C-5), (39.22) 38.65 (C-1). Anal. calcd. for $C_{56}H_{61}NO_{11}$: C 72.79, H 6.65, N 1.52; found: C 72.59, H 6.70, N 1.47. Continued elution of the column provided the β-isomer **35** (58.8 mg, 21%); $[\alpha]_D$ −6 (*c* 0.8, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers) δ: 7.4–7.0 (m, 30H, 6Ph), 5.2–3.0 (complex m, 31H), 3.40 (s, CH_3O). ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 156.0 (CO), 105.61 ($J_{C,H}$ 158.0 Hz, C-1′), 60.64 (CH_3O), 59.71 (C-6), 54.85 (54.53) (C-5), (39.41) 38.98 (C-1).

*2,4-Di-*O*-benzyl-*N*-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-galactopyranosyl)-D-mannitol (**36**)*

A solution of acetate **24** (225 mg, 0.22 mmol) in methanol (5 mL), triethylamine (2 mL), and water (1 mL) was kept for 6 days at room temperature. It was evaporated and the resultant material applied to a column of silica gel (hexane–dichloromethane – ethyl acetate, 5:1:1). Evaporation of the first main fraction provided starting material **24** (51.8 mg, 23%). Continued elution gave **36** (138.4 mg, 64%) as a tough syrup; $[\alpha]_D$ +22.7 ^{1}H NMR ($CDCl_3$, broad, mixture of rotamers) δ: 7.4–7.0 (m, 35H, 7Ph), 5.15–2.90 (complex m, 29H). Anal. calcd. for $C_{62}H_{65}NO_{11}$: C 74.45, H 6.55, N 1.40; found: C 74.50, H 6.57, N 1.35.

*2,4-Di-*O*-benzyl-*N*-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-*O*-(2,3,4-tri-*O*-benzyl-6-deoxy-α-D-glucopyranosyl)-D-mannitol (**37**) and -β-D-glucopyranosyl)-D-mannitol (**38**)*

An anomeric mixture of compounds **26** and **27** (450 mg, 0.48 mmol), triethylamine (4.7 mL), water (2.3 mL), and methanol (11.8 mL) was kept at room temperature for 5 days. It was evaporated and the resultant material applied to a column of silica gel (hexane – ethyl acetate, 3:1) to provide in the first main fraction α-anomer **37** (197 mg, 46%) as a syrup; $[\alpha]_D$ +33.4 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers) δ: 7.50–7.10 (m, 30H, 6Ph), 5.2–3.0 (complex m, 26H), 0.87 (d, 3H, $J_{5',6'}$ 6.2 Hz, H_3-6′). ^{13}C NMR (δ minor rotamer in parentheses) δ: 156.13 (CO), 98.95 ($J_{C,H}$ 171.8 Hz, C-1′), 59.25 (C-6), 53.94 (53.47) (C-5), (39.35) 38.76 (C-1), 17.45 (C-6′). Anal. calcd. for $C_{55}H_{59}NO_{10}$: C 73.89, H 6.65, N 1.57; found: C 73.88, H 6.39, N 1.57. Continued development eluted the syrupy β-isomer **38** (122.1 mg, 28%); $[\alpha]_D$ −16.5 (*c* 0.6, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers) δ: 7.45–7.05 (m, 30H, 6Ph), 5.2–2.8 (m, 26H), 1.13 (d, 3H, $J_{5',6'}$ 6.0 Hz, H_3-6′). ^{13}C NMR (δ minor rotamer in parentheses) δ: 156.28 (CO), 105.47 ($J_{C,H}$ 162.3 Hz, C-1′), (58.67) 58.44 (C-6), 54.51 (54.29) (C-5), 39.32 (38.84) (C-1), 17.72 (C-6′).

*2,4-Di-*O*-benzyl-*N*-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-*O*-(2,3,4-tri-*O*-benzyl-α-D-xylopyranosyl)-D-mannitol (**39**) and -β-D-xylopyranosyl)-D-mannitol (**40**)*

A solution of the anomeric mixture of **28** and **29** (433 mg, 0.47 mmol) in methanol (10 mL), triethylamine (4 mL), and water (2 mL) was kept at room temperature for 7 days. It was evaporated and the product mixture separated on a column of silica gel (hexane–dichloromethane – ethyl acetate, 5:1:1 to 2:1:1) to provide in the first main fraction the α-anomer **39** (193 mg, 47%) as a tough syrup; $[\alpha]_D$ +22.6 (*c* 0.2, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers) δ: 7.40–7.10 (m, 30H, 6Ph), 5.20–3.0 (complex m, 27H). Anal. calcd. for $C_{54}H_{57}NO_{10}$: C 73.70, H 6.53, N 1.59; found: C 73.85, H 6.44, N 1.59. Continued development of the column eluted the β-anomer **40** (100.2 mg, 24%); $[\alpha]_D$ −22.1 (*c* 0.3, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture

For personal use only.

of two rotamers) δ: 7.40–7.10 (m, 30H, 6Ph), 5.10–2.60 (complex m, 27H). ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 156.25 (CO), 106.46 ($J_{C,H}$ 161.5 Hz, C-1′) (58.87) 58.55 (C-6), 54.69 (C-5), (39.19) 38.64 (C-1). Anal. calcd. for $C_{54}H_{57}NO_{10}$: C 73.70, H 6.53, N 1.59; found: C 73.49, H 6.50, N 1.54.

*1,5-Dideoxy-1,5-imino-3-*O*-(2-*O*-methyl-α-D-glucopyranosyl)-D-mannitol-hydrochloride (**41**)*

A mixture of **30** (131 mg, 0.14 mmol), 5% palladium-on-carbon (130 mg), and methanolic 0.12 N hydrochloric acid (1.3 mL, 0.156 mmol) in methanol (7 mL) was hydrogenated in a hydrogen stream for 2 h. Removal of the catalyst by filtration, evaporation, and gel filtration (Sephadex LH 20, ethanol–water, 1:1) provided **41** (50.9 mg, 96%) as a white solid after freeze-drying its aqueous solution; $[\alpha]_D$ +83.3 (*c* 0.2, water). The ^1H and ^{13}C NMR data are reported in Tables 1 and 2.

*3-O-(2-Chloro-2-deoxy-α-D-glucopyranosyl)-1,5-dideoxy-1,5-imino-D-mannitol-hydrochloride (**42**)*

A mixture of **31** (32 mg, 0.034 mmol), 5% palladium-on-carbon (30 mg), and methanolic 0.12 N hydrochloric acid (0.3 mL, 0.036 mmol) in methanol (4.5 mL) was hydrogenated in a hydrogen stream for 4 h. Removal of the catalyst by filtration, evaporation, and gel filtration (Sephadex LH 20, ethanol–water, 1:1) provided **42** (10.9 mg, 83%) as a white solid after lyophilization of an aqueous solution; $[\alpha]_D$ +48.5 (*c* 0.4, water). The ^1H and ^{13}C NMR data are reported in Tables 1 and 2.

*1,5-Dideoxy-3-*O*-(3-deoxy-α-D-*ribo*-hexopyranosyl)-1,5-imino-D-mannitol-hydrochloride (**43**)*

Compound **32** (93 mg, 0.104 mmol), 5% palladium-on-carbon (90 mg), and 0.12 N methanolic hydrochloric acid (1 mL, 0.12 mmol) in methanol (12 mL) were hydrogenated in the hydrogen stream for 1.5 h. Usual processing followed by gel filtration (Sephadex LH 20, ethanol–water, 1:1) provided **43** (32.4 mg, 90%) as a white solid; $[\alpha]_D$ +70.3 (*c* 0.3, water). The ^1H and ^{13}C NMR data are reported in Tables 1 and 2.

*1,5-Dideoxy-3-*O*-(4-deoxy-α-D-*xylo*-hexopyranosyl)-1,5-imino-D-mannitol-hydrochloride (**44**)*

A mixture of compound **33** (163.6 mg, 0.183 mmol), 5% palladium-on-carbon (150 mg), and methanolic 0.12 N hydrochloric acid (1.7 mL, 0.20 mmol) in methanol (18 mL) was hydrogenated in the hydrogen stream for 2.5 h. The catalyst was removed by filtration, followed by evaporation. Gel filtration of the resultant material on a column of Sephadex LH 20 (ethanol–water, 1:1) afforded the title compound **44** (45.6 mg, 72%) as a slightly yellowish powder; $[\alpha]_D$ +77.3 (*c* 0.3, water). The ^1H and ^{13}C NMR data are reported in Tables 1 and 2.

*1,5-Dideoxy-1,5-imino-3-*O*-(4-*O*-methyl-α-D-glucopyranosyl)-D-mannitol-hydrochloride (**45**)*

A mixture of **34** (114.3 mg, 0.12 mmol), 5% palladium-on-carbon (110 mg), and methanolic 0.12 N hydrochloric acid (1.13 mL, 0.14 mmol) in methanol (6 mL) was hydrogenated in the hydrogen stream for 2 h. The catalyst was removed by filtration and the solvent evaporated. The resultant material was passed through a column of Iatrobeads® (chloroform–methanol–water, 65:35:8) followed by gel filtration (Sephadex LH 20, ethanol–water, 1:1) to provide **45** (46.5 mg, 100%) as a solid; $[\alpha]_D$ +81 (*c* 0.4, water). The ^1H and ^{13}C NMR data are reported in Tables 1 and 2.

*1,5-Dideoxy-3-*O*-(α-D-galactopyranosyl)-1,5-imino-D-mannitol-hydrochloride (**46**)*

A mixture of **36** (128 mg, 0.128 mmol), 5% palladium-on-carbon (128 mg), and methanolic 0.12 N hydrochloric acid (1.1 mL, 0.13 mmol) in methanol (7 mL) was hydrogenated in a hydrogen stream for 3 h. The catalyst was removed by filtration, followed by evaporation. The resultant material was subjected to gel filtration (Sephadex LH 20, ethanol–water, 1:1) to provide, after freeze-drying an aqueous solution, title compound **46** (42.5 mg, 92%); $[\alpha]_D$ +91.6 (*c* 0.2, water). The ^1H and ^{13}C NMR data are reported in Tables 1 and 2.

*1,5-Dideoxy-3-*O*-(6-deoxy-α-D-glucopyranosyl)-1,5-imino-D-mannitol-hydrochloride (**47**)*

A mixture of **37** (183.1 mg, 0.21 mmol), 5% palladium-on-carbon (140 mg), and methanolic 0.12 N hydrochloric acid (1.87 mL, 0.224 mmol) in methanol (10 mL) was hydrogenated in the hydrogen stream for 2 h. The catalyst was removed by filtration and the solvent evaporated. The resultant material was passed through a column of Iatrobeads® (chloroform–methanol–water, 65:35:8) followed by gel filtration (Sephadex LH 20, ethanol–water, 1:1) to provide **47** (60.5 mg, 85%) as a white solid, $[\alpha]_D$ +64.4 (*c* 0.5, water). The ^1H and ^{13}C NMR data are reported in Tables 1 and 2.

*1,5-Dideoxy-1,5-imino-3-*O*-(α-D-xylopyranosyl)-D-mannitol-hydrochloride (**48**)*

A mixture of compound **39** (170 mg, 0.19 mmol), 5% palladium-on-carbon (170 mg), methanolic 0.12 N hydrochloric acid (1.6 mL, 0.19 mmol), and methanol (10 mL) was hydrogenated in a hydrogen stream for 3 h. The catalyst was removed by filtration, followed by evaporation and codistillation with water. The product was passed through a column of Sephadex LH 20 (ethanol–water, 1:1) to provide, after freeze-drying an aqueous solution, the title compound **48** (59.6 mg, 93%) as a white solid, $[\alpha]_D$ +63 (*c* 0.3, water). The ^1H and ^{13}C NMR data are reported in Tables 1 and 2.

*3,4,6-Tri-*O*-benzyl-2-deoxy-α-D-*arabino*-hexopyranosyl chloride (**49**) (22)*

49 was prepared just prior to use according to ref. 22 and characterized by ^1H NMR spectroscopy. ^1H NMR ($CDCl_3$) δ: 7.4–7.1 (m, 15H, 3Ph), 6.30 (d, 1H, $J_{1,2ax}$ 3.3 Hz, $J_{1,2eq}$ ~ 1 Hz, H-1), 4.16 (ddd, 1H, $J_{2ax,3}$ 11.0 Hz, $J_{2eq,3}$ 4.5 Hz, $J_{3,4}$ 9.5 Hz, H-3), 4.06 (ddd, 1H, $J_{4,5}$ 9.5 Hz, $J_{5,6}$ 3.7 Hz, $J_{5,6'}$ 1.8 Hz, H-5), 3.81 (dd, 1H, $J_{6,6'}$ 11.0 Hz, H-6), 3.71 (t, 1H, H-4), 3.65 (dd, 1H, H-6′), 2.51 (ddd, 1H, $J_{2eq,2ax}$ 13.5 Hz, H-2eq), 3.73 (ddd, 1H, H-2ax).

*2,4,6-Tri-*O*-benzyl-3-*O*-methyl-α,β-D-glucopyranosyl chloride (**50**)*

2,4,6-Tri-*O*-benzyl-3-*O*-methyl-D-glucopyranose (15) (550 mg, 1.18 mmol) was converted into chloride **50** as described for the preparation of **3**. ^1H NMR ($CDCl_3$, α:β = 2:1) δ: 7.4–7.1 (m, 15H, 3Ph), 5.99 (d, $J_{1\alpha,2}$ 3.5 Hz, H-1α), 5.13 (d, $J_{1\beta,2}$ 8.5 Hz, H-1β), 4.00 (m, $J_{4,5}$ 10.0 Hz, H-5α) 3.64 (s, CH_3O-α), 3.62 (s, CH_3O-β).

*6-O-Acetyl-2,3,4-tri-*O*-benzyl-α,β-D-glucopyranosyl chloride (**51**) (11)*

6-*O*-Acetyl-2,3,4-tri-*O*-benzyl-D-glucopyranose (19) (68 mg, 0.138 mmol) was converted into **51** as described for the preparation of chloride **3**. ^1H NMR ($CDCl_3$, α:β = 1.5:1) δ: 7.4–7.1 (m, 15H, 3Ph), 5.99 (d, $J_{1\alpha,2}$ 3.5 Hz, H-1α), 5.20 (d,$J_{1\beta,2}$ 8.0 Hz, H-1β), 4.33 (dd, $J_{6,6'}$ 12.0 Hz, $J_{5,6}$ ~ 1 Hz, H-6β), 4.25 (d, $J_{6,5}$ 3.2 Hz, 2H-6α), 4.18 (dd, $J_{5,6'}$ 4.5 Hz, H-6′β), 4.12 (dt, $J_{4,5}$ 10.0 Hz, H-5α), 4.04 (t, 1H, $J_{3,4}$ ~ $J_{2,3}$ 9.2 Hz, H-3α), 3.68 (dd, H-2α), 3.51 (dd, H-4α), 2.04, 2.00 (2s, CH_3CO-β, CH_3CO-α).

*6-O-Acetyl-2,4-di-*O*-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-*O*-(3,4,6-tri-*O*-benzyl-2-deoxy-α-D-*arabino*-hexopyranosyl)-D-mannitol (**52**)*

A solution of chloride **49** (0.73 mmol) in dichloromethane (1 mL) was added at −65°C to a stirred mixture of **2** (145 mg, 0.28 mmol), silver trifluoromethanesulfonate (188.3 mg, 0.73 mmol), *sym*-collidine (34.9 μL, 0.26 mmol), and 4 Å molecular sieves (400 mg) in dichloromethane (2 mL). After 1.5 h at this temperature, triethylamine (80 μL, 0.61 mmol) was added and stirring continued for 30 min at room temperature. Usual work-up was followed by chromatography on a column of silica gel to afford **52** (189.3 mg, 73%) as a syrup; $[\alpha]_D$ +26.2 (*c* 0.5, chloroform). ^1H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.4–7.05 (m,

30H, 6Ph), 5.2–3.0 (complex m, 26H), 2.04 (ddd, 1H, $J_{2eq',2ax'}$ 13.5 Hz, $J_{2eq',3'}$ 4.5 Hz, H-2eq'), 1.94 and 1.85 (2s, 3H, CH_3CO), 1.67 (ddd, 1H, $J_{2ax',1'}$ 3.3 Hz, $J_{2ax',3'}$ 12.0 Hz, H-2ax'). Anal. calcd. for $C_{57}H_{61}NO_{11}$: C 73.14, H 6.57, N 1.50; found: C 73.32, H 7.01, N 1.59.

*6-O-Acetyl-2,4-di-O-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-3-O-(2,4,6-tri-O-benzyl-3-O-methyl-α-D-glucopyranosyl)-D-mannitol (**53**) and -β-D-glucopyranosyl)-D-mannitol (**54**)*

A solution of chloride **50** (1.18 mmol) in dichloromethane was added to a stirred mixture of **2** (276 mg, 0.53 mmol), silver trifluoromethanesulfonate (335 mg, 1.30 mmol), *sym*-collidine (56 μL, 0.42 mmol), and 4 Å molecular sieves (500 mg) in dichloromethane (2 mL) at −40°C. The mixture was gradually allowed to reach 0°C and, after 10 h, more *sym*-collidine (100 μL, 0.76 mmol) was added. Conventional work-up was followed by chromatography of the crude product on a column of silica gel (hexane–ethyl acetate, 5:1, 4:1, 3:1) to provide in the first main fraction the β-isomer **54** (111.1 mg, 22%); $[\alpha]_D$ −4.7 (*c* 0.7, chloroform). ^{1}H NMR (broad, mixture of two rotamers in the ratio 3:2) δ: 7.4–7.0 (m, 30H, 6Ph), 5.2–3.1 (complex m, 30H), 3.58 (s, 3H, CH_3O), 1.88 and 1.79 (2s, 3H, CH_3CO). ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 156.0 (CO), 104.86 ($J_{C,H}$ 160.9 Hz, C-1'), 61.35, 61.21 (CH_3O, C-6), 53.07 (52.44) (C-5), 38.40 (37.85) (C-1), 20.58 (CH_3CO). Continued elution gave **53** (277.4 mg, 54%); $[\alpha]_D$ +48.4 (*c* 0.7, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers in the ratio 3:2) δ: 7.4–7.0 (m, 30H, 6Ph), 5.2–3.0 (complex m, 30H), 3.65 (s, 3H, CH_3O), 1.82 and 1.74 (2s, 3H, CH_3CO). Anal. calcd. for $C_{58}H_{63}NO_{12}$: C 72.11, H 6.57, N 1.45; found: C 72.49, H 6.38, N 1.42.

*6-O-Acetyl-3-O-(6-O-acetyl-2,3,4-tri-O-benzyl-α- and -β-D-glucopyranosyl)-2,4-di-O-benzyl-N-benzyloxycarbonyl-1,5-dideoxy-1,5-imino-D-mannitol (**55** and **56**)*

A solution of chloride **51** (0.13 mmol) in dichloromethane (1.5 mL) was transferred into a stirred mixture of **2** (34 mg, 0.065 mmol), silver trifluoromethanesulfonate (43 mg, 0.17 mmol), *sym*-collidine (7.1 μL, 0.054 mmol), and 4 Å molecular sieves (100 mg) in dichloromethane (0.3 mL) at 0°C. After 1 h at this temperature, more *sym*-collidine (10 μL, 0.076 mmol) was added and the reaction mixture was processed as usual. The resultant material was applied to a column of silica gel (hexane – ethyl acetate, 5:1, 4:1) to provide in the first main fraction the β-anomer **56** (14.0 mg, 22%) as a tough syrup; $[\alpha]_D$ −18.9 (*c* 0.3, chloroform). ^{1}H NMR ($CDCl_3$, broad, mixture of two rotamers) δ: 7.4–7.0 (m, 30H, 6Ph). 5.2–3.1 (complex m, 27H), 1.98 (s, 3H, CH_3CO-6') 1.92 and 1.82 (2s, 3H, CH_3CO-6). ^{13}C NMR ($CDCl_3$, δ minor rotamer in parentheses) δ: 170.57 (CH_3CO), 156.40 (OCO), 104.91 ($J_{C,H}$ 161.5 Hz, C-1'), 62.51 (C-6'), 61.20 (61.04) (C-6), 52.90 (52.20) (C-5), 38.37 (37.84) (C-1), 20.77, 20.57 (CH_3CO). Continued elution of the column afforded **55** (40 mg, 62%) as a tough syrup; $[\alpha]_D$ +19.5 (*c* 0.2, chloroform). ^{1}H NMR (broad, mixture of two rotamers) δ: 7.4–7.1 (m, 30H, 6Ph), 5.2–3.0 (complex m, 27H), 1.91 (s, 3H, CH_3CO-6'), 1.83 and 1.75 (2s, 3H, CH_3CO-6). Anal. calcd. for $C_{59}H_{63}NO_{13}$: C 71.28, H 6.39, N 1.41; found: C 71.44, H 6.42, N 1.44.

*2,4-Di-O-benzyl-N,6-O-carbonyl-1,5-dideoxy-1,5-imino-3-O-(3,4,6-tri-O-benzyl-2-deoxy-α-D-*arabino*-hexopyranosyl)-D-mannitol (**57**)*

A solution of **52** (156.6 mg, 0.167 mmol) in methanolic 0.5 N sodium methoxide (1 mL) was kept at room temperature for 3.5 h. The remainder on evaporation was taken up in dichloromethane and the solution washed with water until neutral, followed by evaporation. Column chromatography provided the title compound **57** (108.4 mg, 83%) as a syrup; $[\alpha]_D$ +15 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.4–7.1 (m, 25H, 5Ph), 5.22 (bd, 1H, $J_{1',2ax'}$ 3.0 Hz, $J_{1',2eq'}$ ~ 1 Hz, H-1'), 4.97–4.37 (m, 10H, 5CH_2Ph), 4.28 (t, 1H, $J_{5,6A}$ ~ $J_{6A,6B}$ ~ 8.5 Hz, H-6A), 4.06 (dd, 1H, $J_{1A,1B}$ 14.0 Hz, $J_{1A,2}$ 2.0 Hz, H-1A), 4.01 (m, 1H, H-3'), 3.88 (overlapped, H-2), 2.71 (bd, 1H, H-1B), 2.25 (bdd, 1H, $J_{2eq',2ax'}$ 13.0 Hz, $J_{2eq',3'}$ 11.0 Hz, H-2eq') 1.72 (ddd, 1H, $J_{2ax',3'}$ 11.0 Hz, H-2ax'). ^{13}C NMR ($CDCl_3$) δ: 157.7 (CO), 100.03 ($J_{C,H}$ 169.4 Hz, C-1'), 65.58 (C-6), 57.53 (C-5), 41.12 (C-1), 35.77 (C-2'). Anal. calcd. for $C_{48}H_{51}NO_9$: C 73.35, H 6.54, N 1.78; found: C 73.46, H 6.88, N 1.64.

*2,4-Di-O-benzyl-N-6-O-carbonyl-1,5-dideoxy-1,5-imino-3-O-(2,3,4-tri-O-benzyl-α-D-glucopyranosyl)-D-mannitol (**59**)*

A solution of **55** (400 mg, 0.40 mmol) in methanolic 0.5 N sodium methoxide (4 mL) was kept at room temperature for 15 h. It was diluted with dichloromethane and the solution was washed with 1% hydrochloric acid and water. The product obtained on evaporation was purified on a column of silica gel (dichloromethane – ethyl acetate, 1:2) to provide **59** (294.9 mg, 91%) as a white foam; $[\alpha]_D$ +33.6 (*c* 0.3, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.4–7.0 (m, 25H, 5Ph), 4.99 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 4.20 (dd, overlapped, 1H, $J_{1A,1B}$ 14.5 Hz, $J_{1A,2}$ 2.5 Hz, H-1A), 3.94 (bs, 1H, H-2), 3.46 (dd, 1H, $J_{2',3'}$ 10.0 Hz, H-2'), 2.82 (dd, 1H, $J_{1B,2}$ < 1 Hz, H-1B). ^{13}C NMR ($CDCl_3$) δ: 156.76 (CO), 100.21 (C-1'), 65.77 (C-6), 61.98 (C-6'), 57.47 (C-5), 40.93 (C-1). Anal. calcd. for $C_{48}H_{51}NO_{10}$: C 71.89, H 6.41, N 1.75; found: C 71.68, H 6.36, N 1.60.

*2,4-Di-O-benzyl-N-6-O-carbonyl-1,5-dideoxy-1,5-imino-3-O-(2,3,4-tri-O-benzyl-6-O-methyl-α-D-glucopyranosyl)-D-mannitol (**60**)*

A mixture of **59** (258 mg, 0.32 mmol), silver oxide (410 mg, 1.77 mmol), and methyl iodide (300 μL, 4.82 mmol) in toluene (6.3 mL) was stirred in the dark for 17 h. More methyl iodide (200 μL, 3.21 mmol) was added and stirring continued for another 4 h. Filtration and evaporation of the solvent left a crystalline residue, which was passed through a column of silica gel (dichloromethane – ethyl acetate, 1:1, 1:2) to give **60** (240.3 mg, 91%) as a white solid; $[\alpha]_D$ +22 (*c* 0.3, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.4–7.0 (m, 25H, 5Ph), 4.99 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 4.21 (dd, 1H, $J_{1A,1B}$ 14.5 Hz, $J_{1A,2}$ 2.5 Hz, H-1A), 4.01 (m, 1H, H-2), 3.50 (overlapped, H-2'), 3.27 (s, 3H, CH_3O), 2.82 (dd, 1H, $J_{1B,2}$ < 1 Hz, H-1B). Anal. calcd. for $C_{49}H_{53}NO_{10}$: C 72.13, H 6.55, N 1.72; found: C 72.21, H 6.26, N 1.67.

*2,4-Di-O-benzyl-1,5-dideoxy-1,5-imino-3-O-(3,4,6-tri-O-benzyl-2-deoxy-α-D-*arabino*-hexopyranosyl)-D-mannitol (**61**)*

57 (85.5 mg, 0.109 mmol) in a 0.5 N potassium hydroxide solution in 90% ethanol (9.5 mL) was heated at 60°C for 3 h. It was neutralized with acetic acid, followed by solvent removal. The material was taken up in dichloromethane, and the solution was washed with a little water and evaporated. Chromatographic purification on a column of silica gel (dichloromethane – 3% methanol) afforded **61** (73.6 mg, 89%) as a syrup; $[\alpha]_D$ +20.6 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.45–7.10 (m, 30H, 5Ph), 5.26 (unresolv. dd, 1H, $J_{1',2ax'}$ 3.0 Hz, $J_{1',2eq'}$ ~ 1 Hz, H-1'), 4.02 (ddd, 1H, $J_{3',4'}$ 9.0 Hz, $J_{2ax',3'}$ 11.5 Hz, $J_{2eq',3'}$ 4.5 Hz, H-3'), 3.89 (dt, 1H, $J_{4',5'}$ 9.5 Hz, H-5'), 3.54 (overlapped, H-4'), 3.06 (dd, 1H, $J_{1A,2}$ 2.5 Hz, $J_{1A,1B}$ 14.2 Hz, H-1A), 2.55 (m, 1H, H-5), 2.47 (d, 1H, $J_{1B,2}$ < 1 Hz, H-1B), 2.25 (dd, 1H, $J_{2eq',2ax'}$ 13.0 Hz, H-2eq'), 1.71 (ddd, 1H, H-2ax'). ^{13}C NMR ($CDCl_3$) δ: 99.69 (C-1'), 62.57, 61.66 (C-5, C-6), 46.57 (C-1), 35.82 (C-2'). Anal. calcd. for $C_{47}H_{51}NO_8$: C 74.28, H 7.03, N 1.84; found: C 74.26, H 7.14, N 1.75.

*2,4-Di-O-benzyl-1,5-dideoxy-1,5-imino-3-O-(2,4,6-tri-O-benzyl-3-O-methyl-α-D-glucopyranosyl)-D-mannitol (**62**)*

A solution of **53** (230 mg, 0.24 mmol) in methanolic 0.5 N sodium methoxide (2 mL) was left at room temperature for 17 h. The solvent was evaporated and the remainder (**58**) was taken up in 0.5 N sodium hydroxide in 90% ethanol (4 mL) and heated at 70°C for 30 h. It was neutralized with acetic acid, followed by evaporation. The resultant material was taken up in dichloromethane and the solution washed with a little water, followed by drying and

evaporation of the organic solution. Chromatographic purification of the crude product on a column of silica gel (dichloromethane – 3% methanol) afforded **62** (163.5 mg, 87%) as a tough syrup; $[\alpha]_D$ +31.3 (*c* 0.2, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.4–7.1 (m, 25H, 5Ph), 4.02 (unres. ddd, 1H, $J_{4',5'}$ 10.0 Hz, H-5′), 3.82 (unres. m, 1H, H-2), 3.63 (s, 3H, CH_3O), 3.03 (dd, 1H, $J_{1A,1B}$ 14.5 Hz, $J_{1A,2}$ 4.5 Hz, H-1A), 2.64 (m, 1H, H-5), 2.52 (bd, 1H, H-1B). Anal. calcd. for $C_{48}H_{53}NO_9$: C 73.17, H 6.78, N 1.78; found: C 72.84, H 6.98, N 1.71.

*2,4-Di-*O*-benzyl-1,5-dideoxy-1,5-imino-3-*O*-(2,3,4-tri-*O*-benzyl-6-*O*-methyl-α-*D*-glucopyranosyl)-*D*-mannitol (**63**)*

Compound **60** (220 mg, 0.27 mmol) in 0.9 N potassium hydroxide solution in 90% ethanol (5 mL) was heated at 60°C for 7 h. The mixture was neutralized with glacial acetic acid and evaporated to dryness. The remainder was taken up in dichloromethane, followed by washing of the organic solution with a little water, drying, and evaporation. Column chromatography on silica gel (dichloromethane – 3–5% methanol) provided syrupy **63** (190 mg, 89%); $[\alpha]_D$ +44 (*c* 0.2, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.4–7.15 (m, 25H, 5Ph), 4.01 (m, 2H, H-3′, H-5′), 3.81 (m, 1H, H-2), 3.48 (dd, $J_{1',2'}$ 3.5 Hz, $J_{2',3'}$ 9.5 Hz, H-2′), 3.22 (s, 3H, CH_3O), 3.08 (dd, 1H, $J_{1A,1B}$ 14.5 Hz, $J_{1A,2}$ 5.0 Hz, H-1A), 2.69 (m, 1H, H-5), 2.58 (dd, 1H, $J_{1B,2}$ 1.8 Hz, H-1B).

*1,5-Dideoxy-3-*O*-(2-deoxy-α-*D*-*arabino*-hexopyranosyl)-1,5-imino-*D*-mannitol (**64**)*

Compound **61** (55.4 mg, 0.073 mmol), 5% palladium-on-carbon (50 mg), and methanolic 0.12 N hydrochloric acid (759 μL, 0.09 mmol) in methanol (6 mL) were hydrogenated in the hydrogen stream for 2 h. The excess of acid was neutralized by a minimal amount of triethylamine to avoid hydrolysis of the glycosidic linkage. Usual processing and gel filtration provided **64** (22.2 mg, 88%) as a solid after lyophilization of an aqueous solution; $[\alpha]_D$ +53 (*c* 0.3, water). The ^{1}H and ^{13}C NMR data are reported in Tables 1 and 2.

*1,5-Dideoxy-1,5-imino-3-*O*-(3-*O*-methyl-α-*D*-glucopyranosyl)-*D*-mannitol-hydrochloride (**65**)*

A mixture of **62** (140 mg, 0.18 mmol), 5% palladium-on-carbon (140 mg), and methanolic 0.12 N hydrochloric acid (1.9 mL, 0.23 mmol) in methanol (7 mL) was hydrogenated in a hydrogen stream for 2 h. Usual processing provided **65** (64.3 mg, 96%) as a white solid; $[\alpha]_D$ +72 (*c* 0.2, water). The ^{1}H and ^{13}C NMR data are reported in Tables 1 and 2.

*1,5-Dideoxy-1,5-imino-3-*O*-(6-*O*-methyl-α-*D*-glucopyranosyl)-*D*-mannitol-hydrochloride (**66**)*

Compound **63** (190 mg, 0.24 mmol), 5% palladium-on-carbon (190 mg), and 0.12 N methanolic hydrochloric acid (2.5 mL, 0.3 mmol) in methanol (8 mL) were hydrogenated in the hydrogen stream for 2 h. Usual processing followed by gel-filtration (Sephadex LH 20, ethanol–water, 1:1) provided **66** (82.9 mg, 92%) as a white solid; $[\alpha]_D$ +67.8 (*c* 0.2, water). The ^{1}H and ^{13}C NMR data are reported in Tables 1 and 2.

The synthesis of the isomeric components of San Jose scale pheromone — an illustration of a stereospecific synthesis of trisubstituted alkenes

MARGOT ALDERDICE, CLAUDE SPINO,[1] AND LARRY WEILER[2]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, BC V6T 1Z1, Canada

Received April 14, 1993

MARGOT ALDERDICE, CLAUDE SPINO, and LARRY WEILER. Can. J. Chem. **71**, 1955 (1993).

The three isomeric components of the San Jose scale pheromone, **5**–**7**, have been synthesized from a common β-keto ester intermediate. A study of the alkylation of the dianion of methyl acetoacetate with a series of alkylating agents with the same carbon skeleton has been carried out. The trisubstituted alkenes in **5** and **6** have been synthesized stereospecifically via a copper-catalyzed coupling of a methyl Grignard reagent with the *E* or *Z* enol phosphate from the alkylated β-keto ester. In the case of the *Z* enol derivative, the coupling reaction was carried out on the diethyl- and diphenylphosphates, and the enol triflate. The diethyl enol phosphate gave the highest stereoselectivity. The synthetic pheromones were attractive to San Jose scale in the field.

MARGOT ALDERDICE, CLAUDE SPINO et LARRY WEILER. Can. J. Chem. **71**, 1955 (1993).

Utilisant un β-céto ester commun comme intermédiaire, on a synthétisé les trois isomères **5**–**7** de la phéromone du pou de San José. On a réalisé une étude de l'alkylation du dianion de l'acétoacétate de méthyle par une série d'agents d'alcoylation ayant le même squelette carboné. On a synthétisé les alcènes trisubstitués **5** et **6** d'une manière stéréospécifique en faisant appel à un couplage catalysé par le cuivre d'un méthyl magnésien avec le phosphate d'énol *E* ou *Z* obtenu à partir du β-céto ester alcoylé. Dans le cas du dérivé énolique *Z*, on a réalisé la réaction de couplage sur les phosphates énoliques diéthylé et de diphénylé et sur le triflate énolique. Le phosphate énolique diéthylique donne la meilleure stéréosélectivité. Dans les champs, les phéromones de synthèse attirent le pou de San José.

[Traduit par la rédaction]

Introduction

The ability to introduce alkenes with control of the position and geometry of the double bond has led to significant advances in the synthesis of natural and unnatural products for several decades (1). Those methods which allow one to control the regio- and stereochemistry of the double bond often have the most widespread utility. The synthesis of tri- and tetrasubstituted alkenes is usually more challenging than that of disubstituted alkenes.

3,3-Dimethylacrylate esters undergo regioselective deprotonation (2), and subsequent alkylation of the derived lithium carbanions usually occurs at the α-carbon, although the copper enolate of the dianion from the corresponding acid was found to react with allylic halides at the γ-carbon (3).

A general method to directly alkylate the carbanion corresponding to synthons **A** or **B** has not been reported to date. The Horner-Wadsworth-Emmons reaction has proven useful in the synthesis of molecules of structure **3** in which the group R is "smaller" than the $R'CH_2$ (4) group. The conjugate addition of cuprates to alkynes (5) has provided a highly stereoselective route to compounds of the type **3** (6). A recent very promising method utilizes the stereospecific conjugate addition of a stannyl cuprate to propargyl esters to give either the (*E*)- or (*Z*)-3-stannyl-2-alkenoate depending on the reaction conditions (7). Subsequent coupling of the vinyl stannane or halogenation followed by coupling gives the (*E*)- or (*Z*)-trisubstituted alkene (8).

A few years ago we developed a method for the stereospecific synthesis of the trisubstituted alkenes **3** or **4** (9). This, in combination with the dianion alkylation of β-keto esters such as **1** (10), led to a method to introduce the units **A** or **B** into a synthetic intermediate via the pathway outlined in eq. [1]. In this paper we report the application of this methodology to the synthesis of the three components of the San Jose scale pheromone.

The San Jose scale, *Quadraspidiotus pernicious*, is a widespread insect pest that attacks fruit and ornamental trees. San Jose scale is a particularly serious pest in the apple orchards of the southern Okanagan Valley of British Columbia. The insect is controlled by heavy pruning, and extensive spraying of dormant oil and organophosphates. By optimizing the timing of the organophosphate sprays, which are targeted at the mature male stage of the insect (11), the amount of spray required for control can be reduced significantly. The female scale produces a mixture of three compounds that are highly attractive to the male species. The structures of the three compounds, **5**–**7**, were solved by spectroscopic methods (12) and confirmed by synthesis (13).

Following the preliminary communication of our work (14), two other syntheses of these compounds were reported (15). The first of these syntheses involved a regioselective allylic chlorination of the propionate esters of geraniol or nerol followed by reduction of the allylic halide to give **5** or **6** as shown in eq. [2] (15*a*). The second method relied on the photochemical isomerization of the conjugated ester shown in eq. [3] to a mixture of the β,γ-unsaturated esters in which the desired disubstituted alkene was the major component and it was converted into **7** (15*b*).

[a]Coupling reactions were carried out by adding the enol derivative **11** to a solution of MeCu and MeMgCl in THF at −25°C.
[b]Yield of distilled or chromatographed product **12**.

Results and discussion

We sought a method to prepare all three of the San Jose scale pheromone components from a common intermediate. An obvious choice for this intermediate is the β-keto ester **10**, which would be readily available from the dianion **8** of methyl acetoacetate and an alkylating agent derived from 3-methyl-3-buten-1-ol (**9**, X = OH). This provided an opportunity to evaluate the utility of various alkylating agents in the reaction with the dianion of methyl acetoacetate. Table 1 contains the results of a study of leaving groups in this alkylation. The highest yields are obtained with halides, although the aryl sulfonates are usually easier to prepare and purify. Thus, we found the benzenesulfonate to be best for the large scale preparation of **10**. In the case of hindered alkylating agents we have found that the triflate is the best leaving group (16).

The β-keto ester **10** was converted into the *Z*-enol phosphates and enol triflate **11**. These reactions were very stereoselective. The enol derivative **11***b* was obtained in excellent yield and the greater than 99% *Z* as determined by GC. The stereochemistry of the olefin was proven by ^1H NMR. Next we undertook a study of the coupling reaction of these enol derivatives with the methyl Grignard reagent in the presence of a copper catalyst (17). The diphenyl phosphate and triflate gave a higher yield of **12**, but with a lower stereoselectivity (Table 2). Because of the difficulty in separating the geometric isomers of **12**, experimentally we found the diethyl phosphate coupling to be the most satisfactory to carry out in this case.

The *E*-alkene **12** was then converted into the *E* pheromone **5** by reduction and esterification in greater than 80% yield for the two steps. This compound had identical spectroscopic properties and biological activity to the natural pheromone.

By altering the reaction conditions, we are able to cleanly prepare the *E*-enol phosphate **13**. This stereoselectivity takes advantage of the fact that in ether solvents the metal cation enolates are tight ion pairs and in these solvents exist as the coordinated complex **15**, whereas in more polar solvents, such as HMPA and organic cationic counterions, the enolate is free and exists in the W-conformation **16** in which the negatively charged oxygens are distant from each other (18). In each case the O-alkylating agent traps the enolate before any conformational isomerization. Thus **16** gives **13** in good yield with no trace of any *Z*-enol phosphate **11***b* in the crude reaction mixture as determined by GC. The copper-catalyzed Grignard coupling of **13** then gives **14** in good yield and excellent stereoselectivity. Ester **14** was reduced and esterified to give the pheromone **6**, which was identical to the naturally occurring compound.

The synthesis of the third component of the pheromone mixture, alkene **7**, presented a different problem if we were to use the β-keto ester **10** as starting material. Due to the acidity of the α-methylene protons, Wittig reactions and their variations proceed in low yield on enolizable β-keto esters. We had shown that trimethylsilylmethylmagnesium chlo-

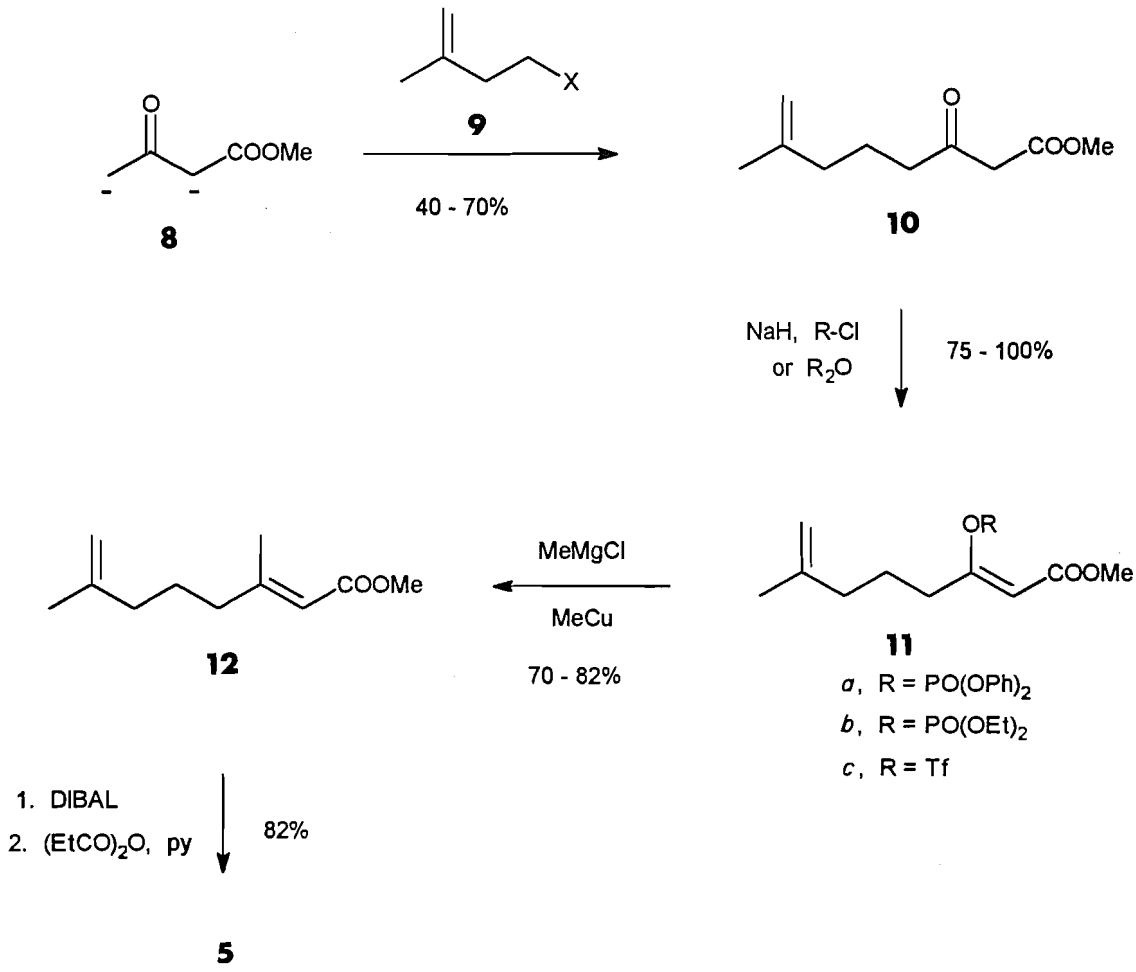
For personal use only.



ride in the presence of nickel(II) added cleanly to enol phosphates of β-keto esters (19). Indeed the addition of these reagents to **11***b* or **13** gave the corresponding allyl silanes **17** and **18**, respectively. Treatment of these allyl silanes with a variety of protic and Lewis acids gave the cyclized compound **19** as the only isolable product. If the reaction was allowed to continue for longer periods of time **19** did slowly isomerize to the endocyclic isomers. Thus electrophilic attack on the terminal disubstituted alkene is faster than attack on the conjugated alkene, and the deactivating effect of the ester must be greater than the activating effect of the allylic trimethylsilyl group (20).

This problem was eventually solved by reducing the ester and then carrying out an olefination reaction. Ester reduction was achieved in two ways. The first involved formation of the monoanion of the β-keto ester **10** and reduction of this monoanion with DIBAL (21) to **20**. In the second method, the ketone carbonyl was converted into its silyl enol ether. The ester was then reduced and the enol ether hydrolyzed during work-up to give **20**. In our hands the latter route, although longer, consistently gave better yields of **20**. The keto alcohol **20** was then esterified and treated with the modified Tebbe reagent (22) to give **7**, which was identical in spectroscopic properties and biological activity to the third component of the San Jose scale pheromone.

Thus we have illustrated the utility of the methodology to stereoselectively introduce the units **A**, **B**, or **C** into a molecule using the alkylation of the dianion of a β-keto ester. The three synthetic components **5**–**7** were used to monitor San Jose scale in the Okanagan Valley. All three isomers were active in the field and the *E* isomer **5** was the most attractive of the three at the same release rates (23).

Experimental section

General procedures

Kugelrohr distillations were performed with a Büchi Kugelrohr apparatus. Infrared spectra were recorded in chloroform solution on a Perkin–Elmer model 710 spectrophotometer, and were calibrated with the 1601 cm^{-1} band of polystyrene. Proton nuclear magnetic resonance spectra were recorded on a Varian T-60 (60 MHz) and a Bruker WP-80 (80 MHz). Chemical shifts are reported on the δ scale, with $CDCl_3$ as solvent and tetramethylsilane as internal standard. The multiplicity, coupling constants (if determined), and integrated peak areas are given in parentheses after each signal. Low-resolution mass spectra were recorded on a Kratos-AEI MS-50, and high-resolution mass measurements were determined on a Kratos-AEI MS-9 or MS-50. Both instruments were operated at an ionization potential of 70 eV. Elemental analyses were performed by Mr. Peter Borda, Microanalysis Laboratory, University of British Columbia.

Silica gel $PF_{254+366}$ (E. Merck) was used for both analytical and preparative thin-layer chromatography, while flash chromatography (24) was carried out using Silica Gel 60, 230–400 mesh ASTM (E. Merck). All mixed solvent systems are expressed in ratios by volume.

The petroleum ether used was of the boiling range 30–60°C. Dry solvents were prepared as follows: diethyl ether and tetrahydrofuran by distillation from lithium aluminium hydride or sodium–

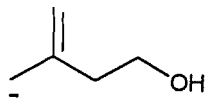
benzophenone; dichloromethane by distillation from phosphorus pentoxide; and acetone by distillation from Drierite. *n*-Butyllithium and diisobutylaluminium hydride solutions were obtained from Aldrich. The *n*-BuLi solutions were standardized by titration against 0.1 M *tert*-butanol solution using 1,10-phenanthroline as indicator (25). Sodium hydride (Aldrich) was weighed as a 60% dispersion in mineral oil and washed with ether or petroleum ether to remove the oil prior to use. All reactions were run under a dry nitrogen at-



c

mosphere and organic extracts were dried with anhydrous magnesium sulfate.

*4-Bromo-2-methyl-1-butene (**9**a)*

This compound was prepared from 1.4 g (16 mmol) of 3-methyl-3-buten-1-ol in 42% distilled yield according to the procedure of Bhanot and Dutta (26) to give a colourless oil; bp 105°C/760 Torr (1 Torr = 133.3 Pa) (lit. (26) bp 105–107°C/760 Torr); ^{1}H NMR (60 MHz) δ: 1.76 (bs, 3H), 2.53 (t, J = 7 Hz, 2H), 3.43 (t, J = 7 Hz, 2H), and 4.7–5.0 (m, 2H).

*4-Iodo-2-methyl-1-butene (**9**b)*

A solution of 10.0 g (42 mmol) of the tosylate **9***d* (see below) was dissolved in 160 mL of a dry acetone-saturated solution of NaI. This solution was stirred at room temperature overnight. Then the solid salts were filtered off and the precipitate was washed several times with acetone. The acetone was evaporated under reduced pressure. The resulting oil was dissolved in 100 mL of ether and washed with 2 × 50 mL of 10% aqueous $Na_2S_2O_3$. The aqueous layers were extracted with 3 × 50 mL of ether. The ether layers were combined, dried, and the solvents were removed under reduced pressure to yield 5.9 g (72%) of a crude product, which was one spot by TLC and was suitable for the subsequent dianion alkylation. This material was a pale orange oil that gradually darkened on standing; ^{1}H NMR (60 MHz) δ: 1.70 (bs, 3H), 2.57 (t, J = 7 Hz, 2H), 3.23 (t, J = 7 Hz, 2H), and 4.77 (bd, J = 4 Hz, 2H); HRMS calcd. for C_5H_9I: 195.9749; found: 195.9753.

*3-Methyl-3-butenyl-1-benzenesulfonate (**9**c)*

A solution of 8.00 g (93 mmol) of 3-methyl-3-buten-1-ol in 100 mL of CH_2Cl_2 was flushed with N_2 and cooled in an ice bath. Pyridine (14.7 g, 15.0 mL, 0.186 mol) and benzenesulfonyl chloride (16.4 g, 11.8 mL, 0.093 mol) were added, and the resulting solution was stirred at 0°C for 4 h. The reaction mixture was then diluted with cold ether and acidified with cold 1 M HCl. The organic layer was separated, washed with cold saturated aqueous $NaHCO_3$ solution, cold brine, dried, filtered, and concentrated to give a quantitative yield (21.0 g) of the benzenesulphonate **9***c* as a yellow oil. The benzenesulfonate is relatively unstable and is best stored at 0°C or lower. The material darkens quickly at room temperature and should be used as soon as possible. ^{1}H NMR (60 MHz) δ: 1.60 (bs, 3H), 2.32 (t, J = 7 Hz, 2H), 4.13 (t, J = 7 Hz, 2H), 4.68 (bd, 2H), and 7.25–7.9 (m. 5H); HRMS calcd. for $C_{11}H_{14}O_3S$: 226.0664; found: 226.0671.

*3-Methyl-3-butenyl-1-p-toluenesulfonate (**9**d)*

This material was prepared from 2.0 g (23 mmol) of 3-methyl-3-buten-1-ol in 97% crude yield according to the procedure of Trost and Kunz (27) to give **9***d* as a yellow oil that was used directly in the dianion alkylation or to prepare the iodide **9***b* above.

*3-Methyl-3-butenyl-1-trifluoromethanesulfonate (**9**e)*

To a solution of 73 μL (0.91 mmol) of pyridine in 1 mL of CH_2Cl_2 at −40 to −50°C was added 140 μL (0.82 mmol) of freshly purified trifluoromethanesulfonic anhydride with stirring. A white precipitate formed immediately and after 5 min a solution of 71 mg (0.82 mmol) of 3-methyl-3-buten-1-ol was added to the mixture. The mixture was stirred at −40 to −50°C for 15 min, The precipitate was filtered off and washed with cold hexane. The filtrates were combined and the solvents removed under reduced pressure while maintaining the temperature below 0°C. The residue was dissolved in cold hexane (−20°C), and filtered. The solvent was removed from the filtrate while maintaining the temperature below 0°C to yield 165 mg (92%) of the triflate **9***e* as a pink oil that was used directly in the dianion step.

*3-Methyl-3-butenyl-1-methanesulfonate (**9**f)*

To a solution of 0.67 mL (4.8 mmol) of triethylamine in 10 mL of ether at 0°C was added a solution of 0.30 g (3.5 mmol) of 3-methyl-3-buten-1-ol in 10 mL of ether. After stirring at 0°C for 5 min, 0.27 mL (3.5 mmol) of methanesulfonyl chloride was added to the reaction, and the mixture was stirred at 0°C for 1 h and then warmed to room temperature. The reaction was quenched with 1 M HCl, and the organic phase was washed with 2 × 10 mL of 1 M HCl, 2 × 10 mL of saturated $NaHCO_3$, once with saturated brine, and dried. The solvent was removed under reduced pressure to yield 0.57 g (quantitative) of the mesylate **9***f* as a colourless oil that could be used directly in the dianion alkylation. A small amount was purified by chromatography using petroleum ether – ethyl acetate (6:1) to give pure **9***f* as a colourless oil; ^{1}H NMR (60 MHz) δ: 1.65 (bs, 3H), 2.45 (t, J = 7 Hz, 2H), 3.01 (s, 3H), 4.35 (t, J = 7 Hz, 2H), and 4.78 (bd, 2H); HRMS calcd. for $C_6H_{12}O_3S$: 164.0507; found: 164.0500.

*Methyl 7-methyl-3-oxo-7-octenoate (**10**)*

The dianion of methyl acetoacetate was prepared by using the following general procedure (10). Sodium hydride (60% by weight in oil, 1.12 equiv.) was weighed into a flask, washed under a N_2 atmosphere with ether, and resuspended in dry tetrahydrofuran. The flask was sealed, flushed with N_2, and cooled in an ice bath. Methyl acetoacetate (1.00 equiv.) was syringed dropwise into the NaH suspension, and the resulting monoanion was stirred at 0°C for 15 min, before the *n*-butyllithium (2.0 M in hexane, 1.12 equiv.) was syringed dropwise into the cooled reaction mixture. The resulting orange dianion solution was stirred at 0°C for 15 min. In the case of the triflate **9***e*, the dianion solution was cooled to −40°C for the addition of the alkylating agent. The alkylating agent (0.80 equiv.) dissolved in minimum dry THF was then syringed dropwise into the flask. No immediate change occurred, but within 5 min the reaction mixture became a lighter orange and was more difficult to stir due to the abundant formation of precipitate. The suspension was stirred for 1 h at 0°C, warmed to room temperature and stirred for a further 2 h.

The reaction mixture was diluted with ether and acidified with 1 M HCl. The organic layer was separated, washed with saturated aqueous $NaHCO_3$ solution, brine, dried, filtered, and concentrated to give the crude β-keto ester. This material was distilled at 0.3 Torr and the distillate boiling from 74–76°C was collected to give the desired product **10**. The yields of pure distilled product are given in Table 1. The β-keto ester **10** is a colourless oil; IR ν_{max}: 900, 1660, 1715, and 1745 cm^{-1}; ^{1}H NMR (80 MHz) δ: 1.70 (bs, 3H), 1.6–2.2 (m, 4H), 2.52 (t, J = 7 Hz, 2H), 3.45 (s, 2H), 3.73 (s, 3H), and 4.65 (m, 2H); MS m/z (relative intensity): 41 (57), 43 (87), 55 (77), 59 (42), 68 (56), 69 (58), 74 (100), 101 (37), 111 (35), 116 (75), 117 (34), 129 (37), 166 (18) and 184 (24). Anal. calcd. for $C_{10}H_{16}O_3$: C 65.19, H 8.75; found: C 65.16, H 8.80.

*Methyl (2Z)-3-(diethylphosphoryloxy)-7-methyl-2,7-octadienoate (**11**a)*

Sodium hydride (60% by weight in oil, 0.238 g, 5.97 mmol) was weighed into a flask, washed under a N_2 atmosphere with 15 mL of ether, and resuspended in 20 mL of fresh ether. The flask was flushed with N_2 and cooled in an ice bath. The β-keto ester **10** (1.00 g, 5.43 mmol) dissolved in 5 mL of ether was added dropwise to the NaH suspension. The resulting monoanion was stirred at 0°C for 15 min before diethyl chlorophosphate (0.984 g, 0.82 mL, 5.70 mmol) was syringed dropwise into the cooled reaction mixture. Within 30 min a thick white precipitate had formed (NaCl) and stirring was continued overnight at room temperature.

The reaction mixture was quenched with saturated aqueous NH_4Cl solution and then acidified with 1 M HCl. The organic layer was separated, washed with saturated aqueous $NaHCO_3$ solution, washed with brine, dried, filtered, and concentrated to give 1.74 g (100%) of the crude enol phosphate, which was suitable for the coupling reaction. The product was >99% *Z* by GC analysis. This material was purified by column chromatography using pe-

troleum ether – ethyl acetate (1:1) to give 1.30 g (75%) of the enol phosphate **11***a* as a pale yellow oil; IR ν_{max}: 990, 1020, 1270, 1420, 1670, and 1725 cm^{-1}; ^1H NMR (80 MHz) δ: 1.35 (dt, J = 1 and 7 Hz, 6H), 1.70 (bs, 3H), 1.6–2 (m, 2H), 2–2.3 (m, 2H), 2.43 (bt, J = 7 Hz, 2H), 3.67 (s, 3H), 4.25 (q, J = 7 Hz, 4H), 4.70 (bs, 2H), and 5.41 (s, 1H); MS m/z (relative intensity): 41 (22), 79 (29), 81 (22), 99 (80), 127 (55), 134 (42), 155 (100), 164 (10), 166 (30), 177 (9), 192 (21), 220 (25), 252 (12), 289 (6), 320 (2). Anal. calcd. for $C_{14}H_{25}O_6P$: C 52.50, H 7.87; found: C 52.57, H 7.90.

*Methyl (2Z)-3-(diphenylphosphoryloxy)-7-methyl-2,7-octadienoate (**11**b)*

This compound was prepared following the same method as for **11***a* using 0.24 g (6.0 mmol) of NaH (60% by weight), 1.0 g (5.4 mmol) of ester **10**, and 1.5 g (5.6 mmol) of diphenyl chlorophosphate to quantitatively yield the enol phosphate **11***b*, which was used in the coupling reaction. A small sample of this material was purified by column chromatography using petroleum ether – ethyl acetate (4:1) to give pure **11***b* as a colourless oil; IR ν_{max}: 1020, 1625, 1685, and 1725 cm^{-1}; ^1H NMR (60 MHz) δ: 1.65 (bs, 3H), 2 (m, 4H), 2.51 (bt, J = 7 Hz, 2H), 3.72 (s, 3H), 4.74 (bs, 2H), 5.64 (s, 1H), and 7.2–7.7 (m, 10H); HRMS calcd. for $C_{22}H_{25}O_6P$: 416.1389; found: 416.1395.

*Methyl (2Z)-3-(trifluoromethylsulfonyloxy)-7-methyl-2,7-octadienoate (**11**c)*

The β-keto ester **10** (1.00 g, 5.43 mmol) in 50 mL of dry THF was added to 0.24 g (6.0 mmol) of NaH (60% by weight) and cooled to −78°C. Then 1.55 g (5.50 mmol) of Tf_2O was slowly added and the reaction mixture was allowed to warm to room temperature over several hours. The reaction mixture was quenched with saturated aqueous NH_4Cl solution and then acidified with 1 M HCl. The organic layer was separated, washed with saturated aqueous $NaHCO_3$ solution, washed with brine, dried, filtered, and concentrated to give 1.7 g (ca. 100%) of the crude enol triflate **11***c*, which was suitable for the coupling reaction. A small amount of this material was purified by thin-layer chromatography using petroleum ether – ethyl acetate (9:1) to give pure **11***c* as a colourless oil; IR ν_{max}: 1630, 1665, and 1735 cm^{-1}; ^1H NMR (60 MHz) δ: 1.68 (bs, 3H), 2 (m, 4H), 2.51 (bt, J = 7 Hz, 2H), 3.70 (s, 3H), 4.65 (bs, 2H), and 5.52 (s, 1H); HRMS calcd. for $C_{11}H_{15}O_5F_3S$: 316.0592; found: 316.0587.

Preparation of the stock methylmagnesium chloride solution

Magnesium turnings (9.37 g, 0.385 mol) were weighed into a 500-mL, three-necked, round-bottom flask, equipped with a Dry Ice condenser and gas bubbling frit. The apparatus was sealed, flushed with N_2, and dried with a hot air gun. Dry THF (250 mL) was syringed into the flask, the condenser was cooled, and methyl chloride was bubbled into the stirred suspension. The Grignard reaction commenced immediately and was so vigorous that an ice bath was required to keep the reaction under control. As the reaction slowed, more methyl chloride was bubbled into solution. This procedure was repeated until all the magnesium had reacted (about 2 h). The resulting solution (with a fine black suspension) was cannulated into a stoppered, N_2 flushed bottle, and then titrated.

The titration was carried out as a back-titration. A 1 mL aliquot of the Grignard reagent was quenched with 50 mL of 0.05 M HCl. The resulting solution was titrated to a phenolphthalein endpoint using 0.1 M NaOH to give the total base concentration.

*Methyl (2E)-3,7-dimethyl-2,7-octadienoate (**12**)*

*(a) From the enol phosphate **11**a*

Purified cuprous iodide (28) (3.57 g, 0.019 mol) and 100 mL of THF were added to a 250-mL flask, which was equipped with an internal thermometer. The flask was flushed with N_2 and cooled to 0°C. Methyllithium (1.25 M in ether, 15 mL, 0.019 mol) was syringed dropwise into the stirred white suspension while keeping the internal temperature below 10°C. The resulting yellow MeCu suspension was stirred at 0°C for 10 min and then cooled to −30°C. Methylmagnesium chloride (1.3 M in THF, 24 mL, 0.031 mol) was syringed dropwise into the flask while maintaining the internal temperature below −25°C. The resulting clear, tan-coloured solution was stirred at −30°C for 15 min before a THF solution of the enol phosphate **11***a* (2.0 g, 6.2 mmol) was syringed into the flask. The resulting deep maroon solution was stirred for 3 h at −25°C.

The reaction mixture was quenched by pouring it quickly into a stirred, ice-cold mixture of NH_4Cl in aqueous NH_4OH. The organic layer was diluted with ether and washed with NH_4Cl in aqueous NH_4OH until these washes were no longer blue. The ethereal layer was washed with brine, dried, and the solvents removed under reduced pressure to give 1.05 g (92%) of the crude product as yellow oil that was purified by flash column chromatography using petroleum ether – ethyl acetate (19:1) to give 0.795 g (70%) of the ester **12**. The ratio of E:Z was determined by GC to be 98:2. The ester is a colourless oil, bp (Kugelrohr distillation) 65°C/0.1 Torr; IR ν_{max}: 1150, 1445, 1655, and 1715 cm^{-1}; ^1H NMR (80 MHz) δ: 1.70 (bs, 3H), 1.5–1.8 (m, 2H), 1.9–2.3 (m, 4H), 2.16 (d, J = 1 Hz, 3H), 3.68 (s, 3H), 4.70 (bs, 2H), and 5.65 (m, 1H); MS m/z (relative intensity): 41 (100), 55 (35), 59 (25), 67 (67), 68 (75), 69 (50), 81 (25), 82 (23), 83 (35), 95 (55), 108 (40), 114 (38), 122 (20), 123 (24), 124 (24), 125 (20), 135 (15), 139 (40), 150 (8), 167 (12), 182 (7). Anal. calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.95; found: C 72.56, H 9.90.

*(b) From the enol phosphate **11**b*

In the same manner as above, using 1.5 g (3.6 mmol) of the diphenyl phosphate **11***b*, 0.51 g (78%) of chromatographed ester **12** was obtained. The ratio of E:Z was 90:10 as determined by GC.

*(c) From the enol triflate **11**c*

In the same manner as above, using 1.2 g (3.8 mmol) of the triflate **11***c*, 0.57 g (82%) of chromatographed ester **12** was obtained. The ratio of E:Z was 88:12 as determined by GC.

(2E)-3,7-Dimethyl-2,7-octadien-1-ol

The α,β-unsaturated ester **12** (1.364 g, 7.48 mmol) was dissolved in 30 mL of ether, flushed with N_2, and cooled to 0°C. As diisobutylaluminium hydride (1 M in hexane, 18.7 mL, 1.87 mmol) was syringed into the flask, the reaction mixture became yellow, but the colour faded as all the DIBAL was added. Stirring was continued for 2 h at 0°C. The reaction was quenched at 0°C with saturated aqueous NH_4Cl solution and allowed to stir at this temperature for 1 h. The aluminum salts solidified into a sticky solid top layer, which was broken up and poured into a separatory funnel along with the aqueous and organic layers. This mixture was acidified with 1 M HCl and was shaken until the solid had dissolved. The ethereal layer was separated, washed several times with brine, dried, and the solvents were removed under reduced pressure to give 1.13 g (98%) of the alcohol as a yellow oil. The crude material was purified by column chromatography using petroleum ether – ethyl acetate (4:1) to give 0.96 g (84%) of the alcohol, which was shown to be 96% pure by GC. IR$_{\nu_{max}}$: 900, 995, 1660, 1680, 3475, and 3625 cm^{-1}; ^1H NMR (80 MHz) δ: 1.2–1.7 (m, 2H), 1.67 (bs, 3H), 1.70 (bs, 3H), 1.8–2.2 (m, 4H), 4.14 (d, J = 7 Hz, 2H), 4.67 (bs, 2H), and 5.65 (t, J = 7 Hz, 1H); MS m/z (relative intensity): 41 (100), 43 (37), 53 (27), 55 (46), 67 (36), 68 (65), 69 (75), 71 (40), 81 (40), 83 (34), 93 (17), 95 (35), 107 (10), 109 (14), 121 (18), 123 (11), 136 (14), 139 (2), 154 (1). Anal. calcd. for $C_{10}H_{18}O$: C 77.87, H 11.76; found: C 77.76, H 11.64.

E *Pheromone **5***

The above E alcohol (1.43 g, 9.27 mmol) and a catalytic amount of 4-dimethylaminopyridine (10 mg) were dissolved in 50 mL of ether under N_2. Propionic anhydride (1.33 g, 1.31 mL, 0.010 mol) and pyridine (1.46 g, 1.49 mL, 0.019 mol) were syringed into the reaction mixture, which was stirred at room temperature for 24 h. The reaction mixture was washed with 1 M HCl to remove pyridine. The organic layer was separated, washed with saturated aqueous $NaHCO_3$ solution and brine, dried, and the solvents were removed under reduced pressure to give 1.94 g (100%) of product

as a light yellow liquid. The crude material was Kugelrohr distilled at 85–90°C/0.05 Torr to give 1.87 g (96%) of the desired propionate **5** as a colourless oil; $IR_{\nu_{max}}$: 1195, 1660, 1680, and 1730 cm^{-1}; ^1H NMR (80 MHz) δ: 1.12 (t, J = 7 Hz, 3H), 1.2–1.7 (m, 2H), 1.70 (bs, 6H), 1.8–2.2 (m, 4H), 2.32 (q, J = 7 Hz, 2H), 4.6–4.8 (m, 4H), and 5.33 (t, J = 7 Hz, 1H); MS m/z (relative intensity): 53 (40), 55 (60), 57 (100), 68 (100), 69 (60), 79 (56), 80 (56), 81 (90), 93 (64), 94 (25), 95 (30), 96 (56), 97 (24), 107 (50), 108 (25), 109 (25), 121 (80), 136 (71), 139 (5), 154 (20), 195 (0.5), 210 (0.5). Anal. calcd. for $C_{13}H_{22}O_2$: C 74.24, H 10.54; found: C 74.00, H 10.65.

*Methyl (2E)-3-(diethylphosphoryloxy)-7-methyl-2,7-octadienoate (**13**)*

4-Dimethylaminopyridine (0.146 g, 1.2 mmol), triethylamine (1.21 g, 1.67 mL, 12.0 mmol), HMPA (2.15 g, 2.09 mL, 12.0 mmol), and the β-keto ester **10** (2.00 g, 10.9 mmol) were added to a flask. The resulting yellow solution was stirred for 30 min at 0°C and then cooled to −20°C. Diethyl chlorophosphate (2.07 g, 12.0 mmol) was added dropwise to the cooled solution and a heavy precipitate began to form immediately. The yellow-orange paste was warmed to room temperature and stirred at this temperature for 4 h. The reaction mixture was diluted with ether and acidified with 1 M HCl. The ethereal extracts were washed with saturated aqueous $CuSO_4$ to remove HMPA, dried and concentrated to give 3.39 g (97%) of product as an orange oil that was suitable for the Grignard coupling step. This material was >99% *E* by GC analysis and a small sample was purified by column chromatography using petroleum ether – ethyl acetate (1:1) to give a pure sample of enol phosphate **13** as a colourless oil; $IR_{\nu_{max}}$: 960, 1030, 1285, 1440, 1650, and 1720 cm^{-1}; ^1H NMR (80 MHz) δ: 1.35 (dt, J = 1 and 7 Hz, 6H), 1.73 (bs, 3H), 1.6–2 (m, 2H), 2–2.3 (m, 2H), 2.79 (bt, J = 7 Hz, 2H), 3.70 (s, 3H), 4.2 (m, J = 7 Hz, 4H), 4.70 (bs, 2H), and 5.85 (d, J = 1 Hz, 1H); MS m/z (relative intensity): 55 (15), 79 (20), 91 (26), 99 (72), 107 (20), 127 (51), 134 (42), 152 (10), 155 (100), 164 (15), 166 (30), 177 (5), 192 (16), 205 (4), 220 (23), 234 (9), 252 (12), 260 (5), 288 (4), 289 (3), 320 (3). Anal. calcd. for $C_{14}H_{25}O_6P$: C 52.50, H 7.87; found: C 52.38, H 7.90.

*Methyl (2Z)-3,7-dimethyl-2,7-octadienoate (**14**)*

This reaction was carried out following the same procedure as in the synthesis of **12** from **11***a* using cuprous iodide (8.91 g, 0.047 mol), methyllithium (1.7 M in ether, 27.5 mL, 0.047 mol), methylmagnesium chloride (1.5 M in THF, 52 mL, 0.078 mol), and the *E* enol phosphate **13** (5.0 g, 0.016 mol). The reaction was worked up to give 2.69 g (95%) of crude ester, which was purified by column chromatography to yield 1.94 g (68%) of a faint yellow oil in which the ratio of *E*:*Z* was determined by GC to be 97:3; bp (Kugelrohr distillation) 60°C/0.2 Torr; $IR_{\nu_{max}}$: 1180, 1440, 1650, and 1710 cm^{-1}; ^1H NMR (80 MHz) δ: 1.73 (bs, 3H), 1.5–1.8 (m, 2H), 1.89 (d, J = 1 Hz, 3H), 1.9–2.3 (m, 4H), 3.65 (s, 3H), 4.68 (bs, 2H), and 5.62 (bs, 1H); MS m/z (relative intensity): 41 (80), 53 (21), 55 (30), 59 (16), 67 (46), 68 (75), 82 (27), 83 (73), 95 (50), 108 (22), 109 (25), 114 (100), 122 (20), 123 (33), 135 (8), 139 (30), 150 (13), 167 (7), 182 (9). Anal. calcd. $C_{11}H_{18}O_2$: C 72.49, H 9.95; found: C 72.70, H 10.10.

(2Z)-3,7-Dimethyl-2,7-octadien-1-ol

This alcohol was produced by reduction of the α,β-unsaturated ester **14** (2.00 g, 0.011 mol) with diisobutylaluminium hydride (1 M in hexane, 27.5 mL, 0.0275 mol) according to the same procedure as for the ester **12** above. The reaction, on work-up, yielded 1.74 g (>100%) of crude alcohol, which was purified by chromatography using petroleum ether – ethyl acetate (4:1) to yield 1.40 g (82%) of the desired *Z* alcohol, which was greater than 90% *Z* by GC and was distilled (Kugelrohr) at 64°C/0.2 Torr; $IR_{\nu_{max}}$: 895, 985, 1650, 1670, 3450, and 3625 cm^{-1}; ^1H NMR (80 MHz) δ: 1.2–1.7 (m, 2H), 1.75 (bs, 6H), 1.8–2.2 (m, 4H), 4.12 (d, J = 6 Hz, 2H), 4.68 (bs, 2H), and 5.40 (t, J = 6 Hz, 1H); MS m/z (relative intensity): 41 (100), 43 (30), 53 (27), 55 (50), 56 (25), 67 (32), 68 (40), 69 (50), 71 (30), 81 (34), 83 (27), 93 (14), 95 (17), 107 (7), 109 (9), 121 (13), 123 (8), 136 (9), 139 (3), 154 (2). Anal. calcd. for $C_{10}H_{18}O$: C 77.87, H 11.76; found: C 77.57, H 11.89.

*Z Pheromone **6***

The above *Z* alcohol (0.90 g, 5.8 mmol) was esterified with a catalytic amount of 4-dimethylaminopyridine (10 mg), propionic anhydride (0.83 g, 0.82 mL, 6.4 mmol), and pyridine (0.93 g, 0.95 mL, 0.012 mol) as above for **5** to yield, after chromatography, 1.13 g (92%) of a colourless oil that distilled (Kugelrohr) at 60°C/0.02 Torr; $IR_{\nu_{max}}$: 1105, 1665, 1687, and 1725 cm^{-1}; ^1H NMR (80 MHz) δ: 1.12 (t, J = 7 Hz, 3H), 1.2–1.7 (m, 2H), 1.72 (bs, 3H), 1.74 (bs, 3H), 2.1 (bq, J = 7 Hz, 4H), 2.25 (q, J = 7 Hz, 2H), 4.5–4.7 (m, 4H), and 5.35 (bt, J = 7 Hz, 1H); MS m/z (relative intensity): 41 (98), 43 (20), 53 (38), 55 (70), 57 (100), 67 (62), 68 (91), 69 (78), 79 (49), 80 (52), 81 (99), 93 (66), 94 (25), 95 (42), 96 (54), 97 (23), 98 (41), 107 (47), 108 (23), 109 (28), 121 (74), 136 (76), 154 (20), 196 (1), 210 (1). Anal. calcd. for $C_{13}H_{22}O_2$: C 74.24, H 10.54; found: C 74.45, H 10.61.

*Methyl (2Z)-3-(trimethylsilylmethyl)-7-methyl-2,7-octadienoate (**17**)*

The Grignard reagent was prepared from magnesium turnings (0.304 g, 0.0124 mol) and trimethylsilylmethyl chloride (1.66 g, 0.014 mol) in 20 mL of dry ether. This solution was cannulated into a clean flask under N_2 to remove any unreacted magnesium and then treated with 0.08 g (0.31 mmol) of nickel(II) acetylacetonate. Then 2.00 g (6.2 mmol) of the enol phosphate **11***b* was slowly added to the Grignard solution. After 0.5 h and 1.5 h, additional portions of the $Ni(acac)_2$ catalyst were added (0.08 g each time). The reaction was stirred overnight and quenched with 20 mL of dilute HCl. The aqueous phase was extracted with 3 × 20 mL of ether. The extracts were combined, washed with brine, dried, and the solvents removed under reduced pressure to yield 1.6 g of a crude product that was purified by column chromatography using petroleum ether – ethyl acetate (40:1) to give 1.37 g (87%) of a pale yellow oil; $IR_{\nu_{max}}$: 1620 and 1710 cm^{-1}; ^1H NMR (60 MHz) δ: 0.05 (s, 9H), 1.2–1.7 (m, 2H), 1.75 (bs, 3H), 1.8–2.2 (m, 4H), 2.45 (s, 2H), 3.65 (s, 3H), 4.7 (bs, 2H), and 5.65 (bs, 1H).

*Methyl (2E)-3-(trimethylsilylmethyl)-7-methyl-2,7-octadienoate (**18**)*

This compound was prepared in the same way as **17** using magnesium turnings (0.10 g, 4.0 mmol), trimethylsilylmethyl chloride (0.55 g, 5.0 mmol), 0.08 g (0.31 mmol) of nickel(II) acetylacetonate (0.03 g × 3), and the enol phosphate **13** (0.68 g, 2.1 mmol) to yield, after chromatography, 0.32 g (60%) of the *E* ester **18**; $IR_{\nu_{max}}$: 1635 and 1715 cm^{-1}; ^1H NMR (60 MHz) δ: 0.08 (s, 9H), 1.2–1.7 (m, 2H), 1.75 (bs, 3H), 1.8–2.2 (m, 2H), 2.15 (s, 2H), 2.6 (m, 2H), 3.62 (s, 3H), 4.65 (bs, 2H), and 5.6 (bs, 1H).

*Methyl 2,2 dimethyl-6-methylenecyclohexanecarboxylate (**19**)*

This compound was prepared with a variety of Lewis acid and acid catalysts on **17** or **18** using procedures established earlier in our laboratory (19). The product **19** was isolated in 64–92% yield and had spectroscopic and chromatographic properties identical to the compound prepared earlier (19).

*3-Oxo-7-methyl-7-octen-1-ol (**20**)*

*(a) Directly from the β-keto ester **10***

A solution 0.160 g (0.87 mmol) of the ester **10** in 20 mL of dry ether was added to 42 mg of NaH (60% oil, 1.0 mmol), which had been washed with dry petroleum ether at 0°C. The monoanion was stirred at 0°C for 10 min and then treated with 2.6 mL of a 1 M DIBAL solution in hexane. This reaction was allowed to warm to room temperature with stirring for 1 h. The reaction was quenched with saturated aqueous NH_4Cl and filtered through Celite. The aqueous phase was extracted with 3 × 30 mL of ether. The extracts were combined washed with brine, dried, and the solvents evaporated to give 167 mg of a crude product that was purified by column chromatography using petroleum ether – ethyl acetate (3:2) to give 94 mg (70%) of **20** as a colourless oil; $IR_{\nu_{max}}$: 895, 1060, 1650, 1705, and 3575 cm^{-1}; ^1H NMR (80 MHz) δ: 1.5–2.2 (m,

4H), 1.75 (bs, 3H), 2.47 (t, J = 7 Hz, 2H), 2.70 (t, J = 6 Hz, 2H), 3.87 (t, J = 6Hz, 2H), and 4.7 (bs, 2H); HRMS m/z calcd. for $C_9H_{16}O_2$: 156.1150; found: 156.1143.

(b) Via the enol silyl ether

The β-keto ester **10** (0.250 g, 1.36 mmol) was dissolved in 25 mL of dry ether and then 0.20 mL (1.4 mmol) of triethylamine was added and the solution was stirred for 10 min before 0.17 mL (1.36 mmol) of trimethylsilyl chloride was added. A thick, white precipitate formed immediately and the reaction was stirred overnight. The reaction mixture was filtered through Florisil and the column was washed with 25 mL of dry ether. The solvents were removed under reduced pressure to give 0.34 g (97%) of the silyl enol ether, which was used directly in the next step; ^{1}H NMR (60 MHz) δ: 0.4 (s, 9H), 1.8 (bs, 3H), 1.4–2.3 (m, 4H), 2.8 (t, J = 7 Hz, 2H), 3.75 (s, 3H), 4.7 (bs, 2H), and 5.15 (bs, 1H). This enol ether (0.163 g, 0.64 mmol) was dissolved in 1 mL of dry ether and added to a solution of 25 mg (0.64 mmol) of $LiAlH_4$ in 2 mL of dry ether at 0°C. The reaction was stirred at 0°C for 0.5 h and allowed to warm to room temperature for 0.5 h. The reaction was quenched with 1 M HCl and extracted with 3 × 10 mL of ether. The extracts were combined, washed with brine, dried, and the solvents removed to yield 101 mg of a pale yellow oil that was purified as above to yield 89 mg (89%) of the alcohol **20**.

Pheromone 7

A solution of the alcohol **20** (1.20 g, 7.68 mmol), 1.10 g (8.45 mmol) of propionic anhydride, 1.22 g (15.4 mmol) of pyridine, and a catalytic amount of DMAP were dissolved in 75 mL of ether and stirred overnight. The reaction mixture was washed with 1 M HCl, saturated aqueous $NaHCO_3$, and brine, then dried and the solvents removed under reduced pressure to yield 1.62 g (99%) of crude propionate ester. The crude ester was purified by column chromatography using petroleum ether – ethyl acetate (9:1) to give 1.46 g (90%) of pure keto ester; $IR_{\nu_{max}}$: 900, 1190, 1650, 1725, and 1740 cm^{-1}; ^{1}H NMR (80 MHz) δ: 1.14 (t, J = 7 Hz, 3H), 1.4–2.05 (m, 4H), 1.70 (bs, 3H), 2.38 (five-line pattern, 4H), 2.75 (t, J = 7 Hz, 2H), 4.35 (t, J = 7 Hz, 2H), and 4.7 (m, 2H); HRMS m/z calcd. for $C_{12}H_{20}O_3$: 212.1412; found: 212.1422.

To a stirred slurry of zinc dust (11.5 g, 0.176 mol) and dibromomethane (4.04 mL, 0.056 mol) in 100 mL of THF at −40°C was added 4.6 mL (0.042 mol) of $TiCl_4$ over 0.5 h in a well-vented fume-hood. The reaction was vigorous and copious amounts of a green gas evolved. After the addition of the $TiCl_4$, the reaction mixture was a gray slurry and was stirred at −40°C for 2 h and then at 0°C for at least 24 h before use. This solution of the active methylene complex could be stored in the freezer for up to 2 weeks.

A solution of 101 mg (0.48 mmol) of the above keto propionate in 3 mL of dry CH_2Cl_2 was treated with 3 × 3 mL of the above active methylene complex. The reaction was followed by TLC after each addition; the solution turned black immediately after each addition and then slowly cleared until after the final addition when the solution remained black. The reaction mixture was poured into a mixture of saturated aqueous $NaHCO_3$ and ether, and stirred until the ether layer became clear. The ether layer was removed, washed with brine, dried, and the solvents removed under reduced pressure to yield 90 mg of crude product, which was purified by column chromatography on Florisil using petroleum ether – ethyl acetate (19:1) to give 77 mg (83%) of **7** as a colourless oil; $IR_{\nu_{max}}$: 890, 1190, 1645, and 1730 cm^{-1}; ^{1}H NMR (80 MHz) δ: 1.12 (t, J = 7 Hz, 3H), 1.5–1.8 (m, 2H), 1.72 (bs, 3H), 1.85–2.5 (m, 8H), 4.20 (t, J = 7 Hz, 2H), 4.70 (bs, 2H), and 4.83 (bs, 2H); HRMS m/z calcd. for $C_{13}H_{22}O_2$: 210.1620; found: 210.1622.

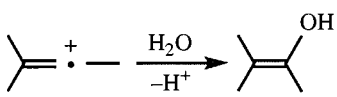
Photosolvolysis of α-(2,6-dimethoxyphenyl)vinyl chloride in trifluoroethanol solution at 25°C was found to produce the α-(2,6-dimethoxyphenyl)vinyl cation as a transient species with the lifetime τ = 1 μs. Addition of water reduced this lifetime markedly, until, at compositions greater than 80% water, it was too short to measure (τ < 20 ns); extrapolation of the data suggests τ = 9 ns in pure water. Hydration of this cation gave the much longer lived enol of 2,6-dimethoxyacetophenone, whose rates of ketonization were measured in dilute perchloric acid and sodium hydroxide solutions. These data, when combined with rates of enolization of the ketone determined by iodine scavenging, give pK_E = 6.98 for the keto–enol equilibrium constant in the 2,6-dimethoxyacetophenone system, pK_a^E = 10.72 for the acidity constant of the enol ionizing as an oxygen acid, and pK_a^K = 17.70 for the acidity constant of the ketone ionizing as a carbon acid; these constants refer to wholly aqueous solution at 25°C and ionic strength = 0.10 M.

YVONNE CHIANG, ROBERT ELIASON, JOEL JONES, A. JERRY KRESGE, KEVIN L. EVANS et RICHARD D. GANDOUR. Can. J. Chem. **71**, 1964 (1993).

On a trouvé que la photosolvolyse du chlorure de α-(2,6-diméthoxyphényl)vinyle en solution dans le trifluoroéthanol, à 25°C, conduit au cation α-(2,6-diméthoxyphényl)vinyle comme espèce transitoire dont le temps de vie, τ = 1 μS. L'addition d'eau au milieu réactionnel réduit ce temps de vie d'une façon importante jusqu'à des compositions en eau supérieures à 80% alors que les temps de vie deviennent trop courts pour être mesurés (τ < 20 ns); l'extrapolation des données suggère que τ = 9 ns dans l'eau pure. L'hydratation de ce cation conduit à l'énol de la 2,6-diméthoxyacétophénone dont la longueur de vie est beaucoup plus longue et dont on a mesuré les vitesses de cétonisation dans des solutions diluées d'acide perchlorique et d'hydroxyde de sodium. Lorsqu'on combine ces données avec les vitesses d'énolisation de la cétone telles que déterminées par piégeage d'iode, elles fournissent des valeurs de pK_E = 6,98 pour la constante d'équilibre céto–énolique du système 2,6-diméthoxyacétophénone, de pK_a^E = 10,72 pour la constante d'acidité de l'énol s'ionisant sous la forme d'une oxyacide et de pK_a^K = 17,70 pour la constante d'acidité de la cétone s'ionisant sous la forme d'une acide carboné; ces constantes se réfèrent à des solutions entièrement aqueuses, à 25°C et à une force ionique de 0.10 M.

[Traduit par la rédaction]

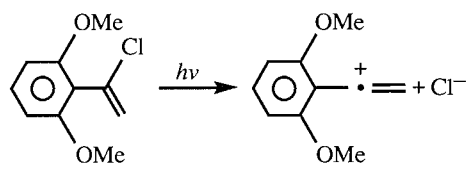
Vinyl cations have been observed as short-lived transient species formed by flash photolytic photosolvolysis of vinyl halides or photohydration of acetylenes in organic solvents such as acetonitrile (1, 2), acetic acid (2), and trifluoroethanol (3). There is evidence that they are formed by these reactions in aqueous solution as well, for their enol hydration products, eq. [1], have been observed as transients in



this medium; the ions themselves, however, have not been seen in this solvent, presumably because none of the systems examined so far give vinyl cations with sufficiently long lifetimes to allow detection by the methods that have been employed.

We have investigated the flash photolysis of α-(2,6-dimethoxyphenyl)vinyl chloride, **1**, in the hope that the stabilizing effect of the two *ortho* methoxyl groups in the vinyl cation formed from this substrate, **2**, eq. [2], coupled with the steric hindrance that these groups might provide to attack of water at the cationic center, would be sufficient to permit observation of this ion in wholly aqueous solution. This hope, unfortunately, was not realized: we were able to see this ion in trifluoroethanol solution and also in trifluoroethanol–water mixtures up to a water content of 80%; above this point, however, the lifetime of the ion became less than 20 ns, which is the limit of detection of our system.

[2]



1 **2**

Although we did not see this ion in wholly aqueous solution, we could observe its enol hydration product, **3**, in this medium. We therefore studied the ketonization of this enol, eq. [3], and the results we obtained, in combination with information on enolization of the corresponding ketone, 2,6-dimethoxyacetophenone, **4**, have allowed us to characterize this keto–enol system. These results are of special interest

Experimental section

Materials

α-(2,6-Dimethoxyphenyl)vinyl chloride was prepared by treating 2,6-dimethoxyacetophenone with phosphorus pentachloride under conditions that prevent chlorination of the benzene ring (*6*). All other materials were best available commercial grades and were used as received.

Kinetics

Flash photolysis was performed using a conventional flash lamp system for the slower reactions and a laser system for the faster ones. Details of the conventional system have already been published (*7*). The laser system used a Lumonics Ex-510 excimer laser operating at λ = 248 nm for excitation and a pulsed Oriel model 66002 Xenon-arc lamp as monitoring light source. The monitoring light, after leaving the sample, was passed through an Oriel model 77250 monochrometer and onto a Hamamatsu 1P28 photomultiplier whose output was fed into a Tektronix model SCD1000 transient digitizer. Data analysis was performed with a Tektronix PEP 301 computer using Enzfitter software (Elsevier-BIOSOFT) for fitting to exponential functions. Reaction mixtures were contained in quartz cuvettes placed in a brass holder whose temperature was controlled at 25.0 ± 0.1°C by water circulating from a constant temperature bath.

Rates of enolization of 2,6-dimethoxyacetophenone were determined by iodine scavenging in the presence of iodide ion using the absorbance of I_3^- to monitor the reaction. Absorbance measurements were made with a Cary model 118C spectrometer whose cell compartment was thermostatted at 25.0 ± 0.1°C. Iodine concentrations in the reaction mixtures were 3×10^{-5} M; iodide ion concentrations, 7×10^{-4} M; and 2,6-dimethoxyacetophenone concentrations, 7×10^{-4} M. Reactions were followed to about 1% completion and zero-order rates of change of absorbance with time, $\Delta A/\Delta t$, were converted into observed first-order rate constants, k_{obs}, according to eq. [6]. In this expression K_{I_3} (= 1.5×10^{-3} M) (*8*) is the equilibrium

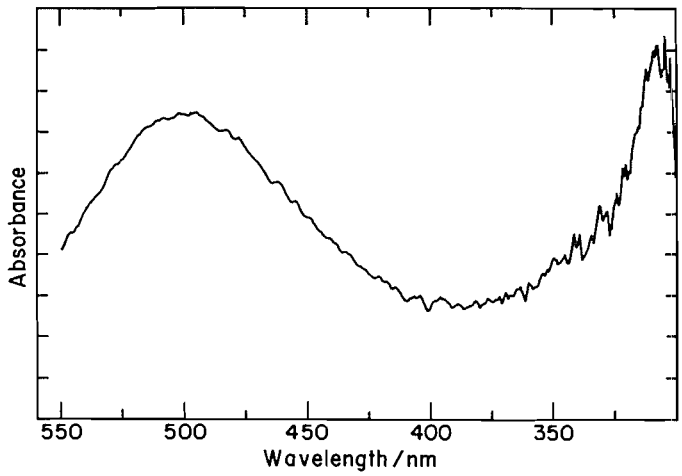

FIG. 1. Absorption spectrum of the shorter lived of the two transients produced upon flash photolysis of α-(2,6-dimethoxyphenyl)vinyl chloride in trifluoroethanol solution.

$$[6] \quad k_{obs} = (\Delta A/\Delta t)(1 + K_{I_3}/[I_3^-])/\epsilon_{351}[S]$$

constant for dissociation of I_3^- into I_2 and I^-, ϵ_{351} (= 2.6×10^4 M^{-1} cm^{-1}) (*8*) is the extinction coefficient of I_3^- at λ = 351 nm, the wavelength at which the measurements were made, and [S] is the concentration of 2,6-dimethoxyacetophenone.

Results

The UV spectrum of α-(2,6-dimethoxyphenyl)vinyl chloride dissolved in water consists of an absorption maximum at λ = 280 nm, plus strong end absorption at low wavelengths with a shoulder at λ = 240 nm. Upon irradiation of an aqueous solution with a few pulses from our conventional flash photolysis apparatus, these spectral features move to lower wavelengths and give a spectrum similar to that of an authentic sample of 2,6-dimethoxyacetophenone, with λ_{max} = 265 nm and a shoulder at λ = 220 nm. This shows that photolysis of α-(2,6-dimethoxyphenyl)vinyl chloride in aqueous solution gives 2,6-dimethoxyacetophenone as an ultimate reaction product. Flash photolytic examination of this transformation shows that it occurs via short-lived vinyl cation and enol intermediates.

Vinyl cation

Flash photolysis of α-(2,6-dimethoxyphenyl)vinyl chloride dissolved in trifluoroethanol produces a transient species with absorption maxima at λ = 300 and 500 nm (Fig. 1) and a lifetime of τ ≅ 1 μs. Degassing the solution has no effect on this lifetime, but addition of chloride ion or water shortens it markedly. This behavior indicates that this transient is the α-(2,6-dimethoxyphenyl)vinyl cation, **2**, formed as expected according to eq. [2]. In the absence of added reagents, the lifetime of this ion is governed by its reaction with the solvent to give the corresponding trifluoroethyl vinyl ether, and also by its reaction with chloride ion produced by the photoionization to regenerate the starting material. Addition of chloride ion to the photolysis solution speeds up the latter reaction, shortening the lifetime of the vinyl cation. Water has a similar lifetime-shortening effect through its reaction with the cation to give enol according to eq. [1].

Decay of this transient absorbance attributed to the vinyl

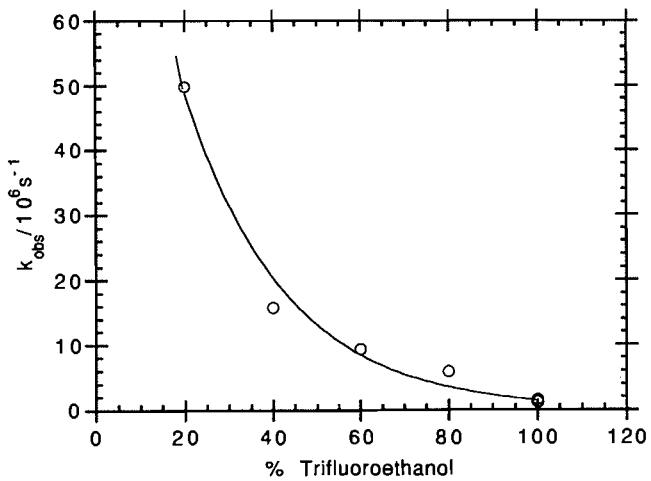

FIG. 2. Relationship between solvent composition and rates of decay of the α-(2,6-dimethoxyphenyl)vinyl cation in trifluoroethanol–water mixtures.

cation conformed to the first-order rate law, and first-order rate constants were determined in trifluoroethanol–water mixtures of increasing water content. The data are summarized in Table 1 and are displayed in Fig. 2. It may be seen that the rate of reaction increases markedly with water content, especially in the more water-rich mixtures, suggesting an exponential dependence of rate upon water content. As Fig. 3 shows, there is a reasonably good linear relationship between the logarithms of observed rate constants and percent trifluoroethanol, $\log(k_{obs}/s^{-1}) = 8.07 - 0.0190$ (% TFE), which allows extrapolation to a wholly aqueous solvent. The result of this extrapolation, $k_{obs} = (1.2 \pm 0.3) \times 10^8\ s^{-1}$, gives $\tau = 9$ ns as the lifetime of the α-(2,6-dimethoxyphenyl)vinyl cation in aqueous solution. This is shorter, by about a factor of two, than the shortest excitation pulse available from our flash photolysis apparatus, and that renders this ion unobservable in wholly aqueous solution with our equipment.

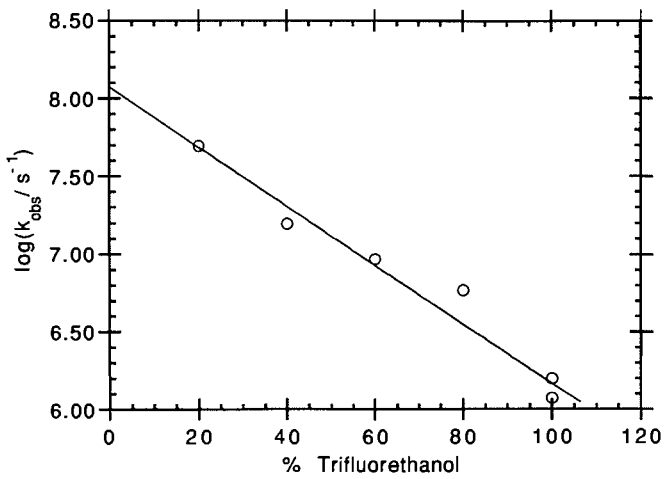

FIG. 3. Logarithmic relationship between solvent composition and rates of decay of the α-(2,6-dimethoxyphenyl)vinyl cation in trifluoroethanol–water mixtures.

The relationship of Fig. 3 gives $k = (1.5 \pm 0.2) \times 10^6\ s^{-1}$ as the rate constant for decay of the present vinyl cation in 100% trifluoroethanol solution; this is similar to $k = 1.3 \times 10^6\ s^{-1}$ reported for reaction of the α-(*p*-methoxyphenyl)-vinyl cation in the same solvent (3).

Enol

This very rapid reaction of the α-(2,6-dimethoxyphenyl)-vinyl cation in wholly aqueous solution appeared as an instantaneous rise in absorbance at lower wavelengths, in the vicinity of λ = 300 nm, where the enol is expected to absorb. This rise, which took place within the excitation pulse, was then followed by an additional further increase in absorbance as the enol was converted to the still more strongly absorbing ketone. This latter absorbance change is similar to that observed in the hydrolysis of the vinyl ether analog of this enol, ethyl α-(2,6-dimethoxyphenyl)vinyl ether, (5) **6**, which gives the same ketone as its reaction product (eq. [5]).

Rates of ketonization of the enol were measured in dilute perchloric acid and sodium hydroxide solutions; these data are summarized in Tables 2 and 3. As Fig. 4 shows, observed first-order rate constants determined in perchloric acid solutions proved to be accurately proportional to acid concentration. This is the behavior expected for enol ketonization; it represents rate-determining protonation of the enol on its β-carbon atom followed by rapid removal of the oxygen-bound proton of the ketone conjugate acid thus formed, eq. [7] (9). Linear least-squares analysis of the data gave $k^K_{H^+} = 120\ M^{-1}\ s^{-1}$ as the hydronium-ion catalytic coefficient for this ketonization reaction.

Ketonization was also catalyzed by sodium hydroxide but, as Fig. 5 demonstrates, observed first-order rate constants

$k_0' = (3.21 \pm 0.11) \times 10^3\ s^{-1}$
$K_a^E = (1.91 \pm 0.19) \times 10^{-11}$ M
$pK_a^E = 10.72 \pm 0.04$

[a]Ionic strength = 0.10 M.
[b]See eq. [9]; $1.59 \times 10^{-14} = K_w/f_{H^+}f_{HO^-}$ using values of the activity coefficients f_{H^+} and f_{HO^-} for ionic strength = 0.10 M recommended by Bates (10).

were proportional to hydroxide-ion concentration only at low basicity; at progressively higher basicities this proportionality gave way to saturation of catalysis, and rate constants approached a constant value. This again is as expected for enol ketonization; it represents reaction through the much more reactive enolate ion under conditions where the initial state shifts from enol at low basicity to enolate at high basicity, as shown in eq. [8] (9). The rate law that applies in this situation is given as eq. [9], in which k_0' is the rate

[8] 
[9] $k_{obs} = k_0' K_a^E[HO^-]/(K_a^E[HO^-] + K_W)$

constant for carbon protonation of the enolate ion by water, K_a^E is the acidity constant of the enol, and K_W is the autoprotolysis constant of water. Nonlinear least-squares fitting of the data to this expression gave $k_0' = 3.21 \times 10^2\ s^{-1}$ and $K_a^E = 1.91 \times 10^{-11}$, $pK_a^E = 10.72$; the latter is a concentration dissociation constant that applies at the ionic strength of the measurements (0.10 M).

Enolization

Rates of enolization of 2,6-dimethoxyacetophenone were measured in dilute perchloric acid solutions; the data are summarized in Table 4. Observed first-order rate constants proved to be proportional to acid concentration, as expected for enolization of a ketone (9), and linear least-squares analysis of the data gave $k_{H^+}^E = 1.26 \times 10^{-5}\ M^{-1}\ s^{-1}$ as the hydronium-ion catalytic coefficient for this enolization reaction.

Discussion

The amount of enol tautomer in equilibrium with a simple ketone, such as 2,6-dimethoxyacetophenone, in aqueous solution is generally very small, and it is consequently often difficult to evaluate keto–enol equilibrium constants in such systems by direct determination of enol concentration. An equilibrium constant, however, can also be evaluated as the ratio of rate constants for the reaction in the forward and reverse directions, and the hydronium-ion catalytic coefficients determined here for the enolization of 2,6-dimethoxyacetophenone and ketonization of its enol may therefore be used to determine the keto–enol equilibrium constant for this system: $K_E = k_{H^+}^E/k_{H^+}^K = (1.05 \pm 0.06) \times 10^{-7}$, $pK_E = 6.98 \pm 0.02$.

This enolization reaction plus the acid dissociation of the enol, whose equilibrium constant was determined here by the ketonization rate measurements in sodium hydroxide solutions, form two legs of a thermodynamic cycle whose third member is ionization of the ketone as a carbon acid, eq. [10]. The equilibrium constant for this carbon acid ionization,

[10] 
K_a^K, may therefore be evaluated as the product of the equilibrium constants for the other two reactions: $K_a^K = K_E K_a^E = (2.00 \pm 0.23) \times 10^{-18}$, $pK_a^K = 17.70 \pm 0.05$.

It is interesting that this equilibrium constant, as well as those for the other two reactions of the scheme shown in eq. [10], are quite similar to the corresponding values for

the 2,4,6-trimethylacetophenone (**5**) keto–enol system: the numbers, listed in Table 5, show hardly any differences at all. There are, on the other hand, significant differences between these two ketones and the parent, unsubstituted acetophenone, values for whose reactions are also listed in Table 5.

The largest difference occurs in the pK_E values: the keto–enol equilibrium constants for the substituted ketones are an order of magnitude greater than that for acetophenone. This difference may be understood by making a further comparison with acetaldehyde, which has no aromatic substituent and for which $pK_E = 6.23$ (7). There is thus a marked decrease in keto–enol equilibrium constant upon introduction of a phenyl substituent; this can be attributed to a difference in stabilization of the keto and enol forms produced by conjugation with the phenyl group. Conjugation of phenyl with the carbonyl group of the keto isomer is strong because the carbonyl carbon atom bears a partial positive charge, whereas conjugation with the neutral double bond of the enol is considerably weaker. The keto isomer is thus stabilized relative to the enol form, and the keto–enol equilibrium constant is decreased. *Ortho* substituents, such as those in 2,6-dimethoxyacetophenone and 2,4,6-trimethylacetophenone, inhibit this conjugation and shift the equilibrium constant back toward that of the acetaldehyde system.

It is significant that most of this increase in keto–enol equilibrium constant upon introduction of *ortho* substituents appears as a decrease in the rate of ketonization and that rates of enolization are hardly affected: the data of Table 5 show $k^K_{H^+}$ values for 2,6-dimethoxyacetophenone and 2,4,6-trimethylacetophenone that are an order of magnitude less than those for acetophenone but $k^E_{H^+}$ values that are virtually the same. This is consistent with little conjugative effect on the stability of the enol isomer and a stronger effect on both the keto isomer and the transition state of the reaction. The effect on the transition state and the keto isomer might, in fact, be expected to be of similar strength because both species have partial positive charges in positions where charge can be delocalized into the phenyl group; this similarity of conjugative effect on ketone and transition state is attested to by the fact that a Yukawa–Tsuno correlation of rates of acid-catalyzed enolization of ring-substituted acetophenones gives a resonance ρ value that is vanishingly small (12).

There are also differences in pK^E_a and pK^K_a values between acetophenone and *ortho*-substituted derivatives, but these are smaller than the differences in pK_E. The slightly weaker acidity of the enols of 2,6-dimethoxyacetophenone and 2,4,6-trimethylacetophenone may be attributed to the electron-supplying nature of their methoxyl and methyl groups, which will tend to destabilize the enolate ions. This effect, however, is overwhelmed in the carbon acid ionization of the ketones, for here 2,6-dimethoxyacetophenone and 2,4,6-trimethylacetophenone are stronger acids than acetophenone. This inversion of relative acidity can be ascribed to the conjugative effects discussed above, which destabilize the substituted ketones relative to the parent acetophenone.

The acid-catalyzed ketonization of enols bears a close mechanistic resemblance to the acid-catalyzed hydrolysis of vinyl ethers: both reactions occur by rate-determining proton transfer from the catalysts to the β-carbon atom of the substrate, and mechanistic differences occur only after this step (9, 13). The effects of structure on reactivity for the two reactions might therefore be expected to be similar, and this, in fact, is the case: hydronium-ion catalytic coefficients for enol ketonization have been found to parallel those for methyl vinyl ether hydrolysis over a wide range of structural vari-

ation spanning five orders of magnitude in reactivity, with the ketonisation reactions consistently 10–100 times faster than the hydrolyses (9). A comparison of the two reactions can be made for the present system, for the hydronium-ion catalytic coefficient has recently been measured for the hydrolysis of methyl α-(2,6-dimethoxyphenyl)vinyl ether, **6** (5). This comparison shows the present enol to be 42 times more reactive than the vinyl ether, which is nicely consistent with previous experience.

The reduction of Fe^{3+} by coal surfaces has been followed colorimetrically. The kinetics of the reaction in coals with a relatively high O/C ratio are sensitive to mild air oxidation, those having a low O/C ratio are relatively insensitive.

RONALD R. MARTIN, JINJIANG LI et J. ANTHONY MACPHEE. Can. J. Chem. **71**, 1970 (1993).

On a fait appel à une méthode colorimétrique pour suivre la réduction du Fe^{3+} par des surfaces de charbon. Les cinétiques des réactions dans les charbons, avec un rapport relativement élevé de O/C, sont sensibles à une oxydation douce par l'air alors que celles avec un faible rapport O/C sont relativement insensibles.

[Traduit par la rédaction]

Introduction

Coal confronts chemists with formidable analytical problems. Defined as a rock consisting of more than 65% carbon by weight and constructed largely from plant material metamorphosed by time, temperature, and pressure in the earth's crust, it is essentially a non-repeating polymer of immense complexity. It remains a puzzle to organic and inorganic chemists alike since it is known to include in its structure virtually all the naturally occurring elements in the periodic table. It remains as the focus of intense study both because it is an interesting problem in its own right and because of its industrial importance. The value of coal increases significantly if it can be used to make coke for steel production. The coking properties of a given coal are usually inferred from optical reflectance data while thermal coal is usually valued on the basis of the degree of oxidation of the material. Both the coking and thermal properties of coal deteriorate more or less rapidly after mining for reasons that, while clearly related to air oxidation (so-called low-temperature oxidation), are poorly understood. The oxygen content is normally obtained from difference measurements and is generally regarded as being the least accurate value obtained in normal coal analysis. Surface-sensitive techniques usually yield O/C ratios that are higher than those obtained from bulk analysis. A simple chemical analysis that would be reflective of the O/C ratio would find wide utility in coal characterization.

Coal research is often frustrated by the variability of the parent material from mine to mine and often within a given coal seam. A series of coal samples representative of North American coal has been prepared as part of the Argonne Premium Coal Sample Program for use by researchers to insure a common set of starting materials. These samples, from which the coal samples used in this study were drawn, are described in detail elsewhere (1).

$Ba(OH)_2$ has been used as an indicator of ion-exchange sites, which could then be identified using scanning electron microscopy (2). Iron salts have been used to stain coal surfaces as an aid in optical and electron microscopy (3). We suggest that the development of blue colours on the coal surfaces following exposure to $Fe^{3+}/Fe(CN)_6^{3-}$ solutions results from oxidation of the coal surface by Fe^{3+} with the subsequent formation of a charge-transfer complex (prussian blue) $Fe^{2+}/Fe^{3+}(CN)_6^{3-}$. Since this complex absorbs strongly in the visible region the reaction can be followed by colorimetry of appropriate coal slurries. The kinetics of the Fe^{3+} reduction are a direct measure of the reactivity of individual coals with these reagents and may provide a means of predicting coal quality in specific industrial uses.

Experimental

Five 100 mesh Argonne Premium coal samples, Pocahontas, Stockton, Illinois no. 6, Wyodak, and North Dakota, chosen to give a wide range of O/C ratios (Table 1), were exposed with rapid stirring to 0.6 M $FeCl_3$ solutions having a pH of 2.6 at 30°C. The resulting slurry contained 3 g of coal per 100 mL. Approximately 1 mL of solution was withdrawn from the slurry at appropriate time intervals using a syringe fitted with a 0.8 μm filter. This solution was added to 10 mL 0.3 M $K_3Fe(CN)_6$, which served as an indicator due to the formation of $Fe^{2+}/Fe^{3+}(CN)_3^{3-}$ (prussian blue.) The progress of the reaction was followed by UV–VIS spectroscopy using the strong absorption line at 700 nm. The procedure was repeated with the same set of coal samples after they had been exposed to air at 105°C for 5 days, and with fresh coals that had been demineralized by soaking overnight in concentrated HCl.

A single sample was prepared by adding $K_3Fe(CN)_6$ directly to the coal–$FeCl_3$ slurry. The coal was withdrawn and the infrared spectrum of both fresh and exposed coal was obtained on KBr discs. In addition, X-ray photoelectron spectra (XPS) were obtained from coal surfaces after exposure to $FeCl_3$.

Results and discussion

The sample prepared by adding $K_3Fe(CN)_6$ directly to the coal–$FeCl_3$ slurry showed only minimal reduction of the Fe^{3+}. Since the $K_3Fe(CN)_6$ clearly acted as an inhibitor to the Fe(III) reduction we suggest that it adsorbed on the coal surface, blocking the reduction sites against further reaction. The IR

spectra from this coal and untreated material are shown in Fig. 1. The intense absorption at around 2100 cm^{-1}, the C≡N vibration, in the treated sample that is resistant to reaction with Fe^{3+}, is consistent with the suggestion that CN^-

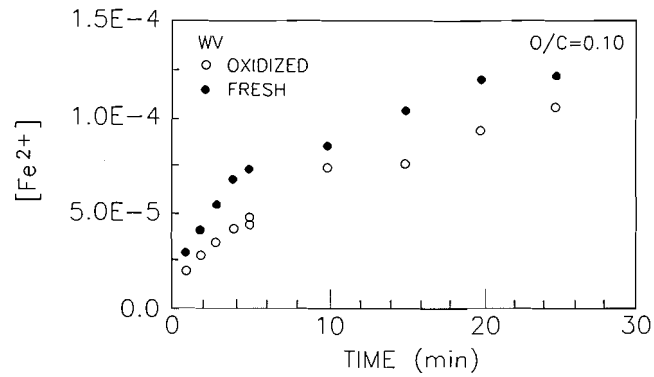

FIG. 3. $[Fe^{2+}]$ vs. time for Stockton coal before and after oxidation in air at 105°C.

adsorbs, possibly as $Fe(CN)^{3-}$, on active sites on the coal surface inhibiting reduction of Fe^{3+} species in the bulk slurry.

The XPS spectrum shows several iron species including Fe_3O_4 (708.3 eV), Fe_2O_3 (711.1 eV), and FeO (709.5 eV). These results, coupled with the formation of prussian blue, would account for the suite of colours observed by Salehi and Hamilton (3).

The other results obtained are recorded in Tables 1 and 2 and are displayed in Figs. 2–6. The kinetics of Fe^{3+} reduction in this system cannot be fixed with certainty for several reasons. The first is purely mechanical: separation of the solution from the slurry requires rapid withdrawal of material through a fine mesh and therefore easily clogs the filter. Secondly, although a large excess of Fe^{3+} is used, thus ensuring pseudo-zero-order kinetics for iron, the nature and distribution of the reactive surface species (i.e., the concentration) is unknown and probably varies rapidly during the course of reaction. Finally, the possibility that Fe^{2+} is oxidized back to Fe^{3+} cannot be rigorously excluded. Nevertheless, the following analysis, which is meant to assess the relative reactivities of the coals studied, is internally consistent.

The two coals having the highest O/C ratios, Figs. 5 and

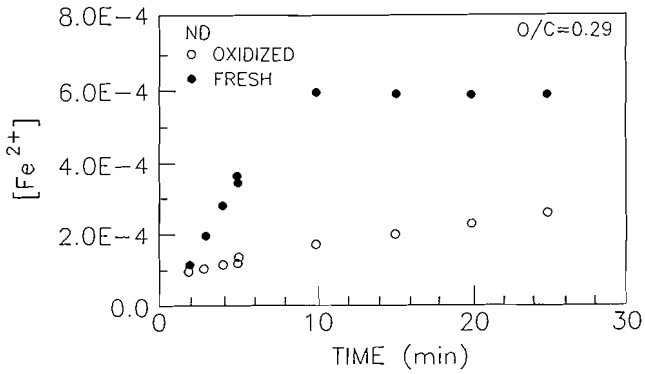

FIG. 6. $[Fe^{2+}]$ vs. time for North Dakota before and after oxidation in air at 105°C.

6, show two distinct reaction regimes, an initial fast reaction that appears to be close to completion after 5 min followed by a relatively slow reaction. These regions become progressively less distinct as the O/C ratio falls, Figs. 4, 3, and 2, and the fast reaction appears to be completely absent in the coal of lowest O/C, Pocahontas, Fig. 2. The fast reaction is probably due to reactive oxygen functional groups, which are more abundant in the coals of highest O/C ratio, while the slow reaction originates from less reactive oxygen species and (or) basic nitrogen groups (4). In an attempt to quantify these results, reaction rates (shown in Figs. 2–6) for the various coals were compared by taking the slope of the $[Fe^{2+}]$ vs. time plot between 2 and 4 min to avoid either forcing the data through the origin or biasing the results to later times in the reaction sequence. A second reaction rate was determined by taking the slope between 10 and 20 min. These data, together with the names and O/C ratios of the coals used are recorded in Tables 1 and 2. This relatively simple approach was chosen because a more sophisticated treatment is precluded by the scatter of the data and uncertainty about the concentration of the surface-reactive material, which can only be inferred from the O/C ratio. We refer to the two time regions as the fast and slow reactions, respectively, although this description is most appropriate for the North Dakota and Wyodak coals (Figs. 5 and 6). The lowest O/C coals, Pocahontas (Fig. 2), may well present a single continuous reaction while Stokton and Illinois (Figs. 3 and 4) appear to represent an intermediate case. The reaction rate for both regions is a clear function of the O/C ratio of the parent coal.

After air oxidation, the initial fast reaction is absent in the coals having the highest O/C ratio and appears to be much reduced in coals with intermediate O/C ratios (Figs. 2–6). There is little or no change in the initial reaction rate in the coal with the lowest O/C values. The slower reaction, i.e., that estimated from the slope after 10 min, appears to extend continuously into the "pre 5-min" region for the coals of highest O/C ratio after air oxidation (Figs. 5 and 6); for this reason we have chosen to describe this reaction simply as "not observed" in Table 2. The intermediate O/C coals (Figs. 3 and 4) still show a second process, while the lowest O/C material (Fig. 2) shows essentially one process. Thus the reactive sites may be divided into two classes, those sensitive to both air oxidation and oxidation by Fe^{3+} and those sensitive to oxidation by Fe^{3+} only. The standard reduction potential for the quinone/hydroquinone system is −0.7 V while that for Fe^{3+}/Fe^{2+} is 0.77; although the concentration of surface species is unknown, it is clear that oxygen-based organic functional groups are capable of reducing Fe^{3+} and that a continuous series of reactive sites having structures similar to the quinone system could be responsible for the behaviour we observe.

Mineral matter has been shown to be capable of reducing Fe^{3+}; however, there is no charge in kinetics after demineralization with concentrated HCl. Consequently, we do not believe that indwelling minerals play a significant role in iron reduction.

Conclusions

Fe^{3+} oxidizes coal and the reaction kinetics can be followed colorimetrically using $K_3Fe(CN)_6$ as an indicator. The formation of various iron oxides and $Fe^{2+}/Fe^{3+}(CN)_6^{3-}$ on the coal surface is responsible for the colours observed by Salehi and Hamilton (3) after treating coal with these reagents. Fresh coal having a relatively high O/C appears to exhibit two oxidation processes of differing kinetics. The differences between the two rates appear to be absent in coals having low O/C ratios and are more pronounced in coals with high O/C ratios. In any case the rates are a smooth function of the O/C ratio of the parent coal. Mild air oxidation effectively eliminates the first, more rapid, reaction, allowing

For personal use only.

the active species to be divided into two types, those oxidized by Fe^{3+} and air oxidation and those oxidized by Fe^{3+} only. The coal may thus be viewed as containing a series of functional groups of varying oxidation potential. The kinetics of Fe^{3+} oxidation of coal may provide a direct measure of coal quality in industrial applications.

In situ Fourier transform infrared spectroelectrochemical studies of the oxidation of some octaethylporphyrin complexes

A. Scott Hinman[1] and Temitayo Olorunyolemi
Department of Chemistry, The University of Calgary, Calgary, AB T2N 1N4, Canada

Received June 1, 1993

A. Scott Hinman and Temitayo Olorunyolemi. Can. J. Chem. **71**, 1975 (1993).

The oxidations of OEPNi(II), OEPCu(II), OEPFe(III)Cl, OEPMn(III)ClO_4, OEPAg(II), OEPCo(II), and OEPZn(II) (OEP = 2,3,7,8,12,13,17,18-octaethylporphyrin dianion) have been studied by in situ FTIR reflectance spectroelectrochemistry in dibromomethane. One-electron oxidation of the porphyrin ring to produce a π-cation radical results in the appearance of a strong new absorbance band near 1550 cm^{-1}. Other features typical of π-cation radical formation are a strong absorbance increase near 1470 cm^{-1}, and absorbance decreases near 1270 and 1018 cm^{-1}. Oxidation of the metal centre, as observed for OEPCo(II) in the presence of CH_3CN, and for OEPAg(II), results in considerably less perturbation of the vibrational spectra of the complexes. For OEPCo(II) in dry dibromomethane, initial oxidation at the porphyrin ligand is followed by a second oxidation at the metal centre. This order is reversed when acetonitrile is added to solution. Production of porphyrin π-dications was observed for OEPCu(II) and OEPNi(II). This results in a shift of the 1550 cm^{-1} π-cation radical marker band to higher energy, and a strong absorbance increase near 1380 cm^{-1}. Unusual spectral changes observed on one-electron oxidation of OEPZn(II) are suggested to result from the formation of a dimer.

A. Scott Hinman et Temitayo Olorunyolemi. Can. J. Chem. **71**, 1975 (1993).

Faisant appel à la spectroélectrochimie par FTIR à réflectance in situ, on a étudié les oxydations du OEPNi(II), OEPCu(II), OEPFe(III)Cl, OEPMn(III)ClO_4, OEPAg(II), OEPCo(II) et OEPZn(II) (OEP = le dianion 2,3,7,8,12,13,17,18-octaéthylporphyrine) dans le dibromométhane. L'oxydation du noyau porphyrine par un électron conduisant à un radical π-cationique donne lieu à l'apparition d'une forte bande d'absorption près de 1550 cm^{-1}. D'autres caractéristiques typiques de la formation d'un radical π-cationique sont la forte augmentation de l'absorption près de 1470 cm^{-1} et une diminution de l'absorption près de 1270 et 1018 cm^{-1}. L'oxydation du centre métallique observé avec le OEPCo(II) en présence de CH_3CN et avec le OEPAg(II) provoque beaucoup moins de perturbation dans les spectres de vibration des complexes. Avec le OEPCo(II) dans le dibromométhane sec, l'oxydation initiale du coordinat porphyrine est suivie par une deuxième oxydation du centre métallique. Cet ordre en inversé lorsqu'on ajoute de l'acétonitrile à la solution. On a observé la formation de dications-π de la porphyrine avec le OEPCu(II) et le OEPNi(II). Dans ces cas, on observe un déplacement de la bande typique des radicaux π-cationiques de 1550 cm^{-1} vers des énergies plus élevées et une forte augmentation de l'absorption vers 1380 cm^{-1}. Des changements spectraux inhabituels observés lors de l'oxydation du OEPZn(II) par un électron suggèrent qu'il y aurait formation d'un dimère.

Introduction

One-electron oxidation of a metalloporphyrin complex may result in loss of an electron from the porphyrin ring, to form a π-cation radical, or from the central metal atom of the complex. Since both types of process have been implicated in the biological action of heme-proteins, porphyrin chemists have directed considerable attention to the problem of identifying the oxidation site within the complex, and a number of criteria have been developed in this regard (1).

While infrared spectroscopy has been suggested to provide the simplest criteria for identifying the oxidation site within the complex (2), it has not yet been widely exploited for this purpose. Goff, Reed, and co-workers (3) were the first to investigate the applicability of infrared spectra to determining the site of oxidation in metalloporphyrins. These workers isolated a number of metalloporphyrin complexes following one-electron oxidation of the porphyrin ring. In the case of 5,10,15,20-tetraphenylporphyrin (TPP) complexes a strong new band at ca. 1280 cm^{-1} was observed in the solid state infrared spectra of the oxidized products, and this band was suggested to be diagnostic of π-cation radical formation. Similarly, a band near 1550 cm^{-1} was suggested as a diagnostic criterion for porphyrin ring oxidation in 2,3,7,8,12,13,17,18-octaethylporphyrin (OEP) complexes.

This laboratory was the first to apply in situ Fourier transform infrared reflectance spectroelectrochemistry to observe changes to the vibrational spectra of metalloporphyrins accompanying electrochemical oxidation of the porphyrin ring (4, 5). In this technique, infrared radiation passes through a thin layer of solution (10–100 μm) onto a polished Pt electrode, and is reflected back to the detector. The intensity of the infrared radiation is determined prior to and following electrolysis of the thin layer of solution. Because replacing the solution in the thin-layer cavity requires repositioning of the electrode, it is difficult to precisely determine a background spectrum in the absence of electroactive species. The technique is thus not well suited to determining individual spectra of the electroactive species prior to and following electrolysis. On the other hand, the difference in absorbance resulting from electrolysis of the thin layer of solution is readily measurable. This is determined by rationing the energy spectrum obtained following electrolysis to that obtained prior to electrolysis and taking the logarithm. No repositioning of the electrode or cell assembly is required in obtaining these spectra.

In a series of studies (4–7), we have investigated the application of in situ FTIR reflectance spectroelectrochemistry to studies of the one-electron oxidation of metal–tetraphenylporphyrin complexes in a variety of solvents or solvent mixtures. In addition to facilitating identification of the oxidation site within the complexes (4, 5), the tech-

nique has proven useful for observing axial coordination changes accompanying the oxidation (4), and for characterizing products of irreversible homogeneous reactions following the electron transfer (7).

In situ FTIR spectroelectrochemistry is now, in our view, well established as a technique for identifying the oxidation site within tetraphenylporphyrin complexes, but considerably less work in this regard has been done with octaethylporphyrins. As noted above, Goff, Reed, and co-workers (3) observed a band near 1550 cm^{-1} in the infrared spectra of some solid isolated iron and zinc octaethylporphyrin π-cation radicals and suggested that this band might serve as a marker for oxidation of the porphyrin ring. Kadish et al. (8) similarly observed a band near 1550 cm^{-1} in an electrochemically generated iridium octaethylporphyrin π-cation radical by in situ FTIR transmission spectroelectrochemistry.

Because the octaethylporphyrin complexes are the second most commonly studied class of synthetic metalloporphyrins, following the tetraphenylporphyrins, and since they are structurally more similar to naturally occurring metalloporphyrins, we have utilized in situ FTIR reflectance spectroelectrochemistry to examine the infrared difference spectra associated with the oxidation of a variety of octaethylporphyrin complexes including Ag, Co, Cu, Fe, Mn, Ni, and Zn. Our results are reported here.

Experimental

Metalloporphyrins

Octaethylporphyrin ($OEPH_2$) and its Co(II), Cu(II), Fe(III)Cl, Mn(III)Cl, and Zn(II) complexes were obtained from Aldrich and used as received. OEPAg(II) was prepared by refluxing Ag(I)-CF_3CO_2 with $OEPH_2$ for ca. 30 min according to the method of Adler *et al.* (9), and purified chromatographically on an alumina column using methylene chloride as eluent. The electronic absorbance spectrum of the purified product was identical to that reported in the literature (10).

OEPMn(III)Cl was converted to $OEPMn(III)ClO_4$ by precipitation from methanol to which a small quantity of dilute aqueous perchloric acid had been added. The procedure is identical to that previously reported for the preparation of perchlorato(tetraphenylporphinato)manganese(III) ($TPPMnClO_4$) (11). The presence of perchlorate in the product was confirmed by the appearance of a strong band at 1146 cm^{-1} in the infrared spectrum (KBr disk). The product was further characterized by elemental analysis, which gave satisfactory results assuming the presence of one water molecule per porphyrin unit. (Calculated for $OEPMnClO_4 \cdot H_2O$: C 61.67%, H 6.03%, N 7.99%, found: C 62.09%, H 5.98%, N 7.90%.) The presence of water was similarly indicated in crystalline $TPPMnClO_4$ prepared by the same method (11).

Solvents and supporting electrolyte

Tetra-*n*-butylammonium hexafluorophosphate was used as supporting electrolyte in all electrochemical and spectroelectrochemical experiments. This was prepared, purified, and dried as previously reported (5). Dibromomethane (Aldrich) was used as solvent throughout. This was shaken with activated alumina, distilled from P_2O_5, and stored in the dark over CaH_2 prior to use. Acetonitrile was refluxed over CaH_2 and distilled prior to use.

Spectroscopy, electrochemistry, and spectroelectrochemistry

A Hi Tek model DT2101 potentiostat operating in conjunction with a Hi Tek PPRI waveform generator was utilized for potential control in all cyclic voltammetric and UV–visible spectroelectrochemical experiments. Control of electrode potential in in situ FTIR reflectance spectroelectrochemistry was accomplished with either the Hi Tek potentiostat or a PAR model 174 polarographic analyzer. A home-built saturated calomel reference electrode (SCE) was utilized as reference electrode throughout.

Conventional cyclic voltammetry utilized a two-compartment three-electrode cell, which has been described previously (7). The cell utilized for in situ FTIR reflectance spectroelectrochemistry and time-resolved thin-layer UV–visible reflectance spectroelectrochemistry has similarly been described in detail (6), the only modification being the inclusion of a stray light deflector to prevent light reflected from the front surface of the window from reaching the detector. The cell was fitted with a CaF_2 window for infrared measurements, and a quartz window for UV–visible measurements. A Pt disc, polished to a mirror finish, was utilized as working electrode in both cases.

A Nicolet 8000 FTIR spectrometer fitted with a narrow-range MCT detector was utilized for in situ FTIR reflectance spectroelectrochemistry. The methodology, instrumentation, and optical configuration were as described in previous publications (4–6). Infrared difference spectra are reported as the difference between absorbance of the thin-layer solution resulting from switching the potential from a base potential, $E1$, at which no oxidation occurs, and a second potential, $E2$, chosen to facilitate the desired oxidation.

The instrument employed for time-resolved thin-layer UV–visible reflectance spectroelectrochemistry employed a Rofin–Sinar RSO 6101 spinning-grating monochromator. Its construction and implementation have been described in detail in a previous publication (12).

Absolute infrared absorbance spectra of all of the unoxidized porphyrins were determined in dibromomethane. Either a Mattson 4030 Galaxy series FTIR spectrometer or a Nicolet 5DX FTIR spectrometer was used. Saturated solutions were used in a 0.2-mm pathlength cell fitted with KBr windows.

Results and discussion

Comparison of metal vs. ligand oxidation: OEPAg(II) and OEPCo(II)

OEPAg(II) and OEPCo(II) are both well known to be subject to oxidation at the metal centre as well as at the porphyrin ligand. As such, these complexes provided an opportunity to compare directly the changes to the vibrational spectrum of the complexes arising from metal-centred oxidation with those due to oxidation at the porphyrin ligand.

Cyclic voltammetry of OEPCo(II) in CH_2Br_2/0.1 M $TBAPF_6$ indicates the presence of three clean reversible one-electron oxidations with half-wave potentials of 0.69, 0.98, and 1.29 V vs. SCE, respectively. In dry dichloromethane containing perchlorate as counterion, the first oxidation has been shown to result in loss of an electron from the porphyrin ring to form the $OEP^{\cdot}Co(II)^{+}$ π-cation radical, while the second oxidation is metal centred, forming the $OEP^{\cdot}Co(III)^{2+}$ doubly charged species (13, 14).

Figure 1 illustrates in situ infrared difference spectra associated with the first two oxidations of OEPCo(II) in CH_2Br_2 containing 0.1 M $TBAPF_6$. A strong absorption band of the CH_2Br_2 solvent removes most of the incident radiation in a narrow range around 1200 cm^{-1}, accounting for the high noise level in this region of the spectra.

Loss of one electron from OEPCo(II) (Fig. 1*a*) results in major perturbation of the vibrational spectrum of the porphyrin ligand, as evidenced by major appearance features (absorbance increases) at 1587, 1562, and 1471 cm^{-1}, and major disappearance features (absorbance decreases) at 1272 and 1018 cm^{-1}. By way of contrast, the first oxidation of TPPCo(II), which is well established as a metal-centred process (4, 5, 15, 16) has been shown to result in only very slight changes to the vibrational spectrum of the porphyrin

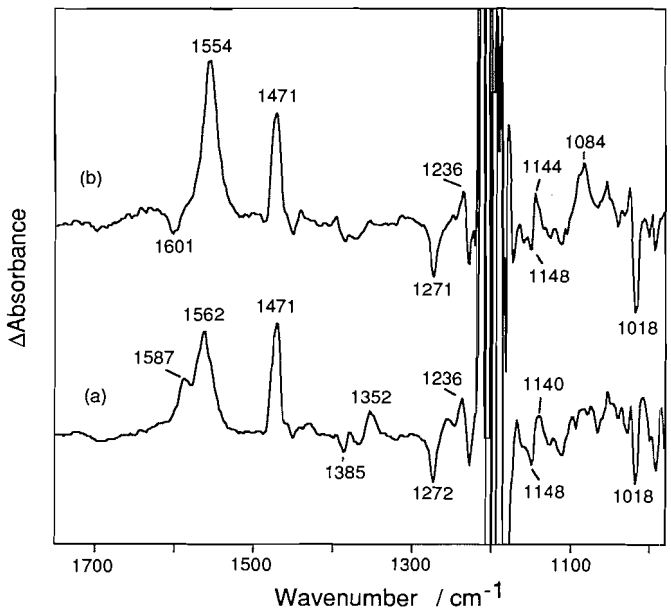

FIG. 1. In situ FTIR difference spectra for (*a*) one- and (*b*) two-electron oxidation of OEPCo(II) in CH_2Br_2 containing 0.1 M $TBAPF_6$. In *a*, *E*1 = 0.50 V and *E*2 = 0.85 V vs. SCE. In *b*, *E*1 = 0.50 V and *E*2 = 1.25 V vs. SCE.

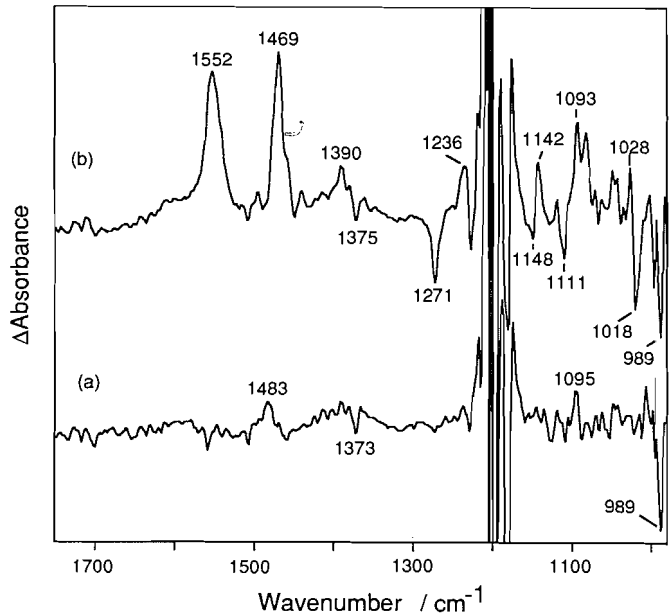

FIG. 2. In situ FTIR difference spectra for (*a*) one- and (*b*) two-electron oxidation of OEPCo(II) 1.44 mM in CH_2Br_2 containing 0.1 M $TBAPF_6$ and 0.01 M CH_3CN. In *a*, *E*1 = 0.40 V and *E*2 = 0.80 V vs. SCE. In *b*, *E*1 = 0.40 V and *E*2 = 1.20 V vs. SCE.

(4, 5). The observations in the present case thus support the conclusions (13, 14) of previous workers that one-electron oxidation of OEPCo(II) in dry noncoordinating media is porphyrin ligand centred. This is further supported by the appearance of a strong new absorption band at 1562 cm^{-1} in the oxidized complex. New absorbance bands in this region of the spectrum were previously suggested to be diagnostic of porphyrin ring oxidation (3).

Removal of a second electron from OEPCo(II) (Fig. 1*b*) results in collapse of the 1587 and 1562 cm^{-1} bands of the singly oxidized product into a single band at 1554 cm^{-1}. In other respects the difference spectra observed on one and two-electron oxidation are very similar. In dry noncoordinating media, the second oxidation of OEPCo(II) is metal centred (13, 14), and a similar situation is expected to pertain in the present case. An alternate assignment of the difference spectra of Fig. 1*b* as arising from formation of the $OEPCo(II)^{2+}$ π-dication rather than the $OEP^{\cdot}Co(III)^{2+}$ π-cation radical is inconsistent with observations of difference spectra arising from formation of other OEP π-dications (vide infra). In these cases, a strong new absorption band near 1385 cm^{-1} is observed, and a band near 1550 cm^{-1} due to the corresponding π-cation radical is observed to shift to higher wavenumber rather than to lower wavenumber, as in the present case.

When dry CH_3CN is added to CH_2Br_2/0.1 M $TBAPF_6$ solutions of OEPCo(II), the half-wave potential for the first oxidation shifts negatively, indicating that complexation of CH_3CN is involved in the electrode process. For a solution containing 1.44 mM porphyrin and 0.01 M CH_3CN, the first oxidation occurred with a half-wave potential of 0.560 V vs. SCE. Subsequent reversible oxidations were observed at half-wave potentials of 0.94 and 1.29 V vs. SCE. The number of coordinating CH_3CN species and the magnitude of the relevant binding constants are currently under investigation.

Figure 2 illustrates in situ infrared difference spectra observed on one and two-electron oxidation of OEPCo(II) in the presence of excess CH_3CN. In contrast to observations in the absence of CH_3CN, one-electron oxidation (Fig. 2*a*) results in very little perturbation of the vibrational spectrum of the porphyrin, suggesting that oxidation is associated with the metal centre rather than the porphyrin ligand. Removal of a second electron (Fig. 2*b*) produces a difference spectrum very similar to that observed in Fig. 1*b* for formation of $OEP^{\cdot}Co(III)^{2+}$ in the absence of CH_3CN. In conjunction with the observation of a strong band at 1552 cm^{-1}, this clearly indicates a porphyrin ring-centred oxidation to produce a π-cation radical species. Thus, addition of CH_3CN results in a reversal of the order of oxidation of the metal and porphyrin ring redox sites, with the first electron now being derived from the metal and the second from the porphyrin ring. Previous workers similarly indicated that the order of oxidation for the two sites in OEPCo(II) is reversed in the presence of H_2O or CH_3OH (14), as well as in the presence of Cl^-, Br^-, or $SbCl_6^-$ (13).

OEPAg(II) undergoes two reversible one-electron oxidations in CH_2Br_2/0.1 M $TBAPF_6$ with half-wave potentials of 0.44 and 1.54 V vs. SCE. The first oxidation was established by a variety of techniques as a metal-centred process producing the $OEPAg(III)^+$ cation (10, 17–19). The second oxidation results in removal of an electron from the porphyrin ring to produce the $OEP^{\cdot}Ag(III)^{2+}$ π-cation radical (10).

Figure 3 shows in situ FTIR difference spectra observed on one- and two-electron oxidation of OEPAg(II). Removal of the first electron from the complex (Fig. 3*a*) results in somewhat greater perturbation of the porphyrin vibrational spectrum than was observed for metal oxidation of OEPCo(II) in the presence of CH_3CN (Fig. 2*a*), but considerably less than observed for ring-centred oxidations of the cobalt–por-

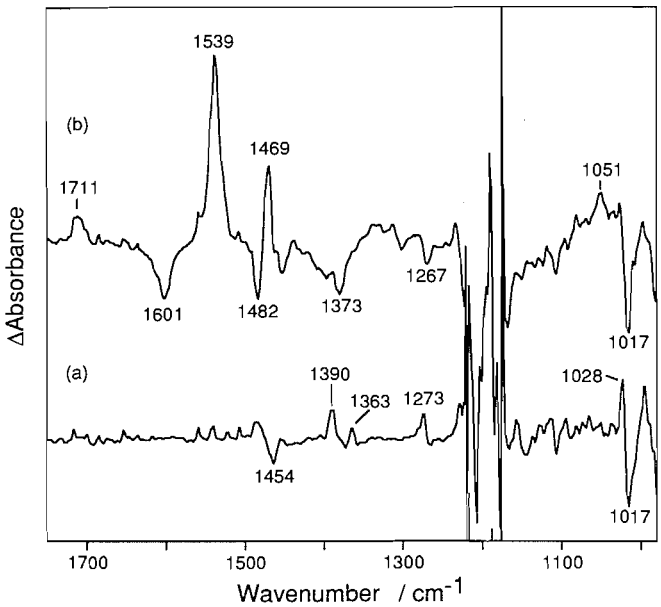

FIG. 3. In situ FTIR difference spectra for (*a*) one- and (*b*) two-electron oxidation of OEPAg(II) in CH_2Br_2 containing 0.1 M $TBAPF_6$. In *a*, $E1 = 0.30$ V and $E2 = 0.60$ V vs. SCE. In *b*, $E1 = 0.30$ V and $E2 = 1.65$ V vs. SCE.

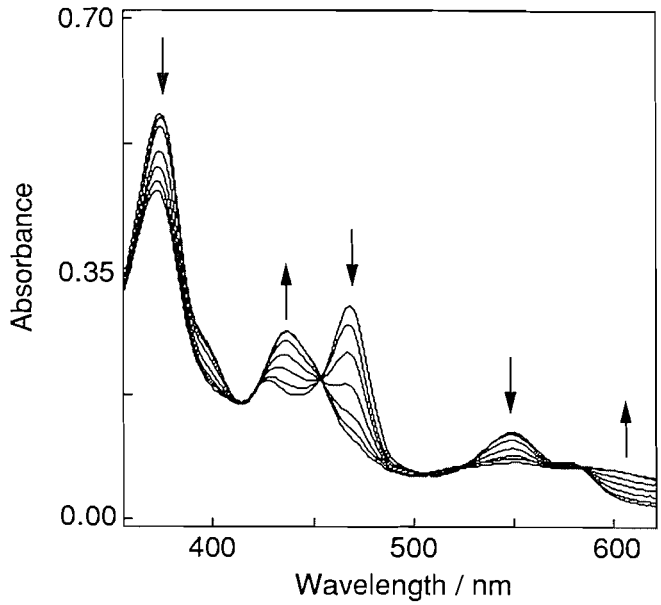

FIG. 4. Time-resolved UV–visible thin-layer spectroelectrochemistry observed during the one-electron oxidation of $OEPMnClO_4$ (1.0 mM) in CH_2Br_2 containing 0.1 M $TBAPF_6$. Spectra were recorded at 10.6 s intervals during a potential step from 1.0 to 1.3 V vs. SCE.

TABLE 1. Half-wave potentials[a] (V vs. SCE) for oxidation of OEP complexes

Complex	Metal oxidation	Ligand oxidation	Additional oxidation
OEPNi(II)		0.77	1.42
OEPCu(II)		0.75	1.35
OEPFe(III)Cl		0.99	1.47
$OEPMn(III)ClO_4$		1.19	1.52
OEPAg(II)	0.44	1.54	
OEPZn(II)		0.71	1.04
OEPCo(II)	0.98	0.69	1.29
OEPCo(II) + CH_3CN[b]	0.560	0.94	1.29

[a]All measurements in CH_2Br_2 containing 0.1 M $TBAPF_6$.
[b][OEPCo(II)] = 1.44 mM, [CH_3CN] = 0.01 M.

phyrin adducts. In particular, no strong new absorbance near 1550 cm^{-1} is found. Removal of a second electron from OEPAg(II) (Fig. 3*b*) results in far more substantial changes to the porphyrin spectrum, and causes the appearance of a strong new absorption at 1539 cm^{-1}. These observations are clearly consistent with the first electron deriving from the Ag(II) metal centre, and the second electron being removed from the porphyrin ring.

Similarities in difference spectra observed on ring oxidation in OEP complexes

To provide a comparison of the infrared difference spectra for formation of a greater variety of OEP π-cation radicals, the oxidations of OEPCu(II), OEPNi(II), OEPFe(III)Cl, and $OEPMn(III)ClO_4$ were investigated. Cyclic voltammetry in CH_2Br_2 indicates that all of these complexes undergo two reversible oxidations with half-wave potentials as indicated in Table 1. Table 1 also includes potentials for oxidation of the Co(II) and Ag(II) complexes (vide supra) as well as for OEPZn(II) (vide infra).

The one-electron oxidation products of OEPCu(II) (19–21), OEPNi(II) (21), and OEPFe(III)Cl (21–23) have all been previously characterized as porphyrin π-cation radicals. Because $OEPMn(III)ClO_4$ has not, to our knowledge, been previously investigated, we monitored the oxidation of this compound by visible as well as infrared spectroelectrochemistry. Figure 4 illustrates the spectral changes accompanying one-electron oxidation of this compound as observed by time-resolved thin-layer UV–visible reflectance spectroelectrochemistry. The oxidation is accompanied by well-defined isosbestic points, indicating the reversible nature of the redox couple. The spectrum of the final oxidation product displays a broad, featureless absorbance in the 500–620 nm region. This is typical of porphyrin π-cation radicals, but is not characteristic of species where electron abstraction has occurred at the metal centre (1). As such, the spectral changes indicate that the one-electron oxidation product may be formulated as the $OEP^{\cdot}Mn(III)ClO_4^+$ π-cation radical.

Prior to investigating the difference spectra observed on oxidation of the OEP complexes, the infrared spectra of all unoxidized species were first measured in CH_2Br_2. Table 2 lists the strong and medium intensity infrared absorptions in the 1800–1000 cm^{-1} region for all species investigated in this study. The porphyrin core vibrational modes ν_{38}–ν_{44} and ethyl substituent vibrational modes for OEPNi(II) were assigned in accordance with a recent detailed analysis by Li et al. (24). Because our measurements were done on solution species, while those of Li et al. were based on KBr disc spectra, some small differences in band position are evident. The assignments for bands of other complexes were made on the basis of their proximity to those of OEPNi(II).

In situ FTIR difference spectra for one-electron oxidation of OEPNi(II), OEPCu(II), OEPFe(III)Cl, and $OEPMn(III)ClO_4$ are presented in Figs. 5*a*, 6*a*, 7, and 8, respectively. In comparing these among themselves, and with the spectra

discussed previously for oxidation of the porphyrin ring in Ag and Co OEP complexes (Figs. 1–3), there are several features common to all, or at least the majority, of the cases studied. These are indicated in Table 3.

The most notable feature common to all spectra is the presence of at least one strong new absorption band in the region 1537–1589 cm^{-1}. This is in accordance with the suggestion of previous workers (3) of a 1550 cm^{-1} marker band for OEP π-cation radical formation.

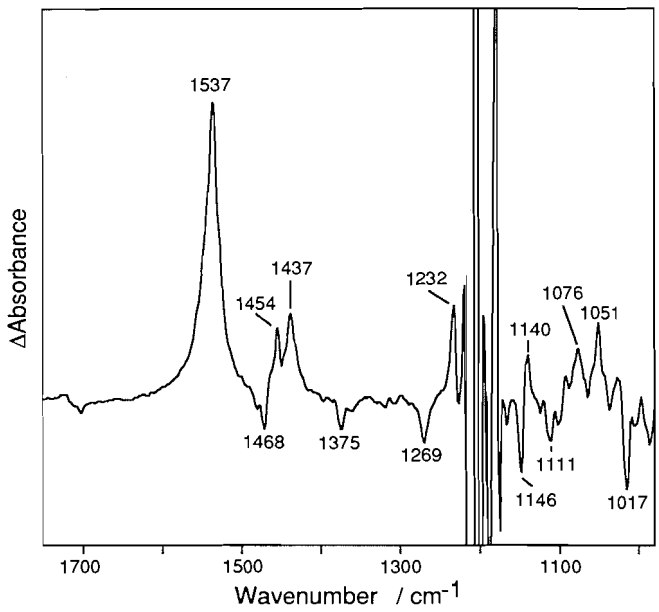

FIG. 7. In situ FTIR difference spectra for one-electron oxidation of OEPFe(III)Cl in CH_2Br_2 containing 0.1 M $TBAPF_6$. $E1$ = 0.85 V and $E2$ = 1.25 V vs. SCE.

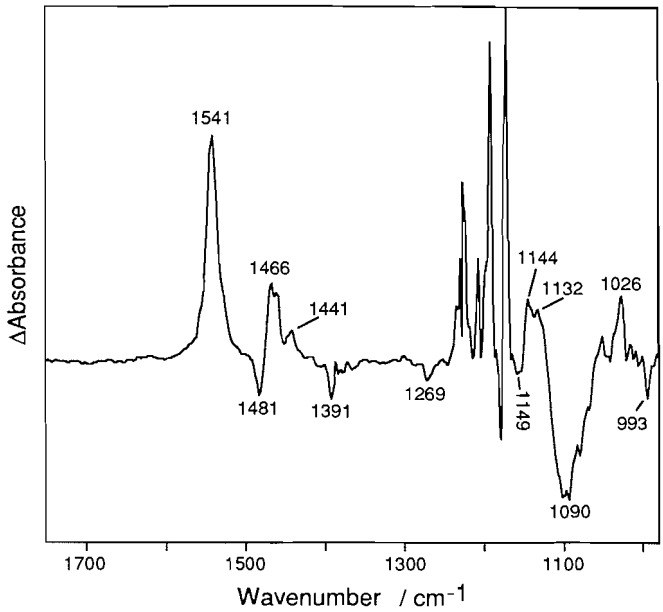

FIG. 8. In situ FTIR difference spectra for one-electron oxidation of $OEPMn(III)ClO_4$ in CH_2Br_2 containing 0.1 M $TBAPF_6$. $E1$ = 1.00 V and $E2$ = 1.35 V vs. SCE.

Also apparent is the presence of one or more strong appearance bands near 1470 cm^{-1}. In most of these cases, especially for OEPAg(III) (Fig. 3*b*), OEPCu(II) (Fig. 6*a*), OEPFe(III)Cl (Fig. 7), and $OEPMn(III)ClO_4$ (Fig. 8), this feature occurs in conjunction with a disappearance feature at higher wavenumber, as apparent in Table 3. For the Ag, Cu, and Mn complexes, this disappearance coincides with ν_{39} as indicated in Table 2. The appearance of a 1470 cm^{-1} band for these cases in the difference spectra is thus suggested to result from a shift to lower energy and increase in intensity of ν_{39} of the parent compound as a result of porphyrin ring oxidation. For OEPFe(III)Cl, the disappearance at 1468 cm^{-1} coincides more closely with that expected for the ethyl CH_2 scissors mode, as indicated in Table 2. However, the similarity in this region of the difference spectrum for OEPFe(III)Cl and those obtained for the other complexes suggests the same band is responsible in all cases.

In most of the difference spectra, as indicated in Table 3, there is evidence of a disappearance feature near 1147 cm^{-1} that coincides with ν_{43} from Table 2. This usually appears in conjunction with an appearance feature with a lower energy of approximately 5 cm^{-1}, suggesting that ν_{43} of the unoxidized complexes shifts to lower energy on removal of an electron from the porphyrin ring.

Also apparent in most cases are disappearance features near 1380, 1270, and 1018 cm^{-1}. The 1380 cm^{-1} band lies close to the positions expected for either the ν_{40} porphyrin core vibrational mode, or the ethyl CH_2 wagging mode, as indicated in Table 2. The disappearance at 1270 cm^{-1} coincides with a band observed in all the solution spectra of the unoxidized porphyrins studied here, and which was assigned by Li et al. (24) to CH_2 twisting in the ethyl substituents for OEPNi(II). In an earlier study by Abe et al. (25), a band at 1268 cm^{-1} in the solid state infrared spectrum of OEPNi(II) was assigned as the ν_{42} porphyrin core vibrational mode. The disappearance near 1018 cm^{-1} coincides with the C_1–C_2 stretching mode of the ethyl groups indicated in Table 2. While the difference spectra clearly indicate a loss in absorbance of these bands, they do not provide clear insight as to whether a shift in band position also occurs.

Metalloporphyrins are believed to possess two nearly degenerate highest occupied molecular orbitals (HOMOs), designated a_{1u} and a_{2u} (26). The pyrrole C_β–C_β interaction is anti-bonding in the a_{1u} orbital, but bonding in the a_{2u} orbital. In resonance Raman studies (21, 27), it was observed that bands thought to possess appreciable C_β–C_β stretching character shift to higher energy on oxidation of the porphyrin ring in OEP complexes, but to lower energy in TPP complexes. This led to the suggestion that, in general, oxidation results in loss of an electron from the a_{1u} orbital for OEP complexes, and from the a_{2u} orbital in TPP complexes (21).

The infrared spectrum of OEPNi(II) displays a band at 1601 cm^{-1}, which has been assigned as arising from the ν_{38} porphyrin core vibrational mode (24). This mode is thought to be primarily C_β–C_β stretching in character. As indicated in Table 2, all of the OEP complexes except OEPFe(III)Cl display an infrared band at this position. In accordance with the suggestion (21) that oxidation of the porphyrin ring in OEP complexes is associated with loss of an electron from the a_{1u} orbital, a shift to higher wavenumber would be anticipated to be evident in the difference spectra obtained on oxidation of the complexes in this study. A disappearance coincident with this band is observed in the difference spectra obtained for formation of $OEP^{\cdot}Ag(III)^+$ (Fig. 3*b*) and $OEP^{\cdot}Co(III)^{2+}$ (Fig. 1*b*), but no shift to higher wavenumber is apparent. In the rest of the cases investigated, no perturbation of this band is observed at all. Shifts in band positions that are observed do not provide clear insight as to the ground state configuration of the π-cation radical complexes. Thus, at present, in situ FTIR spectroelectrochemistry does not appear to have the same utility for assigning

ground state configurations in porphyrin π-cation radicals as does resonance Raman spectroscopy.

The in situ FTIR difference spectrum observed for oxidation of $OEPMn(III)ClO_4$ shown in Fig. 8 displays a strong disappearance feature at 1090 cm^{-1} that was not observed on oxidation of any of the other OEP complexes investigated. This frequency corresponds to that observed for free solution perchlorate in dibromomethane solutions containing tetra-*n*-butyl ammonium perchlorate (4). The disappearance is accompanied by strong absorption at 1132 cm^{-1}, and a weaker one at 1051 cm^{-1}. Bands at these positions are typical of coordinated perchlorate (4). These features in the difference spectrum indicate that the perchlorate anion in $OEPMn(III)ClO_4$ dissociates, at least partially, on dissolution in CH_2Br_2. The binding constant is enhanced on oxidation to the π-cation radical, resulting in a loss of absorbance due to free perchlorate and an increase of absorbance bands due to coordinated perchlorate. Enhanced coordination of perchlorate has similarly been indicated in the in situ FTIR difference spectra observed on oxidation of the porphyrin ring in several TPP complexes (4).

In situ FTIR difference spectra observed on formation of OEP π-dications

For OEPCu(II) and OEPNi(II), we were able to observe reproducible difference spectra associated with removal of a second electron from the complexes. The spectral changes were reversible, as indicated by a return of the difference spectra to a flat baseline when the applied potential was returned to its base value, *E*1. We were not able to observe reproducible and spectrally reversible behavior for removal of a second electron from OEPFe(III)Cl or $OEPMn(III)ClO_4$.

Figure 6*b* illustrates the difference spectra observed on removal of a second electron from OEPCu(II). The product in this case was previously characterized as the $OEPCu(II)^{2+}$ π-dication (10). In comparing the spectrum with that in Fig. 6*a* for one-electron oxidation, it is evident that the 1549 π-cation radical marker band shifts to 1608 cm^{-1} on removal of a second electron from the porphyrin ring. Also apparent are major appearance features at 1385 and 1377 cm^{-1}. By way of contrast, removal of an electron from the metal centre in $OEP^{\cdot}Co(II)^{+}$ results in a shift of the π-cation radical marker band to lower energy, as apparent in Fig. 1, and produces no major new appearance features in the region near 1380 cm^{-1}.

The in situ FTIR difference spectrum observed on removal of a second electron from OEPNi(II) is illustrated in Fig. 5*b*. Similar to the changes observed for the second oxidation of OEPCu(II), loss of the second electron from OEPNi(II) results in a shift to higher energy of the 1568 cm^{-1} π-cation radical marker band (Fig. 5a) to 1612 cm^{-1}, and the observation of a major appearance feature at 1390 cm^{-1}. The product of the second oxidation of OEPNi(II) does not appear to have been conclusively identified, and Ni(III) porphyrin complexes are known (28). However, the similarity of the difference spectrum to that observed for the second oxidation OEPCu(II) suggests that, at least under the present conditions, the second electron from OEPNi(II) is derived from the porphyrin ring producing the $OEPNi(II)^{2+}$ π-dication.

Unusual difference spectrum observed for oxidation of OEPZn(II)

Figure 9 illustrates the in situ FTIR difference spectrum observed on removal of a single electron from OEPZn(II). The spectrum does possess an appearance band at 1535 cm^{-1}, but in other respects is considerably different from the spectra observed on one-electron oxidation of the porphyrin ring for the other OEP complexes in this study. In particular, very intense appearance features are observed at 1427, 1342, 1269, 1097, and 1007 cm^{-1} that do not appear to be typical of simple π-cation radical formation. Fuhrhop et al. (29, 30) suggested that the $OEP^{\cdot}Zn(II)$ π-cation radical formed by chemical oxidation of OEPZn(II) exists in equilibrium with a diamagnetic π–π dimer. As one possibility, the dimer was suggested to involve multicentred face-to-face overlap of the half-filled π-orbitals of two π-cation radicals. The visible spectrum of one-electron oxidized OEPZn(II) observed under our conditions by time-resolved UV–visible thin-layer reflectance spectroelectrochemistry appears identical to that reported by Fuhrhop et al. (29) for solutions of the dimer. Dimer formation thus appears to provide a plausible expla-

Using the X-ray crystal geometry as input, the ^{13}C NMR chemical shifts of benzo-9-crown-3 ether have been calculated via *ab initio* methods using a localized orbital local origin (LORG) approach. Reasonable agreement is found between the calculated values for an isolated molecule in the gas phase and those obtained in the ^{13}C CPMAS NMR spectrum. Solid phase ^{13}C spectra of the C7,10-d_4 derivative confirm the existence of a 7.9 ppm shift difference between these sites in the solid, whereas in solution they are conformationally averaged to one resonance. The effects of C—H bond length variation on calculated ^{13}C shifts have been explored.

G.W. BUCHANAN, A.B. DRIEGA, A. MOGHIMI, C. BENSIMON, R.A. KIRBY et T.D. BOUMAN. Can. J. Chem. **71**, 1983 (1993).

Utilisant la géométrie déterminée par diffraction des rayons X comme donnée et faisant appel à des méthodes *ab initio* impliquant une approche d'orbitale localisée à l'origine locale, on a calculé les déplacements chimiques de la RMN du ^{13}C de l'éther benzo-9-couronne-3. On a obtenu un accord raisonnable entre les valeurs calculées pour une molécule isolée en phase gazeuse et celles obtenue par RMN CPMAS du ^{13}C. Le spectre RMN du ^{13}C en phase solide du dérivé C7,10-d_4 confirme l'existence d'un déplacement chimique de 7,9 ppm entre ces sites dans le solide alors que, en solution, la moyenne conformationnelle les fait apparaître comme une seule résonance. On a examiné les effets de la variation de la longueur des liaisons sur les déplacements chimiques calculés du ^{13}C.

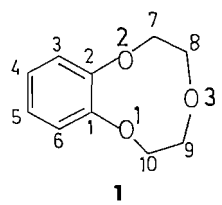
Introduction

The study of crown ether conformations in solution and in the solid phase has become an area of considerable recent research activity. In several cases correlations have been presented between experimentally observed ^{13}C NMR chemical shifts in the solid and X-ray crystallographic structural features. The benz-annelated crown ether systems that have been examined via these techniques to date are 30-crown-10 (1), 24-crown-8 (1), 15-crown-5 (1, 2), 14-crown-4 (3), 13-crown-4 (4), and 12-crown-4 (5). In no case, however, have there been any theoretical calculations of the ^{13}C shifts for the particular system under study, a situation arising mainly from the complexity of the molecules examined. This complexity has made the number of basis functions in a reasonable basis set representation of the molecule so large that NMR chemical shift calculations could not be done using available computing facilities.

In the present work we report the X-ray crystallographic structure of 2,3-benzo-1,4,7-trioxacyclonona-2-ene (benzo-9-crown-3) **1**, as well as its ^{13}C NMR spectrum in the solid phase and ^1H and ^{13}C spectra in solution. The relative simplicity of this molecule has permitted an *ab initio* calculation of its ^{13}C chemical shifts via the LORG (6–8) method, using as input for the calculations the geometry for C and O atoms obtained from the X-ray crystal structure.

Since the X-ray derived C—H bond lengths show a large range (0.06 Å), these bond lengths cannot be used as input for the LORG calculations. Rather, plausible proton positions have been determined via geometry optimization and used as input for LORG.



1

FIG. 1. Structure and numbering scheme for benzo-9-crown-3 ether (**1**).

The synthesis of **1**-7,10-d_4 has been carried out and its solid phase ^{13}C spectrum obtained to check that the large shift difference calculated between these two carbons (8.5 ppm) is consistent with experiment.

Results and discussion

Figure 1 contains numbering scheme used for **1**. Its ORTEP diagram is presented in Fig. 2 while the solid phase ^{13}C CPMAS spectrum is shown in Fig. 3. Figure 4*a* contains the normal ^{13}C CPMAS spectrum of the C7,10-d_4 derivative of **1**, while the dipolar dephased spectrum of this molecule is shown in Fig. 4*b*. Bond lengths and angles are collected in Table 1 while the torsional angles for ring skeletal atoms are provided in Table 2. ^{13}C NMR chemical shifts are in Table 3. Crystallographic data are presented in Table 4 and the atomic parameters in Table 5. In Table 6 are presented LORG

calculated isotropic ^{13}C shifts for ethane as a function of C—H bond length.

(a) Solution ^{13}C and ^{1}H NMR spectra

In the 400 MHz ^{1}H NMR spectrum of **1**, multiplets observed for both the ether and aromatic protons are characteristic of AA'BB' spin systems, as has been reported (9) for the dimer of **1**, dibenzo-18-crown-6, **2**. Data for the ethereal protons of **1**, as determined via iterative analysis, are as follows: δ_A = 4.334 ppm, δ_B = 3.895 ppm, $J_{AA'}$ = −10.91 Hz, $J_{BB'}$ = −11.01 Hz, J_{AB} = $J_{A'B'}$ = 6.17 Hz, $J_{A'B}$ = $J_{AB'}$ = 2.69 Hz. The magnitude of these coupling constants is consistent with a situation in which there is rapid conversion between rotamers in which the oxygen atoms are *gauche* to one another (9). This observation is also consistent with the X-ray data for **1**, where the O2—C7—C8—O3 and O3—C9—C10—O1 angles are 63.3° and 66.7°, respectively.

Assignments of the aliphatic protons of **1** were made via results from a NOESY experiment. A weak cross peak was noted between the resonance centered at 4.34 ppm and the aromatic proton resonance. Such a cross peak could only arise from relaxation between the *ortho* aromatic protons and the protons on C7,10 of **1**. No such correlation was found for the aliphatic multiplet centered at 3.89 ppm, since this arises from the more distant (from the aromatic ring) C8,9 site. With the NOESY results in hand, a $^{1}H^{13}C$ HETCOR experiment furnished the ^{13}C assignments of **1** in solution. These assignments were confirmed by comparison of spectra for **1**-d_4.

The solution ^{13}C spectrum of **1** is independent of temperature (apart from minor chemical shift changes) over the range 300–173 K. Hence the conformational interconversions in the nine-membered ring must remain fast on the NMR timescale at all accessible temperatures.

(b) Solid phase ^{13}C NMR spectrum

In the solid phase, the ^{13}C NMR spectral multiplicity will reflect the asymmetric unit in the crystal if no unusual crystal packing effects or nonequivalent molecules in the unit cell are present (1). For **1**, neither of these complicating phenomena is present in the crystal structure and one thus expects to see 10 distinct resonances in the ^{13}C CPMAS spectrum. The experimental ^{13}C CPMAS spectrum is shown in Fig. 3 and there are indeed 10 clearly resolved lines with the expected relative intensities based on the X-ray crystallographic structure.

(c) Ab initio *calculations: agreement between theory and experiment*

It has been demonstrated (10) that calculated ^{13}C shieldings are very sensitive to C—H bond lengths, i.e., a decrease of 2 ppm per 0.01 Å increase in the length of the C—H bond for the CH_4 molecule. Accordingly, the X-ray derived C—H bond lengths for **1** (Table 1), which show a range of 0.06 Å, are not of sufficient accuracy for use as input for the LORG calculations. The LORG calculations for **1** were carried out using the X-ray data only for the C and O atoms and plausible proton positions were determined via geometry optimization using the MOPAC (11) routine.

It is known (12) that the MNDO Hamiltonian produces C—H bond lengths that are within 0.014 Å of experimental values and bond angles which are within 2.8° of experiment. We assume that the present optimized H positions for **1** are within these approximate ranges of true experimental values. To test the variation of LORG calculated ^{13}C shifts as a function of C—H bond length at the D95V basis set, ethane has been examined. The results in Table 6 indicate a variance of only 1.37 ppm when all six C—H bonds are shortened by 0.01 Å. For the shortening of a single C—H bond, the isotropic ^{13}C shift changes by only 0.38 ppm at the bonded carbon and 0.08 ppm at the neighbouring site. Hence it appears that the use of plausible proton positions will not compromise the overall validity of the calculated ^{13}C shieldings for **1**.

(i) Aromatic carbons

The LORG calculations for **1** indicate, for the carbons bearing oxygen, that C2 should be deshielded relative to C1 by 2.9 ppm (i.e., 152.9 vs. 150.0). The observed difference between these sites is 2.3 ppm (151.0 vs. 148.7), in excellent agreement with the theory. The X-ray data indicate that the torsional angle for the C7—O2—C2—C3 network is 170.3°, while that for the corresponding C10—O1—C1—C6 network is 79.9°. As a result of the C7—O2—C2—C3 geometry, one of the lone pairs of electrons on O2 occupies an orbital that is nearly perpendicular to the plane of the aromatic ring. This geometry is optimal for conjugative electron release by oxygen. Hence C2 is expected to be deshielded relative to C1 because of the enhanced double-bond character of the O2—C2 bond relative to the O1—C1 bond.

The LORG calculations predict, for the nonoxygenated aromatic carbons, a range of shifts of 11 ppm (i.e., 126.9–

137.9 ppm). The observed range in solid **1** is 8.2 ppm (i.e., 119.0–127.2). Since our calculations are for an isolated molecule in the gas phase and the size of the molecule limits our basis set representation, we regard this agreement with experimental solid phase ^{13}C shift data as satisfactory. It is interesting to note that the theoretical calculations have C3 being shielded relative to its counterpart C6, and C5 being shielded relative to C4. Such results are consistent with more effective conjugative electron release from the lone pairs on O2 vs. O1. Thus enhanced partial negative charge is built up at C3 over C6 and at C5 over C4. This resonance model for the stereochemical dependence of the *ortho* ^{13}C shielding effect in oxygenated aromatic systems is consistent with recent anisotropic ^{13}C shift tensor results for 1,4-dimethoxybenzene (13).

with both π and σ charge densities as well as mobile bond order terms (14), so that, of course, caution must be exercised when using any electron density argument to rationalize ^{13}C shieldings.

(ii) Aliphatic carbons

With respect to the four crown ether carbons, the range of shifts calculated spans 8.2 ppm (i.e., 61.9–70.1) while that observed is 7.9 ppm (68.2–76.1). The calculations predict that C8 and C9, being most remote from the aromatic ring, will have a negligible shift difference. In contrast, a difference of 8.2 ppm is calculated for C7 vs. C10, with C7 the more shielded of this pair. Experimentally, C8 and C9 are separated by 2.5 ppm, while C7 and C10 differ by 7.9 ppm. The dipolar dephased ^{13}C CPMAS spectrum (Fig. 4*b*) of **1**, which has been selectively deuterated at C7,10, shows only carbons bearing no protons. Hence the appearance of lines at 68.5 and 76.2 ppm confirms these as arising from C7 and C10. No experimental method is presently available, however, to distinguish between C7 and C10 resonances.

It remains to isolate the origin of the substantial shielding differences between C7 and C10. Anisole represents a convenient model for examining the effects of aryl-O—C geometry on the aliphatic carbon ^{13}C shielding. In Fig. 5 the calculated total shielding for the methyl group of anisole is depicted as a function of the CH_3—O—C—C torsional angle. For a torsional angle of 79.9°, i.e., the same as that for C10—O1—C1—C6 of **1**, the total shielding is calculated to be 136.8 ppm. In contrast, for a torsional angle of 170.3°, i.e., the same as that for C7—O2—C2—C3 of **1**, the total shielding is calculated to be 143.0 ppm. Thus using anisole as a model for the LORG calculations, the prediction is that C7 of **1** will be more shielded than C10 of **1** by 6.2 ppm. The present calculations for anisole are in good agreement with results reported earlier (13), in which the isotropic ^{13}C chemical shift of a perpendicular CH_3 of anisole was calculated to be 7 ppm downfield from the case of a planar CH_3 group. The LORG calculations on **1** itself predict that C7 will be shielded by 8.2 ppm relative to C10, in substantially better agreement with the experimental difference of 7.9 ppm.

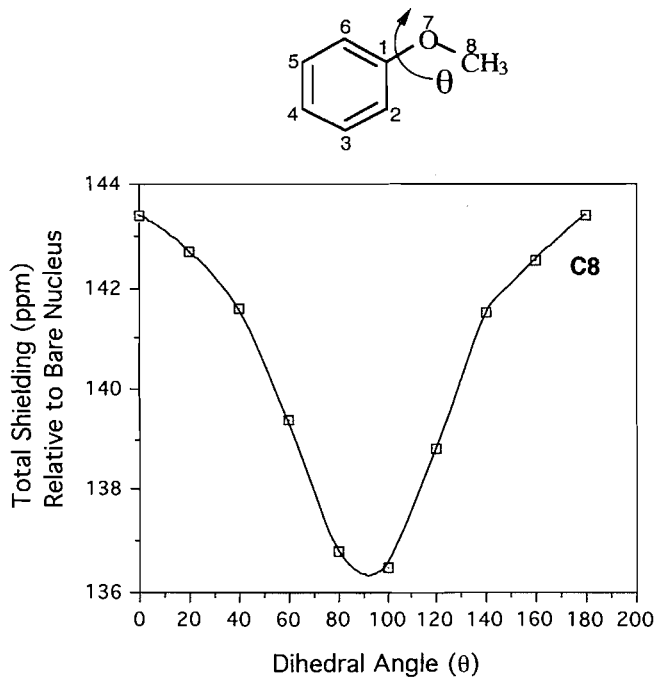

FIG. 5. LORG calculation of angular dependence of total ^{13}C shielding for the methyl group of anisole.

Conclusions

This work illustrates that satisfactory agreement between *ab initio* LORG calculated ^{13}C NMR chemical shifts at a D95V basis set level and solid phase experimental results is possible for medium molecular weight materials, provided that X-ray data for the solids are available. With more powerful computing capabilities becoming available, one can anticipate extension of studies of this nature to molecules of increasing complexity.

Experimental

Materials

The syntheses of **1** and its 7,10-d_4 analog have been described elsewhere (15).

Spectra

The solid phase ^{13}C NMR spectrum of **1** was recorded on a Bruker CXP-180 spectrometer at 45.3 MHz under conditions described previously (3). The dipolar dephasing experiments were carried out with a delay of 40 μs.

Solution NMR spectra were obtained using a Bruker AMX 400 spectrometer. The ^1H spectra were obtained at 400.14 MHz using sweep widths of 4 kHz and 32 K data points. Pulse angles were 45° with a recycle time of 1 s. The ^{13}C spectra were obtained at 100.62 MHz under conditions of complete ^1H noise decoupling. Sweep width was normally 10 kHz with 32 K data points employed. Pulse angles were 30° with an acquisition time of 1.6 s and a pulse delay of 1 s. Samples for both ^1H and ^{13}C NMR were contained in 5-mm tubes at a concentration of 0.1 M in $CDCl_3$ solution.

Crystallographic measurements and structure solution and refinement

A single crystal of **1** was hand-picked, mounted on a glass capillary, and measured on a Rigaku diffractometer. Accurate cell parameters and intensity data were obtained at room temperature using graphite-monochromated MoKα radiation. Crystal data are provided in Table 4. The space group *Pcab* was uniquely defined based on systematic absences and the data were corrected in the usual fashion for Lorentz and polarization effects (16). The structure was solved using direct methods. All atoms were refined anisotropically except hydrogens, which were calculated. Weights based on counting statistics were used and all calculations were performed using the NRCVAX crystallographic software package (17). Bond lengths and angles are presented in Table 1, while torsional angles involving ring skeletal atoms are given in Table 2. Details of the crystallographic data are presented in Table 4 and refined coordinates for C and O atoms are listed in Table 5. Available as Supplementary Material are structure factor tables and tables of anisotropic temperature factors, all torsional angles, and H atomic parameters.[3]

Computations

Calculations were done at SIUE using the experimental geometry for **1** obtained by X-ray analysis for the heavy atoms and MOPAC (11) optimized positions for the H atoms. A Silicon Graphics 4D/310S computer was employed for all calculations with shielding constants calculated using the RPAC molecular properties program (18). Molecular wavefunctions used in the RPAC program were calculated using the Gaussian 90 (19) set of programs.

Computed shift values for **1** were obtained by calculating shielding constants for the atoms in **1** and finding the difference between these and the carbon of TMS (198.62 ppm from the bare nucleus). The D95V basis set (20) was used to calculate the molecular wavefunction of **1** and the D95V coefficients and exponents were used to represent the carbon and hydrogen atoms in the TMS calculation. The silicon atom of TMS, however, was represented with D95 coefficients and exponents since the D95V basis set does not represent the silicon atom. The geometry used for the TMS calculation was determined from the MOPAC (11) geometry optimization routine. It should be noted that the TMS value calculated herein differs from the accepted value of 186.0 ppm calculated previously (21, 22).

For anisole, the shielding constants were obtained from D95V basis set utilization with geometries also obtained from MOPAC (11). Bond lengths and bond angles were optimized at each dihedral angle for which shielding constants were calculated. The NOSORT localization scheme was used in the RPAC (17) program for the calculation of shielding constants in **1**, anisole, and TMS.

Hammett ρσ correlation for reactions of lactoperoxidase compound II with phenols

HONGCHANG ZHANG AND H. BRIAN DUNFORD[1]
Department of Chemistry, University of Alberta, Edmonton, AB T6G 2G2, Canada

Received August 31, 1992[2]

HONGCHANG ZHANG and H. BRIAN DUNFORD. Can. J. Chem. **71**, 1990 (1993).

A stopped-flow kinetic study shows that the reaction rates of lactoperoxidase compound II with substituted phenols are greatly dependent upon the substituent on the benzene ring. Of the 15 phenols studied, it has been possible to relate the reaction rate constants with the ionization constants of 11 phenols by a linear Hammett free-energy relationship: (log $(k_X/k_H) = \rho\sigma$) at pH 7.0 and 25.0°C. The 11 *m*-and *p*-substituted phenols yield a ρ value of -2.7 ± 0.2. The data do not correlate with σ^+ values using the Brown–Okamoto equation. These results can be explained by a mechanism in which the substrate simultaneously gives an electron and a proton to lactoperoxidase compound II, and they indicate that the active site is accessible to substrate. To explain the abnormal behavior of the four phenols that do not fit the Hammett plot we used Hansch hydrophobic factors π for all of the substituents. The resultant best-fit equation: log $(k_X/k_H) = \rho\sigma + r\pi + c$ yielded the values $\rho = -2.1 \pm 0.5$, $r = 0.4 \pm 0.1$, and $c = -0.2 \pm 0.1$. The rates of reduction of lactoperoxidase compound II by *p*-iodophenol have been studied from pH 6.5 to 11.2. The kinetics are influenced by an acid group of pK_E 9.5 in the active site of lactoperoxidase compound II and by the ionization of the substrate (pK_S 9.0). The acidic form of lactoperoxidase compound II and the electrically neutral, unionized form of phenol are the reactive species. A reanalysis of data on reactions of horseradish peroxidase compounds I and II with substituted phenols using more recent σ values yielded Hammett ρ values of -5.5 ± 0.3 and -4.5 ± 0.2.

HONGCHANG ZHANG et H. BRIAN DUNFORD. Can. J. Chem. **71**, 1990 (1993).

Une étude cinétique par flux stoppé montre que les vitesses de réaction du composé II de la lactoperoxydase avec les phénols substitués dépend beaucoup du substituant présent sur le noyau benzénique. Des 15 phénols étudiés, il a été possible d'établir une corrélation linéaire d'énergie libre de Hammett entre la vitesse de réaction et les constantes d'ionisation de 11 phénols : (log $(k_X/k_H) = \sigma\rho$) à un pH = 7,0 et à 25,0°C. La valeur de ρ pour les 11 phénols *m*- et *p*-substitués est égale à $-2,7 \pm 0,2$. Il n'existe pas de corrélation entre les données et les valeurs de σ^+ de l'équation de Brown–Okamoto. Ces résultats peuvent être expliqués par un mécanisme dans lequel le substrat donne simultanément un électron et un proton au composé II de la lactoperoxydase et ils indiquent que le site actif est accessible au substrat. Afin d'expliquer le comportement anormal des quatre phénols qui ne donnent pas de corrélation de Hammett, on a fait appel aux facteurs hydrophobes π de Hansch pour tous les substituants. L'équation résultante qui fournit la meilleure corrélation, $\log(k_X/k_H) = \rho\sigma + r\chi + c$, conduit à des valeurs de $\rho = -2,1 \pm 0,5$, $r = 0,4 \pm 0,1$ et $c = -0,2 \pm 0,1$. On a étudié les vitesses de réduction du composé II de la lactoperoxydase par le *p*-iodophénol à des pH allant de 6,5 à 11,2. Les vitesses sont influencés par un groupe acide de pK_E 9,5 dans le site actif du composé II de la lactoperoxydase et par l'ionisation du substrat (pK_S 9,0). Les espèces réactives sont la forme acide du composé II de la lactoperoxydase et la forme non ionisée et électriquement neutre du phénol. Une nouvelle analyse des données relatives aux réactions des composés I et II de la peroxydase du raifort avec les phénols substitués faisant appel à des valeurs plus récentes de σ conduit à des valeurs respectives de ρ de Hammett de $-5,5 \pm 0,3$ et $-4,5 \pm 0,2$.

[Traduit par la rédaction]

Introduction

The reactions of phenols (and other organic substrates) with lactoperoxidase may be summarized as follows (1–3):

[1] $\text{LPO} + \text{H}_2\text{O}_2 \rightarrow \text{LPO-I} + \text{H}_2\text{O}$

[2] $\text{LPO-I} + \text{AH}_2 \rightarrow \text{LPO-II} + \cdot\text{AH}$

[3] $\text{LPO-II} + \text{AH}_2 \rightarrow \text{LPO} + \cdot\text{AH}$

[4] $2 \cdot \text{AH} \rightarrow \text{A}_2\text{H}_2 \text{ or } \text{A} + \text{AH}_2$

where lactoperoxidase and its two oxidized intermediates, compounds I and II, are represented by LPO, LPO-I, and LPO-II, the phenols by AH_2, and their free radical product by $\cdot$AH. Because of their ability either to scavenge free radicals or to react directly with oxidant (4), phenols are widely used as antioxidants. An example of physiological significance is the fat-soluble α-tocopherol (Vitamin E) (5). *p*-Methoxyphenol exhibits action against malignant melanomas (6). It has been suggested that peroxidases could be used commercially to remove phenol contaminants from water supplies (7–9).

In this study, 15 phenols are reacted with LPO-II to gain information on the mechanism of their reactions and to determine whether there is any linear free-energy correlation in their relative reactivities. In one case the pH–rate profile is obtained.

Materials and methods

Lactoperoxidase (EC 1.11.1.7, donor-H_2O_2 oxidoreductase) was purchased from Sigma. The RZ (A_{412}/A_{280}) of the sample used in experiments was 0.70–0.85 and its concentration was determined by using a molar absorptivity of $1.12 \times 10^5\ \text{M}^{-1}\ \text{cm}^{-1}$ at 412 nm (10). LPO-II (λ_{max} 430 nm) (11) was obtained after mixing 2 μM LPO with 4 μM H_2O_2. It did not exhibit significant decay over a period of 6 min. Hydrogen peroxide was obtained as a 30% solution from Fisher; the concentrations of diluted stock solutions were determined by the peroxidase assay (12).

Solutions of all substrates were prepared each day by dissolving a weighed amount of the compound in an appropriate volume of water (deionized in a Milli-Q water purification system) to make fresh stock solutions of about 10 mM. The solutions were stored in bottles wrapped in aluminum foil and placed in ice to prevent photochemical reactions. The substrate solutions for each experiment were then made by diluting portions of the stock solution to

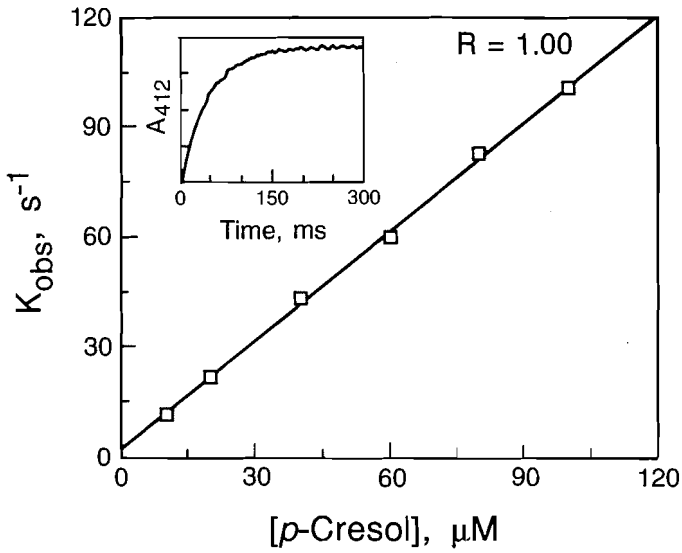

FIG. 1. Linear plot of pseudo-first-order constant versus [*p*-cresol] for the reaction between LPO-II and *p*-cresol. pH 7.0; ionic strength 0.11 M; temperature 25.0°C; [LPO-II] 1.0 μM. The inset shows an example of a first-order exponential trace (20 μM *p*-cresol) from which k_{obs} was obtained.

give a desired range of concentrations, using phosphate buffer of pH 7.0 (0.025 M, ionic strength μ = 0.11). In the case of *p*-iodophenol, buffers in the range of pH 6.5–11.2 were used in the determination of the pH–rate profile. At least a 10-fold excess of substrate over the enzyme was always used so that the reaction occurred by a pseudo-first-order process. Stock buffer solutions used for both enzyme and substrate were made up to ionic strength μ = 0.11 M by adding sufficient KNO_3 to 0.025 M buffer. For solutions of pH 6.0–7.0, citrate–phosphate buffers were used. Phosphate buffers were used between pH 7.0 and 9.0, and carbonate buffers were used above pH 9.0.

Kinetic measurements were made on a Photal (formerly Union Giken) stopped-flow spectrophotometer model RA-601. The 1-cm cells were thermostated at 25.0°C for all the experiments. One of the drive syringes of the stopped-flow spectrophotometer was filled with LPO-II solution, freshly prepared prior to the experiment, and the other syringe was filled with substrate. The reaction was then followed by monitoring the appearance of the native LPO at 412 nm. Each result quoted in this paper is an average of 10–20 experimental values.

Spectra of native LPO in the presence of each of the 15 phenols used in this study were examined in the Soret region and also in the region around 280 nm, where the aromatic amino acid residues absorb, in a search for indicators of possible different binding sites for different phenols.

Results

Pseudo-first-order traces were observed when the substrate concentration was 10 times larger, or more, than that of LPO-II. An example is shown in the inset to Fig. 1. The apparent second-order rate constant, k_{app}, was found to be related to the observed pseudo-first-order rate constant, k_{obs}, by the expression:

$$[5] \quad k_{obs} = k_{app}[S] + k_0$$

where [S] is the concentration of substrate. Thus k_{app} was determined from the slope of the plot of k_{obs} against substrate concentration. Figure 1 is an example, where k_{app} is 1.13×10^6 M^{-1} s^{-1}. The intercept k_0 is close to, but not equal to, zero in Fig. 1, which can be explained by the small autodecay of LPO-II (15). Second-order rate constants determined in this study for 15 *meta*- and (or) *para*-substituted phenols reacting with LPO-II at pH 7.0 are listed in Table 1 with corresponding literature values for Hammett σ (13), Brown–Okamoto σ^+ (14), and Hansch π (13) parameters.

Hammett plot

A Hammett plot (16) according to eq. [6]

$$[6] \quad \log (k_X/k_H) = \rho\sigma$$

is shown in Fig. 2. A rate constant, k_H, of 1.40×10^6 M^{-1} s^{-1} for unsubstituted phenol reacting with LPO-II is used as reference; k_X is the rate constant for the substituted phenol. The value of ρ, the Hammett reaction constant or susceptibility factor, is -2.7 ± 0.2, from the slope of the linear plot in Fig. 2. The electronic substituent constant σ depends on the nature and position of the substituent group. It can be seen that four of the phenols, labelled with asterisks in Table 1 and as open squares in Fig. 2, do not fit the plot. For these four phenols at least, something else, in addition to the electronic substituent effect, must also affect the reaction rate constant.

Possible role of a hydrophobic factor

By analyzing the data in Table 1, we found that not only electronic factors (σ constants) but also the hydrophobic properties (π constants) of the substituents appear to play a role in the activity of phenols. The reaction rate constants are increased by substituents that are electron donating or are hydrophobic, but they are decreased by substituents that are electron withdrawing or are hydrophilic. This is well illustrated in comparisons of phenol with *p*-hydroxybenzoic acid and *p*-hydroxybenzaldehyde with *p*-hydroxyphenol.

Quantitative analysis of structural effects was conducted for all 15 phenols by using an extended eq. [7], which covers both electronic and hydrophobic effects:

$$[7] \quad \log (k_X/k_H) = \rho\sigma + r\pi + c$$

In eq. [7], π is the Hansch hydrophobic parameter, r is its coefficient, and c is a constant. The term $\rho\sigma$ has the same meaning as in the Hammett relation.

Multiple linear regression of the experimental data yielded the following equation:

$$[8] \quad \log (k_X/k_H) = -(2.1 \pm 0.5)\sigma + (0.4 \pm 0.1)\pi - (0.2 \pm 0.1)$$

Figure 3, a logarithmic plot of the measured values of k_X/k_H against their calculated values from eq. [8], shows that the four phenols that do not fit the simple Hammett plot fit the extended equation better. The standard deviation of all points from the multiple linear regression analysis is 0.17.

Attempted Brown–Okamoto plot

An attempted plot according to the Brown–Okamoto equation (14):

$$[9] \quad \log (k_X/k_H) = Q\sigma^+$$

is shown in Fig. 4 for the eight phenols for which σ^+ values are available. Q is the reaction constant, which depends on the reaction and the conditions under which it occurs. It is obvious that there is not a linear correlation.

pH dependence

A log k_{app} versus pH plot is shown in Fig. 5 for the reaction of *p*-iodophenol with LPO-II. The reaction mechanism that is used to fit the experimental data is

$$\begin{array}{ccccc} & \text{HE-II} & + & \text{HS} & \xrightarrow{k} \text{products} \\ [10] & K_E \downarrow\uparrow H^+ & & K_S \downarrow\uparrow H^+ & \\ & \text{E-II} & & \text{S} & \end{array}$$

where HE is the protonated form of LPO-II and HS is unionized *p*-iodophenol. Equation [10] leads to:

$$[11] \quad k_{app} = \frac{k}{\left[1 + \frac{K_E}{[H^+]}\right]\left[1 + \frac{K_S}{[H^+]}\right]}$$

where k_{app} is the experimentally determined pH-dependent second-order rate constant and k is defined in eq. [10]. K_E and K_S are acid dissociation constants of LPO-II and substrate, respectively. A best fit to the experimental data was obtained using a nonlinear least-squares program in which k, K_E, and K_S are adjustable parameters. From the fit, $k = (1.9 \pm 0.2) \times 10^6\ M^{-1}\ s^{-1}$, $pK_E = 9.5 \pm 0.4$, and $pK_S = 9.0 \pm 0.3$, which are in agreement with reported values for pK_E of 9.7 (17) and pK_S of 9.3 (18). The best-fit line is shown in Fig. 5 as the solid line. If one simplifies eq. [11] by setting either equilibrium constant K equal to zero, and allows the nonlinear least-squares program to adjust the remaining single K to its best-fit value, a value of $pK_a = 8.9$ is obtained. The best-fit curve in this case is shown as a dashed line in Fig. 5, which is not a satisfactory fit.

Discussion

The Hammett plot in Fig. 2 shows a reasonable correlation of log (k_X/k_H) versus σ values of 11 phenols. Thus, for those 11 phenols, the electron-donating or -withdrawing effect of *meta* and *para*-substituents is sufficient to explain the relative reactivities. Electron-donating groups (negative σ values) enhance the reaction rate and the converse is also true. From Fig. 2, it can be seen that four points do not fit the Hammett plot. The observed values of k_X for *p*-Cl, *p*-I, and *m*-OC_2H_5 substituted phenols are 10 times greater and that for *p*-COO^- is 100 times less than those predicted by the linear correlation for the other substituted phenols. For those four phenols deviating from the Hammett plot for LPO-II,

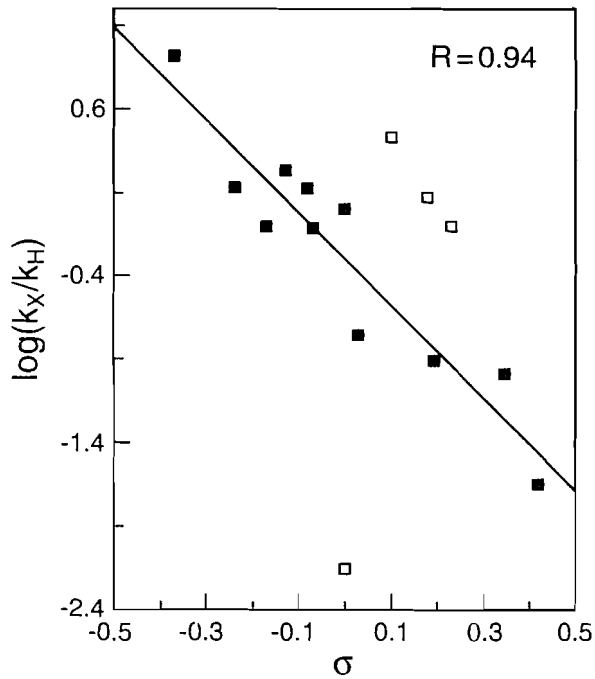

FIG. 2. Hammett plot for reactions of LPO-II with 15 phenols at 25°C, pH 7.0, and ionic strength 0.11 M. The slope yields $\rho = -2.7 \pm 0.2$ with a correlation coefficient, R, of 0.94 for the 11 phenols denoted by solid squares. The four phenols with large deviations, indicated by open squares, were not included in the linear least-squares analysis.

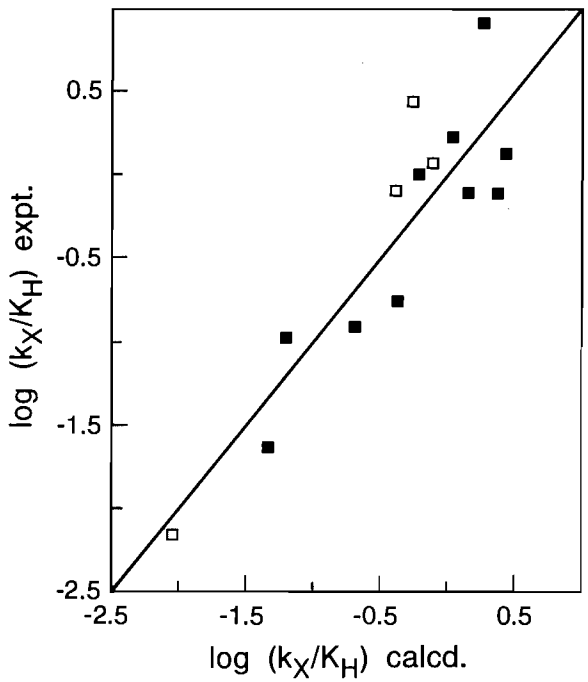

FIG. 3. Logarithmic plot of the experimentally measured values of k_X/k_H against the calculated values from eq. [8]. It can be seen that phenols denoted by open squares, which correspond to the open squares in Fig. 2, correlate better with the other phenols because of inclusion of hydrophobic factors for all phenols. The standard deviation of all 15 phenols from the multiple linear regression analysis of eq [8] is 0.17.

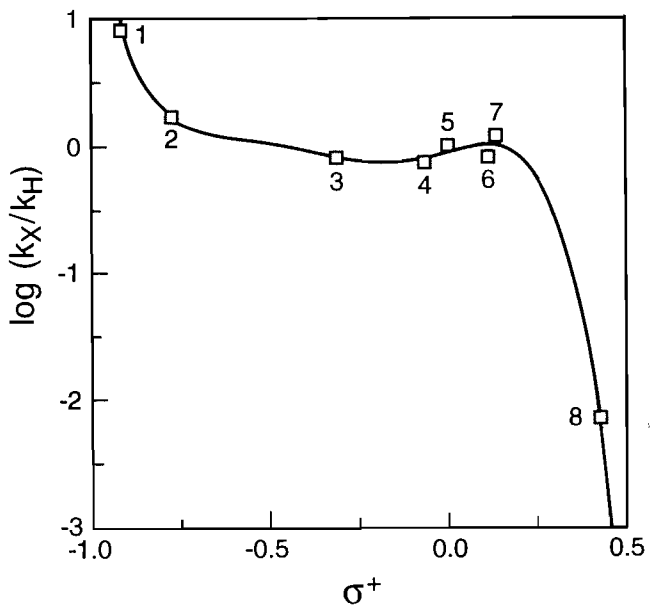

FIG. 4. Brown–Okamoto plot for the rate constants of LPO-II reduction by various substituted phenols at pH 7.0, ionic strength 0.11 M, and temperature 25°C. Substituent: (1) *p*-OH, (2) *p*-OCH_3, (3) *p*-CH_3, (4) *m*-CH_3, (5) H, (6) *p*-Cl, (7) *p*-I, (8) *p*-COO^-.

introduction of Hansch π parameters accounts for their anomalously high (or low) reactivities. *p*-COO^- is a strongly hydrophilic group; this will interfere with the accessibility of *p*-COO^- substituted phenol to the active site of LPO-II,

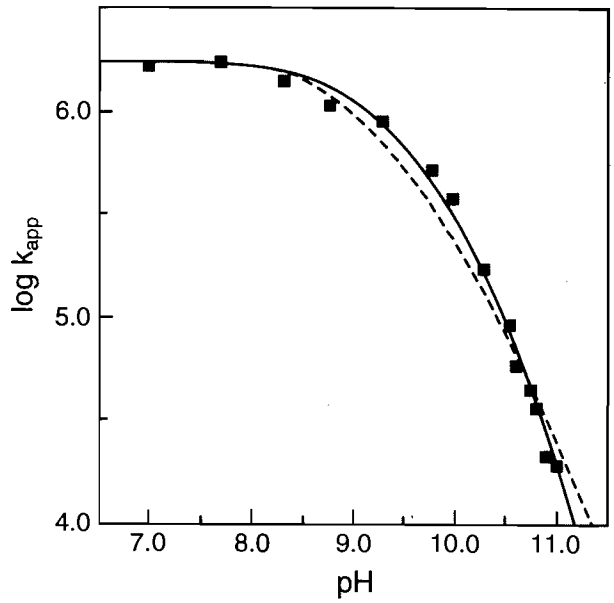

FIG. 5. pH–rate profile for the reaction of LPO-II with *p*-iodophenol at 25°C and ionic strength 0.11 M. Experimental (solid squares), best-fit curve with two *K*'s (solid line), best-fit curve with single *K* (dashed line). The fit is obviously better with the inclusion of two ionization constants.

so the reaction rate is slowed. However, *p*-Cl, *p*-I, and *m*-OC_2H_5 are hydrophobic groups that will promote binding to a hydrophobic region in the active site of LPO-II. Therefore their reaction rates are increased. There is no logical reason to apply Hansch π values selectively. No pattern of different spectral properties for the native enzyme–phenol complexes was observed for the four phenols that do not fit the simple Hammett equation. Therefore the extended equation including hydrophobic factors was applied to all the data.

We have reanalysed the data of Job and Dunford (19) for the reactions of HRP-I with phenols, using the σ values of Hansch and Leo (13), which were published three years after the original HRP-I publication. The result is a value of ρ of -5.5 ± 0.3 compared to the original value of -6.94. We regard the new value as more accurate. Because of their enhancement of luminescence of the HRP–luminol reaction (20), the reactions of three more phenols with HRP-I have been studied (21) and they are more reactive than predicted by the Hammett correlation. These are phenols with the substituents *p*-phenyl, *p*-I, and *p*-Cl, which all have high hydrophobic π values.

We have also reanalysed the data for the Hammett correlation of HRP-II–phenol reactivities. The originally published ρ value was -4.6 (22). Since then another study of HRP-II reactions with phenols has been completed (23), which is generally in agreement with the earlier data (22). An exception is the rate of reaction of *p*-Cl phenol and we have reason to believe the newer value is more accurate. Using only σ values of Hansch and Leo where possible, we obtain an identical ρ value of -4.5 ± 0.2 by inclusion of data for 20 of 23 phenols from refs. 22 and 23. Of the remaining three phenols, two are exceptionally unreactive phenols (*p*-NH_2 and *p*-COO^- substituents) and we note that they are hydrophilic. The other is more reactive (*m*-Cl substituent). The phenolic luminescence enhancers, with *p*-phenyl, *p*-I, and *p*-Cl substituents, are also more reactive with HRP-II than

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

predicted by the Hammett correlation (23). All four of the latter phenols are hydrophobic. Therefore the trend for both HRP-I and HRP-II reactions is the same as for LPO-II: most phenols fit a Hammett correlation well, and, for the few exceptions, strongly hydrophilic substituents retard the reaction and hydrophobic groups enhance it.

A recent study showed that the rate constants for phenols reacting with prostaglandin H synthase (PGHS) compound II also fit a Hammett plot, with $\rho = -2.0$ at 4°C (24). There were dual effects of phenols on the cyclooxygenase activity of PGHS, with small concentrations of phenols enhancing cyclooxygenase activity and large concentrations causing inhibition. Both electronic and hydrophobic effects are evident. Multiple linear regression analysis according to eq. [7] led to ρ values of -2.2 (stimulation) and -2.6 (inhibition) at 25°C (24).

The pH–rate profile for the reaction of LPO-II with *p*-iodophenol (Fig. 4) is not the same as that reported by Hodgson and Jones (20) for the reaction between the same substrate and horseradish peroxidase compound II (HRP-II), where the pH dependence of log k_{app} above pH 8.0 is linear with a slope of -1. In our case, with increasing pH, the plot of log k_{app} versus pH has a slope that changes from zero to increasingly negative values, as LPO-II and phenol each lose a proton. By inclusion of ionization constants for both LPO-II and phenol, the excellent fit shown by the solid line in Fig. 4 is obtained. If one postulates that only a single ionization is affecting the kinetics, the fit to the experimental data is not as good, as shown by the dashed line in Fig. 4. The data are entirely consistent with a protonated form of LPO-II reacting with the un-ionized *p*-iodophenol. The phenoxide ion appears to be unreactive (22).

Brewster et al. (25) used semiempirical molecular orbital methods to calculate several properties of substrate molecules and compared them with rates of reaction of HRP-II. They did not make a choice between a hydrogen atom versus an electron transfer mechanism. Sakurada et al. (23) showed that the HRP-II reaction rates with phenols correlate HOMO and LUMO energy levels well.

Our major conclusion, applicable to substrates such as phenols and aromatic amines (23, 26) that react via a normal peroxidatic cycle, native peroxidase → compound I → compound II → native peroxidase, is the following. The Hammett $\rho\sigma$ correlations, in themselves providing a rationale for the rates of most phenols and aromatic amines, indicate that these substrates react by hydrogen atom transfer: an electron and a proton are transferred simultaneously from the reducing substrate to the enzyme. Hydrophobicity (or hydrophilicity) can account, at least qualitatively, for most deviations from the Hammett correlations. The hydrogen atom transfer mechanism is in accord with the proton balance for conversions of compound I to II and compound II to native enzyme (27). The same mechanism explains the results obtained with enols. Schematic representations of the mechanisms for enols and phenols (28, 29) and aromatic amines (26) have been published, which show that the active sites of compounds I and II are accessible to substrate.

RENÉ ROY, FRANÇOIS D. TROPPER, ANTONY J. WILLIAMS, and JEAN-ROBERT BRISSON. Can. J. Chem. **71**, 1995 (1993).

^{13}C spin-lattice and spin–spin relaxation times and nuclear Overhauser enhancements have been used to examine the molecular dynamics of the α- (**1**) and β- (**2**) anomeric forms of poly(acrylamide-*co*-allyl 2-acetamido-2-deoxy-D-glucopyranoside) glycopolymers. The timescale of motions and the spatial restriction of these motions were determined by using various forms of the "model-free" approach. It is shown that the motions of the C—H vectors of the polymer backbone may be described by a scaled Lorentzian spectral density function, giving rise to an effective correlation time for overall tumbling. The temperature dependence of this correlation time suggests that the overall motion is dependent on viscosity. The overall motion of the polymer molecules is shown to be anisotropic in nature by including the spin–spin relaxation data in the analysis. The *N*-acetyl methyl and sugar hydroxymethyl (C_6) groups exhibit internal motions. The activation energies associated with these internal motions are derived. The difference in relaxation rates between the α and β anomeric forms, though small, suggests that the motions of the sugar ring may be different for the two systems. This conclusion is supported by potential energy contour map calculations, which indicate that the β anomer (**2**) has almost twice the conformational flexibility of the α anomer (**1**).

RENÉ ROY, FRANÇOIS D. TROPPER, ANTONY J. WILLIAMS et JEAN-ROBERT BRISSON. Can. J. Chem. **71**, 1995 (1993).

On a utilisé les temps de relaxation spin-réseau et spin–spin en RMN du ^{13}C ainsi que des expériences d'effets Overhauser nucléaires pour étudier la dynamique moléculaire des formes anomères α (**1**) et β (**2**) des glycopolymères poly(acrylamide-*co*-2-acetamido-2-désoxy-D-glucopyranoside d'allyle). On a déterminé l'ordre de grandeur des vitesses des mouvements et de la restriction spaciale de ces mouvements en faisant appel à diverses formes de l'approche ⟨⟨non-modèlisée⟩⟩. On a montré que l'on peut décrire les mouvement des vecteurs C—H de la structure de polymère par une fonction de Lorentz de densité spectrale qui donne lieu à une corrélation efficace du temps de renversement global. La relation entre la température et ce temps de corrélation suggère que le mouvement global dépend de la viscosité. En incluant les données de relaxation spin–spin dans l'analyse, on montre que le mouvement global de la molécule est naturellement anisotrope. Les groupes *N*-acétylméthyle et hydrométhyle (C_6) du sucre présentent des mouvements internes. On a déduit les énergies d'activation associées à ces mouvements internes. Les différences dans les vitesses de relaxation entre les formes anomères α et β, même si elles sont faibles, suggérent que les mouvements du cycle du sucre peuvent être différents pour les deux systèmes. Cette conclusion est en accord avec les calculs des cartes de contour de l'énergie potentielle qui indiquent que la flexibilité de l'anomère β (**2**) est deux fois plus grandes que celle de l'anomère α (**1**).

[Traduit par la rédaction]

Introduction

Water-soluble glycopolymers (1)[4] have attracted considerable interest since their first appearance (2), and have demonstrated a number of useful bio- and immuno-chemical properties (3). Glycopolymers containing sialic acid have recently been shown to be inhibitors of host cell adherences by human influenza viruses (4). They also constitute valuable tools as coating antigens in enzyme-linked immunosorbent assays (ELISA). In this technique, the water-soluble glycopolymers are adsorbed by hydrophobic interactions to the surface of the plastic (polyvinyl chloride or polystyrene) microtiter plates. The carbohydrate portions of the polymers are then freely exposed to the aqueous surroundings and thus are accessible for bindings to antibodies and lectins.

In ongoing research (1, 5), directed at studies of molecular recognition between multivalent carbohydrates and lectins as models in cellular interactions, we have demonstrated the relative binding of pairs of anomers of *N*-acetylglucosaminides towards wheat germ agglutinin.[5] This lectin has been well characterized by X-ray data and binding experiments using serological methods (6). Wheat germ agglutinin is a dimeric, carbohydrate-free protein composed of two identical subunits and presenting primary and secondary binding sites, each of which possesses three subsites. Our glycopolymers were designed to provide directed access to the inner and (or) outer subsites by carefully controlling the length of the spacer arms between the carbohydrate ligands and the polymer backbone. In these studies, we observed that the α anomer of the poly(acrylamide-*co*-allyl 2-acetamido-2-deoxy-α-D-glucopyranoside) (**1**) showed higher binding properties (higher affinities) than its homologous β anomer

[4]The term "glycopolymer" is introduced here. It is suggested as a replacement for "pseudopolysaccharide" inadequately utilised previously. The term has been chosen in analogy to glycoproteins and glycolipids. In the present context, it is used to indicate water-soluble polymers bearing covalently bound carbohydrate. However, the new term should be equally well applicable to insoluble polymers such as those used in affinity chromatography.

(**2**) (see Fig. 1). This behaviour is seemingly contradictory to what one might anticipate on the basis of overall carbohydrate mobility and accessibility within the glycopolymers, even for an outer binding subsite. To probe and, hopefully, to correlate the physical properties of these glycopolymers with their ligand properties, we have examined their motional properties by ^{13}C NMR relaxation measurements and examined their conformational flexibilities by potential energy calculations using MM2 computations taking *exo*-anomeric effects into consideration.

Experimental

Preparation of compounds

Materials and methods

All reagents were obtained from Aldrich. Solvents were obtained from various sources but were all of reagent grade, and used without further purification. Polymers were dialysed using cellulose tubing (obtained from Sigma) having a molecular weight cutoff of 12 kDa. Lyophilizations were performed using a Virtis model 24 freeze dryer. Polymer molecular weight estimations were measured on a Waters HPLC model 625LC equipped with a Waters 991 diode array detector using a TSK G4000 SWXL column (7.5 mm × 30 cm). A phosphate buffer (0.1 M, pH 7.0) was used as eluant at a flow rate of 1 mL/min. Poly(acrylic acid) with molecular weights of 50, 90, 150, and 200 kDa with M_n/M_w of 7 ± 3 were used as standards (Polyscience Inc., Warrington, Pa.) after transformation into polyacrylamide using usual carbodiimide (EDC) activation and quenching with ammonia.

Preparation of allyl 2-acetamido-2-deoxy-D-glucopyranosides

Allyl 2-acetamido-2-deoxy-D-glucopyranosides in both the α and β anomeric configurations were prepared according to previously published procedures (7) with only slight modifications (2c). All physical data were in good agreement.

Copolymer preparation

*(i) Poly(acrylamide-*co*-allyl 2-acetamido-2-deoxy-α-D-glucopyranoside), **1**:* 0.50 g (7.03 mmol) of acrylamide, 1.00 g (3.83 mmol) of allyl 2-acetamido-2-deoxy-α-D-glucopyranoside, and 10 mg (0.4 mol%) of ammonium persulfate ($(NH_4)_2S_2O_8$) were boiled in 10 mL of deoxygenated water for 10 min under a nitrogen atmosphere. The viscous solution was allowed to cool to room temperature after which it was exhaustively dialysed against distilled water. Lyophilization of this solution gave 1.00 g of a white, spongy solid. The incorporated monomer ratio was determined as 1:5.1 glycoside to acrylamide units by ^1H NMR. Elemental analysis gave C 45.41, H 6.98, N 12.38, corresponding to a monomer incorporation ratio of 1:5.3 with a retained water content of 10.3% by weight.[6]

[6]The monomer incorporations calculated by elemental analysis should be established using $(C_3H_5NO)_x(C_{11}H_{19}NO_6)_y(H_2O)_n$ as the general structure of the copolymer obtained after freeze-drying since polyacrylamides are known to strongly retain some water of hydration. By setting up three equations for percent C, H, and N in addition to $x + y + n = 1$, four simultaneous equations with three unknowns can be solved and verified algebraically:

$$\%\ \text{Element} = \frac{\text{am}_{\text{element}} \times \sum_{x,y,n} E_{\text{mu}} \times M_{\text{mu}}}{\text{Mol. Wt. of the average repeating unit}}$$

where

$\text{am}_{\text{element}}$ = atomic mass of the element

E_{mu} = number of elements per monomer unit

M_{mu} = molar fraction of each monomer unit (x,y,n)

(For example, for % C: $\%C = 12.0115\,(3x + 11y)/(71.0794x + 261.2772y + 18.0152n)$). Note that this method has the distinct advantage that the water content (variable from batch to batch) in the polymers can be calculated and taken into consideration during serological studies.

*(ii) Poly(acrylamide-*co*-allyl 2-acetamido-2-deoxy-β-D-glucopyranoside), **2**:* 0.78 g (2.99 mol) of allyl 2-acetamido-2-deoxy-β-D-glucopyranoside, 0.39 g (5.49 mmol) of acrylamide, and 8 mg (0.4 mol%) of ammonium persulfate were boiled in 8 mL of deoxygenated water under a nitrogen atmosphere for 12 min. The polymer was processed as above and 0.54 g of material was obtained. The incorporated monomer ratio was determined as 1:5.0 by ^1H NMR.

NMR spectroscopy

Polymer characterization

Proton NMR spectra were obtained at 300 MHz using a Varian XL-300 spectrometer. Monomer incorporations in the glycopolymers were determined by comparison of the integrations of the glycoside resonances (2.3–4.5 ppm; 9H) to the backbone methylene and methine resonances (1.0–2.6 ppm; 3H) after correction for the *N*-acetyl methyl resonance at 2.0 ppm (3H).

^{13}C NMR measurements

All spectra were obtained on solutions of the appropriate polymer dissolved in D_2O (50 mg/mL) allowing measurements to be made under conditions of internal lock. The samples were contained in sealed 5-mm NMR tubes and were degassed using a number of freeze–thaw cycles to remove dissolved oxygen and other gases.

^{13}C NMR spectra were obtained at four different magnetic field strengths corresponding to resonance frequencies of 50.29, 75.43, 100.62, and 125.73 MHz. The spectrometer systems used were a Varian Gemini-200, Varian XL-300, Bruker AM-400, and Bruker AM-500, respectively. Averaging of >2000 scans gave a good signal-to-noise ratio at all fields.

T_1 relaxation times were determined at each of these fields using the fast inversion–recovery technique (8) (FIRFT) with a pulse repetition time of $>3T_1$, where T_1 was the estimated value for the methyl group. A suitable number of dummy scans were used to generate a steady-state magnetization. Between 12 and 15 τ-values were generally used to characterize the relaxation decay, and the intensities of the peaks were fitted to a three-parameter exponential function using spectrometer system software. T_1's of all resolved protonated carbons were measured simultaneously using a selection of carefully chosen τ-values to characterize each of the different relaxation rates. All relaxation rates measured were accurate to better than 5% at each magnetic field.

Nuclear Overhauser enhancements (nOe's) were determined at 75.43 and 100.62 MHz using a direct comparison of gated decoupled and fully decoupled spectra. A relaxation delay of 10 times the T_1 of the methyl group was used between scans and a 90° pulse was used prior to acquisition of the spectrum. The individual spectra were acquired in blocks of eight scans to average out possible temperature inhomogeneities during the experiment.

Spin–spin relaxation times were obtained at 30°C at a resonance frequency of 75.43 MHz by measurement of the half-height linewidth rather than the spin-echo determination and using an inhomogeneity contribution of 1 Hz (based on the natural line width of a reference sample of acetone). Due to the number of types of backbone methylene and methine resonances, linewidths were only determined for the sugar resonances (C_1–C_6) and for the *N*-acetyl methyl group.

The experimental temperature was determined at each magnetic field, under decoupling conditions to correct for decoupler heating effects, using a calibrated copper–constantan thermocouple. The uncertainty in temperature is estimated to be ±1°C. Heating effects due to decoupling were partly circumvented by using the WALTZ composite decoupling mode.

Viscosity measurements

Temperature dependence of viscosity

Viscosities were measured as a function of temperature over the range 20–60°C using an Ostwald viscometer. The viscometer was suspended in a thermostated water bath that controlled the temper-

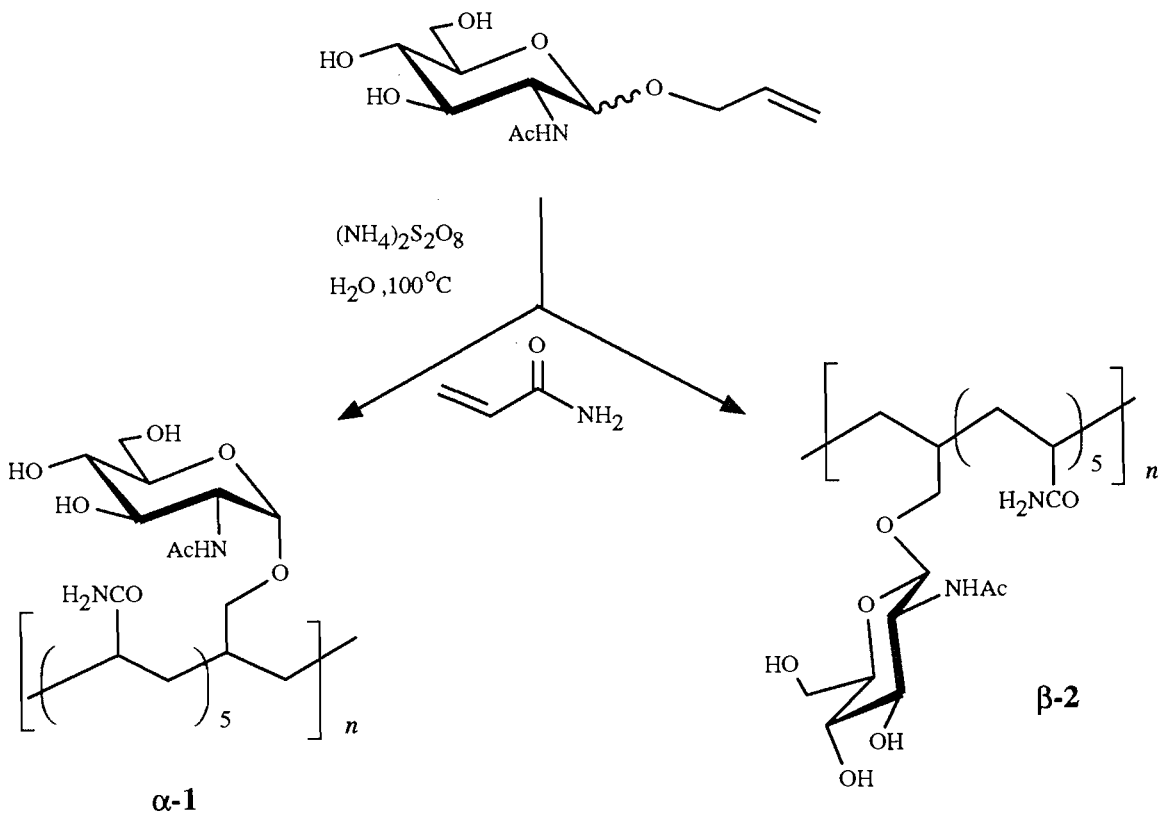

FIG. 1. Polymerization of allyl 2-acetamido-2-deoxy-α/β-D-glucopyranoside to give the α- (**1**) and β- (**2**) poly(acrylamide-*co*-allyl 2-acetamido-2-deoxy-D-glucopyranosides).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

ature to ±0.2°C. The temperature of the bath was measured with an electronic thermometer using a Cr–Al thermocouple. Distilled water was used as the calibrating liquid. Flow times were measured twice, to within ±0.1 s, for each liquid and at each temperature. The densities of both the water and the polymer solution were identical within experimental error.

Molecular weight determination of polymer by viscosity measurements and HPLC

The viscosity average molecular weight of the α-glycopolymer was calculated from the measured intrinsic and specific viscosities in H_2O at 25.0°C as described by Flory (9). Flow times, relative to water, for 10.0-mL samples were measured using the equipment described above for seven twofold dilutions of a stock polymer solution originally prepared by dissolving 332.0 mg of lyophilized polymer (containing 10.3% of H_2O by weight) in 20.0 mL of H_2O. Extrapolation to infinite dilution gave values of 40.3 and 40.4 for intrinsic and specific viscosities (correlation coefficients >0.995). The viscosity is related to the Mark–Houinik expression (9, 10) $\eta = KM^a$. Assuming similar behavior for the glycopolymer **1** and simple polyacrylamide in a "good" solvent such as water, values of 5.6×10^{-3} and 0.80 were used for K and **a**, respectively, as suggested by Molyneux (10). This method gave a molecular weight average of 66.4 kDa for the glycopolymer.

Relative mobility through agarose gel gave an average molecular weight of 50–80 kDa (1). The glycopolymers **1** and **2** had retention times between 7 and 12 min, centred at 10.0 min in gel permeation chromatography over a TSK G4000 SWXL column relative to polyacrylamide with 50 kDa as molecular weight centred at 11.2 min on the same column. The 90 kDa polyacrylamide had a retention time of 8.4 min, thus confirming the above viscometry measurements and justifying the **a** and K values used for the Mark–Houinik equation.

Using the calculated intrinsic viscosity, the partial specific volume of the polymer in solution was calculated to be 16.1 $cm^3\ g^{-1}$. Therefore, the volume occupied by an average polymer molecule in a random-coil arrangement is 1.57×10^{-24} m^3.

Molecular mechanics calculations

The starting geometry of the backbone repeating unit around the carbohydrate portion was built using ALCHEMY (Tripos Associates, Inc.). It was then submitted to a complete refinement of bond lengths and valence and torsion angles through MM2(87) computations (QCPE). The coordinates for the glucosaminide units were obtained from MM2(87) minimizations of the crystal structures (11, 12).

The conformational analyses for the α (**1**) and β (**2**) glycopolymers were performed using the Potential for Oligosaccharides (PFOS) approach, which included the partitioned contributions arising from van der Waals interactions, and torsional and *exo*-anomeric potentials (13). Rotational barriers of 1.0 and 0.5 kcal/mol were used for φ and ψ, respectively. No electrostatic contributions were considered. The pyranose ring geometry was treated as invariant, and hydroxylic hydrogen atoms were not taken into account. The angles for the glycosidic bond were defined as φ = (H1—C1—O1—C6′) and ψ = (C1—O1—C6′—C3′). The glycosidic bond angle C—O—C was set at 117°. Potential energy maps were generated for φ and ψ under the following conditions. For a setting of the torsional angles φ and ψ, the amide group was allowed to rotate over the whole angular range in increments of 20°. All other torsion angles were allowed to adopt staggered orientations of −60°, 180°, and 60°, except for the C1′—C2′—C3′—C4′—C5′ orientation, which was kept in the *trans* position. The glycosidic torsional angles φ and ψ were stepped in increments of 20° over the whole angular range and the minimum energy for each grid point upon rotation of all other torsional angles was plotted. This allowed the calculations to simulate a flexible structure where all pendant groups can adopt minimum energy conformations. Calculations were repeated for other staggered orientations of the

backbone C1′—C2′—C3′—C4′—C5′ and no expansion of the allowable conformational space for ϕ and ψ was observed. All calculations were performed on a Micro VAX 3500.

Theory

It is assumed that the ^{13}C nuclei examined here are relaxed solely by dipolar interactions with attached proton(s). The general expressions for T_1, T_2, and nOe are given by (14)

$$[1] \quad \frac{1}{T_1} = R_1 = \frac{N_i}{20}\left[\frac{\mu_0\gamma_H\gamma_C h}{8\pi^2 r_{C-H}^3}\right]^2 \times (J(\omega_H - \omega_C) + 3J(\omega_C) + 6J(\omega_H + \omega_C))$$

$$[2] \quad \frac{1}{T_2} = R_2 = \frac{N_i}{40}\left[\frac{\mu_0\gamma_H\gamma_C h}{8\pi^2 r_{C-H}^3}\right]^2 \times (4J(0) + J(\omega_H - \omega_C) + 3J(\omega_C) + 6J(\omega_H) + 6J(\omega_H + \omega_C))$$

$$[3] \quad \eta = \frac{1}{20}\gamma_H^3\gamma_C\left[\frac{\mu_0 h}{8\pi^2 r_{C-H}^3}\right]^2 (N_i T_{1i}) \times (6J(\omega_H + \omega_C) - J(\omega_H - \omega_C))$$

where T_1, T_2, and η are the spin-lattice and spin–spin relaxation times and nOe for a specific carbon in the molecule. μ_0 is the permeability of a vacuum, γ_H and γ_C represent the magnetogyric ratios of the proton and carbon nuclei respectively, and r_{C-H} denotes the C—H bond length (vide infra). The $J(\omega)$'s are spectral densities, N_i is the number of protons directly attached to carbon i, ω_H and ω_C are the Larmor frequencies of the protons and carbons at a given magnetic field, and all other constants have their usual meanings.

The motions of polymers are inherently complex and the interpretation of NMR measurements for such systems is often not unique. For polymers undergoing internal or segmental motions as well as overall reorientational motion, there are many motional processes, which may necessitate analyzing the data in terms of an empirical distribution of correlation times (15). Since analyses have proven useful for the analysis of relaxation data in recent years, a certain preference has been given to the utilization of the "model-free" approach of Lipari and Szabo (16) (equivalent in spectral density form to the "two-step" model suggested by Wennerstrom et al. (17)). A number of authors have applied this model-free approach to the molecular dynamics of a number of biologically related systems (18–21). In particular, and in relation to this work, the model has been adapted to examine both the internal and overall motions of a number of saccharides (22–24).

Lipari and Szabo (16) derived a simple form for the spectral density function for a nonrigid molecule undergoing overall and internal motions. For a ^{13}C–^1H vector attached to an isotropically reorienting molecule, the spectral density function is given by

$$[4] \quad J(\omega) = S^2\left[\frac{2\tau_c}{1 + \omega^2\tau_c^2}\right] + (1 - S^2)\left[\frac{2\tau}{1 + \omega^2\tau^2}\right]$$

where

$$[5] \quad 1/\tau = 1/\tau_c + 1/\tau_{eff}$$

Here, τ_c is the correlation time, which describes the overall isotropic motion of the whole molecule, S is a generalized order parameter, and τ_{eff} is an effective correlation time for reorientation of the ^{13}C–^1H vector being examined. This equation is valid if $\tau_c >> \tau_{eff}$ and only if the overall motion is isotropic. The order parameter S describes the spatial restriction of the internal motions and may vary between 1, when the motion at that carbon is completely restricted, and zero, the limit of completely unrestricted motion. When $S^2 = 1$, eq. [4] reduces to the rigid isotropic case ($J(\omega) = 2\tau_c/(1 + \omega^2\tau_c^2)$).

The effective correlation time τ_{eff} provides a limit for the timescale describing the internal motions and is defined as the area of the internal motion correlation function. This effective correlation time holds no specific value unless it is interpreted in the framework of an appropriate model.

Equation [4] assumes that the internal motions of the C—H vectors are independent of the overall motion of the molecule. If the internal motions are assumed to be within the extreme narrowing regime, then $\omega^2\tau^2 << 1$ and

$$[6] \quad J(\omega) = S^2\left[\frac{2\tau_c}{1 + \omega^2\tau_c^2}\right] + (1 - S^2)2\tau$$

If the internal motions are assumed to be *much* more rapid than the overall motion, then with $\tau << \tau_c$ we obtain

$$[7] \quad J(\omega) = S^2\left[\frac{2\tau_c}{1 + \omega^2\tau_c^2}\right]$$

The restriction of extreme narrowing to the internal motions is not required by the theory and may well be inapplicable, especially for the relaxation data obtained at the higher field strengths.

For the case where the overall motion cannot be described by a single isotropic correlation time, the anisotropic motional spectral density function is given by

$$[8] \quad J(\omega) = 2\left[\frac{AS^2\tau_1}{1 + (\omega\tau_1)^2}\right] + \left[\frac{(1 - A)S^2\tau_2}{1 + (\omega\tau_2)^2}\right] + \left[\frac{A(1 - S^2)\tau'}{1 + (\omega\tau')^2}\right] + \left[\frac{(1 - A)(1 - S^2)\tau''}{1 + (\omega\tau'')^2}\right]$$

where

$$[9] \quad (\tau')^{-1} = \tau_{eff}^{-1} + \tau_1^{-1}$$

$$[10] \quad (\tau'')^{-1} = \tau_{eff}^{-1} + \tau_2^{-1}$$

For a nucleus rigidly attached to an anisotropically reorienting backbone on a macromolecule, $S^2 = 1$ and eq. [8] simplifies to

$$[11] \quad J(\omega) = A\left[\frac{2\tau_1}{1 + \omega^2\tau_1^2}\right] + (1 - A)\left[\frac{2\tau_2}{1 + \omega^2\tau_2^2}\right]$$

When $\tau_1 = \tau_2$ or $A = 1$ then the spectral density for the rigid isotropic case is recovered.

Results and discussion

Assignments

The natural abundance ^{13}C NMR spectrum of both the α- and β-glycopolymers is dominated by backbone resonances due to the methine and methylene groups (see (Fig. 2). This range of chemical shifts for the backbone resonances is presumably due to the variety of substituted methines (R^1R^2CHX, X = $CONH_2$, CH_2OR) in combination with the

atactic nature of the polymer. Different head-to-head, head-to-tail, and tail-to-tail polymerization combinations might also play a role to some extent. The singlet to lowest frequency is due to the *N*-acetyl methyl group. The sugar methine and hydroxymethyl resonances are to low field of the bulk chain (between 50 and 100 ppm), and are assigned according to Roy et al. (25). A number of carbonyl resonances are also observed at ca. 180 ppm.

Qualitative analysis of relaxation parameters of the α-glycopolymer (1)

Spin-lattice relaxation times and nOe values were measured for all resolvable peaks. Table 1 gives the spin-lattice relaxation times (NT_1), obtained for the α-glycopolymer (**1**) as a function of temperature and magnetic field strength. The magnetization relaxation curves were all single exponential in nature for all fields. The relaxation times for the groups

For personal use only.

of resolvable methylene and methine groups within the backbone are all within error, and an average value for both types of carbon was thus used for further analysis. A similar approach was taken for analysis of the methine sugar resonances. No attempt was made to measure accurate values of the carbonyl T_1's due to the possible contributions of chemical shift anisotropy to the relaxation.

The T_1 data obtained show several interesting features. If the sugar ring (C_1–C_5) and attached hydroxymethyl group (C_6) were experiencing the same motions, then NT_1 should be identical. However, at each magnetic field $NT_1(CH_2OH) > NT_1$(sugar). This suggests that the hydroxymethyl group has added mobility over the sugar. This can be imagined to be the spinning of the -CH_2OH group, similar to the C_3 rotation of a methyl group about its axis, though probably more restricted. A similar observation for the relative NT_1's can be made for the polymer backbone methylene groups compared to the methine segments. In this case the methylene groups have slightly more mobility than the CH groups, as shown by a longer NT_1 value. Since the methylene and methine NT_1 values are averages of all possible configurations of these groups, it would be expected that the added freedom of the methylene group attached to the sugar moiety may increase NT_1 to such an extent that the average value may have a bias to the motions of the side-chain methylenes.

Quantitative analysis of relaxation parameters for the α-glycopolymer (1)

To calculate accurate correlation times from the relaxation data using any of the equations given above, an accurate value of the C—H bond length is required. Consultation of the literature shows that for alkyl chains the bond length used varies between 1.09 (26) and 1.11 Å (27). For the ring-carbon atoms in sucrose, the C—H bond length is 1.10 Å by neutron diffraction (28). However, the effective bond length is influenced by vibrational motions, and Brown and Levy (28) estimated a bond length of 1.11 Å from their neutron diffraction data. Using a correction suggested by Henry and Szabo (29) based on the combined effect of harmonic and anharmonic C—H stretching force constants, McCain and Markley (22) showed that the best estimate for the r_{C-H} bond length is 1.12 Å.

The overall contribution to the relaxation of the carbon nuclei will be from distant protons as well as directly attached protons. By using crystal structure data, and including all the hydrogen atoms in sucrose except those in the hydroxyl groups, McCain andl Markley (22) calculated an extra contribution to the relaxation of the ring-carbon atoms from distant protons. This added contribution, equivalent to an extra 5% C—H dipolar relaxation, can be estimated as an apparent r_{C-H} bond length of 1.11 Å. For internal consistency, this bond length has been adopted for all C—H bonds for the data analyses made in this work. Other values of r_{C-H} have been used to examine errors in the fits (vide infra).

Polyacrylamide is known to exist in solution as random-coil polymers (30). Lipari and Szabo (16) suggested that for polymers in such a random-coil conformation, the macromolecule would be expected to deviate from a sphere, and that the data for such systems should be analysed using the double-exponential correlation function given by eq. [8].

The information regarding the overall anisotropic motion of the polymer is extracted from the backbone carbons. Assuming the anisotropic form of the spectral density function (eq. [11]), the relaxation data for the different carbon atoms within the polymer backbone should be describable by a global parameter τ_1, and a pair of (A, τ_2) parameters corresponding to the methine and methylene carbons. The complete set of parameters that reproduces the data gives a global minimum in the error.

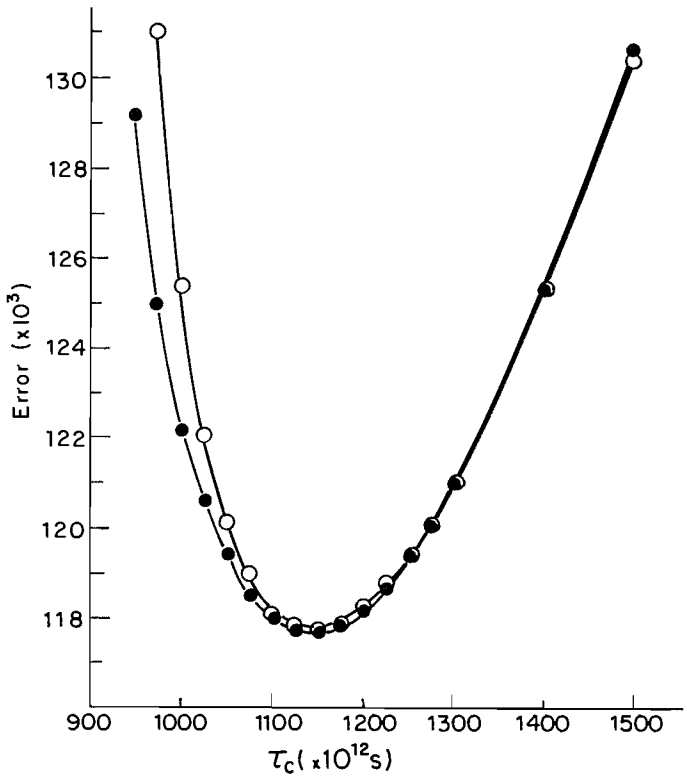

FIG. 3. The representation of the error minimization using the error function (see text) as a funcction of τ_1.

The approach taken here is to choose a value of τ_1 from the experimental ^{13}C R_1 values obtained at the different magnetic field strengths and calculate values of τ_2 and A using an iterative fit to the multifrequency relaxation data. Since the errors for the nOe data are larger than for the rate data, ±20% compared to ±5%, only the relaxation rate data were used to calculate the motional parameters. The values of τ_1, τ_2, and A that minimize the error function (26)

$$[12] \quad \text{error} = \frac{(R_{obs} - R_{calc})^2}{(R_{obs})^2}$$

are then chosen as the best values for the whole molecule. In this function R_{obs} and R_{calc} are the observed and calculated relaxation rates, respectively. Using these values as global constants allows τ_{eff} and S^2 values describing internal motions to be calculated for the remaining carbons in the molecule, i.e., for the sugar resonances (C_1–C_6) and the *N*-acetyl methyl.

Figure 3 illustrates the result of the minimization procedure obtained by fitting the multifrequency relaxation data for the polymer backbone methylene groups. Two curves are evident, corresponding to the minimized errors obtained using r_{C-H} bond lengths of 1.098 and 1.110 Å in the dipolar interaction constant. Note that for the narrow range of corre-

[b]See Table 1 for assignments.

lation times examined, there is only one minimum for the different values of r_{C-H} corresponding to τ_1 = 1.15 ± 0.02 ns. A similar fit to the methine relaxation data gives the same overall correlation time within error. It is obvious that the motions may be sufficiently described by the single correlation time τ_1 since the error in τ_2 makes the parameter meaningless. In this case eq. [11] may be reduced to the same functional form as eq. [7] with S^2 replaced by A.

The question remains as to whether this calculated correlation time of 1.15 ns is appropriate for the expected dimensions of the polymer as derived from the viscosity measurements. For a sphere rotating in a medium of viscosity η, the Debye theory (31) gives the following expression for τ_c:

$$[13] \quad \tau_c = fV\eta/kT$$

where V is the volume of a sphere (calculated earlier to be 1.57×10^{-24} m^3) (32) and f is the microviscosity factor. Assuming that the randomly coiled polymer molecules may be approximated as tumbling spheres (9, 10, 30), and using a typical value for the microviscosity factor (33) of 0.16, the correlation time for overall tumbling of a polymer sphere at 30°C, using the viscosity given in Table 2, is 1 μs. This correlation time is far outside the range that spin-lattice relaxation and nOe measurements can probe, and only spin–spin relaxation can provide confirmation of such a timescale of motion due to the presence of the zero-frequency spectral density component $J(0)$ in eq. [2]. However, due to the problem of many overlapping methylene and methine backbone resonances in the ^{13}C spectrum, attempts to correlate the spin–spin relaxation time, or its associated linewidth, with a correlation time of this magnitude is not possible.

Figure 4 illustrates the error function, eq. [12], as a function of τ_1 over a range up to and including 1 μs. It is obvious that at large values of τ_1 a plateau is reached where the error is almost equivalent to that obtained for the first minimum (error values; 0.1197 cf. 0.1177). At long τ_1, the values of τ_2 and A that are extracted become highly insensitive to the magnitude of τ_1; for example, with τ_1 = 200 ns, τ_2 = 1225 ps and A = 0.365, while for τ_1 = 2000 ns, τ_2 = 1254 ps and A = 0.359. Since τ_1 correlation times of this magnitude will have only a negligible effect on the spin-lattice relaxation times and nOe's, the contribution of this timescale of motion to spin-lattice relaxation may be ignored. Measurements of molecular motions of a timescale of 200–2000 ns would be possible via $T1\rho$. However, spectrometer limitations did not allow these determinations to be made as contributors to the relaxation. As a result, the overall motions may be described by a function of the form given in eq. [7], where S^2 is replaced by $(1 - A)$. Using this function returns us to the situation where the overall correlation time is 1.15 ns.

The spin-lattice relaxation times of the sugar ring carbons are identical within the experimental error limits, and it is correct to assume that the reorientational motion of the sugar fragment is isotropic. Table 3 lists the S^2 and τ_{eff} values obtained for the remainder of the molecule using eq. [4]. The values of the parameters are listed for an r_{C-H} bond length of 1.110 Å. It is obvious that, within error, an effective internal or "fast" correlation time cannot be extracted from the data obtained for the sugar ring carbons, while both the hydroxymethyl group and the *N*-acetyl methyl group have associated fast correlation times.

McCain and Markley (22, 23) examined the internal motions in sucrose while Kovacs et al. (24) probed the internal motions in sucrose and a disaccharide methyl 3-*O*-(α-D-rhamnopyranosyl)-α-D-glucopyranoside. Both groups of workers analysed the relaxation data of the sugar rings in terms of a "reduced" spectral density, equivalent in functional form to eq. [7], where the fast motions were assumed to be vibrations or torsional oscillations. The normal Lorentzian spectral density is premultiplied by a so-called "amplitude factor," equivalent to our S^2 parameter, which indicates the importance of vibrational motions to the relaxation. As the vibrational motions increase in importance, then the amplitude factor decreases.

For sucrose, amplitude factors of 0.89 and 0.94 have been obtained (22, 24). These values were in different solvent systems with different viscosities and H-bonding capabilities, and a slight change in the amplitude factor would be expected. The overall correlation time was also shown to be viscosity dependent by McCain and Markley (22, 23).

For our system, the S^2 parameter obtained can be thought of as being equivalent to the A parameter that is associated with the backbone motions since no internal motions can be

detected for the sugar. The value of A found for the sugar agrees, within error, with those values obtained for the backbone. This observation does not preclude the fact that librational motions may also be contributing to the relaxation of the ring, but rather than their contribution to the overall relaxation is small and this contribution is rendered undetectable, within error, by the added complication of anisotropic overall motion.

The hydroxymethyl group attached to the sugar has a smaller order parameter than the sugar ring, as well as an associated τ_{eff} correlation time (48 ± 22 ps). Rotation of the CH_2OH fragment relative to the ring would be expected to contribute to the relaxation, while librational motion of the ring itself, if it occurs, would be superimposed on this rotation.

McCain and Markley (23) attempted to detect the internal motions of the three hydroxymethyl groups in aqueous sucrose. Their studies failed to detect a rotational motion of the hydroxymethyl group, and again the relaxation of this group was expressed in terms of torsional librations and overall motion, the conclusion previously derived for the ring-carbon atoms (22). Their data showed that the motional amplitudes for the three hydroxymethyl groups of sucrose are similar and that none of them rotates freely, supporting the known existence of intramolecular hydrogen bonds within sucrose (23).

The internal motion of the -CH_2OH group detected in this work is indicative that the fragment may not be suffering intramolecular H-bonding as exists in the sucrose molecule. By relaxing this constraint, the fragment would be expected to rotate. The motions are still obviously restricted, however, as shown by the magnitude of the S^2 parameter.

The observation that the polymer backbone methine and methylene resonances as well as the sugar resonances can, within error, be described by the same values of τ_c and A suggests that the polymer network, including the saccharide side chain, is being relaxed by anisotropic tumbling. The similarity between the T_1 values for the sugar carbons was earlier accepted to be an indication of isotropic overall tumbling. The errors present for the T_1 values of the sugar resonances may be disguising the presence of anisotropic motion. The freer motions of the N-acetyl methyl and hydroxymethyl groups are superimposed upon the overall molecular tumbling. The hydroxymethyl group may suffer intermolecular hydrogen bonding with water, thereby restricting its rotation, while the methyl group would be expected to have less hindrance to its internal rotation.

Using eq. [4], an effective correlation time of ca. 10 ps can be calculated for the N-acetyl methyl group. If symmetric rotation occurs about the methyl group axis, then S^2 is given (17) by

$$[14] \quad S^2 = S^2_{axis}(3\cos^2\beta - 1) = 0.111\, S^2_{axis}$$

where β is the angle between the axis of the methyl group and the C—H bond. The angle β is taken to be 70.5°, assuming perfect tetrahedral geometry (17). The maximum value of S^2 is thus 0.111 if these assumptions are correct. Since S^2 is 0.023 for this system, the indications are that the relaxation of the methyl group cannot be described by methyl group rotation alone but by another superimposed motion, possibly the motion of the -NH-C=O side chain attached to the sugar.

Nuclear Overhauser enhancements

Nuclear Overhauser enhancements are inherently difficult to measure with the same degree of accuracy as spin-lattice relaxation times. Table 4 lists the experimental and calculated nOe's obtained at 75.4 and 100.6 MHz for the α polymer (**1**). The calculated nOe's were obtained using the global parameter τ_c = 1.15 ns and the individual pairs of S^2 and τ_{eff} parameters for the hydroxymethyl and methyl groups in eq. [4]. For the methine, methylene, and sugar ring carbons, the nOe's were calculated using the "reduced" form of the spectral density (eq. [7]).

It is important to note that the nOe is a ratio of spectral density terms, and is therefore unaffected by the S^2 parameter as a pre-multiplier. By using the "reduced" form of the spectral density only the dependence of the nOe on correlation time is probed. This is the reason that the calculated values for the methine, methylene, and sugar carbons are identical, even though the S^2 parameters used from Table 3 vary slightly. At both field strengths, the experimental nOe's for these carbon atoms are very similar, in accordance with the suggestion of the relaxation being brought about by only overall motion.

The agreement between observed and calculated nOe's at both field strengths is quite good, normally within about 25%. Estimates of the overall correlation time can be determined by averaging the observed nOe's at both field strengths for the backbone and sugar carbons. At 75.4 MHz the average nOe is 0.77, corresponding to τ_c = 0.82 ns. At 100.6 MHz the average nOe is 0.26, corresponding to τ_c = 1.75 ns. The average of these parameters is 1.28 ± 0.46 ns, in fairly good agreement with the overall correlation time of 1.15 ± 0.02 ns obtained from the spin-lattice relaxation rate data.

The observed nOe's for the hydroxymethyl and methyl groups are in fairly good agreement with those calculated, again within 25%. An indication of the possible errors in the magnitude of the errors in nOe can be established by consideration of the values calculated using the various pairs of error parameters of S^2 and τ_{eff} determined from fitting of the relaxation rate data. For the methyl group, nOe's of between 1.13 and 1.51, a change of approximately 25%, can be calculated using minimum τ_{eff}/maximum S^2 and maximum τ_{eff}/minimum S^2 parameters, respectively. In any case, the theoretical ordering of the nOe's at each magnetic field is observed experimentally; sugar ≈ polymer(methylene ≈ methine) < hydroxymethyl < N-acetyl methyl.

Spin–spin relaxation times

As discussed earlier, it is probable that the larger of the correlation times describing the anisotropic tumbling is of such a magnitude that the spin-lattice relaxation times and nOe's would not be affected. Due to the zero-frequency spectral density contribution to spin–spin relaxation, the half-height linewidths may provide information regarding the magnitude of this parameter.

Since the polymer backbone resonances exhibit approximately the same T_1 and nOe behaviour as the sugar resonances, it could be expected that the T_2 relaxation for these carbons will also be similar. This is not necessarily a safe assumption, however, since the saccharide side chain may exhibit some wobbling motion relative to the more restricted motions of the backbone. The overlap of the polymer backbone methine and methylene groups of resonances circumvents their use for examination of the behaviour of the T_2 relaxation of the backbone.

The sugar resonances (C_1–C_6) are well resolved. Examination of the 300 MHz ^{13}C spectrum (see Fig. 2) shows that C_1 is a factor of two broader than the other carbons within the sugar ring. This is presumably due to slight differences in the shift of C_1 brought about by the atactic nature of the polymer. The linewidth for C_1 increases by a factor of ca. three between the different resonance frequencies of 75 and 100 MHz, and observation of distinct fine structure at a resonance frequency of 125 MHz verifies this suggestion. Similar increases in linewidth are observed for the *N*-acetyl methyl group.

At 75.3 MHz resonance frequency the average linewidth for C_2–C_5 is 10.7 ± 1 Hz while at 100.6 MHz the linewidth is 11.3 ± 1 Hz. Using the spectral density defined by eq. [11] and fixing τ_2 = 1150 ps and A = 0.333, gives τ_1 = 21 and 23.5 ns at 75 and 100 MHz, respectively. The linewidths at these frequencies for C_6 are 9.3 and 9.5 Hz, which gives τ_1 = 18 and 19.5 ns when using eq. [8] with τ_2 = 1150 ps, A = 0.333, τ_{eff} = 48 ps, and S^2 = 0.472. These values of τ_1 for C_2–C_6 are in excellent agreement with each other, and give an average of 20.5 ns for τ_1. This timescale is not *necessarily* the second timescale associated with the anisotropic tumbling of the polymer networrk, but may be some average correlation time describing overall tumbling as well as wobbling of the saccharide side chain.

Activation energies of motions by variable temperature

T_1 *measurements*

Spin-lattice relaxation times for the α polymer (**1**) measured as a function of temperature, from 20 to 64°C in increments of ca. 10°C, are given in Table 1. It was assumed that both the overall and internal motions could be described by a normal Arrhenius activation energy, while the S^2 and A parameters were assumed to be temperature independent. Other workers (23) have suggested that S^2 may be temperature dependent, but this dependence is expected to be small.

The activation energy for overall motions was obtained by application of the "reduced" spectral density to the backbone methine and methylene and the sugar methine carbon relaxation data. Relaxation times were calculated for each of these groups by fixing S^2 and changing τ_c to give the observed experimental relaxation times. A linear fit of these calculated τ_c values as a function of $1/T$ allowed the activation energy to be obtained (see Table 5).

TABLE 5. Activation energies for overall and internal motions in the α-glycopolymer (**1**)[a]

Carbon	E_a (τ) (kJ mol^{-1})	τ_{eff} (ps)
Methine[b]	16.9 ± 0.9	—
Methylene[b]	15.5 ± 0.7	—
Sugar (C_1–C_5)[b]	17.6 ± 0.7	—
Hydroxymethyl (C_6)[c]	47.8 ± 20.6	24.6 ± 6.7
Methyl (N-Ac)[c]	4.2 ± 1.4	11.2 ± 0.4

[a]See text for details of calculations.
[b]Activation energies calculated using τ_1 = 1.15 ns.
[c]Activation energies calculated using τ_1 = 1.15 ns, E_a (τ_1) = 16.7 kJ mol^{-1}, and S_2 parameters given in Table 3.

The activation energy associated with the overall tumbling correlation time is $\langle E_a(\tau_c)\rangle_{av}$ = 16.7 ± 1.1 kJ mol^{-1}. If this activation energy is associated with the overall motion, then it should be related to the activated energy associated with viscosity (32). Table 2 lists the viscosities of the α-glycopolymer (**1**) as a function of temperature. According to the Debye equation (31) the overall correlation time is proportional to η/T and the activation energy obtained from the slope of a plot of $\ln(\eta/T)$ against $1/T$ should therefore be associated with the tumbling of the molecule. From the viscosity data given in Table 2, a value of $E_a(\eta/T)$ = 18.7 ± 0.2 kJ mol^{-1} is obtained, while a value of $E_a(\eta)$ = 16.1 ± 0.1 kJ mol^{-1} is obtained from a plot of $\ln(\eta)$ against $1/T$. The activation energy associated with overall tumbling agrees well with both of these viscosity related activation energies.

Using the value $\langle E_a(\tau_c)\rangle_{av}$ = 16.7 kJ mol^{-1} as a fixed parameter, and using the values of τ_c and S^2 given in Table 3, the correlation times and activation energies associated with the internal motions of the methyl and hydroxymethyl groups were calculated. For both groups the correlation times, τ_{eff}^{301K}, were within error of those determined by fitting of the magnetic field dependent relaxation data. For the methyl group the value obtained was τ_{eff}^{301K} = 11.2 ± 0.4 ps compared with 9.9 ± 2.0 ps, while for the hydroxymethyl group τ_{eff}^{301K} = 24.6 ± 6.7 ps compared with 48.1 ± 22.5 ps.

$E_a(\tau)$ for the methyl group (*N*-acetyl) is small (see Table 5). As discussed above, the rotation of the methyl group is probably superimposed on some other motion(s) due to the magnitude of the S^2 parameter. The activation energy is therefore characterizing a number of motions, and no further meaningful information can be gleaned from its magnitude.

$E_a(\tau)$ for the hydroxymethyl group (C_6) of **1** is quite large (47.8 kJ mol^{-1}), and has a large error associated with it (±20.6 kJ mol^{-1}). Due to the nature of the hydroxymethyl group, the activation energy may also be characterizing the change in hydrogen-bonding as a function of temperature as well as an internal barrier to rotation. The authors are unaware of any literature data referring to this rotation.

Comparison of relaxation times in the α- (1) and β- (2) glycopolymers

Table 6 lists the relaxation times obtained for the α- and β-glycopolymers at a temperature of 30°C and 300 MHz resonance frequency. Examination of these data shows that the T_1 values for the β polymer are all greater than those obtained for the α polymer. These differences could be due to a number of minor factors, including slightly different mo-

TABLE 6. ^{13}C relaxation times (s) for the α- and β-glycopolymers at 30°C and 75.43 MHz[a]

Carbon[b]	α Polymer (**1**)	β Polymer (**2**)
Methine	0.199 (0.004)	0.201 (0.005)
Methylene	0.107 (0.003)	0.114 (0.009)
Sugar (C_1–C_5)	0.211 (0.005)	0.238 (0.005)
Hydroxymethyl (C_6)	0.130 (0.004)	0.139 (0.006)
Methyl (N-Ac)	0.901 (0.043)	0.889 (0.064)

[b]See Table 1 for assignments.

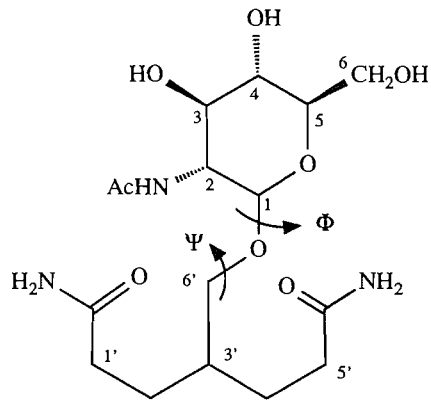
lecular weights and therefore different viscosities or different motions in the two polymers. An alternative possibility could be differential retention of water in the polymers after lyophilization, thereby affecting the weight of actual polymer dissolved in the solutions, and therefore again affecting the viscosities.

It is to be expected that the overall motion would be more affected by a change in viscosity than would the internal motions (32). The overall motion contribution to the relaxation times for the different carbon nuclei in the molecule will therefore be affected and the T_1's will change. Assuming this argument, the observed T_1's suggest that the β polymer (**2**) has a faster overall motion than the α polymer (**1**). This observation does *not* preclude differences in internal motion as well.

The internal motions are of particular interest and the configuration at the anomeric center may affect the motions of the sugar unit. A suitable comparison to probe differences in internal motions is to observe the differences in motion between the backbone and the sugar itself.

Assuming a 5% error in the T_1 values, the ratio of the methine T_1's to the methylene T_1's is the same for both anomers. To establish a level of error comparison, the ratios of T_1(sugar, C_1–C_5) to T_1(hydroxymethyl, C_6) were calculated. These ratios are 1.62 and 1.71 for the α and β anomers, respectively, agreeing to within <5%. Repeating this process for the methine and methylene resonances of the backbone shows an agreement to better than 2%. However, relating the sugar T_1's to the backbone T_1's (methine and methylene) by this method suggests a difference of ca. 8% between the two anomers. There are some possible sources of error involved with this analysis, but the results are *suggestive* that the motions of the sugar ring in the α anomer are more restricted than those obtained for the β anomer.

This restriction of motion can be explained in terms of a change in the motion of the ring relative to the side chain. The earlier discussion suggested that the relaxation of the ring carbons could be influenced by a librational process and by some wobbling of the sugar ring relative to the backbone. For the α polymer (**1**) the proximity to the backbone (see Fig. 1) may lead to additional H-bonding between the sugar hydroxyl groups and protons on the backbone, thereby affecting the extent of motion of the ring. This behaviour is exposed by the difference in T_1's between the two anomers. However, since there are two contributions to the spin-lattice relaxation, the overall difference in the relaxation between the two polymers would be expected to be small. For the sugar ring in the α polymer the relaxation is ca. 65%:35% slow motions to fast motions (vide supra).



1 R = α-GlcNAc
2 R = β-GlcNAc

FIG. 5. The structures used for the potential energy calculations.

Comparison of the conformational flexibility of the α- (1) and β- (2) glycopolymers by molecular mechanics calculations

To evaluate whether there is a difference in the conformational flexibility of the two polymers, **1** and **2**, the ϕ,ψ energetically allowable conformational space was explored with the use of potential energy calculations. A suitable structure was constructed (vide supra) that could reproduce all the degrees of freedom present in the glycopolymer (Fig. 5) near the vicinity of the glycosidic bond. The potential energy as a function of ϕ and ψ, where the molecule is allowed to adopt a minimum energy conformation for each setting of the glycosidic torsion angles, is shown in Figs. 6 and 7 for the α and β forms of the glycopolymers.

Comparison of these figures immediately indicates that the β anomer has far greater conformational flexibility than the α anomer. The β anomer samples a total ϕ angular displacement of ca. 270° while the β anomer is restricted in motion, allowing sampling of a ϕ range of only 100°.

This observation of the different conformational flexibilities of the different anomers supports the observation of different spin-lattice relaxation behaviour, and the approach of comparing the relaxation times of the sugar rings relative to the backbone is shown to be valid.

Conclusion

The objective of this study was to examine the molecular motions and relative conformational flexibilities of the α (**1**) and β (**2**) anomeric forms of poly(acrylamide-*co*-alkenyl *O*-glycosides) to determine whether NMR relaxation measurements could offer any information regarding the overall and internal motions in these types of systems. This study indicates the importance of determining all relaxation parameters for polymers, T_1, T_2, and nOe, to allow all timescales of motion to be examined. The faster motions are readily accessible by T_1 and nOe measurements, though only the T_2 determinations provide information regarding much slower overall motions. The applicability of the model-free approach in its various forms to the analysis of ^{13}C relaxation data has been illustrated fully.

The derived global dynamic parameters of the polymer

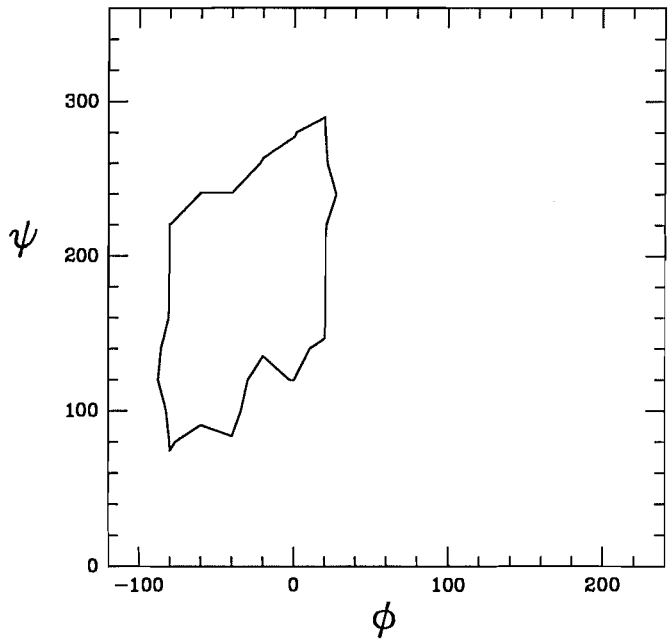

FIG. 6. The potential energy contour map for the α-glycopolymer (**1**). The 10 kcal/mol level with respect to the global minimum is shown.

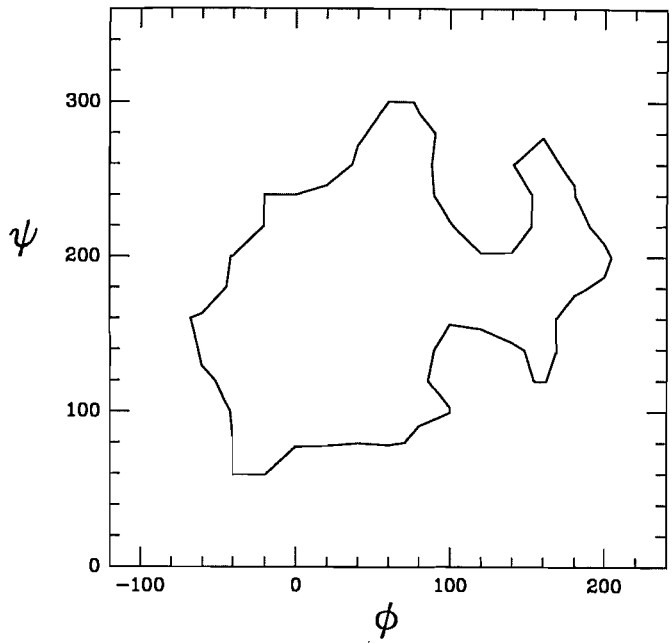

FIG. 7. The potential energy map for the β-glycopolymer (**2**). The 10 kcal/mol level with respect to the global minimum is shown.

molecules suggest anisotropic motion that supports a random-coil arrangement for this macromolecule in solution. These motions are characterized by a correlation time of the order of 1.15 ns, which appears to probe the viscosity of the surroundings as shown by similarity of the temperature dependences of the viscosities and the overall motion.

Internal motions of the *N*-acetyl methyl and sugar hydroxymethyl groups are evident in the relaxation data, and their associated activation energies have been obtained. The spin-lattice relaxation and nOe data for the sugar ring support an overall tumbling correlation time of 1.15 ns, but the spin–spin relaxation data suggest that a slower motion, of the order of 20 ns, is affecting the relaxation. This may characterize the rate of wobbling of the sugar and supporting side chain relative to the backbone.

The *small* change in the relaxation rates for the sugar ring *suggests* that the motions of the α anomer (**1**) are slightly more restricted than those of the β anomer (**2**). This observation is supported by the results of molecular mechanics calculations, which indicate that the β anomer has greater conformational flexibility than the α anomer.

The data obtained for the α- and β-glycopolymers, and the derived information regarding the motions, suggest that the better binding properties of the α-glycopolymer (**1**), in spite of lower overall mobility and perhaps lower accessibility of the sugar moiety than the β-glycopolymer (**2**), might be associated with other geometrical constraints.

Styrylbenzodiazinones 1. Synthèse, structure et propriétés photophysiques

LOUIS CAZAUX,[1] MOURAD FAHER, CLAUDE PICARD et PIERRE TISNÈS

Synthèse et physicochimie organique, Unité de recherche associée au Centre national de la recherche scientifique, n° 471, Université Paul Sabatier, 118 route de Narbonne, 31062 Toulouse Cédex, France

Reçu le 25 février 1993

LOUIS CAZAUX, MOURAD FAHER, CLAUDE PICARD et PIERRE TISNÈS. Can. J. Chem. **71**, 2007 (1993).

Plusieurs dérivés 3-styryliques de la 1,4-benzodiazine-2-one et de la 1-méthyl-1,4-benzodiazine-2-one ont été préparés. Une étude structurale de ces composés a été réalisée par RMN ^1H et ^{13}C ainsi que par modélisation moléculaire. L'isomérie rotationnelle autour de la liaison reliant les groupes imine et vinyle de ces *E* styrylbenzodiazinones est discutée; le rotamère s-*cis* est le rotamère prédominant. Enfin, les propriétés photophysiques de ces colorants fluorescents sont décrites.

LOUIS CAZAUX, MOURAD FAHER, CLAUDE PICARD, and PIERRE TISNÈS. Can. J. Chem. **71**, 2007 (1993).

Several 3-styryl derivatives of 1,4-benzodiazine-2-one and of 1-methyl-1,4-benzodiazine-2-one were prepared. A structural study of these compounds by ^1H and ^{13}C NMR and by molecular modelling was carried out. The rotational isomerism around the bond connecting the imine and vinyl groups in these *E* styrylbenzodiazinones is discussed. The s-*cis* rotamer is shown to be the predominant isomer. The photophysical properties of these fluorescent dyes are reported.

Les colorants fluorescents couvrent un vaste champ d'applications, soit en tant que traceurs, soit dans le domaine de l'électronique (colorants laser, concentrateurs solaires, capteurs de fibres optiques . . .) ou bien dans les domaines de l'immunologie, de la biochimie, de la biologie cellulaire et de la neurochimie. Bien évidemment ce sont les propriétés spectrales développées par ces molécules organiques qui régissent leur domaine d'utilisation; il est donc primordial de pouvoir disposer de plusieurs classes de colorants fluorescents. Nous nous sommes ainsi intéressés aux styrylbenzodiazinones qui sont des analogues structuraux des styrylbenzoxazinones dont les propriétés de fluorescence ont été montrées récemment (1). Ces styrylbenzoxazinones font partie des rares composés qui émettent au-delà de 520 nm avec un effet de Stokes important et un rendement quantique élevé, autant de caractéristiques essentielles pour une bonne sonde biologique. Toutefois leur nature lactone peut les rendre vulnérables aux estérases de certains milieux biologiques. Aussi, la substitution d'un cycle lactone par un cycle lactame dans les styrylbenzodiazinones devrait entraîner une plus grande résistance de ces molécules aux estérases et fournir une possibilité supplémentaire de substitution sur l'azote lactamique, par exemple pour en modifier la lipophilie.

Les quelques styrylbenzodiazinones connues (2, 3) n'ayant pas fait l'objet d'étude de leurs propriétés physicochimiques, nous nous proposons dans ce mémoire d'en synthétiser deux séries et d'analyser leurs propriétés structurales et photophysiques. Dans un autre mémoire (4) nous nous sommes intéressés plus particulièrement à deux chromo et fluoroionophores dérivés de ces styrylbenzodiazinones et comportant un motif éther couronne, le mono aza-15-c-5.

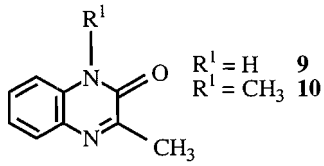
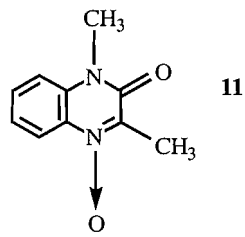
[1]Auteur à qui adresser toute correspondence.

Les propriétés photophysiques des dérivés styryliques dépendant fortement de la polarité des substituants aux extrémités du système, nous avons synthétisé les composés **1–8** répartis en deux séries.

La synthèse et l'étude structurale de ces huit styrylbenzodiazinones ont nécessité la préparation des benzodiazinones suivantes :



$R^1 = H$ **9**
$R^1 = CH_3$ **10**



11

Résultats

Synthèse

Les benzodiazinones précurseurs **9** et **10** ont été obtenues avec de bons rendements par chauffage à reflux de l'orthophénylènediamine en présence de pyruvate d'éthyle dans l'éthanol (**9**) suivie d'une méthylation par le paratoluène sulfonate de méthyle dans le diméthylformamide en présence de carbonate de potassium (**10**). Les styrylbenzodiazinones s'obtiennent par condensation des benzodiazinones précurseurs avec des aldéhydes aromatiques selon la méthode de Badr *et al.* (3) utilisant comme base la pipéridine en présence ou non de pyridine.

À côté de cette méthode, il nous a paru intéressant d'en étudier deux autres : la méthode à l'anhydride acétique utisée pour préparer les styrylbenzoxazinones à partir des benzoxazinones (1*a*, 1*b*) et la méthode au diisopropylamidure de lithium (DAL).

Méthode à la pipéridine

Elle donne en général de bons rendements mais doit être utilisée de préférence avec des composés de point de fusion peu élevé ($F < 120°C$); en effet l'emploi de pyridine comme solvant avec les composés de point de fusion élevé diminue sensiblement le rendement. Dans le premier cas un chauffage de 15–20 min suffit alors que dans le second le temps de réaction doit être porté à 6–8 h.

9	7,82	7,34	7,50	7,30	8,0	1,5	7,5	1,5	8,0
10	7,78	7,31	7,51	7,27	7,8	1,55	7,8	1,55	8,3

Méthode à l'anhydride acétique

L'aldéhyde en léger excès (10%) est mélangé à la benzodiazinone et à l'anhydride acétique et l'ensemble est porté au reflux de l'anhydride (140°C) pendant plusieurs heures. En série benzoxazinone (1*b*) un aldéhyde comportant un substituant *para* électrodonneur donne un faible rendement, tandis qu'avec un substituant électroattracteur les rendements peuvent atteindre 70–80%, ce qui semble assez évident à première vue.

Méthode au DAL

Elle est basée sur la formation de carbanion de type allylique sur le méthyle proche de la fonction imine. Cette méthode a été utilisée avec succès par Meyers dans le cas des méthyl oxazolines pour l'obtention des 2-alcényl oxazolines (5). La formation du carbanion et la condensation avec l'aldéhyde s'opèrent à −78°C dans le THF.

Une comparaison des trois méthodes de synthèse des styrylbenzodiazinones a d'abord été réalisée sur le composé **8**. On note des rendements compris entre 20 (Ac_2O) et 45% (pipéridine). La méthode au DAL (41%) conduit à un rendement proche de celle à la pipéridine; l'utilisation de *N*,*N*,*N*′,*N*′-tétraméthyléthylènediamine (TMEDA) pour dissocier la paire d'ions par chélation du lithium n'a pas amélioré le rendement.[2]

On constate, de plus, que la synthèse des styrylbenzodiazinones par la voie de l'anhydride acétique dépend moins fortement du caractère électroattracteur ou électrodonneur du substituant R^2 que celle des styrylbenzoxazinones. En effet, les composés **2**, **4**, **5** et **8** sont obtenus par cette méthode avec des rendements respectifs de 39, 12, 3 et 20%. La méthode au DAL semble par contre pratiquement indépendante de ce facteur puisque les composés **5**, **6** et **8** à substituants Me, CF_3 et NMe_2 présentent le même rendement voisin de 40%; tout comme celle à la pipéridine : **7** (48%) et **8** (45%)

En résumé, la méthode à la pipéridine, quoique nous ayant donné des rendements inférieurs à ceux annoncés par Badr et al. (3), se révèle très intéressante pour les styrylbenzodiazinones issues de benzodiazinones à faible point de fusion comme **10**; celle au DAL peut lui être dans chaque cas substituée avec succès, la méthode à l'anhydride acétique étant réservée aux composés à substituants électrodonneurs et dont la benzodiazinone de départ, peu soluble dans le THF, a un point de fusion élevé. Quoi qu'il en soit les rendements en produits isolés ne dépassent pas 50%.

Analyse structurale

La nature styrylique des styrylbenzodiazinones pose deux problèmes structuraux: (*i*) configuration *Z* ou *E* des substituants de la liaison styrylique, (*ii*) conformation s-*cis* ou s-*trans* de cette liaison par rapport à la fonction imine de la partie benzodiazinone. Si par la seule RMN ^{1}H on peut facilement résoudre le premier problème (configuration *E* de cette liaison), le deuxième (isomérie rotationnelle) sera abordé conjointement par RMN, mécanique moléculaire et spectrofluorimétrie (durée de vie des états excités). Il est à noter que le problème d'isomérie s-*cis*, s-*trans* dans les systèmes styryliques a fait récemment l'objet d'une mise au point (7).

RMN ^{1}H

Les caractéristiques RMN ^{1}H des benzodiazinones et styrylbenzodiazinones étudiées sont reportées dans les tableaux 1 et 2 dans $CDCl_3$ sauf exceptions signalées.

La préparation de la nitrone **11**, forme *N*-oxyde du composé **10**, et l'examen comparé des spectres RMN ^{1}H de ces deux composés nous ont permis d'assigner de manière univoque les signaux RMN du motif benzodiazinone. Le passage de **10** à **11** se traduit par le déplacement à champ faible

[2]L'utilisation du THF comme solvant pourrait expliquer ce résultat (6).

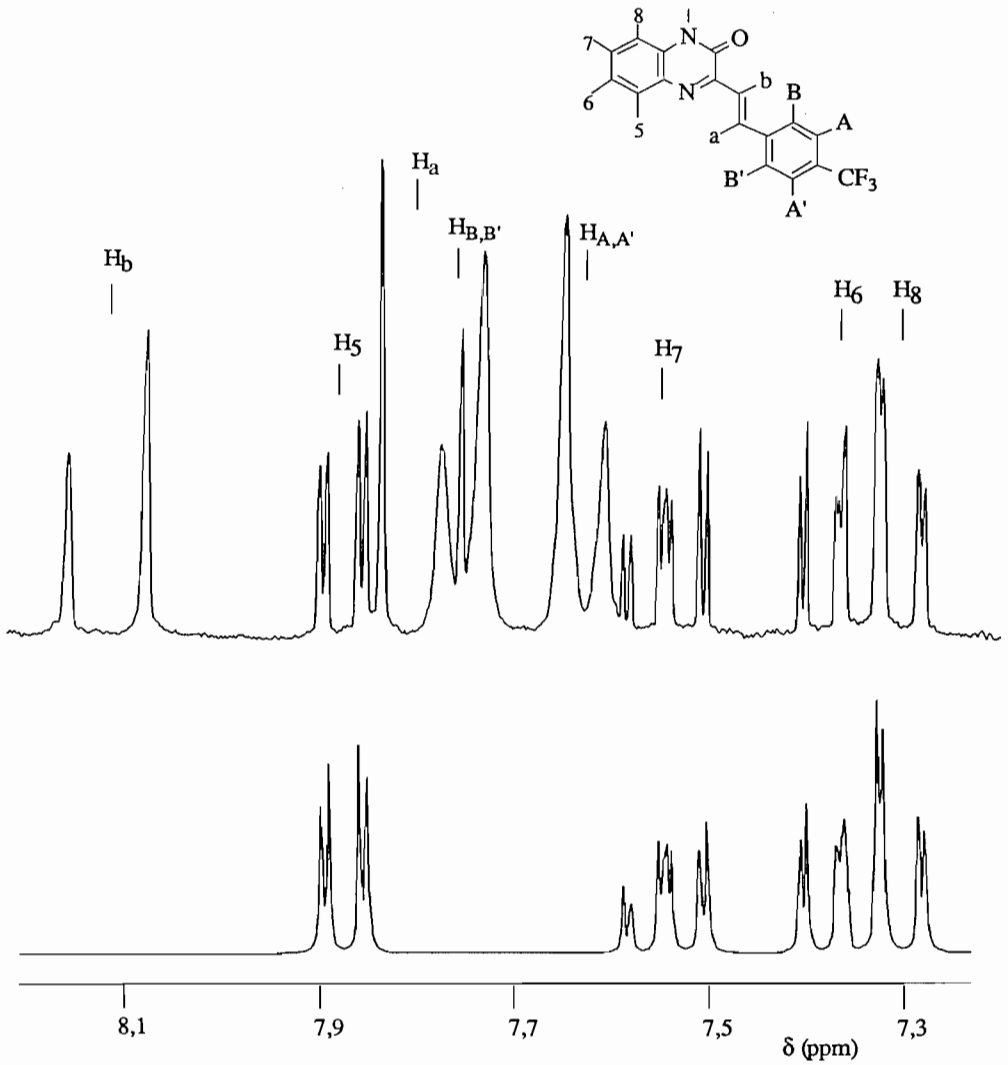

FIG 1. Spectres expérimental et simulé pour la partie benzodiazinone du composé **6** à 200 MHz dans $CDCl_3$.

($\Delta\delta$ = 0,71 ppm) du signal d'un des protons aromatiques, signal qui a été attribué au proton H-5. En effet, dans **11**, le proton H-5, en *péri* de la fonction *N*-oxyde est le plus déblindé (8,49 ppm) et présente deux constantes de couplage de 8 et 2 Hz avec les protons en *ortho* et *méta*. Il est à noter qu'un déblindage du même ordre de grandeur ($\Delta\delta$ = 0,4–0,6 ppm) pour ce même type de proton a été observé dans la série des quinoxalines et de leurs formes *N*-oxydes (8). L'analyse des spectres ^1H à 200 MHz de **9** et **10** et leurs simulations avec le programme LAOCOON 3 nous a alors permis de déduire les paramètres rassemblés dans le tableau 2.

L'analyse détaillée des spectres de **6**, **7** et **8** à 200 MHz permettra une généralisation aux autres styrylbenzodiazinones des deux séries étudiées. À titre d'exemple le spectre du composé **6** (Fig. 1) montre au premier abord un système AB attribué aux protons H_a et H_b de la liaison styrylique avec une constante de couplage de 16 Hz qui indique une configuration *E*. Le système AA′BB′ de la partie trifluorométhylbenzène donne deux doublets avec une constante J_{AB} = 8,5 Hz. La largeur à mi-hauteur du signal des protons H_B et $H_{B'}$ (W = 3,0 Hz) est supérieure à celle du signal de H_A et $H_{A'}$ (W = 2,0 Hz) du fait du couplage de H_B et $H_{B'}$ avec le proton éthylénique H_a, ce dernier étant lui-même élargi (W = 1,5 Hz) par rapport à H_b (W = 1,0 Hz). On en déduit les déplacements suivants pour le système AA′BB′ : $\delta_{A,A'}$ = 7,58 ppm et $\delta_{B,B'}$ = 7,81 ppm. Les protons aromatiques de la partie benzodiazinone présentent des déplacements chimiques et des constantes de couplage très proches de ceux du précurseur **10**.

RMN ^{13}C

Les attributions sont effectuées sur la base des valeurs calculées (9) à partir des tables d'incréments[3] et des spectres corrélés ^1H-^{13}C pour les composés **7**, **9** et **10**. D'autre part (*i*) les carbones c et d (notation des schémas du tableau 3) présentent des signaux d'intensité double par rapport aux autres carbones tertiaires; (*ii*) les carbones b, e, h, i, j, o sont quaternaires et leur attribution a été établie à partir des spectres *J* modulé et des spectres enregistrés sans découplage des protons, les carbones o et j en position α d'un atome d'azote ne pouvant pas être distingués; (*iii*) les carbones quaternaires i et h des groupes carbonyle et imine ont été différenciés par enregistrement des spectres ^{13}C couplés ^1H à 62,9 MHz. Les carbones des groupes imine et carbonyle

[3]La partie des carbones f→p est simulée par le groupe vinyle.

[a]DMSO-d_6.
[b]$CDCl_3$ + CD_3OD.

présentent des constantes de couplage avec les protons du groupe méthyle en position 3 de 7,2 et 2,7 Hz respectivement dans le cas des benzodiazinones et de 5,6 et 2.8 Hz dans le cas des styrylbenzodiazinones (couplage avec le proton vinylique); (*iv*) les déplacements chimiques des carbones a, b et c du composé fluoré **6** ont été attribués en tenant compte des couplages avec le fluor (^1J = 272 Hz, ^2J = 37 Hz et ^3J = 3,8 Hz).

De l'analyse du tableau 2, il ressort que les carbones h du type imine subissent un blindage du fait de la conjugaison du système styrylique. Par contre, les autres carbones sp^2 du motif benzodiazinone conservent des déplacements chimiques pratiquement identiques à ceux correspondants des benzodiazinones **9** et **10** et ceci quelle que soit la nature du substituant R^2.

En vue d'une éventuelle mise en évidence d'une isomérie rotationnelle s-*cis*, s-*trans* autour de la liaison N , l'examen des déplacements chimiques des carbones f et g de la liaison styrylique conduit à remarquer que leur différence (Δδ en ppm) traduit bien l'effet des substituants R^2 sur la polarisation de la liaison styrylique dans les deux séries étudiées (9) soit : R^2 = CHO (10,3 et 11,7), CF_3 (11,5), $CH(OCH_3)_2$ (13,8), H (15,1), CH_3 (17,0) et $N(CH_3)_2$ (22,9 et 21,6). Compte tenu de ce large effet du substituant il paraît difficile de déceler l'influence de la structure s-*cis* ou s-*trans* sur le déplacement chimique en RMN ^{13}C.

Mécanique moléculaire

Le problème de l'isomérie rotationnelle autour de la liaison N de systèmes styryliques a déjà été étudié par mécanique moléculaire avec le programme MACROMODEL pour les 1-(2-naphtyl)2-pyrazin-2-yl éthylène (10). Dans la présente étude le même programme dans sa version V 3.5 X est utilisé avec les champs de force MM2* et MM3* (11). Pour vérifier la validité de ces deux champs de force deux tests ont été réalisés. Un premier test a été effectué sur les isomères s-*cis* et s-*trans* du butadiène et de l'acroléine. Des valeurs de 2,6 et 1,75 kcal/mol (exp : 2,5 (12)) ont été trouvées respectivement avec MM2* et MM3* pour le butadiène; 1,6 et 1,86 kcal/mol (exp : 1,7 (13)) pour l'acroléine. Ces résultats confirment ceux obtenus par Pettersson et coll. (14) indiquant que MM2* est la méthode de choix pour le calcul des énergies conformationnelles sur les hydrocarbures et les composés oxygénés et azotés. Un deuxième test a été réalisé sur les angles de torsion («tilts») autour de la liaison C—Ar des *Z* (φ_1) et *E*(φ_2) stilbènes. Avec MM2* et MM3* on obtient respectivement des angles φ_1 de 47° et 42° et φ_2 de 31° et 18° pour des valeurs expérimentales déterminées par diffraction électronique de 43° ± 10 (15) et 32°2 (16). Nos résultats peuvent ainsi compléter ceux discutés récemment par Hohlneicher *et al.* (17). Avec les deux champs de force nous trouvons que la forme *E* est la plus stable de 2,6 (MM2*) ou 2,0 (MM3*) kcal/mol.

Compte tenu de ces résultats encourageants nous avons abordé l'analyse de l'isomérie rotationnelle autour de la liaison N de la styrylbenzodiazinone **8**. Pour cela nous avons calculé l'énergie conformationnelle de la configuration *E* à chaque rotation d'un angle θ = 30° suivie d'une minimisation effectuée grâce à l'algorithme PRCG jusqu'à un RMS < 0,008 (Fig. 2).

Il apparaît clairement que c'est la forme s-*cis* qui est d'énergie minimale avec un minimum (MM3*) ou deux minima (MM2*) très rapprochés (0 ± 30°). La forme s-*trans* oscille également entre deux minima à 180 ± 26° (MM2*). La différence d'énergie entre les deux formes est de 0,7 kcal/mol (MM2*) ou 1,5 kcal/mol (MM3*). Les barrières à la rotation sont respectivement de 2,6 (MM2*) et 3,9 (MM3*) kcal/mol.

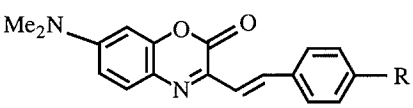
Propriétés photophysiques

Les propriétés photophysiques des deux séries de styrylbenzodiazinones étudiées sont rassemblées dans le tableau 4. Nous y avons également reporté celles des trois dérivés styryliques d'aminobenzoxazinones suivants (18) :



R = NMe_2	BOZ-NMe_2
R = H	BOZ-H
R = CHO	BOZ-CHO (DFSBO)

Les dérivés styryliques **1–8** présentent des absorptions à 382,5–456 nm ($CHCl_3$), 381,5–440,5 nm (CH_3CN) et 389–448 (EtOH). Les émissions de fluorescence correspondantes sont : 456–568 nm ($CHCl_3$), 454,5–604 nm (CH_3CN) et 453–631,5 nm (EtOH). Les deux composés **4** et **8** à groupement diméthylamino émettent comme prévu aux plus fortes longueurs d'onde dans le rouge; par contre, le composé **5** méthyl substitué émet aux plus faibles longueurs d'onde.

Cette classification se retrouve au niveau des déplacements de Stokes $\bar{\nu}_{abs} - \bar{\nu}_{em} = 10^7 (1/\lambda^{abs}_{max} - 1/\lambda^{em}_{max})$ (en cm^{-1}) qui peuvent être reliés linéairement à $\Delta f = (\epsilon - 1)/(2\epsilon + 1) - (n^2 - 1)/(2n^2 + 1)$ (19); la pente de la droite étant proportionnelle[4] au carré de la différence entre le moment dipolaire dans l'état excité et dans l'état fondamental $(\mu_e - \mu_f)$ soit $s = 2 (\mu_e - \mu_f)^2/hca^3$.

À partir des mesures (tableau 4) réalisées en solvant aprotique (chloroforme et acétonitrile) nous pouvons ainsi déterminer la pente de la droite relative à la corrélation : déplacement de Stokes en fonction[5] de Δf. On observe des pentes faibles ($(4 \pm 0,5) \times 10^3$) pour les composés **2**, **6** et **7** à substituant R^2 électroattracteur, presque nulle ($0,5 \times 10^3$) pour **5** ($R^2 = CH_3$) et très fortes ($11,5 \times 10^3$) pour **4** et **8** à substituant diméthylamino fortement électrodonneur.

En comparant ces valeurs aux pentes des styrylbenzoxazinones correspondantes (18) : $7,4 \times 10^3$ (BOZ-CHO), $4,4 \times 10^3$ (BOZ-H) et $7,3 \times 10^3$ (BOZ-NMe_2) on note une variabilité du déplacement de Stokes avec la polarité du solvant plus importante dans le cas des styrylbenzodiazinones et donc de plus grandes variations entre moments dipolaires de l'état excité et de l'état fondamental, soit 31,5 D ($R^2 = NMe_2$), 18,5 D (R = CHO ou CF_3) et 5,6 D (R^2 = Me). Le fort déplacement solvatochromique et donc l'important moment dipolaire à l'état excité observés pour **4** et **8**, supérieurs à ceux de BOZ-NMe_2, seraient dus vraisemblablement comme pour ce dernier (1*g*) à l'existence d'un état TICT (twisted intramolecular charge transfer state) fluorescent formé par torsion de la simple liaison N–Ph sous excitation. Le substituant diméthylamino fortement électrodonneur entraîne donc le plus grand déplacement de Stokes et le plus grand transfert de charge, mais il s'accompagne par contre d'un rendement quantique peu élevé ($\phi_f \sim 0.20$).

D'autre part, on observe que la méthylation sur l'atome d'azote lactamique n'entraîne qu'une faible variation sur les propriétés photophysiques des styrylbenzodiazinones (comparaison de **2** et **7**, **4** et **8**).

Cette comparaison avec les styrylbenzoxazinones peut se poursuivre sur la question de savoir si les styrylbenzodiazinones peuvent être considérées comme des benzodiazinones substituées ou comme des chromophores de type stilbène substitués. Pour les styrylbenzoxazinones la première proposition a été démontrée (18) notamment en considérant que le substituant en *para* sur le groupe phényle n'était pas impliqué dans le transfert de charge photoinduit; en effet le maximum d'émission de BOZ-H n'est pas intermédiaire de ceux de BOZ-NMe_2 et de BOZ-CHO dans les solvants étudiés (respectivement 542, 627 et 558 nm dans le chloroforme). Avec les styrylbenzodiazinones les valeurs correspondantes dans $CHCl_3$ sont respectivement 456, 568 et 462 nm. Elles conduisent donc à une conclusion analogue à celle des styrylbenzoxazinones.

Enfin, la durée de vie (τ) des états excités de la styrylbenzodiazinone **8** a été mesurée dans le chloroforme (tableau 5) et les constantes radiatives (k_r) et non radiatives (k_{nr}) ont été calculées selon les formules classiques $k_r = \phi/\tau$ et $k_{nr} = (1 - \phi)/\tau$. Le meilleur accord pour la fonction de décroissance de fluorescence est obtenu par l'utilisation de deux exponentielles. Les deux durées de vie différentes reflètent des constantes de vitesse radiatives différentes plutôt que des rendements quantiques différents (7).

[4] *h* est la constante de Planck, *c* la vitesse de la lumière et *a* le rayon en Å de la cavité sphérique selon Onsager.

[5] Δf = 0,148 ($CHCl_3$), 0,304 (CH_3CN).

Discussion

On a vu que, par leurs propriétés photophysiques, les styrylbenzodiazinones se rapprochent plus des benzodiazinones que des dérivés du stilbène. À l'instar des styrylbenzoxazinones, on peut donc considérer que le transfert électronique responsable de ces propriétés pourrait impliquer le carbonyle et l'atome d'azote hétérocyclique comme groupes électroattracteurs et comme groupe électrodonneur non plus le groupe diméthylamino de la partie benzo inexistant dans les styrylbenzodiazinones étudiées ici mais l'atome d'azote du groupe amide que l'on sait être fortement polarisé.

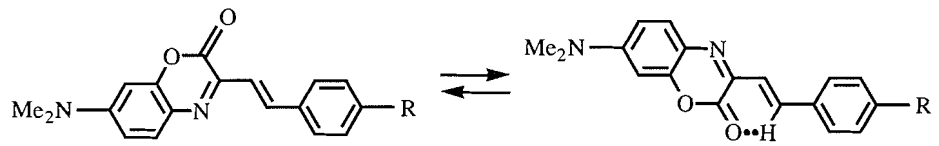
La nature styrylique des composés étudiés intervient cependant au niveau de la possibilité d'existence d'une isomérie rotationnelle autour de la liaison N .

En particulier, deux rotamères sont souvent observés dans les diaryléthylènes (7) et même dans les styrylbenzoxazinones (18) où la fonction de décroissance de fluorescence ne peut s'expliquer que par une décroissance à double exponentielle. L'équilibre suivant est alors proposé dans la série des BOZ.

L'apparition d'un second rotamère serait favorisée dans les solvants non polaires ou dans les solvants visqueux. Ce qui, d'après les auteurs, indiquerait qu'un des rotamères de forme s-*trans* serait stabilisé par liaison hydrogène comme déjà postulé pour le DFSBO (20).

TABLEAU 5. Durées de vie (τ) et constantes radiatives (k_r) et non radiatives (k_{nr}) du composé **8** dans le chloroforme

Formes %	τ (ns) ± 20%	ϕ_f	k_r (ns^{-1})	k_{nr} (ns^{-1})
70	0,5	0,20	0,28	1,72
30	4,2		0,014	0,22



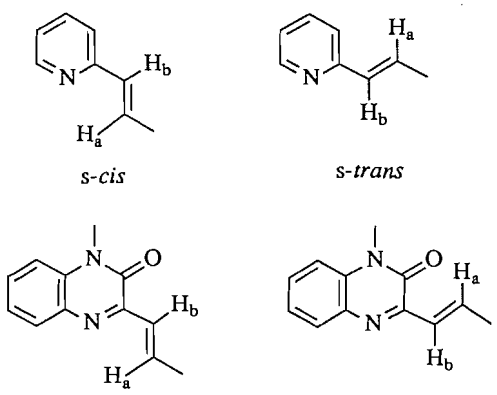


SCHÉMA 1

Toutefois, peu de démonstrations de l'isomérie rotationnelle dans les *E* 1,2 diaryléthylènes ont été faites par RMN (7). Il est cependant à noter que les molécules de type éthylène disubstitué par un noyau pyridine ont leur protons éthyléniques H_a et H_b (schéma 1) dans un environnement tel que leurs déplacements chimiques sont très sensibles à l'anisotropie de cycle et aux effets magnétiques et électriques de l'atome d'azote, particulièrement H_a dans la forme s-*cis*. Ainsi Coletta *et al.* (22) ont déterminé que dans $CDCl_3$ la forme s-*cis* est préférentielle avec δH_a = 7,62 ppm (styryl-2 pyridine) ou 7,69 ppm (1,2-di[pyridyl(2)]éthylène) alors qu'après calcul une valeur de 7,8 ppm serait attendue pour le même proton dans cette forme et une valeur de 7,2 ppm pour H_b dans la forme s-*trans*.

Le proton H_a dans les styrylbenzodiazinones (tableau 1) résonne dans le chloroforme deutérié en moyenne à 8,12 ppm; le proton H_b à 7,70 ppm. Ce résultat serait donc plutôt en faveur de la forme s-*cis*. Toutefois on ne peut exclure la forme s-*trans* car H_a dans s-*trans* pourrait être déblindé par participation à une éventuelle liaison H C=O···H_a (*vide infra*).

La préférence de la forme s-*cis* est trouvée dans la détermination des énergies conformationnelles des styrylbenzodiazinones par mécanique moléculaire. On a vu effectivement que la forme s-*cis* du composé **8** était plus stable que sa forme s-*trans* de 0,7 ou 1,5 kcal/mol selon le champ de force utilisé. La différence d'énergie entre les deux formes est donc suffisamment basse pour que l'existence de 10–30% de forme s-*trans* soit plausible. L'intervention dans cette forme d'une interaction C=O···H_a attractive comme suggéré par Mialocq et Meyer (20) pour les styrylbenzoxazinones ne peut pas être démontrée par mécanique moléculaire.[6] Une différence d'énergie ≤ 1,6 kcal/mol entre formes s-*cis* et s-*trans* et une barrière à la rotation autour de la liaison N=C inférieure à 4 kcal/mol laissent la possibilité d'avoir une ou deux formes indifféremment selon le substituant R^2 et le type de solvant; la forme s-*cis* demeurant majoritaire.

Pour la styrylbenzodiazinone **8** dans le chloroforme une détermination des durées de vies de fluorescence nous a montré que la fonction de décroissance de fluorescence s'interprétait par deux exponentielles montrant l'existence de deux populations en proportion 70 : 30.[7] D'après ce qui précède la configuration s-*cis* devrait être la forme majoritaire, les rotamères dans l'état excité singulet étant différents et ne s'interconvertissant pas (7).

Conclusion

Au cours de ce travail nous avons montré que les styrylbenzodiazinones synthétisées présentaient dans le chloroforme une configuration *E* au niveau de la liaison styrylique. De plus, l'isomérie s-*cis* s-*trans* autour de la liaison N=C, rendue possible par une barrière à la rotation peu élevée, est à l'avantage de la forme s-*cis* de moindre énergie à l'état gazeux ou dans un solvant aprotique peu polaire. Les propriétés photophysiques de ces composés sont proches de celles des styrylbenzoxazinones et diffèrent peu dans les deux séries étudiées. On note cependant pour les dérivés diméthylaminés des déplacements de Stokes supérieurs à celui de BOZ-NMe_2 mais dont l'origine est vraisemblablement la même. De même, dans les deux cas, la durée de vie des états excités est analogue, leur analyse par une décroissance de fluorescence de type double exponentielle supportant l'existence de l'isomérie s-*cis* s-*trans* précitée.

Même si les rendements quantiques de fluorescence des styrylbenzodiazinones étudiées sont relativement faibles, les déplacements de Stokes élevés, leur nature lactame et la possibilité de substitution sur l'azote lactamique confèrent à ces composés un intérêt au plan fondamental voire appliqué. En effet, la facilité de greffage d'éthers couronnes de type notamment aza-15-couronne-5 en prise directe sur le système conjugué peut entraîner des modifications spectrales exploitables, par exemple, pour le dosage sélectif de cations métalliques.

Partie expérimentale

Les points de fusion (*F*) ont été déterminés au banc Köfler. Les spectres infra-rouges ont été enregistrés à l'aide d'un spectrophotomètre Perkin–Elmer 883 (dans des pastilles de KBr) et les spectres RMN ^1H et ^{13}C sur les appareils Brüker AC 80, AC 200 ou AC 250 (avec le TMS comme référence interne, les déplacements chimiques étant exprimés en ppm). Pour une description détaillée des

[6]Le résultat de la figure 2 irait plutôt à l'encontre de la liaison H mais MM2* ne tient pas compte de manière très précise des énergies de liaison H et les inclut généralement dans la composante électrostatique de l'énergie totale (21). Cependant, vu le très faible caractère acide du proton éthylénique, si cette liaison existe, elle doit être très faible.

[7]En supposant que le principe de non équilibration des rotamères excités s'applique aux styrylbenzodiazinones comme aux *trans*-1,2-diaryléthylènes (7), la barrière d'interconversion dans l'état excité est alors remarquablement plus haute que celle de l'état fondamental. Dans ces conditions on peut assimiler abondance relative des espèces excitées et proportion des populations à l'état fondamental.

spectres RMN ^1H, il faut se reporter aux tableaux 1 et 2 et pour les spectres RMN ^{13}C au tableau 3. Les spectres de masse ont été effectués sur un appareil Nermag R 10-10C (mode d'ionisation : DCI/NH_3). Les analyses centésimales ont été réalisées au service commun de microanalyse élémentaire UPS-INP à Toulouse. Les spectres d'absorption ont été effectués sur un spectrophotomètre Perkin–Elmer Lambda 17 et les spectres d'émission sur un spectrofluorimètre Perkin–Elmer LS-3B ou Aminco SPF 500 C interfacé à un microcalculateur. Les rendements quantiques de fluorescence ont été mesurés en prenant comme standarts le sulfate de quinine (ϕ_f = 0,54 dans H_2SO_4 0,1 N), la coumarine **6** (ϕ_f = 0,78 dans l'éthanol (23)), le DFSBO (ϕ_f = 0,76 dans le chloroforme, ϕ_f = 0,60 dans l'éthanol (1*c*)). Les relevés des déclins de fluorescence sont effectués sur une chaîne de mesure Edinburg Instrument modèle 199. Les détails de conception de cet appareillage et les techniques de déconvolution qui conduisent aux durées de vies ont été déjà décrites (24). Les séparations par chromatographie liquide (CPL) sont réalisées sur colonne de silice Merck Kieselgel 60 (70–230 μm ATM). La pureté des produits a été vérifiée par chromatographie sur couche mince (CCM) sur plaque de gel de silice Merck 60 F 254 prête à l'emploi. Les calculs de mécanique quantique ont été effectués sur une station Silicon Graphics Iris 4D-30 à l'aide du programme MACROMODEL V 3.5 X.

*3-Styryl-1,4-benzodiazine-2-one : **1***

Une solution de 5,4 mmol (0,864 g) de composé **9** et 6,4 mmol (0,678 g) de benzaldéhyde fraîchement distillé dans 5 mL de pyridine est portée à reflux pendant 8 h en présence de cinq gouttes de pipéridine. Après refroidissement la pyridine est éliminée sous vide et le solide résiduel est purifié par CPL (éluant dichlorométhane/acétate d'éthyle 75/25). Une recristallisation dans le dioxane fournit 0,620 g de **1**. Rdt 46%, fines aiguilles jaunes, *F* = 254°C (litt. (3*a*) 252°C); IR : 3438 (NH), 1657 (C=O), 1626 (C=N), 1595 (C=C) cm^{-1}; UV (chloroforme) : λ_{max} = 382,5 nm (ϵ = 21 000 M^{-1} cm^{-1}); RMN ^1H (DMSO-d_6) : 7,70–8,63 (m, 11H, arom. et vinyl), 12,4 (s, 1H, NH); SM : *m/e* 249 $[M+H]^+$, 100%. Anal. calc. pour $C_{16}H_{12}N_2O$: C 77,40, H 4,87, N 11,28; trouvée : C 77,35, H 4,90, N 11,25.

*3-(4-Formylstyryl)-1,4-benzodiazine-2-one : **2***

On chauffe durant 5 h, au bain d'huile, à 140°C, 4 mmol (0,640 g) de composé **9** et 4,4 mmol (0,590 g) d'aldéhyde téréphtalique dans 2 mL d'anhydride acétique. Le milieu réactionnel est ensuite dilué avec de l'eau et évaporé à sec sous vide. L'opération est répétée plusieurs fois de façon à éliminer l'acide acétique formé et l'excès d'anhydride acétique. Le résidu ainsi obtenu est partagé entre l'eau et l'excès d'anhydride acétique. Le résidu solide de la phase organique est ensuite traité par un petit volume d'acétone. Après filtration et recristallisation dans l'éthanol on obtient 0,430 g de **2**. Rdt 39%, cristaux jaune clair, *F* = 247°C; IR : 3436 (NH), 1700 (C=O aldéhyde), 1660 (C=O amide), 1625 (C=N), 1598 (C=C) cm^{-1}; UV (chloroforme) : λ_{max} = 389 nm (ϵ = 20 200 M^{-1} cm^{-1}); RMN ^1H (DMSO-d_6) : 7,24-8,19 (m, 10H, arom, et vinyl), 10,04 (s, 1H, CHO), 12,50 (s, 1H, NH); SM : *m/e* 277 $[M+H]^+$, 100%. Anal. calc. pour $C_{17}H_{12}N_2O_2$: C 73,90, H 4,38, N 10,14; trouvée : C 73,75, H 4,32, N 10,07.

*3-(4-Diméthoxyméthylstyryl)-1,4-benzodiazine-2-one : **3***

À 276 mg (1 mmol) de composé **2** dissous dans 50 mL d'un mélange chloroforme/méthanol (50/50), on ajoute 7 μL de chlorure de thionyle (0,1 mmol). Aprés 1 nuit d'agitation à température ambiante et évaporation des solvants sous pression réduite on obtient 320 mg de **3**. Rdt 100%, huile jaune; IR (entre lames de KBr) : 3440 (NH), 1660 (C=O), 1625 (C=N) cm^{-1}; UV (éthanol) : λ_{max} = 398 nm (ϵ = 9500 M^{-1} cm^{-1}); RMN ^1H ($CDCl_3$/CD_3OD) : 3,35 (s, 6H, CH_3), 5,38 (s, 1H, CH), 7,25–8,18 (m, 10H, arom. et vinyl). Anal. calc. pour $C_{19}H_{18}N_2O_3$: C 70,79, H 5,63, N 8,69; trouvée : C 71,05, H 5,75, N 8,49.

*3-(4-Diméthylaminostyryl)-1,4-benzodiazine-2-one : **4***

Ce composé a été obtenu par condensation dans l'anhydride acétique entre le *p*-diméthylaminobenzaldéhyde et la benzodiazine-2-one **9** suivant le mode opératoire décrit pour le composé **2**. La recristallisation est effectuée dans le toluène. Rdt 12%, cristaux rouges, *F* = 257°C (litt. (3*a*) 256°C); IR : 3438 (NH), 1665 (C=O), 1625 (C=N), 1600 (C=C) cm^{-1}; UV (chloroforme) : λ_{max} = 456 nm (ϵ = 30 000 M^{-1} cm^{-1}); RMN ^1H ($CDCl_3$) : 3,03 (s, 6H, $N(CH_3)_2$), 6,50 (s, 1H, NH), 6,70–8,20 (m, 10H, arom. et vinyl). Anal. calc. pour $C_{18}H_{17}N_3O$: C 74,21, H 5,88, N 14,42; trouvée : C 74,20, H 5,80, N 14,49.

*1-Méthyl-3-(4-méthylstyryl)-1,4-benzodiazine-2-one : **5***

À une solution de 5,88 mmol de diisopropylamidure de lithium (préparée à partir de quantités équimolaires de *n*-butyllithium et de diisopropylamine, 0°C, THF) dans 20 mL de THF anhydre, refroidie à −78°C et sous atmosphère d'argon, on additionne goutte à goutte 1 g (5,75 mmol) de **10** dissous dans 3 mL de THF. Après 1 h d'agitation on obtient une solution noire à laquelle on ajoute 0,690 g (5,75 mmol) de 4-méthyl benzaldéhyde. Après 1 heure d'agitation à −78°C on traite le milieu réactionnel avec 2 mL de méthanol et on le laisse revenir à température ambiante. À la solution orangée on ajoute alors 20 mL d'eau saturée en chlorure d'ammonium. La phase organique est séparée, la phase aqueuse est extraite avec du chloroforme. Les phases organiques combinées sont lavées avec une solution à 10% de bisulfite de sodium, puis avec de l'eau saturée en chlorure de sodium et séchées ($MgSO_4$). Après évaporation des solvants, le résidu est traité par un petit volume d'acétone. Après filtration et recristallisation dans de l'éthanol on obtient 0,60 g de **5**. Rdt 38%, cristaux jaunes, *F* = 150°C (litt. (3*b*) *F* 149–150°C); IR : 1647 (C=O), 1625 (C=N), 1598 (C=C) cm^{-1}; UV (chloroforme) : λ_{max} = 394 nm (ϵ = 19 400 M^{-1} cm^{-1}); RMN ^1H ($CDCl_3$) : 2,35 (s, 3H, Ar-CH_3), 3,66 (s, 3H, N-CH_3), 7,11–8,22 (m, 10H, arom. et vinyl). Anal. calc. pour $C_{18}H_{16}N_2O$: C 78,24, H 5,84, N 10,14; trouvée : C 78,22, H 5,80, N 10,05.

5 a également été préparé par la méthode à l'anhydride acétique (voir préparation de **2**) avec un rendement de 3%.

*1-Méthyl-3-(4-trifluorométhylstyryl)-1,4-benzodiazine-2-one : **6***

6 a été préparé par condensation entre la benzodiazine-2-one **10** et le 4-trifluorométhyl benzaldéhyde en présence de DAL suivant le mode opératoire décrit pour le composé **5**. La recristallisation est effectuée dans le toluène. Rdt 39%, cristaux jaunes, *F* = 156°C; IR : 1656 (C=O), 1625 (C=N), 1603 (C=C) cm^{-1}; UV (chloroforme) : λ_{max} = 389 nm (ϵ = 20 600 M^{-1} cm^{-1}); RMN ^1H ($CDCl_3$) : 3,67 (s, 3H, N-CH_3), 7,28–8,18 (m, 10H, arom. et vinyl); RMN ^{19}F ($CDCl_3$, référence : CF_3COOH) : 12,86 ppm; SM : *m/e* 331 $[M+H]^+$, 100%. Anal. calc. pour $C_{18}H_{13}F_3N_2O$: C 65,45, H 3,97, N 8,48; trouvée : C 65,54, H 3,84, N 8,36.

*1-Méthyl-3-(4-formylstyryl)-1,4-benzodiazine-2-one : **7***

On a chauffé 500 mg (2,87 mmol) de benzodiazine-2-one **10** et 460 mg (3,44 mmol) d'aldéhyde téréphtalique pendant 20 min à 170°C en présence de 5 gouttes de pipéridine. On réalise une purification par CPL (éluant dichlorométhane/acétate d'éthyle 95/05). On obtient ainsi 400 mg de **7**. Rdt 48%, cristaux jaunes, *F* = 187°C; IR : 1689 (C=O aldéhyde), 1647 (C=O amide), 1628 (épaulement, C=N), 1600 (C=C) cm^{-1}; UV (chloroforme) : λ_{max} = 397,5 nm (ϵ = 28 100 M^{-1} cm^{-1}); RMN ^1H ($CDCl_3$) : 3,76 (s, 3H, N-CH_3), 7,30–8,24 (m, 10H, arom. et vinyl), 10,02 (1H, s, CHO); SM : *m/e* 291 $[M + H]^+$, 100%. Anal. calc. pour $C_{18}H_{14}N_2O_2$: C 74,47,H 4,86, N 9,65; trouvée : C 74,25,H 4,79, N 9,66.

*1-méthyl-3-(4-diméthylaminostyryl)-1,4-benzodiazine-2-one : **8***

8 a été préparé à partir de la benzodiazine-2-one **10** et du *p*-diméthylaminobenzaldéhyde par la méthode au DAL (cf. mode opératoire de **5**) avec un rendement de 41%, par la méthode à la pipéridine (cf. mode opératoire de **7**) avec un rendement de 45%, par la méthode à l'anhydride acétique (cf. modc opératoire de **2**) avec un rendement de 20%. **8** est cristallisé dans l'éthanol et purifié par recristallisation dans le benzène. Cristaux rouge vif, *F* = 198°C (litt. (3*b*) *F* 197–198°C); IR : 1651 (C=O), 1625 (C=N)

cm^{-1}; UV (chloroforme) λ_{max} = 452,5 nm (ϵ = 32 000 M^{-1} cm^{-1}); RMN ^1H ($CDCl_3$) : 2,99 (s, 6H, $N(CH_3)_2$), 3,68 (s, 3H, N-CH_3), 6,60-8,14 (m, 10H, arom. et vinyl.); SM : *m/e* 306 $[M + H]^+$, 100%. Anal. calc. pour $C_{19}H_{19}F_3N_3O$: C 74,73, H 6,27, N 13,76; trouvée : C 74,93, H 6,39, N 13,70.

*3-Méthyl-1,4-benzodiazine-2-one : **9***

Une solution d'orthophénylène diamine dans l'éthanol est chauffée au reflux en présence de pyruvate d'éthyle (1,05 équivalent) pendant 3 à 4 h. Après refroidissement de la solution, le précipité est filtré et recristallisé dans l'éthanol. Rdt 100%, aiguilles blanches, *F* = 242°C (litt. (25) *F* 245°C).

*1,3-Diméthyl-1,4-benzodiazine-2-one : **10***

À une suspension de 0,60 g (3,75 mmol) de **9** et de 0,83 g (6 mmol) de carbonate de potassium dans le DMF (7 mL) maintenue à 135°C, on ajoute goutte à goutte 1,40 g (7,50 mmol) de paratoluène sulfonate de méthyle dissous dans 5 mL de DMF. Après l'addition on laisse le mélange 20 min à 135°C avant retour à température ambiante. Le précipité est filtré, lavé au DMF et purifié par CPL (éluant dichlorométhane/acétate d'éthyle 50/50). On obtient ainsi 0,392 g de **10**. Rdt 60%, *F* = 85°C (litt. (26) *F* 85–86°C).

*1,3-Diméthyl-4-oxyde-1,4-benzodiazine-2-one : **11***

On a chauffé 1 g (5,75 mmol) de **10** dans 7 mL d'acide acétique et 2,4 mL de peroxyde d'hydrogène à 30% dans l'eau à 65°C pendant 4 h 30. Après refroidissement, la solution est diluée avec de l'eau et concentrée sous vide. Le résidu est neutralisé avec du bicarbonate de sodium et extrait au dichlorométhane. Une purification par CPL (éluant dichlorométhane/acétate d'éthyle 50/50) fournit 0,22 g de **11**. Rdt 20%, cristaux oranges, *F* = 201°C; IR : 1639 (C=O), 1630 (ép, C=N), 1590 (C=C), 1223 (N → O) cm^{-1}; RMN ^1H ($CDCl_3$) : 2,60 (s, 3H, CH_3), 3,73 (s, 3H, NCH_3), 7,36–7,43 (m, 2H, H_6 et H_8), 7,62–7,71 (m, 1H, H_7), 8,46–8,51 (dd, 1H, H_5). Anal. calc. pour $C_{10}H_{10}F_3N_2O_2$: C 63,15, H 5,30, N 14,73; trouvée : C 62,98, H 5,14, N 14,63.

Remerciements

Les auteurs remercient A. Lopez (UPR CNRS 8221, Toulouse) pour la mesure des durées de vie de fluorescence, ainsi que le Centre National de la Recherche Scientifique et la Direction de la Recherche et des Études Doctorales pour leur soutien financier.

A mechanistic study of the carbocation route from tetrahydrodicyclopentadiene to the adamantane ring

ROGER P. KIRCHEN, TED S. SORENSEN,[1] AND STEVEN M. WHITWORTH
The Department of Chemistry, University of Calgary, Calgary, AB T2N 1N4, Canada

Received March 24, 1993

ROGER P. KIRCHEN, TED S. SORENSEN, and STEVEN M. WHITWORTH. Can. J. Chem. **71**, 2016 (1993).

The energy profile for the transformation of the *endo*-tetrahydrodicyclopentadienyl cation **A** into the 1-adamantyl cation **R** has been probed by means of six separate experiments employing superacid techniques. Of the approximately 14 cations between **A** and **R**, required as *intermediates* for the above transformation, it can be shown that only one of these is capable of direct observation. This cation, the tricyclo[5.2.1.$0^{3,8}$]dec-3-yl (homobrendyl) cation **J**, is characterized in detail in one of the six experiments. The rate of the rearrangement of **J** into the 1-adamantyl cation has been measured. Cation **J** also undergoes a degenerate rearrangement, the dynamics of which can be probed using NMR line-broadening and selective inversion–recovery experiments. The relationship between the *exo* and *endo* tetrahydrodicyclopentadienyl cations **D** and **A** has been studied. Only **A** is directly observable, even though in some experiments direct precursors of **D** were used as cation sources. Several experimental probes were made in an attempt to detect the presence of a small equilibrium concentration of **D**, without success, and a rationale is provided for the much greater stability of **A** vs. **D**. The remaining four experiments involved the addition of neutral precursors to superacid solutions, but the initially formed (expected) cations could not be observed, only cations **A**, **J**, or **R** being observed instead. These "partitioning"-type experiments prove whether the corresponding left-hand or right-hand transition-state barriers are the lower in energy. In the case of starting with transient cation intermediate **E**, only observable cation **J** is obtained, showing that the barrier between **B** and **E** is the high point on the overall carbocation reaction profile.

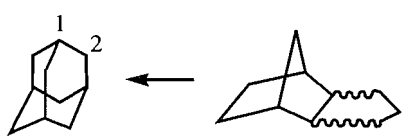
ROGER P. KIRCHEN, TED S. SORENSEN et STEVEN M. WHITWORTH. Can. J. Chem. **71**, 2016 (1993).

En se basant sur six expériences séparées faisant appel à des techniques de superacide, on a étudié le profil d'énergie de la transformation du cation *endo*-tétrahydrodicyclopentadiényle **A** en cation 1-adamantyle **R**. Des 14 cations requis comme intermédiaires pour la transformation de **A** en **R**, on peut montrer qu'un seul peut être observé directement. On a caractérisé en détail ce cation, **J**, le cation tricyclo[5.2.1.$0^{3,8}$]déc-3-yle (homobrendyle), au cours de l'une des six expériences. On a mesuré la vitesse de réarrangement du cation **J** en cation 1-adamantyle. Le cation **J** subit aussi un réarrangement dégénéré dont on a examiné la dynamique par des expériences d'élargissement des raies de RMN et par récupération d'inversion sélective. On a étudié la relation entre les cations *exo* et *endo* tétrahydrodicyclopentadiényles **D** et **A**. Seul le cation **A** peut être observé directement, même si dans quelques expériences on a utilisé des précurseurs directs de **D** comme sources. Dans le but de détecter la présence d'un faible quantité de **D** à équilibre, on a développé sans succès plusieurs sondes expérimentales; on présente une rationalisation de la stabilité beaucoup plus grande de **A** par rapport à **D**. Les quatre dernières expériences impliquent l'addition de précurseurs neutres à des solutions de superacides; lorsque les cations formés (attendus) initialement n'ont pu être observés, seuls les cations **A**, **J** ou **R** ont été observés. Ces expériences de «partition» ont permis de déterminer si les barrières «gauche» ou «droite» correspondantes sont d'énergie plus basse. Dans le cas où le cation transitoire intermédiaire est le **E**, le seul cation observable est le **J**; ce résultat démontre que la barrière entre les cations **B** et **E** est un maximum sur le profil réactionnel global du carbocation.

[Traduit par la rédaction]

Introduction

Adamantane **1** is produced commercially by the rearrangement of tetrahydrodicyclopentadiene **2** using strong Lewis acid catalysts and a hydride transfer initiator. The reactive intermediates in this process are carbocations, and the overall reaction is "driven" by the thermodynamic stability



1 **2**

of the adamantane ring. At any given time in the reaction process, *most of the organic material exists as neutral $C_{10}H_{16}$ hydrocarbons* and only a small proportion is in the form of $C_{10}H_{15}^{+}$ cations.

By way of contrast, one can also prepare the adamantane skeleton by converting all of the starting skeleton **2** to an observable carbocation, and this has also been shown to rearrange to the 1-adamantyl cation (1, 2). In this case, *almost all of the organic material exists as $C_{10}H_{15}^{+}$ carbocations*, with negligible amounts of neutral hydrocarbons present at any given time.

Because of these key characteristics, the above reactions exhibit different behavior, yet one knows that the underlying rearrangement mechanisms should be reasonably similar in each case. These differences can be summarized as follows:

1. Excluding three- and four-membered rings and other high-energy geometries,[2] there are a total of 19 neutral tri-

[2]The number of hydrocarbon skeletons included in "adamantaneland" involves some arbitrary decisions, since a theoretical connectivity surface for $C_{10}H_{16}$ contains several other skeletons, even excluding three- and four-membered rings. These systems all involve steric strain of variable severity ("inverted" bridgeheads, severe bond angle "distortions") and range from plausible synthetic possibilities to "impossible" structures.

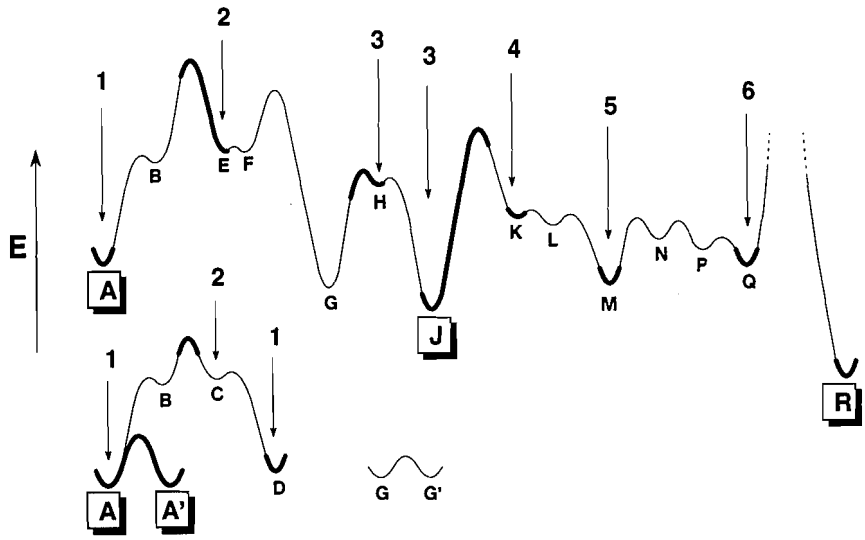

FIG. 1. Qualitative picture of the overall energy profile deduced for the rearrangement of the *endo*-tetrahydrodicyclopentadienyl cation **A** to the 1-adamantyl cation **R** (see Fig. 2 for the structures of the cations). The numbers 1–6 refer to individual experiments carried out in this work to probe various sections of the profile. Heavy lines indicate that either attempts were made to generate the cation concerned or that barriers for various transition states were determined (either directly or from closely related systems). Cations that can be directly observed are highlighted. In addition to our superacid work, several of the cationic transformations were previously probed by solvolysis studies, e.g., **H** → **J** and **P** → **Q**. The separate profile shown in the lower left involves a major diversion prior to the rate-determining step, including a degenerate rearrangement of **A** itself. A degenerate rearrangement of **G** is shown next to this (the barrier is based on a model system) because this is important in understanding how one can probe the profile in the **G**–**H**–**J** region. The **Q** → **R** transformation is an intermolecular process and the hypothetical intramolecular shift is known to be very high in energy (>25 kcal/mol), hence the open-ended profile.

cyclic $C_{10}H_{16}$ isomers (known as "adamantaneland"). All have now been synthesized, mainly through the recent efforts of Ganter and co-workers (3). Only seven of the hydrocarbons are considered to be on the most direct pathway from **2** to **1** (the Whitlock–Siefkin (W–S) mechanism) (4), although most of the others are also convertible to adamantane using acid catalysis. In all cases, those hydrocarbons considered as intermediates in the **2** → **1** reaction have been independently studied in the isomerization process (5) and the general outline of the W–S mechanism is firmly established.

2. In contrast to the rich chemistry of $C_{10}H_{16}$ neutral compounds, the carbocation from **2** rearranges to the 1-adamantyl cation with *no detectable intermediates*. Nevertheless, observable carbocation studies are inherently better for gauging the magnitude of transition-state barriers and other specifics of carbocation rearrangements and in this paper we have looked in detail at this carbocation route. From our work, it turns out that under the normal low-temperature methods used to prepare and study solution carbocations, *only one carbocation* (i.e., other than the tertiary carbocations from **1** or **2**) among the 14 or so intermediate carbocations that are part of the W–S mechanism is capable of direct observation.

This paper reports on the characterization and rearrangement behavior of this key species, on further attempts to form other observable carbocations that are on the W–S route, and on studies in which the partitioning reactions of high-energy transient carbocations are investigated. From this, and various older studies of simple 2-norbornyl cations, one can piece together a reasonably complete unified "picture" of the complex energy surface whereby the tertiary cation from **2** is transformed into the 1-adamantyl cation. With appropriate modifications, much of this work is directly relevant to the Lewis acid catalyzed rearrangement route and provides one with a more complete understanding of the process than is given by the more qualitative W–S mechanistic formulations.

Results and discussion

Figure 1 shows the overall energy profile for the rearrangement of cations **A** or **D** (from *endo*- or *exo*-**2**) into the 1-adamantyl cation **R** as determined in this work. The actual reaction scheme corresponding to this energy profile is shown in Fig. 2 and follows the general lines of the W–S mechanism, but is elaborated in considerably more detail. In Fig. 1, various parts of the overall profile are specifically identified by means of a heavy line and an accompanying arrow and number. These provide a point of reference for the six sets of experiments that were performed in this work in order to determine this data. In order not to clutter Fig. 1, no quantitative (ΔH-ΔG-ΔS) or ($\Delta H^{\neq}$, $\Delta G^{\neq}$, $\Delta S^{\neq}$) data are shown, but are provided when discussing each case.

The key new observable intermediate, mentioned in the Introduction, is **J**, the tricyclo[5.2.1.$0^{3,8}$]dec-3-yl (homobrendyl) cation,[3] and this cation, highlighted with a circle in Fig. 2, occupies a central position in the overall rearrangement. The *observable* cations **A**, **J**, and **R** (all tertiary carbocations) are indicated in Figs. 1 and 2 in accented type.

[3]The systematic name and numbering. For ease of description, the numbering scheme used for cations **A** and **J** in the following discussion is non-systematic and is based on the usual 2-norbornyl cation labelling scheme. The experimental description of the neutral precursors again uses systematic numbering.

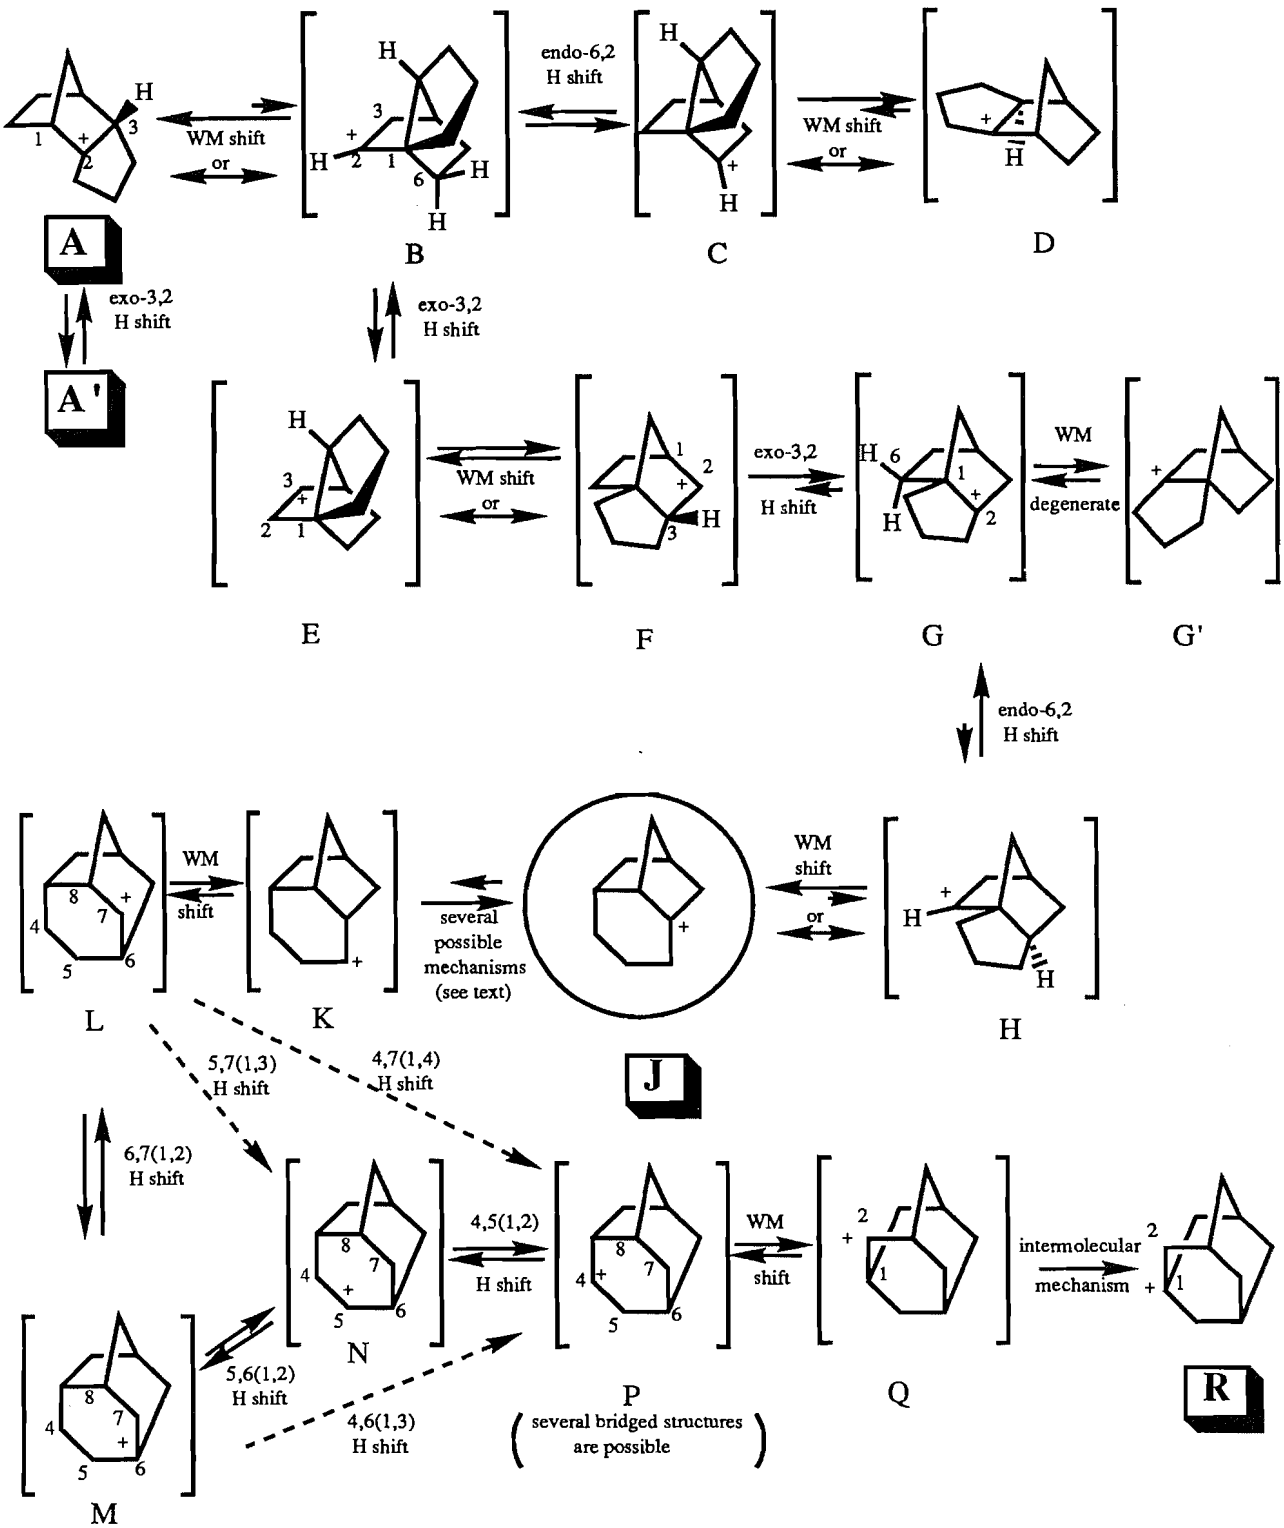

FIG. 2. Detailed reaction scheme corresponding to the energy profile shown in Fig. 1. As explained in the text, it is uncertain whether "pairs" of 2-norbornyl-type cations, e.g., **A**–**B**, **C**–**D**, **E**–**F**, **G**–**H**, separated by a "formal" C6—C1 → C6—C2 Wagner–Meerwein rearrangement are in fact distinct species, as defined in the context of existing for at least one vibration. The 7-protoadamantyl cation **L** may be a carbon-bridged species, as also may be the case for the 4-protoadamantyl cation **P** (see text). The three directly observable cations in this sequence are highlighted.

There are three other tertiary carbocations shown in Figs. 1 and 2, i.e., **D**, **G**, and **M**, but these turn out to be not directly observable, as we will show, because of a combination of unfavorable thermodynamics and low barriers connecting them to the more stable **A**, **J**, and **R**, respectively.

Each of the experimental regions 1–6, shown in Fig. 1, will now be treated in order.

Region 1 of Fig. 1

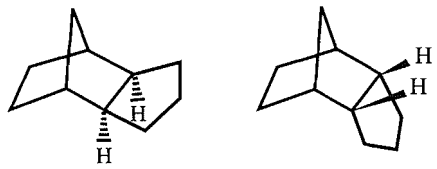
Cations **A** and **D** (Fig. 2) are tertiary 2-norbornyl cations, with an *endo* (**A**) or *exo* (**D**) trimethylene bridge. However, when one prepares cations from logical precursors of both **A** and **D**, only a single ion appears to be formed. This cation (the stereochemistry undefined) was originally prepared by Olah and co-workers in 1964 (1) and shown to rearrange to the 1-adamantyl cation **R**. In 1985, a full paper appeared (2), in which the cation was assigned the **A** structure. Our laboratory also studied this cation briefly a number of years ago (^{13}C NMR), but with recent advances in NMR spectroscopy we have now undertaken a more complete study.

Cation A

In Figs. 1 and 2, cation **A** is shown to be involved in three processes: (1) a degenerate rearrangement involving an *exo*-3,2-hydride shift, (2) an irreversible rearrangement to the 1-adamantyl cation, and (3) a reaction sequence shown as **A** $\rightleftarrows$ **[B]** $\rightleftarrows$ **[C]** $\rightleftarrows$ **D**, with transition states much lower than that for the rearrangement to the 1-adamantyl cation. The fact that organic precursors of **D**, when added to SbF_5–SO_2ClF at −135°C, produce only **A**, allows one to set a maximum possible lifetime ($t_{1/2}$) for **D** of ca. 20 min at −135°C (a generous estimate of the carbocation preparation time and time involved in the NMR measurement). Using the Eyring equation, this translates into a maximum possible $\Delta G^{\neq}$ of 10 kcal/mol for the barrier separating **A** and **D** (measured from the **D** side). This maximum $\Delta G^{\neq}$ estimate is reasonably in line with measured barriers of ca. 11 kcal/mol for this same overall rearrangement mechanism involving a number of different polymethyl-2-norbornyl cations (6). Since this **D** → **A** barrier is much lower than that for the 1-adamantyl cation formation from **A**, one expects to form an equilibrium mixture of the tertiary cations **A** and **D**. Since it was already apparent from the earlier NMR results that no detectable **D** was in fact present in these cation **A** solutions, the present study involved only a more stringent search for a small equilibrium population of **D** and a more complete characterization of the ^{1}H NMR spectrum of **A**.

The "ordinary" ^{13}C NMR spectrum of **A** at low temperatures (e.g., −100°C) shows no detectable peaks due to any other cation and, from S/N estimations, **D** cannot be present in amounts exceeding 2–3%. A search for a possibly even smaller equilibrium population of **D** was carried out in two ways: (1) a conventional NMR search employing high S/N conditions and (2) a search for possible line-broadening in the peaks of **A** that might be caused by the dynamic exchange of **A** with a small equilibrium population of **D** (7, 8). This latter experiment necessitates some estimate of the probable barrier so that one covers the appropriate temperature range, and based on the measured <10 kcal/mol (**D** → **A**), and values of 11 kcal/mol for model systems, we chose the range of 11–14 kcal/mol (**A** → **D**) as a reasonable estimate. In neither case could we obtain any evidence for the existence of **D**. One can put a lower limit on the possible equilibrium population of **D** using both methods, ca. 1% for method (1), at −100°C, $\Delta\Delta G > 3$ kcal/mol, and ca. 0.4% for method (2) at −20 to −60°C, $\Delta\Delta G > 2.5$ kcal/mol. In Fig. 1, much of the energy profile for the **A**–**B**–**C**–**D** interconversion is left as a light line to indicate that no quantitative data on barrier heights were directly obtained, but we emphasize that the overall mechanism shown in Fig. 2 has considerable precedent from the studies on methyl-substituted 2-norbornyl cations.

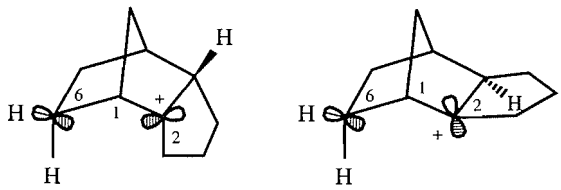
In the *exo* and *endo* hydrocarbons **2***a* and **2***b*, the *exo* isomer is actually the more stable (K = 100, $\Delta\Delta G$ = 2.7 kcal/mol, at 25°C) (5). Why then is the *exo* cation **D** so unstable relative to the *endo* cation **A**?



2a **2b**

Semi-empirical MO calculations (MNDO) provide no guide here. For the fully optimized structures, the calculated energies are ΔH = 202.1 kcal/mol for **D** and 203.0 for **A**, i.e., giving **D** > **A** in stability. The calculated **A**–**D** energy difference of 0.9 kcal/mol is thus in the same direction as that found for the hydrocarbons **2a** and **2b** and likely reflects some steric factor favoring the *exo* isomer in each case.

We believe that the greater stability of the *endo* isomer **A**(vs. **D**) is the result of a stabilizing "partial bridging" that is sterically much more favorable in **A**. This "partial bridging" has been observed in simple tertiary 2-methyl-2-norbornyl cations (6*a*) and others (9), and also shows up in the X-ray structure of a 1,2-dimethyl-2-norbornyl derivative (10). For our purposes, this partial C2–C6 bridging can be described as a "back-lobe" interaction of the C—*exo*-H6 bond with the carbocation *p*-orbital and, in the two ions **A** and **D**, the directionality of the C^+ orbital is likely to be much more favorable in the **A** case. This "back-lobe" interaction results in an abnormally low-field ^{1}H NMR shift for the *exo*-H6 proton, as shown in the ^{1}H data for a number of 2-methyl-2-norbornyl cations. The previously reported (1) ^{1}H NMR spectrum of **A** was not well resolved and the *exo*-H6 proton shift could not be identified. At 400 MHz, however, the cation **A** ^{1}H shifts are mostly assignable (Table 1), with the aid of a COSY spectrum, and in Table 2 we have collected the δ *exo*-H6 shifts for several of the model systems and for **A**, and there is a close similarity. It is unfortunate that the corresponding *exo*-H6 chemical shift for cation **D** has been impossible to obtain since one would expect a much higher field value. In conclusion, we suggest that the experimental >3 kcal/mol stability of **A** over **D** is mostly a result of this partial C2–C6 bridging delocalization.



A **D**

The degenerate *exo*-3,2-hydride shift observed in cation **A** (shown in Figs. 1 and 2) is essentially irrelevant to the 1-adamantyl cation rearrangement picture except for isotopic labelling schemes. Olah et al. obtained an estimate of $\Delta G^{\neq}$ = 7.2 kcal/mol for the barrier (2). Using ^{13}C NMR line-broadening data, and simulating this in the usual way, we obtained a similar value of $\Delta G^{\neq}$ = 7.2 kcal/mol, $\Delta H^{\neq}$ = 8 kcal/mol, $\Delta S^{\neq}$ = +3 eu. The ^{13}C NMR assignments are

listed in Table 3. The *exo*-3,2-hydride shift barrier found for **A** is similar to that observed in other tertiary 2-norbornyl cations (6*c*, 11).

Finally,the rate for the cation **A** → **R** rearrangement was measured at 20°C by conventional kinetic methods (monitoring by ^{1}H NMR spectroscopy) using 1:1 SbF_5–FSO_3H solution. The reaction follows simple first-order kinetics, giving $\Delta G^{\neq}$ = 22 ± 1 kcal/mol. This value is consistent with qualitative data obtained by Olah et al., but differs from another measurement made in sulfur dioxide solvent in being somewhat larger (1). The magnitude of this barrier, as previously mentioned, makes the **A**–**B**–**C**–**D** group, with mutual interconnecting barriers half this size, completely able to equilibrate before conversion to the 1-adamantyl cation **R**. A similar kinetic result is found in the Lewis acid catalyzed rearrangements, although in this case, as previously mentioned, the *endo* hydrocarbon **2***b* is initially converted almost completely to the *exo* isomer **2***a*, i.e., completely opposite to the cation behavior.

The measured barrier of 22 ± 1 kcal/mol is obviously the highest point in the overall energy profile from **A** to **R**, but it tells one very little about the actual position of this barrier since one has numerous transition states spanning this structural change. The next experiment, however, clears up this point.

Region 2 of Fig. 1

The formulation of the secondary cations **E** and **F** (Fig. 2) as distinct species is questionable since the evidence is now overwhelming that the 2-norbornyl cation itself is a symmetrically bridged structure (single minimum) (12). However, this need not absolutely be the case for **E** and **F** since no natural symmetry exists in these cations, and Bentley et al. have described an example where a secondary 2-norbornyl cation was not symmetrical (13). To leave the matter open, we show a very small barrier between **E** and **F** (a somewhat similar problem ensues when considering cations such as **A** and **B** (or **C** and **D**), where it is also possible that **B** or **C** do not represent energy minima, although MINDO/3 and MNDO optimizations of these do not "fall-back" to the tertiary ions).

The tricyclic hydrocarbon corresponding to cations **B**, **C**, or **E** has been synthesized by Holm and co-workers (15), Jäggi and Ganter (3*d*), and Tobe et al. (16*a*). A small sam-

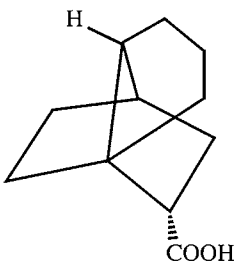
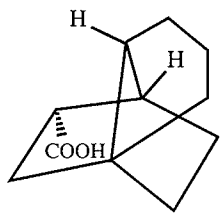
ple of a mixture of the isomeric acids **3***a* and **3***b* in a ca. 2:1 ratio was made available to us. The mixture was converted to the corresponding chlorides using a modified Hunsdiecker



3a



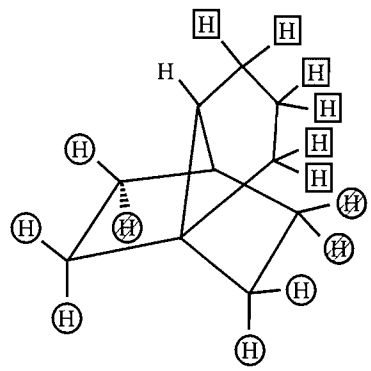
3b

reaction. On treatment with SbF_5 in SO_2ClF at −135°C, these two chlorides should lead to the instantaneous production of cations **C** and **E**, respectively (see Figs. 1 and 2). In fact, cations **A** and **J** (see subsequent discussion) were the products observed and were produced in the same ratios as present in the chloride precursors, i.e., transient ion **C** → **A** and transient ion **E** → **J**. Given the previous discussion concerning the Region 1 experiment, the transformation **C** → **A** is anticipated, even though **D** is the first tertiary ion that one would expect to produce.

More significant is the observation that **E** is transformed into cation **J**. From the non-observation of **E** under these low-temperature conditions, the barrier for **E** → **J** is placed at <11 kcal/mol. Also, since **E** does *not go backwards* to **A**, the overall barrier for the **A** → **R** reaction is established as the barrier immediately to the left of **E**, i.e., the *exo*-3,2-hydride shift. This barrier from **A** actually consists of two parts, a ΔG contribution for a secondary-tertiary cation energy difference and a $\Delta G^{\neq}$ component for the *exo*-3,2-hydride shift. The measured $\Delta G^{\neq}$ for **A** → **R** (see previous section) is 22±1 kcal/mol. An independent estimate for $\Delta G^{\neq}$ for the 3,2-hydride shift in 2-norbornyl cation is ca. 11 kcal/mol (14), leaving 11 kcal/mol for the energy difference between **A** and **B**. The latter seems a little large, so it is probable that the former is somewhat larger than 11 kcal/mol.

To summarize to this point, starting with cation **A**: (1) the degenerate rearrangement to **A** is very fast ($\Delta G^{\neq}$ = 7.2 kcal/mol) but somewhat irrelevant; (2) an **A** ⇄ **D** equilibrium must exist, but the low population of **D** precludes any direct detection of **D**; (3) the overall rearrangement barrier for **A** → **R** involves a combined ΔG value from **A** ⇄ [**B**] and a $\Delta G^{\neq}$ contribution for [**B**] → [**E**].

Schleyer et al. (15) have previously shown that hydrocarbon **4** occupies a pivotal dividing point for the neutral hydrocarbon studies, i.e., **4** gives both **2** and **1** using Lewis acid catalysis, together with at least one other "adamantane-land" hydrocarbon. One can be specific about why **4** occupies this "watershed" position in the acid-catalysis process, i.e., hydride abstractions from ○ hydrogens in structure **4** will ultimately give **2**, while those from ⊘ will ultimately produce **1**. Also, as originally postulated by Schleyer et al., abstraction of □ hydrogens could be responsible for an



4

"aberrant" pathway. This has been confirmed by Ghatak and Ganter, using functionalized derivatives (16*b*). Formation of this "aberrant" cation by a cation–cation rearrangement (i.e., an intramolecular hydride shift) is a less likely process, and this illustrates why the overall rearrangement is a simpler process at the "observable" carbocation level.

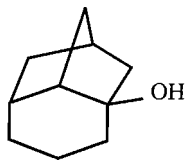
Region 3 of Fig. 1

The very low temperature formation of **J** from **E** (previous section) implies that no "nearer" intermediates more stable than **J** are present in the system (see Fig. 1) and that all cation–cation transition state barriers between **E** and **J** are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

less than 11 kcal/mol. In particular, the tertiary carbocation **G** is a required part of the W–S mechanism and **G** precedes **J** in the overall carbocation progression. It is clear therefore that **G** is not observable under stable carbocation preparation and observation conditions. In this section we now look at cation **J** in detail. The initial impetus was to verify the structure of the then unknown ion produced from **E** (see previous section) and, secondly, to understand the nature of a degenerate rearrangement that was detected when we prepared an authentic sample of **J** and looked in detail at the NMR spectrum. It turns out that an understanding of this rearrangement ultimately allows for an exploration of the energy surface "backwards" from **J** to **G**.

Cation **J**, previously unreported, was prepared from the corresponding alcohol **5** and was characterized by both ^{13}C and ^{1}H NMR spectroscopy (Tables 1 and 3). A combination of 1D and 2D techniques allows one to assign all of the peaks (a necessity for understanding the degenerate rearrangement).

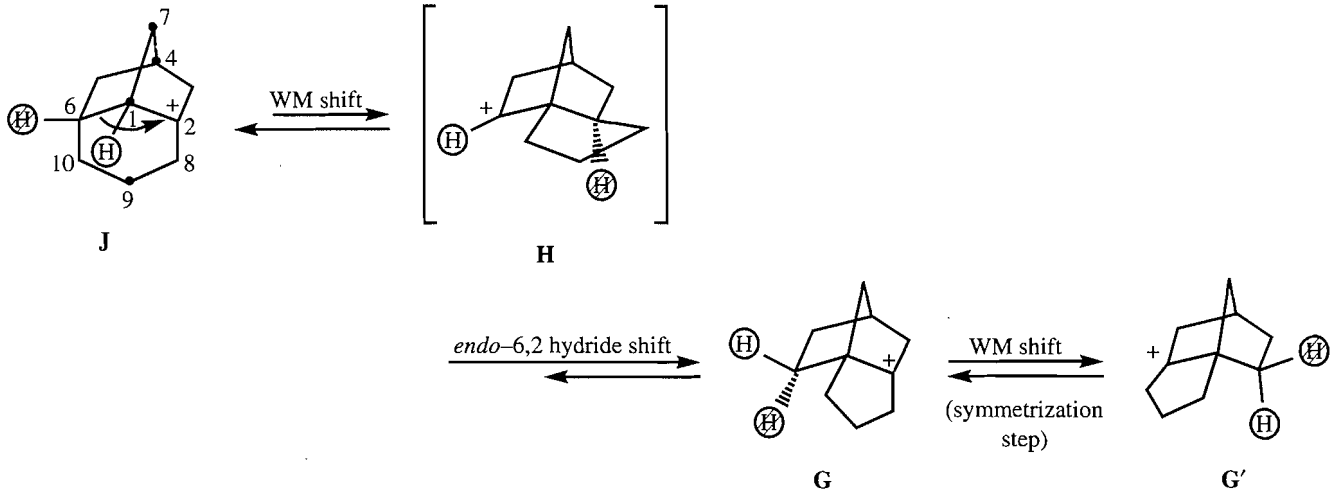


5

The degenerate rearrangement in **J** is characterized by a noticeable line-broadening of six of the ten ^{13}C peaks as one warms the cation solution to −40°C. This is the maximum temperature for which the ^{13}C data for **J** could be obtained because the irreversible rearrangement to the 1-adamantyl cation **R** is becoming fairly rapid at this temperature. The six peaks that are line-broadened are those shown in structure **J** *without* a dark circle. The line-broadening in **J** could be accounted for if the H6 proton were to reversibly migrate to C2 (see eq. [1]), but this seems a very unlikely process for steric reasons. Further insights were provided by looking at the ^{1}H 2-D NOESY exchange spectrum, where one sees qualitatively the exchange of H5*exo*–H3*exo*, H5*endo*–H3*endo*, and the H8–H10 protons. These results are expected based on the ^{13}C spectral observations, but there is also qualitative evidence from this NOESY spectrum for the *further exchange* of H6 and H1, i.e., a process *not* simply related to a symmetry plane through C4-C7-C1-C9, as shown in dark circles in structure **J** of eq. [1]. On the basis of the ^{13}C NMR line-broadening data, the rate of the symmetrization process can be determined by simulation of the experimental data in the usual way. The exchange of H1 and H6 was also quantified using spin-inversion transfer procedures. Since the chemical shift difference of these two protons is only 0.096 ppm, we used a 400 MHz field and a Dante pulse train (17) for the selective 180° pulse. A typical sequence is shown in Fig. 3, using varying delay times prior to the final "reading" pulse. Experiments in which both H1 and H6 were separately irradiated at a number of temperatures were carried out and analyzed to give both T_1 and the rate constants for the exchange process (18). Within experimental error, the latter values are the same as those obtained from the ^{13}C line-broadening results, $\Delta G^{\neq} = 12.5 \pm 0.5$ kcal/mol.

With reference to Figs. 1 and 2, the degenerate rearrangement observed in **J** can be uniquely rationalized by the following mechanism (eq. [1]):

[1]



J **H** **G** **G′**

As stated previously, the existence of secondary cations such as **H** is not proven, and the reaction could proceed from **J** to **G** by direct migration of H6 to H1. However, we will consider for this discussion that **H** occupies a shallow potential well minimum (see Fig. 1). The symmetrization process observed in the NMR spectrum of **J** actually takes place via a small equilibrium population of **G** (undetectable in a direct sense by NMR). The degenerate rearrangement **G** ⇄ **G′** exchanges the three pairs of carbons referred to previously and the H6 and H1 protons of **J** (which have transformed to H6 *exo* and *endo* (**G**-labelling) in the actual exchange process undergone by **G**). Based on the NMR S/N level observed for **J**, the maximum possible **G** population is 2%, giving ΔG (**J**–**G**) ⩾ 1.7 kcal/mol at −60°C. Cation **G** is closely related structurally to the well-known 1,2-dimethyl-2-norbornyl cation (19), for which both solvolysis data and observable ion measurements show a very small barrier for the degenerate WM shift ($\Delta G^{\neq} \leq 3$ kcal/mol). A similar small barrier has been incorporated into Fig. 1 for the **G** ⇄ **G′** process. It has also been shown in the Lewis acid

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12

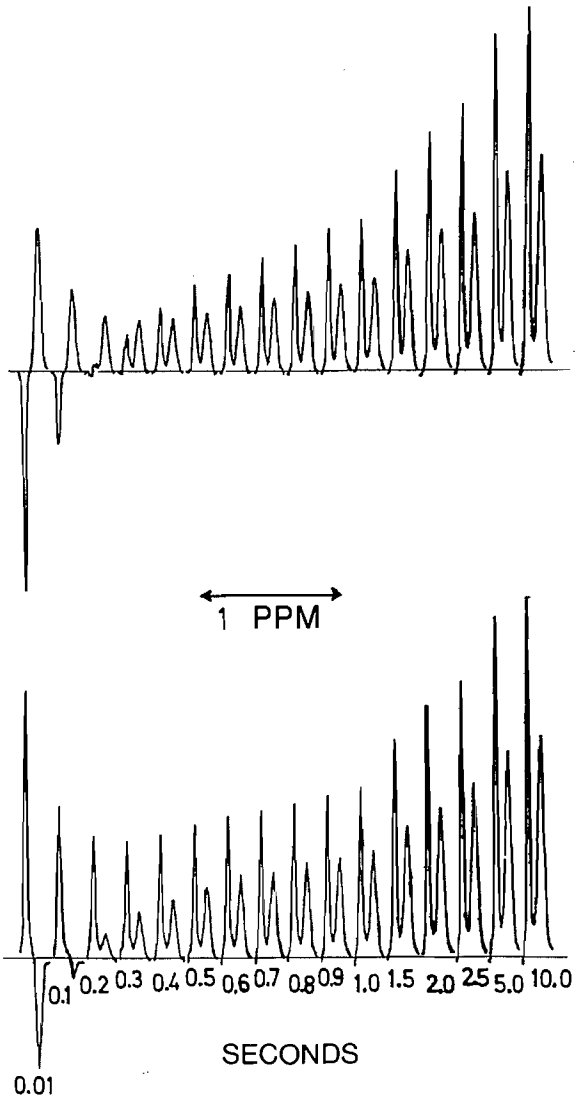

FIG. 3. The 400 MHz ^{1}H NMR spectra showing only the H1–H6 protons of cation **J**. Each of the 16 plots involves a different delay time in the spin inversion transfer experiment. The spectra illustrate the selectivity of the DANTE pulse since the two exchanging protons are separated by only 0.1 ppm. The solution temperature is 223 K.

catalyzed rearrangement of one of the hydrocarbons corresponding to **G**, using a ^{13}C labelled compound (20*a*) or with deuterated analogs involving both neutral **G** hydrocarbons (20*b,c,d*), that the degenerate **G** $\rightleftarrows$ **G′** process must take place here as well. Also relevant to this discussion is the fact that the **H** cation skeleton (as the alkene) is the synthetic precursor of the cation **J** skeleton (the alcohol **5**), via a facile acid-catalyzed rearrangement (21), thereby showing that the **H** $\rightarrow$ **J** barrier is also small.

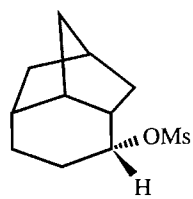
The rate of the irreversible rearrangement of **J** into **R** was obtained by conventional kinetic measurements using ^{13}C NMR peak areas. The reaction is first order and gives $\Delta G^{\neq} = 18 \pm 0.5$ kcal/mol.

All of these data are shown qualitatively in Fig. 1, but the experiments described here show that **G** is $\geqslant$1.7 kcal/mol less stable than **J**, the barrier from **G** to **J** is $\leq$11 kcal/mol (see previous data on Region 2 of Fig. 1), and the barrier from **J** to **G** is 12.5 kcal/mol (the degenerate rearrangement data on J). The difference between $\geqslant$11 kcal/mol and 12.5 kcal/mol, i.e., $\geqslant$1.5 kcal/mol for the **J–G** energy difference, is quite consistent with the independently determined $\geqslant$1.7 kcal/mol (see above). Finally, although **J** is structurally distant from **R**, the 18 kcal/mol barrier for this rearrangement occurs between **J** and **K**, as shown in the next section.

Before proceeding to this section, it is worth noting that cation **J** itself is of some interest. The low-field nature of H6 in the ^{1}H NMR spectrum suggests that the partial C2–C6 bonding, discussed earlier for **A**, is also present in **J**. It seems probable from the structure of **J** that the cation center would be substantially nonplanar, and MNDO calculations are in agreement with this assessment, the dihedral angles being about 160°. Interestingly, cation **J** was originally regarded by Whitlock and Siefkin as *the* high energy "bottle-neck" in the acid-catalyzed rearrangement of **1** to **2**, principally on the basis of the expected nonplanarity (and hence instability) of the C^+ center in **J**. Clearly this nonplanarity is not a particularly destabilizing effect. In particular, as we have shown, cation **J** is $\geqslant$1.7 kcal/mol more stable than **G**, even though the calculated (MNDO) C^+ dihedral angles in **G** are much closer to a planar structure (average dihedral angles of ca. 173°). However, like the semi-empirical computations involving cations **A** and **D**, those involving **G** and **J** are at odds with the experimental energies, $\Delta\Delta E_{\text{calc. MNDO}}$ **G** > **J** by 4.5 kcal/mol, $\Delta\Delta G_{\text{exp.}}$ **J** > **G** by $\geqslant$1.7 kcal/mol, so the calculated geometries of **G** and **J** should be regarded with some suspicion. Elegant studies by Ganter and co-workers (20*b,c,d*) have shown that the neutral hydrocarbon of **J** is more stable than either of the hydrocarbons related to **G**.

Region 4 of Fig. 1

Cation **J** is still some structural "distance" from **R** and is confronted at one stage in the pathway by a relatively high barrier of 18 kcal/mol (previous section). We suspected that this barrier probably involved the transformation of **J** into **K**, and this was confirmed by starting with the mesylate **6**, a logical precursor of **K**, which on addition to 1:1 FSO_3H–SbF_5 in SO_2ClF at −100°C gives only the 1-adamantyl cation **R**; i.e., **K** is on the other side of the 18 kcal/mol barrier. It is not entirely clear how one proceeds from **J** to **K**



6

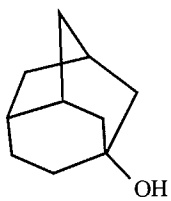
since the direct 1,2-hydride shift suffers from a poor overlap angle between either of the two possible migrating methylene protons (circled in **J**, below) and the C^+ center. An alternative to a direct shift could proceed by way of two separate steps, an *exo*-1,2-hydride shift from the other side of the cation, followed by a 1,3-hydride shift, as shown in eq. [2] (the number description of hydride shifts is generic and does not refer to the actual carbon–hydrogen skeletons involved):

[2] 
J H K

The observed barrier of 18 kcal/mol for **J** → [**K**] is actually only about 2–4 kcal/mol larger than that observed for a number of other carbocation transformations where a stable tertiary species proceeds to a secondary carbocation intermediate via a 1,2-hydride shift; for example, the transformation of the 1-ethylcyclopentyl cation to the 1-methylcyclohexyl cation involves a barrier of 15.4 kcal/mol (22). In this model case the 1,2-hydride shift presumably involves a favorable overlap angle, so, for the **J** → [**K**] case, the somewhat larger $\Delta G^{\neq}$ value is consistent with either a more difficult direct 1,2-hydride shift or the combination of a 1,2 and 1,3-hydride shift as shown in eq. [2]. However, for simplicity we have shown the transformation in Fig. 1 as a direct 1,2-hydride shift.

Region 5 of Fig. 1

The previous experiment shows that there are no barriers greater than ca. 11 kcal/mol, between cations **K** and **R**, i.e., no other cations than **R** are observed when the transient **K** is produced at −100°C. The step between **K** and **L** (Fig. 1) is a Wagner–Meerwein shift between secondary cations and is expected to have a very small barrier. Cation **L** is the 7-protoadamantyl skeleton but, in order to reach **R**, the 4-protoadamantyl cation **P** is a required intermediate. A direct 1,4-hydride shift could conceivably be involved in this process, i.e., **L** → **P**, in which case the tertiary 6-protoadamantyl cation **M** need not be involved. If this were so, it seemed possible that the 6-protoadamantyl cation (coincidentally the most stable of the tertiary protoadamantyl cations) (23) might be experimentally observable as a non-direct-pathway species. However, addition of the alcohol **7** to 1:1 FSO_3H–SbF_5 in SO_2ClF at −100°C yields only the 1-adamantyl cation **R**. Since the hydride shift connecting **L** to **M** is favorably aligned, and since 1,2-hydride shifts generally have lower barriers than 1,3- or 1,4-shifts, it therefore seems very probable that **M** would lie on the direct path from **A** to **R**.



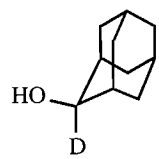
7

The conversion of **M** to **P** can again be a direct process (a 1,3-hydride shift) or it might involve the 5-protoadamantyl cation **N** if two 1,2-hydride shifts were involved. We have no direct evidence on this point, although the latter may be a lower energy pathway, given that 1,3-hydride shifts generally have a somewhat higher barrier than 1,2-shifts. Both possibilities are presented in Fig. 2, while Fig. 1 for simplicity shows only the 1,2-hydride shift pathways. Any attempts to generate transient cations **L**, **N**, or **P** would be uninformative since one already knows that no observable ions, save **R**, will be produced. However, some deuterium-labelled versions of these cations would offer useful information; for example, a transiently produced 6-deutero-**L** cation might allow one to distinguish between a 1,2-hydride shift mechanism, giving a transient **M**, and those involving a direct 1,3- or 1,4-hydride shift. In Fig. 1, all 1,2-hydride shifts involving secondary cations **L** or **N** are shown with very low barriers, since model systems like the cyclopentyl cation have, experimentally (24), very low 1,2-hydride shift barriers, ≤3 kcal/mol.

Region 6 of Fig. 1

Solvolysis work on the 4-protoadamantyl system shows that cations **P** and **Q** are connected by a very low barrier (a Wagner–Meerwein shift) (25). *Ab initio* calculations are also consistent with this conclusion (26).

The conversion of the secondary adamantyl cation **Q** to the tertiary cation **R**, the final product, is known to involve intermolecular hydride shifts (27) and, at least in sulfuric acid carbonylation studies (28), the rearrangement is clearly a second-order rate process. We have had an ongoing interest in characterizing the 2-adamantyl cation **P** as an observable species. One approach has involved an attempt to prepare very dilute solutions of the cation at very low temperatures in the hope that bimolecular processes could be slowed down to such an extent that one might be able to observe **P** by NMR spectroscopy. However, even at a projected 10 μg **Q**/0.5 mL (1.5×10^{-4} M) solution level, the NMR spectra at −120°C show only the 1-adamantyl cation **R**. In other studies, 2-deuteroadamantan-2-ol **8** was used as a potential precursor to **Q**. In 1:1 FSO_3H–SbF_5/SO_2ClF, the alcohol is protonated at low temperatures and only slowly solvolyzes to the



8

cation (hence low initial concentrations of **Q** would be expected). However, the 1-adamantyl cation **R** is still the only simple carbocation observed, although at intermediate times in the reaction there is a clear indication in the ^1H and ^2H NMR spectra for the presence of mono-functionalized 1-adamantyl cation peaks, which we believe are formed from a hydride transfer to a transient 2-adamantyl cation from a tertiary C-H position in the starting protonated alcohol. This mono-functionalized carbocation can then rereact with the

just-formed adamantane to form the 1-adamantyl cation **R** and regenerate the protonated alcohol; i.e., the latter acts as a chain hydride transfer agent. Alternatively, the adamantane can serve as a hydride transfer chain carrier by itself reacting with the transient 2-adamantyl cation. Whitlock and Siefkin even reported (4) that preformed 1-adamantyl cations will undergo subsequent intermolecular hydride transfer.

All rearrangement steps up to **Q** in Figs. 1 and 2 have been regarded as unimolecular transformations. However, in light of the bimolecular [**Q**] → **R** rearrangement, is this justified? The overall barrier for **A** → **R** and the subsidiary **J** → **R** both appear to follow first-order kinetics and the rate is not noticeably concentration dependent. Thus, these barriers themselves do not involve bimolecular reactions. Furthermore, in many studies of rearrangements in tertiary 2-norbornyl cations, bimolecular reactions have not been observed, and cations **A–B–C–D–E–F–G–H–I–J–K** in Figs. 1 and 2 all have this ring system in part. In fact, it is quite possible that the adamantane ring skeleton is an unique system in allowing bimolecular hydride transfers. For example, the Whitlock–Siefkin work involving hydride transfers in preformed 1-adamantyl cation is most easily explained if one postulates the existence of transient adamantane dications. Of all the ring systems in Figs. 1 and 2, the adamantane skeleton would appear to be the most feasible, and perhaps only, candidate for a reasonably low energy (di-tertiary) dication intermediate.

Comparison of the cation–cation route with the Lewis acid catalysis route

The W–S mechanism is divisible into two kinds of carbocation rearrangement steps: (1) those involving WM shifts which interconvert members of "adamantaneland" and (2) those that involve "moving" the C^+ center from one position to another within a given skeleton.

In terms of Figs. 1 and 2, the transformations **B–C**, **B–E**, **F–G–H**, **J–K**, **L–M–N–P**, and **Q–R** are in the latter category, while **A–B**, **C–D**, **E–F**, **H–J**, **K–L**, and **P–Q** are in the former. Category 1 steps are not likely to be much affected by reaction conditions, whereas those in category 2 most certainly are. In the Lewis acid catalyzed reactions it seems likely that virtually all of the category 2 steps will involve *intermolecular hydride transfers*, particularly if this process can circumvent a "difficult" unimolecular process, whereas for the cations, as previously mentioned, only the **Q–R** transformation appears to be bimolecular. An examination of Figs. 1 and 2 shows that the cation–cation barriers for **A** → **R** or **J** → **R** do indeed involve several difficult unimolecular hydride shifts, e.g., **B** → **E** or **J** → **K**, which can thus be short-circuited in the Lewis acid catalysis route. On the surface, it might appear somewhat remarkable that the Lewis acid catalyzed formation of adamantane from tetrahydrodicyclopentadiene is about as fast as, or even faster than, the carbocation route, but one can now see the reasons for this.

A second distinction between carbocation studies and the Lewis acid catalyzed rearrangements involves secondary and tertiary carbocations. Since these are very different in energy, we cannot hope to directly observe those hydrocarbon skeletons with a secondary carbocation functionality. As it turns out, of course, we do not even directly observe several of the tertiary carbocation systems either. With neutral hydrocarbons, differences in stability between various "adamantaneland" skeletons is the determining factor, and since these involve reasonably small energy differences, one expects to pick up the appearance of many more of the rearrangement intermediates in such reactions.

Conclusions

For the rearrangement of the observable *endo*-tetrahydrodicyclopentadiene cation **A** into the observable 1-adamantyl cation **R**, the reaction mechanism energy profile has been mapped out for much of the route. A new cationic intermediate has been found and it is also shown that the three other tertiary cations on or near the rearrangement route are not observable under superacid conditions. In fact no other ions in the whole rearrangement pathway will be observable under the present preparation techniques (even in the whole "adamantaneland", there may be no further observable cations (29)). The highest barrier occurs early in the overall reaction and the experimental $\Delta G^{\neq}$ value for this can be correlated with values for the combined secondary–tertiary energy difference in 2-norbornyl cations and the transition state for an *exo*-3,2-hydride shift.

Experimental

NMR spectra were obtained on a Bruker WH-90, AM-400, or on a Varian XL-200 spectrometer. Deuterochloroform was used as a solvent for all neutral compounds. Carbon multiplicities were determined by off-resonance decoupling or by DEPT-90 and 135 sequences. Carbocation preparations for NMR measurement purposes were made up directly in the NMR tube. Several procedures were used: (*a*) for work on the WH-90 spectrometer, 10-mm tubes were used, and a small volume of $CFCl_3$ was used to dissolve the organic precursor prior to the addition to the acid solution. The ^{19}F peak of SO_2ClF was used as the lock and $^{13}CFCl_3$ was used as the internal reference, δ = 117.9; (*b*) for work on the XL-200 or AM-400 spectrometers, a small volume of CD_2Cl_2 was used as organic solvent and as a ^2H lock. Spectra were referenced relative to $^{13}CD_2Cl_2$ = δ 53.8. Proton (^1H) NMR spectra were run using the latter procedure, where the internal $CHDCl_2$ reference was taken as δ 5.32. The inversion-transfer experiments were performed at 400 MHz using 16 delay times for each run, as illustrated in Fig. 3. The kinetic analysis for this process is given in ref. 30. HETCOR, COSY, NOESY, and INADEQUATE spectra were obtained at 400 MHz. Semi-empirical molecular orbital calculations were carried out at the MINDO/3 or MNDO level with full optimization of all geometric parameters (31).

8-exo-*Hydroxy*-exo-*tricyclo[5.2.1.0^{2,6}]decane* (32), *8*-endo-*hydroxy*-exo-*tricyclo[5.2.1.0^{2,6}]decane* (33), and *8*-exo-*chloro*-exo-*tricyclo[5.2.1.0^{2,6}]decane* (34) were prepared as described in the literature.

2-exo-*Hydroxy*-endo-*tricyclo[5.2.1.0^{2,6}]decane* and 2-endo-*hydroxy*-exo-*tricyclo[5.2.1.0^{2,6}]decane* were prepared as described by Takaishi et al. (35).

Identification of cation A by quenching

8-exo-Chloro-*exo*-tricyclo[5.2.1.0^{2,6}]decane (10.7 mg) in 50 μL of CD_2Cl_2 was added to 0.5 mL of a 1:4 mixture of FSO_3H–SbF_5 in SO_2ClF, contained in a 5-mm NMR tube, at −78°C and with stirring. After verifying the presence of cation **A**, the cold solution (−78°C) was quenched by cautiously pouring it into ambient aqueous K_2CO_3 with stirring (fumehood). The aqueous solution was extracted with ether; dried, and, after ether removal, the residue was taken up in a small volume of methylene chloride, filtered through a pad of silica gel, and the solvent removed. A comparison of GLC retention times and ^1H NMR spectra with authentic material confirmed the quench product as 2-*exo*-hydroxy-*endo*-tricyclo-[5.2.1.0^{2,6}]decane.

Attempts to prepare cation ***D***

Both 8-*exo*-chloro-*exo*-tricyclo[5.2.1.$0^{2,6}$]decane and 2-*endo*-hydroxy-*exo*-tricyclo-[5.2.1.$0^{2,6}$]decane were used as organic precursors. The former is expected to rapidly rearrange to the tertiary cation system by way of an *endo*-6,2-hydride shift, and one would therefore initially expect **D** to be formed. From the alcohol, **D** should be formed directly. In both cases, carbocation preparation and measurement were carried out at ca. −135°C, but the ^{1}H NMR spectra failed to show any peaks other than those for cation **A**.

Mixture of endo-*7-chloro- and* endo-*9-chlorotricyclo[4.2.2.*$0^{1,6}$*]decane*

A small sample of the mixed *endo*-carboxylic acids **3***a* and **3***b* was a gift from K. Holm and L. Skattebøl, University of Oslo, Norway (15). Initially it was believed that the two acids were the *endo*-7 and *exo*-7 isomers, and so this mixture was converted to what was expected to be the *endo*- and *exo*-7 chloro derivative. However, the acid is actually a mixture of the *endo*-7 (**3***b*) and *endo*-9 (**3***a*) isomers and so the chlorides were later reassigned the title structures. To a solution of 0.697 g (0.39 mmol) of the mixed acid and 2.46 g (1.84 mmol) of *N*-chlorosuccinimide in 3 mL of a 3:1 mixture of DMF and glacial acetic acid, and under an argon atmosphere, was added 1.65 g (0.62 mmol) of lead tetraacetate (36). Provision was made for monitoring evolved gas volumes and the mixture was slowly heated with an oil bath. At ca. 55°C, the reaction was strongly initiated and gas evolution (180 mL) was complete after 3 min. The semisolid mixture was extracted twice with pentane, water was added to dissolve the precipitate, and the aqueous mixture was extracted twice with pentane. The combined pentane extracts were washed successively with dilute perchloric acid, sodium carbonate solution, and water, dried over $MgSO_4$, and most of the pentane removed. Column chromatography on neutral alumina, activity 1, using a pentane eluent led to the isolation of several fractions of a mixture of two chlorides with resolved GLC peaks. Distinctive ^{1}H NMR peaks were observed at δ 4.18 and 4.26 (both broad doublets, *J* ca. 4 Hz). For the carbocation work, a fraction containing a 3:2 ratio of the two chlorides was used, along with a preparation temperature of ca. −135°C (using SbF_5 in 3:1 SO_2ClF–SO_2F_2). One sees only cations **A** and **J**, in a ca. 3:2 ratio. The 9-chloro isomer is expected to initially form tertiary cation **D**, so this experiment represents a third precursor of **D** that fails to give this cation.

Tricyclo[5.2.1.$0^{3,8}$*]decan-3-ol* was prepared as described by Corey and Glass (21). A definitive assignment of all of the ^{13}C peaks was desired as an aid in characterizing the corresponding cation **J**. To unambiguously assign these, a 2D ^{13}C INADEQUATE spectrum was obtained. ^{1}H NMR, δ: 2.21 (bs, H1), 2.13 (m, H7), 1.70 (d, *J* = 4, H8), 1.73–1.83 (2H, H9 and H4). 1.65–1.3 (complex, 9H), 1.22 (d, *J* = 9.5, H9), 0.84 (d, m, *J* = 12, H10 *endo*). ^{13}C NMR, δ: 37.0 (C1), 44.7 (C2), 77.0 (C3), 35.8 (C4), 18.5 (C5), 26.3 (C6), 34.0 (C7), 49.9 (C8), 39.6 (C9), 31.3 (C10).

Tricyclo[5.2.1.$0^{3,8}$*]decan-4-one* and *tricyclo[5.2.1.*$0^{4,8}$*]decan-3-one* were prepared as a mixture, as described (37) by Majerski and Janjatovic and were separated by preparative HPLC. The first-named ketone was reduced with lithium aluminum hydride to a single oily alcohol, *tricyclo[5.2.1.*$0^{3,8}$*]decan-4-ol*, most probably of the 1*R**3*R**4*S**7*S**8*R** stereochemistry. ^{1}H NMR, δ: 3.6–3.8 (m, 1H), remaining peaks from 2.3–0.8, including a fully resolved peak at 0.88 (d, t, *J* = 12, 3, 1H). ^{13}C NMR, δ: 70.5 (CH), 42.6 (CH), 41.7 (CH), 40.8 (CH_2), 36.7 (CH), 33.6 (CH_2), 32.7 (CH), 28.8 (CH_2), 25.8 (CH_2), 23.6 (CH_2). The crude alcohol was converted to the *mesylate*, ^{1}H NMR, δ: 4.82 (m, 1H), 2.98 (s, 3H), 2.42 (m, 1H), 2.20 (m, 1H), 2.04 (m, 1H), 1.96 (m, 1H), 1.2–1.9 (complex), 0.94 (d, *J* = 12, 1H). ^{13}C NMR, δ: 83.2 (CH), 43.0 (CH), 40.9 (CH_2), 39.6 (CH), 38.7 (CH_3), 36.8 (CH), 33.4 (CH_2), 32.2 (CH), 29.6 (CH_2), 25.6 (CH_2), 21.5 (CH_2). Addition of the mesylate to 1:1 FSO_3H–SbF_5 in SO_2ClF at −100°C yielded only the 1-adamantyl cation **R**.

Tricyclo[4.3.1.$0^{3,8}$*]decan-6-ol* was prepared as described (38), ^{13}C NMR, δ: 71.3 (q), 48.1 (CH_2), 41.2 (CH_2), 41.0 (CH_2), 36.6 (CH_2), 36.4 (CH_2), 35.9 (CH), 34.9 (CH), 33.3 (CH), 24.2 (CH_2). Addition of the alcohol to 1:1 FSO_3H–SbF_5 in SO_2ClF at −100°C yielded only the 1-adamantyl cation **R**.

Tricyclo[3.3.1.$1^{3,7}$*]decan-2-ol-2*-d was prepared by reducing the ketone with $LiAlD_4$.

Acknowledgements

We thank Christian Falkenberg-Anderson and Susan Ranson for help in some of the synthetic work. We are grateful to Professor L. Skattebøl and Dr. K. Holm, University of Oslo, Norway, for a small sample of the mixed acids **3***a* and **3***b*. The Natural Sciences and Engineering Research Council of Canada is thanked for the generous funding of this research.

DANYA YANG, THOMAS EGGIMANN, HAL WIESER, ARVI RAUK, and GENNADII SHUSTOV. Can. J. Chem. **71**, 2028 (1993).

The vibrational circular dichroism (VCD) spectra of 2,3-dimethylaziridine **1** and 1,2-dimethylaziridine **2** were measured experimentally and interpreted with the help of *ab initio* Vibronic Coupling Theory (VCT) both in the common origin (CO) and distributed origin (DO) gauge. The absolute magnitudes of the VCD intensities by the VCT-CO method in the mid-IR range are closer to the experimental measurement. Both VCT-DO and VCT-CO methods, however, predict the same signs for almost all VCD bands. In general, both VCT-DO and VCT-CO methods predict VCD and IR spectra that are both in good agreement with the experimental spectra. The VCT method together with the 6-31G*$^{(0.3)}$ basis set can be employed with confidence in determining the absolute configuration of a chiral molecule. The theoretical and experimental VCD spectra of **1** and **2** were compared with the VCD spectra of the isostructural 2,3-dimethyloxirane and -thiirane. One of the Me rocking motions, in the wave number range 1050–1150 cm^{-1}, was found to serve as a possible marker for the stereochemistry of the molecular skeleton. Two other modes were identified whose Cotton effects (CEs) are characteristic of the *local* asymmetry, and for which chirality rules were proposed. The first is a methyne vibration, ‖CH, which is expected to have a (−) CE at a three-ring centre with (*R*) absolute configuration. The second is an umbrella motion of a methyl group, which is expected to have a (+) CE when attached to a three-ring centre with (*R*) absolute configuration.

DANYA YANG, THOMAS EGGIMANN, HAL WIESER, ARVI RAUK et GENNADII SHUSTOV. Can. J. Chem. **71**, 2028 (1993).

On a déterminé les spectres VCD expérimentaux des 2,3-diméthylaziridine (**1**) et 1,2-diméthylaziridine (**2**) et on les a interprétés à l'aide de la théorie *ab initio* du couplage vibronique (VCT) avec origine commune (CO) ou distribution d'origine (DO). Les amplitudes absolues des intensités des spectres VCD obtenues par la méthode VCT-DO pour la plage de l'infrarouge moyen se rapprochent le plus des valeurs expérimentales. Toutefois, les deux méthodes, VCT-DO et VCT-CO, prédisent les mêmes signes pour toutes les bandes VCD. En général, les méthodes VCT-DO et VCT-CO prédisent des spectres IR et VCD qui sont en accord avec les données expérimentales. On peut donc utiliser en toute confiance la méthode VCD de concert avec un ensemble 6-31G*$^{(0.3)}$ pour déterminer la configuration absolue d'une molécule chirale. On a comparé les spectres VCD expérimentaux et théoriques des composés **1** et **2** avec le spectre VCD des 2,3-diméthyloxirane et -thiirane isostructurales. On a trouvé que l'un des mouvements de balancement du méthyle, dans la région de nombre d'onde de 1050 à 1150 cm^{-1} peut éventuellement servir de marqueur pour la stéréochimie du squelette moléculaire. On a aussi identifié deux autres modes dont les effets Cotton (EC) sont caractéristiques d'une asymétrie *locale* et pour lesquels on propose des règles de chiralité. Le premier est une vibration méthyne, ‖CH, qui devrait posséder un EC négatif et un configuration absolue (*R*) lorsqu'il est attaché à un centre à trois cycles. Le deuxième est un mouvement de parapluie d'un groupe méthyle pour lequel on attend un effet Cotton positif avec une configuration absolue (*R*) lorsqu'il est attaché à un centre à trois cycles.

[Traduit par la rédaction]

Introduction

Vibrational circular dichroism (VCD) has become a powerful spectroscopic tool for probing absolute configurations and conformation of chiral molecules in solution and in the gas phase. The observed VCD bands have to be interpreted using suitable and reliable theoretical models. The magnetic field perturbation (MFP) theory (1), the vibronic coupling theory (VCT) (2), and the localized molecular orbital (LMO) theory (3) are based on *ab initio* quantum chemical formulations, and their reliability has been established by direct comparisons of theoretical predictions to the experimental data. We have applied the VCT method to calculate a series of small ring molecules, for which experimental data are available and *ab initio* calculations of VCD intensities are possible. The VCT method along with a modest-sized basis set, designated 6-31G*$^{(0.3)}$ (4), has proved to be successful in producing the correct patterns of most VCD bands of substituted oxiranes (5, 6) and thiiranes (6, 7), and of 2-methylaziridine (8). In the latter case, the analysis was complicated by the existence of inversional (at N) diastereomers. The inverted configuration at N resulted in the prediction of opposite handedness in many of the VCD bands, and the ensuing partial cancellation of the VCD spectrum was proffered as an explanation for the very weak experimental VCD spectrum. To explore the relative roles of the heteroatom configuration and the skeletal asymmetry as defined by the σ framework of the molecule, we have synthesized two dimethyl aziridines, which have the same skeletal configuration but which differ in the position of the N atom. In this paper, we present the experimental and theoretical VCD spectra of (2*S*,3*S*)-2,3-dimethylaziridine (**1**) and (1*R*,2*R*)-1,2-dimethylaziridine (**2**), and provide an analysis of the spectroscopic implications by the VCT/6-31G*$^{(0.3)}$ method. The VCD and IR (9) spectra of another substituted aziridine, 2-methylaziridine, were reported earlier.

In the VCT method (2), the individual electric and mag-

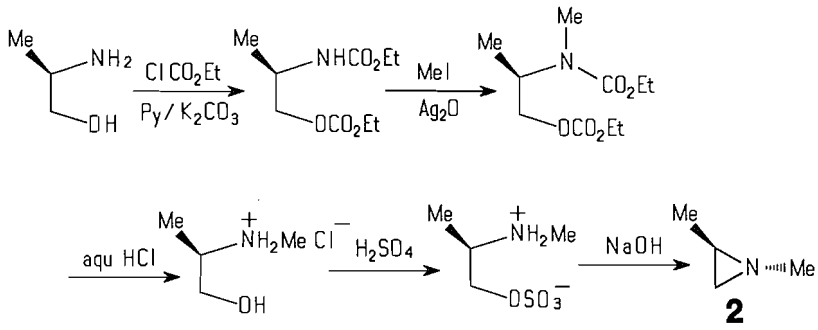
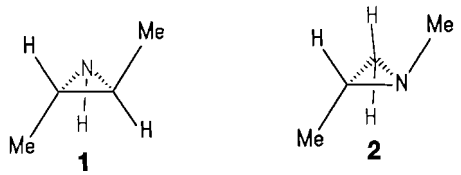


SCHEME 1



netic dipole transition moments are, respectively,

$$[1]\quad (\mu)^j_{00,01} = e\left(\frac{\hbar}{2\omega_j}\right)^{1/2}\left[\sum_n^{\text{atoms}} Z_n \mathbf{S}^j_n - 2\sum_n^{\text{atoms}}\sum_i^{\text{electrons}} \left\langle \Psi_0 \left| \mathbf{r}_i \frac{\partial}{\partial \mathbf{R}_n} \right| \Psi_0 \right\rangle \mathbf{S}^j_n\right]$$

and

$$[2]\quad (\mathbf{m})^j_{01,00} = \frac{e}{2c}\left(\frac{\hbar\omega_j}{2}\right)^{1/2}\left[i\sum_n^{\text{atoms}} Z_n\left(\mathbf{R}^0_n \times \mathbf{S}^j_n\right) + \frac{2\hbar}{m_e}\sum_n^{\text{atoms}}\sum_i^{\text{electrons}}\sum_e^{\text{ex}} \langle \Psi_0|\mathbf{r}_i \times \mathbf{p}_i|\Psi_e\rangle \left\langle \Psi_e \left| \frac{\partial}{\partial \mathbf{R}_n} \right| \Psi_0 \right\rangle \mathbf{S}^j_n \frac{1}{E_e - E_0}\right]$$

where Z_n is the bare nuclear charge of atom n with positional vector $\boldsymbol{R}_n$ and displacement vector $\boldsymbol{S}^j_n = (\partial \boldsymbol{R}_n/\partial Q_j)$ during a normal vibrational mode Q_j, $\boldsymbol{r}_i$ and $\boldsymbol{p}_i$ are the position and momentum of the ith electron, ω_j is the frequency of the jth normal mode, and $E_e - E_0$ is the vertical electronic excitation energy. The electronic wavefunctions are denoted Ψ_0 and Ψ_e. The energy difference and all matrix elements are evaluated at the equilibrium geometry of the ground state. The subscript (00,01) signifies that the transition is between the $v = 0$ and $v = 1$ vibrational levels of the ground electronic state of the molecule. The VCT rotational strength is the imaginary part of the scalar product of $(\mu)^j_{00,01}$ and $(\boldsymbol{m})^j_{01,00}$, eqs. [1] and [2], respectively.

The VCT formalism has been implemented at the *ab initio* level of theory in both the common origin (CO) (10) and the distributed origin (DO) (6, 11) gauges. In the CO gauge, all transition moments are calculated in the same coordinate system, i.e., the same origin gauge. In the distributed origin gauge, the magnetic transition moments corresponding to each atom are calculated by using different origin gauges for different atoms.

Experimental and computational details

Synthesis

(2R,3R)-2,3-Dimethylaziridine, bp 74–75°C, $[a]^{20}_D$ −101.6 (*c* 1.7 heptane) was synthesized according to ref. 12. Synthesis of *(2R)-1,2-dimethylaziridine* followed Scheme 1.

Ethyl chloroformate (8.68 g, 0.08 mol) was added dropwise to (2*R*)-2-aminopropanol (2.5 g, 0.022 mol) and K_2CO_3 (5.53 g, 0.04 mol) in 30 mL absolute pyridine with cooling (0°C) and stirring. After 8 h at 20°C, the precipitate was filtered off and the solvent was evaporated in vacuo. The product was extracted from the residue with ether and, after removal of ether, was dissolved in DMF (70 mL).

Silver(I) oxide (15.5 g, 0.066 mol) and methyl iodide (37.8 g, 0.266 mol) were successively added to the resulting solution with cooling (10°C) and stirring. After 20 h of stirring at 20°C, the precipitate was filtered off and the solution was mixed with ether (300 mL). The resulting solution was decanted from the dark residue, washed by water and brine, and was dried ($MgSO_4$). After removal of the solvent in vacuo, the residue (dark red oil, 3.6 g) was dissolved in aqueous 50% H_2SO_4 (8.4 mL). After about 7 mL of H_2O had been distilled from the mixture (at 20 Torr; 1 Torr = 133.3 Pa), the residue was dissolved in MeOH (15 mL) and precipitated by ether. The solid sulfate (3.4 g) was placed in a distilling flask and a cold solution of NaOH (4 g, 0.1 mol) in H_2O (16 mL) was added. The mixture was heated and 40 mL of distillate (bp 40–100°C) was collected. The distillate was cooled and saturated with KOH (pellets); the organic layer was separated and dried (KOH pellets), and twice distilled over the fresh KOH pellets, providing (2*R*)-1,2-dimethylaziridine (0.2 g, bp 42–44°C (lit. (13); bp 42–44°C), $[\alpha]^{20}_D$ −46.1 (*c* 0.9 CCl_4). ^{1}H NMR spectrum in $CDCl_3$ (200 MHz) δ, ppm (*J*, Hz): 1.12 d (H_A, $^3J^{cis}$ = 6.1), 1.15 (Me, ^3J = 5.0), 1.25 m (H_C), 1.45 d (H_B, $^3J^{trans}$ = 3.3), 2.29 (MeN).

Measurement

The absorption spectrum was measured with a Nicolet 8000 FT-IR spectrometer and, for VCD, a linear polarizer, a ZnSe photoelastic modulator (Hinds International), a f/1 ZnSe focusing lens, and the necessary electronic equipment were added to the instrument as described elsewhere (14). A narrow band MCT detector cooled with liquid nitrogen was used for all experiments. The interferometer was operated at an effective resolution of 4 cm^{-1}, coadding 50 scans and 20 000 scans for the absorption and VCD spectra, respectively.

Solutions of (2*R*)-1,2-dimethylaziridine (0.969 M and 1.67 M (VCD), and 0.969 M (IR)) and (2*S*,3*S*)-2,3-dimethylaziridine (0.87 M (VCD and IR)) in carbon tetrachloride were prepared to record absorption and VCD spectra. Neat CCl_4 was utilized to subtract the VCD background. The sample cell had KBr windows and a path length of 0.1 mm.

Computations

All calculations were done with the 6-31G*$^{(0.3)}$ basis set (a modification of the conventional 6-31G* basis set in which the *d*

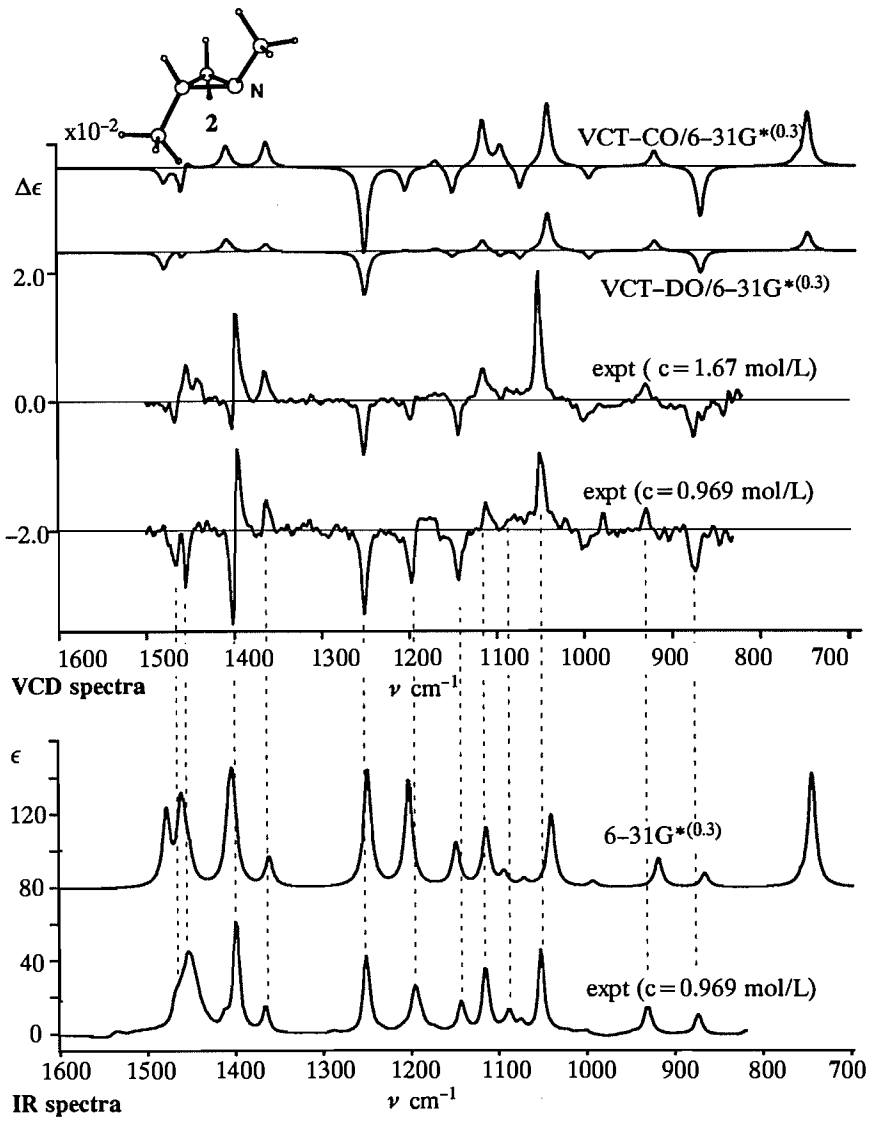

FIG. 3. Theoretically simulated and experimental VCD and IR spectra of (1*R*,2*R*)-1,2-dimethylaziridine **2** in the region 700–1600 cm^{-1}.

chosen as the common origin in the CO gauge, and the nuclear positions were used as origins in the DO gauge. The electronic ground state in eqs. [1] and [2] is approximated by the Hartree–Fock (SCF) determinantal wave function, and the excited states involved in the summation in eq. [2] are approximated as singlet-spin-adapted singly excited configurations derived from the Hartree–Fock wave function.

The theoretical results are displayed as simulated spectra using Lorentzian line shapes with 10 cm^{-1} band width (full width at half height) in Figs. 2 and 3. The *ab initio* harmonic frequencies were uniformly scaled by 0.9 to compensate for systematic errors in the computation of force constants at the Hartree–Fock level (17) and to make comparison with the experimental spectra easier. The assignments of the vibrational modes in Tables 2 and 3 were from computer animation of normal modes based on the 6-31G*$^{(0.3)}$ force fields, and only the major group motions are identified, in decreasing order of their apparent involvement. The nature of the vibrations is particularly complex in the range 800–1400 cm^{-1} for the two molecules discussed here, and the assignments listed in Tables 2 and 3 are only approximate. The notations used in assigning vibrational modes are: ⊥ = perpendicular to df or gh plane; ∥ = parallel to df or gh plane (Fig. 1); str = stretch; def = deformation; umb = umbrella motion; scis = scissor. Wherever available, the experimental frequencies are mentioned in the discussion below.

Results and discussion

The 6-31G*$^{(0.3)}$ geometries of (2*S*,3*S*)-2,3-dimethylaziridine **1** and (1*R*,2*R*)-1,2-dimethylaziridine **2** are shown in Fig. 1. In the latter case, the structure of the *cis* diastereomer, (1*S*,2*R*)-**2**, was also determined. Since this diastereomer was found to be 10.6 kJ mol^{-1} less stable (MP2/6-31G*$^{(0.3)}$//RHF/6-31G*$^{(0.3)}$), it will have no spectroscopic consequences and was not considered further. Complete details of the structures in terms of parameters defined in Fig. 1 are listed in Table 1. Partial experimental data of 2-methylaziridine deduced from MW studies (18) are also given in Table 1 for comparison. Neither complete experimental nor theoretical structures of the two molecules have previously been reported. The lengths of ring C—C and C—N bonds in **1** are close to those of the corresponding bonds in 2-methylaziridine. The ring C—N bonds in **2** are notice-

ably shorter (Table 1, Fig. 1). The N—CH_3 bond in **2** is also shorter than the ring C—N bonds in the two molecules.

(2S,3S)-2,3-Dimethylaziridine ***1***

The vibrational properties of this molecule are summarized in Table 2. The experimental and the simulated IR and VCD spectra in the range of 700–1600 cm^{-1} are shown in Fig. 2. Qualitatively, the similarities between the experimental and the simulated IR and VCD spectra are striking, especially the VCD spectrum calculated by the VCT-CO method.

For the IR spectra, the band at 879 cm^{-1}, which is due to the symmetric C—N stretching motion, is both observed and calculated to be the strongest band in the range of 700–1600 cm^{-1}. The VCD feature at this band is correctly reproduced by the VCT-CO method, but underestimated by the VCT-DO method. There is a noticeable inconsistency between the simulated and the experimental IR spectra near 1030 cm^{-1}, where two bands with about equal absorption intensities show up in the experimental spectrum. Of these two bands, the one at 1041 cm^{-1} (an asymmetric C—CH_3 stretching mode) is calculated to be too weak, and the one at 1020 cm^{-1} (a mixed mode of ‖NH and -CH_3 rocking) is calculated to be too intense. The VCD features of these two bands are, however, reproduced reasonably well, especially by the VCT-CO method. The simulated VCD spectrum by the VCT-CO method is generally in better agreement with the experiment, and the VCT-DO method underestimates the magnitudes of the VCD intensities for most of the bands in the experimental range for this molecule. The band at 1226 cm^{-1} appears as a very weak negative VCD, but is calculated as a weak positive VCD by both VCT-CO and VCT-DO methods, and this is the only noticeable inconsistency between the theoretical VCD predictions and the experimental measurements for this molecule. The four -CH_3 deformation modes with closely spaced theoretical frequencies between 1462 and 1446 cm^{-1} are calculated to be almost equally strong in the VCD spectrum. Correspondingly, only three frequencies are observed, at 1454, 1444, and 1430 cm^{-1}. Of these four -CH_3 deformation bands, the highest frequency band is calculated to have positive rotatory strength, and the other three are calculated to have negative rotatory strengths (which appear as a broad negative peak in the simulated VCD spectra). Three negative VCD bands are observed in the experimental VCD spectrum in this range; a positive VCD band, however, is not observed. It is possible that a mode with a positive rotatory strength is buried under other negative bands, and that the calculated frequencies are in error.

(1R,2R)-1,2-Dimethylaziridine ***2***

The vibrational properties of this molecule are summarized in Table 3. The simulated IR spectrum bears remarkable resemblance to the experimental IR spectrum (Fig. 3). The only noteworthy difference between the two is the region near 1450 cm^{-1}, where the four nearly degenerate -CH_3 deformation modes yield a broad absorption band in the experimental IR spectrum, while in the simulated IR spectrum the four are split into two bands. The sum of the four absorptions is, however, close to the experimental observation.

Two experimental VCD spectra (measured at different concentrations) are available for **2** (Fig. 3). Some of the band appearances in the two experimental VCD spectra differ considerably, which may be caused by strong underlying absorptions at these bands. The absolute magnitudes calculated by the VCT-CO method are generally closer to the experimental observations than those calculated by the VCT-DO method. All distinguishable signs and intensities of the VCD bands in the range of 800–1380 cm^{-1} in the experimental VCD spectra are reproduced well in the simulated VCD spectrum by the VCT-CO method. The VCT-DO calculations reproduce the signs of the VCD bands but underestimate the VCD intensities overall. One possible error is the calculated negative rotatory strength at 1076 cm^{-1}, which is due to mode ν_{13} (a mixed mode of -CH_2 wagging and -CH_3 rocking), where no clear negative VCD band appears in either experimental VCD spectrum. The band at

1090 cm^{-1}, which is due to mode ν_{14} (a mixed mode of -CH_2 wagging and -CH_3 rocking), is calculated to have oppositely signed rotatory strength by the VCT-CO and VCT-DO methods. It is again difficult to judge which is correct since the experimental feature at this position is not clear. The relative intensities of the three moderately strong negative VCD bands at 1144, 1196, and 1251 cm^{-1} in the simulated VCD spectrum are closer to those of the corresponding bands in the experimental spectrum recorded at the higher concentration. The appearance of the VCD feature at the band of 1053 cm^{-1} is different in the two experimental VCD spectra; while a very strong positive VCD band appears in the higher concentration spectrum, the absolute intensity of this band is much smaller in the more dilute VCD spectrum. The VCD feature at this band in the higher concentration VCD spectrum may be misleading because the absorption at this band is strong, which may mistakenly yield strong absorption in the VCD spectrum. The calculated magnitude of this VCD band by the VCT-CO method is closer to the observed one in the lower concentration spectrum.

The experimental spectra in the range of 1350–1500 cm^{-1} yield a few uncertainties, which may be largely caused by the strong absorptions in this range. The four -CH_3 deformation modes near 1450 cm^{-1} yield two distinguishable negative VCD bands in the simulated VCD spectra. While the lower concentration experimental VCD spectrum supports the calculations for these four modes, the higher concentration VCD spectrum gives totally different appearance in this range. The prominent bisignate feature near 1400 cm^{-1} in the lower concentration VCD spectrum is doubtful, since the corresponding feature in the higher concentration VCD spectrum has a different appearance, that of a stronger positive VCD and much weaker negative VCD. There is only one observable absorption band corresponding to the above-

mentioned two VCD bands. Two calculated frequencies, 1402 and 1408 cm^{-1} (modes ν_{21} and ν_{22}) are close to the observed frequency, 1400 cm^{-1}. The calculated VCD intensities at these two bands are much weaker and both positive.

Local and global stereochemistry

As stated in the introduction, the two dimethyl aziridines, **1** and **2**, have the same skeletal symmetry. One might expect that the Cotton effects (CEs) of *skeletal* vibrations, that is to say, normal modes that are composed of many strongly coupled local motions, should reflect the *global* stereochemistry and have the same sign, characteristic of the absolute handedness of the molecular skeleton (the *global* environment). On the other hand, as suggested by the stereochemical labels, (2*S*,3*S*) and (1*R*,2*R*), respectively, some regions of the molecule have different *local* symmetry. For instance, the environments of the methyne bond (CH) in **2** and both CH bonds in **1** are essentially, although not exactly, antipodal, as are the environments of the C—Me groups. If localized motions can be identified, the corresponding CEs should have opposite signs, and be characteristic of the absolute handedness of the *local* environment. The experimental VCD spectra of **1** and **2** are reproduced in Fig. 4b, together with the VCD spectra of (2*S*,3*S*)-2,3-dimethylthiirane (**7**) and (2*S*,3*S*)-2,3-dimethyloxirane (**4**), both of which also have the same *global* chirality. VCT-CO/6-31G*(0.3) simulated VCD spectra are also available for the four compounds, and these are reproduced in Fig. 4*a*. A cursory glance reveals little similarity between the four sets of spectra, experimental or theoretical. However, some commonality is readily adduced upon inspection of the descriptions of the normal modes as given in Tables 2 and 3 and in corresponding tables of refs. 4 and 7. These mode descriptions were derived from the theoretical calculations. Features that are most similar in the four compounds, as judged by the mode descriptions and correlation of theoret-

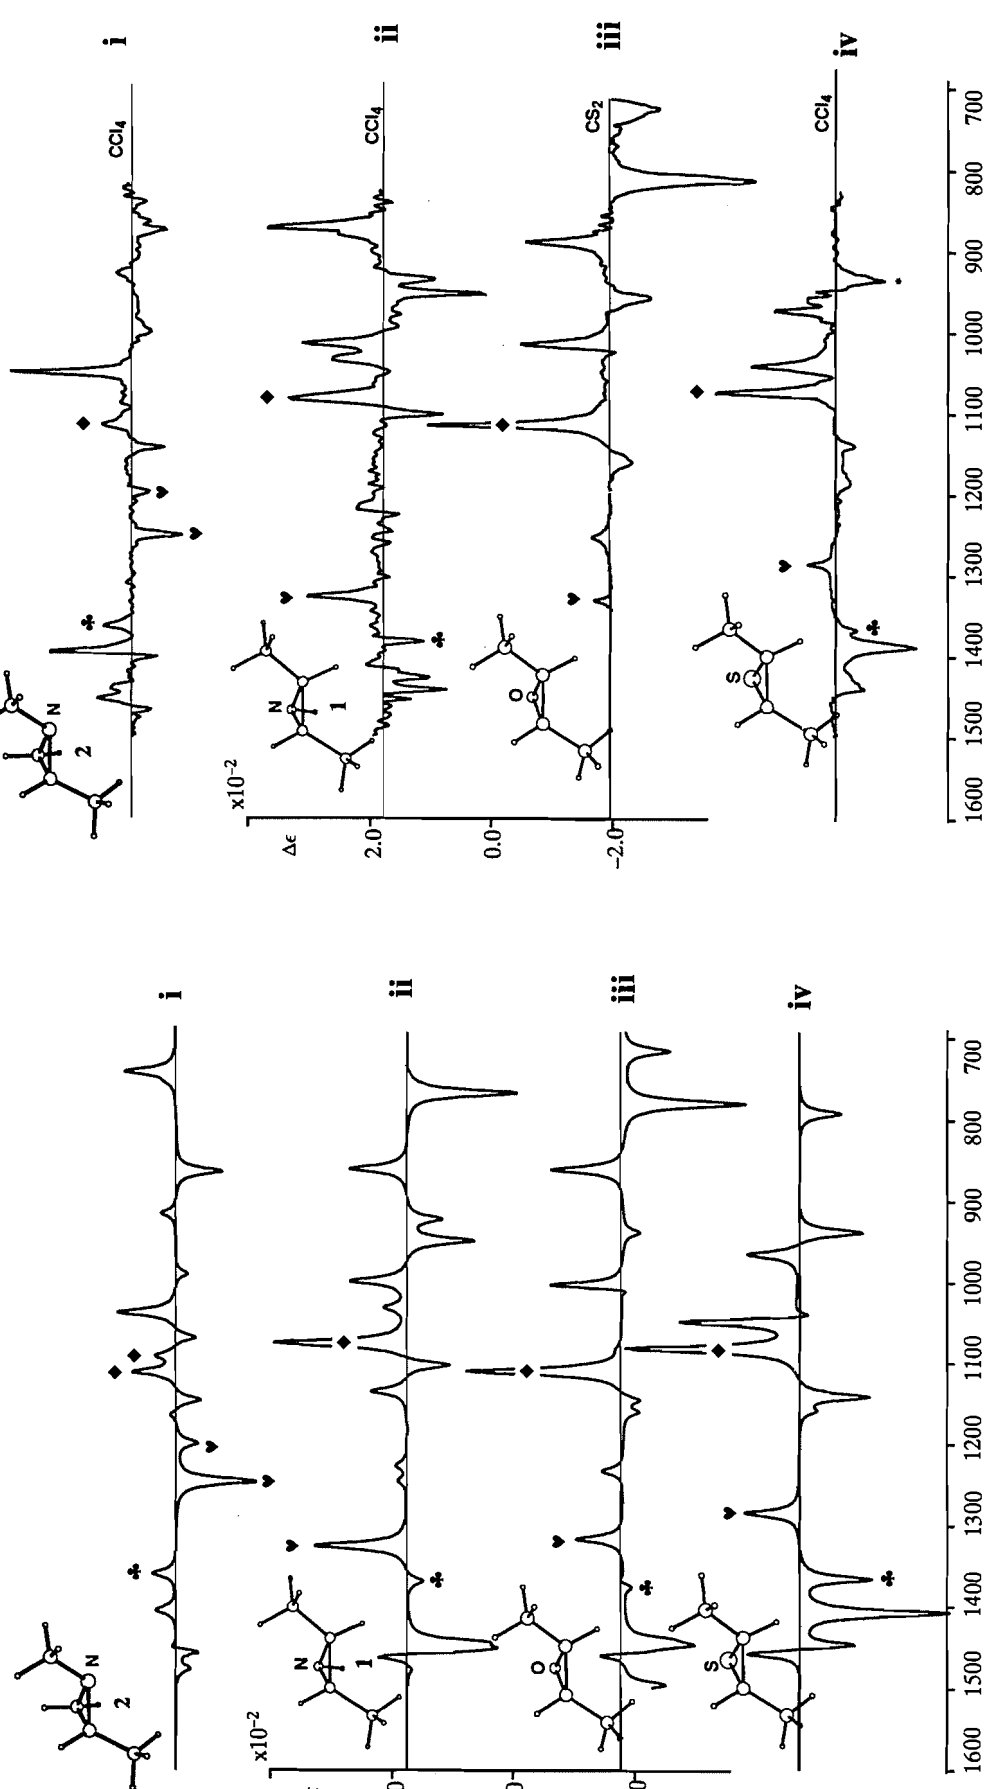

FIG. 4. (*a*) Theoretical VCT-CO/6-31G*$^{(0.3)}$ and (*b*) experimental VCD spectra of (1*R*,2*R*)-1,2-dimethylaziridine **2** (**i**), (2*S*,3*S*)-2,3-dimethylaziridine **1** (**ii**), (2*S*,3*S*)-2,3-dimethyloxirane (**iii**), (2*S*,3*S*)-2,3-dimethylthiirane (**iv**), in the region 700–1600 cm^{-1}.

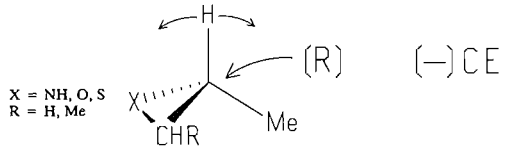


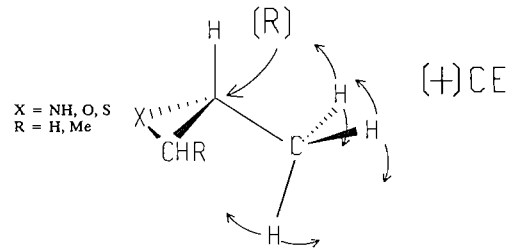
SCHEME 2. Chiral rule for ‖CH mode.

ical and experimental frequencies and intensities, are marked by common symbols in Fig. 4.

The strongest VCD feature in the spectra of each of the 2,3-dimethyl heterocycles is a methyl rock (◆), which has mixed into it CH and some ring CC stretching component. In the O and S compounds both the *a* and *b* symmetry modes have a (+) CE, the *a* symmetry mode being stronger in the oxirane, while both modes are moderately strong in the thiirane, the *b* symmetry mode dominating. The corresponding mode, also with (+) CE, is mixed with a wag of the NH bond in **1**. In **2**, the corresponding rock of the Me groups is mixed with perpendicular motions (wags) of the CH and CH_2 protons, and appears in two modes, both with (+) CE. This prominent feature would appear to be characteristic of the skeletal chirality. In principal, there are four combinations of the methyl rocking motions that should contribute to the fundamental vibrations of the molecule in the region 1050–1150 cm^{-1}. These are almost invariably mixed with other modes, participating in truly skeletal vibrations. The particular combination that gives rise to the prominent VCD feature (◆) corresponds to a rocking motion about an axis more or less in the plane of the exocyclic substituents (e.g., the gh plane, Fig. 1).

Several other features also appear to persist with the same sign in each of the four compounds. However, analysis of the composition yields little similarity in terms of local motions and these are unlikely to prove to be as reliable indicators of skeletal chirality as the Me rocks.

In the three-ring molecules, two types of motions of the CH (methyne) bonds are observed, either perpendicular to the plane formed by the exocyclic bonds (⊥), or in the plane of these bonds (‖). When not coupled by symmetry, these motions are in some cases highly localized. Modes in the four compounds where the dominant component is ‖CH are labelled with ♥ in Fig. 4. These correspond to modes of *b* symmetry in the C_2 compounds and are coupled in the same "antisymmetric" fashion in **1**. In each case (in the C_2 compounds) the mode has a moderately strong (+) CE. The "handedness" of the methyne environment ((*S*) absolute configuration) is the same in each of the compounds, except **2**. In **2**, the ‖CH motion occurs in an antipodal environment ((*R*) absolute configuration) and appears with (−) CE. It is of interest that the same ‖CH mode may be identified in 2-methyloxirane (mode 13, Tables 4 and 5 of ref. 4), 2-methylthiirane (calcd. frequency 1146 cm^{-1}, Table 6 of ref. 7), and 2-methylaziridine (mode 13 of both *cis* and *trans* forms, ref. 8). In each case, the calculated (VCT-CO/60-31G*$^{(0.3)}$) CE is consistent with the chiral rule shown in Scheme 2. Thus, the "‖CH" motion of a methyne attached to a chiral centre with (*R*) absolute configuration is expected to display a (−) CE, and vice versa. The ‖CH mode is readily identified in the experimental VCD spectra of all compounds except 2-methylthiirane where it is overlapped with two other vibrational modes and displays a weak CE in the region (near 1160 cm^{-1}) that is inconsistent with the rule.



SCHEME 3. Chiral rule for Me umb mode.

The individual methyl groups also may function as a probe for the *local* chirality. In each of the 2,3-dimethyl heterocycles of Fig. 4, the methyl groups are attached to a centre with the same chirality ((*S*) absolute configuration), whereas in the 1,2-dimethyl aziridine 2, the C-Me group "sees" the antipodal environment ((*R*), as shown in Scheme 2). The umbrella motions are marked with ♣ in Fig. 4. In **2**, the umbrella motions of the two methyl groups are well separated from each other and other fundamental vibrations, the C-Me umbrella motion appearing at 1367 cm^{-1}, with (+) CE. In **1**, the in- and out-of-phase Me umbrella vibrations are only separated by 5 cm^{-1}, with the in-phase (sym) combination having the larger, and (−) CE. In the case of the dimethyloxirane, relatively small rotatory strengths of opposite sign are calculated for the umbrella modes of a and b symmetry with the larger corresponding to the b symmetry mode. In the dimethyl thiirane, the two umbrella modes are also calculated to have oppositely signed CEs, with the a symmetry mode having the much larger value. *In each case*, and in the case of the corresponding monomethyl heterocycles, the calculated and observed CE in the Me umbrella region is consistent with the Me umb chirality rule as shown in Scheme 3. The umbrella motion at a centre of (*R*) absolute chirality has a (+) CE, and vice versa.

Conclusions

In summary, for the two aziridines discussed above, VCT-CO calculations predict generally stronger VCD in mid-IR range and VCT-DO calculations predict generally stronger VCD in the C—H stretching range. This pattern is similar to that observed for the oxiranes (5) and thiiranes (7). The absolute magnitudes of the VCD intensities by the VCT-CO method in the mid-IR range are closer to the experimental measurement. Both VCT-DO and VCT-CO methods, however, predict the same signs for almost all VCD bands. In general, both VCT-DO and VCT-CO methods predict VCD and IR spectra that are both in good agreement with the experimental spectra. The VCT method together with the 6-31G*$^{(0.3)}$ basis set can be employed with confidence in determining the absolute configuration of a chiral molecule.

The theoretical and experimental VCD spectra of **1** and **2** were compared with the VCD spectra of the isostructural 2,3-dimethyloxirane and -thiirane. One of the Me rocking motions, in the wave number range 1050–1150 cm^{-1}, was found to have a similar description in each of the compounds and give rise to a strong VCD band whose sign may serve as a marker for the skeletal stereochemistry. Two other modes were identified whose CE are characteristic of the local asymmetry, and for which chirality rules could be proposed. The first is a methyne vibration, ‖CH, which is expected to have a (−) CE at a three-ring centre with (*R*)

absolute configuration (Scheme 2). The second is an umbrella motion of a methyl group, which is expected to have a (+) CE when attached to a three-ring centre with (*R*) absolute configuration (Scheme 3).

Activity coefficients and standard Gibbs free energies of transfer of NaCl and KCl from water to aqueous solution of 2-butoxyethanol by EMF studies

YVONNE MACPHERSON AND R. PALEPU[1]

Department of Chemistry, University College of Cape Breton, Sydney, NS B1P 6L2, Canada

Received April 8, 1993

YVONNE MACPHERSON and R. PALEPU. Can. J. Chem. **71**, 2038 (1993).

From the emf measurements of the cell Na- or K-glass electrode|2-butoxyethanol, H_2O, NaCl or KCl|Cl ion-selective electrode, the standard potentials were determined at 298 K for five different compositions of the solvent. From the emf data the mean activity coefficients of NaCl and KCl were calculated and fitted to an empirical equation. The standard Gibbs free energies of transfer of NaCl and KCl from water to mixtures of water and 2-butoxyethanol were calculated from the cell potential.

YVONNE MACPHERSON et R. PALEPU. Can. J. Chem. **71**, 2038 (1993).

Utilisant des fém mesurées à 298 K pour la cellule électrode de verre de Na ou de K|2-butoxyéthanol, H_2O, NaCl ou KCl|électrode à membrane sélective à l'ion Cl, on a déterminé les potentiels standard pour cinq compositions différentes de solvant. À partir des données de fém, on a calculé les coefficients moyens d'activité du NaCl et du KCl et on les a ajusté dans une équation empirique. Utilisant le potentiel de la cellule, on a calculé les énergies libres standard de transfert de Gibbs du NaCl et du KCl de l'eau vers des mélanges d'eau et de 2-butoxyéthanol.

Introduction

The solution properties of aqueous mixtures of 2-butoxyethanol (B.E.) have received considerable attention in the literature (1–5). It is well established that 2-butoxyethanol forms microaggregates in a very dilute aqueous solution and is used as a cosurfactant in microemulsions (6). In the systems of water, 2-butoxyethanol, and NaCl or KCl a phase separation occurs at certain compositions of the system. To calculate the enthalpy of this process the data on activity coefficients of NaCl and KCl are required. Mean activity coefficients of these electrolytes are also required to calculate the counterion binding of various micelles in 2-butoxyethanol + water systems by the standard calibration method (7). The value of counterion binding is an important quantity in understanding the role of 2-butoxyethanol in microemulsions.

The use of ion-selective electrodes (I.S.E.) to study the thermodynamic properties of solutions is simple and safe compared to the classical amalgam cells. Ion-selective electrodes were recently used to determine the activity coefficients of alkali-metal halides in various binary mixtures of alcohols with water (8–10). This paper reports the determination of the activity coefficients of NaCl and KCl in binary mixtures of aqueous 2-butoxyethanol solutions at 298 K.

Experimental

The experimental cell can be represented as

Anion (Cl^-)-responsive I.S.E.	MCl H_2O + B.E.	Cation (M^+)-responsive I.S.E.

A Ross sodium electrode (84-11), Corning monovalent cation glass electrode (Catalogue no. 416220), and an Orion solid state chloride electrode (94-17) were used in the present investigation. Analytical reagent grades of sodium and potassium chloride of either Merck or B.D.H. chemicals were used without further purification. The crystals were dried prior to use. Concentration changes in the emf cell were made by adding a weighed quantity of sodium or potassium chloride directly to the cell containing the electrodes in either pure water or a binary solution of 2-butoxyethanol and H_2O. Thus electrodes remained in the same cell throughout a particular run. The cell was kept in a thermostatted water bath at 25.00 ± 0.05°C. The cell solutions were stirred by an air-driven magnetic stirrer. The cell potentials were measured with an Orion research microprocessor ion analyzer/901 and this arrangement allowed the emf to be read to ±0.1 mV. All solutions were made with NANO pure water and 2-butoxyethanol (Aldrich) of stated purity better than 99+%. The electrode system was periodically tested by determining the activity coefficients of aqueous NaCl or KCl over the concentration range 0.05–0.5 mol kg^{-1}. The activity coefficients of electrolytes in the mixed solvents were determined only after the values obtained for the activity coefficients of NaCl and KCl in water agreed with the values reported in the N.B.S. tables (11). The electrodes were stored in 0.1 M MCl solution when not in use.

Results and discussion

The emf, E, of the cell applied in this work is given by

$$[1] \quad E = E^0 + 0.1183 \log m\gamma_{\pm}$$

where E is the standard electrode potential of the M^+ (I.S.E.) and chloride (I.S.E.), and $\gamma_{\pm}$ is the mean ionic coefficient of MCl of molality m. The standard emf E^0 in eq. [1] was obtained in the following manner. Introducing the Debye–Hückel expression (12) for the rational activity coefficient in eq. [1] yields the equation:

$$[2] \quad E' = E - 0.1183 \log m + \frac{0.1183\, A \sqrt{C}}{1 + B\, a \sqrt{C}} + 0.1183 \log (1 + 0.002\, \bar{M}m)$$

where the last term represents the difference between the rational and molal mean activity coefficients, A and B are the values of the Debye–Hückel constants for each solvent composition, a is the ionic size parameter in A^0, and $\bar{M}$ is the average molecular mass of the solvent mixture. The molarity C in eq. [2] was obtained from the molality (m) and the density of solution. The values of E^0 were obtained by extrapolation of E' to zero ionic strength, $m = 0$. The E' val-

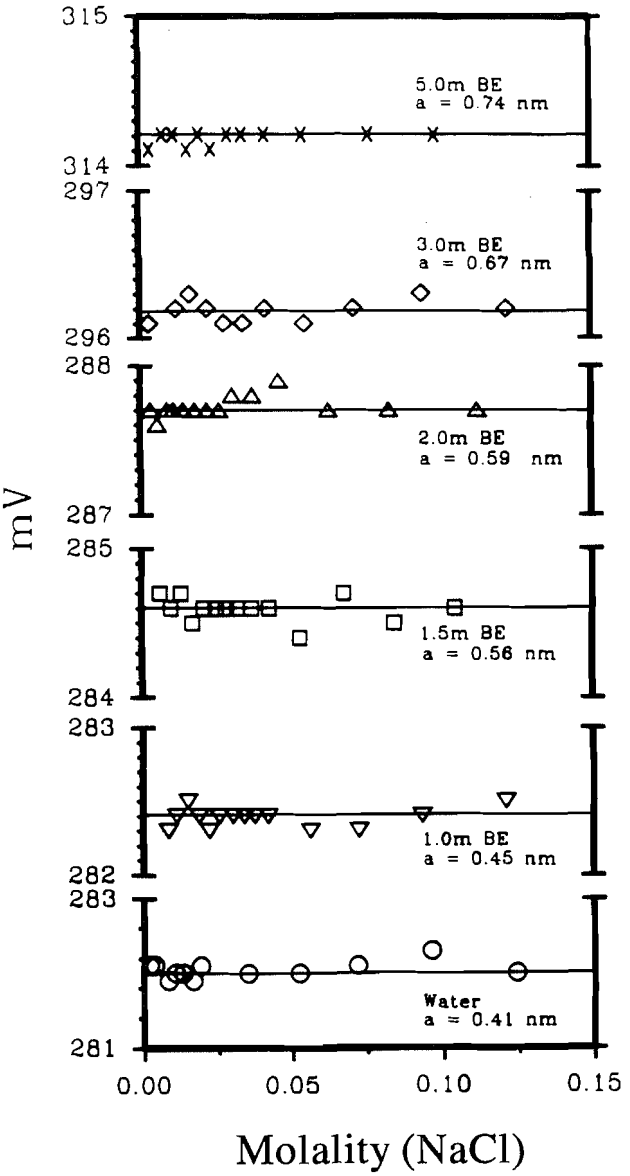

FIG. 1. E' as a function of m for NaCl in different compositions of the B.E. + H_2O system. The corresponding value of the ionic diameter as indicated (eq. [2]).

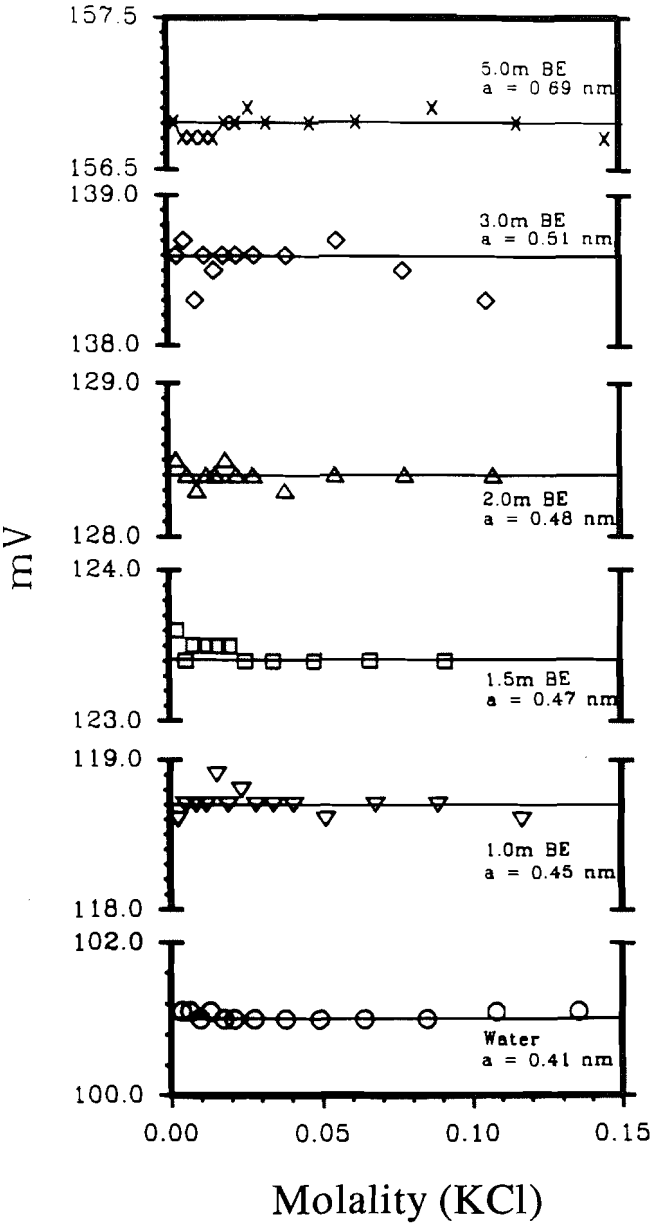

FIG. 2. E' as a function of m for KCl in different compositions of the B.E. + H_2O system. The corresponding value of the ionic diameter as indicated.

ues of the solution and the magnitude of the ion size parameter were determined by the method described by Harned (13, 14). In this procedure, E' in eq. [2] was solved for various values of a. The values used ranged from 0.40 to 0.75 nm. The E' values were plotted against the molality. The proper value gives a zero slope for such a curve. These curves also give the values of E^0, the standard electrode potentials. The results are illustrated in Figs. 1 and 2. The constants used in eq. [2] for the evaluation of E^0 are given in Table 1.

The mean molal activity coefficient values of NaCl and KCl were computed from experimental data according to eq. [1]. These values were fitted by the method of least squares to the empirical equation (15).

$$[3]\quad \log \gamma_A = \log \gamma_A^0 + m_B\,[B_{10} + B_{11}\,m_A^{1/2} + B_{12}\,m_A + B_{13}\,m_A^{3/2}] + m_B^2\,[B_{20} + B_{21}\,m_A^{1/2}]$$

[a]σ = standard deviation.

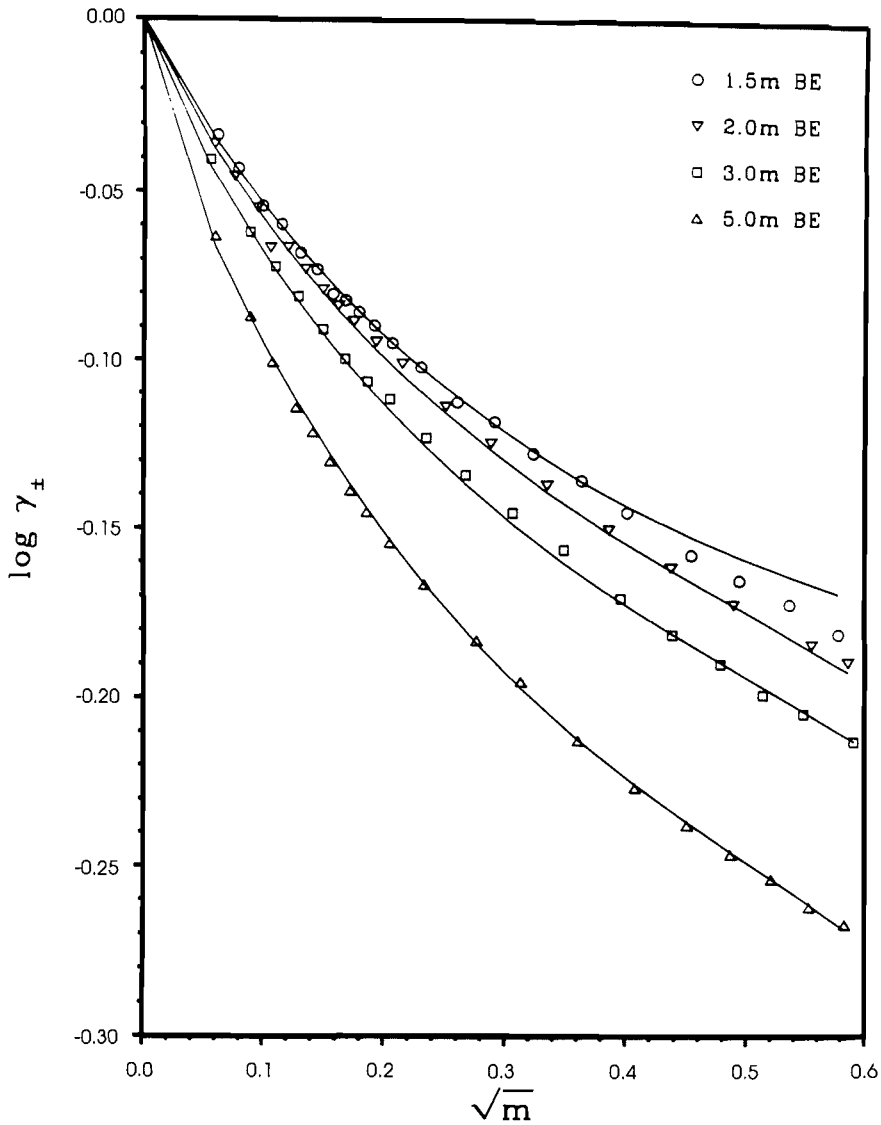

FIG. 3. The mean molal activity coefficients of NaCl in B.E. + H_2O systems as a function of $\sqrt{m}$. The curve for 1.0 *m* B.E. is not included for clarity purposes.

calculated using Pitzer's treatment (16). The values of the parameters for the above equation are presented in Table 2. The mean activity coefficient values of NaCl and KCl are plotted against $\sqrt{m}$ (Figs. 3 and 4) and the continuous curves were generated with the aid of the parameters in Table 2. It is obvious that eq. [3] expresses adequately the results within the experimental errors. The activity coefficient values decrease with the values of the dielectric constant of the media, leading to an increase in the short-range interactions.

The standard free energies of monovalent salt in a mixed solvent are given by:

[4] $\Delta G^0_{t(m)} = F \cdot \Delta E^0_{t(m)}$

where F is Faraday's constant and

[5] $\Delta E^0_{t(m)} = [E^0_{(B.E.+H_2O)} - E^0_{H_2O}]$

The calculated values of $\Delta G^0_{t(m)}$ at various binary mixtures

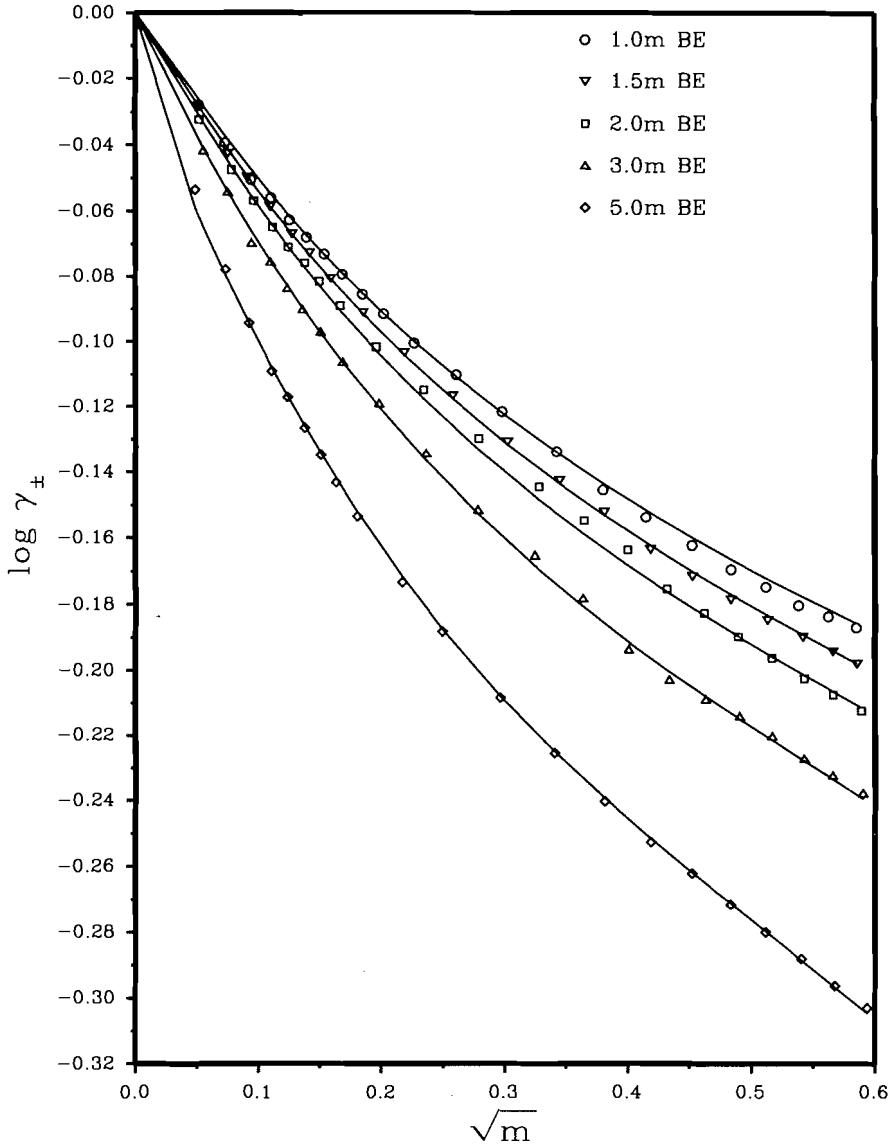

FIG. 4. The mean molal activity coefficients of KCl in B.E. + H_2O systems as a function of $\sqrt{m}$.

of 2-butoxyethanol are presented in Table 3. The free energies of transfer of the ion are the difference between the free energies of solvation of the ion in the different solvent mixtures. The values of $\Delta G^0_{t(m)}$ are found to be dependent on the 2-butoxyethanol content in the solvent mixture. This dependency may be due to the change in the solvation of Na^+, K^+, and Cl^- ions by the presence of 2-butoxyethanol molecules in the mixture. Some water molecules in the primary shell might be substituted by 2-butoxyethanol molecules or the microaggregates. The change in the nature of the solvation process is currently under investigation using viscosity, ultrasonic velocity, and spectroscopic measurements.

Conclusions

Ion-selective electrodes were proven to be valuable in the determination of mean activity coefficient values of NaCl and KCl at various concentrations of 2-butoxyethanol in water, and the data were fitted into an empirical equation. This process allows one to obtain the values of $\gamma_{\pm}$ at various concentrations. The Gibbs free energies of transfer were calculated and found to be very small.

Metal-thiolate chemistry: The structure of the first adamantane-type cation, $[(\mu\text{-SPh})_6(HgPPh_3)_4]^{2+}$

JAGADESE J. VITTAL, PHILIP A.W. DEAN, AND NICHOLAS C. PAYNE[1]
Department of Chemistry, University of Western Ontario, London, ON N6A 5B7, Canada

Received June 18, 1993

JAGADESE J. VITTAL, PHILIP A. W. DEAN, and NICHOLAS C. PAYNE. Can. J. Chem. **71**, 2043 (1993).

The compound $[(\mu\text{-}SC_6H_5)_6\{HgP(C_6H_5)_3\}_4][ClO_4]_2$ crystallizes in the triclinic space group $P\bar{1}$ as a bis(chloroform) solvate with cell dimensions a = 15.799(4), b = 26.813(5), c = 15.040(5) Å, α = 96.35(2), β = 114.52(2), γ = 100.45(2)° and two formula units per cell. The crystal and molecular structures of this salt were solved by X-ray diffraction techniques using 9898 counter data with $I > 2.5\sigma(I)$ recorded at −50(2)°C. Refinement of 477 variables by full-matrix least-squares converged at an agreement factor R = 0.046. The cation has adamantane-type stereochemistry with a $(\mu\text{-SPh})_6Hg_4$ cage and four terminal triphenylphosphine ligands. The S—C_α vectors of the bridging SC_6H_5 groups adopt the configuration [aae, aae, aee, aee] with the minimum number of two 1,3-axial, axial substituent interactions. There is a significant flattening of the two Hg_3S_3 rings with two axial substituents into an envelope conformation; each has two torsion angles less than 25°, instead of the ideal values of ±60° in adamantane. One perchlorate ion is doubly solvated by chloroform molecules in an unusual, weakly hydrogen bonded, $[ClO_4 \cdot 2HCCl_3]^-$ complex.

JAGADESE J. VITTAL, PHILIP A.W. DEAN et NICHOLAS C. PAYNE. Can. J. Chem. **71**, 2043 (1993).

Le composé $[(\mu\text{-}SC_6H_5)_6\{HgP(C_6H_5)_3\}_4][ClO_4]_2$ cristallise dans le groupe d'espace triclinique $P\bar{1}$ sous la forme d'un composé solvaté par deux molécules de chloroforme, avec a = 15,799(4), b = 26,813(5) et$c$ = 15,040(5) Å, α = 96,35(2), β = 114,52(2) et γ = 100,45(2)° et deux formules unitaires par motif. On a résolu les structures moléculaires et cristallines par des techniques de diffraction des rayons x utilisant 9898 données avec $I > 2{,}5\ \sigma(I)$ enregistrées à −50(2)°C. On a affiné 477 variables par la méthode des moindres carrés jusqu'à une valeur de R = 0,046. Le cation posséde une stéréochimie semblable à celle de l'adamantane avec une cage de $(\mu\text{-}SC_6H_5)_6Hg_4$ et quatre triphénylphosphine comme coordinats terminaux. Les vecteurs S—C_α des groupes SC_6H_5 agissant comme ponts adoptent la configuration [aae, aae, aee, aee] avec le nombre minimal d'interactions 1,3-axiale, axiale entre les substituants. On observe un aplatissement notable des deux noyaux Hg_3S_3 avec deux substituants axiaux dans une conformation enveloppe; chacun présente deux angles de torsion inférieurs à 25° par rapport aux valeurs idéales de ±60° dans l'adamantane. Un ion perchlorate est doublement solvaté par des molécules de chloroforme et il forme un complexe inhabituel avec une faible liaison hydrogène, $[ClO_4 \cdot 2HCCl_3]$.

[Traduit par la rédaction]

Introduction

In the chemistry of metal-thiolates, a frequently encountered structural unit is the adamantane-type tetranuclear cluster with a $(\mu\text{-SR})_6M_4$ core (1–3). More than twenty such compounds have been characterized by X-ray structure analyses to date (4–24, footnote 2) with metal atoms M = Mn(II), Fe(II), Co(II), Zn(II), Cu(II), and Cd(II). In most cases the cluster is an anion; in no case is it a cation. Five of these are complexes of the Group 12 atoms Zn and Cd. By contrast, the structural chemistry of the Hg congener is undeveloped, though the nature of the $(\mu\text{-SR})_6Hg_4$ cage is of interest in connection with the mercury-binding site of metallothioneins (25). Previously, some of us have reported (26) the synthesis of various complex cations of formula $[(\mu\text{-SR})_6(HgPR'_3)_4]^{2+}$, and their characterization in solution by multinuclear magnetic resonance spectroscopy. Kunkely and Vogler (27) have described the electronic and photoluminescence spectra of the species with R = R′ = phenyl.

We present here an account of our studies of the compound $[(\mu\text{-SPh})_6(HgPPh_3)_4](ClO_4)_2 \cdot 2CHCl_3$, **1** which is unique in two ways: as the first example of a cationic thiolate cluster complex with the adamantane-type stereochemistry, and as the first case of a $(\mu\text{-SR})_6Hg_4$ cage characterized by X-ray crystallography.

Experimental

General procedures

The salt $[(\mu\text{-SPh})_6(HgPPh_3)_4](ClO_4)_2$ was synthesized as reported earlier (26), and solvated crystals of a quality suitable for diffraction experiments were grown by diffusing diethyl ether into a chloroform solution at 5°C.

X-ray crystallography

Crystals of $[(\mu\text{-SPh})_6(HgPPh_3)_4](ClO_4)_2 \cdot 2CHCl_3$ are colorless, transparent, and fairly stable in air, though they show a tendency to decompose on prolonged exposure to X-radiation. Precession and Weissenberg photographs were taken to establish the space group and to obtain preliminary cell dimensions. The crystal density was measured by the neutral buoyancy method in mixtures of carbon tetrachloride and 1,2-dibromoethane. Data collection was carried out on an Enraf-Nonius CAD4F diffractometer (28) at a reduced temperature of −50(2)° to retard decomposition. Intensity data were recorded in ω–2θ scan mode at variable scan speeds within a maximum time per datum of 50 s. Static background estimates were made at scan extensions on each side. Standard reflections were monitored every 180 min of X-ray exposure time. Lorentz, polarization, and decay corrections were applied using the NRCVAX programs (29) running on a Sun 3/80 workstation. A Gaussian absorption correction (30) was applied to the data, which were then averaged to yield 15 282 unique data with $I > 0$ for structure solution and refinement. Crystal and experimental data are summarized in Table 1.

The structure was solved by a combination of MULTAN (31) and difference Fourier syntheses, and refined by full-matrix least-squares techniques on F using the SHELX76 software (32) running on a CDC Cyber 2000 computer. Scattering factors for Hg

were taken from the International tables (33). In the refinement, all Hg, P, and S atoms were assigned anisotropic thermal parameters. The phenyl ring carbon atoms were constrained to regular hexagonal geometry with C—C = 1.392 Å and allotted isotropic thermal parameters. All phenyl hydrogen atoms were located successfully by difference Fourier methods, placed in calculated positions (C—H = 0.95 Å), and included in the structure factor calculations. Some disorder was present. One of the perchlorate anions showed a 60:40 occupancy of two orientations related approximately by a 60° rotation about one Cl—O bond. It was modelled by refining rigid groups of T_d symmetry and a Cl—O bond length of 1.42 Å. The phenyl ring on S (34) had large C atom thermal parameters and was accompanied by significant residual electron density in a difference Fourier synthesis. A disorder model using rigid groups could not be formulated, so individual anisotropic thermal parameters were assigned. The resulting model is the best we could achieve, with C—C bond lengths ranging from 1.32(3) to 1.42(3) Å. The chloroform solvent molecules were refined with a restrained geometry, Cl—C—Cl 110° and H—C—Cl 108°, varying an overall C—Cl bond length to a final value of 1.715(3) Å. A secondary extinction correction was applied to the data. An analysis of variance suggested that the weighting scheme was appropriate. With three reflections omitted, refinement converged at agreement factors $R = \Sigma(||F_o| - |F_c||)/\Sigma(|F_o|) = 0.046$ and $R_1 = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w F_o^2)^{1/2} = 0.050$.

Selected experimental details of the X-ray determination are given in Table 1. Final positional parameters for **1** are given in Table 2, supplementary experimental details, hydrogen atom parameters and anisotropic thermal parameters have been deposited as Tables S1, S2, and S3.[3]

[3]Copies of supplementary experimental details, hydrogen atom parameters, anisotropic thermal parameters, selected non-bonded contacts, supplementary dimensions, and structure amplitudes may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, ON K1A 0S2, Canada.

Results and discussion

The synthesis of the Hg salt $[(\mu\text{-}SC_6H_5)_6\{HgP(C_6H_5)_3\}_4][ClO_4]_2$ has been described previously (26).

The crystal structure consists of well-separated complex cations, perchlorate anions, and $[ClO_4 \cdot 2CHCl_3]^-$ anionic complexes, Fig. 1. The closest cation–anion and anion–anion distances of approach, and complex dimensions, are given in Table S4. The doubly solvated perchlorate ion appears to be unprecedented in the literature. In essence the anion is bracketed in linear fashion (H1. . .Cl(1) 3.08, Cl(1). . .H2 2.94 Å, H1. . .Cl(1). . .H2 176°) by the hydrogen atoms of two chloroform molecules (C(1)—H1. . .Cl(1) 168, (C(2)—H2. . .Cl(1) 179°). The O. . .H distances range from 2.38 to 2.55 Å, slightly less than the sum of van der Waals radii, 2.70 Å, with C—H. . .O angles varying remarkably little from 148 to 152°. A search of the Cambridge Structural Database (CSD) (34) found 19 entries containing at least one perchlorate anion and one chloroform molecule. Of these, only three studies (35–37) reported coordinates for the hydrogen atom, two of which (36, 37) proved to contain a $[ClO_4 \cdot CHCl_3]^-$ anion–solvent complex of closely similar geometry. Dimensions from these two studies are included in Table S4. Although the pK_a of chloroform is only 24.1 (38), we characterize this interaction as weak, bifurcated hydrogen bonding, similar, for example, to that observed in $MgSO_4 \cdot 4H_2O$ (39).

The cage skeleton of the cation in **1** is depicted in Fig. 2. The mercury atoms, each with a terminal triphenylphosphine ligand, are located at the vertices of a tetrahedron, with phenylthiolate ligands bridging the six edges. Thus each face of the tetrahedron is composed of a six-membered $Hg_3(\mu\text{-}S)_3$ ring in approximate chair conformation, to give an adamantane-like stereochemistry. Isomerism can occur in such a cage due to the difference between the lone pair and phenyl substituents upon the sulphur atoms. The phenyl groups are po-

[a]Anisotropic thermal parameters are given in the form of isotropic equivalent parameter defined as $U_{eq} = (1/3)\,\Sigma_i\Sigma_j U_{ij} \cdot a_i^* \cdot a_j^* \cdot a_i \cdot a_j$.

[b]Cl(2) through O(8) have multiplicity 0.6, Cl(2)′ through O(8)′ multiplicity 0.4.

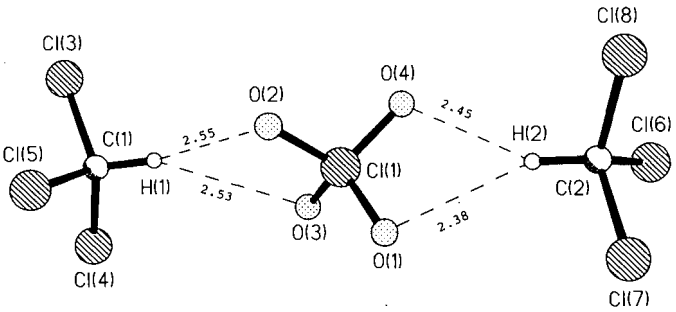

FIG. 1. A view of the $[ClO_4 \cdot 2CHCl_3]^-$ assembly.

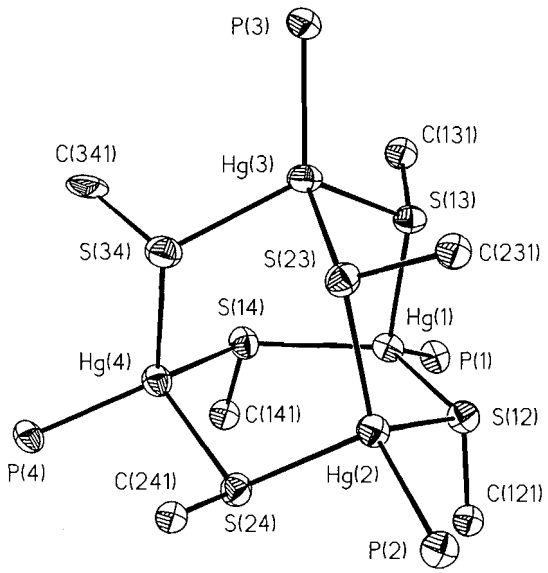

FIG. 2. The adamantane-like skeleton of the cation. Thermal ellipsoids are drawn at the 50% probability level.

sitioned either axially (a) or equatorially (e) in each ring (1). However, where two rings share a common edge formed by a bridging thiolate ligand, the adoption of an axial disposition with respect to one ring, *ipso facto* defines this group as equatorially disposed with respect to the other; there are thus always six axial and six equatorial substituents.

The four geometric isomers of $Hg_4(\mu\text{-}SR)_6$ that are possible (40) differ in the number of energetically disfavored 1,3-axial,axial substituent–substituent non-bonded interactions (3). The cation in **1** adopts the stereochemistry of isomer III, [aee, aee, aae, aae]. This isomer has only two axial–axial pairs of interactions, and occurs in twelve of the twenty one reported $(\mu\text{-}SR)_6M_4$ cages (3–24, footnote 2). Isomer III has point symmetry C_1 and can exist in enantiomeric forms. Both enantiomers are present in the crystal lattice, since **1** crystallizes in the centrosymmetric space group $P\bar{1}$.

Selected interatomic distances and angles for **1** are given in Table 3, the remainder have been deposited as Table S5. The non-bonded Hg. . .Hg distances range from 4.276 to 4.392 and the S. . .S values from 3.397 to 4.227 Å. The Hg—S distances range from 2.534(3) to 2.610(3) Å, and around the Hg atoms the S—Hg—S angles vary particularly widely, from 82.0(1) to 123.0(1)°, the S—Hg—P angles less so, from 107.1(1) to 121.0(1)°. The Hg—S—Hg angles also differ, ranging from 111.9(1) to 117.0(1)°.

TABLE 4. Torsion angles in degrees for Hg_3S_3 rings

	Atom 1	Atom 2	Atom 3	Atom 4	Angle[a]
Ring 1	S(13)	Hg(1)	S(12)	Hg(2)	73.14(15)
	S(23)	Hg(2)	S(12)	Hg(1)	−66.25(16)
aee	S(12)	Hg(2)	S(23)	Hg(3)	44.44(16)
	S(13)	Hg(3)	S(23)	Hg(2)	−43.68(16)
	S(23)	Hg(3)	S(13)	Hg(1)	73.18(15)
	S(12)	Hg(1)	S(13)	Hg(3)	−84.20(14)
Ring 2	S(14)	Hg(1)	S(12)	Hg(2)	−24.24(21)
	S(24)	Hg(2)	S(12)	Hg(1)	49.96(16)
aae	S(12)	Hg(2)	S(24)	Hg(4)	−76.67(14)
	S(14)	Hg(4)	S(24)	Hg(2)	66.17(15)
	S(24)	Hg(4)	S(14)	Hg(1)	−30.60(19)
	S(12)	Hg(1)	S(14)	Hg(4)	13.70(22)
Ring 3	S(13)	Hg(3)	S(34)	Hg(4)	13.25(20)
	S(14)	Hg(4)	S(34)	Hg(3)	−36.59(16)
aae	S(34)	Hg(4)	S(14)	Hg(1)	76.82(17)
	S(13)	Hg(1)	S(14)	Hg(4)	−76.74(17)
	S(14)	Hg(1)	S(13)	Hg(3)	38.59(15)
	S(34)	Hg(3)	S(13)	Hg(1)	−14.70(19)
Ring 4	S(23)	Hg(3)	S(34)	Hg(4)	−85.51(15)
	S(24)	Hg(4)	S(34)	Hg(3)	73.52(16)
aee	S(34)	Hg(4)	S(24)	Hg(2)	−39.75(15)
	S(23)	Hg(2)	S(24)	Hg(4)	40.66(15)
	S(24)	Hg(2)	S(23)	Hg(3)	−67.65(16)
	S(34)	Hg(3)	S(23)	Hg(2)	77.91(15)

[a]An angle is positive if, when viewed from atom 2 to atom 3, a clockwise rotation superimposes the bond from atom 1 to atom 2 upon that from atom 3 to atom 4.

Moreover, an inspection of the torsion angles in Table 4 shows that the ideal chair conformation of the two Hg_3S_3 rings bearing aae substituents is flattened into one better described as an envelope. Thus in this cationic mercury complex there are significant deviations from ideal adamantane-type stereochemistry.

The Hg—P distances vary from 2.478(3) to 2.509(3) Å, values significantly shorter than those of 2.527(4) and 2.547(4) Å observed in the $[Hg(PMe_2Ph)_4]^+$ cation (41). There is good agreement between P—C and S—C bond lengths, with mean values of 1.811(5) and 1.780(13) Å, respectively.

The structural chemistry of mercury thiolates shows a fascinating variety of assemblies containing both common Hg(II) coordination geometries, linear and tetrahedral. Bridging thiolate ligands are common, with a wide range of Hg—S distances. A search of the CSD (34) yielded thirteen entries describing a total of fifteen structures with $(\mu_2\text{-}SR)$ ligands (42–52). The structures of the complexes and geometries of the Hg—S—Hg bridges are summarised in Table 5. The prevalent structural feature is the infinite —(—Hg—SR—)$_n$— chain (42–46), cross-linked into sheets or three-dimensional networks. With dithiolate ligands, an infinite chain of $[Hg_2(SCH_2CH_2S)_3]^{2-}$ dianions is formed by 1,2-dithiolatoethane (47), while *trans*-1,2-dithiolatocyclohexane forms a dinuclear complex with Hg_2S_2 core (48). $Hg(SCH_2CH_2CH_2CH_3)_2$ crystallizes with two HgS_4 tetrahedra linked by edge and corner sharing into helical chains (49), and the $[Hg_2(SCH_3)_6]^{2-}$ ion forms a centrosymmetric, doubly bridged dimer (50). Hg_3S_8 cores are known (47, 51), as are eight-membered Hg_4S_4 rings (43, 52). The cation in **1** consists of four HgS_3P tetrahedra, each interlinked by $(\mu_2\text{-}SR)$ ligands

at three corners. The major differences between **1** and other structures containing (μ_2-SR) ligands are the much larger Hg—S—Hg angles and the greater Hg. . .Hg separations in the adamantane-like structure.

We have noted that the isomer of $[(\mu\text{-}SC_6H_5)_6\{HgP(C_6H_5)_3\}_4]^+$ found in the solid state, isomer III, is that with the smallest number of 1,3-axial, axial phenyl non-bonded interactions. In an earlier study of related Cd and Zn selenolate complex anions (24), we suggested that the skeleton distorts to minimise the unfavourable repulsive interactions between axially disposed substituents. The presence of bulky triphenylphosphine ligands on the Hg atoms apparently magnifies this distortion. Further studies are planned to explore this hypothesis.

Limiting quantum yield measurements for the disappearance of 1-propanol and propanal: an oxidative reaction study employing a TiO_2 based photoreactor

GIUSEPPE P. LEPORE, BHUVAN C. PANT, AND COOPER H. LANGFORD[1]

Department of Chemistry, University of Calgary, 2500 University Drive N. W., Calgary, AB T2N 1N4, Canada

Received March 30, 1993

GIUSEPPE P. LEPORE, BHUVAN C. PANT, and COOPER H. LANGFORD. Can. J. Chem. **71**, 2051 (1993).

Relative initial quantum yields ($\Phi'_{0\ dis}$) for the disappearance of 1-propanol and propanal were estimated based on total light intensity entering the reaction vessels. Two types of photocatalytic reactor geometries were compared, a commercial prototype flow reactor with immobilized TiO_2 and a conventional reactor with TiO_2 dispersion. A maximum relative quantum yield, $\Phi'_{lim} \approx 1$, was extrapolated for pure propanol and propanal in both geometries. The high quantum yields were attributed to efficient competition of substrate oxidation with electron–hole recombination, at high surface coverage. Propanal was identified as the primary intermediate generated from 1-propanol in both reactor systems, but yields of propanal were systematically 10 times lower than 1-propanol loss, indicating that there was an effective pathway for propanal oxidation on the surface prior to desorption. The inhibition of 1-propanol reaction caused by accumulation of product arises because both reactant and product compete for active sites on the photocatalyst surface. These propositions were confirmed by introducing propanal into the feed. The relative quantum yields converge to unity for pure substrates, suggesting that they are true yields. That is to say, absorption by TiO_2 of light entering the reactor is efficient in these geometries.

GIUSEPPE P. LEPORE, BHUVAN C. PANT et COOPER H. LANGFORD. Can J. Chem. **71**, 2051 (1993).

En se basant sur l'intensité totale de la lumière entrant dans les récipients réactionnels, on a évalué les rendements quantiques relatifs initiaux ($\Phi'_{0\ dis}$) de disparition du 1-propanol et du propanal. On a comparé deux types de géométries pour les réacteurs photocatalytiques, un prototype commercial d'un réacteur à écoulement avec du TiO_2 immobilisé et un réacteur conventionnel avec une dispersion de TiO_2. Pour chacune des géométries, on a pu extrapoler un rendement quantique relatif maximal, $\Phi'_{lim} \approx 1$, pour le propanol pur ainsi que pour le propanal. On attribue les valeurs élevées des rendements quantiques à une compétition efficace, à une couverture élevée de la surface, de l'oxydation du substrat avec la recombinaison électron–trou. Pour chacun des réacteurs, on a identifié le propanal comme intermédiaire primaire généré par le 1-propanol, mais les rendements en propanal sont systématiquement 10 fois plus lents que les pertes du 1-propanol; ces observations indiquent que, avant la désorption, il existe à la surface une voie efficace pour l'oxydation du propanal. L'inhibition de la réaction du 1-propanol avec accumulation de produits a été attribuée à une compétition entre le réactif et le produit pour les sites actifs présents à la surface du photocatalyseur. Ces propositions sont confirmées par l'introduction de propanal dans la source. La convergence des rendements quantiques relatifs vers l'unité pour les substances pures suggère que ces valeurs correspondent au rendement quantique vrai, c'est-à-dire que, pour ces géométries, l'absorption par le TiO_2 de la lumière entrant dans le réacteur est efficace.

Introduction

This work studies the band gap excitation of TiO_2 in the photochemical destruction of organic wastes. References 1–13 cover this topic. Photochemical activation excites an electron from a valence band to a conduction band, leaving a vacancy ("hole") in the valence band. The electron–hole pair may then migrate to and be trapped at the surface of the semiconductor. The holes in the valence band and the electrons in the conduction band can then oxidize or reduce the adsorbed species, surface groups, or the semiconductor itself. When there are no suitable hole or electron scavengers at the surface, carrier recombination dominates (and can occur within a few nanoseconds) and the energy absorbed will dissipate energy as heat (13–15). Since interfacial charge transfer can occur in less than 10 ps (15, 37), it can compete effectively with recombination.

In an aqueous medium, water is the dominant adsorbate. The primary product of interfacial electron transfer is often an adsorbed hydroxyl radical (16, 17). Moreover, this radical can be detected directly by spin trapping and electron paramagnetic resonance (18–20). Hydroxyl radicals are often assumed to be active in the photocatalytic degradation of many contaminants by initiating reactions of organic compounds. Since electron transfer rates are expected to correlate with the over-potential according to the Levich equation (21–23), an adsorbed organic molecule may capture holes from TiO_2 faster than water. Recent studies clearly indicated that reaction takes place on the TiO_2 surface rather than in the solution (7, 24–26). However, the distinction between a surface-bound hydroxyl radical and a trapped hole may be little more than semantic (35).

In the past six years, there have been studies to immobilize TiO_2 on various supports. Serpone et al. have bound titanium dioxide onto glass beads (27) and Matthews successfully immobilized TiO_2 onto the interior of glass (28) and Teflon (29) tubing, woven glass mesh (30), and sand (31). The fibre glass mesh has been used in a commercial prototype photoreactor.[2] To understand TiO_2 reactions, one must first answer the following questions. Does electron–hole recombination in TiO_2 limit its efficiency as a catalyst? Or, is substrate conversion controlled by mass transport, adsorption and the relative rates of primary intermediates compete with substrate desorption? What is the relation of the mechanism on the titanium dioxide surface to that indicated by intermediates observed after desorption into the liquid bulk? This paper will address these issues by examining a small prototype photoreactor from Nutech Envi-

ronmental[2] and a dispersion of TiO_2 in a reactor of similar geometry.

We choose to focus on a parameter related to quantum yield rather than on rate constant, since it deals with efficiency more directly. The choice of 1-propanol is to bias results toward maximum quantum yield, which in turn will shed better light on electron–hole recombination.

Experimental

Chemicals

Anhydrous 1-propanol 99+%, propionaldehyde (propanal) 99+%, 1,10-phenanthroline 99+% and propionic acid 99+% gold label were purchased from Aldrich. Titanium dioxide, Degussa P-25, was a gift from Degussa. Ferric chloride (J.T. Baker Co.) and potassium oxalate (Fisher) were laboratory grade reagents. These reagents required no further purification and their solutions were prepared in doubly deionized distilled water.

Instruments

A Perkin–Elmer Sigma 2 gas chromatograph combined with a Chromosorb 101 packed column (Chromatographic Specialties Inc.) and a flame ionization detector, interfaced with a Sigma 10 data station, was used to quantitatively monitor reactant and product concentrations. The operating conditions were as follows: column temperature (isothermal) 140°C, injection port temperature 180°C, detector temperature 200°C, and the carrier gas was prepurified nitrogen at a flow rate of 30 mL/min. Product qualitative analysis used a Hewlett–Packard GC–MSD (5890 gas chromatograph – 5970 mass selective detector) interfaced with a 9000/216 data station. The analyses were conducted by temperature programming: initial temperature, 70°C, temperature increment, 1°C/min; final temperature, 120°C. The injection port was set to 150°C and the detector zone, 250°C. The column was a Hewlett-Packard Pona capillary, crossed-linked methyl silicon gum (50 m × 0.2 m × 0.5 μm film thickness). The flow rate of the prepurified helium was 8 mL/min. The MSD was set to scan 20–500 amu.

A Hewlett–Packard diode array spectrophotometer (model HP8452) was used to determine absorbance during the chemical actinometry experiments. Surface area analysis was conducted with a Micrometrics instrument at low temperature using N_2 adsorption.

Photocatalytic reactors

In this work we use two geometries: Reactor I, a control system that contains TiO_2 suspensions (Fig. 1*a*), and Reactor II, a commercial prototype flow photoreactor (courtesy of Nutech Environmental[2]), which incorporates a TiO_2 film that is firmly bound to a fiberglass mesh (Fig. 1*b*).

Reactor I: The reaction vessel was a stainless steel tray (2.0 cm high × 4.5 cm wide × 38.0 cm long). It has two grooves, each at the end of the layout to accommodate a 20-W, tubular, low-pressure mercury fluorescent lamp (Phillips Electronics Ltd., "TL" 44 D25/09N) (Fig. 1*a*). According to the manufacturer's specification, the lamp emits radiation between 320 and 390 nm with a maximum intensity at 350 nm. The depth of the reaction vessel was 1.75 cm from the lamp, providing a maximum volume of 300 mL. However, the solution was set at 250 mL, a level well below the lamp. The 250 mL solution was thoroughly mixed by three stirring bars positioned at different locations along the tray. During illumination experiments the entire reactor was placed inside a wooden box which had a nonreflecting interior. The photoactive catalyst for this system was a finely dispersed white powder of titanium dioxide (Degussa P-25). Its B.E.T. (Brunauer–Emmett–Teller) surface area was confirmed to be 55.7 ± 0.5 m^2/g. An appropriate catalyst loading was determined experimentally by studying the conversion of a 0.010 M 1-propanol solution. A catalyst density of 0.3 g/L proved to be an effective quantity for this reactor. The conversion of 1-propanol was found to be insensitive to further increase of semiconductor loading. This insensitivity comes from the reaction geometry, which permits essentially total light absorption. Samples of these finely dispersed particles were taken by removing 2.00 mL aliquots after various exposure times and then centrifuging for 20 min at 4750 rpm. A portion of the centrifuged liquid was withdrawn with a Pasteur pipette and transferred to 2-mL sealed vials that were refrigerated for later analysis.

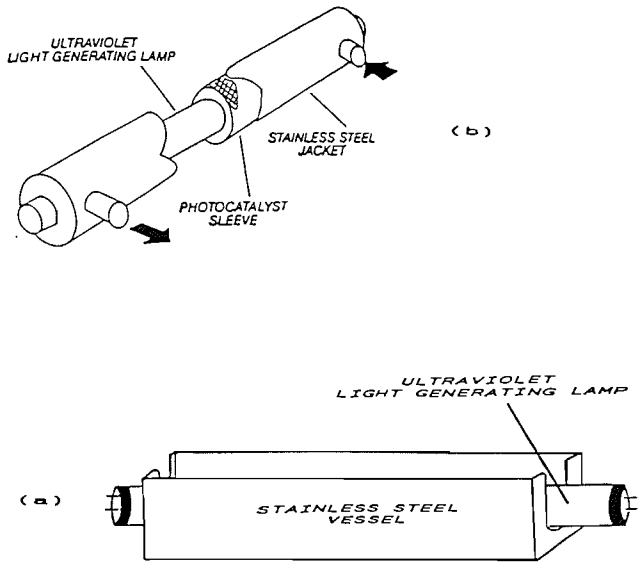

FIG. 1. Two photoreactor geometries examined in this investigation: (*a*) Reactor I, which employed a TiO_2 suspension and (*b*) Reactor II, a commercial prototype photoreactor that incorporates immobilized TiO_2.

Reactor II: The prototype flow reactor was fabricated from a stainless steel jacket (34 cm long by 2.3 cm inner radius), which accommodated a lamp and a photocatalytic mesh (Fig. 1*b*). An identical lamp to that in Reactor I (Phillips Electronics Ltd., "TL" 44 D25/09N, 20 W) was arranged coaxially within the jacket. Encircling the lamp was a fiberglass mesh (30 cm in length by 45 cm in width and an average 95 μm thick) coated with a firmly bonded layer of anatase titanium dioxide made via a sol–gel method.[2] The bound titanium dioxide layer had a B.E.T. surface area of 8.20 ± 1.48 m^2/g in comparison to the bare fiberglass mesh area of 6.56 ± 0.78 m^2/g. Its estimated coverage thickness was ≈2 μm and the catalyst loading on the fibers was calculated to be roughly 1 g/L, taking 20 as the number of perforations per cm^2 and each opening having an average area of 4×10^{-2} cm^2.

The total volume of solution circulated in the reactor was 750 mL. The reactor itself, excluding a reservoir, had a dead volume of 410 mL. The liquid was recirculated with an oscillating pump (Gormann–Rupp Industries Inc.) with a flow rate of 150 mL/min from a 1-L reservoir. The perforations and configuration of the mesh in the reactor create turbulent mixing that ensures good contact between the reactants and the photocatalyst.[2] A magnetic stirring bar was placed in the reservoir. To assure proper mixing and aeration, the outflow from the reactor entered the reservoir a few centimetres above the surface of the bulk solution. Materials in contact with the solution were stainless steel, polypropylene (pump valve housings), glass, and Tygon tubing.

Stock solutions were prepared in 2-L volumetric flasks to simplify comparison between dark controls and the photocatalytic experiments. Samples were taken by removing 1.00 mL aliquots from the reservoir after different exposure times. These aliquots were then placed into 2-mL sealed vials and refrigerated for later analysis. After every run the reactor was left on and flushed several times with water and the effluent was monitored until no residual organ-

For personal use only.

ics could be detected. The reactor was then rinsed with an another 4 L of water.

In both reactors, the lamps were warmed up for 10 min prior to photolysis. Furthermore, the solution in the reactor was in constant contact with air to ensure complete O_2 (gas–liquid) equilibration. Parallel dark experiments (controls) were performed to monitor the possibility of substrate loss and susceptibility to air oxidation. Substrate losses encountered during dark experiments were subtracted from losses measured in the photocatalysis study. As well, the bulk solution was monitored for pH and temperature changes in both reactors.

Quantum yield measurements

The quantum yield is the ratio of the amount in moles of product formed or reactant consumed to the amount in einsteins of energy absorbed. An elementary reaction that is completely energy efficient will have a quantum yield of unity. Thus, the quantum yield is the best parameter to indicate the efficiency of a photocatalyst. Unfortunately, quantum yield is not easily measured in heterogeneous photochemical reactions, since the amount of light absorbed by a catalyst cannot be measured in a reliable manner. Several authors (41, 42) have recently overcome this obstacle. Sciavello et al. (41) used photon flux to measure the amount of reflected and absorbed light at the entrance and exit of the light-tight photoreactor, which contained a selection of commercially available titanium dioxide preparations. Lepore et al. (42) evaluated true quantum yields for essentially transparent, suspended P-25 TiO_2 particles (diameter $\approx$ 124 nm) under monochromatic irradiation at 313 nm. The absorbed light intensity was calculated from the incident photon intensity and the known absorbance of TiO_2 at 313 nm.

In this paper we discuss a parameter (Φ') that reduces to the quantum yield Φ if, by using a sufficiently concentrated chemical actinometer, all the light entering the reactor is absorbed by the photocatalyst TiO_2 (5, 10, 43, 44). Trott, Henwood, and Langford (38) described this approach and recognized that the values obtained must be less than or equal to the true quantum yield since it assigns the maximum possible value to the denominator. This parameter was introduced as a tool for the comparison of relative efficiencies of some photodegradations under sunlight illumination.

A well-established chemical actinometer, potassium ferrioxalate, was selected for its sensitivity, ease of use, and wide spectral range (200–546 nm). The actinometry procedure was taken from the literature (34) and, since both reactors employed equivalent light sources, comparison of the two reactors was simplified. A 0.006 M actinometer concentration used for the two geometries was sufficient to absorb all entering light. This was confirmed by the insensitivity of light intensity to changes in actinometer concentrations. The duration of irradiation was chosen to limit the conversion of ferrioxalate to less than 15% to avoid secondary photo-processes. The static design of Reactor I accommodated an actinometer volume of 250 mL, which was continuously stirred and illuminated for 60 s. However, for the recirculating system (Reactor II) the flow rate (150 mL/min) and irradiation time (5 min) were selected for maximum light exposure of the 750 mL solution.

The quantity of Fe^{2+} formed upon irradiation was spectrophotometrically determined by the complexation of ferrous ions with 1,10-phenanthroline (phen) to form the red $[Fe(phen)_3]^{2+}$ moiety, which has an absorption maxima at λ = 510 nm (ϵ = 1.11 $\times$ 10^4 M^{-1} cm^{-1}). The reported quantum yield $\phi_{Fe^{2+}}$ for the production of Fe^{2+} is 1.21 at 350 nm.

Results

The radiant intensity inside Reactor II was determined to be 1.30 $\times$ 10^{18} photons per second either with or without the TiO_2 bound mesh. This value represents the maximum photon absorption rate for the anchored photocatalyst during photoreaction. The actual absorption of photons by the TiO_2 might be lower in both systems, especially in Reactor II, because of the low catalyst loading.

The light intensity in the static system (Reactor I) in the absence of the photocatalyst suspension was 1.60 $\times$ 10^{18} photons per second. The photon fluxes agreed within 4%, each time the chemical actinometer was employed in either system. Furthermore, the lamps could be interchanged between reactors. The difference in light intensities between the two reactor geometries may be due to the shadowing of the lamp ends in Reactor II.

Weak dependence of measured light intensity on actinometer concentration was seen in the commercial photoreactor. Since theoretical and mechanistic interest focuses on measurement of true quantum yields (Φ), the value quoted is in the concentration-independent region. Because variation of actinometer concentration has little effect on changes in the depth of light penetration around the TiO_2 bonded mesh, Φ' must closely approach the true quantum yield. The only reason for such weak dependence is absorption by the mesh of all photons reaching the mesh. We note below that the overall results support this view. It is important to interpretation of Φ' that in Reactor II no appreciable difference was observed for the ferrioxalate actinometer in the absence or presence of the immobilized TiO_2 mesh.

Relative values of Φ' given below for various propanol and propanal concentrations remain significant in any case since the variations of nonabsorbing substrate concentrations do not affect the efficiency of light absorption by TiO_2. The quantity Φ' is a lower limit to the true quantum yield as explained above. The relative quantum yield (Φ') is calculated from eqs. [1] and [2]

$$[1] \quad \Phi' = \frac{C_p}{I}$$

$$[2] \quad \Phi'_{dis} = \frac{(C_0 - C_i)}{I}$$

where Φ'_0 is the relative initial quantum yield (intercept at t = 0); Φ', the quantum yield of product formed, Φ'_{dis}, the quantum yield of the sum of products formed or the disappearance of the reactant; C_p represents moles of individual product formed (1°, 2°, 3° . . . etc.); C_0, initial moles of reactant; C_i, moles of reactant remaining in the ith irradiated sample; and I, the intensity, in einsteins, of light entering the reactor.

The difference in system geometry and dead volumes between the two reactors determines the amount of light delivered to the reaction zone in each. In Reactor II, several experiments were performed with 1-propanol and propanal separately as a function of substrate concentration, while in Reactor I only 1-propanol was investigated for reasons given below. In both reactors the solutions were well aerated so that oxygen could be an efficient acceptor for conduction band electrons. Prior to photocatalysis, blank experiments were conducted under illumination in the absence of TiO_2 for each substrate, for a duration of 70 min. Since none of these compounds absorb light above 300 nm, any change in their respective concentrations would be due to evaporation, thermal decomposition, or air oxidation. Furthermore, parallel dark experiments were also carried out in the presence of TiO_2 for a period of 70 min. The blank and dark samples

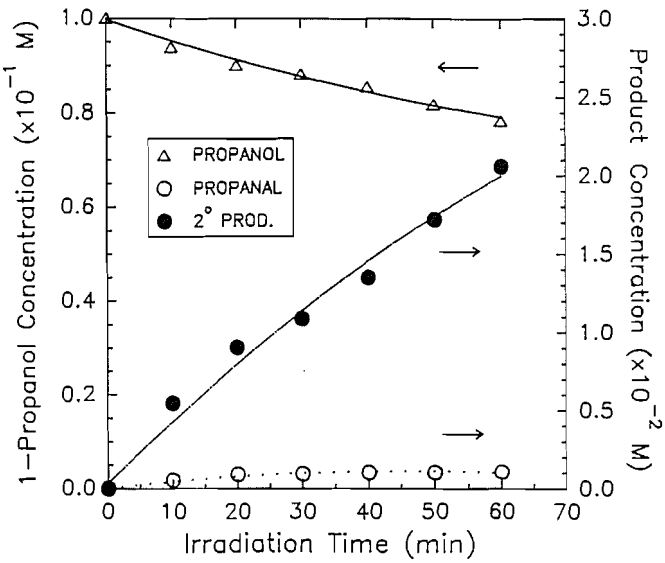

FIG. 2. The photocatalytic conversion of 1-propanol (open triangles) employing Reactor I. The measured concentration of 1-propanol remaining is delineated on the left vertical axis ($\times 10^{-1}$ M). Concentrations of generated products, propanol (open circles) and 2° prod. (filled circles), are represented on the right vertical axis ($\times 10^{-2}$ M).

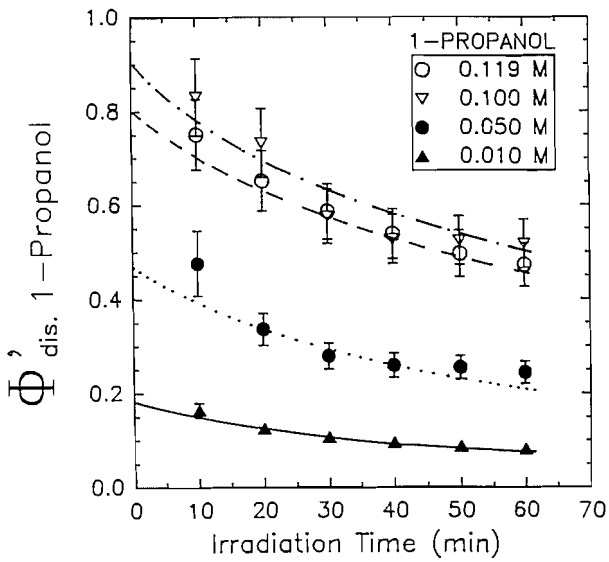

FIG. 3. Quantum yields of disappearance of 1-propanol (Φ'_{dis}) in Reactor I measured as a function of illumination time at four different reactant concentrations: 0.010 M (filled triangles), 0.050 M (filled circles), 0.100 M (inverted open triangles), 0.119 M (open circles).

were analyzed several times by GC–MSD, and under these circumstances only some evaporation could be demonstrated as a loss mechanism.

Significant losses were observed in Reactor I under blank conditions for propanal solutions. This confined the investigation to 1-propanol, since it is less volatile and it is also possible to monitor its oxidation intermediates. All photocatalysis results were corrected for small substrate losses from the blank controls. In all cases, as discussed below, the apparent quantum yields exhibited distinct decreases with increasing illumination time. This behavior is not simply a reflection of substrate loss since it becomes significant at low conversion. One major contributor to the decline in quantum yields is reactant–product competition for active surface sites. However, quantitative discussion is limited in most cases to values of Φ' extrapolated to time zero (Φ'_0), a parameter that eliminates the need for blank correction and the influence of product buildup, and thus makes interpretation more straightforward.

Reaction temperatures were monitored throughout this study, and were found not to exceed 30°C for either system. It has been documented that reaction rates are influenced by the solution temperature (32, 33). Moreover, Harvey et al. (33) reported that activation energies (277–313 K temperature range) for rutile TiO_2 are insensitive to reaction conditions, but are influenced by changes in excitation wavelengths. This insensitivity implicates processes within the photocatalyst instead of in the photocatalysed reaction. The contribution of thermal decomposition proved to be insignificant: in an experiment in which a 0.062 M 1-propanol solution (in the presence of TiO_2) was maintained at 35°C for 90 min in the dark, no intermediates were detected. The pH was also monitored (initial pH 5.5) but no significant change was observed. Prior to illumination, substrate solutions were thoroughly mixed for 5 min in the reactors.

Experiments using Reactor I

A typical experiment using the dispersion of P-25 TiO_2 is shown in Fig. 2. An initial concentration of 0.100 M 1-propanol was illuminated for a duration of 60 min. Over this time span the propanol concentration decreased by about 20%. The slight upward curvature indicates declining apparent quantum yield. Notice that measurable propanal produced never exceeds 20% of 1-propanol consumed; this curve was corrected for losses averaged over three dark controls. At longer irradiation times (>90 min) propanal concentration decreased almost to zero. If propanal is the primary intermediate, it is not efficiently desorbed. The flat propanal curve suggests an **A** → **B** → **C** sequence. On this assumption, the curve for secondary intermediate(s) (2° prod.) is calculated. Quantitative analysis performed with GC–MSD revealed that the 2° prod. includes a small amount of propionic acid and ethane; however, all further stages of oxidation to CO_2 may contribute.

The reaction sequence (**A** → **B** → **C**) was confirmed by an independent study of propanal in a closed system that revealed clearly the presence of propionic acid. In the series of experiments with initial 1-propanol concentration ranging from 0.030 to 0.119 M, secondary intermediate(s) occur in greater quantity than propanal. It seems that further photolysis of propanal is relatively rapid compared to desorption. This phenomenon was also observed for Reactor II, which implies that propanal is adsorbed more strongly than the alcohol. Contributions due to propanal evaporation would be inconsistent with this interpretation, since results were corrected for losses.

Relative quantum yields for 1-propanol disappearance (Φ'_{dis}) were calculated for the full range of the alcohol concentrations (0.010–0.119 M) and plotted versus irradiation time (Fig. 3). The individual curves displayed a high apparent yield (>0.2) at time zero, which falls with continued illumination. Yields of propanal found in the solution are

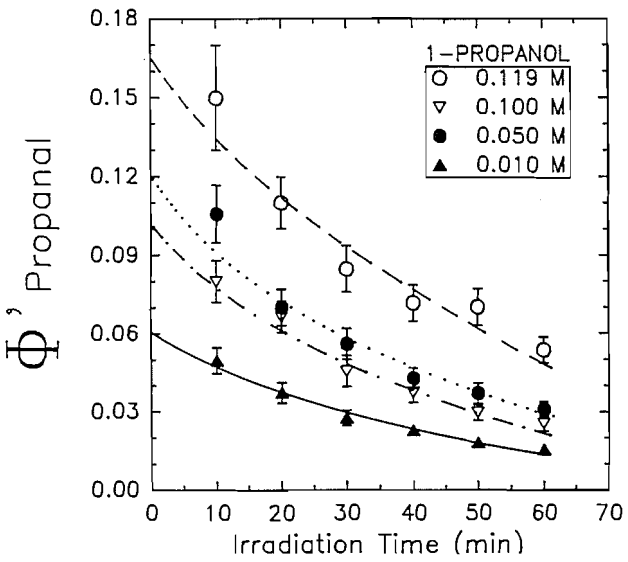

FIG. 4. Quantum yield for the production of propanal (Φ′) plotted as a function of irradiation time in Reactor I. Four distinct curves were obtained, each corresponding to an initial 1-propanol concentration: 0.010 M (filled triangles), 0.050 M (filled circles), 0.100 M (inverted open triangles), 0.119 M (open circles).

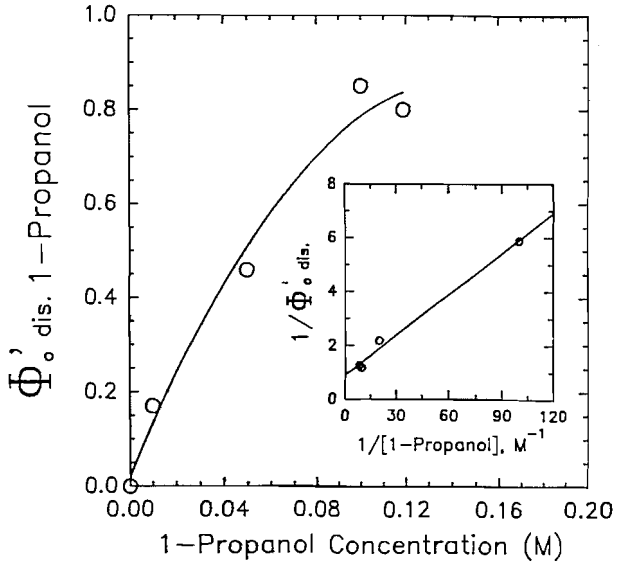

FIG. 5. A concentration dependence plot; initial quantum yields of disappearance of 1-propanol ($\Phi'_{0\ dis}$). The inset represents the double reciprocal plot of $\Phi'_{0\ dis}$ vs. propanol concentration, for the evaluation of limiting quantum yield conversion and apparent binding constant for the reactant.

illustrated in Fig. 4. The apparent quantum yields of observable propanal are all low (<0.2). The intermediate (propanal) decreases with prolonged exposure to irradiation in a way comparable to the reactant, 1-propanol. The changes are more pronounced at higher total concentration, which corresponds to higher surface coverage. This suggests that propanal is retained on the surface long enough to be efficiently oxidized in competition with its desorption into solution.

Langmuir–Hinshelwood kinetics (L–H) have often been applied to TiO_2 photocatalysis (eq. [3]). This expression represents surface unimolecular reactions that arise from light excitation of TiO_2 in cases where the reactant is more strongly adsorbed than the intermediate(s) (which may be minimal or absent). The above results imply strong adsorption of intermediates. Relative quantum yields for 1-propanol disappearance were extrapolated to time zero $\Phi'_{0\ dis}$, where there is no product accumulation. There, Langmuir–Hinshelwood kinetics may apply. The solvent (water) may adsorb competitively but its concentration is much greater than that of the solute and remains essentially constant. Thus water has been omitted from the expression. Its competitive effect enters into the equilibrium adsorption–desorption coefficient, K (binding constant).

$$[3] \quad \Phi'_{0\ dis} = \frac{\Phi'_{lim}\, K[C_0]}{1 + K[C_0]}$$

In eq. [3], Φ'_{lim} is the limiting quantum yield of conversion at high surface coverage. The Φ'_{lim} is a function of the competition between interfacial electron transfer and carrier recombination. Equation [3] can be transformed into a linear expression (eq. [4]), where the intercept gives the limiting quantum yield and the slope allows calculation of K.

$$[4] \quad \frac{1}{\Phi'_{0\ dis}} = \frac{1}{\Phi'_{lim}} + \frac{1}{\Phi'_{lim}\, K[C_0]}$$

Figure 5 shows the linearized plot of initial quantum yields for the disappearance of 1-propanol ($\Phi'_{0\ dis}$) as a function of initial reactant concentration. The limiting yield is extrapolated to neat (infinite) 1-propanol levels, and is determined from the best-fit straight line to be about one. This is in agreement with an aspect of earlier work by Ergeton and King (39), for *pure* isopropanol. These authors reported a maximum unit quantum yield under unfiltered uv light, which decreased at 335 nm (filtered light) by about one half and at 404 nm (filtered light) by approximately one third. However, extrapolation to pure substrate levels does not imply that this is the critical concentration for attaining such a maximum quantum yield. The important factor in reaching Φ'_{lim} is complete surface coverage of the photocatalyst, which may well occur at lower substrate concentration as our results suggest.

The slope of the best-fit linearized plot in Fig. 5 gave an approximate equilibrium binding constant of 18 M^{-1}. The limiting value of unity for $\Phi'_{0\ dis}$ suggests that this parameter is in fact the true quantum yield, since a true yield above one is unlikely and Φ′ is always less than Φ. The photocatalyst, TiO_2, appears to absorb all the photons in this reactor configuration.

Experiments using Reactor II

The next stage of this investigation was to evaluate the change of geometry imposed by the commercial prototype photoreactor and to further investigate the points suggested by the study in Reactor I. In a typical experiment (Fig. 6), the photolysis of 0.0615 M 1-propanol solution for a period of 70 min in the presence of an immobilized TiO_2 resulted in a decline in the initial concentration of alcohol, with low production of propanal. The calculated secondary component was once again the major observed product in the system.

The apparent $\Phi'_{0\ dis}$ values for various initial 1-propanol concentrations in the reservoir were obtained by extrapolation. The data were then treated with the modified L–H

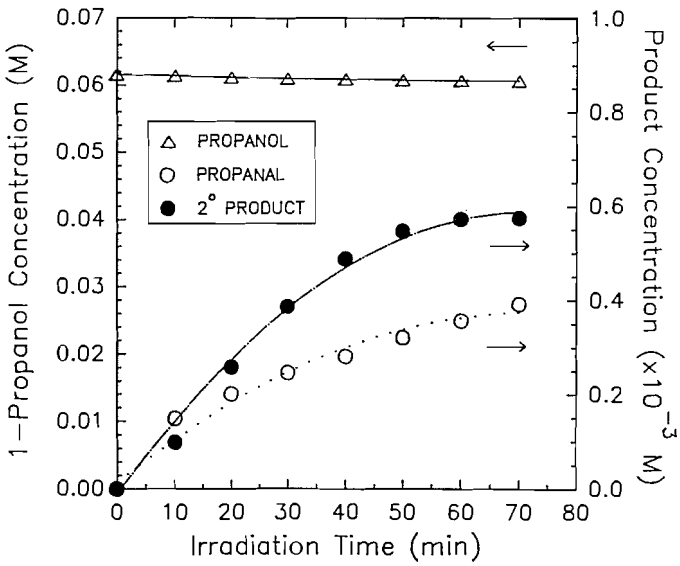

FIG. 6. The photocatalytic oxidation of 1-propanol (open triangles) in a prototype photoreactor (Reactor II) is represented on the left vertical axis. Product accumulation, propanal (open circles) and 2° prod. (filled circles), is delineated on the right vertical axis ($\times 10^{-3}$ M).

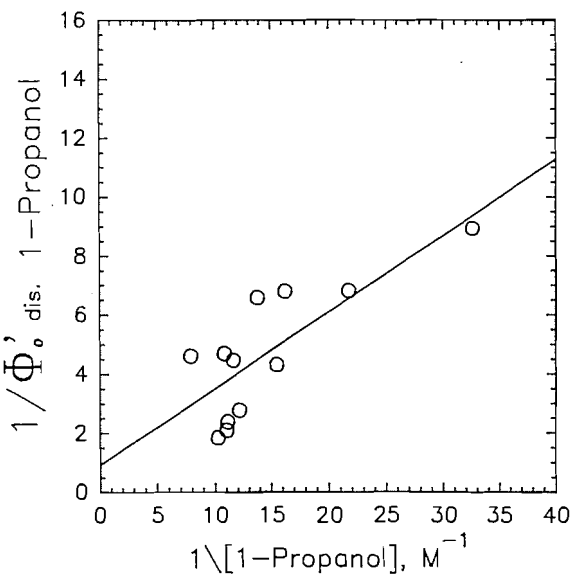

FIG. 7. Double reciprocal plot of initial quantum yields of disappearance ($\Phi'_{0\,dis}$) vs. initial 1-propanol concentration for the estimation of limiting quantum yield and apparent binding constant (Reactor II).

expression (double reciprocal plot) to estimate the Φ_{lim} and the equilibrium binding constant (Fig. 7). The best-fit double reciprocal plot gave an approximate limiting quantum yield near unity with a binding constant of 3.6 M^{-1} for 1-propanol. The high noise in Fig. 7 is characteristic of the high reactant concentrations required, which made it difficult to measure the loss of 1-propanol. The data are consistent with earlier results, indicating a limiting yield of one. Since three experiments imply a limiting yield near one using objective linear least-squares fitting techniques, we must comment on the precision of the limits. The standard deviation of the intercepts ranges from 17% in the best case (propanal) to over 100% in the worst case (propanol on the mesh). However, these overstate the uncertainty of the estimation of the intercept. The slope/intercept fitting uses all data points equally; the intercepts are most strongly determined by the *few points* at the highest concentrations and these do not support such large variation in intercept. Certainly, the higher points are not consistent with an intercept much below one. Only deviations from values greater than one could be large. We would need to view the present results as mainly qualitative, indicating large yields. Our confidence in the assignment of values near one depends on a supplementary confirming study. Lepore et al. (42) developed a separation of dispersion of Degussa P-25 TiO_2, which produced dispersions that are transparent in the visible with definable absorption at 313 nm. It was possible to measure precise and well-defined quantum yields for these dispersions using conventional spectrophotometric absorption techniques. As reported in detail (42), we can confirm unit limiting quantum yield with an uncertainty of less than 10%. We do not believe that particle size segregation is a critical factor and we propose to interpret the indications of the present study at face value.

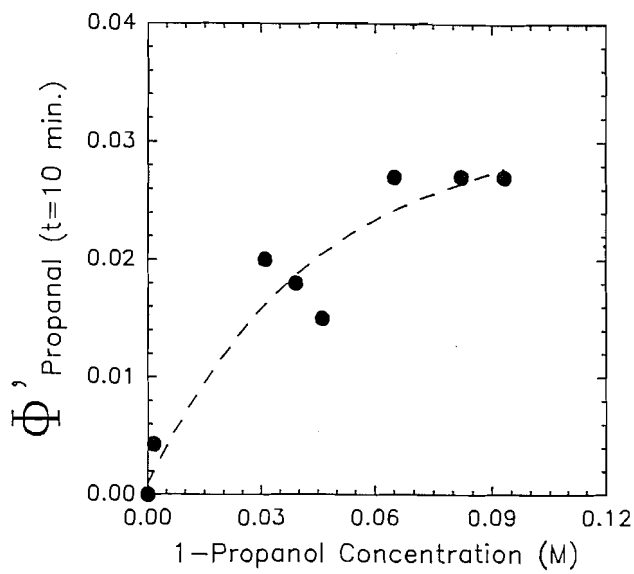

FIG. 8. A plot of quantum yield for the production of propanal (Φ') vs. initial reactant concentration (1-propanol). The Φ' were measured at an illumination time of 10 min (Reactor II).

The significant differences between the results for the particle dispersion (Reactor I) and the TiO_2 film on a glass mesh (Reactor II) are the lower apparent K in the second case and the reduced ratio of propanal produced to 1-propanol consumed in the TiO_2 film reactor. The consecutive accumulation of propanal (Φ') from the photocatalytic oxidation of 1-propanol was measured at an illumination time of 10 min (Fig. 8). The curve manifests a relative maximum quantum yield for the production of propanal at elevated alcohol concentrations. This optimum production of propanal (Φ') in the bulk solution is approximately 20 times lower than the consumption of 1-propanol.

To investigate the suggestion that propanal adsorbs strongly and can subsequently be efficiently oxidized, propanal was introduced into the feed in the next series of experiments. As noted above, a parallel experiment was not feasible in Re-

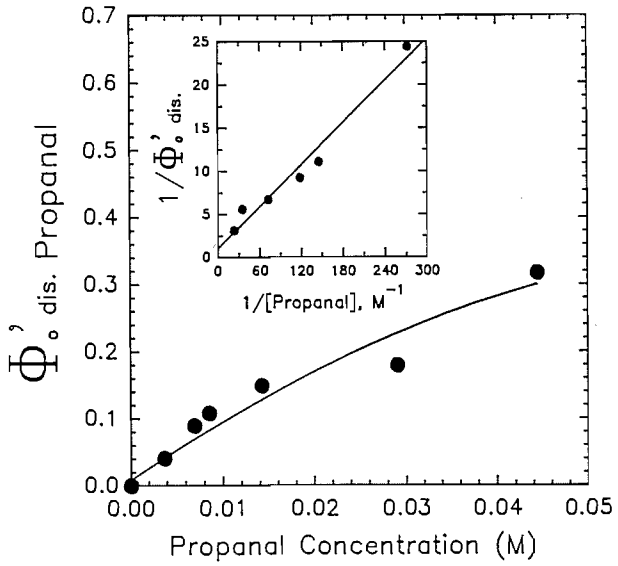

FIG. 9. Initial quantum yields of propanal disappearance plotted against initial propanal concentration, employing Reactor II. The inset figure depicts a double reciprocal plot of $\Phi'_{0\ dis}$ vs. initial reactant concentration.

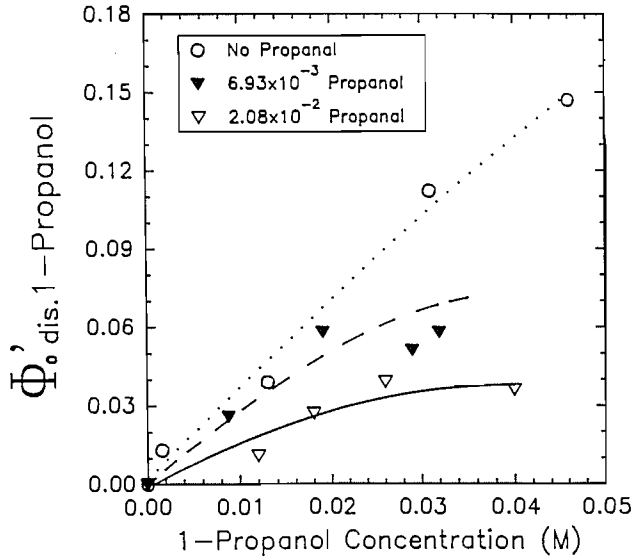

FIG. 10. Two-component mixture to exemplify reactant–product competition (Reactor II). Propanal concentration was maintained constant while concentration of 1-propanol was varied. The $\Phi'_{0\ dis}$ of the alcohol were extrapolated and plotted against initial 1-propanol concentration. The figure displays three curves: no propanal present (open circles), 6.93×10^{-3} M propanal (inverted filled triangles), and 2.08×10^{-2} M propanal (inverted open triangles).

actor I. A plot with less scattering was obtained as a result of good conversion at lower total propanal concentration (Fig. 9). A double reciprocal plot of the data (Fig. 9, inset) revealed once again a best-fit extrapolated Φ_{lim} of ≈ 1.0 with an equilibrium binding constant $K = 13\ M^{-1}$. This value is 3.8 times greater than the binding constant of 1-propanol, which confirms that propanal is more strongly adsorbed than 1-propanol over the immobilized metal oxide. This result provides a background for direct propanol–propanal competition experiments. Equation [3] may be written in a general form (eq. [5]) to accommodate several competitive adsorbates: C_0, C_1, . . . C_n; other symbols have meanings parallel to those given for eq. [3].

$$[5] \quad \Phi'_{0\ dis} = \frac{\Phi'_{lim} K[C_0]}{1 + K[C_0] + K_1[C_1] + \ldots K_n[C_n]}$$

Ideally, we would wish to evaluate directly the competition for 1-propanol offered by propanal generated as an intermediate on the surface of the metal oxide. Unfortunately, data for reaction of propanal introduced in solution do not give direct access to this information, since the equilibrium for adsorption from solution includes diffusional transport to the surface, which causes the dependence on bulk concentration. As a second best, mainly suggestive, experiment, we establish competition between 1-propanol and propanal, both from the solution.

Two-component mixtures were fed into the reactor with propanal concentration maintained constant and that of 1-propanol varied. The individual solutions were illuminated for a period of 70 min and $\Phi'_{0\ dis}$ values for 1-propanol were estimated by extrapolating to time zero. These $\Phi'_{0\ dis}$ values were plotted against initial 1-propanol concentration (Fig. 10). Three curves are presented in Fig. 10: one curve depicts a solution containing exclusively 1-propanol (dotted curve), the other two curves represent two-component mixtures, which contained 6.93×10^{-3} M (broken lines) and 2.08×10^{-2} M propanal (solid curve). The data clearly illustrate propanal inhibition of 1-propanol photocatalytic oxidation, which is qualitatively consistent with the relative K values obtained above.

Discussion

The first consequence of this investigation was to demonstrate, by employing different reactor geometries, that high quantum yields on TiO_2 surfaces can be obtained. Our related results (42) add additional "geometries". If the quantum yields for electron–hole pair separation (surface carrier trapping) following band-gap excitation can reach unity, then it is plausible to capture most, if not all, of these surface reactive species with suitable scavengers. For reaction quantum yields to reach unity over the surface of the semiconductor oxide, substrate reactions must occur quite rapidly. As earlier picosecond transient spectroscopy indicated (15, 37), interfacial electron transfer can compete effectively with electron–hole recombination. However, colloidal particles of TiO_2 were used in these investigations. The reaction sequence on larger particles (with a space charge layer) is more complex. The transit times for diffusion of minority carriers to the surface of large particles are longer and consequently may make recombination effects important in competition with surface trapping (36). With TiO_2 bound to supports there should be no significant difference from the TiO_2 dispersions, with the exception of extremely small colloidal dispersions (36). Thus a low limiting quantum yield for conversion of a readily oxidizable substrate in the fixed TiO_2 geometry would reveal the contributions of recombination events.

The assumption that the reactor geometries used here lead to a TiO_2 photon absorption of 100% implies that Φ approaches a limit of 1.0 in both systems. Any failure of light absorption by the photocatalyst causes Φ' to fall below the

Propanal (0.001 M)	—	—	13	0.013

true quantum yield (Φ). Conversely, if Φ' exceeds unity, the implication of a "current doubling" type of mechanistic route (25) must not be overlooked. This could arise if conduction band electrons scavenged by molecular oxygen give rise to superoxide radical anions ($O_2^{\cdot -}$) that disproportionate to hydroxyl radicals (·OH). This could lead to a maximal Φ of two. However, it is more likely that superoxide intermediates contribute the second oxidative equivalent required in two-electron overall organic oxidations. The common convergence on 1.0, along with the relative insensitivity of measured intensity to changing concentrations of actinometer solution in actinometry experiments, favours the conclusion that all the photons in the reactive zones of these two reactor configurations are absorbed by TiO_2. Of course, many photons can be initially reflected and scattered but ultimately absorbed.

The extrapolated limiting quantum yield of 1 reflects conditions of high surface coverage, no longer comparable to conditions encountered at typical trace contamination levels of 10^{-6} to 10^{-3} M often studied in the literature. At the Φ_{lim} value, diffusion and mass transfer effects are minimized and high apparent substrate binding constants are no longer crucial for optimum conversion (under the assumption that product accumulation is negligible). Therefore, photo-processes become rate determining.

We now consider differences between the two reactors. When quantum yields for low-level contaminants are assessed, all of the photochemical and mass transfer factors contribute to the observed Φ'. An estimate of $\Phi'_{0\,dis}$ at different substrate concentrations has been tabulated (Table 1) for both reactor geometries. The data show that at 0.02 M, Reactor I (dispersion) is about 4 times more efficient than Reactor II (stationary TiO_2). This reflects substrate coverage on TiO_2 and the number of active sites available for conversion. It is well documented that the surface of TiO_2 is readily hydroxylated when in contact with moisture (45–49), where both molecular and dissociated water is bound to the surface. Most researchers report coverages of 7–10 OH^-/nm^2 at room temperature (46–49). Since OH^- groups and water are the most abundant sites on the surface of the photocatalyst, adsorption of propanol may well occur through these sites (i.e., H bonding). If we then compare the density of surface sites of the slurry reactor to that of the stationary TiO_2 Reactor II, we find that 1.7×10^{20} OH^- sites are available in the dispersed phase (Reactor I) and 1.7×10^{19} sites on the stationary TiO_2 in Reactor II. On a per site basis, Reactor II may be more efficient, but the final calculation of the balance of factors is complex.

It has been reported that reaction quantum efficiency may vary with illumination levels (I) (10, 39, 40) and inversely with wavelength. For light intensities above 1 sun, the quantum efficiency can change as a function of $I^{-0.5}$ to $I^{-1.0}$ for high photon fluxes. At lower intensities, the quantum efficiency is constant and the reaction rate is catalyst dependent. This dependency reflects the competitive rate of carrier recombination to that of interfacial charge transfer. In this investigation the lamp intensities exceeded 1 sun; however, the high scavenger concentrations employed compete effectively with the recombination process. The generated reactive surface species were all captured by the adsorbed substrate. Therefore, quantum efficiency dependence on light intensities (I) is not seen in this study as would be the case at low surface coverage.

The next significant observation is that the quantum yield for the production of the observed primary intermediate is always found to be an order of magnitude smaller than the quantum yield for alcohol consumption. This indicates that propanal reacts further on the surface prior to desorption. This conclusion is consistent with the observation that apparent quantum yield for alcohol consumption decreases beyond $t = 0$, especially in the context of the result that the binding constant for propanal is larger than that for 1-propanol. The efficiency of any particular step of a photocatalytic oxidation sequence is determined by the relative adsorption of the particular substrate and its immediate product and their relative reactivity. The single L–H treatment assumes weak product adsorption. In the present case, it can be applied only to the time limit $t = 0$, before buildup of any intermediate(s).

It is unfortunate that the most intriguing question is not readily addressable. It would be of great interest to measure the relative rate of oxidation of 1-propanol, propanal, and water on the surface. All of the present observations are consistent with either the hypothesis that all three rates are very rapid and similar or that all three are proportional to their respective electrochemical over-potentials. At present, we are only able to show qualitative agreement with a two-component L–H model (Fig. 10) when feeds include both 1-propanol and propanal. The noise level in our experiments proved too high to permit quantitative evaluation of Φ_{lim} values in two-feed component competition experiments.

Conclusion

This work establishes that interfacial electron transfer involving organic substrates on the titanium dioxide surface can compete efficiently with "carrier recombination." All holes are surface trapped and available. A recent paper (35) makes the point that a trapped hole at the TiO_2–water interface may be only semantically distinguished from an adsorbed hydroxyl radical. From this point of view, carrier recombination is the back reaction of an adsorbed hydroxyl radical with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

surface-trapped electrons (Ti^{3+} sites). If so, our conclusion can be reexpressed as the proposition that adsorbed hydroxyl radicals react more rapidly with alcohol and aldehyde substrates than with surface-trapped electrons (Ti^{3+} centres). The central point for the development of TiO_2 photocatalytic systems for organic oxidation is that the conclusion for alcohol and aldehyde substrates is likely to be generalized to many organic substrates. Thus, the aim should be to design systems that appropriately control adsorption–desorption. As well, mass transport will be critical at low substrate concentrations.

The results contain one warning for TiO_2 photocatalytic studies that have diagnosed reaction pathways from intermediates found in solutions. These intermediates may be arising on inefficient pathways, while the intermediates of the most efficient pathways may never be significantly released. For example, in some qualitative runs on methanol oxidation, we were unable to detect any methanal.

Acknowledgments

Much of this investigation was performed at Concordia University (Chemistry and Biochemistry Department). We would like to thank the Concordia Ecotoxicology Laboratories, Dr. P. Anderson for providing access to instruments and Mr. B. Sjiariel for carrying out the B.E.T. surface area measurements. A substantial portion of the work on the dispersion reactor was performed by Mr. D. Palacios as his undergraduate project at Concordia. The collaboration of Nutech Environmental, especially through Dr. H. Al-Ekabi, has been very valuable. This study was supported by grants from the Natural Sciences and Engineering Research Council of Canada (NSERC), the Fonds pour la formation de chercheurs et l'aide à la recherche (FCAR) du Québec, and the Ministère d'enseignement supérieur et de la science (MESS) du Québec.

Preparation and structure of oxo-rhenium(V) complexes with 7-azaindole

ANNE-MARIE LEBUIS AND ANDRÉ L. BEAUCHAMP[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal, QC H3C 3J7, Canada

Received March 17, 1993

ANNE-MARIE LEBUIS and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **71**, 2060 (1993).

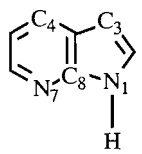
Four Re(V) oxo compounds were obtained from 7-azaindole (Haza) and $ReOCl_3(PPh_3)_2$: the oxo-bridged dimer $Re_2O_3Cl_4(Haza)_4$ (**1**), the oxo–ethoxo monomers $ReO(OEt)Cl_2(Haza)_2$ (**2**) and $ReO(OEt)Cl_2(Haza)(PPh_3)$ (**3**), and the dioxo $[ReO_2(Haza)_4]Cl$ salt (**4***a*). $[ReO_2(Haza)_4]I$ (**4***b*) was also prepared from $ReO_2I(PPh_3)_2$. The $ReO(OEt)Cl_2(Haza)_2$ complex was shown by X-ray diffraction ($C2/c$, a = 16.292, b = 9.395, c = 12.104 Å, β = 101.47°, R = 0.041) to consist of individual molecules of the *trans–trans* isomer in which azaindole is N7-bonded. Crystals of $[ReO_2(Haza)_4]Cl \cdot 4H_2O \cdot \frac{1}{2}CHCl_3$ ($C2/m$, a = 15.422, b = 13.055, c = 9.086 Å, β = 91.13°, R = 0.059) contain well separated Cl^- anions and *trans*-dioxo cations. The N7-bonded azaindole ligands are held parallel to the O=Re=O direction by intramolecular N1—H···O hydrogen bonds, but the relative orientation of the four ligands cannot be determined because of disorder. Characteristic Re—oxygen vibrations are observed in infrared for each type of compounds. The ^1H and ^{13}C NMR spectra are discussed in relation with the azaindole binding mode.

ANNE-MARIE LEBUIS et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **71**, 2060 (1993).

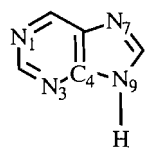
Quatre composés oxo du Re(V) ont été obtenus par réaction du 7-azaindole (Haza) avec $ReOCl_3(PPh_3)_2$: le dimère à pont oxo $Re_2O_3Cl_4(Haza)_4$ (**1**), les monomères oxo-éthoxo $ReO(OEt)Cl_2(Haza)_2$ (**2**) et $ReO(OEt)Cl_2(Haza)(PPh_3)$ (**3**), et le sel dioxo $[ReO_2(Haza)_4]Cl$ (**4***a*). $[ReO_2(Haza)_4]I$ (**4***b*) a aussi été obtenu à partir de $ReO_2I(PPh_3)_2$. La diffraction des rayons X a montré que $ReO(OEt)Cl_2(Haza)_2$ ($C2/c$, a = 16,292, b = 9,395, c = 12,104 Å, β = 101,47°, R = 0,041) renferme le monomère *trans–trans*, où l'azaindole est lié par N7. Les cristaux de $[ReO_2(Haza)_4]Cl \cdot 4H_2O \cdot \frac{1}{2}CHCl_3$ ($C2/m$, a = 15,422, b = 13,055, c = 9,086 Å, β = 91,13°, R = 0,059) contiennent des anions Cl^- et des cations *trans*-dioxo. Les ligands azaindoles liés par N7 sont retenus en position parallèle à la direction O=Re=O par des liaisons hydrogène N1—H···O intramoléculaires, mais l'orientation relative des quatre ligands ne peut pas être déterminée à cause du désordre. Des vibrations Re—O caractéristiques sont observées en infrarouge pour chaque type de composés. On discute des spectres RMN ^1H et ^{13}C en relation avec le mode de coordination de l'azaindole.

Introduction

In many of the complexes formed by 7-azaindole[2] (Haza) (**I**), the monoanion plays a bidentate bridging role in dinuclear molecules (1–5) or units of higher nuclearity (2). As the neutral form, where N7 is the only donor atom available, the ligand behaves somewhat like pyridine (6, 8, footnote 3). However, the hydrogen-bonding ability of the N1—H bond, directed on the same side as the N7 lone pair, combined with ring rigidity and general hydrophobic surface, can favour interesting molecular architectures (9, 10).



I



II

The present paper reports on oxo-Re(V) complexes with neutral azaindole, which are being considered as potential precursors to metal-metal bonded Re(III) dimers of the "paddle-wheel" type (1, 11, footnote 4). This ligand serves as a simplified and less reactive model for purines (**II**), having only two endocyclic nitrogens oriented similarly to N3 and N9 of purines.

Our efforts were first directed toward oxo-Re(V) compounds of the types known to form with pyridines (13–16). In recent years, oxo complexes of various metals, including mono and dioxo complexes of Re(V) with pyridine and related ligands, have attracted increasing attention in connection with electron (17) and oxo (18) transfer reactions. These compounds exhibit interesting electrochemical (19) and excited-state emission properties (20), which can be used for various applications (21).

In the present study, four new oxo-rhenium(V) compounds were prepared with azaindole and the crystal structures of two of them were determined.

Experimental

Reactants and methods

PPh_3, $KReO_4$, and 7-azaindole were used as received from Aldrich. $ReOCl_3(PPh_3)_2$ and $ReO_2I(PPh_3)_2$ were synthesized according to literature methods (22, 23). Solvents were dried over Na and distilled under argon before use, except for spectrograde methanol and absolute ethanol, which were used as received.

Infrared spectra were recorded as KBr or CsI pellets on a Perkin-Elmer 783 spectrophotometer. Nuclear magnetic resonance spectra were run in $CDCl_3$ (Cambridge Isotopes) or CD_2Cl_2 (Merck, Sharp & Dohme or Aldrich). ^1H spectra were recorded on a Varian VXR 300 MHz spectrometer and referenced to residual solvent signals ($CHCl_3$, δ 7.265; CH_2Cl_2, δ 5.320 ppm). ^{13}C and ^{31}P spectra were also recorded on this instrument at 121.42 and 75.43 MHz, respectively. The ^{31}P spectrum was referenced to external D_3PO_4 (δ 0 ppm) and the ^{13}C spectrum to the residual solvent signal ($CDCl_3$, δ 76.94, CD_2Cl_2; δ 53.79 ppm). The ^{13}C CP-MAS spectrum of **1** was recorded on the same instrument and referenced to the aromatic carbons of hexamethylbenzene (δ 132.1 ppm). Other conditions: relaxation delay, 50 s; spinning rate, 4.5 kHz; side-band suppression routine used. The solution ^{13}C spectrum of **4***b* was recorded at 100.62 MHz on the Bruker WH-400 spectrophotometer of the Centre Régional de RMN Haut Champ located at the Université de Montréal.

Preparative work

Compounds **1** and **2** are sensitive to moisture and readily hydrolyse in wet solvents. Preparations were done in a Schlenk system. Compounds **3** and **4***a*,*b* could be filtered in open air, although **3** is sensitive in solution.

*$Re_2O_3Cl_4(Haza)_4$, **1***

$ReOCl_3(PPh_3)_2$ (0.81 g, 0.98 mmol) and a 50% excess of Haza (0.36 g, 3.05 mmol) were mixed in toluene at room temperature and two drops of deionized water were added. Stirring was maintained for 3 h, after which time the solution had become brownish and a light green solid had deposited. This solid was filtered, washed with toluene and diethyl ether, and then dried under vacuum. This product crystallized with 1/2 toluene molecule, as indicated by the ^{13}C CP-MAS NMR spectrum (see below) and elemental analysis. Anal. Calcd. for $C_{31.5}H_{28}Cl_4N_8O_3Re_2$: C 35.01, H 2.61, N 10.37; found: C 35.14, H 2.48, N 10.02. Yield: 0.42 g, 79%. IR (cm^{-1}): 966 ν(Re=O), 677 ν(Re—O—Re). The product obtained by recrystallization from CH_2Cl_2 is toluene-free, as evidenced from the ^1H NMR spectrum. Crystals suitable for X-ray work could not be grown.

*$ReO(OEt)Cl_2(Haza)_2$, **2***

Compound **1** (0.150 g, 0.139 mmol) was refluxed in ethanol. After 24 h, the solution had turned blue. After 48 h, the mixture was reduced to half volume and a blue product deposited. The solid was filtered, dried under vacuum, and redissolved in CH_2Cl_2. Slow evaporation to 1/10 volume yielded a homogeneous sample of blue crystals. One of these crystals was used for the X-ray diffraction study described hereafter. Yield: 0.124 g, 81%. IR (cm^{-1}): 955 ν(Re=O), 915 δ(O—CH_2).

*$ReO(OEt)Cl_2(Haza)(PPh_3)$, **3***

$ReOCl_3(PPh_3)_2$ (0.83 g, 1 mmol) and Haza (0.29 g, 2.5 mmol) were refluxed in absolute ethanol (100 mL) for 25 min. The bright blue precipitate was filtered, and washed with ethanol (15 mL) and diethyl ether (15 mL). Anal. Calcd. for $C_{27}H_{26}Cl_2N_2O_2PRe$: C 46.42, H 3.75, N 4.01, Cl 10.15; found: C 46.17, H 3.38, N 3.91, Cl 10.14. Yield: 0.41 g, 59%. IR (cm^{-1}): 941 ν(Re=O), 906 δ(O—CH_2). ^{31}P NMR (ppm): −7.47 (s). The dark brown filtrate yielded 0.11 g of **4***a*.

*$[ReO_2(Haza)_4]Cl$, **4**a*

$ReOCl_3(PPh_3)_2$ (0.84 g, 1.01 mmol) and Haza (0.71 g, 6.0 mmol) were mixed at room temperature in toluene (50 mL) and eight drops of deionized water were added. After 3 h, a light brown solid was filtered and washed with toluene. This raw material contained a small amount of PPh_3. Recrystallisation from methanol/toluene gave a pure orange powder. Yield: 0.56 g. IR (cm^{-1}): 794 ν(O=Re=O). Recrystallization from $CHCl_3$ in open air yielded orange platelets of the $CHCl_3$–water solvate (**4***a*′) studied by X-ray diffraction (see below).

This product was also obtained from **1** (0.72 g, 0.70 mmol) by refluxing with 4 equivalents (0.34 g) of Haza in absolute ethanol (40 mL). The solution turned very dark brown rapidly, volume was reduced to 15 mL, and diethyl ether (100 mL) was added to precipitate the dark brown solid. The product was isolated by filtration and washed with small amounts of methanol and acetone to afford the orange salt. Yield: 0.36 g.

*$[ReO_2(Haza)_4]I$, **4**b*

The method used was adapted from Brewer and Gray (14). $ReO_2I(PPh_3)_2$ (0.90 g, 1.04 mmol) was stirred at room temperature with Haza (1.17 g, 9.9 mmol) in methanol. The solution turned orange immediately. The mixture was refluxed for 20 min, after which time the solution had become dark orange. Toluene (50 mL) was added and the volume was reduced by half. The orange powder was filtered off, washed with toluene and hexane, and dried under vacuum. The compound is solvent-free, as evidenced from the ^1H NMR spectrum, which contains only the Haza signals observed for the Cl^- salt. Yield: 0.67 g. IR (cm^{-1}): 795 ν(O=Re=O).

Crystallographic measurements and structure resolution

X-ray work on both compounds was carried out on an Enraf-Nonius CAD-4 diffractometer with graphite-monochromatized MoK$\bar{\alpha}$ radiation. The reduced cell was determined from 25 centred reflections ($20° \leq 2\theta \leq 25°$) and checked with long-exposure axial photographs along the three axes. C-centred monoclinic cells were indicated by the Niggli coefficients and confirmed by axial photographs about the new axes. Final cell parameters were obtained by least-squares fit on the settings of the 25 reflections. Crystallographic data and conditions of data collection for both structures are summarized in Table 1. During data collection, orientation was monitored every 200 measurements and intensity was checked every hour with standard reflections.

*$ReO(OEt)Cl_2(Haza)_2$ (**2**)*

A total of 3091 $\bar{h}\bar{k}l$, $\bar{h}k\bar{l}$ and $h\bar{k}\bar{l}$, and $hk\bar{l}$ reflections with $h + k = 2n$ were measured. Averaging the $k/\bar{k}$ pairs yielded 1602 unique hkl and $\bar{h}kl$ reflections, of which 1279 with $I \geq 3.0\sigma(I)$ were retained for structure determination and refinement. The data were corrected for the effects of Lorentz, polarization, and absorption (Gaussian integration).

Space groups $C2/c$ and Cc were consistent with the monoclinic Laue symmetry and systematic absences (hkl, $h + k \neq 2n$; $h0l$, $l \neq 2n$). The structure was solved in the centric $C2/c$ space group by the heavy-atom method. Re was positioned from a Patterson map. All other non-hydrogen atoms were located by successive ΔF maps. The C_2H_5 group was found to be disordered, C(11) and C(12) occupying symmetry-related positions off the twofold axis.

Refinement was done on $|F_0|$ by full-matrix least-squares procedures. The function minimized was $\Sigma w(|F_0| - |F_c|)^2$, with weights $w = 1/(\sigma^2(|F_0|) + 0.0016|F_0|^2)$. Refinement was anisotropic for all non-hydrogen atoms, except C(12). Hydrogen atoms were introduced at idealized positions (C—H = 0.95 Å, N—H = 0.85 Å, U_{iso} = 0.075 Å^2). Their parameters were not refined, but the coordinates were recalculated after each cycle. The final residuals were $R = 0.041$, $R_w = 0.048$ and $S = 1.44$ for 119 parameters refined. The general background in final ΔF synthesis was below ± 0.48 e/Å^3, with five low residuals of $\pm|0.62 - 0.82|$ e/Å^3 near Re.

Attempts were made to refine the structure in the non-centric Cc space group. Refinement was extremely unstable with very high correlation coefficients and the ethoxo group remained disordered. Thus, the above $C2/c$ model was retained.

*$[ReO_2(Haza)_4]Cl \cdot 4H_2O \cdot \frac{1}{2}CHCl_3$ (**4**a′)*

A whole sphere of data was measured, providing 6291 reflections with $h + k = 2n$. Space groups $C2$, Cm, and $C2/m$ were consistent with Laue symmetry and the lack of systematic absences besides hkl, $h + k \neq 2n$. The data set was corrected for absorption (Gaussian integration) and the hkl and $hk\bar{l}$ octants were used to solve the structure. After the space group was identified as $C2/m$, equivalent reflections were averaged, yielding 1684 unique hkl and $hk\bar{l}$ reflections, of which 1245 with $I \geq 3.0\sigma(I)$ were retained for final refinement. The data were corrected for the effects of Lorentz and polarization.

Solving this structure was extremely laborious. The centrosymmetric $C2/m$ space group was considered first. The Patterson map indicated that two Re atoms occupied an equipoint with $2/m$ site symmetry and the origin ($2a$) (24) was arbitrarily chosen. A ΔF map revealed clear features for the apical oxygen (equipoint $4g$, twofold axis) and for two independent N7-coordinated azaindole ligands in general positions. These units, repeated by $2/m$ site symmetry, generated a *trans*-ReO_2N_4 coordination. However, the azaindole units, perpendicular to the mirror plane, had to be disordered over two orientations, with the five-membered rings directed above and below the plane, respectively. A new ΔF map phased on this model showed a number of residual peaks, in a pocket along the b axis ($y \sim 0.5$), surrounded by complex cations. None of these peaks were high enough to correspond to full occupancy by Cl^- and short inter-peak distances indicated extensive disordering. After testing a large number of combinations, two main

$^aR = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$; $S = [\Sigma w(|F_o| - |F_c|)^2/(N - V)]^{1/2}$.

patterns (Fig. S-2)[5] could be unravelled. In pattern *a*, water W(3) is present along with a $CHCl_3$ molecule and an extra water molecule occupying the C/W site, symmetry equivalent to the $CHCl_3$ carbon. In pattern *b*, the Cl^- ion is part of an infinite chain containing water molecules W(1), W(2), and W(3).

A number of attempts were made to solve the structure in space groups $C2$, Cm and even $C1$. $C1$ led to the same disordered structure, described with more parameters and giving extremely unstable refinement of highly correlated variables. Thus, the centrosymmetric $C2/m$ model is retained as the best interpretation of our results.

Refinement was done on $|F_o|$ with weights $w = 1/(\sigma^2(|F_o|) + 0.0016|F_o|^2)$. Only Re was refined anisotropically. All azaindole atoms were assigned half occupancies, as required by space group symmetry. In order to provide one Cl^- ion per Re atom, the two $Cl^-/H_2O/CHCl_3$ patterns *a* and *b* must have equal populations. Appropriate occupancy factors were assigned and the nitrogen scattering curve was used for the C/W position statistically occupied by a water oxygen and the $CHCl_3$ carbon. The coordinates and temperature factors of all non-hydrogen atoms were refined. Residuals in the ΔF map indicated that W(3) was slightly off the twofold axis: it was moved away from the axis and its three coordinates were refined. The final agreement factors were $R = 0.059$, $R_w = 0.077$, $S = 2.06$ for 113 parameters refined. The residuals in the final ΔF synthesis were below ±0.7 e/Å^3.

Considering the severe crystallographic problems encountered, the refined model is totally satisfactory. The only anomaly is the rather small temperature factor found for W(3). This may result from some protonated $[ReO(OH)(Haza)_4]^{2+}$ cations occupying the $[ReO_2(Haza)_4]^+$ site in the lattice. The W(3) site could then be occupied occasionally by the extra Cl^- ion needed to balance the charge for each such protonated species present. The O(1)—W(3) distance of ~2.8 Å is on the short side of the range for a O—H···Cl hydrogen bond (25), but the actual O(1)—Cl distance could well be greater than indicated by the refined W(3) position, defined primarily by water occupying the site most of the time. No evidence was provided from spectroscopic data for the presence of the protonated complex in the non-recrystallized material, but the ^1H NMR spectrum on a CD_2Cl_2 solution of the crystals showed a small amount of an additional species as well as the $CHCl_3$ found in the structure. This new species could not be identified, but it does not correspond to free neutral or protonated azaindole. Thus, the presence of coordinated azaindole signals would be consistent with the above assumption.

[5]The supplementary material includes a table of infrared frequencies and the following crystallographic material: diagram of the disorder in the $Cl^-/H_2O/CHCl_3$ region of **4***a*′, unit cell of **2** and probable short-range non-disordered structure of **4***a*′, lists of observed and calculated structure factor amplitudes, anisotropic thermal parameters, hydrogen coordinates, distances and angles in the ligands, and atom-to-plane distances for the structures (28 pages). A complete set of data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada.

Stereo view of the unit cell, hydrogen atom coordinates, and distances and angles in the azaindole ligand for $ReO(OEt)Cl_2(Haza)_2$, **2**, and distances and angles in the azaindole ligand and chloroform molecule for $[ReO_2(Haza)_4]Cl \cdot 4H_2O \cdot \frac{1}{2}CHCl_3$, **4***a* have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

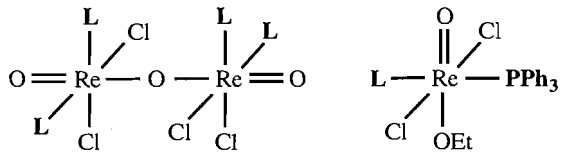
All calculations were done with the NRCVAX package (26). The refined coordinates for both structures are listed in Tables 2 and 3, respectively.[5]

Discussion

The light green oxo-bridged dimer $Re_2O_3Cl_4(Haza)_4$ (**1**) was obtained from $ReOCl_3(PPh_3)_2$ and excess azaindole in moist toluene. By the same method, Johnson, Taha, and Wilkinson (13) isolated the pyridine analog, which was shown to be the *cis*-dichloro-*cis*-pyridine isomer (**III**) (27). The same stereoisomer is likely obtained here, since the *trans-trans* isomer observed with 1-methylimidazole gives a dark blue solid.[6]



III

IV

The blue oxo-ethoxo monomer $ReO(OEt)Cl_2(Haza)_2$ (**2**) was prepared by refluxing **1** in ethanol, a method used by Johnson, Taha, and Wilkinson (13) for pyridine. The crystal structure (Fig. 1) confirmed the *trans-trans* stereochemistry. When Haza was refluxed with $ReOCl_3(PPh_3)_2$ in absolute ethanol, a new type of ethoxo complex $ReO(OEt)Cl_2(Haza)(PPh_3)$ (**3**) was obtained, in which only one phosphine was displaced. The ethoxo group is undoubtedly *trans* to the oxo group, as in **2** and all related octahedral Re(V) systems (15, 29, 30). Because of steric effect, the *trans-trans* structure **IV** is preferred for this complex.

The *trans*-dioxo salt $[ReO_2py_4]Cl$ was prepared from $ReOCl_3(PPh_3)_2$ and neat pyridine containing a little water (31). To obtain $[ReO_2(Haza)_4]Cl$ (**4***a*), six equivalents of the ligand, which is a solid, were reacted in moist toluene. As the Cl^- salt deteriorates slowly, the corresponding iodide (**4***b*) was also prepared from $ReO_2I(PPh_3)_2$, as described recently for pyridines by Brewer and Gray (14).

Infrared spectroscopy

The infrared spectrum of 7-azaindole has been discussed elsewhere (1, 9, 10). Complexation via N7 does not greatly change the azaindole bands (Table S-9)[5]. Owing to differences in hydrogen bonding, the ν(N—H) vibrations are sharper and shifted from 2900 to 3300–3430 cm^{-1}, whereas the γ(N—H) mode is displaced from 850 cm^{-1} to the 550 cm^{-1} region (9). Characteristic changes previously attributed to N7 coordination (9, 10) are generally observed here. The spectrum of **3** shows extra features due to PPh_3, namely a strong doublet at 738/745 cm^{-1} and a series of characteristic peaks near 500 cm^{-1} (32). Well-defined bands near 1374, 1115, and 1078 cm^{-1} correspond to the ethoxo group.

In **4***a* and **4***b*, the *trans*-dioxo unit shows a single $\nu_{as}(O{=}Re{=}O)$ band at 795 cm^{-1}, halfway between those found for $[ReO_2(CN)_4]^{3-}$ (775 cm^{-1}) (34) and other N-donor ligands (~815 cm^{-1}) (33–35). The terminal ν(Re=O) bands in the ethoxo compounds are found at 955 cm^{-1} for **2** and 941 cm^{-1} for **3**, whereas a strong band characteristic of the Re—O—Et unit appears near 910 cm^{-1}, as with $ReO(OEt)X_2(PPh_3)_2$ (33). For **1**, the terminal Re=O and asymmetric Re—O—Re stretching modes (966 and 677 cm^{-1}, respectively) show greater separation than for the corresponding pyridine and ethylenediamine compounds (935 and 730 cm^{-1}, respectively). The weak $\nu_{as}(ReO_2)$ mode near 800 cm^{-1}, mentioned by Jezowska-Trzebiatowska et al. (34) for the latter compounds, would be masked here by the very strong γ(C—H) azaindole bands at 790–800 cm^{-1}.

Crystal structure of $ReO(OEt)Cl_2(Haza)_2$, 2

The crystals contain roughly octahedral molecules of the *trans-trans* isomer (Fig. 1), in which the neutral azaindole ligand is coordinated via N(7). The same stereoisomer was found in the analogous pyridine compound (36). Selected distances and angles are given in Table 4.

The Re—Cl (2.414(3) Å) and Re—N distances (2.136(8) Å) are similar to those found for $ReO(OEt)Cl_2(py)_2$ (mean values 2.404 and 2.138 Å, respectively) (36). The Re=O(1) distance of 1.702(11) Å, although slightly longer than those found in the pyridine analogue (1.684(7) Å) and various oxo-Re(V) complexes (mean 1.691 Å, σ = 0.025) (37), compares well with those reported for the $ReO(OEt)X_2(PPh_3)_2$ series (X = I, 1.699(4); Cl, 1.678(6); Br, 1.715(9) Å) (15, 29, 30) and $ReO(OEt)(Ph_2PNPh_2Se)_2$ (1.70(2) Å) (38). The Re—O(2) distance of 1.845(10) Å, shorter than in the above compounds (1.880(6)–1.896(6) Å), indicates some multiple bond character, as discussed by other workers (15, 39).

The octahedron is only slightly distorted. Re, O(1), and O(2), all situated on the crystallographic twofold axis, define a perfectly linear unit. N(7) and Cl are slightly displaced away from the Re=O(1) bond, thereby making the O(1)—Re—Cl(N) angles 1–3° greater than 90°, with a corresponding reduction of the O(2)—Re—Cl(N) angles. The ethoxo group is disordered over two equally populated orientations about the axis, with positions for C(11) and C(12) being resolved. This type of disorder has also been observed for the phosphine analogues $ReO(OEt)X_2(PPh_3)_2$ (X = Cl, Br) (29, 30). A broad range (138–176°) is found in the literature for the Re—O—Et angle (15, 29, 30, 36): our Re—O(2)—C(11) angle (155.9(15)°) lies in the middle of this range.

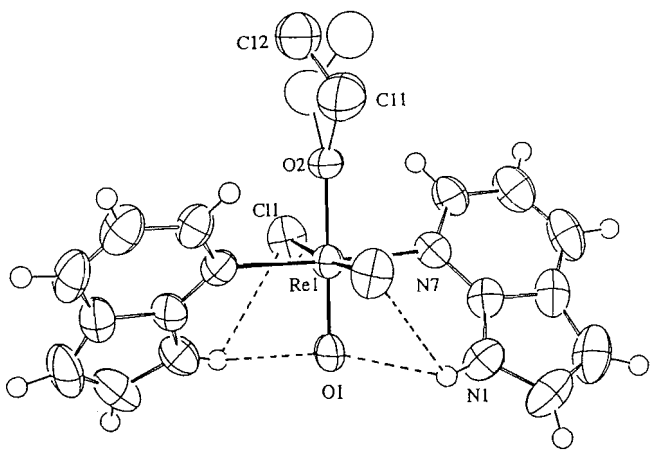

FIG. 1. Structure of the $ReO(OEt)Cl_2(Haza)_2$ molecule (**2**). The O(1)=Re—O(2) unit lies on a crystallographic twofold axis. The ethyl group is disordered over two equally populated orientations (second orientation shown as hollow spheres, ethyl hydrogens omitted). Azaindole atoms are labelled as in **I**. Ellipsoids correspond to 50% probability. Dashed lines represent possible hydrogen bonding interactions.

This is one of the few known complexes in which the 7-azaindole ligand is not disordered. The distances and angles are normal (40) and the two-ring system is planar within 0.02 Å (1.3σ)[5]. The plane of the ligand is roughly a bisector of the O(1)—Re—Cl angle (O(1)—Re— N(7)—C(8) torsion angle = −38.1(8)°). The same ligand orientation observed for the pyridine analogue has been ascribed to minimum intramolecular contacts with Cl, O(1), and alkoxo hydrogens (36). In the present case, the N(1)—H group is close enough to Cl and O(1) to form an intramolecular hydrogen bond (Table 4, Fig. 1), but the interaction is probably weak, especially with oxygen, since the Re=O unit is known not to be very nucleophilic in these systems.

A view of the unit cell is provided in Figure S-1.[5] The molecules are packed individually, and interact via normal van der Waals contacts and a weak intermolecular N(1)—H···Cl bond (Table 4).

Crystal structure of $[ReO_2(Haza)_4]Cl \cdot 4H_2O \cdot \frac{1}{2}CHCl_3$, **4**a'

Despite the severe crystallographic problems encountered, the presence of the *trans*-$[ReO_2(Haza)_4]^+$ cation containing N7-bonded azaindole is decisively established. However, the relative orientations of the ligands could not be determined from the X-ray results. Since the site occupied by Re has crystallographic $2/m$ (C_{2h}) symmetry, each azaindole ligand appeared in the electron density map as two overlapping images with the five-membered ring oriented either up (*u*) or down (*d*). The two most likely rotamers, shown in Fig. 2, correspond to *uudd* and *udud* ligand sequences about the O=Re=O axis, respectively.

Selected distances and angles corresponding to the patterns of Fig. 2 are listed in Table 5. In both cases, the *cis* N—Re—N angles remain within 90 ± 3° and the O—Re—N

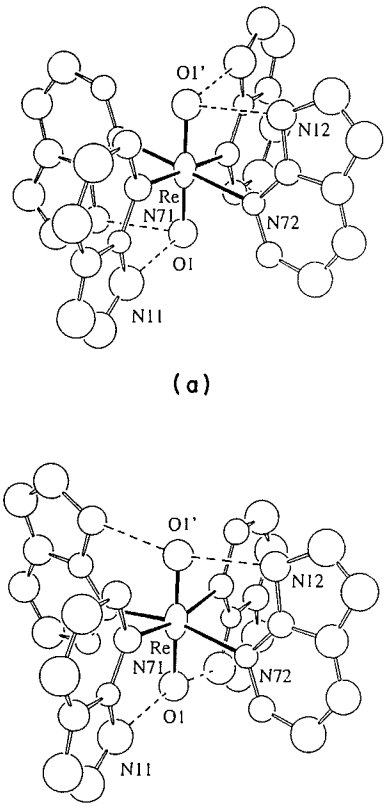

FIG. 2. Structure of the $[ReO_2(Haza)_4]^+$ cation in **4***a*′. The two most likely rotamers, whose geometry is described in Table 5, are represented: *uudd* (*a*), *udud* (*b*). Ellipsoids correspond to 50% probability. In the symbols used for the azaindole ligands, the first digit represents the position in the ring, as given in **I**, whereas the second digit is used to differentiate between the two independent ligands. Dashed lines represent hydrogen bonds.

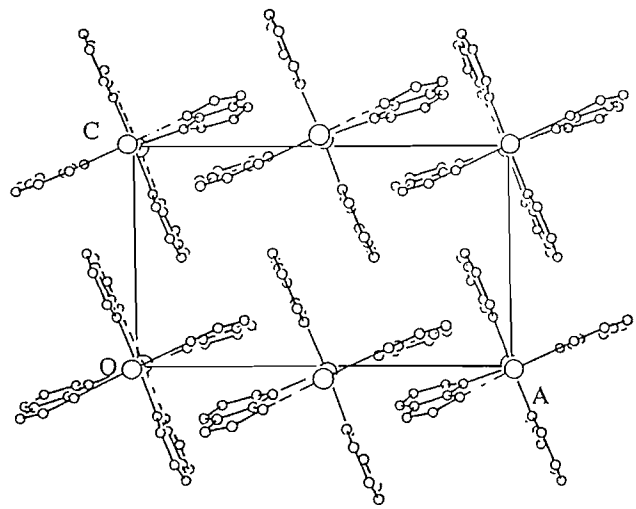

FIG. 3. Packing of the cations in **4***a*′ down the *b* axis, showing the parallel orientation of the azaindole ligands of the windmill-shaped cations. Cl^- and solvent molecules are omitted for simplicity. Ellipsoids correspond to 50% probability. Dashed lines represent hydrogen bonds.

angles range from 80 to 100°. The *trans* N—Re—N angles are 180° (by symmetry) and 165° in the *uudd* and *udud* rotamers, respectively, whereas the O=Re=O angles are always 180°. Thus, both geometries are reasonable. The Re=O(1) distance of 1.782(12) Å is comparable with those found for other $[ReO_2L_4]^+$ compounds, whereas the Re—N distances (mean 2.18 Å) seem to be slightly longer (31, 41–43).

Details on the geometry of coordinated azaindole are given in the supplementary material.[5] The distances and angles do not greatly differ from those of the free molecule (40). The rings are planar and aligned with the O=Re=O direction, as a result of a short intramolecular N1—H · · · O(1) hydrogen bond (~2.6 Å) to oxo groups (Table 5).

Figure 3 gives a projection of the unit cell down the *b* axis, along the O=Re=O bonds. The windmill-shaped cations are oriented so as to make the "vanes" of adjacent cations parallel. By repeating this pattern in the *b* direction, the O=Re=O units remain aligned and exactly above one another. They are separated by pockets containing the disordered Cl^- ions and lattice water and $CHCl_3$ molecules. A short-range ordered pattern consistent with the disorder observed is given in Fig. S-3.[5]

Nuclear magnetic resonance spectroscopy

^1H NMR data for all compounds are given in Table 6. Assignments are based on earlier work on CH_3Hg^+ compounds (10). The close H4 and H6 signals could be identified from their coupling constants to H5: ^3J(H5—H6) (~4.8 Hz) is smaller than ^3J(H4—H5) (~7.8 Hz) and it increases slightly when N7 is methylated (44) or metallated (10). ^{13}C NMR results are given in Table 7. The chloride **4***a* decomposed during acquisition, but the spectrum is not expected to be very different from that of the iodide **4***b*. Compounds **1** and **2** were not soluble enough to give good ^{13}C solution spectra. However, the solid-state CP-MAS spectrum of **1** could be recorded on the toluene solvate. For **3**, the strongest signals were easily assigned to the PPh_3 ligand (28). The ethoxo signals in both the ^1H and ^{13}C spectra occur at positions similar to those of *fac*-$(CO)_3$(dppe)Re(OEt) (12).

All compounds show only one set of azaindole signals in both types of spectra. This does not provide stereochemical information on the oxo-bridged dimer **1**, since both *cis-cis* and *trans-trans* stereochemistries about Re would make the four ligands equivalent in a species where the rotation barrier about the Re—O—Re axis is low. Similarly, rotamers cannot be identified for the *trans*-dioxo cation **4**, because fast rotation should take place about the Re—N7 bond.

The spectra are consistent with the ligand being bound to Re via N7 in all compounds. The N1—H proton produces a broad signal at low field. Coupling with this proton is always detected for the H2 and H3 signals, although the multiplet is not well resolved in some cases. Most of the solution ^{13}C signals for $ReO(OEt)Cl_2(Haza)(PPh_3)$ (**3**) and $[ReO_2(Haza)_4]I$ (**4***b*) follow the trends observed earlier for the N7-bonded $[CH_3Hg(Haza)]^+$ ion (10): substantial shifts upfield for C8 and downfield for C2, C4, and C9, lesser downfield shifts for C3 and C5. The spectrum of the oxo-bridged dimer $Re_2O_3Cl_4(Haza)_4$ (**1**) was obtained in the solid state and intermolecular interactions probably contribute to shifting some signals by 1–2 ppm, namely those of the well exposed C3 and C4 carbons.

Most of the ^1H resonances, together with the ^{13}C signal of C6, show large variations among the different Re compounds and differ from the CH_3Hg^+ model. In the case of $[CH_3Hg(Haza)]^+$ (10), H4 was the most affected by com-

plexation, being shifted downfield by 0.47 ppm. A similar displacement is found here with the oxo-bridged dimer **1**, but the *trans*-dioxo complex **4** shows an upfield shift of 0.23 ppm, whereas the signal is barely displaced for the ethoxo complexes **2** and **3**. The C6 and H6 signals in the *trans*-dioxo cation **4** are much more deshielded than in the other compounds. The crystal structure of **4***a* (Fig. 2) shows that the four azaindole rings are parallel to the O=Re=O axis, bringing C6—H6 just above the Re=O bond. The downfield shifts on these resonances could be connected with the ligands being aligned with the O=Re=O unit, but it is difficult to decide which of Re=O anisotropy or particular backbonding is responsible for the observed deshielding.

Concluding remarks

7-Azaindole forms oxo-Re(V) compounds of the types known for pyridine, together with a mixed azaindole/PPh_3 species of a type isolated so far only when the nitrogen donor is part of a chelating agent (7). Binding occurs via N7 in all cases, but the presence of the N1—H bond, roughly parallel to the lone pair, introduces interesting structural features by making certain conformations more favoured. The $[ReO_2(Haza)_4]^+$ ion is particularly interesting, since strong hydrogen bonding to the oxo groups keeps the four ligands parallel to the O=Re=O axis. Rotation about the Re—N7 bond is likely to occur in solution, exchanging the direction of individual ligands, but the molecule probably spends most of its time in one of the possible "windmill" arrangements. In the solid state, the compound shows an interesting packing pattern with the O=Re=O directions of all molecules aligned along a crystallographic axis. Thus, this compound could be particularly suitable for studying optical properties, namely, the effect this particular configuration has on excited-state properties of the cation. Hydroxyl groups are known to quench luminescence for such systems and water molecules are hydrogen-bonded to the Re=O groups in the present dioxo complexes. Solid-state effects have been noted for guest/host complexes involving ReO_2^+ type molecules and clays (21). Because of disorder, the rotamer(s) present in the crystal could not be formally identified. Salts with various anions failed to provide suitable material for crystallographic studies so far, but work is underway to circumvent these difficulties.

Acknowledgments

We wish to thank M. Simard and F. Bélanger-Gariépy for assistance in collecting the X-ray data, and S. Bélanger for supplying $ReO_2I(PPh_3)_2$.

Non-stoichiometric chloride salts of dioxotetrakis(imidazole)rhenium(V) cations

ANNE-MARIE LEBUIS, JIM M.C. YOUNG, AND ANDRÉ L. BEAUCHAMP[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal, QC H3C 3J7, Canada

Received June 21, 1993

ANNE-MARIE LEBUIS, JIM M.C. YOUNG, and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **71**, 2070 (1993).

Orange $[ReO_2L_4]Cl$ salts were prepared with L = imidazole and 2-methylimidazole. The presence of a strong Re=O stretching band in the infrared spectra near 785 cm^{-1} is consistent with a *trans*-dioxo octahedral structure. With 1,2-dimethylimidazole, red-violet solids were obtained, which were studied by X-ray diffraction. Form I (from methanol): cubic, $Ia\bar{3}d$, a = 25.205 Å, R = 0.032, 986 observed reflections; form II (from ethanol–dichloromethane): cubic, $Ia\bar{3}d$, a = 25.520 Å, R = 0.056, 766 observed reflections. Both materials are non-stoichiometric, containing *trans*-$[ReO_2L_4]^+$ and protonated *trans*-$[ReO(OH)L_4]^{2+}$ in an approximate ratio of 3:1 for I and 2:1 for II. In both cases, the unit cell contains 1 "normal" Cl^- ion and 2/3 H_2O per complex. In form I, the additional charge of $[ReO(OH)L_4]^{2+}$ is balanced by an extra Cl^- ion partly occupying the unit cell origin, where it is replaced by disordered methanol the rest of the time. In form II, ReO_4^- and CH_2Cl_2 play the corresponding roles. In the infrared spectra, besides the characteristic band for the dioxo species, both forms show an extra peak at ~932 cm^{-1} originating from the protonated species, whereas form II shows an additional band at 907 cm^{-1} for uncoordinated ReO_4^-. The ^1H and ^{13}C NMR spectra of both forms in D_2O are identical to those of the pure $[ReO_2L_4]^+$ salt, indicating that the protonated species is strongly acidic.

ANNE-MARIE LEBUIS, JIM M.C. YOUNG et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **71**, 2070 (1993).

Les sels orangés $[ReO_2L_4]Cl$ ont été préparés pour L = imidazole et 2-méthylimidazole. La présence d'une bande forte vers 785 cm^{-1} dans les spectres infrarouges pour l'élongation Re=O est en accord avec la structure octaédrique *trans*-dioxo. Avec le 1,2-diméthylimidazole, des solides rouge violet ont été obtenus et étudiés par diffraction des rayons X. Forme I (obtenue du méthanol) : cubique, $Ia\bar{3}d$, a = 25,205 Å, R = 0,032, 986 réflexions observées; forme II (éthanol–dichlorométhane) : cubique, $Ia\bar{3}d$, a = 25,520 Å, R = 0,056, 766 réflexions observées. Les deux solides sont non-stoechiométriques et contiennent l'ion *trans*-$[ReO_2L_4]^+$ et l'espèce protonée *trans*-$[ReO(OH)L_4]^{2+}$ dans un rapport approximatif de 3 : 1 pour I et de 2 : 1 pour II. Dans les deux cas, la maille renferme 1 ion Cl^- «normal» et 2/3 H_2O par complexe. Dans la forme I, la charge additionnelle de $[ReO(OH)L_4]^{2+}$ est équilibrée par un ion Cl^- supplémentaire occupant partiellement l'origine de la maille, où il est remplacé le reste du temps par du méthanol désordonné. Dans la forme II, ces rôles sont joués par ReO_4^- et CH_2Cl_2 respectivement. Dans les spectres infrarouges, en plus de la bande caractéristique de l'espèce dioxo, les deux formes présentent une bande vers 932 cm^{-1} provenant de l'espèce protonée, alors que la forme II possède une bande supplémentaire à 907 cm^{-1} pour l'ion ReO_4^- non-coordonné. Les spectres RMN ^1H et ^{13}C des deux formes dans D_2O sont identiques à celui du sel dioxo $[ReO_2L_4]^+$ pur, ce qui indique que l'espèce protonée est fortement acide.

Introduction

Dioxo complexes of Re(V) have recently drawn considerable interest, partly because of their potential applications in catalysis (1, 2). Electrochemical and photophysical properties of numerous compounds containing the $[ReO_2]^+$ core have been studied (3–6). In this regard, imidazoles (Scheme 1) are an interesting family of ligands, since it has been shown that rigidity is a prime factor in the control of the emission properties of $[ReO_2L_4]^+$ cations (7). Another potential use for Re(V) oxo complexes is as radiopharmaceuticals, since the β-emitter ^{186}Re and ^{188}Re nuclei have been proposed for use in radiotherapy (8–10). Combining the $[ReO_2]^+$ core with ligands such as imidazoles, which are themselves of biological importance, seemed to be a promising route to follow. The imidazole ring is naturally present in the body as part of histidine and its structural analogy to purines makes it a potentially valuable part of drugs aimed at DNA. With Ru(III), for instance, imidazole-containing complexes have been proposed as tumour targeting agents (11, 12). The photochemistry of $[ReO_2L_4]^+$ complexes in the presence of DNA has also been studied in an attempt to identify the site of interaction (13).

We describe here the preparation and characterization of $[ReO_2L_4]Cl$ complexes with three imidazoles. Orange compounds of the type known for other N-heterocyclic ligands (4, 14, 15) were isolated with imidazole and its 2-methyl derivative. On the other hand, our experiments yielded red-violet solids with 1,2-dimethylimidazole. These materials were examined carefully by X-ray diffraction and found to be non-stoichiometric phases containing some protonated $[ReO(OH)L_4]^{2+}$ species.

Experimental

Reactants and methods

PPh_3, $KReO_4$, and the ligands were used as received from Aldrich. $ReOCl_3(PPh_3)_2$ was prepared according to the literature method (16). Toluene was dried over Na and distilled under argon before use. All other solvents were used as received.

IR spectra were recorded as KBr or CsI pellets on a Perkin–Elmer 783 spectrophotometer. The NMR spectra were generally run in D_2O (Cambridge Isotopes). ^1H NMR spectra were recorded on a Varian VXR 300 MHz spectrometer and referenced to the residual solvent signal (δ 4.80 ppm). ^{13}C spectra were run on the same instrument at 75.43 MHz (dioxane signal at 66.56 ppm as internal reference) (17). Spectra of the complexes were obtained at near

For personal use only.

saturation. The ^{13}C CP-MAS spectrum was recorded on the same instrument and was referenced to the aromatic carbon signal of hexamethylbenzene (δ 132.1 ppm). Other conditions: relaxation delay, 10 s; spinning rate, 3.9 kHz; side-band suppression routine used.

Preparative work

Method 1

The method originally described by Johnson et al. (15) for pyridine was applied using a lower excess of ligand. $ReOCl_3(PPh_3)_2$ (1.00 g, 1.2 mmol) in ethanol (20 mL, not dried) was refluxed (2 h) with 6 equivalents of the imidazole ligand. Solvent was partly evaporated and CH_2Cl_2 was added to precipitate the product. With imidazole, a dark brown powder (0.58 g, 83%) of $[ReO_2(ImH)_4]Cl \cdot 2H_2O$ was obtained. IR: 790 cm^{-1} ν_{as}(O═Re═O). Anal. calcd. for $C_{12}H_{20}ClN_8O_4Re$: C 25.65, H 3.59, N 19.94; found: C 25.60, H 3.48, N 19.97. With 2-MeImH, the product was prepared as an orange oil, which was not further studied since better samples of the same complex were obtained by method 2. In the case of 1,2-Me_2Im, the crystals obtained (0.70 g) were red-violet and found by X-ray diffraction (see below, form II) to contain both $[ReO_2L_4]^+$ (IR: 781 cm^{-1} ν_{as}(O═Re═O)) and $[ReO(OH)L_4]^{2+}$ (IR: 931 cm^{-1} ν(Re═O)).

Method 2

$ReOCl_3(PPh_3)_2$ (0.41 g, 0.49 mmol) and 6 equivalents of ligand were stirred under nitrogen in 40 mL of toluene to which 4 drops of distilled water had been added. After 1–4 h, depending on the ligand, an orange sludge formed, which was filtered and washed with benzene to eliminate traces of PPh_3. Although this procedure led to oxo-bridged $[OReCl_2L_2]_2O$ dimers with pyridine (18), dioxo salts were isolated here. With ImH, recrystallization from methanol gave 0.22 g (83%) of a brown microcrystalline powder showing the same IR and NMR spectra as the compound isolated by method 1. With 2-MeImH, 0.20 g (68%) of an orange microcrystalline material of composition $[ReO_2(2\text{-MeImH})_4]Cl \cdot H_2O$ was obtained. IR: 780 cm^{-1} ν_{as}(O═Re═O). Anal. calcd. for $C_{16}H_{26}ClO_3N_8Re$: C 32.02, H 4.37, N 18.67, Cl 5.91; found: C 32.52, H 3.88, N 18.50, Cl 6.06. Again, 1,2-Me_2Im gave red-violet crystals (0.22 g), whose structure determined by X-ray diffraction (form I, see below) showed the presence of $[ReO_2L_4]^+$ and $[ReO(OH)L_4]^{2+}$.

Method 3

This procedure is a variation of a method initially proposed by Chakravorty (19) for pyridine complexes. $KReO_4$ (4.2 g) and KI (5.9 g) in concentrated HCl (50–70 mL) were heated to dryness until no purple vapours formed. The ligand (8 equivalents) was added as an aqueous solution (20 mL) and the mixture was refluxed for 2 h. Ethanol (150 mL) was then added and the mixture was filtered to remove the precipitated KCl. The filtrate was concentrated to afford a dark red-brown solution, from which crystals precipitated upon standing. The ImH compound was obtained in good yield (5.8 g, 71%). In contrast with the above methods, the 1,2-Me_2Im complex was orange and no protonated cations were present. IR: 795 cm^{-1} ν_{as}(O═Re═O). However, the sample also contained some $KReO_4$ (identified from the X-ray powder pattern and IR band at 907 cm^{-1}) that could not be easily removed.

Crystallographic measurements and structure resolutions

Two varieties of red-violet crystals obtained with 1,2-Me_2Im were studied. In both cases, the X-ray work was carried out on an Enraf–Nonius CAD-4 diffractometer, using graphite-monochromatized CuKα̅ radiation. The reduced cells were determined from 25 centred reflections found by the search routine of the CAD-4 software. The metrically rhombohedral reduced cells ($a = b = c$, $\alpha = 109.45°$) were checked with long-exposure axial photographs along the three axes and then converted to the I-centred cubic cell indicated by the Niggli matrix. Axial photographs on these new cells showed the presence of Laue mirror planes perpendicular to each of the three axes. A limited data collection showed equivalence in the *hkl/klh/lhk/lkh/hlk/khl* group as expected for *m3m* Laue symmetry. The cell parameters obtained by least-squares fit on the settings of the 25 reflections ($20° \leq 2\theta \leq 25°$) are given in Table 1. Intensity data were collected following the usual procedure (20). Orientation was monitored every 200 measurements and intensity was checked every hour with standard reflections.

Crystal I had the following dimensions (mm) between the indicated pairs of faces: 0.129 (101–$\bar{1}0\bar{1}$) × 0.175 ($\bar{1}10$–$1\bar{1}0$) × 0.243 (110–$\bar{1}\bar{1}0$). A whole octant (7222 reflections) was collected. The data were corrected for absorption (Gaussian integration, 10 × 10 × 10 grid, transmission range: 0.19–0.39). Inspection of the full data set confirmed the *m3m* Laue symmetry. The averaged data set consisted of 1252 unique reflections, of which 986 with $I \geq 3.0\ \sigma(I)$ were retained for structure determination. The systematic absences (*hkl* $h + k + l$ odd, *Okl* k odd, *hhl* $2h + l$ odd, and all cyclic permutations) unambiguously identified $Ia\bar{3}d$ (No. 230) (21) as the space group. The data were finally corrected for the effects of Lorentz and polarization.

Work on crystal II was originally undertaken as a check on the results with crystal I. The cell edges were found to be ~1% longer, but the same steps as above led again to space group $Ia\bar{3}d$. A minimum data set (*hkl*, $h + k + l$ *even*, $h \leq k \leq l$) was collected. The data set consisted of 1322 unique reflections, of which 766 with $I \geq 3.0\ \sigma(I)$ were retained for structure determination. The specimen used was a roughly spherical fragment of mean radius 0.11 mm without well-defined faces and no absorption correction could be applied.

The structures were solved by the heavy-atom method. Refinement was done on $|F|$ by full-matrix least-squares procedures. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with weights $w = 1/(\sigma^2(F_o) + k F_o^2)$, where $k = 0.0001$ for I and 0.001 for II. The Patterson map calculated for crystal I indicated that special positions *24c* and *24d* (21) were occupied by Re and Cl, but could not distinguish between the two possible distributions. The ΔF map calculated with one of the models failed to reveal any chemically reasonable fragment. With the other model (Re on *24c* and Cl on *24d*), the Re-bonded oxygen (*48g*) and the non-hydrogen atoms in the 1,2-Me_2Im ligand (general position) were located. The next ΔF map showed residual electron density in two regions. A peak of 5 e $Å^{-3}$ at (1/8, 1/8, 1/8) was obviously due to a water molecule hydrogen bonded to Re═O groups. A stronger peak (9 e $Å^{-3}$) at the origin was too far from already identified units to be covalently or hydrogen bonded. Among various models considered, partial occupancy by Cl^- turned out to best fit the data. This extra Cl^- ion would balance the charge of either H_3O^+ ions replacing some water molecules at (1/8, 1/8, 1/8) or oxo-protonated $[ReO(OH)(1,2\text{-}Me_2Im)_4]^{2+}$ cations randomly replacing $[ReO_2(1,2\text{-}Me_2Im)_4]^+$ in the crystal. The latter model was retained since it allowed us to interpret unexplained features in the infrared spectra. A Cl(2) atom was positioned at (0, 0, 0) (*16a*) and assigned an isotropic temperature factor of 0.05 $Å^2$ (mean of U_{iso} for ligand atoms). The known atoms were refined anisotropically, and the occupancy factor for Cl(2), whose coordinates were fixed by symmetry, was included in the refinement. Occupancy converged to 0.35: this value was retained for the rest of the refinement. In the subsequent ΔF map, the water region was found to contain two close, but resolved, residuals: one peak W(2) of 2.5 e $Å^{-3}$ at (0.10, 0.10, 0.10) (*32e*) and the W(1) counterpart of 5 e $Å^{-3}$ at (0.125, 0.125, 0.125) (*16b*). With U_{iso} fixed at 0.05 $Å^2$ as above, the position of W(2) and the occupancy factors of W(1) and W(2) were allowed to refine. The converged values were 0.57 and 0.15, respectively. When equipoint multiplicities are taken into account, this corresponds to a roughly 2:1 ratio between the water populations on the W(1) (16 × 0.57 = 9.1) and the W(2) sites (32 × 0.15 = 4.8). These values were normalized to 0.65 and 0.17 to provide a whole water molecule in this region and were fixed for the rest of the interpretation. The question concerning the species present 65% of the time near the origin, when Cl(2) is absent, was answered by the next ΔF map. A peak of 4.1 e $Å^{-3}$ remained at

(0.03, 0.03, 0.03), too close to Cl(2) to be present simultaneously, but close enough (1.6 Å) to the symmetry-related site at (−0.03, −0.03, −0.03) to define a methanol molecule with the CH_3 and OH groups statistically interchanged by disorder across the origin. This site (MET) was described with the scattering curve of nitrogen and occupancy was fixed to 0.65. The eight hydrogens on the 1,2-Me_2Im ligand were also visible in the ΔF map. They were fixed at idealized positions (C—H = 1.0 Å) with temperature factors 0.01 Å^2 greater than those of the corresponding carbons. The fractional hydrogens of lattice methanol were not found in the ΔF map and were neglected. In the final cycles, all adjustable coordinates of all non-hydrogen atoms were refined and temperature factors were anisotropic, except for the disordered atoms Cl(2)/MET and W(1)/W(2), which were kept isotropic. The final residuals were $R = 0.032$ and $R_w = 0.041$. The general background in the final ΔF map was below ±0.7 e Å^{-3}, except for a peak of 1.2 e Å^{-3} at (0.04, 0.04, 0.04), in the disordered Cl(2)–methanol region.

Form II belongs to the same space group. Again, the two starting points indicated by the Patterson map were tested and the above distribution of Re(1) and Cl(1) on *24c* and *24d*, respectively, proved to be correct. The coordinates obtained above for O(1) and the non-hydrogen atoms in 1,2-MeIm were then introduced. In the ΔF map, electron density was present near (1/8, 1/8, 1/8) for water molecules but, near the origin, a very high residual (18 e Å^{-3}) was found at (0.03, 0.03, 0.03). It was assigned to the Re atom of a fractional ReO_4^- ion, since it was surrounded by a tetrahedron of smaller peaks, assigned to oxygen, at ~1.65 Å: O(20) on the threefold axis (*32e*) and O(21) in general position. This interpretation was supported by the presence of an unexplained peak corresponding to uncoordinated ReO_4^- in the infrared spectrum. Hence, substitution of $[ReO_2(1,2\text{-}MeIm)_4]^+$ by $[ReO(OH)(1,2\text{-}MeIm)_4]^{2+}$ was again taking place and, in this case, the extra anion required for each protonated species present was not Cl^-, but ReO_4^-. Using the same strategy as above, U_{iso} factors of 0.05 Å^2 were assigned to W(1), W(2), and Re(2), and their positions and occupancies were adjusted, while the rest of the structure was refined anisotropically. Occupancy of Re(2) converged to 0.27. Fixed occupancies of 0.27 were then used for Re(2), O(20), and O(21). The refined occupancies of W(1) and W(2) (0.41 and 0.24) were normalized to 0.46 and 0.27, respectively, as above. Therefore, the amount of W(2) corresponds to the number of extra anions present. Occupancies of W(1) and W(2) were fixed for the rest of the interpretation. After refining this model, the ΔF map contained three residual peaks of 2.8, 1.6, and 1.0 e Å^{-3} near the ReO_4^- ion. They could be assembled into a CH_2Cl_2 molecule disordered over six orientations with Cl(3) lying on the threefold axis. Occupancies were fixed at 0.23 for Cl(3) and 0.08 for C(10) and Cl(2), assuming that the region around the origin is fully occupied by either ReO_4^- or CH_2Cl_2. Attempts to refine all parameters in this region led to high instability, because of the proximity of the disordered atoms. In the final model, Cl(2) and C(10) were fixed at the positions found in the ΔF map. All other adjustable coordinates of all non-hydrogen atoms were refined and temperature factors were anisotropic, except for the disordered atoms ReO_4/CH_2Cl_2 and W(1)/W(2), which were kept isotropic. The position of O(20) was also fixed, since refinement displaced it towards the origin making the Re—O distance too small. Hydrogens were not visible in the ΔF map. The final agreement factors were $R = 0.056$ and $R_w = 0.056$. The general background in the final ΔF map was below ±0.98 e Å^{-3}, except for a peak of 2.8 e Å^{-3} at origin. This peak could be an artefact due to our fixing O(20), but the possibility that a small amount of Cl^- (or ReO_4^-) is present at this site cannot be ruled out. No attempts were made, however, to introduce a third contributor to this disordered region.

All calculations were done with the NRCVAX system (22). The refined coordinates are listed in Table 2.[2]

Discussion

Three methods were applied to prepare $[ReO_2L_4]Cl$ with imidazole derivatives. For ImH and 2-MeImH, reacting $ReOCl_3(PPh_3)_2$ with 6 equivalents of ligand in ethanol led to the expected $[ReO_2L_4]^+$ ion. Thus, the very large ligand excess originally used to prepare the pyridine analogue (15) can be reduced without loss of efficiency, as noted in the case with 7-azaindole (23). The same ImH and 2-MeImH compounds were isolated from the reaction of $ReOCl_3(PPh_3)_2$ with 6 equivalents of ligand in moist toluene. With pyridine and azaindole, this method led to the oxo-bridged dimer $\{ORECl_2L_2\}_2O$, but dioxo monomers were isolated here and sample crystallinity was better than with the first method.

The two above methods, when applied to 1,2-Me_2Im, led to a red-violet, instead of orange, material. Under the microscope, it was clear that colour variability was not due to a mixture of two types of solids, since the samples were homogeneous both in colour and crystal morphology. Colour was eventually explained when X-ray work (see below) became available, showing that both materials were non-stoichiometric phases containing some protonated $[ReO(OH)L_4]^{2+}$ species together with the normal $[ReO_2L_4]^+$ unit. The protonation-free $[ReO_2L_4]^+$ salt could be prepared via a $KReO_4$/KI/HCl mixture by a method described by Chakravorty (19) for pyridine, but some $KReO_4$ impurity remained.

Infrared spectroscopy

Tables of infrared frequencies for the various complexes are given as supplementary material.[2] Assignments for the

[2]The supplementary material includes lists of observed and calculated structure factor amplitudes, anisotropic thermal parameters, hydrogen coordinates, distances and angles in form II, and atom-to-plane distances for both structures, as well as a table of infrared frequencies (22 pages). Complete set of data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A OS2 Canada.

The tables of hydrogen coordinates (forms I and II) and of distances and angles in form II (2 pages) have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

ImH system are based on earlier studies (24–28). Tentative assignments for the methylated ligands and their complexes are discussed elsewhere (29).

Metal coordination introduces characteristic shifts on a number of vibrations. Except for N—H bands in ImH and 2-MeImH, these changes are relatively small and they will not be described in detail here. However, a large shift in the interference-free 340–420 cm^{-1} region of the 2-methylated derivatives is worth mentioning: bands at 418 cm^{-1} in 1,2-Me_2Im and 345 cm^{-1} in 2-MeImH are displaced to higher frequency by ~50 cm^{-1} in the complexes. Since these bands likely originate for the δ(C—CH_3) mode, they probably reflect steric effects on the methyl group next to the coordination site.

The Re–oxygen stretching modes are usually easy to identify in the infrared spectra. The strong ν_{as}(O=Re=O) band, observed at ~820 cm^{-1} for the pyridine and ethylenediamine analogues (30), is clearly shifted below 800 cm^{-1} in the imidazole complexes, but assignment is not straightforward, since the ligands also show strong γ(C—H) bands in this region. Furthermore, the γ(N—H) mode of free ImH at ~950 cm^{-1} is known to move to the 700–850 cm^{-1} range in various complexes (29, 31, 32), mainly because of changes in hydrogen bonding. From comparisons within the present set of $[ReO_2L_4]^+$ compounds and with complexes of other metals, the ν(O=Re=O) mode was assigned to the strong component in the 780–795 cm^{-1} range. Similar values were found for the *trans*-ReO_2 units with 7-azaindole (23) and a tetraaza macrocyclic ligand (cyclam) (33). In the non-stoichiometric phases with 1,2-Me_2Im, besides the normal $[ReO_2L_4]_2^+$ band at 781 cm^{-1}, the red-violet crystals give a broader feature at 932 cm^{-1} for the ν(Re=O) mode of $[ReO(OH)L_4]^{2+}$. The similar band for the protonated species was observed at 981 cm^{-1} for ethylenediamine (30) and 969 cm^{-1} for cyclam (33). Also present in the sample obtained by method 1 (form II) is a band at 907 cm^{-1}, due to uncoordinated ReO_4^- acting as the counterion for the $[ReO(OH)L_4]^{2+}$ formed.

NMR spectroscopy

^{1}H and ^{13}C data obtained on D_2O solutions are collected in Tables 3 and 4, respectively. Assignments are based on previous studies (34–36). For free ImH and 2-MeImH, the N—H proton participates in a fast tautomeric exchange between the two nitrogens, leading to averaged signals for H4/H5 and C4/C5. Fast exchange does not take place in the complexes and individual resonances are observed.

The ^{13}C chemical shifts for the ring carbons are assigned in the order C2 > C4 > C5 reported by Henderson et al. (36) for $(NH_3)_5$Co(III)–imidazoles complexes. This same order has also been noted for acetone solutions of the Ni(II) complexes $[RNi(imidazoles)]^+$, where R = 7-amino-4-methyl-5-aza-3-hepten-2-one (37). C2 is found to be shifted ~2 ppm downfield by coordination, as noted for these two systems. The separation between C4 and C5 is greater in the present complexes. The displacements on C4 and C5 upon coordination (Table 4) are different for 1,2-Me_2Im when compared with ImH and 2-MeImH, but it should be remembered that these Δδ values are calculated from the averaged C4/C5 signal for the latter two ligands. If the chemical shifts for uncoordinated ImH and 2-MeImH are taken from spectra in the solid state (29, 38), where fast tautomeric exchange does not take place, similar shift patterns are noted for the three compounds: all ring signals are moved downfield and all methyl signals upfield.

The ligand ^{1}H chemical shifts are highly solvent-sensitive: they can vary by as much as 1 ppm by going from a protic solvent to an aromatic one (29). Since the ^{1}H studies on the above Co(III) and Ni(II) compounds were conducted in DMSO and acetone, respectively, comparisons with these systems are less straightforward. In all our compounds, the H4 and H5 resonances are closer together. From the Δδ values (Table 3), H5 seems to be the most affected by complexation, showing a downfield shift of ~0.16 ppm, whereas H4 shows smaller upfield shifts. Again, these comparisons are made with respect to the averaged H4/H5 signals for ImH and 2-MeImH.

Both types of spectra for the non-stoichiometric 1,2-Me_2Im materials were identical to those of the nonprotonated form, indicating that the $[ReO(OH)(1,2\text{-}Me_2Im)_4]^{2+}$ ion is acidic enough to be dissociated in water. Complex decomposition eventually occurred, since aged water solutions showed extra signals for $[1,2\text{-}Me_2ImH]^+$ (pK_a ~7) (34). A ^{13}C CP-MAS

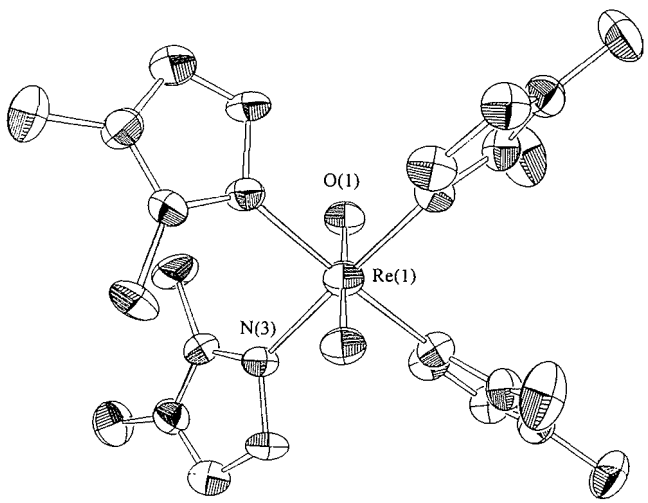

FIG. 1. ORTEP drawing of the *trans*-$[ReO_2(1,2\text{-}Me_2Im)_4]^+$ cation. Local symmetry at Re is *222* (D_2), the twofold axes lying along the O=Re=O bonds and bisecting the N—Re—N angles, respectively. Ellipsoids correspond to 50% probability. Hydrogens are omitted.

spectrum of form II was also recorded (Table 4) as an attempt to detect the presence of both neutral and protonated species. No splitting was observed and the δ values are in agreement with the solution data. Protonation of a remote Re=O group seems not to affect appreciably the ligand carbon resonances.

Crystal structures of the red-violet 1,2-dimethylimidazole compounds

The two types of crystals can be regarded as isostructural, the major building units being *trans*-$[ReO_2(1,2\text{-}Me_2Im)_4]^+$ cations and Cl^- anions. The cation (Fig. 1) occupies a site with crystallographic *222* (D_2) symmetry. The O=Re=O unit, lying on a crystallographic twofold axis, is perfectly linear. Selected distances and angles are listed in Table 5. The less accurate results from crystal II (Table S-4)[2] are not significantly different. The Re–ligand distances are normal (39–42). The steric effect of the imidazole 2-methyl group renders the Re(1)—N(3)—C(2) angle ~10° greater than Re(1)—N(3)—C(4) and displaces N(3) from the ReN_4 plane by 0.075 Å, producing a small tetrahedral distortion. The geometry of the imidazole itself is not affected (43*a*).[3]

Although the major Re species is *trans*-$[ReO_2(1,2\text{-}Me_2Im)_4]^+$, a significant number of these cations are found to be protonated. Besides the 24 $ReO_2(1,2\text{-}Me_2Im)_4$ units and the 24 "normal" Cl^- anions, there are 5.6 additional Cl^- in the unit cell of I and 8.6 ReO_4^- ions in that of II. As each such additional anion requires the presence of a protonated cation, the extent of protonation is 23% in I and 36% in II. Differences in Re–oxygen distances are expected between the O=Re—OH (33, 44) and the O=Re=O units, but since only 11% of the bonds in I and 18% in II are actually Re—OH, the extent of substitution is too small to produce a detectable variation of the average bond length or an elongated thermal ellipsoid (Fig. 1).

The structure shows interesting packing features. In Fig. 2, Re=O bonds in three $ReO_2(1,2\text{-}Me_2Im)_4$ units related by the threefold axis are directed toward a water molecule, with which they form hydrogen bonds. Our crystallographic results indicate that the occupancy in the W(1)/W(2) region is correlated with the number of extra anions near the origin and, consequently, with the extent of protonation of the $ReO_2(1,2\text{-}Me_2Im)_4$ unit. When the Re=O groups are not protonated, the water molecule occupies the W(1) site (*32* symmetry), at the intersection of the crystallographic twofold axes along O=Re=O. The W(1)—H···O(1) bonds

[3]The distances (not given in the paper) were calculated from the coordinates retrieved from the Cambridge Crystallographic Database of Organics and Organometallics (Refcode DIZZIV), ref. 43*b*.

are moderately strong (2.69 Å) and the O(1)—W(1)—O(1) angles very favourable (120°). The two hydrogens in water molecule W(1) are obviously unable to form three hydrogen bonds at a time, so that the molecule is disordered over three orientations about the threefold axis. On the other hand, when one of the three Re=O groups in Fig. 2 is protonated, the water molecule remains on the threefold axis, but it no longer lies along the O=Re=O direction, probably to better accept the hydrogen bond from the bent Re—OH group. The O(1)—W(2) distance is then 2.85 Å and W(2) lies 0.88 Å above the plane through the three O(1) atoms.

Figure 3 shows the $0 < z < 1/4$ slice of the unit cell projected down the c axis. The "normal" Cl^- ion has an interesting environment, consisting only of imidazole C-H and $-CH_3$ hydrogens. This type of cation–anion interaction is probably restricted to N-methylated imidazoles, since ligands with N-H groups would impose a different pattern of interionic interactions. The pocket near the unit cell origin is extensively disordered. It contains the extra anion, or a solvent molecule when the anion is absent. Since the distances and angles involving the $ReO_2(1,2\text{-}Me_2Im)_4$ unit, Cl(1), W(2), and W(3) are essentially the same in both structures, the slightly greater cell edge found for II reflects the greater size of this pocket at origin: it is reasonable to assume that 0.54 ReO_4^- and 0.46 CH_2Cl_2 in form II take more space than 0.65 CH_3OH and 0.35 Cl^- ion form I.

Concluding remarks

Pure chloride salts of $[ReO_2L_4]^+$ were obtained with ImH and 2-MeImH. The fact that under similar conditions 1,2-Me_2Im led to a non-stoichiometric phase containing substantial amounts of $[ReO(OH)L_4]^{2+}$ can be related to four features of molecular packing: (*a*) the complex cations and water molecules form an efficient hydrogen-bonding framework, in which each water molecule interacts with three oxo or hydroxo groups; (*b*) the very high symmetry of the crystal allows both ends of the O-Re-O unit to participate in hydrogen bonding without forcing the Re-OH end to adopt a particular direction; (*c*) the structure contains a pocket near the origin, which can accommodate either the extra counter-anion or a solvent molecule; (*d*) since the ligand is devoid of hydrogen-bond donors, the environment of the "normal"

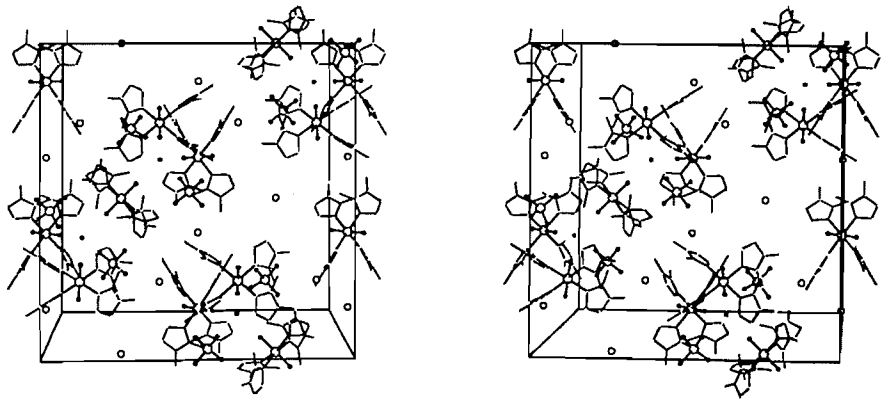

FIG. 3. Stereoview of the unit cell of form II down the c axis ($0 < z < 1/4$). Hydrogens are omitted for clarity. The isolated spheres are Cl^- ions (large) or water molecules (small). The tetrahedral ReO_4^- anion showed near the origin corresponds to one of two disordered orientations of this anion.

Cl^- counterion consists of ring or methyl C-H hydrogens only. For non-N1-methylated imidazoles, hydrogen bonding with the N1-H groups should impose a totally different architecture, in which such favourable conditions could hardly be achieved, so that more conventional stoichiometric materials, protonated or not depending on pH, will probably be isolated.

Chloride salts of various $[ReO_2L_4]^+$ cations have been found to show some instability (19). With 7-azaindole, replacing Cl^- by I^- improved stability (23), but this does not seem to be the case with pyridines (14). For cyclam, the iodide of the monoprotonated complex decomposed during recrystallization and X-ray diffraction work had to be done on the ReO_4^- salt (33). Brewer and Gray (14) noted that salts with larger noncoordinating counter-anions made the compound more resistant to ligand loss. Work is underway to obtain complexes with a variety of imidazoles with other counter-anions, in order to study their acid–base and optical properties.

Received June 14, 1993

J. LOGAN, J. TREURNIET, A.D.O. BAWAGAN, S. RIZZETTO, J.M. BRAUN, and B.D. AGUDA. Can. J. Chem. **71**, 2079 (1993).

An apparatus for the study of the discharge patterns generated in gaseous dielectric breakdown is described. The discharge patterns are imaged using a fast optical imaging system (≈ 40 ns exposure time) and are found to be fractals. The experimental fractal dimension obtained using a +17 kV pulse in air at atmospheric pressure is $D_{expt} \approx 1.8 \pm 0.1$, which is in very good agreement with previous studies.

J. LOGAN, J. TREURNIET, A.D.O. BAWAGAN, S. RIZZETTO, J.M. BRAUN et B.D. AGUDA. Can. J. Chem. **71**, 2079 (1993).

On décrit un appareil permettant d'étudier les patrons de décharge générés lors de décharges diélectriques gazeuses. On obtient l'image des patrons de décharge en faisant appel à un système d'imagerie optique rapide (≈ 40 ns de temps d'exposition) et on a trouvé qu'ils sont de nature fractale. La dimension fractale expérimentale obtenue en utilisant une pulsation de +17 kV, dans l'air, à la pression atmosphérique, $D_{exp} \approx 1{,}8 \pm 0{,}1$, est en très bon accord avec les valeurs obtenues antérieurement.

[Traduit par la rédaction]

1. Introduction

A high-voltage discharge generates a "tree-like" or branched pattern, which is commonly described as a random structure. Recent studies (1, 2), however, have indicated that these tree-like structures can be described as a fractal or self-similar pattern (3) in what is now known as the dielectric breakdown (DB) model (1). For a fractal structure in two dimensions the total length $N(r)$ of all branches inside a circle of radius, r, is related as follows:

[1] $$N(r) \approx r^D$$

Clearly, a plot of log N versus log r will yield a linear relationship characterized by a slope equal to D, or what is referred to as the fractal dimension or the Hausdorff dimension (3, 4).

A significant amount of theoretical work has led to an understanding of a wide range of physical phenomena characterized by some stochastic feature in one way or another. Several reviews are available in the literature (5). In particular, the qualitative description of dielectric breakdown of gases in terms of fractals has paved the way to a systematic study of such structures. By extension of these pioneering studies (1) to other chemical systems, the determination and elucidation of various fractal parameters in dielectric breakdown are now feasible.

Our interest in the description of dielectric breakdown of gases in terms of fractals stems from practical and fundamental reasons. An understanding of dielectric breakdown is motivated by an urgent need for *quantitative* models of gas insulating systems (6), which are essential components of electrical power delivery installations. The economic importance of proper design of gas insulating systems can therefore not be overemphasized. Of more basic interest is the introduction of a new mathematical language (i.e., the language of fractals) that allows us to study such seemingly disparate chemical processes (5) as diffusion-limited aggregation, electrodeposition, soot formation, and dielectric breakdown. The language of fractals in itself has brought significant understanding of "old problems" such as turbulence and phase transitions (7). It is foreseeable that the language of fractals will also provide the necessary descriptive tools that would allow us to unravel many more very complex phenomena such as, for example, electron–electron

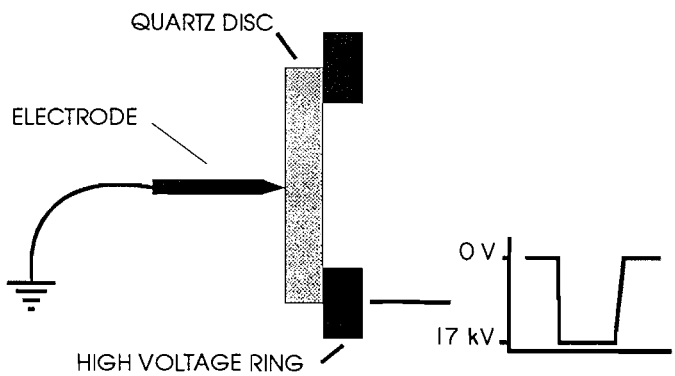

FIG. 1. Basic schematic for the generation of a surface-leader discharge. A positive high voltage is effectively introduced to the electrode by "grounding" the electrode. As the thyratron (see Fig. 2) switches on, the normally grounded ring goes negative. This produces a potential between the electrode and the ring that is of *positive* polarity.

many–body interactions (8). However, the more immediate goal of the present investigation is to provide a "phenomenological link" between microscopic gas phase information (e.g., photoionization cross sections, reaction rates, thermal relaxation rates, etc.) and the macroscopic structures generated in a surface-leader discharge. Although at first glance this may appear as a daunting task, recent theoretical investigations (9), indicate that the language of fractals has made small but significant advances.

In the present paper we describe an apparatus for the generation of experimental fractals using a high-voltage discharge. The general schematic of the instrument and representative experimental fractal images are presented. A significant advantage of the present experiment compared to that conducted by Niemeyer et al. (1) is the capability to produce time-resolved images of the dielectric breakdown in the nanosecond range. The result is unprecedented since earlier published results (1) dealt with dielectric breakdown images that are time-integrated photographs in the microsecond range. The central result of the present work is to show that the time development of the dielectric breakdown is also a fractal, as revealed by an analysis of each single frame.

Computer-generated fractal images based on the DB model of Niemeyer et al. (1) are also presented. The DB model treats the growths of the dielectric breakdown patterns as a random process with the growth probability directly proportional ($\eta = 1$) to the local electric fields. The DB model is actually very general ($\eta \geq 0$) and can be applied to other problems by varying η. For example, as $\eta \sim 0$ the Eden model is recovered (1).

2. Description of apparatus

The gaseous dielectric breakdown experiment is shown schematically in Fig. 1. A positive high-voltage pulse (+17 kV, 1 μs width) is introduced to a sharp stainless steel electrode that is located in the center of a quartz disc (2 mm thick). The positive input voltage is referenced relative to a stainless steel ring (20 mm inner radius) situated at the rim of the quartz disc. The leader[2] surface discharge that results is observed from the back side of the quartz disc. The arrangement is very similar to the arrangement introduced by Niemeyer et al. (1) except that the present experiments are conducted in air at atmospheric pressure as opposed to high pressure SF_6. To a good approximation, this arrangement produces an equipotential channel system growing in a plane. The growth is therefore two-dimensional even though the electric field lines are three-dimensional (1).

The details of the high-voltage electronics and fast optical imaging system are shown in Fig. 2. The high-voltage electronics and breakdown apparatus were fabricated at Carleton University whereas the fast optical imaging system was provided by the Ontario Hydro Research Division. The fast high-voltage pulse is generated using a stable high-voltage DC supply (Brandenburg 25-P), a storage capacitor (1300 pF), and a grounded grid thyratron (EG&G HY-1102). The low impedance and stable switching ability of the thyratron allow the reproducible production of fast high-voltage pulses ($t_{rise} \approx 30$ ns). A bias supply and a heater are attached to the thyratron to maintain stable and consistent switching capability. The dielectricc breakdown apparatus can be triggered in two ways. First, a hand-held trigger is used with a delay/timing generator. This mode is used when a slow optical device like a charge-coupled device (CCD) camera (exposure time ≥5 ms) is employed to photograph the discharge patterns. Second, an inductive pickup device is used when a fast optical device like the IMACON streak camera (exposure time ≤1 μs) is employed to photograph the discharge patterns. The whole apparatus is housed and shielded in a mobile 19.5-in. electronics rack.

The fast optical imaging system is composed of several optical devices coupled together to achieve the maximum possible gain (Fig. 2). Because of the small exposure times necessary to ob-

[2]The microscopic processes involved in a surface discharge are called streamers and leaders (9, 10). The initial process involves the formation of streamers, which have very low optical luminosity, followed by the leader discharge, which is of higher luminosity. The final stage is referred to as the "spark-over," which is characterized by extreme brightness and sometimes a "sonic boom." The current experiments are concerned only with the streamer and leader processes (i.e., pre-breakdown).

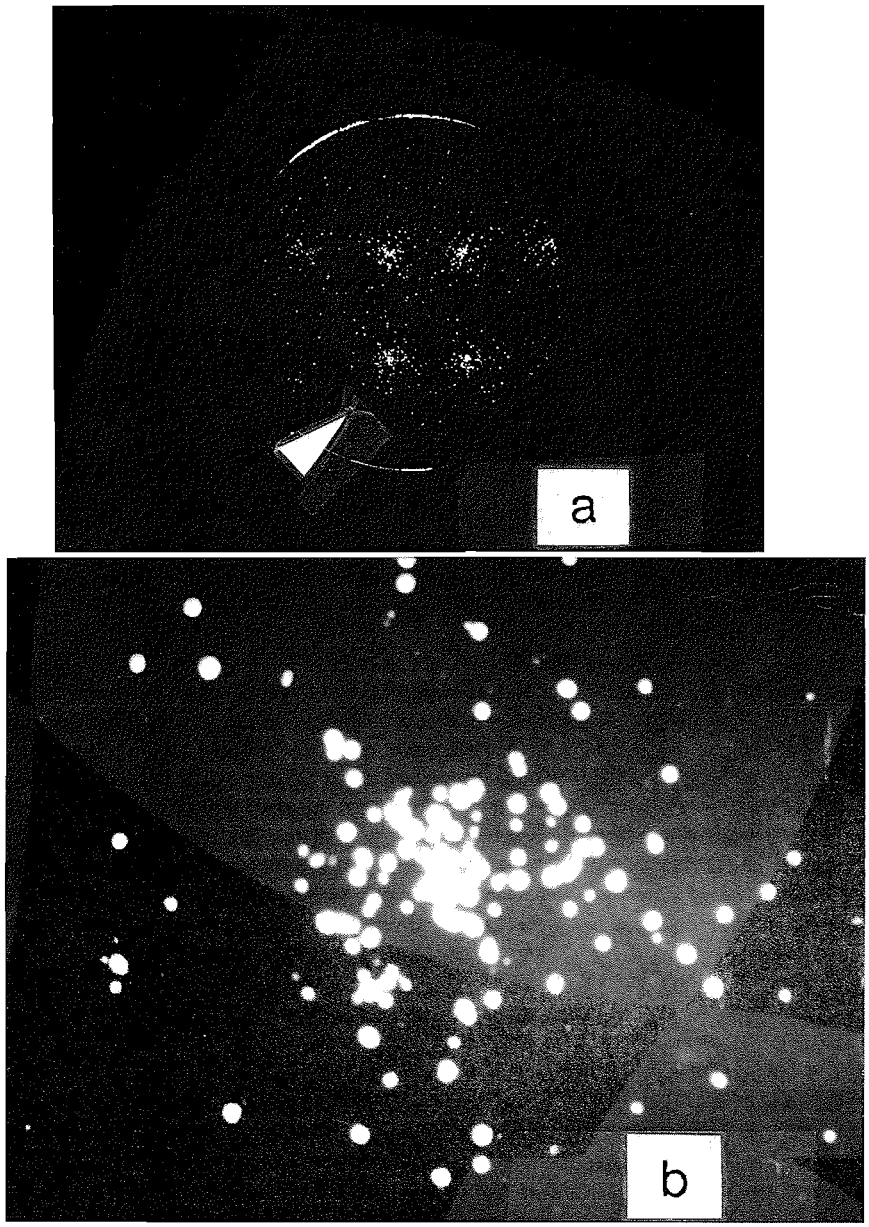

FIG. 3. (*a*) Time-resolved IMACON images generated by a fast +17 kV pulse. Exposure time is ≈40 ns per frame. See text for details. (*b*) Expanded view of a selected frame (indicated by arrow) of the IMACON image.

serve the streamer-leader discharge and the low visible photon flux generated during the pre-breakdown period, a total gain of $\geq 10^5$ was necessary. A macro lens (Canon) is attached to the back end of the quartz disc (Fig. 1) and after this an image intensifier (Star-Tron MK 303ABN) operated at maximum gain (≈60 000) was used. The image generated by the Star-Tron MK 303ABN is then photographed using a streak camera (IMACON 790 with IMACON 50/40 Intensifier) operated in framing mode with an exposure time of 40 ns per frame. The IMACON camera is triggered by inductive pickup from the dielectric breakdown apparatus. A total of 6–8 frames are generated for each single discharge and these frames are permanently recorded on Polaroid 612 film (20 000 ASA). The interframe time difference is ~160 ns, thus giving a total time record of 1600 ns for 8 frames (i.e., for each discharge).

3. Results and discussion

3.1 Characteristics of high-voltage pulse

An oscilloscope trace of the high-voltage pulse (+17 kV) generated using our apparatus was obtained. The estimated rise time (10% to 90%) is approximately 30 ns and the pulse duration is 1–3 μs. The variation in the pulse duration is due to the stochastic nature of the discharge. The current is dissipated from the quartz disc whenever the streamer–leader discharge reaches the rim of the disc (i.e., at "spark-over"). Careful shielding and high-voltage protection were necessary to generate reproducible fast high-voltage pulses. In practice, 2 min were made to elapse between discharges to allow the dielectric breakdown apparatus and the fast optical imaging system to stabilize. In the present application, it is also important to prevent the resulting discharge from overloading the optical imaging system. The dielectric breakdown apparatus was carefully calibrated to determine the spark-over conditions and to set the high voltage slightly *below* this value. The optimum condition was obtained for +17 kV. Changes in the thickness of the quartz disc will clearly change this optimum high voltage.

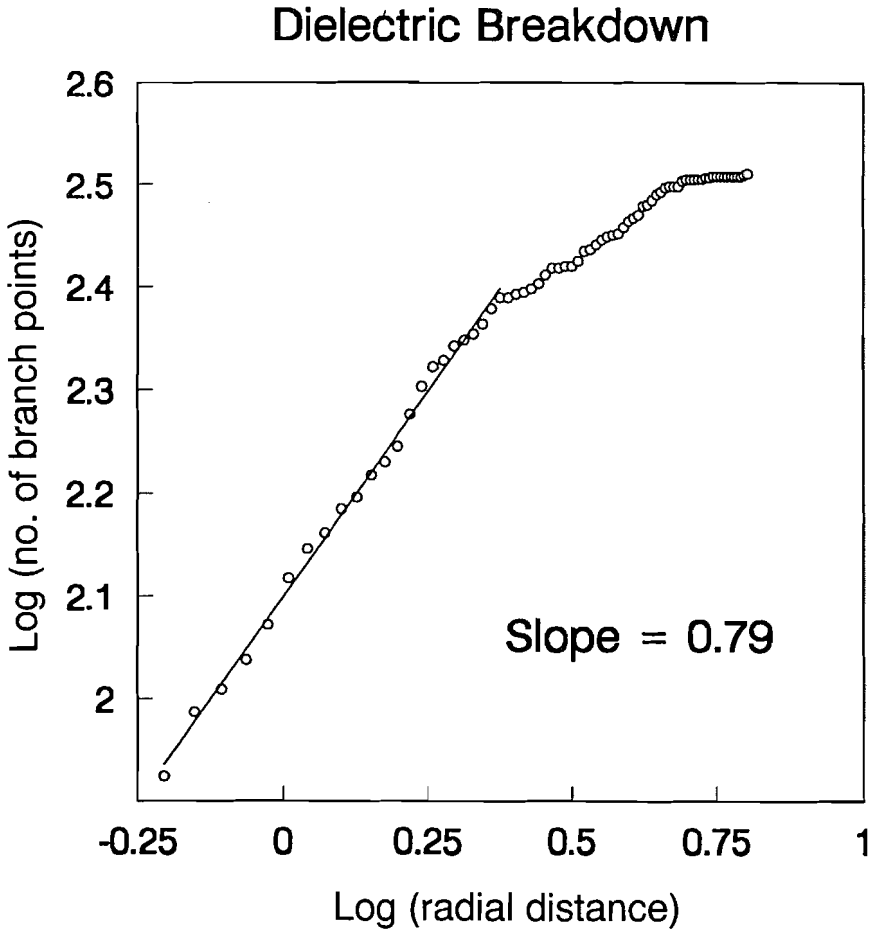

FIG. 4. Experimental fractal dimension of the time-resolved dielectric breakdown images. The number of branch points $b(r)$ occurring within a radial distance r is plotted in logarithmic scale. The experimental fractal dimension obtained from the slope is $D_{expt} \approx 1.8 \pm 0.1$. The estimated uncertainty corresponds to statistical limits and does not include systematic errors.

3.2 Experimental fractal patterns

An example of the IMACON images obtained from the dielectric breakdown apparatus is shown in Fig. 3*a*. One of the frames (indicated by an arrow) is enlarged and shown in Fig. 3*b*. The images obtained in the present experiment have an exposure time of 40 ns, in stark contrast to the images obtained by Niemeyer et al. (1), which are *time-integrated* and are equivalent to ≈1 μs exposure time. The resulting images were analyzed using a PC-based digitizer (Sigmascan JS-2). Each point on the IMACON image was digitized[3] and the radial distance from the electrode point was calculated. A log–log plot of the number of points, $b(r)$, as a function of the radial distance, r, is shown in Fig. 4. The linear relation obtained at $-0.5 \leq \ln r \leq 1.0$ clearly indicates that the time-resolved dielectric breakdown images are indeed *fractal images*. The points in the IMACON images (Fig. 3) are interpreted as the branch points, $b(r)$, of the surface-leader discharge. This is very plausible, especially in consideration of the detailed microscopic mechanism of streamer–leader formation. Spectroscopic studies by Gallimberti et al. (10) revealed that the brightest (in the visible range) region of the streamer–leader is the *tip* of the growing streamer–leader formation. The tip is essentially the growth point for new streamers and may be considered a branch point. It can then be argued that the number of branch points $b(r)$ at large enough values of r is proportional to the number of branches, which in turn is related to $N(r)$ (1):

$$[2] \quad b(r) \approx \frac{dN(r)}{dr} \approx r^{D-1}$$

and the slope of log b versus log r would then be equal to $D - 1$. Equation [2] involves several assumptions and a more rigorous derivation is presented elsewhere.[5] This result, which was originally derived by Niemeyer et al. (1), requires further theoretical investigation and is beyond the scope of the present study. Nevertheless it should be noted that the main result of the present work is to illustrate the fractal nature of the dielectric breakdown images at short exposure times (see Fig. 4). The calculated slope for the IMACON images is ≈0.8 (see Fig. 4) which gives an experimental fractal dimension, $D_{expt} \approx 1.8 \pm 0.1$,[4] based on eq. [2]. This experimental value is in very close agreement with the fractal dimension ($D_{theor} = 1.75$) predicted and also observed experimentally by Niemeyer and co-workers (1, 11) using time-

[3]Some faint points may not be visible in Fig. 3.

[4]The estimated error limits are statistical errors based on several discharge patterns and do not include systematic errors.

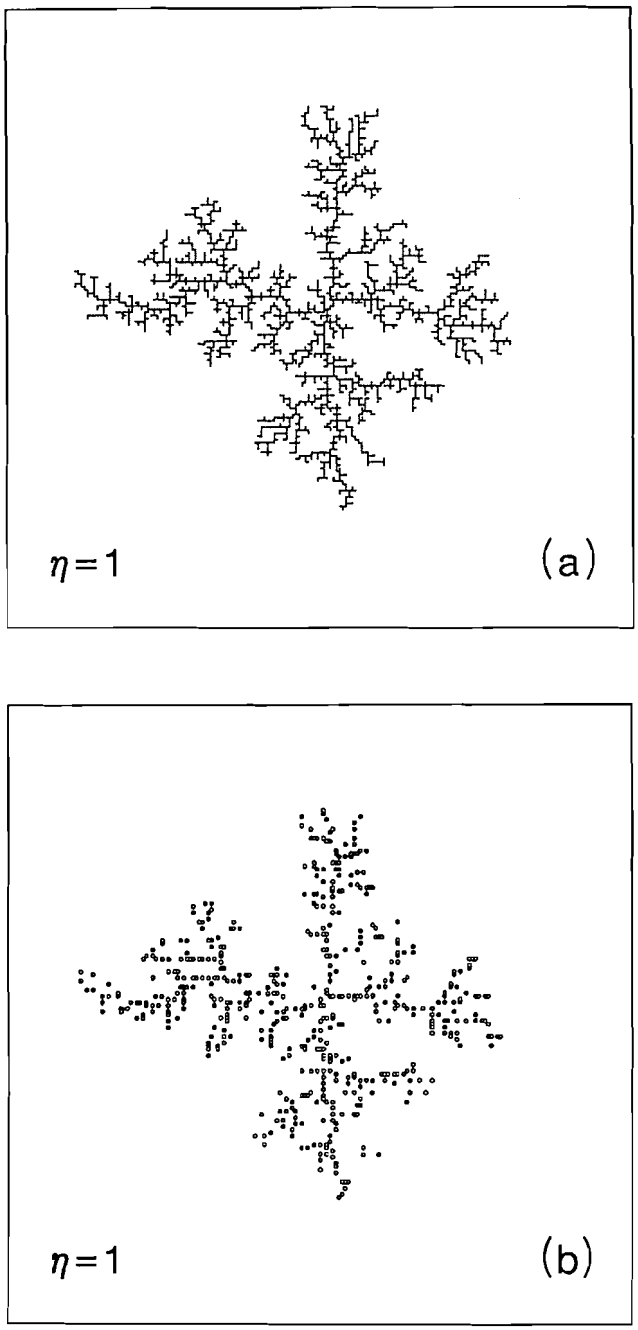

FIG. 5. Computer simulation of the dielectric breakdown images using the DB model of Niemeyer et al. (1). (*a*) Simulation of dielectric breakdown using $\eta = 1$ and 2270 points. Further details, see footnote 5. (*b*) Reproduction of Fig. 5*a* but displaying only the branch points (open circles). The exact relationship between dielectric breakdown IMACON images (Fig. 3) and the simulated branch points is currently under detailed investigation; however, some similarity can be noted.

integrated DB images. Using the theoretical stochastic model proposed by Niemeyer et al. (1), we have also developed a computer program to simulate the dielectric breakdown phenomenon and the results are shown in Fig. 5. We obtain a theoretical fractal dimension of $D_{\text{theor}} = 1.76 \pm 0.03$ based on five simulations reproducing the earlier results of Niemeyer et al. (1). Further analysis of the experimental fractals and the details of the computer simulation will be reported in a separate paper.[5] It should be noted that each frame in Fig. 3*a* corresponds to a 40 ns time slice of a single growing discharge. By summing each of the frames a "time-integrated image" with branched structure is recovered[5] that is analogous to that obtained in previous time-integrated studies (1, 11).

4. Conclusions

In summary, we have developed a dielectric breakdown apparatus coupled to a fast optical imaging system capable of producing *short exposure time* images (~40 ns) of the streamer–leader discharge pattern produced by a +17 kV pulse in air at atmospheric pressure. Preliminary analyses reveal that these images are fractals, which can be characterized by a fractal dimension of $D_{\text{expt}} \approx 1.8 \pm 0.1$. This is in close agreement with previous experimental and theoretical studies (1) of gaseous dielectric breakdown. Future experiments will involve more accurate measurements of the experimental fractal dimensions as well as the fractal dimensions for high-voltage discharges in different chemical environments.

Isotope effects in nucleophilic substitution reactions. IX. The effect of bond strength on substituent effects on the structure of S_N2 transition states

KENNETH CHARLES WESTAWAY
Chemistry Department, Laurentian University, Sudbury, ON P3E 2C6, Canada

Received January 4, 1993[1]

KENNETH CHARLES WESTAWAY. Can. J. Chem. **71**, 2084 (1993).

The effects of substituents on the structure of S_N2 transition states suggested by kinetic isotope effects and Hammett ρ values are often different and, moreover, often do not agree with substituent effects predicted by current theories whether the change in substituent is made in the nucleophile, in the leaving group, or at the α-carbon. The importance of the strength of the reacting bonds in determining the effects of substituents on transition-state structure is investigated. A bond strength hypothesis that suggests there will be a significant change in the weaker reacting bond but little or no change in the stronger reacting bond in an S_N2 transition state when a substituent in the nucleophile, the substrate, or the leaving group is altered in an S_N2 reaction, predicts a high percentage of the experimental results.

KENNETH CHARLES WESTAWAY. Can. J. Chem. **71**, 2084 (1993).

Les effets des substituants sur la structure des états de transition S_N2 suggérés par les effets isotopiques cinétiques et par les valeurs ρ de Hammett sont souvent différents et, de plus, ils ne sont pas en accord avec les effets de substituants prédits par les théories actuelles que le changement de substituant soit fait dans le nucléophile, le groupe partant ou au niveau du carbone α. On a étudié l'importance de la force des liaisons qui réagissent pour évaluer les effets de substituants sur la structure de l'état de transition. Une hypothèse de force de liaison qui suggère que, pour un état de transition S_N2 dans lequel on modifie le nucléophile, le substrat ou le groupe partant, on observera un changement important si la liaison réagissante est faible mais peu ou pas de changement avec une liaison réagissant plus forte permet de prédire un fort pourcentage des résultats expérimentaux.

[Traduit par la rédaction]

Introduction

Chemists have been trying to determine and rationalize the effects of substituents on the structure of S_N2 transition states, eq. [1], for some time (1–10). The most useful tools for determining substituent effects on transition-state structure are kinetic isotope effects and linear free energy relationships. For example, Westaway and co-workers (11, 12) used these techniques to model the transition states of two different series of S_N2 reactions in some detail and were able to show how substituents in the leaving group, and at the α-carbon, alter the lengths of both the nucleophile–α-carbon and the α-carbon – leaving group bonds in S_N2 transition states. In spite of (*i*) these and other studies that have determined substituent effects experimentally (1, 2, 6–25), (*ii*) several theoretical studies (26–31), and (*iii*) several semi-empirical methods that have attempted to describe how substituents affect transition-state structure by altering the vibrational modes of the transition-state (32, 33) or the energy surface for the reaction (9, 34–37), the effects of substituents on the structure of S_N2 transition states are not well understood.

[1] $$Nu:^- + -\overset{|}{\underset{|}{C}}-L \longrightarrow [Nu^{\delta-} \cdots \overset{|}{\underset{|}{C}} \cdots L^{\delta-}]^{\ddagger -} \longrightarrow Nu-\overset{|}{\underset{|}{C}}- + L:^-$$

One of the problems in determining substituent effects on transition-state structure is that most of the studies have only indicated how a substituent affects one of the reacting bonds in the S_N2 transition state and give no information about the behaviour of the other reacting bond (2, 6, 7). Thus, one does not know how the total transition state is altered when a substituent is changed. An even greater problem is that the effects of substituents on the structure of S_N2 transition states found in similar systems are not the same. Finally, the theories that are most commonly used to predict substituent effects on transition-state structure (9, 32–37) often fail to predict the substituent effects suggested by experimental data when they are tested in detail (11, 12).

It is important that the systems used to assess substituent effects on the transition-state structure of S_N2 reactions are chosen carefully. In fact, we have only considered systems in which the *meta* or *para* substituent on a benzene ring that is bonded to the α-carbon or to the nucleophilic atom of the nucleophile or leaving group of an S_N2 reaction has been changed. This ensures that the observed substituent effects are the result of the electronic effects of the substituents and eliminates systems in which the structural change(s) in the transition state might be the result of other influences, for example, differences in the steric requirements of the two reactions or changes in solvation of the transition states.

Kinetic isotope effects and Hammett ρ values are widely used to deduce the structure of the S_N2 transition state. A larger heavy-atom leaving group kinetic isotope effect indicates a longer α-carbon – leaving group bond in the transition state (38), a larger Hammett $|\rho|$ value found by changing a substituent in the nucleophile (leaving group) is indicative of a shorter nucleophile–α-carbon (longer α-carbon – leaving group) transition-state bond[2] (12, 42), and the

[1]Revision received August 13, 1993.

[2]Hoz et al. (39) used the results of calculations on homolytic cleavage reactions to question the use of Hammett ρ values to determine transition-state structure. However, many workers are currently using linear free energy relationships such as ρ values to indicate differences in transition-state structure (40, 41). Although there is no experimental proof to show which position is correct, the author believes that ρ values found in closely related systems like those used in this study (vide infra) are related to transition-state structure. It is worth noting that ρ values have only been used in five out of the 37 reaction series used to test the bond strength hypothesis and, in two of the five systems, the changes in transition-state structure suggested by the ρ values have been confirmed by kinetic isotope effects (11, 12).

TABLE 1. The change in the nucleophile–α-carbon and α-carbon – leaving group transition-state bonds based on the change found in the isotope effects and Hammett ρ values when a substituent was changed in an S_N2 reaction

Change in transition-state structure predicted from isotope effects and (or) ρ values	The effect of changing to a better nucleophile[a]	The effect of adding a more electron-donating group to the α-carbon[b]	The effect of changing to a better leaving group[c]
A longer Nu--C_α bond	2	3	4
A shorter Nu--C_α bond	2	3	4
No change in the Nu--C_α bond	0	0	0
A longer C_α--L bond	0	5	0
A shorter C_α--L bond	4	1	0
No change in the C_α--L bond	3	5	1

[a]When a better nucleophile is used in an S_N2 reaction, the Nu--C_α bond is shorter in two reaction series and longer in two others. In the seven reaction series where the length of the C_α--L bond was determined, the C_α--L bond was shorter in four reaction series and did not change in three other reaction series when a better nucleophile is used.

[b]When a more electron-donating substituent is added to the phenyl group on the α-carbon of an S_N2 reaction, the Nu--C_α bond is longer in three reaction series and shorter in three others. When the C_α--L bond was monitored and a more electron-donating substituent was on the phenyl group on the α-carbon, the C_α--L bond was longer in five reaction series, shorter in one series, and did not change significantly in five other reaction series.

[c]When a better leaving group is used in an S_N2 reaction, the Nu--C_α bond is shorter in four reaction series and longer in four others. When the C_α--L bond was monitored, the C_α--L bond did not change significantly when a better leaving group was present.

transition state is tighter with a shorter nucleophile – leaving group distance when a smaller secondary α-deuterium kinetic isotope effect is observed (11, 12). When the experimental kinetic isotope effects and Hammett ρ values found in suitable series of S_N2 reactions (1, 2, 6–25) are interpreted in the above manner, one can deduce, Table 1, how the α-carbon–nucleophile and (or) α-carbon – leaving group transition-state bonds change when a substituent is altered in an S_N2 reaction.

In spite of the precautions taken in choosing the reaction systems for Table 1, it is clear that the substituent effects indicated by experimental data are not consistent. For example, changing to a better nucleophile leads to a longer C_α--Nu bond in two cases and to a shorter C_α--Nu transition-state bond in two other series of S_N2 reactions. The same problem is observed when one examines how changing to a better nucleophile affects the C_α--L bond length in the S_N2 transition state. The C_α--L bond becomes shorter in four of the seven suitable S_N2 reaction systems but does not change appreciably in the three other S_N2 reaction systems when a better nucleophile is used.

The changes that are found in the C_α--Nu and C_α--L transition-state bonds when a more electron-donating group is added to the α-carbon of the substrate are even more varied, Table 1. The C_α--Nu bond shortens in three of the suitable systems and lengthens in the other three suitable series of S_N2 reactions. The same difficulty is observed with the substituent effect on the C_α--L bond. When the 11 suitable reaction series in the literature are analyzed, a longer C_α--L bond is found in five systems, a shorter C_α--L bond is found in one system, and the C_α--L bond length does not change significantly in the five remaining series of S_N2 reactions when a more electron-donating group is added to the α-carbon.

Finally, the same problem is observed when a better leaving group is used in an S_N2 reaction. Changing to a better leaving group, Table 1, leads to a transition state with a longer C_α--Nu bond in half of the eight suitable systems and to a shorter C_α--Nu bond in the other four reaction series.

The marked variations in substituent effects found experimentally and the fact that less than 50% of the substituent effects shown in Table 1 are predicted by the simple application of Thornton's Reacting Bond Rule (32) or Harris and Kurz's extention of this rule (33) and the More O'Ferrall – Jencks energy surface method (35, 36), clearly indicate that some other factor(s) must play a role in determining how changes in substituents affect the structure of S_N2 transition states.

The substituent effects we found in one study (11) indicated that the major effect of changing the structure of the reactants in an S_N2 reaction was observed in the weakest reacting bond in the transition state and that little or no change occurred in the stronger reacting bond. A qualitative rationale for this behaviour is possible. Changing a substituent in the nucleophile, the substrate, or the leaving group of an S_N2 reaction changes the free energy of the transition state (32). This change in free energy will alter the lengths of the weak reacting bonds, i.e., the partially formed nucleophile–α-carbon and α-carbon – leaving group bonds. However, the greatest change in bond length should be observed in the weakest bond because the curvature of the potential energy surface for a weak bond is smaller (16). Thus, in an S_N2 transition state, the greatest change in structure would occur in the weakest transition-state bond and one would expect to see a greater change in the length of the weakest reacting bond and very little or no change in the length of the stronger reacting bond in the S_N2 transition state when the structure of the nucleophile, the substrate, or the leaving group is varied in an S_N2 reaction. In fact, this is what is observed in many S_N2 reactions (vide infra).

Explanation of the theory

Once the idea that the relative strengths of the two reacting bonds in an S_N2 transition state would determine the substituent effect on transition-state structure was accepted, a simple method for determining the strong and the weak reacting bonds in the transition state had to be adopted so that one could test the "bond strength" hypothesis, i.e., demonstrate that only the weak bond changes significantly when a substituent is altered. Unfortunately, it is impossible to measure the strength of the partially formed and partially broken bonds in a transition state. The best one can do is to assume that the relative strengths of the transition-state bonds

TABLE 2. The infrared stretching frequencies of several different types of bonds that are commonly used in the study of substituent effects in S_N2 reactions

Bond	$1/\lambda$ (cm^{-1})[a]	Reference	$\mu(\times 10^{23})$	Force constant (mD/Å)
C—OPh	1172	44	1.138	5.55
C—OH	1033	45	1.138	4.31
C—OTs/OTf	970	47	1.138	3.80
C—N^+	975	[c]	1.073	3.62

C—I	533	52	1.820	1.83

[a]These stretching frequencies are for methyl compounds. The corresponding frequencies for the benzyl compounds are within a few percent of those quoted for the methyl substrates and do not affect the relative bond strengths significantly. Changing the *para* substituent on a benzene ring only causes small changes in the stretching frequencies (12).

[b]Based on a theoretical calculation at the 6-31G* and 6-31+G(d) levels.

are related to the strengths of the corresponding bonds in the reactant and in the product of the S_N2 reaction.[3]

The next problem was to choose a simple and rapid method of *estimating* the relative strengths of the appropriate bonds in the reactant and product. Although the strengths of the reacting bonds could be obtained from enthalpy measurements on stable molecules, they were *estimated* from the infrared stretching frequency (43). Equation [2],

$$[2] \quad k = 4\pi^2 c^2 \mu(1/\lambda)^2$$

where c is the speed of light and μ is the reduced mass calculated from the masses of the two atoms in the bond, was used to convert the wavenumber of the infrared stretching vibration ($1/\lambda$) into the force constant (k) for the bond. This method was chosen because the force constant is related to the curvature of the reaction coordinate surface, i.e., to the strength of the bond. Many of the α-carbon – leaving group stretching frequencies for methyl compounds are available in the literature and, since changing the alkyl group does not appear to alter the wavenumber of the stretching vibration significantly, this approach provides a rapid and simple method of *estimating*[5] the relative strengths of the reacting bonds in most S_N2 transition states. The infrared stretching frequencies, the reduced masses, and the force constants (approximate bond strengths) for some of the reacting bonds in methyl compounds are given in Table 2.

Testing the bond strength hypothesis

Once a method of estimating the relative strengths of the reacting bonds in an S_N2 transition state had been chosen, the importance of bond strength in determining the substituent effects on transition-state structure could be tested against the experimental results. The most useful tools for determining substituent effects on transition-state structure are kinetic isotope effects and linear free energy relationships. Unfortunately, there are only a few reactions for which one knows how a change in substituent affects the structure of both the nucleophile–α-carbon *and* the α-carbon – leaving group bond in an S_N2 transition state and can test the bond strength hypothesis completely. In the cases in which only one of the reacting bonds was monitored, one can say only that the substituent effects on transition-state structure are consistent with the bond strength hypothesis. The relationship between the strength of the reacting bonds and substituent effects on transition-state structure is examined in the following sections.

Systems in which a substituent on the α-carbon is changed

One of the few systems for which the changes in the nucleophile–α-carbon and the α-carbon – leaving group transition-state bonds were determined in a series of S_N2 reactions is the reactions between *para*-substituted thiophenoxide ions and *para*-substituted benzyl chlorides in methanol at 20°C (12), eq. [3].

[3] 
The results obtained for this system of S_N2 reactions are

[3]Theoretical calculations of the transition states for the series of S_N2 reactions, $Nu^- + CH_3—L \rightarrow Nu—CH_3 + L^-$, where $Nu^- = F^-$, Cl^-, OH^-, SH^-, SCH_3^-, and NH_2^- and $L = F^-$ and Cl^- at the 6-31+G* level[4] have shown that the Nu--C_α and C_α--L transition-state bonds are 35.4 ± 14.5% longer than the corresponding bonds in the reactants and products. Because the bonds are lengthened by roughly the same percentage in going to the transition state, a reasonable *estimate* of the relative strengths of the reacting bonds in *most* S_N2 transition states can be obtained from the strengths of their ground-state bonds. This approach would obviously fail when the transition state is very reactant-like or product-like, i.e., where the reacting bonds are very different in the transition state.

[4]R.A. Poirier and K.C. Westaway. Unpublished results.

[5]These force constants are approximate because off-diagonal force constants involving the methyl group have not been considered. The error caused by ignoring the off-diagonal force constants will probably not change the relative bond strengths for a reaction.

TABLE 3. The relative chlorine and secondary α-deuterium kinetic isotope effects, Hammett ρ values, and transition-state structures for the S_N2 reactions between *para*-substituted thiophenoxide ions and *para*-substituted benzyl chlorides in methanol – lithium methoxide at 20°C

[b]These reactions were originally thought to occur partially by a carbocation mechanism. Subsequent research by the original authors has shown them to be S_N2 reactions (53, 54).

shown in Table 3. The chlorine kinetic isotope effects measured by Grimsrud (12, 22) remain effectively constant when the *para* substituent on the benzene ring on the α-carbon is altered from methoxy to nitro, i.e., the standard deviation for the average chlorine isotope effect is only 0.00029 for all the substituents and, more important, there is no trend in isotope effect with electron-withdrawing power of the substituent. Thus, it appears that there is little or no change in the α-carbon – leaving group transition-state bond when the substituent on the α-carbon is altered. However, the secondary α-deuterium kinetic isotope effects decrease regularly as a more electron-withdrawing substituent is placed in the *para* position of the benzene ring on the α-carbon. This indicates that the transition state is tighter, i.e., the nucleophile – leaving group distance is shorter when a more electron-withdrawing substituent is on the α-carbon. Since the α-carbon – leaving group bond is virtually the same for all the substituents, the nucleophile–α-carbon bond must be shorter in the transition state with a more electron-withdrawing substituent. This conclusion is confirmed by the Hammett ρ values found by changing the substituent on the nucleophile. The Hammett ρ value increases in a regular fashion from −0.26 (estimated at 20°C), when the substituent on the substrate is methoxy, to −0.96, when the substituent on the substrate is nitro. A larger (more negative) ρ value indicates that there is a greater change in charge on the sulfur atom in going from the reactant to the transition state. This means the sulfur–α-carbon bond is more fully formed (significantly shorter) in the transition state with a more electron-withdrawing substituent. Since the sulfur–carbon bond is weaker than the α-carbon–chlorine bond, the major change in the structure of the transition state is observed in the weaker reacting bond and there is little or no change in the stronger carbon–chlorine transition-state bond in this series of S_N2 reactions. Both these changes in transition state structure are predicted by the bond strength hypothesis.

Leaving group kinetic isotope effects have been measured in several other S_N2 reactions of *para*-substituted benzyl chlorides. Grimsrud (22) and Hill and Fry (14) measured the chlorine kinetic isotope effects in the S_N2 reactions between several different nucleophiles and a series of *para*-substituted benzyl chlorides in methanol at 20°C and in 80% aqueous dioxane at 30°C, respectively. An examination of the observed kinetic isotope effects in Tables 4 and 5 shows that there are two different kinds of behaviour. In the S_N2 reactions where the nucleophile is methoxide ion, cyanide ion, and thiosulfate ion, Table 4, the chlorine kinetic isotope effect always decreases when a more electron-withdrawing substituent is placed on the benzene ring on the α-carbon of the substrate. For example, when the substi-

tuent is altered, the magnitude of the kinetic isotope effect decreases by 0.0012 when methoxide ion is the nucleophile, by 0.0016 when thiosulfate ion is the nucleophile, and by 0.0022 when cyanide ion is the nucleophile. Since the average error in each chlorine isotope effect is approximately 0.00015, a decrease of between 0.0012 and 0.0022 means there is a significant change in these isotope effects and thus in the α-carbon–chlorine transition-state bond lengths when the substituent on the substrate is varied.

The chlorine kinetic isotope effects (Table 5) found for the S_N2 reactions between other nucleophiles and a series of *para*-substituted benzyl chlorides, on the other hand, are effectively constant and do not change with substituent in a regular way when a more electron-withdrawing group is added to the substrate. For example, when the nucleophile is water, the chlorine kinetic isotope effect only changes by 0.0003 when the substituent changes from *para*-methyl to *para*-nitro and there is no trend in the isotope effects with electron-withdrawing power of the substituent. In fact, the average kinetic isotope effect for all the substituents is 1.0077 with a standard deviation of 0.00015, which is the error in the individual isotope effect. The same behaviour is observed with the isotope effects found for the S_N2 reaction with iodide ion. Here, the isotope effect changes by only 0.0002 and the standard deviation on the average isotope effect is only 0.00013. The same behaviour is observed in the S_N2 reactions where *n*-butylthiolate ion is the nucleophile. In this case, the maximum difference in the isotope effect is 0.00035 and the standard deviation on the average isotope effect is only 0.00017. Finally, the maximum difference in the chlorine isotope effects in the reactions using thiophenoxide ion as the nucleophile is only 0.0006, the standard deviation of the average isotope effect is 0.00029, and there is no clear trend in isotope effect as a more electron-withdrawing substituent is added to the benzene ring on the α-carbon.

All of these seemingly contradictory results are predicted by the bond strength hypothesis. When the nucleophile is methoxide ion, cyanide ion, or thiosulfate ion, a stronger carbon–oxygen, carbon–carbon, or carbon–sulfur[6] bond, respectively, forms and a weaker carbon–chlorine bond is broken. Thus, changing the substituent on the benzene ring should lead to the change in the chlorine isotope effect (the length of the weaker carbon–chlorine transition-state bond) that is observed.

When the nucleophiles are iodide ion, water, *n*-butylthiolate ion, and thiophenoxide ion, the nucleophile–α-carbon bond that forms in the S_N2 reaction is weaker than the carbon–chlorine bond that is broken, i.e., the carbon–iodine, the carbon–O^+, and the carbon–sulfur bonds are all weaker than the carbon–chlorine bond. The bond strength hypothesis predicts that the nucleophile–α-carbon bond will change significantly but that there will be little or no change in the stronger carbon–chlorine bond (chlorine isotope effect) when the substituent on the benzene ring of the substate is altered. Thus, the apparent differences between the two types of substituent effects on the chlorine isotope effects in these S_N2 reactions of *para*-substituted benzyl chlorides are all consistent with, and rationalized by, the bond strength hypothesis. It is worth noting that these results are not predicted by the straightforward application of the other methods that predict how substituents alter transition-state structure (9, 32–37).

Harris et al. (8) also investigated the effect of changing the substituent in the substrate on the solvolysis of *para*-substituted benzyl tosylates in 70% aqueous ethanol. The smaller secondary α-deuterium kinetic isotope effects and Grunwald–

[6]The C_α—S bond in solid 4-nitrobenzylthiosulfate absorbs at 723 cm^{-1} whereas the C_α—Cl bond in solid 4-nitrobenzyl chloride absorbs at 701 cm^{-1}. Thus, the C_α—S bond in the thiosulfate (k = 2.69 mD/Å) is stronger than the C_α—Cl bond (k = 2.60 mD/Å) in the chloride.

Winstein "*m*" values found with a more electron-withdrawing substituent, Table 6, show that the transition state is tighter when a more electron-withdrawing substituent is present. The greater selectivity found with the more electron-withdrawing substituent indicates that the nucleophile–α-carbon transition-state bond is shorter in the reaction with the more electron-withdrawing substituent. Thus the weaker O^+—C_α bond shortens when the substituent is more electron withdrawing, as the bond strength hypothesis suggests. Unfortunately, there is no information to suggest how the stronger O—C_α bond (55) is altered with a change in substituent.

Systems in which the nucleophile is changed

Yamataka and Ando (10, 15–17) determined the rate constants for several S_N2 reactions between *para*-substituted *N,N*-dimethylanilines and benzyl benzenesulfonates, eq. [4].

[4] 
The data collected by these workers enabled us to calculate the Hammett ρ values for a change in substituent at both the nucleophile and the leaving group, Table 7. The Hammett ρ values found by changing the substituent on the leaving group in the reactions involving different nucleophiles range from 2.09 to 2.13, with an average value of 2.11 ± 0.02, when the nucleophile is changed from *para*-methoxy-*N,N*-dimethylaniline to *N,N*-dimethylaniline. The effectively constant Hammett ρ values suggest that the α-carbon – leaving group bond does not change significantly when the structure of the nucleophile is altered. This is exactly what the bond strength hypothesis predicts because the α-carbon – leaving group (C—O) bond is the stronger reacting bond in the S_N2 transition state.

The Hammett ρ values found when the substituent on the nucleophile is varied change markedly, from −3.63 when the leaving group is tosylate to −1.63 when the leaving group is *meta*-nitrobenzenesulfonate, Table 7. This is also consistent with the bond strength hypothesis because these ρ values indicate that the length of the weaker α-carbon–nucleophile (nitrogen–carbon) reacting bond is altered when the structure of the leaving group is varied. Thus, the bond strength hypothesis predicts the effect on both transition-state reacting bonds whether the substituent change is made in the nucleophile or in the leaving group.

Lee et al. (25) have determined the secondary incoming group (nucleophile) deuterium kinetic isotope effects, i.e., when deuterium replaces hydrogen in the N—H bonds of aniline or benzylamine in S_N2 reactions with benzyl, methyl, and ethyl benzenesulfonates in acetonitrile at 30°C. When a better nucleophile is used in these reactions, Table 8, the secondary deuterium isotope effect decreases (is more inverse) for two of the reactions but increases in the other two reactions. Since a more inverse isotope effect indicates a shorter Nu--C_α transition-state bond, changing to a better nucleophile leads to a transition state with a shorter C_α--Nu bond in the reactions between the benzyl benzenesulfonates and aniline or benzylamine but to a transition state with a longer Nu--C_α bond in the methyl and ethyl benzenesulfonate S_N2 reactions. Although the changes in transition-state structure are different in these reactions, all the changes are consistent with the bond strength hypothesis because the weaker C—N^+ bond changes in all four reactions. It would, of course, be of interest to determine how the stronger C—O bond is affected by the change in nucleophile.

The effect of changing to a better leaving group

The transition states for the S_N2 reactions between *para*-substituted thiophenoxide ions and *para*-substituted phenylbenzyldimethylammonium ions in DMF, eq. [5], have also been modeled in some detail (11).

[5] 
The nitrogen kinetic isotope effects, Table 9, are the same or increase very slightly when a better leaving group is used, i.e., when the substituent Y is more electron withdrawing. This means that the C_α--N transition-state bond length does not change or increases very slightly when a better leaving group is used. The smaller secondary α-deuterium kinetic isotope effects observed with the better leaving group, Table 9, indicate that the transition state is tighter, i.e., the nucleophile – leaving group distance is shorter, when a better leaving group is present. Since the C_α--N transition-state bond length does not change or increases slightly with a better leaving group, changing to a better leaving group must lead to a significant shortening of the nucleophile–α-carbon bond in the transition state (11). The shorter S--C_α transition-state bond with a better leaving group is confirmed by the Hammett ρ values found by changing the substituent on the nucleophile. The larger (more negative) ρ value found with the best leaving group indicates that there is a greater change in the charge on the sulfur atom in going to the transition state and that the nucleophile–α-carbon bond is more fully formed (shorter) in the transition state with a better leaving group.

[a]The error in the individual isotope effects ranges from 0.00034 to 0.0009.
[b]The errors in these isotope effects range from 0.007 to 0.020. Work in our laboratory has shown that the secondary α-deuterium kinetic isotope effect in S_N2 reactions is different when the reacting sodium thiophenoxide is an ion pair and when it is a free thiophenoxide ion. All of these isotope effects were measured at thiophenoxide ion concentrations where only one form of the nucleophile is present.
[c]The error in the ρ values is between 0.016 and 0.047.

Thus, changing to a better leaving group in this S_N2 reaction shortens the weaker C_α--S transition-state bond significantly but does not alter the length of the stronger C_α--N transition-state bond appreciably. Both these effects are predicted by the bond strength hypothesis.

A second series of S_N2 reactions in which the leaving group was altered was investigated by Lewis and Vanderpool (23). Hammett ρ values were calculated from the rate constants observed when the substituent on the nucleophile (a series of *para*-substituted thiophenoxide ions) was changed in the

[b]At 65°C.

S_N2 reactions of methyl mesylate and methyl triflate in sulfolane at 42°C. These Hammett ρ values, which indicate the relative lengths of the nucleophile–α-carbon transition-state bonds for these reactions, changed from −3.23 when the leaving group was tosylate ion to −2.91 when the leaving group was triflate ion. Thus, the length of the weaker nucleophile–α-carbon (S--C_α) reacting bond is altered when the leaving group is changed in these S_N2 reactions. Although there is no information concerning the behaviour of the stronger carbon–oxygen reacting bond in these reactions, the changes that are observed in the weaker bond are consistent with the bond strength hypothesis.

Lee et al. (25) measured the secondary incoming group (nucleophile) deuterium kinetic isotope effects in the S_N2 reactions between benzyl, methyl, and ethyl benzenesulfonates and various *para*-substituted anilines and benzylamines deuterated at the N-H hydrogens. The results in Table 10 show that changing to a better leaving group leads to a more inverse isotope effect (a shorter nucleophile–α-carbon transition-state bond) in the benzyl benzenesulfonate reactions, but to a longer Nu--C_α bond when the substrates are methyl and ethyl benzenesulfonates. Although the substituent effects are different for the four reactions, they are all consistent with the predictions of the bond strength hypothesis because the weaker N^+--C_α transition-state bond changes in all four reactions when the leaving group is altered. It is worth noting that the weaker N^+--C_α transition-state bond changes in these reactions whether the nucleophile, Table 8, or the leaving group is changed, Table 10. This is not predicted by the usual methods for predicting substituent effects on S_N2 reactions (32, 35–37).

The effect of changing the solvent

Although a change in solvent is not, strictly speaking, a substituent effect, it seemed likely that a change in solvent might be viewed in the same way as a substituent effect. Certainly, a change in solvent alters the free energy of the transition state just as does a change in substituent. The effect of this change in free energy should again be found primarily in the weakest reacting bond in the S_N2 transition state. In fact, it appears that the results obtained in reactions for which the solvent has been changed are consistent with the predictions of the bond strength hypothesis.

Graczyk, Taylor, and Turnquist (7) reported that the chlorine kinetic isotope effects in the S_N2 reaction between *n*-butyl chloride and thiophenoxide ion, eq. [6],

[a]The individual errors in the isotope effects are <0.0009.

did not change significantly when the solvent was altered over a very wide range of solvents, i.e., from the dipolar aprotic solvents, DMSO and DMF, to the less polar aprotic solvents diglyme and tetraglyme, to polar, protic solvents such as methanol and 1-propanol. In fact, the chlorine leaving group kinetic isotope effects found in these different solvents, Table 11, are the same within experimental error, i.e., the isotope effects range from a high of 1.00964 to a low of 1.00930 (only change by 0.0003) with an average isotope effect of 1.00944 ± 0.00012 when the solvent changes from DMSO to methanol and the rate constant changes by more than 1000. It is worth noting that the very small decrease in the isotope effects in going from the dipolar aprotic to the protic solvents may be the result of hydrogen bonding to the developing chloride ion in the S_N2 transition state (56, 57). However, since all of the isotope effects are within one standard deviation of the average isotope effect in all of the solvents, one must conclude that there is little or no change in the α-carbon–chlorine transition-state bond when the solvent is changed in this S_N2 reaction.[7] This is what one would expect if the bond strength hypothesis was important in determining how a change in solvent affects the structure of the S_N2 transition state, i.e., the stronger α-carbon–chlorine bond is not altered significantly even when the solvent is changed over a wide range and the rate is altered by more than 1000. Unfortunately, we do not know how the change in solvent affects the weaker sulfur–α-carbon transition-state bond in this reaction and the bond strength hypothesis cannot be tested completely. All that can be said is that the experimental results are consistent with the bond strength hypothesis.

Saunders and co-workers (61) obtained completely different results when they investigated how a change in solvent affected the transition-state structure of an S_N2 reaction. These workers measured the sulfur leaving group kinetic isotope effects in the S_N2 reactions between ethoxide ion and trimethylsulfonium ion in various ethanol – dimethyl sulfoxide mixtures at 60°C, eq. [7].

[7] $$C_2H_5O^- + CH_3{-}\overset{+}{S}(CH_3)_2 \rightarrow C_2H_5O{-}CH_3 + S(CH_3)_2$$

The sulfur kinetic isotope effect, Table 12, decreases significantly from 1.0095 to 1.0035 when the solvent is changed from 0 to 65 mol% DMSO. This means that changing the solvent changes the length of the α-carbon – leaving group (C--S) transition-state bond markedly. This different response to a change in solvent is consistent with the bond strength hypothesis because the carbon–S^+ bond is considerably weaker than the carbon–oxygen bond. Since the different experimental results are both consistent with the predictions based on the bond strength hypothesis, the bond strength hypothesis may be useful for predicting how a change in solvent will affect the structure of an S_N2 transition state.

Conclusion

Analysis of the 37 sets of experimental data that were suitable for testing the bond strength hypothesis led to the results shown in Table 13. First, it is important to note that the substituent effects in all three systems in which the effects of substituents were determined for both the nucleophile–α-carbon and α-carbon – leaving group transition-state bonds are predicted by the bond strength hypothesis.

The results also show that 30 out of 37, or 81% of the systems studied are consistent with the predictions based on the bond strength hypothesis. The weaker bond changes significantly in 8 out of 11 or 73% of the suitable systems when the structure of the nucleophile is varied. In the systems where the substituent on the substrate is altered, 12 out of 16 or 75% of the cases are consistent with the predictions based on the relative strengths of the reacting bonds. The weakest reacting bond changes in 8 out of 8 or 100% of the systems when the structure of the leaving group is altered. Finally, 100% or 2 out of 2 sets of experimental results found when the solvent is changed are consistent with the predictions based on the bond strength hypothesis. Because over 80% of the substituent effects found in suitable S_N2 reactions are predicted by the bond strength hypothesis, it appears that the strength of the reacting bonds plays an

[7]Calculations by McLennan et al. (58) have suggested that chlorine leaving group kinetic isotope effects can be levelled by hydrogen bonding to the developing chloride ion in an S_N1 reaction. Levelling becomes significant when the C_α--Cl bond order is ≤0.5 and the H--Cl bond order is fairly large, i.e., $0.3(1 - n)$ where "n" is the C_α--Cl transition-state bond order. However, since there is less C_α--Cl bond rupture in S_N2 transition states than in S_N1 transition states (59, 60) and since theoretical calculations[4] suggest the C_α--Cl bond order is approximately 0.65 in the S_N2 transition state, levelling should not be important even if the H--Cl bond order is as large as $0.3(1 - n)$. In any case, even if one argues that the chlorine isotope effect in the protic solvents is levelled, the isotope effects in all the aprotic solvents are, within experimental error, the same.

73%	75%	100%	100%	81%

important role in determining substituent effects on the structure of the transition state.

Both Thornton (32) and Jencks (36) suggest that the curvature of the reaction coordinate surface, which is related to the force constant (the strength) of a reacting bond, will influence the effect of a change in substituent on the structure of a transition state. However, the More O'Ferrall – Jencks method does not indicate how to adjust for the strength of the reacting bonds. It is worth noting that Thornton (32) suggested that bond strength *might* be considered in cases where a substituent is changed at the α-carbon of the substrate. In fact, if one (*i*) considers that these substituent effects are completely determined by the effect of the substituent change on only the strongest bond of the S_N2 transition state as Thornton suggested *might* be necessary, and (*ii*) assumes that the parallel and perpendicular vibrations are equally important in determining the change in transition-state structure, Thornton's Reacting Bond Rule correctly predicts (*i*) that the weakest bond, but not the strongest bond, will change when a substituent is altered *and* (*ii*) the correct change in the weakest transition state bond, Table 4.

Thus, Thornton's Rule does predict the experimental substituent effects in systems where the substituent in the substrate is altered *if* one considers (*i*) the relative strengths of the reacting bonds in the S_N2 transition state and (*ii*) that the perpendicular and parallel vibrations are equally important in determining the substituent effect on transition-state structure.

In spite of the fact that Thornton's Rule predicts how a change in substituent alters the structure of an S_N2 transition state when the change in substituent is at the α-carbon, Thornton's Rule fails to predict most of the changes that are observed in transition-state structure when the substituent is changed in the nucleophile or the leaving group. Unfortunately, taking account of the relative strengths of the two reacting bonds or changing the relative importance of the parallel and perpendicular effects in the More O'Ferrall – Jencks energy surface method does not solve this problem.

The important observations, however, are (*i*) that the substituent effects based on experimental evidence are often different in similar reactions, (*ii*) that none of the methods available for predicting substituent effects consistently predicts the changes in the isotope effects and Hammett ρ values that are observed experimentally, and (*iii*) that the above analysis suggests that the strength of the reacting bonds plays an important role in determining substituent effects on the structure of S_N2 transition states.

Possible exceptions to the bond strength hypothesis

Although the agreement between the substituent effects based on experimental evidence and the predictions based on the bond strength hypothesis is high enough to suggest that the relative strengths of the reacting bonds should be considered when one is trying to determine how changing a substituent affects the structure of an S_N2 transition state, there are several reactions for which the experimental results do not agree with the predictions based on the bond strength hypothesis. These discrepancies may arise for the following reasons.

The relative strengths of the reacting bonds in an S_N2 transition state obviously cannot be measured. The relative strengths of the reacting bonds in S_N2 transition states were estimated from the infrared stretching frequencies of stable bonds in the reactants and products. One could only expect to obtain good estimates of the relative strengths of the reacting bonds in S_N2 transition states from the force constants of stable bonds if the two reacting bonds in the transition state had the same, or almost the same, bond order. In these circumstances, the bond strength hypothesis would be expected to be successful in indicating which transition-state bond will change when a substituent is altered in an S_N2 reaction. In fact, the success of the bond strength hypothesis in predicting the substituent effects in S_N2 transition states suggests that the reacting bonds in most S_N2 transition states have similar bond orders.

However, if one reacting bond were much shorter and stronger than the other reacting bond in a product-like or reactant-like transition state, the ground-state bond strengths would not give a good estimate of the relative strengths of the two reacting bonds in the S_N2 transition state and the bond strength hypothesis might fail to predict the substituent effect correctly. The bond strength hypothesis would also be expected to fail in reactions in which the strengths of the reacting bonds were equal or almost equal. In this instance, one would probably find that both of the reacting bonds would change when a substituent was changed. The rule would also be expected to fail in reactions where changing the structure of one of the reactants changed the relative strengths of the two reacting bonds in the S_N2 transition state, for example, if the substituent change was sufficient to change the nucleophile–α-carbon bond from the weakest bond to the strongest bond in the S_N2 transition state.

Although some reactions would be expected to violate the predictions of the bond strength hypothesis, the ability of this approach to rationalize many of the substituent effects that are not predicted by the simple theories suggests that this approach is valid. Because some substituent effects are not predicted by the bond strength hypothesis, other factor(s) may play a role in determining how substituents affect the structure of S_N2 transition states.

Received March 31, 1993

MA PILAR BOSCH, JOSÉ LUIS PARRA, and FRANCISCO SÁNCHEZ-BAEZA. Can. J. Chem. **71**, 2095 (1993).

The physicochemical behaviour of bolaamphiphile derivatives with an anionic, a cationic, or a non-ionic polar group and their mixtures is studied mainly by surface tension measurements, quasi-elastic light-scattering studies, ^{1}H NMR spectroscopy, and surface monolayers. Bolaamphiphiles are synthesized by classical methods from a non-expensive mixture of α,ω-dicarboxylic acids, obtained by thermal Diels–Alder type cyclization of methyl 10-*E*,12-*E* linoleate, obtained from tall oil. The anionic and cationic bolaamphiphiles synthesized are water soluble and form stable monolayers when they are compressed. The anionic and the cationic bolaamphiphiles with an iodide atom as counter-anion show a behaviour between liquid-condensed and liquid-expanded. The other synthesized cationic bolaamphiphiles and the (1 : 1) mixtures of anionic–cationic bolaamphiphiles behave as liquid-condensed.

MA PILAR BOSCH, JOSÉ LUIS PARRA et FRANCISCO SÁNCHEZ-BAEZA. Can. J. Chem. **71**, 2095 (1993).

Le comportement physico-chimique des dérivés bolaanfifiliques avec les groups polaires anionique, cationique ou non-ionique et leurs mélanges ont été étudiée par la mesure de la tension superficielle, diffusion quasi-élastique de la lumière, spectroscopie ^{1}H RMN et formation de couches monomoléculaires superficielles. Les composés bolaanfifiliques ont été synthetisés suivant des méthodes classiques utilisant une mélange des acides α,ω-dicarboxyliques pas chers, obtenu suivant la reaction de cyclisation thermique de Diels–Alder de l'ester méthylique de l'acid 10-*E*,12-*E* linoléique, obtenu à partir de l'huile de graisse. Les composés bolaanfifiliques anioniques et cationiques présentent solubilité dans l'eau et forment des couches monomoléculaires stables quand ils sont comprimés. Les composés bolaanfifiliques anionique et cationique avec un atome d'iode comme contre-ion présentent un comportement entre liquide condensé et liquide expandu. Les autres composés bolaanfifiliques synthetisés et leurs melánges (1 : 1) anionique–cationique présentent un comportement comme liquide condensé.

Introduction

The chemistry beyond the molecule, supramolecular chemistry (1), is the designed chemistry of the intermolecular bond, just as molecular chemistry is that of the covalent bond. It is a highly interdisciplinary field of science covering the chemical, physical, and biological features of compounds held together and organized by means of intermolecular (non-covalent) binding interactions.

During recent decades much work has been done to study properties and functions of biomembranes (2–9), Langmuir–Blodgett films (10), and vesicles (11, 12). They are different membrane models, but each of them allows the investigation, of only certain features of the properties of natural membranes (2, 13, 14). Vesicles constitute a model for the first "membrane material" that appeared on Earth before any form of life (15, 16). One of the interesting questions that has been raised is whether it is possible to develop new materials that simulate natural supramolecular systems in that their functioning is determined by self-tridimensional organization (1).

Bipolar lipids or *bolaform* molecules contain two polar head groups of equal or different polarity, connected by one or more hydrocarbon chains, which aggregate in aqueous media (5, 17). We wonder about the effect of different head groups on the aggregation properties of these compounds. A non-expensive mixture of α,ω-dicarboxylic acids **2** (dimeric acid or DA), obtained by thermal Diels–Alder type cyclization of methyl 10-*E*,12-*E* linoleate **1** obtained from tall oil (18), was used as starting material, followed by hydrogenation and saponification reactions. A dianionic bolaamphiphile with sodium sulphate as head group **3**, dicationic bolaamphiphiles *N,N,N*-trimethylethanaminium and di-*N,N,N*-trimethyl-*N'*-methylethanaminium with iodide **6** and **10**, respectively, chloride **7**, or bicarbonate **8** as counterion head groups, and, as non-ionic bolaamphiphiles, a digluconamide **9**, a di-*N*-[(2-(dimethylamino)ethyl **4**, and a di-*N*-[(2-methylamino)ethyl]aminomethyl **5** with neutral head groups were synthesized.

Physicochemical properties were studied by surface tension measurements, ^{1}H NMR spectroscopy, quasi-elastic light-scattering, and surface monolayers.

Results and discussion

Synthesis

As shown in Fig. 1, activation of the acid groups of dimeric acid, DA **2**, with thionyl chloride (19) and reaction with the amine, followed by quaternization reaction and ion exchange, gives the cationic acid amides, DAC-I **6**, DAC-Cl **7**, DAC-CO_3 **8**, and DAC-NMe_2I **10** with yields of 81, 88, 86, and 74%, respectively. The dianionic bolaamphiphile with sulphate as head groups (DAS **3**) was obtained with 65% yield and the non-ionic bolaamphiphiles DAC-NMe_2 **4**, DAC-NHMe **5**, and DAG **9** were obtained after activation of the acid group by the acid chloride or the mixed anhydride (19) with yields of 87, 95, and 64%, respectively. These yields are in agreement with those described for related compounds in the literature (19).

FIG. 1. Scheme of synthesized compounds.

TABLE 1. Surface tension and transition temperature measurements

Compound	γ_L (mN/m)	Critical micelle concentration (M)	T_c (K)
DAS **3**	38	1.92×10^{-3}	≤r.t.
DAC-I **6**	34	2.02×10^{-5}	333
DAC-Cl **7**	40	3.2×10^{-3}	343
DAC-CO_3 **8**	33	3.5×10^{-4}	333
DAC-NMe_2 **4**	32	5.4×10^{-4}	—
DAG **9**	—	—	343

All products gave satisfactory spectra (IR, NMR, FAB/MS) and elemental analyses.

The infrared spectra of the cationic **6, 7, 8**, and **10** and non-ionic bolaamphiphiles **4, 5**, and **9** contained amide bands around 1645 (amide I st) and 1630 (amide II st) cm^{-1}, showing that the coupling reaction between the activated dimeric acid and the amines was accomplished. For the anionic bolaamphiphile **3** the strong signal at 1240 cm^{-1} shows the presence of the sulphate groups.

The ^1H NMR spectra of the intermediate and the end products are in agreement with the expected chemical shifts. The mass spectra obtained contain molecular weight recognition as well as sequence information. Sometimes $[M^+ + H]$ or $[M^+ + Na]$ are the more characteristic peaks. For the dicationic bolaamphiphiles the loss of one or two counterions $[M^+ - X]$ or $[M^+ - XH]$ are the more characteristic signals. The FAB/MS spectra of the synthesized compounds indicate an E_2 Hofmann elimination for DAC-I **6**, DAC-Cl **7**, and DAC-CO_3 **8**, with a lower value of elimination for the compound with iodide as counter-anion. Like results are given in the literature (20) from 2-halopentanes to 1-pentene; the chloride and iodide derivatives show a 37% and 20% of elimination reaction, respectively. The bolaamphiphile **7** with chloride as counter-anion decomposes when heated over 353 K, as shown by heating and TLC control studies and by the ^1H NMR study at different temperatures. The spectrum at 353 K has broader signals and has no fine structure, contrary to the behaviour observed for the cationic bolaamphiphile **6** with iodide as counter-anion.

Physicochemical properties

In Table 1 the surface tension values, γ_L, and the critical micelle concentration (cmc) for some of the synthesized products are given. The lowest value of the cmc, 2×10^{-5} M, corresponds to the cationic surfactant **6** with the iodide atom as counterion. The iodide atom is the bulkiest counterion used and has the bulkiest hydration sphere. Thus it is able to aggregate with fewer molecules to reach the cmc value than are the other bolaamphiphiles. In aqueous solution, the iodide derivative **6** forms a laminar liquid crystalline gel phase from a concentration of 4.3 to 20%. At lower concentration it becomes a fluid phase. The presence of the amide hydrogen bond facilitates a high water solubility and the change of the position of one methyl group may affect the solubility in aqueous solutions. Bolaamphiphiles **4** and **8** (DAC-NMe_2 and DAC-CO_3) and **3** and **7** (DAS and DAC-Cl) have cmc values of the same order, 5.4×10^{-4} M, 3.5×10^{-4} M, 1.92×10^{-3} M, and 3.2×10^{-3} M, respectively. DAG **9**, DAC-NHMe **5**, and DAC-NMe_2I **10** are water-insoluble and

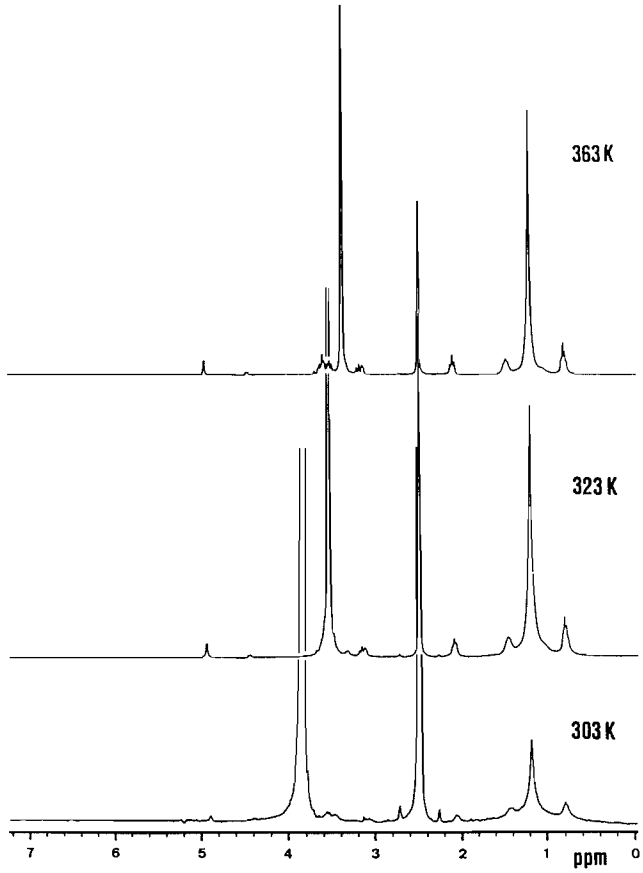

FIG. 2. NMR study of the behaviour of DAG **9** with temperature.

DAC-NMe_2 **4** presents low water solubility. Transition temperature values, also included in Table 1, will be discussed in the next paragraph.

^1H NMR studies

In the dispersed state, amphiphiles in water may produce well-defined high-resolution spectra due in part to the fact that the magnetic field heterogeneity effects that are present with coarse aggregates are averaged out when the phase consists of finer particles. This principle has been used for studying molecular interactions in biomembranes. Lipid–water systems sometimes give only slightly broadened spectra, because of the considerable mobility of various groups.

As previously described, surfactants give rise to a variety of phases depending upon the relative concentrations of the components and upon the temperature. Investigations of the state of water molecules, their motion, diffusion, mobility of the alkyl chains, and binding of small ions in the various phases have been undertaken by use of NMR. Lineshape, relaxation time data have been used in attempts to understand these systems, particularly for biological systems and micellar solutions (21). Abrupt changes in apparent NMR linewidths are usually observed at phase transitions and may in part be caused by variations in relaxation times resulting from differential freedom of motion (22).

A study of the NMR shifts and linewidths of the protons that build up the hydrophobic and hydrophilic moieties was carried out for all the synthesized compounds, at temperatures from 303 to 363 K. As shown in Fig. 2, the behav-

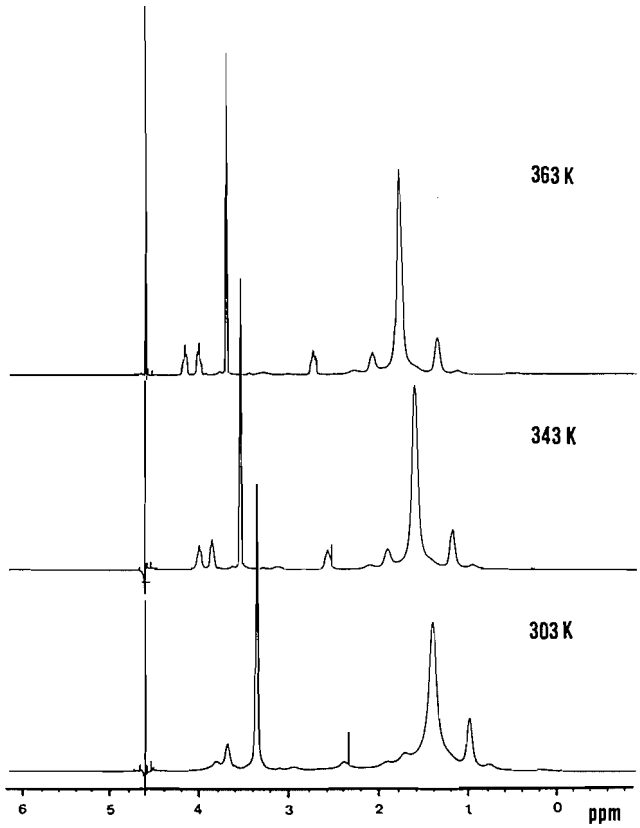

FIG. 3. NMR study of the behaviour of DAC-I **6** with temperature.

iour of the non-ionic bolaamphiphile DAG **9** in the NMR study at different temperatures shows narrow signals with increase of temperature, with linewidths of the hydrophobic part from 17.7 to 6.5 Hz (303–363 K, respectively). The signal sharpness at elevated temperature (363 K) shows that the methylene group bound to the amide nitrogen atom at δ 3.18 ppm is not involved in hydrogen bonding. At low temperature (303–343 K) the signal is broadened and no splitting remains. Also, the signals of the hydrocarbon chains broaden, and the mobility in the gel state of the hydrophobic moiety is greatly reduced. The HDO signal is affected with a downfield shift of 0.33 ppm from 303 to 363 K. DAG molecules may be organized as bilayers because the absorptions of the hydrophobic and hydrophilic moieties have a small linewidth; this indicates mobility and long relaxation times. Examination of the linewidths of the hydrophobic and hydrophilic parts shows that the transition temperature is around 343 K.

In the case of the cationic bolaamphiphile DAC-I **6**, as shown in Fig. 3, the ^{1}H NMR spectrum at 303 K shows the hydrophobic and hydrophilic moieties completely solidified. There is a bilayer highly packed with low water content. At 323 K (spectrum not shown in Fig. 3) the graph obtained is consistent with the presence of a bilayer structure that may even be packed. However, at 343 K the polar head groups have enough mobility because more defined peaks are observed in the range 3.6–4.0 ppm. At 363 K the second transition to liquid crystal is not accomplished. This indicates a bilayer structure with strong interactions because the hydrophobic absorption is broader than 15 Hz. The transition temperature is around 333 K and the mobility increases with the temperature. With heating, the absorption of the trimethylammonium polar group, the hydrocarbon chains, and the methyl end groups from the hydrocarbon chains is shifted upfield 0.54, 0.58, and 0.57 ppm, respectively. Another interesting fact is that the signal due to the CH_2 α to the nitrogen amide group is broader (59 Hz) than at 363 K, that a fine splitting is observed (13 Hz), and no gel structure is present. The CH_2 α to the trimethylammonium signal at 303 K has disappeared with the heating and a fine splitting is observed. Also, the CH_2 α and β to the carbon atom of the amide group present the same behaviour, showing that the amide proton is not involved in any hydrogen bond.

DAS **3**, DAC-Cl **7**, DAC-CO_3 **8**, and DAC-NH_2 **4** are structured as micelles from 303 to 363 K. The mobility of the hydrophobic part increases with the temperature, showing normal micelle behaviour. The transition temperatures studied by NMR for these compounds are lower than room temperature, 333 and 343 K, respectively, as shown in Table 1. From NMR spectra obtained for these compounds, it can be deduced that the signal due to the CH_2 α to the nitrogen amide bond does not present the broadness of the absorption on cooling, and no gel structure was seen.

Surface monolayers

Pressure–area isotherms (23, 24) of some bolaamphiphilic film monolayers spread on water surfaces were measured. Bolaform amphiphiles and aqueous surfaces may have different positions and conformations: both the hydrophobic and the hydrophilic moieties may lie on the water surface or head groups may lie on the water surface and the hydrophobic chain be turned out from the surface. When a monolayer is compressed, the head groups may remain on the aqueous surface or one of them may be lifted from the water surface (3). As shown in Table 2, the monolayer buildup by dimeric acid derivatives **3**, **6**, **7**, **8**, and their mixtures **3** + **6**, **3** + **7**, **3** + **8** collapses at low pressure values of 45–53 mN/m. This is a normal behaviour for bolaform monolayers on water, showing their apparent instability. The unusually large molecular area for compound DAC-I **6** of 116 Å^2/mol was unexpected, taking into account that the van der Waals diameter of chloride and iodide anions are 4.2 and 4.6 Å, respectively. Iodide, like ClO_4^-, is also known as a chaotropic anion (25), which tightly binds to the trimethylammonium head group. However, in the case of the chloride anion, this may remain in the water bulk phase not so tightly bound to the trimethylammonium head group. In fact, if we design these dimeric acid derivatives by molecular models according to Stuart and Briegleb, it is possible to appreciate that formation of a hydrogen bond could take place between the two amide groups of the two chains with the two polar head groups, building a macrocycle of 18 carbon atoms and a distance for the hydrogen bond of 2.51 Å. This peculiar molecular arrangement of DAC-I could be explained if we consider that the formation of a macrocycle and the chaotropic effect of iodide anion may force the cyclohexane ring to lie on the water surface. However, in the case of the bolaamphiphilic compound **7** with chloride as counteranion, the cyclohexane ring may remain vertical to the water surface, occupying less surface area per molecule. This would agree with the values of 116 and 62 Å^2/molecule obtained for compounds DAC-I **6** and DAC-Cl **7**, respectively. As shown in Table 2, the κ_{35} and K values show the behaviour

TABLE 2. Studies with the surface film balance

Compound(s)	Collapse point (mN/m)	Å²/molecule	κ_{35} (m/mN)	K (mN/m)	Behaviour
3	45	100	1.11×10^{-2}	90.3	Between liquid condensed and liquid expanded
6	46	116	1.07×10^{-2}	94	Between liquid condensed and liquid expanded
7	45	62	9.8×10^{-3}	102	Liquid condensed
8	48	78	8.5×10^{-3}	117	Liquid condensed
3+6	53	215	6.2×10^{-3}	162	Liquid condensed
3+7	49	161	6.7×10^{-3}	148	Liquid condensed
3+8	53	164	7×10^{-3}	139	Liquid condensed

of the molecules on the water surface. Values of κ_{35} below 100 may indicate behaviour between liquid-condensed and liquid-expanded, e.g., **3** and **6**; at values above these, the molecules may behave as liquid-condensed, e.g., **7, 8** and their mixtures **3** + **6**, and **3** + **7**, and **3** + **8**. The mixtures of cationic bolaamphiphiles **6, 7**, and **8** with anionic bolaamphiphile **3** may possess stability because one cationic compound may pack on the water surface close to an anionic compound, building a lipid layer on the water surface with values of the molecular surface area as shown.

Light-scattering studies

From the physicochemical point of view it is useful to study certain aspects of the molecular arrangement of the synthesized compounds by quasi-elastic light-scattering measurements. The results, for average size, obtained for DAC-I **6**, DAC-CO_3 **7**, and DAC-Cl **8** were 141.9, 31.7, and 15.7 nm, respectively. For the anionic disulphate bolaamphiphile DAS **3** the average mean size measured was 61 nm. From the results obtained for the synthesized compounds, the possible formation of micelles or small unilamellar vesicles must be considered. However, experiments carried out on all the bolaamphiphiles synthesized to investigate their entrapping availability using pyranine dye were unsuccessful. Nevertheless, TEM and image analysis studies carried out on sonicated dispersions of all the synthesized compounds permit us to establish different molecular associations based on open bilayer structures; their tridimensional arrangement depends on the type of polarity and the nature of the counterion of each bolaamphiphile (26).

Conclusions

1. For the first time the following bolaamphiphiles were synthesized:
   Anionic: DAS 3
   Non-ionic: DAG **9**, DAC-NMe_2 **4**, DAC-NMeH **5**
   Cationic: DAC-I **6**, DAC-Cl **7**, DAC-CO_3 **8**, DAC-NMe_2I **10**
2. The structural organization of the synthesized compounds was measured by light-scattering studies (from 15.7 to 142 nm), the critical micelle concentration ($2 \times 10^{-5} - 2 \times 10^{-3}$ M), and the static surface tension γ_L (32–40 mN/m).
3. The transition temperature was measured for each lipid.
4. The size of the counterion controls the organisation of the lipid: DAC-I **6** and DAG **9** are structured as bilayer structures; DAS **3**, DAC-Cl **7**, and DAC-CO_3 **8** are structured as micelles.
5. The synthesized bolaamphiphiles build stable surface monolayers. The dianionic bolaamphiphile **3** and the cationic bolaamphiphile **6** with I as counter-anion show behaviour between liquid-condensed and liquid-expanded. The other dicationic bolaamphiphiles **7, 8**, and their mixtures with the dianionic bolaamphiphile **3** behave as liquid-condensed.

Experimental

Commercial dimeric acid, Versadyme **2**, is a nonexpensive α,ω-dicarboxylic acid of appropriate chain length for the formation of vesicle membranes, supplied by Henkel S.A. Barcelona. Its spectra (^{1}H NMR, MS, IR) and elemental analysis were in agreement with the structure **2**. No attempts were made to separate the isomers.

The bolaamphiphiles were characterized by elemental (Carlo Erba 1108) and group analyses. Melting points were determined on a Kofler hot stage and are uncorrected. IR spectra were recorded on a Shimadzu IR-435 infrared spectrophotometer. The ^{1}H NMR spectra were run in a Bruker WP 80SY or Varian Unity Instrument of 300 MHz; the solvent used is specified in the description of each compound. Chemical shifts are reported in ppm downfield from HDO or DMSO signals. FAB-mass spectra (positive ion) were measured with an Auto Spec-Q instrument fitted with an atom gun of Cs. Ions produced were extracted and accelerated with a potential of 25 kV. Samples (≤0.1 mg) were dispersed in DMSO–glycerol used as probe matrix.

Synthesis

Dimeric sulphate 3

Dimeric acid **2** was converted to the dimeric alcohol by $LiAlH_4$ reduction (27). Dimeric alcohol (28) (2 g; 3.73 mmol) in diethyl ether (4 mL) was stirred at 273 K. Then chlorosulfonic acid (0.5 mL; 7.53 mmol) was added with care. The mixture was stirred during 3 h, followed by addition of ice, neutralization with a saturated solution of Na_2CO_3, and extraction with ether (3 × 20 mL). The aqueous solution was saturated with Na_2SO_4 and extracted with *n*-butanol (3 × 20 mL). The two organic phases were dried over Na_2SO_4 and evaporated to dryness, 2.15 g. Crystallization from methanol–ether gave white crystals of dimeric disulphate **3**, 1.81 g (65%) mp 166–168°C. IR ν: 1240 (SO_4^{2-}) cm^{-1}. ^{1}H NMR (DMSO, 300 MHz), δ: 0.85 (t, 3H each, $-CH_3$), 1.2 (s, 32H each, $-CH_2-$, -CH-), 3.65 (t, 2H each, $-CH_2O-$). FAB/MS (Mol. wt. 741.05): 764 [M^+ + Na], 93%; 661 [$M^+ - SO_3$], 100%. Anal. calcd. for $C_{36}H_{70}O_8S_2Na_2 \cdot 2H_2O$: C 55.63, H 9.61, S 8.25; found: C 56.02, H 9.49, S 8.37.

Dimeric di-N,N,N-trimethylethanaminium iodide 6

Dimeric di-acyloylchloride prepared from dimeric acid **2** (4.06 g; 7.19 mmol) and thionylchloride (1.32 mL; 18.29 mmol) was dissolved in 42 mL dry toluene. N,N-Dimethylethylenediamine (1.56 mL; 14.38 mmol) in 10 mL dry toluene was added dropwise to the stirred solution at room temperature and stirring was

continued for 1 h. The solution was then extracted with sodium carbonate (0.5 M), washed with water, dried over Na_2SO_4, and evaporated to dryness. The residual oil (4.40 g) was dissolved in a mixture of 40 mL CH_3NO_2 and 15 mL $CHCl_3$. Iodomethane (2.5 mL) was added and the mixture was stirred at room temperature for 3 h. The solvent was evaporated and the residue (6.06 g) was recrystallized from acetone, 5.76 g, yield 81%, mp 112–114°C. IR ν: 3350 (NH), 1650 (amide I), 1540 (amide II) cm^{-1}. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.84 (t, 3H each, $-CH_3$), 1.26 (s, 32H each, $-CH_2-$, -CH-), 1.56 (s, 2H each, $-CH_2-CH_2-CONH-$), 2.19 (br, 2H each, $-CH_2-CONH-$), 3.18 (s, 9H each, $-N^+(CH_3)_3$), 3.5 (br, 2H each, $-CONH-CH_2-$), 3.66 (br, 2H each, $-CH_2N^+-$), 7.7 (s, 1H each, -CONH-). FAB/MS (Mol. wt. 989.09): 863 [$M^+ - I + H$], 20%; 676 [$M^+ - 2I - (NC_3H_9)$, 25%; 615 [$M^+ - 2I - 2(NC_3H_{10})$], 100%. Anal. calcd. for $C_{46}H_{94}N_4O_2I_2$: C 55.86, H 9.58, N 5.66; found: C 55.91, H 9.69, N 5.50.

*Dimeric di-*N,N,N*-trimethylethanaminium chloride* **7**

Dimeric di-*N,N,N*-trimethylethanaminium iodide 6 (0.4 g; 0.40 mmol) was chromatographed three times on an ion-exchange resin (Dowex 1 × 2); affording 0.270 g of dimeric di-*N,N,N*-trimethylethanaminium chloride **7**. Yield 84%. IR ν: 3450 (NH), 1660 (amide I), 1560 (amide II) cm^{-1}. ^1H NMR (D_2O, 300 MHz) δ: 0.71 (bd, 3H each, $-CH_3$), 1.19 (s, 32H each, $-CH_2$, -CH-), 1.48 (bd, 2H each, $-CH_2CH_2CO-$), 2.18 (bd, 2H each, $-CH_2CH_2CONH-$), 2.14 (bd, 2H each, $-CH_2CONH-$), 3.1 (s, 9H each, $-N^+(CH_3)_3$), 3.38 (bd, 2H each, $-CH_2N^+-$), 3.56 (bd, 2H each, $-CH_2NH-$), 7.7 (s, 1H each, -CONH-). FAB/MS (Mol. wt. 806.18): 771 [$M^+ - ClH$], 100%; 677 [$M^+ - 2Cl - NC_3H_9 + H$], 8%; 617 [$M^+ - 2Cl - 2(NC_3H_9) + H$], 53%. Anal. calcd. for $C_{46}H_{94}N_4O_2Cl_2$: C 68.53, H 11.75, N 6.95, Cl 8.80; found: C 68.02, H 12.04, N 6.69, Cl 8.47.

*Dimeric di-*N,N,N*-trimethylethanaminium bicarbonate* **8**

Dimeric di-*N,N,N*-trimethylethanaminium iodide **6** (0.4 g; 0.4 mmol) was chromatographed three times on an ion-exchange resin (Dowex 1 × 2); affording 0.35 g of dimeric di-*N,N,N*-trimethylethanaminium bicarbonate **8**, yield after recrystallization 0.28 g (82%). IR ν: 3450 (NH), 1660 (amide I), 1560 (amide II) cm^{-1}. ^1H NMR (D_2O, 300 MHz) δ: 0.77 (bd, 3H each, $-CH_3$), 1.19 (s, 32H each, $-CH_2-$), 1.48 (s, 2H each, $-CH_2CH_2CONH-$), 2.14 (bd, 2H each, $-CH_2CONH-$), 3.1 (s, 9H each, $-N^+(CH_3)_3-$), 3.38 (bd, 2H each, $-CH_2N^+-$), 3.56 (bd, 2H each, $-CH_2NH-$), 7.7 (s, 1H each, -CONH-). FAB/MS (Mol. wt. 985.48): 674 [$M^+ - 2CO_3H - NCH_3H_9$], 14%; 615 [$M^+ - 2CO_3H - 2NC_3H_{10}$], 100%. Anal. calcd. for $C_{48}H_{96}N_4O_8$: C 67.23, H 11.3, N 6.53; found: C 67.06, H 11.57, N 6.77.

*Dimeric di-(*D*-glucopyranos-2-yl-carbamoyl)* **9**

Dimeric acid **2** (4.03 g; 7.09 mmol) in 115 mL DMF at 0°C was mixed under argon with 2.34 mL (21.28 mmol) *N*-methylmorpholine and 2.32 mL (17.75 mmol) isobutyl chloroformate. This mixture was stirred for 30 min at −15°C to yield the mixed anhydride. Then, 4.06 g (18.88 mmol) of 2-amino-2-deoxy-D-glucose hydrochloride and 4.0 mL (30 mmol) of triethylamine in 20 mL ethanol were added, and the mixture was stirred another 2 h. The solution was then cooled to room temperature. Colorless salts were removed by filtration and the solvents by evaporation. The residue (10.62 g) was recrystallized 3 times from methanol–ether. Yield 4.02 g (64%). IR ν: 3350 (NH), 1645 (amide I), 1545 (amide II) cm^{-1}. ^1H NMR (DMSO, 300 MHz) δ: 0.84 (t, 3H each, $-CH_3$), 1.22 (s, 32H each, $-CH_2-$, -CH-), 1.42 (bd, 2H each, $-CH_2CH_2-CONH-$), 2.2 (bd, 2H each, $-CH_2CONH-$), 3.0–3.7 (m, 6H each, 2,6 CH glucose), 4.4 (d, J = 8 Hz, 1H each, 1β-H glucose), 4.9 (d, J = 3 Hz, 1α-H), 7.5 (d, J = 9 Hz, D_2O inactive NH, 1H each, -CONH). FAB/MS (Mol. wt. 886.4): 887 [$M^+ + H$], 82%; 553 [$M^+ - 2(C_6H_{12}O_5N) + Na$], 20%; 369 [$(C_6H_{12}O_5N) + C_{11}H_{20}O + Na$], 100%. Anal. calcd. for $C_{48}H_{90}O_{12}N_2$: C 64.96, H 10.24, N 3.15; found: C 64.88, H 10.3, N 3.2.

*Dimeric di-*N,N,N*-trimethyl-*N'*-methylethanaminium iodide,* **10**

Dimeric di-acyloylchloride prepared from dimeric acid **2** (4.04 g; 7.16 mmol) and thionylchloride (1.28 mL; 17.64 mmol) was dissolved in 42 mL dry toluene. *N,N'*-Dimethylethylenediamine (1.54 mL; 14.28 mmol) in 10 mL dry toluene was added dropwise to the stirred solution at room temperature and stirring was continued for 1 h. The solution was then extracted with sodium carbonate (0.5 M), washed with water, dried over Na_2SO_4, and evaporated to dryness. The residual oil 4.74 g was dissolved in a mixture of 40 mL CH_3NO_2 and 15 mL $CHCl_3$, 2.5 mL of iodomethane was added, and the mixture was stirred at room temperature for 3 h. The solvent was evaporated and the residue (5.05 g) was recrystallized, yield 74%. IR ν: 1650 cm^{-1}. ^1H NMR ($CDCl_3$, 300 MHz) δ: 0.88 (t, 3H each, $-CH_3$), 1.22 (s, 32H each, $-CH_2-$,-CH-), 1.54 (s, 2H each, $-CH_2-CH_2-CONH-$), 2.2 (s, 3H each, CH_3-N-), 2.25 (br, 2H each, $-CH_2-CONH-$), 3.1 (s, 9H each, $-N^+(CH_3)_3$), 3.4 (br, 2H each, $-CH_2-N^+-$), 3.5 (br, 2H each, -CONMe-CH_2-); FAB/MS (Mol. wt. 1017.3): 706 [$M^+ - 2I - NC_3H_9 + 2H$], 15%; 617 [$M^+ - 2I - N(CH_3)_3 - (CH_2)_2N(CH_3)_3$], 100%; 586 [$M^+ - 2I - 2N(CH_3)_3 - N(CH_3)(CH_2)_2 - 2H$], 60%. Anal. calcd. for $C_{48}H_{98}N_4O_2I_2$: C 56.67, H 9.72, N 5.51; found: C 56.39, H 9.51, N 5.20.

Physicochemical properties

A Du Noüy ring tensiometer Krüss K12 with a platinum–iridium ring was used for surface tension measurements (γ_L). Aqueous solutions were allowed to equilibrate at 298 K until stabilization of surface tension readings. Critical micelle concentration (cmc) were determined from the γ_L–log C curves.

^1H NMR studies

^1H NMR spectra were recorded on a Varian Unity instrument (300 MHz). The solution was made from 10 mg of the bolaamphiphiles in 1 mL of D_2O (99.9% D) for water-soluble or from DMSO + D_2O for water-insoluble solutes. The NMR spectra were measured at six different temperatures. The line widths of the CH_2 band at 1.3 ppm were measured; 1024 scans were accumulated each time.

Surface monolayers

Monolayers were prepared at the air–water interface of a rectangular trough of poly(tetrafluoroethylene) on a Langmuir film balance, Lauda FW 2 (29). The compounds were spread as dilute solutions (0.4–0.6 mg/mL) in chloroform or in chloroform–methanol (4:1) if the compound was insufficiently soluble in chloroform. When a mixture of two compounds was measured, one of them was used as a matrix. Then an equimolar solution (1:1) was mixed and spread on the water surface. The films were allowed to rest for 2 min before compression by a movable barrier at a constant rate of 0.1 nm^2/(molecule.min). Doubly distilled water was filtered by a Milli-Q standard system. The subphase was pure water. The temperature of the subphase was 292 K, and was constant within 0.05 K. Air temperature was constant within 3 K. Each experiment was measured at least twice until reproducible.

Light-scattering studies

Dynamic light-scattering measurements were made on a Malvern-4700 instrument at 298 K with a scattering angle of 90°. Doubly distilled water was filtered by a Milli Q standard system. The samples were prepared by dissolution of bolaamphiphile (0.35%) and NaCl (0.1 M) in 2 mL water. Previously, the water was filtered three times through a Millipore 0.22 μm membrane. The solutions were centrifuged for 1 h at 5000 rpm.

Acknowledgments

We are grateful to Henkel Ibérica S.A. for supplying us the starting material; to Dr. J. Rivera from the Lab. Espectrometría de Masses, Dep. Química Ambiental (CID–CSIC) for carrying out the FAB/MS spectra of the isolated compounds; and to A. Pascual and M^a A. Pes for assistance in the experimental work. Hydrophilic analogs of (*R*,*R*)-diaminocyclohexane dichloroplatinum (DACH) and the influence of relative stereochemistry on antitumor activity

STEPHEN HANESSIAN[1] AND JIANGUO WANG

Department of Chemistry, Université de Montréal, Box 6128, Station A, Montréal, QC H3C 3J7, Canada

Received June 3, 1993

STEPHEN HANESSIAN and JIANGUO WANG. Can. J. Chem. **71**, 2102 (1993).

A series of analogs of (*R*,*R*)-1,2-diaminocyclohexane dichloroplatinum(II) (DACH) containing stereochemically defined hydroxy groups and appropriate acidic leaving groups were synthesized and tested as antitumor agents. The (1α,2β,3α,4β)-1,4-dihydroxy-2,3-diaminocyclohexane analog showed the highest potency against P388 leukemia in mice. The results indicate that increasing the hydrophilicity of the platinum complex to a certain extent could improve the antitumor activity of the drug. It is also likely that the stereochemical disposition of the substituents on the cyclohexane ring affects the antitumor activity.

STEPHEN HANESSIAN et JIANGUO WANG. Can. J. Chem. **71**, 2102 (1993).

Des analogues du (*R*,*R*)-1,2-diaminocyclohexane dichloroplatine(II) (DACH) qui contiennent des groupes hydroxy et des groupes partant acides ont été synthétisés en vue d'obtenir des substances antitumorales. L'analogue (1α,2β,3α,4β)-1,4-dihydroxy-2,3-diaminocyclohexane s'est avéré être le plus actif contre la leucémie P388 chez la souris. Les résultats indiquent que l'augmentation de l'hydrophilicité de ces complexes pourrait aider à l'amélioration de l'activité antitumorale. Il est aussi possible que l'activité puisse dépendre sur la stéréochimie des substituants sur le noyau cyclohexanique.

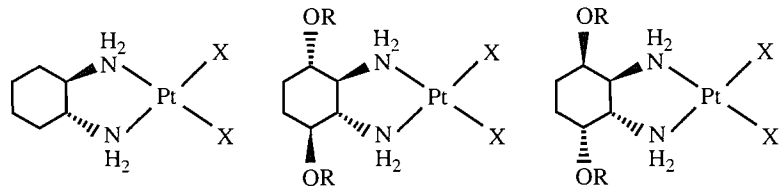
In spite of the multitude of structural analogs of the antitumor agent *cis*-diamine dichloroplatinum(II) (cisplatin) (1) only a few are presently used in clinical practice (2). Of these, *trans*-1,2-diaminocyclohexane dichloroplatinum(II) (DACH) and its variants with different anionic counterparts appear to be the most effective (3) (Fig. 1). Since the molecule is chiral, the relevance of stereochemical issues has been addressed by a number of investigators (4). In spite of conflicting views (5), the consensus is that the (*R*,*R*) isomer is generally more active than the (*S*,*S*) isomer (6), although activity has also been demonstrated with the (*R*,*S*) isomer (7). With regard to the stereochemistry of the complexes, the *trans* isomer is more active than the *cis* isomer (8). As in the case of the parent cisplatin, the antitumor activity of DACH is accompanied by some toxicity. The emergence of resistance, and low water solubility that can affect the pharmacokinetics, are additional features that must be improved in the quest for a more effective analog. An obvious choice for platinum II complexes that can increase water solubility in this series is the introduction of hydrophilic groups such as the hydroxyl group into the molecule. Witiak and co-workers (9) as well as other groups (10) have reported on the synthesis and antitumor activity of a series of 4-mono- and 4,5-dihydroxy 1,2-diaminocyclohexane dichloroplatinum derivatives. Although these derivatives are sparingly soluble in water, the monohydroxy analogs are more active than the dihydroxy analogs. This enhanced potency was attributed to subtle differences in crystalline structure, thus affecting drug dissolution and bio-availability (9).

As part of a program aimed at the discovery of novel cisplatin-type antitumor agents with improved solubility, bioavailability, and efficacy, we have prepared acyclic (11) and heterocyclic (12) hydroxylated vicinal *trans* diamino platinum complexes. In addition to exhibiting potent antitumor activity in vitro as well as in vivo, these derivatives are also quite water soluble compared to cisplatin or related analogs.

[1]Author to whom correspondence may be addressed.

We now report on the synthesis of diastereomeric 3,6-dihydroxy-1,2-diaminocyclohexane dichloroplatinum derivatives, in addition to other anionic analogs, as well as their *O*-methyl variants. The intended structures shown in Fig. 1 were patterned after DACH where a *trans* relationship exists between the vicinal diamino groups with a relative (*R*,*R*) configuration. An important symmetry element in the design of the dihydroxy derivatives was to ensure a C_2 symmetrical relationship in an all-*trans* structure such as in **2**, and to assess the influence of stereochemical changes as in **3**. Since the 4,5-dihydroxy and the 4-hydroxy analogs of **1** showed differences in their biological activity (9) and they were sparingly soluble in water, it was of interest to assess the behavior of analogs **2** and **3**.

Scheme 1 illustrates the synthetic route to two diastereomeric 1,4-dihydroxy-2,3-diaminocyclohexanes, corresponding to **2** and **3** (R = H), respectively. 1,3-Cyclohexadiene **4** was transformed into the (±)*trans*-2-cyclohexene-1,4-diol **5** according to a known procedure (13). Epoxidation and protection of the resulting epoxide as the tetrahydropyranyl ether gave **8** in excellent overall yield. Alternatively, formation of the THP ether **6** followed by epoxidation led to the same epoxide **8**. Treatment of the epoxide **8** with ammonium azide, formed in situ from sodium azide and ammonium chloride in aqueous methoxyethanol (14) led to the mixture of stereoisomeric monoazido derivatives **9** in excellent yield. Although epoxides of cyclohexane derivatives are subject to predominant diaxial opening (15), some diequatorial opening is not uncommon, which is the origin of the contaminating stereoisomer in **9**. Treatment of the isomeric hydroxy azide derivative **9** with triphenylphosphine in refluxing toluene led to a single aziridine derivative **10** in 94% yield. Opening of the aziridino group with ammonium azide as for **8** gave a mixture of two amino azides that could be separated by preparative HPLC into the *cis-trans-cis* isomer **11** and the *trans-trans-trans* isomer **12** (5:1 ratio respectively). The preponderance of **11** can be explained by the known preference for diaxial opening (16), which was also



1 (DACH) **2** **3**

X = Cl, dicarboxylate, etc R = H, Me

Reagents: (a) *N*-(ethoxycarbonyl) phthalimide, THF; (b) PPTS, EtOH; (c) KH, CH_3I, 18-crown-6, THF; (d) $NH_2NH_2 \cdot H_2O$, 95% EtOH; (e) Pd/C (10%), H_2, MeOH–H_2O; (f) K_2PtCl_4, H_2O

SCHEME 2

corroborated by ^1H NMR studies on **13** and its derivatives. The C_2 symmetrical analog **12** was the product of diequatorial opening as in the case of the epoxide **8**. Removal of the THP protective group from **11** and **12** led to **13** and **14**, respectively, which were transformed into the corresponding diamines **15** and **16** by catalytic hydrogenation. An alternative procedure was to use **11** and **12** as a mixture, and to separate **13** and **14** by column chromatography. Treatment of these diamines with dipotassium tetrachloroplatinate in aqueous solution gave the desired complexes **17** and **18** as pale yellow crystalline compounds. In view of the known influence of the anionic counterparts of cisplatinum complexes of vicinal diamines (17) on solubility and biological activity, we deemed it necessary to prepare the cyclobutane 1,1-dicarboxylate derivatives of **15** and **16** by adaptations of known procedures (18). Thus, the complexes **17** and **18** were individually transformed into the corresponding dinitrates and these were treated with dipotassium cyclobutane 1,1-dicarboxylate to give the corresponding complexes **19** and **20**, respectively. A single crystal X-ray analysis of **17** hydrate unequivocally confirmed its structure (19).

To assess the possible influence of polar vs. steric effects, we had envisaged the synthesis of the *O*-methyl derivatives of **17** and **18**, respectively. In view of the conditions of the methylation procedure, it was necessary to avoid the presence of a free amino group as in **11** or **12**. Consequently, a mixture of **11** and **12** (designated as **21**) was converted into a mixture of isomeric mono-*N*-phthalimido derivatives **22** (Scheme 2).

After cleavage of the THP group, it was possible to separate the diastereomeric diols **23** and **24** by column chromatography. As expected, the original 5:1 ratio present in the amino azides **11, 12** was retained. Methylation with potassium hydride and methyl iodide in the presence of 18-crown-6 led to the respective dimethyl ethers **25** and **27**, which upon hydrazinolysis led to **26** and **28**, respectively. Catalytic hydrogenation led to **29** and **30**, respectively. A yellow crystalline complex **31** was isolated from **29**, but the product from **30** was amorphous.

Biological results and discussion

The antitumor activities of the complexes **17, 18, 19, 20**, and **31** against P388 Leukemia were tested in vivo. BDF_1 mice (6 or 3 mice/group) were subjected to intraperitoneal transplants of 10^6 P388 tumor cell/mouse, and samples were administered i.p. in 0.2% Klucel brand methyl cellulose in water on days 1, 5, 9. Analysis of antitumor activity was

For personal use only.

carried out according to the NCI protocol by comparing the median survival time (MST) of the treated groups vs. the untreated control groups. Increases in lifespan were expressed as % ILS, defined as the MST in a drug-treated group divided by the MST of the placebo-treated control group.

Preliminary data indicated that compound **18** had comparatively the highest antitumor activity with a % ILS value obtained with optimal ip dose (25 mg/kg) of 209, and an excellent MST (median survival time) of 34 days post tumor inoculation. Cisplatin showed a % ILS of 150 at 2 mg/kg with an MST of 27.5 days. Complexes **17, 20, 19**, and **31** showed very weak antitumor activity against P388 with poor survival ratios. It is thus possible that the stereochemistry of the dihydroxy cyclohexyldiamine platinum isomers may have a influence on their antitumor activities. Complex **18**, which contains a *trans-trans-trans* arrangement of substituents, was found to be significantly more active than the *cis-trans-cis* isomer **17**. The results of antitumor testing also showed that the complexes with hydroxyl group substituents (e.g., **17, 18**) were substantially more active than the complexes of the corresponding *O*-methyl ethers (e.g., **30, 31**). It seems that increasing the hydrophilicity of the DACH platinum complex to a certain extent could improve the antitumor activity of the drug.

Experimental

Melting points (mp) were determined on a Buchi melting point apparatus and they are uncorrected. Proton magnetic resonance (^{1}H NMR) spectra were determined on either a 300 MHz Varian or a 400 MHz Bruker spectrometer in deuterated chloroform, dimethyl sulfoxide-d_6, methanol-d_4, or deuterium oxide (D_2O) with $CHCl_3$ (δ_{ppm} = 7.265), Me_4Si (δ_{ppm} = 0.00), or dioxane (δ_{ppm} = 67.40 for ^{13}C) as references. Coupling constants are expressed in hertz (Hz). The abbreviations used for the description of the peaks are as follows: s, singlet; d, doublet; dd, doublet of doublets; dt, doublet of triplets; t, triplet; q, quartet; m, multiplet; br, broad. ^{13}C NMR spectra were recorded on a Varian VRX 300 at 75 MHz. Low-resolution mass spectra were determined on a VG Micro Mass 1212 mass spectrometer by using desorption chemical ionization (DCI), or by fast atom bombardment (FAB). High-resolution mass spectra were determined on a Kratos MS-50 TCTA mass spectrometer by using electron impact (EI) at 70 eV or by the fast atom bombardment (FAB) techniques. Infrared spectra (IR) were recorded on a Perkin–Elmer 781 infrared spectrophotometer. The spectra of solids were recorded as Nujol mulls. Liquid samples were determined as films between sodium chloride plates. Combustion analyses were performed by Guelph Laboratories Ltd, Guelph, Ontario. Flash chromatography was done according to the procedure of Still et al. (20) using Kieselgel 60 silica gel. Preparative HPLC was performed on a Waters Associates Prep LC/System 500 liquid chromatograph using Prep PAK-500/silica cartridge (5.7 × 30 cm) containing 325 g of silica gel.

(d,l)-trans-*1,4-Bis[(tetrahydropyran-2-yl)oxy]cyclohex-2-ene (6)*

A suspension of *trans*-2-cyclohexene-1,4-diol **5** (114 mg, 1 mmol) and dihydropyran (0.56 mL, 6 mmol) in dry CH_2Cl_2 (5 mL) containing a catalytic quantity of pyridinium *p*-toluenesulfonate (PPTS) was stirred for 7 h at room temperature. The reaction mixture was diluted with 20 mL ether, then washed with half-saturated brine (2 × 5 mL), dried with Na_2SO_4, and evaporated to give a colorless syrup, which was applied to a silica gel column. Elution with EtOAc/hexane (1:1), then concentration, gave **6** (242 mg, 83%) as a mixture of THP ethers: IR (film): 3030, 2940, 2870 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.55–2.15 (m, 16H), 3.48–3.52 (m, 2H), 3.88–3.94 (m, 2H), 4.25–4.29 (m, 2H), 4.75–4.84 (m, 2H), 5.83–5.89 (m, 2H); MS *m/e*: 282 $(M)^+$; HRMS calcd. for $C_{16}H_{26}O_4$: 282.1832; found: 282.1812.

(d,l)-trans-*7-Oxabicyclo[4.1.0]heptane-2,5-diol (7)*

To a cold suspension of *trans*-2-cyclohexane-1,4-diol **5** (580 mg, 5 mmol) in 50 mL of dry CH_2Cl_2 was added dropwise a solution of 3-chloroperoxybenzoic acid (*m*-CPBA) (1.1 g, 5.1 mmol) at 0°C. The mixture was stirred at 0°C for 1 day, then a few drops of dimethyl sulfide were added to decompose the excess hydroperoxide. The solution was neutralized with triethylamine and evaporated to dryness. Purification by flash chromatography gave product **7** (0.64 g, 97%) as hygroscopic crystals: IR (Nujol) 3300 (br, OH) cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.24–1.38 (m, 2H, H-5,6), 1.73–1.82 (m, 2H, H-5,6), 3.28–3.39 (m, 2H, H-2,3), 4.07 (m, 2H, H-1,4); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 23.98, 28.46, 55.90, 59.25, 64.97, 67.21; MS *m/e*: 131 $(M + 1)^+$.

(d,l)-trans-*2,5-Bis[(tetrahydropyran-2-yl)oxy]-7-oxabicyclo[4.1.0]heptane (8)*

Method A

To a suspension of epoxide **7** (7.50 g, 57.7 mmol) in 500 mL of dry CH_2Cl_2 was added dihydropyran (21 mL, 225 mmol) followed by PPTS (720 mg, 2.9 mmol). The mixture was stirred at room temperature for 1 day, then washed with half-saturated NaCl, dried with Na_2SO_4, and evaporated to give a syrup, which was applied to a silica gel column. Elution with hexane–EtOAc (5:1, then 1:2) gave the THP ether isomers **8** (14.30 g, 83%) as a syrup that was crystallized at 5°C overnight.

Method B

To a cold (0°C) solution of compound **6** (240 mg, 0.85 mmol) in 5 mL of dry CH_2Cl_2 was added a solution of *m*-CPBA (190 mg, 1.08 mmol) in 5 mL of dry CH_2Cl_2. The mixture was allowed to warm to room temperature and stirred for 1 day, then diluted with 10 mL of CH_2Cl_2, washed with 10% of sodium sulfite, saturated $NaHCO_3$, water, and brine, dried with Na_2SO_4, and evaporated to give a syrup that was applied to a silica gel column. Elution with EtOAc–hexane (1:3) gave the epoxide **8** (100 mg, 40%): mp 69–70°C; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.15–2.00 (m, 16H), 3.13–3.34 (m, 1H), 3.38–3.40 (m, 1H), 3.48–3.53 (m, 2H), 3.83–3.98 (m, 3H), 4.02–4.10 (m, 1H), 4.68–4.89 (m, 2H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 19.15, 19.23, 19.29, 19.55, 20.08, 20.34, 21.73, 22.01, 25.14, 25.24, 26.14, 26.25, 28.08, 28.15, 30.61, 30.77, 53.21, 53.33, 55.31, 57.13, 57.29, 57.48, 61.99, 62.06, 62.32, 62.38, 62.71, 69.36, 69.73, 69.77, 71.70, 72.07, 72.45, 72.67, 97.03, 97.10, 97.20, 97.59, 97.67, 98.19; MS *m/e*: 299 $(M + 1)^+$; HRMS calcd. for $C_{16}H_{26}O_5$: 298.1781; found: 298.1779.

(d,l)-*(1α,2β,3α,6β)-2-Azido-3,6-bis(tetrahydropyran-2-yloxy)cyclohexanol and* (d,l)-*(1α,2β,3β,6α)-2-azido-3,6-bis(tetrahydropyran-2-yloxy)-cyclohexanol (9)*

To a solution of the epoxide **8** (1.0 g, 3.35 mmol) in 30 mL of 2-methoxyethanol–water (14:1) was added NaN_3 (1.30 g, 20 mmol) and NH_4Cl (0.54 g, 10 mmol). The mixture was heated at 90°C for 1 day and evaporated to give a residue that was applied to a short silica gel column (25 × 50 mm). Elution with EtOAc–hexane (1:1) gave a colorless syrup (1.10 g, 94%) that was the mixture of azide derivatives **9**: IR (film): 3430 (br, OH), 2105 (N_3) cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.33–1.90 (m, 16H), 3.54 (m, 3H), 3.85–4.17 (m, 5H), 4.50–4.80 (m, 2H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 18.52, 18.70, 19.44, 19.58, 19.79, 20.98, 21.04, 24.12, 24.47, 24.75, 24.94, 25.09, 25.22, 25.47, 25.62, 30.45, 30.62, 30.71, 30.75, 31.40, 61.48, 61.76, 62.64, 62.77, 63.14, 63.76, 63.91, 64.20, 64.89, 64.97, 69.27, 69.49, 69.67, 69.87, 71.55, 71.61, 76.14, 100.10, 100.27, 100.67; MS *m/e*: 342 $(M + 1)^+$, 341 $(M)^+$.

(d,l)-trans-*2,5-Bis(tetrahydropyran-2-yloxy)-7-azabicyclo[4,1,0]heptane (10)*

To a solution of the mixture of azide derivatives **9** (0.766 mg, 2.24 mmol) in 20 mL of dry toluene was added triphenylphosphine (710 mg, 2.7 mmol). The mixture was stirred at 105°C for 1 day, then evaporated to give a syrup that was applied to a silica gel column. Elution with EtOAc–hexane (3:1), then EtOAc, in the presence of 1% triethylamine gave the THP ether isomers **10** as a

(d,l)-*[SP-4-2-(1β,2α,3β,6β)]-Cyclobutane-1,1-dicarboxylato(3,6-dihydroxycyclohexane-1,2-diamine*-N,N′*) platinum* ***(19)***

A suspension of **15** (100 mg, 0.24 mmol) in 25 mL of deionized water was heated until it dissolved. To this solution was added a solution of silver nitrate (82 mg, 0.48 mmol) in 5 mL of deionized water. The reaction mixture was stirred in the dark at room temperature for 20 h. The resulting white precipitate was filtered through Celite and washed with deionized water. The filtrate was concentrated to ca. 6 mL, then transferred into a solution of dipotassium cyclobutane-1,1-dicarboxylate (54 mg, 0.24 mmol) in 0.5 mL of deionized water. The mixture was stirred manually, and the clear solution was left standing in the dark. Crystals began to form after 2 days and they were filtered after 7 days, washed with deionized water, and dried over P_2O_5 under vacuum to afford **19** (77 mg, 66%, as white crystals); mp 260–265°C (dec.); IR (Nujol): 3440 (br, OH), 3270, 3240, 3180, 3100 (NH), 1660 (C=O), 1615 cm^{-1}; ^1H NMR (300 MHz, DMSO-d_6) δ: 1.25–1.28 (m, 2H, Hax-4,5), 1.52–1.55 (m, 2H, Heq-4,5), 1.58–1.69 (m, 2H, cyclobutane H-3), 1.58–1.69 (m, 2H, H-1,2), 2.63–2.71 (m, 4H, cyclobutane H-2,4), 3.81 (m, 2H, H-3,6), 4.48–4.55 (m, 2H, NH_2), 4.97 (d, 2H, J = 3.7 Hz, OH), 5.89–5.93 (m, 2H, NH_2); ^{13}C NMR (75 MHz, DMSO-d_6) δ: 15.21, 25.88, 30.38, 55.62, 60.15, 66.53, 177.53; MS *m/e*: 484 $(M + 1)^+$, 483 $(M)^+$, 482 $(M - 1)^+$; HRMS (FAB) calcd. for $C_{12}H_{21}N_2O_6Pt$: 484.1048; found:

(d,l)-N-*2-Azido-3,6-bis(tetrahydropyran-2-yloxy)cyclohexyl-phthalimide (**22**)*

To a cold solution of *N*-(ethoxycarbonyl)phthalimide (1.05 g, 5 mmol) in 2 mL of dry THF was added a solution of **21** (mixture of **11** and **12**) (1.70 g, 5 mmol) in 2 mL of dry THF, followed by 1 mL of triethylamine at 0°C. The mixture was stirred at room temperature for 1 h, and then heated at reflux for 2 days. After removal of the solvent, the remaining syrup was dissolved in EtOAc, washed with 10% HCl, water, saturated $NaHCO_3$, water and brine, dried (Na_2SO_4), and evaporated to give a syrup, which was applied to a silica gel column. Elution with EtOAc–hexane (1:2) gave **22** (1.35 g, 58%) as a mixture of the THP isomers, which was used for the next reaction without further purification: IR (film): 2105 (N_3), 1800, 1775, 1720 (C=O) cms^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 0.85–2.05 (m, 16H), 2.91–3.10 (m, 1H), 3.40–3.85 (m, 2H), 3.89–3.97 (m, 1H), 4.08–4.28 (m, 2H), 4.35–4.50 (m, 1H), 4.60–4.68 (m, 1H), 4.84–4.93 (m, 2H), 7.70–7.76 (m, 2H, ArH), 7.85–7.89 (m, 2H, ArH); MS *m/e*: 471 $(M + 1)^+$.

(d,l)-*(1α,2α,3β,4β)-2-Azido-3-phthalimidocyclohexane-1,4-diol (**23**) and* (d,l)-*(1β,2α,3β,4α)-2-azido-3-phthalimidocyclohexane-1,4-diol (**24**)*

To a solution of **22** (1.34 g, 2.85 mmol) in 60 mL of 100% EtOH was added PPTS (0.1 g, 0.4 mmol). The reaction mixture was stirred at 55–60°C for 1 day. After removal of the solvent, the mixture was separated by flash chromatography with EtOAc–hexane (1:1) to give **23** (100 mg, 12%) and its isomer **24** (480 mg, 56%) as white crystals. For **23**: mp 174–175°C; IR (film): 3450 (br, OH), 2260, 2110 (N_3), 1780, 1720 (C=O) cm^{-1}; ^1H NMR (300 MHz, CD_3OD) δ: 1.62–1.76 (m, 2H, Hax-5,6), 2.00–2.07 (m, 2H, Heq-5,6), 4.08–4.09 (m, 1H, H-1), 4.31–4.32 (m, 1H, H-4), 4.53 (dd, 1H, J = 2.6 Hz, 12.0 Hz, H-2), 4.84 (dd, 1H, J = 2.8 Hz, 12.0 Hz, H-3), 7.79–7.88 (m, 4H, ArH); MS *m/e*: 303 $(M + 1)^+$: Anal. calcd. for $C_{14}H_{14}N_4O_4$: C 55.62, H 4.67, N 18.54; found: C 55.68, H 5.08, N 18.27. (d,l)-N-*[(1β,2α,3α,6β)-2-Azido-3,6-dimethoxycyclohexyl] phthalimide (**25**)*

To a cold solution of **23** (800 mg, 2.65 mmol) in 40 mL of dry THF was added methyl iodide (1.0 mL, 16.0 mmol), 18-crown-6 ether (catalytic), followed by potassium hydride (35% in oil) (730 mg, 6.37 mmol) suspended in 2 mL of THF. The mixture was stirred at 0°C for 5 h with the exclusion of moisture and the resulting precipitate was filtered and washed with 400 mL of ether. The filtrate was washed with cold water and brine, dried (Na_2SO_4), and evaporated to give a syrup that was purified by flash chromatography. Elution with EtOAc–hexane (1:1) gave **25** (0.63 g, 72%) as a syrup that crystallized on standing: mp 123–124°C; IR (film): 2105 (N_3), 1775, 1720 (C=O) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 1.65–1.94 (m, 4H, H-4,5), 3.22 (s, 3H, OCH_3), 3.44 (s, 3H, OCH_3), 3.65 (m, 1H, H-3), 3.88 (m, 1H, H-6), 4.60 (dd, 1H, J = 2.9 Hz, 12.3 Hz, H-2), 4.85 (dd, 1H, J = 2.9 Hz, 12.3 Hz, H-1), 7.73 (m, 2H, ArH), 7.87 (m, 2H, ArH); MS *m/e*: 331 $(M + 1)^+$. Anal. calcd. for $C_{16}H_{18}N_4O_4$: C 58.17, H 5.49, N 16.96, found: C 57.98, H 5.11, N 16.71.

(d,l)-N-*[(1β,2α,3β,6α)-2-Azido-3,6-dimethoxycyclohexyl] phthalimide (**27**)*

Compound **27** was prepared from **24** in 57% yield following the same procedure that was used for the preparation of **25**: IR (film): 2105 (N_3), 1775, 1715 (C=O) cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 1.18–1.48 (m, 2H, Hax-4,5), 2.21–2.31 (m, 2H, Heq-4,5), 3.23 (s, 3H, OCH_3), 3.25 (ddd, 1H, J = 4.2 Hz, 9.3 Hz, 11.0 Hz, H-3), 3.49 (s, 3H, OCH_3), 3.36–3.45 (m, 2H, H-2,6), 4.16 (dd, 1H, J = 9.3 Hz, 11.3 Hz, H-1), 7.73–7.78 (m, 2H, ArH), 7.87 (m, 2H, ArH); MS *m/e*: 331 $(M + 1)^+$. Anal. calcd. for $C_{16}H_{18}N_4O_4$: C 58.17, H 5.49, N 16.96; found: C 57.99, H 5.19, N 16.86.

(d,l)-*(1β,2α,3α,6β)-3,6-Dimethoxy-2-azidocyclohexylamine (**26**)*

To a solution of compound **25** (620 mg, 1.88 mmol) in 30 mL of 95% EtOH and THF (2:1) was added hydrazine monohydrate (4.5 mL, 93 mmol). The reaction mixture was stirred at room temperature for 2 days and the resulting white precipitate was filtered and washed with ethanol. After concentration of the filtrate, excess 10% HCl was added and the resulting precipitate was filtered. The pH of the filtrate was adjusted with KOH to pH > 13 and the solution was extracted with ether. The extracts were dried (Na_2SO_4) and evaporated to give a syrup that was purified by flash chromatography, eluting with CH_2Cl_2–MeOH (15:1), to give compound **26** (262 mg, 70%) as a colorless syrup: IR (film): 3390, 3320 (NH), 2105 (N_3), 1580 cm^{-1}; ^1H NMR (300 MHz, D_2O) δ: 1.32–1.46 (m, 2H, Hax-4,5), 1.60–1.75 (m, 2H, Heq-4,5), 2.88 (m, 1H, H-1), 3.16 (s, 3H, OCH_3), 3.19 (s, 3H, OCH_3), 3.43 (m, 2H, H-2,6), 3.67 (m, 1H, H-3); MS *m/e*: 201 $(M + 1)^+$.

(d,l)-*(1β,2α,3β,6α)-3,6-Dimethoxy-2-azidocyclohexylamine (**28**)*

Compound **28** was prepared from **27** in 65% yield following the same procedure that was used for the preparation of **26**: IR (film): 3390, 3320 (NH), 2105 (N_3), 1580 cm^{-1}; ^1H NMR (300 MHz, D_2O) δ: 0.90–1.13 (m, 2H, Hax-4,5), 1.98–2.10 (m, 2H, Heq-4,5), 2.41 (t, 1H, J = 10.1 Hz, H-1), 2.95 (dt, 1H, J = 4.4 Hz, 10.6 Hz, H-6), 3.01 (t, 1H, J = 10.1 Hz, H-2), 3.17 (dt, 1H, J = 4.6 Hz, 10.9 Hz, H-3), 3.21 (s, 3H, OCH_3), 3.28 (s, 3H, OCH_3); MS *m/e*: 201 $(M + 1)^+$.

(d,l)-*(1β,2α,3α,6β)-3,6-Dimethoxycyclohexane-1,2-diamine (**29**)*

To a solution of azide **26** (260 mg, 1.3 mmol) in 15 mL of MeOH and deionized water (1:1) was added 10% Pd/C (100 mg) suspended in 2 mL of MeOH. After stirring under an atmosphere of hydrogen at room temperature overnight, the catalyst was removed by filtration through Celite and the filtrate was evaporated to give the diamine **29** (147 mg, 65%) as a syrup: ^1H NMR (300 MHz, D_2O) δ: 1.55 (m, 2H, H-4,5), 1.90 (m, 2H, H-4,5), 2.86 (m, 2H, H-1,2), 3.38 (s, 6H, OCH_3), 3.62 (m, 2H, H-3,6); MS *m/e*: 175 $(M + 1)^+$; HRMS calcd. for $C_8H_{18}N_2O_2$: 174.1369; found: 174.1352.

(d,l)-*(1α,2β,3α,6β)-3,6-Dimethoxycyclohexane-1,2-diamine (**30**)*

The diamine **30** was prepared from **28** in 60% yield following the same procedure that was used for the preparation of **29**: ^1H NMR (300 MHz, D_2O) δ: 1.20 (m, 2H, H-4,5), 2.25 (m, 2H, H-4,5), 2.59 (m, 2H, H-1,2), 3.13 (m, 2H, H-3,6), 3.43 (s, 6H, OCH_3);

MS *m/e*: 175 $(M + 1)^+$; HRMS calcd. for $C_8H_{18}N_2O_2$: 174.1369; found: 174.1366.

(d,l)-*[SP-4-2-(1β,2α,3α,6β)]-Dichloro(3,6-dimethoxycyclohexane-1,2-diamine-*N,N′*) platinum (31)*

Potassium tetrachloroplatinate(II) (310 mg, 0.75 mmol) was dissolved in 3.5 mL of deionized water and the insoluble material was filtered. To this dark red filtrate was added a solution of diamine **29** (130 mg, 0.75 mmol) in 2 mL of deionized water. The mixture was stirred manually until homogeneous and the solution was left standing in the dark at room temperature. Crystallization began after 3 h. When the original red color of the solution became yellow or orange yellow, the crystals were filtered, washed with cold water several times, and dried over P_2O_5 under vacuum in the absence of light to afford the platinum complex **31** (250 mg, 76%) as bright yellow crystals: IR (Nujol): 3280, 3260, 3220, 3180, 3105 (NH) cm^{-1}; ^1H NMR (300 MHz, DMSO-d_6) δ: 1.13–1.26 (m, 2H, Hax-4,5), 1.54–1.65 (m, 2H, Heq-4,5), 2.54–2.57 (m, 2H, H-1,2), 3.21 (s, 6H, OCH_3), 3.45–3.47 (m, 2H, H-3,6), 4.18–4.23 (m, 2H, NH), 5.53–5.66 (m, 2H, NH); ^{13}C NMR (75 MHz, DMSO-d_6) δ: 20.44, 56.61, 60.52, 76.10; MS *m/e*: 441 $(M + 1)^+$, 440 $(M)^+$, 439 $(M - 1)^+$; HRMS (FAB) calcd. for $C_8H_{18}Cl_2N_2O_2Pt$: 439.0395; found: 439.0442. Anal. calcd. for $C_8H_{18}Cl_2N_2O_2Pt$: C 21.82, H 4.12, N 6.36, Cl 16.11; found: C 21.68, H 3.80, N 6.13, Cl 15.78.

Acknowledgments

We wish to thank the National Cancer Institute (NCI) (Canada) and the Natural Sciences and Engineering Research Council of Canada for financial support. Biological tests were carried out at Lederle Laboratories, Pearl River, N.Y. We thank Dr. S. Lang for his support.

Heats of hydrolysis of *N*-methylformanilide dimethyl acetal have been measured in basic solution. The heat of formation of *N*-methylformanilide was obtained by determining the equilibrium constant in aqueous solution for its formation from formic acid and *N*-methylaniline as a function of temperature: $\Delta H_f^0(l) = -33.78 \pm 1.85$ kcal/mol. These data permit the calculation of the heat of formation of *N*-methylformanilide dimethyl acetal, $\Delta H_f^0(l) = -72.95 \pm 1.85$ kcal/mol. The free energy of formation of the tetrahedral intermediate in the hydrolysis of *N*-methylformanilide was calculated by methods we have previously reported. Consideration of the energetics of the intermediates and the known rates of reaction leads to the conclusion that the rate-determining step for alkaline hydrolysis is cleavage of the C—N bond.

J. PETER GUTHRIE, JONATHAN BARKER, PATRICIA A. CULLIMORE, JINQIAO LU et DAVID C. PIKE. Can. J. Chem. **71**, 2109 (1993).

Opérant en solution basique, on a mesuré les chaleurs d'hydrolyse l'acétal diméthylique de la *N*-méthylformanilide. On a obtenu la chaleur de formation de la *N*-méthylformanilide en déterminant la constante d'équilibre en fonction de la température (en solution aqueuse) pour sa formation à partir de l'acide formique et la *N*-méthylaniline: $\Delta H_f^0(l) = -33{,}78 \pm 1{,}85$ kcal/mol. Ces données permettent de calculer la chaleur de formation de l'acétal diméthylique de la *N*-méthylformanilide, $\Delta H_f^0(l) = -72{,}95 \pm 1{,}85$ kcal/mol. Utilisant des méthodes décrites antérieurement, on a calculé l'énergie libre de formation de l'intermédiaire tétraédrique impliqué dans l'hydrolyse de la *N*-méthylformanilide. Une considération des énergies des intermédiaires et des constantes de vitesse connues mène à la conclusion que l'étape qui détermine la vitesse de la réaction de l'hydrolyse alcaline est le clivage de la liaison C—N.

Introduction

Slebocka-Tilk et al. (1) recently studied ^{18}O exchange accompanying hydrolysis of anilides in acid. Brown, Guthrie, and co-workers (2) showed that this can be explained in terms of a detailed mechanism including the proton transfer steps interconverting different protonation states of the tetrahedral intermediates. Neither proton transfer nor bond rotation were rate determining, although proton transfers were concerted with the heavy atom bond-making and -breaking steps. To test this interpretation it would be desirable to have energies of the tetrahedral species on the reaction path for hydrolysis of these amides. We have undertaken to determine these energies for intermediates derived from *N*-methylformanilide by our thermochemical method (3).

Results

The first anilide derivative that we studied was *N*-methylformanilide dimethyl acetal, which will permit determination of the free energy of *N*-methylformanilide hydrate. This compound was chosen for reasons of experimental convenience, because the formanilide acetal is relatively stable to thermal decomposition, and so can be purified and studied relatively conveniently.

Base-catalyzed hydrolysis could be studied in 50% DMSO – water; in 90% DMSO – water the hydrolysis was too slow for calorimetry, while the acetal was too insoluble in water to permit measurement of the heat of reaction. Alternatively, hydrolysis could be studied in 50% methanol – water. Experimental results, heats of reaction and solution, are summarized in Table 1. The directly measured heat of hydrolysis refers to the process:

[1] $HC(OMe)_2N(Me)Ph\ (l) + H_2O\ (soln) \rightleftharpoons x[HCON(Me)Ph\ (soln) + 2MeOH\ (soln)] + (1 - x)[HCOOMe\ (soln) + PhNHMe\ (soln) + MeOH\ (soln)]$

It should be remembered that HCOOMe (soln) will actually be sodium formate plus methanol, the products of the rapid alkaline hydrolysis of methyl formate. The heat of reaction for process [1] must be converted, by combining with heats of solution, to the hypothetical reaction with all species in their standard states (process [2]) in order to allow convenient calculation of the standard enthalpy of formation.

[2] $HC(OMe)_2N(Me)Ph\ (l) + H_2O\ (l) \rightleftharpoons x[HCON(Me)Ph\ (l) + 2MeOH\ (l)] + (1 - x)[HCOOMe\ (l) + PhNHMe\ (l) + MeOH\ (l)]$

The stoichiometry of the hydrolysis, x, must also be known, and was determined by experiments using DMSO-d_6:D_2O or CD_3OD:D_2O as solvent. The products in both cases were >95% *N*-methylformanilide and <5% methyl formate by nmr analysis. Thus in base, $x = 1.0$, and the hydrolysis can be written.

[3] $HC(OMe)_2N(Me)Ph\ (l) + H_2O\ (l) \rightleftharpoons HCON(Me)Ph\ (l) + 2MeOH\ (l)$

To obtain a heat of formation for *N*-methylformanilide we determined the heat of reaction for process [4].

[4] $HCOOH(aq) + PhNHMe(aq) \rightleftharpoons HCON(Me)Ph(aq)\ (+ H_2O(l))$

Methyl formate	-12.11 ± 0.37[b]
N-Methylaniline	$+2.13 \pm 0.02$[b]
	$+0.33 \pm 0.11$[d]

[a]At 25°C.
[b]In 50% DMSO, 50% water, with 0.1 N tetraethylammonium hydroxide.
[c]In 50% methanol, 50% water, with 0.1 N NaOH.
[d]In aqueous solution, pH 8.0 phosphate buffer, ionic strength 0.1 M.

TABLE 2. Transamidation[a]

Temperature	K[b]
24.90	2.41 ± 0.16
35.00	2.33 ± 0.34
45.90	2.40 ± 0.18

$\Delta H_{reaction}$[c] $= -0.06 \pm 0.31$ kcal/mol

[a]In aqueous solution, initial concentrations were 24.83 mM PhNHMe, 200.2 mM NH_2OH, and either 10.04 mM *N*-methylformanilide or 9.8 mM formohydroxamic acid, at ionic strength 1.0 (KCl). Suitable scaling corrections were made for the small differences in initial amide concentrations.
[b]Equilibrium constant for the reaction: HCONHOH + PhNHMe $\rightleftharpoons$ HCON(Me)Ph + NH_2OH. The standard state for all species is 1 M aqueous solution.
[c]From a van't Hoff plot of ln K vs. $1/T$.

This was done by van't Hoff analysis of the equilibrium constants at 25, 35, and 45°C for processes [5] and [6].

[5] HCONHOH(aq) + PhNHMe(aq) $\rightleftharpoons$ HCON(Me)Ph(aq) + NH_2OH(aq)

[6] HCOOH(aq) + NH_3OH^+(aq) $\rightleftharpoons$ HCONHOH(aq) + H^+(aq)

The equilibrium constant for the formation of *N*-methylformanilide from formohydroxamic acid and *N*-methylaniline, process [5], was determined by the method of Fersht and Requenna (4), which is based on determining the initial changes in concentration of formohydroxamic acid for process [5] under pseudo-first-order conditions for *N*-methylaniline and hydroxylamine, starting with either formohydroxamic acid or *N*-methylformanilide. Equilibration was slow at 25°C, with a pseudo-first-order rate constant for approach to equilibrium between formohydroxamic acid and *N*-methylformanilide of 1.7×10^{-3} h^{-1} at pH 6.12, 0.20 M total hydroxylamine, 0.025 M *N*-methylaniline. The equilibrium constants at the three temperatures are found in Table 2. From a van't Hoff plot we obtain an enthalpy of reaction of -0.06 ± 0.31 kcal/mol. At 25°C,

$$K = [HCON(Me)Ph][NH_2OH]/[HCONHOH][PhNHMe] = 2.41 \pm 0.16$$

TABLE 3. Formation of formohydroxamic acid[a]

Temperature	$10^4 K$[b]	
24.90	5.09[c]	5.02[d]
35.00	5.39[c]	5.20[d]
45.20	5.65[c]	5.49[d]

$\Delta H_{reaction}$[e] $= 0.97 \pm 0.04$ kcal/mol

[a]In aqueous solution, solutions contained 2.00 M HCOOH, 0.90 M $NH_2OH \cdot HCl$, and 0.1 MHCl, or 1.98 M HCOOH, 0.88 M $NH_2OH \cdot HCl$, 20.2 mM formohydroxamic acid, and 0.12 M HCl. These solutions were calculated to end with identical concentrations of all species.
[b]Equilibrium constant for the reaction: HCOOH + NH_3OH^+ $\rightleftharpoons$ HCONHOH + H^+ ($+H_2O$). [H^+] was taken as 10^{-pH}. pH was 0.906 for reactions starting with no formohydroxamic acid and 0.930 for reactions starting with 0.0202 formohydroxamic acid. The standard state of water was the pure liquid; for all other species the standard state was 1 M aqueous solution. K is then dimensionless.
[c]Initial formohydroxamic acid concentration was zero.
[d]Initial formohydroxamic acid concentration was 0.0202 M.
[e]From a van't Hoff plot of ln K vs. $1/T$.

The next step was to determine the enthalpy of reaction for formation of formohydroxamic acid according to reaction [6]. The apparent equilibrium constant for the formation of formohydroxamic acid was measured at 25, 35, and 45°C, following the method of Fersht and Requenna (4), which is based on determination of the final equilibrium concentration of formohydroxamic acid for solutions 2 M in formic acid, 0.1 M in HCl, and 0.9 M in hydroxylammonium. The equilibrium constant data are found in Table 3. These data led to a heat of reaction of $+0.97 \pm 0.04$ kcal/mol.

At 25°C Fersht and Requenna (4) derived a value for the equilibrium constant:

$$K = [HCONHOH]/[NH_2OH][HCOOH] = 934 \pm 37\ M^{-1}$$

From the heats of reaction for processes [5] and [6], the heat of formation data in Table 4, and heats of solution for *N*-methylaniline and *N*-methylformanilide, we can calculate the heat of formation of formohydroxamic acid in aqueous solution, and thence the heat of formation of *N*-methylformanilide in aqueous solution. This calculation required a heat of formation of *N*-methylaniline in aqueous solution, which was unexpectedly difficult to determine because of the low solubility of *N*-methylaniline, and in particular the slow dissolution of this compound. The pure liquid was injected into pH 8 phosphate buffer (ionic strength 0.1 M) and the temperature change was recorded. Immediately after determining the heat of solution, a sample was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

removed, taking care to avoid contamination by undissolved amine, and the concentration of dissolved amine was determined by uv spectroscopy. This allowed determination of the heat of solution as 0.33 ± 0.11 kcal/mol. The heat of solution of *N*-methylformanilide was readily determined as 0.20 ± 0.06 kcal/mol. With these values in hand we are finally able to calculate the heat of formation of liquid *N*-methylformanilide as −33.71 ± 1.84 kcal/mol. The principal source of error in this estimate is the uncertainty in the heat of formation of *N*-methylaniline. This means that the absolute values we derive have substantial errors, but values of heats or free energies of reaction for processes involving *N*-methylaniline will have smaller errors.

A second estimate of the heat of formation of *N*-methylformanilide is possible starting with the equilibrium constant for amide formation from formic acid and *N*-methylaniline, process [4]. This allows calculation of the free energy of formation of *N*-methylformanilide in aqueous solution. Now we use the free energy of transfer to calculate the free energy of formation of *N*-methylformanilide as the gas. The free energy of transfer is available from the solubility, measured in this work as 0.26 M, and the vapor pressure, estimated (5) from the vapor pressure at 8 Torr (1 Torr = 133.3 Pa), using the heat of vaporization estimated (5) from the available vapor pressure data (6–9), an estimated heat capacity of vaporization (10), and a method based on that of Prausnitz (5, 11). We then used the standard entropy of *N*-methylformanilide to calculate the heat of formation of the gaseous anilide. The entropy was estimated using a disproportionation reaction, assuming that there is no entropy change except that due to symmetry numbers for the process:

[7] $HCON(Me)_2 + HN(Me)Ph \rightleftharpoons HCON(Me)Ph + HN(Me)_2$

The standard entropy of *N,N*-dimethylformamide was calculated from the vibrational frequencies (12), moments of inertia and reduced moments of inertia calculated from the MM2 geometry, and values for the rotational barriers from ref. 12; the rotational barrier used for the amide bond was that for formamide (12). These data lead to S_{tr} = 38.78, S_{rot} = 25.55, S_{vib} = 4.04, S_{hr} = 6.28, and $S^0(g)$ = 74.65 cal deg^{-1} mol^{-1}. The standard entropy of gaseous dimethylamine is 65.24 (13).

Finally, from the heat of vaporization, estimated as already described, we were able to estimate a heat of formation for liquid *N*-methylformanilide as −34.87 ± 1.93 kcal/mol, which is within the uncertainty limits of the other value. This confirms the internal consistency of our calculations.

Heats of formation of *N*-methylformanilide and *N*-methylformanilide dimethyl acetal are found in Table 4, which includes thermodynamic data for all compounds discussed in this paper.

With the enthalpy of formation of *N*-methylformanilide dimethyl acetal in hand, we proceed to calculate the free energy of formation of this compound in aqueous solution. First we require the heat of vaporization. This was estimated from the boiling point at reduced pressure, as previously described (5). Next we needed the standard entropy of the molecule in the gas phase. This was estimated by Benson's bond and group additivity schemes (14, 15); to apply group additivity it was necessary to estimate values for $[CH(O)_2(N)]$ (estimated from the bond additivity contributions as [C—H] + 0.5(2[C—O] + [C—N])), and for $[N(C_B)(C)_2]$ (taken as approximately $[N(C)_3]$). These two estimates were in good agreement. Finally, we needed a free energy of transfer. This cannot be measured because of the rapid hydrolysis of the amide acetal in aqueous solution (16), and so must be estimated. We did so using a method which we reported recently (17), making use of group additivity modified by a Taft $\rho^*-\Sigma\sigma^*$ correlation to allow for "Distant Polar Interactions" (18). The free energy of transfer requires contributions for each structural feature, and ρ^* values for each non-aliphatic group to allow for the effect of other polar substituents on the solvation of that group. ρ^* for ether oxygen is known (17) but we required a value for ρ^* for N(Me)Ph. To determine this we prepared $CF_3CH_2N(CH_3)Ph$ and determined its free energy of transfer. Since the ρ^* for F is known, the only thing required to calculate the free energy of transfer is ρ^* for N(Me)Ph, which was found to be 1.10, which is slightly larger than the value, 0.872, for aliphatic N. The free energy of transfer of *N*-methylformanilide dimethyl acetal can now be calculated as 2.48 kcal/mol. The free energy of formation of *N*-methylformanilide dimethyl acetal can now be calculated as −2.18 kcal/mol. The results of all of these calculations are found in Table 4.

The quantity of interest is the free energy of formation of the corresponding carbonyl hydrate, $HC(OH)_2N(Me)Ph$. This is calculated by our usual method (3) using the hypothetical hydrolysis process:

[8] $HC(OMe)_2N(Me)Ph + 2H_2O \rightleftharpoons HC(OH)_2N(Me)Ph + 2MeOH$

for which we estimate the free energy change, allowing for electronic, steric, and symmetry effects (19). When this is done we obtain the value found in Table 4.

Discussion

We are now going to use the free energies of formation of the tetrahedral intermediates to analyze the kinetic data for hydrolysis of *N*-methylformanilide. In doing this we will consistently report free energies or log *K* values to two decimal points. In terms of absolute values based on thermochemical data this is too many significant figures, as the associated uncertainty limits will show. However, giving this many digits provides guard figures to prevent accumulation of roundoff error, and allows calculation of differences in energy that may be, and often are, considerably more accurate than the absolute free energy values.

It is now possible to calculate the equilibrium constant for addition of water to *N*-methyl formanilide, process [9], from the

[9] $HCO\text{-}N(Me)Ph + H_2O \rightleftharpoons HC(OH)_2\text{-}N(Me)Ph$

free energies of formation of each of the species involved. The value so calculated is log K_{H_2O} = −10.22 ± 3.26, based on the pure liquid standard state for water. By estimating the pK_a of this covalent hydrate we can calculate the equilibrium constant for the addition of hydroxide, as log K_{OH^-} = −8.19 ± 3.41. From the intrinsic barrier for addition of hydroxide to carbonyl compounds, $\hat{G}$ = 8.7 kcal/mol (20), we can estimate the free energy of activation of OH^- addition as 17.61 kcal/mol relative to separate starting materials. This estimate allows for the partial desolvation of hydroxide when it diffuses into contact with the carbonyl carbon (20). The

TABLE 4. Thermodynamic values for compounds discussed in this paper[a]

(a) Compounds for which free energies of formation have been reported

HCO-N(Me)Ph	−33.78 ± 1.85[o]	0.20 ± 0.06[v]	−33.56 ± 1.84[h]

[a]All at 25°C; enthalpies and free energies are in kcal/mol, entropies are in cal deg^{-1} mol^{-1}, standard states are the ideal gas at 1 atm and 1 M aqueous solution with an infinitely dilute reference state. Unless otherwise noted, enthalpies of formation are from ref. 47, entropies are from ref. 48, free energies of formation in the gas phase are calculated from the corresponding enthalpies of formation and the standard entropies, and free energies of formation in aqueous solution are calculated from the corresponding free energies of formation in the gas and free energies of transfer.

[b]Reference 49, standard state is the pure liquid.

[c]Reference 50.

[d]Reference 51.

[e]Estimated starting from the value for HN(Et)Ph given in Pedley et al. (47), 13.46 ± 1.41 kcal/mol. This was adjusted for removal of CH_2 using Benson's (15) group contribution value for [CH2(N)(O)] = −6.6; the error was taken as 0.5. Thus we obtained ΔH_f^0(g) = 20.06 ± 1.73 kcal/mol for HN(Me)Ph; Vriens and Hill give 20.4 (52).

[f]Reference 52.

[g]Estimated starting from the value for HN(Et)Ph, given in Pedley et al. (47) as 12.50 ± 1.00 kcal/mol. This was adjusted for removal of CH_2 using a group contribution (53) for [CH2(N)(O)] = 0.43 ± 0.13. This led to ΔH_{vap} = 12.07 ± 1.41 kcal/mol. Vriens and Hill give 12.7 (52).

[h]Calculated from other values in this table.

[i]Vriens and Hill give 7.7 (52).

[j]Calculated from the solubility, measured in this work, and the vapor pressure at 25°C (52).

[k]Estimated by disproportionation as described in the text.

[l]Calculated from boiling point data. For *N*-methylformanilide the following values were available: bp (°C), *p* (Torr), derived heat of vaporization (kcal/mol); 118., 8., 16.99 (this work); 134., 20., 16.66 (ref. 6: Beil, 12, H, 234); 142., 20., 17.34 (ibid); 253., 716., 17.00 (ibid); 244., 760., 16.22 (ibid); 251., 760., 16.69 (ibid); 132., 22., 16.31 (ref. 7: Beil, 12, II, 136); 121., 8., 17.25 (ibid); 123., 13., 16.54 (ref. 8: Beil, 12, III, 454); 95., 4., 16.13 (ibid); 152., 40., 16.74 (ref. 9: Beil, 12, IV, 370); 130., 15., 16.87 (ibid); 95.5, 1.5, 17.72 (ibid); average 16.80 ± 0.44.

[m]Calculated from equilibrium constants and other data as described in the text.

[n]Calculated from the solubility, measured in this work, and the vapor pressure, estimated as described in the text.

[o]Calculated from heats of formohydroxamic acid formation and transamidation as described in the text.

[p]Estimated by group additivity as described in the text.

[q]Calculated from boiling point data: bp 87°C at 1.5 Torr leads to ΔH_{vap} = 16.91 kcal/mol.

[r]Calculated from the heat of hydrolysis as described in the text.

[s]Estimated as described in the text.

[t]Calculated using ΔG^0 values for hypothetical hydrolysis reactions as described in the text.

[u]Calculated from the heat of reaction as described in the text.

value so estimated is significantly less than the observed value, 22.56 kcal/mol (30).

When we plot log k_{HO^-} vs. log K_{HO^-} we find that most carbonyl compounds fall approximately on a single curved line (21) but *N*-methylformanilide does not; see Fig. 1. The assumption that all carbonyl compounds would fall on one curve is equivalent to assuming that the addition step is always rate determining, which is not always the case, as has been recently shown for amides (22). If we estimate the rate constant for expulsion of *N*-methylaniline, assuming the mechanism proposed (22) for expulsion of dimethylamine in base-catalyzed hydrolysis of *N,N*-dimethyltoluamide, we obtain a good match to the observed rate constant.

First we estimate pK_a values leading to the anionic zwitterion, $HC(O^-)_2$–N^+H(Me)Ph, as previously described (22). These estimates require σ* values for N(Me)Ph and NH^+(Me)Ph; in the absence of data allowing better estimates, we use the values for NHPh and NH_2^+Ph (2), 1.19 and 4.07, respectively. The pK_a values that we estimated are given in Scheme 1. We carried out similar estimates for the

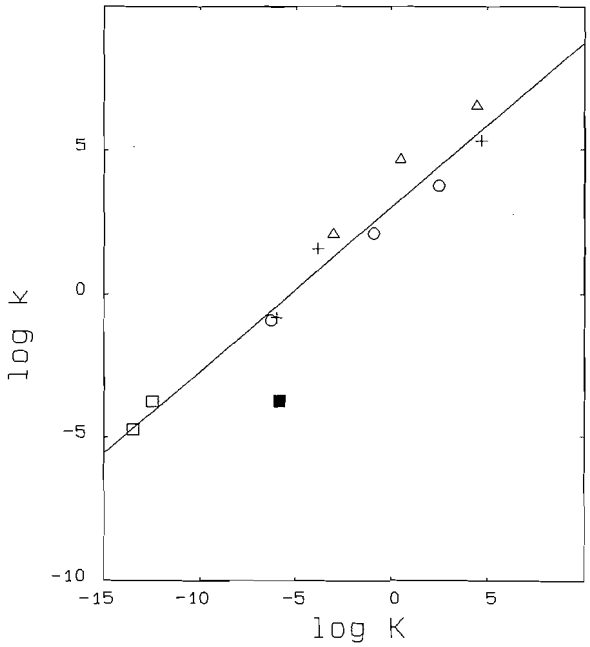

FIG. 1. Rate equilibrium correlation for the reaction of hydroxide with RCOZ, where the carbonyl compound can be *N*-methylformanilide (■), an amide (□), an ester (○), a thioester (⁺), or an aldehyde or ketone (△).

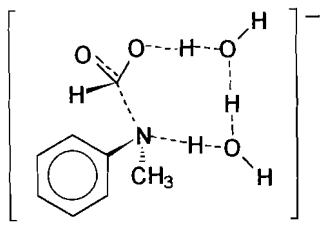
tetrahedral intermediates derived from *N,N*-dimethylformamide; these values are given in Scheme 2. Other pK_a values were needed in order to estimate the energies of "corner intermediates" for the application of Multidimensional Marcus Theory (23). These pK_a values are given in Table 5.



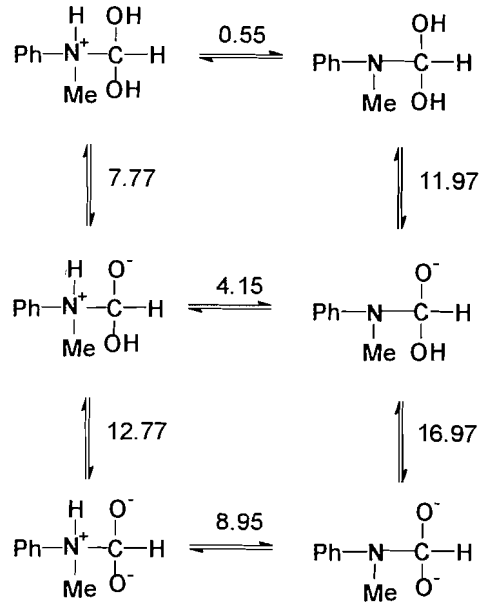
Multidimensional Marcus Theory (23) is an extension of our treatment of concerted reactions (20, 23*b*) to higher numbers of reaction coordinate dimensions. We have written computer programs (23*a*) to find the lowest transition state on the energy hypersurface. The position of the transition state on the hypersurface tells whether a reaction is stepwise, with essentially only one reaction coordinate changing in the transition state, or concerted, with two or more reaction coordinates changing in the transition state.

From the pK_a values estimated above we calculate the equilibrium constant for converting the anionic hydroxide adduct to the anionic zwitterion as log $K = -8.02$. From the equilibrium constants for overall reaction with hydroxide, addition of hydroxide, and anionic zwitterion formation, we can calculate the equilibrium constant for breakdown of the anionic zwitterion to products as log $K = 23.15$.

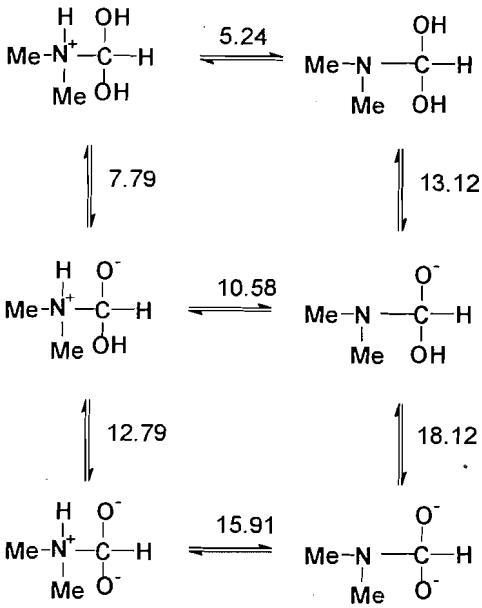
To calculate a rate constant for this breakdown process [10], we need the intrinsic barrier. For the addition of

[10] H-C(O^-)$_2$–N^+H(Me)Ph ⇌ H-COO^-, NH(Me)Ph

aniline, we can deduce an intrinsic barrier from data for the



SCHEME 1. pK_a values for tetrahedral intermediates from *N*-methylformanilide.



SCHEME 2. pK_a values for tetrahedral intermediates from *N,N*-dimethylformamide.

reaction of aniline with *p*-chlorobenzaldehyde (24). The rate constant for addition leading to the zwitterionic tetrahedral intermediate, process [11], is 60 M^{-1} s^{-1}. The equilibrium

[11] *p*ClPh-CHO + NH_2Ph ⇌ *p*ClPh-CH(O^-)(N^+H_2Ph)

constant for addition to give the neutral carbinolamine is 0.0089 M^{-1}. We estimate the pK_a for the NH^+ in the protonated carbinolamine, dissociation process [12], as follows: beginning

[12] *p*ClPh-CH(OH)(N^+H_2Ph)

⇌ *p*ClPh-CH(OH)(NHPh) + H^+

[b]Reference 25.
[c]Reference 54.
[d]Estimated, after ref. 55, from the pK_a of dimethylammonium ion in water using a plot of the pK_a of ammonium ions in water against the pK_a of the corresponding amines in DMSO.
[e]Reference 56; this value is for aniline and is assumed to be approximately correct for *N*-methylaniline as well.
[f]Reference 55.
[g]Reference 36.
[h]Reference 57.
[i]Estimated from the pK_a for protonated DMF assuming the effect of replacing methyl by phenyl is the same as in *N*-methylacetamide (pK_{BH^+} = −0.42 (58)) and acetanilide (pK_{BH^+} = −0.99 (58)).
[j]Taken as the pK_{BH^+} of benzoic acid, since *p*-chlorobenzaldehyde and benzoic acid are half protonated at the same concentration of sulfuric acid (59).
[k]Estimated using the correlation equations reported in ref. 36, except that for oxonium ions we constrained the line to pass through the pK_{BH^+} for ethanol reported by Lee and Demchuk (60), and we now use $\sigma^*(H) = 0.0$ for oxonium ions. The σ^* values were from ref. 26 except for: PhN(Me)- (assumed to be the same as PhNH-, $\sigma^* = 1.19$ (2), H_2O^+-, $\sigma^* = 5.1$ (36), Me_2N-, $\sigma^* = 0.62$ (62).
[l]Dissociation from nitrogen to give the neutral species.
[m]Dissociation from oxygen to give the zwitterion.
[n]Dissociation from nitrogen to give the anion.
[o]Dissociation from oxygen to give the anionic zwitterion.

with *N*-methylanilinium ion, pK_a 4.85 (25), the effect of replacing methyl by benzyl is taken from the difference in pK_a between dimethylammonium, 10.64 (25), and benzylmethylammonium, 9.58 (25), this gives 3.97 for *N*-benzylanilinium ion. The effect of the *p*-chloro is taken from a Hammett correlation for benzylamines (26), $\Delta pK_a = 0.25$. The effect of the carbinolamine OH is taken as the average value recommended by Hine, $\Delta pK_a = 1.88$ (27). These corrections lead to a pK_a of 1.66 for the NH of the protonated carbinolamine. The pK_a for dissociation of the OH in the protonated carbinolamine, dissociation process[13], is estimated

[13] $p\text{ClPh-CH(OH)}(N^+H_2Ph) \rightleftharpoons p\text{ClPh-CH}(O^-)(N^+H_2Ph) + H^+$

as follows: beginning with hydroxymethylanilinium ion, pK_a 9.58 (28), the effect of replacing CH_2 by CHPh is taken from the difference in pK_a between methanol, 15.54 (25), and benzyl alcohol, 15.44 (25); this gives a pK_a for Ph-NH_2^+-CH(Ph) of 9.48. The effect of the *p*-chloro is taken from a Hammett correlation for benzylamines (26), leading to a pK_a for OH dissociation of the protonated carbinolamine of 9.23. The two pK_a values lead to a zwitterion content, $pK_z = 7.57$, and an

[14] $K_2 = [p\text{ClPh-CH}(O^-)(N^+H_2Ph)]/[p\text{CLPh-CH(OH)(NHPh)}]$

equilibrium constant for addition of aniline to *p*-chlorobenzaldehyde to give the zwitterionic carbinolamine of 2.39×10^{-10} M^{-1}. With rate and equilibrium constants for the rate-determining step in place, we may calculate the intrinsic barrier as 6.05 kcal/mol, using a work term calculated using only simple encounter with no favorable or unfavorable interactions (29). We will use this value for *N*-methylaniline as well. The zwitterionic tetrahedral intermediate formed from aniline and *p*-chlorobenzaldehyde has a very short lifetime, because it is so high in energy, and it will undergo a rapid water-mediated proton switch to give the neutral tetrahedral intermediate. When we apply Multidimensional Marcus Theory we find that the rate-determining step for addition of aniline is essentially pure C—N bond formation; the water-mediated proton switch is after the transition state.

With this intrinsic barrier, we see that the anionic zwitterion will probably have no lifetime, breaking down to products as fast as it is formed. This implies that the rate-determining step will be the water-mediated proton switch converting the anionic tetrahedral intermediate into the anionic zwitterion. We can estimate the rate constant for the breakdown of the anionic intermediate, by way of the anionic zwitterion, using Multidimensional Marcus Theory (23). The overall free energy of activation is predicted to be 21.47 kcal/mol relative to starting materials, and the tran-

sition state is predicted to be essentially proton transfer, with no C—N bond breaking.

In applying Multidimensional Marcus Theory we must estimate the free energies of formation of the various "corner intermediates" that would arise from the various stepwise processes that must occur to get from starting material to products. The energies of these corner intermediates are given in Table 6.

Comparison of the predicted transition state energies for hydroxide addition, 17.45 kcal/mol, and for breakdown by way of the anionic zwitterion, 20.08 kcal/mol (both relative to the separated starting materials), clearly shows that the second process is expected to be slower and rate determining. The relative activation energies for these processes, which both depend on the free energy of the anionic tetrahedral intermediate, should be more reliable than the absolute values. Error analysis suggests that the free energy of hydration of *N*-methylformanilide has an uncertainty of ±2.4 kcal/mol, and there will be an additional uncertainty from the Multidimensional Marcus Theory calculations. The observed free energy of activation is 22.56 kcal/mol (30). The detailed reaction coordinate diagram that we are now able to draw is shown in Fig. 2, based on the mechanism shown in Scheme 3.

For the base-catalyzed hydrolysis of acetanilides and formanilides, there is a consensus that the C—N cleavage process is rate limiting (31–33). Deslongchamps et al. (34) report extensive ^{18}O exchange accompanying hydrolysis of *N*-methylformanilide by aqueous KOH at 90°C.

Anilides are known (30–33) to hydrolyse in base by two paths, one first order and one second order in base. We will now do Multidimensional Marcus calculations for the latter path. We start with the encounter complex of hydroxide and the monoanionic form of the tetrahedral intermediate, and end with the encounter complex of formate ion, aniline, and hydroxide. This allows for the possibility of general base and (or) general acid-catalyzed breakdown of the intermediate, with hydroxide as possible general base, and water as possible general acid. The result is that the reaction is predicted to have a transition state with the dianion completely formed, and in the process of cleaving the C—N bond, and negligible transfer of proton from water to nitrogen. The predicted free energy of activation (relative to separate starting materials) is 18.90 kcal/mol. The observed value is 21.68 kcal/mol (30).

We must now look briefly at the case of *N,N*-dimethylformamide, for which hydroxide-catalyzed hydrolysis was assumed in our earlier papers (35, 36) to have rate-limiting addition of hydroxide, with the mechanism in process [15]. When we

$$[15]\quad HCO\text{-}NMe_2 + HO^- \rightleftharpoons HC(O^-)(OH)\text{-}NMe_2 \rightleftharpoons HC(O^-)_2\text{-}N^+HMe_2 \rightleftharpoons HCOO^- + NHMe_2$$

estimate the equilibrium constant for anionic zwitterion formation in this case, following the same pattern as above, we find that because of the greater basicity of the nitrogen the proton-switch equilibrium actually favors the anionic zwitterion. For loss of dimethylamine we deduced a barrier of 10.5 kcal/mol, based on the rate and equilibrium constants for addition reactions of dimethylamine (22). When we apply Multidimensional Marcus Theory to the breakdown of the

[a]All in aqueous solution at 25°C. Standard states are 1 M ideal solutions with an infinitely dilute reference state, except for water for which the standard state is the pure liquid at unit activity. For the formation of encounter complexes with neither stabilizing nor destabilizing interactions we follow Hine (29) and estimate the equilibrium constant as $0.0085n$, where n is the number of equivalent positions in which one reactant could be found in a water lattice relative to the other reactant; we assume a diamond lattice as in ice as an approximation to the short-range order in water. Species other than water that are separated by a comma are in an encounter complex; water molecules are included where appropriate so that all species in a set have the same composition. Hydrogen bond energies are calculated using the equation of Stahl and Jencks (48); because we explicitly correct for encounter, we extract the pure hydrogen bonding contribution from the Stahl and Jencks result, which gives the overall equilibrium that includes both encounter and hydrogen bonding. Electrostatic interactions are calculated relative to the ion pair interaction; the net energy for ion pair formation in water is 0.1 kcal/mol (61), which is the sum of encounter and electrostatics. Since encounter is 2.42 kcal/mol, electrostatics must be −2.32 kcal/mol. For the various species involved we made approximate estimates using a single interatomic distance, assumed the same for all, bonding or not, and a standard geometry based on a regular pentagon for cyclic arrays of atoms. Since electrostatic interactions are small in water, such crude calculations do not introduce large errors.

[b]Encounter is assumed to have four possible locations for hydroxide relative to the amide.

[c]Encounter is assumed to have two possible locations for hydroxide relative to the amide, and loss of one hydrogen-bonded water at a cost of 7.1 kcal/mol.

[d]Encounter is assumed to have two possible locations for the hydroxide relative to the amide, the energy of the zwitterion relative to the neutral form of the intermediate is calculated from pK_a values in Table 5, and the hydrogen bond energy is calculated as described.

[e]Based on a pK_a value in Table 5.

[f]Based on hydration and pK_a.

[g]Based on hydration, pK_a values, encounter with one position for the hydronium ion, and the hydrogen bond energy for H_3O^+ hydrogen bonded to the dianionic tetrahedral intermediate.

[h]Based on hydration, pK_a values, pK_w, encounter (three ways for hydronium hydroxide to form, one way for this to form a cyclic complex with the tetrahedral intermediate), hydrogen bonds between HO^- and H_3O^+ and HO^- and the monoanionic tetrahedral intermediate, and the ion pairing between H_3O^+ and HO^-.

[i]Based on hydration, pK_a values, encounter (one place for hydroxide next to the ammonium ion), hydrogen bonding between HO^- and ammonium ion, and electrostatic interactions between HO^- and the zwitterion.

[j]Based on hydrolysis, pK_a values, encounter (two ways for the amide ion to be next to formic acid), desolvation of the amide ion (difference in pK_a between water and DMSO).

[k]Based on hydration, pK_a values, encounter (one way for the hydronium to be next to the intermediate with a cyclic array of hydrogen bonds), and ion pairing.

[l]Based on hydration, pK_a values, pK_w, encounter (three ways for hydronium hydroxide to form, one way for this to form a cyclic complex with the tetrahedral intermediate), hydrogen bonding of H_3O^+ and HO^-, H_3O^+ with the oxyanion, and HO^- with the ammonium ion, and electrostatic interactions.

[m]Based on hydrolysis, pK_a values, encounter (two ways for the amide ion to be next to formate ion, one way for hydronium ion to be next to this with a cyclic array of hydrogen bonds), electrostatic interactions (essentially ion pairing), hydrogen bonding of H_3O^+ and formate ion, and desolvation of the amide ion (estimated as described above).

[n]Based on hydration, pK_a values, encounter (one way for HO^- to be next to the intermediate and give a cyclic hydrogen bond array), electrostatic interactions of HO^- with the zwitterion, and hydrogen bonding of HO^- with the hydroxyl of the intermediate.

[o]Based on hydrolysis, pK_a values, pK_w, encounter (three ways for hydronium hydroxide to form, one way for it to bind to the tetrahedral intermediate), electrostatic interactions in the ion triple, amide ion, H_3O^+, HO^-, and hydrogen bonding of HO^- with the hydroxyl of the intermediate, of HO^- with H_3O^+, and of H_3O^+ with the amide ion.

[p]Based on hydrolysis, encounter (two ways for the amine to encounter formic acid, one way for HO^- to bind with a cyclic hydrogen bonding array), and hydrogen bonding of HO^- and the amine.

[q]Based on hydration and pK_a values.

[r]Based on hydrolysis, pK_a values, encounter (two ways for the amine to encounter formate ion, one way for H_3O^+ to bind with a cyclic hydrogen bonding array), electrostatic interactions of H_3O^+ with the two anions, and hydrogen bonding of H_3O^+ with the amine.

[s]Based on hydrolysis, pK_a values, pK_w, encounter (two ways for the amine to encounter formate ion, three ways for hydronium hydroxide to form an ion pair, one way for this ion pair to bind with a cyclic hydrogen bonding array), electrostatic interactions of H_3O^+ with the two anions, and hydrogen bonding of H_3O^+ with formate ion and with HO^- and of HO^- with the amine.

[t]Based on hydrolysis, encounter of HO^- with formic acid (two ways this could happen), and hydrogen bonding between formic acid and HO^-.

[u]Based on hydrolysis and pK_a values.

[v]Based on encounter (two ways for hydronium to encounter the amide) and hydrogen bonding of H_3O^+ to the amide carbonyl.

[w]Based on encounter (two ways for hydronium to encounter the amide, three ways for the hydronium hydroxide pair to form, two ways for this ion pair to encounter the amide), electrostatic interactions, hydrogen bonding of H_3O^+ to the amide carbonyl and of H_3O^+ to HO^-, and desolvation of the HO^-.

[x]Based on hydration of the amide, pK_a values, encounter of H_3O^+ with the tetrahedral intermediate (two mechanistically significant positions), electrostatic interactions, and hydrogen bonding of H_3O^+ to the anionic end of the zwitterion.

[y]Based on the pK_a value for the amide.

[z]Based on hydration, pK_a values, encounter (three ways for hydronium to encounter the new OH, two mechanistically significant ways for hydronium to encounter the new oxyanion), and hydrogen bonding of H_3O^+ to the anion of the tetrahedral intermediate and of H_3O^+ to the hydroxyl of this intermediate.

[aa]Based on pK_a values, encounter (three ways for the hydronium hydroxide pair to form, two ways for this ion pair to encounter the amide), hydrogen bonding of H_3O^+ to HO^-, and desolvation of the HO^-.

[ab]Based on hydration and the pK_a value.

TABLE 6 (*continued*)

[ac]Based on hydration and encounter (three ways for hydronium to encounter the new OH).

[ad]Based on hydration, encounter (one way for hydronium to encounter the nitrogen of the tetrahedral intermediate), and hydrogen bonding of H_3O^+ to this nitrogen.

[ae]Based on hydration and the pK_a value.

[af]Based on hydrolysis pK_a values, encounter (two ways for amide ion to encounter formic acidium ion, one way for hydronium ion to encounter the amide ion), electrostatic interactions of amide ion with H_3O^+ and formic acidium ion, hydrogen bonding of H_3O^+ and the amide ion, and desolvation of the amide ion.

[ag]Based on hydration, pK_a values, encounter (three ways for H_3O^+ to encounter the oxyanion of the tetrahedral intermediate, one way for H_3O^+ to encounter the nitrogen of the intermediate), hydrogen bonding between H_3O^+ and the oxyanion of the tetrahedral intermediate and H_3O^+ to the nitrogen of the intermediate, and electrostatic interactions.

[ah]Based on hydrolysis, the pK_a value, and encounter (two ways for amine to encounter formic acidium ion).

[ai]Based on hydration, pK_a values, encounter (three ways for H_3O^+ to encounter the oxyanion of the tetrahedral intermediate), hydrogen bonding of H_3O^+ to the oxyanion of the tetrahedral intermediate, and electrostatic interactions.

[aj]Based on hydrolysis, pK_a values, encounter (two ways for the amide ion to encounter formic acid, two ways for H_3O^+ to encounter the carbonyl of formic acid, one way for H_3O^+ to encounter the amide ion), hydrogen bonding between H_3O^+ and the carbonyl of formic acid and H_3O^+ and the amide ion, electrostatic interactions, and desolvation of the amide ion.

[ak]Based on hydrolysis, encounter (two ways for H_3O^+ to encounter the carbonyl of formic acid, one way for the amine to encounter formic acid), and hydrogen bonding of H_3O^+ to the carbonyl of formic acid.

[al]Based on hydration, pK_a values, encounter (three ways HO^- can encounter the hydroxyl of the tetrahedral intermediate), hydrogen bonding between HO^- and the hydroxyl of the tetrahedral intermediate, and electrostatic repulsion between the negative charges.

[am]Based on hydration and pK_a values.

[an]Based on hydrolysis, pK_a values, encounter (two ways HO^- can encounter formic acid and two ways the amide ion can encounter formic acid), hydrogen bonding between HO^- and formic acid, electrostatic interactions, and desolvation of the amide ion.

[ao]Based on hydration, pK_a values, encounter (three ways HO^- can encounter the hydroxyl of the tetrahedral intermediate, one way HO^- can encounter the ammonium of the tetrahedral intermediate), hydrogen bonding between HO^- and the hydroxyl of the tetrahedral intermediate and HO^- and the ammonium of the tetrahedral intermediate, and electrostatic interactions.

[ap]Based on hydrolysis, pK_a values, encounter (two ways the amide ion can encounter formate ion), electrostatic repulsion between the anions, and desolvation of the amide ion.

[aq]Based on hydration, pK_a values, encounter (one way HO^- can encounter the ammonium ion of the tetrahedral intermediate), hydrogen bonding between HO^- and the ammonium ion of the tetrahedral intermediate, and electrostatic interactions.

[ar]Based on hydrolysis, pK_a values, encounter (two ways HO^- can encounter formic acid, two ways the amine can encounter formic acid, one way the HO^- can encounter the amine), hydrogen bonding of HO^- with formic acid and of HO^- with the amine, and electrostatic repulsion between the two HO^- ions.

[as]Based on hydrolysis, pK_a values, encounter (two ways the amine can encounter formate ion, one way HO^- can encounter the amine), hydrogen bonding between HO^- and the amine, and electrostatic repulsion between HO^- and formate ion.

[at]Based on encounter (two ways aniline can encounter an aldehyde).

[au]Based on pK_a values, encounter (three ways hydronium ion can encounter anilide ion, and two ways this complex can encounter an aldehyde), hydrogen bonding between H_3O^+ and anilide, ion pairing, and partial desolvation of anilide ion.

[av]Based on addition and pK_a values.

[aw]Based on pK_a values, encounter (three ways hydronium hydroxide can form, two ways aniline can encounter an aldehyde, and two ways the hydronium hydroxide pair can form a cyclic hydrogen-bonded complex with the amine aldehyde pair), hydrogen bonding of H_3O^+ with HO^- and with aldehyde and of HO^- with aniline, and ion pairing.

[ax]Based on pK_a values, encounter (two ways HO^- can encounter protonated aldehyde, and two ways aniline can encounter aldehyde), hydrogen bonding of HO^- and protonated aldehyde, and ion pairing.

TABLE 6 (*concluded*)

[ay]Based on addition, pK_a values, encounter (two ways H_3O^+ can encounter the tetrahedral intermediate oxyanion and form a cyclic hydrogen bond array), hydrogen bonding of H_3O^+ and the tetrahedral intermediate oxyanion, and ion pairing.

[az]Based on pK_a values, encounter (two ways anilide can encounter the aldehyde and two ways H_3O^+ can encounter the carbonyl oxygen), hydrogen bonding of H_3O^+ to aldehyde, ion pairing, and partial desolvation of the anilide.

[ba]Based on pK_a values, encounter (three ways H_3O^+ and HO^- can encounter, two ways anilide can encounter protonated aldehyde, and two ways the two pairs can meet and form a cyclic hydrogen-bonded array), hydrogen bonding of H_3O^+ to HO^- and to anilide and of HO^- to protonated aldehyde, electrostatic interactions in the ion quartet, and partial desolvation of the anilide.

[bb]Based on addition, pK_a values, encounter (three ways the H_3O^+ and HO^- can encounter, and two ways this pair can form a cyclic hydrogen-bonded array with the zwitterion), hydrogen bonding of H_3O^+ with HO^- and the oxyanion and of HO^- with the ammonium ion, and electrostatic interactions in the ion quartet.

[bc]Based on addition, pK_a values, encounter (two ways HO^- can encounter the hydroxyl of the tetrahedral intermediate), hydrogen bonding of HO^- with this hydroxyl, and ion pairing.

[bd]Based on pK_a values, encounter (two ways aniline can encounter protonated aldehyde, and two ways hydroxide can encounter aniline in this complex), hydrogen bonding of HO^- and aniline, and ion pairing.

[be]Based on addition, pK_a values, encounter (two ways H_3O^+ can encounter the oxyanion of the tetrahedral intermediate and form a cyclic hydrogen-bonded array), hydrogen bonding of H_3O^+ to the oxyanion of the tetrahedral intermediate, and ion pairing.

[bf]Based on addition, pK_a values, encounter (three ways H_3O^+ and HO^- can encounter, and two ways this pair can encounter the tetrahedral intermediate), hydrogen bonding of H_3O^+ to HO^- and to the amine and of HO^- to the hydroxyl, and ion pairing.

[bg]Based on pK_a values, encounter (two ways anilide can encounter protonated aldehyde), ion pairing, and partial desolvation of the anilide.

[bh]Based on addition, pK_a values, encounter (two ways HO^- can encounter the ammonium of the tetrahedral intermediate), hydrogen bonding of HO^- and the ammonium of the tetrahedral intermediate, and ion pairing.

[bi]Based on addition.

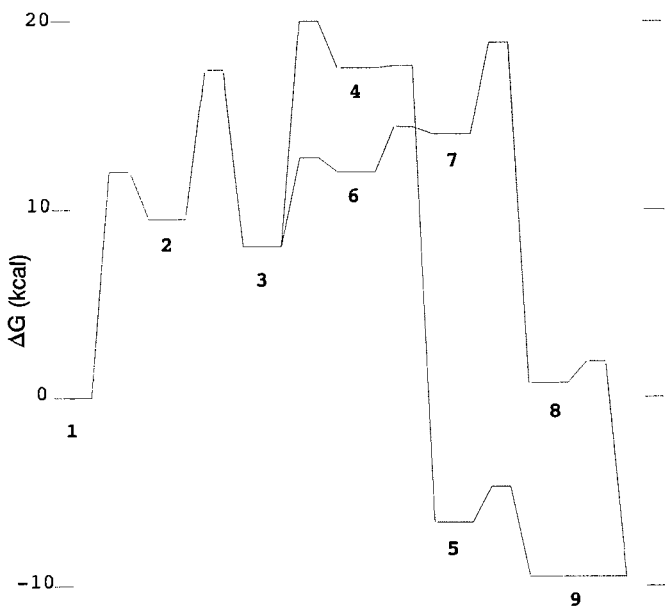

FIG. 2. Reaction coordinate diagram for the alkaline hydrolysis of *N*-methylformanilide. Species are identified in Scheme 3.

anionic intermediate to products by way of the anionic zwitterion, we obtain a predicted free energy of activation of 4.35 kcal/mol relative to the anionic intermediate or 21.91 kcal/mol relative to starting materials. This transition state is lower in energy than that for hydroxide addition, predicted to be 22.8 kcal/mol relative to starting materials; the observed transition state is at 22.56 kcal/mol relative to starting materials. The agreement is satisfactory, and we predict relatively little exchange, which is in accord with what is known. The detailed reaction coordinate diagram for this reaction is shown in Fig. 3, based on the mechanism, shown in Scheme 4.

We return to *N*-methylformanilide to discuss the rate of acid-catalyzed hydrolysis. We assume a general mecha-

nism for this addition starting with the hydrogen-bonded complex of hydronium ion and the amide oxygen, and proceeding through possibly concerted proton transfer from hydronium to amide oxygen, addition of water, and loss of proton from this water to a second water molecule. We use Multidimensional Marcus Theory to predict which steps will have occurred before, or be occurring at the transition state. The calculated free energy of activation is 19.76 kcal/mol (relative to separate starting materials), and the transition state has almost complete proton transfer from hydronium to carbonyl oxygen, but only a small extent of proton transfer from the nucleophilic water to the general base water. Breakdown of the *N*-protonated tetrahedral intermediate is similarly predicted to have a free energy of activation of 20.88 kcal/mol relative to anilide plus hydronium ion. These results would predict ^{18}O exchange accompanying acid-catalyzed exchange of *N*-methylformanilide, which is contrary to observation. Brown and co-workers have studied the kinetics of acid-catalyzed hydrolysis and accompanying ^{18}O exchange of acetanilide (2) and *N*-methylformanilide.[2] For *N*-methylformanilide they found no detectable exchange. From the rate constants for hydrolysis of acetanilide at 72°C, taken as 3.41×10^{-6} M^{-1} s^{-1} (based on kinetics in dilute HCl (2), and at 25°C, taken as 2.81×10^{-6} s^{-1} (based on a rate constant at 1.42 M HCl, the pK_{BH^+} and H_A for HCl solutions (37)) we calculate the rate factor, $k_{72°C}/k_{25°C}$, to be 121. We assume the same rate factor for *N*-methylformanilide, and from the rate constant at 72°C, 2.18×10^{-2} M^{-1} s^{-1} (based on kinetics in dilute HCl[2]), we estimate a rate constant at 25°C of 1.80×10^{-4} M^{-1} s^{-1}, leading to a value of 22.57 kcal/mol for $\Delta G^{\ddagger}$. Again we observe that the calculated value is about 2 kcal too low. The difference between the energies of the transition states for reversion to starting material and cleavage to products was only 1.12 kcal/mol, by contrast to the situation in base, where the predicted difference was 2.6 kcal/mol. Furthermore, in acid the transition state for cleavage involves C—N bond breaking, and therefore its energy is dependent upon the intrinsic barrier for C—N bond breaking involving *N*-methylaniline. We were forced to use a barrier based on aniline for lack of suitable information for reactions of *N*-methylaniline. If the intrinsic barrier for *N*-methylaniline were a few kcal/mol smaller, the relative heights of the transition states would be correct. Since methanol/methoxide has a smaller intrinsic barrier for addition to a carbonyl than water/hydroxide (20), this is not impossible. In any case the prediction of ^{18}O exchange in acid is much weaker than the prediction of ^{18}O exchange in base. When the uncertainties in the energy levels are considered, all we can really say is that in acid ^{18}O exchange might be observable but would be of modest importance at best. The calculations depend on imperfectly known terms for encounter, hydrogen bonding, electrostatic interactions, and p*K*a's of various reaction intermediates. The detailed reaction coordinate diagram for this reaction is given in Fig. 4, based on the mechanism shown in Scheme 5.

In general, although the agreement between predicted and observed free energies of activation is within the experimental uncertainty in the energy levels of the tetrahedral intermediates, the predicted values are consistently low by a bit over 2 kcal. This suggests that our tetrahedral intermediate free energies are too low by a similar amount.

Experimental

Materials

N-Methylaniline (Aldrich) was redistilled before use: bp 84–85°C, 15 Torr. *N*-Methylformanilide was prepared by the Organic Synthesis (38) procedure, bp 117–119°C, 8 Torr; ^1H nmr (60 MHz,

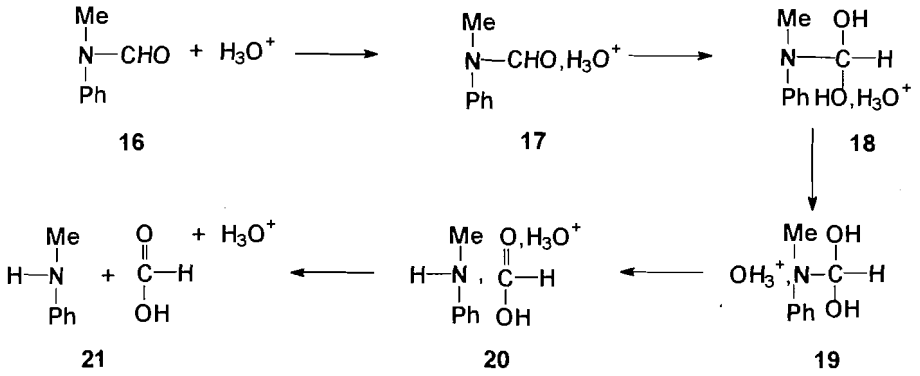

SCHEME 5. Mechanism for acid hydrolysis of *N*-methylformanilide.

$CDCl_3$) δ: 3.30 (s, 3H, NCH_3), 7.28 (m, 5H, aromatic H), 8.44 (s, 1H, formyl H).

N-*Methylformanilide dimethyl acetal*

A mixture of *N*-methyl formanilide (11.1 g, 82.5 mmol), trimethyloxonium tetrafluoroborate (39) (12.2 g, 82.5 mmol), and dry methylene chloride (100 mL) in a 500-mL three-necked flask was stirred at room temperature under a dry nitrogen atmosphere. After 3 h all of the trimethyloxonium tetrafluoroborate had dissolved and a 60 MHz ^{1}H nmr spectrum indicated that all the formanilide had been converted to oxonium salt. The reaction mixture was then cooled in a Dry Ice – acetone bath and a solution of sodium (1.9 g, 82.6 mmol) in anhydrous methanol was added dropwise over 30 min. The contents of the flask were then allowed to warm to room temperature and the solution separated from solid by centrifugation. Solvent was removed by flash distillation at 40 Torr using a 10°C water bath and the residue was stored in a freezer under a dry nitrogen atmosphere. The residue was purified by distillation, yielding 10 mL of a clear colourless liquid with bp 86–88°C at 3 Torr. This was redistilled for calorimetry, bp 86–88°C at 1.5 Torr, 70–71°C at 0.6 Torr, 63–64°C at 0.5 Torr; ^{1}H nmr (200 MHz, $CDCl_3$) δ: 2.86 (s, 3H, NCH_3), 3.32 (s, 6H, OCH_3), 5.36 (s, 1H, formyl H), 6.87 (m, 3H, aromatic H), 7.24 (m, 2H, aromatic H).

Formohydroxamic acid was prepared by the method of Bernhard et al. (40): mp 75–77°C, (lit. (40) mp 77.5°C; (4) mp 75–77°C). Hydroxylamine hydrochloride (Aldrich), potassium chloride (Baker), and potassium hydroxide (BDH) were used without further purification.

N-*Methyl*-N-*(2,2,2-trifluoroethyl)-aniline*

N-Methyl-*N*-phenyltrifluoroacetamide was prepared by the literature method (41); mp 26–27°C, satisfactory nmr. The amide was reduced, following Gribble et al. (42), by sodium borohydride – trifluoroacetic acid in dry THF, to give *N*-methyl-*N*-trifluoroethylaniline, bp 90°C at 19.5 Torr (lit. (42) bp 54°C at 0.4 Torr).

Methods

The calorimeter was modified to increase the stability of the base line and permit accurate determination of heats of reaction for slow reactions. A box was constructed surrounding the Dewar flask (20 cm × 20 cm × 40 cm). This box contains a coil for cooling water made of copper tubing surrounding, 2 cm away from, and up to the height of the Dewar flask. In a lower corner of the box is a coil of 1 ft of Nichrome wire (total resistance of wire 3 ohms) connected to a Powerstat variable transformer. One upper corner contains a small fan and in a second upper corner is a thermometer (24–30°C) with a Thermo-Watch detector (L6-1000) attached. A Powerstat is plugged into the Thermo-Watch and set at 8% of full voltage. Thus the internal air temperature of the box is regulated and routinely maintained at 24.00 ± 0.03°C. Cables connected to the solvent heating coil, the thermistor, and the solvent stirrer pass through holes in the box; a door allows access to the sample injection hole in the lid of the Dewar.

This modification has eliminated the influence of the variable room temperature on the temperature of the solution in the calorimeter. The temperature vs. time trace is now consistently a straight line instead of often being a curve. At the beginning of a set of measurements with a batch of solvent the temperature can be set slightly below 24°C so that there is a slow increase in the temperature vs. time trace. The calorimeter can be calibrated by passing a known amount of current through a heating resistor, and heats of reaction or heats of solution of samples can be measured with a gradual but quite explicable decrease in slope of the temperature vs. time trace.

Initial attempts at measuring the heat of hydrolysis of *N*-methylformanilide dimethyl acetal in 0.1 N sodium hydroxide in water were unsuccessful because the acetal was very slow to dissolve and the temperature vs. time trace did not return to its pre-injection slope until about 1.5 h after injection. An attempt was made to increase the solubility by using 0.1 N tetraethylammonium hydroxide in 90% DMSO, 10% water. There was no change in slope of the temperature vs. time trace upon injection of acetal. There was simply a very small instantaneous displacement of the line toward a lower temperature. This displacement presumably reflects the heat of solution. When the reaction solvent was 0.1 N sodium hydroxide in 50% DMSO, 50% water, reaction occurred but took appreciable time to occur. The temperature vs. time trace had returned to the pre-injection slope after about 20 min. The deflection was measured as the distance between the pre- and post-injection lines at the time of injection. We presume that at this solvent composition the solubility and the rate of reaction are adequate, although time is required for dissolution.

The solubility of *N*-methylformanilide in pH 7 aqueous phosphate buffer, ionic strength 0.1 M, was determined by ^{1}H nmr spectroscopy, integrating the signals from the *N*-methyl relative to the signal from 0.098 M *tert*-butyl alcohol added as an internal standard. There were two *N*-methyl singlets in a ratio of 6:1 attributed to the geometrical isomers of the amide. The same solubility was determined by integrating the formyl proton relative to the *tert*-butyl alcohol.

N-Methylformanilide dimethyl acetal used for calorimetry in aqueous methanol was found to contain 5 mol% of methanol and methyl formate; thus it had a purity of 97 mass percent.

Heat of reaction for amide formation and transamidation

The equilibrium constant for the reaction of *N*-methylaniline with formohydroxamic acid to give *N*-methylformanilide and hydroxylamine was studied at 25, 35, and 45°C in order to determine the heat of reaction. The procedure of Fersht and Requenna was used; because the reactions are slow and there seem to be side reactions, the initial changes in concentration of *N*-methylformanilide and formohydroxamic acid, for reactions starting with no *N*-methylformanilide and no formohydroxamic acid, respectively, were used to determine the equilibrium constant (4). In all cases the formohydroxamic acid concentration was determined by the ferric

For personal use only.

hydroxamate assay, as described below. The initial slope of absorbance vs. time was determined for each solution. Points taken at short times deviated from the line, presumably because of the delay for temperature equilibration within an ampoule; these points were discarded, as were points at long times when deviations from the initial slope became severe. The results are found in Table 2.

The formation of formohydroxamic acid was studied at 25, 35, and 45°C in order to determine the heat of reaction. At each temperature the equilibrium was approached from both directions. The procedure of Fersht and Requenna (4) was followed. Each initial solution was sealed in an ampoule and thermostatted for a suitable period until equilibrium was attained. This required 17 h at 45.9°C, 33 h at 35°C, and 62 h at 24.9°C. An ampoule was cooled to room temperature, opened, and 500 μL added to 2.0 mL of ferric chloride solution (20% by mass in 1.4 M HCl) contained in a 1.000-cm uv cell. The absorbance of the ferric hydroxamate solution was read 2.0 min after adding the ferric chloride solution. Absorbance readings were calibrated by performing the same analysis using a standard solution of formohydroxamic acid in water. The results are found in Table 3. Our conditions closely match those reported by Fersht and Requenna, and our results are in good agreement at 25°C as to the extent of formohydroxamic acid formation. The apparent equilibrium constant is K_{app} = [CHONHOH][H^+]/[NH_3OH^+][HCOOH]: Fersht reports (4) $K_{app} = 4.47 \times 10^{-3}$ [H^+]; we find $K_{app} = 4.11 \times 10^{-3}$[$H^+$] (starting with no formohydroxamic acid) and $K_{app} = 4.29 \times 10^{-3}$ [H^+] (starting with 0.0202 M formohydroxamic acid). However, Fersht reports a final pH of 0.75, which was used to calculate an effective [H^+] = 10^{-pH} in calculating the final equilibrium constant. We obtain a pH of 0.91 or 0.93, calibrating our meter against 0.1 N HCl, taken as pH 1.1 (43). It seems clear that there are serious deviations from ideality, because the expected H^+ concentration, using a pK_a for formic acid (25) corrected for the effect of 1 M ionic strength using the Davies equation (44), is 0.107, and the activity coefficient for H^+, estimated using the Davies equation, is 0.699. Thus one would have expected pH = $-\log a_{H^+}$ = 1.13. The solvent, with 2 M formic acid, is no longer water, and this must be perturbing the activity coefficients. Acidity function studies (45) led to an H_0 value of 1.54 for 2 M formic acid. Taken at face value, this suggests that the effective pK_a of formic acid has become more acidic in this mixed solvent. This would increase the concentration of H^+, but only modestly; the HCl contribution would still dominate. To use a pK_a value for hydroxylammonium ion based on aqueous solution, even though it was determined at 1 M ionic strength, to calculate the concentration of free hydroxylamine, seems optimistic. Unfortunately we do not see a better way to extract the true equilibrium constant from these results. Rather than confuse the literature we will use Fersht's value for the equilibrium constant for formohydroxamic acid formation at 25°C.

Measurement of free energy of transfer for N-*methyl*-N-*(2,2,2-trifluoroethyl)-aniline*

The solubility was determined by measuring the concentration of a saturated solution in 0.1 N NaOH, by determining the uv absorbance at 243 nm, $\epsilon = 1.48 \times 10^4$ M^{-1} cm^{-1}. The value obtained was 6.89×10^{-4} M. The vapor pressure was determined using a semimicro ebulliometer (46); the values obtained were: bp(°C)/*p*(Torr); 77.8/10.7; 90.0/19.5; 104.2/36.0; 111.4/48.3; 119.0/61.3; 124.8/82.0; 130.0/101.8; 135.0/121.5; 140.0/143.5. These data were transformed to $\log_{10} p$, $1/T$(K), and fitted to $\log_{10} p = 2624/T + 8.505$; this allows extrapolation to give the vapor pressure at 25°C as 0.504 Torr.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada for financial support of this work. We thank Professor R.A. McClelland for kindly providing a sample of *N*-methylformanilide dimethyl acetal for our initial experiments. We thank Professor R.S. Brown for providing rate constants for hydrolysis and exchange of *N*-methylformanilide in advance of publication.

Energetics of acetic acid enol in aqueous solution. A new method for thermodynamic estimation

J. Peter Guthrie
Department of Chemistry, University of Western Ontario, London, ON N6A 5B7, Canada

Received May 26, 1993

J. Peter Guthrie. Can. J. Chem. **71**, 2123 (1993).

A new disproportionation calculation allows the estimation of the free energy of formation of the enol of acetic acid as 65 ± 2 kcal/mol. The value of pK_E derived from this free energy, $pK_E = 21 \pm 2$, is in satisfactory agreement with information from the literature about rates of exchange. Analysis of the data on rates of exchange of the C-H protons of acetic acid using Marcus theory allows an independent estimate of the enol content. Exchange in acid and in base lead to internally consistent estimates, $pK_E = 19.3 \pm 2.2$, which are within the combined uncertainties of the values from the thermodynamic estimate.

J. Peter Guthrie. Can. J. Chem. **71**, 2123 (1993).

Un nouveau calcul de dismutation permet d'évaluer que l'énergie libre de formation de l'énol de l'acide acétique est égale à 65 ± 2 kcal/mol. La valeur du pK_E, 21,2 ± 2, que l'on peut obtenir à partir de cette énergie libre est en bon accord avec l'information disponible dans la littérature au sujet des vitesses d'échange. L'analyse des données sur les vitesses d'échange des protons C-H de l'acide acétique réalisée à l'aide de la théorie de Marcus permet une évaluation indépendante de la quantité d'énol. Les échanges en milieux acide et basique conduisent à des évaluations autocohérentes, $pK_E = 19{,}3 \pm 2{,}2$, qui sont à l'intérieur des limites des incertitudes combinées des valeurs obtenues par des évaluations thermodynamiques.

Introduction

Accurate values for the enol contents of simple aldehydes and ketones have been determined by Kresge and Wirz (1–4). Recently Kresge also determined the enol content of mandelic acid (5).

The techniques used to generate the enol appear to require the presence of the α-hydroxyl group, and will not easily be generalized to give the simplest carboxylic acid enol, that of acetic acid. The enol content of mandelic acid is very small, so that indirect methods for determining the enol content are difficult at best. Accordingly, it seemed of interest to devise ways to estimate the enol content of very simple carboxylic acids, as a possible guide to experimentation. I wish to report such a method, based on a novel application of the idea of disproportionation. It is also possible to calculate the enol content from exchange data, by making use of Marcus theory (6–8). This procedure leads to results consistent with those of the disproportionation assumption.

Results and discussion

Disproportionation

The basis of this approach is the assumption that the free energy change for process [1] will be approximately zero.

[1] $CH_2{=}CX_2 + 2\ Ph\text{-}OH \rightleftharpoons CH_2{=}C(OH)_2 + 2\ Ph\text{-}X$

This assumption is only plausible if X has an electronegativity very similar to that of oxygen, so that all interactions on the left-hand side of the equation are closely balanced by the analogous interactions on the right-hand side. In effect this limits X to being F or Cl, which have electronegativities similar to O, and are also similar in size.

The basis of this assumption can be tested by seeing how well the available data support the related assumption, that the free energy change for process [2] will be approximately zero.

[2] $CH_2{=}CXR + Ph\text{-}OH \rightleftharpoons CH_2{=}C(OH)R + Ph\text{-}X$

Data are available for R=H, X=Cl, F, and for R=CH_3, X=Cl; all thermodynamic data are given in Table 1. For each case we have calculated the free energy of formation of $CH_2{=}C(OH)R$ assuming that the change in free energy for process [2] is zero, and have compared this with the known free energy of formation. The results, Table 2, show that within about 2 kcal/mol the assumption for process [2] appears to be valid; the most serious discrepancy is for acetone enol, for which the corresponding chloro compound has a large uncertainty in ΔG_f^0(aq). This encourages one to look at the results of applying the same procedure to process [1] and thus predicting the free energy of formation for $CH_2{=}C(OH)_2$. When this is done, Table 2, we obtain two quite similar estimates, leading to a predicted value of −65 ± 2 kcal/mol for the free energy of formation of the enol of acetic acid in aqueous solution. This value, combined with the free energy of formation in aqueous solution of acetic acid itself, −94.35 kcal/mol (9), leads to a free energy change for the enolization shown in process [3] of +29 ± 2 kcal/mol, or to a $pK_E = 21$.

[3] $CH_3\text{-}COOH \rightleftharpoons CH_2{=}C(OH)_2$

There might be a geminal effect (anomeric effect) that, if substantial, would invalidate the disproportionation assumptions. This can be tested by comparison of the situation in process [4] for which geminal effects are known (10–12) with that in process [5].

[4] $CH_2X_2 + CH_4 \rightleftharpoons 2\ CH_3X$

[5] $CH_2{=}CX_2 + CH_2{=}CH_2 \rightleftharpoons 2\ CH_2{=}CHX$

Free energies of formation are available for both processes for X = Cl or F, and for process [4] with X = OCH_3; the values are given in Table 1.

For process [4], $\Delta G^0 = +9.3 \pm 2.7$ kcal/mol for X = F, -1.12 ± 0.44 for X = Cl, and $+9.33 \pm 0.37$ for X = OCH_3. For process [5], $\Delta G^0 = -3.39 \pm 1.26$ kcal/mol for X = F and -0.83 ± 0.61 for X = Cl.

TABLE 1. Thermodynamic data for compounds discussed in this paper[a]

(*a*) Compounds for which the free energy of formation in aqueous solution has not been reported

Compound	ΔH_f^0(g)	S^0(g)	ΔG_f^0(g)	ΔG_t	ΔG_f^0(aq)
Fluoromethane	−56.8 ± 2.	54.25 ± 0.3	−51.07	1.68 ± 0.5	−49.39 ± 2.06
Chloromethane	−19.57 ± 0.12	56.04 ± 0.3	−13.98	1.34 ± 0.1	−12.64 ± 0.18
Difluoromethane	−108.08 ± 0.22	58.94 ± 0.3	−101.45	1.48 ± 0.5	−99.97 ± 0.55
Dichloromethane	−22.85 ± 0.29	64.59 ± 0.3	−16.51	0.49 ± 0.1	−16.02 ± 0.32
Fluoroethene	−33.17 ± 0.41	60.39 ± 0.3[b]	−29.17	1.81 ± 0.1	−27.36 ± 0.43
Chloroethene	8.91 ± 0.31	63.08 ± 0.3	12.82	1.31 ± 0.1	14.13 ± 0.34
1,1-Difluoroethene	−80.07 ± 1.08	63.38 ± 0.3	−74.36	3.53 ± 0.1	−70.83 ± 1.08
1,1-Dichloroethene	0.62 ± 0.31	68.85 ± 0.3	6.10	3.49 ± 0.1[c]	9.59 ± 0.34
2-Chloro-1-propene	−5.02 ± 2.25	70.84 ± 0.3[d]	6.28	1.31 ± 1.0[e]	7.59 ± 2.46
Fluorobenzene	−27.72 ± 0.33	72.33 ± 0.3	−16.35	1.07 ± 0.1	−15.28 ± 0.36
Chlorobenzene	12.43 ± 0.31	74.92 ± 0.3	23.73	0.78 ± 0.1	24.50 ± 0.34

(*b*) Compounds for which the free energy of formation in aqueous solution has been reported[f]

Compound	ΔG_f^0(aq)	Compound	ΔG_f^0(aq)
Methane	−8.14 ± 0.16	Ethenol	−24.84 ± 0.21
Ethene	19.50 ± 0.16	1-Propen-2-ol	−27.02 ± 0.21
Acetic acid	−94.35 ± 0.38	Phenol	−12.60 ± 0.25
Dimethyl ether	−27.00 ± 0.18	Dimethoxymethane	−55.19 ± 0.23

[a]All at 25°C, enthalpies and free energies are in kcal/mol, entropies are in cal deg^{-1} mol^{-1}, standard states are the ideal gas at 1 atm and 1 M aqueous solution with an infinitely dilute reference state. Unless otherwise noted, enthalpies of formation are from ref. 36, and entropies are from ref. 37. Unless otherwise noted, free energies of transfer are calculated from solubilities from ref. 38, and vapor pressures from ref. 39. Free energies of formation are calculated from other values in the table.

[b]Reference 40.

[c]Calculated using a vapor pressure estimated by extrapolation from data in ref. 41.

[d]Reference 42.

[e]Estimated by additivity, assuming that the methyl increment from chloroethene to 2-chloropropene will be the same as from ethene to propene.

[f]All from ref. 9.

TABLE 2. Free energy changes (kcal/mol) for isodesmic reactions

	Prediction[a]	Observed value[b]	Difference
Fluoroethene	−24.67 ± 0.61	−24.84 ± 0.21	0.17
Chloroethene	−22.98 ± 0.54	−24.84 ± 0.21	1.86
2-Chloro-1-propene	−29.52 ± 2.50	−27.02 ± 0.21	−2.50
1,1-Difluoroethene	−65.46 ± 0.62		
1,1-Dichloroethene	−64.62 ± 0.60		

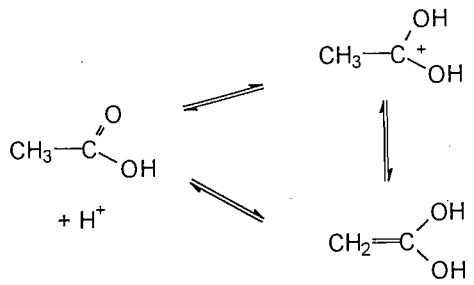
[a]Based on disproportionation as described in the text, using free energy of formation values in Table I. Errors are calculated using the experimental errors in free energy values with no contribution for the uncertainty in the assumed free energy change of zero for the disproportionation reaction.

[b]From Table 1.

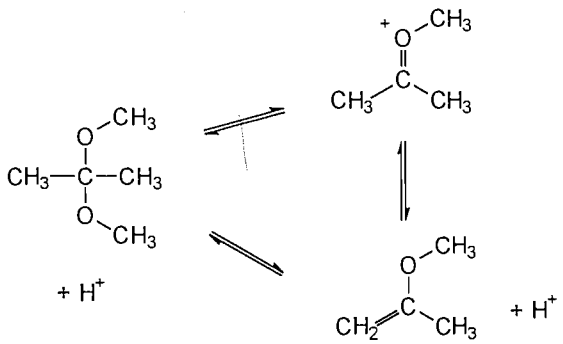
The message seems to be that there can be important geminal effects stabilizing CX_2 for sp^3 carbon when X is F or OCH_3, but that such effects are much smaller and *destabilizing* for sp^2 carbon. Furthermore, the difference between the destabilizing effect for F and Cl is only 2.56 ± 1.40 kcal/mol whereas the difference between the effects at sp^3 carbon for F and Cl was 10.4 ± 2.7 kcal/mol.

Thus it seems quite reasonable to expect *small* perturbations from this sort of interaction for process [1] where the *number* of electronegative substituents remains the same. Since the two examples of process [1], X = Cl and X = F, led to very similar estimates of the free energy of formation of $CH_2{=}C(OH)_2$ it seems likely that this is justified.

There have been various molecular orbital calculations addressing the question of the enol content (in the gas phase) of acetic acid, but the calculations for the most part were not



SCHEME 1



SCHEME 2

at a level that compels belief. Only ΔE was calculated but, assuming that the entropy change is small (13), these values can be translated into pK_E as follows: Nguyen and Hegarty (14), pK_E = 20.5 (STO-3G) (at this level, pK_E for acetaldehyde is predicted to be 13.5 (46), where the experimental value (gas phase) is 6.66 (15)); Heinrich et al. (16), pK_E = 26 (6-31G*) (at this level pK_E for acetone is predicted to be 12.3 (16) where the experimental value is 7.69 (gas phase) (15); Andraos et al. (17), pK_E = 18.8 (3-21G) (at this level pK_E for acetaldehyde is predicted to be 6.2 (13), experimental 6.66 (15). Unfortunately, this good result is the consequence of fortuitous cancellation of errors because "better" calculations, even MP4SDTQ/6-31G**//6-31G**, lead to poorer agreement (13). The best theoretical estimate so far, including zero point corrections, leads to pK_E = 10.9 (18), which differs significantly from the experimentally derived value of 6.66 (15). Apeloig et al. (13) have suggested that the experimental value may be in error because of the necessarily indirect way it is calculated. If this is so, and pK_E is really 10.9 for acetaldehyde, then the 3-21G calculations are in error, and are likely to be so for acetic acid as well. At the MP4/6-31G** level, calculations give good results for heats of isodesmic reactions of saturated molecules (19) and thus may be used to calculate heats of formation, given suitable reference values. Such calculations are distinctly less satisfactory for unsaturated molecules, for which higher level CI corrections are essential (19). Thus none of the calculations of the enol content reported to date can be expected to lead to "thermochemical" precision, i.e., ±1 kcal/mol.

To convert a gas phase value of ΔE into a solution phase ΔG requires the entropies (which can generally be estimated with useful accuracy) and the free energies of transfer. Unfortunately there is as yet no experimental basis for estimating free energies of transfer. Direct determination is impossible for such reactive species. Indirect calculation requires free energies of formation in both gas and aqueous solution. If one attempts to calculate group additivity terms for free energies of transfer, there are data (15) allowing evaluation of [CdH(O)] = 2.2 or 6.1 kcal/mol, and [Cd(C)(O)] = 1.8 or −2.8 kcal/mol. In either case the uncertainty in the average value is 2 kcal or greater. This presumably reflects uncertainties in the gas phase values, because free energies of transfer are generally predicted quite well by group additivity (44). From Keefe and Kresge's analysis of enthalpy data in the gas phase and in solution (43), there is a difference of 2.7 kcal in the double bond stabilization effect of OH between gas phase and solution, which must be reflected in the free energy of transfer. At the present time estimation of free energies of transfer will have uncertainties of at least 2–3 kcal/mol.

Exchange data

Our value for the enol content of acetic acid can be compared with other information from the literature bearing on the question of the enol content of acetic acid. The rate constant for acid-catalyzed exchange is known. Data permitting evaluation of the intrinsic barrier are available. We will then use Marcus theory to evaluate the equilibrium constant.

From the rate constants for deuterium exchange into acetic acid at higher temperatures, Bok and Geib (20) reported a rate constant for acid-catalyzed exchange: $\log k_{H^+} = -9.98$ (k in $M^{-1}\ s^{-1}$). Estimation of the solvent deuterium kinetic isotope effect by the method of Schowen (21–23) leads to a kinetic isotope effect of 0.69, and a revised estimate of the rate constant of $\log k_{H^+} = -10.14$. The rate-determining step is presumably deprotonation at carbon of acetic acidium ion, for which the pK_a is −6.56 (24, 25); see Scheme 1. The rate constant for deprotonation of acetic acidium ion by solvent water is then $\log k = -3.58$.

Now we must calculate the intrinsic barrier for this sort of C-protonation/deprotonation. We will use the set of reactions shown in Scheme 2. The rate constant for protonation of 2-methoxypropene is known, 970 $M^{-1}\ s^{-1}$ (26). The equilibrium constant for oxocation formation from 2,2-dimethoxypropane can be calculated from the rate constant for hydrolysis of acetone dimethyl acetal, 2950 $M^{-1}\ s^{-1}$,[1] and the rate constant for trapping of the cation by methanol, $1.08 \times 10^6\ M^{-1}\ s^{-1}$, (27), as 0.0027. Free energies of formation of 2,2-dimethoxypropane, 2-methoxypropene, and methanol (9) are available, which allows calculation of the equilibrium constant for conversion of 2,2-dimethoxypropane to 2-methoxypropene plus methanol as $\log K$ (M) = −2.79. This is substantially less favorable than the corresponding equilibrium constant for conversion of acetophenone dimethyl acetal to its enol ether, $\log K$ (M) = −1.22 (45). It is then possible to calculate the equilibrium constant for C-protonation of 2-methoxypropene as 1.7 M^{-1}. With rate and equilibrium constants for protonation of 2-methoxypropene in hand we will be able to calculate an intrinsic barrier once we allow for the work term for the protonation reaction. The "work term" in Marcus theory is the energy cost of bringing reactants together in an encounter complex. We follow Hine (28) and estimate the work terms for bringing two species together with the reactive atom of one species

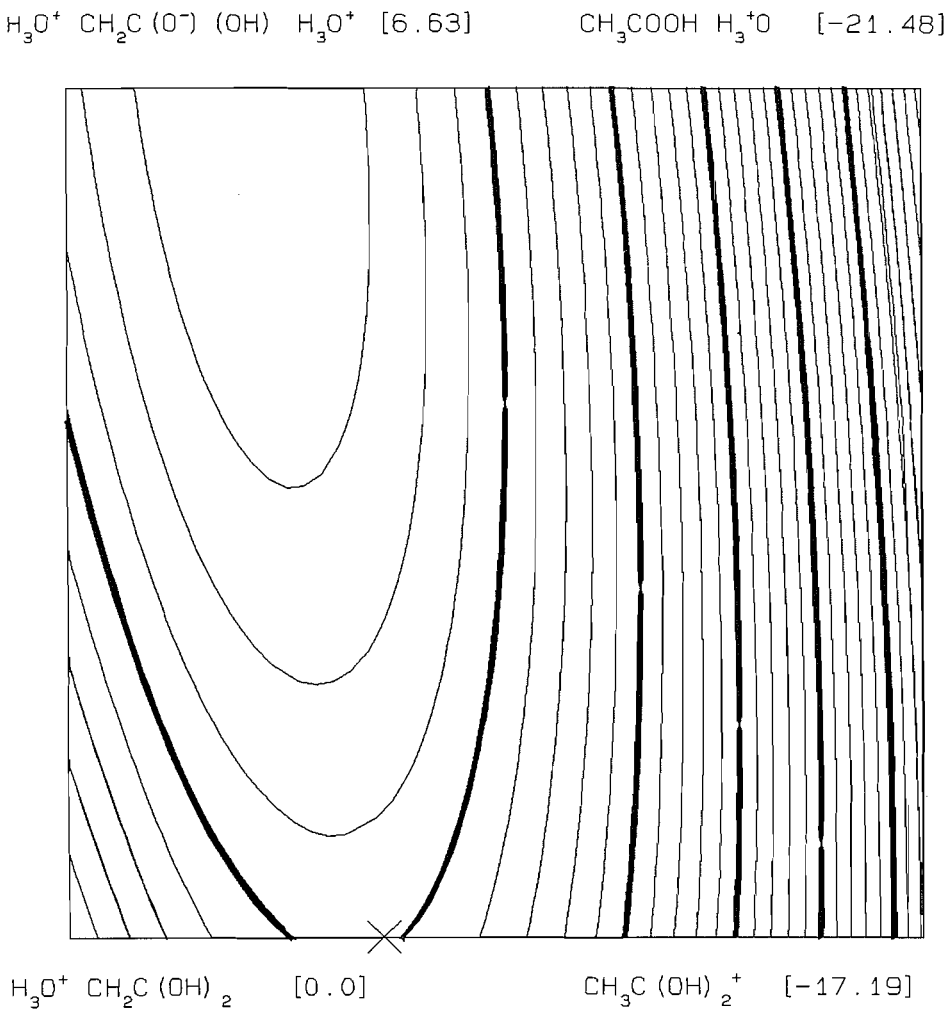

FIG. 1. Energy surface for protonation of acetic acid enol. Calculated using intrinsic barriers of 1 kcal/mol for oxygen to oxygen proton transfer and 12.3 kcal/mol for oxygen to carbon proton transfer. Contours are every kilocalorie with heavier contours every 5 kcal.

at either of two positions corresponding to the two lobes of the *p*-orbital of the other species, and with no net attraction or repulsion, as $K_{complex} = 0.017$ M. This assumes that there is hydrogen bonding of H_3O^+ to the π-cloud of the enol or enol ether, similar to the hydrogen bond of H_3O^+ to water. Given this assumed work term, the intrinsic barrier is 12.3 kcal/mol.

This barrier is expected to apply, at least approximately, to related reactions such as protonation of acetone enol or acetic acid enol. Now we can calculate the equilibrium constant for deprotonation at carbon of acetic acidium ion, and thence the equilibrium constant for enolization of acetic acid. To assess the sensitivity of the result to the value of the intrinsic barrier we assign an uncertainty of ±2 kcal/mol to this barrier. The value for the enolization equilibrium calculated as just described is $pK_E = 17.4 \pm 3$, in satisfactory agreement with the thermodynamic estimate. This analysis implies that protonation of the enol of acetic acid is much faster (log k (M^{-1} s^{-1}) is predicted to be 7.2) than protonation of ketene dimethyl acetal (log k (M^{-1} s^{-1}) was observed to be 5.86 (29)), because of the greater stability of acetic acidium ion relative to acetic acid enol than of methyl dimethoxymethylcarbenium ion relative to ketene dimethyl acetal. This is despite the expectation that methyl dimethoxymethylcarbenium ion will have at least a short lifetime, while acetic acidium ion will have no lifetime at all; it will lose a proton to water in less time than required for a vibration. Nonetheless an analysis using two-dimensional Marcus theory (6–8, 30, 31) suggests that the transition state for protonation of acetic acid enol is along the C-protonation edge: see Fig. 1.

We can also extract an estimate of the enol content from data for exchange catalyzed by OD^-. To do this we must consider the effect of ionization equilibria. Scheme 3 shows the various ionization and enolization processes possible for acetic acid. We assume that pK_1^0 will be 6.6 (5), the same as for mandelic acid enol, based on the very small substituent effect upon the pK_a of phenol by either *o*-phenyl or *o*-hydroxyl (32). We assume that substituent effects on the pK_a of a phenol are a suitable model for substituent effects on the pK_a of a carboxylic acid enol. Because this will not be exact we assign an uncertainty of ±1 to pK_1^0. pK_2^0 is estimated to be 11.6 ± 1.5 by applying Pauling's rules (33). Given these values and $pK_a^K = 4.76$ (32), K_1^C, K_2^E, and K_2^C are all calculable from K_1^E, and vice versa. The rate constant for the reaction of OD^- with CH_3COO^- is log $k = -8.25$ (20). Estimation of the solvent deuterium isotope effect for this process by the method of Schowen (21–23) using the frac-

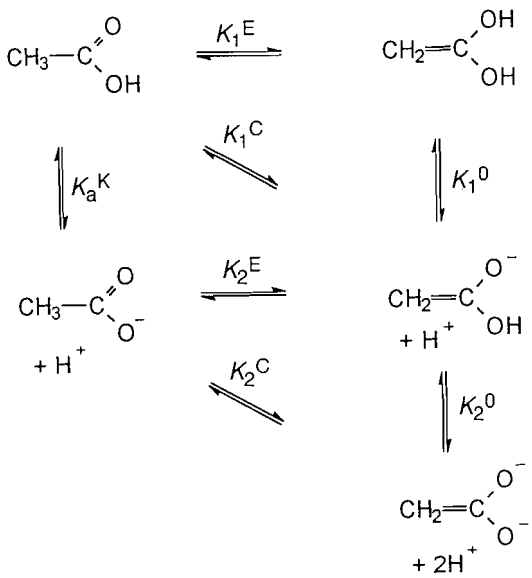

SCHEME 3

tionation factors for hydroxide ion and its solvating waters from Gold and Grist (34) leads to a kinetic isotope effect of 0.46, and a revised estimate of the rate constant of log $k = -8.59$. The intrinsic barrier for removal of the α-hydrogen from an aldehyde or ketone by hydroxide ion is 10.7 kcal/mol (35). This value is based on a work term calculated by assuming that the hydroxide must be partially desolvated, losing one hydrogen bond to water, in order to make contact with the hydrogen to be removed. Applying this value to the reaction with acetate leads to an equilibrium constant of log $K = 17.6 \pm 2.2$ or a $pK_2^E = 20.0 \pm 2.7$. Thence we can calculate $pK_1^E = 18.2 \pm 2.8$, in excellent agreement with the value derived from acid-catalyzed exchange of acetic acid.

The procedure that we have employed for estimation of free energies of formation by disproportionation seems to lead to reasonable answers, and could be employed to predict the free energies of formation of additional, currently interesting, enol intermediates if only there were thermodynamic data available for the corresponding halogen compounds. Since the latter are stable species there is no impediment, other than the work involved, in gathering these data, and this may prove to be the easiest way to get usefully accurate values for the corresponding enols. Exchange data provide an alternative general method, but represent a very large experimental effort.

After completing this work we learned that a kinetic determination of the pK_a of ethyl acetate[2] led to a value completely consistent with the enol contents reported here.

Received June 30, 1993

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **71**, 2129 (1993).

The syntheses of the sterically hindered *N,N'*-dihydroxyaminals; *N,N'*-bis(1-ethoxycarbonyl-1-methylethyl)-*N,N'*-dihydroxymethanediamine, **1***b*, and *N,N'*-bis(1,1-dimethylethyl)-*N,N'*-dihydroxymethanediamine, **1***c*, and their reactions with phenylboronic acid to yield the 1,3,5-trioxa-6,8-diaza-2,4-diboracyclooctanes **3** and **4**, respectively, are described. Crystals of **1***b* are tetragonal, a = 18.413(1), c = 9.867(2) Å, Z = 8, space group $I4_1$; those of **3** are monoclinic, a = 20.420(4), b = 8.272(4), c = 17.851(5) Å, β = 117.34(1)°, Z = 4, space group $C2/c$; and those of **4** are monoclinic, a = 9.493(4), b = 16.202(4), c = 14.783(3) Å, β = 101.90(2)°, Z = 4, space group $P2_1/c$. The structures were solved by direct methods and were refined by full-matrix least-squares procedures to R = 0.034, 0.039, and 0.040 (R_w = 0.035, 0.034, and 0.036) for 1550, 1438, and 2187 reflections with $I \geq 3\sigma(F^2)$, respectively. In the solid state, both **3** and **4** exhibit transannular N···B interactions. In **3** there are two identical (by symmetry) interactions with N···B = 2.433(3) Å that have estimated bond orders of 0.06, while the single transannular interaction in **4** has N—B = 1.953(3) Å and a bond order of about 0.3. The intermediate-strength transannular interaction in **4** is the first to be reported for this type of molecule.

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **71**, 2129 (1993).

On décrit la synthèse des *N,N'*-dihydroxyaminals stériquement empechés : *N,N'*-bis(1-éthoxycarbonyl-1-méthyléthyl)-*N,N'*-dihydroxyméthanediamine (**1***b*) et *N,N'*-bis(1,1-diméthyléthyl)-*N,N'*-dihydroxyméthanediamine (**1***c*) et leurs réactions avec l'acide phénylboronique qui conduisent aux 1,3,5-trioxa-6,8-diaza-2,4-diboracyclooctanes **3** et **4** respectivement. Les cristaux du composé **1***b* sont tétragonale, groupe d'espace $I4_1$, avec a = 18,413(1) et c = 9,867(2) Å et Z = 8; ceux du composé **3** sont monocliniques, groupe d'espace $C2/c$, avec a = 20,420(4), b = 8,272(4) et c = 17,851(5) Å, β = 117,34(1)°, Z = 4 et ceux du composé **4** sont monocliniques, groupe d'espace $P2_1/c$, avec a = 9,493(4), b = 16,202(4) et c = 14,783(3) Å, β = 101,90(2)', Z = 4. On a résolu les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de R = 0,034, 0,039 et 0,040 (R_w = 0,035, 0,034 et 0,036) pour respectivement 1550, 1438 et 2187 réflexions avec $I \geq 3\sigma(F^2)$. À l'état solide, les composés **3** et **4** présentent tous les deux des interactions transannulaires B···N. Dans le composé **3**, il existe deux interactions identiques (par symétrie) avec B···N = 2,433(3) Å dont l'indice de liaison est évaluée à 0,06 alors que pour la seule interaction transannulaire du composé **4** N—B = 1,953(3) Å et que son indice de liaison est égale à environ 0,3. La force intermédiaire de l'interaction transannulaire observée dans le composé **4** est la première de ce type à être rapportée pour ce genre de molécules.

[Traduit par la rédaction]

Introduction

The reaction of the sterically hindered *N,N'*-bis(α-cyanoalkyl) substituted *N,N'*-dihydroxyaminal **1***a* (R = CMe_2CN) with phenylboronic acid gives the eight-membered heterocycle **2**, the structure of which has been established by an X-ray crystallographic analysis (1). As noted earlier (1, 2), the features of the molecular geometry of **2** are consistent with at least one weak transannular N···B interaction with an estimated bond order of about 0.05. It was of interest to investigate what effects on the transannular N—B bond formation would result from an enhanced basicity of the ring nitrogen atom without any major changes in the steric environment about the nitrogen atom. Varying the *N*-substitution from α-cyanoalkyl to α-alkoxycarbonyl and then to simple alkyl should distinctly increase the basicity (3). We have therefore synthesized the *N,N'*-dihydroxyaminal **1***b* (R = CMe_2COOEt), a compound not previously reported in the literature, and also the bis-*tert*-butyl derivative **1***c* (R = CMe_3) (4). The condensation reaction with phenylboronic acid gave crystalline compounds in both cases that show the elemental composition of heterocyclooctanes analogous to **2**. The infrared and ^1H nmr spectra of the products provide additional support for this formulation. The ^{11}B nmr spectrum of compound **3** (obtained from **1***b*) in $CDCl_3$ solution gives one broad signal having the same chemical shift value of $\delta(Et_2OBF_3)$ = 28.7 ppm that was reported for compound **2** (1). A broad singlet appears in the ^{11}B nmr spectrum of compound **4** at 23.3 ppm, similar to the value of ~22 ppm reported for the *N*-methyl derivative **5** (5). The bicyclic structure of **5** in the solid state has been established by an X-ray analysis (6). In each case the appearance of only one ^{11}B nmr signal for both boron nuclei is probably indicative of either a fluxional process in solution by which the two

N···B coordinative bonds exchange, or of an essentially symmetric ring system having two equivalent boron atoms (1, 5, 6). To provide detailed structural information on the transannular N···B interactions in the solid state and to establish the crystal and molecular structures of both compounds, **3** and **4**, X-ray analyses were undertaken.

An X-ray analysis of the crystalline adduct **1***b* was also performed to clarify the molecular structure and, in particular, the nature of the hydrogen bonding in the crystal. It had been found that the *N*-methyl derivative **1** (R = Me) possesses a highly symmetric hydrogen-bonded dimeric structure of the type **8** in the solid state (7). Although intramolecular hydrogen bridging like that in **9** or **10** can be excluded from consideration, compound **1***b*, being somewhat less basic at the aminal nitrogen centres, might possibly form intramolecular O—H···O=C hydrogen bonds such as those in **11** or **12**. The synthesis of **1***b* started with the *N*-alkylation of (*Z*)-benzaldoxime with ethyl 2-bromo-2-methylpropionate to give the corresponding nitrone, which was then hydroxylaminolyzed to *N*-(1-ethoxycarbonyl-1-methylethyl)-hydroxylamine. This hydroxylamine derivative and formaldehyde were condensed to the aminal **1***b*. To elucidate the structure of **1***b* and to assess structural changes after its condensation with phenylboronic acid, we prepared single crystals for an X-ray analysis.

Experimental

*N,N′-Bis(1-ethoxycarbonyl-1-methylethyl)-N,N′-dihydroxymethanediamine, 1*b*, and its precursor compounds*

(*Z*)-Benzaldoxime (12.1 g, 100 mmol) and ethyl 2-bromo-2-methylpropionate (21.5 g, 110 mol) were reacted together with sodium (2.30 g, 100 mmol) following the prescribed method (8), yielding 19.5 g (83%) of colorless needles of *1-ethoxycarbonyl-1-methylethyl-N-(phenylmethylene)amine N-oxide*, mp 62°C (from ether – petroleum ether). Infrared (KBr): 1740 (C=O) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$ TMS) δ (ppm): 1.29 (t, J = 7 Hz, CH_2CH_3), 1.83 (s, $C(CH_3)_2$), 4.20 (q, J = 7 Hz, CH_2CH_3), 7.25–7.43

(m, 3 aromatic H), 7.44 (s, N=CH), 8.12–8.30 (m, 2 aromatic H). Anal. calcd. for $C_{13}H_{17}NO_3$: C 66.36, H 7.28, N 5.95; found: C 66.12, H 7.33, N 5.86.

1-Ethoxycarbonyl-1-methylethyl-*N*-(phenylmethylene)amine *N*-oxide (1.18 g, 5.00 mmol) and hydroxylamine hydrochloride (0.35 g, 5.0 mmol) were reacted according to the literature (9) to yield 0.43 g (58%) of a colorless oil, N-*(1-ethoxycarbonyl-1-methylethyl)hydroxylamine*. This material was not further purified. Infrared (film): 3500–3100 (br, O-H, N-H), 1740 (C=O) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$–TMS) δ(ppm): 1.28 (t, J = 7 Hz, CH_2CH_3), 1.33 (s, $C(CH_3)_2$), 4.16 (q, J = 7 Hz, CH_2CH_3), 5.55 (s, br, exchangeable, NHOH). Anal. calcd. for $C_6H_{13}NO_3$: C 48.97, H 8.90, N 9.52; found: C 49.10, H 9.15, N 9.56.

N-(1-Ethoxycarbonyl-1-methylethyl)hydroxylamine (1.18 g, 8.00 mmol) was dissolved in 10 mL of ethanol (99%). After the addition of formaldehyde solution (aqueous, 35%, 5 mmol) the mixture was stirred for 1 h at 40°C. Cooling of the partially evaporated solution gave 0.80 g (65%) of colorless crystals of **1***b*, mp 58°C (from benzene – petroleum ether). Infrared (KBr): 3210 (O-H), 1740 and 1715 (C=O) cm^{-1}; ^1H nmr (90 MHz, d_6-benzene–TMS) δ(ppm): 1.05 (t, J = 7 Hz, 2 CH_2CH_3), 1.51 (s, 2 $C(CH_3)_2$), 4.01 (q, J = 7 Hz, 2 CH_2CH_3), 4.07 (s, N-CH_2-N), 9.31 (s, br, exchangeable, 2 OH). Mass spectrum (EI, 70 eV) *m/z*: 159 (36%, $H_2C{=}N(O)C(CH_3)_2COOC_2H_5$), 87 (36%, $H_2C{=}N(OH)$-$C(CH_3)_2$), 74 (100%, $(CH_3)_2CNHOH$), 59 (27%). Anal. calcd. for $C_{13}H_{26}N_2O_6$: C 50.97, H 8.55, N 9.14; found: C 51.03, H 8.64, N 9.09. Crystals suitable for X-ray analysis were obtained by very slow recrystallization from benzene – petroleum ether.

N,N'-*Bis(1,1-dimethylethyl)*-N,N'-*dihydroxymethanediamine,* ***1****c*

N-tert-Butylhydroxylamine (8.90 g, 100 mmol) and formaldehyde (5.29 g of 35% aqueous solution, 50.0 mol) were reacted according to the literature (4). Yield: 5.73 g (60%), mp 101°C (from ethanol) (lit. (4) mp 100–101°C). Infrared (KBr): 3190 (O-H) cm^{-1}; ^1H nmr (90 MHz, d_6-benzene–TMS) δ(ppm): 1.20 (s, 2 $C(CH_3)_2$), 3.70 (s, N-CH_2-N), 9.84 (s, br, exchangeable, 2 OH). Mass spectrum (EI, 70 eV) *m/z*: 102 (72%, $H_2C{=}N(OH)C(CH_3)_3$), 74 (24%, $(CH_3)_2CNHOH$), 57 (100%, $C(CH_3)_3$). Anal. calcd. for $C_9H_{22}N_2O_2$; C 56.81, H 11.65, N 14.72; found: C 56.80, H 11.75, N 14.69.

6,8-Bis(1-ethoxycarbonyl-1-methylethyl)-2,4-diphenyl-1,3,5-trioxa-6,8-diaza-2,4-diboracyclooctane, ***3***

1*b* (0.61 g, 2.0 mmol) and phenylboronic acid (0.49 g, 4.0 mmol) were dissolved (or suspended) in 15 mL of benzene and refluxed for 1 h under continuous removal of reaction water in a Dean Stark trap. The solvent was distilled off, and the residue recrystallized from toluene – petroleum ether. Yield: 0.68 g (69%) of colorless crystals, mp 103–105°C. Infrared (KBr): 1740 (C=O), 1600 (C=C) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$–TMS) δ (ppm): 1.21 (t, J = 7 Hz, 2 CH_2CH_3), 1.33 (s, 2 $C(CH_3)_2$), 4.11 (s, N-CH_2-N), 4.13 (q, J = 7 Hz, 2 CH_2CH_3), 7.18–7.45 (m, 6 aromatic H), 7.70–7.88 (m, 4 aromatic H); ^{11}B nmr (64.2 MHz, $CDCl_3$–Et_2OBF_3) δ (ppm): 28.7 ($w_{1/2}$ = 685 Hz). Mass spectrum (EI, 70 eV, 90°C) *m/z*: 496 (8%, M^+), 423 (44%, $M^+ - COOC_2H_5$), 264 (100%, $M^+ - H_2C{=}N(O)C(CH_3)_2COOC_2H_5 - COOC_2H_5$), 236 (4%, $M^+ - ONC(CH_3)_2COOC_2H_5 - (CH_3)_2COOC_2H_5$), 105 (4%, C_6H_5BOH). Anal. calcd. for $C_{25}H_{34}B_2N_2O_7$: C 60.52, H 6.91, B 4.36, N 5.65; found: C 60.43, H 6.95, B 4.51, N 5.66. Crystals suitable for X-ray analysis were obtained by repeated recrystallization from toluene – petroleum ether.

6,8-Bis(1,1-dimethylethyl)-2,4-diphenyl-1,3,5-trioxa-6,8-diaza-2,4-diboracyclooctane, ***4***

1*c* (0.95 g, 5.0 mmol) and phenylboronic acid (1.22 g, 10.0 mmol) were reacted in 20 mL of benzene as described for compound **3** (above). Yield: 1.80 g (95%) of colorless crystals, mp 118–119°C (from toluene – petroleum ether). Infrared (KBr): 1605 (C=C) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$–TMS) δ (ppm): 1.15 (s, 2 $C(CH_3)_2$), 3.63 (s, N-CH_2-N), 7.18–7.38 (m, 6 aromatic H), 7.75–7.92 (m, 4 aromatic H); ^{11}B nmr (64.2 MHz, $CDCl_3$–Et_2OBF_3) δ (ppm): 23.3 ($w_{1/2}$ = 640 Hz). Mass spectrum (EI, 70 eV, 90°C) *m/z*: 380 (28%, M^+), 365 (28%, $M^+ - CH_3$), 264 (100%, $M^+ - H_2C{=}N(O)C_4H_9 - CH_3$), 236 (66%, $M^+ - C_4H_9NO - C_4H_9$), 105 (19%, C_6H_5BOH), 77 (15%, C_6H_5), 56 (74%, $H_2C{=}C(CH_3)_2$). Anal. calcd. for $C_{21}H_{30}B_2N_2O_3$: C 66.36, H 7.96, B 5.69, N 7.37; found: C 66.21, H 8.05, B 5.86, N 7.18. Crystals suitable for X-ray analysis were obtained by recrystallization from toluene – petroleum ether.

X-ray crystallographic analyses of ***1****b*, ***3****, and* ***4***

Crystallographic data for **1***b*, **3**, and **4** appear in Table 1. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 91.2°–113.2°, 20.6°–33.4°, and 25.1°–34.7°, respectively. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, showed only small random fluctuations in each case. The data were processed,[3] corrected for Lorentz and polarization effects, and absorption (empirical, based on azimuthal scans for three reflections).

The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps or from subsequent difference Fourier syntheses. The structure analysis of **3** was initiated in the centrosymmetric space group $C2/c$ on the basis of the *E*-statistics, this choice being confirmed by the subsequent successful solution and refinement of the structure. In the structure of **1***b* there are two crystallographically independent molecules, each having exact C_2 symmetry. Molecules of **3** are also situated on a crystallographic C_2 axis. The thermal parameters and geometry involving the ethyl ester atoms C(13) and C(14) of one of the independent molecules of **1***b* suggest libration about the C(9)—C(12) bond, but not of such amplitude as to necessitate the use of a disordered model. Furthermore, the nearly isotropic cross section of the thermal motion of these atoms (viewed along the one small eigenvector) would lead to difficulties in producing a reasonable disordered model. Non-hydrogen atoms were refined with anisotropic thermal parameters. The carbon-bound hydrogen atoms were fixed in idealized positions (C—H = 0.98 Å, B_H = 1.2 $B_{\text{bonded atom}}$, methyl groups staggered) and the O-H hydrogen atoms of **1***b* were refined with isotropic thermal parameters. Corrections for secondary extinction were applied for all three structures, the final values of the extinction coefficients being $6.67(11) \times 10^{-6}$ for **1***b*, $1.06(3) \times 10^{-6}$ for **3**, and $1.12(4) \times 10^{-6}$ for **4**. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (10). A parallel refinement of the mirror-image structure of **1***b* gave slightly higher residuals, the R and R_w factor ratios being 1.003 and 1.002, respectively. Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, and bond angles appear in Tables 2–4, respectively. The structure of **1***b* is shown in Fig. 1, and the structures of **3** and **4** are shown in Fig. 2. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and measured and calculated structure factor amplitudes for the three structures are included as supplementary material.[4]

Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

Results and discussion

The X-ray analyses confirm the postulated cyclooctane skeletons for **3** and **4**. Both of these compounds have the cyclic pyroboronate structure found previously for **2** (1) that features an eight-membered ring having a distorted boat-boat ("saddle") conformation, typical for medium-sized heterocyclic rings with stabilizing transannular interactions (11). The transannular N···B interactions are effective to different extents in **3** and **4**. In the symmetric ring system of **3** the two N···B distances are equal (2.433(3) Å) with an estimated N—B bond order of 0.06 (empirical, corrected for hybridization and electronegativity effects). Both N···B interactions in **3** are slightly stronger than the single transannular N···B interaction in **2** (2.475(3) Å, N—B bond order 0.05) (1, 2), probably reflecting the increased basicity at the nitrogen centres of **3**. In compound **4**, possessing even more basic nitrogen centres, one of the N···B distances (N(2)—B(1) = 1.953(3) Å, bond order 0.29) approaches a transannular N—B bond as observed in the bicyclo[3.3.0]octane skeleton of compound **5** (mean 1.733 Å, bond order 0.62) (2, 6).

Steric factors (ring strain in particular) may be responsible for the lengthening of the N···B distance for the second donor–acceptor pair in **4** to N(1)—B(2) = 2.897(3) Å. This effect is even more pronounced in compound **5** (6), having a shorter mean N—B bond of 1.733 Å and an even longer mean nonbonded N···B distance of 3.083 Å. The substantial difference between the transannular N(2)···B(1) distances in **4** and **5** (1.953(3) and mean 1.733 Å, respectively) clearly demonstrates a steric impediment to the Lewis basicity at the nitrogen centres in **4**. The inductive (+*I*) effect of the *N-tert*-butyl substituents in **4** should induce an increased basicity compared to the *N*-methyl groups in **5**, leading to a stronger coordinative N—B interaction in **4**.

Including the transannular N···B interactions, compound **3** possesses a tricyclo[3.3.0.0^{3,7}]octane skeleton that corresponds roughly to the D_{2d} dinoradamantane ring system (12). The ring system of **3** is more similar to the D_{2d} "cradle" structures of S_4N_4, **6** (13), As_4S_4 (14), P_4S_4 (15), or N_4Se_4 (16). The bond order of the transannular S···S interaction in **6** has been estimated to be 0.4–0.5 (13*d*) and can be described as a $^3p_\sigma$–$^3p_\sigma$ bond (13*e*), different in nature from the N···B interaction in **3**.

Structural parameters for the N···B interactions in compounds **2–5** are compiled in Table 5. The degree of pyramidalization of the trigonal planar boronate group in its

transition to a tetrahedral geometry (2) can be assessed by both the displacement of the boron atom from the O_2C plane towards the nitrogen atom (ΔB) and the "tetrahedral character" (THC) proposed recently by Toyota and Oki (17). The transition to tetrahedral geometry is just beginning in compound **2** (1), is slightly more pronounced for the two iden-

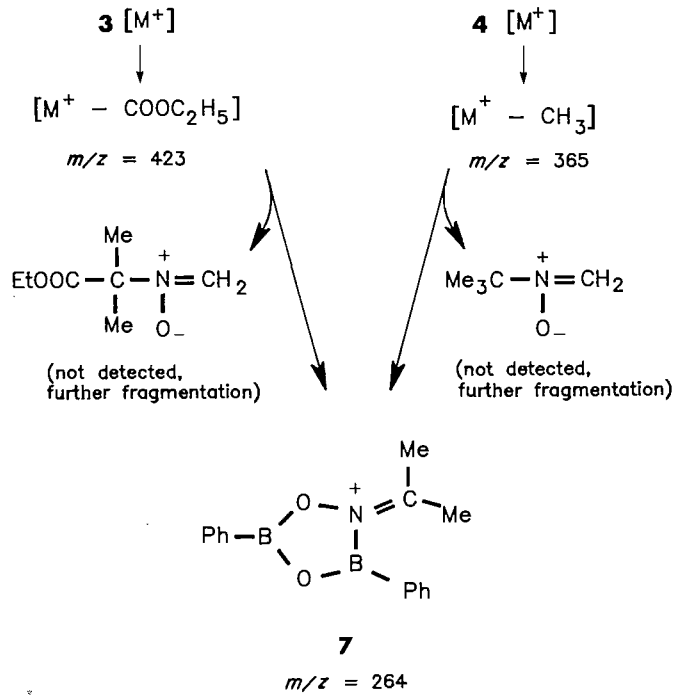
tical transannular interactions in **3**, and is quite marked in the case of **4**. The THC value and the N—B distance in **5** are similar to those in other sterically hindered systems (Ref. 17, and references therein). The intermediate-strength interaction in **3** is unprecedented in systems of this type.

As discussed earlier (1), the difference between the two transannular N···B contacts in **2** and **5** is reflected by the C—N bonds of the aminal function. The C—N bond length increases with increasing positive charge: the $^{+}$N—C and C—N distances in the $^{+}$N—C—N moieties are 1.467(2) and 1.454(3) Å in **2** (1), 1.480(3) and 1.452(3) Å in **4**, and mean values of 1.475 and 1.447 Å (1.479 and 1.452 Å corrected for libration) in **5** (6). In compound **3**, where the two nitrogen atoms are involved in identical weak interactions, the symmetry-equivalent $^{\delta+}$N—C distances are 1.463(2) Å. The N—O bonds at the nitrogen atoms with higher positive charge are shorter than the other N—O bonds in **2** (1.446(2) vs. 1.452(2) Å), **4** (1.454(2) vs. 1.461(2) Å), and **5** (mean 1.447 vs. 1.459 Å), while both N—O distances in **3** are 1.449(2) Å.

Like **2** and **5**, compounds **3** and **4** each have the same configuration at both nitrogen centres (the (6*R*,8*R*) enantiomers are depicted in Fig. 2, or, if the boron centres are also considered tetracoordinate, the (2*S*,4*S*,6*R*,8*R*) enantiomers).[5] The centrosymmetric crystals of **3** and **4** each contain equal numbers of (2*S*,4*S*,6*R*,8*R*) and (2*R*,4*R*,6*S*,8*S*) enantiomers. Structures **3** and **4** are both consistent with the EI mass spectra, which show a fragmentation pattern very similar to those of compounds **2** (1) and **5** (5), the parent peak showing an elimination product **7** having the oxime pyroboronate complex structure previously postulated for this type of fragment (refs. 1, 5, and references therein). This fragment is identical in the mass spectra of both **3** and **4**.

The X-ray analysis of the *N*,*N*′-dihydroxyaminal **1***b* shows that, like the *N*-methyl derivative (**1**, R = Me) (7), the solid state structure of **1***b* consists of hydrogen-bonded dimeric pairs of enantiomers.[6] The *N*-(1-ethoxycarbonyl-1-methylethyl) substituents are found in an antiperiplanar orientation with respect to the adjacent geminal nitrogen substituents. The *N*-hydroxy groups are both in *trans-gauche* positions. The dimer (Fig. 1) has exact C_2 symmetry with the twofold axis passing through the central carbon atoms (C(1) and C(8)) of each of the two crystallographically independent molecules. Four intermolecular N—O—H···N bridges form a dimeric unit of the type **8** in the solid state (N(1)—O(1)—H(1)···N(2)(1 − *x*, −*y*, *z*) and N(2)—O(4)—H(2)···N(1), H···N = 2.00(4) and 2.03(4) Å, O···N = 2.858(3) and 2.901(3) Å, O—H···N = 172(3)° and 165(3)°, respectively). The C_2 symmetry of the **1***b* dimer is lower than the S_4 symmetry observed for the **1** (R = Me) dimer, presumably as an effect of crystal packing and (or) the greater complexity of the *N*-substituent in the present case. The N—O distances in the two independent half-molecules of **1***b* (N(1)—O(1) = 1.456(3) and N(2)—O(4) = 1.434(3) Å) differ significantly. Differences in the hydrogen bonding, conformation, and thermal motion are likely responsible for this observation. The remainder of the corresponding bond distances in the two independent half-molecules are in good agreement. On the basis of the structure analysis, the intramolecular hydrogen-bridging structures **9–12** can be excluded from consideration, at least for the solid state.



Mass spectral fragmentation of **3** and **4** (selected common fragments)

The N—C—N angle at the aminal carbon atom in dimeric **1***b* is somewhat compressed (108.6(3)° and 108.9(3)°)

[5]Designations refer to systematic, not crystallographic, numbering. The nitrogen atoms are in positions 6 and 8 and the boron atoms in positions 2 and 4.

[6]Because of the conformational differences between the two enantiomeric molecules comprising the dimer in the solid state, they are not true mirror images of one another but do have opposite configurations at the chiral centres. It is a reasonable assumption that in solution, or in the liquid and gaseous states, the enantiomers exist as true mirror images.

compared to the corresponding angle of 110.9(2)° in **1** (R = Me) (7). This corresponds to the slightly "elongated" overall structure of the **1***b* dimer and is further supported by the longer hydrogen bonds in **1***b* (O···N = 2.858(3) and 2.901(3) Å) relative to those in dimeric **1** (R = Me) (O···N = 2.775(3) Å) (7). An even greater angular compression occurs for the N—C—N bond angle in complex **3** (102.1(2)°), a phenomenon already noted for the bicyclic complex **5** (102.4(2)° and 102.6(2)°) (6) and assumed to be a result of the transannular coordinative bond forces. Similar angular compressions are also observed at the (N)C—N—O moieties, which show angles of 105.3(2)° and 105.6(1)° in dimeric **1***b* and an even smaller angle of 104.0(1)° in the phenylboronate complex **3**. Unlike the asymmetric bicyclo-[3.3.0]octane-type complex **5** (6), the aminal C—N bonds in the symmetric complex **3** are equal (1.463(2) Å) and not significantly different from those in dimeric **1***b* (mean C—N = 1.470(2) Å). Unlike compound **5** (6), the N—C(C) bonds of the *N*-alkyl substituents in **3** are shortened by an average of 0.019 Å relative to those in **1***b* (N(1)—C(2) = 1.478(3) Å in **3**, mean of N(1)—C(2) and N(2)—C(9) = 1.497(5) Å in **1***b*). This is most likely due to a combination of steric (packing) and electronic effects.

The *trans-gauche* conformation of the $RN(O)CH_2N(O)R$ moiety in **1***b* is retained after the condensation with phenylboronic acid, the two symmetry-related N—C—N—R torsion angles being −168.0(2)° and 166.4(2)° for the two independent molecules of **1***b* and 170.4(2)° for **3**. The configurations at the four nitrogen centres in the dimer **1***b* (Fig. 1) are *S* at N(1) and N(1′), *R* at N(2) and N(2′).

Catalysis of the deprotonation of β-keto esters by cyclodextrins

OSWALD S. TEE,[1] N. RANI IYENGAR, AND BRYAN K. TAKASAKI

Department of Chemistry and Biochemistry, Sir George Williams Campus, Concordia University, Montreal, QC H3G 1M8, Canada

Received April 26, 1993

OSWALD S. TEE, N. RANI IYENGAR, and BRYAN K. TAKASAKI. Can. J. Chem. **71**, 2139 (1993).

The rates of deprotonation of several β-keto esters in basic aqueous solution are elevated by α- and β-cyclodextrin (α- and β-CD). In most cases saturation kinetics are observed that indicate fairly strong binding of the esters to the CDs (K_d = 0.22–11 mM); catalytic ratios (k_c/k_u) are in the range 1.9–17. For esters of the form RCO-CH_2COOEt with both α- and β-CD the values of K_d and k_c/k_u show little sensitivity to the acyl group, RCO (R = Me, Et, Pr, i-Pr), and for 2-carboethoxycyclopentanone, a cyclic analogue, these parameters are similar. In contrast, for R-$COCH_2$CO-OR′ (R = Me or Et; R′ = Me, Et, allyl) there is a marked dependence of the parameters on the alkoxyl group, OR′. These results suggest that the β-keto esters studied bind to the CDs with their alkoxyl groups in the CD cavity and that the catalysis ensues from the complexes thus formed. Variations in two other kinetic parameters, $k_2 = k_c/K_d$ (substrate selectivity) and $K_{TS} = k_u/k_2$ (apparent constant for dissociation of CD from the transition state) support this interpretation. Apparent second-order rate constants for the reaction of the esters with neutral CD ($k_2 = k_c/K_d$) are 1900–360 000 M^{-1} s^{-1} (at pH ≈ 10), whereas for hydroxide ion attack on ethyl acetoacetate k_{OH} = 5500 M^{-1} s^{-1}. Assuming the pK_as of the CDs are 12.2 and 12.3, deprotonation of the esters by the CD anions has rate constants of 10^5 to 5 × 10^7 M^{-1} s^{-1}. Thus, binding of the β-keto esters in the CD cavities, adjacent to a basic oxyanion site, enhances the reactivity of the CD anions towards these weak carbon acids *by at least 2–4 orders of magnitude*.

OSWALD S. TEE, N. RANI IYENGAR et BRYAN K. TAKASAKI. Can. J. Chem. **71**, 2139 (1993).

Lés vitesses de déprotonation de plusieurs β-cétoesters en solutions aqueuses basiques sont augmentées par la présence d'α- ou de β-cyclodextrine (α- et β-CD). Dans la plupart des cas, on observe des cinétiques de saturation qui indiquent la présence d'une forte liaison des esters sur les CD (K_d = 0,022–11 mM); les rapports catalytiques (k_c/k_u) sont de l'ordre de 1,9 à 17. Pour des esters de la forme RCO-CH_2COOEt avec des CD tant α que β, les valeurs de K_d et de k_c/k_u ne présentent qu'une faible sensibilité à la nature du groupe acyle, RCO (R = Me, Et, Pr, i-Pr); pour le 2-carboéthoxycyclopentanone, un analogue cyclique, ces paramètres sont semblables. Par ailleurs, pour les esters du type R-$COCH_2$CO-OR′ (R = Me ou Et; R′ = Me, Et ou allyle), il existe une dépendance marquée des paramètres sur la nature du groupe alcoxyle, OR′. Ces résultats suggèrent que les β-cétoesters se lient par leurs groupes alcoxyles à la cavité des CD et que la catalyse découle de la formation de ces complexes. Les variations dans deux autres paramètres cinétiques, $k_2 = k_c/K_d$ (sélectivité du substrat) et $K_{TS} = k_u/k_2$ (constante apparente de la dissociation de la CD de l'état de transition) sont en accord avec cette interprétation. Les constantes apparentes de vitesse du deuxième ordre pour la réaction des esters avec de la CD neutre ($k_2 = k_c/K_d$) varient de 1900 à 360 000 M^{-1} s^{-1} (à un pH ≈ 10), alors que pour l'attaque de l'ion hydroxyde sur l'acétoacétate d'éthyle k_{OH} = 5500 M^{-1} s^{-1}. Faisant l'hypothèse que les pK_a des CD sont respectivement de 12,2 et 12,3, les constantes de vitesse de déprotonation des esters par les anions CD varient de 10^5 à 5 × 10^7 M^{-1} s^{-1}. La liaison des β-cétoesters dans les cavités des CD, dans une position adjacente à un site oxyanion basique, augmente donc la réactivité des anions CD vis-à-vis de ces faibles acides carbonés par *au moins 2 à 4 puissances de 10*.

[Traduit par la rédaction]

Introduction

Cyclodextrins (CDs) are cyclic oligomers of glucose that form guest–host complexes with many species in solution (and in the solid phase), most notably with organic guests (1, 2). Because of such complexation, CDs can have significant effects on the rates and products of organic reactions. Of special interest, they can function as catalysts in various kinds of reactions (1), although most attention has been paid to the hydrolysis of esters of various kinds, photochemical reactions, and various biomimetic reactions (1–11).

Recently, we have studied the effects of α- and β-cyclodextrin on the cleavage of certain aryl alkanoate esters in basic solution (7). Generally speaking, in this reaction an ionized secondary hydroxyl group of the CD host functions as a nucleophile towards the guest ester and acyl transfer occurs (1, 5–10). However, with some benzoate esters the CD anion acts as a general base that assists the nucleophilic attack of water (11) so that true catalysis takes place. Accordingly, we speculated that CD anions may also function as simple basic catalysts in the deprotonation of acidic organic substrates included in their cavities and we found two examples in the literature (12*a*,*b*) to support this speculation. Daffe and Fastrez (12*a*) studied the deprotonation and hydrolysis of some oxazolones in basic media containing CDs. Subsequently, in a paper that was primarily concerned with catalysis by amylose, Cheng et al. (12*b*) noted that CDs catalyze the deprotonation of some β-keto esters in basic aqueous DMSO.[2]

β-Keto esters appeared to be excellent choices for further study of this type of catalysis for several reasons. Firstly, a wide variety of such esters are available or accessible. Secondly, formation of their enolate anions gives rise to a strong absorption band in the uv region (12*b*, 13). Thirdly, purely aliphatic β-keto esters might serve as useful probes of the effects on reactivity of the inclusion of alkyl chains in the

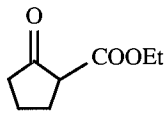
hydrophobic cavities of CDs (6, 7*b–d*, 10, 14, 15).[3] Fourthly, it should be possible to study the effects of complexation by CDs on the various processes involved in keto–enol tautomerism.

We hereby report an initial study of the deprotonation of some β-keto esters (**1**, **2**, **3**) in the presence of α- and β-cyclodextrin (α-CD and β-CD)[4] in basic aqueous solution. The results have been summarized in two reviews (6).

1: $R\text{-}COCH_2COOEt$ (R = Me, Et, Pr, i–Pr)

2: $R\text{–}COCH_2COO\text{–}R'$ (R = Me or Et; R′ = Me, Et, allyl)

3:



Results and discussion

All of the β-keto esters **1**, **2**, and **3** showed significant catalysis of deprotonation in the presence of added α- or β-CD.[4] For the two methyl esters the rate increases were linear with [CD] over the concentration range studied (0–5 mM), but all the others exhibited saturation-type kinetics, indicative of 1:1 binding of the substrates with the CDs (1, 6, 7). Therefore, the majority of the results are consistent with the reactions in eqs. [1*a*] and [1*b*]:

[1a] $S \xrightarrow{k_u}$ product

[1b] $S + CD \underset{K_d}{\rightleftharpoons} S \cdot CD \xrightarrow{k_c}$ product + CD

For the condition $[CD] \gg [S \cdot CD] < [S]_0$, the variation of the observed rate constant with [CD] is given by:

[2] $$k^{obsd} = (k_u K_d + k_c[CD])/(K_d + [CD])$$

Appropriate analysis of the rate data affords the constants k_c and K_d, with k_u fixed at the experimental value (1, 6, 7, 8*a*).

A derived value is $k_2 = k_c/K_d$, the apparent second-order rate constant for the reaction of S with CD; it is analogous to k_{cat}/K_M for enzymes (16). It is a useful measure of reactivity since it reflects the Gibbs energy difference between S + CD and the reaction transition state, regardless of the mode of binding of S to CD in the S · CD complex (6, 7). Viewed in other terms, k_2 is a measure of the selectivity of the CD for different substrates.

We also advocate (6) the use of another quantity:

[3] $$K_{TS} = \frac{[TS] \cdot [CD]}{[TS \cdot CD]} = \frac{k_u K_d}{k_c} = \frac{k_u}{k_2}$$

which is the apparent dissociation constant of the transition state of the catalyzed reaction (*symbolised* as TS · CD) into the transition state of the normal reaction (TS) and the catalyst, (here a CD). It provides a useful measure of the stabilization of the transition state by the catalyst (6). The derivation of eq. [3], which was originally due to Kurz (17), follows from the application of transition-state theory to k_u and k_c (or k_2). His approach has been adopted and elaborated on by enzymologists (18), but ignored by most physical organic chemists except for its recent usage for some reactions showing metal ion catalysis (19). We have shown that values of K_{TS} are useful parameters for discussing various reactions mediated by cyclodextrins, as well as by other catalysts (6). In particular, by looking at the variation of K_{TS} with structure one may be able to distinguish between different modes of transition-state binding, as distinct from the substrate binding, which is reflected in K_d.

First, we studied the deprotonation of some ethyl acylacetates ($RCOCH_2COOEt$, **1**) in basic solution and found that all gave saturation kinetics (eq. [2]) with added CD. Analysis of the results gave the constants k_u, k_c, and K_d in Table 1 and the derived quantities k_c/k_u, k_2, and K_{TS} in Table 2. For both α- and β-CD the dissociation constants (K_d) vary little with the acyl group, RCO (1.1–3.5 mM for α-CD; 2.4–11 mM for β-CD). Similarly, the catalytic ratios (k_c/k_u) are not particularly sensitive to the acyl group, although they are larger for α-CD (6.7–12) than for β-CD (1.9–4.9). Furthermore, the rate constants k_2 fall within narrow ranges: 18 000–51 000 M^{-1} s^{-1} for α-CD; 3300–7700 M^{-1} s^{-1} for β-CD. In a similar way, the values of K_{TS}, which are considered to reflect binding to the CD in the transition state (6), show remarkably little sensitivity to the acyl group: 0.26–0.40 (α-CD); 1.2–2.3 mM (β-CD). Note also that the greater catalysis (larger k_c/k_u and larger k_2) found for α-CD is largely due to more transition-state stabilization (lower K_{TS} values).

We have also studied the cyclic ester, 2-carboethoxycyclopentanone (**3**). This substrate has less conformational freedom and a more hindered acidic hydrogen than **1** but with α-CD it behaves just like the esters **1** (Table 1), although its reactivity is somewhat lower and its binding to the CD is weaker. In contrast, with β-CD the rate of deprotonation of **3** increases linearly with [CD], indicating very weak or insignificant binding. From the linear increase the second-order rate constant (k_2) is only 760 M^{-1} s^{-1}, so that **3** reacts with β-CD 5–10 times more slowly than the esters **1**. Correspondingly, its value of K_{TS} is 3–6 times larger than those for **1**.

Our more limited results[5] for β-keto esters with structural variation in the alkoxyl group (**2**) are also summarized in Tables 1 and 2. The two methyl esters do not show saturation kinetics, only linear increases of k^{obsd} for [CD] = 0–5 mM, and so binding of these esters to α-CD must be weak or nonexistent. In contrast, the ethyl esters do show saturation and stronger catalysis; the allyl ester binds more strongly and is more reactive still. Overall, the values of k_2 for $MeCOCH_2COOR'$ increase dramatically from 1.87×10^3 to 3.57×10^5 M^{-1} s^{-1} and the transition state dissociation constants decrease significantly (K_{TS} = 5.8, 0.40, 0.026 mM). Thus, as the reactivity increases by a factor of 200 the transition-state stabilization increases in direct pro-

[3]The binding of aliphatic compounds by CDs has been studied, though not in the same detail as that of aromatic compounds (1, 2, 6, 10), probably for practical reasons (lack of suitable chromophores, etc.). For example, while the binding of alcohols (10, 15) and of various detergents (14) has been documented, the effect of CDs on the reactivity of purely aliphatic substrates has received relatively little attention (1, 5–7).

[4]α-Cyclodextrin (cyclohexaamylose, α-CD) has six glucose units joined in a torus whereas β-cyclodextrin (cycloheptaamylose, β-CD) has seven such units. Thus, the sizes of their cavities differ in width, but not in depth (1).

[5]Various larger esters were tried unsuccessfully, as a result of their low solubility in water.

[a]As in Table 1. Some of the values in this table (and Table 1) differ slightly from those summarized in ref. 6 because in the present work more significant figures were carried before rounding. Values of k_2 are the apparent second-order rate constants for reaction of neutral ester with the CD.
[b]As in Table 1.
[c]The entry for this compound in Table IV of ref. 6*a* was incorrect due to a transcription error.
[d]See footnote *c* of Table 1.

portion. The two esters $EtCOCH_2COOR'$ (R′ = Me and Et) show similar behaviour.

The variation of K_d values with the alkoxyl group of the ester (OR′ of **2**) and their relative invariance with changes in the acyl group (RCO in **1**) both suggest that the β-keto esters bind to CDs through the ester group rather than through their acyl moieties. Likewise, the sensitivity of the various kinetic parameters to OR′ and their insensitivity to RCO, as well as the similar behaviour of the cyclic ester **3**, all support CD-catalyzed deprotonation through a transition state in which the ester group is bound (**4** → **5**) and not through one involving acyl group binding (**6** → **7**). Thus, the present results provide an example where the modes of initial-state and transition-state binding of a catalyst are the same. In general this need not be the case and in many instances it is not (6, 7).

The high values of the second-order rate constants (k_2), up to $3.6 \times 10^5\ M^{-1}\,s^{-1}$, for the apparent reaction of neutral CDs with the β-keto esters are quite remarkable when compared to the rate constant for deprotonation of ethyl acetoacetate by hydroxide ion: $k_{OH} = 5500\ M^{-1}\,s^{-1}$ (see below). If one makes allowance for the experimental pHs and the pK_as of α-CD and β-CD (12.2 and 12.3) (20) the actual second-order rate constants for reaction of the CD anions range from 1.3×10^5 to $4.7 \times 10^7\ M^{-1}\,s^{-1}$. So, the CD anions are much more reactive than expected, given that their intrinsic reactivity should be less than that of OH^-. Thus, binding of the β-keto esters to the CDs greatly enhances the reactivity of the CD anions towards these weak carbon acids, *by at least 2–4 orders of magnitude.*

For background purposes, and as a test of our experimental method, we also studied the deprotonation of ethyl ace-

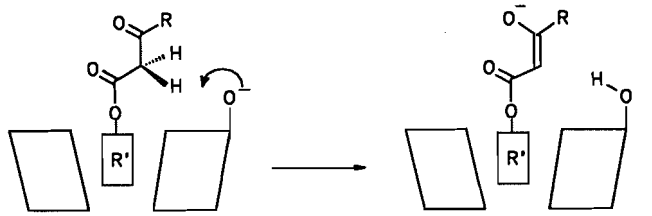
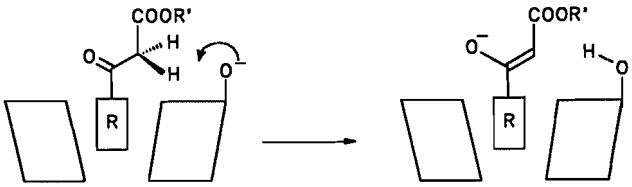
For personal use only.

toacetate as a function of $[OH^-]$. At pHs near the pK_a of this ester ($\approx$ 10.7) (21) the reaction should be considered as an equilibration of the keto form, the enolate, and the enol (eq. [4]) and so the observed rate constant should have the form of eq. [5].



4 5



6 7

[4] $$\text{keto} + OH^- \underset{k_w}{\overset{k_{OH}}{\rightleftharpoons}} \text{enolate}^- \underset{H^+}{\overset{K_E}{\rightleftharpoons}} \text{enol}$$

[5] $$k^{obsd} = k_f + k_d = k_{OH}[OH^-] + k_w K_E/(K_E + [H^+])$$

However, experiments were carried out at pH > 10.5 > $pK_E \approx 9$ (21)[6] so that in the present case $K_E > [H^+]$, which means that the amount of enol is negligible and eq. [5] simplifies to:

[6] $$k^{obsd} = k_{OH}[OH^+] + k_w$$

The observed data show this a good linear dependence on hydroxide ion (cc = 0.9979) and they afford values of k_{OH} = 5460 M^{-1} s^{-1} and k_w = 6.43 s^{-1}, from which $K_a = k_{OH} K_w/k_w = 1.34 \times 10^{-11}$ M and so pK_a = 10.87, taking pK_w as 13.80 (for I = 1.0 M) (22). These values are in close agreement with those from temperature-jump studies of the enolization of ethyl acetoacetate in basic solution, carried out under slightly different conditions (21); literature values of the pK_a range from 10.64–10.90 (21). Our values differ somewhat from the very recent values of Bunting and Kanter,[6] obtained from a more detailed stopped-flow study, and with the ionic strength fixed at 0.1 M: k_{OH} = 3700 M^{-1} s^{-1}; k_w = 1.4 s^{-1}; pK_a = 10.57. Regardless of these differences, we feel our results for the β-keto esters in Tables 1 and 2 provide a useful overview of an interesting cyclodextrin-catalyzed deprotonation reaction.

Summary

In basic solution, α- and β-cyclodextrin catalyze the deprotonation of some β-keto esters of the form $RCOCH_2COOR'$ to their enolates. We propose that the catalysis arises from binding of the ester in the CD cavity and basic attack by an ionized (secondary) hydroxyl group since the reactivity of the CD anions is much greater than expected for oxyanions of $pK_a \approx 12$. Because both values of K_d and K_{TS} (and other kinetic parameters) are much more sensitive to the nature of the alkyl of the alkoxyl group (OR′) than that of the acyl group (RCO) we conclude that both substrate binding and transition-state binding involve inclusion to some extent of the ester alkoxyl (**4** → **5**). Presumably, with other substituents, better suited to binding in the CD cavity in the transition state, one could find even stronger catalysis. However, more detailed studies will probably require the use of mixed solvent systems, such as aqueous DMSO (12*b*), since the solubility of larger β-keto esters in water is very low.

Experimental

The β-keto esters were obtained from Aldrich. Any samples that were of inferior grades or were discoloured were distilled before use. While some of the esters gave perfectly acceptable kinetics results, other did not. Several larger esters were tried but due to their low solubility in water the experiments were unsuccessful.

Overall, the general quality of the kinetics was not high. This was for three reasons: (*i*) the "infinity" readings, taken after 10 half-lives, were often not stable, tending to rise with time; (*ii*) some of the catalyzed rates are high, approaching the limits of the stopped-flow equipment used; (*iii*) some of the esters have low solubility in water and so it is difficult to ensure that all of the substrate is in solution. The origin of reason (*i*) is not clear: it is not due to ester hydrolysis, which is much slower than deprotonation (13); it may be related to (*iii*). Another possibility is that in aqueous solution a fraction of the ester molecules are hydrated at the β-keto group ($RC(OH)_2CH_2COOR'$) so that when the ester is mixed with strong base some hydrate anion is formed rapidly which then converts slowly to the enolate.

Kinetics were measured using an Aminco DW2a uv–vis spectrophotometer, with an Aminco–Morrow stopped-flow accessory, interfaced to a microcomputer (23). The observation chamber was kept at 25°C by water circulation from a thermostat. In one syringe of the apparatus was a dilute solution (0.2–0.4 mM) of the β-keto ester in aqueous solution containing twice the desired [CD] (= 0, 1, 2, 3, 4, 5 mM) while the other syringe contained a sodium bicarbonate/carbonate buffer (0.02 M). These two solutions were mixed (1:1) in the stopped-flow apparatus. The total ionic strength was 1.0 M, maintained with NaCl, in the final, mixed solution. Most of the reaction pHs were nominally 10, chosen to ensure a reasonable production of the enolate while keeping the rate of reaction not too fast. In some instances higher pHs were necessary (see Table 1). Deprotonation was monitored by the appearance of the β-keto ester anion in the region 270–290 nm (13). The reverse reaction may also be followed (Table 1, second entry). Absorbance readings were taken for 10 half-lives, and whenever possible those covering 3–4 half-lives were analyzed for first-order behaviour, in the normal way (7). In cases where the infinity readings were not stable (vide supra), values were estimated by the Kezdy–Swinbourne method (24).

Saturation behaviour was analyzed in terms of eq. [2] by non-linear fitting of k_c and K_d, keeping k_u fixed at the experimental value, and using in-house computer software based on the Marquardt algorithm (25).

Received March 10, 1993

HASSAN A. ALBAR, AHMAD S. SHAWALI, and MAGDA A. ABDALIAH. Can. J. Chem. **71**, 2144 (1993).

The kinetics of the azo coupling of eight *para*-substituted benzenediazonium tetrafluoroborates **2***a–h* with indole and its 1-, 2-,and 3-methyl derivatives **1***a–d*, respectively, were studied in acetonitrile at 25°C under pseudo-first-order conditions. The relation k_1(obs) = k_2[diazonium salt] was found applicable in all cases. The logarithms of the rate constants k_2 for each reaction series were correlated by the Hammett equation. A plot of the values of the reaction constant, ρ, obtained against the acidity constants pK_a of **1***a–d* gave a straight line: ρ = 2.97 − 0.15 pK_a. These results indicate that the azo-coupling reactions of indoles **1***a–d* follow one general mechanism involving rate-limiting initial electrophilic attack at the 3-position for all four compounds, contrary to the previous conclusion of Jackson and Lynch that the final deprotonation step is rate limiting.

HASSAN A. ALBAR, AHMAD S. SHAWALI et MAGDA A. ABDALIAH. Can. J. Chem. **71**, 2144 (1993).

Opérant dans l'acétonitrile, à 25°C, dans des conditions de pseudo premier ordre, on a étudié la cinétique du couplage azo de huit tétrafluoroborates de benzènediazonium *para*-substitués, **2***a–h*, avec l'indole et ses dérivés 1-, 2- et 3-méthylés, **1***a–d*. On a trouvé que, dans tous les cas, la relation k_1(obs) = k_2 [sel de diazonium] peut s'appliquer. L'équation de Hammett permet d'établir une corrélation entre les logarithmes des constantes de vitesse k_2 de chaque série de réactions. Une courbe des valeurs de la constante de la réaction, ρ, en fonction des constantes d'acidité, pK_a, des composés **1***a–d* donne une ligne droite, ρ = 2,97 − 0,15 pK_a. Ces résultats indiquent que les réactions de couplage azo des indoles **1***a–d* se produisent par un mécanisme général impliquant une attaque électrophile initiale limitant la vitesse qui se produit en position 3 de chacun de ces composés; ce mécanisme est en désaccord avec les conclusions proposées antérieurement par Jackson et Lynch selon lesquelles la déprotonation finale serait l'état limite.

[Traduit par la rédaction]

Introduction

The mechanism of azo-coupling reactions of indole and its 1-, 2-, and 3-methyl derivatives **1***a–d* has been studied by several investigators (Scheme 1) (1–5). However, little is known about the substituent effects on the reaction rate. So far only Challis and Rzepa (3) have reported the rates of azo coupling of **1***c* with a series of five *para*-substituted benzenediazonium ions in aqueous dioxane. Here, we wish to report the results of our kinetic investigation of the azo-coupling reactions of **1***a–d* each with a series of eight *p*-substituted benzenediazonium tetrafluoroborates **2***a–h* in dry acetonitrile at 25°C (Chart 1). The goal of this study is the determination of the Hammett reaction constants (ρ) for the four reaction series in question under similar conditions and the correlation of the values of these constants with the acidity constants, p*K*a, of **1***a–d* (6–9). The knowledge of such data is necessary to support or to invalidate the recently reported mechanism for the reaction of **1***d* with *p*-nitrobenzenediazonium ion **2***h* in acetonitrile (Scheme 1) (4), and to cast light on the rate-limiting step in the reactions studied.

Results and discussion

Coupling of indole and its 1- and 2-methyl derivatives **1***a–c* each with the diazonium salts **2** in dry acetonitrile at 25°C yielded the corresponding 3-arylazoindole derivatives **3–5**, respectively (Scheme 1). 3-Methyl indole **1***d* couples with **2** under similar conditions to give 2-arylazo-3-methylindoles **6** (Scheme 1). The structures of the new products **3–6** (each *a–g*) were corroborated by their elemental analyses and spectral (^{1}H NMR and UV) data (Tables 1–4). Furthermore, the mass spectra of the products **3–6** were consistent with their assigned structures. Thus, each of the products **4–6** showed, in addition to the molecular ion ($M^{\cdot+}$) peak, two characteristic peaks at *m/e* 158 and 130. Such peaks correspond to the fragments ($M^{\cdot+}$ − Ar) and ($M^{\cdot+}$ − Ar − N_2), respectively. The mass spectra of the products **3** showed the peaks of the latter fragments at *m/e* 144 and 116, respectively. It is worth noting that the base peak in the spectra of the products **3–5** corresponds to the fragment ($M^{\cdot+}$ − Ar − N_2), whereas for the products **6** it corresponds to the molecular ion species ($M^{\cdot+}$). This observation suggests that the radical cation of 2-arylazo-3-methylindole **6** is more stabilized than that of the corresponding 3-arylazoindoles **3–5**.

The kinetics of the reactions of **1***a–d* each with tenfold excess or more of **2***a–h* in dry acetonitrile at 25°C were followed by the rate of appearance of the corresponding azoindole derivatives at their characteristic wavelengths (Table 5). In all cases good first-order plots of log(D_∞ − D_t) against time, *t*, were obtained. The pseudo-first-order rate constants, k_1 (obs), were calculated from the slopes of such plots by using the least-squares method. The plots of k_1 (obs) against [diazonium salt] were, in each case, linear, indicating that the azo-coupling reactions of the indoles **1***a–d* follow the equation

$$k_1(\text{obs}) = k_2\,[\text{diazonium salt}]$$

Table 6 lists the k_2 values, calculated by the least-squares method, from the slopes of such plots. The correlation coefficients were in the range 0.986–0.990.

CHART 1

The results in Table 6 show that the azo-coupling reactions of **1***a–d* are affected by the substituent present in the diazonium salt, the reaction being retarded by electron-donating and enhanced by electron-withdrawing substituents. Figure 1 shows the plots of log k_2 values against the Hammett substituent constant σ (10). As shown, the relations are linear, following the equation: $\log (k/k_0)_2 = \rho\sigma$. The results of such correlations are summarized in Table 7. The lower susceptibility to substituent effects (ρ = 3.0) found in this work for the diazo coupling to 2-methylindole **1***c* in acetonitrile as compared to that (ρ = 3.3) reported for the same reaction in 20% (v/v) aqueous dioxane at pH 4.0 (3) seems to be due to solvent effects. It has been reported that in polar aprotic solvents the diazo-coupling reactions proceed faster than in protic solvents (13) and thus ρ decreases in the former solvents.

An examination of these data shows that the sensitivity of the reactions of **1***a–d* each with **2***a–h* decreases in the order: **1***d* > **1***a* > **1***b* > **1***c*. This is opposite to the order of the pK_a values reported for **1***a–d* (6–9), that is, the azo coupling with the less basic **1***d* is much more susceptible to polar requirements than the reaction of the stronger base **1***c*. This can also be seen by the excellent linear plot of the ρ values versus the pK_a values of the indoles studied, **1***a–d* (Fig. 2). The equation of the regression line is $\rho = 2.97 - 0.15\ pK_a$, with $r = 0.998$; $s = \pm 0.016$ and $S_\rho = \pm 0.005$.

This correlation seems to indicate that the nucleophilicity of the indoles studied, **1***a–d*, towards the diazonium cation is closely related to their pK_a values. In fact the plots of the log k_2 values of the reactions of **1***a–d* with a given diazonium salt against the pK_a values were linear in all cases examined. A similar relationship between the reactivity of

phenols was found in the coupling reaction of *p*-substituted phenols with diazobenzene-4-sulfonic acid (11).

Evidently, on the basis of (*i*) the similarity between protonation of **1***a–d* and the initial step in their azo-coupling reactions and (*ii*) the fact that the basicity pattern of **1***a–d* has been shown to be consistent with the concept of preferred protonation at the 3-position (6–9), it is not unreasonable to conclude that the azo-coupling reactions of the indoles **1***a–d* proceed in all cases by initial electrophilic attack of the diazonium cation at the 3-position as outlined in Scheme 1.

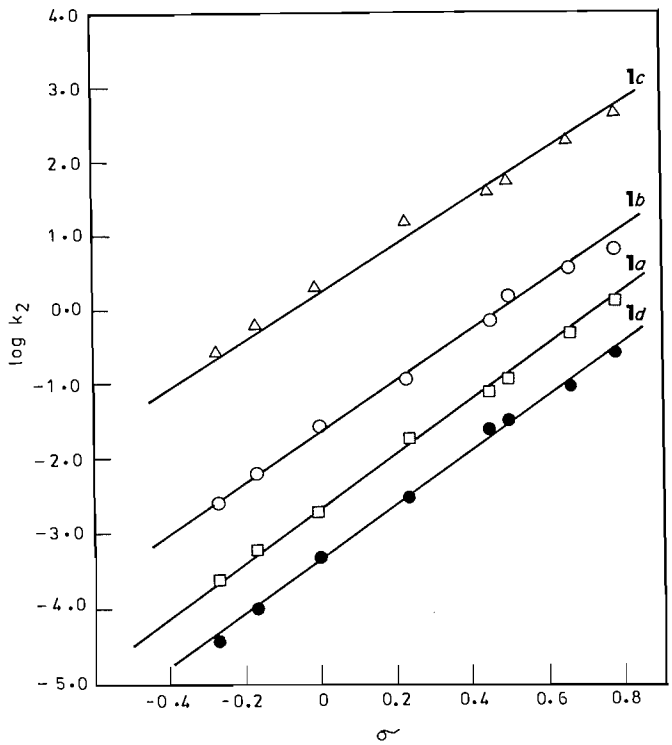

FIG. 1. Correlations of the second-order rate constants of the azo-coupling reactions of indoles **1***a–d* with *p*-substituted benzenediazonium ions **2***a–h* in acetonitrile at 25°C with the Hammett substituent constants σ.

Furthermore, the close similarity of the ρ value for 3-methylindole to those for indole and 1- and 2-methylindoles implies that the initial step must be the rate-limiting step for the reaction of all four compounds. This conflicts with the claim of Jackson and Lynch (4) that H^+-expulsion from the 2-position is rate limiting for diazo coupling of 3-methylindole **1***d*. The fact that ρ values correlate with the indole pK_a values also implies a common rate-limiting step for all four substrates **1***a–d*. This finding was also evident in Jackson and Lynch's study (4) but they chose to ignore its consequence in favour of a small positive isotope effect (ca. 2) for reactions with 2-[$^2H_1$]-3-methylindole.

Experimental

Melting points are uncorrected. UV spectra were determined with a Cary-17 spectrophotometer. ^{1}H NMR spectra were determined with a Varian 90 MHz instrument with tetramethylsilane as internal reference. Mass spectra were measured with a Varian CH5-D instrument by an electron impact, direct-insertion probe at 70 eV and 50 mA. IR spectra were recorded on a Unicam SP 200 grating spectrophotometer. Acetonitrile was distilled over anhydrous phosphorus pentoxide under nitrogen, the fraction of bp 82°C being collected. Elemental analyses were carried out using a Technicon CHN auto-analyser at the University of Wales, College of Cardiff.

Indole, 2-methylindole, and 3-methylindole were Aldrich reagents and were crystallized from light petroleum ether (60–80°C) before use in the kinetic experiments: indole, mp 51–52°C; 2-methylindole, mp 61°C; and 3-methylindole, mp 94–95°C. 1-Methylindole was prepared by methylation of indole using a literature procedure (4).

The diazonium salts **2** were prepared according to a previously described method (12) using amyl nitrite instead of *tert*-butyl nitrite. The purity of the salts was checked by ^{1}H NMR analyses (12).

Kinetics

The reactions were carried out in 1-cm ground-glass stoppered, fused-silica, absorption cells. The reactions were followed by rate of appearance of the azoindole absorption maximum (Table 5). Stock solutions of the diazonium tetrafluoroborate **2***a–h*, usually 10^{-2} M, were prepared in acetonitrile. Stock indole solutions, usually 10^{-3} M, were also prepared in the same solvent. Appropriate concentrations of the diazonium salts **2** and indole **1** were prepared by dilution of the stock solutions with acetonitrile. All indole concentrations were 5×10^{-5} M. All solutions were thermostated at 25 ± 0.1°C.

Reactions were followed up to 95% completion under pseudo-first-order conditions in which at least a tenfold excess of the diazonium salt over indole was used. Duplicate or triplicate runs were performed for each concentration and readings taken in any kinetic run cover a range of 96% transmittance. The pseudo-first-order

rate constants, k_1(obs), were calculated from log $(D_\infty - D_t)$ against time, t, data using the least-squares method. D_t and D_∞ are the absorbance values of the reaction mixture at time, t, and infinite time, respectively. The average deviation from the mean value of the rate constant in duplicate or triplicate experiments was ±5% or less.

Isolation of products

To a solution of the appropriate indole **1** (0.001 mol) in acetonitrile (20 mL) was added a solution of the appropriate diazonium tetrafluoroborate (0.01 mol) in the same solvent (10 mL), with stirring, at room temperature. After 36 h, the solvent was evaporated under reduced pressure, the crude oil left was triturated with an ethanol–water mixture, and the solid formed was collected and crystallized from aqueous ethanol. The physical constants of azo-coupling products **3–6** are listed in Tables 1–4 together with their spectral data.

Electrostriction volumes of α-amino acids from density measurements in water and in aqueous HCl and NaOH solutions at 25°C

M. ABBATE, G. CASTRONUOVO,[1] V. ELIA, AND S. PUZZIELLO

Department of Chemistry, University Federico II of Naples, Via Mezzocannone, 4, 80134 Naples, Italy

Received October 24, 1991[2]

M. ABBATE, G. CASTRONUOVO, V. ELIA, and S. PUZZIELLO. Can. J. Chem. **71**, 2150 (1993).

The values of the limiting partial molar volumes, $\bar{V}^0$, for some α-amino acids bearing alkyl chains, in pure water and in aqueous solutions of hydrochloric acid and sodium hydroxide, have been obtained from density measurements. From these data it is possible to determine the volume change, ΔV_{zw}, due to the formation of the amphionic molecule from the corresponding neutral molecule.

M. ABBATE, G. CASTRONUOVO, V. ELIA et S. PUZZIELLO. Can. J. Chem. **71**, 2150 (1993).

Faisant appel à des mesures de densités et opérant dans de l'eau pure et dans des solutions aqueuses d'acide chlorhydrique et d'hydroxyde de sodium, on a déterminé les valeurs des volumes molaires partiels limites, $\bar{V}^0$, de quelques acides α-amineés portant des chaînes alkyles. À partir de ces données, il est possible de déterminer le changement de volume, ΔV_{zw}, accompagnant la formation de la molécule amphionique à partir de la molécule neutre correspondante.

[Traduit par la rédaction]

Introduction

The thermodynamic properties of α-amino acids in aqueous solutions have attracted the attention of many authors for the role played by these substances in determining the properties of proteins. In recent years, a considerable amount of thermodynamic data concerning amino acids (1), studied either calorimetrically (2–4) or volumetrically (5–7), has appeared in the literature. That permits the testing of simple additivity schemes for the prediction of the properties of molecules or biochemical systems (8–17).

Many approaches proposed to predict partial molar volumes assume that the contributions of the various groups present in a molecule are additive. However, to caution against the danger of such a simple treatment, Leslie and Lilley (18) studied isomeric species that differed only in the disposition of the groups on the backbone of some amino acid amides. Significant differences were found that led to doubts about simple atom or large group additivity. Even a change in the residue sequences for two dipeptides causes a volume difference of almost 2.5 $cm^3\ mol^{-1}$. The difficulties in reproducing the experimental values of $\bar{V}^0$ for amino acids and peptides were largely due to the dependence of the group contributions on the series from which they were derived. That has led some authors (6) to the conclusion that it is impossible to estimate the values of the group contributions when two functional groups are present simultaneously in a compound. In the case of α-amino acids, these difficulties are compounded because of the extreme preximity of the amino and carboxylate groups.

Many authors (12–17) have been concerned with the problem of determining the volume change, ΔV_{zw}, relative to the formation of the zwitterion from uncharged species:

[1] $\quad A \rightarrow A^{+/-}$

where $A^{+/-}$ represents the zwitterionic form $R(COO^-NH_3^+)$. Unfortunately, this determination cannot be accomplished experimentally, as equilibrium [1] is largely shifted to the right. Several methods have been proposed to calculate ΔV_{zw} that are dependent on the way the volume of the hypothetical neutral form in solution is calculated. Usually, the volume of the latter is evaluated from group contribution approaches or from the relations:

(*i*) $\quad \bar{V}^0$ (neutral amino acid) $\equiv \bar{V}^0$ (corresponding hydroxyamide)

(*ii*) $\quad \bar{V}^0$ (neutral amino acid) = $\bar{V}^0$ (glycolamide) + $\bar{V}^0$ (real amino acid) − $\bar{V}^0$ (real glycine)

Alhuwalia et al. (14) obtained the contribution of the neutral molecule by comparing the $\bar{V}^0$ of selected molecules regardless of whether they were mono-, or bifunctional. Cabani et al. (8) calculated $\bar{V}^0$ values from a group contribution approach using only hydrocarbons and monofunctional compounds. The main conclusion of this work was that ΔV_{zw} for α-amino acids is practically independent of the nature of the alkyl group, and that the average value of -14.7 ± 0.8 $cm^3\ mol^{-1}$ is due to reaction [1]. ΔV_{zw} greatly depends, instead, on the distance between the two charges, reaching the maximum value of -18.5 ± 0.4 when four or more $-CH_2-$ groups separate them.

In the present paper we report the densities, in pure water and in aqueous solutions of hydrochloric acid and sodium hydroxide, of some α-amino acids bearing alkyl chains of increasing length and branching: glycine, L-α-alanine, D-α-aminobutyric acid, D-valine, L-norvaline, L-leucine, L-isoleucine, and L-norleucine. The aim is to gain more direct information on the electrostriction volume for reaction [1]. That will be accomplished through the determination of limiting volumetric contributions to the total volume of the α-amino acids in the protonated, deprotonated, and zwitterionic forms.

Experimental

The α-aminoacids (glycine, L-α-alanine, D-α-aminobutyric acid, D-valine, L-norvaline, L-leucine, L-isoleucine, and L-norleucine) were Sigma products. Their purity was checked by several methods, as already described in ref. 2. Solutions were prepared by weighing the dried solutes and the bidistilled water, which was filtered on a Millipore membrane. Solutions were prepared by dissolving the solutes in a weighed quantity of the various solvents (pure water; (HCl or NaOH 1 mol L^{-1})). Densities of solutions were

measured using an Anton Paar densimeter (DMA 620), at 25 ± 0.005°C. The data were obtained from the difference between the measured frequency of the solution and that of the respective solvent. The densimeter was calibrated using dry air and bidistilled water. Hydrochloric acid and sodium hydroxide solutions were prepared using a Normex (Carlo Erba), having care to use the same stock for all measurements of each system.

Thermodynamic relations

The excess Gibbs free energy of a system containing a single nonelectrolytic solute, x, and a solvent, s, is given by:

$$[2]\quad G^E(m_x) = G(m_x) - G^{id}(m_x) = G(m_x) - G_s^0 - m_x \bar{G}_x^0 - RTm_x(\ln m_x - 1)$$

where $G^E(m_x)$ is the excess free energy, $G(m_x)$ is the free energy of the solution, G_x^0 the standard free energy of 1 kg of solvent, $\bar{G}_x^0$ the limiting partial molar energy of the solute, and m_x the molality. In the case of the first derivative of the free energy with respect to the pressure, namely the volume, the term $RTm_x(\ln m_x - 1)$ is null.

According to the McMillan–Mayer solution theory, a thermodynamic excess property is usually expressed as a polynomial in the solute molality (19–21), and then the excess volume is given by

$$[3]\quad V^E(m_x) = V(m_x) - (V_s^0 + m_x\bar{V}_x^0) = v_{xx}m_x^2 + v_{xxx}m_x^3 + \text{higher terms}$$

where V_s^0 is the volume of 1 kg of solvent (pure water or aqueous solutions of 1 M hydrochloric acid or sodium hydroxide), $\bar{V}_x^0$ is the standard state partial molar volume of the solute, and v_{xx} and v_{xxx} are the second and third coefficients of the virial expansion of the excess volume.

Densities, d, were used to calculate the volume of the solution containing 1 kg of solvent (pure water or aqueous solutions of hydrochloric acid or sodium hydroxide) as follows:

$$[4]\quad V(m_x) = (1000 + m_xM_x)/d$$

where M_x is the molar mass of the solute.

The following three cases were examined, where the volumes of solutions containing m_x moles of amino acid per kg of solvent were calculated by means of eq. [4].

(a) Hydrochloric acid 1 mol L^{-1} as solvent

In this solvent the zwitterion is forced to assume a proton, according to the following reaction:

$$[5]\quad A^{+/-} + H^+ \rightarrow A^+$$

where A^+ is the protonated form $R(COOH\ NH_3^+)$ of the amino acid. Then, the volume of this solution is described by the following relation:

$$[6]\quad V = \Sigma_i n_i\bar{V}_i = n^s_{H_2O}\bar{V}_{H_2O} + n_{H^+}\bar{V}_{H^+} + n_{Cl^-}\bar{V}_{Cl^-} + n_{A^+}\bar{V}_{A^+}$$
$$= [n^s_{H_2O}\bar{V}_{H_2O} + n_{Cl^-}(\bar{V}_{H^+} + \bar{V}_{Cl^-})] + mA^+(\bar{V}_{A^+} - \bar{V}_{H^+})$$
$$= V_{(solvent)} + m_{A^+}(\bar{V}_{A^+} - \bar{V}_{H^+})$$

where $n^s_{H_2O}$ is the number of water molecules present in the solvent. The value of the difference, $V'(m)$, between the volume of the solution and that of the solvent is

$$[7]\quad V'(m) = m_{A^+}(\bar{V}_{A^+} - \bar{V}_{H^+}) = V^*m_{A^+} + b_vm_A^2 + \ldots$$

where V^* is the difference of two limiting values

$$V^* = \bar{V}^0_{A^+} - \bar{V}^0_{H^+}$$

and b_v is a constant depending on the volumetric cross coefficients.

(b) Sodium hydroxide 1 mol L^{-1} as solvent

In this solvent the amino acid is in the A^- form, according to:

$$[8]\quad A^{+/-} + OH^- = A^- + H_2O$$

where A^- is the deprotonated form $R(COO^-\ NH_2)$. The volume of the solution is then:

$$[9]\quad V = \Sigma_i n_i\bar{V}_i = n_{H_2O}\bar{V}_{H_2O} + n_{Na^+}\bar{V}_{Na^+} + n_{OH^-}\bar{V}_{OH^-} + m_{A^-}\bar{V}_{A^-}$$
$$= (n^s_{H_2O} + m_{A^-}\bar{V}_{H_2O} + n_{Na^+}\bar{V}_{Na^+} + (n_{Na^+} - m_{A^-})\bar{V}_{OH^-} + m_{A^-}\bar{V}_{A^-}$$
$$= [n^s_{H_2O}\bar{V}_{H_2O} + n_{Na^+}(\bar{V}_{Na^+} + \bar{V}_{OH^-})] + m_{A^-}(\bar{V}_{A^-} + \bar{V}_{H_2O} - \bar{V}_{OH^-})$$
$$= V_{(solvent)} + m_{A^-}(\bar{V}_{A^-} + \bar{V}_{H_2O} - \bar{V}_{OH^-})$$

The value of $V'(m)$ is in this case:

$$[10]\quad V'(m) = m_{A^-}(\bar{V}_{A^-} + \bar{V}_{H_2O} - \bar{V}_{OH^-}) = V^*m_{A^-} + b_vm^2_{A^-} + \ldots$$

The values of the coefficient of the interpolating polynomial are

$$V^* = \bar{V}^0_{A^-} + \bar{V}^0_{H_2O} - \bar{V}^0_{OH^-}$$

and b_v, which is again a constant depending on the volumetric cross coefficients. Then, solutions containing amino acid species are multicomponent solutions, because of the necessity of taking into account the H^+ and OH^- species reacting with the amino acid, during the preparation of the solutions.

(c) Pure water

In this case the solutions are binary ones, since they contain only zwitterionic species.

The value of $V'(m)$ is:

$$[11]\quad V'(m_x) = V(m_x) - V_w = V^*m + b_vm^2 + \text{higher terms}$$

As in the two preceding cases, the parameters of Eq. [11] have the usual meaning of limiting partial molar volume and interaction self-coefficients of the amino acid in the zwitterionic $A^{+/-}$ form.

Equations [7], [10], and [11] were interpolated by means of a least-squares procedure, choosing the polynomial of highest degree whose coefficients were larger than their own 95% confidence limits. For all of the systems studied, only two parameters (V^*, b_v) were necessary to represent the data adequately, underlining that Debye–Hückel corrections are not necessary.

Results and discussion

In Table 1, the V^* values are reported for solutions of all the amino acids studied in the three solvents employed. The values of $V_{A+/-}$ measured in water are in good agreement with the literature data. They fall in the 95% confidence indexes of the mean values reported by Cabani et al. (8). Up to now there are no data in the literature obtained in solvents other than pure water.

The V^* values obtained in the three solvents were interpolated as a function of the number of carbon atoms. The three relations were found to be linear and with the same mean slope, 15.7 ± 0.3 $cm^3\ mol^{-1}$, which is within the limits of variability reported in the literature, 14.8 ± 0.5 to 15.8 ± 0.6 (8). Intercepts and slopes of the three straight lines are reported in Table 2. The very similar values of the slopes indicate that the contribution of an added CH_2 can be considered the same regardless of the solvent and of the charge of the functional groups. To evaluate the influence of the different solvents on the hydration of the alkyl chain, measurements of limiting volumetric properties in the same three

[a]Values in parentheses are the 95% confidence limits. The number of experimental data for each system varies from a maximum of 28 for L-isoleucine in HCl to a minimum of 12 for L-leucine in water.

TABLE 2. Parameters of the straight lines interpolating V* as a function of the number of carbon atoms for α-amino acids and alcohols at 25°C

Substances	Intercept[a]	Slope[a]
Amino acids (H_2O)	28.1(0.8)	15.7(0.2)
Amino acids (HCl)	34.8(1.7)	16.1(0.5)
Amino acids (NaOH)	52.0(1.5)	15.5(0.4)
Alcohols[b]	23.4(0.9)	15.4(0.3)
Average		15.7(0.3)

[a]Units are cm^3 mol^{-1}.
[b]The data for alcohols are fitted all together, regardless of the solvent used. Values in parentheses are the 68% confidence limits.

solvents were made using typical hydrophobic solutes, namely, alcohols bearing the same alkyl chains as those present in the amino acids studied. The alcoholic -OH group is not appreciably influenced by the pH changes on going from HCl to NaOH solutions. In these cases, where no reactions occur between solutes and solvent, the extrapolated values really give the partial molal volumes at infinite dilution of the solutes in the proper solvent. In Table 3 the $\bar{V}^0$ values determined in the three solvents are reported for methanol, ethanol, *n*-propanol, i-propanol, *n*-butanol, i-butanol, and *s*-butanol. It must be emphasized that these values were evaluated with the sole aim of obtaining an approximate $\bar{V}^0_{CH_2}$ value, to check whether large variations occur in the different solvents. The trends of $\bar{V}^0$ as a function of the number of carbon atoms in the three solvents were found to be linear, almost coincident, and with the same slope. This is a clear indication of an unaltered hydration of the alkyl chain. In Table 2, the parameters of the interpolating line are reported: they were evaluated by fitting all the data together, regardless of the solvent used and of some discrepancies concerning *n*- and i-butanol. The value of the slope (about 16 cm^3 mol^{-1}), which represents the contribution of a CH_2 to $\bar{V}^0_x$, is the same as that obtained for the α-amino acids in the three solvents. It is in good agreement with the values reported by other authors and obtained for aliphatic hydrocarbons and other neutral molecules.

Here we want to propose a method through which it is possible to deduce the value of the electrostriction volume ΔV_{zw} from the V^* values obtained for the amino acids in the three solvents. This method postulates the identity between the sum of the limiting volumes of the two species bearing one charge and the sum of the volumes of the zwitterionic and neutral forms:

$$\bar{V}^0_{A^+} + \bar{V}^0_{A^-} = \bar{V}^0_{A} + \bar{V}^0_{A^{+/-}}$$

Hence, the overall intramolecular interactions between charged and uncharged functional groups (right side of the relation) are considered to be equivalent to those between two charged groups (left side). Therefore, the following scheme holds:

$$V^*(\mathrm{HCl}) + V^*(\mathrm{NaOH}) - 2V^*(H_2O) = \bar{V}^0_{A^+} + \bar{V}^0_{A^-} - \bar{V}^0_{A^{+/-}} - \bar{V}^0_{A^{+/-}} + \bar{V}^0_{H_2O} - \bar{V}^0_{H^+} - \bar{V}^0_{OH^-}$$

Taking into account the postulated identity, it follows:

$$\begin{aligned}\bar{V}^0_{A} + \bar{V}^0_{A^{+/-}} - \bar{V}^0_{A^{+/-}} - \bar{V}^0_{A^{+/-}} - \Delta V_w &= \bar{V}^0_{A} - \bar{V}^0_{A^{+/-}} - \Delta V_w \\ &= -\Delta V_{zw} - \Delta V_w \\ &= 34.8 + 52.0 - 2 \times 28.1 \\ &= 30.6\end{aligned}$$

where ΔV_w is the volume change upon dissociation of one mole of water (22): its value, -22.2 cm^3 mol^{-1}, is assumed to be the same in the three solvents used. Then, ΔV_{zw} is -8.4 ± 3.0 cm^3 mol^{-1}, where the standard deviation is computed from those on the intercepts, assuming that on ΔV_w to be ± 0.2 cm^3 mol^{-1}. Because of the large error in ΔV_{zw}, this value can be assumed to be constant within the series of α-amino acids studied. Other approaches reported in the literature lead to ΔV_{zw} values that seem to be affected by a smaller error. However, the errors in the starting quantities are neglected in computing the derived result. In the group contribution approach, for instance, the various terms are considered unaffected by errors. On the other hand, comparison of the ΔV_{zw} values obtained by different methods (8) demonstrates the great variability of the derived results. In fact, differences of 2–4 cm^3 mol^{-1} are not unusual.

To test the reliability of our approach, we have applied it to the literature data concerning densities of hydrochloride and sodium salts of α,ω-amino acids. Using our notation we have: \

TABLE 3. Values of $\bar{V}^0$ for the alcohols reported below, in water and in aqueous solutions of hydrochloric acid and sodium hydroxide, 1 mol L^{-1}, at 25°C[a]

Alcohol	$\bar{V}^0(H_2O)$ (cm^3 mol^{-1})	$\bar{V}^0(HCl)$ (cm^3 mol^{-1})	$\bar{V}^0(NaOH)$ (cm^3 mol^{-1})	Concentration range (mol kg^{-1})
Methanol	38.2[b]	38.0(0.1)	37.7(0.1)	0.64–0.11
Ethanol	55.10[b]	54.0(0.1)	53.9(0.1)	0.66–0.12
n-Propanol	70.70[b]	70.1(0.1)	69.8(0.2)	0.54–0.11
i-Propanol	71.3(0.1)	71.2(0.2)	70.5(0.3)	0.5 –0.04
n-Butanol	85.6(0.1)	85.4(0.1)	80.9(0.3)	0.6 –0.02
i-Butanol	85.5(0.1)	85.1(0.2)	82.0(0.2)	0.5 –0.03
s-Butanol	85.1(0.1)	85.1(0.2)	84.8(0.2)	0.6 –0.03

[a]Values in parentheses are the 95% confidence limits. The number of experimental data for each system varies from a maximum of 17 for *n*-butanol in water, to a minimum of 10 for i-butanol in water.

[b]Ref. 24.

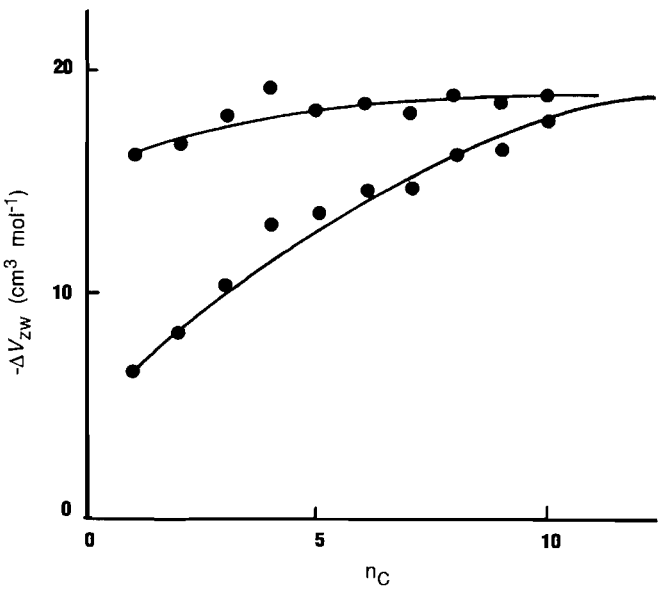

FIG. 1. ΔV_{zw} values for several α,ω-amino acids reported as a function of the number of carbon atoms of the alkyl chain, n_C. The values falling on the upper curve are from ref. 8. The values falling on the lower curve are obtained by the reelaboration of the data reported in ref. 15.

$$\bar{V}^0_{(\text{hydrochloride})} = \bar{V}^0_{A^+} + \bar{V}^0_{Cl^-}$$

$$\bar{V}^0_{(\text{sodium salt})} = \bar{V}^0_{A^-} + \bar{V}^0_{Na^+}$$

Then:

$$\bar{V}^0_{(\text{hydrochloride})} + \bar{V}^0_{(\text{sodium salt})} - 2\,\bar{V}^0_{A^{+/-}} = \bar{V}^0_{A^+} + \bar{V}^0_{A^-} + \bar{V}^0_{A^{+/-}} - \bar{V}^0_{A^{+/-}} + \bar{V}^0_{Cl^-} + \bar{V}^0_{Na^+} = \bar{V}^0_{A} + \bar{V}^0_{A^{+/-}} - \bar{V}^0_{A^{+/-}} - \bar{V}^0_{A^{+/-}} + \bar{V}^0_{NaCl} = \bar{V}^0_{A} - \bar{V}^0_{A^{+/-}} + \bar{V}^0_{NaCl} = -\Delta V_{zw} + \bar{V}^0_{NaCl}$$

where $\bar{V}^0_{NaCl}$ is 16.6 cm^3 mol^{-1} (23). For these substances, we find that ΔV_{zw} is largely dependent on the alkyl chain length. In Fig. 1 the ΔV_{zw} for α,ω-amino acids are reported as a function of the number of carbon atoms, n_C, constituting the alkyl chain. The lower curve describes the values obtained reelaborating the data of Shahidi and Farrell (15, 17) through our approach. The values increase almost linearly up to 6-aminohexanoic acid and then they tend slowly to a plateau. The upper curve describes the ΔV_{zw} data obtained by Cabani et al. (8) through a group contribution approach. A linear regression on the double reciprocal plot of $(\Delta V_{zw})^{-1}$ vs. $(n_C)^{-1}$ gave a value of -19.6 ± 1.3 in the first case, and a value of -19.2 ± 0.3 in the second case, in agreement with the reported mean value of -18.5 ± 0.4 cm^3 mol^{-1} (8). As can be seen, the two curves converge when the number of CH_2 groups separating the charges is larger than six or seven, while they greatly diverge for the shortest α,ω-amino acids: this is a strong indication that our model takes intramolecular interactions partially into account, an effect that becomes less important when the two functional groups are well separated. Moreover, as a further test, the Shahidi and Farrell data for glycine (15) were used to calculate ΔV_{zw}. It is found to be -7.2 cm^3 mol^{-1}, while using our data a value of -7.8 cm^3 mol^{-1} is obtained. The very good agreement between the two values underlines the validity of the proposed experimental procedure in the three solvents.

As a conclusion, the difference of about 6 cm^3 mol^{-1} between the presently determined value for ΔV_{zw} (-8.4 ± 3.0 cm^3 mol^{-1}) and that reported in the literature (-14.7 ± 0.8 cm^3 mol^{-1}) for α-amino acids (8) could be attributed to two reasons: (*i*) hydroxyamide may not be a good model of neutral amino acids, and (or) (*ii*) the group contribution approach cannot account for the different intramolecular interactions when the charges are extremely close, as in α-amino acids.

SUBRATA MUKHOPADHYAY, SWAPAN CHAUDHURI, RINA DAS, and RUPENDRANATH BANERJEE. Can. J. Chem. **71**, 2155 (1993).

In the pH range 6.6–8.6, $[MnL_2(H_2O)_2]^+$ and $[MnL_2(H_2O)(OH)]$ (HL = acetylacetone) oxidize oxalate ion (ox^{2-}) to CO_2 through the inner-sphere intermediates $[MnL_2(ox)]^-$ and $[MnL_2(OH)(ox')]^{2-}$, where ox′ is a half-bonded (unidentate) oxalate ion. Their rate constants of decomposition are 1.0×10^{-4} s^{-1} and 11.2×10^{-2} M^{-1} s^{-1} at 30°C and at I = 1.0 M ($NaClO_4$). Decomposition of these mixed complexes produces free radicals, presumably CO_2^-, which is further oxidized to CO_2 by another Mn(III) in a fast step. At pH 4.2, $[Mn(ox)_3]^{3-}$ is produced quantitatively when $[ox]_0 \geq 0.12$ M, which has been characterized spectrally, and its unimolecular decomposition rate constant k ($= 2.7 \times 10^{-4}$ s^{-1} at 30°C and I = 1.0 M) compares well with that reported earlier (2.44×10^{-4} s^{-1} at 25°C and I = 1.0 M).

SUBRATA MUKHOPADHYAY, SWAPAN CHAUDHURI, RINA DAS et RUPENDRANATH BANERJEE. Can. J. Chem. **71**, 2155 (1993).

Dans la plage de pH allant de 6,6 à 8,6, les entités $[MnL_2(H_2O)_2]^+$ et $[MnL_2(H_2O)(OH)]$ (HL = acétylacétone) oxydent l'ion oxalate (ox^{2-}) en CO_2 par le biais d'intermédiaires de sphère interne $[MnL_2(ox)]^-$ et $[MnL_2(OH)(ox')]^{2-}$, dans lequel ox′ est un ion oxalate à demi lié (monocoordiné). Leurs constantes de vitesse de décomposition sont respectivement $1{,}0 \times 10^{-4}$ s^{-1} et $11{,}2 \times 10^{-2}$ M^{-1} s^{-1}, à 30°C et à I = 1,0 M ($NaClO_4$). La décomposition de ces complexes mixtes fournit des radicaux libres, probablement de CO_2^-, qui sont oxydés en CO_2 par un autre Mn(III) dans une étape rapide. À un pH de 4,2 et une $[ox]_0 \geq 0{,}12$ M, il y a formation de $[Mn(ox)_3]^{3-}$ avec un rendement quantitatif; ce composé a été caractérisé par spectroscopie et sa constante de vitesse de décomposition unimoléculaire, $k = 2{,}7 \times 10^{-4}$ s^{-1}, à 30°C et I = 1,0 M, se compare bien avec celle rapportée antérieurement $k = 2{,}44 \times 10^{-4}$ s^{-1}, à 25°C et I = 1,0 M.

[Traduit par la rédaction]

Introduction

The oxidation of oxalate ion and its conjugate acids by higher valent manganese species has been a subject of kinetic study for more than a century (1–14). Thus, the involvement of oxalatomanganese(III) species in such reactions has been established, but the detailed mechanism is still not clear. Tris(acetylacetonato)manganese(III), $[MnL_3]$, is a well-characterized Mn(III) complex. The complex and its hydrolytic derivatives $[MnL_2(H_2O)_2]^+$ and $[MnL_2(H_2O)(OH)]$ oxidize glyoxylate (gox^-) (15), thiosulfate (16), hypophosphite (17), and sulfur(IV) (18) through inner-sphere adducts. Whether oxalate, which has some structural resemblance to glyoxylate, reacts similarly is an interesting question, particularly because it is known that (*trans*-1,2-cyclohexanediaminetetraacetato)manganate(III) ion, $[Mn(cdta)]^-$, oxidizes oxalate by an outer-sphere process (19) although $[Mn(cdta)]^-$ and (ethylenediaminetetraacetato)manganate(III), $[Mn(edta)]^-$ react with a variety of reductants such as S(IV), N_3^-, H_2O_2, V(IV), NO_2^-, etc., through an inner-sphere mechanism (20–24).

Experimental

Materials

Preparation of the Mn(III) complex and the standard $NaClO_4$ solution and purification of acetylacetone and N_2 gas have been described elsewhere (18, 25–27).

Oxalic acid dihydrate (G.R., E. Merck) solutions were prepared by direct weighing. All other chemicals, including acrylonitrile, were of reagent grade and were used as received.

Instrumentation has been described earlier (15–18).

Product analyses and stoichiometry

Analyses were carried out after all Mn(III) had reacted under kinetic conditions. Free acetylacetone was determined colourimetrically at 510 nm using *o*-phenylenediamine as the colour-forming reagent (28). We verified that neither Mn^{2+} nor oxalate interferes in this determination. Carbon dioxide was qualitatively detected by passing purified (Chromus scrubbed) dinitrogen through the reaction mixture and passing the outcoming gas through a narrow, long, absorber tube containing lime water (29). We verified that acetylacetone does not interfere with the detection procedure. Unreacted oxalate was determined gravimetrically by adding hot $CaCl_2$ solution to precipitate excess oxalate as $CaC_2O_4 \cdot H_2O$, which was weighed as $CaCO_3$ (30).

Kinetic measurements

Disappearance of Mn(III) in the presence of excess oxalate (at least 10 times the amount of Mn(III)) was generally followed at 560 nm with a 1-cm quartz cell in a thermostated (±0.1°C) cell housing.

Between absorbance measurements the cells with the kinetic mixtures were kept outside the light path to minimize any possible photoreaction (31). Ionic strength in most of the kinetic runs was 1.0 M, maintained by $NaClO_4$. No external buffer was used during the entire study to avoid any possible complexation with Mn(III) and because pH drift during the reactions was at most 0.05. Under the conditions the observed pseudo-first-order rate constants (k_0) were obtained from log(absorbance) against time plots, which were linear for as much as two half-lives. A built-in linear least-squares program of a Casio (Model fx 3600 P) calculator was used for evaluating the slopes of such straight lines. The individual rate constants and the equilibrium constants were evaluated by graphical solution of the appropriate rate law or by numerical analyses, e.g., Gauss's method of solving a set of linear observation equations (32). Associated errors were estimated using standard formulas (33).

Results and discussion

Spectral observations and stoichiometry

Immediate spectral changes are observable on adding oxalate to a solution of the Mn(III) complex in excess acetylacetone (0.1–1.0 M) in the pH range 4.0–7.0. In the pH range 4.0–6.5 a cherry-red colour appears, the equilibrium

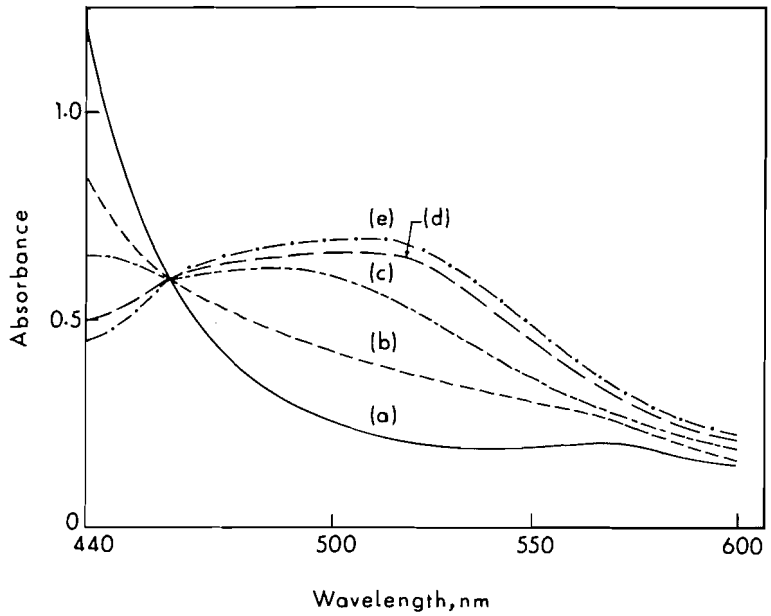

FIG. 1. Spectrum of (*a*) 2 mM of the manganese(III) complex in 0.5 M $[L]_0$ at pH 4.2 at 30°C. The spectra (*b*), (*c*), (*d*), and (*e*) resulted immediately on mixing 0.02, 0.04, 0.08, and 0.12 M $[ox]_0$, respectively, with the complex solution (*a*) under the same conditions. No further change in spectra results on increasing $[ox]_0$; spectrum (*e*) is identical to that reported for $[Mn(ox)_3]^{3-}$.

intensity of which, at a fixed pH, increases with increasing oxalate concentrations. At pH 4.2 and $[L]_0$ (total acetylacetone concentration) 0.5 M, the maximum colour intensity is observed when $[ox]_0 \geq 0.12$ M (Fig. 1). Under such conditions the solution spectrum is identical to one reported earlier for $[Mn(ox)_3]^{3-}$ (5, 6). Evidently all Mn(III)–L complexes are transformed to $[Mn(ox)_3]^{3-}$ quantitatively under such conditions. Mixed ligand complexes, viz. $[MnL_2(ox)]^-$ and $[MnL(ox)_2]^{2-}$, are also possible, along with $[Mn(ox)_3]^{3-}$, through equilibria [1]–[3] at higher pH and lower $[ox]_0$ (total oxalate concentration).

$$[1] \quad [MnL_3] + Hox^- \rightleftharpoons [MnL_2(ox)]^- + HL$$

$$[2] \quad [MnL_2(ox)]^- + Hox^- \rightleftharpoons [MnL(ox)_2]^{2-} + HL$$

$$[3] \quad [MnL(ox)_2]^{2-} + Hox^- \rightleftharpoons [Mn(ox)_3]^{3-} + HL$$

The intensity of the cherry-red colour decreases with increase in pH as $[Mn(ox)_3]^{3-}$ decreases. Above pH 6.5, the cherry-red colour disappears and $[Mn(ox)_3]^{3-}$ is practically absent as indicated by the spectral changes, which are completely different from Fig. 1, but analogous to the spectral changes observed for $[MnL_3]$–gox^- mixtures in the range pH 5.5–7.5 (15). Spectral changes above pH 6.5 are thus interpreted in terms of equilibria [4]–[6], which are analogous to those assigned for the $[MnL_3]$–gox^- system and are fully consistent with the kinetic observations expressed later.

$$[4] \quad [MnL_3] + H^+ + 2H_2O \overset{K_1}{\rightleftharpoons} [MnL_2(H_2O)_2]^+ + LH$$

$$[5] \quad [MnL_2(H_2O)_2]^+ \overset{K_h}{\rightleftharpoons} [MnL_2(H_2O)(OH)] + H^+$$

$$[6] \quad [MnL_2(H_2O)_2]^+ + ox^{2-} \overset{K_c}{\rightleftharpoons} [MnL_2(ox)]^- + 2H_2O$$

All the reaction mixtures discussed above, eventually decay slowly to a final absorbance of less than 0.02 at 560 nm. In this process, under kinetic conditions, very nearly two moles of Mn(III) are consumed per mole of oxalate oxidized to CO_2 under both aerobic and anaerobic conditions; no acetylacetone is consumed within the limit of experimental uncertainty. Five stoichiometric measurements were made in the following ranges of reagent concentrations: $[Mn(III)]_0 = 0.002$–0.004 M; $[ox]_0 = 0.004$–0.005 M; $[L]_0 = 0.05$–0.1 M; pH 6.0–8.0. The average value of $|\Delta[Mn(III)]|/|\Delta[ox]|$ was found to be 2.06 ± 0.11. This is represented in the stoichiometric equation [7].

$$[7] \quad 2Mn(III) + C_2O_4^{2-} \rightarrow 2Mn(II) + 2CO_2$$

The slow decrease in absorbance of the reaction mixture follows first-order kinetics for at least two half-lives but curves towards lower rate constants at longer times if the reaction mixture is not deoxygenated. Therefore, rate constants under aerobic conditions were determined from the initial linear portions (~two half-lives) of the reaction. In completely deoxygenated solutions, the first-order plots proved to be linear for at least 90% completion of the reaction. Moreover, k_0 values obtained from such plots are within 5% of the k_0 values obtained under aerobic conditions. The following changes in the reaction conditions had, within experimental error, no detectable influence on the values of k_0: a fivefold variation (1–5 mM) in complex concentration, addition of excess $Mn(ClO_4)_2$ up to 0.02 M (see later), and a variation in the monitoring wavelength in the range 500–650 nm. Polymerization occurs over the entire experimental range when 6% acrylonitrile is added to the reaction mixture. A free radical mechanism is thus indicated although no epr signals were received. Duplicate runs reproduced individual k_0 values within 4% and some representative values are summarized in Table 1. Under all experimental conditions the autodecomposition of the complex was negligible.

At pH 4.2, $[L]_0 = 0.5$ M and $[ox]_0 \geq 0.12$ M; $k_0 =$

[a][complex] = 2.0 mM; I = 1.0 M.

$(2.7 \pm 0.2) \times 10^{-4}$ s^{-1} at 30°C and I = 1.0 M, and is in very good agreement with the reported rate constant (2.44×10^{-4} s^{-1} at 25°C and I = 1.0 M) for the redox decomposition of $[Mn(ox)_3]^{3-}$. The reaction path at lower pH, therefore, appears to be equilibrium [8]:

$$[8] \quad Mn(III) + 3Hox^- \overset{\text{fast}}{\rightleftharpoons} [Mn(ox)_3]^{3-} + 3HL \xrightarrow{\text{slow}} \text{Products}$$

We have not attempted an evaluation of the kinetic activity of mixed ligand complexes possible for pH ≤ 6.5 for want of equilibrium data on this unstable complex system. Moreover, kinetic analysis of such complex systems may lead to erroneous mechanistic conclusions because the precision achievable in k_0 values may not be enough to distinguish even between an $[ox]_0^2$ and an $[ox]_0^3$ path, for example.

In the pH range 6.6–8.6 k_0 against $[ox]_0$ plots follow saturation kinetics and $1/k_0$ against $1/[ox]_0$ plots are found to be linear ($r > 0.98$), which strongly suggests $[MnL_2(ox)]^-$ to be a kinetically active species. This kinetic observation and also the observed spectral behaviour in this pH range are explicable by the following scheme, with the rapid preequilibrium steps [4]–[6].

$$[9] \quad [MnL_2(ox)]^- \xrightarrow{k_c} Mn(II) + CO_2 + CO_2^- + 2L^-$$

$$[10] \quad [MnL_2(H_2O)(OH)] + ox^{2-} \xrightarrow{k_h} Mn(II) + CO_2 + CO_2^- + 2L^-$$

$$[11] \quad L^- + H^+ \overset{K_2}{\rightleftharpoons} LH$$

$$[12] \quad Mn(III) + CO_2^- \xrightarrow{\text{fast}} Mn(II) + CO_2$$

Selected values of the known equilibrium constants are summarized in Table 2. The radical CO_2^- being quickly oxidized by a second Mn(III), this scheme is comparable to that proposed earlier for the reaction of glyoxylate with these Mn(III) complexes; step [10] is necessary to explain the observed dependence of k_0 on pH. According to this scheme, the rate law derived is

$$[13] \quad k_0 = \frac{2(k_c K_c K_1[H^+] + k_h K_h K_1)[ox]_0}{([HL] + K_c K_1[H^+][ox]_0)}$$

In deriving eq. [13] it was assumed that $(K_1[H^+] + K_1K_h)$ is negligible compared to $([HL] + K_cK_1[H^+][ox]_0)$ under the reaction conditions.

K_c was evaluated from the linear plots ($r \geq 0.98$) of $1/k_0$ against $1/[ox]_0$ at every temperature. Using these K_c values, plots of $k_0([HL] + K_cK_1[H^+][ox]_0)$ against $[H^+]$ at any fixed $[ox]_0$ and temperature were found to be good straight lines (Fig. 2, $r > 0.98$), slopes and intercepts of which yielded the rate constants k_c and k_h. Equation [13] was also solved numerically following Gauss's method using the kinetically estimated K_c values at each temperature, (giving equal weight to all the observations), and the rate constants k_c and k_h thus evaluated agree nicely (within 3%) with the graphically evaluated values. The rate constants thus obtained, along with their activation parameters, are given in Table 3. They reproduce all k_0 values within 2–7%.

The proposed production of CO_2^- (or $C_2O_4^-$) by the intramolecular one-electron oxidation of oxalate by Mn(III) is a well-established process. Since CO_2^- is known to be a very strong reductant (34), it can rapidly reduce another Mn(III). But CO_2^- may also initiate other reactions, e.g., [14]–[16] under aerobic conditions (14, 35–37).

$$[14] \quad CO_2^- + O_2 \rightarrow CO_2 + O_2^-$$

$$[15] \quad O_2^- + Mn(III) \rightarrow Mn(II) + O_2$$

$$[16] \quad Mn(II) + O_2^- + 2H^+ \rightleftharpoons Mn(III) + H_2O_2$$

The overall effect of reactions [14] and [15] is same as reaction [12] and they should not affect kinetics and stoichiometric results. But equilibrium [16] might affect both kinetics and stoichiometry if the equilibrium is significantly displaced to the right. Probably such is the case under our conditions, only when [Mn(III)] is low, e.g., after two half-lives. Consequently, any effect of equilibrium [16] on the measured stoichiometry is hidden within the experimental uncertainties and the kinetics are affected only after at least 75% of the reaction is over. Hence, added Mn(II) does not affect k_0 that were measured from the first two half-lives. We have also verified that the Mn(III)–L complexes are reduced by

TABLE 2. Selected literature values of the equilibrium constants

Equilibrium	Value	Reference

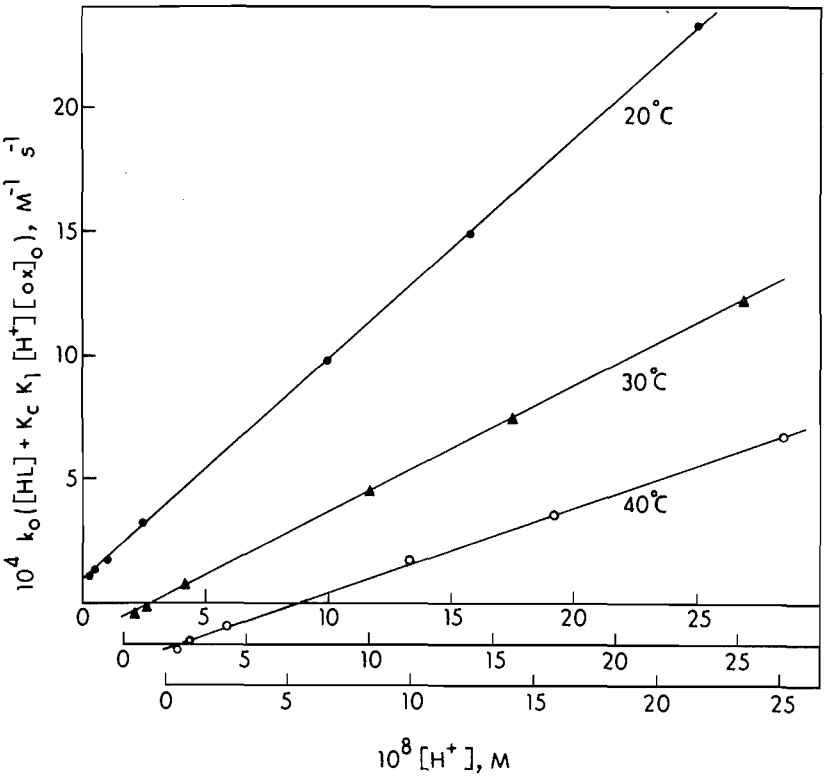

FIG. 2. Evaluation of rate constants k_c and k_h: plots of $k_0([HL] + K_c K_1[H^+][ox]_0)$ against $[H^+]$ at different temperatures. $[ox]_0$ = 0.08 M; I = 1.0 M ($NaClO_4$).

TABLE 3. Rate constants and activation parameters for the reaction of oxalate with Mn(III)–L complexes at I = 1.0 M ($NaClO_4$)[a]

T(°C)	$10^4\ k_c$ (s^{-1})	$10^2\ k_h$ ($M^{-1}\ s^{-1}$)	K_c[b] (M^{-1})
20	0.80 ± 0.04	8.5 ± 0.2	5750 ± 400
30	1.0 ± 0.04	11.3 ± 0.3	2750 ± 200
40	1.3 ± 0.04	16.1 ± 0.3	1550 ± 130
$\Delta H^{\neq}$ (kJ mol^{-1})	16 ± 2	22 ± 3	
$\Delta S^{\neq}$ (J K^{-1} mol^{-1})	−270 ± 30	190 ± 25	

[a]These k_c, k_h, and K_c values are obtained from the graphical solution of eq. [13]. The K_1 and K_h values (see Table 2) used to calculate the rate constants, k_c and k_h, are known under conditions somewhat different from those used in the kinetic studies. However, we found that the choice of K_1 and K_h is not particularly telling on the values of rate constants, e.g., a 15% change in K_1 changes k_1 by no more than 1%, but a simultaneous 15% change in both K_1 and K_h has a stronger effect; k_h then changes by 15%.
[b]ΔH = −50 ± 5 kJ mol^{-1}; ΔS = −100 ± 15 J K^{-1} mol^{-1}.

H_2O_2 at a moderate rate. Involvement of equilibrium [16] in the present system is therefore a distinct possibility.

Mechanism

A moderate $\Delta H^{\ddagger}$ and highly negative $\Delta S^{\ddagger}$ for both k_c and k_h paths dictate the formation of a compact transition state indicative of an inner-sphere mechanism. The high K_c values justify the postulation of the inner-sphere adduct $[MnL_2(ox)]^-$. This K_c value is higher than the formation constant of $[MnL_2(gox)]$ (15) from $[MnL_2(H_2O)_2]^+$ and gox^- and reflects the general tendency of binegative oxalate ion to form a more stable complex than by the uninegative glyoxylate ion with Mn(III). Macartney and Sutin, and Pelizzetti, observed that in oxidation reactions of Mn(III) the aqua path should be much more important than the hydroxo path for a given outer-sphere reductant (38). Since this is not the case in the present system, an inner-sphere mechanism probably is operative also for the k_h path via the plausible intermediate $[MnL_2(OH)(ox')]$, where ox′ represents unidentate oxalate ion. Unidentate behaviour of the oxalate ion is well known (39).

Mn(III)–L species do not prefer outer-sphere pathways, probably due to their weakly oxidizing nature (16), and oxidize oxalate ion via an inner-sphere pathway. Nevertheless, such a path is also not available for $[MnL_3]$ due to its coordinately saturated, pseudo-aromatic, stable chelate ring structure (40). Although $[MnL_3]$ is kinetically labile (estimated ligand exchange rate 1 s^{-1} at 25°C in MeCN) (40), the equilibrium constant for reaction [17] is only ~0.4, thus

$[MnL_2(ox)]^-$ is formed almost exclusively through reaction [6] for

[17] $[MnL_3] + ox^{2-} \rightleftharpoons [MnL_2(ox)]^- + L^-$

which the equilibrium constant K_c is of the order 10^3 M^{-1}. Probably for these reasons $[MnL_3]$ is inactive towards oxalate. In contrast to these Mn(III) species, the anionic complex $[Mn(cdta)]^-$ oxidizes oxalate through an outer-sphere path, probably because of its greater oxidizing power (41) than the Mn(III)–L complexes.

An interesting comparison may arise for the difference in redox behaviour of glyoxylate and oxalate towards the Mn(III) complexes. The gox^- anion catalytically reduces Mn(III). Neutral $gox^{\cdot}$ radical formed by the rate-determining inner-sphere oxidation of gox^- by Mn(III) is not further oxidized by a second Mn(III); rather, the radical is reduced back to gox^- by acetylacetone. In the present investigation, CO_2^- radical anion is quickly reoxidized by a second Mn(III), and the $[L]_0$ content before and after the reaction remains unaltered. This probably indicates that the neutral $gox^{\cdot}$ radical is a weaker reducing agent than the anionic radical species CO_2^-, which is known to be a very powerful reducing agent (34) and hence directly reduces Mn(III).

Evaluation of organic compounds as new cathode active materials in primary cell systems

R. UDHAYAN[1] AND DEVENDRA P. BHATT
Central Electrochemical Research Institute, Karaikudi 623 006, India

Received January 18, 1993

R. UDHAYAN and DEVENDRA P. BHATT. Can. J. Chem. **71**, 2160 (1993).

The performance characteristics of magnesium/trichloroisocyanuric acid (Mg/TCIA) and magnesium/trichloromelamine (Mg/TCM) cells have been reported in this paper. These cells show higher open circuit (>2.5 V) and working voltages (>2.0 V) than known primary organic cells such as magnesium/*meta*-dinitrobenzene (OCV: 1.5 V; CCV: 1.0 V). The capacity, energy density, and coulombic efficiency of these cells are calculated using the galvanostatic technique and the results are compared with magnesium/dichloroisocyanuric acid (Mg/DCIA) cell.

R. UDHAYAN et DEVENDRA P. BHATT. Can. J. Chem. **71**, 2160 (1993).

On a examiné la performance des cellules magnésium/acide trichloroisocyanurique (Mg/ATCI) et magnésium/trichloromelamine (Mg/TCM). Ces cellules des voltages en circuit ouvert (>2,5 V) et de travail (>2,0 V) plus élevés que ceux obtenus avec des cellules organiques primaires connues comme magnésium/*méta*-dinitrobenzène (OCV: 1,5 V; CCV: 1,0 V). On a calculé la capacité, la densité d'énergie et l'efficacité coulombique de ces cellules en faisant appel à la technique galvanostatique et on a comparé les résultats avec ceux obtenus avec la cellule magnésium/acide dichloroisocyanurique (Mg/ADCI).

[Traduit par la rédaction]

Introduction

In the development of modern battery devices, magnesium-organic batteries have received much attention in recent years because of their high energy density and voltage stability. A series of organic depolarisers have been coupled with magnesium or zinc; among them aromatic nitrocompounds, e.g. *meta*-dinitrobenzene has dominated others because of its multielectron transfer property during electrochemical reduction (1–4). Nitro compounds have the following limitations: very low cathode potential, low power density, high solubility, and high toxicity. Halogens, on the other hand, have long been considered attractive materials for cathodes in battery devices because of their high electrode potential and high specific capacity (5). However, their corrosive nature and handling problems make them difficult ingredients in battery devices. To circumvent these problems, halogen-containing compounds (e.g. *N*-halogen organic compounds) have been used as attractive depolarisers in our recent series of publications (6–10). The present investigation demonstrates the electrochemical characteristics of magnesium cells with trichloroisocyanuric acid (TCIA) and trichloromelamine (TCM) as cathode depolarisers. The cells are activated using 2.0 M magnesium perchlorate solution and the performance characteristics have been evaluated and compared with Mg/DCIA cells.

Experimental details

The experimental details are similar as described elsewhere (6–8).

Results and discussion

Organic compounds used in battery devices are well known for their relatively low conductivity (4, 11), thus heterogeneous electrode reaction takes place primarily at the surface. Supplementary conducting materials which occupy critically desired space and contribute nothing coulometrically is typically required for the preparation of the cathode blends. The case is similar with *N*-halogen organic compounds chosen for this study. We have therefore decided to add a well-known conductor such as acetylene black to prepare our cathode mixes. We then subjected Mg/TCIA cells to a constant current drain of 25 mA to determine their actual capacities with varying amounts of acetylene black. The working voltage of the cell increases with increasing amount of acetylene black. Cell capacities using 10, 20, 30, 40 and 50% acetylene black are 31, 100, 176, 225, and 244 Ah (kg of TCIA)$^{-1}$, respectively. These results are further confirmed by voltage–current measurements. The observed linearity is indicative of the fact that the polarisation is ohmic in nature (Fig. 1). The internal resistance of the cell is 9.72, 6.24, 4.02, 3.41, and 3.00 mΩ for 10, 20, 30, 40, and 50% acetylene black, respectively. The capacity has been found to be maximum in 50% acetylene black at which concentration the internal resistance of acetylene black seems to be the lowest and the water retention property of acetylene black seems to be the highest. The internal resistance of a Mg/TCM cell using 50% acetylene black is found to be 7.34 mΩ. However, for cells with greater than 50% acetylene black, there is negligible difference in cell capacity and internal resistance. Thus 50% is considered an effective and optimum amount of acetylene black for Mg/TCIA and Mg/TCM cells.

The half cell potentials of TCIA and TCM cathodes have been measured separately at various current drains. The open circuit potentials (OCP) of TCIA and TCM are observed to be 1150 and 1030 mV (vs. Ag/AgCl), respectively. These figures are significantly higher than other organic depolarisers, e.g. OCP of *meta*-dinitrobenzene is 120 mV (vs. Ag/AgCl) (6). The higher observed potential of TCIA and TCM cathodes can be attributed to the presence of loosely attached chlorine (i.e. an electron-attracting group) in the ring of the organic compounds.

The electrochemical reactions of TCIA and TCM cells are represented by

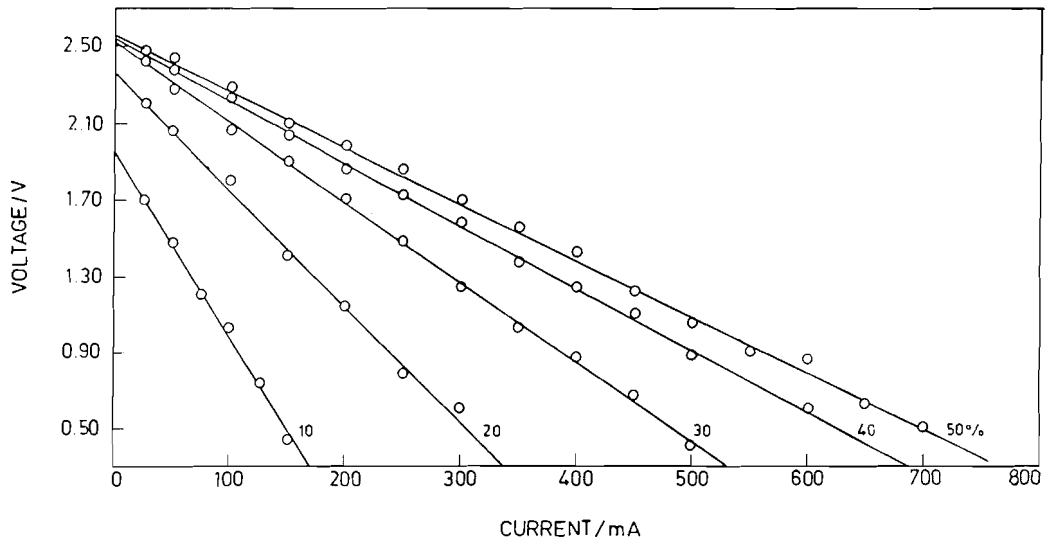

FIG. 1. Voltage–current relationship of Mg/TCIA cell with different percentages of acetylene black.

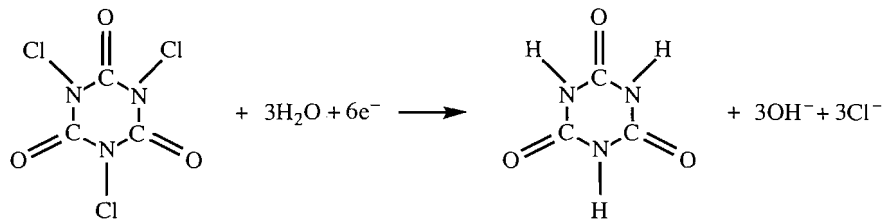
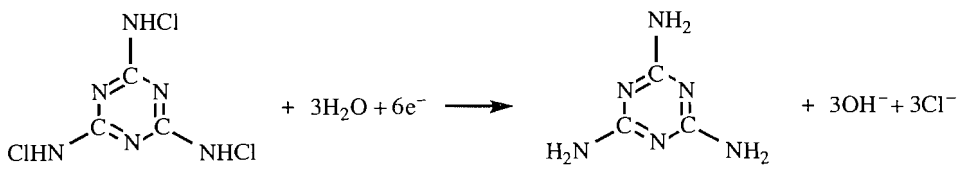
TABLE 1. Comparative evaluation of Mg/TCIA, TCM, DCIA organic cells (current drain: 25 mA)

Organic cell system	OCV (V)	IR (mΩ)	Capacity (Ah kg^{-1})	Energy density (Wh kg^{-1})	Utilisation efficiency (%)
Mg/TCIA	2.67	3.00	244	488	35.2
Mg/TCM	2.51	7.34	25	43	6.2
Mg/DCIA	2.45	3.65	180	371	43.0

TCIA cathode:



TCM cathode:



The discharge characteristics of Mg/TCIA and Mg/TCM cells are studied galvanostatically under continuous discharge at various current drains (Fig. 2). The open circuit voltage (OCV) of the cells are 2.67 and 2.51 V for Mg/TCIA and Mg/TCM systems, respectively. The closed circuit voltage (CCV) of Mg/TCIA cells are found to be in the range 2.52–1.90 V when the current drain is varied from 10 to 250 mA. Similarly, in the case of Mg/TCM cells, the CCV at 10, 25, and 50 mA current drains are found to be 2.22, 2.01, and 1.64 V, respectively. It is noticed that a further increase in current drain of Mg/TCM system results in the loss of cell capacity due to an increase in cathode polarisation.

The capacity and energy density of the Mg/TCIA cell systems are shown in Fig. 3. The coulombic efficiency at discharge rates of 10, 25, 50, 75, 100, 125, 150, 200, and 250 mA is found to be 43.4, 35.2, 32.5, 30.8, 28.9, 27.2, 23.6, 19.3, and 12.0%, respectively. The capacity, energy density, and coulombic efficiency for Mg/TCM cells at 10,

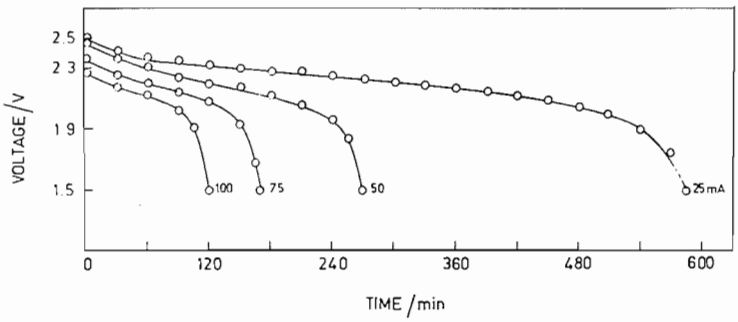

FIG. 2. Effect of current drain on the cell voltage of Mg/TCIA cell.

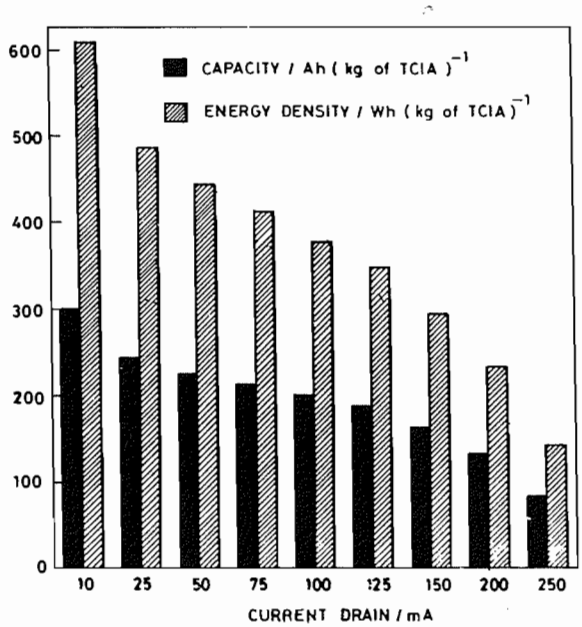

FIG. 3. Experimental histogram of Mg/TCIA cell showing the variation of battery parameters with current drain.

25, and 50 mA are 50, 25, and 17 Ah (kg of TCM)$^{-1}$; 93, 43, and 27 Wh (kg of TCM)$^{-1}$; 7.1, 6.2, and 2.4%, respectively. It is also evident from Fig. 3, that an increase in current drain from 10 to 250 mA brings about a gradual decrease in cell capacity and energy density. These characteristics reveal that a cell can perform more efficiently at lower current drains and also indicate that this cell can find application wherever higher energy density and voltages are basic requirements. Capacity measurements have been carried out on the Mg/DCIA cell system (8) and various battery parameters are compared in Table 1.

The lowest capacity observed in TCM is explained by extensive conjugation of the double bond in between N and —CNHCl, in addition to the electron-donating property of —NHCl group by which the entire —NHCl bond is tightened towards the cyclic ring and hence leads to a maximum stability of the compound. In this case, the electron-donating property of —NHCl is expected to dominate over the electron-withdrawing property of —NCl in TCIA. The maximum stability of TCM could also be attributed to the strong basicity owing to the presence of three nitrogen atoms in the form of N and —NHCl wherein the positive charge on the lone pair of electron on nitrogen atom is comparatively more intact. Hence, a change from —NHCl to —NH_2 is difficult and therefore less capacity is realised in TCM-based cells.

In the case of TCIA, the release of Cl is expected to be relatively easier in comparison with TCM primarily due to a loose bonding between N and Cl in the former compound. This is mainly attributed to the field effect caused by the influence of ion pairs of the electrons of the two atoms, viz. Cl and O, through space interactions which change the vibrational frequency of both atoms (or groups). In this case, an electrostatic repulsion takes place between the nonbonding electrons of oxygen and chlorine, causing a change in the hybridisation state of —CO group and enabling it to repel from the plane of the double bond. Moreover, the three N atoms (—NCl) have positive charge due to the adjacent presence of a highly electrophilic carbonyl group. Hence, the —NCl group can be easily reduced when compared to TCM (—NHCl). Because of these reasons, TCIA cells have realised higher capacity than the TCM-based systems. The presence of one additional —NCl reducible group in TCIA, compared with two additional —NCl groups in DCIA might account for the maximum capacity of cells using the former compound.

Conclusions

A concentration of 50% acetylene black is found to be optimum for TCIA and TCM cathodes. The OCP of TCIA and TCM cathodes are found to be 1150 and 1030 mV (vs. Ag/AgCl), respectively. Similarly, the open circuit (>2.5 V) and working voltages (>2.0 V) are much higher in comparison with known Mg/*meta*-dinitrobenzene cell systems (i.e., OCV: 1.5; CCV: 1.0 V). These type of new cell systems can also find application wherever higher energy density and voltages are considered basic factors for the application. These organic depolarisers are non-toxic (7) and are thus acceptable materials in the battery industry. The meterological department uses Mg/Cu_2Cl_2 system to monitor climatic conditions. Because of their higher voltage and higher capacity, Mg/*N*-halogen organic systems are useful materials or substitutes in Mg/AgCl (or $PbCl_2$, Cu_2Cl_2) cells for the appropriate applications.

Kinetics and mechanism of oxidation of hydroxylamine by hexachloroiridate(IV) ion in buffer solutions

MS. REKHA, ADITYA PRAKASH, AND RAJ N. MEHROTRA[1]
Department of Chemistry, University of Jodhpur, Jodhpur 342 005, India

Received June 23, 1993

MS. REKHA, ADITYA PRAKASH, and RAJ N. MEHROTRA. Can. J. Chem. **71**, 2164 (1993).

The oxidation of hydroxylammonium ion by $[IrCl_6]^{2-}$ ion in acetic acid – acetate buffer solutions, studied by stopped flow, has the stoichiometric ratio $\Delta[IrCl_6]^{2-}/\Delta[NH_2OH] = 1$. The oxidation involves the species $[IrCl_6]^{2-}$ and NH_3OH^+ although spectral analysis of the spent reaction mixture indicates $[IrCl_5(OH_2)]^{2-}$ to be the main product (almost to the extent of 80%). This anomaly arises because of the aquation of the reduced product $[IrCl_6]^{3-}$. The rate is retarded both by H^+ and Cl^- ions and the plots of k_2^{-1} against respective concentrations are linear. The proposed mechanism is given by reactions [*i*]–[*v*].

$$[i] \quad NH_3OH^+Cl^- \underset{}{\overset{K_{ipd}}{\rightleftharpoons}} NH_3OH^+ + Cl^-$$

$$[ii] \quad IrCl_6^{2-} + NH_3OH^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [IrCl_6(NH_2OH)]^{2-} + H^+$$

$$[iii] \quad [IrCl_6 \cdot NH_2OH]^{2-} \underset{k_{-et}}{\overset{k_{et}}{\rightleftharpoons}} [IrCl_6^{3-} \ldots NH_2OH^{\cdot +}]$$

$$[iv] \quad [IrCl_6^{3-} \ldots NH_2OH^{\cdot +}] \underset{k_{-d}}{\overset{k_d}{\rightleftharpoons}} [IrCl_6]^{3-} + NH_2OH^{\cdot +}$$

$$[v] \quad 2NH_2OH^{\cdot +} \xrightarrow{\text{fast}} N_2 + 2H_2O + 2H^+$$

The values of the rate constants at 25°C are as follows: $k_1 = 147$ dm^3 mol^{-1} s^{-1} and $10^2 k_{et}K_{ia} = 2.8$ s^{-1}. The related activation parameters are $\Delta H^{\ddagger}_{k_1} = 29 \pm 2$ kJ mol^{-1}, and $\Delta S^{\ddagger}_{k_1} = -115 \pm 6$ J K^{-1} mol^{-1} and, $\Delta H^{\ddagger}_{k_{et}K_{os}} = 15 \pm 2$ kJ mol^{-1} and $\Delta H^{\ddagger}_{k_{et}K_{os}} = -233 \pm 3$ J K^{-1} mol^{-1}, respectively. The value of K_{ipd} is 2.91 ± 0.03 mol dm^{-3} and that of K_{ipa} ($= 1/K_{ipd}$) is 0.344 ± 0.004 dm^3 mol^{-1}; both values are almost independent of temperature.

MS. REKHA, ADITYA PRAKASH et RAJ N. MEHROTRA. Can. J. Chem. **71**, 2164 (1993).

L'oxydation de l'ion hydroxyammonium par l'ion $[IrCl_6]^{2-}$ dans des solutions tamponnées d'acétate et d'acide acétique a été étudiéc par la technique du flux stoppé a un rapport stoechiométrique $\Delta [IrCl_6]^{2-}/\Delta[NH_2OH] = 1$. L'oxydation implique les espèces $[IrCl_6]^{2-}$ et NH_3OH^+ même si l'analyse spectrale du mélange réactionnel résiduel indique que le produit principal de la réaction (pratiquement 80%) est l'ion $[IrCl_5(OH_2)]^{2-}$. Cette anomalie est due à l'aquation du produit réduit, le $[IrCl_6]^{3-}$. La vitesse de la réaction est retardée par les ions H^+ ainsi que Cl^- et les courbe de k_2^{-1} en fonction des concentrations sont linéaires. Le mécanisme proposés est représenté par les équations (*i*)–(*v*) :

$$[i] \quad NH_3OH^+Cl^- \underset{}{\overset{K_{ipd}}{\rightleftharpoons}} NH_3OH^+ + Cl^-$$

$$[ii] \quad IrCl_6^{2-} + NH_3OH^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [IrCl_6(NH_2OH)]^{2-} + H^+$$

$$[iii] \quad [IrCl_6 \cdot NH_2OH]^{2-} \underset{k_{-et}}{\overset{k_{et}}{\rightleftharpoons}} [IrCl_6^{3-} \ldots NH_2OH^{\cdot +}]$$

$$[iv] \quad [IrCl_6^{3-} \ldots NH_2OH^{\cdot +}] \underset{k_{-d}}{\overset{k_d}{\rightleftharpoons}} [IrCl_6]^{3-} + NH_2OH^{\cdot +}$$

$$[v] \quad 2NH_2OH^{\cdot +} \xrightarrow{\text{rapide}} N_2 + 2H_2O + 2H^+$$

Les valeurs des constantes de vitesse à 25°C sont : $k_1 = 147$ dm^3 mol^{-1} s^{-1} et $10^2 k_{et}K_{ia} = 2.8$ s^{-1}. Les paramètres d'activation apparentés sont respectivement $\Delta H^{\ddagger}_{k_1} = 29 \pm 2$ kJ mol^{-1} et $\Delta S^{\ddagger}_{k_1} = -115 \pm 6$ J K^{-1} mol^{-1} et $\Delta H^{\ddagger}_{k_{et}K_{os}} = 15 \pm 2$ kJ mol^{-1} et $\Delta S^{\ddagger}_{k_{et}K_{os}} = -233 \pm 3$ J K^{-1} mol^{-1}. La valeur de K_{ipd} est égale à $2,91 \pm 0,03$ mol dm^{-3} et celle de K_{ipa} ($= 1/K_{ipd}$) est égale à $0,344 \pm 0,004$ mol dm^{-3}; les deux valeurs sont pratiquement indépendantes de la température.

[Traduit par la rédaction]

Introduction

Hydroxylamine is an intermediate in the enzymatic oxidation of ammonia to nitrite and (or) nitrate or in the reverse reduction of these ions to ammonia (1). This and the fact that it acts both as an oxidizing and reducing agent with transition metals and their complexes has stimulated a keen interest in investigating its redox and ligand properties (2). Amongst several oxidations, the oxidation by hexachloroiridate(IV) ion in the presence of perchloric acid has been studied (3). The rate, studied in low $[HClO_4]$ (0.01–0.15 mol dm^{-3}), showed an inverse dependence on $[H^+]$, and k_{obs} $[H^+]$ was constant. The simple two-step mechanism considered the formation of an $[IrCl_6(NH_2OH)]^{2-}$ complex in an equi-

librium step prior to its disproportionation to $[IrCl_6]^{3-}$ and NHOH' free radical in the rate-determining step. The rate was found to become complex at $[HClO_4] > 0.15$ mol dm^{-3} and the reason was attributed to the probable formation of $[HIrCl_6]^-$. However, $[IrCl_6]^{2-}$ is considered to have a negligible base strength and is therefore unlikely to be protonated (4). The interesting feature was the detection and estimation of $[IrCl_5(OH_2)]^{2-}$ (<10%) in the spent reaction mixtures but no explanation for its probable formation was given.

The redox chemistry of NH_2OH with transition metals in solution is complicated. A variety of oxidation products, viz., N_2, N_2O, NO, NO_2, NO_2^-, or NO_3^-, depending on the fate of the $H_2NO\cdot$ radical that undergoes reactions [1]–[3], are formed under different conditions (2). Reaction [3] is the dimerization of $HNO\cdot$ to hyponitrous acid (5), which exists in *cis* and *trans* forms. The *trans* form, more stable than the *cis* form, decomposes into N_2O (6). In the case of strong oxidants such as Mn^{3+}(aq) and Ag^{2+}(aq) (7), the free radical is oxidized to NO_3^- by excess oxidant. The formation of the $H_2NO\cdot$ radical in oxidations by one-electron oxidants has been demonstrated by esr spectroscopy (8).

[1] $NH_2O\cdot \rightarrow 0.5N_2 + H_2O$

[2] $H_2NO\cdot \rightarrow HNO + H^+ + e^-$

[3] $2HNO \rightarrow H_2N_2O_2 \rightarrow N_2O + H_2O$

This study was, therefore, undertaken in the pH range 3.42–5.23 (acetic acid – sodium acetate buffer) to check if NH_2OH, which could be easily produced as a result of increased dissociation of NH_3OH^+ at such low $[H^+]$, happened to be reactive and whether $[IrCl_5(OH_2)]^-$ is the reactive Ir(IV) entity in view of the fact that $[IrCl_5(OH_2)]^{2-}$ was reported to be one of the oxidation products (3). We were further inclined to investigate whether the reaction proceeded through an Ir(IV)–hydroxylamine complex, and the same could be substantiated by a rapid-scan technique that might help to characterize its character as an *outer* or *inner* sphere. Preliminary studies indicated that the rates are retarded by H^+ and Cl^- ions; retardation by the latter ion was observed for the first time in an Ir(IV) oxidation although an acceleration of the rate in hydrazine oxidations by Ir(IV) (9) and $[Fe(CN)_6]^{3-}$ (10) was reported without any explanation being given.

Experimental

Fresh solutions of Ir(IV), using either H_2IrCl_6 (Soekawa Chemicals) or $Na_2IrCl_6\cdot 6H_2O$ (JM), were standardized spectrophotometrically (Shimadzu 240 Graphicord) using $\epsilon_{488} = 4050$ dm^3 mol^{-1} cm^{-1} (11) and were used within a few hours. Solutions of hexachloroiridate(III) (JM) were similarly prepared and standardized using $\epsilon_{358} = 74$ dm^3 mol^{-1} cm^{-1}) (12). However, we could more closely reproduce the ϵ_{460} literature value of 2080 dm^3 mol^{-1} cm^{-1} (12), more often, in a given sample in which ϵ_{488} showed considerable variation from the literature value of 4075 ± 25 dm^3 mol^{-1} (see Spectrophotometry section).

Solutions of hydroxylamine hydrochloride (E. Merck, puriss), prepared in distilled water purged with nitrogen, were standardized bromometrically (13). Solutions of lithium and sodium perchlorate were prepared by neutralizing lithium hydroxide (G.F. Smith) and sodium carbonate (E. Merck, GR) by perchloric acid. The solutions were cooled, the pH was adjusted to 7, and the concentration was determined by evaporating the water from weighed aliquots and drying to a constant weight. The buffer solutions of desired pH values were prepared by mixing solutions of sodium acetate (E. Merck, GR) and E. Merck's GR acetic acid (14) ($[CH_3COO^-] = 0.06$ mol dm^{-3}) and the pH was checked with a pH meter. While adjusting the ionic strength (I), CH_3COONa was assumed to be completely ionized.

One of the reviewers has drawn our attention to the catalysis by trace levels of Cu^{2+} ion (15); moreover, addition of Fe^{2+} at the level of 10^{-4} mol dm^{-3} is stated to accelerate the rates by more than a factor of 1000. Although the samples were not purified and were used as received, we feel in the light of observed linear correlations between the respective rate and concentration that these samples did not contain any Cu^{2+} or Fe^{2+} ions as impurity, at least at levels that could affect the rates.

Twice-distilled water, once from alkaline permanganate from an all-glass still, was purged with nitrogen before use.

Spectrophotometry

The uv–visible spectra of the various solutions, described below, were recorded using an HP8452 diode array spectrophotometer having a band width of 2 nm and using an integration time of 1 s. The reference in each case was a water solution having the other constituents of the same concentration. Although the spectra were recorded between 190 and 820 nm, the spectra in each of the various figures are shown over the relevant range of wavelength. The $[IrCl_6]^{2-}$ sample was about 3–4 months old.

A 25 mL stock solution of Ir(IV) was prepared by weighing 0.044 g (0.00314 mol dm^{-3}) of a $Na_2IrCl_6\cdot 6H_2O$ (JM) sample in $[HClO_4] = 1$ mol dm^{-3}. The spectrum of the diluted solution (1.57×10^{-4} mol dm^{-3}) in 3 mol dm^{-3} perchloric acid showed an absorbance of 0.497 and 0.263 at 488 (λ_{max}) and 460 (λ_{min}) nm, respectively, from which $\epsilon_{488} = 3163$ and $\epsilon_{460} = 1678$ dm^3 mol^{-1} cm^{-1} were calculated. These values, smaller than those obtained for a solution similarly diluted with chlorine-saturated perchloric acid of the same concentration (see below), indicate that the sample had some $[IrCl_6]^{3-}$ as the impurity. The fact that the characteristic peak of $[IrCl_6]^{3-}$ at 358 nm was not observed could well be due to its relatively small concentration present as impurity and to the small value of ϵ_{358}, 74 dm^3 mol^{-1} cm^{-1} (12*b*). The absorbance of the solution deteriorated slightly after 24 h.

The visible spectrum of a similarly diluted stock solution in chlorine-saturated perchloric acid (3 mol dm^{-3}) is shown in Fig. 1. The reference solution was 3 mol dm^{-3} perchloric acid saturated with chlorine. The absorbance at 488 and 460 nm was 0.554 and 0.328, respectively, giving $\epsilon_{488} = 3525$ against 4050 and $\epsilon_{460} = 2086$ against 2080 dm^3 mol^{-1} cm^{-1} (12*a*). The increase in the absorbance at both wave lengths could be ascribed to the oxidation of $[IrCl_6]^{3-}$, present as an impurity, by chlorine. The extent of $[IrCl_6]^{3-}$ present as impurity, calculated on the basis of the amount of the sample weighed and calculated on the basis of the ϵ_{488} value, is about 13%.

The $\epsilon_{460} = 2086$ dm^3 mol^{-1} cm^{-1}, closer to the literature value, was obtained more often, whereas a significant difference in the ϵ_{488} value existed in the same sample, for which we have no explanation at the moment. One of the reviewers felt that hydrolysis of Ir(IV) chloride could be the probable reason for the discrepancy. Although it was not investigated by us, the fact that the acidic $[IrCl_6]^{2-}$ solutions were spectrophotometrically shown to be stable for at least 7 days (4) negates such a possibility.

Next, the reaction mixture ($10^4[IrCl_6^{2-}] = 3.14$, $10^4[NH_3OH^+] = 4$, and $[HClO_4] = 1$ mol dm^{-3}) was left overnight for completion as the reaction was slow at this $[H^+]$ value. The spectrum of a twice-diluted reaction mixture in $[HClO_4] = 3$ mol dm^{-3} had a peak at 342 nm and an absorbance = 0.0227. The peak probably corresponds to $[IrCl_5(OH_2)]^{2-}$, which has a λ_{max} at 347 nm (12*a*). The peak at 358 nm corresponding to $[IrCl_6]^{3-}$ was not obtained. This indicates that the expected $[IrCl_6]^{3-}$ was aquated and converted to $[IrCl_5(OH_2)]^{2-}$, since the specific rate of aquation of $[IrCl_6]^{3-}$ is ca. 400 times that of $[IrCl_6]^{2-}$ at 50°C (11).

The spectral characters of $[IrCl_6]^{3-}$ and $[IrCl_5(OH_2)]^{2-}$ are very similar, making it difficult to distinguish one from the other. The spectra of the corresponding Ir(IV) species are, however, differ-

ent. Since Ir(III) complexes are rapidly and quantitatively oxidized to the corresponding Ir(IV) complexes by chlorine (11), the spent reaction mixture was oxidized with perchloric acid saturated with chlorine. The details are given below.

The spent reaction mixture was twice diluted with chlorine-saturated perchloric acid ($\simeq$ 3 mol dm^{-3}). The reference was a solution of the same perchloric acid of the same strength. The spectrum of this solution, Fig. 2, showed a peak absorbance of 0.477 at 448 nm, which is same as the known λ_{max} at 450 nm for $[IrCl_5(OH_2)]^-$ (12). Using ϵ_{450} = 3320 dm^3 mol^{-1} cm^{-1}, the $[IrCl_5(OH_2)^-]$ was calculated to be 1.44 × 10^{-4} mol dm^{-3}, indicating that it is present to the extent of almost 92% of the initial $[IrCl_6^{2-}]$. And this includes the conversion of 13% of $[IrCl_6]^{3-}$ present as impurity in the sample.

Rapid scan of the reaction mixture

The successive rapid-scan spectra of the reaction mixture, recorded using 482 nm as the central wavelength on an Union–Giken RA-415 stopped-flow spectrophotometer with an interval (the time lapsing between the two consecutive scans) of zero time and a gate time (time taken to complete the scan) of 2 ms, are shown in Fig. 3. The reference was a spent reaction mixture allowed to remain in the mixing cell of the stopped-flow instrument for a period much greater than 9 half-lives of the reaction. The scan (–O–O–O–) corresponds to pure $[IrCl_6]^{2-}$. It is to be noted that the absorbance of the scan recorded after 4 ms of mixing was greater than that of the pure solution. The absorbance of the successive scans, recorded at time intervals of 8, 12, 16, 20, 26, and 32 ms, decreased and tended to reach a saturation value. That the gradual decrease in the absorbance, indicative of the formation of new species believed to be an *outer*-sphere complex, is not due to the decrease of $[IrCl_6^{2-}]$ used in oxidizing of hydroxylamine during the period of measurement is supported by the rate constant at much higher $[NH_3OH^+]$. The equilibrium for the complex formation is probably attained in about 32 ms when the absorbance assumes a constant value.

Kinetic measurements

The kinetics were studied in acetate buffer under pseudo-first-order conditions ($[NH_2OH] \geqq 10[IrCl_6^{2-}]$) at constant ionic strength (I) maintained with $NaClO_4$. The solutions of NH_3OH^+ in the desired buffer and of Ir(IV), taken separately in the stock cylinders of the Union–Giken RA-401 stopped-flow spectrophotometer, were brought to thermal equilibrium at the desired temperature (±0.1°C). The temperature was maintained by circulating water from a Haake D8G refrigerated circulatory water bath. The instrument has a dead time of about 0.5 ms for a 2 mm flow cell. The rate was followed in terms of disappearance of $[IrCl_6]^{2-}$ at 488 nm, at which wavelength other components of the reaction mixture are transparent. The averaged volt–time curves, at least from 10–12 runs, were analysed for the values of the pseudo-first-order rate constant, k_{obs}, by an in-built program in the computer used for collecting the data. The reproducibility was within ±5%.

Test for free radical

The reactant solutions were purged with nitrogen and 1 mL of acrylonitrile was added to each solution. No polymerization of the monomer was noted over ca. 5–10 min. However, a curdy white

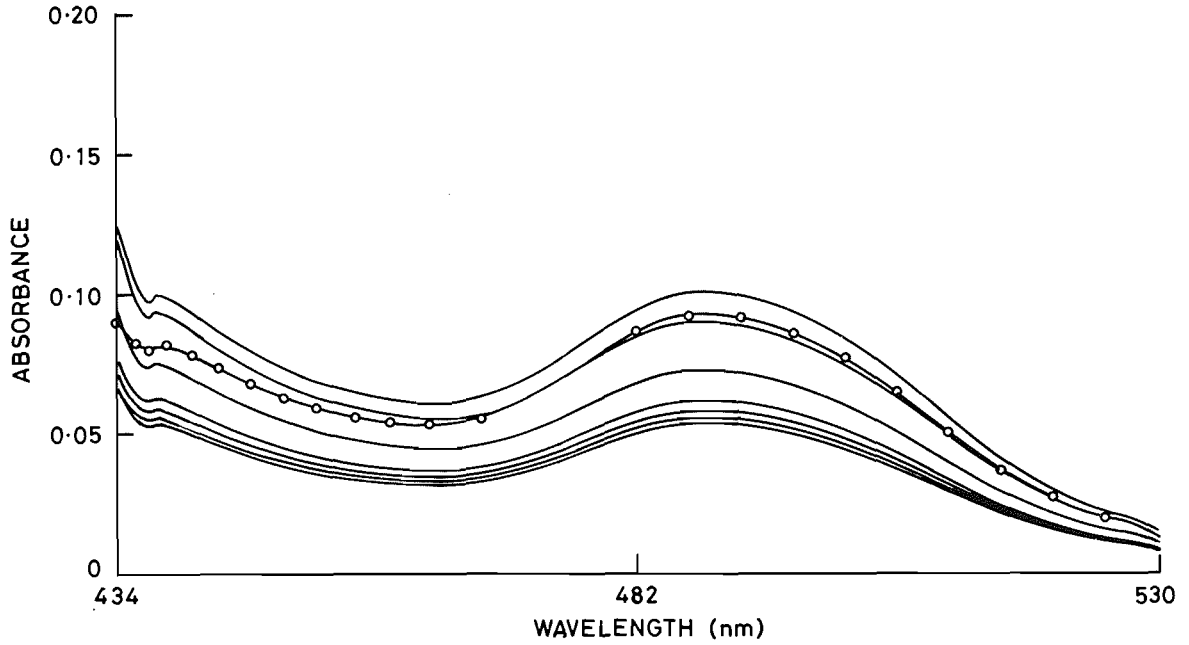

FIG. 3. The rapid-scan spectrum of the reaction mixture having $10^5[IrCl_6^{2-}] = 2.5$, $10^5[NH_3OH^+] = 5.0$ mol dm^{-3}, pH 4.27, and 20°C. The spectrum (–○–○–○–) corresponds to pure $[IrCl_6]^{2-}$ solution of the same concentration (absorbance = 0.0925, hence calculated ϵ = 3700 dm^3 mol^{-1} cm^{-1}). The solid line spectra, top to bottom, were recorded at the beginning of 4, 8, 12, 16, 20, 26, and 32 ms after mixing.

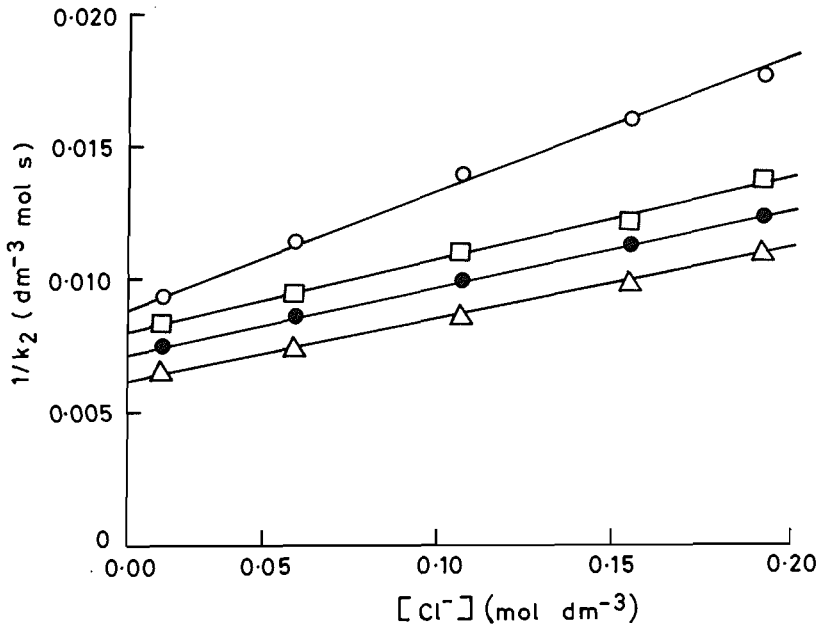

FIG. 4. Plots of k_2^{-1} vs. $[Cl^-]$ at temperatures 25°C (○), 30°C (□), 35°C (●) and 40°C (△). ($10^4[Ir(IV)] = 1.0$, $10^3[NH_3OH^+] = 1.0$, $[Na^+] = 0.4$, and $I = 0.4$ mol dm^{-3}).

precipitate appeared on mixing the two solutions, indicating the formation of a free radical in the reaction mixture.

Results

Stoichiometry

The stoichiometry is dependent upon the concentrations of the reactants. The $\Delta[IrCl_6^{2-}]/\Delta[NH_3OH^+]$ increased from 1.03 ± 0.04 to 2.13 ± 0.07 with decreasing $[NH_3OH^+]$ (Table S1[2]). The results could be expressed by the stoichiometric equations [4] and [5] under the two conditions.

[4] $$2[IrCl_6]^{2-} + 2NH_3OH^+ \rightarrow 2[IrCl_6]^{3-} + N_2 + 2H_2O + 4H^+$$

[5] $$4[IrCl_6]^{2-} + 2NH_3OH^+ \rightarrow 4[IrCl_6]^{3-} + N_2O + H_2O + 6H^+$$

[a]$10^4[IrCl_6^{2-}] = 1.0$, $10^3[NH_2OH] = 1.0$, $I = 0.3$ mol dm^{-3}.

A variable stoichiometry as a function of excess [oxidant] is known for one-electron oxidants (8, 9, and 16). Since the primary interest in the kinetics is the characterization of the initial product, the rates were measured in excess of $[NH_3OH^+]$, limiting the study represented by eq. [4].

Kinetic measurements were made over a broad range of [Ir(IV)] to confirm first-order dependence in [Ir(IV)]. The rate increased proportionately with $[NH_3OH^+]$ at different pH, and the plots of k_{obs} vs. $[NH_3OH^+]$ were linear, passing through the origin. The slope ($k_{obs}/[NH_3OH^+]$ of the plot is taken as the measure of k_2, the second-order rate constant. The k_{obs} was unaffected by the outside addition of $[IrCl_6]^{3-}$ (Table S2[2]). It was noted that changing the ratio of CH_3COOH and CH_3COO^- in the buffer did not affect the rate. The k_{obs} was independent of $[LiClO_4]$ but increased by 23% when $NaClO_4$ was increased by almost fivefold (Table S3[2]). The increase in the rate is, perhaps, due to medium effects of the sodium ion. The medium effect is an important factor in redox and substitution reactions (17), and is usually not so marked for intramolecular redox reactions (18).

The effect of $[Cl^-]$ on k_{obs} (Table S4[2]), was studied at constant $[Na^+] = 0.4$ mol dm^{-3}, being the sum total concentrations of NaCl, $NaClO_4$, and CH_3COONa present in the reaction mixture, to avoid variations in the rate due to the medium effects of the ion by using mixtures of NaCl and $NaClO_4$. Since the ionic strength and $[Na^+]$ are constant and $[ClO_4^-]$ has no effect on the rate, the decrease in the rate is considered to be due to chloride ions. At the suggestion of one of the referees, the effect of $[Cl^-]$ on the rate was briefly checked using mixtures of LiCl and $LiClO_4$. These results confirmed that the inhibition of the rate was due to the Cl^- ions. The linear plots of k_2^{-1} against $[Cl^-]$ have intercepts on the rate ordinate at each temperatures (Fig. 4). The data in Tables S1–S4 are presented as supplementary material.[2]

Dependence on pH

The effect of pH variation on the rate at different temperatures is given in Table 1. The values of k_2 increase with the pH. The plots of k_2^{-1} vs. $[H^+]$ are linear with positive intercepts on the rate ordinate at different temperatures (Fig. 5).

Thus the empirical rate law for the dependence of both $[H^+]$ and $[Cl^-]$ is expressed by eq. [6].

$$[6] \qquad k_2 = \frac{a}{b[X] + d}$$

where X represents H^+ and Cl^- ions.

Discussion

The evidence, provided by the inertness of $[IrCl_6]^{2-}$ to substitution,[3] the stoichiometry, the induced polymerization of acrylonitrile, and the empirical rate law, can be simply explained by an *outer*-sphere mechanism in which the intermediate $NH_2OH^{\cdot+}$ is not oxidized further by the deficient Ir(IV) present in the reaction mixture. The lack of rate dependence on [Ir(III)] indicates that it does not appear on the product side of any equilibrium involved, either at the rate-determining step or at any step preceding it.

The rate is retarded by both Cl^- and H^+ ions in an identical manner. It suggests the existence of equilibria in which these ions appear on the product side. For chloride ion, such an equilibrium could be as in eq. [7]:

$$[7] \qquad [IrCl_6]^{2-} + NH_3OH^+ \rightleftharpoons [IrCl_5(NH_3OH)] + Cl^-$$

However, the formation of an *inner*-sphere complex, $[IrCl_5(NH_3OH)]$, is considered improbable because $[IrCl_6]^{2-}$ is substitution inert (19). The retarding effect of Cl^- ion could therefore be attributed to either of the equilibria shown in eqs. [8] and [9] where $NH_3OH^+Cl^-$ is an ion-pair. These two equilibria offer scope for proposing two different mechanisms, each leading to a rate law that is consistent with the empirical rate law in eq. [6]. The mechanism based on equilibrium [8] will be discussed in detail whereas the mechanism based on equilibrium [9], in which $[IrCl_5(OH_2)]^-$ would react with NH_3OH^+ as in reaction [13], is less likely, in view of the fact that the spectra of freshly prepared solutions and those aged for 24 h are the same, indicating that

[2]Tables of supplementary data (Tables S1–S4) can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A OS2, Canada.

[3]It means that substitution is not complete in less than 1 min. See ref. 10. Hence the formation of such an *inner*-sphere complex for a reaction taking place on the stopped-flow time scale is simply inadmissible.

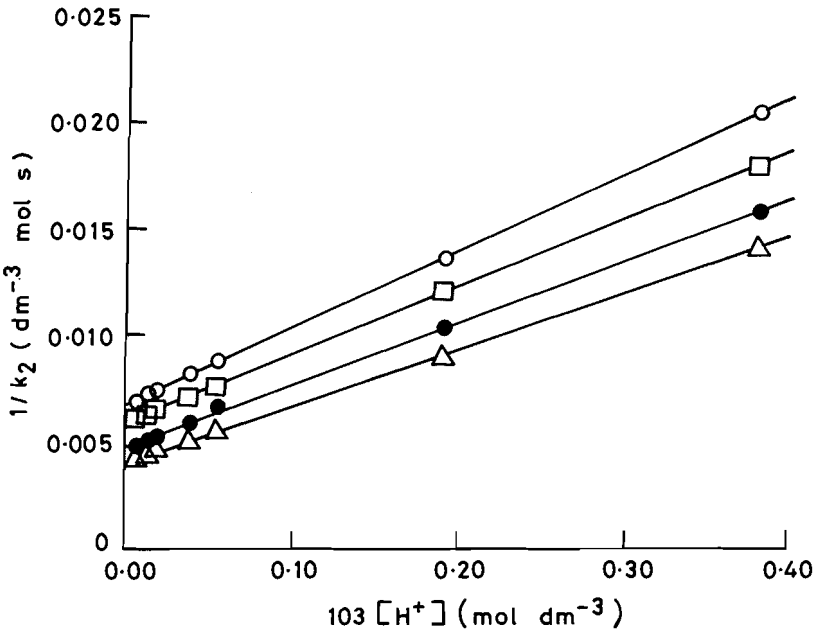

FIG. 5. Plots of k_2^{-1} vs. $[H^+]$ at 25°C (○), 30°C (□), 35°C (●), and 40°C (△). (10^4[Ir(IV)] = 1.0, 10^3[NH_3OH^+] = 1.0, and I = 0.3 mol dm^{-3}).

no species other than $[IrCl_6]^{2-}$ was initially present in the solution.

[8] $NH_3OH^+Cl^- \rightleftharpoons NH_3OH^+ + Cl^-$

[9] $[IrCl_6]^{2-} + H_2O \rightleftharpoons [IrCl_5(OH_2)]^- + Cl^-$

With support from the rapid-scan spectrum for the formation of an *outer*-sphere complex, the following mechanism is postulated. It might be mentioned that a chloride-bridged intermediate $[IrCl_5ClSO_3]^{4-}$, analogous to a cyanide-bridged intermediate $[Fe(CN)_5CNSO_3]^{5-}$ (19), was suggested in the Ir(IV) oxidation of sulphite ion (4). The formation of the intermediate was confirmed in a recent reinvestigation of the reaction (20). The formation of an *outer*-sphere complex is further probable on the basis of the analogy that the sulfur atom in SO_3^{2-} and the nitrogen atom in NH_2OH each have an s^2 pair of unshared electrons, and $[IrCl_6]^{2-}$ and $[Fe(CN)_6]^{3-}$ each have one unpaired d electron.

[8] $NH_3OH^+Cl^- \overset{K_{ipd}}{\rightleftharpoons} NH_3OH^+ + Cl^-$

[13] $[IrCl_6]^{2-} + NH_3OH^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [IrCl_6NH_2OH]^{2-} + H^+$

[14] $[IrCl_6NH_2OH]^{2-} \underset{k_{-et}}{\overset{k_{et}}{\rightleftharpoons}} [IrCl_6^{3-}\ldots NH_2OH^{\cdot+}]$

[15] $[IrCl_6^{3-}\ldots NH_2OH^{\cdot+}] \underset{k_{-d}}{\overset{k_d}{\rightleftharpoons}} [IrCl_6]^{3-} + NH_2OH^{\cdot+}$

[16] $2NH_2OH^{\cdot+} \xrightarrow{\text{fast}} N_2 + 2H_2O + 2H^+$

where K_{ipd} is the equilibrium constant for the dissociation of the $NH_3OH^+Cl^-$ ion pair, K_{os} ($= k_1/k_{-1}$) is the equilibrium constant for the formation of the outer-sphere complex $[IrCl_6NH_2OH]^{2-}$, k_{et} is the rate constant for the electron transfer within the outer-sphere complex, and k_d is the rate constant for the dissociation of the product after the electron transfer. Reaction [16], with an excess of Ir(IV), is replaced by the reactions [16*a*] and [16*b*], leading to the formation of N_2O, and thus explaining the high stoichiometric ratio with excess of Ir(IV).

[16*a*] $NH_2OH^{\cdot+} + Ir(IV) \rightarrow Ir(III) + 2H^+ + HNO$

[16*b*] $2HNO \rightarrow N_2O + H_2O$

From the application of the steady-state treatment, one obtains:

$$[17]\quad [IrCl_6^{3-}\ldots NH_2OH^{\cdot+}] = \frac{k_{et}[IrCl_6NH_2OH]^{2-}}{k_{-et} + k_d}$$

$$[18]\quad [IrCl_6NH_2OH]^{2-} = \frac{k_1[IrCl_6]^{2-}\,[NH_3OH^+]}{k_{-1}[H^+] + k_{et}}$$

$$[19]\quad [NH_3OH^+] = \frac{K_{ipd}[NH_2OH\cdot HCl]_0}{K_{ipd} + [Cl^-]}$$

With the assumption that $k_d \gg k_{-et}$, the k_{obs} is expressed by eq. [20].

$$[20]\quad k_{obs} = \frac{K_{ipd}k_{et}k_1[NH_2OH\cdot HCl]_0}{(k_{-1}[H^+] + k_{et})(K_{ipd} + [Cl^-])}$$

Equation [20] can be rearranged to eq. [21] where $[NH_2OH\cdot HCl]_0/k_{obs} = k_2^{-1}$.

$$[21]\quad \frac{1}{k_2} = \frac{(k_{-1}(H^+) + k_{et})}{k_1k_{et}} + \frac{(k_{-1}[H^+] + k_{et})[Cl^-]}{K_{ipd}k_1k_{et}}$$

Equation [21] is consistent with the linear plots between k_2^{-1} and $[Cl^-]$, Fig. 4, at the different temperatures investigated. The estimated values of K_{ipd}, at different temperatures, from the intercepts and slopes of these plots are given in Table 2. It is interesting to note that the K_{ipd} values, 2.91 ± 0.03 mol dm^{-3}, are almost independent of temper-

TABLE 2. The values of the rate constants k_1 and $k_{et}K_{os}$ and the equilibrium constant K_{ipd} at different temperatures, and the respective activation parameters.

	Temperature (°C)			
	25	30	35	40
k_1 (dm^3 mol^{-1} s^{-1})	147	168	209	249
$10^2 k_{et}K_{os}$ (s^{-1})	2.80	3.18	3.46	3.77
K_{ipd} (mol dm^{-3})	2.94	2.92	2.91	2.87
K_{ipa} (dm^3 mol^{-1})	0.340	0.342	0.344	0.348
$\Delta H^{\ddagger}_{k_1} = 29 \pm 2$ kJ mol^{-1}		$\Delta H^{\ddagger}_{k_{et}K_{os}} = 15 \pm 2$ kJ mol^{-1}		
$\Delta S^{\ddagger}_{k_1} = -115 \pm 6$ J K^{-1} mol^{-1}		$\Delta S^{\ddagger}_{k_{et}K_{os}} = -233 \pm 3$ J K^{-1} mol^{-1}		

ature. This could be rationalized if the ΔH_{ipd} has a small value. The value of K_{ipd} ($= 1/K_{ipa}$) was computed from the Fuoss equation (21) using 1.40 and 1.81 Å as the radii of NH_3OH^+ and Cl^- ions, respectively.

Again, in the absence of $[Cl^-]$ eq. [20] can be written as eq. [22], which explains the dependence of the rate on $[H^+]$.

$$[22] \qquad k_{obs} = \frac{k_{et}k_1[NH_2OH \cdot HCl]_0}{k_{-1}[H^+] + k_{et}}$$

Equation [22] can be rearranged to eq. [23] $k_1/k_{-1} = K_{os}$, which is consistent with the plots of k_2^{-1} vs. $[H^+]$ (Fig. 5).

$$[23] \qquad \frac{[NH_2OH \cdot HCl]_0}{k_{obs}} = \frac{1}{k_2} = \frac{[H^+]}{k_{et}K_{os}} + \frac{1}{k_1}$$

The computed values of k_1 and $k_{et}K_{os}$ are given in Table 2 together with the associated activation and thermodynamic parameters. In conclusion, NH_3OH^+ rather than NH_2OH is the reactive hydroxylamine species and the skeleton mechanism proposed by Sen Gupta et al. (3) is confirmed. However, it must be noted that the retardation in the rate by H^+ is due to reaction [13] and is not due to the dissociation $NH_3OH^+ \rightleftharpoons NH_2OH + H^+$. Thus the mechanism of the oxidation of hydroxylamine by $[IrCl_6]^{2-}$ is different from its oxidation by isostructural $[PtCl_6]^{2-}$ studied in the same pH range (22).

Complexation of aqueous iodine by 18-crown-6

WARREN HIRSCH,[1] JONATHAN GREENMAN, AND RICHARD PIZER
Department of Chemistry, Brooklyn College of The City University of New York, Brooklyn, NY 11210, U.S.A.

Received June 1, 1993

WARREN HIRSCH, JONATHAN GREENMAN, and RICHARD PIZER. Can. J. Chem. **71**, 2171 (1993).

The reaction of 18-crown-6 with aqueous iodine has been monitored by UV and visible spectrophotometry. The stability constant for the reaction has been determined as well as the spectra for the pure aqueous complex. This stability constant has been related to other equilibrium constants for the complexation of molecular iodine. The relation appears to predict correctly the stability constant for the iodine–water charge-transfer complex.

WARREN HIRSCH, JONATHAN GREENMAN et RICHARD PIZER. Can. J. Chem. **71**, 2171 (1993).

Faisant appel à la spectrophotométrie UV–visible, on a suivi la réaction de l'éther 18-couronne-6 avec l'iode aqueux. On a déterminé la constante de stabilité pour cette réaction ainsi que le spectre du complexe pur en solution aqueuse. On a établi une corrélation entre cette constante de stabilité et d'autres constantes d'équilibre pour la complexation de l'iode moléculaire. La relation semble prédire correctement la constante de stabilité pour le complexe de transfert de charge iode–eau.

Introduction

Crown ethers are cyclic ethers known for their ability to form inclusion complexes with cations and neutral molecules. 18-Crown-6 contains 12 carbon atoms and 6 oxygen atoms within its ring. However, the cavity has a diameter of 260–320 pm and is not large enough to accommodate an iodine molecule with a covalent diameter of 530 pm (1). Moreover, the van der Waals diameter of 390 pm for an iodine atom makes it unlikely that even a single iodine atom may be accommodated. Nevertheless, crown ether – iodine complexes have been observed in solutions of methylene chloride, cyclohexane, and carbon tetrachloride (2, 3). These are presumed to be charge-transfer-type complexes, without inclusion, in which the lone pairs of electrons on the oxygen atoms of the crown ethers are donated to vacant $b_{2\sigma u}$ molecular orbitals of iodine (2).

Charge-transfer complexes involving I_2 and a donor molecule with nonbonding electrons have been the subject of extensive research. Their absorption spectra are characterized by the appearance of a strong band in the near-ultraviolet region, at about 250–300 nm, and a blue shift of the I_2 visible peak (3–5). Aqueous I_2 solutions exhibit the characteristic UV spectrum (6). In the present work, the visible peak is blue—shifted by the addition of 18-crown-6 and the charge-transfer band grows in intensity. This indicates the formation of a complex between the ether and I_2 in aqueous solution. Both the UV charge transfer and visible spectra of the pure complex as well as its stability constant have been determined.

Experimental section

18-Crown-6 (Aldrich) was used without further purification. It was stored in a freezer with the sealed reagent bottle inside a larger sealed bottle. Iodine (Fisher Reagent Grade), which had been resublimed, was dissolved in distilled, deionized water. Concentrations were checked by titration with standard sodium thiosulfate (Baker). During spectrophotometry, weighed samples of the solid crown were added directly to 2.7×10^{-4} M aqueous iodine in the quartz cuvette. Since crown concentrations were kept low, volume changes due to mixing were negligible. Absorption spectra were obtained with a Perkin–Elmer Lambda Three spectrophotometer, which was driven by an IBM compatible computer using Perkin–Elmer software. Experiments were performed at 25 ± 1°C.

Scans in the ultraviolet and visible regions were obtained in separate experiments, using separate crown additions. This helped insure reproducibility of the stability constants obtained from each type of scan. Furthermore, it was found that the aqueous iodine solutions containing the higher crown concentrations would form a black precipitate upon standing for several hours. Therefore, it was desirable to complete the scans as quickly as possible to minimize the chance of the latter reaction interfering with the data obtained from the complex in solution. Performing UV and visible scans separately facilitated this end.

Results

The data from the absorption spectra in aqueous solution are characteristic of charge transfer spectra. The visible spectrum (Fig. 1) shows a noticeable blue shift. The maximum absorption for pure I_2 (aq) occurs at 449 nm. The absorbance maximum for the spectrum calculated for the complex using eq. [1] (below) occurs at 422 nm. At the same time, the UV absorbance in the charge-transfer region (Fig. 2) shows about a threefold increase in going from pure I_2(aq) to the calculated spectrum of the complex.

The formation constant for the reaction between I_2 (aq) and 18-crown-6, as well as the spectrum of the pure complex were determined by use of the equation

$$[1] \quad (A - A_0)/F_D = K_{DA}(A - A_\infty)$$

where A is the absorbance, F_D is the total concentration of the added crown ether (donor), A_0 is the initial absorbance of aqueous I_2 (aq) with no crown added, A_∞ is the absorbance of the pure complex (after the addition of "infinite" crown), and K_{DA} is the formation constant of the complex. Equation [1] is a form of the Ketelar equation (7). It may be derived from the conservation equations for iodine-containing species and crown-containing species with the proviso that the concentration of the crown is much greater than the initial concentration of iodine. (A large excess of crown was, in fact, used during the experiments.) In addition, the equilibrium expression for the formation of the crown ether – iodine complex in aqueous solution (see eq. [4] below), and Beer's law are used in the derivation. The Beer's law expression assumes that both I_2(aq) and the complex ab-

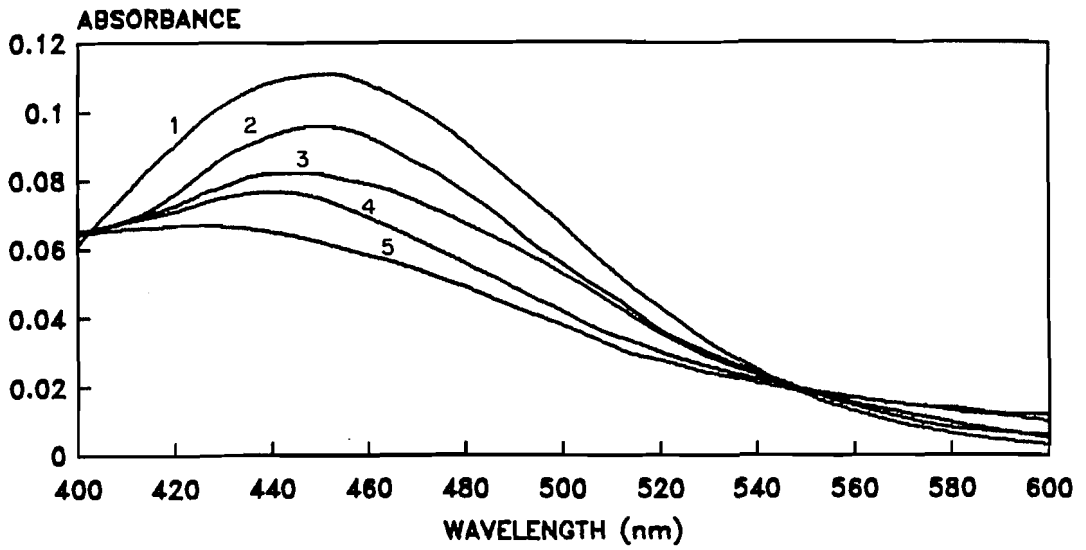

FIG. 1. Addition of 18-crown-6 to iodine (aq), visible data. (1) Pure 2.7×10^{-4} M I_2 (aq); (2) 0.048 M 18-C-6; (3) 0.18 M 18-C-6; (4) 0.31 M 18-C-6; (5) pure complex.

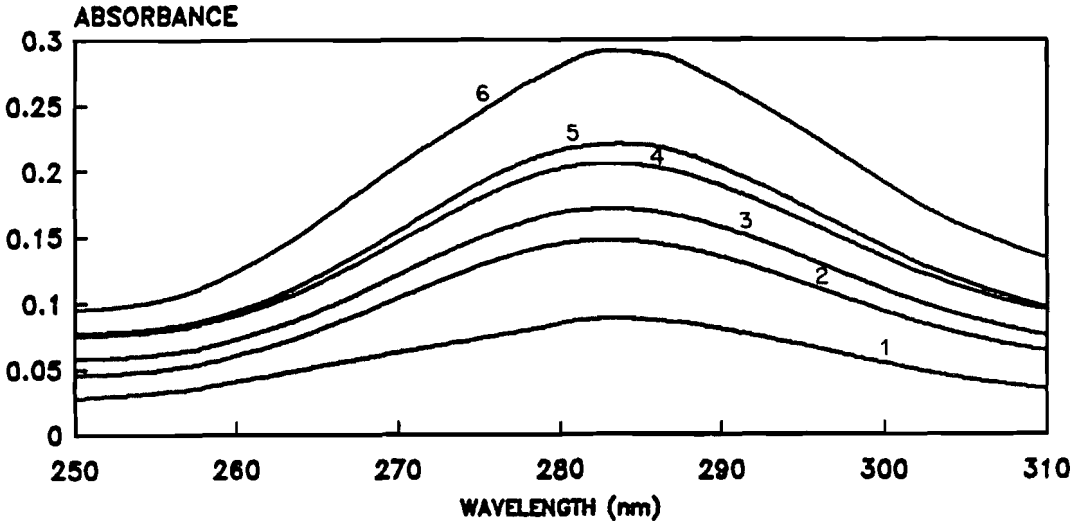

FIG. 2. Addition of 18-crown-6 to iodine (aq), ultraviolet data. (1) Pure 2.7×10^{-4} M (aq); (2) 0.0369 M 18-C-6; (3) 0.0781 M 18-C-6; (4) 0.132 M 18-C-6; (5) 0.170 M 18-C-6; (6) pure complex.

sorb. This assumption is valid since the absorption bands for I_2(aq) and the complex overlapped in both the visible and the ultraviolet.

The average results of linear least-square plots of eq. [1] in the visible region were 11.2 ± 1.7 $(mol/L)^{-1}$ at 25 ± 1°C. The average results of linear least-square plots for results in the ultraviolet charge-transfer region using separate solutions in separate experiments were 10.2 ± 0.9 $(mol/L)^{-1}$ at 25 ± 1°C. The results are nearly equal, within experimental error, so that reproducibility is demonstrated. The average of the two results, giving equal weight to each, is 10.7 ± 1.3 $(mol/L)^{-1}$ at 25 ± 1°C. This equilibrium constant can be directly related to other equilibrium constants for molecular iodine complexation as discussed below.

The reaction of I_2 with crown ether donor (D) in aqueous solution may occur in two different ways. In the first, molecular iodine in water reacts directly with D (the nature of aqueous D will be discussed later), forming a charge-transfer complex as represented in eq. [2], below. In the second, a charge-transfer complex first forms between molecular iodine and excess water. This complex, in turn, reacts with D forming a second charge-transfer complex (DI_2) accompanied by deaquation. These equilibria are indicated by eqs. [3] and [4], below.

[2] $I_2 + D \rightleftarrows DI_2$

[3] $I_2 + H_2O \rightleftarrows I_2 \ldots H_2O$

[4] $I_2 \ldots H_2O + D \rightleftarrows DI_2 + H_2O$

The relationship among the equilibrium constants for these reactions is given by:

[5] $K_2 = K_3K_4$

If the literature value (2) for the formation of the crown ether – iodine complex in the inert solvent cyclohexane at

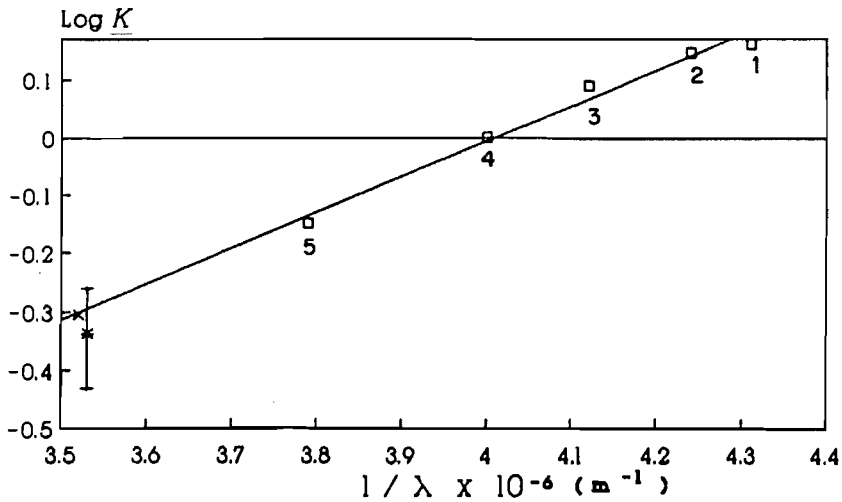

FIG. 3. Log K vs. $1/\lambda$. (1) Methanol; (2) *tert*-butanol; (3) ethanol; (4) ethyl ether; (5) dioxane; (*) water (eq. [5]) × 18-C-6.

25°C (4.93 ± 0.33) is substituted for K_2 and the above value of 10.7 ± 1.3 is substituted for K_4 (assuming that the huge excess of water drives eq. [3] almost to completion, so that eq. [4] is the principal reaction in the current experiments), one obtains the value of 0.46 ± 0.09 for K_3, the formation constant of the charge-transfer complex between iodine and water. To assess whether this value is reasonable, a semiempirical plot of log K vs. $1/\lambda_{max}$ was constructed (Fig. 3) using literature values for the formation constants and charge-transfer band maximum wavelengths for several compounds of the form R-O-R′ (8–11). The plot is well correlated (r = 0.991) and the value for water calculated from eq. [5] fits well, within experimental error.

The motivation for such a plot stems from the idea that after the formation of a contact pair between the donor and acceptor molecules, the electron from the donor can be placed in a vacant MO of the acceptor, upon the absorption of a UV photon. The promotion of the electron may hence be viewed as resulting in an excited state of a very weak van der Waals complex, represented by D + A, below. Therefore, with D in excess, so that its concentration is essentially constant, a Boltzmann distribution may be applied. Hence,

$$[6] \quad UV + D + A \overset{K'}{\rightleftharpoons} DA$$

and

$$[7] \quad K' = [DA]/[D][A] = \exp(-hc/\lambda_{max}\, kT)$$

In logarithmic form,

$$[8] \quad \log K' = -hc/\lambda_{max}\, kT$$

Therefore, for a group of similar donors with the same acceptor, the plot in Fig. 3 seems justified.

It is interesting to note that the plot in Fig. 3 does not immediately seem to predict the literature value of the stability constant for the crown ether – iodine complex (2), 4.93 ± 0.33. When the reciprocal of the wavelength of maximum absorbance for the pure complex from the present work (Fig. 2) is used as the abscissa in Fig. 3 the predicted value for K obtained from the ordinate is 0.45 ± 0.12. However, if this value is multiplied by a statistical factor of 6, accounting for the six oxygens in the crown, one obtains 2.7 ± 1.2 for the predicted stability constant, which is a bit closer to the above literature value. In fact, another reference (3) lists the formation constant for the complex of 18-crown-6 with iodine in a carbon tetrachloride medium at 25°C as 2.8 ± 0.8. This seems to support the contention of the author of ref. 2 that cooperative action of oxygen atoms in the formation of the 18-crown-6 complex with iodine is not an important effect. On the other hand, the literature value for the stability constant in 1,3-dioxane fits the plot well (9). De Maine (9) concluded, by similar statistical considerations, that the two oxygens might well act cooperatively to form the iodine adduct. Figure 3 and eqs. [6]–[8] seem to support this assertion, since the action of two oxygen atoms together should indeed affect the maximum wavelength, whereas oxygen atoms acting independently, as in the crown ether case, should not.

The possibility exists, particularly in cases where the guest is too large to form an inclusion complex with the host, that "sandwich"-type complexes having a guest to host ratio of 1:2 may occur (12). The linear least-square plots of eq. [1], which assumes 1:1 stoichiometry, were well correlated. It is therefore likely that the complex in solution is indeed of the latter type.

A black precipitate was mentioned in the experimental section. The precipitate was air dried, collected, and analysed by titration with standard sodium thiosulfate and by pyrolysis. It was composed of 20.4% carbon, 3.6% hydrogen, 15.6% oxygen, and 58.6% iodine by mass. From this composition, one may surmise the formula for the non-stoichiometric complex

$$C_{12}H_{24}O_6I_{3.3}\cdot H_2O$$

In this formula, the ratio of iodine atoms to crown is greater than two, precluding a "sandwich" complex in the solid. More likely is the possibility that, besides 18C6–I_2, 18C6–$I^+I_3^-$ may occur. The existence of mixed halogen oxidation states in charge-transfer complexes is well established (13).

Properties of some alkali fluoride–chloride salt mixtures I. Primary crystallization and density measurements

N. RAJAGOPALAN, J.B. BELAWADI, AND UTPAL SEN[1]
Central Electrochemical Research Institute, Karalkudi 623 006, Tamilnadu, India

Received May 12, 1992[2]

N. RAJAGOPALAN, J.B. BELAWADI, and UTPAL SEN. Can. J. Chem. **71**, 2175 (1993).

The primary crystallization and density of the fluoride–chloride salt systems (*i*) NaF–LiCl and (*ii*) NaF–(LiCl + KCl) eutectic were determined experimentally using thermal analysis and the Archimedean technique, respectively. The corresponding liquidus curves for the two systems were constructed and compared. Molar volume and excess volume functions were computed from density data at different compositions and temperatures. The positive values of the excess volumes correspond to volume expansion that increases with temperature for both systems. The results suggest that as far as the primary crystallization and density behaviours are concerned, it is possible to replace the component, pure LiCl, in the fluoride–chloride salt system by the eutectic mixture of (LiCl + KCl) for the system's use as a potential electrolyte for aluminium electrolysis.

N. RAJAGOPALAN, J.B. BELAWADI et UTPAL SEN. Can. J. Chem. **71**, 2175 (1993).

Faisant appel à l'analyse thermique et à la technique d'Archimède, on a déterminé respectivement la cristallisation primaire et la densité des systèmes eutectiques de sels de fluorure–chlorure : (*i*) NaF–LiCl et (*ii*) NaF–(LiCl + KCl). On a construit les courbes liquides correspondantes pour les deux systèmes et on les a comparés. En se basant sur des données de densités à différentes compositions et à différentes températures, on a calculé les fonctions de volume molaire et de volume en excès. La valeur positive des volumes en excès correspond à une expansion de volume qui augmente avec la température dans les deux systèmes. Les résultats suggèrent que, en autant que la cristallisation primaire et les comportements de la densité sont concernés, il est possible de remplacer le composant LiCl pur du système de sel fluorure–chlorure par le mélange eutectique du (LiCl + KCl) pour l'utilisation du système comme électrolyte potentiel pour l'électrolyse de l'aluminium.

I. Introduction

Considering the melting point of metallic aluminium (933 K), the most suitable temperature for Al electrolysis could be expected to be around 973 K. However, to date the commercial Hall–Heroult process for Al electrolysis is still being operated in the temperature range of around 1223–1243 K. The main reason for these high operational temperatures is the high melting point of the bath, which can, however, be reduced with use of suitable additive salts. But the decrease in temperature as well as the presence of many of such additives also brings down the solubility of alumina in the cryolite-based bath electrolyte. One way to avoid the problem of alumina solubility in the bath electrolyte may be to use consumable composite anodes consisting of a paste made of carbon and alumina (1). In this suggested alternative process, cryolite (mp 1285 K) need not be the electrolyte and instead a mixture of NaF and LiCl has been suggested, where the temperature of electrolysis could be around 973–998 K (1). Study of the various physico-chemical properties of such a fluoride–chloride system is therefore important. However, from the viewpoint of commercial application, LiCl is an expensive chemical and any suitable replacement would be welcome.

In the present work the primary crystallization and density of different compositions of two series of fluoride–chloride salt mixtures viz., (*i*) NaF–LiCl and (*ii*) NaF–(LiCl + KCl) eutectic, were studied and a comparative study was made, keeping in view their commercial applications. Fluoride–chloride salt systems also have potentiality for applications in solar thermal energy utilization systems (2). Density data of the bath electrolyte are important in connection with easy separation and collection of the molten metal from the bath electrolyte, whereas molar volume data are important for the estimation of suitability of the systems for their potential use as energy storage materials.

The density readings were used for the determination of different volume functions such as average molar volume (V_M) and molar excess volume (V^E) and the results are discussed in the light of the existing theory and concepts of molten salt mixtures.

II. Experimental

II.1 Thermal analysis

The primary freezing points of the salt mixtures were determined by the thermal analysis method. A vertical muffle furnace, a variable speed strip chart Y–t recorder, and a constant current generator were used. The accuracy of the detection of temperature change is 0.13 K. A Chromel–Alumel thermocouple was used for the temperature measurements. Details of the procedure followed may be found elsewhere (3).

II.2 Density apparatus

The density of the liquid mixtures was determined by employing the Archimedean technique (4, 5). The procedure consisted of measuring the loss of weight of an inert bob (sinker) in the melt. The density of the melt can be given as

$$[1] \qquad \rho_L = (W_I - W_F)/V_B$$

where ρ_L is the density of the liquid, W_I and W_F are the weights of the bob before and after dipping in the melt, respectively, and V_B is the volume of the bob at the measurement temperature.

A conical-shaped bob made of platinum with a hook for the suspension wire attachment was used in the density experiments. The bob was suspended from one arm of a balance by a thin Pt wire (0.25 mm diameter). The volume of the bob was around 1 cm^3. Graphite crucibles (4 cm diameter and 6 cm high) were used in the present experiments to contain the molten salts. The salt mixture

For personal use only.

was melted in a separate furnace and then carefully poured into the graphite crucible to maintain a preset liquid level. The crucible containing the melt was then placed on a steel rod that slides through a tight seal at the bottom of a tubular furnace having a 10 cm constant temperature zone. The vertical movement of the crucible inside the furnace was accomplished by attaching the supporting steel rod to a laboratory jack below the furnace. Initially the crucible with the melt was placed beneath the bob and the crucible was then raised to a predetermined height. The temperature of the melt was measured using a Chromel–Alumel thermocouple placed adjacent to the crucible within the furnace.

To obtain accurate density values of the molten salt systems at elevated temperatures using the Archimedean method, a number of corrections were necessary (5). The main corrections involve the surface tension of the liquid, the cubical expansion of the bob material, and also the buoyancy due to the atmosphere if the readings are not taken in vacuum. These corrections require a lot of calculations involving a number of accurate physical parameters for the materials used in the density measuring process. Moreover, accurate values of the bob volume at the different experimental temperatures are essential for ensuring accurate density measurements.

Usually the bob volume was determined at room temperature by weighing first in air and then in deionized water and was then corrected to the operating temperature using the thermal expansion coefficient values for the materials of which the sinker bob is made (5, 6). We have, however, simplified the correction procedure by calibrating the measurements against a standard salt mixture with known density at different temperatures, which in this case was an eutectic mixture of KCl and NaCl (mp 931 K). A calibration curve was drawn of the weight loss of the platinum bob when dipped into the standard melt against different temperatures. The density (ρ) versus temperature curve of the same system was also drawn from the literature data (7). Now, if it can be assumed that the bob volume at a particular temperature would not change during the course of the experiments, the density of any experimental liquid (ρ_L) may be determined using the following equation:

$$[2] \quad \frac{\text{Weight loss in the experimental liquid}}{\text{Weight loss in the standard liquid}} = \frac{\rho_L}{\rho_{std}}$$

It would be assumed that the effect due to the surface tension of the standard molten salt mixture would not be significantly different from that due to the surface tension of the experimental liquid.

Analytical reagent grade NaF was used. LiCl and KCl, both analytical grade, were dried at about 400°C before use. LiCl is highly hygroscopic and was handled inside a dry box. Weighing was, however, done outside the dry box in a closed vessel. One of the major sources of error in this procedure for density measurement is bubble formation on the bob surface during the actual experiment. This is normally attributed to traces of moisture in the melt (6), and is more likely to occur when hygroscopic salts are involved. The premelting in our case helped to avoid the problem to a large extent. However, the bob was made to move up and down before each measurement. The melt was kept at a constant temperature for at least an hour before each measurement and at the time of recording the weight of the bob immersed into the melt, the temperature reading was also noted. For each preset temperature at least two readings were taken and the average value was used for density calculations. With each particular composition density readings were taken at about eight to ten different temperatures. Care was taken to note the salt deposition on the top portion of the suspension wire. No significant salt deposition was observed. Thermal analysis and density experiments were carried out under N_2 atmosphere.

To check the validity of the present density measurements, we measured the densities of the pure components at different temperatures. The differences between our results and the literature values (7) lie within the experimental error limits.

III. Results

III.1 Primary crystallization

From the experimental readings of the primary crystallization points obtained by thermal analysis of various salt mixtures of known composition, the corresponding liquidus curves for both salt systems were constructed. The plotting was done on the same graph sheet for comparison (Fig. 1). We have the mixture of NaF and LiCl as a true binary system. But the three-component mixture of NaF, LiCl, and KCl was converted to a quasibinary system by keeping the amount of LiCl and KCl in the mixture always in the eutectic proportion of LiCl (58.5 mol %) and KCl (41.5 mol %) (mp 634 K). The (LiCl + KCl) eutectic mixture was treated as a single component. Temperature–composition phase diagrams of binary fluoride–chloride salt systems having a common cation, such as NaF–NaCl, show only one minimum whereas binary systems with different cations, such as KF–NaCl, are known to have liquidus curves showing more than one minimum and maximum (8). The liquidus curve for the NaF–LiCl system (Fig. 1) apparently has two minima (at $x_{NaF} \approx 0.25$ and $x_{NaF} \approx 0.7$) and a rather flat maximum (at $x_{NaF} \approx 0.45$). This kind of liquidus curve may indicate eutectic as well as compound formation with congruent or incongruent melting point (9–11). The maximum observed in the liquidus curve of the NaF–LiCl system does not appear to be well defined, which may mean that the compound formed would be rather unstable (9).

The other system, viz., NaF–(LiCl + KCl), consists of three cations and two anions. The liquidus plot of the corresponding quasibinary system (Fig. 1) does not show any minimum. Addition of eutectic (LiCl + KCl) to NaF decreases the primary crystallization temperature throughout the composition range. The rate of decrease apparently has two breaks at $x_{NaF} \approx 0.75$ and $x_{NaF} \approx 0.3$ and is smallest in the range between them. This kind of liquidus curve for purely binary systems may indicate simple monotectic or partially miscible solid solution with peritectic formations (9). Further studies are necessary to make this information more clear. Nevertheless, the present data may be sufficient to give an approximate idea of the primary crystallization behaviour of the molten salt systems and, from the comparison (Fig. 1), it can be seen that up to the composition $x_{NaF} \approx 0.7$ the liquidus temperature for both systems stays below or near the melting point of metallic aluminum (933 K). This might suggest that as far as the primary crystallization of the mixture is concerned, LiCl can be replaced by the eutectic mixture of LiCl (58.5) and KCl (41.5) as the electrolyte for metal extraction, and the optimum bath composition in these systems may be around the 1:1 mixture of the fluoride–chloride salts.

III.2 Density

Experimental density (ρ) values at different temperatures corresponding to the various mixtures containing different proportions of (*i*) NaF and LiCl and (*ii*) NaF and (LiCl + KCl) eutectic determined using eq. [1] have been presented in Tables S1(*a*) and S1(*b*) respectively.[3]

[3]Tables of experimental density values (Tables S1(*a*) and S1(*b*)), the constants *C* and *D* of eq. [5] and the corresponding standard deviation (S_D) (Table S2), and the expansivity at 1000 K (Table S3) may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A OS2.

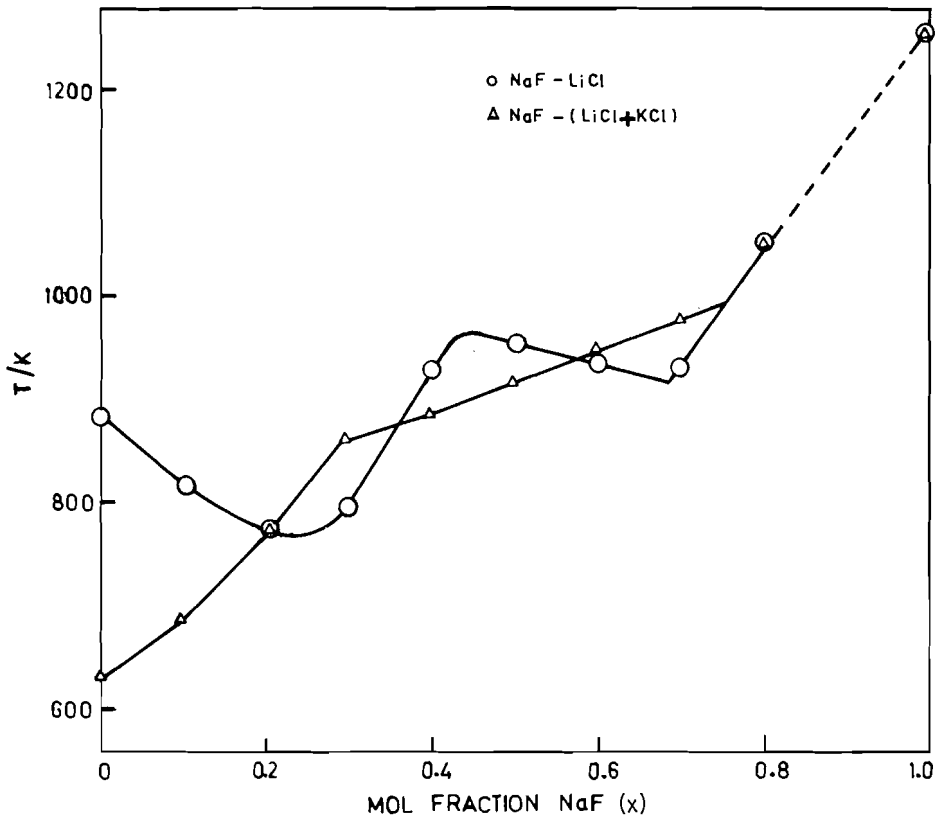

FIG. 1. Fusibility diagram of the two fluoride–chloride systems; ○ NaF–LiCl; △ NaF–(LiCl + KCl).

III.3 Molar volume

From the straight-line plots of density (ρ) vs. temperature (T/K), densities at some rounded temperatures such as 1000, 1050, 1150, and 1250 K have been determined for each composition of the salt mixtures. From such values the corresponding average molar volumes (V_M) have been calculated by using the equation:

$$[3] \quad V_M = M_{AV}/\rho$$

where $M_{AV} = \Sigma M_i x_i$, M_i and x_i being the molar weight and the mol fraction of the individual components, and ρ is the density of the mixture.

In Figs. 2 and 3 the values of V_M obtained from eq. [3] at different temperatures have been plotted against composition for the two salt systems. Since 1000 K may be the nearest temperature of cell operation suggested for the alternative method for aluminum electrolysis as mentioned above (1), a comparison of the variation of the average molar volumes (V_M) with composition (x) in both salt systems at 1000 K is shown in Fig. 4. It can be seen from Fig. 2–4 that the average molar volumes (V_M) for both systems seem to have a maximum at the composition where the mol fraction of NaF is around 0.1 ($x = 0.1$), which means that the corresponding density values at this particular composition are at the maximum for the particular system.

For a given composition the measured densities were found to decrease linearly with increasing temperature. Accordingly, the results were fitted to the linear expression

$$[4] \quad \rho = A + BT$$

where A and B are constants and T is the absolute temperature in degrees Kelvin. The coefficients A and B were determined by the least-squares method. These data are presented in Table 1, which also includes the corresponding standard deviations (S_D).

The average molar volume (V_M) for different compositions increases with temperature. The experimental density data[3] were used to determine the corresponding average molar volumes (V_M), which were then fitted to the linear expression

$$[5] \quad V_M = C + DT$$

where C and D are constants. Table S2 lists the constants C and D along with the corresponding standard deviation (S_D) for the two fluoride–chloride salt systems.[3] Gutierrez and Toguri (12) determined density and molar volume of the ternary systems $PbCl_2$–KCl–NaCl and $PbCl_2$–KCl–LiCl. They fitted their density and molar volume data to linear temperature equations. The constants A, B and C, D did not indicate any regular trends with respect to composition. Similar observations may be made from the results of the present work.

III.4 Expansivity

The coefficient of thermal expansion or expansivity α is given by

$$[6] \quad \alpha = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_P$$

Since $V_M = M_{AV}/\rho$ it may be shown that

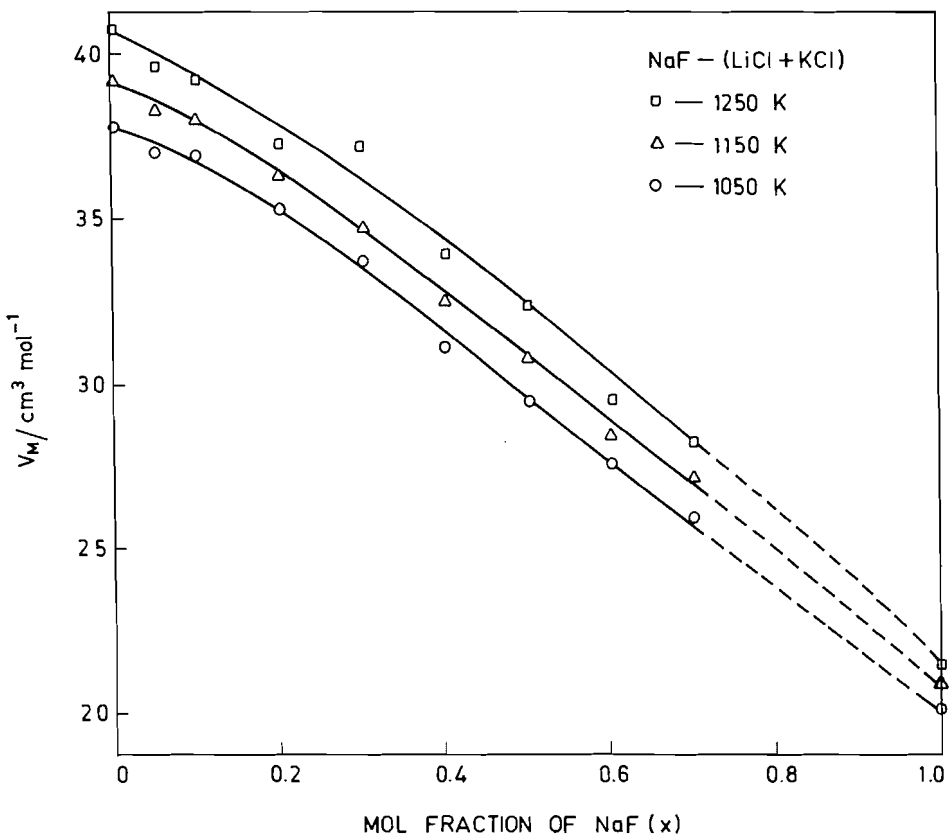

FIG. 3. Variation of average molar volume (V_M) with composition at different temperatures for the NaF–(LiCl + KCl) eutectic system; ○ 1050 K; △ 1150 K; □ 1250 K.

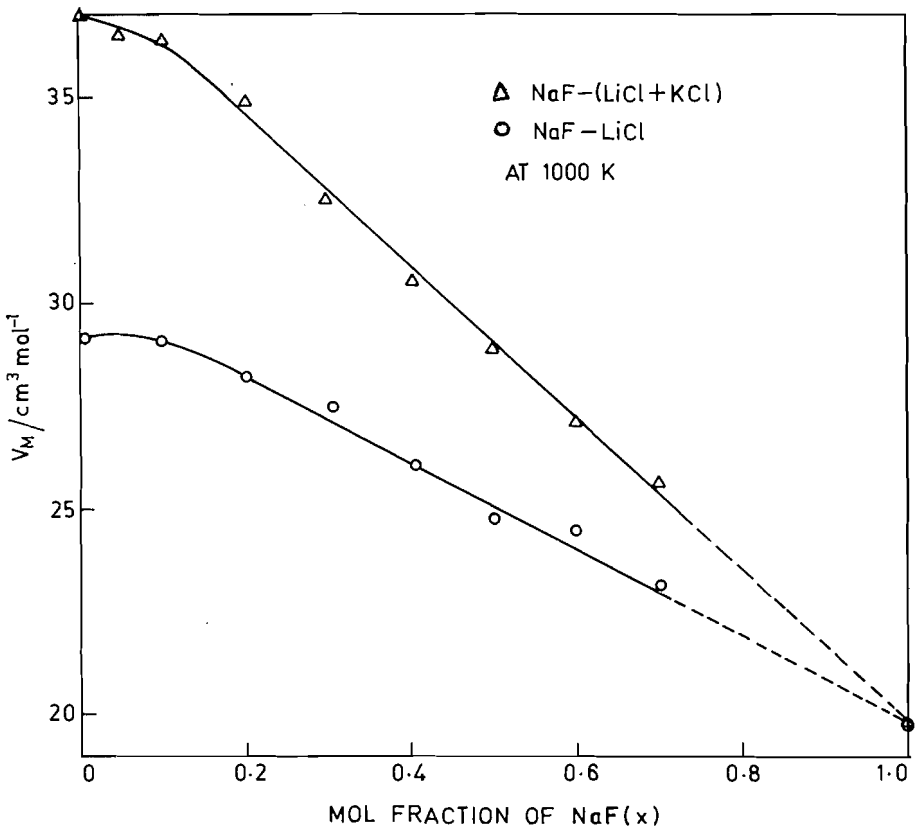

FIG. 4. A comparison of the variation of average molar volume (V_M) with composition for the two fluoride–chloride systems at 1000 K; O NaF–LiCl; Δ NaF–(LiCl + KCl).

$$[7] \quad \alpha = -\frac{1}{\rho}\left(\frac{\partial \rho}{\partial T}\right)_P$$

Substituting $\rho = A + BT$ in the above equation one obtains

$$[8] \quad \alpha = \frac{-B}{A + BT}$$

From the results of this study, it is observed that the density decreases with increasing temperature and α is positive.

Table S3 lists the values of α at 1000 K for the two systems (3). Carmichael and Flengas (13) determined α values for the $MnCl_2$–NaCl–CsCl system at different compositions and plotted them against the corresponding mol fraction of $MnCl_2$. They found that α values exhibited some maxima and minima before approaching the values of the pure individual components. Somewhat similar behaviour but no regular trends are, however, observed with respect to the variation of α values with composition in the present work.

III.5 Molar excess volume

Although the use of direct methods for measuring molar excess volume (V^E) may now be standard practice in the study of liquids at room temperature, nearly all V^E values for fused salts have been derived from density measurements using the following equation

$$[9] \quad V^E = V_M - \sum V_i^0 x_i$$

where V_i^0 and x_i are the molar volume and the mol fraction of each individual pure component in the mixture.

This procedure involves the subtraction of two nearly equal quantities. At least three densities have to be measured for any binary system to obtain an excess volume, which magnifies the error due to uncertainty in the temperature measurements. Any inaccuracy in the data for either of the pure components will give rise to systematic errors in the V^E values for all the mixtures. Very few attempts of direct measurements of V^E for molten salts have been reported in the literature (14, 15), and these were confined to low-melting salt systems such as molten nitrate salt mixtures, and as such they may not be suitable for high-melting fluoride–chloride salt systems. In the present work V^E values have been generated from the density data.

From the smooth plots of V_M vs. composition, the values of V_M at the rounded temperatures were obtained by interpolation and such values were utilised to obtain the corresponding molar excess volume (V^E) function by using eq. [9]. Density values for the individual pure components NaF, LiCl, and KCl were obtained from the literature (14, 15). It was assumed that the use of literature values of the densities of the pure components would not introduce any significant error. Some extrapolation had to be done beyond the actual recommended limits to generate liquid density values (from literature data) to cover the entire temperature range of interest to us (7, 16). The present temperature range, 1000 – 1250 K, would fairly represent the range between the lowest possible temperature of aluminum electrolysis to the temperature of operation of the only commercially viable conventional Hall–Heroult cells for aluminium electrolysis (17).

From analysis of the experimental data of the present work

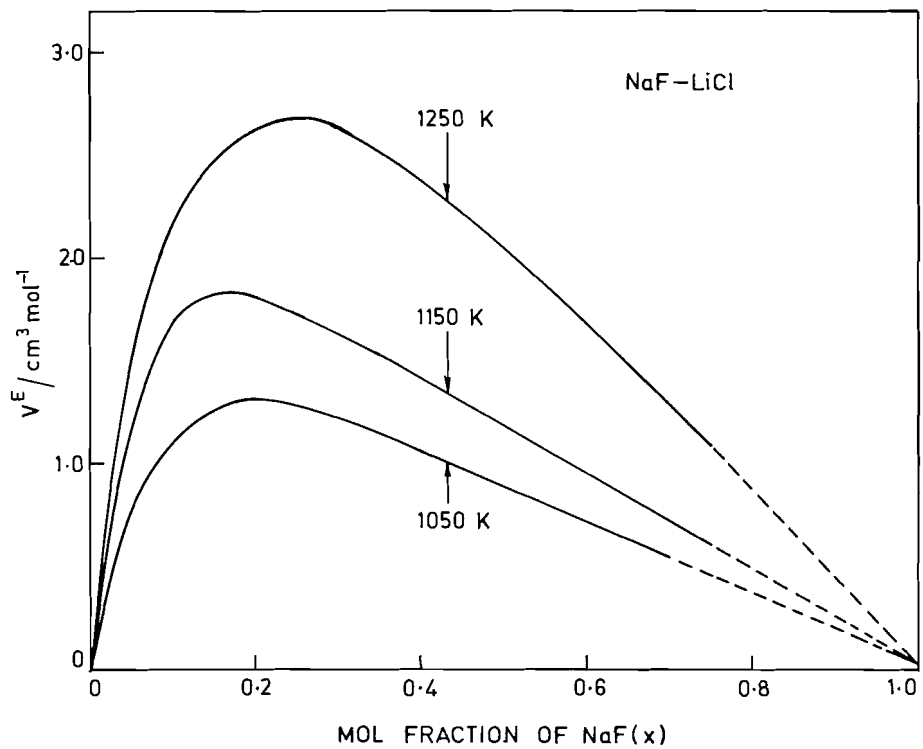

FIG. 5. Variation of molar excess volume (V^E) with composition at different temperatures for the NaF–LiCl system.

involving molten mixtures of (*i*) NaF – LiCl and (*ii*) NaF – (LiCl + KCl) eutectic it has been found that an uncertainty of about 0.4% in the experimental density readings could cause an uncertainty of about 0.08 cm^3 in the corresponding molar volume (V_M) data. This might introduce an error of as much as twice the magnitude in the calculated values of molar excess volume (V^E).

Figures 5 and 6 show the plots of the molar excess volume (V^E) with respect to composition (x) at some rounded temperatures for the two salt systems. V^E values are always positive and the value apparently reaches a maximum when the mol fraction of NaF approximates 0.3 ($x \approx 0.3$) for both salt systems at all temperatures. Similar detailed studies of molar excess volume functions at different temperatures have perhaps not been reported for high-temperature molten salt systems.

We also expressed the excess molar volume data at different temperatures as a function of composition by fitting them to the polynomial expansion (18)

$$[10] \quad V^E = x(1 - x)(a + bx + cx^2 + dx^3 + ex^4 + fx^5)$$

where x is the mol fraction of NaF and a, b, c, d, e, and f are the coefficients of the polynomial. The details of the calculations are shown in Table 2.

IV. Discussion

Grjotheim et al. (18) recalled that there is no *a priori* reason to expect that the mixing of two salts proceeds without volume change. For the same reason, the mixing of spheres of unequal size does not yield an additive volume. They also noted that when the two salts are very similar, the volume change, as expected, is usually observed to be small. Therefore, a rational way of presenting the excess volume results is by the deviation from additivity. Nevertheless, molar excess volume is often identified with nonideality in the mixing of the components. In the present work the positive values of V^E for all the compositions in the systems increase with increasing temperature (See Figs. 5 and 6). This may suggest that the so-called nonideality in mixing has in general a tendency to increase with temperature.

When a mixing of any two salt components introduces some nonideality (i.e., $V^E \neq 0$) it may be expected that at 50 mol% composition of the binary system (i.e., 0.5 mol fraction) the introduced nonideality would reach a maximum unless there are some complex formations. In the present case, however, the maximum positive value of V^E is reached when the mol fraction of NaF is well below 0.5. Significant differences in the behaviour of alkali fluoride–chloride systems from that of other halide–halide systems were observed earlier (13, 19, 20).

The positive excess volume is normally attributed to purely Coulombic interactions between ions in the molten salt systems (21). For such systems a second-order theory, based on the conformal solution theory, has been advanced by Reiss, Katz, and Kleppa (21). According to such a concept, V^E

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 203.198.23.82 on 09/08/12
For personal use only.

would be a function of the ionic distances in the melt system. The function is rather simple in the case of a binary salt mixture with a common anion or cation (15). The present fluoride–chloride systems are, however, more complicated and involve a number of ions. Further work is necessary to test the applicability of the above concept in molten salt mixtures containing different cations and anions.

V. Conclusion

1. Though the presence of different cations in alkali metal fluoride–chloride salt systems introduces, among other things, some unstable compound formation, the liquidus temperatures for both of the systems studied in this work are around or below the melting temperature of Al metal (at least up to $x_{NaF} = 0.7$).

2. The density values for both systems in the temperature range from 1000 to 1200 K remain close to each other.

It may therefore be concluded that as far as the primary crystallization and density behaviour are concerned, it may be possible to replace the pure LiCl component in the fluoride–chloride salt system by a eutectic mixture of (LiCl + KCl) without decreasing the capability of the system as an electrolyte for aluminium electrolysis.

Topological investigations of aniline and substituted anilines in binary solutions containing methylene bromide

V.K. SHARMA,[1] PREM PAUL SINGH, SANJEEV MAKEN, AND B. SINGH
Department of Chemistry, Maharshi Dayanand University, Rohtak-124 001, India

Received April 21, 1993

V.K. SHARMA, PREM PAUL SINGH, SANJEEV MAKEN, and B. SINGH. Can. J. Chem. **71**, 2183 (1993).

Molar excess volumes and molar excess enthalpies for various (i + j) binary methylene bromide (i) + aniline or *N*-methyl aniline and + *N*,*N*-dimethyl aniline (j) mixtures have been determined as a function of composition at 308.15 K. The data have been analysed in terms of the graph-theoretical approach and Sanchez and Lacombe theory. The graph-theoretical analyses of V^E data suggest that aniline, *N*-methyl aniline, and *N*,*N*-dimethyl aniline exist as equilibrium mixtures of monomer and dimer and that these mixtures contain 1:1 molecular complexes. The IR studies lend further credence to the nature and extent of interaction along with support for the proposed structure of molecular species in these mixtures.

V.K. SHARMA, PREM PAUL SINGH, SANJEEV MAKEN et B. SINGH. Can. J. Chem. **71**, 2183 (1993).

Opérant à 308,15 K, on a déterminé les volumes molaires en excès et les enthalpies molaires en excès de divers mélanges binaires (i + j) de bromure de méthylène (i) + aniline (ou de *N*-méthylaniline et *N*,*N*-diméthylaniline) (j) en fonction de la composition. On a analysé les données en fonction de l'approche théorique des graphes ainsi que de la théorie de Sanchez et Lacombe. L'analyse des données de V^E par le théorie des graphes suggère que, dans ces mélanges, l'aniline, la *N*-méthylaniline et la *N*,*N*-diméthylaniline existent sous la forme de mélanges à l'équilibre de monomères et de dimères et que ces mélanges contiennent de complexes moléculaires 1:1. Des études infrarouges apportent un certain support à la nature, au degré d'interactions et à la structure des espèces moléculaires présentes dans ces mélanges.
[Traduit par la rédaction]

Introduction

Aniline and substituted anilines are known to be associated (1, 2) in the pure state through hydrogen bonding and electron donor–acceptor interactions. Bellamy and Williams (3) have shown that aniline in the pure state exists as a monomer; Wolff and Mathias (4) and Kreglewski and Wilhoit (5) favor the associated structure of aniline and suggest that only one of the hydrogens of its NH_2 group is free to form a hydrogen bond and the other hydrogen atom is involved in weak interactions with the π-electron cloud of the aniline molecule. The addition of a compound like methylene bromide to aniline and substituted anilines may tend either to rupture or enhance the self-association of the latter components. As the state of association of aniline and substituted anilines in pure as well as in binary solutions may or may not be the same, it follows that thermodynamic equilibrium properties of aniline or substituted anilines + methylene bromide mixtures may provide valuable insight into the state of aggregation of these compounds and the nature of the species present in these mixtures.

Experimental

Aniline (A) (E. Merck, AR Grade), methylene bromide (MB), *N*-methyl aniline (MA), and *N*,*N*-dimethyl aniline (DMA) (Fluka, Purris quality) were purified by standard methods (6, 7). The purities were then checked by measuring their densities at 298.15 ± 0.01 K and these agreed to $\pm 5 \times 10^{-5}$ gm cm^{-3} with their corresponding literature values (8–10) (the density of MB at 298.15 K was calculated from the density versus temperature data (11)).

Molar excess volumes V^E, for the various (i + j) mixtures were determined at 308.15 K in a V-shaped dilatometer that has been described elsewhere (12). The temperature of the water thermostat was controlled to ±0.01 K by means of a toluene regulator and the uncertainty in the measured V^E values was about 0.5%.

Molar excess enthalpies, H^E, for the various binary mixtures were measured at 308.15 K in a flow microcalorimeter (LKB Broma, Sweden) in a manner described elsewhere (13) and the uncertainty in the measured H^E values was ca. 1%.

Samples for IR spectroscopic studies were prepared by mixing i and j in a 1:1 (w/w) ratio and their IR spectra were recorded on a Beckmann IR spectrophotometer (model 4250) using sodium chloride optics.

Results

The measured V^E and H^E data for MB(i) + A or MA or DMA (j) binary mixtures (recorded in Tables 1 and 2) were expressed as

$$[1] \qquad X^E(X = V \text{ or } H) = x_i (1 - x_i) \sum_{n=0}^{2} X^{(n)} (2x_i - 1)^n$$

where $X^{(n)}$ (n = 0–2) are adjustable parameters and x_i is the mole fraction of component i in the (i + j) mixture. These parameters were evaluated (14) by fitting eq. [1] to $X^E/x_i(1 - x_i)$ data by the least-squares method and are recorded along with the standard deviations, $\sigma(X^E)$ of $X^E(X = V \text{ or } H)$, defined by

$$[2] \qquad (X^E) = [\Sigma (X^E_{\text{expt}} - X^E_{\text{calcd.eq.[1]}})^2/(m - p)]^{0.5}$$

(where m is the number of data points and p is the number of adjustable parameters in eq. [1], in Tables 1 and 2.

Discussion

We are unaware of any V^E and H^E data with which to compare our results. V^E for MB(i) + A, +MA, and + DMA(j) mixtures are all positive and for an equimolar mixture vary in the order DMA > MA > A. On the other hand, while H^E data for MB(i) + A and + MA(j) mixtures are negative, those for the MB(i) + DMA(j) mixture are positive and for an equimolar mixture vary in the order A < MA < DMA.

Aniline and substituted anilines are known to be associated in the pure state (1, 2) through hydrogen bonding and

electron donor–acceptor interactions. The observed V^E and H^E data for MB (i) + A, + MA and + DMA(j) mixtures may then be explained if it be assumed that (i) aniline and substituted anilines are associated in the pure state through hydrogen bonding and electron donor–acceptor interaction, (*ii*) aniline and substituted anilines interact with the methylene bromide, and (*iii*) there is steric repulsion between substituted anilines and methylene bromide.

Since V^E for the binary mixture reflects the packing of the components of that mixture, V^E data for the MB(i) + A(j) mixture suggest that contributions due to factors (i) and (*iii*) far outweigh contributions due to factor (*ii*), so that the overall V^E for this mixture is positive. Further, as the measured H^E is due to the cumulative effects of (i), (*ii*), and (*iii*), the negative H^E values for the MB(i) + A(j) mixture suggest that the heat effect due to factor (*ii*) outweighs those due to (i) and (*iii*). The introduction of a CH_3 group in aniline, as in MA, would then increase electron density around the nitrogen atom, so the association in N-methyl molecules will be less than that in aniline molecules. The contribution to V^E and H^E due to factor (i) will then be greater in the case of MB(i) + MA(j) than in MB (i) + A(j) mixtures. In other words, while V^E for the MB(i) + MA(j) mixture should be more positive than that of the MB(i) + MA(j) mixture, H^E for the MB(i) + MA(j) mixture should be less negative than for the MB(i) + A(j) mixtures. The experimental V^E and H^E data for these mixtures lend credence to this viewpoint. Further, the presence of two methyl groups in aniline, as in DMA, would not allow DMA molecules to undergo a hydrogen-bonded interaction with MB, so that V^E and H^E data for the MB(i) + DMA(j) mixture should be more positive than those for MB(i) + A or MA(j) mixtures. This is indeed true.

If the addition of MB(i) to A, MA, and DMA(j) causes changes in the topology of i and or j, it must be reflected in the equilibrium thermodynamic properties of the (i) + (j) mixtures. It would, therefore, be worthwhile to analyse V^E data of MB(i) + A, + MA and + DMA(j) mixtures in terms of an approach (15) that employs the graph-theoretical concept of the third degree of the constituents of these (i + j) mixtures. According to this approach (15), V^E is given by

$$[3] \quad V^E = \alpha_{ij}\,[\{x_i\,({}^3\xi_i)_m + x_j({}^3\xi_j)_m\}^{-1} - \Sigma\, x_i/{}^3\xi_i]$$

where ${}^3\xi_i$ and $({}^3\xi_i)_m$ in eq. [3] denote, respectively, the values of component i in the pure state and in the mixture and are defined (16) by

$$[4] \quad {}^3\xi = \sum_{m\le n\le o\le p} (\delta^v_m \cdot \delta^v_n \cdot \delta^v_o \cdot \delta^v_p)^{-0.5}$$

where δ^v_m etc. have the same significance as explained elsewhere (16).

Since the degree of association of j is not known with certainty and as no theoretical method is available to evaluate $({}^3\xi_j)_m$ of j in the (i + j) mixtures, we regarded $({}^3\xi_i)_m$, $({}^3\xi_j)_m$, ${}^3\xi_i$, and ${}^3\xi_j$ as adjustable parameters and evaluated them by fitting experimental V^E data to eq. [3]. Only those $({}^3\xi_i)_m$ and ${}^3\xi_i$ values were retained that best reproduced the experimental V^E data, i.e., for which the variance to fit, ρ, defined by $\rho = \{\Sigma(V^E_{\text{exptl.}} - V^E_{\text{calcd.}})^2/(Q\text{-}P)\}^{0.5}$ (where $(Q\text{-}P)$ is the number of degrees of freedom) was minimum. Such $({}^3\xi_i)_m$, ${}^3\xi_i$ etc. values along with the V^E values (calculated using eq. [3]) at various x_i are recorded in Table 3.

A number of structures were then assumed for A, MA, and DMA, and their ${}^3\xi'_j$ values were determined from structural considerations. These ${}^3\xi'_j$ values were next compared with the corresponding ${}^3\xi_j$ values obtained for them via eq. [3] from V^E data; any structure or a combination of structures (for a component) that yielded a ${}^3\xi'$ value that compares favourably with its ${}^3\xi$ values was taken to be a good representation of the structure of that component. For the present (i + j) mixtures, we assumed that A, MA, and DMA exist as **1**–**2**, **3**–**4**, **5**–**5***a* entities. It was, however, assumed that in entities **2**, **4**, and **5**, δ^v (π) = 1 (16) (where the π-electron cloud of molecule is involved in specific interaction with another molecule). The δ^v values for the various vertices in the various entities are shown in Scheme 1.

The ${}^3\xi'_j$ values for the entities **1**–**5***a* were then calculated to be 1.361, 1.89, 1.256, 1.814, 2.10, and 1.181, respectively. Since the ${}^3\xi_j$ values of A, MA, and DMA (j) in the present (i + j) are 1.65, 1.728, and 1.88 (Table 3), they suggest that in these mixtures A, MA, and DMA exist, as an equilibrium mixture of monomer and dimer. Further, in MB(i) + A, + MA and + DMA(j) mixtures, it was assumed that these (i + j) mixtures may contain molecular entities **6**, **7**, and **8**, respectively (Scheme 2). In evaluating $({}^3\xi'_j)_m$ values for the molecular entities **6** and **7**, it was next assumed that only one C—Br edge of MB is involved in

TABLE 2. Measured molar excess enthalpies, H^E, data for various $i + j$ mixtures as functions of mole fractions, x_i, of i at 308.15 K; also included are the various $H^{(n)}$ (n = 0–2) parameters and standard deviations $\sigma(H^E)$[a]

hydrogen-bond interaction with one hydrogen atom of the NH_2 group of A and MA, and the molecular entity **8** may be characterized by specific interaction between the vacant 3d level of the bromine atom of MB and the π-electron cloud of the aromatic ring of DMA. The $({}^3\xi_j')_m$ values for the molecular entities **6**, **7**, and **8** were then calculated to be 1.85, 1.77, and 1.414, respectively. Since the $({}^3\xi_j')_m$ values suggest that these mixtures contain the molecular entities **6**, **7**, and **8**, the presence of molecular entities **6** and **7** would then suggest that there must be changes in the C—Br vibration of MB and the N—H stretching vibration of A and MA. On the other hand, molecular entity **8** suggests that there must be a change in the ring vibration of DMA and the C—Br stretching of MB in the mixture.

We next analysed the infrared spectral data of pure i,j, and their equimolar mixtures. It was observed that while MB and A in the pure state show characteristic absorption at 620 cm^{-1} (C—Br stretch) (17) and 3400 cm^{-1} (N—H stretch) (17), the infrared spectrum of the equimolar mixture of MB(i) + A and + MA(j) shows characteristic bands at 610 and 605 cm^{-1} (C—Br stretch) and 3380 and 3385 cm^{-1} (N—H stretch), respectively. The infrared spectra of the MB(i) + A and + MA(j) mixtures clearly suggest that the addition of j to i does influence the C—Br vibration of MB and the N—H stretching vibration of A and MA and thus lends support to the presence of molecular entities **6** and **7** in MB(i) + A and + MA(j) mixtures. On the other hand, in the MB(i) + DMA(j) mixture, it was observed that DMA(j) in the pure state exhibits ring vibrations (17) at 1590, 1500, and 1430 cm^{-1}. The infrared spectrum of the MB(i) + DMA(j) mixture shows characteristic bands at 1582, 1490, 1422 cm^{-1} (ring vibration), and 602 cm^{-1} (C—Br stretch). The infrared spectrum of MB(i) + DMA(j) thus suggests that the addition of j in i influences the ring vibrations and C—Br stretching in the mixture and so points to the molecular entity in the mixture.

To understand the energetics of the various interactions involved in these binary mixtures, if A, MA, and DMA exist as an associated entity, then the present ($i + j$) binary mixture may be visualized (18) to involve (*i*) the establishment of unlike i–j contacts between i and j, (*ii*) this unlike contact formation between i and j would then cause depolymerization of j to yield free j monomers, and (*iii*) the monomers of j would then undergo a specific interaction with the bromine atom of MB to form the ij molecular entity. Molecular entities of the type i_2j, ij_2, and i_2j_2 may also be present in these mixtures containing ij molecular entities and the contributions made by other entities are very small compared to the H^E for these mixtures. This is also consistent with the information provided by the analysis of their V^E data in terms of eq. [3].

Consequently, if X_{ij} is the molar enthalpy interaction parameter of unlike i–j contact formation, then the change in enthalpy due to (*i*) would be given (19, 20) by

$$[5] \quad \Delta H_1 = x_i X_{ij} S_j$$

where S_j is the surface fraction of j involved in ($i - j$) contact and is defined (21, 22) by

$$[6] \quad S_j = x_j V_j / \Sigma x_i V_i$$

so that

$$[7] \quad \Delta H_1 = x_i x_j X_{ij} V_j / \Sigma x_i V_i$$

Further if X_{jj} and X_{12} are the molar enthalpy interaction parameters of $j - j$ and specific 1–2 interactions, respectively, then change in molar enthalpy due to processes (*ii*) and (*iii*) would be given (21) by

$$[8] \quad \Delta H_2 = x_i^2 x_j V_j X_{jj} / \Sigma x_i V_i$$

and

$$[9] \quad \Delta H_3 = x_i x_j^2 V_j X_{12} / \Sigma x_i V_i$$

The overall change in molar enthalpy due to processes (*i–iii*) would then be expressible (22) by

$$[10] \quad H^E = \sum_{i=1}^{3} \Delta H_i = [x_i x_j V_j / \Sigma x_i V_i] [X_{ij} + x_i X_{jj} + x_j X_{12}]$$

Since V_j/V_i has been taken equal to ${}^3\xi_i/{}^3\xi_j$ ($=Y$) then eq. [10] reduces to

$$[11] \quad H^E = [x_i x_j Y / (x_i + x_j Y)] (X_{ij} + x_i X_{jj} + x_j X_{12})$$

For MB(i) + A, + MA and + DMA(j) mixtures, it would, however, be more reasonable to assume that $X_{ij} = X_{jj} = X'_{jj}$ so that eq. [11] reduces to

$$[12] \quad H^E = [x_i x_j Y / (x_i + x_j Y)] [(1 + x_i) X'_{jj} + x_j X_{12}]$$

Equation [12] contains two adjustable parameters X'_{jj} and X_{12},

and these were calculated from the H^E data of the $(i + j)$ mixtures at two arbitrary compositions $x_i = 0.4$ and 0.5, which were subsequently employed to predict H^E data for the $(i + j)$ mixture at other values of x_i. Such H^E data along with various interaction parameters x_{jj} and X_{12} are recorded in Table 3 and are also compared with their corresponding experimental values.

Examination of Table 3 shows that H^E data calculated from eq. [12] for the $(i + j)$ mixtures compare reasonably well with their corresponding experimental values. This lends support to the assumption made in deriving eq. [12] and also to the validity of the assumption $V_j/V_i = {}^3\xi_i/{}^3\xi_j$.

Further examination of Table 3 reveals that the enthalpy interaction parameter X'_{jj} for A is more negative than that for MA, which is not true. The failure of X'_{jj} values to explain the boiling point of A and MA can be explained by the fact that in deriving eq. [12] it has been assumed that overall H^E is due to chemical interactions between the components of the $(i + j)$ mixtures. Since H^E is small for MB + A and + MA mixtures, it suggests that physical interactions play an important role in determining their H^E values. As

$$H^E = H^E_{phys} + H^E_{chem}$$

and if H^E for the reference system (23) MB(i) + cyclohexane (j) is taken to be H^E_{phys} for these systems, then the resulting H^E_{chem} for MB(i) + A and + MA(j) mixtures should be analysed in terms of eq. [12]. Such H^E_{chem} values at $x_i = 0.4$ and 0.5 were then employed to evaluate X^*_{jj} and X^*_{12} values, which were next employed to evaluate H^E_{chem} at other values of x_i. Such H^E_{chem} values along with interaction parameters X^*_{jj} and X^*_{12} are recorded in Table 3 as H(chem)* and also compared with their corresponding H^E_{chem} values.

Examination of Table 3 now reveals that H^E_{chem}* data[2] calculated from eq. [12] for MB + A and + MA mixtures compare reasonably well with their corresponding H^E_{chem} values and, further, the X^*_{jj} value for MA is more negative than A, which suggests that the boiling point of A must be less than that of MA. This is indeed true, which lends sup-

[2]H(chem)* values correspond to H^E values evaluated from eq. [12] utilizing X^*_{12} and X_{jj} data recorded in Table 3.

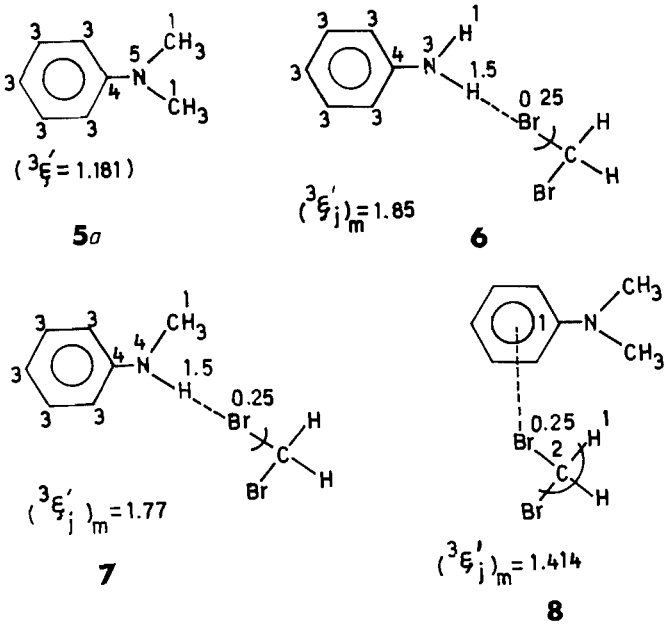

SCHEME 2

port to our assumption that H^{E}_{phys} plays an important role in the H^{E} data for MB(i) + A and + MA(j) mixtures.

V^{E} and H^{E} data for MB(i) + A, + MA and + DMA(j) mixtures were next analysed in terms of Sanchez and Lacombe theory in the manner explained earlier (24, 25). V^{E} and H^{E} values calculated according to this theory for the present (i + j) binary mixtures at x_i = 0.1, 0.3, 0.7, and 0.9 are recorded in Table 3 and are also compared with their corresponding experimental values. Examination of Table 3 has revealed that V^{E} and H^{E} values so calculated show poor agreement with the experimental values. This poor agreement between the calculated and experimental V^{E} and H^{E} for these (i + j) mixtures may be attributed to the failure of these mixtures to satisfy the equation of state of the mixture.

The present analysis thus has shown that the graph-theoretical approach reproduces well not only the V^{E} and H^{E} data of the present (i + j) mixtures but it can also be employed to understand the state of aggregation of the components and the energetics of molecular interaction between them, and that all the information is consistent with the general principles of organic chemistry.

Molecular dynamics simulation of interhalogen compounds using two potential models 2. Liquid bromine trifluoride (BrF_3) — structure and thermodynamics[1]

VIVEK SAXENA
Department of Chemistry, University of Delhi, Delhi—110 007, India

Received September 16, 1992

VIVEK SAXENA. Can. J. Chem. **71**, 2189 (1993).

This paper reports on the molecular dynamics simulation results of liquid bromine trifluoride (BrF_3) at 299, 315, and 363 K. We have assumed that the molecules interact via Lennard–Jones 12–6 site–site pair potential and Lennard–Jones site–site + fractional charges over atomic sites. Lennard–Jones potential parameters of Singer et al. (Mol. Phys. **33**, 1757 (1977)) have been used for Br–Br, and F–F interactions and cross interaction terms are calculated using Lorentz–Berthelot mixing rules. Fractional charges are assigned to reproduce the experimentally determined gaseous-state molecular dipole moment. Various structural and thermodynamic properties for liquid state are reported and compared in detail with results from diffraction studies (Mittkin et al. J. Struct. Chem. **28**, 60 (1987)). Some mechanical properties such as mean-square force and torque, self-diffusion coefficient have also been calculated. The repulsive part of the proposed atom–atom pair potential is a good approximation since both molecular configurations are in good agreement with experimental results.

VIVEK SAXENA. Can. J. Chem. **71**, 2189 (1993).

On rapporte les résultats de simulations de la dynamique moléculaire du trifluorure de brome (BrF_3) à 299, 315 et 363 K. On a fait l'hypothèse que les molécules interagissent par le biais d'une paire de potentiel de Lennard–Jones à 12–6 site–site et de Lennard–Jones site–site + charges fractionnaires sur les sites atomiques. On a utilisé les paramètres du potentiel de Lennard–Jones rapportés par Singer et al. (Mol. Phys. **33**, 1757 (1977)) pour les interactions Br–Br et F–F et on a calculé les termes d'interactions croisées à l'aide des règles de mélange de Lorentz–Berthelot. On a obtenu les charges fractionnaires sous la forme de valeurs attribuées pour reproduire le moment dipolaire expérimental de la molécule dans son état gazeux. On rapporte diverses propriétés structurales et thermodynamiques de l'état liquide et l'on effectue une comparaison en profondeur avec les études de diffraction (Mittkin et al. J. Struct. Chem. **28**, 60 (1987)). On a aussi calculé quelques propriétés mécaniques comme la force et le moment de torsion quadratique moyen et le coefficient d'autodiffusion. La partie répulsive de la paire de potentiel atome–atome proposée est une bonne approximation puisque la configuration moléculaire de deux molécules est en bon accord avec les valeurs expérimentales.

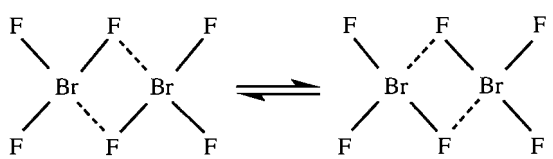
Introduction

As an extension of our work on interhalogen compounds (1), this article reports on the molecular dynamics (MD) simulation results of liquid bromine trifluoride (BrF_3). Simulations are carried out at three temperatures 299, 315, and 363 K using two potential models: (*i*) Lennard–Jones site–site pair potential and (*ii*) the first version slightly modified by including fractional charges over the atomic sites. The repulsive part of the atom–atom pair potential proposed by Singer et al. (2) has found to be good at predicting short range structure in the liquid state. Our structural properties are in good agreement with those from diffraction study and our two possible molecular configurations agree well with literature (3–7).

Chemical and structural information have been obtained from fluorine-19 nmr spectra of bromine trifluoride (4). Infrared studies (6) showed the presence of the following compounds in the liquid state:



These structures provide a very simple and attractive mechanism for an exchange of non-equivalent fluorine atoms. The same observation applies to both chlorine trifluoride and bromine trifluoride. Probably, the dimer transient in the liquid state is stable in a rigid matrix (6).

The simulation averages for structural properties (radial distribution functions, closest contact distances, and possible molecular configurations for the two molecules), thermodynamic properties, and certain mechanical properties such as mean-square force, mean-square torque, and self-diffusion coefficients have been evaluated for the two models.

Method

Simulations have been carried out for microcanonical ensembles for liquid bromine trifluoride around temperatures 299, 315, and 363 K, yielding densities as given in Table 1. Molecular structure is assumed to be in a twisted "T" form for bromine trifluoride (Fig. 1), as confirmed by electron diffraction studies (8). Details in simulation and calculation of the properties have been described (1, 9). Lennard–Jones 12–6 site–site potential parameters used in the simulation are as follows: $\sigma_{F-F} = 2.83$ Å, $\epsilon_{F-F} = 58.8$ K, $\sigma_{Br-Br} = 3.54$ Å, and $\epsilon_{Br-Br} = 275.2$ K (2) and cross interaction terms σ_{ab} and ϵ_{ab} are obtained according to the Lorentz–Berthelot rule as:

$$\sigma_{ab} = \frac{\sigma_{aa} + \sigma_{bb}}{2} \quad \text{and} \quad \epsilon_{ab} = \sqrt{\epsilon_{aa}\,\epsilon_{bb}}$$

The second potential model is an improvement over the first; it included fractional charges at the atomic sites ($Q_F = -0.1264$ and $Q_{Br} = 0.3792$). These values are calculated to reproduce the molecular dipole moment ($\mu = 1.19$ D) (10). Charges are assigned to atoms while molecular electrical

neutrality is maintained. The molecular dipole moment μ and the fluorine charges q are related by

$$[1] \quad \mu = 2 \cdot q \cdot r \cdot \cos\theta + q \cdot R$$

where r and R are defined in Fig. 1. All calculations were carried out using the MDPOLY and MDMANY program (FORTRAN 77 coded) developed by Thompson and Ficham (9) for LJ and LJ + FC models, respectively. The electrostatic forces and energies in MDMANY are calculated by using the Ewald method (9).

Results and discussion

Site–site radial distribution functions (rdf's) for liquid bromine trifluoride are obtained by simultaneous analysis of molecular trajectories during simulation. Pair separations were then sorted in histograms each of width 0.01 nm. The rdf's describe the gross structural features of liquid bromine trifluoride at the three temperatures. Integration of the function $r^2g(r)$ up to the first minimum yields the coordination number n_0 of the first shell around a moiety (a molecule or a site). The first maximum represents the most probable distance r_{max} between the two moieties. Values for r_{max} and n_0 of the two models are listed in Tables 2 (LJ) and 3 (LJ + FC). Since there is no noticeable difference in short-range liquid structural properties (see r_{max} and n_0 values in Tables 2 and 3) we only list a few representative values. Including fractional charges in the first potential model only improves the attractive tail of the potential. Judging from the r_{max} and n_0 values in Tables 2 and 3, the centre-of-mass rdf's given for the two models in Fig. 2 did not seem to effect r and g(r) of the first peak of the various rdf's. It shows that the short range structure of the liquid depends on the repulsive part of the potential (11).

Molecular scattering of liquid bromine trifluoride by X-ray diffraction (5) at 298 K shows a sharp maximum at s = 1.55 Å^{-1}, which corresponds to a 4.54 Å mean molecular distance in the liquid state. Our simulation result from the center-of-mass yields r_{max} = 4.5 Å. Thus the potential seems to be well-behaved at short range in the liquid state. However, a mean molecular distance of 4.54 Å (5) is substantially smaller than that obtained by rigid rotator approximation (5.4 Å) for a molecular liquid corresponding to a density of 2.8040 g cm^{-3} at 298 K. Other studies such as infrared (6), and ^{19}F NMR (4) spectroscopy, X-ray diffraction (5), and high Trouton's constant (10), seem to indicate molecular association in the liquid state.

A radial distribution function calculated from the trajectories obtained from simulation results using both models gave 2.4, 2.9, and 3.4 Å to be the distances of closest ap-

proach for intermolecular F—F, Br—F, and Br—Br, respectively. They are in good agreement with results from X-ray diffraction study (5). The radial distribution function derived from X-ray diffraction study (5) shows a peak at 2.8 ± 0.1 Å. The intermolecular F–F, Br–F, and Br–Br distances derived from this peak correspond to 2.5 to 3.3 Å.

Since our short range structure parameters are in good agreement with spectral studies, the repulsive part of our proposed potential must be a good approximation. However, the heat of evaporation (−42.8 kJ mol^{-1} for liquid bromine trifluoride at boiling point (10)) is significantly different from the calculated configurational energy, i.e. −23.43 kJ mol^{-1} (LJ) and −25.15 kJ mol^{-1} (LJ + FC). Steinhauser and Neumann (12) proposed to remove this discrepancy by increasing the depth of the potential well (ϵ). They also suggested that the discrepancy did not affect the short range structure and dynamical properties. Weeks et al. (11) suggested that only the repulsive part in the pair potential was responsible for the short range structure of the liquid. Therefore, any improvement in the attractive portion would not appreciably change the liquid structure properties. It might be interesting to study the short range static and dynamic behaviour using our model.

Figure 3 shows our two dimer configurations at closest approach. The one in Fig. 3*a* matches well with that derived from an infrared spectral study of BrF_3 in argon matrix (6).

Table 1 lists simulation thermodynamic properties ρ, P/ρ, and ν for liquid bromine trifluoride. Table 4 lists the thermodynamic properties E, U, R, C_v, and ν at the three average temperatures 299, 315 and 363 K.

The mean-squared force and mean-squared torque are significant since they appear in short-time expansions of velocity, angular velocity correlation functions, and memory functions (13). They are also important in determining the quantum corrections to the free energy. They can be measured experimentally by infrared and Raman spectroscopy and neutron scattering. As far as we know, these values have not appeared in the literature. Table 5 lists our mean-squared force $\langle F^2 \rangle$ and mean-squared torque $\langle \Gamma_i^2 \rangle$ about axis i and self-diffusion coefficient D which is one sixth the slope of the MSD(t) line. An improvement in the potential model brings a net improvement in the mean-squared torque Γ_{XX}.

WEI ZOU, ASISH K. SEN, WALTER A. SZAREK, and DAVID B. MACLEAN. Can. J. Chem. **71**, 2194 (1993).

The title compound (**19**), a conjugate of a trisaccharide based upon the repeating trisaccharide of α-D-rhamnose, which comprises the polysaccharide portion of "A-band" lipopolysaccharide from a mutant (AK1401) of *Pseudomonas aeruginosa*, strain PAO1, with bovine serum albumin (BSA) was synthesized starting with methyl α-D-mannopyranoside. Suitably protected D-rhamnose derivatives, namely, ethyl 3,4-di-*O*-benzyl-1-thio-α-D-rhamnopyranoside (**11**) and 3-*O*-acetyl-2,4-di-*O*-benzyl-α-D-rhamnopyranosyl chloride (**12**), were used as the glycosyl acceptor and donor, respectively, in the synthesis of disaccharide **13**. *O*-Deacetylation of **13** gave **14**, a glycosyl acceptor that reacted with **12** to yield the trisaccharide **15**. *N*-Iodosuccinimide – trifluoromethanesulfonic acid was used as an activator of the thioglycoside in the synthesis of **16** and **17** from **15**. Compound **16** was converted into the hydrazide **18** by treatment with hydrazine. The conjugation was achieved by coupling of the intermediate acyl azide derivative of **18** with BSA.

WEI ZOU, ASISH K. SEN, WALTER A. SZAREK et DAVID B. MACLEAN. Can. J. Chem. **71**, 2194 (1993).

Utilisant l'α-D-mannopyranoside de méthyle comme produit de départ, on a synthétisé le composé **19** mentionné dans le titre, un conjugué d'un trisaccharide basé sur l'homoséquence du trisaccharide de l'α-D-rhamnose qui comprend la portion polysaccharidique de la «bande-A» du lipopolysaccharide d'un mutant (AK1401) du *Pseudomonas aeruginosa*, souche PAO1, d'une albumine de sérum bovin (ASB). On a utilisé des dérivés D-rhamnose protégés d'une façon appropriée, soit les 3,4-di-*O*-benzyl-1-thio-α-D-rhamnopyranoside d'éthyle (**11**) et le chlorure de 3-*O*-acétyl-2,4-di-*O*-benzyl-α-D-rhamnopyranosyle (**12**) comme respectivement accepteur et donneur de glycosyle dans la synthèse du disaccharide **13**. La *O*-déacétylation de **13** conduit à **14**, un accepteur de glycosyle, qui par réaction avec **12**, fournit le trisaccharide **15**. On a utilisé la combinaison *N*-iodosuccinimide – acide trifluorométhanesulfonique comme activant du thioglycoside dans la synthèse des composés **16** et **17** à partir du composé **15**. Par traitement avec de l'hydrazine, on a transformé le composé **16** en son hydrazide **18**. On a réalisé la conjugaison en procédant au couplage du dérivé intermédiaire **18** avec le BSA.

Introduction

During the past decade an increasing number of studies have demonstrated that carbohydrate–protein conjugates possess important seroreactivity (1–6); some of the conjugates were developed with the intention of preparing synthetic antigens and vaccines (1–6). *Pseudomonas aeruginosa* is an opportunistic pathogen that infects persons having compromised immune systems, such as cystic fibrosis patients (7). Vaccines currently used against pathogenic Gram-negative bacteria commonly consist of a mixture of O-antigens from several serotypes of the same species. "A-band" lipopolysaccharide (LPS) is often expressed in established colonies of *Pseudomonas aeruginosa* that do not express O-antigen; since the "A-band" LPS is conserved upon infection, and since it is a common antigen (8), vaccines based on this type of LPS might be more successful in preventing pulmonary infections of *P. aeruginosa* than the current vaccines based on O-antigens.

Recently we (9) reported the results of structural studies on the polysaccharide portion of "A-band" LPS from a mutant (AK1401) of *Pseudomonas aeruginosa* strain PAO1. The main structural feature is a repeating trisaccharide of α-D-rhamnose having the following structure: [→ 2)-*O*-α-D-Rha*p*-(1 → 3)-*O*-α-D-Rha*p*-(1 → 3)-*O*-α-D-Rha*p*-(1 →]$_n$; this structural assignment has been confirmed by further studies involving methylation analysis and Smith-degradation studies (10). As part of our program concerned with the synthesis of glycoconjugates for the investigation of their serological activity, with the intention of preparing synthetic vaccines based upon subunits of the structure that could be used for protection against *Pseudomonas* infections, it was planned to synthesize a trisaccharide based upon this trisaccharide repeating unit by a strategy that would permit the trisaccharide units to be joined readily to the extent of a nonasaccharide. It was also planned to make neoglycoproteins of the tri-, hexa-, and nona-saccharides.

Methods for the synthesis of glycoconjugates include diazo coupling, formation of isothiocyanates, amidation, amination, guanidination, and amidination (see ref. 6). Conjugates containing several types of spacer arms, such as a nine-carbon chain (11–14), and chains containing dioxa (15–17), amide (18), thioether (19–23), phenylthiourea (24), or *p*-*N*-acryloylphenyl (25) functional groups, have been prepared. Four-, seven-, twelve-, and fifteen-carbon spacer arms have also been employed (26). Here we describe the synthesis of a conjugate of the trisaccharide and bovine serum albumin (BSA) by using a 12-carbon spacer arm.

Results and discussion

Methyl 2,3-*O*-isopropylidene-α-D-rhamnopyranoside (**3**) was prepared from methyl 2,3-*O*-isopropylidene-α-D-mannopyranoside (**1**) in two steps (27) by treatment of **1** with

iodine–triphenylphosphine to give **2**, followed by catalytic hydrogenation of **2**. Benzylation of **3** with benzyl chloride – potassium hydroxide in dimethyl sulfoxide at room temperature gave **4** in good yield; the product, without further purification, was converted into **5** (28, 29) in 79% yield (from **3**) by treatment with 60% aqueous acetic acid at boiling temperature.

Benzylation of **5** to form methyl 2,4-di-*O*-benzyl-α-D-rhamnopyranoside (**6**) in 82% yield was performed in toluene at room temperature, in the presence of the phase-transfer catalyst, tetra-*n*-butylammonium iodide, and powdered potassium hydroxide. A selective benzylation of **5** to give **6** has been achieved also by a two-phase reaction in chloroform – aqueous sodium hydroxide using tetra-*n*-butylammonium bromide (28). In the present study, in addition to compound **6**, small amounts of methyl 3,4-di-*O*-benzyl-α-D-rhamnopyranoside (**7**) (ref. 30, for *L*-enantiomer, see refs. 31, 32) and another component having a higher R_f value, presumably methyl 2,3,4-tri-*O*-benzyl-α-D-rhamnopyranoside, were isolated also. Compound **7** could be prepared from **5** in large scale in 69% yield by reaction with (di-*n*-butyl) tin oxide, by way of its stannylene derivative (see refs. 33, 34), in toluene–benzene. Acetolysis of **6** or **7** with a 1.5% solution of sulfuric acid in acetic anhydride – acetic acid (5:2, v/v) at room temperature did not afford simply the corresponding acetate **8** (for L-enantiomer, see ref. 14) or **9** (32, 35), but resulted also in debenzylation. 1,2-Di-*O*-acetyl-3,4-di-*O*-benzyl-α-D-rhamnopyranose (**9**) could be obtained in 84% yield by hydrolysis of **7** in a 3% solution of sulfuric acid in water – acetic acid – acetone (1:1:1, v/v) at reflux temperature for 20 h, followed by acetylation with acetic anhydride – pyridine at room temperature for 4 h.

Ethyl thioglycosides have usually been synthesized by the reaction of a glycosyl acetate with thioethanol in the presence of a Lewis acid; however, in many cases the protecting groups are labile under these conditions. Although boron trifluoride etherate has been used (35) in the preparation of thioglycoside **11**, debenzylation has been observed (36) under such conditions. Consequently, in the present work glycosyl chloride **10**, which was prepared quantitatively by treatment of **9** with hydrogen chloride in acetic acid – dichloromethane at room temperature for 2 h, was treated with potassium thioethoxide in acetone at room temperature for 10–15 min to give **11** in 91% overall yield; no β isomer was isolated. Gated ^{13}C NMR measurements revealed $J_{H\text{-}1,C\text{-}1}$ = 166.48 Hz, a value in the range reported (37) for the α anomer of some *O*-glycosides of mannose derivatives. The other suitably protected, monosaccharide unit **12** was obtained from **6** in good yield by the same methods as those used in the preparation of **10** from **7**.

The reaction of the glycosyl acceptor **11** with the glycosyl donor **12** was performed in the presence of silver triflate and powdered 4 Å molecular sieves at −5 to −10°C to give the protected disaccharide **13** in 76% yield. The assignment of the configuration of the inter-glycosidic linkage was based on precedents in the literature (see, for example, refs. 37*a*, 37*b*, 38) for the synthesis of mannose-containing oligosaccharides under the same conditions. ^1H and ^{13}C NMR spectroscopy indicated the stereochemical integrity of **13**. *O*-Deacetylation of **13** with 0.5% sodium methoxide in methanol at room temperature for 4 h afforded quantitatively the glycosyl acceptor **14**, which was, in turn, glycosylated with the glycosyl donor **12**, again by use of silver triflate and powdered 4 Å molecular sieves, to give protected trisaccharide **15** as a syrup in 80% yield. ^1H NMR spectroscopy showed the presence of signals for three anomeric protons at δ 5.09 (H-1″), 5.19 (H-1′), and 5.21 (H-1); in the spectrum of **13** the signals for the two anomeric protons were observed at δ 5.14 (H-1′) and 5.25 (H-1).

The thioglycoside **15** was treated with methyl 12-hydroxydodecanoate using *N*-iodosuccinimide – trifluoromethanesulfonic acid as an activator (39, 40), to give the two diastereomers **16** and **17** (~1:1) in 68% yield. The ratio of **16** to **17** and the yield were not changed significantly by changing the reaction temperature from 0°C to room temperature. The trisaccharides **16** and **17** were separated by chromatography on silica gel. The ^1H NMR resonances of **16** and **17** were assigned on the basis of 2D ^1H-homonuclear chemical-shift correlated (^1H-COSY) experiments.

Attempted *O*-debenzylation of **16** by catalytic hydrogenolysis over 10% Pd–C in methanol was unsuccessful possibly because of the presence of a trace of sulfide derived from the thioglycoside precursor; however, the *O*-debenzylation was achieved in a binary solvent of 40% acetic acid in methanol at room temperature. The product was then converted into the hydrazide **18** in 62% yield by treatment overnight with hydrazine hydrate in ethanol; during the conversion process the 3″-Ac group was also removed. The ^1H and ^{13}C NMR spectral data, including data from ^1H-COSY experiments, and the MS(FAB) spectrum were consistent with the structure assigned for **18**. In the ^1H NMR spectrum of **18** in CD_3OD at 25°C the signal of the anomeric proton (H-1) at δ 4.71 was obscured by a protiated-solvent signal; signals for only two anomeric protons were observed (δ 4.85 and 4.99). When the temperature was raised to 30°C the signals of three anomeric protons were clearly observed at δ 4.77 (H-1), 4.91 (H-1′), and 5.04 (H-1″) (see Fig. 1).

The hydrazide **18** was converted into its acyl azide, which was conjugated to the carrier protein, bovine serum albumin, by the method described by Chatterjee et al. (13), to give the glycoconjugate **19**. The conjugate **19** could be purified by column chromatography on Bio-Gel P-30. The fractions were monitored for carbohydrate by the phenol – sulfuric acid colorimetric method (41); protein was assayed using bicinchoninic acid (Pierce BCA Protein Assay Reagent). The results in Fig. 2 indicated a successful conjugation. The glycoconjugate material was dialyzed, lyophilized, and stored at 4°C prior to serological analyses.

Preliminary tests have shown that both **18** and **19** possess binding reactivity to the "A-band"-specific monoclonal antibody, MAb N1F10 (see refs. 8, 42). The syntheses of

hexa- and nona-saccharides and their conjugates should be achievable from **15** and **16** by the reactions described in this article.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Optical rotations were measured with a Perkin–Elmer model 241 automatic polarimeter for solutions in a 0.1-dm cell at room temperature. Nuclear magnetic resonance (^{1}H NMR and ^{13}C NMR) spectra were recorded on a Bruker AM-400 or Bruker AC-F200 spectrometer; chemical shifts (δ) are given in ppm downfield from the signal of Me_4Si. CI mass spectra were recorded on a VG Analytical ZAB-E mass spectrometer; the FAB mass spectrum was recorded on a VG Quattro mass spectrometer using *m*-nitrobenzyl alcohol as the matrix.

Thin-layer chromatography (TLC) was performed using glass precoated with E. Merck Silica Gel 60 F-254. The developed plates were dried and sprayed with a solution of cerium (IV) sulfate (1%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid, and heated at 150°C. Column chromatography was performed using E. Merck 7734 Silica Gel 60 (70–230 mesh) as the solid phase. Solvents were evaporated under reduced pressure at <40°C.

Methyl 4-O-benzyl-α-D-rhamnopyranoside (5)

To a solution of **3** (27) (4.4 g, 20.1 mmol) in dimethyl sulfoxide (25 mL) were added powdered potassium hydroxide (4.0 g) and benzyl chloride (3.0 mL, 25.8 mmol) with stirring at room temperature, and the mixture was stirred for a further 4 h. Ice-water (50 mL) was then added and the solution was extracted with chloroform (3 × 50 mL). The combined organic solution was then washed with water (2 × 50 mL), dried over anhydrous sodium sulfate, and concentrated to give methyl 4-*O*-benzyl-2,3-*O*-isopropylidene-α-D-rhamnopyranoside (**4**) as an oil.

To the oil obtained above was added 60% aqueous acetic acid (50 mL) and the mixture was then stirred at 100°C for 1 h. Evaporation under reduced pressure gave a residue that crystallized in a short time after the addition of hexane (100 mL) to give a sample of **5** (4.31 g, 79.5% from **3**). The sample was recrystallized from ethyl acetate – hexane; mp 108–109°C, $[\alpha]_D$ +72.4 (*c* 1.56, $CHCl_3$) (lit. (28) mp 105°C, $[\alpha]_D$ +66.3 (*c* 5.3, $CHCl_3$); lit. (29) mp 105–107°C, $[\alpha]_D$ +72 (*c* 4, $CHCl_3$)); ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.35 (3H, d, $J_{5,6}$ = 6.2 Hz, 6-CH_3), 2.32 (2H, br, 2-OH and 3-OH),

*Methyl 2,4-di-*O*-benzyl-α-*D*-rhamnopyranoside (6)*

To a solution of **5** (2.31 g, 8.62 mmol) in toluene (50 mL) were added tetra-*n*-butylammonium iodide (1.6 g, 4.3 mmol) and powdered potassium hydroxide (2.3 g), followed by benzyl bromide (1.47 g, 8.62 mmol). The mixture was stirred at room temperature for 4 h. Ice-cold water (50 mL) and ethyl acetate (50 mL) were added and the mixture was stirred for 10 h. The organic layer was then washed with water (2 × 50 mL), dried over anhydrous sodium sulfate, and evaporated to give a residue that was fractionated by column chromatography on silica gel (hexane – ethyl acetate (3:1, v/v)) to give compound **6** as an oil (2.52 g, 82%) and a small amount of **7**; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.34 (3H, d, $J_{5,6} = 6.2$ Hz, 6-CH_3), 2.24 (1H, br, 3-OH), 3.33 (3H, s, OMe), 3.35 (1H, t, $J_{3,4} = J_{4,5} = 9.4$ Hz, H-4), 3.64 (1H, dq, $J_{4,5} = 9.4$ Hz, $J_{5,6} = 6.2$ Hz, H-5), 3.73 (1H, dd, $J_{1,2} = 1.4$ Hz, $J_{2,3} = 3.7$ Hz, H-2), 3.94 (1H, dd, $J_{2,3} = 3.7$ Hz, $J_{3,4} = 9.4$ Hz, H-3), 4.59 and 4.76 (2H, d and d, $J_{gem} = 11.9$ Hz, CH_2Ph), 4.72 (1H, br, H-1), 4.66 and 4.91 (2H, d and d, $J_{gem} = 11.1$ Hz, CH_2Ph), and 7.26–7.50 (10H, m, 2 Ph).

*Methyl 3,4-di-*O*-benzyl-α-*D*-rhamnopyranoside (7)*

To a solution of **5** (4.0 g, 14.93 mmol) in benzene–toluene (1:1, v/v, 200 mL) was added (di-*n*-butyl)tin oxide (4.1 g), and the mixture was heated at reflux temperature with azeotropic removal of water for 5 h. Benzene was removed by distillation, and tetra-*n*-butylammonium iodide (5.6 g, 15.16 mmol) and benzyl bromide (2.65 mL, 20.6 mmol) were added; the mixture was heated at reflux temperature for 3 h and then cooled to room temperature. Water (100 mL) and ethyl acetate (100 mL) were added and the organic layer was washed sequentially with an aqueous solution of sodium hydrogen carbonate and water. The organic solution was dried over anhydrous sodium sulfate and concentrated to a residue that was fractionated by column chromatography on silica gel (hexane – ethyl acetate (3:1, v/v)) to give compound **7** as an oil (3.67 g, 69%); ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.37 (3H, d, $J_{5,6} = 6.2$ Hz, 6-CH_3), 2.79 (1H, s, 2-OH), 3.37 (3H, s, OMe), 3.51 (1H, t, $J_{3,4} = J_{4,5} = 9.2$ Hz, H-4), 3.72 (1H, dq, $J_{5,6} = 6.2$ Hz, $J_{4,5} = 9.2$ Hz, H-5), 3.87 (1H, dd, $J_{3,4} = 9.2$ Hz, $J_{2,3} = 3.5$ Hz, H-3), 4.05 (1H, dd, $J_{1,2} = 1.5$ Hz, $J_{2,3} = 3.5$ Hz, H-2), 4.69 and 4.86 (2H, d and d, $J_{gem} = 11$ Hz, CH_2Ph), 4.72 (2H, s, CH_2Ph), 4.75 (1H, d, $J_{1,2} = 1.5$ Hz, H-1), and 7.25–7.45 (10H, m, 2 Ph).

*1,3-Di-*O*-acetyl-2,4-di-*O*-benzyl-α-*D*-rhamnopyranose (8)*

A solution of **6** (6.2 g, 17.32 mmol) in a 3% solution of sulfuric acid (80 mL) in acetic acid – water–acetone (1:1:1, v/v) was

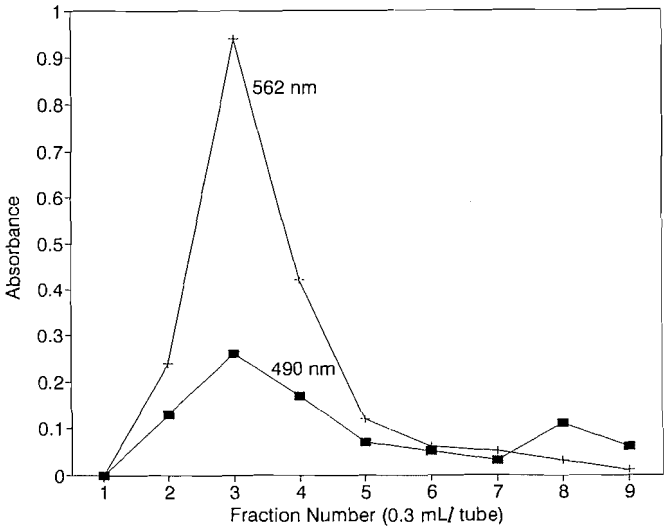

FIG. 2. Gel filtration chromatography of conjugate **19** on Bio-Gel P-30 (10 × 0.4 cm, water as eluant). Carbohydrate was assayed by the phenol – sulfuric acid colorimetric method at 490 nm (■); protein was assayed using bicinchoninic acid (Pierce BCA Protein Assay Reagent) at 562 nm (+).

heated at reflux temperature for 20 h. The solution was cooled to room temperature and extracted with chloroform (3 × 50 mL). The organic solution was washed sequentially with water (20 mL), an aqueous solution of sodium hydrogen carbonate (20 mL), and water (20 mL), dried over anhydrous sodium sulfate, and evaporated; the residue was treated with acetic anhydride – pyridine (1:1, v/v, 30 mL) at room temperature for 4 h. The mixture was poured into ice-water and extracted with ethyl acetate (4 × 25 mL). The solution was concentrated to a residue that was purified by column chromatography on silica gel (hexane – ethyl acetate (3:1, v/v)) to give compound **8** as a syrup (4.4 g, 60%), and another component (0.8 g) that appeared to be a mixture of α and β isomers; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.37 (3H, d, $J_{5,6}$ = 6.2 Hz, 6-CH_3), 1.98 and 2.09 (3H each, s and s, 2 Ac), 3.72 (1H, t, $J_{3,4} = J_{4,5}$ = 9.2 Hz, H-4), 3.95–3.98 (2H, m, H-2 and H-5), 4.69–4.80 (4H, m, 2 CH_2Ph), 5.13 (1H, dd, $J_{2,3}$ = 2.9 Hz, $J_{3,4}$ = 9.2 Hz, H-3), 6.09 (1H, d, $J_{1,2}$ = 1.4 Hz, H-1), and 7.20–7.40 (10H, m, 2 Ph). Anal. calcd. for $C_{24}H_{28}O_7$: C 67.27, H 6.59; found: C 67.66, H, 6.70.

*1,2-Di-*O*-acetyl-3,4-di-*O*-benzyl-α-D-rhamnopyranose (**9**)*

Compound **7** (2.8 g, 7.82 mmol) was treated as described for the preparation of **8** from **6** to give **9** in crystalline form from hexane and a mixture of α and β isomers (total 2.85 g, 84%); mp 107°C, $[\alpha]_D$ +22.8 (*c* 1.36, $CHCl_3$) (lit. (35) mp 106–108°C, $[\alpha]_D$ +22.3 (*c* 0.73, $CHCl_3$); for *L*-enantiomer, lit. (32) mp 107–109°C, $[\alpha]_D$ −20 (*c* 1.1, CH_2Cl_2)); ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.33 (3H, d, $J_{5,6}$ = 6.2 Hz, 6-CH_3), 2.07 and 2.17 (3H each, s and s, 2 Ac), 3.47 (1H, t, $J_{3,4} = J_{4,5}$ = 9.5 Hz, H-4), 3.81 (1H, dq, $J_{5,4}$ = 9.5 Hz, $J_{5,6}$ = 6.2 Hz, H-5), 3.92 (1H, dd, $J_{3,4}$ = 9.5 Hz, $J_{2,3}$ = 3.4 Hz, H-3), 4.54 and 4.72 (2H, d and d, J_{gem} = 11.1 Hz, CH_2Ph), 4.62 and 4.92 (2H, d and d, J_{gem} = 10.7 Hz, CH_2Ph), 5.35 (1H, dd, $J_{1,2}$ = 2.0 Hz, $J_{2,3}$ = 3.4 Hz, H-2), 6.00 (1H, d, $J_{1,2}$ = 2.0 Hz, H-1), and 7.28–7.35 (10H, m, 2 Ph); ^{13}C NMR (50.32 MHz, $CDCl_3$) δ: 18.02 (C-6), 20.91 and 20.98 (2 CH_3C=O), 67.83 (C-5), 70.05, 71.94 (CH_2Ph), 75.63 (CH_2Ph), 77.63, 79.53, 91.17 (C-1), 127.88, 128.04, 128.12, 128.46, 137.76, and 138.24 (2 Ph), 168.53 and 170.04 (2 C=O). Anal. calcd. for $C_{24}H_{28}O_7$: C 67.27, H 6.59; found: C 67.41, H 6.56.

*2-O-Acetyl-3,4-di-O-benzyl-α-D-rhamnopyranosyl chloride (**10**)*

A solution of **9** (1.92 g, 4.5 mmol) in dichloromethane – acetic acid (1:1, v/v, 50 mL) was saturated with HCl(g) at 0°C for 4 h; TLC (hexane – ethyl acetate (3:1, v/v)) showed that the starting material had been completely converted into a product having a higher R_f value. Dichloromethane (50 mL) was added and the solution was washed sequentially with ice-water (twice), an aqueous solution of sodium hydrogen carbonate, and ice-water. The organic solution was dried over anhydrous sodium sulfate and concentrated to give compound **10** in quantitative yield.

*Ethyl 3,4-di-*O*-benzyl-1-thio-α-D-rhamnopyranoside (**11**)*

To a solution of potassium thioethoxide (0.5 g, 5 mmol) in acetone (10 mL) was added a solution of **10** (1.8 g, 4.4 mmol) in acetone (15 mL). The mixture was stirred at room temperature for 10 min; TLC (hexane – ethyl acetate (3:1, v/v)) showed that the reaction was complete. The mixture was diluted with chloroform (100 mL) and washed with water several times. The organic solution was then concentrated to a residue that was purified by chromatography on silica gel (hexane – ethyl acetate (3:1, v/v)) to give compound **11** as a syrup (1.6 g, 92%); $[\alpha]_D$ +150.6 (*c* 1.6, $CHCl_3$) (lit. (35) $[\alpha]_D$ +127 (*c* 0.56, $CHCl_3$)); ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.29 (3H, t, *J* = 7.4 Hz, SCH_2CH_3), 1.36 (3H, d, $J_{5,6}$ = 6.3 Hz, 6-CH_3), 2.58 (2H, m, SCH_2CH_3), 3.00 (1H, br, 2-OH), 3.55 (1H, t, $J_{3,4} = J_{4,5}$ = 9.2 Hz, H-4), 3.83 (1H, dd, $J_{2,3}$ = 3.3 Hz, $J_{3,4}$ = 9.2 Hz, H-3), 4.06–4.20 (2H, m, H-2 and H-5), 4.68 (2H, s, CH_2Ph), 4.61 and 4.92 (2H, d and d, J_{gem} = 11.0 Hz, CH_2Ph), 5.33 (1H, d, $J_{1,2}$ = 1.1 Hz, H-1), and 7.25–7.36 (10H, m, 2 Ph); ^{13}C NMR (50.32 MHz, $CDCl_3$) δ: 14.92 (SCH_2CH_3), 17.83 (C-6), 24.97 (SCH_2CH_3), 67.90 (C-5), 70.15, 72.10 (CH_2Ph), 75.34 (CH_2Ph), 80.30 (2 C's), 83.20 (C-1, $J_{C1,H1}$ = 166.48 Hz), 127.71, 127.93, 128.03, 128.38, 128.58, 138.07, and 138.46 (2 Ph). Anal. calcd. for $C_{22}H_{28}O_4S$: C 68.01, H 7.26, S 8.25; found: C 67.65, H 7.23, S 8.59.

*3-O-Acetyl-2,4-di-O-benzyl-α-D-rhamnopyranosyl chloride (**12**)*

Compound **12** was prepared from **8** by the procedure described for the preparation of **10**.

*Ethyl 2-O-(3'-O-acetyl-2',4'-di-O-benzyl-α-D-rhamnopyranosyl)-3,4-di-O-benzyl-1-thio-α-D-rhamnopyranoside (**13**)*

To a solution of **11** (1.0 g, 2.58 mmol) in dichloromethane (15 mL) were added powdered 4 Å molecular sieves (2 g) and silver triflate (1.3 g, 5.06 mmol). The mixture was stirred at −10°C under N_2. A solution of compound **12** (0.9 g, 2.22 mmol) in dichloromethane (12 mL) was slowly added and the mixture was stirred at −5 to −10°C for 30 min and then at room temperature for 5 h. The reaction mixture was diluted with dichloromethane (20 mL) and filtered through Celite. The filtrate was washed with an aqueous solution of sodium hydrogen carbonate and water, dried over anhydrous sodium sulfate, and concentrated to a residue. The residue was purified by column chromatography on silica gel (hexane – ethyl acetate (4:1, v/v)) to give compound **13** as a syrup (1.27 g, 76%); $[\alpha]_D$ +44 (*c* 1.67, $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.34 (3H, t, *J* = 7.4 Hz, SCH_2CH_3), 1.36 (3H, d, $J_{5',6'}$ = 6.3 Hz, 6'-CH_3), 1.41 (3H, d, $J_{5,6}$ = 6.2 Hz, 6-CH_3), 2.03 (3H, s, 3'-Ac), 2.66 (2H, m, SCH_2CH_3), 3.59 (1H, t, $J_{3',4'} = J_{4',5'}$ = 9.4 Hz, H-4'), 3.69 (1H, t, $J_{3,4} = J_{4,5}$ = 9.4 Hz, H-4), 3.87 (1H, dd, $J_{3,4}$ = 9.4 Hz, $J_{2,3}$ = 2.9 Hz, H-3), 3.95–4.10 (3H, m, H-2', H-5, and H-5'), 4.19 (1H, m, H-2), 4.32–4.99 (8H, m, 8H, 4 CH_2Ph), 5.14 (1H, d, $J_{1',2'}$ = 1.8 Hz, H-1'), 5.25 (1H, d, $J_{1,2}$ = 1.3 Hz, H-1), 5.34 (1H, dd, $J_{2',3'}$ = 3.4 Hz, $J_{3',4'}$ = 9.4 Hz, H-3'), and 7.26–7.38 (20H, m, 4 Ph); ^{13}C NMR (50.32 MHz, $CDCl_3$) δ: 15.09 (SCH_2CH_3), 17.80 and 18.12 (C-6 and C-6'), 21.14 (CH_3C=O), 25.42 (SCH_2CH_3), 68.24 and 68.65 (C-5 and C-5'), 72.55 and 72.74 (2 CH_2Ph), 73.45, 74.94 and 75.44 (2 CH_2Ph), 76.03, 76.80, 79.33, 80.55, 80.68, 83.61 (C-1), 99.57 (C-1'), 127.75, 127.86, 128.00, 128.28, 128.44, 128.51, 138.53, and 138.72 (4 Ph), and 169.50 (C=O); MS (CI, NH_3): 774 $(M + NH_4)^+$, 684, 494. Anal. calcd. for $C_{44}H_{52}O_9S$: C 69.81, H 6.93, S 4.24; found: C 69.68, H 6.75, S 3.99.

*Ethyl 3,4-di-O-benzyl-2-O-(2',4'-di-O-benzyl-α-D-rhamnopyranosyl)-1-thio-α-D-rhamnopyranoside (**14**)*

A solution of compound **13** (0.49 g, 0.648 mmol) in 0.5% sodium methoxide – methanol (20 mL) was stirred at room temper-

ature for 4 h; TLC (hexane – ethyl acetate (4:1, v/v)) showed that the reaction was complete. Amberlite IR-120 (H^+ form) ion-exchange resin (5 mL) was added to the solution. The mixture was stirred for 5 min, filtered, and the filtrate was concentrated to give compound **14** in quantitative yield; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.28 (3H, t, J = 7.4 Hz, SCH_2CH_3), 1.31 (3H, d, $J_{5',6'}$ = 6.2 Hz, 6′-CH_3), 1.36 (3H, d, $J_{5,6}$ = 6.2 Hz, 6-CH_3), 2.40 (1H, d, J = 8.0 Hz, 3′-OH), 2.60 (2H, m, SCH_2CH_3), 3.40 (1H, t, $J_{3',4'} = J_{4',5'}$ = 9.3 Hz, H-4′), 3.52 (1H, t, $J_{3,5} = J_{4,5}$ = 9.4 Hz, H-4), 3.85–3.94 (3H, m, H-3′, H-5, and H-5′), 4.04–4.14 (2H, m, H-2′ and H-3), 4.19 (1H, dd, $J_{1,2}$ = 1.1 Hz, $J_{2,3}$ = 2.8 Hz, H-2), 4.35 and 4.50 (2H, d and d, J_{gem} = 11.9 Hz, CH_2Ph), 4.61 and 4.75 (2H, d and d, J_{gem} = 10.9 Hz, CH_2Ph), 4.70 and 4.97 (4H, d and d, J_{gem} = 11.0 Hz, 2 CH_2Ph), 5.19 (1H, d, $J_{1',2'}$ = 1.2 Hz, H-1′), 5.25 (1H, d, $J_{1,2}$ = 1.1 Hz, H-1), and 7.25–7.35 (20H, m, 4 Ph).

Ethyl 2-O-{3′-O-(3″-O-acetyl-2″,4″-di-O-benzyl-α-D-rhamnopyranosyl)-2′,4′-di-O-benzyl-α-D-rhamnopyranosyl}-3,4-di-O-benzyl-1-thio-α-D-rhamnopyranoside (15)

To a solution of **14** (0.47 g, 0.648 mmol) in dichloromethane (8 mL) were added powdered 4 Å molecular sieves (2 g) and silver triflate (0.3 g). The mixture was cooled to −10°C under N_2, and a solution of compound **12** (0.28 g, 0.692 mmol) in dichloromethane (3 mL) was added slowly; the mixture was stirred at −5 to −10°C for 1 h and then at room temperature overnight. The reaction mixture was processed as described for the preparation of **13**. Compound **15** was obtained as a syrup (0.56 g, 80%); $[\alpha]_D$ +52.5 (*c* 2.12, $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.22 (3H, d, $J_{5,6}$ = 6.2 Hz, 6-CH_3), 1.26 (3H, t, J = 7.4 Hz, SCH_2CH_3), 1.27 (3H, d, $J_{5',6'}$ = 6.2 Hz, 6′-CH_3), 1.29 (3H, d, $J_{5'',6''}$ = 6.2 Hz, 6″-CH_3), 1.95 (3H, s, 3″-Ac), 2.60 (2H, m, SCH_2CH_3), 3.44 (1H, t, $J_{3',4'} = J_{4',5'}$ = 9.4 Hz, H-4′), 3.62 (1H, t, $J_{3'',4''} = J_{4'',5''}$ = 9.4 Hz, H-4″), 3.66 (1H, t, $J_{3,4} = J_{4,5}$ = 9.4 Hz, H-4), 3.78–3.83 (3H, m, H-2′, H-3, and H-5), 3.87–3.89 (2H, m, H-2″ and 5″), 4.02 (1H, dq, $J_{5',6'}$ = 6.2 Hz, $J_{4',5'}$ = 9.4 Hz, H-5′), 4.12 (1H, dd, $J_{1,2}$ = 1.4 Hz, $J_{2,3}$ = 2.5 Hz, H-2), 4.19 (1H, d, J_{gem} = 12.0 Hz, one of CH_2Ph), 4.21 (1H, dd, $J_{2',3'}$ = 3.0 Hz, $J_{3',4'}$ = 9.4 Hz, H-3′), 4.39–4.88 (11H, m, 5.5 CH_2Ph), 5.09 (1H, d, $J_{1'',2''}$ = 1.4 Hz, H-1″), 5.19 (1H, d, $J_{1',2'}$ = 1.3 Hz, H-1′), 5.21 (1H, d, $J_{1,2}$ = 1.2 Hz, H-1), 5.32 (1H, dd, $J_{2'',3''}$ = 3.1 Hz, $J_{3'',4''}$ = 9.4 Hz, H-3″), and 7.2–7.4 (30H, m, 6 Ph); ^{13}C NMR (50.32 MHz, $CDCl_3$) δ: 15.07 (SCH_2CH_3), 18.02 (C-6, C-6′, and C-6″), 21.09 (CH_3C=O), 25.49 (SCH_2CH_3), 68.26, 68.50, and 69.03 (C-5, C-5′, and C-5″), 72.38, 72.76, 74.73, and 75.38 (6 CH_2Ph), 73.65, 76.59, 76.92, 77.06, 77.70, 79.12, 80.39, 80.70, 80.86; 83.72 (C-1), 99.38 (C-1′ and C-1″), 127.10, 127.52, 127.59, 127.67, 127.86, 127.99, 128.26, 128.35, 128.40, 128.48, 138.09, and 138.52 (6 Ph), and 170.00 (C=O); MS (CI, NH_3): 1100 $(M + NH_4)^+$, 1010, 820, 774, 712, 638. Anal. calcd. for $C_{64}H_{74}O_{13}S$: C 70.95, H 6.89, S 2.95; found: C 70.90, H 6.81, S 2.79.

11-(Methoxycarbonyl)undecyl 2-O-{3′-O-(3″-O-acetyl-2″,4″-di-O-benzyl-α-D-rhamnopyranosyl)-2′,4′-di-O-benzyl-α-D-rhamnopyranosyl}-3,4-di-O-benzyl-α-D-rhamnopyranoside (16)

To a solution of **15** (0.31 g, 0.287 mmol) and methyl 12-hydroxydodecanoate (0.1 g, 0.435 mmol) in dichloromethane (8 mL) were added powdered 4 Å molecular sieves (0.3 g) and *N*-iodosuccinimide (0.15 g, 0.667 mmol). Trifluoromethanesulfonic acid (20 μL) was added at 0°C under N_2 and the mixture was stirred at room temperature for 4 h. Triethylamine (0.2 mL) in dichloromethane (5 mL) was added to neutralize the solution. The reaction mixture was filtered and the filtrate was concentrated to a residue that was fractionated by column chromatography on silica gel (hexane – ethyl acetate (3:1, v/v)) to give compound **16** (66 mg), its β form **17** (73 mg), and their mixture (184 mg) (68% combined yield).

Compound 16: $[\alpha]_D$ +10 (*c* 1.54, $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.22 (3H, d, $J_{5,6}$ = 6.2 Hz, 6-CH_3), 1.27–1.34 (20H, m, 2 6-CH_3 and $(CH_2)_7$), 1.54 (2H, m, CH_2CH_2C=O), 1.64 (2H, m, OCH_2CH_2), 1.95 (3H, s, 3″-Ac), 2.31 (2H, t, J = 7.6 Hz, CH_2C=O), 3.35 (1H, m, one of $OCH_2(CH_2)_7$), 3.40 (1H, t, $J_{3,4} = J_{4,5}$ = 9.4 Hz, H-4), 3.61 (1H, t, $J_{3'',4''} = J_{4'',5''}$ = 9.5 Hz, H-4″), 3.63 (1H, t, $J_{3',4'} = J_{4',5'}$ = 9.6 Hz, H-4′), 3.65 (1H, m, one of $OCH_2(CH_2)_7$), 3.66 (1H, m, H-5), 3.67 (3H, s, OMe), 3.75–3.82 (3H, m, H-2′, H-5′, and H-5″), 3.83–3.88 (2H, m, H-2″ and H-3), 4.05 (1H, dd, $J_{1,2}$ = 1.5 Hz, $J_{2,3}$ = 2.5 Hz, H-2), 4.19 (1H, dd, $J_{2',3'}$ = 2.9 Hz, $J_{3',4'}$ = 9.6 Hz, H-3′), 4.38 and 4.20 (2H, d and d, J_{gem} = 12.2 Hz, CH_2Ph), 4.50–4.90 (10H, m, 5 CH_2Ph), 4.71 (1H, d, $J_{1,2}$ = 1.5 Hz, H-1), 5.13 (1H, d, $J_{1',2'}$ = 1.4 Hz, H-1′), 5.18 (1H, d, $J_{1'',2''}$ = 1.3 Hz, H-1″), 5.30 (1H, dd, $J_{2'',3''}$ = 3.3 Hz, $J_{3'',4''}$ = 9.5 Hz, H-3″), and 7.15–7.40 (30H, m, 6 Ph); ^{13}C NMR (50.32 MHz, $CDCl_3$) δ: 18.01 (C-6, C-6′, and C-6″), 21.07 (CH_3C=O), 24.98, 26.17, 29.17, 29.26, 29.45, 29.56, and 34.13 ($(CH_2)_{10}$), 51.40 (OMe), 67.56 ($OCH_2(CH_2)_{10}$), 67.90, 68.21, and 68.83 (C-5, C-5′, and C-5″), 72.30, 72.42, 72.73, 74.70, and 75.42 (6 CH_2Ph), 73.63, 76.92, 77.39, 77.88, 79.11, 80.14, 80.61, 80.85; 98.94, 99.12, and 99.38 (C-1, C-1′,and C-1″), 127.03, 127.51, 127.58, 127.64, 127.74, 128.07, 128.24, 128.31, 128.40, 138.07, 138.11, 138.39, 138.57, and 138.72 (6 Ph), and 170.09 (C=O); MS (CI, NH_3): 1268 $(M + NH_4)^+$, 1178, 942, 820, 728, 638. 11-Carbazoylundecyl O-α-D-rhamnopyranosyl-(1″ → 3′)-O-α-D-rhamnopyranosyl-(1′ → 2)-α-D-rhamnopyranoside (18)

A solution of **16** (0.24 g, 0.19 mmol) in 3:2 (v/v) methanol – acetic acid (10 mL) was subjected to a hydrogen pressure of 50 psig (1 psi = 6.9 kPa) in the presence of 10% Pd–C (0.2 g) at room temperature for 20 h; TLC (ethyl acetate) showed that the debenzylation was complete. The catalyst was removed by filtration and the filtrate was concentrated to a residue under vacuum. The residue was dissolved in 95% ethanol (5 mL) and the solution was treated with hydrazine (0.2 mL) for 16 h at room temperature. The solvent was evaporated and traces of hydrazine were removed by codistillation with ethanol; the residue was dried under vacuum. Purification on a column of Sephadex LH-20 (40 × 1 cm, methanol) gave **18** (80 mg, 62%); $[\alpha]_D$ +77.3 (*c* 0.44, MeOH); ^{1}H NMR (400 MHz, CD_3OD) δ: 1.18 (3H, d, $J_{5,6}$ = 6.1 Hz, 6-CH_3), 1.19 (3H, d, $J_{5',6'}$ = 6.2 Hz, 6′-CH_3), 1.22 (3H, d, $J_{5'',6''}$ = 6.2 Hz, 6″-CH_3), 1.26 (14H, br, $(CH_2)_7$), 1.53 (4H, m, OCH_2CH_2 and CH_2CH_2C=O), 2.09 (2H, t, J = 7.5 Hz, CH_2C=O), 3.28–3.38

(3H, m, H-4″, H-5, and one of OCH_2CH_2), 3.43–3.53 (2H, m, H-3 and H-4′), 3.60 (1H, m, H-5″), 3.68 (1H, m, one of OCH_2CH_2), 3.65–3.72 (3H, m, H-3″, H-4, and H-5′), 3.72–3.75 (2H, m, H-2 and H-3′), 3.92 (1H, dd, $J_{1'',2''}$ = 1.6 Hz, $J_{2'',3''}$ = 3.3 Hz, H-2″), 4.00 (1H, dd, $J_{1',2'}$ = 1.6 Hz, $J_{2',3'}$ = 2.9 Hz, H-2′), 4.77 (1H, d, $J_{1,2}$ = 1.6 Hz, H-1), 4.91 (1H, d, $J_{1',2'}$ = 1.6 Hz, H-1′), and 5.04 (1H, d, $J_{1'',2''}$ = 1.6 Hz, H-1″); ^{13}C NMR (100.61 MHz, CD_3OD) δ: 17.94, 17.99, and 18.15 (C-6, C-6′, and C-6″), 26.84, 27.30, 30.24, 30.40, 30.46, 30.55, 30.58, 30.65, and 35.00 ($(CH_2)_{10}$), 68.55 (OCH_2), 69.86, 70.13, and 70.51 (C-5, C-5′, and C-5″), 71.80, 72.14, 72.17, 73.23, 74.04, 74.29, 79.22, 80.16; 100.26, 103.88, and 103.95 (C-1, C-1′, and C-1″), and 175.37 ($CONHNH_2$); MS (FAB): 691 $(M + Na)^+$, 669 $(M + H)^+$, 523, 539, 377, 231. Anal. calcd. for $C_{30}H_{56}N_2O_{14}$: C 53.88, H 8.44, N 4.19; found: C 53.73, H 8.58, N 3.87.

*O-α-D-Rhamnopyranosyl-(1″ → 3′)-O-α-D-rhamnopyranosyl-(1′ → 2)-O-α-D-rhamnopyranosyl-(1 → 12)-oxydodecanoyl-BSA (**19**)*

To a stirred solution of **18** (8 mg) in dry *N,N*-dimethylformamide (0.2 mL) at −30°C was added 1.3 M HCl–1,4-dioxane (60 μL). *tert*-Butyl nitrite in *N,N*-dimethylformamide (1:10, w/v, 50 μL) was added, and the solution was stirred for 10 min at −30°C. The solution of the acyl azide (−30°C) was added dropwise to a solution of BSA (15 mg) in 0.1 M $Na_2B_4O_7$ at 0°C. The solution was stirred at 0°C for 4 h and dialyzed for 20 h against five changes of deionized water using a membrane that retains proteins of molecular weight 12 000 or greater. The water was removed by lyophilization to give **19** (18 mg).

Three minor indole alkaloids have been isolated from "hairy roots" of *Rauwolfia serpentina* Benth.: 3-epi-α-yohimbine (**1**), 18β-hydroxy-3-epi-α-yohimbine (**2**), and 12-hydroxyajmaline (**3**). The latter compound (**3**) is a novel alkaloid. The alkaloid structures have been determined by spectroscopic data.

HEIKE FALKENHAGEN, JOACHIM STÖCKIGT, INNA KUZOVKINA, IRENE E. ALTERMAN et HEINZ KOLSHORN. Can. J. Chem. **71**, 2201 (1993).

On a isolé trois alcaloïdes de l'indole mineurs à partir des «racines poilues» du *Rauwolfia serpentina* Benth. : 3-épi-α-yohimbine (**1**), 18β-hydroxy-3-épi-α-yohimbine (**2**) et 12-hydroxy-ajmaline (**3**). Ce dernier composé (**3**) est un nouvel alcaloïde. On a déterminé les structures des alcaloïdes sur la base des données spectroscopiques.

Introduction

In a recent paper we compared the alkaloid formation in cell suspension cultures with that of the "hairy roots" of the Indian medicinal plant *Rauwolfia serpentina* Benth. The results obtained clearly indicated that, in comparison with the normal *Rauwolfia* root bark used for the commercial extraction of alkaloids, both systems produced quite different alkaloids and that the amount of total alkaloids is lower in hairy roots than in the cell suspension (1).

The major alkaloids of the hairy roots were well-known *Rauwolfia* alkaloids but there were three minor compounds that could only be isolated from larger batches of roots. The isolation and structure elucidation of these alkaloids, one of them being a novel compound, is described in this paper.

Results and discussion

During the last few years we have successfully established an efficiently growing root culture of *Rauwolfia serpentina* by genetic transformation with the Ri plasmid A-4. The successful transformation could easily be demonstrated by determination of the opines agropine and mannopine. The *Agrobacterium* A-4 used produces agropine and also mannopine and both could be electrophoretically shown to be present in the hairy roots by the method of Petit et al. (2). As expected for a transformation with the Ri plasmid, the roots showed excellent growth characteristics with a doubling time of 5–7 days. The transformed roots allowed the accumulation of enough biomass for alkaloid extraction, even for alkaloids occurring only in trace amounts.

Alkaloid extraction and purification by flash and thin-layer chromatography (TLC) afforded three alkaloids, the structures of which could be determined by mass spectral data and detailed analyses of ^1H and ^{13}C NMR data.

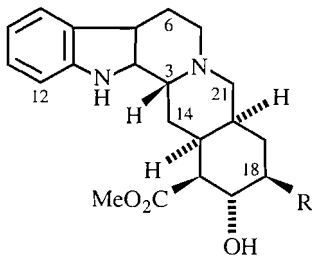
Compound **1** revealed UV and MS data typical for an indole chromophore and a heteroyohimbine or yohimbine alkaloid, e.g., the fragmentation pattern of m/z 144, 156, 169, 184. The M^+ of **1** at 354 m/z pointed to a yohimbine structure (3). Acetylation of **1** gave a monoacetate the MS fragmentation of which was consistent with a yohimbine structure. Careful inspection of the ^1H and ^{13}C NMR data also suggested such an alkaloid, and comparison of the data of **1** with literature values (4) finally showed identity with data reported for 3-epi-α-yohimbine (5–8).

The component **2** showed the same UV data as **1** and a very similar CAS reaction, indicating that **2** could be of the same alkaloid group (yohimbine). The molecular ion of this compound was at M^+ 370 m/z, 16 amu higher than found for the alkaloid **1**. This observation coupled with the higher polarity of **2** on TLC and the formation of a diacetate (M^+ 454 m/z) was indicative of a hydroxyyohimbine structure. Because the characteristic MS fragments of the A-B-C ring system were not shifted towards higher values, the location of the additional OH group was expected in the D-E ring system and the following NMR data indicated clearly the position of the OH at C-18.

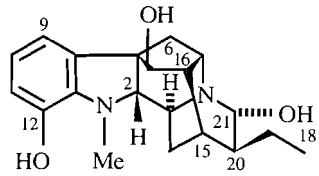
Comparing ^1H NMR data of **1** and **2**, the coupling pattern of H-17 is changed from a triplet of doublets (δ 3.85, J = 10.5, 10.5, 4.5 Hz) in **1** to a triplet in component **2** due to the equatorial hydroxyl group at C-18. In addition, H-18 at 3.5 ppm in **2** exhibits the same coupling as H-17 in **1**, indicating two axial and one equatorial hydrogens at neighbouring carbons C-17 and C-19. These findings are further confirmed by ^{13}C shifts of C-17, C-18, C-19 (δ 71.4, 74.0, 31.1) and carbons C-16 and C-20 (δ 51.4, 24.0), which ex-

[1]Author to whom correspondence may be addressed.

hibit non-steric upfield shifts of −2.4 and −1.6 ppm in comparison to corresponding carbons in 3-epi-α-yohimbine (**1**). The stereochemistry of ring connection in **2** is deduced from diagnostic ^{13}C shielding for C-3, C-6, C-14, and C-21 (δ 53.8, 16.6, 24.1, 49.2), indicating *cis* fusion of rings C/D and ring D/E (4).



1:R = H; **2**:R = OH



3

These data are consistent with the structure of 18β-hydroxy-3-epi-α-yohimbine (**2**), an alkaloid that has already been isolated (9, 10).

The third alkaloid was expected to be of the ajmaline type, because its reaction with CAS was slightly orange and the UV spectrum gave maximum absorption at 250 and 290 nm. However, all the major fragment ions in the mass spectrum were found to be 16 amu higher than in ajmaline. Conclusively, this alkaloid is a hydroxylated ajmaline with the OH group on the aromatic ring A represented by the fragment ion at 160 *m/z* instead of 144 *m/z*.

Inspection of the aromatic region of the ^1H NMR revealed two doublets (δ 7.5, 6.62) and one triplet (δ 6.58) with *ortho* coupling, which agrees with OH substitution at C-9 or C-12. In addition, the ^{13}C spectrum showed three signals for aromatic CH carbons (δ 119.8, 115.1, 114.9) and three quaternary carbons (δ 144.0, 140.8, 137.1). Analysis of ^1H and ^{13}C NMR data using known hydroxyl increments and NOE difference spectra clearly indicated that the OH group is located at C-12 of ajmaline. Further confirmation was deduced from the downfield shift for the N-CH_3 group, which showed an ^1H shift at δ 2.92 and a ^{13}C shift at δ 39.9, while ajmaline exhibits shifts at δ 2.64 and δ 34.3, indicating the proximity of the OH and NCH_3 groups in 12-hydroxyajmaline (**3**). The assignment of the remaining carbon atoms was established by 2-D HETCOR measurements and confirmed the final assignments made for ajmaline (11).

Experimental

Plant material

Hairy roots of *R. serpentina* were grown in liquid, hormone-free, B 5 medium on gyratory shakers (100 rpm) in 1000-mL Erlenmeyer flasks in the dark. The root material was harvested after 28 days of growth, freeze-dried, and stored at −25° C.

Chromatography

TLC was performed on 0.25 mm and 0.5 mm Silicagel 60 F_{254} plates (Merck, Darmstadt). Flash chromatography was carried out with silica gel 60 (230–400 mesh) from the same company. The following solvent systems were used: (a) $CHCl_3$–MeOH–NH_3 (4:1:0.01); (b) $CHCl_3$–MeOH–NH_3 (2.5:2.5:0.01); (c) MeOH–NH_3 (5:0.01); (d) EtOH–cyclohexane–diethylamine (4:4:1); (e) EtOAc–MeOH–H_2O–NH_3 (3.5:1:0.5:0.01); (f) EtOAc–EtOH–cyclohexane–NH_3 (2:2:0.5:0.01). Alkaloidal compounds on TLC were sprayed with ceric ammonium sulphate (CAS reaction).

Instrumentation

UV spectra in MeOH were recorded using a Perkin Elmer Lambda 2 photospectrometer. Mass spectra (EI) were obtained with a Finnigan MAT 44 S (quadrapole instrument) at 70 eV. The ^1H and ^{13}C NMR spectra were recorded using Bruker AM 400 and ARX 400 instruments.

Alkaloid isolation

The freeze-dried, powdered roots (30 g) were extracted twice with 500 mL MeOH by sonication for 60 min. The organic layer was filtered and evaporated, and the residue (1.5 g) was fractionated by flash chromatography with the solvent systems (a)–(c). Four major fractions were obtained containing ceric ammonium sulphate positive alkaloids. From these fractions the single alkaloids were isolated by TLC. Fraction 2 afforded 1.8 mg 12-hydroxyajmaline (**3**) exhibiting R_f values of 0.61 and 0.50 in solvent systems (d) and (f), respectively. From fractions 2 and 3 respectively, 3-epi-α-yohimbine (**1**) (2.5 mg) was isolated and purified in TLC solvents (a) and (b), R_f values 0.68 and 0.37, respectively. Fractions 3 and 4 gave 18β-hydroxy-3-epi-α-yohimbine (**2**) (1.9 mg) after purification with the solvent systems (a) and (b); R_f values were 0.4 and 0.31 respectively.

Spectroscopic data

3-Epi-α-yohimbine (1). UV λ_{max} (MeOH): 224, 282, 290 nm. ^{13}C NMR (100 MHz, $CDCl_3$) δ: 135.7 (C-13), 132.0 (C-2), 127.6 (C-8), 121.7 (C-11), 119.6 (C-10), 118.0 (C-9), 110.9 (C-12), 108.0 (C-7), 65.8 (C-17), 54.0 (C-3), 53.8 (C-16), 51.0 (C-5), 49.5 (C-21), 35.6 (C-20), 33.2 (C-18), 32.2 (C-15), 24.1 (C-19), 23.6 (C-14), 16.6 (C-6), 52.0 (OCH_3), 173.8 (CO). EI-MS *m/z* (rel. int.): 354 (M^+, 100), 353 (M^+ − H, 89), 339 (12), 295 (14), 223 (19), 197 (18), 184 (37), 170 (38), 169 (57), 156 (33), 144 (32).

18β-Hydroxy-3-epi-α-yohimbine (2). UV λ_{max} (MeOH):224, 282, 290 nm. ^{13}C NMR (100 Hz, $CDCl_3$) δ: 135.6 (C-13), 131.7 (C-2), 127.6 (C-8), 121.6 (C-11), 119.6 (C-10), 118.1 (C-9), 110.9 (C-12), 108.3 (C-7), 74.0 (C-18), 71.4 (C-17), 53.8 (C-3), 51.4 (C-16), 51.0 (C-5), 49.2 (C-21), 34.0 (C-20), 32.3 (C-15), 31.1 (C-19), 24.1 (C-14), 16.6 (C-6), 52.1 (OCH_3), 172.8 (CO). EI-MS *m/z* (rel. int.): 370 (M^+, 94), 369 (M^+ − H, 93), 353 (13), 352 (13), 293 (10), 237 (19), 224 (20), 221 (19), 197 (17), 182 (42), 169 (100), 156 (47), 144 (62), 129 (34); diacetate: *m/z* (rel. int.): 454 (M^+, 100), 412 (16), 411 (16), 394 (31), 393 (54), 351 (12), 335 (24), 221 (66), 197 (35), 184 (39), 170 (57), 169 (77), 156 (27), 144 (46), 129 (31).

12-Hydroxyajmaline (3). UV λ_{max} (MeOH): 250, 290 nm. ^1H NMR (400 MHz, DMSO-d_6, benzene-d_6) δ: 7.70 (1H, dd, J = 7.5, 1.5 Hz, H-9), 6.62 (1H, dd, J = 7.5, 1.5 Hz, H-11) 6.57 (1H, t, J = 7.5, H-10), 5.13 (1H, s, OH-17), 4.27 (1H, s, H-17), 4.15 (1H, s, H-21), 3.50 (1H, d, J = 9.5 Hz, H-3), 2.92 (4H, s, H-5, N-CH_3), 2.51 (1H, s, H-2), 2.15 (1H, m, H-15), 1.95 (1H, t, J = 6 Hz, H-16), 1.83 (1H, dd, J = 12.0, 5.0 Hz, H-6a), 1.76 (1H, d, J = 12 Hz, H-6b), 1.67 (1H, t, J = 12.0 Hz, H-14a), 1.55 (1H, dd, J = 12.0, 5.0 Hz, H-14b), 1.36 (2H, m, H-19), 1.33 (1H, m, H-20), 0.92 (3H, t, J = 7.5 Hz, H-18). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 144 (C-13), 140.0 (C-8), 137.1 (C-12), 119.8 (C-10), 115.1 (C-9), 114.9 (C-11), 87.4 (C-21), 80.0 (C-2), 76.1 (C-17), 56.1 (C-7), 52.6 (C-5), 48.5 (C-20), 44.5 (C-16), 41.8 (C-3), 39.9 (N-CH_3), 35.3 (C-6), 31.1 (C-14), 28.3 (C-15), 25.2 (C-19), 12.2 (C-18). EI-MS *m/z* (rel. int.): 342 (M^+, 50), 327 (13), 312 (14), 215 (28), 199 (47), 198 (56), 182 (23), 173 (34), 162 (55), 160 (100), 147 (37); triacetate: *m/z* (rel. int.): 468 (M^+, 82), 426 (100), 411 (21), 384 (22), 369 (17), 341 (5), 323 (13), 240 (20), 198 (94), 183 (22), 173 (28), 160 (76), 147 (30).
